We now consider $\lambda$ of phase $\alpha$ under pressure, in particular the volume dependence, $g = (\partial \ln \lambda / \partial \ln \rho)_T$. As described above in section 3.1.2, $\lambda(P)$ was quite sensitive to the presence of a small proportion of ice Ih in the sample. We concluded that our best estimate, at 130 K, of $\lambda(P)$ for phase $\alpha$ was obtained for the sample of composition $THF \cdot 15.87H_2O$. Thus, we obtained $(\partial \ln \lambda / \partial P)_T = 0.058\ GPa^{-1}$ for phase $\alpha$, as may be deduced from Table 2. Whalley (28) has estimated that the compressibility of a structure II clathrate hydrate will be 1.162 times that of ice Ih, and we take the compressibility of ice Ih to be $0.11\ GPa^{-1}$ (29). Putting these results together we obtain $g = 0.45$ for phase $\alpha$. This result for $g$ supersedes the estimate given previously (19), where, in a preliminary report, we failed to take adequate account of the influence of a small proportion ice Ih in the measured value of $(\partial \lambda / \partial P)_T$.

This value of $g$ for phase $\alpha$ is very small in magnitude. Normal (8) and plastic (30) crystal phases usually have $g$ values in the range 5–10. $g$ is usually in the range 1–4 for liquids and glasses (8, 31), with the smallest magnitude previously recorded being 0.65 for quartz glass (8). The glass-like solid phase $\alpha$ evidently has a value of $g$ similar to glasses and liquids. If, as suggested above, the thermal resistivity of phase $\alpha$ is closely connected with the rotational vibrations of the THF guest molecules, the latter might be expected to be relatively insensitive to pressure in a clathrate hydrate. On the other hand, the host structure is "ice-like", and ice Ih is known (23) to have a negative value of $g$. Slack (32) has discussed this behaviour of ice Ih in terms of a transverse acoustic mode which dominates thermal conduction, and which softens under pressure. Data for the pressure dependence of transverse and longitudinal sound velocities would be necessary to apply Slack's type of analysis to phase $\alpha$.

*4.2 Phase* $\beta$

Lack of other data precludes detailed discussion of this phase. It was argued above that phase $\beta$ is probably a structure I clathrate hydrate. If so, then Whalley (28) has estimated that the compressibility should be 1.135 times that of ice Ih. Combined with our data at 130 K, we estimate $g = 2.5$ for phase $\beta$, a value similar to glasses and liquids (8, 31).

*4.3 Phase* $\gamma$

$\lambda(T)$ for phase $\gamma$ was very different from that for phases $\alpha$ and $\beta$, as may be seen by comparing Figs. 2 and 3. The structure of phase $\gamma$ is not known. It is presumably not a clathrate hydrate, on the basis of composition. There was no evidence for "clathrate-like" behaviour from our measurements of $\lambda(T)$. Moreover, as described above, $\lambda$(solid)/$\lambda$(liquid) was much larger for phase $\gamma$ than for phase $\alpha$ or $\beta$, and closer to values found previously (8) in connection with normal crystal phases.

Except for the weak maxima in $\lambda(T)$ near 130 K, we found that for $T \lesssim 160$ K the data shown in Fig. 3 could be approximated with reasonable accuracy by $\lambda \sim T^n$ with $n = -0.8$. As described in section 1, we expect $n = -1$ for a normal crystal phase, where the thermal resistivity arises entirely from three-phonon umklapp processes. At higher temperatures, $\lambda$ gradually became nearly independent of $T$ for phase $\gamma$. This may indicate the effect of some form of structural disorder.

We now consider the weak maximum in $\lambda(T)$, and weak minimum in $\rho c_p(T)$, shown in Fig. 3 at about 130 K. Sandberg and Bäckström (11) observed such behaviour previously, and concluded that it was an artifact of the transient hot-wire method. Specifically in relation to a glass, they argued that at the glass transition the energy of the heat pulse of the hot-wire method would be shared. If such sharing took place between the phonon field and the "hole" field of the glass, the observed peak in $\lambda$ would result. There seems no reason why the "hole" field of the glass could not be generalized to include other thermally-activated structural rearrangements in a crystal. This would be necessary if the explanation advanced by Sandberg and Bäckström (11) is to be applied to phase $\gamma$, where there is no evidence for a glass transition. At $P = 0.55$ GPa, the deviation from near-normal crystal behaviour started at a temperature (160 K) about 30 K higher than the weak maximum in $\lambda(T)$ (130 K). Even if structural disorder began to be activated at about 130 K, $d\lambda/dP$ was about the same above and below this temperature (Fig. 4).

From Fig. 4 and Table 2 it may be deduced that $d \ln \lambda / dP \approx 0.35\ GPa^{-1}$ for phase $\gamma$ in the temperature range 110–150 K. There are no data or estimates for the compressibility of phase $\gamma$, but if we assume the value which has been estimated (33) for ice VI we obtain $g = 4.7$ for phase $\gamma$. This is a larger value of $g$ than for phases $\alpha$ or $\beta$, but still relatively small for a normal crystal phase (8). If structural

For personal use only.

disorder existed in phase γ it would tend to reduce $g$ below a value typical for a normal crystal phase.

*4.4 Phase α′*

The evidence we found for a transition from phase α at 1.1 GPa and 130 K was described in section 3.2.4. The temperature dependence of λ for phase α′, shown in Fig. 6, suggests that it may be a clathrate hydrate. If so, it presumably arises from a densification of the host lattice of the structure II clathrate hydrate, perhaps by a rearrangement analogous to the formation of the high pressure ices (24). No precedent for this suggestion is known from previous studies of clathrate hydrates (2).

*4.5 Astrophysical implications*

We would like to mention briefly that our results may have astrophysical implications. Low-density satellites, such as Ganymede and Callisto, are considered to be icy bodies. Structural models of these satellites (34) depend to some degree on calculations of heat flow. One such calculation (35) took into account preliminary laboratory data for λ of high pressure ice modifications, but not more recent results (23, 25). If significant quantities of a clathrate hydrate were present, as might perhaps be the case for Titan (35), our results suggest that heat-flow calculations would be significantly affected. For example, if we take $\lambda(\text{clathrate}) \approx \frac{1}{2}$ W $m^{-1}$ $K^{-1}$, then $\lambda(\text{ice Ih})/\lambda(\text{clathrate}) \approx 5$ at 250 K and ≈ 15 at 100 K.

## 5. Conclusions

The structure II clathrate hydrate, phase α, has been found to have a thermal conductivity λ similar to that of other glass-like crystalline solids. The temperature dependence of λ indicated that rotational vibrations of THF guest molecules were probably closely connected with the thermal resistivity. If so, such vibrations provide a specific example of a low-energy excitation affecting the thermal properties of a glass-like solid (15). The thermal resistivity was relatively insensitive to density.

Phase β was probably a structure I clathrate hydrate, stable only under pressure. The thermal properties of phase β were similar to those of phase α.

There was no evidence that phase γ was a clathrate hydrate. The thermal properties of this phase indicated that three-phonon umklapp processes were the main mechanism for thermal resistivity at low temperatures. Near melting, the thermal resistivity became nearly independent of temperature, which was perhaps connected with structural disorder.

There was evidence that, on pressurization at 130 K, phase α transformed at 1.1 GPa to a metastable modification of the same composition (phase α′). Phase α′ showed characteristics which indicated that it was probably a clathrate hydrate. If so, it must be considered to be a new high-density form of clathrate hydrate, perhaps involving a host structure having some similarities to high pressure ice modifications.

# A kinetic and surface study of the oxidation of ethane by nitrous oxide and by oxygen over manganese(III) oxide

CRAIG FAIRBRIDGE[1]

*Department of Chemistry, Lakehead University, Thunder Bay, Ont., Canada P7B 5E1*

AND

ROBERT ANDERSON ROSS

*Alcan International Limited, Kingston Laboratories, Box 8400, Kingston, Ont., Canada K7L 4Z4*

Received August 13, 1981

CRAIG FAIRBRIDGE and ROBERT ANDERSON ROSS. Can. J. Chem. **60**, 893 (1982).

The kinetics of the nitrous oxide/ethane and oxygen/ethane reactions on manganese(III) oxide have been studied from 573 to 673 K and from 523 to 593 K, respectively. The apparent activation energy for carbon dioxide formation was $130 \pm 4$ kJ mol$^{-1}$ in both reactions while that for nitrogen formation in the nitrous oxide/ethane reaction changed from $106 \pm 4$ kJ mol$^{-1}$, 573–613 K, to $133 \pm 4$ kJ mol$^{-1}$, 623–673 K. The kinetic results for both reactions fit the same rate equation:

$$r = \frac{kap_{C_2H_6}bp_x}{(1 + ap_{C_2H_6} + bp_x)^2} \cdot (p_{C_2H_6}p_x)$$

where $p_x$ represents either $p_{N_2O}$ or $p_{O_2}$. The rate-controlling step has been associated with the interaction of adsorbed species on the catalyst surface while both ethane and the oxidising gas appear to be directly involved in further steps in the mechanism. Samples were analysed routinely by scanning electron microscopy, X-ray powder diffraction, and infrared spectroscopy. Electron spectroscopy results from samples treated in various ways with hydrocarbon/oxidant mixtures gave O(1*s*) values from 528.7 to 529.7 eV which are indicative of binding energies usually associated with chemisorbed oxygen. No N(1*s*) spectrum was obtained from catalysts exposed to hydrocarbon/nitrous oxide mixtures, in agreement with the absence of bands in the infrared which are usually associated with nitrates or nitrogen/oxygen complexes. A binding energy value of 406.5 eV was measured in the comparable N(1*s*) spectrum of a catalyst used at 623 K for the oxidation of ethane by nitric oxide — a result which confirms conclusions from previous surface studies on the same system using infrared spectroscopy.

CRAIG FAIRBRIDGE et ROBERT ANDERSON ROSS. Can. J. Chem. **60**, 893 (1982).

La cinétique des réactions entre le protoxyde d'azote et l'ethane et entre l'oxygène et l'éthane a été étudiée sur l'oxyde de manganèse (III) à 573 jusqu'à 593 K respectivement. La valeur de l'énergie apparente d'activation du dioxyde de carbone était $130 \pm 4$ kJ mol$^{-1}$ dans les deux réactions, pendant que la valeur originelle de $106 \pm 4$ kJ mol$^{-1}$, 573–613 K, pour la formation de l'azote dans la réaction du protoxyde d'azote avec l'éthane augmentait à $133 \pm 4$ kJ mol$^{-1}$, 623–673 K. Les valeurs cinétiques pour les deux réactions s'accordent avec la même équation de vitesse:

$$r = \frac{kap_{C_2H_6}bp_x}{(1 + ap_{C_2H_6} + bp_x)^2} \cdot (p_{C_2H_6}p_x)$$

dans laquelle $p_x$ représente $p_{N_2O}$ ou $p_{O_2}$. Le procédé du contrôle de vitesse semble être lié avec l'interaction des éléments adsorbés sur la surface catalytique; mais l'influence directe de l'éthane aussi que celle du gaz oxydant apparément ne se manifeste que pendant les étapes suivantes du mécanisme. Un microscope électronique explorant, la diffraction de rayons X des poudres et la spéctroscopie infrarouge ont été utilizés dans une analyse courante des échantillons. Les résultats d'une analyse par la spéctroscopie électronique obtenus pour des échantillons traîtés de diverses manières par des mélanges des carbures d'hydrogène et d'un agent oxydant représentent les valeurs O(1*s*) de 528.7 à 529.7 eV, caractéristiques pour les énergies de liaison normalement associées avec l'oxygène absorbé chimiquement. Des catalyseurs exposés aux mélanages de la carbure d'hydrogène et du protoxyde d'azote ne produisaient pas de spêctre N(1*s*) et cela s'accorde avec l'absence des bandes normalement associées avec les nitrates ou les complexes nitrogène–oxygène en analyse par la spéctroscopie infrarouge. La valeur de l'énergie de liaison de 406.5 eV était obtenue en mesurant un spectre N(1*s*) comparable d'un catalyseur utilisé pendant l'oxydation de l'éthane par l'oxyde nitrique à 623 K cette valeur est en accord avec les résultats des analyses infrarouge executées auparavant à l'étude des surfaces d'un système identique.

## Introduction

In previous, related studies the kinetics of the nitrous oxide/carbon monoxide reaction were evaluated on several transition metal oxides (1–5) and the reaction mechanism held to involve the adsorption and reaction of carbon monoxide with surface oxygen followed by the formation of a surface carbonate. In a similar way, investigations of the water–gas shift reaction over manganese(II) oxide led to the proposal that the rate-controlling step was associated with the reducing action of adsorbed carbon monoxide on a surface oxygen species (6). Further, the decomposition of nitrous oxide on manganese oxides has been explained by a redox-

type mechanism which would be enhanced by conditions which preserve the 3+ oxidation state of the metal (7).

Those features of the surface chemical properties of manganese oxides which appeared to contribute to catalysis were most recently investigated in a kinetic study of the reaction of nitric oxide with ethane over manganese(III) oxide (8). A contiguous investigation of the oxidation of ethane by both oxygen and nitrous oxide is reported here with the experimental rate data supplemented by structure analysis including the results of electron spectroscopic measurements on selected catalyst samples.

## Experimental

*Apparatus and procedure*

A quartz reactor and Pyrex flow system (9) were used for the kinetic studies in conjunction with a Hewlett-Packard Research Chromatograph Model 5754B. Nitrogen, oxygen, carbon dioxide, nitrous oxide, ethane, and water were analysed by a thermal conductivity bridge using stainless steel columns 244 × 0.32 cm od packed with 61 cm Carbosieve B and 183 cm Poropak T. The column oven was temperature programmed with a 2 min post-injection interval at 353 K followed by a 60 K $min^{-1}$ rise to 443 K where the temperature was maintained for 5 min prior to recycling.

Surface areas were determined by application of the BET theory to low-temperature krypton adsorption (77 K, $\sigma$ = 21.5 Å$^2$).

The experimental conditions for which reaction rates were not influenced by internal or external diffusion were determined in the usual way by altering space velocity, catalyst mass, and particle size (10). Hence, kinetic measurements were conducted at a total flow rate of 350 $dm^3$ $min^{-1}$ (NTP) on 1.0 g catalyst samples, <37 μm maximum diameter with surface area 15.5 $m^2$ $g^{-1}$, and were recorded as the rate of nitrogen or carbon dioxide production after steady catalyst activity had been attained and at less than 15% total conversion to products. The temperature regions adopted for kinetic measurements were defined at the high end by the maximum of 15% conversion and at the low end by the reasonable limits of detection of nitrogen and carbon dioxide on the gas chromatograph, $>10^{-4}$ mol $L^{-1}$. The only products observed were nitrogen, carbon dioxide, and water in the nitrous oxide/ethane reaction, and carbon dioxide and water in the oxygen/ethane reaction. Because of the tailing involved in the water peak in the chromatogram, the area under the peak, and hence the water concentration, could not be estimated with acceptable accuracy.

Infrared spectra were obtained using KBr pellets (0.5% w/w) with a Beckman IR-12 Spectrophotometer.

X-ray photoelectron spectra were obtained on a Vacuum Generator Limited ESCA-3 spectrometer using Al $K_\alpha$ radiation. A 50 eV electron analyzer pass energy was used. Samples were run as powders, mounted on double-sided tape and the spectra were corrected for charging by reference to the C(1*s*) line at 284.0 eV.

*Materials*

Manganese(III) oxide was prepared and analysed as described previously (11). No change in the nature of the catalyst was observed from XRD, scanning electron microscopy, chemical analysis, or surface area measurements after reaction.

Ethane (99.0%) and oxygen (99.99%) were supplied by Matheson of Canada Ltd. Carbon dioxide (99.5%), nitrogen (99.99%), and helium (99.995%) were obtained from Canadian Liquid Air Ltd. and nitrous oxide (99.9%) from Liquid Carbonic Ltd. The water in the gas saturators was distilled and de-ionized prior to use.

## Results

*Reaction rate orders*

Rate order measurements based upon the rates of nitrogen, $r_1$, or carbon dioxide, $r_2$, formation were determined at 623 K for the $N_2O/C_2H_6$ reaction and at 573 K for the $O_2/C_2H_6$ reaction.

*Nitrous oxide/ethane*

With the partial pressure of ethane held constant at 2.66 kPa, the effects of the partial pressure of nitrous oxide on $r_1$ and $r_2$ were observed and the results plotted as ln (rate) against ln (partial pressure), Fig. 1. A reaction rate order of 0.8 was obtained with respect to nitrous oxide partial pressure from 0.665 to 5.32 kPa.

The effects of variations in ethane partial pressure were observed with the partial pressure of nitrous oxide held at 2.66 kPa. A reaction rate order of 0.7 was obtained from 0.665 to 3.325 kPa and, as indicated in Fig. 1, a rate order of 0.2 was determined from 3.325 to 5.32 kPa.

With both ethane and nitrous oxide partial pressures held constant at 2.66 kPa, the effects on the rates of the partial pressures of the products, nitrogen and carbon dioxide, were observed from 0.333 to 5.32 kPa. In both cases, the reaction rate order was zero. Similarly, the addition of from 0.04 to 1.5 kPa of water vapour had no effect upon the reaction rates.

The experimental rate of reaction was therefore represented by the expressions:

$$[1] \quad r = k p_{N_2O}^{0.8} p_{C_2H_6}^{0.7}$$

for $0.665 < p_{C_2H_6} < 3.325$ kPa and

$$[2] \quad r = k p_{N_2O}^{0.8} p_{C_2H_6}^{0.2}$$

for $3.325 < p_{C_2H_6} < 5.32$ kPa where $r$ and $k$ represent either $r_1$ and $k_1$ or $r_2$ and $k_2$.

*Oxygen/ethane*

The dependence of the reaction rate, $r_2$, on variations in the oxygen partial pressure from 0.665 to 5.32 kPa was examined with ethane partial pressure maintained at 2.66 kPa. At 573 K, a reaction rate order of 0.5 was obtained, Fig. 1. With the partial pressure of oxygen held at 2.66 kPa, the rate order with respect to ethane partial pressure was 0.6 from 0.665 to 2.66 kPa and 0.85 from 2.66 to 5.32 kPa. The experimental reaction rate was not affected by variations in the carbon dioxide or water vapour partial pressures as in the nitrous

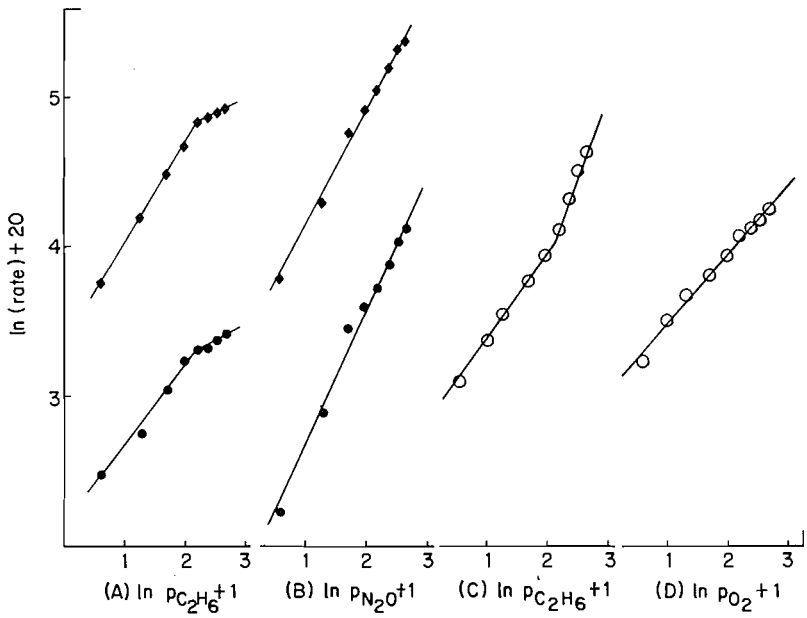

FIG. 1. Nitrogen (◆) and carbon dioxide (● in *A* and *B*, ○ in *C* and *D*) rate dependency on variations in the partial pressure of ethane (*A*) and nitrous oxide (*B*) in the $N_2O/C_2H_6$ catalytic reaction over $Mn_2O_3$ at 623 K; and ethane (*C*) and oxygen (*D*) in the $O_2/C_2H_6$ reaction at 573 K.

oxide/ethane reaction. The experimental reaction rate was therefore expressed as:

$$[3] \quad r_2' = k_2' p_{O_2}^{0.5} p_{C_2H_6}^{0.6}$$

where $0.665 < p_{C_2H_6} < 2.66$ kPa and

$$[4] \quad r_2' = k_2' p_{O_2}^{0.5} p_{C_2H_6}^{0.85}$$

where $2.66 < p_{C_2H_6} < 5.32$ kPa.

*Temperature effects*

*Nitrous oxide/ethane*

Steady catalytic activity was obtained after 2 h exposure to the standard mixture of 2.66 kPa each of nitrous oxide and ethane at 673 K. Reaction rate constants were calculated by integration of the rate equation [1] as a function of concentration from 673 to 573 K. Two apparent activation energies were obtained using $r_1$, namely 133 ± 4 kJ mol$^{-1}$ from 673 to 623 K and 106 ± 4 kJ mol$^{-1}$ from 613 to 573 K, Fig. 2. The pre-exponential factors were $6.35 \times 10^8$ and $3.27 \times 10^6$ mol L m$^{-2}$ s$^{-1}$, respectively.

*Oxygen/ethane*

After catalyst pretreatment with 2.66 kPa oxygen and 2.13 kPa ethane at 593 K for 3 h, the rate of carbon dioxide formation was determined from 593 to 523 K at 10 K intervals. Rate constants were calculated from the integrated form of eq. [3] and plotted in the Arrhenius fashion, Fig. 2. The results lay on the same straight line as those for the rate of carbon dioxide formation in the nitrous oxide/ethane reaction. The apparent activation energy was 130 ± 4 kJ mol$^{-1}$ and the pre-exponential factor, $9.72 \times 10^7$ mol L m$^{-2}$ s$^{-1}$.

*Infrared spectra*

The infrared spectra of the catalysts after reaction with nitrous oxide/ethane or oxygen/ethane were similar to those observed previously for samples of manganese(III) oxide after catalysis in the nitric oxide/ethane reaction (8). However, a major difference was the absence of any nitrate bands in the spectra. Peaks were noted at 615(s), 490(s), 425(m), and 350(m) cm$^{-1}$ which may possibly suggest the presence of some $Mn_3O_4$ phase as a surface trace since both chemical analysis and XRD indicated no apparent change from the original $Mn_2O_3$ composition.

*X-ray photoelectron spectroscopy*

O(1*s*) spectra on the fresh, unreacted manganese oxide gave a binding energy value of 528.7 eV. Samples exposed to 2.66 kPa each of ethane and nitrous oxide from 573 to 673 K in a kinetic temperature cycle gave an O(1*s*) value of 529.0 eV while 529.5 eV was obtained for the binding energy in a catalyst sample after exposure to the standard mixture of ethane and oxygen in a cycle from 523 to 593 K. All of these energy values are close to that expected for chemisorbed oxygen in metal oxides

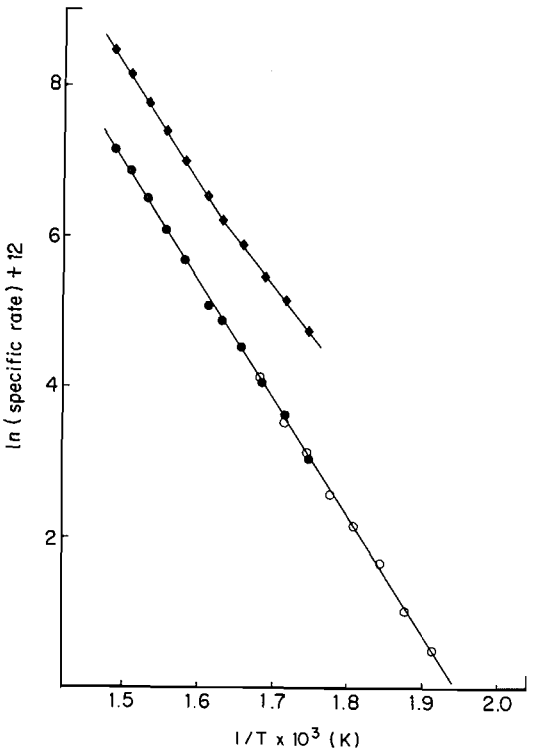

FIG. 2. Arrhenius plots for the $N_2O/C_2H_6$ (◆, $r_1$; ●, $r_2$) and $O_2/C_2H_6$ (○, $r_2$) catalytic reactions over $Mn_2O_3$.

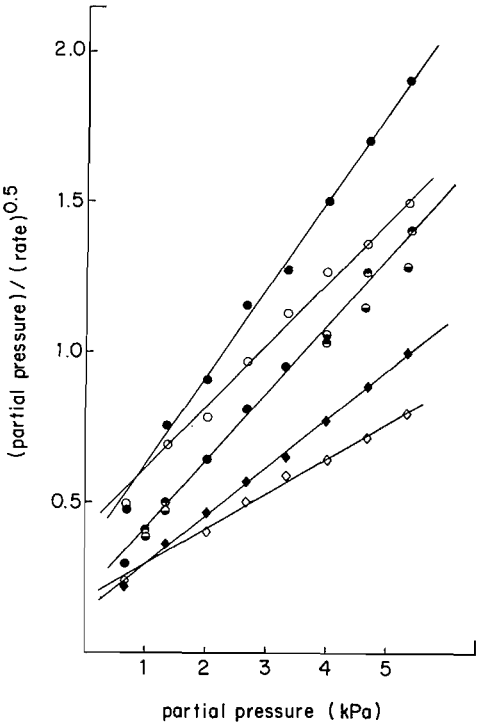

FIG. 3. Reduced plots corresponding to eq. [5] for the nitrous oxide (◇, $r_1$; ○, $r_2$) and ethane (◆, $r_1$; ●, $r_2$) rate orders in the $N_2O/C_2H_6$ reaction; and for the oxygen (◓, $r_2$) and ethane (◒, $r_2$) rate orders in the $O_2/C_2H_6$ reaction over $Mn_2O_3$.

and significantly less than an O(1*s*) value of 532–533 eV which usually characterises the presence of molecular oxygen (12).

Only two of the catalyst samples tested gave N(1*s*) spectra. Catalyst exposed to 2.66 kPa each of ethane and nitric oxide at 623 K, steady state, gave a binding energy of 406.5 eV and a sample used in a cycle from 573 to 673 K with the same gases before cooling to room temperature gave an N(1*s*) value of 406.4 eV.

Manganese(IV) oxide was not detected in any sample and it is difficult to distinguish between manganese(II) and manganese(III) oxides using this technique solely because the Mn/O intensities are similar in the two oxides (13). X-ray diffraction and chemical analysis confirmed that the metal was present as $Mn_2O_3$ in all bulk samples.

## Discussion

Several plausible mechanistic schemes were evaluated by computer tests of the rate order results in many kinetic expressions related mainly to the Langmuir–Hinshelwood model (14, 15). The significance of such statistical criteria in the evaluation of the step-by-step nature of the catalytic process has been frequently analysed (16–18) and recently reviewed (19). The approach has been adopted here to obtain a broad guide to the interpretation of the kinetic results.

Only one kinetic expression clearly accommodated the rate order data. It was the same for both reactions:

$$[5]\quad r = \frac{kap_{C_2H_6}bp_x}{(1 + ap_{C_2H_6} + bp_x)^2}(p_{C_2H_6}p_x)$$

where $p_x$ represents the partial pressure of nitrous oxide or oxygen and $a$ and $b$ are adsorption coefficients. As shown in Fig. 3, plots of $p/r^{0.5}$ versus $p$ were linear for both nitrogen and carbon dioxide rate order results in the nitrous oxide/ethane reaction and for the carbon dioxide results in the oxygen/ethane reaction. A similar kinetic expression was evaluated previously for the nitric oxide/ethane reaction (8). It may be interpreted to represent an irreversible bimolecular reaction between reactive species adsorbed on the same type of site (20). The reaction rate is proportional to the probability that the reactants are adsorbed on neighbouring sites, and thus also proportional to the product of the fraction of surface covered by each reactant, $\theta_{C_2H_6}$ and $\theta_{N_2O}$ or $\theta_{O_2}$. The $(p_{C_2H_6}p_x)$ multiplier term in eq. [5] suggests that additional

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

interactions involve nitrous oxide and ethane or oxygen and ethane in the appropriate reaction.

On a test/reject basis (6), surface mechanisms consistent with eq. [5] were formulated:

*Nitrous oxide/ethane*

[6] $N_2O_{(g)} = N_2O_{(ads)}$

[7] $C_2H_{6(g)} = C_2H_{6(ads)}$

[8] $C_2H_{6(ads)} + N_2O_{(ads)} + [O] \rightarrow C_2H_{5(ads)} + [OOH] + N_2$

[9] $C_2H_6 + [OOH] \rightarrow H_2O + C_2H_{5(ads)} + [O]$

[10] $2C_2H_{5(ads)} + 13N_2O \rightarrow 4CO_2 + 5H_2O + 13N_2$

with an overall stoichiometry:

[11] $C_2H_6 + 7N_2O \rightarrow 2CO_2 + 3H_2O + 7N_2$

*Oxygen/ethane*

[12] $O_{2(g)} = O_{2(ads)}$

[13] $C_2H_{6(g)} = C_2H_{6(ads)}$

[14] $C_2H_{6(ads)} + O_{2(ads)} + [\ ] \rightarrow C_2H_{5(ads)} + [OOH]$

[15] $C_2H_6 + [OOH] \rightarrow H_2O + C_2H_{5(ads)} + [O]$

[16] $2C_2H_{5(ads)} + [O] + 6O_2 \rightarrow 4CO_2 + 5H_2O + [\ ]$

with an overall stoichiometry:

[17] $2C_2H_6 + 7O_2 \rightarrow 4CO_2 + 6H_2O$

Previous studies of ethane oxidation over nickel(II) oxide have indicated that the hydrocarbon was adsorbed prior to surface reaction with preadsorbed oxygen while chemisorption of ethane on iron(III) and nickel(II) oxides was shown to involve C—H bond rupture to give a $C_2H_{5(ads)}$ species (21). The rate-determining step in the oxidation of ethane over nickel(II) oxide was thought to be either the adsorption of ethane as a $C_2H_5$ radical or the interaction of adsorbed oxygen with gas phase or adsorbed ethane through attack at the C—H bond (22). In the homogeneous oxidation of ethane by oxygen the formation of $C_2H_5$ and $HO_2$ radicals was postulated as the initial step (23); indeed, peroxide species are often formed in gas phase hydrocarbon oxidation reactions.

It seems likely then that the rate-limiting step in the oxidation of ethane over manganese(III) oxide involves the formation of an adsorbed $C_2H_5$ species, which may occur through the interaction of adsorbed ethane with adsorbed nitrous oxide or oxygen, eqs. [8] or [14]; or through the action of a surface peroxide radical on gas phase or weakly adsorbed ethane, eqs. [9] or [15].

The apparent activation energies are in good agreement with those determined for the nitrous oxide/carbon monoxide reaction, 493 to 573 K (3), the decomposition of isopropyl alcohol, 483 to 638 K (11), and the dehydration of formic acid, 523 to 573 K (24), all over similar manganese oxide catalysts. These reactions, together with the water–gas shift reaction (6), all appear to involve both $Mn^{2+}$ and $Mn^{3+}$ reactive surface species in the catalytic cycle. The same species may also occur in the present reactions, as well as in the oxidation of ethane by nitric oxide (8).

# Développement d'un détecteur à plasma micro-onde pour chromatographie en phase gazeuse

GILLES CHEVRIER, TOSHIHIKO HANAI, KHANH-CHI TRAN ET JOSEPH HUBERT[1]

*Département de chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal (Qué.), Canada H3C 3V1*

Reçu le 20 novembre 1981

GILLES CHEVRIER, TOSHIHIKO HANAI, KHANH-CHI TRAN et JOSEPH HUBERT. Can. J. Chem. **60**, 898 (1982).

Le développement d'un détecteur à émission atomique comme détecteur de chromatographie en phase gazeuse a été décrit. Un plasma micro-onde d'hélium à pression atmosphérique généré à l'aide d'un dispositif appelé Surfatron a été utilisé comme source d'atomisation et d'excitation. Les caractéristiques d'opération de ce détecteur ont été définies et ses performances analytiques pour l'analyse du carbone, chlore, brome et iode ont été déterminées. Des limites de détection de l'ordre du pg/s ont été obtenues et les domaines de linéarité du détecteur couplé à une colonne en silice s'étendent sur trois ordres de grandeur en concentration.

GILLES CHEVRIER, TOSHIHIKO HANAI, KHANH-CHI TRAN, and JOSEPH HUBERT. Can. J. Chem. **60**, 898 (1982).

The development of an atomic emission detector for gas chromatography is described. An atmospheric pressure microwave helium plasma generated with an original device called Surfatron was used as an atomization and excitation source. The characteristics of operation are defined and the analytical performances for carbon, chlorine, bromine, and iodine analyses are measured. Detection limits are in the order of pg/s and the dynamic range of the detector covers three orders of magnitude.

## Introduction

La grande complexité d'échantillons d'origine environnementale ou biologique associée au développement de colonnes chromatographiques à très grande résolution a nécessité le développement de nouveaux détecteurs sélectifs en chromatographie en phase gazeuse. Plusieurs détecteurs sélectifs ont été développés et utilisés, leur principale limitation vient de leur manque de flexibilité: seul un nombre restreint d'éléments sont détectables et la détection d'un autre élément nécessite souvent l'achat d'un autre détecteur.

Un détecteur qui ne possède pas ces limitations a été décrit par McCormack *et al.* (1). Ce détecteur est basé sur la spectroscopie d'émission atomique et la source d'atomisation et d'excitation est un plasma d'argon induit par micro-onde. Plusieurs auteurs ont étudié des détecteurs similaires en utilisant des plasmas d'argon à diverses pressions ou d'hélium sous pression réduite (2–5). L'étude la plus complète des performances de ce détecteur à plasma sous pression réduite a été faite par Van Dalen *et al.* (6). En 1977, Beenakker (7) a rapporté quelques performances analytiques d'un plasma d'hélium à pression atmosphérique induit par micro-onde à l'aide d'une nouvelle cavité ($TM_{010}$). Les limites de détection obtenues sous conditions non chromatographiques étaient généralement supérieures à celles obtenues précédemment. Le même type de plasma mico-onde a été utilisé par d'autres auteurs (8–12) comme source d'excitation d'un détecteur chromatographique.

Plusieurs problèmes concernant l'opération de ces détecteurs ont été rapportés: la sensibilité du plasma au solvant organique utilisé en chromatographie, le dépôt de carbone sur les tubes de décharge du plasma et le couplage entre la cavité dans laquelle le plasma est généré et le générateur micro-onde.

En 1979, nous avons rapporté le développement d'un nouveau système de génération de plasma micro-onde à pressions réduites et atmosphérique basé sur la propagation d'une onde de surface (13); ce dispositif appelé Surfatron permet d'obtenir des plasmas stables d'argon, d'hélium ou d'azote à pression atmosphérique. Les premières applications comme détecteur de chromatographie ont été rapportées (14).

Dans cet article, les conditions optimales d'utilisation et les performances analytiques de ce détecteur en chromatographie en phase gazeuse sont rapportées pour quatre éléments en termes de limite de détection, sélectivité et domaine de linéarité.

## Partie expérimentale

Le schéma du montage expérimental utilisé est représenté à la figure 1.

1. *Système chromatographique*

Un chromatographe en phase gazeuse (FM Scientific Corporation 810R-15) a été modifié pour l'utilisation d'une colonne capillaire en silice (HP, Phase stationnaire SE-30, 12 m, diamètre intérieur 0,2 mm). L'injecteur a été modifié pour permettre l'injection de tout l'échantillon sur la colonne. A la sortie de la colonne un raccord en T permet d'augmenter le débit d'hélium. L'extrémité de la colonne capillaire est placée à des distances de 2 à 5 mm en arrière du plasma dans le tube à décharge. Un système d'injection continue basé sur l'évaporation d'un produit volatil contenu dans un tube capillaire a été adapté au système chromatographique. Ce système sert à repérer la

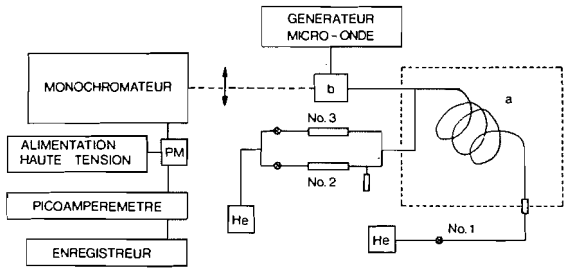

FIG. 1. Schéma du montage expérimental. (a) Colonne capillaire en silice; (b) plasma d'hélium; (c) tube d'évaporation.

longueur d'onde d'émission de l'analyte et à effectuer le travail d'optimisation. Les débits d'hélium dans le chromatographe (≃1 mL/min) (No. 1) et dans le circuits No. 2 et No. 3 (Fig. 1) peuvent être ajustés indépendamment.

2. *Système de détection*

Le Surfatron utilisé, représenté à la figure 2, est refroidi à l'air comprimé sec. Le tube de décharge est constitué de tubes de quartz de différents diamètres internes. Pour la partie chromatographique, on a utilisé un tube de 2,8 mm de diamètre interne et de 6,0 mm de diamètre externe.

Le plasma est amorcé à l'aide d'une bobine Tesla en faisant passer dans le tube de décharge un débit d'hélium d'environ 25 mL/min. La puissance du générateur est ensuite ajustée à 90 W. Le coupleur et la longueur de la cavité sont ajustés de façon à minimiser la puissance réfléchie (≃ 0 W). Il est à souligner que cet ajustement se fait au début et ne change pas durant les manipulations. La longueur d'onde du spectrophotomètre est ajustée en injectant de manière continue un produit volatil par l'intermédiaire du circuit de gaz No. 2 (Fig. 1).

Un générateur à micro-onde Microtron 200, Mark III (Electromedical Supplies, England) capable de produire jusqu'à 200 W de puissance à 2,45 GHz a été utilisé. Le plasma est observé axialement et son image est formée sur la fente d'entrée du monochromateur à l'aide d'une lentille en quartz ($f$ = 10 cm). Un grossissement de 4 a été utilisé. Un monochromateur Spex modèle 1800-2 de 0,75 m de distance focale équipé d'un réseau à 1200 traits/mm "blazé" à 500 nm, un photomultiplicateur Hamamatsu R-446, une alimentation haute tension Hamner (modèle N-4035), un picoampèremètre Keithley (modèle 410) et un enregistreur Brinkmann (modèle 2541) ont été utilisés. Les fentes d'entrée et de sortie étaient fixées à 40 μm.

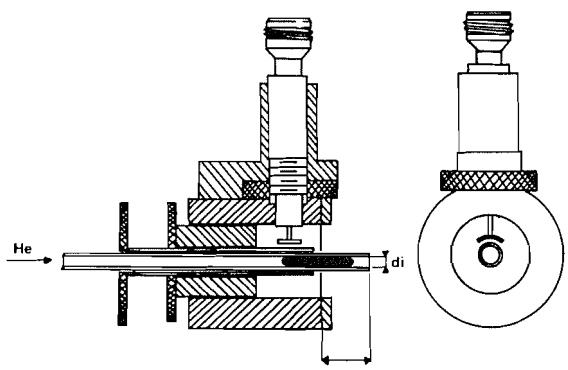

FIG. 2. Schéma du Surfatron.

*Mode opératoire pour l'optimisation du détecteur*

Pour pouvoir étudier l'effet de différents paramètres sur l'intensité du signal analytique, on a placé dans le circuit No. 2 (Fig. 1) un tube capillaire de 1,2 mm de diamètre intérieur et de 10 cm de longueur contenant un composé halogéné ($CCl_4$, $C_6H_5Cl$, $CH_2Br_2$ ou $C_3H_7I$). En faisant passer un débit d'hélium constant au-dessus de ce capillaire, on entraîne une quantité constante d'analyte vers le plasma. Pour un tube à décharge de 2,8 mm de diamètre interne et un débit d'hélium au-dessus du tube capillaire de 17 mL/min, le taux d'évaporation est de 21 nL/min de $CCl_4$ liquide à 19°C. Ceci conduit à une concentration de 0,03% (volume de $CCl_4$ gazeux/volume d'hélium) de $CCl_4$ dans le plasma pour un débit total d'hélium de 17 mL/min. En conservant le débit au-dessus du tube capillaire constant et en faisant varier le débit d'hélium (No. 3, Fig. 1), on fait varier la concentration et le temps de séjour de l'analyte dans le plasma.

Pour déterminer les limites de détection, les domaines de linéarité et les sélectivités, on a injecté 20 nL d'une solution d'un produit contenant l'analyte dans le dodécane. L'ensemble des produits incluant le solvant, passe directement dans le plasma à la sortie de la colonne.

## Résultats et discussion

1. *Optimisation*

Les principaux paramètres qui affectent les performances analytiques du détecteur sont: le débit du gaz plasmagène, la puissance d'opération, le diamètre intérieur ($d_i$) et la position ($l$) du tube à décharge dans le Surfatron (Fig. 2). Pour cette étude, une quantité constante de $CCl_4$ a été entraînée vers le plasma par évaporation sous un débit d'hélium de 17 mL/min et a été mélangée à une quantité variable d'hélium. L'intensité émise par le chlore (479,5 nm) a été mesurée pour diverses conditions expérimentales.

1. a. *Position du tube à décharge*

La position du tube à décharge ($l$, Fig. 2) affecte la stabilité du plasma d'hélium. Les débits minimum limites d'opération du plasma pour une position et une puissance donnée sont rapportés sur la figure 3. Pour une puissance de 90 W, le plasma ne peut pas être entretenu à des débits inférieurs à 40 mL/min, si la longueur $l$ n'est pas au moins de 2 cm. Cette distance peut être plus courte, si l'on augmente le débit. Cet effet n'a pas encore été rapporté lors des études antérieures et il a été établi que l'instabilité du plasma provient de la rétrodiffusion de l'air vers le plasma. Ceci a été mis en évidence par l'augmentation des bandes moléculaires du système $N_2$ lorsqu'on diminue $l$ pour un débit donné ou le débit pour une valeur de $l$ donnée. La rétrodiffusion de l'air change les caractéristiques du plasma, qui devient un plasma mixte hélium–air et par conséquent affecte le couplage entre le plasma et le générateur. Si l'on réajuste le couplage en diminuant le débit d'hélium, on peut conserver un plasma pour un débit d'hélium nul, il s'agira

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

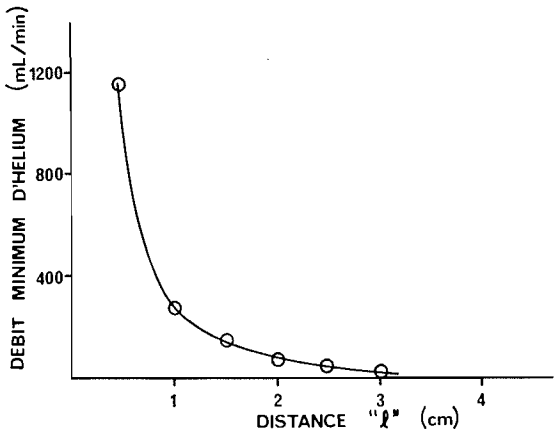

FIG. 3. Stabilité du plasma en fonction de la position du tube à décharge. Puissance: 90 W, $d_i = 2{,}8$ mm.

alors d'un plasma d'air. Par la suite ce paramètre ($l$) a été fixé à 3 cm, ce qui a permis d'opérer à des débits d'hélium de 20 mL/min et plus.

1. b. *Puissance*

La variation du signal net émis par le chlore en fonction de la puissance est rapportée à la figure 4. Pour le domaine de puissance étudié, le fond continu et le bruit ne varient pas. Une augmentation de plus de 50% du signal est obtenu lorsqu'on passe de 100 à 150 W. Une opération du plasma à plus haute puissance améliorera donc la sensibilité et les limites de détection; cependant pour fins de comparaison avec des études antérieures, notre étude a été faite à 90 W. Le même effet a été observé pour le carbone, le brome et l'iode.

1. c. *Débit d'hélium et diamètre du tube à décharge*

L'influence de ces deux paramètres est illustrée sur les figures 5 et 6. Pour un tube à décharge donné, on observe généralement une augmentation rapide, un maximum et une décroissance du signal

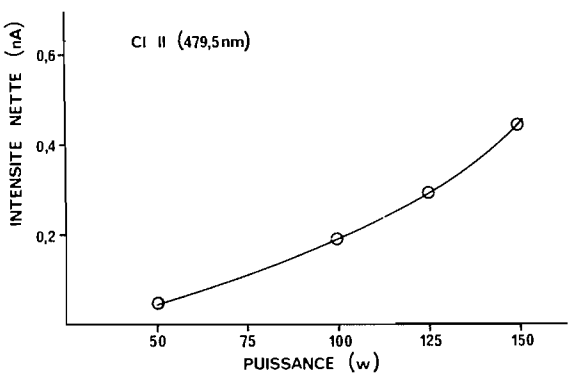

FIG. 4. Effet de la puissance sur le signal net émis par le chlore. $d_i = 2{,}8$ mm, l = 3,0 cm, débit d'hélium 21,5 mL/min.

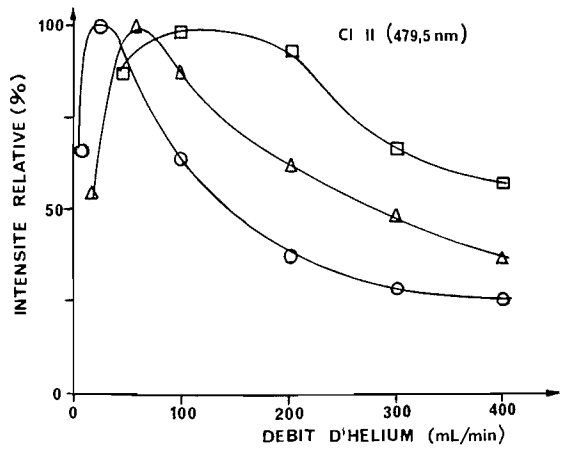

FIG. 5. Effet du débit d'hélium et du diamètre du tube à décharge sur le signal émis par le chlore. ○ $d_i = 1{,}5$ mm; Δ $d_i = 2{,}8$ mm; □ $d_i = 4{,}5$ mm.

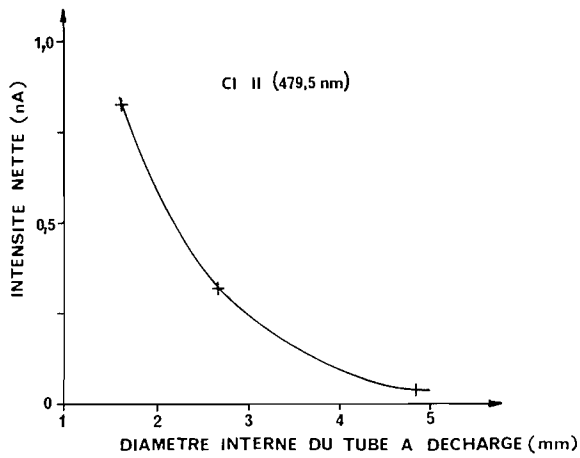

FIG. 6. Effet du diamètre interne du tube à décharge sur l'intensité émise par le chlore.

émis par l'analyte en fonction du débit. A très faibles débits (20 mL/min pour un tube de 3 mm de diamètre interne), le plasma est peu stable et l'excitation est peu efficace. Une augmentation de débit d'une part stabilise le plasma et favorise l'excitation, et d'autre part diminue la concentration en analyte et le temps de séjour de l'analyte dans le plasma. La superposition de ces effets entraîne une augmentation rapide de l'intensité émise, suivie d'une décroissance rapide à forts débits.

Ce comportement se retrouve également pour le carbone et les autres halogènes. Le débit correspondant au maximum d'émission pour le carbone est généralement inférieur à celui des halogènes. Ceci provient probablement du fait que la raie utilisée pour le carbone est une raie atomique facile à exciter.

TABLEAU 1. Limites de détection

| Elément | Raie | Longueur d'onde (nm) | Limite de détection[a] (pg/s) | Limite de détection[b] absolue (pg) |
|---|---|---|---|---|
| C | I | 247,9 | 2–5 | 14–38 |
| Cl | II | 479,5 | 2–4 | 9–124 |
| Br | II | 470,5 | 7–12 | 37–565 |
| I | I | 206,2 | 0,2–2 | 1–12 |

[a]La limite de détection est définie comme la masse d'analyte par unité de temps qui produit un signal égal à 2 fois l'écart-type sur l'intensité du fond continu.
[b]La limite de détection absolue est égale au produit de note [a] par la largeur à la base du pic chromatographique (15).

Lorsqu'on change le diamètre interne du tube à décharge, l'allure globale de la courbe de variation de l'intensité relative émise par l'analyte en fonction du débit demeure la même. On note cependant qu'en diminuant le diamètre du tube de décharge, le maximum est déplacé vers des débits plus faibles et que ce maximum devient plus étroit. Le déplacement du maximum peut être expliqué par la plus grande stabilité du plasma dans un tube à décharge de petit diamètre, donc par une meilleure excitation à faible débit. L'excitation est liée au temps de séjour dans le plasma et une augmentation de débit d'hélium se traduit par une augmentation de la vitesse de passage de l'analyte dans le plasma. Pour un tube à décharge de faible diamètre la vitesse du gaz qui produit une émission maximale est de l'ordre de 20 cm/s ($d_i$ = 1,55 mm, débit de 25 mL/min) et on retrouve sensiblement la même vitesse pour le maximum observé avec un tube de plus grand diamètre ($d_i$ = 2,8 mm, débit de 75 mL/min). Pour le tube de petit diamètre, une augmentation de débit de 5 mL/min au voisinage du maximum se traduit par une augmentation de vitesse de plus de 18% et donc par une diminution du temps de séjour. La même variation de débit pour un tube de plus grand diamètre (2,8 mm) se traduit par une augmentation de vitesse de 1%. Cette faible diminution explique la plus grande largeur du maximum observé pour ce tube à décharge. L'importance du temps de séjour a également été mise en évidence en enregistrant les variations d'intensité du signal du carbone présent sous forme d'impuretés dans l'hélium ordinaire en fonction du débit d'hélium. Un maximum d'émission a été observé vers 75 mL/min ($d_i$ = 3 mm), ce qui correspond à des vitesses de l'ordre de 15 cm/s.

Sur la figure 6, on a représenté la variation de l'intensité nette mesurée au maximum d'émission pour divers tubes à décharge à 90 W. On constate que l'utilisation d'un tube à décharge plus petit permet d'obtenir une intensité plus forte avec un fond continu et un bruit constant. Cependant la durée de vie du tube à décharge diminue et par la suite nous avons utilisé un tube à décharge de 2,8 mm de diamètre pour nous permettre de faire l'ensemble des mesures avec le même tube.

Le même type de comportement a été observé lorsqu'on injecte le même échantillon dans le chromatographe en phase gazeuse en faisant varier les divers paramètres précédents.

2. *Performances analytiques*

Les performances analytiques ont été mesurées en mode chromatographique, la puissance a été fixée à 90 W, le tube à décharge avait 2,8 mm de diamètre interne et de débit d'hélium total était compris entre 20 et 30 mL/min.

2. a. *Limite de détection*

Les limites de détections pour une cinquantaine de composés de structure moléculaire et de volatilité différentes ont été mesurées. Les valeurs obtenues sont résumées au tableau 1.[2] Ces limites de détection sont inférieures ou équivalentes à celles obtenues par d'autres auteurs (6–11). Il faut cependant souligner que ces valeurs ne sont qu'indicatives et peuvent être réduites en diminuant le diamètre du tube à décharge et/ou en augmentant la puissance. Les limites de détection sont également moins dépendantes de la structure de la molécule comme il avait été observé précédemment (14) et ceci provient d'un meilleur contrôle du plasma.

2. b. *Domaine de linéarité et sélectivité*

Les domaines de linéarité du détecteur pour les divers éléments ont été mesurés et sont rapportés au tableau 2. Le domaine de linéarité pour la plupart des éléments est de l'ordre de $10^3$, ce qui est du même ordre de grandeur que celui obtenu pour des détecteurs similaires (11, 12). La limite supérieure du domaine de linéarité est due à la capacité de la colonne de silice et non au plasma.

La sélectivité du détecteur par rapport au carbone a été mesurée et les valeurs obtenues sont

[2]L'ensemble des valeurs obtenues est disponible et peut être obtenu à un prix nominal, en s'adressant au Dépôt de données non publiées, ICIST, Conseil national de recherches du Canada, Ottawa, (Ont.), Canada K1A 0S2.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

TABLEAU 2. Domaine de linéarité et sélectivité

| Elément | Domaine de linéarité | Sélectivité par rapport au carbone[a] |
|---|---|---|
| C | $10^3$ | — |
| Cl | $10^3$ | 600 |
| Br | $1{,}5 \times 10^3$ | 1100 |
| I | $15 \times 10^3$ | 800 |

[a]La sélectivité est le rapport de l'intensité du signal produit par un atome-gramme de l'élément X (Cl, Br ou I) sur l'intensité du signal produit par un atome-gramme de carbone. Les hydrocarbures utilisés comme références sont le cumène et l'éthylbenzène.

rapportées au tableau 2. Ces valeurs sont comparables à celle obtenues avec des montages optiques équivalents et peuvent être améliorées par l'utilisation de fentes plus petites sur le système dispersif, par l'utilisation d'un monochromateur à plus haute résolution ou par de la modulation de longueur d'onde (16).

Des exemples de chromatogrammes obtenus pour des mélanges de produits organiques en utilisant le détecteur aux longueurs d'onde du carbone, chlore, brome et iode sont représentés à la figure 7.

Ces chromatogrammes ont été obtenues en mode séquentiel, notre système optique ne nous permettant pas une analyse simultanée à plusieurs longueurs d'onde.

Le système qui a été décrit, ne présente pas le problème associé à divers modes de génération de plasmas micro-ondes (1–12), à savoir l'instabilité du couplage entre le générateur et le plasma avec le temps. Les conditions d'ajustement du Surfatron sont uniques et reproductibles d'une manipulation à l'autre. Ce système contrairement aux autres systèmes décrits précédemment peut également être opéré avec une puissance réfléchie de zéro dans des conditions expérimentales très variées (gaz plasmagène, débit, diamètre de tube à décharge et puissance différents).

Les variations du signal émis en fonction du débit du gaz plasmagène ont été étudiées sur un plus grand intervalle de débits et de diamètre de tube à décharge par rapport aux études antérieures ou parallèles (6, 8, 11). Un diamètre ($d_i$) de 3 mm a été trouvé comme étant le meilleur compromis entre la durée de vie du tube à décharge et des limites de détection acceptables.

Aucun maximum du rapport signal sur fond continu en fonction de la puissance a été observé pour les quatres éléments étudiés, contrairement à l'étude d'Estes *et al.* (11). Cette différence provient du plus petit tube à décharge (0,5 mm) utilisée par ces auteurs.

Les performances analytiques décrites rendent ce détecteur intéressant pour des applications où

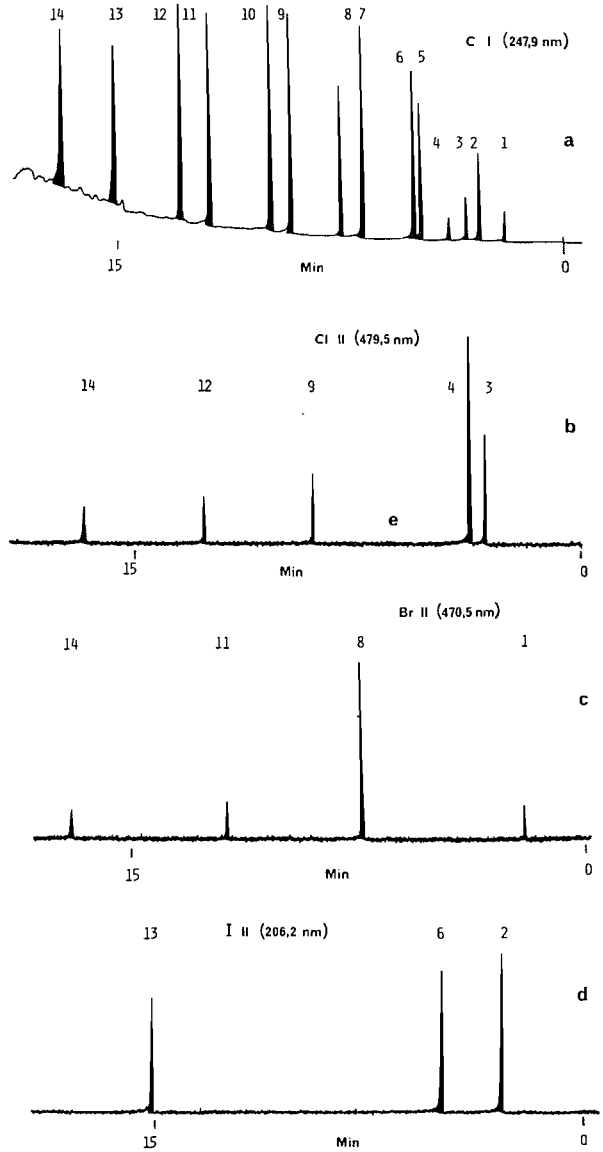

FIG. 7. Chromatogrammes d'un mélange de produits organiques. (a) Détection du carbone; (b) détection du chlore; (c) détection du brome; (d) détection de l'iode. Produits: bromoéthane (1), iodoéthane (2), 1,4-dichloroéthane (3), tétrachlorure de carbone (4), 2,2,4-triméthylpentane (5), iodopropane (6), toluène (7), 1,4-dibromoéthane (8), chlorobenzène (9), ethylbenzène (10), bromobenzène (11), 4-chlorotoluène (12), iodobenzène (13), 3-chlorobromobenzène (14). # Nuclear analogs of β-lactam antibiotics. XV.[1] Synthesis of 6-substituted 2-methylpenem-3-carboxylic acids

YASUTSUGU UEDA,[2] ALAIN MARTEL,[2] JEAN-PAUL DARIS, BERNARD BELLEAU, AND MARCEL MÉNARD

*Bristol Laboratories of Canada, 100 Industrial Boulevard, Candiac, P.Q., Canada J5R 1J1*

Received November 2, 1981

YASUTSUGU UEDA, ALAIN MARTEL, JEAN-PAUL DARIS, BERNARD BELLEAU, and MARCEL MÉNARD. Can. J. Chem. **60**, 904 (1982).

The synthesis of 6-substituted 2-methylpenem-3-carboxylic acids is described. The dianion **6** was prepared *in situ* from 2-methylpenem-3-carboxylic acid (**5**) by the addition of two equivalents of *n*-butyllithium in THF at −78°C. This dianion reacted with deuterated acetic acid, acetone, acetaldehyde, benzaldehyde, and methyl thiomethylsulfonate to give 6-deuterio-, 6-(2′-hydroxy-2′-propyl)-, 6-(1′-hydroxyethyl)-, 6-(1′-hydroxybenzyl)-, 6-methylthio-2-methylpenem-3-carboxylic acids and their sodium or potassium salts, **7–11**, respectively. The stereochemistry of the products is also discussed.

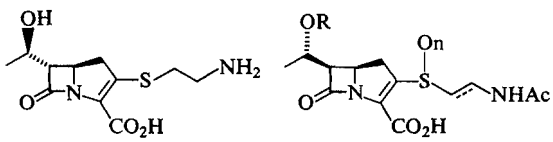
YASUTSUGU UEDA, ALAIN MARTEL, JEAN-PAUL DARIS, BERNARD BELLEAU et MARCEL MÉNARD. Can. J. Chem. **60**, 904 (1982).

On décrit la synthèse d'acides méthyl-2 penèmecarboxyliques-3 substitués en position 6. On a préparé le dianion **6** *in situ* à partir de l'acide méthyl-2 penèmecarboxylique-3 (**5**) par l'addition de deux équivalents de *n*-butyllithium dans le THF à −78°C. Les réactions de ce dianion avec l'acide acétique deutéré, l'acétone, l'acétaldehyde, le benzaldéhyde et le thiométhylsulfonate de méthyle conduisent respectivement aux acides deutéro-6, (hydroxy-2 propyl-2)-6, (hydroxy-1′ éthyl)-6, (hydroxy-1′ benzyl)-6 et méthylthio-6 méthyl-2 penèmecarboxyliques-3 (**7–11**) aussi qu'à leurs sels de sodium ou de potassium. On discute aussi de la stéréochimie des produits.

[Traduit par le journal]

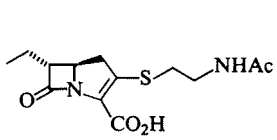
Naturally occurring carbapenem antibiotics, isolated from *streptomyces* species, were shown to differ markedly from the classical penicillins and cephalosporins in the composition of their side chain at position 6: thienamycin (**1**) (1) and the olivanic acids (**2**) (2) possess a 1-hydroxyethyl moiety while PS-5 (**3**) (3) and carpetimycins (or C-19393) (**4**) (4) carry a simple ethyl group and a 2-hydroxypropyl group respectively as a substituent.

In order to assess the influence of the side chain on the biological activity of the analogous penems, members of a new class of totally synthetic antibiotics (5), we prepared a series of 6-substituted penem-3-carboxylic acids (6). In this paper[3] we report the most direct and most desirable approach to 6-substitution: a one-step introduction of the 6-substituent onto a preformed 6-unsubstituted 2-substituted penem-3-carboxylic acid by metallation and subsequent reaction with electrophiles.

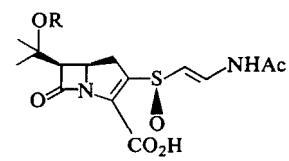


**1**

**2** (R = H, $SO_3H$)



**3**



**4** (R = H, $SO_3H$)

Although metallation of monocyclic β-lactams is well documented (7–9) and this method has been used in the total synthesis of thienamycin (10) and in the synthesis of 6-substituted penem acids (5*e*, 6*c*), a direct metallation on 6-unsubstituted penem acid has not been reported. Furthermore, electrophilic additions to enolates of the penam and the cephem nuclei have been achieved (11, 12) but, because of the lability of the penem system, especially toward strong bases, it was generally assumed (5*e*) that such a process would not be possible with the penem nucleus.

The dianion **6** was prepared from 2-methylpenem-3-carboxylic acid (**5**) (6*a*) by the addition of two equivalents of *n*-butyllithium in the presence or absence of diisopropylamine (2 equiv.) in THF at −78°C. This species was stable enough at −78°C to react with a variety of electrophiles to give the 6-substituted penem acids. Thus, the dianion, so prepared, reacted with $CD_3CO_2D$, acetone, acetaldehyde, benzaldehyde, or methyl thiomethylsul-

SCHEME 1

fonate to yield 6-substituted 2-methylpenem-3-carboxylic acids or the corresponding sodium or potassium salts, **7–11**, in 6–60% yield. Most of the penem acid products were immediately converted to their sodium or potassium salts, **8***a*, **9**, **10**, and **11***a*. 6-(1′-Hydroxyethyl) or 6-(1′-hydroxybenzyl) derivatives could not be isolated in the acid form without serious decomposition.

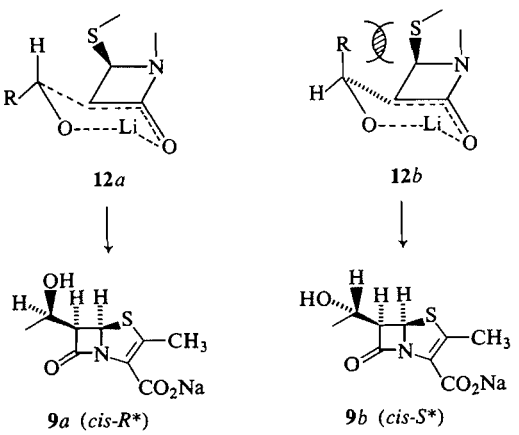
The infrared spectrum of each product showed a strong β-lactam carbonyl band in the 1750–1793 $cm^{-1}$ region. The ultraviolet spectrum of each product exhibited a maximum at around 300 nm. These data indicated that the penem ring system had been retained.

Examination of the $^1$Hmr spectrum of each product revealed that the reaction of this dianion with the above electrophiles produced a mixture of *cis* and *trans* 6-substituted penem acids or the corresponding salts. The *cis–trans* ratio varied from 4:1 to 3:7 as listed in Table 1. The relative stereochemistry at C5—C6 of each product was determined based on the fact that *cis* β-lactam coupling constants (~4 Hz) were larger than *trans* coupling constants (~2 Hz) (13). Deuterated acetic acid, acetaldehyde, and methyl thiomethylsulfonate gave the *cis* isomers as the major product. Among these, the smallest electrophile, $CD_3CO_2D$, produced the highest ratio of the *cis* isomer (80% *cis*). This preferential formation of the sterically more hindered *cis* isomers is quite unusual, although there are a few examples in similar systems (8, 12). However, when bulkier electrophiles such as acetone were employed, steric hindrance between the incoming electrophile and the thiazoline ring was large enough to force the electrophile to come from the other side of the thiazoline group, yielding the *trans* isomer as the major product. In the case of benzaldehyde the situation was well balanced, giving a 1:1 mixture of *cis* and *trans* isomers. Two diastereomers were found in the *trans* isomer and only one diastereomer in the *cis* isomer.

Although acetone and methyl thiomethylsulfonate gave a mixture of *cis* and *trans* isomers, we were able to isolate each pure *trans* isomer (**8***b* and **11***b*) in the acid form by crystallization.

It is worth mentioning that the aldol condensation of the dianion **6** with acetaldehyde gave only a single diastereomer of *cis*-6-(1′-hydroxyethyl)-penem as was the case for benzaldehyde. In both cases, the other diastereomer was not detected on the scale on which our reactions were performed. We presumed this diastereomer was a *cis-R**[4] isomer because we expected that in the transition state depicted by **12** (14), **12***a* will form in preference to **12***b* because of the severe repulsive interaction between the R-group of the electrophiles and the thiazoline ring in **12***b* (11). This *cis-R** stereochemistry in the product was unambiguously confirmed by total synthesis of both isomers (*cis-R**, **9***a* and *cis-S**, **9***b*)[5] from *N-tert*-butyldimethyl-(*cis-R** and *cis-S**)-3-(1′-hydroxyethyl-4-tritylthioazetidin-2-ones (**13***a* and **13***b*) (6*c*). This will be reported in a forthcoming publication.[6]

R = Me or Ph



SCHEME 2

[4]All compounds described here are racemic. All structural formulae and stereochemical designations refer to the enantiomer related to natural products, such as the penicillins and thienamycin.

[5]Examination of $^1$Hmr spectra of the two diastereomers **9***a* and **9***b* revealed that although $J_{6-1'}$ or $\delta_{6-H}$ were not different enough to allow the two isomers to be distinguished from one another, $\delta_{1'-Me}$ was distinctly different for the two compounds. The signal for *cis-R** methyl (1.23 ppm) appeared at higher field than the signal for *cis-S** methyl (1.31 ppm).

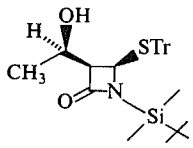
TABLE 1. 6-Substituted 2-methylpenem-3-carboxylic acids and their salts **7–11**

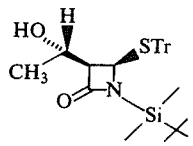
| Penems | Electrophiles | R | R′ | Yield (%) | *cis*/*trans*[a] |
|---|---|---|---|---|---|
| **7** | $CD_3CO_2D$ | D | H | 60 | 4/1 |
| **8***a* | $CH_3COCH_3$ | | K | 26 | 3/7 |
| **8***b* | $CH_3COCH_3$ | | H | 23 | *trans* only |
| **9** | $CH_3CHO$ | | Na | 9 | *cis* major |
| **10** | PhCHO | | K | 20 | 1/1 |
| **11***a* | $CH_3SSO_2CH_3$ | $CH_3S$ | K | 28 | 5/3 |
| **11***b* | $CH_3SSO_2CH_3$ | $CH_3S$ | H | 6 | *trans* only |

[a]À *cis*/*trans* ratio was determined from integration of C5–H signals in the $^1$Hmr spectra.

Since the aldol condensation with acetaldehyde, unlike the reaction with benzaldehyde, did not give a sufficient amount of the *trans* isomer, after isolation as the sodium salt, we were unable to measure the *cis*–*trans* ratio in the product. An attempt to obtain more of the *trans* isomer using $ZnCl_2$, a chelate stabilizing agent which is known to change the stereochemistry of aldol products (14*a*), was not successful. No penem product was isolated in this reaction.

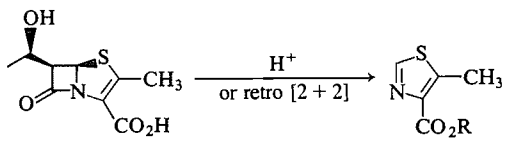


**13***a*



**13***b*

A major acidic by-product in the reaction with acetaldehyde was identified as 5-methylthiazole-4-carboxylic acid (**14**) based on a singlet at 2.63 ppm which was assigned to 5-Me protons and a broad singlet at 8.63 ppm, assigned to 2-H. More of this thiazole **14** was found when the crude product was left in the acid form. This indicates that the thiazole **14** may have formed during the work-up by the acid-catalyzed decomposition of the penem nucleus or by the retro [2 + 2] process as shown in Scheme 3 (5*a*). Separation of sodium salt **9** from the crude product (which was contaminated with thiazole sodium salt **15**) was achieved in two ways. The



**16** → (H$^+$ or retro [2 + 2]) → **14**: R = H; **15**: R = Na

SCHEME 3

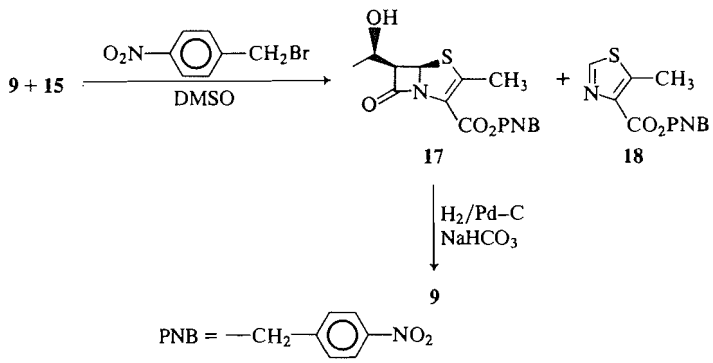
first involved several steps as shown in Scheme 4. A mixture of the crude material was converted to the *p*-nitrobenzyl esters, **17** and **18**, which were separated by chromatographic means. Catalytic hydrogenation of **17** gave the corresponding sodium salt **9**. Alternatively, the salt **9** precipitated out without contamination of thiazole **15** by addition of sodium 2-ethylhexanoate to the crude acid in EtOAc. When $Et_2O$ was used as a solvent, both salts (**9** and **15**) precipitated.

We also attempted the direct introduction of 6-substituents on the methoxymethyl ester of **5** by the method described above using, in this case, one equivalent of *n*-butyllithium in the presence of diisopropylamine (with or without HMPA). In this experiment, we expected that the monoanion, generated *in situ*, would react more cleanly with electrophiles to give 6-substituted penem esters. In fact this reaction gave a complex mixture in which the desired product was not detected. This is presumably due to the fact that lithium diisopropylamide reacts, in the absence of HMPA, with the α,β-unsaturated ester moiety to give the Michael adduct (15). The deprotonation at the γ-position of this unsaturated ester moiety also creates more complications in the reaction with LDA-HMPA.

In summary, we have described here the synthesis of 6-substituted 2-methylpenem-3-carboxylic acids by direct metallation on 6-unsubstituted penem acid followed by the reaction with electrophiles, producing a mixture of *cis* and *trans* isomers, the ratio varying from *cis*-major to *trans*-major.

## Experimental

Melting points were determined on a Gallenkamp melting point apparatus and are not corrected. The infrared spectra were recorded on a Perkin–Elmer 267 Grating Infrared spectrophotometer.



SCHEME 4

The $^1$H nuclear magnetic resonance spectra were taken with either a Varian EM-360A (60 MHz) or a Varian CFT-20 (80 MHz) nmr spectrometer. Tetramethylsilane (for solution other than deuterium oxide) and sodium 4,4-dimethyl-4-silapentane-1-sulfonate (for solutions of deuterium oxide) were used as internal standards and chemical shifts are reported in parts per million (δ) relative to the internal standards.

The ultraviolet spectra were recorded on either an Unicam SP-800 or SP 8-100 uv spectrophotometer. Tetrahydrofuran was freshly distilled from $LiAlH_4$.

Commercial $CH_3CHO$ was distilled prior to use. Diisopropylamine was distilled from $CaH_2$ and stored over NaOH. *n*-Butyllithium in hexane (Aldrich) and $CD_3CO_2D$ (99.5%, MSD) were used as supplied. 2-Methylpenem-3-carboxylic acid (**5**) was prepared as described before (6*a*). Methyl thiomethylsulfonate was prepared by the procedure of Slusarchyk *et al.* (16).

*6-Deuterio-2-methylpenem-3-carboxylic acid (7)*

To a stirred solution of 2-methylpenem-3-carboxylic acid (**5**) (50 mg, 0.27 mmol) in THF (10 mL) was added at −78°C under a nitrogen atmosphere a solution of *n*-butyllithium in hexane (1.66 *M*, 0.36 mL, 0.60 mmol). After a half minute, $CD_3CO_2D$ (0.4 mL, a large excess) was injected. The yellow reaction mixture was stirred (−78°C, $N_2$) for 5 min and then diluted with EtOAc (15 mL). This was washed with brine (×2), dried ($Na_2SO_4$), and evaporated, yielding 45 mg of yellow solid. This solid was rinsed with a small amount of anhydrous $Et_2O$ to obtain 30 mg (0.16 mmol, yield 60%) of the title compound **7** as a mixture of the *cis* and *trans* isomers in a ratio of 4:1. This material was contaminated with a small amount of **5**, mp 113–117°C (dec.); ir (KBr disc) $\nu_{max}$: 2400–3100 ($CO_2H$), 1775 (β-lactam), and 1670 ($CO_2H$) cm$^{-1}$; uv (EtOH) $\lambda_{max}$: 262 (ε 4330) and 305 nm (ε 6680); $^1$Hmr (acetone-$d_6$; CFT-20) δ: 2.34 (3H, s, 2-Me), 3.41 (1/5 H, dt, $J_{6-5\,trans}$ = 2 Hz, $J_{H-D}$ = 2 Hz, H-6), 3.81 (4/5 H, dt, $J_{6-5\,cis}$ = 4 Hz, $J_{H-D}$ = 2 Hz, H-6), and 5.71 ppm (1H, 2d, $J_{5-6\,cis}$ = 4 Hz and $J_{5-6\,trans}$ = 2 Hz, H-5; the both isomers appeared at the same place). The signals for **5** appeared at 3.40 (dd, $J$ = 2 Hz, $J_{gem}$ = 16.5 Hz, H-6) and 3.85 ppm (dd, $J$ = 4 Hz, $J_{gem}$ = 16.5 Hz, H-6).

*Potassium 6-(2′-hydroxy-2′-propyl)-2-methylpenem-3-carboxylate (8a)*

To a solution of diisopropylamine (0.098 mL, 0.699 mmol) in THF (2 mL) *n*-butyllithium in hexane (1.6 *M*, 0.44 mL, 0.70 mmol) was added at −78°C under a nitrogen atmosphere and stirred (−78°C, $N_2$) for 30 min. To this solution was added a solution of 2-methylpenem-3-carboxylic acid (**5**) (116 mg, 0.627 mmol) in THF (4 mL) and the mixture was stirred for 5 min at −78°C, followed by successive addition of diisopropylamine (0.098 mL; 0.699 mmol) and *n*-butyllithium in hexane (1.6 *M*, 0.44 mL, 0.70 mmol) at −78°C. It was then stirred for 10 min at −78°C and treated rapidly with acetone (5 mL). After 10 min at −78°C, it was acidified (pH 2) with 1% HCl, diluted with EtOAc (40 mL), and the organic layer was washed with brine (3 × 20 mL), dried ($Na_2SO_4$), and evaporated to give a crude residue which was taken up in $CH_2Cl_2$. The crude acid (yield 90 mg) was dissolved in cold methylisobutylketone (2 mL) and treated dropwise with a solution of potassium 2-ethylhexanoate in *n*-BuOH (50%). After addition of anhydrous $Et_2O$, it gave 36.4 mg (0.13 mmol, yield 20.6%) of the title compound as a mixture of the *cis* and *trans* isomers in a ratio of 7:3; ir (Nujol mull) $\nu_{max}$: 3600–3100 (OH), 1765 (β-lactam), and 1582 (—$CO_2^-$) cm$^{-1}$; uv (EtOH) $\lambda_{max}$: 257 (ε 3920) and 300 nm (ε 4020); $^1$Hmr (DMSO-$d_6$) δ: 1.32, 1.35 (2s, di-Me), 1.40, 1.47 (2s, di-Me), 2.34 (3H, s, $CH_3$), 3.50 (br s, OH), 3.62 (d, $J_{6-5\,trans}$ = 2 Hz, H-6), 3.93 (d, $J_{6-5\,cis}$ = 4 Hz, H-6), 5.55 (1 × 7/10 H, d, $J_{5-6\,trans}$ = 2 Hz, H-5), and 5.60 ppm (1 × 3/10 H, d, $J_{5-6\,cis}$ = 4 Hz, H-5).

trans-*6-(2′-Hydroxy-2′-propyl)-2-methylpenem-3-carboxylic acid (8b)*

To a stirred solution of 2-methylpenem-3-carboxylic acid (**5**) (50 mg, 0.27 mmol) in THF (4 mL) diisopropylamine (0.08 mL, 0.58 mmol) was added at 0–5°C under a nitrogen atmosphere. The mixture was cooled to −78°C and *n*-butyllithium (0.38 mL, 1.6 *M* in hexane, 0.60 mmol) was added. After 5 min at −78°C, acetone (0.5 mL) was injected into this orange mixture. The resulting yellow mixture was stirred for 10 min at −78°C. This was neutralized with 0.1 *N* HCl (12 mL) and extracted with EtOAc (3 × 20 mL). The EtOAc extracts were washed with brine, dried ($Na_2SO_4$), and evaporated to yield 59 mg of a crude oil. This oil was extracted with $Et_2O$, removing the insoluble material to give 53 mg of an oily solid. This was characterized by $^1$Hmr as a mixture of the *cis* and *trans* isomers in a ratio of 7:3; $^1$Hmr ($CDCl_3$) δ: 3.75 (7/10 H, d, $J$ = 1.5 Hz, 6-$H_{trans}$), 4.00 (3/10 H, d, $J$ = 4 Hz, 6-$H_{cis}$), 5.62 (d, $J$ = 1.5 Hz, 5-$H_{trans}$) and 5.70 ppm (d, $J$ = 4 Hz, 5-$H_{cis}$). This oily solid was triturated with a small amount of $CHCl_3$ and $Et_2O$ to yield 15 mg (0.062 mmol, yield 23%) of the title compound **8*b*** as white crystals, mp 117–121°C; ir (Nujol mull) $\nu_{max}$: 3500 (OH), 1765 (β-lactam), and 1660 ($CO_2H$) cm$^{-1}$; uv (EtOH) $\lambda_{max}$: 265 (ε 3400) and 309 nm (ε 5700); $^1$Hmr (acetone-$d_6$) δ: 1.30 (3H, s, 2′-$CH_3$), 1.35 (3H, s, 2′-$CH_3$), 2.35 (3H, s, 2-$CH_3$), 3.77 (1H, d, $J$ = 1.8 Hz, 6-H), and 5.63 ppm (1H, d, $J$ = 1.8 Hz, 5-H).

*Sodium* cis-*6-(1′-hydroxyethyl)-2-methylpenem-3-carboxylate (9)*

To a stirred solution of 2-methylpenem-3-carboxylic acid (**5**) (1.00 g, 5.40 mmol) in THF (80 mL) *n*-butyllithium (7.00 mL, 1.6 *M* in hexane, 11.2 mmol) was added dropwise at −78°C under a nitrogen atmosphere. After 1 min $CH_3CHO$ (1.2 mL) was added to this reddish mixture and the resulting pale yellow

For personal use only.

mixture was stirred (−78°C, $N_2$) for 10 min. To this mixture was added saturated $NH_4Cl$ (100 mL) followed by brine (50 mL). The aqueous layer was collected and washed with EtOAc (2 × 60 mL). This aqueous layer, mixed with EtOAc (60 mL), was cooled in an ice-bath and acidified carefully with a cold 0.1 *N* HCl solution (120 mL), saturated with NaCl, and extracted quickly with EtOAc (3 × 60 mL). The EtOAc extracts were washed with brine, dried ($Na_2SO_4$), and evaporated to reduce the volume to ca. 25 mL. To this was added sodium 2-ethylhexanoate in *n*-BuOH (10% w/w, 2.1 mL) and the precipitate was collected by a centrifuge and washed with EtOAc to yield 123 mg (0.490 mmol, yield 9.1%) of the title compound **9** as a yellow powder; ir (Nujol mull) $\nu_{max}$: 3350 (OH), 1750 (β-lactam), and 1590 ($CO_2Na$) $cm^{-1}$; uv ($H_2O$) $\lambda_{max}$: 252 (ε 4200) and 297 nm (ε 3400); $^1$Hmr ($D_2O$) δ: 1.23 (3H, d, $J$ = 6 Hz, 1′-$CH_3$), 2.28 (3H, s, 2-$CH_3$), 3.85 (1H, dd, $J_{6-5\,cis}$ = 4 Hz, $J_{6-1'}$ = 8 Hz, 6-H), and 5.65 ppm (1H, d, $J_{5-6\,cis}$ = 4 Hz, 5-H).

To the supernatant solution was added $Et_2O$ and the precipitate was collected by a centrifuge and washed with $Et_2O$ to give 145 mg of a mixture of the title compound **9** and sodium 5-methylthiazole-4-carboxylate (**15**) as a white solid; $^1$Hmr ($D_2O$) δ: thiazole peaks at 2.63 (3H, s, 5-Me) and 8.63 ppm (1H, s, 2-H). This material was purified as follows.

The material containing **9** and **15** (total 201 mg) was converted to the mixture of the corresponding *p*-nitrobenzyl ester by treating it with *p*-nitrobenzyl bromide (104 mg, 0.9 mmol) in dimethylsulfoxide (2 mL) at room temperature overnight (21 h). The crude products were separated by preparative tlc (E. Merck silica gel 60F-254, benzene–$Et_2O$ 1:1), collecting 40 mg (0.14 mmol) of *p*-nitrobenzyl 5-methylthiazole-4-carboxylate (**18**) as white crystals (fast moving band), mp 128–130°C; ir (Nujol mull) $\nu_{max}$: 1720 (ester), 1603, 1520 ($NO_2$), and 1350 ($NO_2$) $cm^{-1}$; uv (EtOH) $\lambda_{max}$: 256 nm (ε 12 500); $^1$Hmr ($CDCl_3$) δ: 2.80 (3H, s, 5-$CH_3$), 5.47 (2H, s, —$CH_2$—), 7.53–7.68–8.15–8.30 (2H, $A_2'B_2'$, aromatic H's), and 8.60 ppm (1H, br s, 2-H); and 41 mg (0.11 mmol) of **17** as white crystals (slow moving band), mp 140–143°C; ir (Nujol mull) $\nu_{max}$: 3400 (OH), 1770 (β-lactam), and 1705 (ester) $cm^{-1}$; uv (EtOH) $\lambda_{max}$: 265 (ε 12 000) and 309 nm (ε 9200); $^1$Hmr ($CDCl_3$) δ: 1.25 (3H, $J$ = 6 Hz, 1′-$CH_3$), 2.40 (3H, s, 2-$CH_3$), 3.78 (1H, dd, $J_{6-5}$ = 4 Hz, $J_{6-1'}$ = 9 Hz, 6-H), 4.35 (1H, m, 1′-H), 5.03–5.27–5.37–5.60 (2H, AB type, —$CH_2$Ar), 5.61 (1H, d, $J_{5-6}$ = 4 Hz, 5-H), and 7.52–7.67–8.13–8.24 ppm (2H, $A_2'B_2'$, aromatic H's).

A solution of **17** (40 mg, 0.11 mmol) in THF (4 mL) was mixed with $Et_2O$ (8 mL), $H_2O$ (4 mL), $NaHCO_3$ (9.5 mg, 0.11 mmol), and 30% Pd–Celite (45 mg; Engelhard) and hydrogenated at room temperature ($H_2$, 30 psi) for 3 h. After filtration of the catalyst over Celite, the filtrate and the washings were combined. The aqueous layer was washed once with $Et_2O$ and lyophilized to yield 24 mg (0.096 mmol, yield 87%) of the title compound (**9**) as a greyish powder; ir (Nujol mull) $\nu_{max}$: 3350 (OH), 1760 (β-lactam), and 1585 ($CO_2Na$) $cm^{-1}$; uv ($H_2O$) $\lambda_{max}$: 297 (ε 3000) and 254 nm (ε 2900); $^1$Hmr (DMSO-$d_6$) δ: 1.03 (3H, d, $J$ = 6 Hz, 1′-$CH_3$), 2.20 (3H, s, 2-$CH_3$), 3.53 (1H, dd, $J$ = 4 Hz, $J$ = 9 Hz, 6-H), 3.9 (1H, m, 1′-H), and 5.40 ppm (1H, d, $J$ = 4 Hz, 5-H).

*Potassium 6-(1′-hydroxybenzyl)-2-methylpenem-3-carboxylate (**10**)*

To a solution of diisopropylamine (0.084 mL, 0.599 mmol) in THF (2 mL) was added at −78°C under a nitrogen atmosphere 1.6 *M* *n*-butyllithium in hexane (0.380 mL, 0.608 mmol) and stirred (−78°C, $N_2$) for 30 min. To this solution was added dropwise a solution of 2-methylpenem-3-carboxylic acid (**5**) (100 mg, 0.54 mmol) in THF (6 mL) and the mixture stirred for 5 min at −78°C, followed by successive addition of diisopropylamine (0.084 mL, 0.599 mmol) and 1.6 *M* *n*-butyllithium in hexane (0.380 mL, 0.608 mmol). It was then stirred for 7 min at −78°C and treated rapidly with benzaldehyde (0.3 mL). The mixture was allowed to react at −78°C for 20 min. It was acidified with 1% HCl (pH ≃ 2), diluted with EtOAc (40 mL), washed with $H_2O$–brine (1:1, 3 × 20 mL) and brine (1 × 20 mL). It was dried over $Na_2SO_4$ and evaporated to give a residue which was dissolved in methylisobutylketone (2 mL). This was treated dropwise with a solution of potassium 2-ethylhexanoate in *n*-BuOH to give 35 mg (0.11 mmol, yield 20%) of the title compound **10** as a diastereomeric mixture (*cis*–*trans* ≃ 1:1); ir (Nujol mull) $\nu_{max}$: 3600–3100 (OH), 1760 (β-lactam), and 1590 ($CO_2K$) $cm^{-1}$; uv ($H_2O$) $\lambda_{max}$: 262 (ε 5100) and 296 nm (ε 3000); $^1$Hmr (DMSO-$d_6$) δ: 2.35 (3H, 2s, $CH_3$), 3.65 (br s, OH), 3.90 (m, H-6), 4.25 (dd, $J_{6-5\,cis}$ = 4 Hz, $J_{6-1'}$ = 10 Hz, H-6), 5.0 (m, H-1′), 5.35 (d, $J_{5-6\,cis}$ = 4 Hz, H-5), 5.45 (d, $J_{5-6\,trans}$ = 1.5 Hz, H-5), 5.57 (d, $J_{5-6\,trans}$ = 1.5 Hz, H-5), and 7.95 ppm (5H, s, aromatic H's).

*Potassium 6-methylthio-2-methylpenem-3-carboxylate (**11**a)*

A solution of 2-methylpenem-3-carboxylic acid (**5**) (100 mg, 0.54 mmol) in THF (5 mL) was added dropwise to a cold (−78°C) THF (2 mL) solution of lithium diisopropylamide, made from diisopropylamine (0.084 mL, 0.599 mmol) and 1.6 *M* *n*-butyllithium – hexane (0.380 mL, 0.608 mmol). The mixture was stirred for 7–8 min, followed by successive addition of diisopropylamine (0.084 mL, 0.599 mmol) and 1.6 *M* *n*-butyllithium – hexane (0.380 mL, 0.608 mmol). It was then stirred for 7 min at −78°C and treated rapidly with methyl thiomethylsulfonate (0.30 mL, excess). The mixture was allowed to react at −78°C for 5 min. It was acidified with 1% HCl (pH ≃ 2), diluted with EtOAc (40 mL), washed with 1:1 $H_2O$–brine (3 × 20 mL) and then brine (20 mL). The organic solution was dried ($Na_2SO_4$) and evaporated to give a residue which was dissolved in cold methylisobutylketone (2 mL). To this solution was added dropwise a solution of potassium 2-ethylhexanoate in *n*-BuOH (50% w/w). The precipitate was collected to yield 40 mg (0.15 mmol, yield 28%) of the title compound **11***a* as a 5:3 mixture of *cis* and *trans* isomers, mp 115–120°C (dec.); ir (Nujol mull) $\nu_{max}$: 1770 (β-lactam) and 1600 ($CO_2K$) $cm^{-1}$; uv ($H_2O$) $\lambda_{max}$: 252 (ε 4200) and 297 nm (ε 3700); $^1$Hmr (DMSO-$d_6$) δ: 2.25 (s, $SCH_3$), 2.33 (s, $CH_3$), 2.37 (s, $SCH_3$), 3.42 (br s, OH), 4.72 (1H, d, $J_{6-5\,trans}$ = 1.5 Hz, H-6), 4.87 (1H, d, $J_{6-5\,cis}$ = 4 Hz, H-6), 5.57 (1H, d, $J_{5-6\,trans}$ = 1.5 Hz, H-5), and 5.85 ppm (1H, d, $J_{5-6\,cis}$ = 4 Hz, H-5).

trans-*6-Methylthio-2-methylpenem-3-carboxylic acid (**11**b)*

Diisopropylamine (1.16 g, 11.4 mmol) was added at 5°C to a solution of 2-methylpenem-3-carboxylic acid (**5**) (1.00 g, 5.40 mmol) in THF (800 mL). The mixture was cooled to −78°C and treated with 2.52 *M* *n*-butyllithium – hexane (4.4 mL, 11.1 mmol). After stirring at −78°C for 5 min, methyl thiomethylsulfonate (750 mg, 5.90 mmol) was added and it was stirred at −78°C for an additional 10 min. Then the reaction mixture was poured into a saturated $NH_4Cl$ solution, extracted with $CH_2Cl_2$, acidified to pH 3 with dilute HCl, and again extracted with $CH_2Cl_2$. The organic extracts were washed with brine, dried ($MgSO_4$), and evaporated to give a mixture of *cis*- and *trans*-6-methylthio-2-methylpenem-3-carboxylic acids. However, crystallization from $Et_2O$ afforded 75 mg (0.32 mmol, yield 6%) of the pure *trans* isomer **11***b*, mp 109–112°C; ir ($CH_2Cl_2$) $\nu_{max}$: 1793 (β-lactam) and 1681 ($CO_2H$) $cm^{-1}$; uv (EtOH) $\lambda_{max}$: 303 nm (ε 4348); $^1$Hmr ($CDCl_3$) δ: 2.24 (3H, s, —$SCH_3$), 2.37 (3H, s, —$CH_3$), 4.56 (1H, d, $J$ = 1.6 Hz, H-6), and 5.49 ppm (1H, d, $J$ = 1.6 Hz, H-5).

## Acknowledgements

We would like to thank Professor T. Durst of the University of Ottawa for helpful discussions, Dr. T. Conway for part of the preliminary experiments,

and C. Damas and J. Lajeunesse of these laboratories for technical assistance during the course of this work.

ERRATA

# A comparison of the relative binding energies of $H^+$ and $NO^+$ to aromatic and haloaromatic bases by high pressure mass spectrometry

JOHN A. STONE, DENA E. SPLINTER, AND SOON YAU KONG

*Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6*

Received October 2, 1981

JOHN A. STONE, DENA E. SPLINTER, and SOON YAU KONG. Can. J. Chem. **60**, 910 (1982).

Proton transfer equilibria ($B_1H^+ + B_2 \rightleftharpoons B_1 + B_2H^+$) and $NO^+$ transfer equilibria ($B_1NO^+ + B_2 \rightleftharpoons B_1 + B_2NO^+$) have been studied for the following bases B, benzene, toluene, *o*-, *m*-, and *p*-xylene. $NO^+$ transfer equilibria for fluoro- and chlorobenzene have also been studied. Pulsed electron beam, high-pressure ion source mass spectrometry has been used to obtain the equilibrium constant $K$ and hence the free energy changes $\Delta G^0$ and from van't Hoff plots, $\Delta H^0$ and $\Delta S^0$. Entropy changes are in general much smaller for $NO^+$ transfer than for $H^+$ transfer but the magnitude of the changes in the proton affinity and $NO^+$ affinity of toluene caused by a fluorine substituent is about the same, even though the absolute value of the proton affinity is greater by a factor of 4. The position of the F substituent on toluene has a marked effect on proton affinity but no effect on $NO^+$ affinity. The latter appears to be responsive only to the inductive effect.

JOHN A. STONE, DENA E. SPLINTER et SOON YAU KONG. Can. J. Chem. **60**, 910 (1982).

On a étudié les équilibres de transfert du proton ($B_1H^+ + B_2 \rightleftharpoons B_1 + B_2H^+$) et les équilibres de transfert du $NO^+$ ($B_1NO^+ + B_2 \rightleftharpoons B_1 + B_2NO^+$) dans les bases B suivantes: benzène, toluène, *o*-, *m*- et *p*-xylène. On a également étudié les équilibres de transfert de $NO^+$ pour les fluoro et chlorobenzènes. On a utilisé le faisceau d'électrons pulsés d'un spectromètre de masse à source d'ions à haute pression pour obtenir la constante d'équilibre $K$ et par la suite les variations d'énergie libre $\Delta G^0$; les courbes de Van't Hoff fournissent le $\Delta H^0$ et $\Delta S^0$. Les variations d'entropie sont en général plus faibles pour le transfert de $NO^+$ que pour celui du $H^+$ mais l'ordre de grandeur des variations de l'affinité du proton et du $NO^+$ pour le toluène, provoqué par le substituant fluor est environ le même, même si la valeur absolue de l'affinité du proton est plus grande d'un facteur de 4. La position du fluor comme substituant sur le toluène a un effet marqué sur l'affinité du proton mais n'en a aucun sur l'affinité du $NO^+$. Ce dernier semble être responsable uniquement de l'effet inductif.

[Traduit par le journal]

## Introduction

Our understanding of substituent effects in solution chemistry has been considerably aided by thermodynamic data obtained from measurements of gas phase ion–molecule equilibria (1). Most gas phase studies have concentrated on proton transfer equilibria although a growing body of information is becoming available for electrophilic reactions involving other cations (2, 3).

Liquid phase electrophilic aromatic substitution has a long experimental history but arguments concerning the actual reaction mechanism still prevail. It is now widely accepted that the transition state is a σ-bonded complex (arenium ion) (4) but there are arguments in favour of a π-bonded transition state in certain cases (5). Although these arguments have been criticized on the grounds that they are based on experimental artefacts (6), the controversy has not been fully resolved. Comparisons of the thermodynamic properties of stable σ and π complexes in the gas phase in the absence of solvent should aid in the understanding of the properties of such transients in solution.

Experimental results and theoretical calculations agree that the stable, protonated aromatics observed in the gas phase are σ bonded (7, 8). In contrast, nitrosated benzene, $C_6H_6NO^+$, formed by transfer of $NO^+$ from nitrosated methylnitrite to benzene, is a π complex which is clearly distinguishable from protonated nitrosobenzene, $C_6H_5NOH^+$ (9). The main evidence in favour of π bonding is the demonstrated ability of $C_6H_6NO^+$ to transfer $NO^+$ rather than $H^+$ to the stronger base pyridine. The experiments were conducted at low pressure ($\sim 10^{-6}$ Torr) in an ion cyclotron resonance (icr) spectrometer. We have confirmed this behaviour in a high pressure ($\sim 1$ Torr) photoionization mass spectrometer (10). Reents and Freiser have recently determined standard free energy changes at 300 K for $NO^+$ transfer equilibria for a large and diverse series of bases (11). Correlations were found between basicity towards $NO^+$ ($\Delta G^0$) and proton affinity ($\Delta H^0$) for several classes of compounds. In discussion of the binding between $NO^+$ and the bases they assumed that entropy changes in such reactions are small. In this paper we report a confirmation of this assumption.

A major argument for π-complex participation in the rate-determining step of aromatic electrophilic substitution reactions in solution is the relatively small effect of ring substituents compared with the effects observed for σ complexes (4). The presence of anomalous substituent effects on ion–molecule reaction rates in the gas phase has also been ascribed to π-complex formation (12). It is, therefore, of value to make further comparisons of

0008-4042/82/070910-06$01.00/0

proton affinities (σ bonding) with $NO^+$ affinities (π bonding). For the reasons given below we have chosen to study benzene, halobenzenes, toluene, and the three fluorotoluenes.

We have recently determined by high pressure mass spectrometry the proton affinities of $C_6H_6$, $C_6H_5F$, and $C_6H_5Cl$ (13) and shown, in agreement with Lau and Kebarle (14), that proton affinity *decreases* in the order $C_6H_5F > C_6H_5Cl > C_6H_6$. Evidently stabilization of the ion by π donation from halogen situated *para* to the protonation site more than compensates for electron withdrawal by the inductive-field effect. We have examined the $NO^+$ affinity of this group of compounds to determine whether a similar behaviour is observed for π complexes.

The energetically favoured protonation site in toluene is *para* to $CH_3$ (15). The location of a substituent on the toluene ring is therefore expected to have a marked effect on proton affinity whereas for a π complex, whose binding site involves at least two ring C atoms, a different effect of the same substituent might be expected. We have investigated substituent positional effects on the proton affinities (PA) and $NO^+$ affinities (NOA) of *o*-, *m*-, and *p*-fluorotoluene. Neither of these sets of data has been previously reported.

## Experimental

The two high pressure mass spectrometers, one a quadrupole (10) and the other a magnetic sector instrument (16), used in this study have been described previously. The field-free source of the quadrupole photoionization instrument (10) has been replaced by a simple electron impact source, modeled on one previously described (13). The lower LiF window has been replaced by a blank, stainless steel flange and the upper one by a similar flange containing a slit fabricated from razor blades of dimensions 1.5 × 0.05 $mm^2$. The flanges are sealed by gold "O" rings. Ionization is by 500 eV electrons and the electron beam may be pulsed on and off by removal and application of a blocking potential on the first of two electron beam defining electrodes which is −90 V with respect to the filament (13). The vacuum system of this instrument has also been modified to give differential pumping. The source is now separated from the ion-focusing lenses and quadrupole mass analyzer by a stainless steel skimmer plate with a 2 mm circular orifice which is placed 1.5 cm from the ion exit slit. The analyzer side is pumped by a 4 in. diffusion pump while the original 6 in. pump evacuates the ion source housing. The vacuum in the analyzer section is less than $5 \times 10^{-6}$ Torr when the ion source pressure is 1 Torr.

The nitric oxide (Matheson) and methane (Matheson 99.99%) were not dried since water has a much lower basicity towards both $NO^+$ and $H^+$ than any of the compounds used. Benzene (J. T. Baker, Ultrex) and toluene, the fluorotoluenes and the halobenzenes (all Aldrich) were of the highest purity available and were used as received.

Only the quadrupole instrument was used for the $NO^+$ studies. The heated 1 L glass reservoir was filled with NO at 760 Torr and 20 μL of a binary liquid mixture of aromatic compounds of accurately known composition together with 5 μL of carbon tetrachloride were injected and allowed to equilibrate. The carbon tetrachloride was added to attach electrons and reduce the rate of ambipolar diffusion (16). The gaseous mixture was passed into the ion source via a heated all metal valve. Helium was also bled into the source via a separate valve so that the total pressure in the source might be varied independently of the sample pressure. The equilibrium thermodynamic data obtained are independent of the total pressure (range 0.5–1.5 Torr), the NO/He ratio, the molar ratio of the two bases and the amount of sample.

Proton transfer equilibrium measurements were made on both the magnetic and quadrupole instruments, the equilibrium thermodynamic data obtained being identical within experimental error. The buffer gas employed was $CH_4$ rather than the He/NO mixture, otherwise the method for the study of both $NO^+$ and $H^+$ complexes was the same

## Results and discussion

### *Proton affinities of toluene and the fluorotoluenes*

Equilibria of the form

[1] $B_1H^+ + B_2 \rightleftharpoons B_1 + B_2H^+$

were studied to determine the equilibrium constant $K$ from the known ratio of concentrations of neutrals $[B_1]/[B_2]$ and the measured ion current ratio at long residence times, $i_{B_2H^+}/i_{B_1H^+}$ (13). Determination of $K$ leads to $\Delta G^0 = -RT \ln K$. The $\Delta G^0$ values for equilibria between *o*- and *p*-fluorotoluene and toluene are large so an intermediate standard, methyl formate, was employed. The use of this standard limited measurements to high temperature where proton bound dimer formation is not a problem. Entropy changes, $\Delta S^0$, for proton transfer equilibria are in general very small (< 2 cal $K^{-1}$ $mol^{-1}$) for the types of compounds employed and they can be calculated with reasonable accuracy by statistical thermodynamics from changes in external rotational symmetry numbers (17, 18). Relative proton affinities defined as $\Delta H^0$ for reaction [1] were determined from $\Delta H^0 = \Delta G^0 + T\Delta S^0$.

The difference in proton affinity between toluene and methylformate is 1.9 kcal $mol^{-1}$ (high pressure measurements at 600 K (14, 18) and 1.0 kcal $mol^{-1}$ (icr measurements at ~300 K (17)). The discrepancy is substantial. As shown in Table 1, the present value of 1.3 kcal $mol^{-1}$ for an intermediate temperature of 478 K lies between the two literature values which may signify that for this particular system the entropy change upon protonation is not accurately given by calculated changes in symmetry numbers alone or that there is mass discrimination in either or both of the high and low pressure techniques.

The measured reproducibility for the results shown in Table 1 is better than ±0.1 kcal $mol^{-1}$ for $\Delta G^0$ values below 2 kcal $mol^{-1}$ and ±0.2 kcal $mol^{-1}$ for those above. The results are invariant with

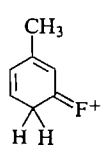
change in neutral concentration ratio but for the measurement of the large $\Delta G^0$ values the range over which this ratio could be varied and equilibrium still be observed was very limited.

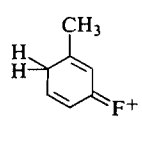
A ring-fluorine substituent on toluene, no matter what its position, decreases the proton affinity in contrast to the increase observed for benzene (13). The position of the substituent does, however, have a very marked effect, both *ortho*- and *para*-fluorine causing a large decrease while a *meta*-fluorine has little effect.

Toluene protonates in the *para* position although *ortho* protonation is energetically only slightly less favoured (15). It is therefore not surprising that *p*-F-toluene has the lowest proton affinity since the protonation site will necessarily change and become *ortho* to methyl but *meta* to fluorine. In this position the latter substituent is electron attracting (19). *o*-F-Toluene presumably protonates *para* to $CH_3$ and *meta* to F and the proton affinity of toluene is consequently again lowered considerably although not quite to the same extent as for the *para*-substituted compound.

Only in *m*-F-toluene are canonical structures involving $\pi$-resonance contributions from fluorine available to enhance the stabilization of the protonated form when protonation is either *para* or *ortho* to $CH_3$ (**I** and **II**). **II** may be favoured by a lessening of the destabilizing inductive effect with distance between F and the tetrahedral ring carbon atom.



**I**



**II**

The observed substituent effects in the fluorotoluene are not a simple superposition of individual effects, but are qualitatively in agreement with expectations.

*$NO^+$ affinities*

NO has been studied as a potentially useful chemical ionization reagent gas (20). Since abundant yields of the association ion $MNO^+$ were observed for internal olefins and dienes M, at pressures in the range 0.5–1.0 Torr it is surprising that NO containing small concentrations of aromatics under CI conditions yielded $MNO^+$ ions as the major product only for compounds with ionization potentials close to that of NO (9.26 eV) (21). When M has a lower ionization potential, charge transfer yielding $M^+$ was the major reaction. Probably the presence of a repeller field, an ion source temperature of 100–200°C and a low pressure (0.5 Torr) did not allow time for collisional stabilization of the initially formed, excited $MNO^+$ complexes. At low pressures only the charge-transfer reaction

[2] $NO^+ + M \rightleftharpoons NO + M^+$

is observed by icr although $MNO^+$ may be readily formed by transfer from nitrosated methylnitrite (11).

The only ions observed in the present work in He/NO mixtures (10–60% NO) at pressures from 0.5 to 1.5 Torr and temperatures around 45°C are $He^+$, $NO^+$, and $(NO)_2^+$. $NO^+$ constitutes more than 90% of the total ion intensity and $(NO)_2^+$ less than 1%. When the electron beam is pulsed, charge transfer from $He^+$ to NO is observed, the lifetime of the $He^+$ being exceedingly short. The presence of a very small amount (~0.1 mol%) of an alkyl or halo-aromatic leads to the rapid disappearance of $NO^+$, the only observed products being $MNO^+$ and for some compounds, a very small amount of $M^+$ (< 2%). The amount of the latter increases to a small extent with increasing temperature but it is only present in significant yields (< 10% total ionization) for one compound *p*-F-toluene and that at 220°C. The reaction scheme is

[3] $M + NO^+ \rightleftharpoons MNO^{+*}$

[4*a*] $MNO^{+*} \xrightarrow{M} MNO^+$

[4*b*] $MNO^{+*} \rightarrow M^+ + NO$

Approximate pseudo second-order rate constants for the disappearance of $NO^+$ may be obtained from the slopes of linear plots such as the one shown in Fig. 1. Values obtained are in the range $1–6 \times 10^{-10}$ cm$^3$ molecule$^{-1}$ s$^{-1}$. All the aromatics employed have ionization potentials within 8 kcal mol$^{-1}$ of that of NO and even though the reaction to

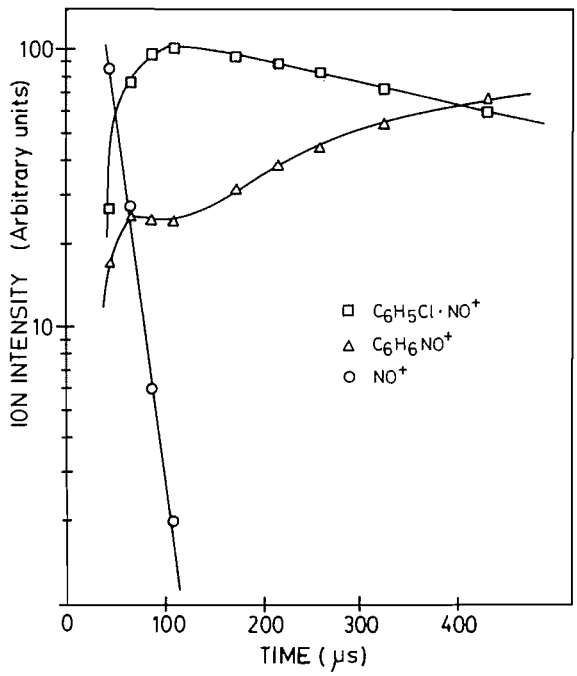


FIG. 1. The variation of ion intensities with time for a mixture containing 0.5 Torr He, 0.5 Torr NO, $5 \times 10^{-4}$ Torr $C_6H_5Cl$, and $2 \times 10^{-5}$ Torr $C_6H_6$ (350 K, 50 μs electron pulse).

form $MNO^+$ does not occur with 100% efficiency, charge transfer is not a significant alternate channel. The dissociation of $MNO^{+*}$ to M and $NO^+$ is efficient.

Provided that the equilibrium constant is not too large ($\Delta G^0 < 5$ kcal $mol^{-1}$), a judicious choice of relative concentrations for two aromatic compounds allows the attainment of equilibrium at long ion residence times (Fig. 2). The equilibrium constant for the reaction

[5] $C_6H_5FNO^+ + C_6H_5Cl \rightarrow C_6H_5F + C_6H_5ClNO^+$

calculated using the invariant ratio of ion currents at long residence times, is constant with change of relative concentrations of $C_6H_5F$ and $C_6H_5Cl$ by at least a factor of 5. The enthalpy change ($\Delta H^0$) is obtained from the temperature dependence of the equilibrium constant (Fig. 3). The results obtained are presented in Table 2 while in Table 3, the $\Delta G^0$ values obtained by Reents and Freiser (11) for toluene, benzene, and the halobenzenes at low pressure are compared with the present values which were obtained by extrapolation of the van't Hoff plots to 298 K since the lowest operating temperature with the present instrumentation is 328 K.

The ordering of the basicities is the same under low (icr) and high pressure conditions and the internal consistency is good for each method. The

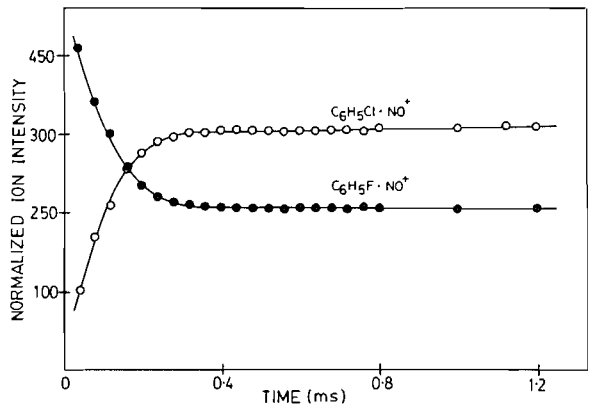

FIG. 2. The normalized ion yields for a mixture containing 0.53 Torr He, 0.20 Torr NO, $7 \times 10^{-4}$ Torr $C_6H_5Cl$, and $3 \times 10^{-3}$ Torr $C_6H_5F$ (328 K, 50 μs pulse).

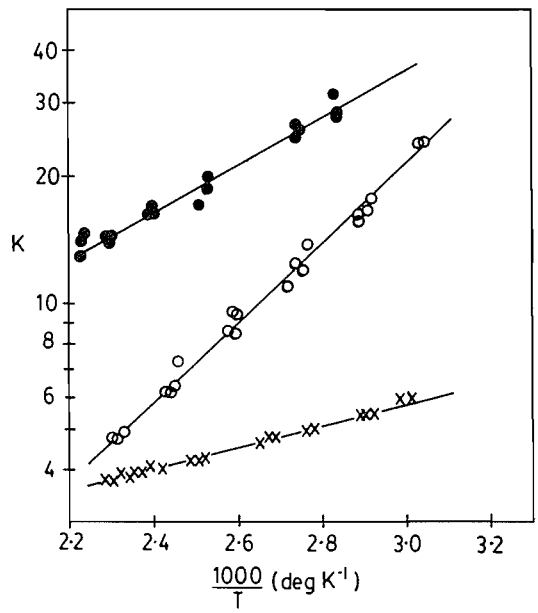

FIG. 3. van't Hoff plots of equilibrium constants for reactions $B_1NO^+ + B_2 \rightleftharpoons B_1 + B_2NO^+$: ($B_1$, $B_2$): × ($C_6H_5F$, $C_6H_5Cl$); ○ ($C_6H_5F$, $C_6H_6$); ● ($C_6H_5Cl$, $C_6H_6$).

absolute values do differ somewhat and it is a little disturbing that $\Delta G^0$ differs by almost a factor of 2 for the only pair ($C_6H_5F/C_6H_5Cl$) for which direct determinations were made at both pressures. We plan to investigate a wider range of compounds to determine whether there is a significant difference between the results obtained by the two methods. There will be limitations to this range since we find from preliminary experiments that, as with proton transfer equilibrium measurements, there can be complications due to further solvation when polar molecules are investigated. For example, nitrobenzene readily forms $(C_6H_5NO_2)_2NO^+$.

TABLE 2. Standard enthalpy changes (kcal $mol^{-1}$) and standard entropy changes (cal $K^{-1}$ $mol^{-1}$, in parentheses) for the reaction $B_1NO^+ + B_2 \rightleftharpoons B_1 + B_2NO^+$; $B_2$ is situated above $B_1$

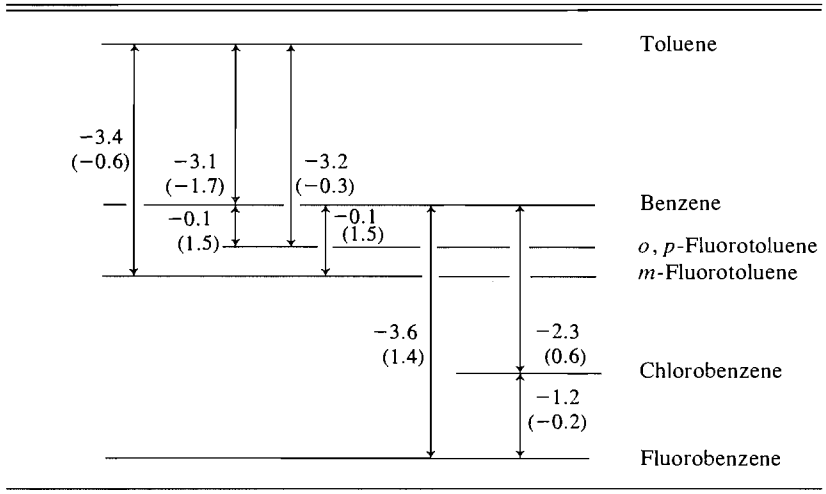

TABLE 3. Standard free energy changes for the reaction $B_1NO^+ + B_2 \rightleftharpoons B_1 + B_2NO^+$

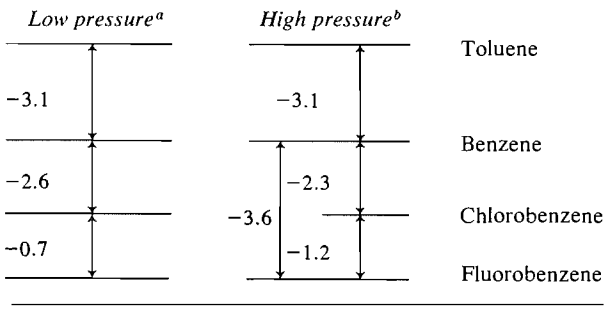

[a]Reference 11, 298 K.
[b]This work, extrapolation to 298 K. Units: kcal $mol^{-1}$. Basicity increases in the upward direction.

By analogy with the definition of proton affinity (PA), the nitric oxide cation affinity (NOA) of a compound M will be defined as the enthalpy change for the reaction

[5] $MNO^+ \rightarrow M + NO^+$

The differences and similarities between NOA and PA values are immediately obvious when data from Tables 1 and 2 and ref. 13 are compared. (In the latter reference the relevant data are: $PA(C_6H_5F)$ $PA(C_6H_6) = +0.7$ kcal $mol^{-1}$.) (*i*) The stabilizing effect of a $CH_3$ group for the $\pi$ complex is less than 50% that for the $\sigma$ complex (NOA(toluene) − NOA(benzene) = 3.1 kcal $mol^{-1}$, PA(toluene) − PA(benzene) = 8.4 kcal $mol^{-1}$ (14)). (*ii*) An F substituent raises PA(benzene) by 1.4 kcal $mol^{-1}$ but NOA is decreased by 3.6 kcal $mol^{-1}$. A Cl substituent behaves similarly but its effect on both PA and NOA is less than that of F. (*iii*) An F substituent decreases NOA(toluene) by roughly the same extent as that of benzene. This decrease is practically independent of position whereas, as discussed earlier, the effect on PA is very sensitive to the position of the substituent.

In the $\sigma$ complex the proton forms a covalent bond with a ring carbon whose character changes from $sp^2$ to $sp^3$. The positive charge is delocalized over the ring and is subject to stabilization or destabilization by both substituent-inductive and resonance effects. Bonding in $MNO^+$ will mainly involve overlap of the vacant $2\pi$ antibonding orbital of $NO^+$ with the highest filled aromatic orbital ($E_{1b}$) in benzene, the most stable structure presumably having $C_{6v}$ symmetry with nitrogen closest to the ring. Fluorine shows an electron-withdrawing effect in destabilizing both the benzene and toluene $NO^+$ complexes. We therefore agree with Reents and Freiser that the electron-donating or -withdrawing ability of the substituent is the important parameter in deciding the stability of the $\pi$ complex (11). Resonance effects are not of significance.

It is interesting to note that although the PA values of the molecules studied are more than four times the NOA values (NOA(toluene) ~49 kcal $mol^{-1}$ (11)), the absolute value of the effect of a halogen substituent is as great on NOA as on PA.

*Entropy changes in $NO^+$ transfer equilibria*

All the entropy changes shown in Table 3 are small, the only ones that are significantly different from zero involve benzene. Entropy changes for proton transfer equilibria between benzene and the halobenzenes are about three times larger than for

$NO^+$ and in the opposite direction, i.e., there is an increase in entropy when $C_6H_6$ (rotational symmetry number $\sigma = 12$) becomes $C_6H_7^+$ ($\sigma = 2$) (13). The nitrosation of $C_6H_6$ seems to consistently give a decrease in entropy of 0.6–1.5 cal $K^{-1}$ $mol^{-1}$ which cannot be accounted for by appropriate statistical calculations with reasonable and consistent geometries for the complexes. It is to be noted that the ladder of entropies is not very self-consistent even allowing for a reproducibility of $\pm 0.4$ in entropy difference measurements. Entropy determinations, unlike enthalpy determinations, are very sensitive to any mass discrimination in ion sampling from the source or in the analysis system. At the moment we can only conclude that the entropy changes in $NO^+$ transfer equilibria are very small.

# The pressure dependence of the rate of isomerization of cyclopropane at 897 K

HIROSHI FURUE AND PHILIP D. PACEY

*Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J5*

Received December 15, 1980[1]

HIROSHI FURUE and PHILIP D. PACEY. Can. J. Chem. **60**, 916 (1982).

The isomerization of cyclopropane has been studied in a flow reactor at 897 K and from 4 to 406 Torr. The pressure dependence of the rate constants from this work and from the literature have been compared with predictions obtained from two models based on the theory of Yau and Pritchard and from three RRKM models. The collisional deactivation efficiency was found to generally decline with increasing temperature. The average energy removed per collision was calculated by the method of Tardy and Rabinovitch and was found to have values from 15 to 23 kJ mol$^{-1}$ at 897 K. Combining the results of this work with data from the literature from 690 to 1038 K, the limiting high pressure rate constants follow the relation $\log k_\infty = 15.50 \pm 0.14 - (276.0 \pm 2.1 \text{ kJ mol}^{-1})/2.3RT$.

HIROSHI FURUE et PHILIP D. PACEY. Can. J. Chem. **60**, 916 (1982).

L'isomérisation du cyclopropane a été étudiée à 897 K, à des pressions comprises entre 4 et 406 Torr et en réacteurs dynamiques. On a comparé les résultats avec les prédictions de la théorie RRKM, en utilisant trois hypothèses différentes pour la structure du complexe activé, et avec les prédictions de la théorie de Yau et Pritchard. La probabilité de désactivation collisionelle diminue aux hautes températures. L'énergie moyenne transférée par collision est entre 15 et 23 kJ mol$^{-1}$ à 897 K, selon la méthode de Tardy et Rabinovitch. Les paramètres d'Arrhénius à la limite de hautes pressions, en tenant compte des résultats antérieurs entre 690 et 1038 K, sont $\log A = 15{,}50 \pm 0{,}14$ et $E_A = 276{,}0 \pm 2{,}1$ kJ mol$^{-1}$.

## Introduction

The isomerization of cyclopropane has played an important part in the study of unimolecular reactions. Because it is a reasonably clean reaction system, it was the subject of early, successful experimental investigations (1, 2). In turn, because of the availability of the experimental data, it was one of the first reactions used to test RRKM theory (3, 4). It has now been the subject of at least 20 experimental studies (1, 2, 5–22) and at least three RRKM models (3, 4, 23).

Despite this impressive body of work, some questions remain. RRKM models which were developed to reproduce the fall-off of the rate constant at low pressures at one temperature have been found to be unsuccessful at other temperatures (4). It has been suggested (16, 17) that this is caused by a decline in β, the efficiency of collisions in removing excess vibrational energy, as the temperature increases. The evidence for this is strong for collisions of cyclopropane with small molecules like He, for which β is said to fall from 0.08 at 771 K (16) to 0.006 at 1175 K (20). The evidence is weaker for collisions of cyclopropane with itself, where β is said to fall from unity at 771 K to 0.5 ± 0.05 at 973 K (17).

When one examines the experimental data, certain strengths and weaknesses are evident. Most studies (1, 2, 7, 8, 17) agree that the Arrhenius parameters at the high pressure limit are in the following ranges: $\log_{10} A$ (s$^{-1}$) = 15.2–15.5, $E_A$ = 272–276 kJ mol$^{-1}$. For the rate constants themselves, reliable, limiting high pressure values, $k_\infty$, based on extrapolation of data from a number of pressures, have been obtained between 718 K and 773 K (1, 2, 5, 7). There have been six recent studies of the pressure dependence of the rate at higher temperatures (17–22), but the pressure ranges were narrow and the authors did not extrapolate their data to determine $k_\infty$. In the studies of the collision efficiency at high temperatures (16, 18, 20, 22), $k_\infty$ was calculated starting with the above Arrhenius parameters determined at lower temperatures. Even these relatively precise Arrhenius parameters can lead to an uncertainty in $k_\infty$ at 1000 K of 50%.

The purpose of the present work is to study the reaction at high pressures and high temperatures using a flow system. Such a system can provide activation energies (24) and reaction orders (25), d ln $k$/d ln $P$, with a precision of 2 or 3%. This precision is not better than that of the activation energy quoted above, so experiments were restricted to a single temperature, 897 K. At this temperature the pressure has been varied by two orders of magnitude. The data from this study, together with data from the literature, are compared with the predictions of RRKM theory, using three different structures for the activated complex, and with the predictions of a newer theory due to Yau and Pritchard (26). These comparisons are achieved by making horizontal and vertical adjustments to theoretical and experimental plots of log $k$ versus log $P$. As explained in the discussion, this comparison provides estimates of $k_\infty$ and β. Values of $k_\infty$ are compared with literature values in the form of an

Arrhenius plot and the temperature dependence of β is examined.

## Experimental

A general description of the apparatus has been given elsewhere (24, 25, 27). Quartz flow reactor tubes of 2 and 8 mm inside diameter were heated by a 45 cm long, Nichrome-wound resistive furnace. For the 2 mm reactor, a thermocouple was placed inside a coaxial quartz tube of 8 mm inside diameter, but for the 8 mm reactor it was placed in a 4 mm outside diameter tube positioned along the reactor axis. The platinum/platinum–13% rhodium thermocouple was calibrated against the melting point of gold.

Product concentrations were analyzed in a gas chromatograph with a 2 m, 10% silicone oil on Chromosorb W column at 0°C. Cyclopropane (Matheson) was degassed at nitrogen-boiling and isopentane-melting temperatures. It contained about 0.3% propylene as an impurity.

## Results

Experiments have been performed from 3.9 to 406 Torr, the useful range of the Bell and Howell 4-366-0006-03MO pressure transducer employed. Rate constants, $k$, were calculated from measured yields of propylene. At pressures above 100 Torr it was necessary to increase the calculated rate constant by from 3 to 10% because of the effect of incomplete radial heat transfer (27). The values of $k$ obtained are shown in Fig. 1.

## Discussion

The data were compared to the predictions of RRKM theory for three activated complex structures: Model *a* (ref. 23), Model *b* (ref. 20), and Model *c* (ref. 4). Most details of these models are given in the appropriate references. For Model *a*, the vibrational frequencies (in $cm^{-1}$) in the complex were chosen as 3056(6), 1452(3), 1116(5), 640(2), and 530(4). The degeneracies are given in parentheses. The density of states in the biradical intermediate, included in ref. 23, was omitted here, because it was found to have little influence (23). The properties of the reactant were obtained from ref. 28. All vibrations were assumed to be harmonic. The hard sphere collision diameter was taken as 0.44 nm, as found at 773 K in ref. 17. Calculations were performed using an extended version of the Bunker–Hase RRKM program (29). Densities of reactant states were calculated using the Whitten–Rabinovitch technique. Numbers of activated complex states were obtained by a direct count. The integration was carried out over a range of 120 kJ $mol^{-1}$ above the barrier height with a step size of 1.6 kJ $mol^{-1}$.

Results of these calculations are shown as the smooth curves in Fig. 1. It is clear that all of the models lead to a high pressure, limiting rate constant, $k_\infty$, less than that indicated by the experimental data.

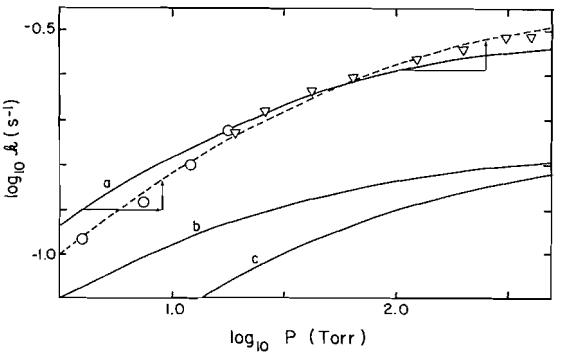

FIG. 1. Experimental and theoretical values of $k$ at 897 K; ▽, data from 2 mm id reactor; ○, data from 8 mm id reactor; *a*, *b*, *c*, predicted by Models *a*, *b*, *c*, respectively, --- curve *a* shifted horizontally and vertically to improve the fit.

The theoretical curves were then shifted vertically and horizontally to improve the fit with experiment. The dotted curve shows the result of shifting curve *a*. This procedure has been used previously for RRKM curves in this laboratory (25), for Kassel curves by Powell (30), and for analytical fits to RRKM curves by Troe (31). A shift to the right by an amount ε corresponds to a decrease of ε in log β; an upwards shift, to an increase in log $k_\infty$. The change in β assumes that β is constant within the experimental pressure range. The vertical shift involves an apparent contradiction: to change $k_\infty$ it is necessary to change either the pre-exponential factor or the activation energy in the RRKM model itself. This introduces two conceptual difficulties. Firstly, the structure of the complex for the shifted curve must be different from the structure for the original curve. This difficulty cannot be avoided; some complexes cannot fit all the data. Secondly, changing the structure of the complex can shift the fall-off to higher or lower pressures. In other words, a vertical shift may entail a horizontal shift; the two dimensions are not independent. This difficulty can be avoided if the pre-exponential factor, $A$, and activation energy, $E_A$, are changed simultaneously in such a way that they induce equal and opposite horizontal shifts. In ref. 4 it was shown that multiplying $A$ by γ leads to a horizontal shift of log γ. Similarly, increasing $E_A$ by δ leads to a horizontal shift of $-\theta\delta/(2.3RT)$. Here θ was shown to be approximately 0.24 for cyclopropane (4). The shifts are equal and opposite, then, when $\log \gamma = \theta\delta/(2.3RT)$. For example, in Fig. 1, curve *c* can be shifted upward without affecting the horizontal

axis if $E_A$ is decreased by 7.9 kJ mol$^{-1}$ and log $A$ is decreased by 0.11. In summary, the method illustrated in Fig. 1 has conceptual limitations, but it does provide a means of comparing experimental data with the results of sophisticated theoretical calculations.

A similar method was used to compare the data with the results of the theory of Yau and Pritchard (26), which uses different expressions for the rates of energy transfer and reaction by energized molecules. Model *d* is the same as that proposed for cyclopropane in ref. 26, but with the collision diameter changed to 0.44 nm. Model *e* has the Arrhenius parameters changed so that no vertical adjustment is required at 764 and 897 K.

Adjusted values of $k_\infty$, determined from vertical shifts, depended only slightly on the structure of the complex used to obtain the theoretical curves. For example, the values of $k_\infty$ obtained from Fig. 1 were 0.363, 0.368 and 0.369 s$^{-1}$, after adjustment of curves *a*, *b* and *c*, respectively. Model *d* yielded 0.361 s$^{-1}$. By a least-squares fit of the data of Fig. 1 to an expression of the form (32),

$$[1] \quad k^{-1} = k_\infty^{-1} + aP^{-\alpha}$$

where $a$ and $\alpha$ are adjustable parameters, $k_\infty$ was found to be $0.353 \pm 0.012$ s$^{-1}$. (Here the uncertainty is a standard deviation, $a = 15.6 \pm 0.9$, and $\alpha = 0.62 \pm 0.03$. Points were given a weighting proportional to $k^2$.) The two methods of extrapolation are in substantial agreement.

Figure 2 shows an Arrhenius plot for $k_\infty$. For the results of refs. 5, 7, 18, 19, and this work, the values shown were obtained by the procedure illustrated in Fig. 1. For refs. 10, 14, and 15, values of $k_\infty$ were taken from the original articles. For refs. 1, 2, 6, and 8, quoted values of $k$ have been multiplied by the value of $k_\infty/k$ calculated for the experimental pressure and temperature using Model *c*. This model was selected as, without adjusting the original value of $\beta$, it came closest to reproducing the pressure dependence observed at 718 (7), 764 (5) and 897 K. The five highest temperature points were obtained from experiments in shock tubes (14, 15, 18, 19), for which temperatures are difficult to calculate and for which adjustments of $k$ to $k_\infty$ are greater. For these reasons, data from shock tube experiments at even higher temperatures have been omitted.

The straight line in Fig. 2 was obtained from the most extensive set of experimental data (8). The Arrhenius parameters for this line are given in the first row of Table 1. Arrhenius parameters for a fit to all the points in Fig. 2 are given in the second line of the table.

The activated complex theory expressions for $k_\infty$ according to the three RRKM models (before any vertical adjustments) have been differentiated to obtain the following parameters:

$$[2] \quad E_A = -R(\mathrm{d} \ln k_\infty / \mathrm{d}T^{-1})$$

$$[3] \quad A = k_\infty \exp(E_A/RT)$$

$$[4] \quad C = \mathrm{d}E_A/\mathrm{d}T$$

The values of the parameters determined at 750 K are quoted in Table 1. The values of $\log_{10} A$ and $E_A$

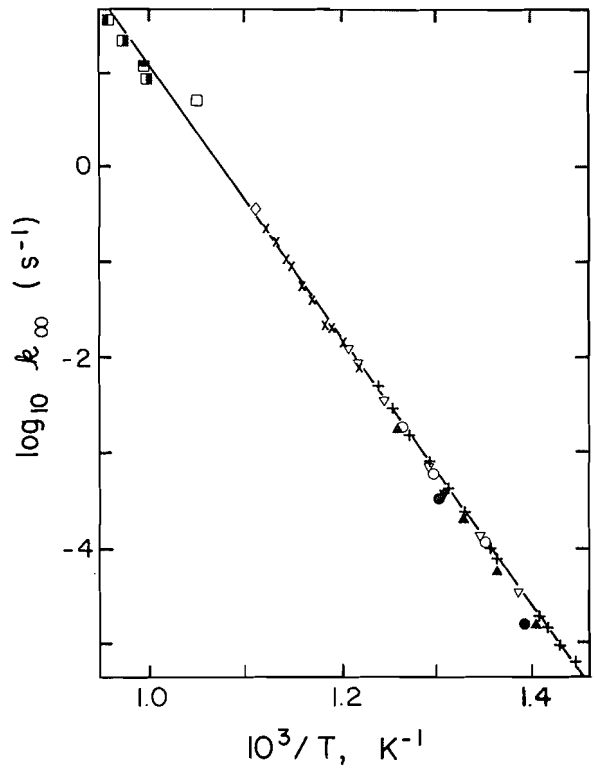

FIG. 2. Arrhenius plot of $k_\infty$: ○, ref. 1; ▲, ref. 2; ▼, ref. 5; ▽, ref. 6; ●, ref. 7; +, ref. 8; ×, ref. 10; ◨, ref. 14; □, ref. 15; ◧, ref. 18; ◒, ref. 19; ◇, this work. The straight line is a least-squares fit to the points from ref. 8.

[b]kJ mol$^{-1}$. Calculated from $\beta$, the average order of reaction and $\langle E^+\rangle$, using the results of ref. 34 for a stepladder model.
[c]From the data of ref. 7.
[d]From the data of ref. 5.

for Model $a$ are the closest to those observed experimentally. The positive values of $C$ indicate that these models predict a slight upward curvature of the Arrhenius plot. This curvature would be too small to be detected experimentally.

The Arrhenius parameters for Model $e$, quoted in Table 1, are too large to be reasonable. This is caused by the fact that the points in Fig. 2 at 764 K and 897 K are 0.14 log units low and 0.07 units high, respectively, compared to the straight line.

Values of $\beta$ determined from the horizontal shifts required in Fig. 1 and from similar fits to the data of refs. 5 and 7 are quoted in Table 2.

The values of $\beta$ were found to be greatest from Model $e$. This was expected, as this model had the largest value of $A$ (4). The values of $\beta$ for Models $b$ and $c$ did not follow the order of the values of $A$. This is caused by the greater values of $E_A$ and $C$ in Model $b$. (Forst (33) has shown that a large value of $C$ requires a smaller value of $\beta$.) Model $d$ also gives lower values of $\beta$, as was noted when the model was originally developed (26).

Table 2 also shows that $\beta$ declines in most cases with increasing temperature. This confirms the recent experimental findings of Rabinovitch and co-workers (16, 17, 20–22) and the theoretical predictions of Tardy and Rabinovitch (34) and of Troe (31). The decline is clearest from 718 to 764 K.

The above-mentioned theories also indicate that it is possible to determine $\langle\Delta E\rangle$, the average energy removed per collision, from measurements of $\beta$ and the order. The theory of Tardy and Rabinovitch requires the assumption of a model for deactivation of reactant molecules and a calculation of $\langle E^+\rangle$, the average energy of reacting molecules above the barrier height in the second order regime. They recommend the use of a stepladder model of deactivation for efficient deactivators like cyclopropane. Values of $\langle E^+\rangle$ have been obtained by numerical integration of the expression,

$$[5]\quad \langle E^+\rangle = \frac{\int_{E_0}^{\infty} (E - E_0)N(E)\exp(-E/RT)\mathrm{d}E}{\int_{E_0}^{\infty} N(E)\exp(-E/RT)\mathrm{d}E}$$

where $E$ is the energy, $E_0$, the barrier height, and $N(E)$, the density of states. Using the quasi-universal graphs in ref. 34, values of $\langle\Delta E\rangle$ have been calculated and are listed in Table 2.

Rabinovitch and co-workers (16, 17, 21) have recently found evidence for a decline in $\langle\Delta E\rangle$ with increasing temperature in the isomerization of 1,1-cyclopropane-$d_2$. They measured rate constants and kinetic isotope effects and compared their data with the predictions of a modified RRKM calculation, based on a structure for the activated complexes like the present Model $b$. At 773 K, they found $\langle\Delta E\rangle \approx 40$ kJ mol$^{-1}$. This is greater than the values in Table 2 at 718 and 764 K. The method of Rabinovitch and co-workers, involving a competition between isotopically distinct reaction channels, is a more powerful method for finding $\langle\Delta E\rangle$ than the present method. We do not have an explanation of the difference in the results, but we note that, when $\beta$ approaches unity, as at low temperatures, any uncertainty in $\beta$ leads to a substantially greater uncertainty in $\langle\Delta E\rangle$. At 973 K Rabinovitch and co-workers (21) found $\langle\Delta E\rangle \approx 22$ kJ mol$^{-1}$. This is in satisfactory agreement with the results of the present work at 897 K.

# A reactive lactonic dienophile – 3-carbethoxy-5,5-dimethyl-2(5*H*)-furanone. Application to the synthesis of a monoterpenoid lactone

HSING-JANG LIU, ERIC N. C. BROWNE, AND PURUSHOTTAM R. PEDNEKAR

*Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2*

Received November 2, 1981

HSING-JANG LIU, ERIC N. C. BROWNE, and PURUSHOTTAM R. PEDNEKAR. Can. J. Chem. **60**, 921 (1982).

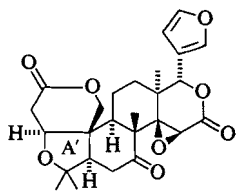
In contrast to the low dienophilicity generally observed for α,β-unsaturated lactones, the title compound **2** is shown to be a reactive dienophile. Under stannic chloride catalysis, it undergoes Diels–Alder reaction regio- and stereoselectively with a variety of dienes at room temperature. The synthesis of (±)-*o*-mentha-1,3-dien-1→8-olide (**20**) has been achieved by a two-step sequence using lactone ester **2**. Addition of **2** to 1-acetoxy-1,3-butadiene afforded epimeric acetoxy lactones **12** and **13** which were converted to the monoterpenoid lactone **20** by treatment with lithium iodide dihydrate in collidine.

HSING-JANG LIU, ERIC N. C. BROWNE et PURUSHOTTAM R. PEDNEKAR. Can. J. Chem. **60**, 921 (1982).

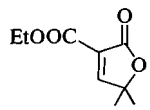
Alors que les lactones, α,β-non saturées ne sont généralement pas de bons dièmophiles, le composé **2** est un dièmophile réactif. Sous l'effet de la catalyse acide du chlorure stanneux, il subit, à la température ambiante, une réaction de Diels–Alder régio- et stéréo-sélective avec divers dièmes. On a réalisé la synthèse du (±)-*o*-menthadiène-1,3 olide-1→8 (**20**) en deux étapes à partir de la lactone ester **2**. L'addition de **2** à l'acétoxy-1 butadiène-1,3 fournit les acétoxy lactones épimères **12** et **13** qui peuvent être transformées dans la lactone **20** par traitement avec le dihydrate de l'iodure de lithium dans la collidine.

[Traduit par le journal]

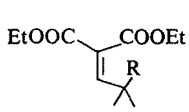
Although α,β-unsaturated esters and carboxylic acids have long been characterized as reactive dienophiles and have been widely used as such in organic synthesis (1), the Diels–Alder reaction of the corresponding lactones has not been extensively studied in spite of its potential utility as a more direct approach to useful intermediates. Possibly this is due to the expectation of a low level of reactivity for such compounds. In one known example (2), addition of 2,3-dimethyl-1,3-butadiene to coumarin was effected in only 22% yield under severe conditions while butadiene and isoprene failed to react. Fortunately, the reactivity of an α,β-unsaturated lactone should be enhanced, as predicted by the Alder rule (3), by introduction of an additional electron-withdrawing substituent to the potentially dienophilic double bond. For instance, γ,γ-dimethylaconic acid has been shown to be a useful dienophile which reacts efficiently with isoprene at high temperature (4). In our experience as well (5–7), the addition of a carbalkoxy substituent can produce a substantial increase in reactivity relative to the unsubstituted parent system. Our interest in lactonic dienophiles stems from a projected synthesis of the citrus bitter principal limonin (1) (8, 9). Carbethoxy activated lactone **2** would be a useful synthon for the introduction of the A′ ring. A close examination of the Diels–Alder characteristics of **2** (reactivity, orientation, and stereochemistry of adducts) is warranted prior to proceeding toward the ultimate objective of employing **2** in a Diels–Alder approach to limonin.



**1**



**2**



**3** R = H
**4** R = Br

Lactone ester **2**[1] was prepared in 67% yield from the known diester **3** (11) by bromination with *N*-bromosuccinimide followed by the cyclization of the resulting bromide **4** using silver oxide in aqueous tetrahydrofuran. Interestingly, a more economical procedure proved to be the pyrolytic cyclization of bromide **4** to give lactone ester **2** in 51% overall yield. In general, lactone ester **2** was found to react efficiently with a variety of dienes under stannic chloride catalysis.[2] The reaction occurred readily in ether at room temperature to give adducts in good yield (Table 1) with the exception of furan which produced only addition product **14**. With unsymmetrically substituted dienes (Entries 2 and 4–6), the adducts were found to be those predicted on the basis of the normal rules

[1]After the completion of this work, the preparation of the corresponding methyl ester was described using similar procedures (10).

[2]Under similar conditions, two other Lewis acids were briefly examined as potential catalysts. Boron trifluoride etherate gave virtually no reaction while reactions catalyzed by ferric chloride proved to be very slow relative to those catalyzed by stannic chloride.

TABLE 1. Diels–Alder reactions of lactone ester **2**

| Entry | Diene[a] | Time(h)[b] | Adduct(s) (ratio) | % Yield |
|---|---|---|---|---|
| 1 | | 6 |  **5** | 91 |
| 2 | | 3 |  **6** | 86 |
| 3 | | 0.25 |  **7** + **8** (20:1)[d] | 100 |
| 4 | | 24 |  **9** + **10** (7:3)[e] | 75 |
| 5 | | 22 |  **11** | 93 |
| 6 | | 24[c] |  **12** + **13** (4:1)[f] | 60 |
| 7 | | 19 |  **14** | 89 |

[a]In each case 20 equiv. of diene was used except for that of 1-acetoxyl-1,3-butadiene in which 10 equiv. was used.
[b]Unless otherwise specified, reactions were performed in ether at ambient temperature using stannic chloride (0.5 equiv.) as a catalyst.
[c]This reaction was carried out at 0°C using 1 equiv. of stannic chloride.
[d]Separation was effected by column chromatography on silica gel.
[e]Separation was effected by flash chromatograph (12).
[f]Inseparable mixture was obtained. The ratio was based on the $^1$Hmr spectrum of the mixture.
[g]A single product was obtained, the stereochemistry of which could not be readily assigned.

(*ortho* and *para*) governing the orientation of Diels–Alder addition (1). In cases where differing secondary orbital overlap (13) would affect the stereochemistry of the adducts (Entries 3–6), experimental results showed a strong preference of the diene to overlap with one carbonyl over the other.

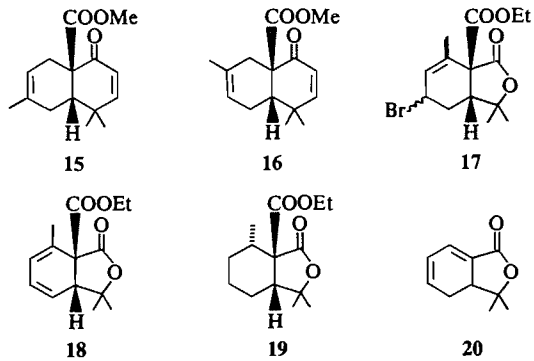
Several aspects of the structural assignments should be discussed. With respect to the orientation of the adducts derived from unsymmetrical dienes, assignments in cases of **9–13** were easily made since in each case the signal which was readily assigned to the ring junction proton appeared as a doublet of doublets in the $^1$Hmr indicating the presence of two protons on the adjacent carbon. Assignment of the regiochemistry of adduct **6** was concluded after comparison of the $^{13}$Cmr spectrum with those of the structurally related compounds **15** and **16**, the structures of which have been rigorously established (7). The adduct **6** showed two triplets at δ 28.1 and 27.1 for the two carbocyclic methylene carbons similar to the cor-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

responding carbons (δ 29.0 and 28.7) in compound **15** and in marked contrast to the signals at δ 33.1 and 24.2 observed in isomer **16**.

With regard to the stereochemical assignments, the ring junction stereochemistry of all the adducts follows from the *cis*-principle (1) for which no violations have been observed. The complete stereochemistry of cyclopentadiene adducts **7** and **8** was further deduced as follows. Examination of Dreiding models showed the lactone ring junction proton should be shielded by the double bond in structure **7** while in structure **8** this proton should not be affected (14). Examination of the $^1$Hmr spectrum of the major adduct showed a signal at δ 2.37 which was assignable to the ring junction proton while the corresponding proton in the minor isomer showed a relatively normal shift of δ 2.92 (δ 2.66–3.29 for other compounds in this series). In cases of adducts **9–13** which are conformationally flexible, the complete stereochemistry could not be assigned without ambiguity by spectroscopic analysis. A number of chemical methods were attempted[3] but were not succesful. The depicted stereochemistry of these compounds was tentatively assigned based mainly on the results obtained for cyclopentadiene, which indicated that the Diels–Alder reaction proceeded with a preferential secondary overlap of the diene with the ester carbonyl rather than the lactone carbonyl.

This report enlarges the scope of application of Diels–Alder reactions to the synthesis of lactone-containing systems and further demonstrates the advantage of using an activated dienophile to prepare useful adducts from relatively less reactive dienophile systems. A simple application of this particular dienophile (**2**) to the synthesis of natural products is illustrated by the two-step synthesis of



**15** **16** **17**

**18** **19** **20**

*o*-mentha-1,3-dien-1→8-olide (**20**), a monoterpene lactone isolated from the urine of the koala bear (*Phascolarctos cinereus*) (15). The mixture of the epimeric acetoxy lactones **12** and **13**, prepared in 60% yield from **2** and 1-acetoxy-1,3-butadiene, was treated with lithium iodide dihydrate in collidine at reflux for 1 h. Racemic *o*-menthane lactone **20** was isolated in 50% yield and showed spectroscopic properties identical to those reported for the levorotatory natural compound (15).

## Experimental

*General*

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. Elemental analyses were performed by the microanalytical laboratory of this department. The ir spectra were recorded on a Nicolet 7-199 FT-IR spectrophotometer and, except where otherwise stated, were obtained on solutions in chloroform. The $^1$Hmr spectra were recorded on a Varian HA-100, Bruker WH-200, or WH-400 spectrometer and, except where otherwise stated, were obtained on solutions in carbon tetrachloride with tetramethylsilane as internal reference. The $^{13}$Cmr spectra were recorded on a Bruker WP-60/Nicolet BNC-12 system or a Bruker WH-400 spectrometer and were obtained on solutions in deuteriochloroform using tetramethylsilane as internal reference. Mass spectra (ms) were recorded using A.E.I. model MS12 or MS50 mass spectrometers. Unless stated otherwise, anhydrous magnesium sulfate was used for drying organic solutions.

*Ethyl 4-bromo-2-carbethoxy-4-methyl-2-pentenoate (4)*

Diester **3** (5.14 g, 24 mmol) was dissolved in carbon tetrachloride (50 mL) under an argon atmosphere and *N*-bromosuccinimide (4.7 g, 26.4 mmol) was added followed by benzoyl peroxide (100 mg, 0.41 mmol). The mixture was heated at reflux for 1 h, cooled to room temperature, filtered, and concentrated to give the crude bromo ester **4** (7.55 g). A portion of this material (1.114 g) was purified by column chromatography on silica gel. Elution with 15% ether in petroleum ether gave pure bromo ester **4** (936 mg; 91% yield); ir: 1733 (C=O) and 1643 (C=C) cm$^{-1}$; $^1$Hmr δ: 6.95 (s, 1H, —CH=), 4.20, 4.18 (both q, 2H each, $J$ = 7 Hz each, 2 × —$OCH_2$—), 1.91 (s, 6H, 2 × —$CH_3$), 1.31, and 1.29 (both t, 3H each, $J$ = 7 Hz each, 2 × —$OCH_2CH_3$). *Anal.* calcd. for $C_9H_{12}O_3Br$: C 45.07, H 5.85, Br 27.26; found: C 45.06, H 5.93, Br 27.44.

*3-Carbethoxy-5,5-dimethyl-2(5H)-furanone (2)*

Crude bromo ester **4** (2.84 g, ~9.7 mmol) was dissolved in

[3]In one approach, both compounds **9** and **10** were converted, via bromide **17**, to diene **18** (>60% yield; ir (neat): 1768, 1742, 1729, 1640, 1600, and 1995 cm$^{-1}$; $^1$Hmr ($CDCl_3$) δ: 5.84–6.18 (complex, 2H, —C(=)CH—CH=), 5.55 (dd, 1H, $J$ = 8, $J'$ = 6 Hz, =CH—CH—), 4.15 (q, 2H, $J$ = 7 Hz, —$OCH_2$—), 3.38 (d, 1H, $J$ = 6 Hz, —CH—), 1.94 (s, 3H, =C(—)—$CH_3$), 1.47 (s, 3H, —$CH_3$), 1.21 (t, 3H, $J$ = 7 Hz, —$OCH_2CH_3$), and 1.18 (s, 3H, —$CH_3$); ms $M^+$ 250.1202 (calcd. for $C_{14}H_{18}O_4$: 250.1203)) by allylic bromination (*N*-bromosuccinimide (1 equiv.) and α,α′-azodiisobutyronitrile (trace) in refluxing carbon tetrachloride; 1 h) and dehydrobromination (1,5-diazabicyclo[4.3.0]non-5-ene in refluxing benzene; 8 h). In an attempt to prepare compound **19** to compare with the dihydro-derivative of **9** or **10**, catalytic hydrogenation of **18** resulted only in the saturation of the disubstituted double bond even under severe conditions (e.g. Pt in EtOAc; $H_2$; 1500 psi). The transformation of **9** and **10** to the same diene **18** nevertheless serves to confirm their epimeric relationship and orientation.

For personal use only.

tetrahydrofuran (50 mL) and water (25 mL). Silver oxide (2.48 g, 10.67 mmol) was added. After stirring for 48 h at room temperature, the reaction mixture was filtered and tetrahydrofuran was removed under reduced pressure. The aqueous solution was extracted with methylene chloride. The extracts were washed with water, dried, and concentrated. Column chromatography on silica gel eluting with 50% ether in petroleum ether gave lactone ester **2** (1.12 g; 67% yield from diester **3**); mp 68–70°C (ether); ir: 1763 (C=O), 1714 (C=O), and 1638 (C=C) $cm^{-1}$; $^1$Hmr δ: 8.06 (s, 1H, —CH=), 4.24 (q, 2H, $J$ = 7 Hz, —$OCH_2$—), 1.52 (s, 6H, 2 × —$CH_3$), and 1.35 (t, 3H, $J$ = 7 Hz, —$OCH_2CH_3$); $^{13}$Cmr δ: 167.1, 160.4, 124.6, 83.5, 61.7, 25.0, and 14.1; ms $M^+$ 184.0744 (calcd. for $C_9H_{12}O_4$: 184.0735). *Anal.* calcd. for $C_9H_{12}O_4$: C 58.69, H 6.57; found: C 58.76, H 6.66.

A less expensive method was found to be the pyrolytic cyclization of the crude bromo ester **4**. Lactone ester **2** was produced directly on attempted distillation of **4** (70.8 g) at 1 Torr. The fraction collected at 128°C was pure lactone ester **2** (15.9 g). Additional **2** (4.8 g) was obtained by column chromatography of the combined lower boiling fractions (102–120°C). The total yield was 51% from diester **3**.

*Diels–Alder reactions of lactone ester 2*

The reactions were carried out using the general procedure illustrated below with 2,3-dimethyl-1,3-butadiene. Temperature and time of reactions as well as quantities of dienes and stannic chloride relative to **2** are noted in Table 1.

Lactone ester **2** (500 mg, 2.71 mmol) was dissolved in ether (25 mL) under an argon atmosphere. The solution was chilled to 0°C and stannic chloride (354 mg, 1.36 mmol) was added. A dense white precipitate was observed immediately. After 5 min, 2,3-dimethyl-1,3-butadiene (6.13 mL, 54.3 mmol) was added and stirring was continued for 6 h at room temperature. Water (20 mL) was added and the resulting mixture was extracted with methylene chloride. The extracts were washed with water, dried, filtered, and concentrated. Column chromatography on silica gel eluting with 10–20% ether in petroleum ether gave adduct **5** (657 mg; 91% yield); ir: 1769 (C=O) and 1736 (C=O) $cm^{-1}$; $^1$Hmr δ: 4.16 (q, 2H, $J$ = 7 Hz, —$OCH_2$—), 2.84 (dd, 1H, $J$ = 7, $J'$ = 3 Hz, —CH—), 2.63, 2.22 (both d, 1H each, $J$ = 16 Hz each, —$CH_2$—), 1.78–2.12 (complex, 2H, —$CH_2$CH—), 1.68 (s, 6H, 2 × =$CCH_3$), 1.43 (s, 3H, —$CH_3$), 1.28 (t, 3H, $J$ = 7 Hz, —$OCH_2CH_3$), and 1.24 (s, 3H, —$CH_3$); $^{13}$Cmr δ: 174.6, 171.0, 125.4, 125.1, 85.9, 62.1, 56.2, 47.3, 34.5, 30.1, 29.4, 23.9, 19.0, 18.8, and 14.0; ms $M^+$ 266.1516 (calcd. for $C_{15}H_{22}O_4$: 266.1518). *Anal.* calcd. for $C_{15}H_{22}O_4$: C 67.65, H 8.33; found: C 67.37, H 8.36.

The adducts **6–14** showed the following spectral data.

Compound **6**; mp 43–44°C (ether – petroleum ether); ir: 1767 (C=O) and 1736 (C=O) $cm^{-1}$; $^1$Hmr δ: 5.46 (m, 1H, —CH=), 4.18 (q, 2H, $J$ = 7 Hz, —$OCH_2$—), 2.98 (dd, 1H, $J$ = 7, $J'$ = 2 Hz, —CH—), 2.87, 2.22 (both md, 1H each, $J$ = 14 Hz each, =$CHCH_2$—), 1.84–2.12 (complex, 2H, —$CH_2$CH—), 1.72 (s, 3H, —$CH_3$), 1.46 (s, 3H, —$CH_3$), 1.29 (t, 3H, $J$ = 7 Hz, —$OCH_2CH_3$), and 1.24 (s, 3H, —$CH_3$); $^{13}$Cmr δ: 174.6, 170.6, 133.2, 118.4, 86.0, 62.1, 53.5, 46.6, 29.8, 28.1, 27.1, 23.4, 23.2, and 14.0; ms $M^+$ 252.1368 (calcd. for $C_{14}H_{20}O_4$: 252.1361). *Anal.* calcd. for $C_{14}H_{20}O_4$: C 66.65, H 7.99; found: C 66.76, H 8.28.

Compound **7**; ir: 1761 (C=O) and 1726 (C=O) $cm^{-1}$; $^1$Hmr δ: 6.13–6.34 (complex, 2H, —CH=CH—), 4.16 (q, 2H, $J$ = 7 Hz, —$OCH_2$—), 3.38 (m, 1H, =CHCH—), 3.01 (br s, 1H, =CHCHCH—), 2.37 (s, 1H, —CH—), 1.54 (s, 3H, —$CH_3$), 1.51 (m, 2H, —$CH_2$—), 1.43 (s, 3H, —$CH_3$), and 1.29 (t, 3H, $J$ = 7 Hz, —$OCH_2CH_3$); ms $M^+$ 250.1206 (calcd. for $C_{14}H_{18}O_4$: 250.1205). *Anal.* calcd. for $C_{14}H_{18}O_4$: C 67.18, H 7.25; found: C 67.18, H 7.04.

Compound **8**; ir: 1762 (C=O) and 1732 (C=O) $cm^{-1}$; $^1$Hmr δ: 6.29 (ddd, 1H, $J$ = 6, $J'$ = 3, $J''$ = 1 Hz, =CH—), 6.17 (dd, 1H, $J$ = 6, $J'$ = 4 Hz, =CH—), 4.23 (q, 2H, $J$ = 7 Hz, —$OCH_2$—), 3.38 (m, 1H, =CHCH—), 3.02 (m, 1H, =CHCH—CH—), 2.92 (d, 1H, $J$ = 4 Hz, —CH—), 1.68 (m, 2H, —$CH_2$—), 1.45 (s, 3H, —$CH_3$), 1.34 (s, 3H, —$CH_3$), and 1.33 (t, 3H, $J$ = 7 Hz, —$OCH_2CH_3$); ms $M^+$ 250.1205 (calcd. for $C_{14}H_{18}O_4$: 250.1205). *Anal.* calcd. for $C_{14}H_{18}O_4$: C 67.18, H 7.25; found: C 67.26, H 7.13.

Compound **9**: ir: 1770 (C=O) and 1728 (C=O) $cm^{-1}$; $^1$Hmr δ: 5.78 (m, 1H, —CH=), 5.62 (ddd, 1H, $J$ = 10, $J'$ = 3, $J''$ = 2 Hz, —CH=), 4.16 (q, 2H, $J$ = 7 Hz, —$OCH_2$—), 2.66 (dd, 1H, $J$ = 7, $J'$ = 5 Hz, —$CH_2$CH—), 2.53 (mq, 1H, $J$ = 7 Hz, =CHCH—), 2.36, 1.92 (both md, 1H each, $J$ = 16 Hz each, =$CHCH_2$—), 1.35 (s, 3H, —$CH_3$), 1.30 (s, 3H, —$CH_3$), 1.28 (t, 3H, $J$ = 7 Hz, —$OCH_2CH_3$), and 1.20 (d, 3H, $J$ = 7 Hz, —$CHCH_3$); $^{13}$Cmr δ: 174.0, 170.0, 131.8, 125.8, 84.5, 61.7, 58.1, 48.1, 33.5, 29.8, 23.8, 22.4, 15.6, and 14.1; ms $M^+$ 252.1361 (calcd. for $C_{14}H_{20}O_4$: 252.1362).

Compound **10**; ir: 1768 (C=O) and 1730 (C=O) $cm^{-1}$; $^1$Hmr δ: 5.88 (m, 1H, =$CHCH_2$—), 5.70 (ddd, 1H, $J$ = 8, $J'$ = 3, $J''$ = 2 Hz, =CH—), 4.21 (q, 2H, $J$ = 7 Hz, —$OCH_2$—), 2.79 (dd, 1H, $J$ = 8, $J'$ = 3 Hz, —$CH_2$CH—), 2.69 (dq, 1H, $J$ = 7, $J'$ = 2 Hz, —$CHCH_3$), 2.33, 2.01 (both m, 1H each, —$CH_2$—), 1.35 (s, 3H, —$CH_3$), 1.30 (s, 3H, —$CH_3$), 1.30 (d, 3H, $J$ = 7 Hz, —$CHCH_3$), and 1.30 (t, 3H, $J$ = 7 Hz, —$OCH_2CH_3$); $^{13}$Cmr δ: 173.0, 172.0, 135.1, 127.5, 84.4, 62.1, 61.8, 50.9, 34.9, 30.9, 25.2, 24.0, 15.0, and 14.1; ms $M^+$ 252.1362 (calcd. for $C_{14}H_{20}O_4$: 252.1362).

Compounds **12** and **13**; ir (neat): 1769 (C=O) and 1740 (C=O) $cm^{-1}$; ms $M^+$ 296.1261 (calcd. for $C_{15}H_{20}O_6$: 296.1260). *Anal.* calcd. for $C_{15}H_{20}O_6$: C 60.81, H 6.75; found: C 60.79, H 6.88. The $^1$Hmr ($CDCl_3$) of the inseparable mixture showed two sets of signals integrated to a ratio of 4:1; major set (**12**) δ: ~6.01–6.25 (complex, 2H, —CH=CH—), 5.98 (d, 1H, $J$ = 4 Hz, —OCH—), 4.25 (q, 2H, $J$ = 7 Hz, —$OCH_2$), 3.14 (dd, 1H, $J$ = 9, $J'$ = 6 Hz, —$CHCH_2$—), ~2.46–1.98 (complex, 2H, —$CH_2$—), 2.04 (s, 3H, —$COCH_3$), 1.57 (s, 3H, —$CH_3$), 1.45 (s, 3H, —$CH_3$), and 1.30 (t, 3H, $J$ = 7 Hz, —$OCH_2CH_3$); minor set (**13**) δ: ~6.01–6.25 (complex, 2H, —CH=CH—), 5.81 (d, 1H, $J$ = 5 Hz, —OCH—), 4.28 (q, 2H, $J$ = 7 Hz, —$OCH_2$—), 3.29 (dd, 1H, $J$ = 8, $J'$ = 4 Hz, —$CHCH_2$—), ~2.46–1.98 (complex, 2H, —$CH_2$—), 2.09 (s, 3H, —$COCH_3$), 1.46 (s, 3H, —$CH_3$), 1.38 (s, 3H, —$CH_3$), and 1.30 (t, 3H, $J$ = 7 Hz, —$OCH_2CH_3$).

Compound **14**; ir: 1781 (C=O) and 1737 (C=O) $cm^{-1}$; $^1$Hmr δ: 7.35 (dd, 1H, $J = 2, J' < 1$ Hz, =CHO—), 6.30 (dd, 1H, $J = 4$, $J' = 2$ Hz, —C*H*=CHO—), 6.19 (dd, 1H, $J = 4$, $J' < 1$ Hz, —CH=C—), 4.21 (q, 2H, $J = 7$ Hz, —$OCH_2$—), 3.90 (s, 2H, —CHCH—) 1.64 (s, 3H, —$CH_3$), 1.31 (t, 3H, $J = 7$ Hz, —$OCH_2CH_3$), and 1.10 (s, 3H, —$CH_3$); ms $M^+$ 252.1002 (calcd. for $C_{13}H_{16}O_5$: 252.0998). *Anal.* calcd. for $C_{13}H_{16}O_5$: C 61.90, H 6.39; found: C 62.09, H 6.45.

*(±)-o-Mentha-1,3-dien-1→8-olide (20)*

Lithium iodide dihydrate – collidine reagent (1.28 *N*) was freshly prepared by the sequential addition of lithium iodide (514 mg, 3.84 mmol) and water (138 μL, 7.68 mmol) to 2,4,6-collidine (3.05 mL). A mixture of acetoxy lactones **12** and **13** (152 mg, 0.51 mmol) was dissolved in this reagent (2.3 mL) under an argon atmosphere. The resulting solution was heated at reflux with stirring for 1 h. After cooling to room temperature, the reaction mixture was acidified with ice-cold 5% aqueous hydrochloric acid and extracted with ether. The extracts were washed with ice-cold aqueous hydrochloric acid and water, dried, filtered, and concentrated. Flash chromatography (12) of the residue on silica gel eluting with 5% ether in petroleum ether gave racemic *o*-menthane lactone **20** (42 mg; 50% yield); ir (neat): 1749 (C=O), 1664, and 1570 (C=C) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 6.89 (m, 1H, —C=CH—), 6.06–6.24 (complex, 2H, —CH=CH—), 2.98 (m, 1H, —CH—), 2.12–2.46 (complex, 2H, —$CH_2$—), 1.54 (s, 3H, —$CH_3$), and 1.36 (s, 3H, —$CH_3$); ms *m/e*: 164.0837 ($M^+$; 22.59%; calcd. for $C_{10}H_{12}O_2$: 164.0837), 106.0427 (95.21%; $C_7H_6O$), 105.0351 (100%; $C_7H_5O$), 78.0492 (43.03%; $C_6H_6$), and 77.0375 (20.35%; $C_6H_5$).

Reçu le 4 juin 1981

C. RABILLER, A. DEHNEL et G. LAVIELLE. Can. J. Chem. **60**, 926 (1982).

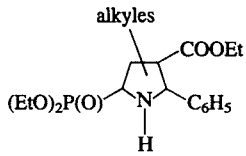
Une série de diéthylphosphono-2 carbéthoxy-4 pyrrolidines est étudiée par rmn du proton (à 250 MHz) et du carbone ($^{13}$C). L'étude des déplacements chimiques permet d'établir les configurations alors que l'analyse des constantes de couplages $^3J_{HH}$, $^3J_{PH}$ et $^3J_{PC}$ conduit à préciser les conformations privilégiées adoptées par ces cycles. Un bon accord est observé entre les relations de dépendance angulaire liant ces différentes constantes de couplage aux angles dièdres.

C. RABILLER, A. DEHNEL, and G. LAVIELLE. Can. J. Chem. **60**, 926 (1982).

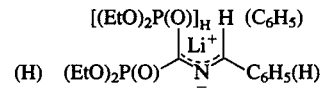
A series of 2-diethylphosphono 4-carbethoxy pyrrolidines has been studied by 250 MHz $^1$H nmr and $^{13}$C nmr. A study of the chemical shifts allows us to establish the structures and the analysis of the $^3J_{HH}$, $^3J_{PH}$ and $^3J_{PC}$ coupling constants leads to designation of preferred conformations for these rings. Good agreement is noted between the angular dependence of these coupling constants and the dihedral angles.

[Journal translation]

Une nouvelle méthode de synthèse régio et stéréospécifique (1*a*) permet d'accéder à une série de diéthylphosphono-pyrrolidines diversement substituées du type:



Afin de pouvoir étudier le mécanisme de formation de ces composés, il était important de connaitre les dispositions relatives des différents substituants. En effet, l'anion azaallylique de départ pouvait se présenter sous quatre configurations (1*b*, *c*): *cis–trans*, *trans–trans*, *trans–cis* et *cis–cis*.

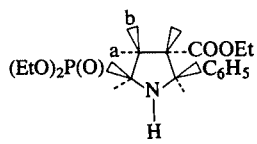


La réaction ne conduisant qu'à un seul diastéréoisomère, on devait pouvoir démontrer la structure de l'anion de départ et préciser la stéréochimie de cette condensation. Par ailleurs ce type de molécule présente la particularité de posséder un groupement (O)P·(OEt)$_2$. Or, des travaux antérieurs ont montré l'existence de relations de dépendances angulaires des couplages $^3J_{PH}$ (2, 3) et $^3J_{PC}$ (3 à 9). Il était intéressant de confronter ces résultats à ceux obtenus dans cette série et d'obtenir des informations sur les conformations adoptées par ces cycles.

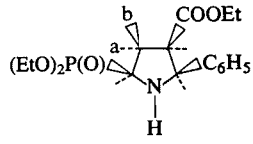
[1]Auteur à qui toute correspondance sera adressée.

## Résultats

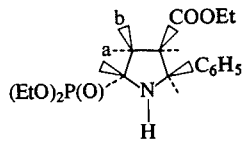
La liste ainsi que la structure des composés étudiés est décrite dans le tableau 1. La substitution du cycle pyrrolidinique par les groupements (O)P-(OEt)$_2$, COOEt et $C_6H_5$ implique l'existence théorique de quatre diastéréoisomères dont 3 seulement ont été mis en évidence.



I



II



III

Les paramètres rmn sont rassemblés dans les tableaux 2 (déplacements chimiques δ $^1$H), 3 (constantes de couplage $J_{^1H^1H}$ et $J_{^1H^{31}P}$), 4 (déplacements chimiques δ $^{13}$C) et 5 (constantes de couplage $J_{^{13}C-^{31}P}$).

La grande majorité des spectres protoniques sont analysables au 1er ordre à la condition d'utiliser un spectrographe à haut champ (250 MHz).

*On mesure le couplage $^{2}J_{P-C^2-CH_3}$ pour les composés **I**-*2* (7,6 Hz) **II**-*2* (6,0 Hz), **II**-*6* (~ 0 Hz), **II**-*7* (5,6 Hz).
†Le signe des constantes de couplage $^{1}J_{PC}$, $^{3}J_{PCCC}$ et $^{3}J_{PCNC}$ est positif (17).

L'attribution des signaux de résonance des atomes de carbone ($^{13}C$) ne pose pas de problème particulier et leur distinction s'effectue en comparant les spectres $^{13}C$ des diverses pyrrolidines et en considérant les valeurs relatives des couplages $J_{^{13}CH}$ et $J_{^{13}CP}$.

A. *Configuration des pyrrolidines étudiées. Étude des déplacements chimiques*

1. *Stéréochimie au niveau de la liaison $C^4$—$C^5$*

Les déplacements chimiques du proton constituent un excellent critère pour l'attribution structurale des cycles à 5 chainons (10, 11). Ainsi, on peut aisément déterminer les positions relatives du phényle et du COOEt en considérant les déplacements des protons méthylènes et méthyles de la fonction ester éthylique (voir tableau 2).

On observe en effet une remarquable constance des valeurs de $\delta_{CH_2}$ et de $\delta_{CH_3}$ au sein de deux séries:

série **I** $\delta_{CH_3} \sim 1{,}1$ à $1{,}2$ ppm
$\delta_{CH_2} \sim 4{,}05$ à $4{,}16$ ppm

série **II**, **III** $\delta_{CH_3} \sim 0{,}8$ à $0{,}9$ ppm
$\delta_{CH_2} \sim 3{,}5$ à $3{,}8$ ppm

Compte tenu de l'anisotropie magnétique du groupe phényle, on en déduit que dans la série **I**, la disposition des deux substituants est *trans* et *cis* dans les séries **II** et **III** (12). Cette observation est confirmée par l'analyse des déplacements du carbone $\delta$ $^{13}C$ (voir tableau 3) bien que les effets soient relativement moins importants que dans le cas du proton.

2. *Influence des méthyles sur les protons et les carbones: établissement des structures **I**-1 à 3 et **II**-1 à 9*

Il est maintenant bien établi que sauf cas particuliers (10, 11), un substituant en *cis* d'un proton vicinal déplace celui-ci à champ fort, alors que l'effet inverse est produit si le substituant se situe en *trans*.

Par ailleurs, il faut noter que les effets de plusieurs substituants sont additifs (10) et c'est ainsi que pour le composé **II**-*7* diméthylé en 2 et 4, on trouve une différence de déplacement chimique $\Delta\delta_{H^3}$ (**II**-*7*) = $\delta_{H^{3b}} - \delta_{H^{3a}} = 1{,}7$ ppm. Une telle valeur ne peut s'expliquer que si les deux méthyles se situent en *cis* l'un par rapport à l'autre, ce qui nous permet de conclure à une disposition *cis* des trois autres substituants ($C_6H_5$, COOEt et (O)P·$(OEt)_2$).

La comparaison du $|\Delta\delta_{H^3}$ (**II**-*7*)| aux valeurs $|\Delta\delta_{H^3}$ (**I**-*1*)| = 0,05 ppm $|\Delta\delta_{H^3}$ (**II**-*1*)| = 0,29 ppm ainsi que des résultats antérieurs (11) concernant l'influence d'un méthyle sur les protons vicinaux, nous permettent de déduire que le composé **II**-*1* possède la même structure que celle de **II**-*7*. On établit ainsi de proche en proche la structure **II** pour les pyrrolidines **II**-*2*, **II**-*3*, **II**-*4*, **II**-*5*, **II**-*6*, **II**-*8*, **II**-*9* (voir tableau 6) et **I** pour les pyrrolidines **I**-*1*, **I**-*2*, **I**-*3*. Par ailleurs, si nous utilisons les incréments structuraux déterminés dans la série **II** à partir des

TABLEAU 6. Influence des méthyles sur les déplacements des protons du cycle pyrrolidinique

TABLEAU 8. Influence des méthyles sur les déplacements chimiques des carbones ($^{13}C$, valeurs en ppm)

| No | $\alpha(n)$ | $\beta$-$n(m)$* | $\alpha$-$n(m)$ |
|---|---|---|---|
| **I-*2*** | $\alpha(2) = 5,4$ | $\beta$-2 (3) = 8,6 | $\gamma$-2 (4) = 1,4 |
| **I-*3*** | $\alpha(3) = 6,4$ | $\beta$-3 (2) = 7,8 | $\gamma$-2 (5) = −2 |
| | | $\beta$-3 (4) = 5,2 | $\gamma$-3 (5) = −2,9 |
| **II-*2*** | $\alpha(2) = 5,3$ | $\beta$-2 (3) = 6,2 | $\gamma$-2 (4) = −1 |
| **II-*3*** | $\alpha(3) = 8,3$ | $\beta$-3 (2) = 6,9 | $\gamma$-2 (5) = −2,6 |
| | | $\beta$-3 (4) = 8,8 | $\gamma$-3 (5) = −1,3 |
| **II-*4*** | $\alpha(4) = 5,3$ | $\beta$-4 (3) = 7,9 | $\gamma$-4 (2) = −0,8 |
| **II-*5*** | $\alpha(5) = 2,1$ | $\beta$-4 (5) = 8,4 | $\gamma$-5 (3) = −0,6 |
| | | $\beta$-5 (4) = 6,7 | $\gamma$-5 (2) = −1,4 |

*$\beta$-$n(m)$ ou $\gamma$-$n(m)$ se rapportent à l'influence d'un méthyle en position $n$ sur le carbone $C^m$ du cycle.

TABLEAU 9. Valeurs calculés des déplacements chimiques ($\delta$ $^{13}C$ en ppm/TMS) des pyrrolidines dimethylées (valeurs expérimentales entre parenthèses)

| No | $\delta_{C^2}$ | $\delta_{C^3}$ | $\delta_{C^4}$ | $\delta_{C^5}$ |
|---|---|---|---|---|
| **II-*6*** | 66,7 (62,2)* | 45,2 (39,5)* | 57,4 (56,9) | 61,7 (61,3) |
| **II-*7*** | 59,0 (59,5) | 44,1 (45,9) | 53,9 (54,5) | 72,0 (71,8) |
| **II-*8*** | 60,6 (60,1) | 46,2 (40,2)* | 63,7 (58,1)* | 72,7 (73,3) |
| **II-*9*** | 60,0 (59,9) | 37,7 (39,0) | 65,1 (65,7) | 64,8 (65,3) |

*Le mauvais accord observé dans ce cas est attribuable à l'intéraction de deux méthylés en *cis* portés par des carbones voisins (18). Ainsi pour les composés **II-*6*** et **II-*8***, ce fait se traduit par un abaissement d'environ 4,5 à 5 ppm des $\delta$ $^{13}C$ des carbones impliqués.

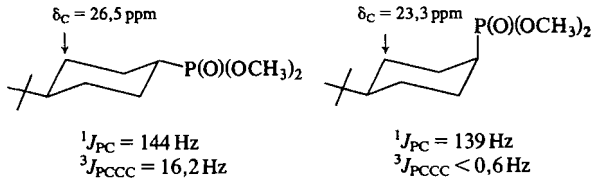
dérivés monométhylés (tableau 6) au calcul théorique des déplacements des dérivés diméthylés (voir tableau 7) on s'aperçoit que l'accord avec les valeurs expérimentales est excellent. Cette observation constitue une preuve supplémentaire de l'analogie structurale des composés considérés et indique de surcroit une grande homogénéité conformationnelle. De plus une approche similaire réalisée sur les déplacements du carbone ($\delta$ $^{13}C$) conduit aux mêmes conclusions (voir tableaux 8 et 9).

### 3. *Structures de* I-10, II-10, I-12, II-12, III-12 *et III*-9

L'analyse structurale des composés **I-*10*** et **II-*10*** est plus délicate en ce sens que l'utilisation des incréments de déplacement chimique conduit à des résultats difficilement interprétables et laisse supposer des variations sensibles de conformation (voir discussion sur les conformations).

L'étude comparée des déplacements $^{13}C$ des méthyles 3a et 3b (composés **I-*10*** et **II-*10***) à ceux des méthyles des autres composés de la série permet d'attribuer les structures compte tenu de l'effet stérique $\gamma$. Ainsi les valeurs respectives $\delta_{CH_3{}^{3a}}$ et $\delta_{CH_3{}^{3b}} = 25,4$ et 25,8 ppm (pour **I-*10***), 22,0 et 31,7 ppm (pour **II-*10***), indiquent que les groupes $O{=}P(OEt)_2$ et COOEt sont en *trans* dans le 1er cas en *cis* dans le second.

De la même façon, on peut déduire les structures de **I-*12*** et **II-*12***, en considérant les valeurs de $\delta_{C^{3a}}$ et $\delta_{C^{3b}}$ (carbones du cyclohéxyle). Le faible écart $|\delta_{C^{3a}} - \delta_{C^{3b}}|$ mesuré pour **III-*12*** indique une structure *trans* du COOEt par rapport au $O{=}P(OEt)_2$. Pour le composé **III-*9*** la valeur de $\delta_{CH_3{}^{3a}}$ (**III-*9***) = 14,1 ppm montre que les deux groupements $O{=}P{-}(OEt)_2$ et COOEt sont situés en *trans*. Dans ces conditions, la position de ce méthyle par rapport à ces deux substituants reste à déterminer. Les valeurs des couplages $^3J_{PC^4}$ et $^3J_{PC^5} \sim 2,5$ et 4,2 Hz (tableau 5) indiquent que le phosphore de **III-*9*** est essentiellement axial (8) ce qui est en plein accord avec la constatation selon laquelle $^1J_{PC}$ est plus faible dans un composé à phosphore axial que dans un composé à phosphore équatorial (7, 13)[2] ainsi:



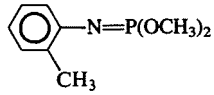
$^1J_{PC} = 144$ Hz, $^3J_{PCCC} = 16,2$ Hz

$^1J_{PC} = 139$ Hz, $^3J_{PCCC} < 0,6$ Hz

Or, nous avons $^1J_{PC^2}$ (**III-*9***) = 153,6 Hz et $^1J_{PC^2}$ (**II-*9***) = 166,5 Hz.

Une autre indication intéressante réside dans l'interaction $\gamma$ du phosphore axial produisant un effet diamagnétique sur les carbones (7, 13) (voir schéma ci-dessus). Le fait que pour **II-*9*** et **III-*9***, on mesure respectivement $\delta_{C^4} = 65,7$ et 62,2 ppm nous

[2]L'un des rapporteurs nous a fait remarquer que le plus grand couplage $^3J_{PNCC}$ connu a été mesuré dans le composé suivant couplage, notablement plus grand que celui observé dans notre cas est probablement à mettre sur le compte de la conjugaison existant entre les atomes impliqués.



$^3J_{PNCC} = 22,7$ Hz

TABLEAU 10. Angles dièdres (en degrés) calculés à partir des relations de Karplus

| **III**-*12* | — | — | — | — | −131 | −123 |

amène aux conclusions suivantes pour **III**-*9*: (*i*) le groupement $O{=}P(OEt)_2$ est axial, et (*ii*) la différence de déplacement entre le $\delta_{C^4}$ (**II**-*9*) et le $\delta_{C^4}$ (**III**-*9*) indique que pour ces deux dérivés, la seule différence structurale tient à la position du phosphore. En conséquence le méthyl 3 est situé en *trans* du COOEt et en *cis* du $O{=}P(OEt)_2$. Notons également la valeur du déplacement δ $^{13}C$ pour le méthyle 5. Si le composé possédait la structure **I** ce méthyle serait blindé relativement au même méthyle dans la structure **II**-*9* ce qui n'est pas le cas. Cette interprétation est par ailleurs confirmée par les valeurs des déplacements chimiques protoniques observés pour **III**-*9* (tableau 2).

4. *Structure* ***II***-11

On montre aisément que la pyrrolidine **II**-*11* possède la structure **II** et que la jonction pyrrolidine/cyclohexane est *cis*. En effet le proton $H^3$ est équatorial vis à vis du cyclohexane (du fait de l'absence de couplage diaxial avec l'un des protons de ce cycle), dans ces conditions la jonction des deux cycles est nécessairement *cis*. Par ailleurs, on mesure $^3J_{H^2H^3}$ = 11,8 Hz (tableau 3): $H^2$ et $H^3$ adoptent donc une disposition *trans*–diaxiale.

B. *Constantes de couplage et analyse conformationnelle. Étude des couplages* $^3J_{HH}$, $^3J_{PH}$, $^3J_{PC}$

Nous avons élucidé la stéréochimie des pyrrolidines étudiées essentiellement à l'aide des déplacements chimiques $^1H$ et $^{13}C$. L'étude des constantes de couplage doit nous permettre de préciser plus particulièrement les conformations adoptées par ces cycles. Par ailleurs, nous disposons d'un ensemble de constantes de couplage du type $^3J_{H-H}$, $^3J_{P-H}$, $^3J_{P-C}$, or pour ces trois couplages, différents auteurs ont établi des relations de dépendance angulaire. Il était donc intéressant de comparer les résultats obtenus à l'aide de chacune de ces relations. Dans une série de nicotines, Pitner et coll. (14, 15) ont établi les relations

[A] $^3J_{H-H} = 7{,}8 \cos^2 \phi + 2 \quad (0° < \phi < 90°)$

[B] $^3J_{H-H} = 10{,}5 \cos^2 \phi + 2 \quad (90° < \phi < 180°)$

Pour les pyrazolines Pudovik et coll. (2) ont déterminé:

[C] $^3J_{P-C-C-H} = 22 \cos \phi \quad (0° < \phi < 90°)$

[D] $^3J_{P-C-C-H} = -(1 + 21 \cos \phi + \cos 2\phi) \pm 1 \quad (90° < \phi < 180°)$

De la même façon, Thiem et Meyer (8) ont calculé:

[E] $^3J_{P-C-C-C} = 7{,}35\text{-}1{,}76 \cos \phi + 7{,}86 \cos 2\phi \quad (0 < \phi < 180°)$

(ϕ représente l'angle dièdre existant entre les atomes couplés.)

Les angles calculés à l'aide de chacune de ces relations et des couplages impliqués sont rassemblés dans le tableau 10. Si nous remarquons que l'on doit théoriquement avoir les égalités suivantes:

$$|PC^2—C^3C^4| = |H^2C^2—C^3H^{3b}|_{(trans)} = |PC^2—C^3H^{3b}|_{(cis)} + 120° = |H^2C^2—C^3H^{3a}|_{(cis)} + 120°$$

on constate que l'accord entre les angles calculés, sans être parfait, donne indubitablement des indications précieuses sur les conformations.

En effet dans la série des isomères **II**, l'influence des méthyles se fait peu sentir et le phosphore adopte une position essentiellement équatoriale

($PC^2$—$C^3C^4$ ~ 150°). Les composés **II**-*10* et **II**-*12* disubstitués en position 3 s'écartent notablement de ce type de conformation, comme nous l'avions supposé lors de l'étude des déplacements chimiques. Contrairement à la majorité des dérivés **II** la substitution du cycle par des méthyles sur les dérivés **I** introduit des variations importantes de conformation. Ainsi pour **I**-*2* (méthylé en 2) le groupement $P(O)(OEt)_2$ est préférentiellement axial. Cette constatation confirme par ailleurs les structures: les composés **II** sont entièrement *cis* ($OP(OEt)_2$, COOEt et $C_6H_5$) alors que les isomères **I** différent de ces derniers par la position du COOEt. Dans le premier cas, les trois substituants *cis* tendent à adopter dans tous les cas une disposition hors du cycle (encombrement minimum) alors que dans le second cas l'introduction d'un méthyle est suffisante pour que l'un des substituants se place axiallement. On note également une tendance similaire dans la série **III**. Par ailleurs, l'examen du tableau 10 indique une bonne concordance entre les angles obtenus à l'aide des couplages $^3J_{PH}$ et $^3J_{HH}$. Par contre les écarts assez importants entre ces résultats et ceux calculés avec les couplages $^3J_{PCCC}$ semblent montrer que la relation [E] soit à modifier quelque peu. De plus cette relation devient inapplicable dans le cas de couplages $^3J_{PCNC}$. En effet les valeurs de $^3J_{PCNC}$ sont plus élevées que celles de $^3J_{PCCC}$ et laissent à penser que les hétéroatomes pourraient avoir un effet sur la valeur de $^3J_{CP}$. Ainsi $^3J_{PCNC}$ (**II**-*10*) = 21,4 Hz alors que le couplage $^3J_{PC}$ maximum observé pour un angle de 180° est de 16,2 Hz (13*a*, *b*). Il est probable cependant qu'une relation de dépendance angulaire doit également gouverner en partie ce couplage. Si nous admettons que pour un cycle à cinq chainons, l'angle diédre maximum a une valeur de 170° environ (16), la valeur $^3J_{PCNC}$ (**II**-*10*) = 21,4 Hz pourrait être attribuable à cet angle. L'introduction de ces valeurs dans la relations [E] conduit à la relation corrigée [F]:

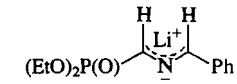
$$[F] \quad {}^3J_{PCNC} = 12{,}25 - 1{,}76 \cos \phi + 7{,}86 \cos 2\phi$$

qui permet le calcul des angles $PC^2$—$NC^5$.

Il est raisonnable d'admettre la relative validité de cette relation ainsi que la dépendance angulaire de ce couplage dans la mesure où l'angle $PC^2$—$NC^5$ calculé pour **III**-*9* est de 87°. Le phosphore occupe en conséquence une position axiale ce qui est un excellent agrément avec nos conclusions concernant les déplacements chimiques δ $^{13}C$ (voir chapitre précédent).

## Conclusion

Les déplacements chimiques δ $^{13}C$ et δ $^1H$ ont permis d'établir les structures des pyrrolidines isomères **I**, **II**, **III**. Les analogies structurales constatées confirment les résultats de synthèse. Ainsi dans la série **II**, les groupes phosphono, carbéthoxy et phényle sont situés en *cis*. Ce fait montre deux choses:



(*1*) L'anion azaallylique a réagi sous la forme *trans–trans*

(*2*) La forme *cis–cis* qui conduirait également à des composés à phényl et phosphore en *cis*, ne semble pas suffisamment stable dans nos conditions pour être envisagée.

Ce résultat est en accord avec les données de la littérature qui montrent que la confirmation *trans–trans* est en général prépondérante (1*b*).

Bien que non concertée, la réaction est stéréospécifique et conduit à un composé peu stable qui peut-être isomérisé. Par ailleurs connaissant les configurations, nous avons pu préciser les conformations privilégiées adoptées par ces cycles à l'aide des constantes de couplage. La bonne concordance observée entre les résultats obtenus par analyse des déplacements δ $^1H$ et δ $^{13}C$ et ceux donnés par les couplages confirme toutes les conclusions avancées au sein de la série **II**.

## Partie expérimentale

*Synthèse des pyrrolidines*

La synthèse de ces différents cycles est décrite dans la référence 1*a*.

*Spectres rmn*

(a) *Résonance $^1H$*

Les spectres sont enregistrés sur spectrographe Cameca à 250 MHz fonctionnant en onde continue. L'analyse des spectres est réalisable dans presque tous les cas au 1er ordre sauf pour **II**-*3* **II**-*8* et **III**-*9*. Pour ces composés les spectres sont très complexes (recouvrement de massifs) et très fortement couplés. Nous n'avons pas effectué d'analyse au 2ème ordre. Les déplacements chimiques donnés pour ces trois composés sont donc approximatifs.

Les déplacements chimiques des protons de tous les autres produits et les constantes de couplage $J_{HH}$ sont respectivement précis à ± 0,01 ppm et 0,1 Hz près. Les solutions utilisées sont concentrées à 1 *M*/L environ dans $CDCl_3$.

(b) *Résonance du $^{13}C$*

Les spectres $^{13}C$ sont enregistrés sur spectrographe Varian XL.100.12 opérant en transformée de Fourier et équipé d'une sonde de 8 mm. Les solutions utilisées sont concentrées à 1 *M*/L environ dans $CDCl_3$. Les déplacements chimiques sont précis à 0,1 ppm près.

# The crystal structure of bis(μ-trichloroacetato-*O*,*O'*)-bis[dimethyltin(IV)] and its relationship to other μ-acetato derivatives

THOMAS BIRCHALL[1] AND JAMES P. JOHNSON[2]

*Department of Chemistry and Institute for Materials Research, McMaster University, 1280 Main Street West, Hamilton, Ont., Canada L8S 4M1*

Received September 3, 1981

THOMAS BIRCHALL and JAMES P. JOHNSON. Can. J. Chem. **60**, 934 (1982).

The X-ray crystal structre of bis(μ-trichloroacetato-*O*,*O'*)-bis[dimethyltin(IV)] has been determined: $R' = 0.0518$. The crystals were monoclinic, space group $P2_1/c$, $a = 10.223(3)$ Å, $b = 7.539(2)$ Å, $c = 12.711(4)$ Å, $\beta = 97.76(2)$ and $Z = 2$. The molecular structure consists of a planar $(CH_3)_2Sn$—$Sn(CH_3)_2$ unit with the tin atoms bridged asymmetrically by two trichloroacetato groups to give each tin atom five coordination.

THOMAS BIRCHALL et JAMES P. JOHNSON. Can. J. Chem. **60**, 934 (1982).

On a déterminé la structure cristalline du bis(μ-trichloroacétato-*O*,*O'*)-bis[diméthyl étain(IV)] par diffraction des rayons X: $R' = 0{,}0518$. Les cristaux sont monocliniques, groupe d'espace $P2_1/c$, $a = 10{,}223(3)$, $b = 7{,}539(2)$, $c = 12{,}711(4)$ Å, $\beta = 97{,}76(2)$ et $Z = 2$. La structure moléculaire comporte une unité $(CH_3)_2Sn$—$Sn(CH_3)_2$ plane dont les atomes d'étain sont reliés d'une façon asymétrique aux deux groupes trichloroacétato; la coordination de chaque étain est de cinq.

[Traduit par le journal]

## Introduction

The preparation and spectroscopic properties of a series of bis(μ-haloacetato-*O*,*O'*)-bis[dimethyltin(IV)] compounds have been reported by us (1). The spectroscopic data were interpreted in terms of a tetramethylditin(IV) moiety in which the two tin atoms were bridged by two acetato ligands, thus completing the five coordinate environment about each tin. It was concluded that the changes observed in the spectroscopic data were associated with the nature of the substituted acetato ligand in the axial positions, and that only minor changes would be observed in the $(CH_3)_2Sn$—$Sn(CH_3)_2$ framework which constitutes the equatorial plane. Infrared, Raman, and Mössbauer data suggested that the average Sn—O bond length increases as the electronegativity of the R substituent on the acetato ligand increases.

Preliminary X-ray crystallographic data have been reported for the monochloroacetato (2) and the trifluoroacetato (3) derivatives and here we report the structure of the trichloroacetato compound and make a comparison between all three structures. The compounds are confirmed as being five coordinate in the solid state, with the acetato groups bridging the two tin atoms in an asymmetric fashion. The spectroscopic data are evaluated in light of the crystallographic data.

## Experimental

The preparation of the title compound has already been described (1). Crystals suitable for an X-ray study were obtained from the reaction product at 0°C and mounted in a thin quartz tube for examination.

*Crystal data*

$C_8H_{16}Cl_6O_4Sn_2$ mw = 622.27

Monoclinic, $a = 10.223(3)$ Å, $b = 7.539(2)$ Å, $c = 12.711(4)$ Å, $\beta = 97.76(2)°$, $U = 970.7(5)$ Å$^3$, $Z = 2$, $D_m = 2.06(2)$ g cm$^{-3}$, $D_c = 2.13$ g cm$^{-3}$, $F(000) = 588$, $\lambda(Mo - K_\alpha) = 0.719\,69$ Å, and $\mu(Mo - K_\alpha) = 34$ cm$^{-1}$.

The unit cell parameters were obtained from a least-squares refinement of 15 well centred reflections with $17.96° < 2\theta < 29.71°$. Zero and first layer precession photographs showed the systematic absence $0k0$ ($k$ odd), and $h0l$ ($l$ odd) indicating the space group $P2_1/c$ (No. 14) (4) and the structure was successfully refined in this space group.

*X-ray intensity measurements*

An almost spherical crystal of radius 0.15 mm sealed in a dry quartz capillary was mounted on a Syntex $P2_1$ diffractometer for data collection. Intensities were measured with graphite-monochromated radiation, using a $\theta$–$2\theta$ scan, for a total of 2560 reflections with $0 \le h \le 13$, $-1 \le k \le 9$, $-16 \le l \le 16$, and $3.23° \le 2\theta \le 55.13°$: equivalent reflections were averaged and the systematically absent reflections were removed from the data set. Of these 2051 reflections, 725 were "unobserved", i.e. had intensities less than $3\sigma$, where $\sigma$ is the error based on counting statistics. Two standard reflections (2, 3, −1); (2, 1, −4) were measured every 50 reflections and these showed a small but significant variation during data collection because of surface decomposition. The data were divided into three batches for refinement, each set with a different scale factor. A spherical absorption correction was necessary since $\mu(Mo - K_\alpha)R = 0.5$.

*Structure determination and refinement*

The positional parameters of the tin atom in the asymmetric unit were obtained from a three-dimensional Patterson synthesis, and were used to phase the initial structure-factor calculations. Least-squares refinement, using the locally written program CUDLS, of positional and isotropic thermal parameters of the tin atom gave a $R^1$ index of 0.39. The positional parameters of the remaining atoms were located by a difference-Fourier synthesis. By varying the coordinates and anisotropic temperature factors of all atoms the $R^1$ index dropped to 0.073 and a

weighting scheme was then imposed on the data set along with a secondary extinction correction,

$$F^* = F[1 + 0.542 \times 10^{-6} \times \beta\ (2\theta)F^2]^{1/2}$$

given by Larson (5). The refinement converged at $R = 0.0527$ and

$$R' = \{[\Sigma\omega(|F_o| - |F_c|)^2/\Sigma|F_o|^2]^{1/2}\} = 0.0518$$

where

$$\omega = [\sigma^2 + (0.027F_o)^2]^{-1}$$

$\sigma$ being the standard error in $F_o$ derived from counting statistics. The maximum value of shift over error was 0.004 for the $x$ coordinate of the tin atom, and the average shift over error for all variables was 0.0009. The final value of

$$[\Sigma\omega(|F_o| - |F_c|)^2/(N_F - N_p)]^{1/2} = 1.08$$

where $N_F$ = number of reflections and $N_P$ = number of refined parameters (= 94). This indicates that the model accounts for all structurally significant information in the observed structure factors. A final electron-difference map did not reveal the positions of the hydrogen atoms of the methyl groups. The largest feature was a peak of 1 e Å$^{-3}$ within 1 Å of the tin atoms along the Sn—Sn axis, with a minimum of $-1$ e Å$^{-3}$ at the centre of symmetry of the molecule. All other features were $\pm 0.5$ e Å$^{-3}$ with random distribution throughout the cell. Atomic scattering factors corrected for anomalous dispersion were taken from ref. 4.

The final positional co-ordinates of the atoms in the asymmetric unit are given in Table 1, bond lengths and bond angles in Table 2. Anisotropic temperature (Table 3) and structure factors have been deposited on supplementary information and are available on request.[3]

## Discussion

The molecular structure consists of independent $(CH_3)_4Sn_2(O_2CCCl_3)_2$ units, one of which is shown in Fig. 1. As has been found for the other structures of this type (2, 3, 6), the $C_2Sn$—$SnC_2$ unit is planar with a tin—tin bond of 2.711(1) Å which can be compared to the sum of the covalent radii, 2.80 Å. The $H_3C$—Sn bond lengths average 2.127(8) Å and are of normal length. The coordination about each tin atom is completed by two oxygen atoms, one above and one below the $C_2$—Sn—Sn—$C_2$ plane from two trichloroacetato ligands. Each tin is then five coordinate, there being no other significant interactions. These Sn—O distances, 2.286(6) Å and 2.333(5) Å, are significantly different so that the trichloroacetato ligand bridges the two tin atoms in an asymmetric fashion. Because of this one might have expected that the C(1)—O bonds within the trichloroacetato ligand would also be of different lengths. The values are 1.235(11) Å and 1.251(9) Å, and are not significantly different.

In the equatorial plane about each tin atom, the mutual repulsions between the two methyl groups and the bulky $(CH_3)_2Sn$ group results in a closing down of the C—Sn—C angle from 120° to 117.6(4)°. A consequence of the trichloroacetato ligand having a bite which is smaller than the tin–tin distance (2.711 Å) is that the Sn—Sn—O angles are significantly less than 90° and the O(1)—C(1)—O(2) angle is much greater than 120°. These effects have been observed for the analogous trifluoroacetato molecule (3).

A comparison of the structure of the title compound with the monochloro (2) and trifluoroacetato (3) complexes and with $(C_6H_5)_4Sn_2(O_2CCH_3)_2$ (6) reveals some interesting trends. Table 4 summarises the more important parameters for these four structures. The tin–tin distances are relatively short at ~2.7 Å and essentially invariant in all four molecules as are the tin–carbon (methyl or phenyl) distances. This invariance in bond lengths in the $C_2Sn$—$SnC_2$ framework is consistent with the lack of any changes in the $^{119}$Sn Mössbauer isomer shifts or in the $^1$H nmr parameters which we reported earlier (1).

[3]Complete set of data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

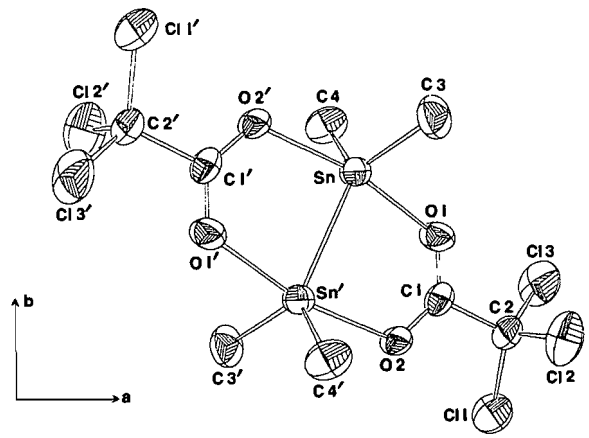

FIG. 1. A view of bis(μ-trichloroacetato-*O*,*O*′)-bis[dimethyltin(IV)] down the *c* axis.

Systematic changes are noted in the C—O and Sn—O bond lengths across this series of compounds, and we had predicted, based on ir spectroscopic data, that the $CCl_3$ derivative would have the most asymmetric C—O bond distances while the $CH_2Cl$ and $CF_3$ compounds would be the most symmetric (1). This does not appear to be the case and it is the $CCl_3$ derivative which appears the most symmetric. Undoubtedly the $\nu_{C-O}$ vibrations are strongly influenced by the Sn—O interactions and cannot be considered in isolation.

The variations in the Sn—O bond lengths for the three $(CH_3)_4Sn_2(O_2CR)_2$ compounds are, however, significantly greater than the errors on these distances. It would appear that the Sn—O(2) bond length is invariant at 2.34 Å while the Sn—O(1) distances are 2.241(7) Å, 2.286(6) Å, and 2.319(4) Å in the $CH_2Cl$, $CCl_3$, and $CF_3$ compounds, respectively. Thus the $CF_3$ derivative is the most symmetrically bonded with the longest average Sn—O bond length at 2.332 Å while the $CH_2Cl$ is the most asymmetric but with the shortest average Sn—O bond length at 2.285 Å.

These average tin–oxygen distances are consistent with the $^{119}$Sn Mössbauer quadrupole coupling constants which we have already reported (1). The longer the average Sn—O distance, the greater is the quadrupole coupling constant. Based upon data for series of trimethyltin carboxylates, it was suggested (7, 8) that the Mössbauer quadrupole coupling constants reflected the asymmetry in the tin–oxygen distances. In these molecules, the carboxylate ligand bridges the $(CH_3)_3Sn$ moieties intermolecularly with one short and one long Sn—O bond. These different bond lengths were attributed to an increase in double bond character of one C—O bond at the expense of the other C—O bond of the carboxylate as the electronegativity of the R group increases. If such were the case, then one might expect a corresponding difference in the Sn—O distances in related organo-tin carboxylates as R becomes more electronegative. For the series of trimethyltin carboxylates the difference in Sn—O bond distances does increase from 0.186(5) Å to 0.281(21) Å as the R group is changed from $CH_3$ to $CF_3$ (8), which supports the above suggestion about the quadrupole coupling constants (7, 8). However, in the tetramethylditin carboxylates reported here the difference in the two Sn—O bond lengths decreases as the ligand electronegativity increases (0.108(10), $-CH_2Cl$; 0.047(8), $-CCl_3$; 0.026(6), $-CF_3$).

Although the type of carboxylate bridge is quite different in these two series of compounds, the concept of partial contributions to the Mössbauer quadrupole splittings appears valid in the two series (9). It seems reasonable to conclude that with increasing electronegativity of the R group, the average Sn—O distance will also increase and that this will be manifested in larger quadrupole splittings, though the Sn—O distances may not be different. In the trimethyltin carboxylates the average Sn—O distance increases from 2.298(5) Å for R = $CH_3$ to 2.318(21) Å for R = $CF_3$ and although this increase is not statistically significant, it does parallel the increase observed in the tetramethyl-

ditin series discussed here. These asymmetries are a common feature in organotin carboxylates. The Sn—O distances, being nearly equal in the tetramethylditin series, are larger for the trimethyltin series and largest for the tribenzyltin acetate where the Sn—O distances are 2.14(2) Å and 2.65(2) Å (10). In tricyclohexyltin acetate the Sn—O distances are 2.12(3) Å and 2.95(4) Å and this compound is best regarded as an example of a monomeric four-coordinate tin compound (11). The bonding scheme in the tetramethylditin carboxylates does not appear to be explicable in terms of a localised bonding arrangement of the carboxylate ligand and we must look elsewhere for an explanation of the trends in Sn—O distances.

In all of these molecules the Sn—Sn—O angles are all significantly less than 90° and while there are small changes in these values as $R$ is varied, we attach little significance to them. They are undoubtedly the result of the bite of the acetato ligand being less than the tin–tin distance of 2.7 Å. The more interesting angles are those about C(1) of the acetato group. That the O(1)—C(1)—O(2) angles are greater than 120° is not surprising in view of the constraints imposed by the bite of the acetato ligand as mentioned above. In the $CCl_3$ and $CR_3$ derivatives this angle is nearly 130° with the C(2)—C(1)—O(1) and C(2)—C(1)—O(2) angles being equal at ~115°. The $CH_2Cl$ derivative is somewhat different in having a smaller O(1)—C(1)—O(2) angle at 125.5°, but more surprising is the fact that the other two angles at C(1) are not equal, one being 122.0° and the other 112.5°. A similar situation exists in the $(C_6H_5)_4Sn_2(O_2CCH_3)_2$ molecule though in this case the structure is not as well refined and large errors in the angles ($3\sigma = 8.4°$) were quoted (6). There is no obvious reason for such a distortion in this molecule. On the other hand, in the monochloroacetato complex the strong repulsions between the Cl and O(2) would open up the C(2)—C(1)—O(2) angle to the observed value; the chlorine atom is in the same plane as all of the other atoms of the monochloroacetato group except the hydrogens (2). One might have expected that the chlorine atom would move out of this plane in order to relieve the repulsions and allow the ligand to bridge symmetrically. That it does not do so must be because the observed arrangement can pack much more efficiently in the crystal. This arrangement is aided by hydrogen-bonded interactions between the hydrogens of the $CH_2Cl$ group and the oxygens of neighbouring molecules. The position of the hydrogen atoms of the $CH_2Cl$ group were deduced from chemical considerations and correspond to a peak of 0.5 e $Å^{-3}$ in the final difference synthesis. The orientation of the —$CH_2Cl$ group is such as to allow for one hydrogen atom from two different $CH_2Cl$ groups to form hydrogen bonds of length 3.06 Å to the oxygen atom forming the long Sn—O bond in a third molecule.

The most symmetrically bonded ligand is the trifluoroacetato group and it has been noted that the fluorines of this ligand are either disordered or rotating in the crystal (3). Calculation of bond valences for the atoms in the trifluoroacetato group, using the method of Brown and Shannon

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

(12), showed that one of the oxygen atoms was short of this normal bond valence of two and that this could be made up at least partially by two additional interactions to hydrogens of adjacent methyl groups (3) giving hydrogen bonds of 3.2 Å. There was also evidence for hydrogen bonded interactions to the fluorines of the $CF_3$ groups which aided the keying together of the molecules in the crystal. In the case of the trichloroacetato group, the $CCl_3$ group cannot rotate, partly because of the size of the chlorines and possibly also because of hydrogen bonded interactions which occur between these atoms and the methyl hydrogens. Repulsions are minimised by a slight rotation of the $CCl_3$ group so that none of the chlorines lie in the plane of the C—$CO_2$ atoms, and the C(2)—C(1)—O angles remain equal.

# The structures of phyllanthostatin 1 and phyllanthoside from the Central American tree *Phyllanthus acuminatus* Vahl[1]

GEORGE R. PETTIT,[2] GORDON M. CRAGG, DEVENS GUST, PETER BROWN,[3] AND JEAN M. SCHMIDT

*Cancer Research Institute and Department of Chemistry, Arizona State University, Tempe, AZ 85287, U.S.A.*

Received January 28, 1982

GEORGE R. PETTIT, GORDON M. CRAGG, DEVENS GUST, PETER BROWN, and JEAN M. SCHMIDT. Can. J. Chem. **60**, 939 (1982).

A new antineoplastic glycoside, phyllanthostatin 1, and the related glycoside, phyllanthoside, have been isolated from the Central American tree, *Phyllanthus acuminatus* Vahl. The structures of phyllanthostatin (**1***a*) and phyllanthoside (**1***b*) were completely assigned by analyses of spectral data, principally by high resolution (400 MHz) nmr. In addition to exhibiting activity against the National Cancer Institute's P388 lymphocytic leukemia, phyllanthoside was found to possess a curative level of activity against the murine B16 melanoma.

GEORGE R. PETTIT, GORDON M. CRAGG, DEVENS GUST, PETER BROWN et JEAN M. SCHMIDT. Can. J. Chem. **60**, 939 (1982).

On a isolé d'un arbre de l'Amérique Centrale, le *Phyllanthus acuminatus* Vahl, un nouveau glycoside antinéoplastique, la phyllanthostatine 1, et le glycoside apparenté phyllanthoside. L'analyse des données spectrales obtenues principalement par la rmn à haute résolution (400 MHz) a permis d'établir complètement les structures de la phyllanthostatine (**1***a*) et du phyllanthoside (**1***b*). En plus de montrer une activité contre la leucémie lymphocytique P388 de l'Institut National du Cancer, on a trouvé que le phyllanthoside possède une certaine activité curative contre mélanoma B-16 de la murine.

[Traduit par le journal]

The Euphorbiaceae family is rich in plants with a long history of human medicinal applications (2, 3). The Euphorbiaceae genus *Phyllanthus* (about 600 species ranging from free floating aquatic forms to trees) contains several species that have been employed in the primitive treatment of cancer (4, 5). Because of the U.S. National Cancer Institute's (NCI) exploratory plant evaluation program, in collaboration with the U.S. Dept. of Agriculture (USDA), the roots of a tree believed[4] to be *P. brasiliensis* Muell were collected about a decade ago in Costa Rica. An ethanol extract of the original collection was found to inhibit growth of the NCI murine P388 lymphocytic leukemia (PS system), and the Kupchan group (6) isolated and partially characterized a PS active glycoside termed phyllanthoside from a 1974 re-collection. We now report the isolation of a new anticancer glycoside designated phyllanthostatin 1 (**1***a*, 52% life extension against the PS leukemia) and a substance spectroscopically identical to phyllanthoside (**1***b*)[5] from the roots of *P. acuminatus* Vahl,[4] re-collected (1978) in Costa Rica. Structure elucidation of these unusual 1 → 2 linked disaccharides (**1***a*, **1***b*) has been accomplished. Also we are pleased to note that phyllanthoside (**1***b*) has exhibited a curative level (at 8 mg/kg with an average 62–74% life extension over the dose range 4–16 mg/kg) of antineoplastic activity against the NCI murine B16 melanoma and is presently being considered for eventual human clinical trial.

The chipped roots (81.5 kg) of *P. acuminatus* were processed by a convenient new technique[6] for initial plant and animal extraction involving the use of methylene chloride – methanol (1:1) at ambient temperatures (7). After extraction enough water

[3]The study reported herein is dedicated to the memory of Professor P. Brown who passed away March, 1981.

[4]Later, information was uncovered by Drs. J. Duke and R. Spjut of the USDA indicating *P. brasiliensis* does not extend into Central America. A detailed study of the taxonomic problem by Dr. Spjut has revealed (private communication) that the plant collection provided for the original isolation of phyllanthoside was in actuality the very closely related Central American *P. acuminatus* Vahl. Thus the re-collections (about 150 kg of root from Costa Rica) of this plant, kindly provided by Dr. J. Duke and employed in the present investigation, have been identified as *P. acuminatus*.

[5]Unfortunately, no specimens of phyllanthoside or phyllanthocin remain from the original separations. Part of the large scientific and medical loss was due to Prof. M. Kupchan's untimely death in 1976.

[6]Developed by one of us (G.R.P.) with Drs. D. L. Doubek and D. L. Herald. Application of the safer (for personnel) methylene chloride (in place of chloroform) for most solvent partition and chromatographic procedures has been summarized with pertinent references as part of another study (7*a*).

was added to separate the methylene chloride phase. The latter fraction[7] (475 g) was partitioned using the sequence 9:1 → 4:1 → 3:2 methanol–water with ligroin → carbon tetrachloride → methylene chloride (7, 8). Combination of the carbon tetrachloride (44 g) and methylene chloride (210 g) fractions followed by gel permeation (Sephadex LH-20, methanol) and repeated silica gel (98:2:0.1 chloroform–methanol–water) column chromatography of a 38 g aliquot afforded 0.24 g of pure (by hplc, μ-Porasil column with 97:3.0:0.2 methylene chloride – methanol–water) phyllanthostatin 1 (**1***a*) as an amorphous solid, mp 125–126°C; $[\alpha]_D^{26}$ −3.6° (*c* 0.83, $CHCl_3$); $\lambda_{max}$(MeOH) (log ε): 216 (4.19), 222 (4.12), and 277 (4.29) nm; ir (KBr) $\nu_{max}$: 3450, 1755, 1740, 1710, 1640, 1452, 1380, 1310, 1245, 1170, 1075, and 770 $cm^{-1}$; FD ms *m/e*: 805 ($M^+$ + H). Additional silica gel chromatography of PS active fractions yielded 0.6 g of pure (by hplc, as above) **1***b* as an amorphous solid with the following characteristics: mp 125–127°C; $[\alpha]_D^{22}$ +16.9° (*c* 0.71, $CHCl_3$); $\lambda_{max}$(MeOH) (log ε): 216 (4.25), 222 (4.19), and 277 (4.34) nm; ir (KBr) $\nu_{max}$: 3475, 1750, 1735, 1710, 1640, 1452, 1380, 1311, 1253, 1173, 1080, and 770 $cm^{-1}$; FD ms *m/e*: 805 ($M^+$ + H). Comparison of spectral data with that recorded for authentic phyllanthoside (**1***b*) indicated that both are identical.[5]

The complete structures of phyllanthostatin 1 and phyllanthoside were deduced by interpreting the $^{13}C$ nmr (22.63 MHz, $CDCl_3$), $^1H$ nmr (400 MHz, $CDCl_3$), and EI high resolution and FD mass spectra.[8] Although the structure of glycoside **1***b* was not previously known, Kupchan *et al.* (6) reported structural studies of two degradation products which proved very useful in the present study. Methanolysis of glycoside **1***b* gave an aglycone (phyllanthocin (**1***d*) by X-ray crystallographic analysis) and a disaccharide, $C_{12}H_{22}O_9$. Acid hydrolysis of the disaccharide yielded 6-deoxy-D-glucose and spectral evidence suggested that the disaccharide portion contained two acetate groups.

Examination of the $^1H$ and $^{13}C$ nmr results for **1***a* and **1***b* indicated that these potent antineoplastic plant constituents have identical aglycones and differ only in the disaccharide portion. Both glycosides afforded identical peracetates (**1***c*, mp 122–126°C, $[\alpha]_D^{24}$ +26.3° (*c* 1.1, $CHCl_3$)) and were readily interconverted via an acetyl shift upon standing at room temperature for periods exceeding 24 h in 90% aqueous ethanol.[9] Thus, glycosides **1***a* and **1***b* differ only in the location of one acetyl group on the disaccharide unit and consist of aglycone **1***e* joined via an ester linkage to a diacetylated 6-deoxy-D-glucose disaccharide. In addition, the $^3J_{HH}$ coupling constants of ~8 Hz measured for both anomeric protons of glycosides **1***a* and **1***b* indicated β-linkages at the anomeric centers. At this point only location of the three 6-deoxy-D-glucose ester groups and position of the disaccharide linkage of **1***a* and **1***b* remained to be solved.

The $^1H$ nmr spectrum of phyllanthoside (**1***b*) exhibited two 6-deoxy-D-glucose ring proton resonances at δ 4.78 and 4.90 ppm. The ca. 1 ppm downfield shift of these resonances from the usual positions for such protons clearly indicated attachment to carbon atoms bearing ester groups (9). And $^1H$ nmr decoupling studies revealed that these two ester linkages were at S-3 and S-3′. The $^{13}C$ and $^1H$ nmr results showed that the third ester linkage was at S-1 (S-1: $^{13}C$ 92.06, $^1H$ 5.50, d, $J$ = 8.1 Hz; S-1′: $^{13}C$ 103.84, $^1H$ 4.00, d, $J$ = 7.8 Hz). Similar

[7]The NCI PS in vivo and in vitro lymphocytic leukemia bioassays were employed to guide each step of the separation.

[8]The spectral data were quite consistent with the assigned structures and will be summarized in a future complete report. Elemental analytical results were also consistent with structures **1***b* and *c*. The instrumental analyses were conducted using Varian-MAT 731, Bruker WH-90, and Bruker WH-400 instruments. We are pleased to thank Drs. R. R. Inners, P. D. Ellis, J. A. McCloskey, and J. Witschel, Jr. for expert assistance with these measurements.

[9]More polar products resulting from hydrolysis of the acetates are also formed. Similar interconversion occurs with solutions of the compounds in 0.9% saline containing 5% ethanol.

studies of phyllanthostatin (**1***a*) indicated that the ester linkages were at S-1, *S-4*, and S-3′. Because chemical (acetylation) evidence suggested that glycosides **1***a* and **1***b* differed only in the location of an acetate group, the ester at S-3 in phyllanthoside and S-4 in phyllanthostatin 1 must be acetate. Furthermore, treatment of phyllanthoside with cellulase in an acetate buffer (pH 5.0) yielded a monoacetyl derivative. Here $^1$H nmr studies of this derivative showed that the S-3′ proton resonance was shifted upfield ca. 1 ppm, whereas resonances for the aglycone and the other glucose protons remained essentially unchanged. Accordingly, the second acetate group resides at S-3′ in both glycosides **1***a* and **1***b* and the aglycone must be linked to the disaccharide at S-1.

The final structural question concerned the nature of the disaccharide linkage. Because carbon atoms S-1 and S-3 in phyllanthoside (**1***b*) and S-1 and S-4 in phyllanthostatin (**1***a*) bear ester groups, the 6-deoxy-D-glucose units must, by elimination, be linked 1 → 2. This rather unusual linkage was confirmed by the following experiments. Methanolysis (0.1 *M* sodium methoxide in methanol) of phyllanthoside gave aglycone methyl ester **1***d* and disaccharide **2** (6), mp 217–219°C; $[\alpha]_D^{26}$ −3.3° (*c* 1.51, $H_2O$); $^1$H nmr (100 MHz, $D_2O$) δ: 1.27 and 1.31 (6H, d, $J$ = 6 Hz, 6,6′-$CH_3$), 3.06–4.12 (9H, m), 4.67 (d, $J$ = 8 Hz), 5.4 (d, $J$ = 4 Hz) ppm. Acetylation (acetic anhydride in pyridine) yielded a peracetate whose $^1$H nmr spectrum featured two methyl group doublets at δ 1.18 and 1.22, acetate methyl resonances at 2.00–2.20, a three-proton multiplet at 3.40–4.05, a group of resonances from 4.55–5.6, and an α-anomeric proton ($^3J_{HH}$ = 3 Hz) at 6.29 ppm. The resonance at 6.29 ppm was assigned to S-1. The low-field resonances at 4.55–5.6 ppm were attributed to S-1′ plus the protons of the acetate-bearing ring carbon atoms which experienced an expected (9) downfield shift, relative to the parent disaccharide. The three protons appearing at 3.40–4.05 ppm correspond to S-5, S-5′, and the proton on the carbon involved in the anomeric linkage to the second sugar. Proton decoupling experiments showed resonances at 3.55 and 3.93 ppm which belong to S-5 and S-5′ and a doublet of doublets at 3.90 coupled to the resonance at 6.29 ppm which must arise from S-2. Therefore the anomeric linkage at S-2 was confirmed and the phyllanthostatin 1 (**1***a*) and phyllanthoside (**1***b*) structural assignments were completed.

We have also found that *P. acuminatus* contains a series of antineoplastic glycosides related to **1***a* and **1***b* and the structures of these new and potentially useful cancer chemotherapeutic agents are presently under investigation.

Received December 11, 1981

ALAIN MARTEL, PIERRE DEXTRAZE, JEAN-PAUL DARIS, ROGER SAINTONGE, PHILIPPE LAPOINTE, TERRY T. CONWAY, IVO MONKOVIC, GERRY KAVADIAS, YASUTSUGU UEDA, PATRICK ELIE, SHAM PATIL, GILLES CARON, JAMES L. DOUGLAS, MARCEL MÉNARD, and BERNARD BELLEAU. Can. J. Chem. **60**, 942 (1982).

The preparation of (4-tritylthio-2-azetidinon-1-yl)triphenylphosphoranylideneacetates from 4-acetoxyazetidin-2-one is described. They are easily converted to mercuric or silver mercaptides. These mercaptides are acylated with a wide variety of acylating agents and cyclized to 2-substituted penem-3-carboxylates.

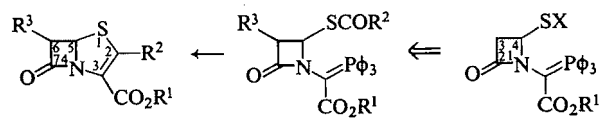
On décrit la préparation des (tritylthio-4 azètidinone-2 yl-1) triphénylphosphoranylidèneacétates à partir de l'acétoxy-4 azétidinone-2. On les transforme facilement en sulfures de mercure ou d'argent. On acyle ces sulfures avec une grande variété d'agents acylants et on les cyclise en pénèmecarboxylates-3 substitués en position 2.

[Traduit par le journal]

In connection with our continuing effort in modified β-lactam antibiotics (1) the penicillin–cephalosporin hybrid nature of the penem nucleus **1** looked especially attractive to us. The "Wittig route" to the penems, as devised by Woodward (2), was ingenious but too restrictive: the potential substituents on the nucleus must be introduced early in a long sequence, which severely limits the preparation of a series of analogs (3). Consequently we searched for a more versatile modification of the approach.[3] A recent publication by Farmitalia (4) has since described a similar approach to the synthesis of penems.

We considered that a building block such as **3**, with a sulfur protecting group that (a) allows introduction of $R^2$ through acylation at sulfur, (b) could potentially allow introduction of $R^3$ (e.g. hydroxyethyl) through anion generation at C(3),[4] and (c) is commercially available and devoid of asymmetric centers, would possess the required versatility. We found that a trityl group fulfilled all the above requirements as a sulfur protecting group.



**1** **2** **3**

SCHEME 1

In this paper we describe the preparation of penems substituted in position 2 via (1) synthesis of 4-tritylthioazetidinonylphosphorane carboxylic acids (**8**) protected by two alcohol residues, (2) transformation of **8** to heavy metal mercaptides **9** (M = Ag, Hg), (3) their reaction with various acylating agents, and (4) their cyclization followed by deprotection.

Nucleophilic displacement of the acetoxy group of azetidinone **4** is well known (5). Reaction with sodium triphenylmethyl mercaptide gave a high yield (90%) of crystalline 4-triphenylmethylthio-2-azetidinone (**5**). *N*-substitution with two glyoxylic acid esters ($R^1$ = *p*-nitrobenzyl and trimethylsilylethyl), reaction with thionyl chloride, and then with triphenylphosphine following well documented procedures[4] afforded the key intermediates **8** (66% and 68% overall from **5** for the respective esters). Whereas both carboxylic acid protecting groups were found suitable for conversion to 2-substituted penems, the trimethylsilylethyl ester

of **8** was the candidate of choice particularly for 6-substitution.[5]

Acylation of the key intermediate at sulfur was achieved through its conversion to metal mercaptides. Reaction of **8** with silver nitrate (6) or mercuric acetate (7) precipitated the corresponding silver (85%, $R^1$ = *p*-nitrobenzyl; 100%, $R^1$ = trimethylsilylethyl) or mercuric (91%, $R^1$ = *p*-nitrobenzyl) mercaptides **9** in high yield.[6] These mercaptides were found to be stable solids that could be stored for months without any sign of alteration; they are soluble in some organic solvents and readily acylated.

Acylation of the mercaptides **9** was found to be a simple process that can be carried out under a wide variety of conditions depending on the nature and stability of the substituents on the acylating moiety. The acylating species can vary from simple acid chlorides (8) to anhydrides, mixed anhydrides ($R^2CO_2OCOR$, $R^2CO_2SO_2CH_3$), or Vilsmeier complexes ($R^2CO_2CH{=}\overset{+}{N}Me_2\bar{Cl}$), thus making possible the synthesis of penems **11** with a wide variety of functional groups in the substituent at position 2. The phosphoranes **10***a–e*, so obtained, were thermally cyclized to penems (**11***a–e*) (2) in refluxing toluene ($R^1$ = *p*-nitrobenzyl) or benzene ($R^1$ = trimethylsilylethyl). The acid protecting groups were finally cleaved with appropriate reagents ($R^1$ = *p*-nitrobenzyl: $H_2$/30% Pd/Celite or sodium dithionite; $R^1$ = trimethylsilylethyl: tetrabutylammonium fluoride) and gave penems **12** ($R^1$ = H, K, or Na) in reasonable yields (see Table 1).

[5]The methodology for the preparation of 2,6-disubstituted penems from intermediates **8** will be the subject of a following paper.

[6]The mercaptide **9** (M = Ag, $R^1$ = *p*-nitrobenzyl) can also be obtained in high yield (78% to 93%) by treatment (in MeOH) of the corresponding 4-acetylthio-2-azetidinonephosphorane **10** ($R^2$ = $CH_3$) with $AgNO_3$ under basic (DBU, $Na_2CO_3$) or nucleophilic basic (pyrrolidine) conditions (for preparation of **10** see ref. 2*d*).

# One-electron photooxidation of carbazole in the presence of carbon tetrachloride. Part I. Carbon tetrachloride and ethanol used as reaction media

BOGUMIL ZELENT[1] AND GILLES DUROCHER

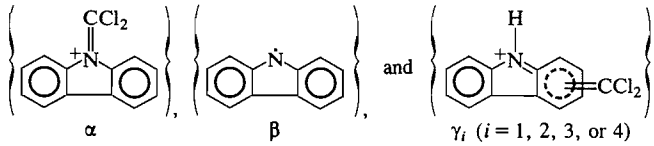
*Département de Chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal (Qué.), Canada H3C 3V1*

Received July 29, 1981

*This paper is dedicated to Professor Camille Sandorfy on the occasion of his 60th birthday*

BOGUMIL ZELENT and GILLES DUROCHER. Can. J. Chem. **60**, 945 (1982).

The photochemical reaction products of carbazole with carbon tetrachloride in ethanol have been isolated and identified along with photoproducts in the irradiated solution of carbazole in pure $CCl_4$ using water and ethanol added after the irradiation. This allowed us to discuss the complex mechanism of secondary photochemical changes in the carbazole–$CCl_4$ system. We propose that the electron transfer from carbazole to $CCl_4$ molecule in the excited CT complex, $^1(C^{\delta+}\cdots CCl_4^{\delta-})^*$, is the primary photochemical reaction followed by an heterolytic dissociation of a C—Cl bond which gives rise to the primary photoproducts in the solvent cage $[C^{+\cdot}Cl^-\dot{C}Cl_3]$. Secondary photochemical reactions initiate transformation of the radical cation of carbazole in the solvent cage giving rise to the following intermediate species:



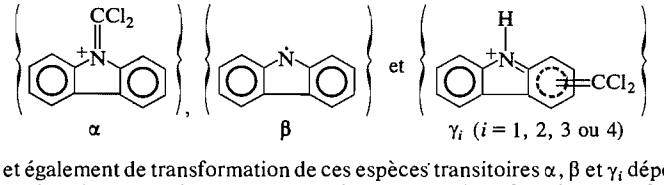
α β $\gamma_i$ ($i$ = 1, 2, 3, or 4)

The probability of formation and further transformations of these transient products: α, β, and $\gamma_i$, depends strongly on the nature of the reaction media. Thermodynamically stable products are formed depending on the reaction media; (carboethoxy)carbazoles, (carbo-*N*-carbazyl)carbazoles, and carbazole – carboxylic acids can serve as a proof for the formation of the above listed intermediates. All the results reported on the secondary photochemical reactions strongly support the electron-transfer primary mechanism used to explain the fluorescence quenching of carbazole by $CCl_4$.

These results also explain the changes observed in the fluorescence spectrum of carbazole when the ethanol solution of carbazole in the presence of $CCl_4$ is irradiated.

BOGUMIL ZELENT et GILLES DUROCHER. Can. J. Chem. **60**, 945 (1982).

Nous avons isolé et identifié les produits de la réaction photochimique entre le carbazole et le tétrachlorure de carbone d'abord dans l'éthanol comme solvant mais aussi dans le $CCl_4$ pur utilisé comme solvant pendant l'irradiation alors que l'eau et l'éthanol étaient ajoutées au $CCl_4$ après l'irradiation. Ceci nous a permis de discuter du mécanisme complexe des réactions photochimiques secondaires dans le système carbazole–$CCl_4$. Nous proposons que l'étape photochimique primaire soit le transfert électronique du carbazole au $CCl_4$ par l'intermédiaire d'un complexe de transfert de charge excité $^1(C^{\delta+}\cdots CCl_4^{\delta-})^*$ suivi par une dissociation hétérolytique d'un lien C—Cl donnant lien à l'apparition des photoproduits primaires $[C^{+\cdot}Cl^-\dot{C}Cl_3]$ dans la cage du solvant. Par réactions photochimiques secondaires, les espèces intermédiaires suivantes seraient formées dans la cage du solvant:



α β $\gamma_i$ ($i$ = 1, 2, 3 ou 4)

La probabilité de formation et également de transformation de ces espèces transitoires α, β et $\gamma_i$ dépend beaucoup de la nature des milieux réactionnels. La nature des photoproduits thermodynamiquement stables formés est en fonction de la nature du milieu réactionnel. Les molécules de (carboéthoxy)carbazoles, de (carbo-*N*-carbazyl)carbazoles et d'acides carbazole – carboxylique formées démontrent bien l'importance des espèces transitoires ci-haut mentionnées dans l'élaboration du mécanisme réactionnel. Tous les résultats obtenus sur les réactions photochimiques secondaires sont en accord avec un mécanisme primaire impliquant un phototransfert électronique lequel mécanisme est responsable pour la désactivation de la fluorescence du carbazole en présence de $CCl_4$. Ces résultats expliquent également les modifications observées dans le spectre de fluorescence du carbazole dans l'éthanol en présence de $CCl_4$ au cours de l'irradiation.

## Introduction

Carbon tetrachloride is a well-known fluorescence quencher of various aromatic electron donors (1–6). The mechanism of quenching is most commonly connected with the photochemical reaction in which $CCl_4$ participates as an electron acceptor, favorable conditions being created by the distinctive electron affinity of $CCl_4$ (2.12 eV) (7) and comparatively low C—Cl bond energy (231.2 kJ $mol^{-1}$) (8).

The electron transfer mechanism has proved to

explain the fluorescence quenching of carbazole in non-polar solvents (1) whereas in hydrogen bonding solvents like ethanol, the fluorescence quenching decay rate did not follow the usual correlation with the ionization potential of the first excited singlet donor state (2). Carbazole cation-radicals have been observed when alcoholic solutions of carbazole were irradiated into the $^1L_b$ or the $^1L_a$ states of the carbazole molecule and the number of these radicals was found to increase in the presence of $CCl_4$ (9). The explanation of the fluorescence quenching mechanism of carbazole by $CCl_4$ in alcoholic solvents requires more extended studies. Therefore it became interesting to study the photochemical reaction in the carbazole–$CCl_4$ system in ethanol as the reaction medium. In this paper we made an attempt to discuss the photochemical reaction mechanisms responsible for all the photochemical substituted carbazoles obtained and identified when a $CCl_4$ solution of carbazole is irradiated in presence of ethanol or when ethanol or water were added to the photolite after irradiating the carbazole molecules in pure $CCl_4$.

## Results and discussion

When an ethanol solution of carbazole ($1 \times 10^{-4}$ *M*) in the presence of $CCl_4$ (0.1 *M*) is irradiated in its longwave absorption band, the typical carbazole fluorescence disappears and new fluorescence emissions appear at approximately 375, 400, and 425 nm as can be seen in Fig. 1. The excitation spectra of these new emissions are shifted to the red compared to the excitation spectrum of carbazole. This, coupled to the fact that the charge transfer exciplex "carbazole–$CCl_4$" was found to be non-emissive (2), strongly suggests that these new fluorescence emissions might be due to photochemical products.

As our studies progressed we discovered that photoproducts created in the carbazole–$CCl_4$ system are of the transient character and are stable only in pure $CCl_4$ medium, but when ethanol or water are present they easily undergo further transformation giving as a result, proper mono- and di-substituted derivatives of carbazole: (carboethoxy)carbazoles, (carbo-*N*-carbazyl)carbazoles, and carbazole – carboxylic acids.

Table 1 shows the photoproducts identified from the photoreaction of carbazole with $CCl_4$ in ethanol as a solvent (first column) and also in pure $CCl_4$ (second and third columns). These photoproducts were obtained and identified when the solution was first irradiated in pure $CCl_4$ followed by additions of ethanol or water.

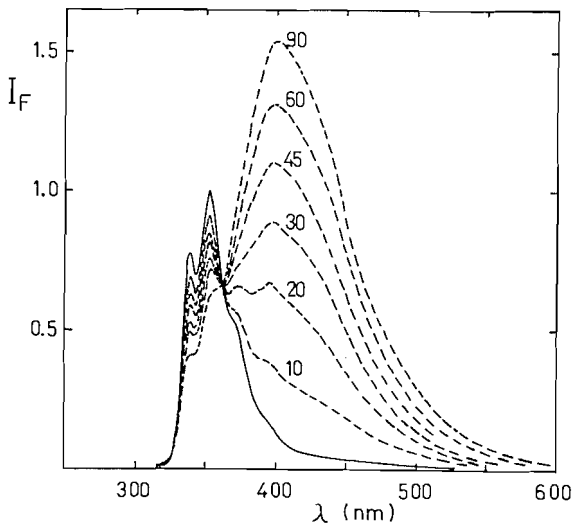

FIG. 1. Fluorescence spectra of an ethanol solution of carbazole ($1 \times 10^{-4}$ *M*) in the presence of $CCl_4$ (0.1 *M*) before irradiation (—), and after the specified time of irradiation in seconds (---). The excitation wavelength was fixed at 320 nm.

We found that derivatives of carbazole, namely mono-substituted in positions 1 and 3, and di-substituted in positions 1 and 6 or 3 and 9(N), are the main products obtained from the photochemical reaction of carbazole with $CCl_4$.

Considering the well-known photophysical results (1, 2, 5–7, 10) and also the photochemical reaction products obtained, we propose the following primary photophysical and photochemical processes:

[1] $\quad C + h\nu \rightarrow {}^1C^*$

[2] $\quad {}^1C^* \rightarrow C + h\nu_F$

[3] $\quad {}^1C^* + CCl_4 \rightsquigarrow {}^3C^* + CCl_4$
$\qquad\qquad\qquad\qquad\quad \rightsquigarrow C + CCl_4$

[4] $\quad {}^1C^* + CCl_4 \rightsquigarrow {}^1(C^{\delta+} \cdots CCl_4{}^{\delta-})^*_{solv}$
$\qquad\qquad\qquad\qquad\quad \rightsquigarrow {}^3C^* + CCl_4$

[5] $\quad {}^1(C^{\delta+} \cdots CCl_4{}^{\delta-})^*_{solv} \rightsquigarrow {}^1C^* + CCl_4$
$\qquad\qquad\qquad\qquad\quad \rightsquigarrow C + CCl_4$

[6] $\quad {}^1(C^{\delta+} \cdots CCl_4{}^{\delta-})_{solv} \rightsquigarrow \{C^+ \cdot Cl^- CCl_3\}_{solv}$

The energy loss into the singlet state manifold may proceed through emission of radiation (reaction [2]) or radiationless processes via the external spin–orbital coupling with $CCl_4$ molecule, internal conversion (reaction [3]) or via complexation (reactions [4] and [5]). Furthermore, when transient excited CT complex is formed, electron transfer may occur from carbazole molecule to $CCl_4$ molecule. It is followed by an heterolytic dissociation of

a C—Cl bond giving rise to the possible primary products in the solvent cage (reaction [6]).

The secondary products obtained and identified along with the data published (11–20) allow us to propose the following mechanism of transformation of the carbazole radical cation in the solvent cage:

For personal use only.

The electron densities calculated for the carbazole molecule show that among a variety of mesomeric structures of the radical-cation, the 1, 3, 6, 8, and 9(N) positions are likely to be favored (11, 12). This was later confirmed by the analysis of the electrochemical oxidation products of carbazole and its substituted derivatives (12, 13). Radical recombination reactions [7] and [9] in the solvent cage then become very probable, giving the intermediate ionic products α and $\gamma_i$ (mainly with $i = 1$ or 3). The presence of chlorine ion in the solvent cage makes possible the transformation of the radical-cation of carbazole to carbazyl radical β. A similar reaction has already been discussed in the literature (21). But since the N—H and H—Cl bond energies are nearly the same at 431 kJ mol$^{-1}$ (14), reaction [8] is probably reversible (15). However, radicals β and $CCl_3$ appearing close to each other in the solvent cage can immediately react with themselves. This reaction can occur with the participation of the ring or the nitrogen in radical β. If the ring is involved (reaction [8*b*]) then the transient products $\gamma_i$ are formed. On the other hand, because of steric hindrance, reaction [8*a*] can only occur through an activated complex which dissociates to cation α and chloride ion after the electron transfer has taken place into the complex. Reaction of radical $CCl_3$ and radical β with simultaneous chlorine atom split off is another way that the nitrogen atom can be involved (reaction [10]).

[10] 

Reaction [10], in which radical δ is formed, is supposedly more probable outside the solvent cage where the presence of chlorine atom acceptor or/and hydrogen atom donor facilitates its occurrence.

*N*-(Trichloroethylene)carbazole (**2**) found among the products of the photochemical reaction probably forms when radical δ reacts with radical $CCl_3$ following the pattern of reaction [11]. Because of steric hindrance, reaction of radicals δ and $CCl_3$ is only possible when accompanied by the cleavage of at least one C—Cl bond. So this reaction occurs when acceptor Cl or/and donor H is present.

In pure $CCl_4$ as well as in polar medium, product **2** forms with low yield. However, this compound is the main product of the reaction in 3-methylpentane non-polar medium which favours radical reactions. This fact supports the assumed radical mechanism of reactions [10] and [11]. In addition to reaction

[11] δ + $\dot{C}Cl_3$ 

**2**

[10], it has also been suggested that radical δ can be formed from cation α when electron donor is present (22).

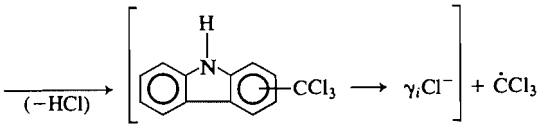
Along with the possibilities of transformation of the carbazole radical cation in the solvent cage discussed above, the substitution reactions of the carbazole radical cation with chloride ion or chlorine atom probably take place in this reaction medium. Such reactions are suggested by the formation of chloroderivatives of carbazole. We have found 1-chlorocarbazole (**3**) among the products. Substitution reactions between aromatic radical cations and chloride ions are known in the literature (23). On the other hand, $CCl_4$ is the reaction medium in which chlorine atoms are easily generated (8, 19).

[12] 

Carbon tetrachloride or trichloromethyl radical can be hydrogen acceptors while the chloride ions can serve as proton acceptors in reaction [12].

The carbon tetrachloride medium favours the chain photochemical reaction mechanism initiated by electron transfer from the electron donor to the $CCl_4$ molecule (16, 20, 24). The great photochemical activity of carbazole in $CCl_4$ can also be explained by chain reaction initiated by $CCl_3$ radicals in the presence of $CCl_4$. Comparatively low C—Cl bond energy in the $CCl_4$ molecule makes possible the participation of $CCl_4$ in the reaction as a hydrogen acceptor, the reaction scheme is as follows:

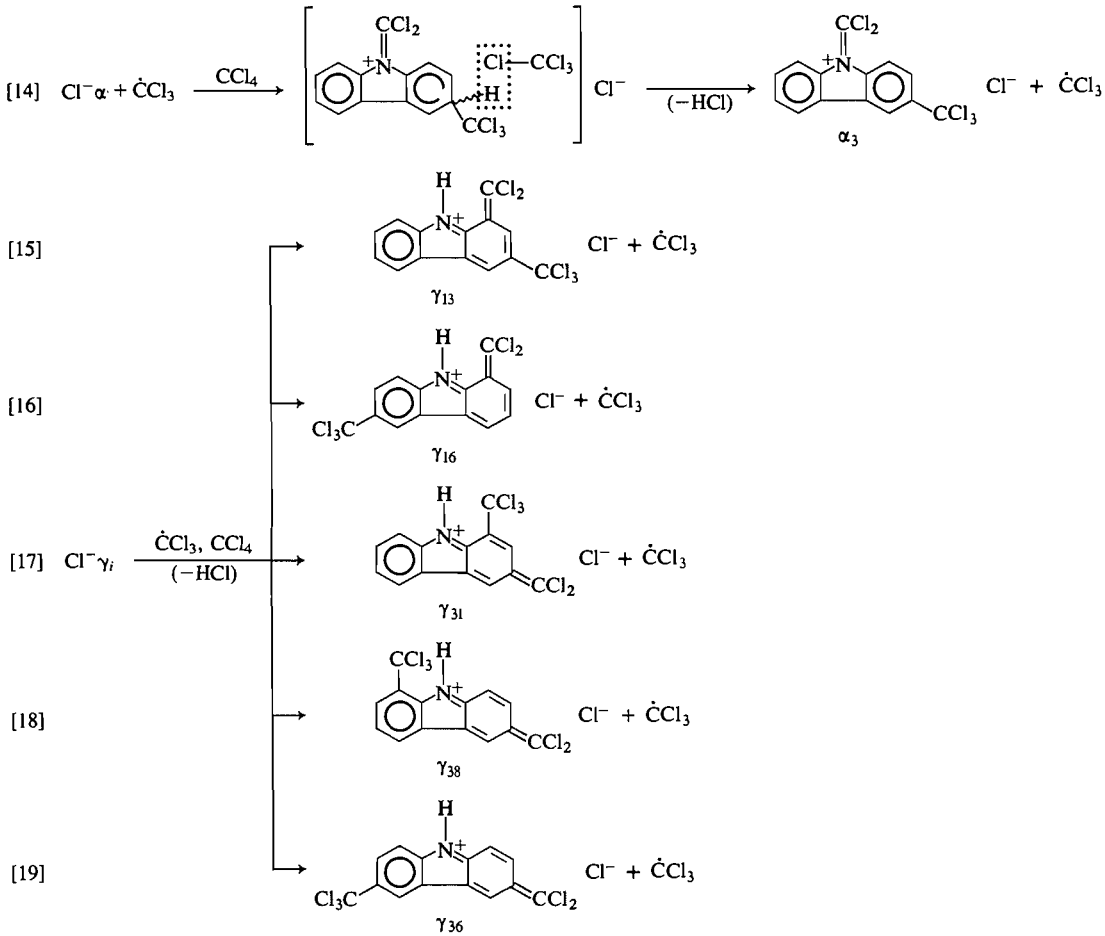
[13] **C** + $\dot{C}Cl_3$ $\xrightarrow{CCl_4}$ 



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

In the reaction above, the sum of bond energies undergoing splitting is smaller than the sum of energies of new bonds formed (14). Therefore reaction [13] might be an additional source of $Cl^-\gamma_i$ intermediates.

The reaction of $CCl_3$ radicals with $\alpha$ and $\gamma_i$ cations in $CCl_4$ explains the formation mechanism of di-substituted transient products (reactions [14] to [19]).



The closing chain reaction might be

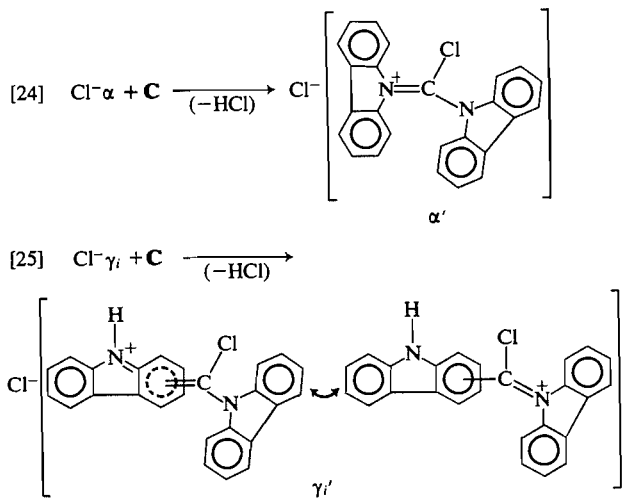
[20] $\mathbf{C} + \dot{C}Cl_3 \longrightarrow \beta + CHCl_3$

[21] [22] $\beta + \dot{C}Cl_3 \rightarrow \alpha Cl^-$, $\gamma_i Cl^-$

[23] $2\dot{C}Cl_3 \longrightarrow C_2Cl_6$

**1**

In pure $CCl_4$, ionic products $\alpha$ and $\gamma_i$ can undergo further reactions with carbazole molecules resulting in the correspondingly $\alpha'$ and $\gamma_i'$ monocations. The reaction scheme is as follows:



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

The mechanism proposed above for the photochemically initiated reaction in the carbazole–$CCl_4$ system has been strongly supported by a collection of data achieved while studying the reaction products. This will now be described more extensively.

*Use of water after irradiation*

If we add water to the photolysis solution, transient products, showing significant stability in pure $CCl_4$, undergo easy hydrolysis resulting in corresponding (carbo-*N*-carbazyl)carbazole and carbazole – carboxylic acids (see Table 1).

The hydrolysis of intermediates $\alpha'$ and $\gamma_i'$ partially explains the formation mechanism of *N*,*N*′-carbodicarbazyl (**17**), 1-(carbo-*N*-carbazyl)carbazole (**18**), and 3-(carbo-*N*-carbazyl)carbazole (**19**) according to the following scheme:

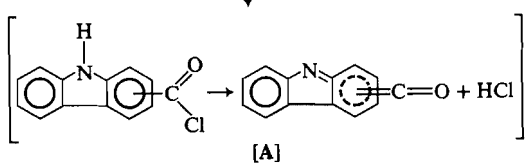
[26] $Cl^-\alpha' \xrightarrow[(-2\,HCl)]{H_2O}$ 
**17**

[27] $Cl^-\gamma_i' \xrightarrow[(-2\,HCl)]{H_2O}$ 
**18, 19**

Intermediates $\gamma_i$, being the precursors of carbazole-1-carboxylic acid (**15**), and carbazole-3-carboxylic acid (**16**), easily undergo further transformation in the presence of water until the proper acid chlorides [**A**], which are of intermediate character, are formed (reaction [28]), this transformation being followed by the formation of the acids (reaction [29]). The labile acid chlorides formed from intermediates $\gamma_i$ can also undergo reaction with carbazole thus acting as additional source of products **18** and **19** (reaction [30]).

[28] $Cl^-$ 
$\gamma_i$

$H_2O\,|\,(-2\,HCl)$



**[A]**

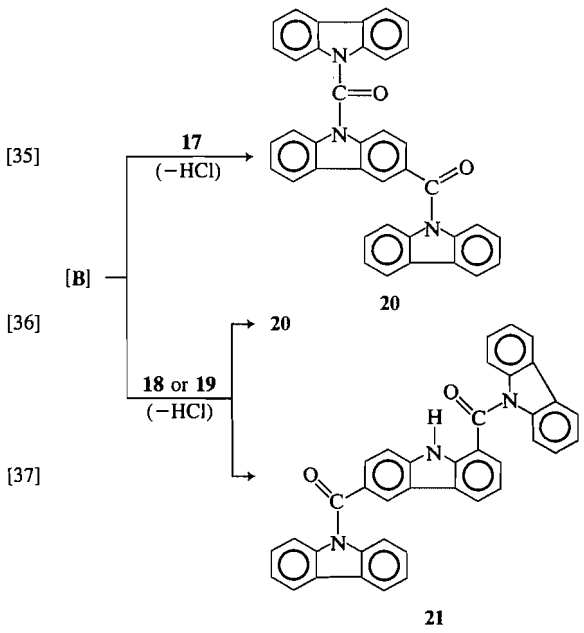
[29] 
**15, 16**

[30] 
Intermediate α present in the reaction medium undergoing the reaction with water can give rise to not only mono-substituted but also to di-substituted (carbo-*N*-carbazyl)carbazoles. During the first step of the reaction, cation α undergoes transformation in the presence of water until *N*-(carbochloro)-carbazole as an intermediate product [**B**] is formed (reaction [31]). Then [**B**] can undergo reaction with carbazole leading to the formation of **17** (reaction [33]) or **18** and **19** (reaction [34]). In the presence of water it should also undergo reaction resulting in the formation of unstable carbazole-*N*-carboxylic acid which presumably decomposes to carbazole and carbon dioxide (25), reaction [32].

[31] $Cl^-\alpha \xrightarrow[(-2\,HCl)]{H_2O}$ 
**[B]**

[32] 
[33] **17**

[34] 
Intermediate [**B**] formed in the reaction medium can also undergo reaction with products **17**, **18**, and **19** present, thus explaining the formation of 3,9-di(carbo-*N*-carbazyl)carbazole (**20**), and 1,6-di-(carbo-*N*-carbazyl)carbazole (**21**), (reactions [35]–[37]). The formation of 1,3- and 3,6-di-substituted (carbo-*N*-carbazyl)carbazoles is less probable.



The remaining part of carbazole present among the products of photolysis is efficiently used in reactions [30], [33], and [34]. This can be observed by TLC method.

Probably di-substituted (carbo-*N*-carbazyl)carbazoles can also be formed in another way. If intermediates $\alpha'$ and $\gamma_i'$, formed in the reactions [24] and [25] undergo reactions with the transient product $\alpha$, these reactions lead to the corresponding di-cations, mainly to 1,6- and 3,9-di-substituted carbazole derivatives. These di-cations undergoing hydrolysis would explain the second way in which products **20** and **21** are formed. But it is presently difficult to estimate to what extent these reactions contribute to the formation of the above mentioned products.

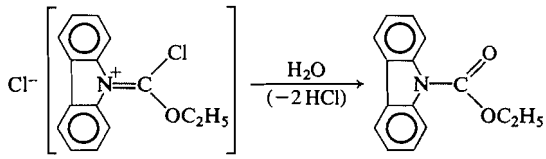
Intermediate di-substituted monocations in the presence of water probably undergo transformations to proper carbazole – dicarboxylic acids. We did not manage to isolate these compounds.

*Use of ethanol after irradiation*

If we add ethanol to the photolysis solution, the transient products formed in pure $CCl_4$ undergo reactions with alcohol, and mono- and di-substituted (carboethoxy)carbazoles are formed as a result. As ethanol contains traces of water, (carbo-*N*-carbazyl)carbazoles as well as carboxylic acids appear but with significantly lower yield than in the case when water is used (Table 1). In the reaction discussed there exists a probability of the participation of water from the surface of silica gel used as a filling of chromatographic column.

*N*-(carboethoxy)carbazole (**4**) appearing among the products when ethanol is added after irradiation, as well as *N*-cyanocarbazole found when the irradiated solution was saturated with ammonia gas (22) confirm the formation of transient $\alpha$ cation in the system of carbazole–$CCl_4$. The reaction mechanism between $\alpha$ cation and ethanol to give product **4** can be suggested as follows:

[38] $Cl^-\alpha \xrightarrow[(-HCl)]{C_2H_5OH}$



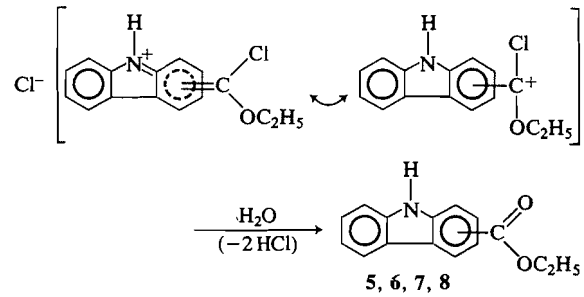
**4**

[39] $Cl^-\alpha \xrightarrow[(-2HCl)]{H_2O} [B] \xrightarrow[(-HCl)]{C_2H_5OH} \mathbf{4}$

If intermediate $\alpha$ reacts first with an ethanol molecule (or two molecules) and then with the water molecule, the reaction results directly in **4** (reaction [38]), but when $\alpha$ reacts with the water molecule first, the transient product appearing in the reaction should be [**B**] which can undergo transformation in the presence of an excess of ethanol, mainly to **4** (reaction [39]). But when compared to the other products in this reaction, **4** is formed with relatively low yield.

Similar pattern exists for the reaction of transient products $\gamma_i$ in the presence of ethanol during which 1-(carboethoxy)carbazole (**5**), 2-(carboethoxy)carbazole (**6**), 3-(carboethoxy)carbazole (**7**), and 4-(carboethoxy)carbazole (**8**) are formed (reactions [40] and [41]):

[40] $Cl^-\gamma_i \xrightarrow[(-HCl)]{C_2H_5OH}$



**5, 6, 7, 8**

[41] $Cl^-\gamma_i \xrightarrow[(-2HCl)]{H_2O} [A] \xrightarrow[(-HCl)]{C_2H_5OH}$ **5, 6, 7, 8**

Products **5**, **6**, **7**, and **8** confirm the existence of intermediates $\gamma_i$ in the system carbazole–$CCl_4$ when irradiated. On the other hand di-substituted (carboethoxy)carbazoles: 3,9-di(carboethoxy)car-

bazole (**9**), 1,3-di(carboethoxy)carbazole (**10**), 1,6-di(carboethoxy)carbazole (**11**), and 3,6-di(carboethoxy)carbazole (**13**) found among the products indicate that di-substituted cations are formed alongside with transient mono-substituted α and $\gamma_i$ when the carbazole–$CCl_4$ system is irradiated. The probable mechanism of formation of di-substituted intermediates, as a result of the reactions between α and $\gamma_i$ and $CCl_3$ radicals in the presence of $CCl_4$, was described by reactions [14] to [19].

The formation of **9**, **10**, **11**, and **13** can be assessed as follows:

[42] $Cl^-\alpha_3 \xrightarrow[(-6\,HCl)]{C_2H_5OH(H_2O)}$ **9**

[43] $Cl^-\gamma_{13\text{ or }31} \xrightarrow[(-6\,HCl)]{C_2H_5OH(H_2O)}$ **10**

[44] $Cl^-\gamma_{16\text{ or }38} \xrightarrow[(-6\,HCl)]{C_2H_5OH(H_2O)}$ **11**

[45] $Cl^-\gamma_{36} \xrightarrow[(-6\,HCl)]{C_2H_5OH(H_2O)}$ **13**

*Use of ethanol as a solvent*

When ethanol is used as a solvent of carbazole in the presence of $CCl_4$, the secondary photochemical transformation is significantly changed in comparison with the reactions in pure $CCl_4$ described above.

The polar reaction medium favours the formation of ionic intermediates in the solvent cage which is supported by the products found in this reaction (Table 1).

Intermediates α and $\gamma_i$ which have appeared during irradiation can immediately undergo further reactions ([38] to [41]) which result in the formation of all the mono-substituted (carboethoxy)carbazoles. So, active participation of ethanol in the reaction medium probably eliminates reactions [14]–[19] leading to di-substituted cations. Furthermore, reactions of intermediates α and $\gamma_i$ with carbazole molecules become less probable (reactions [24], [25]).

Attention should be paid to the fact that *N*-(carboethoxy)carbazole is formed with comparatively lower yield than 1-(carboethoxy)carbazole and 3-(carboethoxy)carbazole. This can be observed when TLC method is used. This fact suggests that the ethanol medium mainly favours the formation of intermediates $\gamma_i$ which can be the result of both reactions [9] and [13]. When ethanolic solution of carbazole with $CCl_4$ was irradiated the mono(carboethoxy)carbazoles, formed during irradiation, also undergo photochemical reactions in the presence of $CCl_4$. This leads to di-substituted (carboethoxy)carbazoles, **9**, **10**, **11**, **12**, **13**, and **14** these being formed from the corresponding intermediate products (reaction [46]).

[46] 
$\xrightarrow{CCl_4,\ h\nu}$ $\{\text{intermediate products}\}_{solv}$

$\xrightarrow[(-n\,HCl)]{C_2H_5OH(H_2O)}$ **9** + **10** + **11** + **12** + **13** + **14** + ···

Reaction [46] can be used as a method of photochemical synthesis of di(carboethoxy)carbazoles.

The mechanism of one-electron photooxidation of carbazole in the presence of carbon tetrachloride already suggested by us in a recent paper (22) has been extended above and strongly supported by the qualitative study of the various reaction products obtained.

## Fluorescence spectra

We are now in a good position to explain the new fluorescence emissions observed when ethanol solutions of carbazole in the presence of $CCl_4$ are irradiated (Fig. 1). We showed in Table 2 the wavelength of the maximum fluorescence intensity for a series of (carboethoxy)carbazoles. Obviously, the new fluorescence band at about 400 nm appearing in Fig. 1 during irradiation of the solution might be a complex mixture of the (carboethoxy)-carbazole fluorescences. The spectroscopy and the

photophysics of all these molecules are now being studied in our laboratory.

## Experimental

*Apparatus*

$^1$H-nmr spectra were measured with a Bruker WH-90 spectrometer operating at 90 MHz. Chemical shift values are given in a δ scale with respect to TMS as an internal standard. Infrared spectra were recorded on a Perkin-Elmer 710B infrared spectrophotometer and mass spectra were taken with an AE1 MS902 mass spectrometer.

The absorption spectra were recorded on a Cary 14 spectrophotometer using a 10 mm optical path cell. The emission spectra were recorded on a fluorescence spectrophotometer Model SF-1 "Fluorispec" (Baird-Atomic, INC; Cambridge, MA). All solutions examined in fluorescence were first degassed by the well-known freeze–thaw method.

*Materials*

Carbazole was an Eastman Organic chemical and was used without any further purification. Carbon tetrachloride from American Chemicals was of spectrograde quality and it was washed with a saturated sodium carbonate solution and then repeatedly with water, dried with calcium chloride and $P_2O_5$, and redistilled. Ethanol was purified by refluxing with concentrated sulfuric acid (4 mL $H_2SO_4$/1000 mL solvent) for 24 h and then was distilled twice before use.

Benzene and petroleum ether were distilled before use.

*General procedure*

Carbazole solutions (0.005 *M*) in pure $CCl_4$ or 0.1 *M* $CCl_4$ in ethanol were deoxygenated with oxygen-free argon and irradiated in a Pyrex Hanovia immersion-well reactor for 1 h with an Hanovia 679A36; 450 W medium-pressure mercury lamp. Hydrogen chloride generated during these reactions was neutralized with sodium carbonate. 1% sodium carbonate water solution or ethanol with sodium carbonate were added to the irradiated solution of carbazole in pure $CCl_4$. But only sodium carbonate was added to the irradiated carbazole solution with $CCl_4$ in ethanol. Solutions containing ethanol were mixed and then the sediment was separated by filtration. The remaining solutions were concentrated. The solution containing water (biphase system) was shaken, and then the $CCl_4$ was evaporated under vacuum. The remaining products not dissolved in water were precipitated at the bottom of the flask. Then water was decanted and products were dried using a stream of air.

The photochemical products were then analysed by TLC detected by uv (using Eastman-Kodak TLC plates, silica gel 13181) and separated by column chromatography. The columns were packed with silica gel (Kieselgel 60, Merck, particle size 0.040–0.063 mm). Developing systems consisted of petroleum ether (low-boiling fraction) and ethyl ether or benzene and ethanol. Identified products have been listed in Table 1 and their $R_f$ values on TLC plates with silica gel in Table 3.

*Spectral characteristics of the photochemical products*

*Hexachloroethane* (**1**): single crystals, unobserved by TLC. This compound is going down first on the chromatographic column. The product has been identified by comparison with the infrared and mass spectra of an authentic sample.

N-*(Trichloroethylene)carbazole* (**2**): was identified as described previously (22).

*1-Chlorocarbazole* (**3**): colorless crystalline solid; $^1$H-nmr ($CDCl_3$) δ 7.09–7.53 (m, 5H, arom), 7.92, 8.01, 8.10 (3s, 2H, arom), 8.28 (s, 1H, N—H), ($d_6$-acetone) 7.10–7.70 (complex m, 5H, arom), 8.04–8.20 (m, 2H, arom), ~10.65 (s, broad band, 1H, N—H).

Infrared (film) $\tilde{\nu}_{max}$ 3400 (s, N—H), 1620 (w), 1600 (m), 1555 (m), 1485 (m), 1445 (s), 1415 (s), 1360 (vw), 1325 (m), 1310 (m), 1260 (w), 1220 (w), 1200 (vw), 1175 (m), 1125 (m), 1020 (m), 920 (w), 845 (w), 790 (vw), 770 (w), 730 (vs) cm$^{-1}$.

Mass spectrum (70 eV) (mol wt for $C_{12}H_8NCl$ 201.66), *m/e* 203 ($M^+$, 33.7), 201 ($M^+$, 100), 166 (42), 165 (29.4), 164 (26.2), 138 (42), 137 (11.7).

N-*(Carboethoxy)carbazole* (**4**): white crystalline solid; $^1$H-nmr ($CDCl_3$) δ 1.56 (t, *J* = 7 Hz, 3H, methyl), 4.60 (q, *J* = 7 Hz, 2H, methylene), 7.27–7.58 (m, 4H, arom), 7.94–8.04 (m, 2H, arom), 8.27–8.37 (m, 2H, arom).

Infrared (film) $\tilde{\nu}_{max}$ 3040–2830 (m), 1730 (vs, C=O), 1590 (w), 1480 (m), 1455 (m), 1440 (vs), 1420 (m), 1390 (s), 1365 (vs), 1335 (s), 1320 (vs), 1295 (vs), 1245 (s), 1215 (s), 1200 (vs), 1100 (s), 1040 (s), 1005 (m), 920 (m), 840 (m), 750 (vs), 740 (vs), 705 (s) cm$^{-1}$.

Mass spectrum (70 eV) (mol wt for $C_{15}H_{13}NO_2$ 239.28), *m/e* 239 ($M^+$, 41.5), 180 (59.6), 167 (100), 166 (62.8), 140 (37.2), 139 (24.8).

*1-(Carboethoxy)carbazole* (**5**): white crystalline solid; $^1$H-nmr ($CDCl_3$) δ 1.48 (t, *J* = 7 Hz, 3H, methyl), 4.50 (q, *J* = 7 Hz, 2H, methylene), 7.16–7.57 (m, 4H, arom), 8.05, 8.14, 8.22, 8.31 (2d, 3H, arom), 9.97 (s, 1H, N—H), ($d_6$-acetone) 10.78 (s, broad band, 1H, N—H); ir and ms are the same as described previously (22).

*2-(Carboethoxy)carbazole* (**6**): white crystalline solid; $^1$H-nmr ($CDCl_3$) δ 1.44 (t, *J* = 7 Hz, 3H, methyl), 4.43 (q, *J* = 7 Hz, 2H, methylene), 7.21–7.50 and 7.90–8.20 (2m, 3H and 4H, arom), 8.25 (s, 1H, N—H), ($d_6$-acetone) 10.63 (s, 1H, N—H).

Infrared (film) $\tilde{\nu}_{max}$ 3400 (s, N—H), 1685 (vs, C=O), 1620 (s), 1490 (w), 1450 (m), 1435 (s), 1375 (w), 1350 (w), 1330 (m), 1315 (w), 1285 (m), 1260 (m), 1210 (m), 1080 (w), 1015 (w), 980 (vw), 860 (m), 825 (w), 810 (vw), 760 (vw), 735 (vs), 710 (s) cm$^{-1}$.

## Conclusion

The following scheme describes the complex mechanism of photochemical reactions in the carbazole–$CCl_4$ system in pure $CCl_4$ as well as in ethanol as the reaction media:

$$^1(C^{\delta+}\cdots CCl_4^{\delta-})^* \rightarrow [C^+\,{}^\bullet Cl^-\,\dot{C}Cl_3] \rightarrow \alpha, \beta, \text{and } \gamma_i \rightarrow \text{products}$$

The electron transfer from the electronically excited carbazole molecule to $CCl_4$ molecule in the excited CT complex is the primary photochemical reaction followed by the primary photoproducts in the solvent cage. The radical cation of carbazole undergoes transformations in the presence of chloride ion and trichloromethyl radical in the solvent cage giving radical β and cations α and $\gamma_i$. Following that, depending upon the reaction media used, intermediates α, β, and $\gamma_i$ undergo further transformation to proper thermodynamically stable products. This mechanism of one-electron photooxidation of carbazole in the presence of carbon tetrachloride was strongly supported by a qualitative study of the various reaction products obtained.

Reçu le 30 juillet 1981

E. VAUTHIER, S. ODIOT et F. TONNARD. Can. J. Chem. **60**, 957 (1982).

Un formalisme pour le calcul de σ dans le cadre de la méthode des perturbations finies est développé en gardant hermitienne la matrice de perturbation au premier ordre en ***B***. Le formalisme de σ est séparé en termes de contributions mono, di, triatomiques et l'importance des densités électroniques des liaisons proches et lointaines est mise en évidence. Les déplacements chimiques du $^{13}C$ ne dépendent que très peu des liaisons lointaines contrairement au $^{1}H$. Un calcul de la constante d'écran sur une série de 16 carbones $sp$, $sp^2$, donne une précision moyenne de 5 ppm pour le noyau $^{13}C$.

E. VAUTHIER, S. ODIOT, and F. TONNARD. Can. J. Chem. **60**, 957 (1982).

A formalism for the calculation of σ in the finite perturbation method is developed by keeping hermitian the first order perturbed matrix in ***B***. The σ formalism is separated into mono, di, and triatomic terms, and the importance of the electron densities of neighboring and remote bonds is shown. $^{13}C$ chemical shifts depend only slightly on the remote bonds in contrast to those for $^{1}H$. A calculation of the screening constant for a series of 16 $sp$ and $sp^2$ carbons gives an average precision of 5 ppm for the $^{13}C$ nuclei. [Journal translation]

## Introduction

Le calcul a priori des constantes d'écran en résonance magnétique nucléaire (rmn) présente un grand intérêt dans la mesure où la précision du calcul est suffisante. Pour le $^{13}C$, par exemple, une précision de ~1 ppm faciliterait considérablement l'identification de structures organiques. Les méthodes de calcul présentement employées reproduisent les déplacements chimiques du $^{13}C$ avec une précision moyenne n'excédant pas ~10 ppm dans la majorité des cas (1).

Quatre formalismes de calcul sont actuellement utilisés, soit (*i*) la méthode Hartree–Fock couplée (CHF) (2, 3), (*ii*) la méthode des perturbations finies (FPM) (4), (*iii*) la théorie des perturbations classique de Pople (5) et, finalement (*iv*), la méthode des variations (6, 7). Les calculs CHF en *ab initio* conduisent à des résultats qui dépendent du choix de l'origine des axes moléculaires (8). Aussi, pour pallier cet inconvénient majeur, Ditchfield a introduit des orbitales atomiques jauge invariantes (GIAO) (9). Ce formalisme, récemment appliqué sur des composés du lithium (10), a également été adapté à la méthode "Extended Hückel" (EHT) et conduit ainsi au calcul de déplacements chimiques avec une précision moyenne de ~15 ppm pour le $^{13}C$ et de ~0,5 ppm pour $^{1}H$ (11). Par ailleurs, la méthode classique de Pople a été utilisée par Webb sur une base GIAO aux niveaux CNDO/S et INDO (12–17), avec une précision moyenne sur le $^{13}C$ de ~10 ppm dans une série de coumarines (12) et de ~8 ppm dans une série d'éthyléniques méthylés (14). Dans le formalisme variationnel de Stephen (18) et Didry et Guy (7), Aminova *et al.* (19) a introduit les orbitales GIAO ce qui a conduit, aux niveaux EHT et INDO, à une précision moyenne de ~10 ppm pour le $^{13}C$ et de ~26 ppm pour $^{1}H$.

La méthode des perturbations finies utilisée ici est due à Pople *et al.* (4). Elle a donné lieu à des calculs *ab initio* avec (20, 21) ou sans GIAO (22). Pour le proton, un calcul LEMAO-5G (21) donne une précision moyenne (sur 9 valeurs) de l'ordre de 0,7 ppm et de 10 ppm pour le $^{13}C$. Ce formalisme a aussi été utilisé au niveau INDO (23–26) afin d'éviter le coût excessif des calculs *ab initio*. Les premiers travaux (23) découlent d'une application stricte des approximations INDO lors du développement du formalisme, ce qui entraîne l'élimination de la perturbation due au champ magnétique dans les éléments de la matrice de Fock. De plus, dans ce formalisme INDO, il s'introduit des approximations CNDO dans l'expression des éléments de matrice $G_{\mu\nu}$. Plus récemment, Garber *et al.* (26), toujours dans un cadre INDO et en évitant, pour la première fois, l'approximation de London, ne néglige plus l'effet important du champ magné-

tique. Toutefois, les approximations INDO détruisent dans son formalisme le caractère nécessairement hermitique de la matrice $H$.

Nous avons donc repris l'écriture de ce formalisme avec les approximations INDO sur une base de GIAO et avec l'approximation de London, en conservant la condition d'hermiticité. Le rôle des interactions lointaines, traduites par des intégrales à trois centres dans les termes dia et paramagnétiques, n'a pas été clairement démontré (26), à l'exception du proton pour le terme paramagnétique (11). Aussi, l'un des buts de notre travail est-il de mettre en évidence l'importance de ces liaisons lointaines en ne faisant aucune approximation dans le calcul des intégrales tricentriques et d'étudier leurs effets relatifs sur le déplacement chimique du $^{13}C$ et du $^{1}H$. Nous montrons, enfin, que l'amélioration apportée au formalisme par le maintien de la condition d'hermiticité des matrices se traduit par une précision moyenne égale à 5 ppm pour le $^{13}C$.

## Théorie

En présence d'un champ magnétique externe $\boldsymbol{B}$ et du moment magnétique $\mu_M$ d'un noyau résonnant $M$, l'hamiltonien électronique d'une molécule à couche complète s'écrit, en unités atomiques

$$(\boldsymbol{B}, \mu_M) = \sum_k \boldsymbol{H}_k + \sum_{k<l} 1/r_{kl}$$

où $H_k$ est l'opérateur monoélectronique $= \frac{1}{2}[\boldsymbol{P}_k + (1/c)\boldsymbol{A}_k]^2 + V_k$ et $\boldsymbol{A}_k = \frac{1}{2}\boldsymbol{B}\Lambda\boldsymbol{r}_k + \mu_M\Lambda\boldsymbol{r}_{Mk}/r_{Mk}^3$ est le potentiel vecteur au point repéré par le vecteur $\boldsymbol{r}_k$ dans un système d'axes moléculaires.

La fonction d'onde $\psi(\boldsymbol{B}, \mu_M)$ est un déterminant de Slater construit sur des orbitales moléculaires $\phi_i$, combinaisons linéaires d'orbitales atomiques (GIAO).

$$\phi_i = \sum_\nu C_{\nu i}\chi_\nu \text{ avec } \chi_\nu = \chi_\nu^0\left(\exp -\frac{i}{c}\,\boldsymbol{A}_\nu\cdot\boldsymbol{r}\right) \quad \text{et} \quad \boldsymbol{A}_\nu = \tfrac{1}{2}\boldsymbol{B}\Lambda\boldsymbol{R}_\nu$$

où $\boldsymbol{R}_\nu$ repère la position du centre porteur de l'orbitale $\chi_\nu$ et $\chi_\nu^0$ est l'orbitale atomique en absence de $\boldsymbol{B}$. La fonction d'onde $\psi(\boldsymbol{B}, \mu_M)$ est la solution de l'équation

$$\mathcal{H}(\boldsymbol{B}, \mu_M)\psi(\boldsymbol{B}, \mu_M) = E(\boldsymbol{B}, \mu_M)\psi(\boldsymbol{B}, \mu_M)$$

L'énergie Hartree Fock perturbée, $\boldsymbol{E}(\boldsymbol{B}, \mu_M)$ se met sous la forme classique $E(\boldsymbol{B}, \mu_M) = \Sigma_{\mu\nu}\boldsymbol{P}_{\mu\nu}H_{\mu\nu} + \frac{1}{2}\Sigma_{\mu\nu}\boldsymbol{P}_{\mu\nu}G_{\mu\nu}$ avec

$$H_{\mu\nu} = \left\langle \chi_\nu \left| \frac{1}{2}\left(\boldsymbol{P} + \frac{1}{c}\boldsymbol{A}\right)^2 + V \right| \chi_\nu \right\rangle$$

[1] $$G_{\mu\nu} = \sum_{\eta\sigma} P_{\eta\sigma}[(\mu\nu|\eta\sigma) - \tfrac{1}{2}(\mu\sigma|\eta\nu)]$$

$$(\mu\nu|\eta\sigma) = \iint \chi_\mu^*(1)\chi_\nu(1)\frac{1}{r_{12}}\chi_\eta^*(2)\chi_\sigma(2)\,d\tau_1\,d\tau_2$$

*Expression des éléments matriciels* $H_{\mu\nu}$

Il est connu que

[2] $$H\chi_\nu = H\chi_\nu^0\left(\exp -\frac{i}{c}\boldsymbol{A}_\nu\cdot\boldsymbol{r}\right)$$

$$= \left(\exp -\frac{i}{c}\boldsymbol{A}_\nu\cdot\boldsymbol{r}\right)\left\{\frac{1}{2}\left[\boldsymbol{P} + \frac{1}{c}(\boldsymbol{A} - \boldsymbol{A}_\nu)\right]^2 + V\right\}\chi_\nu^0$$

$$= \left(\exp -\frac{i}{c}\boldsymbol{A}_\nu\cdot\boldsymbol{r}\right) H_\nu\chi_\nu^0$$

Un élément $H_{\mu\nu}$ devient ainsi

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

[3] $$H_{\mu\nu} = \int \left[ \exp \frac{i}{c} (A_\mu - A_\nu) \cdot r \right] \chi_\mu^{0*} H_\nu \chi_\nu^0 \, d\tau$$

$$H_\nu \chi_\nu^0 = H^0 \chi_\nu^0 - \frac{i}{2c} B \cdot r_\nu \Lambda \nabla \chi_\nu^0 - \frac{i}{c} \mu_M \frac{r_M \Lambda \nabla}{r_M^3} \chi_\nu^0 + \frac{1}{2c^2} \sum_{\alpha\beta} \left( \frac{r_\nu \cdot r_M \delta_{\alpha\beta} - r_{\nu\alpha} r_{M\beta}}{r_M^3} \right) \chi_\nu^0 \mu_{M\alpha} B_\beta$$

Où $$r_\nu = r - R_\nu$$

Il est important de remarquer que l'énergie perturbée $E(B \cdot \mu_M)$ est une quantité réelle (27) et qu'en conséquence, la matrice $H_{\mu\nu}$ doit rester hermitienne. Cette condition d'hermiticité impose que l'on doit avoir constamment $\int \chi_\mu^* H \chi_\nu \, d\tau = \int \chi_\nu (H\chi_\mu)^* \, d\tau$. Or, les approximations usuelles pour l'estimation des éléments $H_{\mu\nu}$ peuvent détruire cette condition d'hermiticité. Ainsi en est-il de l'approximation de London: $r = \frac{1}{2}(R_\mu + R_\nu)$ qui détruit (5) l'hermiticité même au niveau *ab initio*. Les approximations de la méthode INDO détruisent aussi, à elles seules, l'hermiticité. Dans ce présent travail, qui fait appel à la fois à l'approximation de London et aux approximations INDO, il y a donc lieu, selon Pople (5), de retenir dès à présent la partie hermitienne de $H_{\mu\nu}$ dans le formalisme général, soit (28)

$$[H_{\mu\nu}] \text{ herm} = \tfrac{1}{2}[H_{\mu\nu} + H_{\nu\mu}^*]$$

Partant de [3] on obtient

[4] $$H_{\nu\mu}^* = \int \left[ \exp \frac{i}{c} (A_\mu - A_\nu) \cdot r \right] \chi_\nu^0 \left\{ (H^0 \chi_\mu^0)^* + \frac{i}{2c} B \cdot r_\mu \Lambda \nabla \chi_\mu^{0*} + \frac{i}{c} \mu_M \cdot \frac{r_M \Lambda \nabla}{r_M^3} \chi_\mu^{0*} + \frac{1}{2c^2} \sum_{\alpha\beta} \left( \frac{r_\mu r_M \delta_{\alpha\beta} - r_{\mu\alpha} r_{M\beta}}{r_M^3} \right) \chi_\mu^{0*} \mu_{M\alpha} B_\beta \right\}$$

En ajoutant [3] à [4] après développement de l'exponentielle et en adoptant des $\chi_\mu^0$ réels, on trouve:

$$|H_{\mu\nu}|_{\text{herm}} = \int \chi_\mu^0 H^0 \chi_\nu^0 \, d\tau + \frac{i}{4c} B \left\{ \int \chi_\mu^0 ((R_\mu - R_\nu) \Lambda r) H^0 \chi_\nu^0 \, d\tau + \int \chi_\nu^0 ((R_\mu - R_\nu) \Lambda r) H^0 \chi_\mu^0 \, d\tau \right\} - \frac{i}{4c} B \left\{ \int \chi_\mu^0 (r_\nu \Lambda \nabla) \chi_\nu^0 \, d\tau - \int \chi_\nu^0 (r_\mu \Lambda \nabla) \chi_\mu^0 \, d\tau \right\} + \text{termes en } \mu, \mu B, \text{ etc. ...}$$

A ce niveau, l'introduction de l'approximation de London dans l'expression précédente donne pour l'élément de matrice perturbé par la composante $B_\alpha$ du champ l'expression suivante

[5] $$[H_{\mu\nu}(B_\alpha)]_{\text{herm}} = H_{\mu\nu}^0 + \frac{i}{2c} B_\alpha (R_\mu \Lambda R_\nu)_\alpha H_{\mu\nu}^0 - \frac{i}{4c} B_\alpha \left\{ \int \chi_\nu^0 l_\alpha^\nu \chi_\nu^0 \, d\tau - \int \chi_\nu^0 l_\alpha^\mu \chi_\mu^0 \, d\tau \right\}$$

avec $l_\alpha^\mu = (r_\mu \Lambda \nabla)_\alpha$.

Cette dernière équation représente la base pour nos calculs de déplacements chimiques.

*Expressions des éléments* $G_{\mu\nu}$

Sur une base GIAO, dans le cadre des approximations INDO, les parties réelle r et imaginaire i des $G_{\mu\nu}$ (eq. [1]) s'écrivent dans les trois éventualités suivantes

$\mu \in A, \ \nu \in A, \ \mu \neq \nu$

$$G_{\mu\nu}^r = P_{\mu\nu}^r \{ \tfrac{3}{2}(\mu^0\nu^0|\mu^0\nu^0) - \tfrac{1}{2}(\mu^0\mu^0|\nu^0\nu^0) \}$$
$$G_{\mu\nu}^i = P_{\mu\nu}^i \{ \tfrac{1}{2}(\mu^0\mu^0|\nu^0\nu^0) - \tfrac{1}{2}(\mu^0\nu^0|\mu^0\nu^0) \}$$

$\mu \in A, \ \nu \in B$

$$G_{\mu\nu}^r = -\tfrac{1}{2} P_{\mu\nu}^r (\mu^0\mu^0|\nu^0\nu^0)$$
$$G_{\mu\nu}^i = \tfrac{1}{2} P_{\mu\nu}^i (\mu^0\mu^0|\nu^0\nu^0)$$

$\mu = \nu \in A$

$$G_{\mu\mu}^i = 0$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

La partie réelle est alors donnée par

$$[6] \quad G^{r}_{\mu\mu} = \left\{ \sum_{B}^{\text{tous les atomes}} \sum_{\eta \in B} P^{r}_{\eta\eta}(\mu^0\mu^0|\eta^0\eta^0) \right\} - \frac{1}{2} P^{r}_{\mu\mu}(\mu^0\mu^0|\mu^0\mu^0) - \frac{1}{2} \sum_{\eta \neq \mu}^{A} P^{r}_{\eta\eta}(\mu^0\eta^0|\eta^0\mu^0)$$

Il convient de relever que cette équation [6] diffère de l'équation [A-5] de la référence 23 par la présence du dernier terme qui s'annule *seulement* dans les approximations CNDO. Les éléments $G_{\mu\nu}$ sont donnés en fonction des paramètres $F^0$, $F^2$, $G^1$ classiques (29) dans l'appendice I.

*Tenseur d'écran* $\sigma^{M}_{\alpha\beta}$

Sur la base des équations déduites ci-haut, notamment les éqs. [5] et [6] qui correspondent à un développement plus rigoureux du formalisme FPM, il devient maintenant possible de donner des expressions rigoureuses pour le tenseur d'écran.

L'énergie Hartree–Fock perturbée est

$$E(\boldsymbol{B}, \mu_M) = \sum_{\mu\nu} P_{\mu\nu} \{ [H_{\mu\nu}(\boldsymbol{B}, \mu_M)]_{\text{herm}} + \tfrac{1}{2} G_{\mu\nu}(\boldsymbol{B}) \}$$

Par définition, l'expression de la constante d'écran pour un noyau $M$ est

$$\sigma^{M}_{\alpha\beta} = \left[ \frac{\partial^2 E(\boldsymbol{B}, \mu_M)}{\partial B_\beta \partial \mu_{M_\alpha}} \right] \mu_M = \boldsymbol{B} = 0$$

Les GIAO étant indépendantes de $\mu_M$, Pople (4) a montré que l'on peut appliquer le théorème de Hellman–Feymann à cette méthode variationnelle sur $\boldsymbol{B}$, pour obtenir la première dérivée par rapport à $\mu_{M_\alpha}$ (30). Pour la dérivée seconde, on obtient

$$\sigma^{M}_{\alpha\beta} = \lim_{\mu = B = 0} \left\{ \sum_{\mu\nu} \frac{\partial P_{\mu\nu}(B_\beta)}{\partial B_\beta} \left\{ \frac{1}{2} \int \chi^*_\mu \frac{\partial}{\partial \mu_{M_\alpha}} H \chi_\nu \, d\tau + \frac{1}{2} \int \chi_\nu \frac{\partial}{\partial \mu_{M_\alpha}} (H\chi_\mu)^* \, d\tau \right\} \right.$$
$$\left. + \sum_{\mu\nu} P_{\mu\nu}(\boldsymbol{B}) \frac{\partial}{\partial B_\beta} \left\{ \frac{1}{2} \int \chi^*_\mu \frac{\partial}{\partial \mu_M} H \chi_\nu \, d\tau + \frac{1}{2} \int \chi_\nu \frac{\partial}{\partial \mu_{M_\alpha}} (H\chi_\mu)^* \, d\tau \right\} \right\}$$

Les perturbations apportées par $\mu$ et $\boldsymbol{B}$ étant imaginaires, les coefficients perturbés sont imaginaires et les parties réelle et imaginaire de $P_{\mu\nu}$ s'écrivent

$$P^{r}_{\mu\nu} = 2 \sum_{i}^{occ} (C^{r}_{\mu i} C^{r}_{\nu i} + C^{i}_{\mu i} C^{i}_{\nu i}); \quad P^{i}_{\mu\nu} = 2 \sum_{i}^{occ} (C^{r}_{\mu i} C^{i}_{\nu i} - C^{i}_{\mu i} C^{r}_{\nu i})$$

Une fois effectuées les dérivations, on obtient

$$\sigma^{M}_{\alpha\beta} = \sum_{\mu\nu} \left[ \frac{\partial P_{\mu\nu}(B_\beta)}{\partial B_\beta} \right]_{B_\beta = 0} (\text{intégrales 1}) + \sum_{\mu\nu} P_{\mu\nu}(O) \ (\text{intégrales 2})$$

La dérivée $[\partial P_{\mu\nu}(B_\beta)/\partial B_\beta]_{B_\beta=0}$ est calculée numériquement selon la méthode des perturbations finies (4) par la formule approchée suivante

$$\left[ \frac{\partial P_{\mu\nu}(B_\beta)}{\partial B_\beta} \right]_{B_\beta = 0} \simeq \frac{1}{2h_\beta} [P_{\mu\nu}(h_\beta) - P_{\mu\nu}(-h_\beta)]$$

où $h_\beta$ est une petite valeur attribuée à $B_\beta$.

En remarquant que $F^{r}_{\mu\nu}(-h_\beta) = F^{r}_{\mu\nu}(h_\beta)$ et $F^{i}_{\mu\nu}(-h_\beta) = -F^{i}_{\mu\nu}(h_\beta)$, on montre que $C^{r}_{\mu i}(-h_\beta) = C^{r}_{\mu i}(h_\beta)$ et $C^{i}_{\mu i}(-h_\beta) = -C^{i}_{\mu i}(h_\beta)$, ce qui entraîne

$$\left[ \frac{\partial P^{r}_{\mu\nu}(B_\beta)}{\partial B_\beta} \right]_{B_\beta = 0} = 0 \quad \text{et} \quad \left[ \frac{\partial P^{i}_{\mu\nu}(B_\beta)}{\partial B_\beta} \right]_{B_\beta = 0} = \frac{P^{i}_{\mu\nu}(h_\beta)}{h_\beta}$$

L'expression rigoureuse du tenseur d'écran est alors

$$[7]\quad \sigma^M_{\alpha\beta}=\frac{1}{2c^2}\sum_{\mu\nu}P_{\mu\nu}(O)\left\{\int \chi^0_\mu \frac{\boldsymbol{r}_\nu\cdot\boldsymbol{r}_M\delta_{\alpha\beta}-r_{\nu\alpha}r_{M\beta}}{r_M^3}\,\chi^0_\nu\,d\tau-(R_\nu\wedge R_\mu)_\beta\int\chi^0_\mu\frac{l^M_\alpha}{r_M^3}\chi^0_\nu\,d\tau\right.$$
$$\left.-\int\chi^0_\mu(\boldsymbol{R}_{\mu\nu}\wedge\boldsymbol{r}_\nu)_\beta\frac{l^M_\alpha}{r_M^3}\chi^0_\nu\,d\tau\right\}+\frac{1}{c}\sum_{\mu\nu}\frac{P^{i}_{\mu\nu}(h_\beta)}{h_\beta}\int\chi^0_\mu\frac{l^M_\alpha}{r_M^3}\chi^0_\nu\,d\tau$$

où $\boldsymbol{R}_{\mu\nu}=\boldsymbol{R}_\nu-\boldsymbol{R}_\mu$. L'expression du tenseur moyen avec l'approximation de London s'écrit

$$[8]\quad \sigma^M=\frac{1}{3c^2}\sum_{\mu\nu}P_{\mu\nu}(O)\int\chi^0\frac{\boldsymbol{r}_\nu\cdot\boldsymbol{r}_M}{r_M^3}\chi^0_\nu\,d\tau-\frac{1}{6c^2}\sum_{\mu\nu}\sum_{\alpha=x,y,z}P_{\mu\nu}(O)(R_\nu\wedge R_\mu)_\alpha$$
$$\times\int\chi^0_\mu\frac{l^M_\alpha}{r_M^3}\chi^0_\nu\,d\tau+\frac{1}{3c}\sum_{\mu\nu}\sum_{\alpha=x,y,z}\frac{P^{i}_{\mu\nu}(h_\alpha)}{h_\alpha}\int\chi^0_\mu\frac{l^M_\alpha}{r_M^3}\chi^0_\nu\,d\tau$$

On a démontré (1) que l'approximation de London ne détruit pas le caractère "gauge invariant" de $\sigma^M$. Les $P^{i}_{\mu\nu}(h_\alpha)$ seront obtenus en résolvant l'équation de Roothan $Fc=\varepsilon Sc$ avec une petite valeur $h_\alpha$ pour $B_\alpha$ (voir Appendice I).

Afin de mettre en évidence les contributions relatives des différentes densités électroniques au déplacement chimique du $^{13}C$ et $^1H$ nous séparerons l'équation [8] en contributions électroniques mono, di, ou tricentriques (11, 23, 26) et développons comme suit les différentes contributions (eq. [9]).

$$[9]\quad \sigma^M=\sigma^d(M)+\sigma^d(KK)+\sigma^p(M)+\sigma^p(KK)+\sigma^d(MK)+\sigma^d_0(MK)+\sigma^p_0(MK)$$
$$+\sigma^d(M,A,B)+\sigma^d_0(M,A,B)+\sigma^p_0(M,A,B)$$

avec

$$\sigma^d(M)=\frac{1}{3c^2}\sum_{\mu\nu}^{M}P_{\mu\nu}(O)\left\langle\chi^{0M}_\mu\left|\frac{1}{r_M}\right|\chi^{0M}_\nu\right\rangle;\quad \sigma^d(KK)=\frac{1}{3c^2}\sum_{\mu\nu}^{K\neq M}P_{\mu\nu}(O)\left\langle\chi^{0K}_\mu\left|\frac{\boldsymbol{r}_K\cdot\boldsymbol{r}_M}{r_M^3}\right|\chi^{0K}_\nu\right\rangle$$

$$\sigma^p(M)=\frac{1}{3c}\sum_{\mu\nu}\sum_\alpha\frac{P^{i}_{\mu\nu}(h_\alpha)}{h_\alpha}\left\langle\chi^{0M}_\mu\left|\frac{l^M_\alpha}{r_M^3}\right|\chi^{0M}_\nu\right\rangle$$

$$\sigma^p(KK)=\frac{1}{3c}\sum_{\mu\nu}^{K\neq M}\sum_\alpha\frac{P^{i}_{\mu\nu}(h_\alpha)}{h_\alpha}\left\langle\chi^{0K}_\mu\left|\frac{l^M_\alpha}{r_M^3}\right|\chi^{0K}_\nu\right\rangle$$

$$\sigma^d(MK)=\frac{1}{3c^2}\sum_{\mu}^{K\neq M}\sum_{\nu}^{M}P_{\mu\nu}(O)\left\langle\chi^{0K}_\mu\left|\frac{1}{r_M}\right|\chi^{0M}_\nu\right\rangle+\frac{1}{3c^2}\sum_{\mu}^{M}\sum_{\nu}^{K\neq M}P_{\mu\nu}(O)\left\langle\chi^{0M}_\nu\left|\frac{\boldsymbol{r}_K\cdot\boldsymbol{r}_M}{r_M^3}\right|\chi^{0K}_\nu\right\rangle$$

$$\sigma^d_0(MK)=-\frac{1}{6c^2}\sum_\alpha\sum_{\mu}^{K\neq M}\sum_{\nu}^{M}P_{\mu\nu}(O)(R_\nu\wedge R_\mu)_\alpha\left\langle\chi^{0K}_\mu\left|\frac{l^M_\alpha}{r_M^3}\right|\chi^{0M}_\nu\right\rangle$$
$$-\frac{1}{6c^2}\sum_\alpha\sum_{\mu}^{M}\sum_{\nu}^{K\neq M}P_{\mu\nu}(O)(R_\nu\wedge R_\mu)_\alpha\left\langle\chi^{0M}_\mu\left|\frac{l^M_\alpha}{r_M^3}\right|\chi^{0K}_\nu\right\rangle$$

$$\sigma^p_0(MK)=\frac{1}{3c}\sum_\alpha\sum_{\mu}^{K\neq M}\sum_{\nu}^{M}\frac{P^{i}_{\mu\nu}(h_\alpha)}{h_\alpha}\left\langle\chi^{0K}_\mu\left|\frac{l^M_\alpha}{r_M^3}\right|\chi^{0M}_\nu\right\rangle+\frac{1}{3c}\sum_\alpha\sum_{\mu}^{M}\sum_{\nu}^{K\neq M}\frac{P^{i}_{\mu\nu}(h_\alpha)}{h_\alpha}\left\langle\chi^{0M}_\mu\left|\frac{l^M_\alpha}{r_M^3}\right|\chi^{0K}_\nu\right\rangle$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

$$\sigma^{d}(M,A,B) = \frac{1}{3c^2} \sum_{A}^{\neq M} \sum_{B}^{\neq M} \sum_{\mu}^{A} \sum_{\nu}^{B \neq A} P_{\mu\nu}(O) \left\langle \chi_{\mu}^{0A} \left| \frac{r_B \cdot r_M}{r_M^3} \right| \chi_{\nu}^{0B} \right\rangle$$

$$\sigma_{o}^{d}(M,A,B) = -\frac{1}{6c^2} \sum_{\alpha} \sum_{A}^{\neq M} \sum_{B}^{\neq M} \sum_{\mu}^{A} \sum_{\nu}^{B \neq A} P_{\mu\nu}(O)(R_\nu \wedge R_\mu)_\alpha \left\langle \chi_{\mu}^{0A} \left| \frac{l_\alpha^M}{r_M^3} \right| \chi_{\nu}^{0B} \right\rangle$$

$$\sigma_{o}^{p}(M,A,B) = \frac{1}{3c} \sum_{\alpha} \sum_{A}^{\neq M} \sum_{B}^{\neq M} \sum_{\mu}^{A} \sum_{\nu}^{B \neq A} \frac{P_{\mu\nu}^{i}(h_\alpha)}{h\alpha} \left\langle \chi_{\mu}^{0A} \left| \frac{l_\alpha^M}{r_M^3} \right| \chi_{\nu}^{0B} \right\rangle$$

Dans ces expressions, les indices supérieurs d et p repèrent, respectivement, les parties dia- et para-magnétiques. L'indice inférieur o représente un terme qui dépend de l'origine des coordonnées. Il est à noter que les sommes $\sigma_o^d(MK) + \sigma_o^p(MK)$ et $\sigma_o^d(M,A,B) + \sigma_o^p(M,A,B)$ sont indépendantes de l'origine des coordonnées. Afin de calculer l'éq. [9], il est nécessaire d'évaluer toutes les intégrales (Appendice II).

## Modalités de calcul[1]

Afin de tenir compte d'un effet d'environnement moléculaire différent pour chaque atome, nous avons modifié les exposants de Slater $\zeta_{MM}$ dans les intégrales portant sur σ par la formule classique.

$$\zeta_{MM} = [Z^+ - 0{,}35\,(P_{MM} - Z_{MM})]/n^+$$

avec $Z^+$ = charge nucléaire effective, $n^+$ = nombre quantique effectif, $P_{MM}$ = population électronique totale de la couche de valence et $Z_{MM}$ = charge de cœur. Pour $^1$H la valeur 0,35 a été remplacée par 0,31 conformément aux règles de Slater.

Pour le proton et le carbone, afin de pallier l'erreur introduite par l'approximation de London, nous avons modifié les paramètres $\beta_H^0$ et $\beta_C^0$ classiques INDO. Ceux-ci ont été paramétrisés selon la méthode de Garber *et al.* (26) sur la série $CH_4$, $C_2H_6$, $C_2H_4$ et $C_2H_2$, ce qui a conduit à $\beta_H^0 = -14{,}31$ et $\beta_C^0 = -16{,}57$ eV. Ces paramètres représentent les meilleures valeurs dans le cadre de l'approximation de London.[3] Tous les autres paramètres sont standards (29), ainsi que les géométries (31).

## Résultats

La comparaison entre les déplacements chimiques calculés et observés (Tableau 1) indique une erreur moyenne de 5,6 ppm sur 15 composés couvrant un domaine de ~145 ppm. Ce résultat se compare avantageusement aux calculs *ab initio* LEMAO-5G avec invariance de jauge (21) qui donnent lieu à une erreur moyenne de 10,2 ppm sur la même série de composés.

On constate également que le propène et le propyne sont bien reproduits par notre calcul, alors que les calculs *ab initio* sans GIAO conduisent à un ordre renversé des déplacements chimiques (22).

Nos résultats illustrent un fait bien connu, à savoir que le terme diamagnétique local $\sigma^d(M)$ est pratiquement constant alors que le terme paramagnétique local $\sigma^p(M)$ subit de fortes variations. Par contre, un fait moins connu a trait à la somme des terms $\sigma^d(MK) + \sigma_o^d(MK) + \sigma_o^p(MK)$ décrivant l'effet de la densité électronique de première liaison, somme dont les variations peuvent atteindre ~8 ppm et qui ne peut donc pas être négligée. Ceci permet de comprendre que parmi les nombreuses corrélations (34) entre charges atomiques et déplacements chimiques, les meilleures sont celles décrites par Fliszar et coll. (35). En effet, ces dernières tiennent explicitement compte de ces contributions, en utilisant des charges de type Mulliken incluant une considération appropriée des populations de recouvrement. La validité de corrélations entre déplacements chimiques et charges atomiques, représentant, elles, des propriétés strictement locales, est illustrée par nos résultats qui montrent que les liaisons lointaines ne participent que très peu à la constante d'écran d'éléments lourds tel que le $^{13}$C.

Ce dernier point mérite une attention particulière. Ainsi convient-il d'évaluer l'importance des intégrales à trois centres, soit la somme des termes $\sigma^d(M,A,B) + \sigma_o^d(M,A,B) + \sigma_o^p(M,A,B)$ qui représente la contribution à l'écran du $^{13}$C des densités électroniques lointaines. Pour visualiser l'effet des densités autres que celles dues au premiers voisins, nous avons dressé le tableau 2 pour l'éthylène et le

[1]Programme Fortran NMR CINDO-80.[2]

Ce programme calcule $\sigma^M$ sous la forme décrite ci-dessus pour les noyaux $^1$H, $^{13}$C, $^{15}$N, $^{17}$O, $^{19}$F en version INDO ou CNDO (IBM version, 10 000 cards, 35 atoms, 120 OA, 1050 K bytes of central memory, 78 000 K bytes of direct access memory).

[2]Le programme est disponible sur demande adressée au premier auteur.

[3]La paramérisation a été effectuée en n'utilisant que les premiers termes de l'équation [9]; ceci est une approximation justifiée a posteriori pour le $^{13}$C.

[b]Référence 39.

propène. Une telle analyse des effets lointains n'a pas encore été rapportée bien que des "effets lointains" aient été occasionnellement invoqués (26) pour expliquer les écarts entre le calcul et l'observation. Nos résultats indiquent clairement que, sur une échelle de variations de ~220 ppm pour le $^{13}C$, les liaisons lointaines ne participent que très peu à la constante d'écran. L'importance de leur contribution, qui est faible au départ, est encore atténuée dans une échelle établie pour des atomes de même type (e.g., les carbones $sp^2$) en se référant à un des membre de cette classe.

Ces résultats conduisent à une conclusion qu'il convient de relever. La faible contribution des intégrales à trois centres impliquant les atomes lointains suggère que les termes prépondérants relèvent des distributions électroniques locales, ce qui justifie à posteriori l'existence de corrélations entre déplacements chimiques et charges atomiques pour des classes de composés bien définies. Bien entendu, la présence de tout atome (même lointain) est reflétée dans la fonction d'onde moléculaire et c'est en participant à l'établissement des charges atomiques qu'elle se manifeste. De plus, le peu d'influence des centres lointains justifie en partie le modèle du solvaton (36), récemment utilisé par Jallah-Heravi et Webb (37).

Ces considérations, basées sur des calculs concernant les atomes de carbone, sont également valables pour l'oxygène et l'azote (38). Pour l'hydrogène, cependant, il en est tout autrement.

Les constantes d'écran des noyaux du propène et de l'éthylène $^1H$ ont été calculées en retenant l'éq. [9] dans son entier, en utilisant les géométries standards ainsi que les paramètres $\beta^0_H = -14{,}31$ et $\beta^0_C = -16{,}37$ eV (Tableau 3). La précision moyenne, ~0,4 ppm, est comparable à celle obtenue par Ducasse (11) pour une plus grande série de composés. Le fait le plus frappant est l'importance des intégrales à trois centres dans le calcul de $\sigma$.

Le calcul sans intégrales à trois centres donne un ordre aléatoire des déplacements chimiques du $^1H$ (Tableau 4), alors que l'inclusion de ces intégrales rétablit pratiquement l'ordre des résonances, en ce sens que le proton $H_7$ est calculé comme résonnant à champ faible par rapport à l'éthylène. Ceci montre bien que le $^1H$ est extrêmement sensible à la présence de toutes les liaisons dans la molécule et non pas seulement en ce qui a trait à la première liaison. Aussi le $^1H$ sera extrêmement sensible au solvant.

*Conclusion*

Le calcul des déplacements chimiques du $^{13}C$ et du $^1H$ dans une série d'hydrocarbures a été effectué dans le cadre de la méthode des perturbations finies en maintenant l'invariance de jauge, ce qui représente une condition essentielle. Le formalisme utilisé conserve, tout au long des approximations de London et INDO, le caractère hermitien de la matrice des $H_{\mu\nu}$ perturbée par le champ magnétique extérieur et, de plus, tient explicitement compte des intégrales à trois centres.

La précision obtenue pour le $^{13}C$ est supérieure à celle d'autres calculs, même *ab initio*, ne respectant pas les conditions mentionnées ci-dessus. Elle passe, en effet, de ~10 à ~5 ppm en valeur moyenne en se rapprochant ainsi des conditions requises pour l'identification de structures difficiles à atteindre par les moyens classiques et, notamment, pour permettre de distinguer des effets conformationnels.

L'analyse des contributions "atomiques" et "de liaison" à la constante d'écran indique clairement que le $^{13}C$ est pratiquement insensible aux modifications de structure électronique des atomes et

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

liaisons lointains, en justifiant ainsi la faiblesse des effets de solvant. De plus, on justifie ainsi le rôle essentiel de la charge locale du carbone incluant une partie de la densité électronique des liaisons dans lesquelles il est engagé et, par conséquent, l'existence de relations entre déplacements chimiques et charges atomiques.

Il n'en est pas de même pour le proton, très sensible aux liaisons lointaines, dont les contributions sont tout aussi importantes que celles des contributions locales: toutes les intégrales à trois centres doivent être retenues. Il en découle que le choix des données expérimentales choisies en vue de comparaisons avec la théorie doit être, dans ce cas, particulièrement critique et judicieux en raison des effets de solvant.

## Appendice II

*Evaluation des intégrales nécessaires sur une base d'orbitales atomiques de Slater*

*1. Intégrales à deux centres*

Afin de réduire au maximum les temps de calcul de ces intégrales nous avons calculé les intégrales à deux centres dans un système de coordonnées elliptiques. Toutes ces intégrales ont été tabulées à la référence 1. Dans le système d'axe choisi les intégrales

$$\left\langle \chi^K_\mu \left| \frac{\mathbf{r}_K \cdot \mathbf{r}_M}{r^3_M} \right| \chi^K_\nu \right\rangle \quad \text{et} \quad \left\langle \chi^M_\mu \left| \frac{\mathbf{r}_K \cdot \mathbf{r}_M}{r^3_M} \right| \chi^K_\nu \right\rangle$$

sont une somme d'intégrales du type

$$I_{mn}(k,b) = \int_1^\infty d\xi \int_{-1}^{+1} \xi^m \eta^n (\xi + \eta)^{-1} e^{-k\xi} e^{-b\eta} d\eta$$

qui peuvent être calculées analytiquement selon la méthode de Guy *et al.* (40) et exprimées en termes d'intégrales auxiliaires $A_n(y)$ et $B_n(y)$ bien connues

$$A_n(y) = \int_1^\infty x^n e^{-yx} dx \quad \text{et} \quad B_n(y) = \int_{-1}^{+1} x^n e^{-yx} dx$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

Les intégrales

$$\left\langle \chi_\mu^K \left| \frac{r_M \wedge \nabla}{r_M^3} \right| \chi_\nu^K \right\rangle$$

apparaissent dans la littérature (41) et nous avons développé les formules générales données par l'auteur afin de les obtenir sous une forme plus programmable (1).

Pour les intégrales

$$\left\langle \chi_\mu^M \left| \frac{r_M \wedge \nabla}{r_M^3} \right| \chi_\nu^K \right\rangle$$

l'opérateur $r_M \wedge \nabla$ est développé sur le centre $K$ (42) et exprimées en termes des $I_{mn}(k, b)$ puis en termes des $A_n(y)$ et $B_n(y)$. Toutes les autres intégrales sont reportées dans la littérature (26) ou aisément calculables.

*2. Intégrales à trois centres*

Pour les intégrales du type

$$\left\langle \chi_\mu^A \left| \frac{r_B \cdot r_C}{r_C^3} \right| \chi_\nu^B \right\rangle \quad \text{et} \quad \left\langle \chi_\mu^A \left| \frac{l_\alpha^C}{r_C^3} \right| \chi_\nu^B \right\rangle$$

nous avons utilisé la technique de transformation d'une STO en terme d'une GTO au moyen de la transformée de Laplace (43)

$$\int (\exp - \alpha r_a) = \frac{\alpha}{2\pi^{1/2}} \int_0^\infty s^{-3/2} \left( \exp - \frac{\alpha^2}{4s} \right) (\exp - s r_a^2)\, \mathrm{d}s$$

Nous avons d'abord obtenu

$$[10] \quad \int (\exp - s_1 r_a^2) \frac{r_b r_c}{r_c^3} (\exp - s_2 r_b^2)\, \mathrm{d}\tau$$

$$= 2\pi \left( \exp - \frac{s_1 s_2}{s_1 + s_2} \overline{AB}^2 \right) \left[ \frac{3}{s_1 + s_2} \int_0^1 t^2 [\exp - (s_1 + s_2)\overline{PC}^2 t^2]\, \mathrm{d}t + \frac{2s_1}{s_1 + s_2} \boldsymbol{AB} \cdot \boldsymbol{PC} \right.$$

$$\left. \times \int_0^1 t^2 [\exp - (s_1 + s_2)\overline{PC}^2 t^2]\, \mathrm{d}t - 2\overline{PC}^2 \int_0^1 t^4 [\exp - (s_1 + s_2)\overline{PC}^2 t^2]\, \mathrm{d}t \right.$$

avec $\overline{AB}_\alpha = A_\alpha - B_\alpha$, $PC_\alpha = P_\alpha - C_\alpha$, $P_\alpha = (s_1 A_\alpha + s_2 B_\alpha)/(s_1 + s_2)$.

Puis en terme de STO nous avons obtenu

$$[11] \quad \int (\exp - \alpha_a r_a) \frac{r_b r_c}{r_c^3} (\exp - \alpha_b r_b)\, \mathrm{d}\tau = \alpha_a \alpha_b [3/2(1, -3/2, -3/2, -3) + \overline{AB}^2(1, 1/2, -3/2, -2)$$

$$+ \boldsymbol{AB} \cdot \boldsymbol{BC}(1, -1/2, -3/2, -2) - \overline{AB}^2(2, 1/2, -3/2, -2) - 2\boldsymbol{AB} \cdot \boldsymbol{BC}(2, -1/2, -3/2, -2)$$

$$- \overline{BC}^2(2, -3/2, -3/2, -2)]$$

où la notation $(m,n,l,p)$ signifie:

$$(m,n,l,p) = \int_0^1 \int_0^1 \int_0^\infty t^{2m} u^m (1-u)^l z^p \left[ \exp - \frac{1}{4} \left( \frac{\alpha_a^2}{u} + \frac{\alpha_b^2}{1-u} \right) \frac{1}{z} \right]$$

$$\times \{\exp - [u(1-u)AB^2 + t^2(u^2 AB^2 + 2u\, \boldsymbol{AB} \cdot \boldsymbol{BC} + BC^2)]z\}\, \mathrm{d}t\, \mathrm{d}u\, \mathrm{d}z$$

$z. \in |0, \infty|$, $u. \in |0, 1|$, $t. \in |0, 1|$

L'expression de $(m,n,l,p)$ peut être simplifiée en écrivant

$$p_1 = ua + b;\ a = A - B;\ b = B - C;\ f = u(1-u)\overline{AB}^2;\ g = \frac{1}{4}\left[\frac{\alpha_a^2}{u} + \frac{\alpha_b^2}{1-u}\right]$$

et on obtient seulement une double quadrature

$$(m,n,l,p) = 2\int_0^1 u^n(1-u)^l g^{(p+1)/2} \int_0^1 \frac{t^{2m}}{(f+p_1^2t^2)^{(p+1)/2}} K_{p+1}[2\sqrt{g(f+p_1^2t^2)}]\,dt\,du$$

où $K$ est la fonction de Bessel modifiée de seconde espece. Afin d'éviter la manipulation de grands nombres dans l'ordinateur on peut utiliser la fonction de Bessel réduite $k_\nu(z)$ définie par $k_\nu(z) = K_\nu(z)z^\nu$. Nous n'avons rencontré que des valeurs négatives pour $p$. Dans ces conditions on obtient

$$[12]\quad (m,n,l,p) = \frac{2^{|p|}}{2^{2|p+1|}} \int_0^1 u^n(1-u)^l \frac{1}{g^{|p+1|}} \int_0^1 t^{2m} k_{|p+1|}(2\sqrt{g(f+p_1^2t^2)})\,dt\,du$$

L'expression [12] conduit à une double quadrature numérique qui a été faite par une méthode Gauss Legendre (44) à 32 points pour l'intégration sur $t$ et à 14 points pour l'intégration sur $u$. Les intégrales

$$\left\langle \chi_\mu^A \left| \frac{l_\alpha^c}{r_c^3} \right| \chi_\nu^B \right\rangle$$

ont été reportées par Tokuhiro (45). L'auteur trouve

$$[13]\quad \int e^{-ar_a} \frac{l_\alpha^c}{r_c^3} e^{-br_b}\,d\tau = -2ab(1,-1/2,-1/2,-1)\Gamma_\alpha \quad \text{avec} \quad \Gamma_\alpha = (\boldsymbol{B}\wedge\boldsymbol{A} + \boldsymbol{A}\wedge\boldsymbol{C} + \boldsymbol{C}\wedge\boldsymbol{B})_\alpha$$

Les intégrales portant sur des STO, $2s$, $2px$, $2py$, $2pz$ ont été calculées par dérivation des formules [11] et [13].

*3. Vérification du programme d'ordinateur NMR CINDO-80*

Nous avons programmé indépendamment le formalisme des intégrales à 2 et 3 centres. En utilisant le formalisme des intégrales à 3 centres $\langle A|C|B\rangle$ nous avons reproduit les valeurs numériques des intégrales à deux centres avec une précision absolue de 0,005.

# The ultraviolet and visible absorption spectra of berberrubine

ZVONIMIR GAŠPAREC
*The Faculty of Pharmacy and Biochemistry, University of Zagreb, Zagreb, Yugoslavia*

ŠEBOJKA KOMORSKY-LOVRIĆ
*OUR "Ljekarne", Zagreb, Yugoslavia*

AND

MILIVOJ LOVRIĆ
*Center for Marine Research, "Ruder Bošković" Institute, Zagreb, Yugoslavia*

Received October 8, 1981

ZVONIMIR GAŠPAREC, ŠEBOJKA KOMORSKY-LOVRIĆ, and MILIVOJ LOVRIĆ. Can. J. Chem. **60**, 970 (1982).

The absorption spectra of berberrubine in the visible and uv spectral range were recorded. The measurements were made in four different solvents (water, absolute methanol, absolute ethanol, and absolute propanol) changing the acidity and the alkalinity of the solutions in the wide range from pH 2 to pH 13 by the addition of HCl and KOH. The experimental and theoretical results, derived by simple Hückel MO calculations, were compared and discussed.

ZVONIMIR GAŠPAREC, ŠEBOJKA KOMORSKY-LOVRIĆ et MILIVOJ LOVRIĆ. Can. J. Chem. **60**, 970 (1982).

On a enregistré les spectres d'absorbtion de la berberrubine dans le visible et l'uv. On a effectué ces mesures dans quatre solvants différents (eau, méthanol, éthanol et propanol) et on a fait varier le pH de 2 à 13 par addition de HCl ou de KOH aux solutions. On compare et on discute des résultats expérimentaux et des valeurs théoriques obtenues par des calculs simples OM de Hückel.

[Traduit par le journal]

Berberrubine belongs to the group of protoberberinic alkaloids (Fig. 1). It has been, so far, isolated only from *Berberis vulgaris* L., family Berberidaceae (1), but as early as 1903 Berkurst and Frerichs (2) had synthesized it from berberine chloride by pyrolysis at 200°C with urea.

The alkaloids of the berberine group are known to form complexes with biologically important macromolecules, such as alcohol dehydrogenase from horse liver (3) and some nucleic acids (4). In the spectrophotometric study of these interactions it was first necessary to determine the absorption properties of the alkaloids. Recently, Pavelka and co-workers have published several papers dealing with the ultraviolet and visible absorption (5, 6) and fluorescence (7) spectra of protoberberinic alkaloids. The authors have paid much attention to berberrubine because of some of its special properties. Unfortunately, their measurements were done only in 96% ethanol solution at undefined pH.

The aim of this work is to report the results of the measurements of the absorption spectra of berberrubine in four different solvents with pH of the solutions changing in the range between 2 and 13. Besides, some simple Hückel MO calculations were performed for berberine and its derivatives jatrorhizine, berberrubine, and jatrorubine and the results will be compared with present and previously published (9, 10) experimental spectroscopic data. The calculations were made for all three possible ionic forms of these alkaloids (quaternary amine cation, carbinolic, and open amino-aldehydic forms) in order to gain a better understanding of the possible ionic transformation of berberrubine under the influence of acid or base.

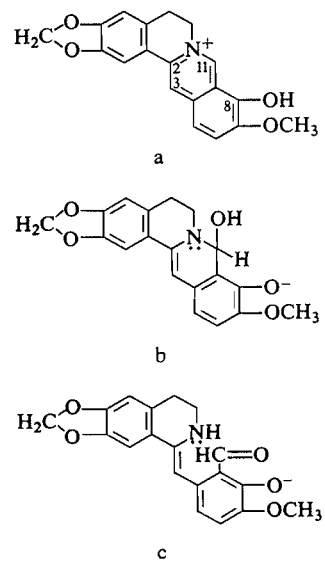

FIG. 1. The structural formulae of berberrubine; (a) the quaternary amine form (the numbers assign certain carbon atoms), (b) the carbinolic form, (c) the open amino-aldehydic form.

## Experimental

For the preparation of solutions, the following chemicals were used: absolute methanol, absolute ethanol, absolute propanol, KOH, HCl (all p.a. "Merck"), distilled water, and berberrubine chloride synthesized in our laboratory. The purity of berberrubine was checked by thin-layer chromatography (stationary phase Stahl's silica-gel and mobile phase 15% solution of $NH_4OH$ in methanol). Stock solutions of berberrubine, KOH, and HCl in all four solvents were prepared. Four series (20 solutions each) of $5 \times 10^{-5}$ (mol $dm^{-3}$) berberrubine chloride were prepared. The concentrations of HCl and KOH added varied from $2.5 \times 10^{-5}$ to 0.5 (mol $dm^{-3}$). In every series there was one solution in which neither HCl nor KOH was added. The pH measurements were performed by a E 603 Metrohm Herisau pH-meter with a combined glass–calomel electrode. The pH-values of the alcoholic solutions were measured directly in the absolute alcohols. A Carl Zeiss Jena Universal spectrophotometer with 1 cm glass vessels and a PMQ II Zeiss-Opton spectrophotometer with 1 cm quartz vessels were used for the measurements in the visible and ultraviolet spectral ranges, respectively. All the measurements were done at room temperature.

Hückel MO calculations were performed according to Streitwieser's suggestion (12) that $h$ values for $N^+$ and N: are 2 and 1.5, respectively, and that the $k$ value for the CN bond is equal to unity. Besides, the influence of the undissociated OH group in jatrorhizine, berberrubine, and jatrorubine, which is supposed to exist in the strongly acidic solutions of these alkaloids, is neglected. Under this assumption, all four alkaloids in strongly acidic medium possess the same aromatic structure. The appearance of possible carbinolic or amino-aldehydic forms is supposed to happen only after the dissociation of hydroxy groups in these alkaloids. The recommended (12) $h$ and $k$ values for O: and C—O bonds are 2 and 1, respectively.

## Results

In Table 1, the positions of the absorption maxima and corresponding extinction coefficients of berberrubine in four solvents are presented. The disappearance of the absorption maxima at 441–450 and 348–359 (nm) and the appearance of three new maxima at 328–333, 380–399, and 490–516 (nm) in the basic solutions can be noted. The number and the positions of the absorption maxima do not change further in strongly alkaline solutions. The choice of the solvent has significant influence on the absorption spectra causing the bathochromic shifts of all the peaks except the third one. The results of the measurements in ethanolic solutions are in agreement with the results of Pavelka and Smekal (5). Some small differences have probably arisen from the fact that their measurements were done in the mixed solvent.

In Fig. 2, the absorption spectrum of berberrubine in aqueous solutions in the uv spectral range is given as an example.

In Table 2, the experimental spectroscopic data for berberine (9), jatrorhizine (10), and jatrorubin (11) are compiled. Compared with the results of berberrubine, this table shows that the spectral

TABLE 1. The absorption maxima of berberrubine

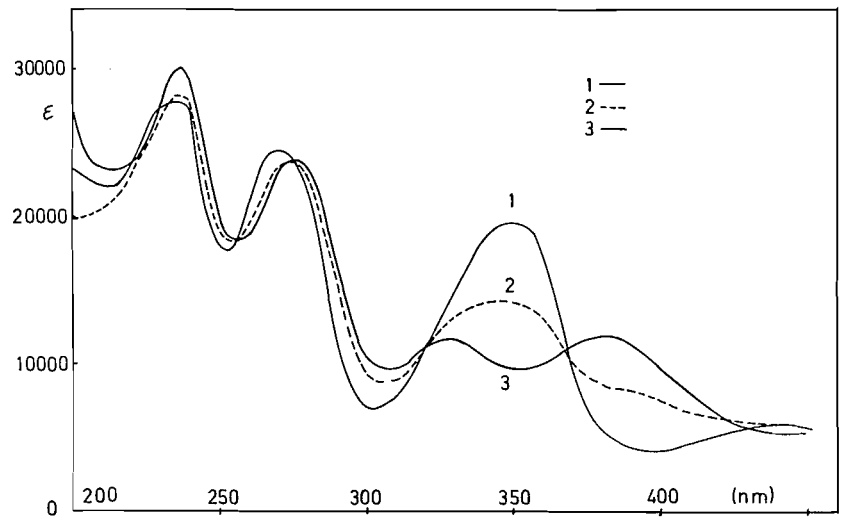

FIG. 2. The absorption spectra of water solutions of berberrubine (uv spectral range); (1) pH = 5.03; (2) pH = 6.51; (3) pH = 8.52.

changes in the solutions of jatrorhizine, jatrorubine, and berberrubine are in principle similar, but jatrorhizine exhibits an additional maximum at about 240 nm instead of the one at 330 nm. Differences appear in strongly alkaline ethanol and propanol solutions of jatrorhizine (where the maximum in the visible spectral range disappears, which is similar to the behaviour of berberine in all alcoholic solutions containing larger concentrations of alkali) and in propanol solution of jatrorubin where the maximum at 460 nm exists in parallel with that at 540 nm. As berberine does not possess an OH group, its spectral changes are less dramatic, but the similarity between the spectra of all four alkaloids in strongly acidic media must be noted.

The results of Hückel MO calculations (eigenvalues, total energies, resonance energies, bond orders and lengths, $\pi$-charges, etc.) are available on request.[1] Here we shall report only general theoretical characteristics of the investigated molecules. In the quaternary amine ions an extraordinarily high positive charge appears on the carbon atom in the neighborhood of the $N^+$ atom (C11) which enables these alkaloids to undergo nucleophilic substitution on this site (berberine +0.331 net charge, jatrorhizine +0.326, berberrubine +0.327, and jatrorubine +0.323). The positive charge on the N atom in all four molecules is bigger than that on the C11 atom, but the difference is small and can be compensated by possible polarization of $\sigma$ N—C bonds. The carbinolic molecules of all alkaloids still possess a small positive charge on nitrogen and its neighboring (C2) atom, but a negative charge on the C3 atom. These charges become even greater if open amino-aldehydic forms occur, but in this case an additional and large positive charge appears on the aldehydic carbon atom (C11) because the aldehydic bond seems to be highly polarized. So, from the point of view of charge distribution in the molecule, the appearance of the open aldehydic ionic form seems to be unlikely under the conditions which prefer nucleophilic substitution.

After the dissociation, the jatrorhizinic and berberrubinic hydroxy groups do not have the same negative charge (jatrorhizine −0.901 net charge, berberrubine −0.887, jatrorubine −0.901 and −0.886, respectively). The latter one contributes more to the annihilation of positive charge on the nitrogen and C2 atoms. That is why we can expect that between these two hydroxy groups in jatrorubine the berberrubinic one will dissociate first.

The values for the bond lengths (13, 14) are in agreement with some experimental data (18, 19). Except for jatrorubine, all the alkaloids have the longest bond between the quinolinic and benzenoid parts of the molecule, which can be considered as proof of a certain charge separation between these two parts.

If the $\beta$ part of the total energy of $\pi$ electrons, divided by the number of $\pi$ electrons ($E_\beta$/el.) is chosen as the criterion for stability of a certain ionic form, we can see that the most stable form of berberine is its quaternary amine form and the most unstable its carbinolic form. For jatrorhizine, berberrubine, and jatrorubine, under the same crite-

rion, the most stable is the quaternary amine form with dissociated hydroxy groups and the most unstable form is again the carbinolic one. If the criterion is resonance energy per electron ($E_R^*$/el., calculated after Milun *et al.* (17)), the most stable form for all four alkaloids is their open aminoaldehydic form, but the carbinolic forms of berberine and jatrorhizine are as stable as their quaternary amine ions while in the other two alkaloids the carbinolic form is less stable than their quaternary amine ions with dissociated hydroxy groups. This could be a reason why only berberine and jatrorhizine exhibit the appearance of the carbinolic ionic form in some strongly alkaline alcoholic solutions. From these criteria it also appears that the carbinolic form of berberrubine is unlikely to be expected.

In Table 3 the values of the energy separations between the frontier orbitals of all four alkaloids are given. In the parentheses are the positions of the absorption maxima corresponding to these energy separations ($B_b$, $L_b$, and $L_a$). These values were calculated with the parameters reported by Zahradnik and Koutecký (15*b*) for pyridine-type resonance molecules. The parameters probably do not fit exactly for the molecules under our consideration so that the analyses of theoretical absorption spectra must be made under the assumption that $B_b$ and $L_a$ bands are fairly accurate and that $L_b$ is always about 60 nm too small (see Table 2). Looking first at berberine we notice that theory predicts the $B_b$ and $L_b$ bands of the carbinolic form to be shifted hypsochromically for 26 and 32 nm, respectively, while the $L_a$ band stays almost untouched in comparison to their quaternary amine form. The experimental results (9) (Table 2) show that there are no spectral changes in water solutions, but in strongly alkaline alcoholic solutions the extinction coefficients of $B_b$ and $L_b$ decrease (especially of the latter band so that color of the solution totally vanishes). The hypsochromic shifts of the maxima can hardly be noted. On the other hand, our simple MO calculations did not give us the values of theoretical extinction coefficients, so that we have to accept the observed spectral changes as proof of appearance of the carbinolic form. The theoretical spectra of jatrorhizine, berberrubine, and jatrorubine show that the influence of dissociation of the hydroxy group manifests itself in the bathochromic shift of all maxima, but this shift is not large. The influence of the jatrorhizinic group is greater than of the berberrubinic one, but if both of them dissociate (in jatrorubine) the effect is approximatively the sum of both effects. Carbinolic forms of these alkaloids shift all the peaks hypsochromically. On the contrary, for the

open amino-aldehydic form, the theoretical analysis predicts the probability of two strong absorption maxima in the visible spectral range and only one (beside $B_a$) in the uv range (and this prediction is based on energy separation and not only on correlation parameters). A similar prediction is valid for amino-aldehydic forms of all four alkaloids, so that we can safely say that no significant amount of this form appears in any of the solutions.

## Discussion

According to Gadamer's theory (16), the quaternary amine cations are in equilibrium with their carbinolic (which appears as the result of $OH^-$ or $OR^-$ group attachment on a C atom in the neighborhood of the $N^+$ atom) and open amino-aldehydic forms (which appears as the further step of molecular rearrangement) (8). This theory was criticized in at least two comprehensive review articles (15*a*, *c*) and the main criticism was given to the lack of experimental support for the existence of the open amino-aldehydic form, except in several special cases. As their authors have pointed out, the spectroscopic measurements which were performed to confirm this theory not only failed to do so in many cases (15*a*), but are in principle incapable of doing so because of their low sensitivity which does not enable them to detect the presence or absence of the open amino-aldehydic form in trace amounts (15*c*). The intention of our Hückel MO calculations was to analyse the probable spectroscopic and electronic characteristics of all three ionic forms of our alkaloids. The comparison of theoretical and experimental spectroscopic data could be used for predictions about the significant appearance of certain forms in the measured system.

The experimental results for berberrubine show three theoretically unpredicted details: (a) the influence of the undissociated hydroxy group (theoretically neglected) is manifest in a bathochromic shift for $L_b$ of about 20 nm (compared with $L_b$ of berberine), (b) the influence of dissociation of the hydroxy group is also about 20 nm bigger than predicted, and (c) instead of a simple bathochromic shift, the $L_a$ band undergoes splitting into two smaller bands, one shifted towards longer and another to the shorter wave lengths. All these differences (especially the last one) can be attributed to the probable differences between absorption maxima/energy splitting correlation parameters for simple amino and both amino and oxy substituted aromatic compounds. Besides, the literature about uv and visible absorption spectra (19) of other substituted aromatic compounds shows that the influence of substituent frequently can manifest itself in the splitting of the original aromatic band into two or more less intensive bands. In the light of probable smaller electron exchange between benzenoid and quinolinic parts of these molecules, we can postulate, although rather nonexactly, that the absorption bands $B_a$ and $B_b$ are more influenced by the electronic conditions in the benzenoid part of molecule while the bands $L_a$ and $L_b$ are more influenced by the quinolinic part. Under this assumption, we can expect that the dissociation of the berberrubinic hydroxy group will act towards splitting the $L_a$ band (which is more sensitive to substituent) and this can be seen in Table 1 for

berberrubine and in Table 2 for jatrorubine (moreover, from this assumption we can recognize the berberrubinic group in jatrorubine to be dissociated, which is in agreement with our expectation on the basis of MO diagrams of jatrorubine), while the dissociation of the jatrorhizinic group will split the $B_b$ band as can be seen in Table 2 for jatrorhizine where the additional peak at 240 nm appears, but the $L_a$ and $L_b$ bands are only bathochromically shifted. Nevertheless, except in the case of ethanolic and propanolic strongly alkaline solutions of jatrorhizine, where the experimentally noted criterion for carbinolic form appearance (the vanishing of absorption maxima in the visible range) is satisfied, in all other cases we are not able to note any spectral change which could, according to our theoretical predictions, be attributed to the carbinolic form appearance, but all the changes can be described solely by hydroxylic group dissociation.

In the light of the above discussion, the analysis of present spectroscopical results for berberrubine can, finally, be summarized in the following manner.

(a) In strongly acidic media, berberrubine exhibits four absorption maxima $B_a$ (235–240 nm), $B_b$ (268–278), $L_a$ (348–359), and $L_b$ (441–450 nm), which can be attributed to the quaternary amine ionic form.

(b) In all alkaline solutions, the $L_b$ band shifts bathochromically to 490–516 nm, the $L_a$ band splits into two smaller bands, the first one at about 330 nm and the second one between 380 and 399 nm, while the $B_a$ and $B_b$ bands do not change. This spectral rearrangement can be attributed to the dissociation of the hydroxy group in the molecule.

(c) The appearance of neither carbinolic nor open amino-aldehydic forms of berberrubine was noted in any of the investigated solutions. While the latter is unlikely to exist, because of the charge distribution in the molecule, the possibility of existence of the former cannot be rejected, at least in more strongly alkaline conditions than investigated. The dissociation of the hydroxy group does not change the positive charge on the active C11 carbon atom, but only neutralizes slightly the positive charges on the nitrogen and C2 atoms. The only way that dissociation can prevent the nucleophilic attack on the C11 atom would be if we suppose that two or more berberrubine dipole molecules form ionic pairs or clusters in which the C11 sites will be unapproachable. The probable ionic pairs are usually blamed for weak solubility of berberrubine in slightly alkaline solutions.

(d) The choice of solvent can influence the position of absorption maxima. The hypsochromic shift is proportional to polarity of the solvent. The pH of a pure solution of berberrubine (when neither HCl nor KOH was added) changes from 5.03 in water to 6.25 in absolute propanol, which can be connected with the changes in $pK_a$ values of these four solvents. The color of the solutions and the absorption spectra of berberrubine in pure solutions show that only in propanol is its hydroxy group totally dissociated while in other solutions both forms are still in comparable concentrations. The solutions of berberrubine can serve as a kind of pH indicator because it changes its color throughout the whole pH range.

# Introduction of 9-fluorenylmethyloxycarbonyl, trichloroethoxycarbonyl, and benzyloxycarbonyl amine protecting groups into O-unprotected hydroxyamino acids using succinimidyl carbonates[1]

ALENKA PAQUET

*Food Research Institute, Canada Department of Agriculture, Ottawa, Ont., Canada, KIA 0C6*

Received August 12, 1981

ALENKA PAQUET. Can. J. Chem. **60**, 976 (1982).

9-Fluorenylmethyl succinimidyl, pentachlorophenyl, and benzotriazole-1-yl carbonates were prepared and their reactivity with L-serine and L-serine benzyl ester was compared. The most efficient reagent, 9-fluorenylmethyl succinimidyl carbonate, was used for the preparation of 9-fluorenylmethyloxycarbonyl derivatives of other hydroxyamino acids and hydroxyamino acid esters in high yields. The use of trichloroethyl and benzyl succinimidyl carbonates for an efficient conversion of hydroxyamino acids and their esters into the corresponding *N*-trichloroethoxycarbonyl and benzyloxycarbonyl derivatives is described.

ALENKA PAQUET. Can. J. Chem. **60**, 976 (1982).

On a préparé les carbonates de fluorènyl-9 methylsuccinimidile, de pentachlorophényle et de benzotriazolyle-1 et on a comparé leur réactivité vis-à-vis la L-sérine et son ester benzylique. On a utilisé le réactif le plus efficace, le carbonate du fluorènyl-9 méthylsuccinimidile, pour préparer avec d'excellents rendements des dérivés fluorènyl-9 méthyloxycarbonyles d'autres acides hydroxyaminés et de leurs esters. On décrit l'utilisation des carbonates de trichloroéthyle et de benzyle succinimidile pour la transformation efficace des acides hydroxyaminés et de leurs esters en dérivés *N*-trichloroéthoxycarbonyle et benzyloxycarbonyle correspondants.

[Traduit par le journal]

Amino acids bearing urethane-type protecting groups are commonly used in peptide synthesis because they can be coupled without racemization. Except for *N-tert*-butoxycarbonylamino acids, they are usually prepared using the alkoxycarbonyl chloride under Schotten–Baumann conditions. An alternative reagent which does not require the presence of base is the mixed carbonate containing a substituted phenolic group (1) and more recently the succinimidyl group (1–3). New protecting groups are continually being proposed for use in peptide and general organic chemistry, and methods for their introduction are necessary. This paper describes a new method of preparing 9-fluorenylmethyloxycarbonyl (Fmoc-),[2] trichloroethoxycarbonyl (Tec-), and benzyloxycarbonyl (Z-) amino acids with particular attention to the hydroxyamino acids using succinimidyl carbonates as reagents and the free amino acids or amino acid esters as substrates. The possibility of using other carbonates was also examined.

The Fmoc group (4) which is labile to secondary amines is being promoted for use both in solid phase (5, 6) and solution (7) peptide synthesis, particularly because it eliminates the need for a potentially harmful acid deprotection cycle. Fmoc-amino and hydroxyamino acid derivatives have been obtained using Fmoc-chloride in the presence of aqueous sodium carbonate (8). Fmoc-amino acid esters have been obtained by subsequent esterification (4, 8). The Tec group is an attractive protecting group as it can be cleaved by zinc in acetic acid (9) or organic solvents (10, 11) leaving other functional groups unaffected. However, it has been little used in peptide chemistry possibly because of the uncertainty over its stability to hydrogenolytic conditions (12). It also has been reported that an attempt to convert serine into Tec-Ser-OH using trichloroethoxycarbonyl chloride in the presence of 1 *N* sodium hydroxide failed (11).

Mixed carbonates have been obtained by reaction of alkyl chloroformates with alcohols in pyridine (1) and more recently with the thallium salt of *N*-hydroxysuccinimide in organic solvents (3). But thallium salts are toxic and their preparation involves handling of the unstable and toxic thallium ethoxide. We have now found that the dicyclohexylammonium salts of alcohols, which are readily obtained by mixing the two components in an organic solvent, serve as well for the preparation of mixed carbonates from alkyl chloroformates. Thus 9-fluorenylmethyl, trichloroethyl, and benzyl succinimidyl carbonates **1**, **4**, and **5** were prepared in high yields in this manner. As well, 9-fluorenylmethyl pentachlorophenyl carbonate **2** and benzo-

[1]Contribution No. 473 from the Food Research Institute, Agriculture Canada, Ottawa, Ont., Canada.

triazole-1-yl carbonate **3** were obtained from 9-fluorenylmethyloxycarbonyl chloride and the dicyclohexylammonium salt of the corresponding alcohols.

Succinimidyl carbonate **1** was also obtained by the reverse procedure, namely by reaction of 9-fluorenylmethanol with succinimidyl chloroformate. Again, the dicyclohexylammonium instead of the thallium salt (3) of *N*-hydroxysuccinimide served for the preparation of the chloroformate using phosgene. We found a literature procedure (13) to be a convenient source for 9-fluorenylmethanol.

9-Fluorenylmethyl carbonates **1–3** were reacted with one equivalent of L-serine in a water–acetone mixture in the presence of one equivalent of sodium bicarbonate, and with serine benzyl ester hydrochloride in chloroform in the presence of 1.5 equivalents of triethylamine. Under these conditions, the succinimidyl carbonate **1** gave excellent yields of Fmoc-Ser-OH and Fmoc-Ser-OBzl, the pentachlorophenyl carbonate **2** gave no Fmoc-Ser-OH and a moderate yield of the ester, and the benzotriazole-1-yl carbonate **3** gave an excellent yield of the ester but only a moderate yield of the acid derivative. The results are given in Table 1. On this basis, the succinimidyl carbonate **1** was chosen for further study. It reacted smoothly with valine and valine methyl ester giving the Fmoc-derivatives in

TABLE 1. Reactivity of reagents **1–3** with serines

| | H-Ser-OH | | H-Ser-OBzl | |
|---|---|---|---|---|
| Reagent | Time (h) | Yield (%) | Time (h) | Yield (%) |
| **1** | 2 | 87 | 2 | 87 |
| **2** | 48 | — | 48 | 50 |
| **3** | 48 | 64 | 2 | 89 |

good yields. Other amino acid derivatives prepared are described in Table 2. The results demonstrate that the use of 9-fluorenylmethyl succinimidyl carbonate is indeed a good alternative to the use of the chloroformate for the preparation of Fmoc-derivatives. It has the advantage that it eliminates the possibility that the mixed anhydride might form during the acylation reaction. The mixed anhydride could give rise to some protected dipeptide in addition to the desired *N*-protected amino acid, a side-reaction encountered in the original synthesis of benzoylglycine (14, 15).

The pentachlorophenyl carbonate **2** also proved unsatisfactory for acylating valine and valine methyl ester, 50% of **2** being recovered even after 72 h.

Using the same conditions as for the preparation of the Fmoc-derivatives, trichloroethyl succinimidyl carbonate **4** and benzyl succinimidyl carbonate **5** gave good yields of the corresponding derivatives when reacted with hydroxyamino acids and esters. The compounds prepared are described in Tables 3 and 4.

All amino acid derivatives obtained gave correct elemental analyses, exhibited absorptions at 3420 (N—H), 1695–1710 (urethane carbonyl), and 1510 (urethane C—N) $cm^{-1}$ in ir and showed amide proton signals in nmr spectra. This served as a proof that the amino group was acylated.

## Experimental

Melting points (uncorrected) were taken by the capillary method. The nmr spectra were recorded on a Varian T-60 spectrometer in deuterochloroform unless stated otherwise. The ir spectra were obtained with a Beckman-IR-20 spectrometer in chloroform. Optical rotations were determined on Perkin–Elmer model 141 polarimeter. Solutions were dried over $Na_2SO_4$.

9-Fluorenylmethanol was prepared according to the literature (13) or purchased from Fluka, A. G. Buchs, Switzerland. Amino acids and their esters were purchased from Sigma Chemical Company (Saint Louis, Missouri, USA). Serine benzyl ester hydrochloride and tyrosine benzyl ester were prepared as indicated in the literature (16).

*N*-Protected amino acid esters with the exception of tyrosine esters were prepared as shown for the preparation of Fmoc-Ser-OBzl. *N*-Protected tyrosine ester derivatives were synthesized as described for the preparation of Fmoc-Tyr-OBzl.

For personal use only.

succinimide·DCHA in methylene chloride (100 mL) at −30°C was added liquified phosgene (20 mL) under a stream of nitrogen. The reaction was stirred for 4 h at −5°C and the excess of phosgene was removed at room temperature with a stream of nitrogen in a well vented fume-hood. Methylene chloride was added, the mixture was cooled to −2°C, the precipitate was filtered off and washed with cold methylene chloride. The combined filtrate and washings were washed with a cold 10% solution of sodium bicarbonate, water, dried, and the solvent was evaporated giving 2.85 g (80%) of the title compound; ir: 1740–1760 (chloride carbonyl), 1790–1800, and 1820 (imide carbonyl) $cm^{-1}$.

*9-Fluorenylmethyl succinimidyl carbonate (1)*

*A. From 9-fluorenylmethyl chloroformate and N-hydroxysuccinimide·DCHA salt*

To a stirred solution of 14.06 g of Fmoc-chloride (54.4 mmol) in chloroform (100 mL) was added 16.12 g (54.4 mmol) of *N*-hydroxysuccinimide·DCHA salt in portions. The stirring was continued overnight, the precipitate was filtered off and washed with chloroform. The filtrate and washings were combined and washed with 1/3 of the volume each of 10% citric acid, 10% sodium bicarbonate, and water, and dried. The solvent was distilled off *in vacuo* and the residue was recrystallized from chloroform–ether giving 16.5 g (90%) of the title compound, mp 151°C. *Anal.* calcd. for $C_{19}H_{15}NO_5$: C 67.65, H 4.48, N 4.15; found: C 67.85, H 4.60, N 4.05.

*B. From 9-fluorenylmethanol and succinimidyl chloroformate*

To a stirred solution of 7.22 g (36.8 mmol) of 9-fluorenylmethanol and 2.9 g (36.8 mmol) of pyridine in methylene chloride (7.5 mL) was added 6.54 g (36.8 mmol) of succinimidyl chloroformate in methylene chloride (6.5 mL) under cooling with tap water. The stirring was continued for 5 h at room temperature. Ice-water was added, and the organic layer was washed with 1/3 of the volume each of 10% hydrochloric acid (2 times), saturated sodium bicarbonate (2 times), water, and dried. Solvent was removed *in vacuo* and the residue recrystallized from chloroform–ether giving 8.95 g (72%) of the compound **1**, which was identical with the product obtained by method A (identical mp and ir spectra).

*9-Fluorenylmethyl pentachlorophenyl carbonate (2)*

This compound was obtained from 2.58 g (10 mmol) of Fmoc-chloride and 4.47 g (10 mmol) of pentachlorophenol DCHA salt as described for the synthesis A of ester **1**. Crystallization of the product from chloroform afforded 4.0 g (82%) of the title compound, mp 162–164°C. *Anal.* calcd. for $C_{21}H_{11}O_3Cl_5$: C 51.62, H 2.26, Cl 36.28; found: C 51.64, H 2.20, Cl 36.10.

*9-Fluorenylmethyl benzotriazole-1-yl carbonate (3)*

This compound was p ep red from 2.59 g (8.2 mmol) of 1-hydroxybenzotriazol DCHA salt and 2.12 g (8.2 mmol) of fluorenylmethyl chloroformate in methylene chloride (15 mL) as described for the synthesis of ester **1** giving 2.42 g (83%) yield, mp 180°C. *Anal.* calcd. for $C_{21}H_{15}N_3O_3$: C 70.58, H 4.23, N 11.75; found: C 70.76, H 4.39, N 11.17.

*Trichloroethyl succinimidyl carbonate (4)*

This compound was obtained from trichloroethyl chloroformate and the DCHA salt of *N*-hydroxysuccinimide as indicated for preparation of carbonate **1** (method A). Yield, 89%; mp 114–115°C (lit. (3) mp 113°C).

*Benzyl succinimidyl carbonate (5)*

This synthesis was carried out from benzyl chloroformate and the DCHA salt of *N*-hydroxysuccinimide as shown for the preparation of carbonate **1**. Yield, 90%; mp 80–81°C (lit. (2) mp 79–81°C).

N-*(9-Fluorenylmethyloxycarbonyl)*-L-*serine*

To a stirred solution of 525 mg (5 mmol) of L-serine and 420 mg (5 mmol) of sodium bicarbonate in a mixture of water (7 mL) and acetone (7 mL) was added 1.68 g (5 mmol) of reagent **1**. After stirring overnight the mixture was acidified to pH 2 with concentrated hydrochloric acid and acetone was removed *in vacuo*. The product was taken up in chloroform and washed with 0.1 *N* HCl and water. The combined organic phases were dried, evaporated *in vacuo*, and the residue was crystallized.

N-*Trichloroethoxycarbonyl*-L-*serine*

To a stirred solution of 526 mg (5 mmol) of L-serine and 420 mg (5 mmol) of sodium bicarbonate in water (10 mL) and tetrahydrofurane (5 mL) was added 1.45 g (5 mmol) of reagent **4**. The mixture was stirred overnight, acidified with concentrated hydrochloric acid, the organic solvent was distilled off, and the aqueous layer was extracted with chloroform (3 × 5 mL). The combined extracts were washed with water, dried, and evaporated *in vacuo*, and the crude product was recrystallized.

N-*Trichloroethoxycarbonyl*-L-*valine*

This compound was obtained from 117 mg (1 mmol) of L-valine and (1 mmol) of carbonate **4** as shown for the synthesis of Tec-Ser-OH.

N-*Benzyloxycarbonyl*-L-*serine*

To a stirred solution of 525 mg (5 mmol) of L-serine and 420 mg (5 mmol) of sodium bicarbonate in a mixture of water (7 mL) and acetone (7 mL) was added 1.24 g (5 mmol) of ester **5**. The mixture was stirred overnight, acetone was removed *in vacuo*, and the solution was washed twice with methylene chloride (3 mL). The aqueous layer was acidified to pH 2.5 by concentrated hydrochloric acid and extracted with ethyl acetate (3 × 5 mL). The combined ethyl acetate layers were washed with water, dried, solvent removed *in vacuo*, and the residue recrystallized.

N-*(9-Fluorenylmethyloxycarbonyl)*-L-*threonine*

This compound was prepared from 119 mg (1 mmol) of L-threonine and 337 mg (1 mmol) of reagent **1** following the procedure described for the preparation of Fmoc-Ser-OH. It was crystallized as its DCHA salt by adding 181 mg (1 mmol) of dicyclohexylamine to the crude product in ethyl acetate. The mixture was stirred for 2 h, the volume was reduced *in vacuo*, ether was added, and the crystalline product was separated by filtration.

*9-Fluorenylmethyloxycarbonyl*-L-*valine*

This derivative was obtained from 117 mg (1 mmol) of L-valine and 337 mg (1 mmol) of reagent **1** using the procedure described for Fmoc-Ser-OH.

N-*(9-Fluorenylmethyloxycarbonyl)*-L-*serine benzyl ester*

A solution of 232 mg (1 mmol) of L-serine benzyl ester hydrochloride, 0.21 mL of triethylamine (1.5 mmol), and 337 mg (1 mmol) of ester **1** in methylene chloride (5 mL) was stirred at room temperature for 2 h. The mixture was washed with 0.1 *N* hydrochloric acid and water, the organic phase was dried, and the residue was recrystallized after removal of the solvent.

N-*(9-Fluorenylmethyloxycarbonyl)*-L-*tyrosine benzyl ester*

A solution of 271 mg (1 mmol) of tyrosine benzyl ester and 337 mg (1 mmol) of compound **1** in chloroform (5 mL) was stirred at room temperature overnight. The mixture was washed with water (3× 1 mL) and dried. The solvent was removed *in vacuo* and the residue was recrystallized.

Reçu le 5 octobre 1981

JEAN BOLTE, COLETTE DEMUYNCK, GEORGES JEMINET, JEAN JUILLARD et CLAUDE TISSIER. Can. J. Chem. **60**, 981 (1982).

Nous avons déterminé par une méthode potentiométrique, la stoechiométrie et la stabilité des associations formées dans le méthanol, entre ces trois ionophores naturels et les cations alcalins et alcalino-terreux. Avec les alcalins, ils forment des complexes neutres de stoechiométrie 1:1 pour X.537 A et A.23187, 2:1 pour X.14547 A. Des complexes de plus grande stabilité sont obtenus avec les divalents, correspondant à des associations 1:1 chargées et 2:1 neutres. A.23187 et X.14547 A ont un comportement comparable quant aux séquences de formation des deux types de complexes mais les constantes sont beaucoup plus élevées pour le premier cité. Pour X.537 A, l'existence du complexe 2:1 n'est pratiquement pas décelable par la méthode utilisée, sauf dans le cas du magnésium.

Nous avons également étudié le transport du calcium par ces ionophores dans une cellule modèle: phase aqueuse/phase chloroformique/phase aqueuse. Nous tentons de relier les flux ioniques obtenus aux constantes d'équilibre précédentes.

JEAN BOLTE, COLETTE DEMUYNCK, GEORGES JEMINET, JEAN JUILLARD, and CLAUDE TISSIER. Can. J. Chem. **60**, 981 (1982).

Using a potentiometric method, both the stoechiometry and the stability of complexes formed in methanol between the three natural ionophores and cations $I_A$ and $II_A$ have been obtained. With alkali metal ions, neutral complexes of stoechiometry 1:1 for X.537 A and A.23187, 2:1 for X.14547 A are formed. Complexes of higher stability are obtained with alkaline-earth cations, corresponding to two types of association; 1:1 charged and 2:1 neutral. A.23187 and X.14547 A show similar behaviour as far as the sequence of formation of these two complexes is concerned, but the stability constants are higher for the first one. For X.537 A, the existence of a 2:1 complex is not detectable by our method, except for magnesium.

Calcium transport by these ionophores through a cell such as: aqueous phase/chloroformic phase/aqueous phase has also been studied. An attempt is made to relate ionic fluxes to the preceding equilibrium constants.

## Introduction

L'étude des phénomènes de transport cationique à travers les membranes connaît un développement important. Celui-ci est lié, en particulier, à la découverte de nouveaux antibiotiques, dont la propriété fondamentale est de s'associer spécifiquement aux cations alcalins ou alcalino-terreux, et de permettre sous cette forme, le passage de ces cations à travers les phases membranaires. Ces ionophores (1) d'origine bactérienne sont devenus, de ce fait, des outils d'exploration très utilisés en biologie expérimentale (2). Ils présentent des structures polydentées macrocycliques neutres (peptides, depsipeptides, macrotétrolides) (3) ou en chaîne ouverte (acides carboxyliques polyéthers) (4).

Au fil des années, ce deuxième groupe d'ionophores a pris une grande importance en raison du nombre de représentants qui ont été isolés. Actuellement, plus de soixante composés de ce type sont connus; ce sont essentiellement des transporteurs biologiques des cations alcalins et notamment de $K^+$, quelques composés transportent cependant plus sélectivement $Ca^{++}$ ou $Mg^{++}$, pour cette raison ils offrent un intérêt particulier. Les principaux connus à ce jour sont X.537 A (lasalocide) (5), A.23187 (calcimycine) (6), X.14547A (7) et ionomycine (8). Dans ce travail, nous nous intéresserons aux trois premiers mentionnés (Fig. 1).

Le mécanisme du transport membranaire d'un cation, par l'intermédiaire d'un transporteur, peut être discuté en considérant les grandes étapes suivantes: (*1*) formation d'une association transporteur–cation, soit en solution, soit à l'interface membrane–solution; (*2*) diffusion du complexe liposoluble à travers la membrane; (*3*) dissociation du complexe à l'autre interface ou dans la solution; (*4*) diffusion en retour du transporteur vers le premier interface. L'efficacité globale du transport semble déterminée, pour l'essentiel, par les étapes (*1*) et (*3*) (9); celles-ci présentent une similitude avec les processus correspondants de formation et de dissociation des complexes en milieu homogène qui sont plus faciles à étudier.

Ces observations d'un caractère général, permettent de comprendre la motivation des études

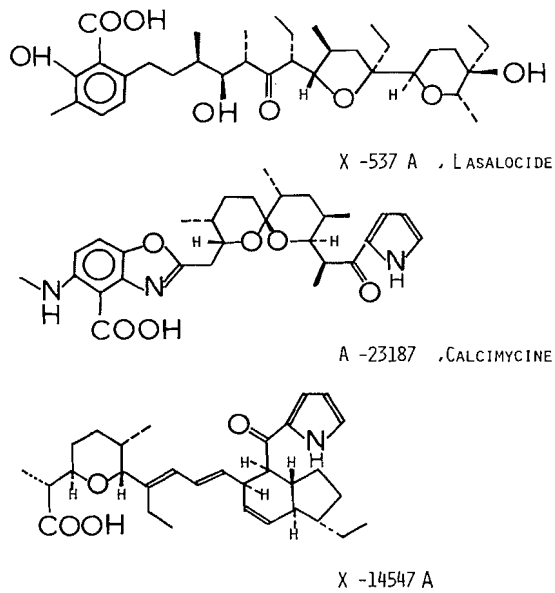

FIG. 1. Structure des trois ionophores étudiés.

entreprises depuis quelques années dans le domaine de la complexation et du transport des cations.

Pour le cas des deux ionophores X.537 A (10) et A.23187 (11), on a peu, jusqu'à présent, examiné dans le détail les équilibres de complexation en milieu homogène; par ailleurs, les études de transport sont généralement effectuées dans des membranes biologiques (mitochondries, reticulum sarcoplasmique, etc.) ou des bicouches artificielles, dans des zones de pH peu étendues, qui rendent difficiles des comparaisons entre ces transporteurs naturels. L'ionophore X.14547 A n'a fait l'objet d'aucune étude.

Dans un travail précédent, nous avons déterminé la stabilité des associations de A.23187 avec les cations alcalins et alcalino-terreux, dans le méthanol à 25°C (12). Le choix du solvant est imposé par l'insolubilité des composés dans l'eau; la plupart des études en milieu homogène sont généralement effectuées dans le méthanol, considéré comme le solvant protique le plus proche de l'eau. Nous poursuivons ici ces mesures, dans les mêmes conditions, en examinant le cas des ionophores X.537 A et X.14547 A. Nous utilisons une méthode complexométrique classique qui consiste à suivre le pH de la solution, lors du dosage de l'antibiotique par une base, ceci en présence ou non d'ions métalliques; les méthodes de calcul faisant intervenir la fonction de formation de Bjerrum permettent de préciser les différents complexes qui se forment (12), et d'apporter des compléments aux résultats antérieurs de Degani et Friedman (13) en ce qui concerne X.537 A.

Dans la suite de ce travail, nous nous intéressons plus précisément au transport de $Ca^{++}$ d'une phase aqueuse de départ à une phase aqueuse d'arrivée, à travers une "membrane liquide épaisse" constituée par du chloroforme qui contient l'un des ionophores. La comparaison des flux ioniques permet de discuter les aptitudes respectives des trois transporteurs. Les résultats obtenus, fonctions du pH des phases aqueuses, sont reliés aux constantes d'équilibre mesurées dans le méthanol.

## Partie expérimentale

*Obtention des ionophores*

X.537 A (ou lasalocide) est disponible commercialement (Sigma) sous la forme de son sel de sodium, il a été traité pour obtenir l'acide libre. A.23187 (ou calcimycine) est isolé à partir d'une culture en fermenteur de la souche de *Streptomyces chartreusis* NRRL 3882, selon un procédé qui a été décrit (12).

L'antibiotique X.14547 A est isolé à partir d'une souche de *Streptomyces antibioticus* NRRL 8167. La culture de la souche est réalisée en fermenteur de 20 L, dans le milieu suivant pour 1 litre d'eau: glucose 10 g, mélasses de sucrerie 20 g, soyoptim 5 g, $CaCO_3$ 2 g, extrait de levure Mérieux 1 g. Le pH de départ est ajusté à 7,2. On utilise l'antimousse B Rhône-Poulenc. On maintient la quantité d'air dissous à 90%. L'agitation est de 620 tours/min à 27°C. Après 6 jours de culture, on sépare le mycelium par centrifugation. Le jus est extrait trois fois par l'acétate d'éthyle, le mycelium finement broyé est extrait deux fois à l'éthanol. Les différentes solutions organiques sont concentrées à l'évaporateur cyclone. Le résidu total est repris par HCl 0,1 *N*, puis extrait à l'éther. L'huile brunâtre résiduelle est purifiée par chromatographie sur colonne (kieselgel 60 Merck, 70–230 mesh ASTM) avec un gradient d'élution cyclohexane–éther puis cyclohexane – acétate d'éthyle. La structure de l'antibiotique ainsi isolé a été vérifiée par comparaison de ses propriétés physiques avec celles d'un échantillon authentique fourni généreusement par le docteur J. W. Westley, à l'aide des techniques suivantes: spectrométrie de masse I.E., polarimétrie, spectroscopies infrarouge et uv–visible, rmn $^1H$ et $^{13}C$. Les résultats obtenus sont en accord avec ceux publiés (21).

*Mesures complexométriques dans le méthanol*

Les solvants et réactifs utilisés, la technique des mesures potentiométriques ainsi que le traitement des valeurs ont été présentés dans la référence 12.

*Mesures du transport de $Ca^{++}$*

La cellule utilisée est un tube en U (Fig. 2). Les valeurs de flux mesurées sont fonctions des conditions expérimentales (forme de la cellule, agitation, température, concentrations relatives cation–ionophore). Pour cette étude comparative, un protocole très bien défini a été suivi.

La cellule est thermorégulée 25.0 + 0.1°C par une circulation d'eau. Diamètre intérieur du tube: 11 mm. Volumes des phases A et C: 4 mL, de la phase B: 9 mL. Agitation des phases A et C par des agitateurs constitués d'une baguette de verre (diamètre 3 mm), terminée par une pale rectangulaire de 6 × 3 mm, mue par un petit moteur électrique synchrone tournant à 600 tours/min. Le bas de la pale est situé à 20 mm de l'interface eau/chloroforme. La phase B est agitée par un barreau magnétique cylindrique (diamètre 2 mm, hauteur 10 mm), tournant à 600 tours/min.

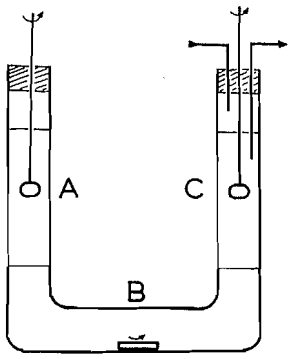

FIG. 2. Schéma de la cellule de transport utilisée.

Les solutions aqueuses sont tamponnées par un mélange tricine–triéthanolamine $10^{-2}$ *M* ou tricine – hydroxyde de tétraméthyl ammonium pour les pH supérieurs à 8. La phase aqueuse d'arrivée contient un indicateur de $Ca^{++}$, l'arsenazo III (Fluka) à la concentration $2 \times 10^{-4}$ *M* ce qui permet un dosage en continu du cation grâce à un système à circulation passant dans la cuve d'un spectrophotomètre (Beckman DU 8), lecture à 650 nm. La concentration du calcium dans cette phase ne dépasse jamais $4 \times 10^{-5}$ *M*; lorsque cette valeur est atteinte, la solution est renouvelée, le pH est toujours maintenu à 7,0. La solution aqueuse de départ contient $Ca(ClO_4)_2$ (Merck) à la concentration $10^{-2}$ *M*, le pH est mesuré avec une précision de 0,02 unités. La phase B est constituée de chloroforme, préalablement saturé d'eau, qui contient l'ionophore à la concentration $4 \times 10^{-4}$ *M*. En l'absence d'ionophore, aucun apport de calcium n'est observé dans la phase C.

On mesure le flux d'ions $Ca^{++}$ exprimé en mol $s^{-1}$ $cm^{-2}$. Au cours de l'expérience, ce flux augmente d'abord en fonction du temps puis reste constant. La première période correspond à l'établissement du régime quasi-stationnaire.

Chaque point des courbes a, b, c de la figure 3 est obtenu dans les conditions où le flux est constant. Le spectrophotomètre muni d'un calculateur donne une valeur du flux toutes les 5 min; la durée de chaque expérience, pour un pH donné, est comprise entre 1 h et 4 h. La précision sur la mesure du flux est de l'ordre de 5%.

## Résultats

### A. *Complexation des cations alcalins et alcalino-terreux dans le méthanol*

Si l'on désigne respectivement par $M^+$ et $M^{++}$ le cation alcalin et alcalino-terreux, par AH l'ionophore carboxylique sous sa forme protonée; les différents équilibres mis en évidence au cours de cette étude s'écrivent:

avec $H^+$ [1] $AH \rightleftharpoons A^- + H^+$

avec $M^+$ [2] $A^- + M^+ \rightleftharpoons AM$

[3] $A^- + AH + M^+ \rightleftharpoons A_2HM$

avec $M^{++}$ [4] $A^- + M^{++} \rightleftharpoons AM^+$

[5] $2A^- + M^{++} \rightleftharpoons A_2M$

Dans ce qui suit, les constantes de formation $\beta_1$–$\beta_5$ correspondent aux équilibres [1]–[5].

#### 1. *X.537 A (lasalocide)*

Les résultats obtenus pour les deux séries de cations sont rassemblés dans les tableaux 1 et 2 où figurent également les résultats précédemment acquis pour A.23187 (12). Pour X.537 A, la constante de formation $\beta_5$ du complexe 2:1 avec les cations divalents, est le plus souvent très faible et hormis dans le cas du magnésium, il n'a pas été possible d'obtenir la valeur numérique de cette constante.

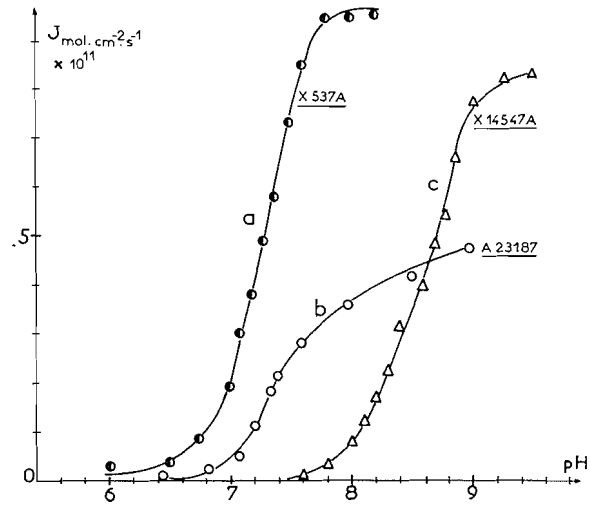

FIG. 3. Variations du flux ionique en fonction du pH du compartiment de départ.

Sur la figure 4 sont reportées les courbes de titrage de l'antibiotique en présence des divers cations métalliques. Pour calcium, strontium et baryum on note une formation quasi-totale du complexe 1:1, $AM^+$ qui correspond au premier palier. La neutralisation de l'antibiotique restant par la base correspond au second palier. A ce niveau, le fait que les courbes représentatives du dosage soient alors confondues est significatif; il n'y a pour aucun de ces cations de formation notable de sel complexe 2:1, $A_2M$.

Dans le cas du magnésium par contre, le calcul

par des méthodes déjà décrites (12) a permis d'accéder aux deux constantes de formation ($\beta_4$ et $\beta_5$).

On peut remarquer sur les tableaux 1 et 2, le bon accord entre nos résultats et ceux de Degani et Friedman (13), si l'on tient compte du fait que la méthode utilisée est différente. Une divergence existe en ce qui concerne le p$K_a$ de l'acide (éq. [1]); la valeur obtenue ici 8,23 peut être comparée à celle de l'acide salicylique dans le même milieu 7,79 (14); un affaiblissement de cet ordre de grandeur de l'acidité pouvait être attendu du fait de la substitution du cycle aromatique.

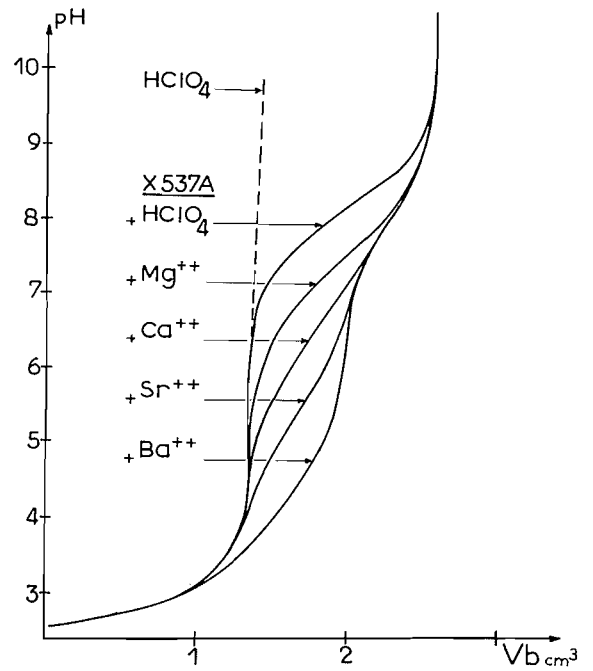

FIG. 4. Courbes de titrages de l'ionophore X.537 A (lasalocide) en présence d'acide perchlorique par le méthoxyde de tétrabutylammonium, ceci en l'absence et en présence des divers perchlorates alcalins: pH en fonction du volume de solution basique $V_b$ ajouté.

2. *X.14547 A*

La constante de dissociation de la fonction acide carboxylique mesurée (p$K_a$ = 10.22) est voisine de celle obtenue précédemment pour des antibiotiques ionophores polyéthers du même groupe spécifiques des alcalins: grisorixine, 10.24; nigéricine, 10.32; alborixine, 10.29 (15); qui présentent un groupement terminal substitué analogue, il s'agit d'un acide propionique 2-tétrahydropyranyl di- ou trisubstitué sur le cycle.

Pour ce composé, les courbes obtenues en potentiométrie avec les cations alcalino-terreux sont facilement interprétées si l'on prend en considération les équilibres [4] et [5], les valeurs $\beta_4$ et $\beta_5$ correspondantes sont mentionnées dans le tableau 2. Une certain nombre d'essais ont été effectués avec les cations alcalins, ils ont permis de montrer que la complexation de $Li^+$ est pratiquement inexistante, celles de $K^+$ et $Rb^+$ par contre bien que faibles, ne sont pas totalement négligeables. Le traitement des données conduit à privilégier la formation de complexe AH $A^-$ $M^+$ (éq. [3]). Les résultats obtenus sont particulièrement probants avec $Rb^+$ (log $\beta_3$ = 5.2 ± 0.1), $K^+$ donne une constante de formation du même ordre de grandeur mais avec une incertitude plus grande.

B. *Transport de $Ca^{++}$ à travers une membrane liquide*

Dans les expériences effectuées, à l'aide d'un système à trois phases, eau/chloroforme/eau, le pH du compartiment aqueux de départ varie entre 5,0 et 9,0. L'ensemble des résultats obtenus pour $Ca^{++}$, dans des conditions expérimentales identiques (voir Partie expérimentale) est représenté sur la figure 3. Nous pouvons affirmer que les trois ionophores étudiés présentent une aptitude à transporter l'ion calcium à travers une membrane liquide chloroformique, ce transport dépend du pH. Considérons l'exemple de X.537 A (courbe a), à pH < 6 le flux de calcium est inférieur à $10^{-12}$ mol $s^{-1}$ $cm^{-2}$ qui est la limite inférieure de sensibilité de

TABLEAU 3. Flux ioniques exprimés en mol $s^{-1}$ $cm^{-2}$ pour $Ca^{++}$, dans une cellule à trois phases eau/$CHCl_3$/eau

|---|---|---|---|
| X.537 A (lasalocide) | 10,2 | 7,3 | 8,23 |
| A.23187 (calcimycine) | 5,2 | 7,5 | 10,94 |
| X.14547 A | 8,2 | 8,6 | 10,22 |

[a] $pH_{1/2}$ = pH pour lequel $J = J_{max}/2$.

notre méthode. $J$ augmente jusqu'à atteindre une valeur limite $J_{max}$ pour pH > 7,8. Le même type de courbe sigmoïde est obtenue pour les deux autres composés, mais dans des zones de pH différentes. X.14547 A (courbe c) diffère des deux autres ionophores en ce qui concerne la zone de pH du transport très déplacée vers les domaines basiques. A noter que dans le cas de la calcimycine (courbe b) la valeur $J_{max}$ est entachée d'imprécision en raison de la faible solubilité du complexe calcique aux pH élevés qui tend à cristalliser à l'interface eau–chloroforme. Pour chacune des courbes, on définit une valeur $pH_{1/2}$ correspondant au point où le flux est égal à $J_{max}/2$ (Tableau 3). Cette valeur ne varie pas sensiblement suivant les conditions expérimentales (cellule, agitation, concentrations en $Ca^{++}$ et ionophore), contrairement à celle de $J_{max}$ qui en dépend.

## Discussion

Les trois antibiotiques étudiés ont fait l'objet de déterminations cristallographiques aux rayons X sur les acides libres ou leurs sels complexes, la conformation des squelettes et le mécanisme d'encagement des cations se trouvent donc précisés à l'état solide. A cet égard, X.537 A a donné lieu à de nombreux travaux sur différents complexes avec $Ag^+$ (16), $Ba^{++}$ (17) et $Na^+$ sous la forme monomère (10) ou dimère (18) et sur l'acide libre cristallisé avec une molécule de méthanol (19). La structure de A.23187 a été élucidée sur son acide libre (6), le complexe dimérique avec $Ca^{++}$ a également été étudié (20). On ne dispose actuellement que d'une seule étude cristallographique, concernant un dimère particulier (21), pour X.14547 A. Ces données structurales sont complétées par des mesures spectroscopiques en solution, par résonance magnétique nucléaire dans différents solvants pour X.537 A (22) et A.23187 (23). On ne discutera pas dans le détail, les résultats qui ont été acquis dans ce domaine.

La connaissance de la stabilité thermodynamique des associations avec des cations de différentes tailles, dans une même série, apporte des éléments d'information supplémentaires concernant la nature des associations en solution. C'est ce point que nous nous proposons de développer en relation avec les études structurales citées.

*Complexation des alcalins*

Pour X.537 A, l'ordre d'association s'écrit $Cs^+ \sim Rb^+ \sim K^+ > Na^+ \gg Li^+$, il n'y a pas de spécificité marquée pour un cation, comme dans le cas de la grisorixine ou la monensine (12), par ailleurs le maximum de stabilité observé pour $K^+$ n'excède pas 3,5 ($\log \beta_2$). Deux éléments structuraux se conjugent pour entraîner cette sélectivité médiocre: la longueur trop faible de la chaîne complexante et les irrégularités qui existent dans la disposition des sites oxygènes donneurs. La structure du sel de sodium, étudiée par Chiang et Paul (10) fait apparaître assez clairement ces deux points.

Quant à la calcimycine, une inversion véritable s'opère dans la séquence: $Li^+ > Na^+ > K^+ > Rb^+ \sim Cs^+$. Seul $Li^+$ (0,78 Å) doit pouvoir se loger dans la cavité ménagée par la molécule repliée dont l'existence est mise en évidence dans la structure cristalline de l'acide libre (6). On note une constante très faible pour $K^+$: 2,4 ($\log \beta_2$).

Il s'agit ici de la première étude de complexes des alcalins avec X.14547 A. Le type de complexes obtenus est différent des deux ionophores précédents; il implique la participation d'une molécule d'acide et de son anion dans une association 2:1 avec le cation, telle qu'on l'a déjà observée dans la structure cristalline avec l'ion R(+) bromo-4 phényl-1 éthyl ammonium (21). Cette différence de comportement est très vraisemblablement liée à la structure particulière du composé. L'examen des modèles moléculaires montre qu'une conformation repliée de la chaîne ne laisse pas apparaître une cavité complexante permettant l'accueil d'un cation, ce qui est dû en particulier à la géométrie de la molécule, imposée par le groupement *trans*-butadiényle et la conformation bloquée du tétrahydroindane; seule des associations du type 2:1 semblent possibles à réaliser si l'on se réfère à l'étude cristallographique (21).

*Complexation des alcalino-terreux*

Sur la figure 5 sont comparées les constantes de formation des complexes 1:1 et 2:1, correspondant aux équilibres

[4] $A^- + M^{++} \rightleftharpoons AM^+$

et

[6] $AM^+ + A^- \rightleftharpoons A_2M$

A.23187 a déjà été discutée (12), cette molécule qui présente un nombre faible de degrés de liberté de rotation dans sa chaîne est remarquablement construite pour s'associer à $Ca^{++}$ et $Mg^{++}$, dans un

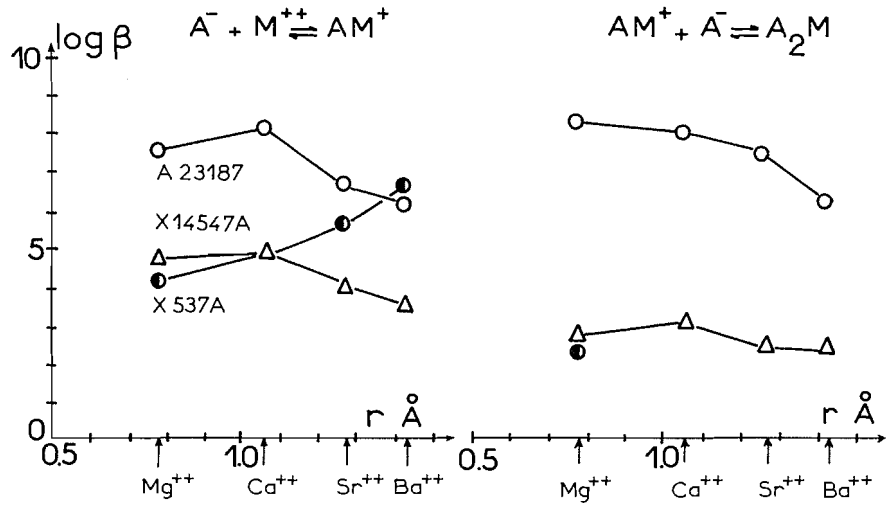

FIG. 5. Constantes de formations successives, dans le méthanol, des complexes des ions alcalino-terreux avec les trois ionophores: log $\beta_4$ et $\beta_6$ en fonction du rayon ionique de ces ions.

mécanisme en deux étapes bien définies. En effet, si on considère les constantes de formation successives, on peut noter qu'elles sont pour chacun des cations étudiés, du même ordre de grandeur. Ceci est assez inhabituel; le plus souvent, comme il est observé ici pour X.14547 A, les constantes de stabilité décroissent au fur et à mesure qu'augmentent le nombre de coordinats participants au complexe. Pour ces deux ionophores la séquence de formation des deux types de complexes est analogue: $Ca^{++} \sim Mg^{++} > Sr^{++} > Ba^{++}$, mais les constantes de stabilité sont beaucoup plus grandes dans le cas de A.23187. Si on possède des informations sur la structure des complexes 2:1 à l'état solide avec $Ca^{++}$ (20) et $Mg^{++}$ (24) ou en solution (23) pour cet ionophore, aucune étude n'a encore été effectuée pour les complexes analogues de X.14547 A. La différence essentielle, déjà soulignée pour ce composé, réside dans la partie centrale de la chaîne *trans*-butadiène qui est totalement différente du spirocétale de A.23187 qui porte et oriente convenablement les deux "bras" où sont situés les sites de complexations et amorce ainsi la formation d'une cavité complexante.

Pour X.14547 A, le complexe 1:1 avec les cations divalents est suffisamment stable pour être pris en compte dans les calculs, ce n'est pas le cas avec les cations monovalents: l'interaction avec les sites de coordination est plus forte avec les cations doublements chargés.

Pour X.537 A, l'association croit d'une manière monotone en fonction de la taille du cation $Ba^{++} > Sr^{++} > Ca^{++} > Mg^{++}$, et pratiquement le complexe 2:1 ne se forme pas dans le méthanol, hormis pour $Mg^{++}$. Il paraît pourtant nécessaire que la charge du métal divalent soit neutralisée dans le complexe pour que le cation puisse migrer à travers la barrière membranaire. De fait, la situation n'est sans doute pas la même dans un milieu apolaire, comme le chloroforme étudié plus loin, ou l'hexane dans lequel Degani et Friedman (13) ont montré que le complexe 2:1 se formait de façon exclusive. Cette tendance à une formation préférentielle du complexe 1:1 en solvant protique, soulignée également par Chiang et Paul (10), peut être rapprochée du fait que dans la structure cristalline du sel 2:1 étudiée avec $Ba^{++}$ (17), une des molécules du ligande joue un rôle privilégié (intervention de six sites coordinants) par rapport à l'autre (intervention de deux sites coordinants).

Pour les trois ionophores, les p$K_a$ des groupements acide carboxylique d'une part et les constantes d'associations avec les cations alcalino-terreux d'autre part diffèrent. Le degré de formation de chacun des complexes varient donc de façon très spécifique avec le pH dans le méthanol, comme cela apparaît sur la figure 6, pour $Ca^{++}$. On notera que dans les domaines de concentrations choisis: pour A.23187 la formation du complexe 1:1 est faible et présente un maximum vers pH ~ 4; elle est beaucoup plus importante pour X.14547, avec un maximum voisin de pH 8. Pour X.537 A, elle est totale à partir d'un pH de l'ordre de 7. Le complexe 2:1 se forme à très bas pH pour A.23187 alors que pour X.14547 A il apparaît vers pH 8.

Les mesures effectuées en phase homogène, dans le méthanol, font ainsi apparaître une nette disparité de comportement de ces trois ionophores avec les cations divalents. On peut se demander comment cette différence se traduit dans un pro-

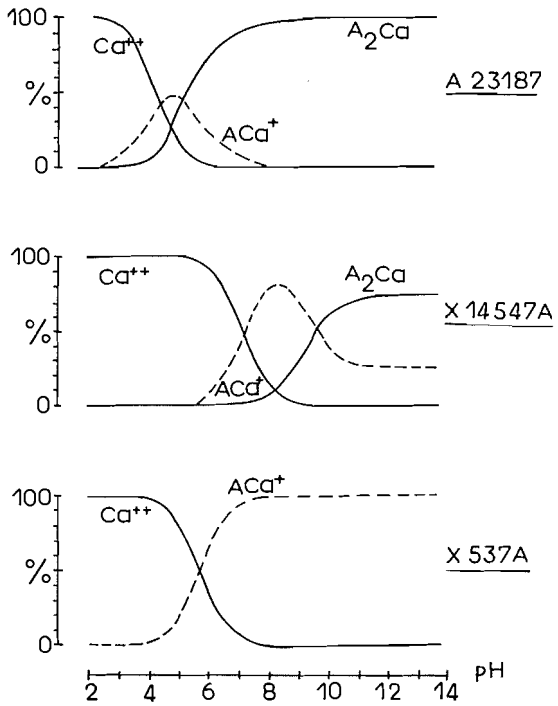

FIG. 6. Courbes de formation, dans le méthanol, des complexes du calcium avec les trois ionophores, en fonction du pH.

cessus de transport membranaire. Nous avons abordé ce problème avec différents types de membranes. Dans le présent travail nous apportons des éléments de réponse dans le cas d'une "membrane épaisse liquide" constituée par du chloroforme. Le cation examiné est $Ca^{++}$ dont l'activité biologique est liée à son mouvement transmembranaire, mouvement que les biologistes ont abondamment étudié ces dernières années en se servant précisément des ionophores X.537 A et A.23187.

*Transport de $Ca^{++}$ à travers une phase chloroformique*

Les variations de flux observées (Fig. 3), pour les trois ionophores étudiés, montrent clairement que la dissociation de la fonction acide est une des étapes importantes du transport. Dans la mesure où les trois phases sont agitées, nous pensons que les processus de diffusion peuvent être négligés et seuls les phénomènes intervenant aux interfaces sont pris en compte. Le fait que les flux observés pour divers ionophores puissent être très différents conforte cette hypothèse. Dans toutes les expériences effectuées, le pH du compartiment d'arrivée est maintenu constant, ce qui autorise une analyse des résultats en se référant seulement au premier compartiment aqueux où a lieu l'extraction du cation par l'ionophore. Dans la succession des équilibres envisageables à l'interface eau/chloroforme, schématisés sur la figure 7 pour un processus limite simple, on voit que la dissociation du transporteur constitue l'étape d'initiation du transport. Les $pK_a$ des ionophores ne sont pas connus à l'interface; nous sommes amenés à supposer qu'il existe une corrélation entre ceux-ci et ceux mesurés dans le méthanol; nous avons fait la même démarche pour les constantes des réactions correspondant aux étapes 2 et 3.

Après l'étude de Reusch et Cussler (25), Kirch et Lehn (26), puis Lamb *et al.* (27) ont pu pour des macrocycles neutres de synthèse, en utilisant une cellule du même type que la nôtre, montrer qu'il existe une relation entre vitesses de transport des cations alcalins et alcalino-terreux et constantes d'associations mesurées dans le méthanol. Dans le cas des transporteurs à fonction dissociable, une étude a été réalisée pour la monensine (28), les auteurs utilisent une cellule à diaphragme imprégné d'octanol. Notre approche expérimentale est différente, la phase intermédiaire chloroformique est agitée, par ailleurs cette étude implique un ionophore carboxylique et un cation divalent, le nombre d'étapes à prendre en considération est nécessairement plus élevé que pour tous les travaux précédemment cités. Il est également vraisemblable que les mécanismes diffèrent d'un ionophore à l'autre. Nous pouvons seulement faire ici, comparant les ionophores deux à deux, un certain nombre de remarques qui découlent de l'examen des tableaux 2 et 3 pour l'ion $Ca^{++}$ et des figures 3 et 5.

A.23187 et X.14547 A ont des $pK_a$ très voisins, ils devraient présenter des valeurs de $pH_{1/2}$ proches si la déprotonation de l'acide était l'étape détermi-

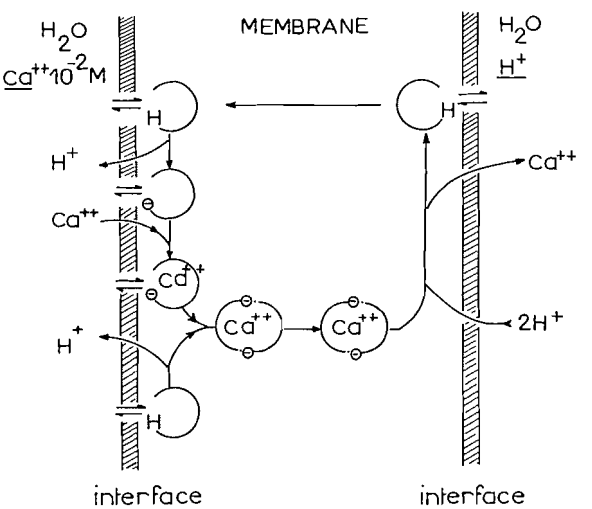

FIG. 7. Schéma limite possible pour l'extraction d'un ion $Ca^{++}$ à l'interface eau/chloroforme (les processus de libération de $Ca^{++}$ à l'autre interface sont en cours d'étude).

nante; en fait, le premier ionophore a une valeur $pH_{1/2}$ très nettement inférieure ce qui s'explique par des constantes de formation des complexes $\beta_4$ et $\beta_5$ nettement plus élevées. X.14547 A et X.537 A présentent des constantes $\beta_4$ du même ordre de grandeur, leur $pK_a$ diffère nettement; ceci se retrouve sur les valeurs de $pH_{1/2}$ qui varient dans le même sens. A.23187 et X.537 A ont des $pH_{1/2}$ très voisins bien que leurs $pK_a$ soient différents ainsi que leurs constantes $\beta_4$. Les grandeurs $\log \beta_7 = pK_a - \log \beta_4$ représentatives de l'équilibre

[7] $AH + M^{++} \rightleftharpoons AM^{+} + H^{+}$

sont par contre voisines pour les deux ionophores (respectivement 2,7 et 3,8); ceci suggère que la formation du complexe 1:1 à partir de l'acide protonné serait l'étape limitante dans le transport. De nouvelles expériences sont en cours pour vérifier cette hypothèse.

Un certain nombre d'études ont été effectuées dans des membranes beaucoup plus proches de la membrane biologique. Kafka et Holtz (29) utilisent des bicouches de phosphatidylcholine dans lesquelles ils incorporent A.23187 ou X.537 A; les deux composés transportent $Ca^{++}$, mais avec une efficacité supérieure pour A.23187. Caswell et Pressman (30) aboutissent à la même conclusion en utilisant des vésicules reconstitués du réticulum sarcoplasmique. Nous avons fait l'observation inverse: le flux maximum atteint est supérieur pour X.537 A. Dans la cellule à "membrane liquide épaisse" utilisée, seuls les échanges ioniques aux interfaces interviennent dans la cinétique globale du transport, la diffusion du complexe n'étant pas à considérer du fait de l'agitation du compartiment central. Il est vraisemblable que dans le cas d'une membrane bicouche, la vitesse de translocation du complexe formé, d'un interface à l'autre, doit intervenir dans la cinétique globale du transport, de ce fait, les valeurs $J_{max}$ obtenues avec ces deux types de membranes ne sont pas nécessairement comparables.

Wulf et Pohl (31) ont étudié d'une manière approfondie le transport de $Ca^{++}$ par A.23187 dans des bicouches de phosphatidylcholine. Il est intéressant de noter que le flux mesuré est multiplié par 5 lorsque le pH augmente de 6 à 8, ce qui est en bon accord avec nos observations dans la membrane chloroformique, tant du point de vue de l'augmentation du flux que de la zone de pH. Il semble donc que nous puissions, dans une certaine mesure, utiliser notre technique simple pour modéliser le comportement de ces ionophores dans une membrane biologique. X.537 A et A.23187 apparaissent alors comme des transporteurs de $Ca^{++}$ intéressants compte tenu de leur zone de pH efficace, ceci a été amplement prouvé par les études biologiques. Il nous paraît, par contre, peu probable que X.14547 A soit un transporteur efficace de $Ca^{++}$, au pH physiologique.

NOTE: Pendant la soumission de ce travail, une intéressante étude concernant le transport des ions alcalins par des ionophores carboxyliques de synthèse, dans une membrane épaisse liquide, a été publiée dans ce journal (32).

# Aryl radicals from hexazadienes and tetrazenes

DONALD MACKAY AND DEANE DOUGLAS MCINTYRE

*Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1*

Received September 29, 1981

DONALD MACKAY and DEANE DOUGLAS MCINTYRE. Can. J. Chem. **60**, 990 (1982).

Aryl radicals are produced from both ends of the hexazadienes **1** and **2** and from the tetrazene **3**, either thermally or photolytically. They attack aromatic compounds in the nucleus, the yield of biaryl being in the range 40–70%, though it can be made nearly quantitative by using *m*-dinitrobenzene as an additive. The aryl radicals also oxidize 2-propanol to acetone, the reduction products being the halogenobenzene and 1,2-diacetylhydrazine.

Photolysis of **1** goes mainly by way of the tetrazene **3**, and this may also be a significant pathway in the thermal reaction. Azodiacetyl is an intermediate in the thermal reaction of **1** with 2-propanol and may be generally so in all its reactions.

Radical induced decomposition is believed to be important in the reactions of **1**, **2**, and **3**, and it is probably responsible for the formation of 1-acetyl-1-arylhydrazines, routinely produced in yields of up to 25%.

---

DONALD MACKAY et DEANE DOUGLAS MCINTYRE. Can. J. Chem. **60**, 990 (1982).

On a préparé des radicaux aryles à partir des deux extrêmités des hexadiènes **1** et **2** et à partir du tétrazène **3** soit thermiquement ou photochimiquement. Ils attaquent les composés aromatiques au niveau du noyau, le rendement en dérivés biaryles étant de l'ordre de 40 à 70%. Ce rendement peut être quantitatif si on utilise le *m*-dinitrobenzène comme additif. Les radicaux aryles oxydent également le propanol-2 en acétone, avec comme produits de réduction l'halogénobenzène et la diacétyl-1,2 hydrazine.

La photolyse du composé **1** se fait principalement au moyen du tétrazène **3** et ceci peut constituer également un mécanisme important dans la réaction thermique. L'azodiacétyle est un intermédiaire dans la réaction thermique du composé **1** avec le propanol-2 et il peut en être ainsi dans toutes ses réactions.

On pense que la décomposition induite par les radicaux est importante dans les réactions des composés **1**, **2** et **3** et qu'elle est probablement responsable de la formation des acétyl-1 aryl-1 hydrazines, produits couramment avec des rendements allant jusqu'à 25%.

[Traduit par le journal]

## Introduction

The thermal decomposition of linear N to N unsaturated polyaza compounds, like that of simple azo compounds, is expected to yield radicals. There is a common presumption, which is generally but not invariably true, that the more N atoms there are in the system the less stable it is. Thus polyaza compounds with more than four contiguous N atoms are expected to decompose more easily than tetrazenes or triazenes.

Pentazadienes (1), hexazadienes (2) (there is no record anywhere of a heptaza compound), and octazatrienes (3) have all been known for over 70 years, though since then there have been relatively few references to their chemistry. In many of the reactions described radical pathways are either not involved or are not clearly established. Examples in which nitrogen–nitrogen homolysis has been demonstrated are found for 1,3,5-tri-*p*-tolyl-1,4-pentazadiene both by a product study of its thermolysis in cumene (4), and by the observation of a CIDNP effect in $CHCl_3$ at 70°C (5), and for other pentazadienes by their ability to initiate polymerization (6–8). Octazatriene homolysis was inferred in the case of 1,8-di-*p*-tolyl-3,6-diphenyl-1,4,7-octazatriene by its reaction with cumene (9), and in the case of the tetraphenyl analogue by the successful polymerization of ethylene (8).

One hexazadiene has been used as a polymerization initiator (8) but, in the only other papers describing this class of compounds (10, 11), no reactions are reported which are unambiguously homolytic in nature.

Recently we carried out a crystal determination on 1,6-di-*p*-chlorophenyl-3,4-diacetyl-1,5-hexazadiene (**1**) (12), which showed that its *N*-acetyl groups had an unusually high degree of single bond character in the C to N bond (1.403 Å) and of double bond character in the C to O bond (1.200 Å). This led to the prediction that the acetyl group should be very electrophilic, which was verified by its ability to form esters from alkoxides and phenoxides and acetamide derivatives from primary and secondary amines; the amine reactions showed very high selectivity, particularly to steric factors. In all these and in the hydrolysis reactions described by earlier workers (10) heterolytic cleavage of **1** is obviously involved. Since no product studies have been carried out in any reaction of a hexazadiene where homolysis might be likely, we decided to extend our work with **1** in that direction.

We report here on the efficient production of *p*-chloro- and *p*-bromophenyl radicals by thermolysis and photolysis both of the hexazadienes **1** and **2**, and of the tetrazene **3** whose chemistry is interconnected with that of **1** in some of these reactions.

2 Ar = $p$-$BrC_6H_4$

## Results and discussion

The hexazadienes **1** and **2**, prepared by the coupling of two equivalents of the diazonium solution with one of diacetylhydrazine (10, 12), are extraordinarily stable once purified. Samples of **1** remain unaffected indefinitely at room temperature, even in an open atmosphere and unprotected from light. Its stability in solution to acids (10) and to hindered secondary amines (12) has been noted. It has a half-life of several hours in refluxing benzene (though it accelerates thereafter), and of almost 5 minutes in refluxing chlorobenzene.

Though 1-aryl-3,4-diacetyl-1-tetrazenes have been implicated as intermediates in the formation of hexazadienes (10), **3** is the first example of such a compound isolated and characterized. It crystallizes as a monohydrate in excellent yield when a solution of $p$-chlorophenyldiazonium chloride is added to a carbonate solution of one equivalent of diacetylhydrazine.[1] It also is stable to ambient conditions but decomposes very much more rapidly in solution than the hexazadienes; immediate and copious evolution of nitrogen is observed when a solution in benzene is heated.

Dilute solutions (usually 0.025 *M*) of **1** or **2** were completely decomposed in refluxing benzene (80°C) or chlorobenzene (131°C), or in bromobenzene (also at 131°C). Quantitative analysis of the yields of the major products, the biaryls and diacetylhydrazine, were determined by high resolution gas–liquid chromatography (glc).

The coupled products obtained in benzene were $p$-chlorobiphenyl from **1** and $p$-bromobiphenyl from **2**. In chlorobenzene **1** and **2** gave all three 4′-halo-chlorobiphenyls and the analogous 4′-halo-bromobiphenyls in bromobenzene. Yields were in the range of 40–70%. The absence of other significant coupling products, and in particular the *o*:*m*:*p* isomer ratios observed in chlorobenzene and bromobenzene, are unmistakeably diagnostic of the involvement of $p$-chloro- and $p$-bromophenyl radicals (13, 14).

[1]It crystallizes out in fact much more rapidly than **1**, which can cause problems in the synthesis of the latter. On occasion we had to resort to making **1** in a laboratory in which **3** had never been prepared or worked with.

The tetrazene **3** was also decomposed (a much faster reaction) in both refluxing benzene and chlorobenzene. The isomer ratios from the latter solvent are again indicative of $p$-chlorophenyl radical reactions, though the $o$-ratio is rather higher and the $p$-ratio lower than in the corresponding reaction of **1** in chlorobenzene (Table 1).

The yields of biaryls and their isomer ratios from thermolysis of **1–3** in chlorobenzene and bromobenzene are shown in Table 1, along with the yields and ratios from related thermolyses to be discussed later.

The following compounds were not detected (< 1%, glc) in the pyrolysis reactions: $p$-chlorophenyl azide and 1-$p$-chlorophenyl-3-acetyltriazene,[2] $p,p'$-dichloroazobenzene, 1,2-di-$p$-chlorophenylhydrazine, $p$-chloroaniline, $p$-chloroacetanilide, and 1-$p$-chlorophenyl-5-methyltetrazole, an expected hydrolysis product of **3** (10) (by which route it was synthesized), or of 1-$p$-chlorophenyl-4-acetyltetrazene (15).

Since the biaryls and diacetylhydrazine are the major products, the main overall process must be the dehydrogenation of the initially formed arylcyclohexadienyl radicals (13, 14) by one or more intermediates containing the *N*,*N*′-diacetyl fragment (reaction [1]).

[1] $ArC_6H_5Z\cdot \xrightarrow{[O]} ArC_6H_4Z + (MeCONH)_2$

A plausible set of steps leading to these products from both the hexazadiene **1** and the tetrazene **3**, are shown in reactions [2]–[12]. Reactions [2][3] and [8] suppose only spontaneous fission of substrate. If induced fission also occurs, as appears to be the case for **1** at least, many other decomposition pathways are possible. Of those leading to biaryls[4,5] the processes involving the diazanyl radical **6** (from reactions [6] or [8]), or the cyclohexadienyl radical **5** (from reaction [3]) are probably important examples; these are shown in reactions [9]–[12]. Indeed [11] and [12] between them, in chain reac-

[2]The triazene was shown in a control experiment to be stable to the reaction conditions. These two products are quantitatively formed in the reaction of **1** with nucleophiles (10, 12).

[3]We reject as unlikely the one-step decomposition of the hexazadiene to 2 Ar· + 2 $N_2$ + MeCON=NCOMe.

[4]Another route to biaryls of course, is the disproportionation of 2 moles of the arycyclohexadienyl radical to biaryl and cyclohexadiene; this is significant only if oxidation or trapping of the radical cannot intervene (see later discussion).

[5]Attack of Ar· on **1** or **3** would give the symmetrical biaryl. In view of the high reactivity and hence low concentration of such radicals this reaction is unlikely in dilute solution. No $p,p'$-dichlorobiphenyl was obtained when **1** was decomposed in benzene.

tions together with [3], could account completely for the formation of biaryl from **1** and **3**.

The spontaneous or induced decomposition of **1** or **3** (reactions [2], [8], [9], [11], [12]) produces aryl radicals, directly if loss of $N_2$ is concerted with fission, or otherwise by way of unstable aryldiazenyl radicals $ArN_2^{\cdot}$. Evidence in favour of the latter can be found in the decomposition of 1,3,5-tri-*p*-tolyl-1,4-pentazadiene (5). If the radicals $ArN_2^{\cdot}$ are involved we assume that loss of $N_2$ precedes attack on the solvent by reaction [3].

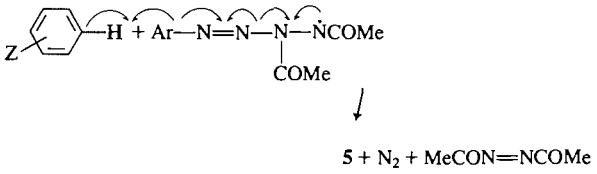
Certainly they do not attack the solvent to form N to C bonds, since neither azo compounds nor the related diarlyhydrazines were detected in the reactions.

Reaction [3] normally provides the only route to the cyclohexadienyl radical **5** in radical arylations, but reaction [5] suggests another mechanism by which formation of **5** might become possible, the driving force being the creation of two stable molecules (Scheme 1). This could be a concerted reaction between **4** and ArH (Scheme 1), or a two-step process with **4** first decomposing to the aryl radical, followed by reaction [3].



SCHEME 1

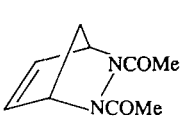
The oxidation of **5** to biaryl can take place either by a neutral molecule or by encounter with another radical. An example of the former is reaction [6], in which the dehydrogenating power of an azodicarbonyl compound is utilized. So too are reactions [11] and [12], in the induced decomposition, the radical source (**1** or **3**) being the oxidizing agent. The analogous oxidation of the phenylcyclohexadienyl radical by benzoyl peroxide in benzene has been shown to be significant even in dilute solution (16). Oxidation of **5** by another radical is exemplified by reactions [4] and [7]. Processes of this type are very important in radical arylations where induced decomposition of the radical source is absent. They have ample precedent in the unimolecular decomposition of diaroyl peroxides in aromatic solvents (13, 14, 16).

Examination of reactions [2]–[12] shows that two stable intermediates have been invoked, the tetrazene **3** and azodiacetyl. These may, but need not, be independent of each other. For example, in the unimolecular decomposition of **1** the sequence [2], [4], [8], [7], and in its induced decomposition the sequence [11], [12], involve only **3**. Similarly azodiacetyl only is produced in the sequence [2], [5], [6], [7] when **1** decomposes unimolecularly. Reaction [9] of course produces both, as do sequences like [2], [4], [5], [6]. In the decomposition of **3** azodiacetyl could be involved, as in sequence [8], [10], [5].

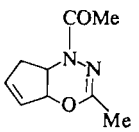
While both intermediates are probably involved in thermolysis of **1**, we believe azodiacetyl is of greater importance than the tetrazene.

This choice is made on the basis of the different isomer ratios found in the thermolysis of **1** and **3** in chlorobenzene. The tetrazene **3** gives *o* and *p* ratios of 61 and 14% and a total dichlorobiphenyl yield of 60%. If the thermolysis of **1**, which gives *o* and *p* ratios of 51 and 22% and a total biaryl yield of 67%, goes only by way of **3**, and the latter again gives a 60% biaryl yield, then it follows that the first oxidation step in the thermolysis (reaction [4] in the sequence [2], [3], [4]) affords an *o* and *p* ratio of 43 and 29%. This amount of divergence from the normal spread of *o*/*p* ratios, produced by other sources of aryl radicals, has not been observed in any other work and we regard it as quite unlikely.[6]

We tried to detect the intermediacy of azodiacetyl by allowing a solution of **1** in refluxing chlorobenzene to decompose in the presence of a large excess of cyclopentadiene, in the hope that the latter might trap the azo compound as its known adduct **7** (17). Much polymeric material from the diene was formed, and a reduced yield of biaryl, but no trace of **7** or its product of thermal rearrangement **8** (17) could be detected by glc analysis. Azodiacetyl is evidently more efficiently trapped by **5** than by the diene at this temperature. Using the diene, however, in the reaction of **1** with 2-propanol at 83°C (described below), the involvement of azodiacetyl was established, and so it is reasonable that it can also be an intermediate in the reactions in aromatic solvents.



7



8

Photolysis of **1** or **3** also yields aryl radicals. Decomposition in benzene or chlorobenzene at 10°C with a medium pressure mercury lamp gave diacetylhydrazine and biaryl; the yields and isomer ratios are shown in Table 2. The lower temperature allowed the reaction of **1** to be monitored by $^1$H nmr spectroscopy for the presence of the thermally labile azodiacetyl or tetrazene. While the former could not be conclusively detected, the tetrazene was seen to be the major coproduct of the first arylation step, an observation consistent with the closeness of the isomer ratios in the photolysis of **1** and **3** in chlorobenzene (cf. the thermolysis results). Concentrations of **3** greater than 60% of theoretical (determined by $^1$H nmr analysis) were obtained before separation of solids made further analysis

[6]The spread of ratios between **1** and **3** is quite large but is within the range observed in arylations with different radical sources in other reported work (14).

TABLE 2. Yields (%) of products[a] of photolysis[b] of **1** and **3** in benzene and chlorobenzene

| | | Biaryl | | | |
|---|---|---|---|---|---|
| | | | Isomer ratios | | |

| **1** | $C_6H_6$ | 65 | | | |
| | $C_6H_5Cl$ | 43 | 62.7 | 24.4 | 12.9 |
| **3** | $C_6H_6$ | 82 | | | |
| | $C_6H_5Cl$ | 48 | 66.5 | 21.0 | 12.5 |

[a]1,2-Diacetylhydrazine and 1-acetyl-1-arylhydrazine also produced but yields not determined.
[b]450 W lamp.
[c]Measured as for Table 1.

unreliable (Table 3). Work-up of a partially reacted solution gave a slightly impure sample of **3**.

Though the yields of biaryls in the reactions described were moderate to good they showed some degree of variation among themselves, even with duplicate runs on the same system.[7] A limiting factor in the success of the reaction is, of course, the ability of the cyclohexadienyl radical **5** to get oxidized to biaryl before it either disproportionates to the cyclohexadiene and biaryl or couples to the tetrahydroquaterphenyl (13, 14). This problem has been addressed in great detail in diaroyl peroxide chemistry, particularly by Hey and by Williams, and their co-workers. They found that a range of N=O containing additives (nitrobenzene, *m*-dinitrobenzene, nitrosobenzene, azoxybenzene) greatly improved the yield of biaryl and aroic acid (the coproduct of the oxidation–reduction), without being chemically changed themselves (18, 19). The use of nitrobenzene in the decomposition of benzoyl peroxide in benzene was examined in detail (19). It was shown that "the nitro group effect" operates by trapping the very reactive phenylcyclohexadienyl radical, probably by σ-bond addition

TABLE 3. Proportions (%)[a] of **1**, **3**, and other Me-containing products from photolysis[b] of **1** in benzene

| Initial [1] | Time (min) | 1 | 3 | Other |

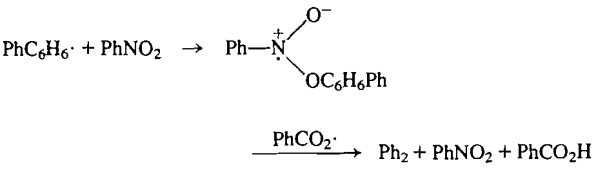
[7]The isomer ratios, however, remained constant (± 1.6%).



SCHEME 2

at nitro oxygen (Scheme 2), the new, more stable, radical being capable of survival till encounter with the benzoyloxy radical gives benzoic acid, biphenyl, and recovered nitrobenzene.

This approach to optimizing yields has not to our knowledge been applied to arylations from radical sources other than peroxides, but the principle should be equally applicable. In reactions of **1**, radicals such as **4** and **6** take the place of the benzoyloxy radical. We repeated the thermolysis of **1** in bromobenzene with 0.67 molar equivalent of *m*-dinitrobenzene and obtained yields of >90% of both the chlorobromobiphenyls and diacetylhydrazine.

The isomer ratio was not significantly changed and is thus independent of yield, a point firmly established in peroxide work (20). Gas–liquid chromatography showed that the dinitrobenzene was recovered, and though its amount was not measured, the nearly quantitative nature of the arylation establishes that its role must again have been strictly catalytic. This result suggests that reactions like [4] and [7] are important, and that induced decomposition alone (reactions [11], [12]) cannot be responsible for biaryl formation.

Degassing the solution and maintenance of a nitrogen atmosphere during the decomposition of **1** in bromobenzene caused a large reduction in the yield of biaryl, with an increase in the amount of material appearing in the late stages of the chromatogram. Thus oxygen has a beneficial effect in the reactions in untreated solvents, explaining the slight variations of yields in the latter. High oxygen levels were deleterious, since decomposition of **1** in bromobenzene in the presence of the dispersed gas gave a reduction in yield and the appearance of many new products in the chromatogram. This result is at variance with others involving diaroyl peroxides (20, 21), where a dramatic increase in biaryl yields and a reduction of side products was clearly demonstrated. Oxidative degradation of **1** is presumably a competing process.

The hexazadienes were also decomposed in other representative monosubstituted benzenes. Isomer ratios were determined, but not yields, though glc again showed that in all cases the biaryls and diacetylhydrazine were by far the major products. These results are also shown in Table 1.

Both **1** and **2** gave very similar results in iodobenzene; there is a notable absence of any steric effect, even for attack of the *p*-bromophenyl radical at the *o*-position. A similar isomer distribution is reported in the decomposition of the corresponding diaroyl peroxides in iodobenzene, but radical displacement of iodine was also observed leading to the aryl iodides (22). We did not look for these in our reactions.

In the reaction of **1** in toluene there was very little side chain attack, less than 5% of that of ring substitution where the isomer ratios were similar to those observed in the halogenated benzenes. *p*-Chlorobenzoyl peroxide attacks the side chain of toluene more extensively (11%), but substitution ratios have not been reported (23). In biphenyl **1** gave the expected monochloroterphenyls, in a ratio predictably low in the *o*-isomer, and similar to that found in the benzoyl peroxide reaction (24).

In our earlier work with **1** it was shown to be a mild and selective acetylating agent for primary and secondary amines (12). We considered that it might also function as an acetylating agent towards an electron-rich aromatic nucleus in the presence of a Friedel–Crafts catalyst. In fact with anisole containing $AlCl_3$ there was no evidence of the formation of methoxyacetophenones. The methoxybiphenyls were produced in the normal free radical ratio, similarly observed without the catalyst and noted by others (20).

2-Propanol was chosen as a readily oxidizable solvent in which **1** might be expected to react readily by aryl (or other) radical abstraction. The oxidation of ethanol by **1** has already been demonstrated, though a mechanism was not determined (10). Radical oxidation of 2-propanol has been effected by benzoyl peroxide, both phenyl and benzoyloxy radicals being involved (25), as well as by other radical sources (26, 27). Reaction of **1** was rapid at the bp of the alcohol, giving acetone (not estimated), chlorobenzene (81%), and diacetylhydrazine (99%). Similar reaction of **2** gave bromobenzene (90%). Since the products are equally consistent with an ionic mechanism, we tried to prove the involvement of radicals by repeating the oxidation in an equimolar mixture of alcohol and chlorobenzene. A low yield (21%) of the three dichlorobiphenyls was obtained in the normal isomer ratio for radical attack.[8] Since this isomer mixture was rapidly obtained at a temperature (83°C) at which **1** itself reacts very slowly, the presumption is that *p*-chlorophenyl radicals are generated by reaction with the alcohol. The stoicheiometry of the oxidation is thus described by [13] and the mechanism must operate mainly by induced decomposition. Reasonable sets of steps are shown in reactions [14]–[20].

[13] $\mathbf{1} + 2\,Me_2CHOH \rightarrow 2\,C_6H_5Cl + 2\,N_2 + MeCONHNHCOMe + 2\,Me_2CO$

[14] $Ar\cdot + Me_2CHOH \rightarrow ArH + Me_2\dot{C}OH$

[15] $Me_2\dot{C}OH + \mathbf{1} \rightarrow Me_2CO + ArH + N_2 + ArN{=}N{-}\underset{\displaystyle COMe}{\underset{|}{N}}{-}\dot{N}COMe$ (**4**)

[16] $\mathbf{4} + Me_2CHOH \rightarrow ArH + N_2 + MeCON{=}NCOMe + Me_2\dot{C}OH$

(or $\mathbf{4} \rightarrow Ar\cdot + N_2 + MeCON{=}NCOMe$, followed by [14])

[17] $Me_2\dot{C}OH + MeCON{=}NCOMe \rightarrow Me_2CO + MeCONH\dot{N}COMe$ (**6**)

[18] $\mathbf{6} + Me_2CHOH \rightarrow MeCONHNHCOMe + Me_2\dot{C}OH$

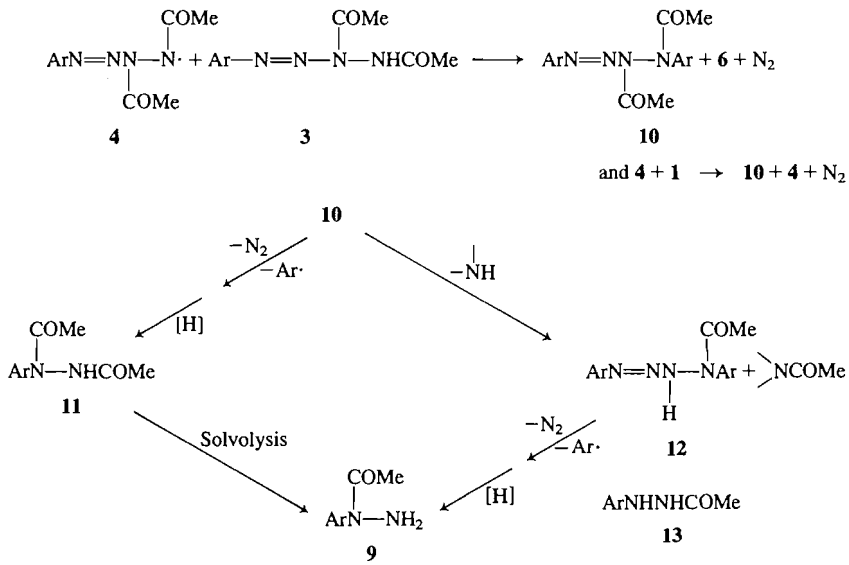
[19] $\mathbf{4} + Me_2CHOH \rightarrow \mathbf{3} + Me_2\dot{C}OH$

[20] $Me_2\dot{C}OH + \mathbf{3} \rightarrow Me_2CO + ArH + N_2 + \mathbf{6}$

Initiation by, for example, the aryl radicals (reaction [14]) gives the 2-hydroxy-2-propyl radical which with **1** gives **4**, but which is regenerated by reaction of **4** with alcohol (reaction [16], in a one- or two-step process). The sequence [15], [16] is thus a chain process completing the reduction of both equivalents of aryl radicals and the oxidation of one equivalent of alcohol. The other product, azodiacetyl, completes the oxidation of alcohol by the repeating sequence [17], [18] which involves the radical **6**. Alternatively **4** can react with alcohol to give **3** and the 2-hydroxy-2-propyl radical (reaction [19]); these react to product and **6**, which with alcohol completes the chain (reactions [20], [18]). Thus a sequence involving azodiacetyl ([15]–[18]) or one involving tetrazene ([15], [19], [20], [18]) is possible, but we made no attempt to assess the relative contributions of these. However, we were able to confirm the involvement of azodiacetyl at least, by repeating the oxidation in the presence of cyclopentadiene. The glc analysis of the products showed the formation of both the adduct **7** and its thermal isomer **8**. The amounts were not estimated.

Consistently reported in yields of 10–25% in Tables 1, 2, and 3 is the formation of 1-acetyl-1-*p*-chloro(or -bromo)phenylhydrazine (**9**) in thermal and photolytic reactions of **1**, **2**, or **3**. It was absent, or almost so, only in the reaction of **1** with 2-propanol, and with chlorobenzene in the presence of *m*-dinitrobenzene, where the yields of

[8]Even in the absence of added chlorobenzene the amount generated in the alcohol oxidation was sufficient to allow the formation of a detectable mixture of the dichlorobiphenyls.



SCHEME 3

chlorophenyl-containing products were very high.

No obvious simple pathway to this product is apparent, involving as it does overall aryl migration to an acetyl-bearing nitrogen, followed by *N*-acetyl cleavage β to the aryl group. Spontaneous aryl migration in **1** or **3** is possible but is much less likely than an intermolecular aryl transfer from **1** or **3** to a suitable *N*,*N*′-diacetyl containing nitrogen-centred radical. By far the best candidate is the radical **4** and we propose that the key intermediate generated is the (presumably) unstable 1,4-diaryl-3,4-diacetyl-1-tetrazene (**10**). Its formation from **4** and possible reactions leading from it to **9** are shown in Scheme 3.

A sequence of spontaneous or induced homolysis of **10**, followed by hydrogen abstraction by the resulting radical ArN(COMe)NCOMe, would give the *N*,*N*′-diacetylarylhydrazine (**11**). However, **11** does not seem a probable precursor for **9**. It is difficult to imagine a mechanism for the transformation **11** → **9** except one of selective solvolysis, which would require a more reactive nucleophile than any likely to be present in the reaction.

We propose that deacetylation of **10** occurs directly to give **12**. The acetyl group on the nitrogen α to the azo group is expected to be highly electrophilic (12), and a mild nucleophile should be capable of displacing it. The nucleophile must be a basic nitrogen derivative, though certainly not *p*-chloroaniline, since both it and its acetyl derivative were not reaction products.[9] Conversion of **12** → **9**[10] would again involve radical decomposition and hydrogen abstraction of the resulting radical ArN(COMe)NH·.

Since **9** is the only reaction product containing both the aryl and diacetylhydrazine fragments we thought that it might be the major product when **1** was decomposed in the absence of solvent. Injection of an ethereal solution of **1** in the inlet of the gas chromatogram (250°C, a temperature at which **1** explodes in the condensed state) indeed gave **9** (25%) as well as diacetylhydrazine (24%) as by far the major simple products, though the yield is no greater than in other decomposition reactions. Chlorobenzene (8%), not otherwise routinely tested for, was also a product; so too was *p*,*p*′-dichlorobiphenyl, in very low yield, but significantly free of the *o*- or *m*-isomers. It must arise by the induced decomposition: $p$-$ClC_6H_4$· + **1** → ($p$-$ClC_6H_4)_2$ + $N_2$ + **4**. Pyrolysis of **1** at 150°C, dispersed thinly on the surface of sand, gave an almost identical result.

Though we have not succeeded in isolating **9**, its identity has been clearly established. Work-up of the photolysate of **1** in benzene gave a fraction very rich in **9** (glc). The $^1H$ nmr of this fraction showed a strong absorption in the acetyl region as well as the expected *p*-chlorophenyl splitting pattern. A gc–ms analysis showed it had a mol. wt. of 184 (based

[9]A variety of basic products may be involved since no other peak of major significance in the glc chromatogram was unaccounted for.

[10]The alternative decomposition of **12** → $ArN_3$ + ArNHCOMe would be analogous to the solvolysis pathway observed for **1** with bases to give $ArN_3$ + ArN=NNHCOMe (10, 12). However, in the latter reaction the triazenyl anion is the leaving group and has a resonance stabilization not matched by the anilide anion.

on $^{35}Cl$), one Cl atom (isotope ratio), and one acetyl group (strong $M - 42$ peaks); the products from the sand pyrolysis also showed a very intense peak at *m/e* 184. We were able to rule out the other monoacetyl isomer **13**, since an authentic sample of it had a shorter glc retention time, thus confirming the structure as **9**. An attempt to synthesize **9**, by acetylation of 1-*p*-chlorophenyl-2-formylhydrazine followed by acid hydrolysis, gave a mixture of mono and diacyl *p*-chlorophenylhydrazines of which **9** was one (glc coinjection with a pyrolysis reaction mixture).

## Experimental

Melting points are uncorrected. Infrared spectra were recorded on a Beckman IR-10 spectrometer. Nuclear magnetic resonance spectra were obtained on a Perkin–Elmer R12B ($^1H$) or a Bruker WP-80 ($^1H$, $^{13}C$) spectrometer, and are referred against internal tetramethylsilane. All gas–liquid chromatographic analyses were carried out on a Hewlett–Packard 5830 or 5840A Chromatograph with flame ionization detection and He or $N_2$ as carrier gas; glass columns 6 ft × 1/8 in. id with an Aue packing of Carbowax 20M on Chromosorb W were used. Gas chromatographic – mass spectrometric measurements were made on a Hewlett–Packard 5992 instrument. Conventional mass spectra were run on a Varian MAT-CH7.

*Starting materials and reference compounds*

Solvents were dried by conventional methods, but were not degassed for most routine decompositions. For reactions done in the absence of oxygen the solvent was first refluxed to expel all gases and an atmosphere of $N_2$ then maintained during the decomposition.

*Hexazadienes 1 and 2*

These were prepared as described earlier (10, 12).

*1-p-Chlorophenyl-3,4-diacetyl-1-tetrazene (3)*

A freshly prepared solution (150 mL) of *p*-chlorophenyldiazonium chloride from *p*-chloroaniline (12.7 g, 0.10 mol), sodium nitrite (6.9 g, 0.10 mol), and 12 *M* hydrochloric acid (50 mL) was added to a stirred ice-cold solution (300 mL) containing 1,2-diacetylhydrazine (11.6 g, 0.10 mol) and sodium carbonate (50 g), covered with diethyl ether (100 mL; it efficiently removes colored impurities and dissolves very little of the product at this temperature). There was rapid separation of **3** as the colorless crystalline hydrate. Stirring was continued for 15 min, the whole was filtered, the product washed with water and dried, finally, in a vacuum desiccator over phosphorus pentoxide; $^1H$ nmr analysis showed it to be the monohydrate (16 g, 65%).

A purified sample of **3** could not be obtained crystalline and free of solvent. In solvents not rigorously dried it formed the hydrate, and from anhydrous solvents containing ether the solid obtained showed ether in its $^1H$ nmr spectrum. Prolonged evacuation was without effect on the bound solvents. Solutions of **3** could be dried with magnesium perchlorate and gave water-free spectra, but evaporation of such solutions gave a gummy residue.

It was best recrystallized from undried chloroform-pentane as the monohydrate, which melted with decomposition at 90°; ν(anhydrous $CHCl_3$): 3405 (NH), 1720 (C=O) $cm^{-1}$; $^1H$ nmr ($CDCl_3$) δ: 8.05 (1H, s, NH), 7.3–7.6 (4H, m, $ClC_6H_4$), 2.60 (3H, s, N(3)—$COCH_3$), 2.17 (3H, s, N(4)—$COCH_3$); $^{13}C$ nmr ($CDCl_3$) δ: 170.4, 168.4 (C=O), 146.1 (C1), 135.7 (C4), 129.4 (C3), 123.8 (C2), 22.0 ($CH_3$), 20.5 ($CH_3$). *Anal.* calcd. for $C_8H_{11}ClN_4O_2 \cdot H_2O$: C 44.05, H 4.80, N 20.54; found: C 43.92, H 4.78, N 20.49%.

*p*-Chlorobiphenyl was prepared from *p*-chloroaniline by the Gomberg–Hey reaction (28). *p*-Bromo-*p'*-chlorobiphenyl was obtained by bromination of *p*-chlorobiphenyl in acetic acid, and *p,p'*-dichlorobiphenyl by chlorination of biphenyl in acetic acid (29); *p,p'*-dibromobiphenyl was obtained in an analogous manner (30).

1-Acetyl-2-*p*-chlorophenylhydrazine (15) was made from *p*-chlorophenylhydrazine and one equivalent of acetic anhydride.

*Gas–liquid chromatographic analyses*

Biphenyl was used as an internal standard for all glc analyses.

In the case of the *p,p'*-dihalogenated biphenyls the linearity of response (signal area) over a 10-fold range of concentrations ($10^{-3}$–$10^{-2}$ *M*, greater than that encountered in the experimental work) was established; the standard deviation for six trials was 1.6%. It is known that for halogenated biphenyls the FID response shows almost no variation between different isomers (31). Thus the calibration for all isomers was based on results from standard solutions of the *p,p'*-isomer and biphenyl.

1,2-Diacetylhydrazine gave a nonlinear FID response especially at very low concentrations. A calibration curve was determined using ten standard solutions spanning the concentration range of interest. In most of the decomposition reactions the diacetylhydrazine separated out of the solution. Addition of methanol to give a homogeneous solution was necessary before the glc determination was carried out. The yield of diacetylhydrazine was not determined in all reactions.

For the determination of 1-acetyl-1-*p*-chlorophenylhydrazine (**9**) the isomeric 1-acetyl-2-*p*-chlorophenylhydrazine (**13**) was used. It was assumed they would have the same FID response.

*Determination of half-life of 1*

A solution of **1** and dimethyl phthalate (as internal standard) (0.26 *M* each) in benzene in an nmr tube was immersed in refluxing benzene and the proton spectrum run at intervals. A first order plot became nonlinear after a few hours, showing that the reaction was accelerating. The half-life was about 6.4 h.

In refluxing chlorobenzene the half-life was less than 5 min.

The half-life of **3** in refluxing benzene could not be readily determined since evolution of nitrogen began almost immediately on warming.

*Thermolyses*

The thermal decompositions in solution were carried out using 20 mL of ca. 0.025 *M* solutions of **1**, **2**, or **3**, at suitable temperatures: benzene 80°C, chlorobenzene, bromobenzene, iodobenzene, 131°C; anisole, 100°C; biphenyl, 190°C; 2-propanol, 83°C. The reactions were followed by observing the disappearance of the acetyl methyl singlets in the $^1H$ nmr spectrum.

Where yields were determined a known weight of biphenyl was added to the solution after completion of the reaction.

In the case of the reaction of **1** with benzene and chlorobenzene the final solutions were evaporated and the hexane-soluble portions of the residue worked up to give *p*-chlorobiphenyl and *p,p'*-dichlorobiphenyl. These were crystallized from methanol and identified by mixture mp.

*Photolyses*

Irradiation by a 100 or a 450 W Hanovia medium pressure mercury immersion lamp was used through quartz walls.

Routinely solutions 0.026 *M* (reactor volume 250 mL) in **1** or **3** were photolyzed (450 W) at a temperature of about 10°C. Samples were periodically removed and monitored in the aliphatic region by $^1H$ nmr spectroscopy. The complete decomposition required about 6 h for **1** and 2 h for **3**.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

*Work-up of products of photolysis of 1 in benzene*

The photolysate from complete reaction of **1** (2.0 g) in benzene (250 mL) was evaporated to dryness and the residue extracted with refluxing pentane (2 × 100 mL). The pentane solution afforded 1.0 g (52%) of almost pure *p*-chlorobiphenyl; recrystallized from methanol it had mp and mixture mp 144–145°C. The pentane-insoluble fraction was then extracted with refluxing ether (2 × 100 mL) which yielded a residue (0.72 g) which had both aromatic and methyl (several peaks) absorption in its $^1$H nmr spectrum. A major component was **9** (δ 2.0), which was established by gc–ms evidence, as described later. The pentane- and ether-insoluble residue contained diacetylhydrazine, which was isolated as the insoluble product obtained on addition of chloroform.

*Detection of 3 as intermediate in photolysis of 1*

A total of 4 mL of a solution of **1** (0.15 *M*) in benzene was divided among seven 5-mm nmr tubes arrayed around the 100 W lamp. Photolysis was carried out and the proton spectrum was periodically checked using different tubes randomly. After 1 1/2 hours the balance between **3** and accumulating by-products was judged to be optimal and the reaction was stopped. The combined solutions were set aside whereupon crystallization of a small amount of material soon occurred. The $^1$H nmr spectrum of the crystals showed them to consist of the tetrazene **3** (δ(Me) 2.60 and 2.17, and the characteristic water peak at ca. 2.7) contaminated by a small amount of diacetylhydrazine.

*Kinetic analysis of photolysis of 1 in benzene (see Table 3)*

A 5-mm nmr tube containing a solution of **1** (0.26 *M*) in benzene was irradiated by the 100 W lamp as described above. Integration at suitable intervals of the methyl region of the proton spectrum enabled the proportions of **1**, **3**, and all other methyl-containing products to be determined. After the midpoint of the reaction separation of solid precluded further analysis.

The experiment was repeated at half the concentration (0.13 *M*). In this case the solution remained clear till after 80% of the reaction was complete. As expected this reaction was much slower, but the relative proportions of products were essentially unchanged.

The estimated error in the analysis was about ± 3%.

*Effect of additives or catalysts on 1*

In the decomposition of **1** in bromobenzene the following variations were carried out (substrate concentration as before): (*i*) 0.67 mol of *m*-dinitrobenzene included; (*ii*) solvent first degassed by refluxing, then $N_2$ atmosphere maintained during reaction; (*iii*) $O_2$ passed through solution during reaction.

In the anisole reaction the decomposition was carried out both without catalyst and with 3 mol of $AlCl_3$.

*Azodiacetyl trapping experiments*

(*i*) A solution of **1** in chlorobenzene was heated in the usual manner (131°C) except that cyclopentadiene (10 mL) was added dropwise with stirring during the course of the reaction. The glc analysis failed to detect the presence of either of the adducts **7** or **8** (17).

(*ii*) The experiment was repeated using refluxing 2-propanol as solvent. Both adducts **7** and **8** were observed in the glc, their identity being confirmed by coinjection with authentic samples of the adducts.

*Identification of 1-acetyl-1-p-chlorophenylhydrazine (9)*

Refluxing of *p*-chlorophenylhydrazine with ethyl formate for 30 min gave the 2-formyl derivative (70%), mp 185.5–186.5°C (lit. (32) mp 186–187°C).

The formyl derivative (0.10 g) was heated with acetic anhydride (1 mL) for 1 hour. Evaporation and examination of the residue by $^1$H nmr spectroscopy showed it consisted of a mixture of products. The mixture was hydrolyzed by heating it in 1 *N* $H_2SO_4$ (25 mL) for 15 min at 100°C, neutralized with $Na_2CO_3$, and extracted with ether. Gas–liquid chromatography of the extract showed a mixture having one peak with the same retention time as the major, otherwise unidentified, product obtained in the thermolysis and photolysis reactions; coinjection with a worked-up sample rich in this product (from a photolysis reaction as described above) gave a single peak. The retention time was longer than that of synthetic 1-acetyl-2-*p*-chlorophenylhydrazine.

The enriched sample was also subjected to gc–ms analysis which showed the product to have a parent peak at *m/e* 184 ($^{35}$Cl), one chlorophenyl ring (isotope ratio), and an acetyl group (strong peak at *m/e* 142). In the mass spectrum of the pyrolysate from the sand reaction, the peak at *m/e* 184 was the most intense. The combination of glc and ms evidence thus establishes the product as **9**.

*Decompositions without solvent*

(*i*) *Gas-liquid chromatographic injection*

A 3 μL sample of a solution of **1** (0.025 *M*) in ether containing biphenyl as internal standard was introduced into the injection port (250°C) of the gas chromatograph; the chromatogram was run under the usual operating conditions.

(*ii*) *Pyrolysis on sand*

Clean sand (20 g) was added to a solution of **1** (0.50 g, 1.27 mmol) in dichloromethane (20 mL) and the solvent removed on a rotary evaporator. The coated sand was then heated at 150°C under a Dry-Ice condenser until the reaction was judged to be complete (15 min, by which time the surface of the sand was very discolored). The product was extracted with ether, and the solution and ethereal washings from the condenser combined. Internal standard was added and the solution analyzed in the usual way.

# $^{13}C$ nuclear magnetic resonance and Raman investigations of aqueous carbon dioxide systems

THERESA M. ABBOTT,[1] GERALD W. BUCHANAN, PEETER KRUUS, AND KEITH C. LEE[2]

*Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6*

Received September 17, 1981

THERESA M. ABBOTT, GERALD W. BUCHANAN, PEETER KRUUS, and KEITH C. LEE. Can. J. Chem. **60**, 1000 (1982).

$^{13}C$-nmr spectra of carbon dioxide in water are reported for a wide range in pH. Chemical shifts were determined for the following species: $CO_2(g)$, $CO_2(aq)$, $HCO_3^-(aq)$, $CO_3^{2-}(aq)$. A linear relationship was found between the shift of the $^{13}C$ line and the fraction of carbonate ion calculated to be present, as well as between the ratio of the area under the 1067 $cm^{-1}$ (carbonate) Raman peak to the sum of the area under the 1067 $cm^{-1}$ and 1017 $cm^{-1}$ (bicarbonate) peaks and the fraction carbonate.

THERESA M. ABBOTT, GERALD W. BUCHANAN, PEETER KRUUS et KEITH C. LEE. Can. J. Chem. **60**, 1000 (1982).

On rapporte les spectres de rmn du $^{13}C$ du bioxyde de carbone dans l'eau et à des pH très variés. On a déterminé les déplacements chimiques des espèces suivantes: $CO_2(g)$, $CO_2(aq)$, $HCO_3^-(aq)$, $CO_3^{2-}(aq)$. On a trouvé une relation linéaire entre le déplacement des pics du $^{13}C$ et la fraction de l'ion carbonate qui existe d'après les calculs; on a aussi décelé une relation linéaire entre le rapport de la surface du pic Raman à 1067 $cm^{-1}$ (carbonate) sur la somme des surfaces des pics à 1067 et 1017 $cm^{-1}$ (bicarbonate) et la fraction carbonate.

[Traduit par le journal]

## Introduction

Carbon dioxide is of vital interest in the chemistry of natural waters, both with regard to inorganic (e.g. refs. 1–3) and biochemical (e.g. ref. 4) aspects. The species and reactions involved are usually taken to be the following:

[1] $CO_2(g) \rightleftharpoons CO_2(aq)$

[2] $CO_2(aq) + H_2O \rightleftharpoons H_2CO_3(aq)$

[3] $H_2CO_3(aq) \rightleftharpoons H^+(aq) + HCO_3^-(aq)$

[4] $HCO_3^-(aq) \rightleftharpoons H^+(aq) + CO_3^{2-}(aq)$

[5] $K^+(aq) + CO_3^{2-}(aq) \rightleftharpoons (KCO_3)^-(aq)$

The existence of the species $H_2CO_3(aq)$ has been postulated due to kinetic considerations (5, 6). No actual spectroscopic evidence of this species seems to exist, and quantum mechanical calculations suggest that it is not a stable species in the gas phase (7, 8). Stable species with two hydroxyl groups on one carbon are also rare in organic chemistry.

Even if $H_2CO_3(aq)$ were a stable species rather than a transition state, it would be present only in a very small amount relative to $CO_2(aq)$ due to the low value of the equilibrium constant in [2] (5). In calculations, $CO_2(aq)$ and $H_2CO_3(aq)$ are often considered together (1) as

[6] $$[H_2CO_3^*(aq)] = [H_2CO_3(aq)] + [CO_2(aq)] \simeq [CO_2(aq)]$$

The square brackets indicate concentration in mol $L^{-1}$ ($M$).

Reactions [3] and [4] involve only proton transfers and have rapid reaction rates, with relaxation times of the order of $10^{-9}$ s (9). This is less than the characteristic time for nmr measurements, but greater than that for Raman spectroscopy. Thus nmr will average the $^{13}C$ over its environments as the species $CO_3^{2-}(aq)$, $HCO_3^-(aq)$, and possibly $H_2CO_3(aq)$. Raman spectroscopy will however differentiate between these species.

The ion pairing reaction [5] is shown for the $K^+$ and $CO_3^{2-}$ ions, as this is the most likely equilibrium to be of consequence in the studies reported here. Equilibria involving divalent cations are of more importance in natural waters (3), and the $HCO_3^-$ ion would also be involved in such equilibria (10, 11). It is not certain whether Raman spectroscopy would distinguish between species such as $CO_3^{2-}$ and $K^+$. $CO_3^{2-}$ as the influence of the neighbouring $K^+$ may not be sufficient to change the vibrational modes of $CO_3^{2-}$ significantly. The presence of $K^+$ next to $CO_3^{2-}$ would affect the chemical shift of $^{13}C$, but again the magnitude of this effect is not known.

Considering the importance of the carbon dioxide – water system, it is surprising that only one $^{13}C$-nmr study has been carried out on it (12). Some $^{13}C$ nmr, however, has been used to study the enzyme catalysis of reactions [2] and [3] (4). Raman studies have been carried out previously on this system (13–15).

A more thorough $^{13}C$-nmr study is reported here, with the nmr results evaluated in the context of the

assumed speciation reactions [1] to [5]. The discussion is supported by further Raman data and speciation calculations.

## Experimental

$^{13}C$ nmr spectra were determined at 25.16 MHz using a Varian XL-100-12 spectrometer equipped with a Nicolet TT-100 Fourier Transform data system. Chemical shifts were measured relative to an external methanol capillary and were converted to the TMS scale using a value of 49.3 ppm for the $^{13}C$ shift of neat methanol (16). Spectral widths were 5000 Hz and 8 K data points were employed. Typically the pulse angle was 45° and the pulse delay, 1 s. In nearly all cases, standard 5 mm tubes were used, but thick-walled 8 mm tubes were used for some samples when pressures above 1 atm (up to 10 atm) were present (samples 27, 28 in Table 1). Spectra were taken at 305 ± 2 K in nearly all cases.

Samples with a pH > 7 were made up by mixing the appropriate amounts of solutions of $K_2CO_3$ and HCl (samples 1 to 24 in Table 1). Samples with total carbon dioxide content $C_c$ of the order of 0.5 *M* (samples 1 to 11) were made up with natural $K_2CO_3$ (Fisher Certified Reagent), but a small amount (< 10%) of $^{13}C$-enriched $K_2CO_3$ (90% $^{13}C$ Merck, Sharp and Dohme) was added to some of these samples. Lower concentration samples (12 to 24) were made up with isotope-enriched $K_2CO_3$.

The stock solution of isotope-enriched $K_2CO_3$ was made up in $D_2O$ as deuterium is required as a frequency lock for $^{13}C$ spectra on the XL-100. Thus many of the samples were primarily in $D_2O$. Some ordinary water was present from the HCl solution, but this was usually a small amount as concentrated (> 1 *M*) acid was used. Measurements of pH (or pD) were taken on a Fisher Accumet Model 620 with an E-5A electrode. For samples 1 to 24, the pH was taken at 305 K. There is an increase of 0.10 in the pH at 305 K as compared to the 293 K value for most solutions.

Samples with pH < 7 (26 to 34) were prepared by introducing a sample of water (26 to 28) or a solution of base (NaOH or $NH_4OH$, 20 to 34) into an nmr tube, attaching the tube to a vacuum system, freezing the contents by immersing the tube end in liquid nitrogen, evacuating the system, subliming measured amounts of $^{13}C$-enriched $CO_2$ gas (90% $^{13}C$ Merck, Sharp and Dohme) into the tube, sealing the tube with a glass-blowing torch, and removing it to allow for equilibration. It was not possible to measure the pH of these sealed samples; approximate concentrations are given in Table 1.

Samples for Raman spectrometry (Table 2) were also made up in nmr tubes by the method described for nmr samples 1 to 24.

†% Area modified by scattering coefficients from ref. 14.
‡Na rather than K salt.
§Using eqs. [7] to [12].

Ordinary $K_2CO_3$ and water were used; the presence of deuterium introduces an extra line (due to $DCO_3^-$) into the spectrum. Only samples with $C_c \simeq 0.5\ M$ were prepared, as 0.05 $M$ samples would have insufficient scattering for reasonable resolution. A Jobin-Yvon Raman HG2S spectrometer with a CR-4 or CR-12 ion laser was used. Curve resolution of the spectra (Fig. 1) was done using the curve-resolving program of the Nicolet 1180 system computer. A Lorentz–Gaussian distribution (20% Gaussian) was used to form the resolved peaks. Spectra were taken at room temperature (293 ± 2 K).

## Results and discussion

*(a) Positions of nmr lines (acidic range)*

Table 1 indicates the $^{13}C$ shifts for various samples using the $\delta_c$ scale relative to TMS = 0. Spectra of the liquid portion of samples 26 and 27 ($CO_2$ in $D_2O$) show a line at 125.9 ± 0.1 ppm. The major species present must be $CO_2$(aq) in these samples. Patterson and Ettinger (12) report 125 ppm for $CO_2$(aq), and Stothers (16) quotes it as 124.2. A change of solvent (to $H_2O$) does not change the peak position to a noticeable extent. The position is also relatively insensitive to temperature (samples 26 to 34).

The spectrum of sample 28 (high pressure $CO_2$) taken with part of the gas phase observed showed an additional peak at 124.5 ppm. This must correspond to $CO_2$(g).

The spectra for samples 29 and 30 are shown in Fig. 2. With a greater amount of base (sample 29), the magnitude of the $HCO_3^-$(aq) peak at 161.3 ppm is increased relative to the $CO_2$(aq) peak at 125.9 ppm. Quantification of peak sizes and $CO_2/HCO_3^-$ ratios cannot be easily done since accurate analysis of the sample contents was not possible for the sealed samples, and since the magnitudes of the $^{13}C$ peaks are not necessarily proportional to the concentrations. The 161.3 ppm position for $HCO_3^-$(aq) found here compares well with the 161 ppm in ref. 12 and 160.0 ppm in ref. 16. Again there is little temperature dependence for this resonance (samples 33, 34).

Separate peaks exist for $CO_2$(aq) and $HCO_3^-$(aq) as the kinetics of exchange between these species (reactions [2], [3]) is relatively slow (6). Use of an enzyme such as carbonic anhydrase speeds up the kinetics so that line broadening is present (4), but coalescence of lines is not achieved.

The $H_2CO_3$(aq), if present as an equilibrium species (7), is present in very small quantities relative to $CO_2$(aq). Extrapolation of the peak positions of $CO_3^{2-}$(aq) (at 169.5 ppm) and $HCO_3^-$(aq) (at 161.3 ppm), suggests that the $H_2CO_3$(aq) peak should be at about 153 ppm. Such a peak would be so small relative to the $CO_2$(aq) peak (of the order of 1:600) that it would not be observable with the XL-100. The presence of $H_2CO_3$(aq) should, in principle, shift the position of the $HCO_3^-$(aq) peak from 161.3 towards 153 ppm due to the rapid exchange (reaction [3]). However, as $H_2CO_3$(aq) would never be present to an appreciable extent relative to $HCO_3^-$(aq), then such a shift would not be observable in practise.

Peaks were observed at 151.5 ppm in several samples such as 31 and 32. As indicated in Fig. 2, the 151.5 ppm peaks were observed when both the 125.9 and 161.3 ppm peaks were present (sample 31) and with only the 125.9 ppm present (sample 32). This 151.5 ppm peak was, however, not stable with time. After the tubes had aged for a month, it was no longer observable. A species such as $H_2CO_3$ may have been formed on the glass surface in the procedure used for preparation of such sam-

ples, and the equilibration time for such species may be greater than the allowed-for day or two. Non-equilibrium conditions in aqueous carbon dioxide systems are not unknown (e.g. ref. 17).

*(b) Calculation of concentrations of species*

A discussion of the experimental results from Raman and $^{13}$C-nmr spectroscopy of basic solutions involves quantitative analysis of the concentrations of $HCO_3^-$(aq) and $CO_3^{2-}$(aq). The pH, the total concentration of carbon dioxide species, $C_c$, and the concentration of other ions ($K^+$, $Cl^-$), $C_I$, are known in these samples.

Stumm and Morgan (1) give the basic equations for such a calculation for an ideal state, where concentrations equal activities:

$$[7] \quad [CO_3^{2-}] = C_c \left[ \frac{[H^+]^2}{K_1 K_2} + \frac{[H^+]}{K_2} + 1 \right]^{-1}$$

$$[8] \quad [HCO_3^-] = C_c \left[ \frac{[H^+]}{K_1} + \frac{K_2}{[H^+]} \right]^{-1}$$

$$[9] \quad [H_2CO_3^*] = C_c \left[ 1 + \frac{K_1}{[H^+]} + \frac{K_1 K_2}{[H^+]^2} \right]^{-1}$$

Here $[H_2CO_3^*]$ is defined by eq. [6] and the equilibrium constants $K_1$, $K_2$ are defined by [10] and [11] below.

Relationships [7–9] can be used for non-ideal systems if $K_1$, $K_2$ are taken to be concentration equilibrium constants, i.e.

$$[10] \quad K_1 = K_{1,c} = K_{1,a}/K_{1,y} = K_{1,a} \frac{1}{y_{H^+} y_{HCO_3^-}}$$

$$[11] \quad K_2 = K_{2,c} = K_{2,a}/K_{2,y} = K_{2,a} \frac{y_{HCO_3^-}}{y_{H^+} y_{CO_3^{2-}}}$$

Here $y$ is used to denote the activity constants on the molar scale. $K_{1,a}$ and $K_{2,a}$ are the activity equilibrium constants for reactions [3] and [4], and are thus invariant with concentrations and/or ionic strengths. The concentration equilibrium constants $K_{1,c}$ and $K_{2,c}$ are not invariant.

The molar activity coefficients $y$ can be calculated using several equations (18). Here an equation similar to that of Davies (18) was used.

$$[12] \quad \log_{10} y_i = -A z_i^2 \left( \frac{\sqrt{I}}{1+\sqrt{I}} - 0.2I \right)$$

Here $I$ is the ionic strength, $z_i$ the charge type of the $i$th species, and $A$ the Debye–Hückel constant (18). The Debye–Hückel limiting law and the Guntelberg equation (as [12] but with no $0.2I$ term) were also tested.

Calculations were done on a computer using iteration. First the $y_i$ were assumed to be unity and [7], [8], and [9] were used to calculate the concentrations with $[H^+] = 10^{-pH}$. The ionic strength was obtained from these results and the $y_i$ calculated using [12]. New equilibrium constants $K_1$ and $K_2$ were then obtained from [10] and [11] and $[H^+]$ set as $10^{-pH}/y_{H^+}$. A revised set of concentrations were calculated and the same procedure repeated until no further change occurred in the concentrations.

Some examples of results are shown in Table 3. The activity coefficients $y_{HCO_3^-}$ for the 0.05 *M* solutions agree to two significant figures with those in ref. 19. Those for the 0.5 *M* solutions are higher (0.72 as compared to 0.57 in ref. 19). The $y_{CO_3^{2-}}$ at high ionic strength compare reasonably with those calculated for surface sea water (3) (0.27 compared to 0.20). They are, however, vastly different to the experimental value (0.02) quoted in ref. 3.

Activity coefficients obtained from one experimental method are not always applicable to consideration of speciation using another method (9). The Raman and $^{13}$C-nmr data probably have insufficient resolution to differentiate between free $CO_3^{2-}$ and $CO_3^{2-}$ in the form of an ion pair. Conductivity and electromotive force experiments would, however,

exclude ion paired $CO_3^{2-}$ from being considered as $CO_3^{2-}$(aq). Thus values of $y_{CO_3^{2-}}$ should be considerably lower for emf and conductivity experiments than those relevant for Raman and $^{13}$C-nmr.

*(c) Raman spectra*

Raman spectroscopy of carbon dioxide in water is discussed in some detail in refs. 13–15. Here only the region around 1000 $cm^{-1}$ is of interest. As shown in Fig. 1, this region contains the 1067 $cm^{-1}$ ($CO_3^{2-}$) and the 1017 $cm^{-1}$ ($HCO_3^-$) bands.

Recent work on sulfuric acid (20) suggests that such bands can be further resolved to give separate, but overlapping, peaks for free and ion paired species. It was not attempted to resolve the peaks as shown in Fig. 1 further to test whether this could be the case for $HCO_3^-$ and $CO_3^{2-}$ lines. This may be possible in further, more extensive spectroscopic work. The degree of ion pairing in the solutions should be significant. A solution 0.5 $M$ in $K_2CO_3$ should have 53% of the $CO_3^{2-}$ in the form $(K^+ \cdot CO_3^{2-})^{-1}$, while a solution 0.5 $M$ in $KHCO_3$ should have 33% of $HCO_3^-$ as $(K^+ \cdot HCO_3^-)^0$ if ion pairing constants for the sodium salts (21) are assumed valid also for the potassium salts.

Figure 3 shows the ratio of the 1067 $cm^{-1}$ area to the sum of the 1067 $cm^{-1}$ and 1017 $cm^{-1}$ areas as plotted versus the percentage of $CO_3^{2-}$ as calculated using the procedure in (*b*). It is probably somewhat fortuitous that the plot is so close to a linear relation (correlation coefficient 0.996) as the scattering coefficients of these two bands are not necessarily equal.

Using the results in ref. 14, the scattering coefficient of the 1067 $cm^{-1}$ line is calculated to be 1.80 times that of the 1017 $cm^{-1}$ line. When this ratio is used, the relation in Fig. 3 is not as linear. The 1.80 ratio used was derived from intensity–concentration curves measured relative to the 459 $cm^{-1}$ band of $CCl_4$. However, in a previous publication (13), it is apparent that scattering from the 1067 $cm^{-1}$ band is more intense, but seemingly only by a factor of about 1.4 rather than 1.8.

The effect of the equation used to calculate the percentage of $CO_3^{2-}$ is shown in Fig. 3 to be of vital importance. Equation [12] appears to be quite reasonable for the calculation of $y$'s relevant to Raman spectroscopy, but it may be very misleading for $y$'s useful to an experimental method such as conductivity.

If $H_2CO_3$(aq) exists, then some signs of it should be apparent in Raman spectra at high $CO_2$ pressures; this was not observed (15).

*(d) Nuclear magnetic resonance spectra in the high pH range*

The position of the $^{13}$C peak for $CO_3^{2-}$(aq) seems to be at 169.5 ppm. This compares with 171 ppm reported in ref. 12 and 170.0 ppm in ref. 16. Sample 25, 6 $M$ in $K_2CO_3$, showed a peak at 170.3 ppm, but in such a concentrated solution (ion-to-water ratio 2:5) a very different environment from a more dilute solution should be expected to be present.

Figure 4 shows a plot of the resonance position for the 0.5 $M$ solutions as a function of the percentage $CO_3^{2-}$. As the exchange in reaction [4] is rapid, the shift would be 161.3 ppm for 0% $CO_3^{2-}$ (100% $HCO_3^-$), and 169.5 ppm for 100% $CO_3^{2-}$. It should vary linearly between these extremes as the chemi-

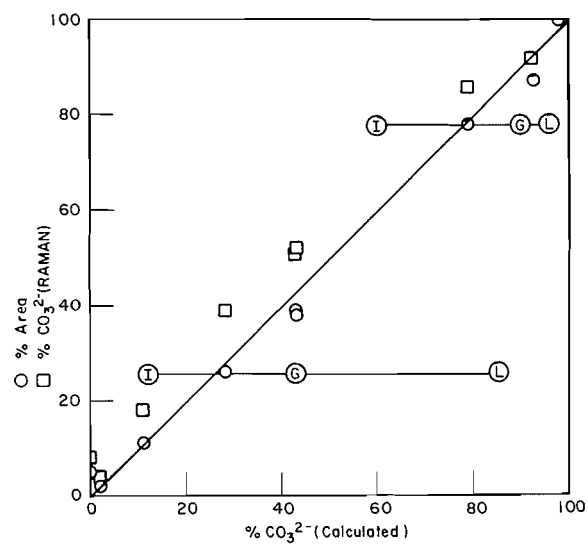

FIG. 3. Percentage area ○ and percentage of $CO_3^{2-}$ from Raman □ versus percentage $CO_3^{2-}$ calculated (data from Table 2). Ⓘ, Calculated percentage of $CO_3^{2-}$ assuming $y = 1.0$; Ⓖ, assuming $y$ follows the Guntelberg equation; Ⓛ, assuming $y$ follows the Debye–Hückel limiting law.

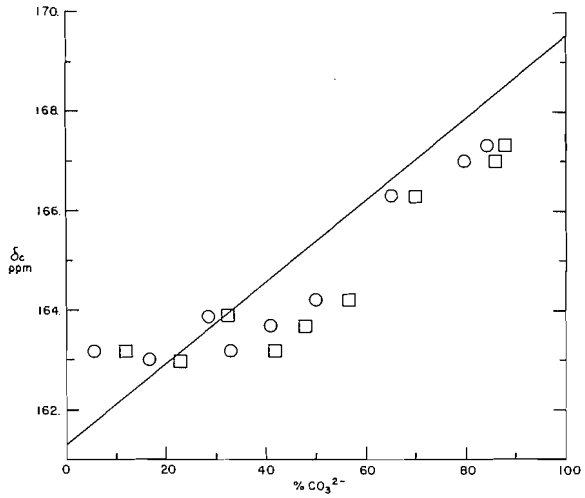

FIG. 4. $^{13}C$ chemical shift versus percent $CO_3^{2-}$ for $C_c \simeq 0.5\,M$ (samples 1–4, 6–11 in Table 1). ○, calculated percentage of $CO_3^{2-}$ ($K_2 = 5.32 \times 10^{-11}$), □ percentage of $CO_3^{2-}$ interpolated from Raman data as shown in Fig. 3.

cal shift would be the concentration average of the two values. Figure 4 shows points where the percentage of $CO_3^{2-}$ is given both as that calculated from eq. [12] and as that obtained by interpolation of a percentage of $CO_3^{2-}$ versus pH curve constructed from the Raman data in Table 2.

Neither set of points gives a particularly good fit to a linear relation (correlation coefficient 0.919). The Raman-derived percentage $CO_3^{2-}$ points have not been corrected for a change in temperature (293 K to 305 K) or for the presence of some $D_2O$ in the nmr samples (1 to 11). Such corrections would not change the positions of the points very much, and would increase the percentage of $CO_3^{2-}$ and bring most points even further off the curve.

The deviations are possibly due to ion pairing. It is likely that the presence of a $K^+$ ion would shift the $CO_3^{2-}$ signal towards the direction of the $HCO_3^-$, i.e. upfield, and also the $HCO_3^-$ signal upfield. The magnitudes of such shifts can not be determined on the basis of the data currently available.

Relatively dilute samples can be used for nmr studies if $^{13}C$-enriched material is used. A series of solutions with $C_c \simeq 0.05\,M$ (samples 12 to 24) were thus studied. For such lower ionic strength solutions, calculation of $y$'s through eq. [12] would be more meaningful and effects such as ion pairing would be smaller. Figure 5 shows that the calculated percentage of $CO_3^{2-}$ is for this case not quite as sensitive to the form of the equation used for $y$.

When the usual value of the dissociation constant for $HCO_3^-$ at 305 K is used ($5.32 \times 10^{-11}$), then as can be seen from Fig. 5, a plot of chemical shift versus the percentage of $CO_3^{2-}$ is definitely non-linear. The samples were, however, made up in $D_2O$, and according to ref. 22, the p$K$ of an acid with p$K \simeq 10$ is 0.62 units higher in $D_2O$. When a value $1.28 \times 10^{-11}$ is used for $K_2$, then the points approximate a linear relationship quite well (correlation coefficient 0.997). Table 3 indicates how large an effect a change in the $K_2$ value has on the calculated percentage of $CO_3^{2-}$ when pH $\simeq$ p$K_2$ (sample 17).

The uncertainty in the points in Fig. 5 is about $\pm 0.2$ ppm in the chemical shift and up to $\pm 5\%$ in the percentage of $CO_3^{2-}$. The temperature-control on the XL-100 can vary up to $\pm 2$ K, and such variations can change the value of $K_2$ by several percent.

## Conclusions

The $^{13}C$ nmr shifts of the various species present in a carbon dioxide – water system are as follows: $CO_2$ 124.5 ppm, $CO_2$(aq) 125.9 ppm, $HCO_3^-$(aq) 161.3 ppm, $CO_3^{2-}$(aq) 169.5 ppm. An unstable species with a shift of 151.5 ppm was also detected.

The $^{13}C$ nmr and Raman spectra obtained for samples at various pH are in agreement with the kinetics and equilibria assumed for the carbon dioxide – water system. No direct evidence of the species $H_2CO_3$(aq) was obtained.

Activity coefficients of relevance to these experimental methods can be obtained with reasonable accuracy from an equation such as the Davies equation, even at high ion strengths (> 1).

Further $^{13}C$-nmr studies of aqueous carbonate solutions seem promising as a means of increasing

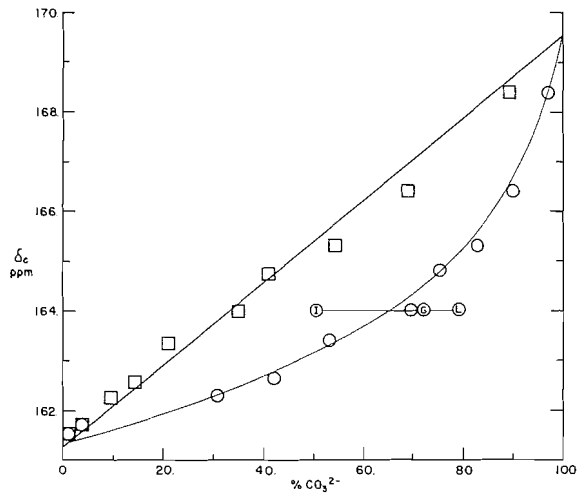

FIG. 5. $^{13}C$ chemical shift versus calculated percentage of $CO_3^{2-}$ for $C_c \simeq 0.5\,M$ (samples 12–17, 19, 21–24 in Table 1) ○, $K_2 = 5.32 \times 10^{-11}$; □, $K_2 = 1.28 \times 10^{-11}$. Ⓘ, $y = 1$; Ⓖ, $y$ from Guntelberg; and Ⓛ, $y$ from the limiting law.

understanding of speciation in such systems. It is necessary to make allowances for changes in equilibrium constants in these systems if heavy water is used.

M. TERESA NUNES, VICTOR M. S. GIL, and ANTÓNIO V. XAVIER. Can. J. Chem. **60**, 1007 (1982).

A full pH range $^1H$ and $^{13}C$ nmr study was performed of the complexation of $UO_2^{2+}$ with malic acid, for variable concentrations and molar ratios. Spectral evidence for the existence of at least five complexes was found, and their stoichiometry and dependence on pH were investigated. Information on the conformation of the bound ligand molecules was also obtained.

M. TERESA NUNES, VICTOR M. S. GIL et ANTÓNIO V. XAVIER. Can. J. Chem. **60**, 1007 (1982).

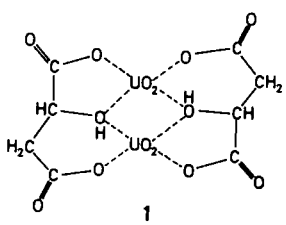
On a étudié la rmn du $^1H$ et du $^{13}C$ à tous les pH des produits de complexation de $UO_2^{2+}$ avec l'acide maléique à des concentrations et des rapports molaires variables. On a obtenu des preuves spectrales de l'existence d'au moins cinq complexes et on a étudié leur stoichiométrie et l'influence du pH. On a également obtenu des informations sur la conformation des ligands.

[Traduit par le journal]

## Introduction

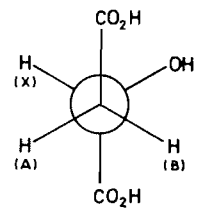
The interaction of uranyl ion with malic acid has been previously studied by potentiometric (1–4), polarographic (4, 5), spectrophotometric (1, 4, 6, 7), and polarimetric (8) methods. It has been found that, in equimolar solutions and for the pH region 2–4, a binuclear complex involving tridentate chelation is formed (as has also been shown for the solid by ir spectroscopy (9)); at pH > 4 this dimer seems to react further with hydroxyl ions to form ternuclear species (1, 2). Dimerization and trimerization constants have been reported (2, 10).

The nmr proton coupling constants and chemical shifts obtained for the binuclear complex 1:1 (0.2 *M* solution at pH = 3) gave indication about the type of dimer present (11), thus confirming the structure previously postulated by Rajan and Martell (3): OH groups of the ligands acting as bridges between the U atoms (**1**, or its isomer of $C_s$ symmetry)

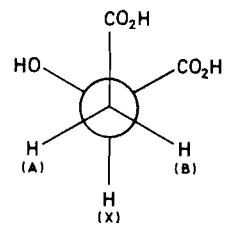


**1**

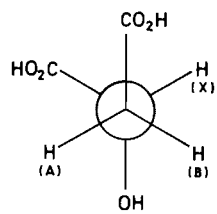
the ligand being in a conformation close to $c_1$



$c_1$



$c_2$



$c_3$

The pH range from 3 to 5.6 has also been investigated by proton nmr spectroscopy, using equimolar solutions (0.16 and 0.2 *M*); as a result, the simultaneous existence of three complexes was suggested (4): the monomer ($UO_2$) Mal, the dimer (**1**) and another dimer (**2**)

corresponding to an hypothesis proposed by Feldman *et al.* (1, 2, 11) and requiring $c_2$ as the ligand conformation.

Aiming at a clarification of the number and structure of the complexes, we report in this paper a full pH range study using $^1H$ and $^{13}C$ nmr spectroscopy. It being a very complicated system, due in particular to the hydrolysis of $UO_2(H_2O)_n^{2+}$ with the resulting formation of polynuclear species, we have only partly succeeded, and this on account of the great stability of the complexes formed and their being, in general, in sufficiently slow exchange for different spectra to be observed for different species.

## Experimental

$D_2O$ solutions (0.5 *M*), prepared from commercially available

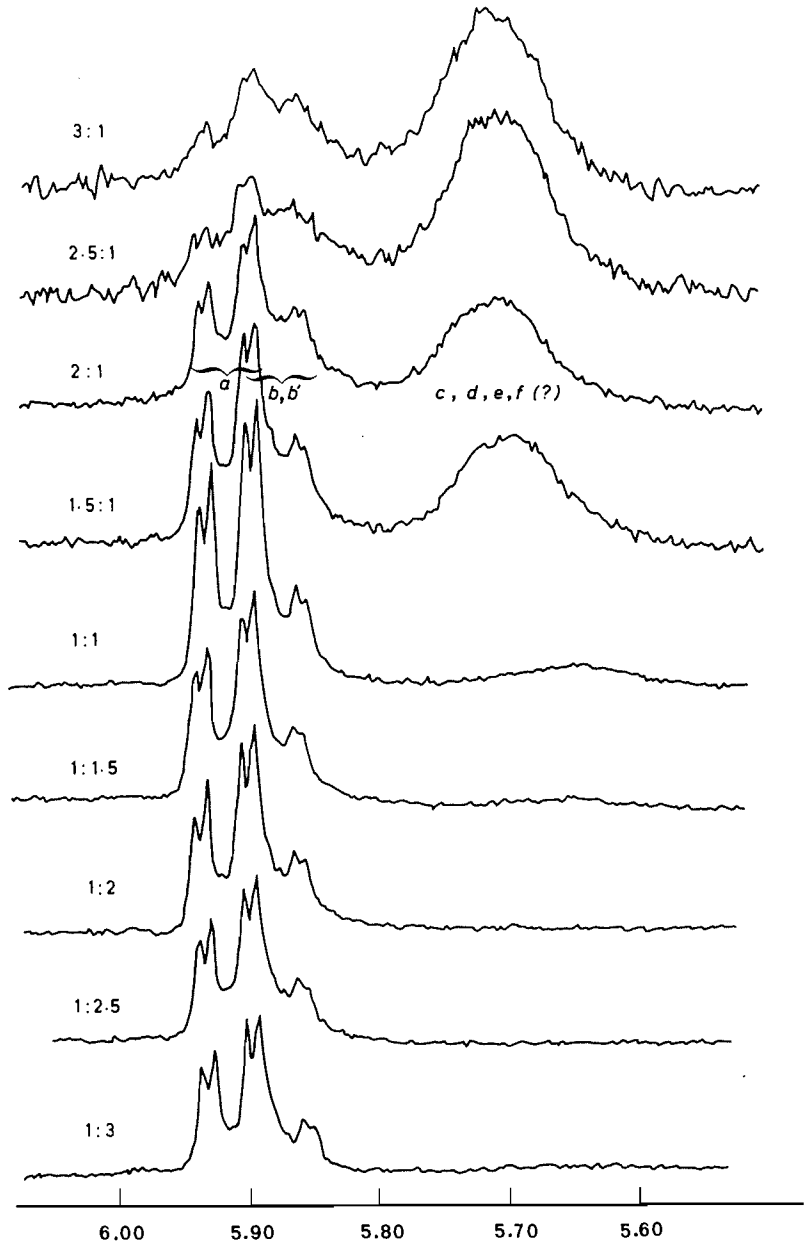

FIG. 4. X sub-spectra of bound ligand for pH* = 5.2, for variable metal/ligand ratios.

pure uranyl nitrate and (L) – malic acid, were standardized by gravimetry and potentiometry, respectively. The solutions actually used were obtained by dilution of those parent solutions and the pH was adjusted with NaOD and DCl; the pH* values quoted are the direct meter readings.

The $^1H$ spectra were recorded on a Bruker CXP-300 nmr spectrometer and in a JEOL PS-100 spectrometer in the Fourier transform mode. The $^{13}C$ spectra were run with proton decoupling on the JEOL spectrometer. *tert*-Butanol ($\delta = 1.23$) and *p*-dioxan ($\delta = 67.40$) were used as internal references, respectively, for $^1H$ and $^{13}C$ resonances. Unless otherwise specified, the measurements were done at 293 K.

## Results and discussion

### *$^1H$ nuclear magnetic resonance spectra*

The methylene and methine protons of malic acid give rise to an ABX spectrum, at 300 MHz. Depending on pH, from 2.7 to 10.7, and on the uranyl/malic acid molar ratio, at least seven different X signals of bound ligand are identified, besides that of free ligand when in excess (the case of 1:*n* molar ratios with $n \gtrsim 1.5$ for pH $\lesssim 9.5$ and $n \gtrsim 1$ for pH $\simeq 10.5$); the AB sub-spectra of bound species

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

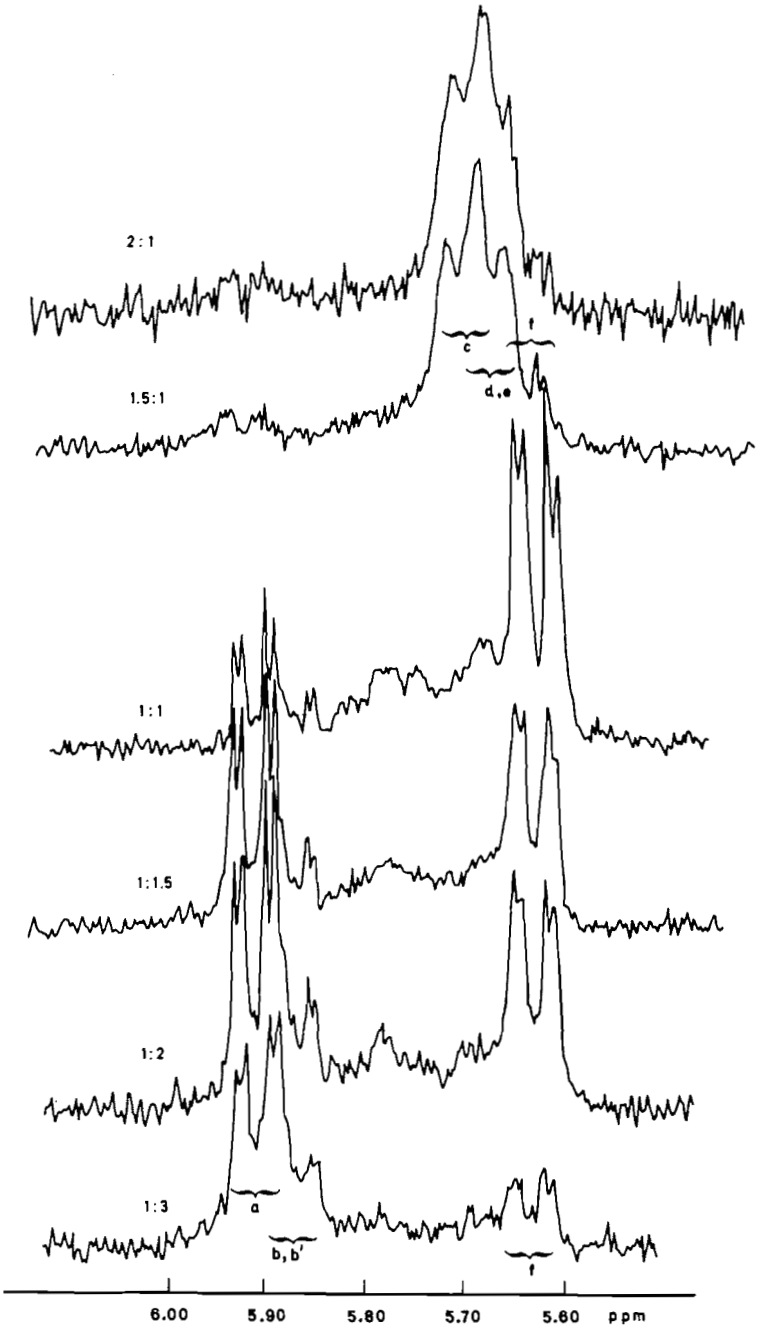

FIG. 5. X sub-spectra of bound ligand for pH* = 6.7, for variable metal/ligand ratios.

are in part suppressed. This AB pattern lies about 1.3 ppm to low field of the mid point of the AB sub-spectrum of free ligand; the low-field shift of the X signals upon complexation ranges from about 2.6 to 2.8 ppm. A typical full spectrum is shown in Fig. 1.

The fact that different spectra are observed for different species means that, at room temperature, they are undergoing exchange processes that are slow in the nmr time scale. However, some of the X-signals can be exchange broadened, the degree of broadening depending on pH and molar ratio.

Figures 2–6 show the X sub-spectra of bound ligand for pH* values ranging from 2.7 to 7.9 and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

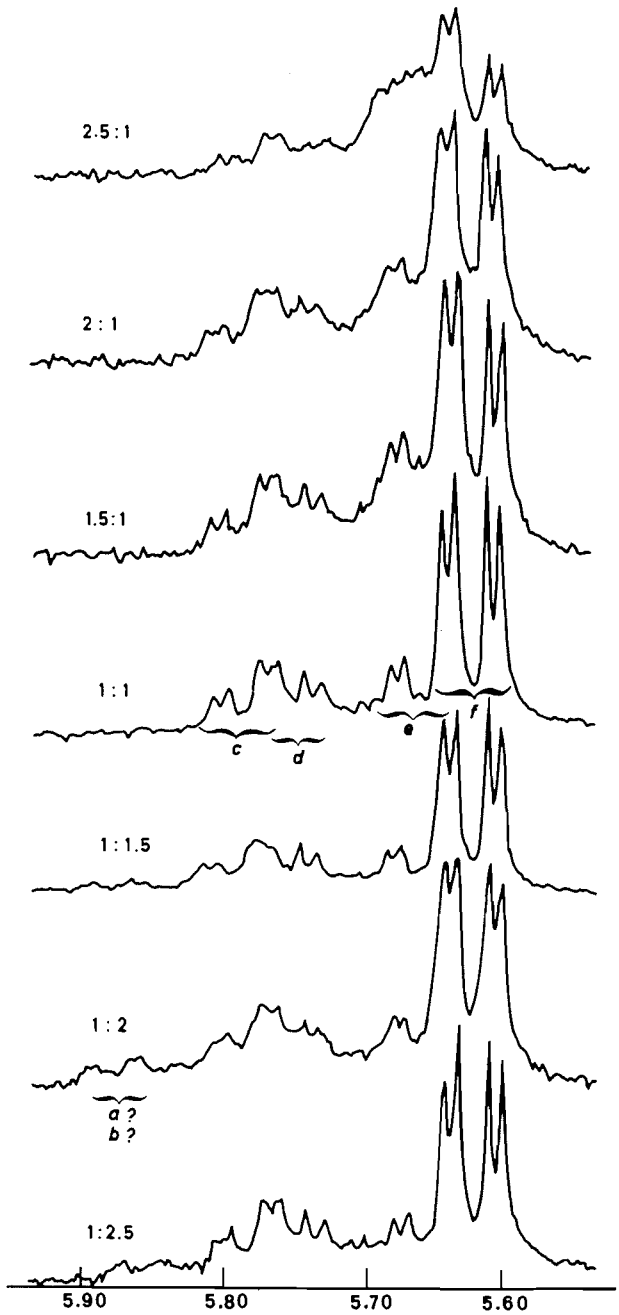

FIG. 6. X sub-spectra of bound ligand for pH* = 7.9, for variable metal/ligand ratios.

for variable molar ratios (usually, from 3:1 to 1:3); Fig. 7 shows the X signals obtained for three solutions (1:1, 1:1.5, and 1:2) at pH = 10.7. The total concentration of the complexing species ($UO_2^{2+}$ + malic acid) was kept constant (0.075 *M*), so that Job's plots based on the spectral intensities could be constructed, as shall be discussed later.

Two quartets a and b are clearly identified at pH* = 2.7 (Fig. 2) and pH* = 3.9 (Fig. 3); another less resolved signal (b') can be detected in the latter case. Quartet a is dominant for molar ratios from 1:3 up to 2:1, b becoming dominant for higher molar ratios, specially at pH* = 3.9.

At pH* = 5.2, quartets a and b remain, but a very broad signal at 5.66 ppm appears for molar ratios $n$:1 with $n \geq 1$ (Fig. 4). On increasing the pH of these solutions to pH* = 6.7, the broad signal sharpens (c, d, e), while the intensities of the a and b quartets greatly decrease (Fig. 5). However, for higher ligand contents these quartets become intense again; at the same time, a well defined quartet at high field is detected (f).

For pH* = 7.9, the intensities of signals a and b become very weak, and three other weak and partially superposed quartets, c, d, and e are detected, as well as the intense quartet f at higher field (Fig. 6). At pH* = 10.7, the major difference is the appearance of a new signal, g, to the high field side of quartet f (Fig. 7).

The ligands responsible for signals c, d, e, and f in Fig. 5 seem to be in intermediate exchange at pH* = 5.2, thus accounting for the broad peak observed. At pH* = 7.9, the various signals are still relatively broad due to exchange; this is confirmed by the effect of lowering the temperature on the sharpness of the signals. This is also observed at higher pH; Fig. 8 shows the spectrum obtained for pH* = 9.5 at 273 K. Similarly, exchange processes may be responsible for the low-field shift of the resonances of species a with the increase of the population of b (see Figs. 2–4).

The effect of exchange is also revealed in Fig. 9 where the 100 MHz spectra of a 1:1 solution of pH* = 5.5 at 293 and 343 K are compared. Whereas the a quartet broadens, the hump due presumably to c, d, e, and f sharpens into a well defined quartet. Further work is in progress on the details of the exchange processes in such a complex system.

From a comparison of the intensities of the a, b, f, and g X-signals, in various conditions, we may immediately conclude that they arise from four different complexes and not from nonequivalent ligand moieties in a smaller number of complexes. The remaining three X-signals (c, d, and e) are too weak to enable a conclusion on whether they correspond to three other less abundant complexes or to two or even just one; in the latter case, three magnetically nonequivalent malate ligands should be present per molecule.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

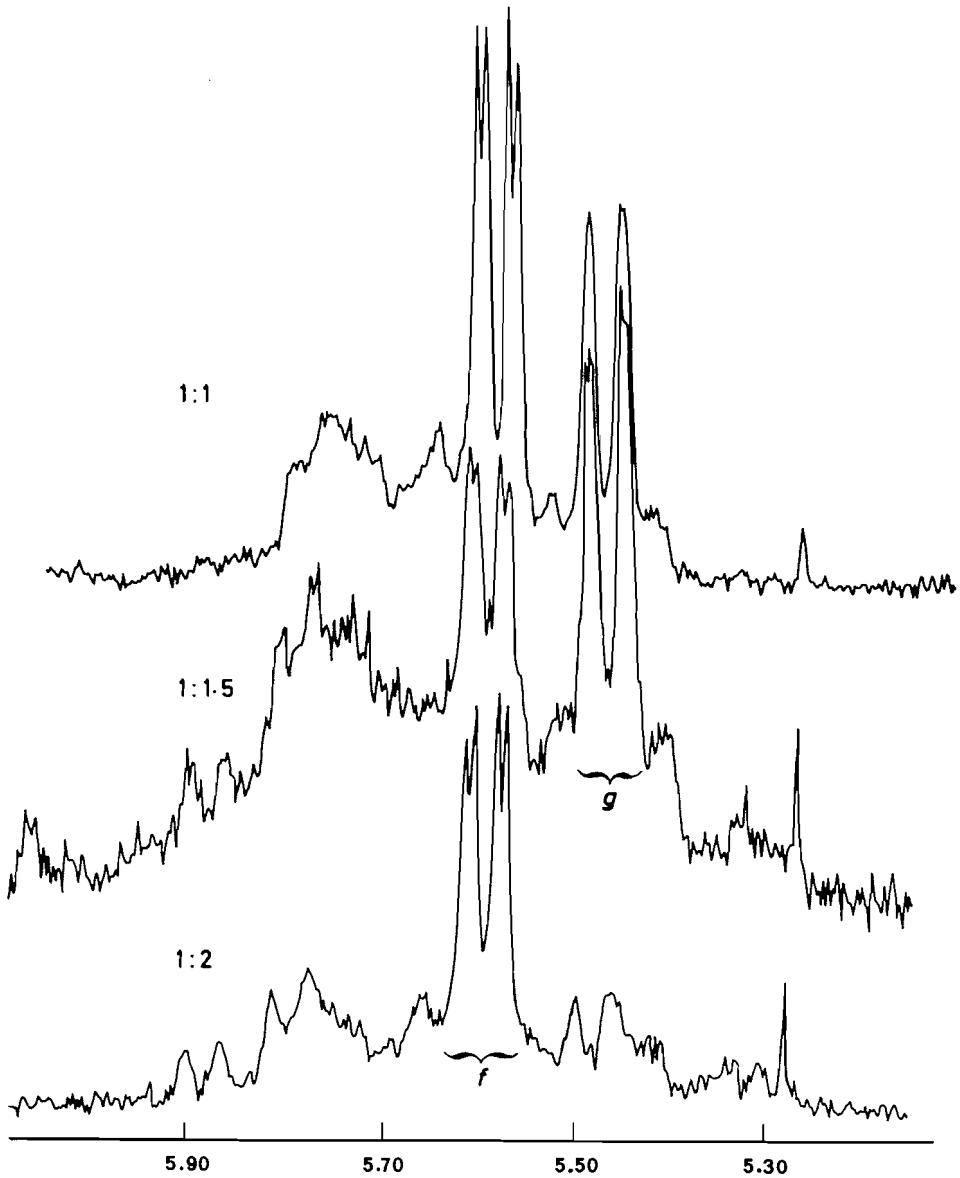

FIG. 7. X sub-spectra of bound ligand for pH* = 10.7, for variable metal/ligand ratios.

From the intensities of the X-signals in Figs. 2–6 (and that for free ligand when in excess), the concentrations of species a, b, f, and g are estimated as a function of molar ratio. The corresponding Job's plots for a and b at pH* = 2.7, for a at pH* = 6.7, for f at pH* = 7.9, and for g at pH* = 10.7, are given in Figs. 10 and 11. We must be cautious when drawing conclusions from these curves. In fact, Job's method is only expected to give directly the stoichiometry of a given complex when other complexes (or other equilibria) are present, if certain conditions are met. In particular, it is necessary that the solution of the complex under study having a maximal concentration has the other species in sufficiently smaller concentration. These are approximately the conditions in the study of complexes a and b at low pH (Figs. 2 and 3) and f at pH* $\simeq$ 8 (Fig. 6). Thus, Job's plots such as those of Fig. 10 confirm that a, the dominant complex in an equimolar solution at low pH, is a 1:1 complex, as previously reported (actually 2:2) (3, 11); this complex is accompanied by another species b of

†The results are for: a 1:1 solution, pH* = 2.75. a′ 1:3 (metal/ligand) solution, pH* = 6.70, $T$ = 280 K. b 2.5:1 (metal/ligand) solution, pH* = 3.91. b′ 1.5:1 (metal/ligand) solution, pH* = 3.91. c, d, e 1:2 (metal/ligand) solution, pH* = 7.48, $T$ = 277 K. f 1:1.5 (metal/ligand) solution, pH* = 7.94. g 1:1.5 (metal/ligand) solution, pH* = 10.75, $T$ = 273 K.
‡1:1 solution, pH* 2–4, 100 MHz spectra (ref. 11).

composition $n$:1, with $n \gtrsim 2.5$. From the f curve in Fig. 11 it may be inferred that complex f is another 1:1 compound.

The conditions mentioned above are not present for pH* = 6.7 (Fig. 5) and pH* = 10.7 (Fig. 7). Accordingly, the maximal concentration of a is found in a solution of molar ratio $n$:1, with $n \simeq 1.5$ (Fig. 11). Also, the stoichiometry of complex g could not be obtained from a Job's plot, because there is always a large concentration of f and, in addition, it was not possible to run spectra for higher contents of $UO_2^{2+}$ at pH* ≃ 11, due to precipitation.

Dilution of a 1:2 solution of pH* ≃ 6.7 by a factor of 50 does not show significant change of the relative populations of complexes a and f. This suggests that they have the same degree of polymerization (2:2). The pH dependence of the relative

For personal use only.

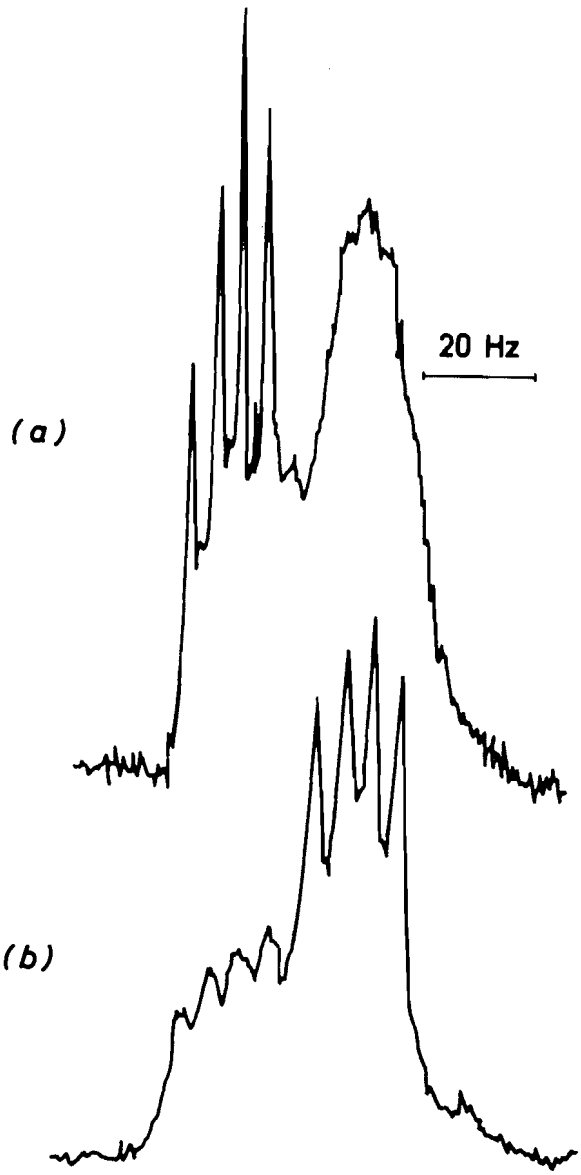

FIG. 9. 100 MHz X sub-spectra of a 1:1 solution for pH* = 5.5 at: (a) 293 K; (b) 343 K.

populations of a and f is compatible with these two complexes being an acid species and its conjugate base in slow exchange.[2] The fact that their equilibrium is slow in the nmr time scale may be due to a conformational modification linked with the protonation, f possibly being caused by a geometric isomerization of a. A different result is observed for pH* = 10.7 with respect to f and g, the former having a higher degree of polymerization.

Figures 12–14 show the relative populations of the various complexes detected for molar ratios of 2:1; 1:1, and 1:2 as a function of pH.

By choosing appropriate conditions, the full ABX analysis of the spectra of the a, b, f, and g complexes could be performed. In the case of the less intense signals b′, c, d, and e only a partial analysis could be done. The $^1H$ nmr parameters for the various complexes are given in Table 1. From the values of the vicinal coupling constants we see that in all complexes the ligand conformation is such that an approximately *trans* and a *gauche* arrangement of H atoms is present. This excludes conformation $c_2$ proposed by Feldman *et al.* (1, 2, 11).

*$^{13}C$ nuclear magnetic resonance spectra*

The solutions used for $^{13}C$ spectra were about 100 times as concentrated as those for $^1H$ data. In these conditions and for pH ranging from 3.0 to 10.1 only three distinct spectra of bound ligand were identified, besides that of free ligand for molar ratios 1:*n* with $n \gtrsim 1.5$. At pH* = 3.0 and for a 2:1 solution (1.50 *M* : 0.75 *M*) two separate ligand spectra are found and attributed to complexes a and b. For pH* in the range ~ 5 (solution 1:1) to ~ 7 (solution 1:2) signals attributed to complex a are observed (the spectrum of complex b is much too weak to be observed) and another spectrum assigned to complex f is clearly identified. At pH* ≃ 10 only spectrum f is observed. The assignment of the peaks was made by comparison with the spectra for various molar ratios and/or pH. The relative abundance of a and f is very sensitive to pH in the region of pH* = 6.3 (if they are an acid–base conjugate pair, then $pK_a \simeq 6.3$).

The $^{13}C$ chemical shifts (in ppm) for a 2:1 (1.50 *M* : 0.75 *M*) metal/ligand solution at pH* = 3.0 relative to the malate ion are to low field as follows

| $^-O_2C$ | $CH_2$ | CH(OH) | $CO_2^-$ |
|---|---|---|---|
| Complex a 5.7 (or 5.5) | 1.76 | 13.71 (or 14.20) | 8.3 (or 8.5) |
| Complex b 5.5 (or 5.7) | 1.76 | 14.20 (or 13.71) | 8.5 (or 8.3) |

It has been assumed that the relative position of the carboxylic peaks observed for the free ligand is retained on complexation; otherwise, the shifts for the β $CO_2H$ groups would be 4.6 and 4.4 and those for α 9.4 and 9.6, respectively, for complexes a and b.

For a 1:2 (0.75 *M* : 1.50 *M*) solution at pH* = 6.3,

the values are

| | $^{-}O_2C$ | $CH_2$ | CH(OH) | $CO_2^{-}$ |
|---|---|---|---|---|
| Complex a | 4.6 | 1.63 | 12.56 | 7.9 |
| Complex f | 5.5 | 1.88 | 13.77 | 9.4 |

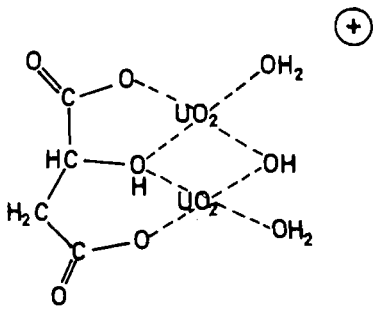
The observed difference in the shifts for complex a is probably due to exchange processes as already discussed.

The big low-field shift of the methyne $^{13}C$ nucleus in comparison with $^{13}CH_2$ is a clear indication of involvement of the OH group of malic acid in complexation. The shifts of carboxylic $^{13}C$ nuclei of a and b with respect to the $CO_2H$ groups of the acid are consistent with participation of both groups in bonding to $UO_2^{2+}$. The similitude of shifts for complexes f and a, at pH* = 6.3, suggests that the same conclusion applies to complex f.

## Conclusion

We may thus conclude the following.

(*a*) At low pH values (approximately 2–4), uranyl and malic acid form at least two complexes. One is a 1:1 compound (a) and the other has a higher content of uranyl (b). The ligand is tridentate in both, but its conformation is not $c_2$; the HH coupling constants indicate a conformation close to $c_1$, or $c_3$. This is consistent with the existence of a 2:2 complex with structure **1**, as previously reported (3, 11) (ligand in conformation close to $c_1$) or its isomer of symmetry $C_s$, and a 2:1 complex of similar structure, for instance **3**,



**3**

although other hypothesis (for instance 4:2 complexation as for Mo(VI)–malic acid (12)) cannot be ruled out.

(*b*) At pH from ~ 5 to about 10, at least two further complexes are formed, the most abundant of which is another 1:1 species (f). This seems to be a polynuclear complex (2:2) as indicated by dilution studies. The ligand is again tridentate, with a conformation close to $c_1$ or $c_3$. This complex might be a conjugate base of the acidic species appearing at low pH.

(*c*) At pH ≃ 11 a new complex is formed of stoichiometry difficult to ascertain. Again, the conformation of the ligand is one having two H nuclei in a *trans* orientation ($c_1$ or $c_3$).

Work is in progress regarding a complete clarification of this complex system, as well as of the various exchange phenomena present.

A model for the active conformation of methionine-enkephalin containing a β-turn was derived from computer modeling. Using a *trans*-perhydronaphthalene as a structural template and a mimic of the β-turn, target compounds were designed and synthesized. Thus, a key intermediate, *trans*-3-oxo-5β-formamidomethyl-8a-phenylmethylperhydronaphthalene, was prepared by two different routes from cyclohexanone.

The addition of a methionine-like side-chain to this key intermediate was best achieved by a reaction with the anion of methyl 2-trimethylsilyl-4-methylthiobutanoate. This led to the preparation of an *exo*-tetrasubstituted double bond in high yield. Subsequent addition of tyrosine through coupling with the 5β-aminomethyl group provided the desired perhydronaphthalene mimics of met-enkaphalin.

A l'aide d'un ordinateur, on a déduit un modèle de la conformation active de la méthionine-encéphaline contenant une hélice β. Utilisant le perhydronaphtalène-*trans* comme modèle de structure et une imitation de l'hélice β, on a proposé et synthétisé les composés cibles. Ainsi on a préparé un intermédiaire principal, l'oxo-3 formamidométhyl-5 β phénylméthyl-8a perhydronaphtalène par deux voies différentes, en partant de la cyclohexanone.

L'addition de la méthionine, comme chaîne latérale, sur cet intermédiaire principal se fait mieux par une réaction avec l'anion du triméthylsilyl-2 méthyl-4 thiobutanoate de méthyle. Ceci conduit à la préparation d'une double liaison *exo*-tétrasubstituée avec un rendement élevé. L'addition subséquente de la tyrosine à travers le couplage avec le groupe aminométhyl-5 β conduit au perhydronaphtalène désiré qui est une réplique de la mét-encéphaline.

[Traduit par le journal]

## Introduction

In the realm of compounds that act on the central nervous system to combat pain, the opiate alkaloids (for example, morphine) have been the preeminent drugs for many years. More recently, the discovery and characterization of the naturally occuring opiate receptor agonists, the enkephalins, has renewed interest in this field (1), increasing the hope that analogs of the enkephalins would lead to drugs having reduced side-effects while maintaining a high analgesic activity.

We felt that it should be possible to design nonpeptide compounds which would mimic the enkephalins, which would be less conformationally mobile and could therefore interact specifically with the enkephalin receptors. To do this it was necessary to derive a model of what we perceived to be the active conformation for the enkephalins. Many conformational studies have been published using nmr (2, 3), fluorescence (4), theoretical studies (5–7), and more recently X-ray studies (8). Some of the conformations proposed can be correlated with synthetic opiates (9, 10). However, among the many published studies which derived "active conformations" for the enkephalins there has been no real consensus. Most do agree that the tyrosine group is very important and that the molecule is bent on itself in a β-turn. The glycines are generally thought to be positioning groups and the phenylalanine aromatic system is considered to be important for activity.

We have derived a model of the bioactive conformer of enkephalins, shown in Fig. 1, based on a combination of structure–activity relationships for the enkephalins and for the opiates, computer modeling, and comparisons with the opiates. A key feature of this model is the presence of a β-turn which adds rigidity to the flexible enkephalin

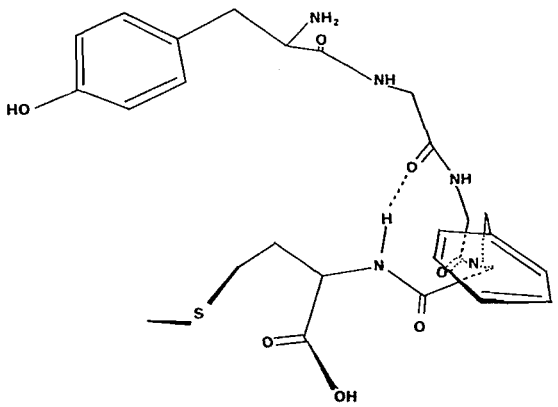

FIG. 1.

backbone and also acts as a template positioning the key groups (the tyrosine and the phenylalanine's phenyl group) in space as is found in very active opiates (e.g. morphine, etorphine). The modeling studies carried out on this conformer have revealed it to be a low energy conformer.

Using this model we sought to design novel rigid nonpeptide mimics of the enkephalins with the aid of the Merck Modeling System and the compare (superimposition) program. The β-turn in the model, with its hydrogen bond between gly$^2$ and met$^5$, makes a 10-membered ring and thus one of our most interesting structures derived by computer modeling was based on a perhydronaphthalene backbone. The perhydronaphthalene could serve to position the key groups in space as does the β-turn in the enkephalin model (Fig. 2). We therefore chose **1** as our target.

## Results and discussion

In our synthetic strategy to **1** it was considered expedient to prepare the *E* and *Z* olefin isomers, and as the addition of the tyrosine moiety to the perhydronaphthalene backbone would create diastereomers, a total of four isomers of the final

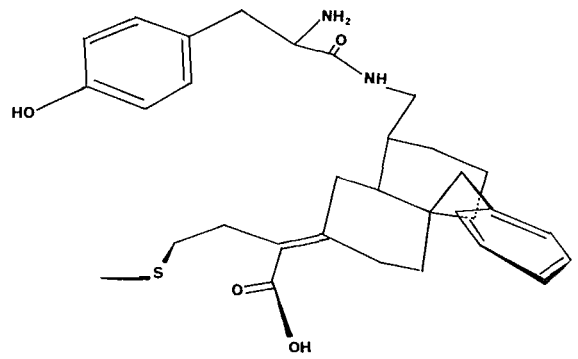

FIG. 2.

system were expected. Thus the preparation of **1** had to be achieved in as efficient and stereospecific a manner as possible. A potential difficulty was to ensure the *trans* ring junction and diaxial orientation of side chains. Strategic analysis identified the amino ketone **2***a* or a derivative such as **2***b* as key intermediates to **1**.

Compound **2***b* was prepared via two routes from cyclohexanone. The first route is outlined in Scheme 1. The key C-5 substituent was introduced via a Vilsmeier–Haack formylation reaction (11).

Cyclohexanone (**3**) was converted to 2-phenylmethylcyclohexanone (**4**) via alkylation of the pyrrolidine enamine with phenylmethylchloride following the method of Stork *et al.* (12). Subse-

quent Robinson annellation (13) with methyl vinyl ketone provided 1,2,3,5,6,7,8,8a-octahydro-3-oxo-8a-phenylmethylnaphthalene (**5**). Treatment with methyl orthoformate gave the dienolether **6** which upon Vilsmeier– Haack formylation (11) provided the 5-formyl derivative **7***a* and thence the oxime **7***b* in 26% overall yield from **5** utilizing conditions similar to those developed by Yoshikoshi and co-workers (11) in their synthesis of (±) bulnesol. Thus the functionality at C(3) and C(5) were in place and it remained to introduce the required *trans* stereochemistry at the ring junction and the β-configuration at C(5). It was felt that hydrogenation of **7***b* would be nonselective whereas if a β-substituent were present at C(3), then a stereospecific reduction could be expected (14). As the oxime function led to complications in subsequent steps, it was converted to the nitrile **8** via treatment with trichloroacetonitrile (15). Hydrolysis of the enolether provided a mixture of olefinic ketones **9** which formed a single enolacetate **10**. Compound **10** was smoothly reduced by sodium borohydride to provide 5-cyano-3β-hydroxy-1,2,3,4,6,7,8,8a-octahydro-8a-phenylmethylnaphthalene (**11**). The β stereochemistry was assigned by analogy with the work of Heathcock and Kelly (16) in their β-eudesmol synthesis. Despite many trials, selective hydrogenation of the double bond could not be achieved. Hydrogenation over 10% palladium on

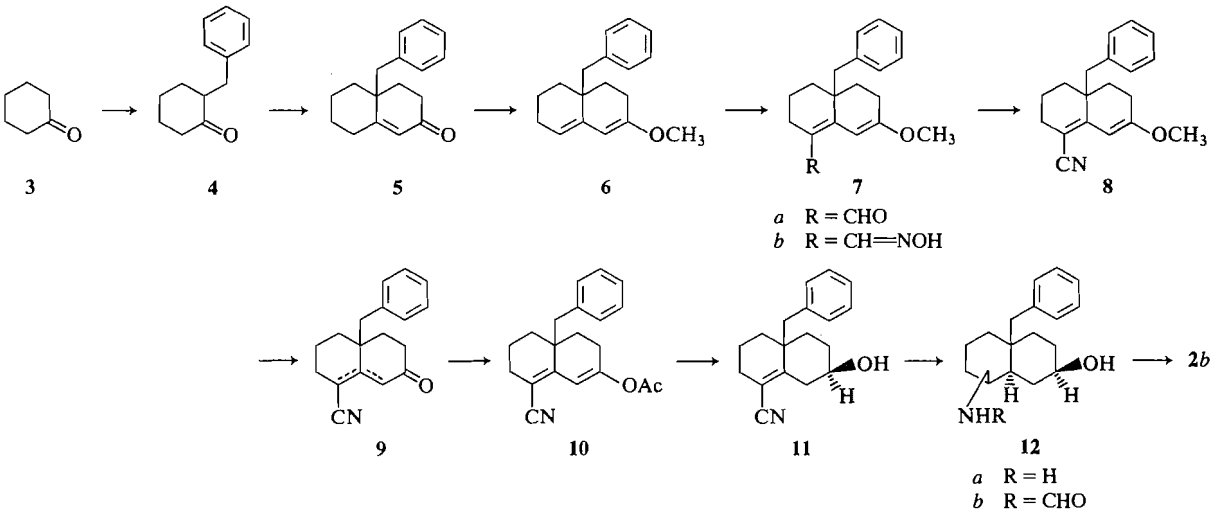

SCHEME 1

charcoal provided the aminoalcohol **12***a* contaminated with some material where the aromatic ring had been reduced. Compound **12***a* was converted to its *N*-formyl derivative **12***b* and the alcohol was oxidized with the Sarett reagent as modified by Ratcliffe and Rodehorst (17) to provide the crystalline *N*-formylketone **2***b*.

Due to the partial reduction of the aromatic ring in the hydrogenation step and also due to difficulties anticipated in scaling up the synthesis, an alternative route to **2***b* was devised and is summarized in Scheme 2.

Thus, following a scheme similar to that utilized by Marshall *et al.* (14, 18) in their synthesis of β-eudesmol, **5** was converted to the deconjugated ketal **13**. Hydroboration of **13** provided, after oxidative work-up, a mixture of *cis*-fused alcohols, **14** and **15**, plus small amounts of ketal cleavage products in a ratio of approximately 25:70:5. The desired alcohol **15** could be readily purified by chromatography or the mixture could be used as such for the subsequent oxidation ($CrO_3$·2pyr) to provide the *cis*-fused ketone **16** which, on reaction with methylenetriphenylphosphorane in the presence of excess base, first isomerized the ring junction to **17** and then effected the methylene addition. This provided the ketal olefin **18**, readily purified at this point, in 44% overall yield from **5**.

Hydroboration of **18** occurred exclusively from the α-face to provide, after oxidative work-up, the primary alcohol **19***a*, which was converted to the crystalline mesylate **19***b* (60% yield from **18**). Treatment of **19***b* with sodium azide in DMF provided the azide **20** plus the exocyclic olefin **18** in ca. 4:6 mixture. After chromatographic separation, the olefin **18** could be recycled. Reduction (LAH),

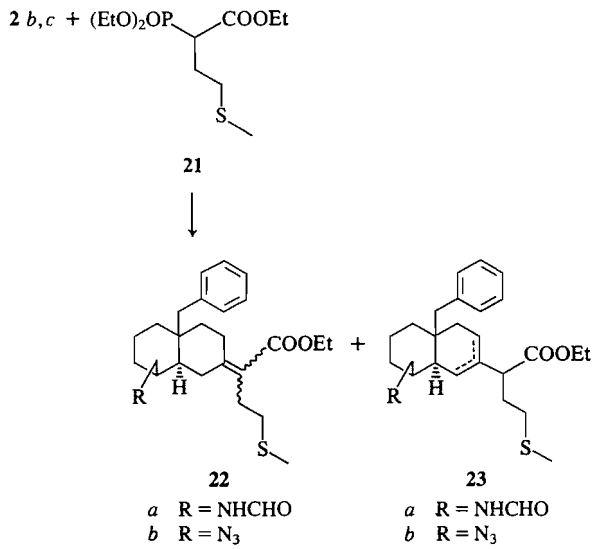
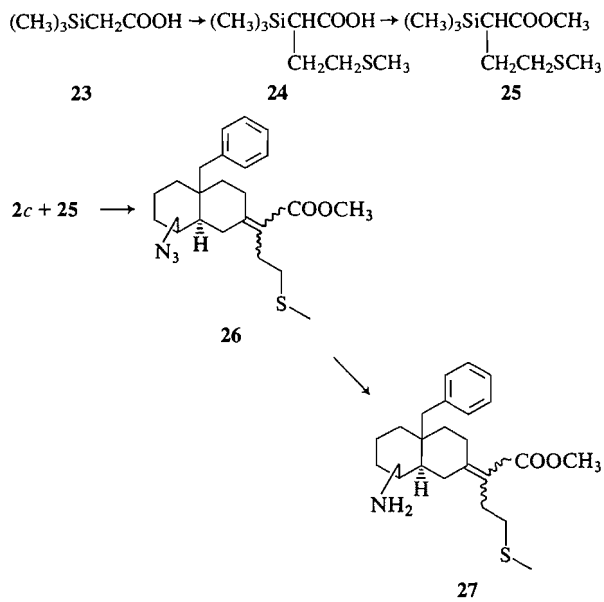
hydrolysis, and formylation of the ketal provided the *N*-formyl ketone **2***b* identical to that obtained from the previous route.

Having the required perhydronaphthalene backbone in hand, attention was directed towards the attachment of the side chain at C(3). Several possible methods were explored. Addition via a Reformatsky reaction was considered but was rapidly set aside when it was found that the dehydration of model compound proved to be nonspecific and led to mixtures of conjugated and deconjugated olefins under acidic conditions.

As it is known that endocyclic β,γ-unsaturated esters should be more stable than the exocyclic α,β-unsaturated isomers in cases such as these (19), a more specific method was sought. It was felt that the Wadsworth–Emmons phosphonate modification of the Wittig reaction (20) could provide a direct introduction of the side chain. Thus ethyl-2-diethylphosphono-4-methylthiobutyrate (**21**), readily prepared by alkylating triethylphosphonoacetate with methyl-β-chloroethyl sulfide, was found to react at best sluggishly (80–100°C, 18 h) with **2***b* or **2***c* when reacted with sodium hydride in dimethoxyethane. The mixture of *E* and *Z* adducts **22***a* or **22***b* were obtained only in rather poor yield (40–50%) and always with varying amounts of β,γ-unsaturated by-products **23***a* or **23***b*, probably due to base catalyzed isomerization of the products under these harsh conditions.

The possibility of utilizing α-trimethylsilylesters to effect the olefination was explored (21, 22). This method has not been used previously to prepare tetrasubstituted olefins but seemed worthy of investigation despite the reported failure of α,α-bistrimethylsilylesters to react with ketones (23).





SCHEME 3

As shown in Scheme 3, alkylation of the dianion of α-trimethylsilylacetic acid **23** with β-methylthioethyl chloride and subsequent esterification of **24** led to **25** in good yield. Treatment of **25** at 0°C with one equivalent of lithium diisopropylamide (LDA) followed by cooling to −78°C and addition of the azido ketone **2***c* effected a rapid and efficient (80–90% yield) reaction to provide the desired mixture of *E* and *Z* α,β-unsaturated esters **26***a*, **26***b* with no detectible traces of deconjugated by-products. The isomers were not separable at this point. Reduction of the azide was thought to be potentially a problem due to the other functionality present in the molecule. It was found that aluminium amalgam effected a clean but rather inefficient conversion of **26***a*, **26***b* to the *E* and *Z* mixture of amines **27***a*, **27***b* (42–50%). However, somewhat surprisingly, the reduction could be very cleanly effected in high yield (90%) by hydrogenation over Adams catalyst. The resultant amines could now be readily separated via column chromatography to provide the pure crystalline amines **27***a* (less polar) and **27***b* (more polar) in a 1:1 mixture.

The relative stereochemistry and ultimate proof of structure of the series was obtained via an X-ray structure determination on **27***a*, which is shown in Figure 3. Thus the less polar isomer has the *E* stereochemistry for the side chain and the more polar isomer has the *Z* stereochemistry. The rigid nature of the two cyclohexane rings with chair conformations in the *trans* perhydronaphthalene system forces the functional groups on the periphery into specific conformations. Because of a 1,3

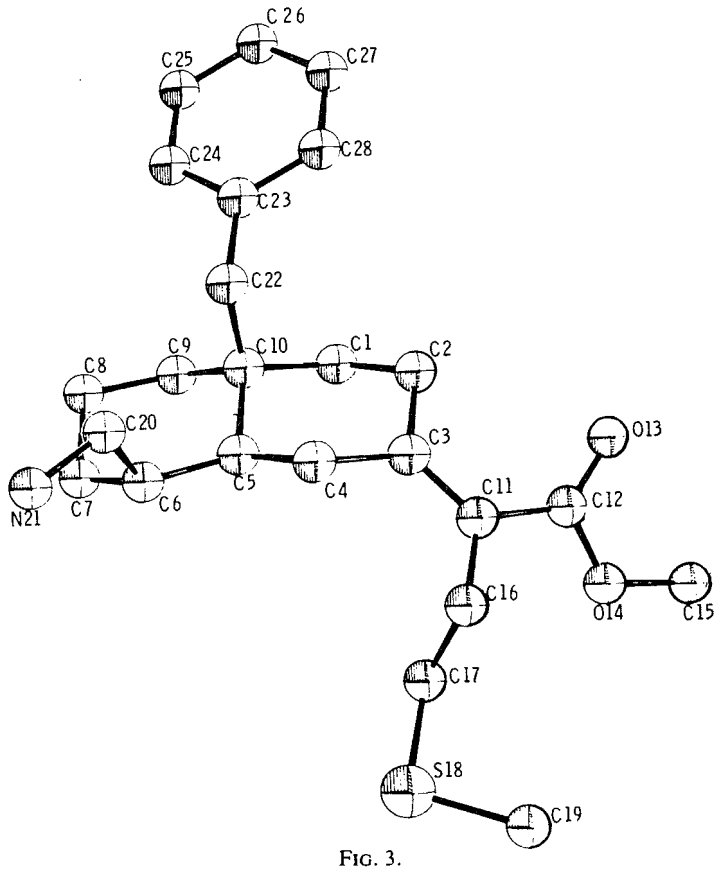


FIG. 3.

diaxial interaction C(20) and C(22) are pushed away from each other. This is clearly seen by examining the torsional angles C(8)—C(7)—C(6)—C(20) and C(10)—C(5)—C(6)—C(20) which are 79° and −77°, respectively, compared to ± 60° for an ideal chair geometry. In addition the phenyl group is forced away from the perhydronaphthalene system so that the torsional angle C(5)—C(10)—C(22)—C(23) is 176°. Also because of a nonbonded interaction between the equatorial H(2b) and O(13) the ester cannot fully conjugate with the exocyclic double bond but is twisted with a torsional angle for C(3)—C(11)—C(12)—O(13) at 37°.

It is interesting to observe that the considerable deformation of the bond angles had been predicted by our computer modeling studies (24) but prior to determining the X-ray structure, we felt that the modeling program had exaggerated this effect.

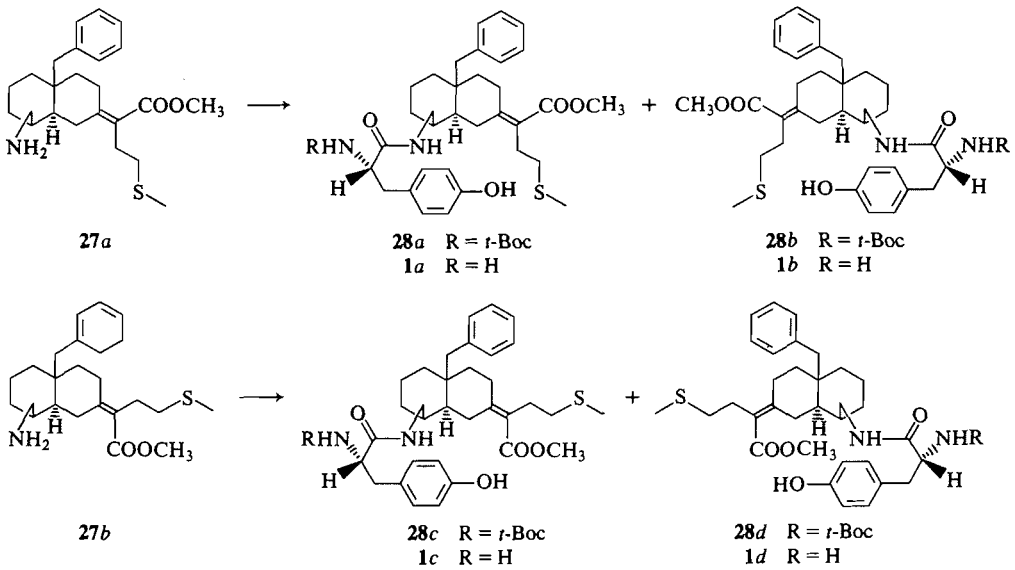
The final conversion to the target structures was achieved via DCC coupling (25) of **27***a* and **27***b* to *N*-*t*-BOC-tyrosine to provide the *N*-protected adducts in good yields (88% and 91%, respectively) as mixtures of diastereomers. These diastereomeric pairs could be separated in each case via hplc to provide the four pure isomers **28***a*–*d*. Acid treatment in each case liberated the amino function and gave the final four isomeric target molecules directly as the hydrochloride salts **1***a*–*d*. Attempts to obtain crystalline material from these products, suitable for X-ray analysis, were unsuccessful.

These compounds have all been tested in the $^3$H-Naloxone Binding Assay (26) and, unfortunately, were found to have only weak binding activity. The possibility remains that the tyrosine side chain in these molecules does not adopt the predicted, desired conformation at the receptor site. In addition, the drastic changes done by approximating the β-turn with a perhydronaphthalene could also explain these biological results.

## Conclusion

It would therefore seem that our model has failed to accurately mimic the enkephalin active conformation. Of course activity can be affected by very subtle changes and it is possible that the steric requirements of the perhydronaphthalene unit are not tolerated by the opiate receptor. It is notable that subsequent experiments (27) have demonstrated that enkephalin derivatives where the carbonyl of the glycine 3-residue is reduced to a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.



methylene group have been shown to be inactive and thus it would appear that the β-turn portion of the enkephalins has significance in binding with the receptor, rather than merely acting as a template. Thus mimics such as ours which replace these hydrophilic amide bonds with more hydrophobic methylene groups may introduce an unacceptable degree of lipophilicity into this region of the receptor.

## Experimental

Melting points were taken on a Thomas Hoover apparatus in open capillary tubes and are uncorrected. Infrared spectra were recorded on a Perkin–Elmer 267 grating spectrophotometer. A Varian EM-360 spectrometer was used to record nmr spectra. Proton chemical shifts are relative to tetramethylsilane (TMS) as internal standard. Elemental analyses were performed by Dr. C. Daesslé of Montreal or by Galbraith and Associates, Knoxville, TN. The low resolution mass spectral analyses were performed by the Morgan–Schaffer Corporation, Montreal. A Syntex $P2_1$ automatic four-circle diffractometer was used to collect the X-ray diffraction data.

All reactions as well as column chromatography were monitored routinely with the aid of thin layer chromatography (tlc) using precoated 0.25 mm silica gel plates (Eastman Kodak) or silica gel GF plates (Analtech).

*1-Pyrrolidino-1-cyclohexene*

1-Pyrrolidino-1-cyclohexene was prepared according to the method of Stork *et al.* (12); bp 70°C/15 Torr.

*2-Benzylcyclohexanone (4)*

To 1-pyrrolidino-1-cyclohexene (238 g; 1.58 mol) dissolved in dioxane (1 L) was added benzyl chloride (277 g; 2.19 mol) and the mixture was refluxed 16 h. Water (250 mL) was then added and reflux was continued for 2.5 hours more. The dioxane was removed under vacuum and the aqueous phase was extracted four times with ether (4 × 500 mL). The combined extracts were washed with 5% aqueous hydrochloric acid (50 mL), and with water (50 mL), then dried ($Na_2SO_4$) and concentrated to an oily residue that was distilled to yield **4** (163 g; 55%), bp 105°C/0.5 Torr; ir (film) $\nu_{max}$: 1700 (C=O) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 1.2–2.6 (10H, m), 3.20 (1H, m), 7.13 (5H, s, aromatic).

*1,2,3,5,6,7,8,8a-Octahydro-3-oxo-8a-phenylmethylnaphthalene (5)*

Ketone **4** (550 g; 2.92 mol) in ether (2 L) was added to a solution of potassium hydroxide (33 g; 0.59 mol) in absolute ethanol (110 mL) maintained at 0°C. It was followed by the dropwise addition of methyl vinyl ketone (242 g; 2.92 mol) over a period of 4 hours. After warming to room temperature, water (1 L) was added and the organic layer was separated, washed with water, dried ($Na_2SO_4$), and concentrated to an oil. The residue was distilled to give 345 g (49%) of α,β-unsaturated ketone **5**, bp 155°C/0.5 Torr, which solidified on standing; mp 74–75°C; ir (KBr) $\nu_{max}$: 1660 (C=O), 1610 (C=C) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 2.80 (2H, s, benzylic $CH_2$), 5.72 (1H, s, H4), 7.10 (5H, s, aromatic). *Anal.* calcd. for $C_{17}H_{20}O$: C 84.95, H 8.38; found: C 85.39, H 8.49.

*5-Formyl-1,2,6,7,8,8a-hexahydro-3-methoxy-8a-phenylmethylnaphthalene (7a)*

Ketone **5** (1.06 g; 0.005 mol) was dissolved in trimethylorthoformate (7 mL) at room temperature and the solution was cooled in an ice–water bath. *p*-Toluenesulfonic acid (10 mg) was added and stirring was continued for 3 hours. Pyridine (20 mL) was added and the mixture was evaporated under high vacuum to provide crude dienol ether **6** as a brown oil which was used directly in the next reaction; $^1$Hmr ($CDCl_3$) δ: 2.80 (2H, s, benzylic $CH_2$), 3.70 (3H, s, $OCH_3$), 6.43 (1H, s, H4), 7.20 (5H, s, aromatic and H5).

Phosphorous oxychloride (0.9 mL; 9.6 mmol) was added to an ice-cooled solution of dimethylformamide (3 mL) in methylene chloride (8 mL). Dienol ether **6** from the previous reaction (1 g; crude) in methylene chloride (15 mL) was added over 15 min. The mixture was stirred at room temperature under nitrogen for 4 hours. A 20% solution of sodium acetate was added and the mixture was stirred for 30 min, then extracted with methylene chloride. The organic layers were successively washed with 10% aqueous sodium bicarbonate and with water, then dried ($Na_2SO_4$) and concentrated *in vacuo* to a brown oil, which on treatment with ether yielded crystalline **7a** (400 mg; 34% yield). Recrystallization from ether gave an analytical sample, mp 117–120°C; ir (KBr) $\nu_{max}$: 1650 (C=O), 1610 (C=C) $cm^{-1}$; $^1$Hmr

($CDCl_3$) δ: 2.87 (2H, s, benzylic $CH_2$), 3.80 (3H, s, OMe), 6.47 (1H, s, H4), 7.20 (5H, s, aromatic), 10.27 (1H, s, CHO). *Anal.* calcd. for $C_{19}H_{22}O_2$: C 80.81, H 7.85; found: C 80.68, H 7.91.

*Oxime of* 7a

The 5-formyl derivative *7a* (0.141 g; 0.5 mmol) was dissolved in methanol (4 mL) and pyridine (0.1 mL). Hydroxylamine hydrochloride (0.10 g) was added and the mixture was stirred at room temperature for 30 min. Water (10 mL) was added and the resulting oxime *7b* (0.11 g; 76%) was filtered off, washed with water, and air-dried; mp 146–147°C; ir (KBr) $\nu_{max}$: 3300 (OH), 1650 (C=N), 1620 (C=C) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 2.77 (2H, s, benzylic $CH_2$), 3.67 (3H, s, $OCH_3$), 5.80 (1H, s, H4), 7.20 (5H, s, aromatic), 8.43 (1H, s, —C*H*=NOH). *Anal.* calcd. for $C_{19}H_{23}NO_2$: C 76.73, H 7.80, N 4.71; found: C 76.83, H 7.73, N 4.53.

*5-Cyano-1,2,6,7,8,8a-hexahydro-3-methoxy-8a-phenylmethylnaphthalene (8)*

The oxime *7b* (600 mg; 2.02 mmol) was dissolved in trichloroacetonitrile (2 mL) and the solution was stirred at room temperature for 30 min. The mixture was stripped to dryness under high vacuum, leaving a brown oil which was taken up in $CCl_4$, filtered, and concentrated to an oil. This oil was taken up in ether, washed with 5% sodium hydroxide and with water. The organic layer was dried ($Na_2SO_4$) and evaporated to dryness to yield cyano derivative **8** (500 mg; 85% yield), mp 106–107°C; ir (KBr) $\nu_{max}$: 2210 (C≡N) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 2.80 (2H, s, benzylic $CH_2$), 3.72 (3H, s, OMe), 5.83 (1H, s, H4), 7.20 (5H, s, aromatic). *Anal.* calcd. for $C_{19}H_{21}NO$: C 81.68, H 7.58, N 5.01; found: C 81.71, H 7.70, N 5.08.

*Enol acetate of* ***10***

The cyano derivative **8** (184 mg; 0.66 mmol) was dissolved in tetrahydrofuran (2 mL) and concentrated hydrochloric acid (0.5 mL) was added. The mixture was stirred at room temperature for 1 hour. The mixture was taken up in methylene chloride (100 mL) and washed with water (10 mL). The organic phase was dried ($Na_2SO_4$) and concentrated to dryness to give a pale yellow oil (175 mg) which was used directly in the next reaction. Spectroscopic analysis indicated that the product **9** was largely in the enolic form; ir (film) $\nu_{max}$: 2200 (CN), 1720 (CO), 1670 (C=O conj.), 1625 (C=C) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 2.73 (2H, s, benzylic $CH_2$), 5.97 (1H, s, olefinic CH), 7.17 (5H, s, aromatic), 7.57 (1H, broad, OH of enol).

Compound **9** (175 mg from previous reaction) was dissolved in benzene (5 mL) and acetyl chloride (1 mL) was added, followed by the addition of triethylamine (5 drops). The mixture was kept for 28 h in the refrigerator, then was poured onto water and extracted with methylene chloride. The organic phase was dried ($Na_2SO_4$), and concentrated under vacuum to yield a yellowish oil. Purification by preparative tlc (hexane–ether 1:1 v/v) gave 0.128 g of colorless oil that crystallized on standing. Triturated in ether, **10** melted at 115–116°C; ir (KBr) $\nu_{max}$: 2050 (CN), 1765 ($OCOCH_3$), 1655 (C=C) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 2.17 (3H, s, OAc), 2.80 (s, 2H, benzylic $CH_2$), 6.4 (1H, m, H4), 7.2 (5H, s, aromatic). *Anal.* calcd. for $C_{20}H_{21}NO_2$: C 78.15, H 6.87, N 4.56; found: C 77.75, H 6.75, N 4.72.

*5-Cyano-3β-hydroxy-1,2,3,4,6,7,8,8a-octahydro-8a-phenylmethylnaphthalene (11)*

Enol acetate **10** (0.391 g; 1.28 mmol) dissolved in a mixture of tetrahydrofuran (8 mL), ethanol (7 mL), and water (1.5 mL) was cooled under nitrogen, to −3°C. Sodium borohydride (0.5 g) was added and the mixture was stirred overnight. A solution of 5% sodium hydroxide (2 mL) was added and the mixture was diluted with brine (20 mL) and extracted with methylene chloride (150 mL). The organic phase was washed with water, dried ($Na_2SO_4$), and evaporated to dryness. The oily residue was purified by preparative tlc (ether–hexane 7:3 v/v). Extraction of the major band yielded a colorless oil which crystallized on standing. Trituration in a small volume of ether gave 0.26 g (76%) of **11**, mp 102–104°C; ir (KBr) $\nu_{max}$: 3450 (OH); 2210 (CN), 1620 (C=C) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 2.87 (2H, d, benzylic $CH_2$), 3.70 (1H, broad, C*H*OH), 7.20 (5H, m, aromatic). *Anal.* calcd. for $C_{18}H_{21}NO$: C 80.86, H 7.92, N 5.24; found: C 80.79, H 8.16, N 5.27.

*3β-Hydroxy-6β-formamidomethyl-8a-phenylmethyl-*trans*-perhydronaphthalene (12*b*)*

Cyano derivative **11** (0.205 g; 0.77 mmol) was dissolved in glacial acetic acid (25 mL) and hydrogenated at 30 psi over 5% platinum on charcoal (0.133 g) for 2 hours. The catalyst was filtered off through Celite and washed with absolute ethanol (100 mL). The filtrate was concentrated *in vacuo* to yield the amino derivative **12***a* (200 mg) as a pale oil that was used for the next step; ir (film) $\nu_{max}$: 3400 (NH and OH) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 2.82 (2H, m, benzylic $CH_2$), 3.68 (1H, broad, CHOH), 7.18 (5H, s, aromatic).

Crude **12***a* (195 mg; 0.71 mol) dissolved in formic acid (5 mL) and acetic formic anhydride (2 mL) was heated on a steam bath for 30 min. The mixture was evaporated to dryness and taken up in methylene chloride. The resulting solution was washed with 5% sodium hydroxide, with water, dried ($Na_2SO_4$), and evaporated giving the diformyl compound (222 mg) as a pale yellow oil; ir (KBr) $\nu_{max}$: 3300 (NH), 1720 (OCHO), 1660 (NCHO) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 2.78 (2H, s, benzylic $CH_2$), 4.93 (1H, m, CHOCO), 7.17 (5H, s, aromatic), 8.03 (1H, s, OCHO), 8.15 (1H, s, NCHO).

The crude diformyl intermediate isolated above (0.222 g) was dissolved in methanol (5 mL) and 5% aqueous bicarbonate (2 mL) was added. The reaction mixture was stirred at room temperature for 3 hours. It was then taken up in methylene chloride and the organic phase was washed with water, dried ($Na_2SO_4$), and concentrated to give **12***b* as a pale yellow oil which solidified on standing. Trituration in ether gave 168 mg (72% from **11**) of crystalline **12***b*, mp 212–213°C; ir (KBr) $\nu_{max}$: 3300 (OH), 1660 (NCHO) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 2.50 (1H, d, $J$ = 14 Hz, benzylic CH), 3.00 (1H, d, $J$ = 14 Hz, benzylic CH), 3.65 (1H, broad m, =C*H*OH), 7.20 (5H, s, aromatic), 8.15 (1H, s, NCHO). *Anal.* calcd. for $C_{19}H_{27}NO_2$: C 75.71, H 9.02, N 4.65; found: C 75.41, H 9.24, N 4.89.

*6β-Formamidomethyl-3-oxo-8a-phenylmethyl-*trans*-perhydronaphthalene (2*b*)*

The hydroxy derivative **12***b* (0.15 g; 0.5 mmol) was added as a solution in dry pyridine (3 mL) to a mixture made up by adding chromium trioxide (0.5 g) to a solution of pyridine (0.8 mL) in methylene chloride (30 mL). The mixture was stirred at room temperature under nitrogen for 2 hours. The methylene chloride solution was decanted off from the brown gum which had deposited. The gum was washed with methylene chloride (6 × 50 mL) and the combined extracts were washed with 5% sodium hydroxide, water, dried ($Na_2SO_4$), and evaporated to dryness to yield a residue that was purified by preparative tlc (ether–methanol 95:5 v/v) to give pure **2***b*, mp 193–195°C (0.12 g; 81%) after trituration with ether; ir (KBr) $\nu_{max}$: 3300 (NH), 1710 (C=O), 1665 (NHCHO) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 2.83 (2H, s, benzylic $CH_2$), 6.35 (1H, broad, —N*H*CHO), 7.23 (5H, s, aromatic), 8.20 (1H, s, —NHC*H*O). *Anal.* calcd. for $C_{19}H_{25}NO_2$: C 76.21, H 8.41, N 4.68; found: C 76.00, H 8.64, N 4.65.

*3-Ethylenedioxy-1,2,3,4,6,7,8,8a-octahydro-8a-phenylmethylnaphthalene (13)*

Ketone **5** (50 g; 0.208 mol) was refluxed in benzene (1 L) with ethylene glycol (50 mL) and *p*-toluenesulfonic acid monohydrate (1 g) for 18 h under a Soxhlet containing calcium hydride.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

The solution was washed with water (500 mL), 1 *N* sodium hydroxide (100 mL), water (500 mL), dried ($Na_2SO_4$), and concentrated. The residue was taken up in ether (50 mL) and left to crystallize. The resulting crystals were filtered and washed with hexane, providing 31.5 g of **13**. The mother liquors, recycled through the above procedure, yielded a further 14.7 g for a total yield of 46.2 g (77%), mp 91–93°C; $^1$Hmr ($CDCl_3$) δ: 2.80 (2H, m, benzylic $CH_2$), 3.87 (4H, s, $CH_2CH_2$), 5.40 (1H, m, olefinic H), 7.10 (5H, s, aromatic). *Anal.* calcd. for $C_{19}H_{24}O_2$: C 80.24, H 8.50; found: C 80.47, H 8.71.

*3-Ethylenedioxy-5*β*-hydroxy-8a-phenylmethyl-*cis-*perhydronaphthalene (**15**)*

To a solution of olefin **13** (21 g; 74 mmol) in anhydrous tetrahydrofuran (100 mL) cooled at 0°C was added dropwise and under nitrogen a solution of diborane in tetrahydrofuran (150 mL of 1 *M* solution). The reaction mixture was stirred at room temperature for 3 hours. It was then cooled to 0°C and methanol (30 mL) was added slowly. Sodium hydroxide (50 mL, 1 *N*) was then added, followed by the addition of 30% hydrogen peroxide (20 mL). The excess hydrogen peroxide was destroyed by adding a solution of sodium bisulfite until no peroxide was detected by starch iodide paper. The mixture was then extracted three times with methylene chloride and the combined extracts were washed with water and dried ($Na_2SO_4$). Concentration under vacuum gave crude **15** (27.3 g) which was used as such for the next step.

A sample of the crude mixture was purified by preparative tlc (ether–hexane 70:30 v/v) to yield the desired alcohol **15** as an oil and the tertiary alcohol **14** also as an oil. The ratio of **15** to **14** was 3:1.

Secondary alcohol **15**; ir (film) $\nu_{max}$: 3450 ($OH^-$), 1604 (aromatic) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 2.80 (2H, s, benzylic $CH_2$), 3.93 (4H, s, ethylenedioxy protons), 7.17 (5H, s, aromatic).

Tertiary alcohol **14**; ir (film) $\nu_{max}$: 3520 (OH), 1601 (aromatic) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 2.83 (1H, d, $J$ = 14 Hz, benzylic CH), 3.13 (1H, d, $J$ = 14 Hz, benzylic CH), 4.00 (4H, s, ethylenedioxy protons), 7.17 (5H, s, aromatic).

*3-Ethylenedioxy-5-oxo-8a-phenylmethyl-*cis-*perhydronaphthalene (**16**)*

Crude **15** (27.3 g; 0.09 mol) dissolved in acetone (500 mL) was oxidized by adding slowly 55 mL of 1.15 *M* Jones reagent (28). After stirring at room temperature for 30 min, ether (250 mL) was added. The two layers were separated and the organic layer was washed with dilute sodium hydroxide and with water, dried ($Na_2SO_4$), and concentrated to a residue that solidified on standing (26.2 g). The crude **16** was used as such in the following step.

A 200 mg sample was purified by preparative tlc (ether–hexane 1:1 v/v). Recrystallized from methanol, pure *cis*-**16** had mp 117–118°C; ir (KBr) $\nu_{max}$: 1705 (C=O), 1602 (aromatic) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 2.57 (2H, AB quartet, $J_{A,B}$ = 14 Hz, benzylic $CH_2$), 3.84 (4H, s, ethylenedioxy protons), 7.17 (5H, s, aromatic). *Anal.* calcd. for $C_{19}H_{24}O_3$: C 75.97, H 8.05; found: C 76.24, H 8.24.

*3-Ethylenedioxy-5-oxo-8a-phenylmethyl-*trans-*perhydronaphthalene (**17**)*

Purified *cis*-ketone **16** (670 mg; 2.2 mmol) and sodium methoxide (100 mg) in methanol (20 mL) were refluxed under nitrogen for 2.5 hours. The mixture was poured into water (10 mL), extracted with chloroform (3 × 10 mL), washed with brine, dried ($Na_2SO_4$), and evaporated to dryness. The residue was chromatographed on preparative tlc (ether–hexane 70:30 v/v) to yield the *trans* isomer **17** (440 mg) and the *cis* isomer **16** (180 mg). Recrystallized from methanol, the *trans* isomer **17** had mp 119–120°C; ir (KBr) $\nu_{max}$: 1703 (C=O), 1602 (aromatic) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 2.57 (2H, AB quartet, $J_{A,B}$ = 14 Hz, benzylic protons), 3.97 (4H, s, ethylenedioxy protons), 7.20 (5H, m, aromatic protons). *Anal.* calcd. for $C_{19}H_{24}O_3$: C 75.97, H 8.05; found: C 75.42, H 7.84.

*3-Ethylenedioxy-5-methylene-8a-phenylmethyl-*trans-*perhydronaphthalene (**18**)*

A. *Preparation from compound **17***

*trans*-Ketone **17** (50 mg; 0.17 mmol) was added at −78°C to the ylid formed by reacting at 0°C triphenylmethylphosphonium bromide (800 mg; 2 mmol) with *n*-butyllithium (0.7 mL of 2.4 *M* solution in hexane). The mixture was stirred 15 min at −78°C and then allowed to warm to room temperature for 1 hour. It was poured into water, extracted with ether, and the organic extracts were washed with water, dried ($Na_2SO_4$), concentrated *in vacuo*, and purified by preparative tlc, eluting with ether–hexane (50:50 v/v). The resultant oil was triturated with hexane and, after recrystallization from hexane, **18** melted at 75–77°C; ir (KBr) $\nu_{max}$: 3080, 1645, and 898 (exocyclic methylene) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 2.60 (2H, s, benzylic $CH_2$), 3.95 (4H, s, ethylenedioxy), 4.52 and 4.83 (2H, two broad s, $=CH_2$), 7.17 (5H, s, aromatic). *Anal.* calcd. for $C_{20}H_{26}O_2$: C 80.49, H 8.78; found: C 80.51, H 8.54.

B. *Preparation from compound **16***

The crude **16** (26 g) from the previous reaction dissolved in THF (100 mL) was added over 10 min, under $N_2$, to an ice-cold solution of methylenetriphenylphosphorane (0.219 mol) (previously prepared by stirring together for 1 hour at room temperature in THF (400 mL) potassium *tert*-butoxide (29.4 g; 0.262 mol) and methyltriphenylphosphonium bromide (78.1 g; 0.219 mol)).

The reaction mixture was warmed to room temperature, then refluxed for 20 min. It was then cooled, poured into water (500 mL), and extracted with dichloromethane (3 × 250 mL). The organic layer was washed with brine (500 mL), dried ($Na_2SO_4$), and concentrated. The residue was partitioned between 400 mL of hexane and 400 mL of 75% aqueous methanol. The lower phase was washed with another 400 mL of hexane. The combined hexane layers were dried ($Na_2SO_4$) and reduced to dryness to give a residue (23.3 g) which was purified by column chromatography on silica gel. Elution with 10% ether–hexane yielded pure **18** (11.1 g; 43.5% based on **13**), mp 75–77°C.

*Mesylate of 3-ethylenedioxy-5*β*-hydroxymethyl-8a-phenylmethyl-*trans-*perhydronaphthalene (**19**a)*

Under $N_2$ atmosphere, 150 mL of 1 *M* borane in THF was added dropwise over 15 min to an ice-cold solution of *trans* olefin **18** (20.4 g; 68.4 mmol) in dry THF (100 mL). The mixture was stirred at room temperature for 1.5 hours, cooled in an ice–water bath, and 30 mL of methanol was added dropwise to decompose excess borane. Sodium hydroxide (1 *N*, 30 mL) and then 30% hydrogen peroxide (20 mL) were added, each over a period of 15 min. After stirring for 15 min at 0°C, a solution of sodium sulfite (18 g) in water (100 mL) was added dropwise to decompose excess peroxide. The mixture was extracted with methylene chloride (3 × 500 mL). The organic layer was washed with water, dried ($Na_2SO_4$), and evaporated. The crude residue was chromatographed on silica gel eluting with 2.5% methanol–chloroform, to yield **19***a* (13.6 g, 63%); ir (KBr) $\nu_{max}$: 3400 (OH), 1600 (aromatic) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 2.60 (2H, AB quartet; $J_{A,B}$ = 14 Hz, benzylic), 3.67 (2H, m, $—CH_2O$), 3.90 (4H, s, ethylenedioxy), 7.17 (5H, s, aromatic); *m/e*: 316 ($M^+$).

To an ice-cold solution of the alcohol derivative **19***a* (6.8 g; 21.5 mmol) in pyridine (100 mL) was added methanesulfonyl chloride (3.7 g; 32 mmol). The mixture was stored at 0°C for 3 days, then was evaporated to dryness *in vacuo* and the residue was partitioned between ether and water. The organic layer was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

washed with water, dried ($Na_2SO_4$), and evaporated to provide the solid mesylate **19***b*, mp 121–126°C (8.1 g; 95%). Recrystallization from cyclohexane raised the mp to 141–143°C; ir (KBr) $\nu_{max}$: 1350, 1175 ($SO_2$) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 2.58 (2H, AB quartet, $J_{A,B}$ = 14 Hz, benzylic $CH_2$), 2.97 (3H, s, $OSO_2CH_3$), 3.97 (4H, s, ethylenedioxy), 4.25 (2H, m, —$CH_2O$), 7.17 (5H, s, aromatic); *m/e*: 394 ($M^+$). *Anal.* calcd. for $C_{21}H_{30}SO_5$: C 63.93, H 7.66, S 8.12; found: C 64.00, H 7.73, S 8.11.

*5β-Azidomethyl-3-ethylenedioxy-8a-phenylmethyl-*trans*-perhydronaphthalene (20)*

A mixture of mesylate **19***b* (8.5 g; 21.5 mmol), sodium azide (17 g; 262 mmol), and 100 mL of DMF was heated in an oil bath preheated to 125°C, under $N_2$ for 1 hour. The mixture was poured into water and extracted with ether. The organic layer was washed with water, dried ($Na_2SO_4$), and evaporated to give a mixture (5.8 g) which was chromatographed on silica gel, eluting with 10% ether – *n*-hexane to give regenerated olefin **18** (3.1 g; 49%) and the desired azide **20** (2.0 g; 28%), which crystallized on standing, mp 88–89°C; ir (KBr) $\nu_{max}$: 2100 ($N_3$) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 2.63 (2H, AB quartet, $J_{A,B}$ = 14 Hz, benzylic $CH_2$), 3.43 (2H, m, $CH_2N_3$), 3.97 (4H, s, ethylenedioxy), 7.17 (5H, s, aromatic). *Anal.* calcd. for $C_{20}H_{27}N_3O_2$: C 70.35, H 7.97, N 12.30; found: C 70.39, H 8.15, N 12.00.

*5β-Aminomethyl-3-oxo-8a-phenylmethyl-*trans*-perhydronaphthalene (2*a*)*

To a suspension of LAH (1.0 g; 26 mmol) in THF (150 mL) was added the azide **20** (3.5 g; 10.3 mmol) in THF (25 mL). After stirring under $N_2$ for 30 min at room temperature, the reaction was quenched with water (0.5 mL), 15% NaOH (0.5 mL), and water (1.5 mL). The mixture was filtered and the filtrate concentrated to yield crude 5β-aminomethyl-3-ethylenedioxy-8a-phenylmethyl-*trans*-perhydronaphthalene (3.4 g) which was taken up in methanol (150 mL), water (10 mL) and concentrated HCl (5 mL). This mixture was heated under $N_2$ for 30 min at 70°C, then stirred at room temperature for 30 min. The resultant crystals were filtered and washed with ether to yield **2***a* (3.0 g; 64% from **20**), mp 285°C (dec.); ir (KBr) $\nu_{max}$: 1710 (C=O) $cm^{-1}$; $^1$Hmr (DMSO-$d_6$) δ: 2.2–3.2 (6H, m, $CH_2$—CO—$CH_2$ and —$CH_2$—$NH_2$), 7.27 (5H, s, aromatics). *Anal.* calcd. for $C_{18}H_{25}NO.HCl$: C 70.22, H 8.51, N 4.55, Cl 11.51; found: C 69.93, H 8.88, N 4.46, Cl 11.41.

*3-Oxo-5β-formamidomethyl-8a-phenylmethyl-*trans*-perhydronaphthalene (2*b*)*

To the HCl salt **2***a* (210 mg; 0.77 mmol) in formic acid (10 mL) was added formic acetic anhydride (5 mL) and sodium bicarbonate (500 mg). The reaction mixture was refluxed overnight, then concentrated *in vacuo*, diluted with methylene chloride, washed with sodium bicarbonate, dried ($Na_2SO_4$), and concentrated *in vacuo*, to yield a residue which was purified by preparative tlc (5% methanol–chloroform). Recrystallization from methylene chloride – hexane yielded **2***b*, mp at 198–199°C.

This material, compared to the formyl derivative prepared by Scheme 1, was found to be identical and had mixture mp 197–199°C.

*5β-Azidomethyl-3-oxo-8a-phenylmethyl-*trans*-perhydronaphthalene (2*c*)*

The ketal **20** (9.5 g; 28.7 mmol) was dissolved in methanol (200 mL) and 3 *N* hydrochloric acid (50 mL) was added slowly. The mixture was stirred at room temperature for a period of 2.5 hours. The resultant crystals were filtered off to yield **2***c* (7.6 g, 89%), mp 155–157°C; ir (KBr) $\nu_{max}$: 2100 ($N_3$), 1690 (C=O) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 2.77 (2H, AB quartet; *J* = 14 Hz, benzylic), 3.47 (2H, m, $CH_2N_3$), 7.17 (5H, s, aromatic). *Anal.* calcd. for $C_{18}H_{23}N_3O$: C 72.70, H 7.79, N 14.13; found: C 72.90, H 7.76, N 13.91.

*Ethyl-2-diethylphosphono-4-methylthiobutyrate (21)*

Triethylphosphonoacetate (4.4 g; 20 mmol) was added slowly to a suspension of sodium hydride (0.95 g of 50% dispersion in oil) in dimethylformamide (15 mL). Methylthioethylchloride (4.4 g; 40 mmol) was then added and the resulting mixture was heated overnight at 80°C. A precipitation of sodium chloride occurred after three hours. The reaction mixture was cooled, filtered, and evaporated to dryness. The residue was then distilled to yield first unreacted triethylphophonoacetate: bp 105°C/0.5 Torr and then **21**; bp 127–135°C/0.5 Torr (2.8 g; 42% yield); ir (film) $\nu_{max}$: 1735 (C=O) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 1.37 (9H, m, $3CH_3$), 2.17 (3H, s, $SCH_3$), 2.5 (4H, m), 3.03 (1H, m), 4.2 (6H, m, $3CH_2$). *Anal.* calcd. for $C_{11}H_{23}PO_5S$: C 44.28, H 7.77, S 10.75; found: C 44.09, H 7.80, S 10.70.

*Z- and E-3-(3'-Methylthio-1'-carbomethoxypropylidin-1'-yl)-5β-formamidomethyl-8a-phenylmethyl-*trans*-perhydronaphthalene (22*a*)*:

To sodium hydride (25 mg; 50% dispersion in mineral oil, 0.54 mmol) suspended in dimethoxyethane (5 mL) at 0°C under $N_2$ was added ethyl 2-diethylphosphono-4-methylthiobutyrate (150 mg; 0.5 mmol). After stirring for 30 min, the mixture was cooled to −78°C and ketone **2***b* (30 mg; 0.1 mmol) in dimethoxyethane (2 mL) was added. The mixture was stirred at −78°C for 1 hour and then warmed to an internal temperature of 80°C for 6 hours. The mixture was poured into water and extracted with ether. The organic layer was washed with water, dried ($Na_2SO_4$), and concentrated *in vacuo* to yield a residue (197 mg) that was chromatographed on a preparative tlc plate, eluting with 2% methanol–chloroform. The product, $R_f$ = 0.2 (19 mg; 43%), was a mixture of desired **22***a* and of isomer **23***a* as could be determined by the presence of two carbonyl absorptions at 1685 $cm^{-1}$ and 1735 $cm^{-1}$ respectively in the ir spectrum.

*Z- and E-3-(3'-Methylthio-1-carbomethoxy propylidinyl)-5β-azidomethyl-8a-phenylmethyl-*trans*-perhydronaphthalene (22*b*)*:

To a suspension of sodium hydride (47 mg; 50% dispersion in mineral oil; 1 mmol) in dimethoxyethane (5 mL) at 0°C under $N_2$ was added **21** (300 mg; 1 mmol). After stirring for 30 min, ketone **2***c* (27 mg; 0.1 mmol) in DMF (1 mL) was added. The reaction mixture was heated at 80°C for 4 hours. It was then poured into water and extracted with ether. The organic layer was washed with water, dried ($Na_2SO_4$), and concentrated *in vacuo*. The residue was chromatographed on a preparative tlc plate, eluting with ether–hexane 1:5 v/v to give 18 mg (41%) of a mixture of **22***b* and **23***b* as a yellowish oil. The presence of a mixture was again demonstrated by ester absorptions of equal intensity at 1730 $cm^{-1}$ and 1700$^{-1}$.

*Methyl 2-trimethylsilyl-4-methylthiobutyrate (25)*

To a solution of diisopropylamine (128 g; 1.27 mol) in anhydrous THF (1 L) cooled to 0°C was added dropwise over 20 min *n*-butyllithium (557 mL of 2.28 *M* in hexane). The mixture was stirred for 30 min at 0°C. α-Trimethylsilylacetic acid (**23**) (76.3 g; 0.58 mol) dissolved in anhydrous THF (100 mL) was then added dropwise over a period of 15 min and the resulting mixture was stirred at 0°C for 30 min. 2-Methylthioethylchloride (67 g; 0.60 mol) was then added dropwise over 15 min. The reaction mixture was refluxed for 70 h, then was cooled to room temperature and poured into 1.5 liters of water. The organic layer was removed and the aqueous layer was further washed with ether. The aqueous layer was acidified with 20% citric acid and extracted several times with ether. These ether extracts were washed with water, dried ($Na_2SO_4$), and evaporated to give a crude residue that was distilled under vacuum to provide **24**, bp 130°C/0.2 Torr (27 g; 23% yield); $^1$Hmr δ: 0.1 (9H, s,

For personal use only.

—$SiMe_3$), 2.1 (3H, s, $SCH_3$), 10.3 (1H, b, exchanged by $D_2O$, COOH).

The acid was esterified ($CH_2N_2$, excess) in ether. The resulting solution was washed with sodium bicarbonate (5%), dried ($Na_2SO_4$), concentrated, and purified by preparative hplc (5% ether–hexane) to give 19 g (69%) of methyl-2-trimethylsilyl-4-methylthiobutyrate **25**; ir (KBr) $\nu_{max}$: 1712 $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 0.15 (9H, s, $SiMe_3$), 2.07 (3H, s, $SCH_3$), 3.67 (3H, s, $COOCH_3$). *Anal.* calcd. for $C_9H_{20}SSiO_2$: C 49.04, H 9.15, S 14.55; found: C 49.23, H 9.18, S 14.32.

*3-(3'-Methylthio-1'-carbomethoxypropylidinyl)-5β-azidomethyl-8a-phenylmethylperhydronaphthalene (**26**)*

To a solution of diisopropylamine (4.75 mL; 36 mmol) in tetrahydrofuran (100 mL) at 0°C under $N_2$ was added a 2.2 *M* solution of *n*-butyl lithium in hexane (16.36 mL; 36 mmol). The mixture was stirred at 0°C for 15 min and then cooled at −78°C. Ester **25** (8 g; 36.4 mmol) dissolved in 10 mL tetrahydrofuran was added over 5 minutes. The resulting mixture was stirred for 20 min at −78°C and then ketone **2***c* (5.23 g; 17.6 mmol) in 40 mL tetrahydrofuran was added dropwise over a period of 10 min. The reaction mixture was stirred at −78° for another 10 min, and was allowed to warm to room temperature. The mixture was poured into water and extracted with ether. The organic phase was washed successively with 3 *N* hydrochloric acid and with water, dried ($Na_2SO_4$), and evaporated to dryness to yield a pale yellow oil which was chromatographed on silica gel. Elution with 5% ether–hexane gave successively methyl ester **25** (5.2 g), and the mixture of *E* and *Z* isomers of the desired product **26** (7.2 g; 96%); ir (NaCl) $\nu_{max}$: 2100 ($N_3$), 1705 (C=O) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 2.13 (3H, s, $SCH_3$), 2.60 (4H, s, $CH_2CH_2$), 3.50 (2H, m, $CH_2N_3$), 3.73 (3H, s, $OCH_3$), 7.17 (5H, s, aromatic); *m/e*: 427 (weak, $M^+$), 399 (M − $N_2$), 384 (M − $HN_3$).

*Z and E Isomers of 3-(3'-methylthio-1'-carbomethoxypropylidinyl)-5β-aminomethyl-8a-phenylmethyl-*trans*-perhydronaphthalene (**27**a and **27**b)*

The *Z* and *E* mixture of azide **26** (7.5 g; 17.6 mmol) was dissolved in methanol (300 mL) and hydrogenated in a Parr hydrogenator at 30 psi for one hour over platinum oxide (500 mg). The reaction mixture was filtered through Celite and concentrated *in vacuo* to yield an oil which was chromatographed on silica gel. Elution with methanol–chloroform – aqueous ammonia (2000:40:5 v/v/v) gave the *E* isomer (3.6 g) and the *Z* isomer (3.4 g) successively (99% combined yield). The *E* isomer **27***a* recrystallized from ether gave an analytical sample, mp 96.5–97.5°C; ir (KBr) $\nu_{max}$: 1705 ($COOCH_3$), 1610, 3350 ($NH_2$) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 2.10 (3H, s, $SCH_3$), 2.53 (4H, s, —$CH_2CH_2S$—), 3.75 (3H, s, $OCH_3$), 7.07 (5H, s, aromatic); *m/e*: 401 ($M^+$), 386 (M − $CH_3$), 370 (M − $OCH_3$), 354 (M − $SCH_3$), 340 (base peak, M − $CH_2SCH_3$), 310 (M − $CH_2C_6H_5$). *Anal.* calcd. for $C_{24}H_{35}NO_2S$: C 71.78, H 8.78, N 3.49, S 7.98; found: C 71.89, H 8.92, N 3.42, S 7.69.

The *Z* isomer **27***b* recrystallized from ether gave an analytical sample, mp 104–106°C; ir (KBr) $\nu_{max}$: 1705 ($COOCH_3$), 1610, 3350 ($NH_2$) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 2.10 (3H, s, $SCH_3$), 2.53 (4H, s, —$CH_2CH_2S$—), 3.73 (3H, s, $OCH_3$), 7.07 (5H, s, aromatic); *m/e*: 401 ($M^+$), 386, 370, 354, 340 (base peak), 310. *Anal.* calcd. for $C_{24}H_{35}NO_2S$: C 71.78, H 8.78, N 3.49, S 7.98; found: C 71.93, H 8.89, N 3.43, S 7.71.

*X-ray structure determination of **27**a*

Suitable crystals of **27***a* for single crystal X-ray diffraction experiments formed from ether containing traces of chloroform. Preliminary diffraction experiments indicated that the space group was *P*1 with $a$ = 11.029(4) Å, $b$ = 13.460(4), $c$ = 8.709(2), α = 97.80(2)°, β = 110.34(2), and γ = 68.78(2) for $Z$ = 2. Of the 3061 reflections collected using CuKα radiation (λ = 1.5418 Å), 2624 were observed and corrected for Lorentz and polarization effects. Application of direct methods (29) and tangent formula recycling procedures (30) provided initial coordinates for all nonhydrogen atoms. After refinements and Fourier calculations hydrogens were placed and refined. The function $\Sigma w(|F_o| - |F_c|)^2$ was minimized with full matrix least squares techniques (31) to give an unweighted residual factor of 0.077. Tables 1, 2, and 3 contain the final atomic coordinates and temperature parameters, bond distances, and bond angles, respectively.[1]

*The coupling of **27**a with* N-t-*BOC-tyrosine*

A solution of the *E* isomer **27***a* (2.63 g; 6.56 mmol), *t*-BOC tyrosine (3.72 g; 13.2 mmol), dicyclohexylcarbodiimide (2.72 g; 15 mmol), and 1-hydroxybenzotriazole (2.03 g; 15 mmol) in methylene chloride (140 mL) was stirred at room temperature overnight. The reaction mixture was diluted with ether and was then filtered. The cake was washed with ether. The combined filtrates were washed with 20% citric acid, with 5% sodium bicarbonate, and with water. After drying over sodium sulfate, the solution was evaporated to a foam (6.08 g).

The mixture of diastereoisomers was separated by chromatography on silica gel eluting with a mixture of 1% butanol–chloroform to yield the desired coupled products **28***a* and **28***b*. The less polar isomer, arbitrarily assigned structure **28***a* (1.78 g; 44% yield), was a glass, mp 104–106°C. The more polar isomer, arbitrarily assigned structure **28***b* (1.85 g, 45% yield), was a glass, mp 106–108°C.

**28***a*: ir (KBr) $\nu_{max}$: 3350 (NH amide), 1700, 1665 $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 1.40 (9H, s, —$C(CH_3)_3$), 2.10 (3H, s, $SCH_3$), 2.55 (4H, broad s, —$CH_2CH_2$—S—), 3.73 (3H, s, $OCH_3$), 4.13 (1H, m, tyrosyl methyne), 5.33 (b d, exchanged by $D_2O$, $J$ = 8 Hz, tyrosyl NH—BOC), 5.53 (1H, broad, NH amide, exchanged by $D_2O$), 6.80 (4H, $A_2B_2$ quartet, tyrosyl aromatics), 7.10 (5H, s, aromatics), 7.85 (s, 1H, OH, exchanged by $D_2O$).

**28***b*: ir (KBr) $\nu_{max}$: 3340, 1700, 1660 $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 1.37 (9H, s, —$C(CH_3)_3$), 2.07 (3H, s, $SCH_3$), 2.53 (4H, b, $CH_2CH_2S$), 3.68 (3H, s, $OCH_3$), 4.18 (1H, m, tyrosyl methyne), 5.20 (1H, d, $J$ = 8 Hz, tyrosyl—NH—BOC, exchanged by $D_2O$), 5.97 (1H, broad, NH amide, exchanged by $D_2O$), 6.77 (4H, $A_2B_2$ quartet, tyrosyl aromatics), 7.07 (5H, s, aromatics), 7.97 (s, 1H, OH, exchanged by $D_2O$).

*The coupling of **27**b with* N-t-*BOC tyrosine*

Similarly, reacting the *Z* isomer **27***b* (2.5 g) with *t*-BOC tyrosine (3.46 g), dicyclohexylcarbodiimide (2.53 g), and 1-hydroxybenzotriazole (1.9 g) in methylene chloride (125 mL) afforded after extraction with ether 5.7 g of a crude mixture of diastereoisomers that was separated by chromatography on silica gel.

**28***c*: (less polar diastereoisomer), 1.5 g (39%) as a glass, mp 100–104°C; ir (KBr) $\nu_{max}$: 3350, 1700, 1660 $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 1.40 (9H, s, *t*-Bu), 2.08 (3H, s, $SCH_3$), 2.57 (4H, broad s, $CH_2CH_2S$), 3.67 (3H, s, $OCH_3$), 4.17 (1H, m, tyrosyl methyne), 5.23 (1H, $J$ = 8 Hz, d, NH—BOC, exchanged by $D_2O$), 6.17 (1H, b, amide NH, exchanged by $D_2O$), 6.80 (4H, $A_2B_2$ quartet, $J_{AB}$ = 8 Hz, tyrosyl aromatic), 7.05 (5H, s, aromatic), 7.85 (1H, b s, OH, exchanged by $D_2O$).

**28***d*: (more polar diastereoisomer), 1.22 g (31%) as a glass, mp 108–111°C; ir (KBr) $\nu_{max}$: 3350, 1700, 1660 $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 1.40 (9H, s, *t*-Bu), 2.07 (3H, s, $SCH_3$), 2.53 (4H, b s, $CH_2CH_2S$), 3.67 (3H, s, $OCH_3$), 4.2 (1H, m, tyrosyl methyne), 5.13 (1H, d, $J$ = 8 Hz, NH—BOC exchanged by $D_2O$), 5.90 (1H, b s, NH amide, exchanged by $D_2O$), 6.80 (4H, $A_2B_2$ quartet, $J_{AB}$ = 8 Hz, tyrosyl aromatic), 7.07 (5H, s, aromatic), 7.40 (1H, b s, OH, exchanged by $D_2O$).

*The four isomers of* trans-*methyl-2-(decahydro-4β-(phenylmethyl)-8β-(L-tyrosylaminomethyl)-2-naphthalenylidene)-4-(methylthio)butanoate HCl monohydrate* **1**a–d

The blocked derivatives **28***a–d* dissolved in chloroform (25 mL) were saturated with anhydrous hydrogen chloride and the resulting mixtures were stirred at room temperature for one hour. In each case the excess hydrogen chloride was blown off with a stream of nitrogen and the chloroform solution was washed with sodium bicarbonate and with water. The organic phase was dried over sodium sulfate and evaporated to dryness, leaving a residue which was purified by preparative hplc, eluting with 3% methanol–chloroform. The resulting derivative was taken up in chloroform, treated with hydrogen chloride, and evaporated to dryness. The residue was triturated in ether and filtered. Thus **28***a* (1.68 g) gave **1***a* (1.37 g; 89%), mp 154–156°C, $[\alpha]_D^{22}$ 0 (*c* 1.0, MeOH); ir (KBr) $\nu_{max}$: 3500–2600 ($NH_3^+$), 1700, 1670 $cm^{-1}$; $^1$Hmr ($CDCl_3$) (on free base) δ: 2.10 (3H, s, $SCH_3$), 2.57 (4H, s, $CH_2CH_2S$), 3.73 (3H, s, $OCH_3$), 3.80 (3H, $NH_2$ and OH, exchanged by $D_2O$), 6.90 (4H, $A_2B_2$ quartet, $J = 8$ Hz, tyrosyl aromatics), 7.13 (5H, s, aromatic), 7.45 (1H, b, amide NH, exchanged by $D_2O$); *m/e*: 564 ($M^+$), 503 ($M^+ - CH_2SCH_3^+$). *Anal.* calcd. for $C_{33}H_{44}N_2O_4S.HCl.\frac{1}{2}H_2O$: C 64.83, H 7.71, N 4.65; found: C 64.95, H 7.59, N 4.59.

Similarly **28***b* (1.77 g) gave **1***b* (1.30 g; 80%), mp 162–164°C, $[\alpha]_D^{22}$ +67.7° (*c* 1.0, MeOH); ir (KBr) $\nu_{max}$: 3500–2600 ($NH_3^+$), 1700, 1670 $cm^{-1}$; $^1$Hmr ($CDCl_3$) (on free base) δ: 2.10 (3H, s, $SCH_3$), 2.57 (4H, s, $CH_2CH_2S$), 3.73 (3H, s, $OCH_3$), 3.70 (3H, $NH_2$ and OH, exchanged by $D_2O$), 6.87 (4H, $A_2B_2$ quartet, $J = 8$ Hz, tyrosyl aromatic), 7.10 (5H, s, aromatic), 7.40 (1H, b s, NH amide, exchanged by $D_2O$); *m/e*: 546 ($M^+$), 503 ($M^+ - CH_2SCH_3$). *Anal.* calcd. for $C_{33}H_{44}N_2O_4S.HCl.\frac{1}{2}H_2O$: C 64.83, H 7.71, N 4.65; found: C 64.53, H 7.58, N 4.54.

Similarly, **28***c* (1.5 g) gave **1***c* (0.75 g; 54%), mp 149–151°C, $[\alpha]_D^{22}$ −17.1° (*c* 1.0, MeOH); ir (KBr) $\nu_{max}$: 3500–2600 ($NH_3^+$), 1700, 1670 $cm^{-1}$; $^1$Hmr ($CDCl_3$) (free base) δ: 2.10 (3H, s, $SCH_3$), 2.57 (4H, s, $CH_2CH_2S$), 3.73 (3H, s, $OCH_3$), 3.70 (3H, $NH_2$ and OH, exchanged by $D_2O$), 6.87 (4H, $A_2B_2$ quartet, $J = 8$ Hz, tyrosyl aromatic), 7.10 (5H, s, aromatic), 7.40 (1H, b s, NH amide, exchanged by $D_2O$), 7.47 (1H, b s, NH amide, exchanged by $D_2O$); *m/e*: 564 ($M^+$), 503 ($M - CH_2SCH_3$). *Anal.* calcd. for $C_{33}H_{44}N_2O_4S.HCl$: C 65.92, H 7.54, N 4.66; found: C 65.78, H 7.62, N 4.50.

Similarly, **28***d* (1.15 g) gave **1***d* (0.750 g; 54%), mp 157–160°C, $[\alpha]_D^{22}$ +79.1° (*c* 1.0, MeOH); ir (KBr) $\nu_{max}$: 3500–2600 ($NH_3^+$), 1700, 1670 $cm^{-1}$; $^1$Hmr ($CDCl_3$) (free base) δ: 2.13 (3H, s, $SCH_3$), 2.57 (4H, s, $CH_2CH_2S$), 3.60 (3H, $NH_2$ and OH, exchanged by $D_2O$), 3.70 (3H, s, $OCH_3$), 6.87 (4H, $A_2B_2$ quartet, $J = 8$ Hz, tyrosyl aromatic), 7.13 (5H, s, aromatic), 7.57 (1H, b s, NH amide, exchanged by $D_2O$); *m/e*: 546 ($M^+$), 503 ($M - CH_2SCH_3$). *Anal.* calcd. for $C_{33}H_{44}N_2O_4S.HCl.\frac{1}{2}H_2O$: C 64.83, H 7.71, N 4.65; found: C 65.33, H 7.86, N 4.48.

## Acknowledgments

The authors wish to thank Dr. P. Gund and G. M. Smith (Merck Sharp & Dohme Research Laboratories, Rahway, New Jersey) for their help and discussions regarding the Merck Modeling System, and Dr. F. M. Robinson (Merck Sharp & Dohme Research Laboratories, Rahway, New Jersey) for useful and frequent discussions on analgesics.

# Enzymes in organic synthesis. 23.[1] Effects of organic solvents on horse liver alcohol dehydrogenase-catalyzed oxidation

J. Bryan Jones and Harold M. Schwartz

*Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1*

Received November 2, 1981

J. Bryan Jones and Harold M. Schwartz. Can. J. Chem. **60**, 1030 (1982).

The effects have been evaluated of up to 50% (v/v) of methanol, *tert*-butyl alcohol, dimethylsulfoxide, sulfolane, acetonitrile, dimethylformamide, *N*-methyl-2-pyrrolidone, hexamethylphosphoramide, acetone, 2-butanone, tetrahydrofuran, dimethoxyethane, diglyme, and dioxane on horse liver alcohol dehydrogenase (HLADH)-catalyzed oxidation of the representative alcohol substrate cyclohexanol. With the exception of dimethylsulfoxide and dimethylformamide, all solvents tested are suitable for use as cosolvents with HLADH in the oxidative and reductive directions.

J. Bryan Jones et Harold M. Schwartz. Can. J. Chem. **60**, 1030 (1982).

Utilisant des concentrations de solvant allant jusqu'à 50% (v/v), on a étudié l'effet du méthanol, du *tert*-butanol, du diméthylsulfoxyde, du sulfolane, de l'acétonitrile, du diméthylformamide, de la *N*-méthylpyrrolidone-2, de l'hexaméthylphosphoramide, de l'acétone, de la butanone-2, du tétrahydrofuranne, du diméthoxyéthane, du diglyme et de la dioxanne sur l'oxydation d'un alcool typique, le cyclohexanol, catalysée par la dehydrogénase d'alcool du foie de cheval (DAFC). A l'exception du diméthylsulfoxyde et du diméthylformamide, tous les solvants utilisés peuvent servir de cosolvants à la DAFC aussi bien pour l'oxydation que pour la réduction.

[Traduit par le journal]

Most of the compounds and intermediates encountered in organic synthesis are hydrophobic in nature and do not dissolve to any significant extent in water. Accordingly, for the full potential of enzymes in organic synthesis to be realized, it is necessary to induce sufficient solubility of hydrophobic compounds in the aqueous media preferred by enzymes to ensure that such organic substrates are readily accessible to the enzymic catalysts. The most convenient general method for achieving this goal is by the addition of water-miscible organic solvents to the reaction medium and we are currently surveying this topic (1*a*–*d*) in order to identify the most suitable organic cosolvents for preparative-scale applications of enzymes.

Alcohol dehydrogenases, which catalyze alcohol oxidations and ketone reductions of central asymmetric synthetic importance via the reaction pathway depicted in eq. [1][2], are among the most useful

[1] $\rangle CHOH + NAD^+ \rightleftharpoons \rangle C{=}O + NADH + H^+$

enzymes of current value for preparative-scale reactions (1*f*). In this paper, we report on the effects of various solvents on the catalytic activity of HLADH-catalyzed oxidation of its representative alcohol substrate, cyclohexanol.

[1]For Part 22, see ref. 1*a*. Abstracted from the Ph.D. thesis of H.M.S., University of Toronto (1979).

[2]Abbreviations used: $NAD^+$ and NADH, oxidized and reduced forms respectively of nicotinamide adenine dinucleotide; HLADH, horse liver alcohol dehydrogenase; DMSO, dimethylsulfoxide; DMF, dimethylformamide; NMP, *N*-methyl-2-pyrrolidone; HMPA, hexamethylphosphoramide; THF, tetrahydrofuran.

## Results

As in the reductive mode study carried out previously (1*a*), a range of common water-miscible protic and aprotic solvents of different polarities was considered. The solvents used were, protic: methanol and *tert*-butyl alcohol; aprotic: DMSO, sulfolane, acetonitrile, DMF, NMP, HMPA, acetone, 2-butanone, THF, dimethoxyethane, diglyme, and dioxane. The effects of up to 50% of each cosolvent on HLADH-catalyzed oxidation were evaluated using cyclohexanol as representative substrate. The oxidations were carried out in 0.1 *M* glycine – NaOH buffer pH 9.0 at 0.5 m*M* $NAD^+$ and 1, 5, and 25 m*M* cyclohexanol concentrations. The relative activities recorded, based on initial velocities, are summarized in Table 1. While all solvents have a deleterious influence at their highest concentrations, HLADH is seen to be remarkably tolerant of many of the added solvents when operating in its oxidation mode. The worst cosolvents are DMSO and DMF, both of which inhibit strongly at low concentrations. The most remarkable effects are seen with NMP, HMPA, and diglyme, in the presence of which the activity of the enzyme is actually increased initially. Attempts to identify the nature of the generally inhibitory effects of the solvents using Lineweaver–Burk and Dixon analyses (2) of the Table 1 data were inconclusive, with nonlinear plots being obtained in each case.

## Discussion

As for the analogous study on HLADH-catalyzed reduction (1*a*), the solvents were chosen to en-

[c]Intermediate activities were observed at 2 and 3% organic solvent levels.

compass as broad a range of the common, water-miscible, solvents as possible. Both protic and aprotic solvents were considered, with dielectric constant used as the guide to polarity. The choice of protic solvents was restricted to methanol and *tert*-butyl alcohol since the other common alcohol solvents were themselves substrates. However, with the enzyme operating in its oxidation mode, the ketone solvents acetone and 2-butanone, excluded in the reductive study (1*a*) because they were substrates, could now be evaluated.

Cyclohexanol was selected as the substrate since

its behaviour with HLADH is representative of organic alcohol substrates in general (1*e*) and the mechanism of its HLADH-catalyzed oxidation has been thoroughly investigated (3). Cyclohexanol has a relatively low $K_m$ of 0.7 m*M* (3*a*) thus permitting facile evaluation of its oxidation at saturating levels. Furthermore, above a 5 m*M* concentration, substrate activation takes place (3*a*). In order to determine the effects of cosolvents under differing kinetic conditions, the cyclohexanol concentration values selected for the current study were set at a value close to the $K_m$ (1 m*M*) at the beginning of the substrate activation range (5 m*M*), and at 25 m*M*, a level ensuring considerable substrate activation. A saturating concentration (0.5 m*M*) of the $NAD^+$ coenzyme was employed throughout.

For each cosolvent studied, the initial oxidation velocities were determined in glycine–NaOH buffers of pH 9.0, the normal preparative-scale pH for oxidation reactions (1*f*). Neither the apparent pH's of the assay solutions (4), nor the reaction rates, were sufficiently affected by the added organic solvents to require corrections to be made to the raw data. While additions of organic cosolvents do affect the pH optima of enzymes, the deviations induced at the solvent concentrations employed in this study are seldom >0.5 pH units (1*a*, *c*, *d*).

For each cosolvent, the concentration was increased progressively until the enzyme retained ~15% or less of its initial activity, a level selected as representing the effective lower limit of activity in any practical preparative-scale use of HLADH.

The enzymic activities were determined by monitoring the 340 nm absorbance charges of the coenzyme. When methanol, HMPA, and acetonitrile were present, increases in the 340 nm absorption occurred even when the substrate was not present. For methanol, this substrate-independent rate is likely due to its slow HLADH-catalyzed oxidation to formaldehyde (5, 6). The effect of HMPA may be due to its known affinity for electrophiles (7), which would result in the formation of an addition complex with $NAD^+$ (8). The effect on $NAD^+$ of acetonitrile is probably the result of nucleophilic addition of the trace of cyanide which is present even in doubly distilled acetonitrile (9). The relative activity rates of Table 1 have been corrected for these nonenzymic solvent-induced rates.

The Table 1 data show that HLADH is remarkably tolerant of added cosolvents when operating in its oxidation mode. This is in sharp contrast to the situation observed for HLADH-catalyzed reduction, where the enzyme was found to be much more sensitive to the presence of cosolvents (1*a*). Of the Table I solvents, the only strong inhibitors at low concentration levels are DMSO and DMF. Their deleterious effects were expected since both are known to coordinate to the catalytically essential zinc ion at the active site (10). For all of the other cosolvents tested, HLADH retains significant activity at concentration levels as high as 20% (v/v), with sulfolane and NMP remaining viable up to 40% (v/v). HMPA is the most remarkable of all, with preparatively useful enzyme activity levels being retained even in 50% (v/v) solutions.

Another feature which distinguishes the oxidation situation from that of reduction is the pronounced enhancement of HLADH activity induced by several of the cosolvents. For HLADH-catalyzed reduction of cyclohexanone, only one instance of a modest rate increase, in 5% HMPA solution, was observed. In contrast, for the oxidation reactions of the current study, each of NMP, HMPA, and diglyme stimulated the enzymic activity over a range of different concentration levels. The effect is most dramatic for HMPA, where the normal aqueous solution activity of the enzyme is exceeded within the cosolvent concentration range of 1–30% (v/v). The behaviour of the enzyme in HMPA solutions, being stimulated at lower, and inhibited at higher, concentrations resembles the response of HLADH to imidazole (11), a modifier which can bind to the active site zinc ion (12). The solvent-mediated protein conformation changes (13) responsible for this activation phenomenon are clearly catalytically much more effective in the oxidation than the reduction direction. Again, as noted in the previous reductive solvent effects study (1*a*), no correlation of the inhibitory power of a solvent with its dielectric constant, nor its aprotic or protic character, is evident from the Table 1 results.

In the reductive mode study (1*a*), Lineweaver–Burk and Dixon plot analyses provided useful information on the nature of the inhibition by most of the solvents studied. It is unfortunate that similar analyses of the Table 1 data did not give interpretable plots since the literature data on the influence of solvents on HLADH-catalyzed oxidations is very limited. To our knowledge, detailed studies have been performed only for methanol, which forms a ternary $E{\cdot}NAD^+{\cdot}MeOH$ complex (14), and DMSO, a competitive inhibitor which acts by binding to the active site zinc ion (10, 15, 16).

For some solvents, increasing the substrate concentration affords partial protection against the inactivation process. These include methanol, sulfolane, acetonitrile, HMPA, acetone, and THF. For the other solvents, substrate concentration changes have little effect on the activity at any one cosolvent concentration.

*Summary of solvent effects on HLADH-catalyzed oxidation and reduction*

The presence of high concentrations of organic cosolvents is generally deleterious to HLADH activity. However, the effects are considerably more adverse for the reductive reaction (1*a*). In fact, HLADH is remarkably tolerant of high organic solvent concentrations in its oxidative mode.

DMSO and DMF are strongly inhibitory in both directions and should not be used as cosolvents. Also, the common solvents that are potential substrates must clearly be excluded. These include primary and secondary alcohols (methanol, ethanol, 2-propanol) in oxidation reactions, and ketones (acetone, 2-propanone) for the reductive direction. Those solvents that interact with the coenzyme should also be avoided if possible. Methanol, HMPA, and acetonitrile are in this category for both oxidative and reductive directions, although they are suitable for short- to medium-term reactions involving rapidly transformed substrates. The peroxide contaminants of the ethereal solvents THF, dimethoxyethane, diglyme, and dioxane may also cause problems during long-term use.

The most innocuous solvents for general use in HLADH-catalyzed oxidations appear to be *tert*-butyl alcohol, sulfolane, NMP, and acetone. The corresponding list for reduction is ethanol, *tert*-butyl alcohol, and sulfolane. Unfortunately, sulfolane and NMP are not very effective cosolvents for hydrophobic substrates. However, *tert*-butyl alcohol provides a good balance of hydrophobic and hydrophilic properties and should be a good general cosolvent for many substrates in either catalytic direction. For substrates with unique characteristics or unusual combinations of functional groups, the general recommendations made above may not give optimum results. In such cases, data provided by the current and previous (1*a*) studies will aid the selection of the most suitable cosolvent for any individual substrate. Also, it should always be borne in mind that it is not necessary to achieve complete substrate solubility. Satisfactory reaction rates will result as soon as sufficient substrate is accessible to the enzyme. These levels are often attained when only a small proportion of the substrate has been brought into solution.

## Experimental

HLADH, prepared by the method of Roy and Nishikawa (17), was generously donated by Hoffmann-La Roche. The enzyme may also be purchased from Sigma. The solvents were purified as described previously (1*a*) and were redistilled immediately prior to use, as was cyclohexanol.

*Relative rate studies*

These were carried out by the general procedure described for the previous HLADH-catalyzed reduction study (1*a*) at 25°C in 0.1 *M* glycine – NaOH buffer pH 9.0 containing varying proportions of cosolvent, $5.00 \times 10^{-4}$ *M* in $NAD^+$, $9.92 \times 10^{-8}$ *M* in HLADH, and with cyclohexanol concentrations of 1.0, 5.0, and $25.0 \times 10^{-3}$ *M*. The initial oxidation rates were determined from the rate of increase in optical density at 340 nm. The relative rates are recorded in Table 1. Those obtained in methanol, HMPA, and acetonitrile solutions have been corrected for the nonenzymic, solvent-induced, reactions.

## Acknowledgements

We thank NSERC for their generous financial support and Hoffmann-La Roche, Nutley, New Jersey, for their much appreciated and continuing aid. We are also grateful to Drs. G. Sanyal and T. H. Maren (University of Florida) for providing details of their work on the cyanide content of acetonitrile in advance of publication (9).

# Electron and cation transport in fluid dimethyl ether: effects of density and temperature

NORMAN GEE AND GORDON R. FREEMAN

*Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2*

Received October 13, 1981

NORMAN GEE and GORDON R. FREEMAN. Can. J. Chem. **60**, 1034 (1982).

The effect of molecular electric dipole moment $D$ on charge transport in fluids was examined by measurement of electron and ion mobilities in dimethyl ether ($D$ = 1.3 D) and comparing them with the behavior in hydrocarbons. The fluid density was varied continuously from that of the normal vapor to that of the normal liquid, passing through the critical region. The density normalized mobility $n\mu_e$ of electrons in dimethyl ether vapor at low densities is 30-fold smaller than that in propane, although for the cations $n\mu_+$ in the ether is only 1.4-fold smaller than that in the alkane. The permanent dipole moment of the ether dominates the scattering of low energy electrons but not that of cations. The electron momentum transfer cross section is roughly 33% larger than that predicted by the Altshuler point dipole model, and has a minimum at ~0.12 eV. The energy gained from the electric field is removed mainly through inelastic collisions, even in the thermal energy range.

Molecular clustering decreases both electron and ion mobilities, but the effect on the former is much larger due to the greater change in reduced mass. The extent of electron quasilocalization in the dense vapor of dimethyl ether is four times greater than that in nonpolar hydrocarbons. Electrons form relatively stable localized states in the liquid at $n/n_c > 2.0$. Ion mobility undergoes a transition from "density control" to "viscosity control" with increasing density in the low density liquid. Viscosity control is operative at $n/n_c > 2.4$.

NORMAN GEE et GORDON R. FREEMAN. Can. J. Chem. **60**, 1034 (1982).

On a étudié l'effet du moment dipolaire électrique moléculaire $D$ sur le transport de charge dans les fluides en mesurant les mobilités des électrons et des ions dans l'éther méthylique ($D$ = 1,3 D) et en les comparant avec leur comportement dans les hydrocarbures. On a fait varier la densité du fluide d'une façon continue à partir de celle de la vapeur normale à celle du liquide normal en passant par la région critique. La mobilité normalisée pour la densité, $n\mu_e$, des électrons dans la vapeur d'éther à de faibles densités est 30 fois plus petite que celle dans le propane, bien que le valeur de $n\mu_+$ des cations soit 1,4 fois plus petit dans l'éther que dans l'alcane. Le moment dipolaire permanent de l'éther domine la dispersion des électrons de faible énergie mais pas celle des cations. La section droit de transfert du momentum de l'électron est approximativement 33% plus grande que celle prédite par le modèle du point dipolaire de Altshuler et il a un minimum à ~0,12 eV. L'énergie gagnée à partir du champ électrique est enlevée principalement à travers les collisions non élastiques, même dans le domaine d'énergie thermique.

L'entassement moléculaire diminue les mobilités des électrons et des ions, mais l'effet du premier est plus grand à cause d'une plus grande variation de la masse réduite. Le taux de quasilocalisation de l'électron dans la vapeur dense d'éther est 4 fois plus grand que celui dans les hydrocrabures non polaires. Les électrons forment des états localisés relativement stables dans le liquide à $n/n_c >$ 2,0. La mobilité des ions subit une transition du "contrôle de densité" au "contrôle de viscosité" avec une augmentation de la densité dans le liquide de faible densité. Le contrôle de viscosité est opérant à $n/n_c > 2,4$.

## Introduction

Electrons in dense gases can be localized in several ways. The electrons can be ephemerally localized by density fluctuations; this transitory localization occurs in the heavier noble gases argon (1) and xenon (2) as well as in all hydrocarbons studied to date (3–10). These hydrocarbons range from methane (3), which is the simplest alkane, and ethene (5) the simplest alkene, to more complex structures such as benzene and toluene (10). Quasilocalization occurs to a similar extent in all these compounds and the density normalized mobility $n\mu$ decreases by a factor up to three or so. However, in helium (11–15), nitrogen (16), carbon dioxide (17), and ammonia (18, 19), much stronger localization processes occur. The electron mobility decreases by factors up to several orders of magnitude and may approach that of heavy ions. The mobility transition in helium is attributed to bubble formation, due to the strong electron–helium repulsive interaction. In carbon dioxide it is attributed to electron attachment to the molecules, in a multibody process; in ammonia attachment to molecular clusters (incipient solvation) is invoked. The difference between the extent of localization in ammonia and that in hydrocarbons is presumably caused by the larger dipole moment of the former. Ammonia has a dipole moment of 1.47 D (20). The largest dipole moment of the previously studied hydrocarbons was that of isobutene, 0.49 D (20). To clarify the role of dipole moment in the localization process, the mobilities of electrons and ions have been studied in dimethyl ether, which has a dipole moment of 1.3 D (20).

## Experimental

Dimethyl ether (Matheson, 99.87%) was further purified in a grease-free, glass, vacuum line. Transfer of the gas from the cylinder to the vacuum line was effected through a length of flexible stainless steel tubing welded to the cylinder valve at one end and to a Kovar-glass seal at the other. About 50 cm$^3$ of liquid ether was purified at a time. The sample was degassed by trap-to-trap distillation, the receiver being cooled by liquid

nitrogen and continually open at the back to the vacuum system. The ether was then transferred to a bulb containing potassium hydroxide pellets and held overnight as a liquid at 195 K (Dry Ice/acetone). It was then degassed again, transferred onto freshly activated molecular sieves (Davison 3A), and held overnight at 195 K. It was then treated with four fresh potassium mirrors for 1 day each at 195 K. Two different procedures were then used. Process *A*: the ether was held on a fifth mirror for 2–8 weeks at 195 K prior to use. Process *B*: the sample was transferred onto a liquid sodium–potassium alloy (20% sodium) and stirred gently for 4 weeks at 270 K prior to use.

Other experimental details are described in refs. 2, 3, 7, and 21. Ion and electron mobilities were obtained from times of flight (7), except for electrons in liquid ether at $T < 355$ K. In the latter instance electron capture interfered with the time of flight measurement, so a conductance method was used (22). Both methods were used at 372 K and conductance gave a mobility value 11% higher than that from time of flight. The free ion yields needed in the conductance method were measured at the same temperatures, as described in ref. 22.

Densities at $n > 3 \times 10^{20}$ molecules/cm$^3$ were obtained from ref. 23; those at $n < 1 \times 10^{20}$ were calculated from the van der Waals equation (24). Intermediate densities were obtained by graphical interpolation. The critical parameters are $T_c = 400$ K, $P_c = 52$ atm, and $n_c = 3.55 \times 10^{21}$ molecules/cm$^3$ (23, 24).

Dielectric constants of the liquid were obtained from refs. 25 and 26. The experimental values could be fitted to Onsager's equation (ref. 27, p. 26) using a dipole moment of 1.4 D. This moment is 8% larger than the gas phase value (1.3 D), and agrees with the trend noted in diethyl ether, for which the dipole moment in benzene solvent was found to be 6% higher than that in the vapor (ref. 27, p. 48).

## Results

Mobilities of the electrons and ions were measured over wide ranges of density, temperature, and electric field strength. Conditions were varied from those of the normal liquid and vapor to that of the supercritical fluid.

### *Electrons*

The density normalized mobility of electrons, $n\mu_e$, in the low density vapor is plotted in Fig. 1 for several temperatures. The mobility increases with temperature and with field strength. The threshold field $(E/n)_{thr}$ increases slightly with temperature, being ~3 Td at 252 K and ~5 Td at 466 K, where Td = $10^{-17}$ V cm$^2$/molecule. Earlier measurements near 295 K gave $n\mu_e$ values 20–30% (29) and ~10% (30) higher than the present ones (Fig. 1).

At $E/n > 20$ Td the mobility decreases (Fig. 1). The temperature coefficient of $n\mu_e$ is smaller at high fields than at low fields.

Increasing the vapor density along the vapor–liquid coexistence curve up to ~$2 \times 10^{20}$ molecules/cm$^3$ has little effect upon $n\mu_e$ (Fig. 2). At higher densities $n\mu_e$ decreases and $(E/n)_{thr}$ increases.

The value of $n\mu_e$ passes through a minimum near the critical density (Fig. 3), increases to a low maximum in the liquid phase at $n/n_c \approx 1.4$, then decreases rapidly at higher densities. The shape of the curve is an intermediate to those observed previously in ethane (4) and cyclopropane (6). However, the low density value of $n\mu_e$ in dimethyl ether is 50-fold lower than those for ethane and cyclopropane.

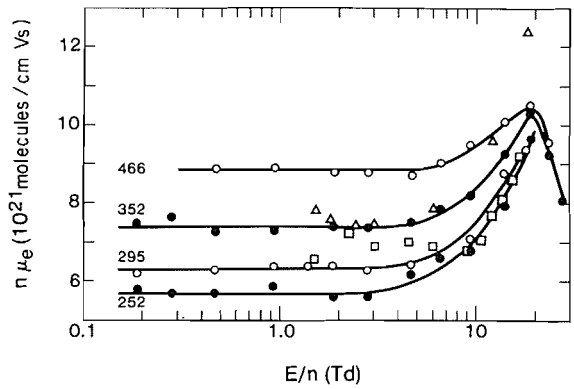

FIG. 1. Density normalized plot of electron mobility against field strength in low density dimethyl ether vapor. Circles, $n = 3.32 \times 10^{19}$ molecules/cm$^3$, numbers labelling curves are $T$ (K). △, 293 K, 6–80 ($10^{16}$ molecules/cm$^3$), ref. 29; □, 297 ± 3 K?, ~5 × $10^{18}$ molecules/cm$^3$?, ref. 30. Td = $10^{-17}$ V cm$^2$/molecule.

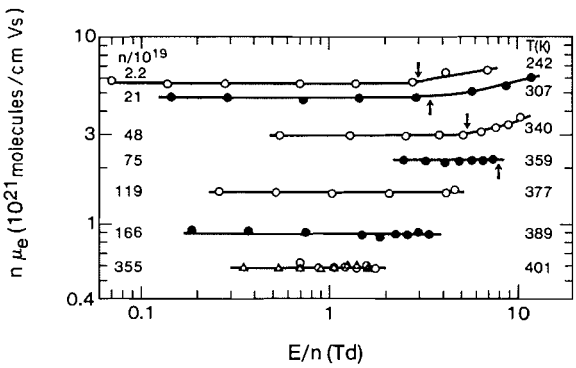

FIG. 2. Effect of density on $n\mu_e$ in the coexistence vapor. The arrows indicate approximate values of $(E/n)_{thr}$. The supercritical gas ($n = 355 \times 10^{19}$, $T = 401$) was approached both from the gas (○) and liquid (△) phases.

The temperature coefficient of $\mu_e$ increases with density at $n > 1 \times 10^{20}$ molecules/cm$^3$ (Figs. 4 and 5). The coefficient in the low density gas is approximately equivalent to an Arrhenius $E_\mu$ of 2 kJ/mol, which increases to 4 kJ/mol at $2 \times 10^{20}$ molecules/cm$^3$ and ~50 kJ/mol at $36 \times 10^{20}$ (Table 1).

In the coexistence liquid phase $\mu_e$ and its temperature coefficient increase steadily with temperature (Figs. 4 and 6).

### *Cations*

The relative variation of $n\mu_+$ with density in the

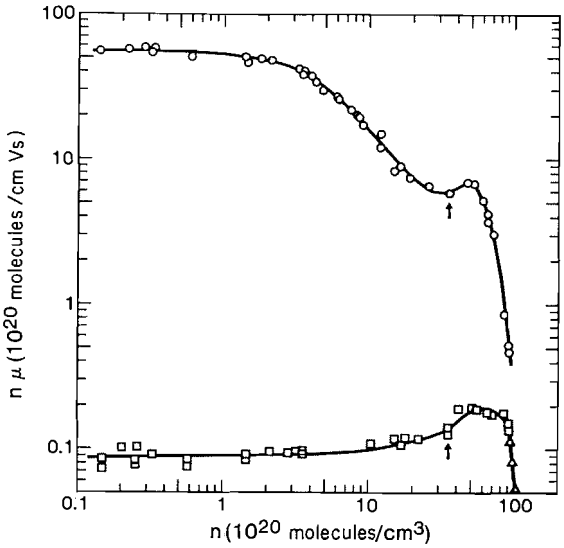

FIG. 3. Effect of density on the density normalized mobilities of thermal electrons (○) and cations (□) in the coexistence vapor and liquid. The arrows mark the critical density $n_c$. The ether was purified by process *B*. △, cations in liquid, ref. 26.

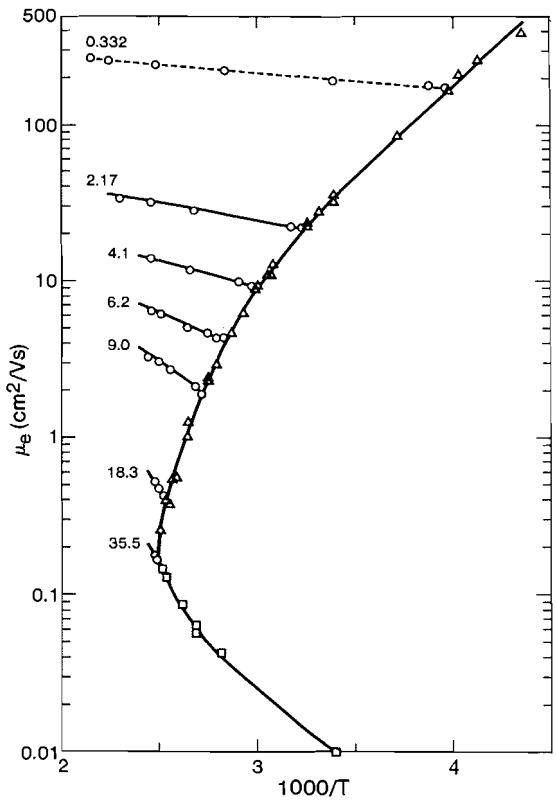

FIG. 4. Arrhenius plots of $\mu_e$ in the gas at several constant densities (○). The numbers labelling the curves are $n/10^{20}$. The dashed line near the top was calculated from eq. [1] or [10], using the appropriate electron scattering cross sections in Fig. 11. The sample with $6.2 \times 10^{20}$ molecules/cm³ contained 0.08 mol% of methanol. △, coexistence vapour; □, coexistence liquid.

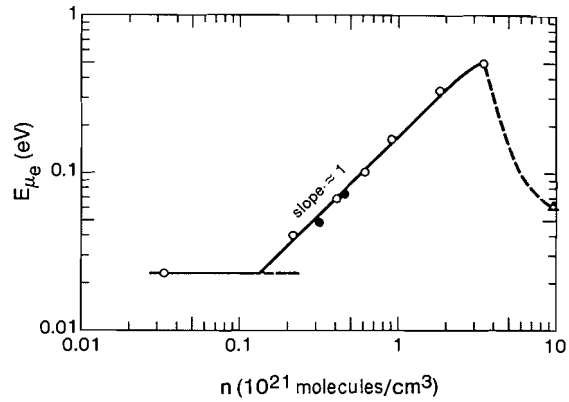

FIG. 5. $E_{\mu_e}$ as a function of fluid density. ○, vapor, Fig. 4; ●, vapor, dash–dot lines in Fig. 7; △, liquid, ref. 26.

coexistence liquid and dense gas was much smaller than that for electrons (Fig. 3). The value of $n\mu_+$ does not decrease with increasing density in the coexistence gas phase, but rather increases slightly at $n/n_c > 0.3$. The near constancy of $n\mu_+$ up to the critical density is similar to the behavior in nonpolar hydrocarbon vapors (21, 31) and the value of $n\mu_+$ is similar to that for cyclopentane (21).

There is a small maximum in $n\mu_+$ at $n/n_c \approx 1.5$, as there is for $n\mu_e$ (Fig. 3), and as there is for cations in nonpolar hydrocarbons. There is also a slight maximum in $\mu_+$ itself at $T$ just below $T_c$ in the liquid phase (Fig. 6); such a maximum was observed previously only for the cyclic hydrocarbons (21, 31, 32).

The temperature coefficient of $\mu_+$ in the constant density vapor increased with density (Fig. 6 and Table 1). The apparent values of $E_\mu$ are similar for cations and electrons at a given density (Table 1), although the values of $n\mu_+$ are nearly three orders of magnitude smaller than those of $n\mu_e$.

*Effect of impurity on apparent value of* $\mu_e$

Ether purified by process *A* (Experimental section) gave low values of mobilities in the coexistence vapor when $n > 2 \times 10^{20}$ molecules/cm³; at $n > 1 \times 10^{21}$ molecules/cm³ only a heavy ion mobility could be measured. Extending the potassium mirror treatment to 3 months increased the mobility values in this material to those obtained in ether from process *B* (Fig. 3). Longer treatment with mirror or alloy did not further increase the mobilities.

The impurity effect in the dense vapor was greatest near the coexistence curve. Heating the gas at constant density reduced the effect of the impurity (Fig. 7). The Arrhenius temperature coefficient of the apparent mobility in $10.8 \times 10^{20}$ molecules/cm³ near the coexistence curve is ~150 kJ/mol, while that at $4.6 \times 10^{20}$ is 100 kJ/mol. This

behavior suggests $e^- + S \rightleftharpoons S^-$, where $S^-$ only forms in association with a cluster of ether molecules. The clusters are destroyed by heating the vapor at constant density. The temperature coefficients obtained from the dash–dot lines in Fig. 7 agree with those in the clean sample (Fig. 5), so an unclustered S does not interfere with $\mu_e$. This conclusion is supported by the absence of an impurity effect at low vapor densities.

Traces of methanol and carbon dioxide were detected in the unpurified ether by mass spectral analysis (33).[1] Small amounts of methanol or carbon dioxide were therefore added to purified (process *B*) ether to measure their effect on $\mu_e$. A sample

[1]Probable impurities are methanol, carbon dioxide, and methyl formate.

with $n = 6.2 \times 10^{20}$ molecules/cm$^3$ containing 0.08 mol% methanol gave curved traces of electron current against time, but the estimated mobilities were the same as those expected from pure samples (Figs. 3 and 4). The main effect of methanol was to scavenge electrons at the lower field strengths, thereby decreasing the $E/n$ range over which $\mu_e$ could be measured.

Addition of 0.015 and 0.04 mol% of carbon dioxide caused $\mu_e$ along the coexistence curve to decrease at $T \gtrsim 320$ K (Fig. 8, $n \gtrsim 3 \times 10^{20}$ molecules/cm$^3$), while 0.24% caused the electron signal to disappear. The Arrhenius temperature coefficient in the gas at $n = 8.5 \times 10^{20}$ containing 0.04% carbon dioxide was 120 kJ/mol near the coexistence curve (Fig. 8). This behavior is similar to that obtained with dimethyl ether from process $A$, so it is concluded that process $A$ left a trace of carbon dioxide in the ether.

Examples of oscilloscope traces obtained with pure and impure ethers are shown in Fig. 9. The presence of carbon dioxide caused the signal trace to become curved, which is the usual effect of electron scavengers, but the product of the signal decay time and the field strength increased, which

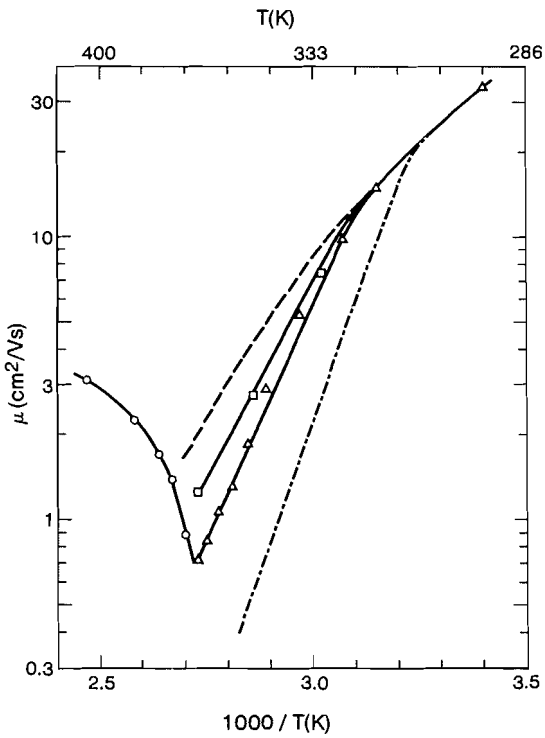

FIG. 8. Effect of carbon dioxide upon electron mobility in dimethyl ether vapor. Ether, coexistence vapor: -·-·-, process $A$; ---, process $B$; □, $B$ + ~0.015 mol% $CO_2$; △, $B$ + ~0.04% $CO_2$; ○, $n = 8.5 \times 10^{20}$, $B$ + ~0.04% $CO_2$.

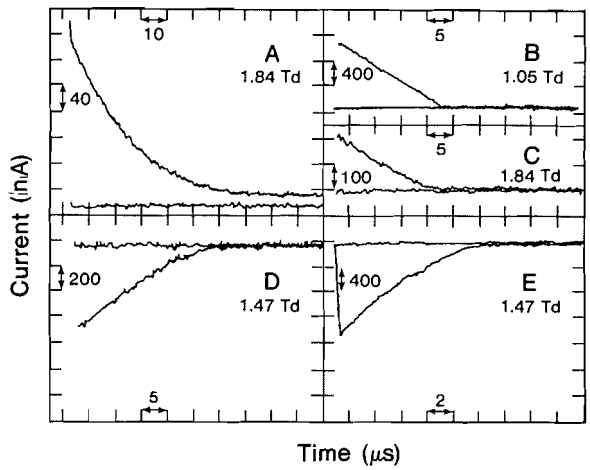

FIG. 9. Oscilloscope traces illustrating the current–time signals in pure and impure ether vapors at 12.5 kV/cm ($E/n \approx$ 1–2 Td). Radiation dose $\approx 1 \times 10^{10}$ eV/g. The values of $T$(K) are: $A$, 356; $B$, 377; $C$, 356; $D$, 370; $E$, 387. The ether purities are: $A$, process $A$ (dirtiest); $B$, process $B$ (cleanest); $C$–$E$, process $B$ + 0.04% $CO_2$. Signals $A$–$C$ are coexistence vapors, while $D$ and $E$ are for temperatures above the coexistence curve.

is the opposite of the usual scavenger effect. In the pure ether, trace $B$ Fig. 9, $t_dE/n = 2.2$ ($10^{-22}$ s V cm$^2$/molecule), while in the impure ethers, traces $A$ and $C$, $t_dE/n = 8.8$ and 3.2 units, respectively. However, heating the impure gas to remove it from the coexistence region reduced the value of $t_dE/n$: trace $D$, 370 K, $t_dE/n = 3.8$ units; trace $E$, 387 K, $t_dE/n = 1.5$ units.

To check the effect of the third listed possible impurity in the unpurified ether (33), ~0.003 mol% of methyl formate was added to process $B$ ether at $n = (4–9) \times 10^{20}$. The electrons were completely scavenged.

## Discussion

### *Electrons*

#### *1. Low density gas*

##### *(a) Scattering cross sections*

In the low density coexistence vapor $n\mu_e$ is nearly independent of density (Fig. 3). Similar behavior was found in nonpolar vapors (1–10). In the alkane series ethane (4), propane (6), $n$-pentane (8), and $n$-hexane (9) the $n\mu_e$ values decrease with increasing molecular size or mean polarizability. The presence of a permanent dipole moment $D$ decreases $n\mu_e$ as well, with $n\mu_e \propto D^{-2}$ for point dipoles (34). Thus, while propane, propene, and dimethyl ether have similar mean polarizabilities (ref. 20, section 14207), their respective dipole moments increase and values of $n\mu_e$ decrease in the order listed (Table 2). The values of $D$ and $n\mu_e$ in low density ammonia vapor are similar to those in

dimethyl ether, although the former is a much smaller molecule (Table 2). Electron scattering by the ether and ammonia is therefore dominated at low energies by interaction with the permanent dipole moments.

The momentum transfer cross section $\sigma_m$ as a function of electron velocity $v$ was extracted from the temperature dependence of $n\mu_e$ at low densities. The procedure was to fit the measured set of ($n\mu_e$, $T$) values to eq. [1] (36, 37).

$$[1] \quad n\mu_e = (5.23 \times 10^{-14}/T^{2.5}) \times \int_0^\infty (v^3/\sigma_m) \exp(-3.30 \times 10^{-12} v^2/T) dv$$

As a first trial, the point-dipole scattering cross sections of Altshuler (34) were used:

$$[2] \quad \sigma_m(\text{Alt}) = (8\pi/3)(eD/\hbar v)^2$$

where $h = 2\pi\hbar$ is Planck's constant. The calculated values of $n\mu_e$ so obtained were roughly 33% too high (Fig. 10). Multiplying the Altshuler cross sections by 1.33 gave approximately correct values of $n\mu_e$, but the temperature coefficient was too small. By adjusting the cross sections to obtain a best-fit to the experimental $n\mu_e$ values, the curve depicted with open circles in Fig. 11 was obtained.

The energy range to which the curve fitting is most sensitive is that near the maximum of the integrand in eq. [1]. Over the present temperature range, 252–466 K, the most sensitive energy range is ~0.03–0.18 eV, and the integrand peaks at 0.09–0.12 eV. The integrand $F$ is plotted for 359 K in Fig. 11; it displays the relative contributions of electrons at different energies to the drift of the swarm.

The cross sections at $\varepsilon > 0.15$ eV were chosen so that the curve would smoothly join earlier results for $\varepsilon \geq 1$ eV (38).

*(b) Field effect*

At $E/n > 3$ Td in the low density gas at 252 K the electrons gain more energy from the field than they lose by collisions with the dimethyl ether molecules. The electrons become heated and $n\mu_e$ increases (Figs. 1 and 2). For two other molecules of similar size, propane and propene, the threshold fields at 250 K are 0.09 and 0.3 Td, respectively (39). The threshold drift velocities $v_d^{thr}$ in propane, propene, and dimethyl ether are 1.4, 1.5, and 1.6 km/s, respectively. The ratio of $v_d^{thr}$ to the speed of low frequency sound $c_0$ in the gas is an indicator of the contribution of inelastic processes to the electron scattering: $v_d^{thr}/c_0 \lesssim 1$ when elastic scattering dominates (2–5, 40). The value of $c_0$ is given by (41):

$$[3] \quad c_0 = (\gamma kT/M)^{1/2}$$

where $\gamma$ is the heat capacity ratio,[2] $k$ is Boltzmann's constant, and $M$ is the molecular mass. At 250 K this gives $c_0 = 232$, 236, and 225 m/s in propane, propene, and dimethyl ether; the respective values of $v_d^{thr}/c_0$ are 6.0, 6.4, and 7.1. Thus inelastic collisions dominate the electron energy loss processes near thermal energies in these three gases.

It should be mentioned that the mobility is limited by the momentum transfer collisions even when inelastic collisions govern the electron energy.

*2. Dense gas and liquid*

In many nonpolar and slightly polar gases the values of $n\mu_e$ decrease at high densities to reach a minimum at a density roughly half that of the critical fluid (1–10). The ratio of the value of $n\mu_e$ at low densities to the minimum value in the dense gas is typically 2–3. Anion formation in nitrogen (16) and carbon dioxide (17) increases the ratio to $\gtrsim 100$. The ratio in ammonia is 40 at $T/T_c = 0.99$ and $n/n_c = 0.3$ (19). By analogy with the optical absorption of localized electrons that was observed in dense vapors of ammonia (43) and water (44), the low mobility in dense ammonia vapor was attributed to electron localization in van der Waals clusters of molecules. In dimethyl ether the ratio is 9 (Fig. 3). The behavior is intermediate between those in nonpolar gases and that in ammonia. The greater degree of electron localization in dense ammonia vapor may be attributed to a tendency of the electron to be attracted to the H—N protons.

As the density is increased through and past $n_c$ the value of $n\mu_e$ increases, goes through a maximum at $n/n_c = 1.4$, then decreases (Fig. 3). In the liquid, electron transport is a stronger function of temperature than of density. The liquid phase electron mobilities (Fig. 6) can be analyzed using the two-state model of electron transport widely applied to dielectric liquids (6, 26, 45). The relevant equations have been discussed (26, 45) and are simply listed here. The electron mobility $\mu_e$ is given by

$$[4] \quad \mu_e = (1 - \chi)\mu^0_{il} \exp(-E_{il}/kT) + \chi\mu^0_h$$

where $\chi$ is the fraction of electrons in the high mobility state with mobility $\mu^0_h$. $\mu^0_{il}$ and $E_{il}$ are respectively the pre-exponential factor and activation energy of mobility in the localized (ion-like) state.

$$[5] \quad \chi = \int_{-\infty}^{\infty} N(E)[1 + \exp(E/kT)]^{-1}\, dE$$

$$[6] \quad N(E) = \pi^{1/2}\sigma^{-1} \exp[-(E - E_0)^2/\sigma^2]$$

$$[7] \quad E_0 = E(O) - aT$$

$$[8] \quad \sigma = \sigma(O) + bT$$

$$[9] \quad \mu^0_h = \mu^0_{ref} (d_{ref}/d_T)^2 (T_{ref}/T)$$

where $N(E)dE$ is the fraction of localized states that lie at energies between $E$ and $E + dE$ from the high mobility state, $E_0$ is the center of the transition energy distribution, $\sigma$ is the dispersion parameter, and $d_{ref}$ is the liquid density at $T_{ref}$. Equations [7]–[9] are adequate at $E \gg kT$. The mobilities of electrons in the two states must be different and the electrons must spend an appreciable time in each of the two states. The parameters $\mu^0_{il}$ and $E_{il}$ can be estimated from the liquid-phase ion mobility (26). The dashed line through the liquid-phase electron mobility results in Fig. 6 was calculated using $\mu^0_{il} = 0.01$ cm$^2$/V s, $E_{il} = 0.04$ eV, $E_0 = 0.60 - 0.00085T$, $\sigma = 0.168$ eV, and $\mu^0_{ref} = 2.6$ cm$^2$/V s at $T_{ref} = 296$ K. Agreement is good except near the critical point.

*Ions*

*1. Low density gas*

When the most important interaction between the ion and the gas molecule is the polarization force, $n\mu_+$ is solely a function of the average polarizability $\bar{\alpha}$ and the reduced mass of the ion–molecule pair (46). The temperature independent polarization limit can be obtained from the diffusion expression derived by Maxwell in 1866 (47). For the small $C_1$ to $C_4$ hydrocarbons, the low density coexistence vapor values of $n\mu_+$ are approximately temperature independent (48). The values are a function of $(\bar{\alpha}M_r)^{1/2}$ (Fig. 12), although they are about half those predicted by the theory.

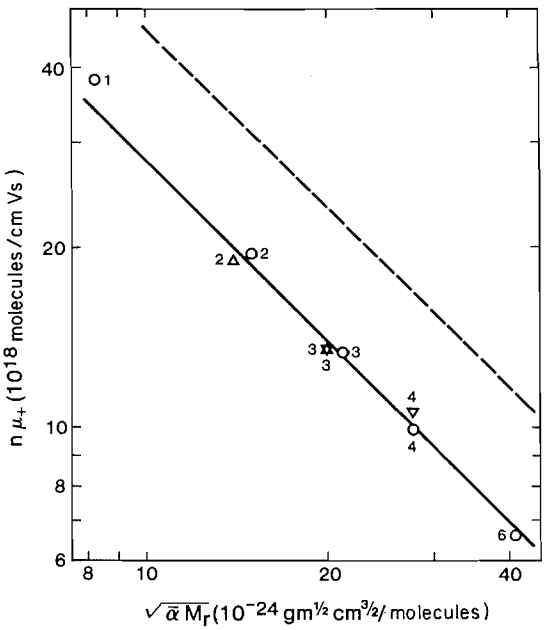

FIG. 12. Density-normalized ion mobility plotted against the square root of the product of average polarizability and reduced mass. The symbols represent: ○, *n*-alkanes; △, alkenes; and ▽, cyclopropane and isobutane. The numbers beside the symbols indicate the number of carbon atoms in the molecule. The dashed line indicates the $n\mu_+$ values expected at the polarization limit (ref. 46). The average polarizabilities are from ref. 20, section 14207, $M_r$ is taken to be the molecular mass and $n\mu_+$ values are from refs. 31 and 48.

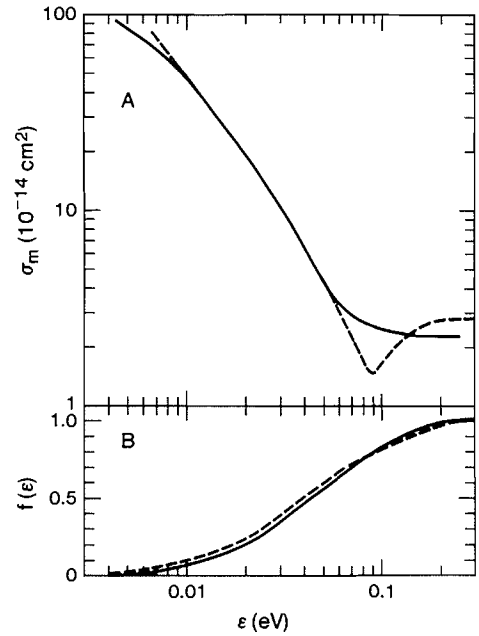

FIG. 13. *A*: Cation-momentum transfer cross-sections $\sigma_m$ of low density gaseous dimethyl ether. ———, chosen through attempting to have no minimum in the curve; ---, obtained when the foregoing restriction was removed. The two curves give equivalent matchings of the experimental ($n\mu_+$, *T*) data. *B*; $f(\varepsilon)$ at 353 K. $f(\varepsilon)$ is the fraction of the integral in eq. [10] that has been contributed by ions of kinetic energies up to ε. The full and dashed curves correspond to those in *A*.

The dimethyl ether value of $n\mu_+ = 9 \times 10^{18}$ at $(\bar{\alpha}M_r)^{1/2} = 19.9 \times 10^{-24}$ is below the $C_3$ hydrocarbon points. This is due to the much larger dipole moment in dimethyl ether, 1.3 D, compared to the next largest value of 0.3 D for propene.

In analogous fashion to the electrons, the temperature dependence of $n\mu_+$ at constant *n* can be used to extract the energy dependence of the ion–molecule momentum transfer cross-section. The mobility equation of ref. 49 was used:

$$[10] \quad n\mu_+ = \frac{\dfrac{3e}{8M_r}\sqrt{\pi}\left(\dfrac{2kT}{M_r}\right)^{5/2}}{\displaystyle\int_0^\infty v^5\sigma_m \exp(-M_r v^2/2kT)\,dv}$$

where $M_r$ is the ion–molecule reduced mass and $\sigma_m$ is the ion–molecule momentum transfer cross-section. The experimental set of ($n\mu_+$,*T*) was matched to a set of ($\sigma_m$, ε) values through iterative calculations. A $\sigma_m$ curve obtained in this manner is not unique, and two curves that give equivalent fits to the mobilities are shown in Fig. 13*A*. The full curve was obtained by attempting to have no minimum in $\sigma_m$ in the manner used for monomeric $CO_3^-$ ions in $N_2$ gas (48). The dashed curve was obtained when the foregoing restriction was removed, and it has a minimum in $\sigma_m$ at 0.09 eV. Curves intermediate between these would also be possible. Another source of information would be needed to choose between them.

The function $f(\varepsilon)$ in Fig. 13*B* shows the fraction of the integral in eq. [10] that has been contributed by the ions in the swarm with energies up to ε. Ions at energies between those corresponding to $f(\varepsilon) \approx 0.1$ and 0.9 make the major contribution to transport of the swarm. At 353 K this energy range is ~0.012–0.12 eV; $f(\varepsilon) = 0.5$ at 0.042 eV, which is $1.4kT$.

The value of $n\mu_+$ in dimethyl ether at 298 K is approximately half those in propane, propene-(48), and ammonia (28) (Table 2). The average ion scattering cross section of ammonia is only 20% smaller than that of dimethyl ether (Table 2); most of the mobility difference is due to the smaller mass of the former.

The average electron scattering cross-section of dimethyl ether is 25 times greater than that of propane, whereas the average cation cross-sections differ by a factor of only 1.8 (Table 2).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

It has been suggested that for polar gases eq. [10] should also be used for electrons (35, 42). Use of eq. [10] leads to lower cross-sections (solid circles in Fig. 11) than does eq. [1]. At $\varepsilon \leq 0.01$ eV the same cross-sections could be used in either equation. The average cross-section at 295 K is $2.13 \times 10^{-14}$ cm$^2$ from eq. [1] and $1.90 \times 10^{-14}$ cm$^2$ from eq. [10], in agreement with the earlier observation that eq. [10] gives average cross-sections ~13% lower than eq. [1] (35).

References 35 and 42 also offer useful discussions of molecular structure effects in charge scattering.

*2. Dense gas and liquid*

At $n \lesssim 1 \times 10^{21}$ molecules/cm$^3$ the value of $n\mu_+$ is nearly independent of $n$ in the coexistence vapor (Fig. 3); the slight increase with increasing $n$ is due to the concomitant increase of temperature. At $n \gtrsim 1 \times 10^{21}$ molecules/cm$^3$ the value of $n\mu_+$ increases more rapidly with $n$ (Fig. 3). The increase may be attributed to the mutual interference of the long range, attractive potentials when the ion interacts with more than one molecule at a time.

The value of $n\mu_+$ passes through a maximum at $n \approx 6 \times 10^{21}$ molecules/cm$^3$ and decreases at higher densities (Fig. 3). The steep decrease occurs at $n > 2.4n_c$ for cations, whereas for electrons it occurs at $n > 1.7n_c$ (Fig. 3). The decrease of $n\mu_e$ is due to the increasing stability of the localized state of the electron, whereas $n\mu_+$ decreases due to molecular crowding when the average free distance between molecules is much smaller than the molecular diameter. The van der Waals diameter of dimethyl ether is $3.9 \times 10^{-8}$ cm (ref. 24, calculated from $b/4$), whereas the Wigner–Seitz diameter at $>2.4n_c$ is $<6.2 \times 10^{-8}$ cm (estimated by assuming that the average volume available per molecule is spherical); the mean free distance between molecules at these densities is $< 0.6d_{vdw}$.

Viscosities $\eta$ have not been reported for dimethyl ether, but by analogy with the behavior in hydrocarbons (48) one may assume that in the liquid phase at $\eta/\eta_c > 2$, the ion mobility is approximately proportional to $\eta^{-1}$. In the low density region where $n\mu_+$ is constant, the mobility is limited by ion collisions with single molecules. In the high density region where $\eta\mu_+$ is nearly constant the mobility is limited by multibody interactions and liquid dynamics. The transition region corresponds to $0.3 \lesssim n/n_c \lesssim 2.0$ and $0.5 \lesssim \eta/\eta_c \lesssim 3$, where the critical fluid is denoted by the subscript c (48).

The temperature coefficient of $\mu_+$ in the dense vapor over a small temperature range near the coexistence curve is large (Table 1). The effect is attributed to clustering of molecules about the ion:

[11] $M^+ + M \rightleftharpoons M_2^+$

[12] $M_2^+ + M \rightleftharpoons M_3^+$

and so on

which are equivalent to

[13] $M^+ + mM \rightleftharpoons M_{m+1}^+$

The clusters are largest in number and size in the dense gas near the coexistence curve. Heating the gas at constant density removes it from the coexistence region and decreases the average size of the clusters, thereby increasing the mobility. A larger cluster has a larger reduced mass and a larger collision diameter, both of which decrease $\mu$. The Arrhenius temperature coefficient ~68 kJ/mol of ions in ether at $n_c$ near $T_c$ corresponds to the energy of evaporation of several molecules from each cluster.

The value of $n\mu_+$ in the coexistence vapor increases slightly in the dense vapor, instead of decreasing as one might expect from the clustering (Fig. 3). The evidence for clustering is the large temperature coefficients (Fig. 6 and Table 1). The effects of increased reduced mass and hard core radius are more than compensated by the mutual interference of the charge–dipole attractive potentials when the ion interacts with more than one gas molecule at a time.

*Effect of carbon dioxide on the value of $\mu_e$*

A trace of carbon dioxide has no effect on $n\mu_e$ in the low density gas. In the dense gas at temperatures near the coexistence curve carbon dioxide decreases the mobility. Heating the gas at constant density reduces the effect. This behavior is characteristic of transient capture of electrons by molecular clusters that contain a $CO_2$ molecule.

[11] $e^- + (CO_2)M_n \rightleftharpoons (CO_2^-)M_n$

where $M_n$ is a van der Waals cluster of $n$ molecules of M. The large temperature coefficient $E_{\mu_e} = 120$ kJ/mol near the coexistence curve, for $n = 8.5 \times 10^{20}$ with 0.04% $CO_2$, implies that the capturing clusters are quite large. The value of $n$ in $M_n$ is probably $> 10$. The behavior is similar to, but more marked than, quasilocalization in the denser pure ether vapour.

*Summary*

The scattering of electrons in low density polar gases is dominated by the magnitude of the dipole moment. A large dipole moment also enhances quasilocalization of the electrons in the dense gas and localization in the dense liquid. By contrast, the cation mobility in fluid dimethyl ether is only about 40% lower than that in propane at the same density $n$. The dipole moment has a much smaller effect upon ion transport in these fluids.

# Arene carbonyl rhodium(I) complexes

MAURICIO VALDERRAMA

*Department of Inorganic Chemistry, Institute of Chemical Sciences, Catholic University of Chile, Santiago, Chile*

AND

LUIS A. ORO[1]

*Department of Inorganic Chemistry, University of Zaragoza, Zaragoza, Spain*

Received August 26, 1981

MAURICIO VALDERRAMA and LUIS A. ORO. Can. J. Chem. **60**, 1044 (1982).

The arene carbonyl rhodium complexes, $[Rh(C_6Me_6)(CO)_2]PF_6$ and $[Rh(C_6Me_6)(CO)PPh_3]PF_6$, have been prepared by treating the dimeric complexes, $[RhCl(CO)_2]_2$ and $[RhCl(CO)PPh_3]_2$, with $AgPF_6$ in the presence of hexamethylbenzene. The reaction of $[Rh(C_6Me_6)(CO)_2]PF_6$ with tetrafluorobenzobarrelene affords $[Rh(C_6Me_6)(TFB)]PF_6$. On the other hand, the reaction of [Rh(arene)$(CO)_2]PF_6$ with a stoichiometric amount of triphenylphosphine gives [Rh(arene)$(CO)PPh_3]PF_6$ (arene = $C_6Me_6$ or $C_6H_3Me_3$), whereas with excess of this ligand $[Rh(CO)(PPh_3)_3]PF_6$ is formed. The related $[Rh(C_6Me_6)(CO)P(p\text{-}MeC_6H_4)_3]PF_6$ derivative has also been prepared.

The reactivity of both hexamethylbenzene carbonyl rhodium complexes has been examined. The addition of bipyridine to solutions of $[Rh(C_6Me_6)(CO)L]PF_6$ (L = CO or $PPh_3$) causes the immediate displacement of the coordinated hexamethylbenzene. Their reactions with the nucleophiles, acetylacetonate, tropolonate, or pyrazolate in the presence of triethylamine afford neutral derivatives of the type $[RhA(CO)L]_x$ (L = CO or $PPh_3$; A = acac or trop, $x = 1$; A = pz, $x = 2$).

MAURICIO VALDERRAMA et LUIS A. ORO. Can. J. Chem. **60**, 1044 (1982).

On a préparé les complexes $[Rh(C_6Me_6)(CO)_2]PF_6$ et $[Rh(C_6Me_6)(CO)PPh_3]PF_6$ en faisant réagir les complexes $[RhCl(CO)_2]_2$ et $[RhCl(CO)PPh_3]_2$ avec $AgPF_6$ en présence d'hexaméthylbenzène. La réaction du $[Rh(C_6Me_6)(CO)_2]PF_6$ avec le tétrafluorobenzobarrèlène fournit le $[Rh(C_6Me_6)(TFB)]PF_6$. Par ailleurs, la réaction du [Rh(arène)$(CO)_2]PF_6$ avec une quantité stoichiométrique de triphénylphosphine donne le [Rh(arène)$(CO)PPh_3]PF_6$ (arène = $C_6Me_6$ ou $C_6H_3Me_3$), alors qu'avec un excès de ce ligand, il y a formation de $[Rh(CO)(PPh_3)_3]PF_6$. On a aussi préparé le dérivé $[Rh(C_6Me_6)(CO)P(p\text{-}MeC_6H_4)_3]PF_6$ apparenté.

On a étudié la réactivité des deux complexes hexaméthylbenzène rhodium carbonyle. L'addition de bipyridine à des solutions de $[Rh(C_6Me_6)(CO)LPF_6]$ (L = CO ou $PPh_3$) provoque le déplacement immédiat de l'hexaméthylbenzène coordonné. Leurs réactions avec des nucléophiles comme l'acétylacétonate, le tropolonate ou le pyrazolate, en présence de triéthylamine, conduit à des dérivés neutres du type $[RhA(CO)L]_x$ (L = CO ou $PPh_3$; A = acac ou trop, $x = 1$; A = pz, $x = 2$).

[Traduit par le journal]

## Introduction

In recent years several types of arene rhodium(I) derivatives have been described. In particular cationic complexes of the types [Rh(arene)(diolefin)]A (1–5), [Rh(arene)$(C_2H_4)_2$]A (1, 2), [Rh(arene) (diphos)]A (6), and [Rh(arene)$\{P(OPh)_3\}_2$]A (1, 7) have been reported.

Furthermore, the tetraphenylborate group or diphosphine ligands can be coordinated to the metal by $\pi$-interaction of an arene ring with formation of complexes of the type $RhL_2PhBPh_3$ ($L_2$ = diolefin (8, 9), phen (10), diphos (11); L = $C_2H_4$ (8), $PR_3$ (8, 12, 13), $P(OR)_3$ (7, 14, 15)), or $[Rh(diphos)]_2A_2$ (16, 17). The crystal structures of some of these complexes show the rhodium atom $\pi$-bonded to the arene ring but in no case is the arene planar (4, 7, 11, 15).

As far as we know, no arene carbonyl rhodium complexes have hitherto been described in the literature. We now report the synthesis and properties of $[Rh(C_6Me_6)(CO)_2]PF_6$, **1**, $[Rh(C_6Me_6)(CO)PPh_3]PF_6$, **2**, and other related complexes.

## Experimental

The C and H analyses were made with a Perkin-Elmer 240 microanalyzer. Infrared spectra were recorded on a Perkin-Elmer 567 spectrophotometer (over the range 4000–200 $cm^{-1}$) using Nujol mulls between KBr discs or in dichloromethane solution between NaCl plates. Conductivities were measured in ca. $5 \times 10^{-4}$ *M* acetone solutions with a Philips 9501/01 conductimeter and the decomposition temperature with a Buchi apparatus. $^1$Hmr spectra were recorded on a Varian XL-100 instrument relative to tetramethylsilane.

All reactions were carried out under a dry argon atmosphere and solvents were dried and distilled prior to use. The starting dimer $[RhCl(CO)_2]_2$ was purchased from Strem Chemical Co. Tetrafluorobenzobarrelene (TFB) was prepared according to literature procedure (18).

*Preparation of complexes*

*$[Rh(C_6Me_6)(CO)_2]PF_6$*

A slurry of 200 mg (0.52 mmol) of $[RhCl(CO)_2]_2$, 169 mg (1.04 mmol) of hexamethylbenzene, and 263 mg (1.04 mmol) of $AgPF_6$ in acetone was stirred for 1 h at room temperature. The AgCl was removed by filtration through kieselguhr and the pale-yellow solution obtained was evaporated to dryness. The solid thus obtained was crystallized from dichloromethane–diethyl-ether (311 mg; 65% yield). *Anal.* calcd. for $C_{14}H_{18}F_6O_2PRh$: C 36.07, H 3.89; found: C 35.81, H 3.91; mp 130°C. $\Lambda_M(Me_2CO)$: 127 $ohm^{-1}$ $cm^2$ $mol^{-1}$. The $^1$Hmr in $(CD_3)_2CO$ shows the presence of the coordinated arene (δ: 2.62, Me) along with free $C_6Me_6$.

*[Rh(C$_6$Me$_6$)(CO)PPh$_3$]PF$_6$*

The complex was prepared by two methods:

(*i*) The addition of a stoichiometric amount of triphenylphosphine (19.8 mg; 0.07 mmol) to a solution of [Rh(C$_6$Me$_6$)(CO)$_2$]PF$_6$ (35.2 mg; 0.07 mmol) in dichloromethane produced the immediate evolution of carbon monoxide. The solution obtained was stirred at room temperature for 1 h, evaporated to a small volume, and crystallized by addition of diethylether (16 mg; 30% yield).

(*ii*) [RhCl(CO)PPh$_3$]$_2$ (19) (85.7 mg; 0.1 mmol) was treated with AgPF$_6$ (50.6 mg; 0.2 mmol) and hexamethylbenzene (32.5 mg; 0.2 mmol) in acetone. The mixture was stirred for 1 h at room temperature and evaporated to dryness. The addition of 25 mL of dichloromethane and the filtration through kieselguhr gave a yellow solution which was evaporated to a small volume and crystallized by adding diethylether (62.1 mg; 44% yield).

In both cases, a yellow–orange microcrystalline solid was obtained. *Anal.* calcd. for C$_{31}$H$_{33}$F$_6$OP$_2$Rh: C 53.16, H 4.74; found: C 53.08, H 4.38; mp 190–192°C. $\Lambda_M$(Me$_2$CO): 129 ohm$^{-1}$ cm$^2$ mol$^{-1}$. The $^1$Hmr in (CD$_3$)$_2$CO show the presence of the coordinated arene (δ: 2.46, Me) along with free C$_6$Me$_6$.

*[Rh(C$_6$H$_3$Me$_3$)(CO)PPh$_3$]PF$_6$*

[RhCl(CO)]$_2$ (77.8 mg; 0.2 mmol) was treated with 101.1 mg (0.4 mmol) of AgPF$_6$ and 0.06 mL (slight excess) of 1,3,5-trimethylbenzene in acetone. The mixture was stirred for 1 h at room temperature and evaporated to dryness. The residue obtained was extracted with 30 mL of dichloromethane and filtered off through kieselguhr. To the yellow filtrate was added the stoichiometric amount of triphenylphosphine and the solution was stirred for 30 min. Partial evaporation and addition of diethylether gave a yellow-brownish microcrystalline solid (142.5 mg; 54% yield). *Anal.* calcd. for C$_{28}$H$_{27}$F$_6$OP$_2$Rh: C 51.08, H 4.13; found: C 51.75, H 3.65; mp 138–140°C.

*[Rh(C$_6$Me$_6$)(CO)P(p-MeC$_6$H$_4$)$_3$]PF$_6$*

The addition of a stoichiometric amount of P(*p*-MeC$_6$H$_4$)$_3$ (30.4 mg; 0.1 mmol) to a solution of [Rh(C$_6$Me$_6$)(CO)$_2$]PF$_6$ (46.6 mg; 0.1 mmol) in dichloromethane involved the evolution of carbon monoxide. The solution obtained was stirred under reflux for 1 h, evaporated to a small volume, and crystallized by addition of diethylether (67.6 mg; 91% yield). *Anal.* calcd. for C$_{34}$H$_{39}$F$_6$OP$_2$Rh: C 55.00, H 5.29; found: C 54.12, H 5.19; mp 178–180°C. $\Lambda_M$(Me$_2$CO): 129 ohm$^{-1}$ cm$^2$ mol$^{-1}$. The $^1$Hmr in (CD$_3$)$_2$CO shows the presence of [Rh(C$_6$Me$_6$)(CO)P(*p*-MeC$_6$H$_4$)$_3$]$^+$ (δ: 2.42, Me (arene) and 2.24, Me (phosphine)) and [Rh(CO)P(*p*-MeC$_6$H$_4$)$_3${(CD$_3$)$_2$CO}$_x$]$^+$ (δ: 2.38, Me (phosphine)).

*[Rh(C$_6$Me$_6$)(TFB)]PF$_6$*

[Rh(C$_6$Me$_6$)(CO)$_2$]PF$_6$ (46.6 mg; 0.1 mmol) was treated with an excess of TFB (45.2 mg; 0.2 mmol) in dichloromethane under reflux for 2 h. A small quantity of orange solid was separated by filtration and the yellow solution obtained was evaporated to ca. 3–4 mL. A pale-yellow solid was crystallized by adding diethylether (54.2 mg; 85% yield). *Anal.* calcd. for C$_{24}$H$_{24}$F$_{10}$PRh: C 45.30, H 3.80; found: C 45.58, H 3.77; mp 235°C. $\Lambda_M$(Me$_2$CO): 135 ohm$^{-1}$ cm$^2$ mol$^{-1}$. $^1$Hmr ((CD$_3$)$_2$CO) δ: 5.2–5.3 (CH); 3.7–3.9 (CH=CH), and 2.52 (Me).

The orange solid obtained in small yield (1%) was identified as [Rh(TFB)$_2$]PF$_6$ (20).

## Results and discussion

### *Preparation and properties of [Rh(C$_6$Me$_6$)(CO)$_2$]PF$_6$*

The dimeric complex [RhCl(CO)$_2$]$_2$ reacts in acetone with AgPF$_6$ and hexamethylbenzene:

[1] (1/2)[RhCl(CO)$_2$]$_2$ + AgPF$_6$ + C$_6$Me$_6$ → [Rh(C$_6$Me$_6$)(CO)$_2$]PF$_6$ + AgCl

**1**

The isolated complex **1** show a yellow or light olive–green colour depending on the precipitation conditions. The CH$_2$Cl$_2$ solution ir shows two ν(CO) strong bands at 2095 and 2045 cm$^{-1}$, characteristic of a *cis*-dicarbonyl structure (21, 22). In fact, the crystal structure of the related complex [Rh(C$_6$H$_5$Me){P(OPh)$_3$}$_2$]ClO$_4$ (7) shows a P(1)—Rh—P(2) angle of 90.07°. Solid-state infrared measurements on **1** show absorptions in the carbonyl region at 2100 s, 2080 w,sh, 2050 s, 2020 w,sh, and 2010 w cm$^{-1}$, along with the characteristic bands of uncoordinated PF$_6^-$ (840 vs, 560 s cm$^{-1}$) (23, 24).

The presence of the PF$_6^-$ anion seems to be important. Thus, although the formation of [Rh(C$_6$Me$_6$)(CO)$_2$]ClO$_4$ can be observed by a reaction similar to [1], when AgClO$_4$ was used instead of AgPF$_6$, the perchlorate complex was too unstable to be isolated in the solid state. The $^1$Hmr spectrum shows the presence of the following equilibrium

[2] [Rh(C$_6$Me$_6$)(CO)$_2$]PF$_6$ + *x*(CD$_3$)$_2$CO ⇄ [Rh(CO)$_2${(CD$_3$)$_2$CO}$_x$]PF$_6$ + C$_6$Me$_6$

displaced towards the right (58% for a saturated solution).

The reaction of **1** with tetrafluorobenzobarrelene (TFB) (18) in dichloromethane under reflux leads to the displacement of the carbon monoxide, with the formation of [Rh(C$_6$Me$_6$)(TFB)]PF$_6$, **3**. Although the bubbling of carbon monoxide (1 atm, room temperature) through solutions of [Rh(diolefin)L$_2$]A complexes usually lead to the formation of several types of cationic carbonyl derivatives (L = group Vb ligands) (13, 20–22, 25), no reaction was observed when complex **3** was treated with carbon monoxide. This behaviour is in contrast with the carbonylation reaction observed for [Rh(C$_6$H$_5$Me){P(OPh)$_3$}$_2$]ClO$_4$, where [Rh(CO)$_3${P(OPh)$_3$}$_2$]ClO$_4$ (7) was formed.

Addition of acetonitrile to dichloromethane solutions of **1** shows the existence of the equilibrium

[3] [Rh(C$_6$Me$_6$)(CO)$_2$]PF$_6$ + 2MeCN ⇄ [Rh(MeCN)$_2$(CO)$_2$]PF$_6$ + C$_6$Me$_6$

that can be detected by infrared spectroscopy. The equilibrium can be partially shifted towards the right by addition of an excess of acetonitrile. Even in pure acetonitrile, the solution infrared spectrum shows the presence of [Rh[(MeCN)$_2$(CO)$_2$]PF$_6$ (ν(CO): 2090 and 2020 cm$^{-1}$) as the major product, along with [Rh(C$_6$Me$_6$)(CO)$_2$]PF$_6$ (ν(CO): 2110 and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

2055 $cm^{-1}$). Nevertheless, the addition of diethylether to the acetonitrile solution of **1**, causes the precipitation of $[Rh(MeCN)_2(CO)_2]PF_6$ (1) as a single product.

The reaction of complex **1** with 2,2′-bipyridine in dichloromethane leads to the immediate displacement of the arene group, with the formation of $[Rh(bipy)(CO)_2]PF_6$ (21).

The reaction of **1** with some nucleophiles was also examined. Thus, acetylacetone, tropolone, and pyrazole, in the presence of triethylamine react with **1** to give the previously reported neutral derivatives, Rh(acac)$(CO)_2$ (26), Rh(trop)$(CO)_2$ (27), and $[Rh(pz)(CO)_2]_2$ (28):

[4] $[Rh(C_6Me_6)(CO)_2]PF_6 + HA + NEt_3 \rightarrow [RhA(CO)_2]_x + HNEt_3PF_6$,

where A = acac or trop, $x = 1$; A = pz, $x = 2$.

No reaction was observed when excess of perchloric acid was added to Rh(trop)$(CO)_2$ in the presence of hexamethylbenzene. On the contrary, under the same conditions Rh(trop)(COD) (29) reacts according to reaction [5].

[5] $Rh(trop)(COD) + HClO_4 + C_6Me_6 \rightarrow [Rh(C_6Me_6)(COD)]ClO_4 + Htrop$

When reaction [1] was performed with other arenes with less methyl substituents, e.g. $C_6H_3Me_3$, the formation of the corresponding arene carbonyl complexes was observed spectroscopically (e.g. $[Rh(C_6H_3Me_3)(CO)_2]PF_6$,[2] ν(CO): 2100 and 2035 $cm^{-1}$ ($CH_2Cl_2$)), but the products were not isolated.

All attempts to prepare the complex $Rh(CO)_2PhBPh_3$, related to the well-known Rh(diolefin)$PhBPh_3$ derivatives (8), by reaction of $[RhCl(CO)_2]_2$ with $NaBPh_4$ in polar solvents were unsuccessful.

*Preparation and properties of [Rh(arene)(CO)(triarylphosphine)]$PF_6$*

The reaction of $[RhCl(CO)PPh_3]_2$ (19) with $AgPF_6$ and hexamethylbenzene in acetone leads to the formation of **2**.

[6] $(1/2)\ [RhCl(CO)PPh_3]_2 + AgPF_6 + C_6Me_6 \rightarrow [Rh(C_6Me_6)(CO)PPh_3]PF_6 + AgCl$

**2**

An alternative and competitive route is the reaction of $[Rh(arene)(CO)_2]PF_6$ (arene = $C_6Me_6$ or $C_6H_3Me_3$) with a stoichiometric amount of $PPh_3$, whereas with excess of the ligand, $[Rh(CO)(PPh_3)_3]PF_6$ is formed (reaction [7]).

[7] $[Rh(arene)(CO)_2]PF_6 \xrightarrow{+\ PPh_3} [Rh(arene)(CO)PPh_3]PF_6$

$\xrightarrow{+\ 2\ PPh_3} [Rh(CO)(PPh_3)_3]PF_6$

These complexes were isolated as a stable yellow–orange microcrystalline solid that behaves as 1:1 electrolyte in acetone. The $^1$Hmr of the complexes show a high dissociation of the coordinated $C_6Me_6$ (73% for a saturated solution) while the $C_6H_3Me_3$ derivative is completely dissociated in deuteroacetone. The ir show absorptions characteristic of uncoordinated $PF_6^-$ and coordinated CO (ν(CO): 2015 $cm^{-1}$, $C_6Me_6$; 2005 $cm^{-1}$, $C_6H_3Me_3$ ($CH_2Cl_2$)). On the other hand, the related complex $[Rh(C_6Me_6)(CO)P(p\text{-}MeC_6H_4)_3]PF_6$ (ν(CO): 2010 $cm^{-1}$ ($CH_2Cl_2$)) has also been prepared in dichloromethane according to reaction [7], but refluxing conditions were used.

Complex **2** reacts with 2,2′-bipyridine with the formation of $[Rh(bipy)(CO)PPh_3]PF_6$ (21). The latter complex shows a strong carbonyl absorption at 1985 $cm^{-1}$, whilst the $[Rh(CO)(PPh_3)_3]PF_6$ complex shows it at 2030 $cm^{-1}$.

As expected, complex **2** reacts with acetylacetone, tropolone, and pyrazole in the presence of triethylamine to give Rh(acac)$(CO)PPh_3$ (26), Rh(trop)$(CO)PPh_3$ (30), and $[Rh(pz)(CO)PPh_3]_2$ (31).

[2]In $(CD_3)_2CO$ the $^1$Hmr show that the arene is completely dissociated.

# Magnetic and spectroscopic studies of structure and bonding in hexafluorophosphate and hexafluoroarsenate complexes of copper(II)

RAYMOND M. MORRISON[1] AND ROBERT C. THOMPSON

*Department of Chemistry, The University of British Columbia, Vancouver, B.C., Canada V6T 1Y6*

Received October 14, 1981

RAYMOND M. MORRISON and ROBERT C. THOMPSON. Can. J. Chem. **60**, 1048 (1982).

Complexes of composition $CuL_4(EF_6)_2$ (where L is pyridine, 3-methylpyridine, or 4-methylpyridine and E is P or As) have been prepared and characterized by epr, electronic and infrared spectroscopic, and magnetic susceptibility studies. Results are consistent with elongated tetragonal–octahedral structures with coordinated anions. The coordinating strength of $PF_6^-$ is estimated to be less than that of $AsF_6^-$ and both are considered weaker than perchlorate. Analysis of the epr data indicates significant metal to heterocyclic ligand $\pi$-electron delocalization, the extent and nature of which depends on the orientation of the heterocyclic ring in the $CuL_4$ chromophore. Analysis of infrared data suggests that the intensities of the $\nu_1$ and $\nu_2$ vibrations as they occur in $EF_6^-$ complexes generally provide an indication of the strength of metal–anion interactions.

RAYMOND M. MORRISON et ROBERT C. THOMPSON. Can. J. Chem. **60**, 1048 (1982).

On a préparé des complexes de formule $CuL_4(EF_6)_2$ (où L = pyridine, méthyl-3 pyridine ou méthyl-4 pyridine et E = P ou As) et on les a caractérisé par des études de rpe, de spectroscopie infrarouge et de susceptibilité magnétique. Les résultats sont en accord avec des structures tétragonales–octahédriques allongées avec des anions coordonés. On évalue la force de coordination de $PF_6^-$ comme étant inférieure à celle de $AsF_6^-$ et on considère ces deux forces plus faibles que celle du perchlorate. L'analyse des données de la rpe indique une délocalisation importante de l'électron $\pi$ du ligand hétérocyclique par rapport au métal. La nature et le taux de cette délocalisation dépendent de l'orientation de l'hétérocycle dans le chromophore $CuL_4$. L'analyse des données infrarouges suggère que les intensités des vibrations $\nu_1$ et $\nu_2$ telles qu'elles se produisent dans les complexes de $EF_6^-$ constituent généralement une indication de la force des interactions métal–anion.

[Traduit par le journal]

## Introduction

Through the synthesis and study of pyridine and methylpyridine complexes containing hexafluorophosphate and hexafluoroarsenate it has been possible to examine the coordinating tendencies of these very weakly basic anions (1–6). The $PF_6^-$ and $AsF_6^-$ ions have been shown to be non-coordinated in complexes of composition $M(4mpy)_8(H_2O)_2(EF_6)_2$ (where 4mpy is 4-methylpyridine and M is Co or Ni) (4) and $M(py)_6(EF_6)_2$ (where py is pyridine and M is Co or Ni) (2, 3) and in the complexes $Co(py)_4(EF_6)_2$ and $Co(4mpy)_4(EF_6)_2$ (3, 5). Complexes in which these anions are definitely coordinated to metal ions are less common. On the basis of a single crystal X-ray structure study of $Ni(4mpy)_4(PF_6)_2$ and some vibrational spectral studies it was concluded that the diamagnetic $Ni(py)_4(EF_6)_2$ and $Ni(4mpy)_4(EF_6)_2$ complexes have structures involving essentially square planar $NiL_4$ units with anions which, although not fully coordinated, are nonetheless held in axial positions by weak metal–anion interactions(6). The strongest evidence for conventional anion coordination has been found for a low temperature form of $Ni(py)_4(AsF_6)_2$ (6).

The copper(II) complex, $Cu(py)_4(PF_6)_2$, was the first compound of this general type to have been prepared and studied in any great detail (1). Good evidence for conventional anion coordination, or at least "semi-coordination", was obtained from a combination of electronic, epr, and infrared spectral studies. As an extension of this earlier work and to obtain a more thorough comparison of the coordinating properties of $PF_6^-$ and $AsF_6^-$ with those of more basic anions we report here the synthesis and study of a series of copper(II) complexes of the type $CuL_4(EF_6)$ (where L is py, 4mpy, or 3mpy). Structure and metal–ligand bonding in these compounds have been examined primarily through electronic and epr spectroscopy. In addition, to complement our earlier studies in which we established infrared criteria for non-coordinated anions in $EF_6^-$ complexes (4), we have examined the infrared spectra for the effects of increased metal–anion interactions on the fundamental vibrations of the $EF_6^-$ moieties.

## Experimental

*Preparations*

Tetrakis(pyridine)copper(II) hexafluorophosphate and hexafluoroarsenate were prepared using procedures similar to that described previously for the preparation of $Cu(py)_4(PF_6)_2$ (2). Copper(II) nitrate trihydrate (4.8 g) was dissolved in 50 mL water and 16 mL pyridine. A filtered aqueous solution of $NH_4PF_6$ (6.5 g in 150 mL water) or $KAsF_6$ (9.2 g in 250 mL water) was added. A blue-mauve powder precipitated immediately.

| $Cu(3mpy)_4(PF_6)_2$ | 18.9 | 19.4 | 19.0(77) | 1.88 | 1.87 | 1.86 |
| $Cu(4mpy)_4(PF_6)_2$ | 19.1 | 19.6 | 19.0(69) | 1.85 | 1.89 | 1.90 |

[a] Molar absorptivities, ε, in parentheses.
[b] $\mu_{eff} = 2.828\,((\chi_m - \text{t.i.p.})T)^{1/2}$ where $\chi_m$ is the molar magnetic susceptibility corrected for the diamagnetism of all atoms and t.i.p. is the temperature independent paramagnetism calculated from t.i.p. = $4N\beta^2/10Dq$.

After 1/2 h of stirring, the precipitate was filtered, washed with a solution of 5 mL pyridine in 50 mL water, and dried "in vacuo" for 48 h. The infrared spectra of the materials showed the presence of non-coordinated pyridine. Heating at 40°C under vacuum for 24 h gave the desired $Cu(py)_4(EF_6)_2$ products as mauve powders.

*Anal.* calcd. for $CuC_{20}H_{20}N_4P_2F_{12}$: C 35.86, H 3.01, N 8.36; found: C 35.68, H 3.02, N 8.45. *Anal.* calcd. for $CuC_{20}H_{20}N_4As_2F_{12}$: C 31.70, H 2.66, N 7.39; found: C 31.51, H 2.57, N 7.27.

Tetrakis(4-methylpyridine)copper(II) hexafluorophate and hexafluoroarsenate were prepared as described above except that the solutions used were four times more dilute. The more dilute solutions were required in these preparations to avoid contamination of products by nitrate. Precipitates were filtered, washed, dried "in vacuo" for 48 h, and finally heated to 40°C under vacuum for 24 h as before. The final products were obtained as mauve powders.

*Anal.* calcd. for $CuC_{24}H_{28}N_4P_2F_{12}$: C 39.71, H 3.89, N 7.72; found: C 39.68, H 3.88, N 7.91. *Anal.* calcd. for $CuC_{24}H_{28}N_4As_2F_{12}$: C 35.42, H 3.47, N 6.88; found: C 35.57, H 3.47, N 7.00.

In the preparations of tetrakis(3-methylpyridine)copper(II) hexafluorophosphate and hexafluoroarsenate, the reagents, $Cu(NO_3)_2 \cdot 3H_2O$, 3-$CH_3C_5H_4N$, and $NH_4PF_6$ (or $KAsF_6$), were mixed as described for the preparation of the pyridine complexes. In this instance, however, instead of immediate precipitation occurring, a two-liquid phase system developed with an upper weakly coloured aqueous phase and a more dense and strongly coloured, blue–purple, oily phase. After the reaction flask was allowed to stand for one week, blue–purple crystals formed in the oily phase. The crystals have been characterized as having the composition $Cu(3mpy)_6(H_2O)_2(EF_6)_2$ (7). When these crystals were ground up and dried under vacuum for 24 h, the desired $Cu(3mpy)_4(EF_6)_2$ compounds were obtained as mauve powders.

*Anal.* calcd. for $CuC_{24}H_{28}N_4P_2F_{12}$: C 39.71, H 3.89, N 7.72; found: C 39.67, H 3.91, N 7.67. *Anal.* calcd. for $CuC_{24}H_{28}N_4As_2F_{12}$: C 35.42, H 3.47, N 6.88; found: C 35.31, H 3.46, N 6.86.

Elemental analyses were done by P. Borda of the Department of Chemistry, The University of British Columbia.

*Spectroscopic and magnetic measurements*

Magnetic susceptibility measurements, electronic spectroscopy, and infrared spectroscopy were done as described previously (5). The equipment and methods used in the epr studies have also been described before (8).

## Results and discussion

### *Electronic spectra and magnetic susceptibilities*

The complexes exhibit electronic spectra consisting of a single broad assymmetrical band in the visible region with band maxima around 18 000 to 19 000 cm$^{-1}$. The spectra are consistent with either a square-coplanar $CuN_4$ chromophore (and non-coordinated anions) or with an elongated tetragonal–octahedral ligand field as would be obtained in a structure involving four neutral ligands forming a square plane about copper with anions coordinated in axial positions (9). The epr data presented below provide clear support for the second structural type.

The energies of the visible band maxima are given in Table 1. In each instance where a solution spectrum was recorded (the py complexes were not sufficiently soluble in dichloromethane), there is excellent agreement with the corresponding diffuse reflectance spectrum, thus indicating retention of the solid state molecular structure on dissolution. The extinction coefficients (67 to 77 $M^{-1}$ cm$^{-1}$) are similar to those observed earlier for other tetragonally elongated $CuL_4X_2$ complexes (8). The mull spectra consistently show higher energy maxima than the diffuse reflectance spectra. This phenomenon was observed previously (8), where it was suggested that the relative intensities of different components of the visible band could be different in the two phases. Whatever the cause of this difference between mull and reflectance spectra, its presence requires that comparisons between complexes always be made on the same phase. The spectrum of $Cu(py)_4(PF_6)_2$ at room temperatures has been reported previously as a Kel-F mull (band maximum at 19 100 cm$^{-1}$ (2)) and as a powder by diffuse reflectance (band maximum at 18 300 cm$^{-1}$ (1)). Our diffuse reflectance spectrum agrees well with the earlier report. Although our spectra are broad we could find no clear indication of the shoulders previously reported at 16 200 cm$^{-1}$ and 16 700 cm$^{-1}$ in the mull and reflectance spectra respectively. We have prepared complexes of com-

position $Cu(3mpy)_6(H_2O)_2(EF_6)_2$ and $Cu(4mpy)_8(H_2O)_2(EF_6)_2$ (7) which have absorptions in the region of these reported shoulders and it is possible that impurities of species analogous to these were present in the samples of $Cu(py)_4(PF_6)_2$ reported earlier. In the present work we found it necessary to remove traces of water and free pyridine (detected by ir spectra) by heating to about 40°C under vacuum. This precaution does not appear to have been taken in the previous work.

In polarized, single-crystal, electronic spectral studies on related complexes, Hathaway *et al.* have found that of the three electronic transitions possible in $D_{4h}$ symmetry, $^2B_{1g} \rightarrow {}^2A_{1g}$, $^2B_{1g} \rightarrow {}^2B_{2g}$, and $^2B_{1g} \rightarrow {}^2E_g$ ($\Delta E_{z^2}$, $\Delta E_{xy}$, and $\Delta E_{xz,yz}$ respectively), the last forms the highest energy component of the visible band and a shift in the position of this transition to higher energy as a result of increasing tetragonal distortion results in an overall shift in the visible band (10). The position of the visible band maximum thus provides a measure of the degree of tetragonal distortion in complexes of this type and this has been used previously to rank the coordinating abilities of a number of polyatomic anions (8). The band maxima in the diffuse reflectance spectra of the $Cu(py)_4(EF_6)_2$ complexes are higher in energy than observed in other $Cu(py)_4X_2$ complexes and clearly indicate greater tetragonal distortion than in, for example, the corresponding perchlorate and fluorosulfate complexes (8). This is consistent with the weaker basicity associated with the $PF_6^-$ and $AsF_6^-$ anions. The energy of the band maxima in the 3mpy and 4mpy complexes is consistently higher than in the corresponding py complexes consistent with the greater basicity of the methylpyridine ligands. Moreover, it is interesting to note that in comparing $PF_6^-$ complexes with corresponding $AsF_6^-$ complexes the band maxima are approximately the same or slightly higher in energy for $PF_6^-$, suggesting a slightly higher degree of tetragonality and weaker anion basicity in these complexes. This could possibly account for our earlier observation that while $Ni(py)_4(AsF_6)_2$ has a low temperature form in which the anions are fully coordinated to nickel, the corresponding $PF_6^-$ complex appears to exist only in the form in which the anions are not fully coordinated (6).

Magnetic susceptibilities were measured at about 10 different temperatures over the range 80 to 300 K for each of the complexes. Values of $\mu_{eff}$ at three temperatures interpolated from plots of $\mu_{eff}$ vs. $T$ are given in Table 1. The moments which are essentially temperature independent are of a magnitude normally observed for magnetically dilute copper(II) complexes. Variations of magnetic moments for different complexes are not sufficiently great to permit an evaluation of the effects of tetragonal distortion on magnetic moments.

*Electron paramagnetic resonance*

The general features of the epr spectra of all six complexes are the same and may be illustrated by the discussion which follows for $Cu(3mpy)_4(AsF_6)_2$. The room temperature dichloromethane solution spectrum consists of four lines arising from copper nuclear hyperfine interaction (Fig. 1). At liquid nitrogen temperature two regions of absorption occur centred at $g_{||}$ and $g_\perp$. As seen in Fig. 2, nuclear hyperfine splitting of $g_{||}$ is observed with two of the four components clearly resolved and the other two obscured by the $g_\perp$ peak. The splitting of $g_\perp$ is not resolved because of superimposed nitrogen hyperfine coupling and because of the relatively smaller magnitude of $A_\perp$ compared to $A_{||}$. Although exchange coupling normally broadens the epr spectrum of copper(II) complexes in the solid state to an extent that hyperfine data is masked (11), such is not the case here. The epr spectrum of the room temperature powdered sample (Fig. 3) is very similar to that of the frozen solution spectrum. This phenomenon has been observed before (12–14); however, it is not common.

The epr parameters, calculated employing equations which include magnetic hyperfine coupling to second order (15), are listed in Table 2 (together with data for related $Cu(py)_4X_2$ complexes for comparison (8)). The complexes are listed in order of increasing $\Delta E_{xz,yz}$ and therefore increasing tetragonality. The isotropic $g_0$ and $A_0$ values were calculated from the room temperature solution spectra and the $g_{||}$ and $A_{||}$ values were obtained

from the frozen solution spectra. The values of $A_\perp$ and $g_\perp$ were obtained from the equations $3A_0 = A_{\|} + 2A_\perp$ and $3g_0 = g_{\|} + 2g_\perp$ (16). For comparison, values of $g_{\|}$, $g_\perp$, and $A_{\|}$ have been estimated from the room temperature powder spectra and these are also given in Table 2. We note that, as a consequence perhaps of exchange coupling, the values of $g_{\|}$ are consistently greater in the solid state spectra while $A_{\|}$ is generally smaller. The accuracy of the $g_\perp$ determination is too low to permit any meaningful comparison.

The fact that these complexes exhibit two $g$-value spectra in which the lowest $g$-value is equal to or greater than 2.04 is consistent according to Hathaway and Billings (17), with an elongated tetragonal–octahedral environment about copper in which the unpaired electron occupies the $d_{x^2-y^2}$ orbital in the ground electronic state. We note also that there are small but significant differences in the epr parameters between $Cu(py)_4(PF_6)_2$ and $Cu(py)_4(AsF_6)_2$ (and similarly for the 3mpy and 4mpy complexes). This is not consistent with a structural formulation involving square-coplanar $CuL_4^{2+}$ moieties with non-coordinated anions but instead supports the elongated tetragonal–octahedral structure.

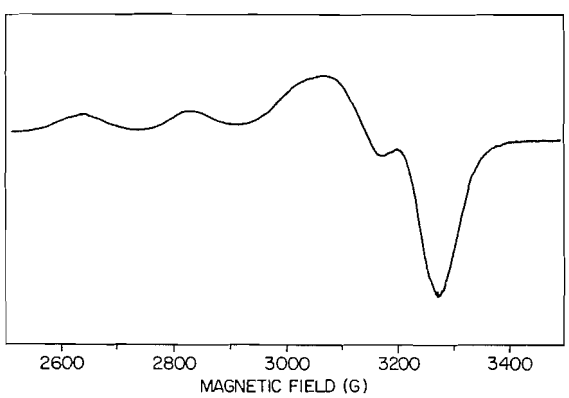

FIG. 2. Tetrakis(3-methylpyridine)copper(II) hexafluoroarsenate in dichloromethane; epr spectrum at liquid nitrogen temperature.

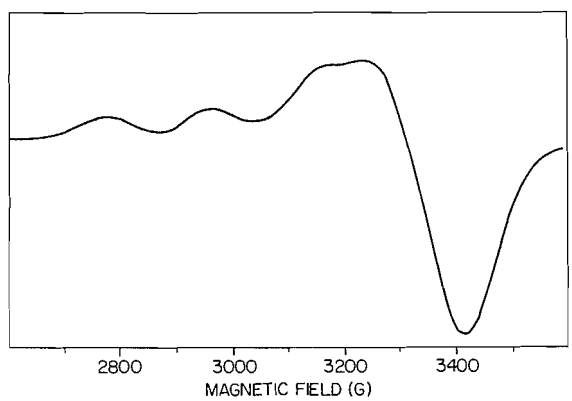

FIG. 3. Tetrakis(3-methylpyridine)copper(II) hexafluoroarsenate; epr spectrum of powdered sample at room temperature.

In our earlier studies of the epr spectra of some $Cu(py)_4X_2$ complexes (8) we noted that as the coordinating strength of the anion decreases, and therefore the tetragonality of the complex increases, the value of $g_\perp$ decreases. It is clear from the present work that this trend does not continue into the $PF_6^-$ and $AsF_6^-$ series of compounds. In spite of the fact that these anions are less basic than $ClO_4^-$, for example, the value of $g_\perp$ tends to be greater in all cases. As stated in the earlier paper, a decrease in $g_\perp$ would be expected to occur with increasing tetragonality only in the absence of a significant decrease in electron delocalization from copper (relatively larger increase in the magnitude of the orbital reduction factor). Moreover, we note that on going from complexes containing the relatively more strongly coordinating fluorosulfate and tosylate anions to those containing $PF_6^-$ and $AsF_6^-$ anions, the value of $g_\parallel$ decreases and $A_\parallel$ increases. This, in fact, parallels the findings of Antosic *et al.* (16) who investigated the epr parameters of weak complexes of copper(II) β-ketoenolates with chloroform. To try to understand more fully the observed variations in the epr parameters we have evaluated bonding parameters for all of the complexes under discussion.

Using the notation and equations of Gersmann and Swalen (18) and the methods of Herring *et al.* (19) (modified to suit $D_{4h}$ symmetry), the magnetic parameters are:

$$[1]\quad g_\parallel = g_e - (8\lambda/\Delta E_{xy})(\alpha^2\beta^2)$$

$$[2]\quad g_\perp = g_e - (2\lambda/\Delta E_{xz,yz})(\alpha^2\beta^2)$$

$$[3]\quad A_\parallel = -K - \frac{4}{7}\alpha^2 P - 2\lambda\alpha^2 P \times \left(\frac{4\beta^2}{\Delta E_{xy}} + \frac{3}{7}\frac{\delta^2}{\Delta E_{xy,yz}}\right)$$

$$[4]\quad A_\perp = -K + \frac{2}{7}\alpha^2 P - \frac{22}{14}\frac{\lambda\alpha^2\delta^2}{\Delta E_{xz,yz}} P$$

The Fermi contact term can be obtained from

$$[5]\quad -K = \frac{1}{3}[(A_\parallel + 2A_\perp) - P[(\Delta g_\parallel + 2\Delta g_\perp)]$$

and $\alpha^2$ from

$$[6]\quad \alpha^2 = \frac{7}{4P}\left[-A_\parallel - K + P\left(\Delta g_\parallel + \frac{3}{7}\Delta g_\perp\right)\right]$$

where $\Delta g_\parallel = g_\parallel - 2.0023$ and $\Delta g_\perp = g_\perp - 2.0023$ and the signs of $A_\parallel$ and $A_\perp$ are taken to be negative (19). The following parameter values were used: $\lambda = -828\,cm^{-1}$ and $P = 360 \times 10^{-4}\,cm^{-1}$. The value of $\Delta E_{xz,yz}$ was taken as the position of the band maximum in the solution spectrum of each complex (diffuse reflectance for the $Cu(py)_4(EF_6)_2$ complexes) and for $\Delta E_{xy}$ the value $13.5 \times 10^3\,cm^{-1}$ was used for all complexes. The assumption that $\Delta E_{xy}$ should be approximately the same for all complexes is reasonable in that variations of axial substituents should have relatively little effect on this transition since neither the $d_{xy}$ nor the $d_{x^2-y^2}$ orbital has a $Z$ component. Moreover, changing the in-plane ligand in this series of complexes should also have little effect since differences in ligand field parameters for analogous pyridine and methyl–pyridine complexes have been shown previously to be small (4). The value of $13.5 \times 10^3\,cm^{-1}$ was estimated by assuming $\Delta E_{xy} = 10\,Dq$ (octahedral) (20) and by obtaining the latter from the measured $10\,Dq$ for $[Ni(py)_6]^{2+}$ (4) and the "ligand field $g$-parameters" for $Cu^{2+}$ and $Ni^{2+}$ (21).

The bonding parameters α, β, δ, and $K$ were calculated as described previously (19) and are given in Table 2. Uncertainties in these parameters resulting from the fact that they are obtained from epr results at two different temperatures (8) and as a consequence of having to assume values of $P$ and $\Delta E_{xy}$ should not significantly affect their relative values and hence comparisons from one compound to another should be valid. We estimate that the measured parameters $\Delta g_0$, $A_0$, $\Delta g_\parallel$, and $A_\parallel$ are obtained from the epr spectra with an uncertainty of less than 2%. This gives rise to a maximum error of approximately ±0.04 in the α and β parameters and 0.07 in the δ parameter. We note that α, which measures σ-bonding, is constant within experimen-

tal error throughout the series. The parameter which measures in-plane π-bonding, β, is measurably smaller than unity consistent with the presence of metal–ligand π-electron delocalization. Moreover, there appears to be a marginal decrease in the β values with increasing tetragonality.

It seems reasonable to expect that out-of-plane π-bonding will experience greater sensitivity to variations in the nature of the axial ligands than in-plane π-bonding. Unfortunately, the out-of-plane π-bonding parameter, δ, is the least precisely measured. Nevertheless, it is clear from the data in Table 2 that the variation in δ over the series is large and exceeds the range permitted by the uncertainty in δ. Some interesting comparisons may be made between individual complexes. The δ value for $Cu(py)_4(PF_6)_2$ is measurably greater than that of $Cu(py)_4(ClO_4)_2$. Since the tetragonality of the hexafluorophosphate complex is greater than that of the perchlorate, one might have expected the former compound to show stronger metal–pyridine bonding and hence more, rather than less, electron delocalization. A possible explanation for the poor out-of-plane π-bonding in the hexafluorophosphate derivative is that, in this compound, the anions are sufficiently weakly coordinated that the pyridine rings are able to adopt an orientation such that the angles between the planes of the rings and the $CuN_4$ plane are near 90°. Such a ring orientation, which has been observed in the analogous $Ni(4mpy)_4(PF_6)_2$ complex (6), would result in poor orbital overlap between pyridine π-orbitals and the metal $d_{xz}$ and $d_{yz}$ orbitals. In contrast, it seems likely that in the perchlorate derivative (and also probably in the tetrafluoroborate and sulfonate derivatives), the anions are sufficiently strongly bonded to the metal that the angles that the planes of the pyridine rings make with the $CuN_4$ plane are closer to 45°. Ring orientation of this type, which has been seen in the related $Cu(py)_4(CF_3CO_2)_2$ (22, 23) and Ni(3,5-dimethylpyridine)$_4(ClO_4)_2$ (24) complexes, would be more favourable to out-of-plane π-bonding. Finally we note that the other two hexafluorophosphate complexes studied here and the $Cu(4mpy)_4(AsF_6)_2$ complex also have δ values which suggest ring orientations which disfavour out-of-plane π-bonding.

*Infrared spectroscopy*

The infrared spectra of all complexes showed the absence of water and free heterocyclic ligand; moreover, bands arising primarily from anion vibrations and those arising from coordinated neutral ligand vibrations were usually easily distinguished. Infrared bands reported previously at 600 and 407 $cm^{-1}$ for $Cu(py)_4(PF_6)_2$ (2) are due to non-coordinated pyridine and were seen in this work in freshly precipitated samples but not in the final (dried at 40°C under vacuum) product. Otherwise our spectrum of $Cu(py)_4(PF_6)_2$ is in good agreement with the previously published data (1, 2). Some selected stereochemically sensitive pyridine and 4-methylpyridine bands are listed in Table 3 for comparison with earlier tabulations (3, 4). Frequencies assigned to the fundamental vibrations of the anions are listed in Table 4.

Free $EF_6^-$ anions have $O_h$ symmetry and should exhibit only two infrared absorptions, $\nu_3(T_{1u})$ and $\nu_4(T_{1u})$. Other transitions such as $\nu_1(A_{1g})$ and $\nu_2(E_g)$ are formally forbidden in $O_h$ symmetry (1). In complexes where the anions are formally non-coordinated, there may be some breakdown of these rules; it was found earlier that such complexes are characterized by spectra which show strong $\nu_3$ bands (possibly split by up to 25 $cm^{-1}$), strong and unsplit $\nu_4$ and, sometimes, weak $\nu_1$ or $\nu_2$ bands (4). In complexes where the anions are formally coordinated through one fluorine atom to the metal the anion symmetry can be no higher than $C_{4v}$. Under these circumstances the vibrational modes alter.

The formerly forbidden $\nu_1$ mode becomes allowed ($A_1$ symmetry), $\nu_2$ splits into $A_1$ and $B_1$ (the latter forbidden in infrared), $\nu_3$ and $\nu_4$ both split into formally allowed transitions of $A_1$ and $E$ symmetry. Two additional infrared-active $E$ modes derived from $\nu_5$ and $\nu_6$ (in $O_h$ symmetry) are also predicted in $C_{4v}$ symmetry; however, these bands are expected to be at low frequencies and possibly because of this or interference with other ligand vibrations these have not been observed in earlier work (1, 2) or in the present study. In summary, then, the presence of coordinated $EF_6^-$ groups should be indicated by strong and split $\nu_3$ and $\nu_4$ vibrations and medium to strong $\nu_1$ and $\nu_2$ bands.

These criteria for anion coordination were applied previously, to conclude that $Cu(py)_4(PF_6)_2$ contains "semi-coordinated" anions (1) and that the $Ni(py)_4(EF_6)_2$ and $Ni(4mpy)_4(EF_6)_2$ complexes contain weakly interacting anions (4, 6). These criteria for anion coordination are clearly met in the copper complexes studied in the present work (Table 4). In all complexes, $\nu_3$ is very broad or split, $\nu_4$ is assymetric (evidence for unresolved splitting) in the $PF_6^-$ compounds and relatively broad in the $AsF_6^-$ complexes. In all complexes, $\nu_1$ and $\nu_2$ are medium to strong in intensity.

Comparing the infrared spectra of the copper complexes studied here with those of analogous $CoL_4(EF_6)_2$ and $NiL_4(EF_6)_2$ complexes, it seems that the most sensitive test of anion coordination involves the $\nu_1(A_{1g})$ and $\nu_2(E_g)$ transitions. These bands are weak or not observed in the cobalt complexes where the anions are non-coordinated. In the nickel complexes, where weak anion coordination is present these bands appear with medium intensity and in the copper complexes, where even stronger anion coordination is evident, the bands are generally more intense, $\nu_2$ being split into strong $A_1$ and weak $B_1$ components in the hexafluoroarsenate complexes.

# Rearrangement of 10-acetoxy-10-vinylcamphene

NANCY LAMB, THOMAS MONEY, STEVEN J. RETTIG, AND JAMES TROTTER

*Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6*

Received December 2, 1981

NANCY LAMB, THOMAS MONEY, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **60**, 1055 (1982).

Treatment of 10-acetoxy-10-vinylcamphene with $BF_3$ or $HClO_4$ results in rearrangement to a bicyclo[3.2.1]octane derivative in preference to 5-*endo*-trigonal cyclization. Alkaline hydrolysis of this bicyclooctane yields a diol, crystals of which are orthorhombic, $a = 9.571(1)$, $b = 12.416(1)$, $c = 18.860(2)$ Å, $Z = 8$, space group $C222_1$. The structure was solved by direct methods and was refined by a full-matrix least-squares procedure to $R = 0.035$ and $R_w = 0.044$ for 930 reflections with $I \geq 3\sigma(I)$. The structure analysis has unambiguously identified the diol as 2,3-dimethyl-4-vinylbicyclo[3.2.1]octan-2,3-diol.

NANCY LAMB, THOMAS MONEY, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **60**, 1055 (1982).

Sous l'action du $BF_3$ ou du $HClO_4$, l'acétoxy-10 vinyl-10 camphène se transpose en un dérivé du bicyclo[3.2.1] octane plutôt que de subir une cyclisation 5-*endo* trigonale. L'hydrolyse alcaline de ce dérivé fournit un diol dont les cristaux sont orthorombiques, $a = 9,571(1)$, $b = 12,416(1)$, $c = 18,860(2)$ Å, $Z = 8$, groupe spatial $C222_1$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs de $R = 0,035$ et $R_w = 0,044$ pour 930 réflexions avec $I \geq 3\sigma(I)$. Cette analyse permet d'attribuer sans ambiguité la structure du diol: diméthyl-2,3 vinyl-4 bicyclo[3.2.1] octanediol-2,3.

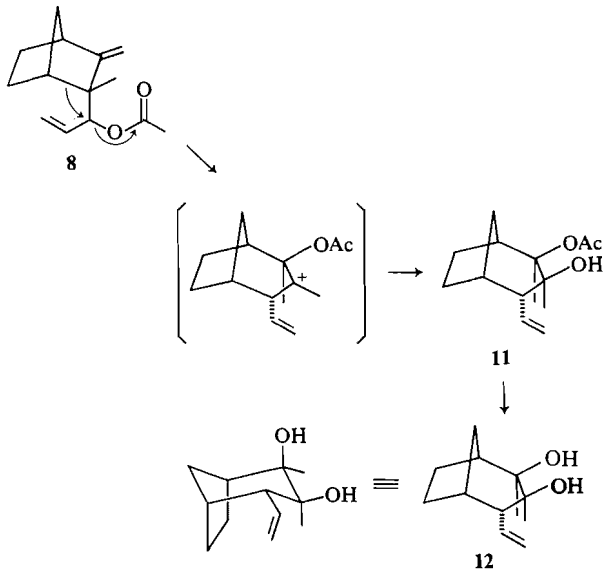
[Traduit par le journal]

## Introduction

The key step in a recent attempt to synthesize the former structure (**10**) (1) of (−)-albene[1] involved cyclization of 10-acetoxy-10-vinylcamphene, **8**, derived from 9-bromocamphor, **1** (cf. Scheme 1). Treatment of **8** with $HClO_4/CHCl_3$ or $BF_3/CH_2Cl_2$ led to the formation of a crystalline hydroxyacetate, **11**, in 25% yield.[2] The nmr, ir, and mass spectrum of **11** indicated the presence of

$>CHCH{=}CH_2$, $CH_3{-}\overset{|}{\underset{|}{C}}{-}$, and $CH_3{-}\overset{|}{\underset{|}{C}}{-}OAc$

groups and led us to suspect that rearrangement of the bicyclo[2.2.1]heptane skeleton of **3** had occurred. Alkaline hydrolysis of **11** provided a crystalline diol, **12**, whose structure has been established by X-ray crystallographic analysis.



SCHEME 1

[1]During the course of this work a new structure (**13**) for (−)-albene was established by chemical and X-ray crystallographic evidence (2).

[2]The isomeric hydroxyacetate structure is not, of course, excluded by our evidence.

## Experimental

Unless otherwise stated the following are implied. Melting points (mp) were determined on a Kofler micro heating stage or a Thomas Hoover capillary melting point apparatus and are uncorrected. Gas chromatography was carried out on either a Hewlett-Packard model 5831A gas chromatograph using 6 ft × 1/8 in. columns and nitrogen as carrier gas, or a Varian Aerograph model 90-P with 5 ft × 1/4 in. columns and helium as carrier gas. Carrier gas flow rate for 1/4 in. columns was about 60 mL/min and for 1/8 in. columns about 35 mL/min. The 60 MHz nmr spectra were recorded on a Varian Associates model T-60 and 100 MHz spectra were recorded on a Varian Associates model HA-100 or XL-100. Signal positions are given in δ with tetramethylsilane (TMS) as an internal reference. Signal multiplicity and integrated area are indicted in parentheses. Infrared spectra were recorded on a Perkin-Elmer 137 spectrophotometer and optical rotations were measured with either a Perkin-Elmer model 141 or 241 MC polarimeter. Low resolution mass spectra were recorded on a Varian/Mat model CH4B mass spectrometer and high resolution mass spectra were determined on the AE1 model MS902 or model MS50 instrument. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver. All the solvents used for nmr, ir, and optical rotations were of Spectral grade.

phosphoramide[3] was refluxed under nitrogen for 24 h. Addition of water, extraction with ether, and work-up in the usual way gave a brown oil (7.27 g) which was purified by column chromatography (silica gel) followed by distillation (bp 66–68°C, 0.04 Torr; lit. (3) bp 123°C (5 Torr)) to provide (+)-9-acetoxycamphor, **2**, as a colorless oil (6.55 g, 86% yield), $[\alpha]_D^{30}$ + 53.2° (c 0.88, $CHCl_3$); δ($CCl_4$), 4.15 and 3.90 (two doublets, 2 H, $J$ = 12 Hz, – $CH_2OAc$), 2.01 (singlet, 3H, $CH_3COO$—), 0.92 and 0.90 (two singlets, 6 H, tertiary methyls); $\nu_{max}$ ($CCl_4$), 2950 and 2900 (broad, medium, CH), 1750 (sharp, strong, C=O), 1240 $cm^{-1}$ (broad, strong, C—O—C); *m/e* 210 ($M^+$), 167, 164, 150, 137, 122, 108, 107, 95, 93, 79, 67, 43 (base peak). Fw calcd. for $C_{12}H_{18}O_3$: 210.1256; found (high resolution mass spectrometry): 210.1251. *Anal.* calcd. for $C_{12}H_{18}O_3$: C 68.54, H 8.63; found: C 68.59, H 8.80.

*10-Acetoxycamphene, 4*

A solution of (+)-9-acetoxycamphor, **2** (3.71 g, 17.7 mmol), in ethanol was added slowly with stirring to a mixture of sodium borohydride (1.92 g, 50.9 mmol) and ammonium chloride (1.59 g, 29.7 mmol) in 95% ethanol at 0°C. The reaction mixture was then stirred at room temperature for 30 min before dilute hydrochloric acid was added. Usual work-up provided a mixture of 9-acetoxyisoborneol, **3**, and 9-acetoxyborneol as a colorless oil (3.43 g), which was used in the subsequent Wagner–Meerwein rearrangement without purification.

The crude reduction product was treated with *p*-toluenesulphonyl chloride (3.9 g, 20 mmol) in refluxing dry pyridine for 15 h. Work-up in the usual fashion provided a yellow oil (2.87 g) which was distilled (36–38°C, 1.2 Torr) to afford 10-acetoxycamphene, **4**, as a colorless oil (1.92 g, 56% overall yield); δ($CCl_4$), 4.82 and 4.57 (two broad singlets, 1 H each, $=CH_2$), 3.90 (broad signal, 2 H, $—CH_2OAc$), 2.70 (broad multiplet, 1 H, half-width 8 Hz, bridgehead allylic methine), 2.00 (singlet, 3 H, $CH_3COO$—), 1.07 (singlet, 3 H, tertiary methyl); $\nu_{max}$($CCl_4$), 2950 and 2850 (sharp, medium CH), 1755 (sharp, strong, C=O), 1660 (broad, weak, C=C), 1240 (broad, strong, C—O—C), 895 $cm^{-1}$ (broad, medium, $=CH_2$); *m/e* 194 ($M^+$), 134, 121 (base peak), 106, 93, 91, 89, 87, 43. Fw calcd. for $C_{12}H_{18}O_2$: 194.1306;

[3]Acetic acid was previously used as solvent in this reaction (3).

found (high resolution mass spectrometry): 194.1305. *Anal.* calcd. for $C_{12}H_{18}O_2$: C 74.19, H 9.34; found: C 74.10, H 9.33.

*10-Hydroxycamphene, 5*

A mixture of 10-acetoxycamphene, **4** (1.9 g, 10 mmol), and potassium hydroxide (2.0 g, 35 mmol) in 95% ethanol (15 mL) was refluxed for 4 h. Dilution with water, extraction with ether, work-up in the usual way gave yellow crystals (1.37 g) which were sublimed (bath temperature 110°C, atmospheric pressure) and subsequently recrystallized from petroleum ether (30–60) to provide 10-hydroxycamphene, **5**, as colorless needles, mp 93–95°C (sealed tube); $[\alpha]_D^{25}$ +88.6° (c 1.00, $CHCl_3$); δ($CCl_4$), 4.75 and 4.44 (two broad signals, 1 H each, $=CH_2$), 3.49 and 3.35 (two doublets, 2 H, $J$ = 11 Hz, $—CH_2OH$), 2.67 (broad multiplet, 1 H, half-width, 7 Hz, bridgehead allylic methine), 1.07 (singlet, 3 H, tertiary methyl); $\nu_{max}$($CCl_4$), 3700 (sharp, medium, non-hydrogen-bonded OH), 3500 (broad, medium, hydrogen-bonded OH), 1670 (sharp, medium, C=C), 1045 and 1025 (broad, strong, C—O), 890 $cm^{-1}$ (sharp, strong, $=CH_2$); *m/e* 152 ($M^+$), 124, 122, 121 (base peak), 93, 91, 79, 77. Fw calcd. for $C_{10}H_{16}O$: 152.1201; found (high resolution mass spectrometry): 152.1203. *Anal.* calcd. for $C_{10}H_{16}O$: C 78.90, H 10.59; found: C 78.60, H 10.47.

*10-Oxocamphene, 6*

A solution of dry pyridine (32 mL, 400 mmol) in carbon tetrachloride (25 mL) was cooled to 0°C under nitrogen while chlorosulphonic acid (4.6 mL, 8 g, 69.4 mmol) was slowly added with stirring. The white solid formed was allowed to warm up to room temperature over 15 min, washed with *n*-hexane, and dissolved in dry dimethylsulphoxide (DMSO). A solution of (+)-10-hydroxycamphene, **5** (4.2 g, 27.6 mmol), in dry DMSO (30 mL) and dry triethylamine (55 mL, 40 g, 395 mmol) was added. The reaction mixture was stirred at room temperature for 2 h, then quenched with water and extracted with ether. Work-up in the usual way followed by distillation (35°C, 40 Torr) provided aldehyde **6** as a pale yellow liquid (2.7 g) which was homogenous on glc (3% SE 30, Varaport 30; 115°C) and tlc (silica gel) and exhibited nmr spectral data consistent with structure **6**; δ($CCl_4$), 9.50 (singlet, 1H, —CHO), 4.84 and 4.44 (two broad singlets, 1 H each, $=CH_2$), 2.70 (broad signal, 1 H, half-width 7 Hz, bridgehead allylic methine), 1.02 (singlet, 3 H, tertiary methyl).

Aldehyde **6** was used without purification in the Grignard reaction described below.

*10-Hydroxy-10-vinylcamphene, 7*

Magnesium turnings (1.3 g, 54 mmol) and a crystal of iodine were vigorously stirred in dry THF. The reaction flask was fitted with a dry ice – acetone condenser and a solution of vinyl bromide (about 10 g, 100 mmol) in dry THF was added over 30 min. After all the magnesium had dissolved the yellow suspension was stirred for 1 h before the condenser was removed and excess vinyl bromide was allowed to evaporate. A solution of crude 10-oxocamphene, **6**, (2.6 g, 17 mmol) in dry THF was added over 10 min and the mixture stirred at room temperature for 15 h. Acidification with dilute ammonium chloride, extraction with ether, and work-up in the usual way gave a yellow oil (3.1 g), which on distillation (43–45°C, 0.03–0.04 Torr) provided 10-hydroxy-10-vinylcamphene, **7**, as a colorless oil (2.5 g, 83% yield); δ($CCl_4$), 5.92 (doublet of doublets of doublets, 1 H, $J_{AM}$ = 10 Hz, $J_{BM}$ = 17 Hz, $J_{MX}$ = 4 Hz, $—CH_XOH—CH_M{=}CH_AH_B$), 5.33 (doublet of doublets of doublets, 1 H, $J_{AB}$ = 2 Hz, $J_{BM}$ = 17 Hz, $J_{BX}$ = 2 Hz, $—CH_XOH—CH_M{=}CH_AH_B$), 5.15 (doublet of doublets of doublets, 1 H, $J_{AM}$ = 10 Hz, $J_{AB}$ = 2 Hz, $J_{AX}$ = 2 Hz, $—CH_XOH—CH_M{=}CH_AH_B$), 4.87 and 4.79 (two broad singlets, 2 H, $—CH_2$), 4.09 (doublet of multiplets, 1 H, $J_{MX}$ = 4 Hz, $J_{AX}$ = 2 Hz, $J_{BX}$ = 2 Hz, $CH_XOH—CH_M{=}CH_AH_B$), 2.68 (broad signal, 1 H, half-width 8 Hz, bridgehead allylic methine), 0.95 (singlet, 3 H, tertiary methyls); $\nu_{max}$($CCl_4$), 3650 (broad, medium, OH), 3100, 2900, and 2830 (sharp, strong, CH), 1660 (broad, medium, C=C), 995 and 930 (broad, strong, $—CH{=}CH_2$), 900 $cm^{-1}$ (broad, strong, $—C{=}CH_2$); *m/e* 178 ($M^+$), 160, 150, 122, 121 (base peak), 105, 94, 93, 91, 79, 77. Fw calcd. for $C_{12}H_{18}O$: 178.1358; found (high resolution mass spectrometry): 178.1352.

*10-Acetoxy-10-vinylcamphene, 8*

10-Hydroxy-10-vinylcamphene, **7** (2.36 g, 14 mmol), was treated with acetic anhydride (3.22 g, 31.5 mmol) in refluxing dry pyridine (15 mL) for 15 h. Work-up in the usual way gave a brown oil (3.13 g) which was distilled (49–53°C, 0.01 Torr) to provide 10-acetoxy-10-vinylcamphene, **8**, as a colorless oil (2.53 g, 84% yield). $[\alpha]_D^{25}$ +17.7 (c 1.13, $CHCl_3$); δ($CCl_4$), 5.84 (doublet of doublets of doublets, 1 H, $J$ = 16, 10, 5 Hz, $—CHOAc—CH{=}CH_2$), 5.30 (multiplet, 2 H, $—CH{=}CH_2$), 5.14 (multiplet, 1 H, allylic $—CHOAc$), 4.73 and 4.62 (two broad singlets, 1 H each, $=CH_2$), 2.69 (broad signal, 1 H, half-width 8 Hz, bridgehead allylic methine), 2.03 (singlet, 3 H, $CH_3COO—$), 1.04 (singlet, 3 H, tertiary methyl); $\nu_{max}$($CCl_4$), 3130, 2900 and 2850 (sharp, medium, CH), 1750 (sharp, strong, C=O), 1650 (broad, weak, C=O), 1240 (broad, strong, C—O—C), 980, 970, 940 and 925 (broad, medium $—CH{=}CH_2$), 895 $cm^{-1}$ (sharp, medium, $—C{=}CH_2$); *m/e* 220 ($M^+$), 194, 161, 160, 145, 132, 122, 121 (base peak), 93, 89, 43. Fw calcd. for $C_{14}H_{20}O_2$: 220.1464; found (high resolution mass spectrometry): 220.1464.

*Cyclization of 10-acetoxy-10-vinylcamphene, 8, with perchloric acid*

A solution of 10-acetoxy-10-vinylcamphene, **8** (274 mg, 1.25 mmol) in chloroform was cooled by a dry ice – carbon tetrachloride bath. Perchloric acid (70%) (six drops) was added and the reaction mixture was stirred at −20°C for 1 h. It was then allowed to warm up to room temperature and stirred for 4 h. Usual aqueous work-up afforded a yellow oil (326 mg) which was purified by column chromatography (silica gel (activity grade III), elution with ether:petroleum ether (1:4)) to provide acetate **11** as colorless crystals (74 mg), mp 85–89°C (hot stage); δ($CCl_4$), 5.96 (doublet of doublets of doublets, 1 H, $J$ = 17, 12, 6 Hz, olefinic proton), 5.06 (doublet of triplets, 1 H, $J$ = 17, 2 Hz, olefinic proton), 3.25 (multiplet, 1 H, allylic methine), 2.04 (singlet, 3 H, $CH_3COO—$), 1.50 and 1.03 (two singlets, 3 H each, methyls); $\nu_{max}$($CCl_4$), 3600 (sharp, medium, non-hydrogen-bonded OH), 3500 (broad, weak, hydrogen-bonded OH), 1745 (sharp, strong, C=O), 1640 (sharp, weak, C=C), 1240 (broad, strong, C—O—C), 910 $cm^{-1}$ (broad, medium, =CH); *m/e* 238 ($M^+$), 195, 178, 153, 137, 135, 107, 106, 98, 79, 67, 43 (base peak). *Anal.* calcd. for $C_{14}H_{22}O_3$: C 70.65, H 9.30; found: C 70.37, H 9.17.

*Cyclization of 10-acetoxy-10-vinylcamphene, 8, with boron trifluoride*

10-Acetoxy-10-vinylcamphene, **8** (200 mg, 0.94 mmol), was dissolved in methylene chloride (100 mL). Boron trifluoride gas was bubbled through the solution until it was saturated and the reaction mixture was stirred at room temperature for another 10 min. Aqueous work-up gave a yellow oil (195 mg) which was purified by column chromatography (silica gel, activity grade III) followed by short-path distillation (130–150°C, 5 Torr) to provide colorless crystals (42.5 mg) which showed spectral data identical to those of acetate **11**.

Hydrolysis of the crystalline product **11** with potassium hydroxide in refluxing ethanol (95%) provided pale yellow needles which were purified by preparative glc (207 DEGS, Chromosorb W; 110°C) to provide colorless needles of diol **12**, mp 78–84°C; δ($CCl_4$), 5.91 (doublets of doublets, 1 H, $J$ = 16, 11, 4 Hz, olefinic proton), 5.06 (doublet of multiplets, $J$ = 11 Hz,

For personal use only.

olefinic proton), 5.02 (doublet of multiplets, $J$ = 16 Hz, olefinic proton), 1.13 and 1.06 (two singlets, 3 H each, tertiary methyls); $\nu_{max}(CCl_4)$, 3500 (broad, strong, OH), 3100 (sharp, weak), and 2850 (broad, strong) (CH), 1645 (sharp, medium, C=C), 985 and 915 $cm^{-1}$ (broad, strong, =CH); *m/e* 196 ($M^+$), 178, 163, 153 (base peak), 137, 135. *Anal.* calcd. for $C_{12}H_{20}O_2$: C 73.43, H 10.27; found: C 73.42, H 10.20.

*X-ray crystallographic analysis of* **12**

A crystal ca. 0.46 × 0.38 × 0.30 mm in size was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections measured on a diffractometer with Mo Kα radiation (λ = 0.71073 Å). Crystal data at 22°C are:

$C_{12}H_{20}O_2$ fw = 196.30

Orthorhombic, $a$ = 9.571(1), $b$ = 12.416(1), $c$ = 18.860(2) Å, $V$ = 2241.2(4) Å$^3$, $\rho_m$ = 1.15 (by flotation in aqueous KI), $Z$ = 8, $\rho_c$ = 1.164 g $cm^{-3}$, $F(000)$ = 864, $\mu$(Mo Kα) = 0.43 $cm^{-1}$. Absent reflections: $hkl$, $h + k \neq 2n$, and $00l$, $l \neq 2n$ uniquely indicate the space group $C222_1$ ($D_2^5$, No. 20).

Intensities were measured with graphite-monochromatized Mo Kα radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 1.12–6.71° $min^{-1}$ over a range of (0.55 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 52°. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 3%.

After data reduction, no absorption correction was made in view of the low value of μ. Of the 1253 independent reflections measured, 930 (74.2%) had intensities greater than 3σ($I$) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with $S$ = scan count and $B$ = background count.

The structure was solved by direct methods, the coordinates of the oxygen and carbon atoms being determined from an $E$-map. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to $R$ = 0.085, a difference map gave the positions of all 20 hydrogen atoms which were refined with isotropic thermal parameters in subsequent least-squares cycles. The hydroxyl hydrogen atoms were both found to be twofold disordered and in view of both equal peak heights on the difference map and physical considerations discussed below, the site occupancies were kept fixed at 0.5. In the final stages of refinement, the thermal parameters of H(02a) and H(02b) were not refined since whenever the temperature factors of all four disordered hydrogen atoms were refined, at least two of them refined to negative values. The absolute configuration of **12** is determined by that known for the chiral precursor **8**. The scattering factors of ref. 5 were used for non-hydrogen atoms and those of ref. 6 for hydrogen atoms. The weighting scheme, $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. Convergence was reached at $R$ = 0.035 and $R_w$ = 0.044 for 930 reflections with $I \geq 3\sigma(I)$. For all 1253 reflections $R$ = 0.059 and $R_w$ = 0.047. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.07 and 0.65 σ respectively. The maximum shift/error was associated with the $z$ coordinate of disordered H(01a). The mean error in an observation of unit weight was 1.362. A final difference map showed maximum fluctuations of ±0.23 e Å$^{-3}$. The final positional and thermal parameters appear in Tables 1 and 2[4] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[4]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (7). The rms standard error in the temperature factor σ$U_{ij}$ (derived from the least-squares analysis) is 0.0015 Å$^2$. Analysis of all non-hydrogen atoms gave rms $\Delta U_{ij}$ = 0.0022 Å$^2$ and physically reasonable rigid-body parameters. The appropriate bond distances have been corrected for libration (7, 8), using shape parameters $q^2$ of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 4. Intra-annular torsion angles defining the conformations of the seven-, six-, and five-membered rings of the bicyclo[3.2.1]octane system are listed in Table 5. Distances and angles involving hydrogen atoms and a complete list of torsion angles (Tables 6–8) are included as supplementary material.[4]

## Results and discussion

The structure analysis unambiguously identifies **12** as 2,3-dimethyl-4-vinylbicyclo[3.2.1]octan-2,3-diol, having the absolute configuration (1*R*,2*S*,3*R*,-4*R*,5*S*). The geometry of the bicyclo[3.2.1]octane system is in good agreement with that observed previously (9, 10). The mirror symmetry of the bicyclo[3.2.1]octane system is slightly disrupted by the asymmetric substitution of the C(2)—C(3)—C(4) fragment, but is retained within experimental error in the unsubstituted portion of the molecule. The bond between tetrasubstituted atoms C(2) and

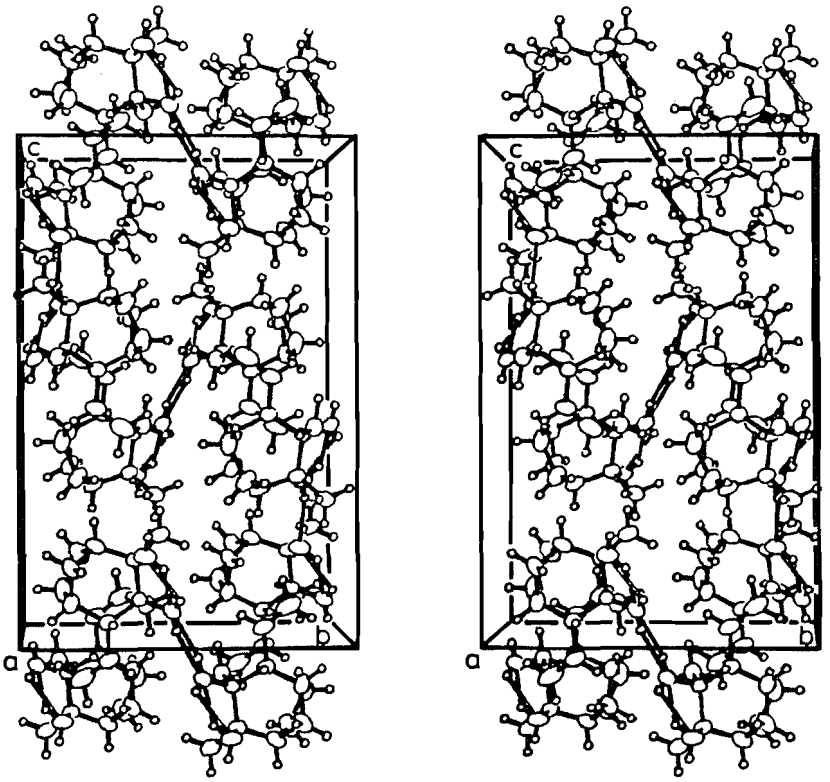

FIG. 2. Stereoscopic view down the *a* axis of the structure of **12**.

C(3), 1.580(3) Å, is significantly longer than the C(3)—C(4) bond of 1.560(3) Å. Other deviations from mirror symmetry involve bond angles at C(1), C(5), C(2), and C(4) in the six-membered ring and intra-annular torsion angles involving the C(1)—C(2), C(5)—C(4), C(2)—C(3), and C(3)—C(4) bonds (see Tables 4 and 5), in each case the difference between corresponding values not exceeding 2.0°. The C(2)—O(1) distance of 1.460(3) Å is significantly longer than the less sterically crowded C(3)—O(2) bond of 1.434(3) Å. The five-, six-, and seven-membered rings comprising the bicyclo-[3.2.1]octane system have envelope, distorted chair, and distorted boat conformations respectively. Other bond lengths and angles in the molecule are as expected.

In each molecule there is an intramolecular O—H···O hydrogen bond (O(1)···O(2) = 2.502(3) Å) involving either H(01b) (O···H = 1.89(9) Å, O—H···O = 131(7)°) or H(02a) (O···H = 2.17(5) Å, O—H···O = 109(5)°). Molecules are each linked to two others by intermolecular O—H···O hydrogen bonds (O(1)—H(01a)···O(1)(1 − *x*, *y*, 3/2 − *z*), O···O = 2.805(4), O···H = 2.05(5) Å, O—H···O = 168(4)°; O(2)···H(02b)—O(2) (*x*, 1 − *y*, 1 − *z*), O···O = 2.803(4), O···H = 2.04(5) Å, O···H—O = 160(4)°) forming continuous chains which spiral about the twofold screw axes along *c*. Molecules in these chains must alternately have the "a" and "b" OH positions occupied. If any two adjacent molecules were to have the same OH positons occupied, unrealistically short intermolecular H···H distances would result (H(01a)···H(01a) = 1.29(9)

TABLE 5. Intra-annular torsion angles (deg), standard deviations in parentheses

or H(02b)···H(02b) = 1.31(9) Å). This implies equal occupancy of the disordered OH sites.

Thus we can conclude that treatment of dieneacetate **8** with $HClO_4$ or $BF_3$ results in rearrangement and ring expansion to the bicyclo[3.2.1]octane framework (cf. Scheme 1). The failure of **8** to provide the required tricyclic product **9** is probably due to the fact that this would involve an unfavorable 5-*endo*-trigonal cyclization reaction (11). As a result we are currently investigating an alternative synthetic route to albene, **13**, which involves a more favorable 5-*endo*-digonal cyclization reaction.

# Interaction en milieu eau–dioxane des ions $Cu^{2+}$, $Ni^{2+}$ et $Ag^{+}$ avec les acides furannecarboxylique-2 et tetrahydrofurannecarboxylique-2

EMMANUELLE MICHAUD, GILLES PIVERT, GÉRARD DUC, MICHELLE PETIT-RAMEL[1] ET GERMAINE THOMAS-DAVID

*Laboratoire de Chimie Analytique II, Université Claude Bernard, Lyon I, 43 boulevard du 11 Novembre 1918, 69622 Villeurbanne Cedex, France*

Reçu le 24 septembre 1981

EMMANUELLE MICHAUD, GILLES PIVERT, GÉRARD DUC, MICHELLE PETIT-RAMEL et GERMAINE THOMAS-DAVID. Can. J. Chem. **60**, 1063 (1982).

Les constantes de protonation des acides furanne-2 carboxylique (HFC) et tétrahydrofuranne-2 carboxylique (THFC), puis les constantes de stabilité des complexes 1:1 formés avec le cuivre, le nickel et l'argent, ont été mesurées dans un mélange mixte 50% eau – 50% dioxane ($I$ = 0,1 ($NaNO_3$); $t$ = 25°C). L'étude potentiométrique a été complétée par des mesures spectrophotométriques uv–visible. Les résultats sont discutés et une structure chélate a été mise en évidence pour le système Cu – acide tétrahydrofuranne-2 carboxylique.

EMMANUELLE MICHAUD, GILLES PIVERT, GÉRARD DUC, MICHELLE PETIT-RAMEL, and GERMAINE THOMAS-DAVID. Can. J. Chem. **60**, 1063 (1982).

The protonation constants of furan-2 carboxylic (HFC) and tetrahydrofuran-2 carboxylic (THFC) acids and the stability constants of their copper, nickel and silver 1:1 complexes have been measured in water containing 50% dioxane ($I$ = 0.1 ($NaNO_3$); $t$ = 25°C). Treatment of the potentiometric data has been completed by uv–visible spectrophotometric measurements. The results are discussed and a chelate structure is displayed for the Cu – tetrahydrofuran-2 carboxylic acid system.

## Introduction

Un certain nombre d'antibiotiques naturels, ionophores, cycliques ou non, contiennent plusieurs hétéroatomes susceptibles de coopérer à la complexation d'un cation et, dans ces molécules, les atomes d'oxygène donneurs font partie, soit de cycles tétrahydrofuranne, soit de fractions carbonyle, alcool ou acide carboxylique. Nous nous intéressons particulièrement aux ligands qui contiennent un groupement carboxylique situé en α de l'hétéroatome (l'oxygène) et, dans un premier temps les études sont faites sur des molécules modèles contenant un seul motif furanne ou tétrahydrofuranne, fréquemment rencontrés dans les produits naturels, pour pouvoir, dans un second temps, apprécier l'effet coordinant de structures polycycliques. Les complexes correspondants sont relativement peu étudiés et concernent généralement les espèces formées avec les ions $Mn^{2+}$, $Cu^{2+}$, $Zn^{2+}$, d'intérêt biologique évident (1 à 4). Pour notre part nous avons retenu le cuivre(II), jouant principalement le rôle d'élément de référence, le nickel(II) et l'argent(I) et nous nous proposons, à l'aide du calcul de leurs stabilités thermodynamiques de mettre en évidence la formation éventuelle d'espèces chélatées.

Dans un autre domaine, il faut noter que la stabilité des complexes comme celle du ligand est nettement influencée par la composition du solvant et se traduit en général par un accroissement de stabilité avec la diminution de la constante diélectrique du milieu. En outre, les noyaux furanne et tétrahydrofuranne se révélant peu solubles en solution aqueuse, nous avons utilisé le mélange eau ($D$ = 80) – dioxane ($D$ = 2,2) qui offre une large gamme de constantes diélectriques puisque cet éther cyclique est miscible à l'eau en toutes proportions.

## Partie expérimentale

L'étude systématique des coordinats et des complexes a été réalisée par une méthode protométrique à l'aide d'une chaîne de titration automatique Tacussel. Les cellules de mesure sont thermostatées à 25°C ± 0,1°C. Dans le cas des complexes de l'argent nous avons muni l'électrode au calomel d'une allonge contenant $NaNO_3$ afin d'éviter la précipitation de AgCl. En outre la cellule de travail a été peinte en noir opaque pour prévenir toute réaction photochimique des sels d'argent.

Toutes les mesures sont effectuées en présence de sel neutre ($NaNO_3$ $10^{-1}$ $M$ dans eau – dioxane 50%) de manière à maintenir aussi constants que possible les coefficients d'activité, le potentiel de jonction liquide et la force ionique dans toute l'échelle de pH considérée ($2 < pH < 11$).

L'ensemble des résultats est donné pour un solvant mixte eau – dioxane 50% en volume ce qui correspond à une constante diélectrique voisine de 40.

### 1. *Etalonnage de la chaîne de mesure*

La pente du couple d'électrodes a été déterminée en milieu aqueux avec les solutions étalons de Bates. De plus, la correspondance entre la valeur expérimentale $pH_{exp}$ et le cologarithme de la concentration réelle en protons ($pH_{théorique}$) dépend du milieu, de la force ionique et du couple d'électrodes utilisé. L'étalonnage de la chaîne de mesure a donc été fait dans le milieu mixte sur une série de solutions de titre connu en acide nitrique par addition de soude et donne le ΔpH de correction. Cette valeur est en accord avec les résultats graphiques obtenus par la méthode de Van Uitert et Haas (5).

2. *Produit ionique de l'eau*

Nous avons utilisé le même protocole d'étude que Roletto et Zelano et coll. (6 à 8) en calculant, à partir de la mesure du $pH_{exp}$, la concentration en ions $H^+$ théorique de solutions acides et basiques. Pratiquement, ceci est réalisé lors de l'étalonnage en suivant la fem au delà du point d'équivalence. La connaissance des valeurs de $pH_{théor.}$ et pOH permet alors de calculer $pK_e$.

La fem, $E$, de la cellule à 25°C est donnée par l'équation de Nernst:

$$[1] \quad E = E^0 - a\text{pH} + C\,|H^+|$$

$E^0$ est une constante de cellule, $a$ est la pente de la droite d'étalonnage mV/pH et $C|H^+|$ est le potentiel de jonction liquide.

En ce qui concerne ce paramètre $C|H^+|$, Roletto et Zelano ont montré que dans le domaine de concentration étudié, la contribution du potentiel de jonction liquide était négligeable. L'expression [1] devient:

$$[2] \quad \text{En milieu acide } E = E_a^0 - a\ \text{pH}$$

$$[3] \quad \text{En milieu alcalin } E = E_b^0 + a\ \text{pOH}$$

$$[4] \quad pK_e = \text{pH} + \text{pOH}$$

$$[5] \quad pK_e = E_a^0 - E_b^0/a$$

Il suffit alors de déterminer expérimentalement $E_a^0$ et $E_b^0$ à partir des dosages protométriques de solutions d'acide nitrique. Dans nos conditions expérimentales $pK_e = 15{,}22$.

3. *Réactifs*

*Tampons, electrolyte support, base, solvant*

Les solutions tampons de phtalate acide de potassium et de borax sont préparées par pesée et dissolution dans l'eau de produits cristallisés Merck "pro analysis". Le nitrate de sodium est un produit Prolabo R.P. cristallisé. La base est une soude Titrisol Merck préparée dans un mélange 50%eau – 50% dioxane et dosée potentiométriquement par du phtalate acide de potassium. Le dioxane est un produit Prolabo R.P. pour analyse.

*Sels métalliques*

Les cations $Cu^{2+}$, $Ni^{2+}$, sont introduits sous forme de solutions de nitrate titrées par complexométrie EDTA. Le nitrate d'argent est préparé à partir du produit cristallisé Prolabo et la solution dosée électrochimiquement par NaCl à l'aide d'une électrode reversible aux ions $Ag^+$.

*Ligands*

L'acide furannecarboxylique-2 est un produit Prolabo recristallisé et dosé par potentiométrie. L'acide tétrahydrofurannecarboxylique-2 a été préparé par hydrogénation catalytique de l'acide furoïque-2 (9, 10) et sa pureté vérifiée par chromatographie en phase vapeur. La synthèse du produit ainsi que les mesures de pureté ont été faites au laboratoire de Chimie organique Physique de Lyon I par les soins du Docteur F. Chastrette et ses collaborateurs que nous remercions vivement.

## Résultats et discussion

Considérons l'équilibre général:

$$[6] \quad pM + qH + rL \rightleftarrows M_p\,H_q\,L_r$$

où $p$ représente le nombre d'ions métalliques, M, par ligand, L; $q$ le nombre de protons liés par coordinat; $r$ le nombre de coordinats liés par ion métallique.

Pour les ligands, les équilibres d'ionisation peuvent être représentés par les constantes $\beta_{pqr}$ telles que:

$$[7] \quad \beta_{011} = |HL|/|H||L|$$

Pour chaque valeur de pH, on peut calculer le nombre moyen de protons neutralisables $\bar{q}$ par mole de coordinat.

$$[8] \quad \bar{q} = \frac{C_H - h + oh}{C_L}$$

$C_H$ et $C_L$ étant les concentrations molaires totales des constituants H et L, $h$ et $oh$ étant les concentrations libres en protons et en ions hydroxydes.

L'allure de la courbe $\bar{q} = f(\text{pH})$ indépendante de la concentration en ligand permet de prévoir la convergence rapide du processus d'affinement de la constante $\beta_{011}$ (tableau 1).

En ce qui concerne l'étude spectrale des deux acides, dans le domaine uv, un point isosbestique net à 247–248 nm confirme l'ionisation du groupement carboxylique qui provoque un déplacement vers les courtes longueurs d'onde et une diminution de l'intensité d'absorption en relation avec la diminution de résonance des molécules. Le calcul des coefficients d'absorption moléculaire (tableau 1) de chaque forme protonée met en évidence l'influence importante des doubles liaisons du cycle sur l'absorption:

$$[9] \quad \varepsilon_{(HFC)} \gg \varepsilon_{(THFC)}$$

Les constantes de stabilité des complexes ML telles que:

$$[10] \quad M + rL \rightleftarrows ML_r$$

avec:

$$[11] \quad \beta_{10r} = \frac{[ML_r]}{[M][L]_r}$$

ont été déterminées pour plusieurs rapports coordinat/métal. Les courbes de neutralisation ont été tracées en présence d'un excès de ligand et leurs transformées sous forme $\bar{q}_{exp} = f(\text{pH})$ présentent les mêmes caractéristiques de plus en plus nettes de l'argent au cuivre et nickel.

Pour des pH supérieurs à 5, les potentiels d'électrodes deviennent instables et le milieu réactionnel se trouble; il y a alors compétition entre hydrolyse et complexation du métal, la concentration des ions hydroxydes devenant supérieure à celle des ions libres du coordinat.

Pour chaque métal, les courbes de formation $\bar{r} = f(\text{pL})$ restent confondues et tendent vers 1, quel que soit le rapport ligand/métal envisagé; il ne se forme donc qu'un seul complexe ML (tableau 2) à l'exclusion d'autres espèces.

L'absorption dans le domaine visible (maximum à 715 nm pour le cuivre) confirme les résultats

TABLEAU 1. Constantes de protonation et coefficients d'absorption molaire des acides furannecarboxylique-2 (HFC) et tétrahydrofuranne carboxylique-2 (THFC)[a]

potentiométriques relatifs à la distribution des espèces: domaine étroit de variation d'intensité et de fréquence entre le métal libre et le métal complexé correspondant à de faibles perturbations des électrons *d*, donc à des stabilités thermodynamiques relativement peu élevées. A 715 nm on peut facilement calculer l'absorptivité molaire $\varepsilon_{101}$ = 9,5 pour le système Cu–HFC.

La presque totalité des travaux concernant les interactions métal–coordinat avec des ligands contenant un hétéroatome porte davantage sur la comparaison des stabilités selon la nature de l'hétéroatome (soufre, oxygène, azote) que sur son influence dans le phénomène de chélation (1, 11, 12). Pour notre part, nous nous attacherons à montrer la formation possible de chélate en comparant les stabilités thermodynamiques déterminées dans ce travail avec celles des complexes formés avec des ligands modèles linéaires comme les acides chloracétique (I), formique (II), β-chloropropionique (III), acétique (IV) et propionique (V). Comme l'a montré Sigel *et al.* (1), la constante de stabilité $\beta_{101}$ d'un complexe de cuivre, par exemple, est une fonction linéaire de la stabilité protonique $\beta_{011}$ du ligand correspondant (Fig. 1).

Le système Cu–THFC, reporté sur cette figure, fait apparaître un net accroissement de stabilité par rapport à la basicité du groupement carboxylique. Il faut noter que cet écart est cependant moins important que pour le complexe Cu – acide hydroxyacétique (Cu–HOAc) où l'oxygène α-substitué est qualifié de "dur" dans la classification de Pearson (13, 14). Il n'y a donc plus simple complexation mais formation d'un chélate à cinq chaînons dans lequel intervient l'hétéroatome.

Le point figuratif du système Cu–HFC se situe

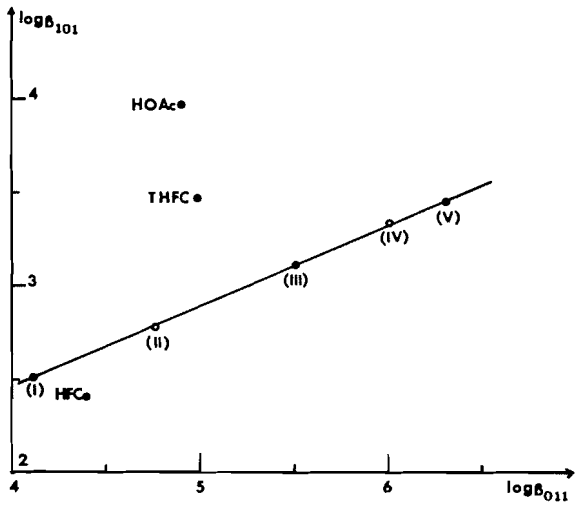

FIG. 1. Relation entre $\log \beta_{101}$ et $\log \beta_{011}$ pour les complexes du cuivre. Acides chloracétique(I) (1), formique(II) (1), β-chloropropionique(III) (1), acétique(IV) (1), propionique(V) (1), hydroxyacétique(HOAC) (1), tétrahydrofuranne(THFC) et furanne(HFC).

sensiblement en dessous de la droite précédente et ne permet donc pas d'avancer la formation d'un cycle de chélation.

D'un point de vue plus général, l'examen du tableau 2 permet d'élargir la discussion sur les valeurs relatives des stabilités des complexes formés.

Le cuivre et le nickel, complexés sous la forme ML, s'inscrivent normalement dans la série d'Irving et Williams (15) applicable aux espèces dans lesquelles les ligands n'occupent pas plus de quatre positions de coordination dans le même plan; la valeur de la constante de stabilité pour l'argent reste la plus faible.

Ces conclusions se retrouvent, en outre, être en excellent accord avec la classification de Pearson: le cuivre et le nickel se situent à la limite des acides de Lewis "durs" et "doux" alors que l'argent reste localisé dans les "doux"; l'oxygène donneur étant une base "dure" les stabilités thermodynamiques ne pourront que décroître dans le sens $Cu^{2+} > Ni^{2+} > Ag^{+}$.

Received September 9, 1981

VANGA S. RAO. Can. J. Chem. **60**, 1067 (1982).

Carbon-13 chemical shifts and $^{13}C—^1H$ couplings are reported for some substituted 2-methoxy-1,3-dioxanes and related tetrahydropyran derivatives. These data, together with nuclear Overhauser enhancement experiments, provided evidence for a favored orientation of the methoxyl group. From an analysis of the $^{13}C$ chemical shifts and the magnitude of vicinal $^{13}C—^1H$ coupling between $—OCH_3$ and H-2, a possible dynamic-equilibrium orientation for the methoxyl group is proposed, and an evaluation of the significance of a "generalized *exo*-anomeric effect" is presented.

VANGA S. RAO. Can. J. Chem. **60**, 1067 (1982).

On rapporte les déplacements chimiques et les constantes de couplage du $^{13}C$ et du $^1H$ des méthoxy-2 dioxannes-1,3 substitués et des dérivés tétrahydropyranniques apparentés. Ces données ainsi que les expériences d'augmentation de l'effet Overhauser nucléaire, confirment l'existence d'une orientation préférentielle du groupe méthoxy. A partir de l'analyse des déplacements chimiques du $^{13}C$ et de la grandeur du couplage vicinal $^{13}C—^1H$ entre le $O-CH_3$ et le H-2, on propose une orientation possible de l'équilibre dynamique du groupe méthoxy et on présente une évaluation de la signification "d'un effet *exo*-anomère généralisé".

[Traduit par le journal]

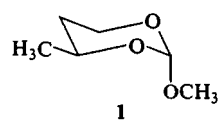
## Introduction

In a recent publication (1) attention was drawn to a differential shielding influence by a γ-*anti* anomeric oxygen atom on the $^{13}C$ chemical shifts of C-3 and C-5 in aldopyranoses and derivatives, resulting in a larger upfield displacement for C-5 (4–5 ppm). This shielding difference was rationalized by invoking the *exo*-anomeric conformation (2) in which the *p*-type lone pair[1] of the anomeric oxygen (O-1) is oriented *anti* with respect to the C1—O5 bond, thus affecting C-5 more strongly. In extending these observations the diastereoisomeric orthoformates, *cis*- and *trans*-2-methoxy-4-methyl-1,3-dioxanes (5*a*), were prepared and their nmr data were analyzed.

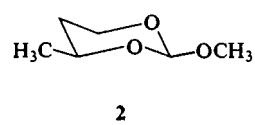
## Results and discussion

### *The question of a "generalized* exo*-anomeric" effect*

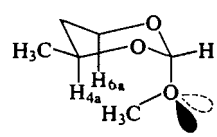
The presence of the 4-methyl group in *cis*- and *trans*-2-methoxy-4-methyl-1,3-dioxanes effectively renders these isomers conformationally homogeneous (biased). Thus in the *trans* isomer (**1**) the methoxy group is in the preferred axial position (double anomeric effect) whereas the methyl substituent is in its preferred equatorial position. By contrast, the corresponding *cis* isomer (**2**) has both the methoxy and methyl groups in equatorial orientations. The *cis* isomer, **2**, is particularly well suited for studying what may be termed a "generalized *exo*-anomeric effect". It is conceivable for it to manifest a double *exo*-anomeric effect due to the presence of two equivalent adjacent ring oxygen atoms. As the methoxy group is not spherically symmetrical, in principle it can assume several rotameric states. In the *trans* isomer, **1**, the *exo*-anomeric stabilization should be at a maximum when both lone pairs ($sp^3$) of the exocyclic oxygen can participate simultaneously in the presumed electronic interaction, as in **3**. However, this "Me-inside" rotameric conformation should experience severe steric constraints due to interactions of the O-methyl group with H-4a and H-6a, as well as parallel orientation of $O—CH_3$ with O3—C4 and O1—C6 bonds. It is perhaps unreasonable to



**1**



**2**



**3**

[1]Although an oxygen atom is conventionally regarded as $sp^3$ hybridized, there is theoretical (3) and experimental (4) evidence to suggest that the lone pairs are directionally nonequivalent, one occupying a higher energy orbital with considerable *p*-character (*p*-type), and the other a lower energy orbital (*s*-type). In the present paper, both concepts are utilized for comparative purposes.

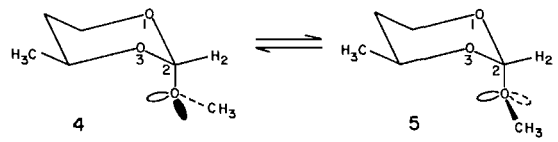
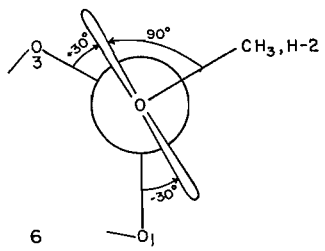
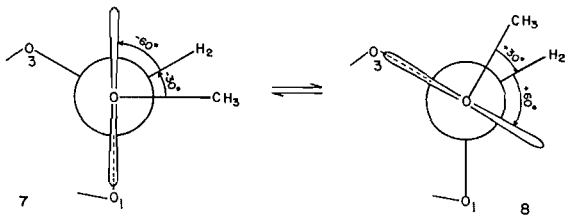
assume that the *exo*-anomeric stabilization alone could exceed or outweigh these destabilizing repulsive interactions, so as to maintain **1** in the conformation shown in **3**. A more probable conformation, then, is one in which each $sp^3$ lone pair interacts sequentially with the C2—O1 (**4**) and C2—O3 (**5**) bonds in a dynamic process involving an unfavorable eclipsing barrier between the O—Me group and C2—H2 bond. Alternatively, with a $sp^2$ hybridized oxygen, a symmetric conformation for **1** is conceivable in which the O—$CH_3$ and C2—H2 bonds are eclipsed and the *p*-type orbital is oriented symmetrically with respect to the C2—O1 and C2—O3 bonds, forming dihedral angles of ± 30° with these bonds, and lying orthogonal to the C2—H2 bond as shown in the Newman projection **6**. With this stereochemistry, the unfavorable O—$CH_3$ and C2—H2 eclipsing interaction may be more than compensated for by the stabilizing *exo*-anomeric effect, although when θ = ± 30°, the latter would be somewhat weaker. In fact, this orientation for the methoxy group was proposed recently (6) in rationalizing relative rates of hydrogen atom abstraction from some diastereoisomeric orthoesters of types **1** and **2** by the *tert*-butoxy radical.





*Nuclear Overhauser enhancement experiments and vicinal $^{13}C$—$^1H$ couplings*

Nuclear magnetic resonance spectral evidence has now been obtained favoring a *cis* relationship between the O—Me and C2—H2 bonds, as in **6**. Thus, saturation of the methoxy protons of **1** resulted in an 18% nuclear Overhauser enhancement in the signal intensity of the methine proton (H-2).[2] This is similar to the level of enhancement observed with aldopyranoses and their derivatives (2*d*, 8). Another measurement was that of three-bond carbon–hydrogen coupling ($^3J_{OCH_3,\ H_2}$) between O—$CH_3$ and H-2, which amounted to 2.2 Hz. It is now well known that measured (9) and calculated (10) carbon–hydrogen vicinal couplings follow an approximate Karplus-type relationship. The observed value of 2.2 Hz appears too low (based on carbohydrate derivatives (11)) for a dihedral angle close to 0° between the O—$CH_3$ and H-2 (6), despite the presence of an additional electronegative oxygen attached to the carbon carrying the coupled proton. Hence, these results are more in accord with an entropy-favorable dynamic equilibrium (analogous to that between **4** and **5**) in which the *p*-type orbital on the exocyclic oxygen is oriented *anti* with respect to the C2—O1 (**7**) and C2—O3 (**8**) bonds, in turn. This conformation then gives dihedral angles of ± 30° between the O—$CH_3$ and C2—H2 and ± 60° between the *p*-type lone pair and C2—H2. As this ± 60° angle between the lone pair and C2—H2 is unfavorable for the



arrangement required (6) to assist homolytic fission of the C2—H2 bond, the geometries in **7** and **8** are consistent with the published results (6).

With the *cis* isomer, **2**, the preferred orientation of the methoxy group, incorporating the *exo*-anomeric effect, would be one in which each of the $sp^3$ lone pairs is *anti* with respect to the C2—O1 and C2—O3 bonds simultaneously (**9**), i.e., an *anti* orientation between O—$CH_3$ and H-2 ("Me-up rotamer"). This is also the conformation for the methoxy group proposed (6) to account for the rate of hydrogen atom abstraction in this molecule relative to **1**. Nuclear Overhauser enhancement (nOe) experiments with **2** showed no significant enhancement in the intensity of the H-2 signal when the O—$CH_3$ protons were saturated, which is taken as evidence that the O—$CH_3$ and H-2 are *trans*, as in **9**. Also, this tends to rule out the possibility of a dynamic equilibrium between two methoxy conformations in this system; one in which the $sp^3$ lone pairs are *anti* with respect to the C2—O1 and C2—H2 bonds, and the other in which they are *anti*

[2]Irradiation of the methine proton (H-2) did not cause any measurable nOe in the methoxy signal intensity. This lack of reciprocity, by analogy with a similar situation (7), may be attributed to spin-rotation and the intramethyl group dipole–dipole relaxation dominating the dipole–dipole contribution to relaxation of the methoxy group.

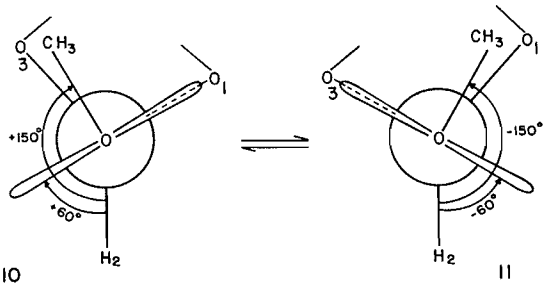
9

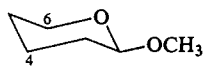


10 11

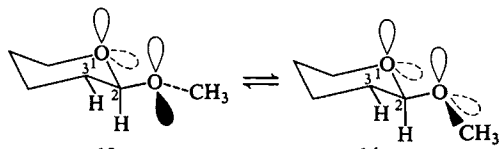
with respect to the C2—O3 and C2—H2 bonds, passing through an eclipsing barrier between the O—$CH_3$ and C2—H2 bonds. The measured coupling between O—$^{13}CH_3$ and H-2 in **2** ($^3J_{OCH_3, H_2}$) was 3.7 Hz. This is low for an *anti* arrangement between the coupled nuclei, when compared with a coupling of 5–6 Hz between $^{13}C_3$ and $H_1$ in α-D-glucopyranose (9), although the additional oxygen atom on the coupling path in **2** is expected (10) to cause a slight reduction. One way in which the magnitude of the vicinal coupling (3.7 Hz) may be rationalized is by assuming that the *p*-type lone pair on the exocyclic oxygen is oriented *anti* with respect to the C2—O1 and C2—O3 bonds *in turn*, in a dynamic equilibrium which, notably, is without any eclipsing barrier because of the *trans* arrangement between O—$CH_3$ and H-2, which probably represents two extreme ends of a flat bottomed potential energy well. This would then give a dihedral angle of ± 150° (**10** and **11**) between O—$CH_3$ and H-2, which is in better agreement with the $^{13}C$—$^1H$ coupling observed, and ± 60° between the lone pair and H-2, which again is in accordance with the published (6) rates of hydrogen atom abstraction.

### $^{13}C$ *Chemical shifts*

Turning to a consideration of $^{13}C$ chemical shifts, data for 2-alkoxy-1,3-dioxanes **1** and **2** and related compounds are presented in Table 1. The chemical shifts for **1** and **2**, unlike those of aldopyranoses and their derivatives (1) indicate no dramatic γ-*anti* differential shielding effects by the methoxy substituent. An upfield shift attributable to the γ-*anti* exocyclic oxygen in **2**, in comparison with 1,3-dioxane, is only slightly higher for C-6 (2.0 ppm) than for C-4 (1.2 ppm). Thus, reduction in the magnitude of γ-*anti* shielding as compared with aldopyranoses, and also the nearly equal effect observed on C-4 and C-6 by the methoxy substituent in **2** appears to reinforce the proposed dynamic equilibrium between **10** and **11**, because a *p*-type lone pair on the exocyclic oxygen would then be *anti* to the C2—O1 or C2—O3 bond only *half* of the time. The interpretation of the $^{13}C$ chemical shifts for *trans* isomer **1** is complicated by the superposition of γ-*gauche* upfield shifts on C-4 and C-6 by the methoxy substituent and thus of no direct concern in the present context. It is notable, however, that the upfield shifts observed for C-4 and C-6 (Table 1) are approximately of the same magnitude. Also, not surprisingly, they are larger than in cyclohexanes (12), consistent with a closer spatial relationship between the involved atoms across a shorter C–O–C bond sequence in **1** as compared with the longer C–C–C sequence in cyclohexanes. The $^{13}C$ chemical shifts of equatorial 2-methoxy-tetrahydropyran (**12**) (13) and 2-methylthio-tetrahydropyran (**26**) are of special interest in the context of the γ-*anti* upfield shifts observed in **2** (Table 1). That is, when compared with tetrahydropyran (**25**), **12** exhibits no significant differential γ-*anti* upfield shifts by the



12



13 14

anomeric —$OCH_3$ for C-6 and C-4, as in **2**, but in contrast to the aldopyranose derivatives (1). The upfield shift on C-6 (1.9 ppm) is about twice that on C-4 (0.7 ppm). Furthermore, the γ-shifts are very nearly of the same magnitude as those in **2**. To account for these observations, an equilibrium between two conformations for the O—$CH_3$ group is envisaged, one in which the O—$CH_3$ bond is *gauche* with respect to C2—O1 and *anti* with respect to the C2—C3 bond (**13**), and the other conformation (**14**) in which these relationships are reversed. Appropriate variations can be realized if the exocyclic oxygen is $sp^2$ hybridized, rather than $sp^3$ as in **13** and **14**. The apparent nonbonded steric interactions in **13** are ($CH_3$:lone-pair), (H:lone-pair), as compared with (lone-pair:lone-pair) and ($CH_3$:H) interactions in **14**. If the lone pairs are considered bigger or nearly equal in size to the hydrogens, a matter of long controversy (14), the

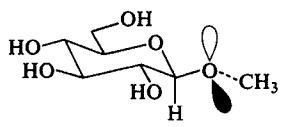
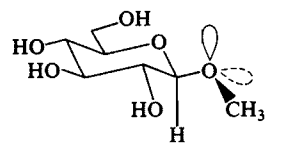
steric interactions depicted may cancel out, thus allowing for a contribution of **14** as well as **13** to the overall (total) rotamer population, provided the electronic interactions alone[3] do not dictate the conformations in these molecules. However, it is possible for the O—$CH_3$ group to assume a single rotameric state if steric and electronic effects both favor such a conformer. Such a situation can be realized in β-pyranosides. Of the two conformations, **15** and **16**, for methyl β-D-glucopyranoside, **15** is favored by both steric and electronic interactions, although the electronic component ("*exo*-anomeric effect") appears to be viewed as the more important.

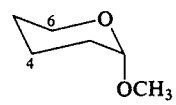
$^{13}C$ Chemical shifts of axial 2-methoxy tetrahydropyran (**17**) (Table 1) are complicated by γ-*gauche* upfield influences. It is noteworthy, however, that the γ-*gauche* upfield shift on C-6 (9.0 ppm) is approximately of the same magnitude as that for **1** (8.6 ppm average, C-4, 6). The smaller upfield shift for C-4 (5.2 ppm) is analogous to that in cyclohexanes (12*b*) and in saturated six-membered heterocycles (15). It is also known (12) that geminal substituents experience steric compression, resulting in local ring distortions which manifest themselves as discrepancies in $^{13}C$ chemical shifts (see ref. 14*b*, p. 194) and other nmr parameters to varying degrees within the ring. Such discrepancies (13) are to be noted when the $^{13}C$ chemical shifts of **18** are compared with those of **17** and **19** (Table 1).



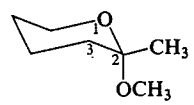
**15**



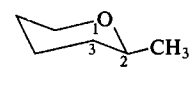
**16**



**17**

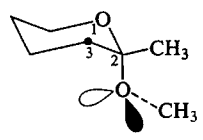


**18**

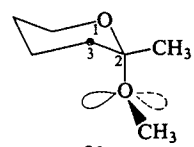


**19**

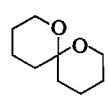
These discrepancies provide a useful example of the fact that when extending the nmr parameters from one system (e.g., THP and sugars) to another (e.g., 1,3-dioxanes), allowance should be made for intramolecular torsional variations, which can be complex and cause local or total geometries to deviate from the ideal situation. Consider the chemical shifts of **17**, **18**, and **19**. Geminal substitution of C-2 in **19** by an axial methoxy group (giving **18**) causes a 1.3 ppm downfield shift of $CH_3$-2 and a 1.1 ppm downfield shift of C-3. The O$CH_3$ signal of **18** is shifted upfield by 7.3 ppm as compared with the corresponding resonance of **17**, consistent with the *gauche* relationship between the two methyl groups in **18**. If the orientation of the $OCH_3$ group is as shown in **20**, then the observed 1.3 ppm downfield shift on $CH_3$-2 can be rationalized in the following way. There are two effects to be considered. The deshielding β-effect of the exocyclic oxygen, superimposed upon the γ-*gauche* shielding effect of the O-methyl group. As there is an overall downfield shift of 1.3 ppm on $CH_3$-2 the β-effect appears to dominate. The upfield shift of 7.3 ppm experienced by the O$CH_3$ due to the γ-*gauche* interaction with $CH_3$-2 may be considered complementary, thus making it possible to estimate the β-effect by the exocyclic oxygen as 7.3 + 1.3 = 8.6 ppm. Now C-3 should experience the same β-effect, but little influence due to the O—$CH_3$ group, because the latter is in the γ-*anti* arrangement (**20**). Hence, the predicted shift for C-3 is 8.6 ppm downfield, whereas the measured shift is only 1.1 ppm deshielding which, incidentally, is about equal to the observed shift for $CH_3$-2 (1.3 ppm). Hence, it appears necessary to examine another orientation for the $OCH_3$ group, one in which the group may be symmetrically disposed between the $CH_3$-2 substituent and C-3. This arrangement is realized in the conformation shown in **21**. Here, the $OCH_3$ is still *gauche* to $CH_3$-2, but is also *gauche* to C-3, rather than the ring oxygen atom as in **20**. Now, the preceding analysis, used to explain the net 1.3 ppm deshielding observed for $CH_3$-2, may once again be recalled in its entirety to explain the 1.1 ppm downfield shift observed for C-3. The steric requirements of **20** and **21** may not be very different, thus allowing for a substantial contribution of **21** (which is required) to the total rotamer population. Even if molecule **18** exists partly in the ring inverted form, with axial —$CH_3$ and equatorial —$OCH_3$, it appears that a major contribution of the conformation in which the —$OCH_3$ is doubly *gauche* to $CH_3$-2 and the ring C-3 is necessary to rationalize the $^{13}C$



**20**



**21**



**22**

[3]Another example of the balance between electronic and steric factors is evident in the equilibration of aldoses. It may be recalled in this context that D-glucopyranose exists in aqueous solution as α- and β-anomers in the ratio 36:64, respectively (see ref. 14*a*, p. 160), even though one might have expected the α-anomer to preponderate on the basis of electronic interactions alone. Obviously this ratio is determined by a number of parameters.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

chemical shifts. An interesting extension of **18** is the spiro-bicyclic compound **22**. A re-evaluation of the $^{13}C$ chemical shift data for **22** seems necessary, in view of the preceding analysis for **18** for which the contribution of conformation **21** appears unavoidable. This might then point to a conformation for **22** analogous to that for **21**, in contrast to what has been postulated (13).

*One-bond $^{13}C$—$^{1}H$ coupling constants*

Finally, it may be noted that the magnitude of one-bond coupling between C-2 and H-2 ($^{1}J_{C\text{-}2,\ H\text{-}2}$) in **1** and **2** appears to be related to the C—H bond orientation (9), just as in aldopyranoses and their derivatives. A value of 192.2 Hz is observed when H-2 is equatorial (**1**), whereas the value is 10 Hz smaller for its axial isomer **2** (182.2 Hz). Although these values are larger than those of aldopyranoses, the difference of 10 Hz between the equatorial and axial C—H bonds is in accordance with the orientation effects of lone pairs of the adjacent ring oxygen atoms on the magnitude of these couplings (1). The additional ring oxygen in the 1,3-dioxane derivatives does not affect this difference. Hence, although there are two oxygen atoms in the ring, there is only one axial C—H bond, and only one C—H antibonding orbital for interaction with the adjacent lone pairs of the oxygen atoms. This, incidentally, is in contrast to the situation in *cis*-1,4-dioxane-2,6-diol (1) wherein there is one *anti* lone pair of the adjacent oxygen atom but two degenerate antibonding C—H orbitals. The apparent increase in the $^{1}J_{C\text{-}2,\ H\text{-}2}$ (164.6 Hz) of this diol as compared to the aldopyranoses may have some bearing on this general question. The one-bond coupling between C-6 and H-6e in **2** ($^{1}J_{C\text{-}6,\ H\text{-}6e}$ = 147.2 Hz) is 9.2 Hz larger than that between C-6 and H-6a (138.0 Hz), as expected from the earlier results (1).

## Experimental

4-Methyl-1,3-dioxane (**23**) (*5b*), *cis*-2,4-dimethyl-1,3-dioxane (**24**) (*5b*), and *cis*- and *trans*-2-methoxy-4-methyl-1,3-dioxanes (**2** and **1**) (*5a*) were all prepared by literature procedures, and had physical properties in agreement with the literature.

*Nuclear magnetic resonance spectroscopy*

The $^{13}C$ nmr spectra were recorded at 22.63 MHz with a Bruker WH-90 spectrometer equipped with a B-NC 12 computer and $^{1}H$ nmr spectra were recorded at 200 MHz with a Varian XL-200 spectrometer, using $CDCl_3$ as the solvent. Chemical shifts are reported with reference to tetramethylsilane. The proton-coupled $^{13}C$ spectra were recorded in the "gated" $^{1}H$-irradiation mode with a repetition time ~2.0 s, the decoupling time ~0.6 s and the pulse width 90° (~ 18 μs). A spectral width of 3000 Hz and 8K points were used giving a digital resolution of 0.73 Hz after Fourier transformation (4K real data points).

*Nuclear Overhauser experiments*

A mixture of **1** and **2** (~ 30 mg) in approximately 54:46 ratio in $CDCl_3$ (0.7 mL) solution was freed of oxygen by slow passage of dry nitrogen gas for about two hours. The percent nuclear Overhauser enhancement in the intensity of the methine proton (H-2) was calculated from the intensities of the methine proton (H-2) with and without the irradiating frequency applied to the methoxyl protons. Several irradiating power levels were used, some well below the complete saturation of the signal, and in each case, the methine proton (H-2) was observed and integrated several times. The mean integrated intensities were used for the calculation of the percent nOe.

## Acknowledgements

The author acknowledges the kindness of Prof. A. S. Perlin in providing invaluable assistance in the preparation of this manuscript and, together with McGill University, for financial support during the course of this investigation. The author also expresses his gratitude to L. Ayotte and Dr. F. Sauriol for their generous help in recording the nmr spectra.

Received October 14, 1981

JOHN M. MCINTOSH, MASOOD A. KHAN, and LOUIS T. J. DELBAERE. Can. J. Chem. **60**, 1073 (1982).

The crystal structures of 1-azoniatricyclo[4.4.4.$0^{1,6}$]tetradecane bromide (**1**) and 1-azoniatricyclo[4.4.3.$0^{1,6}$]tridecane bromide (**2**) are reported. Compound **1**, $C_{13}H_{24}NBr$, crystallizes in space group $P6_3/mmc$ with $a = 8.383$ (2) Å, $c = 10.092$ Å, $\gamma = 120°$, $Z = 2$. Compound **2**, $C_{12}H_{22}NBr$, crystallizes in space group $P6_3/mmc$ with $a = 8.283$ (2) Å, $c = 10.046$ (2) Å, $\gamma = 120°$, $Z = 2$. The crystal structures of **1** and **2** are statistically disordered with both enantiomers occurring in the unit cell. Compound **2** is further disordered with the one five-membered ring and the two six-membered rings of the cation being averaged over the same site in the unit cell.

The structures confirm the previously reported conclusions based on the 400 MHz nmr spectra of **1**.

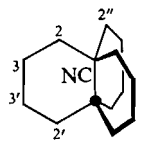
JOHN M. MCINTOSH, MASOOD A. KHAN et LOUIS T. J. DELBAERE. Can. J. Chem. **60**, 1073 (1982).

On rapporte les structures des cristaux des bromures de azonia-1 tricyclo[4.4.4.$0^{1,6}$] tétradécane (**1**) et de azonia-1 tricyclo[4.4.3.$0^{1,6}$] tridécane (**2**). Le composé **1**, $C_{13}H_{24}NBr$, cristallise dans le groupe d'espace $P6_3/mmc$ avec $a = 8{,}383(2)$ Å et $c = 10{,}092$ Å, $\gamma = 120°$, $Z = 2$. Le composé **2**, $C_{12}H_{22}NBr$ cristallise dans le groupe d'espace $P6_3/mmc$ avec $a = 8{,}283(2)$ Å et $c = 10{,}046(2)$ Å, $\gamma = 120°$, $Z = 2$. Les structures des cristaux **1** et **2** sont statistiquement désordonnées avec les deux énantiomères présents dans la maille élémentaire. Le composé **2** est encore plus désordonné avec le cycle à cinq chaînons et les deux cycles à six chaînons du cation situés en moyenne au dessus du même site de la maille élémentaire.

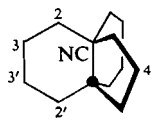
Les structures confirment les conclusions tirées antérieurement à partir des spectres de rmn à 400 MHz du composé **1**.

[Traduit par le journal]

Recently, one of us reported the synthesis of the tricyclic ammonium salts **1** and **2** (1, 2). The background for the interest in these molecules lies in their application as the basic structural unit of chiral phase-transfer catalysts. In our analysis of the requirements for effective transfer of chirality during such a process (1, 3), it became clear that only salts in which one of the four faces of the tetrahedral nitrogen atom was available for association with an anion would be effective and salts such as **1** and **2** appeared to possess this property. However, to predict the nature and effectiveness of steric and/or polar interactions between these salts which bear further substitution on the exposed face and developing asymmetry in the transition state of the catalyzed reaction, a knowledge of the three-dimensional shape of such molecules is required.



**1** ● = NC′ = $N^+$
**3** ● = NC′ = C



**2** ● = NC′ = $N^+$

While the 400 MHz nmr spectra provided important information regarding the dynamic properties of **1**, especially with regard to its rate of racemization (2), we felt that an X-ray crystallographic structure determination would provide important data upon which the design of substituted materials might be based. The results of the X-ray experiments on **1** and **2** and a brief comparison with **3**, the hydrocarbon analog of **1**, are reported here.

## Experimental

The crystal data for compounds **1** and **2** are given in Table 1. The systematically-absent reflections that occurred for the crystals of **1** and **2** are $hh\bar{2}hl$ ($l = 2n + 1$) and these are consistent with the following three space groups: $P6_3mc$ (No. 186), $P\bar{6}2c$ (No. 190), and $P6_3/mmc$ (No. 194).

All three of these possible space groups contain a three-fold axis which relates the three rings of the cation in both **1** and **2** to each other; i.e. the three rings are crystallographically equivalent. The six-membered rings of **1** have been shown to be present in the chair conformation in solution (2) and this conformation should also be maintained in the crystals. Regardless of whichever of these three space groups is correct, disorder of these rings must be present. Space group $P6_3mc$ (No. 186) contains a mirror plane which passes through the four planar atoms (NC, NC′, C3, C3′) of the six-membered ring chair. Space group $P\bar{6}2c$ (No. 190) contains a mirror plane perpendicular to the plane of these four atoms which would relate these atoms, in equivalent pairs, across this mirror plane (NC .. NC′, C3 .. C3′). Space group $P6_3/mmc$ (No. 194) contains both of these mirror

TABLE 1. Crystal data for compounds **1** and **2**

| Parameter | Compound 1 | Compound 2 |
|---|---|---|
| Formula | $C_{13}H_{24}NBr$ | $C_{12}H_{22}NBr$ |
| fw | 274.2 | 260.2 |
| Space group | $P6_3/mmc$ | $P6_3/mmc$ |
| $a = b$ (Å) | 8.383 (2) | 8.283 (2) |
| $c$ (Å) | 10.092 (2) | 10.046 (2) |
| $\gamma$ (°) | 120 | 120 |
| $V$ (Å) | 614.2 | 596.9 |
| $Z$ | 2 | 2 |
| $\rho_o$ (g cm$^{-3}$) | 1.47 | 1.46 |
| $\rho_c$ (g cm$^{-3}$) | 1.48 | 1.45 |
| Crystal dimensions (mm) | 0.10 × 0.15 × 0.25 | 0.16 × 0.16 × 0.2 |
| Radiation | $CuK_\alpha$ ($\lambda = 1.5418$ Å) | $MoK_\alpha$ ($\lambda = 0.71069$ Å) |
| 2θ max | 140 | 55 |
| Total reflections measured | 253 | 801 ($-h,k,l$; no. of unique sets = 4; $R(I) = 1.95\%$) |
| No. of unique reflections with net $I > 3\sigma(I)$ | 239 | 244 |
| $R = (\Sigma\|\|F_o\| - \|F_c\|\|/\Sigma\|F_o\|)$ | 0.068 | 0.058 |
| $Rw = (\Sigma W\Delta^2/\Sigma WF_o^2)^{1/2}$ | 0.077 | 0.051 |
| $\mu$(cm$^{-1}$) | 47.5 | 36.1 |
| Min/max absorption corr. | 1.51/2.22 | 1.72/1.92 |

planes. Regardless of whether space group $P6_3mc$ or $P\bar{6}2c$ is used, as a consequence of the mirror plane operating on the other two atoms (C2 and C2′) of the six-membered ring chair, the second (pseudo-) mirror plane is produced by the resulting position of the two equivalent atoms C2″ and C2‴; i.e. the symmetry corresponding to space group $P6_3/mmc$ is produced. Attempted least-squares refinement, in either space group $P6_3mc$ or $P\bar{6}2c$, of crystallographically independent C2 and C2′ atoms results in a very unstable refinement with one of the C2 or C2′ atoms being shifted to a chemically unreasonable location due to the high correlation between the coordinates of these atoms. Only in space group $P6_3/mmc$, where the C2 and C2′ atoms were crystallographically equivalent, was the least-squares refinement well-behaved and a chemically-meaningful result produced. Thus only this space group will be further considered in this paper. As a consequence of the symmetry of this space group, the quaternary nitrogen and carbon atoms of the cations are statistically disordered over the same atomic site (denoted as NC) in the crystal structures. As a consequence, weighted mean scattering factors (4*a*) were used (50% N, 50% C) for this atom position.

Crystals of **1** were colorless hexagonal prisms exhibiting the forms $\{10\bar{1}0\}$ and $\{0001\}$. The crystal data are given in Table 1. A single crystal of **1** was used for the data collection on an Enraf Nonius CAD4F diffractometer. Nickel-filtered $CuK_\alpha$ radiation was employed with an W/2θ scan. A total of 253 reflections were measured of which 239 unique reflections had net $I > 3\sigma(I)$. Observational weights for the reflections were derived from the formula

$$w = 1/(T + (0.02)^2T^2 + r^2B)$$

where $w$ is the derived weight, $T$ is the total peak count, $B$ is the total background counting time ($r = 2$ for this data). Lorentz and polarization corrections as well as an analytical absorption correction (5) were applied.

For **2** the crystals were needle-shaped with hexagonal cross-section. The data were collected on a Syntex P2 diffractometer equipped with a molybdenum X-ray tube and a highly oriented graphite monochromator. The procedure for data collection and processing is described elsewhere (6). A total of 801 reflections (with indices $h, k, l$) were measured and reduced to 244 unique observed data ($I > 3\sigma(I)$). During the data collection, the intensities of three monitor reflections did not change significantly. The data were corrected for Lorentz and polarization effects and an analytical absorption correction was also carried out.

*Structure determination*

The position of the bromide ion in the crystal structure of **1** was determined by inspection of the Patterson map. An $R$ index of 0.326 was obtained for the structure factor calculation based on this anion. A subsequent difference map revealed the positions of the nonhydrogen atoms of the structure. Full matrix least-squares refinement using isotropic temperature factors produced an $R$ index of 0.098. The methylene carbon atoms (C2) are also disordered and have a one-half population parameter throughout the crystal. The disorder of C2 is due to both enantiomers of the molecule being present in the crystal structure, with each of the half-occupied positions of C2 corresponding to one enantiomer. Full matrix anisotropic least-squares analysis of the atomic parameters converged with an $R$ index of 0.068. The final atomic parameters are given in Table 2. Crystallographic computations for **1** were carried out using the XRAY76 System (7) on a DEC 2060 computer at the University of Saskatchewan.

For **2**, the position of the bromide anion was obtained from a sharpened three-dimensional Patterson synthesis. A difference Fourier synthesis based on the bromide ion gave the positions of NC, C2, and C3. The structure was refined isotropically with proper multiplicity and population factors (Table 2) for these atoms to a $R$-value of 0.08. A difference map at this stage clearly indicated the disorder and showed a peak for the C4 atom. Since no separate peak for the C2 position in the five-membered ring could be observed, it was assumed that its displacement from the position of the analogous atoms in the six-membered rings is too small to be visible in the difference map. The parameters of these atoms, including the C4 atom, were refined anisotropical-

[a]The esd of the last digit is given in parentheses.
[b]Standard deviations given in parentheses.
[c]Anisotropic temperature factors are of the form:
$\exp[-2\pi^2(h^2a^{*2}U_{11} + k^2b^{*2}U_{22} + l^2c^{*2}U_{33} + 2hka^*b^*U_{12} + 2hla^*c^*U_{13} + 2klb^*c^*U_{23})]$

ly; ten cycles of full-matrix least-squares refinement converged at a final $R$-value of 0.058.[2] In the final cycle of refinement, the largest shift/error ratio was 0.01 and the final difference map had no features of chemical significance. Least-squares refinement minimized the function $\Sigma w(|F_o| - |F_c|)^2$, unit weights were used in the initial stages of refinement, while in the final cycles of calculation a weighting scheme of the form $w = (1/(\sigma^2(F) + 0.01F^2))$ was employed. Positional and thermal parameters are given in Table 2. All calculations for **2** were performed at the University of Windsor on the IBM 3031. Programs used during the structural analysis include SHELX (Fourier and L.S. refinement calculations) (8), ABSORB (absorption correction) (9), and ORTEP (thermal ellipsoid plotting program) (10). Scattering factors, including anomalous dispersion and correction terms ($\Delta f'$) and ($\Delta f''$) for the bromide ion, were taken from ref. 4*b*.

## Results and discussion

The bond lengths and angles as determined for **1** and **2** are shown in Table 3 and the torsion angles in Table 4. Also included in these tables are the corresponding weighted mean average values for hydrocarbon **3** (11). Perspective drawings of **1** and **2** are given in Fig. 1.

Compound **1** has $C_3$ symmetry and exists as two enantiomers which are interconverted by chair–chair ring inversion of all three six-membered rings. In solution, the barrier to this inversion is 17.6 kcal/mol (12*a*), while in **3** the value is 15.7 (12*b*). The crystal unit cell contains both enantiomers which results in crystal disorder. The bond lengths

TABLE 3. Bond distances and angles[a,b,c]

(A) Bond distances (Å)

| | Length | | |
|---|---|---|---|
| Bond | **1** | **2** | **3** |

[c]Symmetry equivalent positions: ′ is $(x, x-y, 3/(2-z))$; ″ is $(1-y, x-y, z)$.

[2]The observed and final calculated structure amplitudes are available at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

TABLE 4. Torsion angles (degrees)[a,b]

| Bond | Angle 1 | 2 | 3 |
|---|---|---|---|
| C2—NC—NC′—C2′ | 50.5 | 44.8 | 48.8 |
| C3—C2—NC—NC′ | −53.1 | 51.6 | −52.4 |
| C3′—C3—C2—NC | 53.7 | 52.0 | 55.4 |
| C2′—C3′—C3—C2 | −51.2 | −47.3 | −54.6 |

[a]Symmetry equivalent position ′ is $(x, x-y, 3/(2-z))$.
[b]The esd of the last digit is of the same magnitude as in Table 3B.

and angles in **1** are very similar to those in **3** (Table 3). The small differences may seem somewhat surprising when the effect of the positive center and the presence of the bromide ion is contemplated. The mean of the torsion angles in **1** (52.1°) (in **3**, 52.8°) is significantly smaller than those in cyclohexane (55.1°),[3] which indicates a flattening of the ring from the pure chair form. This observation is in accord with the 400 MHz nmr spectrum of **1** which lacks one of the expected coupling constants between the equatorial proton on C2 and the protons on C3 (2). Models indicate that a flattening of the ring would tend to bring the equatorial protons on C2 and C3 close to a 90° relationship, which would cause a vanishingly small coupling between them according to the standard Karplus relationship (14). The decrease in the mean torsion angle is compensated for largely by the NC—C2—C3 bond angle of 115.4(7)° which is significantly larger than the tetrahedral value. Again, this is similar to **3** where the corresponding angle is 114° (11).

The nmr spectra of derivatives of **1** indicate that, in solution, the anion does associate with only the exposed face of the nitrogen atom (2). Similarly, in the crystal of **1**, the bromide ion interacts with this face, the distances being 4.27 Å (NC—Br) and 4.01 Å (C2—Br).

The crystal structure of salt **2** was complicated by the occurrence of severe crystal disorder. It appears that the crystal forces are insufficient to cause a unique lattice structure with the result that the five-membered ring is randomly oriented with respect to the other two rings. As a result, the central methylene group of the five-membered ring shows a 1/3 occupancy in all three rings. In addition, the methylene groups adjacent to the quaternary centers are not resolved between the two ring sizes and are refined as a weighted mean average position. Consequently the accuracy of the bond lengths and angles involving C2 is drastically lowered. This can be seen in the calculated value of the NC—C2—C3 angle of 120.3° and the C2—C4 distance of 1.74 Å. Nevertheless it can be seen that, in general, reducing the size of one of the rings to five atoms causes only minor alterations in the bond lengths and angles of the other six-membered rings.

[3]Calculated from the cyclohexane phase II crystal data given in ref. 13.

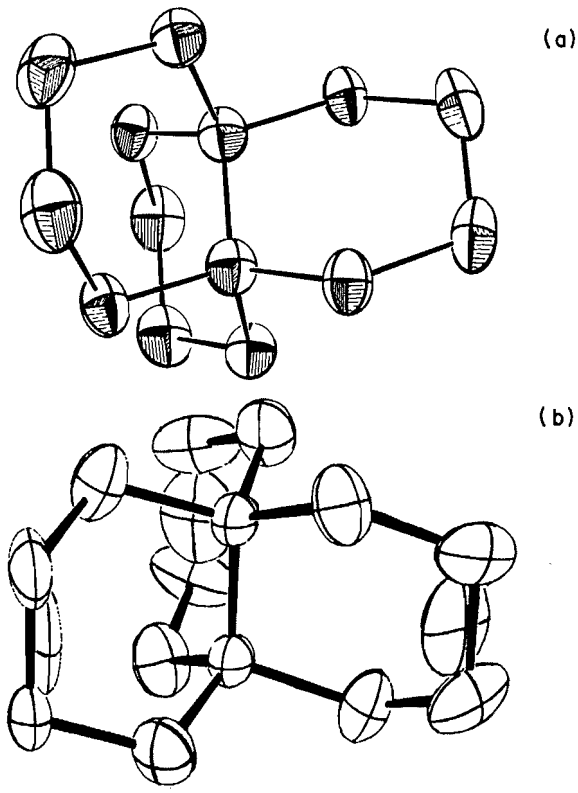

FIG. 1. ORTEP perspective drawings of (a) **1** and (b) **2**.

## Conclusions

The results presented here amply confirm our expectation that salt **1** is in the all-chair form with some small distortion of the bond angles. They also provide a framework upon which the design of substituted materials can be based. The small variations between **1** and **3** are noteworthy in that the presence of a charged atom and counterion might have been expected to have caused larger structural changes. Models indicate that, with appropriate substitution, ring inversion in **1** should become very slow, thus allowing the preparation of optically stable derivatives. Experiments toward that end are currently in progress.

Received October 14, 1981

D. F. R. GILSON and S. BROWNSTEIN. Can. J. Chem. **60**, 1078 (1982).

The $^{19}F$ nmr spectra of fluoranil (2,3,5,6-tetrafluoro-*p*-quinone) partially oriented in a phenyl-cyclohexyl type of nematic solvent have been studied as a function of temperature and the anisotropy of the fluorine chemical shift determined. The results, $\sigma_{zz} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy}) = 185$ ppm and $(\sigma_{xx} - \sigma_{yy}) = -41$ ppm are in good agreement with the values obtained for the solid phase.

D. F. R. GILSON et S. BROWNSTEIN. Can. J. Chem. **60**, 1078 (1982).

On a étudié les spectres de rmn du $^{19}F$ du fluoranil (tétrafluoro-2,3,5,6 *p*-quinone) partiellement orienté dans un solvant nématique du type phényl-cyclohexyle, en fonction de la température; on a aussi déterminé l'anisotropie du déplacement chimique du fluor. Les résultats, $\sigma_{zz} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy}) = 185$ ppm et $(\sigma_{xx} - \sigma_{yy}) = -41$ ppm, s'acordent très bien avec les valeurs obtenues dans la phase solide.

[Traduit par le journal]

## Introduction

The anisotropy of the nuclear shielding can be studied by multiple pulse coherent averaging techniques for solid phase samples or by partial orientation of a solute molecule dissolved in a liquid crystal solvent (1). The two methods can provide complementary information since the first will give values of the three principal tensor elements but not their directions (unless a single crystal is used), while the liquid crystal approach gives only differences between the tensor elements but does relate these to the molecular axes. Relatively few molecules, however, have been examined by both methods (1, 2). The first application of the coherent averaging technique to the anisotropy of a fluorine chemical shift was for fluoranil (2,3,5,-6-tetrafluoro-*p*-quinone), where the tensor elements were assigned with the assumption that the direction of greatest shielding is perpendicular to the molecular plane, by analogy with aromatic fluorocarbons (3, 4). Fluoranil has not been examined in a liquid crystal solvent, perhaps because this molecule is one of the strongest $\pi$-acceptor species (5) and can form charge transfer complexes, followed by reaction, with the commonly used nematic solvents. The availability of nematic materials based upon cyclohexyl derivatives rather than aromatic systems has made it possible to determine the chemical shift anisotropy in an oriented phase and to compare the results with those of the coherent averaging method.

## Experimental

A solution of fluoranil, 2% by weight, in a eutectic nematic solvent M1132 was used. This solvent, obtained from B.D.H., consists of a mixture of alkylcyclohexyl-phenyl and -biphenyl cyanides and has a wide temperature range nematic phase. There does not appear to be any chemical reaction with fluoranil. The FT spectra were obtained at different temperatures using a Varian XL-100 spectrometer operating at 94.18 MHz. Temperatures were measured from the proton shift difference in an ethylene glycol sample recorded either immediately before or after obtaining the $^{19}F$ sample spectrum. Fluorine chemical shifts were measured relative to an external trifluoracetic acid capillary but no corrections were applied for any temperature dependence of the reference shift position. Spectra were recorded with and without the reference sample capillary and improved resolution occurred in the latter case but at each temperature both spectra were analysed and the results averaged. Spectral width and memory size were chosen to give a digital resolution of 1.16 data points/Hz with the capillary and 2.048 without the reference. Calculations were performed using an AIM65 microprocessor with BASIC language programs.

## Results and discussion

### *Direct dipole coupling constants and motional constants*

The analysis of the spectrum of an oriented four-spin system with $D_{2h}$ symmetry has been given by Bulthuis *et al.* (6). The spectrum consists of six pairs of lines but the difference between two transitions is small and often indistinguishable. These two transitions, however, are the only ones which involve second order contributions and the

*To high field from trifluoroacetic acid (external). 65.6 ppm in the isotropic phase.

spectra can be solved quite simply to give the three direct dipole coupling constants using the remaining four pairs of lines. Of these the outermost lines were the most intense at all temperatures and therefore all direct dipole coupling constants must have the same sign (negative) and the fluoranil molecule aligns with the principal axis parallel to the liquid crystal director axis. Only the sum of the indirect coupling constants $J_{13} + J_{14}$ is obtainable from the remaining pair of lines. A value of +5 Hz was obtained, which falls within the range of reported values (7, 8).

For molecules with $D_{2h}$ symmetry two motional constants, or orientation parameters, are required to describe the average orientation of the solute molecule. Thus, using Snyder's notation (9), the direct dipole coupling constants are given by eq. [1]

$$[1]\quad D_{ij} = -\frac{K}{\sqrt{5}}\left\{C_{3z^2-r^2}\left(\frac{2(\Delta z_{ij})^2}{r_{ij}^5} - \frac{(\Delta x_{ij})^2}{r_{ij}^5} - \frac{(\Delta y_{ij})^2}{r_{ij}^5}\right) + \sqrt{3}C_{x^2-y^2}\left(\frac{(\Delta x_{ij})^2}{r_{ij}^5} - \frac{(\Delta y_{ij})^2}{r_{ij}^5}\right)\right\}$$

where $K$ is a constant involving the magnetogyric ratio, $r_{ij}$ is the internuclear distance, and $\Delta x_{ij}$, $\Delta y_{ij}$, and $\Delta z_{ij}$ are the components of $r_{ij}$ along coordinate axes in the molecular framework. In the present case all $\Delta z_{ij}$ are zero, $\Delta x_{14} = r_{14}$ and $\Delta y_{12} = r_{12}$. If one internuclear distance, e.g. $r_{12}$, is assumed then there are three parameters, $C_{3z^2-r^2}$, $C_{x^2-y^2}$, and $r_{14}$ to be determined from three direct dipole coupling constants. Alternatively, eq. [1] for each $D_{ij}$ can be recast in terms of the ratio between $r_{12}$ and $r_{14}$ and the motional constants eliminated to give a single eq. [2]

$$[2]\quad D_{13}(1+\rho^2)^{5/2} - D_{14}\rho^5 - D_{12} = 0$$

where $\rho = r_{14}/r_{12}$. A plot of $D_{14}/D_{12}$ versus $D_{13}/D_{12}$ can be used to derive a value for ρ. Figure 1 shows that the magnitudes of the direct dipole coupling constant ratios are such that valid geometrical information can be obtained and, since a straight line plot will fit the data at different orientations,

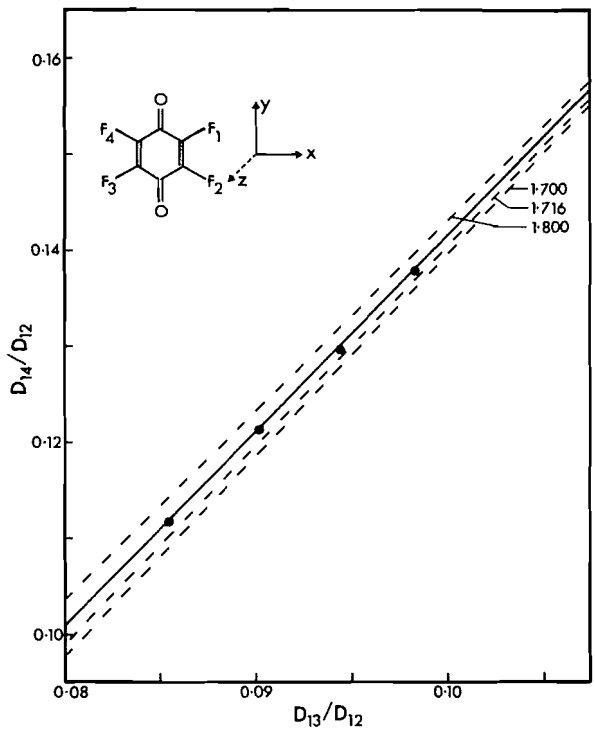

FIG. 1. Plot of $D_{14}/D_{12}$ versus $D_{13}/D_{12}$. The dotted lines are calculated for various values of ρ, including = 1.716, the value obtained from an X-ray crystallographic study. The solid line is a least-squares fit to the points, ρ = 1.746.

the anisotropy in the indirect coupling constants is small (10).

A least-squares fit gave a value of ρ = 1.746, which can be compared with the results of X-ray crystallographic (11) and electron diffraction (12) structure determinations. There is poor agreement between the present results and that obtained in the X-ray study of 1.716. However, the electron diffraction value, ρ = 1.731, is much closer, and is similar to that found in a study of fluoranil in the solid charge transfer complex with perylene (13) of 1.739. Thus the nmr value supports the contention of Schei *et al.* (12) that the reliability of the X-ray

investigation is lower than the reported error limits would indicate.

*Anisotropy of the fluorine chemical shift*

The chemical shift difference, $\Delta\sigma$, between the partially oriented and isotropic solutions is given by eq. [3]

$$[3]\quad \Delta\sigma = \frac{2}{3\sqrt{5}} C_{3z^2-r^2}\{\sigma_{zz} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy})\} + \frac{1}{\sqrt{15}} C_{x^2-y^2}\{\sigma_{xx} - \sigma_{yy}\}$$

If only one measurement of this shift difference is made then only a linear relationship between the tensor elements can be derived, but if the dependence of $\Delta\sigma$ upon orientation is known, for example by changing concentration or temperature, then a plot of $\Delta\sigma/C_{3z^2-r^2}$ versus $C_{x^2-r^2}/C_{3z^2-r^2}$ can be used to give $\{\sigma_{z^2} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy})\}$ from the intercept and $\{\sigma_{xx} - \sigma_{yy}\}$ from the slope. However, the values of the motional constants depend upon the assumed internuclear distances and thus the calculated shift anisotropy will reflect the uncertainty in $r_{12}$ and $r_{14}$. Figure 2 shows the plots for the two values of $\rho$, obtained from the direct dipole coupling constant ratios and from the electron diffraction structure, and the shift anisotropy terms are listed in Table 2. The agreement with the results of Mehring *et al.* (4) is quite good and shows that their assumption that the direction of largest shielding is perpendicular to the molecular plane was correct. In comparing the results of solid phase and oriented solution measurements, the possibility of contributions to $\Delta\sigma$ from the change in local environment cannot be excluded. The vibrational spectra of fluoranil in the solid, solution, and vapour phases show only small changes in vibrational frequencies (14) indicating that there are no strong intermolecular interactions in the solid. In the solution phase the possibility exists of charge transfer complex formation between fluoranil and the aromatic regions of the solvent molecules. Such complex formation, however, is probably very slight since the solvent molecules should be poor donors due to steric effects and the cyano substituent causes acceptor rather than donor ability. An attempt to measure the anisotropy of the chemical shift of fluoranil in a charge transfer complex was unsuccessful since addition of hexamethylbenzene to the fluoranil solution resulted in crystallization of the donor–acceptor complex.

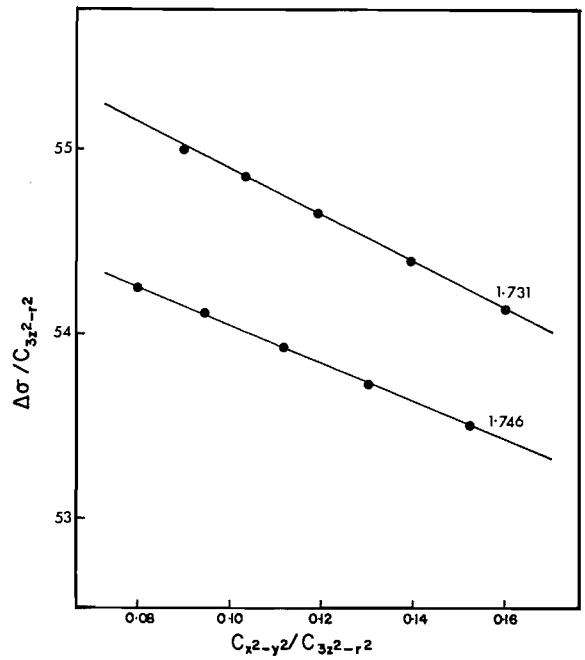

FIG. 2. Plot of $\Delta\sigma/C_{3z^2-r^2}$, ppm, versus $C_{x^2-y^2}/C_{3z^2-r^2}$. The solid lines are least-squares fits for two different values of $\rho$.

# Total synthesis of zizaane sesquiterpenes: (−)-khusimone, (+)-zizanoic acid, and (−)-epizizanoic acid

HSING-JANG LIU AND WING HONG CHAN

*Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2*

Received November 23, 1981

HSING-JANG LIU and WING HONG CHAN. Can. J. Chem. **60**, 1081 (1982).

Three sesquiterpenes of the zizaane family, khusimone (**1**), epizizanoic acid (**3**), and zizanoic acid (**2**) have been synthesized in optically active form from the ammonium salt of (−)-*l*-10-camphorsulfonic acid in sixteen, nineteen, and twenty steps respectively.

HSING-JANG LIU et WING HONG CHAN. Can. J. Chem. **60**, 1081 (1982).

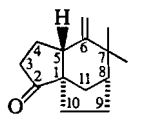
Partant de l'acide (−)-*l*-camphresulfonique-10, on a synthétisé dans une forme optiquement active trois sesquiterpènes de la famille du zizaane soit la khusimone (**1**) et les acides zazinoïque (**2**) et épizazinoïque (**3**); ces synthèses requièrent respectivement seize, vingt et dix-neuf étapes.

[Traduit par le journal]

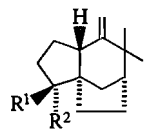
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

We wish to report a stereoselective total synthesis of khusimone (**1**) (1, 2), zizanoic acid (**2**) (3) (also known as khusenic acid (4)), and epizizanoic acid (**3**) (5), three tricyclic sesquiterpenes of the zizaane family which have been isolated from the essential oil of vetiver varieties. Zizaane sesquiterpenes have been the subject of considerable synthetic activity and several total syntheses have been accomplished during the last decade (6–13). A successful synthetic approach to this class of natural products must address three principal problems: (*i*) the construction of the tricyclo[6.2.1.$0^{1,5}$]-undecane ring system which is characteristic of the class, (*ii*) installation of an *exocyclic* methylene unit, and (*iii*) control of the stereochemistry, particularly the less stable *trans*-fused hydroindan ring junction. Although the tricyclic ring system has been assembled by a number of elegant approaches, simple solutions to the latter two problems are still in demand.

Khusimone (**1**)[1] was chosen as the primary target of our study because of its considerable importance to the perfume industry and for the possibility of its ready conversion to other members of the zizaane family. Our projected scheme (Scheme 1) would employ an intramolecular photochemical process (**4** → **5**) as a means to control the stereochemistry and facilitate the introduction of the *exocyclic* double bond. Not only does the stereochemistry of the resulting ketone **5** at C-1 and C-6 coincide with that of the two crucial centers, C-5 and C-8 respectively, of the natural products, but the replacement of the ketone carbonyl with a methylene unit (**5** → **7**) via the dehydration of alcohol **6** could



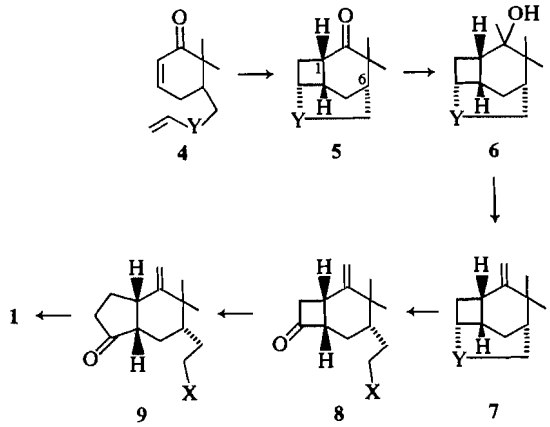
**1**



**2** $R^1 = COOH$; $R^2 = H$
**3** $R^1 = H$; $R^2 = COOH$

be expected to proceed without difficulty since the formation of an *endocyclic* double bond by dehydration of **6** would impose additional angular strain to the already strained cyclobutane ring. It was further anticipated that ring expansion of cyclobutanone **8** (derived from olefin **7**) to cyclopentanone **9** followed by cyclization would effectively complete the khusimone synthesis.

Towards this end, several 2-cyclohexenone derivatives of type **4** were prepared and their photochemistry was examined. (−)-α-Campholenic acid (**10**) possessing the same chirality as the natural khusimone (**1**) was obtained in 52% yield from the commercially available *l*-10-camphorsulfonic acid



**4** **5** **6** **7** **8** **9** **1**

SCHEME 1

[1](±)-Khusimone has been synthesized previously by Büchi *et al.* (11). For a preliminary account of our work leading to (−)-khusimone, see ref. 14.

ammonium salt by fusion with potassium hydroxide (15). Esterification of acid **10** with potassium carbonate and methyl iodide in refluxing acetone (16) gave a quantitative yield of ester **11** which was subjected to ozonolysis at −78°C in a solution of methylene chloride – methanol (1:1). Reductive work-up using triphenyl phosphine[2] (18) gave keto aldehyde **13** which, without purification,[3] was immediately treated with *p*-toluenesulfonic acid in refluxing benzene to give enone ester **14** (70% yield from **11**).

For the transformation of enone ester **14** to a tricyclic compound of type **5** via an intramolecular photocycloaddition reaction, vinyl ester **15** was an attractive intermediate. Apart from its anticipated ease of preparation from enone ester **14**, the cycloaddition of vinyl ester **15** was expected to proceed in a head-to-tail fashion, well precedented by the addition of vinyl acetate to 2-cyclohexenones by an intermolecular photochemical process,[4] to give product **16** with the desired orientation. The conversion of enone ester **14** into vinyl ester **15** was indeed straightforward. The latter compound was obtained in 60% yield when the former was hydrolyzed with sodium hydroxide and the resulting acid **17** was treated with vinyl acetate in the presence of a catalytic amount of mercuric acetate and concentrated sulfuric acid (22). The attempted photocycloaddition of vinyl ester **15** using a variety of conditions was, however, completely fruitless and resulted in recovery of the starting material. Although the observed unreactivity of vinyl ester **15** remains to be understood, we hoped that the photochemical reaction would take a different course by increasing or reducing its side chain by one atom. Thus, allyl ester **18** was prepared by esterification of acid **17** using allyl bromide and potassium carbonate. Disappointingly, allyl ester **18** was found to be equally unreactive. The photochemistry of enone acetate **19**, which has a shorter side chain than that of vinyl ester **15**, was also examined. This compound was prepared from enone ester **14** in four steps as follows. Enone ester **14** was first reduced to diol **20** (72% yield) by lithium aluminium hydride. Oxidation of **20** with four equiv. of pyridinium chlorochromate (23) afforded keto aldehyde **21** in 69% yield. Treatment of **21** with a slight excess of vinylmagnesium bromide at −78°C followed by acetylation of the resulting ketols **22** with acetic anhydride in pyridine gave an inseparable mixture of two epimeric keto acetates **19** (1:1) in 50% yield. Irradiation of a methanolic[5] solution of keto acetates **19** for 4 h caused the complete disappearance of the starting material. The product which was obtained in 43% yield showed in the ir spectrum the appearance of an absorption band at 1700 $cm^{-1}$ and the absence of the 1675 $cm^{-1}$ band previously observed for the conjugated enone system, suggesting that the photocycloaddition had taken place. This was confirmed by the mass spectrum displaying a molecular ion peak at 236.1419 and by the absence of low field signals for olefinic protons in the nmr spectrum. The nmr spectrum showing three sharp methyl singlets at δ 1.00, 1.21, and 1.95 further suggested that the product was a single compound which might have resulted from selective isomerization or destruction of one epimer of the starting material during the irradiation. The cycloaddition in principle can proceed in two different ways, head-to-tail and head-to-head, to give adducts **23** and **24** respectively. The available spectral data, however, did not permit unambiguous definition of the orientation of the isolated product. Nor did the examination of a Dreiding model reveal the preference of one orientation to the other. The conclusive evidence was provided by the following chemical transformations whereby the structure of the product was found to be as depicted in **24** with the undesired orientation. Hydrolysis of the acetate **24** with aqueous potassium carbonate in refluxing methanol gave the corresponding alcohol **25** which was oxidized with Jones reagent to diketone **26**. When treated with *m*-chloroperbenzoic acid in dichloromethane, diketone **26** underwent selective Baeyer–Villiger oxidation to give lactone **27**. Hydrolysis of **27** with aqueous potassium carbonate in refluxing methanol induced concomitant cyclobutane ring cleavage, apparently by a retro-aldol, giving rise to acid **28**,[6] the structure of which was further confirmed by esterification with diazomethane to give the corresponding methyl ester **30**.

Although it would be of general interest to investigate the photochemistry of other suitable derivatives of keto ester **14** such as **31** and **32** in

[2]Attempted reductive work-up using dimethyl sulfide (17) was proven to be ineffective and a single ozonide **12** (ir (neat): 1750 (C=O) $cm^{-1}$; nmr ($CCl_4$) δ: 5.62 (t, 1H, $J$ = 1 Hz, —OCHO—), 3.58, 1.36, 1.12, and 0.93 (all s, 3H each, 4 × —$CH_3$)) was isolated in 42% yield.

[3]Keto aldehyde **13** was shown to be rather unstable. Attempted purification resulted in substantial loss of material.

[4]For reviews of photocycloaddition reactions, see refs. 19–21.

[5]Similar results were obtained using acetonitrile or benzene as a solvent.

[6]By the reaction sequence, the alternative photochemical product **23** should result in the formation of stable hydroxy acid **29**, and the isolation of acid **28** clearly defines the structures of its precursors as depicted.

particular, the large number of steps required for their synthesis as well as for the later modification preclude their efficient application to khusimone (**1**) synthesis. The subsequent studies were focussed on the addition, in a head-to-tail manner, of a latent ketene unit to the carbon–carbon double bond of keto ester **14** by an intermolecular photochemical process. We realized at the outset that such an approach would not allow profound stereochemical control as the addition could take place from both the α and the β face of the molecule and hence adjustment of stereochemistry at a suitable stage would be necessary. This drawback could, however, be compensated to a certain extent as enone **14** could be used directly without modifying its ester side chain.

Vinyl acetate was initially used as a ketene equivalent. Irradiation of enone **14** with a twenty-fold excess of vinyl acetate in benzene for 3 h at room temperature afforded a mixture of inseparable photoadducts in 77% yield. As shown by the subsequent transformation, both regioisomers **33** and **34** were formed in a ratio of approximately 4:1 with the desired isomer **33** predominating. On treatment with sodium methoxide in methanol at room temperature for 30 min, the mixture of photoadducts gave two products readily separable by column chromatography on silica gel. The minor component isolated in 16% yield was deduced to be a mixture of aldehyde **30** and its C-5 epimer **35** resulting, apparently, from the undesired photoadduct **34**. The major component, which was obtained in 67% yield, was shown to be a mixture of diastereomeric alcohols **36**[7] derived from the desired head-to-tail adducts **33**. Jones oxidation of this mixture gave two separable ketones **37** and **38** in a ratio of 5:6 and in a total yield of 67%. Although the ir and mass spectra of these ketones were very similar, distinct differences were observed in their nmr spectra. The geminal methyl groups of the major isomer appeared as a pair of singlets at δ 1.06 and 1.12 whereas the minor isomer showed two singlets at δ 0.97 and 1.21 for the corresponding methyls. The difference in Δδ (0.24 for the minor vs. 0.06 for the major) observed for the *gem*-dimethyl groups of these two compounds allowed us to tentatively assign their stereochemistry as follows. An examination of Dreiding models reveals that in the most stable contributive conformation of compound **37**, which could be represented by **37***a*, one methyl group lies within the deshielding zone of cyclohexanone carbonyl and the other within the shielding zone of cyclobutanone. On the other hand, in the case of compound **38**, whose stable conformation is depicted in formula **38***a*,

[7]Based on previous observations (24), a *cis* ring junction could be readily assigned to each diastereomer.

both methyls are distant from the cyclobutanone ring and thus devoid of any serious influence from its carbonyl. A larger $\Delta\delta$ for **37** and a smaller one for **38** are therefore expected and it follows that the minor isomer possesses structure **37** and the major structure **38**. These structural assignments were further supported by the optical rotatory dispersion analysis (25). The minor isomer displayed a positive anomalous single Cotton effect curve and the major showed a negative one. With the aid of models, the octant diagrams corresponding to the most stable conformations of the two diastereomers **37** and **38** are represented by Figs. 1 and 2 respectively. In the case of **37** (Fig. 1), since the large ester side chain occupies the positive octant at upper left position while the four-membered ring and the two methyl groups are more or less equally distributed among the positive and the negative octants, the octant rule predicts unambiguously a positive Cotton effect and indeed this was observed. In contrast, the Cotton effect of isomer **38** (Fig. 2) is less predictable, as the cyclobutanone ring and the ester chain are expected to exert opposing effects while two methyl substituents occupy two adjacent octants. It was especially gratifying to find that the major isomer showed a negative Cotton effect, eliminating its alternative structure of **37** (and thus confirming its structural assignment of **38**). The optical rotation dispersion properties of these two diastereomers are compiled in Table 1 which also summarizes the molecular amplitude of each compound. The observation that compound **37** showed a molecular amplitude far greater than that of **38** was in full support of the above analysis of substitution effect.

The transformation of enone ester **14** into diketones **37** and **38** was improved considerably when 1,1-diethoxyethene (26) was used as a ketene equivalent. Its photocycloaddition to **14** in benzene proceeded in a completely regioselective manner to give an inseparable mixture of at least two diastereomers (four sets of partially superimposed $-OCH_2-$ quartets at the $\delta$ 3.39 region in the nmr spectrum) of the head-to-tail adduct **39** in near-quantitative yield. This mixture when treated with dilute hydrochloric acid in acetone gave, as the only products, diketones **37** and **38** (3:5) in a combined yield of 80%.

Of the two diketones **37** and **38**, only the former is synthetically useful. To enhance the efficiency of synthesis, it is highly desirable to invert the stereochemistry of both ring junction carbons of the latter compound. In principle, this could be directly accomplished by a process of double epimerization, since each of the chiral centers in question is $\alpha$ to a ketone carbonyl. In practice, it was found not to be the case; under a variety of reaction conditions the starting material was recovered intact. The unreactivity of the compound was, however, not totally surprising and could be attributed to its inability to undergo first-stage epimerization at either center to give the corresponding *trans*-fused compound, which is expected to be thermodynamically far less stable (24). An alternative approach which is conceivable for the conversion of diketone

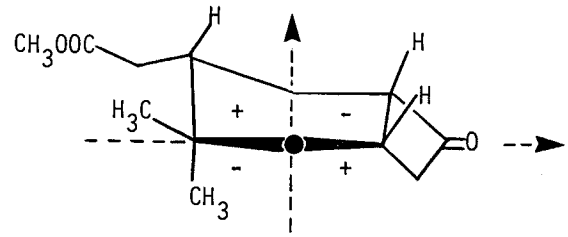

FIG. 1. Octant diagram of diketone **37**.

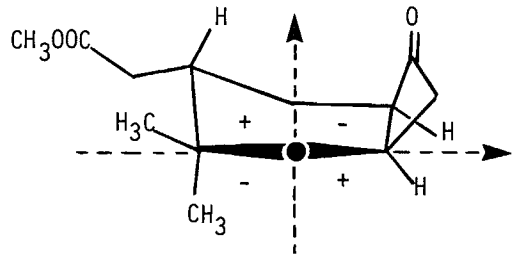

FIG. 2. Octant diagram of diketone **38**.

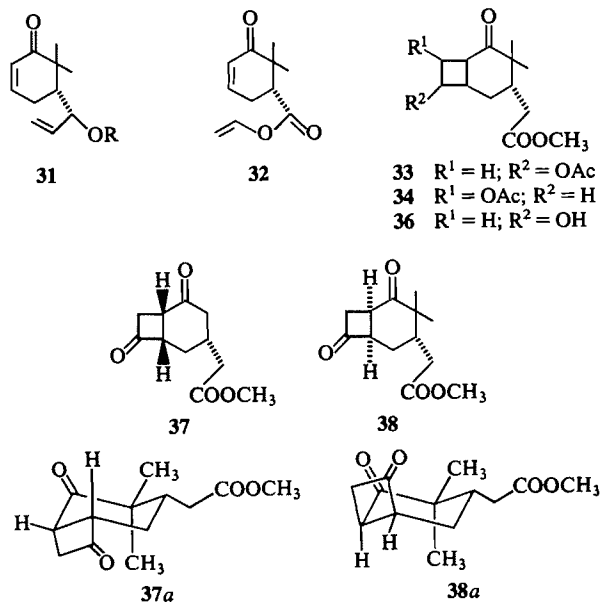

TABLE 1. Optical rotation dispersion properties of diketones **37** and **38**

| Compound | Specific rotation $[\alpha]_D^{25}$ | Molecular rotation $[\phi]_{320}$ | $[\phi]_{278}$ | Molecular amplitude $([\phi]_{320} - [\phi]_{278})/100$ |
|---|---|---|---|---|
| **37** | +119.5° | +17024° | −15679° | +327 |
| **38** | −126.4° | −4164° | +2959° | −71 |

**38** to its diastereomer **37** involves a two-step sequence, dehydrogenation and hydrogenation. This was successfully applied. Although initial attempts to oxidize diketone **38** with standard oxidizing agents such as dichlorodicyanoquinone and selenium dioxide were fruitless, its treatment with pyridinium bromide perbromide in acetic acid induced consecutive bromination and dehydrobromination to give an inseparable mixture of enediones **40** and **41** (ca. 7:1; 66% yield). Reduction of this mixture with zinc dust in acetic acid at room temperature afforded a 3:2 ratio of diketones **37** and **38** in 65% yield.

Before the incorporation of the required *exo*-methylene group into diketone **37**, its cyclobutanone carbonyl was protected. Although standard ketalization conditions ($(CH_2OH)_2$ and *p*-TsOH in refluxing benzene) showed little selectivity, transketalization of diketone **37** with 2-ethyl-2-methyl-1,3-dioxolane at 95°C in the presence of a catalytic amount of *p*-toluenesulfonic acid (27) resulted in the formation of the desired ketal ester **42** in 84% yield. Hydrolysis of **42**[8] with aqueous sodium hydroxide in refluxing methanol followed by treatment of the resulting acid **43** sequentially with sodium hydride[9] (1 equiv.) and methylmagnesium bromide (5 equiv.) at room temperature gave hydroxy acid **45**, which was immediately converted by diazomethane to the corresponding methyl ester **46** (78% yield from **42**). When **46** was exposed to thionyl chloride and pyridine in benzene, it underwent dehydration giving an 89% yield of olefin **47**. The reaction was found to be completely regioselective; no detectable amount of the corresponding endocyclic olefin was produced via the alternative mode of dehydration.

Olefin **47** was subsequently reduced with lithium aluminum hydride in tetrahydrofuran at room temperature to give alcohol **48**. Treatment of this alcohol with phosphorus oxychloride in pyridine afforded chloride **49**, which was hydrolysed with

aqueous hydrochloric acid in acetone to give keto chloride **50** in 75% yield over three steps.

The transformation of keto chloride **50** to (−)-khusimone (**1**) requires two primary operations: homologation of the cyclobutanone ring and cyclization. Each was accomplished by a single step. Keto chloride **50** was subjected to one-carbon ring expansion with ethyl diazoacetate and boron trifluoride etherate in ether (28, 29). The reaction was found to be complete after 1 h at 0°C and 4 h at room temperature and two isomeric products were obtained in a ratio of 2:1 and a total yield of 86%. Tentative assignment of structure **51** to the major isomer and **52** to the minor[10] was made on the basis of previous findings (29, 30) that the boron trifluoride catalyzed homologation of cycloalkanone with ethyl diazoacetate proceeded, without a single exception, via the preferential migration of the less substituted carbon α to the carbonyl group. When heated at reflux with aqueous sodium hydroxide in refluxing methanol[11] for 40 min, the major isomer

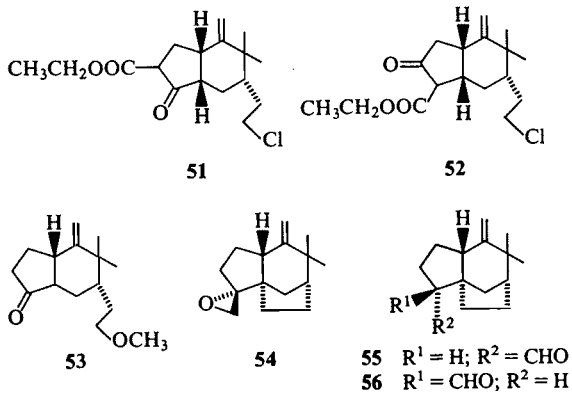
[8]As previously observed for similar systems (6, 8), ketal ester **42** failed to undergo Wittig reaction with methylenetriphenylphosphorane. Its ketone carbonyl also failed to react preferentially with methylmagnesium bromide and methyllithium.

[9]Direct treatment of acid **43** with methylmagnesium bromide produced a substantial quantity of diol **44**.

[10]These assignments were substantiated by the following transformation of the major isomer to (−)-khusimone (**1**).

[11]It was necessary to bring the solution into reflux rapidly using a preheated oil bath. Otherwise a substantial amount of keto ether **53** was formed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.



**51**[12] underwent concomitant decarbethoxylation and cyclization to give a 70% yield (−)-khusimone (**1**). The totally synthetic material was shown to be identical in all respects with the natural product.

Following the completion of the (−)-khusimone synthesis, our efforts were directed towards its extension to the synthesis of other zizaane sesquiterpenes possessing the normal fifteen-carbon skeleton. A scheme leading to (+)-zizanoic acid (**2**) and its (−)-epimer **3**[13] was successfully explored as follows.

The synthetic (−)-khusimone was treated with an excess of dimethylsulfonium methylide (31) in tetrahydrofuran. The addition of the ylide occurred exclusively from the sterically less hindered β face of the molecule to give a single epoxide **54** in 52% yield. Upon brief treatment with boron trifluoride etherate in ether at 0°C, epoxide **54** underwent rearrangement with inversion of stereochemistry (32) to give aldehyde **55** in quantitative yield. Jones oxidation of this compound afforded a 77% yield of (−)-epizizanoic acid (**3**). The ir and nmr spectra of the synthetic material were shown to be identical with those of the natural product.

Aldehyde **55** underwent epimerization on treatment with aqueous sodium hydroxide in methanol at room temperature. After 9 h, an equilibrium mixture consisting of five parts of α-epimer **55** and seven parts of β-epimer **56** (47% combined yield) was established. The latter compound was oxidized to (+)-zizanoic acid (**2**) in 86% yield when treated with Jones reagent. The identity of the synthetic and the naturally occurring material was established by comparison of their ir and nmr spectra.

[12]Under the same conditions, the minor ring expansion product gave rise to a complex mixture in which (−)-khusimone (**1**) was absent. These results were in agreement with its structural assignment.

[13]For existing syntheses of these two compounds, see refs. 6–8.

## Experimental

*General*

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. Optical rotations were measured by a Perkin–Elmer 141 polarimeter. The ir spectra were obtained by using a Perkin–Elmer model 457, 337 spectrophotometer and Nicolet 7199 Fourier transform spectrophotometer. Unless otherwise stated, ir samples were run as thin films. The nmr spectra were recorded on Varian A-60, HR-100, and 90 MHz Perkin–Elmer 32 spectrometers. Unless otherwise stated, carbon tetrachloride was used as solvent and tetramethylsilane as internal standard. Mass spectra (ms) were recorded on an AEI MS-50 mass spectrometer. Elemental analyses were performed by the microanalytical laboratory of this department. Jasco ORD/UV-5-SS-20-2 was used to measure optical rotatory dispersion.

*Materials*

Acetone was treated with potassium permanganate, dried over anhydrous potassium carbonate, and distilled. Dichloromethane used for reactions was distilled from phosphorus pentoxide. Methanol was dried over magnesium turnings at elevated temperature for 2 h and distilled. Ether, tetrahydrofuran, 1,2-dimethoxyethane, and benzene were freshly distilled from lithium aluminium hydride. Ozone was generated with a Welsbach ozonator. Ammonium salt of (−)-*l*-10-camphorsulfonic acid was obtained from Aldrich Chemical Company. Silica gel, 0.15–0.33 mm granulation, was used as adsorbent for column chromatography. Thin-layer chromatography was carried out using Merck silica gel G (type 60).

*(−)-α-Campholenic acid (**10**)*

To the fused potassium hydroxide (120 g, 2.14 mol) in a porcelain casserole, was added slowly with stirring the ammonium salt of (−)-*l*-10-camphorsulfonic acid (100 g, 0.40 mol). After the completion of the addition (ca. 25 min), the molten mass was heated for an additional period of 15 min. Upon cooling, the mass was dissolved with water (800 mL). After extraction with ether (200 mL) and dichloromethane (400 mL), the aqueous solution was acidified with ice-cold dilute hydrochloric acid and extracted with ether (300 mL) and dichloromethane (2 × 300 mL). The organic solution was dried ($MgSO_4$) and filtered. After most of the solvent was removed under the reduced pressure, the viscous residue was distilled to give pure acid **10** (35.4 g, 52% yield); bp 97°C/0.65 Torr; $[\alpha]_D^{25}$ −9.0° (*c* 1.1, $CHCl_3$); ir: 3200–2500 and 1708 (acid) $cm^{-1}$; nmr δ: 11.48 (br s, 1H, —COOH), 5.20 (br s, 1H, —HC=), 1.60 (br s, 3H, $CH_3$—CH=), 0.98 (s, 3H, —$CH_3$), and 0.79 (s, 3H, —$CH_3$); ms $M^+$ 168.1142 (calcd. for $C_{10}H_{16}O_2$: 168.1150).

*Methyl α-campholenate (**11**)*

A mixture of α-campholenic acid (**10**) (2.02 g, 12 mmol) and potassium carbonate (4.14 g, 30 mmol) in acetone (20 mL) was stirred at room temperature for 2 h. Methyl iodide (37 mL, 60 mmol) was introduced by syringe and the reaction mixture was refluxed overnight. After most of the solvent was evaporated under the reduced pressure, water was added and the organic product extracted with dichloromethane. The combined organic extracts were dried ($MgSO_4$), filtered, and evaporated to dryness. Bulb-to-bulb distillation (100°C/2 Torr) of the residue gave methyl ester **11** (2.17 g, 100% yield); ir: 1745 (ester) $cm^{-1}$; nmr δ: 5.20 (br s, 1H, —CH=), 1.58 (br s, 3H, $CH_3C$=). 0.98 (s, 3H, —$CH_3$), and 0.75 (s, 3H, —$CH_3$); ms $M^+$ 182.1308 (calcd. for $C_{11}H_{18}O_2$: 182.1306). *Anal.* calcd. for $C_{11}H_{18}O_2$: C 72.49, H 9.95; found: C 72.46, H 10.12.

*5-Carbomethoxymethyl-6,6-dimethyl-2-cyclohexenone (**14**)*

At −78°C, ozone (condition: $E$ = 80 V, air inlet = 8 psi, ozone

outlet = 0.06 psi) was allowed to pass through a solution of ester **11** (23.58 g, 0.13 mol) in dichloromethane (65 mL) and methanol (60 mL) until a light blue color was retained. The mixture was warmed up gradually to about −25°C under a nitrogen atmosphere and triphenylphosphine (34 g, 0.13 mol) was added. After removal of the solvent, the crude keto aldehyde **13** (ir: 2840, 2740 (aldehyde), 1735 (ester), and 1705 (ketone and aldehyde) $cm^{-1}$; nmr δ: 9.52 (t, 1H, $J$ = 1.5 Hz, —CHO), 3.59 (s, 3H, —$COOCH_3$), 2.11 (s, 3H, —$COCH_3$), 1.07 (s, 6H, 2 × —$CH_3$); ms $M^+$ 198.1250 (calcd. for $C_{11}H_{18}O_3$: 198.1255)) without purification was dissolved in 100 mL of benzene. To this solution *p*-toluenesulfonic acid (2.58 g, 15 mmol) was added. The resulting mixture was refluxed for 5 h with continuous removal of water using a Dean–Stark water separator. After the solvent was removed *in vacuo* ether was introduced to precipitate triphenylphosphine oxide. Filtration and concentration gave a residue which was subjected to bulb-to-bulb distillation at 100°C/2 Torr. Enone ester **14** (15.6 g, 70% yield) thus obtained showed the following physical data: $[\alpha]_D^{25}$ −65.1° (*c* 2.6, $CHCl_3$); ir: 1675 (α,β-unsaturated ketone), 1735 (ester), 1380 and 1368 (geminal methyls) $cm^{-1}$; nmr δ: 6.75 (m, 1H, —COCH=C*H*—), 5.86 (dt, $J$ = 10, $J'$ = 2 Hz, 1H, —COC*H*=CH—), 3.61 (s, 3H, —$COOCH_3$), 1.11 (s, 3H, —$CH_3$), and 0.94 (s, 3H, —$CH_3$); ms $M^+$ 196.1095 (calcd. for $C_{11}H_{16}O_3$: 196.1100). *Anal.* calcd. for $C_{11}H_{16}O_3$: C 67.32, H 8.22; found: C 67.19, H 8.40.

*5-Carboxymethyl-6,6-dimethyl-2-cyclohexenone (**17**)*

Keto ester **14** (2.94 g, 15 mmol) was dissolved in methanol (60 mL) and 2 *N* aqueous sodium hydroxide (30 mL) was added. The mixture was refluxed for 1.5 h. After cooling to room temperature, it was diluted with water and washed with dichloromethane to remove the nonacidic material. Ice-cold hydrochloric acid was introduced to adjust the acidity of the solution to ca. pH 1. The resulting aqueous solution was extracted with dichloromethane. Combined extracts were dried ($MgSO_4$), filtered, and concentrated to give acid **17** (2.73 g, 100% yield) as an oil; $[\alpha]_D^{25}$ −38.7° (*c* 0.9, $CHCl_3$); ir ($CHCl_3$): 3200–2500, 1708 (acid), and 1673 (α,β-unsaturated ketone) $cm^{-1}$; nmr ($CDCl_3$) δ: 10.65 (br s, 1H, —COOH), 6.82 (m, 1H, —COCH=C*H*—), 5.88 (m, 1H, —COC*H*=CH—), 1.21 (s, 3H, —$CH_3$), and 1.04 (s, 3H, —$CH_3$); ms $M^+$ 182.0945 (calcd. for $C_{10}H_{14}O_3$: 182.0943).

*Vinyl (6,6-dimethyl-5-oxo-3-cyclohexenyl)acetate (**15**)*

Acid **17** (900 mg, 4.94 mmol) was dissolved in vinyl acetate (8 mL) and the solution was stirred for 30 min under a nitrogen atmosphere. Mercuric acetate (20 mg) and concentrated sulfuric acid (3 μL) were added. The reaction mixture was refluxed for 4 h. Ice-cold aqueous sodium bicarbonate solution was added and the organic material extracted with dichloromethane. The combined organic extracts were dried over magnesium sulfate. Filtration and concentration yielded 819 mg of crude product which was chromatographed on silica gel (50 g). Elution with pentane–benzene (1:4) afforded pure ester **15** (610 mg, 60% yield) as an oil; ir: 3080, 1642 (olefins), 1748 (ester), 1670 (α,β-unsaturated ketone), 1390 and 1370 (geminal methyls) $cm^{-1}$; nmr δ: 7.28 (dd, $J$ = 14, $J'$ = 6 Hz, 1H, —OC*H*=$CH_2$), 6.80 (m, 1H, —COCH=C*H*—), 5.89 (dt, $J$ = 10, $J'$ = 2 Hz, 1H, —COC*H*=CH—), 4.83 (dd, $J$ = 14, $J'$ = 2 Hz, 1H, —OCH=C*H*H), 4.55 (dd, $J$ = 6, $J'$ = 2 Hz, 1H, —OCH=C*H*H), 1.12 (s, 3H, —$CH_3$), and 0.96 (s, 3H, —$CH_3$); ms $M^+$ 208.1109 (calcd. for $C_{12}H_{16}O_3$: 208.1100). *Anal.* calcd. for $C_{12}H_{16}O_3$: C 69.21, H 7.74; found: C 69.41, H 7.94.

*Allyl (2,2-dimethyl-3-oxo-4-cyclohexenyl)acetate (**18**)*

Acid **17** (346 mg, 1.9 mmol) was dissolved in acetone (8 mL). To this solution, anhydrous potassium carbonate (690 mg, 5 mmol) was added. The resulting mixture was stirred at room temperature for 2 h before allyl bromide (0.87 mL, 10 mmol) was introduced. After heating at reflux for 5 h, the reaction mixture was poured into water and extracted with dichloromethane. Drying ($MgSO_4$), filtration, and concentration gave the crude product which was purified by column chromatography on silica gel (30 g). Elution with benzene gave the allyl ester **18** (331 mg, 79% yield); ir: 3030, 3010, 1660 (olefins), 1675 (α,β-unsaturated ketone), and 1735 (ester) $cm^{-1}$; nmr δ: 6.86 (m, 1H, —COCH=C*H*—), 5.95 (m, 1H, —COC*H*=CH—), 5.75 (m, 1H, —C*H*=$CH_2$), 5.35 (m, 1H, —CH=C*H*H), 5.15 (m, 1H, —CH=C*H*H), 4.50 (m, 2H, —O$CH_2$CH=$CH_2$), 1.12 (s, 3H, —$CH_3$), and 0.95 (s, 3H, —$CH_3$); ms $M^+$ 222.1261 (calcd. for $C_{13}H_{18}O_3$: 222.1256).

*6,6-Dimethyl-5-(2-hydroxyethyl)-2-cyclohexen-1-ol (**20**)*

At 0°C, to a suspension of lithium aluminum hydride (228 mg, 6 mmol) in tetrahydrofuran (10 mL), was added a solution of enone ester **14** (413 mg, 2.1 mmol) in tetrahydrofuran (2 mL). After 15 min the reaction mixture was allowed to warm up to room temperature and stirred for 5 h. The mixture was treated successively with 0.2 mL of water, 0.2 mL of 3 *N* aqueous sodium hydroxide solution, and again with 0.6 mL of water. The inorganic salt was removed by filtration. Concentration of the filtrate gave diol **20** (257 mg, 72% yield); ir ($CHCl_3$): 3340 (alcohol), 3020 and 1660 (olefin) $cm^{-1}$; nmr ($CDCl_3$) δ: 5.58 (m, 2H, —CH=CH—), 3.83 (br s, 1H, —C*H*OH), 3.60 (m, 2H, —C$H_2$OH), 2.55 (br s, 2H, 2 × —OH), 1.00 (s, 3H, —$CH_3$), and 0.70 (s, 3H, —$CH_3$); ms $M^+$ 170.1307 (calcd. for $C_{10}H_{18}O_2$: 170.1307.

*6,6-Dimethyl-5-(2-oxoethyl)-2-cyclohexenone (**21**)*

To a suspension of pyridinium chlorochromate (2.37 g, 11 mmol) in dichloromethane (26 mL), a solution of diol **20** (470 mg, 2.8 mmol) in dichloromethane (4 mL) was introduced in one portion. The mixture was stirred at room temperature for 2 h and diluted with ether (50 mL). The resulting mixture was passed through a short pad of Florisil. Removal of the solvent under reduced pressure gave keto aldehyde **21** (315 mg, 69% yield); ir: 2730, 1735 (aldehyde), and 1680 (α,β-unsaturated ketone) $cm^{-1}$; nmr δ: 9.70 (m, 1H, —CHO), 6.70 (m, 1H, —COCH=C*H*—), 5.83 (dt, $J$ = 10, $J'$ = 2 Hz, 1H, —COC*H*=CH—), 1.12 (s, 3H, —$CH_3$), and 0.96 (s, 3H, —$CH_3$); ms $M^+$ 166.0997 (calcd. for $C_{10}H_{14}O_2$: 166.0994).

*5-(2-Acetoxy-3-butenyl)-6,6-dimethyl-2-cyclohexenone (**19**)*

At −78°C, to a stirred solution of keto aldehyde **21** (181 mg, 1.1 mmol) in tetrahydrofuran (5 mL) under a nitrogen atmosphere, was added a 1.2 *M* solution of vinylmagnesium bromide in tetrahydrofuran (1 mL, 1.2 mmol). After stirring for 30 min, ice-cold aqueous ammonium chloride solution was added. The resulting solution was extracted with ether. The etherate solution was dried ($MgSO_4$) filtered, and evaporated to dryness to give crude keto alcohol **22** (200 mg) which was dissolved in pyridine (2 mL). To this solution, acetic anhydride (0.5 mL) was added. After stirring at room temperature for 16 h the reaction mixture was concentrated. The residue was chromatographed on silica gel (10 g). Elution with a solution of 2% ether in benzene afforded keto acetates **19** (126 mg, 50% yield from **21**); ir: 1735 (ester), 1675 (α,β-unsaturated ketone), 1395 and 1375 (geminal methyls) $cm^{-1}$; nmr δ: 6.68 (m, 1H, —COCH=C*H*—), 5.80 (dt, $J$ = 10, $J'$ = 3Hz, 1H, —COC*H*=CH—), 5.58 (m, 1H, —C*H*=$CH_2$), 5.20 (m, 2H, —CH=C$H_2$), 5.16 (m, 1H, —CHO—), 2.00, 1.98 (both s, total 3H, $CH_3COO$—), 1.11, 1.08, and 0.94 (all s, total 6H, 2 × —$CH_3$); ms $M^+$ 236.1408 (calcd. for $C_{14}H_{20}O_3$: 236.1413).

For personal use only.

*3-Acetoxy-9,9-dimethyltricyclo[4.3.1.0$^{4,7}$]decan-8-one (24)*

Keto acetates **19** (94 mg, 0.4 mmol) were dissolved in 10 mL of methanol. The solution was placed in a Pyrex tube and irradiated at room temperature using a 450 W Hanovia high-pressure quartz mercury vapor lamp for 4 h. The solution was concentrated and the residue chromatographed on silica gel (9 g). Elution with a solution of 2% ether in benzene gave keto acetate **24** (40 mg, 43% yield) as a colorless liquid; ir: 1735 (ester), 1700 (ketone), 1390 and 1372 (geminal methyls) cm$^{-1}$; nmr δ: 4.84 (m, 1H, —CHO—), 1.95 (s, 3H, $CH_3COO$—), 1.21 (s, 3H, —$CH_3$), and 1.00 (s, 3H, —$CH_3$); ms M$^+$ 236.1419 (calcd. for $C_{14}H_{20}O_3$: 236.1412).

*3-Hydroxy-9,9-dimethyltricyclo[4.3.1.0$^{4,7}$]decan-8-one (25)*

Keto acetate **24** (170 mg, 0.72 mmol) was dissolved in methanol (6 mL) and saturated aqueous potassium carbonate (3 mL) was added. The reaction mixture was refluxed for 1.5 h, poured into water, and extracted with dichloromethane. The extracts were dried ($MgSO_4$), filtered, and concentrated to yield an oily product (120 mg) which was chromatographed on silica gel (10 g). Elution with ether–benzene (3:2) gave keto alcohol **25** (91 mg, 65% yield); ir: 3400 (alcohol) and 1695 (ketone) cm$^{-1}$; nmr δ: 3.78 (m, 1H, —CHO—), 1.12 (s, 3H, —$CH_3$), and 0.98 (s, 3H, —$CH_3$).

*9,9-Dimethyltricyclo[4.3.1.0$^{4,7}$]decane-3,8-dione (26)*

At 0°C, to a solution of keto alcohol **25** (91 mg, 0.46 mmol) in acetone (5 mL) was added 8 *N* Jones reagent (0.3 mL) (33). After stirring at room temperature for 10 min, the mixture was diluted with water and extracted with ether. The organic solution was dried ($MgSO_4$), filtered, and evaporated to dryness. The crude product was chromatographed on silica gel (6 g). Elution with a solution of 2% ether in benzene gave diketone **26** (70 mg, 80% yield); ir: 1695 and 1710 (ketone) cm$^{-1}$; nmr δ: 2.96 (d, $J$ = 2.5 Hz, 2H, —$COCH_2$—), 1.13 (s, 3H, —$CH_3$), and 1.08 (s, 3H, —$CH_3$).

*10,10-Dimethyl-4-oxatricyclo[5.3.1.0$^{5,8}$]decane-3,9-dione (27)*

A mixture of the diketone **26** (80 mg, 0.4 mmol), *m*-chloroperbenzoic acid (259 mg, 1.2 mmol), and sodium bicarbonate (200 mg, 2.0 mmol) in dichloromethane (4 mL) was stirred for three days. A 10% aqueous sodium sulfite solution (5 mL) was added and the resulting solution was extracted with dichloromethane. The combined extracts were washed with aqueous sodium bicarbonate solution. Concentration gave an oil which was chromatographed on silica gel (5 g). Elution with a solution of 10% ether in benzene gave keto lactone **27** (50 mg, 60% yield); ir: 1730 (lactone) and 1705 (ketone) cm$^{-1}$; nmr δ: 5.04 (m, 1H, —CHO—), 1.21 (s, 3H, —$CH_3$), and 1.11 (s, 3H, —$CH_3$); ms M$^+$ 208.1105 (calcd. for $C_{12}H_{16}O_3$: 208.1100).

cis-*3-Carbomethoxymethyl-2,2-dimethyl-5-(2-oxoethyl)cyclohexanone (30)*

Lactone **27** (20 mg, 0.1 mmol) was dissolved in methanol (6 mL). To this solution, saturated aqueous potassium carbonate (3 mL) was added. The reaction mixture was refluxed for 30 min under a nitrogen atmosphere. After cooling to room temperature, it was poured into water and extracted with dichloromethane to remove the nonacidic material. The aqueous solution was acidified with hydrochloric acid and extracted with dichloromethane. Drying ($MgSO_4$), filtration, and concentration yielded acid **28** (10 mg, 45% yield); ir ($CHCl_3$): 3200–2500 (acid), 2730 (aldehyde) and 1705 (carbonyls) cm$^{-1}$; nmr ($CDCl_3$) δ: 11.8 (br s, 1H, —COOH), 9.76 (br s, 1H, —CHO), 1.11 (s, 3H, —$CH_3$), and 1.01 (s, 3H, —$CH_3$); ms M$^+$ 226.1207 (calcd. for $C_{12}H_{18}O_4$: 226.1205).

Acid **28** (10 mg) was dissolved in ether (4 mL). At 0°C, to this solution, diazomethane in ether was added dropwise until the light yellow color was retained. Removal of the solvent gave ester **30** (10 mg, 95% yield); ir: 2730 (aldehyde), 1735 (ester), and 1710 (ketone and aldehyde) cm$^{-1}$; nmr δ: 9.72 (s, 1H, —CHO), 3.62 (s, 3H, —$COOCH_3$), 1.15 (s, 3H, —$CH_3$), and 0.98 (s, 3H, —$CH_3$); ms M$^+$ 240.1362 (calcd. for $C_{13}H_{20}O_4$: 240.1362).

*Photocycloaddition of enone 14 to vinyl acetate*

To a photochemical reaction vessel (34) containing enone ester **14** (2.15 g, 11 mmol) in benzene (50 mL) was added freshly distilled vinyl acetate (21 mL, 0.22 mol). The mixture was irradiated using a 450 W Hanovia high-pressure quartz mercury vapor lamp and a Pyrex filter for 1.5 h. The solution was concentrated and the residue chromatographed on silica gel (300 g) with benzene elution to give 2.37 g (77% yield) of photoadducts **33** and **34**; ir: 1735 (ester) and 1698 (ketone) cm$^{-1}$; nmr δ: 3.61 (s, 3H, —$COOCH_3$), 1.95, 1.96 (both s, total 3H, $CH_3COO$—), and 0.9–1.1 (complex, 6H, 2 × —$CH_3$); ms M$^+$ 282.1462 (calcd. for $C_{15}H_{22}O_5$: 282.1467).

*4-Carbomethoxymethyl-7-hydroxy-3,3-dimethylbicyclo[4.2.0]-octan-2-one (36),* cis-*(30) and* trans-*3-carbomethoxymethyl-2,2-dimethyl-5-(2-oxoethyl)cyclohexanone (35)*

At 0°C, sodium (690 mg, 30 g-atom) was added to methanol (35 mL). After all sodium reacted, a mixture of photoadducts **33** and **34** (3.07 g, 10.87 mmol) was added. The resulting mixture, after stirring at room temperature for 45 min, was carefully poured into ice-cold 3 *N* hydrochloric acid (100 mL) and extracted with dichloromethane. The extracts were dried ($MgSO_4$), filtered, and concentrated to give an oily residue which was chromatographed on silica gel (120 g). Elution with a solution of 50% ether–pentane gave keto aldehydes **30** and **35** (0.42 g, 16% yield); ir: 2730, (aldehyde), 1735 (ester), and 1710 (aldehyde and ketone) cm$^{-1}$; ms M$^+$ 240.1355 (calcd. for $C_{13}H_{20}O_4$: 240.1362). The nmr spectrum of the mixture showed, in addition to one set of signals corresponding to keto aldehyde **30** (*vide supra*), the following signals for compound **35**: δ: 9.72 (s, 1H, —CHO), 3.62 (s, 3H, —$COOCH_3$), 1.03 (s, 3H, —$CH_3$), and 0.98 (s, 3H, —$CH_3$).

Further elution with a solution of ether–pentane (4:1) gave a mixture of diastereomeric alcohols **36** (1.75 g, 67% yield); ir: 3450 (alcohol), 1738 (ester), and 1702 (ketone) cm$^{-1}$; nmr δ: 3.60 (s, 3H, —$COOCH_3$), 3.76 (m, 1H, —CHO—), and 0.90–1.21 (six s, total 6H, 2 × —$CH_3$); ms M$^+$ 240.1355 (calcd. for $C_{13}H_{20}O_4$: 240.1362).

*4-Carbomethoxymethyl-3,3-dimethylbicyclo[4.2.0]octane-2,7-diones (37 and 38)*

At 0°C, to a solution of alcohols **36** (3.2 g, 13.3 mmol) in acetone (30 mL), 8 *N* Jones reagent (ca. 5 mL) was introduced dropwise until the brown color persisted for more than 30 s. The mixture was stirred at room temperature for 30 min. After most of the solvent was removed under reduced pressure, water was added. The resulting aqueous solution was extracted with chloroform. The extracts were washed successively with aqueous sodium bicarbonate solution and aqueous sodium chloride solution and dried ($MgSO_4$). Filtration and concentration yielded 2.6 g of crude product which showed two partially overlapping spots on silica gel thin-layer chromatography. Column chromatography on silica gel (150 g), eluting with a solution of 40% ether in pentane, gave diketone **37** (850 mg, 27% yield); $[\alpha]_D^{25}$ +119.5° (*c* 2.0, $CHCl_3$); ir: 1785 (four-membered ketone), 1738 (ester), and 1710 (ketone) cm$^{-1}$; nmr δ: 3.61 (s, 3H, —$COOCH_3$), 1.21 (s, 3H, —$CH_3$), and 0.97 (s, 3H, —$CH_3$); ms M$^+$ 238.1204 (calcd. for $C_{13}H_{18}O_4$: 238.1205). *Anal.* calcd. for $C_{13}H_{18}O_4$: C 65.53, H 7.61; found: C 65.20, H 7.28.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

Further elution with the same solvent system gave a mixture of **37** and **38** (ca. 1:1; 234 mg, 7% yield). This was followed by pure ketone **38** (1.055 g, 33% yield) as a white solid; mp 127–128°C (ether); $[\alpha]_D^{25}$ −126.4° (*c* 1.4, $CHCl_3$); ir ($CHCl_3$): 1785 (four-membered ketone), 1738 (ester), and 1708 (ketone) $cm^{-1}$; nmr δ: 3.67 (s, 3H, —$COOCH_3$), 1.12 (s, 3H, —$CH_3$), and 1.06 (s, 3H, —$CH_3$); ms $M^+$ 238.1205 (calcd. for $C_{13}H_{18}O_4$: 238.1205). *Anal.* calcd. for $C_{13}H_{18}O_4$: C 65.53, H 7.61; found: C 65.79, H 7.80.

*4-Carbomethoxymethyl-7,7-diethoxy-3,3-dimethylbicyclo-[4.2.0]octan-2-one (**39**)*

To a Pyrex tube containing a solution of enone ester **14** (500 mg, 2.5 mmol) in benzene (12 mL), 1,1-diethoxyethene (4.35 g, 37.5 mmol) was added. The reaction mixture was irradiated at room temperature with a 450 W Hanovia high-pressure quartz mercury vapor lamp for 3 h. The solvent and excess reagent were removed under the reduced pressure. The residue was chromatographed on silica gel (40 g). Elution with a solution of 20% ether in pentane gave a diastereomeric mixture of adducts **39** (750 mg, 96% yield); ir: 1735 (ester) and 1700 (ketone) $cm^{-1}$; nmr δ: 3.61 (s, 3H, —$COOCH_3$), 3.31, 3.33, 3.37, 3.39 (all q, $J$ = 7 Hz each, total 4H, —$OCH_2CH_3$), and ~1.10 (complex, total 12H, 4 × —$CH_3$); ms $M^+$ 312.1943 (calcd. for $C_{17}H_{28}O_5$: 312.1937).

*Diketones **37** and **38** from ketal **39***

Ketal **39** (680 mg, 2.2 mmol) was dissolved in 8 mL of acetone and 2 *N* aqueous hydrochloric acid (4 mL) was added. After stirring at room temperature for 3 h, the solution was diluted with water and extracted with dichloromethane. The combined extracts were dried ($MgSO_4$), filtered, and evaporated to dryness. The crude product was chromatographed on silica gel (40 g). Elution with a solution of 40% ether in pentane gave pure diketones **37** (160 mg, 30% yield) and **38** (260 mg, 50% yield).

*Mixture of $\Delta^{1,8}$- (**40**) and $\Delta^{1,6}$-4-carbomethoxymethyl-3,3-dimethylbicyclo[4.2.0]octene-2,7-dione (**41**)*

To a solution of the diketone **38** (100 mg, 0.42 mmol), in glacial acetic acid (4 mL), pyridinium bromide perbromide (268 mg, 0.84 mmol) was added. The reaction mixture was stirred at room temperature for 16 h. It was cautiously made basic with ice-cold saturated aqueous sodium bicarbonate solution. Extraction with dichloromethane followed by the usual work-up of the extracts gave a thick oil which was chromatographed on silica gel (6 g). Elution with a solution of 25% ether in pentane gave enediones **40** and **41** (65 mg, 66% yield); ir: 1785 (four-membered ketone), 1740 (ester), and 1695 (six-membered ketone) $cm^{-1}$; nmr δ: 5.44 (br s, 0.88 H, —CH=C<), 3.65 (s, 3H, —$COOCH_3$), 3.42 (m, 0.24 H, —$COCH_2$C=), 1.22, 1.28 (both s, total 3H, —$CH_3$), and 1.08 (s, 3H, —$CH_3$); ms $M^+$ 236.1048 (calcd. for $C_{13}H_{16}O_4$: 236.1049).

*Reduction of enediones **40** and **41***

Zinc dust (1 g, 0.015 g-atom) was added to a solution of enediones **40** and **41** (523 mg, 2.21 mmol) in glacial acetic acid (8 mL). The resulting mixture was stirred at room temperature for 5 h. It was then cautiously made basic with ice-cold saturated aqueous sodium bicarbonate solution. Extraction with dichloromethane followed by concentration of the organic solution gave an oily product which was chromatographed on silica gel (30 g). Elution with a solution of 40% ether in pentane afforded diketones **37** (192 mg, 39% yield) and **38** (135 mg, 26% yield).

*4-Carbomethoxymethyl-7,7-ethylenedioxy-3,3-dimethylbicyclo[4.2.0]octan-2-one (**42**)*

Diketone **37** (655 mg, 2.76 mmol) was dissolved in 2-methyl-2-ethyl-1,3-dioxalane (8 mL) and *p*-toluenesulfonic acid (40 mg, 0.26 mmol) was added. The mixture was heated at 95°C (oil bath temperature) for 12 h. After cooling to 0°C, aqueous sodium bicarbonate solution was added. Extraction with dichloromethane followed by the usual work-up of the extracts gave the crude product which was chromatographed on silica gel (30 g). Elution with a solution of 40% ether in benzene gave ketal **42** (650 mg, 84% yield); $[\alpha]_D^{25}$ +71.8° (*c* 1.5, $CHCl_3$); ir: 1735 (ester) and 1715 (ketone) $cm^{-1}$; nmr δ: 3.75 (m, 4H, —$OCH_2CH_2O$—), 3.72 (s, 3H, —$COOCH_3$), 1.06 (s, 3H, —$CH_3$), and 0.96 (s, 3H, —$CH_3$); ms $M^+$ 282.1471 (calcd. for $C_{15}H_{22}O_5$: 282.1467).

*4-Carbomethoxymethyl-7,7-ethylenedioxy-2-hydroxy-2,3,3-trimethylbicyclo[4.2.0]octane (**46**)*

To a solution of ketal **42** (209 mg, 0.74 mmol) in methanol (6 mL) was added 2 *N* aqueous sodium hydroxide (3 mL). The resulting mixture was refluxed for 1 h. After cooling to room temperature, the mixture was poured into ice-cold dilute hydrochloric acid and extracted with dichloromethane. The usual work-up of the extracts gave crude acid **43**. The crude acid was then dissolved in 1,2-dimethoxyethane (10 mL) and cooled to 0°C. Sodium hydride (36 mg, 50% oil dispersion, 0.75 mmol) was added. After the evolution of gas ceased, a 2 *M* solution of methylmagnesium bromide in ether (1.8 mL, 3.6 mmol) was slowly introduced. The mixture was allowed to warm up to room temperature and stirred for 20 h under a nitrogen atmosphere. Saturated aqueous ammonium chloride solution was added and the resulting mixture was extracted with dichloromethane. The combined extracts were dried ($MgSO_4$), filtered, and concentrated to give a mixture of acids **43** and **45** as a light yellow liquid. This acidic material was dissolved in ether (6 mL) and a slight excess of ethereal diazomethane was introduced. The residue obtained upon concentration was chromatographed on silica gel (20 g). Elution with a solution of 40% ether in pentane gave the starting ketal **42** (39 mg, 19% recovery). Further elution with a solution of 50% ether in pentane afforded alcohol **46** (140 mg, 78% yield based on consumed **42**); ir: 3520 (alcohol) and 1735 (ester) $cm^{-1}$; nmr δ: 3.81 (br s, 4H, —$OCH_2CH_2O$—), 3.63 (s, 3H, —$COOCH_3$), 1.10 (s, 3H, —$CH_3$), 0.96 (s, 3H, —$CH_3$), and 0.92 (s, 3H, —$CH_3$); ms $M^+$ 298.1777 (calcd. for $C_{16}H_{26}O_5$: 298.1780). *Anal.* calcd. for $C_{16}H_{26}O_5$: C 64.41, H 8.78; found: C 64.19, H 8.68.

*4-Carbomethoxymethyl-7,7-ethylenedioxy-3,3-dimethyl-2-methylidenebicyclo[4.2.0]octane (**47**)*

To a solution of alcohol **46** (1.5 g, 5.0 mmol) and pyridine (4 mL), in benzene (50 mL), was added a solution of thionyl chloride (1 mL) in benzene (5 mL). The reaction mixture was stirred at room temperature under an atmosphere of nitrogen for 30 min. It was acidified with ice-cold 2 *N* aqueous hydrochloric acid and extracted with dichloromethane. The combined organic extracts were dried ($MgSO_4$), filtered, and concentrated. Column chromatography of the residue on silica gel (80 g), eluting with a solution of 20% ether in pentane, gave olefin **47** (1.176 g, 89% yield); $[\alpha]_D^{25}$ +41.4° (*c* 1.0, $CHCl_3$); ir: 3100, 1630, 890 (olefin), and 1740 (ester) $cm^{-1}$; nmr δ: 4.96 (br s, 1H, —C=C*H*H), 4.78 (br s, 1H, —C=C*H*H), 3.75 (br s, 4H, —$OCH_2CH_2O$—), 3.60 (s, 3H, —$COOCH_3$), 1.10 (s, 3H, —$CH_3$), and 1.03 (s, 3H, —$CH_3$); ms $M^+$ 280.1674 (calcd. for $C_{16}H_{24}O_4$: 280.1674). *Anal.* calcd. for $C_{16}H_{24}O_4$: C 68.55, H 8.63; found: C 68.80, H 8.69.

*7,7-Ethylenedioxy-4-(2-hydroxyethyl)-3,3-dimethyl-2-methylidenebicyclo[4.2.0]octane (**48**)*

To a suspension of lithium aluminium hydride (200 mg, 5.3 mmol) in tetrahydrofuran (20 mL) at 0°C, a solution of ester **47** (1.176 g, 4.2 mmol) in tetrahydrofuran (2 mL) was added. The

For personal use only.

reaction mixture was stirred at room temperature under a nitrogen atmosphere for 16 h. Water (0.2 mL), 3 *N* sodium hydroxide (0.2 mL), and again water (0.6 mL) were successively added. Filtration followed by concentration of the filtrate gave alcohol **48** (1.05 g, 99% yield); $[\alpha]_D^{25}$ +39.2° (*c* 1.3, $CHCl_3$); ir: 3420 (alcohol), 3100 and 1630 (olefin) $cm^{-1}$; nmr δ: 4.91 (s, 1H, —C(—)=C*H*H), 4.27 (s, 1H, —C(—)=C*H*H), 3.74 (br s, 4H, —$OCH_2CH_2O$—), 1.06 (s, 3H, —$CH_3$), and 1.03 (s, 3H, —$CH_3$); ms $M^+$ 252.1730 (calcd. for $C_{15}H_{24}O_3$: 252.1725). *Anal.* calcd. for $C_{15}H_{24}O_3$: C 71.39, H 9.59; found: C 71.70, H 9.66.

*4-(2-Chloroethyl)-7,7-ethylenedioxy-3,3-dimethyl-2-methylidenebicyclo[4.2.0]octane (**49**)*

Alcohol **48** (190 mg, 0.75 mmol) was dissolved in pyridine (2 mL) and cooled to 0°C. Phosphorus oxychloride (0.5 mL) was introduced. The mixture was stirred at room temperature under a nitrogen atmosphere for 16 h and poured into ice-cold water. The resulting mixture was extracted with dichloromethane. The organic solution was dried ($MgSO_4$), filtered, and concentrated to give an oily residue which was chromatographed on silica gel (15 g). Elution with a solution of 10% ether in pentane yielded chloride **49** (150 mg, 75% yield); $[\alpha]_D^{25}$ +29.7° (*c* 0.7, $CHCl_3$); ir: 1630 (olefin) $cm^{-1}$; nmr δ: 4.92 (s, 1H, —C(—)=C*H*H), 4.75 (s, 1H, —C(—)=C*H*H), 4.74 (br s, 4H, —$OCH_2CH_2O$—), 3.50 (m, 2H, —$CH_2Cl$), 1.07 (s, 3H, —$CH_3$), and 1.03 (s, 3H, —$CH_3$); ms $M^+$ 270.1380 and 272.1362 (calcd. for $C_{15}H_{23}OCl$: 270.1386 and 272.1357).

*4-(2-Chloroethyl)-3,3-dimethyl-2-methylidenebicyclo[4.2.0]-octan-7-one (**50**)*

Chloride **49** (120 mg, 0.44 mmol) was dissolved in acetone (4 mL) and 2 *N* aqueous hydrochloric acid (2 mL) was added. After stirring at room temperature for 8 h, the mixture was poured into water and extracted with dichloromethane. Drying ($MgSO_4$), filtration, and concentration gave ketone **50** (100 mg, quantitative yield; $[\alpha]_D^{25}$ +48.6° (*c* 1.3, $CHCl_3$); ir: 1785 (ketone) and 1640 (olefin) $cm^{-1}$; nmr δ: 5.04 (d, *J* = 2 Hz, 1H, —C(—)=C*H*H), 4.91 (d, *J* = 2 Hz, —C(—)=C*H*H), 3.50 (m, 2H, —$CH_2Cl$), 1.16 (s, 3H, —$CH_3$), and 1.11 (s, 3H, —$CH_3$); ms $M^+$ 226.1124 and 228.1090 (calcd. for $C_{13}H_{19}OCl$: 226.1124 and 228.1095).

*8-Carboethoxy-4-(2-chloroethyl)-3,3-dimethyl-2-methylidenebicyclo[4.3.0]nonan-7-one (**51**) and 7-carboethoxy-4-(2-chloroethyl)-3,3-dimethyl-2-methylidenebicyclo-[4.3.0]nonan-8-one (**52**)*

At 0°C, to a solution of ketone **50** (100 mg, 0.46 mmol) in ether (8 mL), was added boron trifluoride etherate (0.12 mL, 1 mmol). After stirring at 0°C for 15 min, ethyl diazoacetate (0.1 mL, 1 mmol) was introduced. The mixture was stirred under a nitrogen atmosphere at 0°C for 1 h and at room temperature for 4 h. Ice-cold saturated aqueous sodium bicarbonate solution was added dropwise. Extraction with dichloromethane followed by the usual work-up of the organic solution gave an oily product which showed two spots in thin-layer chromatography. Their separation was effected by column chromatography on silica gel (10 g). Elution with a solution of 8% ether in pentane afforded keto ester **51** (82 mg, 57% yield); $[\alpha]_D^{25}$ +31.9° (*c* 0.6, $CHCl_3$); ir: 1760 (ketone), 1735 (ester), and 1650 (olefin) $cm^{-1}$; nmr δ: 4.90 (br s, 2H, —C(—)=$CH_2$), 4.12 (q, *J* = 7 Hz, 2H, —$COOCH_2CH_3$), 3.54 (m, 2H, —$CH_2Cl$), 1.24 (s, 3H, —$CH_3$), 1.23 (t, *J* = 7 Hz, 3H, —$COOCH_2CH_3$), and 1.06 (s, 3H, —$CH_3$); ms $M^+$ 312.1490 and 314.1445 (calcd. for $C_{17}H_{25}O_3Cl$: 312.1492 and 314.1462).

Further elution with the same solvent system gave keto ester **52** (42 mg, 29% yield); ir: 1750 (ketone), 1730 (ester), and 1635 (olefin) $cm^{-1}$; nmr δ: 4.98 (s, 1H, —C(—)=C*H*H), 4.72 (s, 1H, —C(—)=C*H*H), 4.14 (q, *J* = 7 Hz, 2H, —$COOCH_2CH_3$), 3.52 (m, 2H, —$CH_2Cl$), 1.25 (t, *J* = 7 Hz, 3H, —$COOCH_2CH_3$), 1.15 (s, 3H, —$CH_3$), and 1.01 (s, 3H, —$CH_3$); ms $M^+$ 312.1488 and 314.1466 (calcd. for $C_{17}H_{25}O_3Cl$: 312.1492 and 314.1463).

*(−)-Khusimone (**1**)*

To a solution of the keto ester **51** (122 mg, 0.39, mmol) in methanol (3 mL) under a nitrogen atmosphere, was added 2 *N* aqueous sodium hydroxide solution (1.5 mL). The resulting solution was immediately brought into reflux using a preheated oil bath. After 40 min, ice-cold water was added. Extraction with dichloromethane, drying ($MgSO_4$), filtration, and concentration gave a solid which was recrystallized from petroleum ether to give (−)-khusimone (**1**) (56 mg, 70% yield); mp 78°C; $[\alpha]_D^{25}$ −108.7° (*c* 2.0, $CHCl_3$); ir ($CHCl_3$): 3140, 1640 (olefin), 1728 (ketone), 1395 and 1360 (geminal methyls) $cm^{-1}$; nmr ($CDCl_3$) δ: 4.84 (br s, 1H, —C(—)=C*H*H), 4.68 (br s, 1H, —C(—)=C*H*H), and 1.06 (s, 6H, 2 × —$CH_3$); ms $M^+$ 204.1514 (calcd. for $C_{14}H_{20}O$: 204.1512).

*2,12-Epoxyzizaene (**54**)*

At 0°C, to a suspension of trimethylsulfonium iodide (100 mg, 0.5 mmol) in tetrahydrofuran (6 mL) under a nitrogen atmosphere, was added a solution of 2 *M* butyllithium in ether (0.16 mL, 0.32 mmol). After stirring at room temperature for 1 h, the mixture was again cooled to 0°C and a solution of (−)-khusimone (**1**) (40 mg, 0.2 mmol) in tetrahydrofuran (4 mL) was added. The resulting mixture was stirred at room temperature for 2.5 h. Water was added and the aqueous solution extracted with dichloromethane. The usual work-up of the extracts gave an oil which was chromatographed on silica gel (6 g). Elution with a solution of 2% ether in pentane gave epoxide **54** (15 mg, 52% based on consumed starting material); ir: 3110 and 1645 (olefin), 1385 and 1365 (geminal methyls) $cm^{-1}$; nmr δ: 4.77 (m 1H, —C(—)=C*H*H), 4.58 (br s, 1H, —C(—)=C*H*H), 2.67 (d, *J* = 12 Hz, 1H, —OC*H*H), 2.53 (d, *J* = 12 Hz, 1H, —OC*H*H), and 1.06 (s, 6H, 2 × —$CH_3$); ms $M^+$ 218.1674 (calcd. for $C_{15}H_{22}O$: 218.1670).

Further elution with a solution of 5% ether in pentane afforded 13 mg of the starting material.

*12-Oxoepizizaene (**55**)*

Epoxide **54** (17.5 mg, 0.08 mmol) was dissolved in ether (4 mL) and cooled to 0°C. Boron trifluoride etherate (0.05 mL, 0.41 mmol) was introduced. The mixture was stirred under a nitrogen atmosphere at 0°C for 1 h, and then at room temperature for 30 min. It was made basic with saturated sodium bicarbonate and extracted with ether. The organic solution was dried ($MgSO_4$), filtered, and concentrated to give aldehyde **55** (17.5 mg, quantitative yield); ir: 2710, 1720 (aldehyde), 1640 (olefin), 1380 and 1360 (geminal methyls) $cm^{-1}$; nmr δ: 9.73 (d, *J* = 2 Hz, 1H, —CHO), 4.80 (s, 1H, —C(—)=C*H*H), 4.60 (s, 1H, —C(—)=C*H*H), 1.10 (s, 3H, —$CH_3$), and 1.06 (s, 3H, —$CH_3$); ms $M^+$ 218.1670 (calcd. for $C_{15}H_{22}O$: 218.1670).

*(−)-Epizizanoic acid (**3**)*

At 0°C, to a solution of the aldehyde **55** (16 mg, 0.073 mmol) in acetone (3 mL), was slowly added 8 *N* Jones reagent until a brown color persisted. The mixture was stirred for 5 min, added to ice-cold aqueous sodium chloride solution (50 mL), and extracted with dichloromethane. The usual work-up of the extracts gave the crude product which was taken up in ether and extracted with saturated sodium bicarbonate. The extracts were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

combined and acidified with hydrochloric acid. This was followed by extraction with dichloromethane. Drying ($MgSO_4$), filtration, and concentration gave (−)-epizizanoic acid (14) (13 mg, 77% yield); mp 110°C (petroleum ether); $[\alpha]_D^{25}$ −1.0° (*c* 1.2, $CHCl_3$); ir ($CHCl_3$): 3200–2500, 1691 (acid), 1638 (olefin), 1380 and 1360 (geminal methyls) $cm^{-1}$; nmr δ: 11.7 (s, 1H, —COOH), 4.75 (s, 1H, —C(—)=C*H*H), 4.56 (s, 1H, —C(—)=C*H*H), 1.08 (s, 3H, —$CH_3$), and 1.05 (s, 3H, —$CH_3$); ms $M^+$ 234.1626 (calcd. for $C_{15}H_{22}O_2$: 234.1619).

*Epimerization of aldehyde 55*

To a solution of aldehyde **55** (13 mg, 0.06 mmol) in methanol (4 mL), was added 2 *N* aqueous sodium hydroxide solution (1 mL). The reaction mixture was stirred at room temperature under a nitrogen atmosphere for 9 h. Saturated aqueous sodium chloride solution was added. The resulting solution was extracted with dichloromethane. Drying ($MgSO_4$), filtration, and concentration gave a mixture of epimeric aldehydes **55** and **56** which was separated by column chromatography on silica gel (5 g). Elution with a solution of 5% ether in petroleum ether gave pure β-aldehyde **56** (2.5 mg), a mixture of α- and β-epimers (1:1; 2 mg), followed by pure α-aldehyde **55** (1.6 mg). β-Aldehyde **56** showed the following spectral data; ir: 2720, 1720 (aldehyde), 1640 (olefin), 1380 and 1360 (geminal methyls) $cm^{-1}$; nmr δ: 9.80 (d, $J$ = 2 Hz, 1H, —CHO), 4.78 (dd, $J = J'$ = 2 Hz, 1H, —C(—)=C*H*H), 4.63 (dd, $J = J'$ = 2 Hz, 1H, —C(—)=C*H*H), and 1.07 (s, 6H, 2 × —$CH_3$); ms $M^+$ 218.1667 (calcd. for $C_{15}H_{22}O$: 218.1670).

*(+)-Zizanoic acid (2)*

At 0°C, to a solution of aldehyde **56** (2.5 mg, 0.011 mmol) in 2 mL of acetone, was added 8 *N* Jones reagent until a brown color persisted. After stirring at room temperature for 15 min, the reaction mixture was added to water and extracted with dichloromethane. The usual work-up of the extracts gave (+)-zizanoic acid (**2**) (2.3 mg, 86% yield); $[\alpha]_D^{25}$ +22.2° (*c* 0.23, $CHCl_3$); ir ($CHCl_3$): 3200–2600, 1701 (acid), 1639 and 891 (olefin) $cm^{-1}$; nmr δ: 4.77 (dd, $J = J'$ = 1.5 Hz, 1H, —C(—)=C*H*H), 4.63 (dd, $J = J'$ = 1.5 Hz, 1H, —C(—)=C*H*H), 2.68 (m, 1H, —C*H*COOH), 1.10 (s, 3H, —$CH_3$), and 1.07 (s, 3H, —$CH_3$); ms $M^+$ 234.1621 (calcd. for $C_{15}H_{22}O_2$: 234.1620).

# Formation and reactivity of 1,3-benzodioxol-2-yl, 1,3-benzodioxan-2-yl, and related radicals. A search for an aromatic analog of the radical acetoxy rearrangement (Surzur–Tanner reaction)

FEREIDOON SHAHIDI AND THOMAS T. TIDWELL

*Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1*

Received November 6, 1981

FEREIDOON SHAHIDI and THOMAS T. TIDWELL. Can. J. Chem. **60**, 1092 (1982).

Reaction of the 1,3-dioxole, **9**, the 1,3-dioxan, **18**, and the 1,3-dioxepin, **29**, with *tert*-butoxy radicals gave evidence in each case for formation of the corresponding 1,1-dioxyethyl radicals. No conclusive evidence for formation of any of these radicals by cyclization of acetoxyaryl radicals could be obtained. Several of the 1,1-dioxyethyl radicals reacted by rearrangement.

FEREIDOON SHAHIDI et THOMAS T. TIDWELL. Can. J. Chem. **60**, 1092 (1982).

Lors de la réaction du dioxole-1,3 (**9**), du dioxanne-1,3 (**18**) et de la dioxépine-1,3 (**29**) avec les radicaux *tert*-butoxy, on a observé dans chacun des cas la formation des radicaux dioxy-1,1 éthyles correspondants. On n'a pas pu prouver que ces radicaux peuvent être préparés par la cyclisation des radicaux acétoxyaryles. Plusieurs de ces radicaux réagissent en se transposant.

[Traduit par le journal]

1,3-Dioxan-2-yl radicals (**1**) and 1,3-dioxol-2-yl radicals (**2**) have recently been the subject of intense investigation (1, 2). The most common

**1**

**2**

route for formation of these species has been hydrogen atom abstraction from the dioxane or dioxole (e.g. eq. [1]). Rearrangements of 2-acyloxyethyl radicals (the Surzur–Tanner reaction)[1] (3) evidently proceed through transition states resembling **2** as illustrated in eq. [2], but cyclized radical intermediates apparently are not formed in these processes (3).

[1] 
[2] 
Only recently have there been any studies of the benzo analogs of **1** or **2**. Radical **3** was generated by hydrogen atom abstraction (eq. [3]) and its esr spectrum was observed (1*a*). However, when α-acetoxyphenyl radicals (4) were generated by thermolysis of diacyl peroxides (eq. [4]), no rearrangement to dioxolyl radicals **5** could be detected (4). This rearrangement involves breaking a carbon–oxygen double bond and forming an aryl carbon–oxygen single bond and would be exothermic by about 13 kcal/mol.[2] It was suggested that geometrical constraints prevented favorable orbital overlap in the transition state for cyclization and precluded the rearrangement from occurring.

[3] 
**3**

Recently we have been interested in the formation of substituted furanyl radicals by cyclization reactions involving free radicals (5) and report

[4] 
**4***a* R = H
**4***b* R = Me

**5***a* R = H
**5***b* R = Me

herein studies of 1,3-benzodioxan-2-yl and 1,3-benzodioxol-2-yl radicals and attempts to form these species by free radical cyclizations.

## Results and discussion

*tert*-Butyl acetylperoxysalicylate (**6**) (6) appeared to be an attractive source of radical **4***a* in order to test for the possible occurrence of the cyclization to

[1]So named following a suggestion of Barclay *et al.* (17). This reaction was evidently discovered independently by Tanner and Law (3*a*) and Surzur and Teissier (3*f*).

[2]See the Appendix for the basis of this estimate.

[5] 

6 7

**5** (eq. [5]). Thermal decomposition of **6** in benzene at 100°C gave the products shown in eq. [6] (the carboxylic acids were isolated by first esterifying with $CH_2N_2$ or $PhCHN_2$). Acetylsalicyclic acid (**8***a*) was found to be converted to salicyclic acid (**8***b*) under the reaction conditions so **8***a* is apparently a precursor to the **8***b* found in the reaction product.

[6] 

10% 36% **8***a* (R = Ac) 12%
**8***b* (R = H) 42%

Similarly reaction of *o*-bromophenyl acetate with *n*-$Bu_3SnH$ gave phenyl acetate but no cyclized product (eq. [7]). These results confirm the conclu-

[7] 

sion of Evanochko and Shevlin (4) that the cyclization of eq. [4] is slow. These authors also concluded (4) that radical **7** has less of a tendency to decarboxylate than $PhC\dot{O}_2$, and the high yields of the nondecarboxylated products **8***a* and **8***b* observed in our work are consistent with this finding.

In order to confirm the postulated stability of **5***a* this radical was generated independently by hydrogen abstraction by *tert*-butoxy radicals from the dioxole **9** (7*a*, *c*). When this reaction was carried out in benzene-$d_6$ the products shown in eq. [8] were identified by gc/ms (gas chromatography/mass spectroscopy) and nmr. The nmr of recovered **9** revealed the presence of deuterium at the methine position (Fig. 1). These products indicate that radical **5***a* was formed; this conclusion was confirmed by observation of the esr spectrum of **5***a* when **9** was photolyzed with *t*-BuOO–*t*-Bu at −110°C: $a^H_{CH_3}$ = 12.41 G, *a* (4 aryl H) = 0.26 G, *g* = 2.00329.[3]

[3]This experiment was carried out by Dr. D. Griller and Dr. K. U. Ingold at the National Research Council, Ottawa.

The source of the deuterium in **9**-*d* is evidently a cyclohexadienyl radical or cyclohexadiene derived from addition of *tert*-butoxy, methyl, or another reactive radical to benzene-$d_6$.

[8] 

**9**-*d* (24%) **10** (23%) **11***a* (R = $C_6D_6$, 2%)
**11***b* (R = *t*-BuO, 2%)
**11***c* (symmetrical dimer, 3%)

Product **10** apparently arises from decomposition of **11***b* which was observed to occur during gas chromatography. Products **11***a* and **11***b* could arise from combination of **5***a* with $C_6D_6$ or *t*-$Bu\dot{O}$, and **11***c* from dimerization of **5***a*. The fact that these products form indicates a reasonable lifetime for **5***a*.

Our results, and those of Evanochko and Shevlin (4), are all consistent with a greater thermodynamic stability of **5***a* relative to **4***a*. The failure of the rearrangement to occur can be accounted for by the proposal (4) that the geometry of **4***a* does not permit facile bond formation between the singly occupied σ orbital of **4***a* and the bonding π orbital at the carbonyl oxygen. Such geometrical and stereoelectronic constraints on free radical reactions are becoming increasingly well identified (3*d*, 5, 8). Acetoxyalkyl radicals (eq. [2]) are apparently sufficiently less rigid than acetoxyaryl radicals so that rearrangement is feasible.

In selected cases it is possible for a phenyl radical to cyclize with formation of a 5-membered ring, as in the reported example shown in eq. [9] (8). Such

[9] 

cyclizations involving formation of exocyclic radicals are predicted (8*b*, 9) to be favored, as opposed to reactions such as that of eq. [4], which is not observed, and is predicted not to be favored. The observation (8*a*) that the radical in eq. [10] cyclized

[10] 

94% <1%

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

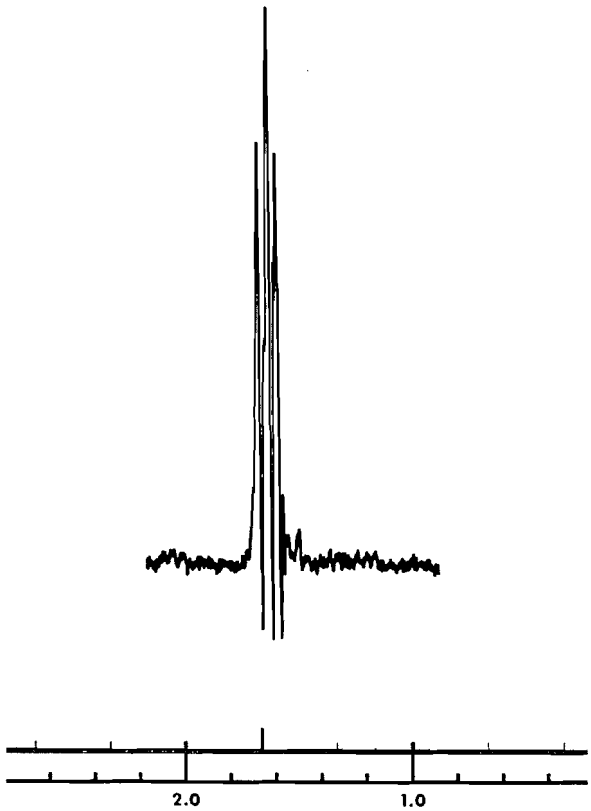

FIG. 1. The $^1H$ nmr absorption of $CH_3$ in a mixture of **9** and **9-*d***.

to the extent of less than 1% is another example of the barrier to formation of endocyclic radicals.

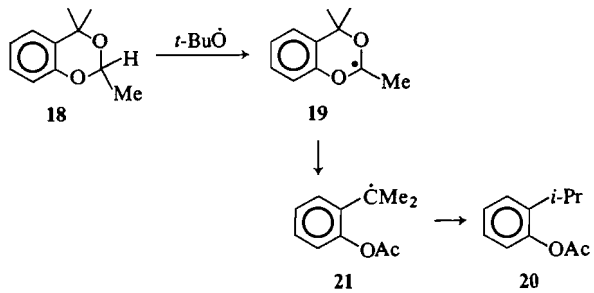
When the homologous acetal **12** was reacted with *tert*-butoxy radicals the only radical visible by esr was **13** (eq. [11]). Evidently formation of the

[11] 

isomeric radical **14** was not competitive with abstraction to give the benzylic radical **13**. An attempt to generate **14** from cyclization of 2-acetoxybenzyl (**15**) also failed. Thus 2-acetoxytoluene (**16**) was reacted with *tert*-butoxy radicals in $C_6D_6$ as shown in eq. [12]. The formation of the dimer **17** indicates formation of **15**, but no evidence of cyclization to **14** was obtained.

[12] 

Reaction of **18**, which has no reactive benzylic hydrogens, with *tert*-butoxy radicals led to esr observation of the radical **19** and isolation of the ring opened product **20**. Ring opening of **19** to give the benzylic radical **21** is likely to be exothermic so this path appears plausible.

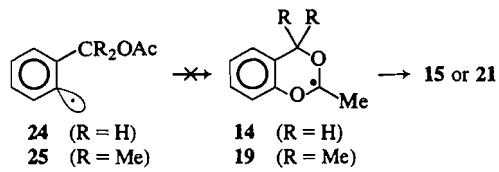


Reaction of **20** with *tert*-butoxy radicals gave the product distribution in eq. [13], as analyzed by

[13] 

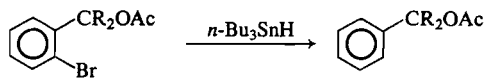
gc/ms. These products indicate that radical **21** was formed, but there is no evidence for cyclization to **19**, in agreement with the observation that **19** rearranges to **21**.

These results suggest that evidence for the formation of the radicals **14** and **19**, or their rearrangement products **15** and **21**, could be obtained if these species were indeed formed from



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

aryl radicals **24** and **25**. Furthermore, conversion of **24** and **25** to **14** and **19**, respectively, ought to be exothermic. However, treatment of the appropriate aryl halide precursors **26** and **27** with $n$-$Bu_3SnH$

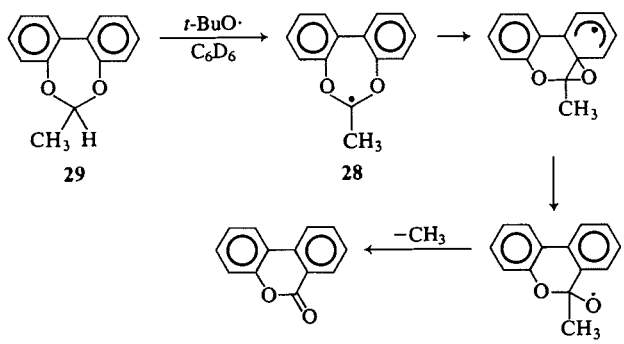


**26** (R = H), **27** (R = Me)

gave only reduction to the unrearranged acetates. Evidently rearrangements to **14** and **19** suffer from sufficiently high kinetic barriers so as not to be able to compete with direct reduction. Rate constants for this latter process are high so the aryl radicals from **26** and **27** are short lived under these conditions.

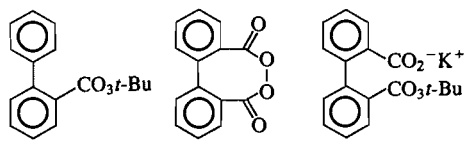
Generation of the 1,3-dioxepinyl radical **28** was also attempted by reaction of **29** with *tert*-butoxy radicals. No radical was detected by esr, but surprisingly an 85% yield of benzocoumarin (**30**) was identified in the reaction mixture by gc/ms, along with 10% recovered **29**. A reasonable mechanism for the formation of **30** is shown (eq. [14]).

[14]



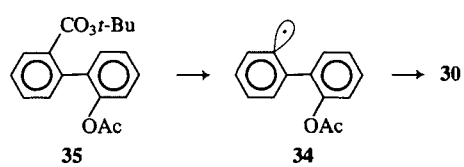
**29** **28** **30**

There is a high propensity for formation of **30** from many precursors, including **31**–**33** (10, 11), but the extensive rearrangement from **28** is certainly one of the most unusual.



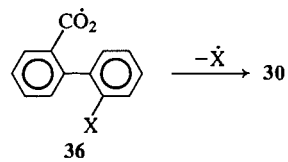
**31** **32** **33**

Radical **34** appeared as a plausible precursor to give an aryl Surzur–Tanner cyclization, and photolysis or thermolysis of the perester **35** did give a high yield of **30** analogous to the reaction of **29**. However, this result does not confirm that acetoxy cyclization has occurred. Reaction of the biphenylpercarboxylate **31** also gave a high yield of **30** (10), but apparently by a route involving homolytic aromatic substitution by an intermediate carboxy radical. Similarly 2′-substituted biphenyl-2-carboxy radicals **36**, generated from peresters or by oxidation of carboxylic acids, also gave **30** by homolytic *ipso* substitution (12).



**35** **34**

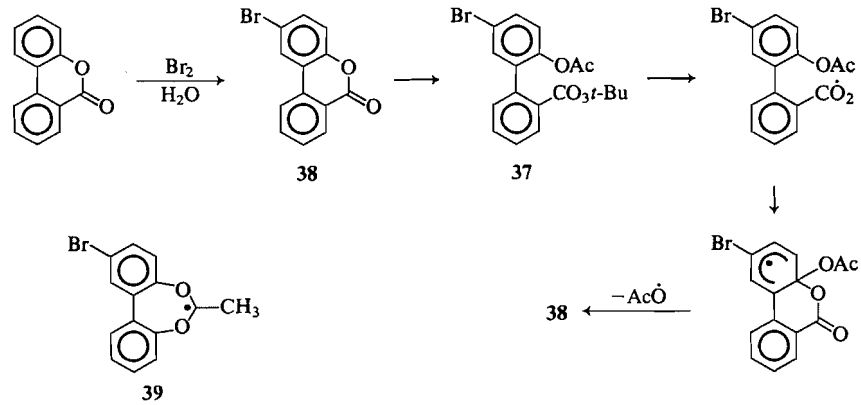
To test for the path followed by **35** the bromo analog **37** was prepared by the route shown from the lactone **38** and was found to reform this compound as the only lactonic product on decomposition. If a structure **39** analogous to **28** had been



**36**

formed then ring opening to form 2 isomeric lactones would have been expected. It may be concluded that the formation of **28** or **39** by an acetoxy cyclization has yet to be convincingly demonstrated. The mechanism of eq. [14] appears likely for the conversion of **29** to **30**, while the intervention of **28** in the conversion of **34** to **30** is possible but is not established.

In summary it is apparent that intramolecular attack on an acetoxy group by an aryl radical is an elusive process, despite the fact that it is apparently favorable thermochemically. Benzo derivatives of 1,3-dioxol-2-yl and 1,3-dioxan-2-yl radicals display some fascinating reactivity, but confirmation of



formation of these species by a rearrangement route must await further more inspired study.

## Experimental

Qualitative ir spectra were measured on a Perkin–Elmer 237 instrument. The nmr spectra were recorded on a Varian T-60 spectrometer. Elemental analyses were performed by A. G. Gygli Microanalysis Ltd., Toronto.

*Products from* tert-*butyl acetylperoxysalicylate (6)*

A solution of **6** (1.02 g, 4.0 mmol) in 10 mL benzene was heated 48 h at 100°C in a sealed tube. In separate experiments the reaction product was esterified with $CH_2N_2$ or $PhCHN_2$ and the product analyzed by vpc separation and isolation using a 1.5 m × 4 mm SE-30 column. Products were identified by their nmr spectra and, in the case of 2-acetoxybiphenyl, by its mass spectral molecular weight. Product yields (independent of the method of esterification) were phenyl acetate (10%), salicyclic acid (42%), acetylsalicyclic acid (12%), and 2-acetoxybiphenyl (36%). Methyl and benzyl esters of acetic acid were also isolated and it was found that acetylsalicyclic acid formed salicyclic acid and acetic acid under the reaction conditions.

*Reaction of 2-bromophenyl acetate* (0.43 g) with 0.4 g *n*-$Bu_3$-SnH (Aldrich) by photolysis in 5 mL ether containing 10 mg *t*-BuOO–*t*-Bu gave a product containing 35% phenyl acetate (isolated by vpc) but no **9**.

*2-Methyl-1,3-benzodioxole (9)* was originally prepared by a reported procedure (*7a*) utilizing pyrocatechol and paraldehyde but the reaction was highly irreproducible and gave low or nil yields of product. Therefore a modification of a reported (*7b*) method for preparation of acetals of *o*-dihydroxyaromatics was utilized. A solution of pyrocatechol (11.0 g, 0.10 mol), 1,1-dichloroethane (11.2 g, 0.11 mol), CuO (1.6 g), and $K_2CO_3$ (41.4 g, 0.30 mol) in 120 mL DMF was flushed with $N_2$ and heated at 125°C overnight. The mixture was cooled, poured into ice water, extracted with ether, and the ether layer was extracted once with 3% HCl, eight times with 20% $K_2CO_3$ solution, and once with water. The ether layer was dried with Drierite and evaporated and the product separated by vpc using a 1.5 m × 4 mm 10% SE-30 column at 160°C to give 2.3 g (0.017 mol, 17%) **9** with nmr ($CCl_4$) δ: 1.75 (d, 6, $J$ = 5 Hz, $CH_3$), 6.20 (q, 1, $J$ = 5 Hz, C*H*Me), 6.78 (s, 4, Ar).

*Reaction of 9 with di-*tert-*butyl peroxyoxalate (DBPO) in benzene-*$d_6$

A solution of **9** (0.2 g, 1.5 mmol) in 2 mL $C_6D_6$ with DBPO (0.5 g, 2 mmol) was degassed and sealed in a glass tube and allowed to stand at 25°C for 3 days. The mixture was separated by vpc (4 mm × 2 m 10% SE-30 column) and the products identified by nmr, **9** (40% $d_0$ and 24% $d_1$ by nmr, see Fig. 1), **10** (23%); nmr ($CDCl_3$) δ: 2.48 (s, 3, $CH_3CO$), 5.60 (broad s, 1, OH), 7.1 (m, 4, Ar). The identifications of **11***a–c* are tentative and depend on mass spectral data ($M^+$ peaks for **11***a* and **11***c*, an $M^+ - t$-Bu peak for **11***b*) and an nmr of **11***b* contaminated with **6**; nmr **11** ($CDCl_3$) δ: 1.28 (s, 9, *t*-Bu), 1.68 (s, 3, Me), 6.76 (s, 4, Ar).

*2-Methyl-1,3-benzodioxan (12)*

1,1-Dichloroethane (7.5 g, 0.074 mol) was added to a solution obtained by adding 9.3 g (0.075 mol) *o*-hydroxybenzyl alcohol (Aldrich) in 50 mL DMF to an ice-cooled mixture of 3.6 g (0.15 mol) pentane-washed NaH in 200 mL dry DMF. The resulting solution was heated overnight at 100°C, cooled, poured into ice water, and extracted with ether. The ether layer was washed repeatedly with 10% KOH solution, once with 10% HCl, dried over $MgSO_4$, and evaporated. Separation by vpc gave 0.25 g (1.7 mmol, 2%) **12**, identified by nmr ($CDCl_3$) δ: 1.54 (d, 3, $J$ = 5 Hz, $CH_3$), 4.85 (center of AB quartet of $CH_2$), 5.10 (q, 1, $J$ = 5 Hz, CHMe), 6.7–7.1 (m, 4, Ar).

*Reaction of 2-acetoxytoluene (16) with DBPO* was carried out analogously to the reaction of **9** using $C_6D_6$ as solvent. Formation of 12% **17** was indicated by gc/ms.

*2,4,4-Trimethyl-1,3-benzodioxan (18)* was prepared in 3–5% yields by the same procedure used for **12** from *o*-hydroxycumyl alcohol prepared by reacting excess MeLi in ether with *o*-hydroxyacetophenone. The product **18** was purified by vpc (1.5 mm × 4 m SE-30 at 140°C) and identified by nmr ($CDCl_3$) δ: 1.50 (d, 3, $J$ = 5 Hz, $CHCH_3$), 1.60 (s, 6, $CMe_2$), 5.16 (q, 1, $J$ = 5 Hz, $CHCH_3$), 6.7–7.3 (m, 4, Ar).

*Reaction of 18 with DBPO*

A $C_6H_6$ solution of **18** (0.18 g, 1.0 mmol) and 0.18 g DBPO (0.75 mmol) in dry benzene was sealed in an evacuated tube and let stand at 25°C for 2 days. Analysis of the product by gc/ms revealed the presence of 73% unreacted **18** and 27% *o*-acetoxycumene (**20**).

o-*Acetoxycumene 20* was prepared by reaction of 13.6 g (0.1 mol) *o*-hydroxycumene with 10 mL pyridine and 78 g (1 mol) acetyl chloride in 150 mL ether at 0°C. After one day the reaction mixture was poured into ice water, extracted with ether, and the ether layer washed with 10% HCl, 10% KOH, dried over $MgSO_4$, and evaporated. The product was identified by nmr ($CDCl_3$) δ: 1.10 (d, 6, $J$ = 7 Hz, $CH(CH_3)_2$), 2.32 (s, 3, $CH_3CO$), 3.00 (heptet, 1, $J$ = 7 Hz, $CHMe_2$), 7.0–7.4 (m, 4, Ar).

*2-Bromobenzyl acetate (26) and* n-$Bu_3SnH$

A solution of 2.3 g (10 mmol) **26** (obtained from reaction of Aldrich 2-bromobenzyl bromide and NaOAc) and 3.2 g (11 mmol) *n*-$Bu_3SnH$ (Alfa) in 8 mL benzene with 0.2 g azoisobutyronitrile was heated in a sealed tube at 90°C for 48 h. Distillation of the benzene and then the product showed benzyl acetate as the only volatile product.

*2-Chlorocumyl acetate (27)* was obtained by reaction of

*o*-chloroacetophenone with methyllithium, followed by treatment of the isolated 2-chlorocumyl alcohol with KH and acetyl chloride in ether. This was reacted with $n$-$Bu_3SnH$ as described for **26**, and gc/ms analysis of the product showed cumyl acetate as the major volatile product.

*2-Methyl dibenzo[d,f][1,3]dioxepin (29)* was prepared in 6% yield by the same procedure used for **12** from *o,o'*-biphenol (Aldrich). The material was purified by vpc separation on a 6 m SE-30 column, mp 48–49°C, and was identified by nmr ($CDCl_3$) δ: 1.62 (d, 3, $J$ = 5 Hz, $CH_3$), 5.78 (q, 1, $J$ = 5 Hz, C*H*Me), 7.0–7.8 (8, m, Ar).

*Products from 29 and DBPO*

The reaction was carried out with 70 mg (0.5 mmol) **29** and 120 mg (0.5 mmol) DBPO in 1 mL $C_6D_6$ as described for **9**.

*2-Acetoxy-2'*-tert-*butylpercarboxylbiphenyl (35)* was prepared by adding to the known (13) acid chloride of 2-acetoxy-2'-biphenylcarboxylic acid (1.37 g, 5 mmol), in 150 mL ether stirred at 0°C, a solution of 1.0 g (11 mmol) *t*-BuOOH and 1 mL pyridine in 30 mL ether. The mixture was stirred overnight, poured into water, extracted into ether, washed with 10% NaOH and then 10% HCl, dried, and the solvent evaporated. The crude product was chromatographed on a 20 cm silica gel column with 1:1 pentane/ether to give 0.52 g **35** (1.6 mmol, 32%); nmr ($CDCl_3$) δ: 1.12 (s, 9, *t*-Bu), 1.96 (s, 3, $CH_3CO$), 7.2 (m, 8, Ar).

*Products from 35*

Solutions of **35** (0.165 g, 0.5 mmol) in 2 mL of solvent were sealed in evacuated Pyrex tubes and decomposed either thermally (40 h at 110°C) or photochemically (72 h irradiation with a Hanovia medium pressure Hg lamp). The products were analyzed by gas chromatography as shown (±5%):

| | Photochemical | | Thermal |
|---|---|---|---|
| Product | Benzene | Toluene | Benzene |
| *o*-Acetoxybiphenyl | 2 | 9 | 2 |
| 2-(2'-Acetoxyphenyl)benzoic acid | 14 | 11 | 2 |
| **30** | 80 | 80 | 90 |

*2-Acetoxy-5-bromo-2'*-tert-*butylpercarboxybiphenyl (37)* was obtained by a route analogous to **35** beginning with **38** (14), which on reaction with NaOH and $Ac_2O$ gave 2-(2'-acetoxy-5'-bromophenyl)benzoic acid (mp 126–127°C), which on reaction with $SOCl_2$ followed by *t*-BuOOH/pyridine gave **37** as an oil; nmr ($CDCl_3$) δ: 1.23 (s, 9, *t*-Bu), 2.03 (s, 3, Ac), and 7.0–8.0 (m, 7, Ar). *Anal.* calcd. for $C_{19}H_{19}BrO_5$ (mol. wt. 407.27): C 56.03, H 4.70, Br 19.62; found: C 56.52, H 4.36, Br 19.46. Product studies on **37** carried out analogously to **35** gave **38** as the only lactonic product detected, as identified by nmr and mass spectroscopy.

## Appendix

The $\Delta\Delta H_f^0$ for the conversion of **4*a*** to **5*a*** at 25°C may be derived from the $\Delta H_f^0$ values for phenyl acetate (−51.4 kcal/mol) and **9** (−55.7 kcal/mol, not corrected for ring strain) calculated by the method of group equivalents (15) and the estimated C—H bond dissociation energies of phenyl acetate to form **4*a*** (110 kcal/mol) and of **9** to form **5*a*** (93 kcal/mol) (16). The latter value applies to H—$CH(OH)CH_3$ and the actual value is probably less.

# Anionic decomposition of an organic peroxide leading to *o*-xylene

FEREIDOON SHAHIDI AND THOMAS T. TIDWELL

*Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1*

Received November 6, 1981

FEREIDOON SHAHIDI and THOMAS T. TIDWELL. Can. J. Chem. **60**, 1098 (1982).

Reaction of 1,2-dimethyl-1,2-dihydrophthalic anhydride (**8**) with *t*-BuOONa at 40°C gave *o*-xylene as the only observed product. This reaction is proposed to occur through intermediacy of the anionic peroxide **10** whose conversion to *o*-xylene is calculated to be exothermic by 84 kcal/mol. Extension of this reaction to systems that do not have the possibility for gaining aromatic stabilization was unsuccessful.

FEREIDOON SHAHIDI et THOMAS T. TIDWELL. Can. J. Chem. **60**, 1098 (1982).

L'anhydride de l'acide diméthyl-1,2 dihydro-1,2 phtalique (**8**) réagit avec le *tert*-BuOONa à 40°C en donnant uniquement du *o*-xylène. On pense que cette réaction se produit par l'intermédiaire du peroxyde anionique **10** qui par la transformation en *o*-xylène libèrerait 84 kcal/mol. On a vainement tenté d'étendre cette réaction aux systèmes qui n'ont pas la possibilité d'acquérir la stabilité aromatique.

[Traduit par le journal]

The reactions of peroxides derived from 1,2-dicarboxylic acid systems have been the subject of continuing interest. Examples include reaction of di-*tert*-butylperoxy *meso*-2,3-diphenylsuccinate (**1**), which proceeds with rate limiting scission of one peroxide bond to give the benzylic radical **2**, which gives exclusive formation of *trans*-stilbene (eq. [1]) (1). This general reaction was developed as a general synthetic method for the conversion of 1,2-dicarboxylic acid systems to alkenes (eq. [2] (2).

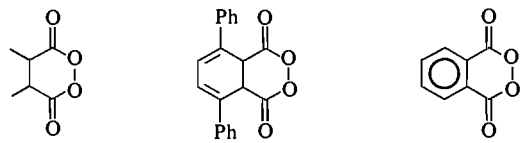
[1] 

[2] 

The aromatic analog di-*tert*-butylperoxy phthalate (**3**) was the object of careful study in our laboratory (3), and it was found that, although the free radical reactions of this substrate did not involve direct interaction between the two carboxyl groups, there was evidently a nonradical decomposition of the peroxidic intermediate **4** involved (eq. [3]) as one of the reaction paths followed.

[3] 

Related studies have dealt with cyclic diacyl peroxides **5–7** derived from 1,2-dicarboxylic acids.



**5** **6** **7**

The study of **5** and several related systems was reported by Dervan and Jones (4), who presented evidence for their thermal decomposition according to eq. [4]. Even though these reactions were

[4] 

potentially sufficiently exothermic to produce excited states of the product alkenes, the evidence indicated that this did not occur. However, in the reaction of eq. [5] the species **6** was evidently

[5] 

generated and the observation of fluorescence in the reaction indicated that the product terphenyl was formed as an excited singlet (5).

The most recent of a variety of studies of the reactivity of phthalyl peroxide (**7**) involves electron transfer from pyrene (*5b*).

The goal of the present study was to search for a case of concerted reaction of a derivative of a vicinal dicarboxylic acid system. A system of the type **6** appeared to be most appropriate, as the potential for aromatization of the ring would in-

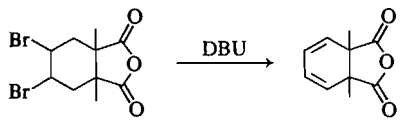
crease the exothermicity of a bisdecarboxylation. However, the presence of reactive α-hydrogens in **6** and its immediate precursors appeared undesirable because of their potential for facile isomerization to α,β-unsaturated carbonyl derivatives.

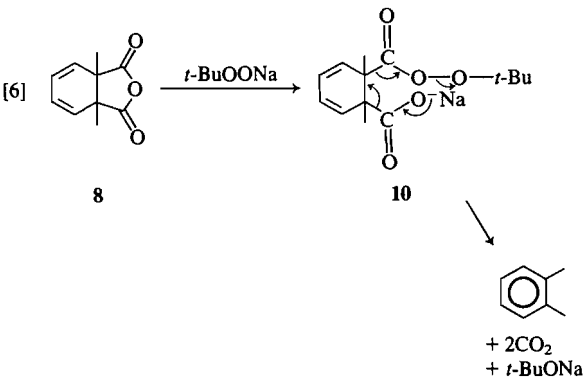
## Results and discussion

The anhydride **8**, originally prepared (6*a*) in one of two classic syntheses of cantharidin (6), was selected for study. The preparation followed the established methods, but the yield of **8** from the dibromide **9** was increased to 78% from the previously reported 11% by the use of 1,5-diazabicyclo[5.4.0]undec-5-ene (DBU) as base instead of the previously utilized trimethylamine (6*a*). The hydrolysis of **8** to the corresponding diacid was carried out by the reported procedure (6*a*) but all attempts to convert the diacid or **8** to a diacyl chloride led to isolation of only **8** in every case. Consequently preparation of a cyclic peroxide or bisperester from **8** could not be attempted.



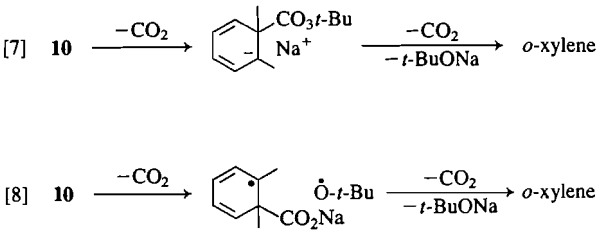
**9** **8**

Reaction of **8** with *t*-BuOONa in a mixed solvent (DME–$CH_2Cl_2$–pentane) at 40°C followed by distillation of the solvent at 60°C and vpc separation of the volatile products led to the isolation of *o*-xylene as the only product derived from **8**. Similarly reaction of **8** with *t*-BuOOK in THF-$d_8$ at 0°C and prompt observation of the nmr spectrum showed signals ascribable to *o*-xylene and *t*-BuOK as the only products. One possible route to these products is shown (eq. [6]). The method of group equivalents (7) predicts the decomposition of the conjugate acid of **10** to $2CO_2$ + *t*-BuOH to be exothermic by about 84 kcal/mol and it would appear that the reaction of eq. [6] would be equally exothermic. Other pathways for the process may be envisaged, including stepwise ionic (eq. [7]) or radical (eq. [8]) routes.

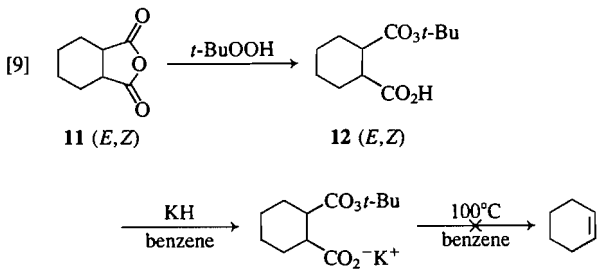


**8** **10**

The powerful driving force for the concerted pathway suggests that this route is favored. The cyclohexadienyl anion and radical formed in eqs. [7] and [8], respectively, would not appear to be sufficiently stabilized to form under these conditions.



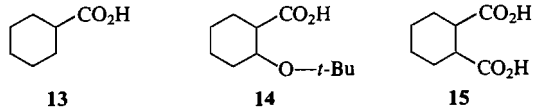
Thus our goal of observing a facile bisdecarboxylation reaction has been met, although in a rather unexpected and novel fashion. The possibility of developing a preparatively useful procedure for biscarboxylation in analogous systems that do not lead to aromatic systems occurred to us, but in several experiments (e.g., eq. [9]) this goal has not yet been realized. Variable amounts of the products **13**–**15** were identified by their nmr spectra, but the inconsistency of the yields suggested that radical-induced decompositions may have been occurring. Comparable results were obtained in benzene or toluene, with or without added KH or $Et_3N$.



**11** (*E*,*Z*) **12** (*E*,*Z*)

A semiquantitative kinetics determination for decomposition of *E*-**12** gave a rate constant of $5.3 \times 10^{-5}$ $s^{-1}$ at 98.0°C in toluene. Comparison to the value of $6.9 \times 10^{-4}$ $s^{-1}$ at 110°C reported (8) for *tert*-butyl cyclohexanepercarboxylate indicates similar rate limiting steps for these two peresters.

Other anionic decompositions of organic perox-



**13** **14** **15**

ides include the reaction of diphenic anhydride (**16**) with *t*-BuOONa yielding lactone as shown in eq. [10] (9). This reaction was proposed to involve the

[10] 

**16** **17**

intermediate **17**, but it may be noted that the reaction conditions (refluxing tetrahydrofuran) would not ordinarily be sufficient to result in homolytic reaction of a model compound such as *tert*-butyl perbenzoate.

Another reported (10) case of anionic decomposition of a peroxide is shown in eq. [11] and may be seen to be closely related to the proposal of eq. [6].

[11] $t\text{-BuOOCMe}_2\text{CO}_2^- \longrightarrow t\text{-BuO}^- + \text{O=CMe}_2 + \text{CO}_2$

## Experimental

Qualitative ir spectra were measured on a Perkin–Elmer 237 instrument. The nmr spectra were recorded on a Varian T-60 spectrometer. Elemental analyses were performed by A. B. Gygli Microanalysis Ltd., Toronto. Dimethoxyethane (DME) was freshly distilled from Na.

*1,2-Dimethyl-1,2-dihydrophthalic anhydride (**8**)*

A mixture of 1.7 g (5.0 mmol) dibromide **9** (*6b*) and 1.52 g (8.6 mmol) DBU (Aldrich) were heated 5 min at 150°C. Sublimation gave 0.69 g (3.9 mmol, 78%) of **8**, mp 64°C (lit. (*6a*) mp 63–67°C); nmr ($CDCl_3$) δ: 1.35 (s, 6, 2Me); 5.5–6.2 (m, 4, $A_2B_2$ pattern of vinyl H).

*Reaction of **8** with t-BuOONa*

A solution of 0.078 g (0.44 mmol) **8** in 5 mL $CH_2Cl_2$ and 3 mL pentane was added dropwise to a mixture of 1 mmol NaH (washed free of oil) and 1 mmol *t*-BuOOH in 15 mL dry DME. The mixture was heated 4 h at 40°C, poured into ice water, and extracted twice with ether. The combined ether layers were washed twice with 10% HCl, dried, and the solvent was distilled away below 60°C. Separation of the residue by vpc using a 3 m × 10 mm OV-17 column gave 36 mg (0.34 mmol, 77%) of *o*-xylene, identified by nmr. Reaction of **8** (1.0 mmol) in 1.0 mL THF-$d_8$ with *t*-BuOOK (1.5 mmol, from *t*-BuOOH and KH) with ice cooling, followed by prompt measurement of the nmr spectrum, gave peaks ascribable to *o*-xylene and a *tert*-butyl signal as the only reactant-derived absorptions.

*E-2-Carbo-*tert*-perbutoxy cyclohexanecarboxylic acid (E-**12**)*

*trans*-1,2-Cyclohexanedicarboxylic anhydride (7.2 g, 50 mmol, Fluka) was added over 0.5 h to a mixture of 50 mmol NaH (washed free of oil with pentane) and 50 mmol *t*-BuOOH in 100 mL dry ether. The solution was stirred 1 h at 25°C, poured into ice water, acidified with HCl, and extracted with ether. After drying and evaporation of solvent there was obtained 9.3 g (38 mmol, 76%) of *E*-**12** which was recrystallized from $CHCl_3$/pentane (10:1), mp 114–116°C (resolidification and remelting at 225–229°C); ir (toluene): 1710 $cm^{-1}$ (C=O of $CO_2H$), 1775 (C=O of $CO_3$-*t*-Bu) $cm^{-1}$; nmr ($CDCl_3$) δ: 1.30 (s, 9, *t*-Bu), 1.4–2.2 (m, 8, $(CH_2)_4$), 2.7 (m, 2, 2 methine H), 10 (broad s, 1, $CO_2H$). *Anal.* calcd. for $C_{12}H_{20}O_5$ (244.29): C 59.00, H 8.25; found: C 58.77, H 8.18.

*Z-2-Carbo-*tert*-perbutoxy cyclohexanecarboxylic acid (Z-**12**)*

This isomer was prepared in the same way as the *E*-isomer from the *Z* anhydride (Aldrich) and recrystallized from $CHCl_3$, mp 196–198°C; ir ($CHCl_3$): 1710 (C=O of $CO_2H$), 1765 (C=O of $CO_3$-*t*-Bu) $cm^{-1}$. nmr ($CDCl_3$) δ: 1.30 (s, 9, *t*-Bu), 1.4–2.0 (m, 8, $(CH_2)_4$), 3.0 (m, 2, 2 methine H), 8.5 (broad s, 1, $CO_2H$). *Anal.* calcd. for $C_{12}H_{20}O_5$ (244.29): C 59.00, H 8.25; found: C 59.18, H 8.26.

*Product studies from* E-**12** *and* Z-**12**

The perester (0.6 g, 2.5 mmol) was dissolved in 10 mL solvent, sealed in a glass tube, and heated at 100°C for 24 h. The product was esterified with $CH_2N_2$ and analyzed by vpc with a 5 m × 3 mm Carbowax column at 130°C and 60 mL/min He flow. Products were isolated and identified by their nmr spectra and mass spectral molecular weights. Authentic samples of the methyl esters of cyclohexanecarboxylic acid and the 1,2-cyclohexanedicarboxylic acids were prepared for comparison. An authentic sample of methyl 2-*tert*-butoxycyclohexanecarboxylate was not available so this identification must be regarded as tentative. The nmr spectrum ($CDCl_3$) of this material from either *E*- or *Z*-**12** showed pairs of closely spaced sharp singlets at δ 1.15 and 3.65 attributable to the *t*-BuO and MeO groups, respectively, of an *E*/*Z* mixture of products from either source.

*Kinetics of decomposition of* E-**12**

Ampules of a 0.064 *M* solution of the perester were removed at intervals from a constant temperature bath at 98.0°C and the disappearance of the perester band at 1775 $cm^{-1}$ was monitored as a function of time using a Perkin–Elmer 180 spectrophotometer. A single run was performed, which gave good first order kinetics ($r = 0.999$).

# Ring opening reactions of *N*-substituted-5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxamides

MARSHALL KULKA AND W. A. HARRISON
*Uniroyal Limited, Research Laboratories, Guelph, Ont., Canada N1H 6N3*
Received November 2, 1981

MARSHALL KULKA and W. A. HARRISON. Can. J. Chem. **60**, 1101 (1982).

The amides prepared from 5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl chloride **2** and imidamides **4**, carbamimidothioates **4**, 2-benzimidazolamine **7**, 2-benzothiazolamine **12**, and 2-thiazolamine have been studied. The reaction of **2** with imidamides **4** and with carbamimidothioates **4** in the presence of base gave the amides **5**, which when heated in toluene underwent the 1,4-oxathiin ring opening and rearrangement to produce 2-substituted-5-[(2-hydroxyethyl)thio]-6-methyl-4(1*H*)-pyrimidinones **6**. Acylation of 2-benzimidazolamine **7** with **2** yielded the amide **10**. This, in boiling ethanol, ring opened and rearranged to give the compound **11**. The reaction of 2-benzothiazolamine **12** with **2** gave the rearrangement product **14** directly and neither of the possible amides **13** and **15** could be detected. The amide **15** was synthesized by an unambiguous route from 2-aminobenzenethiol and 5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl isothiocyanate **3**. It would not undergo ring opening and rearrangement when heated. Acylation of 2-thiazolamine with **2** yielded a mixture from which the amide **19** and the rearrangement ester **18** were separated. Structural assignments are based mainly on nmr, uv, and ir spectral evidence.

MARSHALL KULKA et W. A. HARRISON. Can. J. Chem. **60**, 1101 (1982).

On a étudié les amides préparés à partir du chlorure de dihydro-5,6 méthyl-2 oxathiine-1,4 carbonyle-3 (**2**) et des imidamides **4**, des carbamimidothioates **4**, de la benzimidazolamine-2 (**7**), du benzothiazolamine-2 (**12**) et de la thiazolamine-2. Le composé **2** réagit avec les imidamides **4** et avec les carbamimidothioates **4** en milieu basique en donnant les amides **5**, qui par chauffage dans le toluène, subissent une ouverture du cycle oxathium-1,4 et se transposent en donnant les [(hydroxéthyl-2) thio]-5 méthyl-6 (1*H*)-pyrimidinones-4 (**6**) substitués en position 5. L'acylation de la benzimidazolamine-2 (**7**) avec le composé **2** donne l'amide **10**. Ce dernier dans l'éthanol bouillant subit une ouverture de cycle et une transposition qui conduisent au composé **11**. La benzo-2 thiazolamine **12** réagit avec le composé **2** en donnant le produit de transposition **14** directement et on n'a pas pu déceler les amides **13** et **15** qu'il serait possible d'obtenir. On a synthétisé l'amide **15** selon une méthode non équivoque à partir de l'amino-2 benzènethiol et de l'isothiocyanate de dihydro-5,6 méthyl-2 oxathiine-1,4 carbonyle **3**. Le chauffage de ce composé ne provoque pas d'ouverture de cycle ni de transposition. L'acylation de la thiazolamine-2 avec le composé **2** donne un mélange à partir duquel on isole l'amide **19** et l'ester **18** résultant d'une transposition. On a attribué les structures en s'appuyant principalement sur les spectres de rmn, uv et ir.
[Traduit par le journal]

The discovery in 1966 (1) of the systemic fungicides 5,6-dihydro-2-methyl-*N*-phenyl-1,4-oxathiin-3-carboxamide (VITAVAX®) and its 4,4-dioxide (PLANTVAX®),[1] now used throughout the world to control fungal plant pathogens, has created a great deal of interest in the biological activity and the chemistry of 1,4-oxathiins.

Publications (2, 3) from this laboratory record studies of ring opening reactions of *N*-substituted-5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxamides of the type **1** where X = O and Y = NHR (2), where X = S and Y = NHR (3), and where —C(=X)Y equals 2-pyridyl and 2-pyrimidinyl. In each case, the ring-opening reaction takes place through an attack at the 2-position of the 1,4-oxathiin ring by the nitrogen function followed by rearrangement to form 4(1*H*)-pyrimidinone derivatives.

This paper describes the ring-opening and rearrangement reactions of *N*-substituted-5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxamides of the type **1** where X = NH and Y = alkyl, aryl, alkylthio, and aralkylthio and where —C(=X)Y is 2-benzimidazolyl, 2-benzothiazolyl, and 2-thiazolyl.

Acylation of 2,2,2-trichloroethanimidamide (**4**, Y = $CCl_3$) with 5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl chloride (**2**) in the presence of triethylamine gave the amide **5** (Y = $CCl_3$) in 80% yield. When the amide **5** (Y = $CCl_3$) was dissolved in toluene and the solution heated under reflux, the 1,4-oxathiin ring opening and rearrangement occurred to form 5-[(2-hydroxyethyl)thio]-6-methyl-2-(trichloromethyl)-4(1*H*)-pyrimidinone (**6**, Y = $CCl_3$). The amides **5** prepared from **2** and the hydrochlorides of benzeneethanimidamide (**4**, Y = phenylmethyl), benzenemethanimidamide (**4**, Y = phenyl), ethanimidamide (**4**, Y = methyl), and butanimidamide (**4**, Y = propyl) in the presence of aqueous sodium hydroxide were sensitive to heat and no attempts were made to purify them. Instead the crude products were heated in toluene to form the 4(1*H*)-pyrimidinones **6** where Y = phenylmethyl, phenyl, methyl, and propyl respectively. The structural assignments were based on the elemental analysis and on the ir and nmr spectra. It

is believed that the compounds **5** exist predominantly in the amino form (RCON=C($NH_2$)Y) in view of the fact that their uv spectra are similar to that of *N*-(1-aminoethylidene)benzamide (**5**, R = phenyl, Y = methyl) which exists in the amino form (4).

5,6-Dihydro-*N*[[(2-chlorophenyl)methylthio]-aminomethylene]-2-methyl-1,4-oxathiin-3-carboxamide (**5**, Y = 2-chlorophenylmethylthio), prepared from **2** and the hydrochloride of 2-chlorophenylmethyl carbamimidothioate (**4**, Y = 2-chlorophenylmethylthio), appeared to be stable and could be recrystallized from boiling methanol. However, when it was heated on the steam bath in toluene it quickly underwent the ring-opening and rearrangement reaction to form the 4(1*H*)-pyrimidinone **6** (Y = 2-chlorophenylmethylthio). Similarly, six other amides **5** (Y = 4-chlorophenylmethylthio, phenylmethylthio, 4-nitrophenylmethylthio, 4-methoxy-3-nitrophenylmethylthio, 1-(2,5-dimethylphenyl)-ethylthio, and 2-methyl-2-propenylthio) were prepared and rearranged to the corresponding **6**. An attempt to rearrange 5,6-dihydro-2-methyl-*N*-[[(1-methylethyl)thio]aminomethylene]-1,4-oxathiin-3-carboxamide (**5**, Y = 1-methylethylthio) to the corresponding 4(1*H*)-pyrimidinone **6** was not successful.

The tautomeric forms of 2-benzimidazolamine (**7**) on acylation with **2** could lead to two amides **8** and **10**, which might undergo the 1,4-oxathiin ring opening and rearrangement to yield the pyrimidinones **9** and **11** respectively. Actually, when 2-benzimidazolamine (**7**) was treated with **2** in the presence of triethylamine only one compound could be isolated (in 70% yield). To this compound was assigned the structure **10**, not **8**, on the basis of the following evidence. In boiling ethanol it quickly changed to a less soluble compound to which the rearrangement structure **11** was assigned. This assignment is based on the fact that the aromatic proton in the 6 position of the nmr spectrum shows a shift of almost 1 ppm downfield from the other aromatic protons. This shift is attributed to the deshielding effect of the 6-proton by the keto group of the 4-pyrimidinone **11**, whereas a similar effect is not possible in the 2-pyrimidinone **9**, which might arise from the amide **8**. The assignments of the structure **11** to the rearrangement product and the structure **10** to the intermediate amide are in agreement with previous assignments (2) to the rearrangement product and its intermediate amide from 2-pyridinamine and **2**.

The reaction of 2-benzothiazolamine (**12**) with **2** yielded only one compound to which the rearrangement structure **14** was assigned on the basis of ir and nmr spectra. Neither of the intermediate amides **13** and **15** could be detected. However, the amide **15** was prepared by an unambiguous route from 2-aminobenzenethiol and 5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl isothiocyanate **3** (3) and this amide (**15**) would not undergo rearrange-

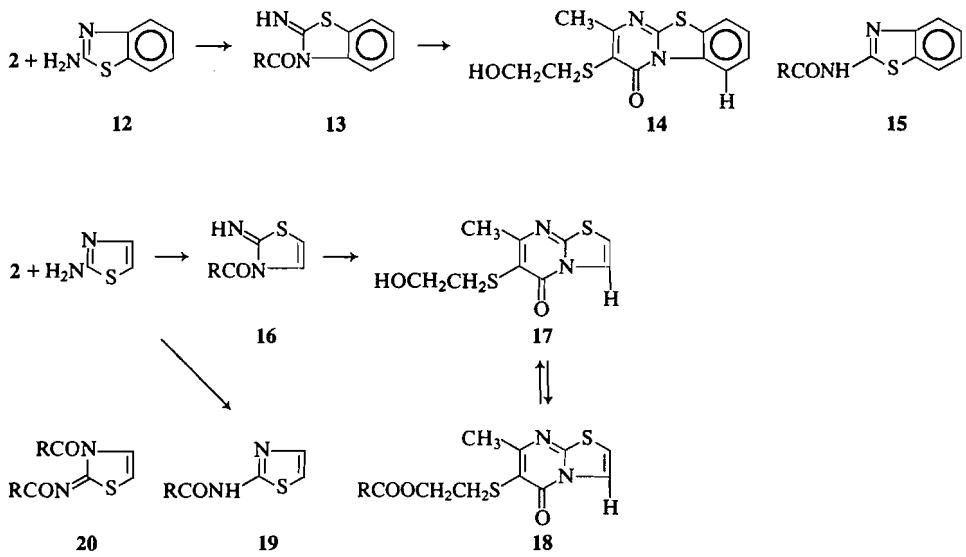
For personal use only.



ment even on prolonged heating on the steam bath in toluene in the presence of triethylamine or its hydrochloride. Therefore the amide **15** could not have been the intermediate in the formation of **14**. Further support for the structure **14** comes from the nmr spectra. The aromatic 6-proton is shifted by 1.5 ppm downfield from the other aromatic protons. This is attributed to the deshielding effect by the keto group in the 4-pyrimidinone **14**. A similar effect is not possible in a 2-pyrimidinone structure that might arise from the amide **15**.

The reaction of 2-thiazolamine with the acid chloride **2** was more involved because of the unexpected esterification in addition to the rearrangement reaction. When 2-thiazolamine was treated with **2**, a mixture of two compounds was obtained which was separated by fractional recrystallization from methanol. The more soluble compound was identified as the amide **19** (5, 6) by nmr spectrum, elemental analysis, and by the fact that it was stable and would not rearrange on heating. The less soluble component of the mixture was identified as the ester **18** by elemental analysis, nmr and ir spectra, and by its hydrolysis to the alcohol **17**. The nmr spectra exhibited the aromatic 3-proton shift downfield due to the deshielding of the keto group in not only the ester **18** but also in its hydrolysis product **17**. In another experiment, when 2-thiazolamine was treated with two moles of the acid chloride **2** (instead of one), a 70% yield of the ester **18** was obtained and none of the amide **19** could be isolated. The possibility of the reaction product of 2-thiazolamine and **2** being the bisamide **20** and not the ester **18** was eliminated by evidence from hydrolysis and esterification experiments. Hydrolysis of the ester **18** gave the alcohol **17** which on treatment with **2** gave back the ester **18**. While it is possible that hydrolysis of the bisamide **20** could lead to the alcohol **17** via a rearrangement reaction, the esterification of the alcohol **17** could only lead to the ester **18** and not to the bisamide **20**.

## Experimental

The ir spectra were obtained on Perkin–Elmer 237B or 521 grating spectrometers. The nmr spectra were recorded using an R-20 Hitachi Perkin–Elmer spectrometer and are expressed in ppm (δ values) relative to tetramethylsilane as standard. The uv spectra were obtained on a Varian model G34 spectrophotometer. Melting points were determined on a Gallenkamp melting point apparatus and are uncorrected. The elemental analyses were performed on a Perkin–Elmer 240 elemental analyzer.

*5,6-Dihydro-2-methyl-*N*-(2,2,2-trichloro-1-aminoethylidene)-1,4-oxathiin-3-carboxamide (**5**, Y = $CCl_3$)*

To a solution of 5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl chloride (**2**) (2) (prepared from 12 g of the corresponding acid) in toluene (100 mL) was added triethylamine (10 g) followed by 2,2,2-trichloroethanimidamide (**4**, Y = $CCl_3$) (12 g) in toluene (50 mL) keeping the temperature of the reaction mixture below 50°C by cooling occasionally. The reaction mixture was allowed to stand overnight and then the triethylamine hydrochloride was filtered off. The filtrate was concentrated *in vacuo* below 50°C to about 50 mL and allowed to cool. The yellow prisms were filtered, washed, and dried, mp 122–124°C, yield 18.1 g or 80%. The melting point was 125–126°C after recrystallization from methanol; uv ($CH_3OH$) $\lambda_{max}$: 212, 277 nm (ε 7018, 4021); ir (KBr): 3400, 3180, 1640 $cm^{-1}$; nmr ($CDCl_3$) (after standing in $CDCl_3$ solution for 24 h at 34°C): 8.5 (2H, m, $NH_2$), 4.35 (2H, m, $OCH_2$), 2.98 (2H, m, $SCH_2$), 2.50 (3H, m, $CH_3$) (a tautomeric mixture is indicated in a fresh solution). *Anal.* calcd. for $C_8H_9Cl_3N_2O_2S$: C 31.64, H 2.97, N 9.19; found: C 31.78, H 2.92, N 9.22.

*5-[(2-Hydroxyethyl)thio]-6-methyl-2-(trichloromethyl)-4(1*H*)-pyrimidinone (**6**, Y = $CCl_3$)*

A solution of 5,6-dihydro-2-methyl-*N*-(2,2,2-trichloro-1-

aminoethylidene)-1,4-oxathiin-3-carboxamide (**5**, Y = $CCl_3$) (8 g) in toluene (50 mL) was heated under reflux for 3 h and then allowed to cool overnight. The white prisms were filtered, washed, and recrystallized from toluene, mp 161–162°C, yield 4.5 g or 56%; nmr (DMSO-$d_6$): 3.55 (2H, m, $OCH_2$), 3.05 (2H, m, $SCH_2$), 2.68 (3H, s, $CH_3$), OH and NH broad. *Anal.* calcd. for $C_8H_9Cl_3N_2O_2S$: C 31.64, H 2.98, N 9.22; found: C 31.91, H 3.01, N 9.17.

*5-[(2-Hydroxyethyl)thio]-6-methyl-2-phenylmethyl-4(1H)-pyrimidinone (**6**, Y = phenylmethyl)*

To a stirred suspension of benzeneethanimidamide (**4**, Y = phenylmethyl) hydrochloride (12 g) in acetone (150 mL) was added portionwise with cooling (below 20°C) a solution of sodium hydroxide (5 g) in water (10 mL). To this reaction mixture was added portionwise with stirring and cooling a solution of the acid chloride **2** (2) (prepared from 10 g of the corresponding acid) in acetone (40 mL) keeping the temperature below 20°C. The reaction mixture was stirred overnight, filtered, and the filtrate distilled *in vacuo*. The residue was extracted with ether, the extract washed with aqueous sodium bicarbonate, and the ether distilled off. The liquid residue was heated on the steam bath for 1 h. The resulting solid product was extracted with dilute hydrochloric acid, the extract filtered, and the filtrate neutralized with solid sodium bicarbonate. The white precipitate was filtered, washed with water, and crystallized from methanol to yield 8.5 g (or 50%) of white crystals melting at 179–180°C; ir (KBr): 3260, 1663 $cm^{-1}$; nmr (DMSO-$d_6$): 7.32 (5H, s, aromatic), 3.86 (2H, s, $CH_2$), 3.46 (2H, m, $OCH_2$), 2.90 (2H, m, $SCH_2$), 2.43 (3H, s, $CH_3$), OH and NH broad. *Anal.* calcd. for $C_{14}H_{16}N_2O_2S$: C 60.86, H 5.84, N 10.14; found: C 60.98, H 5.82, N 10.02.

*5,6-Dihydro-N-[[(2-chlorophenyl)methylthio]aminomethylene]-2-methyl-1,4-oxathiin-3-carboxamide (**5**, Y = 2-chlorophenylmethylthio)*

Solid 2-chlorophenylmethyl carbamimidothioate (**4**, Y = 2-chlorophenylmethylthio) hydrochloride (34 g) was added in portions over 0.5 h to a stirred and ice-cooled (3 to 5°C) solution of the acid chloride **2** (prepared from 22 g of the corresponding acid) in dry toluene (200 mL) and triethylamine (35 g). The stirring was continued at 3 to 5°C for 2 h and then at room temperature overnight. The precipitated triethylamine hydrochloride was filtered and the solvent removed from the filtrate *in vacuo* at room temperature. The residue was dissolved in ether, the solution washed with water, and the ether distilled off. The residue was crystallized from methanol to give light-yellow prisms (28 g or 60%) melting at 105–106°C; uv ($CH_3OH$) $\lambda_{max}$: 215, 268 nm (ε 16 825, 14 085); ir (KBr): 3330, 3240, 1610 $cm^{-1}$; nmr ($CDCl_3$): 8.05 (2H, s, $NH_2$), 7.70 (H, m, aromatic), 7.30 (3H, m, aromatic), 4.60 (2H, s, $SCH_2$), 4.33 (2H, m, $OCH_2$), 2.95 (2H, m, $SCH_2$), 2.40 (3H, s, $CH_3$). *Anal.* calcd. for $C_{14}H_{15}ClN_2O_2S_2$: C 49.04, H 4.41, N 8.16; found: C 49.01, H 4.30, N 8.43.

*Other N-[(substituted)-aminomethylene]-5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxamides* prepared, for which analysis, yields, and nmr spectra are available from the Depository of Unpublished Data[2] are **5** where Y = phenylmethylthio, mp 79–80°C; Y = 4-chlorophenylmethylthio, mp 120–121°C; Y = 4-nitrophenylmethylthio, mp 131–133°C; Y = 4-methoxy-3-nitrophenylmethylthio, mp 105–107°C; Y = α,2,5-trimethylphenylmethylthio, mp 109–110°C; Y = 2-methyl-2-propenylthio, liquid, and Y = 1-methylethylthio, mp 101–103°C.

[2]Photocopies may be obtained at a nominal charge upon request from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

*2-[(2-Chlorophenyl)methylthio]-5-[(2-hydroxyethyl)thio]-6-methyl-4(1H)-pyrimidinone (**6**, Y = 2-chlorophenyl)-methylthio)*

A solution of 5,6-dihydro-*N*-[[(2-chlorophenyl]methylthio]-aminomethylene]-2-methyl-1,4-oxathiin-3-carboxamide (**5**, Y = (2-chlorophenyl)methylthio) (16 g) in toluene (12 mL) was heated on the steam bath for 3 h and then allowed to cool. The white solid was filtered and recrystallized from toluene, mp 134–136°C, yield 10 g or 63%; nmr (DMSO-$d_6$): 7.50 (4H, m, aromatic), 4.50 (2H, s, $SCH_2$), 3.50 (2H, m, $OCH_2$), 2.90 (2H, m, $SCH_2$), 2.52 (3H, s, $CH_3$), OH and NH broad. *Anal.* calcd. for $C_{14}H_{15}ClN_2O_2S_2$: C 49.04, H 4.41, N 8.16; found: C 49.01, H 4.32, N 8.55.

*Other 2-Substituted-5-[(2-hydroxyethyl)thio]-6-methyl-4(1H)-pyrimidinones* prepared for which analysis, yields, and nmr spectra are available from the Depository of Unpublished Data[2] are **6** where Y = phenyl, mp 221–223°C; Y = methyl, mp 151–153°C; Y = propyl, mp 141–143°C; Y = phenylmethylthio, mp 144–145°C; Y = 4-chlorophenylmethylthio, mp 172–173°C; Y = 4-nitrophenylmethylthio, mp 187–189°C; Y = 4-methoxy-3-nitrophenylmethylthio, mp 183–184°C; Y = α,2,5-trimethylphenylmethylthio, mp 148–150°C; and Y = 2-methyl-2-propenylthio, mp 128–130°C.

*2,3-Dihydro-3-(5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl)-1H-benzimidazol-2-imine (**10**, R = 5,6-dihydro-2-methyl-1,4-oxathiin-3-yl)*

To a solution of 2-benzimidazolamine (**7**) (6.7 g) in dry acetone (150 mL) and triethylamine (7 g) was added portionwise with stirring a solution of the acid chloride, **2** (prepared from 8.5 g of the corresponding acid), in acetone (25 mL), keeping the temperature below 35°C by occasional cooling. The reaction mixture was stirred for 5 h, cooled to −5°C, filtered, washed with cold acetone and with water, and dried. The white solid weighed 9.7 g (or 70%) and melted at 245–247° dec. Infrared (KBr): 3420, 3100, 1680 $cm^{-1}$; nmr (DMSO-$d_6$): 7.15 (4H, m, aromatic); 4.48 (2H, m, $OCH_2$); 3.18 (2H, m, $SCH_2$), 1.86 (3H, s, $CH_3$), 2NH broad. *Anal.* calcd. for $C_{13}H_{13}N_3O_2S$: C 56.72, H 4.76, N 15.27; found: C 56.61, H 5.13, N 14.95.

*3-[(2-Hydroxyethyl)thio]-2-methylpyrimido[1,2-a]benzimidazol-4(10H)-one (**11**)*

A solution of 2,3-dihydro-3-(5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl)-(1*H*)-benzimidazol-2-imine (**10**) (10 g) in 95% ethanol (120 mL) was heated under reflux for 2 h (precipitation began soon after the heating started). The mixture was cooled, filtered, washed, and dried. The white solid (8.5 g or 85%) melted at 254–255° dec. Infrared (KBr): 3400, 1675 $cm^{-1}$; nmr (DMSO-$d_6$): 8.43 (1H, m, aromatic), 7.45 (3H, m, aromatic), 3.55 (2H, m, $OCH_2$), 2.86 (2H, m, $SCH_2$), 2.62 (3H, s, $CH_3$), NH and OH broad. *Anal.* calcd. for $C_{13}H_{13}N_3O_2S$: C 56.72, H 4.76, N 15.27; found: C 57.30, H 4.90, N 14.80.

*3-[(2-Hydroxyethyl)thio]-2-methyl-4H-pyrimido[2,1-b]benzothiazol-4-one (**14**)*

A solution of the acid chloride, **2** (prepared from 12 g of the corresponding acid), in toluene (50 mL) was added to a solution of 2-benzothiazolamine (**12**) (10 g) in toluene (100 mL) and triethylamine (12 g). The temperature went up to 45°C. The reaction mixture was allowed to stand overnight. The precipitate was filtered, washed with methanol, with warm water and with methanol, and dried, mp 144–145°C after recrystallization from ethanol, yield 10 g or 45%. The same results were obtained when the reaction was carried out at 0°C. Infrared (KBr): 3425, 1675 $cm^{-1}$; nmr ($CDCl_3$): 9.05 (H, m, aromatic), 7.55 (3H, m, aromatic), 3.70 (3H, m, $OCH_2$ and OH), 2.98 (2H, m, $SCH_2$), 2.70 (3H, s, $CH_3$); *Anal.* calcd. for $C_{13}H_{12}N_2O_2S_2$: C 53.43, H 4.14, N 9.59; found: C 53.34, H 4.23, N 9.45.

*N-(2-Benzothiazolyl)-5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxamide (**15**)*

To a solution of 5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl isothiocyanate (**3**) (3) (prepared from 12 g of the corresponding acid via the acid chloride **2** and ammonium thiocyanate) in dry toluene (100 mL) was added a solution of 2-aminobenzenethiol (9.5 g) in toluene (15 mL). The reaction mixture was heated at 70–80°C for 4 h to liberate the hydrogen sulfide, then concentrated *in vacuo* to about 60 mL and allowed to cool. The precipitate was filtered and recrystallized from ethanol, golden prisms, mp 173–175°C, yield 11.1 g or 50%; nmr ($CDCl_3$): 9.75 (H, m, NH), 7.82 (2H, m, aromatic), 7.35 (2H, m, aromatic), 4.40 (2H, m, $OCH_2$), 2.90 (2H, m, $SCH_2$), 2.36 (3H, s, $CH_3$). This compound remained unchanged when heated in toluene on the steam bath for 3 h in the presence of triethylamine or triethylamine hydrochloride. *Anal.* calcd. for $C_{13}H_{12}N_2O_2S_2$: C 53.43, H 4.14, N 9.59; found: C 53.19, H 4.17, N 9.50.

*5,6-Dihydro-2-methyl-N-(2-thiazolyl)-1,4-oxathiin-3-carboxamide (**19**) and 2-[(7-methyl-5-oxo-5H-thiazolo[3,2-a]pyrimidin-6-yl)thio]ethyl-5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxylate (**18**)*

A solution of the acid chloride (**2**) (prepared from 12 g of the corresponding acid) in toluene (30 mL) was added portionwise to a solution of 2-thiazolamine (8 g) in toluene (120 mL) and triethylamine (15 g), keeping the temperature below 50°C by occasional cooling. The reaction mixture was allowed to stand at room temperature for 2 days and then filtered. The filtrate was taken to "dryness" *in vacuo* and the residue fractionally crystallized from methanol. The more soluble component (2.8 g) melted at 120–122°C after repeated crystallization from toluene (lit. (5) mp 96–98°C and (6) 114–116°C). Infrared (KBr): 3120, 1655 $cm^{-1}$; nmr ($CDCl_3$): 10.95 (1H, s, NH), 7.45 (1H, m, aromatic), 6.98 (1H, m, aromatic), 4.42 (2H, m, $OCH_2$), 2.98 (2H, m, $SCH_2$), 2.25 (3H, s, $CH_3$). This compound remained unchanged when heated under reflux in toluene in the presence of triethylamine or its hydrochloride. *Anal.* calcd. for $C_9H_{10}N_2O_2S_2$: C 44.63, H 4.16, N 11.57; found: C 44.85, H 4.23, N 11.09.

The less soluble component of the above mixture on recrystallization from methanol and from toluene yielded (1.7 g) the pure ester **18** melting at 140–141°C. In another experiment, when 2-thiazolamine was treated with 2 moles of the acid chloride **2** as above instead of one mole, a 70% yield of the ester **18** was obtained (about half the ester precipitated out of the reaction mixture along with triethylamine hydrochloride). No amide **19** could be found. Infrared (KBr): 1690, 1675 $cm^{-1}$; nmr ($CDCl_3$): 8.00 (1H, m, aromatic), 7.12 (1H, m, aromatic), 4.30 (4H, m, $2OCH_2$), 3.25 (2H, m, $SCH_2$), 2.90 (2H, m, $SCH_2$), 2.68 (3H, s, $CH_3$), 2.30 (3H, s, $CH_3$). *Anal.* calcd. for $C_{15}H_{16}N_2O_4S_3$: C 46.88, H 4.20, N 7.29; found: C 46.74, H 4.26, N 7.30.

*6-[(2-Hydroxyethyl)thio]-7-methyl-5H-thiazolo[3,2-a]pyrimidin-5-one (**17**)*

The ester **18** (10 g) was dissolved in boiling ethanol (200 mL), concentrated hydrochloric acid (25 mL) in water (110 mL) added, and the reaction mixture was heated one hour on the steam bath. Concentration of the reaction mixture to 50 mL, *in vacuo*, neutralization with sodium bicarbonate, and extraction with ether yielded 5 g of white crystals melting at 89–91°C after recrystallization from toluene. Infrared (KBr): 3410, 3065, 1650 $cm^{-1}$; nmr ($CDCl_3$): 8.00 (1H, d, aromatic), 7.25 (1H, d, aromatic), 4.20 (1H, m, OH), 3.68 (2H, m, $OCH_2$), 2.95 (2H, m, $SCH_2$), 2.70 (3H, s, $CH_3$). *Anal.* calcd. for $C_9H_{10}N_2O_2S_2$: C 44.63, H 4.16, N 11.57; found: C 44.69, H 4.09, N 11.58.

This compound (**17**), when treated with the acid chloride **2** and triethylamine, regenerated the ester **18**.

# New catalysts and procedures for the dimethoxytritylation and selective silylation of ribonucleosides[1]

GHOLAM H. HAKIMELAHI, ZBIGNIEW A. PROBA, AND KELVIN K. OGILVIE[2]

*Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6*

Received December 2, 1981

GHOLAM H. HAKIMELAHI, ZBIGNIEW A. PROBA, and KELVIN K. OGILVIE. Can. J. Chem. **60**, 1106 (1982).

Procedures have been developed for the selective formation of (a) 2′,5′-silylated ribonucleosides and (b) 3′,5′-silylated ribonucleosides. These procedures also permit the selective silylation at either the 2′- or 3′-position of dimethoxytritylated ribonucleosides. The procedures involve nitrate or perchlorate ion catalysis for selective reaction at 2′-positions and a combination of silver ion and DABCO or 4-nitropyridine *N*-oxide for selective reaction at the 3′-position. During the course of this work a general and rapid procedure was developed for the preparation and isolation of the 5′-dimethoxytrityl derivatives of the four common ribonucleosides. Silver ion was found to have a marked effect on dimethoxytritylation reactions.

GHOLAM H. HAKIMELAHI, ZBIGNIEW A. PROBA et KELVIN K. OGILVIE. Can. J. Chem. **60**, 1106 (1982).

On a mis au point des méthodes de formation sélective des ribonucléosides silylés en positions 2′ et 5′ et des ribonucléosides silylés en positions 3′ et 5′. Ces méthodes permettent également la silylation sélective en positions 2′ ou 3′ des ribonucléosides diméthoxytritylés. Les méthodes impliquent une catalyse par l'ion nitrate ou l'ion perchlorate pour la réaction sélective en position 2′ et une combinaison de l'ion argent et du DABCO ou du *N*-oxyde de nitro-4 pyridine pour la réaction sélective en position 3′. On a développé, au cours de ce travail, une méthode rapide générale de préparation et de séparation des dérivés diméthoxytrityl-5′ des quatres ribonucléosides ordinaires. On a trouvé que l'ion argent a un effet marqué sur les réactions de diméthoxytritylation.

## Introduction

Progress in the chemical synthesis of oligodeoxynucleotides has culminated in the development of automated procedures for the synthesis of gene fragments (1). This success in the deoxy area is due principally to the early establishment of adequate and versatile protecting groups for the amino, hydroxyl, and phosphate functions of the growing chains (2). With the protecting group problem out of the way, successive developments in condensation procedures (3–6) have led to automation of the synthesis using a solid-support procedure.

Ribonucleotides have posed a more difficult challenge in terms of protecting groups. The presence of the 2′-hydroxyl group in ribonucleosides not only requires protection but places serious limitations on the nature of the protecting groups used. During the last few years we have been refining a new approach to the total synthesis of ribonucleotides (7). The approach is based on our development of the alkylsilyl protecting groups for the 2′-position of ribonucleosides (8). During this developmental stage we have used monomethoxytrityl protection of 5′-hydroxyl groups and trichloroethyl protection of phosphates. Amino groups have either been protected with benzoyl groups or left unprotected. Condensations have been effected using the "phosphite–triester" approach. We have recently adapted these developments to a solid-support procedure (*7a*) for ribonucleotide synthesis.

The procedures developed for the synthesis of ribonucleotides possessing the 3′–5′ phosphate bridge have been extended to 2′–5′ linked nucleotides (9). These molecules are of considerable interest because of the implication of 2′–5′ linked oligoadenylates in the interferon process (10). Thus the ready availability of 3′,5′-diprotected ribonucleosides is of importance.

At this stage in the development of a total procedure for ribonucleotide synthesis it became essential to reduce to a minimum the time involved in protection–deprotection of nucleosides and nucleotides. In terms of deprotection of nucleotides we wished to take advantage of the 10-fold reduction in time required to remove a dimethoxytrityl group compared to a monomethoxytrityl group. We also sought to speed up the rate of tritylation and silylation of ribonucleosides and to increase the selectivity of 2′ vs. 3′-silylation. In this report we describe: (1) procedures for the rapid and efficient dimethoxytritylation of ribonucleosides; (2) procedures for the rapid and highly selective 2′-silylation of ribonucleosides, and (3) procedures for the rapid and highly selective 3′-silylation of ribonucleosides.

## Discussion

### *Dimethoxytritylation*

The general procedures for dimethoxytritylation of ribonucleosides (Scheme 1) are based on those originally developed by the Khorana group in the

[1]This manuscript constitutes part XIX in a series on silyl protecting groups in nucleoside and nucleotide chemistry. Part XVIII is ref. 20.

deoxy area (11, 12). Two of the desired compounds **2***a* (13) and **2***d* (14) have been described in the literature. By this standard procedure the nucleoside and dimethoxytrityl chloride (DMT-Cl) are dissolved in pyridine and, after about 12 h, products are isolated by chromatography. We found that by using this procedure a mixture of desired product, ditritylated (2′,5′ and 3′,5′) material, *N*-tritylated material, and unreacted starting material was always obtained and that separation of these components was time-consuming.

We observed that a simple change in the procedure led to a much cleaner product mixture which could easily be separated on short column chromatography. Thus the nucleoside was completely dissolved in pyridine or pyridine–DMF (1:1) and dimethoxytrityl chloride was added in eight equal portions (1 per hour) to the solution maintained at 0°C. At the end of the reaction period (9 h) the solvent was concentrated at reduced pressure and mixed with an aqueous sodium bicarbonate solution. If this bicarbonate treatment was eliminated a significant amount of detritylation occurred. The product was then extracted into methylene chloride. Thin-layer chromatography at this point indicated that only a very little by-product was present. Consequently the solution was concentrated and applied to a short silica gel column from which the desired product was rapidly eluted. Yields ranged from 69% for the guanosine derivative **2***f* to 85% for the cytidine derivative **2***d*. The elimination of by-products was particularly evident in the preparation of the adenosine derivative **2***b* in 80% yield. *N*-Tritylation was not a problem in this case. However, *N*-tritylation is a serious problem using the original procedure (8*a*). The only drawback to this modified procedure was the time involved (8–10 h). However, we found that the addition of silver nitrate gave a marked improvement in the rate of product formation.

The use of silver nitrate was based on our initial use of this reagent in the selective silylation of nucleosides to be described below. The results summarized in Table 1 show that the use of silver nitrate caused complete reaction within 1 h leading to yields of **2** ranging from 70% for **2***d* to 95% for **2***f*. The results also show that while ditritylation could be rapidly achieved using silver nitrate catalysis, selective ditritylation occurred only for the uridine case (**3***a* (80%), **4***a* (15%)). It appears that *N*-protection is necessary when using silver nitrate since in a test reaction on adenosine (**1***b*) a significant amount of *N*-tritylation was observed.

Silver ion is the effective catalyst in these reactions. As expected, silver trifluoroacetate gave the same results as silver nitrate, while tetrabutylammonium nitrate was ineffective.

### *Silylations*

#### A. *Selective 2′-silylations*

We have previously described procedures for the silylation of ribonucleosides and their 5′-methoxytrityl derivatives (8). These procedures always lead to a mixture of 2′,5′ and 3′,5′ derivatives in nearly equal amounts. While these isomers can be separated by silica gel chromatography, the yield of the 2′,5′-diprotected compound was lower than desired. We have investigated numerous procedures in an effort to obtain higher yields of the 2′,5′-protected compounds. Most of these procedures, including slow addition of silylating agent at lowered temperature, gave no significant improvement in selectivity. However, the addition of nitrates and perchlorates gave a remarkable improvement in the selectivity of silylation.

The reactions are outlined in Scheme 2 and the results are summarized in Table 2. The general procedure can be illustrated with the silylation of 5′-dimethoxytrityl-*N*-benzoylcytidine (**2***d*). The nucleoside is dissolved in THF after which pyridine (3.7 mmol/mmol $AgNO_3$) and silver nitrate (1.2 mmol/mmol nucleoside) are added and the solution

*Solvent was THF except for + where THF–DMF (1:1) was used and DMT–Cl was added portionwise in this case only. The time was 1 h in all cases except the last entry for **1***f* where 1.5 h were used. For the general procedure see the Experimental.

is stirred until the silver nitrate is completely dissolved (~ 5 min). At this point *tert*-butyldimethylsilyl chloride (TBDMS-Cl, 1.3 mmol/mmol **2***d*) is added all at once and the resulting mixture is stirred at room temperature for 1.5 h. The mixture is then filtered and the clear solution is mixed with 5% aqueous $NaHCO_3$ to prevent detritylation. The product is extracted into methylene chloride. The products are separated on short column chromatography to yield 5′-DMT-2′-TBDMS-$C^{Bz}$ (**6***d*) in 68% and the 3′-isomer, **8***d*, in 21% yield. These results show very high conversion yields with remarkable selectivity in all cases except for *N*-benzoylguanosine derivatives which will be discussed later.

The scope of the reaction was investigated using the unprotected nucleoside. Treatment of **1** with 2.2 equivalents each of TBDMS-Cl and $AgNO_3$ in THF led to exclusive formation of the 5′-TBDMS derivatives **5** in ~ 95% isolated yields (Table 2) within 3 h. No disilylation was observed in doubling the amounts of reagents (entry 6). However, if the solvent were changed to DMF, a mixture of mono, di, and trisilylated products was obtained. Repeating the original THF reaction but adding 5 equivalents of pyridine gave a rapid and highly selective disilylation. Yields of the 2′,5′-disilyl derivatives **7** were 82–90%.

An interesting contrast exists between guanosine (**1***e*) and *N*-benzoylguanosine (**1***f*). In the former case the reaction showed good selectivity, while in the latter there was very little selectivity. We believe this is due to steric hindrance created by the $N^2$-benzoyl group in the vicinity of the 2′-hydroxyl group. In this regard it may be of interest to note our observations on separating isomeric-protected guanosine derivatives. These isomers have always given us considerable difficulty. However, we have found that in acetone – petroleum ether – triethyl amine (6:5.5:0.5) the 2′,5′-protected compound **6***f* has an $R_f$ of 0.59 while the 3′,5′-isomer **8***f* has an $R_f$ of 0.21. If the triethylamine is eliminated from this solvent, both isomers have an $R_f$ of 0.41. In chloroform–acetone–triethylamine (9:0.5:0.5) compound **6***f* had an $R_f$ of 0.30 while **8***f* was at 0.05. In the absence of triethylamine both had an $R_f$ value of 0.28. This suggests that there may be hydrogen bonding between the 2′-hydroxyl in **8***f* and the 2-amide group. This H-bonding would be destroyed in the presence of triethylamine leading to a more polar structure for **8***f* and a resultant decreased $R_f$ value (stronger absorption). As expected, we were not able to observe a similar effect with the other nucleosides.

Nitrates which are soluble in the reaction medium all give good results. For example, tetrabutylammonium nitrate (entries 33 and 34) gives the same rate and selectivity as silver nitrate. In

*All reactions were carried out in THF except for No. 7 which was in DMF and Nos. 21, 23, and 24 which were carried out in THF–DMF (1:1). Abbreviations used are: py = pyridine, col = collidine, im = imidazole, DMAP = 4-dimethylaminopyridine, and 4-Acpy = 4-acetylpyridine.

another experiment in which adenosine was dissolved in THF–DMF (1:1) along with 2 equivalents each of TBDMS-Cl and potassium nitrate and 5 equivalents of pyridine, compounds **7***b* and **9***b* were produced in a 1.5:1 ratio.

Soluble perchlorates give equally good results in selective silylations (Table 3). Silver perchlorate and $(n\text{Bu})_4NClO_4$ give excellent yields of 2′-silylated derivatives. The use of nitrates and perchlorates as catalysts in silylations is not new (15, 16) but the selectivity described here is unprecedented. Other soluble silver salts such as silver carbonate, silver trifluoroacetate, and silver cyanate have no effect on silylation under these conditions.

Pyridine is required for disilylation to occur. In the absence of pyridine, reaction stops at the 5′-monosilyl stage. Replacing pyridine with the hindered base 2,4,6-trimethylpyridine gives only monosilylation even after 20 h. These results represent an excellent procedure for the highly selective monosilylation of nucleosides.

In a separate experiment one equivalent each of TBDMS-Cl and $AgNO_3$ were mixed together in THF. The mixture was stirred at room temperature and after 30 min the solution was decanted and distilled. The presumed *tert*-butyldimethylsilyl nitrate distilled at 140–142°C (1 atm) and was collected as a pale yellow liquid. This material, TBDMS-$NO_2$, silylated uridine in the presence or absence of pyridine with the same results as described for TBDMS-Cl and $AgNO_3$.

B. *Selective 3′-silylation*

The selective protection of the 3′-position in ribonucleosides cannot be achieved with most common protecting groups. Only acylation has been reported (17) to give high yields of 3′-derivatization. This occurs through migration from the 2′-position and selective crystalization of the 3′-

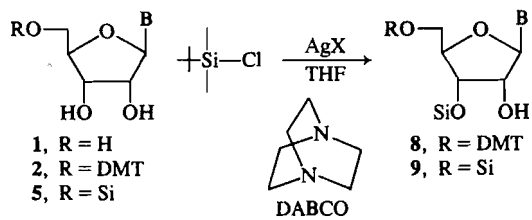
*Reaction conditions are the same as for Table 2 and are described in the Experimental.

isomer from solution. Markiewicz (18) has described a novel bifunctional silylating agent, 1,3-dichloro-1,1,3,3-tetraisopropyl disiloxane which reacts with both the 5′- and 3′-positions. To date there has not been a report of the direct and selective protection of the 3′-position of ribonucleosides using a monofunctional silylating agent. We have developed procedures which accomplish this objective (Scheme 3). A preliminary account of some of these results has appeared (19, 20).



SCHEME 3

Two procedures have been developed. The first involves the silylation of ribonucleosides in the presence of DABCO (1,4-diazabicyclo[2.2.2]-octane) and silver salts. The second procedure employs silver salts with 4-nitropyridine *N*-oxide.

The reaction involving ribonucleosides, TBDMS-Cl, DABCO, and silver salts leads to 3′,5′-di-TBDMS derivatives (**9**) in yields as high as 94% (Table 4). It is apparent from Table 4 that the silver ion is important in the reaction. All soluble silver salts tested ($AgNO_3$, $AgClO_4$, $AgOCOCF_3$) produce excellent selectivity while the salts $(n\text{Bu})_4NNO_3$ and $(n\text{Bu})_4NClO_4$ have no effect. In the absence of DABCO only 5′-silylation occurs. The procedure works equally well with dimethoxytritylated nucleosides (**2**) giving 3′-TBDMS-5′-DMT nucleosides (**8**) in yields of 70–93%.

The reaction with 4-nitropyridine *N*-oxide (Scheme 4) also leads to selective reaction at the 3′-position when silylation is carried out in THF with silver salts and TBDMS-Cl. We have only observed selectivity with the 4-nitropyridine *N*-oxide among those tested (Table 5). The one drawback with this procedure is that the reaction conditions rapidly remove dimethoxytrityl groups (e.g. from **2**). It is interesting to note that 4-nitropyridine (**14**) produces similar results to 4-nitropyridine *N*-oxide (**10**) but in a much slower reaction (10–20 h). This result contrasts with 4-acetylpyridine which gives a slow, but highly selective, silylation at the 2′-position (Table 2, entries 26–29).

*Reactions were carried out in THF (25 mL/mmol of nucleoside) using TBDMS-Cl (2.2 mmol/mmol of **1**) as described in the Experimental.

These selective silylations at the 3′-position apparently involve direct attack at the 3′-position since the 2′-silyl derivatives (e.g. **6** and **7**) appear to be stable under the reaction conditions (i.e., they do not rearrange to the 3′-position). The mechanistic implications of the combination of silver ion and DABCO or 4-nitropyridine *N*-oxide are being explored.

## Conclusion

This report describes procedures for the facile preparation of ribonucleosides protected with two of the most versatile and useful blocking groups, the dimethoxytrityl group and the *tert*-butylmethylsilyl group. The procedures incorporate truly novel catalytic effects leading to highly selective protection at the 2′-position and the unprecedented highly selective silylation at the 3′-position.

## Experimental

*General methods*

Thin-layer chromatographic data ($R_f$ values) are recorded from Merck Kieselgel 60 F 254 analytical sheets. All uv spectra were recorded on a Cary 17 spectrophotometer. Nuclear magnetic resonance spectra were recorded on a Varian T-60A instrument. Infrared spectra were obtained on a Perkin Elmer 297 spectrophotometer. Melting points were determined on a Fisher–Johns melting point apparatus and are reported uncorrected.

Reagent grade pyridine was distilled first from *p*-toluenesulfonyl chloride, redistilled from calcium hydride, and stored over molecular sieves (type 4A). Tetrahydrofuran was refluxed with benzophenone and sodium for at least 3 h and was freshly distilled before use. *N*,*N*-Dimethylformamide (DMF) and 2,4,6-trimethylpyridine were distilled from calcium hydride and stored over molecular sieves (type 4A).

*Short column chromatography*

Short columns of Merck silica gel 60 (230–400 mesh) were packed in glass columns 5 cm in diameter using 10 g of silica gel per gram of crude mixture. Columns were washed first with a low polarity solvent to remove tritanol and other fast-moving impurities. The desired products were then eluted with a more polar solvent. Solvents used are indicated for each preparation described below. Fractions of 15 mL were collected every 5 min using a fraction collector. Contents of fractions were determined by analytical tlc.

*General preparation of 5′-dimethoxytritylnucleosides*

(a) *5′-Dimethoxytrityluridine (**2a**)*

Uridine (**1***a*, 24.4 g, 0.10 mol) was dissolved in pyridine (200

*The nmr and ir spectra of all compounds agreed with the reported structures.
†Solvents employed were (a) chloroform–methanol (9:1); (b) chloroform–methanol (9.5:0.5); (c) chloroform–triethylamine (9.5:0.5); (d) hexane–ether (1:3); (e) chloroform–methanol–triethylamine (9.5: 0.5: 0.5); (e) acetone – petroleum ether (6:5.5); (g) acetone – petroleum ether – triethylamine (6:5.5:0.5); (h) chloroform–acetone–triethylamine (9:0.5:0.5); (i) chloroform–acetone (9:0.5).

mL) and kept at 0°C. Dimethoxytrityl chloride (41 g, 0.12 mol) was added in portions (5.1 g, 0.015 mol) during an 8 h period. After an additional 2 h methanol (50 mL) was added and the solution was concentrated at reduced pressure. A 5% $NaHCO_3$ solution (200 mL) was added and the resulting solution was extracted with methylene chloride (500 mL). The methylene chloride solution was washed once with water, then dried over magnesium sulfate and evaporated to leave the crude product.

The residue was washed with chloroform–hexane (1:20, 100 mL) to remove residual pyridine. The residue was then applied to a short column (5 cm diameter) packed with 450 g (10 g/g of crude product) of Merck silica gel 60 (230–400 mesh). The column was washed with ether (500 mL) to remove impurities, followed by ethyl acetate (800 mL). Fractions of 15 mL were collected (fraction collector) every 5 min. The product was recovered from the ethyl acetate fractions which, on evaporation, gave 43.7 g of **2***a* (80%). Compound **2***a* crystallizes from ether: mp 111–112°C. Properties of **2***a* are listed in Table 6.

(b) *5′-Dimethoxytrityladenosine (2*b)

This procedure was very similar to that of (a) except that the solvent consisted of 100 mL each of pyridine and DMF. At the end of the reaction period (10 h) the solution was poured into 2 liters of cold water. A pale yellow precipitate was obtained which was collected by filtration, washed with water, and dried under air. The crude product was dissolved in hot xylene (2500 mL) and, on cooling, the product **2***b* crystallized as a white solid which was collected by filtration and washed with ether (yield 80%, mp 145–146°C). Properties of **2***b* are listed in Table 6.

(c) *5′-Dimethoxytrityl-*N*-benzoylcytidine (2*d)

This procedure was virtually the same as that described for **2***a*, including isolation of the product on short silica gel column chromatography using first chloroform (400 mL) and then chloroform–methanol (9:1, 600 mL) as solvent. The yield of **2***d* was 85% (mp 109–111°C). Properties are listed in Table 6.

(d) *5′-Dimethoxytrityl-*N*-benzoylguanosine (2*f)

This preparation was identical to that described above for **2***d* except that, during short column chromatography of the reaction products, 500 mL of chloroform was used to wash off impurities and the product was recovered in 800 mL of chloroform–methanol (9:1). The yield of **2***f* was 69% and its properties are listed in Table 6.

*Preparation of dimethoxytritylated nucleosides using silver nitrate as catalyst*

The general procedure is outlined for the synthesis of 5′-dimethoxytrityl-*N*-benzoyladenosine (**2***c*). *N*-Benzoyladenosine was dissolved in THF (30 mL/mmol of nucleoside). Pyridine (5 mmol/mmol of **1**), silver nitrate (1 mmol/mmol **1**), and dimethoxytrityl chloride (1 mmol/mmol **1**) were added successively and the mixture was stirred at room temperature for 1 h. The mixture was filtered and the solution added to a 5% sodium bicarbonate solution. The product was extracted into methylene chloride which was dried and evaporated to give **2***c* in an 80% yield.

When the above reaction was repeated except that the amounts of pyridine, silver nitrate, and dimethoxytrityl chloride were doubled, the 2′,5′ and 3′,5′-ditritylated products **3***c* and **4***c* were each obtained in 40% yields. The results for all of the nucleosides are listed in Table 1 and the properties of the products are listed in Table 6.

*Silylation of dimethoxytritylated nucleosides **2** using nitrate (or perchlorate) catalysts*

(a) The standardized procedure can be illustrated by the silylation of 5′-dimethoxytrityladenosine (**2***b*). Compound **2***b* (5.69 g, 10 mmol) was dissolved in THF (100 mL) followed by the addition of pyridine (3 g, 37 mmol) and silver nitrate (2 g, 12 mmol). The solution was stirred (5 min) until all the silver nitrate had dissolved and then *tert*-butyldimethylsilyl chloride (2 g, 13 mmol) was added and the mixture was stirred at room temperature for 5 h. The solution was then filtered into a 5% $NaHCO_3$ solution (100 mL). This solution was extracted with methylene chloride (300 mL) and the extracts were dried and evaporated.

Ether (100 mL) was added to the crude product (6.5 g). The solution was separated from undissolved **2***b* by filtration. The ether solution was concentrated, at reduced pressure without heating, to about 60 mL. During this period the 2′-silylated derivative precipitated and 3 g of **6***b* was collected by filtration. By repeated concentration it has been possible to collect most of the 2′-isomer. However, a more direct procedure is to collect the residue from the remaining ether solution and apply it directly to short column chromatography using chloroform–methanol (9.5:0.5) for elution. The yield of the 2′-isomer **6***b* was 65%, and that of the 3′-isomer **8***b* was 21%. Properties of these compounds are collected in Table 6.

(b) 5′-Dimethoxytrityluridine was silylated using the same procedure. Products **6***a* and **8***a* were obtained in 70% and 15% yields respectively from short column chromatography using ether–hexane (1:1). Properties are listed in Table 6.

(c) 5′-Dimethoxytrityl-*N*-benzoylcytidine was silylated using the standard procedure. Products **6***d* and **8***d* were obtained in 68% and 20% yields respectively after short column chromatography using ether–hexane (3:1). Properties of products are listed in Table 6.

(d) 5′-Dimethoxytrityl-*N*-benzoylguanosine was silylated using the standard procedure except that 1.5 equivalents of silver nitrate and 1.7 equivalents of TBDMS-Cl were used. The products were separated on short column chromatography using chloroform – methylene chloride – triethylamine (9:0.5:0.5). The collected fractions were neutralized by passing them through Dowex 50W × 8 ($H^+$ form) resin. The solvent was evaporated and the individual products were obtained as white solids on precipitation from chloroform with petroleum ether. The 2′-isomer **6***f* was obtained in 45% yield and the 3′-isomer **8***f* in 40% yield. Properties are summarized in Table 6.

*Silylation of nucleosides* **1**

The general procedure is illustrated for the silylation of uridine. Uridine (1 mmol) was dissolved in THF (30 mL). Pyridine (5 mmol) and silver nitrate (2.2 mmol) were added and stirring was continued for 5 min until all silver nitrate had dissolved. TDBMS-Cl (2.2 mmol) was added and the mixture was stirred for 1 h. The solution was collected by filtration and the solvents concentrated to a small volume and applied to 4 tlc plates which were developed in ether–hexane (4:1). The yields are shown in Table 2 for all compounds tested.

For monosilylation the above procedure is repeated exactly except that pyridine is omitted. Yields of the 5′-monosilyl derivatives are collected in Table 2. All silylated compounds were identified by comparison to authentic material (8).

The general procedure described above was employed for all nitrate and perchlorate salts tested. The results of all of these reactions are summarized in Tables 2 and 3. It is important to add the reagents in the order described above. All solvents used in the reactions should be purified by distillation.

*Selective 3′-silylations*

A. *General procedure using DABCO*

The general procedure is much the same as described above. DABCO (0.67 g, 6 mmol/mmol of nucleoside) was dissolved in dry THF (25 mL/mmol nucleoside). Silver nitrate (0.37 g, 2.2 mmol/mmol of nucleoside) was added and the solution was stirred for 5 min. At this point *tert*-butyldimethylsilyl chloride (0.35 g, 2.2 mmol/mmol of nucleoside) was added. After an additional 5 min the nucleoside (1 mmol) was added and stirring continued (for time of reaction, see Table 4). At the end of the reaction period the solution was collected by filtration, diluted with 50 mL of water, and extracted with chloroform (80 mL). The organic layer was dried and concentrated and the products were isolated by short column chromatography.

The results of individual experiments are collected in Table 4.

B. *General procedure using pyridine* N-*oxide*

This procedure is identical to that described in A above except that a pyridine *N*-oxide is used in place of DABCO. The ratio of reagents used and the results of individual experiments are collected in Table 5.

# Alkylation of enolate anions with dimethyl 3-bromo-2-ethoxypropenylphosphonate. A convergent cyclopentenone annulation method

EDWARD PIERS AND BRIAN ABEYSEKERA

*Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6*

Received December 2, 1981

EDWARD PIERS and BRIAN ABEYSEKERA. Can. J. Chem. **60**, 1114 (1982).

A new, convergent synthesis of 2-cyclopenten-1-ones is reported. Treatment of dimethyl 2-oxopropylphosphonate (**21**) with excess triethyl orthoformate in the presence of ferric chloride hexahydrate provides the enol ether **22**, which upon allylic bromination with *N*-bromosuccinimide yields the allylic bromide **19**. Alkylation of the ketones **24–28** with **19**, followed by mild acid hydrolysis of the resultant products **29–33**, affords the diketo phosphonates **34–38**. When the latter substances are treated with sodium hydride in dimethoxyethane, the corresponding 2-cyclopenten-1-ones **40–44** are formed in good yields.

EDWARD PIERS et BRIAN ABEYSEKERA. Can. J. Chem. **60**, 1114 (1982).

On rapporte une nouvelle synthèse convergente des cyclopentène-2 ones-1. L'oxo-2 propylphosphonate de diméthyle (**21**) réagit avec un excès d'orthoformiate de triéthyle en présence du chlorure ferrique hexahydraté en donnant l'éther énolique **22** qui par bromation allylique avec la NBS conduit au bromure **19**. L'alkylation des cétones **24–28** avec le composé **19** suivie d'une hydrolyse acide douce des produits obtenues (**29–33**) conduit aux dicétophosphonates **34–38**. Ces derniers composés réagissent avec l'hydrure de sodium dans le diméthoxyéthane en donnant les cyclopentène-2 ones-1 correspondantes (**40–44**) avec de bons rendements.

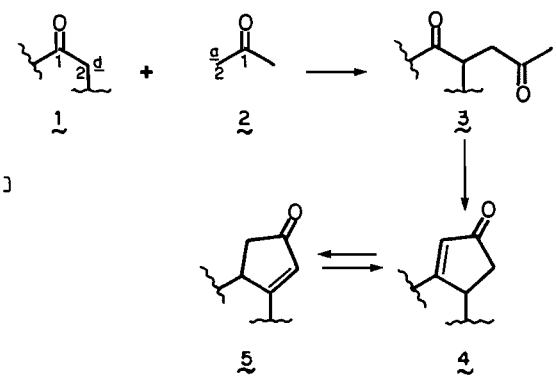
## Introduction

Functionalized cyclopentane rings are very commonly found in structurally novel, physiologically active, and/or commercially important natural products. Consequently, it is not surprising to find that, particularly in recent times, a great deal of effort has gone into developing new, efficient methods for synthesizing five-membered ring systems.

The overall annulation scheme represented in general terms by eq. [1] constitutes an important, much employed method for preparing substituted 2-cyclopenten-1-ones. In this process, the (theoretical) combination of a $d^2$ synthon **1** (normal reactivity) (1) with an $a^2$ synthon **2** (reactivity umpolung) (1) results in the formation of a 1,4-diketone system **3**. Subjection of the latter substance to base-promoted intramolecular aldol condensation, followed by dehydration, would provide the desired enone **4**.



[1]

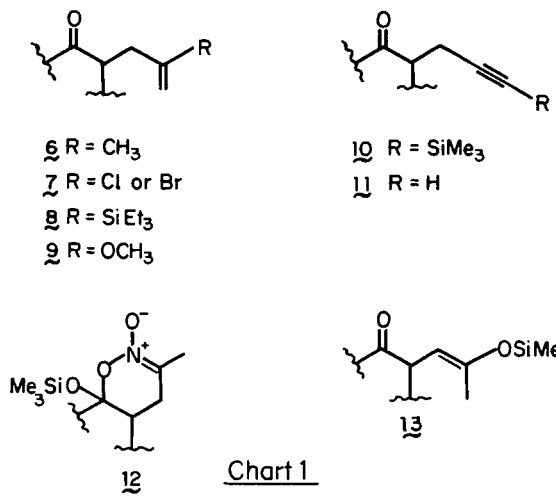


Chart 1

Various species (e.g. enolate anions, enol ethers) corresponding to the $d^2$ synthon **1** are prepared very readily from the corresponding ketone. However, there has been an ongoing search for efficient and generally applicable synthetic equivalents to the $a^2$ synthon **2**, and, thus far, a number of reagents have been employed successfully. For example, alkylation of enolate anions with 3-halo-2-methylpropenes (2–4) 2,3-dihalopropenes (5, 6), 3-iodo-2-(triethylsilyl)propene (7), 3-bromo-2-methoxypropene (8), 3-bromo-1-(trimethylsilyl)-propyne (9–11), or 3-bromopropyne (12) provides the corresponding substances of general structure **6–11**, respectively (see Chart 1). On the other hand, reaction of trimethylsilyl enol ethers with 2-nitropropene in the presence of stannic chloride or

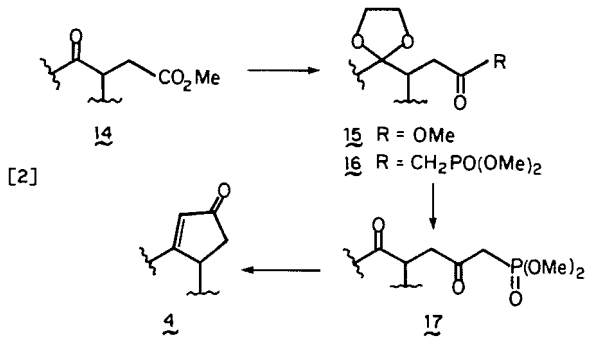
titanium tetrachloride (13) or with diazoacetone in the presence of cupric acetylacetonate (14) yields compounds of general structures **12** or **13**, respectively.

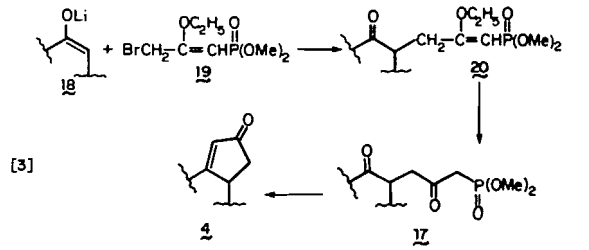
A diversity of reagents and experimental conditions are involved in converting the appendages in **6–13** into the required acetonyl side chain (cf. **3**): **6**, cleavage of the carbon–carbon double bond by ozonolysis (2, 3) or osmium tetroxide – sodium periodate (2, 4); **7**, hydrolysis of the vinyl halide function with concentrated sulfuric acid (5, 6); **8**, epoxidation with peracid, followed by acid hydrolysis of the resultant epoxy silane (7); **9**, hydrolysis of the enol ether function with aqueous oxalic acid (8); **10** and **11**, hydration of the carbon–carbon triple bond with aqueous acid in the presence of mercuric salts (10–12); **12**, hydrolysis with water – stannic chloride (or titanium tetrachloride) in refluxing dichloromethane (13); **13**, hydrolysis of the trimethylsilyl enol ether with water (14).

In general, the methods for converting **1** into **4**, as summarized above, suffer mainly from two difficulties. Firstly, the conditions required to introduce or unmask the various synthetic equivalents to the $a^2$ synthon **2** often have (or would have) deleterious effects on other functional groups which might be present in the ketonic (or enol ether) substrate. For example, carbon–carbon double or triple bonds and/or acid-sensitive groups[1] would certainly be susceptible to chemical reaction when subjected to many of the reagents and/or conditions summarized above. Secondly, the intramolecular aldol condensation process (**3** → **4**) can be accompanied by an undesirable base-catalyzed isomerization of the initially formed product (**4** ⇆ **5**, see eq. [1]).[2]

A method which circumvents very efficiently the second difficulty mentioned above has been reported by Heathcock and co-workers (16) and is summarized in eq. [2]. Conversion of the keto ester **14** (obtained by alkylation of the requisite ketone with methyl haloacetate) into the corresponding ketal **15**, followed by treatment of the latter substance with 2 equivalents of lithium dimethoxyphosphinylmethide ($LiCH_2PO(OMe)_2$) affords the keto phosphonate **16**. Acid-catalyzed hydrolysis of **16** gives the diketo phosphonate **17**. Treatment of **17** with base (e.g. sodium hydride) effects an intramolecular Horner–Emmons reaction, providing the annulation product **4** in good yield. Importantly, the last step produces in addition to the desired product only the weak base sodium dimethylphosphate, which is incapable of causing isomerization of the initially formed cyclopentenone **4**.



The Heathcock methodology, however, does not eliminate the first drawback mentioned previously. Clearly, the steps involving introduction and removal of the ketal protecting group (formation of **15** and **17**) could readily affect other acid-sensitive groups which might be present in the ketonic substrate. We describe herein an efficient, convergent method for effecting the conversion of **1** into **4** via a route which removes this limitation as well.[3] Essentially, the overall process, summarized in general terms in eq. [3], involves the following steps: (a) treatment of an enolate anion **18** with dimethyl 3-bromo-2-ethoxypropenylphosphonate (**19**) (cf. ref. 18) to provide the alkylation product **20**, (b) hydrolysis of **20** to give the required diketo phosphonate **17**, and (c) intramolecular Horner–Emmons reaction (**17** → **4**).



## Results and discussion

### (a) *Preparation of dimethyl 3-bromo-2-ethoxypropenylphosphonate* (19)

The required alkylating agent **19** was prepared efficiently as follows (see Chart 2). Treatment of dimethyl 2-oxopropylphosphonate (**21**) with excess triethyl orthoformate in the presence of a catalytic

[1]For an example of hydration of the triple bond of the propargyl group (cf. **11**) with retention of a ketal moiety, see ref. 12.

[2]Recently, an intramolecular, base-promoted aldol condensation of the type **3** → **4** was achieved without causing subsequent isomerization of the initially formed product (15). See also ref. 3.

[3]For a preliminary report regarding this work, see ref. 17.

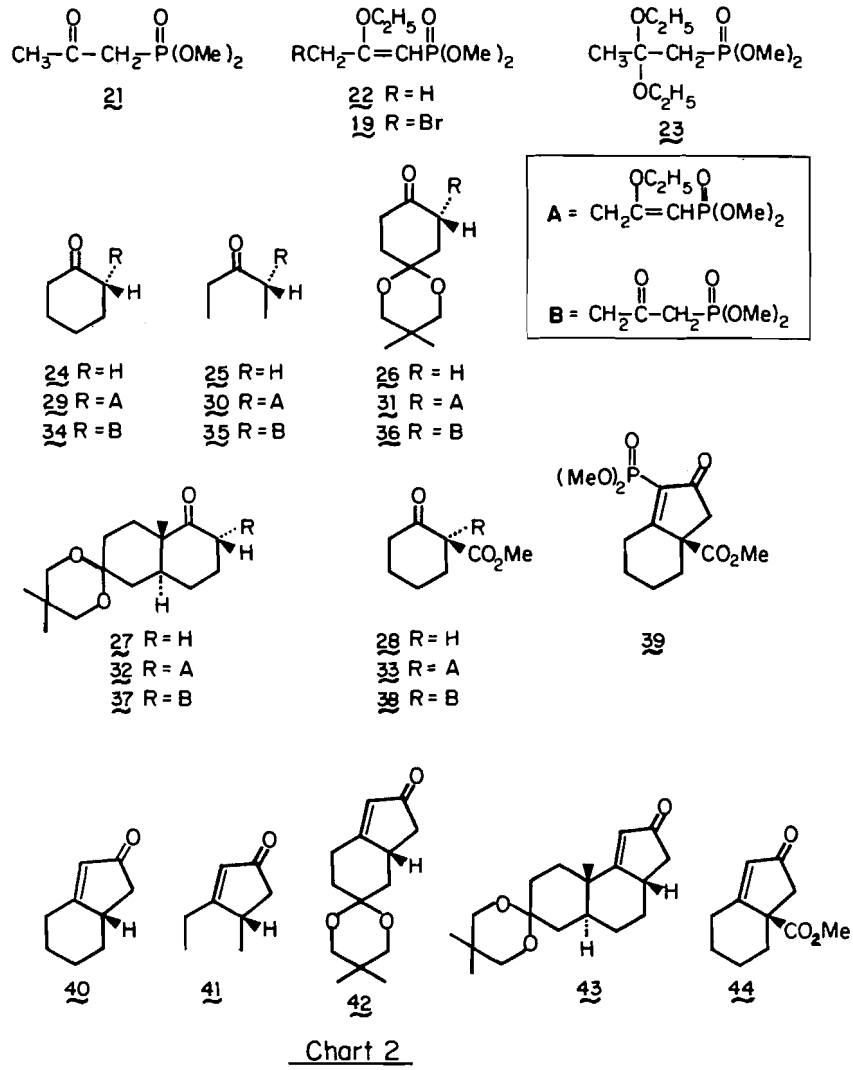


Chart 2

amount of ferric chloride hexahydrate (19) afforded mainly the desired enol ether **22**. In most of the attempts to carry out this transformation, the latter substance was accompanied by small amounts of starting material **21** and variable amounts of a second component which appeared to be dimethyl 2,2-diethoxypropylphosphonate (**23**). Therefore, in each of these cases, a dichloromethane solution of the crude product was treated with an appropriate amount of sodium hydride, which converted **23** into the desired **22** and transformed **21** into the corresponding insoluble (20) sodium salt. Filtration of the resultant mixture, followed by isolation and purification of the product, provided the enol ether **22** in 94% yield.

Allylic bromination of **22** with *N*-bromosuccinimide (21; see also ref. 18) in carbon tetrachloride afforded, after purification of the crude product by column chromatography, dimethyl 3-bromo-2-ethoxypropenylphosphonate (**19**) (76% yield). Although the $^1$H nmr spectra of compounds **22** and **19** indicated that each of these compounds consisted very largely of one isomer, their configuration is not known. However, this point is irrelevant to the synthetic work reported herein, and therefore did not receive further attention.

(b) *Alkylation of the ketones* ***24–27*** *and the keto ester* **28** *with the bromide* **19**

The allylic bromide **19** proved to be an excellent alkylating agent. Thus, when the enolate anion of cyclohexanone was allowed to react with **19** in tetrahydrofuran (THF) (−78°C, 30 min; 0°C, 30 min; room temperature, 30 min), the alkylation product **29** was formed in quantitative yield (see Chart 2). In identical fashion, 3-pentanone (**25**)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12

For personal use only.

could be converted quantitatively into the alkylated material **30**. On the other hand, application of this procedure to the keto ketal **26** (22)[4] gave the desired product **31** in mediocre yield (~40%). However, a notable improvement could be realized when 1 equivalent of hexamethylphosphoramide (HMPA) was added to the reaction mixture prior to addition of the alkylating agent **19**. This minor modification led to the formation of **31** in 78% yield. In similar fashion, alkylation (**19**, THF, 1 equivalent of HMPA) of the lithium enolates of the keto ketal **27**[5] and the keto ester **28** afforded good yields of compounds **32** and **33**, respectively. In the case of the transformation of **28** into **33**, a longer reaction time (room temperature, 6 h) was required for completion of the reaction.

It is clear from the experiments summarized above that the bromo compound **19** alkylates enolate anions very efficiently. In this sense, **19** compares favorably with the alkylating reagents involved in the formation of compounds of general structure **6–11** (*vide supra*).

(c) *Hydrolysis of compounds **29–33**. Formation of the diketo phosphonates **34–38***

The crucial step in each of the annulation sequences described herein involved hydrolysis of the enol ether functional group in the side chain of each of the compounds **29–33**. Although this transformation was expected to be straightforward in the case of the alkylation products **29**, **30**, and **33**, the keto ketals **31** and **32** were particularly important examples of the present methodology, since, in each case, the enol ether group would have to be hydrolyzed under conditions which would not affect the ketal function.

When an acetone solution of **29** containing 1 *N* hydrochloric acid was allowed to stir at room temperature for 30 min, the desired diketo phosphonate **34** was obtained in quantitative yield. An identical procedure also effected smooth conversion of **30** into **35**.

An unexpected difficulty arose in connection with attempted hydrolysis of the alkylation product **33**. Thus, subjection of the latter substance to conditions very similar to those employed for **29** and **30** gave, in addition to some of the expected product **38**, a compound which exhibited *m/e* 330 ($M^+$) in the mass spectrum. Although the latter material was not fully characterized, the mass spectral data along with a fairly intense infrared absorption at 1605 $cm^{-1}$ (carbon–carbon double bond stretching vibration) suggested that this substance possessed structure **39**. Apparently, under the reaction conditions, some of the initially formed diketo phosphonate had undergone intramolecular aldol condensation. After some experimentation, it was found that this difficulty could be largely avoided quite simply by carrying out the hydrolysis of **33** with more dilute acid (0.5 *N* hydrochloric acid, acetone, room temperature, 35 min). Although the infrared spectrum of the crude product indicated that these conditions still produced small amounts of the enone **39**, the material thus obtained was sufficiently pure to be used directly for the next step.

With respect to the hydrolysis of the keto ketals **31** and **32**, it was eventually found that conditions similar to those employed for compound **33** (0.5 *N* hydrochloric acid, acetone, room temperature) were quite satisfactory. Under these conditions, the enol ether moiety was, in each case, hydrolyzed smoothly, while the ketal function remained essentially unaffected. In the case of compound **31**, reaction times of up to 2 h left the ketal group intact. Using this procedure, the hydrolysis products **36** and **37** were obtained in high yield (92%, 96%, respectively).

(d) *Intramolecular Horner–Emmons reaction of the diketo phosphonates **34–38***

Cyclization of the diketo phosphonates **34–38** was accomplished by treatment of each of these substances with sodium hydride in dimethoxyethane (DME) (16, 24). In general, the reactions were quite efficient, the yields of the products **40** (8), **41** (25), and **42–44** being 74, 82, 72, 86, and 70% (based on **33**), respectively. Importantly, in accord with previous observations (16), the products **41–43** were very clean and, in each of these cases, there was no indication of isomerization to the corresponding isomeric cyclopentenone.

## Conclusion

The convergent annulation sequence described in this paper would appear to constitute a general, efficient method for the construction of functionalized 2-cyclopenten-1-one systems. It is appropriate to note that, very recently, this method has been employed successfully in an elegant well-designed synthesis of (±)-quadrone, a structurally novel sesquiterpenoid which exhibits antitumor properties (26).

Finally, two additional pertinent items should be mentioned. Firstly, after appearance of our prelim-

[4]We are grateful to Mr. M. Burmeister for supplying a sample of this compound.

[5]This substance was prepared in a straightforward, unambiguous fashion from the Wieland–Miescher ketone (23). Details will be reported elsewhere.

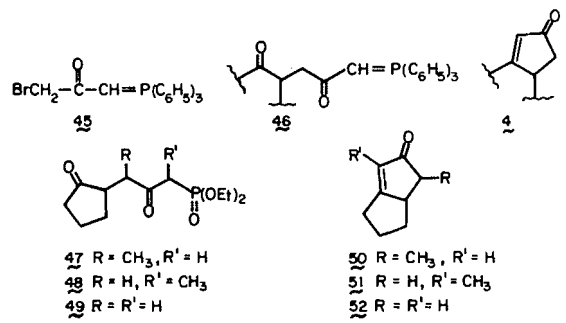

Chart 3

inary report, Altenbach described (27) the alkylation of enolate anions with (bromoacetylmethylene)triphenylphosphorane (**45**) (see Chart 3). Subsequent intramolecular Wittig reaction of the resultant diketo phosphoranes **46** (not isolated) provided the corresponding cyclopentenones **4**. Although, in principle, the Altenbach methodology is very similar to that described in this paper, the reported yields of the annulation products were low (14–39%). Secondly, Pattenden and co-workers have reported (28) very recently that although treatment of the diketo phosphonates **47** and **48** (Chart 3) with sodium hydride in DME at 60°C provided good yields of the bicyclic enones **50** and **51**, respectively, attempted conversion of **49** into **52**[6] under similar conditions failed. Instead, a "tarry mass" was produced. Attempts to transform **49** into **52** using alternative reaction conditions were also unsuccessful.

## Experimental

*General*

Melting points were taken on a Fisher–Johns melting point apparatus and are uncorrected. Distillation temperatures (also uncorrected) refer to the mean air bath temperature during a short path (bulb-to-bulb) distillation. Infrared (ir) spectra were obtained on liquid films or chloroform solutions, employing Perkin Elmer models 710 or 710B spectrophotometers. Proton magnetic resonance ($^1$H nmr) spectra (deuterochloroform solution) were measured using Bruker WP-80 or WH-400 instruments or Varian Associates T-60, HA-100, and/or XL-100 spectrometers. Signal positions are given in $\delta$ units, with tetramethylsilane as the internal standard. Gas–liquid chromatography (glc) was carried out with a Hewlett–Packard model 5832A gas chromatograph. High resolution mass spectrometric measurements were recorded on a Kratos MS-50 mass spectrometer. Microanalyses were carried out by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver, B.C.

The solvents and reagents employed were freshly distilled under an atmosphere of argon as follows: THF and DME from sodium benzophenone ketyl; HMPA from barium oxide; diisopropylamine from calcium hydride; carbon tetrachloride and dichloromethane from phosphorus pentoxide.

*Dimethyl 2-ethoxypropenylphosphonate (22)*

To dimethyl 2-oxopropylphosphonate (**21**) (5.1 g, 37.8 mmol) was added triethyl orthoformate (9.0 g, 60.8 mmol) and ferric chloride hexahydrate (0.2 g). The mixture was stirred briefly and then allowed to stand at room temperature for 3 days. The volatile byproducts and excess triethyl orthoformate were removed under reduced pressure and the residual material was dissolved in 50 mL of dry dichloromethane. The solution was treated with 0.5 g of sodium hydride (washed free of mineral oil with hexane) and the resultant mixture was stirred for 10 min and then filtered. Removal of the solvent from the filtrate, followed by distillation (air bath temperature 80°C/0.05 Torr) of the residual material gave 6.89 g (94%) of the enol ether **22** as a colorless oil; ir (film): 1605, 1250, 1050, 1025 cm$^{-1}$; $^1$H nmr $\delta$: 1.33 (t, 3H, $J$ = 7 Hz, $CH_3CH_2O$), 2.14 (d, 3H, $J_{H-P}$ = 2 Hz, vinyl methyl), 3.65 (d, 6H, $J_{H-P}$ = 11 Hz, $PO(OCH_3)_2$), 3.77 (q, 2H, $J$ = 7 Hz, $CH_3CH_2O$), 4.35 (d, 1H, $J_{H-P}$ = 7 Hz, vinyl proton). *Anal.* calcd. for $C_7H_{15}O_4P$: C 43.30, H 7.79; found: C 43.13, H 7.70. *Exact mass* calcd.: 194.0707; found: 194.0708.

*Dimethyl 3-bromo-2-ethoxypropenylphosphonate (19)*

To a solution of the enol ether **22** (3.0 g, 15.5 mmol) in 150 mL of dry carbon tetrachloride was added 3.1 g (17.4 mmol) of *N*-bromosuccinimide. The well-stirred mixture was heated (reflux) while it was being irradiated with a sun lamp (Westinghouse, 275 W, 110–120 V). After 15 min the reaction mixture was cooled and filtered. The filtrate was concentrated under reduced pressure to a volume of approximately 50 mL and then cooled in an ice-bath to precipitate residual succinimide. The mixture was filtered through a small amount of neutral alumina (Act. I). Removal of the solvent from the filtrate gave a yellow oil which was subjected to column chromatography on silica gel (160 g). Elution of the column with ethyl acetate, followed by distillation (air bath temperature 110°C/0.05 Torr) of the crude oil thus obtained gave 3.2 g (76%) of dimethyl 3-bromo-2-ethoxypropenylphosphonate (**19**) as a colorless oil, which exhibited one peak by glc analysis and one spot by tlc analysis; ir (film): 1605, 1250, 1050–1025 (broad) cm$^{-1}$; $^1$H nmr $\delta$: 1.39 (t, 3H, $J$ = 7 Hz, $CH_3CH_2O$), 3.76 (d, 6H, $J_{H-P}$ = 11 Hz, $PO(OCH_3)_2$), 3.91 (q, 2H, $J$ = 7 Hz, $CH_3CH_2O$), 4.42 (s, 2H, $CH_2Br$), 4.57 (d, 1H, $J_{H-P}$ = 5 Hz, vinyl proton). *Exact Mass* calcd. for $C_7H_{14}{}^{79}BrO_4P$: 271.9813; found: 271.9815.

*Alkylation of the ketones 24–27 and the keto ester 28 with the allylic bromide 19*

(a) *Preparation of compound 29*

To a cold (−78°C) stirred solution of lithium diisopropylamide (LDA) (1.2 mmol) in dry THF (2 mL) under an atmosphere of argon was added 98 mg (1 mmol) of cyclohexanone. The cooling bath was removed and replaced by an ice-water bath, and the solution was allowed to stir for 1 h. The reaction mixture was recooled to −78°C and 330 mg (1.2 mmol) of the alkylating agent **19** was added. After the reaction mixture had been stirred at −78°C for 30 min, at 0°C for 30 min, and at room temperature for 30 min, the THF was removed under reduced pressure. The residual material was dissolved in dichloromethane and the resultant solution was washed twice with brine and dried over anhydrous sodium sulfate. Removal of the solvent under reduced pressure (water aspirator, followed by vacuum pump) gave 290 mg (100%) of the alkylated ketone **29** as a colorless oil. Both tlc and glc indicated that this material consisted of one component; ir (film): 1710, 1605, 1250, 1060–1025 (broad) cm$^{-1}$; $^1$H nmr $\delta$: 1.26 (t, 3H, $J$ = 7 Hz, $CH_3CH_2O$), 1.42–3.06 (diffuse,

11H), 3.62 (d, 6H, $J_{H-P}$ = 11 Hz, $PO(OCH_3)_2$), 3.72 (q, 2H, $J$ = 7 Hz, $CH_3CH_2O$), 4.36 (d, 1H, $J_{H-P}$ = 7 Hz, vinyl proton). *Exact Mass* calcd. for $C_{13}H_{23}O_5P$: 290.1283; found: 290.1301.

(b) *Preparation of compound* ***30***

This compound was prepared via a procedure identical with that described above. From 86 mg (1 mmol) of 3-pentanone there was obtained, after distillation (air bath temperature 140°C/0.05 Torr) of the crude product, 278 mg (100%) of the alkylated material **30** as a colorless oil, which exhibited one peak by glc analysis and one spot by tlc analysis; ir (film): 1705, 1605, 1250, 1050–1025 (broad) $cm^{-1}$; $^1H$ nmr δ: 1.04 (t, 3H, $J$ = 7 Hz, $CH_3CH_2CO$), 1.12 (d, 3H, $J$ = 6 Hz, secondary methyl), 1.28 (t, 3H, $J$ = 7 Hz, $CH_3CH_2O$), 2.50 (q, 2H, $J$ = 7 Hz, $CH_3CH_2CO$), 2.66–2.98 (diffuse, 3H), 3.66 (d, 6H, $J_{H-P}$ = 11 Hz, $PO(OCH_3)_2$), 3.76 (q, 2H, $J$ = 7 Hz, $CH_3CH_2O$), 4.39 (d, 1H, $J_{H-P}$ = 6 Hz, vinyl proton). *Exact Mass* calcd. for $C_{12}H_{23}O_5P$: 278.1283; found: 278.1277.

(c) *Preparation of compound* ***31***

For the alkylation of the keto ketal **26** (198 mg, 1 mmol) the procedure described above was modified as follows. Just prior to addition of the alkylating agent **19**, HMPA (180 μL, 1 mmol) was added to the reaction mixture (−78°C). After work-up, most of the HMPA was removed from the crude product (air bath temperature ~100°C/0.05 Torr) and the residual oil was subjected to column chromatography on silica gel (10 g). Elution of the column with ethyl acetate gave 304 mg (78%) of the alkylated ketone **31** as a colorless oil which, according to analyses by glc and tlc, consisted of one component; ir (film): 1715, 1610, 1250, 1030 $cm^{-1}$; $^1H$ nmr δ: 0.94, 1.01 (s, s, 3H each, tertiary methyls), 1.30 (t, 3H, $J$ = 6 Hz, $CH_3CH_2O$), ~1.4–3.2 (diffuse, 9H), 3.48 (s, 4H, ketal methylene protons), 3.67 (d, 6H, $J_{H-P}$ = 11 Hz, $PO(OCH_3)_2$), 3.78 (q, 2H, $J$ = 6 Hz, $CH_3CH_2O$), 4.43 (d, 1H, $J_{H-P}$ = 6 Hz, vinyl proton). *Exact Mass* calcd. for $C_{18}H_{31}O_7P$: 390.1808; found: 390.1796.

(d) *Preparation of compound* ***32***

Alkylation of **27** was accomplished via a procedure identical with that described above (preparation of **31**). From 266 mg (1 mmol) of the keto ketal **27**, there was obtained 348 mg (76%) of the alkylated substance **32** as a white solid. Recrystallization (ether–hexane) of a small amount of this material provided an analytical sample, mp 99–100°C; ir ($CHCl_3$): 1705, 1610, 1250, 1060–1020 (broad) $cm^{-1}$; $^1H$ nmr δ: 0.93, 1.02, 1.16 (s, s, s, 3H each, tertiary methyls), 1.32 (t, 3H, $J$ = 7 Hz, $CH_3CH_2O$), ~1.4–3.2 (diffuse, 14H), 3.4–3.6 (m, 4H, ketal methylene protons), 3.72 (d, 6H, $J_{H-P}$ = 11 Hz, $PO(OCH_3)_2$), 3.80 (q, 2H, $J$ = 7 Hz, $CH_3CH_2O$), 4.44 (d, 1H, $J_{H-P}$ = 6 Hz, vinyl proton). *Exact Mass* calcd. for $C_{23}H_{39}O_7P$: 458.2434; found: 458.2412.

(e) *Preparation of compound* ***33***

Alkylation of 2-carbomethoxycyclohexanone (**28**) (156 mg, 1 mmol) was carried out via a procedure very similar to that employed for the preparation of compounds **31** and **32**. However, 1.5 mmol of each of LDA, the allylic bromide **19** (413 mg), and HMPA (270 μL) were employed instead of the quantities indicated above and the reaction mixture was stirred at room temperature for 6 h instead of for 30 min. Distillation (air bath temperature 180°C/0.05 Torr) of the material obtained from the chromatography column afforded 247 mg (71%) of the alkylated keto ester **33** as a colorless oil. Both glc and tlc indicated that this material consisted of one component; ir (film): 1740, 1710, 1610, 1240, 1060–1020 (broad) $cm^{-1}$; $^1H$ nmr δ: 1.28 (t, 3H, $J$ = 7 Hz, $CH_3CH_2O$), ~1.5–2.5 (diffuse, 8H), 3.11, 3.37 (d of d, d of d, 1H each, $J_{H-H}$ = 16 Hz, $J_{H-P}$ = 2 Hz in each case, allylic methylene protons), 3.56–3.84 (a series of partially overlapped signals consisting of: d, 6H, $PO(OCH_3)_2$; s, 3H, $CO_2Me$; q, 2H, $CH_3CH_2O$), 4.40 (d, 1H, $J_{H-P}$ = 5 Hz, vinyl proton). *Exact Mass* calcd. for $C_{15}H_{25}O_7P$: 348.1338; found: 348.1333.

*Hydrolysis of the enol ether functional group of the alkylation products* ***29–33***

(a) *Preparation of compound* **34**

To a stirred solution of compound **29** (290 mg, 1 mmol) in 25 mL of acetone at room temperature was added 0.5 mL of 1 *N* hydrochloric acid. After the resultant mixture had been stirred at room temperature for 30 min, the acid was neutralized by addition of anhydrous potassium carbonate and the acetone was removed under reduced pressure. Dichloromethane was added to the residual material and the organic solution was washed twice with saturated aqueous potassium bicarbonate and then was dried over anhydrous sodium sulfate. Removal of the solvent, followed by distillation (air bath temperature 182°C/0.02 Torr) of the residual oil gave 262 mg (100%) of the diketo phosphonate **34** as a colorless oil, glc and tlc analyses of which indicated that it consisted of one component; ir (film): 1710, 1260, 1030 $cm^{-1}$; $^1H$ nmr δ: ~1.1–2.6 (diffuse, 9H), ~2.75–3.2 (diffuse, 2H), 3.16, 3.36 (d, d, 1H each, $J$ = 14 Hz, —$COCH_2PO$—), 3.72 (d, 6H, $J_{H-P}$ = 11 Hz, $PO(OCH_3)_2$). *Exact Mass* calcd. for $C_{11}H_{19}O_5P$: 262.0970; found: 262.0987.

(b) *Preparation of compound* ***35***

Hydrolysis of the enol ether **30** was accomplished by a procedure identical with that described above. The crude product obtained from 278 mg (1 mmol) of **30** was subjected to column chromatography on 8 g of silica gel. Elution of the column with ethyl acetate, followed by removal (reduced pressure) of the solvent from the appropriate fractions, gave 250 mg (100%) of compound **35** as a colorless oil. Analysis of this material by glc and tlc indicated that it consisted of one component; ir (film): 1710, 1270, 1040 $cm^{-1}$; $^1H$ nmr δ: 1.07 (t, 3H, $J$ = 8 Hz, $CH_3CH_2CO$), 1.08 (d, 3H, $J$ = 8 Hz, secondary methyl group), 2.42–2.88 (m, 3H, $CH_3CH_2CO$ and tertiary proton), 2.90–3.40 (m, 4H, $CH_2COCH_2PO$—), 3.75 (d, 6H, $J_{H-P}$ = 11 Hz, $PO(OCH_3)_2$). *Exact Mass* calcd. for $C_{10}H_{19}O_5P$: 250.0970; found: 250.0965.

(c) *Preparation of compound* ***36***

To a stirred solution of compound **31** (195 mg, 0.5 mmol) in 25 mL of acetone at room temperature was added 0.5 mL of 0.5 *N* hydrochloric acid. After the reaction mixture had been stirred at room temperature for 2 h, it was subjected to a work-up procedure identical with that described above (preparation of compound **34**). The crude product was purified by means of column chromatography on silica gel (8 g). Elution of the column with ethyl acetate, followed by removal (reduced pressure) of the solvent from the appropriate fractions gave 167 mg (92%) of the diketo phosphonate **36** as a colorless oil (one peak by glc analysis and one spot by tlc analysis); ir (film): 1710, 1260, 1025 $cm^{-1}$; $^1H$ nmr δ: 0.98, 1.04 (s, s, 3H each, tertiary methyl groups), ~1.35–3.30 (diffuse, 11H), 3.42–3.64 (m, 4H, ketal methylene protons), 3.81 (d, 6H, $J_{H-P}$ = 11 Hz, $PO(OCH_3)_2$). *Exact Mass* calcd. for $C_{16}H_{27}O_7P$: 362.1494; found: 362.1491.

(d) *Preparation of compound* ***37***

This substance was prepared by hydrolysis of compound **32** via a procedure identical with that described above (preparation of **36**), except that the reaction time was 15 min instead of 2 h. From 229 mg (0.5 mmol) of **32** there was obtained 206 mg (96%) of the diketo phosphonate **37** as a colorless oil which could be crystallized from ether–hexane. Recrystallization provided a pure sample, mp 107–109°C; ir ($CHCl_3$): 1705, 1260, 1030 $cm^{-1}$; $^1H$ nmr (400 MHz) δ: 0.90, 1.03, 1.17 (s, s, s, 3H each, tertiary methyl groups), 1.32–1.85 (diffuse, 8H), 1.94 (d of t, 1H, $J$ = 2, 13 Hz), 2.08 (m, 1H), 2.32–2.43 (m, 2H), 2.97–3.16 (8-line m,

For personal use only.

2H), 3.28–3.65 (m, 6H), 3.80, 3.81 (d, d, 3H each, $J_{H-P}$ = 11 Hz in each case, $PO(OCH_3)_2$). *Exact Mass* calcd. for $C_{21}H_{35}O_7P$: 431.2198; found: 431.2159.

(e) *Preparation of compound 38 (crude)*

To a stirred solution of compound **33** (174 mg, 0.5 mmol) in 15 mL of acetone at room temperature was added 0.5 mL of 0.5 *N* hydrochloric acid. After the resultant mixture had been stirred at room temperature for 35 min, it was subjected to a work-up procedure identical with that described above (preparation of compound **34**). Since the crude product thus obtained contained a small amount of the bicyclic keto ester **39** in addition to the desired product **38**, it was not purified further but was used directly for the next step.

*Intramolecular Horner–Emmons reactions of the diketo phosphonates 34–38*

(a) *Preparation of compound 40*

To a cold (0°C), stirred suspension of sodium hydride (14 mg, 0.6 mmol) in dry DME (2 mL), under an atmosphere of argon, was added, dropwise, a solution of the diketo phosphonate **34** in 1 mL of dry DME. After the reaction mixture had been stirred at room temperature for 30 min, it was warmed to 65°C and kept at that temperature for 1 h. The cooled mixture was poured into aqueous sodium chloride solution and the resultant mixture was extracted thoroughly with ether. The combined extract was washed with water and dried over anhydrous sodium sulfate. Removal of the solvent, followed by distillation (air bath temperature 45°C/0.02 Torr) of the residual oil gave 51 mg (74%) of the bicyclic enone **40** (8) as a colorless liquid (one peak by glc analysis); ir (film): 1700, 1620 $cm^{-1}$; $^1H$ nmr δ: 1.02–2.92 (diffuse, 11H), 5.88 (s, 1H, olefinic proton). *Exact Mass* calcd. for $C_8H_{12}O$: 136.0888; found: 136.0891.

(b) *Preparation of compound 41*

This substance was prepared via a procedure identical with that described above, except that the reaction mixture was stirred at 65°C for 3 h instead of for 1 h. Distillation (air bath temperature 100°C/15 Torr) of the crude product gave 51 mg (82%) of 3-ethyl-4-methyl-2-cyclopenten-1-one (**41**) (25) as a colorless liquid which exhibited one peak by glc analysis; ir (film): 1700, 1610 $cm^{-1}$; $^1H$ nmr δ: 1.20 (t, 3H, $J$ = 7 Hz, $CH_3CH_2$), 1.21 (d, 3H, $J$ = 7 Hz, secondary methyl group), 1.96–2.96 (diffuse, 5H), 5.94 (narrow m, 1H, olefinic proton). *Exact Mass* calcd. for $C_8H_{12}O$: 124.0888; found: 124.0893.

(c) *Preparation of compound 42*

The procedure employed was identical with that used for the preparation of the cyclopentenone **41**, except that the quantities of reactants used were sodium hydride, 9 mg (0.38 mmol) and diketo phosphonate **36**, 118 mg (0.33 mmol). The crude product was subjected to chromatography on 4 g of silica gel. Elution of the column with ethyl acetate produced a light yellow solid which was distilled (air bath temperature 155–160°C/0.05 Torr) to yield 56 mg (72%) of the bicyclo enone **42**. An analytical sample, obtained by recrystallization of this material from ether–hexane, exhibited mp 73–74°C; ir ($CHCl_3$): 1700, 1620 $cm^{-1}$; $^1H$ nmr δ: 1.00, 1.02 (s, s, 3H each, tertiary methyl groups), ~1.2–3.1 (diffuse, 9H), 3.56 (s, 4H, ketal methylene protons), 5.91 (broad s, 1H, olefinic proton). *Exact Mass* calcd. for $C_{14}H_{20}O_3$: 236.1412; found: 236.1422.

(d) *Preparation of compound 43*

This compound was prepared via a procedure identical with that employed for the synthesis of **42**, except that the reaction mixture was maintained at 65°C for 2 h instead of for 3 h. The crude product obtained from 142 mg (0.33 mmol) of the diketo phosphonate **37** was purified by chromatography on 4 g of silica gel. Elution of the column with ethyl acetate – hexane (1:1) gave 86 mg (86%) of the tricyclic enone **43** as a white solid, an analytical sample of which was obtained by recrystallization of this material from ether–hexane, mp 116–117°C; ir ($CHCl_3$): 1680, 1610 $cm^{-1}$; $^1H$ nmr (400 MHz) δ: 0.94, 1.00 (s, s, 3H each, ketal methyl groups), 1.13 (s, 3H, angular methyl group), 1.18 (q of d, 1H, $J$ = 5 Hz, 13 Hz), 1.39–1.67 (diffuse, 6H), 1.73 (q of d, 1H, $J$ = 4, 14 Hz), 1.96 (d of d, 1H, $J$ = 2, 18 Hz), 1.99 (d of t, 1H, $J$ = 3, 13 Hz), 2.18 (m, 1H), 2.34 (d of q, 1H, $J$ = 3, 13 Hz), 2.58 (d of d, 1H, $J$ = 7, 18 Hz), 2.98 (m, 1H), 3.42–3.61 (m, 4H, ketal methylene protons), 5.80 (d, 1H, $J$ = 1.5 Hz, olefinic proton). *Exact Mass* calcd. for $C_{19}H_{28}O_3$: 304.2039; found: 304.2029.

(e) *Preparation of compound 44*

The crude diketo phosphonate **38** (*vide supra*) was subjected to cyclization via a procedure identical with that described above (preparation of **40**), except that the reaction mixture was stirred at 65°C for 2 h instead of for 1 h. Distillation (air bath temperature 110°C/0.05 Torr) of the crude product gave 68 mg (70%, based on the enol ether **33**) of the bicyclic keto ester **44** (colorless oil, one peak by glc analysis and one spot by tlc analysis); ir (film): 1730, 1710, 1625 $cm^{-1}$; $^1H$ nmr δ: ~1.2–2.9 (diffuse, 8H), 2.26, 2.60 (d, d, 1H each, $J$ = 18 Hz, $—CH_2CO$), 3.66 (s, 3H, $CO_2CH_3$), 5.93 (d, 1H, $J$ = 2 Hz, olefinic proton). *Exact Mass* calcd. for $C_{11}H_{14}O_3$: 194.0944; found: 194.0944.

# Syntheses of condensed imidazoles by lead tetraacetate oxidation of amidines

S. CHAUDHURY, A. DEBROY, AND M. P. MAHAJAN[1]

*Department of Chemistry, North-Eastern Hill University, Shillong 793 003, India*

Received September 23, 1981

S. CHAUDHURY, A. DEBROY, and M. P. MAHAJAN. Can. J. Chem. **60**, 1122 (1982).

2-Phenylbenzimidazoles, 2-benzylbenzimidazoles, 2-phenyl-1*H*-naphtho[1,2-*d*]imidazole, and 2-benzyl-1*H*-naphtho[1,2-*d*]-imidazole have been synthesized in excellent yields (77–98%) by lead tetraacetate oxidation of suitable *N*-arylbenzamidines, *N*-arylphenylacetamidines, *N*-α-naphthylbenzamidine, and *N*-α-naphthylphenylacetamidine respectively. The mechanism of nitrene insertion and intramolecular competitive nitrene insertion leading to these heterocycles has also been discussed.

S. CHAUDHURY, A. DEBROY et M. P. MAHAJAN. Can. J. Chem. **60**, 1122 (1982).

On a synthétisé, avec d'excellents rendements (77–98%), les composés suivants: phényl-2 benzimidazoles, benzyl-2 benzimidazoles, phényl-2 1*H*-naphtho[1,2-*d*] imidazole et benzyl-2 1*H*-naphtho[1,2-*d*] imidazole par l'oxydation, au moyen du tétraacétate de plomb, des composés suivants convenablement choisis: *N*-arylbenzamidines, *N*-arylphénylacétamidines, *N*-α napthylbenzamidine et *N*-α naphthylphénylacétamidine respectivement. On discute également des mécanismes d'insertion du nitrène et d'insertion intramoléculaire compétitive du nitrène conduisant à ces hétérocycles.

[Traduit par le journal]

Because of the increasing importance of benzimidazoles, a simpler approach to the synthesis of these heterocyclics was thought to be of great value. The procedure for the synthesis of benzimidazoles usually involves the condensation of *o*-phenylenediamine or *o*-nitroaniline with a carboxylic acid derivative. In each case, the cyclization involves coupling at the *o*-phenylene nitrogens.

Since *N*-arylamidines are easily available (1–3), it appeared that substituted amidines could be potential precursors for the synthesis of benzimidazoles, if they could be induced to cyclize by some oxidative means. The formation of benzimidazoles from *N*-arylamidines was first reported by Partridge and Turner and required the prior conversion of *N*-arylamidines to *N*-hydroxy amidines (4). Later on it was found that *N*-arylamidine hydrochlorides could be transformed into benzimidazoles with one mole of sodium hypochlorite and base (5, 6). Often the yields of *N*-chloro derivatives are unsatisfactory, which in turn is reflected in lower yields of benzimidazoles.

We report here the syntheses of various 2-phenyl and 2-benzyl condensed imidazoles, in excellent yields (77–98%), by lead tetraacetate (LTA) oxidation of suitable amidines (Schemes 1–3). The object of the present investigation has also been to explore intramolecular competitive nitrene insertions and the nitrene insertion mechanism leading to these heterocycles.

In the case of LTA oxidation of *N*-*o*-tolylbenzamidine, where there is a possibility of nitrene insertion into both the C—H bond of methyl and the C—H bond of phenyl, insertion takes place exclusively into the C—H bond of phenyl. This is perhaps due to the aromatic stabilization of the benzimidazole ring formed by insertion into the phenyl C—H bond, which is not the case with dihydroquinazoline formed by insertion into the methyl C—H bond (Scheme 2). Similarly, in the case of oxidation of *N*-*m*-chlorophenylbenza-

midine there exists a possibility of nitrene insertion into the C—H bond either *ortho* or *para* to chlorine. The product formed in this case is 4(7)-chloro-2-phenylbenzimidazole (**7**) confirmed by its superimposable ir spectrum and undepressed mixture melting point with the product obtained by oxidation of *N*-*o*-chlorophenylbenzamidine. This observation indicates that the nitrene insertion has taken place into the C—H bond *ortho* to chlorine (Scheme 2).

In the case of LTA oxidations of *N*-arylphenylacetamidines in refluxing dichloromethane, the yield of the 2-benzylbenzimidazoles was always between 20–30%. The tlc of the reaction mixture, even on addition of excess of LTA (2 equiv.), always showed the presence of unreacted amidine. A number of futile attempts were made to improve the yields of 2-benzylbenzimidazoles, e.g., by carrying out the oxidation (*i*) in refluxing benzene; (*ii*) in acetic acid. In the case of oxidation with LTA/acetic acid, 2-benzylbenzimidazole was not formed at all. It was concluded that the acetic acid was perhaps protonating amidine and inhibiting the attack of nitrogen on lead of LTA. With this in mind pyridine was used as a scavenger for acetic acid and oxidations of *N*-arylphenylacetamidines with LTA/$CH_2Cl_2$/pyridine gave excellent yields (85–98%) of 2-benzylbenzimidazoles.[2]

In the case of LTA oxidations of *N*-arylphenylacetamidines (**8**), there exists a possibility of nitrene insertion into a C—H bond of either of the two phenyl groups. But the intermediate azomethine nitrene (**9**), in this case, appears to be highly selective in undergoing cyclization leading to 2-benzylbenzimidazoles (Scheme 3).

In the case of LTA oxidation of *N*-*o*-tolylphenylacetamidine the product obtained was also that of nitrene insertion into the phenyl C—H bond. The oxidation of *N*-*m*-chlorophenylphenylacetamidine gave the same product as obtained by oxidation of *N*-*o*-chlorophenylphenylacetamidine, indicating again that the nitrene insertion has taken place into the phenyl C—H bond which is *ortho* to chlorine.

This oxidation method was extended to the synthesis of 2-phenyl-1*H*-naphtho[1,2-*d*]imidazole[3] and 2-benzyl-1*H*-naphtho[1,2-*d*]imidazole by the oxidation of *N*-α-naphthylbenzamidine and N-α-naphthylphenylacetamidine with LTA/$CH_2$-

$Cl_2$/pyridine. It may be mentioned here that LTA oxidation of *N*-α-naphthylbenzamidine in refluxing dichloromethane gave only about 30% of the product and the yield improved tremendously by carrying out the oxidation in the presence of pyridine.

In the case of oxidation of *N*-arylbenzamidines (**1**), the probable intermediate azomethine nitrene (**3**) may lead to 2-phenylbenzimidazoles (**2**) by any of the four paths shown in Scheme 1. The probable intermediate **3** may lead to 2-phenylbenzimidazoles (**2**) by direct insertion of nitrene into the C—H bond (Path I); it may lead to imidazole ring formation by ring expansion of the diazirine intermediate **4** (Path II); the resonance stabilization of the azomethine nitrene **3** may lead to 2-phenylbenzimidazoles via intermediates **5** and **6** (Path III); or the intermediate **3** may, via the electrocyclic ring closure to intermediate **6**, lead to **2** (Path IV).

The biradical mechanism involved in Path III may be ruled out because it has been shown by Lwowski and others that acylnitrenes, to which **3** bears a more than superficial resemblance, insert into C—H as singlets (7–11)

Direct insertion (Path I) may be ruled out of the other alternatives, and the electrocyclic ring closure mechanism (Path IV) favoured, on the basis of the following observations.

(*i*) As already pointed out in the case of LTA oxidations of *N*-arylphenylacetamidines (**8**), there exists a possibility of nitrene insertion into a C—H bond of either of two phenyl groups. Direct nitrene insertion would lead to 2-benzylbenzimidazoles (**10**) or 2-anilinoindoles (**11**), both of which possess aromatic stabilization. But the intermediate **9** appears to be highly selective in undergoing cyclization leading to 2-benzylbenzimidazoles rather than 2-anilinoindoles (Scheme 3). This discrimination between two possible ring closures may be attributed to electron delocalization[4] in an intermediate azomethine nitrene (**9**), indicating the preference for reaction Path IV for the formation of these benzimidazoles via **9***a*.

(*ii*) In the case of oxidation of *N*-*m*-chlorophenylbenzamidine and *N*-*m*-chlorophenylphenylacetamidine, insertion of nitrene takes place *ortho* to chlorine, though insertion at the *para* position should be favoured for steric reasons. This can also be explained by a delocalization mechanism, i.e., Path IV is favoured and insertion at the *ortho* position takes place because of the pull of electrons towards chlorine due to its inductive effect.

[4]This kind of electron delocalization is absent for the formation of 2-anilinoindoles (**11**).

(*iii*) In the case of oxidation of *N*-*o*-tolylbenzamidine the exclusive formation of 4(7)-methyl-2-phenylbenzimidazole can also be explained by this electrocyclic ring closure mechanism (Path IV).

Further work on such reactions in the presence of various 1,3-dipolarophiles, in order to trap the nitrene intermediate and to look into its spin multiplicities, is in progress.

## Experimental

All the mp's are uncorrected. The ir spectra were recorded on a Perkin–Elmer Model 297 ir spectrometer. The nmr traces were recorded on a Varian EM-390 90 MHz nmr spectrometer.

The following *N*-arylbenzamidines and *N*-arylphenylacetamidines, with yields (%), mp (°C), (lit. mp (°C)), and (reference) were prepared by the reported methods (2, 3). *N*-phenylbenzamidine, 75, 113–114 (116) (12); *N*-phenylphenylacetamidine, 70, 134–135 (133–135) (13); *N*-*o*-tolylbenzamidine, 98, 102–103; *N*-*o*-tolylphenylacetamidine, 71, 107–108; *N*-*p*-tolylbenzamidine, 76, 99–100, (100.5–101) (12); *N*-*p*-tolylphenylacetamidine, 84, 117–118 (119) (12); *N*-*o*-chlorophenylbenzamidine, 85, 109–110; *N*-*o*-chlorophenylphenylacetamidine, 42, 109–110 (111–112) (12); *N*-*m*-chlorophenylbenzamidine, 34, 106–107; *N*-*m*-chlorophenylphenylacetamidine, 82, 87–88; *N*-*p*-chlorophenylbenzamidine, 99, 116–119; *N*-*p*-chlorophenylphenylacetamidine, 68, 114–115; *N*-*p*-bromophenylbenzamidine, 65, 115–116; *N*-*p*-bromophenylphenylacetamidine, 57, 119–120; N-α-naphthylbenzamidine, 54, 139–140 (140–142) (14); *N*-α-naphthylphenylacetamidine, 39, 123–124.

*LTA oxidation of* N-*phenylbenzamidine*

To a stirred solution of *N*-phenylbenzamidine (1.96 g, 0.01 mol) in dichloromethane (25 mL) was added LTA (4.88 g, 0.011 mol) in small portions over 15 min. After the complete addition of LTA, the reaction mixture was refluxed for 1½ hours. After careful removal of the solvent, the reaction mixture was treated with hot benzene and filtered. The filtrate was then washed with water and dried over anhydrous sodium sulphate. The solvent was removed under reduced pressure and the 2-phenylbenzimidazole (1.73 g; 89%), obtained on addition of a mixture (1:1) of benzene and hexane to the residue, was recrystallized from a mixture (9:1) of benzene and ethanol; mp. 288–289°C (lit. (14) mp 289–290°C); ir (Nujol) $\nu_{max}$: 3400 (weak broad band, $\nu_{N-H}$), 2960, 2920, 2860 ($\nu_{C-H}$), 1590, 1540, 1495 (v. weak), 1465, 1445 ($\nu_{C=C}$ and $\nu_{C=N}$). (These ir bands are common in all the 2-arylbenzimidazoles reported in this paper). *Anal.* calcd. for $C_{13}H_{10}N_2$: C 80.41, H 5.16, N 14.43%; found: C 80.77, H 5.09, N 13.94%. Mol. Wt. calcd.: 194; found (ms): 194.

Other 2-phenylbenzimidazoles (Table 1, 2–6) were obtained similarly by LTA oxidation of the corresponding *N*-arylbenzamidines.

*LTA oxidation of* N-*phenylphenylacetamidine*

To a stirred solution of *N*-phenylphenylacetamidine (2.10 g; 0.01 mol) in dichloromethane (25 mL) and pyridine (8 mL) was added LTA (4.88 g; 0.011 mol) in small portions in about 15 min. After the complete addition of LTA, the reaction mixture was heated in an oil bath (80–90°C) for 1½ hours. The solvent was then removed under reduced pressure and the residue so obtained was extracted with hot benzene. The benzene extracts were washed with water and dried over anhydrous sodium sulphate. The solvent was then removed under reduced pressure and the 2-benzylbenzimidazole (1.89 g; 90%), obtained on addition of a mixture (1:1) of benzene and hexane, was

# The mechanism of electrochemical reduction of *N*-haloamides in acetonitrile: trapping of intermediate amide anions and father–son protonation[1,2]

DENIS BÉRUBÉ[3] AND JEAN LESSARD

*Département de chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1*

Received September 8, 1981

DENIS BÉRUBÉ and JEAN LESSARD. Can. J. Chem. **60**, 1127 (1982).

The electrochemical reduction of *N*-haloamides (ZCONRX) in acetonitrile involves two consecutive one-electron transfers and generates the amide anion. Attempts to trap the intermediate amidyl radical resulting from the first electron transfer were unsuccessful. In the case of the N-*halo*-N-*hydroamides* (R = H), the amide anion formed at the electrode abstracts a proton from an incoming *N*-halo-*N*-hydroamide molecule to give the parent amide and the conjugate base of the *N*-haloamide (father–son protonation). Thus, half of the *N*-halo-*N*-hydroamide reaching the electrode is reduced, the other half being converted to its conjugate base. In acetonitrile–$LiClO_4$ (0.2 *M*) containing 0.2% water, the conjugate base is reducible and the polarograms therefore show two waves (irreversible and diffusion controlled) of *equivalent intensities* due respectively to the reduction of the *N*-halo-*N*-hydroamide and to the reduction of its conjugate base. In the case of the N-*chloro*-N-*alkyl(aryl)amides* (X = Cl, R = alkyl or aryl), the amide anion abstracts a proton from the medium to give the parent amide and anionic species that react with the starting *N*-chloroamide regenerating the amide anion. Hence, the coulometric results are low (≃ 0.5 F/mol). However, in the presence of acetic acid, the reduction consumes 2 F/mol as expected. The *N*-alkylamide anion has been trapped by *N*-alkylation and *N*-acylation. The voltammograms of *N*-chloro-*N*-alkyl(aryl)amides show multiple waves on mercury and platinum due to passivation–adsorption phenomena but a single wave on vitreous carbon.

DENIS BÉRUBÉ et JEAN LESSARD. Can. J. Chem. **60**, 1127 (1982).

La réduction électrochimique des *N*-haloamides (ZCONRX) fait intervenir deux transferts consécutifs d'un électron et conduit à l'anion de l'amide. Le radical amidyl résultant du transfert du premier électron n'a pu être piégé. Dans le cas des N-*halo*-N-*hydroamides* (R = H), l'anion de l'amide est protoné par le *N*-halo-*N*-hydroamide arrivant à l'électrode pour donner l'amide et la base conjuguée du *N*-haloamide (protonation père-fils). Ainsi, la moitié du *N*-halo-*N*-hydroamide atteignant l'électrode est réduite et l'autre moitié est convertie en sa base conjuguée. Dans le milieu acétonitrile–$LiClO_4$ (0.2 *M*) contenant 0.2% d'eau où la base conjuguée du *N*-halo-*N*-hydroamide peut être réduite, les polarogrammes montrent donc deux vagues (irréversibles et contrôlées par la diffusion) d'*intensités égales*; la première est due à la réduction du *N*-halo-*N*-hydroamide et la deuxième à la réduction de sa base conjuguée. Dans le cas des N-*chloro*-N-*alkyl(aryl)amides* (X = Cl, R = alkyl ou aryl), l'anion de l'amide abstrait un proton du milieu pour donner l'amide et des espèces anioniques qui réagissent avec le *N*-chloroamide de départ pour regénérer l'anion de l'amide, ce qui conduit à des coulométries observées faibles (≃ 0.5 F/mol). Cependant, en présence d'acide acétique, la coulométrie est de l'ordre de 2 F/mol tel qu'attendu. L'anion des *N*-alkylamides a été piégé par *N*-alkylation et *N*-acylation. Les voltammogrammes des *N*-chloro-*N*-alkyl(aryl)amides montrent plus d'une vague sur électrodes de mercure et de platine à cause de phénomènes d'adsorption mais ne révèlent qu'une seule vague sur carbone vitreux.

Our previous work (1) on the electrochemical reduction of *N*-haloamides (ZCONRX) led us to the conclusion that the reduction involves two consecutive one-electron steps as described by reactions [1] and [2] and that the intermediate amidyl radical (step [1]) might have been captured by intramolecular hydrogen abstraction. We now report further studies on the mechanism of electroreduction of *N*-halo-*N*-hydroamides (R = H) and *N*-halo-*N*-alkyl(aryl)amides (R = alkyl or aryl) in acetonitrile which show clearly that the reduction leads to the amide anion (reactions [1] and [2]). No evidence for the trapping of the electrochemically generated amidyl radical (step [1]) could be obtained.

$$[1]\quad ZCONRX + e^- \xrightarrow{\text{slow}} ZCO\dot{N}R + X^-$$

$$[2]\quad ZCO\dot{N}R + e^- \xrightarrow{\text{fast}} ZCO\bar{N}R$$

## Results and discussion

### N-*Halo*-N-*hydroamides (ZCONHX)*

#### *Polarographic studies*

*Amperometric titrations*: As reported in the previous paper (1), the polarograms of *N*-halo-*N*-hydroamides show two irreversible and diffusion-controlled reduction waves in methanol as well as in acetonitrile using lithium perchlorate (0.2 *M*) as supporting electrolyte.[4] For instance, in the case of *N*-chlorourethane (NCU) (**1***a*), $(E_{1/2})_1 = -0.60$ V and $(E_{1/2})_2 = -0.96$ V vs. a saturated calomel

[1]Part II in the series "Electroreduction of *N*-haloamides". For part I, see ref. 1.

electrode (sce)[5] in methanol and, in acetonitrile, $(E_{1/2})_1 = -0.22$ V and $(E_{1/2})_2 = -1.22$ V (1). *The limiting currents of the two waves are nearly equivalent in both solvents:* $I_1 \simeq I_2$. Upon adding 1 equiv. (or more) of a base such as the methoxide anion, the *N*-halo-*N*-hydroamide (**1**) is converted to its conjugate base **2** (reaction [3])[6] and the first

[3] $\underset{\mathbf{1}}{\text{ZCONXH}} + \text{CH}_3\text{O}^- \longrightarrow \underset{\mathbf{2}}{\text{ZCON}^-\text{X}} + \text{CH}_3\text{OH}$

wave disappears; the limiting current of the second wave is then nearly twice that in the neutral medium ($I \simeq 2I_2$ or $I \simeq I_1 + I_2$). This is illustrated in Fig. 1 (part *A*) in the case of *N*-bromoacetamide (NBA) (**1***b*). When acetic acid is added to the resulting solution (Fig. 1, part *B*), the excess of base is neutralized first, then the addition of about 1 equiv. of acid regenerates the neutral medium with its two equivalent waves ($I_1 \simeq I_2$); the addition of a second equivalent (or more) of acid causes the disappearance of the second wave, the limiting current of the first wave being now nearly twice that in the neutral medium ($I \simeq 2I_1$ or $I \simeq I_1 + I_2$). The lithium salts **2** of some *N*-halo-*N*-hydroamides have been obtained independently as solids (1). When dissolved in acetonitrile–$LiClO_4$ (0.2 *M*), they show the second wave only; upon addition of acetic acid, they behave as the lithium salts obtained *in situ*: compare Fig. 1, part *B*, and Fig. 2.[7]

The amperometric titrations just described show that the first wave must correspond to the reduction of the *N*-halo-*N*-hydroamide **1** and the second wave, to the reduction of its conjugate base **2** as previously proposed (1). However, no explanation was given for the equivalence of the limiting

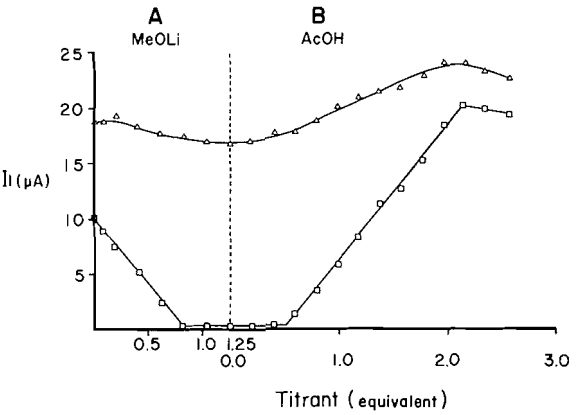

FIG. 1. Amperometric titration of NBA (**1***b*) (3.3 m*M*) in acetonitrile–$LiClO_4$ (0.2 *M*) at 0°C. The addition of lithium methoxide (part A) is followed by that of acetic acid (part B): □, limiting current of the first wave ($I_1$); △, total limiting current ($I_1 + I_2$).

currents of the two waves ($I_1 \simeq I_2$) in a neutral medium (1). The equivalence is due to the fact that the two-electron cleavage of the >N—X bond leads to the amide anion **3** (reaction [4] which is the sum of reactions [1] and [2] where R = H) which then abstracts a proton from an incoming molecule of *N*-halo-*N*-hydroamide **1** to give the parent amide and the conjugate base **2** of the *N*-haloamide **1** (reaction [5]). The amide anion **3** is a much stronger base than **2**[8] and the proton exchange must be fast enough to prevent the incoming molecules of *N*-halo-*N*-hydroamide **1** to reach the electrode (see below). Reaction [5] constitutes a clear-cut example of a *father–son protonation* (4) and other cases of such reactions can be found in the literature (5, 6). Reaction [6] represents the sum of reactions [4]

[4] $\underset{\mathbf{1}}{\text{ZCONHX}} + 2e^- \longrightarrow \underset{\mathbf{3}}{\text{ZCON}^-\text{H}} + \text{X}^-$

[5] $\underset{\mathbf{3}}{\text{ZCON}^-\text{H}} + \underset{\mathbf{1}}{\text{ZCONHX}} \longrightarrow \text{ZCONH}_2 + \underset{\mathbf{2}}{\text{ZCON}^-\text{X}}$

[6] $\underset{\mathbf{1}}{2\text{ZCONHX}} + 2e^- \longrightarrow \text{ZCONH}_2 + \underset{\mathbf{2}}{\text{ZCON}^-\text{X}} + \text{X}^-$

and [5] and it shows clearly that at the first wave potential, only *half* of the *N*-halo-*N*-hydroamide **1** reaching the electrode is reduced, the other half being converted to its conjugate base **2** (not reduced at the first wave level). Similarly, at the second wave potential where the reduction of **2** does occur, only *half* of the *N*-halo derivative **1** reaching the electrode is converted to **2**, the other half being

[5]All the potentials reported in this paper were measured with respect to an aqueous saturated calomel electrode (sce).

[6]The $pK_a$ of $CH_3OH$ is close to 16 and that of ZCONHZ varies between 2.9 and 8.0 in water, 3.6 and 10.2 in 75% ethanol, depending on Z and X (2), so the equilibrium constant of reaction [3] must be large (e.g. $K_{eq.} \simeq 10^8$ for NCU in water) in methanol and acetonitrile as well.

[7]For the amperometric titration of NCU (**1***a*) in methanol (1), it took exactly 1 mol sodium methoxide to generate the conjugate base (disappearance of the first wave) and exactly 1 mol acetic acid to cause the disappearance of the second wave. The titration of the lithium salt **2***a* of NCU in acetonitrile with acetic acid is also exact (Fig. 2). However, in the case of NBA (**1***b*), less than 1 equiv. lithium methoxide (≃ 0.85 equiv.; Fig. 1, part *A*) was needed to convert NBA to its conjugate base **2***b*. This can be accounted for by the partial decomposition of **2***b* (e.g. Hoffmann degradation). Consequently, the amount of acetic acid needed to neutralize **2***b* (Fig. 1, part *B*) was also less than 1 equiv. (≃ 0.8 equiv.). It can be seen from Fig. 1 and Fig. 2 that the total limiting current ($I_1 + I_2$) varies during the titration and this can be attributed to differences in the diffusion coefficients of the *N*-halo-*N*-hydroamide **1** and of its conjugate base **2**.

[8]For instance, the $pK_a$ of $CH_3CONH_2$ is 15 (3) and that of NBA in water is 7.89 (2) which would give $K_{eq} \simeq 10^7$ for reaction [5].

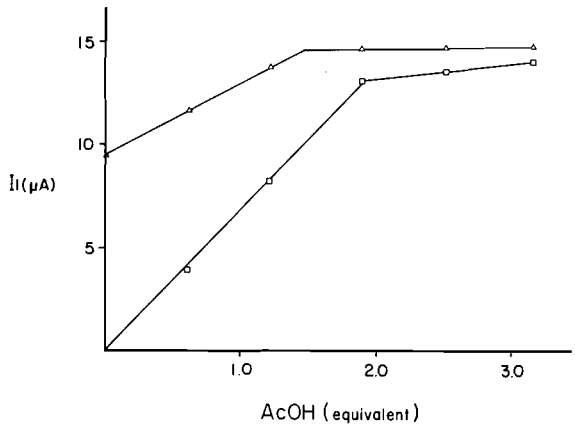

FIG. 2. Amperometric titration of the lithium salt of NCU (1.41 m*M*) in acetonitrile–$LiClO_4$ (0.2 *M*) with acetic acid: □, limiting current of the first wave ($I_1$); △, total limiting current ($I_1 + I_2$).

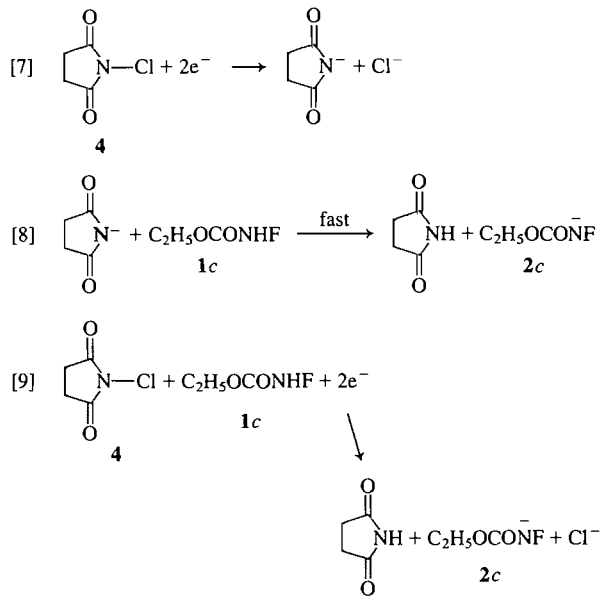
converted to the electroinactive parent amide $ZCONH_2$. Hence $I_1 \simeq I_2$.

In order to verify that proton exchange (reaction [5]) can be fast in acetonitrile, even when dry, we studied the polarographic behavior of a mixture of *N*-chlorosuccinimide (NCS) (**4**) and *N*-fluorourethane (NFU) (**1***c*) in dry acetonitrile[9] using tetraethylammonium perchlorate (TEAP) (0.1 *M*) as supporting electrolyte. The polarogram of NCS in that medium shows one wave ($E_{1/2} = -0.12$ V) described by reaction [7]. When NFU was added, we could not observe its reduction wave ($E_{1/2} = -1.81$ V) until more than 1 equiv. with respect to NCS had been added. This is because 1 equiv. of NFU is used to protonate the conjugate base of NCS (eq. [8])[10] produced near the electrode (reaction [7]). Reaction [9] represents the sum of reactions [7] and [8] and it shows that when 1 equiv. (or less) of NFU is present, all the incoming NFU is converted to its electroinactive conjugate base.[11] Therefore, the proton-transfer reaction [8] is fast enough to prevent the NFU to reach the electrode.

The effect of the father–son reaction [5] should be eliminated by adding to the medium, in sufficient amount (1 equiv. or more), an acid which is stronger than the *N*-halo-*N*-hydroamide **1**. Indeed, in the case of NCU (**1***a*) with a $pK_a$ of 8.02 (2) and NBA (**1***b*) with a $pK_a$ of 7.89 (2), the addition of 1



equiv. or more of acetic acid ($pK_a = 4.76$) causes the disappearance of the second wave[12] (due to the reduction of the conjugate bases **2***a* and **2***b*) and a twofold increase in the limiting current of the first wave ($I \simeq 2I_1$), as already pointed out. Thus the effect of the father–son protonation has been suppressed (reaction [10] and/or reaction [11]) and *all* the *N*-halo-*N*-hydroamide reaching the electrode is now reduced as shown by reaction [12] which is the sum of reactions [5] and [10] or the sum of reactions [5], [6], and [11].

*Influence of water*: For the above polarographic studies, the acetonitrile used contained about 0.2% of water (wet acetonitrile) as already indicated. When using dry acetonitrile, the polarograms of NCU (**1***a*) and NBA (**1***b*) showed the first wave only at the same potentials as in wet acetonitrile, the limiting currents being also the same: $I = I_1 \simeq 1/2(I_1 + I_2)$. Thus the father–son protonation (reaction [5]) does take place also in dry acetonitrile in agreement with the fact that the analogous proton exchange reaction [8] was fast in dry acetonitrile. At the second wave level, an ill-defined maximum was observed and, upon adding water, it changed gradually to a well-defined wave when about 0.2%

[9]The water content of dry acetonitrile was ≃ 0.01% (see Experimental section).

[10]NCS has a $pK_a$ of 9.6 (7) and that of NFU is 5.69 (2) which gives, for reaction [8], $K_{eq} \simeq 10^4$ in water.

[11]The electrochemical and chemical behavior of NFU (**1***c*) is, in many respects, different from that of the other *N*-halo-*N*-hydroamides studied and this will be reported and discussed in a forthcoming paper.

[12]In fact, in methanol, the second wave disappears completely (8) but in acetonitrile, it does not disappear entirely as can be seen from Fig. 1, part B, and Fig. 2. According to the $pK_a$ values in water, the conjugate bases **2***a* and **2***b* should be neutralized to an extent of 99.9% or more ($K_{eq} \simeq 1.4–1.8 \times 10^3$) in the presence of 1 equiv. of acetic acid. However, in acetonitrile, and particularly in the double layer region, acetic acid might be a less efficient proton donor towards the conjugate base **2** than expected from the $pK_a$ values in water.

[10] $\underset{\mathbf{3}}{\text{ZCO}\bar{\text{N}}\text{H}} + \text{CH}_3\text{COOH} \rightarrow \text{ZCONH}_2 + \text{CH}_3\text{COO}^-$

[11] $\underset{\mathbf{2}}{\text{ZCO}\bar{\text{N}}\text{X}} + \text{CH}_3\text{COOH} \rightleftharpoons \underset{\mathbf{1}}{\text{ZCONHX}} + \text{CH}_3\text{COO}^-$

[12] $\underset{\mathbf{1}}{\text{ZCONHX}} + \text{CH}_3\text{COOH} + 2e^- \rightarrow \text{ZCONH}_2 + \text{CH}_3\text{COO}^- + \text{X}^-$

(or more) water had been added. The fact that the second wave cannot be observed before the reduction of the solvent-supporting electrolyte system ($E_{\text{limit}} \simeq -3.2$ V) when the medium is dry shows that the reduction of the conjugate base **2** becomes easier in the presence of water.[13] Indeed, the insertion of the first electron into the anion **2** should lead to the radical dianion shown in reaction [13] or

[13] $\underset{\mathbf{2}}{\text{ZCO}\bar{\text{N}}\text{X}} + e^- \not\rightarrow [\text{ZCONX}]^{2-\cdot} \rightarrow \text{Products}$

to a transition state closely resembling that radical dianion, a species of high energy. In the presence of a sufficient amount of water (or of a protic solvent), the formation of such an energetic species can be avoided (reaction [14]) and the reduction of the

[14] $\underset{\mathbf{2}}{\text{ZCO}\bar{\text{N}}\text{X}} + \text{H}_2\text{O} + e^- \rightarrow [\text{ZCONHX}]^{-\cdot} + \text{OH}^- \rightarrow \text{ZCO}\dot{\text{N}}\text{H} + \text{X}^-$

conjugate base **2** becomes easier than that of the solvent-supporting electrolyte system. In reaction [14], water could intervene before the electron exchange (solvation or preprotonation of the anion **2**) or during the electron exchange. Reaction [15]

[15] $\underset{\mathbf{2}}{\text{ZCO}\bar{\text{N}}\text{X}} + 2\text{H}_2\text{O} + 2e^- \rightarrow \text{ZCONH}_2 + \text{X}^- + 2\text{OH}^-$

describes the overall two-electron reduction of the conjugate base **2** in the presence of water.

It must be stressed that water is needed in the double layer in order to observe the reduction of the conjugate base **2**. By using TEAP (0.1 *M*) as supporting electrolyte, the polarogram of NCU (**1***a*) showed the first wave only ($E_{1/2} = -0.15$ V) even when the bulk solution did contain as much as 10% of water (the half-wave potential and the limiting current did not change upon the addition of water). Tetraalkylammonium salts are indeed known to render the double layer anhydrous when electrolytic reductions are carried out in an aprotic medium containing water (9). However, the addition of 1 equiv. or more of acetic acid led to a twofold increase of the limiting current (Fig. 3), thus showing that the double layer contains enough acetic acid to suppress the father–son protonation [5]:[14] all the *N*-halo-*N*-hydroamide **1** reaching the electrode is then reduced according to reaction [12].

*Preparative electrolyses*

The exhaustive electrolysis of NCU (**1***a*) in methanol–$LiClO_4$ (0.2 *M*) at −0.7 V and in wet acetonitrile–$LiClO_4$ (0.2 *M*)[4] at −0.3 V, on a mercury or platinum electrode, has been reported to give over 90% of urethane (1), thus showing that the conjugate base **2** can be reduced under these conditions even at potentials near the half-wave potential of the first wave. The lithium salt of NCU (conjugate base **2***a*) has been quantitatively reduced (−1.2 V) to urethane in methanol (1). However, in dry acetonitrile – $LiClO_4$ (0.2 *M*),[9] attempts to reduce this salt at a platinum electrode were unsuccessful: no significant current was observed before the reduction of the solvent–electrolyte system (−3.2 V). These results agree with the above polarographic studies showing that water (or a protic solvent like methanol) is needed in order to observe the reduction of the anion **2** (reaction [15]).

The exhaustive electrolysis of NCU in dry acetonitrile – $LiClO_4$ (0.2 *M*) led to only 25% of the NCU anion **2***a* instead of the expected 50% (reaction [6]) according to polarographic and iodometric analyses. The reaction mixture was treated with sodium bisulfite and urethane was the sole product detected by vapor phase chromatography (vpc) (81% yield). The fact that only 25% of **2***a* was left after the exhaustive electrolysis can be attributed mainly to the thermal and/or photochemical decomposition of **2***a* during the 9 h required for the electrolysis to be completed as shown by a control experiment carried out on the lithium salt of NCU (see Experimental section). Other authors have also observed the decomposition of the NCU anion **2***a* in an aprotic medium (11). In the presence of acetic acid, the exhaustive electrolysis led to the complete consumption of NCU as expected (reaction [12]) and the yield of urethane (the sole product detected by vpc and $^1$H nmr) was 80%. For these experiments in a dry medium, the coulometric determinations gave 1.9 F per mol of NCU consumed, indicating a two-electron reduction of the

[13] The conjugate base **2** is reduced in methanol according to polarographic studies and preparative electrolyses (1).

[14] Acetic acid (0.005 *M*) is far superior than water (up to about 5 *M*) as a proton donor towards anions **2** and/or **3** in acetonitrile–TEAP (0.1 *M*) as would be expected from the p$K_a$ values and from the fact that acetic acid would be expected to be more soluble than water in the double layer. Interestingly, Fry and Reed (10) have found that, in dimethylformamide – tetraethylammonium bromide (0.1 *M*), acetic acid was a less efficient proton donor than water towards carbanions. The protonation of anions **2** and/or **3** probably occurs in the outer Helmholtz layer whereas the more basic carbanions must be reacting in the inner layer.

N—Cl bond as found previously in methanol and wet acetonitrile (1).

NCU (**1***a*) has been added to olefins (14–18% yield) in electrochemical reductions carried out under very special conditions (1). In a control experiment where no potential was applied, a 1% yield of addition products was obtained (1). These facts were interpreted as evidence of trapping of the electrochemically generated intermediate amidyl radical (reaction [1]) (1). However, in the electrochemical experiment, the resistivity of the catholyte was probably quite high and the temperature of the cathode compartment higher than in the control experiment, which should result in an enhanced yield of thermal addition of NCU. Therefore, the formation of 1,2-addition products in 14–18% yield in the presence of olefins under such conditions cannot be considered as evidence for the capture of the intermediate amidyl radical resulting from the first electron transfer (reaction [1]).

N-*Chloro*-N-*Alkyl(aryl)amides (ZCONRCl)*

The electroreduction of *N*-chloro-*N*-alkyl(aryl)-amides should involve two electrons and lead to the amide anion (see reaction [16] which is the sum of

[16] $ZCONRCl + 2e^- \rightarrow ZCO\bar{N}R + Cl^-$

reactions [1] and [2] where X = Cl, R = alkyl or aryl) as in the case of the *N*-halo-*N*-hydroamides **1** (reaction [4]). However, in contrast to their *N*-hydro analogues, *N*-chloro-*N*-alkyl(aryl)amides do not bear any acidic hydrogen ($pK_a > 20$). As a consequence, a father–son protonation appears unlikely and all the *N*-chloro derivative reaching the electrode should be reduced. Therefore, the voltammograms would be expected to show one wave only and coulometric results should be close to 2 F/mol. However, the voltammograms at a mercury or a platinum electrode did show two waves and, in controlled potential electrolyses (cpe), usually less than 1 F/mol was needed for the nearly complete consumption of the *N*-chloro derivative. We shall discuss first the cpe studies which provide evidence for the two-electron reduction of *N*-chloro-*N*-alkyl(aryl)amides leading to the amide anion (reaction [16]) and then consider the voltammetric studies.

*Controlled potential electrolyses*

The results recorded in Table 1 show that controlled potential electrolysis of *N*-chloro-*N*-alkyl(aryl)amides in acetonitrile–TEAP (0.1 *M*) gives the parent amide as the main reaction product and requires less than 1 F/mol. For instance, the nearly exhaustive electrolysis (more than 98% of active chlorine reduced according to iodometric titration) of *N*-chloro-*N*-methylurethane (**5**) at a mercury or a platinum electrode consumed about 0.5 F/mol only and led to a 90% yield of *N*-methylurethane (entries 1 and 2). A radical chain reaction involving steps [17] and [18] with reaction [19] as the termination step could have explained

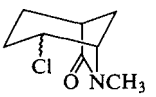
[17] $ZCO\dot{N}R + CH_3CN \rightarrow \underset{\text{Parent amide}}{ZCONHR} + \cdot CH_2CN$

[18] $\cdot CH_2CN + ZCONRCl \rightarrow ClCH_2CN + ZCO\dot{N}R$

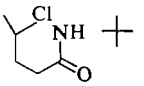
[19] $2\cdot CH_2CN \rightarrow (CH_2CN)_2$

the low coulometry. However, using appropriate substrates, we did not succeed in capturing the electrochemically generated *N*-alkyl(aryl)amidyl radical (reaction [1]) while the amide anion ([16] = [1] + [2]) has been efficiently trapped. Thus the insertion of the second electron (reaction [2]) must be faster than most of the reactions of amidyl radicals.[15]

*Attempts to trap the electrochemically generated amidyl*: The radical cyclization of *N*-chloro-*N*-methyl-3-cyclohexenecarboxamide (**6**), under a variety of initiating conditions, has been shown to be very efficient giving the bicyclic products **10** and **11** in yields greater than 95% (12, 13). However, its



**10** (*exo*)
**11** (*endo*)



**12**

electrochemical reduction (Table 1, entry 3) did not give any bicyclic products which might have resulted from intramolecular trapping of the amidyl radical; the sole product detected and identified was the parent amide. Therefore, the reduction of the electrochemically generated amidyl must be faster than its intramolecular addition to the double bond. It is therefore not surprising that the electrochemical reduction of *N*-chloro-*N*-methylurethane (**5**) in the presence of a large excess of 1-octene gave the parent amide only (Table 1, entry 1). The radical 1,2-addition of **5** to 1-octene has been achieved upon photochemical initiation (14).

The photolysis of *N*-chloro-*N*-tertiobutylpentanamide (**7**) in benzene was reported to give the 4-chloro derivative **12** in a 43% yield via

[15]The breakage of the *N*-halogen bond to give the amidyl radical and the halide ion (reaction [1]) is most probably concerted with the insertion of the first electron but we cannot exclude the possibility that an *N*-haloamide radical anion is first formed and then breaks down rapidly into the amidyl and the halide anion.

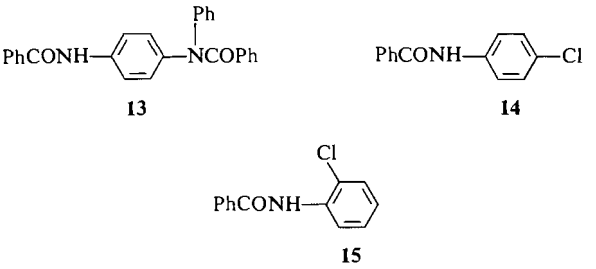
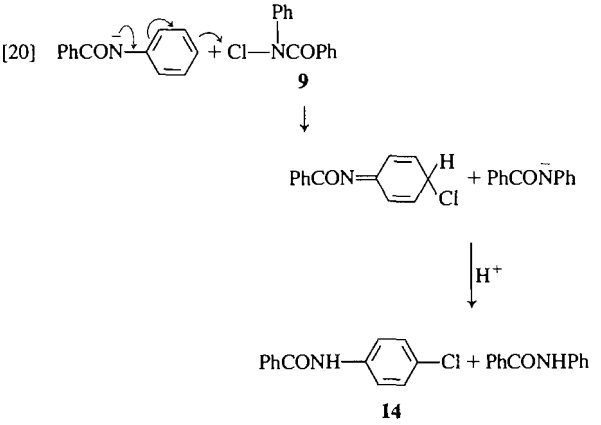
For personal use only.

intramolecular hydrogen abstraction by the amidyl radical generated in the initiation step (15). As seen from Table 1, entries 4 and 5, the electrochemical reduction of **7** gave the parent amide together with a small amount (≤2%) of the 4-chloro derivative **12**. However, about 1% of **12** was already present in the starting *N*-chloroamide **7**. Thus, if any 4-chloro derivative **12** was formed during the electrolyses, the amount produced was negligible and was probably due to thermal and/or photochemical decomposition of the *N*-chloroamide **7**; it did not arise from the electrochemically generated amidyl radical.[16] Indeed, in control experiments in which no potential was applied, we observed the disappearance of **7** after 4 to 5 days at room temperature (iodometric titration) and the formation of **12** in yields ranging from 20% (in the dark) to 50% (in the presence of mercury and not in the dark[17]).

The electrochemical reduction of *N*-chlorobenzanilide (**9**) was then investigated (Table 1, entries 7 to 10). Ford *et al.* (16) had reported the isolation, in a 26% yield, of the head-to-tail dimer **13** resulting from the coupling of two *N*-phenylbenzamidyl radicals when a concentrated solution (2 *M*) of **9** in benzene was treated with dimethyl azobisisobutyrate. The probability of radical coupling should be larger when the radicals are generated at the surface of an electrode than when they are produced in an homogeneous medium where they should be farther apart. However, from the reduction of **9** at a mercury electrode (entries 7 and 8) no dimer could be detected whereas at a platinum electrode (entries 9 and 10) between 1 to 2% of dimer **13** was formed. Thus it appears that the electrochemically generated *N*-phenylbenzamidyl radical might have been trapped to a very small extent. We also studied the photolysis of *N*-chlorobenzanilide (**9**) in acetonitrile–TEAP (0.1 *M*) and obtained 67% of 4′-chlorobenzanilide (**14**) and 12% of 2′-chlorobenzanilide (**15**); no dimer **13** was detected and very little parent amide, if any, was formed (see Experimental section). In contrast, the electroreduction of **9** (Table 1, entries 7 to 10) gave the parent amide in yields ranging from 76 to 84% and small amounts only of **14** (4 to 10%) and **15** (0 to 3%). Therefore, in these electrochemical reductions, the parent amide must have originated from the *N*-phenylbenzamide anion (proton abstraction from the medium) resulting from the two-electron cleavage of the N—Cl bond. Although the ring chlorinated products **14** and **15** could have been formed via a chain reaction involving the *N*-phenylbenzamidyl radical, we believe that the *N*-phenylbenzamide anion is responsible for their formation as illustrated in reaction [20] (father–son chlorination).





In one electrochemical experiment, 2′,4′-dichlorobenzanilide (**16**) was isolated in a 2% yield (Table 1, entry 10) and it was probably formed by chlorination of the anion derived from **14** (reaction [20]) and/or from **15**.

*Trapping of the amide anion*: In order to confirm unequivocally that the electrochemical reduction of *N*-chloro-*N*-alkylamides does lead to the amide anion (reaction [16]), the latter was trapped by *N*-alkylation and *N*-acylation. Indeed, intermolecular alkylation of amide anions has been reported to lead to *N*-alkylated products whereas alkylation of amides under neutral conditions occurs at oxygen

[16]In ref. 1, we reported that the electrochemical reduction of *N*-chloro-*N*-tertiobutylpentanamide (**7**) at a mercury electrode in acetonitrile–$LiClO_4$ (0.2 *M*) did give the 4-chloro derivative **12** in a 37% yield together with the parent amide (55% yield) and this was considered as evidence for the trapping of the electrochemically generated amidyl radical. In this experiment, a platinum auxiliary electrode had been used. The formation of **12** in significant amount when platinum is used as the auxiliary electrode instead of magnesium is most probably due to the oxidation of some of the *N*-chloro derivative **7** which migrates into the anolyte compartment. Indeed we have shown that the oxidation of **7** at a platinum electrode leads to the formation of the 4-chloro derivative **12** (27%). We are currently studying the electrochemical oxidation of *N*-haloamides.

[17]A grey precipitate was formed as in the experiment reported in ref. 1. However, the latter experiment had been stopped after 24 h, 31% only of *N*-chloroamide **7** had reacted, and the 4-chloro derivative **12** had not been detected.

TABLE 1. Controlled potential electrolysis of *N*-chloro-*N*-alkyl(aryl)amides in acetonitrile–TEAP (0.1 *M*)[a]

| Entry | *N*-Chloroamide | Working electrode | $E^b$ (V) | $n_{app}$ (F/mol) | Electrolysis product(s) | Yield[c] (%) |

[a]Unless otherwise stated, the electrolyses were carried out at room temperature using a magnesium auxiliary electrode, and were stopped when 2% or less active chlorine was left (iodometric titration). The mixture was treated with sodium bisulfite to remove the residual active chlorine (see Experimental section).
[b]*E* vs sce.
[c]The yields were determined by vpc in entries 1 to 5 and they refer to products isolated by preparative layer chromatography (plc) in entries 7 to 10.
[d]1-Octene was present in large excess (40% solution v/v in acetonitrile–TEAP).
[e]The cell was cooled in an ice bath.
[f]Lithium perchlorate (0.2 *M*) was used as supporting electrolyte.
[g]By $^1$H nmr spectroscopy. Some 4-chloro derivative **12** was already present (1–2%) in the starting *N*-chloroamide 7 according to its $^1$H nmr spectrum.
[h]The electrolysis was carried out at −30°C and was stopped when 21% of active chlorine was still present.
[i]The crude product consisted essentially of the parent amide according to its $^1$H nmr spectrum.
[j]A grey precipitate was formed during the electrolysis.

and requires strong alkylating agents (17). The results reported in Table 2, entries 3 and 4, show that methyl bromide (entry 4) was more efficient than methyl tosylate (entry 3) as a trapping agent for the amide anion. Trapping by *N*-acylation (entry 5) was more efficient than by *N*-alkylation. The parent amides were recovered unchanged when treated with an excess of alkylating or acylating agent under the conditions of the electrolyses and work-up. We hoped that intramolecular trapping would be more efficient than intermolecular trapping. However, the reduction of *N*-chloro-*N*-methyl-α-chloroorthotoluamide (**17**) led to only 31% of *N*-methyllactam **22** (Table 2, entry 6) resulting from intramolecular *N*-alkylation of the amide anion (Scheme 1). The major product isolated was the iminolactone **21** (56%) arising from the cyclization of the parent amide formed during the electrolysis (Scheme 1). Indeed the cyclization of the amide was found to be fairly easy either in solution or in solid state to afford quantitatively the iminolactone hydrochloride **20**[18] (see Experimental section). The iminolactone **21** was isolated after basic work-up. We have also shown that the amide anion generated by treatment with lithium diisopropylamide in dry tetrahydrofuran afforded exclusively and quantitatively the *N*-methyl lactam **22**.[18] Thus it appears that proton abstraction from the medium (SH in Scheme 1) by the amide anion generated electrochemically from the reduction of **17** in acetonitrile – TEAP is about 1.8 times faster than intramolecular alkylation.

*Coulometry*: As can be seen from Table 2, the coulometric results ($n_{app}$) parallel the trapping efficiency, the values ranging from 0.5–0.9 F/mol in the absence of a trapping agent (entries 1 and 2) to

[18]The behavior of *N*-methyl-α-chloroorthotoluamide parallels that of 4-bromo-*N*-cyclohexylbutyramide: the thermal cyclization of the neutral amide was reported to give *N*-cyclohexyliminobutyrolactone hydrobromide while the anion afforded *N*-cyclohexylbutyrolactam (18).

TABLE 2. Trapping of the amide anion during the electrolysis, at a platinum electrode, of *N*-chloro-*N*-alkylamides in acetonitrile–TEAP (0.1 *M*)[a]

| Entry | *N*-Chloroamide | Trapping agent[b] | $E^c$ (V) | $n_{app}$ (F/mol) | Yield of parent amide (%) | Product(s) of trapping | Yield (%) |
|---|---|---|---|---|---|---|---|
| 1[d] | $C_2H_5OCON(CH_3)Cl$ (5) | None | −1.0 | 0.49 | 92 | None | |
| 2[e] |  (8) | None | −0.8 | 0.87 | >90 | None | |
| 3 | | $CH_3OTs$ | −1.0 | 0.95 | 68[f] |  (18) | 15[f] |
| 4 | | $CH_3Br$ | −1.0 | 1.04 | 59[f] | 18 | 29[f] |
| 5[g] | $C_2H_5OCON(CH_3)Cl$ (5) | $C_2H_5OCOCl$ | −1.0 | 1.45 | [h] | $(C_2H_5OCO)_2NCH_3$ (19) | 50[f] |
| 6[i] |  (17) | — | −1.0 | 1.83 | 56[j] |  (22) | 31[k] |
| 7[l] |  (8) | $CH_3COOH$ | −1.0 | 1.85 | | Parent amide | >90[l] |

[a]See footnote *a* of Table 1.
[b]An excess of more than 8 mol per mol of *N*-chloroamide was used except in the case of acetic acid (entry 7) where 1 equiv. was added.
[c]*E* vs. sce.
[d]Taken from Table 1, entry 2.
[e]Taken from Table 1, entry 6.
[f]By vpc.
[g]The electrolysis was stopped after the consumption of 35% of active chlorine.
[h]Not determined.
[i]The amount of active chlorine still present when the electrolysis was stopped was 10–11%.
[j]The amide was isolated as the iminolactone **21** (see Scheme 1 and Experimental section).
[k]Yield of isolated product.
[l]The crude product consisted of the parent amide according to its $^1H$ nmr spectrum.

about 1.45 F/mol for the most efficient intermolecular alkylating reaction (entry 5). A value close to the theoretical value of 2 F/mol was obtained when a good proton donor was present: the hydrochloride **20** in entry 6 and acetic acid in entry 7.[19] The fact that the number of coulombs increases as the trapping of the amide anion becomes more efficient or when protons are readily available indicates (*i*) that a secondary reaction must consume the starting *N*-chloroamide and give a non-electroactive compound, and (*ii*) that the amide anion must generate anions or bases responsible for the secondary reaction. Since the parent amide is the main product of the electrochemical reductions reported in Table 1, the amide anion must abstract a proton from the medium, most probably from acetonitrile (SH = $CH_3CN$ in reaction [21]). The acetonitrile anion ($S^- = {}^-CH_2CN$) could react with acetonitrile to give basic polymers ($A^- = (CH_2CN)_n^-$ in reaction [21]) as proposed by Saveant *et al.* (18). An orange-to-brown coloration did appear during all the electrolyses recorded in Table 1 and disappeared upon acidification of the reaction medium. Such a coloration has been observed by Saveant *et al.* (18) in electroreductions where bases were generated and it was attributed to anionic polymeric species generated from acetonitrile. These polymeric species would then react with the starting *N*-chloroamide to give non-electroactive C-chlorinated derivatives (ACl in reaction [22]). Most

[21] $ZCO\bar{N}R + SH \rightarrow ZCONHR + S^- (\rightarrow A^-)$

[22] $ZCONRCl + S^- \text{ (or } A^-) \rightarrow ZCO\bar{N}R + SCl \text{ (or ACl)}$

carbon–chlorine bonds should be electroinactive at the potentials used for the controlled potential electrolyses (from −0.1 to −1.0 V) (20). The amide ion is regenerated in reaction [22] so the consumption of the *N*-chloroamide would involve a chain reaction, hence the low coulometric values or the high coulometric yields observed (e.g. ≃ 400% based on the *N*-chloroamide in entries 1 and 2).[20]

[19]The amide anion has been trapped also by the magnesium ion, a Lewis acid, probably to form the magnesium enolate. Indeed, the reduction of *N*-chloro-*N*-tertiobutylacetamide (**23**), at a mercury electrode ($E$ = −0.45 V), in acetonitrile–TEAP (0.1 *M*) containing 2 equiv. of magnesium perchlorate or using magnesium perchlorate (0.1 *M*) as the supporting electrolyte, gave a coulometry of 1.83 to 1.89 F/mol.

[20]It is interesting to compare the electroreduction of *N*-chlorosuccinimide **4** with that of an *N*-chloro-*N*-alkyl(aryl)-amide. In acetonitrile–TEAP (0.1 *M*), NCS gives a coulometry of 1.85 F/mol both at a mercury and a platinum electrode, thus showing that no secondary reactions consume the starting *N*-chloro compound. This is because the succinimide anion resulting from the two-electron reduction of the N—Cl bond, being much less basic ($pK_a$ = 9.6 (7)) than an amide anion ($pK_a$ = 15–17), presumably cannot abstract a proton from acetonitrile.

The acetonitrile ion itself generated in reaction [21][21] does not appear to be involved to a significant extent in the decomposition of the starting *N*-chloroamide (reaction [22]) since chloroacetonitrile (SCl = $ClCH_2CN$) was not detected; succinonitrile and the *N*-cyano derivative $ZCONRCH_2CN$, respectively the alkylation product of the acetonitrile anion and of the amide anion by chloroacetonitrile, were not detected either. Although residual water can certainly act as a proton source towards the amide anion (SH = $H_2O$ in reaction [21]), its concentration was less than 10% of that of the starting *N*-chloroamide in most of the electrolyses. Furthermore, the attack of the hydroxyde ion on the *N*-chloroamide (reaction [23]) would not con-

[23] $ZCONRCl + HO^- \rightarrow ZCONHR + OCl^-$

tribute to lower the coulometric results since the hypochlorite ion should be reducible in the potential range used.[22] The tetraethylammonium ion could also act as a proton donor towards the electrochemically generated amide anion (reaction [16]) and/or the acetonitrile anion generated in reaction [21] leading to triethylamine and ethylene by a Hoffman elimination (10, 22, 23). However, such a reaction with the supporting electrolyte would not contribute to the low coulometry observed and we did not try to determine if ethylene was evolved or not.

### *Voltammetric studies*

*Polarography*:

As recorded in Table 3, all the *N*-chloro-*N*-alkyl(aryl)amides studied give rise to two waves at a dropping mercury electrode in acetonitrile–TEAP (0.1 *M*). The reduction is truly irreversible ($\alpha n$ values of 0.3 for the first wave and ≃ 0.4 for the ill-defined second wave) as in the case of the *N*-chloro-*N*-hydroamides. The first wave shows passivation–adsorption phenomena (abnormal current–time curve during the lifetime of a drop) and its limiting current, $I_1$, becomes practically independent of the concentration of the *N*-chloroamide for concentrations higher than ca. $5 \times 10^{-4}$ *M* (Fig. 3). The second wave, even if ill-defined due to incipient maxima, is diffusion controlled: the total limiting current, $I_1 + I_2$, increases linearly with concentration (Fig. 3).

The anomalous polarographic behavior obser-

[21]The electrochemically generated acetonitrile anion has been trapped by carbonyl compounds (21).

[22]In fact the water content of the medium had no effect on the coulometric results. Other experimental conditions such as the temperature, the nature of the electrode (Hg or Pt), the electrolyte, and the potential had also little effect on the coulometry.

TABLE 3. Half-wave potentials[a] for the reduction of *N*-chloro-*N*-alkyl(aryl)amides in acetonitrile–TEAP (0.1 *M*)

| Entry | *N*-Chloroamide | Electrode | $(E_{1/2})_1$[b] V vs. sce | $(E_{1/2})_2$[b] V vs. sce |
|---|---|---|---|---|
| 1 | $C_2H_5OCON(CH_3)Cl$ (5) | Hg | −0.13 | −0.40 |
| 2 | | Pt | −0.2 (none) | −1.40 (−0.76) |
| 3 | | C | None | −0.60 (−0.65) |
| 4 | PhCON(Ph)Cl (9) | Hg | −0.11 | −0.35 |
| 5 | | Pt | 0.0 (none) | −0.80 (−0.60) |
| 6[c] | | C | None | −0.70 (−0.70) |
| 7 | $CH_3CON(t\text{-}C_4H_9)Cl$ (23) | Hg | −0.11 | −0.45 |
| 8 | | Pt | −0.30 (none) | −0.75 (−0.90) |
| 9 | $CH_3(CH_2)_3N(t\text{-}C_4H_9)Cl$ (7) | Hg | −0.11 | −0.55 |
| 10 |  —$CON(CH_3)Cl$ (6) | Hg | −0.13 | −0.40 |

[a]The half-wave potentials were determined by classical dc polarography (mercury electrode) and by linear voltammetry using a rotating disc electrode (platinum and vitreous carbon discs).
[b]For the platinum and vitreous carbon electrodes, values in parentheses were obtained on reverse scan.
[c]In acetonitrile–$LiClO_4$ (0.2 *M*).

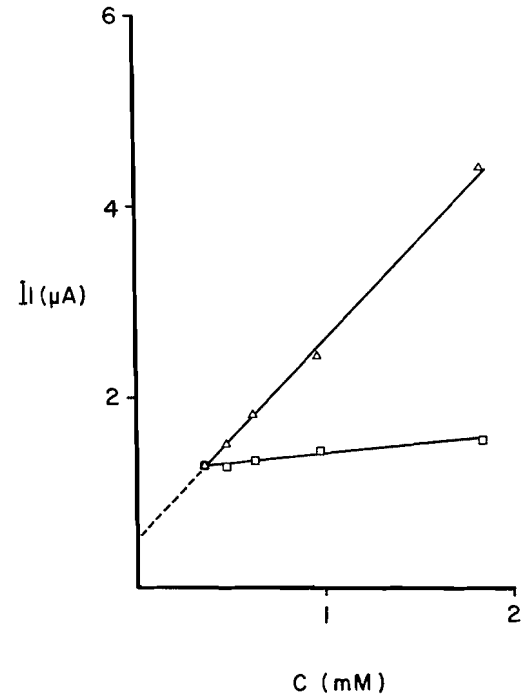

FIG. 3. Variation of the limiting currents (*Il*) with the concentration of *N*-chloro-*N*-methylurethane (**5**) in acetonitrile–TEAP (0.1 *M*): □, limiting current of the first wave ($I_1$); △, total limiting current ($I_1 + I_2$).

ved could be attributed, at least in part, to the presence of electrogenerated strong bases (anions) at the surface of the electrode. Thus, the addition of about 0.5 to 0.6 equiv. of acetic acid did eliminate the passivation–adsorption phenomena and gave only one well-defined, diffusion-controlled, and irreversible wave ($\alpha n = 0.4$) at a potential close to that of the first wave (e.g. −0.18 V and −0.14 V for *N*-chloro-*N*-methylurethane (**5**) and *N*-chloro-*N*-tertiobutylacetamide (**23**) respectively). The use of magnesium perchlorate (0.1 *M*), a Lewis acid, as supporting electrolyte did eliminate also the anomalous polarographic behavior leading to only one well-defined wave at more anodic potentials (e.g. + 0.06 V and +0.14 V for *N*-chloroamides **5** and **23** respectively).[23] In the case of the *N*-chloro-*N*-hydroamides which are quite acidic (although weaker acids than acetic acid) and do act as proton donors in their reduction as already pointed out (reaction [5]), the polarograms show well-defined waves. Finally, the polarographic reduction of *N*-chlorosuccinimide (**4**) in acetonitrile–TEAP (0.1 *M*), which leads to the much less basic succinimide anion (reaction [7]), shows a normal behavior giving only one well-defined, diffusion-controlled, and irreversible wave ($\alpha n = 0.3$) at a potential (−0.12 V) near that of the first wave of the *N*-chloroamides of Table 3.[24]

In relation to the phenomena observed in the polarographic reduction of *N*-chloro-*N*-alkyl(aryl)amides, it is informative to look again at their electrolysis at a mercury electrode, taking *N*-chlorobenzanilide (**9**) as an example (see Table 1, entries 7 and 8). We have already discussed the

[23]Both the addition of acetic acid and the use of magnesium perchlorate as supporting electrolyte caused an increase of the total limiting current: a 20% to 30% increase upon the addition of 0.5 to 0.6 equiv. of acetic acid with no further effect when adding more acid, and a 50% increase in the case of magnesium perchlorate.

[24]The addition of acetic acid had no effect on the position of the wave and on the limiting current. However, the use of magnesium perchlorate (0.1 *M*) as supporting electrolyte did lead to an anodic displacement of the wave ($E_{1/2} = +0.14$ V) and to an increase (≃ 30%) of the limiting current as in the case of *N*-chloro-*N*-tertiobutylacetamide (**23**).

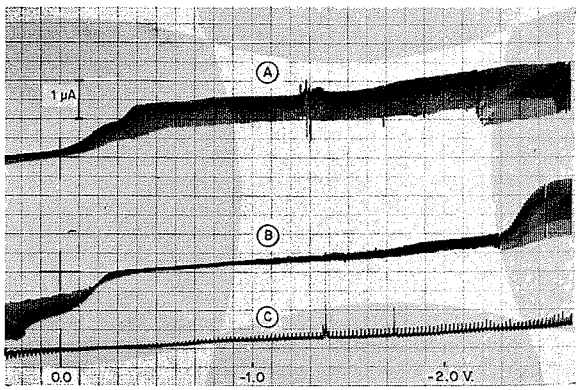

FIG. 4. Electrolysis of *N*-chlorobenzanilide (*9*) at −0.6 V in acetonitrile–TEAP (0.1 *M*) followed by polarography: *A*, before the electrolysis (*C* = 0.4 m*M*); *B*, after the electrolysis; *C*, residual current.

products formed; their yield and relative proportion is about the same whether the electrolysis was carried out at −0.1 V (first wave) (entry 7) or at −0.6 V (second wave) (entry 8). The electrolyses were followed by polarography. We will first consider the electrolysis carried out at −0.6 V. The polarograms of Fig. 4 have been recorded before the electrolysis (polarogram A) and after the complete disappearance of *N*-chloroamide **9** (polarogram B). In polarogram B, the two waves due to the starting *N*-chloroamide have disappeared as expected, a wave due to the reduction of *N*-phenylbenzamide can be seen at $E_{1/2} = -2.3$ V, and an *anodic* wave is present at a potential corresponding to that of the first wave of polarogram A. This anodic wave can be attributed to the oxidation of mercury in the presence of electrogenerated anions (24) and such an oxidation could account for the polarographic phenomena observed at the first wave level.

For the electrolysis carried out at −0.1 V, the coulometric results were very low (Table 1, entry 7) and some current continued to flow through the cell even after the complete disappearance of the substrate **9** (iodometric titration). A grey precipitate was formed. Polarography showed the wave due to the parent amide and the complete disappearance of the second wave. In a control experiment, where an aliquot of the starting cathodic solution was stirred with non-polarized mercury, a grey precipitate was also formed, *N*-chloroamide **9** was completely consumed (iodometric titration), and polarography showed the wave due to the parent amide, the disappearance of the second wave, and a very small current at the first wave level. Therefore, a potential of −0.1 V was not sufficient to prevent the chemical reaction between *N*-chloroamide **9** and mercury. Such chemical reaction with mercury was observed with all the other *N*-haloamide studies (see also ref. 1). This suggests that organomercurials might be involved as intermediates in the electroreduction of *N*-haloamides as described in reactions [24] and [25].

[24] $ZCONRX + Hg^0 \rightarrow ZCONRHgX$

[25] $ZCONRHgX + 2e^- \rightarrow ZCONR^- + Hg^0 + X^-$

Organomercurials have been obtained by allowing mercury to react with allyl or benzyl halides and they have been proposed as intermediates in the electroreduction of organic halides (25–30). It seems that organomercurials derived from *N*-haloamides are not stable, at least in acetonitrile, but this does not rule out their participation as intermediates in the electroreduction of *N*-haloamides.

*Linear sweep voltammetry*:

In order to eliminate the interactions with mercury, we used smooth platinum and vitreous carbon as electrode material. The half-wave potentials obtained by linear sweep voltammetry at a rotating disc electrode are reported in Table 3. The limiting current did increase with the concentration of the *N*-haloamide and the rotation rate ω. Unfortunately, the waves were not reproducible and it was not possible to obtain a linear relationship between the concentration and the limiting current on one hand, and between $\omega_{1/2}$ and the limiting current on the other hand, as expected for diffusion-controlled waves. On smooth platinum, two waves were observed for all the *N*-chloro-*N*-alkyl(aryl)amides studied (Table 3). As seen from Fig. 5, the amplitude of the first wave is small and it disappears almost completely on reverse scan; furthermore the position of

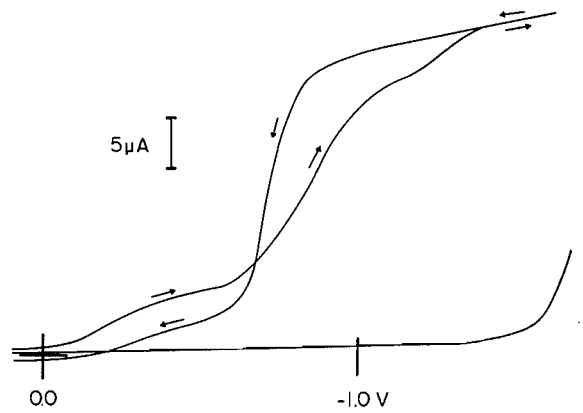

FIG. 5. Linear voltammetry on a platinum rotating disc electrode (ω = 350 rpm) of *N*-chloro-*N*-methylurethane (**5**) in acetonitrile–TEAP (0.1 *M*). The sweep rate was 5 mV/s. The arrows indicate the direction of scanning. The residual current is also indicated.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

the second wave does vary with the direction (forward or backward) of the scan (hysteresis). Holding the potential at the level of the first wave (e.g. at ca. −0.4 V in the case of *N*-chloro-*N*-methylurethane (**5**)) led to zero current after a few minutes so that it was not possible to carry out any electrolysis at potentials close to that of the first wave. On vitreous carbon, however, only one wave was observed and its half-wave potential was practically independent of the direction of the scan (little or no hysteresis) (Table 3). Thus it appears that the multiple waves and hysteresis observed on smooth platinum originates from surface phenomena (adsorption of halide and/or amide ions or of anions derived from amide ions).[25] However, further studies would be needed to fully understand the voltammetric behavior of *N*-chloro-*N*-alkyl-(aryl)amides.

## Experimental

Most of the pertinent general information concerning the analysis of products and starting materials is the same as that given in ref. 1. In addition to an OS-138 (polyphenyl ether, 15%) column, SE-30 (10%) and UCON Polar 50-HB-2000 (5%) columns were used for vapor phase chromatography (vpc); for these three columns (6 ft × 0.25 in.), the support was acid washed and dimethylsilylated Chromosorb W 60/80 mesh. In a few cases, the $^1$H nmr spectra were recorded on a Bruker WP-60 instrument.

*Acetonitrile*

Technical grade acetonitrile was purified by a method described by Mann *et al.* (34). The resulting acetonitrile contained about 0.2% of water. When refluxed for 2 days over calcium hydride then distilled, the water content dropped to below 0.01% (to about 0.003% in many cases) as determined with a coulometric Karl Fisher titrator. Such dry acetonitrile was used immediately after its distillation and transferred into the electrochemical cell with a syringe and under dry nitrogen (sometimes a glove box was used). Regular controls at the end of an electrolysis showed that the medium contained about 0.03% of water when dry acetonitrile was used to start with.

*Electrolytes*

Lithium perchlorate (anhydrous reagent, Alfa inorganics, Co.) was used after drying in a vacuum oven for 24 h at 100°C. Tetraethylammonium perchlorate, prepared from tetraethylammonium bromide and perchloric acid (35), was recrystallized from water until the silver ion test was negative. It was then dried in a vacuum oven for 2 days at 75°C. Magnesium perchlorate (anhydrous reageant, Matheson, Coleman and Bell) was used as such.

[25]Allyl bromides and iodides (31), and 9-fluorenyl and benzyhydryl chlorides and bromides (32) also show multiple waves on platinum and a single wave on vitreous carbon when reduced in acetonitrile or dimethylformamide. The surface effects on platinum have been attributed to adsorption of halide ions (31, 32) or to electrocatalysis from electrode impurities or adventions impurities (32). Merz and Bard (31) have stressed that "surface effects in the reduction of halo compounds at platinum electrodes are a frequent occurrence and deserve further studies".

*Amides*

The commercially available amides were used without further purification. The preparation of *N*-methyl-3-cyclohexenecarboxamide has been reported (13*a*). The other amides were prepared from the corresponding amine and acid chloride (2 mol amine per mol of acid chloride) in ether at 0°C in yields ranging from 70% to 80% after purification. N-*Tertiobutylpentanamide*, mp 47–49°C (lit. (15), 48–49°C). N-*Methylorthotoluamide*, mp 77–78°C (lit. (36), 78–79°C). N-*Tertiobutylacetamide*, mp 97–98°C (lit. (37) 98–99°C). N-*Methyl*-α-*chloroorthotoluamide*, mp 207–209°C (dec.);[26] $\nu_{max}$($CHCl_3$) 3460, 1660, and 1520 cm$^{-1}$; δ($CDCl_3$) 3.01 (d, $J$ = 5 Hz, 3H), 4.83 (s, 2H), 6.37 (m, 1H), and 7.43 ppm (m, 4H); *m/e* 183, 185 (3:1, $M^+$). *Anal.* calcd. for $C_9H_{10}ClNO$: C 58.87, H 5.49, N 7.63; found: C 58.71, H 5.55, N 7.57. 2-Chloromethylbenzoyl chloride was prepared from phtalide according to a published procedure (38): bp 104–105°C, 3 Torr.

Upon heating the solid at 90°C in an oven for 24 h and upon refluxing a solution in chloroform for 2 h, *N*-methyl-α-chloroorthotoluamide was converted quantitatively to N-*methyliminophtalide hydrochloride* (**20**), mp 205–206°C (decour.); $\nu_{max}$($CHCl_3$) 2550 (broad) and 1705 cm$^{-1}$; δ($CDCl_3$) 3.31 (s, 3H), 5.86 (s, 2H), 7.5 to 8.0 (m, 4H), and 9.20 ppm (m, NH). The hydrochloride **20** was dissolved in water. The aqueous solution was made basic by addition of sodium hydroxide then extracted with methylene chloride. The organic phase was washed with brine then dried and the solvent evaporated to give the pure imino lactone **21** identical (ir, $^1$H nmr) to the authentic sample prepared below.

At room temperature, according to $^1$H nmr spectroscopy, 40% of solid amide was converted to the hydrochloride **20** after 1 week and a solution of amide in $CD_3CN$–TEAP (0.1 *M*) gave 30% of hydrochloride **20** after 6 h.

N-*Haloamides*

NCU (**1***a*) (99% active chlorine) was prepared by the sodium hypochlorite method (39) and NBA (**1***b*) was purchased from Aldrich (>99% active chlorine after recrystallization from methylene chloride). Their lithium salts **2***a* and **2***b* were obtained as previously described (1) with appreciable loss of material (≃ 50%). The $^1$H nmr spectrum of **2***a* in $D_2O$ showed the absorptions due to the salt at δ 1.21 (t, $J$ = 7 Hz, 3H) and 4.08 ppm (q, $J$ = 7 Hz, 2H) together with very weak peaks due to urethane.

The preparation of N-*chloro*-N-*methyl*-3-*cyclohexenecarboxamide* (**6**) has been described (13*b*) as well as that of N-*chloro*-N-*tertiobutylpentanamide* (**7**) (1) and N-*chloro*-N-*tertiobutylacetamide* (**23**) (14). N-*Chloro*-N-*methylurethane* (**5**) and N-*chloro*-N-*methylorthotoluamide* (**8**) were prepared by treatment of 0.01 mol of amide in methylene chloride (25 mL) with 0.02 to 0.04 mol of sodium hypochlorite (5% aqueous solution) containing sodium bicarbonate in the dark at 0°C (ice bath), monitoring the reaction by $^1$H nmr spectroscopy. The organic phase was separated, washed with water, dried, and the solvent removed under vacuum in a rotatory evaporator (bath temperature: <30°C): **5**, 87% yield (98% active chlorine); **8**, 98% yield (99% active chlorine).

N-*Chlorobenzanilide* (**9**) was obtained as above but at room temperature and using methanol (150 mL) instead of methylene chloride. Methanol was then partly removed under vacuum, water was added, and the mixture was extracted with methylene chloride. The organic phase was washed with water, dried, and the solvent evaporated under vacuum (≤30°C). The residue was recrystallized from water–methanol (1:1): mp 78–79°C (lit. (40) 78–80°C), 56% yield (99% active chlorine). The recrystallized

[26]This is the melting point of the hydrochloride **20** since the amide cyclizes readily upon heating (see below).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

material was treated with sodium bisulfite to give the parent amide contaminated with some (≃ 0.7%) 4'-chlorobenzanilide (**14**) separated by preparative layer chromatography on silica gel and identified to an authentic sample; no trace of head-to-tail dimer **13** was detected.

N-*Chloro*-N-*methyl*-α-*chloroorthotoluamide* (**17**) was also prepared by treatment of a methylene chloride solution of the amide with excess sodium hypochlorite but in the presence of hydrochloric acid (0.01 mol) instead of sodium bicarbonate: 65% yield (90% active chlorine); $\nu_{max}(CHCl_3)$ 1660 $cm^{-1}$ plus a weak peak at 1760 $cm^{-1}$ (C=O of phtalide); $\delta(CDCl_3)$ 3.25 (s, 3H), 4.54 (s, 2H), and 7.23 ppm (m, 4H) plus a singlet at 5.17 ppm due to the methylene group of phtalide. According to the integration, the molar ratio of phtalide to **17** was 0.11 (≃ 7% by weight). Some parent amide was also present (≤2%).

*Authentic samples*

*Head-to-tail dimer* ***13***: *N*-Phenylparaphenylenediamine (258 mg, 1.40 mmol), triethylamine (287 mg, 2.84 mmol), and benzoyl chloride (417 mg, 2.97 mmol) in dry toluene (35 mL) were heated to reflux for 7.5 h. Chloroform (150 mL) was added and the resulting solution washed successively with 5% hydrochloric acid (100 mL), 4 *N* sodium hydroxide (100 mL), and water (100 mL). The organic phase was dried and the solvent evaporated. Purification of the crude product by preparative layer chromatography (chloroform–methanol 95:5) gave 4-*benzamido*-N-*benzoyldiphenylamine* (**13**) (370 mg, 65% yield), mp 203°C (lit. (16), 203°C); *m/e* 392 ($M^+$).

*4'-Chlorobenzanilide* ***(14)*** *and 2'-chlorobenzanilide* ***(15)***: They were prepared from the corresponding chloroanilines and benzoyl chloride according to the general method described above for the preparation of amides: **14**, mp 192–193°C (lit. (41), 192–193°C); **15**, mp 97–98°C (lit. (42), 99°C).

N,N-*Dimethylorthotoluamide* ***(13)***: It was prepared from dimethylamine and orthotoluyl chloride according to the same general method (100% yield). The analytical sample was obtained by microdistillation at 80–85°C (0.25 Torr): $\nu_{max}(CHCl_3)$ 1630 $cm^{-1}$; $\delta(CDCl_3)$ 2.22 (s, 3H), 2.73 (s, 3H), 3.03 (s, 3H), and 7.03 ppm (narrow m, 4H); *m/e* 163 ($M^+$). *Anal.* calcd. for $C_{10}H_{13}NO$; C 73.59, H 8.03, N 8.58; found: C 73.62, H 8.00, N 8.66.

*Ethyl*-N-*methylazamalonate* ***(19)***: Ethyl azamalonate was prepared from urethane and ethylchloroformate as described by Tompkins and Degering (43): mp 48–49°C (lit. (43), 49–50°C); $\nu_{max}(CHCl_3)$ 3430, 1815, 1780, 1740, and 1500 $cm^{-1}$; $\delta(CDCl_3)$ 1.32 (t, $J$ = 7 Hz, 6H), 4.35 (q, $J$ = 7 Hz, 4H), and 7.68 ppm (m, NH). According to the method of Sheehan and Balhoper (44), ethyl azamalonate (458 mg, 2.84 mmol) was converted to its potassium salt which was then treated with excess methyl iodide. Separation of the crude product by preparative layer chromatography (ether–hexane 1:1) led to the recovery of ethyl azamalonate (184 mg, 40%) and gave the *N*-methyl derivative **19** (201 mg, 40%) as a colorless liquid: $\nu_{max}(CHCl_3)$ 1795, 1745, and 1695 $cm^{-1}$; $\delta(CDCl_3)$ 1.32 (t, $J$ = 7 Hz, 6H), 3.23 (s, 3H), and 4.28 ppm (q, $J$ = 7 Hz, 4H); *m/e* 175 ($M^+$).

N-*Methyliminophtalide* ***(21)***: Phtalide (12.0 g, 89.5 mmol) was added to a saturated solution of methylamine in methanol. After 36 h, evaporation to dryness gave α-hydroxy-*N*-methyltoluamide (14.7 g, 99.5%), mp 123–124°C; $\nu_{max}(CHCl_3)$ 3460, 3360, 1655, and 1535 $cm^{-1}$; δ(acetone-$d_6$) 2.85 (d, $J$ = 5 Hz, and m, $CH_3$ and OH), 4.50 (s, 2H), and 7.28 ppm (m, 4H), no detectable absorption for the NH. To a stirred solution of this hydroxyamide (5.0 g, 30 mmol) in pyridine (50 mL) cooled in an ice bath, solid paratoluenesulfonyl chloride (6.4 g, 33 mmol) was added in small portions in order to keep the temperature of the reaction mixture below 10°C. The solution turned orange, then pink, and a white solid separated out after 15 min. The reaction mixture was stirred at room temperature for 45 min then poured onto crushed ice. Hydrochloric acid was added (300 mL of a 10% solution) and the mixture washed with methylene chloride. The ice-cold aqueous phase was made basic by addition of solid sodium hydroxide (pellets) then extracted with methylene chloride. The organic phase was washed with brine then dried and the solvent was evaporated. Molecular distillation at 70–75°C (0.3 Torr) afforded the imino lactone **21** (3.7 g, 87% yield); $\nu_{max}(CHCl_3)$ 1700 $cm^{-1}$; $\delta(CDCl_3)$ 3.18 (s, 3H), 5.30 (s, 2H), 7.3 to 7.9 ppm (4H); *m/e* 147 ($M^+$). *Anal.* calcd. for $C_9H_9NO$: C 73.45, H 6.16, N 9.52; found: C 72.76, H 6.31, N 9.37. An impurity was formed during distillation according to the $^1H$ nmr spectrum.

N-*Methylphtalimidine* ***(22)***: It was prepared from *N*-methylphtalimide and zinc in acetic acid according to the method described by Brewster *et al.* (45), mp 113–114°C (lit. (45), 114.5–115.5°C); *m/e* 147 ($M^+$).

*Photochemical decomposition of* N-*chlorobenzanilide* ***(9)***

The *N*-chloro derivative **9** (381 mg, 97% active chlorine, 1.54 mmol) in acetonitrile–TEAP (0.1 *M*) (30 mL) was irradiated at 2537 Å in a Vycor cell with a Rayonnet RPR-100 reactor for 2.5 h (negative starch iodide paper test). Water was added and the mixture extracted with ether. The crude product (322 mg) was separated by plc (benzene–chloroform 95:5) to give three fractions consisting respectively of 2'-*chlorobenzanilide* (**15**), mp 96–97°C (44 mg, 12%), 4'-*chlorobenzanilide* (**14**), mp 187–189°C (238 mg, 67%), and benzanilide, mp 162–163°C (23 mg), identified (ir, $^1H$ nmr, tlc) to authentic samples. The amount of benzanilide isolated did correspond to that present in the starting material.

*Electrochemical instrumentation and methods*

All solutions were deoxygenated by bubbling through them dry and oxygen-free nitrogen saturated with acetonitrile. A nitrogen atmosphere was then maintained over the solution throughout the experiments which were carried out at a room temperature (without cooling the cell) unless otherwise stated. All voltammetric analyses and mass electrolyses were carried out using a three electrode system. Potentials were measured with respect to an aqueous saturated calomel electrode (sce) which has been described in ref. 1.

*Voltammetry*: The three electrode potentiostat used was a PAR-174. For the polarograms, the drop time (automatic drop dislodger supplied with the PAR-174) was generally 2 s, the sweep rate was 10 mV/s, and the potential range was 0.0 to −3.0 V. In the case of NBA (1*b*), Nujol was added at the bottom of the cell to isolate the solution from mercury and the cell was cooled in an ice bath (1). For the voltammograms, the platinum or vitreous carbon discs of the rotating electrode (Tacussel type ED1 with controvit speed controller) had a surface of 10 to 20 $mm^2$ and they were polished on a Carbimet-600 paper (Buehler) before each use. Platinum was regularly washed with nitric acid then rinsed with water and dried in an oven. The rotation rates varied from 500 to 5000 rpm.

*Mass electrolyses*: Controlled potential electrolyses (cpe) were performed with a Tacussel type ASA-100 three electrode potentiostat having both a Tacussel type IG-5 integrator and an ammeter connected in series within the auxiliary circuit. A glass cell described by Peltier and Moinet (46) was used with a mercury pool or a platinum plate as the working electrode, and a magnesium bar as the counter electrode. Two auxiliary electrode compartments differing in their length (depth) were used. With the shorter one, the volume of the catholyte varied from 90 to 175 mL and that of the anolyte from 15 to 40 mL; with the longer one, the volume of the catholyte varied between 15 and 25 mL and that of the anolyte, between 5 and 15 mL. The electrolyses were carried out on 2.5 to 7.5 mmol of *N*-haloamide (concentrations ranging from 0.03 to 0.3 *M*). In all electrolyses, a white precipitate of magnesium halide was formed in the anode

For personal use only.

compartment. Since the cell was not cooled, heating of the solution (up to 40°C) was noted at the beginning of the electrolysis when the current density was high. The progress of the electrolysis was followed by iodometry and sometimes by polarography. Unless otherwise specified, the electrolyses were stopped when practically no current was flowing through the cell; about 98% of the starting active chlorine had been consumed by then.

In some cases (Table 1, entry 5, and Table 2, entries 3 to 7), passivation of the electrode did occur towards the end of the electrolysis and it was necessary to apply an anodic potential (+1.2 V) for 1 min to remove the species adsorbed on the electrode, then apply the working potential until passivation occurred again and the procedure was repeated until the electrolysis was completed. The coulometric results ($n_{app}$) are given in Tables 1 and 2 together with the applied potential and the cathode material. The larger the scale the longer was the time required for the electrolyses. The final solutions showed an orange to brown coloration which disappeared when sulfuric or perchloric acid was added. When the electrolysis was stopped, the catholyte and anolyte were combined, the acetonitrile was evaporated, and the residue was treated with a saturated aqueous solution of sodium bisulfite to destroy any residual active halogen. The resulting mixture was extracted with ether (a continuous extraction for 2 days was needed in the case of the urethane derivatives). The organic layer was dried, the solvent evaporated under vacuum or distilled at atmospheric pressure, and the resulting solution transferred into a volumetric flask. Aliquots were used for vpc and other analyses, and for chromatographic (plc) separations. All the products reported were identified to be authentic by ir and $^1$H nmr spectroscopy, vpc and/or tlc, and sometimes by mass spectrometry. The yields reported in Tables 1 and 2 were determined by vpc or plc. A few typical electrolyses are described below.

*Attempt to reduce the lithium salt of NCU (2a) in dry acetonitrile*

A freshly prepared solution of **2a** in dry acetonitrile (45.5 mL of a 0.11 *M* solution, 5.00 mmol) was added to the cathode compartment containing 100 mL of a 0.2 *M* solution of $LiClO_4$ in dry acetonitrile. The anode compartment contained 25 mL of the 0.2 *M* electrolyte solution. The cathode (Pt) potential was increased from −1.4 to −1.8 V during the first 2 h (25 C only were consumed) then to −3.2 V (reduction of the solvent–electrolyte system) for 13 h (436 C were consumed). Iodometric titration showed a loss of 27% of active chlorine. In a control experiment under the same conditions but without applying any potential, the loss of active chlorine after 15 h was 28%. Therefore the loss of active chlorine in the electrochemical experiment was not due to the reduction of **2a** but to its thermal and/or photochemical decomposition. The same work-up was applied to the two experiments: evaporation of the solvent, acidification with dilute sulfuric acid, continuous extraction with ether for 2 days. The vpc analyses (OS-138) showed the presence of urethane and *N*-chlorourethane (**1a**) in the same relative proportions for the two experiments.

*Reduction of* N-*Chloro*-N-*methyl-3-cyclohexenecarboxamide (6) (Table 1, entry 3)*

*N*-Chloroamide **6** (944 mg, 94% active chlorine, 5.11 mmol) was added to the cathode compartment containing 125 mL of a 0.1 *M* solution of TEAP in acetonitrile. The anode compartment contained 25 mL of the 0.1 *M* electrolyte solution. A potential of −0.8 V (Hg cathode) was applied until the current had reached a near zero value (4.5 h, <2% of active active chlorine left, 493 C). The anolyte and catholyte were combined and the solvent was evaporated. The residue was treated with a saturated $NaHSO_3$ solution then extracted with ether. The organic phase was dried, then concentrated in a rotatory evaporator. The resulting solution was transferred into a 50 mL volumetric flask. Analysis by vpc (OS-138) gave a 76% yield of *N*-methyl-3-cyclohexenecarboxamide (parent amide) and showed the presence of about 1% of the bicyclic compounds **10** and **11** which were already present in the starting material in similar quantities. An aliquot was separated by plc to give a pure sample of parent amide, mp 86–87°C, identified (ir, $^1$H nmr) to an authentic sample (13*a*).

*Reduction of* N-*chloro*-N-*methylorthotoluamide (8)*

*In the absence of a trapping agent* (Table 1, entry 6): *N*-Chloroamide **8** (795 mg, 98.5% active chlorine, 4.27 mmol) was added to the cathode compartment containing 15 mL of a 0.1 *M* solution of TEAP in acetonitrile. The anode compartment contained 5 mL of the electrolyte solution. The cell was cooled to −30°C and a potential of −0.8 V (Pt cathode) was applied. After 5.5 h, the current had dropped from 10.0 to 0.6 mA/cm² (327 C). The electrolysis was stopped and 21% of active chlorine was still present according to the iodometric titration. After the usual work-up, the ether solution was evaporated to dryness to afford *N*-methylorthotoluamide (659 mg) with a purity greater than 90% according to the $^1$H nmr spectrum.

*In the presence of methyl tosylate* (Table 2, entry 3): *N*-Chloroamide **8** (765 mg, 98.5% active chlorine, 4.11 mmol) and methyl tosylate (7.0 g, 38 mmol) were added to the cathode compartment containing 40 mL of a 0.1 *M* solution of TEAP in dry acetonitrile. The anode compartment contained 10 mL of the electrolyte solution. A potential of −1.0 V (Pt cathode) was applied until essentially nearly all the active chlorine was consumed (6.5 h, ≤2% of active chlorine left, 397 C). Towards the end of the electrolysis, passivation of the electrode occurred and an anodic potential has to be applied regularly as already described. After the usual work-up, the solvent was removed *in vacuo* and the residue was refluxed for 2 h in methanol–water (9:1, 40 mL) containing potassium iodide (6.4 g, 38 mmol) to convert the excess methyl tosylate into methyl iodide. Water was added and the mixture was extracted with ether. The ether layer was dried and the solvent stripped off in a rotatory evaporator. The $^1$H nmr of the crude product (605 mg) showed the presence of *N*-methylorthotoluamide and N,N-*dimethylorthotoluamide* (**18**) in a 5.7/1.0 molar ratio. The yields of parent amide (68%) and **18** (15%) were determined by vpc (OS-138). An aliquot was separated by plc for identification with authentic samples.

In control experiments, *N*-methylorthotoluamide and methyl tosylate were heated to reflux for 5 h either in the presence of potassium iodide in methanol–water (9:1) or in a 0.1 *M* solution of TEAP in acetonitrile. After the usual work-up, no trace of *N*,*N*-dimethylorthotoluamide (**18**) could be detected in either of the crude products by vpc, tlc, and $^1$H nmr spectroscopy.

The electrolysis and control experiments in the presence of methyl bromide were carried out in a similar way except that it was not necessary to destroy the excess methyl bromide. A green coloration appeared during the electrolysis. The yields are reported in Table 2, entry 4.

*Reduction of* N-*Chlorobenzanilide (9)*

*N*-Chloroamide **9** (701 mg, 99% active chlorine, 2.97 mmol) was added to the cathode compartment containing 40 mL of a 0.1 *M* solution of TEAP in dry acetonitrile. The anode compartment contained 10 mL of the electrolyte solution. A potential of −0.8 V (Pt cathode) was applied and after 3 h the current had dropped from 13.5 to 0.0 mA/cm² (287 C). After the usual work-up, the crude product (565 mg) was separated by plc (benzene–chloroform 95:5) to give *2′,4′-dichlorobenzanilide* (**16**), mp 116–116.5°C (lit. (42), 115–117°C) (2 mg, 2.5%), *2′-chlorobenzanilide* (**15**), mp 95–96°C (6 mg, 1%), *4′-chlorobenzanilide* (**14**), mp 192–192.5°C (71 mg, 10%), and benzanil-

For personal use only.

ide, mp 162–163°C (446 mg, 76%). The most polar fraction was separated again (chloroform–methanol 89:11) to give the head-to-tail dimer **13**, mp 161–162°C (2 mg, 1.5%).

*Reduction of* N-*chloro*-α-*chloro*-N-*methylorthotoluamide* (**17**)

*N*-Chloroamide **17** (622 mg, 90% active chlorine, 2.55 mmol) in 40 mL of a 0.1 *M* solution of TEAP in acetonitrile (anode compartment: 10 mL of the electrolyte solution) was electrolysed at −1.0 V (Pt cathode) until passivation of the electrode (8 h); 89% of active chlorine (2.27 mmol) had been consumed (iodometric titration). The usual work-up procedure was applied except that the aqueous solution was made basic before extracting with ether. The $^1$H nmr spectrum of the crude product (471 mg) showed the presence of the iminolactone **21**, the *N*-methyllactam **22**, and the parent amide in a 1.55/1.00/0.58 molar ratio. Taking the quantity of **22** isolated below as the amount present in the crude product, the yields of **22** and **21** were 31% and 48% respectively (based on 2.27 mmol of **17** reduced). The amount of parent amide in the crude product was 0.41 mmol; assuming that the 0.28 mmol of **17** remaining after the electrolysis was quantitatively converted to the parent amide by sodium bisulfite, the yield of parent amide was 6%. The crude product was dissolved in chloroform and heated to reflux for 2 h to convert the parent amide into the hydrochloride **20** as seen above. The resulting solution was extracted with 5% hydrochloric acid. The organic phase was washed with brine, dried, and the solvent evaporated. Separation of the residue (171 mg) by plc (ether–methanol 99.5:0.5) gave some phtalide (16 mg) present in the starting material and N-*methylphtalimidine* (**22**), mp 111–113°C (104 mg, 31%). The acidic phases (from the extraction with hydrochloric acid) were combined, ice was added, and the mixture was made basic by adding solid sodium hydroxide. It was extracted with methylene chloride. The organic phase was washed with brine, dried, and the solvent was evaporated to afford pure N-*methyliminophtalide* (**21**) (226 mg, 56% yield).

*Cyclization of the anion of* α-*chloro*-N-*methylorthotoluamide*

The amide (108 mg, 0.59 mmol) in dry tetrahydrofuran (15 mL) was added, under argon at −78°C, to a solution of lithium diisopropylamide (0.67 mmol) in THF (4 mL). The addition took 30 min. The mixture was then allowed to warm up to room temperature. Ice was added and the basic medium extracted with methylene chloride. The organic phase was dried and the solvent evaporated to afford pure N-*methylphalimidine* (**22**), mp 110–112°C (88 mg, 100%).

## Acknowledgements

We are grateful to the "Ministère de l'Education du Québec" and to the Natural Sciences and Engineering Research Council of Canada for financial assistance. We thank Professor F. M. Kimmerle for helpful discussions and Y. Couture for carrying out the experiments on the cyclization of *N*-methyl-α-chloroorthotoluamide and its anion.

Received April 15, 1981

PATRICK M. HENRY, NITA A. LEWIS, and HENRY TAUBE. Can. J. Chem. **60**, 1143 (1982).

The Pd(II)-catalysed alkylation of ferrocene with acrylonitrile has been reinvestigated. We were not able to prepare the 1,1′-bis-(2-cyanovinyl)ferrocene using 1,1′-bis(chloromercuri)ferrocene and Pd(II) under stoichiometric conditions. Using ethanol as solvent, a side-product, 3,3-diethoxypropanenitrile, was obtained. Using methanol, the corresponding 3,3-dimethoxypropanenitrile was produced. Acetonitrile as solvent gave a small amount of the desired product. The reaction of chloromercuriferrocene with acrylonitrile under conditions catalytic in Pd(II) produced the 2-cyanovinylferrocene species. Mixtures of *cis* and *trans* isomers were obtained. The *cis*/*trans* ratio was 20/80, 30/70, and 50/50 in methanol, ethanol, and acetonitrile, respectively. The pure *trans* product was obtained by refluxing the *cis*/*trans* mixture with $I_2/CHCl_3$. The isomers were also separated by chromatography on alumina.

PATRICK M. HENRY, NITA A. LEWIS et HENRY TAUBE. Can. J. Chem. **60**, 1143 (1982).

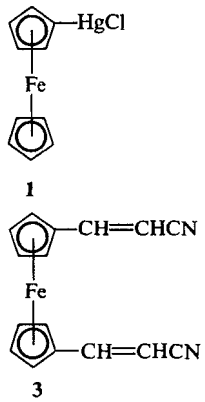
On a étudié de nouveau l'alkylation, catalysée par le Pd(II), du ferrocène avec l'acrylonitrile. Nous n'avons pas pu préparer le bis(cyano-2 vinyl)-1,1′ ferrocène en utilisant le bis(chloro-mercure)-1,1′ ferrocène et le Pd(II) en quantités stochiométriques. On obtient un produit secondaire, le diéthoxy-3,3 propanenitrile, lorsqu'on utilise l'éthanol comme solvant. Dans le méthanol, on obtient le diméthoxy-3,3-propanenitrile comme produit secondaire. L'utilisation de l'acétonitrile comme solvant permet d'obtenir une faible quantité du produit désiré. Le chloromercureferrocène réagit avec l'acrylonitrile en présence du Pd(II) comme catalyseur en donnant des cyano-2 vinyl ferrocènes. On a obtenu des mélanges d'isomères *cis* et *trans*. Le rapport *cis*/*trans* est de 20/80, 30/70 et 50/50 respectivement dans le méthanol, l'éthanol et l'acétonitrile. On obtient le produit *trans* à l'état pur en portant un mélange d'isomères *cis*/*trans* au reflux avec de l'iode dans le chloroforme. On a également séparé les isomères par chromatographie sur alumine.

[Traduit par le journal]

## Introduction

It has been reported that alkyl and 1,1′-dialkyl substituted ferrocenes may be prepared by the reactions of olefins with chloromercuriferrocene (**1**) or 1,1′-bis(chloromercuri)ferrocene (**2**), respectively, in the presence of lithium chloropalladite. Our repeated attempts to prepare 1,1′-bis(2-cyanovinyl)ferrocene (**3**) by the reaction of the dimercurial (**2**) with acrylonitrile in ethanol showed that the reaction is not as simple as was reported earlier (2).

The yield of product was always extremely low and side reactions, one of which involved the solvent, were found to interfere. All possible combinations of *cis*/*trans* isomeric products were produced for **3** and **4**; these were separated and characterised independently in the case of 2-cyanovinylferrocene, **4**. Since these reactions did not proceed as expected, we wish to report the results of our detailed studies on these systems.



## Experimental

*Chemicals and reagents*

All chemicals were reagent grade and were used as supplied except for the acetonitrile and acrylonitrile which were freshly distilled prior to being used. Solvents were purchased from Baker Chemicals, $PdCl_2$ from Engelhardt or Alfa, ferrocene and

$HgCl_2$ from BDH. The commercial sample of 1,1'-bis(chloromercuri)ferrocene (**2**) was obtained from Aldrich.

The dimercurial (**2**) was prepared by three different procedures. The first sample was synthesised according to the method of Fish and Rosenblum (3), the second was the commercial sample (Aldrich) and the third was made using the procedure of Rausch *et al.* (4). This third sample was thoroughly extracted with acetone to remove the 1,2-bis(chloromercuri)ferrocene which is a common contaminant. All samples of the dimercurial were found to be insoluble in all common solvents except dimethylformamide or dimethylsulphoxide, and in these media, they were only sparingly soluble. The nmr spectra of all three samples in $d^6$-dmso showed that the dimercurial (**2**) was at least 95% pure.

*Physical measurements*

The nmr measurements were performed on a Varian A60 instrument. All values are quoted in ppm from TMS on the δ scale. Elemental analyses were performed by Guelph Chemical Laboratories Ltd.

*Preparation of palladium(II) chloride stock solutions.* The solutions were 0.10 *M* in Pd(II) and contained sufficient lithium chloride to solubilize the palladium(II) chloride. In acetonitrile, LiCl is sparingly soluble but 1 mol LiCl dissolves along with 1 mol $PdCl_2$ to give a species with the composition $LiPdCl_3$ which spectral evidence suggests is the dimer, $Li_2Pd_2Cl_6$, similar to the species present in acetic acid (ref. 1, p. 15). On the other hand, in methanol and ethanol 2 mol LiCl per mole of $PdCl_2$ are required to dissolve $PdCl_2$. This suggests that the species is largely the monomer, $Li_2PdCl_4$, and a spectral study has supported this supposition (ref. 1, p. 15).

*Reaction of 1,1'-bis(chloromercuri)ferrocene (2) with acrylonitrile using Pd(II) under stoichiometric conditions.* The method used was essentially the same as that of Kasahara *et al.* (2). To 100 mL of the appropriate palladium(II) chloride stock solution was added acrylonitrile (40 mmol, 2.64 mL) and 1,1'-bis(chloromercuri)ferrocene (**2**) (10 mmol, 3.28 g) and the solution was allowed to stir for 16 h at room temperature. The solvent was then allowed to evaporate and the residue was chromatographed on neutral alumina using benzene and chloroform as eluents.

In reactions using methanol or ethanol as solvent, organic oxidation products, 3,3-dimethoxypropanenitrile and 3,3-diethoxypropanenitrile, respectively, were sometimes observed with yields less than 5% based on Pd(II) used in both cases (see Results and discussion). Samples of these materials were also made by leaving out the dimercurial in the above reaction. These samples were purified by distillation and were found to have nmr spectra identical with those of the compounds formed in the presence of the dimercurial. *Anal.* calcd. for $C_5H_9NO_2$: C 52.16, H 7.89, N 12.17; found: C 51.80, H 8.03, N 12.56. *Anal.* calcd. for $C_7H_{13}NO_2$: C 58.71, H 9.17, N 9.78; found: C 58.72, H 9.25, N 10.16.

*Reaction of 1,1'-bis(chloromercuri)ferrocene (2) with acrylonitrile using Pd(II) under catalytic conditions.* To 100 mL of the acetonitrile stock solution acrylonitrile (100 mmol, 7.0 mL), $CuCl_2$ (20 mmol, 2.69 g), and **2** (5 mmol, 3.28 g) were added. The solution was allowed to stir at 30°C for 1 week. The reaction mixture was then diluted with $CH_2Cl_2$ and extracted thrice with 3 *M* HCl to remove the metal salts, then thrice with water. The remaining organic layer was dried over magnesium sulphate, concentrated, and then chromatographed on neutral alumina using hexane/$CH_2Cl_2$ mixtures as eluents. The total yield of 2-cyanovinylferrocene was 15–20% with each of the *cis* and *trans* isomers accounting for about half of the product (see Results and discussion).

*Reaction of chloromercuriferrocene with acrylonitrile under conditions catalytic in Pd(II).* A 10 mL aliquot of the palladium(II) chloride/acetonitrile stock solution was diluted to 100 mL with $CH_3CN$. To this solution acrylonitrile (100 mmol, 7.0 mL), $CuCl_2$ (20 mmol, 2.69 g), and **1** (10 mmol, 4.20 g) were added. To 100 mL of the solvent $PdCl_2$ (1.0 mmol, 0.177 g) and LiCl (2 mmol, 0.08 g) were added. After these compounds had dissolved, acrylonitrile (100 mmol, 7.0 mL), $CuCl_2$ (20 mmol, 2.69 g), and **1** (10 mmol, 4.20 g) were added. The solution was allowed to stir for 24 h and was then worked-up as described for the catalytic mixture in the previous reaction. The *cis*/*trans* isomers separated cleanly on the alumina column if the separation were performed slowly by using a low concentration (2–5%) of $CH_2Cl_2$ in the $CH_2Cl_2$/hexane mixture. The total yield of 2-cyanovinylferrocene was 17–20%; the proportion of each isomer obtained depended on the solvent employed (see Results and discussion). *Anal.* calcd.: C 65.86, H 4.68, N 5.91; found: *cis* C 65.37, H 4.75, N 5.56, *trans* C 65.99, H 4.68, N 6.02.

## Results and discussion

In experiments run under conditions stoichiometric in Pd(II) and using the dimercurial prepared according to the method of Fish and Rosenblum (3), the major product was a volatile liquid. The nmr spectrum and analysis of this material showed it to be 3,3-diethoxypropanenitrile (**5**) (see Fig. 1 and Table 1). The expected quartet due to the protons on the methylene carbon of the ethoxy groups was unexpectedly split to give a doublet of quartets. Since a similar splitting does not occur in the peaks due to the methine proton, this fine structure must be due to the existence of two different diastereomers in solution.

The acetal product (**5**) is that expected from the oxidation of acrylonitrile in the absence of mercurial, by analogy (ref. 1, pp. 133–147) to the oxidation of acrylonitrile in water which gives the product cyanoacetaldehyde (5). The formation of the acetal probably depends on the acidity of the medium since acids are known to inhibit the acetal forming reaction (6). Similar results were obtained using methanol as solvent. In this case, 3,3-dimethoxypropanenitrile (**6**) (see Table 1) was formed. The organic oxidation product could be obtained under the same reaction conditions (stoichiometric in Pd(II)) in the absence of any mercurial. The major products produced in all experiments with mercurial present were intractable polymers.

The reactions of either the commercial sample of the dimercurial (**2**) or the sample prepared according to the method of Rausch *et al.* (4) with acrylonitrile and Pd(II) used in stoichiometric amounts in ethanol did not produce any detectable amounts of the disubstituted product, 1,1'-bis(2-cyanovinyl)ferrocene (**3**). Neither was any of the organic oxidation product observed in experiments with these starting materials, presumably because the trace amounts of acid were greater in these two preparations. The only materials obtained after

chromatography on alumina were small amounts of ferrocene and 2-cyanovinylferrocene (**4**) as determined by nmr spectroscopy. Most of the starting material was converted to polymeric materials which could not be removed from the alumina.

Recrystallisation of the product mixture from hexane gave an analytically pure sample of **4**. However, the nmr spectrum had an extra set of peaks which were not reported earlier (2), in the vinyl region (7.36, 7.08(d); 7.05, 6.86(d); and 5.48,

| | Unsubstituted ring | Substituted ring | $Fc-\overset{H_A}{\underset{|}{C}}=$ | $=\overset{H_B}{\underset{|}{C}}-CN$ |
| *cis*-(2-Cyanovinylferrocene) | 4.21 (s, 5) | 4.46 (t, 2)[b]<br>4.85 (t, 2) | 5.17 (d, 1)[c] | 6.96 (d, 1) |
| *trans*-(2-Cyanovinylferrocene) | 4.12 (s, 5) | 4.39 (s, 4) | 5.34 (d, 1)[d] | 7.22 (d, 1) |

[a]The solvent used was $CDCl_3$ with internal TMS standard.
[b]The coupling between the two types of protons on the substituted ring was $J$ = 1.8 Hz.
[c]The coupling constant for *cis*-2-cyanovinyl protons was $J$ = 11.4 Hz.
[d]The coupling constant for *trans*-2-cyanovinyl protons was $J$ = 16.8 Hz.

5.20(d); 5.26, 5.07(d)) which suggested that this compound existed as a mixture of *cis* and *trans* isomers. The total yield of the isomeric mixture of **4**, using either the commercial sample or the sample prepared according to Rausch *et al.* (4), was low, about 3% based on Pd(II).

The use of acetonitrile as solvent produced somewhat different results, although they were the same for all three preparations of the dimercurial. A small amount of material was obtained which had an nmr spectrum consistent with that of the expected product, 1,1′-bis(2-cyanovinyl)ferrocene (**3**) (2). The yield of **3** was about 2% based on Pd(II). The nmr spectrum in the vinyl region indicated that the material was a mixture of *cis*/*cis*, *trans*/*trans*, and *cis*/*trans* isomers. Traces of other products were obtained but these were present in such minute quantities that they could not be identified. Again, the major products were polymers which could not be characterised.

The formation of traces of the monosubstituted product, 2-cyanovinylferrocene (**4**) in the reaction of the dimercurial, **2**, could result from impurities of the monomercurial, **1**. It could also result from demercuration of the dimercurial under the reaction conditions to give the monomercurial, **1**, which could then react with acrylonitrile as usual to give **4**.

There is some analogy for this reaction since palladium(II) acetate can dehalogenate bromo- and iodobenzene (7).

Since the earlier study (2) reported only the *trans* isomers from the preparations of both 1,1′-bis-(2-cyanovinyl)ferrocene (**3**) and 2-cyanovinylferrocene (**4**), we decided to investigate further the reaction leading to the latter product. It had been reported (2) that the reaction of chloromercuriferrocene and acrylonitrile proceeded nicely under conditions catalytic in Pd(II) by using Cu(II) to reoxidise the expensive palladium catalyst.

The yield of 2-cyanovinylferrocene (**4**) obtained under these catalytic conditions was 17–20% based on chloromercuriferrocene used. A small amount (<5%) of unreacted chloromercuriferrocene and diferrocene was also obtained from each preparation. The remainder of the starting material was converted to sparingly soluble polymeric material which would not pass through the alumina column and which defied characterisation.

The product, 2-cyanovinylferrocene, always contained some *cis* isomer, the amount depending on the solvent used in the reaction. The *cis*/*trans* ratio was 20/80, 30/70, and 50/50 in methanol, ethanol, and acetonitrile, respectively. The pure *trans* product could be obtained by refluxing the isomeric mixture in $CHCl_3$ containing $I_2$ for a period of one week.[1] The nmr of the material obtained in this fashion was similar to that reported earlier for the pure *trans* compound (2). This spectrum is anomalous for a monosubstituted ferrocene compound. Normally the peaks for the protons on the substituted rings appear as two triplets but in this spectrum (see Table 2) they are present as a singlet, at 4.39 δ.

The two isomers could also be separated efficiently by chromatography on alumina. The nmr spectrum of the pure *cis* product is given in Table 2. The spectrum is the expected one for a monosub-

stituted ferrocene derivative with a singlet for the unsubstituted ring and two triplets for the substituted one. Borovyak *et al.* (8) reported the same results for the nmr spectra of the *cis* and *trans* isomers of **4** prepared by an alternative method (9). In addition, they determined the crystal structure of the *trans* isomer (8).

We attempted to make the complex 1,1′-bis(2-cyanovinyl)ferrocene, **3**, by the catalytic route using $PdCl_2$ and $CuCl_2$ to reoxidise the palladium. In all cases, we obtained only the monosubstituted derivative **4** in surprisingly high yield (about 15–20% based on dimercurial used). This lends support to the idea that demercuration does indeed occur (*vide supra*). The remainder of the starting material was converted to polymeric materials.

The isolation of *cis* products may seem a bit surprising since the olefin arylation reaction usually gives *trans* products (ref. 1, pp. 147–178) but in the case of acrylonitrile, the arylation reaction, for some reason, gives mixtures of *cis* and *trans* isomers (10–12).

# Étude structurale d'aldimines derivées des furanne-, thiophène- et *N*-méthylpyrrolecarboxaldéhydes-2. I. *N*-hétéroarylidèneanilines

PAUL AUDOYE, RENÉ-CHARLES COUMES, ANTOINE GASET ET JEAN-PIERRE GORRICHON[1]

*Laboratoire de Chimie Organique et d'Agrochimie, Ecole Nationale Supérieure de Chimie (INPT), 118, route de Narbonne, 31077 Toulouse Cédex, France*

Reçu le 14 mai 1981[2]

PAUL AUDOYE, RENÉ-CHARLES COUMES, ANTOINE GASET et JEAN-PIERRE GORRICHON. Can. J. Chem. **60**, 1148 (1982).

Nous avons étudié une série de cinq *N*-hétéroarylidèneanilines, nitrées ou non sur l'hétérocycle et dans lesquelles l'hétéroatome peut être O, S ou N—$CH_3$. Les résultats obtenus en uv et en rmn du carbone-treize permettent de penser que, comme pour la benzylidèneaniline, ces molécules ne sont pas entièrement planes. De plus, la rmn du proton montre qu'il n'existe qu'un seul rotamère (ou à la limite un équilibre entre deux rotamères en échange rapide) sur les quatre possibles.

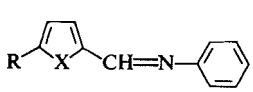
PAUL AUDOYE, RENÉ-CHARLES COUMES, ANTOINE GASET, and JEAN-PIERRE GORRICHON. Can. J. Chem. **60**, 1148 (1982).

We have studied a series of five *N*-heteroarylideneanilines, either nitrated or not on the heterocyclic ring, in which the hetero atom can be O, S or N—$CH_3$. The uv and $^{13}C$ nmr results obtained suggest that these molecules are, as in the case of benzylideneaniline, not entirely planar. In addition, $^1H$ nmr shows that only a single rotamer exists out of the four possibilities (or, at the limit, a rapid equilibrium between two rotamers).

[Journal translation]

## Introduction

Dans le cadre d'une étude des propriétés antibactériennes (1) et antiparasitaires (2) d'aldimines issues d'aldéhydes hétérocycliques et de diverses amines, nous avons été amené à synthétiser des molécules du type:



| | | | |
|---|---|---|---|
| R = H | X = O | | 1 |
| | X = S | | 2 |
| | X = N—Me | | 3 |
| R = $NO_2$ | X = O | | 4 |
| | X = S | | 5 |

De nombreuses études structurales ont été menées sur les *N*-benzylidèneanilines (3–10) à l'aide de différentes techniques physicochimiques. De ces divers travaux, on peut conclure que pour ces molécules, seul l'isomère *E* (*anti*) est présent à l'équilibre et que la structure n'est pas plane. Dans le cas de la benzalaniline (4), le plan du noyau benzénique provenant de l'aniline semble être perpendiculaire au plan du reste phényliminique. De plus, il a été proposé (4), en prenant en compte l'énergie électronique de ce composé, que l'hybridation de l'azote est proche du type *sp*.

Les résultats comparables en série hétérocyclique à cinq chaînons sont peu nombreux (11–14) et demeurent peu concluants voire contradictoires. Nous avons donc entrepris l'étude de ces cinq composés en spectroscopies infrarouge, ultraviolette et de résonance magnétique nucléaire du proton et du carbone-13.

## Résultats et discussion

Pour de telles molécules, on peut prévoir deux isomères *E* et *Z* autour de la double liaison >C= N—. Ces molécules présentent quatre isomères de rotation que nous avons représentés dans la figure 1.

La chromatographie en phase gazeuse ne permet de détecter qu'un seul isomère. De plus, dans le cas de la thiénylidèneaniline, **2**, nous avons enregistré une série de spectres ultraviolets après irradiation (de 2 à 60 minutes) à des longueurs d'onde de 254 et 350 nm. Le fait que le spectre n'est pas modifié lors de cette expérience, indique bien que nous sommes en présence d'un seul isomère de ce dérivé. Compte tenu des résultats de la littérature obtenus pour les benzylidineanilines et de l'encombrement stérique, on peut penser qu'il s'agit de l'isomère *E*.

### *Spectrographie infrarouge*

Les fréquences d'absorption $\nu_{C=N}$ et $\nu_{NO_2}$ que nous observons pour les cinq composés étudiés (cf. tableau 1) sont conformes à celles déjà présentés dans la littérature (12, 13, 15). Signalons simplement que la présence du groupement —$NO_2$, si elle n'a que peu d'influence sur la position de la vibration $\nu_{C=N}$, semble affaiblir considérablement l'intensité de la bande d'absorption correspondante.

Il est à noter que Head et Jones (13), ont pu montrer que pour le dérivé **6** (cf. figure 2), la fréquence de la bande d'absorption $\nu_{N-H}$ est en accord avec une liaison N—H...N (et non avec une liaison N—H...π), ce qui renforce l'hypothèse

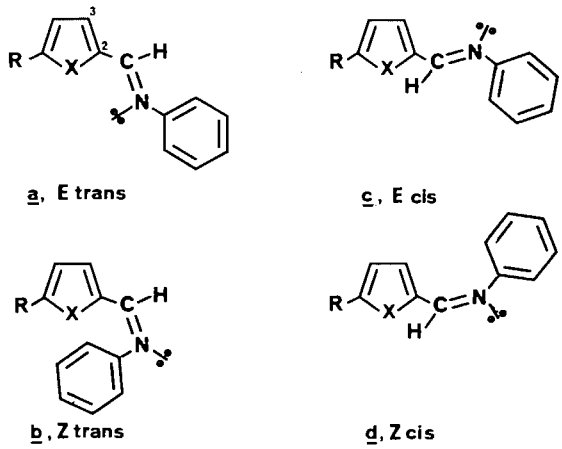

FIG. 1. Isomères de rotation des aldimines 1 à 5. La notation *cis* ou *trans* correspond aux positions *s-cis* ou *s-trans* des doubles liaisons C=N et C(2)=C(3) (intracyclique).

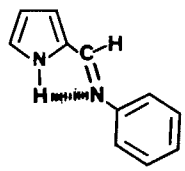

FIG. 2. 2-Pyrrolylméthylèneaniline 6.

d'une seule configuration *E* pour ce type de substrat.

*Spectroscopie ultraviolette*

Le problème de la non coplanéité des composés de la même série que la benzylidèneaniline a été étudié, nous l'avons déjà vu, par divers auteurs avec l'aide de la spectroscopie ultraviolette (3–6). Leurs discussions font intervenir deux modes de participation du groupement azomethine $\rangle CH=N-$ dans la conjugaison de la molécule: d'une part, au moyen des électrons $\pi$ de la double liaison, d'autre part de la paire libre portée par l'atome d'azote.

Si bien que l'on peut s'attendre à trois bandes d'absorption correspondant aux systèmes représentés dans la figure 3. La présence de ces trois bandes dans le spectre uv doit alors confirmer la structure non planaire du composé étudié.

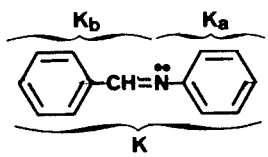

FIG. 3. Types de bandes d'absorption observées en uv pour la benzylidèneaniline.

Nous avons envisagé un travail similaire pour les aldimines **1** à **5**. Les valeurs des maxima d'absorption et des coefficients d'extinction sont rassemblées dans le tableau 1.

Pour les composés non nitrés **1**, **2** et **3**, on constate effectivement l'existence de bandes du type *K*, $K_a$ et $K_b$. Les bandes situées entre 315 et 324 nm représentent le système totalement conjugué. En effet, cette bande disparaît lorsque l'on hydrolyse ces imines en milieu acide. Les bandes comprises entre 287 et 302 nm sont composées et attribuables d'une part à la transition $\pi-\pi^*$ du type de celle des aldéhydes de départ (273–288,5 nm; cf. tableau 2) et d'autre part à la transition $n-\pi^*$ de la paire libre d'électrons de l'atome d'azote telle qu'elle existe dans la molécule d'aniline (286 nm selon réf. 11).

Les bandes correspondantes à la transition $\pi-\pi^*$ de l'aniline (235 nm selon réf. 11) apparaissent à 237 et 240 nm dans le cas des dérivés **1** et **2**. Elle est probablement masquée par l'absorption qui se trouve à 220 nm dans le cas de la *N*-méthyl pyrrolylméthylèneaniline **3**.

On note de plus, dans le cas des composés **2** et **3**, une bande d'absorption respectivement à 269 et 260 nm. Nous pensons qu'elles sont attribuables au système $K_a$ puisqu'on retrouve des bandes de ce type et à des maxima très voisins, aussi bien dans les aldéhydes que dans des imines où la bande *K* de conjugaison totale n'existe pas (cf. tableau 2). Toutefois pour vérifier cette hypothèse et s'assurer qu'il ne s'agit pas d'une bande due à une hydrolyse partielle des composés au cours de la dilution nécessaire à l'enregistrement des spectres uv, nous avons réalisé le spectre du produit **2** à la concentration *M*/1000 dans l'éthanol pour une cuve de 0,1 cm. Le spectre obtenu est identique à celui que donne une solution *M*/20 000 dans une cuve de 1 cm. Après évaporation du solvant, le spectre de rmn du proton, dans le benzène deutérié, ne révèle aucune trace d'hydrolyse.

En ce qui concerne les composés nitrés **4** et **5**, on retrouve les trois types de bandes (cf. tableau 1), mais fortement décalées vers les hautes absorptions par la présence du groupement $-NO_2$. Ainsi dans le cas de la *N*-(nitro-5)thiénylidèneaniline, **5**, on observe le système *K* à 377 nm et le système $K_b$ sous forme d'inflexion à 293 et 340 nm (cf. la *N*-(nitro-5)thiénylidènebenzylamine dans le tableau 2).

*Résonance magnétique nucléaire du proton*

Nous avons enregistré les spectres de rmn du proton à 250 MHz pour les composés **1** à **5**. Pour

cette valeur du champ magnétique appliqué, les spectres sont tous analysables au premier ordre. Les déplacements chimiques et constantes de couplage que nous en avons déduits, sont rassemblés dans le tableau 3.

Du point de vue des déplacements chimiques, on peut noter que les protons H(3) (cf. tableau 3) de tous les dérivés sont moins déblindés que les mêmes protons dans les aldéhydes correspondants (cf. tableau 4). Ceci montre que l'effet électronique

du groupe imine est très inférieur à celui du groupement carbonyle. Toutefois, en comparant les valeurs des déplacements chimiques de ces protons H(3) dans **1**, **2** et **3** avec celles des mêmes protons respectivement dans le furanne, le thiophène et le *N*-méthylpyrrole (tableau 4), on voit qu'il subsiste des déblindages de −0,49, −0,33 et −0,52 ppm. Les protons impliqués se trouvent donc dans le cône de déblindage de la double liaison >C=N—. Si on admet que ce cône d'anisotropie est de la même forme que celui proposé par Karabatsos *et al.* (19) pour le groupement carbonyle (cf. figure 4), on peut en déduire que le rotamère *E trans* (*a* de la figure 1) sera privilégié. De plus, les spectres de rmn du proton des composés **1** et **2** ne changent pas lorsque l'on abaisse la température de l'échantillon à −100°C. Ceci suggère, soit la présence d'un seul rotamère, soit une interconversion rapide entre deux isomères de rotation même à cette température.

Les résultats d'une étude de l'effet Overhauser dans de telles molécules (composés **1** et **3**, tableau 5) sont encore en faveur de cette hypothèse. On observe, en effet, à température ordinaire, des augmentations de surface des signaux traduisant la proximité des protons H(1) et H(3) d'une part, H(1) et H(7–11) d'autre part. Cela exclut totalement la conformation *Z cis* (*d* de la figure 1) et suggère soit la présence du seul rotamère *a* (où ces deux effets existent) soit un équilibre avec un des deux autres

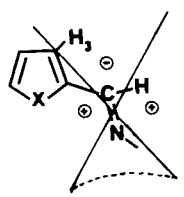

FIG. 4. Cône d'anisotropie de la liaison C=N—.

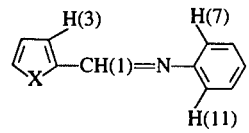
TABLEAU 5. Effet Overhauser observé dans les composés **1** et **3**



| Proton irradié | Effet (%)[a] sur H(1) | H(3) | H(7–11) | H(4) |
|---|---|---|---|---|

rotamères *b* ou *c* (dans lesquels un seul des ces effets Overhauser peut être rencontré).

Au sujet des constantes de couplage, il faut surtout remarquer que les couplages lointains ont toujours lieu entre le proton aldiminique H(1) et le proton H(5) sur l'hétérocycle. Nous n'observons pas de constantes $^5J_{H(1)-H(4)}$ même dans les composés nitrés, où la position 5 sur l'hétérocycle est occupée par le groupement nitro. Si on compare ces résultats à ceux obtenus par Roques et coll. (17, 18, 20, 21), sur la stéréospécificité des couplages lontains dans des aldéhydes hétérocycliques, on peut penser que les valeurs $^5J_{H(1)-H(5)}$ = 0,7 et 1,0 Hz observées respectivement pour les furanne- et thiophènealdimines sont en accord avec un rotamère majoritaire X—N *cis* (*a* ou *b* dans la figure 1). Le cas du composé 3 est plus surprenant puisque $^5J_{H(1)H(5)} \leq 0{,}4$ Hz, alors que pour un rotamère N—O *cis* (17) on mesure $^5J_{CHO-H(5)}$ de l'ordre de 1,1 Hz. Si ce composé présente un équilibre entre deux rotamères *cis* et *trans*, on devrait mesurer une constante $^5J_{CHO-H(4)}$ de l'ordre de 0,70 Hz, ce qui n'est pas le cas.

Cette étude des constantes de couplage à longue distance permet de faire des hypothèses quant à l'existence de rotamères uniques ou en équilibre pour ces molécules. Malheureusement, elle n'apporte aucun renseignement sur la structure spatiale de ces dérivés. En effet, selon Bell *et al.*, les torsions des groupements formyles ou aldiminiques ne semblent pas toujours affecter fortement la grandeur du couplage lointain (22). Ceci s'expliquerait, selon ces auteurs, par la participation à la transmission de ce couplage, entre autres d'une contribution π de l'hétérocycle.

[a]Spectres enregistrés dans $CDCl_3$.
[b]Couplages non visibles sur le spectre à 62,86 MHz.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

*Résonance magnétique nucléaire du carbone-treize*

L'enregistrement des spectres de rmn du $^{13}C$ des composés **1** à **5** a été réalisé à 15,08 MHz en découplage total et à 62,86 MHz sans découplage des protons. Les attributions des déplacements chimiques des divers carbones ont été effectuées à l'aide de données de la littérature (23–27) et au moyen d'irradiations sélectives de certains protons lorsque cela s'avérait nécessaire. Les résultats de cette analyse et les constantes de couplage $J_{^{13}C-H}$ mesurées sont rassemblés dans le tableau 6.

Pour les composés **1** à **3**, si l'on compare les effets du substituant —CH=N— sur les déplacements des divers carbones des hétérocycles, à ceux, déjà connus, du groupement —CH=O, on s'aperçoit (tableau 7) qu'ils se traduisent par un déblindage de tous les carbones quel que soit l'hétéroatome (N—$CH_3$, O ou S), considéré. Ils sont cependant plus faibles sur C(4) que sur C(3) et C(5), ce qui est en accord avec les effets de résonance et les délocalisations de charge attendus entre le substituant et le noyau hétérocyclique. De plus, dans l'ensemble, les effets du groupement —CH=N sont plus faibles que ceux du groupe —CH=O. Ceci pourrait traduire soit une diminution des effets précédemment cités quand on remplace un oxygène par un azote dans la double liaison, soit une noncoplaneité de la molécule, puisque dans ce cas l'atome d'azote serait sollicité par une conjugaison avec le noyau phényle.

Dans le cas des dérivés **4** et **5**, l'effet électroattracteur du groupement —$NO_2$ perturbe considérablement les effets de délocalisation de charge et de résonance au point que le groupement —CH=O a une influence inférieure à celle du groupe imine. Ce phénomène paraît encore en faveur de la noncoplanéité de ces molécules.

Les constantes de couplage $^1J_{^{13}C(n)-H(n)}$, pour les carbones des différents hétérocycles étudiés, ont des valeurs normales, comparables à celles de la littérature (23, 24, 28, 30). Dans tous les cas, la valeur de $^1J_{C-H}$ pour le carbone aldiminique est plus faible et se situe entre 157 et 166 Hz. Cette diminution traduit une augmentation du caractère $sp^2$ du carbone en question (31) en rapport avec la présence de l'azote doublement lié au carbone. On peut aussi noter que c'est le seul carbone qui ne présente pas de couplage à distance avec des hydrogènes. En particulier, il n'est donc pas couplé avec le proton H(3) de l'hétérocycle.

TABLEAU 7. Effet des substituants —CH=N— et —CH=O sur les déplacements chimiques des carbones hétérocycliques des composés **1** à **5**[a]

| No | $\Delta\delta_R$[b] | C(2) | C(3) | C(4) | C(5) |
|---|---|---|---|---|---|
| **1** | —CH=N— | −9,3 | −6,3 | −2,3 | −2,7 |

## Partie expérimentale

La synthèse des composés **1** à **5** a déjà été décrite (1, 32). La chromatographie en phase gazeuse est effectuée sur le brut de manipulation sur un appareil Intersmat IGC 120 DFL muni d'une colonne SE 30 de 1,5 m utilisée en isotherme à 180°C avec un débit d'azote de 25 mL/min. La température de l'injecteur et du détecteur est fixée à 240°C.

Les spectres ir ont été réalisés sur un appareil Beckman IR 20 en solution *M*/20 dans le tétrachlorure de carbone pour **1**, **2** et **3** dans le chloroforme à saturation pour **4** et **5**. Les spectres uv ont été enregistrés dans un spectrophotomètre Cary, modèle 15, pour des solutions *M*/20 000 dans l'éthanol avec des cuves de 1 cm. La rmn du proton a été effectuée sur un appareil Cameca 250. Les composés sont solubilisés (environ *M*/20) dans le chloroforme deutérié avec le TMS comme référence interne.

La mesure des effets Overhauser a été effectuée selon la méthode décrite par Bell et Saunders (33), sur des solutions soigneusement filtrées mais non dégazées.

L'enregistrement des spectres de rmn du carbone-treize a été conduit: soit sur un appareil Bruker WP 60 travaillant à 15,08 Mz pour des composés à saturation dans le chloroforme deutérié, avec découplage total des protons; soit sur un appareil Cameca 250 travaillant à 62,86 MHz pour des composés *M*/20 dans le chloroforme deutérié. Dans ce cas, nous n'avons pas utilisé le découplage des protons, de façon à conserver l'information concernant les constantes de couplage $J_{^{13}C-H}$.

Les valeurs des déplacements chimiques des carbones des hétérocycles de base et des aldéhydes utilisés dans le tableau 6 sont données ci-dessous.

*Furanne*: rmn $^{13}C$ à 15,08 MHz, chloroforme deutérié; δ ppm; C(2): 142,8; C(3): 109,8.

*Thiophène*: rmn $^{13}C$ à 15,08 MHz, chloroforme deutérié; δ ppm; C(2): 125,6; C(3): 127,4.

*N-méthylpyrrole*: rmn $^{13}C$ à 25,14 MHz, chloroforme deutérié, réf. 26; δ ppm; C(2): 121,7; C(3): 107,8; $CH_3$: 35,8.

*Nitro-2 furanne*: rmn $^{13}C$ à 25,14 MHz, acétone deutérié, réf. 28; δ ppm; C(2): 153,7; C(3): 114,5; C(4): 112,6; C(5): 146,9.

*Nitro-2 thiophène*: rmn $^{13}C$ à 25,14 MHz, acétone deutérié, réf. 29; δ ppm; C(2): 151,2; C(3): 129,9; C(4): 128,4; C(5): 134,7.

*Furannecarboxaldéhyde-2*: rmn $^{13}C$ à 22,63 MHz, chloroforme deutérié, réf. 25; δ ppm; C(2): 153,1; C(3): 122,2; C(4): 112,9; C(5): 148,6; *C*HO: 178,1.

*Thiophènecarboxaldéhyde-2*: rmn $^{13}C$ à 22,63 MHz, chloroforme deutérié, réf. 25; δ ppm; C(2): 143,7; C(3): 136,6; C(4): 128,3; C(5): 135,6; *C*HO: 183,0.

N-*méthylpyrrolecarboxaldéhyde-2*: rmn $^{13}C$ à 25,14 MHz, chloroforme deutérié, réf. 26; δ ppm; C(2): 131,4; C(3): 123,5; C(4): 109,0; C(5): 131,4; *C*HO: 178,7; *C*$H_3$: 36,2.

*Nitro-5 furannecarboxaldéhyde-2*: rmn $^{13}C$ à 15,08 MHz, chloroforme deutérié; δ ppm; C(2): 151,2; C(3): 112,3; C(4): 120,4; C(5): 153,5; *C*HO: 178,7.

*Nitro-5 thiophènecarboxaldéhyde-2*: rmn $^{13}C$ à 15,08 MHz, chloroforme deutérié; δ ppm; C(2): 145,4; C(3): 126,5; C(4): 128,2; C(5): 152,6; *C*HO: 168,3.

# Utilisation d'une méthode d'ajouts pour la détermination précise des volumes molaires partiels des constituants dans un solvant mixte. Application au système eau–méthanol

PIERRE LETELLIER ET MICHEL BIQUARD

*Laboratoire de Physicochimie des Solutions, Associé au C.N.R.S. no 161, E.N.S.C.P., 11 rue Pierre et Marie Curie, F-75231, Paris, Cedex 05, France*

Reçu le 29 septembre 1981

PIERRE LETELLIER et MICHEL BIQUARD. Can. J. Chem. **60**, 1155 (1982).

La détermination des volumes molaires partiels de l'eau et du méthanol dans leurs mélanges a été effectuée avec précision par une *méthode d'ajouts*. Outre le fait que l'on retrouve bien la grandeur d'excès totale en faisant la somme des volumes molaires partiels caractéristiques de l'eau et du méthanol dans le mélange, cette technique permet de proposer des fonctions polynômiales thermodynamiquement cohérentes pour décrire les variations de volumes molaires partiels des deux composants de la solution. Cette méthode de détermination est utilisable pour caractériser chaque élément dans des solutions qui font intervenir différents solvants et solutés en forte concentration.

PIERRE LETELLIER and MICHEL BIQUARD. Can. J. Chem. **60**, 1155 (1982).

The determination of partial molar volumes of each component in a binary mixture is usually the result of the derivation of the polynomial function which describes the whole excess curve. The accuracy of the present available densimeters (vibrating densimeter Piker type) allows direct access to the values of partial molar volume by a method requiring successive additions of various components. The method of calculation is discussed in this paper and applied for the water–methanol system. Partial molar volumes of water and methanol are calculated for different phase compositions, and each variation is described by polynomial functions which are related to each other by thermodynamic rules. This technique may be extended to mixtures which contain different solvents and highly concentrated solutes.

## Introduction

L'étude des propriétés physicochimiques de solutés à faible concentration dans les milieux mixtes obtenus par le mélange de plusieurs solvants miscibles pose le problème des interactions spécifiques qui s'établissent entre le soluté et chacun des composants du mélange.

Une étude précédente (1) effectuée dans les mélanges eau–diméthylsulfoxyde montre à ce propos que l'on retrouve dans l'expression des volumes molaires partiels à dilution infinie ($\bar{V}_{MX}^{0}$) des halogénures alcalins MX, les propriétés volumétriques partielles des deux cosolvants ($\bar{V}_{H_2O}$, $\bar{V}_{DMSO}$) différemment amplifiées selon l'affinité des sels pour l'un ou l'autre des deux solvants.

La "grandeur molaire d'excès", qui est une grandeur globale caractéristique du milieu (écart à l'idéalité) n'est pas alors adaptée pour décrire les interactions soluté–cosolvants et l'on doit dans ce cas déterminer très précisément les grandeurs molaires partielles individuelles de chacun des constituants de la solution.

Les déterminations sont parfois délicates et le but principal de cet article est de proposer une technique expérimentale simple qui permette d'accéder, avec une grande précision, aux valeurs des grandeurs molaires partielles recherchées. Afin d'illustrer notre propos, nous avons choisi de traiter l'exemple du calcul des volumes partiels pour une série de mélanges eau–méthanol à la température de 25°C. La technique proposée peut bien évidemment être généralisée et appliquée à la mesure d'autres paramètres extensifs (l'enthalpie par exemple) dans des milieux plus complexes (milieux salins, ternaires ...).

## I. Détermination des grandeurs molaires partielles

### *I-1. À partir de la grandeur d'excès*

Dans le cas d'un mélange binaire (mélange de solvant A et de solvant B) la méthode la plus couramment utilisée consiste à calculer tout d'abord la "grandeur molaire d'excès", $Y_E$, pour un grand nombre de mélanges et de décrire ses variations avec la composition du milieu (fraction molaire $X_B$) au moyen d'une fonction polynômiale d'ordre $n$. Celle-ci peut prendre plusieurs formes mais la plus utilisée à cet effet est celle proposée par Redlich et Kister (2) ou Wilson et Scatchard (3, 4)

$$Y_E = X_B(1 - X_B)\left[\sum_{j=0}^{j} a_j(2X_B - 1)^j\right]$$

qui admet comme cas particulier celui des courbes symétriques en ne conservant que les valeurs de $j$ paires. En théorie, l'application des relations habituelles de la thermodynamique, permet à partir des dérivées de la fonction $Y_E$ par rapport à la fraction molaire $X_B$ d'accéder aux propriétés molaires partielles de chacun des deux cosolvants.

Toutefois cette manière de procèder est sujette à plusieurs difficultés: (a) pour être "paramétrable", la courbe d'excès doit comporter un nombre minimum de points expérimentaux régulièrement espacés sur l'échelle des abscisses. Par exemple, une bonne description de la courbe de variation pour un polynôme d'ordre 6 ne peut s'obtenir qu'à partir d'environ 40 points expérimentaux répartis sur l'échelle des fractions molaires. Lorsque cette condition est remplie, la dérivation (ou la détermination de la tangente) peut alors s'effectuer; mais elle conduit bien souvent à des valeurs généralement erronées pour les parties à faible courbure.[1] De ce fait, même en effectuant un nombre important de mesures, la dérivation de la courbe polynômiale donnera rarement satisfaction sur l'ensemble de la courbe d'excès. (b) Avant de pouvoir procéder à son exploitation, la méthode précédente impose de connaître la totalité de la courbe d'excès ce qui limite généralement le calcul des grandeurs molaires partielles aux solvants totalement miscibles. Sont exclus de ce type de développement les solutés solides moléculaires ou salins, qui entrent cependant dans la composition de nombreux milieux réactionnels de grand intérêt (eau–urée, milieux salins, milieux micellaires ...). (c) La description par le polynôme devient de moins en moins satisfaisante au fur et à mesure que l'on approche des bornes du domaine d'étude.

*I-2. Détermination expérimentale directe*

La méthode de calcul présentée ci-dessous présente l'avantage de résoudre les problèmes évoqués; elle nécessite, en contrepartie, l'acquisition de nombreuses données expérimentales, donc une étude plus longue que celles généralement effectuées pour ce type de mesure.

Si l'on considère le milieu mixte non idéal constitué de $n_A$ moles de solvant A et $n_B$ moles de solvant B de volumes molaires respectivement $V_A^0$ et $V_B^0$, le volume du mélange obtenu est égal à $V = n_A\bar{V}_A + n_B\bar{V}_B$ où $\bar{V}_A$ et $\bar{V}_B$ sont les volumes molaires partiels des cosolvants A et B. La méthode des perturbations que nous proposons consiste à modifier ce mélange par de faibles ajouts de l'un ou de l'autre des constituants et d'en étudier les conséquences sur le volume du milieu.

Si l'on ajoute un nombre de moles $\varepsilon_A$ de solvant A au milieu, le volume total varie et peut s'écrire en attribuant à l'ajout l'essentiel de la perturbation $P_A$ observée sur le volume total:

$$V' = n_A\bar{V}_A + n_B\bar{V}_B + \varepsilon_A P_A$$

$P_A$ intervient comme une grandeur molaire partielle apparente et peut être calculée comme telle.

$$P_A = \frac{V' - V}{\varepsilon_A} = \frac{\Delta V}{\varepsilon_A}$$

La valeur limite de la perturbation $P$ lorsque l'ajout $\varepsilon$ tend vers 0 s'identifie à celle du volume molaire du cosolvant ajouté, tous les autres paramètres étant fixés.

$$[1] \qquad \lim_{\varepsilon_A \to 0} P_A = \bar{V}_A$$

La quantité $P_A$ est facilement calculable pour des additions finies de A à partir des masses volumiques $\rho_x$ des solutions ainsi constituées.

$$[2] \qquad P_A = \frac{n_A M_A + n_B M_B}{\varepsilon_A}\left(\frac{1}{\rho_x} - \frac{1}{\rho_s}\right) + \frac{M_A}{\rho_x}$$

où $\rho_s$ est la masse volumique du solvant étudié, $M_A$ et $M_B$ les masses molaires des cosolvants A et B.

La valeur cherchée $\bar{V}_A$ sera obtenue par extrapolation des valeurs de $P_A$ à "ajout nul".[2] L'étude complète d'un mélange binaire comportera donc pour chaque concentration envisagée l'étude de deux séries d'ajouts. A titre d'exemple nous présentons ci-dessous le cas des mélanges eau–méthanol à 298 K.

## II. Volumes molaires partiels de l'eau et du méthanol dans leurs mélanges

Les solvants eau et méthanol[3] ont été purifiés par distillation et les mesures des masses volumiques ont été réalisées à l'aide d'un densimètre vibratomètre à flux Piker Modèle 03D maintenu à la température constante de 298 K par un thermostat Setaram régulant à $\pm 3 \times 10^{-3}$ K (13).

*II-1. La grandeur molaire d'excès*

Les mélanges eau–méthanol (MeOH) sont connus pour présenter des écarts importants à l'idéalité (5–10). La grandeur d'excès $V_E$ qui caractérise cet

[1] Une régression polynômiale d'ordre supérieur à 1 ne peut en aucun cas décrire avec précision une partie linéaire. Or ces zones, lorsqu'elles existent, sont primordiales car elles correspondent généralement à des solutions diluées d'un des deux constituants dans l'autre.

[2] La loi d'extrapolation à adopter ne pose aucun problème dans ce cas. Les écarts entre la courbe et sa tangente sont des fonctions linéaires de l'incrément imposé tant que celui-ci reste suffisamment faible. Nous avons toujours vérifié expérimentalement que les valeurs de $P$ s'extrapolaient linéairement avec le nombre de moles de solvant ajouté, et que bien souvent les variations du paramètre $P$ étaient suffisamment petites pour que l'incertitude sur $\bar{V}$ reste inférieure à $\pm$ 0,2 cm$^3$ mol$^{-1}$.

[3] La teneur en eau du méthanol après distillation est inférieure à 0,1%.

écart pour le volume peut être calculée classiquement par la mesure de la masse volumique ($\rho_X$) pour chaque solution.

$$V_E = X_A M_A \left(\frac{1}{\rho_X} - \frac{1}{\rho_A{}^0}\right) + X_B M_B \left(\frac{1}{\rho_X} - \frac{1}{\rho_B{}^0}\right)$$

$X_A$ et $X_B$ sont les fractions molaires de A et B dans le mélange; $\rho_A{}^0$ et $\rho_B{}^0$ les masses volumiques de A et B purs.

Les résultats obtenus pour différentes solutions d'eau et de méthanol sont reportés dans le tableau 1.

*II-2. Application de la méthode des perturbations*

Pour chaque mélange indiqué dans le tableau 1 nous avons effectué deux séries d'au moins 5 ajouts d'eau et de méthanol. Afin d'accroître la précision sur les valeurs recherchées nous avons procédé par dilution d'une solution "mère" obtenue à partir d'une addition assez importante de cosolvant (de l'ordre de $\varepsilon_A = 1/20\, n_A$).

Les résultats trouvés pour le milieu $X_{CH_3OH} = 0{,}0446$ sont reportés dans le tableau 2 à titre d'exemple. Des variations tout à fait comparables sont obtenues dans les autres milieux. Les très faibles quantités de produit ajouté permettent d'obtenir une droite d'extrapolation à "ajout nul" pratiquement horizontale pour l'eau et le méthanol.

TABLEAU 1. Volumes d'excès des mélanges eau–méthanol $\rho^0_{eau} = 0{,}997047$ g/cm³; $\rho^0_{MeOH} = 0{,}78555$ g/cm³

| $N_{MeOH}$ | $\rho^*_x$ g/cm³ | $V_E$ cm³mol⁻¹ |
|---|---|---|
| 0 | 0,997047 | 0 |
| 0,0227 | 0,9898 | −0,063 |
| 0,0446 | 0,9830 | −0,119 |
| 0,0978 | 0,9700 | −0,306 |
| 0,1552 | 0,9569 | −0,495 |
| 0,2196 | 0,9422 | −0,671 |
| 0,2930 | 0,9256 | −0,826 |
| 0,3784 | 0,9066 | −0,944 |

| 0,9480 | 0,7936 | −0,154 |
| 1,0000 | 0,78555 | 0 |

*La moindre précision donnée sur ces valeurs par rapport à celles reportées dans le tableau 2 peut paraître surprenante. Cette différence tient à notre mode opératoire qui comporte deux étapes distinctes: la première consiste à préparer une masse importante de solvant mixte d'une *manière volumétrique*. La masse volumique de ce liquide peut être déterminée avec une grande précision mais la composition du milieu ainsi préparé n'est pas suffisamment reproductible pour que cette précision ait un sens, c'est pourquoi nous ne donnons dans ce tableau que 4 chiffres caractéristiques (sauf pour les deux milieux purs). La deuxième étape, en revanche, fait intervenir de l'addition de faibles quantités d'eau et de méthanol suivies par *gravimétrie* ce qui permet d'exploiter au maximum les qualités de l'appareil.

TABLEAU 2. Perturbations sur le volume du mélange $X_{MeOH} = 0{,}0446$ de masse volumique $\rho_s = 0{,}983000$ g/cm³ par ajout d'eau et par ajout de méthanol

| Ajout d'eau* $\varepsilon_{H_2O}$ | $\rho_x$ g/cm³ | $\Delta\rho = \rho_x - \rho_s$ $10^6$ g/cm³ | $P_{H_2O}$ cm³·mol⁻¹ |

*ε est exprimé en nombre de moles ajoutées pour 1000 g de solvant.

L'incertitude sur les valeurs extrapolées peut être estimée à ± 0.2 cm³·mol⁻¹ (figure 1).

Comme le montre fort bien le tableau 2, la nécessité d'ajouter de très petites quantités d'un des constituants du mélange, conduit à de très faibles variations du paramètre mesuré (voir la colonne Δρ du tableau 2).

La mise en œuvre expérimentale de la méthode proposée ne peut donc être envisagée que si l'on dispose de moyens de mesures suffisamment précis,

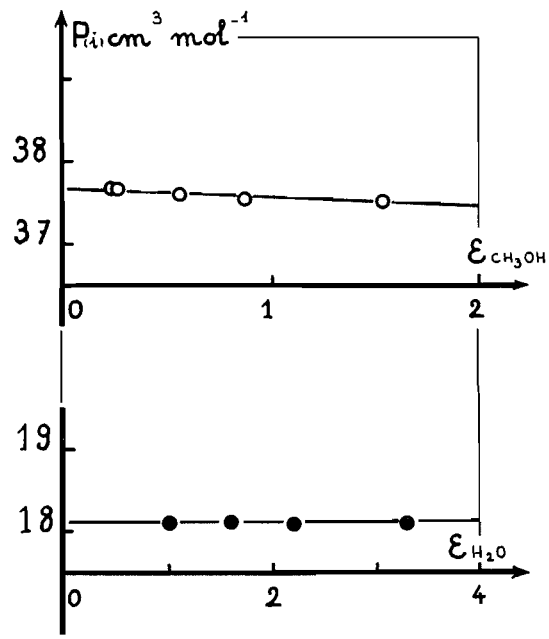

FIG. 1. Variation de la perturbation $P$ lors d'ajouts successifs de méthanol (ou d'eau) dans le milieu hydroalcoolique $X_{CH_3OH} = 0{,}0446$. La quantité ε portée en abscisses correspond au nombre de moles de solvant pur ajouté à 1 kg de mélange eau–méthanol.

*Les valeurs calculées ont été déterminées au moyen de la relation [3] à partir des valeurs $\bar{V}$ de l'autre cosolvant.

comme c'est le cas ici pour le volume (précision sur la masse volumique $\pm 2 \times 10^{-6}$ g/cm³). Cette restriction liée à la qualité de l'appareillage de mesure limite, dans sa généralité, l'extension de cette méthode à d'autres grandeurs thermodynamiques.

Les volumes molaires partiels de l'eau et du méthanol obtenus par cette méthode pour différents mélanges sont reportés dans le tableau 3.

*Remarque*: La masse volumique du solvant étant connue, la détermination du volume molaire partiel d'un seul des deux constituants est en théorie suffisante pour accéder à la valeur de l'autre.

Avec les notations précédentes, $\bar{V}_B$ peut être calculé connaissant $\bar{V}_A$ par la relation:

$$[3] \quad \bar{V}_B = \frac{X_A}{X_B}\left(\frac{M_A}{\rho_S} - \bar{V}_A\right) + \frac{M_B}{\rho_S}$$

Cette propriété peut effectivement être mise à profit pour éviter un certain nombre de manipulations dans des zones où l'un des deux cosolvants est en excès devant l'autre (on se servira exclusivement de la valeur expérimentale relative au liquide le plus dilué si l'on veut garder au résultat du calcul une précision acceptable).

Nous avons reporté dans le tableau 3 différents résultats obtenus par ce calcul qui montrent l'excellente cohérence entre les valeurs expérimentales et calculées.

*II-3. Discussion sur les valeurs obtenues*

La détermination précise des grandeurs molaires partielles d'excès $\overline{\Delta V} = (\bar{V} - V^0)$ pour chaque cosolvant par des manipulations indépendantes comme celles décrites précédemment, permet de retrouver parfaitement la grandeur d'excès totale.

A l'inverse, et la figure 2 le montre parfaitement, il est difficile de calculer, à partir de la courbe d'excès totale, les valeurs précises des volumes molaires partiels d'excès des constituants du mélange, en particulier lorsque celles-ci présentent des maximums (4, 12).

Comme nous l'avions suggéré dans l'introduction de ce travail, l'utilisation d'une équation polynômiale de type Redlich devrait donc être réservée dans son emploi à la seule description de la courbe expérimentale représentative de la grandeur d'excès. L'exploitation thermodynamique de ce type d'équation (particulièrement les opérations qui mettent en jeu la dérivation), (11) ne peut être entreprise qu'au risque d'attribuer aux grandeurs physiques recherchées des valeurs très imprécises et parfois même assez éloignées de la réalité physique, particulièrement dans le domaine des solutions diluées ($X < 0{,}1$ ou $X > 0{,}9$).

Seule une méthode directe du type de celle que nous proposons permet d'évaluer avec précision ces grandeurs qui peuvent alors être traitées théoriquement dans le cadre d'un modèle de solution.

En revanche, l'opération inverse qui consiste à retrouver la courbe d'excès à partir de la description des variations des deux grandeurs molaires partielles d'excès pour chacun des deux cosolvants est parfaitement licite, à condition bien entendu, de respecter les relations thermodynamiques qui relient ces différentes grandeurs, ce qui sera examiné dans le paragraphe suivant.

## III. Représentations mathématiques. Relations entre les différentes grandeurs d'excès

Comme il a été vu précédemment l'écart à l'idéalité pour le volume d'un mélange de 2 solvants A et B de composition $X_B = x$ peut être caractérisé par le volume d'excès $V_E$:

$$V_E = x(\bar{V}_B - V_B^0) + (1-x)(\bar{V}_A - V_A^0)$$

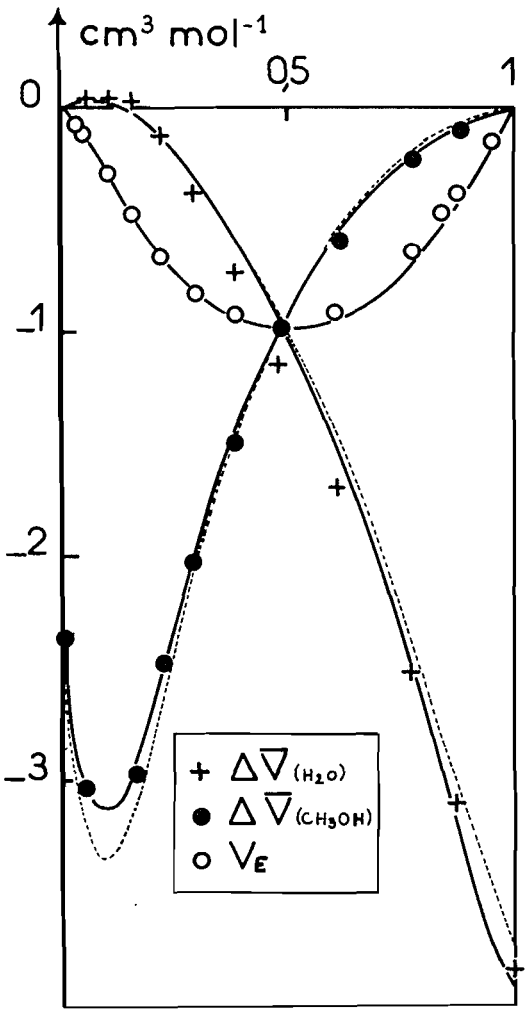

FIG. 2. Variation des grandeurs d'excès individuelles et totale en fonction de la composition du mélange (points expérimentaux). Les courbes, en traits pleins, sont tracées à partir de l'équation [10]. Les courbes de variations des $\Delta\bar{V}_{H_2O}$ et $\Delta\bar{V}_{CH_3OH}$ obtenues par Benson et Kiyo Hara (12) ont été indiquées en traits pointillés. Les principaux écarts, avec nos valeurs expérimentales, apparaissent aux extremums et à proximité des deux liquides purs.

Les valeurs $\bar{V}_B$ et $\bar{V}_A$ étant déterminées expérimentalement pour différents mélanges, il est alors possible de proposer pour leurs variations deux fonctions représentatives $f(x)$ et $h(x)$ dont les propriétés sont résumées ci-dessous.

(a) Pour le cosolvant A:

$$\bar{V}_A - V_A^0 = h(x)\cdot(\bar{V}_A^0 - V_A^0)$$

La fonction $h(x)$ doit s'annuler pour $x = 0$ car A est alors pur ($\bar{V}_A = V_A^0$) et doit être égale à l'unité pour $x = 1$ puisque A est alors infiniment dilué dans B ($\bar{V}_A = \bar{V}_A^0$).

(b) Pour le cosolvant B:

$$\bar{V}_B - \bar{V}_B^0 = f(x)\cdot(V_B^0 - \bar{V}_B^0)$$

La fonction $f(x)$ possède les mêmes bornes que $h(x)$: pour $x = 0, f(0) = 0$, B est infiniment dilué dans A ($\bar{V}_B = \bar{V}_B^0$); pour $x = 1, f(1) = 0$, B est pur ($\bar{V}_B = V_B^0$).

Les fonctions $f(x)$ et $h(x)$ ainsi définies ne sont pas indépendantes car elles doivent satisfaire aux conditions imposées par la loi de Gibbs–Duhem

$$x\,d\bar{V}_B + (1-x)d\bar{V}_A = 0$$

soit en faisant apparaître les fonctions $f(x)$ et $h(x)$

$$df(x) = -\frac{\bar{V}_A^0 - V_A^0}{V_B^0 - \bar{V}_B^0}\cdot\frac{1-x}{x}\,dh(x)$$

Cette équation différentielle, intégrée entre les bornes 0 et $x$ ($f(0) = 0$) conduit à:

$$f(x) = -\frac{\bar{V}_A^0 - V_A^0}{\bar{V}_B^0 - V_B^0}\left[h(x) - \int_0^x \frac{dh(x)}{x}\right]$$

Les variations relatives aux solvants A et B peuvent être représentées à partir d'une seule et même fonction $h(x)$:

$$[4]\quad \bar{V}_A - V_A^0 = (\bar{V}_A^0 - V_A^0)h(x)$$

$$[4']\quad \bar{V}_B - \bar{V}_B^0 = (\bar{V}_A^0 - V_A^0)\left[h(x) - \int_0^x \frac{dh(x)}{x}\right]$$

Les équations [4] et [4'] permettent de retrouver l'expression du volume d'excès:

$$[5]\quad V_E = (\bar{V}_A^0 - V_A^0)\left[h(x) - x\int_0^x \frac{dh(x)}{x}\right] + (\bar{V}_B^0 - V_B^0)x$$

Cette relation peut être écrite sous une forme plus simple en remarquant que les valeurs limites pour les grandeurs molaires partielles de A et B sont liées:

$$[6]\quad V_B^0 - \bar{V}_B^0 = (\bar{V}_A^0 - V_A^0)\left[1 - \int_0^1 \frac{dh(x)}{x}\right]$$

en posant[4]

$$A = \int_0^1 \frac{dh(x)}{x}$$

[4]La relation [6] montre que les grandeurs molaires partielles limites dans un mélange binaire ne sont pas indépendantes une fois la loi de variation définie.

Le volume d'excès prend la forme simple:

$$[7] \quad V_E = (\bar{V}_A^0 - V_A^0) \times \left[ h(x) - x \left( 1 - A + \int_0^x \frac{dh(x)}{x} \right) \right]$$

Le problème réside alors dans le choix de la meilleure fonction $h(x)$ pour décrire simultanément les variations de $\bar{V}_A$, $\bar{V}_B$ et $V_E$.

Pour les mélanges eau–méthanol en l'absence d'un type particulier de variation imposé par le choix d'un modèle de solution une représentation polynômiale de $h(x)$ reste la plus simple à envisager.

Un tel développement ne peut toutefois s'effectuer qu'à l'ordre minimum 2, car la constante $A$ [6] devant être finie, il ne peut exister de termes d'ordre 1 pour $x$ qui conduirait à une valeur infinie pour $A$.

$$[8] \quad h(x) = \sum_{j=2}^{n} a_j x^j$$

Les différentes valeurs des volumes d'excès sont représentées par les équations:

$$[9] \quad \begin{cases} \bar{V}_A - V_A^0 = (\bar{V}_A^0 - V_A^0) \left( \sum_{j=2}^{n} a_j x^j \right) & \text{(a)} \\ \bar{V}_B - \bar{V}_B^0 = (\bar{V}_A^0 - V_A^0) \left[ \sum_{j=2}^{n} a_j x^j - \sum_{j=2}^{n} a_j \frac{j}{j-1} x^{j-1} \right] & \text{(b)} \\ V_E = (\bar{V}_A^0 - V_A^0) \cdot x \left[ \sum_{j=2}^{n} \frac{a_j}{j-1} (1 - x^{j-1}) \right] & \text{(c)} \end{cases}$$

En procédant par ajustements successifs des coefficients des polynômes représentatifs des 3 grandeurs d'excès, il est possible d'obtenir pour $h(x)$ ($x = X_{CH_3OH}$) une forme permettant une description convenable de l'ensemble des courbes expérimentales pour les mélanges eau–méthanol:

$$[10] \quad \begin{cases} \bar{V}_A - V_A^0 = 9{,}77x^2 - 95{,}81x^3 + 238{,}74x^4 - 252{,}2x^5 + 95{,}56x^6 & \text{(a)} \\ \bar{V}_B - \bar{V}_B^0 = -19{,}54x + 153{,}49x^2 - 414{,}13x^3 + 554{,}00x^4 - 368{,}01x^5 + 95{,}56x^6 & \text{(b)} \\ V_E = -2{,}495x - 9{,}77x^2 + 47{,}905x^3 - 79{,}58x^4 + 63{,}05x^5 - 19{,}11x^6 & \text{(c)} \end{cases}$$

Dans le cas le plus général où l'on est conduit à décrire les variations d'une grandeur totale d'excès, caractéristique d'un mélange binaire, au moyen d'une équation de forme polynômiale, l'utilisation de la relation [9c] sous la forme

$$[11] \quad Y_E = (\bar{Y}_A^0 - Y_A^0) \left( x \sum_{j=1}^{n} b_j - \sum_{j=1}^{n} b_j x^{j+1} \right)$$

peut être considérée comme une alternative avantageuse à la description habituelle.

La relation [11], outre le fait qu'elle s'établit très facilement par une régression polynômiale classique d'ordre $n$, met un accent particulier sur la description du comportement d'un des constituants du système ($\bar{X}_A^0 - X_A^0$) lors d'un changement de composition du milieu. Elle permet, et c'est là son avantage principal, d'accéder aux variations des grandeurs d'excès individuelles par simple identification des coefficients des polynômes représentatifs (voir relations [9]).

## Conclusion

Le calcul des grandeurs molaires partielles caractéristiques des produits (solutés et solvants) qui entrent dans la composition de milieux réactionnels n'a généralement été entreprise que dans le cas simple des mélanges binaires à partir des valeurs de grandeurs d'excès.

La méthode expérimentale de détermination que nous proposons, outre le fait qu'elle conduit à des valeurs très précises pour ces paramètres, permet de traiter le cas des solvants mixtes complexes composés à la fois de solvants et de solides dissous, ce qui ne pouvait être envisagé par les techniques précédentes.

Le cas particulier du mélange binaire d'eau et de

méthanol traité à titre d'exemple montre que la forme des courbes représentatives des variations des grandeurs d'excès individuelles de l'eau et du méthanol, avec la composition du milieu ne pouvait être retrouvée aisément à partir de la courbe d'excès globale (4) et qu'une détermination expérimentale s'imposait.

En revanche, l'opération inverse qui consiste à représenter l'une des variations individuelles au moyen d'une équation polynômiale permet de décrire convenablement l'autre variation individuelle, et bien entendu de retrouver la courbe d'excès globale. La discussion des conditions thermodynamiques auxquelles doivent obéir les différents paramètres mesurés permet de proposer une équation polynômiale représentative des variations des grandeurs d'excès pour les mélanges binaires, dont l'intérêt principal est de pouvoir, lorsqu'elle est établie, accéder aux variations des grandeurs d'excès individuelles par simple identification des coefficients des polynômes représentatifs.

Reçu le 7 décembre 1981

GENEVIÈVE PFISTER-GUILLOUZO, SERGE GERIBALDI et JEAN-FRANÇOIS GAL. Can. J. Chem. **60**, 1163 (1982).

Nous avons enregistré les spectres photoélectroniques de 32 cyclohexène-2 ones-1 diversement substituées en 3 ainsi que de 10 acétophénones *para*-substituées. Une attribution de la plupart des bandes de cyclohexénones est proposée et les effets de substituant sur les potentiels d'ionisation des électrons π et de la paire libre de l'oxygène sont discutés. Les relations linéaires entre le potentiel d'ionisation de la paire libre de l'oxygène du carbonyle de ces cétones et les constantes de type $\sigma_p$ ainsi que celles entre les potentiels d'ionisation et les enthalpies de complexation $\Delta H^0$ des cétones avec le trifluorure de bore dans le chlorure de méthylène permettent de supposer que l'interaction conjugative directe entre les substituants et la fonction carbonyle est faible dans la cétone libre et qu'elle devient très importante dans l'état complexé ou protoné. L'existence de deux relations distinctes $\Delta H^0 = f(\mathrm{PI}\ n_O)$ pour les cyclohexénones directement substituées en 3 et les cétones aromatiques montre que ce type de relation ne peut être utilisé pour la comparaison des basicités au sens de Lewis de différents types de cétones; par contre, ces relations peuvent permettre d'apprécier la basicité relative des cétones d'un même type.

GENEVIÈVE PFISTER-GUILLOUZO, SERGE GERIBALDI, and JEAN-FRANÇOIS GAL. Can. J. Chem. **60**, 1163 (1982).

We have recorded the photoelectronic spectra of 32 differently 3-substituted 2-cyclohexen-1-ones as well as those of 10 *para*-substituted acetophenones. Assignment of most of the cyclohexenone bands is made and the substituent effects on the π-electron ionization potentials and of the oxygen lone pair are discussed. The linear relationship between the ionization potential of the carbonyl oxygen lone pair and $\sigma_p$-type constants as well as those between the ionization potentials and the enthalpies of complexation ($\Delta H^0$) of the ketones with $BF_3$ in methylene chloride allows us to propose that the direct conjugative interaction between the substituents and the carbonyl group is weak in the free ketone but becomes very strong in the complexed or protonated state. The existence of two distinct relationships ($\Delta H^0 = f(\mathrm{PI}\ n_O)$ for 3-substituted cyclohexenones and the aromatic ketones indicates that this type of expression cannot be used for the comparison of the Lewis basicities of different types of ketones; on the contrary, these expressions do allow for the comparison of the relative basicities of the same type.

[Journal translation]

## Introduction

Les cétones α,β-éthyléniques constituent une classe de composés dont la réactivité est influencée par la conformation du motif α-énonique et surtout par la nature des substituants fixés sur ce motif. En ce qui concerne les réactions entre ces α-énones et des entités électrophiles, les notions de contrôle de charge ou de contrôle frontalier sont généralement invoquées (1). La connaissance des énergies des dernières orbitales moléculaires occupées de l'entité nucléophile se révèle ainsi une information utile pour la prévision et la compréhension de la réactivité de ces composés. Ces énergies orbitales et les effets consécutifs à une substitution peuvent être estimées si l'on admet la validité du théorème de Koopmans (2) par le biais de la spectroscopie photoélectronique. Deux études détaillées de composés carbonylés non saturés cycliques (3, 4) et un travail exhaustif sur des aldéhydes et des cétones α,β-insaturées substitués par des groupements alkyles (5) ont paru dans ce domaine.

Nous nous proposons dans ce travail d'étudier par spectroscopie photoélectronique les effets de substitution en β dans des séries de cétones α,β-éthyléniques et plus particulièrement les intéractions substituants – foyers nucléophiles (C=C et C=O). Nous tenterons de relier les différents potentiels d'ionisation observés, d'une part aux constantes classiques de substituant et d'autre part à divers paramètres caractéristiques des structures α-énoniques, en particulier aux enthalpies de complexation $\Delta H^0$ de ces cétones avec le trifluorure de bore dans le chlorure de méthylène, paramètres caractérisant la basicité au sens de Lewis de ces composés (6).

Notre choix a porté sur des diméthyl-5,5 cyclohexène-2 ones-1 substituées en 3 par des groupements X ou $p$-$XC_6H_4$, dont le motif cyclique se retrouve dans de nombreux composés naturels ou

de synthèse d'intérêt biologique ou pharmaceutique. Ce modèle présente l'avantage d'être dans une conformation figée *s-trans*. On élimine ainsi les possibilités d'élargissement ou d'éclatement des bandes des spectres de photoélectrons dues à l'isomérie *s-cis* – *s-trans* (5). Enfin, les atomes d'oxygène et de carbones 1, 2, 3, 4 et 6 étant coplanaires (7), il n'y a pas d'interaction spatiale entre l'orbitale du doublet libre de l'oxygène du carbonyle et l'orbitale π du système conjugué. On peut donc supposer que les variations de structure électronique π n'influenceront qu'indirectement la paire libre du carbonyle, par exemple en modifiant la charge nucléaire effective de l'atome d'oxygène (8).

Les cyclohexénones étudiées ont été scindées en trois séries.

## Techniques expérimentales et calcul théorique

Toutes les cyclohexénones ont été préparées au laboratoire par l'adaptation de méthodes déjà décrites ou par la mise au point de nouvelles voies de synthèse (9, 10).

Les spectres ont été enregistrés sur un spectromètre photoélectronique Perkin–Elmer PS 18 en utilisant comme références les doublets $P_{1/2}$ et $P_{3/2}$ de l'argon et du xénon, ainsi que le pic à 15,60 eV de l'azote. Les raies HeI (584 Å) et HeII (304 Å) ont été utilisées comme source de radiation ionisante. Les potentiels d'ionisation ont été déterminés avec une précision de ± 0,03 eV.

Dans le cas du composé **10**, les énergies orbitales ont été calculées selon la méthode CNDO/S. La géométrie de la molécule a été déduite du spectre microonde de la cyclohexénone (7) et des valeurs standards (11).

Nous avons adopté un angle dièdre de 30° entre les plans du système α-énonique et du noyau benzénique.

## Résultats et discussion

### *Spectres photoélectroniques*

Pour les cyclohexénones directement substituées en 3 (série 1) seuls les trois premiers potentiels d'ionisation verticaux ont pu être mesurés avec précision. A l'exception des composés azotés ou soufrés dont l'hétéroatome du substituant possède une paire libre facilement ionisable, les deux premiers potentiels d'ionisation des cétones de la série 1 peuvent être attribués sans ambiguïté à l'ionisation des électrons de l'orbitale non liante $n_O$ de l'oxygène de la fonction carbonyle et de la combinaison antisymétrique $\pi_-$ entre l'orbitale $\pi_{C=C}$ et l'orbitale $\pi_{C=O}$, la combinaison symétrique $\pi_+$

For personal use only.

étant associées à une des bandes du massif non résolu au delà de 11 eV. L'attribution des deux premiers potentiels d'ionisation du composé **1** à 9,24 eV ($n_O$) et à 9,99 eV ($\pi_-$) est en accord avec celle proposée pour l'hexène-2 one-4 (5) et la cyclopentène-2 one-1 (8, 12).

Les valeurs des potentiels d'ionisation des composés de la série 1 sont rassemblées dans le tableau 1. Le spectre du composé **8** est reporté dans la figure 1.

Contrairement à l'hypothèse avancée par certains auteurs (13), l'introduction d'un groupement *gem* diméthyl en position 5 ne semble pas provoquer une altération significative de la planéité du motif α-énonique du composé **1** par rapport à son homologue non diméthylé. En effet, les trois premiers potentiels d'ionisation de la cyclohexène-2 one-1 sont très voisins (9,23, 10,10 et 11,73 eV) de ceux du composé **1**. Comme dans les séries à chaine ouverte (5), l'introduction d'un groupement alkyle supplémentaire sur les carbones éthyléniques provoque une destabilisation des orbitales $n_O$ et $\pi_-$ dans le composé **2** par rapport à **1** (−0,17 eV pour $n_O$ et −0,45 eV pour $\pi_-$). La légère stabilisation de l'orbitale non liante de l'oxygène et la destabilisation des niveaux $\pi_-$ des deux cétones halogénées **3** et **4** par rapport au composé **1** sont en accord avec la nature des effets inductifs attracteurs et mésomères donneurs des halogènes (14). La première bande relativement large des éthers d'énol **5** et **6** est associée à l'ionisation des électrons de l'orbitale non liante du carbonyle et de l'orbitale $\pi_-$ qui ont approximativement la même énergie (15). Cependant, si la destabilisation de l'orbitale $\pi_-$ (−1,04 eV pour **5** et −1,12 eV pour **6**) est en accord avec l'effet d'un groupement alkoxy introduit sur l'éthylène (−1,43 eV en passant de l'éthylène (14) au *n*-butyl vinyl éther (16), la destabilisation observée pour l'orbitale $n_O$ (−0,29 eV et −0,37 eV)

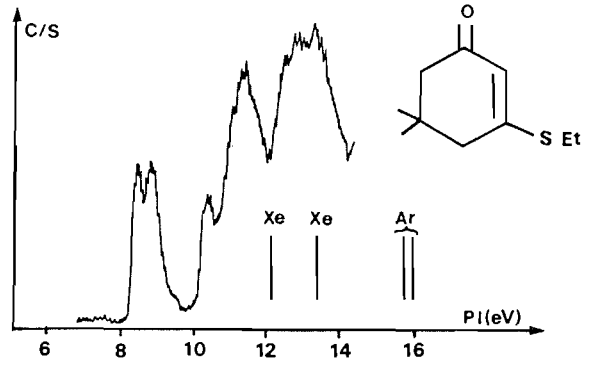

FIG. 1. Spectre photoélectronique (HeI) de l'éthylthio-3 cyclohexènone-2.

TABLEAU 1. Attributions des premiers potentiels d'ionisation des composés de la série 1

| Composés[a] No | X | $n_S$ ou $n_N$ (eV) | $n_O$ (eV) | $\pi_-$ (eV) | PI non attribué (eV) |
|---|---|---|---|---|---|
| **1** | H | | 9,24 | 9,99 | 11,30 |
| **2** | $CH_3$ | | 9,07 | 9,54 | 11,14 |
| **3** | Cl | | 9,35 | 9,73 | 11,30 |
| **4** | Br | | 9,35 | 9,71 | 10,73 |
| **5** | $OCH_3$ | | 8,95 | 8,95 | 11,81 |
| **6** | $OC_2H_5$ | | 8,87 | 8,87 | 11,66 |
| **7** | OH[b] | | 9,45[b] | 9,92[b] | 11,62[b] |
| **8** | $SC_2H_5$ | 8,46 | 8,82 | 10,40 | |
| **9** | CN | | 9,72 | 10,33 | 10,48 |
| **11** | $NH_2$ | 8,55 | 8,55 | 11,05 | |
| **12** | $N(CH_3)_2$ | 7,88 | 8,49 | 10,41 | |

[a]Le composé **10** (X = $C_6H_5$) sera étudié avec la série 3.
[b]Ces potentiels d'ionisation correspondent à ceux d'une forme dicétonique en accord avec Houk *et al.* (15).

par rapport à **1** semble en contradiction avec la stabilisation de nature inductive suggérée par Houk *et al.* (15). L'ensemble de ces résultats (ceux de Houk et les notres) reste cependant homogène si nous tenons compte des variations de l'effet inductif de R des substituants OR pouvant être décrit par les constantes σ* de Taft (17) (tableau 2).

Pour le composé **8**, les différences d'intensité observées lors du passage du rayonnement HeI à HeII (18) permettent d'attribuer le premier potentiel d'ionisation (8,46 eV) à l'ionisation de la paire libre non liante localisée sur l'atome de soufre alors que le second potentiel d'ionisation correspond à l'ionisation de la paire libre $n_O$. La stabilisation de l'orbitale $\pi_-$ (troisième potentiel d'ionisation) s'interprête par l'interaction entre l'orbitale de la paire libre de symétrie π du soufre et l'orbitale $\pi_-$ du motif α-énonique. L'importante interaction conjugative entre le système π et l'hétéroatome entraine une forte destabilisation de l'orbitale $n_O$.

Les effets inductifs (−I) et conjugatif (−R) du groupement CN sont à l'origine des stabilisations des potentiels d'ionisation associés aux orbitales $n_O$ et $\pi_-$ (respectivement 9,72 et 10,33 eV) du composé **9** par rapport à la cyclohexénone non substituée **1**.

$^a\Delta E$ (eV) = $(n_N + \pi_-) - (n_N - \pi_-)$

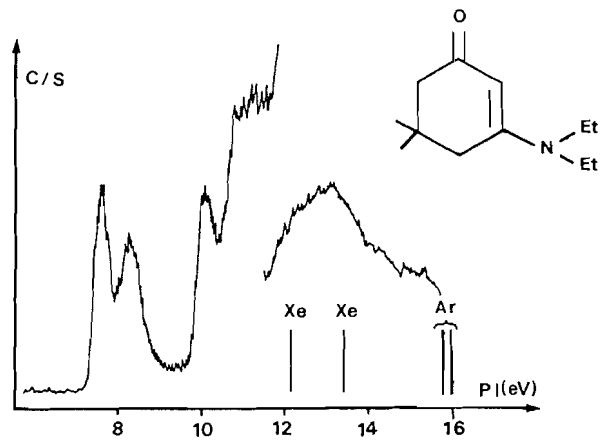

FIG. 2. Spectre photoélectronique (HeI) du diéthylamino-3 cyclohexénone-2.

Pour les énaminocétones **11** et **12**, le premier potentiel d'ionisation est attribuable à l'ionisation d'une orbitale essentiellement localisée sur l'atome d'azote. Si l'on compare le potentiel d'ionisation de la paire libre de l'azote dans le composé **11** et celui de la cyclohexylamine (9,15 eV, réf. 19) ou du composé **12** et celui de la quinuclidine (8,02 eV, réfs. 19, 20) la destabilisation observée (respectivement −0,60 et −0,14 eV) ne peut pas être expliquée par l'effet inductif (−I) du motif α-énonique qui provoquerait une variation inverse. Comme dans le cas des énamines (20), il faut envisager une forte interaction entre la paire libre de l'azote et l'orbitale $\pi_-$ du motif α-énone. Le premier potentiel d'ionisation correspond donc à l'ionisation d'un électron d'une orbitale du type $n_N - \pi_-$. En conséquence, l'orbitale $\pi_-$ du composé **1** se trouve stabilisée dans les énaminones **11** et **12** (respectivement 11,05 eV et 10,40 eV). Cette interaction conjugative entre l'azote et le système π induit comme dans le cas du composé soufré, un effet secondaire de destabilisation de l'orbitale $n_O$ des cétones **11** et **12**.

Les potentiels d'ionisation des énaminones de la série 2 sont attribués par analogie aux composés **11** et **12** (tableau 3). Le spectre du composé **13** est reporté dans la figure 2.

Compte tenu de la précision des mesures, la séparation moyenne ente les orbitales $n_N + \pi_-$ et $n_N - \pi_-$ due à l'interaction entre les orbitales de base $n_N$ et $\pi_-$ est identique pour l'ensemble des composés ($\overline{\Delta E}$ = 2,53 eV). Cette valeur est comparable à celles obtenues pour les *N*,*N*-diméthylamino-1 cyclopentène et cyclohexène (20), pour la *N*,*N*-diméthylaniline (21) et pour le méthyl-2 aza-2 bicyclo[3.2.1] octène-3 (22). On peut donc supposer que l'angle dièdre entre le plan contenant l'axe de la paire libre de l'azote et la liaison $C_3$—N et le plan contenant cette liaison et l'axe de l'orbitale 2*p* de $C_3$ est voisin de zéro pour l'ensemble des composés étudiés ou tout au moins qu'il varie très peu en fonction des substituants alkyles de l'azote. Pour les phényl-3 cyclohexène-2 ones-1 (série 3) (fig. 3) nous n'avons reporté dans le tableau 4 que les quatre premiers potentiels d'ionisation dont les bandes se situent entre 7, 8 et 11 eV. L'attribution est basée sur les observations faites pour la série 1 et sur les données concernant les benzènes substitués (23–28) et en particulier les styrènes (29–31).

Ces attributions sont en accord avec les énergies orbitales calculées en CNDO/S pour la cyclénone **23**: 10,17 eV ($Ph_S - \pi_-$); 10,58 eV ($n_O$); 10,99 eV ($Ph_A$) et 11,77 eV ($\pi_- + Ph_S$).

Dans diverses séries de benzènes disubstitués, McAlduff et coll. (26–28) montrent qu'il existe des relations linéaires entre les potentiels d'ionisation des orbitales associées au noyau phényle et les potentiels d'ionisation de l'orbitale $Ph_S$ des benzènes monosubstitués (26). Ceci est vérifié pour nos composés:

$$\text{PI}\ (Ph_S - \pi_-\ \text{série 3}) = (0{,}769 \pm 0{,}047)\ \text{PI}\left(Ph_S\ X\text{—}\langle\bigcirc\rangle\right) + 1{,}73$$
$$r = 0{,}987 \qquad S = 0{,}08\ \text{eV}$$

L'existence de cette relation, tout en confirmant nos attributions, met en évidence que pour ce système aromatique disubstitué, la sensibilité aux effets de substituant est moins importante que dans le système

For personal use only.

benzénique par suite de la délocalisation des électrons π du noyau benzénique sur le système α-énonique. L'orbitale $\pi_- + Ph_S$ beaucoup plus localisée sur ce système est encore moins sensible aux effets de substituant que l'orbitale $Ph_S - \pi_-$ comme l'indique la valeur de la pente de la relation suivante:

$$PI\ (\pi_- + Ph_S) = (0{,}687 \pm 0{,}049)\ PI\ (Ph_S - \pi_-) + 4{,}10$$
$$r = 0{,}983 \qquad S = 0{,}06\ eV$$

*Corrélations avec les constantes de substituant*

Ayant une estimation directe de l'effet électonique d'une substitution du squelette α-énonique sur l'énergie de la paire libre de l'oxygène du carbonyle, nous avons cherché à vérifier si cet effet pouvait être corrélé avec les valeurs des constantes de type Hammett. De telles corrélations ont déjà été tentées dans diverses séries de composés carbonylés aromatiques (25, 26, 28). Si nous faisons exception de la cétone **8**, une bonne corrélation est obtenue entre les potentiels d'ionisation attribués à l'orbitale $n_O$ dans la série 1 et les constantes $\sigma_p$ de McDaniel et Brown (32):

$$\text{Série 1}\ PI\ (n_O) = (0{,}852 \pm 0{,}031)\ \sigma_p + 9{,}17$$
$$r = 0{,}995 \qquad S = 0{,}041\ eV$$

L'anomalie observée pour le composé **8** est en partie explicable par le fait que les substituants de type −SR possèdent une "constante" $\sigma_{R^+}$ variable suivant la réaction étudiée (33) et que la constante $\sigma_p$ contient une part non négligeable d'effet de résonance direct entre la fonction et le substituant (34).

Bien que la précision des mesures et le domaine de variations soient faibles dans la série 3, nous obtenons une corrélation correcte:

$$\text{série 3: } PI\ (n_O) = (0{,}362 \pm 0{,}046)\ \sigma_p + 8{,}93$$
$$r = 0{,}949 \qquad S = 0{,}058\ eV$$

Les deux relations précédentes sont représentées dans la figure 4.

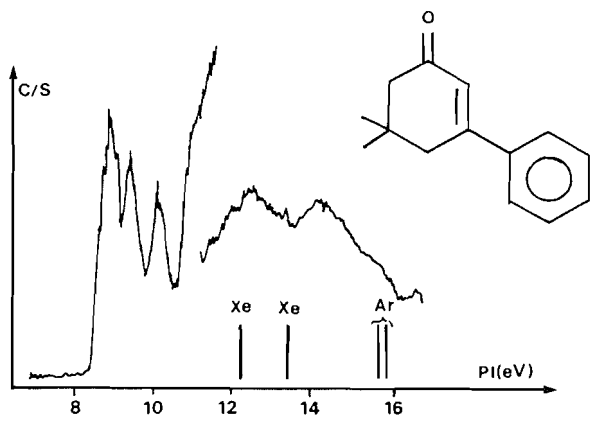

FIG. 3. Spectre photoélectronique de la phényl-3 cyclohexénone-2.

L'introduction d'un groupement phényle entre le substituant et l'enchainement α-énone entraine comme l'on pouvait s'y attendre une atténuation de l'effet de substituant sur l'énergie de la paire libre de l'oxygène. Le rapport des pentes des deux relations précédentes conduit à un facteur d'amortissement du noyau phényle égal à 0,42.

De la même façon, la comparaison des pentes des relations de Hammett pour la série 3 et les acétophénones conduit au coefficient d'amortissement apporté par un relais vinylique introduit entre une fonction carbonyle et le noyau phényle. Bien qu'une relation ait été obtenue par McAlduff (28) pour les acétophénones *para*-substituées, nous avons préféré utiliser une série de valeurs homogènes acquises dans les mêmes conditions expérimentales (tableau 5).

Pour tous les substituants, la relation suivante est obtenue:

$$PI\ (n_O) = (0{,}590 \pm 0{,}060)\ \sigma_p + 9{,}42$$
$$r = 0{,}962 \qquad S = 0{,}079\ eV$$

Le coefficient de transmission du relais vinylique est donc égal à 0,362/0,590 = 0,61. Cette valeur est en accord avec celle mesurée à partir des enthalpies de complexation avec le trifluorure de bore pour les cyclénones de la série 3 et les acétophénones 0,62 (35).

La principale caractéristique des trois relations de Hammett précédentes est qu'elles font intervenir les constantes de type σ. La fonction carbonyle

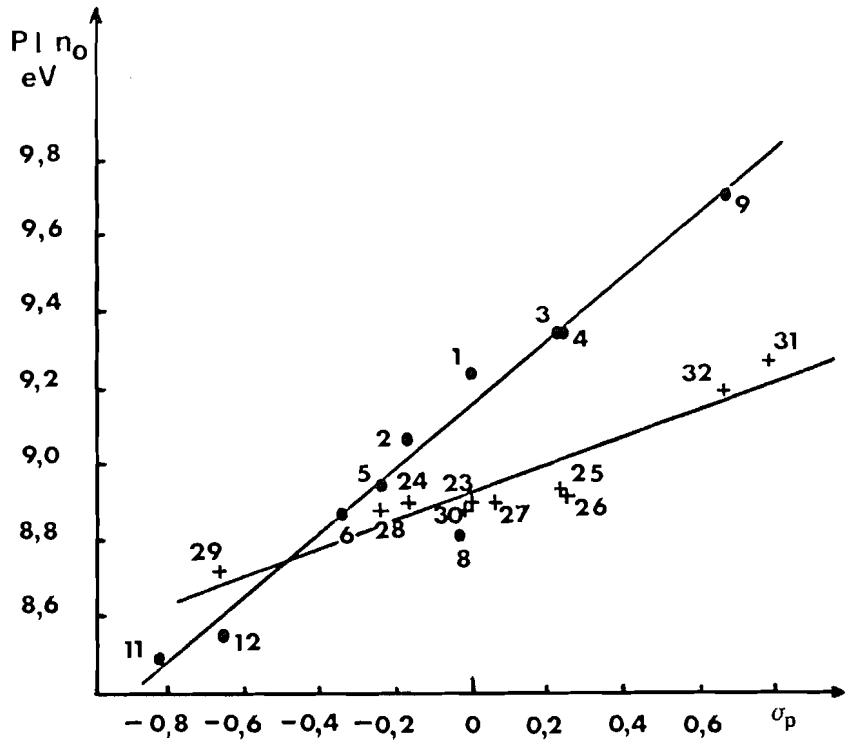

FIG. 4. Relations PI ($n_0$) = $f(\sigma_p)$ pour les séries 1 (●) et 3 (+).

étudiée étant de type −R l'on pouvait espérer un fort effet de conjugaison directe entre la fonction et les substituants de type +R (34) comme nous l'observons lors des relations établies pour les réactions de complexation avec $BF_3$ ou les réactions de protonation (6, 9, 35). Toutefois en phase gazeuse et donc en l'absence de solvatation l'effet de résonance direct dans l'ion radical ne semble pas aussi important que pour l'entité $BH^+$ ou B: $BF_3$ en solution. En ce qui concerne la série 3 et les acétophénones, cette hypothèse est vérifiée par l'existence de relations correctes entre les potentiels d'ionisation et les constantes dites "normales" $\sigma^0$ de Yukawa (36):

$$\text{série 3: PI } (n_0) = (0{,}434 \pm 0{,}053)\,\sigma^0 + 8{,}88 \qquad r = 0{,}944 \quad S = 0{,}057 \text{ eV}$$

$$\text{Acétophénones: PI } (n_0) = (0{,}694 \pm 0{,}078)\,\sigma^0 + 9{,}36 \qquad r = 0{,}953 \quad S = 0{,}087 \text{ eV}$$

Pour les énaminocétones de la série 2, dans l'hypothèse où l'angle dièdre θ varie très peu autour d'une valeur moyenne proche de zéro, le niveau $n_0$ ne devrait donc être influencé en premier lieu que par les effets polaires des substituants H ou alkyles de l'azote quantifiés par les constantes σ* de Taft (17) et Hall (37). En fait, il existe deux droites parallèles représentant les relations PI ($n_0$) = $f$ ($\Sigma\sigma^*$) pour les énaminocétones mono et disubstituées, ce qui permet d'établir la relation unique (figure 5):

$$\text{PI } (n_0) = (1{,}00 \pm 0{,}15)\,\Sigma\sigma^* + 0{,}48n + 7{,}53 \qquad r = 0{,}93 \quad S = 0{,}05 \text{ eV}$$

où $n$ représente le nombre de substituants alkyles de l'azote ($n$ = 0, 1 ou 2) et $\Sigma\sigma^*$ la somme des σ* des substituants H ou alkyles de l'azote. La valeur de 0,48 eV correspond donc à la destabilisation apportée par l'effet d'une alkylation sur le site $NH_2$.

Compte tenu de la précision des mesures (± 0,03 eV) l'écart type de la relation est correct, cependant l'intervention d'un effet stérique de la part des substituants alkyles, modifiant également l'interaction $p$–π n'est pas à exclure dans l'interprétation des déviations.

*Corrélations avec la basicité au sens de Lewis*

Dans la mesure où la labilité de la paire libre d'un

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

TABLEAU 5. Potentiels d'ionisation de la paire libre de l'oxygène du carbonyle d'une série d'acétophénones *para* substituées (eV)

| Composés | | | Composés | | |
|---|---|---|---|---|---|
| No | X | $n_0$ (eV) | No | X | $n_0$ (eV) |
| **33** | H | 9,51 | **38** | CN | 9,82 |
| **34** | Cl | 9,52 | **39** | $CH_3$ | 9,38 |
| **35** | Br | 9,55 | **40** | $NO_2$ | 9,98 |
| **36** | $OCH_3$ | 9,20 | **41** | $C_6H_5$ | 9,33 |
| **37** | $NH_2$ | 9,08 | **42** | $COCH_3$ | 9,61 |

hétéroatome (O, N, P...) est le facteur prédominant de l'affinité protonique et où le potentiel d'ionisation peut être considéré comme une mesure de l'aptitude de cette paire à céder ses électrons, de nombreux auteurs se sont attachés à relier ce potentiel d'ionisation à la basicité en phase gazeuse des séries de composés hétéroatomiques (19, 38–43). Ne possédant pas les affinités protoniques des cyclohexénones, nous avons donc tenté de relier les potentiels d'ionisation de la paire libre de l'oxygène du carbonyle des cyclohexénones et des acétophénones à un paramètre s'approchant le plus de la basicité en phase gazeuse à savoir l'enthalpie de complexation des cétones en solution dans le chlorure de méthylène par le trifluorure de bore gazeux. Nous avons démontré que ce paramètre $\Delta H^0$ pouvait être considéré comme une mesure de la basicité au sens de Lewis de ces composés en milieu organique peu solvatant (6, 9, 35). Les valeurs de $\Delta H^0$ pour les cyclohexénones des séries 1 et 3 et pour les acétophénones sont reportées dans le tableau 6.

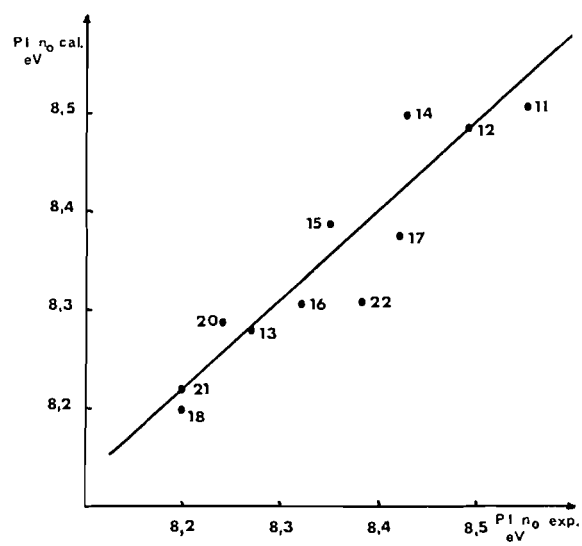

FIG. 5. Energies $n_0$ (calc.) vs. énergies $n_0$ (exp.) pour les énaminocétones (série 2).

Toutes les cétones possédant un groupement $-NH_2$ ou —NHR n'ont pu être étudiées par microcalorimétrie, car les associations intermoléculaires dues à la présence d'une liaison N—H conduisent à des valeurs erronées de $\Delta H^0$.

Nous obtenons une relation $\Delta H^0 = f(\text{PI } n_0)$ unique pour les cyclohexénones de la série 3 et les acétophénones *para*-substituées

$$\Delta H^0 = (20{,}8 \pm 1{,}1)\ \text{PI}\ n_0 - 272{,}30$$
$$r = 0{,}980 \qquad S = 1{,}53\ \text{kJ mol}^{-1}$$

Il semblerait donc que le potentiel d'ionisation de la paire libre de l'oxygène soit une mesure correcte de la basicité au sens de Lewis en milieu organique peu solvatant pour la classe des cétones aromatiques. Par contre, les cyclohexénones de la série 1 ne peuvent être inclues dans cette relation. En excluant les dérivés **5** ($OCH_3$), **6** ($OC_2H_5$) et **12** ($N(CH_3)_2$), nous obtenons une relation de pente et d'ordonnée à l'origine différentes de la précédente:

$$\Delta H^0 = (37{,}1 \pm 2{,}1)\ \text{PI}\ (n_0) - 424{,}81$$
$$r = 0{,}994 \qquad S = 1{,}41\ \text{kJ mol}^{-1}$$

Ainsi, le potentiel d'ionisation PI $n_0$ ne peut être utilisable pour la comparaison des basicités de différents types de cétones; par contre, ces potentiels d'ionisation peuvent permettre de comparer la basicité relative de cétones d'un même type. Les deux relations précédentes sont représentées dans la figure 6.

L'obtention d'une relation linéaire correcte pour la série 1 a nécessité l'exclusion de trois dérivés correspondant à des substituants possédant un important effet mésomère donneur ($N(CH_3)_2$, $OCH_3$, $OC_2H_5$). Les déviations de ces points sont en accord avec le fait que les potentiels d'ionisation ($n_0$) sont fonction des constantes $\sigma_p$ alors que les $\Delta H^0$ sont reliés aux $\sigma_p^+$ (9, 35). L'hypothèse émise précédemment est donc vérifiée, à savoir que l'interaction conjugative directe entre le substituant et la fonction carbonyle est assez faible dans les cyclohexénones et les acétophénones libres et devient très importante dans l'état complexé par $BF_3$. Cette exaltation des effets entre substituant et site basique lors du passage état initial – état final complexé ou protoné a été récemment mise en évidence par Taft et coll. (44) au cours d'une étude sur l'affinité protonique des pyridines substituées. Ces auteurs démontrent que l'énergie d'interaction substituant – pyridine substituée est environ huit fois plus faible que l'interaction substituant – ion pyridinium.

*Corrélations avec les résultats de résonance magnétique nucléaire*

Des corrélations entre les potentiels d'ionisation

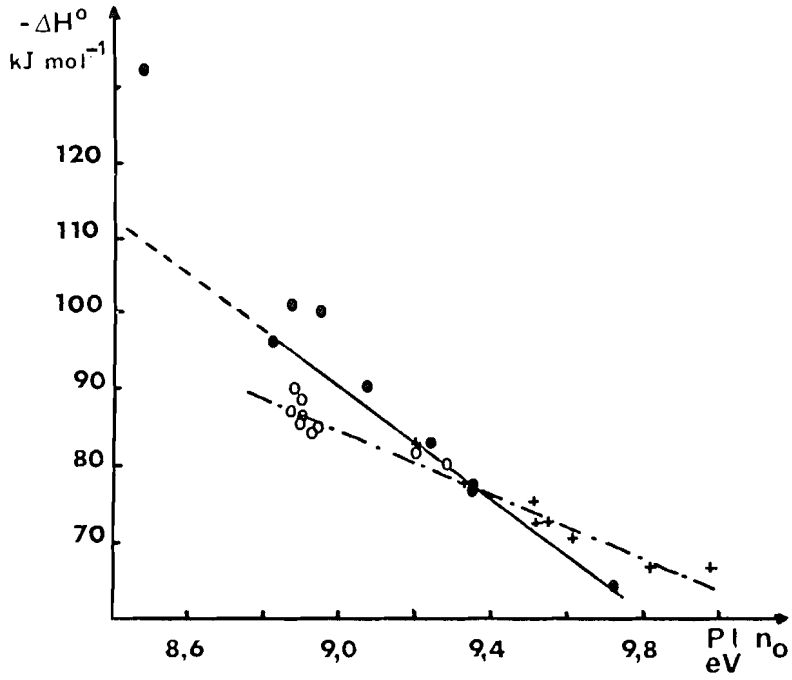

FIG. 6. Relations $\Delta H^0 = f(\text{PI } n_0)$ pour les cyclohexénones de la série 1 (●), et de la série 3 (○) et pour les acétophénones (+).

et des déplacements chimiques de rmn ont déjà été tentées avec succès dans diverses séries de composés carbonylés aromatiques aussi bien en rmn du $^{13}C$ et du $^{15}N$ (26) qu'en rmn protonique (28). Pour les cyclohexénones, nous avons récemment démontré que le déplacement chimique du carbone éthylénique $C_2$ en α de la fonction carbonyle est essentiellement influencé par la densité électronique π de ce carbone, une augmentation de densité entrainant un blindage et inversement (45, 46). Les orbitales $\pi_-$ pour la série 1 et $\pi_+$ PhS pour la série 3 sont celles dans lesquelles il y a la plus forte localisation sur le carbone $C_2$. Si nous faisons exception des composés dans lesquels il existe une très forte interaction entre l'orbitale $\pi_-$ et le doublet libre de l'hétéroatome du substituant (composés **8**, **11** et **12**) il existe effectivement une relation linéaire entre $\delta^{13}C_2$ de la série 1 (tableau 7)

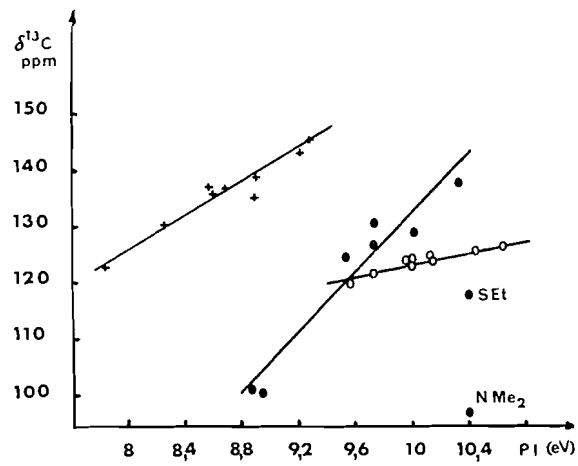

FIG. 7. $\delta^{13}C = f(\text{PI})$ pour le $C_2$ de la série 1 (●) pour le $C_2$ (○) et le $C_7$ (+) de la série 3.

[a]Référence 9. Déplacements chimiques mesurés dans $CDCl_3$ par rapport au TMS.
[b]Référence 47. Déplacements chimiques mesurés dans le dioxanne par rapport à $H_2O$.

et les potentiels d'ionisation relatifs à l'orbitale $\pi_-$:

$$\delta^{13}C_2 \text{ (série 1)} = (26{,}6 \pm 3{,}7)\ PI\ (\pi_-) - 132{,}55$$
$$r = 0{,}995 \qquad S = 4{,}75 \text{ ppm}$$

Cette relation devient nettement meilleure pour la série 3:

$$\delta^{13}C_2 \text{ (série 3)} = (5{,}40 \pm 0{,}59)\ PI\ (\pi_- + Ph_S) + 69{,}75$$
$$r = 0{,}961 \qquad S = 0{,}54 \text{ ppm}$$

Le même raisonnement peut être tenu pour le potentiel d'ionisation de l'orbitale $Ph_S - \pi_-$ et le carbone $C_7$ en *para* du substituant variable dans la série 3 dont le déplacement chimique est essentiellement fonction de la densité électronique (48):

$$\delta^{13}C_7 \text{ (série 3)} = (11{,}54 \pm 0{,}82)\ PI\ (Ph_S - \pi_-) + 37{,}20$$
$$r = 0{,}985 \qquad S = 1{,}07 \text{ ppm}$$

L'anomalie observée pour le dérivé fluoré a été également rencontrée dans la série des benzamides *para*-substituées (26). Les trois relations précédentes sont schématisées dans la figure 7.

Récemment Fiat et Coll. (47) ont recherché des relations permettant de prévoir et d'interpréter les déplacements chimiques de l'oxygène 17 de la fonction carbonyle des acétophénones. Ils ont pour cela tenté de relier les déplacements chimiques aux constantes de substituants ainsi qu'à divers paramètres

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

spectroscopiques et en particulier à la longueur d'onde d'absorption de la transition $n \rightarrow \pi^*$. Ils en concluent que la plus importante contribution à la constante d'écran de l'oxygène est apporté par le terme paramagnétique et à l'intérieur de celui-ci par l'énergie $\Delta E^{-1}{}_{n\rightarrow\pi^*}$. Cependant, d'autres auteurs considèrent que le terme $\langle r^{-3}\rangle$ où $r$ représente le rayon de l'orbitale $2p$ de l'oxygène joue également un rôle dans l'évaluation du terme paramagnétique (49). Nous avons donc recherché une relation entre les déplacements chimiques $\delta^{17}O$ des acétophénones mesurés par Fiat et coll. (47) (tableau 7) et un paramètre lié indirectement à $\langle r^{-3}\rangle$ et à l'énergie de la transition $n \rightarrow \pi^*$ à savoir le potentiel d'ionisation de l'orbitale $2p$ de l'oxygène. Si nous excluons le composé portant le groupement $NH_2$, une excellente corrélation est obtenue (fig. 8):

$$\delta^{17}O \text{ (ppm) acétophénones} = (40{,}5 \pm 1{,}6)\ PI\ (n_O) + 163{,}4$$
$$r = 0{,}996 \qquad S = 1{,}0 \text{ ppm}$$

L'écart observé pour le composé **37** est explicable par l'existence de liaisons hydrogènes dues au groupement $NH_2$ qui ont pour effet de blinder anormalement l'oxygène du carbonyle (47).

Nous avons tenté sans succès d'enregistrer les spectres de rmn de l'oxygène 17 des cyclohexé nones sans enrichissement isotopique, ce qui nous aurait permis de confirmer la validité de la relation $\delta^{17}O = f(PI\ n_O)$ dans la prédiction du déplacement ainsi que dans son interprétation théorique.

Received May 14, 1981

HELMUT BEIERBECK, JOHN W. EASTON, JOHN K. SAUNDERS, and RUSSELL A. BELL. Can. J. Chem. **60**, 1173 (1982).

The $^{13}C$ nmr relaxation time data for a number of compounds related to podocarpic acid are presented. The $T_1$ values of these molecules were satisfactorily reproduced by application of Woessner's equations for an asymmetric top assuming that the preferred principal axis of the rotational diffusion tensor was either the preferred principal inertial axis or an axis containing the centre of mass and the heterosubstituent at C-4. The values for hindrance to rotation for the various methyl groups are given and their variations discussed.

HELMUT BEIERBECK, JOHN W. EASTON, JOHN K. SAUNDERS et RUSSELL A. BELL. Can. J. Chem. **60**, 1173 (1982).

On rapporte les temps de relaxation en rmn $^{13}C$ d'un certain nombre de composés apparentés à l'acide podocarpique. On peut reproduire assez fidèlement les valeurs $T_1$ de ces molécules en faisant appel aux équations de Woessner pour un sommet asymétrique en faisant l'hypothèse que l'axe principal préféré par le tenseur de diffusion rotationnelle est soit l'axe principal préféré d'inertie ou un axe comprenant le centre de masse et l'hétérosubstituant en C-4. On rapporte des données relatives à l'empêchement à la rotation de divers groupes méthyles et on les discute.

[Traduit par le journal]

For an asymmetric top molecule the rotational diffusion constants can be obtained from eq. [1]

$$[1]\quad \frac{1}{T_1} = \frac{\hbar^2\gamma_H^2\gamma_C^2}{(r_{C-H})^6}\left[\frac{C_1}{4R_1+R_2+R_3} + \frac{C_2}{4R_2+R_1+R_3} + \frac{C_3}{4R_3+R_1+R_2} + \frac{C_4}{6[R+(R^2-L^2)^{\frac{1}{2}}]} + \frac{C_5}{6[R-(R^2-L^2)^{\frac{1}{2}}]}\right]$$

where $R_1$, $R_2$, and $R_3$ are the respective rotational diffusion rates about the principal axes of the diffusion tensor, $R = 1/3\,(R_1 + R_2 + R_3)$, $L^2 = 1/3\,(R_1R_2 + R_1R_3 + R_2R_3)$ and the $C$'s are geometrical functions defined in ref. 1. The calculation of diffusion constants about the principal axes requires *a priori* that these axes have been defined. The usual method using Woessner's equations is to use the principal axes of inertia of the molecule. This appears to be quite satisfactory, when molecules containing only carbon and hydrogen are studied (2), or when a diffusional axis is coincident with an inertia axis (3, 4). As pointed out by Stilbs and Moseley (5), the assumption that the principal axes of the diffusion and the inertia tensors are coincident may not be valid if heterosubstituents are present when the carbon–heterosubstituent bond is not coincident with a symmetry axis of the molecule. They found that the use of Woessner's equation did not give satisfactory values for relatively concentrated solutions of borneol in $CDCl_3$. Recently we have reported (6) the results for a number of norbornane and adamantane derivatives including borneol where satisfactory agreement was obtained between experimental values and those calculated using Woessner's equation for a symmetric top (1). The best correlation was obtained by assuming that the principal axis of the diffusion tensor passes through the heterosubstituent and the centre of mass of the molecule. In other words, the oxygen is "fixed" by intermolecular interactions whereas the movement of the hydrocarbon portion is controlled by inertial effects which correspond with volume effects. This does not necessarily infer that the centre of mass of the molecule is the origin of the diffusion tensor since the geometrical terms of eq. [1] refer only to direction cosines relative to the various axes. Thus, it is necessary only to define the principal axis of rotation and the direction of two mutually perpendicular axes. This can be seen by comparing monosubstituted benzene and adamantane derivatives. In the former, the principal axis of the diffusion tensor is coincident with the *para* C—H bond and this carbon is found (3) to have a shorter

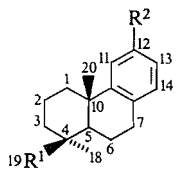
[a]In seconds estimated error ± 10%.

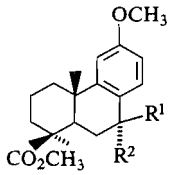
$T_1$ than the other carbons since rotation about the principal axis does not modulate this C—H bond vector. In 1-substituted adamantanes, the C—H *endo* bond of the δ carbon is parallel but not coincident with the $C_3$ symmetry axis which is the principal axis of the rotation tensor. This carbon has a shorter $NT_1$ than the other protonated carbons for the same reason (4).

The experimental $^{13}C$ $T_1$ values for the diterpenoid compounds **1** to **8**, which are related to podacarpic acid, are given in Table 1. These compounds were studied as approximately 1 *M* solution in $CDCl_3$. These values imply significant anisotropic motion for these molecules, since $NT_1$ for C-3 and C-13 are less than for other protonated carbons. The $T_1$ values were converted into diffusion constants using eq. [1] and these are recorded in Table 2.

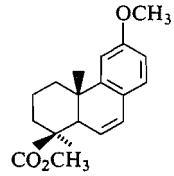
The calculations were performed using two assumptions about the orientation of the principal axes; in the first, (A), the principal axes of the diffusion constant tensor are assumed to be coincident with those of the moments of inertia and in the second, (B), the principal axis of rotation passes through the centre of mass of the molecule and the axial substituent at C-4. For **1**, the rotational constants were also calculated by assuming that the principal axis passes through the centre of mass and the oxygen at C-12. The discrepancy between calculated and experimental was much larger using this last assumption and it was taken to be invalid. This was verified with several other compounds and found to hold true in each case.



**1** $R^1 = CH_2OH$, $R^2 = OCH_3$
**2** $R^1 = CO_2CH_3$, $R^2 = OCH_3$
**3** $R^1 = CHO$, $R^2 = OCH_3$
**4** $R^1 = CH_3$, $R^2 = OCH_3$
**5** $R^1 = CO_2CH_3$, $R^2 = O_2CCH_3$



**6** $R^1 + R^2 = O$
**7** $R^1 = OH$, $R^2 = H$



**8**

The calculations using either assumption A or B reproduce satisfactorily the observed variations in the $NT_1$ values for C-3 and C-13 relative to other protonated carbons. There are more subtle variations at carbons 1, 2, 6, and 7 in the calculated values. In most cases the experimental values for these carbons are within experimental error of those calculated by either choice of axes. In fact, with only one or two exceptions, the difference between calculated and experimental value is less than 10% for each carbon in each molecule. The results are not precise enough to distinguish between the two assumptions. Inspection of the illustration of **2** relative to the inertia axes shown in Fig. 1 shows that the principal axis passes in relatively close proximity to the substituent at C-4 and it is therefore not unexpected that the differences between the two assumptions are minimal. Further discussion on the subtle differences is imprudent for at least two reasons. Firstly, the observed values are not sufficiently accurate and secondly, the representation in space of the molecules was obtained from molecular models assuming normal bond angles and bond lengths. X-ray data for these compounds were not available but data (7) from similar compounds show that molecular distortions are present. For example the ring junction at C-5 is flatter than in models with tetrahedral angles of 109.47°. In each compound the observed $T_1$ for C-5 is less than that calculated, which could be indicative of a shorter C—H bond. Any molecular deformation will obviously result in variations in the C—H bond vectors and hence in the $T_1$ values.

The diffusion constant for internal rotation of a

methyl group undergoing 120° jumps can be determined from eq. [2] (8), where ρ is $R_{int}/R$ and $A$, $B$, and $C$ are geometrical constants. Equation [2] is valid for isotropic motion.

$$[2] \quad \frac{T_1(CH)}{3T_1(CH_3)} = \left[\frac{A}{6} + \frac{B+C}{6+\rho}\right]$$

For molecules undergoing anisotropic motion equations similar to [2] have been derived (9). A parameter ($V_R$) characterizing the hindrance to rotation (10) can be estimated from the relationship (11) $R_{int} = R_o \exp(-V_R/RT)$ where $R_o = 3/2\ kT/I$ and $I$ is the moment of inertia of the methyl group. In earlier work, we had observed that the value of $V_R$ depends on the number of 1,3 diaxial hydrogen interactions to which the $CH_3$ group is subjected. Furthermore, replacement of one of these axial hydrogens by an OH group had little effect on the value of $V_R$. The $V_R$ values for the methyl groups C-18 and C-20 in compounds **1–8** were calculated and are given in Table 3.

The $V_R$ value for C-18 of compound **4**, with a methyl group at C-4 is 15.6 kJ/mol, which can be compared to the value of 14.4 kJ/mol found in 4,4-dimethyl adamantan-2-one (6). Both compounds have only one 1,3 diaxial $CH_3$ group – hydrogen interaction. The replacement of the axial methyl by a carbomethoxy group does not alter $V_R$ since each of the compounds which contain this group at C-4, with the exception of **8**, has a value of 15.7 ± 0.4 kJ/mol. Inspection of molecular models

suggests that the 1,3-interaction between H-6 and C-18 in **8** is more severe than in the other compounds. The two entries with either a $CH_2OH$ or a CHO group at C-4 have a slightly lower barrier.

The $V_R$ value for the methyl group, C-20, shows a more marked dependence on substituent than C-18. As for C-18, the C-20 values for compounds with a $CO_2CH_3$ at C-4 do not vary significantly with the exception of **8**. Compound **8** contains a double bond at C-6,C-7 and thus has one 1,3 diaxial methyl–hydrogen interaction less than the other compounds and thus the hindrance to relation is greater. Replacing a $CO_2CH_3$ by a CHO group only marginally decreases the hindrance to rotation. When a $CH_3$ group is present at C-4, $V_R$ is reduced significantly and this decrease is even more pronounced when a $CH_2OH$ group is present. The accepted explanation of rapidly rotating *syn* diaxial methyl groups is that they turn in a gear wheel type of fashion. This explanation cannot, however, be invoked in the present examples since the rotation rates of C-19 and C-20 are quite different in both compounds **1** and **4**. The $NT_1$ value of C-19 in **1** is within experimental error of that calculated for a rigid carbon and therefore the rate of rotation about the C-4,C-19 bond must be relatively very slow. For **4**, the rotation rate about the C-4,C-19 is more rapid than that about the C-10,C-20 bond.

The $T_1$ values for the two $OCH_3$ groups, when present, are given in Table 1. The absolute values may have a larger error than those for the other carbons since these were not of primary interest for this study. The trends, however, are correct in that the methyl carbon of the carbomethoxy group always has a longer $T_1$ than the aromatic methoxy methyl. Estimation of the hindrance to rotation cannot be performed since rotation about more than one bond is possible. It is to be expected that the rotation about the aromatic carbon–oxygen bond and the carbonyl carbon–oxygen bond would be relatively slow due to overlap of the nonbonding electrons of the oxygen and the $\pi$ system. The difference then will be due to differences in rotation rates about the O—$CH_3$ bonds or a relatively rapid rotation rate about the C-(4)—C(19) bond. The barrier to rotation about a carbon–carbonyl bond is known to be small (12). Whatever the explanation, this difference in $T_1$'s is useful for distinguishing between the two O—$CH_3$ groups.

## Experimental

Carbon-13 relaxation time data were obtained using the inversion recovery methods on a Bruker HX-90 as previously described (6). Sweep widths of 4000 Hz were generally employed. In some cases, much smaller sweep widths were also employed (2000 Hz) in which case the values for the aliphatic and aromatic regions were obtained in separate experiments. The values for the two types of experiments were within experimental error. Errors limits are estimated to be ± 10% in $T_1$ values which give rise to estimated errors of ± 15% in $R$ and ± 0.3 kJ/mol in $V_R$ (6).

The compounds used have all been reported in the literature. Spectral data and melting points corresponded to those reported.[3] The corresponding references are **1** (13), **2** (14), **3** (15), **4**, **6**, **8** (16), **5** (17), and **7** (18).

The chemical shift data for **1–3** (19) and **4** (20) have been reported. The spectra of the remaining compounds were readily assigned using these data and the substituent effects observed for similar compounds (19). The chemical shifts of **1** were verified by use of shift reagent. Carbons 11 and 13 have similar chemical shifts but they can easily be assigned from the coupled spectra (19).

The influence of solvent on the equilibrium position of the tautomeric forms of 2,4-pentanedione was studied by calorimetric and nmr spectroscopic techniques. For solvents such as $CCl_4$ and cyclohexane the intramolecular bond of the enol form persists and bulk solvent effects account for the equilibrium enol–keto content. In solvents such as DMSO, disruption of the intramolecular bond occurs and the percentage of enol falls due to unfavorable entropy changes. The enol intramolecular bond is disrupted by the solvents water and methanol. Enol hydrogen bond formation through self-association and with the solvent accounts for the entropy changes upon enolization in these solvents. The thermodynamic parameters for enolization in neat 2,4-pentanedione are rationalized by the disruption of the enol intramolecular hydrogen bond through consequent polymerization of the enol tautomer.

J. N. SPENCER, ERIC S. HOLMBOE, MINDY R. KIRSHENBAUM, DANIEL W. FIRTH et PATRICIA B. PINTO. Can. J. Chem. **60**, 1178 (1982).

Faisant appel aux techniques de la calorimétrie et de la spectroscopie de RMN, on a étudié l'influence du solvant sur la position à l'équilibre des formes tautomères de la pentanedione-2,4. Dans le cas de certains solvants, tels le $CCl_4$ et le cyclohexane, la liaison intramoléculaire de la forme énolique persiste et les effets d'encombrement du solvant interviennent dans l'équilibre céto–énolique. Dans le cas du DMSO, il se produit une rupture de la liaison intramoléculaire et le pourcentage d'énol diminue beaucoup par suite des variations défavorables de l'entropie. Les solvants, tels le méthanol et l'eau, rompent la liaison intramoléculaire de l'énol. La formation de liaisons hydrogènes par suite d'une auto-association ou d'une association avec le solvant est responsable des variations d'entropie lors de l'énolisation dans ces solvants. On rationnalise les paramètres thermodynamiques de l'énolisation de la pentanedione-2,4 à l'état pur en considérant que la liaison hydrogène intramoléculaire de l'énol est rompue conduisant ainsi à une polymérisation de l'énol tautomère.

## Introduction

In contrast to the low enol content of monocarbonyl compounds, the enol form of the tautomeric species of β-diketones generally predominates over the corresponding keto form. Solvent effects on the equilibrium position of β-diketones are pronounced. The enol content of 2,4-pentanedione in $CCl_4$ is 95% at 298 K but falls to 16% in water at 298 K. This report deals with a calorimetric and nmr investigation of solvent effects on the keto–enol equilibrium in 2,4-pentanedione.

## Experimental

The calorimeter and methods of calculation of the enthalpies of solution have been described previously (1, 2).

Spectra of solutions containing 2–4% of 2,4-pentanedione in various solvents were recorded on a Perkin-Elmer 732 90 megaherz nmr spectrometer equipped with a variable temperature accessory. The temperature range was 0 to 80°C. Assignments of the resonance peaks to the tautomeric forms have been reported (3). The ratio of the integrated areas and the peak heights of the resonance signals corresponding to the two tautomeric forms was used to calculate the percentage of enol. The equilibrium constant was calculated as the ratio of mole fraction of enol to keto tautomer. Plots of $\ln k$ vs. $T^{-1}$ were used to find $\Delta H^0$ and $\Delta S^0$. In order to provide as wide as possible variation in the equilibrium constant, data were recorded at temperature intervals of 15–20° over the temperature range. An average of about 10 determinations were made at each temperature using different freshly prepared solutions.

The purification of *N*,*N*-dimethylacetamide (DMA) has been given (4). Fisher Spectranalyzed methanol was fractionally distilled from magnesium under nitrogen atmosphere. Fisher Reagent Grade 2,4-pentanedione was fractionally distilled under reduced pressure. Fisher Spectranalyzed cyclohexane was refluxed over $P_2O_5$ and distilled under nitrogen. Fisher Certified ACS DMSO was refluxed over NaOH pellets and distilled under nitrogen. Fisher Certified ACS $CCl_4$ was refluxed over $P_2O_5$ and distilled under nitrogen. $CCl_4$, DMSO, DMA, and cyclohexane were stored over molecular sieves prior to distillation. Solution preparation was done in a nitrogen atmosphere.

## Results

Enthalpies of solution at infinite dilution are given in Table 1. The results of nmr analysis and comparisons with previously reported parameters for the enolization of 2,4-pentanedione are given in Table 2. The solvation enthalpy of the keto and enol tautomers was calculated by application of the Euler's theorem for homogeneous functions of

degree one. The enthalpy of a mixture of keto and enol forms is given by

$$H = X_k\bar{H}_k + \bar{X}_e\bar{H}_e$$

where $X_k$ and $X_e$ are the mole fractions of keto and enol tautomers respectively in a given phase; $\bar{H}_k$ and $\bar{H}_e$ are the enthalpies of the keto and enol tautomers in that phase. The transfer enthalpy from phase β to phase α may be written as

$$[1]\quad H_\alpha - H_\beta = (X_{k\alpha}\bar{H}_{k\alpha} + X_{e\alpha}\bar{H}_{e\alpha}) - (X_{k\beta}\bar{H}_{k\beta} + X_{e\beta}\bar{H}_{e\beta})$$

where $H_\alpha - H_\beta$ is the transfer enthalpy, $\Delta H_{\underset{\beta\to\alpha}{tr}}$, from phase β to phase α. For this study phase β was taken to be the gas phase and phase α the solvent under consideration. Manipulation of eq. [1] gives

$$[2]\quad \Delta H_{\underset{g\to\alpha}{tr}} = (\bar{H}_{k\alpha} - \bar{H}_{kg}) + X_{e\alpha}\Delta H_\alpha{}^0 - X_{eg}\Delta H_g{}^0$$

where $\Delta H_\alpha{}^0$ is the enthalpy change for enolization in solvent α and $\Delta H_g{}^0$ is the enthalpy change in the gas phase. Equation [1] may also be rearranged to give

$$[3]\quad \Delta H_{\underset{g\to\alpha}{tr}} = (\bar{H}_{e\alpha} - \bar{H}_{eg}) - X_{k\alpha}\Delta H_\alpha{}^0 + X_{kg}\Delta H_g{}^0$$

$\Delta H_{\underset{g\to\alpha}{tr}}$ may be calculated from the enthalpy of vaporization of 2,4-pentanedione (5) and the enthalpies of solution given in Table 1. The enthalpy changes in a given solvent, $\Delta H_\alpha{}^0$, $X_{e\alpha}$, and $X_{k\alpha}$ were obtained from nmr analysis; $\Delta H_g{}^0$, $X_{eg}$, and $X_{kg}$ were taken from the literature. Equations [2] and [3] may then be used to calculate $(\bar{H}_{k\alpha} - \bar{H}_{kg})$ and $(\bar{H}_{e\alpha} - \bar{H}_{eg})$. The enthalpies of the keto and enol tautomers in the gas phase, $\bar{H}_{kg}$ and $\bar{H}_{eg}$ were arbitrarily set to zero so that the terms $(\bar{H}_{k\alpha} - \bar{H}_{kg})$ and $(\bar{H}_{e\alpha} - \bar{H}_{eg})$ give the enthalpies of the keto and enol tautomers in the solvent α relative to the gas phase enthalpies. These quantities are given in Table 3 along with the enthalpy and entropy changes, the mole fraction enol as determined from nmr analysis, and the dielectric constant of the solvent. The difference $(\bar{H}_{k\alpha} - \bar{H}_{e\alpha})$ obtained from columns two and three of Table 3 gives the solvation difference between keto and enol tautomers of 2,4-pentanedione in a given solvent. Because the enol form is more stable by 2.2 kcal mol$^{-1}$ in the gas phase it is necessary to add −2.2 kcal mol$^{-1}$ to $(\bar{H}_{k\alpha} - \bar{H}_{e\alpha})$ to obtain $\Delta H_\alpha{}^0$ for the enolization in a given solvent. For example, in cyclohexane the enol form is enthalpically stabilized by solvation interactions over the keto form by −0.8 kcal mol$^{-1}$. Because the enthalpy of the enol form in the gas phase was arbitrarily assigned as zero enthalpy, the enthalpy change for enolization in cyclohexane is −3.0 kcal mol$^{-1}$. Of the 3.0 kcal mol$^{-1}$, 0.8 kcal mol$^{-1}$ is due to solvent interaction to stabilize the enol tautomer. In general, as the dielectric constant of the medium increases the keto tautomer becomes increasingly enthalpically stabilized as does the enol tautomer. However, as subsequent analysis will show, the nature of the solvent interaction which enthalpically stabilizes the two tautomers is different in different bases.

The enthalpy changes given in column four of Table 3 show that with the exceptions of DMA and DMSO, the enthalpy of enolization is more exothermic in solution than in the gas phase. In these solvents interaction with the enol tautomer is greater than with the keto form.

The entropy changes for enolization in $CCl_4$ and cyclohexane are more negative than those in the

[a]Error limits were estimated by consideration of the linearity of a ln $K$ vs. $T^{-1}$ plot and the uncertainty in the equilibrium constant. The error in $K$ is ±10%. The uncertainty in the percentage of enol is ±1%.

gas phase. The corresponding enthalpy changes are also more negative but the free energy change is such that the mole fraction of enol in these solvents is slightly greater than that in the gas phase. Thus the greater enthalpy due to to interaction of the enol tautomer with the solvent is sufficient to shift the equilibrium from the gas phase toward greater enol content in these two solvents. The greater interaction enthalpy of the enol tautomer is probably due to a closer approach of solvent molecules which gives stronger Van der Waals interactions. Reeves (3) and Allen and Dwek (6) report no chemical shift for 2,4-pentanedione resonance signals results upon dilution in cyclohexane. This supports a bulk interaction effect by the solvent.

The entropy changes in the solvents other than $CCl_4$ and cyclohexane are considerably more negative than those for gas phase enolization. Only for water as a solvent does it seem possible that these more negative entropy changes could result from structural effects on the solvent molecules. DMSO and DMF have been shown to disrupt intramolecular hydrogen bonds (7, 8) and because DMA is a strong proton acceptor, it seems reasonable that DMA could also disrupt the intramolecular hydrogen bond. The similarity of the thermodynamic functions for DMA and DMSO in Table 3 indicates that the solvent–solute interactions in DMA and DMSO must be similar. The entropy and enthalpy changes in these two solvents can be rationalized by the disruption of the intramolecular hydrogen bond of the enol tautomer and the consequent formation of an intermolecular hydrogen bond with the solvent. The enthalpy terms $\bar{H}_{k\alpha}$ and $\bar{H}_{e\alpha}$ for these solvents thus give the enthalpic stabilization of the keto form which must be primarily due to dipole–dipole interactions and the enthalpic stabilization of the enol form which consists partly of a stabilization due to hydrogen bond formation with the solvent. The mole fraction of enol in these two solvents drops markedly from the gas phase value, due primarily to the unfavorable entropy change. The disruption of the intramolecular bond and consequent reduction of freedom of the solvent molecules by association with the enol tautomer accounts for the unfavorable entropy change. Likewise the less favorable enthalpy change relative to $CCl_4$ and cyclohexane is in part due to the enthalpy required to disrupt the intramolecular hydrogen bond of the enol form.

The enthalpy changes for enolization (Table 3) in water and methanol are identical and similar to those found in $CCl_4$ and cyclohexane. The entropy changes in water and methanol, however, are the most unfavorable for any of the solvents. For water such an unfavorable entropy change is not surprising because of the well-documented structural changes water can undergo. Such structural changes do not seem as likely for methanol but it appears that the large negative entropy changes reflect the disruption of the intramolecular bond of the enol tautomer in both solvents. With water, additional structural changes may also occur, leading to a further entropy reduction. The enthalpy data of columns two and three of Table 3 show that the enol tautomer in water is enthalpically stabilized relative to the keto tautomer in contrast to the situation in the solvents DMA and DMSO. Water molecules must hydrogen bond to the keto tautomer as well as to the enol tautomer. If disruption of the intramolecular bond occurs in water, an additional enthalpic stabilization of the enol tautomer is possible through self-association and through association with the solvent.

Melia and Merrifield (5) have reported enthalpies and entropies of formation for the pure keto and enol tautomers in both liquid and gas phases for 2,4-pentanedione (Table 4). The enthalpy change on passing from the gas phase to pure liquid for the keto tautomer is −9.1 kcal mol$^{-1}$ and that for the enol tautomer is −9.8 kcal mol$^{-1}$. The corresponding entropy changes are −27.8 cal deg$^{-1}$ mol$^{-1}$ for the keto tautomer and −32.8 cal deg$^{-1}$ mol$^{-1}$ for the enol tautomer. The enthalpy of vaporization of the

| Equilibrium mixture (g) | −91.92 | 95.3 |

[a]Reference 5.

equilibrium liquid mixture of 2,4-pentanedione may be found from the data given in Table 4, and the mole fractions of enol in gas and liquid phase may be used in eq. [2] to calculate $\bar{H}_{kl} - \bar{H}_{kg}$, the enthalpy of the keto tautomer in the equilibrium liquid mixture minus the enthalpy of the keto tautomer in the gas phase. Equation [3] may be used to calculate the corresponding enthalpy difference for the enol tautomer. The enthalpy changes so calculated are $\bar{H}_{kl} - \bar{H}_{kg} = -9.1$ kcal mol$^{-1}$ and $\bar{H}_{el} - \bar{H}_{eg} = -9.7$ kcal mol$^{-1}$. Thus the interactions experienced by the keto tautomer in the equilibrium liquid mixture relative to the gas phase are nearly the same as the interactions experienced by the keto tautomer in pure liquid keto form. The interactions of the enol tautomer in pure enol or in the liquid equilibrium mixture are also similar. Thus the keto and enol tautomers must find themselves in essentially the same environment in the pure liquid keto and enol forms as in the liquid mixture which consists of both tautomeric forms. The pure enol tautomer is more stable enthalpically than the pure keto tautomer. The entropy of the pure liquid enol tautomer is also lower than that of the pure liquid keto tautomer. These data seem to be consistent only if the intramolecular hydrogen bond of the enol tautomer is disrupted in the liquid equilibrium mixture and in pure enol. The enol form without the intramolecular hydrogen bond would be expected to form an intermolecular hydrogen bond with itself and with the keto form in the equilibrium mixture. If this occurred, the enthalpy and entropy of the enol tautomer could be more negative than that of the keto tautomer. However, intermolecular hydrogen bond formation by the enol to the keto form would be expected to enthalpically stabilize the keto tautomer. This would mean that the enthalpy of the keto form in pure liquid keto would not be the same as that of the keto tautomer in the equilibrium mixture. The most likely way for these considerations to be satisfied is through self-association of the enol tautomer, thus reducing hydrogen bonding to the keto tautomer.

Burdett and Rogers (9) report an upfield shift in the enol hydroxyl and enol α-proton resonance signals of 2,4-pentanedione with increasing temperature. They suggest that an intermolecularly hydrogen bonded species is present and becomes less favored at higher temperatures. Thus their results are consistent with the disruption of the intramolecular hydrogen bond in neat 2,4-pentanedione. Rogers and Burdett (10) also interpret the chemical shift on dilution of 2,4-pentanedione to inter and intramolecularly bonded species.

## Conclusions

The usual rule that is applied to rationalize the effect of solvent on the percentage of enol in a β-diketone is that the enol tautomer is less polar than the keto tautomer and therefore polar solvents stabilize the keto tautomer over the corresponding enol tautomer. In solvents which do not specifically interact with the keto or enol forms, as for example through hydrogen bond formation, the keto form is increasingly stabilized with increasing dielectric constant of the solvent. The interaction which stabilizes the keto form is electrostatic in origin. For these solvents the entropy of enolization should not show much variation from solvent to solvent.

In solvents like DMA and DMSO which can disrupt the intramolecular hydrogen bond, an unfavorable entropy of enolization results. Solvents of this type which can disrupt the intrabond can also stabilize the keto form by electrostatic interactions. Thus the percentage of enol in these solvents will decrease in accordance with increasing dielectric constant, but to a greater extent than expected because of the unfavorable entropy change.

In solvents that can act as hydrogen bond proton donors and acceptors, the keto tautomer is enthalpically stabilized by hydrogen bonding to the carbonyls but is not stabilized as much as the enol tautomer. The entropy of enolization is unfavorable for these solvents, but due to the enthalpic stabilization of the enol tautomer the percentage of enol is greater than would be expected on the basis of dielectric constant.

Powling and Bernstein (11) have correlated sol-

[c]Reference 6 at 38°C.

vent influence and thermodynamic parameters using the Onsager–Kirkwood theory of solvent interaction. The percentage of enol as a function of the Onsager–Kirkwood dielectric function for those solvents not capable of undergoing hydrogen bonded interactions or disruption of the intramolecular enol hydrogen bond was plotted and the best least-squares fit was made. Table 5 compares the percentage of enol calculated from the fitted data with experiment. For these solvents the fit is good, the percentage of enol drops as the dielectric function increases due to greater stabilization of the keto form by solvent interaction.

The observed values for the percentage of enol in solvents DMA and DMSO which can disrupt the intramolecular hydrogen bond fall below the percentages calculated from the least-squares relation. This is due mainly to the unfavorable entropy change resulting from the disruption of the intrabond by the solvent. Methanol and ethanol, on the other hand, show a higher percentage of enol than that calculated from the least-squares relation. The higher percentage is due to the significant enthalpic stabilization of the enol form due to hydrogen bond formation with these solvents.

Received October 13, 1981

J. N. SPENCER, E. S. HOLMBOE, M. R. KIRSHENBAUM, S. W. BARTON, K. A. SMITH, W. S. WOLBACH, J. F. POWELL, and C. CHORAZY. Can. J. Chem. **60**, 1183 (1982).

The proton-donating and -accepting abilities of water and methanol to various nitrogen-containing compounds have been determined by calorimetric analysis. Water is a better proton donor than methanol but methanol is a better proton acceptor than water. The interactions by water and methanol at the nitrogens of the diazines follow trends expected from relative proton affinities, p*K*'s, and theoretical calculations. Electrostatic interactions by the diazine nitrogens with pyridine parallel the interactions found for methanol and water at these nitrogens.

J. N. SPENCER, E. S. HOLMBOE, M. R. KIRSHENBAUM, S. W. BARTON, K. A. SMITH, W. S. WOLBACH, J. F. POWELL et C. CHORAZY. Can. J. Chem. **60**, 1183 (1982).

On a déterminé, par l'analyse calorimétrique, les capacités de l'eau et du méthanol d'agir comme accepteurs et donneurs de protons en présence de divers composés azotés. L'eau est un meilleur donneur de proton que le méthanol, mais ce dernier est un meilleur accepteur de proton. Les interactions de l'eau et du méthanol sur les atomes d'azote des diazines suivent les tendances prévues à partir des p*K*, des affinités relatives du proton et de calculs théoriques. Les interactions électrostatiques des atomes d'azote de la diazine avec la pyridine se comparent aux interactions trouvées dans le cas du méthanol et de l'eau sur ces atomes d'azote.

## Introduction

The ability of water to act as a proton donor and acceptor is in part responsible for its remarkable solvating properties. The usual methods employed to study proton-donating ability require the preparation of a dilute solution of the donor in an inert solvent which contains a proton acceptor. Because of the difficulty of obtaining accurately known concentrations of water in organic solvents, few measurements of the proton-donating properties of water have been reported. Even for those systems for which measurements can be made, the solvation of water by organic solvents makes difficult the interpretation of actual proton-donating ability. Studies of water acting as a proton acceptor are even more limited because the usual spectroscopic methods which involve measurements in the hydroxyl stretching region are not possible. Similar difficulties are encountered for methanol as a proton acceptor. Solutes which can act as donors and acceptors in solvents which can also behave as donors and acceptors cannot be studied by the usual spectroscopic techniques. Measurements carried out on dilute solutions of water or methanol in suitable solvents do not give information on the behavior of these species when present in bulk. The pure base calorimetric method allows determination of proton-accepting enthalpies in solvents such as water and methanol, and enthalpies of solution allow the determination of the proton-donating abilities of these solvents. In this study, enthalpies due to interactions for the solvents methanol and water acting as donors and acceptors have been determined by calorimetric analysis.

## Experimental

The calorimeters and method of analysis have been previously described (1, 2).

Purifications for NMF (3), DMF (4), pyrrole (1), *N*-methylpyrrole (1), imidazole (5), and methylimidazole (5) have been given. Benzene was refluxed over $P_2O_5$ and fractionally distilled under nitrogen. Pyridine was dried over fresh BaO and fractionally distilled under nitrogen. 1,4-Diazine (pyrazine) was vacuum sublimed, 1,2-diazine (pyridazine) was dried over sieves and distilled under nitrogen, 1,3-diazine (pyrimidine) was Aldrich 99+% and used without further purification. Pyrazole was vacuum sublimed. Methanol was dried over sieves and then twice redistilled under nitrogen. Deionized water was doubly distilled under nitrogen and used immediately.

## Results

Enthalpies of solution for the various solutes and solvents are given in Table 1. Enthalpies of vaporization and sublimation are also given in Table 1.

### *Calculation of enthalpies due to interactions*

The hydrogen bond enthalpy of the N—H proton of imidazole and of *N*-methyl formamide to water and methanol was determined by the pure base calorimetric method (6). The parameters to be used in this calculation for water have been given (2), and the parameters necessary for the calculations for methanol solvent are given in Table 2.

The enthalpies due to interactions by methanol and water at the nitrogens of pyridine and the

[a] For details of the pure base calculations see refs. 2 and 6. The parameters used for methanol per —$CH_2$— are: cavity term 1.6 kcal mol$^{-1}$, dispersion term 2.3 kcal mol$^{-1}$, and dipole-induced-dipole 0.1 kcal mol$^{-1}$.
[b] Estimated stepwise enthalpies due to interactions. The numbers in parentheses refer to the first and second stepwise enthalpy respectively.
[c] Reference 5.
[d] Reference 2.

diazines were obtained by taking the difference between the transfer of benzene from the gas phase to either solvent and the transfer of the nitrogen-containing base from the gas phase to the respective solvent. For example, the transfer enthalpy for benzene from gas phase to water is −7.6 kcal mol$^{-1}$; that of pyridine is −11.9 kcal mol$^{-1}$; the difference between the two transfers, −4.3 kcal mol$^{-1}$, is attributed to interactions at the nitrogen of pyridine. The same transfer for 1,3-diazine, −14.3 kcal mol$^{-1}$, gives an enthalpy due to interactions at the two nitrogens of −6.7 kcal mol$^{-1}$.

The interactions at either nitrogen of the diazines may be due in most part to hydrogen bonded interactions. Due to inductive effects for the diazines, the interaction enthalpy of a second hydrogen bonded species will be less than the first. Thus, the addition of solvating species to the diazines may be considered in a stepwise fashion. The data do not allow an exact division of the total heat produced by solvation of the diazine nitrogens into the heat associated with the stepwise solvation of each nitrogen. However, an estimate of the enthalpies at each nitrogen may be made by consideration of the relative proton affinities (Table 3) of pyridine and the diazines. The PA of pyridine is greater than that of 1,2-diazine; therefore, it would be expected that the enthalpy of interaction for the solvation of the first nitrogen site in 1,2-diazine would be less than that of the solvation of the pyridine nitrogen. For solvation by water the enthalpy due to interactions at the first nitrogen of 1,2-diazine must be less exothermic than −4.3 kcal mol$^{-1}$. The sum of the solvation enthalpies for 1,2-diazine in water is −7.3 kcal mol$^{-1}$. Thus, the solvation enthalpy for the first nitrogen site should be more exothermic than the average solvation enthalpy of the two sites. This gives a range of −4.3 to −3.7 kcal mol$^{-1}$ for the first interaction site on 1,2-diazine. An estimate of −4.0 kcal mol$^{-1}$ for the first interaction enthalpy of water with 1,2-diazine should not be in error by more than 0.3 kcal mol$^{-1}$. Then the enthalpy

[e]Average enthalpy due to interactions at two nitrogen sites.

due to interaction at the second nitrogen would be $-3.3$ kcal mol$^{-1}$.

For the other diazines the range is too large to provide reliable estimates of the stepwise solvation. If it is assumed that the ratio of interactions at the two nitrogen sites is the same for all the diazines, the 1,2-diazine ratio of stepwise enthalpies may be used to calculate the interaction on 1,3- and 1,4-diazine. The interactions so calculated are given in Table 2.

The interaction enthalpies of methanol and water at the imidazole $N_3$ can be determined by a comparison of the transfers of pyrrole from the gas phase to a given solvent and of imidazole from the gas phase to the same solvent. The gas phase to water transfer for pyrrole is $-10.0$ kcal mol$^{-1}$. If the pyrrole N—H to water hydrogen bond enthalpy, $-2.3$ kcal mol$^{-1}$, is subtracted from this transfer enthalpy, the interaction of the pyrrole ring structure with water, $-7.7$ kcal mol$^{-1}$, is determined.

The transfer from gas phase to water for imidazole is the sum of three terms: the N—H hydrogen bond enthalpy with water, the $N_3$ interaction with water, and the interaction and cavity terms for the pyrrole ring structure of imidazole. The N—H hydrogen bond enthalpy (Table 2) and pyrrole ring structure term are known. Thus, the interaction at $N_3$ may be found by difference. The $N_3$ interaction for imidazole with water and that for methanol with imidazole, similarly determined, are given in Table 2.

## Discussion

The p$K$ for the autoprotolysis of methanol is 16.9 compared to 15.7 for water at 25°C. Comparison of the data for the hydrogen bonding of water and methanol to pyridine and the diazines given in Table 2 shows that water is a better proton donor than methanol. Comparison of the hydrogen bond enthalpies for the N—H of imidazole and *N*-methylformamide to methanol and water (Table 2) shows that methanol is a better proton acceptor than water. It was not possible to obtain the hydrogen bond enthalpy of the pyrrole $N_1$—H to water directly because the model compound to be used in the pure base method, *N*-methylimidazole is not sufficiently soluble in water. However, an estimate of the hydrogen bond enthalpy in water can be made by comparison of the relative proton-donating abilities of imidazole and pyrrole. For hydrogen bonded complexes of imidazole and pyrrole with pyridine, *N*,*N*-dimethylformamide and acetonitrile, the ratio of the pyrrole hydrogen bond strength to that of imidazole is $0.85 \pm 0.01$ (5). Thus if the imidazole–water hydrogen bond is $-2.7$ kcal mol$^{-1}$, the pyrrole hydrogen bond with water may be inferred to be $-2.3$ kcal mol$^{-1}$.

The pyrrole–methanol hydrogen bond enthalpy was determined by direct use of the pure base method. The ratio of the hydrogen bond enthalpy of the pyrrole–methanol complex to that of the imidazole–methanol complex is 0.79, a ratio not far removed from 0.85 (a difference of 0.1 kcal mol$^{-1}$ in either hydrogen bond enthalpy makes the ratio 0.82). This can be taken to mean that the methanol interaction at $N_3$ of imidazole does not substantially alter the hydrogen bond enthalpy for the imidazole $N_1$—H proton.

Table 3 compares proton affinities (PA), and p$K$, of the bases to the observed enthalpies due to interactions at the nitrogens of pyridine, 1,2-diazine, 1,3-diazine, and 1,4-diazine. The theoretical calculations given in the same table correspond to a complex made up of single water molecule and the base. The enthalpies due to interactions given in column 6 of Table 3 correspond to interactions at all sites. The numbers in parentheses (column 6) denote the average interaction enthalpy. The expected trends in enthalpies due to interactions with PA and p$K$ are observed, and the theoretical calculations predict the observed order of interaction enthalpies.

SCF calculations (7) for pyridine and the diazines give no correlation between the total or $\pi$ electron populations and the proton affinities of these bases. The electron populations in the diazines seem to

reflect inductive effects of the two nitrogen atoms (7). The favorable alignment of molecular dipole moments accounts for the order of stability of pyridine and the diazine complexes with water given in Table 3.

The interactions of pyridine and the diazines with pyridine are given in Table 2. These interactions were determined by using benzene as a model and attributing differences between the gas phase to pyridine transfers of benzene and the diazines to interactions at the nitrogen. The interactions of pyridine solvent with the diazines are dipolar. The molecule with the largest dipole moment undergoes the strongest interaction. These electrostatic interactions parallel the interactions attributed largely to hydrogen bonding for methanol and water solvent. The imidazole $N_3$ and pyridine nitrogen interactions are very similar enthalpically in pyridine solvent as are the enthalpies due to interactions at these nitrogens in hydrogen bonding solvents.

The solvation of pyrrole, imidazole, pyridine, and the diazines relative to the gas phase is found by using the enthalpies of solution and the enthalpies of sublimation or vaporization in Table 1. This total solvation enthalpy may be divided into an enthalpy due to interactions in the first solvation shell, and an enthalpy due to interactions with the ring structure of the systems studied. The first solvation shell enthalpies are given in Table 2. The enthalpy due to interaction with the ring structure can be found by the difference between the total solvation and the first solvation shell interactions given in Table 2. The diazines are more strongly solvated by water than by methanol because of the greater proton-donating ability of water. Pyrrole and imidazole are more strongly solvated by methanol than by water because of the better proton-accepting abilities of methanol. The difference between the solvation of the ring system in water and methanol is not great for either the pyrrole-type ring structure or the pyridine-type ring structure. Thus, the difference in total solvation is determined largely by the interactions in the first hydration shell. These interactions for methanol and water solvent are principally hydrogen-bonded interactions.

Imidazole is solvated by about 2 kcal $mol^{-1}$ more by water and methanol than is pyrazole. Both imidazole and pyrazole are more strongly solvated by methanol than by water. The transfer enthalpies from water to methanol for imidazole ($-1.32$ kcal $mol^{-1}$) and for pyrazole ($-1.16$ kcal $mol^{-1}$) indicate that the thermodynamic states of the two solutes in methanol and water are similar. Thus, the proximity of the nitrogens of pyrazole must lead to dipole interactions which enthalpically destabilize pyrazole by 2 kcal $mol^{-1}$ relative to imidazole.

The total solvation enthalpies of the diazines by pyridine follow the solvation trends set by methanol and water. This seems to support the contention that the interactions of water with these diazines are determined largely by the dipolar moment of the diazine.

# The generation and vibrational spectrum of matrix isolated thioformaldehyde and dideuterothioformaldehyde

M. TORRES, I. SAFARIK, A. CLEMENT, AND O. P. STRAUSZ

*Department of Chemistry, University of Alberta, Edmonton, Alta., Canada, T6G 2G2*

Received October 23, 1981

M. TORRES, I. SAFARIK, A. CLEMENT, and O. P. STRAUSZ. Can. J. Chem. **60**, 1187 (1982).

The photolysis of inert matrix isolated methylene trithiocarbonate at 10 K has been shown to be a clean source of thioformaldehyde. The $CH_2S$ and $CD_2S$ molecules produced this way are indefinitely stable under these conditions and their FTIR spectra could be recorded. A normal coordinate analysis has been carried out and all the normal frequencies of both molecules have been assigned.

M. TORRES, I. SAFARIK, A. CLEMENT et O. P. STRAUSZ. Can. J. Chem. **60**, 1187 (1982).

La photolyse de la matrice inerte de trithiocarbonate de méthylène obtenu à 10 K, a montré qu'elle est une source propre de thioformaldéhyde. Les molécules de $CH_2S$ et de $CD_2S$ obtenues de cette façon sont indéfiniment stables dans ces conditions et on peut enregistrer leurs spectres de IR-TF. On a réalisé une analyse normale de coordonnées et on a identifié toutes les fréquences normales de ces deux molécules.

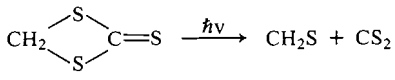
For personal use only.

Thioformaldehyde **1**, although known in its trimer form for decades (1), has only recently been prepared in its pure monomeric form by the thermolysis of methylsulfenyl chloride in the presence of stoichiometric amounts of hydrogen chloride (2). Several other methods have been described for the generation of **1** (3) but most of them are also based on thermolysis, which poses severe constraints on the use of spectroscopic methods of analysis because of the tendency of **1** to trimerize. Infrared studies have been reported in the gas- and argon-matrix phase but in both cases the method of generation, H-abstraction by fluorine atoms (4) and vacuum uv photolysis of $CH_3SH$ (5), resulted in the formation of substantial amounts of by-products that obscure large parts of the spectrum of **1**, and therefore the results are fragmentary. Recently more detailed studies of the spectrum of **1** by laser stark spectroscopy in the 10 μm region (6), and by single rotational level resonance fluorescence (7), have been reported and in parallel developments a force field and the vibrational spectrum have been calculated for **1** by an *ab initio* mo computation (8).

We have recently reported that photolysis of vinylene trithiocarbonates (9) and thioxocarbonates (10) resulted in the extrusion of $CS_2$ and COS and the formation of thiirenes and ketenes, respectively. It appears, therefore, that elimination of $CS_2$, which is reasonably transparent in the 3500–400 $cm^{-1}$ region, is a primary photochemical process of trithiocarbonates and, consequently, methylene trithiocarbonate **2** should be an excellent source compound for the generation of **1**.



**2** **1**

In the present article we wish to report the generation of thioformaldehyde **1** and dideuterothioformaldehyde **3** by the photolysis of argon-matrix isolated methylene trithiocarbonate **2** and dideuteromethylene trithiocarbonate **4** respectively at 10 K. We have also reexamined the ir spectra of **1** and **3** with the aid of FTIR spectroscopy, allowing the assignment of the ir frequencies of **1** and **3**, and have carried out a normal coordinate analysis.

## Experimental

An Air-Products and Chemicals Inc. Model CS-202 Displex closed-cycle-helium refrigeration system coupled to a high vacuum line was employed as described before (11). The light source was a Hanovia low pressure resonance mercury lamp equipped with a Vycor filter. Mass spectra were recorded on a Metropolitan Vickers MS-12 spectrometer at an ionization potential of 70 eV and ir spectra of matrix isolated species were obtained on a Nicolet 7199 FT infrared spectrophotometer at 1 $cm^{-1}$ resolution.

Methylene trithiocarbonate **3** was prepared as described (12) and purified by sublimation; mp 55–56°C; ms (30°C): 122(70) 76(44.5) 46(100); and methylene trithiocarbonate-$d_2$ **4** (99% *d*) was prepared similarly from diiodomethane (99% *d*, Merck, Sharp and Dohme Canada Ltd.); ms (50°C): 124(38.8) 76(46.1) 48(100).

## Results and discussion

Photolysis of argon-matrix isolated **2** at 10 K and at $\lambda = 254$ nm resulted in the disappearance of the initial ir spectrum, Fig. 1a, and the appearance of a new spectrum, Fig. 1b, in which $CS_2$ could be readily identified by the absorptions at 2180(w), 1528(vs), and the $^{13}CS_2$ satellite at 1479(w) $cm^{-1}$. The remaining absorptions could be clearly identified as thioformaldehyde **1** by the agreement with

those absorptions that have previously been assigned to **1**, Table 1. All the absorptions appeared as doublets, indicating different trapping sites (14). The photolysis proceeded rapidly and cleanly to completion without the formation of other products, in agreement with the mass spectrum of **2** which showed exclusive decomposition into $CS_2$ and **1** under electron impact. The split absorptions of argon-matrix isolated **1** have been reported to be replaced by single absorptions in a nitrogen matrix (5). However, in our case, although nitrogen-matrix experiments resulted in single absorptions for $CS_2$, the splitting of the absorptions for **1** in nitrogen, xenon, or CO matrices remained. In each case only the strongest band, for each fundamental, underlined in Table 1, will be mentioned in the assignments and these have been used in the calculations.

The exclusive formation of $CS_2$ (CS was not detected), and the good agreement between the remaining spectrum and the known $CH_2S$ absorptions leave no doubt that **1** is responsible for the observed spectrum and that **2** is a clean source compound for the photochemical generation of **1**. Similarly, photolysis of dideuteromethylene trithiocarbonate **4** resulted in the formation of $CS_2$ and thioformaldehyde-$d_2$, **3**, Fig. 2, in which a similar matrix effect in the splitting of the $CS_2$ and **3** bands was observed upon changing the host from argon to nitrogen. The observed bands are listed in Table 2.

Thioformaldehyde has a planar structure with $C_{2v}$ symmetry. The six normal vibrations form the representation $3a_1 + b_1 + 2b_2$ and all are ir active.

*C—H stretchings*

Three bands have been observed for **1** in the

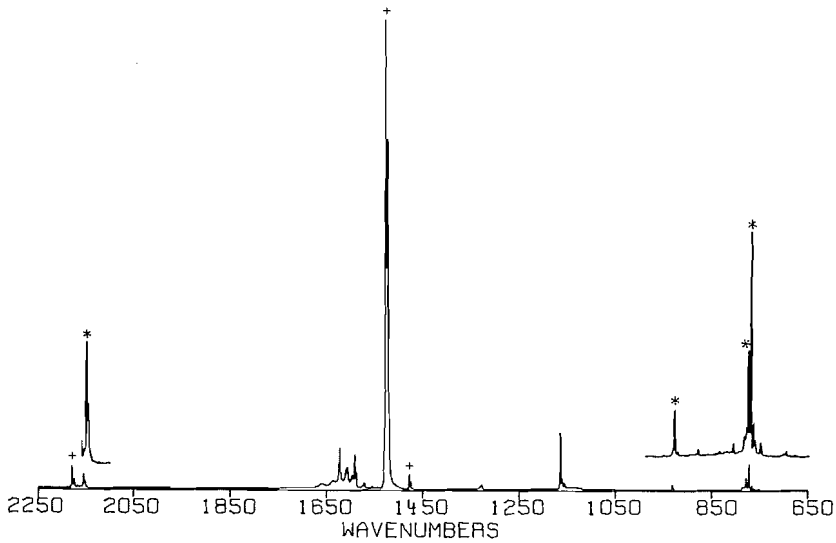

FIG. 2. FTIR spectrum of argon-matrix isolated dideuteromethylene trithiocarbonate **4** after 10 min photolysis with $\lambda = 254$ nm. Bands marked (+) are assigned to $CS_2$, and bands marked (*) are assigned to thioformaldehyde-$d_2$ **3**.

C—H stretching region at 2869(w), 2965(m), and 3017(broad, vw) $cm^{-1}$, in agreement with previous observations, Table 1, whereas in the C—D stretching region **3** featured only a single clear absorption at 2155 $cm^{-1}$; a weak, very broad absorption centered at 2280 $cm^{-1}$ is also tentatively assigned to **3**. The shift upon deuteration, and the similarity between the relative intensities of the 3017 and 2965 $cm^{-1}$ absorptions of **1** (the antisymmetric C—H stretch is weaker than the symmetric one) and those of formaldehyde (15) support Johns and Olson's assignment of these bands to the antisymmetric and symmetric C—H stretches, respectively (4) based on the rotational assignment of the gas phase spectrum. The 2869 $cm^{-1}$ band originally assigned to a $2\nu_6$ by Johns and Olson (4) should be reassigned to a $2\nu_2$, based on the observed $\nu_2$ (7).

*C═S stretch*

In agreement with Jacox and Milligan (5) and Bedwell and Duxbury (6) we have retained the assignment of the 1052 $cm^{-1}$ and the 932 $cm^{-1}$ bands to ν(C═S) in **1** and **3**, respectively. The weakness of these bands contrasts with the very strong ν(C═S) at ~1160 $cm^{-1}$, typical of trithiocarbonates, and also present in the spectra of **2** and **4**.

[b]Only observed in nitrogen-matrix.
[c]$\nu_{gas} - \nu_{matrix}$.

*C—H deformations*

The symmetric $CH_2$ deformation mode had often been assigned to a band at ~1530 $cm^{-1}$ hidden by the prominent 1528 $cm^{-1}$ $CS_2$ band, although the actual band had never been seen. Recently, Clouthier *et al.* (7) were able to observe the $CH_2$ symmetric deformation mode at 1457 $cm^{-1}$. In argon and xenon matrices the band appears at 1447 $cm^{-1}$, and the fact that the band could not be seen in the nitrogen-matrix experiments in which there is a shift between +2 and +11 $cm^{-1}$ in the position of all the other bands may be due to the fact that the $a_1$ $CH_2$ deformation mode experiences a larger shift of +30 $cm^{-1}$ and becomes hidden in the $^{13}CS_2$ satellite at 1479 $cm^{-1}$. Similarly, upon deuteration no band is observed in the argon-matrix photolysis that could be assigned to the symmetric $CD_2$ def, which is probably obscured by the prominent 1165 $cm^{-1}$ absorption of **2**. However, in nitrogen matrices a distinct absorption could be observed at 1167 $cm^{-1}$, Fig. 3.

For the remaining $CH_2$ deformations, the out-of-plane and the in-plane, there is only one remaining absorption which is apparently split into various bands in the 992–980 $cm^{-1}$ region, Fig. 4. However, in agreement with the recent results of Bedwell and Duxbury (6), Table 1, and on the basis of the splitting as compared to the other bands and their

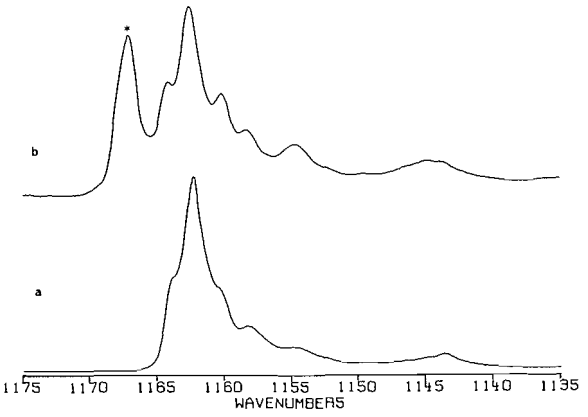

FIG. 3. 1175–1135 $cm^{-1}$ region FTIR spectrum of nitrogen-matrix isolated dideuteromethylene trithiocarbonate (a) after deposition, (b) after 15 min photolysis at $\lambda = 254$ radiation (*, assigned to thioformaldehyde-$d_2$ **3**).

behaviour in different matrices, the presence of two fundamentals is clearly indicated. We have tentatively assigned the strongest to the CH out-of-plane deformation based on the similar situation for formaldehyde (15). These two bands have their counterparts in thioformaldehyde-$d_2$ at 779 and 773 $cm^{-1}$.

*Product rule*

The theoretical Teller–Redlich rule (16) was calculated for thioformaldehyde based on the moments of inertia obtained from the geometrical parameters ($R$(C═S) = 1.6108 Å, $R$(C—H) = 1.0925 Å, and α(HCH) = 116.87°) determined by Johnson *et al.* (17) from the microwave spectra. The values obtained are in very good agreement with the observed values for each symmetry species, Table 3, strongly supporting the assignment.

*Normal coordinate analysis*

The seven internal coordinates used for the calculation are the changes in the three bond lengths ($\Delta r_1$, $\Delta r_2$, $\Delta R$), the changes in the HCH angle and the two HC═S angles ($\Delta\alpha$, $\Delta\beta_1$, $\Delta\beta_2$) and in the angle between the C═S bond and the HCH plane ($\Delta\beta$). The symmetry coordinates constructed with these internal coordinates are as follows:

$$\begin{aligned} a_1 \quad & S_1 = (\Delta r_1 + \Delta r_2)/\sqrt{2} \\ & S_2 = (2\Delta\alpha - \Delta\beta_1 - \Delta\beta_2)/\sqrt{6} \\ & S_3 = \Delta R \\ b_1 \quad & S_4 = \Delta\delta \\ b_2 \quad & S_5 = (\Delta r_1 - \Delta r_2)/\sqrt{2} \\ & S_6 = (\Delta\beta_1 - \Delta\beta_2)/\sqrt{2} \end{aligned}$$

The force field obtained by Jaquet *et al.* (8) for thioformaldehyde by *ab initio* mo methods was used as our initial force field which was then adjusted to fit the observed frequencies of thioformaldehyde-$d_0$ **1** and thioformaldehyde-$d_2$ **3**. The vibrational frequencies were calculated using a computer program (VSEC) written by Schachtschneider (18).

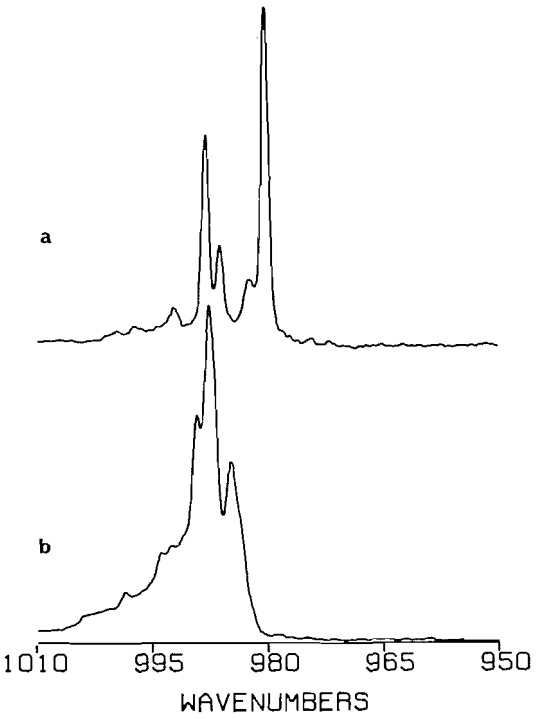

FIG. 4. 1010–950 $cm^{-1}$ region FTIR spectra of methylene trithiocarbonate **2** after $\lambda = 254$ nm photolysis for 10 min (a) argon-matrix (b) nitrogen-matrix.

TABLE 3. Theoretical vs. observed product rule ratios[a]

| Species | Theoretical | Observed |
|---|---|---|
| $a_1$ | 0.511 | 0.519 |
| $b_1$ | 0.788 | 0.789 |
| $b_2$ | 0.568 | 0.586 |

[a]The observed values are slightly higher due to the anharmonicity. When the band was split, due to matrix effects, only the stronger band was used in the calculation.

The calculated normal frequencies together with the observed values are listed in Table 4. The derived force field, in terms of the symmetry coordinates listed above, is given in Table 5, together with the force field from the *ab initio* calculation (8). The off-diagonal elements which can be calculated fairly reliably by *ab initio* methods have not been changed in the iteration with the exception of $F_{56}$. The value given by Jacquet *et al.* is rather low, and the one used in our calculations is in agreement with the relationship $F_{13} = 3^{-1/2}F_{56}$

[a]*ab initio* calculation.

found to be valid in the case of formaldehyde (19). The diagonal force constants are rather different mainly because we could not use anharmonic corrections, but the relative magnitudes agree well with those obtained from the *ab initio* calculation.

After submission of the present manuscript we became aware of a gas-phase FTIR study of thioformaldehyde, **1**, and dideuterothioformaldehyde, **3**, by Mills and co-workers (13). The FTIR gas-phase values have been included in Tables 1 and 2 together with the matrix shift. As seen from the data, the matrix shift is in the range of −3 to −10 $cm^{-1}$ with the exception of $\nu_6$ for $CD_2S$ which has a value of +22 $cm^{-1}$. When splitting of a band occurs in the matrix, $\Delta\nu$'s are computed for the most intense component of the split band.

# Metal hydride reductions of unsymmetrical cyclic anhydrides. The importance of the antiperiplanar effect on the regioselectivity of these reactions

MARGARET M. KAYSER[1]

*Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4*

AND

GEORGES WIPFF

*Institut le Bel, Université Louis Pasteur, 1 Rue Blaise Pascal, 67000 Strasbourg, France*

Received November 9, 1981

MARGARET M. KAYSER and GEORGES WIPFF. Can. J. Chem. **60**, 1192 (1982).

A quantum mechanical study by the SCF *ab initio* method of the interaction of $H^-$ with methylsuccinic and 2,2-dimethylsuccinic anhydrides (naked and in the presence of a cation) suggests that nonperpendicular rearside attack cannot be the factor responsible for the regioselectivity of hydride transfer to the more sterically hindered carbonyl group. In this model, the nucleophilic attack at the less hindered carbonyl group is calculated to be of lower energy (with or without cation). Deformation of the planar succinic anhydride ring to the quasi-chair conformation is energetically favoured as it allows the nucleophile to attack both carbonyl functions antiperiplanar to a quasi axial C—H or C—C bond. The attack antiperiplanar to the C—$CH_3$ bond is lower in energy than the attack antiperiplanar to the C—H bond suggesting that the reduction will occur at the sterically more hindered carbonyl group which is in agreement with the experimental findings.

MARGARET M. KAYSER et GEORGES WIPFF. Can. J. Chem. **60**, 1192 (1982).

Une étude, par la méthode SCF *ab initio*, de l'interaction de $H^-$ avec les anhydrides méthyl- et diméthyl-2,2 succiniques (seuls ou en présence d'un cation) suggère que l'attaque non-perpendiculaire ne peut être le facteur responsable de la régiosélectivité du transfert d'hydrure au groupe carbonyle le plus stériquement encombré. Dans ce modèle, on calcule que l'attaque nucléophile sur le groupe carbonyle le moins encombré requiert moins d'énergie (avec ou sans cation). La déformation du cycle plan de l'anhydride succinique en une conformation quasi-chaise est favorisée énergétiquement puisqu'elle permet au nucléophile d'attaquer les deux fonctions carbonyles antipériplanaires jusqu'à une liaison quasi-axiale C—H ou C—C. L'attaque antipériplanaire à la liaison C—H demande moins d'énergie que l'attaque antipériplanaire à la liaison C—H. Ce fait suggère que la réduction se fera sur le carbonyle le plus encombré, ce qui s'accorde avec les résultats expérimentaux.

[Traduit par le journal]

Metal hydride reductions of unsymmetrically substituted cyclic anhydrides (1, 2) and succinimides (3) frequently occur regioselectively at the carbonyl function adjacent to the most highly substituted carbon atom. Greatest selectivity is observed in reductions of *gem*-disubstituted succinic anhydrides and succinimides. In monosubstituted compounds, generally mixtures of the two regioisomers are obtained, although even there reduction occurs preferentially at the carbonyl group next to the substituent. This problem is well illustrated by reduction of 2,2-dimethylsuccinic anhydride and 2-methylsuccinic anhydride (Scheme 1) (2).

It has been suggested that a variety of factors may be involved in controlling regioselectivity of these reactions (2). The intrinsic reactivities of the two carbonyl groups toward the nucleophilic addition (expressed in terms of the size of LUMO coefficients on the carbon atoms of the carbonyl functions) correlate satisfactorily with regioselectivity patterns for a series of substituted succinic anhydrides (4). The observed regioselectivity could also be due to the nonperpendicular, restricted path of nucleophilic approach. This assumption was based on crystallographic analysis (5) and *ab initio* calculations (6, 7) of nucleophilic addition to the carbonyl group. Models of succinic anhydrides (8) and succinimides (9, 10) suggested that the approach of a nucleophile to the β-carbonyl function, along the preferred reaction path, might be effec-

tively more hindered by the substituents than the approach to the α-carbonyl group.

The purpose of this paper is to determine if such models (Fig. 1) are theoretically justified and can be used to rationalize and predict regioselectivity of metal hydride reductions, and to present alternative arguments based on ring nonplanarity and the "antiperiplanar effect".

## Results and discussion

*Ab initio* molecular orbital calculations using the programme Gaussian 70 (11) with the standard STO-3G basis set were carried out for methylsuccinic and 2,2-dimethylsuccinic anhydrides and all regioisomeric "supermolecules" (anhydride + $H^-$ and anhydride–proton + $H^-$). To reduce computation costs we have represented compounds **1** and **2** by realistic models based on crystallographic data for the parent succinic anhydride (12) while standard bond lengths and bond angles (13) were used for the substituents. The optimum orientation for the methyl group(s) was found to be fully staggered in the naked molecules **1** and **2** as well as in the "supermolecules" (Fig. 2).

To obtain a qualitative description of the anhydride–$H^-$ "supermolecule" we have scanned a number of points on the potential surface. The choice of positions was guided by the existing knowledge of the geometry of nucleophilic addition to the carbonyl group in formaldehyde. The $H^-\cdots$ C=O distance was maintained constant at 2 Å and the reacting carbonyl group was not pyramidalized.

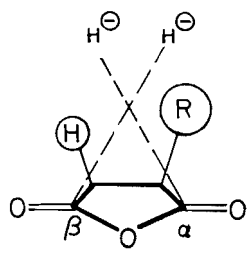

FIG. 1. Model of minimum energy path for $H^-$ approach to the more hindered α-carbonyl group and the less hindered β-carbonyl group suggesting that the attack at the α group is effectively more opened.

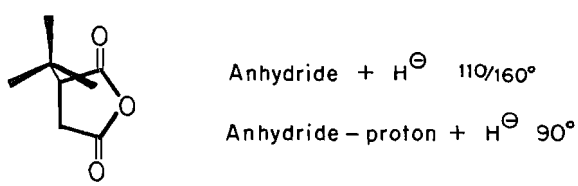

FIG. 2. The optimum orientation of the methyl group(s) in "naked" anhydrides **1**, **2**, and in the corresponding "supermolecules."

*Optimum geometry calculations for anhydride + $H^-$ "supermolecule"*

The calculations of the optimum geometry for hydride attack at the carbonyl group in succinic anhydride show that at the distance $H^-\cdots$C=O of 2 Å the preferred position for the hydride ion is on the bisector of the C=O group at an angle of ca. 110° to the molecular plane (4). Thus although the calculations confirm the nonperpendicular attack they do not predict a shift away from the ring oxygen atom as was suggested in the model (8, 14) (Fig. 3). This may result from the steric repulsion with the H atom(s) protruding above the plane of the ring or from the attractive interaction with the opposite carbonyl's carbon atom.

In the presence of the substituents (Me, Ph) in the position 2, nucleophilic attack occurs at the neighbouring α-, rather than more remote β-carbonyl group. This selectivity has been explained in terms of nonperpendicular rearside attack by a nucleophile (8–10). We have decided to test computationally the validity of such a hypothesis, by calculating the preferred position of $H^-$ attack at the α- and β-carbonyl group in methyl succinic and 2,2-dimethylsuccinic anhydride. No geometry relaxation of the anhydride was allowed, the five membered ring was kept planar, and the distance $H^-\cdots$C=O was fixed at 2 Å. Four values of the angle of attack (90°, 100°, 110°, and 120°) were computed for each point of the scan about the carbon atom of the "reacting" carbonyl group. Five scan points were chosen for the values of angle δ: 120°, 150°, 180°, 210°, and 240° (Fig. 4).

The optimum structures for each regioisomeric "supermolecule" are listed in Table 1. The results show that (a) the nucleophile is shifted away from the methyl substituent rather than from the ring

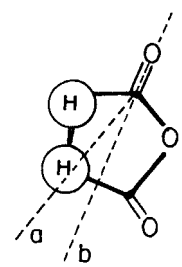

FIG. 3. Projections of the $H^-$ position onto the molecular plane; (a) a shift in space away from the ring oxygen atom suggested in the model for nucleophilic attack on the carbonyl group in succinic anhydrides; (b) the STO-3G calculated $H^-$ position falls directly on the bisector of the carbonyl group.

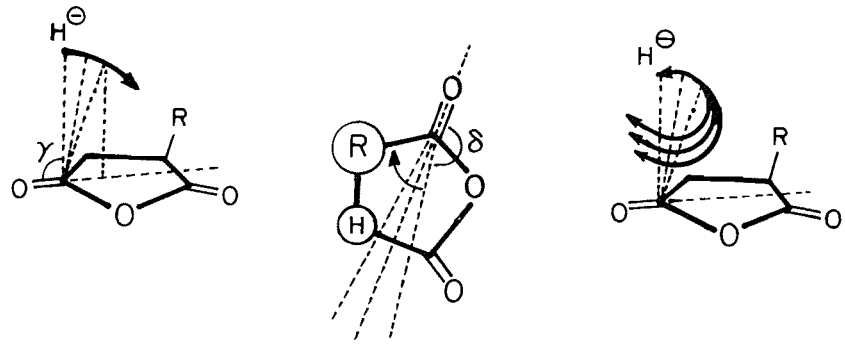

FIG. 4. The search for the optimum geometry for $H^-$ attack on the carbon atom of the carbonyl group in the β regioisomer of the model compound 1*b*. The angle γ between the incoming $H^-$ and the molecular plane varied from 90° to 120° by increments of 10°. The angle δ between $H^-$ projection on the plane of the ring and the C=O bisector varied from 120° to 240° by increments of 10°.

TABLE 1. Optimum geometries for regioisomeric "supermolecules" in the absence of a cation

|  | 110/160 | −450.86150 | −6.4 |

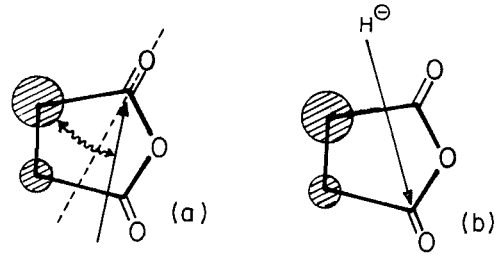

FIG. 5. The path of nucleophilic approach at 2 Å distance is shifted away from the methyl substituent in the attack on the α-carbonyl group, suggesting that in this model the α-carbonyl group is in effect more sterically hindered (a). The attack at the β-carbonyl group is energetically favoured (b).

oxygen atom (Fig. 5); and (b) the attack at the β-carbonyl group is energetically more favourable. These results are inconsistent with both the proposed model for the nucleophilic attack on succinic anhydrides and with the experimentally observed regioselectivity. The discrepancy most likely lies not in the calculations per se but rather in the model chosen for the transition state, particularly with regard to the planarity of the anhydride ring and the carbonyl groups.

*The optimum geometry for anhydride–proton + $H^-$ "supermolecule"*

We should point out that all the above calculations have been performed for hydride ion and naked substrate molecule. Neither solvent nor a cation normally present in the reaction medium were taken into account. Nevertheless, it has been demonstrated that in the absence of cations ($H^+$, $Li^+$, $Na^+$) and protic solvents the isolated carbonyl groups are not reduced (15*a*) by metal hydrides and reductions of conjugated ketones are considerably slower (15*b*). In order to ascertain if our previous result might not be modified when the more realis-

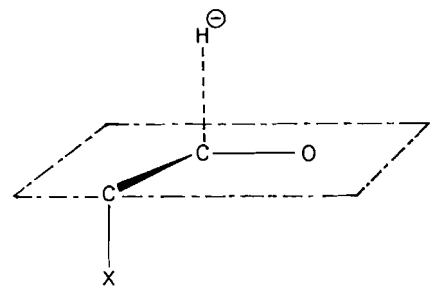
|  | 90 | −412.93601 | −3.2 |
|  | 90 | −412.93608 | −3.3 |

tic model incorporating a cation is used in computation, we have recalculated all regioisomeric supermolecules with a proton (simulating a cation) coordinated to the oxygen atom of the reacting carbonyl group. The results are summarized in Table 2. The equilibrium structures for the nucleophilic attack on the α- and β-carbonyl groups associated with a cation show that the optimum angle of attack is not 110° but is in fact close to perpendicular. This is in agreement with the results obtained by Anh and Eisenstein (16), who have shown that in model ketones the coordination with a cation favours near perpendicular attack. However, even in the presence of a cation, the attack at the less hindered β-carbonyl group remains energetically preferred, contrary to the experimental findings.

In view of these results we have concluded that the explanation of regioselectivity based on the nonperpendicular, restricted path of nucleophilic approach to the carbonyl function in succinic anhydrides is not adequate and thus the major factor influencing regioselectivity of these reactions has eluded us so far.

*The importance of the antiperiplanar effect*

The studies of Anh and co-workers (17) have suggested that in the nucleophilic addition to the carbonyl group in ketones, the transition state is stabilized if there is a neighbouring bond C—X antiperiplanar to the forming partial bond C—$H^-$ as shown in **3**.



**3**

The greatest stabilization is observed when $\sigma^*_{C-X}$ is low in energy. For example the C—C bond antiperiplanar to C—$H^-$ is favoured over the C—H bond since the energy of $\sigma^*_{C-C}$ is lower than the energy of $\sigma^*_{C-H}$. The authors have proposed that in cyclic ketones, where originally there is no antiperiplanarity possible, flattening of the ring and pyrimidalization at the carbonyl carbon atom occurs in order to achieve antiperiplanar geometry in the transition state (17). This hypothesis rationalized successfully the ratios of axial/equatorial attack in a variety of cyclic ketones.

Does the antiperiplanar effect play a role in the nucleophilic addition to systems other than cyclic ketones? If the original interpretation of the particular stability of the Felkin transition states is correct, then in any nucleophilic addition to a carbonyl function where regio and stereoselectivity may occur, antiperiplanarity between the incipient $H^-$—C bond and an adjacent σ bond of lowest energy should lead to the favoured transition state, other things being equal. Thus antiperiplanarity allows the correct prediction of regioselective reduction at the more hindered function in unsymmetrical diesters and diacids (18) (Fig. 6).

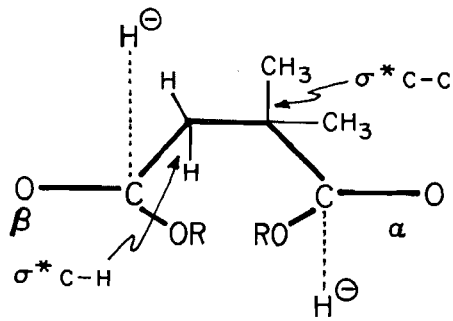


FIG. 6. The attack antiperiplanar to the C—C bond is favoured over the attack antiperiplanar to the C—H bond. Thus the α-carbonyl group is reduced preferentially.

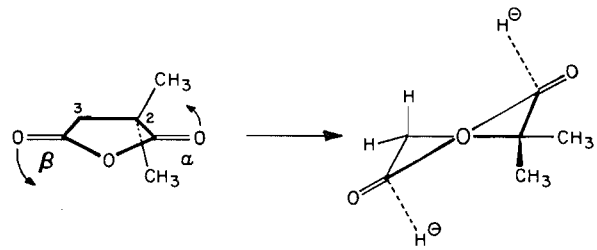

FIG. 7. A deformation of $C_2$ symmetry of the planar ring leads to a quasi-chair conformation. Nucleophilic attack at the α and β carbon atoms can now occur in the antiperiplanar fashion to a C—Me and C—H bond.

At first glance, achieving antiperiplanarity in succinic anhydrides does not appear possible due to the ring angle strain imposed on the planar ring by two trigonal carbon atoms. Crystallographic data have shown that in the crystal form succinic anhydride is indeed almost planar (12). Gas electron diffraction studies of gaseous succinic anhydride (19) suggest deviation from planarity of only 4.8°. Although in succinic anhydride the strain conferred by two trigonal carbon atoms is sufficient to hold the pair of adjacent methylene groups eclipsed in the equilibrium conformation, this may not be the case when succinic anhydride is substituted with larger groups where the ring may be intrinsically nonplanar. Moreover, since the deformation of the ring removes eclipsed interactions in the substrate, releases interactions with the nucleophile, and permits an antiperiplanar attack, the ring nonplanarity may be *enhanced* in the transition state. Upon examination of the model it can be seen that when the ring is twisted as shown in Fig. 7 we obtain a quasi-chair conformation. Now the incipient C—$H^-$ bond is nearly antiperiplanar to the quasi-axial C—C or C—H bond.

A second effect increasing the antiperiplanarity of nucleophilic attack is the pyrimidalization of the carbonyl group. We suggest that this effect is larger in cyclic succinic anhydrides than in open chain ketones or esters because of the strain at the carbonyl carbon atom (C—CO—C angle 110.5°) (19). The situation is analogous to that observed in the inversions at nitrogen (20) and carbanion (21), where the inversion barriers increase with the increasing strain. In addition, it is possible that in a nonsymmetric environment, the carbonyl group may be intrinsically nonplanar (22). The results obtained by Houk and co-workers (23) for model systems show that in the out-of-plane deformation of the carbonyl group the rehybridized π orbital is antiperiplanar to the "axial" C—H or C—Me bonds in the same direction as that which also gives the best antiperiplanar effect in the addition reaction.

As a result, nonplanarity of the anhydride ring increases the possibility of an effective antiperiplanar attack by forcing C—H and C—Me bonds into a pseudo axial orientation and by facilitating pyramidalization of the carbonyl group (Fig. 8) in the direction which permits the best antiperiplanar attack. Thus in methyl and 2,2-dimethylsuccinic anhydrides, nucleophilic attack at the α-carbon atom, antiperiplanar to an "axial" C—Me bond, is expected to be favoured, as is observed experimentally.

Ring flexibility and antiperiplanar effects are supported by 3G calculations carried out on succinic anhydrides and the corresponding supermolecules. We have not included carbonyl pyramidalization in our calculations since the degree of pyramidalization in the transition state, especially in the presence of a cation, is not known.

The calculations carried out for methyl and 2,2-dimethylsuccinic anhydrides show a slight but consistent drop in total energy upon twisting of the molecule into a quasi-chair conformation (Table 3). It should be noted that in the distorted rings, the LUMO coefficients are still more localized on the α than on the β carbon atom (Table 3). Although the fully optimized conformation of the molecules is not for the moment available, these results indicate that the anhydride ring possesses some flexibility and that deformation should not cost much in terms

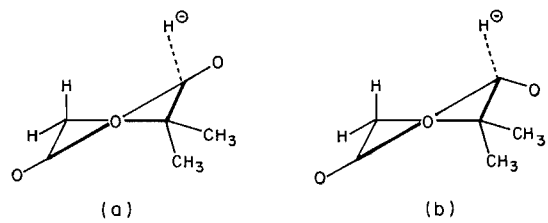

FIG. 8. Nucleophilic attack at planar (a) and pyramidalized (b) carbonyl functions in 2,2-dimethylsuccinic anhydride.

|  | −412.93391 | 0 |
|  | −412.93935 | −3.4 |

of energy. On the other hand, the distortion of the supermolecules in which hydride attack occurs at the α-carbonyl group is definitely energetically favoured (see Table 4).

Finally, we should point out that in the process of distorting of the substrate molecule into a quasi-chair conformation some of the steric congestion about the α-carbonyl group, which is present in a planar molecule, is now removed. As a result nucleophilic attack at the α-carbonyl function in the quasi-chair conformer is preferred to β-attack in the planar molecule. Thus on the basis of the foregoing calculations we should expect regioselective reduction at the α-carbonyl group, which is in agreement with the experimental findings.

## Conclusion

It appears that in the reduction of unsymmetrical cyclic anhydrides by simple metal hydrides two factors must be taken into consideration: (1) in systems possessing a certain flexibility in which, therefore, some degree of antiperiplanarity may be achieved, attack at the carbonyl function adjacent to the most highly substituted carbon atom should be favoured; (2) in rigorously rigid systems, preferred attack should occur at the least hindered carbonyl group. In other words, in succinic anhydrides in which the ring cannot be distorted to accommodate the antiperiplanar attack by a nucleophile, we should expect reduction at the β-carbonyl function.

In summary, we may conclude that theoretical studies of the reductions of cyclic anhydrides by metal hydrides suggest that the search for any single factor capable of explaining all the regioselectivity patterns is an exercise in futility. So far, four different effects controlling the course of these reductions have been identified, the two reported previously (4):

1. intrinsic reactivity of the carbonyl function
2. chelating effect

and the two discussed in this paper, namely:

3. antiperiplanar effect
4. steric congestion.

It is possible that the same factors affect regioselectivity in reductions of other systems such as, for example, cyclic imides and diesters.

Received November 9, 1981

MARGARET M. KAYSER, JUDITH SALVADOR, PETER MORAND, and H. G. KRISHNAMURTY. Can. J. Chem. **60**, 1199 (1982).

A dramatic reversal in regioselectivity is observed in the metal hydride reduction of unsymmetrical cyclic anhydrides such as **2**, **3**, and **4** compared to cyclic anhydrides attached to bridged ring systems (e.g. **1**). The synthesis of model cyclic anhydrides attached to strained rings is described and the ratios of isomeric lactones obtained upon reduction with metal hydride are reported. On the basis of theoretical calculations and, taking into account the intrinsic reactivity of the carbonyl group, the antiperiplanar effect, and steric congestion, an explanation is offered for the regioselectivity observed in the reduction of these compounds.

MARGARET M. KAYSER, JUDITH SALVADOR, PETER MORAND et H. G. KRISHNAMURTY. Can. J. Chem. **60**, 1199 (1982).

On a observé une inversion remarquable de la régiosélectivité dans la réduction par des hydrures métalliques des anhydrides cycliques, tels **2**, **3** et **4**, par opposition aux résultats obtenus avec des anhydrides cycliques attachés à des systèmes cycliques pontés (i.e. **1**). On décrit la synthèse d'anhydrides cycliques modèles attachés à des cycles tendus et on rapporte les proportions de lactones isomères obtenues lors de leurs réductions par les hydrures métalliques. A partir de calculs théoriques et en tenant compte de la réactivité intrinsèque du groupe carbonyle, de l'effet antipériplanaire et de la contrainte stérique, on propose une explication de la régiosélectivité observée lors de la réduction de ces composés.

[Traduit par le journal]

During a recent study of regioselectivity in metal hydride reductions of unsymmetrically substituted cyclic anhydrides we have noted that cyclic anhydrides attached to bridged ring systems such as **1** were reduced selectively at the carbonyl function next to the least substituted carbon atom (1). This observation was surprising in view of the fact that related systems such as **2**, **3**, and **4** are reduced regioselectively at the more hindered carbonyl group (1, 2).

The reversal of regioselectivity observed in the reduction of compound **1** (vs. **2**, **3**, and **4**) was suspected to be related to ring size and/or ring strain in the ring systems to which the anhydride is attached. In order to determine the impact of ring strain/ring size on the regioselectivity of metal hydride reductions, the model anhydrides **5**, **6**, and **7** were synthesized and subsequently reduced with $LiAlH_4$ and $NaBH_4$. Anhydride **7**, the one most closely related to the bridged cyclic system **1**, was reduced selectively at the β-carbonyl function, adjacent to the least substituted carbon atom. A trace amount (constituting < 5%) of the isomeric lactone was detected by glc, isolated by careful chromatography, and identified by proton nmr. Reductions of compounds **5** and **6** yielded mixtures of isomeric lactones in almost equal proportions.

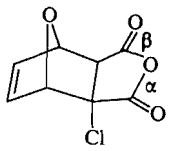
of the ring attached to the cyclic anhydride, and/or the issuing strain in the system, may in some manner be responsible for diminished selectivity in the reduction of compounds such as **5** and **6**, these effects, per se, cannot explain the high regioselectivity observed in the reduction of bridged compounds **1** and **7**. In this paper we propose that the



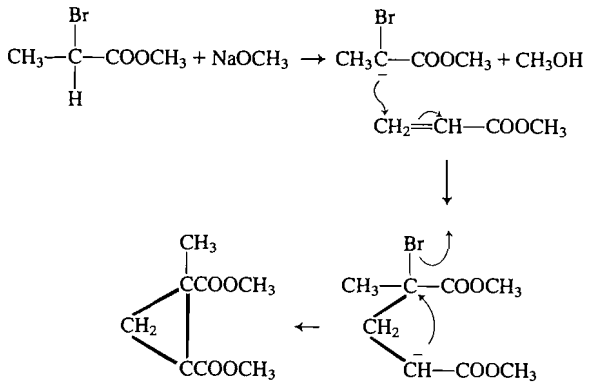
7

most satisfactory interpretation of the results is based on perturbational considerations, stressing the importance of the antiperiplanar effect in the transfer of hydride ion to the carbonyl function in cyclic anhydrides. In cases where antiperiplanar attack is not possible, the fate of the reaction is determined to a great extent by steric factors.

## Experimental results

A. *Synthesis of 1-methylcyclopropane, 1,2-dicarboxylic acid anhydride* **5**, *and 1-methylcyclobutane 1,2-dicarboxylic acid anhydride* **6**

The simplest and most successful method for the preparation of the anhydride **5** proved to be the procedure described by McCoy (3) as outlined in Scheme 1.

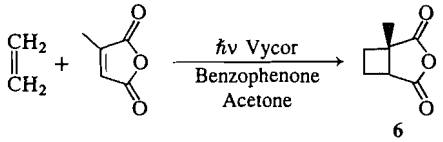


**5** *cis* and *trans*

SCHEME 1

Saponification of this product yielded 62% of the *trans* diacid (4) and 30% of the *cis* diacid which were converted to the anhydrides by treatment with acetic anhydride and separated by sublimation or crystallization.

The synthesis of anhydride **6** in 69% yield was cleanly effected by the photochemical |2 + 2| cycloaddition of ethylene to methylmaleic anhydride (Scheme 2).

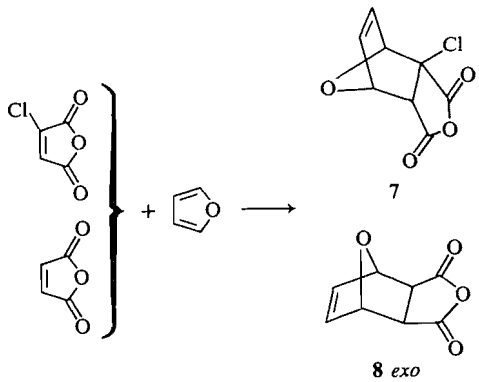


**6**

SCHEME 2

B. *Diels–Alder addition of furan and chloromaleic anhydride* **7**

Diels–Alder adducts derived from furan are generally thermally unstable and susceptible to dissociation with a varying degree of facility. Although furan, a poor diene due to its aromaticity, will not react directly with methyl or dimethyl maleic anhydride (4, 5), it will undergo |4 + 2| cycloaddition with maleic or chloromaleic anhydride simply by stirring the two compounds at room temperature. The commercially available chloromaleic anhydride contains ca. 30% maleic anhydride, which is difficult to remove. We chose to carry out the reaction with this mixture of chloromaleic and maleic anhydrides and to subsequently separate the two adducts (Scheme 3). This was accomplished by hplc or by fractional crystallization. Both **7** and **8** tend to deteriorate upon standing, adduct **8** being considerably more susceptible to decomposition.



**7**

**8** *exo*

SCHEME 3

In theory, two modes of addition are possible, leading to the formation of an *endo* or an *exo* adduct as shown in Scheme 4. The Diels–Alder adduct of maleic anhydride with furan has been shown to have the *exo* configuration (6). Anet (7) demonstrated by proton nmr study that, under the usual conditions, the addition of furan to maleic

TABLE 1. Metal hydride reductions of model cyclic anhydrides

| Anhydride | Products a | Products b | % Yield lactonic product | Observed ratio a/b |
|---|---|---|---|---|

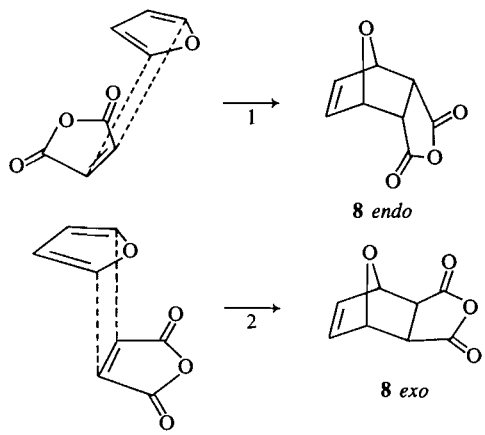
[a]$LiAlH_4$ reduction.
[b]$NaBH_4$ reduction.

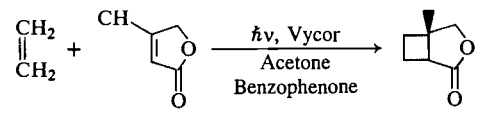
anhydride gives initially the kinetically favoured *endo* product which isomerizes to the more thermodynamically stable *exo* anhydride dissociation and recombination. On the basis of the proton nmr spectrum the addition of chloromaleic anhydride to furan appears to give exclusively the thermodynamically more stable *exo* adduct **7**.



SCHEME 4

The model anhydrides **5**, **6**, and **7** were reduced by $LiAlH_4$ and $NaBH_4$. The various reaction products were isolated and purified as detailed in the experimental section. The results are summarized in Table 1. Reductions by $LiAlH_4$ and $NaBH_4$ gave essentially identical product ratios for each anhydride studied.

The lactone which is more rapidly eluted during glc was in all cases the isomer reduced at the less hindered carbonyl group. The lactones (**5***b*, **6***b*, **7***b*) show a complex multiplet due to two methylene protons at δ 4.2–4.5. The lactones resulting from the reduction of the carbonyl function adjacent to the more highly substituted carbon atom have somewhat longer elution times. The nmr spectra of **5***a* and **6***a* exhibit a characteristic AB quartet for two methylene protons. The structural assignment was confirmed by an independent synthesis of lactone **6***a*, which was prepared by photochemical cycloaddition of ethylene to 4-hydroxy-3-methyl *cis*-crotonic acid lactone **9** (Scheme 5).



**9** **6a**

SCHEME 5

The minor product isolated by chromatography from the $LiAlH_4$ reduction of the adduct **7** was assumed, on the basis of the nmr spectrum, to be the open form (hydroxy acid) of the lactone **7***a*.

minimum STO-3G basis set were performed for 1-methylcyclopropane 1,2-dicarboxylic acid anhydride **5**, 1-methylcyclobutane 1,2-dicarboxylic acid anhydride **6**, and eight "supermolecules" (anhydride–proton and hydride ion) corresponding to all regioisomers. The geometry for the parent succinic anhydride was obtained from crystallographic data (9). The geometries of compounds **5** and **6** were adapted from the crystallographic data for the related compounds (10) and from MINDO/3 calculations of the relative positions of the atoms in the molecule corresponding to minimum energy (11).

Since full optimization for complicated systems is prohibitively expensive and time-consuming, the choice of the geometries for the "supermolecules" was guided by the existing knowledge of the gross features of nucleophilic attack on the activated (by association with a cation) carbonyl group. In these terms nucleophilic attack occurs at the carbon atom of the carbonyl group activated by a cation (simulated in the calculations by $H^+$). The direction of nucleophilic approach is perpendicular to the plane of the trigonal carbon atom and the distance between nucleophile (simulated by $H^-$) and carbon atom remains fixed at 2 Å (Fig. 1).

In order to obtain information on the nature of the substrate molecules **5** and **6** we examined first the "naked molecules". It is generally accepted that a nucleophile adds to the LUMO $\pi^*$ (lowest unoccupied MO) and specifically to the carbon atom of the carbonyl function (12). The carbon atom where the $\pi^*$ orbital has its maximum amplitude (i.e. highest LUMO coefficient), permitting the best overlap, should be the preferred site for nucleophilic attack. Thus, we have suggested that the size of the LUMO coefficient on the carbon atom reflects the intrinsic reactivity of the carbonyl group (13).

The results of the calculations obtained for anhydrides **5** and **6** are shown in Table 2. In 1-methylcyclopropane 1,2-dicarboxylic acid anhydride **5**, the LUMO coefficient on the carbon atom of the α-carbonyl group is considerably higher than the coefficient on the β-carbonyl group. Hence we should expect a better overlap and consequently higher reactivity at the α-carbonyl function. In 1-methylcyclobutane 1,2-dicarboxylic acid anhydride **6** the two LUMO coefficients are almost identical, and therefore, on the basis of intrinsic reactivity alone, no regioselectivity would be expected. However, as was pointed out before (14), three other factors can influence selectivity of nucleophilic addition: (a) possibility of chelation; (b) antiperiplanar attack; (c) steric hindrance.

The chelating effect is obviously not operative in

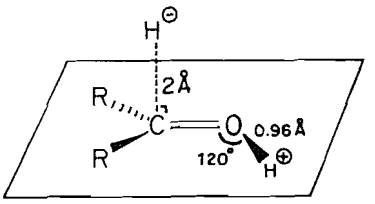

FIG. 1. Geometry of nucleophilic attack (simulated by $H^-$) on activated (by association with a cation simulated by $H^+$) carbonyl group.

systems such as **1**, **5**, **6**, and **7** and can be neglected. On the other hand, the remaining two effects should be examined in relation to our model compounds.

Methylsuccinic and 2,2-dimethylsuccinic anhydride were shown to possess the necessary flexibility to accommodate antiperiplanar attack in the developing transition state (Fig. 2) (14). However, when the anhydride ring is attached to a cyclopropane ring the resistance to torsional motion about the C—C bond is significantly higher. Hence the anhydride ring is rigidly planar and any distortion would require considerable energy input. As a result, antiperiplanar geometry in the supermolecule cannot be achieved and the site of nucleophilic addition will be influenced by the degree of steric hindrance about the two carbonyl functions.

The argument can be extended to 1-methylcyclobutane 1,2-dicarboxylic acid anhydride **6**. It is generally agreed that cyclobutane is puckered with a relatively high barrier to the planar configuration (16). As a result, distortion of the anhydride ring attached to cyclobutane will be energetically unfavourable. Hence in **6**, as in **5**, antiperiplanar attack is not feasible, and we must consider that nucleophilic addition occurs to the planar anhydride ring.

TABLE 2. Comparison between theoretical results (LUMO coefficients) and experimental data (ratio of lactonic products obtained)

| Compound | LUMO coefficients on $C_\alpha$ | LUMO coefficients on $C_\beta$ | Experimental ratio, reduction at $C_\alpha$ | Experimental ratio, reduction at $C_\beta$ |
|---|---|---|---|---|
|  | −0.564 | 0.541 | 62 | 38 |
|  | −0.580 | 0.570 | 43 | 57 |

TABLE 3. Relative energies of isomeric "supermolecules"

| "Supermolecule" | Relative energy $\Delta E$ kcal/mol | "Supermolecule" | Relative energy $\Delta E$ kcal/mol |
|---|---|---|---|
| | 0 | | 0 |
|  | −0.3 |  | −0.1 |
|  | −6.4 |  | −1.1 |
|  | −6.4 |  | −5.4 |

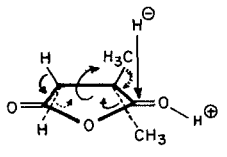

FIG. 2. The transition state is stabilized if there is a neighbouring bond C—X antiperiplanar to the forming partial bond C—$H^-$. The stabilization is greater where X = C than where X = H (15).

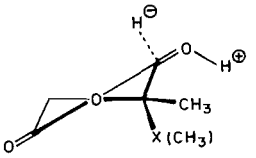

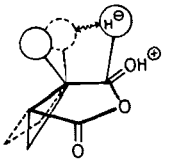

FIG. 3. Superimposed models of compounds **6** and **5**. As the internal angle diminishes from 90° in cyclobutane to 60°C in cyclopropane the substituents (here the anhydride ring and $CH_3$ group) are spread further apart.

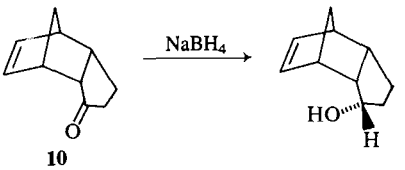
The STO-3G calculations carried out for all isomeric supermolecules (formed by substrate–proton and hydride ion) show that in **5** and **6** nucleophilic attack at the ring side of the molecule is unfavourable. As a result $H^-$ adds preferentially to the methyl bearing face of the molecule. We should caution at this point that, since full optimization of the geometry for the supermolecules is not available, the results of these calculations can provide only a rough guideline to the trends in energy changes. With this in mind we may observe that, while in compound **6** preferential attack should occur at the β-carbonyl function, in compound **5** attack at either the α- or β-carbonyl (13) function is equally favourable (Table 3). This difference between **5** and **6** may be due to the fact that, as a result of the diminution of the internal angle, the substituents on the cyclopropane ring are spread further apart. Hence the methyl substituent in **5** is tilted away from the plane of the molecule and interferes less with the approaching nucleophile. This effect is less pronounced in **6** and therefore steric interaction between the nucleophile and the methyl group is more important (Fig. 3).

Although the effects discussed above are small in magnitude, the combination of the higher intrinsic reactivity and diminished steric hindrance at the α-carbonyl group in **5** add up to increased reactivity at that site. In anhydride **6** the intrinsic reactivity of the two carbonyl groups is the same but as the β-carbonyl function is more exposed to nucleophilic attack a slight excess of β-reduction should result. These predictions correlate well with the experimental findings.

The foregoing arguments allow rationalization of the regioselectivity observed in the reduction of bridged compound **1**. It has been demonstrated before that in related compounds such as **10**, hydride addition takes place from the *exo* side (17), as shown in Scheme 6. By analogy, a similar addition mode should apply to the bridged compound **1**. Due to the strain in the tricyclic system, the anhydride ring in **1** is planar and rigid and the position of the methyl substituent is similar to that



**10**

For personal use only.

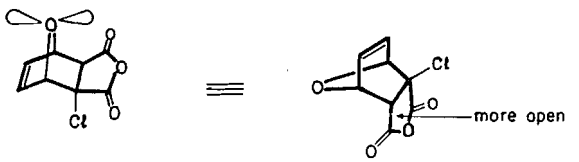

FIG. 4. On the basis of the geometry of this Diels–Alder adduct, the nucleophile should attack the more open (convex) face of the molecule. Therefore the same regioselectivity should be observed as for the *endo* bridged compound **1**.

of the methyl group in planar 2,2-dimethylsuccinic anhydride **4** (10).

Although compound **7** has the *exo* configuration, the structural features dictate that nucleophilic addition should occur from the more open side, i.e. the side on which the chlorine atom is attached (Fig. 4).

The computations performed on planar 2,2-dimethylsuccinic anhydride **4** have shown that the attack at the β-carbonyl function is favoured by −4.5 kcal/mol (14). Hence on the basis of the model calculations, bridged compounds are expected to be reduced preferentially at the β-carbonyl function. This prediction is confirmed by the experimental results.

In summary, it should be underlined that the arguments presented above are the only ones, so far, capable of successful rationalization of all the experimental results.

## Experimental

Melting points were determined on a Thomas–Hoover capillary melting point apparatus and are uncorrected. Infrared spectra were obtained on a Beckman IR-20 spectrophotometer and proton nmr spectra in $CDCl_3$ or DMSO, with TMS as internal standard, on a Varian HA-100 instrument. Tetrahydrofuran was distilled under nitrogen from lithium aluminum hydride into oven-dried flasks containing $LiAlH_4$ or $NaBH_4$.

The general procedures for the reductions were as follows.

(a) Lithium aluminum hydride (0.004 mol) was placed in an oven-dried, three-neck flask into which 60 mL of tetrahydrofuran was subsequently distilled. The flask was fitted with an inlet post for syringes, gas outlet tube, thermometer, and magnetic stirrer. The suspension, swept with a slow stream of nitrogen, was stirred for 15 min at room temperature, then cooled in a dry ice–acetone bath. An anhydride (0.008 mol) dissolved in freshly distilled tetrahydrofuran (40 mL) was injected slowly into the reaction flask. The temperature of the reaction mixture was maintained below −50°C throughout the addition process. The stirred solution was allowed to warm to 0°C over a period of 1½ hours. The flask was then cooled again to −20°C and excess water and 6 *N* HCl were added slowly. The reaction mixture was stirred overnight. The layers were separated and the acidic aqueous layer extracted repeatedly with ether. In some cases liquid/liquid extraction of the aqueous layer with ether was carried out overnight. The combined organic layers were dried, the solvent evaporated, and the product analyzed by proton nmr and using a Gow Mac Series 550 gas chromatograph fitted with an 8 ft, 10% DEGS on Chromosorb column.

(b) Reductions with sodium borohydride were carried out as follows. The suspension of crushed $NaBH_4$ (0.005 mol) in dry tetrahydrofuran (60 mL) was refluxed for 15 min and then cooled in an ice bath. A solution of an anhydride (0.008 mol) in dry tetrahydrofuran (40 mL) was added dropwise to a stirred, ice-cold suspension of $NaBH_4$. The stirring was continued for 2½ hours during which time 2–3 drops of 6 *N* HCl were added to the reaction mixture. After quenching with 6 *N* HCl (to pH 2), excess water was added and stirring continued overnight. The work-up procedure was the same as in the procedure described for $LiAlH_4$ reductions.

*1-Methylcyclopropane 1,2-dicarboxylic acid anhydride* **5**

Anhydride **5** was prepared according to the method of McCoy (3). Commercial sodium methoxide 25% in methanol (Aldrich) was evaporated to dryness on a rotatory evaporator at 50°C (2–3 hours). The solid sodium methoxide was removed from the flask and ground to a fine powder in a glove bag under dry nitrogen. The acrylic ethylester (1.0 mol) and methylbromopropionate (0.5 mol) were treated with sodium methoxide (1.0 mol) added in several small portions, under nitrogen. The temperature of the reaction mixture was kept between 10–30°C by cooling in an ice bath when necessary. After stirring for 1½ hours the reaction was hydrolyzed with a large excess of water and stirred overnight. The organic layer was extracted with water, then with saturated NaCl, dried over $MgSO_4$, and distilled. The yield of pure diester was 46% (10 Torr, 100–108°C). The diester was saponified by refluxing with 50% excess of a 15% aqueous solution of NaOH. After two hours reflux the basic solution was evaporated on a rotatory evaporator. The residue was diluted with water and acidified to pH 2. The acidic mixture was extracted with ether on a continuous liquid–liquid extractor for 36 h. On evaporation of the ether extracts, a mixture of *cis* and *trans* acids was obtained (0.23 mol, 92% yield on the basis of diester). Analysis by $^1H$ nmr showed the ratio *cis*–*trans* to be 67:33.

Alternately 1-methylcyclopropane 1,2-dicarboxylic acid (a mixture of *cis* and *trans*) was prepared under conditions similar to those described by Jonczyk *et al.* (18). α-Chloroacetonitrile (8.95 g, 0.1 mol) was added slowly, with stirring, to a flask containing finely powdered potassium hydroxide (6 g) suspended in benzene (20 mL). The reaction flask was cooled with an ice bath (exothermic reaction). The acrylonitrile (5.3 g, 0.1 mol) was added in small portions to the stirred reaction mixture. The stirring was continued for an additional hour. The mixture was diluted with water and extracted with benzene. The combined organic layers were washed with aqueous sodium chloride solution, dried, and the solvent removed. The oily product (7.0 g) was distilled at 1 Torr. Fraction 1 (2.0 g) collected at 60–70°C was identified as pure *trans* 1-methylcyclopropane 1,2-dinitrile, the second fraction (2.5 g) collected at 110–120°C was pure *cis* 1-methylcyclopropane 1,2-dinitrile. The same reaction run under phase transfer conditions in the presence of the catalyst (benzyltriethylammonium chloride) (19), yielded *trans* dinitrile as the major product (6.0 g) and *cis* dinitrile (2.0 g).

Upon hydrolysis (40% aqueous KOH) of the *trans* isomer, the *trans* diacid was obtained in 25% yield. The hydrolysis of *cis* nitrile under the same conditions gave a mixture of *cis* and *trans* diacids (*cis* 12%, *trans* 15%). The two isomers were separated by fractional crystallization from acetonitrile. The *cis* diacid, mp 133–135°C; $^1H$ nmr $\delta_{DMSO}$: 1.01 (m, 1H), 1.32 (s, 3H), 1.48 (m, 1H), 1.78 (m, 1H); *trans* diacid, mp 163–165°C, $^1H$ nmr $\delta_{DMSO}$: 1.16 (m, 1H), 1.32 (s, 3H), 1.45 (m, 1H), 2.16 (q, 1H).

The mixture of two isomeric diacids was stirred and heated under reflux for ½ hour, with 20% excess acetic anhydride. The unreacted acetic anhydride and acetic acid were removed by distillation under reduced pressure (3 Torr, 35°C). The oily

residue was taken up in dry ether. Upon standing in a Dry Ice – acetone bath, the anhydride **5** precipitated as a white crystalline solid. Crystallization from dry ethylacetate – hexane gave a pure sample, mp 45–46°C (lit. (3) mp 45–47°C); ir $\nu_{max}$: 1775 $cm^{-1}$, 1850 $cm^{-1}$ (C=O anhydride); $^1H$ nmr $\delta_{DMSO}$: 1.40 (s, 3H) 1.58 (m, 1H), 1.86 (m, 1H), 2.76 (m, 1H); $\delta_{CDCl_3}$: 1.50 (m, 1H), 1.58 (s, 3H), 1.75 (m, 1H), 2.56 (m, 1H); *m/e*: $M^+$ 126, $(M^+ - CO_2)$ 82.

1-Methylcyclopropane 1,2-dicarboxylic acid anhydride **5** was reduced with $LiAlH_4$ as described in the general procedure. Upon work-up a mixture of two lactones was obtained. The total yield of lactonic product was 62%. Analysis by glc (column temperature 145°C) indicated that lactones **5***a* and **5***b* (corresponding to the second and first peak respectively) were present in the ratio 55:45. The reduction with $NaBH_4$, according to the general procedure, yielded 60% of lactonic product. The ratio of the two lactones was **5***a*/**5***b* = 60:40. Lactones **5***a* and **5***b* were separated by hplc. Lactone **5***a*: ir $\nu_{max}$: 1765 $cm^{-1}$ (lactone CO); $^1H$ nmr $\delta_{CDCl_3}$: 1.15 (m, 2H), 1.41 (s, 3H), 1.86 (m, 1H), 4.16 (q, 2H); *m/e*: $(M - H)^+$ 111, $(M - CH_3)^+$ 97, $(M - CO)^+$ 84. Lactone **5***b*: ir $\nu_{max}$: 1765 $cm^{-1}$ (lactone CO); $^1H$ nmr $\delta_{CDCl_3}$: 1.05 (m, 2H), 1.44 (s, 3H), 2.10 (m, 1H), 4.20 (m, 2H), *m/e*: $M^+$ 112, $(M^+ - CO)$ 84.

*Synthesis of 1-methylcyclobutane 1,2-dicarboxylic acid anhydride* **6**

A solution of citraconic anhydride (1.25 g, 0.01 mol) and benzophenone (0.05 g) in freshly distilled acetone (400 mL), cooled with a cold water jacket (10–15°C), was irradiated with a high pressure mercury arc lamp through a Vycor filter. Ethylene gas was introduced steadily, during the reaction time (6 hours). Evaporation of the solvent under reduced pressure gave a colourless oil (1.5 g). The oil was taken up in dry ether and hexane was added until the solution was cloudy. Upon cooling in a Dry Ice – acetone bath white crystalline anhydride precipitated. The yield of pure product was 69%, mp 63–65°C; ir $\nu_{max}$: 1775 $cm^{-1}$, 1855 $cm^{-1}$ (anhydride CO); $^1H$ nmr $\delta_{CDCl_3}$: 1.55 (s, 3H), 2.48 (m, 4H), 3.23 (m, 1H); *m/e*: $(M^+ - CO_2)$ 96.

1-Methylcyclobutane 1,2-dicarboxylic acid anhydride **6** was reduced with $LiAlH_4$ under the usual conditions. The work-up procedure yielded 65% of lactonic product. Gas-liquid chromatographic analysis revealed two sharp peaks, a product peak of shorter elution time corresponding to the lactone **6***b*, reduced at the β-carbonyl group, and the second peak corresponding to the lactone **6***a*. The ratio of **6***a* to **6***b* was 44:56. The reduction of anhydride **6** by sodium borohydride according to the general procedure gave 71% yield of lactonic product. Analysis by glc (column temperature 150°C) showed the ratio of lactones **6***a*/**6***b* to be 43:57. The two lactones were separated by hplc. Lactone **6***a*: ir $\nu_{max}$: 1765 $cm^{-1}$ (CO lactone); $^1H$ nmr $\delta_{CDCl_3}$: 1.32 (s, 3H), 2.32 (m, 5H), 4.06 (q, 2H); *m/e*: $M^+$ 126, $(M^+ - CH_3)$ 111, $(M^+ - CCH_3)$ 99, $(M^+ - CO_2)$ 82. Lactone **6***b*: ir $\nu_{max}$: 1760 $cm^{-1}$ (CO lactone); $^1H$ nmr $\delta_{CDCl_3}$: 1.36 (s, 3H), 2.20 (m, 4H), 2.72 (m, 1H), 4.24 (m, 2H); *m/e*: $M^+$ 126, $(M^+ - CO_2)$ 82.

*Photocondensation of 4-hydroxy-3-methyl* cis*-crotonic acid lactone* **9** *with ethylene*

A solution of **9** (0.69 g, 0.007 mol) and benzophenone in purified actone, through which ethylene gas was bubbled slowly, was irradiated under the usual conditions. After 5 hours acetone was removed and an oily product (67% yield) purifid by chromatography. The principal product obtained was identical to lactone **6***a* obtained from the reduction of 1-methylcyclobutane 1,2-dicarboxylic acid anhydride **6**. Some unreacted lactone **9** was also recovered; ir $\nu_{max}$: 1760 $cm^{-1}$ (CO lactone); $^1H$ nmr $\delta_{CDCl_3}$: 1.3 (s, 3H), 2.14 (m, 4H), 2.62 (m, 1H), 4.06 (q, 2H); *m/e*: $M^+$ 126.

*Preparation of Diels–Alder adduct* **7**

Freshly distilled furan (20.0 g, 0.28 mol) and chloromaleic anhydride (commercial product, containing 30% of maleic anhydride, 40.82 g, 0.30 mol) dissolved in dry ether (25 mL) were stirred in a darkened flask for 4 hours at room temperature. After being placed in a refrigerator overnight, the first crop (4.26 g) was isolated and identified as pure adduct **8**. After standing for a day in a refrigerator the second crop (4.05 g) was obtained. This was a mixture of **7** and **8**, with **8** being the major component. The third crop (1.12 g) was identified as pure adduct **7**. Subsequently isolated crops (in all, 6.5 g) were shown to be adduct **7** contaminated with **8** and with traces of unidentified polymeric material. The two compounds could be easily separated by hplc. Both adducts **7** and **8** were recrystallized from acetonitrile and ether and analyzed by glc. Adduct **8**: mp 116–117°C dec.; ir $\nu_{max}$: 1770 $cm^{-1}$ and 1850 $cm^{-1}$ (anhydride CO); $^1H$ nmr $\delta_{DMSO}$: 3.34 (s, 2H), 5.34 (m, 2H), 6.6 (m, 2H); *m/e*: $M^+$ 166. Adduct **7**: mp 106–107°C, **7** gave a positive Beilstein's test for halogens and positive halide test after sodium fusion; ir $\nu_{max}$: 1790 $cm^{-1}$ and 1860 $cm^{-1}$ (CO anhydride); $^1H$ nmr $\delta_{DMSO}$: 3.56 (s, 1H), 5.61 (split singlet 2H), 6.86 (m, 2H); *m/e* $(M^+ - Cl)$ 165, $(M^+ - CO)$ 172, $(M^+ - CO_2H)$ 155. The reduction of chloroadduct **7** by $LiAlH_4$ under the conditions described in the general procedure yielded 74% of oily lactonic product. Analysis by glc (column temperature 160°C) showed one major peak and a trace of a second peak as well as small quantities of unidentified impurities. The chromatography on silica gel (hexane–ethylacetate 2:1) gave a pure sample of lactone **7***a*, mp 83–84°C; ir $\nu_{max}$: 1775 $cm^{-1}$ (C=O anhydride); $^1H$ nmr $\delta_{CDCl_3}$: 2.63 (two doublets, 1H), 4.43 (multiplet consisting of two doublets 4.15, 4.30 and three peaks, the middle one split 4.50, 4.64, 4.82, the multiplet corresponding to 2H), 5.03 (s, 1H), 5.17 (s, 1H), 6.62 (s, 2H); *m/e*: $(M^+ - Cl)$ 151.

Chromatography furnished a trace amount of oily compound which appeared to be the opened form of the isomeric lactone **7***b*; $^1H$ nmr $\delta_{CDCl_3}$: 2.78 (s, 1H), 4.57 (s, 2H), 4.94 (s, 1H), 5.28 (s, 1H), 6.56 (s, 2H).

The reduction of chloroadduct with $NaBH_4$ according to the method described in the general procedure gave 76% yield of crude lactonic product. Analysis by glc showed the presence of only one lactone **7***a*. The reduction of the nonchloroadduct **8** with $NaBH_4$ as described in the general procedure gave a poor yield (30%) of lactone **8***a*; ir $\nu_{max}$: 1770 $cm^{-1}$; $^1H$ nmr $\delta_{CDCl_3}$: 2.66 (m, 2H), 4.34 (complex multiplet, 2H), 4.90 (s, 1H), 5.23 (s, 1H), 6.42 (s, 2H); *m/e*: $M^+$ 152.

RAMUNAS J. MOTEKAITIS, X. B. COX, III, PATRICK TAYLOR, ARTHUR E. MARTELL, BRAD MILES, and TORY J. TVEDT, JR. Can. J. Chem. **60**, 1207 (1982).

The thermal degradation of Ca(II), Mg(II), Zn(II), Fe(II), and Ni(II) chelates of EDTA was investigated in alkaline aqueous solution at elevated temperatures (230–310°C). The kinetics of decomposition were followed by nmr, titrimetry, and spectrophotometry. Reaction products were identified through nmr and by gas chromatography. The relative order of degradation rates, as measured by the loss of EDTA, was found to be Mg(II) > Ca(II) > Zn(II) > Fe(II) > Ni(II). The main degradation products formed in the lower temperature range (~250°C) are iminodiacetic acid, hydroxyethyliminodiacetic acid, and ethylene glycol. Higher temperature products are primarily dimethylamine and carbon dioxide. The rates of degradation of Ca(II), Mg(II), and Zn(II) EDTA chelates are considerably enhanced when either phosphate is present or a glass-lined autoclave is employed.

RAMUNAS J. MOTEKAITIS, X. B. COX, III, PATRICK TAYLOR, ARTHUR E. MARTELL, BRAD MILES et TORY J. TVEDT, JR. Can. J. Chem. **60**, 1207 (1982).

On a étudié la dégradation thermique, en solution aqueuse basique et à des températures élevées (230–310°C), des chelates entre l'EDTA et les ions CA(II), Mg(II), Zn(II), Fe(II) et Ni(II). On a déterminé les cinétiques de décomposition par la rmn, la titrimétrie et la spectrophotométrie. On a identifié les produits de la réaction par la rmn et la chromatographie en phase gazeuse. On a trouvé que l'ordre relatif des vitesses de dégradation, telles que mesurées par la perte de EDTA, est le suivant: Mg(II) > Ca(II) > Zn(II) > Fe(II) > Ni(II). Les principaux produits de dégradation formés dans le domaine de basses températures (~250°C) sont l'acide iminodiacétique, l'acide hydroxyéthyliminodiacétique et l'éthylène glycol. Les produits formés à une température plus élevée sont principalement la diméthylamine et le bioxyde de carbone. La présence du phosphate ou l'utilisation d'un autoclave tapissé de verre augmente considérablement les vitesses de dégradation des chelates de l'EDTA avec les ions Ca(II), Mg(II) et Zn(II).

## Introduction

The numerous applications of ethylenediaminetetraacetic acid, EDTA, include its use in aqueous solutions at high temperatures for metal oxide solubilization and for maintenance of metal ions in a sequestered state in solution. This specific application is of particular interest to the power industry which employs EDTA formulation for the continuous treatment of boiler water in steam generators to prevent excessive build-up of scale. Since EDTA in this application is used at elevated temperatures, aqueous chemistry of EDTA and its chelates should be studied at high temperatures to understand the various reactions affecting the efficacy of this sequestering agent. Two preliminary publications describe the reactions of EDTA at elevated temperatures in aqueous solution (1, 2). At moderate temperatures, ~ 175°C in alkaline solution, EDTA was found to undergo hydrolytic C—N fission to give iminodiacetic acid (IDA) and hydroxyethyliminodiacetic acid (HEIDA) as the main reaction products (2). The half-life for this first order process at 175°C is 4.5 h at pH = 9.4. At somewhat higher temperatures (2) (200°C) this half-life is reduced to 0.5 h, while a concomitant consecutive reaction involving the further hydrolysis of HEIDA to ethylene glycol and IDA also takes place. At still higher temperatures decarboxylation reactions also occur. Thus at 265°C, the initial hydrolysis products decarboxylate to give *N*-methylglycine and dimethylamine.

Another type of degradation reaction of EDTA chelates at elevated temperatures has been described recently (3). EDTA coordinated to Fe(III) or Cu(II) becomes oxidized to ethylenediamine triacetic acid (ED3A) and glyoxylic acid while the iron(III) is reduced to Fe(II) and copper(II) to Cu(0). The half life for Fe(III)–EDTA at pH 9.3 is about 3 h at 125°C. This redox reaction greatly destabilizes EDTA at temperatures just above the boiling point of water. However, the Fe(II) chelate formed was found to be stable at similar or higher temperatures even for periods exceeding several days.

The purpose of this present work is to determine the thermal stabilities and reaction sequences of representative metal chelates of EDTA under conditions of varying temperature, pH, and in the

presence and absence of catalysts. The metal ions employed are those that are not easily reduced, so that thermal degradation reactions would be expected to involve hydrolysis and decarboxylation, rather than redox reactions, in contrast to the reactions of the Fe(III) and Cu(II) chelates.

Very little work has been carried out previously on the thermal degradation of EDTA chelates and related compounds. Yakimets *et al.* (4) studied the thermal reactions of several EDTA chelates of reducible and non-easily reducible metal ions, and found a variety of products. By means of ir spectroscopy and gas chromatography, oxalic acid, formaldehyde, and hydrogen were found in the reaction mixture, but no major components were identified. An extensive study (5) of thermal degradation of NTA chelates of Fe(II), Fe(III), Ni(II), Co(II), and Cu(II) also yielded a wide variety of decomposition products.

## Experimental

*Reagents*

All salts, solvents, and reagents were analytical grade materials and were obtained from various major chemical distributors. Doubly distilled, deionized water was used throughout. Solutions were deoxygenated by scrubbing with prepurified grade nitrogen gas which had been passed through an acidic chromous chloride solution. The metal ion – EDTA solutions were prepared from reagent grade $Ca(OH)_2$, $Mg(OH)_2$, $FeSO_4 \cdot 7H_2O$, MgO, ZnO, $Ni(OH)_2$, $Ni(OAc)_2$ (nickel acetate), $NaH_2PO_4$, and NaOH, as needed.

*Kinetics*

The reactions were conducted under an inert atmosphere in a 2 L Parr all-titanium stirred bench autoclave equipped with temperature and pressure sensors and appropriate valves which were manipulated as needed to obtain samples either from the liquid or gaseous phase as the reaction proceeded.

*Product analyses*

The constituents of the liquid phase were determined by nmr measurements of $D_2O$/NaOD solutions. For Ca(II) and Mg(II) chelates unreacted EDTA was generally determined by titration with standard 0.0200 *M* copper(II) solution in acetic acid-acidified solutions with pyrocatechol violet as an indicator. The products formed at high temperatures do not interfere with this determination.

*Instrumentation*

Gas chromatograms were obtained with a microprocessor controlled Hewlett-Packard Model 5830A gas chromatograph equipped with dual TC and FI detectors. For gaseous sample analysis an 8-ft glass column packed with Chromosorb 101/4% was utilized, while liquid samples were run on a 1/8 in. × 10 ft. SS column packed with OV-1. The nmr spectra were recorded with a Varian T-60 spectrometer equipped with a variable temperature probe. The visible spectra were obtained on a Cary Model 14 spectrophotometer equipped with a Himamatsu photomultiplier tube.

## Results and discussion

In general, it was found that the EDTA molecule is considerably stabilized towards thermal and hydrolytic degradation through coordination to metal ions. Also, the decomposition pathways, the decomposition products, and the kinetics of the degradation of coordinated EDTA have been elucidated. Finally, it was found that phosphate and silicate catalyze this decomposition for some metal ions while not for others. In general, the reaction products at a given temperature were found to be the same for all metal ion tested at that temperature.

*Kinetics of EDTA degradation*

Most of the decomposition rates were measured at the relatively high pH of 10.4 for several reasons. At this pH, the EDTA chelates of the divalent metal ions investigated are completely formed, and the species $ML^{2-}$ (where $L^{4-}$ is the $EDTA^{4-}$ anion) is the only major species present in solutions containing equimolar concentrations of metal ion and ligand. The fact that EDTA is used commercially at high pH to prevent scale build-up in steam generators also offers a practical incentive for determining degradation rates in alkaline solution.

The decomposition rates of the chelates were measured by monitoring the concentration of the remaining EDTA. Ca(II) and Mg(II) EDTA rates were followed titrimetrically in acid solution with standard Cu(II) solution. The ferrous EDTA samples were dried, methyl esterified, and subjected to gas chromatographic analysis. Zinc(II)–EDTA sample solutions were evaporated and measured in NaOD/$D_2O$ by nmr. The nickel(II)–EDTA decomposition rate was likewise followed by nmr after pretreatment with excess $CN^-$ to convert the nickel(II) ion into the diamagnetic $Ni(CN)_4^{2-}$ ion.

Table 1 contains a summary of the first order rate constants for the decomposition of EDTA and its Ca(II), Mg(II), Fe(II), and Zn(II) chelates. The data in Table 1 show that metal chelate formation very strongly protects EDTA against hydrolytic degradation. Uncomplexed EDTA was found to decompose quite rapidly at 190°C ($k_{obs} = 0.37\,h^{-1}$), with a half-life at pH = 10.4 of 1.9 h. On the other hand, the Ca(II) chelate is inert under these conditions and requires heating at 310°C to achieve a similar rate of decomposition. Monitoring the reaction at 320°C showed that the rate of thermal decomposition is four times that measured at 307°C. In comparing the decomposition of the Mg(II) chelate at 307°C with that of the Ca(II) chelate at 310°C, it is seen that the Mg(II) rate is about a factor of two higher than the rate of Ca(II)–EDTA. The Fe(II)–EDTA and Zn(II)–EDTA degradation rates were found to be similar to that of Ca(II) after slight differences in temperature in Table 1 are taken into account. Nickel(II)

TABLE 1. First order rate constants for decomposition of EDTA and its metal chelates at $pH_0 = 10.4$ at various temperatures

| Metal ion | $t$ (°C) | $k_{obs}$ ($h^{-1}$) | Analytical method |
|---|---|---|---|
| None | 190 | 0.37 | Nmr |
| $Ca^{2+}$ | 310 | 0.27 | Titrimetric |
| $Ca^{2+}$ | 320 | 1.1 | Titrimetric |
| $Mg^{2+}$ | 307 | 0.50 | Titrimetric |
| $Fe^{2+}$ | 310 | 0.31 | Gas chromatographic |
| $Fe^{2+}$ | 310 | 0.30 | Spectrophotometric |
| $Zn^{2+}$ | 308 | 0.22 | Nmr |
| $Ni^{2+}$ | 310 | 0.075 | Nmr |

proved to be surprisingly inert, with only about one half the decomposition of the chelate observed at 310°C within the time limitation of the reaction employed.

The trend from the above results can be summarized in terms of a statement of relative rates in decreasing order:

$$\text{None (sodium salt)} > Mg^{2+} > Ca^{2+} \sim Fe^{2+} \sim Zn^{2+} \gg Ni^{2+}$$

The relative rates correlate approximately and inversely with the order of formation constants of the "normal" chelates, designated as $ML^{2-}$. These constants measured at room temperature for $Mg^{2+}$, $Ca^{2+}$, $Fe^{2+}$, $Zn^{2+}$, and $Ni^{2+}$ are respectively 8.8, 10.6, 14.3, 16.4, and 18.5 log units (6).

The inverse stability constant – rate correlation points to a mechanism whereby the predominant pathway near 310°C is a dissociation mechanism resulting in the liberation of the free EDTA anion. The resulting low concentrations of the free ligand may then undergo the type of degradation described previously (1, 2), as follows:

[1] $MEDTA^{2-} \rightleftharpoons M^{2+} + EDTA^{4-}$

[2] $EDTA^{4-} \rightarrow$ decomposition products

In [1] the very low concentration of $EDTA^{4-}$ formed is offered no protection and immediately undergoes rapid degradation. The degree to which equilibrium [1] is shifted is inversely proportional to the magnitude of the stability constant at 310°C. It would be very desirable to know precisely what these values are at 310°C but such information is not available and cannot be measured with techniques currently feasible. Therefore it is necessary to settle for the time being for equilibrium data taken at room temperature. The comparisons made above involve the assumption that the temperature coefficients of stability constants are sufficiently similar to maintain at high temperature the stability order observed at 25°C.

The correlation with inverse stability order described above is very rough and predicts considerably greater differences in decomposition rates of the Ca(II), Fe(II), and Zn(II) chelates on the basis of dissociation tendencies controlled by the stability constants alone (i.e., one would expect the chelates of the transition metal ions to be much more stable than the Ca(II) chelate). For the transition metal ions and the zinc(II) ion, the tendencies to liberate EDTA would be further increased by the tendencies of the metal ions to hydrolyze and precipitate from solution at pH 10. Thus the dissociation reactions may be written as in Table 2.

Through the use of the appropriate solubility products the logarithms of the equilibrium constants of reactions [3]–[5] at pH 10 show that there is considerable difference between the hydroxide precipitation tendencies of the Zn(II) and Fe(II)–EDTA chelates on one hand, and the Ni(II)–EDTA chelate on the other: a consequence of the much higher stability of the Ni(II) chelate. Thus metal hydroxide precipitation is expected to provide an additional driving force for EDTA chelate dissociation and on the basis of the proposed mechanism would increase the degradation rates of the Fe(II) and Zn(II) chelates much more than that of Ni(II), accounting more closely to the observed rate sequence, $Ca^{II} \sim Fe^{II} \sim Zn(II) \gg Ni(II)$.

*Catalysis by glass surface and phosphate ion*

In early experimental runs the use of a Pyrex liner in the autoclave resulted in considerable rate enhancement for calcium(II) and magnesium(II) over those shown in Table 1. For example at 310°C, $k_{obs} = 1.0\ h^{-1}$ for Ca(II)–EDTA, which is almost four times greater than the rate constant determined after the glass liner was removed. For magnesium(II) the rate enhancement was even more dramatic. A measurable rate could not even be obtained near 310°C.

Further investigations revealed that the presence of phosphate ion also enhanced the rates of degradation of EDTA chelates of Mg(II), Ca(II), and Zn(II) but not those of the other metal ions tested. The only explanation for such catalytic behavior is the formation of insoluble Ca(II) and Mg(II) silicates (probably adsorbed on the glass surface) and of Ca(II), Mg(II), and Zn(II) phosphates. Such

insoluble phases would free more EDTA from its metal complexes resulting in enhanced reaction rates. Reaction [6] illustrates the postulated ion exchange process for glass

$$[6] \quad CaL^{2-} \xrightarrow[\text{glass}]{H_2O} (CaSiO_4)\downarrow + L^{4-}$$

Since phosphate ion may be studied over a range of conditions, some details of phosphate catalysis were investigated for Ca(II)–EDTA degradation. Table 3 lists the results of rate measurements under various conditions in the absence and presence of phosphate. The data for this table were obtained from kinetic plots obtained by titrimetric analysis of residual EDTA as a function of time. A typical example is illustrated in Fig. 1.

While the initial concentration of the Ca(II)–EDTA chelate was maintained constant at 0.0133 *M*, the phosphate concentration was varied sufficiently to produce a significant variation in the observed pseudo first order rate constants. Although the intended temperature for the comparison was 230°C, the data in Table 3 show some deviation from this value as well as deviations in pH values.

Equations [7] and [8] describe the proposed rate law for Ca(II)–EDTA decomposition in these solutions and reaction [9] gives the concentration of the phosphate trianion in the experimental solution. Assuming that the phosphate does not become inaccessible to the reactants, then the slope of a plot of $k_{obs}$ vs. phosphate levels can be obtained by combining eqs. [9], [10], and [8] to give eq. [11].

The numerical value of $k'$ calculated from a least-squares plot is 69 ± 12. The large scatter results from lack of precise temperature and pH control. In spite of the uncertainties involved, there does appear to be a direct correlation between reaction rate and phosphate anion concentration.

*Reaction products*

*Ca(II)–EDTA degradation*. At the initial moderately high temperature, nonredox metal chelate reaction products are primarily the result of hydrolytic reactions, as has been clearly shown previously for uncomplexed EDTA (2). The calcium chelate, **1** (Scheme 1), in the presence of 1.5 equiv. of phosphate for example, after about four half-lives at 229°C undergoes the reaction sequence **1** → **2** → **3** + **4** indicated in Scheme 1, yielding predominantly a mixture of hydroxyethyliminodiacetic acid and iminodiacetic acid. A colorless solid found in the reaction mixture dissolves when treated with 6 *M* HCl, but without evolution of gas, and was identified as calcium phosphate (Fig. 2).

When phosphate is absent, the chelate solution must be heated at 300°C to induce decomposition,

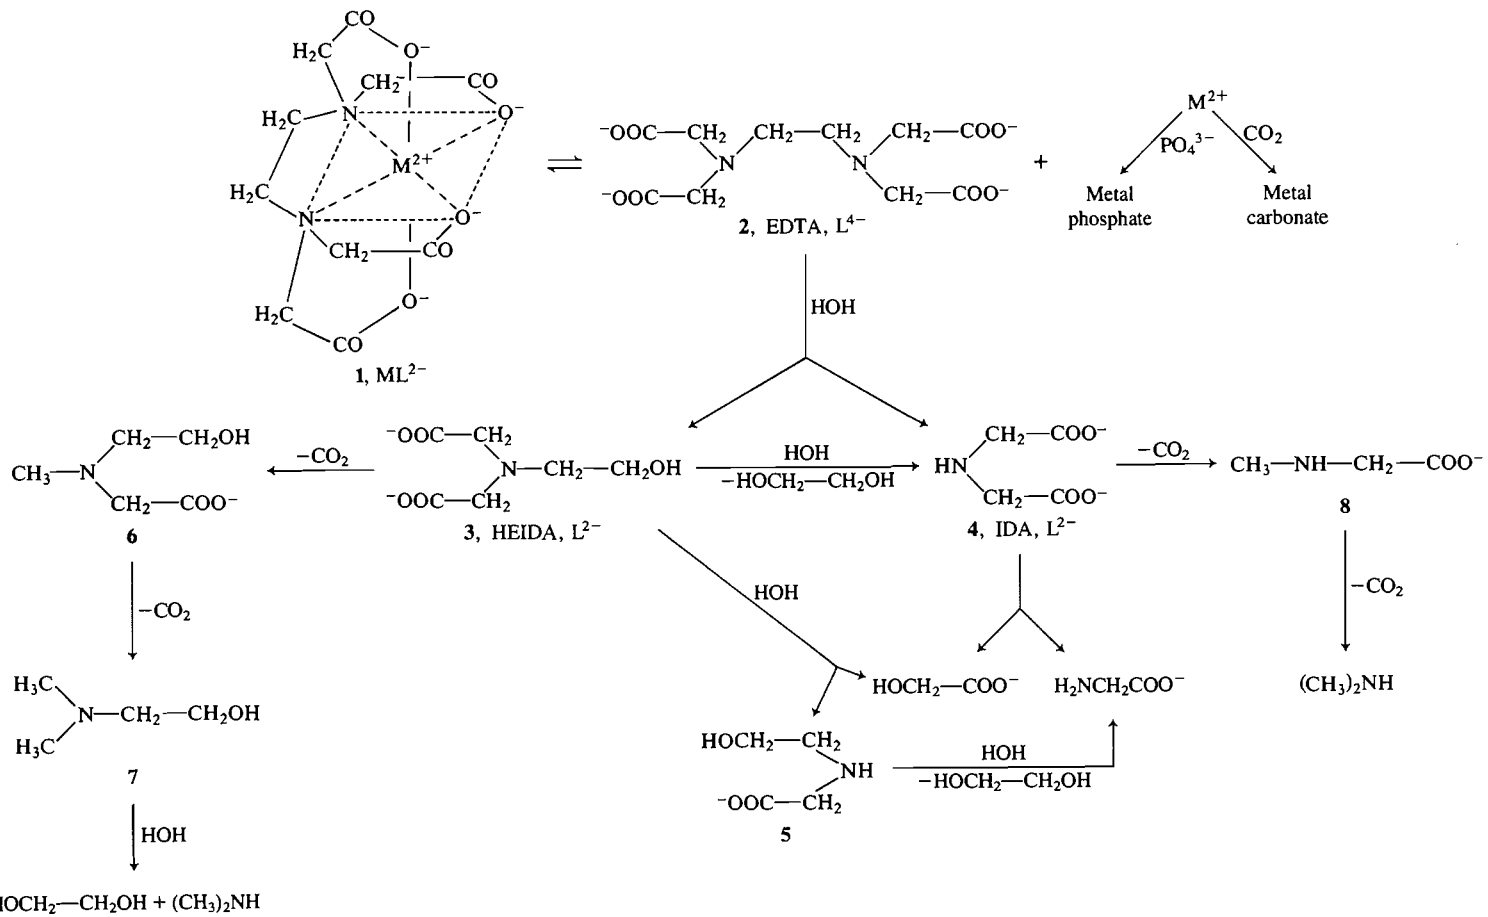
For personal use only.



SCHEME 1. Proposed degradation scheme for EDTA chelates of divalent metal ions in the vicinity of 300°C. Final reaction products: carbon dioxide, ethylene glycol; dimethylamine, glycine, glycolic acid (~300°C), **3**, hydroxyethyliminodiacetic acid (HEIDA); **4**, iminodiacetic acid (IDA) (200–230°C); intermediates (300°C) **3**, hydroxyethyliminodiacetic acid (HEIDA); **4**, iminodiacetic acid (IDA); **5**, *N*-hydroxyethylglycine; **6**, *N*-methyl-*N*-hydroxyethylglycine; **7**, *N*,*N*-dimethylethanolamine; **8**, *N*-methylglycine.

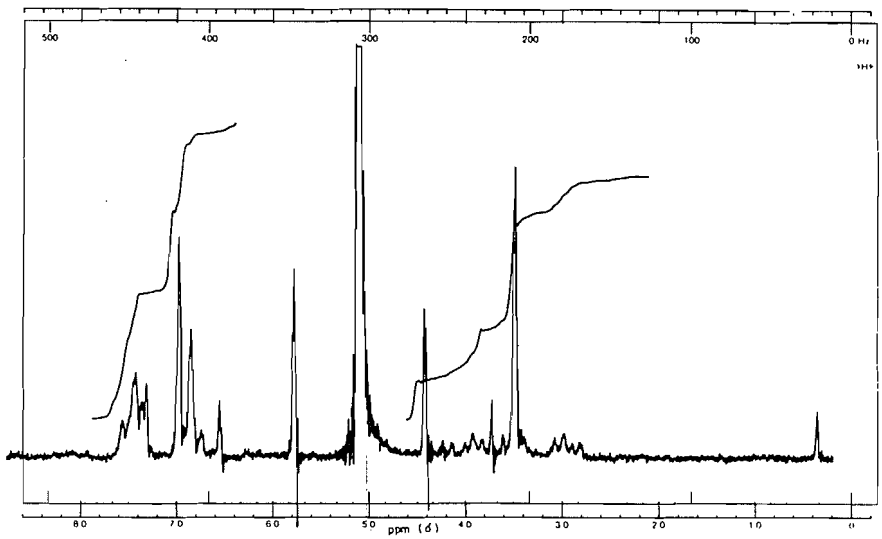


FIG. 2. Nuclear magnetic resonance spectrum of Ca(II)–EDTA solutions after thermal degradation showing the formation of IDA and HEIDA as sole reaction products at 230°C. The low field resonances belong to phenoxide which had been added as an internal standard.

and the degradation reactions proceed far beyond **3** and **4**. The predominant decomposition products found are: dimethylamine, ethylene glycol, and calcium carbonate. The carbonate was inferred from a test with dilute HCl, which produced the evolution of $CO_2$ from the colorless precipitate formed during the reaction. Ethylene glycol was detected by its nmr spectrum at 3.8 ppm, while dimethylamine was isolated in an acid trap from the volatile portion of the reaction. The acid solution was concentrated, made basic, and injected into a gc glass column. A peak at 1.0 min which was duplicated with standard dimethylamine confirmed the assignment.

*Other metal chelates*

Thermal degradation of a sample of Zn(II)–EDTA produced a reaction mixture characterized by the nmr resonances tabulated in Table 4. It is interesting that one of the products appears to be glycolic acid (3.62 or 3.73 ppm). There are at least two types of acetate methylene resonances. Glycine with a $—CH_2—$ resonance at 3.27 ppm, is definitely present. In addition ethylene diamine or substituted ethylenediamine may be present in view of the fact that a resonance was found at 2.80 ppm.

When the spectra of the Fe(II)–EDTA chelate and of the degradation products obtained were compared with those obtained from other metal EDTA chelates near 300°C, they were found to be generally similar, indicating that the distribution of reaction products does not vary much with the type of the metal ion present. A quantitative distinction has not been attempted from the experimental data available at this stage.

TABLE 4. Major nmr resonances of reaction products of Zn(II)–EDTA degradation at 300°C and pH 10

| Chemical shift (ppm)[a] | Assignment |
|---|---|
| 2.30 | $N—CH_3$ |

| 3.80 | Ethylene glycol |

[a]Measurements made in strongly basic $D_2O$ solution with a T-60 Varian nmr spectrometer. Chemical shifts relative to trimethylsilylpropanesulfonate.

In summary, tentative reaction pathways illustrated in the reaction scheme are suggested in order to provide a conceptual picture of the interrelationships of the various degradation products which have been shown to be formed in the present metal–EDTA chelate study.

In the complex reaction mixture formed, the metal ion probably distributes between the lower chelating ligands formed, principally IDA and HEIDA, and precipitated metal carbonate (or phosphate). The intermediate products **6** and **7** are inferred by consideration of the reactions known to take place in this system but have not directly been proved to be present in the reaction mixture. They do, however, lead to the known reaction products. The detection by nmr of the *N*-methyl and 2-hy-

For personal use only.

droxyethyl groups provides some further support for their presence.

Work currently in progress is directed at obtaining further details about the complex degradation reactions of EDTA metal chelates reported for the first time in the present paper. These studies involve the quantitative determination of effects of temperature and pH on the stabilities of the chelates of the primary intermediates, IDA and HEIDA, further amplification of the chemistry of phosphate and silicate catalysis, and the exploration of the thermal stabilites in aqueous solution of other aminopolycarboxylic acids and their metal chelates.

# Pyridazino[3,4,5-*de*]phthalazines. II.[1] Synthesis of nitrogen-substituted derivatives

JOHN E. FRANCIS,[2] KARL J. DOEBEL, PAULA M. SCHUTTE, ERNST F. BACHMANN, AND ROBERT E. DETLEFSEN

*Research Department, Pharmaceuticals Division, CIBA-GEIGY Corporation, Ardsley, NY 10502, U.S.A.*

Received September 8, 1981

JOHN E. FRANCIS, KARL J. DOEBEL, PAULA M. SCHUTTE, ERNST F. BACHMANN, and ROBERT E. DETLEFSEN. Can. J. Chem. **60**, 1214 (1982).

The synthesis of a wide variety of 9-substituted-3-oxo-3*H*-2,9-dihydropyridazino[3,4,5-*de*]phthalazines (**11**) was achieved by treatment of 3-substituted-3,4-dihydro-4-oxophthalazine-5-carboxylic esters (**10**) with hydrazine hydrate. These esters were prepared from 3-hydroxyphthalide-7-carboxylic acid (**7**) by two different routes. Under basic conditions, alkylation of 3-oxo-3*H*-2,9-dihydropyridazino[3,4,5-*de*]phthalazine (**1**) gave 9-substituted products. These undergo further alkylation at the 2-position. Some of them were converted to 3-chloro, 3-thiono, and 3-hydrazino compounds by standard methods. Dehalogenation of selected 3-chloro compounds or desulphurization of 3-thiono derivatives gave 1-substituted-1*H*-pyridazino[3,4,5-*de*]phthalazines (**22**), some of which were also prepared by direct alkylation of the parent heterocycle **2** under basic conditions. However, treatment of **2** or its 1-methyl homologue with methyl iodide resulted in products in which nitrogen attached to carbon had been attacked rather than the 1- or 9-position. Treatment of the acid chloride of 3,4-dihydro-4-oxophthalazine-5-carboxylic acid with methyl hydrazine led to 2-methyl-3-oxo-3*H*-2,9-dihydropyridazino[3,4,5-*de*]phthalazine (**21***a*) which was purified by cyanoethylation at the 9-position, recrystallization, and hydrazinolysis of the cyanoethyl group. Biological testing revealed that many of the compounds lowered blood pressure in animal models but none had a sufficient therapeutic ratio of activity vs. side effects to warrant clinical trial.

JOHN E. FRANCIS, KARL J. DOEBEL, PAULA M. SCHUTTE, ERNST F. BACHMANN et ROBERT E. DETLEFSEN. Can. J. Chem. **60**, 1214 (1982).

On a réalisé la synthèse d'une grande variété d'oxo-3 dihydro-2,9 3*H*-pyridazino[3,4,5-*de*] phtalazines (**11**) substituées en position 9 en faisant réagir les esters des acides dihydro-3,4 oxo-4 phtalazine carboxyliques-5 (**10**) substitués en position 3, avec l'hydrate d'hydrazine. On a préparé ces esters de deux façons différentes en partant de l'acide hydroxy-3 phtalidicarboxylique-7 (**7**). Dans des conditions basiques, l'alkylation de l'oxo-3 dihydro-2,9 3*H*-pyridazino[3,4,5-*de*] phtalazine (**1**) donne des produits substitués en position 9. Ces derniers subissent une alkylation plus poussée en position-2. On transforme certains de ces composés en composés chloro-3, thiono-3 et hydrazino-3 par des méthodes usuelles. Par déshalogénation de dérivés chlorés en position 3 ou par désulfurisation des dérivés thiono-3, on obtient des dérivés *1H*-pyridazino[3,4,5-*de*] phtalazines (**22**) substitués en position 1. On a préparé certains de ces composés par alkylation directe de l'hétérocycle **2** apparenté en milieu basique. Cependant, la réaction du composé **2** ou de son homologue méthylé en position 1 avec l'iodure de méthyle conduit à des produits dans lesquels l'attaque se fait de préférence au niveau de l'atome d'azote attaché au carbone plutôt qu'au niveau des positions 1 ou 9. La réaction du chlorure de l'acide dihydro-3,4 oxo-4 phtalazine carboxylique-5 avec la méthylhydrazine conduit à la méthyl-2 oxo-3 dihydro-2,9 3*H*-pyridazino[3,4,5-*de*] phtalazine (**21***a*) que l'on a purifiée par cyanoéthylation en position 9, recristallisation et hydrazinolyse du groupe cyanoéthyle. Les tests biologiques ont révélé que plusieurs de ces composés abaissent la pression sanguine chez les animaux choisis à titre de modèles, mais qu'aucun d'eux n'a un rapport thérapeutique suffisant par rapport aux effets secondaires pour justifier des essais cliniques.

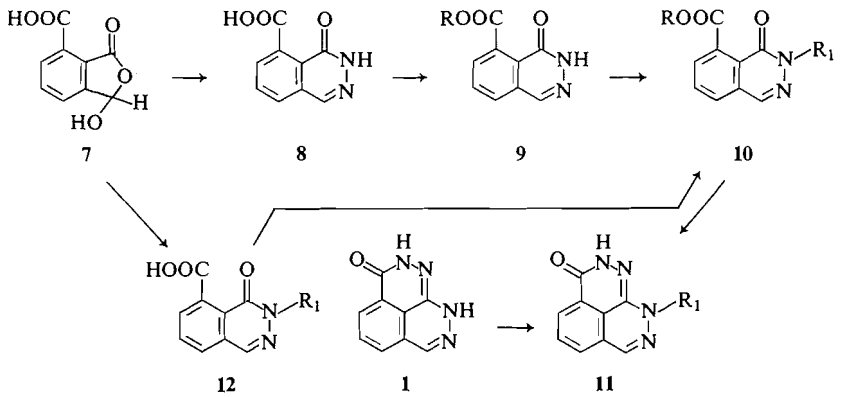

SCHEME 1

densed triazoles which showed no hypotensive activity (2, 3). The first isolated metabolite of hydralazine was not the *N*-acetyl derivative **4***b* as first reported (4) but rather the hydrate of 3-methyl-[1,2,4]-triazolo[3,4-*a*]phthalazine (**6**) (2, 5). The drug todralazine (ecarizine) **4***c*, marketed by Polfa–Pabianice as Binazin®, illustrates that an acylated derivative, albeit a urethane, shows hydralazine-like activity (6). In initial tests, compound **1** showed no activity, but we attributed this possibly to poor absorption. Accordingly, we searched for methods of introducing substituents on one or more of the nitrogens of **1** as a route, not only to a variety of readily absorbed derivatives of **1**, but also to examples of *N*-substituted derivatives of **2** and **3**, thus allowing further exploration of the tricyclic ring system as a possible drug template.

The derivatives of **1** which received our greatest attention were those substituted at the 9-position since they are direct analogs of **1** and potential precursors of *N*-substituted derivatives of **2** and **3**. They were prepared by pathways illustrated in Scheme 1.

As described previously (1), the key intermediate **7** was converted to the phthalazinone acid **8** with aqueous hydrazine in alcohols or acetic acid at reflux. This acid was then esterified to **9**, either the methyl ester **9***a* or the ethyl ester **9***b*, via the acid chloride. Alkylation of the amide nitrogen was accomplished with an alkyl halide in the presence of aqueous sodium hydroxide in an alcohol, or with sodium methoxide in dimethylsulphoxide, or, in two examples, with sodium amide in dimethylsulphoxide. The resulting ester was heated under reflux with aqueous hydrazine to afford the target **11**. Although this route was suitable for alkyl or aralkyl substituted compounds, a more versatile route to **10** involved the reaction of **7** with a monosubstituted hydrazine in alcohol, acetic acid, or water to yield the acid **12** which was then esterified to **10**. This method was used to prepare alkyl-, aryl-, and heterocyclic-substituted products and though often used for the synthesis of 2-aryl-1(2*H*)-phthalazinones (7) it is less commonly illustrated for 2-alkyl-1(2*H*)-phthalazinones (8). Since we have used this method extensively, further explanation for our structure assignments is in order. From 1(2*H*)-phthalazinone, four *N*- or *O*-methylated products can be obtained, all readily differentiated by melting point (9–15). Their structures were only recently confirmed and further characterized by spectroscopy (15–17) and mass spectrometry (18). The only reported method of preparing the *O*-methylated derivative **13** requires conversion of the hydrazide to 1-chlorophthalazine followed by sodium methoxide treatment (9, 10). *O*-Alkylated products are clearly ruled out in our examples since they would react with hydrazine to form structure **1**. In addition, more than two dozen examples of structures **12** (Table 1) and **10** (Table 2) showed strong ir absorption in the range 1640 to 1705 $cm^{-1}$ (Nujol). In the model compounds, it is reported that **14** and **15** show peaks in this region whereas **13** shows two peaks out of this range at 1550 and 1590 $cm^{-1}$ (16). Preparation of the inner salt **15** appears to require a strong alkylating agent under vigorous conditions followed by removal of the proton with base (16) whereas alkylation of the preformed anion or alkylation in the presence of base clearly favours formation of **14** (15, 19–21). The inner salt **15** is converted photochemically in water to the amide **14** but, with acetonitrile as

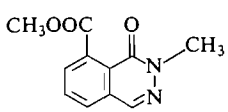
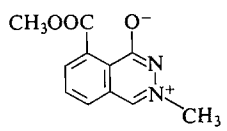
solvent, the intermediate **16** was isolated, which was readily converted to **14** in acid or water (15). The carbonyl frequency of **16** at 1750 $cm^{-1}$ is out of the range of our phthalazinones. Conversion of **7** to **12***a* (**12**: $R^1 = CH_3$) gave the same product as obtained by saponification of **10***b* (**10**: $R = CH_2CH_3$, $R^1 = CH_3$). The synthesis of **14** from phthalaldehydic acid and methylhydrazine is apparently unreported (22)[4] although 2-(dibromomethyl)-benzoic acid, a phthalaldehydic acid precursor (23), reacts with methylhydrazine in ethanol to give **14** in 75% yield (24). We reacted methylhydrazine with phthalaldehydic acid in refluxing acetic acid and obtained **14** in 81% yield. For further confirmation of the structure, we reacted **9***a* with methyltosylate in refluxing chlorobenzene overnight to obtain the tosylate salt from which the inner salt **17**, an isomer of **10***a* (**10**: $R = R^1 = CH_3$), was obtained by reaction with zinc hydroxide. Our phthalazinone esters (Table 2) display a singlet in the $^1$Hmr spectrum in the range 8.55–8.75 δ (DMSO-$d_6$) whereas **17** has a singlet at slightly lower field (8.8 δ) and the tosylate salt a peak well downfield at 10.2 δ. Structure assignment based on the methyl signals is not well defined as it is for **14** and **15**, since all signals in **10***a* and **17** fall in the range 3.65–4.1 δ. More convincing evidence for the structure of **17** is based on infrared analysis. Structure **10***a* showed strong carbonyl absorption at 1730 $cm^{-1}$ (ester) and 1650 $cm^{-1}$ (hydrazide) in Nujol, whereas **17** showed a strong ester band at 1730 $cm^{-1}$ and bands at 1610 and 1555, not attributable to a cyclic hydrazide. Since the structures of **10** and **12** are now established, the structure assignment of **11** must follow. Many examples of **11** were prepared by direct alkylation of **1**, thus supporting the isomer with H at C-9 as the most reasonable depiction of the basic building block **1**.



**10***a*

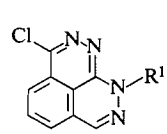


**17**

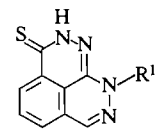
The conversion of **9** to **11** was done in some examples without purification of **10**, generally in low overall yields. Fortunately, the tricyclic structures were well separated from impurities in an aqueous work-up from which the target compounds separated as bright yellow recrystallizable solids. This ease of preparation was also helpful in those examples prepared from **1**. The anion of **1** was preformed with sodium methoxide in dimethylsulphoxide and the alkyl halide added, whereupon the target compounds were obtained in 18 to 88% yields (Table 3). In most examples, no attempts were made to optimize yields although example **11***a* (**11**: $R^1 = CH_3$) was rerun several times by different routes. It was prepared from 3-dibromomethylphthalic anhydride (1) via **8**, **9***a*, and **10***a* in 74% overall yield, via **12***a* and **10***a* in 33% yield, and in two steps via **1** in 18% yield.

As observed with **1**, the 9-substituted compounds **11** could be converted to the corresponding 3-chloro compounds **18** (Table 6), usually with a phosphoryl chloride/phosphorous pentachloride mixture.

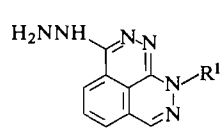
Reaction of **11** with phosphorous pentasulphide in pyridine led to structures of type **19**, as exemplified for $R^1$ = methyl (**19***a*), phenyl (**19***b*), and *N*-morpholinoethyl (**19***c*). Treatment of **18** or **19**



**18**



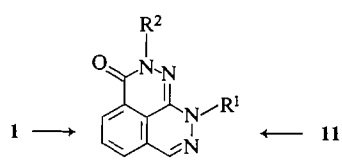
**19**



**20**

with hydrazine hydrate produced the hydrazines **20**, illustrated for $R^1$ = methyl (**20***a*), phenyl (**20***b*), and benzyl (**20***c*). Since most tricyclic compounds were soluble in dimethylsulphoxide, the $^1$Hmr spectra were almost all run in DMSO-$d_6$. We noticed in all examples of **19** and in the spectra of **20***c* and the benzylidene hydrazone of **20***b* that the proton at C-4 appeared as a doublet of doublets shifted downfield from the other aromatic protons. This did not appear in any examples of **11** run in DMSO-$d_6$, nor in **20***a*, run in $D_2O$. However, **11***j* (**11**: $R^1 = CH_2CH_2CH_2C_6H_5$) was soluble in $CDCl_3$ and this spectrum showed the shifted doublet of doublets centred at 8.35 δ.

Inferior yields of **11** via direct alkylation of **1** were due in part to a second alkylation occurring at the 2-position. One such compound, **21***f* (**21**: $R^1 = R^2$ = *N*-morpholinoethyl) (Table 4), was isolated as a by-product of the synthesis of **11***g* (**11**: $R^1$ = *N*-morpholinoethyl). Generation of the anion of **11** with sodium methoxide followed by alkyl halide



**21**

[4]Several Russian references were unavailable to us in the original form and their abstracts do not mention the method of synthesis of **14**.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

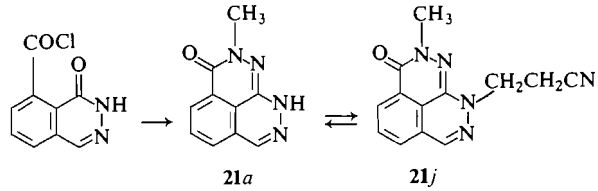
produced other examples of **21**, in which $R^1$ and $R^2$ could be the same or different, in yields as high as 95%. When **1** was treated with two moles of sodium methoxide followed by two moles of alkyl halide, the yields of **21** were generally low with **11** as the principle by-product. The structure assignment of **21** is based on a strong carbonyl band in the infrared in the range 1620–1645 $cm^{-1}$ (Nujol). Also, a sharp singlet at 7.85–8.15 δ in the $^1$Hmr spectrum corresponds to the proton at C-7, comparable to that in examples of **11**, where the range is 7.8–8.1 δ. As observed for **11**, structure **21***b* (**21**: $R^1 = R^2 = CH_3$) shows a doublet of doublets shifted downfield corresponding to the proton at C-4 in $CDCl_3$ but not in DMSO-$d_6$.

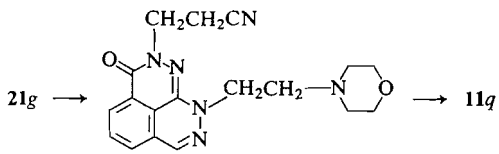
In contrast to the usual alkylation, cyanoethylation of **1** proceeds in high yield. With at least two (preferably three) moles of acrylonitrile in 50% aqueous pyridine with a catalytic amount of Triton B, **21***g* (**21**: $R^1 = R^2$ = cyanoethyl) was obtained in yields exceeding 90%. Attempted monocyanoethylation of **1** produced a mixture of **21***g* and **1** and no detectable amount of the expected product. Since cyanoethylation of **9***a* followed by hydrazine hydrate produced only **1** we were frustrated in our attempt to obtain the monocyanoethyl compound, but instead discovered a method for removing the cyanoethyl group cleanly in our series. This was confirmed by smooth conversion of **21***g* to **1** with hydrazine hydrate. The process was not simply a matter of base catalysis, since excess Triton B in one experiment produced partial hydrolysis of one of the cyanoethyl groups of **21***g* to a carboxyethyl group with no loss of the side chain. Acid stability of the group was also evident, since 80% sulphuric acid converted **21***g* to the diamide **21***i* (**21**: $R^1 = R^2$ = carbamoylethyl) in moderate yield. Under the same cyanoethylation reaction conditions, crotononitrile reacted sluggishly with **1** to give a poor yield of the dialkylated product **21***h* and a considerable recovery of starting material.

The decyanoethylation process was used advantageously in the synthesis of the only derivative of **1** in which only the 2-position was substituted. The acid chloride of **8** was reacted with methylhydrazine in hot chlorobenzene in an effort to prepare **21***a* (**21**: $R^1$ = H, $R^2 = CH_3$). Since the reaction of methylhydrazine with acid chlorides or anhydrides to produce mainly 1-acyl-1-methylhydrazines is well documented (25), we obtained the desired product, but contaminated with an impurity not readily removed by crystallization. Thus the crude product was cyanoethylated to **21***j*, recrystallized, and decyanoethylated with hydrazine hydrate to yield pure **21***a*.



**21***a* **21***j*

Removal of the cyanoethyl group was not only achieved with hydrazine hydrate but also in the following example. When **21***g* was treated with morpholinoethyl chloride in the presence of sodium methoxide in dimethylsulphoxide, the cyanoethyl group at the 9-position was replaced by morpholinoethyl in 35% yield. Proof of the assigned structure **21***e* rested on its conversion to **11***q* by treatment with hydrazine hydrate. Since the yield of **21***e* was mediocre and no attempt was made to isolate other products from the mother liquor, we cannot state that replacement occurs exclusively at position 9. No detailed study of the reaction was made, since products such as **21***e* and **11***q* could be prepared by more straightforward methods. However, the illustrated transformations might find application in the preparation of derivatives of other nitrogen heterocycles.



**21***g* → **21***e* → **11***q*

Derivatives of **2**, i.e. **22**, were prepared by dehalogenation of chloro compounds **18**, by desulphurization of **19**, and by direct alkylation of the parent heterocycle **2** (Table 5). Dehalogenation was achieved with red phosphorous in 47% hydriodic acid and desulphurization was done with Raney nickel. Direct alkylation took place when the anion was first generated with base. Cyanoethylation of **2**, as described for **1**, gave the desired product **22***e* (**22**: $R^1$ = cyanoethyl) although in only 24% yield after purification. Treatment of **22***e* with 10% aqueous sodium hydroxide at reflux followed by acidification gave the acid **22***f* (**22**: $R^1$ = carboxyethyl) in 82% yield. Generally the yields on direct alkylation were poor and required column chromatography before recrystallization. From the few

examples explored it appears that dehalogenation of **18** is the best route to these structures.

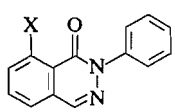
In the course of the work, we attempted to build structures **22** as we had done for **11**, in this case by generation of an aldehyde function in the 8-position of a 2-substituted 1(2*H*)-phthalazinone. Attempts to reduce esters or acid chloride functions at the 8-position to an aldehyde such as **23** or an alcohol such as **24** with metal hydrides by standard literature methods gave, at best, low yields of the expected product. In one instance, the reason for the poor yield was clear. Lithium borohydride, a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

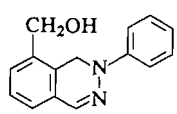
reagent not noted for reducing amides (26) reduced the ester **12***d* to the amino alcohol **25** when used in excess. This is reminiscent of the overreduction of esters and lactones with sodium borohydride in the work of Wenkert *et al.* (27) in which ready intramolecular hydride transfer to a neighbouring carbonyl group occurred from an intermediate obtained from a newly formed primary alcohol combined with excess borohydride. A similar rationale could account for the reduction product **25** and the poor yields in our other attempts.

Comparison of **22***a* (**22**: $R^1 = CH_3$) with **2** will serve to illustrate the significant changes in spectral properties caused by alkylation at the 1-position. The uv spectra are almost identical in neutral and acidic ethanol. The spectrum of **2** undergoes a bathochromic shift with base (1) whereas **22***a* remains unchanged. The broad ir absorption at 2800–2200 $cm^{-1}$ in **2** is missing from the spectrum of **22***a* in Nujol. In the $^1$Hmr spectra (DMSO-$d_6$), the low field exchangeable proton of **2** is replaced in **22***a* by a sharp singlet at 3.7 δ due to the *N*-methyl. The aromatic patterns and shifts are identical but the equivalent vinyl protons in **2** are replaced by singlets at 8.0 δ (H at C-3) and 8.8 δ (H at C-7) in **22***a*. The latter signal is missing in 7-substituted compounds such as **18**. The methanesulphonate of **2** shows a singlet corresponding to the two vinyl protons at 8.8 δ ($D_2O$) whereas **22***a* in DCl/$D_2O$ shows separate singlets at 8.9 δ and 9.1 δ.

Reaction of **2** with methyl iodide or ethyl iodide gave stable quaternary salts, but when the methiodide was treated with freshly prepared silver oxide in aqueous methanol, a red solid was obtained, not identical to **22***a*. This red solid formed a yellow methiodide, mp 313–314°C, isomeric with the methiodide derived from **22***a*, mp 207–208.5°C. The methiodide of **22***a* showed $^1$Hmr signals for methyls at 3.8 δ and 4.3 δ (DMSO-$d_6$) and proton singlets at 8.6 δ and 9.7 δ. Since the position of one methyl group is not in doubt, the lower melting methiodide must be structure **26** or, less likely due to steric

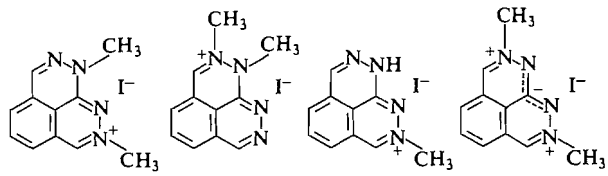


**23** X = CHO
**24** X = $CH_2OH$



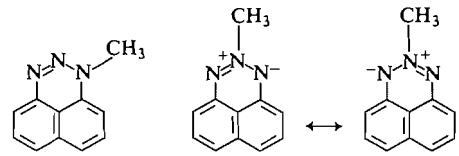
**25**

crowding, **27**. The higher melting methiodide showed equivalent methyl signals at 4.1 δ and a singlet corresponding to two identical vinyl protons at 9.0 δ with an aromatic multiplet centred at 8.0 δ. The spectrum indicates a molecule symmetrical about the C(5)—C(9b)—C(9a) axis. Assignment of structure **28** to the methiodide of **2** and structure **29**



**26** **27** **28** **29**

to the higher melting methiodide derived from **28** accounts for the observed spectral data. The $^1$Hmr patterns of **26** and **28** are virtually identical except for the methyl singlet at 3.8 δ in **26** in place of the broad exchangeable singlet at 13.4 δ in **28**. These results are reminiscent of the two methylation products of 1*H*-naphtho[1,8-*de*]triazine, namely, the expected product **30** and the 2-methylated derivative **31** (28).



**30** **31**

The unusual inner salt **29** is related to the aminimides (29, 30) except that the ammonium imine is stabilized in a

system contained in a flat molecule further stabilized by ring current.

The relative ease with which the phthalazinone esters react with hydrazine to form the tricyclic system deserves comment, particularly in the examples where the nitrogen is substituted. One would not expect to prepare an amidrazone by reaction of an amide with hydrazine, especially a non-enolizable amide. If the reaction involved initial conversion of the ester to the hydrazide followed by intramolecular cyclization, we would have expected to isolate some bicyclic hydrazides, though admittedly we were not looking for them. The reaction of methylhydrazine with the acid chloride of **8** was designed to create a hydrazide in the first stage of the synthesis. This *enolizable* phthalazinone was ring closed only under vigorous conditions and not cleanly. The synthesis of the parent heterocycle **2**, attempted under a variety of conditions (1), suggests that the initial formation of the phthalazinone hydrazone **32** followed by intramolecular attack on the enolizable carbonyl of the phthalazinone moiety is not the major reaction pathway, since most ring closure methods resulted in either intermolecular azine formation or no reaction. Ring closure occurs in nonaqueous highly polar media only under forcing conditions to a

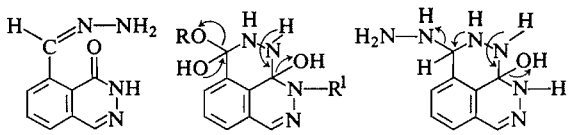
small extent. On the other hand, dilute aqueous hydrazine at reflux was an excellent medium for conversion of **32** to the tricyclic system in good yield and purity. Since hydrazine is a strong nucleophile and the formation of the tricyclic system seems favoured by moderately high dilution in a hydroxylic solvent (water or water/alcohol mixtures) we suggest that the mechanism for the formation of **2** from **32** involves formation of a transient intermediate **34**, which stabilizes itself by



**32** **33** **34**

elimination of hydrazine and water. Similarly, the formation of **11** from **10** involves formation of an intermediate such as **33** which undergoes a double elimination depicted by the arrows to form the highly resonance-stabilized tricyclic system. Furthermore, the distance between the carbonyl carbon atoms of **10** appears optimal for allowing nucleophilic attack by hydrazine to form **33** and subsequently **11**.

## Biological results

Derivatives of the tricyclic system were tested for blood pressure lowering activity, primarily in the acute anaesthetized cat via intraduodenal administration. Secondary screening was done usually in the Goldblatt dog (31). Other models were also used in secondary screening.

Since **3**(*GPA 1595*) (1) was highly active, it was not surprising to find examples of structure **20** also active. The best of the three examples by far was **20***a*, coded as *GPA 2079*. This was highly active in the anaesthetized cat, Goldblatt dog, and the unanaesthetized normotensive dog. Since it was more toxic in mice than *GPA 1595*, it was not further pursued. Many of the 9-substituted derivatives of **1** lowered blood pressure in the anaesthetized cat. The first one to be studied in depth, **11***q* (*GPA 2265*), was also active in the anaesthetized dog but caused emesis in unanaesthetized dogs, cats, and monkeys. Most of the 9-pyridylalkyl compounds were active and the one most thoroughly investigated was **11***w* (*GPA 3166*). This compound was active in anaesthetized cats and dogs, the Goldblatt dog, the DOCA rat, and the neurogenic hypertensive dog (32) with no indication of tolerance on repeated dosage. The drug showed tachycardia in the anaesthetized animals and the Goldblatt dog, but not in the neurogenic dog which suggested that the tachycardia was reflex in origin. Lack of significant autonomic effects suggested a peripheral vasodilator mechanism of action. Further studies in toxicology and pharmacology revealed an unacceptable safety margin and the compound was not pursued clinically. The 9-alkyl and 9-aralkyl deriv-

For personal use only.

atives of **1** were generally poorly active in the cat, except for the *trans*-cinnamyl derivative **11***k* (*GPA 3095*). This was moderately active in the anaesthetized cat, Goldblatt dog, neurogenic dog, and spontaneous hypertensive rat without tachycardia except slightly in the anaesthetized cat. It was inactive in the anaesthetized dog, DOCA rat, and normotensive rat. Even with micronized preparations, absorption was poor as determined by blood level studies in rats. Since pharmacological dose–response results were variable during repeated testing, possibly due to erratic absorption, the compound was not further investigated. The phthalazinone acids and esters were tested for antiinflammatory activity. The most promising of these, acid **12***j* (*GPA 3273*) was active in the anticarrageenin rat paw test with little ulcerogenic potential, but it failed in secondary screening in the 14-day established adjuvant arthritis screen. None of the compounds in Tables 4, 5, and 6 were sufficiently active in the primary screen to warrant further study.

## Experimental

Melting points (uncorrected) were determined on a Thomas–Hoover capillary apparatus or, if above 250°C, on a Reichart hot stage apparatus. Infrared spectra (ir) reported in wave numbers ($cm^{-1}$) over the 3500–1500 $cm^{-1}$ range for the principal peaks in Nujol (N) or chloroform ($CHCl_3$) were measured on a Perkin–Elmer model 137 calibrated with respect to the 1602 $cm^{-1}$ band of polystyrene or on a model 457 grating instrument. Proton magnetic resonance spectra ($^1$Hmr) were measured on a Varian EM-390 spectrometer in DMSO-$d_6$ unless otherwise stated, with peaks reported in ppm relative to tetramethylsilane as internal standard. Ultraviolet spectra (uv) were recorded on a Cary 14B spectrophotometer in nanometers with ε values in parentheses. All new compounds had microanalytical data for C, H, and N fitting within ±0.3. Additional elements are reported.

*2-Methyl-1(2*H*)-phthalazinone (**16**)*

A mixture of phthalaldehydic acid (18 g) and glacial acetic acid (100 mL) was treated with methyl hydrazine (7.6 mL) and the whole stirred at reflux under nitrogen for 18 h. The resulting solution was concentrated to dryness under water vacuum and the residue taken up in methanol (30 mL), treated with water (30 mL), and refrigerated. After 15 h the precipitated solid was collected, washed with methanol, and air dried. The product (15.5 g, 81%, mp 111–113°C) was recrystallized from cyclohexane (800 mL) to afford pure white crystals, mp 111.5–113°C (14.0 g). Literature mp values: 116°C (20); 111–112°C (10); 105–108°C (14); 114°C (9a); 112–114°C (17, 19). Infrared (N) ν: 1637 (C=O) $cm^{-1}$ (lit. (14) ν: 1645 $cm^{-1}$); $^1$Hmr: 3.8 (s, $CH_3$), 7.8–8.5 (m, 4*H*, aryl), 8.5 (s, vinyl *H*); literature (20) values: 3.71 (s, 3*H*), 8.31 (s, *H*), 7.65–8.30 (m, 4*H*).

*Synthesis of 3-substituted-3,4-dihydro-4-oxophthalazine-5-carboxylic esters **10** (Table 2)*

*Method A. From **9** with alkyl halide/alcohol/aqueous sodium hydroxide*

Methyl 3,4-dihydro-4-oxo-5-phthalazine carboxylate (**9***a*, 2.04 g (1)) was suspended in a solution of methanol (20 mL) and methyl iodide (0.75 mL), treated with 4*N* aqueous sodium hydroxide (2.3 mL), and heated under reflux for 1 h. It was quenched in ice, extracted with benzene, and the benzene extract dried ($Na_2SO_4$) and concentrated to dryness at reduced pressure. The residual solid (1.9 g, mp 113–119°C) was recrystallized from water to constant mp (3 recrystallizations) to afford pure **10***a*, mp 125–126°C; ir ($CHCl_3$): 1740, 1650, 1595; $^1$Hmr: 3.65 (s, $CH_3$—), 3.85 (s, $CH_3$—), 7.75–8.2 (m, 3*H*, aryl), 8.5 (s, vinyl *H*).

*Method B. From **12** via the acid chloride*

3-Methyl-3,4-dihydro-4-oxo-5-phthalazine carboxylic acid (**12***a*, 52 g) was suspended in a mixture of thionyl chloride (125 mL) and chlorobenzene (550 mL) and heated 3 h at reflux. The mixture was cooled and the precipitate collected, washed with benzene, and air dried to give the acid chloride (28.3 g, mp 185–190°C). Evaporation of the filtrate and trituration of the residue with hexane gave a second crop (23.4 g, mp 182–186°C) suitable for the next step. The acid chloride (15 g) was stirred at reflux in absolute ethanol (300 mL) during 18 h, cooled, and the white solid collected, washed with ethanol, and dried to afford the pure ester **10***b* (7.8 g, mp 103–104.5°C); ir (N): 1730, 1650, 1595; $^1$Hmr: 1.3 (t, $CH_3$—C), 3.8 (s, $CH_3$—N), 4.4 (q, $CH_2$), 7.8–8.15 (m, 3*H*, aryl), 8.6 (s, vinyl *H*).

*Method C. From **9** with an alkyl halide/sodium methoxide/dimethyl sulphoxide*

A mixture of methyl 3,4-dihydro-4-oxo-phthalazine-5-carboxylate (**9***a*, 40.8 g), sodium methoxide (12 g), and dimethylsulphoxide (300 mL) was treated dropwise under stirring with 3-chloropropenylbenzene (40 g) in dimethylsulphoxide (50 mL). The mixture was stirred at 80°C for 4 h under moisture exclusion and then quenched in ice and excess 2*N* HCl. The brownish solid was collected, washed with water, and extracted with chloroform. The dried ($Na_2SO_4$) extract was concentrated to dryness, taken up in a minimal quantity of hot methanol, treated with charcoal, and filtered. On cooling, pale yellow crystals (42.3 g, mp 116–121°C) were obtained. One crystallization from methanol and two from chloroform–hexane gave pure **10***h* as white crystals, mp 123–124°C; ir (N): 1730, 1650; $^1$Hmr: 3.95 (s, $CH_3$—O), 4.95 (d, $CH_2$—, $J$ = 5), 6.5 (dt, *CH*, $J$ = 5, 16), 6.7 (d, *CH*, $J$ = 16), 7.25–7.65 (m, 5*H*, benzene ring), 7.85–8.2 (m, 3*H*, aryl), 8.65 (s, vinyl *H*). The coupling constants indicate a *trans* double bond.

*Method D. From **9** with an alkyl halide/lithium amide/dimethylsulphoxide*

To a solution of methyl 3,4-dihydro-4-oxo-phthalazine-5-carboxylate (**9***a*, 40.8 g) in dry dimethylsulphoxide (100 mL) under nitrogen was added lithium amide (5 g) and the mixture stirred 2 h at ambient temperature. Additional lithium amide (5 g) was added followed by 2-picolyl chloride hydrochloride (32.8 g) portionwise. The resulting dark solution was stirred 3 h at ambient temperature under nitrogen, poured into water (1.5 L), and refrigerated 3 days. The precipitated product (35 g, mp 109–112°C) was dissolved in a minimal quantity of methanol, treated with an equimolar amount of methanesulphonic acid and the methanesulphonate salt of **10***l* purified by recrystallization from ethanol, mp 170.5–173°C; ir (N) ν: 1660, 1735 (C=O); $^1$Hmr: 2.55 (s, $CH_3$—S), 3.9 (s, $CH_3O$), 5.75 (s, $CH_2$), 7.8–9.1 (m, 7*H*, aryl + pyridyl), 8.65 (s, vinyl *H*), 14.95 (s, O*H*, exchangeable in $D_2O$).

*Ethyl-3,4-dihydro-4-oxo-phthalazine-5-carboxylate (**9**b)*

To a vigorously stirred solution of thionyl chloride (40 mL) in chlorobenzene (200 mL) was added 3,4-dihydro-4-oxo-phthalazine-5-carboxylic acid (1) (30.4 g) and the whole heated 4 h at reflux under moisture exclusion. The solid was collected on a ground glass filter, washed with benzene, pressed dry, and then transferred to a round bottom 1 L flask containing absolute

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

ethanol (305 mL). The mixture was heated at reflux under moisture exclusion 18 h, treated hot with activated charcoal, and filtered. On cooling, off-white crystals were obtained (26.1 g, mp 170–171.5°C) identical to the product obtained by a different route (1) as shown by ir, $^1$Hmr, and mmp.

*Synthesis of 3-substituted-3,4-dihydro-4-oxo-5-phthalazinone carboxylic acids* **12** *(Table 1)*

*Method A. From 3-hydroxyphthalide-7-carboxylic acid and a monosubstituted hydrazine*

A mixture of phenylhydrazine (3.6 mL), 3-hydroxyphthalide-7-carboxylic acid (1) (5.82 g), and glacial acetic acid (100 mL) was stirred 18 h at reflux, concentrated to dryness at reduced pressure, triturated with cold methanol, and collected. The crude acid **12***b* (6.97 g, mp 197–199°C) was recrystallized from benzene to afford pure white crystals, mp 197–198°C; ir (N): 2680, 1705, 1665, 1590; $^1$Hmr: 7.4–7.85 (m, 5*H*, phenyl), 7.9–8.25 (m, 3*H*, aryl), 8.7 (s, vinyl *H*), 13.4 (s, O*H*).

*Method B. From 3-hydroxyphthalide-7-carboxylic acid and a substituted hydrazine salt*

To a stirring solution of *p*-fluorophenylhydrazine hydrochloride (18 g), anhydrous sodium acetate (14.2 g), and glacial acetic acid (1.3 L) was added 3-hydroxyphthalide-7-carboxylic acid (19.4 g) and the mixture stirred 18 h at reflux. The mixture was filtered hot and the filtrate concentrated to one-third volume at reduced pressure and diluted with water. The resulting precipitate (24.2 g, mp 228–234°C) was twice recrystallized from ethyl acetate to afford pure white crystals of **12***c*, mp 234–237°C; ir (N): ~2600, 1695, 1655, 1585; $^1$Hmr: 7.3–8.2 (m, 7*H*, aryl), 8.7 (s, vinyl *H*), 13.3 (s, O*H*). *Anal.* calcd. for $C_{15}H_9N_2O_3F$: F 6.69; found: F 6.63.

*Method C. By hydrolysis of* **10**

A mixture of methyl 3-phenylpropyl-3,4-dihydro-4-oxo-phthalazine-5-carboxylate (**10***m*, 33 g, bp 225°C/2 Torr, prepared from **9***a*) and 2 *N* sodium hydroxide (500 mL) was stirred at reflux for 3 h, cooled, and poured into water (2.5 L). The mixture was extracted with chloroform and the aqueous layer was evaporated at reduced pressure to one-third volume and acidified with 6 *N* HCl under cooling. The mixture was extracted with chloroform, the chloroform layer dried ($Na_2SO_4$), and the material obtained as an oil by evaporation of the solvent at reduced pressure. It was stirred in ethanol at −8°C for 12 h and the solid which formed (**12***i*, 19.7 g, mp 110–112°C) was recrystallized once from methanol and once from benzene–hexane to afford the pure acid (14.2 g), mp 115–117°C; ir (N): ~1910, 1690; $^1$Hmr: 2.15 (m, C*H*$_2$), 2.6 (q, C*H*$_2$, *J* = 7), 4.2 (t, C*H*$_2$, *J* = 7), 7.25–7.45 (m, 5*H*, phenyl), 7.8–8.15 (m, 3*H*, aryl), 8.6 (s, vinyl *H*), 13.35 (s, O*H*).

*Synthesis of 9-substituted-3-oxo-3*H*-2,9-dihydropyridazino-[3,4,5-*de*]phthalazines* **11** *(Table 3)*

*Method A. From* **10**

A mixture of methyl 3-methyl-3,4-dihydro-4-oxophthalazine-5-carboxylate (**10***a*, 95.3 g), hydrazine hydrate (1650 mL), and water (400 mL) was stirred at reflux for 66 h. The mixture was allowed to cool to room temperature and 9-methyl-3-oxo-3*H*-2,9-dihydropyridazino[3,4,5-*de*]phthalazine (**11***a*) was collected, washed with water, and oven dried at reduced pressure. The bright yellow crystals (84 g, mp 292–296°C, 96% yield) were unchanged on recrystallization from 2-methoxyethanol; ir (N): 3130, 1650, 1595, 1555; uv (MeOH, neutral): 218 (21 600), 273.5 (8 900), 299.5 (8 000), 311.0 (7 000), 374.0 (6 000); (MeOH, acid): 253.0 (5 900), 263.0 (6 200), 273.5 (5 900), 300.0 (7 200), 312.0 (7 300), 331.0 (4 700), 364.0 (4 900); $^1$Hmr: 3.55 (s, C*H*$_3$), 7.8 (s, *H* at C-7), 7.7–8.1 (m, 3*H*, aryl), 12.1 (s, N*H*).

*Method B. From* **12**

A mixture of 3-(4-pyridylethyl)-3,4-dihydro-4-oxo-phthalazine-5-carboxylic acid (**12***m*, 64.5 g), thionyl chloride (90 mL), and chlorobenzene (650 mL) was stirred 3 h at reflux under moisture exclusion and then concentrated to dryness at reduced pressure. The residue was treated with absolute methanol (2 L) at reflux for 18 h and then concentrated at reduced pressure to a yellow foam. This material was treated with hydrazine hydrate (800 mL), water (200 mL), and then methanol (300 mL) to produce a homogenous solution. It was heated under stirring and the liquid gradually allowed to distil off at a bath temperature of 130°C. After a further 66 h at this temperature, the mixture was cooled and the yellow solid collected (44 g), washed with water, and then dissolved as well as possible in excess 1 *N* HCl. After filtration to remove 4.4 g of **1**, the solution was made basic with 5% sodium carbonate and the precipitated solid was collected, washed with water, air dried, and recrystallized thrice from ethanol to afford pure **11***z*, mp 200.5–203°C; $^1$Hmr: 3.1 (t, C*H*$_2$, *J* = 5), 4.3 (t, C*H*$_2$, *J* = 5), 7.3 (m, 2 C*H*—C), 7.9 (s, *H* at C-7), 7.75–8.2 (m, 3*H*, aryl), 8.5 (m, 2 C*H*—N), 12.0 (s, N*H*). The free base suspended in warm methanol was treated with an equimolar quantity of methanesulphonic acid, treated with ether to turbidity, refrigerated 90 h, and the *methanesulphonate salt* collected, mp 253–256°C, resolidified and dec. ca. 340°C; ir (KBr): ~2900 (broad), 1660, 1638, 1620, 1600, 1560, 1520, 1503. *Anal.* calcd. for $C_{16}H_{13}N_5O\cdot CH_4O_3S$: S 8.28; found: S 8.28.

*Method C. From* **9**

To a solution of 1 *N* sodium hydroxide (100 mL) in methanol (100 mL) was added *N*-hexamethyleneiminoethyl chloride hydrochloride (20 g) and the resulting mixture added to a solution of methyl 3,4-dihydro-4-oxophthalazine-5-carboxylate (**9***a*, 20.4 g) in methanol (250 mL). Additional 1 *N* sodium hydroxide (100 mL) was added and the whole heated 3 h on a steam bath. It was evaporated to dryness at reduced pressure and the residue triturated with water, extracted with chloroform, and the dried ($Na_2SO_4$) extract concentrated at reduced pressure to a brown oil. This was treated with hydrazine hydrate (420 mL) and water (140 mL) at reflux over 48 h, well cooled, and the precipitate collected, washed with water, and oven dried. The crude yellow solid was triturated with excess 1 *N* HCl, filtered free of impurities, and the filtrate made basic with 20% sodium carbonate solution. The yellow solid which formed was dissolved in chloroform, filtered free of further impurities, and concentrated at reduced pressure to a yellow solid (17.0 g, mp 182–185°C, 55%). Three recrystallizations from ethanol gave pure 3-(*N*-hexamethyleneiminoethyl)-3-oxo-3*H*-2,9-dihydropyridazino-[3,4,5-*de*]phthalazine (**11***t*), mp 183.5–186.5°C; ir(N): 3130, 1655, 1625, 1595. $^1$Hmr: 1.5 (s, 4-C*H*$_2$), 2.5–2.95 (t + m, 3-C*H*$_2$—N), 4.1 (t, C*H*$_2$, *J* = 5), 7.95 (s, *H* at C-7), 7.75–8.15 (m, 3*H*, aryl), 12.0 (s, N*H*).

In examples **11***b*, **11***e*, **11***f*, **11***l*, **11***m*, and **11***x*, the crude solid obtained after hydrazine hydrate treatment was taken up in hot chloroform, filtered free of **1**, evaporated to dryness, and recrystallized. In examples **11***w*, **11***aa*, and **11***bb*, the crude tricyclic compound was converted to the methanesulphonate salt and recrystallized.

*Method D. From* **1**

To a suspension of sodium methoxide (7 g) in dry dimethylsulphoxide (500 mL) was added **1** (18.6 g) and the mixture heated to 60°C. Benzyl bromide (14 mL) was added under stirring and the mixture maintained 2 h at 60°C. The dark mixture was poured into ice water, stirred 0.5 h, and filtered. The dark precipitate was stirred 1 h in ethanol (400 mL) and the resulting tan solid (18.3 g) recrystallized from 2-methoxyethanol with charcoal. On cooling, a first crop (5.3 g) was obtained, combined with a second crop (4.1 g) obtained after 3 days, and recrystallized thrice from ethanol to afford pure 9-benzyl-3-oxo-2,9-dihydropyridazino[3,4,5-*de*]phthalazine (**11***h*), mp 239–243°C; ir (N):

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

3150, 1645, 1590, 1550; $^1$Hmr: 5.2 (s, $CH_2$), 7.4 (s, $C_6H_5$), 8.05 (s, *H* at C-7), 7.85–8.2 (m, 3*H*, aryl), 11.9 (s, N*H*).

In examples **11***c*, **11***p*, **11***q*, and **11***y*, the crude product was dissolved in hot ethanol, filtered free of unreacted **1**, and concentrated to dryness before the final crystallization. In addition, **11***p* and **11***y* were dissolved in 1 *N* HCl, filtered free of impurity, and reprecipitated with aqueous sodium carbonate before the final recrystallization.

*3-Chloro-9-phenyl-9*H*-pyridazino[3,4,5-*de*]phthalazine (**18***b*) (Table 6)*

To a stirring mixture of phosphorous pentachloride (6.3 g) in phosphoryl chloride (40 mL) was added 9-phenyl-3-oxo-3*H*-2,9-dihydropyridazino[3,4,5-*de*]phthalazine (**11***g*, 7.8 g) and the mixture stirred 3 h at reflux. It was poured cautiously onto ice, made alkaline with 20% sodium hydroxide solution, and the yellow precipitate collected and washed thoroughly with water. The crude solid was further triturated with warm water (600 mL), refiltered, and recrystallized from boiling ethanol to afford yellow crystals (5.5 g) of pure **18***b*, mp 225–228°C; ir (N): 1620, 1595, 1530. *Anal.* calcd. for $C_{15}H_9ClN_4$: Cl 12.63; found: Cl 12.67.

In example **18***c*, the reaction mixture was quenched instead in ice-cold ether, filtered, and the precipitate recrystallized. In example **18***d*, phosphoryl chloride alone was used as the chlorinating agent. In example **18***c*, the crude product was extracted from the ice-water mixture with chloroform, concentrated, and filtered through a column of Woelm neutral alumina, grade I, before final recrystallization.

*9-Phenyl-3-thiono-3*H*-2,9-dihydropyridazino[3,4,5-*de*]-phthalazine (**19***b*)*

A mixture of phosphorous pentasulphide (2.5 g), dry pyridine (15 mL), and **11***g* (2.6 g) was stirred at reflux under moisture exclusion for 2.5 h. The dark red solution was cooled, poured into ice-cold saturated sodium chloride solution, and stirred 1.5 h. The precipitated thiono compound was collected, washed thoroughly with water, air dried, and recrystallized from ethanol in golden yellow flakes, mp 230–231°C; ir (N): 3150, ~2400 (broad), 1615, 1590, 1560; $^1$Hmr: 7.4–8.25 (m, 7*H*, phenyl + aryl), 8.3 (s, *H* at C-7), 8.6 (dd, *H* at C-4), 13.8 (s, N*H*). *Anal.* calcd. for $C_{15}H_{10}N_4S$: S 11.52; found: S 11.64.

The *9-methyl compound* **19***a*, prepared by the same route, was obtained in 56% yield after one recrystallization from 2-methoxyethanol. Two further recrystallizations did not change the mp of 299–316°C (dec.); ir (N): ~3180, ~2800 (broad), 1620, 1555, 1520; $^1$Hmr: 3.6 (s, $CH_3$), 8.05 (s, *H* at C-7), 7.8–8.15 (2*H*, aryl), 8.45 (dd, *H* at C-4), 14.0 (s, N*H*). *Anal.* calcd. for $C_{10}H_8N_4S$: S 14.83; found: S 14.72.

*9-(*N*-Morpholinoethyl)-3-thiono-3*H*-2,9-dihydropyridazino-[3,4,5-*de*]phthalazine (**19***c*)*

To a solution of **11***q* (29.9 g) in pyridine (250 mL) was added phosphorous pentasulphide (25 g) and the mixture stirred 5 h at reflux. The dark solution was poured into ice-water and the yellow solid collected, washed with water, and pressed dry on the filter. The crude product (15.5 g), mp 200–204°C dec., was suspended in hot chloroform (500 mL), filtered and the filtrate treated with hexane, whereupon a yellow precipitate formed. This material (6.6 g, one spot in tlc) was twice recrystallized from benzene to afford the pure thiono compound **19***c*, mp 202–204°C, resolidified, and remelted 220–222°C; ir (N): ~3150, 1590, 1555; $^1$Hmr: 2.5 (m, 2$CH_2$), 2.7 (t, $CH_2$), 3.55 (m, 2$CH_2$), 4.15 (t, $CH_2$), 7.85–8.1 (m, 2*H*, aryl), 8.15 (s, *H* at C-7), 8.5 (dd, *H* at C-4), 13.9 (s, N*H*). *Anal.* calcd. for $C_{15}H_{17}N_5OS$: S 10.17; found: S 10.15.

*3-Hydrazino-9-methyl-9*H*-pyridazino[3,4,5-*de*]phthalazine (**20***a*)*

To a hot stirring solution of hydrazine hydrate (162 mL) and water (60 mL) was added **19***a* (6.48 g) and the mixture stirred mechanically 20 h at reflux. It was filtered hot and the filtrate evaporated at reduced pressure to dryness. The residual yellow solid was taken up in 3 *N* HCl (400 mL), filtered to remove insoluble material, and the filtrate evaporated to dryness at reduced pressure. It was dissolved in water (100 mL), again filtered free of impurity, and the filtrate concentrated to dryness. The residual solid was dissolved in water (50 mL), ethanol (50 mL) added and, at 70°C under stirring, treated with benzaldehyde (15 mL) in ethanol (50 mL). Water (25 mL) was added, followed by 1 *N* sodium bicarbonate (100 mL), and the mixture stirred 5 min at 70°C. Bicarbonate solution (100 mL) was again added and the whole heated 10 min at reflux. The mixture was cooled and the orange solid collected, washed with water, and treated with excess 2 *N* HCl at the boil (fume hood) until no odour of benzaldehyde remained and a yellow solution was obtained. It was filtered through sintered glass and the clear yellow filtrate concentrated to dryness at reduced pressure. The residual solid was dried in a dessicator over $P_2O_5$ and recrystallized from methanol–ether to give pale yellow crystals of the dihydrochloride of **20***a* (4.4 g), mp ~260°C, gas evolution; ir (N): ~2600 (broad), 1580, 1545, 1510; $^1$Hmr ($D_2O$): 4.05 (s, $CH_3$), 8.15–8.6 (m, 3*H*, aryl), 8.7 (s, *H* at C-7). *Anal.* calcd. for $C_{10}H_{10}N_6 \cdot 2HCl$: Cl 24.70; found: Cl 24.44.

In a similar way, **19***b* was reacted with aqueous hydrazine hydrate followed by benzaldehyde to afford the benzylidene hydrazone of *3-hydrazino-9-phenyl-9*H*-pyridazino[3,4,5-*de*]-phthalazine* in 63% yield, crude. After three recrystallizations from 2-methoxyethanol, it melted in the range 219–222°C; ir (N): 3350, 1615, 1590, 1565, 1550, 1530; $^1$Hmr: 7.3–7.95 (m, 12*H*, aryl), 8.0 (s, *H* at C-7), 8.3 (dd, *H* at C-4, $J$ = 7, 1.5), 8.4 (s, C*H*=N), 11.5 (s, N*H*).

*9-Benzyl-3-hydrazino-9*H*-pyridazino[3,4,5-*de*]phthalazine hydrochloride (**20***c*) from **11***h*

A mixture of phosphorous pentasulphide (25 g), pyridine (250 mL), and **11***h* (28 g) was stirred 3 h at reflux. The dark mixture was poured into ice-water, stirred 2 h, and the precipitated solid collected and recrystallized from 2-methoxyethanol. The resulting product was suspended in chloroform, filtered, and 7 g of crude thiono compound obtained, mp 275–278°C. It was suspended in hydrazine hydrate (300 mL) and water (80 mL), stirred 20 h at reflux, well cooled, and the solid collected, washed with water, taken up in 3 *N* HCl (400 mL), and filtered. The filtrate was concentrated at reduced pressure and the residue recrystallized from methanol to afford the monohydrochloride of **20***c*, mp 270–271°C; ir (N): 3200, ~2800 (broad), 1650, 1585, 1545; $^1$Hmr: 5.3 (s, $CH_2$), 7.2–7.5 (m, 5*H*, phenyl), 8.05–8.15 (m, 2*H*, aryl), 8.2 (s, *H* at C-7), 8.7 (dd, *H* at C-4). *Anal.* calcd. for $C_{16}H_{14}N_6 \cdot HCl$: Cl 10.81; found: Cl 10.92.

*2,9-Dimethyl-3-oxo-3*H*-2,9-dihydropyridazino[3,4,5-*de*]-phthalazine (**21***b*)*

*(a) **21**b from **11**a*

To a suspension of **11***a* (20 g) in dimethylsulphoxide (200 mL) was added sodium methoxide (10 g) and the mixture stirred at 60°C. A thick yellow suspension formed. Methyl iodide (20 mL) was added whereupon the suspension became a clear yellow solution from which a yellow solid gradually precipitated. The mixture was stirred 3 h at 60°C, cooled, washed with dilute aqueous sodium bisulphite followed by water, and air dried. The yellow solid (20 g, mp 191–192°C, sint. 186°C) was recrystallized from methanol to give pure **21***a*, mp 195–196.5°C; ir ($CHCl_3$):

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

1650, 1625, 1595, 1555; uv (MeOH): 274.5 (8900), 301.0 (7100), 312.5 (6300), 374.0 (6700), unchanged in acidic or alkaline methanol; $^1$Hmr: 3.5 (s, $CH_3$), 3.6 (s, $CH_3$), 7.85 (s, *H* at C-7), 7.6–8.05 (m, 3*H*, aryl); $^1$Hmr ($CDCl_3$): 3.6 (s, $CH_3$), 3.8 (s, $CH_3$), 7.5–7.95 (m, 3*H* aryl + *H* at C-7), 8.25 (dd, *H* at C-4, $J$ = 8, 1.5).

*(b) **21**b from **1***

In an apparatus consisting of a 4-necked flask, thermometer, dropping funnel, mechanical stirrer, and double jacketed condenser surmounted with a nitrogen T-tube, a suspension of **1** (56 g) in dimethylsulphoxide (700 mL) was treated under stirring with sodium methoxide (36 g), whereupon the internal temperature rose to 34°C. After the weak exotherm subsided, methyl iodide (15 g) was added, whereupon the internal temperature rose to 72°C. After stirring 2 h at ambient temperature, the mixture was poured into ice-water (700 mL) containing a little sodium bisulphite. It was made slightly acidic with HCl, stirred 30 min at 0–5°C, and filtered. The filtrate was extracted with chloroform (3 × 750 mL) and the extract dried ($Na_2SO_4$) and concentrated to dryness. The residual yellow solid (15.1 g), mp 186–189°C, was identical (ir, $^1$Hmr) to **21***b* obtained from **13***a*. Evaporation of the aqueous dimethylsulphoxide layer to dryness followed by extraction with chloroform containing 5% methanol yielded a mixture of **21***b* and **13***a* (10.8 g).

*2,9-Bis-(*N*-morpholinoethyl)-3-oxo-3*H*-2,9-dihydropyridazino-[3,4,5-*de*]phthalazine (**21**f) from **1***

To a suspension of **1** (93 g) in dimethylsulphoxide (600 mL) was added sodium methoxide (29 g) and the mixture raised to 80°C under stirring. *N*-Morpholinoethyl chloride (75 g) was added and the mixture stirred 5 h longer at 80°C, quenched in ice-water (3 L), and the yellow precipitate collected. The wet solid (ca. 100 g) was impure **11***q*. The mother liquor was extracted with chloroform and the organic layer extracted with 2*N* HCl. The acidic layer was made basic with 5% sodium carbonate solution and extracted with chloroform. The dried ($Na_2SO_4$) organic layer was concentrated to 20 g of dark semisolid. It was taken up in a minimum quantity of ethyl acetate and chromatographed on Woelm basic alumina, grade III (400 g), with ethyl acetate as eluent. The second 500 mL fraction, on evaporation at reduced pressure, gave a yellow solid. Recrystallization from ethyl acetate gave pure **21***f* (2.2 g), mp 179–182°C; ir (N): 1645, 1620, 1595, 1540; $^1$Hmr: 2.5 (m, 4C$H_2$), 2.75 (t, 2C$H_2$), 3.55 (m, 4C$H_2$), 4.2 (2 overlapping dd, 2C$H_2$), 7.95 (s, *H* at C-7), 7.75–8.2 (m, 3*H*, aryl).

*2,9-Bis-(cyanoethyl)-3-oxo-3*H*-2,9-dihydropyridazino-[3,4,5-*de*]phthalazine (**21**g)*

A mixture of **1** (55.8 g), 50% aqueous pyridine (500 mL), Triton B (40% in $CH_3OH$, 10 mL), and acrylonitrile (60 mL) was heated 18 h at reflux. It was evaporated at reduced pressure to dryness, taken up in water (700 mL), filtered, and the precipitate (80.4 g, mp 186–192°C) recrystallized three times from ethanol (ca. 40 mL/g) to afford the pure sample, mp 188–191.5°C; ir (N): 2220, 1645, 1590, 1545; $^1$Hmr: 3.1 (q, 2C$H_2$), 4.3 (m, 2C$H_2$), 8.05 (s, *H* at C-7), 7.8–8.25 (m, 3*H*, aryl).

*2,9-Bis-(1-methyl-2-cyanoethyl)-3-oxo-3*H*-2,9-dihydropyridazino[3,4,5-*de*]phthalazine (**21**h)*

A mixture of **1** (18.6 g), crotononitrile (20 mL), Triton B (3 mL), and 50% aqueous pyridine (1 L) was heated 18 h at reflux. The red solution was concentrated to dryness at reduced pressure and the residue triturated with water, cooled, and filtered. The solid was taken up in chloroform, filtered to remove residual **1** (6.5 g), and the filtrate concentrated to dryness at reduced pressure. The residue (14 g) was recrystallized from benzene–hexane with charcoal, then thrice from chloroform–ether to afford the pure product (5.6 g, 29% conversion), mp 168–170°C; ir (N): 2230, 1645, 1625, 1595, 1550; $^1$Hmr: 1.5 (t, 2C$H_3$), 3.1 (2d, 2C$H_2$), 5.0–5.65 (m, 2C*H*), 8.0 (s, *H* at C-7), 7.9–8.35 (m, 3*H*, aryl).

*2,9-Bis-(carbamoylethyl)-3-oxo-3*H*-2,9-dihydropyridazino-[3,4,5-*de*]phthalazine (**21**i)*

A mixture of **21***g* (7.17 g) and 80% sulphuric acid (75 mL) was stirred for 20 h under reflux. The resulting yellow suspension was cooled and quenched in ice. The yellow precipitate (7.1 g, mp 230–235°C) was twice recrystallized from water to afford the pure product, mp 234–238°C; ir (N): 3350, 3150, 1650, 1620, 1575, 1530; $^1$Hmr: 2.55 (m, 2C$H_2$), 4.25 (q, 2C$H_2$), 6.95 (s, N$H_2$), 7.5 (s, N$H_2$), 8.0 (s, *H* at C-7), 7.8–8.2 (m, 3*H*, aryl).

*9-Methyl-2-(*N*-morpholinoethyl)-3-oxo-3*H*-2,9-dihydropyridazino[3,4,5-*de*]phthalazine (**21**c)*

Sodium methoxide (2.5 g) was added to a stirring suspension of **11***a* (6 g) in dimethylsulphoxide (200 mL), heated to 80°C, *N*-(2-chloroethyl)morpholine (6 g) added, and the mixture stirred 5 h at 80°C. The orange solution was quenched in ice-water and extracted with chloroform. The organic layer was extracted with 1*N* HCl (500 mL) and the acidic layer made basic with 5% sodium carbonate, extracted with chloroform, dried ($Na_2SO_4$), and concentrated to dryness to give the crude product (9.3 g, mp 171–174°C). Three recrystallizations from benzene gave the pure sample, mp 176–179°C; ir (N): 1645, 1620, 1595, 1550; $^1$Hmr: 2.5 (dd, 2C$H_2$, $J$ = 5), 2.75 (t, C$H_2$, $J$ = 7), 3.5 (s, $CH_3$), 3.6 (dd, 2C$H_2$, $J$ = 5), 4.1 (t, C$H_2$, $J$ = 7), 7.6–8.05 (m, 3*H*, aryl), 7.8 (s, *H* at C-7).

Under similar conditions, **21***d* was prepared from **11***g*, except that the crude product precipitated directly on quenching in ice-water and was obtained pure after three recrystallizations from isopropanol in 40% yield, mp 162–164.5°C; ir (N): 1645, 1620, 1595, 1550; $^1$Hmr: 2.4 (dd, 2C$H_2$, $J$ = 5), 2.6 (t, C$H_2$, $J$ = 7), 3.5 (dd, 2C$H_2$, $J$ = 5), 4.05 (t, C$H_2$, $J$ = 7), 7.3–8.25 (m, 8*H*, aryl), 8.15 (s, *H* at C-7).

*2-Cyanoethyl-9-(*N*-morpholinoethyl)-3-oxo-3*H*-2,9-dihydro-[3,4,5-*de*]phthalazine (**21**e)*

A mixture of **21***g* (12.0 g), dimethylsulphoxide (300 mL), and sodium methoxide was heated to 60°C under stirring and *N*-(2-chloroethyl)morpholine (10 g) added. It was stirred 4 h at 60°C under moisture exclusion, then poured into ice-water. The resulting solid (7.1 g) was suspended in 1*N* HCl, filtered and the filtrate made basic with 5% sodium carbonate solution, extracted with chloroform and the chloroform layer concentrated to dryness at reduced pressure. The residual solid (5.5 g) was recrystallized from methanol to produce the pure **21***e* (3.45 g), mp 195–198°C; ir (N): 2220, 1650, 1615, 1590, 1545; $^1$Hmr: 2.5 (m, 2C$H_2$), 2.7 (t, C$H_2$, $J$ = 7), 3.05 (t, C$H_2$, $J$ = 7), 3.6 (m, 2C$H_2$), 4.2 (t, C$H_2$, $J$ = 7), 4.3 (t, C$H_2$, $J$ = 7), 8.05 (s, *H* at C-7), 7.8–8.25 (m, 3*H*, aryl).

*Preparation of **11**q from **21**e*

A mixture of **21***e* (1.3 g), hydrazine hydrate (30 mL), and water (7 mL) was stirred 20 h at reflux. It was cooled and the yellow precipitate collected, washed with water, and dried. The product (0.8 g, mp 200–203°C) was recrystallized from water to afford 0.6 g, mp 203–205°C, identical by ir, $^1$Hmr, and mmp to **11***q* prepared from **1**.

*2-Methyl-3-oxo-3*H*-2,9-dihydropyridazino[3,4,5-*de*]-phthalazine (**21**a)*

The acid chloride of 3,4-dihydro-4-oxo-phthalazine-5-carboxylic acid, prepared as described in the synthesis of **9***b* (40 g)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

was suspended in chlorobenzene (250 mL) and methylhydrazine (50 mL) added cautiously. The mixture was stirred at reflux 44 h under moisture exclusion, cooled in an ice bath, and treated cautiously with methanol (200 mL). The crude solid (12.8 g, mp ~300°C dec.) was collected and combined with a second batch (17.3 g) and suspended in 50% aqueous pyridine (900 mL). Acrylonitrile (25 mL) and Triton B (5 mL) were added and the mixture stirred 18 h at reflux. The orange solution was concentrated to dryness at reduced pressure and the residue triturated with water and collected. The crude product (15.2 g) was twice recrystallized from ethanol to afford *9-cyanoethyl-2-methyl-3-oxo-3*H-*2,9-dihydro[3,4,5-*de*]phthalazine* (**21***j*), mp 187–193°C; ir (N) v: 2220 (C≡N), 1640 (C=O); $^1$Hmr: 3.1 (t, C$H_2$, $J$ = 7), 3.65 (s, C$H_3$), 4.2 (t, C$H_2$, $J$ = 7), 7.9 (s, *H* at C-7), 7.7–8.1 (m, 3*H*, aryl). The nitrile **21***j* (7.6 g) was treated with hydrazine hydrate (240 mL) and water (60 mL) under reflux for 18 h, cooled in ice, and the yellow precipitate collected, washed with water, and dried. The product **21***a* was thus obtained analytically pure, mp 307–311°C dec.; ir (N): 3200 (sh), 3100, 1655, 1630, 1605, 1590, 1550; $^1$Hmr: 3.6 (s, C$H_3$), 7.85 (s, *H* at C-7), 7.65–8.05 (m, 3*H*, aryl), 12.1 (s, N*H*).

*1-Methyl-1*H-*pyridazino[3,4,5-*de*]phthalazine* (**22**a)

*Method A. From* **18**a

A mixture of **18***a* (10.8 g), 47% hydriodic acid (150 mL), and red phosphorous (10 g) was stirred at reflux for 23 h, poured into ice-water, and filtered. The filtrate was evaporated to a small volume at reduced pressure, made basic with 5% sodium carbonate solution, and extracted with chloroform. The chloroform layer was dried ($Na_2SO_4$), concentrated to a small volume, and chromatographed on Woelm neutral alumina, grade II, in a 2 inch diameter column. The desired compound fluoresced strongly under long wave (3660 Å) uv light and its progress down the column was determined with a Rayteck model LS-7 handheld lamp. After a forerun, the compound was eluted with chloroform (ca. 2 L). Evaporation of the chloroform left 9.3 g of yellow solid, which was combined with a second run (8.0 g) and recrystallized from ethanol with charcoal to afford pure **22***a* (13.1 g), mp 149–151°C; ir (N): 1615, 1590, 1535; uv (MeOH, neutral or alkaline): 254.0 (6 700), 332.2 (11 400), 341.5 (11 500); uv (MeOH + 0.1 *N* HCl): 2445 (9 300), 253.0 (8 400), 312.5 (9 500), 334.5 (5 900), 348.8 (6 000); $^1$Hmr: 3.7 (s, C$H_3$), 7.45–7.9 (m, 3*H*, aryl), 8.0 (s, *H* at C-3), 8.85 (s, *H* at C-7); $^1$Hmr (DCl/$D_2O$): 4.1 (s, C$H_3$), 8.3–8.65 (m, 3*H*, aryl), 8.9 (s, vinyl *H*), 9.1 (s, vinyl *H*).

*Method B. From* **19**a

The thiono compound **19***a* (1.08 g) was suspended in ethanol (200 mL) and Raney nickel slurried in ethanol (ca. 5 g) added a little at a time as the mixture was agitated with an air-driven stirrer. After addition was complete, the whole was stirred on a steam bath for 1 h. It was filtered hot and the filtrate evaporated at reduced pressure. The residual solid was again dissolved in hot ethanol, refiltered, and concentrated to dryness. The residual yellow solid (0.6 g) was recrystallized from benzene–hexane with charcoal to give 0.4 g of product, mp 147–149°C, identical to **22***a* derived from **18***a* as indicated by tlc, ir, and $^1$Hmr. This substance formed a hydriodide with 47% hydriodic acid, mp 247–248°C dec. (from ethanol–ether); ir (N): ~2700 (broad), 1640, 1580, 1570.

Treatment of **22***a* with methanol and methyl iodide at reflux over 25 h gave a methiodide **29**, mp 207–208.5°C (from methanol–ether); ir (N): 1615, 1595, 1550; $^1$Hmr: 3.8 (s, C$H_3$), 4.3 (s, C$H_3$), 8.1–8.5 (m, 3*H*, aryl), 8.6 (s, *H* at C-3), 9.7 (s, *H* at C-7).

*1-Phenyl-1H-pyridazino[3,4,5-*de*]phthalazine* (**22**b)

A mixture of red phosphorous (6.5 g), 47% hydriodic acid (65 mL), and **18***b* (9.0 g) was stirred 18 h at reflux, poured into ice-water, and filtered. The filtrate was made basic with 5% sodium carbonate and extracted with chloroform. The extract was dried ($Na_2SO_4$) and concentrated to dryness at reduced pressure. The residual crude product (6.5 g) was recrystallized from benzene with charcoal and a first crop of 3.1 g obtained. Addition of hexane to the mother liquor gave an additional 0.7 g. The combined material was recrystallized from benzene to give pure **22***b* (2.9 g), mp 168.5–170°C; ir (N): 1600, 1575, 1520; uv (MeOH, neutral or alkaline): 343.2 (13 400); uv (MeOH + 0.1 *N* HCl): 311.7 (9 900), 336.5 (6 400), 351.0 (7 000); $^1$Hmr: 7.4–8.1 (m, 8*H*, aryl), 8.3 (*H* at C-3), 9.1 (*H* at C-7).

*Method C. From* **2**

*1-(*N-*Morpholinoethyl)-1*H-*pyridazino[3,4,5-*de*]phthalazine* (**22**d)

Sodium methoxide (1.7 g) was added to a suspension of **2** (5.1 g) in dimethylsulphoxide (75 mL), the mixture stirred at 60°C, and *N*-(2-chloroethyl)morpholine (5 g) added under moisture exclusion. After 4 h stirring at 80°C, the red solution was poured into ice-water and extracted with chloroform. The extract was washed with 1 *N* HCl and the aqueous acid layer made basic with 5% sodium carbonate and extracted with chloroform. Evaporation of the dried ($Na_2SO_4$) chloroform yielded 6 g of dark semisolid. This was dissolved in a minimal quantity of 5:1 benzene–dimethylformamide and chromatographed on Woelm neutral alumina, grade I (200 g). The first 150 mL fraction, on evaporation, yielded a yellow solid (3 g, mp 131–135°C). This was combined with material from a second run (6 g) and recrystallized from ethanol with charcoal. The product (7.5 g) was again recrystallized from ethanol and twice from isopropanol to afford the pure sample (4.0 g, 16%), mp 138–140°C; ir (N): 1630, 1605, 1545; $^1$Hmr: 2.5 (m, 2C$H_2$), 2.75 (t, C$H_2$, $J$ = 7), 3.55 (m, 2C$H_2$), 4.35 (t, C$H_2$, $J$ = 7), 7.5–8.0 (m, 3*H*, aryl), 8.1 (s, *H* at C-3), 8.9 (s, *H* at C-7).

*1-(2-Pyridyl)-1*H-*pyridazino[3,4,5-*de*]phthalazine* (**22**h)

A mixture of **18***d* (11.24 g), red phosphorous (8 g), and 47% hydriodic acid (100 mL) was stirred 3 h at reflux, cooled, poured into ice-water, and extracted with chloroform. The dried ($Na_2SO_4$) extract was concentrated to dryness and the residual solid (9.7 g, mp 182–188°C) chromatographed on Woelm basic alumina, grade I (500 g), with chloroform as eluent. The eluted product (6.4 g) was recrystallized twice from ethanol to afford the pure compound, mp 198–201°C, in 40% yield; ir (KBr): 1620, 1585, 1565, 1540; $^1$Hmr: 7.5–8.2 (m, 6*H*, 3 aryl + 3 pyridyl), 8.3 (s, *H* at C-3), 8.8 (m, *H* at C-6 in pyridyl ring), 9.1 (s, *H* at C-7).

The free base was treated with an equimolar amount of methanesulphonic acid in methanol, concentrated to dryness at reduced pressure, taken up in water, filtered, and the filtrate concentrated to dryness. The residual solid was twice recrystallized from isopropanol to afford the methanesulphonate salt of **22***h*, mp 186–189°C; ir (KBr): 1640, 1610, 1595, 1570, 1520. *Anal.* calcd. for $C_{15}H_{13}N_5O_3S$: S 9.34; found: S 9.21.

*1-(*N-*Hexamethyleneiminoethyl)-1*H-*pyridazino[3,4,5-*de*]-phthalazine* (**22**g)

To a suspension of **2** (8.5 g) in methanol (200 mL) was added *N*-(2-chloroethyl)hexamethyleneimine hydrochloride (9.9 g) in methanol (100 mL) followed by 1 *N* sodium hydroxide (100 mL). It was stirred 3 h at reflux and then evaporated to dryness at reduced pressure. The dark residue was chromatographed in 5:1 benzene–dimethylformamide on Woelm neutral alumina, grade I, with 100 mL fractions eluted. The second fraction yielded 5.2 g of yellow solid, which was recrystallized from benzene (20 mL) – hexane (300 mL) with charcoal to afford pure **22***g*, mp 117–121°C; ir (N): 1620, 1600, 1535; $^1$Hmr: 1.55 (s, 4C$H_2$), 2.7 (m, 2C$H_2$—N), 2.9 (t, C$H_2$, $J$ = 7), 4.3 (t, C$H_2$, $J$ = 7), 7.55–8.05 (m, 3*H*, aryl), 8.1 (s, *H* at C-3), 8.95 (s, *H* at C-7).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

By the same method, *1*-trans-*cinnamyl-1*H-*pyridazino[3,4,5-de]phthalazine* was obtained after chromatography in a crude yield of 35%, mp 135–140°C. It was twice recrystallized from ethanol to afford pure **22***c*, mp 147–149°C; ir (N): 1620, 1595, 1530; $^1$Hmr: 4.95 (d, C$H_2$, $J$ = 5), 6.6 (dt, C*H*, $J$ = 5, 16), 6.8 (d, C*H*, $J$ = 16), 7.25–8.05 (m, 8*H*, aryl), 8.15 (s, *H* at C-3), 9.0 (s, *H* at C-7).

*1-(2-Pyridylethyl)-1*H-*pyridazino[3,4,5-de]phthalazine (22i)*

A mixture of **2** (8.5 g), 2-vinylpyridine (20 mL), glacial acetic acid (125 mL), and anhydrous cupric sulphate (50 mg) was stirred 4 h at 135–140°C, then evaporated to dryness at 100°C/12 Torr. The residue was triturated with water, well cooled, and the crude product (6.6 g, mp 150–153°C) twice recrystallized from methanol with charcoal to afford pure **22***i*, mp 160–161°C; ir (N): 1620, 1590, 1565, 1540; $^1$Hmr: 3.3 (dd, C$H_2$, $J$ = 9, 7.5), 4.6 (dd, C$H_2$, $J$ = 9, 7.5), 7.2–7.9 (m, 6*H*, aryl + 3 pyridyl), 8.05 (s, *H* at C-3), 8.55 (dd, *H* at C-6), 8.9 (s, *H* at C-7).

*1-(2-Cyanoethyl)-1*H-*pyridazino[3,4,5-de]phthalazine (22e)*

A mixture of **2** (10.2 g), Triton B (2 mL), acrylonitrile (12 mL), and 50% aqueous pyridine (500 mL) was stirred at reflux for 1 h, concentrated to dryness at reduced pressure, triturated with water, and filtered. The residual solid (10.1 g, mp 195–197°C) was combined with 5.1 g from a one-half scale run, dissolved largely in 400 mL of chloroform, filtered, and the chloroform solution treated with hexane (800 mL) and cooled. The precipitate which formed (12.3 g, mp 197–199°C) was chromatographed on Woelm neutral alumina, grade I (450 g), with ethyl acetate as eluent. After removal of an impurity with 1 L of solvent, acetone was used as eluent and 500 mL fractions taken. Fractions 4 to 7 were combined, concentrated to dryness, and recrystallized from benzene to give pure **22***e* (4.8 g), mp 203–206°C; ir (N): 2250, 1620, 1600, 1540; $^1$Hmr: 3.15 (t, C$H_2$, $J$ = 7), 4.5 (t, C$H_2$, $J$ = 7), 7.45–8.05 (m, 3*H*, aryl), 8.2 (s, *H* at C-3), 8.9 (s, *H* at C-7).

*1-(2-Carboxyethyl)-1*H-*pyridazino[3,4,5-de]phthalazine (22f)*

A mixture of **22***e* (11.15 g) and 10% sodium hydroxide (200 mL) was heated 1 h at reflux. The yellow solution was cooled, acidified to pH 4 with 6 *N* HCl, and the crystalline product which formed (9.7 g, mp 245–247°C) was recrystallized twice from wet ethanol to afford **22***f* (4.2 g), mp 251.5–253.5°C; ir (N): 3300, ~2400 (broad), ~1900 (broad), 1715, 1615, 1595, 1520; $^1$Hmr: 2.8 (t, C$H_2$, $J$ = 7.5), 4.4 (t, C$H_2$, $J$ = 7.5), 7.55–8.0 (m, 3*H*, aryl), 8.1 (s, *H* at C-3), 8.95 (s, *H* at C-7), *OH* of carboxyl not visible.

*8-Hydroxymethyl-2-phenyl-1(2*H*)phthalazinone (24)*

The ester **10***c* (5.9 g) suspended in diglyme (15 mL) was treated portionwise with lithium borohydride (0.6 g) in diglyme (20 mL), the whole heated 4 h at 70°C, cooled, and treated cautiously with water. A pale off-white solid precipitated (4.2 g). It was recrystallized once from methanol and twice from benzene to afford colourless needles, mp 178–180°C; ir ($CHCl_3$): 3450, 1635, 1580; $^1$Hmr: 5.15–5.5 (m, C$H_2$, O*H*), 7.45–7.7 (m, 5*H*, phenyl), 7.7–8.3 (3*H*, aryl), 8.6 (s, vinyl *H*).

When the reaction was carried out with twice the amount of lithium borohydride at 70°C for 6 h, work-up yielded 4.1 g of solid. Two recrystallizations from methanol gave 2.66 g of *8-hydroxymethyl-2-phenyl-1,2-dihydrophthalazine (25)*, mp 122–124°C; ir (N): 3280, 3180, 1595, 1560; $^1$Hmr: 4.6 (d, C$H_2$—O, $J$ = 6), 4.9 (s, C$H_2$ at C-1), 5.3 (t, O*H*), 6.9–7.5 (m, 8*H*, aryl), 8.55 (s, *H* at C-3).

*Phenylhydrazone of 23*

To a stirring solution of phenylhydrazine (25 mL) in ethanol (100 mL) was added 3-hydroxyphthalide-7-carboxaldehyde (1) (3.56 g) and the mixture heated 22 h at reflux. After 1.5 h, a yellow precipitate formed. The mixture was cooled to room temperature and the solid collected, washed thoroughly with ethanol, and twice recrystallized from 2-methoxyethanol to give the pure phenylhydrazone of *8-formyl-2-phenyl-1(2*H*)-phthalazinone* (4.77 g, 70%), mp 264°C; ir (N): 3250, 1645, 1600, 1550, 1530; $^1$Hmr: 6.8–8.7 (m, 13*H*, aryl + *H* at C-4), 9.65 (s, —C*H*=N on C-8), 10.8 (s, N*H*).

*Methanesulphonate of 2*

Treatment of **2** with an equimolar amount of methanesulphonic acid in methanol followed by ether gave the salt, mp 288–293°C dec., after two recrystallizations from dimethylformamide; ir (N): 3280, ~2600 (broad), 1635, 1600, 1500; $^1$Hmr ($D_2O$): 2.9 (s, C$H_3$—S), 8.1–8.5 (m, 3*H*, aryl), 8.8 (s, protons at C-3 and C-7). *Anal.* calcd. for $C_{10}H_{10}N_4O_3S$: S 12.04; found: S 11.96.

*Methiodide of 2 (28)*

A mixture of **2** (5.1 g), methyl iodide (16 mL), and methanol (200 mL) was stirred at reflux under moisture exclusion for 16 h. It was concentrated to dryness at reduced pressure and recrystallized from methanol. This product (5.23 g, mp 269–270.5°C) was twice recrystallized from methanol to yield pure methiodide, mp 279–281°C; ir (N): 1640, 1610, 1585, 1510; $^1$Hmr: 4.3 (s, C$H_3$), 8.15–8.5 (m, 3*H*, aryl), 8.6 (s, C*H*=N—), 9.85 (s, C*H*=$\overset{+}{\text{N}}$=), 13.4 (s, N*H*). *Anal.* calcd. for $C_{10}H_{10}N_4I$: I 40.66; found: I 40.63.

In a similar way, the *ethiodide* was prepared in 60% crude yield and purified by two recrystallizations from ethanol, mp 260–262°C; ir (N): 1640, 1610, 1585, 1510; $^1$Hmr: 1.6 (t, C$H_3$, $J$ = 7), 4.5 (q, C$H_2$, $J$ = 7), 8.1–8.5 (m, 3*H*, aryl), 8.6 (s, C*H*=N—), 9.8 (s, C*H*=$\overset{+}{\text{N}}$=), 13.6 (s, N*H*). *Anal.* calcd. for $C_{11}H_{11}N_4I$: I 38.91; found: I 39.02.

*Conversion of 28 to 29*

Silver nitrate (1.7 g) was dissolved in a minimal quantity of water, treated with 1 *N* sodium hydroxide (10 mL) and then quickly with **28** (3.12 g) dissolved in warm methanol (200 mL). The mixture was stirred at 65°C for 20 min and the dark brown mixture filtered. The filtrate was concentrated to dryness at reduced pressure to a dark red solid. This was taken up in hot chloroform, filtered, and the filtrate evaporated at reduced pressure to a brick red solid, mp ~190°C dec. A portion of this (460 mg) was suspended in methanol (35 mL), treated with methyl iodide (2 mL), and the whole refluxed 32 h under moisture exclusion. The mixture was cooled and filtered and the orange-yellow crystals collected (151 mg), mp 312–315°C dec. The methiodide was recrystallized from dimethylformamide to afford orange-yellow needles, mp 313–314°C dec.; ir (N): ~2500 (broad), 1610, 1580, 1540; $^1$Hmr: 4.1 (s, 2C$H_3$), 7.9–8.25 (m, 3*H*, aryl), 9.1 (s, 2C*H*=$\overset{+}{\text{N}}$=). *Anal.* calcd. for $C_{11}H_{11}N_4I$: I 38.91; found: I 38.78.

*5-Carboxy-3,4-dihydro-2-methyl-4-oxophthalazinium hydroxide, inner salt (17)*

A mixture of **9***a* (41 g), methyl *p*-toluenesulphonate (35 mL), and chlorobenzene (100 mL) was heated under nitrogen at reflux for 18 h, more chlorobenzene added (150 mL), and reflux continued another 30 h. The mixture was filtered hot and the white precipitate collected, washed with chlorobenzene, then cyclohexane, and oven dried under vacuum at 120°C. The *p-toluenesulphonate salt of 17* (66 g, 84%), mp 205–207°C, was analytically pure; ir (N): ~2400 (broad), 1725, 1590, 1570, 1505; $^1$Hmr: 2.3 (s, C$H_3$), 3.95 (s, C$H_3$), 4.4 (s, C$H_3$), 7.4 (q, 4*H*, aryl, 1,4-substituted), 8.25–8.65 (m, 3*H*, aryl), 10.2 (s, C*H*=$\overset{+}{\text{N}}$=), 14.6 (s, O*H*).

The tosylate (7.3 g) in warm water (200 mL) was treated dropwise with 2 *N* sodium hydroxide (10 mL). Zinc acetate dihydrate (2.2 g) in water (20 mL) was added, the whole evaporated at reduced pressure at 70°C to ca. 20 mL, and methanol

(240 mL) added. Some solid (0.6 g) formed at once and a second crop (1.6 g) was obtained after overnight refrigeration. The combined material was recrystallized from water to afford colourless plates (1.45 g) which, after drying at 85°C/0.1 Torr for 20 h, gave pure product, mp 302–305°C dec.; ir (N): 1730, 1610, 1550; $^1$Hmr: 3.8 (s, $CH_3O$), 4.1 (s, $CH_3\overset{+}{N}\equiv$), 7.5–7.9 (m, 3*H*, aryl), 8.8 (s, $CH—\overset{+}{N}\equiv$).

*Additional spectral data*

$^1$*Hmr of* ***11****j* (DMSO-$d_6$): 2.1 (m, $CH_2$), 2.65 (t, $CH_2$), 4.0 (t, $CH_2$), 7.3 (s, $C_6H_5$), 7.95 (s, *H* at C-7), 7.75–8.2 (m, 2*H*, aryl), 11.9 (N*H*); ($CDCl_3$): 2.25 (m, $CH_2$), 2.8 (t, $CH_2$), 4.05 (t, $CH_2$), 7.25 (s, $C_6H_5$), 7.75 (s, *H* at C-7), 7.55–8.0 (m, 2*H*, aryl), 8.35 (dd, *H* at C-4, $J$ = 8, 1.5), 11.4 (N*H*).

## Acknowledgements

The authors are grateful to Mr. A. Clemente and Dr. P. Nicolson for microanalytical data, to Mr. D. Spiegel for uv studies, to Mrs. L. Raabis for $^1$Hmr spectra, and to Miss C. Signor and Miss L. Samoyedna for ir spectra. The cardiovascular test results were supplied by Drs. S. J. Ehrreich, R. Lee, M. Antonaccio, and R. Tanz, anti-inflammatory tests by Mrs. M. L. Graeme, the toxicology results by Dr. R. Katz, and the absorption studies by Dr. G. Lucas. We also thank Dr. R. Rodebaugh for helpful discussions related to the $^1$Hmr data.

# The bromination–methanolysis of *N*-acetyl-2,3-dimethylindole[1]

SUSAN F. VICE AND GARY I. DMITRIENKO[2]

*The Guelph–Waterloo Centre for Graduate Work in Chemistry, Waterloo Campus, Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1*

Received October 15, 1981

SUSAN F. VICE and GARY I. DMITRIENKO. Can. J. Chem. **60**, 1233 (1982).

Bromination of *N*-acetyl-2,3-dimethylindole **11** in the presence of excess methanol at room temperature gave a mixture of products consisting of *cis* and *trans* *N*-acetyl-2,3-dimethoxy-2,3-dimethylindoline **17** and **18**, 3-methoxy-2,3-dimethylindolenine **19**, and *N*-acetyl-3-methoxymethyl-2-methylindole **21**. The same reaction performed at −40°C yielded a mixture of **17**, **18**, and *N*-acetyl-2-methoxy-2-methyl-3-methyleneindoline **22**. Bromination of **11** at low temperature in the presence of 1.5 equivalents of methanol followed by treatment with triethylamine yielded **22** quantitatively. Treatment of **22** with acidic methanol readily gave **21**. The mechanistic implications of these transformations are considered.

SUSAN F. VICE et GARY I. DMITRIENKO. Can. J. Chem. **60**, 1233 (1982).

La bromation du *N*-acétyl diméthyl-2,3 indole **11**, en présence d'un excès de méthanol et à température ambiante, donne un mélange de produits comprenant les *N*-acétyl diméthoxy-2,3 diméthyl-2,3 indolines *cis* et *trans* **17** et **18**, le méthoxy-3 diméthyl-2,3 indolenine **19** et du *N*-acétyl méthoxyméthyl-3 méthyl-2 indole **21**. La même réaction effectuée à −40°C donne un mélange des isomères **17** et **18** et de *N*-acétyl méthoxy-2 méthyl-2 méthylène-3 indoline **22**. La bromation du composé **11** à basse température, en présence de 1,5 équivalent de méthanol, suivie d'une réaction avec la triéthylamine donne quantitativement le composé **22**. Ce dernier, en présence de méthanol acidulé, donne facilement le composé **21**. On considère le mécanisme de ces transformations.
[Traduit par le journal]

In connection with our interest in the development of new methods for the synthetic elaboration of 2,3-dialkylindoles **1**, we have recently reported the preparation of 3-methoxyindolenines **7** by bromination–methanolysis of 2,3-dialkylindoles (1). In the presence of triethylamine the corresponding bromindolenines **3** are moderately stable intermediates. Acidification of a solution of **3** in the presence of methanol has been shown to lead to the rapid formation of the methoxyindolenine **7**. We have argued (1*c*) that the methanolysis process likely proceeds via addition of methanol to the *N*-protonated bromoindolenine **2** to give, after deprotonation, the 2-methoxy-3-bromoindoline **4** (see Scheme 1). $S_N1$ type methanolysis of **4** would yield **6** ($R^1$ = H) which upon loss of methanol would generate the methoxyindolenine **7**.

We felt that an examination of the bromination–methanolysis of an *N*-acyl-2,3-dialkylindole **1** ($R^1$ = Ac) might offer some further insight into the nature of the intermediates involved in such processes. As a result, we have examined the bromination–methanolysis of *N*-acetyl-2,3-dimethylindole **11** and report the results of this investigation herein.

A survey of the literature revealed that the only previous studies of the bromination of *N*-acyl-2,3-

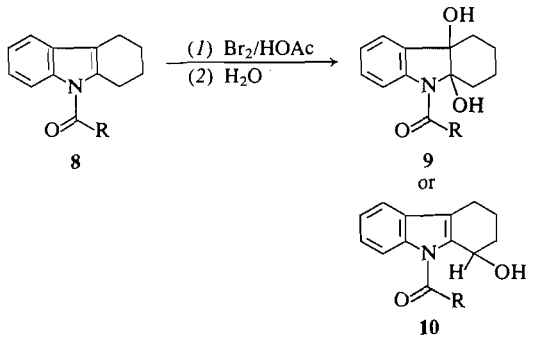
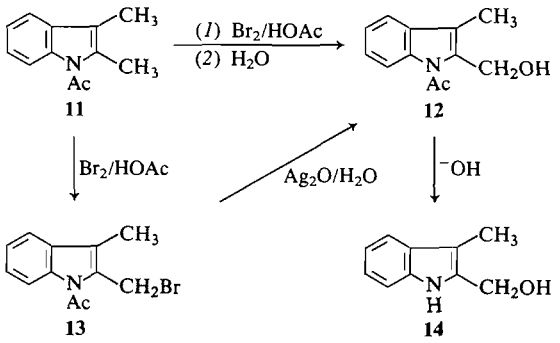


SCHEME 2

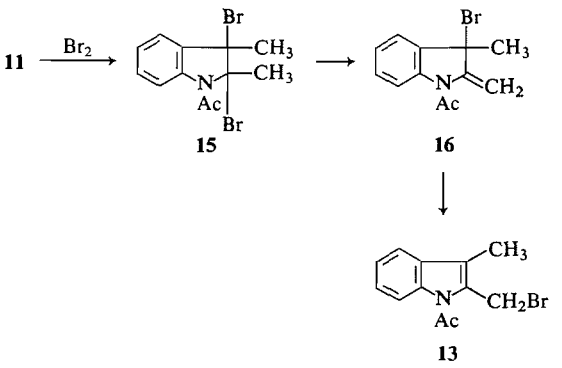
dialkylindoles were those reported by Plant and Tomlinson (2).[3] The bromination of several *N*-acetyltetrahydrocarbazoles **8** with bromine in acetic acid followed by addition of water yielded either *N*-acyl-2,3-dihydroxyindolines **9** or C2-side-chain hydroxylated products **10** (2*a*) (see Scheme 2). There was no apparent correlation between the nature of the *N*-acyl group and the nature of the product produced. In all cases products were isolated in low yield. Of the compounds examined by Plant and Tomlinson, *N*-acetyl-2,3-dimethylindole **11** was studied in greatest detail (2*b*). In this case the product of bromination–hydrolysis was *N*-acetyl-2-hydroxymethyl-3-methylindole **12** (see Scheme 3). In addition, a monobrominated product assumed to be *N*-acetyl-2-bromomethyl-3-methylindole **13** was isolated if the hydrolytic step was avoided. Hydrolysis of **13** in the presence of silver oxide yielded **12**, which upon alkaline hydrolysis gave **14**. Some years later, Taylor (3) provided proof for the assigned structure for **14** by an unambiguous synthesis.



SCHEME 3

The formation of **13** was rationalized as shown in Scheme 4. Bromination of **11** was assumed to give the dibromide **15** which upon elimination of HBr yielded the allylic bromide **16**. Allylic rearrangement of **16** would yield **13** and regenerate the aromatic indole ring system.

In our hands, bromination of **11** in glacial acetic acid as described by Plant and Tomlinson (2*b*) or in methylene chloride gave **13** as the sole product with spectroscopic characteristics compatible with the assigned structure (1*a*). On the other hand, bromination of **11** at room temperature in methanol gave a mixture of products which were separated by column chromatography (Scheme 5). Two of the products were readily recognizable as the dimethoxyindolines **17** and **18**. The proton nmr spectra of the major and minor isomers are compared in Table



SCHEME 4

1. Although we suspect that the major isomer is the *trans*-product **17** and the minor isomer the *cis*-product **18**, the available data does not allow an unambiguous assignment. A very minor product identified in the mixture was 3-methoxy-2,3-dimethylindolenine **19** arising presumably via deacylation of **17** or **18**. In addition a crystalline product, **A**, with elemental composition $C_{13}H_{15}NO_2$ was isolated in 30% yield. Initially, we felt that **A** was *N*-acetyl-2-methoxymethyl-3-methylindole **20**, derivable, in principle, by methanolysis of **13**.

Since **17** and **18** are structurally analogous to the dihydroxyindolines produced in the bromination–hydrolysis of *N*-acyl tetrahydrocarbazoles, and since the monomethoxylated product **A** seemed to be an analog of **12** produced in the bromination–hydrolysis of **11**, it appeared that no new mechanistic information could be gleaned from our product study of the bromination–methanolysis of **11**. However, when authentic *N*-acetyl-2-methoxymethyl-3-methylindole **20** (see Scheme 6) was prepared by methanolysis of **13** it was found to be not identical with **A**. The similarity of the spectroscopic properties of **A** and **20** clearly required that **A** be the isomeric *N*-acetyl-3-methoxymethyl-2-methylindole **21**. This surprising finding prompted us to explore the bromination–methanolysis process further. We have found that, when the reaction is performed at

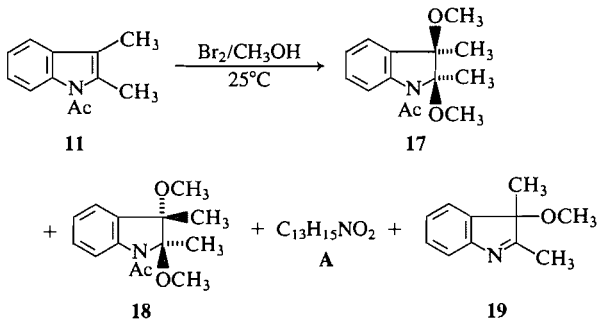
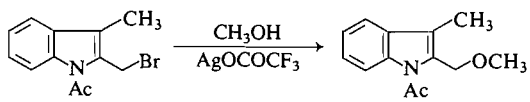


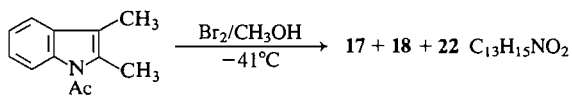
SCHEME 5

low temperature (−40°C), **21** is not observed. Instead, in addition to **17** and **18**, another isomer of **21**, compound **B**, with spectroscopic properties compatible with **22** or **23**, was obtained in 15% isolated yield.

It was also found that **B** was very likely a precursor to **21** in the room temperature bromination–



SCHEME 6

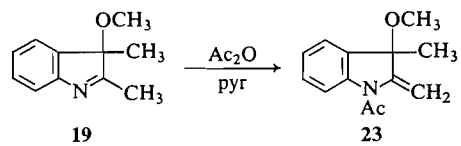


SCHEME 7

SCHEME 8

methanolysis of **11**, since treatment of **B** at room temperature with *p*-toluenesulfonic acid in methanol gave **21** in good yield. This chemical relationship between **B** and **21** clearly suggested that **B** was **22** and not **23**. This was confirmed by the synthesis of authentic **23** by the reaction of 3-methoxy-2,3-dimethylindolenine with acetic anhydride in pyridine (see Scheme 9). The most notable difference in the proton nmr spectra of **22(B)** and **23** is the fact that the methylene hydrogens in the former case appear as two one-proton singlets at δ 5.17 and 5.68 ppm whereas the methylene hydrogens in the latter case appear as two one-proton doublets ($J$ = 2.0 Hz) at δ 5.10 and 5.38 ppm. In the $^{13}C$ spectra the methylene carbon of **22** appears at 104.5 ppm, significantly downfield from that of **23** at 96.8 ppm, reflecting the expected higher electron density of the β-carbon of the "enamide" system of **23**.

Although the formation of **21** seemed, at first, surprising in light of earlier results on bromination–hydrolysis of *N*-acetyl-2,3-dimethylindole, a re-examination of the mechanism suggested earlier for the bromination–methanolysis of 2,3-dialkyl-



SCHEME 9

indoles suggests that the formation of **21** and **22** can be readily rationalized with a minimum of additional mechanistic assumptions. Thus if the bromination of **11** proceeds as suggested for **1** in Scheme 1 (see Scheme 10), one would expect that in the presence of methanol a C2-methoxy-C3-bromoindoline **25** analogous to **4** would be produced. $S_N1$ type methanolysis of **25** via the stabilized carbonium ion **26** would give the mixture of dimethoxyindolines **17** and **18**. In addition, $E_1$ or possibly $E_2$ type elimination of HBr from **25** would give **22** at low temperature, and acid-catalyzed reaction of **22** with methanol would give the allylic rearrangement product **21** observed in the room temperature bromination–methanolysis of **11**.

Thus all of the observed products can be readily rationalized on the assumption that the 2-methoxy-3-bromoindoline **25** is an intermediate and hence our confidence in the intermediacy of **25** in such processes is bolstered. Furthermore, our confidence in the existence of **25** in the formation of **22** and **17** and **18** suggested that the formation of **22** might be favoured by the use of triethylamine to catalyze $E_2$ type elimination. It was found that bromination of **11** in methanol containing excess triethylamine led to a substantial increase in the ratio of **22** to **17** and **18**. However, under these conditions triethylamine

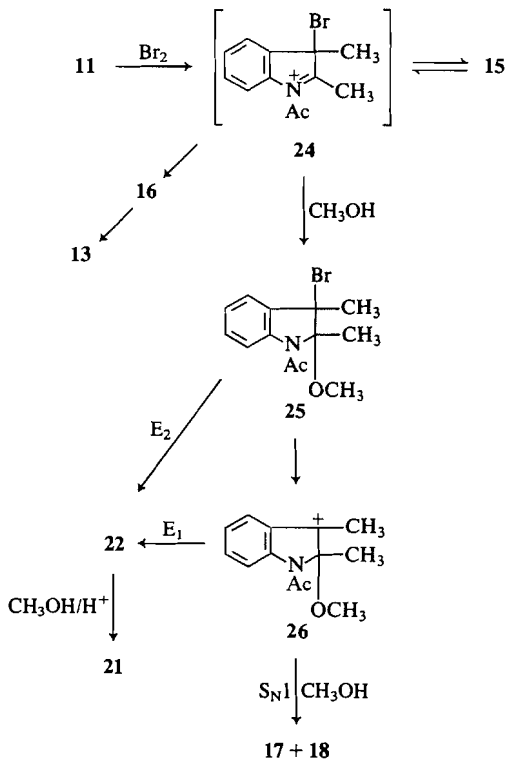
FIG. 1

catalyzes a reaction between methanol and bromine and as a result a large amount of unreacted **11** remained. Further experimentation has led us to the discovery that **22** can be produced quantitatively from **11** via a two-stage process. Thus treatment of **11** with one equivalent of bromine in methylene chloride in the presence of a limited amount of methanol (1.5 equivalents) at low temperature (−78°C) gives a colourless solution which upon treatment with triethylamine and aqueous work-up yields **22**.

This transformation not only represents a facile route to a relatively rare example of a C3-alkylidene indoline, but, coupled with the facile conversion of **22** to **21**, also represents a potentially simple and efficient route to C3 side-chain functionalization of 2,3-dialkylindoles.[4] Continuing studies in our laboratory are aimed at exploiting the synthetic utility of these transformations in the preparation of more complex indole-derived natural products.



SCHEME 10

[4]For an example of the preparation of a C3-alkylidene indoline by reaction of singlet oxygen with C3-vinylindoles, see ref. 4.

## Experimental

Melting points were determined on a Fisher Mel-temp melting point apparatus and are uncorrected. Infrared spectra were recorded on a Beckman IR-10 spectrometer and the frequency ($cm^{-1}$) of significant peaks is reported. A Beckman Model 35 spectrophotometer was used for uv spectra and wavelengths (nm) of absorption bands are reported followed by extinction coefficients (ε) in parentheses. Nuclear magnetic resonance spectra were recorded on a Varian T-60 or Bruker WP80 spectrometer (chloroform-*d* solvent unless otherwise indicated) and chemical shifts are reported on the δ scale, followed in parentheses by an account of the multiplicity and number of protons concerned. Mass spectra were recorded on a VG-7070 mass spectrometer. Microanalyses were performed by Galbraith Laboratories and Guelph Chemical Laboratories. *N*-Acetyl-2,3-dimethylindole was prepared by the method of Dave and Warnhoff (5).

*Bromination of* N-*acetyl-2,3-dimethylindole* ***11*** *in methylene chloride*

*N*-Acetyl-2,3-dimethylindole **11** (0.510 g; 2.73 mmol) was dissolved in methylene chloride (30 mL) and cooled in an ice bath. A solution of bromine (1.1 equivalents) in methylene chloride (3.8 mL) was added dropwise with stirring in a nitrogen atmosphere. After five minutes the solvent was removed *in vacuo* to yield *N*-acetyl-2-bromoethyl-3-methylindole **13** quantitatively as a homogeneous crystalline solid which soon turned purple upon exposure to a normal atmosphere; uv ($CH_2Cl_2$): 290 (11 480); $^1$H nmr: 2.23 (s, 3, C3—$CH_3$), 2.76 (s, 3, —CO—$CH_3$), 5.01 (s, 2, —$CH_2$—Br), 7.02–7.90 (m, 4, Ar—H). Molecular ions at *m/e* 267 ($m^+$ $^{81}$Br) and *m/e* 265 ($m^+$ $^{79}$Br).

An analogous result was obtained with acetic acid rather than methylene chloride as solvent.

*Methanolysis of* N-*acetyl-2-bromomethyl-3-methylindole*

To a stirred solution of *N*-acetyl-2-bromomethyl-3-methylindole **13** (0.426 g; 1.60 mmol) in methanol (50 mL) was added silver trifluoroacetate (0.365 g; 1.76 mmol). The mixture was stirred for 20 min in a nitrogen atmosphere and then filtered through Celite. The Celite was washed with methylene chloride. The combined filtrate was washed with water and saturated aqueous sodium chloride. The organic phase was dried over anhydrous sodium sulfate and evaporated to dryness on a rotary evaporator to give *N*-acetyl-2-methoxymethyl-3-methylindole in 90% yield as a homogeneous viscous oil which could not be induced to crystallize. Infrared (neat): 1675 (s, C=O); uv MeOH: 237 (16 900), 260 (10 700), 288 (6500), 297 (6370); $^1$H nmr: 2.26 (s, 3, C3—$CH_3$), 2.72 (s, 3, —CO$CH_3$), 3.32 (s, 3, —$OCH_3$), 4.66 (s, 2, C2—$CH_2$), 7.19–7.53 (m, 3, C4,5,6—H), 8.09–8.21 (m, 1, C7—H). *Exact mass* calcd. for. $C_{13}H_{15}NO_2$: 217.1103; found: (ms): 217.1093.

*Preparation of* N-*acetyl-2-methyl-3-methoxymethylindole* ***21***

To a solution of *N*-acetyl-2-methoxy-2-methyl-3-methylene indoline **22** in methylenechloride prepared from *N*-acetyl-2,3-dimethylindole (0.216 g; 1.15 mmol) as described below was added methanol (40 mL) followed by a solution of *p*-toluenesulfonic acid (0.360 g) in methanol (2 mL) at room temperature. After 15 min the mixture was washed with water, 10% aqueous ammonia, and saturated aqueous sodium chloride. Removal of solvent from the dried organic phase *in vacuo* yielded **21** as a crystalline solid in quantitative yield. This material was identical in all respects with material isolated from the room temperature bromination of **11**, mp 55°C.

*Preparation of* N-*acetyl-2-methoxy-2-methyl-3-methylene indoline* **22**

To a solution of *N*-acetyl-2,3-dimethylindole **11** (0.101 g; 0.54 mmol) in methylene chloride (40 mL) containing methanol (0.81 mmol, 1.5 equivalents) cooled to −78°C was added dropwise a solution of bromine (0.59 mmol) in methylene chloride (0.76 mL). After 20 min, triethylamine (0.11 mL; 1.5 equivalents) was added and the solution allowed to warm to room temperature. Methylene chloride (20 mL) was added and the organic phase was washed with water and saturated aqueous sodium chloride. Removal of solvent from the dried organic phase *in vacuo* gave a quantitative yield of **22** as a colourless thick oil which could not be induced to crystallize and which darkened rapidly on standing. Infrared (neat): 1665, (N—$COCH_3$); uv ($CHCl_3$): 250 (18 200), 268 (14 400), 317 (3770), 327 (3580); $^1$H nmr: 1.74 (s, 3, C2—$CH_3$), 2.49 (s, 3, —$COCH_3$), 3.03 (s, 3, $OCH_3$), 5.22 (s, 1, =$CH_2$), 5.72 (s, 1, =$CH_2$), 6.96–7.55 (m, 3, C4,5,6—H), 8.36–8.46 (m, H, C7—H). *Exact mass* calcd. for $C_{13}H_{15}NO_2$: 217.1103; found (ms): 217.1100.

*Preparation of* N-*acetyl-3-methoxy-3-methyl-2-methylene-indoline* **23** *from 2,3-dimethyl-3-methoxyindolenine* **19**

To a solution of freshly prepared 2,3-dimethyl-3-methoxy indolenine **19** (1) (0.292 g; 1.68 mmol) in pyridine (2 mL) was added acetic anhydride (1 mL). The solution was heated at 100°C in a nitrogen atmosphere for 19 h. Methylene chloride (20 mL) was added and the solution was washed with water and saturated aqueous sodium chloride solution. The organic phase was dried over anhydrous sodium sulfate and evaporated to dryness on a rotary evaporator.

The residue was chromatographed on silica gel with elution by a 1:1 mixture of ether – petroleum ether (60–80°C) to give **23** as colourless analytically pure crystals, mp 52–54°C, in 42% yield. Infrared ($CHCl_3$): 1657 (C=O); uv (MeOH): 257 (13 400), sh 312 (1500); $^1$H nmr: 1.58 (s, 3, C3—$CH_3$), 2.54 (s, 3, —$COCH_3$), 2.90 (s, 3, —$OCH_3$), 5.10 (d, $J$ = 2 Hz, 1, C2=C$H_2$), 5.38 (d, $J$ = 2 Hz, 1, C2=C$H_2$); ms *m/e* 217 (molecule ion). *Anal.* calcd. for $C_{13}H_{15}NO_2$: C 71.86, H 6.96, N 6.45; found: C 71.94, H 6.89, N 6.58.

*Low temperature bromination – methanolysis of* N-*acetyl-2,3-dimethylindole*

To a cooled (−40°C) solution of **11** (0.538 g; 2.87 mmol) in methanol (175 mL) was added dropwise a solution of bromine (1.0 equivalents) in acetic acid (3.7 mL). After four minutes the solution was poured into cold aqueous (10% v/v) ammonia and the mixture was extracted with methylene chloride. The organic phase was washed with saturated aqueous sodium chloride and dried over anhydrous sodium sulfate. Removal of solvent *in vacuo* yielded a brown oily product (0.76 g). The crude mixture was chromatographed on silica gel with elution by a step-wise gradient of ether – petroleum ether (60–80°C) increasing in ether content in 5% increments at 100-mL intervals from 10% to 50% v/v.

The first material eluted was **11** (0.021 g; 0.11 mmol). Further elution gave **22** (0.093 g; 0.43 mmol) as a colourless oil which darkened on standing, could not be induced to crystallize, and was identical in all respects with the material obtained by stepwise bromination–elimination of **11** described above.

After a number of mixed fractions of **22** and **17** (0.074 g of a 1:4 mixture), pure **17** (0.258 g; 1.04 mmol) was obtained as a crystalline solid, mp 49°C (from petroleum ether (60–80°C)). Infrared (film): 1675 (N$COCH_3$); uv (MeOH): 248 (13 500), 278 sh (2480), 285 sh (1900); $^1$H nmr: 1.46 (s, 3, C3 or C2—$CH_3$), 1.76 (s, 3, C2 or C3—$CH_3$), 2.36 (s, 3, N$COCH_3$), 2.87 (s, 3, C3 or C2—$OCH_3$), 3.07 (s, 3, C2 or C3—$OCH_3$), 6.83–7.70 (m, 4, Ar—H). *Exact mass* calcd. for $C_{14}H_{19}NO_3$: 249.1365; found (ms): 249.1353. *Anal.* calcd. for $C_{14}H_{19}NO_2$: C 67.44, H 7.68, N 5.62; found: C 67.62, H 7.81, N 5.63.

Finally, after a mixed fraction of **17** and **18** (0.109 g, 0.48 mmol), pure **18** (0.060 g; 0.241 mmol) was obtained as a solid, mp 50°C (from petroleum ether (60–80°C)). Infrared (film): 1668 (N—$COCH_3$); uv (MeOH): 250 (11 200), 278 sh (2440), 288 sh (1600); $^1$H nmr: 1.53 (s, 3, C3 or C2—$CH_3$), 1.66 (s, 3, C2 or C3—$CH_3$), 2.42 (s, 3, N$COCH_3$), 3.22 (s, 3, C2 or C3—$OCH_3$), 3.47 (s, 3, C3 or C2—$OCH_3$), 6.98–7.37 (m, 3, C4,5,6—H), 7.91–8.18 (m, 1, C7—H). *Exact Mass* calcd. for $C_{14}H_{19}NO_3$: 249.1365; found (ms): 249.1344. *Anal.* calcd. for $C_{14}H_{19}NO_3$: C 67.44, H 7.68, N 5.62; found: C 67.37, H 7.65, N 5.57.

*Room temperature bromination–methanolysis of* N-*acetyl-2,3-dimethylindole*

To a stirred solution of **11** (1.00 g; 5.35 mmol) in methanol (60 mL) was added dropwise a solution of bromine (1.1 equivalents) in glacial acetic acid (7.6 mL). After 10 min, the mixture was diluted with water (75 mL) and made basic with 10% aqueous ammonia. The mixture was extracted with methylene chloride and the dried organic extract was evaporated to dryness *in vacuo* to yield a brown residue (1.17 g). Part of the crude product (1.09 g) was chromatographed on silica gel with elution by a stepwise gradient of ether – petroleum ether increasing in ether content from 5% to 50% v/v. The first component eluted was the starting material **11** (0.30 g; 1.60 mmol). Further elution gave a mixture of **17** and **21** (0.361 g of a 49:51 mixture) and finally a small fraction (0.007 g) which consisted of a mixture of **18** and **19** in a ratio of 2.8:1.0 as indicated by tlc and nmr analysis.

The mixture of **17** and **21** was chromatographed on silica gel with elution by methylene chloride to give pure **21** as a waxy solid, mp 55°C (white needles from hexane). Infrared ($CHCl_3$): 1700 (C=O); uv: 242 (16 000), 263 (10 300), 289 (4900), 297 (4800); $^1$H nmr: 2.58 (s, 3, C2—$CH_3$), 2.67 (s, 3, C=O—$CH_3$), 3.32 (s, 3, C3—$OCH_3$), 4.50 (s, 2, C3—$CH_2$—), 7.02–8.00 (m, 4, Ar—H); ms *m/e* 217 (molecule ion). *Anal.* calcd. for $C_{13}H_{15}NO_2$: C 71.86, H 6.96, N 6.45; found: C 71.99, H 7.16, N 6.37.

Further elution by methanol – methylene chloride (5:95) gave pure **17** identical in all respects with that obtained from the low temperature bromination–methanolysis.

# Isomerization of acetylenic acids with sodium salt of 1,2-diaminoethane: a one step synthesis of megatomoic acid[1]

S. R. ABRAMS

*Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Sask., Canada S7N 0W9*

Received December 15, 1981

S. R. ABRAMS. Can. J. Chem. **60**, 1238 (1982).

A number of isomeric tetradecynoic acids were isomerized with the sodium salt of 1,2-diaminoethane. Isomers having the triple bond near the carboxyl group rearranged to *E,Z*-3,5- and *E,E*-3,5-tetradecadienoic acids (**1** and **2**), the former compound being the sex pheromone of the black carpet beetle. Isomers having the triple bond closer to the terminus of the chain afforded some 13-tetradecynoic acid along with **1** and **2**. Delocalized anions **12** and **13** are thought to contribute to the formation of **1** and **2**.

S. R. ABRAMS. Can. J. Chem. **60**, 1238 (1982).

On a isomérisé un certain nombre d'acides tétradécynoïques isomères avec le sel de sodium du diamino-1,2 éthane. Les isomères ayant une triple liaison près du groupe carbonyle se transposent en acides tétradécadiènoiques-*E,Z*-3,5 et *E,E*-3,5 (**1** et **2**). Le premier de ces composés est la phéromone sexuelle de l'abeille de tapis noir. Les isomères ayant une triple liaison tout près de l'extrémité de la chaîne fournissent l'acide tétradécyne-13 oïque ainsi que les acides **1** et **2**. On pense que les anions délocalisés **12** et **13** contribuent à la formation des composés **1** et **2**.

[Traduit par le journal]

## Introduction

Very strong bases isomerize internal triple bonds of hydrocarbons and alkyn-1-ols to the terminal position in high yield. The first successful isomerization reagent, the potassium salt of 1,3-diaminopropane, was discovered by Brown and Yamashita (1, 2). We have developed alternative reagents, the sodium salts of 1,3-diaminopropane (3, 4) or 1,2-diaminoethane,[2] which effect the same transformation and which can be prepared simply, reproducibly, and with greater safety.

In the course of developing a general route for the synthesis of naturally occurring terminally hydroxylated fatty acid derivatives, we sought to extend the use of these reagents to the isomerization of acetylenic acids, anticipating that an internal triple bond would be isomerized to give the terminal acetylenic acid. That is, it was thought that the base would abstract one proton from the carboxylic acid group and another from a carbon next to the triple bond. Protonation would give either the starting acetylenic acid or an allenic isomer. Abstraction by the base of an allenic proton would, after reprotonation, give the allenic acid, the original acetylenic acid, or a positional isomer. In the alkyn-1-ol case, such reversible random rearrangements are rapid with our reagents; the reaction sequence is completed when the terminal triple bond is formed and the relatively acidic acetylenic proton abstracted to give the disodium alkoxide acetylide salt.

Although alkali metal alkyl amides had not previously been employed as isomerization reagents, rearrangements of acetylenic acids with other bases have been carried out. Vigorous treatment with molten alkali results in cleavage of the carbon skeleton (the Varrentrapp reaction) (5). Reaction of 4-hexynoic and 4-pentynoic acids at 120–160°C with 9 *N* potassium hydroxide affords the conjugated 2,4-dienoic acids in good yield (6). Under milder conditions the usual acetylene–allene interconversions are observed; a series of 2-alkynoic acids rearranged by sodium amide in ammonia gives mixtures of 3-alkynoic and 2,3-alkadienoic acids (7). Both potassium carbonate (8) and aqueous sodium hydroxide (9) lead to interconversion of short chain 3-alkynoic, 2,3-alkadienoic, and 2-alkynoic acids.

From the foregoing, base mediated rearrangements of alkynoic acids would be expected to follow a course parallel to that of the acetylenic alcohols. We thus anticipated that isomerization of acetylenic acids with our reagents would proceed rapidly to produce as sole products carboxylic acids containing a terminal triple bond. However, the rearrangement did not take the expected course, but rather followed a novel pathway. We now report a study of alkali metal alkyl amide mediated rearrangements of some isomeric tetradecynoic acids including a one step synthesis of the sex pheromone of the black carpet beetle (Attagenus megatomia), *E,Z*-3,5-tetradecadienoic acid (**1**) (10).

## Results and discussion

The fourteen carbon tetradecynoic acid series was chosen to study triple bond isomerizations because the twelve possible isomers are all easily handled, known compounds (11–13). Interconver-

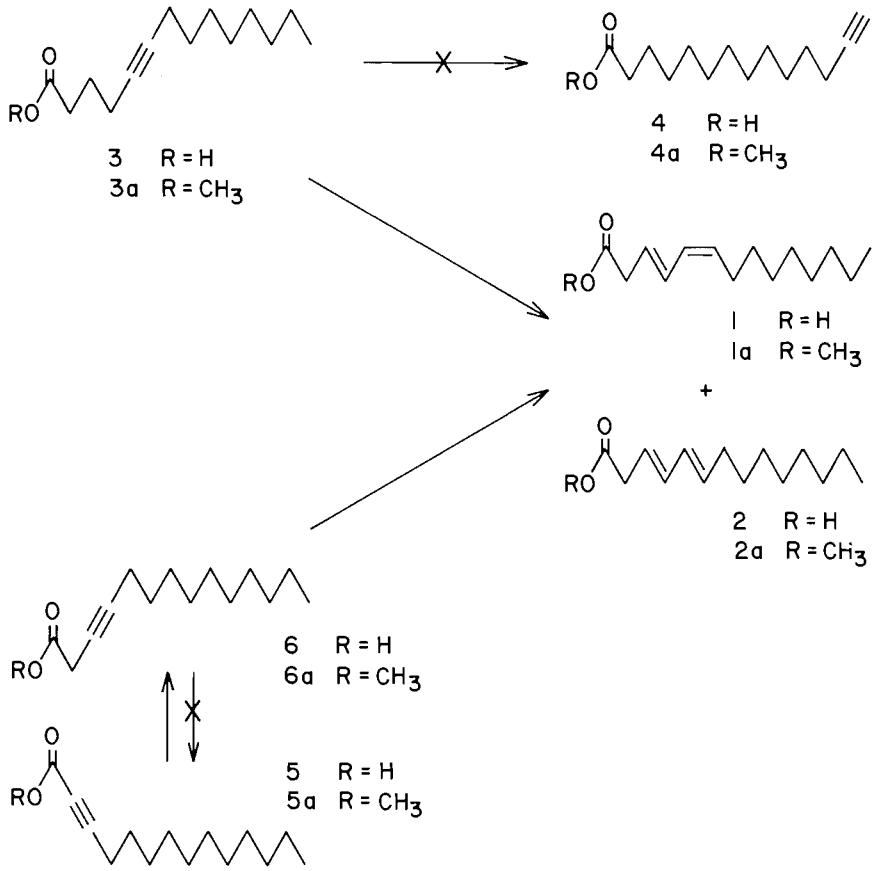

FIG. 1. Products of rearrangement of 2-, 3-, 5-tetradecynoic acid with sodium salt of 1,2-diaminoethane.

sions could be conveniently followed by gas chromatographic analysis of the methyl esters. Isomerizations were carried out by employing a five-fold excess of the sodium salt of 1,2-diaminoethane (DAE) in DAE at 60°C. The reagent was prepared just before use by reaction of sodium hydride with DAE at 60°C for 0.5–1.0 hour.

Isomerization of 5-tetradecynoic acid (**3**) for 2.5 hours gave none of the anticipated 13-tetradecynoic acid (**4**), but rather rearranged smoothly to a 1:1 mixture of two other isomeric compounds (Fig. 1). No intermediate reaction products could be detected by glc. Separation of the crude product by silver resin chromatography gave *E,Z*- and *E,E*-3,5-tetradecadienoic acids (**1** and **2**) in 67% yield. Structure and stereochemistry were established by comparison with published infrared spectra (14), mass spectral and nmr data (15).

To gain further insight into this unusual rearrangement, 2-tetradecynoic acid (**5**) was subjected to the same isomerization conditions. Quenching after 5 minutes, followed by esterification and chromatography, afforded methyl 3-tetradecynoate (*6a*) in 33% yield. The Δ3 isomer, 3-tetradecynoic acid (**6**), prepared independently, was also isomerized for 5 minutes to give a mixture of three components: starting material (50%), and the same two products **1** and **2** (50%, 1:1) isolated from the 5-tetradecynoic acid rearrangement reaction (**1** and **2**). The Δ2 to Δ3 isomerization appears to be irreversible; no 2-tetradecynoic acid was observed in the product of isomerization of 3-tetradecynoic acid. As well, allenic intermediates were not seen, and thus, if formed, must rearrange quickly under the reaction conditions.

To study how far along the carbon skeleton the effect of the carboxyl group extends, tetradecynoic acids with the triple bond closer to the methyl terminus were isomerized (Table 1). 7-Tetradecynoic acid was rearranged cleanly to the same mixture of **1** and **2** observed with the 5-tetradecynoic acid isomerization. Gas–liquid chromatography did not allow distinction between the Δ7- and Δ5-methyl esters. Although 5-tetradecynoic acid

was not isolated, it seems reasonable to postulate that the normal acetylene–allene interconversions occur and that 7-tetradecynoic acid is isomerized to 5-tetradecynoic acid which, in turn, is rearranged to **1** and **2**. Isomerization of 9-tetradecynoic acid, in which the triple bond at the Δ9 position is equidistant from C-5 and C-13, gave **1**, **2** (60%), and 13-tetradecynoic acid (**4**) (20%). The carboxyl group still affects the course of the rearrangement even when the triple bond starts eight positions away. Isomerization of 11-tetradecynoic acid gave similar results: conversion to 13-tetradecynoic acid was 27% and the 3,5-dienoic acids comprised 42% of the crude reaction mixture. Subjection of 13-tetradecynoic acid to the isomerization conditions left the terminal triple bond unchanged.

Fractions of dienoic acids rich in each isomer were subjected to the isomerization reaction conditions. In each case 70% of the material was recovered. Little change in the ratio of isomers was observed. Thus it appears that the isomers do not interconvert and are stable to the reaction conditions.

Based upon these results it seems likely that the triple bond of the fourteen carbon acid is isomerized along the carbon chain in a random fashion through acetylenic and allenic isomers. There appear to be two thermodynamic minima in the system. One, that was anticipated at the beginning of the study, is the terminal acetylenic acid **4**. Its stability is derived from the presence of acidic protons at each end of the molecule. The second thermodynamic well is the 3,5-dienoic acid system.

The formation of the 3,5-tetradecadienoic acids **1** and **2** may be accounted for by consideration of the relative acidities of the various protons in the postulated intermediate species. It is known that some alkali metal alkyl amides, notably lithium diisopropylamide, abstract two protons from carboxylic acids: one from the COOH and one from the carbon α to the carboxyl group (16). The sodium salt of DAE also appears to abstract the α proton. Reaction of 2,2-dideuterohexadecanoic acid with the sodium salt of DAE, followed by quenching with water, results in complete loss of deuterium. The loss of both deuterium atoms may be due to protonation of the dianion with the solvent 1,2-diaminoethane. Dianions may be contributing species in acetylenic acid rearrangements. Thus, Δ5 isomer **3** may give **7** which could be reprotonated by solvent (Fig. 2). Other possible intermediates may be **8** to **11**. Proton shifts from C-3 to C-5 in **10** and from C-6 to C-4 in **11** would result in extended delocalized pi (π) systems **12** and **13** which should have added stability. Protonation of **12** and **13** at C-2 would give the observed products **1** and **2**. Quenching of dianions **12** and **13** with methyl iodide would be anticipated to introduce a methyl group at C-2 giving **14** and **15** (17).

To test this hypothesis, isomerization of 7-tetradecynoic acid was carried out and the reaction quenched with methyl iodide. Two major products (total 90%, 1:1), each closely followed by minor products (10%, 1:1) were observed in the glc of the esterified reaction mixture. The mass spectra of the two major products were identical with those of **1** and **2**. The fragmentation patterns of **1** and **2** are superimposable: 238 ($M^+$), 179 ($M^+ - COOCH_3$, α-cleavage) and 164 ($M^+ - CH_3COOCH_3$, McLafferty rearrangement). The mass spectra of the two minor components were also superimposable, and consistent with **14** and **15** which are alkylated at C-2: 252 ($M^+$), 193 ($M^+ - COOCH_3$, α-cleavage), and 164 ($M^+ - H_2CCH_3COOCH_3$, McLafferty

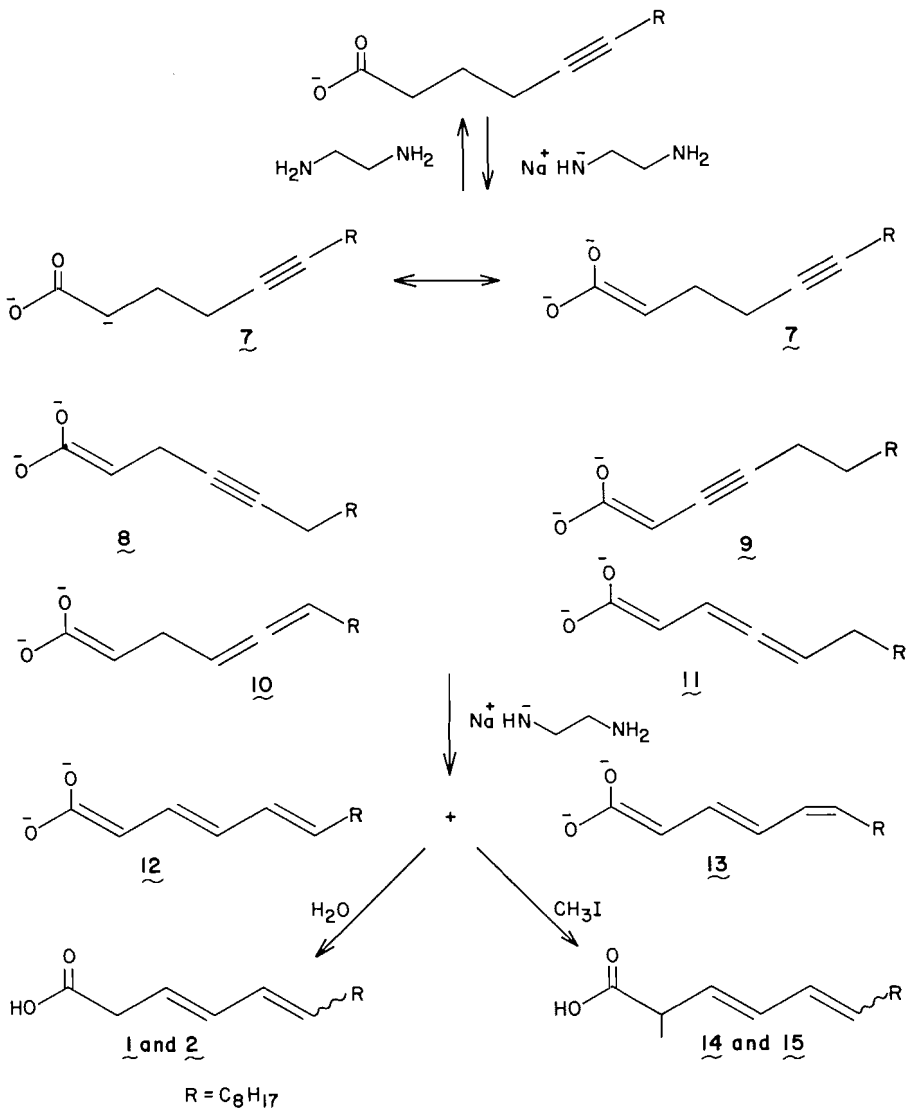

FIG. 2. Postulated intermediates in isomerization of tetradecynoic to 3,5-tetradecadienoic acids.

rearrangement). The peak at *m/z* 164 found in the spectra of the minor compounds and **1** and **2** establishes that alkylation occurs at C-2.

Ionic species having extensive delocalization of the negative charge such as **12** and **13** can only be formed if the starting alkynoic acid has an abstractable proton at C-2. As a further test for the intermediacy of **12** and **13** a 2,2-disubstituted alkynoic acid was prepared and subjected to the isomerization reaction conditions (Fig. 3). Thus, isobutyric acid was treated with two equivalents of lithium diisopropylamide to form the dianion, followed by addition of 1-bromohexadec-7-yne affording 2,2-dimethyloctadec-9-ynoic acid (**16**) according to the method of Cregar (17). Rearrangement of **16** with the sodium salt of 1,2-diaminoethane produced a single isomer, that containing the terminal triple bond, 2,2-dimethyloctadec-17-ynoic acid (**17**).

It appears from the methyl iodide trapping experiment and from the rearrangement of the 2,2-disubstituted alkynoic acid to the terminally substituted isomer that the formation of a delocalized dianion system may be the driving force for the rearrangement of acetylenic to 3,5-dienoic acids. The stereochemistry observed in **1** and **2** is consistent with protonation of **12** and **13**. The barrier for interconversion of **1** and **2** or **12** and **13** must be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

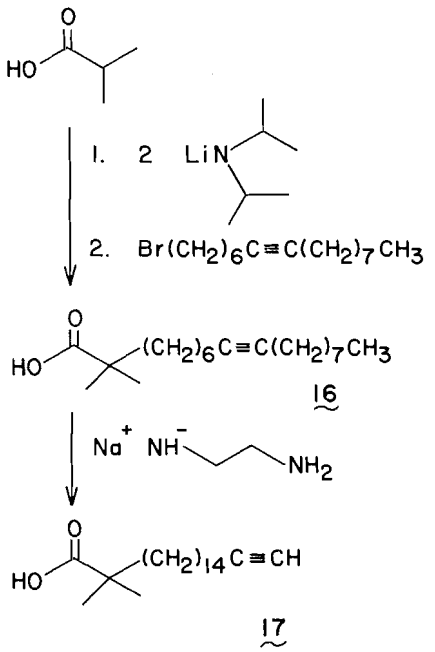

FIG. 3. Synthesis and isomerization of 2,2-dimethyloctadec-9-ynoic acid.

quite high as **1** and **2** did not equilibrate under the reaction conditions.

The rearrangement of a triple bond in the fourteen carbon acetylenic acids affords an improved synthesis of *E,Z*-3,5-tetradecadienoic acid (**1**), megatomoic acid, a component of the sex pheromone of the black carpet beetle (Attagenus megatoma). This insect is a serious pest in stored grain and flour and also attacks fabrics in clothing, rugs, and padding of furniture. The published synthesis of megatomoic acid gives **1** and **2** in 14% yield over 6 steps (15). Rearrangement of either 5- or 7-tetradecynoic acids gives mixtures of **1** and **2** cleanly and in good isolated yield (67% and 65%, respectively).

## Experimental

Infrared spectra were obtained with a Perkin Elmer 237B instrument employing chloroform solutions or neat films. Proton nmr spectra were recorded on an HA-100 spectrometer using deuterochloroform with internal tetramethylsilane as reference. Gas chromatographic separations were carried out on a Varian 3700 instrument with an SP 2100 capillary column (J and W Scientific, 30 m) with a flame ionization detector, and were run isothermally at 160° or 140°C. Acids were converted to methyl esters with diazomethane prior to glc analysis. Mass spectra were recorded on a Finnigan 4000E gc/ms instrument with an Incos 2300 data system and using an SP 2100 column. Mass spectra are reported in mass to charge units (*m/z*) with the relative intensities as percentages of the base peak. Accurate mass measurements were provided by the mass spectrometry laboratory, Psychiatric Research Unit, University of Saskatchewan, with an MS902S instrument with VG console update. Accurate masses were obtained at 1500 resolution and 3 s/decade using accurate mass – low resolution software with PFTBA internal standard. Elemental analyses were performed by Spang Microanalytical Laboratory, Eagle Harbor, Michigan, U.S.A.

The 7 tetradecynoic acids employed in this study are all known compounds. Each was prepared from the corresponding alcohol by Jones oxidation. The 2-, 5-, 7-, 9-, and 11-tetradecyn-1-ols were obtained by alkylation of the appropriate ω-tetrahydropyranyloxy alkyne using lithium amide in dimethoxyethane and alkyl halides as described previously (3). 2-Tetradecyn-1-ol was isomerized with the lithium salt of 1,3-diaminopropane at −11°C for 10 min to give 3-tetradecyn-1-ol (5) (81% conversion); product purified by chromatography over silica gel. Treatment of 2-tetradecyn-1-ol with the sodium salt of 1,3-diaminopropane at 60°C gave 13-tetradecyn-1-ol as previously reported (3).

All rearrangement reactions were carried out using the same experimental conditions, varying only the substrate and reaction time. An isomerization reaction of 7-tetradecynoic acid is described in full.

*Isomerization of 7-tetradecynoic acid*

To a 100 mL flask (flame dried under vacuum), fitted with a magnetic stirring bar and rubber septum through which a slight positive pressure of dry nitrogen was introduced, was added NaH (680 mg, 57% in mineral oil, 17 mmol). The mineral oil was removed with 3 hexane washes and 1,2-diaminoethane (DAE, previously distilled from BaO and stored over molecular sieves, 8 mL) was added. The mixture was stirred and heated at 60°C for 1 h by which time $H_2$ evolution had ceased and a purple solution resulted. A solution of 7-tetradecynoic acid (900 mg, 4 mmol) in DAE (8 mL) was added to the reagent at 60°C. After 5 min the reaction was quenched by addition of ice/water. The mixture was acidified with HCl and was extracted 3 times with ether. The combined extracts were washed with $H_2O$ and NaCl solution, dried over $Na_2SO_4$, filtered, and the solvent evaporated to give 620 mg of product. Gas–liquid chromatographic analysis (160°C) indicated 3 major components in the mixture: methyl tetradecynoates, 12%; **1***a*, 41%; **2***a*, 38%. The crude acidic product was chromatographed over an ion exchange column (Lewatit SP 1080 GR, Merck, $Na^+$ ions replaced by $Ag^+$) eluting with methanol. First to elute was *E,E*-3,5-tetradecadienoic acid (**2**), 180 mg, mp 55.5–57.0°C (plates from petroleum ether), followed by a mixed fraction of 80 mg **1** and **2**, and then by *E,Z*-3,5-tetradecadienoic acid (**1**), 120 mg as an oil. The acids were characterized as the methyl esters: methyl *E,Z*-3,5-tetradecadienoate (**1***a*); ir $\nu_{max}$ (neat film): 1740 (s), 1050 (w), 960 (m), and 940 (m) $cm^{-1}$; $^1H$ nmr δ: 5.2 to 6.7 (m, olefinic H, 4H), 3.68 (s, $OCH_3$, 3H), 3.14 (d, $J$ = 8 Hz, $OCCH_2$, 2H), 2.0 to 2.2 (m, $CH_2C$=, 2H), 1.2 to 1.4 (m, $CH_2$, 12H), and 0.90 (t, $J$ = 6 Hz, $CH_3$, 3H); mass spectrum: 238 ($M^+$, 5.3%), 179 ($M^+$ − $COOCH_3$, 1.6%), 178 ($M^+$ − $HCOOCH_3$, 1.5%), 164 ($M^+$ − $H_3CCOOCH_3$, 5.6%), 79 (81%), 41 (100%). Methyl *E,E*-3,5-tetradecadienoate (**2***a*); ir $\nu_{max}$ (neat film): 1740(s), 980(s) $cm^{-1}$; $^1H$ nmr δ: 5.4 to 6.2 (m, olefinic H, 4H), 3.63 (s, $OCH_3$, 3H), 3.05 (d, $J$ = 8 Hz, $OCCH_2$, 2H), 1.9 to 2.3 (m, $CH_2C$=C, 2H), 1.1 to 1.6 (m, $CH_2$, 12H), 0.88 (t, $J$ = 6 Hz, $CH_3$, 3H); mass spectrum: 238 ($M^+$, 4.3%), 179 ($M^+$ − $COOCH_3$, 1.8%), 178 ($M^+$ − $HCOOCH_3$, 1.2%), 164 ($M^+$ − $H_3CCOOCH_3$, 5.3%), 79 (89%), 41 (100%).

*Attempted isomerizations of* E,E-*3,5-tetradecadienoic acid (2) and of* E,Z-*3,5-tetradecadienoic acid (1)*

A sample of 3,5-tetradecadienoic acids rich in the *E,E*-isomer (86:14), 200 mg, was subjected to the isomerization reaction conditions. After 2 h 140 mg product was recovered, glc analysis gave 78% **2***a* and 13% **1***a*.

Similarly a sample rich in *E,Z*-3,5-tetradecadienoic acid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

For personal use only.

(79:17), 105 mg, was submitted to the reaction conditions for 2 h; 70 mg was recovered. Gas–liquid chromatographic analysis indicated 73% **1***a* and 17% **2***a*.

*Reaction of 2,2-dideuterohexadecanoic acid with the sodium salt of DAE*

To the sodium salt of DAE (7.2 mmol in 4.0 mL DAE) at 60°C was added a solution of 2,2-dideuteropalmitic acid in DAE (300 mg, 1.2 mmol in 3.2 mL DAE). The reaction was quenched after 15 min and worked up to give 300 mg white solid. A small sample was esterified with diazomethane and $^1$H nmr integration of $OCH_3$ to $CH_2CO$ was 3:2 indicating complete exchange of protons for deuterons.

*Isomerization of 7-tetradecynoic acid quenched with methyl iodide*

The isomerization reaction of 7-tetradecynoic acid was repeated using 250 mg Δ7. After 5 min the reaction was cooled in an ice/salt bath and methyl iodide (0.6 mL, 9 equiv.) was added dropwise. After the usual work-up 260 mg product was obtained; glc of the methyl esters at 160°C showed two new products each with slightly longer retention times than **1***a* and **2***a*: methyl tetradecynoates, 11%; **1***a*, 38%; **14***a*, 3.4%; **2***a*, 35%; **15***a*, 3.5%. Mass spectrum of **14***a*: 252 ($M^+$, 5.5%), 193 ($M^+ - COOCH_3$, 6.2%), 192 ($M^+ - HCOOCH_3$, 2.7%), 164 ($M^+ - CH_3COOCH_3$, 3.1%), 81 (94%), 41 (100%); mass spectrum of **15***a*: 252 ($M^+$, 6.0%), 193 ($M^+ - COOCH_3$, 7.4%), 192 ($M^+ - HCOOCH_3$, 2.4%), 164 ($M^+ - CH_3COOCH_3$), 81 (100%). Quenching with a larger excess of methyl iodide led to the same ratios of products.

*2,2-Dimethyloctadec-9-ynoic acid (**16**)*

To a cooled solution of diisopropylamine (1.6 mL, 12 mmol) in dry tetrahydrofuran (THF, distilled from benzophenone ketyl, 50 mL) was added a solution of *n*-butyllithium in hexane (7.0 mL, 14 mmol) maintaining internal temperature less than 0°C. The pale yellow solution was kept at 0°C for 0.5 h, then a solution of isobutyric acid (0.56 mL, 6.0 mmol, distilled from $P_2O_5$) in THF (5 mL) was added. Still at 0°C, after 0.5 h, to the gold solution was added 1-bromohexadec-7-yne (1.6 g, 10 mmol) in THF (10 mL). After warming to ambient temperature and stirring overnight the reaction mixture was poured into ice/dilute HCl and the product extracted 3× with ether. The combined organic phases were washed with NaCl solution, dried over $Na_2SO_4$, filtered, and the solvent evaporated to give 2.8 g product. Filtration over silica gel, eluting first with hexane, gave 550 mg recovered bromide and then with ether gave **16** (1.15 g, 3.7 mmol, 62%) having bp 200°C at 0.1 Torr; ir $\nu_{max}$ (neat film): 3100 (br s), 1700 (s) cm$^{-1}$; $^1$H δ: 2.12 (m, $w_{1/2}$ = 5 Hz, $H_2CC{\equiv}C$, 4H), 1.2–1.6 (m, $w_{1/2}$ = 15 Hz, $CH_2$, 22H), 1.15 (s, $CH_3$, 6H), 0.86 (t, $J$ = 6 Hz, $CH_3$, 3H). *Anal.* calcd. for $C_{20}H_{36}O_2$: C 77.86, H 11.76; found: C 77.46, H 11.79. The methyl ester gave glc retention time 16.7 min at 210°C; mass spectrum *m/z*: 322 ($M^+$, 1%), 102 ($(H_3COCOHC(CH_3)_2)^+$, McLafferty rearrangement, 100%); molecular ion *Exact Mass* calcd.: 322.2872; found: 322.2892.

*2,2-Dimethyloctadec-17-ynoic acid (**17**)*

To the sodium salt of DAE (5.0 mmol in 2.0 mL DAE) at 60°C was added a solution of **16** (250 mg, 0.8 mmol) in DAE (3.0 mL). After 3 h, the reaction was quenched and worked up to give 340 mg crude product. The glc of methyl esters at 210°C gave 2 peaks: retention time 16.7 min (7%) and 17.5 min (92%). The product was distilled at 240°C (0.1 Torr) to give pure **17**, 120 mg (48%); ir $\nu_{max}$ ($CHCl_3$): 3610 (m), 3300 (s), 3100 (br s), 2100 (w), 1700 (s) cm$^{-1}$; $^1$H nmr δ: 2.16 (m, $w_{1/2}$ = 12 Hz, $H_2CC{\equiv}C$, 2H), 1.88 (t, $J$ = 1.5 Hz, $C{\equiv}CH$, 1H), 1.2–1.6 (m, $w_{1/2}$ = 4 Hz, 26H), 1.20 (s, $CH_3$, 6H). *Anal.* calcd. for $C_{20}H_{36}O_2$: C 77.86, H 11.76; found: C 78.27, H 12.14. The methyl ester gave glc retention time 17.5 min at 210°C; mass spectrum *m/z*: 322 ($M^+$, 1%), 102 ($(H_3COCOHC(CH_3)_2)^+$, McLafferty rearrangement, 100%); molecular ion *Exact Mass* calcd.: 322.2872; found: 322.2869.

# The adsorption of tri-*N*-butylphosphate at the benzene–water interface[1,2]

NORMAN H. SAGERT, WOON LEE, AND MICHAEL J. QUINN

*Research Chemistry Branch, Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Man., Canada R0E 1L0*

Received November 25, 1981

NORMAN H. SAGERT, WOON LEE, and MICHAEL J. QUINN. Can. J. Chem. **60**, 1244 (1982).

Adsorption of tri-*n*-butylphosphate (TBP) at the benzene–water interface was studied as a function of the TBP mole fraction in benzene up to 0.018 and at temperatures from 9 to 29°C. The extent of adsorption was calculated from interfacial tension data obtained by the drop-volume technique. Standard free energies of adsorption from benzene ranged from −20.9 kJ/mol at 9°C to −22.5 kJ/mol at 29°C, giving a standard enthalpy of adsorption of +2.5 kJ/mol. Thus the strong adsorption occurs because of entropy changes. Distribution coefficients for the partition of TBP between benzene and water were measured by gas chromatography, and standard free energies of adsorption from water were derived. They ranged from −44.8 kJ/mol at 9°C to −51.1 kJ/mol at 29°C, with standard enthalpies of adsorption ranging from 74 to 15 kJ/mol over the same temperature range.

Results at higher mole fractions were fitted to various equations of state, after using vapor pressure osmometry (at 37°C) to determine that activity corrections were small. The Schofield–Rideal equation described the results adequately, with $A_0$ close to 1.0 nm² and $i$ close to 1.0 at lower temperatures. These values imply that lateral repulsion between TBP molecules in the adsorbed layer is minimal.

NORMAN H. SAGERT, WOON LEE et MICHAEL J. QUINN. Can. J. Chem. **60**, 1244 (1982).

On a étudié l'adsorption du tri-*n*-butylphosphate (TBP) à l'interface benzène–eau, en fonction de la fraction molaire de TBP dans le benzène, jusqu'à une valeur de 0,018 et à des températures allant de 9 à 29°C. On a calculé le taux d'adsorption à partir des données de tension interfaciale obtenues par la technique du volume de la goutte. Les énergies libres standard d'adsorption à partir du benzène varient de −20,9 kJ/mol à 9°C à −22,5 kJ/mol à 29°C pour une enthalpie standard d'adsorption de +2,5 kJ/mol. Ainsi il se produit une forte adsorption par suite des variations d'entropie. On a mesuré la distribution des coefficients de partage du TBP entre le benzène et l'eau en utilisant la chromatographie en phase gazeuse et on en a déduit les énergies libres standard d'adsorption à partir de l'eau. Elles se situent entre −44,8 kJ/mol à 9°C et −51,1 kJ/mol à 29°C avec des enthalpies standard d'adsorption se situant entre 74 et 15 kJ/mol pour le même intervalle de température.

On a accordé les résultats obtenus pour de plus fortes fractions molaires à différentes équations d'état après avoir utilisé l'osmométrie de la pression de vapeur (à 37°C) pour déterminer que les corrections du coefficient d'activité sont faibles. Pour les basses températures, l'équation de Schofield-Ridéal décrit adéquatement les résultats avec $A_0$ voisin de 1,0 nm² et $i$ voisin de 1,0. Ces valeurs impliquent que la répulsion latérale entre les molécules de TBP dans la couche adsorbée est minimale.

## Introduction

As part of a program to study the interfacial properties of solvent extraction systems used in the nuclear industry, we previously studied the adsorption of tri-*n*-butylphosphate (TBP) and the lower trialkylphosphates at the dodecane–water interface (1, 2). That work showed large negative standard free energies of adsorption, as well as fairly large negative enthalpies of adsorption. Recent work by Chifu *et al.* (3, 4) on the adsorption of TBP at the benzene–water interface seemed to show much less negative standard free energies of adsorption, but actual numerical data were not given and enthalpies were not determined. Since there are several reports that indicate significant bonding between alkylphosphates and benzene (5–7), it seemed appropriate to study the thermodynamics of adsorption of TBP at the benzene–water interface. To interpret our results properly, it was necessary to have good values of the distribution ratios of TBP between benzene and water at several temperatures. Hence it was necessary to determine these ratios as well.

## Experimental

The adsorption of TBP at the benzene–water interface was studied by measuring interfacial tensions. For temperatures of 9, 14, 19, 24, and 29°C, up to 50 μmol TBP were added to a system of 50 cm³ water and 50 cm³ benzene, and the system thoroughly equilibrated. At four intermediate temperatures, 11.5, 16.5, 21.5, and 26.5°C, interfacial tensions were measured only in the more dilute region, by adding up to 2.5 μmol TBP to the same water–benzene system. Solutions were not used longer than 72 h. Interfacial tension measurements were made by the drop-volume method using apparatus and procedures that have been described previously (1, 2).

Distribution ratios were measured at 10, 15, 20, 30, and 40°C using procedures that have been described previously (8). Because of the magnitude of these ratios, small amounts of the organic phase in the aqueous phase could have a large effect on the results. Hence, 1.0-cm³ samples of the aqueous phase were withdrawn and centrifuged at 100 Hz for 30 min. The organic phase was diluted by a factor of 100 with pure benzene and then both phases were analyzed for TBP by gas chromatography, using a glass column of 3% nitrile silicone gum OV-225 on Chromosorb G at 220°C.

Osmotic coefficients of TBP in benzene were measured at

37°C using a Mechrolab 301A vapor pressure osmometer, modified by substituting a Hewlett-Packard HP419A null voltmeter for the built-in null detector. Zone-refined biphenyl was used as a standard.

The sources and purification of water and TBP have been described previously (1, 2). The benzene was Phillips Research Grade, and before use it was passed through an alumina column.

## Results

Some typical results,[3] at 24°C, for the adsorption of TBP at the benzene–water interface are shown in Fig. 1. These and similar data were fitted to expressions of the form of eq. [1]

$$[1]\quad \gamma = C_1 + C_2 \ln X + C_3 (\ln X)^2 + C_4 (\ln X)^3$$

where $\gamma$ is the interfacial tension in N/m and $X$ is the mole fraction of TBP in the benzene. The values of the constants, $C_i$, obtained by a least-squares fit to eq. [1], are listed in Table 1. Standard deviations of the fit are also given. In the most dilute region of solute mole fraction, the decreases in interfacial tensions, i.e. the interfacial pressures, become linear with solute mole fraction. Some data, shown at only two temperatures for clarity, are plotted in this form in Fig. 2. Within the claimed experimental error of ±50 μN/m (1) for interfacial tensions, and thus ±100 μN/m for $\pi$, these plots may be considered as linear.

Distribution ratios, defined as the concentration of TBP in benzene divided by that in water, are shown in Fig. 3 as a function of TBP concentration in benzene. These distribution ratios are easily extrapolated to zero solute concentration to obtain the distribution coefficient, $K_D$. The values of $K_D$ so obtained, and of the mole fraction distribution coefficients, $K_D^X$, defined in a similar fashion to $K_D$, are listed in Table 2. The errors here are ±5% as a minimum, and may be as large as ±10%, because of the large absolute values of the distribution ratios and attendant difficulties in the gas chromatographic technique.

[3]All the measured distribution ratios and interfacial tensions are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

## Discussion

*Thermodynamics of transfer*

The standard free energy of transfer of TBP from water to benzene, $\Delta_\alpha^\beta \bar{G}_1^\ominus$, is given by eq. [2]:

$$[2] \quad \Delta_\alpha^\beta \bar{G}_1^\ominus = \mu_1^{\ominus,\beta} - \mu_1^{\ominus,\alpha} = -RT \ln K_D^X$$

where β and α refer to the benzene and aqueous phases, respectively, and subscript 1 refers to the solute, TBP. The standard states are the hypothetical conditions of unit solute mole fraction and unit activity coefficient (8, 9). From the temperature variation of the standard free energies of transfer, standard enthalpies of transfer, $\Delta_\alpha^\beta \bar{H}_1^\ominus$, may be calculated using eq. [3]:

$$[3] \quad \Delta_\alpha^\beta \bar{H}_1^\ominus = \partial(\Delta_\alpha^\beta \bar{G}_1^\ominus/T)/\partial(1/T)$$

Standard entropies of transfer, $\Delta_\alpha^\beta \bar{S}_1^\ominus$, are then easily obtained. Figure 5 shows a plot of $\Delta_\alpha^\beta \bar{G}_1^\ominus/T$ against $1/T$. This plot has significant curvature, and therefore $\Delta_\alpha^\beta \bar{H}_1^\ominus$ varies with temperature. Table 3 lists values of three thermodynamic functions at selected temperatures. The variations in the standard enthalpy of transfer correspond to a standard heat capacity of $-1300 \pm 200$ J mol$^{-1}$ K$^{-1}$.

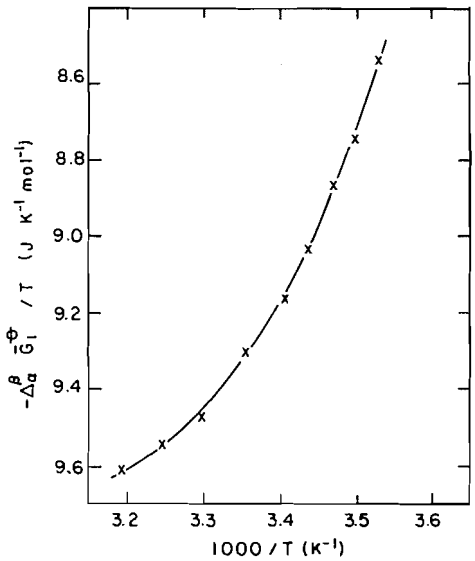

FIG. 5. Determination of the standard enthalpies of transfer of TBP from water to benzene.

TABLE 3. Standard free energies, enthalpies, and entropies of transfer of TBP from water to benzene

| $T$ (°C) | $\Delta_\alpha^\beta \bar{G}^\ominus$ (kJ/mol) | $\Delta_\alpha^\beta \bar{H}^\ominus$ (kJ/mol) | $\Delta_\alpha^\beta \bar{S}^\ominus$ (J K$^{-1}$ mol$^{-1}$) |
|---|---|---|---|
| 15 | −25.57 | 40.2 | 236 |
| 25 | −27.75 | 28.6 | 189 |
| 35 | −29.40 | 16.3 | 148 |

It is instructive to compare the thermodynamic parameters given in Table 3 with similar ones for the transfer of TBP from water to dodecane (8). The standard free energy of transfer of TBP to benzene is much more negative than that to dodecane, reflecting much larger distribution ratios. Weak complexing between TBP and benzene (5–7) could explain the difference. As with dodecane, the standard enthalpy of transfer is positive, indicating that transfer of TBP from water to benzene is opposed enthalpically and takes place only because of the large standard entropy of transfer. The standard enthalpy change at 25°C is equivalent to the breaking of about two hydrogen bonds (10). However, at 35°C it is, perhaps, equivalent to the breaking of only one such bond. The standard entropy of transfer at 30°C is similar to that for the transfer from water to dodecane (8). This is consistent with the commonly accepted picture for "hydrophobic bonding", which attributes the entropy changes largely to the loss of water structure around the hydrocarbon chains as the solute is transferred from water into hydrocarbon (11, 12).

The standard heat capacity of transfer corresponds almost exactly with the negative of the apparent molal heat capacity of three butyl groups in water, as calculated from the additivity relations of Jolicoeur and Lacroix (13). Thus the observed standard heat capacity of transfer can be accounted for by the loss of hydrational heat capacity as the butyl groups are transferred from water to benzene. A larger temperature range was examined in this work than with the dodecane–water system (8), so perhaps it is not surprising that heat capacity effects were not noted in the previous work.

It would be desirable to compare the standard enthalpies of transfer obtained here with those calculated from calorimetric data, since the enthalpy of transfer is simply the difference between the enthalpies of solution in the two phases. The enthalpy of solution of TBP in benzene was determined by Kertes *et al.* (5) to be −1.7 kJ/mol. However, the heat of solution of TBP in water has not been measured because of the low solubility of TBP in water. From our data, we would estimate it as −27 ± 5 kJ/mol at 25°C, somewhat lower than the value of −34 ± 5 kJ/mol deduced previously from the transfer of TBP from water to dodecane. One major difference between measuring enthalpies of transfer directly and obtaining them from calorimetric data is that heats of solution are usually measured in pure phases, whereas in the transfer experiment, the phases are mutually saturated. Since mutual solubilities are much higher in the benzene–water system than in the dodecane–water system, they could be responsible for some of the differences noted.

*Thermodynamics of adsorption*

Standard free energies of adsorption, $\Delta_a\mu^\ominus$, from benzene were calculated from the limiting slopes in Fig. 2 using eq. [4]:

$$[4] \quad \Delta_a\mu^\ominus = -RT \ln (\pi/X)_0$$

where $(\pi/X)_0$ is the limiting slope of the surface pressure $\pi$ against the TBP mole fraction $X$, as both approach zero. The standard states used are unit mole fraction of TBP in benzene, but with unit activity coefficient, and 1.0 mN/m in the surface layer, as used by Aveyard and Briscoe (14, 15). Mole fractions of TBP in the aqueous phases were determined from the distribution coefficients, and standard free energies of adsorption from water were calculated from the same interfacial pressure data. The standard free energies of adsorption from both phases are listed in Table 4. They are somewhat less negative than those for the adsorption of TBP from dodecane or water to the dodecane–water interface (2). This is in accord with evidence that there is some complexing between TBP and benzene (5–7).

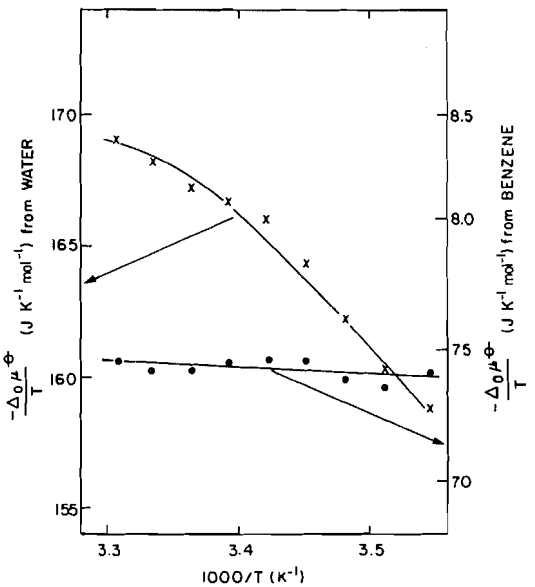

FIG. 6. Determination of the standard enthalpies of adsorption of TBP from benzene (○) and from water (×) to the benzene–water interface.

Standard enthalpies of adsorption, $\Delta_a h^\ominus$, were obtained from the standard free energies of adsorption by using equations analogous to eq. [3]. Plots of $\Delta_a\mu^\ominus/T$ against $1/T$ are shown in Fig. 6, and the derived standard enthalpies and entropies of adsorption are given in Table 5. Since adsorption from both phases involves a positive standard enthalpy of adsorption, adsorption is not favored enthalpically. Adsorption from benzene is only slightly endothermic, whereas adsorption from water is endothermic by an amount equivalent to about two hydrogen bonds at the higher temperatures. However, the overall process must be much more complicated than simply breaking hydrogen bonds, since complexing of TBP with benzene is also involved. It seems that complexing of TBP with benzene begins to occur (5–7) at the same time as the hydrogen bonds with water are broken, when the TBP moves from water to the interface. On moving from the interface into benzene, these two processes are almost balanced.

The positive standard enthalpies of adsorption are, of course, offset by large positive standard entropies of adsorption, $\Delta_a S^\ominus$. For adsorption from the water side, a large fraction of this standard entropy of adsorption is accounted for by the "hydrophobic bonding" involved in transferring the butyl groups from water to benzene (11). This effect has been discussed above. However, there is also a large positive entropy change in going from the bulk to the surface. Since adsorption from dodecane to the dodecane–water interface involves a negative standard entropy of adsorption using the same standard states (12), the standard entropy observed here reflects a loss of benzene structure around the phosphate groups as they approach the interface.

*Surface equation of state*

Surface tension data were fitted to the Schofield–Rideal equation of state (16), eq. [5],

$$[5]\quad \pi(A - A_0) = ikT$$

where $\pi$ is the surface pressure as before, and $i$ and $A_0$ are fitting constants. The area available per molecule, $A$, was calculated from the Gibbs adsorption isotherm using the constants of Table 1, as previously described (1, 2). Activity coefficients of TBP in benzene were taken as 1.0. Values of $i$ and $A_0$ obtained from the least-squares fit are listed in Table 6, and the goodness of the fits is illustrated in Fig. 7. Although $A_0$ is only a fitting constant, it is frequently discussed in terms of the static molecular area of the solute. At the lower temperatures,

| 29 | 0.60±0.18 | 1.78±0.19 |

the $A_0$ values are very close to the geometric area of the TBP and the $i$ values are close to 1.0, as is usual for adsorption at a liquid–liquid interface (17). At higher temperatures, the $i$ values become larger than 1.0 and the $A_0$ values become smaller. This behavior corresponds to increased cohesion in the adsorbed layer, somewhat similar to that for ionized adsorbed layers (17). Some of this repulsion can be accounted for by dipole–dipole repulsion in the adsorbed layer (1, 2), or by variation of $A_0$ with coverage.

Attempts were made to use a two-dimensional solution model for the interface (18, 19) and to fit data to the Van der Waals equation of state (20), but these did not result in any improvements in the fit.

## Acknowledgements

We thank R. J. Porth for preparing TBP, and A. S. Kertes, P. R. Tremaine, and our colleagues at the Whiteshell Nuclear Research Establishment for helpful advice.

# Molecular orbital calculations of the ionization potentials and stabilization energies of aminoalkyl radicals[1]

JOHN D. GODDARD

*Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6*

Received September 11, 1981

JOHN D. GODDARD. Can. J. Chem. **60**, 1250 (1982).

A series of aminoalkyl radicals, $H_2NCH_2$, $H(CH_3)NCH_2$, $(CH_3)_2NCH_2$, $H_2NC(CH_3)H$, $H_2NC(CH_3)_2$, and the corresponding amines have been examined by *ab initio* computations. The first vertical ionization potentials of the radicals calculated by the direct SCF method were very low: $H_2NCH_2$ (6.3 eV), $H(CH_3)NCH_2$ (6.0 eV), and $(CH_3)_2NCH_2$ (5.8 eV) and decreased with methyl substitution at nitrogen. The first ionization potentials of $H_2NC(CH_3)H$ and $H_2NC(CH_3)_2$ were predicted to be 5.9 and 5.6 eV respectively. Radical stabilization energies were calculated from SCF results in several basis sets and with several choices of optimized geometries for $R_2NCR_2 + CH_4 \rightarrow R_2NCR_2H + CH_3$. The aminomethyl radical, $H_2NCH_2$, was calculated to be 8 to 10 kcal/mol stabilized relative to methyl. The present calculations predict that methyl substitution at N has a small destabilizing effect on $H_2NCH_2$ which contrasts with recent experiments. The effect of methyl substitution and details of the "three-electron" bond in aminoalkyl radicals are examined qualitatively by orbital interaction diagrams.

JOHN D. GODDARD. Can. J. Chem. **60**, 1250 (1982).

Faisant appel à des calculs *ab initio*, on a étudié une série de radicaux aminoalkyles $H_2NCH_2$, $H(CH_3)NCH_2$, $(CH_3)_2NCH_2$, $H_2NC(CH_3)H$, $H_2Nc(CH_3)_2$ ainsi que les amines correspondantes. Les premiers potentiels d'ionisation verticaux des radicaux, calculés par la méthode directe SCF, sont très faibles $H_2NCH_2$ (6,3 eV), $H(CH_3)NCH_2$ (6,0 eV) et $(CH_3)_2NCH_2$ (5,8 eV) et diminuent lorsque les substituants méthyles sur l'azote augmentent. On a prévu que les premiers potentiels d'ionisation du $H_2NC(CH_3)H$ et du $H_2NC(CH_3)_2$ seraient respectivement de 5,9 et de 5,6 eV. On a calculé les énergies de stabilisation du radical à partir des résultats SCF dans plusieurs ensembles de base et avec plusieurs choix de géométries optimisées pour la réaction $R_2NCR_2 + CH_4 \rightarrow R_2NCR_2H + CH_3$. On a calculé que le radical aminoéthyle est stabilisé par environ 8 à 10 kcal/mol par rapport au méthyle. Les calculs actuels prédisent que le degré de substitution en méthyle au niveau de l'azote a un faible effet déstabilisateur sur le $H_2NCH_2$ qui contraste avec des expériences récentes.

Utilisant les diagrammes d'interactions d'orbitales, on a étudié qualitativement les effets de la substitution du méthyle et les détails de la liaison à "trois électrons" dans les radicaux aminoalkyles.

[Traduit par le journal]

## Introduction

Aminoalkyl radicals, $R_2NCR_2$, represent an interesting series of compounds in that their properties must be strongly influenced by the carbon–nitrogen "three-electron bond". In recent experiments, Griller and Lossing (1), using in part recent thermochemical data on alkyl immonium ions (2), found remarkably large stabilization energies and low first ionization potentials for $H_2NCH_2$, $H(CH_3)NCH_2$, and $(CH_3)_2NCH_2$. The first ionization potential for $(CH_3)_2NCH_2$ of 5.7 eV measured by Griller and Lossing (1) is the lowest yet reported for an organic species. The stabilization energy, $E_s$, of $NH_2CH_2$ was determined to be $10 \pm 2$ kcal/mol in agreement with earlier kinetics experiments (3). However, the dramatic increase in $E_s$ with *N*-methylation as observed by Griller and Lossing (1) ($E_s(H(CH_3)NCH_2) = 17$, $E_s((CH_3)_2NCH_2) = 20$ kcal/mol) was noteworthy. Earlier data (4) suggesting that $(CH_3)_2N$— was stabilizing by 19 kcal/mol had been discounted (3) on the assumption that $E_s$ should *not* be significantly affected by *N*-alkylation. However, in the somewhat related alkyl immonium ions (2), the stabilizations (changes in heterolytic bond dissociation energy) brought about by substitution by —$NH_2$, —$N(CH_3)H$, and —$N(CH_3)_2$ were 94, 107, and 114 kcal/mol, showing a large change upon *N*-methylation.

The unusual properties of aminoalkyl radicals must be due largely to the presence of the "three-electron" bond between C and N. Qualitative aspects of the three-electron bond have been discussed in the literature (5–7, 9). However, *ab initio* computational studies of such bonding are relatively scarce (8–11) and the CN "three-electron" bond has only recently been examined in detail by such methods (11). In the present computational study, *ab initio* SCF calculations in several basis sets were performed for the "three-electron" bonded radicals: $H_2NCH_2$, $H(CH_3)NCH_2$, $(CH_3)_2NCH_2$, $H_2NC(CH_3)H$, and $H_2NC(CH_3)_2$. All species have been geometry-optimized including the amines necessary to determine radical stabilization energies from the reaction:

$$R_2NCR_2 + CH_4 \rightarrow R_2NCHR_2 + CH_3$$

The computed results are analyzed by qualitative MO methods and compared in detail with recent experimental work (1).

## Methods of calculation

All calculations were performed with a modified version (12) of the GAUSSIAN76 program system (13). Geometries were optimized for all molecules at the 4-31G (14) level using energy gradient methods (15). Some species were also geometry-optimized with the minimal STO-3G (16) and the polarized 6-31G* (17) basis sets. Additional calculations with other basis sets including the 6-31G** set (17) were also carried out at the various optimized geometries. Calculations on the radicals employed the unrestricted Hartree-Fock (UHF) method (18). The 4-31G expectation values of $S^2$ at the optimum geometries ranged from 0.7599 to 0.7613 while the value for a doublet is 0.7500. It is anticipated that spin contamination had no significant effects on the calculated geometries. For aminomethyl in the 4-31G basis set, this assumption was explicitly checked by carrying out an RHF calculation including the energy gradients at the UHF-optimized geometry. The value of $S^2$ for the UHF calculation was 0.7600 in this case. The RHF forces at the UHF geometry were all small with the largest less than $8 \times 10^{-3}$ mdyn-Å/radian in magnitude and indicate that reoptimization with an RHF procedure would lead to very minor changes in geometry. In order to set a scale for the orbital interaction diagram vertical first ionization potentials were predicted from the orbital energy of the singly occupied molecular orbital (SOMO) by Koopmans' theorem. More accurate ionization potentials for comparison with the experimental results (1) were calculated by a direct SCF approach (19) involving a separate SCF calculation on the cation at the 4-31G UHF optimized geometry of the radical. Thus, the calculated ionization potentials refer to a strictly vertical process.

## Results and discussion

### *Geometries*

No detailed discussion of the optimized geometries of the amines or aminoalkyl radicals will be presented here. A few points regarding the structures will be noted to the extent that they bear on the probable reliability of the calculated ionization potentials and radical stabilization energies. The 4-31G basis set is well known (e.g. (20)) to underestimate the pyramidality of trivalent nitrogen and this *systematic error* is present in the results of this study *both* for the amines *and* for the aminoalkyl radicals (see Tables 1 and 2). Other geometrical parameters (e.g. the CN bond lengths) are in good agreement with experiment for the amines (within 0.02 Å) and presumably also for the aminoalkyl

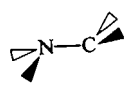
radicals. In determining the radical stabilization energies from

$$R_2NCR_2 + CH_4 \rightarrow R_2NCR_2H + CH_3$$

at the 4-31G geometries and with various basis sets (4-31G, 6-31G*, 6-31G**), it is implicitly assumed that the errors in having the nitrogen too planar are the same in the amines and aminoalkyl radicals and thus approximately cancel. Some computational evidence for this assumption will be presented in the section on stabilization energies where the results of determining these quantities at STO-3G or 6-31G* geometries (which do *not* suffer from the defect of having the nitrogen too planar) will be given. *Trends* in the stabilization energies will be shown to be independent of the reference geometries and basis sets used in the SCF calculations.

The aminoalkyl radicals are all calculated to be at least slightly nonplanar at both N and C and to adopt nontwisted *anti* conformations:



Given the 4-31G basis set's known tendency to underestimate pyramidality, this slight nonplanarity strongly implies that the radicals will be found to be nonplanar experimentally. The predicted geometries agree qualitatively (chair conformation, C and N nonplanar) with suggestions based on esr experiments (21, 22) and semiempirical INDO calculations (21). The methyl substituents on N show a conformation previously seen in methylamine (e.g. (20)) with one long CH bond antiperiplanar to the nitrogen lone pair and two shorter bonds *gauche* to this pair.

A few of the more interesting geometrical parameters are collected in Tables 1 and 2 where some comparisons of the results with different basis sets and with experiment are also given.

## Ionization potentials

Ionization potentials of the aminoalkyl radicals as calculated by Koopmans' theorem and by direct SCF calculations on the radical and cation are given in Table 3. The Koopmans' theorem results which neglect orbital relaxation are not expected to be quantitatively accurate and are ~1.5 eV larger than experiment (1). These values are presented as they provide the orbital energy scale in the qualitative discussion to follow. The direct SCF results are in surprising agreement with experiment (1) being ~0.1 eV larger. The direct SCF method neglects changes in correlation energy between the neutral radical and the closed-shell cation. However, to zeroth order, these species differ only in one singly occupied orbital whereas important correlation effects are due to pairs of electrons. Thus, a direct SCF approach would be expected to yield reliable vertical ionization potentials for the present species. However, the experimental results have previously been assumed to be close to the *adiabatic* values of the ionization potential (25). Methylation at N lowers the first ionization potential by 0.2 to 0.3 eV and follows the experimental trend (1). The same *trend* may be seen in either the Koopmans' theorem or direct SCF results. $H_2NC(CH_3)H$ and $H_2NC(CH_3)_2$, which have not yet been characterized experimentally, are predicted to have low ionization potentials of 5.9 and 5.6 eV respectively. Thus, methylation directly at the carbon radical centre lowers the ionization potential by ~0.1 eV more than methylation at N (e.g. $CH_3(H)NCH_2$ 4-31G ΔSCF 6.04 eV, $NH_2C(CH_3)H$ 4-31G ΔSCF 5.9 eV).

### *Radical stabilization energies*

Radical stabilization energies (in kcal/mol) are reported in Tables 4 and 5. These quantities were calculated from the computed heats of reaction for $R_2NCR_2 + CH_4 \rightarrow R_2NCHR_2 + CH_3$ with several basis sets and geometries. The methyl radical defines a zero on the scale with more stable radicals having negative stabilization energies. In Table 4, the ethyl radical is included for comparison with a very recent experimental determination of its stabi-

lization energy. The ethyl radical is predicted to be ~3 kcal/mol more stable than methyl in good agreement with the value of 4.1 ± 1.0 kcal/mol from experiment (23). The aminomethyl radical, $H_2NCH_2$, is predicted to have a stabilization energy of 8 to 10 kcal/mol which also agrees with the values inferred from experiment (1, 3).

The calculated stabilization energies for $CH_2N(CH_3)H$ and $CH_2N(CH_3)_2$ are particularly noteworthy in that they are slightly *less* than that found for $H_2NCH_2$. This calculated trend disagrees with recent experiments (1) which derived a very dramatic increase in stability with *N*-alkylation to $E_s(CH_2N(CH_3)H) = 17$ and $E_s(CH_2N(CH_3)_2) = 20$ kcal/mol. As can be seen from Table 5, the calculated small decrease in stability of dimethylamino-relative to amino- is *not* due to the use of 4-31G optimized geometries (Table 4) as the same trend appears in SCF calculations at STO-3G or 6-31G* optimized geometries. Further discussion of this discrepancy between computation and experiment will be given in the next section.

The *C*-methylated aminoalkyl radicals are predicted to be slightly more stable than either the simple amino or the *N*-methylated amino radicals. Stabilizations of 9.5 to 11.5 and 11.0 to 12.8 kcal/mol are calculated for $C(CH_3)HNH_2$ and $C(CH_3)_2NH_2$. Thus the additional methyls attached to C are stabilizing by 1.0 to 1.5 kcal/mol relative to $H_2NCH_2$.

### *Qualitative molecular orbital considerations and comparisons with experiment*

Figure 1 illustrates an orbital interaction scheme between the HOMO of ammonia, methylamine, and dimethylamine and the SOMO of the methyl radical to give the "one-" and "two-" electron components of the "three-electron" bond. The

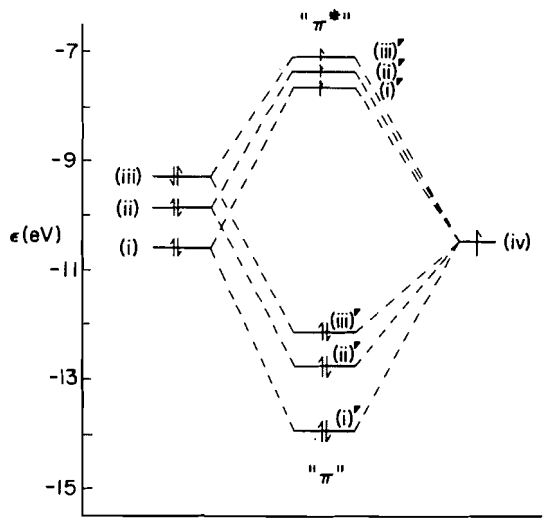

FIG. 1. Orbital interaction diagram for the "three-electron" bond. Orbital energies are from 4-31G calculations for (*i*) ammonia, (*ii*) methylamine, (*iii*) dimethylamine, (*i*)' aminomethyl, (*ii*)' methylaminomethyl, (*iii*)' dimethylaminomethyl, and (*iv*) methyl.

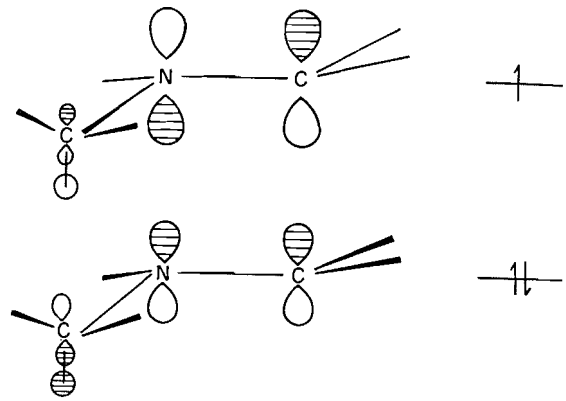

FIG. 2. "π"-type interactions of the methyl group with the "one-" and "two-" electron components of the "three-electron" bond. Orbital phases from the UHF 4-31G α-spin MO.

HOMO of ammonia shifts up with methylation which may be rationalized (e.g. (24)) by a model which considers the methyl group as a pseudo *p* orbital interacting with the *p* component of the nitrogen lone pair. This hyperconjugative interaction results in a lower energy orbital mainly in the methyl group (bonding interaction) and a higher energy (antibonding interaction) consisting mainly of the lone pair. This latter orbital lies at an energy higher than the noninteracting lone pair orbital in ammonia. The increase in energy of the amine HOMO coupled with a constant energy for the methyl SOMO leads to destabilization of both the HOMO (π) and SOMO (π*) orbitals of the aminoalkyl radicals upon methylation at N. Figure 2 shows that at least in the pseudo π system the interactions between the methyl group and the "three-electron" CN bond are destabilizing for the highest two orbitals. The lessened orbital stability in the "three-electron" bond also matches the decreased total stability calculated from the total energies (recall Tables 4 and 5). These trends in radical stabilization energies run contrary to those observed experimentally. However, the decreased stability of the SOMO upon methylation at N matches the experimental decrease in ionization potential. Figures 1 and 2 serve to illustrate an internal consistency in the calculated results. Destabilization in the total energies is reflected in less stable highest molecular orbitals (or vice versa).

The experimental results (1) for the ionization potentials are derived from appearance energies measured by the impact of an energy-resolved electron beam combined with a quadrupole mass spectrometer.

$$AE(R^+) = \Delta H_f(R_1^+) + \Delta H_f(R_2\cdot) - \Delta H_f(R_1R_2)$$

$\Delta H_f(R_1^+)$ were known independently (2) and the $\Delta H_f(R_1R_2)$ estimated by group equivalents. Thus, measurement of the appearance energy, AE, allows a determination of $\Delta H_f(R_2\cdot)$ and the ionization potentials follow from

$$IP(R_2\cdot) = \Delta H_f(R_2^+) - \Delta H_f(R_2\cdot)$$

These ionization potentials have been assumed to be close to the adiabatic values. The agreement between the strictly vertical calculated values (Table 3) and the experimental ones (1) implies either that relaxation energies are small or that the experimental values may be closer to vertical than previously thought. Relaxation effects in changing the CN bond to a true double bond could be substantial. For dimethylaminomethyl, another experiment (26) has yielded an ionization potential of 5.35 eV which is 0.35 eV less than the value in ref. 1. Using this value a radical stabilization energy of only ~14 kcal/mol would follow for $(CH_3)_2NCH_2$. A calculated value (4-31G//STO-3G) for $\Delta E(CH_2OH - CH_2OH^+)$ of 7.2 eV is in the literature (27) which is 0.4 eV *less* than that derived from experiments (1, 28) similar to those performed on the aminoalkyl radicals.

Since the radical stabilization energies were calculated using bond dissociation energies derived from

$$D(R_1H) = \Delta H_f(R_2\cdot) + \Delta H_f(H) - \Delta H_f(R_2H)$$

it is clear that the ionization potentials and radical stabilization energies are strongly interdependent.

## Conclusions

The present work predicts strikingly low vertical ionization potentials of aminoalkyl radicals. The dramatic increase in aminoalkyl radical stability with *N*-methylation as observed experimentally is not predicted by the present *ab initio* SCF calculations. Basis set and geometry effects have essentially been ruled out as causes of the discrepancy. Qualitative MO arguments regarding the "three-electron" bond are internally consistent with a small destabilizing effect due to methylation at N. A remaining possibility on the theoretical side would be an unexpected inability of the SCF method to describe the three-electron bond and/or other interactions in the aminoalkyl radicals. Perhaps correlated wave functions are necessary for even a correct low-order description of these species. On the experimental side, there may exist errors in the exact determination of the appearance potentials and in the group-equivalents scheme used to determine certain of the thermochemical data. In addition, the appearance energies do not appear to be strictly adiabatic and thus some inconsistency in their use with the other thermochemical data is possible. The source of the discrepancy between the theoretical calculations and the derived experimental results is not completely clear. Further calculations including correlation effects by configuration interaction or perturbation theory are in order. A direct photoelectron spectrum of the transient radicals would be an invaluable experiment.

Received November 13, 1981

EDWARD PIERS, KIN FAI CHENG, and ISAO NAGAKURA. Can. J. Chem. **60**, 1256 (1982).

Treatment of the 3-halo-2-cyclohexen-1-ones **11–15** and **17** with an excess of lithium dimethylcuprate provided good to excellent yields of the corresponding 3,3-dimethylcyclohexanones **21–24**. Similar reactions involving the β-bromo cyclopentenones **19** and **20** stopped at the monoaddition stage, producing the cyclopentenones **40** and **43**. Reaction of the β-bromo cyclohexenones **12** and **15** with 1.1 equiv. of lithium dimethylcuprate did not effect clean conversion of these substrates into the corresponding 3-methyl-2-cyclohexen-1-ones. When a series of β-bromo enones **12**, **14–19** were allowed to react with the lithium (phenylthio)(alkyl)cuprates **44–47**, the corresponding β-alkyl enones were, in general, produced cleanly and efficiently. However, reaction of 3-bromo-2-methyl-2-cyclopenten-1-one (**19**) with the cuprate reagent **44** gave mainly the β-phenylthio enone **49**. This undesired result could be avoided by employing, in the place of **19**, the β-iodo cyclopentenone **50**, which reacted smoothly with **44** to give a high yield of 2,3-dimethyl-2-cyclopenten-1-one (**40**). Reaction of 3-bromo-2-cyclohexen-1-one (**14**) with 3 equiv. of the mixed vinylcuprate reagent **48** gave 3-(3-butenyl)-2-cyclohexen-1-one (**32**). Alkylation of 1,3-cyclopentanedione with (*Z*)-1-chloro-2-pentene afforded compound **51**, which was converted into the β-bromo enone **52**. Treatment of the latter substance with lithium dimethylcuprate provided (*Z*)-jasmone (**53**).

EDWARD PIERS, KIN FAI CHENG et ISAO NAGAKURA. Can. J. Chem. **60**, 1256 (1982).

Les halo-3 cyclohexène-2 ones-1 (**11–15** et **17**) réagissent avec le diméthylcuprate de lithium en excès en donnant les diméthyl-3,3 cyclohexanones correspondantes avec des rendements variables. Des réactions analogues mettant en jeu les β-bromo cyclopentènones (**19** et **20**) s'arrêtent à l'étape de monoaddition en produisant les cyclopentènones (**40** et **43**). La réaction des β-bromo cyclohexènones (**12** et **15**) avec 1,1 équivalent de diméthylcuprate de lithium n'affectent pas la transformation franche de ces substrats en méthyl-3 cyclohexène-2 ones-1 correspondantes. Quand on fait réagir une série de β-bromo ènones (**12**, **14–19**) avec les (phenylthioalkyl)cuprates de lithium (**44–47**), on obtient en général les β-alkylènones correspondantes d'une manière efficace et pure. Cependant, la bromo-3 méthyl-2 cyclopentène-2 one-1 (**19**) réagit avec le cuprate **44** en donnant principalement la β-phénylthioénone **49**. On peut éviter ce produit indésirable en remplaçant le produit **19** par la β-iodo cyclopentènone **50** qui réagit doucement avec le réactif **44** en donnant avec un excellent rendement la diméthyl-2,3 cyclopentène-2 one-1 (**40**). La bromo-3 cyclohexène-2 one-1 (**14**) réagit avec 3 équivalents du vinylcuprate mixte (**48**) en donnant la (butène-3 yl)-3 cyclohexène-2 one-1 (**32**). L'alkylation de la cyclopentanedione-1,3 avec le (*Z*) chloro-1 pentène-2 conduit au composé **51** que l'on transforme en β-bromo ènone (**52**). Cette dernière réagit avec le diméthylcuprate de lithium en donnant la (*Z*)-jasmone (**53**).

## Introduction

The reaction outlined in general terms by eq. [1] has been employed a great deal in organic synthesis, particularly in the very recent past. In this process, a β-substituted α,β-unsaturated ketone **1** reacts with a nucleophilic species (or an electron-transfer reagent) to provide initially the conjugate addition intermediate **2**. If Y is a good leaving group, it will be expelled from this intermediate to provide the product **3**. Thus, in an overall sense, a substitution reaction has occurred and, as such, the β-substituted enone **1** acts as a synthetic equivalent to the unsaturated $a^3$ synthon **5** (normal reactivity) (1). On the other hand, if the initially formed product **3** were to react in a conjugate addition sense with a second equivalent of reagent, the final product would be the ketone **4**. In this case, the

original β-substituted enone **1** would be serving as the equivalent to the $a^3$–$a^3$ synthon **6**.

With respect to the nature of Y in eq. [1], a variety of functional groups have been employed successfully: chloro (2–19), bromo (14, 16, 20), alkylthio (21–27), alkylsulfinyl (27, 28), acyloxy (29), alkoxy (23, 30), tosyloxy (31, 32), mesyloxy (33), and diethylphosphonoxy (34). It is clear from a perusal of the chemical literature that the synthetic utility of β-chloro enones has been particularly well established, since the chloro substituent has been displaced successfully by a wide variety of oxygen, nitrogen, sulfur, and carbon nucleophiles (2–19). Until recently, however, efficient substitution of the chloro group by *carbon* nucleophiles had been accomplished only when the carbanions were relatively highly stabilized (e.g. conjugate bases of malonic ester derivatives, β-keto esters, trimethylsulfoxonium chloride, etc.). Obviously, the products of these reactions were enones containing highly functionalized substituents at the β carbon. Although the preparation of structurally simpler β-alkyl or β-alkenyl α,β-unsaturated ketones had been accomplished by the reaction of β-chloro enones with dialkyl- or dialkenylcadmium reagents, the yields were generally poor to mediocre (2).

Recently, we described a new, general method for the preparation of β-halo α,β-unsaturated ketones **8** (35). This method, which involved the reaction of 1,3-diketones **7** with triphenylphosphine dihalides in the presence of triethylamine (eq. [2]), not only provided high yields of β-chloro and β-bromo enones, but also constituted the first general procedure for the preparation of cyclic β-iodo α,β-unsaturated ketones, a previously unknown class of compounds. We report herein that cyclic β-halo enones **8**, particularly the bromo and iodo derivatives, react smoothly and efficiently with a variety of organocuprate reagents to produce the corresponding β,β-dialkyl **9** or, more importantly, the corresponding β-alkyl α,β-unsaturated ketones **10**[2,3] (eq. [3]). As such, the β-halo enones **8** serve as excellent synthetic equivalents to the unsaturated $a^3$ synthon **5** and the $a^3$–$a^3$ synthon **6**.

## Results and discussion

### (a) *Reaction of cyclic β-halo enones with lithium dimethylcuprate*

Our initial work in this area involved a brief study of the use of an excess of the reagent lithium dimethylcuprate ($Me_2CuLi$) with the expectation that the β-halo enones would be transformed into the corresponding β,β-dimethyl ketones (cf. **8** → **9**). The results of some of these experiments are summarized in Table 1. Thus, reaction of 3-chloro-5,5-dimethyl-2-cyclohexen-1-one (**11**) (see Chart 1)

[2] For a preliminary account of some of the work reported herein, see ref. 36.

[3] Prior to our initial communication (36), the reaction of β-halo enones with cuprate reagents had not been described. Subsequently, a few examples of the reaction of β-chloro and/or β-bromo enones with lithium dialkylcuprates or related reagents have been reported (5*b*, 13, 14, 16). It should be noted also that similar transformations have been accomplished with β-alkylthio (21–25), β-acetoxy (29), β-alkoxy (23), β-diethylphosphonoxy (34), and β-mesyloxy (33) enones.

with 3 equivalents of $Me_2CuLi$ at 0°C gave an excellent yield of 3,3,5,5-tetramethylcyclohexanone (**21**) (Table 1, Entry 1). Similarly the corresponding β-bromo and β-iodo enones **12** and **13** were also smoothly converted into the ketone **21**, and the substituted cyclohexanones **22** and **23** could be obtained readily from the β-bromo enones **14** and **15**, respectively (Entries 2–5). In contrast, attempted conversion, under identical reaction conditions, of 3-bromo-2-(2-cyanoethyl)-2-cyclohexen-1-one (**17**) into the corresponding β,β-dimethyl cyclohexanone derivative **24** gave only a poor yield (~25%) of a mixture of products, which included, in addition to the expected compound **24**, a significant amount of the enone **38**. However, when a greater excess (6 equiv.) of reagent was employed and the reaction conditions were altered somewhat, a reasonable yield of the desired product **24** (contaminated with a small amount of the enone **38**) was realized (Entry 6). Thus, although these experiments do not constitute an extensive investigation, it appears that substituted 3-halo-2-cyclohexen-1-ones can serve as convenient precursors for the preparation of the corresponding 3,3-dialkylcyclohexanone systems.

In contrast to these results involving six-membered ring substrates, reaction of the β-bromo cyclopentenones **19** and **20** with excess $Me_2CuLi$ did not result in the formation of the corresponding β,β-dimethyl cyclopentanones. Instead, in both cases, the reaction stopped at the monoaddition stage, and the products were identified as the cyclopentenones **40** and **43** (Entries 7, 8). It is thus clear that conjugate addition of $Me_2CuLi$ to 2,3-disubstituted cyclopentenones is not as facile a process as the corresponding reaction involving 2,3-disubstituted cyclohexanones. From a strictly synthetic point of view, it is pertinent to note that the reaction of 2-alkyl-3-bromo-2-cyclopenten-1-ones with $Me_2CuLi$ constitutes an efficient method for preparing 2-alkyl-3-methyl-2-cyclopenten-1-ones. This reaction was subsequently applied to a synthesis of (*Z*)-jasmone (*vide infra*).

In an effort to determine whether or not the reaction of β-bromo cyclohexenones with $Me_2CuLi$ could be controlled so as to produce only the corresponding 3-methyl-2-cyclohexen-1-ones (cf. **8** → **10**), the reactions of the β-bromo enones **12** and **15** with slightly more than 1 equivalent of the cuprate reagent were investigated. When **12** was allowed to react with 1.1 equivalents of $Me_2CuLi$ at 0°C for 10 min, the major product was the desired 3,5,5-trimethyl-2-cyclohexen-1-one (**25**). However, a small amount of starting material was recovered and, in addition, a significant quantity of the "double addition" product **21** was also formed (Entry 9). When the reaction temperature was lowered to −78°C an improvement was noted, but the product still contained a small amount of the tetramethylcyclohexanone **21** (Entry 10). Furthermore, reaction of 3-bromo-2-methyl-2-cyclohexen-1-one (**15**) with 1.1 equivalents of $Me_2CuLi$ at 0°C for 15 min gave only a 51% yield of the desired enone **33**, along with 31% of the starting material (Entry 11). Longer reaction times led to the disappearance of nearly all of the starting material, but also produced small amounts of the trimethylcyclohexanone **23**.

In view of these results, it was decided to investigate the use of a different type of cuprate reagent with the aim of developing a better method for effecting the clean, efficient conversion of cyclic β-bromo enones into the corresponding

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

β-alkyl enones. After some investigation, we found that lithium (phenylthio)(alkyl)cuprate reagents (37, 38) are generally excellent for this purpose, and the next section of this paper describes the results of this study.

*(b) Reaction of cyclic β-bromo enones with lithium (phenylthio)(alkyl)cuprates*

Solutions of the mixed cuprate reagents **44–48** employed in this study were prepared simply by addition of a solution of the appropriate alkyllithium (or vinyllithium) to a stirred suspension of (phenylthio)copper in dry tetrahydrofuran at −20°C (37, 38). The reactions of these reagents with a number of cyclic β-bromo enones were investigated (see Chart 1 and Table 2).

**45** R = *n*-Bu
**46** R = *sec*-Bu
**47** R = *t*-Bu
**48** R = CH=$CH_2$

In connection with the experiments summarized in Table 2, a number of points should be noted. In some of the experiments involving the cuprate reagents **44–47** (Entries 1–17), the distilled products contained small amounts of starting material (generally <5%). However, in no case were we able to detect any product resulting from further addition to the initially formed β-alkyl enone. Thus, the mixed cuprate reagents **44–47** are, in general, excellent reagents for the conversion of β-bromo enones into the corresponding β-alkyl enones.

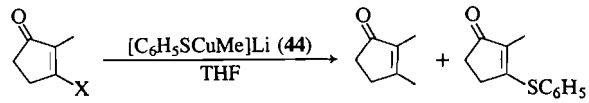
[a]Cuprate reagents $[C_6H_5SCuR]Li$: **44**, R = Me; **45**, R = *n*-Bu; **46**, R = *sec*-Bu; **47**, R = *t*-Bu; **48**, R = CH=$CH_2$. Relative to the quantities of β-bromo enones used, the following amounts of reagents were employed: **44**, 2.0 equiv. (Entries 1–6); **45–47**, 1.5 equiv. (Entries 7–17); **48**, 3.0 equiv. (Entry 18).
[b]The reaction time was 2.5 h in each case.
[c]Yield of distilled product. In some of the experiments, a small amount (generally <5%) of starting material was recovered.
[d]The major product in this case was 2-methyl-3-phenylthio-2-cyclopenten-1-one (**49**) (see text and Experimental).

Although lithium (phenylthio)(methyl)cuprate (**44**) efficiently transformed the 3-bromo-2-cyclohexen-1-ones **12**, **14**, and **15–17** into the corresponding β-methyl enones (Entries 1–5), a similar reaction of **44** with the β-bromo cyclopentenone **19** afforded 2,3-dimethyl-2-cyclopenten-1-one (**40**) in very poor yield (Entry 6). In fact, the major product of this reaction was the crystalline 2-methyl-3-phenylthio-2-cyclopenten-1-one (**49**), showing that, in this case, phenylthio transfer was more facile than methyl transfer.[4] It was subsequently found, however, that the formation of **49** could be avoided nearly completely by use of the iodo enone **50** in place of the corresponding bromo compound **19**. Thus, treatment of **50** with the cuprate reagent **44** afforded 2,3-dimethyl-2-cyclopenten-1-one (**40**) in high yield.



**19** X = Br
**50** X = I

**40**: X = Br 15%; X = I 91%
**49**: 61%; Trace

The reactions involving β-bromo enones and lithium (phenylthio)(*tert*-butyl)cuprate (**47**) proved to be remarkably efficient (Entries 13–17). Although the *tert*-butyl enones **27** (39), **31** (40), and **42** (41) had been prepared previously via entirely different synthetic processes, the yields were generally low. In contrast, the present method provided these substances in excellent yields. Furthermore, even the relatively highly hindered β-bromo enones **15**, **18**, and **19** reacted smoothly with the cuprate reagent **47** to give the corresponding β-*tert*-butyl enones **36**, **39**, and **42** in yields greater than 80%.

Treatment of 3-bromo-2-cyclohexen-1-one (**14**) with 1.3 equiv. of lithium (phenylthio)(vinyl)cuprate (**48**) in tetrahydrofuran at −78°C gave, in addition to starting material, the α,β-unsaturated ketone **32** (ratio ≈7:2, respectively). Clearly, 1,6 addition of the cuprate reagent **48** to the initially formed 3-vinyl-2-cyclohexen-1-one occurred at a rate faster

[4]In general, transfer of the $C_6H_5S$ group was not a problem in these reactions. Although small amounts of the β-phenylthio cycloalkenones were also formed in the experiments summarized in Entries 2–5 and 10, the yields of the desired β-alkyl enones were quite satisfactory.

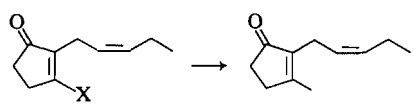
For personal use only.

than the original 1,4 addition to **14**. Reaction of **14** with 3.0 equiv. of the cuprate reagent **48** provided **32** in 70% yield (Entry 18).

*(c) Synthesis of (Z)-jasmone (53)*[5]

From a structural point of view, (*Z*)-jasmone (**53**) is a relatively simple compound. However, partly because of the fact that this substance is an important compound in the perfume industry and partly because it serves as a convenient synthetic target for testing new synthetic methods aimed at cyclopentenone-type compounds, (*Z*)-jasmone (**53**) has been synthesized many times via many different pathways. Reported here is a simple conversion of 1,3-cyclopentanedione into this natural product.

Alkylation of 1,3-cyclopentanedione with (*Z*)-1-chloro-2-pentene afforded compound **51** (41%) which, upon treatment with triphenylphosphine dibromide in the presence of triethylamine (35), was transformed smoothly (82%) into the β-bromo enone **52**. When the latter substance was allowed to react with $Me_2CuLi$ in ether at 0°C, (*Z*)-jasmone (**53**) was produced in 93% yield.



**51** X = OH
**52** X = Br

**53**

## Experimental

*General*

Melting points, which were taken on a Fisher–Johns melting point apparatus, and distillation temperatures are uncorrected. Infrared (ir) spectra were recorded on a Perkin–Elmer model 710 spectrophotometer. Proton magnetic resonance ($^1$H nmr) spectra (deuterochloroform solution) were measured using Varian Associates spectrometers, models T-60 and/or HA-100 or XL-100. Signal positions are given in δ units, with tetramethylsilane as the internal standard. High resolution mass spectrometric measurements were recorded on a Kratos MS-50 mass spectrometer. Gas–liquid chromatography (glc) was carried out with a Hewlett–Packard model 5832A gas chromatograph (analytical) or with a Varian Aerograph model 90-P instrument (preparative). Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver, B.C.

*General procedure for the reaction of β-halo α,β-unsaturated ketones with lithium dimethylcuprate (Table 1)*

To a cold (−78°C), stirred solution of the indicated amount of lithium dimethylcuprate (44) in anhydrous ether (~6–10 mL per mmol of reagent) under an atmosphere of nitrogen was added a solution of 1.0 mmol of β-halo enone (**11–15**, **17**, **19**, **20**) in anhydrous ether (~3 mL). After the resulting solution had been stirred at the designated temperature for the required length of time, it was treated with cold (0°C) saturated aqueous ammonium chloride (~5 mL). The resulting mixture was extracted thoroughly with ether. The combined ethereal extract was washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by bulb-to-bulb distillation of the residual oil under reduced pressure (water aspirator or vacuum pump), afforded the product(s).

*Table 1, Entries 1–3*

The product was 3,3,5,5-tetramethylcyclohexanone (**21**) (45); ir (film): 1710 cm$^{-1}$; $^1$H nmr δ: 1.07 (s, 12H), 1.57 (s, 2H), 2.16 (s, 4H).

*Table 1, Entry 4*

The product was 3,3-dimethylcyclohexanone (**22**) (46); ir (film): 1712 cm$^{-1}$; $^1$H nmr δ: 1.07 (s, 6H), 1.46–2.60 (diffuse, 8H).

*Table 1, Entry 5*

The product was 2,3,3-trimethylcyclohexanone (**23**) (47); ir (film): 1710 cm$^{-1}$; $^1$H nmr δ: 0.79, 1.06 (s, s, 3H each), 0.98 (d, 3H, $J$ = 7 Hz), 1.50–2.53 (diffuse, 7H).

*Table 2, Entry 6*

Analysis of the product by glc indicated the presence of two components, in a ratio of 9:1. The minor component was shown to possess retention times identical with those of the enone **37**, which was prepared via another reaction (*vide infra*). The major component, a pure sample of which was collected by preparative glc, was 2-(2-cyanoethyl)-3,3-dimethylcyclohexanone (**24**); ir (film): 2250, 1705 cm$^{-1}$; $^1$H nmr δ: 0.77, 1.13 (s, s, 3H each), 1.30–2.63 (diffuse, 11H). *Anal.* calcd. for $C_{11}H_{17}NO$: C 73.70, H 9.56, N 7.81; found: C 73.44, H 9.50, N 7.60.

*Table 1, Entry 7*

The product was 2,3-dimethyl-2-cyclopenten-1-one (**40**) (48); ir (film): 1700, 1650 cm$^{-1}$; $^1$H nmr δ: 1.70 (broad s, 3H), 2.05 (s, 3H), 2.23–2.66 (diffuse, 4H).

*Table 1, Entry 8*

The product was 2-allyl-3-methyl-2-cyclopenten-1-one (**43**) (49); ir (film): 1700, 1640 cm$^{-1}$; $^1$H nmr δ: 2.04 (s, 3H), 2.30–2.66 (m, 4H), 2.84–3.12 (m, 2H), 4.86–5.24 (m, 2H), 5.58–6.04 (m, 1H).

*Table 1, Entries 9 and 10*

Analysis of the products from these two experiments showed that in each case the minor product exhibited retention times identical with those of 3,3,5,5-tetramethylcyclohexanone (**21**). The product mixture from the experiment summarized in Entry 9 also contained a small amount (4%) of the starting material, bromo enone **12**. In each case, a sample of the major product was isolated by preparative glc and was shown to be 3,5,5-trimethyl-2-cyclohexen-1-one (**25**); ir (film): 1673, 1635 cm$^{-1}$; $^1$H nmr δ: 1.05 (s, 6H), 1.93 (broad s, 3H), 2.20 (broad s, 4H), 5.90 (m, 1H).

*Table 1, Entry 11*

Gas–liquid chromatographic analysis showed that the material obtained from this experiment consisted of the starting material **15** and 2,3-dimethyl-2-cyclohexen-1-one (**33**), a sample of which was collected by preparative glc; ir (film): 1668, 1635 cm$^{-1}$; $^1$H nmr δ: 1.76 (broad s, 3H), 1.90–2.13 (m, 5H), 2.20–2.60 (m, 4H).

*General procedure for the reaction of β-bromo α,β-unsaturated ketones with lithium (phenylthio)(alkyl)cuprates (Table 2)*

To a cold (−20°C) stirred suspension of (phenylthio)copper (38) (for reagent **44**, 2 mmol; for reagents **45–47**, 1.5 mmol; for reagent **48**, 3 mmol) in dry THF (10 mL), under an atmosphere of nitrogen, was added via syringe a required amount of alkyllith-

[5] A perusal of the chemical literature makes it abundantly clear that there is no lack of (*Z*)-jasmone syntheses (see refs. 42 and 43 and citations therein). However, it is difficult to escape the impression that if a person is actively engaged in research in the area of synthetic organic chemistry, then it is "necessary" for him (her) to report at some time during his (her) career a synthesis of this natural product. Described in this brief section of the paper is our (modest) contribution to this area.

For personal use only.

ium or vinyllithium solution (methyllithium in ether, 2 mmol; *n*-butyllithium in hexane, 1.5 mmol; *sec*-butyllithium in cyclohexane, 1.5 mmol; *tert*-butyllithium in pentane, 1.5 mmol; vinyllithium in THF, 3 mmol).[6] The resultant mixture was stirred at −20°C for 15 min and then was cooled to −78°C. A solution of the appropriate β-bromo enone (1 mmol) in 2 mL of THF was added and the reaction mixture was stirred at the indicated temperature for 2.5 h. Methanol (1 mL), saturated aqueous ammonium chloride (0.5 mL), ether (10 mL), and anhydrous magnesium sulfate (4 g) were added sequentially, the resultant mixture was stirred for a few minutes and then was filtered through a short column of silica gel (~ 10–15 g). The column was eluted with ~ 100 mL of ether. Removal of the solvent from the combined eluate, followed by bulb-to-bulb distillation of the residual oil under reduced pressure (water aspirator), afforded the product. In some of the experiments, gas–liquid chromatographic analysis of the product indicated the presence of a small amount (≤ 5%) of starting material. In each of these cases, a pure sample of the desired β-alkyl enone was obtained by preparative glc.

*Table 2, Entry 1*

The product was 3,5,5-trimethyl-2-cyclohexen-1-one (**25**) (*vide supra*).

*Table 2, Entry 2*

The product was 3-methyl-2-cyclohexen-1-one (**28**); ir (film): 1665, 1630 $cm^{-1}$; $^1H$ nmr δ: 1.76–2.57 (diffuse, 6H), 1.97 (s, 3H), 5.87 (m, 1H).

*Table 2, Entry 3*

The product was 2,3-dimethyl-2-cyclohexen-1-one (**33**) (*vide supra*).

*Table 2, Entry 4*

The product was 2-allyl-3-methyl-2-cyclohexen-1-one (**37**) (52); ir (film): 1665, 1630, 985, 895 $cm^{-1}$; $^1H$ nmr δ: 1.80–2.17 (diffuse, 2H), 1.95 (s, 3H), 2.23–2.60 (m, 4H), 3.08 (broad d, 2H, $J$ = 6 Hz), 4.72–5.20 (m, 2H), 5.44–6.17 (m, 1H).

*Table 2, Entry 5*

The product was 2-(2-cyanoethyl)-3-methyl-2-cyclohexen-1-one (**38**); ir (film): 2255, 1662, 1628 $cm^{-1}$; $^1H$ nmr δ: 1.78–2.15 (diffuse, 2H), 2.05 (s, 3H), 2.22–2.66 (diffuse, 8H). *Anal.* calcd. for $C_{10}H_{13}NO$: C 73.59, H 8.02, N 8.57; found: C 73.25, H 8.15, N 8.29.

*Table 2, Entry 6*

The volatile product was 2,3-dimethyl-2-cyclopenten-1-one (**40**) (*vide supra*). The residue from the distillation was purified by column chromatography on silica gel. Recrystallization (ether) of the solid thus obtained gave 2-methyl-3-phenylthio-2-cyclopenten-1-one (**49**) (61%), mp 96–98°C; ir ($CHCl_3$): 1675, 1595 $cm^{-1}$; $^1H$ nmr δ: 1.87 (broad s, 3H), 2.36 (broad s, 4H), 7.33–7.70 (diffuse, 5H). *Anal.* calcd. for $C_{12}H_{12}OS$: C 70.54, H 5.92; found: C 70.25, H 6.00.

*Table 2, Entry 7*

The product was 3-*n*-butyl-5,5-dimethyl-2-cyclohexen-1-one (**26**) (52); ir (film): 1670, 1630 $cm^{-1}$; $^1H$ nmr δ: 1.03 (poorly resolved t, 3H), 1.17 (s, 6H), 1.23–1.86 (diffuse, 4H), 2.04–2.53 (diffuse, 6H), 6.02 (broad s, 1H).

*Table 2, Entry 8*

The product was 3-*n*-butyl-2-cyclohexen-1-one (**29**) (52); ir (film): 1670, 1625 $cm^{-1}$; $^1H$ nmr δ: 0.90 (poorly resolved t, 3H), 1.13–1.63 (diffuse, 6H), 1.70–2.70 (diffuse, 6H), 5.87 (m, 1H).

[6]The solutions of the alkyllithium reagents were purchased from the Alfa Division of Ventron Corporation, while vinyllithium in THF was prepared by the procedure of Seyferth and Weiner (50). These reagents were standardized by the method of Gilman and Cartledge (51).

*Table 2, Entry 9*

The product was 3-*n*-butyl-2-methyl-2-cyclohexen-1-one (**34**); ir (film): 1670, 1627 $cm^{-1}$; $^1H$ nmr δ: 0.98 (poorly resolved t, 3H), 1.10–1.66 (diffuse, 6H), 1.70–2.63 (diffuse, 6H), 1.83 (t, 3H, $J \approx$ 1 Hz). *Anal.* calcd. for $C_{11}H_{18}O$: C 79.52, H 10.91; found: C 79.52, H 10.96.

*Table 2, Entry 10*

The product was 3-*n*-butyl-2-methyl-2-cyclopenten-1-one (**41**) (53); ir (film): 1705, 1645 $cm^{-1}$; $^1H$ nmr δ: 1.13 (poorly resolved t, 3H), 1.33–1.84 (diffuse, 4H), 1.88 (s, 3H), 2.40–2.87 (unresolved m, 6H).

*Table 2, Entry 11*

The product was 3-*sec*-butyl-2-cyclohexen-1-one (**30**) (54); ir (film): 1665, 1620 $cm^{-1}$; $^1H$ nmr δ: 1.01 (t, 3H, $J$ = 6 Hz), 1.25 (d, 3H, $J$ = 7 Hz), 1.33–2.70 (diffuse, 9H), 6.02 (s, 1H).

*Table 2, Entry 12*

The product was 3-*sec*-butyl-2-methyl-2-cyclohexen-1-one (**35**); ir (film): 1667, 1618 $cm^{-1}$; $^1H$ nmr δ: 0.86 (t, 3H, $J$ = 7 Hz), 1.04 (d, 3H, $J$ = 7 Hz), 1.46 (quintet, 2H, $J$ = 7 Hz), 1.74–2.06 (m, 2H), 1.80 (t, 3H, $J$ = 2 Hz), 2.16–2.52 (m, 4H), 2.81 (hextet, 1H, $J$ = 7 Hz). *Exact Mass* calcd. for $C_{11}H_{18}O$: 166.1357; found: 166.1380.

*Table 2, Entry 13*

The product was 3-*tert*-butyl-5,5-dimethyl-2-cyclohexen-1-one (**27**) (39); ir (film): 1672, 1618 $cm^{-1}$; $^1H$ nmr δ: 1.03 (s, 6H), 1.12 (s, 9H), 2.20 (broad s, 4H), 5.97 (broad s, 1H).

*Table 2, Entry 14*

The product was 3-*tert*-butyl-2-cyclohexen-1-one (**31**) (40); ir (film): 1667, 1613 $cm^{-1}$; $^1H$ nmr δ: 1.13 (s, 9H), 1.65–2.53 (diffuse, 6H), 5.97 (broad s, 1H).

*Table 2, Entry 15*

The product was 3-*tert*-butyl-2-methyl-2-cyclohexen-1-one (**36**); ir (film): 1665, 1592 $cm^{-1}$; $^1H$ nmr δ: 1.26 (s, 9H), 1.70–2.10 (diffuse, 2H), 1.93 (t, 3H, $J$ = 2 Hz), 2.12–2.58 (diffuse, 4H). *Anal.* calcd. for $C_{11}H_{18}O$: C 79.52, H 10.91; found: C 79.77, H 10.85.

*Table 2, Entry 16*

The product was 3-*tert*-butyl-2,5,5-trimethyl-2-cyclohexen-1-one (**39**); ir (film): 1662, 1596 $cm^{-1}$; $^1H$ nmr δ: 0.99 (s, 6H), 1.26 (s, 9H), 1.96 (t, 3H, $J \approx$ 2 Hz), 2.20 (s, 2H), 2.28 (q, 2H, $J \approx$ 2 Hz). *Anal.* calcd. for $C_{13}H_{22}O$: C 80.35, H 11.35; found: C 80.45, H 11.31.

*Table 2, Entry 17*

The product was 3-*tert*-butyl-2-methyl-2-cyclopenten-1-one (**42**) (41); ir (film): 1695, 1640 $cm^{-1}$; $^1H$ nmr δ: 1.26 (s, 9H), 1.84 (t, 3H, $J \approx$ 2 Hz), 2.17–2.70 (diffuse, 4H).

*Table 2, Entry 18*

The product was 3-(3-butenyl)-2-cyclohexen-1-one (**32**) (55); ir (film): 1670, 1625, 980, 895 $cm^{-1}$; $^1H$ nmr δ: 1.75–2.80 (diffuse, 10H), 4.84–5.27 (diffuse, 2H), 5.44–6.06 (diffuse, 1H), 5.91 (broad s, 1H).

*Reaction of 3-iodo-2-methyl-2-cyclopenten-1-one (**50**) with lithium (phenylthio)(methyl)cuprate (**44**)*

To a cold (−20°C) stirred solution of the cuprate reagent **44** (2 mmol) in dry THF (10 mL), under an atmosphere of nitrogen, was added a solution of the iodo enone **50** (222 mg, 1.0 mmol) in 2 mL of THF. The reaction mixture was allowed to warm to 0°C and was stirred at this temperature for 2.5 h. Subjection of the reaction mixture to work-up as described above, followed by distillation (air-bath temperature 65–75°C/21 Torr) of the crude product, gave 100 mg (91%) of 2,3-dimethyl-2-cyclopenten-1-one (**40**) (*vide supra*).

*2-[(Z)-2-Pentenyl]-1,3-cyclopentanedione (**51**)*

To an ice-cold solution of 1,3-cyclopentanedione (750 mg,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

7.5 mmol) in 2 *M* aqueous potassium hydroxide (4 mL, 8 mmol) was added (*Z*)-1-chloro-2-pentene (885 mg, 8.5 mmol) and a small amount of copper powder. The reaction mixture was stirred at 0°C for 1 h and then at room temperature for 3.5 h. The reaction mixture was made alkaline by addition of 10% aqueous sodium hydroxide and the resultant solution was washed with ether, cooled to 0°C, and acidified by addition of 3 *N* hydrochloric acid. The resulting mixture was extracted thoroughly with chloroform. The combined extracts were dried over anhydrous magnesium sulfate. Removal of the solvent gave a yellow oil which, upon crystallization from ether, afforded 510 mg (41%) of 2-[(*Z*)-2-pentenyl]-1,3-cyclopentanedione (**51**), mp 135–136°C; $^1$H nmr δ: 0.92 (t, 3H, $J$ = 7.5 Hz), 2.15 (m, 2H), 2.52 (s, 4H), 2.94 (broad d, 2H, $J$ = 6.0 Hz), 5.36–5.54 (m, 2H), 8.62 (broad s, 1H). The $^1$H nmr spectrum clearly indicated that this compound existed very largely in the enol tautomer. *Anal.* calcd. for $C_{10}H_{14}O_2$: C 72.26, H 8.49; found: C 72.06, H 8.45.

*3-Bromo-2-[(Z)-2-pentenyl]-2-cyclopenten-1-one (52)*

To an ice-cold, stirred solution of triphenylphosphine (435 mg, 1.66 mmol) in benzene (10 mL) was added, dropwise, a 1 *M* solution of bromine in dry benzene (1.66 mL, 1.66 mmol). To the resulting suspension was added triethylamine (167 mg, 1.66 mmol) and a solution of 2-[(*Z*)-2-pentenyl]-1,3-cyclopentanedione (**51**) (250 mg, 1.5 mmol) in benzene (8 mL). The reaction mixture was stirred at room temperature for 4 h and was then diluted with 100 mL of ether. The resulting mixture (suspension) was filtered through a short column of neutral, activity II, silica gel. The column was eluted with an additional 200 mL of ether. Removal of the solvent from the combined eluate, followed by distillation (air-bath temperature 105–115°C/0.5 Torr) of the residual oil gave 283 mg (82%) of 3-bromo-2-[(*Z*)-2-pentenyl]-2-cyclopenten-1-one (**52**) as a clear colorless oil; ir (film): 1700, 1625, 1300, 1195 cm$^{-1}$; $^1$H nmr δ: 0.98 (t, 3H, $J$ = 7.5 Hz), 2.18 (m, 2H), 2.52 (m, 2H), 2.82–3.10 (m, 4H), 5.10–5.62 (m, 2H). *Anal.* calcd. for $C_{10}H_{13}BrO$: C 52.41, H 5.73, Br 34.87; found: C 52.16, H 5.55, Br 34.70.

*(Z)-Jasmone (53)*

To a cold (−78°C) stirred solution of lithium dimethylcuprate (1.15 mmol) in anhydrous ether (8 mL), under an atmosphere of nitrogen, was added over a period of 10 min a solution of 3-bromo-2-[(*Z*)-2-pentenyl]-2-cyclopenten-1-one (**52**) (120 mg, 0.52 mmol) in ether (2 mL). The reaction mixture was allowed to warm to 0°C and was stirred at 0°C for 1 h. Saturated aqueous ammonium chloride was added and the resulting mixture was thoroughly extracted with ether. The combined extracts were dried over anhydrous magnesium sulfate. Removal of the solvent under reduced pressure afforded 80 mg (93%) of pure (*Z*)-jasmone (**53**) as a pale yellow oil; ir (film): 1685, 1640, 1440, 1380, 1340, 1300, 1175, 1070 cm$^{-1}$; $^1$H nmr δ: 0.98 (t, 3H, $J$ = 7.5 Hz), 2.06 (s, 3H), 2.02–2.28 (m, 2H), 2.30–2.70 (m, 4H), 2.95 (d, 2H, $J$ = 6.0 Hz), 5.10–5.56 (m, 2H).

Received September 16, 1981

THOMAS BIRCHALL, RONALD D. MYERS, JACK PASSMORE, W. A. SHANTHA NANDANA, and GEORGE SUTHERLAND. Can. J. Chem. **60**, 1264 (1982).

The iodine-127 Mössbauer spectra of some chalcogen–iodine cations have been recorded and the Mössbauer parameters are discussed in terms of their known structures. These cations are compared to other cationic species of iodine as well as with a molecular compound of iodine which contains a sulphur–iodine bond.

THOMAS BIRCHALL, RONALD D. MYERS, JACK PASSMORE, W. A. SHANTHA NANDANA et GEORGE SUTHERLAND. Can. J. Chem. **60**, 1264 (1982).

On a enregistré les spectres Mössbauer de l'iode-127 de quelques cations chalcogène–iode et on discute des paramètres Mössbauer en fonction de leurs structures connues. On a comparé ces cations avec d'autres espèces cationiques de l'iode aussi bien qu'avec un composé moléculaire de l'iode qui contient une liaison soufre–iode.

[Traduit par le journal]

## Introduction

Compounds between sulfur and iodine were for a long time thought not to exist (1). However, Passmore and co-workers (2–5) and other (6–9) have recently succeeded in isolating compounds containing sulfur–iodine bonds. Some of these novel compounds have been characterized by X-ray crystallography (2–5, 9) but hitherto very little spectroscopic information on these has appeared. We have recently begun a program to measure the iodine-127 Mössbauer spectra of well characterized compounds and to correlate the data obtained with X-ray crystallographic, and other spectroscopic data in an attempt to gain more detailed information about the nature of bonding at the iodine atom.

We present here iodine-127 Mössbauer spectroscopic data for a number of cationic species in which iodine is bonded to sulfur, and in some cases to selenium (10) and tellurium (11). These results are compared with data obtained for other cationic species of iodine (12), and with those obtained for an organosulfur iodide, the latter being obtained by iodine-129 Mössbauer spectroscopy (13).

## Experimental

The compounds were prepared according to the procedures already described (2–5, 10, 11). Mössbauer spectra ($^{127}$I) were recorded using an Elscint AME-40 drive system operating in the constant acceleration triangular wave form mode. The transmitted radiation was detected by a Harshaw NaI(Tl) scintillation counter and the resulting pulses fed to a Tracor-Northern multichannel analyzer operating in the multiscaling mode. Samples of the compounds containing 30 mg of iodine per cm$^2$ were mixed thoroughly with dried prefluorinated Teflon powder and placed in a 20 mm id threaded Kel-F sample holder. The Zn$^{127m}$Te source (10 mCi) was purchased from New England Nuclear Corporation. Both sample and source were immersed in liquid helium (4.2 K) in a research cryostat manufactured by Janis Research Company. The temperature was monitored by means of a calibrated Allen-Bradley 47 ohm, 1/4 watt carbon resistor, and a Cryogenic Research Company temperature controller. The velocity scale was calibrated using an iron foil absorber and a $^{57}$Co/Rh source. The folded spectra were computer fitted using a previously described program which incorporates full transmission integral procedures (14).

## Results and discussion

The iodine-127 Mössbauer parameters for the compounds studied are summarized in Table 1 and the corresponding spectra of $[S_7I]^+[AsF_6]^-$ and $[Se_2I_4]^+[AsF_6]^-$ are shown in Fig. 1. The isomer shifts of all compounds are negative with respect to the reference compound, KI, and since $\delta R/R$ is negative for $^{127}$I, this means that the *s* electron density at the nucleus is higher in these compounds than in KI. This increase in *s* electron density could be achieved by the removal of *p* electrons from the iodine as a result of bonding to the chalcogen atom, and since *p* electrons shield, their removal would cause an increase in the effective *s* electron density. Also, if the positive charge of these cations resides at the iodine, then the *s* electrons will be contracted more strongly than the *p* electrons, also

resulting in a higher $s$ electron density at the iodine nucleus. Both of these effects could be operating simultaneously. What does appear clear is that the binding to iodine is principally of $p$ character and that there is little involvement of the iodine $5s$ electrons in the bonding to the chalcogen atoms.

The compounds which contain the $[S_7I]^+$ unit have structures in which the S—I (exocyclic) distances are nearly constant at 2.355(7) to 2.347(6) Å. Secondary I---F contacts which vary from 2.92 to 2.99(3) Å in these compounds complete an essentially linear S—I---F arrangement. The Mössbauer parameters for the exocyclic iodine in these compounds are essentially the same. The isomer shift of the iodine in these $[S_7I]^+$ cations is more negative than that found for the iodide anion and could be the result of the different charges on the iodine, positive in the former and negative in the latter case. However, the $[S_7I]^+$ cations all show large quadrupole coupling constants, indicating an asymmetric distribution of electrons about the iodine, whereas the iodide anion has a spherical distribution of electrons and hence no quadrupole splitting. Since the quadrupole coupling constants are all negative this indicates that there is an excess of electron density in the $xy$ plane about the iodine atom compared to the $z$ direction which is taken to be along the S—I---F axis.

From the measured values of the quadrupole coupling constants it is usual to estimate the $p$ electron imbalance $U_p$ from expression [1] (15).

$$[1] \quad U_p = \frac{-e^2q_{mol}{}^{127}Q_g/h}{e^2q_{at}{}^{127}Q_g/h}$$

where $e^2q_{at}{}^{127}Q_g/h$ = 2293 MHz (16), and $U_p$ is related to the electron occupation numbers $U_x$, $U_y$, and $U_z$ of the $p_x$, $p_y$, and $p_z$ orbitals by expression [2].

$$[2] \quad U_p = -U_z + 1/2(U_x + U_y)$$

For the $[S_7I]^+$ compounds, $U_p > 1$, indicating that the iodine has had slightly more than one $p$ electron removed from its noble gas valence bond configuration. This removal of $p$ electrons from the iodine is consistent with the observed increase in $s$ electron density compared to the iodide anion. If the assumption is made that $U_p = h_p$, then one can calculate $h_s$ from expression [3],[2] which leads to small positive values for $h_s$ in all cases but one.

$$[3] \quad {}^{127}\delta_{KI} = 3.74h_s - 0.61h_p - 0.12$$ ERRATA

An alternative approach is to assume that there is no $s$ electron contribution to the bond between the iodine and sulfur and one can then use the measured isomer shift to calculate $h_p$ from expression [3]. These calculated values are included in the table and one can see that there is little agreement between the values for $h_p$ calculated from expression [3] and from the measured quadrupole coupling constants. We conclude that these empirical correlations, being based on a rather limited number of compounds, perhaps do not have the general applicability that has been hitherto assumed.

The quadrupole coupling constants are much more negative than those measured for molecular species such as $CH_3I$ and $CF_3I$ (17) and are more like the values found for the central iodine in the

[2]This relationship was recently re-evaluated using the same series of compounds as in ref. 12, but against KI as zero isomer shift.

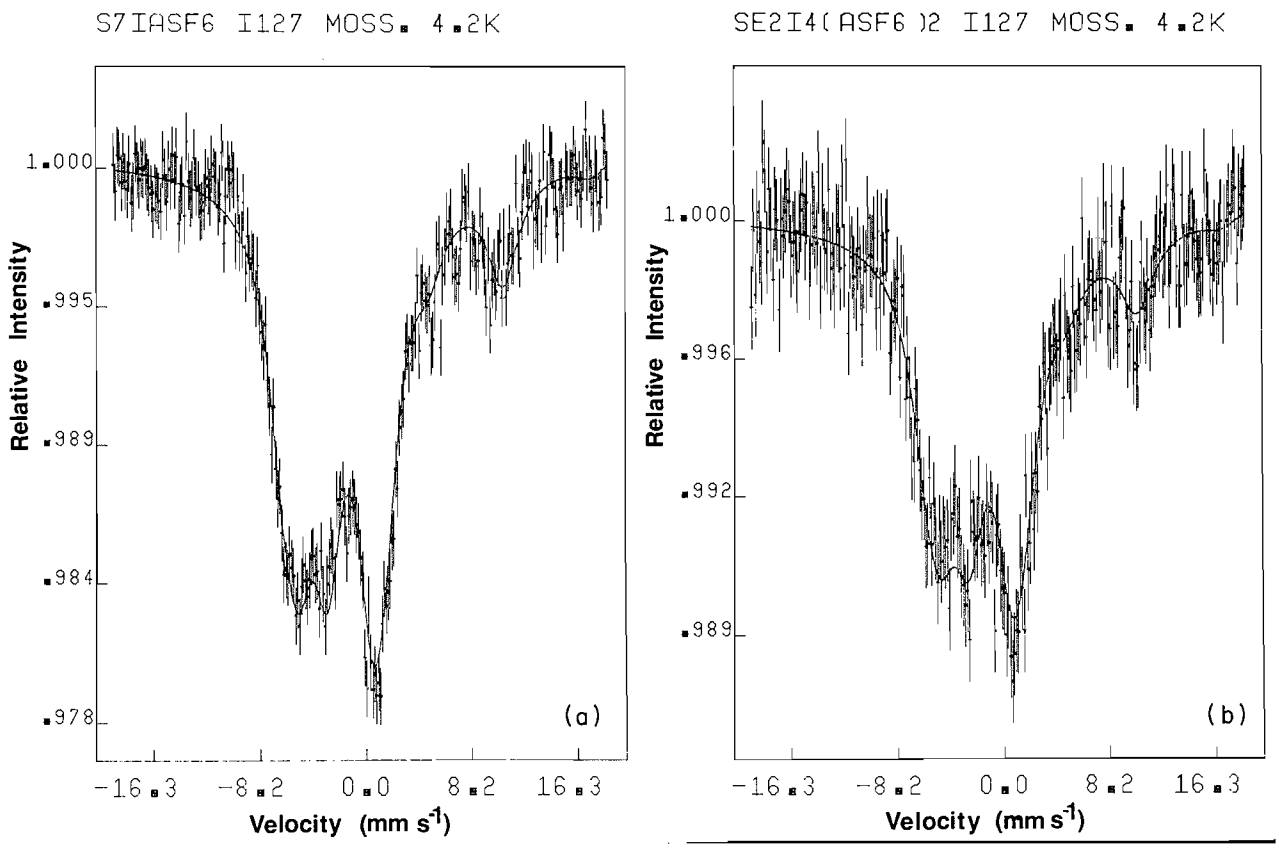

FIG. 1. The iodine-127 Mössbauer spectra at 4.2 K of (*a*) $[S_7I]^+[AsF_6]^-$, (*b*) $[Se_2I_4]^{2+}[AsF_6]_2^-$. The solid lines represent the best fit to the data.

linear $[X—I—Y]^-$ (X, Y = F, Cl, Br, I) compounds (12), being comparable to that of the central iodine in $[I_3]^-$ (18). The secondary I---F interaction in these $[S_7I]^+$ cations is rather long at 2.96 Å, but plays a significant part in influencing the distribution of electrons about the iodine, keeping it in an essentially $sp^3d^2$ hybridised arrangement. Potasek (13) has measured the $^{129}I$ Mössbauer spectrum of RS$^{129}$I (R = *N*-*p*-chlorophenyl-2-(benzyloxycarbonamide)-3-methylbutanamide) and found $^{129}\delta_{ZnTe} = -0.41$ mm s$^{-1}$ and $e^2q_{zz}\,^{129}Q_g/h = -1510$ MHz. After conversion to their iodine-127 equivalents ($^{127}\delta_{ZnTe} = -0.14$ mm s$^{-1}$, and $e^2q_{zz}\,^{127}Q_g/h = -2153$ MHz) (19) their values resemble those found for the RI (R = $CH_3$, $CF_3$, etc.) compounds (17) rather than the cations reported here. This is consistent with the molecular nature of the RI and RSI compounds compared to the charged species discussed here where strong cation–anion interactions occur.

The second iodine site in the compound $[(S_7I)_2I]^{3+}[SbF_6]_3^-\cdot 2AsF_3$ has a slightly less negative isomer shift but similar quadrupole coupling constant compared to the values found for exocyclic iodine atom in the $[S_7I]^+$ cations. This indicates that there is a somewhat lower *s* electron density at the central iodine in $(S_7I)—I—(S_7I)$ than for the $S_7—I$---F iodine. This perhaps indicates that there is less positive charge on this central, bridging iodine than on the exocyclic iodine, since the degree of *p* character in the bonding of these iodines is approximately the same.

X-ray crystallography has shown that $[S_2I_4]^{2+}$-$[AsF_6]_2^-$ has the novel distorted right triangular prismatic structure with one $S_2$ unit asymmetrically bonded to two $I_2$ units: S—S, 1.828(11) Å; $I_1—I_2$, 2.597(2) Å; S—$I_1$, 2.858(6) Å; S—$I_2$, 3.195(6) Å (5). It was of interest to determine $[Se_2I_4]^{2+}$ has a similar structure. We have therefore attempted to fit the spectra of these compounds to two unique iodine sites, but with little success; the Mössbauer fitting program diverges after only a few cycles. Suitable refinement of the spectra occurred when only one site was incorporated in the fitting procedure, and when the value of the asymmetry parameter $\eta$ was allowed to vary in the case of $[S_2I_4]^{2+}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

The $\chi^2$ value for the latter refinement is somewhat high, although not unusual, perhaps suggesting that the bulk sample contained a small amount of impurity or decomposition product which, of course, would not be present in the single crystal selected from the material and used for the X-ray analysis. The selenium analog gave a much better spectrum (Fig. 1) and a good fit to the data was obtained: when the value of $\eta$ was allowed to vary a marginally improved fit was obtained. This may be because the asymmetry parameter is compensating for the presence of two slightly different iodine environments which are probably present in the compound. The isomer shifts of the $[S_2I_4]^{2+}$ and $[Se_2I_4]^{2+}$ cations are nearly the same as those found for the exocyclic iodine site in the $[S_7I]^+$-containing species, but in view of the structures of $[S_2I_4]^{2+}$, $[I_2]^+$ may provide a better comparison. We have recently remeasured the $^{127}I$ Mössbauer spectrum of $[I_2][Sb_2F_{11}]$ and obtained more reliable data than those reported earlier (12). Contrary to our original findings, the isomer shift of $[I_2]^+$ is slightly more negative than molecular iodine (see Table 1), indicating that the *s* electron density at the iodine nucleus has increased. Thus although an electron is removed from a $\pi_g^*$ orbital of $I_2$ upon oxidation, the most important contribution to the observed isomer shift is the positive charge on $[I_2]^+$. This positive charge contracts the *s* orbitals of iodine more strongly than the *p* orbitals, thereby causing an effective increase in the *s* electron density at the nucleus, and hence the more negative isomer shift. As was previously reported (12), the quadrupole coupling constant of $[I_2]^+$ is less negative than that of $I_2$. If there are $\pi$ interactions between the $I_2$ and $S_2(Se_2)$ units in the $[S_2I_4]^{2+}$ and $[Se_2I_4]^{2+}$ cations as has been suggested (4) for $[S_2I_4]^{2+}$ then it would be expected that these latter cations would have Mössbauer parameters intermediate to those of $I_2$ and $[I_2]^+$.

While the isomer shift of the $[Se_2I_4]^{2+}$ cation is between those for $I_2$ and $[I_2]^+$, that for the sulfur analogue is much more negative, indicating a higher *s* electron density. In $[S_2I_4]^{2+}$, the iodine quadrupole coupling constant is about the same as that in $I_2$, indicating that the degree of *p* participation in the bonding is the same, but since the *s* electron density is much greater for $[S_2I_4]^{2+}$ than for $I_2$ there must be quite a high residual positive charge on the iodine in the cation. For the selenium analogue the quadrupole constant is much larger, indicating a greater *p* electron imbalance at iodine. The *s* electron density is much lower than for the sulfur analogue which leads us to conclude that, in this cation, there is much less positive charge on the iodine than in the case of the $[S_2I_4]^{2+}$ cation. Presumably there is a better match of orbitals between Se and I than between S and I, allowing the positive charge on the $[Se_2I_4]^{2+}$ cation to be more delocalized.[3] The remaining two cations $[SeI_3]^+$ and $[TeI_3]^+$ may be compared to the isoelectronic group (V) tri-iodides, $AsI_3$, $SbI_3$, and $BiI_3$ whose iodine-129 Mössbauer spectra have been measured (20). In the trigonal pyramidal $[TeI_3]^+$ cation the average Te—I bond is 2.667(1) Å long and the I—Te—I bond angle is 99.90(3)° (11). Secondary contacts between tellurium and fluorine atoms of the anion are also present at 2.88(1) Å completing a pseudo-octahedral geometry around tellurium. $[SeI_3]^+[AsF_6]^-$ (10) is isomorphous and probably isotructural with $[TeI_3]^+[AsF_6]^-$. The structures of the neutral group V tri-iodides, $AsI_3$ (21), $SbI_3$ (22), and $BiI_3$ (22) are similar to that of $[TeI_3]^+[AsF_6]^-$, where secondary contacts from tellurium to fluorine atoms of the anion have been replaced by long interactions from the central metal atom to iodine atoms of adjacent molecules. In $AsI_3$ and $SbI_3$ the arsenic and antimony atoms are significantly displaced from the centres of the iodine octahedra and have three short contacts to iodine at 2.556(4) and 2.68(10) Å respectively. The octahedra are completed by secondary contacts to iodine at 3.50 and 3.316 Å respectively. In $BiI_3$, however, the bismuth atom is situated at the centre of the iodine octahedron (Bi—I, 3.1 Å) so that the lone pair of electrons is stereochemically inactive in this compound. One might then expect similar Mössbauer parameters for these two series of compounds since the same gross structure is observed by both systems and any differences could perhaps be attributed to the difference in charge and/or to the nature of the secondary contacts to iodine. Since the iodine atoms in $[TeI_3]^+$, and presumably also in $[SeI_3]^+$, are nearly the same distance from the central element the spectra were fitted assuming only one iodine environment. The isomer shifts are very similar to those of the other cations reported in Table 1, but are more negative than the shifts for $AsI_3$, $SbI_3$, and $BiI_3$ (mean $-0.34$ mm $s^{-1}$) (20), after these have been converted from their $^{129}I$ values (19). This is probably due to the charge on the cation which contracts the *s* orbitals, thereby increasing the effective *s* electron density.

Okuda *et al.* (23) have reported $^{127}I$ nqr data for $TeI_4$ while Jones and Mauguin (24) have recently

[3]The structure of $[S_2I_4][Sb_2F_{11}]_2$ has recently been determined. The $[Se_2I_4]^{2+}$ cation has an eclipsed $[S_2O_4]^{2-}$-like, $[I_2\overset{+}{S}\overset{+}{S}eI_2]$ structure, consistent with the $^{127}I$ Mössbauer results (26).

reported the $^{129}I$ Mössbauer spectrum of $TeI_4$ as well as of several other tellurium iodides. The latter workers were able to resolve three independent iodine sites; this finding is consistent with the X-ray crystal structure of $TeI_4$ (25). The terminal iodine atom in $TeI_4$ was found to have a quadrupole coupling constant of 1190 MHz and an isomer shift with respect to the ZnTe source of 0.70 mm $s^{-1}$. The second site which was assigned to the iodine which bridges two tellurium atoms had $e^2q^{129}Q_g/h$ = 600 MHz, $\eta = 1.0$, and the isomer shift was 0.30 mm $s^{-1}$. The final site which corresponds to the iodine atom which bridges three tellurium atoms showed no quadrupole coupling and the isomer shift was 0.40 mm $s^{-1}$. The terminal iodine atoms in $TeI_4$ provide the best comparison with $[TeI_3]^+$ and after conversion to their iodine-127 equivalents, $e^2q^{127}Q_g/h$ = 1700 MHz and the isomer shift with respect to KI is −0.10 mm $s^{-1}$. The isomer shift of the $[TeI_3]^+$ cation is more negative than the neutral compound and this has been attributed to a contraction of the *s* orbitals of the iodine atom in the cation, causing a higher *s* electron density and hence a more negative isomer shift. The quadrupole coupling constant of the iodine atom in $[TeI_3]^+$ is somewhat larger than the converted coupling constant of $TeI_4$. This indicates a larger *p* electron imbalance in the former compound and is caused by the removal of more *p* electron density in $[TeI_3]^+$ probably because of the shorter Te—I bond. The Te—I bond distances in $[TeI_3]^+$ average 2.667 Å (11) while in $TeI_4$ (25) the average terminal Te—I bond distance is 2.768 Å.

The quadrupole coupling constant of $[SeI_3]^+$ is substantially more negative than that of $[TeI_3]^+$, which is consistent with the higher electronegativity of the central atom in the former compound. However, both compounds have quadrupole coupling constants which are significantly larger than those found for the neutral group V tri-iodides. Since the iodine environments are essentially the same in both the neutral and charged species, the larger quadrupole coupling constant in the latter compounds must be a consequence of the positive charge and smaller size of the group VI cation compared to the isoelectronic group V neutral species. Both of these factors contribute to the shorter M—I bond observed in the cationic species, creating a larger electric field gradient and hence more negative quadrupole coupling constant in the cations. The Mössbauer parameters of $[TeI_3]^+$ and $[SeI_3]^+$ clearly indicate that there is considerable *p* character in the M—I bonds.

## Conclusion

The iodine-127 Mössbauer spectra of a number of novel chalcogen–iodine cations have been measured. The data clearly indicate that the nature of the bonding between the group VI atom and iodine is of essentially *p* character. It was also concluded that empirical correlations based on the hyperfine parameters and established earlier, perhaps do not have general applicability. The Mössbauer data discussed are consistent with the known structures of the compounds as established by X-ray crystallography.

# Dihydropyridines in synthesis and biosynthesis. IV.[1] Dehydrosecodine, in vitro precursor of indole alkaloids

JAMES P. KUTNEY, YISHAI KARTON, NORIAKI KAWAMURA, AND BRIAN R. WORTH

*Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6*

Received November 6, 1981

JAMES P. KUTNEY, YISHAI KARTON, NORIAKI KAWAMURA, and BRIAN R. WORTH. Can. J. Chem. **60**, 1269 (1982).

The synthesis of the two isomeric dehydrosecodines is described. Stabilization of these systems is achieved by chromium carbonyl complexation of the dihydropyridine unit in these molecules. Reaction of the complexes with pyridine, or preferably ethylenediamine, allows *in situ* generation of the dehydrosecodines. A study of their chemistry and conversion to alkaloid systems is presented.

JAMES P. KUTNEY, YISHAI KARTON, NORIAKI KAWAMURA et BRIAN R. WORTH. Can. J. Chem. **60**, 1269 (1982).

On décrit la synthèse de deux déhydrosécodines isomères. On a stabilisé ces systèmes en complexant l'unité dihydropyridine de ces molécules à l'aide de chromecarbonyle. La réaction de ces complexes avec la pyridine, ou de préférence avec l'éthylènediamine, permet de former *in situ* les déhydrosécodines. On présente une étude de la chimie de ces composés et de leur transformation en des systèmes d'alcaloïdes.

[Traduit par le journal]

The possible role of dihydropyridines as late-stage intermediates in indole alkaloid biosynthesis has been discussed for some time. Wenkert (2) first provided a postulate involving such systems and others subsequently speculated on the utilization of such intermediates during their various investigations on the later stages of indole alkaloid biosynthesis (3, 4). Scheme 1 illustrates the proposed possible biosynthetic pathway from stemmadenine **1** (a member of the Strychnos family) to catharanthine **2** (Iboga) and vindoline **3** (Aspidosperma). Direct evidence for an intermediate of type "A" (Scheme 1) has been provided via a series of experiments conducted in these laboratories (4–6) and summarized in Scheme 2. Thus, variously labelled forms of secodine **4** were incorporated intact into the alkaloids catharanthine **2**, vindoline **3**, vincamine **5**, and apparicine **6**. Significantly, 50–60% of the tritium in the piperideine unit of **4** was consistently lost during incorporation, suggesting a higher oxidized form of **4** as a better representation of the key, late-stage, biointermediate. Efforts were therefore directed toward the study of the dehydrosecodines **7** and **8**. The unstable nature of **4**, **7**, and **8** has been discussed earlier (6) and the indole protected derivatives **9** and **10**

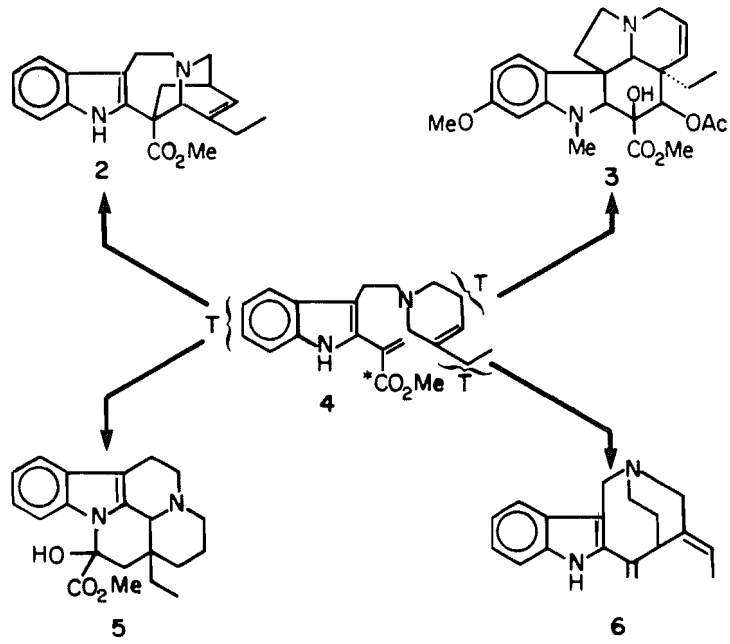
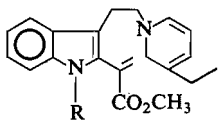


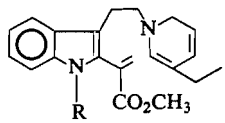
SCHEME 2

were chosen as substrates for a true biomimetic investigation of the latter stages of indole alkaloid formation.

The expected in vitro behaviour of the dehydrosecodines **9** and **10** is outlined in Schemes 3 and 4.



**7** R = H
**9** R = $CH_2C_6H_5$



**8** R = H
**10** R = $CH_2C_6H_5$

For the 1,2-dihydropyridine isomer, **9**, enamine behaviour, via β-alkylation, should lead to the *N*-benzylcleavamine derivative **11** or by transannular cyclization to the pseudo-vincadifformine **12** (7, 8). Alternatively, the dehydrovincadine **13** would arise via δ-alkylation (Scheme 3).

On the other hand, for the 1,6-isomer **10**, β-alkylation would give **13**, or, via transannular cyclization, the tabersonine derivative **14**. Alternatively, δ-alkylation would be expected to yield either **11** or *N*-benzylcatharanthine **15**. Diels–Alder cyclization might also yield **15** (Scheme 4).

In earlier work (9) it was shown that the model compound, *N*-methyl-3-ethyl-1,2-dihydropyridine **16**, derived via controlled borohydride reduction of the pyridinium salt or from the corresponding tricarbonylchromium(0) complex **17**, suffered β-alkylation with benzyl bromide to give the 3,5-disubstituted piperideine **18** (Scheme 5). Recently we have shown that the analogous benzylation of *N*-methyl-3-ethyl-1,6-dihydropyridine **19** (derived from **20**) also gave **18**, indicating preference for δ-alkylation in the 1,6-isomer (Scheme 5). With this information base, it was expected that the 1,2-isomer **9** would undergo β-alkylation to give the cleavamine **11** and the pseudo-vincadifformine **12**, while the 1,6-isomer **10** would suffer δ-alkylation to **11** and *N*-benzylcatharanthine **15**. The tabersonine and quebrachamine derivatives, **14** and **13** respectively, were not expected to arise.

Kuehne *et al.* (10) converted the spiroammonium salt **21** to vincadifformine **22**, and proposed intermediacy of secodine **4**, arising via a Hoffmann elimination, in the transformation. Alternatively, thermolysis of **23** gave **22** again, presumably via **4** (11). Indeed separate syntheses of secodine **4** have been described (5, 12).

To date, no successful synthesis of dehydrosecodines has been reported. Our objective was to synthesize the tricarbonylchromium complexes **24** and **25** by controlled reduction of the salt **26** and to subsequently elaborate to **27** and **28** before removal of the $Cr(CO)_3$ group to generate the dehydrosecodines **9** and **10**.

Initially, Fisher indole synthesis with phenylhydrazine and levulinic acid gave the ester **29** (13) which was reduced with lithium aluminum hydride to yield 2-methyltryptophol (**30**) (14). Condensation with benzyl chloride gave the dibenzyl deriva-

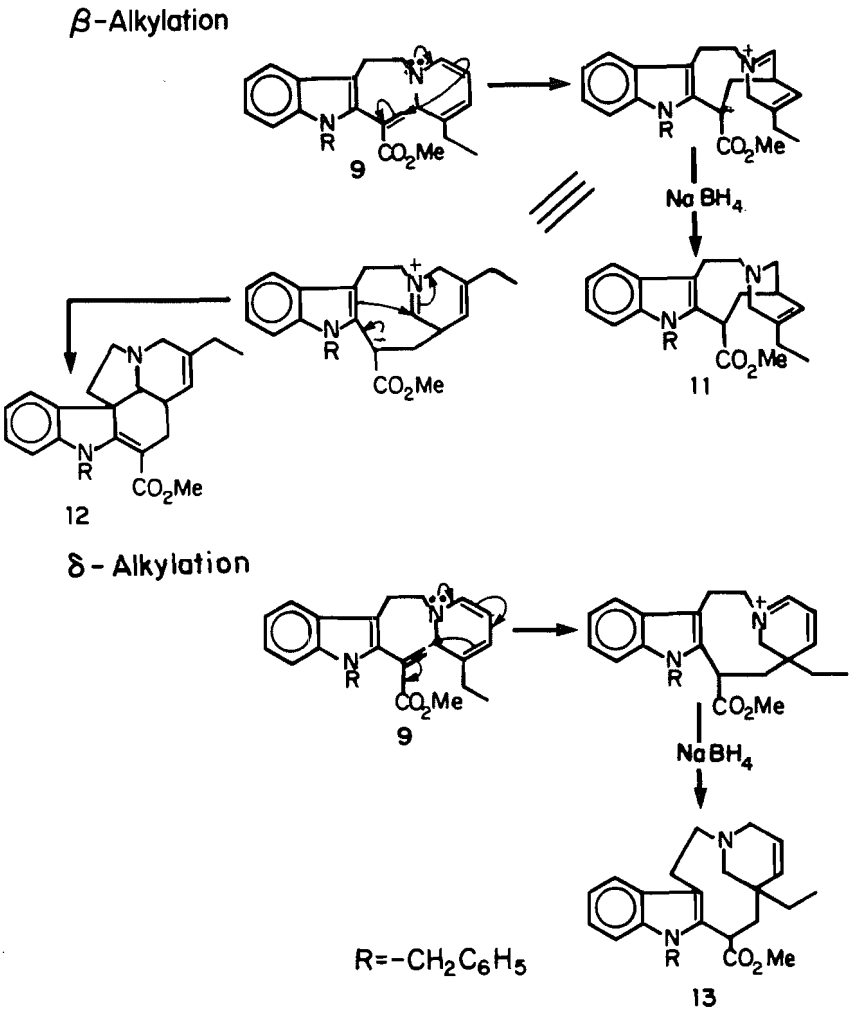
For personal use only.



SCHEME 3

tive **31**. Reaction with *N*-bromosuccinimide in pyridine followed by displacement with cyanide gave nitrile **33** and, after methanolysis, the bromo ester **34**. Alkylation of 3-ethylpyridine gave the required salt **26** (in 10% overall yield from phenylhydrazine (Scheme 7)) analogous to the iodide and chloride salts prepared earlier (5, 6).

Controlled reduction of **26** and complexation using trisacetonitriletricarbonylchromium(0) gave a 54% yield of the two complexes **24** and **25** (6) in the ratio 9:1. The mixture of complexes was treated with KH and Eschenmoser's salt to give the labile amines which were subsequently decomposed ($K_2CO_3$) to give the dehydrosecodine complexes (35%) **27** and **28** in the ratio 4:1. In order to obtain a higher yield of **28**, the mixture of **24** and **25** was equilibrated in refluxing *n*-octane. Subsequent elaboration, as before, gave an approximately equimolar mixture of **27** and **28**.

With the protected dehydrosecodines now in hand, samples of the possible products of in vitro decomplexation and cyclization (viz: **11–15**) were prepared.

Reaction of catharanthine (**2**) with sodium borohydride in acetic acid readily furnished 18β-carbomethoxycleavamine (**35**) (15) which was oxidized and cyclized, with mercuric acetate, to dehydropseudovincadifformine (**36**) (7) and subsequently benzylated (KH, $C_6H_5CH_2Cl$) to **12**. Direct *N*-benzylation of **35** was not possible since *C*-benzylation involving the ester-bearing carbon atom was a competing reaction. However, cleavage of **12** with sodium borohydride in acetic acid gave *N*-benzyl-18β-carbomethoxycleavamine (**11**) (Scheme 8).

*N*-Benzylcatharanthine (**15**) was prepared by direct benzylation of **2**. Similarly, tabersonine (**37**) gave **14** which on reductive cleavage with sodium

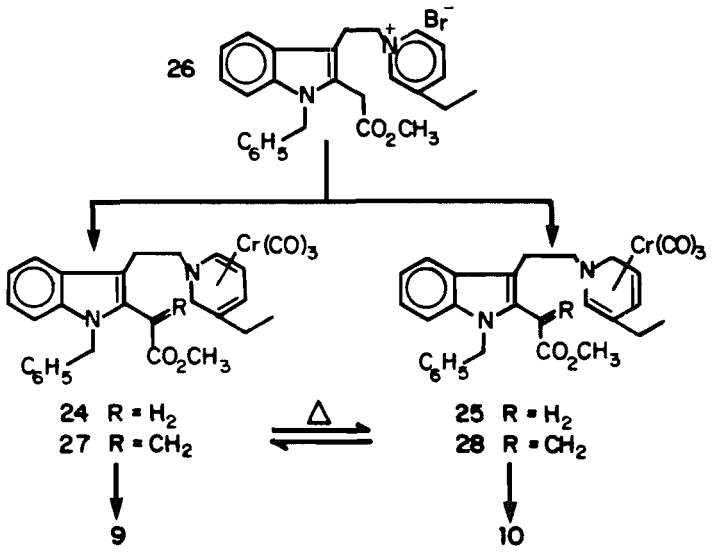
borohydride in acetic acid gave *N*-benzyldehydrovincadine (**13**). Thus all five possible cyclization products were available for analysis (hplc) of reaction product mixtures.

The 1,2-dihydropyridine complex **27** was investigated first. Here, treatment with pyridine at ambient temperature in the usual manner (9) did not give any observable change. At 55°C, however, the red colour of the complex quickly dissipated but the major product after sodium borohydride reduction was **38** arising from simple reduction of **9**. At higher temperature (110°C), the carbazole derivative **39** was isolated (79%). Scott and Cherry (16) had observed the same type of product from the thermolysis of catharanthine or tabersonine and suggest the intermediacy of dehydrosecodine **7** in this reaction.

Ethylenediamine (EDA) was found to be much more effective in removing the tricarbonylchromium group. Table 1 summarizes the large number of experiments carried out to determine optimum conditions for the formation of **11** and **12** from **27**.

Initially, only the *N*-benzylcleavamine derivative **11** was obtained when the 1,2-dihydropyridine complex **27** was treated with EDA followed by sodium borohydride reduction. The transannular cyclization product **12** was not observed under these conditions. However, addition of acetic acid after removal of the tricarbonylchromium group by EDA resulted in the formation of **12**. Compound **11** was also obtained in these reactions even before reduction with sodium borohydride, probably due to the reducing character of the dihydropyridine moiety. As expected from model compound studies (9), no δ-alkylation product was detected in all these experiments with the 1,2-dihydropyridine complex **27**.

Table 2 summarizes the in vitro reactions of the 1,6-dihydropyridine **10** derived from the complex **28**. The latter behaved similarly to the 1,2-isomer when treated with pyridine/$NaBH_4$. The major product obtained was either **38** or **39**. Replacing pyridine with $CH_3CN$ again provided **38** as the major product by simple reduction of **10**. Here again EDA was found to be the most effective reagent for removal of the tricarbonylchromium group. Thus, when **28** was treated with EDA at



SCHEME 6

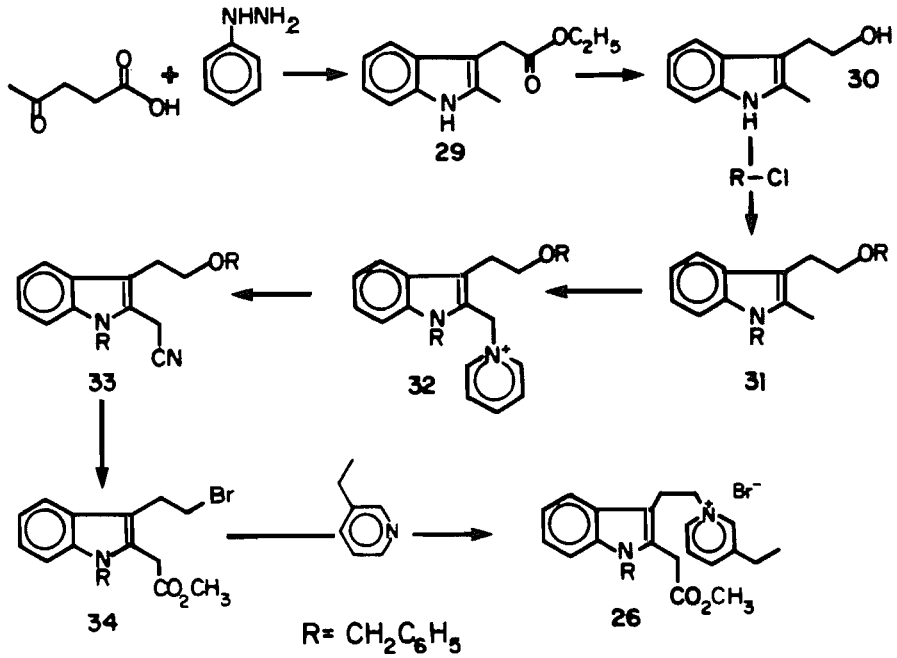
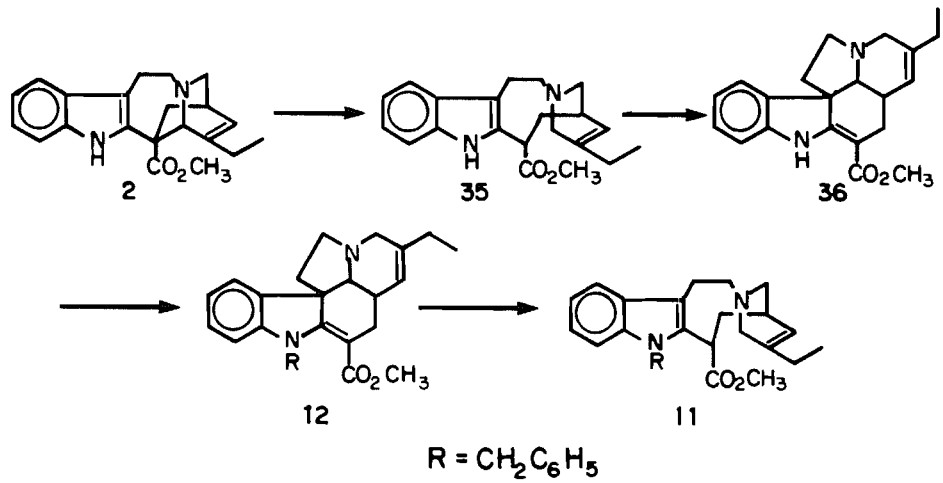


SCHEME 7



SCHEME 8

ambient temperature followed by sodium borohydride reduction, compounds **11** and **15** were obtained in 11% and 1.5% yield respectively. Both **11** and **15** are products which arose from an intramolecular δ-alkylation of the 1,6-dihydropyridine **10**. This is in good agreement with the result described earlier in model compound studies that alkylation occurred preferentially at the δ position for the 1,6-isomer.

We have thus demonstrated for the first time the

formation of *Aspidosperma* and *Iboga* type alkaloids by in vitro reactions of the dehydrosecodines **9** and **10**.

## Experimental

Melting points were determined on a Kofler block and are uncorrected. Ultraviolet (uv) spectra were recorded on a Cary 15 spectrophotometer in methanol solution. The wavelengths of absorption maxima are reported in nanometers (nm) with log ε values in parentheses. Infrared (ir) spectra were measured on a Perkin Elmer model 710 or 457 spectrophotometer in chloroform solution. The absorption maxima are reported in wavenumbers ($cm^{-1}$), calibrated with respect to the absorption band of polystyrene at 1601 $cm^{-1}$. Proton magnetic resonance ($^1Hmr$) spectra were measured in deuteriochloroform ($CDCl_3$) solution at ambient temperature on a Varian XL-100, Nicolet-Oxford H-270, or Bruker WH-400 spectrometer. Chemical shift values are given in the δ (ppm) scale relative to tetramethylsilane (TMS) used as internal standard. The integrated peak areas, signal multiplicities, and proton assignments are given in parentheses. Low resolution mass spectra (ms) were determined on an AEI-MS-902 or Atlas CH-4B spectrometer. High resolution mass spectra were measured on an AEI-MS-902 instrument. Microanalyses were carried out by Mr. P. Borda of the Microanalytical Laboratory, University of British Columbia.

Column chromatography utilized Merck silica gel 60 (70–230 mesh). Preparative high pressure liquid chromatography (hplc) utilized Waters Associates Prep-LC/system 500 Liquid chromatogram. Analytical hplc instruments consisted of two Waters Associates Model 6000 A solvent delivery systems, 730 data module, 740 system controller, RCM-100 with $C_{18}$-radial pak-A column, and 440 uv detector (254 and 280 nm). A solvent system of $MeOH/H_2O$ (4:1), each containing 0.1% $Et_3N$, was used at a flow rate of 2 mL/min.

(0) complex **20** (240 mg) was dissolved in ethylenediamine (1 mL) and the mixture was stirred at ambient temperature for 15 min under a nitrogen atmosphere. The mixture was poured into ice and 2 *N* NaOH and extracted with ether. The ether solution was added to the mixture of 2 *N* NaOH (2.6 mL), methanol (2.6 mL), sodium borohydride (68 mg), potassium iodide (140 mg), and benzyl bromide (1.5 mL) and stirred at ambient temperature for 15 h. The solution was acidified with 2 *N* HCl, washed with ether, and evaporated. The yellow residue (200 mg), lithium hydride (80 mg), and *n*-propyl mercaptan (0.5 mL) were stirred in HMPA (3 mL) at ambient temperature for 18 h under a nitrogen atmosphere. The mixture was cooled, acidified with 2 *N* HCl, and washed with ether. The aqueous layer was basified with 2 *N* NaOH and extracted with ether. The organic extract was dried ($Na_2SO_4$) and evaporated. Chromatography on silica gel afforded **18** (41 mg, 20% yield). The physical data were identical with those of the compound prepared from *N*-methyl-3-ethyl-1,2-dihydropyridinetricarbonylchromium(0) (7).

N,O-*Dibenzyl-2-methyltryptophol* ***31***

A solution of 2-methyltryptophol (**30**) (11, 12) (35 g) in dry ether (100 mL) was added slowly to a suspension of potassium hydride (80 g, 23% suspension) and benzylchloride (45 mL) in dry ether (400 mL) and HMPA (100 mL) at 0°C. The mixture was stirred at ambient temperature for 2.5 h. The mixture was cooled to 0°C and methanol and water were added to destroy the excess hydride. The mixture was extracted with ether. The extract was washed with water, dried ($Na_2SO_4$), and concentrated *in vacuo*. Recrystallization of the residue gave **31** (70 g, 99%); mp 55–57°C; uv $\lambda_{max}$: 293 (3.77), 284 (3.81), 276 (3.78), 225 (4.21); ir $\nu_{max}$: 1500, 1475, 1460; $^1$Hmr (100 MHz) δ: 2.22 (3H, s, —$CH_3$), 3.04 (2H, t, $J$ = 6 Hz, —$CH_2$$CH_2$—O—), 3.64 (2H, t, $J$ = 6 Hz, —$CH_2$$CH_2$—O—), 4.48 (2H, s, —O$CH_2$$C_6H_5$), 5.20 (—N$CH_2$-$C_6H_5$) 6.9–7.8 (14H, m, aromatic H); ms *m/e*: 355 ($M^+$), 234, 91 (100%), 65. High resolution molecular weight determination calcd. for $C_{25}H_{25}NO$: 355.1937; found: 355.1938.

*The dibenzylpyridinium salt* ***32***

*N*-Bromosuccinimide (5.5 g) was added to a solution of **31** (10 g) in benzene (50 mL) and pyridine (0.5 mL) at 0°C. The mixture was stirred at 0°C for 1 h. The precipitate was removed by filtration. The filtrate was stirred with pyridine (30 mL) at 0°C for 1 h. The precipitate was collected by filtration and washed with cold tetrachloromethane to give **32** (13.2 g, 91%) as a yellow powder; mp 105–107°C; uv $\lambda_{max}$: 300 (3.53), 285 (3.73), 273 (3.78), 220 (4.52); ir $\nu_{max}$: 2950, 1485, 1460; $^1$Hmr (400 MHz) δ: 3.26 (2H, t, $J$ = 6 Hz, —$CH_2$$CH_2$—), 4.08 (2H, t, $J$ = 6 Hz, —$CH_2$O—), 4.42 (2H, s, —O$CH_2$$C_6H_5$), 5.77 (2H, s, —N$CH_2$-$C_6H_5$), 6.57 (2H, s, —$CH_2$—$N^+$), 6.6–7.4 (14H, m, aromatic H), 7.55 (1H, t, $J$ = 8 Hz), 7.73 (1H, d, $J$ = 8 Hz), 9.44 (2H, d, $J$ = 8 Hz); ms *m/e*: 435 ($M^+$ − pyridine), 433, 354, 262, 248, 232, 91 (100%). *Anal.* calcd. for $C_{30}H_{31}N_2O_2Br \cdot H_2O$: C 67.80, H 5.90, N 5.27, Br 15.03; found: C 68.07, H 5.87, N 5.40, Br 15.20.

*The nitrile* ***33***

The pyridinium salt **32** (12.6 g) and potassium cyanide (10 g) were heated in refluxing methanol (200 mL) for 24 h. The mixture was cooled and methanol was evaporated. The residue was dissolved in benzene and filtered. The filtrate was evaporated and the residue was chromatographed on silica gel to yield **33** (3.1 g, 33%); uv $\lambda_{max}$: 293 (3.92), 282 (3.99), 275 (3.97); ir $\nu_{max}$: 2260; $^1$Hmr (100 MHz) δ: 3.09 (2H, t, $J$ = 6.5 Hz, —$CH_2$—$CH_2$—), 3.73 (2H, t, $J$ = 6.5 Hz, —$CH_2$O—), 3.75 (2H, s, —$CH_2$CN), 4.51 (2H, s, —O$CH_2$$C_6H_5$), 5.47 (2H, s, —N$CH_2$-$C_6H_5$), 6.9–7.7 (14H, m, aromatic H); ms *m/e*: 380 ($M^+$), 290, 259, 91 (100%). These spectral data of **33** were identical with those of the nitrile prepared previously (2).

*The pyridinium salt* ***26***

The nitrile **33** (16.5 g) was treated with methanol (50 mL) and acetylbromide (20 mL) at 0°C for 1 h. The mixture was heated at 55°C for 72 h. The mixture was cooled and concentrated *in vacuo*. The residue was partitioned between water and dichloromethane. The organic layer was washed with 5% sodium carbonate solution and water, dried ($Na_2SO_4$), and evaporated. Chromatography on silica gel afforded the bromoester **34**. The crude bromoester **34** was heated at 50°C in 3-ethylpyridine (100 mL) for 18 h. Excess 3-ethylpyridine was removed and recrystallization of the residue from acetone afforded **26** (7.9 g, 37% from **33**); mp 119–121°C; uv $\lambda_{max}$: 292 (3.95), 284 (4.00), 265 (4.15), 220 (4.45); ir $\nu_{max}$: 2930, 1740, 1230; $^1$Hmr (400 MHz) δ: 0.94 (3H, t, $J$ = 8 Hz, —$CH_2$$CH_3$), 2.55 (2H, q, $J$ = 8 Hz, —$CH_2$$CH_3$), 3.57 (3H, s, —$OCH_3$), 3.58 (2H, t, $J$ = 6 Hz, —$CH_2$$CH_2$), 3.86 (2H, s, —$CH_2$CO), 5.25 (2H, t, $J$ = 6 Hz, —$CH_2N^+$), 5.31 (2H, s, —N$CH_2$$C_6H_5$), 6.8–7.3 (9H, m, aromatic H), 7.70 (1H, dd, $J$ = 6, 8 Hz, C(5')-H), 7.98 (1H, d, $J$ = 8 Hz, C(4')-H), 8.80 (1H, s, C(2')-H), 9.37 (1H, d, $J$ = 6 Hz, C(6')-H); ms *m/e*: 413 ($M^+$ − Br), 354, 352, 121, 107, 93, 91 (100%). *Anal.* calcd. for $C_{27}H_{29}N_2O_2$-Br: C 65.72, H 5.92, N 5.67, Br 16.19; found: C 65.50, H 6.09, N 5.55, Br 16.00.

*The tricarbonylchromium(0) complexes **24** and **25***

A solution of **26** (1.02 g) in methanol (12.5 mL) was added to a vigorously stirred mixture of 0.2 *M* sodium carbonate solution (12.5 mL), ether (50 mL), and sodium borohydride (117 mg) at 0°C under a nitrogen atmosphere. The two-phase system was stirred at 0°C for 45 min. The ether layer was separated and washed with 0.2 *M* potassium carbonate solution (10 mL), dried ($Na_2SO_4$), and then added to trisacetonitriletricarbonylchromium(0) (1.5 equiv.) at 0°C under nitrogen. The mixture was stirred at 0°C for 2.5 h and then warmed to ambient temperature for 30 min. The solvent was removed *in vacuo* and the red residue was chromatographed on previously degassed silica gel with degassed benzene under a nitrogen atmosphere to afford a mixture of **24** and **25** (614 mg, 54%).

The mixture of **24** and **25** (318 mg; ratio 9:1 by $^1$Hmr) was stirred in refluxing *n*-octane (57 mL) for 65 min under a nitrogen atmosphere. The mixture was cooled and concentrated *in vacuo*. Preparative hplc separation with chloroform – petroleum ether (1:1.1) gave **24** (148 mg) and **25** (143 mg).

*The complex **24***, uv $\lambda_{max}$: 400 (3.59), 295 (4.05), 279 (4.12), 275 (4.15); ir $\nu_{max}$: 1940, 1870, 1830, 1735; $^1$Hmr (270 MHz) δ: 0.95 (3H, t, $J$ = 7.5 Hz, —$CH_2CH_3$), 2.12 (2H, q, $J$ = 7.5 Hz, —$CH_2CH_3$), 2.7–2.95 (4H, m, —$CH_2CH_2N$), 3.33 (2H, s, C(2′)-H), 3.48 (3H, s, —OMe), 3.59 (2H, s, —$CH_2CO$), 4.93 (1H, d, $J$ = 5.5 Hz, C(4′)-H), 5.30 (2H, s, —$NCH_2C_6H_5$), 5.42 (1H, d, $J$ = 4 Hz, C(6′)-H), 5.51 (1H, dd, $J$ = 4, 5.5 Hz, C(5′)-H), 6.9–7.6 (9H, m, aromatic H); ms *m/e*: 550 ($M^+$), 466, 434, 341, 306, 262, 234, 135, 122, 91 (100%). *The dehydrosecodine complexes **27** and **28***

A solution of **24** and **25** (224 mg; 9:1 ratio) in dry tetrahydrofuran (5 mL) was added to a suspension of potassium hydride in dry tetrahydrofuran (10 mL) at −23°C under a nitrogen atmosphere. The mixture was stirred for 15 min at −23°C and for 15 min at 0°C, and gradually allowed to warm to ambient temperature for 17 min. The mixture was cooled to −23°C again and dimethyl (methylene) ammonium iodide (500 mg) was added. The mixture was stirred at −23°C for 5 min and stirring continued for 1 h at ambient temperature. Saturated potassium carbonate solution was added to the red solution at 0°C and the solution was stirred at ambient temperature for 30 min. Ether and water were added and the mixture was extracted with ether. The ether solution was dried and concentrated. Chromatography on silica gel under a nitrogen atmosphere afforded a crude mixture of **27** and **28**; hplc separation with ether – petroleum ether (1:4.1) gave **27** (63 mg, 27%) and **28** (19 mg, 8%).

*The complexes **27** and **28** after isomerization*

Using the procedure described above, the isomerized mixture of **24** and **25** (1:1) (250 mg) gave **27** (51 mg, 20%) and **28** (57 mg, 22%).

*The complex **27***, uv $\lambda_{max}$: 398 (3.6), 291 (4.1), 280 (4.2), 265 (4.2); ir $\nu_{max}$: 1945, 1870, 1840, 1730; $^1$Hmr (400 MHz) δ: 1.00 (3H, t, $J$ = 6 Hz, —$CH_2CH_3$), 2.17 (2H, dq, $J$ = 6, 20 Hz, —$CH_2CH_3$), 2.7–2.95 (4H, m, —$CH_2CH_2N$), 3.30 (2H, s, C(2′)-H), 3.61 (3H, s, —$OCH_3$), 4.99 (1H, d, $J$ = 6 Hz, C(4′)-H), 5.20 (2H, s, —$NCH_2C_6H_5$), 5.37 (1H, d, $J$ = 4.5 Hz, C(6′)-H), 5.57 (1H, dd, $J$ = 4.5, 6 Hz, C(5′)-H), 5.84 (1H, d, $J$ = 1.5 Hz, olefinic H), 6.77 (1H, d, $J$ = 1.5 Hz, olefinic H), 6.9–7.6 (9H, m, aromatic H); ms *m/e*: 562 ($M^+$), 478, 450, 260, 135, 122, 121, 107 (100%), 91. N-*Benzyldehydropseudovincadifformine **12***

Dehydropseudovincadifformine **36** was prepared by mercuric acetate oxidation of 18β-carbomethoxycleavamine **35** (5) which was obtained from catharanthine **2** (13). A solution of **36** (328 mg) in dry tetrahydrofuran (10 mL) was added to a suspension of potassium hydride (0.5 g, 23% in oil) in dry tetrahydrofuran (15 mL) at −23°C. The mixture was stirred at −23°C for 5 min and at ambient temperature for 15 min. The mixture was cooled to −23°C again when benzyl chloride (1 mL) was added. The mixture was stirred at ambient temperature for 30 min, and at 50°C for 3.5 h. Excess potassium hydride was destroyed by additions of methanol and water at −23°C. The mixture was extracted with dichloromethane. The organic layer was washed with water, dried ($Na_2SO_4$), and evaporated; hplc separation of the residue gave **12** (315 mg, 76%); uv $\lambda_{max}$: 331 (4.1), 299 (4.0); ir $\nu_{max}$: 1680, 1600; $^1$Hmr (400 MHz) δ: 1.05 (3H, t, —$CH_2CH_3$), 2.04 (2H, m, —$CH_2CH_3$), 3.37 (3H, s, —$OCH_3$), 5.10 (2H, s, —$NCH_2C_6H_5$), 5.52 (1H, d, $J$ = 6 Hz, olefinic H), 6.7–7.4 (9H, m, aromatic H); ms *m/e*: 426 ($M^+$), 395, 335, 318, 260, 135 (100%), 91. High resolution molecular weight determination calcd. for $C_{28}H_{30}N_2O_2$: 426.2307; found: 426.2311.

N-*Benzyl-18β-carbomethoxycleavamine **11***

A solution of **12** (219 mg) in glacial acetic acid (15 mL) was heated to 90°C. Sodium borohydride (1 g) was added at intervals to keep the solution gently refluxed. The mixture was stirred at 90°C for 1 h, cooled, poured into the ice-cooled aqueous ammonia solution, and extracted with dichloromethane. The organic layer was washed with water, dried ($Na_2SO_4$), and evaporated; hplc separation of the residue gave **11** (107 mg, 49%); uv $\lambda_{max}$: 288 (3.94), 285 (4.00), 273 (3.98); ir $\nu_{max}$: 1720; $^1$Hmr ($C_6D_6$, 400 MHz) δ: 0.98 (3H, t, $J$ = 6 Hz, —$CH_2CH_3$), 1.91 (2H, q, $J$ = 6 Hz, —$CH_2CH_3$), 3.84 (3H, s, —$OCH_3$), 5.30 (2H, q, $J_{AB}$ = 18 Hz, —$NCH_2C_6H_5$), 5.38 (1H, d, $J$ = 6 Hz, olefinic H), 6.06 (1H, d, $J$ = 8 Hz, —$CHCO$—): 6.7–7.8 (9H, m, aromatic H); ms *m/e*: 428 ($M^+$), 413, 305, 279, 149 (100%), 112, 91. High resolution molecular weight determination calcd. for $C_{28}H_{32}N_2O_2$: 428.2463; found: 428.2469.

N-*Benzylcatharanthine **15***

Potassium hydride (0.5 g, 23% in oil) and benzyl chloride (0.7 mL) were added to a solution of catharanthine hydrochloride (320 mg) in dry tetrahydrofuran (12 mL) and HMPA (3 mL) at −23°C. The mixture was heated at 70°C for 5 h, cooled, diluted with water, and extracted with dichloromethane. The organic extract was washed with water, dried ($Na_2SO_4$), and evaporated; hplc separation of the residue gave **15** (212 mg, 57%); uv $\lambda_{max}$: 294 (4.06), 286 (4.10), 225 (4.56); ir $\nu_{max}$: 1730; $^1$Hmr (400 MHz) δ: 1.05 (3H, t, $J$ = 6 Hz, —$CH_2CH_3$), 1.90 (2H, q, $J$ = 6 Hz, —$CH_2CH_3$), 3.03 (3H, s, —$OCH_3$), 5.24 (2H, q, $J_{AB}$ = 18 Hz, —$NCH_2C_6H_5$), 6.13 (1H, d, $J$ = 5 Hz, olefinic H), 6.8–7.7 (9H, m, aromatic H).

N-*Benzyltabersonine **14***

Potassium hydride (2 g, 23% in oil) and benzyl chloride (1.2

# Trichlorosilyl and dichloromethylsilyl derivatives of ruthenium carbonyl

R. K. POMEROY AND XIANG HU[1]

*Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6*

Received November 3, 1981

R. K. POMEROY and XIANG HU. Can. J. Chem. **60**, 1279 (1982).

The preparation of a number of derivatives of the type $Ru(CO)_3(L)(SiRCl_2)(X)$ and $[Ru(CO)_3(SiRCl_2)(X)]_2$ (L = CO, phosphorus donor ligand; R = $CH_3$, Cl; X = H, Cl, Br, I; not all possibilities) is described. The syntheses of $M(CO)_4(SiMeCl_2)_2$ (M = Ru, Os) and *mer*-$M(CO)_3(PPh_3)(SiMeCl_2)_2$ are also reported. The pattern of substitution in the tetracarbonyl molecules is consistent with the $SiRCl_2$ ligand as having a large *trans*-effect in these compounds. From a qualitative study of the rates of substitution, it appears the *trans*-effect of the $SiMeCl_2$ ligand is at least comparable to that of $SiCl_3$.

R. K. POMEROY et XIANG HU. Can. J. Chem. **60**, 1279 (1982).

On décrit la préparation d'une série de dérivés du type $Ru(CO)_3(L)(SiRCl_2)(X)$ et $[Ru(CO)_3(SiRCl_2)(X)]_2$ (L = CO, ligand donneur de phosphore; R = $CH_3$, Cl; X = H, Cl, Br, I; pas toutes les possibilités). On rapporte également les synthèses du $M(CO)_4(SiMeCl_2)_2$ (M = Ru, Os) et du *mer*-$M(CO)_3(PPh_3)(SiMeCl_2)_2$. D'après le schéma des substitutions dans les molécules tétracarbonylées, on en déduit que le ligand $SiRCl_2$ a un large effet *trans* dans ces composés. En se basant sur une étude quantitative des vitesses de substitution, il semble que l'effet-*trans* du ligand $SiMeCl_2$ est au moins comparable à celui du $SiCl_3$.

[Traduit par le journal]

## Introduction

The most common pathway by which transition metal carbonyl compounds undergo substitution reactions is the initial loss of a CO ligand in the rate determining step. For most substituted metal carbonyl complexes the *cis*-effect of the non-carbonyl substituent appears to be a major factor in determining the lability of the carbonyl groups (1).

The compound *cis*-$Ru(CO)_4(SiCl_3)_2$ is, therefore, interesting in that the CO substituents *trans* to the $SiCl_3$ are labile: they undergo stereospecific exchange with $^{13}CO$ when solutions of the complex are stirred at room temperature under 1 atm of $^{13}CO$ (2). Not surprisingly, derivatives of the type $Ru(CO)_{4-n}(L)_n(SiCl_3)_2$ (L = two electron donor ligand; $n$ = 1, 2) may be readily prepared from *cis*-$Ru(CO)_4(SiCl_3)_2$ (3). This is in contrast to the iron and osmium analogues which required much more forcing conditions to bring about substitution of the equatorial carbonyls (3).

In this study we report the preparation of a number of complexes which contain a Ru—$SiRCl_2$ (R = $CH_3$, Cl) linkage. In those compounds which contain a CO group *trans* to the silyl ligand, facile substitution of that carbonyl by phosphines is once again observed.

The preparation and reaction with $PPh_3$ of *cis*-$Ru(CO)_4(SiCl_3)(H)$ has been briefly described in a preliminary communication (4).

## Results and discussion

### *$M(CO)_4(SiMeCl_2)_2$ complexes*

The $M(CO)_4(SiMeCl_2)_2$ (M = Ru, Os) complexes were prepared by the method previously employed in the synthesis of the trichlorosilyl analogues (3). This involved the ultraviolet irradiation of a solution of $M_3(CO)_{12}$ in the presence of excess $HSiMeCl_2$ under 2 atm of carbon monoxide. The yield was almost quantitative.

These compounds have been previously synthesized by the reaction of $M_3(CO)_{12}$ and the silane at 180°C under a high pressure of carbon monoxide (5). For the osmium case this gave a mixture of *cis* and *trans* isomers, whereas the present method yields exclusively the *cis* form. This is probably because the *trans* isomer rearranges to a *cis* geometry on ultraviolet irradiation. It has been established that uv irradiation of *trans*-$Ru(CO)_4(SiCl_3)_2$ causes complete isomerization to the *cis* form and that this occurs via CO dissociation (2).

The observation of five CO stretches in the infrared spectrum of $Ru(CO)_4(SiMeCl_2)_2$ indicates the presence of some *trans* isomer since a maximum of four bands is expected for the *cis* molecule. The presence of approximately 12% of the *trans* isomer has been established by $^{13}C$ nmr spectroscopy (6). It is probable that the *cis* isomer is initially formed in the reaction and, on removal from the uv light, it undergoes a non-dissociative isomerization to give an equilibrium mixture. It has been found that for compounds of the type $M(CO)_4(SiMe_xCl_{3-x})_2$ (M = Fe, Os; $x$ = 1–3), there is a non-dissociative equilibrium between the *cis* and *trans*

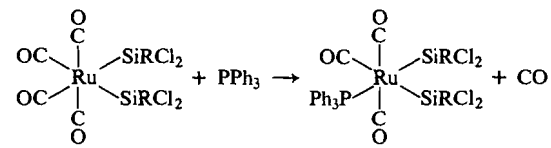
forms which in some cases is rapid on the nmr time-scale at room temperature. It was also found that the barrier to rearrangement increases with increasing chlorine substitution at silicon (6). Since it is known (7) that $Ru(CO)_4(SiCl_3)_2$ isomerizes at a measurable rate above 70°C, it is reasonable that $Ru(CO)_4(SiMeCl_2)_2$ undergoes isomerization at room temperature, at a rate which prevents separation of the two isomers.

It might be argued that the extra CO stretching band observed in the infrared spectrum of $Ru(CO)_4(SiMeCl_2)_2$ arises because of the presence of different forms of the *cis* molecule due to different orientations of the $SiMeCl_2$ ligands about the Ru—Si bond. Such a phenomenon gives rise to a doubling of the CO stretching frequencies in $(C_5H_5)Fe(CO)_2(SiMeCl_2)$ (8). However, it has been observed before (9), and in this study, that in the infrared spectra of the present type of compounds with a M—$SiMeCl_2$ linkage there is only a broadening of the CO stretching absorptions, rather than a splitting, compared to those observed in the $SiCl_3$ analogues.

The reaction of *cis*-$Ru(CO)_4(SiMeCl_2)_2$ with $PPh_3$ to give *mer*-$Ru(CO)_3(PPh_3)(SiMeCl_2)_2$ proceeded at a convenient rate at room temperature. This is in contrast to $Os(CO)_4(SiMeCl_2)_2$ where a temperature of 110°C was required to bring about a comparable rate of reaction with $PPh_3$. A similar pattern was observed for the $SiCl_3$ analogues (3). However, unlike *cis*-$Ru(CO)_4(SiCl_3)_2$ the exchange of $Ru(CO)_4(SiMeCl_2)_2$ with $^{13}CO$ is non-stereospecific.[2] This is presumably due to *cis–trans* isomerization.

It was also noted that the rate of reaction of *cis*-$Ru(CO)_4(SiMeCl_2)_2$ with $PPh_3$ was very similar to that of *cis*-$Ru(CO)_4(SiCl_3)_2$ with the same ligand. Indeed, in a preliminary study, an exact measurement of the rate of substitution of the remaining equatorial carbonyl group in *mer*-$Ru(CO)_3(PPh_3)(SiRCl_2)_2$ by $P(OMe)_3$ showed that the rate of substitution was slightly faster in the $SiMeCl_2$ compound than in the $SiCl_3$ derivative.[3] These results are consistent with the $SiMeCl_2$ ligand as having a *trans*-effect in these molecules at least comparable to the $SiCl_3$ ligand. This pattern was also observed in the $Ru(CO)_4(SiRCl_2)(H)$ molecules. It is a surprising result. The CO stretching frequencies of *cis*-$Ru(CO)_4(SiMeCl_2)_2$ (Table 2) are lower than those of *cis*-$Ru(CO)_4(SiCl_3)_2$ (2150, 2103, 2094, and 2084 $cm^{-1}$). Such a lowering is usually taken to indicate that there is more overlap between the filled metal *d*-orbitals and the $\pi^*$-orbitals on the CO ligands. This would be expected to strengthen the M—C bond and, hence, raise the activation energy for CO dissociation. However, as previously observed (3), there appears to be no correlation between the carbonyl stretching frequencies in these molecules and the ease at which substitution occurs. This is interpreted in that it is the ease of formation of the five-coordinate intermediate which dictates the lability of a particular carbonyl group.

The $^1H$ nmr spectrum of $Ru(CO)_3(PPh_3)(SiMeCl_2)_2$ in the methyl region consists (Table 1) of two doublets. One pair is barely resolved (a difference between the two signals of 0.35 Hz), the other has a larger separation (0.9 Hz). This is consistent with the $PPh_3$ in an equatorial position; i.e., *cis* to one $SiMeCl_2$ group ($J_{P-H}$ 0.35 Hz) but *trans* to the other ($J_{P-H}$ 0.9 Hz). This is shown in **1**.



**1**

The osmium compound is similar.

*Ru(CO)$_4$(SiRCl$_2$)(H) complexes*

The *cis*-$Ru(CO)_4(SiRCl_2)(H)$ (R = Cl, $CH_3$) complexes were isolated in approximately 30% yield, by the ultraviolet irradiation of $Ru_3(CO)_{12}$ and excess $HSiRCl_2$ in pentane under carbon monoxide. The time period of 5–10 h was much shorter than that used in the preparation of the $Ru(CO)_4(SiRCl_2)_2$ compounds. The hydrides were separated from the other products, $[Ru(CO)_4(SiRCl_2)]_2$ and $Ru(CO)_4(SiRCl_2)_2$, by vacuum sublimation (or distillation) at room temperature.

Both the *cis*-$Ru(CO)_4(SiRCl_2)(H)$ compounds are low-melting solids which are extremely air-sensitive. They exhibit four carbonyl stretching bands in the infrared spectrum, expected for a *cis* arrangement of the non-carbonyl ligands. They also show the high field $^1H$ nmr resonance, typical of the metal–hydride linkage. In the mass spectrum of $Ru(CO)_4(SiCl_3)(H)$ the peaks of highest mass corresponded to $[P - CO]^+$. This is consistent with the chemical evidence, reported below, which indicates the carbonyl group *trans* to the $SiCl_3$ is particularly labile. Because of its extreme air-sensitivity, mass spectral and analytical data were not obtained for *cis*-$Ru(CO)_4(SiMeCl_2)(H)$.

The osmium compound *cis*-$Os(CO)_4(SiCl_3)(H)$ was not detected in the preparation of *cis*-

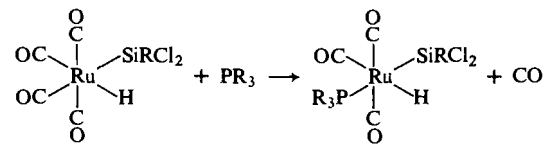
$Os(CO)_4(SiCl_3)_2$ by the uv irradiation of a solution of $Os_3(CO)_{12}$ and $HSiCl_3$ (3). However, *cis*-$Os(CO)_4(SiCl_3)(H)$ and the dichloromethylsilyl analogue have been prepared by the action of carbon monoxide on the appropriate $Os_3H_3(CO)_9(SiRCl_2)_3$ compound. On pyrolysis at 140°C, under vacuum, the *cis*-$Os(CO)_4(SiRCl_2)(H)$ complexes gave mainly $[Os(CO)_4(SiRCl_2)]_2$ (10). In this study, it was found that heating a solution of $Ru(CO)_4(SiRCl_2)(H)$ under vacuum similarly gave $[Ru(CO)_4(SiRCl_2)]_2$. The preparation of the dinuclear compounds, which contain a linear SiRuRuSi backbone, has been reported in the literature (11). A variation of the literature method which gives an improved yield is reported in the Experimental section.

The most interesting property of the $Ru(CO)_4(SiRCl_2)(H)$ molecules is that they also readily undergo substitution by phosphorus donor ligands:



**2**

The geometry (**2**) of the $SiMeCl_2$ derivatives may be unambiguously assigned by $^1$H nmr spectroscopy. For example, the hydride signal in the $^1$H nmr spectrum of $Ru(CO)_3[P(OCH_2)_3CC_2H_5](SiMeCl_2)(H)$ consists of a doublet of quartets (Fig. 1) due to coupling to phosphorus ($J_{P-H}$ 18.8 Hz) and to the silyl methyl protons ($J_{H-H}$ 0.5 Hz). The size of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

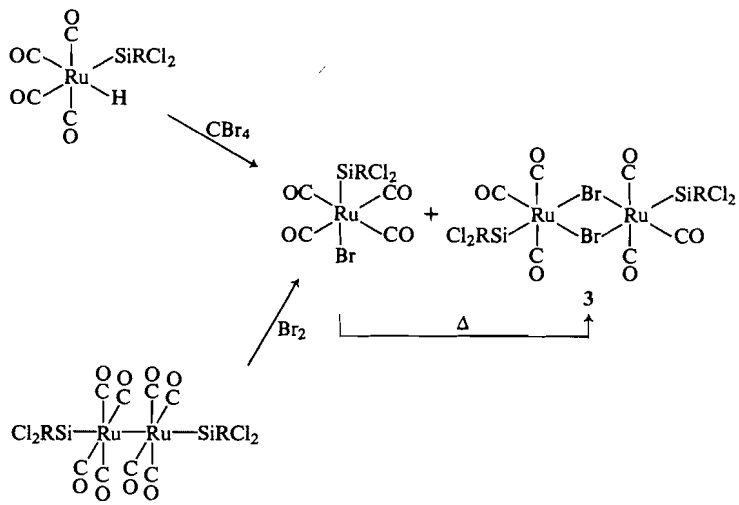
phosphorus coupling is indicative of a *cis* arrangement of the phosphorus–donor ligand and the hydride group (12). The silyl methyl signal (Fig. 1) is a doublet of doublets. The proton–proton coupling to the hydride signal allows the smaller coupling to the methyl signal to be attributed to $J_{H-H}$. The larger coupling may therefore be assigned to $J_{P-H(CH_3)}$. The value of this parameter (1.4 Hz) indicates a *trans* arrangement of the $SiMeCl_2$ and $P(OCH_2)_3CC_2H_5$ ligands (cf. the $^1H$ nmr spectrum of $Ru(CO)_3(PPh_3)(SiMeCl_2)_2$). This is sufficient to establish the geometry as that shown as **2**. It should be also noted that $J_{H-H(CH_3)}$ (0.5 Hz) is consistent with a *cis* arrangement of the H and $SiMeCl_2$ substituents (cf. *cis*-$Ru(CO)_4(SiMeCl_2)(H)$), and that the pattern of absorptions observed in the carbonyl region of the infrared spectrum is typical of a *mer* arrangement of noncarbonyl ligands (as in the $Ru(CO)_3(L)(SiCl_3)_2$ derivatives (3)).

That substitution has occurred *trans* to the $SiRCl_2$ ligand implies that in these molecules the silyl ligand has a greater *trans*-effect than either the carbon monoxide or hydride substituents, both of which are known to exhibit a large *trans*-effect in square-planar complexes (13). It is also interesting that the substitution of CO by $PPh_3$ in $Ru(CO)_4(SiRCl_2)(H)$ proceeds at a faster rate than in $Ru(CO)_4(SiRCl_2)_2$. This could be taken to indicate that the *cis*-effect of hydrogen is greater than the $SiRCl_2$ ligand in these compounds.

Derivatives of the type $Ru(CO)_3(L)(SiRCl_2)(H)$ are reasonably air-stable, white crystalline solids and are easily characterized. As with other compounds with chlorosilyl groups (3), the air-sensitivity appears, in most cases, to be related to the presence of labile carbonyl groups and not to the sensitivity of the Si—Cl bonds to atmospheric moisture.

### *$[Ru(CO)_3(SiRCl_2)(X)]_2$ and* trans-*$Ru(CO)_4(SiRCl_2)(X)$ complexes*

Treatment of the hydrides *cis*-$Ru(CO)_4(SiRCl_2)(H)$ with $CCl_4$ resulted in the rapid formation of the dimeric product $[Ru(CO)_3(SiRCl_2)(Cl)]_2$. A similar reaction with $CBr_4$, in place of $CCl_4$, gave not only $[Ru(CO)_3(SiRCl_2)(Br)]_2$, but also *trans*-$Ru(CO)_4(SiRCl_2)(Br)$.[4] Similar products were obtained when the Ru—Ru bond in $[Ru(CO)_4(SiRCl_2)]_2$ was cleaved with $Br_2$:



In the corresponding reaction of $[Ru(CO)_4(SiRCl_2)]_2$ with $I_2$, to give analogous products, the *trans*-$Ru(CO)_4(SiRCl_2)(I)$ was thermally unstable, with respect to $[Ru(CO)_3(SiRCl_2)(I)]_2$, and could not be completely characterized.

The formation of the dimeric product, $[Ru(CO)_3(SiRCl_2)(X)]_2$, probably results from dimerization of *cis*-$Ru(CO)_4(SiRCl_2)(X)$ (X = Cl, Br, I) which may be formed directly in the reaction, or result from isomerization of *trans*-$Ru(CO)_4(SiRCl_2)(X)$. The mode of the exchange of coordinated CO in $Mn(CO)_5Br$ with free $^{13}CO$, which takes place under mild conditions, is consistent with the bromide ligand as having a *cis*-labilizing effect (14). Similarly, the exchange (which is also facile) in *cis*-$Fe(CO)_4I_2$ (15) and *cis*-$Ru(CO)_4I_2$ (16) is, within the limitations of the experimental method, ran-

[4]The stereochemistry of this compound was indicated by the single carbonyl stretch it exhibited in the infrared spectrum (Table 2).

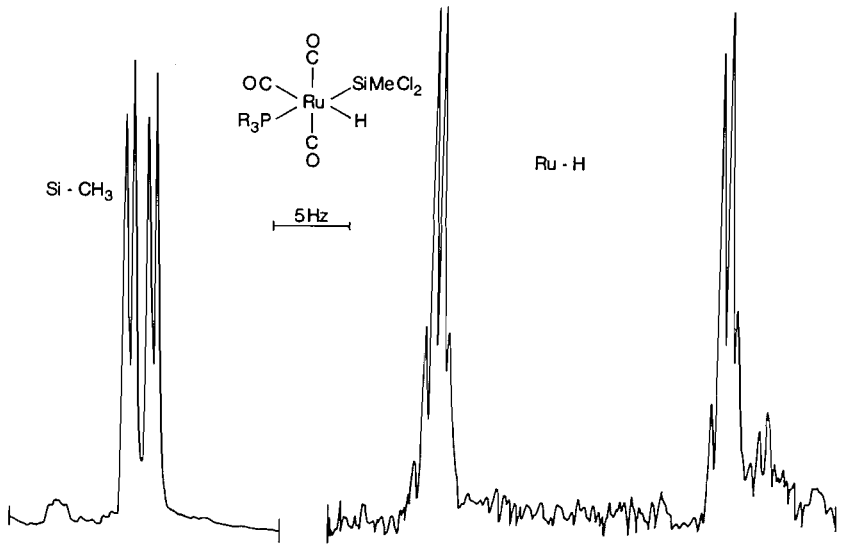


FIG. 1. The silyl methyl and hydride resonances of the 100 MHz $^1$H nmr spectrum of $Ru(CO)_3[P(OCH_2)_3CC_2H_5](SiMeCl_2)(H)$ in toluene-$d_8$.

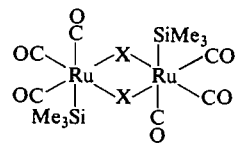
dom. This is also consistent with the halogen substituents in these molecules having a *cis*-labilizing effect (both the axial and equatorial carbonyls are *cis* to at least one iodine atom). It is therefore reasonable that in *cis*-$Ru(CO)_4(SiRCl_2)(X)$, the CO ligand which is both *trans* to the $SiRCl_2$ group and *cis* to X is particularly labile. This suggests that dimerization would readily take place and *cis*-$Ru(CO)_4(SiRCl_2)(X)$ would not be detected in the reaction.

The preparation of the trimethylsilyl derivatives, $[Ru(CO)_3(SiMe_3)(X)]_2$, has been reported (17). These compounds were found to exist as a mixture of isomers. One form was thought to have a structure analogous to that proposed for the present dimeric derivatives (i.e., **3**), the other with the $SiMe_3$ ligands in axial positions as shown in **4**.



**4**

The reason why the trimethylsilyl compounds exist in two isomeric forms, but the chlorosilyl derivatives do not, is not clear. It is not inconceivable that the molecules with $SiMe_3$ groups are nonrigid (not necessarily on the nmr time-scale). As previously mentioned, in the monomeric derivatives $M(CO)_4(SiMe_xCl_{3-x})_2$ (M = Fe, Ru, Os; $x$ = 0–3) the barrier to *cis*–*trans* isomerization is lowest for the trimethylsilyl derivatives (6).

The compounds $[Ru(CO)_3(SiRCl_2)(X)]_2$ rapidly react in solution with phosphorus donor ligands (L) to give $Ru(CO)_3(L)(SiRCl_2)(X)$. The structure of these derivatives is believed to be analogous to the corresponding hydrides: a *mer* arrangement of the non-carbonyl ligands with L *trans* to the $SiRCl_2$ group. This is based primarily on the observation of a P—H coupling of ~ 0.7 Hz for the methyl signal in the $^1$H nmr of $Ru(CO)_3(PPh_3)(SiMeCl_2)(X)$. It is also the geometry one would predict from the *cis*-effect of X and the *trans*-effect of the $SiRCl_2$ group. The pattern of the CO stretching frequencies in the infrared spectra of the $Ru(CO)_3(L)(SiRCl_2)(X)$ (X = Cl, Br, I) compounds is different from the corresponding hydrides (X = H) which might be taken to indicate a different geometry. However, the patterns for *cis*-$Fe(CO)_4(EX_3)(X)$ (E = Ge, Sn; X = Cl, Br, I) (18) and *cis*-$M(CO)_4I_2$ (M = Ru, Os) (16, 19) are different to those of *cis*-$Ru(CO)_4(SiCl_3)(X)$ (X = $SiCl_3$ (2), H). For the latter compounds the most intense absorption has the lowest frequency which is not the case for the halogen derivatives. This difference parallels that observed in the molecules presently under discussion.

It should be pointed out that the geometry favored for the $Ru(CO)_3(L)(SiRCl_2)(X)$ compounds in this study differs from that suggested for the analogous $SiMe_3$ derivatives (17). In that work a P—H($SiMe_3$) coupling of 1–2 Hz, observed in the $^1$H nmr spectra of the complexes, was taken to indicate a *cis* arrangement of the $PPh_3$ and $SiMe_3$ ligands. However, it is apparent from this work that such a coupling signifies a *trans* configuration.

## Conclusion

This study has shown that the $SiRCl_2$ (R = $CH_3$, Cl) ligand exhibits a large *trans*-effect in a number of octahedral, carbonyl–ruthenium complexes. It has also indicated the *trans*-effect of the $SiMeCl_2$ group is at least comparable to that of $SiCl_3$ in these molecules.

## Experimental

The general experimental procedures used in the preparation of the new compounds have been described elsewhere (3). The method of preparation of $M(CO)_4(SiMeCl_2)_2$ and *mer*-$M(CO)_3(PPh_3)(SiMeCl_2)_2$ (M = Ru, Os) was essentially that used to prepare the trichlorosilyl analogues (3). The yields were excellent in all cases. Spectroscopic data for the new compounds are reported in Table 1. Analytical data (Table 2) have been placed in the Depository.[5]

*Preparation of* cis-*Ru(CO)$_4$(SiCl$_3$)(H)*

A quartz tube with $Ru_3(CO)_{12}$ (0.64 g, 1.0 mmol) and $Cl_3SiH$ (3 mL, 30 mmol) in pentane (25 mL) was evacuated at −196°C and the solution degassed with two freeze–thaw cycles. It was allowed to warm to room temperature and then pressurized with carbon monoxide (2 atm). The solution was subjected to uv irradiation for 10 h. The resulting, almost colorless, solution was transferred to a Schlenk flask and the pentane and excess $Cl_3SiH$ were removed on the vacuum line at 0°C. A second Schlenk flask was connected to the first and both were evacuated to $< 5 \times 10^{-3}$ mm. The second flask was cooled to −196°C to which, over 4 h, *cis*-$Ru(CO)_4(SiCl_3)(H)$ (ca. 0.36 g, 35%) distilled. The compound is extremely air-sensitive, turning yellow almost immediately on exposure to air. The melting point was determined by placing a Schlenk flask with the compound in an ice-water bath, allowing the bath to warm slowly, and recording the temperature at which the compound melted.

The products remaining, after removal of *cis*-$Ru(CO)_4(SiCl_3)(H)$, were *cis*-$Ru(CO)_4(SiCl_3)_2$ and $[Ru(CO)_4(SiCl_3)]_2$. The former compound may be separated from the dimer by sublimation at 30°C and $< 5 \times 10^{-3}$ mm to a probe of −78°C (see ref. 3). The dimer, $[Ru(CO)_4(SiCl_3)]_2$, may then be purified by recrystallization from hexane.

The hydride, *cis*-$Ru(CO)_4(SiMeCl_2)(H)$, (mp 2–3°C) was prepared, in similar yield, by the same method. With an irradiation period of 5 h and with use of a glass tube, no $Ru(CO)_4(SiMeCl_2)_2$ formed and $[Ru(CO)_4(SiMeCl_2)]_2$ was the only other product. The dimer could thus be obtained by recrystallization, from hexane, after removal of the hydride.

*Preparation of [Ru(CO)$_4$(SiCl$_3$)]$_2$*

A glass tube with $Ru_3(CO)_{12}$ (0.40 g, 0.63 mmol) and $HSiCl_3$ (0.26 g, 1.92 mmol) in hexane (15 mL) was evacuated, and the solution degassed, as before. The tube was pressurized with carbon monoxide (2 atm) and then heated at 80°C for 2.5 h. An infrared spectrum of the solution at this stage (after removal of the $HSiCl_3$) indicated only $[Ru(CO)_4(SiCl_3)]_2$ with perhaps a trace of $Ru_3(CO)_{12}$. The hexane and the excess $HSiCl_3$ were removed on the vacuum line. The material remaining was recrystallized from hexane to give pure $[Ru(CO)_4(SiCl_3)]_2$ as pale-yellow crystals.

*Pyrolysis of* cis-*Ru(CO)$_4$(SiMeCl$_2$)(H)*

An evacuated round-bottom flask with *cis*-$Ru(CO)_4(SiMeCl_2)(H)$ (0.20 g, 0.61 mmol) in hexane (15 mL) was heated at 50–60°C for 4.5 h. An infrared spectrum of the solution at this point indicated complete conversion to $[Ru(CO)_4(SiMeCl_2)]_2$. The solution was reduced in volume to about 5 mL and placed in the refrigerator to afford crystals of the dimer.

The pyrolysis of $Ru(CO)_4(SiCl_3)(H)$ was similar. It did appear to require a longer period to bring about the conversion, since an infrared spectrum taken of the reaction solution after 7 h indicated a trace of starting material remained.

*Preparation of Ru(CO)$_3$(PPh$_3$)(SiCl$_3$)(H) and related derivatives*

To a solution of *cis*-$Ru(CO)_4(SiCl_3)(H)$ (0.20 g, 0.57 mmol) in pentane (15 mL) was added $PPh_3$ (0.15 g, 0.57 mmol). The solution was stirred for 2 h during which time a white crystalline precipitate formed. After the 2 h period, the solution was placed in the refrigerator at −15°C for several hours to complete the precipitation. The supernatant solution was then removed from the product which was washed with hexane (2 × 5 mL) and dried on the vacuum line. The product, *mer*-$Ru(CO)_3(PPh_3)(SiCl_3)(H)$ (0.31 g, 93%), was thus isolated as a white crystalline solid which appeared reasonably air-stable. The analytical sample was obtained by recrystallization from benzene–hexane.

Other derivatives of the type *mer*-$Ru(CO)_3(L)(SiRCl_2)(H)$ (R = Cl, Me) were prepared in essentially the same manner. The ETPB derivatives were somewhat air-sensitive. Attempts to prepare the $P(OMe)_3$ analogues gave oils, the elemental analyses of which were not quite satisfactory.

*Preparation of [Ru(CO)$_3$(SiCl$_3$)(Cl)]$_2$*

To $Ru(CO)_4(SiCl_3)(H)$ (0.15 g, 0.43 mmol) in hexane (15 mL) was added $CCl_4$ (0.40 mL, 0.64 g, 4.1 mmol) and the solution stirred for 10 min during which time needle-shaped crystals formed. After the solution had stood in the refrigerator for several hours to complete the crystallization, the solvent was removed from the crystals of $[Ru(CO)_3(SiCl_3)(Cl)]_2$, which were washed with hexane (2 × 5 mL) and dried on the vacuum line. There was no spectroscopic evidence for *trans*-$Ru(CO)_4(SiCl_3)(Cl)$ in the reaction.

The preparation of $[Ru(CO)_3(SiMeCl_2)(Cl)]_2$ was similar.

*Preparation of [Ru(CO)$_3$(SiMeCl$_2$)(Br)]$_2$ and* trans-*Ru(CO)$_4$(SiMeCl$_2$)(Br)*

Method 1: to a solution of *cis*-$Ru(CO)_4(SiMeCl_2)(H)$ (ca. 0.30 g, 0.91 mmol) in hexane (12 mL) was added $CBr_4$ (0.25 g, 0.75 mmol). The solution was stirred for 15 min; an infrared spectrum revealed only *trans*-$Ru(CO)_4(SiMeCl_2)(Br)$ and $[Ru(CO)_3(SiMeCl_2)(Br)]_2$. The hexane was removed on the vacuum line and from the residue *trans*-$Ru(CO)_4(SiMeCl_2)(Br)$ obtained by sublimation ($< 5 \times 10^{-3}$ mm) at room temperature to a probe maintained at −78°C. The first fraction which sublimed to the probe was discarded since it may have contained starting materials. The solid remaining after the removal of *trans*-$Ru(CO)_4(SiMeCl_2)(Br)$ was recrystallized from hexane to give pure $[Ru(CO)_3(SiMeCl_2)(Br)]_2$ as yellow crystals.

The trichlorosilyl analogues, $[Ru(CO)_3(SiCl_3)(Br)]_2$ and *trans*-$Ru(CO)_4(SiCl_3)(Br)$, were prepared in the same manner.

Method 2: to $[Ru(CO)_4(SiMeCl_2)]_2$ (0.55 g, 0.84 mmol) in hexane (25 mL) was added bromine (0.30 g, 1.9 mmol) and the solution stirred for 10 min at room temperature. The hexane and excess bromine were removed on the vacuum line to give a mixture which, by infrared spectroscopy, consisted mainly of *trans*-$Ru(CO)_4(SiMeCl_2)(Br)$ and a small fraction of $[Ru(CO)_3(SiMeCl_2)(Br)]_2$. The products were isolated pure as in Method 1.

The iodo analogues were prepared by Method 2. However, *trans*-$Ru(CO)_4(SiMeCl_2)(I)$ was thermally unstable with respect to the dimer even at room temperature. For this reason it was not analyzed. An improved preparation of the dimeric compound is given below.

[5]Complete set of data may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

*Preparation of* $[Ru(CO)_3(SiMeCl_2)(I)]_2$

A glass Carius tube with $[Ru(CO)_4(SiMeCl_2)]_2$ (0.25 g, 0.38 mmol) and iodine (0.10 g, 0.39 mmol) in hexane (15 mL) was evacuated (at −196°C) and the solution degassed. The solution was then heated to 50–60°C for 10 h (the tube was reevacuated three times during this period). An infrared spectrum of the solution at this stage indicated complete conversion of *trans*-$Ru(CO)_4(SiMeCl_2)(I)$ to $[Ru(CO)_3(SiMeCl_2)(I)]_2$. After the 10 h period, the tube was cooled and the solution transferred to a Schlenk tube, concentrated to ~ 5 mL on the vacuum line, and then allowed to stand in the refrigerator at −15°C, whereupon $[Ru(CO)_3(SiMeCl_2)(I)]_2$ was obtained as yellow needles. The crystals are soluble in hexane; they are also somewhat air-sensitive.

Although not confirmed, it is probable that other compounds of the type $[Ru(CO)_3(SiRCl_2)(X)]_2$ (R = Me, Cl; X = Br, I) could be prepared in this manner.

*Preparation of* mer-$Ru(CO)_3(PPh_3)(SiCl_3)(Cl)$ *and related derivatives*

Method 1: a solution of *mer*-$Ru(CO)_3(PPh_3)(SiCl_3)(H)$ (0.37 g, 0.63 mmol) and $CCl_4$ (0.50 mL, 0.79 g, 5.2 mmol) in benzene (10 mL) was placed in a glass Carius tube which was evacuated, and the solution degassed, as before. The tube was then pressurized with carbon monoxide (2 atm) and the bottom half heated in an oil-bath at 100°C for 4.5 h. The tube was then allowed to cool, the solution transferred to a Schlenk flask where the solvent (and the excess $CCl_4$) was removed on the vacuum line. The residue was recrystallized from benzene–hexane to give *mer*-$Ru(CO)_3(PPh_3)(SiCl_3)(Cl)$ as air-stable, plate-shaped crystals. (*Anal.* calcd.: C 40.86, H 2.45; found: C 40.44, H 2.52.)

Method 2: to a solution of $[Ru(CO)_3(SiCl_3)(Cl)]_2$ (0.15 g, 0.21 mmol) in hexane (15 mL) was added $PPh_3$ (0.10 g, 0.38 mmol). The solution was stirred for 15 min during which time crystals formed. The solution was placed in the refrigerator at −15°C to complete the crystallization of the product. The solvent was then removed from the white crystals, which were washed with hexane (2 × 5 mL) and dried on the vacuum line. The yield of *mer*-$Ru(CO)_3(PPh_3)(SiCl_3)(Cl)$ was judged to be almost quantitative.

Related derivatives were prepared according to Method 2.

# Measurement of self-association and ion-pair dissociation constants by solvent extraction using a membrane phase separator

MURRAY CARMICHAEL AND FREDERICK F. CANTWELL[1]

*Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2*

Received November 25, 1981

MURRAY CARMICHAEL and FREDERICK F. CANTWELL. Can. J. Chem. **60**, 1286 (1982).

The "filter-probe" membrane phase separator is used with a gravimetric buret to obtain the following constants at 25°C by measuring solvent-extraction isotherms: dimerization constant of benzoic acid in chloroform (log $K_{2,HBz} = 2.12 \pm 0.01$); "self-ion-pair extraction" constant of Naloxone into chloroform ($K_{I,H_2A.A} < 10^7$); and ion-pair dissociation constant of tetraethylammonium picrate in methylene chloride (log $K_{diss} = -4.52 \pm 0.09$).

MURRAY CARMICHAEL et FREDERICK F. CANTWELL. Can. J. Chem. **60**, 1286 (1982).

On a utilisé la "sonde filtre" d'une phase membraneuse séparatrice avec une burette gravimétrique pour obtenir les constantes suivantes à 25°C en mesurant les isothermes d'extractions à l'aide de solvants: la constante de dimérisation de l'acide benzoique dans le chloroforme (log $K_{2,HBz} = 2{,}12 \pm 0{,}01$); la constante d'extraction de la paire "auto-ionisée" de Naloxone dans le chloroforme ($K_{I,H_2A.A} < 10^7$); et la constante de dissociation de la paire d'ions du picrate de tétraéthylammonium dans le chlorure de méthylène (log $K_{diss} = -4{,}52 \pm 0{,}09$).

[Traduit par le journal]

Association and dissociation reactions occurring in either the aqueous or the organic solvent phase during liquid–liquid extraction can profoundly influence the distribution ratio of the component being extracted. Reversible reactions such as dimerization in one or both phases and dissociation of ion-pairs in the organic phase may be encountered, depending on the nature of the sample and solvent involved (1–3). Such "side-reactions" often lead to a non-linear distribution isotherm over the concentration range where significant fractions of both the associated and dissociated species are present. It is therefore important to have an estimate of the magnitude of their equilibrium constants when designing a solvent extraction separation scheme.

Association/dissociation equilibria can be studied by a variety of techniques including spectroscopy (4), electrical conductivity (5, 6), two-phase potentiometric titrations (7–9), and measurement of liquid–liquid distribution ratios as a function of sample concentration (1, 10). When the equilibrium constants are used to predict solvent extraction behavior, regardless of the technique used, they should be measured in solutions that are saturated with the second liquid phase. This is particularly true when equilibria in the organic phase are under study, since low concentrations of dissolved water can profoundly influence them (3, 11).

A recently described "filter-probe" membrane phase separator has been shown to greatly facilitate the measurement of liquid–liquid distribution equilibria, especially in situations where it is desired to incrementally alter the composition of the system, such as in two-phase titrations and distribution isotherm measurements (12–17). This characteristic makes the "filter-probe" an obvious device to use in solvent extraction studies designed to evaluate association/dissociation equilibria, because such studies are necessarily done as a function of changing sample concentration. In the present investigation we have examined three equilibria using the "filter-probe": dimerization of benzoic acid in chloroform; "self-ion-pair extraction" of Naloxone from water into chloroform, and dissociation of the ion-pair tetraethylammonium picrate in methylene chloride.

## Experimental

*Apparatus*

Measurement of the absorbance of the aqueous phase was made continuously at 25 ± 0.1°C on an apparatus based on the two-phase titration device previously described (12). A three-layer paper membrane was employed. The Mini-Micro 2/6 pump used in the original design was replaced with a variable speed Minipuls-2 peristaltic pump (Gilson France S.A., Villiers-le-Bel, France) and the short Acidflex pump tube was replaced with an 18-cm long, 1.14 mm i.d. tube (Technicon Corp., Tarrytown, NY). Instead of the original micrometer buret, either of two types of gravimetric buret was used. One was simply a gas-tight syringe (2 or 5 mL, Hamilton Co., Reno, Nev.). This was weighed, after deliveries of increments of sample stock solution, on a Mettler PL 200 electronic top-loading balance (18). The second type of gravimetric buret employed a solvent reservoir and remotely activated Teflon valve. It has already been described (15, 19). The weight of sample stock solution added from the buret was converted to volume via its density and incremented to $V_o$ in eqs. [7], [13], or [18], as appropriate.

Necessary pH measurements were made with a glass and

calomel electrode pair using an Accumet Model 520 pH meter (Fisher Scientific Co.).

Wavelengths used were 273 nm for benzoic acid, 281 nm for Naloxone, and 400 nm for picrate, the wavelengths of maximum absorbance.

*Reagents*

Water used throughout was demineralized, distilled, and finally distilled from alkaline permanganate. Reagent grade chloroform was washed four times with equal volumes of water to remove ethanol preservative and then filtered through dry Whatman No. 2 filter paper to remove entrained water. Reagent grade methylene chloride, benzoic acid (HBz) (Fisher Scientific Co.), $Na_2HPO_4 \cdot 7H_2O$, picric acid (Matheson, Coleman and Bell), tetraethylammonium chloride (Eastman #3022), hydrochloric acid, perchloric acid, ammonium chloride, and ammonia water were used without further purification. Naloxone base (1-*N*-allyl-7,8-dihydro-14-hydroxynormorphinone) (Endo Laboratories Inc., Garden City, NY) was used as 100%.

The tetraethylammonium picrate (TEA·P) stock solution in methylene chloride was prepared as follows: 55 mL of an aqueous pH 6.7 phosphate buffer solution containing approximately 0.5 mmol each of picric acid and tetraethylammonium chloride was multiply-extracted with small volumes of methylene chloride to yield a final volume of about 100 mL. Concentration of TEA·P in the final solution was accurately determined by evaporating 1 g of it to dryness, diluting to 50.0 mL with 0.1 *M* NaOH, and measuring the picrate concentration of the resulting solution spectrophotometrically at 400 nm.

*Measurement procedure*

After combining the initial quantities of the two phases specified below in the titration beaker, the Teflon lid containing the filter-probe, the return line, the spoiler, and (when the valve-controlled weight buret was used) the buret tip was clamped in place. The stirrer and pump were started and the 100%T set on the spectrophotometer with the aqueous phase circulating through the flow cell. Increments of sample stock solution were added from the gravimetric buret to the stirred two-phase mixture and, between each increment, the equilibrium absorbance value was recorded as previously described (12). Stock solutions of the three compounds studied and maximum weights of solution added were as follows: 0.1371 mmol/g of HBz in water-washed chloroform, up to 4.0 g added; $0.212_6$ mmol/g of Naloxone in water-washed chloroform, up to 2.3 g added; and $4.62 \times 10^{-3}$ mmol/g of TEA·P in methylene chloride, whose preparation is described above, up to 3.2 g added.

Initially present in the titration beaker in each of the three studies were the following: *HBz study*, 80.0 mL of 0.10 *M* perchloric acid previously equilibrated with chloroform and $20.0_0$ mL of washed chloroform previously equilibrated with 0.1 *M* $HClO_4$. *Naloxone study*, 85.0 mL of 0.14 *M* $NH_3/NH_4Cl$ buffer pH = $8.6_8$ and $20.0_0$ mL of washed chloroform; *TEA·P study*, 70.0 mL of 0.11 *M* phosphate buffer pH = 6.7 and 30.0 mL of methylene chloride.

In the three systems under investigation the association/dissociation reaction takes place in the organic phase. It is, therefore, important to measure the absorbance of the aqueous phase rather than that of the organic since there are no side reactions taking place in the aqueous phase which would cause a change in molar absorptivity with changing sample concentration. For this reason a paper membrane is used in the filter probe. In the experiments the aqueous phase concentration of [HBz], [NAL], or [$P^-$] is calculated from the absorbance and the appropriate molar absorptivity, determined in a separate one-phase experiment. The equilibrium volumes of aqueous ($V$) and organic ($V_o$) phases in the TEA·P study were corrected for the slight mutual solubilities of methylene chloride and water (20), since neither phase was pre-equilibrated in this case. A similar correction was made for the solubility of chloroform in water in the Naloxone study since the aqueous phase was not pre-equilibrated.

## Results and discussion

*Dimerization of HBz*

In a chloroform–water system benzoic acid HBz is involved in the following equilibria:

$$[1] \quad HBz \overset{K_{HBz}}{\rightleftharpoons} (HBz)_o$$

$$[2] \quad 2(HBz)_o \overset{K_{2,HBz}}{\rightleftharpoons} (HBz)_{2,o}$$

where the subscript "o" indicates species in the organic phase, and species without subscript are in the aqueous phase. It is assumed that the aqueous phase is acidified so that ionization of HBz, which has a $pK_a$ value of 4.05 at 0.1 ionic strength (21), can be neglected. The distribution coefficient of monomeric benzoic acid is defined as:

$$[3] \quad K_{HBz} = [HBz]_o/[HBz]$$

and the dimerization constant of HBz in chloroform is,

$$[4] \quad K_{2,HBz} = [HBz]_{2,o}/[HBz]_o^2$$

The species-independent distribution ratio of benzoic acid is given by,

$$[5] \quad D_{HBz} = ([HBz]_o + 2[HBz]_{2,o})/[HBz]$$

Combining eqs. [3]–[5] gives:

$$[6] \quad D_{HBz} = K_{HBz} + 2K_{2,HBz}K_{HBz}^2[HBz]$$

which shows that a plot of $D_{HBz}$ versus [HBz] allows the determination of $K_{HBz}$ from the intercept and $K_{2,HBz}$ from the slope.

In chloroform-saturated 0.10 *M* aqueous perchloric acid the molar absorptivity is $9.51 \times 10^2$, as measured from the linear Beer's Law plot of absorbance vs. [HBz] in a one-phase system. The linearity of this plot supports the view (21–24) that no dimerization of HBz occurs in the aqueous phase.

The following, derived using the mass balance of benzoic acid, allows $D_{HBz}$ to be calculated from [HBz]:

$$[7] \quad D_{HBz} = (T_{HBz} - [HBz]V)/[HBz]V_o$$

where $V$ is the volume of the aqueous phase and is constant throughout the experiment; $V_o$ is the volume of organic phase including both the initial volume and the incremental additions of the chloro-

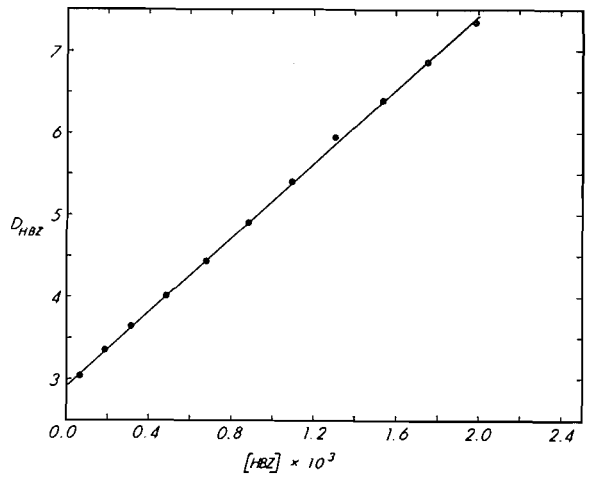

FIG. 1. Distribution ratio of benzoic acid versus concentration of benzoic acid in the aqueous phase, according to eq. [6].

form solution of benzoic acid; and $T_{HBz}$ is the total number of moles of benzoic acid added at any time. Three minutes are required per data point so that triplicate runs of ten points each are performed in under 2 h.

Figure 1 shows a typical plot of the data. Linear least-squares treatment of three such plots yields a slope of 2250 ± 24 sd and intercept of 2.90 ± 0.04 sd. From eq. [6] the constants $K_{HBz} = 2.90 \pm 0.04$ sd and $K_{2,HBz} = 133 \pm 3$ sd are calculated. Corresponding log values are log $K_{HBz} = 0.463 \pm 0.006$ sd and log $K_{2,HBz} = 2.12 \pm 0.01$ sd which may be compared with previously reported log values obtained by batch extraction between chloroform and aqueous phases: 0.50 and 2.09 using 0.1 *M* HCl at 25°C (22); 0.68 and 1.90 using water at 25°C (23); 0.55 and 1.92 using water at 15°C (24); 0.62 and 2.51 using water at 45°C (24). They may also be compared with log values of 0.54 and 1.99 obtained at 25°C by a two-phase potentiometric titration technique using 0.1 *M* NaCl as aqueous phase (21).

Van Duyne *et al.* (25) have shown that benzoic acid extracted into "wet" benzene not only dimerizes but also forms hydrates and, furthermore, that the dimer forms a hydrate. The type and extent of hydrate formation depends strongly on the water content of the organic solvent. Though benzoic acid hydrate formation has not been studied in chloroform, it is likely that similar phenomena occur in this solvent. The values of $K_{HBz}$ and $K_{2,HBz}$ measured by liquid–liquid partition, as in the present study and in the quoted literature studies, does not distinguish between hydrated and unhydrated species and, consequently, the measured constants will vary with the water content of the chloroform phase. It may be that this is, in part, responsible for the rather large range of values of log $K_{HBz}$ and log $K_{2,HBz}$ observed when aqueous phases are used that contain different types and concentrations of electrolyte, since these factors would be expected to influence the water content of the organic phase (3, 26). Differences in type and concentration of electrolyte may also produce differences in salting-out of HBz (3). Considering such possible small differences arising from the above processes, the values of 0.46 and 2.12 obtained using 0.1 *M* $HClO_4$ in the present study are in good agreement with the values of 0.50 and 2.09 obtained using 0.1 *M* HCl (22).

*"Self-ion-pair extraction"*

The synthetic phenanthrene alkaloid Naloxone is an important narcotic antagonist. It is an aminophenol compound whose protonated form is a diprotic acid of charge type $H_2A^+$. In aqueous solution the two acid-dissociation steps are:

[8] $H_2A^+ + H_2O \rightleftharpoons HA + H_3O^+$

[9] $HA + H_2O \rightleftharpoons A^- + H_3O^+$

with $K_{a,H_2A} = 7.53 \times 10^{-9}$ and $K_{a,HA} = 5.87 \times 10^{-10}$.

In a recent paper it was shown that titration of $H_2A^+$ with strong base in a chloroform–water two-phase medium yields a sharp pH-break at the first equivalence point, even when $K_{a,H_2A}$ and $K_{a,HA}$ are close (27). It was possible also to quantitatively predict the shape of the titration curve by inserting all of the independently measured equilibrium constants into the derived titration equation. Measurement of all of the relevant species-distribution coefficients was performed by batch distribution experiments. In those studies a value of 433 was obtained for the distribution coefficient of the species HA. However, because $K_{a,H_2A}$ and $K_{a,HA}$ are close to one another in value, significant concentrations of both $H_2A^+$ and $A^-$ are also present in the aqueous solution near the isoelectric point, and it is therefore possible that the organic cation $H_2A^+$ and organic anion $A^-$ might form a chloroform-extractable ion-pair viz:

[10] $H_2A^+ + A^- \rightleftharpoons (H_2A \cdot A)_o$

[11] $K_{I,H_2A \cdot A} = [H_2A \cdot A]_o/[H_2A^+][A]$

If this reaction occurs, then not only is the value quoted above for the distribution coefficient of HA in error, but also the apparent constant will change with sample concentration.

In order to determine whether the "self-ion-pair extraction" can be neglected the distribution ratio of Naloxone ($D_{NAL}$) has been studied as a function of Naloxone concentration in the aqueous phase at

For personal use only.

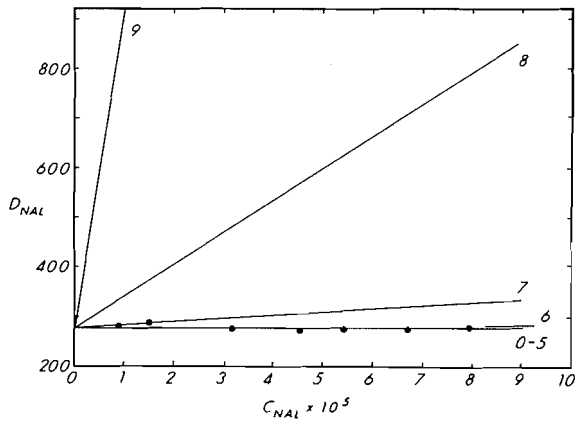

FIG. 2. Distribution ratio of Naloxone versus concentration of Naloxone in the aqueous phase, according to eq. [12]. Points are experimental. Lines are theoretical, assuming values of log $K_{I,H_2A\cdot A}$ from 0 to 9, as shown.

a pH buffered near the isoelectric point. An expression for the distribution ratio has already been derived (27).[2] Since the constants $K_{I,H_2AX}$ and $K_{I,MA}$ in that expression have values of 0.0 and 0.14 ± 0.32 they can be neglected. After inserting the known values of the other constants, the expression takes the following form at pH $8.6_8$:

$$[12] \quad D_{NAL} = k + 0.0642K_{I,H_2A\cdot A}C_{NAL}$$

where $k$ is a constant and $C_{NAL}$ is the formal (analytical) concentration of Naloxone in the aqueous phase. The slope of a plot of $D_{NAL}$ vs. $C_{NAL}$ yields the desired constant $K_{I,H_2A\cdot A}$.

$C_{NAL}$ is calculated from the measured absorbance and the molar absorptivity obtained at pH $8.6_8$ ($\varepsilon_{NAL} = 1.38 \times 10^3$). $D_{NAL}$ is calculated from $C_{NAL}$ as follows:

$$[13] \quad D_{NAL} = \frac{T_{NAL} - C_{NAL}V}{C_{NAL}V_o}$$

in which the symbols are defined as in eq. [7] above.

A plot is shown in Fig. 2. The points fall on a line (not shown) with slope $-1.3 \times 10^5 \pm 1.2 \times 10^5$ sd, which is equal to zero within experimental error. In order to identify the maximum value of $K_{I,H_2A\cdot A}$ which is consistent with the experimental data, plots are made in Fig. 2 of the curves which would be expected for values of $K_{I,H_2A\cdot A}$ of 0 through $10^9$. By comparing the experimental points with these curves it is concluded that $K_{I,H_2A\cdot A}$ is less than $10^7$. (It may, of course, be much less.) Values lower than $10^7$ are too small to produce any perceptible effect on the two-phase potentiometric titration curve of Naloxone hydrochloride (27).

[2]The factor 2 was inadvertently omitted in eq. [10] of ref. 27.

It should be noted that in this experiment the absorbance of the aqueous phase varied between zero and an upper value of 0.12. The membrane so completely excludes the organic solvent phase that the background noise in the absorbance is low enough to permit even these low absorbances to be measured with high precision.

*Ion-pair dissociation*

Dissociation of ion-pairs in the organic phase is often negligible (1, 12–15). However, the tendency toward dissociation is greater when the ions involved are less hydrophobic and when the solvent is more polar (1, 2). The dissociation of the ion-pair tetraethylammonium picrate (TEA·P) in methylene chloride is represented as follows:

$$[14] \quad (TEA\cdot P)_o \rightleftharpoons (TEA^+)_o + (P^-)_o$$

$$[15] \quad K_{diss} = [TEA^+]_o[P^-]_o/[TEA\cdot P]_o$$

The ion-pair extraction constant for TEA·P is given by:

$$[16] \quad K_I = [TEA\cdot P]_o/[TEA^+][P^-]$$

and the distribution ratio of picrate is

$$[17] \quad D_p = ([TEA\cdot P]_o + [P^-]_o)/[P^-]$$

The quantity $D_p$ can be calculated from absorbance measurements of picrate concentration in the aqueous phase using the expression:

$$[18] \quad D_p = (T_{TEA\cdot P} - [P^-]V)/[P^-]V_o$$

where the symbols are defined in eq. [7]. During the course of the experiment incremental additions are made of a methylene chloride stock solution of TEA·P. Extraction of ion-pairs such as TEA·$H_2PO_4$ or Na·P, involving components of the buffer, are expected to be negligible (1, 13), and at pH = 6.7 no picric acid extracts (15). Consequently, mass balance considerations require that $[TEA^+] = [P^-]$ and $[TEA^+]_o = [P^-]_o$. Combining these equalities with eqs. [15] through [17] gives the following expression:

$$[19] \quad D_p = (K_IK_{diss})^{1/2} + K_I[P^-]$$

which suggests that $K_I$ can be obtained from the slope and $K_{diss}$ from the intercept of a plot of $D_p$ vs. $[P^-]$.

Figure 3 shows a typical plot of eq. [19]. From linear least-squares treatment of such data $\log K_I = 2.54 \pm 0.02$ sd and $\log K_{diss} = -4.52 \pm 0.09$ sd. These values, obtained at 25°C using a pH 6.7 aqueous phase of ionic strength 0.18, may be compared with earlier reported values of 2.34 and −4.26 obtained using a pH 7.5 aqueous phase at the lower ionic strength of 0.1 and the lower tempera-

For personal use only.

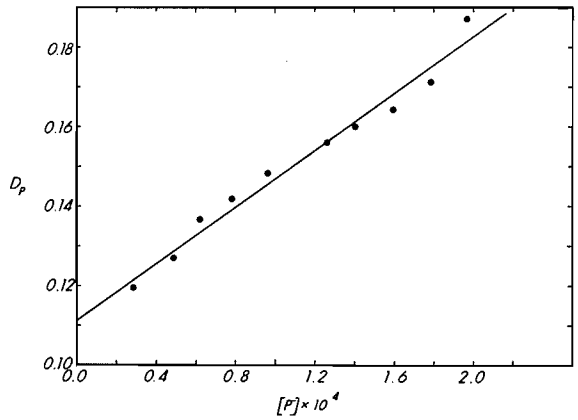

FIG. 3. Distribution ratio of picrate versus concentration of picrate in the aqueous phase, according to eq. [19].

ture of 20°C (28). The fraction of TEA·P extracted is small under all conditions in this experiment. For example, a $D_p$ of 0.15 corresponds to less than 6% of the TEA·P extracted into the organic phase. The rather large scatter in the data points in Fig. 3 is typical for this type of measurement of ion-pair dissociation constants of compounds which extract only slightly into the organic phase (see Fig. 4 in ref. 28). Its origin lies in the fact that the value of $[P^-]V$ is only slightly less than $T_{TEA\cdot P}$. The uncertainty in the numerator of eq. [18] is therefore large, since the numerator is the difference between two similar quantities.

## Conclusion

Use of the filter-probe membrane phase separator combined with a gravimetric buret provides a particularly convenient and rapid technique for measuring liquid–liquid distribution isotherms, by which a variety of association/dissociation equilibria can be studied. In this technique, calculation of distribution coefficients relies on concentration measurements made in one phase combined with the mass balance expression for the sample, as in eqs. [7], [13], and [18]. Therefore, it is important to demonstrate that interfacial adsorption of the sample is negligible, as previously described (14, 16). With especially large or surface-active organic ions adsorption may present a problem. For example, attempts to quantify dimerization of the ionic indicator Calmagite ($A^-$) by studying the distribution isotherm for the extraction of its tetraethylammonium ion-pair (TME·A) were fraught with adsorption problems. However, most of the compounds studied thus far show negligible adsorption, and the filter-probe technique may be considered to be of broad utility in solvent extraction studies.

## Acknowledgements

The authors thank Robert Evans for performing preliminary experiments and James Nolan for assistance in setting up the gravimetric buret. Naloxone free-base was kindly provided by Endo Laboratories Inc., Garden City, NY. Received October 14, 1981

SAUL WOLFE, DAVID JOHN MITCHELL, and H. BERNHARD SCHLEGEL. Can. J. Chem. **60**, 1291 (1982).

Similar substituent and angular constraint effects are noted for pyramidal inversion at tricoordinate nitrogen and inversion at a carbon centre undergoing an $S_N2$ displacement reaction. The former process has been analyzed successfully by a quantitative PMO analysis which focuses on the frontier orbital interactions between X and $NH_2$ in the planar and pyramidal structures of X—$NH_2$ molecules having X = F, $CH_3$, CHO. Based on total energy calculations at the 6-311G*//4-31G level, the effects of X upon the rates of the gas phase $S_N2$ reactions $F^- + XCH_2F \rightarrow XCH_2F + F^-$ are found to be CHO ≫ H > F > $CH_3$ > OH. Taking the treatment of nitrogen inversion as a precedent, the origin of this trend has been examined by a quantitative PMO analysis which focuses on the frontier orbital interactions between X and $CH_2F_2^-$ in the transition states, and between X and $CH_2F$ in the reactants. This has revealed that the rate enhancement associated with an α-carbonyl substituent in these $S_N2$ reactions can be related to the presence of a stabilizing orbital interaction of a new type in the transition state, coupled to an exceptionally low destabilizing orbital interaction.

SAUL WOLFE, DAVID JOHN MITCHELL et H. BERNHARD SCHLEGEL. Can. J. Chem. **60**, 1291 (1982).

On note des effets de substitutants et des effets de contrainte angulaire similaire dans le cas de l'inversion pyramidale au niveau de l'azote tricoordonné et dans le cas de l'inversion au niveau du centre carboné subissant la réaction de déplacement $S_N2$. On a analysé avec succès le premier processus en faisant appel à l'analyse quantitative des OMP qui porte sur les interactions d'orbitales frontières entre X et $NH_2$ dans les structures planes et pyramidales des molécules de X—$NH_2$ où X = F, $CH_3$, CHO. En se basant sur les calculs d'énergie totale au niveau 6-311G*//4-31G, on a trouvé que les effets de X, sur les vitesses des réactions $S_N2$ en phase gaseuze, sont dans l'ordre suivant: CHO ≫ H > F > $CH_3$ > OH. En considérant le traitement de l'azote comme un précédent, on a étudié l'origine de cette tendance par l'analyse quantitative de OMP qui porte sur les interactions d'orbitales frontières entre X et $CH_2F_2^-$ dans les états de transition et entre X et $CH_2F$ dans les réactifs. Cette étude révèle que le taux d'augmentation, associée au substituant en position α du carbonyle dans ces réactions $S_N2$, peut être relié à la présence d'interactions d'orbitales stabilisantes d'un nouveau type dans l'état de transition, qui s'ajoutent à une interaction d'orbitale déstabilisante exceptionnellement faible.
[Traduit par le journal]

The deformation of a carbon atom from tetrahedral to trigonal–bipyramidal geometry makes a significant contribution to the energy barrier associated with an $S_N2$ displacement reaction (1). There is some analogy between such geometrical effects at an initially tetracoordinate centre and the geometrical changes associated with pyramidal inversion at a tricoordinate centre. It is, therefore, not surprising that the two seemingly different processes exhibit rather similar substituent and angular constraint effects. For example, α-halogen or α-alkyl substituents cause an increase in the barrier to pyramidal inversion at nitrogen (2), and a decrease in $S_N2$ reactivity at carbon (3, 4). Conversely, an α-carbonyl substituent causes a substantial decrease in the pyramidal inversion barrier (5), and a substantial increase in $S_N2$ reactivity (4, 6).

Table 1 compares $\Delta G^{\neq}$ for pyramidal inversion at nitrogen in a series of cyclic amines (2) with the $S_N2$ reactivities of the corresponding series of bromocycloalkanes upon reaction with lithium iodide in acetone solvent (4). The same trends with ring size (i.e., angular constraint) are observed in both cases.

TABLE 1. Effect of ring size upon pyramidal inversion at nitrogen in cyclic amines and upon $S_N2$ reactivities of bromocycloalkanes

| Ring size | Nitrogen inversion[a] | $S_N2$ reactivity[c] |
|---|---|---|
| 3 | 23.8[b] | <0.0001[d] |
| 4 | 13.4 | 0.0075 |
| 5 | 10.3 | 1.6 |
| 6 | 13.7 | 0.010 |
| 7 | 9.0 | 0.98 |

[a]Data from ref. 2.
[b]Refers to $\Delta G^{\neq}$ in kcal/mol.
[c]Data from ref. 4.
[d]Relative rates for reaction with lithium iodide in acetone at 25°C ($Me_2CHBr$ = 1.00).

These observations suggested that the effects of substituents upon $S_N2$ displacement reactions might be rationalized by an appeal to interpretations that have been proposed (7) to account for substituent effects upon pyramidal inversion barriers. One such interpretation is based on the perturbational molecular orbital (PMO) approach, and focuses (8)

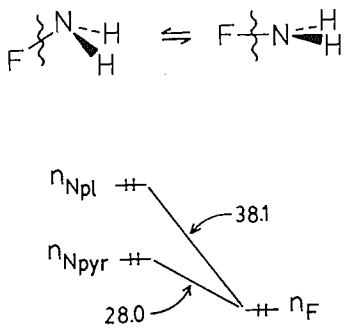

FIG. 1. Frontier orbital interaction between $n_F$, a fluorine lone pair and $n_{N_{pyr}}$ or $n_{N_{pl}}$, the nitrogen lone pairs of the pyramidal and planar forms, respectively, of F—$NH_2$. The numbers shown refer to the magnitude of this interaction in kcal/mol based on 4-31G level computations on the fully optimized pyramidal and planar structures. See ref. 9, eq. [64], and ref. 10.

on the frontier orbital interactions both in the pyramidal ground state and in the planar transition state for the inversion process. The application of this procedure to pyramidal inversion in fluoramine is illustrated in Fig. 1. Replacement of one hydrogen of ammonia by fluorine introduces a two-orbital, four-electron destabilizing interaction between the nitrogen lone pair and a fluorine lone pair. The geometrical change affects principally the orbital energy and overlap associated with the nitrogen lone pair, and leads to a 10.1 kcal/mol difference between the destabilizing interactions in the two structures. This difference compares favorably with the 9.4 kcal/mol difference between the computed pyramidal inversion barriers of ammonia (0.4 kcal/mol) and fluoramine (9.8 kcal/mol).

Although the 4-31G basis set employed to obtain these data is known (11) to be deficient for the quantitative calculation of specific inversion barriers, it should be adequate for the determination of trends associated with substituents. Table 2 summarizes the total energy changes and PMO interaction energy changes associated with $NH_2$ bending in fluoramine, methylamine, and formamide, and appears to validate a frontier orbital analysis of substituent effects upon pyramidal inversion barriers.

For the $S_N2$ displacement reaction $F^- + XCH_2F \rightleftarrows XCH_2F + F^-$, the corresponding frontier orbital analysis refers to the fragmentation $X\cdots CH_2F$ in the reactant, and $X\cdots CH_2F_2^-$ in the transition state. For several reasons the problem is simplified considerably by restriction to a thermoneutral or degenerate process: (*i*) the rates of gas phase $S_N2$ reactions and the geometries of the transition states depend upon the heat of reaction (12, 13); (*ii*) for a degenerate reaction, trends in substituent effects are revealed by a comparison between the energies

of the separated reactants and the transition state (13); (*iii*) the principal effect of a transfer of gas phase data to solution is associated with the different heats of solvation of the entering and leaving groups (14). Restriction to a thermoneutral process should, therefore, allow comparison between the calculated trends and experimental data in solution (4). Unfortunately, direct comparison with experimental gas phase results is not possible, because the latter are complicated by competing reaction channels.[2]

Figure 2 shows the C—F bond lengths (Å) and FCX bond angles (deg) in the series of transition states $XCH_2F_2^-$, in which X = H, F, OH, $CH_3$,

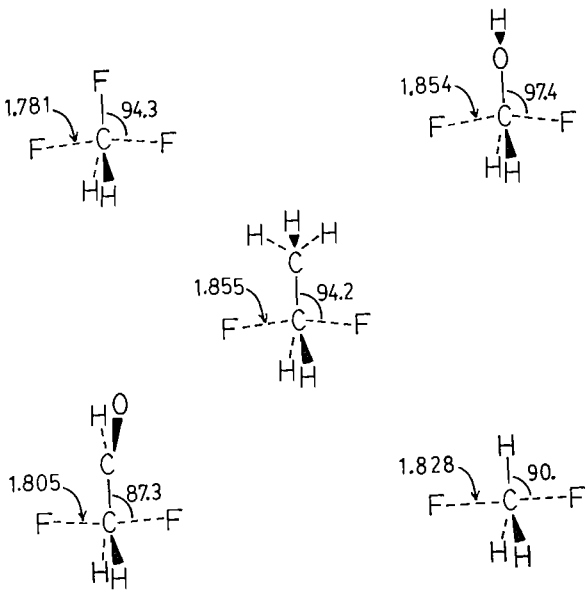

FIG. 2. The C—F bond lengths (Å) and FCX bond angles (deg) in the series of transition states $XCH_2F_2^-$ in which X = H, F, OH, $CH_3$, and CHO. These data are taken from the fully optimized structures at 4-31G.

CHO, from the fully optimized 4-31G level wavefunctions. The total energy data summarized in Table 3 were obtained at the 6-311G* level (15) using the 4-31G geometries of the reactants and transition states. Based on these data, the effects of these substituents on $S_N2$ reactivity at carbon are CHO ≫ H > F > $CH_3$ > OH. The position of the α-oxygen substituent in this sequence strongly suggests that the rate enhancement observed for this substituent in solution (4) is associated with an $S_N1$ process (16). The rate-enhancing effect of an α-carbonyl substituent and rate-retarding effects of α-fluoro and α-methyl substituents are reproduced by the calculations.

For the fragmentation $X\cdots CH_2F_2^-$ in the transition states, the orbital interactions forming the HOMOs were found to be **A**, **B**, and **C**; interactions possibly corresponding to **A** or **B** have often been proposed in the literature (4, 17) to account for the α-carbonyl rate enhancement, but without specification of their stabilizing or destabilizing nature. Interaction **C** has not been considered previously.

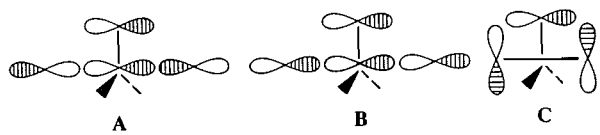

Table 4 summarizes the PMO results and allows the following *qualitative* interpretation of the trends in substituent effects: (*1*) with X = F or OH, interactions **A** and **C** are entirely destabilizing and **B** is stabilizing; (*2*) the availability of acceptor orbitals on $CH_3$ and CHO introduces a stabilizing contribution to **A** and **C**; (*3*) the difference between CHO and F, OH, or $CH_3$ is the result of a small destabilizing interaction of type **A** coupled with a large stabilizing interaction of type **C**; (*4*) correction of the transition state PMOs for the $X\cdots CH_2F$ orbital interactions in the reactants places α-carbonyl more reactive than α-hydrogen, as observed in the total energy calculations.

## Introduction

Le but de cette note est d'interpréter par un calcul théorique les spectres de l'imidazolidinethione-2, de l'héxahydropyrimidinethione-2 et de leurs dérivés *N*-méthylés (molécules **1**, **3**, **1'** et **3'**) ainsi que de la méthylthio-2 Δ-2 imidazoline et de la méthylthio-2 Δ-2 tétrahydropyrimidine (molécules **2** et **4**).

Le calcul des spectres a été fait par la méthode CNDO/S (1, 2) en introduisant des orbitales *d* du soufre qui sont traitées selon le procédé de Schulte et Schweig (3) dans les conditions identiques à celles employées pour les molécules conjuguées que nous avons étudiées précédemment (4, 5).

La géométrie des molécules est celle adoptée dans un travail précédent (6). Elle est donnée en annexe. Les cycles à 5 chainons sont plans, les cycles à 6 chainons ont une forme dérivée du

cyclohexane pour la molécule **3** et du cyclohexène pour la molécule **4**. Les atomes en α des doubles liaisons sont tous maintenus dans le même plan.

## Discussion des résultats

Les résultats sont donnés dans le tableau 1. Ils peuvent y être comparés aux valeurs des transitions expérimentales obtenues précédemment (7, 8) dans l'éthanol. Ils montrent que la seule transition qui a pu être observée expérimentalement est de type $\pi \rightarrow \pi^*$.

Pour les thiones le schéma 1 montre que la configuration intervenant principalement dans cette transition correspond à une orbitale virtuelle fortement localisée sur la double liaison C=S. Ce résultat est identique à celui observé pour la Δ-4 imidazolinethione-2 (4), molécule différant de la molécule **1** par une double liaison supplémentaire entre les deux carbones. Par contre l'orbitale moléculaire occupée correspondante se trouve plus délocalisée dans la Δ-4 imidazolinethione-2 que dans les thiones étudiées ici. Cette orbitale correspond donc à une énergie plus élevée pour ces dernières molécules et cela se traduit par un effet hypsochrome quand l'insaturation diminue. Le calcul CNDO/S rend compte de cet effet en le surestimant, la valeur calculée passant de 270,5 nm pour la Δ-4 imidazolinethione-2 (4) à 234,6 pour **1** alors qu'expérimentalement elle passe dans l'éthanol de 259 à 240 nm. Ceci s'observe pour les thiols correspondants avec une surestimation négligeable, le calcul théorique donnant 252,9 nm pour le méthylthio-2 imidazole (4) et 223,6 nm pour la molécule **2**. Expérimentalement on passe de 250,5 nm à 224 nm dans l'éthanol.

Toutefois on observe dans le cas de la plus insaturée de ces deux molécules que le carré des coefficients de la configuration principale intervenant dans le calcul de la transition est de 0,60 et que les orbitales définissant cette configuration

| | 0,0000 | | 0,0000 | | 0,0000 | | 0,0000 | | 0,0000 | | 0,00504 | |
| $\pi \rightarrow \pi^*$ | 234,6 | 240 | 236,4 | 240 | 223,6 | 224 | 242,5 | 244,5 | 244,9 | 244,8 | 200,0 | 225 |
| | 0,5199 | 4,215 | 0,5145 | 4,230 | 0,4621 | 3,734 | 0,4169 | 4,032 | 0,3997 | 4,125 | 0,3511 | 3,748 |
| $n \rightarrow \sigma^*$ | 201,2 | | 202,5 | | | | | | | | | |
| | 0,0000 | | 0,0030 | | | | | | | | | |
| $\pi \rightarrow \pi^*$ | 195,0 | | 201,8 | | 195,0 | | 201,8 | | 204,9 | | 190,4 | |
| | 0,1354 | | 0,1541 | | 0,0837 | | 0,0162 | | 0,0966 | | 0,0727 | |

[a]Le premier nombre correspond à la longueur d'onde de transition en nanomètres, le second à la force oscillatrice pour la valeur théorique et à log ε pour la valeur expérimentale obtenue en utilisant l'éthanol comme solvant.

sont toutes deux très délocalisées (4). Par contre pour la molécule **2** le carré du coefficient de la configuration principale est de 0,92, les orbitales étant plus localisées, surtout l'orbitale virtuelle comme le montre le schéma 1.

L'agrandissement du cycle correspond pour les thiones à un effet bathochrome expérimental de 4,5 nm surestimé de 3,4 nm par le calcul comme on peut le voir en comparant dans le tableau 1 les valeurs relatives aux molécules **1** et **3**.

Entre les molécules **2** et **4** le très léger effet bathochrome observé n'est pas traduit par le calcul.

L'effet hypsochrome observé expérimentalement entre les molécules **1**′ et **2** d'une part et **3**′ et **4** d'autre part, c'est à dire quand on passe d'une forme thione à une forme thiol, est traduit correctement par le calcul, qui donne les valeurs respectives de 240 et 224 nm pour **1**′ et **2** et de 244,8 et 225 nm pour **3**′ et **4**. On peut remarquer que cela s'observait pour les molécules plus insaturées (4).

De même le schéma 1 permet d'expliquer l'effet bathochrome observé (7, 8) quand on passe de l'éthanol au chlorure de méthylène, c'est à dire d'un solvant protique à un solvant aprotique, le site de protonation étant plus chargé négativement à l'état fondamental qu'à l'état excité.

# Hydrolysis of the thorium(IV) ion in sodium nitrate medium

NIKOLA B. MILIĆ[1]

*Faculty of Science, Svetozar Marković University, 34000 Kragujevac, Yugoslavia*

AND

TEREZIJA M. ŠURANJI

*Faculty of Science, The University, 21000 Novi Sad, Yugoslavia*

Received June 30, 1981

NIKOLA B. MILIĆ and TEREZIJA M. ŠURANJI. Can. J. Chem. **60**, 1298 (1982).

The hydrolysis of the thorium(IV) ion in sodium nitrate medium was studied by the emf method at 25°C. The data show that the extent of the thorium hydrolysis depends both on the concentration of thorium and the sodium nitrate medium. Thus, at a definite pH, the extent of the hydrolysis of thorium increases with increasing its concentration, but decreases with increasing concentration and the hydration energy of the medium ions. The stability constants of complexes $Th_2(OH)_2^{6+}$, $Th_3(OH)_5^{7+}$, and $Th_6(OH)_{15}^{9+}$ also slightly differ going from one concentration of sodium nitrate to another. The observed effect of the medium is in agreement with the linear free energy relationship proposed for the metal ion hydrolysis.

NIKOLA B. MILIĆ et TEREZIJA M. ŠURANJI. Can. J. Chem. **60**, 1298 (1982).

Utilisant la méthode de la fem à 25°C, on a étudié l'hydrolyse de l'ion thorium(IV) dans un milieu de nitrate de sodium. Les données révèlent que le taux d'hydrolyse du thorium dépend à la fois de la concentration en thorium et de la concentration en nitrate de sodium. Ainsi, à un pH défini le taux d'hydrolyse du thorium augmente avec sa concentration; toutefois il diminue lorsqu'on augmente la concentration et l'énergie d'hydratation des ions du milieu. Les constantes de stabilité des complexes du type $Th_2(OH)_2^{6+}$, $Th_3(OH)_5^{7+}$ et $Th_6(OH)_{15}^{9+}$ diffèrent légerement d'une concentration en nitrate de sodium à une autre. L'effet observé pour le mileu est en accord avec la relation linéaire d'énergie libre proposée pour l'hydrolyse de l'ion métallique.

[Traduit par le journal]

## Introduction

Hydrolysis of the thorium(IV) ion has been studied in various ionic media (1). The data indicate that the principal hydrolytic complex of thorium is $Th_2(OH)_2^{6+}$. The composition of the other complexes differs slightly in dependence on the concentration of thorium, the pH range, and the ionic medium. Values of the stability constants of the same complexes formed in various ionic media are also different, indicating the effect of the medium. In our previous work (2, 3), it was observed that this effect depends on concentration, $c$, the hydration energy, $E_h$, and charge, $z$, of the ions of the medium. Correlating these parameters and the hydrolysis extent, the medium factor, $F_{(m)}$,

$$[1] \quad F_{(m)} = c_{(a)}E_{h(a)}z_{(a)} + c_{(c)}E_{h(c)}/z_{(c)}$$

and the linear free energy relationship

$$[2] \quad \log K_{M(w)} - \log K_{M(m)} = nF_{(m)}$$

have been established. In eq. [1] the subscripts (c) and (a) denote cations and anions of the medium. In eq. [2] $K_{M(w)}$ and $K_{M(m)}$ denote equilibrium constants of the metal-ion hydrolysis in pure water and in an ionic medium, respectively. The medium factor, $F_{(m)}$, is characteristic of the medium concerning interaction of its ions with water molecules, whereas constant $n$ is determined by the reaction of the metal ions with anions of the medium. Since there are no available hydrolysis data for diluted media, a possible deviation from linearity in this range might require introduction of some correction of the parameters in the expression for the medium factor. In spite of that, this kind of quantitative examination should lead to evaluation of the contribution of each parameter of the medium to the total medium effect, and consequently to a better understanding of the complicated interactions in water solutions.

In order to get some information on the particular contribution of concentration and the hydration energy of the cations of the nitrate medium to the total medium effect, as well as to check the established relationship, in this work hydrolysis of the thorium(IV) ion has been studied in various concentrations of the sodium nitrate medium.

## Experimental

*Reagents and analysis*

All chemicals were of reagent grade. In addition, thorium and sodium nitrate were purified by double recrystallization. To prevent initial hydrolysis of the thorium(IV) ion in the stock solution, a small amount of nitric acid was added. Its free concentration was determined potentiometrically using a Gran plot (4). The thorium content was determined by precipitation with oxalic acid and ammonia. The precipitates were ignited at 1000°C, and weighted as $ThO_2$. Both methods gave the same results to within ±0.18%.

The sodium nitrate content was determined by evaporating a known volume of solution to dryness at 150°C (5), as well as transforming nitrate to chloride, which was then heated at 600°C to constant weight (6). Both methods gave the same results to within ±0.26%.

Sodium hydroxide, nitric acid, and sodium hydrogen carbonate solutions were standardized by a procedure described elsewhere (7). At these standardizations the equivalence point was determined potentiometrically using a Gran plot. Purification of nitrogen gas for stirring and providing an inert atmosphere was also described in ref. 7.

*Apparatus and procedure*

All emf measurements were carried out as potentiometric titrations with a glass electrode and Ag,AgCl electrode at 25.0 ± 0.2°C (7). Titrations of various concentrations of thorium (2.5, 5.0, 10, 25, 50, and 100 m*M* $Th^{4+}$) in a constant concentration of the sodium nitrate medium (3.0 *M* $(Na)NO_3$),[2] as well as titrations of the constant concentration of the thorium(IV) ion (10 m*M* $Th^{4+}$) in various concentrations of the medium (0.5, 1.0, 1.5, 2.0, 2.5, and 3.0 *M* $(Na)NO_3$) were carried out by adding the sodium hydrogen carbonate solution from one buret and the thorium solution of a twice higher concentration in the same portions from the other buret. All solutions were prepared in corresponding concentrations of sodium nitrate. In this way, the total concentration of thorium (*B*) and the total concentration of nitrate ions were kept constant, while the analytical excess of $H^+$ (denoted as *H*) was decreased, so that it became negative during the course of the titration. The concentration of the free $H^+$ (denoted as *h*) at each point was calculated by the Nernst formula

$$[3] \quad E = E_0 + E_j + 59.16 \log h$$

where *E* is the measured potential, $E_0$ a constant which includes the standard potential of the glass electrode, and $E_j$ the liquid junction potential. The potential was measured after each new addition of the solution from burets, until a constant value was reached. Determination of $E_0$ and $E_j$ has already been described (7). The emf was measured with a Beckman Digital pH meter, Model 4500, or Radiometer pH meter, M-52 b.

## Results and discussion

The emf data of the hydrolysis of 2.5, 5.0, 10, 25, 50, and 100 m*M* $Th^{4+}$ in 3.0 *M* $(Na)NO_3$ medium are represented in Fig. 1, as the dependence of the hydroxide number of thorium on the concentration of the free hydrogen ions, *h*. The hydroxide number of thorium, $Z_{Th}$ (the average number of $OH^-$ ions bonded per thorium), was calculated from the analytical excess of hydrogen ions, *H*, the measured concentration of the free hydrogen ions, *h*, and the total concentration of the thorium(IV) ions, *B*, according to the expression $Z_{Th} = (h - H)/B$. The data obtained show that the thorium(IV) ion hydrolyzes between pH 1.5 and 3.5 depending upon its concentration. Thus, as the thorium concentration increases the beginning of the hydrolysis is shifted to lower pH values. In order to check the reversibility of the hydrolytic process in some experiments (Fig. 1, full symbols) after a certain value of hydroxide number was reached ($Z_{Th}$ = 0.35–0.40), the direction of titration was changed by adding nitric acid instead of sodium hydrogen carbonate, to a solution with negative value of *H*. Good agreement between forward and back titrations indicates reversibility of the hydrolytic reaction under the conditions studied.[3]

The emf data of the hydrolysis of 10 m*M* $Th^{4+}$ in 0.5, 1.0, 1.5, 2.0, 2.5, and 3.0 *M* $(Na)NO_3$ media are represented in Fig. 2, also as a dependence of the hydroxide number of thorium on concentration of the free hydrogen ions. The data show that the hydroxide number of thorium, at definite pH, decreases with increasing concentration of the medium ions.

Representation of the values of the hydroxide number of thorium obtained in 3.0 *M* $(K)NO_3$ (7), 3.0 *M* $(Na)NO_3$ (this work), and 3.0 *M* $(Li)NO_3$ (7) on dependence of the hydration energy of potassium, sodium, and lithium (9) shows that the hydrolysis extent decreases with increasing the hydration energy of the medium cations. Comparison of a decrease of the extent of hydrolysis obtained at the similar enhancement of the concentration of the medium cations and their hydration energies indicates that contribution of the hydration energy of the cation to the total medium effect is higher than contribution of its concentration.

Since it is difficult to obtain reliable values for the equilibrium constants of the hydrolytic reactions, stability constants for the particular complexes, $\beta_{pq}$, or the experimental values of the hydroxide number could be used in consideration of the medium effect. At using the hydroxide number, some deviations from the linearity of the function

$$[4] \quad \log Z_{M(m)} = f(F_{(m)})$$

might appear, because $Z_M$ is not exactly proportional to $\beta_{pq}$ (eq. [8]). The hydroxide number approaches proportionality with $\beta_{pq}$ only if one hydrolysis species predominates or if the $Z_M$ values are chosen in the pH range where only the main complex exists. In spite of these limitations, the linear free energy approach with the experimental values of the hydroxide number might give useful information on the effect of the ionic medium. Therefore, the data obtained in various concentrations of sodium nitrate medium are represented in Fig. 3, as dependence of the hydroxide number on

[2]Notation is in accordance with ref. 8.

[3]Complete set of the potentiometric titration data and results showing the calculation of *Z* may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

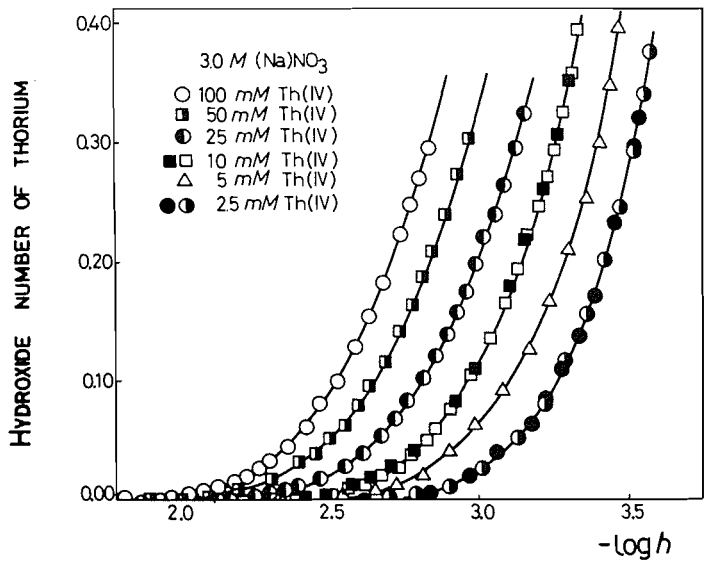

FIG. 1. Hydrolysis of the thorium(IV) ion in 3.0 *M* $(Na)NO_3$ medium (full symbols denote back titrations).

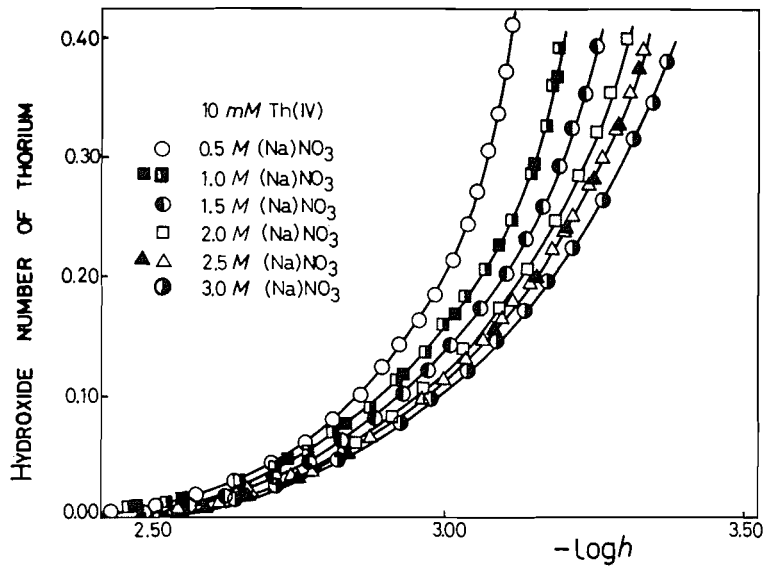

FIG. 2. Hydrolysis of 10 m*M* Th(IV) ion in various concentrations of sodium nitrate medium (full symbols denote back titrations).

the medium factor. The linearity obtained supports the proposed correlation between the extent of hydrolysis and the properties of the medium, enabling the prediction of the thorium hydrolysis in the similar media.

Supposing that the thorium(IV) ion, on interaction with water molecules, forms one or more hydrolytic complexes of general formula $Th_q(OH)_p^{(4q-p)+}$, formation constants $\beta_{pq}$ for each $(p,q)$ species can be defined as the equilibrium constant of the reaction [5]

$$[5] \quad pH_2O + qTh^{4+} \rightleftharpoons Th_q(OH)_p^{(4q-p)+} + pH^+$$

Although the hydrolytic complexes contain a certain number of nitrate ions and water molecules, in reaction [5] the hydration of the individual ions and complex-formation of thorium with nitrate ions are omitted. There are two reasons for this: (*a*) the concentration of both nitrate ions and water molecules is much higher than the concentration of thorium, therefore, there are great difficulties in determining the changes in concentration of nitrate

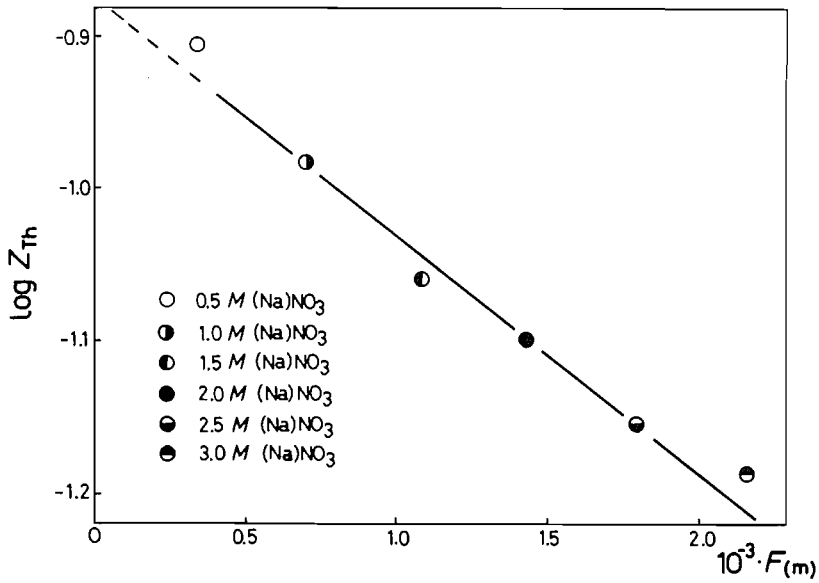

FIG. 3. Dependence of the logarithmic values of the hydroxide number of thorium (obtained in various concentrations of sodium nitrate medium at pH = 2.9) on the medium factor.

TABLE 1. Stability constants, log ($\beta_{pq} \pm 3\sigma$) of the hydrolytic complexes of the $Th^{4+}$ ion obtained in sodium nitrate medium, and corresponding values of the medium factor, $F_{(m)}$*

| Medium $(Na)NO_3$ ($M$) | $F_{(m)}$ | log ($\beta_{pq} \pm 3\sigma$) | | |
|---|---|---|---|---|
| | | $Th_2(OH)_2^{6+}$ | $Th_3(OH)_5^{7+}$ | $Th_6(OH)_{15}^{9+}$ |
| 0.5 | 345 | −5.06±0.07 | −12.59±0.12 | −38.06±0.23 |
| 1.0 | 707 | −5.08±0.06 | −13.04±0.15 | −39.56< −39.41 |
| 1.5 | 1080 | −5.14±0.05 | −13.30±0.16 | −40.47< −40.13 |
| 2.0 | 1430 | −5.16±0.04 | −13.61±0.16 | −41.10< −40.83 |
| 2.5 | 1791 | −5.18±0.03 | −13.79±0.15 | −41.77< −41.42 |
| 3.0 | 2153 | −5.19±0.02 | −14.23±0.17 | −42.32±0.23 |

*In the calculation of the medium factor, $F_{(m)}$, concentrations of the ions of the medium are expressed in mol/dm³, the hydration energies in kJ/mol (ref. 9), while $z$ is the corresponding charge.

ions and water molecules, and ($b$) concentration of nitrate ions was kept constant during each titration, thus the complex-formation appears as a constant effect.

Denoting by $b$ and $h$ the concentrations of the free thorium and hydrogen ions respectively, the concentration of the ($p$,$q$) complexes is given by eq. [6]

$$[6] \quad c_{pq} = \beta_{pq} h^{-p} b^q$$

If the total concentration of thorium ions, $B$ (free and in complexes) is

$$[7] \quad B = b + \Sigma q c_{pq} = b + \Sigma q \beta_{pq} h^{-p} b^q$$

then the hydroxide number of thorium or the amount (in mol/dm³) of $OH^-$ bond to $B$ or, in equivalent, the amount of $H^+$ ions set free by reaction [5], can be represented by expression [8]

$$[8] \quad Z = \Sigma p c_{pq}/B = (\Sigma p \beta_{pq} h^{-p} b^q)/(b + \Sigma q \beta_{pq} h^{-p} b^q)$$

The composition of the hydrolytic complexes and their stability constants has been determined by minimization of the error square sum $U = \Sigma(Z_{cal} - Z_{exp})^2$ using the generalized least-squares program Letagrop (10) and the procedure described in ref. 7.

The hydrolysis data of 2.5–100 m$M$ $Th^{4+}$ in 3.0 $M$ $(Na)NO_3$ medium indicate formation of the polynuclear complexes $Th_2(OH)_2^{6+}$, $Th_3(OH)_5^{7+}$, and $Th_6(OH)_{15}^{9+}$ with stability constants log $\beta_{2,2} = -5.25 \pm 0.02$, log $\beta_{5,3} = -13.76 \pm 0.06$, and log $\beta_{15,6} = -42.35 \pm 0.20$. The same complexes were obtained as a result of the calculation of the hydrolysis data of 10 m$M$ $Th^{4+}$ in 0.5–3.0 $M$ $(Na)NO_3$ media. However, in this case the complex (15,6) is not certain enough, perhaps due to the low

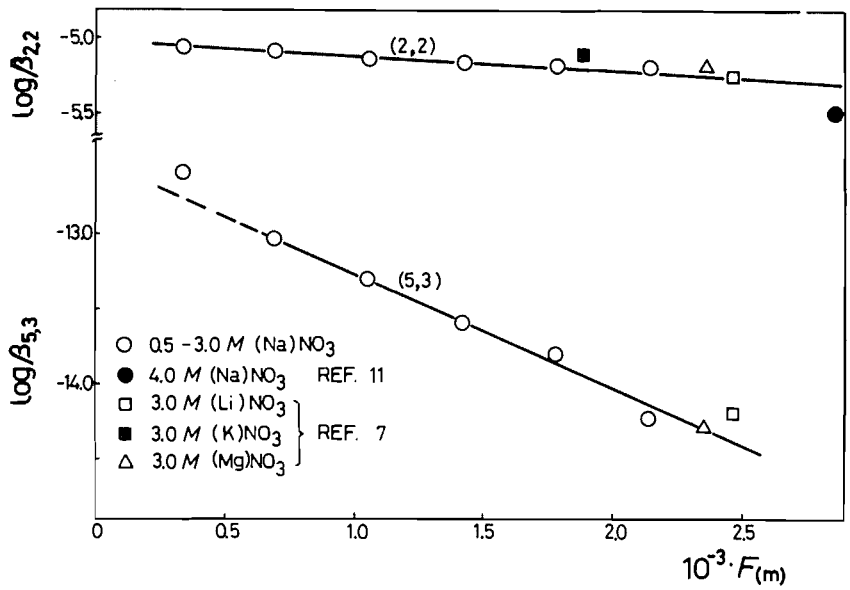

FIG. 4. Dependence of the logarithmic values of the stability constants of the thorium complexes (formed in various nitrate media) on the medium factor.

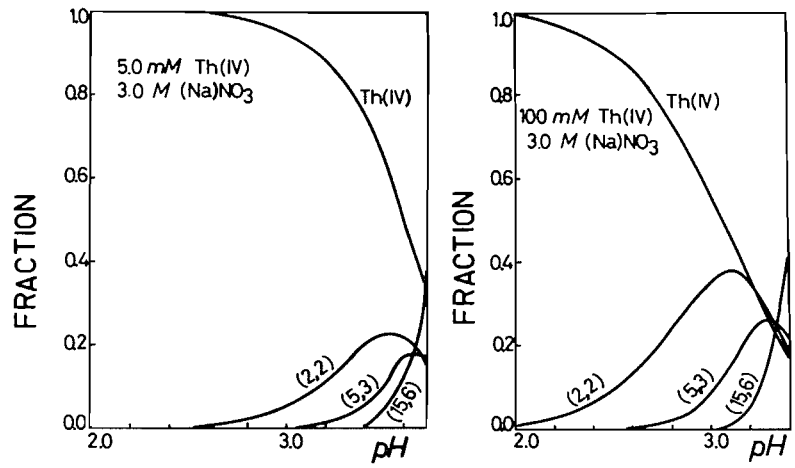

FIG. 5. Distribution of the hydrolytic complexes of thorium formed in 3.0 $M$ $(Na)NO_3$ medium.

concentration of thorium. As the water activity and the activity coefficient of the thorium(IV) ion are different going from one concentration of sodium nitrate to another, calculation of these data was done separately for each concentration of the medium. Table 1 shows that the obtained values of the stability constants, given as $\log(\beta \pm 3\sigma)$, follow changes of the medium factor. Graphical representation of these values, as well as the values obtained in 3.0 $M$ lithium, potassium, magnesium (7), and 4 $M$ sodium nitrate media (11) as a function $\log \beta_{p,q(m)} = f(F_{(m)})$ (Fig. 4) shows a linear dependence confirming the correlation between the free energy changes of the system and the medium factor.

Determination of the distribution of complexes (2,2), (5,3), and (15,6) using the Haltafall program (12) shows that $Th_2(OH)_2^{6+}$ is the principal complex (Fig. 5). Its concentration follows the extent of hydrolysis. Thus, at definite pH, the concentration of complex (2,2) increases with increasing concentration of thorium, but slightly decreases with increasing concentration of the medium. Complexes (5,3) and (15,6) are formed at higher pH, indicating the enhancement of the polynuclearity with increasing pH.

Received November 4, 1981

LOUIS J. FARRUGIA, BRIAN R. JAMES, CLAUDE R. LASSIGNE, and EDWARD J. WELLS. Can. J. Chem. **60**, 1304 (1982).

The octahedral anions $[M(SnCl_3)_5Cl]^{4-}$ (M = Ru, Os) have been fully characterized by $^{119}Sn$ FT nmr spectroscopy. For M = Ru, $^{117}Sn$ and $^{115}Sn$ nmr spectra were also recorded, and an X-ray crystallographic study was carried out on the tetraethylammonium salt, isolated as a disolvate from acetonitrile. The Ru—Sn bond lengths indicate some degree of $d_\pi$–$d_\pi$ interactions. The slight distortions from octahedral geometry are discussed in connection with the packing of the chlorine atoms. The Sn nmr spectra reveal the first observed coupling to a $^{99}Ru$ nucleus ($I = 5/2$, 12.7% natural abundance), very large $^2J(^{119}Sn—^{117}Sn)$ coupling constants, and the first observed second-order effects on a heteronuclear system. The octahedral anion $[Ru(SnCl_3)_5(MeCN)]^{3-}$ was also synthesized as the tetraethylammonium salt and characterized spectroscopically.

LOUIS J. FARRUGIA, BRIAN R. JAMES, CLAUDE R. LASSIGNE et EDWARD J. WELLS. Can. J. Chem. **60**, 1304 (1982).

Faisant appel à la spectroscopie de rmn du $^{119}Sn$ par TF, on a caractérisé complètement les anions octaédriques du type $[M(SnCl_3)_5Cl]^{4-}$ (M = Ru, Os). On a également enregistré les spectres de rmn des anions où M = Ru, $^{117}Sn$ et $^{115}Sn$ et on a fait une étude par cristallographie des rayons X sur le sel de triéthylammonium que l'on a isolé d'une solution dans l'acétonitrile. Les longueurs de liaison Ru—Sn indiquent un certain degré d'interactions $d_\pi$–$d_\pi$. On discute des légères distorsions par rapport à la géométrie octaédrique en les reliant à l'entassement des atomes de chlore. Les spectres de rmn du Sn ont permis d'observer pour la première fois un couplage impliquant un noyau de $^{99}Ru$ ($I = 5/2$, abondance nat. 12,7%), des constantes de couplage très grandes $^2J(^{119}Sn—^{117}Sn)$ et les premiers effets d'ordre deux observés dans un système hétéronucléaire. On a également synthétisé l'anion octaédrique $[Ru(SnCl_3)_5(MeCN)]^{3-}$ sous forme de sel de triéthylammonium et on l'a caractérisé par spectroscopie.

[Traduit par le journal]

## Introduction

Although the reaction of tin(II) chloride with platinum metal halides to give coloured solutions has been known for a long time (1), the exact nature of some of the species present has been ascertained only recently (2–5). Notwithstanding, however, there have been numerous reports on the catalytic activity of such systems for several reactions, including hydrogenation (6), hydroformylation (7), isomerization of olefins (8), dehydrogenation of alcohols (9), and the Water Gas Shift reaction (10, 11). The reaction of $SnCl_2$ with $RuCl_3$ has been reported by several workers. Initially, Young *et al.* (1) formulated the anionic product as $[Ru(SnCl_3)_2Cl_2]^{2-}$ but, on the basis of elemental analysis, later workers (12, 13) preferred the octahedral formulation $[Ru(SnCl_3)_5Cl]^{4-}$. From our studies concerning the potential catalytic activity of the ruthenium system, we report here the full characterization of the $[Ru(SnCl_3)_5Cl]^{4-}$ anion by X-ray crystallography and Sn FT nmr spectroscopy. Brief accounts of some of the work described here have been published previously (14, 15).

## Experimental

*Starting materials*

The $RuCl_3 \cdot 3H_2O$ and $(NH_4)_2OsCl_6$ compounds were used as supplied by Johnson Matthey Ltd.; $SnCl_2 \cdot 2H_2O$ was of reagent grade ACS. The preparative reactions were carried out under argon, although subsequent work-up was performed in air. Acetonitrile was dried over $P_2O_5$, and distilled under $N_2$.

*Preparation of $[NEt_4^+]_4[Ru(SnCl_3)_5Cl]^{4-}$ (I)*

A solution of $RuCl_3 \cdot 3H_2O$ (0.5 g, 41.8% Ru) and $SnCl_2 \cdot 2H_2O$ (3.0 g, 13.3 mmol) in 90 mL 3 *M* HCl was heated on a water-bath until the solution became bright orange (~0.5 h). After cooling the solution to room temperature, $NEt_4^+Cl^-$ (20% in water) was added dropwise until no further orange precipitate formed. The supernatant was pale pink at this stage. On shaking the orange flocculent precipitate over a period of several minutes it crystallized as platelets. These were filtered and washed with 0.1 *M* HCl (*not* water, which caused extensive hydrolysis), methanol, and finally diethyl ether, and dried *in vacuo* to give 3.0 g (81%) of the analytically pure, bright orange salt, **I**. Crystals suitable for X-ray work were obtained as a disolvate by recrystallization from dry acetonitrile.

*Preparation of $[NEt_4^+]_4[Os(SnCl_3)_5Cl]^{4-}$ (II)*

Following the literature method (13), $(NH_4)_2OsCl_6$ (0.30 g, 0.68 mmol) and $SnCl_2 \cdot 2H_2O$ (1.0 g, 4.44 mmol) in 40 mL 3 *M* HCl gave 1.05 g (82%) of straw-yellow platelets of **II**.

*Preparation of $[NEt_4^+]_3[Ru(SnCl_3)_5(MeCN)]^{3-}$ (III)*

A solution of **I** (1.07 g, 0.6 mmol) and $Ag^+SbF_6^-$ (0.24 g, 0.69 mmol) in 40 mL acetonitrile was stirred for 12 h. The

precipitated AgCl was removed and the bright yellow filtrate reduced in volume to 15 mL under vacuum. Addition of diethyl ether (15 mL) gave a canary-yellow precipitate, which was filtered, washed with acetone (2 × 3 mL), and dried *in vacuo* to give a bright yellow powder of analytically pure **III** (0.82 g, 82%). *Anal.* calcd. for $C_{26}H_{66}Cl_{15}N_4RuSn_5$: C 18.76, H 3.97, N 3.36; found C 18.77, H 3.86, N 3.34.

*X-ray crystallographic analysis*

A crystal of complex **I** of approximate dimensions 0.25 × 0.35 × 0.40 mm was mounted along the $a^*$ axis and coated with acrylic glue to prevent loss of solvent. Precession photography revealed orthorhombic symmetry, as well as the absences $h0l$, $l \neq 2n$, and $0kl$, $k \neq 2n$, allowing the space groups $Pmca$ or $P2_1ca$. The crystal was then transferred, in a general orientation, to an Enraf-Nonius CAD4-F diffractometer. Unit cell parameters were refined by least squares on 2 sin θ/λ values for 25 reflections measured on the diffractometer with MoK radiation (λ = 0.71069 Å). Crystal data (at 22°C) were:

$C_{32}H_{80}Cl_{16}N_4RuSn_5 \cdot C_4H_6N_2$ fw = 1864.9

Orthorhombic, $a$ = 19.796(5), $b$ = 13.882(2), $c$ = 24.772(2) Å; $V$ = 6807.5(9) Å$^3$, $Z$ = 4, $D_c$ = 1.833 g cm$^{-3}$, $D_M$ = 1.835 g cm$^{-3}$, $F(000)$ = 3640, μ(MoKα$_1$) = 27.4 cm$^{-1}$. Space group $P2_1ca$ (non-standard setting of $Pca2_1$, $C_{2v}^5$ No. 29) from structure analysis.

Intensities were measured with graphite-monochromatized MoKα radiation. An ω–2θ scan at 2.01–10.06° min$^{-1}$ was employed over a range of (0.60 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurements). Data were collected to 2θ = 50°. Three reflections (5 $\bar{2}$ $\bar{15}$), (2 0 $\bar{12}$), and (5 $\bar{4}$ 8) were used as intensity checks and measured every 3600 s, whilst the orientation of the crystal was rechecked every 100 measurements using the reflections (5 $\bar{2}$ $\bar{15}$), (5 $\bar{5}$ $\bar{11}$), and (5 $\bar{4}$ 8), with a maximum allowable deviation of any scattering vector of 0.05°.

After data reduction, an analysis of the intensity control reflections revealed a decay of ca. 18% following an X-ray exposure time of 42 h. An isotropic decay correction was applied. A total of 6587 independent reflections were measured with 4098 (62%) having intensities greater than 3σ($I$) above background ($\sigma^2(I) = S + 2B + [0.04(S - B)]^2$ with $S$ = scan count and $B$ = background count). An absorption correction using the analytical method was applied with transmission factors ranging from 0.450 to 0.541 (16).

Analysis was initiated in the centrosymmetric space group $Pmca$, on the basis of $E$-statistics and crystal density, but a three-dimensional Patterson function strongly indicated the non-centrosymmetric $Pca2_1$. The positions of six heavy metal atoms were then obtained from an $E$-map using phases generated by MULTAN (17) for 150 reflections with $E > 1.5$. The identities of the heavy metal atoms Ru ($Z$ = 44) and Sn ($Z$ = 50) were determined from chemical sense, and refinement of their thermal parameters. Subsequent least-squares refinements and difference Fourier syntheses revealed the locations of the remaining non-hydrogen atoms.

The refinement of atomic parameters was carried out using full-matrix least-squares techniques on $F$, minimizing the function $\Sigma\omega(|F_o| - |F_c|)^2$ where $|F_o|$ and $|F_c|$ are the observed and calculated structure factor amplitudes, respectively. The weighting scheme, $\omega = 1/\sigma^2(F)$ gave uniform average values of $\omega(|F_o| - |F_c|)^2$ over ranges of $|F_o|$, and was used in all stages of refinement. The scattering factors used were those of Cromer and Mann (18) for the neutral atoms except hydrogen (19). A correction for the real and imaginary components of anomalous dispersion was applied to metal and chlorine atoms (20). A least-squares refinement of all non-hydrogen atoms, with anisotropic thermal parameters for the metal and chlorine atoms and isotropic ones for the carbon and nitrogen atoms, gave $R$ = 0.041. A difference Fourier synthesis calculated at this stage failed to reveal unequivocally the hydrogen atoms, and these were subsequently included at calculated positions (assuming staggered geometry) for the four tetraethylammonium cations only (C—H = 0.98 Å). The hydrogen atoms were assigned isotropic thermal parameters 1.5 times greater than the carbon atoms to which they were attached. The parameters for the hydrogen atoms were not refined but their contributions were included in the structure factor calculations. A final three cycles of refinement, with all non-hydrogen atoms allowed anisotropic thermal parameters, resulted in convergency at $R$ = 0.035, $R'$ = 0.043 for 4098 reflections with $I \geq 3\sigma(I)$. The $R$ values are of the usual form:

$$R = \Sigma(||F_o| - |F_c||)/\Sigma F_o$$

$$R' = \{\Sigma\omega(|F_o| - |F_c|)^2/\Sigma\omega(F_o)^2\}^{1/2}$$

The mean and maximum parameter shifts corresponded to 0.03 and 0.28σ, respectively, whilst the mean error in an observation of unit weight was 1.149. A final difference Fourier synthesis revealed no residuals greater than +0.36 or less than −0.55 e Å$^{-3}$.

The final positional parameters for the non-hydrogen atoms are given in Table 1, whilst their thermal parameters appear in Table 2.[2] The calculated hydrogen atom positional and isotropic thermal parameters are given in Table 3.[2] Table 4 gives selected bond lengths and angles, and Table 5[2] the least-squares mean plane parameters of the octahedral axes. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

*Nuclear magnetic resonance instrumentation and techniques*

Spectra for $^{119}$Sn at 37.3 MHz, $^{117}$Sn at 35.6 MHz, and $^{115}$Sn at 32.7 MHz for $[Ru(SnCl_3)_5Cl]^{4-}$ were obtained on natural abundance samples ($^{119}$Sn (8.58%), $^{117}$Sn (7.61%), $^{115}$Sn (0.35%)) on a modified XL-100 nmr spectrometer using a home-built (21) 22 mm probe. Other $^{119}$Sn spectra at 37.3 MHz for $[Os(SnCl_3)_5Cl]^{4-}$ and $[Ru(SnCl_3)_5(MeCN)]^{3-}$ were obtained in 12 mm tubes again on natural abundance samples using the XL-100 nmr spectrometer in the Fourier Transform mode. The $^{13}$C nmr spectrum of the acetonitrile complex was also obtained on the XL-100 using the 22 mm probe operating at 25.2 MHz.

The $^{119}$Sn nmr spectra at 15.02 MHz were obtained on natural abundance samples in 12 mm tubes (not spun) using a modified Specialities spectrometer with a home-built crossed-coil, external water-lock probe (22). Fourier Transform of the FID was accomplished using a Nicolet 1082 FT system.

Both 5 kHz and 25 kHz spectra were acquired in order to measure all coupling constants of the species studied. The numbers of scans for $^{119}$Sn at 15.02 MHz was usually 500–600 K. For the $^{119,117}$Sn spectra measured using the 22 mm probe, this number was usually 5 K, whilst for the $^{115}$Sn spectra 116 K were required because of the very small natural abundance (0.35%).

At 15.02 MHz the digital resolution was 1.25 and 6.25 Hz, respectively, for the 5 kHz and 25 kHz sweep-widths, whilst at 37.3 MHz the corresponding resolutions were 0.63 and 3.13 Hz. Chemical shifts were all measured relative to external tetramethyltin, and are quoted as positive to high frequency.

[2]The structure factor table and Tables 2, 3, and 5 are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

*Infrared spectra*

Infrared spectra were recorded on a Perkin-Elmer 598 infrared spectrophotometer using KBr discs.

## Results and discussion

It was evident from the reproducible complexity of the $^{119}Sn$ nmr spectrum (*vide infra*) that the orange salt obtained from the reaction of $RuCl_3$ and $SnCl_2$, in a 1:6 molar ratio, could not be $[Ru(SnCl_3)_2Cl_2]^{2-}$ as formulated by Young *et al.*, at least not in solution. Such an anion should show in the $^{119}Sn$ nmr spectra one singlet, together with one set of satellites due to spin–spin coupling to $^{117}Sn$. We were prompted to study complex **I** by X-ray crystallography in the hope that knowledge of the solid state structure would be of use in understanding the solution chemistry.

*X-ray crystallographic analysis*

The asymmetric unit in the crystal structure of complex **I**, $[NEt_4^+]_4[Ru(SnCl_3)_5Cl]^{4-}\cdot 2MeCN$, consists of a discrete anion, associated with four tetraethylammonium cations and two solvent molecules of acetonitrile, all separated by normal Van der Waals distances. A stereoview of the anion (Fig. 1) shows the near idealized $C_s$ symmetry, and the crystallographic numbering system. The Ru—Sn bond lengths (Table 4) range from 2.553(2) to 2.586(1) Å, the shortest distance being associated with the tin atom *trans* to the chloride ligand. Important factors are likely to be the π-acidity and strong *trans* influence of the $SnCl_3^-$ group (23–25). In a number of structural studies of transition metal complexes containing ligated $SnCl_3^-$, a significantly shortened metal–tin bond has been noted (5, 24, 26–29) and attributed to multiplicity of the bond due to metal–tin $d_\pi$–$d_\pi$ interactions. In complex **I** the average Ru—Sn distance of 2.574 Å is considerably shorter than the values derived from the sum of the atomic radii in the respective metals 2.84 Å (30), or of their covalent radii 2.67 Å. The corresponding distances in the complexes $[Ru_2Cl_3(SnCl_3)(CO)_5]$ (24) and $[RuCl(SnCl_3)(CO)(Me_2CO)(PPh_3)_2]$ (29) are 2.565(4) and 2.5935(9) Å, respectively. The competition for the ruthenium $d_\pi$ electrons in complex **I** is more severe for the mutually *trans*-$SnCl_3$ ligands, resulting in a lengthening of these Ru—Sn bonds compared to the Ru—Sn(2) bond *trans* to chlorine.

During the course of this work, a preliminary report on the crystal structure of the analogous osmium anion $[Os(SnCl_3)_5Cl]^{4-}$ appeared (31). The average Os—Sn distance was 2.57 Å, with the shortest distance (2.53 Å) again being associated with the tin atom *trans* to chlorine. The osmium and ruthenium complexes appear to have similar molecular structures, though the lack of detailed

information on the osmium compound precludes a meaningful comparison.

Apart from a distortion along one axis, ∠Sn(5)—Ru—Sn(3) = 167.01(7)°, the coordination about the ruthenium atom is very close to octahedral (Tables 4, 5).[2] The atoms Sn(3) and Sn(5) are bent towards the chlorine atom Cl(1), in the plane defined by Ru, Sn(2), Sn(3), Sn(5), and Cl(1) (Table 5).[2] There is no similar distortion along the Sn(1)—Ru—Sn(4) axis, presumably due to steric repulsions between Cl(1) and Cl(42), and Cl(1) and Cl(13). The respective non-bonded contact distances are 3.922(6) and 3.983(7) Å, whilst in the structure as a whole, non-bonded Cl—Cl close contacts range within the $SnCl_3$ groups from 3.447(7) to 3.603(8) Å, and between groups from 3.671(7) to 4.794(7) Å.

The overall symmetrical configuration of the $SnCl_3$ groups is presumably adopted so as to

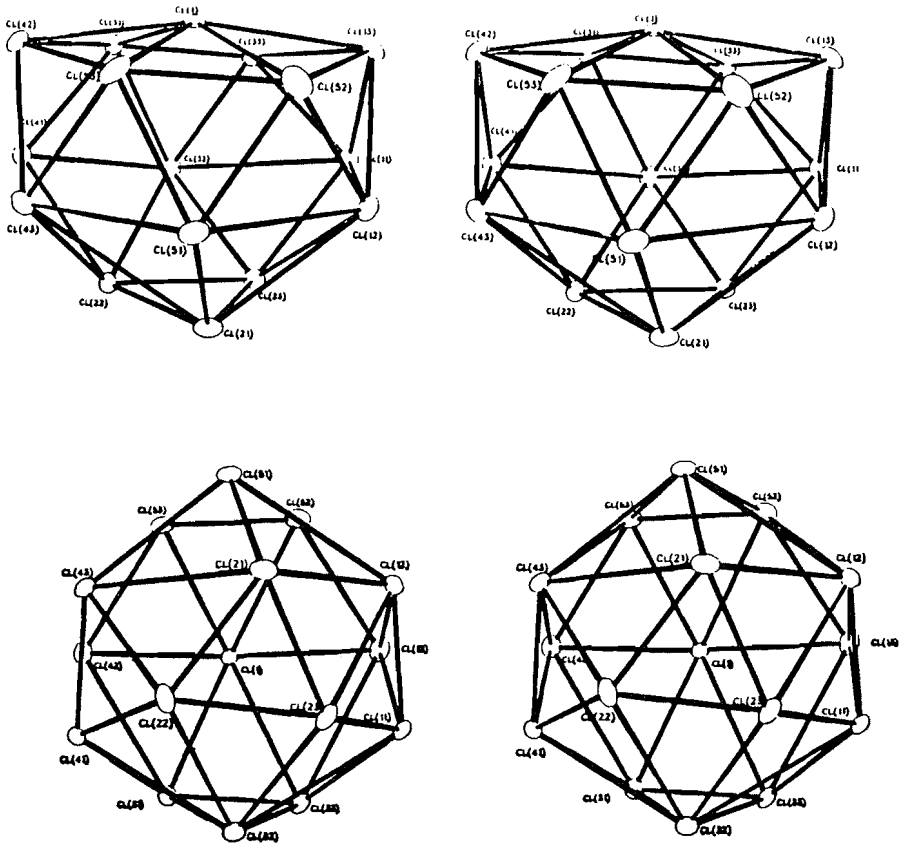

FIG. 2. Two stereoviews of the polyhedral cage of chlorine atoms (see text).

minimize non-bonded interactions between chlorine atoms. From this point of view, it is of interest to examine their arrangement in more detail. Figure 2 presents two stereoviews of the polyhedron formed by the chlorine atoms, showing only nearest neighbour non-bonded contacts. Benfield and Johnson recently reported (32) a study on the configurations of the carbonyl ligands within polynuclear carbonyl clusters. If the $[Ru(SnCl_3)_5Cl]^{4-}$ anion is viewed as a "cluster", the arrangement of the chlorine atoms (Fig. 2) is similar to that of two polyhedra discussed by these workers; Fig. 3*a* represents the most favourable way of packing sixteen identical ligands, while Fig. 3*b* shows the slightly less favourable tetracapped truncated tetrahedron. Since one of the chlorine atoms, Cl(1), in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

Fig. 2 is directly bonded to the ruthenium atom in the centre of the polyhedron, there is a distortion from ideality at this vertex, but otherwise the similarity to the polyhedra of Fig. 3 is very close, suggesting that the ideas of Benfield and Johnson may be extended to systems other than carbonyl clusters. The chlorine atom polyhedron is also similar to that described by Casey *et al.* (33) as [$T_d$-($1v^6633v^63$)-$\Delta^{28}$-*closo*] in their classification of polyboron polyhedra.

The geometry about the tin atoms shows the distortions from idealized tetrahedral symmetry in accordance with Bent's rules (34) and observed previously in related structures (28, 31); the M—Sn—Cl angles are ~10° greater than, and the Cl—Sn—Cl angles ~10° less than 109.5°. The Sn—Cl distances, which range from 2.361(4) to 2.404(6) Å, are longer than in $SnCl_4$, 2.31(2) Å (35), and may be compared with the reported values in $[Os(SnCl_3)_5Cl]^{4-}$ 2.31–2.41, ave. 2.37 Å (31). The Sn—Cl distances in uncoordinated $SnCl_3^-$ are longer still, e.g. 2.425(8)–2.447(2) Å in $[Co(diphos)_2Cl]^+[SnCl_3]^-$ (36), 2.50–2.52 Å in $Cs^+SnCl_3^-$ (37), and 2.54(3)–2.63(3) Å in $KCl\cdot KSnCl_3\cdot H_2O$ (38). We note that in **I** the shortest Sn—Cl distances are associated with Sn(2), which has the shortest Sn—Ru separation.

The Ru—Cl(1) separation of 2.468(4) Å is greater than the range of observed Ru—Cl distances with mutually *trans*-chloride ligands, 2.391–2.446 Å (39), and is presumably due to the *trans* influence of the $SnCl_3^-$ ligand, which is probably similar to that of CO (39). The complex $[RuCl(SnCl_3)(CO)(Me_2CO)(PPh_3)_2]$ with chloride *trans* to $SnCl_3^-$ has a Ru—Cl distance of 2.405(2) Å (29).

The four tetraethylammonium cations in complex **I** are all ordered, and show the expected geometry, with C—C separations ranging from 1.46(3)–1.62(4), ave. 1.51 Å, and C—N distances of 1.45(3)–1.58(3), ave. 1.52 Å. The two crystallographically independent molecules of acetonitrile exhibit large esd's for the positional and thermal parameters, as commonly found for solvate molecules. Their internuclear separations are reasonable, however, and both molecules are approximately linear.

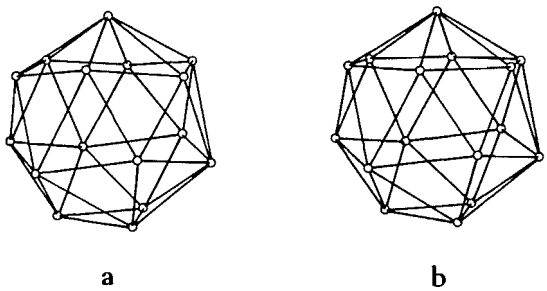

FIG. 3. Two sixteen vertex polyhedra (see text): (*a*), the most energetically favourable polyhedron; (*b*), a tetracapped truncated tetrahedron.

*Infrared spectroscopy*

Infrared spectroscopy proved to be of little use for characterization of the trichlorostannate complexes mainly due to difficulties in bond assignments, particularly in distinguishing M—Cl and Sn—Cl stretching modes (40). The coordinated nitrile in complex **III** was not observed in the expected region (~2300 $cm^{-1}$), but nmr data show the acetonitrile unambiguously (*vide infra*).

*Assignments of the tin nmr resonances*

Figures 4–6 show the $^{119}Sn$ spectra of the $[M(SnCl_3)_5Cl]^{4-}$ anions (M = Ru, Os) recorded at both 15.02 and 37.3 MHz. A knowledge of the structure of complex **I** allows for an unambiguous assignment of all the resonances. The four equivalent equatorial tin nuclei and the unique axial tin nucleus each have distinct chemical shifts (Tables 6, 7), and both resonances are flanked by satellites due to coupling to other tin nuclei. Within the set of four equatorial tin nuclei only $^{119}Sn$—$^{117}Sn$ spin–spin couplings are observable, the *trans* $^{119}Sn$—$^{117}Sn$ couplings being an order of magnitude greater than the corresponding *cis* couplings. Also observable are the couplings of $^{119}Sn_{eq}$ to both $^{119}Sn_{ax}$ and $^{117}Sn_{ax}$. Because of proximity of the chemical shifts, species containing two $^{119}Sn$ nuclei (one in the axial and the other in an equatorial position) give rise to an AB pair. The weaker outer pairs were usually not observed due to noise, but for $[Os(SnCl_3)_5Cl]^{4-}$ recorded at 37.3 MHz (Fig. 6), one of these outer pairs is clearly visible. Calculations were carried out on the AB patterns for all species and at both operating frequencies, assuming the assigned resonances for $^{119}Sn_{ax}$ and $^{119}Sn_{eq}$ and values of $J(^{119}Sn_{eq}—^{119}Sn_{ax})$ calculated from the observed $J(^{119}Sn_{eq}—^{117}Sn_{ax})$. The calculations were all in excellent agreement with the observed line separations and intensities. The resonance due to the unique axial tin is flanked by only one set of satellites due to the $^{119}Sn_{ax}—^{117}Sn_{eq}$(*cis*) coupling.

Also visible in Fig. 4 are lines due to coupling to the $^{99}Ru$ nucleus ($I$ = 5/2, 12.72% natural abundance). Of the expected six lines, four are seen in the 15.02 MHz spectrum and three in the 37.3 MHz spectrum, the missing lines being obscured by other couplings. The line separations were constant at the two observing frequencies, as expected. Figures 5 and 6 also show coupling to $^{187}Os$ ($I$ = ½,

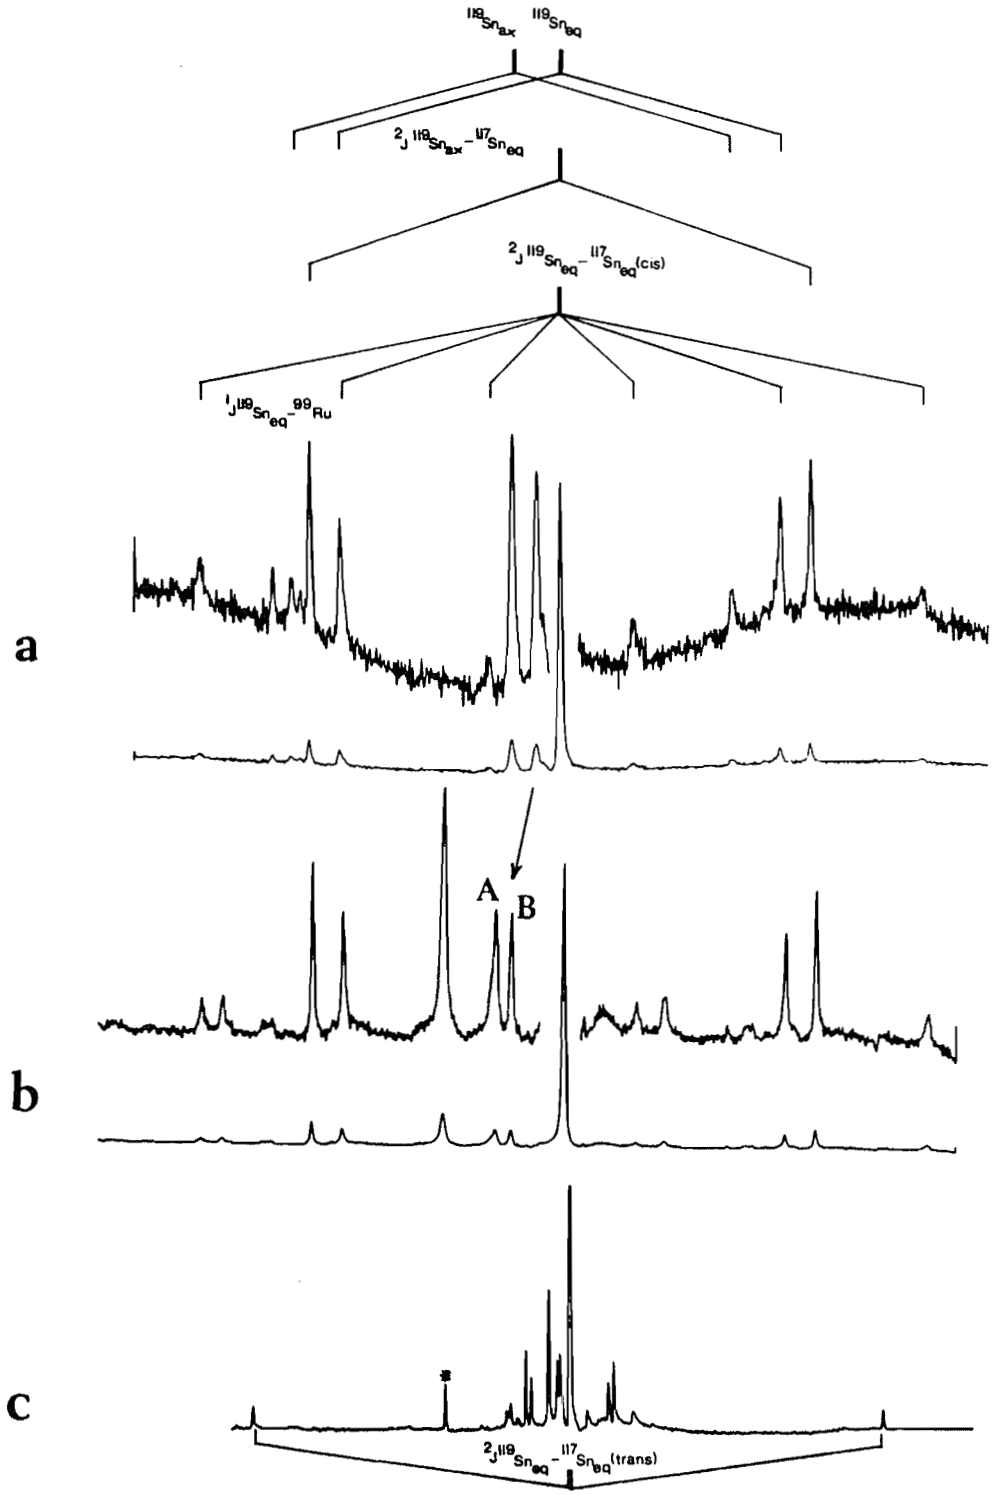

FIG. 4. $^{119}Sn$ nmr spectra of $(NEt_4)_4[Ru(SnCl_3)_5Cl]$ in nitromethane: (*a*) 15.02 MHz, 5 kHz sweepwidth; (*b*) 37.3 MHz, 5 kHz sweepwidth; (*c*) 37.3 MHz, 25 kHz sweepwidth; *impurity. A and B are the central resonances of an AB quartet (see text).

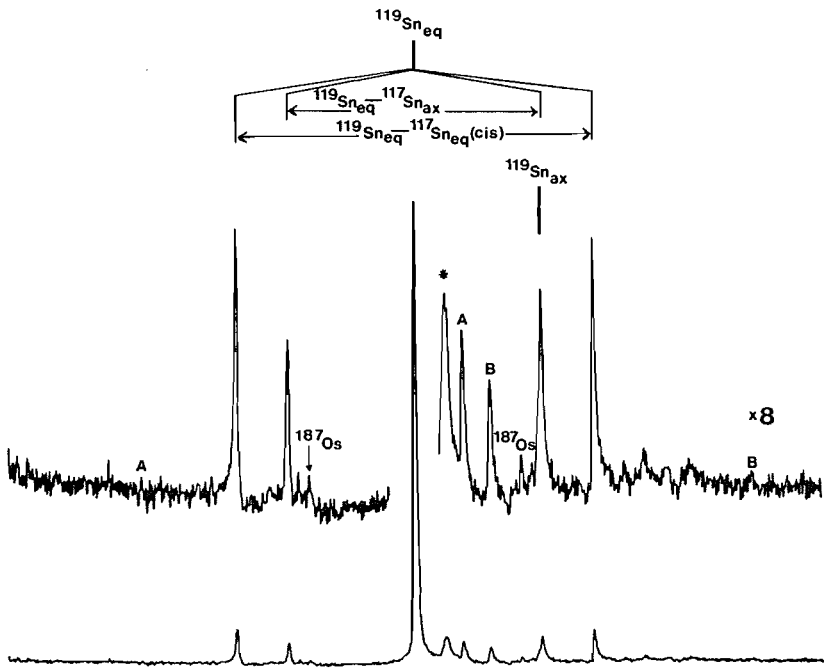

FIG. 5. $^{119}Sn$ nmr spectrum of $(NEt_4)_4[Os(SnCl_3)_5Cl]$ in nitromethane at 15.02 MHz and 5 kHz sweepwidth. AB quartet designated AABB (outer two are from calculations); *impurity.

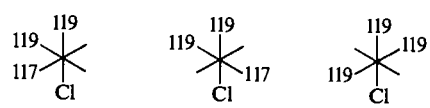
1.64% natural abundance), but otherwise the spectra of the ruthenium and osmium complexes are essentially the same.

The acetonitrile derivative $[Ru(SnCl_3)_5(MeCN)]^{3-}$, prepared by halide abstraction from complex **I** in acetonitrile, shows very similar splitting patterns to the parent complex, except that some of the couplings are less well resolved (Fig. 7). This strongly indicates a geometry analogous to that of complex **I**, and although there was no ir evidence for a C≡N stretch, $^{13}C$ and $^{1}H$ nmr data (*vide infra*) and the microanalysis reveal the presence of coordinated acetonitrile.

Finally, the spectra in the case of $[Ru(SnCl_3)_5Cl]^{4-}$ had such a high S/N ratio that resonances were observed due to extremely minor amounts of species of the type:



Calculations carried out on the assumed axial and equatorial shifts and relevant coupling constants were in excellent agreement with observed line positions, further confirming the correct assignment of these parameters.

*Chemical shifts*

The chemical shifts of the axial and equatorial tin atoms in complex **I** are very similar (Table 6), quite possibly due to the nearly perfect octahedral symmetry of the electric field gradient at the ruthenium nucleus. The corresponding $^{119}Sn$ shifts for the osmium analogue (Table 8) are towards increased shielding. This effect has been observed for a number of compounds involving third-row transition metals (41) and may arise from a decrease in the $d_\pi$–$d_\pi$ overlap between the tin and transition metal, leading to an increase in the average electronic excitation ($\Delta E$) which in turn leads to a decrease in the paramagnetic term. For the heavier third-row metal this $\pi$-interaction and/or the higher polarizability of the larger atom could lead to the low frequency shifts.

Replacement of the chloride in **I** by the less electronegative MeCN produces more shielding and the effect is felt more by the adjacent equatorial tins (97 ppm upfield) than the axial tin (45 ppm upfield), Table 8.

*Spin–spin coupling constants*

*(a) $[Ru(SnCl_3)_5Cl]^{4-}$, I*

The $^{119}Sn$ nmr spectrum reveals resonances due to a number of isotopic species, containing one to

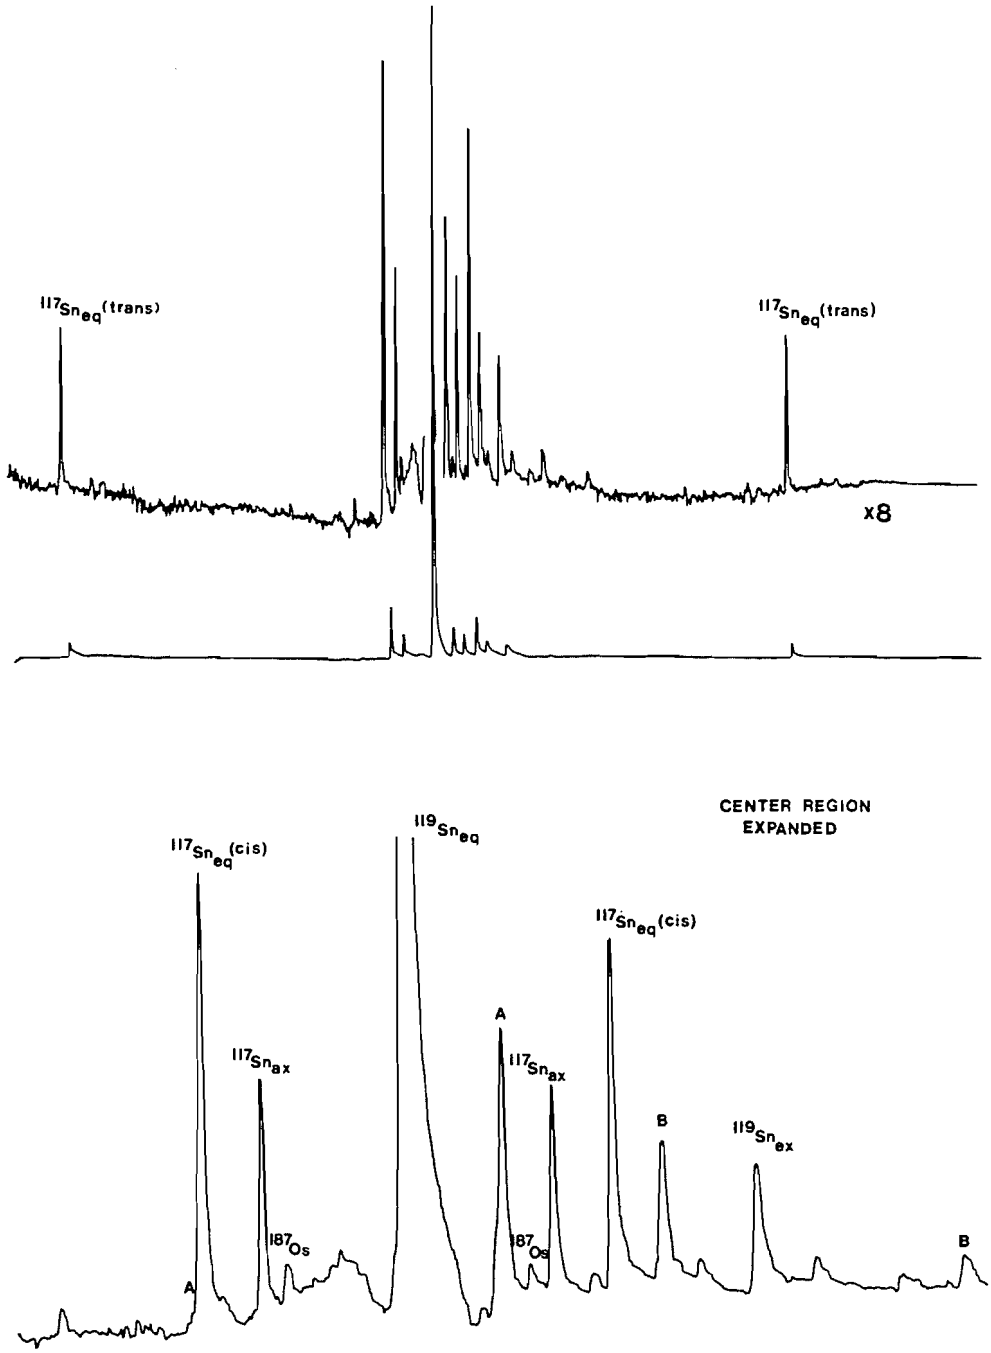

FIG. 6. $^{119}Sn$ nmr spectrum of $(NEt_4)_4[Os(SnCl_3)_5Cl]$ in nitromethane at 37.3 MHz and 25 kHz sweepwidth. AB quartet designated AABB (weak member of A set hidden under the $^{117}Sn_{eq}$(*cis*) signal).

three spin-active tin nuclei ($^{115}Sn$, $^{117}Sn$, and $^{119}Sn$ all have $I = \frac{1}{2}$). Populations of species with more than three spin-active tin nuclei were far too low to be observable. The intensities of the signals due to four equatorial and unique axial tin nuclei are not in the ratio 4:1, since other species also contribute intensity, and the observed ratio of 5.3:1 is very close to that calculated for up to three spin-active tin nuclei, possible differences in $T_1$ relaxation times not being taken into account.

The equatorial $^{119}Sn$ nuclei show three couplings which appear as doublets with $J$ values of 2580,

2934, and 21 245 Hz, that are due to the $^{119}Sn_{eq}—^{117}Sn_{ax}$, $^{119}Sn_{eq}—^{117}Sn_{eq}$(*cis*), and $^{119}Sn_{eq}—^{117}Sn_{eq}$(*trans*) interactions, respectively (Table 6). The extremely large value of $^2J(^{119}Sn_{eq}—^{117}Sn_{eq})$ *trans* is reminiscent of those observed in platinum(II)–$SnCl_3$ complexes (42). The intensity ratios of the three sets of satellites were the expected 1:2:1. The $^{119}Sn_{eq}—^{117}Sn_{ax}$ coupling of 2580 Hz is also observable as a doublet flanking the $^{119}Sn_{ax}$ resonance, i.e., as ($^{119}Sn_{ax}—^{117}Sn_{eq}$), the coupling constant being the same within experimental error. As mentioned above, the $^{119}Sn_{ax}—^{119}Sn_{eq}$ coupling is observed as an AB set at 37.3 MHz ($J(^{119}Sn_{ax}—^{119}Sn_{eq})$ = 2702 Hz, $\delta(^{119}Sn_{ax}—^{119}Sn_{eq})$ = 700 Hz).

The $^{115}Sn$ nmr spectra (Fig. 8) revealed all satellites as doublets due to coupling to both $^{119}Sn$ and $^{117}Sn$. The values of the coupling constants agree in all cases with those calculated from the gyromagnetic ratios, while the $^{115}Sn$ shifts agree quite well with those obtained from the $^{119}Sn$ and $^{117}Sn$ nmr spectra and show no sign of any isotope effect.

During analysis of the $^{119}Sn$ nmr spectrum at 15.02 MHz, it was observed (15) that the doublet caused by coupling of an equatorial $^{119}Sn$ to a $^{117}Sn$ in the *trans* position was asymmetric about the main $^{119}Sn_{eq}$ resonance, which itself results from molecules having only one $^{119}Sn$ in the equatorial position; at 37.3 MHz there was a decrease in this asymmetry. The $^{115}Sn$ nmr spectrum also showed the doublets resulting from $^2J(^{115}Sn—^{119}Sn)$*trans* and $^2J(^{115}Sn—^{117}Sn)$*trans* couplings to be asymmetric about the main resonance, the latter being more asymmetric than the former. We attribute these asymmetries to second-order effects in the heteronuclear systems. The unusually large $^2J(^{119}Sn—^{117}Sn)$*trans* coupling constant (21 248 Hz), together with $\Delta\delta(^{119}Sn—^{117}Sn)$ being 0.668 MHz for $^{119}Sn$ at 15.02 MHz, makes the supposedly "pure" AX pattern begin to show the characteristics of a second-order AB spectrum. In the $^{115}Sn$ nmr spectrum the second-order effect becomes much smaller because $\Delta\delta(^{119}Sn—^{115}Sn)$ = 4.6 MHz and $\Delta\delta(^{117}Sn—^{115}Sn)$ = 2.9 MHz at 2.35T. Calculations have been carried out for the $^{119}Sn$ and $^{115}Sn$ spectra at 2.35T, and the $^{119}Sn$ spectrum at 0.95T, to show this effect (Table 9). Following our first report of these novel second-order effects in $^{119}Sn$ nmr (15), Pregosin and Rüegger independently discovered the same phenomenon in some platinum(II) complexes (43).

The spectrum shown in Fig. 4 also reveals spin–spin coupling between $^{119}Sn$ and $^{99}Ru$ ($I$ = 5/2). The values of $^1J(^{119}Sn—^{99}Ru)$ = 846 Hz, $^1J(^{117}Sn—^{99}Ru)$ = 810 Hz, represent the first reported couplings to the quadrupolar $^{99}Ru$ nucleus. The high symmetry of the anion and the relatively low quadrupole moment, $+0.076 \times 10^{-28}$ m$^2$ (44), minimize the electric field gradient at the $^{99}Ru$ nucleus, thus reducing the quadrupolar relaxation rate and allowing observation of the spin–spin coupling constant, $^1J(^{99}Ru—^{119,117}Sn)$ ($\Delta\nu_{1/2} \simeq 60$ Hz). Coupling to $^{101}Ru$ ($I$ = 5/2; 17.07% natural abundance) with a larger quadrupole moment $+0.45 \times 10^{-28}$ m$^2$ (44) was not observed presumably because of line broadening. (The quadrupole moment ratio of ~6 implies that line-widths for $^{101}Ru$ would be about 2000 Hz.)

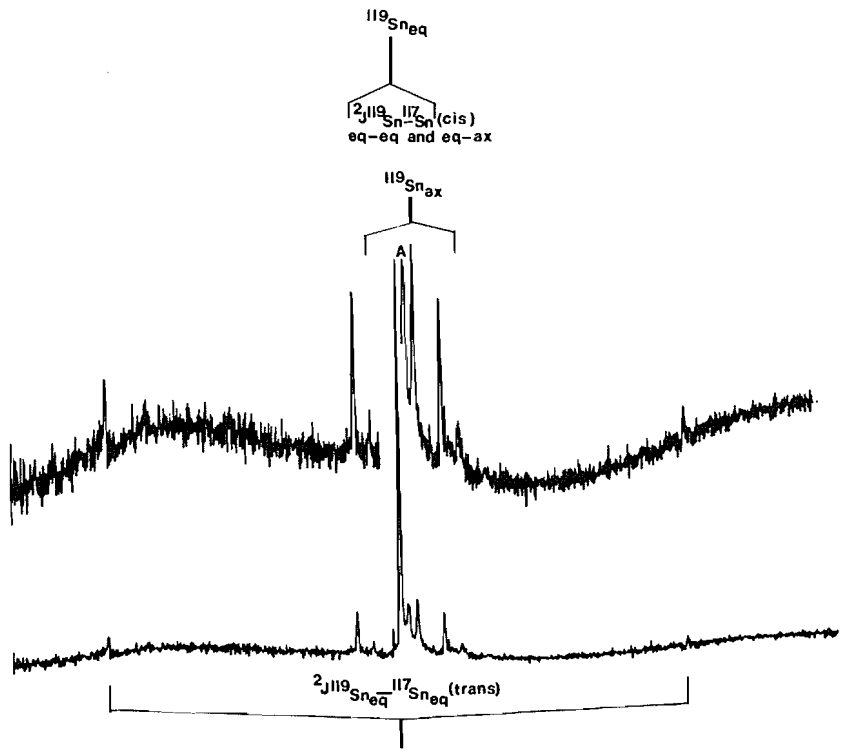

FIG. 7. $^{119}$Sn nmr spectrum of $(NEt_4)_3[Ru(SnCl_3)_5(MeCN)]$ in nitromethane at 15.02 MHz and 25 kHz sweepwidth. Resonance A due to collapsed pair of inner two members of AB pattern.

for the ruthenium analogue (Tables 6, 7), presumably due to the increase in size of the central atom. However, the same relative pattern exists, with the *trans* $^{119}Sn_{eq}$—$^{117}Sn_{eq}$ coupling being an order of magnitude larger than the corresponding *cis* coupling constants.

The large *trans* coupling again shows the second-order asymmetry effects about the main resonance, the calculated asymmetries 258 Hz (at 15.02 MHz) and 104 Hz (at 37.3 MHz) being in excellent agreement with observed values of 264 and 104 Hz, respectively.

Osmium possesses two magnetic isotopes $^{187}$Os ($I = \frac{1}{2}$, 1.64% natural abundance) and $^{189}$Os ($I =$ 3/2, 16.1% natural abundance). Careful observation (Figs. 5, 6) revealed the $^{119}Sn_{eq}$—$^{187}$Os spin–spin coupling at 15.02 and 37.3 MHz (1289 and 1290 Hz, respectively). Splitting due to $^{189}$Os is not observed presumably due to quadrupolar line broadening, $Q = 0.8 \times 10^{-28}$ m$^2$ (44).

*(c) $[Ru(SnCl_3)_5(MeCN)]^{3-}$, III*

The $^{119}$Sn nmr spectrum (Fig. 7, Table 8) reveals the same splitting patterns shown by **I** and **II**, but the couplings are less well resolved due to increased linewidths. No coupling to $^{99}$Ru is observed, whilst compared to **I** the *trans* $^{119}Sn_{eq}$—$^{117}Sn_{ax}$ coupling is reduced to 17 483 Hz. The two other couplings are almost equal (Table 8), and are only resolvable at the higher operating frequency. Heteronuclear second-order coupling effects were again observed for the large *trans* coupling, and calculated and observed asymmetries were in excellent agreement.

## Concluding remarks

Our initial studies aimed at the potential catalytic activity of ruthenium(II)–trichlorostannate(II) systems forced us into using the techniques of X-ray crystallography and tin nmr spectroscopy for characterization of the ruthenium(II) complexes. Although straightforward, the studies have revealed for the first time coupling to a $^{99}Ru$ nucleus ($I = 5/2$), very large two-bond coupling between $^{119}Sn$ and $^{117}Sn$, and the first observed second-order effects in seemingly "simple AX" systems. Studies on the solution chemistry of the ruthenium(II) complexes, particularly their interaction with carbon monoxide and hydrogen, will be reported later.

## Acknowledgements

We thank A. Brook and P. Morris for their efforts in obtaining the tin nmr spectra, Johnson Matthey Ltd. for the loan of ruthenium, and the Natural Sciences and Engineering Research Council of Canada for financial support.

# A surface tension approach to the salting-out of nonpolar nonelectrolytes

ROBERT AVEYARD
*Department of Chemistry, The University, Hull, HU6 7RX England*
Received June 23, 1981

ROBERT AVEYARD. Can. J. Chem. **60**, 1317 (1982).

A simple approach is developed for the salting-out of nonpolar molecules by strongly solvated salts. The standard free energy of transfer of solute from pure solvent to salt solution, and hence the salting coefficient, $k$, is calculated in terms of the surface tension increment caused by the addition of salt to the solvent. In its simplest form the method gives $k$ in terms of the molar volumes of solvent and solute, and the osmotic coefficient of the salt solution. It is more successful in the prediction of $k$ than the McDevit and Long theory, and it also has advantages over the more complex scaled particle theory of salt effects. In addition to a range of nonpolar solutes, the salt effects on some alcohols are also considered but application to polar solutes generally requires a knowledge of experimentally determined surface tension increments which are not widely available. The correct order of magnitude for the temperature coefficient of $k$ at room temperature for some alkanes and $H_2$ in water is given, although minima in $k$ as a function of temperature, which have sometimes been observed, are not reproduced.

ROBERT AVEYARD. Can. J. Chem. **60**, 1317 (1982).

On a mis au point une méthode simple de relargage des molécules non polaires par les sels fortement solvatés. On a calculé l'énergie libre standard de transfert du soluté à partir du solvant pur jusqu'à une solution saline, et par conséquent le coefficient de salinité, $k$, en fonction de l'incrément de la tension de surface provoqué par l'addition de sel au solvant. Dans sa forme la plus simple, la méthode permet d'obtenir $k$ en fonction des volumes molaires de solvant et de soluté et du coefficient d'osmose de la solution saline. Elle a plus de succès dans la prévision de $k$ que la théorie de McDevit et Long et elle a certains avantages sur la théorie plus complexe de la particule à l'échelle des effets de sel. En plus d'une variété de solutés non polaires, on a également considéré les effets de sel sur certains alcools; toutefois son application à des solutés polaires requiert généralement une connaissance des incréments de la tension de surface déterminés expérimentalement et ces incréments ne sont généralement pas disponibles. On donne l'ordre de grandeur réel du coefficient de température de $k$ à la température ambiante pour quelques alcanes et l'hydrogène dans l'eau bien que les minima observés quelque fois pour $k$ en fonction de la température ne soient pas reproduits.

[Traduit par le journal]

## Introduction

The effects which salts have on the activity coefficients of nonelectrolytes in solution (usually in water) have long been of interest. A large body of experimental data exists concerning these "salt effects" and much is known empirically about the way in which different salts and nonelectrolytes behave when together in aqueous solution (1, 2). The situation with regard to the theoretical treatment of the effects, however, is not entirely satisfactory (3). In general, electrostatic theories have proved unsatisfactory, and until recently a thermodynamic approach of McDevit and Long (4) has had the most success in describing experimental results. In 1969 Shoor and Gubbins (5) applied scaled particle theory to the problem, and this has, relative to the McDevit–Long formulation (MLT), had a fair measure of success (6–12). The limitations of all these approaches have been summarised by Cross (3).

In 1975, Aveyard and Heselden (13) advanced an empirical approach to salting-out based on the effect of the salt on the surface tension of the solvent. At that time, however, a knowledge of the experimentally determined surface tension increment was required for the calculation of the free energy change accompanying salting-out. Subsequent work (14, 15) has led to a clearer understanding of salt desorption from liquid surfaces and allowed the fuller and more satisfactory treatment of the surface tension approach to salting-out which is described here. The method is tested on a wide variety of systems for which experimental data already exist.

## Theory

There are various possible contributions to salt effects depending on the kind of systems involved. The present approach is for nonpolar solutes in the presence of strongly solvated salts. It will not be expected to apply in its simple form to weakly solvated salts or to polar nonelectrolytes for reasons that will be apparent.

We consider the transfer, at a given concentration in ideal dilute solution, of 1 mol of nonpolar nonelectrolyte (component 3), from pure solvent (component 1) to 1 molar salt solution. The change in standard chemical potential, $\Delta\mu^{\ominus}$, of the nonelectrolyte for this transfer was previously given as (13)

$$[1] \quad \Delta\mu^{\ominus} = N_A\Omega(\gamma - \gamma_0) = 2.3RT\log f_3 = 2.3RTk$$

where $\Omega$ is the effective surface area of the cavity required to contain a dissolved nonelectrolyte molecule, and $\gamma$ and $\gamma_0$ are the surface tensions of salt solution and pure solvent, respectively. The quantity $k$ ($= \log f_3$) is the salting-out constant in terms of which most experimental data are expressed, and $f_3$ is the activity coefficient of nonelectrolyte in the salt solution, relative to that (unity) in pure solvent. The other symbols have their usual significance. In the case of slightly soluble nonelectrolytes $k$ is usually determined as the initial slope of the plot of log solubility against electrolyte molality, although in practice such plots are almost always linear within the experimental errors, at least up to 1 molal electrolyte.

In writing eq. [1] it has been assumed that (*a*) the "surface tension" of a cavity of molecular dimensions can be taken as the macroscopic value, and (*b*) the solvent–solute interactions are the same in pure solvent and in salt solution. The former assumption is discussed later. With regard to the solvent–solute interactions it is known that strongly solvated salts are desorbed from macroscopic liquid–vapour surfaces (14, 15), and the basis of the present approach is that such salts are similarly repelled from the vicinity of nonpolar molecules in solution. This is equivalent to saying that the nonelectrolyte molecules cannot replace solvent molecules in the primary solvation sheath of an ion. Under these circumstances a solute molecule in salt solution is surrounded in its immediate vicinity by solvent molecules only, and so the predominant "solvent"–solute interactions involve only solvent molecules and not ions. For this reason solvent–solute interactions are supposed not to contribute significantly to salting-out.

The extent of the desorption of several strongly solvated 1,1-electrolytes (component 2) from a macroscopic interface between solvent and a second phase of low relative permittivity (e.g. air or alkane) can be accounted for by assuming the presence of an ion-free layer, thickness $\delta$, at the interface. On this basis it can be shown that (14)

$$[2] \quad d\gamma = c_2\delta\, d\mu_2 = -c_1\delta\, d\mu_1$$

where $\mu$ is chemical potential and $c$ is concentration (mol volume$^{-1}$). The molal osmotic coefficient, $\phi$, of salt solution, molality $m_2$, is defined by (16)

$$[3] \quad \ln a_1 = -\nu m_2 M_1 \phi$$

where $a_1$ is the molal activity of the solvent, $\nu$ the number of mol of ions per mol of salt, and $M_1$ is the molar mass (kg mol$^{-1}$) of solvent. Combination of eqs. [2] and [3] leads to

$$[4] \quad d\gamma = \nu c_1 \delta M_1 RT\, d(m_2\phi)$$

For a linear variation of $\gamma$ with $m_2\phi$, which is frequently observed (14, 15),

$$[5] \quad \Delta\gamma = \gamma - \gamma_0 = \nu c_1 \delta M_1 R T m_2 \phi$$

For $c_2 = 1$ mol dm$^{-3}$, from eq. [1], we have

$$[6] \quad k = N_A \Omega \Delta\gamma_{(c_2=1)}/2.3RT$$

so that, from eqs. [5] and [6]

$$[7] \quad k = \nu N_A \Omega \delta \phi_{(c_2=1)} (c_1 M_1 m_2)_{(c_2=1)}/2.3$$

Since $c_1 M_1 m_2 = c_2 = 1$ mol dm$^{-3}$

$$[8] \quad k = \nu N_A \Omega \delta \phi_{(c_2=1)}/2.3$$

The application of eq. [8] requires methods for the estimation of $\Omega$ and $\delta$. If we make the approximation that the solute (molar volume $V_3$) consists of close-packed spherical molecules in its pure state and assume the cavity area is equal to the surface area of the solute molecule (see Discussion), then

$$[9] \quad \Omega = \pi^{1/3}(4.44V_3/N_A)^{2/3}$$

It has been shown elsewhere (15) that $\delta$ is often approximately equal to $(r_H^+ - r_X^+)$ where $r_H^+$ is the effective radius of the solvated cation (17) and $r_X^+$ is the cation crystallographic radius. In this case

$$[10] \quad k = (\pi N_A)^{1/3}(4.44V_3)^{2/3}\nu(r_H^+ - r_X^+) \times \phi_{(c_2=1)}/2.3$$

Alternatively $\delta$ may be assumed equal to the molecular diameter $d_1$ of the solvent (15). On the assumption that the solvent (molar volume $V_1$) consists of close-packed spherical molecules in its pure state

$$[11] \quad \delta = d_1 = (4.44V_1/\pi N_A)^{1/3}$$

and combination of eqs. [8], [9], and [11] yields for a 1,1-electrolyte the very simple expression

$$[12] \quad k = 3.86 V_1^{1/3} V_3^{2/3} \phi_{(c_2=1)}$$

where the $V$ and $k$ are in m$^3$ mol$^{-1}$.

The quantities $r_H^+$ and $r_X^+$ are available for a variety of ions in water (17). Also $\phi$ values are readily available for many aqueous salt solutions (16), and we now proceed to investigate the applicability of eqs. [10] and [12], or their equivalents, to a range of systems for which experimental $k$ values have been reported.

## Comparison with experimental results

### *(a) Nonpolar solutes in water*

The experimental data referred to subsequently are taken from refs. 4, 7, 8, 13, and 18 to 22. Results for the salting-out from water of nonpolar solutes, from methane to dibenzyl, by LiCl, NaCl, and KCl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

are plotted according to eq. [12] in Figs. 1 and 2. The lines are theoretical, and the agreement for NaCl and KCl is excellent for all the solutes. For LiCl the agreement is good, with the theoretical values of $k$ being about 20% higher than experiment in most cases. It should be mentioned that MLT predicts values of $k$ which are normally high by a factor of between 2 and 3 for the kind of systems of present interest (4). Further results for 1,1-electrolytes are shown in Tables 1 and 2. The values of $\Omega$ for the gases represented in Table 1 were calculated using the equilibrium diameters, $d_{min}$, quoted by de Boer (23), and $k$ was calculated using the equation equivalent to eq. [12].

$$[13] \quad k = 0.715\nu(\pi N_A)^{2/3} d_{min}^2 V_1^{1/3} \phi_{(c_2=1)}$$

For NaCl the agreement is reasonable, the theoretical values (except for He) being low, by up to 50% in the case of Kr. The correct value is given for $H_2$. The predicted $k$ values for both He and Kr with a range of salts are also in good agreement with experiment.

In cases where $\delta$ is known from surface tension measurements $k$ may be calculated using eq. [8] and so for the gases in Table 1 we have

$$[14] \quad k = \nu N_A \pi d_{min}^2 \delta \phi_{(c_2=1)}/2.3$$

Reassuringly this procedure gives values of $k$ very similar to those from eq. [13], as shown in Table 1. The $k$ values obtained from eq. [10], or its equivalent in terms of $d_{min}$, are in some cases lower than $k$ (eq. [14]) and hence in poorer agreement with experiment.

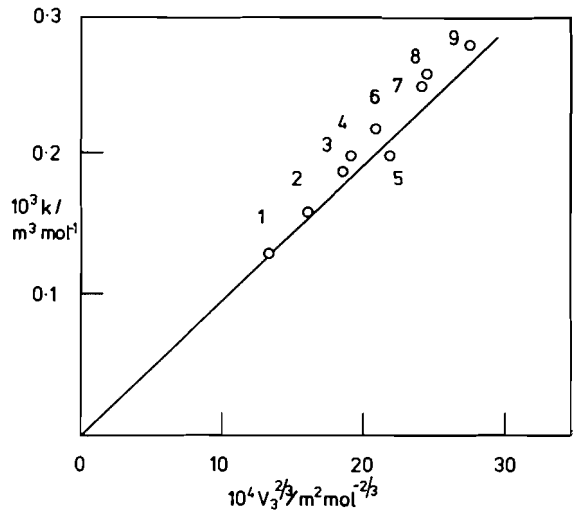

FIG. 1. Salting constants $k$ for nonpolar solutes in aqueous NaCl at 298 K. Full line according to eq. [12]; points are experimental values for *1*, methane; *2*, ethane; *3*, propane; *4*, benzene; *5*, toluene; *6*, butane; *7*, ethyl benzene; *8*, naphthalene; *9*, diphenyl. Molar volumes of methane to *n*-butane (as liquids) obtained by linear extrapolation of molar volumes of liquid alkanes pentane and upwards.

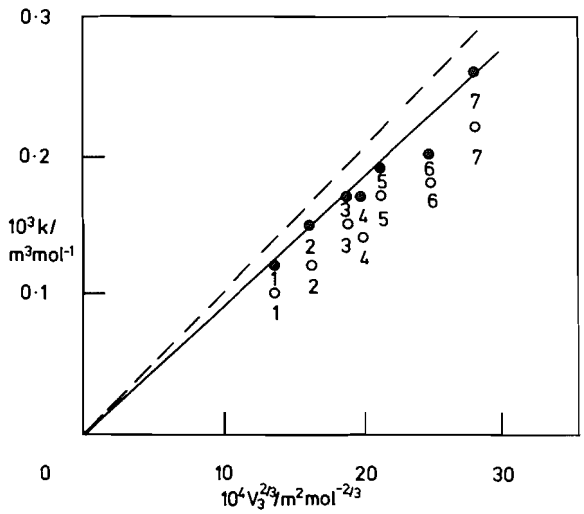

FIG. 2. Salting constants $k$ for nonpolar solutes in aqueous KCl and LiCl at 298 K. Full line and dashed line according to eq. [12] for KCl and LiCl respectively. Points (○ for LiCl and ● for KCl) are experimental values for *1*, methane; *2*, ethane; *3*, propane; *4*, benzene; *5*, butane; *6*, naphthalene; *7*, diphenyl. Molar volumes of alkanes obtained as in legend to Fig. 1.

Results for the salting-out of benzene by alkali halides are shown in Table 2. The $k$ values from eq. [12] are in most cases in very reasonable accord with experiment, the poorest agreement being for CsCl and NaI where $k$ (eq. [12]) is high by a factor of about 2. This is perhaps not surprising since NaI is not strongly repelled from the air–water surface (24), and the same is probably true for CsCl, so that it is likely that solute–ion interactions become important in these instances. Equation [10] also predicts reasonable values for $k$ relative to those given by MLT, which are also shown for comparison in Table 2.

For systems containing salts other than simple strongly solvated 1,1-electrolytes it would be optimistic to expect the simple model on which eq. [12] is based to be very successful; eq. [10] might be thought to offer a better hope. Apparently reliable data exist for the salting-out of hydrocarbons from aqueous solution by $Na_2SO_4$, $Al_2(SO_4)_3$, $NaNO_3$, $NaClO_4$, $BaCl_2$, and $LaCl_3$, and these results are now considered. Results are compared for salts other than $Na_2SO_4$ in Table 3; comparisons for systems containing $Na_2SO_4$ are given in Table 4. With reference to Table 3, eq. [10] gives remarkably good agreement with experiment. Values of $k$ obtained using $\delta$ rather than $(r_H^+ - r_X^+)$ where available, are in even better agreement except for butane with $LaCl_3$ where in any case the experimental value for $k$ at 298 K is in some doubt (19).

The poorest agreement in Table 3 is for benzene with $Al_2(SO_4)_3$; that for systems containing $Na_2SO_4$ (Table 4) is even less satisfactory. It is tempting to suggest that the discrepancies arise in some way from the surface chemical properties of the $SO_4^{2-}$ ion. The values of $(r_H^+ - r_X^+)$ for $Al^{3+}$ and $Na^+$ are 0.425 nm and 0.263 nm respectively and yet the $\delta$ values for the plane surfaces of aqueous solutions of $Al_2(SO_4)_3$ and $Na_2SO_4$ are 0.64 nm and 0.56 nm respectively. It is obvious then that these salts are repelled from the macroscopic air–water surface to a greater extent than would be indicated by the thickness of the cation solvation sheaths. The reasons for this are not known, and indeed judging from the experimental $k$ values it may be that the $\delta$ value around a microscopic cavity is even larger. It is instructive to note that the average separation between ions in a solution of a concen-

tration of 1 mol dm$^{-3}$ is only about 0.8 nm for a 1,2-electrolyte (16). If solvated anion, cation, or both are large it is not difficult to imagine that this, coupled with the requirement for electroneutrality in the "surface" region surrounding a small cavity could mean the desorption here is very different from that at a macroscopic surface. In any event it is interesting that if a $\delta$ value of 1.0 nm is assumed for $Na_2SO_4$ around a cavity excellent agreement between $k(\delta)$ and $k$(expt) is obtained in all cases for the wide range of solutes represented in Table 4.

Finally in this context we note that MLT predicts a linear dependence of $k$ on $\bar{V}_3$ for a given salt and solvent, and the partial molar volume $\bar{V}_3$ can usually, without large error, be equated to $V_3$. In contrast, eq. [12] gives $k \propto V_3^{2/3}$. It can be seen in Fig. 3 that the experimental $k$ values plotted against $V_3^{2/3}$ for the systems in Table 4 lie on a straight line passing through the origin, whereas the plot involving $V_3$ has marked curvature.

*(b) Alcohols in water*

The present approach, based as it is on the desorption of ions from the interface with a region of low dielectric constant, is clearly inappropriate for application to polar regions of nonelectrolyte molecules. However, if $\Delta\gamma$ for the salt desorption (or adsorption) at an interface between the solvent and an appropriate second polar phase is known, the salt effect on the polar group can be estimated and hence $k$ for the whole molecule obtained.

It is assumed that $k$ can be considered to be made up of additive group contributions (7). Then for the salt effect on, say, an alcohol

[15] $k = k_c + k_h$

TABLE 5. Values of $10^3\,k/m^3\,mol^{-1}$ for the salting-out of *n*-alkanols and ethylene glycol at 298 K[a]

(*a*) Sodium chloride

| | Value for solute = | | | | | | |
|---|---|---|---|---|---|---|---|
| Parameter | Methanol | Ethanol | Propanol | Butanol | Pentanol | Hexanol | Ethylene glycol |
| *k* (expt) | 0.07 | 0.12 | 0.17 | 0.19 | 0.21 | 0.23 | 0.04 |
| *k* (eq. [16]) | 0.08 | 0.11 | 0.15 | 0.18 | 0.22 | 0.25 | 0.10 |

(*b*) Sodium bromide

| | Value for solute = | | | |
|---|---|---|---|---|
| Parameter | Methanol | Ethanol | Propanol | Ethylene glycol |
| *k* (expt) | 0.06 | 0.10 | 0.13 | 0.03 |
| *k* (eq. [16]) | 0.05 | 0.07 | 0.10 | 0.06 |

(*c*) Sodium iodide

| | Value for solute = | | | |
|---|---|---|---|---|
| Parameter | Methanol | Ethanol | Propanol | Ethylene glycol |
| *k* (expt) | 0.04 | 0.08 | 0.10 | 0.01 |
| *k* (eq. [16]) | −0.02 | −0.02 | −0.03 | −0.03 |

[a]Experimental results for methanol, ethanol, propanol, and ethylene glycol are from ref. 7 and are for 25°C. For butanol, pentanol, and hexanol data from ref. 13 for 20°C are given. Small adjustments for temperature and concentration scale differences have not been made since they are insignificant in the present context. $\Delta\gamma(c_2 = 1)$ for NaCl at the decanol/water interface = 0.75 mN m$^{-1}$ (25). Corresponding values for NaBr and NaI are unknown but have been assumed equal to those for KBr and KI (0.40 and −0.55 mN m$^{-1}$ respectively) since $\Delta\gamma(c_2 = 1)$ for NaCl is equal to that for KCl. $\Delta\gamma(c_2 = 1)$ for the hydrocarbon/water interfaces are taken from ref. 14 and are 1.41 and 0.95 mN m$^{-1}$ for NaCl and NaBr respectively. The value for NaI has been taken to be equal to that, −0.07 mN m$^{-1}$, for KI.

where subscript c refers to the hydrocarbon moiety and h to the hydroxyl region. Combination of eqs. [6] and [15] gives

$$[16]\quad k = (N_A/2.3RT)(\Omega_c\Delta\gamma_c + \Omega_h\Delta\gamma_h)$$

where $\Delta\gamma$ refers to $c_2 = 1\,mol\,dm^{-3}$.

For the systems considered we have estimated $\Omega$ as follows. On the assumption of spherical close-packed molecules in the pure liquid state the molecular surface areas of methanol and ethylene glycol are 0.67 nm$^2$ and 0.81 nm$^2$ respectively. It is supposed that in each of these molecules the hydroxyl groups contribute half the surface area and the hydrocarbon the other half. In the case of the *n*-alkanols the dissolved alkyl chain has been supposed to be a square prism giving $\Omega$ per methylene group of 0.24 nm$^2$. The appropriate $\Delta\gamma$ values have been taken from desorption studies of salts from hydrocarbon–water and decanol–water interfaces (14, 25). Theoretical values of *k* calculated on this basis are compared with experiment in Table 5, where it is seen that agreement for systems containing NaCl and NaBr is remarkably good. Both $\Delta\gamma$ values (eq. [16]) for NaI are negative so the predicted *k* values are also negative, but small, whereas experimental values are small and positive.

Although this method is fairly successful it is unlikely to be of great use at present since experimental $\Delta\gamma$ are required and these are not generally available.

## Discussion

Previous workers (26–29) have used values of surface or interfacial tension to calculate the free energy of cavity formation in connection with solubilities in various kinds of system. Two obvious difficulties which arise with the application of such methods concern the possible variation of the free energy of cavity formation with curvature of the cavity surface, and the suitable choice of the effective surface of the cavity. Sinanoglu (30) has developed a theory for the estimation of the free energy of formation, $G_c$, of microscopic cavities with highly curved surfaces. The expression for $G_c$ may be written

$$[17]\quad G_c(J\,mol^{-1}) = 29.127K_1^{e}v_2^{2/3}\gamma \times \left\{1 - \left(1 - \frac{K_1^{s}}{K_1^{e}}\right)\left(\frac{\partial \ln\gamma}{\partial \ln T} + \frac{2\alpha T}{3}\right)\right\}$$

where $K_1^e$ and $K_1^s$ are quantities which modify the surface energy and entropy of planar surfaces to allow for curvature, and $\alpha$ is the coefficient of

For personal use only.

thermal expansion of the solvent. In eq. [17], $\gamma$, the solvent surface tension, is in mN m$^{-1}$ and $v_2$, the solute molecular volume, is in Å$^3$. The values for $G_c$ given by eq. [17], however, does not differ greatly from the value of $N_A\Omega\gamma$. For example, the introduction of spherical cavities of diameter 6 Å into water at 25°C using values of $K_1^s$ and $K_1^e$ calculated as described in ref. 30 with the molecular diameter of water taken as 2.75 Å, results in $G_c$ = 51.9 kJ mol$^{-1}$, whereas for the same process $N_A\Omega\gamma$ is 49.0 kJ mol$^{-1}$.

More generally it has been widely supposed that, for liquid droplets and vapour bubbles in liquids, surface tension should vary with curvature (31, 32). Thus for a spherical bubble of radius $r$ in a liquid, the equation

$$[18] \quad \gamma(\infty)/(r) = [1 - (d_1/r)]^{-1}$$

has been advanced, where $\infty$ refers to the plane surface. Equation [18] is based on thermodynamic arguments which may not be expected to hold for very small $r$, where the equation obviously breaks down. It has been suggested that the equivalent of eq. [18] for small droplets considerably overestimates the change in surface tension with curvature (33) and it is interesting that experiments on critical condensation nuclei (with radii between about 1.0 and 1.5 nm) tend to confirm this view (34). Recent work (35) involving the formation of capillary condensed liquids between crossed mica cylinders has also led to the claim that the equations of macroscopic thermodynamics are valid, and macroscopic surface tensions pertain, for highly curved surfaces, in some cases with radii as small as 5 Å.

To calculate the free energy of cavity formation it is necessary to choose the appropriate value of $\Omega$, which is obviously an ill-defined quantity for a molecular cavity. In a discussion of hydrophobic bonding Reynolds *et al.* (36) and Hermann (37) took the surface of hydrocarbon groups in contact with water as being through the centres of water molecules in contact with hydrocarbon. This choice was made because the interest was in the number of water molecules at the "interface"; it has the disadvantage that the area is not zero for a point solute molecule. Israelachvili *et al.* (38), in the calculation of the transfer free energy of hydrocarbon chains from water to hydrocarbon, on the other hand, claim that $\Omega$ should be calculated on the assumption that the surface passes through the van der Waals boundary of the methylene groups. However, the free energy change for the transfer of the —$CH_2$— group from hydrocarbon to water calculated on this basis is high, for any reasonable choice of $\Omega(CH_2)$, by a factor of about 2 (29). Clearly then, there are conceptual and practical ambiguities in the application of ideas appropriate for macroscopic systems to microscopic systems, and the present approach to salting-out must, for the time being, be regarded as semi-empirical at best. It is worth noting, however, that the method only requires that *changes* in free energy of cavity formation on salt addition be correctly given by $\Omega\Delta\gamma$. It is, of course, possible that both $\Omega$ and $\Delta\gamma$ are incorrectly chosen but that their product is correct as a result of the fortuitous cancellation of errors.

An alternative method for the calculation of the free energy of cavity formation is to use the scaled particle theory (SPT) (39). Pierotti has employed SPT to calculate the thermodynamic parameters of solution of nonpolar gases in nonpolar solvents (40) and in water (41), although some aspects of this procedure have been questioned (42, 43). Subsequently Shoor and Gubbins (5) advanced a theory of salt effects on nonpolar nonelectrolytes using SPT, which was developed further by Masteron and Lee (6). Since then several sets of workers have used the approach for both polar and nonpolar solutes and for systems containing tetraalkylammonium ions (7–13).

In the application of SPT to salt effects it is supposed that ions and solvent molecules are randomly distributed around dissolved nonelectrolyte molecules and so changes in solvent–solute interactions accompanying solute transfer must be allowed for. This gives rise to a contribution, $k_i$, to $k$; the contribution from cavity transfer is denoted $k_{cav}$. In the surface tension method $k_i = 0$ so that clearly the two approaches are based on different assumptions.

For NaCl, SPT is successful for small nonpolar solutes but less so for larger molecues such as benzene, the disagreement between experiment and theory being supposed to arise from the magnitude of the calculated ion–solute interactions (6, 8). The present method, on the other hand, is very successful for NaCl with both large and small solute molecules (see Fig. 1). It is interesting that even for small solute molecules such as methane, $k_i$ makes a substantial contribution to $k$ in SPT so that although both approaches give agreement with experiment, the cavity terms are substantially different (see Table 6).

An alternative statistical mechanical approach to salt effects has been advanced by Friedman and co-workers (44, 45). Experimental values of $k$ can

be considered to be made up of additive contributions from ions of the electrolyte (1), and this feature is brought out by Friedman's theory. We cannot say if the surface tension approach reflects this however, since it is not clear from the available data if $d\gamma/dm_2$ is ion additive or not. Further, ion additivity in $k$ suggests that $Li^+$ salts out a given nonelectrolyte less strongly than $Na^+$ and sometimes less than $K^+$. Values of $k$ calculated from the present approach do not reflect this (Table 2) even though eq. [10] (but not eq. [12]) might have been expected to be successful in this respect.

An interesting but tentative conclusion arising from Friedman's work is that it appears possible from the generally negative signs of the ion–nonelectrolyte Gurney parameters (i.e. the free energy change per mol of solvent displaced from the solute cospheres due to overlap) that the nonelectrolyte molecules may penetrate the ion cospheres. In contrast the basis of the surface tension approach is that nonelectrolyte and ions are always separated by the ion solvation sheath, for the kind of systems considered.

A final point from Friedman's work which is relevant in the present context is the way in which $k$ varies with the nonelectrolyte molar volume for a given electrolyte. For 1,1-electrolytes the statistical mechanical approach gives $k$, in the limit of low concentration of salt and nonelectrolyte, as the sum of the osmotic virial coefficients B (volume per mol) for interactions between nonelectrolyte and each of the ion species. The surface tension approach suggests that $k$ is linearly related to the surface area of the nonelectrolyte molecule and hence to $V_3^{2/3}$ (eq. [12]; Figs. 1–3). There appears to be no theoretical basis for supposing that, for a given salt with a series of nonelectrolyte molecules, the sum of the ion–molecule virial coefficients should vary linearly with the molecular surface area, although in practice such an approximate relationship could exist.

The prediction of the temperature variation of $k$ is a much more stringent test of theory than the prediction of $k$ at a single temperature. Enthalpies of transfer of various solutes from water to aqueous solutions of tetraalkylammonium bromides have been calculated by Lucas and Feillolay using SPT with qualitative, and in some cases quantitative success (11, 12), while Desrosiers and Desnoyers have obtained enthalpies of transfer of $Bu_4N^+$ ions from water to mixed aqueous solvents (9). Aveyard and Heselden (13) calculated enthalpies for the salting-out of some alkanols by NaCl obtaining reasonable agreement between experiment and theory. More recently Cross and McTigue (46) have calculated the temperature variation of $k_c$ using SPT but the interaction parameters for various alkyl acetates and (mainly) alkali halides were then obtained by subtraction of the cavity contributions from experimentally determined values. The SPT does not, however, appear to have been used to calculate the temperature dependence of $k$ for the simple kind of systems which are the main concern of this paper.

On the basis of the surface tension approach we have from eq. [1]

$$[19]\quad \frac{\partial k}{\partial T} = -\frac{N_A \Delta\gamma \Omega}{2.3RT^2} + \frac{N_A}{2.3RT} \times \left\{\Omega\left(\frac{\partial \Delta\gamma}{\partial T}\right) + \Delta\gamma\left(\frac{\partial \Omega}{\partial T}\right)\right\}$$

Also from standard thermodynamics

$$[20]\quad \frac{\partial k}{\partial T} = -\frac{\Delta h^\ominus}{2.3RT^2}$$

so that from eqs. [1], [19], and [20]

$$[21]\quad \Delta s^\ominus = -N_A\left\{\Omega\left(\frac{\partial \Delta\gamma}{\partial T}\right) + \Delta\gamma\left(\frac{\partial \Omega}{\partial T}\right)\right\}$$

where $\Delta h^\ominus$ and $\Delta s^\ominus$ are respectively the standard enthalpy and entropy of solute transfer. The quantity $(\partial\Delta\gamma/\partial T)$ is not known for many systems but for NaCl in water it is effectively zero at around room temperature (24). The coefficient $(\partial\Omega/\partial T)$ cannot be calculated with certainty; for methane in water, solute partial molar volumes have been obtained by dilatometry (see ref. 47) at 0 and 50°C, and from these data $(\partial\Omega/\partial T) \simeq 5 \times 10^{-4}\ \mathrm{nm^2\ K^{-1}}$. The contribution to $(\partial k/\partial T)$ from this source is therefore about $+1 \times 10^{-4}\ \mathrm{dm^3\ mol^{-1}\ K^{-1}}$. For the same system the term $-(N_A\Delta\gamma\Omega/2.3RT^2)$ at 298 K is about $-5 \times 10^{-4}\ \mathrm{dm^3\ mol^{-1}\ K^{-1}}$. In this case, and we believe for the other systems (at 298 K) mentioned below, we may therefore write the approximation

$$[22]\quad \frac{\partial k}{\partial T} \simeq -\frac{N_A \Delta\gamma \Omega}{2.3RT^2}$$

In writing eq. [22] we are thus assuming $\Delta s^\ominus$ is negligible. It is interesting that the entropy of cavity transfer from water to aqueous NaCl as calculated by SPT (46) is also about zero.

In Fig. 4 some $k$ values, experimentally determined over a range of temperature, are compared with those calculated from eq. [1] assuming $\Omega$ and $\Delta\gamma$ to be constant. The agreement is moderately good but the calculated $(\partial k/\partial T)$ (eq. [22]) are

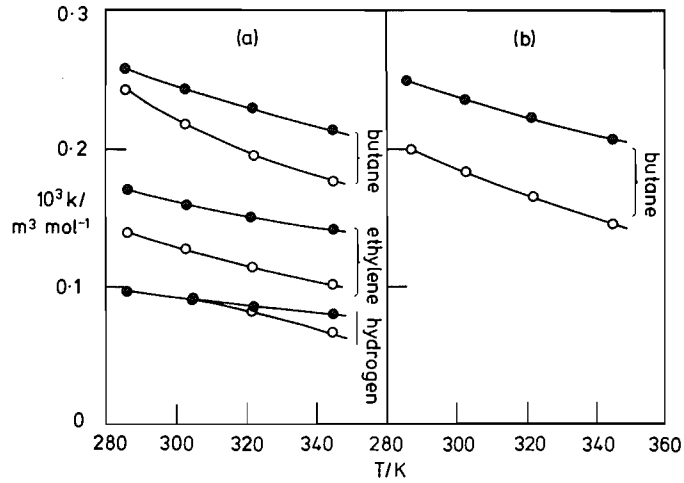

FIG. 4. Salting constants as a function of $T$. (*a*) NaCl, (*b*) KCl. ●, from eq. [1], ○, experimental.

smaller in all instance than the experimental temperature coefficients. Clearly, eq. [1] will not reproduce minima in $k$ versus $T$ plots which have been observed in some cases (48), but it may be that the inclusion of correct values of the terms in $(\partial\Delta\gamma/\partial T)$ and $(\partial\Omega/\partial T)$ in eq. [19] would lead to a prediction of the minima.

## Conclusions

(*1*) The present approach is expected to apply to nonpolar solutes and strongly solvated salts in any solvent, including water.

(*2*) For such systems the method is generally considerably more successful in the prediction of $k$ than the theory of McDevit and Long.

(*3*) The proposed model differs from that assumed in the scaled particle treatment; in particular in the former, ions are supposed to be absent from the immediate surroundings of a solute molecule and so solute–solvent interactions do not contribute to the calculated $k$. The surface tension approach is at least as successful as SPT for appropriate systems and appears to be superior for large solutes.

(*4*) The SPT, though elegant, is not easy to apply unambiguously since the required parameters are not always known with sufficient accuracy. In particular the selection of reliable Lennard–Jones parameters ($\varepsilon$ and $\sigma$) for the solute can be troublesome, and calculated $k$ values are very sensitive to the choice of ion diameters. In contrast, in its simplest form, the surface tension method requires only a knowledge of solvent and solute molar volumes, and of osmotic coefficients.

(*5*) The correct sign and order of magnitude are given for the temperature coefficient of $k$ although eqs. [1] and [22] do not predict minima in $k$ as a function of $T$. It is possible that the full form (eq. [19]) would be successful in this respect.

The simplicity and apparent success of the present approach bring to mind Rothschild's Law (49): "To any problem, no matter how difficult, there is a simple solution if you will only search for it. This solution will turn out to be wrong."

Received August 20, 1981[2]

ANGELA M. CELLI, LUCIA R. LAMPARIELLO, STEFANO CHIMICHI, RODOLFO NESI, and MIRELLA SCOTTON. Can. J. Chem. **60**, 1327 (1982).

The new substituted cyclohexane- and cyclohexene-1,3-diones **3–6** and **9**, **10**, respectively, have been synthesized from tetraacetylethylene **1**, through a ring expansion of the cyclopentenone **2**. The structures of these products, as well as some features of their tautomeric behavior, were established on the basis of chemical properties and spectroscopic data.

ANGELA M. CELLI, LUCIA R. LAMPARIELLO, STEFANO CHIMICHI, RODOLFO NESI et MIRELLA SCOTTON. Can. J. Chem. **60**, 1327 (1982).

On a synthétisé les nouvelles cyclohexane- et cyclohexènediones-1,3 (**3–6** et **9** et **10**), à partir du tétraacétyl-éthylène **1** en faisant appel à une extension du cycle de la cyclopenténone **2**. On a établi la structure de ces composés, aussi bien que quelques caractéristiques de leur comportement tautomère, en s'appuyant sur leurs propriétés chimiques et de données spectroscopiques.
[Traduit par le journal]

Tetraacetylethylene (TAE) **1** has proven to be a quite versatile intermediate for different heterocyclic systems such as furans, pyrans, furo[2,3-*b*]-furans, cyclopenta[*b*]pyrans, pyridazino[4,5-*d*]-, and furo[3,4-*d*]-pyridazines (1–4). In order to ascertain the possibility of employing the same product for the synthesis of carbocyclic derivatives, we carried out some experiments the results of which we report here.

Treatment of TAE in aprotic solvents with a catalytic amount of a base such as 1,5-diazabicyclo[4.3.0]non-5-ene (DBN) or sodium acetate, formed a high yield of cyclopentenone **2** together with a small amount of a dimer, from which the former was separated by column chromatography. The structure of compound **2** followed from analytical and spectral evidence (see Experimental and Table 1).

The possibility of obtaining substituted cyclopentenones seemed very attractive in view of the considerable effort devoted in recent years to the synthesis of these products, potential intermediates for several biologically active compounds (5).

Treatment of **2** with aqueous sodium hydroxide afforded, after acidification, a high yield of a mixture of isomers ($C_{10}H_{14}O_5$) in a ratio 4:1 (mp 108–110°C and 124–126°C respectively). These were formulated as epimeric 2-acetyl-4,5-dihydroxy-4,5-dimethylcyclohexane-1,3-diones **3** and **4** on the basis of their spectroscopic and chemical behavior. The same mixture was also obtained through compound **2** (easily identified by $^1$H nmr monitoring of the reaction) under the same conditions with TAE as starting material. The ir spectra of these products, for which the tautomeric structures **3***a–e* and **4***a–e* are possible in principle, exhibit, besides bands at ca. 3460 and 3440 cm$^{-1}$ (2 × OH) and 1670 cm$^{-1}$ (CO), a very broad diffuse absorption between 3600 and 2400 cm$^{-1}$ and a broad band at about 1570 cm$^{-1}$ which were assigned to a conju-
