Received June 25, 1981

DAVID P. RAINVILLE and JAMES H. WEBER. Can. J. Chem. **60**, 1 (1982).

The dialysis method of metal ion speciation is investigated as a technique to determine complexing capacities of soil fulvic acid (SFA) towards $Cu^{2+}$, $Cd^{2+}$, $Mn^{2+}$, $Ni^{2+}$, and $Zn^{2+}$, between pH 5 and 7. The complexing capacity values for each metal ion usually increase as pH increases. At the same pH the values for $Cd^{2+}$, $Mn^{2+}$, $Ni^{2+}$, and $Zn^{2+}$, are similar, but $Cu^{2+}$ values are significantly higher. The results are interpreted on the basis of a model involving the aggregation of SFA by metal ions, especially $Cu^{2+}$.

DAVID P. RAINVILLE et JAMES H. WEBER. Can. J. Chem. **60**, 1 (1982).

On a étudié la méthode de dialyse des ions métalliques comme technique de détermination des capacités de complexation des acides fulviques du soil (AFS) par rapport aux ions $Cu^{2+}$, $Cd^{2+}$, $Mn^{2+}$, $Ni^{2+}$ et $Zn^{2+}$ à un pH compris entre 5 et 7. La valeur de la capacité de complexation de chaque ion métallique augmente généralement avec le pH. Pour un même pH, les valeurs pour les ions $Cd^{2+}$, $Mn^{2+}$, $Ni^{2+}$ et $Zn^{2+}$ sont semblables, mais elles sont nettement plus élevées dans le cas de l'ion $Cu^{2+}$. On interprète ces résultats en se basant sur un modèle qui implique l'agrégation du AFS par les ions métalliques et plus spécialement par l'ion $Cu^{2+}$.

## Introduction

Increasing public awareness of our environment and the effects of pollutants on it emphasizes a need for additional knowledge about the interaction of metal ions with aquatic humic materials. A variety of methods has been described and utilized to determine the complexing capacity ($C_L$) of both isolated humic matter and humic matter dissolved in natural water systems. These techniques must allow the differentiation of free metal ion species from complexed metal ions without disturbing the equilibrium under study. In a previous paper Truitt and Weber (1) discussed these methods in relation to the determination of complexation capacities of humic materials toward metal ions. Additionally, a recent review (2) has discussed and evaluated critically a variety of metal speciation techniques relevant to the determination of complexing capacities of isolated humic materials and natural water samples.

This paper describes the determination of the complexing capacity of soil fulvic acid (SFA) for $Cu^{2+}$, $Cd^{2+}$, $Mn^{2+}$, $Ni^{2+}$, and $Zn^{2+}$ at various pH values. SFA is a complex mixture of ligands containing phenolic and carboxylic metal binding functional groups. The dialysis titration technique (1) used to determine complexing capacity has a major advantage over other techniques (2). Biological (3), ion selective electrode (4), voltammetric (5), and fluorescence spectrometry (6) techniques all exclude some metal ions of interest. For example, fluorescence quenching studies are most effective for paramagnetic metal ions. In order to study a series of first transition series divalent metal ions and $Cd^{2+}$ we separated free and total metal ions by a dialysis membrane and determined them by atomic absorption spectrometry (AAS). Examination of the complexing capacity results led to a model which involves aggregation of molecules in the SFA mixture induced by metal ions.

## Experimental

*General methods*

Containers used in these experiments were acid washed by soaking in 10% $HNO_3$, and rinsing with distilled, deionized water prior to use.

Solutions were prepared from distilled, deionized water and analytical grade reagents. The soil fulvic acid (SFA) was isolated and characterized by Weber and Wilson (7). The metal ion standard solutions were prepared from Fisher 1000-ppm atomic absorption standard solutions in polypropylene volumetric flasks using disposable polycarbonate tipped pipets.

Dialysis membrane tubing used to prepare dialysis bags (1000 molecular weight cutoff-Spectra/Por 6) and closures were purchased from Spectrum Medical Industries, Los Angeles, CA. They were cleaned prior to use by a procedure already described (1).

Metal ion solutions were acidified by addition of 5 μL of concentrated nitric acid per mL of solution and stored in polypropylene vials prior to atomic absorption spectrometry (AAS) determinations on a Tectron AA5 Spectrometer with less than 3% error. Concentrations of these solutions were determined by a reference to absorbances of standard metal ion solutions. Ultraviolet–visible spectra were recorded on a Cary 14 Spectrophotometer. Solutions were monitored for pH using an Orion Research Model 701A pH potentiometer and a Corning Ag/AgCl glass pH electrode calibrated using buffer solutions.

*Determination of complexing capacity by dialysis*

The complexing capacity of each 10 mg/L SFA aqueous solution was determined by dialysis against an internal 0.001 *M*

$KNO_3$ solution, because 0.001 *M* $KNO_3$ and 10 mg/L SFA solutions have similar ionic strength (8).

To determine the complexing capacity of 10 mg/L SFA solutions toward a metal ion a series of bottled samples (usually 15) was prepared as follows. A strip of dialysis membrane tubing approximately 15 cm in length was tied off at one end with a Teflon string, filled with 10 mL of 0.001 *M* $KNO_3$ solution, and then sealed with a dialysis membrane tubing closure at the other end. The dialysis bag was then placed in a 250 mL polypropylene bottle containing 200 mL of a 10 mg/L SFA solution. All but one sample were then titrated with a volume of a standard metal ion solution so that total metal ion concentrations ranged from 0 to 10 mg/L. After addition of the standard metal ion solutions, the pH of each bottle was adjusted to the proper value by addition of small volumes of 0.1 *M* KOH or 0.1 *M* $HNO_3$. The bottles were then shaken for 48 h with the pH of each bottle being periodically checked for and maintained at the proper value. After the 48 h period, the bottles were sampled. The metal ions in the internal solution within the dialysis bag are considered free since the dialysis bag with its 1000 molecular weight cutoff prevents the migration of most SFA molecules and corresponding complexed metal ions into the dialysis bag (1). The metal ions in the solution external to the dialysis bag are both free and complexed. Since the ratio of the volume of the external solution to the internal solution is 20/1, the external volume approximates the total volume. Thus, metal ion determinations inside the dialysis bag represent free metal ion and those outside the bag are total metal ion. The total metal ion concentration was measured rather than using the calculated values since some metal ions may have been adsorbed onto the containing vessel and dialysis bag.

Figure 1, which for clarity shows only part of the $Cu^{2+}$ pooled data at pH 5 and 6, exemplifies our results. A plot of total metal ion concentration versus free metal ion concentration yields a titration curve which has two linear branches. The lower branch of early data has a slope essentially equal to zero, while the upper branch of data after the titration endpoint is markedly sloped. The complexing capacity ($C_L$) is the *x*-axis intercept of the upper branch as determined by the linear least-squares method.

This procedure was used to determine $C_L$ values of 10 mg/L SFA for $Cu^{2+}$, $Cd^{2+}$, $Mn^{2+}$, $Ni^{2+}$, and $Zn^{2+}$ at pH 5, 6, and 7; and $Cd^{2+}$ at pH 8. In addition $C_L$ values of 0.001 *M* $KNO_3$ for $Cu^{2+}$ were determined at pH 5, 6, and 7 using this procedure (Table 1).

*Determination of the dialysis membrane permeability to $Cu^{2+}$ as a function of time*

The permeability of the 1000 molecular weight cutoff dialysis membrane to $Cu^{2+}$ at pH 5 and 7 in the presence of SFA was determined as a function of time. Typically 2.0 L of either 10 mg/L SFA – 0.001 *M* $KNO_3$ or 10 mg/L SFA – 0.01 *M* $KNO_3$ solutions containing 3.0 mg/L $Cu^{2+}$ (47 μ*M*) were dialyzed against 100 mL of 0.001 *M* or 0.01 *M* $KNO_3$ contained within a dialysis bag 1 m in length. The $Cu^{2+}$ was added on dissolution of SFA or 48 h later. The pH of all internal and external dialysis solutions was adjusted to the desired value by addition of small amounts of 0.1 *M* KOH or 0.1 *M* $HNO_3$. These solutions were stirred by a magnetic stirrer and 5 mL aliquots of internal and external dialysis solutions were withdrawn periodically. The solutions were analyzed for free [$Cu^{2+}$] as a function of time elapsed since addition of $Cu^{2+}$.

*Determination of the dialysis membrane permeability to SFA*

The SFA permeability of the dialysis membrane was determined for the 48 h time period used in the complexing capacity experiment. This was done by dialyzing a 200 mL 10 mg/L SFA solution against a 10 mL 0.001 *M* $KNO_3$ solution at pH 5, 6, and 7. After 48 h 5 mL aliquots of the internal dialysis solutions were withdrawn. The 290 nm absorbance values were obtained and compared to pH 5, 6, and 7 SFA calibration curves (1).

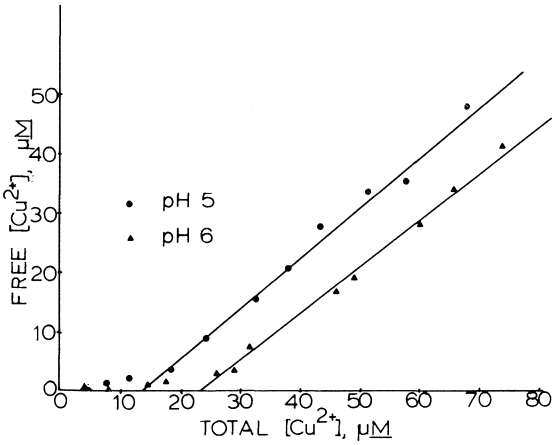

FIG. 1. Sample complexing capacity titration curve, $Cu^{2+}$ at pH 5 and 6.

## Results and Discussion

The complexing capacity ($C_L$) of fulvic acid is defined as its ability to complex free metal ions. In this paper we determined the complexing capacities of well-characterized SFA (7) by dialysis of 10 mg/L SFA – metal ion solutions against 0.001 *M* $KNO_3$. The low [SFA] is similar to that in freshwater samples. We assume that AAS metal ion determinations of internal and external solutions afforded the free metal ion and total metal ion concentrations respectively. The validity of this assumption requires (*1*) that the dialysis membrane effectively excludes complexed metal ions and uncomplexed ligands from the internal solution, and (*2*) that uncomplexed metal ion diffusion through the dialysis membrane is unhindered so that uncomplexed or free metal ion levels are the same in the internal and external solutions. Researchers demonstrated these two points in previous dialysis studies (1, 9–13) and we will prove them valid in the present work.

*Dialysis membrane permeability to SFA*

To test the permeability of the dialysis membrane to SFA we determined the internal/external ratio of SFA absorbance. The ratios determined after 48 h dialysis periods were 14% at pH 5, 4.8% at pH 6, and 3.2% at pH 7. These values are much lower than those of previous 30 day dialysis studies (1). The 48 h dialysis experiments have a major advantage over the 30 day analogs, because metal ions in complexes that permeate the dialysis membrane are considered "free". The net result is that metal complex permeation leads to erroneously low $C_L$ values.

TABLE 1. Complexing capacities ($\mu M$) and slopes for titrations of 10 mg/L soil fulvic acid and 0.001$M$ $KNO_3$ by metal ions[a]

| | pH 5 | | pH 6 | | pH 7 | | pH 8 | |
|---|---|---|---|---|---|---|---|---|
| $M^{2+}$ | $C_L$ | Slope | $C_L$ | Slope | $C_L$ | Slope | $C_L$ | Slope |
| $Cd^{2+}$ | 5.5 | 0.99 | 10.6 | 0.94 | 9.7 | 0.81 | 9.5 | 0.75 |
| $Mn^{2+}$ | 5.2 | 1.02 | 4.8 | 0.94 | 11.6 | 0.94 | | |
| $Ni^{2+}$ | 5.2 | 0.96 | 4.8 | 0.74 | 9.4 | 0.83 | | |
| $Zn^{2+}$ | 0 | 0.95 | 10.2 | 1.08 | 11.8 | 1.09 | | |
| $Cu^{2+}$ | 10.8 | 0.84 | 20.3 | 0.62 | 14.2[d] | 0.24[d] | | |
| $Cu^{2+,b}$ | 0.6 | 0.99 | [c] | 0.92 | [c] | 0.94 | | |

[a] Values obtained by combined linear regression of replicate experiments. At the 90% confidence level the uncertainty is ±8% in slopes and ±15% in $C_L$ values.
[b] Values in 0.001 $M$ $KNO_3$ in absence of soil fulvic acid.
[c] Small, negative value due to experimental error.
[d] This experiment has a large error of ca. 50% in slope and 100% in $C_L$ value.

The error in $C_L$ is not as large as suggested by the absorbance of the internal solution. Templeton and Chasteen (14) found that gel filtration chromatographic separation of our SFA sample produced 91% by weight of larger molecules and 9% of smaller molecules. Furthermore, electron paramagnetic resonance complexation studies revealed that the conditional stability constants of smaller molecules are only 2% that of the larger molecules. In addition Truitt and Weber (1) demonstrated by fluorescence studies that in the absence of metal ions 9% of $Cu^{2+}$ complexing capacity of a 40 mg/L SFA solution permeated the dialysis membrane at pH 5. The 9% value is a high estimate because SFA species increase in size as pH increases (14) and when metal ions are added (1).

*Dialysis membrane permeability to $Cu^{2+}$ in the absence of SFA*

After 48 h the internal and external [$Cu^{2+}$] for 0.001 $M$ $KNO_3$ solutions at pH 5, 6, and 7 are equal. This result means that all $Cu^{2+}$ species, including ones such as $Cu_2(OH)_2^{2+}$ and $Cu(OH)^+$ (15) that might be in the solutions at higher pH, freely permeate the dialysis membrane. The $Cu^{2+}$ species membrane permeability at pH 5 to 7 is important for the future discussion of $Cu^{2+}$ complexation results in that pH range.

*Dialysis membrane permeability to $Cu^{2+}$ as a function of time*

Solutions containing 10 mg/L SFA and 3.0 mg/L $Cu^{2+}$ (47 $\mu M$) were dialyzed against 0.001 $M$ or 0.01 $M$ $KNO_3$ as internal [$Cu^{2+}$] was monitored as a function of time. Some dialysis solutions were prepared and 3 mg/L $Cu^{2+}$ added immediately. Then internal [$Cu^{2+}$] rose rapidly, reaching a maximum after 1.5 h, and then decreased to an equilibrium value within 12 h. In the second experiment, we waited 48 h for equilibrium to occur between the external SFA solution and the internal 0.001 $M$ $KNO_3$ solution before adding $Cu^{2+}$. The [$Cu^{2+}$] rose gradually over 20 h to a maximum level in contrast to the experiment where no equilibrium period was employed. We attribute these observations to minute differences in the ionic environment of the SFA and $KNO_3$ solutions. Additional experiments at pH 5 and 7 in which a 10 mg/L SFA – 0.01 $M$ $KNO_3$ solution containing 3 mg/L $Cu^{2+}$ was dialyzed against a 0.01 $M$ $KNO_3$ solution showed no initial buildup of $Cu^{2+}$ in the internal solution. Despite the fact that [$Cu^{2+}$] reaches a maximum before falling to an equilibrium value in some experiments, this phenomenon does not affect measured $C_L$ values. Anomalous behavior ceases before our 48 h sampling time.

*Complexing capacity results*

Fulvic acid, exemplified in this paper by SFA, is the acid soluble portion of naturally-occurring humic matter. Fulvic acids (FA) are complex mixtures of polyelectrolytes containing carboxyl and phenolic groups. SFA, which is typical of soil- and aquatic-derived fulvic acids, has ca. 50% carbon, ca. 40% oxygen, 8.2 mmol/g carboxyl groups, and 5.2 mmol/g phenolic groups (7). Functional group and elemental analyses are probably the best-known properties of fulvic acids. FA acidic properties, though, have been carefully studied by Gamble and co-workers (16). They found that any equilibrium function measured and defined for a fulvic acid mixture will be a weighted average of values, and will change with changes in FA concentration. This result is not a factor in the present study because of constant 10 mg/L SFA concentration.

There is complication beyond the necessity of using weighted equilibrium functions. Molecules in FA mixtures are thought to undergo conformational and/or aggregation–deaggregation changes as pH, [FA], and solution ionic strength varies. For

example, Ghosh and Schnitzer (17) concluded on the bases of viscosity and surface pressure measurements that in 0.001 *M* NaCl FA solutions change from coiled monomers to linear monomers below ca. 4000 mg/L FA. Reuter (18) observed anomalous reduced viscosity changes in FA at concentrations less than 100 mg/L at pH 7. Gel filtration chromatography (GFC) experiments (14) on our SFA sample suggest increased molecular size between pH 3 and 8. Gjessing (19) in GFC experiments noted that humic materials increase in size with increasing pH and lower ionic strength. Other workers (20) noted that pH changes affect various humic acid fractions in different ways.

The above brief description of fulvic acid mixtures suggest difficulties inherent in describing FA complexation of metal ions. It is not surprising that various research groups have different models describing FA – metal ion complexation. Weber and co-workers (21–23), Buffle and co-workers (24), and the Gamble–Langford group (4) have all used different means of calculating conditional stability constants from their data. The latter calculation (4) is the most detailed because it includes the weighted average $Cu^{2+}$ fulvic acid conditional stability constant as well as that for an infinitesimal portion of the binding sites.

Our past $Cu^{2+}$ (21), $Cd^{2+}$ (22), $Pb^{2+}$ (23, 25) ion selective electrode and fluorescence (6) studies exemplify FA metal ion binding results. Observed conditional stability constants depend on variables such as pH and [FA]. Generally conditional stability constants increase as pH increases (21–23). For example, $Cd^{2+}$–SFA conditional stability constants increase from $1.7 \times 10^3$ at pH 4 to $4.3 \times 10^4$ at pH 8 (22). Effects due to changes in [SFA] are less pronounced; an eightfold increase in [SFA] decreases the $Cd^{2+}$ conditional stability constant by ca. 55% (22).

The above discussion of conditional stability constants suggests that interpretation of complexing capacities ($C_L$) will be difficult, but does not explain how to analyze them. The reason is that researchers calculate conditional stability constants from data before the ligand is saturated with metal ion, while they calculate $C_L$ values from data well after the ligand is saturated with metal ion (1, 26). Also any aggregation processes mentioned above may affect availability of metal ion binding sites, i.e. $C_L$ values in this paper are *x*-intercepts of free $M^{2+}$ vs. total $M^{2+}$ curves (Fig. 1).

Most $C_L$ value trends (Table 1) demonstrate that (*1*) $C_L$ values increase as pH increases for each $M^{2+}$; (*2*) at each pH $C_L$ values are similar for $Mn^{2+}$, $Ni^{2+}$, $Zn^{2+}$, and $Cd^{2+}$; and (*3*) the $Cu^{2+}$ $C_L$ value at each pH is appreciably higher than that for the other four $M^{2+}$. Deviations from these three trends, e.g. $C_L$ of $Zn^{2+}$ at pH 5, are beyond our present understanding. It is tempting to rationalize the $C_L$ trends on the basis of the above FA conditional stability constant discussion, because the values typically increase as pH increases (21–23). In addition $Cu^{2+}$ binds more strongly to SFA than $Cd^{2+}$ or $Ni^{2+}$ under the same experimental conditions (6, 21, 22), and probably shows the same trend as with $Mn^{2+}$ and $Zn^{2+}$. Because of the nature of the dialysis experiments and data treatment, the relative $C_L$ values for different $M^{2+}$ cannot be explained on the basis of conditional stability constant results. If, for example, we did experiments similar to those reported here with a model ligand such as $10^{-5}$ *M* salicylic acid, resulting $C_L$ values would not depend on the nature of $M^{2+}$ or pH. $C_L$ represents the *capacity* for metal ion binding, not the equilibrium extent of metal complex formation. The above statement is true for a mixture of salicylic and phthalic acids (a typical fulvic acid model), or a mixture as complex as fulvic acid itself. Thus, different $C_L$ values for any $M^{2+}$ such as $Ni^{2+}$ and $Cu^{2+}$ cannot be due to weaker binding of the former metal ion with SFA. It is also incorrect to attribute enhanced $C_L$ values for any $M^{2+}$ as pH increases to equilibrium considerations. We must look elsewhere for an explanation.

We start with the assumption that in experiments with 10 mg/L SFA solutions at pH 5 and above, there is little inter- or intramolecular SFA binding. First, in the pH range of this study carboxyl groups are predominantly ionized and FA molecules carry a negative charge (16). For this reason SFA molecules would have an extended conformation in which carboxylate ions are widely separated from each other, and intramolecular bonding is minimal. Second, there would also be negligible intermolecular bonding due to the above reason and the small 10 mg/L [SFA]. Addition of metal ions, however, significantly affects the nature of FA molecules.

Several research groups on the basis of stability constant studies have suggested changes in FA aggregation due to complexation by $Cu^{2+}$ (4, 25), $VO^{2+}$ (14), and $Pb^{2+}$ (23, 25). For example, our group (25) showed by light scattering experiments that SFA in a 32 mg/L solution at pH 4.5 in 0.1 *M* $KNO_3$ aggregates when total [$Pb^{2+}$] is 50 $\mu M$, total [$Cu^{2+}$] is 200 $\mu M$ and total [$Cd^{2+}$] is 1000 $\mu M$. SFA and $M^{2+}$ concentrations in this work are somewhat lower, but unpublished results (27) show that scattering does occur in the $M^{2+}$ and SFA concentration ranges of this experiment. A metal ion binding model based on aggregation agrees with the complexation parameters of Table 1.

A first major trend of the data in Table 1 is that $C_L$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

values at constant pH are similar for $Cd^{2+}$, $Mn^{2+}$, $Ni^{2+}$, and $Zn^{2+}$; and significantly higher for $Cu^{2+}$. We contend that the higher $C_L$ values of $Cu^{2+}$ are due to its ability to cause SFA aggregation, because it forms inner sphere complexes. Nuclear magnetic resonance studies (28) have shown that $Mn^{2+}$ forms an outer sphere complex with FA while $Cu^{2+}$ forms an inner sphere one. This result confirms our conclusion that $Cu^{2+}$ forms different kinds of FA complexes than $Mn^{2+}$, and probably weakly-binding $Cd^{2+}$ (22), $Ni^{2+}$, and $Zn^{2+}$ as well. It is a fact that $Cu^{2+}$ is more effective than $Cd^{2+}$ in causing SFA aggregation (25), and we conclude that $Cu^{2+}$–SFA aggregates bind $Cu^{2+}$ more effectively than SFA alone. Another trend in Table 1 for most $M^{2+}$ is that $C_L$ values increase as pH increases. Fluorescence polarization studies (29) demonstrate the absence of conformational change in our SFA sample between pH 4 and 8, and that phenomenon is not an appropriate rationale. Detailed explanation of the two trends based on aggregation is speculative. First, aggregation might convert two or more monodentate ligands into a polydentate one. Second, the aggregates might serve as a site for polymerization or nucleation of hydrolyzed metal ion species. Third, aggregates might induce the formation of mixed M(SFA)(OH) complexes as suggested by Buffle (24).

Finally, the model must be consistent with another trend in Table 1. That is, the experimental slopes of the free $[Cu^{2+}]$ versus total $[Cu^{2+}]$ curves become considerably less than unity as pH increases. This result is unexpected because free and total $[Cu^{2+}]$ well after the $C_L$ endpoint should be equal. The $Cu^{2+}$–SFA aggregates are binding large amounts of $Cu^{2+}$ with no sign of an endpoint. The 70–130 $\mu M$ $Cu^{2+}$ added sometimes approaches the 132 $\mu M$ concentration of carboxylic/phenolic binding sites, and far exceeds the 66 $\mu M$ concentration if all binding sites were bidentate. The non-unity slopes are attributable neither to a precipitate nor to species such as $Cu_2(OH)_2^{2+}$ or $Cu(OH)^+$. Precipitation assures a constant $[Cu^{2+}]$ once a solubility product constant is exceeded (1). The low slopes are not due to $Cu^{2+}$ hydrolysis products that cannot permeate the dialysis membrane, because experiments in the absence of SFA have slopes near unity (Table 1). One explanation is that excess $Cu^{2+}$ binds predominantly to monodentate carboxylic and phenolic sites on the aggregates, via mixed Cu(FA)(OH) complexes as suggested by Buffle (24). The presence of $OH^-$ in the complexes would decrease the excess positive charge due to $Cu^{2+}$ complexed to monodentate anionic sites thus allowing more $Cu^{2+}$ binding. The conditional stability constants based on a 1:1 binding model must be greater than ca. $2 \times 10^4$ for detection of binding past the initial end point.

The paper cited deals with some interesting aspects of the polymerisation of norbornene by the metathesis catalysts $RuCl_3 \cdot 3H_2O$ and $RuCl_2(P\Phi_3)_3$. These comments deal with the analysis of the results and the subsequent interpretation placed upon them by the authors.

Figure 1 shows the behaviour that is typical of metathesis polymerisations and is similar to that shown by the polymerisation of cyclopentene (1). Of great concern to me however is the interpretation that the authors place on Figs. 3 and 4. These figures show the dependence of conversion on time for polymerisations catalysed by $RuCl_2(P\Phi_3)_3$ and $RuCl_3 \cdot 3H_2O$ respectively. In the first case, Fig. 3 is interpreted as showing that the rate of polymerisation is first order in concentration of monomer for monomer concentrations below 0.13 mol $dm^{-3}$ and zero order for concentrations of monomer greater than 0.13 mol $dm^{-3}$. Figure 4 is similarly interpreted as indicating a zero order dependence of rate of polymerisation on monomer concentration. I suggest these interpretations are incorrect.

For a simple first order reaction,

$$-\mathrm{d[M]}/\mathrm{d}t = k[\mathrm{M}]$$

$k$ may be a composite rate constant and in this case includes the concentration of the catalyst. For a reaction of this type, the well known equation:

$$[\mathrm{M}]/[\mathrm{M}]_0 = \exp -kt$$

is obtained. Surely, for a first order reaction, $[\mathrm{M}]/[\mathrm{M}]_0$ is constant and independent of the initial concentration of monomer for a particular reaction time.

Since

$$\%\,\text{conversion} = \frac{[\mathrm{M}]_0 - [\mathrm{M}]}{[\mathrm{M}]_0} \times 100 = \left(1 - \frac{[\mathrm{M}]}{[\mathrm{M}]_0}\right) \times 100$$

it must also follow that a plot of % conversion against time should be close to a straight line at low conversion, the slope of which is independent of the initial concentration of monomer.

Figure 4 therefore leads to the interpretation that the rate of polymerisation of norbornene is first order with respect to the concentration of norbornene when $RuCl_3 \cdot 3H_2O$ is used as catalyst and Fig. 3 shows that at a concentration of norbornene *greater* than 0.13 mol $dm^{-3}$ the rate is first order with respect to monomer concentration when $RuCl_2 \cdot (P\Phi_3)_3$ is used as initiator.

To develop this argument further for a second order reaction,

$$-\mathrm{d[M]}/\mathrm{d}t = k[\mathrm{M}]^2$$

from which

$$\frac{1}{[\mathrm{M}]} - \frac{1}{[\mathrm{M}]_0} = kt$$

may be obtained. Suitable manipulation of this equation leads to

$$1 - \frac{[\mathrm{M}]}{[\mathrm{M}]_0} = \frac{[\mathrm{M}]_0 kt}{1 + [\mathrm{M}]_0 kt}$$

It may be plausible therefore that at low concentrations of monomer, $[\mathrm{M}]_0 kt$ may be much less than 1. If this is the case

$$\left(1 - \frac{[\mathrm{M}]}{[\mathrm{M}]_0}\right) \times 100 \approx 100\,[\mathrm{M}]_0 kt$$

In this case, a plot of % conversion against time would lead to a straight line, the slope of which would depend on the initial concentration of monomer. It would appear therefore that the interpretation to be placed on Fig. 3 is indeed that the measured order of reaction changes as the concentration of monomer is increased but from two to one and not one to zero, as suggested by the authors.

Obviously this now must call for a complete reappraisal of the mechanism that can be formulated for this reaction and the system does not show features typical of the Langmuir–Hinshelwood model.

# Réponses aux commentaires "Polymérisation du norbornène par des amorceurs au ruthénium. Etude cinétique de la réaction"

A. KIENNEMANN

*Laboratoire Chimie Organique Appliquée, 1 rue Blaise Pascal, 67008 Strasbourg, France*

Reçu le 15 juin 1981

A. KIENNEMANN. Can. J. Chem. **60**, 7 (1982).

L'ordre de la réaction de la polymérisation du norbornène catalysée par des amorceurs au ruthénium (entre 0 et 1 ou entre 1 et 2) est discuté. Le rôle du solvant et l'effet du vieillissement du catalyseur permettent de proposer un schéma réactionnel de type dissociatif.

---

A. KIENNEMANN. Can. J. Chem. **60**, 7 (1982).

The reaction order (between 0 and 1 or between 1 and 2) of the polymerization of norbornene catalyzed by ruthenium initiators is discussed. The role of the solvent and the effect of pretreatment of the catalyst allow the proposal of a reaction scheme of the dissociative type.

[Journal Translation]

Le travail de Amass (1) indique clairement la convergence des résultats sur deux points importants: l'ordre 1 de la réaction par rapport au catalyseur et l'ordre variable par rapport au monomère. La divergence provient de la valeur de cet ordre: entre 0 et 1 dans notre étude, entre 1 et 2 d'après son étude cinétique. Les figs 3 et 4 de notre travail (2) montrent l'influence de la concentration en monomère sur la conversion du norbornène par une représentation du % de conversion en fonction du temps. Elles indiquent clairement que le % de conversion est proportionnel au temps et indépendant de la concentration en monomère quelque soit cette concentration pour la fig 4 et pour des valeurs élevées en monomère pour la fig 3. Nous en avons conclu que l'ordre était nul (fig 4) et variable entre 0 et 1 (fig 3).

Cependant, la démonstration de Amass conduit à d'autres conclusions. Il faut donc penser que la cinétique ne permet peut être pas de trancher et regarder d'autres résultats expérimentaux et plus particulièrement le rôle du solvant alcool et du vieillissement du catalyseur.

Dans un travail précédent (3) nous avions montré que la nature du solvant influait sur la vitesse de réaction dans le cas de $RuCl_3 \cdot 3H_2O$ alors qu'elle n'avait pas d'influence avec $RuCl_2(P\phi_3)_3$. Avec $RuCl_3 \cdot 3H_2O$, l'étape lente de la réaction semble donc être la formation d'un complexe ruthénium–alcool qui ne fait pas intervenir le monomère. L'ordre pour $RuCl_3 \cdot 3H_2O$ doit donc être indépendant de la concentration en monomère. Nous avons montré de plus que l'ordre était zéro par rapport à l'alcool dans le domaine étudié ce qui conduit à supposer un mécanisme dissociatif.

L'étude en fonction du vieillissement confirme ces résultats: (*a*) chauffage à 60°C d'une solution alcoolique de $RuCl_3,3H_2O$ ($4 \times 10^{-5}$ mol) pendant 4,24 et 72 h avant d'additionner le monomère (0,04 mol); (*b*) chauffage de $RuCl_3,3H_2O$ ($4 \times 10^{-5}$ mol) en solution alcoolique avec $8 \times 10^{-5}$ mol de norbornène pendant 24 et 72 h avant addition de 0,04 mol de norbornène. Nous constatons: (*1*) une augmentation très nette de la vitesse initiale de polymérisation pour les essais à 24 et 72 h (expérience (*a*)); (*2*) que l'addition préalable de monomère n'a aucune incidence sur le déroulement ultérieur de la réaction ce qui confirme l'aspect dissociatif du processus.

# Détermination du site de chélation dans des systèmes cycliques arylhydrazone–imine à 6 atomes. Échanges intra- et intermoleculaires du proton chélaté

ROGER PICHON, JEAN-YVES LE GALL ET PIERRE COURTOT[1]

*Laboratoire "Photochimie, Electrochimie et Chimie Moléculaires" de l'Université de Bretagne Occidentale, associé au CNRS (LA 322), 6 avenue le Gorgeu, 29283 Brest, France*

Reçu le 28 janvier 1981

ROGER PICHON, JEAN-YVES LE GALL et PIERRE COURTOT. Can. J. Chem. **60**, 8 (1982).

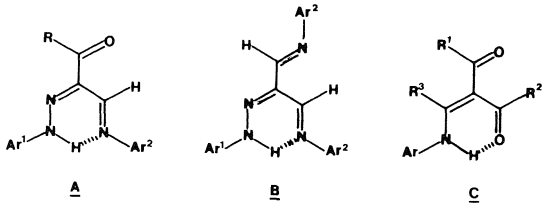
Nous avons déterminé les sites de chélation du proton et les structures des systèmes chélatés cycliques à six atomes que sont les arylhydrazono-2 arylimino-3 propanones-1 et les arylhydrazono-2 bis(arylimino)-1,3 propanes. Deux types d'échange du proton chélaté ont été caractérisés chez ces composés par rmn. Le premier correspond à un échange intramoléculaire entre les deux atomes d'azote des fonctions hydrazone et imine. Nous avons montré que les équilibres de tautomérie interne correspondants dépendent de plusieurs paramètres (solvant, température et substituants des noyaux aromatiques des groupements azo et imino). Le second échange correspond à un échange intermoléculaire, vraisemblablement soluté–soluté, et dépend de la température et de la concentration des solutions.

ROGER PICHON, JEAN-YVES LE GALL, and PIERRE COURTOT. Can. J. Chem. **60**, 8 (1982).

Chelation sites of the proton and structures of chelated six-atom ring systems have been determined for 2-arylhydrazono-3-aryliminopropane-1-ones and 2-arylhydrazono-1,3-bis(arylimino)propanes. Nuclear magnetic resonance spectroscopy allowed determination in these compounds of two types of exchange of the chelated proton. The first type concerns an intramolecular exchange between the two nitrogen atoms of the hydrazono and imino groups. We have shown that the internal tautomeric equilibria are dependent on several factors (solvent, temperature, and substituents fixed on aromatic rings of azo and imino groups). A second type of exchange corresponds to an intermolecular exchange, most probably of the solute–solute type, which depends on the temperature and concentration of the solutions.

La condensation de sels d'aryldiazonium sur les carbanions de composés β-dicarbonylés, β-cétosulfones, β-cétophosphonates conduit à des composés dont la structure hydrazone a été établie et dont les équilibres entre les différents isomères ont été étudiés au cours d'un travail précédent (1, 2). L'absence de tautomérie interne[2] hydrazonocétone–azoénol chez ces composés leur confère des propriétés photochimiques intéressantes résultant de l'isomérisation *syn–anti* de la double liaison C=N (3).

Des propriétés analogues se retrouvent chez les énamines α,α′-dicarbonylées étudiées au laboratoire par Couchouron (10). Ces composés se trouvent en solution sous une seule configuration chélatée énaminocétone **C**, la tautomérie interne énaminocétone–iminohydroxy n'étant pas observée. Afin d'examiner le caractère général des propriétés chimiques et photochimiques des arylhydrazones impliquées dans un cycle de chélation à six atomes et de comparer le pouvoir accepteur du proton chélaté des deux fonctions azo et imine dans un tel environnement, nous nous sommes proposé d'étudier deux séries de composés, les arylhydrazono-2 arylimino-3 propanones **A** et les arylhydrazono-2 bis(arylimino)-1,3 propanes **B**. Une compétition est à prévoir entre les deux atomes d'azote des fonctions azo et imine pour fixer le proton chélaté, ce qui devrait entraîner des propriétés intéressantes.



**A** **B** **C**

## Résultats et discussion

### A. *Structure et stéréochimie des arylhydrazono-2 arylimino-3 propanones-1. Echange intramoléculaire du proton chélaté*

Plusieurs séries d'arylhydrazones ont été préparées afin d'étudier l'influence des différents substituants des fonctions azo et imine sur les équilibres thermodynamiques de ces composés en solution. Leur synthèse est réalisée à partir des arylhydrazono-2 propanediones-1,3 diversement substituées en -3 (R = H, $CH_3$, Ar) sur lesquelles on condense un équivalent d'aniline substituée. Ces composés peuvent exister en solution sous plusieurs configurations que nous avons représentées sur le schéma 1 en ne prenant pas en compte les configurations ne possédant pas de chélation: elles ne sont jamais décelées en solution et elles doivent être fortement défavorisées.

[1]Auteur à qui toute correspondance doit être adressée.

[2]Nous désignons comme tautomères internes, deux chélates qui ne diffèrent que par le site du proton chélaté (par exemple **b** et **c**, schéma 1).

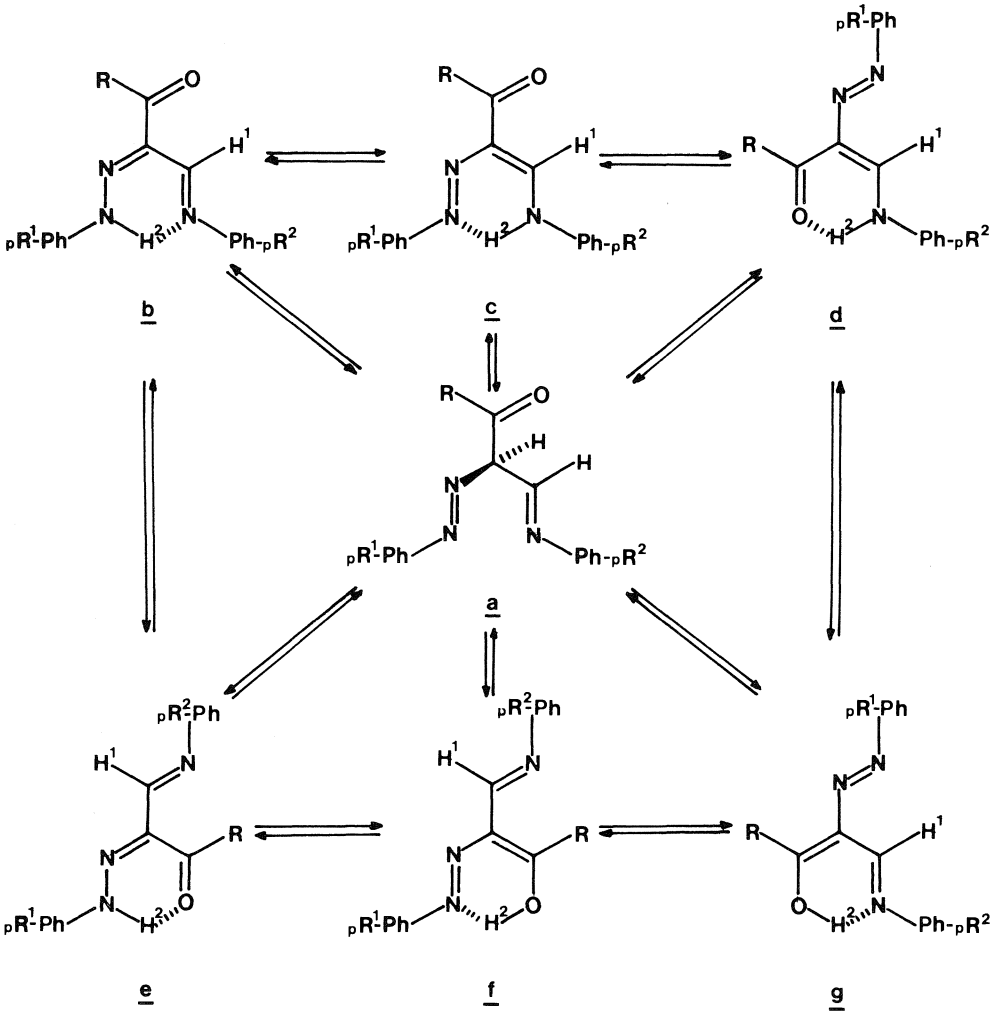

SCHEME 1

Le choix entre les différentes configurations **a**–**g** a pu être effectué à partir des caractéristiques spectroscopiques de ces composés, en particulier à l'aide des arguments rmn dans le cas des arylhydrazono-2 arylimino-3 propanals (R = H), que nous allons exposer en détail avant de généraliser pour les autres séries.

Dans le cas où R = $H^3$, si l'allure des spectres de rmn des composés de cette série (**1** à **10**) reste la même quels que soient les substituants $pR^1Ph$ et $pR^2Ph$ présents (le proton chélaté $H^2$ résonne vers 14,5–15 ppm, les deux protons $H^1$ et $H^3$ entre 8 et 10 ppm et les protons aromatiques entre 6,5 et 8 ppm), la forme du signal correspondant au proton aldimine ou aldéhyde, suivant les configurations envisagées **a**–**g**, diffère selon la nature des substituants. Alors que le premier signal ($H^3$) situé vers 9,5–10 ppm est toujours un singulet, le second ($H^1$) qui résonne à champ plus fort se dédouble plus ou moins nettement suivant les substituants présents sur les noyaux aromatiques des fonctions hydrazone et imine (Fig. 1). Ces deux signaux correspondant chacun à un proton, la présence d'un doublet pour le second signal ne peut résulter que d'un couplage de ce proton avec le proton chélaté, ce qui est vérifié lors d'un découplage de spin en irradiant à la fréquence du proton chélaté. Le signal apparaît alors en singulet, démontrant le couplage de ces protons.

L'allure des spectres nous conduit donc à propo-

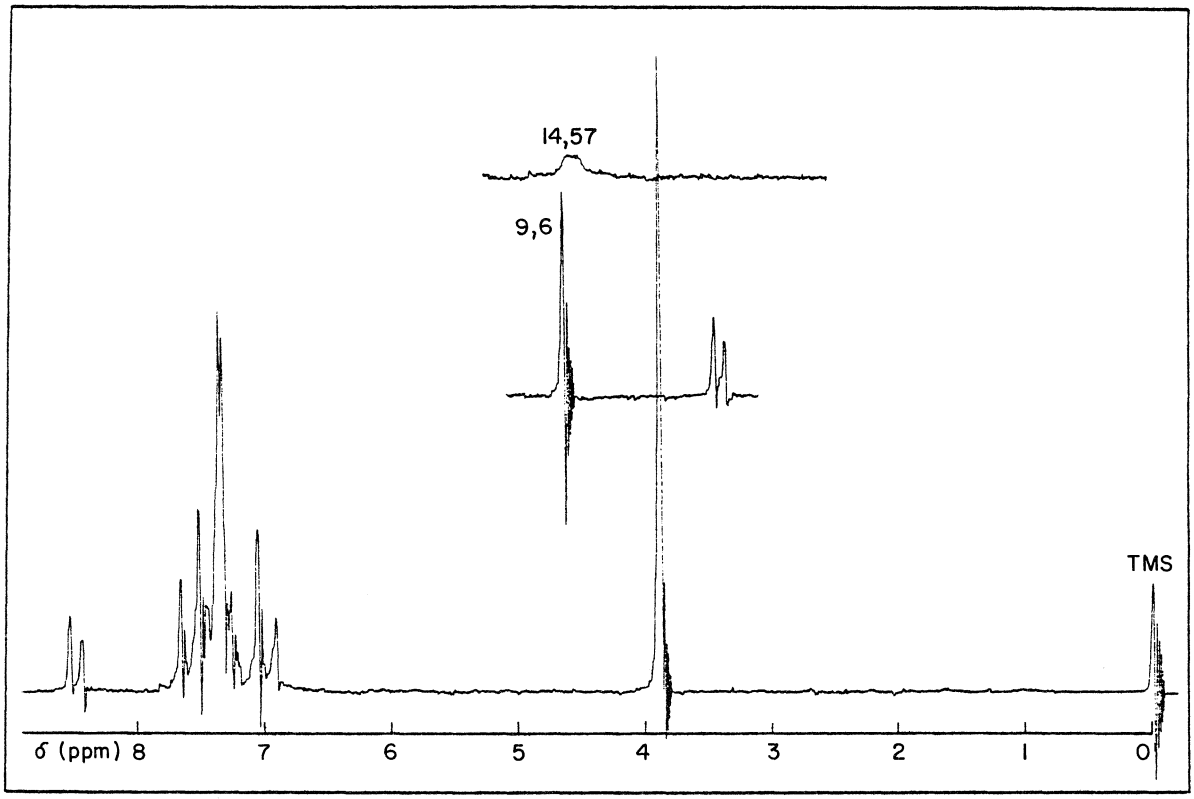

FIG. 1. Spectre rmn du *para*-méthoxyphénylhydrazono-2 phénylimino-3 propanal **4** (R = H, $R^1$ = MeO, $R^2$ = H) en solution dans $CDCl_3$.

ser la présence d'un couple de tautomères "internes" en solution et à exclure – d'une part l'existence de deux isomères, qui auraient entraîné quatre signaux différents pour les protons aldéhydiques et imino libres et chélatés, d'autre part l'existence d'un seul isomère, qui n'expliquerait pas la valeur de la constante de couplage observée sur les spectres rmn. Celle-ci serait nulle dans le cas d'une structure hydrazone ou de 12–13 Hz dans le cas des structures hydroxy ou énamine (4–10).

Si la paire de tautomères internes **d** et **g** peut être exclue, les protons $H^1$ et $H^3$ (R = $H^3$) devant résonner en doublets dédoublés dans ce cas (et le marquage à l'azote-15 le confirme), le choix entre les deux autres paires de tautomères possibles **b** ⇄ **c** et **e** ⇄ **f** peut être réalisé par marquage des atomes d'azote des fonctions imine et azo à l'aide de l'isotope $^{15}N$. Nous avons choisi deux composés caractéristiques pour ce marquage: le phénylhydrazono-2 phénylimino-3 propanal **1** et le *para*-méthoxyphénylhydrazono-2 phénylimino-3 propanal **4**.

La structure arylhydrazone d'un des tautomères est vérifiée dans le cas du composé **1** pour lequel la constante de couplage observée pour le proton aldimino $H^1$ est de l'ordre de 2 Hz dans $CDCl_3$. La fonction hydrazone peut être marquée à l'azote 15 en préparant le sel de phényldiazonium à partir de l'aniline marquée à l'azote 15 (11). L'apparition d'un couplage $^{15}N$—H sur le proton chélaté ($J$ = 77 Hz à 20°C dans $CDCl_3$) confirme la structure hydrazone d'un des tautomères. Le marquage de la fonction imine dans le cas du *para*-méthoxyphénylhydrazono-2 phénylimino-3 propanal **4** conduit également à la mise en évidence d'un couplage $^{15}N$—H ($J$ = 37 Hz dans $CDCl_3$ à 20°C). Ces données permettent d'identifier sans ambiguïté le couple de tautomères internes **b** ⇄ **c** en solution.

Des arguments analogues permettent d'énoncer le caractère général de ce type de tautomérie interne **b** ⇄ **c** chez les autres séries de composés (R = $CH_3$, Ph, *p*MeOPh). Ces configurations sont d'ailleurs confirmées à l'aide des données infrarouge et en ultra-violet.

Tous les composés **1** à **23** possèdent une bande intense correspondant aux fréquences de vibration de valence des carbonyles libres conjugués des fonctions aldéhydes (1680–1690 $cm^{-1}$) ou cétones (1645–1675 $cm^{-1}$) dans un tel environnement (2, 12, 13).

| | MeO | H | **23** | | 8,72 | 15 | 4 | 1638 | 31 | 387 | 125 |

Le maximum d'absorption électronique de ces composés en solution dans le cyclohexane se situe entre 405 et 420 nm, les coefficients d'extinction molaire étant de l'ordre $2,5 \times 10^{-4}$ suivant la nature du substituant sur les noyaux aromatiques. Il y a donc un déplacement bathochrome de l'absorption par rapport à la valeur observée chez les arylhydrazones dérivées de composés β-dicarbonylés dont les maximums d'absorption se situent pour la majorité au-dessous de 400 nm (12).

La structure de ces composés étant établie, subsiste le problème du dosage des tautomères en solution. L'échange intramoléculaire du proton entre les deux sites azotés étant plus rapide que la détection rmn, nous sommes dans des conditions analogues à celles décrites en particulier par Garbisch (5, 14). Nous avons donc utilisé les relations établies par cet auteur dans le cas d'un échange intramoléculaire de proton et vérifiées en particulier par Dudek *et al.* (8, 9) et Gindin *et al.* (4) pour le calcul du pourcentage des tautomères en présence. Suivant les composés préparés deux paramètres peuvent être utilisés: d'une part la constante de couplage $J_{HCNH}$ et d'autre part la constante de couplage $J^{15}_{N-H}$ observées sur le spectre des solutions. Ainsi pour le tautomère **b** ($N_b$ et $J_b$) les constantes de couplage $J_{HCNH}$ et $J^{15}_{N-H}$ sont-elles nulles si l'azote de la fonction imine est marqué. Par contre, pour le tautomère **c** ($N_c$ et $J_c$), ces couplages doivent intervenir: les constantes doivent être déterminées par comparaison avec d'autres systèmes chélatés voisins car nous n'obtenons jamais 100% de cette configuration en solution. Ainsi par rapport aux énamines α,α′-dicarbonylées préparées au laboratoire par Couchouron (10) et aux énamines α-carbonylées décrites par Dudek (9) nous avons pris respectivement 13 Hz et 90 Hz pour les constantes $J_{HCNH}$ et $J^{15}_{N-H}$ (azote du groupement imino marqué).

Les pourcentages des tautomères notés dans le tableau 1 sont donc obtenus de deux façons différentes à l'aide de la relation $J_{obs} = N_b J_b + N_c J_c$ soit dans le cas présent: $N_c = \dfrac{J_{HCNH\,observé}}{13}$ ou $\dfrac{J^{15}_{NH\,obs}}{90}$.

Les équilibres de tautomérie interne que nous venons de décrire dépendent de plusieurs paramètres: la substitution des noyaux aromatiques des fonctions hydrazone et imine, la nature du solvant et la température.

1. *Influence de la substitution des noyaux aromatiques des fonctions hydrazone et imine sur la composition des équilibres de tautomérie interne*

La composition des équilibres de tautomérie interne dépend fortement de la nature des substi-

TABLEAU 2. Variation des constantes de couplage $J_{HC-NH}$ suivant la nature du solvant pour quelques arylhydrazono-2 arylimino-3 propanones à 25°C

| | Composé | | | $J_{HC-NH}$ en Hz | | | | |
|---|---|---|---|---|---|---|---|---|
| R | $R^1$ | $R^2$ | No | $CCl_4$ | $CDCl_3$ | $(CD_3)_2CO$ | $CD_3CN$ | DMSO |
| H | H | H | **1** | 1–1,5 | 2 | 2,5 | 3 | — |
| H | MeO | H | **4** | 3 | 5,25 | 6,5 | 7 | 9,3 |
| H | MeO | MeO | **5** | 1,5 | 3,75 | 4,5 | 5,4 | — |
| Ph | MeO | H | **14** | 2,5 | 4,5 | 5 | 5,4 | — |
| *p*MeOPh | MeO | H | **23** | 2 | 4 | 4,5 | 5,25 | — |

tuants sur les noyaux aromatiques. Ainsi la présence en *para* de groupements électrodonneurs tels que Me et MeO sur le noyau aromatique de la fonction phénylhydrazone déplace l'équilibre vers la forme azoénamine **c**, alors que la substitution par un groupement électro-attracteur semble au contraire favoriser la configuration hydrazonoimine **b**.

Inversement la substitution des noyaux aromatiques de la fonction phénylimine par des groupements donneurs d'électrons déplace l'équilibre vers la formation du tautomère de configuration hydrazonoimine **b**.

Ces variations dans les compositions des équilibres sont à rapprocher des observations effectuées par Berrie *et al.* (15) dans le cas de la substitution des arylazonaphtols; les groupements électrodonneurs en *para* sur le noyau aromatique favorisent également le tautomère azohydroxy. Cependant il nous est difficile d'interpréter précisément ce phénomène faute de données quantitatives sur la répartition des charges dans les différents cycles chélatés. La transmission des effets électroniques des groupements arylés peut en effet s'effectuer de deux façons : modification directe de la densité électronique sur l'atome d'azote adjacent ou modification de la répartition électronique sur le cycle chélaté via les groupements azo et imino.

2. *Influence du solvant sur les équilibres*

La composition des équilibres entre les deux tautomères **b** et **c** varie également avec la nature du solvant (Tableau 2). Les pourcentages des tautomères de structure azoénamine étant proportionnels aux constantes de couplage $J_{HCNH}$ observées sur les spectres, nous donnons pour chaque composé les variations des constantes de couplage suivant la nature du solvant. Nous remarquons ainsi que pour tous les composés, la concentration du tautomère **c** de configuration azoénamine croît avec la polarité du solvant. Cependant nous ne pouvons établir une relation quantitative satisfaisante entre les constantes d'équilibre et le pouvoir solvatant ou la polarité du solvant (paramètres $E_T$, $Z$ ou la constante diélectrique ε).

3. *Influence de la température. Mise en évidence de l'échange intermoléculaire du proton chélaté*

Comme pour la majorité des exemples d'équilibres de tautomérie interne décrits dans la littérature, telles les bases de Schiff dérivées d'aldéhydes ou de cétones aromatiques *ortho*-hydroxylées (16), la composition des équilibres décrits dépend de la température. Une élévation de la température entraîne le déplacement de l'équilibre vers la forme hydrozonoimine **b**. En l'absence d'échange intermoléculaire ($10^{-2}$ *M*), nous avons mesuré les variations d'enthalpie pour les réactions d'échange intramoléculaire du proton en traçant les droites de van't Hoff pour différents composés. Ainsi pour le *para*-méthoxyphénylhydrazono-2 phénylimino-3 propanal **4** en solution dans l'acétonitrile, la variation d'enthalpie $\Delta H^0$ est-elle de $-0{,}68$ Kcal $mol^{-1}$ pour l'équilibre hydrazone ⇄ azo et de $-0{,}72$ Kcal $mol^{-1}$ dans l'acétone.

Comme nous venons de le voir, le proton chélaté s'échange de façon intramoléculaire entre les deux sites azotés de la molécule, mais nous avons montré qu'il peut donner également lieu à un échange intermoléculaire. Cette réaction d'échange a été étudiée plus particulièrement pour deux composés **4** (R = H, $R^1$ = OMe, $R^2$ = H), et **5** (R = H, $R^1$ = $R^2$ = OMe) en suivant l'évolution du signal du proton aldimino $H^1$ en fonction de la température et de la concentration de la solution.

Ainsi dans le cas du composé **5**, en solution dans l'acétonitrile à 50°C, le signal du proton aldimino est-il un doublet lorsque la concentration est de $1{,}875 \times 10^{-2}$ *M*. En augmentant la concentration on observe la coalescence de ce signal et son affinement après la coalescence (Fig. 2).

L'effet de la température sur la forme du signal peut être étudié sur les solutions concentrées. On observe ainsi la coalescence du doublet du proton aldimino lors de l'élévation de température, ce signal s'affinant après la coalescence comme le montrent les spectres rmn (Fig. 3).

Les effets de concentration et de température sur les solutions des autres composés dans $CDCl_3$,

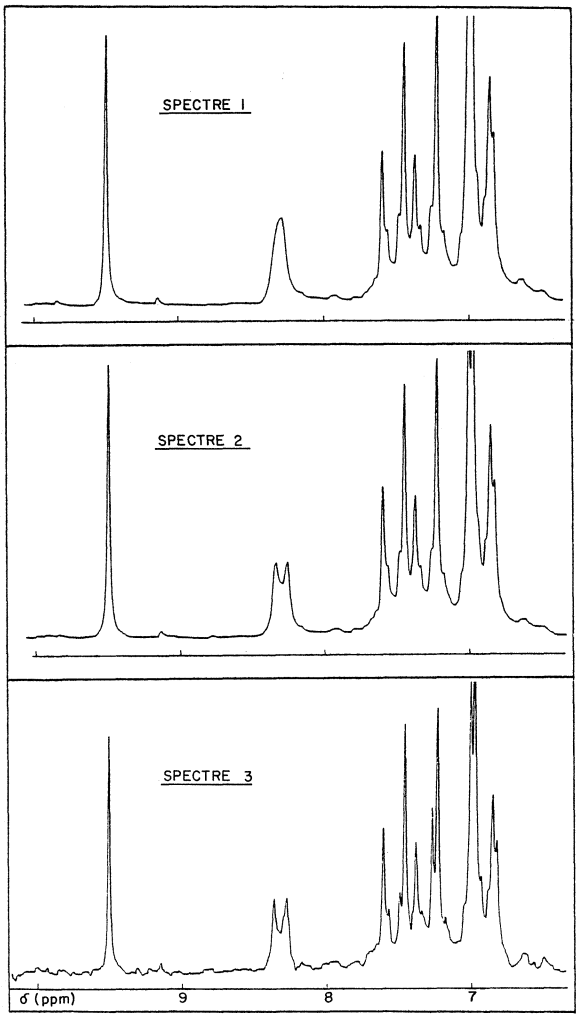

FIG. 2. Spectres rmn du *para*-méthoxyphénylhydrazono-2 *para*-méthoxyphénylimino-3 propanal **5** (R = H, $R^1 = R^2$ = MeO) en solution dans $CD_3CN$ ($t$ = 50°C). Influence de la concentration sur la cinétique d'échange: coalescence du signal du proton aldimino $H^1$ à 8,3 ppm. Spectre 1: concentration $3 \times 10^{-1}$ $M$. Spectre 2: concentration $7{,}5 \times 10^{-2}$ $M$. Spectre 3: concentration $1{,}87 \times 10^{-2}$ $M$.

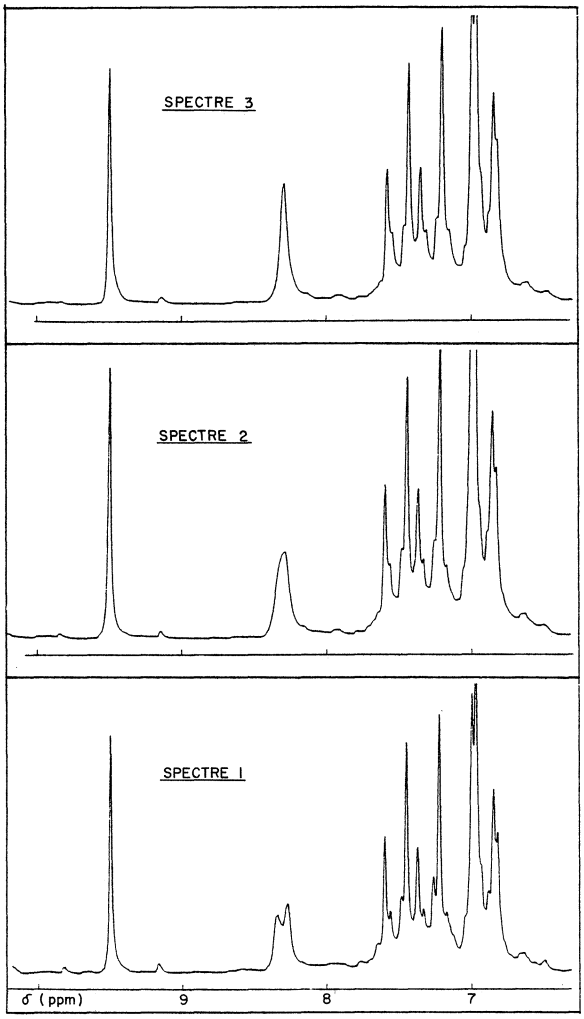

FIG. 3. Spectres rmn du *para*-méthoxyphénylhydrazono-2 *para*-méthoxyphénylimino-3 propanal **5** (R = H, $R^1 = R^2$ = MeO) en solution dans $CD_3CN$ ($C = 3 \times 10^{-1}$ $M$). Influence de la température sur la cinétique d'échange: coalescence du signal du proton aldimino $H^1$ à 8,3 ppm. Spectre 1: 34°C. Spectre 2: 50°C. Spectre 3: 69°C.

$CD_3CN$, $CD_2Cl_2$ et $(CD_3)_2CO$ sont analogues à ceux que nous décrivons. La coalescence des signaux observée sur les spectres rmn caractérise l'échange intermoléculaire du proton $H^2$ dont la fréquence dépasse celle qui permettrait d'observer le couplage des protons $H^1$ et $H^2$.

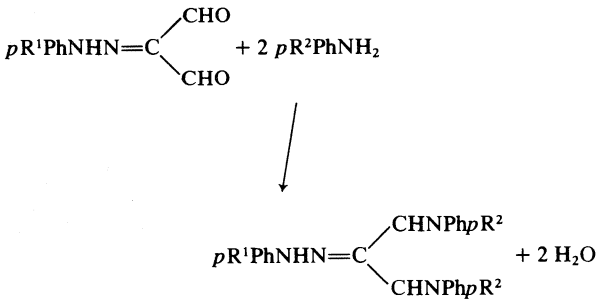
Dahlqvist et Forsen (17) avaient décrit une situation analogue dans le cas de la formyl-1 phényl-1 acétone. A notre connaissance c'était le seul exemple d'échange intermoléculaire du proton chélaté décrit dans la littérature dans le cas de systèmes à six atomes. La difficulté à observer cet échange provient du fait qu'il faut un environnement favorable (couplage HCNH ou HCOH ou $^{15}N$–H) pour le caractériser facilement par rmn.

B. *Structure et stéréochimie des arylhydrazono-2 bis(arylimino)-1,3 propanes*

Ces composés sont préparés à partir des arylhydrazono-2 propanedials sur lesquels on condense deux équivalents d'aniline.

Afin de faciliter la détermination des structures, les deux équivalents d'aniline condensés possèdent la même substitution.

Deux types de structure peuvent être envisagés pour ces composés: soit une forme hydrazone, soit une forme énamine. Si dans le premier cas le



problème du site de chélation ne se pose pas, compte tenu de la symétrie des composés par rapport au motif hydrazone, par contre dans le cas d'une forme énamine nous avons deux sites de chélation possible: la fonction arylazo et la fonction arylimino.

Les éléments les plus intéressants pour la détermination des structures sont fournis par la rmn alors que la spectrophotométrie ultra-violette et l'infra-rouge n'apportent pas d'éléments déterminants pour cette série.

Pour les six composés étudiés (Tableau 3, nos, **24** à **29**), deux isomères peuvent être identifiés facilement en solution par rmn. Le premier, identifié à l'aide du signal du proton chélaté vers 15 ppm et des signaux des protons $H^1$ et $H^2$ respectivement vers 8,2 et 9 ppm (Fig. 4), possède une structure hydrazone **h**. Celle-ci peut être confirmée par marquage de l'atome d'azote porteur du proton de la fonction hydrazone à l'aide de l'isotope $^{15}N$, la présence d'un couplage $^{15}N$–H chez ces composés démontrant la localisation du proton chélaté sur cet atome d'azote.

Le deuxième isomère peut être identifié à l'aide du massif du proton chélaté vers 12,8–13 ppm et du signal correspondant aux deux protons $H^1$ et $H^2$. Le signal unique à 8,7 ppm correspondant à ces deux protons démontre leur équivalence magnétique et seule la structure **k** peut correspondre à de telles caractéristiques. L'évolution de la forme de ce signal en fonction de la concentration et de la température apporte des renseignements complémentaires sur cette structure. A la température ordinaire et pour des concentrations de l'ordre de $3 \times 10^{-2}$ *M*, ces deux protons résonnent en singulet légèrement élargi. Une augmentation de la concentration ou de la température affine ce signal alors

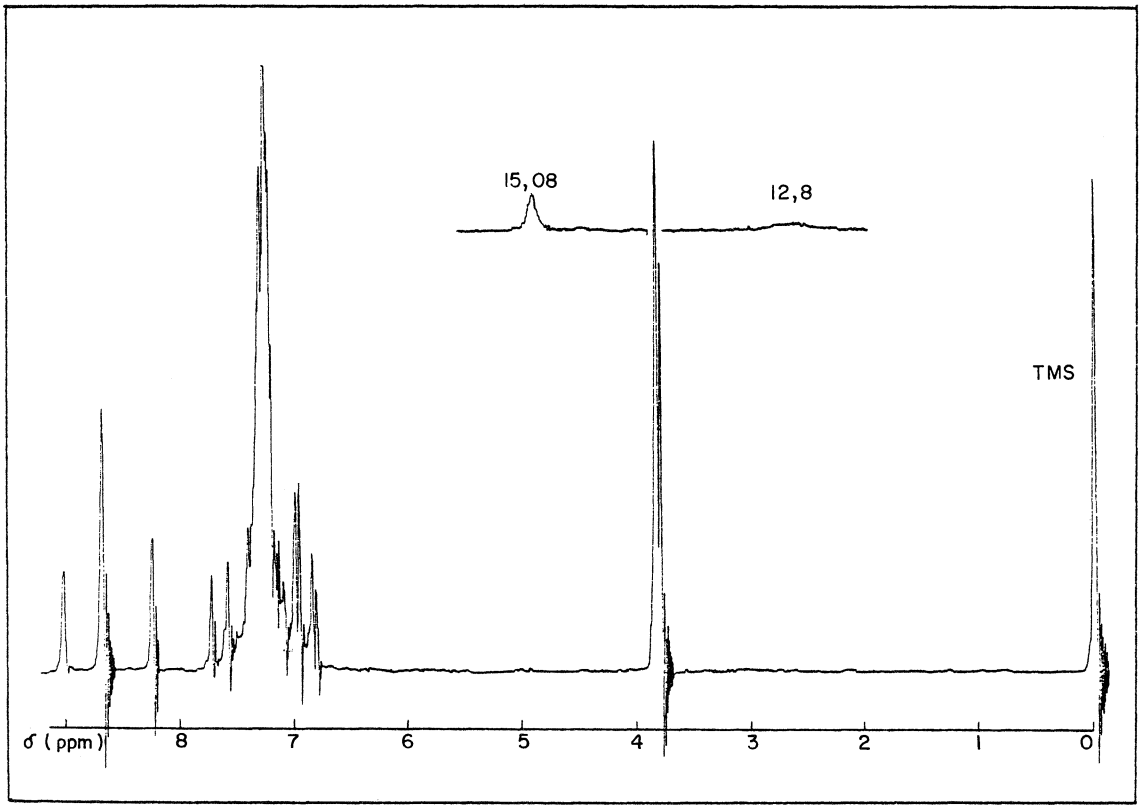

FIG. 4. Spectres rmn du *para*-méthoxyphénylhydrazono-2 bis(phénylimino)-1,3 propane **26** ($R^1$ = MeO, $R^2$ = H) en solution dans $CDCl_3$.

qu'une diminution de la température (−30°C) l'élargit (Fig. 5). Si l'on abaisse encore la température (−76,5°C) on voit le signal à 8,7 ppm se séparer en un singulet à 9,16 (proton $H^2$) et un doublet centré à 8,39 ppm ($H^1$ couplé avec $H^3$ qui sort lui-même en doublet $J$ = 12,2 Hz). Un découplage de spin, à température ordinaire, en irradiant à la fréquence du proton chélaté (12,8–13 ppm) affine le signal des deux protons $H^1$ et $H^2$, démontrant l'existence d'un couplage de ces protons et du proton chélaté.

La disparition du couplage sous l'influence d'une élévation de température ou d'une augmentation de la concentration ne peut s'expliquer que par la présence d'un échange intermoléculaire, vraisemblablement soluté–soluté, du proton chélaté, dont la fréquence devient plus grande que celle du couplage attendu entre les protons $H^1$, $H^2$ et $H^3$, d'où la coalescence du signal correspondant aux deux protons équivalents $H^1$ et $H^2$.

L'existence d'un équilibre entre les deux isomè-

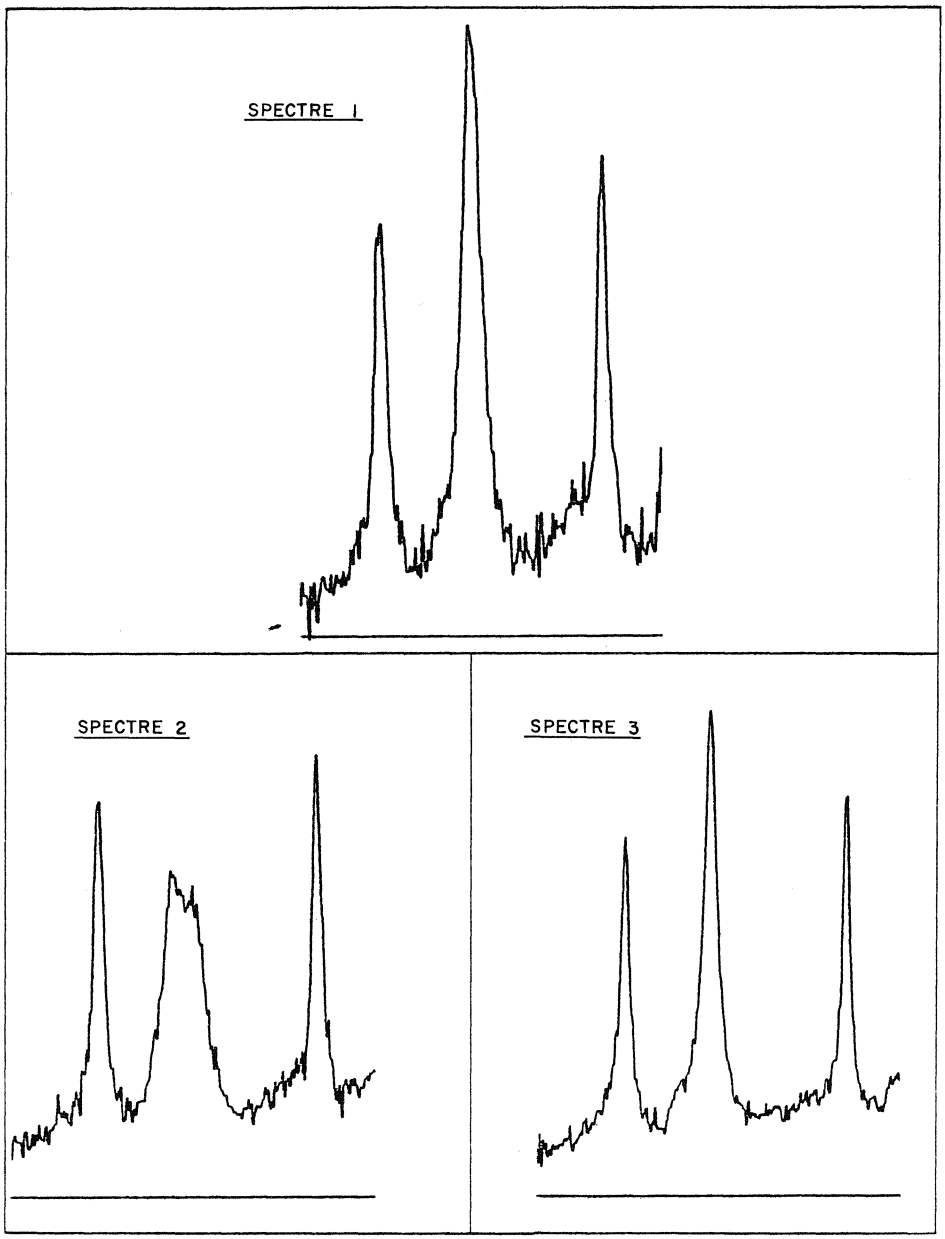

FIG. 5. Evolution des signaux des protons aldimino et énamino en fonction de la température dans le cas du *para*-méthoxyphénylhydrazono-2 bis(phénylimino)-1,3 propane **26** ($R^1$ = MeO, $R^2$ = H). Spectre 1: $t$ = 0°C. Spectre 2: $t$ = −30°C. Spectre 3: découplage de spin à −30°C par irradiation à 12,8 ppm.

res **h** et **k** (auquel s'ajoute l'échange intermoléculaire) implique que l'interconversion de ces deux isomères se fasse obligatoirement via les isomères **i** ou **j**, comme nous le montrerons par la suite.

Les essais de détection de l'isomère **i** en rmn ont été vains quels que soient les composés et les différentes conditions expérimentales utilisées (divers solvants; variations de température).

L'isomère **j** par contre peut être caractérisé lors de l'étude du *para*-méthoxyphénylhydrazono-2 bis(phénylimino)-1,3 propane **26**. Si pour les cinq autres composés préparés les signaux correspondant aux protons $H^1$ et $H^2$ de l'isomère **h** résonnent en singulet fin, dans le cas du composé **26** le signal à champ faible est un singulet élargi. Comme nous l'avons montré dans les séries précédemment décrites (2), ce signal correspond au proton $H^1$ du groupement aldimino impliqué dans la chélation, le

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

déblindage de ce proton étant lié à la plus forte polarisation du groupement chélaté par rapport au groupement libre. Le très faible couplage de ce proton $H^1$ ($J < 1$ Hz) avec le proton chélaté (Figs. 4 et 5) peut être mis en évidence par découplage de spin en irradiant à la fréquence du proton chélaté ($\delta$ = 12,8 ppm) ou par addition de $D_2O$ dans la solution. Dans les deux cas, on observe l'affinement du signal causé par la disparition du couplage.

Ces éléments nous incitent à penser que la tautomère **j** existe en solution en très faibles quantités (<8%) dans ce cas particulier. Bien que pour les autres composés la caractérisation de cet isomère ne soit pas réalisable, nous pensons cependant que l'interconversion **h** ⇄ **k** se fait également via le tautomère interne **j** résultant d'une migration [1,5] d'hydrogène à partir de la forme hydrazonoimine et non via l'isomère **i** résultant d'une migration [1,3] d'hydrogène et conduisant à l'isomère **k** par une seconde migration [1,3] d'hydrogène.

1. *Influence de la substitution des noyaux aromatiques sur les équilibres en solution*

Nous nous retrouvons dans une situation identique à celle de la série précédente. La présence de groupements électrodonneurs en *para* sur le noyau aromatique de la fonction hydrazone déplace l'équilibre vers l'isomère de configuration imino-énamine **k**. Inversement la même substitution sur le noyau aromatique de la fonction imine déplace l'équilibre vers l'isomère **h** de configuration hydrazonoimine

2. *Influence du solvant sur les équilibres en solution*

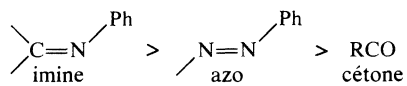
La nature du solvant intervient également sur la composition du mélange des isomères. Tout comme pour les arylhydrazono-2 arylimino-3 propanones-1 précédentes, les solvants polaires favorisent la formation de l'isomère **k** de configuration énamine. Mais pour cette série le déplacement de l'équilibre n'est pas très important puisqu'en passant de $CCl_4$ à $CD_3CN$ l'accroissement du pourcentage de l'isomère **k** de configuration énamine n'est que de 10% dans le meilleur des cas.

3. *Influence de la température sur les équilibres en solution*

L'équilibre entre les deux isomères en solution est légèrement déplacé par variation de température mais ce déplacement est trop faible pour effectuer une étude quantitative satisfaisante, d'autant qu'une variation de température modifie la fréquence de l'échange intermoléculaire du proton chélaté, donc la forme du signal correspondant. Le *para*-méthoxyphénylhydrazono-2 bis(*para*-méthoxyphénylimino)-1,3 propane **27**, qui est le composé le plus sensible à une variation de température, voit ainsi la concentration en isomère **k**, passer de 27% à 32% en élevant la température de −15°C à +50°C dans $CDCl_3$.

La présence en solution des deux structures hydrazone-imine et azo-énamine différencie ces composés des arylhydrazones dérivées de composés β-dicarbonylés, β-cétophosphonates et β-cétosulfones où seule la structure hydrazone était observée (2). On remarque cependant que pour toutes ces séries, la prototropie s'effectue vers l'atome d'azote et non vers l'oxygène d'un groupement carbonylé, quelles que soient les conditions de l'étude: différents solvants et température variable. Les structures du type azohydroxy n'existent pas chez ces composés.

L'orientation de la chélation nous permet de classer les différents groupements en fonction de leur pouvoir accepteur de liaison hydrogène dans un cycle de chélation à six atomes de configuration énamino. Par ordre de pouvoir décroissant on obtient la séquence suivante:



De même, on remarquera l'orientation préférentielle de la chélation du proton de la fonction hydrazone, quels que soient les substituants des noyaux aromatiques, vers le groupement imino et non vers le groupement carbonyle quand ceux-ci sont en compétition.

## Conclusion

L'échange intermoléculaire du proton chélaté est une caractéristique commune aux deux séries de composés étudiés et les distingue des arylhydrazones dérivées de composés β-dicarbonylés pour lesquelles il ne peut être mis en évidence dans les mêmes conditions expérimentales (2). Cet échange intermoléculaire soluté–soluté du proton chélaté, dépendant de la concentration de la solution et de la température, semble donc facilité lorsque les fonctions hydrazone/imine ou imine/énamine sont impliquées dans le cycle de chélation. Cette différence provient vraisemblablement du fait que cet échange est facilité par une plus grande délocalisation sur le cycle de chélation, provenant de l'échange intramoléculaire du proton chélaté entre les deux sites azotés. Par contre, dans le cas des arylhydrazones dérivées de composés β-dicarbonylés nous n'observons pas d'échange intramoléculaire, le proton étant localisé sur l'atome d'azote de la fonction hydrazone. Il semble que l'échange intramoléculaire du proton soit une condition nécessaire mais pas suffisant pour qu'il puisse y avoir échange intermoléculaire à concentration plus élevée.

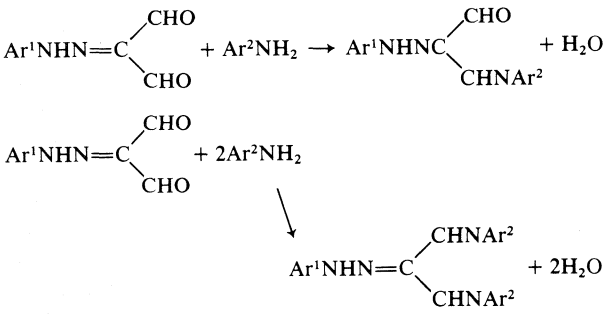
## Partie experimentale

Les spectres rmn ont été enregistrés sur appareil JEOL C60HL et JEOL FX60, les spectres infrarouges sur un spectromètre Perkin–Elmer 225 pour les solutions. Les spectres de masse ont été réalisés sur un spectromètre de masse quadripolaire "Riber" de la Société Nermag. Les points de fusion sont mesurés sur banc de Köfler.

*Synthèse des arylhydrazono-2 arylimino-3 propanones-1 et des arylhydrazono-2 bis(arylimino)-1,3 propanes*

Ces deux séries de composés sont préparées à partir des arylhydrazono-2 propanediones-1,3 (2) qui sont condensées avec un ou deux équivalents d'aniline diversement substituée suivant la série envisagée.



*Mode opératoire général*

Dans un ballon surmonté d'un réfrigérant on place $5 \times 10^{-3}$ mol d'arylhydrazono-2 propanedione-1,3 en solution dans 250 cm³ de chloroforme. On ajoute $5 \times 10^{-3}$ mol ou $10^{-2}$ mol d'aniline diversement substituée suivant la série préparée. La solution est portée à reflux durant six heures au minimum. L'évolution de la réaction peut être suivie directement par rmn. Après évaporation du solvant on obtient des cristaux qui sont recristallisés dans du méthanol. Les caractéristiques principales des composés obtenus sont données dans les tableaux 1 et 3.

# A new cubic-space section model for predicting the specificity of horse liver alcohol dehydrogenase-catalyzed oxidoreductions[1]

J. Bryan Jones and Ignac J. Jakovac

*Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1*

Received May 11, 1981

J. Bryan Jones and Ignac J. Jakovac. Can. J. Chem. **60**, 19 (1982).

A new active site model for predicting and interpreting the structural- and stereospecificity of horse liver alcohol dehydrogenase-catalyzed oxidations and reductions has been formulated from the specificity, X-ray, and kinetic data now available. The new model is based on a cubic-space system and is convenient and easy to use. The model is completely reliable and permits HLADH specificity towards all of its currently known substrates to be predicted with confidence. Its application is illustrated by analyses of representative examples of major substrate types.

J. Bryan Jones et Ignac J. Jakovac. Can. J. Chem. **60**, 19 (1982).

A partir des données de spécicité, de diffraction de rayons X et de cinétique disponibles, on a élaboré un nouveau modèle de site actif pour prédire et interpréter la structure et la stéréospécifité des oxydations et des réductions catalysée par la déshydrogénase de l'alcool du foie de cheval (DHAFC). Le nouveau modèle est fondé sur un système d'espace cubique et est d'emploi facile. Le modèle est complètement fiable et permet de prédire en toute confiance la spécifité de la DHAFC envers tous ses substrats connus. On illustre son utilisation par l'analyse d'exemples représentatifs des principaux types de substrats.

The asymmetric synthetic opportunities provided by the chiral catalytic properties of enzymes are becoming increasingly recognized (2*a*,*b*). Alcohol dehydrogenases, which catalyze oxidoreductions of the type depicted in reaction [1],[2] are among the most useful enzymes for organic synthetic purposes, with the commercially available enzyme from horse liver the best documented.

[1] $H^+ + \rangle C{=}O + NADH \rightleftharpoons \rangle CH(OH) + NAD$

HLADH is an extremely versatile alcohol dehydrogenase, capable of effecting highly stereospecific oxidoreductions on a broad structural range of aldehyde, ketone, and alcohol substrates (2–6).

In order for any enzyme to become widely adopted as a practical synthetic catalyst, it is essential that a reliable active site model be available for predicting the structural- and stereospecificity of the enzyme towards both known and potential substrate structures. Predictive systems of varying degrees of sophistication have been developed for a number of enzymes, including proteases (2*a*), mono-oxygenases (7, 8), and some alcohol dehydrogenases (2*a*, 3, 4, 9). For HLADH, the diamond lattice section approach devised by Prelog (3), and subsequently refined (2*a*, 4), has been very successful for interpreting the steric course of catalyses of cyclohexane and decalin substrates. However, for many of the other types of cyclic structures now known to be substrates (2), stereochemical predictions based on diamond lattice analyses have become increasingly subjective and uncertain.[3] It is clear that, after serving as a valuable active site model for nearly twenty years, the diamond lattice section has become totally inadequate for interpreting the stereochemical course of HLADH-catalyzed oxidoreductions of many of the recently identified, and still expanding, range of substrate structures (2, 6*b*).

Recently, the amino acid sequence of the EE-isozyme of HLADH (10) and the X-ray structures of the apoenzyme (11*a*), of the enzyme–NAD complex (11*b*–*d*) and of several ternary complexes (11*e*) have been published. These data, together with the results of new kinetic experiments on

[1]Enzymes in Organic Synthesis, 20. For Part 19 see ref. 1.

[2]Abbreviations used: NAD and NADH, oxidized and reduced forms respectively of the nicotinamide adenine dinucleotide coenzymes; HLADH, horse liver alcohol dehydrogenase; ADP, adenosine diphosphate.

[3]Several factors have contributed to the unsuitability of the diamond lattice section for general current application. The section was drawn up using substrates composed of cyclohexane rings (3, 4), resulting in a lattice framework based on $sp^3$-hybridized carbon bond lengths and angles. This introduces a psychological bias into the analytical process since it almost inevitably leads to attempts to locate substrate atoms at the lattice intersection points, and also to align bonds along the lines of the lattice. The designation of forbidden regions as points at the lattice intersections, rather than as regions of varying degrees of resistance to substrate penetration, is also a major disadvantage. In addition, the use of the "diamond" terminology is itself misleading to many chemists since it conveys, often unconsciously, the impression of a hard, uncompromising and structurally intolerant active site. Furthermore, the use of the diamond bonding framework, with lines drawn throughout the volume, does not permit the empty regions of the active site capable of accommodating substrates, nor the forbidden regions, to be easily visualized.

alkylcyclohexanones (5, 6*c*,*d*), have provided a picture of the hydrophobic, barrel-like, active site pocket and of the relative orientations of the enzyme-bound substrates and coenzyme. The elegant active site representations so obtained are of considerable structural and kinetic significance. However, they do not lend themselves to the type of specificity analyses required by organic chemists utilizing HLADH for asymmetric oxidoreductions on very varied substrate structures. Accordingly, using all of the information now available, we have formulated a new active site section based on a cubic-space system that reliably predicts HLADH specificity throughout the broad structural range of cyclic substrates identified so far.

## Specification of the cubic-space section for the active site region

A model based on cubic space was selected for several reasons. The use of a cubic framework eliminates many of the chemical and conformational bias disadvantages of previous models based on carbon bond lengths and angles or derived directly from X-ray data. Also, the cubic section can be made as specific and flexible as needed by appropriate selection of the unit volume. Furthermore, cubic active site descriptors have already been widely accepted by chemists. They are convenient to use and their practical value in interpreting and predicting stereospecificity has been demonstrated for several enzymes of general organic synthetic interest (7–9), including one very recent specific application to a group of HLADH-substrates of unusual chirality (9*b*).

All of the specificity, kinetic, and X-ray data (2–6, 10, 11) were taken into account, with the following criteria being of primary importance: (*a*) the ADP-ribose portion of the coenzyme is rigidly bound at the active site. It thus firmly anchors the nicotinamide ring, whose freedom of rotation about the glycosyl bond is also restricted, in place. The nicotinamide ring is oriented with its A-face (12) towards the substrate (5, 11*a*,*f*). This fixes the direction of delivery and removal of the hydride equivalent during reduction and oxidation respectively. (*b*) The oxygen atom of the substrate carbonyl or hydroxyl group is liganded to the active site $Zn^{2+}$ atom (11*f*). This requirement, coupled with the fixed hydride delivery and removal site, establishes the location of the C=O and CH(OH) centres undergoing reduction or oxidation. It also severely limits bond rotations adjacent to them. (*c*) From the specificity analyses used initially to create the diamond lattice section (3, 4) and the additional data presently available (2–6), the active site regions that are open to substrate occupation (allowed regions) and those where substrate binding is precluded (forbidden regions) can now be specified with confidence.[4] The forbidden regions identified in this way correlate well with the positions of various amino acid residues in the X-ray structure (5, 11). In addition, the total kinetic data accumulated (2*a*, 3–5) permit estimation of differences in the degrees to which areas adjacent to forbidden regions are resistant to substrate binding.

The cubic-space section selected is depicted in Fig. 1. The 1.3 Å edge basis selected for the lattice provides a suitable compromise between the need to identify different regions as specifically as possible with our desire to minimize their number in order to keep the model convenient to use.

The space in front of the section is occupied by the coenzyme, with C-4 of the nicotinamide ring being positioned to deliver or receive the hydride-equivalent at the position shown. The C—O function, which projects downward along the **U(C1)–U(D1)** boundary, is designated in its alcohol-like configuration since this is considered to resemble most closely the transition state of the reaction (3).

The 1.3 Å per edge scale is well suited to analyzing substrates largely built-up of $sp^3$-hybridized carbon frameworks since these fit easily into the coordinate system. For example, the C-2 – C-6 separation in cyclohexanone is 2.6 Å. The volume defined by **A–R**, **1–9** is 118 $Å^3$. This is somewhat larger than the currently known substrate-accessible volume of the active site and thus allows for any future expansion required.

At present, not all of the cubic space defined in Fig. 1 needs to be used for analyzing the specificity of the enzyme. The regions incorporated into our current working model are shown in Figs. 2 and 3. The forbidden cubes are **A1,2**; **E1–3**; **G4,5**; **L4–6**; **M7–8**; **Q7–9** and the left-hand halves of **B1**, **H4**, and **N7**. Cubes **O9**, **P8**, and **P9** are also limited or forbidden. These latter regions are omitted from the working model because at present they are very seldom involved in analyses of substrate fit. The front of the section, being occupied by the coenzyme, is the remaining forbidden region. The limited cubes are **J4**, **P7**, and the right-hand halves

[4]Most of the systematic mapping-out of the allowed and forbidden regions of the active site was effected by methodically varying the structures of basic six-membered ring substrates and comparing their relative rates of oxidoreductions (3–5, 13). Dutler (5*b*) has provided the most evocative description of the technique. He states that it "can be compared with an imprisoned squid extending its tentacles in all directions around its body and thereby sensing the topography of the cage".

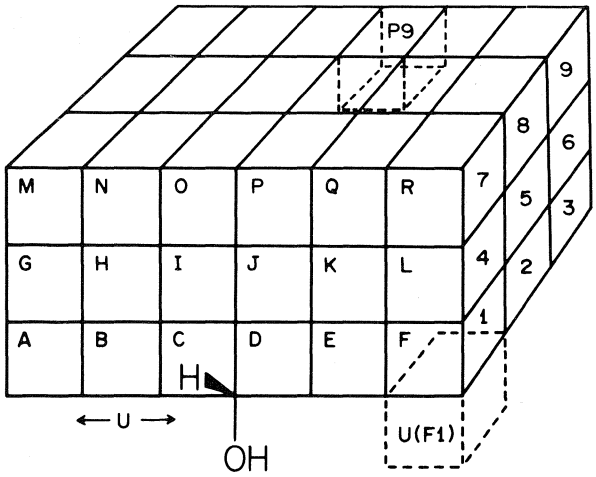

FIG. 1. The cubic-space section encompassing the active site region of HLADH. The cubes each have 1.3 Å edges. The front faces of each cube are labelled alphabetically and the side faces numerically. This permits any individual region to be specified unambiguously, as illustrated for **P9**. Hydride is delivered to or removed from the coenzyme at the front of the lower intersection of **C1** and **D1** as shown. The C—(OH) bond projects downward to coordinate with the active site $Zn^{2+}$ atom. The underneath of the section is designated as **U**. The individual cubes of this bottom region are specified by combining the **U** descriptor with (parenthetically) that of the region immediately above it. Region **U(F1)** is shown.

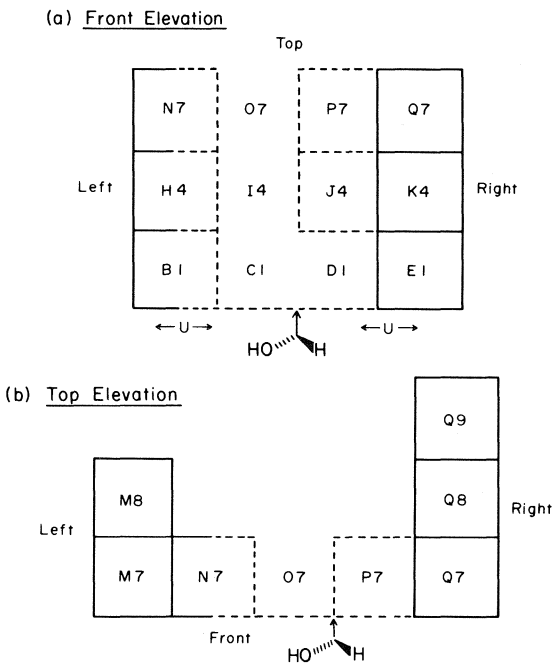

FIG. 2. Specification of the cubic-space model for predicting HLADH stereospecificity. The regions bounded by solid lines (—) are designated as "forbidden". Binding of substrate groups in these regions is precluded because they are already occupied by amino acid side chains of the enzyme. The front of the cubic-space model is occupied by the coenzyme and is also forbidden. The broken-line (---) regions are "limited" in their tolerance of substrate groups due to their being adjacent to amino acid residues or to portions of the coenzyme. While this proximity to forbidden regions does not preclude substrate intrusion into the limited cubes, it does restrict access to these active site areas. Binding in limited areas results in a marked rate decrease. Occupation of limited regions therefore only takes place if binding in the favoured, "allowed", regions is not possible. The allowed regions are represented by the open spaces in the figures. They are areas of the active site that are unoccupied by any enzymic group and can thus readily accommodate substrate groups. In practice, the boundaries between allowed, limited, and forbidden regions are not sharp. Rather, the transition is a graded one where binding of a substrate group becomes increasingly disfavoured the further it penetrates from an allowed space into a limited region and towards a forbidden cube. The projections shown are those of the working model viewed from (*a*) the front and (*b*) the top. Only the outermost cubic faces of each projection are identified alphanumerically. A perspective of the current working model is shown in Fig. 3.

of **B1**, **H4**, and **N7**. The underneath regions reflect the character of the cubes immediately above them. Those below forbidden space, such as **U(E1)**, remain forbidden. Those below limited or allowed cubes will tolerate limited substrate penetration. The cubic portions of the model not specified above are the allowed regions of the active site where substrate binding is freely permitted. This open space corresponds to the "hydrophobic barrel" binding site identified in the X-ray structures (11*f,g*). It curves and opens up towards the rear of the left-hand side of the Fig. 3 model. This active site cleft is depicted from another perspective in Fig. 4.

While our identification of forbidden and limited cubes is largely based on substrate specificity and kinetic data (2–6) it is possible to correlate many of them with the X-ray-derived (5, 11*f, g*) locations of various amino acid residues in the active site region (Fig. 4). Forbidden region **E1** corresponds to the Phe-93 location; **K4**, **Q7** to Ile-116; **E2**, **E3**, **K5** to Phe-110; **O9**, **P9**, and **Q9** to Ile-318. Region **B1** is where Ser-48 is located while Leu-57 occupies the **G4** and **M7**, and half of the **H4** and **N7**, cubes. The **J4** and **P7** cubes are limited regions as a consequence of their proximity to the nicotinamide coenzyme.

It must be stressed that the boundaries between allowed, limited, and forbidden regions are not absolute, with resistance to binding increasing progressively as one proceeds from an allowed region towards a forbidden one. However, as the examples discussed subsequently show, the model permits these distinctions to be made without difficulty.

### General procedure for specificity analyses

Analyses are conveniently performed by constructing the cubic section of Fig. 3, and the

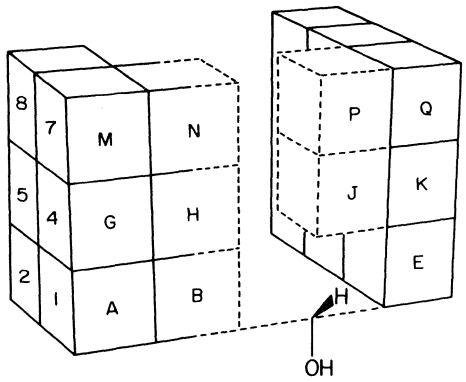

FIG. 3. A perspective of the HLADH cubic-space model used in practice. The model is depicted viewed from a left-front viewpoint. The forbidden regions are shown bounded by solid (—) lines and the limited regions by broken (---) lines. The open spaces are the allowed areas favouring substrate binding. For specificity analyses, the substrate model is built to the same scale. Its C=O or CH(OH) group is first positioned in the required orientation at the oxidation site located at the bottom of the **C1**, **D1** intersection. Its various orientations in the cubic lattice section are then compared in order to identify which, if any, will permit the formation of a productive ES complex. Cubic model and substrate structures constructed from Framework Molecular Models® are convenient.[5]

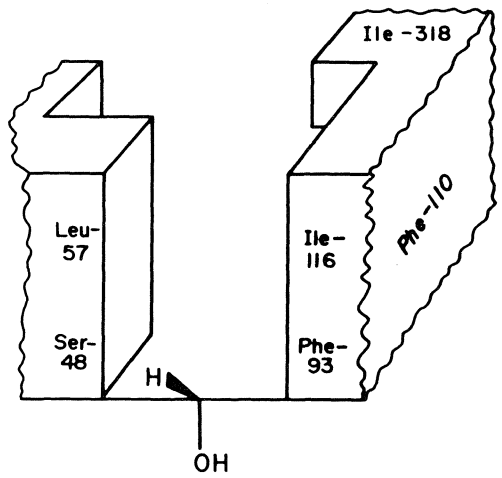

FIG. 4. Schematic representation of the active site binding pocket. The boundaries of the forbidden regions only are shown. The identifications and locations of the amino acid residues responsible for the forbidden regions are based on X-ray data (5*c*, 11).

substrate of interest, from Framework Molecular®, or equivalent, models.[5] The allowed fit, if any, of the substrate at the active site is then established. This is done by identifying, and avoiding if possible, unfavourable interactions that would preclude effective formation of a productive ES complex, in accordance with the following procedure:

(*1*) The carbonyl or hydroxyl group is fixed at the oxidoreduction site such that the C—OH bond being formed or broken is oriented downwards. Hydride delivery or abstraction occurs from the front (the coenzyme binding site) of the cubic section. Because of the rearward-opening nature of the allowed region and the locations of the limited **J4** and **P7** regions (Figs. 2, 3), larger substrates will prefer to bind in a horizontal rather than vertical mode. Thus for cyclohexanol oxidation, the ring adopts a horizontal orientation such that the C—OH bond is axially oriented and the hydride is abstracted from the equatorial direction.

(*2*) For primary alcohol oxidation, the *pro-R* hydrogen atom is removed stereospecifically (14, 15). Conversely, in aldehyde reduction the hydride is delivered to the *Re*-face of the carbonyl group (3).[6]

(*3*) Binding of the substrate must not violate any forbidden regions. A substrate group may occupy a limited region if no allowed cube is accessible, but a slower rate of oxidoreduction must then be anticipated. The rate-reduction effects of occupation of limited areas are cumulative. Location of groups in two or more limited regions becomes virtually equivalent to a forbidden interaction.

(*4*) For potential substrates that are mixtures of stereoisomers, such as racemates or diastereomeric mixtures, each stereoisomer must be analyzed separately.

(*5*) If the substrate is conformationally mobile, the active site interactions of each major conformer of each stereoisomer must be considered independently.

[5]In building the cubic model and substrate structures, we have adopted a 40 mm = 1.54 Å (26 mm = 1 Å) scale. The edge of each cube is 34 mm (1.3 Å). Because the jacks and plastic tubing used to construct the models do take up some space, it is advantageous to extend the edges of cubes **C1**, **D1**, **I1**, and **J1** to 36 mm (1.4 Å) each in order to facilitate positioning of the substrate at the oxidation centre. Octahedral jacks are used for all cubic intersections except for the lower **C1**, **D1** intersection where the CH(OH) function is located. Here a trigonal bipyramidal jack is used to permit the H and OH groups to be oriented in the required directions. Leaving out jacks at structurally non-essential intersections of the framework makes it easier to achieve the positioning of substrate groups in different locations when various substrate orientation possibilities are being compared. We have found it useful to colour-code the cubic model using a traffic light-based convention. The forbidden regions (— in Fig. 3) are bounded in *red* since substrate penetrations are "stopped" by amino acid or coenzyme residues. The limited regions (--- in Fig. 3) are coded *orange* to indicate that one should "proceed with caution" when locating substrate groups in these spaces. The allowed areas are "clear" and *green* tubing is used for their boundaries.

[6]The stereospecificity of hydride delivery always occurs in the same absolute configuration sense. However, for certain ketone substrates, this will not correspond to *Re*-face attack as a consequence of the priority selection rules of the *R*/*S*-system.

(*6*) All stereospecificity predictions apply to oxidoreduction products of kinetic control. Reactions carried out for extended periods may give the thermodynamically preferred compounds whose stereochemistries will reflect free energy differences only and will not be influenced by the initially preferred fit of the substrate at the active site (2*a*, 4).

## Applications of the cubic-space section to HLADH-specificity analyses

Representative examples are given for each major substrate type.

### *(A) HLADH-catalyzed Reductions*

#### *(1) Acyclic Aldehydes and Ketones*

The Prelog rule (3) has been totally reliable in predicting the stereochemistry of reductions of aldehydes[7] and our new model offers no advantage over the simple-to-use Prelog rule. Nevertheless it is worth noting that the cubic space model does predict correctly the stereochemistry of aldehyde reduction (Fig. 5).

The stereochemical course of oxidations of acyclic chiral secondary alcohols (16, 17) and the enantiotopically specific *pro-R* hydrogen abstraction in primary alcohol oxidations (14, 15), are also in accord with the Fig. 5 analysis.

#### *(2) Monocyclic ketones*

##### *(a) 2-Alkylcyclohexanones (1)*

The cubic model analysis for such substrates is illustrated schematically in Fig. 6. For the 2*R*-series, reduction is strongly disfavoured because the required binding of both conformations **I** and **II** would place the R-substituent in the forbidden regions of cubes **B1** or **K4**. Formation of an effective ES complex is therefore precluded for the 2*R*-enantiomers. The same situation holds for the thermodynamically preferred conformer **III** in the 2*S*-series, with its equatorial R-group directed towards the forbidden **E1** region. However, conformation **IV** of (2*S*)-**1** can bind effectively to give a productive ES complex since the axial substituent can be accommodated at the boundary of the allowed **I4** and limited **H4** regions. Reduction in this mode would lead to *trans*-(1*S*,2*S*)-**2**-alkylcyclohexanol (**2**) products. The experimental results are in full agreement with this analysis. The predicted *trans*-(1*S*,2*S*)-**2** alcohols of 100% e.e. are formed when R = Me, Et with the 2*R*-ketones recovered unchanged (5*a*, 6*a*, 18).

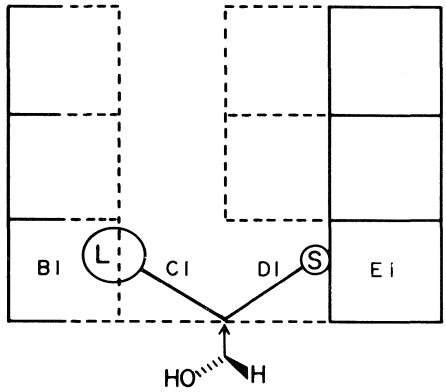

FIG. 5. Analysis of HLADH-catalyzed reductions of acyclic ketones and aldehydes. The favoured orientation is shown in terms of the front elevation of the cubic-space model (Fig. 2*a*), using the Prelog rule convention of (L) and (S) as large and small substituents respectively. The orientation shown permits (S) to occupy the allowed **D1** region while (L) may place itself in the allowed **C1** and limited **B1** sections. The hydride is then delivered to the *Re*-face[6] (for an O > L > S priority sequence (3)) of the carbonyl group to give an alcohol of *S*-configuration (2*a*, *b*, 3). The converse orientation is precluded since it would require (L) to occupy part of **E1**, a strongly forbidden region. Oxidations of chiral acyclic alcohols are analyzed in a microscopic-reverse manner.

Since the productive orientation, conformation **IV** in Fig. 6(*b*), partially occupies the limited region of **H4**, the rate of reduction should be lower than for cyclohexanone itself. This is as found (2*a*, 3–6). Furthermore, as the steric bulk of the R-group is increased, it will intrude further towards the forbidden half of **H4**. This should reflect itself in progressively lower reduction rates, again in accord with the experimental facts. The rate for 2*S*-**1** (R = Et) reduction is less than for 2*S*-**1** (R = Me), while the 2-isopropyl- and 2-*t*-butylcyclohexanones are not substrates at all (5). For the latter two compounds, the substituent at C-2 cannot avoid overlapping a forbidden region, even for conformation **IV**.[8]

[7]HLADH-catalyzed reductions of aldehydes with NAD$^2$H or NAD$^3$H have been widely used for stereospecific preparations of isotopically labelled chiral alcohols for biosynthetic purposes (2*a*,*b*).

[8]Until recently none of the *cis*-isomers of **2**, corresponding to reductions of conformations **I** or **III**, had been detected. However, it has now been demonstrated that when the R-group of **1** is small, such as fluorine (6*a*) or methyl (2*i*), very small amounts (1–4%) of *cis*-2-substituted cyclohexanols of undetermined configurations are produced. These *cis*-isomers must arise from reduction via conformation **I** or **III**. Both orientations are unfavourable (Fig. 6). However, the cubic model predicts that orientation of **I** as in Fig. 6*a* would be the less undesirable since, in contrast to **E1**, the **B1** cube has a limited region that could partially accommodate a small R-group such as fluorine. Thus the minor *cis*-2-fluoro and 2-methylcyclohexanol products should have (1*S*,2*R*) configurations. This point is currently under investigation.

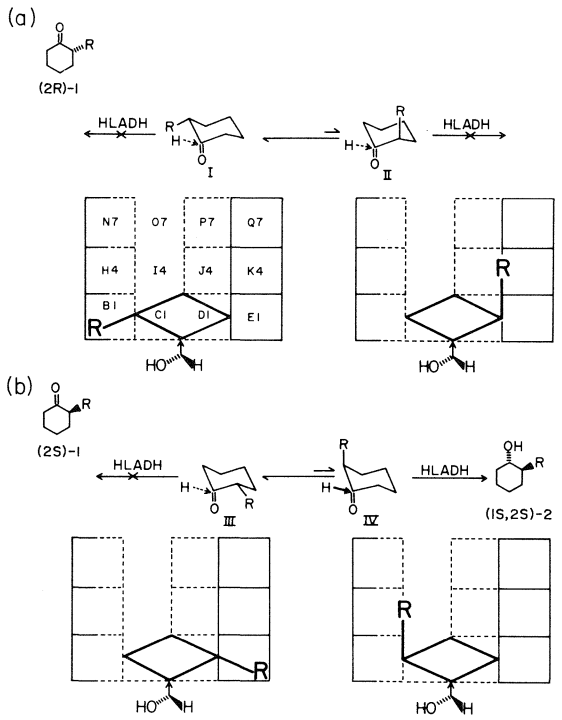

FIG. 6. Interpretation of substrate activity and product stereochemistry for HLADH-catalyzed reductions of 2-alkylcyclohexanones in cubic model terms. Active site binding and orientation of each chair conformation of each enantiomer must be analyzed separately. Part (*a*) covers the 2*R*-series and (*b*) the 2*S*-series. The cyclohexanone rings are shown in the conformations required for correct orientation of the carbonyl group at the hydride delivery site. The direction of hydride delivery from NADH is indicated by the arrows, ---> and → for unreactive and reactive substrate orientations, respectively. The orientations are illustrated with respect to the front elevation of the model (Fig. 2*a*). Only conformation **IV** of the 2*S*-series can bind without violating any forbidden regions.

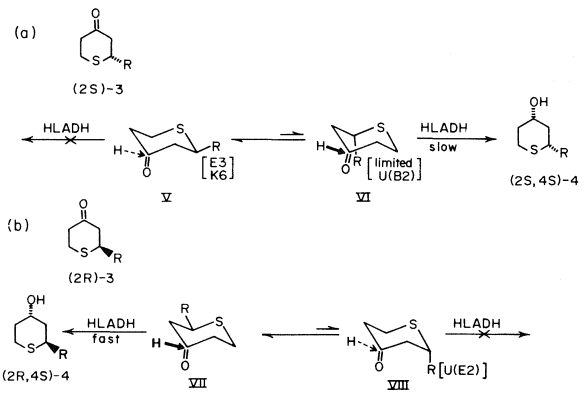

FIG. 7. Interpretations of substrate activity and product stereochemistry for HLADH-catalyzed reductions of 2-alkyltetrahydrothiapyran-4-ones. (*a*) 2*S*[9]-series, (*b*) 2*R*[9]-series. Each conformer is analyzed separately in the manner outlined in the legend for Fig. 6. The orientations of each conformer within the cubic space are depicted from the front elevation perspective (Fig. 2*a*). The regions in which the R-group is required to locate to give a productive ES complex are indicated in square brackets. Reductions via conformations **V** and **VIII** are precluded since R would be placed in forbidden regions **E3,K6** and **U(E2)** respectively. Reduction of **VII** is facile because the **B3,H6** locations accommodating R are allowed. Reduction via **VI** is slower because R must be positioned in **U(B2)**, a cube permitting limited occupation since it lies beneath the allowed area **B2**.

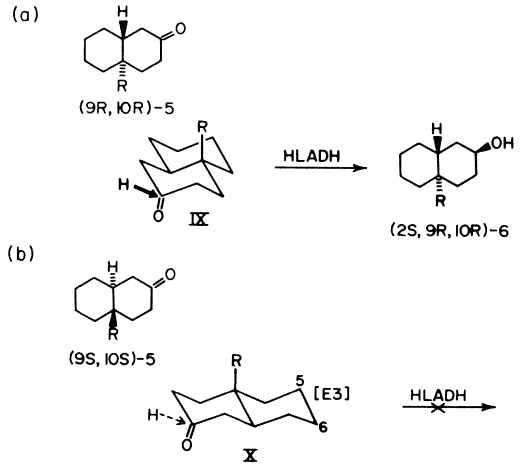

FIG. 8. Representation of *trans*-2-decalone orientations in cubic-space terms. In (*a*), the (9*R*,10*R*)-enantiomers orient as in conformation **IX**, for which all substrate atoms are in allowed regions. Facile reduction to the (2*S*)-alcohol **6** therefore occurs. As shown in (*b*), reduction of the (9*S*,10*S*)-enantiomers is precluded by the fact that binding of conformation **X** cannot avoid locating C-5 and C-6 deep within the forbidden **E3** region.

### *(b) 2-Alkyltetrahydrothiopyran-4-ones (3)*

Heterocyclic substrates can be analyzed in an exactly parallel manner to their carbocyclic analogues. This is illustrated for the sulfur heterocycles (±)-**3**, in Fig. 7. The experimental results with the methyl, ethyl, and isopropyl substituted substrates are as predicted, with the *trans*-alcohols (2*R*,4*S*)-**4** (R = Me, Et) and (2*S*,4*S*)-**4** (R = *i*-Pr)[9] being the major products and *cis*-(2*S*,4*S*)-**4** (R = Me, Et) and (2*R*,4*S*)-**4** (R = *i*-Pr)[9] the minor products (2*c*). With (±)-**3** (R = $C_6H_5$) as substrate, the proportions of *cis*- and *trans*-alcohols are reversed. This is because orientation **VI** has become more preferred than **VII** due to the large phenyl group exceeding the volume of the allowed **B3,H6** region in the direction of the forbidden **G5** cube. All *cis*- and *trans*-alcohol products are of 100% e.e. thus confirming that, as expected, reductions via orientations **V** and **VII** are insignificant.

### *(3) Bicyclic ketones*

### *(a)* trans-*2-Decalones (5)*

Reductions of the *trans*-2-decalones (±)-**5** (R = H, Me) are interpreted in Fig. 8. Formation of the

[9] For **3** or **4** (R = *i*-Pr) the 2*R*- and 2*S*-descriptors are reversed for the Fig. 7 structures.

For personal use only.

2*S*,9*R*,10*R*-stereoisomers of the 2-decalols **6** (R = H, Me) is heavily favoured, and they can be produced in optically pure form by preparative-scale HLADH-mediated reduction of (±)-**5** (R = H, Me). The unreactive (9*S*,10*S*)-2-decalone enantiomers are also isolable in good yield in optically pure form (3, 4, 19).

*(b)* cis-*2-Decalones (7)*

Analysis of the stereochemistry of reduction of *cis*-2-decalones **7** is less straightforward than for their *trans*-isomers owing to their increased conformational mobility. However, only for one of the two all-chair conformations of the 9*R*,10*S*-enantiomers can orientation avoiding all unfavourable regions be achieved. This is shown in Fig. 9. The experimental facts are as predicted, with 2*S*-2-decalols **8** (R = H, Me) of 100% e.e. being the only reduction products isolated in preparative-scale experiments (4, 19).

*(c) Bicyclo[3,2,1]octan-2-one (9)*

Cubic model analysis of the favoured course of HLADH-catalyzed reduction of the bridged bicyclic ketone (±)-**9** is illustrated in Fig. 10. Only for 1*S*,5*S*-**9** is orientation avoiding all forbidden and limited regions possible. This transcribes into formation of the *exo*-alcohol **10** of 1*S*,2*S*,5*S* absolute configuration (Fig. 10*b*). The formation of the other *exo*-alcohol enantiomer is less favourable because it requires C-7 to be positioned in limited region **J4**. However, occupation of a limited cubic space does not preclude a reaction but merely slows it down significantly (*cf.* Fig. 6). Thus in practice the reduction is found to be stereoselective rather stereospecific, giving the 2*S*-*exo* enantiomer of 83% e.e. (2*d*). The *endo*-alcohol isomers are formed in trace amounts only (2*d*, 6*a*). This is because the active site orientations of **9** that are required to give *endo*-products are even more disfavoured by the intrusion of C-5 and C-8 (for 1*S*-**9**) or C-4 and C-5 (for 1*R*-**9**) into both of the limited **J4** and **P7** cubes. As stated previously, intrusion into two limited regions approximates a forbidden interaction.

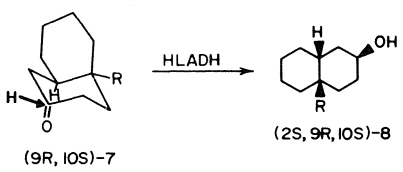

FIG. 9. HLADH-catalyzed reductions of *cis*-2-decalones. Only for the conformation shown of the (9*R*,10*S*)-enantiomers of **7** (R = H,Me) is cubic-space orientation possible that avoids all limited and forbidden regions. Neither of the two all-chair conformations of the (9*S*,10*R*)-enantiomers can be oriented for reduction without C-7 and C-8 violating forbidden positions **E3** and **K5**, or C-6, C-7, and C-8 being placed deep into the limited regions **U(B2)**, **U(B3)**, and **U(C3)**. These enantiomers are thus recovered unchanged.

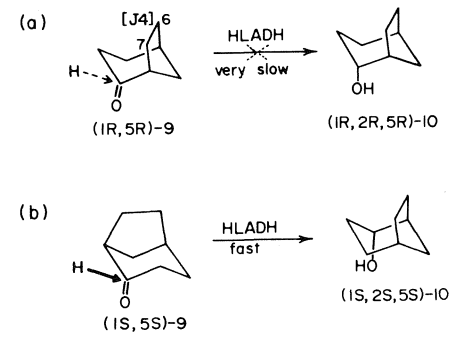

FIG. 10. Interpretation of HLADH-catalyzed reduction of bicyclo-[3,2,1]octan-2-one using the cubic-space system. (*a*) The (1*R*,5*R*)-enantiomer is less readily reduced because its orientation at the oxidation site requires C-7 to locate in limited region **J4**; (*b*) in contrast, the (1*S*,5*S*)-enantiomer can orient with all its atoms in allowed regions. Reduction to 1*S*,2*S*,5*S*-**10** thus occurs readily and is the favoured reaction.

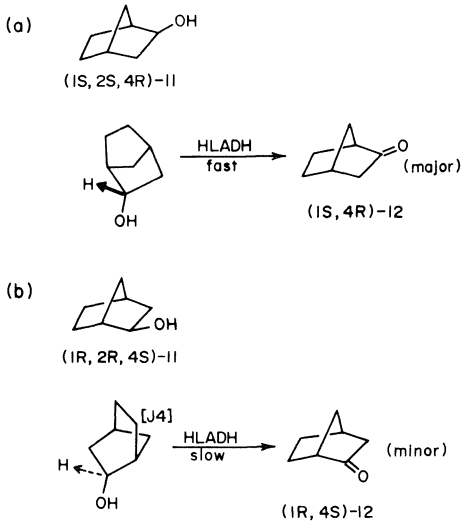

FIG. 11. Analysis of enantioselectivity of HLADH-catalyzed oxidation of (±)-2-norbornanol. (*a*) The (1*S*,2*S*,4*R*)-enantiomer of **11** is readily oxidized since all atoms can be located in allowed positions. (*b*) Oxidation of (1*R*,2*R*,4*S*)-2-norbornanol is slower because C-6 must intrude into limited region **J4**. The net result is a preference for situation (*a*) resulting in the formation of 2-norbornanone (**12**) enriched in the (1*S*,4*R*)-enantiomer as shown.

*(B) HLADH-catalyzed oxidations*

*(1) Mono- and bicyclic secondary alcohols*

Analyses of the stereospecificities of oxidations of such substrates are the microscopic-reverse of the illustrative ketone interpretations described above (Figs. 6–10). The oxidation of (±)-2-norbornanol (**11**) exemplifies this. The stereoselectivity of the catalysis is in accord with the Fig. 11 prediction, with the 2-norboranone (**12**) formed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

being enriched in the (1*S*,4*R*)-enantiomer to the extent of 68% when the reaction is terminated at the 50% oxidation stage (2*d*). The less reactive (1*R*, 2*R*,4*S*)-norbornanol stereoisomer recovered is of 71% e.e.[10]

*(2) Stereospecific and selective oxidations of diols*

In this section, controlled oxidations of substrates possessing one or more primary or secondary alcohol functions are considered. Analyses of primary alcohol oxidations require additional care owing to their increased torsional mobilities.

*(a) Chemo- and enantiospecific oxidation of (±)-*cis*-3(2′-hydroxyethyl)cyclopentanol (13)*

The oxidation of both the primary and secondary alcohol groups must be analyzed separately for each enantiomer. With the primary alcohol functions placed at the oxidation site in the correct orientation for the required *pro-R* hydrogen removal to take place,[11] no orientation can be identified for either enantiomer of **13** for which the C-1 hydroxyl group, or C-1 or C-2, do not violate one or more forbidden regions. Since the forbidden regions are generally hydrophobic, it is particularly unfavourable for a polar group such as the C-1 hydroxyl group even to approach them too closely. Thus oxidation of the primary alcohol function is strongly disfavoured. On the other hand, when the secondary alcohol function of (1*R*,3*S*)-**13** is located at the oxidation site, formation of an unhindered ES complex with all groups in allowed regions is possible (Fig. 12*b*). This cannot be achieved for the (*1S*,3*R*)-enantiomer (Fig. 12*a*). The cubic model analysis is thus in total accord with the experimentally observed results, for which HLADH-catalyzed oxidation of (±)-**13** is found to be totally chemo- and enantiospecific, effecting exclusive oxidation of the secondary alcohol function of the 1*S*,3*R*-enantiomer to give (3*R*)-(2′-hydroxyethyl) cyclopentanone (**14**) of 100% e.e. (2*d*).

Since the determining factor is always the preferred active site fit of a substrate, secondary over primary alcohol oxidation is not always the favoured reaction. For several other substrates possessing both types of hydroxyl functions, exclusive primary alcohol oxidation is observed (2*d*, *e*). In these cases also the enantioselectivities, or lack thereof,[12] and chemospecificities observed are in complete accord with cubic model analyses.

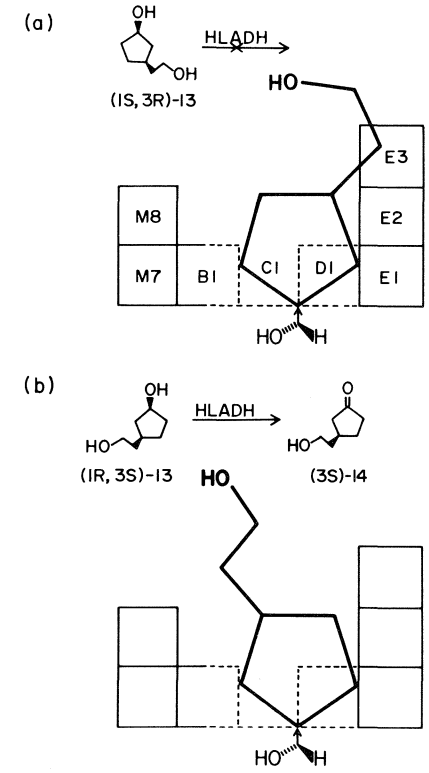

FIG. 12. Interpretation of enantio- and chemospecificity of HLADH-catalyzed oxidation of (±)-*cis*-3-(2′-Hydroxyethyl)-cyclopentanol. Neither $CH_2OH$ group of the enantiomers of **13** can be correctly oriented at the oxidation site for *pro-R* H-removal (11) without C-1, C-2, or the C-1-hydroxyl groups violating one or more of the forbidden positions **U(A3)**, **U(B2)**, **U(C2)**, **U(C3)**, **U(D2)**, **U(D3)**, **U(E3)**, **E2**, **K5**, **M8**, **O9**, or **P9**. Oxidation of the primary alcohol functions is thus precluded. (*a*) Oxidation of the secondary alcohol function of (1*S*,3*R*)-**13** is similarly disfavoured since it would require the C-3—hydroxyethyl function to locate in forbidden region **E3**. This is illustrated using the top elevation perspective of the cubic model (Fig. 2*b*). (*b*) The (1*R*,3*S*)-enantiomer, shown viewed from the same perspective, can be fully accommodated in allowed regions with C-1 at the catalytic site. Oxidation to (3*S*)-**14** is therefore facile.

*(3) Stereospecific oxidations of meso-diols*

All of the cubic-space analyses discussed so far have focussed on identifying differences between binding modes of enantiomeric components of racemic substrates. However, for asymmetric syn-

[10]The enantiomeric excess levels observed in the Figs. 10 and 11 reactions give a semi-quantitative indication of the degree to which requiring a group to be located in a limited rather than allowed region can affect the enantiomeric selectivities of oxidoreductions of such racemates.

[11]The *pro-R* enantiopic specificity of H-abstraction in HLADH-catalyzed oxidations of primary alcohols has been established directly (14, 15). It is also implicit from the stereochemical course of the microscopic-reverse aldehyde-reduction reaction for which delivery of hydride to the *Re*-face of the carbonyl group (*cf.* Figure 5 and discussion thereof) occurs in each of the numerous examples reported (2*a*, *b*, 3).

[12]From the asymmetric synthetic point-of-view the ability to predict when products will be racemic is clearly as important as being able to forecast high enantiomeric discrimination since unproductive enzymic approaches to chiral synthons can then be avoided.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

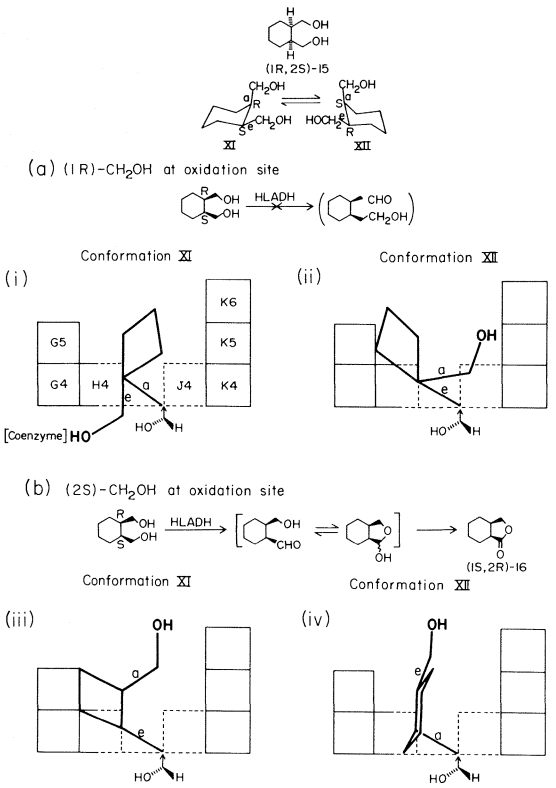

FIG. 13. Analysis of stereospecificity of oxidation of the meso-diol, *cis*-1,2-bis(hydroxymethyl)cyclohexane. The cubic-space orientations of the enantiomeric chair conformers **XI** and **XII** are evaluated separately, with the axial and equatorial $CH_2OH$ groups of each being positioned in turn at the oxidation site, correctly oriented for *pro-R* hydrogen removal. For each analysis, the binding is illustrated from the top elevation perspective (Fig. 2*b*). In (*a*) oxidations of the $CH_2OH$ group attached to the 1*R*-centre are considered. (*i*) Binding for oxidation of the axial-$CH_2OH$ of **XI** to occur cannot take place because the equatorial-$CH_2OH$ attached to the 2*S*-centre would project into the strongly forbidden coenzyme binding zone. Other orientations place parts of the cyclohexane ring in forbidden **U(B2)** and adjacent regions. (*ii*) Oxidations of (1*R*)-$CH_2OH$ group *via* conformation **XII** is also precluded, in this case by the double **H4** and **J4** limited region violations by the cyclohexane C-1—C-6 and (2*S*)-$CH_2OH$ moieties, respectively. (*b*) Oxidation of the (2*S*)-$CH_2OH$ group. (*iii*) Oxidation of the (2*S*)-hydroxymethyl group cannot occur when it is equatorially oriented as in conformation **XI** because the C-3—C-4 region of the cyclohexane ring would violate both limited and forbidden portions of **H4**. (*iv*) Oxidation of the axial (2*S*)-$CH_2OH$ of **XII** is favoured since all of the molecule can occupy allowed regions, except for the minor intrusion of C-3 into the limited region of **B1**. This slows the reaction somewhat but does not prevent it. Oxidation via this ES complex leads initially to the (1*S*,2*R*)-hydroxyaldehyde which undergoes further HLADH-catalyzed oxidation to give the (1*S*,2*R*)-lactone **16** directly (2*f*).

thetic purposes it is much more efficient to perform the desired asymmetric induction on a symmetrical intermediate. Meso-compounds are one such substrate group for which stereospecific enzyme-mediated transformations are possible. HLADH-catalyzed oxidation of *cis*-1,2-di(2′-hydroxymethyl)cyclohexane (**15**) provides a representative example. Interpretation of the reaction in cubic model terms is shown in Fig. 13.

The *cis*-diol **15** is of particular stereochemical interest since its chair conformers are enantiomeric (20, 21). As the Fig. 13 analysis demonstrates, only for oxidation of the axially oriented $CH_2OH$ attached to the 2*S*-centre is formation of a favourable ES complex possible (Fig. 13*b*(*iv*)). The other, unfavourable, binding modes depicted in Fig. 13(*i*), (*ii*), and (*iii*) represent the least disfavoured situations only, with all alternative orientations involving interactions that are equally or more prohibitive. The preparative-scale reaction results confirm this analysis, with HLADH-catalyzed oxidation of the meso-diol **15** occurring with complete stereospecificity to give the (1*S*,2*R*)-lactone **16** of 100% e.e. as the only product (2*f*).

*General applicability of the cubic-space model*

The illustrative examples discussed in this paper represent only a fraction of the known substrates of HLADH. In fact, we have applied the cubic-space analytical method to all of the more than 50 different cyclic and bicyclic compounds presently identified as substrates of HLADH in both published (2–6) and unpublished[13] (22) work. In each case the predictions are in total accord with the experimental observations. The cubic-space model is completely reliable for substrates in which one or more rings are present.[14] It overcomes all of the limitations and uncertainties inherent in the diamond lattice approach[3] and that in recent years have increasingly undermined its credibility. The cubic model is now in routine use in our laboratories and will be extended to new substrate structures as they become known.

[13]These analyses will be reported shortly.

[14]For bifunctional acyclic substrates such as glycerol (23) and pentane-1,5-diols (2*d*,*g*), cubic section analyses are not yet completely unequivocal owing to the multiplicity of conformational and orientation combinations that must be considered. The cubic model is currently being refined to enable such acyclic substrates to be analyzed with confidence.

For personal use only.

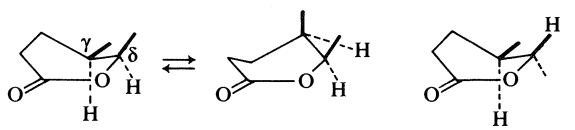
In connection with studies of the effect of substitution on the tendency of δ-hydroxy-acids to lactonize (1), we required a variety of variously-substituted δ-lactones. In this paper we describe the synthesis of the lactones **3**, **5**, **8**, **17**, and **26**; their equilibrium behaviour is described in a companion paper.

The synthesis of the epimers **3** and **5** is shown in Scheme 1. Hydrogenation of the unsaturated ketone **1** in ethanol over palladium-on-charcoal is known to give a 3:2 mixture of **2** and **4** (2). We have found that hydrogenation in ether at −20°C (cf. ref. 3) gives an approximately 85:15 mixture (as determined by nmr) of **2** and **4**. In alkaline solution such a mixture is isomerized almost completely (~90%) to the *trans* ketone **4**. Baeyer–Villiger oxidation of these ketone mixtures with trifluoroperoxyacetic acid gave products consisting in the one case predominantly of the *cis* (**3**) and in the other case predominantly of the *trans*-disubstituted lactone (**5**).

The lactone **5**, a low-melting solid, could be isolated from the reaction mixture in a pure state, and proved to be stable on standing. However, the *cis* lactone **3**, obtained admixed with some **2**, **4**, and **5** as impurities (as shown by nmr), proved surprisingly unstable. In a few days at room temperature it had decomposed to viscous material (presumably polyester), but also in part to more volatile products (carbon dioxide and diene by a reverse Diels–Alder reaction?). In consequence, our characterization of **3** is very incomplete.

It may be expected that **3** exists about equally in the two conformations **3**ea′ and **3**ae′, having one methyl group axial (a) or pseudo-axial (a′), while **5** should exist almost completely in the single conformation **5**ee′. For this reason, the δ-methyl group (δ 1.21; $J$ = 6 Hz) of **3**, being partially pseudo-axial



3ea′ 3ae′ 5ee′

and hence more shielded than the (pseudo-equatorial) δ-methyl of **5** (4), absorbs at higher field than the latter (δ 1.26; $J$ = 6 Hz). The reverse holds true for the δ-protons of **3** (δ 4.3) and **5** (δ 3.8). These protons are part of an $A_3BX$ system ($J_{AX}$ = 6 Hz; cf. methyl splitting, above). The splitting pattern indicates that $J_{BX}$ = 3 Hz for **3** and 8 Hz for **5**. This again accords with the conformations shown above, the dihedral angle between $H_\gamma$ and $H_\delta$ in **5** being close to 180°, and in **3** being close to 60°.

The synthesis of **8** is shown in Scheme 2. The

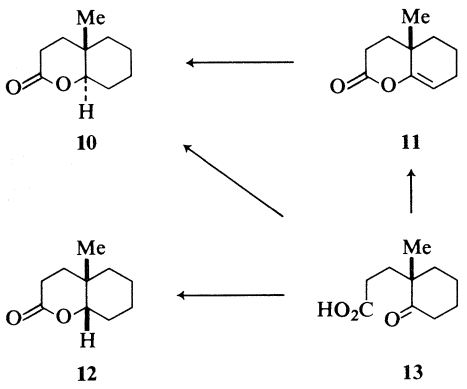
lactones **6** and **8** have hitherto been obtained only as inseparable 1:2 or 2:1 mixtures (6). Treatment of these mixtures with hot polyphosphoric acid gave the unsaturated ketone **7**, from which the *cis* ketone **9** was obtained by hydrogenation. Oxidation of **9** with trifluoroperoxyacetic acid yielded the *cis* lactone **8**, free from the *trans* lactone **6**.

The *cis* lactone **12** has been obtained by a similar stereospecific synthesis (5), but the *trans* lactone **10** has been available only in an inseparable mixture with **12** from the catalytic or borohydride reduction of the keto-acid **13** (Scheme 3) (7). Attempts to obtain isomerically-pure **10** were unsuccessful (8, 9), but the proportion of **10**:**12** could be raised to 83:17 by conversion of **13** into the unsaturated lactone **11**, and hydrogenation of the latter (Scheme 3).



SCHEME 3

The *trans* lactone **16** has been prepared by borohydride reduction of the keto-acid **15**, and the *cis* ("steroid" conformation) lactone **19** by catalytic reduction of **15** in acidic solution (10). The *cis* ("non-steroid" conformation) lactone **17** has now been prepared by the route shown in Scheme 4.

Alkylation of cyclohexanones is known to give initially an axial product (11–13). Consequently, the initial product from the reaction of the enamine of 4-*tert*-butylcyclohexanone with ethyl acrylate, followed by hydrolysis at pH 5–7 (12), must be mostly the axial product **14***c*, contaminated with a small amount of the equatorial ester corresponding to **15***b*. Hydrolysis of the ester group can be expected to be accompanied by epimerization to give mainly the equatorial acid **15** (10). However, this epimerization can be avoided if the carbonyl group is first reduced by hydrogenation over platinum. This gives mainly the β-hydroxy-ester **18**, presumably because approach of the keto group to the catalyst surface takes place more easily when the keto-ester **14** is in the boat conformation **14***b*, so that hydrogen is added to the under-surface of the molecule (see Johnson *et al.* (14) for a closely analogous case). On treatment with acid the hydroxy-ester **18** gave the lactone **17**, accompanied by small amounts of **16** and **19** arising from hydrogenation of the contaminating keto-acid **15**.

The synthesis of **26** (equivalent to **17** with an angular methyl group) is shown in Scheme 5. The stereoelectronic factors which favour the formation of **14** from 4-*tert*-butylcyclohexanone should also favour the formation of the axial product **23** from 4-*tert*-butyl-2-methylcyclohexanone **20**. However, it was found that reaction of the ketone **20** with acrylonitrile went in very low yield. Consequently, the ketone was converted into the trimethylsilyl enol ether **21** (a small amount of the isomeric ether **22** was also formed), and this reacted with methyl lithium to give the lithium enolate. The enolate reacted rapidly with acrylonitrile to give the keto-nitrile **23**, which was hydrolyzed to the keto-acid **24**. Reduction of the latter by either borohydride or catalytic hydrogenation gave only the β-hydroxy-acid **25**, converted by acid to the lactone **26**.

The 9α,10α-configuration of this lactone, advanced above on mechanistic grounds, is supported by its nmr spectrum. The nmr peak for the 9α-proton (δ 3.88) has a band-width $w/2$ at half-height of 18 Hz showing that it is axial (4) and hence 9α.[1] The other possible configuration (9α,10β) with 9α would have the 10-methyl group axial, and hence with an nmr peak at δ ~ 0.97, whereas the peak is at δ 1.12, as expected for an equatorial 10-methyl group (5, 7).

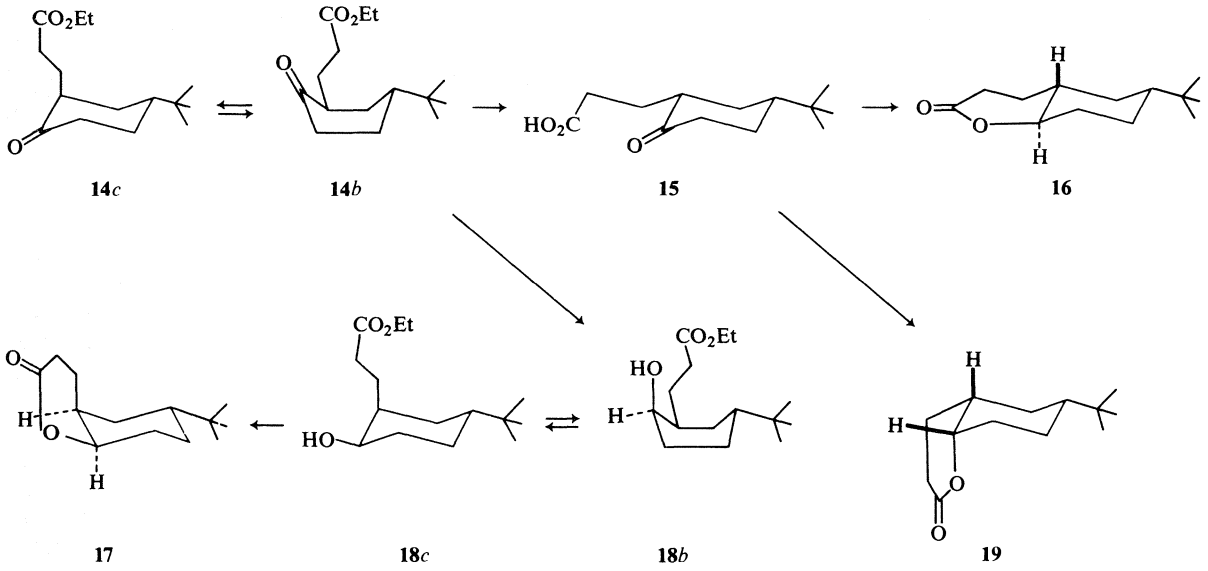
## Experimental

General directions are in ref. 10.

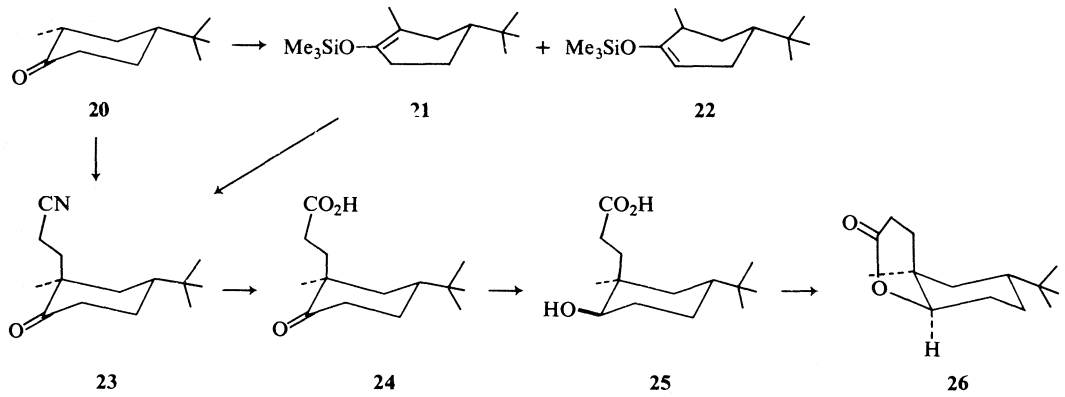
trans-*2,3-Dimethylcyclopentanone (4)*

2,3-Dimethyl-2-cyclopentenone **1** (2) (7.6 g) was hydrogenated over 10% palladium-on-charcoal (8 g) in ethanol (100 mL) until 1460 mL of hydrogen had been absorbed. The catalyst was removed by filtration; vpc (8% QF-1; 6 ft × ¼ in. glass column; 110°C; 100 mL/min $N_2$) of the filtrate showed peaks at 1.4 min (**4**) and 1.8 min (**2**) in the ratio of 1:2. Sodium hydroxide (10 *N*, 2 mL) was added to the filtrate. After 1 h, vpc showed the 1.4 min and 1.8 min peaks in a ratio of 10:1, which did not change further on standing. *trans*-2,3-Dimethylcyclopentanone **4** was isolated in the manner described by Varech *et al.* (2): 6.1 g (79%), bp 30–32°C/5 Torr; $\nu_{max}$ ($CCl_4$): 2955, 2930, 2875, 1740, 1460, 1455, 1408, 1380, 1373, 1355, 1325, 1295, 1270, 1248, 1220, 1215, 1210, 1188, 1158, 1145, 1108, 1080, 1035, 1000, 987, 975, 932, 905, 865, 835 $cm^{-1}$; δ ($CCl_4$): 0.99 (d, 3H, $J$ = 6 Hz), 1.16 (d, 3H, $J$ = 4 Hz), 0.9–2.3 (m, 6H). The semicarbazone had mp 178–179°C (lit. (15) mp 179–180°C), and the 2,4-dinitrophenylhydrazone mp 161.5–164.5°C. *Anal.* calcd. for $C_{13}H_{16}O_4N_4$: C 53.4, H 5.5, N 19.2; found: C 54.4, H 5.8, N 19.6.

[1]The band-width would also be compatible with a 9β,10α-configuration, in which the cyclohexane ring has adopted a boat conformation; however, this lactone would be formed from the hydroxy-acid only under drastic conditions (14), and so it can be excluded.



SCHEME 4



SCHEME 5

trans-γ,δ-*Dimethyl-δ-valerolactone (5)*

A solution of trifluoroperoxyacetic acid was prepared from trifluoroacetic anhydride (39 mL) and 94% hydrogen peroxide (7.8 mL) in methylene chloride (300 mL) (16), and added over 3 h to a stirred solution of *trans*-2,3-dimethylcyclopentanone (6.6 g) in methylene chloride (400 mL) containing suspended disodium hydrogen phosphate (27 g). Stirring was continued for 4 h at room temperature. The solution was filtered, washed with saturated aqueous $NaHCO_3$, saturated aqueous NaCl, and dried ($MgSO_4$). The solvent was then removed by evaporation, and the residue distilled to give a first fraction of starting ketone (0.68 g), bp 30–43°C/5 Torr, followed by the lactone **5** (3.9 g; 51%), bp 100–102°C/5 Torr, purified by a second distillation and then sublimation: mp 26–28°C; $\nu_{max}$ ($CCl_4$): 2980, 2935, 2880, 1740, 1460, 1455, 1419, 1383, 1345, 1326, 1300, 1245, 1220, 1193, 1155, 1110, 1094, 1045, 1031, 982, 968, 910, 850 $cm^{-1}$; nmr δ ($CCl_4$): 0.97 (d, 3H, $J$ = 5 Hz), 1.26 (d, 3H, $J$ = 6 Hz), 1.1–2.5 (m, 5H), 3.87 (m, 1H). *Anal.* calcd. for $C_7H_{12}O_2$: C 65.6, H 9.4; found: C 65.5, H 9.4.

cis-*2,3-Dimethylcyclopentanone (2)*

2,3-Dimethyl-2-cyclopentenone **1** (6.9 g) in diethyl ether (150 mL) was hydrogenated over 10% palladium-on-charcoal (0.08 g) at atmospheric pressure. The temperature was kept between −17°C and −22°C. When hydrogen uptake ceased (4 h), the solution was filtered under $N_2$, and the ether was removed at reduced pressure. Vapor-phase chromatography showed two peaks at 1.4 min (**4**) and 1.8 min (**2**) in the ratio 15:85. To avoid epimerization, the ketone mixture was not distilled: $\nu_{max}$ ($CCl_4$): 2955, 2930, 2875, 1740, 1460, 1450, 1405, 1380, 1370, 1340, 1330, 1295, 1265, 1245, 1215, 1190, 1160, 1155, 1115, 1082, 1045, 1015, 995, 960, 950, 940, 930, 892, 862, 835, $cm^{-1}$; δ ($CCl_4$): 0.92 (d, $J$ = 6.5 Hz), 0.99 and 1.16 (d) (total area: 6H), 1.2–2.6 (m, 6H); δ (benzene-$d_6$): 0.63 (d, $J$ = 6.5 Hz), 0.86 (d, $J$ = 6.5 Hz), 0.92 (d, $J$ = 6 Hz) (total area, 6H), 1.0–2.2 (m, 6H). The 2,4-dinitrophenylhydrazone melted at 161–164°C, and was probably the derivative of **4** because of epimerization under the acidic conditions used to prepare the derivative. *Anal.* calcd. for $C_{13}H_{16}O_4N_4$: C 53.4, H 5.6, N 19.2; found: C 53.9, H 5.7, N 19.2.

cis-γ,δ-*Dimethyl-δ-valerolactone (3)*

Baeyer–Villiger oxidation of **2/4** (85:15) (4.6 g) with trifluoroperoxyacetic acid in methylene chloride was carried out under essentially the same conditions as used above for the oxidation of **4**. The residue from evaporation of methylene chloride was distilled to give starting ketone (0.92 g), bp 30–32°C/5 Torr, followed by a colourless liquid which turned brown in the condenser (0.31 g), bp 66–90°C/5 Torr, and finally the lactone **3**, (2.2 g; 42%), bp 99–102°C/5 Torr; $\nu_{max}$ ($CCl_4$): 1740 $cm^{-1}$; vpc of this material showed only one peak at 12.3 min (same retention time as **5**); however, after several days vpc showed several components eluting before the original component at 12.7 min, and additionally it had become viscous.

*4,5,6,7-Tetrahydroindan-1-one (7)*

3-(2-Oxocyclohexyl) propionic acid (8.5 g) was reduced with sodium borohydride following House *et al.* (6), and the resulting crude lactone mixture **6/8** (6.9 g) was added to polyphosphoric acid (105 g) at 120°C according to the method of Dev and co-workers (17). The mixture was stirred for 2 min every 30 min. After 4.5 h the mixture was placed in the refrigerator overnight, then hydrolyzed with 300 mL of ice–water slush. The mixture was extracted with ether, and the ether solution washed with water, aqueous $NaHCO_3$, aqueous NaCl, and dried ($MgSO_4$). The solvent was removed at reduced pressure and the oily residue distilled at 0.1 Torr to give **7**, bp 66–68°C; $\nu_{max}$ (neat): 2945, 2920, 2869, 1690, 1645, 1460, 1440, 1408, 1405, 1390, 1300, 1275, 1250, 1230, 1210, 1180, 1150, 1130, 1120, 1090, 1060, 1010, 990, 950, 870, 855, 840, 800 $cm^{-1}$; δ ($CCl_4$): complex absorption between 1.6 and 2.5; no olefinic proton. The 2,4-dinitrophenylhydrazone melted at 238–239°C (lit. (18) mp 238.5–239.5°C).

cis-*Perhydroindan-1-one (9)*

4,5,6,7-Tetrahydroindan-1-one (4.1 g) was reduced over 10% palladium-on-charcoal (0.42 g) in ethanol (100 mL) at room temperature and atmospheric pressure according to House and Rasmusson (18). After absorption of one equiv. of hydrogen, the solution was filtered and extracted with ether. The ether solution was washed with sodium bicarbonate and dried ($MgSO_4$). Removal of the ether yielded an oil which was distilled at 0.05 Torr to yield **9** (3.3 g, 81%), bp 32–33°C; $\nu_{max}$ ($CCl_4$): 2940, 2880, 2860, 1735, 1470, 1460, 1445, 1440, 1410, 1355, 1345, 1330, 1310, 1305, 1290, 1280, 1250, 1210, 1190, 1155, 1140, 1105, 1055, 1045, 1030, 990, 970, 925, 905, 870, 850 $cm^{-1}$; δ ($CCl_4$): complex absorption between 1.0 and 2.8. The 2,4-dinitrophenylhydrazone melted at 164–166°C (lit. (19) mp 163–165°C, (20) mp 160–162°C).

cis-*1-Oxadecal-2-one (8)*

Oxidation of **9** (2.3 g) with trifluoroperoxyacetic acid was carried out essentially as described above for **4**. The oily residue was distilled at 0.1 Torr to yield starting ketones (0.2 g) bp 40–41°C, and *cis*-lactone **8** (1.48 g; 55%), bp 78–80°C; vpc (8%, QF-1, 6 ft × ¼ in. glass column, 170°C, 120 mL/min $N_2$) showed only one peak for **8** at 4.4 min, and no peak for **6** at 4.8 min; $\nu_{max}$ ($CCl_4$): 2940, 2850, 1735, 1460, 1445, 1435, 1420, 1370, 1350, 1335, 1295, 1240, 1195, 1180, 1162, 1138, 1110, 1068, 1043, 1005, 993, 940 $cm^{-1}$; δ($CCl_4$): 1.1–2.5 (complex absorption, 13H), 4.43 (multiplet, 1H). *Anal.* calcd. for $C_9H_{14}O_2$: C 70.1, H 9.1; found: C 70.2, H 9.2.

*10-Methyl-1-oxa-Δ⁸-octal-2-one (11)*

3-(1′-Methyl-2′-oxocyclohexyl) propionic acid **13** (21) (92 g) was treated with a solution of acetic anhydride (1 *M*) and perchloric acid (0.001 *M*) in ethyl acetate (1000 mL) according to Edwards and Rao (22) to yield the unsaturated lactone **11** as an oil (71 g; 85%), bp 98–100°C/0.7 Torr; $n_D^{20}$ 1.5058; $\nu_{max}$ ($CCl_4$): 1750, 1680 $cm^{-1}$. *Anal.* calcd. for $C_{10}H_{14}O_2$: C 72.3, H 8.5; found: C 72.3, H 8.4.

*Hydrogenation of 10-methyl-1-oxa-Δ⁸-octal-2-one (11)*

The unsaturated lactone **11** (4.9 g) in cyclohexane (50 mL) was hydrogenated over platinized charcoal (1.3 g) at room temperature and pressure. After absorption of 1 equiv. of hydrogen (16 h), the mixture was filtered, washed with aqueous $NaHCO_3$, dried ($MgSO_4$), and concentrated. The residue on distillation gave an oil (3.09 g; 60%), bp 97–100°C/0.2 Torr; $n_D^{20}$ 1.4913; $\nu_{max}$ ($CCl_4$): 1740 $cm^{-1}$, shown by nmr (5) to be a 83:17 mixture of **10/12**.

4-tert-*Butyl-2-(2′-ethoxycarbonylethyl) cyclohexanone (14)*

Freshly distilled ethyl acrylate (22 g) was added to a solution of 4-*tert*-butyl-1-pyrrolidinocyclohexene (12) (33.6 g) in dry dioxane (300 mL). The mixture was refluxed for 8 h under $N_2$, and then hydrolyzed with dilute acetic acid at pH 5–7 and extracted according to Karady *et al.* (12). The keto-ester **14** was obtained as an oil (20 g; 64%), bp 127–131°C/0.3 Torr; $\nu_{max}$ ($CCl_4$): 2960, 2910, 2870, 1740, 1715, 1392, 1375, 1366, 1328, 1300, 1250, 1100, 1040, 985, 965, 950, 927, 855, 780, 685 $cm^{-1}$.

6α-tert-*Butyl-1-oxa-9α,10α-decal-2-one (17)*

The keto-ester **14** (12.4 g) was hydrogenated at room temperature and 40 psi over pre-reduced platinum oxide (1.26 g) in ethanol (150 mL). After hydrogen absorption had ceased, the solution was filtered and the ethanol removed under reduced pressure to yield the crude, hydroxy-ester **18** as an oil ($\nu_{max}$ ($CCl_4$): 3400 (broad, OH), 1740 $cm^{-1}$.

A solution of the crude hydroxy-ester (6.4 g) in 2 *N* hydrochloric acid (50 mL) was refluxed for 10 h. The resulting mixture was extracted with ether, and the ether solution was washed with aqueous $NaHCO_3$, aqueous NaCl, and dried ($Na_2SO_4$). The residue from evaporation of the ether (4.8 g; 91%) on vpc (6 ft × ¼ in. glass column, 8% QF-1, 175°C, 120 mL/min $N_2$) showed components with retention times of 12 min (**19**), 14 min (**16**), and 17 min (**17**) in the ratio 9:30:60. The third component was collected as a pale yellow oil by preparative vpc, and solidified on standing. It sublimed at 40°C/0.1 Torr to yield **17** as a colourless solid, mp 51.7–53°C; $\nu_{max}$: 2930, 2855, 1735, 1468, 1455, 1448, 1420, 1393, 1383, 1363, 1352, 1345, 1325, 1305, 1280, 1265, 1247, 1230, 1219, 1198, 1187, 1165, 1150, 1118, 1092, 1050, 1042, 1038, 1032, 985, 950, 928, 900, 863 $cm^{-1}$; δ ($CCl_4$): 0.84 (s, 9H), 0.90–2.55 (complex multiplet, 12H), 4.32 (1H). *Anal.* calcd. for $C_{13}H_{22}O_2$: C 74.2, H 10.5; found: C 74.1, H 10.3.

*Trimethylsilyl enol ethers of* 4-tert-*butyl-2-methylcyclohexanone (21/22)*

Chlorotrimethylsilane (6 mL) and triethylamine (14 mL) were added to a solution of 4-*tert*-butyl-2-methylcyclohexanone **20** (23) (6.29 g) in 35 mL of dimethylformamide according to the procedure of House *et al.* (24). The mixture was heated for 24 h, then diluted with ether, washed with cold aqueous $NaHCO_3$, cold aqueous NaCl, and dried ($MgSO_4$). The ether was removed by evaporation, and the residue distilled at 0.2 Torr to give three fractions: A (1.42 g), bp 58–64°C; B (2.22 g), bp 64°C; C (3.91 g), bp 65°C (total yield 78%); vpc (8% QF-1, 6 ft × ¼ in. glass column, 110°C, 80 mL/min $N_2$) showed A and B to be made up of approximately 1:2 mixture of **22** (2.6 min) and **21** (3.3 min); and a small amount of **20** (6.8 min); C to be made up of a 1:5.5 mixture of **22** and **21**: δ ($CCl_4$): 0.17 (s, 9H), 0.85 (s, ca. 9H), 1.48 (s, ca. 3H), 1.05–2.2 (complex, ca. 7H).

4α-tert-*Butyl-2β-(2′-cyanoethyl)-2α-methylcyclohexanone (23)*

*(a) By cyanoethylation of* 4α-tert-*butyl-2ξ-methylcyclohexanone*

Freshly distilled acrylonitrile (4.7 g) was added dropwise to 4α-*tert*-butyl-2ξ-methylcyclohexanone **20** (75.6 g) stirred with Triton B (0.9 g) over 15 min. The mixture was stirred at room temperature for 45 min, then acidified with 50% hydrochloric

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

acid and diluted with ether. The ether layer was washed with aqueous $NaHCO_3$, aqueous NaCl, dried ($MgSO_4$), and concentrated by evaporation. The residue was distilled, and gave **20** (68.0 g), bp 66–68°C/0.4 Torr, followed by crude ketonitrile as a colourless oil (1.0 g; approximately 5%), bp 132–136°C/0.4 Torr; $\nu_{max}$: 2240, 1710 $cm^{-1}$. Vapor-phase chromatography (175°C, 120 mL/min $N_2$) of the crude material showed three components at 7.4, 10.6, and 12.8 min in the ratio 1:1:8. The components were separated by vpc, but only the third component could be obtained pure. It was crystallized from hexane, and then sublimed at 35°C/0.05 Torr to give the white solid **23**, mp 52–52.5°C; $\nu_{max}$ ($CCl_4$): 2950, 2920, 2855, 2240, 1710, 1478, 1460, 1425, 1393, 1381, 1368, 1335, 1282, 1232, 1160, 1115, 1090, 1020, 1000, 952, 925, 935 $cm^{-1}$; δ ($CCl_4$): 0.92 (s, 9H), 0.99 (s, 3H), 1.2–2.5 (complex, 11H). *Anal.* calcd. for $C_{19}H_{23}NO$: C 76.0, H 10.5, N 6.3; found: C 76.0, H 10.3, N 6.3.

*(b) By cyanoethylation of lithium enolates derived from **21**/**22***

To 4.75 g of the trimethylsilyl enol ether mixture (approximately 88% **21** and 12% **22**) in 25 mL of dry glyme (distilled from lithium aluminum hydride) in a three-necked flask fitted with a septum and flushed with dry nitrogen was added 8.3 mL of 2.4 *N* methyl lithium through the septum, using a dry syringe flushed with dry nitrogen. The mixture was stirred at room temperature for 15 min and then cooled to 0°C; 1.2 mL of freshly-distilled acrylonitrile was added by means of a syringe. After 1 min the mixture was quenched with dilute hydrochloric acid. The mixture was diluted with ether, and the ether layer was washed with aqueous $NaHCO_3$, aqueous NaCl, dried ($MgSO_4$), and concentrated. Fractional distillation of the residue gave an oil, bp 134–138°C/0.05 Torr (2.5 g; 56%); $\nu_{max}$ ($CCl_4$): 2240, 1710 $cm^{-1}$, shown by vpc to have three components in the ratio 1:1:8 with retention times of 7.4, 10.6, and 12.8 min (i.e. ca. 80% **23**).

*3-(5′-*tert*-Butyl-1′-methyl-2′-oxacyclohexyl) propionic acid (**24**)*

The crude ketonitrile (approximately 80% **23**) (2.0 g) from the experiment above was refluxed in 10 mL of 10% aqueous sodium hydroxide for 15 h. The reaction mixture was acidified with 50% hydrochloric acid and extracted with ether. The ether extract was washed with aqueous sodium bicarbonate. The bicarbonate solution was acidified and extracted with ether. This ether extract was washed with aqueous NaCl, dried ($MgSO_4$), and concentrated. The residue solidified on standing and was recrystallized from hexane–ether to yield 1.34 g (62%) of the keto-acid **24**, mp 118–119.5°C; $\nu_{max}$ ($CCl_4$): 3350–2500, 2960, 2940, 2875, 1705, 1480, 1460, 1445, 1425, 1400, 1385, 1370, 1340, 1305, 1295, 1280, 1250, 1230, 1172, 1130, 1090, 1020, 1003, 980, 950, 935, 915, 870 $cm^{-1}$; δ ($CCl_4$): 0.92 (s, 9H), 0.97 (s, 3H), 1.05–2.45 (complex 11H), 11.0 (s, 1H). *Anal.* calcd. for $C_{14}H_{24}O_3$: C 70.0, H 10.0; found: C 70.3, H 9.9.

*3-(5′-*tert*-Butyl-1′-methyl-2′-hydroxycyclohexyl)-propionic acid (**25**)*

Sodium borohydride (60 mg) was added to a solution of the keto-acid **24** (700 mg) in 0.2 *N* aqueous sodium hydroxide (20 mL). The mixture was stirred at room temperature for 10 h, then 50% hydrochloric acid was added to destroy excess borohydride. The mixture was stirred for 45 min and extracted with ether. The ether extract was washed with aqueous sodium bicarbonate, aqueous NaCl, and dried ($MgSO_4$). On evaporation of the ether it yielded 69 mg (11%) of the crude lactone **26** (see below).

The sodium bicarbonate solution was acidified and extracted in the usual way to yield an oily solid which crystallized from cold ether–hexane to give the hydroxy-acid **25** (362 mg), mp 140.5–142°C; $\nu_{max}$ (KBr): 3500–2500 (broad), 1715, 1480, 1460, 1440, 1400, 1390, 1375, 1325, 1320, 1300, 1270, 1215, 1205, 1165, 1145, 1110, 1060, 1035, 1010, 940, 930, 925 $cm^{-1}$. Another 91 mg of **25** was obtained from the mother-liquors by preparative tlc.

*6α-*tert*-Butyl-10α-methyl-1-oxa-9α-decal-2-one (**26**)*

*(a) By lactonization of **25***

The hydroxy-acid **25** (432 mg) was refluxed for 15 min in xylene (200 mL) in the presence of *p*-toluenesulfonic acid (150 mg), following the method of Johnson *et al.* (14). The reaction mixture was diluted with ether, and washed with aqueous $NaHCO_3$, aqueous NaCl, and dried ($MgSO_4$). Concentration of the solution left a heavy yellow oil which solidified on standing. It was recrystallized from hexane and then sublimed at 45°C/0.1 Torr to give the lactone **26** (212 mg; 53%), identical with the product from hydrogenation of the keto-acid **24** (see below).

*(b) By hydrogenation of the keto-acid **24***

The keto-acid **24** (537 mg) was hydrogenated over pre-reduced platinum oxide (60 mg) in 4.5 mL of glacial acetic acid containing 0.5 mL of concentrated hydrochloric acid, at room temperature and 45 psi. When absorption had ceased, the solution was filtered and diluted with ether. The ether extract was washed with aqueous $NaHCO_3$, aqueous NaCl, and dried ($MgSO_4$). Evaporation of the ether under reduced pressure left an oil which solidified on standing. Recrystallization from hexane followed by sublimation at 45°C/0.1 Torr gave the lactone **26** as a colourless solid (395 mg; 76%), mp 65–66°C; $\nu_{max}$ ($CCl_4$): 2955, 2935, 2865, 1740, 1470, 1455, 1435, 1420, 1395, 1385, 1370, 1365, 1340, 1320, 1305, 1260, 1238, 1215, 1187, 1165, 1153, 1130, 1105, 1085, 1058, 1003, 960, 945, 920, 850, 840, 830 $cm^{-1}$; δ ($CCl_4$): 0.95 (s, 9H), 1.12 (s, 3H), 1.15–2.55 (complex, 11H), 3.88 (m, 1H). *Anal.* calcd. for $C_{14}H_{24}O_2$: C 74.9, H 10.8; found: C 74.7, H 10.9.

Received June 4, 1981

P. M. DEYÁ, A. COSTA, J. V. SINISTERRA, and J. M. MARINAS. Can. J. Chem. **60**, 35 (1982).

The catalytic protodealkylation mechanism of arenes (R—Ph), using a $SiO_2$–$AlPO_4$ catalyst has been studied using the microcatalytic pulse technique. Two hydrocarbon series were used: normal series (R = Me, Et, *n*-Pr, and *n*-Bu) and α-methylated series (R = Me, Et, *i*-Pr, and *t*-Bu). In all cases it was shown that the process may be described by means of Bassett–Habgood's kinetics. That is to say, the process is a first order reaction ($r = kP_{HC}$) where the rate-controlling step is the surface reaction.

Real activation energies of the superficial process have been determined, all results showing values of the same order within the experimental error, which indicates that the transition state is the same for all alkylbenzenes because all the kinetics are first order.

Correlations between kinetic constants and electrical (σ*) and steric ($E_s$) parameters have been sought. The best are obtained when values for the α-methylated series are plotted against σ* and those for the normal series against $E_s$.

A possible reaction pathway of the $S_E2$ (Ad–E) type is proposed.

P. M. DEYÁ, A. COSTA, J. V. SINISTERRA et J. M. MARINAS. Can. J. Chem. **60**, 35 (1982).

Faisant appel à la technique d'impulsion microcatalytique on a étudié le mécanisme de la protodésalkylation catalysée des arènes (R—Ph) en utilisant le $SiO_2$–$AlPO_4$ comme catalyseur. On a utilisé deux séries d'hydrocarbures: les séries normales (R = Me, Et, *n*-Pr et *n*-Bu) et les séries α méthylées (R = Me, Et, *i*-Pr et *t*-Bu). On a montré, dans tous les cas, que le processus peut être décrit au moyen des cinétiques de Bassett–Habgood. Ceci signifie que le processus est une réaction d'ordre un ($r = kP_{HC}$) où la réaction de surface est l'étape déterminante.

On a déterminé les énergies réelles d'activation de la réaction de surface. Tous les résultats donnent des valeurs ayant le même ordre de grandeur à l'intérieur des erreurs expérimentales, ce qui signifie que l'état de transition est le même pour tous les alkylbenzènes parce que toutes les cinétiques sont d'ordre un. On a cherché à établir des corrélations entre les constantes cinétiques et les paramètres électrique (σ*) et stérique ($E_s$). On a obtenu les meilleures corrélations en tracant des courbes des valeurs des séries α méthylées en fonction de σ* et celles des séries normales en fonction de $E_s$.

On propose un mécanisme réactionnel possible de type $S_E2$ (Ad–E).

[Traduit par le journal]

## Introduction

The catalytic protodealkylation of arenes using acid catalysts can be referred to a $S_E2$ (Ad–E) type reaction according to most authors (1–3). In spite of this wide consensus of opinion, there is great discrepancy as to what type, or types, of active centers take part in the reaction, some authors proposing Bronsted centers (1) and others those of the Lewis type (2). Yet other investigators propose that both types of centers are involved (3).

Concerning the kinetic scheme of the catalytic cracking of monoalkylbenzenes, most authors accept the kinetics proposed by Prater and Lago (4) with only one center involved. This process can be described as:

$$A + L \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} A\cdot L \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} L\cdot C + B$$

$$L\cdot C \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} L + C$$

Still other authors, such as Garcia de la Banda and co-workers (5), propose the participation of two equal active sites with the adsorption of reagents and products, and other authors, such as Campbell and Wojciechowski (6) propose a more complex mechanism called "Delta".

In the present work, we have approached the study of the catalytic protodealkylation of arenes along the lines of investigation followed for the application of $AlPO_4$ and related systems to different organic reactions (7, 8). Several monoalkylbenzenes corresponding to α-methylated and normal series have been used.

## Experimental

*Catalyst*

The method of synthesis of the catalyst called F-72 (80% $SiO_2$ – 20% $AlPO_4$) used in this work has been published in a previous paper (9). This catalyst has been shown to produce the best results in this cracking process (9).

*Apparatus*

The reactor system was similar to that described by Tobin *et al.* (10). The fixed bed vertical reactor was made of 1/4 in. id and

40 mm long stainless steel and heated by an electrical microfurnace (180 W at 220 V). The catalyst particles (0.125–0.250 mm) never exceeded 130 mg in order to avoid interparticular diffusion phenomena and were held in place by two plugs of glass wool. The reaction temperature was measured with a NiCr–Ni thermocouple connected to a Getrosist 96 Phillips controller. Pulses of hydrocarbon were introduced in a nitrogen carrier stream (flow rate 15 mL/min) by means of a 10 μL Hamilton CH 701 RN syringe, and the chromatographic separation of reactants and products was then carried out in a Hewlett–Packard 5834A gas chromatograph using a 2 m by 1/4 in. column, packed with polyphenylether on Chromosorb G, AW DM cs 80–100, heated from 130 to 170°C at a rate of 10°C/min. Under these experimental conditions, diffusion phenomena can be considered to be minimal.

*Procedure*

*(a) Operation of the Microreactor Unit*

Catalyst charges of 20–130 mg were used. The catalyst was stabilized by heating to 200°C for 12 h in flowing nitrogen (10 mL/min). Experiments were carried out at temperatures ranging from 300 to 520°C by inserting several pulses of 0.5 μL at each temperature and charge of catalyst.

The temperature used in every case was chosen in order to avoid secondary reaction products that could complicate the study of the mechanism of the process.

*(b) Determination of the Textural and Acidity Properties of the Catalyst*

From the adsorption–desorption nitrogen isotherms at liquid nitrogen temperature, the surface area ($S_{BET}$) and accumulated pore volume ($\Sigma V_p$) were determined by the B.E.T. method (11). The total acidity of the catalyst was measured by titration in a nonaqueous medium, applying the alterations to the original method (12) proposed by Benesi (13) and Balikova (14), using *p*-dimethylaminoazobenzene as Hammett indicator ($pK_a$ = +3.3).

The results obtained were: $S_{BET} = 393.0 \pm 15.7\ m^2/g$; $\Sigma V_p = 0.56 \pm 0.02$ mL/g, and acidity = $0.19 \pm 0.01$ mequiv/g.

## Results and Discussion

*Kinetic Procedure*

The results obtained by the microcatalytic pulse technique perfectly fit the Bassett–Habgood equation [1] (15) as can be seen in Fig. 1.

$$[1] \quad \ln \frac{1}{1-X} = RTkK \frac{W}{F}$$

From this fitting for both α-methylated series and normal series of hydrocarbons (Fig. 1) it can be deduced that, under our experimental conditions, the system can be described in accordance with Bassett and Habgood's postulates as first-order kinetics, $r = kP_{HC}$, the rate-controlling step being the surface reaction (15). From this, the cracking of alkylaromatic hydrocarbons with our catalyst appears to follow a kinetic scheme analogous to that proposed by Prater and Lago (4), verified by other authors for other kinds of cracking catalysts (3, 5, 6, 16, 17).

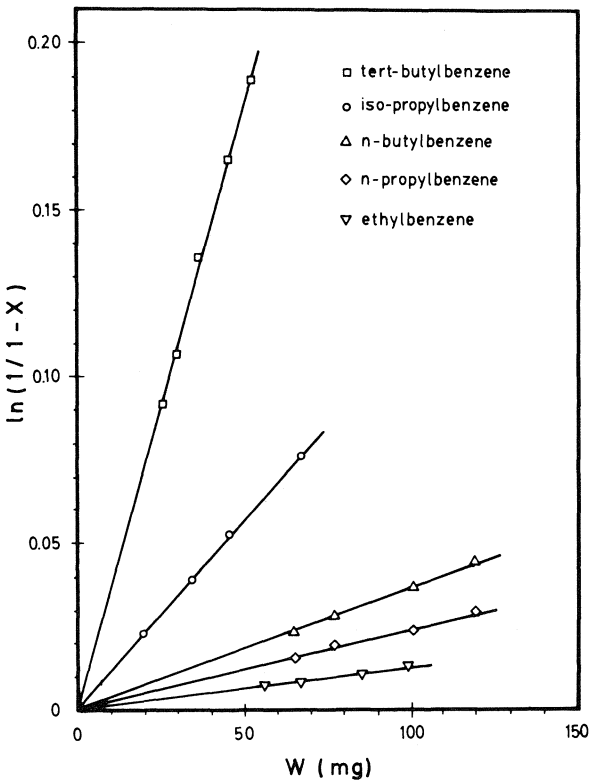

FIG. 1. Plots of ln (1/(1 − *X*)) versus *W* (mg of catalyst).

*Pseudokinetic Constants and Apparent Activation Energies*[1]

Using Bassett and Habgood's kinetic expression [1], it is possible to obtain pseudokinetic constant values (*kK*) at any given temperature by plotting ln (1/(1 − *X*)) versus *W* while the apparent activation energy ($E_{A(ap)}$) is obtained in each case by plotting ln (ln (1/(1 − *X*))) versus 1/*T*. The results obtained are shown in Table 1.

The $E_{A(ap)}$ values are of the same order as some values found in the literature for the cracking of cumene using $SiO_2$–$Al_2O_3$ (5, 18) and zeolites (6, 19).

*Kinetic Constants and Real Activation Energies*

Utilizing adsorption constants (*K*) determined previously (20) by means of a gas-chromatographic technique (21), it is possible to separate the pseudokinetic constant (*kK*) into its component parts: rate constant (*k*) and adsorption constant (*K*). Results are shown in Table 2.

*Reference 20.

The table also shows values for enthalpy of adsorption (20) and activation energies and frequency factors (ln $PZ$) obtained from the study of the variation of ln $k$ with $1/T$. From values obtained in this way, it can be seen that the $E_{A(real)}$ values from the superficial process are practically constant (~33 kcal/mol) within experimental error for all hydrocarbons studied. This, combined with the fact that we are dealing with first order kinetics, seems to indicate that the transition state is of the same type for all the hydrocarbons. The nature of the alkyl chain (R) is not an influencing factor on the transition state type.

This similar transition state can only be explained by supposing that it is analogous to that observed in electrophilic aromatic substitution ($S_E2$) reactions in homogeneous phase where, in the slow step of the reaction, there is a loss of aromaticity leading to the σ complex in which the leaving group, in this case R, has not yet left the ring.

The conceptual distinction between $E_{A(real)}$ and $E_{A(ap)}$ used in this work should be pointed out here to avoid confusion. $E_{A(real)}$ values correspond to the energy difference between the adsorbed state and the transition state, while $E_{A(ap)}$ values refer to the difference in energy between the initial state of the reactants and the transition state. It can be shown in this way that the values obtained by subtracting $E_{A(real)}$ from $E_{A(ap)}$, in every case, coincide with the $\Delta H_{ads}$ values found in a previous study (20) by an experimental technique distinct from that used in the present work, which is in agreement with what we have indicated earlier in this paper.

The $E_{A(real)}$ values found here are of the same order as some values found in the bibliography for the cracking of alkylaromatic hydrocarbons on $SiO_2$–$Al_2O_3$ (4, 22) and zeolites (22, 23).

*Influence of the Nature of R group on the Kinetic Constant*

In an attempt to understand the mechanism of this organic process, the kinetic constants ($k_{460}$, extrapolated by means of ln $k$ vs. $1/T$ plots data at a temperature of 460°C; Table 2) were examined for correlations with electrical (σ* from Taft) and steric ($E_s$ from Taft) parameters taken from the literature (24) in order to observe the behavioural tendency of these plots in the cases where the fit was better.

For the α-methylated series, the best correlations were obtained by plotting the kinetic constant ($k$) against σ* (eq. [2]) and for the normal series, by plotting $k$ values against $E_s$ (eq. [3]):

[2] α-methylated $\log k/k_0 = -17.03\sigma^* + 0.20$ ($r = 0.99$)

[3] normal $\log k/k_0 = -1.22E_s + 0.00$ ($r = 0.99$)

In these equations $k_0$ represents the kinetic constant of ethylbenzene, since no cracking process for toluene was observed.

From the before-mentioned equations it can be deduced that for the α-methylated series the electrical effects (σ*) are primary influences, because plots versus $E_s$ give a correlation coefficient of only 0.91. This is a logical conclusion since the arenes of

this series differ only in the nature of the carbon atom directly joined to the aromatic ring (primary, secondary, or tertiary). For the normal series, on the other hand, steric effects ($E_s$) have the greater influence (the correlation coefficient for the plots vs. $\sigma^*$ was only 0.95). This is also logical, considering that the carbon atoms directly joined to the aromatic ring are secondary in all cases, for which reason their inductive effect is comparable and the only difference is in the length of the R chain, which can produce differences in the steric hindrance. Quantitatively, the negative sign of the constant "ρ" (−17.03; eq. [2]) obtained, indicates that a positive charge is produced on the arene when the reaction takes place, which is in accord with what we stated earlier concerning the σ complex type transition state. On the other hand, the negative sign of the constant "δ" (−1.22; eq. [3]) indicates that the steric hindrance makes difficult the surface reaction process.

We can therefore propose the following reaction pathway ($S_E2$ (Ad–E): aromatic electrophilic substitution, addition–elimination) which progresses through a π complex, type I, that involves the aromatic ring and the P—OH active site of the surface of the catalyst, as has been shown in a previous work (20), applying the criteria of the Frontier Orbital Theory (F.O.T.) to deduce the regioselectivity of the process. This intermediate progresses, in the slow step, towards a σ complex (II) in which R has not left the ring. This would explain why the $E_{A(real)}$ values of the superficial process were approximately constant within the limits of experimental error. In subsequent rapid steps, the leaving of the R group would take place with the formation of the olefin.

## Appendix

*Nomenclature*

A = molecule of reactant

B = benzene

C = olefin
$E_{A(ap)}$ = apparent activation energy (kcal/mol)
$E_{A(real)}$ = real activation energy (kcal/mol)
$F$ = flow rate of carrier gas (mL/s)
$k$ = kinetic constant ($s^{-1}$)
$K$ = adsorption constant (mol $atm^{-1}$ $g^{-1}$)
L = active site
$P_{HC}$ = hydrocarbon pressure (atm)
$PZ$ = frequency factor
$r$ = reaction rate
$R$ = gas constant (atm L $K^{-1}$ $mol^{-1}$)
$S_E2(Ad–E)$ = bimolecular electrophilic aromatic substitution, addition–elimination
$T$ = reaction temperature (K)
$W$ = weight of catalyst (g)
$X$ = molar fractionary conversion

# Solvent extraction separation of Cr(VI)–Mo(VI)–W(VI), Zr(IV)–Hf(IV), and Se(IV)–Te(IV) with sulphoxides

ALAVALAPATI SAMBASIVA REDDY AND BONTHA RAMACHANDRA REDDY
*Department of Chemistry, Sri Venkateswara University, Tirupati – 517 502, India*

Received March 23, 1981

ALAVALAPATI SAMBASIVA REDDY and BONTHA RAMACHANDRA REDDY. Can. J. Chem. **60**, 40 (1982).

Solvent extraction studies have been made on some metals in the same periodic group: Cr(VI)–Mo(VI)–W(VI), Zr(IV)–Hf(IV), and Se(IV)–Te(IV) from hydrochloric acid solutions by dialkyl and aryl sulphoxides. Separation of these metals from one another can be achieved by suitable choice of extraction conditions. The nature of extractable metal species has been elucidated.

ALAVALAPATI SAMBASIVA REDDY et BONTHA RAMACHANDRA REDDY. Can. J. Chem. **60**, 40 (1982).

On a étudié l'extraction à l'aide de sulfoxydes de dialkyles et de diaryles de quelques métaux, en solution dans l'acide chlorhydrique, appartenant à la même période soit Cr(VI), Mo(VI), W(VI); Zr(IV), Hf(IV) et Se(IV), Te(IV). On peut, à l'aide d'un choix judicieux des conditions d'extraction, séparer ces métaux les uns des autres. On a caractérisé la nature des espèces métalliques que l'on peut extraire.

## Introduction

Sulphoxides have gained importance as reagents for the solvent extraction of a number of metals with efficiency and specificity (1–5). It was thought to be of interest therefore, to use dialkyl and aryl sulphoxides for the extraction of some metals in the same periodic group, such as Cr(VI)–Mo(VI)–W(VI), Zr(IV)–Hf(IV), and Se(IV)–Te(IV). Di-*n*-pentyl sulphoxide (DPSO), di-*n*-octyl sulphoxide (DOSO), and diphenyl sulphoxide (DPhSO) have been chosen for this purpose.

## Results and Discussion

*Extraction of Metal Ions*

The distribution ratio, $D$, may be expressed as a function of the metal ion concentration $[M^{m+}]$, $a_{H^+}$, $a_{Cl^-}$, and the ligand concentration [S] (6)

$$\log D = \log K' + (x - 1) \log [M^{m+}] + y \log a_{H^+} + z \log a_{Cl^-} + n \log [S]$$

where

$$K' = \frac{[\text{Complex}]}{[M^{m+}]^x a_{H^+}{}^y a_{Cl^-}{}^z [S]^n}$$

and $x$, $y$, $z$, and $n$ represent the number of metal, hydrogen, and chloride ions and ligand molecules involved in the extracted species. By evaluating $D$ as a function of $[M^{m+}]$, $a_{H^+}$, $a_{Cl^-}$, and [S], the nature of the extracted species has been elucidated.

As shown in Fig. 1, the extraction of W(VI) by 0.03 mol dm$^{-3}$ DPSO in benzene increases with increase in HCl concentration (up to 7 mol dm$^{-3}$) and decreases thereafter. The initial increase in extraction may be attributed to the common ion effect. The slow increase or decrease in extraction at higher acidities is due to compound formation between the extractant and the acid. Because of their basic character, sulphoxides form compounds

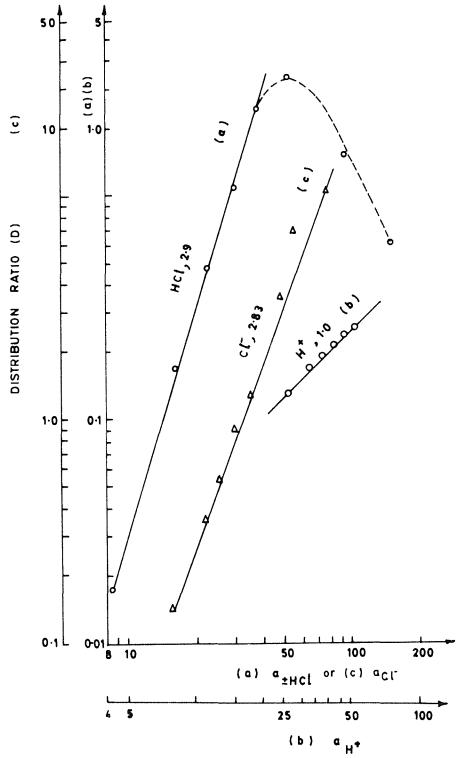

FIG. 1. The distribution of W(VI) between hydrochloric acid solutions (*a*) and DPSO in benzene; and the effect of $H^+$ (*b*) and total $Cl^-$ (*c*) concentrations upon this distribution. Numerical values on the plots are the line gradients.

like HCl·DPSO (7) and HCl·DOSO (7) at high acidities. These adducts may not be able to solvate the metal to the same extent as the free extractants. Partial solubilities of the adducts in the aqueous phase may be an additional factor responsible for the diminution of $D$. At low acidities, the small amount of the acid in the organic phase cannot seriously compete with the metal. The slope of the linear plot of log $D$ versus log $a_{\pm HCl}$ (8) (Fig. 1) is 3, suggesting the extraction of acidic species.

Increase in the $H^+$ concentration at a constant level of $Cl^-$ and that of $Cl^-$ at a given $H^+$ concentration for HCl + LiCl mixtures increases the extraction of the metal. The mean ionic activity coefficients of the mixed electrolyte (HCl + LiCl) system were calculated (9, 10). The log $D$ versus log $a_{H^+}$ (logarithm of the mean ionic activity of HCl at constant $Cl^-$ concentration (5)) plot (Fig. 1) is linear with a slope of unity and the corresponding plot of log $D$ versus log $a_{Cl^-}$ (logarithm of mean ionic activity of HCl at constant $H^+$ concentration (5)) has a slope of 3, confirming the extraction of the monoacidic species, $HWO_2Cl_3$.

At constant HCl concentration (6 mol dm$^{-3}$), the extraction of the metal increases with increase of the ligand concentration (DPSO, DOSO, and DPhSO). The plots of log $D$ versus log [extractant] (Fig. 2) are linear with slopes of 2 for the sulphoxides. Solvation number 2 or 3 is commonly observed with solvating solvents (5, 11, 12). A plot of log equilibrium organic phase metal concentration against log equilibrium aqueous phase metal concentration is linear with a slope of unity indicating the extraction of mononuclear species. Thus the extracted species are disolvates, $HWO_2Cl_3 \cdot 2DPSO$, $HWO_2Cl_3 \cdot 2DOSO$, and $HWO_2Cl_3 \cdot 2DPhSO$.

Analogous experiments to the above using hexavalent Cr, Mo, and W and tetravalent, Zr, Hf, Se, and Te, resulted in identification of the following species: $HCrO_3Cl \cdot 2DPSO$ and $HCrO_3Cl \cdot 2DOSO$, $HMoO_2Cl_3 \cdot 3DPSO$, $HMoO_2Cl_3 \cdot 3DOSO$, and $HMoO_2Cl_3 \cdot 3DPhSO$; $HWO_2Cl_3 \cdot 2DPSO$, $HWO_2Cl_3 \cdot 2DOSO$, and $HWO_2Cl_3 \cdot 2DPhSO$; $ZrCl_4 \cdot 2DPSO$, $ZrCl_4 \cdot 2DOSO$, and $ZrCl_4 \cdot 2DPhSO$; $HfCl_4 \cdot 3DPSO$ and $HfCl_4 \cdot 3DOSO$; $H_2SeOCl_4 \cdot 2DPSO$, $H_2SeOCl_4 \cdot 2DOSO$, and $H_2SeOCl_4 \cdot 2DPhSO$; and $TeOCl_2 \cdot 2DPSO$ and $TeOCl_2 \cdot 2DOSO$.

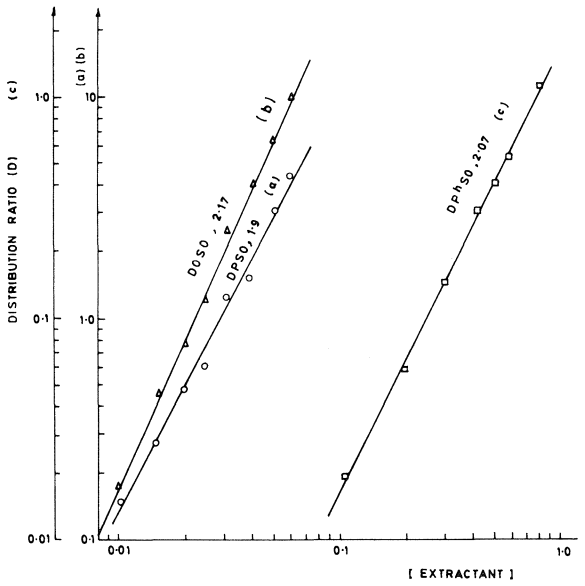

FIG. 2. The distribution of W(VI) as a function of different concentrations of DPSO (*a*), DOSO (*b*), and DPhSO (*c*) at constant hydrochloric acid concentration.

The percentage extraction ($E_{\%}$) and the separation factors ($S$) are given in Table 1.

*Optimum Conditions for Separation of Metals*

The optimum conditions for the separation of the metals from one another are shown in Table 2.

TABLE 2. Optimum conditions for separation of various elements from each other

| Elements to be separated | Aqueous phase | Organic phase | No. of batch extractions | Quantitative extraction |
|---|---|---|---|---|
| Cr(VI), Mo(VI), and W(VI) | 3.5 mol $dm^{-3}$ HCl | 0.02 mol $dm^{-3}$ DPSO in $CCl_4$ | 10 | Cr(VI) |
| | 3.5 mol $dm^{-3}$ HCl | 0.1 mol $dm^{-3}$ DPSO in $CCl_4$ | 6 | Mo(VI) |
| Zr(IV) and Hf(IV) | 6.0 mol $dm^{-3}$ HCl | 0.1 mol $dm^{-3}$ DPSO in $CCl_4$ | 6 | Zr(IV) |
| Se(IV) and Te(IV) | 4.0 mol $dm^{-3}$ HCl | 0.36 mol $dm^{-3}$ DPSO in $C_6H_6$ | 2 | Te(IV) |

TABLE 3. Temperature dependence of distribution ratios ($D$) for various elements for the extraction system hydrochloric acid – DPSO in carbon tetrachloride/benzene

| Element | Aqueous phase | Organic phase | Temperature (K) | | | |
|---|---|---|---|---|---|---|
| | | | 283 | 293 | 303 | 313 |
| Zr(IV) | 6 mol $dm^{-3}$ HCl | 0.1 mol $dm^{-3}$ DPSO | 1.36 | 1.28 | 1.22 | 1.16 |
| Hf(IV) | 7 mol $dm^{-3}$ HCl | 0.1 mol $dm^{-3}$ DPSO | 0.05 | 0.11 | 0.21 | 0.44 |
| Se(IV) | 2 mol $dm^{-3}$ HCl +5 mol $dm^{-3}$ LiCl | 0.2 mol $dm^{-3}$ DPSO | 0.14 | 0.20 | 0.33 | 0.41 |
| Te(IV) | 5 mol $dm^{-3}$ HCl | 0.05 mol $dm^{-3}$ DPSO | 1.34 | 0.73 | 0.43 | 0.30 |

*Temperature Dependence of Extraction*

The dependence of the distribution ratio on temperature for various elements is shown in Table 3. The opposing trend of temperature dependence within a pair of elements further helps to achieve clean separation. Temperature is likely to affect the extraction equilibrium in several ways. Increase in temperature could increase the extraction of the complex due to the increased dehydration of the species, since the complex formation is essentially the replacement of water molecules by the neutral donor groups. On the other hand, increase in temperature could decrease the extraction due to the decreased stability of the complex at higher temperatures (13, 14).

## Experimental

The aqueous phase (3.5 mol $dm^{-3}$ HCl) containing a mixture of Cr(VI), Mo(VI), and W(VI) was equilibrated with an equal volume of the organic phase (0.02 to 1.0 mol $dm^{-3}$ DPSO solution in $CCl_4$) at 303 ± 1 K. Solutions of DOSO (0.01 to 0.06 mol $dm^{-3}$) and DPhSO (0.1 to 0.8 mol $dm^{-3}$) in $C_6H_6$ were also employed. The extraction equilibrium was attained within 5 min in the case of Mo(VI) and W(VI). On the other hand, the extraction of Cr(VI) was found to be a time-dependent process (15). The Cr(VI) content of the equilibrated aqueous phase was estimated spectrophotometrically by the diphenyl carbazide method (16); and the Mo(VI) concentration in the aqueous phase and W(VI) content of the organic phase were determined by the dithiol method (17, 18).

The tracers $^{95}Zr^{4+}$, $^{175+181}Hf^{4+}$, $^{75}Se^{4+}$, and $^{127+129}Te^{4+}$ were supplied by the Isotope Group, Bhabha Atomic Research Centre, India. An aliquot of the tracer stock solution was introduced into a given aqueous phase (pre-equilibrated with an appropriate organic phase) and was equilibrated with an equal volume of 0.1 mol $dm^{-3}$ DPSO solution in $CCl_4$ or in $C_6H_6$ for 30 min. Suitable aliquots of each phase were pipetted out for radioassay of the metals by γ counting using a well-type NaI(Tl) scintillation detector. The distribution ratio, $D$, was taken as the ratio of the activity of the tracer in the organic phase to that present in the aqueous phase.

HENNING THØGERSEN, RAYMOND U. LEMIEUX, KLAUS BOCK, and BERND MEYER. Can. J. Chem. **60**, 44 (1982).

Hard-sphere (HS) calculations predict three conformers for the branched B human blood group antigenic determinant (αLFuc(1→2)[αDGal(1→3)]βDGal) and two conformers for the linear tetrasaccharide (αLRha(1→2)αLRha(1→3)αLRha(1→3)-βDGlcNAc), which constitutes a part of the repeating unit of the *Shigella flexneri* O-antigen, which differ in conformational energy by less than 0.7 and 0.2 kcal/mol, respectively. However, a detailed $^1$H nmr study of specific interunit deshielding effects, quantitative treatment of spin-lattice relaxation times, and nuclear Overhauser enhancements requires that only one of the conformers thus predicted be, in fact, conformationally preferred in solution. These conformers are those predicted by hard-sphere *exo*-anomeric (HSEA) calculations.

HENNING THØGERSEN, RAYMOND U. LEMIEUX, KLAUS BOCK et BERND MEYER. Can. J. Chem. **60**, 44 (1982).

Des calculs de sphères dures (SD) prédisent trois conformères pour le déterminant antigénique ramifié du groupe sanguin humain B (αLFuc(1→2)[αDGal(1→3)]βDGal) et deux conformères pour le tétrasaccharide linéaire (αLRha(1→2)αLRha(1→3)αLRha-(1→3)βDGlcNAc) qui constitue une partie du monomère de l'antigène O du *Shigella flenneri* dont la différence d'énergie conformationnelle est respectivement inférieure à 0,7 et 0,2 kcal/mol. Cependant sur la base d'une étude détaillée par le rmn du $^1$H, des effets spécifiques de déblindage entre unités, d'un traitement quantitatif des temps de relaxation spin-réseau et d'un examen des accroissements Overhauser nucléaire, on peut conclure qu'un seul des conformères prévus est de fait présent en solution. Les conformères sont ceux prédits par les calculs *exo*-anomériques de sphères dures (EASD).

[Traduit par le journal]

## Introduction

We have recently published evidence (1) that the addition of the torsion-angle dependent *exo*-anomeric effect to the ground state energy of an oligosaccharide allowed the conformational preferences about the glycosidic linkages to be assessed by hard-sphere molecular modelling in good agreement with physical evidence based on nmr spectroscopy. The evidence was based mainly on specific interunit deshieldings of protons and interunit nuclear Overhauser enhancements (nOe's) (1, 2). Since then, we have gained more ready access to a high frequency (400 MHz) nuclear magnetic resonance spectrometer and we wish to take this occasion to report a much more detailed $^1$H nmr study than was possible at that time of the human blood group B (αLFuc(1→2)[αDGal(1→3)]βDGal) antigenic determinant and the tetrasaccharide (αLRha(1→2)αLRha(1→3)αLRha(1→3)βDGlcNAc) which constitutes a part of the repeating unit of the *Shigella flexneri* O-antigen.

The B determinant and the tetrasaccharide were chosen because these appeared to present very good tests for the worth of this simple empirical method (based on the Kitaigorodsky expression (3, 4) and *ab initio* molecular orbital calculations (5, 6), and which we have termed the HSEA calculations (1)), for the estimation of the preferred conformation for an oligosaccharide. The reason for the choice of the B determinant will become evident from a consideration of the conformational energy – conformation diagrams reproduced in Fig. 1. The objective was to provide firm evidence in support of the *exo*-anomeric effect by showing that the HSEA calculations do provide conformations that are in good accord with the results obtained in a thorough nuclear magnetic resonance study of the nOe, $T_1$, and chemical shift parameters for this molecule. Similarly, the solution conformation of the *Shigella flexneri* tetrasaccharide as determined from the same nmr parameters (7) is only reproduced by hard-sphere calculations with inclusion of the *exo*-anomeric effect. It is expected that, in turn, the information thus gained will be of continuing assistance to interpretation of immunochemical phenomena (8, 9). Results from similar calculations of the Type 1 and Type 2 blood group determinants are therefore included towards the end of this paper.

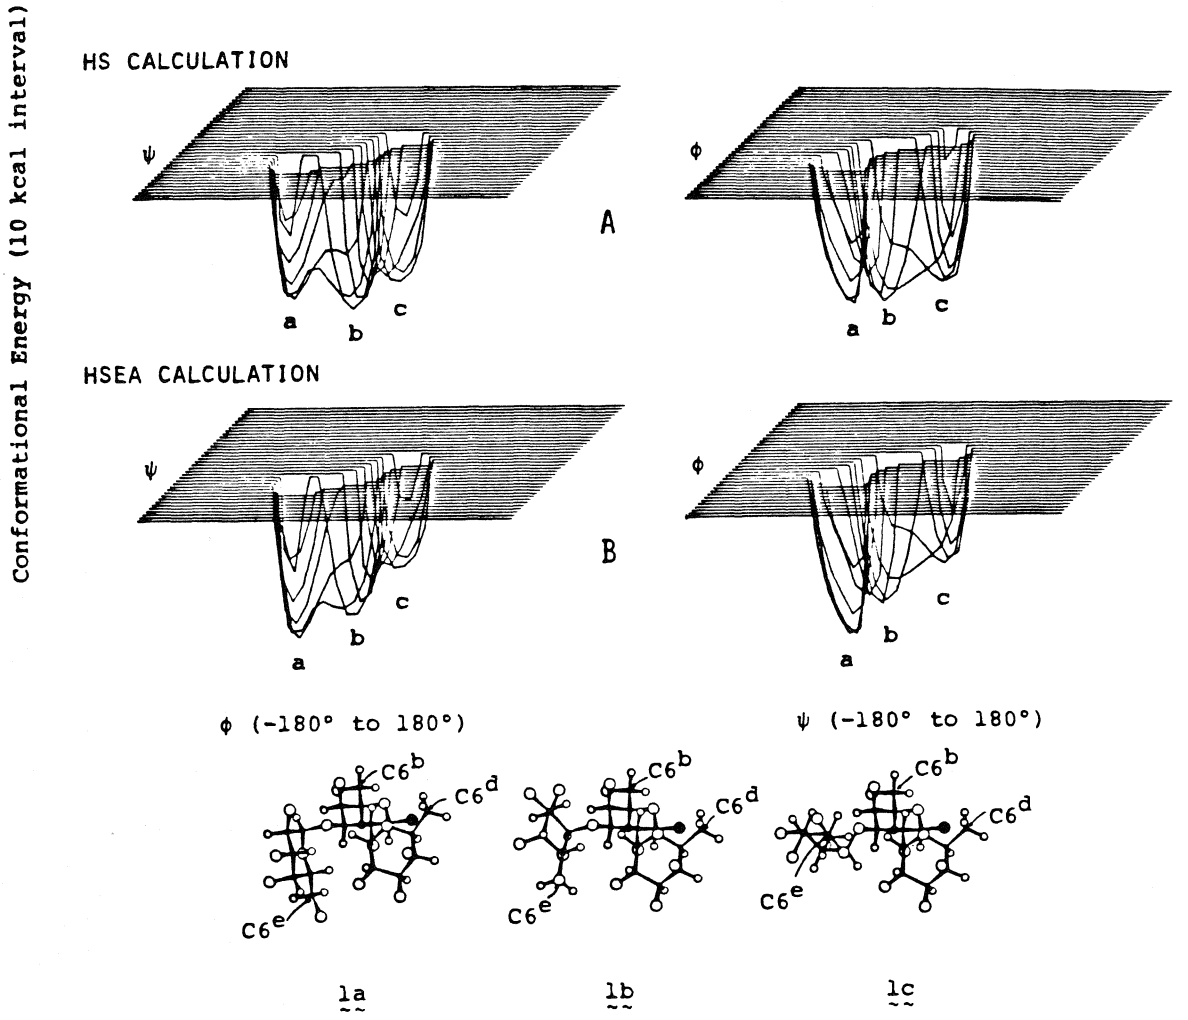

FIG. 1. Three-dimensional diagrams to illustrate the 3 conformational energy wells that are expected to exist for the B human blood group determinant [αLFuc(1→2) (unit d)] [αDGal(1→3) (unit e)]βDGalOR (unit b) with $(\phi,\psi)^d = (55°, 20°)$. Diagrams A were obtained by hard-sphere (HS) calculations. Diagrams B were obtained by hard-sphere *exo*-anomeric (HSEA) calculations. The stick and ball projection formulas are for the lowest energy conformer in each of the wells. The differences in energy for these conformers are given in Table 1.

Figure 1A displays computer-drawn three-dimensional conformational energy plots for the B-trisaccharide that were derived by hard-sphere calculations only and which include all conformers that differ from the minimum energy conformer by 10 kcal/mol or less. On this basis, the trisaccharide would exist in conformations wherein the ϕ and ψ angles (10) have the values listed for the HS calculations in Table 1. Figure 1B provides the same plots but based on the HSEA calculations. The purpose of Fig. 1 is to illustrate clearly that the hard-sphere calculations limit the populations of important conformations to conformers of energy near those of **1***a*, **1***b*, and **1***c*, but that inclusion of a contribution from the *exo*-anomeric effect limits the conformational equilibrium very substantially towards conformers **1***a* of Fig. 1. The purpose of this communication is to provide experimental evidence that, in fact, the B determinant, dissolved in water, resides largely in conformers whose weighted average corresponds well to conformer **1***a* (see Table 1).

The influence of the *exo*-anomeric effect on the conformational equilibrium as judged by the conformational energies of the lowest energy conformer in each of the discernible energy wells can

TABLE 1. The influence of the *exo*-anomeric effect on the populations of the conformers described in Fig. 1

| Method of calculation | Conformer | Conformational preference* ($\phi, \psi$)[d] | Conformational preference* ($\phi, \psi$)[e] | Conformational energy (kcal/mol) | Mole fraction at 296 K |
|---|---|---|---|---|---|
| HS | **1***a* | 55°, 20° | −65°, −50° | −3.26 | 0.22 |
| | **1***b* | 50°, 15° | −10°, −40° | −3.84 | 0.60 |
| | **1***c* | 50°, 15° | 20°, 15° | −3.14 | 0.18 |
| HSEA | **1***a* | 55°, 20° | −65°, −50° | −3.16 | 0.87 |
| | **1***b* | 55°, 20° | −30°, −45° | −2.02 | 0.13 |
| | **1***c* | 50°, 10° | 15°, 15° | 0.35 | ~0 |

*Except when otherwise noted, the $\phi$ and $\psi$ torsional angles refer to $\phi^H$ and $\psi^H$ angles as defined by Lemieux and Koto (10). Calculated in 5° steps. Superscripts d and e refer to the glycosidic units αLFuc and αDGal, respectively.

be assessed from the data presented in Table 1. It is assumed that the lowest energy conformer in each of the wells will usefully reflect the mole fractions of **1** which are present near the bottom of each of the wells. It is seen that the *exo*-anomeric effect is expected to raise the mole fraction of conformer **1***a* from 0.22 to 0.87 while decreasing that of conformer **1***b* from 0.60 to 0.13 and to eliminate conformer **1***c*. The hope was that the results of the $^1$H nmr experiments would be capable not only of distinguishing between these conformational equilibria but to be in good accord with the conformer predicted and, thereby, reinforce the worth of HSEA calculations in an at least *interim* role for the conformational analysis of glycosidic structures. Of course, the *exo*-anomeric effect is not expected to be constant for all glycosides nor to be independent of the environment. However, we believe that these theoretical considerations should not discourage the use of the thoroughly objectively based and consistent method (HSEA calculations) presented herein since, to date, it has provided conformational preferences that are in good accord with the conformational assignments made using the best physical methods (nmr) presently available for the study of glycosides in aqueous solution. The need for a method that can serve as a routine and apparently reliable method for the assessment of the conformational preferences of glycosides is urgent. The main need is in terms of a start toward an understanding of the role of oligosaccharide structures in biological systems (11). However, it must also be realized that, in the absence of molecular models that define the spatial arrangement of the protons in molecules, even an attempt to assess the significance of nOe, $T_1$ measurements (12), and other nmr parameters is denied. We contend that HSEA calculations can serve well in these regards as an approximation that is amenable to routine laboratory work.

## Results and discussion

Figure 2 displays the 400 MHz spectrum for the B-trisaccharide attached to the linking arm $(CH_2)_8$-$COOCH_3$. The presence of this arm has no bearing on the present investigation. Its presence is only due to the fact that this was the form in which the trisaccharide was available. Its possible influence on $^{13}$C nmr and on some of the $^1$H nmr parameters will be discussed later where it will be seen that its presence does not influence the conclusions reached. Although the signals for the hydrogens at positions $1^b$ and $4^b$ of the βDGal unit,[3] at positions $1^d$ and $5^d$ of the αLFuc unit, and at positions $1^e$ and $5^e$ of the αDGal unit are well separated at 400 MHz, selective saturation for nuclear Overhauser enhancement experiments without some irradiation of neighboring protons was not possible. However, it was possible to adjust to this circumstance and to show by way of nuclear Overhauser interunit enhancements that the compound resides largely in conformer **1***a*. Furthermore, it will be demonstrated that both $T_1$ and specific interunit deshielding effects are in accord with this conclusion.

Prior to a consideration of the $^1$H nmr data, we would like to present an adjustment of the *exo*-anomeric effects for α and β-glycosides which were previously used for the HSEA calculations (1). In our first publication (1), the potential energy surfaces published by Jeffrey, Pople, and co-workers (6) for the internal rotational barriers present in dimethoxymethane, as derived by *ab initio* molecular orbital calculation, were used directly to introduce the influence of the *exo*-anomeric effect. It was considered at the time that the quality of the nmr data did not warrant an effort to further refine the method. Also, the *ab initio* calculations (6)

[3]These units are designated as units b (βDGal), d (αLFuc), and e (αDGal) to conform with designations used in the previous publication (1).

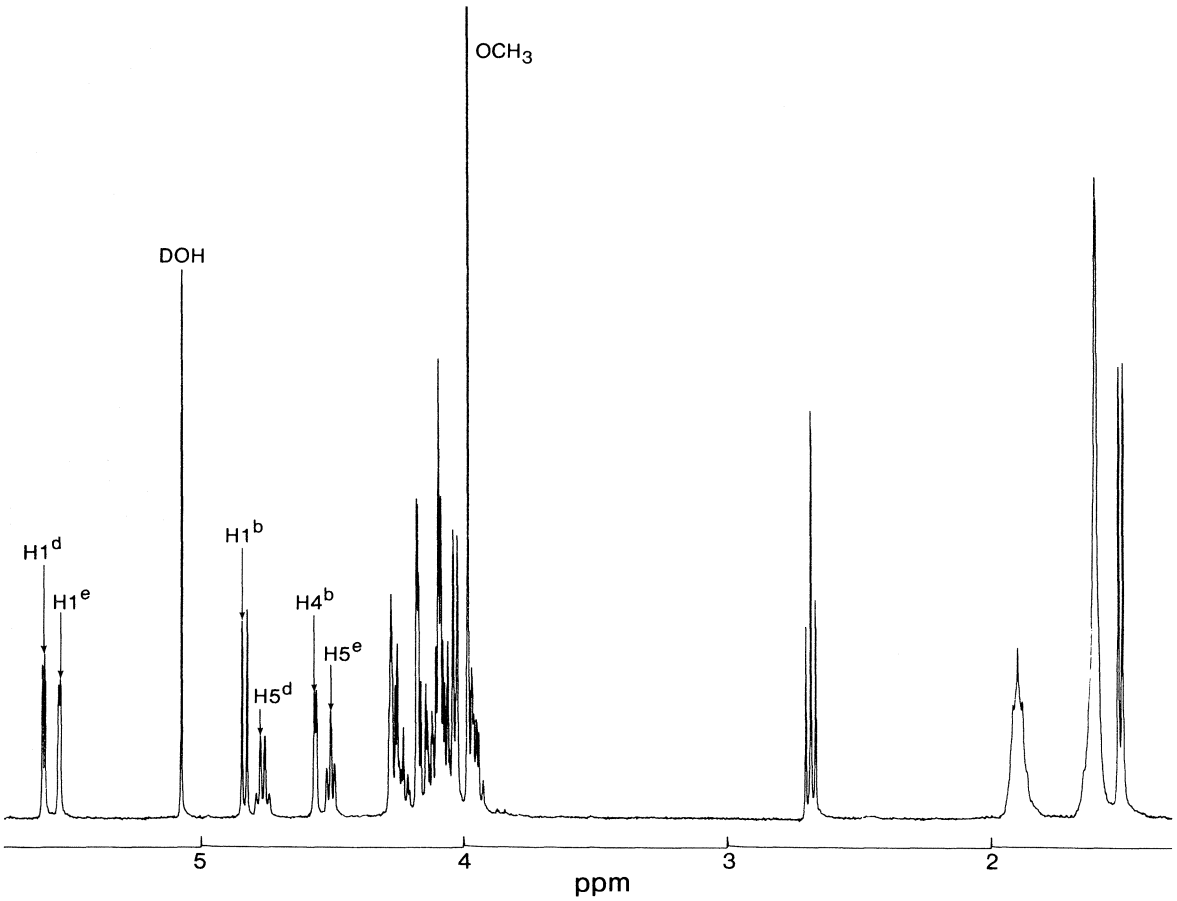

FIG. 2. 400 MHz $^1$H nmr spectrum of αLFuc(unit d) (1→2) [αDGal(unit e) (1→3)]βDGal(unit b)—O$(CH_2)_8COOCH_3$ in $D_2O$ to display the separation of the signals for protons which were saturated in nuclear Overhauser enhancement measurements.

were only carried out in 60° steps and interpolations of these few points were used. Since then, other papers have appeared (13–15) wherein molecular mechanics are used to estimate the conformational preferences for glycosides and which introduce a parameter for the *exo*-anomeric effect. Burkert (16) introduced a torsional potential function of the type:

$$E_{tor} = (V_1/2)(1 - \cos\omega) + (V_2/2)(1 - \cos 2\omega) + (V_3/2)(1 - \cos 3\omega) + \ldots$$

with $V_1 = 0$, $V_2 = -1.80$, and $V_3 = 0.66$ kcal/mol. The negative $V_2$ term was explained as stabilization due to back-donation of the oxygen lone pair orbital into the δ* molecular orbital of the C—O bond and favours the C/O torsion angle of ±90°. Jeffrey and Taylor (17) used a similar expression:

$$E = (V_2/2)(1 - \cos 2\theta)$$

where θ is a lone pair to oxygen torsion angle (e/O in the system —O—C—O—) derived by treating the lone pair of electrons as pseudoatoms with the bond angle e—O—e at an equilibrium value of 140°. Also, Wolfe *et al.* (18) have recently discussed the origin of the anomeric effect as involving lone pair orbital back-bonding interactions. Since for α and β-anomers, the orientations of the lone electron pairs relative to each other are different, it is expected that similar changes in the φ torsion angle will not cause the same changes in energy. Consequently, it is expected that two different curves should be available for assessment of the *exo*-anomeric effect in different anomers. As previously mentioned (19), the *exo*-anomeric effect can be expected to be stronger for β-glycosides.

The atomic parameters for dimethoxymethane which were used in the *ab initio* molecular orbital calculations (6) were also used in hard-sphere

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

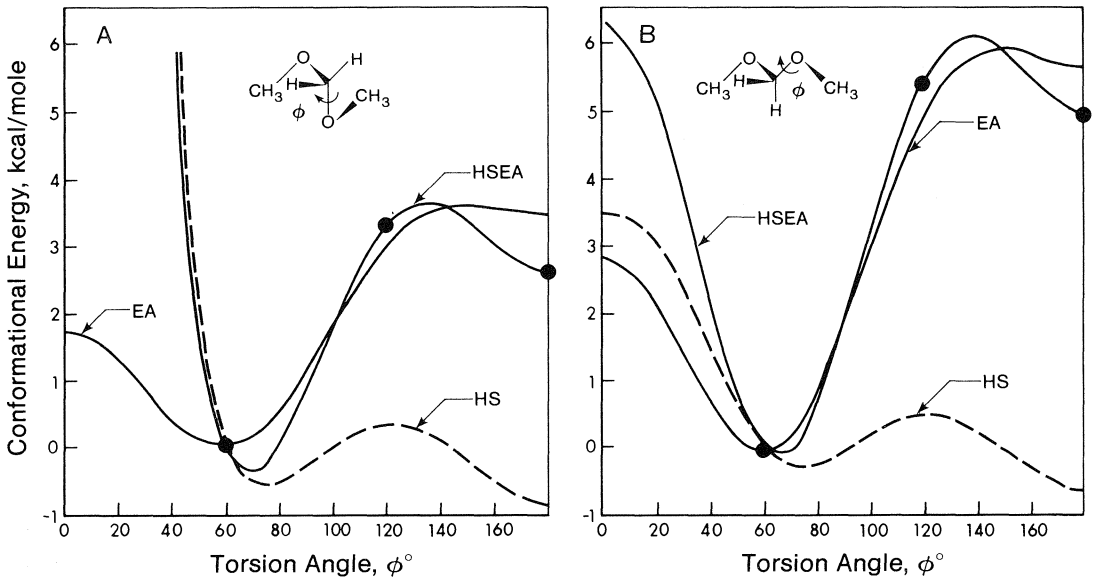

FIG. 3. Potential energy surfaces for dimethoxymethane and involving rotation of one of the $CH_3O—CH_2$ bonds (change in $\phi^o$ torsion angle) while holding the rest of the molecule in the conformations displayed in A and B. A represents changes that occur for rotation about the glycosidic bond of α-glycosides and B similar changes for β-glycosides. The points indicated as black dots are those estimated by *ab initio* molecular orbital calculations (6) except that the energies of the conformers shown in B were lowered so as to bring the energy for $\phi^o = 60°$ to 0 kcal/mol. The curves marked HS were derived by hard-sphere calculation. Those designated EA represent the change in the *exo*-anomeric effect with change in $\phi^o$. The plots termed HSEA are to show that the addition of the HS and EA curves provides curves which in fact pass through the points which were provided (6) by *ab initio* calculations as required by the method used to derive the EA curves.

calculations (20) to estimate the nonbonded interactions for the ranges of conformational change presented in Fig. 3. As seen in Fig. 3A, the conformational changes that correspond to changes in the ϕ torsion angle for α-glycosides contain only three points for the total conformational energy calculated by Jeffrey and co-workers (6). The point at $\phi^o = 0$ is not useful in hard-sphere calculations since it involves very strong van der Waals contacts (17). On the other hand, all four points obtained by the *ab initio* calculations are presented in Fig. 3B which deals with changes in torsion angles encountered in β-glycosides. The goal was to derive an expression using these points and the results of the hard-sphere calculations which would reflect change in the *exo*-anomeric effect with change in the ϕ torsion angle. This was accomplished as is discussed below to provide the curves designated EA in Fig. 3. The EA curves are curves which when added to the HS curves reproduce the points derived by *ab initio* calculation (6).

The four points on the EA curve (0°, 60°, 120°, and 180°) in Fig. 3B were used to set up four expressions of the type mentioned above and used by Burkert (16). The solution of these four simultaneous equations then gave the following expression

$$EA_{\beta\text{-anomers}} = 2.61(1 - \cos\phi^o) - 1.21(1 - \cos 2\phi^o) - 1.18(1 - \cos 3\phi^o) + 2.86\ \text{kcal/mol}$$

The constant (2.86) is the value of *EA* at $\phi^o = 0$.

Since only three points were available for the achievement of the EA curve given in Fig. 3A, the problem was handled in a different way. It was noticed that the ratio of the *EA* value at $\phi^o = 120°$ in Fig. 3A to that in Fig. 3B was 0.60 and that the same ratio existed for these values at $\phi^o = 180°$. It was assumed, therefore, that this relationship would also exist at $\phi^o = 0°$. This assumption then provided the fourth point required to set up the expression,

$$EA_{\alpha\text{-anomers}} = 1.58(1 - \cos\phi^o) - 0.74(1 - \cos 2\phi^o) - 0.70(1 - \cos 3\phi^o) + 1.72\ \text{kcal/mol}$$

As seen in Fig. 3, the assumption provides similar EA curves and implies that the *exo*-anomeric effect is stronger for β-glycosides than for α-glycosides. The use of these expressions provides virtually the same results in HSEA calculations as does the previously described procedure. Furthermore, the

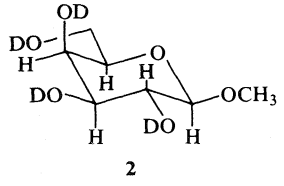
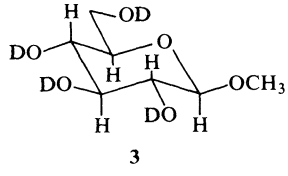
computer program has been rewritten in order to facilitate the practical application in routine work.[4] It should be noted that, although $\phi^H$ and $\psi^H$ values are used in the following discussion of the conformational analysis of the oligosaccharides, the computer program calculates $\phi^{O5}$ from the coordinates of the heavy atoms of the glycosidic bond for each $\phi^H$ value in order to evaluate the contribution of the *exo*-anomeric effect from the formulas given above.

It is well recognized (21) that an nOe is dependent not only on the proximity of the proton observed to the proton which is saturated but also on the immediate proton environment of the former. In rigid systems of known geometry and in which the molecules are tumbling isotropically so that the correlation time ($\tau_c$) is the same for every proton vector, and with intramolecular dipole–dipole relaxation predominating, the observed nOe for proton d on the saturation of proton s is well *approximated*, for the purpose of estimating relative nOe's, by the following expression wherein $r_{ds}$ is the distance between proton d and proton s, and $r_{dj}$ is the distance between proton d and each other proton in the molecule.

$$\mathrm{nOe_d(s)} = r_{ds}^{-6} \Big/ \left(2 \sum_{j \neq d} r_{dj}^{-6}\right)$$



2



3

The nOe's observed for H2 on saturation of H1 for methyl β-D-galactopyranoside (**2**) and for methyl β-D-glucopyranoside (**3**) (Table 2) provide a good example. Simple examination shows that whereas the distances between H1 and H2 are the same, H2 of **2** is much more isolated from other protons than is H2 of **3**. Consequently, the term $\Sigma_{j \neq d} r_{dj}^{-6}$ will be smaller for **2** and the nOe will be larger as observed. In the case of the glucoside (**3**), the signals for H3 and H5 could not be sufficiently well resolved to allow separate nOe assignments. However, both of these protons are more isolated from H4 than in the galactoside (**2**). Therefore, a greater enhancement of H3 and H5 is expected for **3** than for **2** as was the case. The negative enhancement of H4 for **2** arose because this proton is far from the proton (H1) that was saturated but close to protons (H3 and H5) which were enhanced (21). The positive enhancement of H4 of **3** is due to higher order effects.

[4]Listings of computer programs are available at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ontario K1A 0S2, Canada.

TABLE 2. Nuclear Overhauser enhancements by saturating H1 of the methyl β-D-galacto- (**2**) and glucopyranosides (**3**) and spin-lattice relaxation times

| Compound | H2 | H3 | H5 | H4 |
|---|---|---|---|---|
| | nOe (%) | | | |
| **2** | 10 | 9 | 12 | −4 |
| **3** | 5 | —* | 27* | 2 |
| | $T_1$ (s) | | | |
| **2** | 7.1 | 1.7 | 1.1 | 1.8 |
| **3** | 3.4 | 2.0 | 1.5 | 2.0 |
| nOe(**2**)/nOe(**3**)† | 2.0 (2.2) | 0.78 | (0.83)‡ | — |
| $T_1$(**2**)/$T_1$(**3**)† | 2.1 (2.2) | 0.80 | (0.84)‡ | |

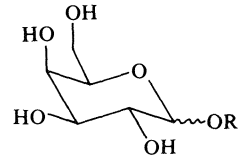
*The sum of the nOe's are given due to overlap of signals.
†The ratios in brackets were calculated from appropriate molecular models.
‡The average of the $T_1$ and nOe's for H3 and H5 are used due to overlap of these protons in compound **3**.

The proton spin-lattice relaxation time ($T_1$) is a measure of the relaxation environment of the proton. Thus, the more intimate the proton environment for a given proton, the shorter the relaxation time; following the expression (21),

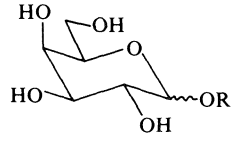
$$(1/T_1)_i = \text{constant} \cdot \tau_c \cdot \sum_{j \neq i} r_{ij}^{-6}$$

Assuming isotropic motion of the molecule and only intramolecular dipole–dipole relaxation, the ratios between the $T_1$'s for the similar hydrogens in **2** and **3** should be the same (everything else being ideal) as the ratios of the nOe's. This is seen (Table 2) to be the case both for H2 and the sums for H3 and H5.

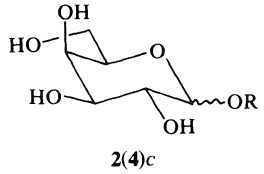
Table 3 lists coupling constants as evidenced by the spacings of the signals for a number of vicinal protons in the B-trisaccharide. These data confirm that the three hexopyranose units exist in their normal chair conformations.



**2(4)***a*



**2(4)***b*



**2(4)***c*

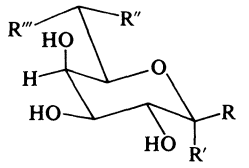
| αDGal | 2.8 | ~10 | — | ~1 | 6.4* | |

*Observed first order coupling constants.

(*b*). Chemical shifts (ppm) of H4 in derivatives of D-galactose



| Compound | R | R′ | R″ | R‴ | Chemical shifts |
|---|---|---|---|---|---|
| **2** | $OCH_3$ | H | H | OH | 4.17 |
| **4** | H | $OCH_3$ | H | OH | 4.21 |
| **5** | H | $OCH_3$ | H | H | 4.04 |
| **6** | $OCH_3$ | H | $CH_3$ | OH | 4.23 |

It was necessary to set a specific conformation for the hydroxymethyl groups in the B-trisaccharide in order to calculate theoretical $T_1$ and nOe values. In the case of the βDGal units, the spacings that reflect $J_{5,6} = 7.8$ Hz and $J_{5,6'} = 4.3$ Hz require that the hydroxymethyl group exist largely in a conformer that has one of the hydrogen atoms at C6 in *anti*-periplanar relationship to H5; i.e., either **2**(**4**)*b* or *c*. This situation was also observed for methyl β-D-galactopyranoside (**2**) (1). The signals for H6 and H6′ could also be sufficiently resolved at 400 MHz to provide this information in the case of methyl α-D-galactopyranoside (**4**). ABX analysis of the H5, H6, and H6′ protons gave $J_{5,6} = 8.2$ Hz and $J_{5,6'} = 4.6$ Hz. Therefore, the orientation of the hydroxymethyl group must be essentially as in **2**(**4**)*b* or **2**(**4**)*c*. The latter orientation could be assigned on the basis of chemical shift data.

The chemical shifts for H4 in the βDGal and αDGal units of the trisaccharide were found (1) to be 4.50 and 4.20 ppm, respectively. The greater deshielding (0.30 ppm) of H4 of the βDGal unit can be assigned to the fact that this unit is substituted by the αDGal unit at the neighboring 3-position (1). As seen in Table 3, the chemical shifts for H4 in methyl β-D- (**2**) and α-D-galactopyranoside (**4**) are nearly the same (4.17 and 4.21 ppm, respectively). This similarity suggests that these hydrogen atoms are in similar environments. If conformer **2**(**4**)*b* existed as the predominant conformer, then the chemical shift could be expected to be near that of methyl 6-deoxy-α-D-galactopyranoside (**5**). However, it is seen to be nearly 0.15 ppm to lower field. This suggests a deshielding of H4 in **2** and **4** by O6 as would be the case for conformer **2**(**4**)*c*. This interpretation is supported by the chemical shift of H4 (4.23 ppm) in methyl 7-deoxy-β-D-*glycero*-D-*galacto*-heptopyranoside (**6**). This compound definitely exists essentially in the conformation shown in Table 3 (22). It is seen that this chemical shift is very nearly the same as that for this atom in **2** and **4**. The previously presented argument (23) based on empirical rules for chemical shifts, in support of a high population of conformer **2**(**4**)*c*, is thus supported and it is on this basis that this orientation was chosen to calculate the $T_1$ and nOe data. The methyl group of the αLFuc unit was considered to be in the staggered conformation.

As was previously discussed in detail (1, 8, 24), the $^1$H nmr spectra of branched oligosaccharides can display large specific interunit chemical shift changes which are attributed to strong nonbonded interaction between the proton and one or more oxygen atoms in another unit. This is seen in Table 4 to be the case for the H5 atoms of both the αLFuc and βDGal units of **1**. We expect that these deshielding interactions occur only when the two atoms are in repulsive van der Waals interaction and, therefore, the internuclear distance should be less than 2.7 Å. On this basis, the internuclear distances listed in Table 5 eliminate conformer **1***c* and would render conformer **1***b* improbable. These conclusions found support in the proton $T_1$ values presented in Table 7. However, it is required to first consider the $^{13}$C spin-lattice relaxation times presented in Table 6.

Assuming isotropic motion and intramolecular dipole–dipole relaxation only, proton $T_1$ values can be related to intramolecular proton–proton distances by the simple expression already presented. Assuming dipole–dipole relaxation only, the anisotropy of molecular tumbling can be judged from a consideration of the $NT_1$ values of the $^{13}$C atoms (Table 6) where $N$ refers to the number of hydrogens directly bound to the carbon atom. It is seen that the $NT_1$ values are in fact almost constant (the values for the C6 atoms are special cases because these are parts of rotating groups). The $NT_1$'s (not listed) for the $(CH_2)_8COOCH_3$ group were larger except for the aglyconic carbon. This indicates, as would be expected, a greater mobility for the side chain. In view of the quality of the data presented in Table 6, it was encouraging to examine the spin-lattice relaxation times and the related nOe phenomena for the protons in **1**. The $T_1$'s that could be accurately measured are listed in Table 7. These values were then used to calculate the $C$ values defined and presented in Table 8 for the B-

| αDGal | 0.69 ($H1^e$) | 0.56 ($H5^e$) |

*Measured in $D_2O$ (0.02 *M*) at 400 MHz, 296 K, by the inversion recovery method with delay times of 0.001, 0.05, 0.1, 0.15, 0.20, 0.25, 0.3, 0.4, 0.5, 0.7, 1.0, and 6.0 s. The relaxation delay was 9.28 s.

trisaccharide (**1**) in the three conformations described in Table 1. The *C* values for $H1^b$ can be neglected from further consideration since their high value is related to neglecting the $O(CH_2)_8$-$COOCH_3$ aglycon in the calculations.

Since the molecule seems to be tumbling isotropically as indicated by the $^{13}C$-$T_1$'s in Table 6 and should the relative dispositions in space of the various hydrogen atoms in the molecule be well represented by one conformer, then the *C* values are expected to be constant (25). This condition is seen to be the best held for conformer **1***a*. Conformer **1***c* obviously is not in accord with expectations and this conformation can therefore be neglected and will not be considered further. The low *C* values of 65 for $H1^e$ in conformer **1***b* already suggest that this conformer is less important than **1***a* in contrast to the prediction based on hard-sphere calculations only (Table 1). This indication found support in the nOe measurements to be presented in Table 11. However, we must first comment on how these measurements were made.

Table 9 presents the nOe's that would be expected on saturation of one of the six protons listed and assuming that the total of the enhancements would be 100%. It is seen that no significant differences in nOe could be expected from the saturation of either protons $H1^b$ or $H5^d$. The experimental results confirmed these relative values and are not presented in Table 11 since these do not bear on the conformational analysis. Inspection of Table 9 did indicate, however, that certain nOe differences should exist that would allow a decision on conformation preference (**1***a* or **1***b*).[5] These values are underlined in Table 9. It was considered, therefore, that if nOe experiments could be conducted that would provide overall results which were consistent with these expectations, then a decision on the relative importance of conformers **1***a* and **1***b* could be reached.

As was mentioned above, it was not possible under the available experimental conditions to selectively saturate a given proton. The application of the transient nOe experiment described by Heatley *et al.* (27) is not possible to perform with accuracy due to the short relaxation times of this fairly large molecule in aqueous solution. However, it proved possible to adjust to the situation as is indicated in Table 10 which presents some of the results achieved in this regard. The results are also plotted in Fig. 4.

Saturation of $H1^d$ at power level 1 (see Experi-

[5]It is of interest that the results of a two-dimensional nOe experiment (26) qualitatively confirmed the existence of the nOe's predicted in Table 9.

TABLE 8. Comparison of $C$ values for the different conformers using the $T_1$ values presented in Table 7

| | $C$ ($D \cdot 10^3$)* | | | | | |

*Hypothetical situation wherein the proton is fully saturated without affecting other protons.
† βDGal (b), αLFuc (d), and αDGal (e).
‡ The proton saturated.
§ These values were small and not calculated since these have no significance to the following discussions.

mental) was found (Table 10) by difference spectroscopy (28) both to saturate H1[e] by 20% and to enhance H5[e] by 2.5%. On the other hand, full saturation of H1[e] saturated H1[d] by 15% and produced an enhancement of H5[e] by 0.5%. Thus, at this power level, an indirect enhancement of H5[e] was observed which was 0.5 × 100/2.5 = 25% of that observed when H1[d] was fully saturated. According to Table 9, saturation of H1[e] should not enhance H5[e] appreciably. Therefore, the enhancements obtained for H5[e] in these two experiments arose from saturation of H1[d] only. The data presented in Fig. 4 were obtained in this way using both 200 and 400 MHz data. The conclusion that the effect of partial saturation could be treated in this way was used to calculate the relative nOe's presented in Table 12 using the data presented in Table 9. It is seen that few comparisons could be made without complication. However, the fact that excellent agreement was obtained in the cases which involved a prediction of greater than 10% of the total of the enhancements, which are underlined in Table 12, and all favor **1***a*, is taken as evidence for the actual existence of the conformer as predicted by HSEA calculations.

In conclusion, we wish to comment on the conformational equilibrium for the linear tetrasaccharide **7**. HS calculation indicated that the terminal trisaccharide unit would exist as conformers **7***a* and **7***b* in about equal populations. These conformers are described in Table 13 and by computer-drawn projection formulas in Table 14. In contrast to this prediction, HSEA calculation supports only conformer **7***a*, and this conformer would be some 3.6 kcal/mol more favorable than **7***b*. Compound **7** therefore offered another situation suitable for the examination of the influence of the *exo*-anomeric effect on the conformational equilibria of oligosaccharides.

It is seen from the data presented in Table 14 that

αLRha(1 → 2)αLRha(1 → 3)αLRha(1 → 3)βDGlcNac

the distances between the nuclei of H1$^c$ and H1$^d$ are significantly different and, therefore, an $^1$H nmr study of **7** was expected to allow a further test of HSEA versus HS calculations. In fact, the calculated and found values for the nOe's observed on saturation of H1$^c$ are clearly in favor of conformer **7***a*. Also, it is seen in Table 14 that the observed $T_1$ values are consistent with conformer **7***a* but not with conformer **7***b*. These results therefore provide further strong experimental evidence in support of molecular modelling procedures which include an important contribution to the conformational energy of a glycoside by the *exo*-anomeric effect.

The $^1$H nmr studies of the Type 1 and Type 2 human blood group determinants which are listed in Table 15 also well substantiated the conformational preferences assigned on the basis of HSEA calculation. In the case of the Type 1 structure, the torsion angles listed differ somewhat from those

*The saturations in square brackets are those not expected (Table 9) to cause the nOe noted.

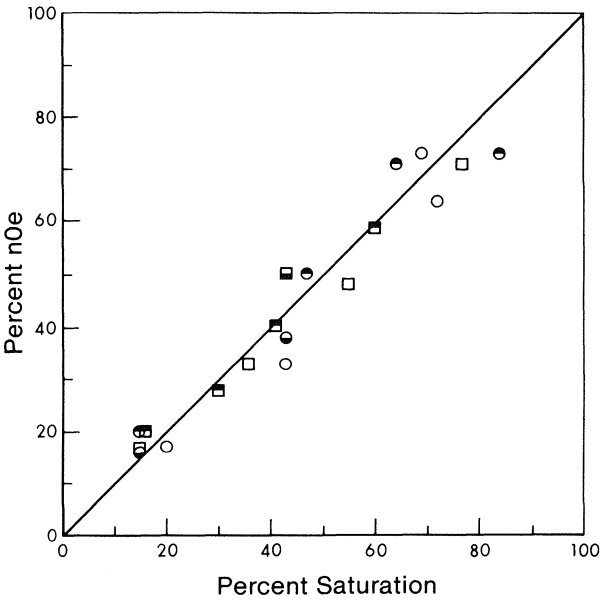

FIG. 4. A plot of the data presented in Table 10 together with the data obtained by the saturation of other signals in the spectrum of the B-trisaccharide (**1**) to show that nuclear Overhauser enhancement is directly proportional to the amount that the signal for the irradiated proton was partly saturated. The symbols indicate which one of the protons was fully saturated; ○ (H4$^b$), ◓ (H1$^d$), ◒ (H2$^d$), □ (CH$_3^d$), ⬒ (H1$^e$), and ⬓ (H5$^e$).

previously reported (1). These differences are not considered significant in the context of what may be expected from HSEA calculations. Nevertheless, these differences arose in part because of the slight modification of the contribution by the *exo*-anomeric effect but also because the improved computer program provided a more extensive iterative procedure than previously used. The $^1$H nmr data will be provided in connection with the syntheses of the structure listed in Table 15.[6]

We have previously (1) commented on the value of nOe experiments for gauging the proximity of

§ No measurable nOe.
+ or ++ The sum of the nOe's observed for these protons in the given experiment was used because these signals overlapped. The sum is presented under that signal which was expected to be most strongly enhanced.

anomeric and aglyconic hydrogen atoms. We now wish to note that, as displayed in Fig. 5, a wide range of different sets of $\phi$ and $\psi$ values can set these hydrogen atoms at the same distance. Therefore, it is important in the assessment of the enhancement of the signal for an aglyconic hydrogen from saturation of the anomeric hydrogen that this enhancement be compared to an interunit enhancement observed in the same experiment for another hydrogen whose distance from the anomeric hydrogen also sets a requirement in terms of $\phi$ and $\psi$ torsion angles. In other words, in the absence of the interunit enhancement which was observed for $H5^d$ (Table 14), the only conclusion that could be reached would be that $H1^c$ and $H3^b$ are separated by about the same distance as $H1^c$ is from $H2^c$;

*Proton saturated.

i.e., about 2.5 Å. This matter is of special importance to the conformational analysis of disaccharides where on occasions the only interunit nOe which is observed is that for the aglyconic hydrogen.

## Experimental

The solutions of the B-trisaccharide (**1**) (30) used in the $^1H$ nmr studies were prepared by freeze-drying the sample twice from $D_2O$ solutions in a specially prepared (31) 5 mm tube and then adding 100% $D_2O$ to provide a 0.02 *M* solution. This solution was then frozen, pumped, and thawed three times prior to the sealing of the tube under vacuum. The samples of methyl β-D-galacto (**2**) and β-D-glucosides (**3**) were similarly prepared.

*Spectroscopy*

The $^{13}C$ nmr spectra were obtained on a Bruker HFX-10 spectrometer operating at 22.63 MHz. The acquisition time of the free induction decay was 0.82 s in 4K data points (Nicolet 1085). A relaxation delay of 1.22 s was used with 3200 scans for each free induction decay which were then zero filled to 16K prior to Fourier transformation using a line-broadening factor of 3.0 Hz. The sweep width was 2500 Hz.

The $^1H$ nmr spectra were recorded on Bruker WH-200 and WH-400 spectrometers (200 and 400 MHz, respectively) using 16K points (Aspect 2000 computer) for the free induction decay and a 90° pulse width of 10 μs.

*Specified as $\phi^H$, $\psi^H$ minimum values, calculated in 5° steps.
†See footnote 3 in text.
‡Similar values are expected for the corresponding A determinants, in which the αDGal(1→3) unit (e) is exchanged with a αDGalNAc unit.
§When this pentasaccharide is linked to a βDGal unit through a (1→3) bond, $(\phi,\psi)_{min}$ values of 60°, −10° are calculated; and when linked to a βDGal unit through a (1→6) bond, $(\phi,\psi^{C5})_{min}$ values of 50°, 130° are calculated. (For discussion of ω angle, see ref. 29.)

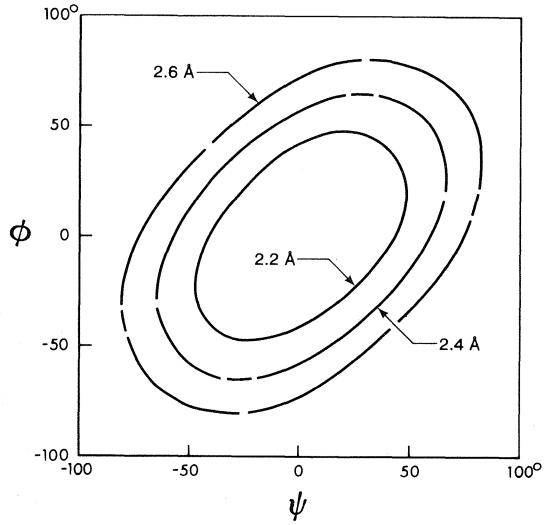

FIG. 5. Plots to illustrate the relationship between the internuclear distance of an anomeric hydrogen atom to its aglyconic hydrogen atom and the φ and ψ torsion angles for the glycosidic bond. The number of discontinuities increases with increasing distance (for a given set of bond angles and bond lengths).

The $T_1$ experiments were done with the inversion recovery method at temperatures and delay times as shown in Tables 6 and 7.

The nOe experiments described in Table 11 were performed in the difference mode (28) with power levels 1, 2, 3, and 4 being 36 db below 0.2 W, 30 db below 0.2 W, 35 db below 0.2 W, and 28 db below 0.2 W, respectively. The enhancements are given in % relative to the proton saturated.

*Hard-sphere calculations*

The procedure was the same as that previously described (1) but using a simplified computer program.[4] The atomic parameters for the αDGal and βDGal units were obtained from the neutron diffraction data obtained on the corresponding methyl D-galactopyranosides recently published by Takagi and Jeffrey (32). X-ray data for the calcium bromide complex of α-L-fucopyranose (33) was used to represent the αLFuc unit except that the coordinates of the hydrogen atoms were synthesized using a C—H bond length of 1.1 Å and a bond vector defined by the appropriate C—C and C—O bond vectors.

The calculations were made with an Amdahl 470V/7 computer. The ball and stick representations used in Fig. 1 were obtained by the Pluto program[7] and the energy profiles by a program which can be used in connection with the HSEA program.[4]

# Syntheses of derivatives of lacto-*N*-biose. I. 4,6-Di-*O*-acetyl-3-*O*-(tetra-*O*-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-α,β-D-glucopyranosyl chloride

R. U. LEMIEUX, S. Z. ABBAS,[1] AND B. Y. CHUNG[2]

*Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2*

Received March 27, 1981

R. U. LEMIEUX, S. Z. ABBAS, and B. Y. CHUNG. Can. J. Chem. **60**, 58 (1982).

Procedures are reported for the synthesis of 4,6-di-*O*-acetyl-3-*O*-(tetra-*O*-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-α,β-D-glucopyranosyl chloride, a reagent useful for the reliable introduction of β-D-Gal*p*-(1→3)-β-D-GlcNAc*p* units (lacto-*N*-biose I units) into oligosaccharide structures. A benzyl glycoside intermediate is hydrogenolyzed to the alcohol which is subsequently converted to the glycosyl chlorides by use of the Vilsmeier reagent in the presence of *sym*-collidine. A comparison is made of the oxazoline method for the preparation of β-glycosides from 2-amino-2-deoxysugars and the phthalimido procedure developed in this laboratory.

R. U. LEMIEUX, S. Z. ABBAS et B. Y. CHUNG. Can. J. Chem. **60**, 58 (1982).

On rapporte des méthodes de synthèse du chlorure de di-*O*-acétyl-4,6-*O*-(tétra-*O*-acétyl-β-D-galactopyrannosyl)-3-déoxy-2-phtalimido-2-α,β-D-glucopyrannosyle, un réactif pratique pour l'introduction d'unités β-D-Galp-(1→3)-β-D-GlcNAc*p* (unités de lacto-*N*-biose I) dans la structure d'oligosaccharides. On hydrogénolyse le glycoside de benzyle intermédiaire en alcool, que l'on transforme ensuite en chlorure de glycosyle en utilisant un réactif de Vilsmeier en présence de *sym*-collidine. On établit une comparaison entre la méthode aux oxazolines pour la préparation des β-glycosides à partir des sucres amino-2-déoxy-2 et la méthode du phtalimide mise au point dans ce laboratoire.

[Traduit par le journal]

Lacto-*N*-biose I (βDGal(1→3)DGlcNAc) was first isolated by partial acid hydrolysis of "lacto-*N*-tetraose" (1) which has this disaccharide β-linked to the 3′-position of lactose. The disaccharide βDGal(1→3)DGlc does not appear to have received a trivial name.

Lacto-*N*-biose I, like *N*-acetyllactosamine, is a building unit of the core chains of human blood group determinants. When present in the terminal tetra- or pentasaccharide of a human ABH antigenic determinant, the resulting structure is said to have the Type 1 chain (2). This is in contrast to the Type 2 chain (2) wherein *N*-acetyllactosamine forms the core structure unit of the ABH determinant. The Lewis family of human blood group determinants are Type 1 structures (3–5). The purpose of this communication is to report the preparation of a reagent **9** which we expect can play an important role in efforts designed to achieve the incorporation of Type 1 (lacto-*N*-biose I) units as β-glycosides.

We consider the use of 2-deoxy-2-phthalimido-glycosyl halides (6) as reagents for the synthesis of a β-linkage between an alcohol and an aminosugar which has the amino group in equatorial orientation to be particularly attractive, both for reasons of reliability and yield. In our experience, the method can be used in the presence of a wide range of both acid- and alkali-labile protecting groups. The yields are generally good to excellent and, to date, the formation of the α-glycoside as a byproduct has not been detected. When the reaction conditions are carefully controlled so as to minimize side reactions (highly pure reagents and solvents, low temperature, and strictly anhydrous conditions), excellent yields are normally achieved using equimolar amounts of the reactants (6).

Since we first announced our interest in the synthesis of the core structural units for the human blood group determinants,[3] a number of contributions to the same end have appeared from other laboratories. These investigations have generally employed the classical oxazoline method (7) for the establishment of a β-linkage between *N*-acetyl-D-glucosamine and another sugar. As a result, there now exists a substantial experimental basis for comparing the oxazoline and phthalimido methods. To do so appears timely since recently condensations using the oxazoline method which led to derivatives of chitobiose were reported (8) and the opinion was stated that the improved oxazoline method which employs 1,2-dichloroethane as solvent (9) provides yields that are as satisfactory as

those by the phthalimido route. We do not believe that the facts support this statement and take this occasion to explain why we hold this opinion.

First of all, we consider that it would have been more appropriate for Kiso *et al.* (8) to compare the 30–36% yields obtained in their synthesis of derivatives of chitobiose by the oxazoline method with the 68% yield that was reported for the synthesis of a chitobiose derivative by the phthalimido method (6). It is particularly important in this regard that the latter work employed an alcohol (2,2,2-trichloroethyl 3,6-di-*O*-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranoside) which is of a type notorious for its resistance to glycosylation (10). After finding the oxazoline method unattractive for the synthesis of paragloboside (βDGal(1→4)βDGlcNAc(1→3)βDGal(1→4)βDGlc) analogs,[4] Ponpipom *et al.* turned to the phthalimido method (11). It was reported that the synthesis was then accomplished in high yield and with excellent stereoselectivity.

Similarly, Bundle and Josephson (12) have reported that whereas 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-glucopyranosyl chloride and the 1,2-oxazoline derivative obtained from it were not effective in the glycosylation of the 2-position of a 3,4-di-*O*-benzyl-α-L-rhamnopyranoside, the phthalimido method provided the desired compound in good yield (70%). These experiences match our own. For example, with a large excess of 2,2,2-trichloroethanol, the oxazoline method after substantial examination provided 2,2,2-trichloroethyl 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranoside in 46% yield along with the α-anomer in 6.1% yield (13). On the other hand, when suitable precautions were taken to exclude water, the phthalimido method provided 2,2,2-trichoroethyl 3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranoside in 89% yield (6) and no α-anomer was detected.

Augé and Veyrières (14) achieved a synthesis of lacto-*N*-triose I (βDGal(1→3)βDGlcNAc(1→3)-DGal) using the oxazoline derived from lacto-*N*-biose I. An 84% yield was reported. However, the yield was based on the alcohol (6-*O*-allyl-1,2,4-tri-*O*-benzyl-α-D-galactose) and a one molar excess of the oxazoline was used in the condensation. Thus, the yield may have been reported as 42%. This is to be contrasted with the condensation of acetylated phthalimido-chloride derived from lactosamine (24) with an equimolar amount of 2,2,2-trichloroethyl 2-*O*-benzoyl-4,6-*O*-benzylidene-α-D-glucopyranoside which proceeded in 80% yield (15).

The condensation of the oxazoline derived from D-glucosamine with 1,2;3,4-di-*O*-isopropylidene-α-D-galactose has provided perhaps the most favorable yield (81%) ever reported (16) using this method. Recently, 6-*O*-(3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranosyl)-1,2;-3,4-di-*O*-isopropylidene-α-D-galactose was synthesized in 86% yield (17). The condensation of **9** with an equimolar amount of 1,2;3,4-di-*O*-isopropylidene-α-D-galactose gave the desired β-glycoside in 75% yield after one recrystallization (15). It is to be noted, however, that the yields were not acceptable when the alcohol was 1,2;5,6-di-*O*-isopropylidene-α-D-galactofuranose (15). In this case, electrophilic attack to open an isopropylidene group appeared to be an important competing reaction.

In contrast to the results obtained by the phthalimido method, virtually all of the yields which have been reported for the establishment of an intersugar glycosidic bond using the oxazoline method are less than 50% when the amount of the oxazoline is used to calculate the yield (18–23). This is of importance since the aminosugar component, especially in the form of higher saccharides, is often the more difficultly available starting material. It is these considerations that prompt us to publish the preparation of the title compound **9**. An accompanying paper (24) describes the preparation of the related structure derived from lactosamine.

The transformations used to achieve **9** are outlined using the formulas **1** to **9** and these are described in detail in the Experimental portion of this paper. The reaction sequence is modelled on the procedure used by Lemieux and Driguez (13) to build the lacto-*N*-biose I portion of the Lewis-a determinant. A point of interest is that the condensation of **4** with acetobromogalactose proceeded in 74% yield under Helferich conditions but using a 133% excess of the bromide. Over one-third of the bromide was converted to tetra-*O*-acetyl-β-D-galactopyranosyl cyanide. This result is to be contrasted with the previously reported (13) condensation of acetobromogalactose with 2,2,2-trichloroethyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-β-D-glucopyranoside under similar conditions. Using only a 50% excess of the bromide, the β-linked disaccharide was obtained in 91% yield. It is apparent, therefore, that the phthalimido group has an important shielding influence on the reactivity of the 3-hydroxyl of **4** and this property may have an important influence on the success of synthetic strategies which follow similar lines.

The replacement of the anomeric hydroxyls of appropriately blocked structures by chlorine is conveniently accomplished (28)[3] using the Vilsmeier reagent (25–27). We conduct the reaction in the presence of *sym*-collidine to neutralize the liberated hydrogen chloride. Since the Vilsmeier reagent is also available in the bromide form (29, 30), the more reactive glycosyl bromides are also available in this way. We would also like to note that the reaction can be applied to such acid-labile compounds as 2,3,4,6-di-*O*-isopropylidene-D-mannopyranose.[5] In the phthalimido method, under the conditions for glycosylation which utilize an equimolar mixture of silver triflate and *sym*-collidine as promotor (6), the more stable chlorides are adequately reactive. No effort was made to separate the α and β-anomers of the glycosyl halides since the mixture was found to provide as good yields in the glycosylation reactions as did the pure β-form.

## Experimental

All solvent extracts were dried over anhydrous sodium sulfate prior to solvent removal using a rotary evaporator under the vacuum of a water aspirator. The $^1$H nmr spectra were measured at 100 MHz (Varian HA-100). Unless otherwise stated, deuteriochloroform was used as a solvent and internal TMS as a standard. Thin layer chromatograms (tlc) were developed on a Silica Gel G (E. Merck A.B., Darmstadt) and visualized with 5% sulfuric acid in ethanol after heating at 100°C. Column chromatography was performed on silica gel (CAMAG). Nitromethane, benzene, acetonitrile, dichloromethane, and 2,4,6-trimethylpyridine (*sym*-collidine) were dried and freshly distilled prior to use. All solid reactants for glycosylation were dried, prior to use, overnight over phosphorus pentoxide under high vacuum. *N,N*-Dimethylchloroforminium chloride (Vilsmeier reagent) was prepared by the method of Bosshard *et al.* (27).

*Benzyl 3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranoside (2)*

A solution of 3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranosyl bromide (6) (**1**), mp 122–123°C, $[\alpha]_D^{24}$ +57.3° (*c* 1.0, $CHCl_3$), (14.95 g, 30 mmol) in dry nitromethane (20 mL) was added to a cooled (−30°C) solution of benzyl alcohol (3.24 g, 30 mmol), silver trifluoromethanesulfonate (8.0 g, 31 mmol), and 2,4,6-trimethylpyridine (3.75 g, 31 mmol) in dry nitromethane (30 mL) under nitrogen. The mixture was stirred at −30°C for 2 h and then diluted with chloroform (100 mL). The solid was removed by filtration and the filtrate was evaporated *in vacuo*. The foamy residue was dissolved in chloroform (100 mL), and washed sequentially with ice-water, 5% aqueous hydrogen chloride, and with aqueous sodium bicarbonate solution. Solvent removal after drying left a foam which was crystallized from diethyl ether (13.88 g, 88%), mp 106–108°C. Recrystallization from ethanol raised the melting point to 108–109°C, $[\alpha]_D^{22}$ −12.6° (*c* 0.5, $CHCl_3$); $^1$H nmr δ: 7.86–7.60 (m, 4H, phthalimido), 7.07 (s, 5H, $C_6H_5$), 5.78 (dd, 9 and 11 Hz, H-3), 5.37 (d, 8 Hz, H-1), 5.17 (t, 9 Hz, H-4), 4.95–3.75 (m, 6H), 2.12, 2.0, 1.84 (s, 3 OAc). *Anal.* calcd. for $C_{27}H_{27}NO_{10}$: C 61.71, H 5.18, N 2.67; found: C 61.66, H 5.11, N 2.48.

*Benzyl 2-deoxy-2-phthalimido-β-D-glucopyranoside (3)*

A solution of the acetate **2** (12.60 g, 24 mmol) in a mixture of acetone (200 mL), water (100 mL), and concentrated hydrochloric acid (40 mL) was kept at 70°C for 6 h. Evaporation of acetone left a suspension which was collected by filtration, washed with cold water, and dried when a solid was obtained (9.20 g, 97% yield), mp 173–175°C. Recrystallization from ethyl acetate raised the melting point to 176–177°C, $[\alpha]_D^{25}$ −34.2° (*c* 0.76, $Me_2CO$). The $^1$H nmr spectrum was consistent with expectations. *Anal.* calcd. for $C_{21}H_{21}NO_7$: C 63.14, H 5.30, N 3.51; found: C 63.09, H 5.27, N 3.43.

*Benzyl 4,6-*O*-benzylidine-2-deoxy-2-phthalimido-β-D-glucopyranoside (4)*

A solution of glycoside **3** (8.0 g, 20 mmol), α,α-dimethoxytoluene (6.08 g, 40 mmol), and *p*-toluenesulfonic acid (200 mg) in freshly distilled acetonitrile (200 mL) was stirred at room temperature for 16 h. Neutralization with triethylamine (2 mL) and solvent

removal left a sticky solid which was triturated several times with Skellysolve "B" and finally collected by filtration. Recrystallization from ethanol yielded colorless needles (8.96 g, 92% yield), mp 183–184°C; $[\alpha]_D^{25}$ −75.4° (*c* 1.2, $CHCl_3$). The $^1H$ nmr spectrum was consistent with expectations. *Anal.* calcd. for $C_{28}H_{25}NO_7$: C 68.98, H 5.17, N 2.88; found: C 68.85, H 5.06, N 2.70.

*Benzyl 3-O-(tetra-O-acetyl-β-D-galactopyranosyl)-4,6-O-benzylidene-2-deoxy-2-phthalimido-β-D-glucopyranoside (5)*

A solution of the alcohol **4** (7.31 g, 15 mmol) in a 1:1 mixture of nitromethane and benzene (600 mL) was distilled until 100 mL of distillate was collected. The temperature was adjusted to 60°C, mercuric cyanide (5.05 g, 20 mmol) and acetobromogalactose (8.22 g, 20 mmol) were added. After the mixture was stirred at 60°C for 24 h, additional amounts of mercuric cyanide (3.74 g) and the bromide (6.17 g, 15 mmol) were added and the mixture was stirred for 28 h at 60°C. The cooled solution was washed with 30% aqueous potassium iodide solution (2 × 250 mL), with aqueous sodium bicarbonate (2 × 250 mL), and with brine (500 mL). Each washing was back-extracted with chloroform (2 × 200 mL). The combined organic layers were evaporated to a foam which was dissolved in 90% aqueous acetic acid (50 mL) and the solution was stirred at room temperature for 30 min in case orthoesters had formed. The solution was diluted with chloroform (200 mL) and washed with ice-water (3 × 200 mL) and sodium bicarbonate solution (2 × 250 mL). Solvent removal left a foam which was passed through a short alumina (Woelm, neutral) column using ethyl acetate – diethyl ether (1:1). Solvent removal yielded a colorless foam (21 g). Addition of diethyl ether caused the crystallization of tetra-*O*-acetyl-β-D-galactopyranosyl cyanide (4.7 g), mp 168–170°C; $[\alpha]_D^{24}$ +36.2° (*c* 2.15, $CHCl_3$) (lit. (31) mp 168–169°C; $[\alpha]_D^{20}$ +37.2° (*c* 7.95, $CHCl_3$)).

Evaporation of the mother liquor left a foam which was applied to a silica gel (180 g) column and eluted with ethyl acetate – hexane–benzene (1:1:1). Solvent removal of the second and main fraction left a colorless foam (12.7 g). This crude product crystallized from diethyl ether but contained traces of tetra-*O*-acetyl-β-D-galactopyranosyl cyanide. Recrystallization from ethanol yielded colorless needles (9.02 g, 73% yield based on compound **4**), mp 170–171°C; $[\alpha]_D^{24}$ −46.3° (*c* 0.66, $CHCl_3$); $^1H$ nmr δ: 7.77 (s, 4H, phthalimido), 7.60–7.32 (m, 5H, phenyl), 7.01 (s, 5H, phenyl), 5.57 (s, 1H, $CHC_6H_5$), 5.14 (d, 9 Hz, H-1), 2.05, 1.90, 1.82, 1.53 (s, 4 OAc). *Anal.* calcd. for $C_{42}H_{43}NO_{16}$: C 61.68, H 5.30, N 1.72; found: C 61.99, H 5.33, N 1.57.

*Benzyl 4,6-di-O-acetyl-3-O-(tetra-O-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-β-D-glucopyranoside (7)*

A solution of the benzylidene compound **5** (8.18 g, 10 mmol) in 60% aqueous acetic acid (100 mL) was stirred at 100°C for 30 min and diluted with water (100 mL). Solvent removal left a foam (**6**) which was not characterized but acetylated directly with a 2:1 mixture of pyridine – acetic anhydride (90 mL). Solvent removal left a foam which was dissolved in chloroform (100 mL) and washed with 5% aqueous hydrochloric acid, sodium bicarbonate solution, and then with ice-water. Solvent removal then left a foam which was applied to a silica gel column and eluted with a mixture of ethyl acetate – hexane (1:1). Solvent removal of the second fraction yielded a solid (6.15 g, 75% yield based on compound **5**), mp 89–92°C; $[\alpha]_D^{23}$ −42.3° (*c* 1.3, $CHCl_3$). The $^1H$ nmr spectrum was consistent with expectations. *Anal.* calcd. for $C_{39}H_{43}NO_{18}$: C 57.56, H 5.33, N 1.72; found: C 57.11, H 5.49, N 1.61.

*4,6-Di-O-acetyl-3-O-(tetra-O-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-D-glucopyranose (8)*

A mixture of compound **7** (4.88 g, 6 mmol) and 5% palladium on carbon (3.0 g) in a 1:1 mixture of ethanol and ethyl acetate (100 mL) was hydrogenated at 50 psi at room temperature for 16 h. The solid was removed by filtration and the filtrate evaporated. The resulting foam was applied to a silica gel column and eluted with a mixture of ethyl acetate – hexane (2:1). The second and main fraction on evaporation left a solid (4.02 g, 93% yield), mp 123–126°C; $[\alpha]_D^{24}$ +12.2° (*c* 1.0, $CHCl_3$). *Anal.* calcd. for $C_{32}H_{37}NO_{18}\cdot H_2O$: C 51.80, H 5.30, N 1.89; found: C 51.97, H 5.12, N 1.77.

*4,6-Di-O-acetyl-3-O-(tetra-O-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-α,β-D-glucopyranosyl chloride (9)*

A solution of compound **8** (3.62 g, 5 mmol), *N,N*-dimethylchloroforminium chloride (Vilsmeier reagent) (2.56 g, 20 mmol), and collidine (2.42 g, 20 mmol) in dry dichloromethane (20 mL) was stirred at 0°C for 3 h. Dilution with dichloromethane (50 mL), washing with cold water, drying over sodium sulfate, and solvent removal gave a foam which crystallized on addition of diethyl ether (3.53 g, 95% yield), mp 104–109°C; $[\alpha]_D^{24}$ +18.7 (*c* 0.7, chloroform). The $^1H$ nmr spectrum of the product showed it to be a 3:7 mixture of α and β-anomers; $^1H$ nmr δ: 8.0–7.74 (m, 4H, phthalimido), 6.11 (d, 0.3H, 4 Hz, H-1), 5.92 (d, 0.7H, 9 Hz, H-1). *Anal.* calcd. for $C_{32}H_{36}NO_{17}Cl$: C 51.79, H 4.89, N 1.88, Cl 4.77; found: C 51.70, H 4.96, N 1.84, Cl 4.90.

# Syntheses of derivatives of *N*-acetyl-D-lactosamine from D-lactal hexaacetate. Hexa-*O*-acetyl-2-deoxy-2-phthalimido-β-D-lactosyl chloride

R. U. LEMIEUX, S. Z. ABBAS,[1] M. H. BURZYNSKA,[2] AND R. M. RATCLIFFE[3]

*Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2*

Received March 27, 1981

R. U. LEMIEUX, S. Z. ABBAS, H. BURZYNSKA, and R. M. RATCLIFFE. Can. J. Chem. **60**, 63 (1982).

Two reaction routes are presented for the preparation of hexa-*O*-acetyl-2-deoxy-2-phthalimido-β-D-lactosyl chloride (**7**) from lactal hexaacetate (**1**). One route involves, in the first stage, reaction of **1** with nitrosyl chloride and proceeds by way of benzyl 2-amino-2-deoxy-α-D-lactoside (**4**) as an intermediate. The other route, which is considered more efficient, involves reaction of **1** with ceric ammonium nitrate and sodium azide and involves the β-anomer (**12**) of **4** as an intermediate. The preparation of **7** is of interest as a reagent for the preparation of 2-amino-2-deoxy-β-D-lactosides. The procedures offer routes for the preparation of D-lactosamine.

R. U. LEMIEUX, S. Z. ABBAS, M. H. BURZYNSKA et R. M. RATCLIFFE. Can. J. Chem. **60**, 63 (1982).

On présente deux méthodes de préparation du chlorure d'hexa-*O*-acetyl-déoxy-2-phtalimido-2-β-D-lactosyle (**7**) à partir de l'hexaacétate de lactale (**1**). Une méthode fait intervenir, dans la première étape, la réaction du composé **1** avec le chlorure de nitrosyle et passe par un intermédiaire benzylamino-2-déoxy-2-α-D-lactoside (**4**). L'autre méthode, que l'on considère plus efficace, fait intervenir la réaction de **1** avec le nitrate d'ammonium cérique et l'azoture de sodium et implique comme intermédiaire l'anomère β (**12**) du composé **4**. L'intérêt de la préparation du composé **7** réside dans le fait qu'il est un moyen d'accès aux amino-2-déoxy-2-β-D-lactosides. Les méthodes ouvrent la voie à la préparation de la D-lactosamine.

[Traduit par le journal]

*N*-Acetyl-D-lactosamine (D-LacNAc) is of widespread occurrence as a component of the oligosaccharide portions of very many *N*- and *O*-linked glycoproteins and the oligosaccharides of milk (1). It is a building unit for the antigenic determinants of a number of certain Ii human blood group activities (2) as well as of the ABH Type 2 determinants (3).

In 1977[4] we announced our involvement in the chemical synthesis of oligosaccharide structures of possible interest to immunochemical investigations of the Ii determinants. On that occasion, the synthesis, amongst others, of βDLacNAc(1→6) and βDLacNAc(1→3) derivatives of both D-galactose and $\beta DGalO(CH_2)_8COOCH_3$ were reported. These syntheses are now reported in detail in an accompanying paper. The role that these products played in establishing the nature of the combining site of the monoclonal anti-I Ma myeloma protein have been reported in separate communications (5, 6). The synthesis of these β-glycosides of *N*-acetyl-D-lactosamine was accomplished by way of hexa-*O*-acetyl-2-deoxy-2-phthalimido-β-D-lactosyl chloride (**7**) using the silver triflate – collidine complex (7) to promote its condensation with the alcohol. The worth of this approach (the phthalimido-chloride method) for the establishment of β-glycosidic linkage from 2-amino-2-deoxy sugars (wherein the amino group is in equatorial orientation) was considered in an accompanying paper (4). We now wish to report details for the preparation of **7** from D-lactal hexaacetate (**1**) by two different routes. One process is based on the procedure for the preparation of 2-amino-2-deoxy-α-glycopyranoside which was developed in this laboratory (8) and which will be termed the nitroso-chloride route. The other process for the preparation of **7** is based on the azidonitration of glycals (9, 10) to form 2-azido-2-deoxy glycopyranosides and which will be designated as the azidonitrate route.

Ponpipom and co-workers (11, 12) have independently used the nitroso-chloride route for the preparation of the phthalimido-chloride **7**. Although full details have not been reported, these investigators used the same reaction sequences except for the conversion of **6** to **7**. Whereas we used the Vilsmeier reagent for this purpose (4), they chose to acetylate **6** for subsequent conversion to **7** using aluminum chloride. Dimitriev *et al.* (13) had previously prepared *N*-acetyl-D-lactosamine by way of a zinc reduction of the oximino-chloride **2**.

Very recently, Arnarp and Lönngren (14) published the use of the azidonitration route to achieve the bromide form of the chloride **7**. The reagent was used in the course of the preparation of hepta- and

pentasaccharides which are building units of "complex type" aspargine-linked glycoproteins.

Although it was not possible to expend much effort toward the optimization of yields, it is noteworthy that the seven-stage process for converting D-lactal hexaacetate (**1**) to **6** by way of the azidonitration route proceeded in 23% overall yield whereas only near half this yield was obtained by way of the six-stage nitroso-chloride route. On the other hand, a number of transformations in the latter process proceeded in yields that likely can be substantially improved. At the time that this process was investigated, the relatively high reactivity of the phthalimido group in α-glycosides toward hydrolysis[5] was not recognized and this property likely had an influence on the low yields obtained in the preparation of compounds **5** (70%) and **6** (60%). Also, the relatively poor yields obtained in the reaction of the nitrosyl chloride adduct **2** with benzyl alcohol and for the diborane reduction of the oximinoacetate **3***b* appear unacceptable in view of our previous experiences (8) with these reactions. Nevertheless, we recommend the process by way of azidonitration as the more convenient and reliable laboratory preparation.

The synthetic sequences are straightforward and warrant little comment beyond the information contained in the experimental portion of this paper. It may be noted that the use (15) of a strongly basic resin for the removal of alkali-labile by-products in the preparation of **4** should prove generally useful for such preparations. The high resistance to hydrogenolysis displayed by the α-benzyl glycoside **5** as compared to its β-anomer **13** was to be expected (16) but was an important disadvantage in the formation of a product **6** which contains groups susceptible to solvolysis. The reduction of the azide **11** to the amine **12** using hydrogen sulfide (17) in the presence of amine proved highly convenient and essentially quantitative. The amine **4** was characterized both as its peracetate and as its *N*-acetyl derivative. The use of the Vilsmeier reagent for the conversion of **6** to **7** has been presented in a separate communication (4). The preparation of the azido-bromide **9** in 42% overall yield by way of the azidonitration of **1** has been reported (10).

## Experimental

The general procedures and analytical methods were the same as previously described (4). The nmr measurements used either TMS (< 1%) as internal standard or 1:1 TMS–$CCl_4$ as external standard.

*Dimeric 3,6-di-*O*-acetyl-(4-*O*-tetra-*O*-acetyl-β-D-galactopyranosyl)-2-deoxy-2-nitroso-α-D-glucopyranosyl chloride (**2**)*

Nitrosyl chloride was added to a solution of D-lactal hexaacetate **1** (18) in dry ethyl acetate (280 mL) (19) to form **2**, mp 122–123°C, $[\alpha]_D^{20}$ +69.2° (*c* 1.0, $CHCl_3$), in 92% yield (lit. (13) mp 120–122°C, $[\alpha]_D^{20}$ +66.7° (*c*, 1.0, $CHCl_3$)).

*Benzyl 3,6-di-*O*-acetyl-4-*O*-(tetra-*O*-acetyl-β-D-galactopyranosyl)-2-deoxy-2-oximino-α-D-*arabino*-hexopyranoside (**3**a)*

A solution of the nitrosyl chloride adduct (**2**) (60.0 g, 0.11 mol) and benzyl alcohol (14.0 g, 0.13 mol) in *N,N*-dimethylformamide (300 mL) was kept at room temperature for 2 days. The solvent was removed, the dark yellow residual oil was dissolved in diethyl ether (500 mL), and this solution was washed with water (3 × 200 mL). Work-up in the usual manner provided a solid foam which was chromatographed on a column of Silica Gel G (E. Merck A.G., Darmstadt) using ethyl acetate – hexane (1:1). The first and main fraction provided a solid (40.0 g, 59% yield), $[\alpha]_D^{24}$ +31.2° (*c* 1.3, $CHCl_3$), whose $^1H$ nmr spectrum was consistent with expectation for the title compound **3***a*. *Anal.* calcd. for $C_{31}H_{39}NO_{17}$: C 53.37, H 5.64, N 2.01; found: C 53.75, H 5.55, N 2.01.

*Benzyl 2-acetoximino-3,6-di-*O*-acetyl-4-*O*-(tetra-*O*-acetyl-β-D-galactopyranosyl)-α-D-*arabino*-hexopyranoside (**3**b)*

Treatment of the oxime **3***a* (27.0 g, 38 mmol) with pyridine – acetic anhydride (2:1) (150 mL) at 5°C for 12 h provided the title compound **3***b* (26.0 g, 90% yield) as a solid, $[\alpha]_D^{24}$ +31.0 (*c* 1, $CHCl_3$) (lit. (13) $[\alpha]_D^{25}$ +12° (*c* 1.45, $CHCl_3$)), with an $^1H$ nmr spectrum consistent with a high degree of purity. *Anal.* calcd. for $C_{33}H_{41}NO_{18}$: C 53.58, H 5.58, N 1.89; found: C 53.19, H 5.51, N 1.72.

*Benzyl 2-amino-2-deoxy-4-*O*-(β-D-galactopyranosyl)-α-D-glucopyranoside (**4**)*

A solution of the oximinoacetate **3***b* (25.0 g, 33.7 mmol) in tetrahydrofuran (200 mL) was added dropwise to a 1 *M* solution of diborane in tetrahydrofuran (800 mL) kept at −70°C in an atmosphere of nitrogen. After completion of the addition, the solution was allowed to warm to room temperature and kept for 24 h and then carefully poured into methanol (600 mL). Evaporation left an oil which was taken up in methanol, rendered acid with acetic acid, and evaporated to a solid residue. This residue was dissolved in methanol and the solution was applied to a column (2.5 × 50 cm) of a basic resin (15) (Dowex I-X8, 200–400 mesh, $OH^-$ form). On elution with methanol and solvent removal, a crystalline solid (8.6 g, mp 138–142°C, 60% yield) was obtained. Recrystallization from ethanol raised the melting point to 164–168°C, $[\alpha]_D^{25}$ +64.6° (*c* 1, $H_2O$). The $^1H$ nmr was consistent with the structural assignment. *Anal.* calcd. for $C_{19}H_{29}NO_{10}\cdot H_2O$: C 49.77, H 7.03, N 3.05; found: C 50.76, H 6.95, N 3.11.

Acetylation of **4** provided benzyl 2-acetamido-3,6-di-*O*-acetyl-4-*O*-(tetra-*O*-acetyl-β-D-galactopyranosyl)-2-deoxy-α-D-glucopyranoside, mp 101–103°C; $[\alpha]_D$N +51° (*c* 0.4, $CHCl_3$) (lit. (12) mp 102–104°C, $[\alpha]_D^{25}$ +56.4 (*c* 1.56, $CHCl_3$)). De-*O*-acetylation readily provided crystalline benzyl 2-acetamido-2-deoxy-4-*O*-(β-D-galactopyranosyl)-α-D-glucopyranoside, mp 226–229°C, $[\alpha]_D^{25}$ +105.5° (*c* 0.85, $H_2O$).

*Benzyl 3,6-di-*O*-acetyl-4-*O*-(tetra-*O*-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-α-D-glucopyranoside (**5**)*

Phthalic anhydride (1.2 g, 8 mmol) was added to a solution of the amine **4** (6.0 g, 13.9 mmol) in pyridine (25 mL). The solution was heated to 60–75°C for 20 min. Triethylamine (1.4 g, 13.9 mmol) and more phthalic anhydride (1.2 g, 8 mmol) were added and the heating was continued for 2 h. Methanol (50 mL) was added and the solution was evaporated to a dry residue which was taken up in 30 mL of a mixture of pyridine – acetic anhydride (2:1). After heating at 90°C for 3 h, the crude solid product was isolated in the usual manner and applied to a

For personal use only.

column (2.5 × 50 cm) of Silica Gel G for chromatography using ethyl acetate – hexane (2:1). The first fraction (7.88 g, 70% yield) was recrystallized from ethyl acetate – hexane, mp 177–180°C, $[\alpha]_D^{25}$ +86.1° (*c* 1.1, $CHCl_3$). The $^1H$ nmr was consistent with the structural assignment. The signals for C-1′ and C-1 occurred at 100.97 and 96.35 ppm, respectively. *Anal.* calcd. for $C_{39}H_{43}NO_{18}$: C 57.56, H 5.32, N 1.72; found: C 57.41, H 5.25, N 1.66.

*Benzyl 3,6-di-O-acetyl-4-O-(tetra-O-acetyl-β-D-galacto-pyranosyl)-2-azido-2-deoxy-β-D-glucopyranoside (**10**)*

A solution of the azidobromide **9** (10), (20.5 g, 30 mmol), mp 156–157°C, $[\alpha]_D^{25}$ +87° (*c* 0.93, $CHCl_3$), in nitromethane (50 mL) was added dropwise to a stirred mixture of benzyl alcohol (10.0 g, 92 mmol), silver carbonate (30.0 g, 109 mmol), and Drierite (30.0 g) which was cooled to −22°C and protected from light and moisture. After stirring at this temperature for 18 h, the solids were removed by filtration and washed with dichloromethane. The combined filtrates were taken to dryness and the residue was dissolved in ethyl acetate – hexane (1:1) for passage through a short column of Silica Gel G. Solvent removal left an oily residue from which the title compound **10** crystallized on the addition of diethyl ether. After one recrystallization from diethyl ether (16.4 g, 77% yield), the melting point was 137–138°C, $[\alpha]_D^{25}$ −9.7° (*c* 2.3, $CHCl_3$). The $^1H$- and $^{13}C$ nmr spectra in $CDCl_3$ were entirely consistent with the assigned structure; for example, in confirming the presence of the benzyl group, the six acetyl groups at 1.96, 2.03, 2.05, 2.11, 2 × 2.15 ppm and the two β-anomeric hydrogens at 4.45 (d, 8 Hz, H-1′) and 4.05 ppm (d, 8.5 Hz, H-1). The signals for C-1′ and C-1 were at 100.88 and 100.07 ppm, respectively. Absorption in the infrared (KBr) at 2110 $cm^{-1}$ confirmed the presence of the azido group. *Anal.* calcd. for $C_{31}H_{39}O_{16}N_3$: C 52.47, H 5.54, N 5.92; found: C 52.22, H 5.64, N 5.68.

*Benzyl 2-azido-2-deoxy-4-O-(β-D-galactopyranosyl)-β-D-gluco-pyranoside (**11**)*

The acetate **10** (8.72 g, 12.3 mmol) was dissolved in 150 mL of 0.01 *N* sodium methoxide in methanol. Solvent removal provided crystals which were washed with a little cold methanol (5.01 g, 89% yield), mp 202–204°C, $[\alpha]_D^{25}$ −1.1° (*c* 0.4, $CH_3OH$). *Anal.* calcd. for $C_{19}H_{27}O_{10}N_3$: C 49.89, H 5.95, N 9.19; found: C 49.84, H 5.86, N 8.97.

*Benzyl 2-amino-2-deoxy-4-O-(β-D-galactopyranosyl)-β-D-glucopyranoside (**12**)*

A slow stream of hydrogen sulfide was bubbled through an ice-cold solution of the azide **11** (10.8 g, 23.5 mmol) in pyridine (210 mL) and triethylamine (60 mL) for 2.5 h. The solution was evaporated to dryness and the residue was extracted with a mixture of methanol–water (1:1). The extract was filtered through a bed of diatomaceous earth and evaporated. The residue (10.65 g) appeared to be the desired amine **12** as assessed by $^{13}C$ nmr and tlc. Although it was contaminated with traces of sulfur, it was used directly for the preparation of the phthalimido compound **13**. In order to remove the sulfur and obtain a sample for analysis, the compound was adsorbed on a cation-exchange resin (AG 50W-X2, 200–400 mesh, 40 g) in the $H^+$ form and, after washing, was desorbed with ammonium hydroxide. After solvent removal, the residue was taken up in water, the solution treated with charcoal and evaporated to a syrup which crystallized, mp 108–111°C, $[\alpha]_D^{25}$ −25.3° (*c* 2.4, $H_2O$); $^{13}C$ nmr ($D_2O$, external TMS): 136.68, 128.62, 128.53, 128.31, 102.95 (C-1′), 101.88 (C-1), 78.97 (C-4), 75.17, 74.76, 74.20, 72.53, 71.39, 70.86, 68.42, 60.81 and 60.27 (C-6 and C-6′), 56.02 (C-2). *Anal.* calcd. for $C_{19}H_{29}NO_{10}\cdot 0.5H_2O$: C 51.81, H 6.86, N 3.18; found: C 51.85, H 6.67, N 2.98.

*Benzyl 3,6-di-O-acetyl-4-O-(tetra-O-acetyl-β-D-galactopyrano-syl)-2-deoxy-2-phthalimido-β-D-glucopyranoside (**13**)*

Treatment of the β-amine **12**, under the conditions described above for the conversion of the α-anomer **4** to **5**, provided the title compound **13** in 79% yield after recrystallization from ethyl acetate – hexane, mp 187–188°C, $[\alpha]_D^{25}$ −9.6° (*c* 2.5, $CHCl_3$). The $^1H$- and $^{13}C$ nmr spectra ($CDCl_3$) were consistent with the structural assignment. The signals for the H-1 and H-1′ atoms were at 5.40 and 4.57 ppm each as doublets with spacings of 8.2 Hz. The low-field signal for H-1 is consistent with the deshielding expected by the vicinal phthalimido group. The signals for C-1′ and C-1 occurred at 101.06 and 97.1 ppm, respectively. *Anal.* calcd. for $C_{32}H_{37}NO_{18}$: C 57.57, H 5.33, N 1.73; found: C 57.57, H 5.44, N 1.72.

*3,6-Di-O-acetyl-4-O-(tetra-O-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-α,β-D-glucopyranose (**6**)*

(a) *From the α-benzyl glycoside **5***

Hydrogenolysis of compound **5** (6.0 g, 7.3 mmol) dissolved in 5% solution of acetic acid in ethanol (100 mL) and using 5% palladium on charcoal (4.0 g) and 50 psi of hydrogen was incomplete after 24 h. The title compound was obtained in 60% yield by chromatography on Silica Gel G column (3 × 60 cm) and developing the column with ethyl acetate – hexane (2:1). It occurred as the second and main fraction, mp 116–120°C. The identity of the product was evident from a consideration of its $^1H$ nmr which, furthermore, was similar to that for the product obtained below. Moreover, both products could be converted to the phthalimido-chloride (**7**) in 82–85% yields.

(b) *From the β-benzyl glycoside **13***

Hydrogenolysis of compound **13** in ethanol – ethyl acetate (1:1) at 70 psi and room temperature using 10% palladium on charcoal proceeded readily to provide the title product, mp 132–140°C, in quantitative yield.

*3,6-Di-O-acetyl-4-O-(tetra-O-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-β-D-glucopyranosyl chloride (**7**)*

The alcohol **6** (2.98 g, 4.13 mmol) was dissolved with *sym*-collidine (0.77 g, 6.4 mmol) in dichloromethane (20 mL). This solution was added dropwise to a suspension of *N*,*N*-dimethylchloroforminium chloride (Vilsmeier reagent) (1.70 g, 12.9 mmol) in dichloromethane (10 mL) kept at 0°C and in an atmosphere of dry nitrogen. The reaction mixture was allowed to warm to room temperature while being stirred for 3 h. Toluene (100 mL) was then added and the solution was washed with cold dilute aqueous hydrochloric acid (30 mL), then with aqueous sodium bicarbonate (30 mL), and finally with water (30 mL). After drying over anhydrous sodium sulfate, the solvent was removed to leave a residue which crystallized readily from dichloromethane – diethyl ether, mp 184–185°C, $[\alpha]_D^{25}$ +34.7° (*c* 1.8, $CHCl_3$) (lit. (12) mp 173–174°C; $[\alpha]_D^{25}$ +29.3° (*c* 1.5, $CHCl_3$)) (2.61 g, 85% yield). The compound was best characterized by its $^{13}C$ nmr spectrum ($CDCl_3$): 170.25, 170.07, 169.96, 169.09, 167.36, 134.54, 131.20, 123.80, 101.07 (C-1′), 85.55 (C-1), 78.60, 77.19, 76.44, 76.30, 75.77, 71.06, 70.96, 70.72, 69.12, 66.65, 62.03, 60.81, 67.91 (C-2), 20.82, 20.58, 20.46. *Anal.* calcd. for $C_{32}H_{36}NO_{17}Cl$: C 51.79, H 4.89, N 1.88, Cl 4.77; found: C 51.63, H 4.85, N 1.87, Cl 4.77.

# Syntheses of core chain trisaccharides related to human blood group antigenic determinants

R. U. LEMIEUX, S. Z. ABBAS,[1] AND B. Y. CHUNG[2]

*Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2*

Received March 27, 1981

R. U. LEMIEUX, S. Z. ABBAS, and B. Y. CHUNG. Can. J. Chem. **60**, 68 (1982).

Trisaccharides related to the core chain of human blood group determinants were synthesized by way of the phthalimido-chloride method; namely, β-D-Gal*p*-(1→3)-β-D-GlcNAc*p*-(1→6)-D-Gal*p* (**3**), β-D-Gal*p*-(1→3)-β-D-GlcNAc*p*-(1→3)-D-Gal*p* (**5**), β-D-Gal*p*-(1→4)-β-D-GlcNAc*p*-(1→6)-D-Gal*p* (**4**), and β-D-Gal*p*-(1→4)-β-D-GlcNAc*p*-(1→3)-D-Gal*p* (**6**). The syntheses of the 8-methoxycarbonyloctyl β-glycosides of these trisaccharides are also reported.

R. U. LEMIEUX, S. Z. ABBAS et B. Y. CHUNG. Can. J. Chem. **60**, 68 (1982).

Faisant appel à la méthode du chlorure phtalimide, on a synthétisé les trisaccharides correspondant à la chaîne centrale des déterminants du groupe sanguin humain: β-D-Gal*p*-(1→3)-β-D-GlcNAc*p*-(1→6)-D-Galp (**3**), β-D-Gal*p*-(1→3)-β-D-GlcNAc*p*(1→3)-D-Gal*p* (**5**), β-D-Gal*p*-(1→4)-β-D-GlcNAc*p*-(1→6)-D-Gal*p* (**4**) et β-D-Gal*p*-(1→4)-β-D-GlcNAc*p*-(1→3)-D-Gal*p* (**6**). On rapporte également les synthèses des méthoxycarbonyl-8-octyl β-glycosides de ces trisaccharides.

[Traduit par le journal]

The core structure of the oligosaccharide structures which lead to the human ABH and Lewis antigenic determinants as terminal units can occur as linear or branched chains (1). In the case of the blood group specific glycoproteins, the first disaccharide unit (βDGal(1→3)αDGalNAc) is attached to either a serine or threonine residue of the core protein as an *O*-glycoside. The oligosaccharide is then elaborated to produce the structures which are incorporated into the basic chain shown in Fig. 1. This chain is taken from the composite megalosaccharide structure proposed by Lloyd *et al.* (2) to include the known structural features. It is not meant to indicate a specific structure.

In the case of the ABH active glycosphingolipids which have been isolated from human red cells, the basic core structure, as illustrated in Fig. 1 for a very simple structure, begins with a βDGal(1→4)-βDGlc (lactose) unit attached to the ceramide. The oligosaccharide is then mainly elaborated in this case by way of *N*-acetyllactosamine residues. Kościelak[3] has classified these as both oligo- and poly(glycosyl)ceramides.

The Ii antigens (5) consist of a chemically ill-defined group of human antigenic determinants. The I antigens are well expressed on the red cells of the majority of adults and the i antigens are found on red cells from the umbilical cords of newborn infants and the red cells of a rare group of adults which lack the I antigens (6–8). The change from i to I specificity occurs gradually during the first year of life (6) and appears to be related to the branching of the core oligosaccharide structures (9, 10). Recently the i specificity has been associated with at least two *N*-acetyllactosamine units which are linked 1→3′ (11). The I specificities appear numerous since a wide range of anti-I antibodies of different specificities are recognized (12). These antibodies are termed cold agglutinins because these do not agglutinate red cells at body temperature. These can occur in the plasma as autoantibodies and give rise to haemolytic disorders (13). It has become evident (14) that many of these anti-I antibodies are directed against carbohydrate structures and that at least some of these structures constitute the inner portions of the carbohydrate chains in the blood-group specific glycoproteins and glycolipids.

We set out several years ago[4] to synthesize portions of the structures shown in Fig. 1 as possible candidates for Ii activities (14). In this context and judging from the structures in Fig. 1, thirteen trisaccharide structures are indicated. In this regard, it must be noted that, since most of the anti-I cold agglutinins (antibodies) are monoclonal, it cannot be expected that a trisaccharide will have strong I activity unless the combining site is directed to the central sugar unit and only to portions of the two terminal units, as has now been

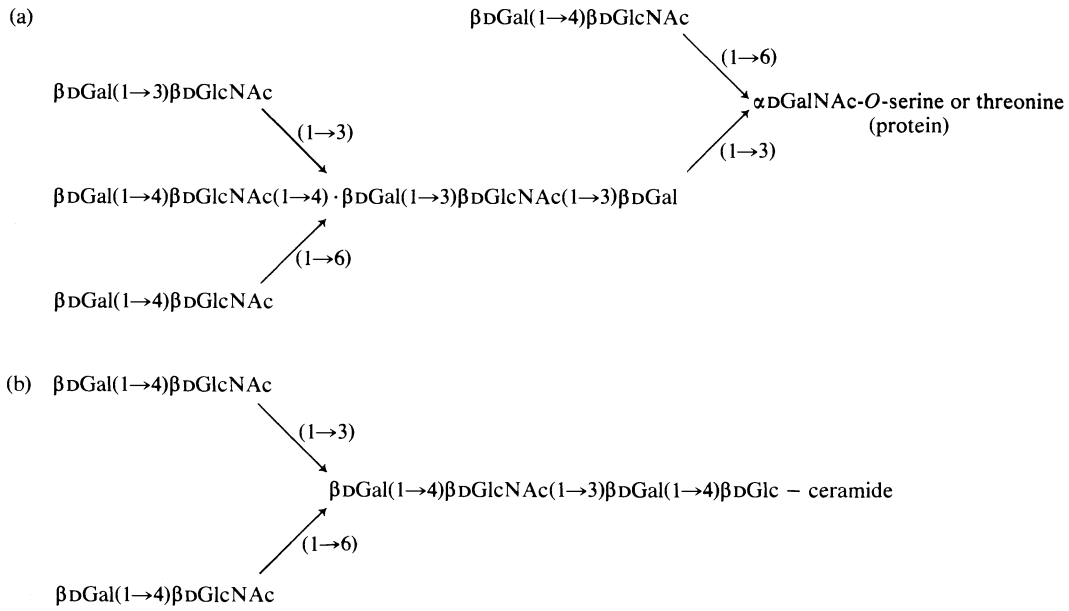

FIG. 1. (a) The composite "megalosaccharide" structure for the branched carbohydrate chains in blood-group specific glycoproteins by Lloyd *et al.* (2). (b) The core structure for the H (Type 2) active glycosphingolipid isolated by Watanabe and co-workers (3) and Kościelak *et al.* (4) have shown that poly(glycosyl)ceramides can have up to 59 glycosyl units and are multibranched.

established for the IMa determinant (15). Consequently, to properly delineate the I activities, it may prove necessary to synthesize tetra-, penta-, and even higher saccharides including branched structures.

We wish to report herein the synthesis of the four core chain trisaccharides both as the reducing trisaccharides (**3** to **6**) and as the glycosides (**9** to **12**). These were synthesized by way of condensation of hexa-*O*-acetyl-2-deoxy-2-phthalimido-α,β-D-lactosyl chloride (16) (**15**) and the corresponding derivative (17) (**14**) of lacto-*N*-biose I with the alcohols **1**, **2**, **7**, **8**, and **13**.

The condensations of the phthalimido-chlorides with the primary hydroxyl of **1** proceeded without complications and in acceptable yield (about 75%). However, the condensations with the secondary hydroxyl group of **2** were not satisfactory. In the case of the Type 1 reagent **14** to form the blocked derivative of **5**, the yield was only 24%. Indeed, attempts to prepare the Type 2 trisaccharide **6** by condensing **2** with the lactosamine derivative **15** also failed. Although the matter was not investigated in detail, we consider that the diisopropylidene compound **2** is unsatisfactory as a starting material because the cationic intermediate, which is liberated on reaction of the silver-triflate – *sym*-collidine complex with the phthalimido-chloride (**14** or **15**), attacks the *O*-isopropylidene groups at an overall faster rate than it attacks the hydroxyl group. Such an occurrence would not be without precedent (18, 19).

In order to achieve a synthesis of **6**, the condensation of hexa-*O*-acetyl-2-deoxy-2-phthalimido-β-D-lactosyl chloride (**15**) with the galactose derivative **13** was examined. In this case, the reaction proceeded smoothly to provide the desired condensation product in 80% yield. The eventual overall yield of **6**, however, proved to be unsatisfactory.

Although the synthesis of oligosaccharides, such as compounds **3** to **6**, which may correspond to antigenic determinants, can play an important role as inhibitors in studies of antibody–antigen interaction, the synthesis of the oligosaccharide attached to an aglycon which can serve as a linking arm for the preparation of artificial antigens and immunoadsorbents (20) should also provide structures which are useful in such inhibition studies. The trisaccharides **3** to **6** were synthesized as β-glycosides (**9** to **12**) of 8-methoxycarbonyloctanol since this aglycon has proven highly attractive as a linking arm (21). These structures were synthesized starting from the alcohols **7** and **8**.

The $^{1}H$- and $^{13}C$-chemical shifts for the glycosides **9** to **12** are presented in Table 1. Inspection of these data will show that the effects of substitutional changes are in accord with previous experi-

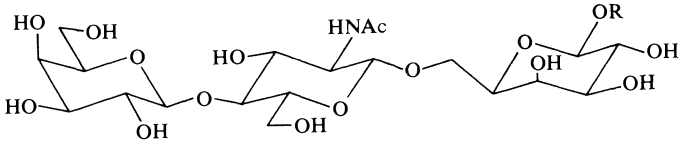
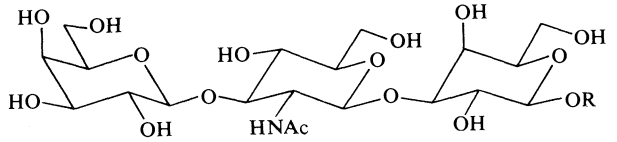
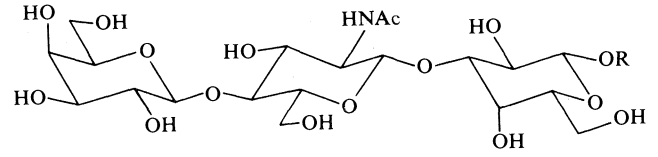
**3** R = H(α, β) **9** R = $(CH_2)_8COOCH_3$



**4** R = H(α, β) **10** R = $(CH_2)_8COOH_3$



**5** R = H(α, β) **11** R = $(CH_2)_8COOCH_3$



**6** R = H(α, β) **12** R = $(CH_2)_8COOCH_3$

ence in these regards (22) and clearly confirm the structural assignments. The $^{13}C$ chemical shifts are seen to be characteristic of a given disaccharide unit (βDGal(1→3)βDGlcNAc, βDGal(1→4)βDGlcNAc, βDGlcNAc(1→6)βDGal, or βDGlcNAc(1→3)βDGal). The only significant changes which occur are at C1 because of a change in aglycon. These observations support the contention that $^{13}C$ nmr can play an important role in structural investigation of complex oligosaccharides especially since these appear to be less sensitive to changes in environment, such as the specific interunit chemical shifts which may be observed in the case of $^{1}H$-chemical shifts (22).

In the preparations of compounds **9** to **12**, intermediates are encountered wherein it is necessary to remove the phthaloyl group in order to convert the phthalimido group to an acetamido group. Initially, we performed this by alkaline hydrolysis to the amino acid and this stage was followed by peracetylation and then conversion of the carboxyl group of the bridging arm to methyl ester using diazomethane. Since then, a controlled hydrazinolysis of the phthalimido group, to avoid transformation of the methyl ester grouping of the linking arm to acyl hydrazide, was developed by Bundle and Josephson (23), which is the method of choice (24).

For personal use only.

inhibit the precipitation of an I active glycoprotein by a variety of anti-I agglutinins (25, 26). As was to be expected, compounds **4** and **10** were excellent inhibitors and, interestingly, provided, under the test conditions used, identical 50% inhibitions. An accompanying paper (27) follows up on this observation by way of the preparation of the diastereoisomeric 6-*C*-methyl derivatives of **4**. The D-isomer proved to be superior to **4** as an inhibitor whereas the L-isomer was virtually ineffective. In this way, it proved possible to establish the conformation of **4** which is bound by the monoclonal anti-I Ma antibody (15).

## Experimental

The general experimental procedures in terms of preparation of solvents and reagents, evaporations, chromatographic separations, and analytical methods were the same as previously described (17).

*1,2;5,6-Di-*O*-isopropylidene-α-D-galactofuranose (**2**)*

Prepared as previously described (28) (see also Morgenlie (29) and Paulsen and Behre (30)).

*8-Methoxycarbonyloctyl 2-*O*-benzoyl-4,6-*O*-benzylidine-β-D-galactopyranoside (**7**)*[5]

A solution of chloroacetyl chloride (27.3 mL, 0.34 mol) and pyridine (0.34 mol) in dichloroethane (100 mL) was added dropwise over 2 h to a stirred solution of 8-methoxycarbonyloctyl 4,6-*O*-benzylidene-β-D-galactopyranoside (123 g, 0.28 mol) (31) in dichloromethane and kept near −78°C. The temperature was then allowed to rise to −10°C and the solution was poured into vigorously stirred water (5 L). The product was isolated in the usual way and then benzoylated without further purification. The $^{13}C$ nmr spectrum of the syrupy product (220 g) indicated that one component represented about 80% of the mixture. This crude product (215 g) was added to dry methanol (2 L) and the mixture was cooled to −30°C. On adding a saturated (−5°C) solution of ammonia in methanol (180 mL), a clear solution was obtained (32). When none of the starting material remained (tlc using ethyl acetate – *n*-hexane (1:1)), the solution was taken to dryness. Column chromatography (silica gel and graded elution using ethyl acetate and *n*-hexane) of a portion of the solid residue provided a fraction (77% yield) which crystallized from ethanol. Recrystallization from ethanol provided the analytical sample, mp 119–120°C, $[\alpha]_D^{24}$ +7.1° (*c* 1, $CHCl_3$). *Anal.* calcd. for $C_{30}H_{38}O_9$: C 66.41, H 7.06; found: C 66.21, H 7.09.

Both the $^1H$ and $^{13}C$ nmr spectra were in accord with those expected for the title compound. The position of the signal for H2 at 5.33 ppm (dd, 8 and 10 Hz) confirmed the structural assignment. Although *O*-chloroacetyl groups can be removed by treatment with thiourea (32), ammonolysis proved more convenient in this case.

*8-Methoxycarbonyloctyl 2-*O*-benzoyl-3,4-*O*-isopropylidene-β-D-galactopyranoside (**8**)*

A solution of compound **7** (3.5 g, 6.45 mmol) in 80% aqueous acetic acid (60 mL) was kept at 75°C for 1 h. Solvent removal left a residue which was triturated with hexane (200 mL). The residue (2.7 g) was dissolved in dry *N,N*-dimethylformamide

[5]Prepared by Y. Fouron, University of Alberta postdoctoral fellow, 1975–1977.

TABLE 1. The $^1H^a$ and $^{13}C$ nmr[b] chemical shifts for glycosides in $D_2O$ (R = $(CH_2)_8COOCH_3$)

| Compound | βDGal[c] | | | βDGlcNAc | | | | | | βDGal[d]—OR | | | |

For personal use only.

(30 mL), and dimethoxypropane (1.17 g, 11.2 mmol) and *p*-toluenesulphonic acid (50 mg) were added. The reaction and isolation of the product were the same as previously described (31) for the preparation of 2,2,2-trichloroethyl 3,4-*O*-isopropylidene-β-D-galactopyranoside. The crude product (2.8 g) was dissolved in dry pyridine (30 mL) and triphenylmethyl chloride (2.28 g) was added. The resulting solution was kept at 65°C for 12 h. The product was isolated in the usual manner and chromatographed on silica gel using a mixture of hexane – ethyl acetate (8:1). The first fraction provided a solid which crystallized from hexane (2.0 g), mp 102–103°C, $[\alpha]_D^{25}$ −5.8° (*c* 1.2, $CHCl_3$). The $^1H$ nmr was consistent with that expected for the 6-*O*-trityl derivative of the title compound **8**. Hydrogenolysis of this product (1.95 g) in ethanol using 5% palladium-on-charcoal at 200 psi of hydrogen pressure gave a solid which was triturated with hexane (100 mL). The residue crystallized from a mixture of hexane–ether (1.18 g, 37% yield from **7**), mp 47–49°C, $[\alpha]_D^{25}$ +17.6° (*c* 0.8, $CHCl_3$). *Anal.* calcd. for $C_{26}H_{38}O_9$: C 63.13, H 7.74; found: C 63.28, H 7.66. The $^{13}C$ nmr spectrum was in complete accord with the structural assignment.

*2,2,2-Trichloroethyl 2-O-benzoyl-4,6-O-benzylidene-β-D-galactopyranoside (**13**)*

2,2,2-Trichloroethyl 3-*O*-benzoyl-4,6-*O*-benzylidene-β-D-galactopyranoside (mp 198–199°C, $[\alpha]s^{24}$ −60.40° (*c* 1, $CHCl_3$)) was readily prepared from 2,2,2-trichloroethyl-β-D-galactopyranoside (33) following the procedure published by Chittenden and Buchanan (34) for the preparation of the analogous benzyl glycoside. In order to have the benzoyl group migrate from the 3- to the 2-position, a solution of the compound (5.0 g, 9.9 mmol) in dimethylsulfoxide (20 mL) was added to 0.05 *N* aqueous sodium hydroxide (20 mL). After 2 min at room temperature, the solution was poured into ice water and immediately extracted with chloroform (250 mL) to afford a product which was subjected to chromatographic separation on a silica gel column using ethyl acetate – chloroform as solvent. The second fraction to appear in the eluate contained a compound (1.7 g, 35% yield) which crystallized readily, mp 206–208°C, $[\alpha]_D^{23}$ −17.5° (*c* 0.9, $CHCl_3$), which was isomeric ($^1H$ nmr) to the starting material, and which necessarily, from a quartet centered at 5.43 ppm with spacings of 8 and 10 Hz, had the benzoyl group at the 2-position. *Anal.* calcd. for $C_{22}H_{21}O_7Cl_3$: C 52.45, H 4.20, Cl 21.11; found: C 52.40, H 4.29, Cl 21.24.

*4,6-Di-O-acetyl-3-O-(tetra-O-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-α,β-D-glucopyranosyl chloride (**14**)*

This reagent was prepared as described in a separate communication (17).

*3,6-Di-O-acetyl-4-O-(tetra-O-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-α,β-D-glucopyranosyl chloride (**15**)*

This reagent was prepared by way of one of the two procedures described in a separate communication (16). The route involving the azidonitration is recommended.

*General methods*

(a) *Glycosylation reactions*

In general, a solution of the phthalimido-chloride (either **14** or **15**) (3.5 mmol) in nitromethane (10 mL) was added dropwise to a solution of the alcohol (3.5 mmol), silver trifluoromethylsulfonate (3.7 mmol), and *sym*-collidine (3.7 mmol) in nitromethane (20 mL) kept at −15° to −30°C. The resulting mixture was stirred at −15°C for 1 h and then at room temperature for 2 h. Chloroform was then added and the solids removed by filtration prior to washing, first with water, then cold dilute hydrochloric acid, then with dilute aqueous sodium bicarbonate solution, and finally with water. The solid foam which remained after solvent removal was dissolved in ethyl acetate and this solution was applied to a short column of neutral alumina. The product obtained on elution with ethyl acetate was purified as is indicated.

(b) *Hydrolysis of O-isopropylidene groups*

In general, the compound (1 mmol) was dissolved in 95% aqueous trifluoroacetic acid (35) at room temperature. After 15 min the solvents were rapidly removed *in vacuo* near room temperature. The residue was then processed as is indicated.

(c) *Removal of the phthaloyl group and* N*-acetylation*

For the products (about 0.5 mmol) formed on glycosylation of the di-*O*-isopropylidene compounds **1** and **2**, both the acetyl and phthaloyl groups were removed simultaneously by reaction with a large excess of hydrazine hydrate (2 mL) in ethanol (20 mL) at reflux. After solvent removal, the residue was dissolved in 50% aqueous methanol (20 mL), acetic anhydride (5 mL) added, and the solution stirred for 2 h. Solvent removal left a residue which was processed as is indicated.

In the case of the products formed on the glycosylation of the compounds **7** and **8**, the *O*-isopropylidene or the *O*-benzylidene group was first removed by acid hydrolysis. Refluxing 80% acetic acid was used to hydrolyze the benzylidene group. A 10% solution (10 mL) of 99% trifluoracetic acid in dichloromethane was used to remove the *O*-isopropylidene group. The resulting product was taken up in 40% aqueous methanol containing an excess of sodium hydroxide and the solution was heated under reflux for 3 h in order to saponify the methyl ester. The solution was then evaporated to dryness. The residual salt-cake was acetylated overnight with an excess of a mixture (2:1) of pyridine – acetic anhydride. Solvent removal left a residue which was treated with cold 0.1 *N* aqueous hydrochloric acid prior to extraction with dichloromethane. The crude acidic product thus obtained was heated under reflux for 3 h with 40% aqueous methylamine in methanol in order to effect deacetylation and removal of the phthaloyl group. The product was then reacetylated using pyridine – acetic anhydride (2:1) in the usual manner.

The resulting product was then dissolved in dichloromethane for treatment with an excess of diazomethane in ether. The peracetate of the desired compound was then isolated by chromatographic separation on a silica gel column (2.5 × 15 cm) using first ethyl acetate – benzene (1:1) and then this solvent mixture containing 5% methanol. It is to be stressed at this point that this multistep procedure was used only because it was convenient at the time these preparations were made. It is not recommended. The procedure developed by Bundle and Josephson (23) and which was recently used in this laboratory (24) is more convenient and proceeds in better yield.

*6-O-[4,6-Di-O-acetyl-3-O-(tetra-O-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-β-D-glucopyranosyl]-1,2;3,4-di-O-isopropylidene-α-D-galactopyranose (**16**)*

The crude product from the reaction of **1** with **14** was applied to a silica-gel column and the chromatogram was developed with ethyl acetate – hexane (1:1). The second fraction contained a colorless solid which was recrystallized from ethanol (76% yield), mp 119–121°C, $[\alpha]_D^{25}$ −39.1° (*c* 0.6, $CHCl_3$). The $^1H$ nmr spectrum required the presence of the phthalimido group, the two isopropylidene groups, and the six acetyl groups. *Anal.* calcd. for $C_{44}H_{55}NO_{23}$: C 54.71, H 5.73, N 1.45; found: C 53.84, H 5.64, N 1.42.

*6-O-[2-Acetamido-2-deoxy-3-O-(β-D-galactopyranosyl)-β-D-glucopyranosyl]-1,2;3,4-di-O-isopropylidene-α-D-galactopyranose (**17**)*

The product from the hydrazinolysis and then *N*-acetylation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

of **16** was passed through a column of Dowex 1-X 8 ($OH^-$ form) using methanol as solvent. Solvent removal left a residue which crystallized from methanol – diethyl ether (74% yield). Recrystallization from methanol–acetone gave an analytically pure compound, mp 225–227°C (dec.), $[\alpha]_D^{24}$ −50.3° (*c* 0.5, $H_2O$). The $^1H$ and $^{13}C$ nmr were consistent with the structural assignment.

*6-O-[2-Acetamido-2-deoxy-3-O-(β-D-galactopyranosyl)-β-D-glucopyranosyl]-D-galactopyranose [βDGal(1→3)βD-GlcNAc(1→6)DGal] (**3**)*

The product from the hydrolysis of **17** using trifluoroacetic acid was recrystallized from methanol (64% yield), mp 175–178°C (dec.), $[\alpha]_D^{23}$ −0.9° (*c* 0.8, $H_2O$) (lit. (36) mp 177–184°C, $[\alpha]_D^{20}$ −9.5° to −1.2° (1 h) (*c* 0.84, water)). *Anal.* calcd. for $C_{20}H_{35}NO_{16}\cdot H_2O$: C 42.62, H 6.61, N 2.38; found: C 42.65, H 6.39, N 2.20.

*6-O-[4,6-Di-O-acetyl-4-O-(tetra-O-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-β-D-glucopyranosyl]-1,2;3,4-di-O-isopropylidene-α-D-galactopyranose (**18**)*

The crude product from the reaction of **1** with **15** crystallized on solvent removal (80% yield) and was recrystallized from ethanol, mp 201–202°C, $[\alpha]_D^{29}$ −19.6° (*c* 0.8, $CHCl_3$). The $^1H$ nmr spectrum confirmed the presence of the phthalimido group, the two isopropylidene groups, and the six acetyl groups. *Anal.* calcd. for $C_{44}H_{55}NO_{23}$: C 54.71, H 5.73, N 1.45; found: C 55.04, H 5.68, N 1.50.

*6-O-[2-Acetamido-2-deoxy-4-O-(β-D-galactopyranosyl)-β-D-glucopyranosyl]-1,2-3,4-di-O-isopropylidene-α-D-galactopyranose (**19**)*

The product from the hydrazinolysis and then *N*-acetylation of **18** was treated as described above in the preparation of **17**. The yield was 87%, mp 212–214°C, $[\alpha]_D^{23}$ −47.2° (*c* 0.9, $H_2O$). The $^1H$ and $^{13}C$ nmr spectra were consistent with the structural assignment. *Anal.* calcd. for $C_{26}H_{43}NO_{16}\cdot H_2O$: C 48.51, H 7.04, N 2.17; found: C 48.49, H 6.69, N 2.06.

*6-O-[2-Acetamido-2-deoxy-4-O-(β-D-galactopyranosyl)-β-D-glucopyranosyl]-D-galactopyranose [βDGal(1→4)βD-GlcNAc(1→6)DGal] (**4**)*

The product from the hydrolysis of **19** using trifluoroacetic acid was recrystallized from ethyl acetate – methanol (73% yield), mp 155–159°C (dec.), $[\alpha]_D^{24}$ +9.6 (*c* 0.5, $H_2O$) (lit. (36) $[\alpha]_D^{20}$ +4.0° (*c* 1, $H_2O$)). *Anal.* calcd. for $C_{20}H_{35}NO_{16}\cdot H_2O$: C 42.62, H 6.61, N 2.48; found: C 42.18, H 6.04, N 2.16.

*3-O-[4,6-Di-O-acetyl-3-O-(tetra-O-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-β-D-glucopyranosyl]-1,2;5,6-di-O-isopropylidene-α-D-galactofuranose (**20**)*

The crude product from the reaction of **2** with **14** was chromatographed on a silica-gel column using ethyl acetate – hexane (1:1). A fraction (24% yield) crystallized, mp 104–107°C, and was recrystallized from ethanol, mp 106–109°C, $[\alpha]_D^{25}$ −15.5° (*c* 0.5, $CHCl_3$). The $^1H$ nmr spectrum confirmed the presence of the phthalimido group, the two isopropylidene groups, and the six acetyl groups. *Anal.* calcd. for $C_{44}H_{55}NO_{23}\cdot H_2O$: C 53.71, H 5.84, N 1.42; found: C 53.63, H 5.51, N 1.79.

*3-O-[2-Acetamido-2-deoxy-3-O-(β-D-galactopyranosyl)-β-D-glucopyranosyl]-1,2;5,6-di-O-isopropylidene-α-D-galactofuranose (**21**)*

The product from the hydrazinolysis and then *N*-acetylation of **20** was crystallized from methanol – ethyl acetate (50% yield), mp 182–184°C (dec.), $[\alpha]_D^{24}$ −13.4° (*c* 0.4, $H_2O$). The $^1H$ and $^{13}C$ nmr spectra were consistent with the structural assignment.

*3-O-[2-Acetamido-2-deoxy-3-O-(β-D-galactopyranosyl)-β-D-glucopyranosyl]-D-galactopyranose [βDGal(1→3)βD-GlcNAc(1→3)DGal or lacto-N-triose I] (**5**)*

The product from the trifluoroacetic acid hydrolysis of **21** crystallized from methanol (60% yield), mp 139–141°C (dec.), $[\alpha]_D^{23}$ +13.6° (*c* 0.5, $H_2O$). These physical constants are substantially lower than those reported by Kuhn *et al.* (37), mp 183–185°C, $[\alpha]_D^{23}$ +19.3° (*c* 2, $H_2O$), and essentially confirmed by Augé and Veyrières (38). Because of the paucity of material (46 mg), this matter was not investigated further except that sugar analysis required the presence of two galactose units per unit of *N*-acetylglucosamine (performed by Professor E. A. Kabat).

*2,2,2-Trichloroethyl 3-O-[3,6-di-O-acetyl-4-O-(tetra-O-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-β-D-glucopyranosyl]-2-O-benzoyl-4,6-O-benzylidene-β-D-galactopyranoside (**22**)*

The product from the reaction of **13** with **15** crystallized in 80% yield (mp 228–231°C) and was recrystallized from ethanol, mp 252–254°C, $[\alpha]_D^{24}$ +8.6° (*c* 0.8, $CHCl_3$). The $^1H$ nmr spectrum confirmed the presence of the three aromatic rings and the six acetyl groups. *Anal.* calcd. for $C_{54}H_{56}NO_{24}Cl_3$: C 53.62, H 4.66, N 1.15, Cl 8.79; found: C 53.26, H 4.58, N 1.04, Cl 8.71.

*2,2,2-Trichloroethyl 2-O-acetyl-3-O-[2-acetamido-3,6-di-O-acetyl-4-O-(tetra-O-acetyl-β-D-galactopyranosyl)-2-deoxy-β-D-glucopyranosyl]-4,6-O-benzylidene-β-D-galactopyranoside (**23**)*

The product of hydrazinolysis of **22** (1.82 g, 1.5 mmol) was acetylated with pyridine – acetic anhydride (2:1). A solution of the peracetate in ethyl acetate was passed through a short column of neutral alumina. Solvent removal left a crystalline solid (mp 144–149°C, 1.35 g, 85% yield) which was recrystallized from ethyl acetate – hexane, mp 150–152°C, $[\alpha]_D^{23}$ −1.9° (*c* 0.8, $CHCl_3$). The $^1H$ nmr spectrum displayed the presence of the benzylidene group and eight acetyl groups. *Anal.* calcd. for $C_{43}H_{54}NO_{23}Cl_3$: C 48.75, H 5.13, N 1.32; found: C 48.60, H 5.19, N 1.23.

*2,2,2-Trichloroethyl 2,4,6-tri-O-acetyl-3-O-[2-acetamido-3,6-di-O-acetyl-4-O-(tetra-O-acetyl-β-D-galactopyranosyl)-2-deoxy-β-D-glucopyranosyl]-β-D-galactopyranoside (**24**)*

Compound **23** (1.00 g, 0.94 mmol) was kept at 100°C in 60% aqueous acetic acid for 40 min. The product was acetylated in pyridine – acetic anhydride (2:1) in the usual manner to provide a solid which crystallized from ethyl acetate – hexane (0.50 g, 50% yield), mp 138–141°C, $[\alpha]_D^{23}$ +2.2° (*c* 1, $CHCl_3$). *Anal.* calcd. for $C_{40}H_{54}NO_{25}Cl_3$: C 45.52, H 5.15, N 1.32, Cl 10.07; found: C 45.19, H 5.09, N 1.24, Cl 10.0.

*2,2,2-Trichloroethyl 3-O-[2-acetamido-2-deoxy-4-O-(β-D-galactopyranosyl)-β-D-glucopyranosyl]-β-D-galactopyranoside (**25**)*

Compound **24** (190 mg, 0.18 mmol) was dissolved in a triethylamine–water–methanol (1:1:8) mixture (12 mL) and the solution left at room temperature for 16 h. The solution was concentrated to dryness and the residue was passed through a short column of Dowex (2-X8, $OH^-$ form) using water. The aqueous fractions were combined and freeze-dried to give a powder (90 mg, 75% yield), $[\alpha]_D^{23}$ −4.88° (*c* 0.84, $H_2O$). The $^1H$ and $^{13}C$ nmr spectra were consistent with the structural assignment. *Anal.* calcd. for $C_{21}H_{36}NO_{16}Cl_3\cdot H_2O$: C 36.93, H 5.60, N 2.05; found: C 36.48, H 5.07, N 1.85.

*3-O-[2-Acetamido-2-deoxy-4-O-(β-D-galactopyranosyl)-β-D-glucopyranosyl]-D-galactopyranose [βDGal(1→4)βD-GlcNAc(1→3)DGal] (**6**)*

Compound **25** (85 mg) in glacial acetic acid (2 mL) was treated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

with a zinc–copper couple (33, 39) (20 mg) at room temperature for 4 h. The product was purified on a silica gel column using chloroform–methanol–water (65:35:8) (40 mg, 57% yield), $[\alpha]_D^{23}$ +17.5° (*c* 0.5, $H_2O$) (lit. (36) $[\alpha]_D^{20}$ +19.5 (*c* 0.62, $H_2O$)). *Anal.* calcd. for $C_{20}H_{35}NO_{16}\cdot H_2O$: C 42.62, H 6.61, N 2.48; found: C 42.27, H 6.29, N 2.20.

*8-Methoxycarbonyloctyl 6-O-[4,6-di-O-acetyl-3-O-(tetra-O-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-β-D-glucopyranosyl]-2-O-benzoyl-3,4-O-isopropylidene-β-D-galactopyranoside (**26**)*

The product obtained on the condensation of compounds **8** and **14** was obtained in 71% yield (mp 87–91°C) after passage through a short column of neutral alumina. Since the $^1H$ nmr spectrum was in good accord with expectation, no attempt was made to achieve higher purity. *Anal.* calcd. for $C_{58}H_{73}NO_{26}$: C 58.04, H 6.13, N 1.16; found: C 58.24, H 6.04, N 1.33.

*8-Methoxycarbonyloctyl 2,3,4-tri-O-acetyl-6-O-[2-acetamido-4,6-di-O-acetyl-3-O-(tetra-O-acetyl-β-D-galactopyranosyl)-2-deoxy-β-D-glucopyranosyl]-β-D-galactopyranoside (**27**)*

Compound **26** (1.35 g, 1.1 mmol) was subjected to the multi-step process for the conversion of all the protecting groups to acetyl groups. The major fraction (amorphous, 372 mg, 30% yield) $[\alpha]_D^{23}$ −13.7° (*c* 0.7, $CHCl_3$), appeared chromatographically pure and possessed an $^1H$ nmr spectrum consistent with that expected for the title compound. *Anal.* calcd. for $C_{48}H_{71}NO_{27}$: C 52.69, H 6.54, N 1.28; found: C 53.53, H 6.80, N 1.12.

*8-Methoxycarbonyloctyl 6-O-[2-acetamido-2-deoxy-3-O-(β-D-galactopyranosyl)-β-D-glucopyranosyl]-β-D-galactopyranoside [βDGal(1→3)βDGlcNAc(1→6)βDGalO(CH$_2$)$_8$COOCH$_3$] (**9**)*

Compound **27** (325 mg, 0.29 mmol) was dissolved in 0.01 *N* sodium methoxide in methanol (15 mL) and the solution was kept overnight at room temperature. After deionization with Amberlite 120H$^+$, the solvent was removed and the residue was dissolved in water, the solution clarified and freeze dried to a colorless powder (196 mg, 97% yield), mp 185–188°C, $[\alpha]_D^{23}$ −20.9° (*c* 1, $H_2O$). The $^1H$ and $^{13}C$ nmr (see Table 1) required a high purity and were consistent with the structural assignment. *Anal.* calcd. for $C_{30}H_{53}NO_{18}\cdot H_2O$: C 49.17, H 7.39, N 1.90; found: C 49.20, H 7.30, N 1.87.

*8-Methoxycarbonyloctyl 6-O-[3,6-di-O-acetyl-4-O-(tetra-O-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-β-D-glucopyranosyl]-2-O-benzoyl-3,4-O-isopropylidene-β-D-galactopyranoside (**28**)*

The product obtained on the condensation of compounds **8** and **15** was obtained in 64% yield as an amorphous powder, $[\alpha]_D^{23}$ +21.3° (*c* 1.2, $CHCl_3$). The $^1H$ nmr was consistent with the structural assignment. *Anal.* calcd. for $C_{58}H_{73}NO_{26}$: C 58.04, H 6.13, N 1.16; found: C 57.93, H 6.06, N 1.17.

*8-Methoxycarbonyloctyl 2,3,4-tri-O-acetyl-6-O-[2-acetamido-3,6-di-O-acetyl-4-O-(tetra-O-acetyl-β-D-galactopyranosyl)-2-deoxy-β-D-glucopyranosyl]-β-D-galactopyranoside (**29**)*

Compound **28** (1.02 g, 0.84 mmol) was subjected to the multi-step procedure for conversion of all the protecting groups to acetyl groups. The major fraction (318 mg, 44% yield), $[\alpha]_D^{23}$ −18.3° (*c* 0.5, $CHCl_3$), appeared chromatographically pure and possessed an $^1H$ nmr spectrum consistent with that expected for the title compound. *Anal.* calcd. for $C_{48}H_{71}NO_{27}$: C 52.69, H 6.54, N 1.28; found: C 52.42, H 6.47, N 1.20.

*8-Methoxycarbonyloctyl 6-O-[2-acetamido-2-deoxy-4-O-(β-D-galactopyranosyl)-β-D-glucopyranosyl]-β-D-galactopyranoside [βDGal(1→4)βDGlcNAc(1→6)βDGalO(CH$_2$)$_8$COOCH$_3$] (**10**)*

De-*O*-acetylation of **29** (194 mg, 0.17 mmol) as was described for the preparation of **9**, provided a powder (118 mg, 94% yield), mp 202–205°C, $[\alpha]_D^{23}$ −15.7° (*c* 0.8, $H_2O$). The $^1H$ and $^{13}C$ nmr spectra (see Table 1) required high purity and were consistent with structural assignment. *Anal.* calcd. for $C_{30}H_{53}NO_{18}\cdot H_2O$: C 49.17, H 7.39, N 1.90; found: C 48.81, H 7.28, N 1.88.

*8-Methoxycarbonyloctyl 3-O-[4,6-di-O-acetyl-3-O-(tetra-O-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-β-D-glucopyranosyl]-2-O-benzoyl-4,6-O-benzylidene-β-D-galactopyranoside (**30**)*

The product obtained on the condensation of compounds **7** and **14** had to be chromatographed on a silica gel column to afford the title compound as an amorphous solid in 34% yield, $[\alpha]_D^{23}$ +1.6° (*c* 0.7, $CHCl_3$). The $^1H$ nmr spectrum was consistent with the structural assignment. *Anal.* calcd. for $C_{62}H_{73}NO_{26}$: C 59.65, H 5.89, N 1.12; found: C 59.38, H 5.85, N 1.12.

*8-Methoxycarbonyloctyl 2,4,6-tri-O-acetyl-3-O-[2-acetamido-4,6-di-O-acetyl-3-O-(tetra-O-acetyl-β-D-galactopyranosyl)-2-deoxy-β-D-glucopyranosyl]-β-D-galactopyranoside (**31**)*

Compound **30** (700 mg, 0.56 mmol) was subjected to the multi-step process for the conversion of all the protecting groups to acetyl groups. The major fraction of the chromatogram provided an amorphous solid (135 mg, 22% yield), $[\alpha]_D^{23}$ +11.1° (*c* 0.9, $CHCl_3$). The $^1H$ nmr spectrum was consistent with the structural assignment and inferred chemical homogeneity. *Anal.* calcd. for $C_{48}H_{71}NO_{27}$: C 52.69, H 6.54, N 1.28; found: C 52.46, H 6.50, N 1.27.

*Methoxycarbonyloctyl 3-O-[2-acetamido-2-deoxy-3-O-(β-D-galactopyranosyl)-β-D-glucopyranosyl]-β-D-galactopyranoside [βDGal(1→3)βDGlcNAc(1→3)βDGalO(CH$_2$)$_8$COOCH$_3$] (**11**)*

De-*O*-acetylation of **31** (125 mg, 0.12 mmol) as was described for the preparation of **9** afforded an amorphous powder (61 mg, 72% yield), $[\alpha]_D^{23}$ −4.7° (*c* 0.9, $H_2O$). The $^1H$ and $^{13}C$ nmr spectra (see Table 1) required high purity and were consistent with the structural assignment.

*8-Methoxycarbonyloctyl 3-O-[3,6-di-O-acetyl-4-O-(tetra-O-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-β-D-glucopyranosyl]-2-O-benzoyl-4,6-O-benzylidene-β-D-galactopyranoside (**32**)*

The product obtained on the condensation of compounds **7** and **15** had to be chromatographed on a silica gel column to afford the title compound in 44% yield as a colorless solid, $[\alpha]_D^{23}$ +31.5° (*c* 0.7, $CHCl_3$). The $^1H$ nmr spectrum was consistent with the structural assignment. *Anal.* calcd. for $C_{62}H_{73}NO_{26}$: C 59.65, H 5.89, N 1.12; found: C 59.90, H 6.01, N 1.23.

*8-Methoxycarbonyloctyl 2,4,6-tri-O-acetyl-3-O-[2-acetamido-3,6-di-O-acetyl-4-O-(tetra-O-acetyl-β-D-galactopyranosyl)-2-deoxy-β-D-glucopyranosyl]-β-D-galactopyranoside (**33**)*

Compound **32** (960 mg, 0.77 mmol) was subjected to the multi-step process for the conversion of all the protecting groups to acetyl groups. The major fraction of the chromatogram provided an amorphous solid (256 mg, 30% yield), $[\alpha]_D^{23}$ +4.6° (*c* 0.75, $CHCl_3$). The $^1H$ nmr spectrum was consistent with the structural assignment and inferred chemical homogeneity.

*8-Methoxycarbonyloctyl 3-O-[2-acetamido-2-deoxy-4-O-(β-D-galactopyranosyl)-β-D-glucopyranosyl]-β-D-galactopyranoside [βDGal(1→4)βDGlcNAc(1→3)βDGalO-$(CH_2)_8COOCH_3$] (12)*

De-*O*-acetylation of **33** (220 mg, 0.21 mmol) as was described for the preparation of **9** afforded an amorphous powder (141 mg, 97% yield), $[\alpha]_D^{23}$ −3.8° (*c* 1, $H_2O$). The $^1H$ and $^{13}C$ nmr spectra (see Table 1) required high purity and were consistent with the structural assignment. *Anal.* calcd. for $C_{30}H_{53}NO_{18}\cdot H_2O$: C 49.19, H 7.39, N 1.90; found: C 48.80, H 7.23, N 1.91.

# Synthesis of βDGlcNAc(1→6) and βDGal(1→4)βDGlcNAc(1→6) derivatives of the $T_N$ (αDGalNAc) human blood group determinant

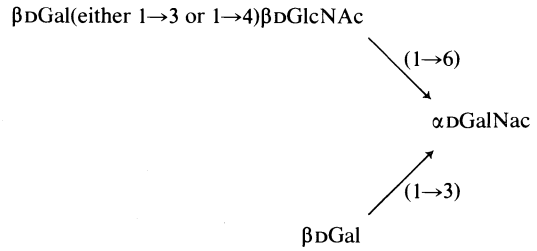
RAYMOND U. LEMIEUX AND MARIA HALINA BURZYNSKA[1]
*Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2*
Received March 27, 1981

RAYMOND U. LEMIEUX and MARIA HALINA BURZYNSKA. Can. J. Chem. **60**, 76 (1982).
In order to investigate the immunological properties of certain I blood group specific glycoproteins, the potential antigenic determinants βDGlcNAc(1→6)αDGalNAc and βDGal(1→4)βDGlcNAc(1→6)αDGalNAc attached as glycosides to 8-methoxycarbonyloctanol were synthesized by way of the phthalimido-chloride method.

RAYMOND U. LEMIEUX et MARIA HALINA BURZYNSKA. Can. J. Chem. **60**, 76 (1982).
Dans le but d'étudier les propriétés immonulogiques de certaines glycoprotéines spécifiques du groupe sanguin I, on a synthétisé, par la méthode du chlorure de phtalimide, les déterminants antigéniques potentiels: βDGlcNAc(1→6)αDGalNAc et βDGal(1→4)-βDGlcNAc(1→6)αDGalNAc attachés en tant que glycosides au méthoxycarbonyl-8-octanol.

[Traduit par le journal]

In 1968, Lloyd *et al.* (1) published a composite structure for the carbohydrate chains of A, B, H, Lewis a, and Lewis b human blood group specific glycoproteins. The structure was presented with the tetrasaccharide,



as the structural unit attached to the core protein. This unit was proposed since alkaline borohydride treatment of a Lewis a active human cyst glycoprotein had produced a substance (Lewis $R_L$ 0.41) with composition and chemical properties consistent with the presence of either one of these units. It was to be expected that the oligosaccharide chains in the glycoprotein would be linked through *N*-acetylgalactosamine to serine and threonine units in the polypeptide portion.

It is now well established that the βDGal(1→3)-αDGalNAc disaccharide is the first disaccharide unit in the carbohydrate chains that are attached as *O*-glycosides to the core protein of the blood group active glycoproteins (2). The αDGalNAc residue is characteristic of the $T_N$ determinant (3) and the βDGal(1→3)αDGalNAc structure is characteristic of the T determinant (4). The T determinant is also related to the M and N human blood group determinants (5). It was therefore of interest to examine in more detail the occurrence of the above-mentioned tetrasaccharide units in human blood group specific glycoproteins, by way of chemical synthesis toward structures which would be amenable to the preparation of immunochemical reagents of possible use in these regards (6).

The syntheses of the tetrasaccharide structures have not as yet been accomplished. Nevertheless, we wish to report the syntheses of the structures βDGlcNAc(1→6)αDGalNAc (**8**) and βDGal(1→4)-βDGlcNAc(1→6)αDGalNAc (**13**) attached to the potential linking arm derived from 8-methoxycarbonyloctanol since these substances proved useful to a study of the combining site of the anti-I Ma monoclonal antibody (7, 8). It was found that structure **13** binds this myeloma protein, on a molar basis, equally as well as do βDGal(1→4)βDGlcNAc(1→6)βDGalO$(CH_2)_8COOCH_3$ and βDGal-(1→4)βDGlcNAc(1→6)[βDGal(1→4)βDGlcNAc-(1→3)]βDGalO$(CH_2)_8COOCH_3$. Therefore it is possible that the antigenic determinant, which was involved in the myelomatosis and proliferation of the neoplastic monoclonal anti-I Ma producing cells, was a βDGal(1→4)βDGlcNAc(1→6)αDGal-NAc unit of the glycoprotein and not necessarily a βDGal(1→4)βDGlcNAc(1→6)βDGal unit (8). The synthesis of βDGal(1→3)αDGalNAcO$(CH_2)_8$-$COOCH_3$ (the T determinant) has been reported (9).

The synthesis of **8** from αDGalNAcO$(CH_2)_8$-$COOCH_3$ **1** (9) by way of the intermediates **2–7** warrants a few comments. Treatment of **2** with benzoyl chloride in pyridine was found to lead to *N*-benzoylation as well as the desired *O*-benzoylation (10). The so-called phthalimido-chloride method (11) was used to establish the β(1→6) linkage of **5**

**3**, R′ = Tr
**4**, R′ = H

**8**

**5**, R′ = Ac, R″ = Bz
**6**, R′ = H, R″ = Bz
**7**, R′ = R″ = H

since this method has proved generally reliable for this purpose (12). Indeed, the yield was 87%. It is of interest that treatment of **5** with sodium methoxide – methanol in the cold allowed the transesterification reaction to be limited to de-*O*-acetylation. The use of magnesium methoxide (13) for this purpose therefore appears advantageous, simply because, as a less active catalyst, it allows more convenient kinetic control. It is remarkable that the treatment of **5** with sodium methoxide under conditions which removed the benzoyl groups preferentially removed the *N*-benzoyl group. Especially in view of the $^{13}C$ nmr data, it seems evident that the compound was an *N*-acetylbenzamido product and not an *O*-benzoyl acetamidate.

In the course of this work, we observed that the phthalimido group remained intact in the course of the deacetylation of **5** and work-up to provide **7**. Meanwhile, Bundle and Josephson (14) reported a similar experience. As was pointed out by Bundle and Josephson (14), this occurrence is a considerable convenience in the context of the need to later remove the phthalimido group without affecting the methoxycarbonyl group of the linking arm. We have now found[2] that the opening of the phthalimido group by the sodium method is strongly influenced by the configurations of the neighboring centers. Our earlier investigations (11) demonstrated the strong nonbonded interaction that exists between an equatorially oriented phthalimido group and an axial neighboring substituent. Thus it was not surprising to find that the reaction of a 2-deoxy-2-phthalimido-α-D-galactopyranosyl unit to form the *o*-methoxycarbonylbenzamido derivative was extremely rapid and quantitative. The product could quite readily be isolated. On the other hand, the reaction of a 2-deoxy-2-phthalimido-β-D-glucopyranosyl unit was relatively much slower, did not proceed quantitatively, and the products could not be isolated. In accordance with these results, the complete removal of the phthalimido group by reaction with hydrazine depends both on the ease of formation of the *o*-hydrazinocarbonylbenzamido intermediate and on how readily this reaction is reversed as compared to the formation of the amine. The method developed by Bundle and Josephson (14) which employs hydrazine at high dilution, followed by *N*-acetylation, was effective for the conversion of **7** to **8** and of **12** to **13** in acceptable yields.

Our initial attempts to prepare the 3,4-*O*-isopropylidene derivative of **1**, namely **9**, met with difficulty and it was for this reason that the preparation of **4** was undertaken. The problem arose because of the ready formation of the 4,6-*O*-isopropylidene derivative. However, it was subsequently found that extended reaction at 5°C gave the desired compound in acceptable (64%) yield. The preparation of **13** by way of the intermediates **10**, **11**, and **12** followed normal procedures for the transformations shown. The conversion of **9** to **10** using hexa-*O*-acetyl-2-deoxy-2-phthalimido-α,β-D-lactosyl chloride (15) and a slight excess of the alcohol **9** proceeded in 75% yield.

## Experimental

The methods used for the isolation of products, solvent purification and removal, spectral analysis, and chromatography were in general the same as those previously reported from this laboratory (12).

[2]R. U. Lemieux and P. Hermentin, in preparation.

*8-Methoxycarbonyloctyl 2-(*N*-acetylbenzamido)-3,4-di-*O*-benzoyl-2-deoxy-α-*D*-galactopyranoside (4)*

This compound was prepared starting from 8-methoxycarbonyloctyl 2-acetamido-2-deoxy-α-D-galactopyranoside (**1**) which was prepared following the directions reported by Ratcliffe *et al.* (9). In this work, the compound was obtained after recrystallization from methanol as an anhydrous product, mp 134°C, $[\alpha]_D^{25}$ + 143.5° (*c* 1, in chloroform). Both the $^1H$ and $^{13}C$ nmr spectra were in accord with expectations.

A solution of compound **1** (670 mg, 1.71 mmol) and triphenylmethyl chloride (500 mg, 1.79 mmol) in pyridine (12 mL) was kept at 65°C for 24 h. Triphenylmethyl chloride (100 mg, 0.36 mmol) was added and the reaction was continued for a further 24 h. The reaction was monitored by tlc (benzene – ethyl acetate – methanol, 10:5:3). The solution expected to contain the trityl compound **2** was then cooled to room temperature for the addition of benzoyl chloride (1.00 g, 7.1 mmol). The resulting mixture was kept at near 23°C for 24 h prior to the addition of dichloromethane (200 mL). This solution was then processed in the usual manner to provide a yellow oil (1.98 g) which was not further purified. However, in a separate experiment, the main product was isolated by column chromatography and found on examination by $^1H$ nmr to contain three benzoyl groups along with one trityl group and one acetyl group. Therefore the product was assigned structure **3**.

The above-mentioned crude product was dissolved in 1% methanolic hydrogen chloride (30 mL) and the solution was kept at near 23°C for 1 h prior to neutralization with triethylamine. Solvent removal left a residue which was dissolved in dichloromethane (100 mL) for extraction with water. After drying and solvent removal, the residue was applied to a column of silica gel (40 g) for chromatographic separation using ethyl acetate – hexane (6:4). The main fraction contained a product which appeared homogeneous on examination by tlc but which resisted crystallization. The overall yield was 61% (740 mg) of a colorless foam; $[\alpha]_D^{25}$ + 133° (*c* 1.1, in chloroform). The $^{13}C$ nmr ($CDCl_3$) spectrum required a high state of purity and structure **4** was supported by the presence of signals for four carbonyl carbons at 165.2, 166.8, 171.6, and 173.6 ppm in addition to that for the methoxycarbonyl group at 174.3 ppm. The signal at 61.07 ppm was assigned to the $CH_2OH$ group. The $^1H$ nmr confirmed the structural assignment both in terms of the relative intensities of the signals which could be unequivocally assigned and the chemical shifts of the hydrogen atoms of the pyranose ring. The occurrence of the signal for H-2 at exceptionally low field (6.18 ppm, $CDCl_3$) is noteworthy. *Anal.* calcd. for $C_{39}H_{46}O_{11}N$: C 66.45, H 6.58, N 1.99; found: C 66.58, H 6.43, N 1.81.

*8-Methoxycarbonyloctyl 2-(*N*-acetylbenzamido)-3,4-di-*O*-benzoyl-2-deoxy-6-*O*-(3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-β-*D*-glucopyranosyl)-α-*D*-galactopyranoside (5)*

A solution of alcohol **4** (915 mg, 1.30 mmol), silver triflate (481 mg, 1.87 mmol), and *sym*-collidine (226 mg, 1.87 mmol) in nitromethane (6 mL) protected from light and moisture was cooled to −30°C. Tri-*O*-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranosyl chloride (**8**) (850 mg, 1.87 mmol) in nitromethane (3 mL) was added dropwise with stirring so as to maintain the temperature near −30°C. After 1 h, the stirring was continued for 2 h at −5°C. The reaction mixture was then diluted with chloroform (150 mL) and the solids were collected by filtration.

The filtrate was washed with ice-cold water (50 mL), cold 3% hydrochloric acid (50 mL), water (50 mL), and dried. Solvent removal left an oily residue (1.85 g) which was purified by chromatography on a silica gel column (60 g) which was developed with a mixture of hexane and ethyl acetate (6:4). On evaporation, the material crystallized and was recrystallized from the same solvents; mp 85–87°C, $[\alpha]_D^{25}$ + 84.7 (*c* 2.12, in chloroform) (1.27 g, 87% yield); $^1$H nmr ($CDCl_3$) δ: 8.1–7.2 (m, 19H, phthalimido and 3 benzoyl groups), 6.06 (dd, 3.5 Hz, 11.5 Hz, 1H, H-2), 5.86 (d, 3.5 Hz, 1H, H-1), 5.74 (dd, 10.5 Hz, 9.5 Hz, 1H, H-3′), 5.56 (dd, 11.5 Hz, 3.5 Hz, 1H, H-3), 5.38 (d, 8.5 Hz, 1H, H-1), 5.14 (t, 9.5 Hz, 1H, H-4′), 4.74 (d, 3.4 Hz, 1H, H-4), 4.35–4.20 (m, 3H, H-2′, H-5, H-6″), 4.08 (dd, 3.2 Hz, 11.0 Hz, 1H, H-6), 3.83 (m, 1H, H-5′), 3.70 (s, 3H, $CH_3O$), 3.61 (dd, 11.0 Hz, 9.0 Hz, 1H, H-6′), 3.30–3.13 (m, 1H, —O—$CH_2$—$(CH_2)_7CO_2CH_3$), 2.58–2.45 (m, 1H, —O$CH_2$—$(CH_2)_7CO_2CH_3$), 2.33 (t, 7 Hz, 2H, $CH_2$—$CO_2CH_3$), 2.08 (s, 3H, $CH_3CONH$), 2.03 (s, 3H, $CH_3CO$), 1.86 (s, 3H, $CH_3CO$), 1.76 (s, 3H, $CH_3CO$), 1.7–1.5 (m, 2H, —$CH_2$—$CH_2CO_2CH_3$), 1.35–0.75 (m, 10H, $CH_2$—$(CH_2)_5CH_2CH_2CO_2CH_3$); $^{13}$C nmr ($CDCl_3$) δ: 174.3 (1C, $CO_2CH_3$), 173.6, 171.6, 170.7 (3C=O), 170.1 (C=O double intensity, 2 C=O phthalimido), 169.4, 167.5, 165.0 (4 C=O), 136.0–123.6 (14C, aromatic carbons), 98.9 (C-1′), 98.3 (C-1). *Anal.* calcd. for $C_{59}H_{64}O_{20}N_2$: C 63.20, H 5.75, N 2.50; found: C 63.08, H 5.79, N 2.39.

*8-Methoxycarbonyloctyl 2-acetamido-2-deoxy-6-O-(2-acetamido-2-deoxy-β-D-glucopyranosyl)-α-D-galactopyranoside (**8**)*

The blocked disaccharide **5** was converted to the desired hapten **8** by way of the intermediate de-*O*-acylated phthalimido compound **7**. It was noted by tlc that treatment of **5** (299 mg, 0.267 mmol) with 0.1 *M* sodium methoxide in methanol (10 mL) at 0°C led after 10 min to essentially one product. Neutralization with Amberlite IR120 ($H^+$) resin and solvent removal provided a product (199 mg) which appeared ($^1$H nmr) to be almost pure **6**. However, when the transesterification was performed at near 23°C for 1.5 h, this product was transformed to compound **7**. The presence of the *N*-acetyl (1.92 ppm) and the methoxycarbonyl (3.68 ppm) groups was clearly evident. The signal for the four hydrogen atoms of the phthalimido group occurred as a broad singlet at 7.83 ppm. The compound was not further purified but used directly for the formation of compound **8** by way of hydrazinolysis followed by *N*-acetylation under conditions similar to those independently developed by Bundle and Josephson (14).

Compound **7** (117.4 mg, 0.172 mmol) was dissolved in methanol (4 mL) containing 97% hydrazine (14.5 mg, 0.44 mmol) and refluxed, monitored by tlc (ethyl acetate – ethanol–water, 8:4:2). After 3 h, an additional amount of hydrazine (7 mg) in methanol (1 mL) was added and the reaction mixture was refluxed for 3 h. Then the solution was cooled to room temperature and acetic anhydride (500 mg) was added. The resulting mixture was left for 30 min and then evaporated to dryness. Ethanol (10%, 4 mL) was added, the solids were gathered by filtration and washed with a small amount of the solvent. The combined filtrates were evaporated and the residue was applied to a Bio-Gel P-2 column and eluted with 10% ethanol. The first fraction to appear in the eluate on evaporation provided an amorphous white powder (70 mg, 79% yield), $[\alpha]_D^{25}$ + 69° (*c* 1.1, water). The nmr spectra required the assigned structure and a high state of purity. Selected parameters are given: $^1$H nmr ($D_2O$) δ: 4.88 (d, 3.8 Hz, H-1), 4.52 (d, 8.5 Hz, 1H, H-1′), 3.68 (s, 3H, $OCH_3$), 2.37 (t, 7.5 Hz, 2H, $CH_2$—$COOCH_3$), 2.03 (s, 3H, $NHCOCH_3$), 2.01 (s, 3H, $NHCOCH_3$); $^{13}$C nmr ($D_2O$) δ: 177.5, 174.3, 174.0 (3 C=O), 101.4 (C-1′), 96.7 (C-1), 75.9 (C-5′), 74.0 (C-3′), 70.1 (C-4′), 69.3 (2C, C-6, C-5), 68.5 (1C, —O—$CH_2$—$(CH_2)_7$—), 67.8, 67.6 (C-4, C-3), 60.9 (C-6′), 55.5 (C-2′), 51.9 ($OCH_3$), 50.0 (C-2). *Anal.* calcd. for $C_{26}H_{46}O_{13}N_2 \cdot H_2O$: C 50.97, H 7.89, N 4.59; found: C 50.88, H 7.42, N 4.54.

*8-Methoxycarbonyloctyl 2-acetamido-2-deoxy-3,4-O-isopropylidene-α-D-galactopyranoside (**9**)*

A solution of compound **1** (9) (1.61 g, 4.12 mmol) in *N,N*-dimethylformamide (50 mL) containing *p*-toluenesulphonic acid (0.1 g, 0.75 mmol) and 2,2′-dimethoxypropane (7 g, 67.30 mmol) was kept at 5°C for 28 h. The reaction mixture was neutralized with triethylamine, evaporated under vacuum, and the residue (2.21 g) was chromatographed on a silica gel column (100 g) eluting with ethyl acetate – hexane (7:3) to provide compound **9** (1.14 g, 64% yield after one recrystallization from the same solvents); mp 64°C, $[\alpha]_D^{25}$ + 109.5° (*c* 2.37, in chloroform); $^1$H nmr ($CDCl_3$) δ: 5.87 (d, 8.5 Hz, 1H, NH), 4.77 (d, 3.5 Hz, 1H, H-1), 4.4–3.2 (m, 8H), 3.65 (s, 3H, $OCH_3$), 2.9–2.7 (m, 1H, O*H*), 2.30 (t, 7 Hz, 2H, $CH_2CO_2CH_3$), 2.02 (s, 3H, NAC), 1.55 (s, 3H, $CH_3$), 1.8–1.2 (m, 15H, $(CH_2)_6CH_2CO_2CH_3$ and $CH_3$); $^{13}$C nmr ($CDCl_3$) δ: 174.36 ($CO_2CH_3$), 170.29 ($NHCOCH_3$), 109.85 (isopropylidene $(CH_3)_2C$), 97.73 (C-1), 74.67, 73.47, 68.22, 67.86 (3 ring carbons and $OCH_2(CH_2)_7CO_2CH_3$), 62.61 (C-6), 51.44 (C-2), 50.81 ($OCH_3$), 34.02, 29.99, 29.33, 29.14, 28.29, 28.05, 26.83, 26.65, 26.03, 24.88, 23.36 ($(CH_2)_7CO_2CH_3$ and 3 $CH_3$). *Anal.* calcd. for $C_{21}H_{37}O_8N$: C 58.45, H 8.64, N 3.25; found: C 58.33, H 8.65, N 3.10.

*8-Methoxycarbonyloctyl 2-acetamido-2-deoxy-6-O-[3,6-di-O-acetyl-4-(2,3,4,6-tetra-O-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-β-D-glucopyranosyl]-3,4-O-isopropylidene-α-D-galactopyranoside (**10**)*

A solution of alcohol **9** (575.8 mg, 1.10 mmol), silver triflate (283.3 mg, 1.10 mmol), and *sym*-collidine (133 mg, 1.10 mmol) in nitromethane (protected from light and moisture) (3 mL) was cooled to −30°C. Hexa-*O*-acetyl-2-deoxy-2-phthalimido-D-lactosyl chloride (15) (745.6 mg, 1.00 mmol) in nitromethane (4 mL) was added dropwise. The resulting solution was stirred at −20°C for 2 h and then at room temperature for 4 h. The solution was diluted with chloroform (100 mL) and the solids were filtered and washed with chloroform. The combined filtrates were washed with cold water (30 mL), a cold aqueous hydrochloric acid solution (10%, 30 mL), cold water (30 mL), an aqueous cold sodium bicarbonate solution (30 mL), and water (30 mL), dried, and evaporated under vacuum. The residue was dissolved in a mixture of ethyl acetate – hexane (1:1) and passed through a short alumina column yielding compound **10** (856 mg, 75% yield from **9**); mp 102–105°C, $[\alpha]_D^{25}$ = +57.3° (*c* 1.77, in chloroform); $^1$H nmr ($CDCl_3$) δ: 7.95–7.6 (m, 4H, phthaloyl), 5.76 (dd, 8 Hz, 10 Hz, H-3′), 3.66 (s, 3H, $OCH_3$), 2.33 (t, 7 Hz, 2H, $CH_2CO_2CH_3$), 2.14, 2.12, 2.06, 2.04, 1.94, 1.93, 1.90 (6 *O*-acetyls, 1 *N*-acetyl), 1.47, 1.14 (each s, 3H, —$CH_3$); $^{13}$C nmr ($CDCl_3$) δ: 174.25 ($CO_2CH_3$), 170.41 ($NHCOCH_3$), 170.17, 170.06, 169.87, 169.69, 169.09 ($CH_3CO$), 134.26, 131.76, 128.41, 123.49 (aromatic), 109.80 (isopropylidene $(CH_3)_2C$), 101.4 (C-1″), 98.96 (C-1′), 97.27 (C-1), 79.31, 77.17, 76.99, 75.05, 74.74, 72.85, 71.10, 70.73, 70.37, 69.28, 67.45, 66.70, 66.59, 62.28, 60.81, 55.13 (C-2′), 51.32 ($CH_3O$), 50.51 (C-2), 34.03, 29.14, 27.89, 26.48, 25.99, 24.89, 23.32, 20.87, 20.58 ($(CH_3)_2C$). *Anal.* calcd. for $C_{53}H_{72}O_{25}N_2$: C 55.98, H 6.38, N 2.46; found: C 55.47, H 6.38, N 2.33.

*8-Methoxycarbonyloctyl 2-acetamido-6-O-[2-acetamido-4-O-(β-D-galactopyranosyl)-2-deoxy-β-D-glucopyranosyl]-α-D-galactopyranoside (**13**)*

Compound **10** (177 mg, 0.1556 mmol) was dissolved in a 10% solution of 99% trifluoroacetic acid in dichloromethane (7 mL) and left at room temperature for 1 h. The solution was diluted with dichloromethane (50 mL), washed with ice-cold water

(25 mL), cold aqueous sodium bicarbonate solution (25 mL), and cold water (25 mL), dried, and evaporated to provide a crude compound **11** (136 mg, 70% yield) which was characterized by $^1$H nmr. Without purification, the product was treated with 0.1 *N* sodium methoxide in methanol (5 mL) for 5 min. The solution was then neutralized with Amberlite IR-120 ($H^+$) resin and evaporated to provide compound **12** (103 mg, 94% yield). The material appeared essentially pure; $^1$H nmr ($CDCl_3$) δ: 7.82 (s, 4H, phthalimido), 5.68 (dd, 8 Hz, 10 Hz, H-3′), 3.64 (s, 3H, $OCH_3$), 2.32 (t, 7 Hz, 2H, $CH_2$—$CO_2CH_3$), 1.90 (s, 3H, *N*-acetyl), 1.8–1.2 (m, 12H, $(CH_2)_6CH_2CO_2CH_3$).

Crude compound **12** (94.2 mg) was dissolved in methanol (5 mL) containing 97% hydrazine (14.5 mg) and the solution was brought to reflux. The course of the reaction could be monitored by tlc (ethyl acetate – ethanol–water, 8:4:2). After 2 H, an additional amount of hydrazine was added (10.8 mg in 1.5 mL of methanol) and the reaction mixture was refluxed for a further 2 h. The solution was cooled to room temperature, acetic anhydride (500 mg) was added, and the mixture was left at room temperature for 20 min. Solvent removal left a solid residue which was extracted with 10% ethanol in water. The combined filtrates were evaporated for application to a Biogel P-2 column and elution with 10% ethanol in water. The major fraction was freeze-dried to a powder (75 mg, 89% yield), $[\alpha]_D^{25}$ + 129° (*c* 2.7, in water); $^1$H nmr ($D_2O$, HOD, 400 mHz) δ: 4.96 (d, 3.8 Hz, H-1), 4.75 (d, 8.3 Hz, H-1′), 4.72 (d, 8.3 Hz, H-1″), 4.37 (dd, 10.8 Hz, H-2), 2.63 (t, 7 Hz, 2H, $CH_2CO_2CH_3$), 2.29, 2.26 (2s, 6H, *N*-acetyls); $^{13}$C nmr ($D_2O$, dioxane) δ: 177.2, 174.1, 173.8 ($COOCH_3$, 2 *N*—$COCH_3$), 102.9 (C-1″), 101.3 (C-1′), 96.7 (C-1), 78.83, 75.29 (C-5″), 74.74, 72.58, 72.47 (C-3″), 70.94 (C-2″), 69.26, 68.52 (C-4″), 67.70, 67.56, 66.5, 60.9 (C-6″), 60.2, 54.97 (C-2′), 51.94, 49.99 (C-2, $OCH_3$), 33.63, 28.32, 28.25, 28.19, 25.24, 24.27, 22.22, 21.95.

# The synthesis and conformational properties of the diastereoisomeric βDGal(1→4)βDGlcNAc(1→6)6-*C*-$CH_3$-D-Gal trisaccharides

RAYMOND U. LEMIEUX, TING C. WONG,[1] AND HENNING THØGERSEN[2]
*Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2*

Received March 27, 1981

RAYMOND U. LEMIEUX, TING C. WONG, and HENNING THØGERSEN. Can. J. Chem. **60**, 81 (1982).

The trisaccharide βDGal(1→4)βDGlcNAc(1→6)DGal was known to be bound strongly by the so-called anti-I Ma monoclonal antibody. In order to help assess the conformation about the 1→6 glycosidic linkage that is accepted by the antibody combining site, the conformationally well-defined βDGal(1→4)βDGlcNAc(1→6) derivatives of 7-deoxy-L-*glycero*-D-*galacto*-heptopyranose and 7-deoxy-D-*glycero*-D-*galacto*-heptopyranose were synthesized. The conformational preferences for these trisaccharides were established by $^1$H nmr spectroscopy and rationalized by computer-assisted molecular modelling.

RAYMOND U. LEMIEUX, TING C. WONG et HENNING THØGERSEN. Can. J. Chem. **60**, 81 (1982).

On sait que le trisaccharide βDGal(1→4)βDGlcNAc(1→6)DGal est lié fortement à l'anticorps monoclonal anti-I Ma. Dans le but d'aider à déterminer la conformation autour de la liaison glycosidique (1→6) qui est accepté par le site combinant de l'anticorps, on a synthétisé les dérivés conformationnellement bien définis βDGal(1→4)βDGlcNAc(1→6) du déoxy-7-L-*glycéro* D-*galacto*-heptopyrannose et du déoxy-7 D-*glycéro*-D-*galacto*-heptopyrannose. On a établi les préférences conformationnelles de ces trisaccharides par la spectroscopie de rmn du $^1$H et on les a rationalisées par des modèles moléculaires fournis par ordinateur.

## Introduction

The myeloma protein which was classified (1) as the monoclonal antibody I Ma (group 1) was found to possess a combining site which binds at the surface of a βDGal(1→4)βDGlcNAc(1→6) structural unit which was common to a number of the oligosacchardies studied.

We have predicted (2) that the conformational preference for the glycosidic linkage at the 4-position of the βDGlcNAc residue should be near $\phi^{C4'/H1''} = 50°$, $\psi^{H4'/C1''} = 10°$. Both for reasons of nonbonded interactions and the *exo*-anomeric effects, it was to be expected that the glycosyl bond of the βDGlcNAc unit to the 6-position of a sugar, which may be either βDGal or αDGalNAc, would possess the $\phi^{C6/H1'}$ torsion angle close to +60°. However, rotation about either the O6—C6 bond (to provide changes in the $\psi^{C5/C1'}$ torsion angle) or the C5—C6 bond (to provide changes in the $\omega^{H5/O6}$ torsion angle) was expected to lead to a number of conformers which differ little in energy (3). Indeed, hard-sphere calculations using the general procedure described by Venkatachalam and Ramachandran (2) while setting $\phi^{C6/H1'} = 60°$ substantiated this expectation.

The procedure was to examine the barriers to rotation about the O6—C6 bond (changes in $\psi^{C5/C1'}$) with the atoms on C5 and C6 in the 3 staggered orientations (namely, $\omega^{H5/O6} = +60°$, 180°, and −60°). In order to simplify the calculation, as in the past (2), the hydroxyl group hydrogen atoms were neglected and the hydroxymethyl groups of the hexose units, when present, were treated as 6-deoxy units. The parameters for the βDGlcNAc unit were derived from the X-ray structures of 4-*N*-(2-acetamido-2-deoxy-β-D-glucopyranosyl)-L-asparagine (4) and lactose (5). The coordinates for the hydrogen atoms attached to carbon were established by fixing the C—H bond length at 1.1 Å and making equal the three bond angles involving this hydrogen atom. The neutron diffraction data (6) for methyl β-D-galactopyranoside were used for the two βDGal units of βDGal(1→4)βDGlcNAc(1→6)βDGal. Since no interaction can be reasonably expected to exist between the two terminal βDGal units, the conformation of the trisaccharide was estimated by examining the structure as two disaccharide units. The calculations showed that the $\psi^{C5/C1'}$ torsion angle could vary within the following ranges without encountering energy barriers greater than ± 0.5 kcal/mol.

Conformers of near equal energy for βDGlcNAc(1→6)βDGal

| $\phi^{C6/H1'}$ | $\omega^{H5/O6}$ | $\psi^{C5/C1'}$ |
|---|---|---|
| 60° | 60° | 120°–290° |
| 60° | 180° | 110°–240° |
| 60° | −60° | 100°–260° |

In view of the very large number of energetically near-equivalent conformers for the βDGlcNAc-(1→6)βDGal disaccharide, no conclusion could be drawn as to which conformer was most likely to be accepted by the I Ma combining site. It was

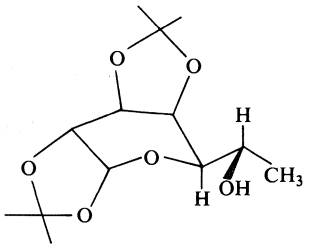
**6** R′ = $CH_3$, R = H
**9** R′ = H, R = $CH_3$

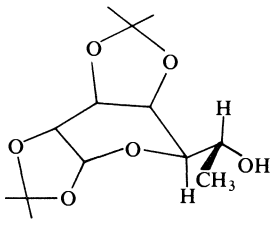
expected, however, that the range of low energy conformers could be narrowed by the substitution of a methyl group for a hydrogen at the C6 atom of the reducing βDGal unit. This would lead to two diastereoisomers depending on which hydrogen atom was substituted; namely, structures **6** and **9**. Since **6** is derived from 7-deoxy-L-*glycero*-D-*galacto*-heptose, it will be referred to as the L-trissaccharide. D-Trisaccharide will be used to refer to the derivative of 7-deoxy-D-*glycero*-D-*galacto*-heptose; namely, **9**. This paper is concerned with the synthesis of the trisaccharides **6** and **9** and a study of their conformational properties. The results obtained in a study of their properties as inhibitors of anti-I Ma is reported in a separate communication (7).

## Discussion

In a study of the binding of antibodies specific for the β-D-galactopyranosyl group, Lemieux *et al.* (8) observed that the addition of methylmagnesium bromide to 1,2;3,4-di-*O*-isopropylidene-α-D-*galacto*-1,6-dialdohexopyranose (9) (**1**) provided the L and D isomers **2** and **3**, respectively, in a ratio of



**2**



**3**

about 3:1. However, these products were not characterized. Instead, the compounds were converted to their methyl β-glycosides to serve as inhibitors in the immunochemical studies. The configuration of the new asymmetric carbon in the minor component was established to be D by relating its physical properties to the enantiomeric structure which had been previously described by Jackson and Hudson (10). It should be noted at this point that there exists an error in the reporting of these compounds by Lemieux *et al.* (8). The correct names are given in the title of the preparation. The first fraction from the chromatogram should have been reported as the D-isomer and the second fraction as the L-isomer. In the present work, the L-compound **2** was readily isolated by direct crystallization. Compound **3** (the minor D-isomer) was obtained after purification by way of its crystalline benzoate. The spacings for the signals for the hydrogens of the pyranose ring in compounds **2** and **3** were virtually the same as those published by Cone and Hough (11) for 1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose. The chemical shifts of H1, H2, and H3 were essentially the same. The shift of H4 was 4.26 ppm for both the galactose compound and the L-isomer (**2**), but the signal for H4 of the D-isomer, probably because of electrostatic deshielding by O6, was 0.2 ppm to lower field. In view of the magnitudes of the coupling constants for H5 and H6 (6.8 Hz for **2** and 7.2 Hz for **3** with $CDCl_3$ as solvent), the compounds must exist extensively in the conformer which maintains these two hydrogens in near *anti*-periplanar orientation. It is noted, however, that the pyranose ring in these compounds is strongly distorted away from the $^4C_1$ conformation (11) as is implied in the conformational formulas.

It was planned to confirm the configurations of the products (**2** and **3**), formed in the reaction of the aldehyde (**1**) with methylmagnesium iodide, by nuclear Overhauser enhancement studies (2, 12) since the C6-methyl group could be expected to reside closer to H4 in the L-isomer than in the D-isomer. However, although saturation of the signals assigned to these methyl groups did, in fact, cause a greater enhancement of H4 in the case of the L-isomer, the significance of this result proved to be obscured by the fact that the experiment could not avoid simultaneous saturation of the isopropylidene groups. This interference by the isopropylidene groups was not present in the case of the trisaccharides **6** and **9** and, as will be seen below, the $^1H$ nmr spectra for these compounds further confirmed these configurational assignments.

The chemical syntheses of compounds **6** and **9** were accomplished by condensation of hexa-*O*-acetyl-2-deoxy-2-phthalimidolactosyl chloride (13) with the alcohols **2** and **3** under the conditions

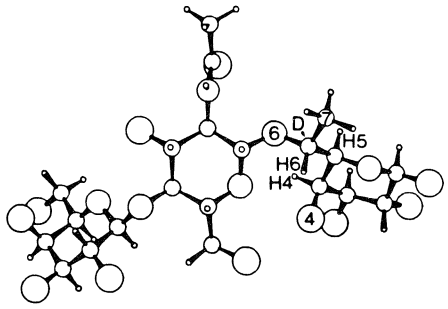
reported (14) for the preparation of 6-*O*-[hexa-*O*-acetyl-2-deoxy-2-phthalimido-β-lactopyranosyl]-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose. The products (**4** and **7**) were treated first with hydrazine to remove the acyl groups and the resulting amines were then *N*-acetylated to provide **5** and **8**. Removal of the isopropylidene groups by hydrolysis in aqueous trifluoroacetic acid afforded the desired trisaccharides **6** and **9**. The overall yields are poor and not to be taken as representative of the methods used, primarily since the preparations were made only once and no effort was made to optimize the reaction and isolation procedures.

The hard-sphere calculations (5° steps) for the D- and L-trisaccharides (**6** and **9**) employed the same atomic parameters mentioned above in connection with the molecular modelling for the βDGal(1→4)-βDGlcNAc(1→6)βDGal trisaccharide, except that the *C*-methyl group was substituted for the particular H6 atom with a C—C bond length of 1.536 Å. In the case of the D-trisaccharide (**9**), the calculation showed the most favorable conformer to be near that with $\phi^{C6/H1'} = 60°$, $\omega^{H5/O6} = 60°$, and $\psi^{C5/C1'} = 130°$. The minimum energy conformers with $\omega^{H5/O6} = 180°$ and 300° were indicated to be about 1 kcal and 3 kcal/mol, respectively, less favorable. The $\omega^{H5/O6} = 60°$ torsion angle requires that the torsion angle be defined by H5 and that H6 be near 180°. Thus, should this inference as to conformational preference be correct, there should exist a coupling constant between the vicinal *anti*-periplanar H5 and H6 atoms of near 10 Hz. Indeed, a coupling of 8.5 Hz was observed. Examination of a molecular model in this conformation shows the C6-methyl group to be close to H5 and H6 only. In fact, saturation of the methyl group led to nuclear Overhauser enhancement of only these two hydrogens. The signal for H4 at 4.17 and 4.24 ppm (α and β anomers) was not affected. When $\omega^{H5/O6}$ was set at 60° and the $\psi^{C5/C1'}$ torsion angles in the range 120–160° examined by HSEA calculations, the best value for the φ torsion angle was found to be +50° with ψ = 130°. In the context of these calculations, the difference of near 0.1 kcal/mol between this conformation and that with $\phi^{C6/H1'} = 60°$ and $\psi^{C5/C1'} = 130°$ is not significant. A projection formula for the D-trisaccharide (**9**) is presented in Fig. 1.

The hard-sphere calculations for the L-trisaccharide (**6**) indicated the staggered conformation with $\omega^{H5/O6} = 190°$ to be most favorable by nearly 1 kcal and that this conformer involved $\psi^{C5/C1'} = 230°$ (−130°) (for this calculation, $\phi^{C6/H1'}$ had been arbitrarily set at 60°). When this value for ω was



**9**

FIG. 1. Computer drawing of the D-trisaccharide (**9**) in the conformation anticipated by HSEA calculation in order to display the *anti*-periplanar orientation of H5 and H6 and the orientation of the C7-methyl group relative to H4.

used in a second iterative HSEA calculation[3] to estimate the most favorable values for φ and ψ, the values $\phi^{C6/H1'} = 50°$ and $\psi^{C5/C1'} = 230°$ were obtained and the total conformational energy was −0.6 kcal/mol for the compound in the conformation (**6***a*) represented in Fig. 2. On applying the HSEA calculation to the conformer with $\omega^{H5/O6} = 290°$ (−70°), the conformer (**6***b*) with $\phi^{C6/H1'} = 45°$ and $\psi^{C5/C1'} = 250°$ (−110°) was indicated as energetically most favorable with a total conformational energy of 0 kcal/mol.

Thus, it appeared that conformer **6***a* should have a substantially higher abundance than **6***b*. However, the $^1$H nmr properties of the L-isomer clearly demand that the conformational equilibrium favor conformer **6***b*. This followed from the observations that (*a*) the coupling constant for the vicinal H5 and H6 atoms was 8.0 Hz, in keeping with a high population of the conformer **6***b*, which has these atoms in *anti*-periplanar orientation, but not **6***a*, where these atoms are in *syn*-clinal orientations, and (*b*) saturation of the signal for the C-methyl group strongly enhanced the signal for H4 as well as those for H5 and H6 in keeping with conformation **6***b* but not **6***a*.

That the HSEA calculations predicted a greater conformational stability for **6***a* whereas **6***b* is undoubtedly more favorable is not necessarily surprising. The calculations may well have underestimated the *syn*-axial like nonbonded interaction between O4 and O6 in **6***a*. The HSEA calculations assume that the van der Waals radius for an oxygen atom is 1.5 Å. However, evidence has been presented that the effective radius for oxygen can vary

[3]The procedure for hard-sphere, *exo*-anomeric (HSEA) calculations (2) has been improved and ref. 15 should be consulted in this regard.

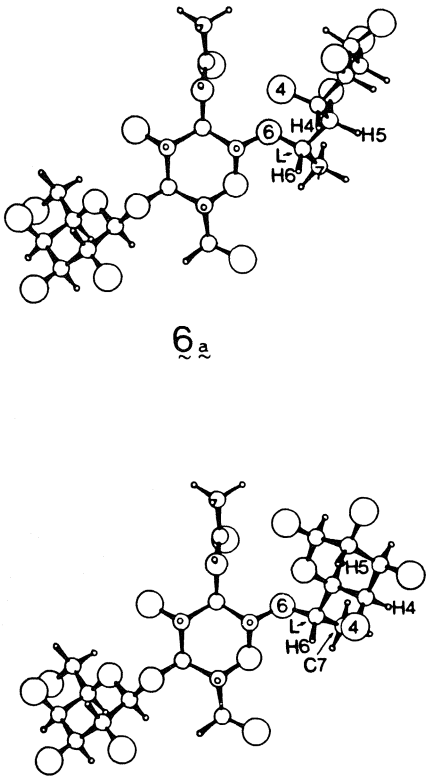

FIG. 2. Computer drawing of the L-trisaccharide (**6**) in the conformation (**6***a*) anticipated to be most favorable by HSEA calculations and in the conformation (**6***b*) best indicated by the $^1$H nmr spectrum. In the case of **6***a*, note the *syn*-axial like arrangement of O4 and O6, the *syn*-clinal orientation of H5 and H6, and that the C7-methyl group is distant from H4. In the case of **6***b*, note that H5 and H6 are in *anti*-periplanar orientation and that the C7-methyl group is in *syn*-axial like orientation with H4.

depending on its substituents (16). Moreover, the calculations do not include either electrostatic terms or a consideration of the effect on the apparent volume of hydroxyl groups when these are hydrogen bonded to the solvent water. We were fortunate in this regard in that **6** proved to be a very poor inhibitor (7) and, therefore, the possible availability of the compound to the antibody combining site in conformation **6***a* did not become an important question.

The study of the interactions of **6** and **9** with the anti-I Ma monoclonal antibody are reported in a separate communication (7) which also reports the results obtained with a number of related compounds. It proved that compound **9** reacts with the antibody even more strongly (about 0.5 kcal/mol) than does the βDGal(1→4)βDGlcNAc(1→6)DGal trisaccharide. This appears to be the first instance in which a complex synthetic structure that is closely related to a natural antigenic determinant binds the antibody more strongly. It is considered that this exceptional event likely occurs, at least in part, because compound **9** is held in the specific conformation that is required for the binding. This matter has a bearing on the notion at times expressed that ground state conformations are not necessarily implicated in antibody–antigen interactions. As expected, the preferred conformation for **9** is amongst the most favorable of the conformations available to the βDGal(1→4)βDGlcNAc-(1→6)DGal trisaccharide.

## Experimental

The purification of the solvents, chromatographic and analytical procedures were the same as previously reported (13).

*1,2;3,4-Di*-O-*isopropylidene*-α-D-galacto-*1,6-dialdo-hexopyranose (1)*

1,2:3,4-Di-*O*-isopropylidene-α-D-galactose was oxidized using the chromium trioxide – pyridine complex in dichloromethane as was described by Arrick *et al.* (9). Examination of the dark green syrupy crude product (95% yield) showed it to be of as good a quality as that obtained by distillation. The $^1$H nmr spectrum was in accord with that published by Horton *et al.* (17).

*1,2;3,4-Di*-O-*isopropylidene-7-deoxy*-β-L-glycero-D-galacto-*heptopyranose(2)*

Methylmagnesium iodide was prepared under standard conditions using magnesium (1.42 g, 58 mmol) and methyl iodide (8.3 g, 58 mmol) in ether (60 mL). A solution of the aldehyde (**1**) (8.0 g, 31 mmol) in diethyl ether (45 mL) was added dropwise with stirring and the mixture was kept at room temperature for 15 h. The reaction mixture was then cooled in ice-water and a 10% solution of ammonium chloride in water (50 mL) was added. Work-up in the usual manner using diethyl ether as extractant, drying over magnesium sulfate, and solvent removal, left a syrup which was decolorized by passing a solution in ethyl acetate through a short column of silica gel. Removal of the solvent left a syrup (7.3 g) which was dissolved in hexane (15 mL). On storage, the solution deposited 3.17 g of crystals which, after three recystallizations from hexane, provided 2.2 g (26%) of **2**, mp 90–91°C; $[\alpha]_D^{23}$ −58.5° (*c* 1.8, chloroform); $^1$H nmr ($CDCl_3$) δ: 5.58 (d, 1H, H-1, $J_{1,2}$ = 4.6 Hz), 4.59 (dd, 1H, H-3, $J_{2,3}$ = 2.1 Hz, $J_{3,4}$ = 8.0 Hz), 4.32 (dd, 1H, H-2), 4.26 (dd, 1H, H-4, $J_{4,5}$ = 2.0 Hz), 3.99 (m, 1H, H-6), 3.48 (dd, 1H, H-5, $J_{5,6}$ = 6.8 Hz), 1.50, 1.44, 1.32 (3s, 12H, O—C(=O)—$C(CH_3)_2$), 1.26 (d, 3H, (C-7)$H_3$, $J_{6,CH_3} \simeq$ 6 Hz). *Anal.* calcd. for $C_{13}H_{22}O_6$: C 56.92, H 8.08; found: C 56.87, H 8.05.

*1,2;3,4-Di*-O-*isopropylidene-7-deoxy*-α-D-glycero-D-galacto-*heptopyranose (3)*

The mother liquor from the first crystallization of the L-isomer (**2**) was taken to a syrup (3.86 g) which was dissolved in dichloromethane (10 mL), pyridine (4 mL), and benzoyl chloride (2 mL). The solution was stirred at room temperature for 3 h and the product was isolated in the usual manner. Solvent removal left a syrup which was taken up in hexane (3 mL) and the solution was kept at −4°C for 2 days. Crystals (0.290 g) were deposited which were debenzoylated in methanol – sodium methoxide without further purification. The product was ap-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

plied to a column of silica gel and eluted with ethyl acetate – hexane (6:4). The main fractions were combined and dissolved in a small amount of hexane and the solution deposited a white solid (0.188 g, 2%) when stored at −4°C overnight. This product, mp 57–58°C, $[\alpha]_D^{23}$ −34.8° (*c* 0.3, chloroform), was not further purified since the $^1$H nmr spectrum revealed it to be a nearly pure substance; $^1$H nmr ($CDCl_3$) δ: 5.55 (d, 1H, H-1, $J_{1,2}$ = 5 Hz), 4.62 (dd, 1H, H-3, $J_{2,3}$ = 2.2 Hz, $J_{3,4}$ = 8.0 Hz), 4.46 (dd, 1H, H-4, $J_{4,5}$ = 2.0 Hz), 4.30 (dd, 1H, H-2), 3.96 (m, 1H, H-6), 3.50 (dd, 1H, H-5, $J_{5,6}$ = 7.2 Hz), 1.51, 1.45, 1.36, 1.32, 1.29 (5 O‖ peaks, 15H, O—C(CH$_3$)$_2$ and (C-7)H$_3$ overlapping). *Anal.* calcd. for $C_{13}H_{22}O_6$: C 56.92, H 8.08; found: C 56.42, H 7.77.

*1,2;3,4-Di-*O*-isopropylidene-6-*O*-[3,6-di-*O*-acetyl-2-deoxy-4-*O*-(tetra-*O*-acetyl-*β*-*D*-galactopyranosyl)-2-phthalimido-*β*-*D*-glucopyranosyl]-7-deoxy-*β*-*L*-glycero-*D*-galacto-heptopyranose (4)*

3,6-Di-*O*-acetyl-4-*O*-(tetra-*O*-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-α,β-D-glucopyranosyl chloride (13) (1.3 g, 1.8 mmol) in nitromethane (5 mL) was added to a solution of the alcohol **2** (0.5 g, 1.8 mmol), *sym*-collidine (0.22 g, 1.8 mmol), and silver triflate (0.49 g, 1.9 mmol) in dry nitromethane (15 mL) cooled to −25°C (18). The mixture was stirred at −25°C for 2 h. The reaction mixture was then stirred at room temperature for 8 h. The solids that were deposited after the addition of chloroform (100 mL) were removed by filtration and the filtrate was washed with sodium thiosulfate solution, cold water, dilute aqueous HCl, and saturated sodium bicarbonate solution. Solvent removal, after drying over sodium sulfate, left a foam which was applied to a silica gel column and eluted with ethyl acetate – hexane (1:1). Solvent removal of the second fraction left a white solid (0.63 g, 36%), mp 119–123°C; $[\alpha]_D^{23}$ −21.6° (*c* 1.1, chloroform); $^1$H nmr ($CDCl_3$) δ: 7.80–7.52 (broad m, 4H, phthalimido), 5.70 (dd, 1H, H-3′, $J_{3',4'}$ = 8.0 Hz, $J_{2',3'}$ = 10.5 Hz), 5.39 (d, 1H, H-1′, $J_{1',2'}$ = 8.5 Hz), 5.23 (broad d, 1H, H-4″, $J_{3'',4''}$ = 3.1 Hz), 5.04 (dd, 1H, H-2″, $J_{1'',2''}$ = 7.5 Hz, $J_{2'',3''}$ = 10.5 Hz), 4.87 (dd, 1H, H-3″), 4.73 (d, 1H, H-1, $J_{1,2}$ = 5.0 Hz), 4.44 (d, 1H, H-1″), 3.18 (broad dd, 1H, H-5, $J_{5,6}$ = 8.2 Hz), 2.06, 2.05, 1.99, 1.97, 1.88, 1.80 (6s, 18H, acetyl CH$_3$), 1.32, 1.18, 1.12, O‖ 0.80, 0.75 (5 peaks, 15H, O—C—(CH$_3$)$_2$ and (C-7)H$_3$). *Anal.* calcd. for $C_{45}H_{57}O_{23}N$: C 55.16, H 5.86, N 1.43; found: C 55.02, H 5.83, N 1.31.

*1,2;3,4-Di-*O*-isopropylidene-6-*O*-[2-acetamido-2-deoxy-4-*O*-(β-*D*-galactopyranosyl)-β-*D*-glucopyranosyl]-7-deoxy-β-*L*-glycero-*D*-galacto-heptopyranose (5)*

A solution of compound **4** (0.56 g, 0.57 mmol) and 85% hydrazine hydrate (0.22 g, 4.39 mmol) in ethanol (5 mL) was refluxed for 3 h. Solvent removal left a syrup which was redissolved in water (5 mL). The solution was neutralized with glacial acetic acid and the precipitate formed was removed by filtration. Dialysis of the filtrate through a UMO5 Diaflo membrane (Amicon, Lexington, MA 02173) afforded, after freeze-drying of the dialyzed solution, a solid (0.25 g). This substance was taken up in methanol–water (1:1, 20 mL) containing acetic anhydride (4 mL) and left at room temperature for 2 h. Solvent removal and crystallization from methanol–ether gave a white solid (0.152 g, 42%), mp 165–169°C; $^1$H nmr ($D_2O$, HOD δ = 4.80) δ: 5.62 (d, 1H, H-1, $J_{1,2}$ = 5.0 Hz), 4.44 (2d, 2H, H′ and H″ overlapping, *J* = 7.5 Hz and 8.0 Hz, 2.07 (s, 3H, NHAc O‖ methyl), 1.52, 1.48, 1.38 (3s, 12H, O—C(CH$_3$)$_2$), 1.30 (d, 3H, (C-7)H$_3$), 4.02–3.48 (m, 17H, remaining protons).

*6-*O*-[2-Acetamido-2-deoxy-4-*O*-(β-*D*-galactopyranosyl)-β-*D*-glucopyranosyl]-7-deoxy-*L*-glycero-*D*-galacto-heptopyranose (6)*

A solution of compound **5** (50 mg, 0.078 mmol) in 95% trifluoroacetic acid (2 mL) was stirred for 3 min at room temperature and rapidly evaporated *in vacuo* to a syrup which was applied to a Sephadex LH-20 (Pharmacia Fine Chemicals AB, Uppsala, Sweden) column and eluted with ethanol–water (1:1). Solvent removal and freeze-drying of the main fraction gave a white solid (13.5 mg, 0.024 mmol, 31%); $^1$H nmr ($D_2O$) δ: 5.28 (d, H-1α, $J_{1,2}$ = 2.5 Hz, H-1β not observed, probably obscured by the HOD peak at 4.80), 4.54 (2d, 2H, H-1′ and H-1″ overlapping, *J* = 7.5 Hz and 7.5 Hz), 2.14, 2.13 (2s, NHAc-α and NHAc-β methyl), 1.33 (2d, 3H, (C-7)H$_3$ α and β), 4.08–3.44 (m, 17H, remaining protons).

*1,2;3,4-Di-*O*-isopropylidene-6-*O*-[3,6-di-*O*-acetyl-2-deoxy-4-*O*-(tetra-*O*-acetyl-β-*D*-galactopyranosyl)-2-phthalimido-β-*D*-glucopyranosyl]-7-deoxy-α-*D*-glycero-*D*-galacto-heptopyranose (7)*

3,6-Di-*O*-acetyl-4-*O*-(tetra-*O*-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-α,β-D-glucopyranosyl chloride (0.213 g, 0.29 mmol) in dry nitromethane (2 mL) was added to a solution of the alcohol (**3**) (60 mg, 0.22 mmol), *sym*-collidine (33 mg, 0.27 mmol), and silver triflate (60 mg, 0.24 mmol) in dry nitromethane (5 mL) cooled to −25°C. The mixture was stirred at −25°C for 2 h and then warmed to room temperature for 16 h. The reaction mixture was diluted with chloroform (20 mL) and the solids were removed by filtration. The filtrate was washed with cold water, aqueous sodium bicarbonate solution, and dilute aqueous HCl. Solvent removal after drying over sodium sulfate left a foam which was applied to a silica gel column and eluted with ethyl acetate – hexane (1:1). Solvent removal of the second fraction left a white solid (0.14 g, 0.14 mmol, 65%), mp 114–119°C, $[\alpha]_D^{23}$ −20° (*c* 0.5, chloroform); $^1$H nmr ($CDCl_3$) δ: 7.80–7.62 (broad m, 4H, phthalimido), 5.66 (dd, 1H, H-3′, $J_{3',4'}$ = 8.0 Hz, $J_{2',3'}$ = 10.5 Hz), 5.41 (d, 1H, H-1′, $J_{1',2'}$ = 8.5 Hz), 5.34 (d, 1H, H-1, $J_{1,2}$ = 4.5 Hz), 5.25 (broad d, 1H, H-4″, $J_{3'',4''}$ = 3.1 Hz), 5.04 (dd, 1H, H-2″, $J_{1'',2''}$ = 7.5 Hz, $J_{2'',3''}$ = 10.5 Hz), 4.86 (dd, 1H, H-3″), 4.46 (d, 1H, H-1″), 2.07, 1.99, 1.98, 1.89, 1.84 (5s, 15H, acetyl CH$_3$), O‖ 1.32, 1.22, 1.20 (3s, 12H, O—C(CH$_3$)$_2$), 0.88 (d, 3H, (C-7)H$_3$). *Anal.* calcd. for $C_{45}H_{57}O_{23}N$: C 55.16, H 5.86, N 1.43; found: C 54.51, H 5.76, N 1.34.

*1,2;3,4-Di-*O*-isopropylidene-6-*O*-[2-acetamido-2-deoxy-4-*O*-(β-*D*-galactopyranosyl)-α-*D*-glucopyranosyl]-7-deoxy-β-*D*-glycero-*D*-galacto-heptopyranose (8)*

Treatment of compound **7** (0.119 g, 0.12 mmol) with 85% hydrazine hydrate, work-up and *N*-acetylation as described above for the preparation of **5**, resulted in the isolation of a white solid (72 mg) which was applied to a Sephadex LH-20 column and eluted with ethanol–water (1:1). Solvent removal from the main fraction gave a white solid (34 mg, 0.053 mmol, 44%), mp 155–158°C; $^1$H nmr ($D_2O$) δ: 5.66 (d, 1H, H-1, $J_{1,2}$ = 5.0 Hz), 4.50 (2d, 2H, H-1′ and H-1″ overlapping, *J* = 7.5 Hz), 2.10 (s, O‖ 3H, NHAc methyl), 1.65, 1.48, 1.45, 1.43 (4s, 12H, O—C(CH$_3$)$_2$), 1.25 (d, 3H, (C-7)H$_3$), 4.20–3.50 (m, 17H, remaining protons).

*6-*O*-[2-Acetamido-2-deoxy-4-*O*-(β-*D*-galactopyranosyl)-β-*D*-glucopyranosyl]-7-deoxy-*D*-glycero-*D*-galacto-heptopyranose (9)*

A solution of compound **8** (21 mg, 0.033 mmol) in 70% trifluoroacetic acid (2 mL) was stirred at room temperature for 4 min and rapidly evaporated *in vacuo* to about 0.5 mL, and 3

drops of triethylamine was added. Filtration through a column of Sephadex LH-20, as described above for the preparation of **6**, provided a main fraction which was freeze-dried to a white solid (14.5 mg, 79%); $^1$H nmr ($D_2O$) δ: 5.24, 4.66 (2d, 1H, H-1α and H-1β, $J$ = 3.0 Hz and 7.5 Hz), 4.58, 4.49 (2d, 2H, H-1′ and H-1″ which shows up at this field position, $J$ = 7.5 Hz and 7.5 Hz), 2.08 (s, 3H, NHAc methyl), 1.26, 1.24 (2d, 3H, (C-7)$H_3$α and (C-7)$H_3$β), 4.26–3.42 (m, 17H, remaining protons).

# Hydrogenation of phosphido bridged ruthenium clusters. A view of P—C bond activation and cleavage in the coordinatively unsaturated molecule $Ru_3(CO)_9(\mu_2\text{-}PPh_2)(\mu_2\text{-}H)$: conversion of $\mu_2\text{-}PPh_2$ to $\mu_3\text{-}PPh$

SHANE A. MACLAUGHLIN, ARTHUR J. CARTY,[1] AND NICHOLAS J. TAYLOR

Received September 11, 1981

SHANE A. MACLAUGHLIN, ARTHUR J. CARTY, and NICHOLAS J. TAYLOR. Can. J. Chem. **60**, 87 (1982).

Treatment of $Ru_3(CO)_8(\mu_3\text{-}\eta^2\text{-}C{\equiv}CR)(\mu^2\text{-}PPh_2)$ (R = $Bu^t$, $Pr^i$) with dihydrogen liberates olefin ($CH_2{=}CHR$) and generates the coordinatively unsaturated cluster $Ru_3(CO)_9(\mu_2\text{-}PPh_2)(\mu_2\text{-}H)$ which has been shown by X-ray diffraction to have an unprecedented $\mu_2$-phosphido bridge in which a P—phenyl group interacts with an electron deficient ruthenium atom. This molecule provides an insight into P—C bond activation leading to cleavage. Further reaction of $Ru_3(CO)_9(\mu_2\text{-}PPh_2)(\mu_2\text{-}H)$ with $H_2$ leads to the phosphinidene cluster $Ru_3(CO)_9(\mu_3\text{-}PPh)(\mu_2\text{-}H)_2$ via elimination of benzene. Conversion of $Ru_3(CO)_9(\mu_2\text{-}PPh_2)(\mu_2\text{-}H)$ to another phosphinidene cluster $Ru_4(CO)_{13}(\mu_3\text{-}PPh)$ occurs on pyrolysis. Hydrogenation of multi-site bound acetylides with $H_2$ is a potentially useful synthetic route to unsaturated clusters. Hydrogenative conversion of $\mu_2\text{-}PPh_2$ to $\mu_3\text{-}PPh$ groups has significance for the synthesis of phosphinidene capped molecules as well as the chemistry of phosphido bridged clusters.

SHANE A. MACLAUGHLIN, ARTHUR J. CARTY et NICHOLAS J. TAYLOR. Can. J. Chem. **60**, 87 (1982).

Le composé $Ru_3(CO)_8(\mu_3\text{-}\eta^2\text{-}C{\equiv}CR)(\mu^2\text{-}PPh_2)$ (R = *t*-Bu, *i*-Pr) libère par hydrogénation l'oléfine ($CH_2{=}CHR$) et produit le groupe insaturé coordonné $Ru_3(CO)_9(\mu_2\text{-}PPh_2)(\mu_2\text{-}H)$ qui par diffraction de rayons X révèle l'existence d'un pont $\mu_2$-phosphido, jusqu'à présent inconnu, dans lequel le groupe P—phényle interagit avec l'atome de ruthénium déficient en électron. Cette molécule apporte des éclaircissements sur l'activation du groupe P—C conduisant au clivage. Une hydrogénation plus poussée du composé $Ru_3(CO)_9(\mu_2\text{-}PPh_2)(\mu_2\text{-}H)$ conduit au groupe phosphinidène $Ru_3(CO)_9(\mu_3\text{-}PPh_2)(\mu_2\text{-}H_2)$ via l'élimination du benzène. Par pyrolyse, on peut transformer le composé $Ru_3(CO)_9(\mu_2\text{-}PPh_2)(\mu_2\text{-}H)$ en un autre groupe phosphinidène. L'hydrogénation des acétylures est une voie d'accès potentielle très utile aux groupes insaturés. La transformation des groupes $\mu_2\text{-}PPh_2$ en groupe $\mu_3\text{-}PPh$ par hydrogénation a une importance dans la synthèse des molécules portant un groupe phosphinidène ainsi que dans la chimie des groupes ayant un pont phosphido.

[Traduit par le journal]

A major drawback to the use of metal cluster compounds as homogeneous catalysts is their inherent tendency to degrade under conditions appropriate for effective catalysis. Thus many high nuclearity carbonyl clusters undergo fragmentation under pressure of CO or in the presence of Lewis bases (1). A solution to this problem has been sought via the design of molecules with stable but flexible supporting bridges capable of maintaining the integrity of a cluster framework while allowing facile metal–metal bond cleavage and reformation. Considerable attention has recently focussed on the synthesis and catalytic behaviour of phosphido ($PR_2$) (2) and phosphinidene (PR) (3) based carbonyls since these groups have a number of features desirable in edge bridging or face capping ligands (4). Two rather notable examples are the use of the dianion $Fe_2(CO)_6(PPh_2)_2^{2-}$ in the synthesis of aldehydes from alkyl halides (5) and the catalytic hydroformylating ability of the phosphinidene complex $Co_4(CO)_8(\mu_2\text{-}CO)_2(\mu_4\text{-}PPh)_2$ (6). We report herein results pertinent to the chemistry of phosphido and phosphinidene clusters under molecular hydrogen and $H_2$/CO mixtures. In particular we have observed the facile reduction of $\mu_2\text{-}PPh_2$ groups in $Ru_3(CO)_8(\mu_2\text{-}PPh_2)(\mu_3\text{-}\eta^2\text{-}C{\equiv}CR)$ (R = $Bu^t$, $Pr^i$) (7) to a $\mu_3$-PPh unit in $Ru_3(CO)_9(\mu_3\text{-}PPh)(\mu_2\text{-}H)_2$ via an intermediate electron deficient hydride $Ru_3(CO)_9(\mu_2\text{-}PPh_2)(\mu_2\text{-}H)$. This coordinatively unsaturated complex contains a novel $\mu_2$-phosphido group activated by a weak P—Ph interaction with a third ruthenium atom.

The X-ray crystal structure of $Ru_3(CO)_9(PPh_2)(H)$ provides an unprecedented view of how a normally stable ligand entity is activated via coordinative unsaturation in a cluster. In the absence of molecular hydrogen, $Ru_3(CO)_9(PPh_2)(H)$ is converted on pyrolysis to another phosphinidene cluster $Ru_4(CO)_{13}(\mu_3\text{-}PPh)$ having a "butterfly" metal framework. These results are significant not only in demonstrating a new strategy for the synthesis of stable phosphinidene complexes but also in pro-

viding an indication that phosphido bridges may be considerably more reactive than has been previously assumed. Finally, the reduction of multisite bound acetylides by dihydrogen may be a useful method for generating coordinatively unsaturated clusters.

The trinuclear acetylide complexes $Ru_3(CO)_6(\mu_2\text{-}CO)_2(\mu_3\text{-}\eta^2\text{-}C{\equiv}CR)(\mu_2\text{-}PPh_2)$ (**I**, R = $Pr^i$; **II**, R = $Bu^t$) react rapidly with dihydrogen (25°C, 1 atm $H_2$, 2 min) resulting in hydrogenation of the acetylide. The principal organic product from **II** was identified as the olefin $H_2C{=}CHBu^t$ by $^1H$ nmr and by comparison with an authentic sample. Chromatography of the solution on Florisil (heptane eluant) afforded $Ru_3(CO)_9(\mu_2\text{-}PPh_2)(\mu_2\text{-}H)$ (**III**; ~ 40%) and $Ru_3(CO)_9(\mu_3\text{-}PPh)(\mu_2\text{-}H)_2$ (**IV**; ~ 10%). The ν(CO) ir spectra of **III** and **IV** showed only terminal carbonyls (ν(CO)($C_6H_{12}$) **III**, 2083 s, 2055 vs, 2014 s, 1993 m, 1986 m; **IV**, 2104 m, 2073 s, 2048 vs, 2030 m, 2017 s, 1998 m, 1986 m). High field nmr resonances typical of metal hydrides were observed in each case ($^1H$ nmr, $C_6D_6$ **III**, δ −15.8(d) $J_{P-H}$ = 24 Hz; **IV**, δ −18.3(d), $J_{P-H}$ = 15.3 Hz). Orange–red crystals of **III** are monoclinic, space group $P2_1/c$, $a$ = 13.369(2), $b$ = 11.824(1), $c$ = 15.417(2) Å; β = 97.32(1)°; $Z$ = 4, $\rho_c$ = 2.038, $\rho_m$ = 2.03 g cm$^{-3}$; μ(MoKα) = 19.22 cm$^{-1}$, $F$(000) = 1424. Solution and refinement of the structure by Patterson, Fourier and least-squares methods was based on 4703 observed ($I \geq 3\sigma(I)$) (7106 measured) reflections with 3.2° < 2θ < 60°, measured on a Syntex $P2_1$ diffractometer with MoKα radiation. With anisotropic thermal parameters for all non-hydrogen atoms and isotropic coefficients for hydrogen atoms refinement proceeded to $R$ and $R_w$ values of 0.035 and 0.039. The molecular structure is shown in Fig. 1. Within the closed triangle of ruthenium atoms there are two normal Ru—Ru distances (Ru(1)—Ru(2) 2.8350(5); Ru(2)—Ru(3) 2.7996(5) Å); the third, longer Ru—Ru vector (Ru(1)—Ru(3) 2.9049(5) Å) is bridged by a hydride (Ru(1)—H(1)—Ru(3) 109.5°) and by a phosphido group. The stereochemistry of the latter is remarkable, with the phosphorus atom "tipped" towards the centre of the $Ru_3$ triangle as a result of an additional weak P–Ph interaction with Ru(2). The extent of the Ru(2)···P—Ph interaction can be gauged not only by the orientation of the phosphido bridge but also by the contact Ru(2)···P (2.779(1) Å) (cf. Ru(3)—P of 2.336(1) Å) and the distance between Ru(2) and the mid point of the P—C(21) bond (2.489 Å). However, the P—C(21) bond length (1.827(5) Å) does not differ significantly from the P—C(11) (1.832(5) Å) distance and the $^{31}P$ nmr

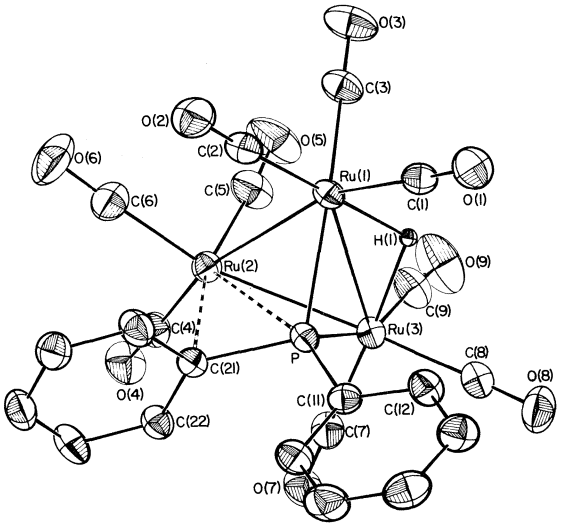

FIG. 1. A perspective view of the molecular structure of $Ru_3(CO)_9(\mu_2\text{-}PPh_2)(\mu_2\text{-}H)$ showing the unusual interaction of a P—phenyl linkage with Ru(2). Important distances and angles not mentioned in the text are: Ru(1)—P 2.331(1), Ru(2)—C(21) 2.518(4) Å; Ru(1)—P—Ru(3) 77.0°, Ru(2)—P—Ru(3) 65.7°.

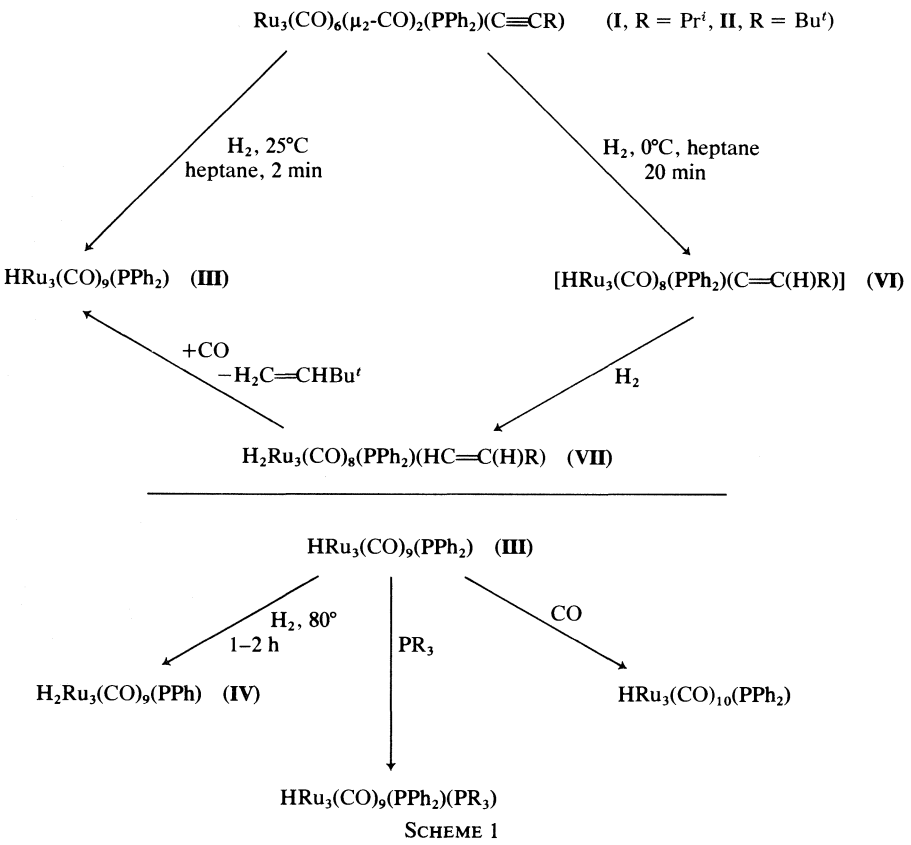
chemical shift (δ = +134.2 ppm) is not unusual for an Ru(1)—P—Ru(3) angle of 77.0° (2, 7). These results together with the facile formation of 1:1 adducts with Lewis bases (*vide infra*) suggest that the Ru(2)···P—Ph interaction is weak in the solid state and that **III** is indeed coordinatively unsaturated in solution. A formal electron count indicates that **III** is a 46 electron species, two electrons short of a closed shell 48 electron configuration for an $Ru_3$ cluster if the $PPh_2$ group contributes three electrons. In particular, Ru(2), with two electron bonds to three CO groups and two other ruthenium atoms, is electron deficient. The attraction of Ru(2) for one P—Ph group of the phosphido bridge can therefore be seen as a direct consequence of the need for Ru(2) to relieve its unsaturation. To our knowledge such behaviour is unprecedented. In other coordinatively unsaturated clusters such as $H_2Os_3(CO)_{10}$ (8) and $H_2Re_2(CO)_8$ (9) multiple metal–metal bonding provides partial relief of electron deficiency. By analogy with the chemistry of these exceedingly reactive clusters, **III** should be hyperreactive. Reaction of **III** with CO in heptane is rapid, affording high yields of $Ru_3(CO)_{10}(\mu_2\text{-}PPh_2)(\mu_2\text{-}H)$($^1H$ nmr, $C_6D_6$, δ, −16.3(d) $J_{P-H}$ = 30.5 Hz (Ru—H—Ru); 8.1 (m), 7.0 (m) ($C_6H_5$); $^{31}P$ nmr $C_6D_6$ δ($H_3PO_4$) +133.8; ν(CO) $C_6H_{12}$, 2098 w, 2054 s, 2048 m, 2020 s, 2002 w, 1996 m, 1987 w cm$^{-1}$) while phosphines $PR_3$ produce instantly the adducts $Ru_3(CO)_9(\mu_2\text{-}PPh_2)(\mu_2\text{-}H)(PR_3)$.

The structure of **III** (Fig. 1) also provides a



SCHEME 1

unique view of an intermediate stage in P—C bond activation and cleavage leading from a phosphido group to a phosphinidene. The predicted loss of an activated phenyl group from **III** was readily achieved. Passage of dihydrogen through a solution of pure **III** in $C_7H_{16}$ (80°C, 2 h) afforded only $Ru_3(CO)_9(\mu_3\text{-PPh})(\mu_2\text{-H})_2$ **IV** in excellent yield (~ 80%). The structure of **IV** as determined by X-ray analysis[2] consists of a triangle of ruthenium atoms capped by a $\mu_3$-PPh group and edge bridged on two sides by hydride ligands (Scheme 1).

While facile loss of a phenyl group from **III** as $C_6H_6$ occurred under reducing conditions, the presence of an activated $PPh_2$ group and a hydride in **III** suggested the possibility of phosphinidene generation via intramolecular reductive elimination of $C_6H_6$. Pyrolysis of **III** (80°C, 4 h, $C_7H_{16}$) resulted in cluster fragmentation and the synthesis of $Ru_4(CO)_{13}(\mu_3\text{-PPh})$ **V**, (ir, ν(CO) $C_6H_{12}$; 2095 w, 2060 vs, 2048 s, 2041 s, 2020 w, 2010 m, 1988 w, 1969 w, sh) in moderate yields (~ 40%). Crystals of **V** are orthorhombic, space group *Pbca* with $a$ = 15.325(2), $b$ = 17.797(2), $c$ = 18.613(5) Å; $Z$ = 8, $\rho_c$ = 2.293, $\rho_m$ = 2.31 g cm$^{-3}$ and $\mu(MoK_\alpha)$ = 24.05 cm$^{-1}$, $F(000)$ = 3312. The intensities of 3041 observed (4473 measured) reflections ($I \geq 3\sigma(I)$) measured on a $P2_1$ diffractometer in the range 3.2° < 2θ < 50°, were used in structure solution and refinement. $R$ and $R_w$ values are 0.040 and 0.046 respectively. The principal structural features of **V** (Fig. 2) are a metal "butterfly" with a $\mu_3$-PPh group capping an open $Ru_3$ face (Ru(1)—P 2.302(2), Ru(2)—P 2.388(2), Ru(4)—P 2.316(2) Å) and distant from the remaining ruthenium atom (Ru(3)—P 3.199(2) Å). While a few "open" triangular mixed metal phosphinidenes are known (12) **V** is the first example of a homotetranuclear butterfly phosphinidene complex to be characterised.

Preliminary mechanistic studies indicate that conversion of **II** to **III** and **IV** proceeds (scheme) via initial oxidative addition of $H_2$ to the cluster generating a transient hydrido (vinylidene) complex H $Ru_3(CO)_8(PPh_2)(C{=}CHBu^t)$, **VI**, which

[2]This molecule has also been recently prepared and structurally characterised by Mays and co-workers (10) as a product of the reaction of $PH_2Ph$ with $Ru_3(CO)_{12}$. The two structures are essentially identical. The iron analogue $Fe_3(CO)_9(\mu_3\text{-PPh})(\mu_2\text{-H})_2$ was earlier prepared by a similar route (11).

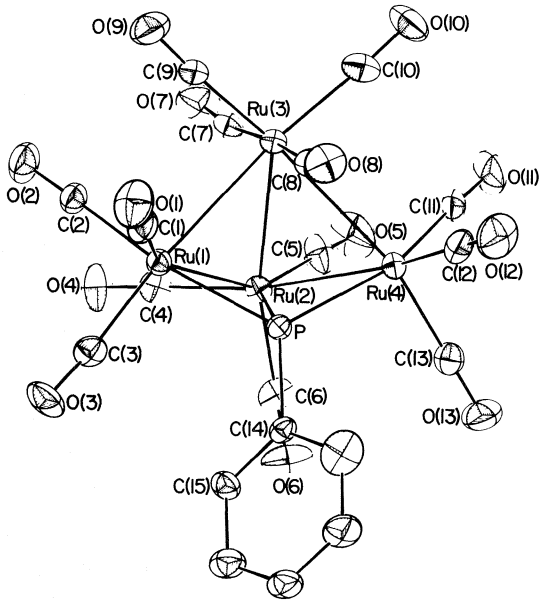

FIG. 2. The molecular structure of $Ru_4(CO)_{13}(\mu_3\text{-PPh})$ showing the atomic numbering. Important bond lengths and angles not included in the text are: Ru(1)—Ru(2) 2.833(1), Ru(1)—Ru(3) 2.861(1), Ru(2)—Ru(3) 2.974(1), Ru(2)—Ru(4) 2.784(1), Ru(3)—Ru(4) 2.924(1) Å; Ru(1)—P—Ru(2) 74.3, Ru(1)—P—Ru(4) 121.1(1), Ru(2)—P—Ru(4) 72.6°.

rapidly adds a second molecule of $H_2$ leading to an unstable dihydrido ($\mu_2$-$\eta^2$-vinyl) complex $H_2Ru_3(CO)_8(PPh_2)(HC{=}C(H)Bu^t)$, **VII**. Under CO **VII** is quantitatively transformed into **III** with loss of *t*-butylethylene. Complex **III** reacts more slowly with CO to yield the coordinatively saturated species $Ru_3(CO)_{10}(H)(PPh_2)$. Carbon monoxide is not, however, required in the direct hydrogenative conversion of **II** to **III**. Complete spectroscopic and structural characterisation of these species will be described elsewhere. It is clear, however, that reduction of $\mu_3$-$\eta^2$-acetylido clusters with $H_2$ under mild conditions is a useful strategy for the synthesis of hydrido-phosphido and hydrido-phosphinidene bridged clusters. Furthermore, our studies indicate that the reactivity of phenyl phosphido bridges under reducing conditions may limit the application of $PPh_2$ bridged clusters in catalysis.[3]

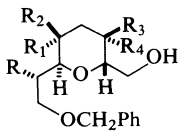
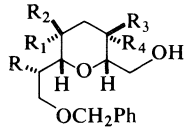
The polyether antibiotics represent a growing and important class of naturally occurring substances. These compounds have received considerable attention in the synthetic field during recent years, because of their unique ionophoric properties as well as the degree of stereochemical complexity of this class of compounds (1). As a part of our program aimed at the synthesis of a variety of ionophore antibiotics, we have been interested in developing a stereospecific and general method for synthesizing the highly substituted tetrahydropyranyl ring systems **1** and **2** from acyclic intermedi-



**1**

*a*: R = $R_4$ = Me, $R_1$ = $R_2$ = $R_3$ = H
(ring A of antibiotic X-14547A)
*b*: R = Et, $R_4$ = Me, $R_1$ = $R_2$ = $R_3$ = H
(ring A of salinomycin)
*c*: R = $R_2$ = Me, $R_1$ = $R_3$ = $R_4$ = H
(ring A of nigericin)



**2**

*a*: R = $R_2$ = Me, $R_1$ = $R_3$ = $R_4$ = H
(ring A of antibiotic X-206)
*b*: R = $R_2$ = $R_3$ = Me, $R_1$ = $R_4$ = H
(ring A of alborixin)

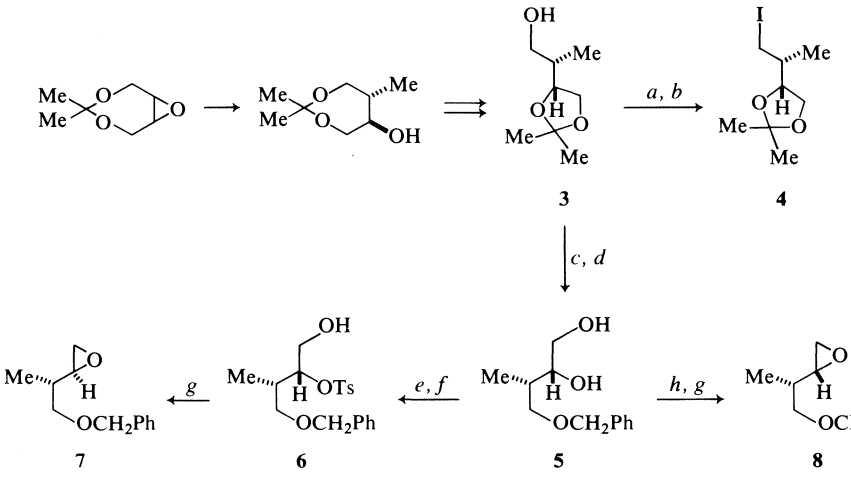
ates. The structural ring systems in the present studies have often been found in the polyether antibiotics. The *trans*-tetrahydropyrans **1** represent ring A of antibiotic X-14547A (for isolation, see ref. 2*a*, for syntheses of the "right wing", see ref. 2*b*–*d*), salinomycin (3), and nigericin (4), while the *cis*-tetrahydropyrans **2** represent ring A of antibiotic X-206 (5) and alborixin (6). Although for future total syntheses of polyether antibiotics, chiral precursors for the construction of tetrahydropyranyl subunits are a crucial point, our exploratory work for the present studies was undertaken with racemic materials.

The starting material **3** for the present investigation was prepared by a modification of literature procedures (7) from commercially available (*Z*)-2-butene 1,4-diol (Scheme 1). The key reaction in the preparation of the enantiomeric pair of the alcohol **3** was the stereospecific *trans* opening of the epoxide with lithium dimethylcuprate. Compound **4**[1] was obtained in quantitative yield by two-step standard procedures from the corresponding primary alcohol **3**. In order to explore the stereospecificity and feasibility of our approach to the tetrahydropyranyl ring systems, two isomeric epoxides **7** and **8** were synthesized from the same enantiomeric pair of alcohol **3** in a straight-forward and unambiguous manner (Scheme 1). The alcohol **3** was converted into the diol **5** in 95% yield by benzylation and mild acidic hydrolysis. For the preparation of the α-epoxide **7**, treatment of the diol **5** with *p*-anisyldiphenylmethyl chloride (1.1 equiv) in pyridine at 0°C overnight and then subsequently with tosyl chloride (1.2 equiv) at room temperature for 1 day gave the crude product, which was treated with 80% aqueous acetic acid at room temperature for 4 h to yield the hydroxyl tosylate **6**. The yield was 84% from the diol **5**. This operation was to invert the configuration at the secondary alcohol when the epoxide was formed in the next step. Exposure of compound **6** to methanolic potassium hydroxide at room temperature for 1 h led to the formation of the desired epoxide **7** in 89% yield. For the preparation of the β-epoxide **8**, the diol **5**, on treatment with tosyl chloride (1 equiv) in pyridine and methylene dichloride at 0°C for 6 h, followed with methanolic potassium hydroxide at room temperature for 1 h furnished the epoxide **8** in 86% yield.

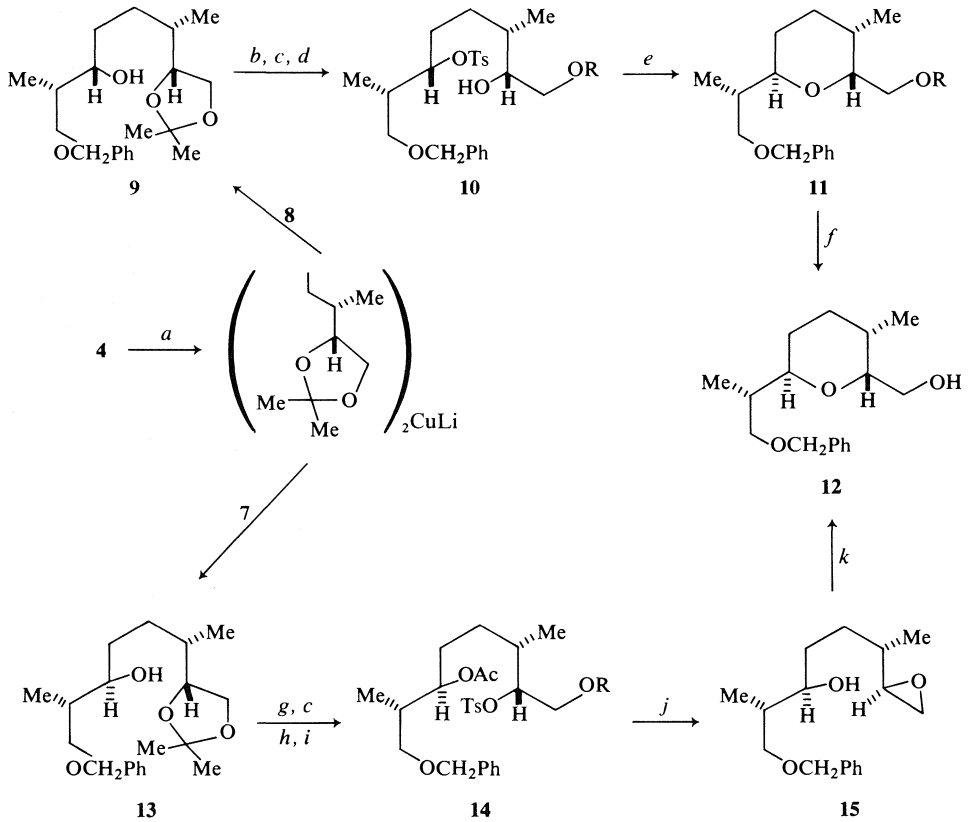
Two alternative elaborations of *trans*-tetrahydropyran **1** by the sequence of reactions shown in Scheme 2 were examined. Thus, treatment of the iodide **4** with *n*-butyllithium (1.1 equiv) in tetrahydrofuran at −70°C for 4 h, followed with cuprous iodide at the same temperature for 1 h resulted in the formation of lithium cuprate derivative, which reacted in the desired manner with the epoxide **8** (the ratio of epoxide-to-iodide was 1 equiv:1.7 equiv) at −70°C for 2 h to give the alcohol **9** in 65–70% yield.[2] Conversion of **9** to the hydroxyl

[1]Satisfactory physical and spectral data have been obtained for all new compounds.

[2]The material obtained from this reaction, as expected, was a pair of diastereoisomers as shown by $^{13}C$ nmr, which could not be separated by HPLC.



SCHEME 1. Reagents and conditions: *a*, TsCl, pyridine, RT; *b*, NaI, acetone, RT, 2 days; *c*, NaH, $PhCH_2Br$, THF, RT; *d*, 80% aqueous HOAc, RT, 6 h; *e*, *p*-anisyldiphenylmethylchloride (1.1 equiv), pyridine, 0°C, 12 h, then TsCl (1.2 equiv), RT, 1 day; *f*, 80% aqueous HOAc, RT, 4 h; *g*, KOH, MeOH, RT, 1 h; *h*, TsCl (1 equiv), pyridine, $CH_2Cl_2$, 0°C, 10 h.



SCHEME 2. R = *p*-anisyldiphenylmethyl. Reagents and conditions: *a*, *n*BuLi (1.1 equiv), THF, −70°C, 4h, then CuI, −70°C, 1h; *b*, TsCl, pyridine, RT; *c*, 80% aqueous HOAc, RT; *d*, *p*-anisyldiphenylmethyl chloride (1.1 equiv), pyridine, RT; *e*, NaH (1.4 equiv), benzene, reflux, 6h; *f*, 80% aqueous HOAc, RT; *g*, $Ac_2O$, pyridine, RT; *h*, *p*-anisyldiphenylmethyl chloride (1.1 equiv), pyridine, RT, 6h, then TsCl (1.2 equiv), RT, 1½ day; *i*, 80% aqueous HOAc, RT, 4h; *j*, KOH, MeOH, RT, 10h; *k*, HOAc, RT, 2 days.

SCHEME 3. Reagents and conditions: *a*, $Ac_2O$, pyridine, RT; *b*, 80% aqueous HOAc, RT; *c*, *p*-anisyldiphenylmethyl chloride (1.1 equiv), pyridine, RT, 6 h, then TsCl (1.2 equiv), RT, 1½ day; *d*, 80% aqueous HOAc, RT, 4 h; *e*, KOH, MeOH, RT, 10 h; *f*, HOAc, RT, 2 days.

tosylate **10** was accomplished in 81% yield by standard procedures, tosylation of the secondary alcohol, generation of the diol by mild acidic hydrolysis, and tritylation of the primary alcohol (Scheme 2). With the complete carbon skeleton and functionality assembled, the *trans*-tetrahydropyranyl ring **11** was smoothly formed in 69% yield by the reaction of compound **10** with sodium hydride (1.4 equiv) in anhydrous benzene under reflux for 6 h.[3] The cyclization reaction from the acyclic intermediate achieved by a $S_N2$ displacement reaction left no doubt about the outcome of the desired stereochemistry of the *trans*-tetrahydropyranyl ring system. Compound **11**, on treatment with 80% aqueous acetic acid at room temperature, afforded quantitatively compound **12**. An alternative route to *trans*-tetrahydropyran **12** was also developed starting with alcohol **13**[2] prepared by the reaction of α-epoxide **7** with the iodide **4** under the same conditions as described above, and proceeding (Scheme 2) via the intermediates **14** and **15**. The overall yield from **7** and **4** to **15** was 53%. When compound **15** was treated with glacial acetic acid at room temperature for 2 days, the cyclization reaction proceeded smoothly to give the identical compound **12** in 92% yield. That two independent routes yielded the identical *trans*-tetrahydropyranyl ring affirm to the complete stereospecificity of the epoxide opening reaction with acetic acid. Clearly, the simplicity and high yield of this approach to compound **12** compared with the first approach make the reaction more attractive to the synthesis of polysubstituted tetrahydropyranyl ring systems.

With the successful development of the *trans*-tetrahydropyran synthesis, we now shifted our direction to the *cis*-ring systems **2**. Scheme 3 summarizes the sequence of reactions for the *cis*-series. Using the same techniques for the preparation of compound **15** from compound **13**, the alcohol **9** was converted into compound **17** in 69% overall yield. Treatment of the hydroxyl epoxide **17** with glacial acetic acid at room temperature for 2 days led to the isolation of the *cis*-tetrahydropyran **18** in 90% yield.[4]

The efficiency and stereospecificity of our method for the construction of various tetrahydropyranyl systems will open a wide synthetic application for many polyether antibiotics. Specifically, compound **12**, which possesses the correct stereochemistry and the required functionality for the synthesis of the recently isolated novel antibiotic X-14547A **19** (2), will be used as a key intermediate for the total synthesis. We are currently synthesizing the optically active compound **12** from tartaric acid and further progress along the line will be reported in due course.

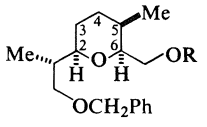
[3]After cyclization, the pair of diastereoisomers **11** and **i**, produced from the reaction of **4** with **8**, could easily be separated by column chromatography on silica gel in 1% methanol in hexane and $CH_2Cl_2$ (**i**, $R_f$ 0.75; **11**, $R_f$ 0.55). The



**i**

stereochemistry of **11** and **i** was assigned based on the chemical shift of their $^1H$ and $^{13}C$ nmr. Compound **11** gave $^1H$ nmr signal at 3.95 ppm and $^{13}C$ nmr signal at 72.9 ppm for hydrogen at C-6, while compound **i** had $^1H$ nmr signal at 3.72 ppm and $^{13}C$ nmr signal at 79.3 ppm for axial hydrogen at C-6.

[4]The pair of diastereoisomers was easily separated by column chromatography on silica gel. Compound **18** gave $^{13}C$ nmr signal at 81.3 ppm for C-6; while its isomer showed signal at 74.6 ppm for C-6 in its $^{13}C$ nmr spectrum.

# Thiol esters in organic synthesis. X.[1] A new approach to 1,5-ketols and 5-hydroxy esters using *S,S'*-diethyl dithiomalonate as an ethanol carbanion equivalent

HSING-JANG LIU AND ISAAC V. OPPONG

*Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2*

Received September 2, 1981

HSING-JANG LIU and ISAAC V. OPPONG. Can. J. Chem. **60**, 94 (1982).

Michael addition of *S,S'*-diethyl dithiomalonate to conjugated enones and α,β-unsaturated esters followed by reduction with Raney nickel gave rise to 1,5-ketols and 5-hydroxy esters respectively in good yields.

HSING-JANG LIU et ISAAC V. OPPONG. Can. J. Chem. **60**, 94 (1982).

L'addition suivant Michael du dithiomalonate de *S,S'*-diéthyle à des énones conjuguées et à des esters α,β-non saturés, suivie par une réduction à l'aide de nickel de Raney conduit, suivant le cas, à la formation de cétols-1,5 et d'hydroxy-5 esters avec de bons rendements.

[Traduit par le journal]

In a recent communication (1*e*), we reported that *S,S'*-diethyl dithiomalonate reacts readily with alkyl halides and other electrophiles and that the dithiomalonate group can be easily reduced by Raney nickel under mild conditions to the ethanol level. One interesting application of *S,S'*-diethyl dithiomalonate as a convenient source of ethanol carbanion equivalent is its use as a Michael donor to facilitate the preparation of 1,5-ketols and 5-hydroxy esters, versatile synthetic intermediates which are particularly useful for the construction of six-membered carbocyclic and heterocyclic systems (2, 3).

In our initial attempts to induce the Michael addition of *S,S'*-diethyl dithiomalonate to α,β-unsaturated carbonyl compounds,[2] the use of the sodium and lithium salts generated *in situ* with strong bases such as NaH, NaSEt, and *t*-BuOLi was found to be ineffective. In each case, the starting material was recovered, presumably due to an unfavorable addition–elimination equilibrium. However, when a tertiary amine was used as a base, the conjugated addition occurred readily. Of several amines examined, 1,4-diazabicyclo[2.2.2]-octane (DABCO) was shown to be most effective, giving consistently high yields of the products under mild conditions. In a typical experiment, a solution of *S,S'*-diethyl dithiomalonate (720 mg, 3.74 mmol), DABCO (420 mg, 3.74 mmol), and 2-cyclohexenone (300 mg, 3.12 mmol) in 1,2-dimethoxyethane (10 mL) was stirred at room temperature under an argon atmosphere for 48 h. The reaction mixture was acidified with 1 *N* aqueous hydrochloric acid and extracted with chloroform. Drying ($MgSO_4$), filtration, and concentration gave the crude product which was purified by column chromatography on silica gel. Elution with a solution

[1]For parts I–IX of this series, see refs. 1*a*–*i* respectively.

[2]The addition of *S,S'*-diethyl dithiomalonate to ethyl acrylate was previously explored by Scheithauer and Mayer (4) using sodium methoxide in methanol to give a mixture of the mono- and bis-adduct in ca. 1:1 ratio.

| 9 | $(EtOOC)_2C{=}CHCH(CH_3)_2$ | 5 | $(EtOOC)_2\underset{\displaystyle CH(CH_3)_2}{\underset{\vert}{C}}HCH(COSEt)_2$ | (95) | 1 |  | (70) |
| 10 |  | 1 |  | (100) | 0.5 |  | (75) |

[a]All new compounds were adequately characterized by spectroscopic methods and by exact mass measurement and/or elemental analysis.
[b]This reaction was carried out at −30°C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

of 30% ether in petroleum ether gave adduct **1** (836 mg; 93% yield): mp 73–74°C (ether – petroleum ether); ir (neat): 1710 (ketone), 1680, and 1658 (thiol esters) $cm^{-1}$; nmr ($CCl_4$) δ: 3.53 (d, 1H, $J = 9$ Hz, —C*H*(COSEt)$_2$), 2.89 (q, 4H, $J = 7$ Hz, —COSC$H_2$—), and 1.26 (t, 6H, $J = 7$ Hz, —C$H_3$); ms $M^+$: 288.0863 (calcd. for $C_{13}H_{20}O_3S_2$: 288.0860). This procedure was found to be general for conjugated enones and α,β-unsaturated esters which are not doubly substituted at the β-carbon. Results obtained for a number of acyclic and cyclic compounds are compiled in Table 1. We have also examined the reactions of *S*,*S*′-diethyl dithiomalonate with mesityl oxide and 3-methyl-2-cyclohexenone, both fully substituted at the β-carbon, but failed to detect any adduct formation.

Upon treatment with Raney nickel, the Michael adducts underwent elimination of one of the thiol ester groups with concomitant reduction of the other to give directly 1,5-ketols or 5-hydroxy esters (Table 1). The best results were obtained using a modified W-2 Ra-Ni prepared by washing sequentially with water, aqueous acetic acid, water, isopropyl alcohol, and benzene instead of the normal water–ethanol combination (5). This acid-washed catalyst suppressed completely the formation of the transesterification products (—COSEt → —COOEt) which were otherwise produced in variable amounts. A general procedure for the reduction is illustrated below with keto dithiomalonate **1**.

At ~5°C, to a suspension of the modified W-2 Ra-Ni (5 mL (settled volume)) in benzene (10 mL), was added a solution of **1** (500 mg, 1.74 mmol) in benzene (10 mL). After stirring at room temperature under an argon atmosphere for 30 min, the mixture was filtered and the residue thoroughly washed with benzene and ethanol. Concentration followed by column chromatography of the crude product on silica gel eluting with ether – petroleum ether (3:1) gave ketol **2** (197 mg; 80% yield).

The foregoing report illustrates a two-step process which allows the overall incorporation of an ethanol unit in a Michael fashion to α,β-unsaturated carbonyl compounds. This procedure for the preparation of 1,5-ketols and 5-hydroxy esters compares favorably with existing methods (2, 3, 6, 7) in terms of simplicity and efficiency.

Received December 24, 1980[1]

J. ZUKERMAN-SCHPECTOR, E. E. CASTELLANO, A. C. MASSABNI and A. DERBLI PINTO. Can. J. Chem. **60**, 97 (1982).

The crystal structure of the title compound has been determined from diffractometric X-ray data and refined by full-matrix least-squares to a final $R$ factor of 0.055 from 1099 independent reflections above background.

The space group and cell dimensions are : $P2_1/n$, $a$ = 7.916(2), $b$ = 10.934(3), $c$ = 13.638(1) Å, $\beta$ = 97.37(1)°, with $Z$ = 4.

The 1-phenyl-3,5-dimethylpyrazole group was found to be positively charged, forming a strong ionic complex with the nitrate ion.

The dihedral angle between the phenyl and pyrazole rings, corresponding to the minimum intramolecular van der Waals energy, was calculated and compared with those reported in different complexes of known structure, showing that there is a narrow range of rotational freedom about the N(1)—C(6) bond.

J. ZUKERMAN-SCHPECTOR, E. E. CASTELLANO, A. C. MASSABNI et A. DERBLI PINTO. Can. J. Chem. **60**, 97 (1982).

On a déterminé la structure cristalline du composé mentionné dans le titre à partir de données de diffraction de rayons X et on l'a affiné par la méthode des moindres carrés (matrice entière) jusqu'à une valeur conventionnelle de $R$ = 0,055 pour 1099 réflexions indépendantes avec $a$ = 7,916(2), $b$ = 10,934(3), $c$ = 13,638(1) Å, $\beta$ = 97,37(1)°, $Z$ = 4, groupe d'espace $P2_1/n$.

On a trouvé que le groupe phényl-1 diméthyl-3,5 pyrazole est chargé positivement, formant un complexe ionique fort avec l'ion nitrate.

On a calculé l'angle dièdre entre les noyaux phényle et pyrazole correspondant à l'énergie de van der Waals intramoléculaire minimale et on l'a comparé à ceux rapportés pour différents complexes de structure connue; ceci révèle l'existence d'un domaine étroit de rotation libre autour de la liaison N(1)—C(6).

## Introduction

1-Phenyl-3,5-dimethylpyrazole (PDMP) has been used as a ligand in some metal complexes of silver(I) (1), copper(II) (2, 3), and cobalt(II) (4). In these complexes the PDMP appears as a neutral group bonded to the metal through the N(2) atom.

At room temperature PDMP is a colourless liquid but addition of nitric acid to the alcoholic solution produces a crystalline precipitate. This fact raised the question of the nature of the PDMP – nitric acid interaction; to investigate this matter, to compare the PDMP molecule with its conformation in the several metal complexes reported, and to see whether the geometry of the pyrazolium moiety was changed or not, a three-dimensional crystal structure analysis was undertaken.

## Experimental

The title compound was prepared as described elsewhere (5) and crystals of adequate size for X-ray analysis were obtained from ethanol by slow evaporation at room temperature.

A prismatic colourless crystal with dimensions 0.7 × 0.25 × 0.3 mm was mounted on an Enraf-Nonius CAD-4 diffractometer. The unit cell dimensions and the orientation matrix for the data collection were obtained by least squares from 25 centered reflections. Systematic absences: $h0l$ for odd $h + l$, and $0k0$ for odd $k$, indicated space group $P2_1/n$.

*Crystal Data*

$C_{11}H_{13}N_2^+ NO_3^-$ fw = 235,24

Monoclinic, space group $P2_1/n$ ($C_{2h}^5$), $a$ = 7.916(2), $b$ = 10.934(3), $c$ = 13.638(1) Å, $\beta$ = 97.37(1)°, $V$ = 1170.6 Å$^3$, $Z$ = 4 formula units per cell, $D_c$ = 1.33 g cm$^{-3}$, $\mu$(CuK$\alpha$) = 8.4 cm$^{-1}$, $\lambda$(CuK$\alpha$) = 1.5418 Å, $t$ = 23°C.

Intensities were measured by the $\theta$–$2\theta$ scan technique at a rate between 1.33 and 20.0 deg min$^{-1}$ determined by a fast prescan of 20.0 deg min$^{-1}$; the $\omega$ scan angle was (0.80 + 0.14 tan $\theta$)° extended at each side by 25% for background determination.

1656 reflections were collected in the range $0 \leq \theta \leq 55°$ using graphite-monochromated CuK$\alpha$ radiation. 1099 reflections having $I \geq 3\sigma(I)$ ($\sigma(I)$ estimated from counting statistics) were retained for structure determination and refinement.

The intensity of one standard reflection was essentially constant over the duration of the experiment. Data were corrected for Lorentz and polarization effects but not for absorption or extinction.

*Structure Solution and Refinement*

The structure was solved by direct methods and refined by full-matrix least-squares using the SHELX-76 system of programs (6). All the non-hydrogen atoms appeared clearly in the first $E$-map. The hydrogen atoms were found from a difference Fourier synthesis calculated when the conventional $R$ was 0.091 and were assigned the isotropic temperature factor of the atom to which they were attached. Further anisotropic refinement for the non-hydrogen atoms was carried out. This resulted in a final $R$ of 0.055 and $R_w$ = 0.061. The function minimized was: $\sum\omega(|F_o| - |F_c|)^2$ with $\omega = 1/[\sigma^2(F_o) + 0.00215\,F_o^2]$, where $\sigma(F_o)$ is the esd for the observed amplitude based on counting statistics. Bonded H-atom scattering factors (7) and complex neutral scattering factors (8, 9) for the remaining atoms were employed. A final difference Fourier map showed no features of

*The standard deviation of $B_{iso}$ was calculated as $\sigma(B_{iso}) = \sum_{ij} T_{ij}\,\sigma(B_{ij})$.

chemical significance. Measured and calculated structure factors, anisotropic thermal parameters for non-hydrogen atoms, and H-atom parameters have been deposited.[2]

Atomic coordinates together with calculated equivalent isotropic temperature factors are given in Table 1. The expression for $B_{iso}$ is of the form:

$$B_{iso} = \sum_{ij} T_{ij}B_{ij},$$

where $T_{ij}$ are the elements of the metric tensor and $B_{ij}$ are the elements of the thermal tensor usually obtained by least-squares refinement (10).

## Discussion

The molecule is depicted in Fig. 1 which also shows intramolecular bond distances and atomic numbering. Thermal ellipsoids are drawn to a 45% probability scale (11). Angles between non-hydrogen bonded atoms are given in Table 2.

The phenyl ring, the pyrazole ring, and the $NO_3^-$ group were found to be planar to within experimental accuracy. Least-squares planes referred to the conventional orthogonalized coordinates, distances of atoms to the planes, and dihedral angles are given in Table 3.

Depending on the different environments the PDMP group is known to have various conformations, as can be seen in Table 4 where the reported dihedral angles between the phenyl and pyrazole rings are given.

The *calculated* dihedral angle corresponding to the conformation of minimum intramolecular van der Waals energy was found using Sakurai and Kobayashi's Molecular Model Building Program (12).

A difference Fourier synthesis unambiguously

| O(3)—N(3)—O(1) | 118.0(3) |
| O(3)—N(3)—O(2) | 121.7(3) |

showed a hydrogen atom bonded to N(2). The H(N2) ... O(1)—N(3) and the N(2)—H(N2) ... O(1) angles of 112° and 176° together with the N(2) ... O(1) and H(N2) ... O(1) distances of 2.66 and 1.75 Å respectively are strong evidence of hydrogen bonding between O(1) and N(2).

The $NO_3^-$ group shows a very approximate $D_{3h}$ local point symmetry although a slightly longer N(3)—O(1) distance is presumably due to the mentioned hydrogen bond.

We conclude that the PDMP group is positively charged forming a strong ionic complex with the $NO_3^-$ anion.

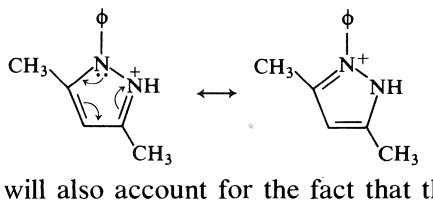
| $[Co(NCS)_2(PDMP)_2]$ | (4) | 72.9 |
| $(PDMP)^+NO_3^-$ | | 48.2 |
| Calculated | | 60.0 |

It is known that in the pyrazole molecule the C(2)—C(3) distance is systematically shorter than the C(1)—C(2) one (1, 13, 14). In the present case the two nitrogen atoms behave as pyrrolic and unless there is a strong interaction between the $p_\pi$ electrons of the phenyl and pyrazole groups the two C—C internuclear distance should be identical. This is actually observed to within our experimental accuracy. In fact, the dihedral angle of 48.2° does not favor a strong π–π overlap. It may be speculated that the positive charge of the PDMP group gives rise to the two resonance forms:



which will also account for the fact that the two C—C bonds in the pyrazolium ion are essentially equal.

# *Ab initio* SCF-MO calculations of features of the lowest triplet state potential surfaces of several tetraatomic carbonyl compounds

A. KAPUR,[1] R. P. STEER, AND P. G. MEZEY

*Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0*

Received May 28, 1981

A. KAPUR, R. P. STEER, and P. G. MEZEY. Can. J. Chem. **60**, 100 (1982).

Non-empirical SCF-MO calculations have been carried out for a series of tetraatomic carbonyl compounds. Portions of the ground singlet and first triplet state potential energy surfaces, in particular those along the out-of-plane bending coordinates, have been determined. Estimates of the first triplet state out-of-plane vibrational frequencies have been calculated.

A. KAPUR, R. P. STEER et P. G. MEZEY. Can. J. Chem. **60**, 100 (1982).

On a effectué des calculs de MO-SCF non empiriques sur une série de composés carbonylés tétraatomiques. On a déterminé des portions des surfaces d'énergie potentielle de l'état fondamental singulet et du premier état triplet. On a évalué les fréquences de vibration hors du plan du premier état triplet.

## Introduction

Tetraatomic carbonyl compounds in their ground and excited electronic states have been the subject of many experimental and theoretical investigations. Foremost among experimental work have been exhaustive studies of the electronic spectroscopy, the photochemistry, and the photophysics of formaldehyde (1–3). Despite these efforts, however, an unequivocal picture of the mechanism(s) of photodissociation of this molecule has yet to emerge, and recent calculations of features of potential energy surfaces relevant to its photofragmentations have proved to be very useful (4). By comparison, little experimental and less theoretical work has been reported on other similar tetraatomic carbonyls, such as the carbonyl halides, a notable exception is an SCF-CI study (5) on the vertical electronic spectrum of $F_2CO$. Tetraatomic carbonyl halides are the subject of the present study.

Recently we reported the results of *ab initio* SCF-MO calculations on the ground and lowest triplet states of several thiocarbonyl compounds (6–8). It was shown that reasonable agreement between computed and experimental ground and lowest triplet equilibrium geometries could be obtained for these molecules even when an economical STO-3G basis set was used. In addition, good estimates of the triplet state inversion frequencies could be obtained by solving the vibrational eigenvalue problem after *ab initio* calculation of the triplet energies at several points along the out-of-plane bending coordinates. A more thorough *ab initio* study of the ground state structures of $H_2CO$, HFCO, HClCO, $F_2CO$, $Cl_2CO$, ClFCO, $H_2CS$, and $F_2CS$ has recently been reported by Oberhammer and Boggs (9). In that work SCF-MO calculations were performed using the Hartree–Fock gradient program of Pulay (10). When 4-21 basis sets were used for second row atoms and 3-3-21 basis sets supplemented with *d* orbitals were used for sulfur and chlorine, good agreement between calculated and experimental geometries was found. With the exception of studies of HFCO and $F_2CO$ (5, 11–12), however, *ab initio* calculations have not been performed on excited states of the tetraatomic carbonyl halides, although several semi-empirical studies have been reported (13–16).

In this paper we present the results of calculations of the lowest triplet state structures and inversion vibrational frequencies of $H_2CO$, HFCO, $F_2CO$, $Cl_2CO$, and ClFCO. Ground state geometries have also been calculated for comparison with previous work.

## Methods of calculation

The *ab initio* calculations were carried out using a modified version of Gaussian-70 (17) adapted for a 36 bit word DEC 2060 computer. The equilibrium geometries of $H_2CO$ and HFCO in their lowest triplet states were obtained by sequential, cyclic optimization of all geometric parameters using both the STO-3G and 4-31G basis sets. In addition, seven other points lying along the out-of-plane bending coordinate on one side of the double minimum potential surface were calculated for these two molecules with both basis sets. For these latter points, all geometric parameters except the out-of-plane angle, $\theta$, were optimized. The equilibrium geometries and energies at various out-of-

plane angles in the lowest triplet states of $F_2CO$, ClFCO, and $Cl_2CO$ were calculated similarly, except that only the more economical STO-3G basis set was employed. For purposes of comparison with previous work, the equilibrium geometries of all five ground state molecules were calculated using the STO-3G basis set and those of $H_2CO$, HFCO, and $F_2CO$ using the 4-31G basis set.

The calculated SCF energies along the out-of-plane bending coordinates of the lowest triplet states of all five molecules were used to find (using a non-linear least-squares fitting program) best values of the parameters, $\lambda$, $A$, and $a^2$, defining the shape of the double minimum potential function (18, 19),

$$[1] \quad V(Q_6) = \frac{1}{2}\lambda Q_6^2 + A \exp(-a^2 Q_6^2)$$

Here $Q_6$ is the mass-weighted out-of-plane bending coordinate whose values must be calculated from the corresponding out-of-plane angles, $\theta$. The eigenvalues and eigenvectors for the inversion vibration were obtained as previously described (6, 7). The vibrational eigenvalues, in multiples of $hc\nu_0$, measured relative to the potential minima, can be obtained in the form (18)

$$[2] \quad \frac{G}{\nu_0} = \frac{E}{hc\nu_0} - \frac{B(\rho + 1)}{(e^\rho - \rho - 1)}$$

where $B = b/\nu_0$ is a dimensionless parameter proportional to the barrier height, $b$; $\rho$ is a shape factor defined by $a^2 = e^\rho\lambda/2A$, and $\nu_0$ is the wavenumber (in $cm^{-1}$) of the harmonic oscillator appropriate to the parabolic part of the potential and is given by $\nu_0 = \lambda^{1/2}/2\pi c$.

Past experience (6, 7) has shown that the eigenvalues are very sensitive to the number of harmonic oscillator basis functions taken and that the number of basis functions required for convergence may be strongly dependent on $\rho$. In the present work, the number of vibrational basis functions has arbitrarily been set to 100. Increasing this number led to no significant numerical change in any of the calculated eigenvalues.

A general method of transforming the out-of-plane angle, $\theta$, to the corresponding mass-weighted coordinate, $Q_6$, involves the use of the appropriate matrix element, $G_{66}$ (ref. 20. For molecules of $C_s$ symmetry the matrix element is $G_{66}$ but is $G_{44}$ for $C_{2v}$ molecules. Here $G_{66}$ is used throughout for convenience). An analytic expression for the $G_{66}$ matrix element of tetraatomic molecules having either $C_{2v}$ or $C_s$ equilibrium symmetry has recently been described (21) and was used in the present work. $Q_6$ and $\theta$ are related via

$$[3] \quad Q_6 = \int_0^\theta G_{66}^{-1/2}\, d\theta$$

and three approximate methods of carrying out this $Q_6$–$\theta$ transformation have been outlined and compared previously (21). The model involves the "best" energy values obtained along the optimized "relaxed" inversion path (corresponding to a non-rigid bender model), combined with the application of a vibrational Hamiltonian preserving some features of a rigid bender. That is, the results refer to a rigid bender model where the energy values along the bending coordinate are replaced by those of the non-rigid molecule. The most general and most accurate of these three methods, involving truncation of the series solution to [3] only after the fourth term, has been used in the present work.

## Results and discussion

The calculated and experimental ground state geometries for the tetraatomic carbonyls considered in this study are given in Table 1. The data of Oberhammer and Boggs (9) are included for comparison. As expected, calculations with the 4-31G basis set reproduce the measured ground state geometries better than those with the STO-3G basis set. It has been noted previously (9, 12) that the use of the latter basis set results in a systematic underestimation of the C=O bond shortening effects of electron-withdrawing substituents. Moreover, the C—Cl bond lengths are systematically overestimated, by as much as 5% in the case of ClFCO. On the other hand, calculations with the 4-31G basis give quite satisfactory agreement with experiment when the differences between the definitions of the calculated and the experimentally measured bond lengths are accounted for (for a discussion of this point see ref. 28).

Despite the fact that either the 4-31G basis set or those used by Oberhammer and Boggs (9) give better ground state geometries, general trends in the predicted geometries are correctly reproduced with the STO-3G basis. Since we were primarily interested in obtaining estimates of the lowest triplet inversion barriers and out-of-plane bending mode frequencies, and since a large number of points along the double minimum paths had to be calculated to do so, only the STO-3G basis set was used for the $F_2CO$, ClFCO, and $Cl_2CO$ triplets.

Table 2 shows the predicted equilibrium geometries and inversion barrier heights for the lowest

triplet states of this series of five tetraatomic carbonyls. Experimental data for θ and $b$ are available only for $H_2CO(^3A'')$, although crude estimates of these quantities may be obtained for triplet HFCO, $F_2CO$, and $Cl_2CO$ from measurements on the corresponding $^1(n,\pi^*)$ states. Thus, there is only limited opportunity to judge the accuracy of the calculated results. Nevertheless, qualitatively the results appear to be reasonable. The C—O bond length generally increases with increasing electronegativity of the substitutent groups ($H_2CO \approx Cl_2CO <$ HFCO ≈ ClFCO < $F_2CO$), and the predicted extent of non-planarity of these triplets is generally in accord with the Walsh postulates (29). As previously noted from CNDO/2 calculations on $n,\pi^*$ states of several carbonyls (13), the change in $p_z$ electron density on the central carbon atom in proceeding from the planar to the equilibrium non-planar conformation, $\Delta\rho(p_z)$, may be correlated with the magnitude of the equilibrium out-of-plane angle and the inversion barrier height. The data for the five molecules chosen for the present study is given in Table 3. In fact, over the range of out-of-plane angles encountered in these five molecules, a linear relationship exists between $\Delta\rho(p_z)$ and $\theta_e$, as shown in Fig. 1. Such a relationship was also observed for a similar series of thiocarbonyl triplets (6, 7) and lends quantitative support to Walsh's Rule.

Figure 2 shows the variation of potential energy along the out-of-plane bending coordinate for all five molecules, calculated with the STO-3G basis set. Only small differences between the parabolic parts of these double minimum curves and those calculated with the 4-31G basis set were noted for HFCO, as illustrated in Fig. 3. The calculated barrier heights were particularly sensitive to choice of basis set for $H_2CO$, however, and, perhaps

fortuitously, better agreement with experiment (19) ($\theta = 37.9°$, $b = 775.6$ cm$^{-1}$) was found when the STO-3G basis was employed. Nevertheless, with either basis set the expected trend in variation of barrier height with electron-withdrawing power of the substituent atoms is predicted. If the order of increasing barrier heights is the same for the $^3A''$ states as for the $^1A''$ states, then the predicted trend is confirmed by experimental data. For the $^1A''$

states of $H_2CO$, HFCO, $Cl_2CO$, and $F_2CO$ barrier heights of 356.2, 2550, 2170, and >4000 $cm^{-1}$, respectively, have been measured (19, 30–32).

The only direct, quantitative comparison that can be made between experimental and the present calculated lowest triplet state geometries is for formaldehyde. For this molecule agreement between the calculated and the measured equilibrium geometry is relatively poor when either basis set is used, compared with the ground state. Similar difficulties in calculating "good" equilibrium geometries and, in particular, inversion barrier heights for the lowest excited states of formaldehyde have been encountered even when more extensive basis sets and CI methods have been used (11, 33, 34). The fact that there is relatively close agreement between the STO-3G calculated inversion barrier (700 $cm^{-1}$) and the experimental barrier (775.6 $cm^{-1}$) deduced from out-of-plane bending frequencies observed in the $^3A'' \leftarrow {}^1A'$ absorption spectrum of $H_2CO$ (19) must therefore be regarded as fortuitous. Nevertheless, on the basis of comparisons with the triplet thiocarbonyl halides (6, 7, 35), for which more extensive experimental data are available, the worst agreement between experiment and calculation might be expected for the molecules with the lowest barriers; $H_2CZ$ (Z = O, S). Recent results on $H_2CS$ have indicated that in our earlier study, the UHF method produced convergence to a solution dominated by a higher triplet state, possibly due to an erratic convergence of density matrices (36), and the poor agreement with experiment is likely to stem from this, as well as from the approximation used to calculate bond angles, valid only in the case of small amplitudes and small out-of-plane angles (37). We have assumed that the relative potential energies along the out-of-plane bending coordinates, calculated in the present study with a minimal basis set, can be used to give reasonable first estimates of the lowest triplet inversion frequencies in the carbonyl halides. These data are not readily obtainable from spectral measurements.

Table 4 presents the predicted eigenvalues of the out-of-plane bending vibrations of the carbonyl halide triplets, relative to the zero point levels which are assigned energies of zero. Also shown are the values of $\rho$, $b$, and $\nu_0$ which provide the best fit of the potential function, eq. [1], to the potentials calculated with the STO-3G basis set, and values of $G(0^+)$, the estimated zero-point energies. Four and five significant figures are quoted in this table only to provide estimates of the resolving power which might be required to observe inversion splittings in the $^3A'' \leftarrow {}^1A'$ near uv absorption spectra of these compounds.

# Charge distributions and chemical effects. XXVI. Relationships between nuclear magnetic resonance shifts and atomic charges for $^{17}O$ nuclei in ethers and carbonyl compounds

MARIE-THÉRÈSE BÉRALDIN, EDOUARD VAUTHIER,[1] AND SÁNDOR FLISZÁR

*Department of Chemistry, Université de Montréal, Montreal, P.Q., Canada H3C 3V1*

Received May 21, 1981

MARIE-THÉRÈSE BÉRALDIN, EDOUARD VAUTHIER, and SÁNDOR FLISZÁR. Can. J. Chem. **60**, 106 (1982).

The $^{17}O$ nuclear magnetic resonance shifts of dialkylethers are linearly related to the electron populations on the oxygen atoms, in a range covering L ~ 130 ppm, showing that any increase of electronic charge at the oxygen atom is accompanied by a downfield nmr shift. The opposite trend is observed for the oxygen atoms of ketones and aldehydes.

MARIE-THÉRÈSE BÉRALDIN, EDOUARD VAUTHIER et SÁNDOR FLISZÁR. Can. J. Chem. **60**, 106 (1982).

Les déplacements chimiques des noyaux $^{17}O$ dans les éthers aliphatiques sont linéairement reliés aux populations électroniques des atomes d'oxygène, dans un domaine couvrant L ~ 130 ppm, toute augmentation de population électronique se manifestant par un déplacement vers les champs faibles. L'effet opposé est observé pour l'oxygène des cétones et des aldéhydes.

## Introduction

Our prime interest in correlations between nuclear magnetic resonance shifts and atomic electron populations originates in the need for practical means enabling the evaluation of atomic charges. The latter play, indeed, an essential role in a number of problems concerning charge-dependent molecular properties, such as thermochemical stabilities (1). Therefore, the theoretical calculation of atomic charges being usually difficult and costly in large systems of chemical interest, while chemical shifts are more readily accessible from experiment, it is felt that some detailed knowledge about charge/shift trends is desirable, despite the fact that the significance or generality of such empirical correlations is not known.

Any attempt at correlating nuclear magnetic resonance shifts with electron populations implies two basic assumptions, namely, (*i*) that one of the major factors governing the shielding of a specific nucleus is its local electron density and (*ii*) that the theoretical method selected for the charge analysis is capable of giving correct results.

Both assumptions are, to a certain extent, empirically justified by simple charge/shift relationships which are verified in a number of occasions (mainly for $^{13}C$ nuclei) in series of closely related compounds. Any additional verification, like the one presented here for $^{17}O$ nuclei in aliphatic ethers, is made with the reservation that results of this sort should not be used to lend unintended support for the unwarranted view that they are necessarily valid in all systems. Of course the validity of any correlation between experimental chemical shifts and calculated atomic charges clearly depends on the validity of the theoretical charge analysis. Interestingly enough, little consideration is usually given to the latter point and a number of different theoretical methods, both semi-empirical and *ab initio*, are used almost indiscriminately for calculating atomic charges for use in charge/shift correlations. A few basic aspects pertaining to this problem are briefly examined as follows.

## Population analysis

Atomic charges are calculated following Mulliken's analysis (2) assuming, however, a more general mode of distributing overlap populations in heteropolar situations. The net (i.e., nuclear minus electronic) charge $q_k$ of atom $k$ is then

$$[2] \quad q_k = q_k^{\text{Mulliken}} + \sum_{l \neq k} p_{kl}$$

where $\sum_{l \neq k} p_{kl}$ is the correction resulting from the departure from the usual halving of the overlap terms (3–5). The overlap populations involving specified $kl$ atom pairs under comparable situations being practically the same in series of closely related compounds, a valid approximation (at least in $\sigma$ systems) is obtained by assuming a constant $p_{kl}$ term for each type of $kl$ bond formed by atom $k$ (4,

5).[2] Consequently, anytime $k$ is engaged in the same binding (e.g., in the comparison of the ethane carbon with that of any other $CH_3$ group attached to a $sp^3$ carbon) we apply the same $\sum_{l \neq k} p_{kl}$ correction and find $\Delta q_k = \Delta q_k{}^{\text{Mulliken}}$. This is, namely, the case in the calculation of charge increments in comparisons involving ether oxygens, for which we use $\Delta q_o = \Delta q_o{}^{\text{Mulliken}}$.

Regarding the quality of the wave functions, it has appeared that both semi-empirical and *ab initio* methods yield charge analyses describing a number of relevant trends in quite similar and consistent fashion, despite the fact that numerically the calculated charges differ, sometimes considerably, from method to method. Detailed comparisons of this sort were presented earlier (6, 7), showing that the most consistent results are obtained from STO-3G calculations involving full optimization of all variational parameters. In this way, detailed and subtle structure-related charge effects were recognized in saturated and ethylenic hydrocarbons (5, 8). On the other hand, lack of full geometry and $\zeta$ exponent optimization does not usually prevent the, somewhat less precise, reproduction of the major trends. In short, STO-3G wave functions appear to be quite adequate for deducing consistent atomic charges, permitting valid comparisons, although they are by no means unique in that respect (4–6).

## Results

The STO-3G calculations were carried out following Pople's recipe, with $r_{CH} = 1.09$, $r_{CC} = 1.54$, $r_{CO} = 1.43$ Å and all angles set at 109.47122° (9), using standard $\zeta$ scale factors, i.e., 5.67 (C1s), 1.79 (C2$s$2$p$), 7.66 (O1$s$), 2.24 (O2$s$2$p$), and 1.18 (H), as determined by Hehre and Pople (10). The Mulliken population analyses are indicated in Table 1.

The net $[Z_k - N(k)]$ atomic charges $q_o$ on the oxygen atoms clearly indicate a build-up of electronic charge with increasing electron-releasing ability of the substituents, reflecting the customary inductive effects. A comparison of the ionisation potentials[3] with the oxygen net charges yields a correlation, IP = $0.0274q_o$ + 18.16 eV (with an average error of 0.040 eV and a correlation coefficient of 0.9914), which reflects the expectation that electron withdrawal becomes easier as the oxygen atom becomes electron-richer. This result is worth mentioning because it illustrates a physical aspect linked to the ordering of the oxygen charges given by Mulliken's analysis, in full agreement with all known aspects related to the inductive effects of alkyl groups. In short, it can be assumed with confidence that the oxygen atom in, say, di-*tert*-butylether is electron-richer than that of dimethylether. This confidence is important in the following comparisons involving $^{17}O$ nuclear magnetic resonance shifts (Table 2, Fig. 1).

These results indicate that *in aliphatic ethers, any gain in electronic charge at the oxygen atom is accompanied by a downfield $^{17}O$ nmr shift*. At variance with the commonly held view that any increase in local electron population should bring about a shielding of the nucleus in question and, hence, an upfield shift, this result is the clear echo of a conclusion reached earlier (4, 5, 13), namely, that *in aliphatic and in six-membered (chair and boat) cycloalkanes any gain in electronic charge at an* $sp^3$ *carbon atom is accompanied by a downfield $^{13}C$ nmr shift*. However, contrary to the case of the ether oxygen atoms, whose charge increments $\Delta q_o$ are directly given by differences in Mulliken atomic populations, for carbon atoms use is made of eq. [1]. At this point it is important to stress that this type of analysis for carbon does *not* introduce any artifact which could be held responsible for the conclusion reached above. Indeed, the same conclusion follows from a comparison involving only $CH_3$ carbon atoms and the corresponding Mulliken populations, because the $\sum p_{kl}$ terms of primary carbons cancel in the calculation of the charge increments $\Delta q_c$ relative to ethane.[4]

It is also important to stress that the shift/charge trends exhibited by the ether oxygen and the $sp^3$ carbon atoms are by no means generally valid. Indeed, using exactly the same charge analysis (eq.

[2]For saturated hydrocarbons, it follows, in this approximation, that $q_H = q_H{}^{\text{Mulliken}} - p_{CH}$ and $q_c = q_c{}^{\text{Mulliken}} + N_{CH}p_{CH}$, where $N_{CH}$ is the number of hydrogen atoms bonded to C. This example shows that if $p_{CH}$ is the error introduced with one CH bond by halving all overlap populations, then the total correction required in calculating $q_c$ simply depends on the number of CH bonds formed by that particular carbon atom.

[3]The ionization potentials (11) used in this comparison are 10.00 (dimethylether), 9.53 (diethylether), 9.27 (di-*n*-propylether), and 9.20 eV (diisopropylether).

[4]For example, the $CH_3$ carbon of diisopropylether (δ 23 ppm from TMS) has a Mulliken net charge of ~ −30.9 me, whereas the primary carbon in diethylether has a Mulliken charge of ~ −28.3 me with δ 15.4 ppm from TMS. These charges were obtained from one cycle of optimizations involving the geometries and the scale factors. While these charges are not true optimum values, they clearly reflect a downfield shift with increasing electron population, as described earlier (4, 5, 13) for $sp^3$ carbon atoms. Indeed, the $CH_3$-carbon net charges obtained from fully optimized STO-3G calculations using Mulliken's population analysis are −20.96 me (δ 5.8 ppm from TMS) for ethane, −23.81 (δ 15.6) for propane, −26.39 (δ 24.3) for isobutane, and −28.66 me (δ 31.5) for neopentane (5).

[1]) as for the $sp^3$ carbon atoms, it was shown for a series of ethylenic compounds that *any gain in electronic charge at* $sp^2$ *carbon atoms is accompanied by an upfield nmr shift* (8). An examination of results obtained for selected aldehydes and ketones now reveals that *an electron enrichment at carbonyl oxygen atoms is accompanied by an upfield* $^{17}O$ *nmr shift* (Table 3), just as it is the case for $sp^2$ carbon atoms. However, because of the narrow range of $\Delta q_0$ variations, lack of precision (~1–2 me) accompanying standard STO-3G calculations makes it difficult to assess how accurately carbonyl-$^{17}O$ nmr shifts and charges are related to one another. Interestingly, the comparison of the carbonyl-$^{13}C$ nmr shifts with net charges (Fig. 2) indicates the same trend as that observed for $sp^3$ carbon atoms in paraffins, namely, a highfield shift with increasing positive net charge.

While these charge/shift correlations clearly illustrate what is understood by the reservation that results obtained for a given nucleus in a well-defined series of compounds should not be unduly generalized; it also appears that, under proper circumstances, chemical shifts are capable of giving in a simple manner useful information about

*The nmr shifts of oxygen (ppm from water) and carbon (ppm from TMS) are extracted from ref. 14. The numbering corresponds to the points in Fig. 2.

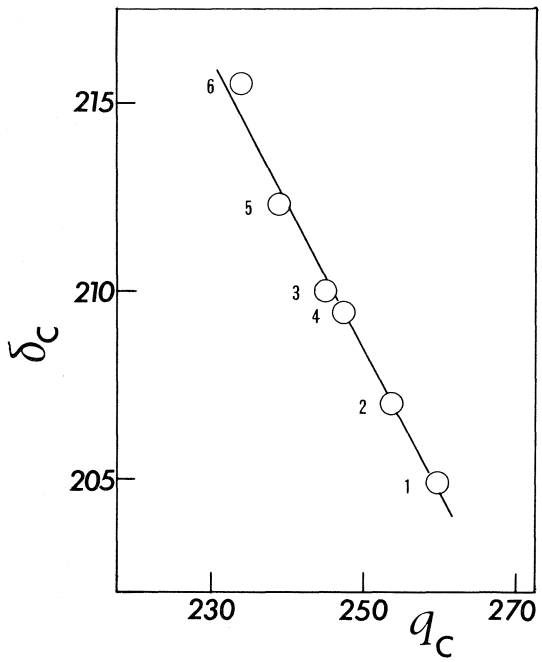

FIG. 2. Comparison of ketone carbonyl – $^{13}C$ nmr shifts (ppm) with net atomic charges (me).

local charges. The use of shift-derived atomic charges of $sp^3$ carbon atoms in the study of charge-dependent thermodynamic properties (1) has met with success, reflected by the accuracy of the calculations in comparisons with experimental results. For future use in the calculation of the enthalpies of formation (and related quantities) of oxygen-containing compounds, we shall now examine more closely the results obtained for the ethers.

In the first place, it is clear that the trends in electron populations at the ROR′ ether oxygen atoms reflect the electron releasing (or withdrawing) abilities of the R,R′ alkyl groups, just as it is the case with the methylene carbons in $RCH_2R'$ hydrocarbons. Since for the ether oxygen and the $sp^3$ carbon atoms it now appears that chemical shifts and atomic charges are linearly related to one another, it follows that the $^{17}O$ nmr shifts of the ROR′ ethers are expected to correlate with the methylene $^{13}C$ shifts of the corresponding $RCH_2R'$ hydrocarbons. This is, indeed, the case, as demonstrated convincingly by Delseth and Kintzinger (12). Moreover, similar correlations (12) between the $^{13}C$ shifts of the carbon atoms in ROR′ ethers and those of the "parent" $RCH_2R'$ hydrocarbons clearly reflect the close correspondence in the structure related effects which govern electron distributions indicating, namely, that the individual C atoms of the alkyl part of the ethers behave quite like hydrocarbon C atoms.

Now, for $sp^3$ carbon atoms, the equation

$$[2] \quad \delta_c = -(237.1/q_c^\circ)\Delta q_c$$

relating their nmr shifts (relative to ethane) to their charge increments (relative to the ethane-C net charge $q_c^\circ$) is accurate in a range of ~40 ppm (at least), with a standard deviation of ~0.3 ppm (4, 5, 13). The charges used in deriving eq. [2] were deduced by means of eq. [1] on the basis of fully optimized STO-3G calculations.[5] In order to deduce an expression for $^{17}O$ nuclei on the same footing as eq. [2], we have carried out an extensive geometry and exponent optimization for the dimethyl-, diethyl-, and diisopropyl-ethers. Although it has appeared that one cycle of optimization is not sufficient for obtaining stable charges for the carbon and hydrogen atoms, which are particularly sensitive to small errors in $\zeta$ exponents, it has also appeared that this type of imperfection in the C and H exponents has little effect on the oxygen charges provided, of course, that the oxygen exponents are properly optimized. Under these conditions, the oxygen STO-3G Mulliken charges of dimethylether (−267 me), diethylether (−295 me), and diisopropylether (−322 me) indicate that the $\delta_o$ vs. $q_o$ slope is ~1/1.8 that of the corresponding $\delta_c$ vs. $q_c$ slope, obtained from the same basis set, *i.e.*

$$\Delta\delta_o/\Delta q_o \simeq (\Delta\delta_c/\Delta q_c)/1.8$$

Consequently, using now the $q_c^\circ = 35.1$ me value determined earlier (1*a*), we obtain from eq. [2] that

$$[3] \quad \Delta q_c = -0.148\delta_c \text{ (me)}$$

$$[4] \quad \Delta q_o = -0.267\delta_o \text{ (me)}$$

These relationships now enable a rapid estimate of atomic charges on the scale which has proven

[5]The validity of eq. [2] does not depend upon the particular choice of the theoretical method selected for calculating charges, since $\Delta q_c/q_c^\circ$ is dimensionless. The $q_c^\circ$ and $\Delta q_c$ values, however, depend on the quality of the wave functions. Fully optimized STO-3G calculations give $q_c^\circ = 69.40$ me (5–7) and larger basis sets lead to a lowering of this value, e.g. 60.0 me (7*s*3*p*/3*s*) and 58 me (6–31G), while the optimum value appears to be 35.1 me (1*a*). Similarly, the $p_{CH}$ value also depends on the quality of the basis set and is, for STO-3G calculations involving full optimization of all variational parameters, $p_{CH} = 30.12$ me (from $^{13}C$ nmr shifts), 30.3 ± 0.3 me (from energies of atomization), and ~ 30.15 invoking the postulate that the carbon net charges in saturated hydrocarbons differ as little as possible from one another (4–6). Finally eq. [2] can be applied directly using SCF-Xα-SW electron populations which are *not* a product of Mulliken's scheme for calculating charges (15).

satisfactory for deriving accurately charge-dependent molecular properties involving $sp^3$ carbon atoms. Applications to the study of thermodynamic properties of ethers are presented in a forthcoming paper, along the lines which have led to accurate calculations of saturated hydrocarbons (1*a*).

The physical reasons underlying the observed charge–shift correlations can be roughly described as follows. Extensive gauge invariant calculations of chemical shifts indicate that for atoms other than hydrogen one can safely neglect the three-center integrals (16), meaning that the shielding is mainly governed by "local" charges. It also appears that the variations in local diamagnetic contributions to the total shielding are, indeed, minor and that the major variations are associated with the paramagnetic contributions which reflect most of the "local" charge effect. Specifically, any increase in electron population is accompanied by a more negative paramagnetic contribution, which is a deshielding effect (17). This general behavior is well illustrated by the $sp^3$ carbon atoms (where the variations in charge occur mainly at the 2*s* level) and the ether oxygens (where the main variations occur at the 2*p* level). Present results suggest that the effect of varying the population at the 2*p* level is significantly less pronounced than that of changing the population at the 2*s* level, as regards the accompanying variations in chemical shifts. This observation possibly explains the fact that for vinylic carbon and carbonyl oxygen atoms an increase in total electronic charge is reflected in a highfield shift. In these cases, indeed, $\sigma$ and $\pi$ electron populations vary in an inverse manner (8, 17, 18) so that an increase in $\pi$ population results in a deshielding accompanied by an inverse effect due to the decrease in $\sigma$ population. The effect of the latter being more pronounced results eventually in a highfield shift although the loss in $\sigma$ population is not quite as important as the gain in $\pi$ population, for a total gain in $(\sigma + \pi)$ electron population. A detailed numerical analysis based on theoretical shift calculations is presented elsewhere (17).

## Conclusions

In aliphatic ethers, any gain in electronic charge at the oxygen atom is accompanied by a downfield $^{17}O$ nmr shift, while the opposite trend is observed with carbonyl oxygen atoms. The general behavior of the ether oxygen atoms is thus similar to that of $sp^3$ carbons whereas carbonyl oxygen atoms exhibit the same trends as $sp^2$ carbon atoms. While these results show that any evaluation of charge/shift trends should be confined to series of closely related compounds, it also appears that the ether $^{17}O$ nmr shifts are linearly related to local electron populations. The $\Delta q_o/\Delta\delta_o$ slope is $\sim 1.8$ times that of $\Delta q_c/\Delta\delta_c$ for $sp^3$ carbon atoms. The discussion of these trends in terms of Mulliken population analyses shows that they are not an artifact due to a particular mode of partitioning overlap population terms.

# Modified phosphotriester method for chemical synthesis of ribooligonucleotides. Part I. Synthesis of riboundecaadenylate and two fragments constituting the sequence of R-17 translation control signal

WING L. SUNG AND SARAN A. NARANG

*Division of Biological Sciences,[1] National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6*

Received August 4, 1981

WING L. SUNG and SARAN A. NARANG. Can. J. Chem. **60**, 111 (1982).

A modified phosphotriester method has been successfully applied for the chemical synthesis of ribooligonucleotides. The starting material is a fully protected ribomononucleoside containing a 3′-phosphotriester group **5**. The coupling reaction is performed using mesitylenesulfonyl tetrazole and purification of the product achieved using reversed phase column chromatography. The effectiveness of this method has been demonstrated by achieving an efficient and rapid synthesis of r-$A_7$, r-$A_{11}$, r5′-AAACAUGAGGA-3′, and r5′-UUACCCAUGU-3′ (R-17, translation control sequence).

WING L. SUNG et SARAN A. NARANG. Can. J. Chem. **60**, 111 (1982).

On a appliqué avec succès une méthode de phosphotriester modifié à la synthèse chimique des ribooligonucléotides. On utilise comme produit de départ un ribonucléoside entièrement protégé contenant un groupe phosphotriester en position 3′(**5**). On a réalisé le couplage en utilisant le mésitylène sulfonyle tétrazole et on a purifié le produit par chromatographie sur colonne en phase inversée. On démontre l'efficacité de cette méthode en réalisant une synthèse rapide et efficace du r-$A_7$, r-$A_{11}$, r5′-AAACAUGAGGA-3′ et du r5′-UUACCCAUGU-3′ (R-17, unité de contrôle de translation).

[Traduit par le journal]

## Introduction

The availability of ribooligonucleotides of well-defined sequence is of great importance in the biological studies of various RNA-regulatory signals, understanding the splicing mechanism of introns and the synthesis of biologically active RNA molecules such as t-RNA or 5S RNA. The recent discovery that $T_4$-RNA ligase enzyme (1) can join small fragments of RNA end to end without their complementary strand offers an additional impetus for the development of an efficient and rapid method of chemical synthesis. In spite of these incentives, progress in chemical synthesis of ribooligonucleotides has lagged behind deoxy synthesis (2). Although the phosphodiester approach was successfully applied by Khorana and coworkers (3) to synthesize all 64 triplet RNA codons, its application to the synthesis of longer sequences is quite laborious (4). Even use of the phosphotriester approach (5), the phosphite modification (6), or solid phase techniques (7) have only very recently proved capable of synthesizing defined sequences of oligoribonucleotides (8–11) with length of 9–16 units, that are of biological interest.

The main difficulty is the presence of an additional 2′-hydroxyl group, the protection of which presents the most critical problems at all stages of ribooligonucleotide synthesis. At the monomer stage, specificity between the 2′- and 3′-hydroxyls must be achieved; any protecting group must be stable enough to remain intact throughout an extended synthesis yet be complementary in its chemical behaviour, i.e. for selective removal to other protecting groups. Increasingly effective phosphorylation/condensation conditions involving the 3′-hydroxyl must be devised to overcome the additional steric hindrance from the protected 2′-hydroxyl group. Finally deprotection must occur under conditions which prevent any 3′ to 2′ migration of the internucleotidic phosphodiester linkages. The most commonly utilized 2′-hydroxyl protecting groups are substituted tetrahydropyran (9) and *O*-nitrobenzyl (12), but their introduction requires multiple chemical steps, whereas *tert*-butyldimethyl silyl (TBDMS), a bulkier protecting group, has been employed by Ogilvie *et al* (13). The main advantages of this protecting group are its ease of protecting the 2′-hydroxyl function and also stability towards acidic and basic conditions in order to avoid migration and cleavage of 3′ → 5′ phosphodiester linkages.

In this study we present a practical solution to the ribopolynucleotide synthesis by employing the modified phosphotriester approach (14) developed in our laboratory for the deoxy series. The basic feature of our approach is to start the synthesis of an oligonucleotide from the fully protected ribomononucleoside containing the 3′-phosphotriester group **5**. Since each intermediate oligonucleotide synthesized thus contained the fully masked 3′-phosphate group, the necessity for a phosphorylation step at each condensation stage was eliminated.

Rapid condensations and simple chromatographic purification of intermediates make this approach comparable in speed to polymer support or phosphite techniques with additional advantages of simplicity in handling the large-scale synthesis. In this paper we wish to demonstrate its application in the efficient synthesis of r-$A_7$, r-$A_{11}$, r-AAACAUGAGGA, and r-UUAACCAUGU fragments. The heterosequence fragments constitute a natural sequence of the R-17 translation control signal (15) (Fig. 1). The sequence of each synthetic fragment has been analyzed by the mobility shift method (16) and the radioaudiograms are shown in Fig. 5.

## Discussion

### *Large-scale preparation of fully protected ribomononucleoside 3′-phosphotriester* 5

In our present studies we chose the *tert*-butyldimethyl silyl protecting group (TBDMS) for the 2′-hydroxyl which was easily prepared by treating **1** with *tert*-butyldimethyl silyl chloride and imidazole (13); a mixture of 2′- and 3′-monoprotected isomers was produced. Previously, these isomers were purified by preparative thin layer chromatography (13) which would not be suitable for any large-scale synthesis because of economic and time factors. We have effectively solved this problem using short silica gel column chromatography to collect a pure fraction containing the faster moving 2′-protected isomer. The remaining mixture was eluted from the column and further equilibrated to a mixture of 2′- and 3′-isomers with triethylamine–methanol. On subsequent chromatography, more of the pure 2′-protected isomer was isolated. Repetition of this sequence three times produced pure 2′-protected isomer (25–30 g, 45–64% isolated yield) in less than 7 h. The general method of preparation is outlined in Fig. 2.

The presence of *tert*-butyldimethyl silyl, a bulkier protecting group, at the 2′-position makes the 3′-hydroxyl function less accessible to the phosphorylation reaction due to steric hindrance. Consequently, phosphorylation with *p*-chlorophenyl phosphoryl ditriazolide (17) in dioxane with a stoichiometric amount of triethylamine was found to be slow (overnight) and migration of the 2′-protecting group to the 3′-hydroxyl was also observed under these conditions, possibly due to the presence of residual triethylamine. Obviously, a more powerful phosphorylating reagent was required to phosphorylate the 3′-position quantitatively in a minimum time period to avoid possible migration of the 2′-silyl protecting group. We next attempted phosphorylation with *p*-chlorophenyl phosphoryl ditetrazolide (Fig. 3). As expected, the phosphorylation reaction was over in less than 5 min without any migration and on subsequent addition of β-

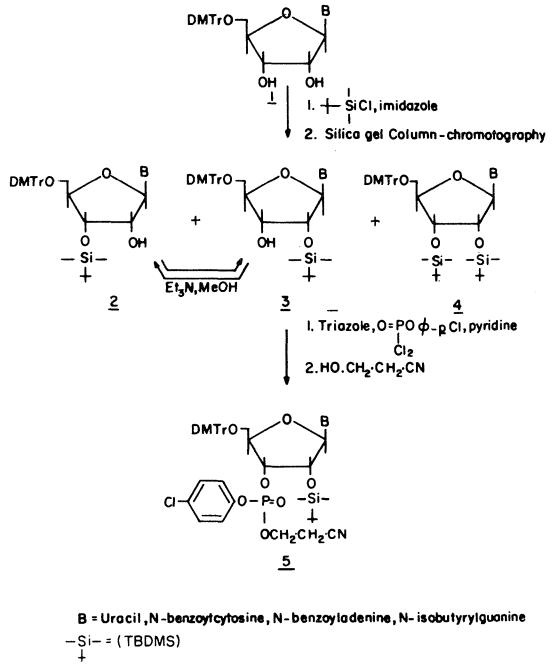

FIG. 2. General method of preparation of fully protected ribomononucleoside containing 3′-phosphotriester group.

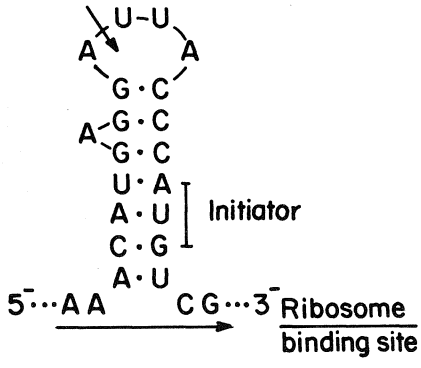

FIG. 1. Sequence of R-17 translational control region.

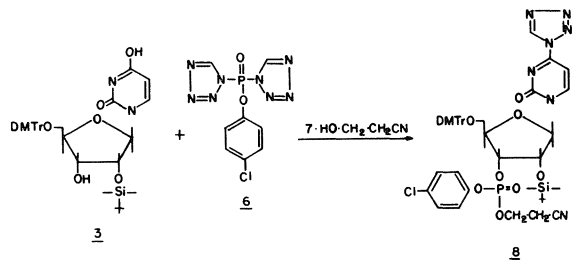

FIG. 3. Modification of uridine moiety.

cyanoethanol, a fully protected ribomononucleotide was prepared and isolated by short silica gel column chromatography in about 70–80% yield. However, in the case of 5′,2′-protected uridine, we observed an unexpected maxima of 324 nm in uv spectra analysis in addition to the regular maximum at 259 nm. Mass spectrometric analysis by the plasma absorption technique (18) also showed an unexpected increase of 52 units in the mass value, which is equivalent to addition of a tetrazole moiety.[2] On complete deblocking the unprotected nucleotidic material had a uv spectra identical to cytidine. Obviously, *p*-chlorophenyl phosphoryl ditetrazolide reagent has introduced a tetrazole moiety at the 4-position of uridine as shown in Fig 3. Subsequently, we discovered that Reese and Ubasawa (19) have also observed a similar modification on prolonged treatment with mesitylenesulfonyl tetrazolide and diphenylphosphate. We overcame this problem by modifying our original phosphorylation procedure by treating 5′-dimethoxytrityl ribomononucleoside 2′-*tert*-butyldimethyl silyl protected compound **3** with *p*-chlorophenyl phosphodichloridate in the presence of excess triazole in pyridine[3] solution *in situ*. Under these conditions, the phosphorylation reaction at the 3′-position was complete in less than 5 min and on subsequent treatment with an excess of β-cyanoethanol the fully protected desired mononucleotide **5** was prepared in 70–80% yield. Under these reaction conditions, no modification and migration were observed. Each of the four fully protected monoribonucleotides in 20–30 g amounts was easily purified on a short reversed phase silanized silica gel column and stored as a dry foamy material at 4°C.

*Modified procedure for amino group protection of cytidine*

Generally, *N*-protection in the case of cytidine, adenosine, and guanosine involves the complete acylation of all the hydroxyl as well as amino functions followed by partial deacylation with sodium hydroxide to generate *N*-protected compound. In the case of cytidine, we have developed a "one-pot" method in which the hydroxyl groups are first silylated on treatment with trimethylsilylchloride followed by the addition of benzoyl chloride *in situ* to benzoylate the amino function. The reaction mixture was decomposed with water–dichloromethane followed by evaporation *in vacuo*. The *O*-silyl groups are hydrolyzed by the benzoic acid produced *in situ* to yield a pure *N*-benzoylated cytidine in quantitative yield. Unfortunately, similar approaches to produce *N*-protected adenosine and guanosine were not successful.

*Di-isopropylamine as a more efficient reagent for the selective removal of the β-cyanoethyl group from* **5**

In our synthetic studies of deoxyribooligonucleotides, it became apparent that a most time-consuming part is the decyanoethylation of the 3′-phosphotriester group **5** on treatment with triethylamine–pyridine (20) (pyrimidine bases required 4 h and purines 2 h). Even in the case of dimer or trimer blocks, the rate of removal of the β-cyanoethyl group was dependent on the nature of the 3′-terminal base. In order to improve on this aspect we examined a variety of bases and found a more suitable base, di-isopropylamine, with $pK_a$ 11.05 compared to triethylamine ($pK_a$ 10.05) which in anhydrous pyridine removes the β-cyanoethyl group in less than 1 h in both the deoxy- and ribo-series. Under this condition, *N*-acyl and *p*-chlorophenyl at the internucleotide phosphate groups were found to be *completely intact* as checked by tlc. The results of these comparative studies are summarized in Table 1.

*Modified phosphotriester approach for oligoribonucleotide synthesis*

The basic strategy of this approach is to start the synthesis from a fully protected ribomononucleoside 3′-phosphotriester **5** as outlined in Fig. 4. The chain was elongated from the 3′- towards the 5′-end by using the 2′,3′-diTBDMS derivative as the 3′-end. Mesitylenesulfonyl tetrazole (21) was used routinely for 15 min as a coupling reagent. One of the major problems in the phosphotriester ap-

[a]Concentration of mononucleotide (0.1 mmol) in an appropriate amine (0.5 mL) and pyridine (2 mL). The course of reactions was followed by tlc on silanized silica gel using acetone containing 30% water as solvent.

[2]Thanks to C. J. McNeal, Texas A & M University, for performing this experiment.

[3]Gait *et al.* (ref. 2, p. 251) have reported a variation of this reaction condition in which *p*-chlorophenyl phosphorodichloridate was mixed with anhydrous triazole in pyridine solution for 20 min separately and then treated with 5-O′-protected deoxynucleoside.

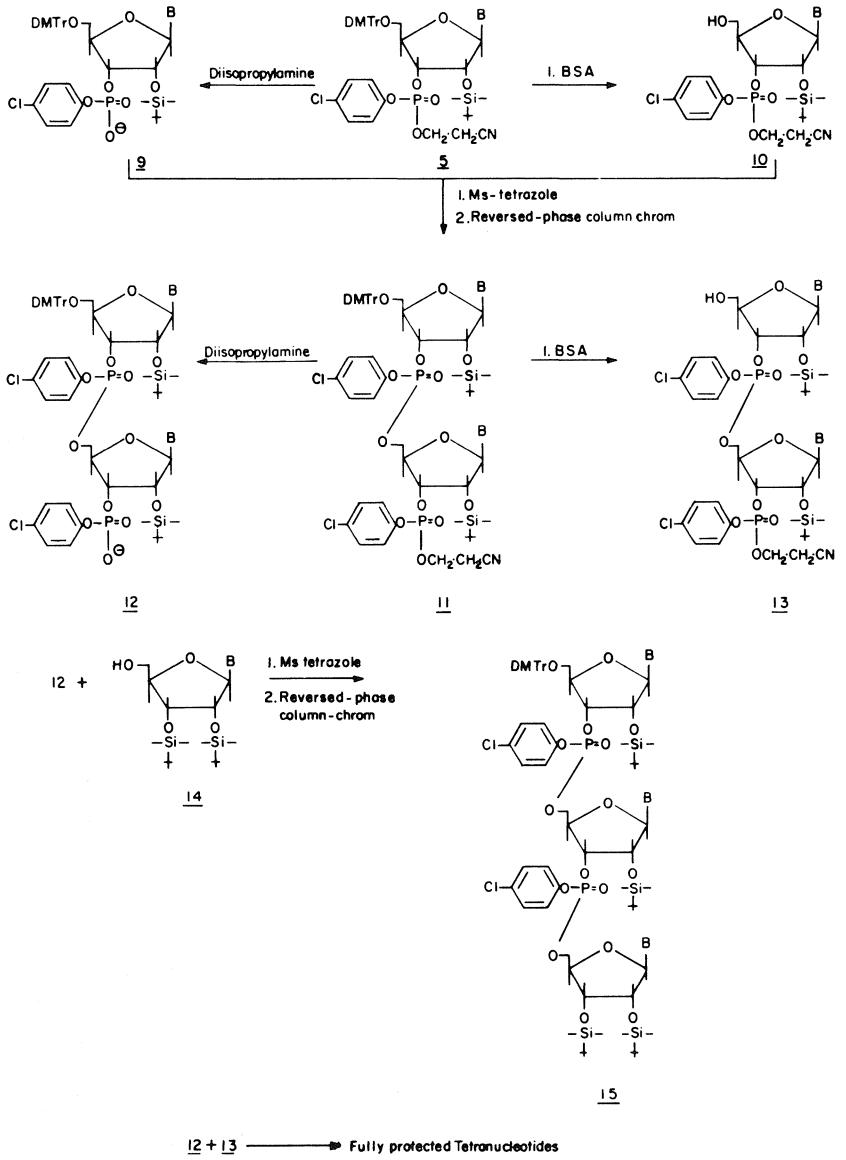

FIG. 4. General method of synthesis by the modified phosphotriester approach.

proach of synthesis is isolation of the pure desired product. In the case of ribooligonucleotide synthesis, the addition of the TBDMS protecting group at each 2′-position causes serious streaking problems in silica gel chromatography. We overcame this problem by developing a short reversed phase column chromatography using an acetone–water solvent system which has the following advantages: (*i*) separation of reaction mixture components is achieved according to the size, i.e. desired product, usually the largest size fragment is the slowest moving component; (*ii*) a 50 mg–10 g amount can be purified easily in less than 1 h time period; and, finally, (*iii*) recovery is quantitative. The reaction conditions and their isolated yields are given in Table 2.

*Final deblocking steps*

The sequential removal of all protecting groups is one of the most difficult as well as critical steps in the successful development of a chemical synthetic approach. Our strategy included initial removal of the 5′-dimethoxytrityl group with 2% benzenesulfonic acid in chloroform–methanol (22), followed by a two-step concentrated ammonia treatment (23) to remove *N*-protecting groups as well as

[a] Abbreviations are as suggested by IUPAC-IUB (1970) Biochemistry 9, 4022. A phosphodiester linkage is represented by a hyphen and phosphotriester linkage is represented by a (∓) symbol. Each internucleotidic phosphate is protected by a *p*-chlorophenyl (ClPh) group and each 2′-hydroxyl of each nucleoside is protected by a *tert*-butyldimethyl silyl (TBDMS) group.
[b] The 2′- and 3′-*cis*-hydroxyl groups of the 3′-terminal residue are protected by two *tert*-butyldimethyl silyl (TBDMS) groups.
[c] Mesitylenesulfonyl tetrazole (MS-Tet).
[d] Pure fully protected product was isolated by short column RP-2 chromatography.
[e] Using mesitylenesulfonyl tetrazole, in 2 to 3-fold equivalents, the sulfonated side product was obtained in 5–10% yields.

*p*-chlorophenyl from the internucleotidic phosphotriester bonds.[4] Under these conditions, the *tert*-butyldimethyl silyl group is still intact at every 2′-position. After washing with ether the partially deblocked material was then evaporated to dryness *in vacuo* and the dry powdery residue was treated with an excess of tetrabutylammonium fluoride in tetrahydrofuran under anhydrous conditions at room temperature. The time required to deblock all the silyl groups is mainly dependent upon the size of the fragment (dimer, 30 min; undecamer, 4 h). After evaporation, the residual material was applied, and excess salt from the applied band was washed with spray of methanol and water. The isolated yield of the desired pure material after total deblocking was 70–80%. The main side products were degradation products formed during the deblocking procedure.

*Characterization*

*Unprotected ribooligonucleotides containing 3′ → 5′ phosphodiester linkages*

(a) *Confirmation of the presence of 3′ → 5′ phosphodiester linkages*

Of paramount importance in ribo-synthesis is the proof of the preservation of each internucleotidic phosphodiester linkage as a 3′ → 5′ bond after all chemical reactions. The presence of each 3′ → 5′ phosphodiester linkage was established as follows.

Each ribooligonucleotide was labeled at the 3′-end with [$^{32}$P]Cp using $T_4$-RNA ligase (2). The labeled compound was purified on 20% gel electrophoresis which on treatment with spleen phosphodiesterase enzyme completely digested the labeled material to a radioactive monomer thus establishing that each linkage of the phosphodiester band is indeed 3′ → 5′.

(b) *Sequence analysis*

Each of the ribooligomers was labeled with [$\gamma$-$^{32}$P]-ATP with $T_4$-polynucleotide kinase and the labeled compound was sequenced by the mobility shift method (16) after partial digestion with snake venom phosphodiesterase or nuclease $P_1$-enzyme (24), and the results of each sequencing experiment are shown in Fig. 5.

[4]We also carried the deblocking procedure as recommended by de Rooij *et al.* (26) which involved, first, treatment with concentrated ammonia to remove the *p*-chlorophenyl group from the internucleotidic phosphotriester and *N*-acyl groups, followed by acidic treatment to remove the 5′-dimethoxytrityl group. After removing all the TBDMS groups from the 2′-positions, we compared the separation patterns on 20% gel electrophoresis with our original procedure (21) and found that these were almost comparable in terms of yields of the desired product and various side products.

*Conclusion*

In the present studies, we have demonstrated that the rapid and efficient synthesis of ribooligonucleotides can be achieved by a modified phosphotreister approach, comparable to the phosphotriester (5) as well as the phosphite route (6).

## Experimental

*General methods and materials*

Uridine, cytidine, adenosine, and guanosine (Sigma), *tert*-butyldimethyl chlorosilane (TBDMS), diphenyl-*tert*-butyl chlorosilane, triphenyl chlorosilane, tetrabutylammonium fluoride (Aldrich), *p*-chlorophenyl phosphodicloridate (Alfa-Ventron), RP-2 silanized silica gel (Brinkman), $T_4$-RNA ligase (RNAse free) and nuclease-$P_1$ enzyme (P-L Biochemical), and [$^{32}$P]Cp (Amersham) were purchased commercially.

5′-Dimethoxytrityl *N*-benzoyl adenosine, 5′-dimethoxytrityl *N*-isobutyryl guanosine, 5′-dimethoxytrityl uridine, and 5′-dimethoxytrityl *N*-benzoylcytidine were prepared according to the published procedures (3).

*Solvent systems*

The homogeneity of each fully protected compound was established by reversed phase (RP-2) tlc using acetone containing 20–30% water (v/v).

*Modified method of* N-*benzoylcytidine preparation*

Chlorotrimethylsilane (420 g, 3.9 mol) was added, with stirring, to a solution of cytidine (100 g, 0.41 mol) in pyridine (1.7 L) and kept for 1 h at room temperature. This was followed by the addition of benzoyl chloride (72 g, 0.52 mol). After 1 h, the reaction mixture was decomposed by adding a mixture of water and dichloromethane (700 mL each). The organic layer was separated and the removal of solvent from the organic extract *in vacuo* gradually yielded white crystals which were resuspended in dichloromethane (500 mL) overnight. The crystals were filtered, washed with acetone, and on drying *in vacuo* yielded pure *N*-benzoylcytidine (133 g) in 93% yield which was identical to an authentic sample (mp 234–236°C, lit. (25) mp 238–239°C).

*Large-scale silylation of 5′-dimethoxyribonucleoside*

Each of the ribonucleosides was prepared by the modification of the published procedure (13) as described below.

*5′-Dimethoxytrityl 2′-*tert*-butyldimethyl silyl* N-*benzoylcytidine* ***3***

5′-Dimethoxytrityl *N*-benzoylcytidine (50 g, 77 mmol) in pyridine solution (150 mL) was treated with *tert*-butyldimethyl chlorosilane (17 g, 113 mmol) and imidazole (15 g, 220 mmol) at room temperature. After 4 h, the reaction mixture was decomposed with water (200 mL) and dichloromethane (350 mL). The aqueous layer was extracted with dichloromethane (100 mL × 2) which was mixed with the organic layer. Evaporation of solvent *in vacuo* yielded a gum which was dissolved in ether (100 mL) and precipitated by pouring slowly into petroleum ether (40–60°C, 800 mL) with stirring. The precipitate was collected and washed twice with petroleum ether, then was dissolved in 30% petroleum ether – dichloromethane and chromatographed on silica gel (160 g) (short column of 6 cm diameter). Elution of column with (*i*) dichloromethane containing 30% petroleum ether (40–60°C, 400 mL) removed the 2′,3′-disilylated derivative (2.0 g); (*ii*) dichloromethane solvent (500 mL) eluted pure 2′-silylated isomer (30 g); and, finally, (*iii*) dichloromethane containing 8% acetone (2 L) removed the 3′-silylated isomer contaminated with the 2′-isomer (16 g).

The last fraction containing mainly the 3′-*tert*-butyldimethyl

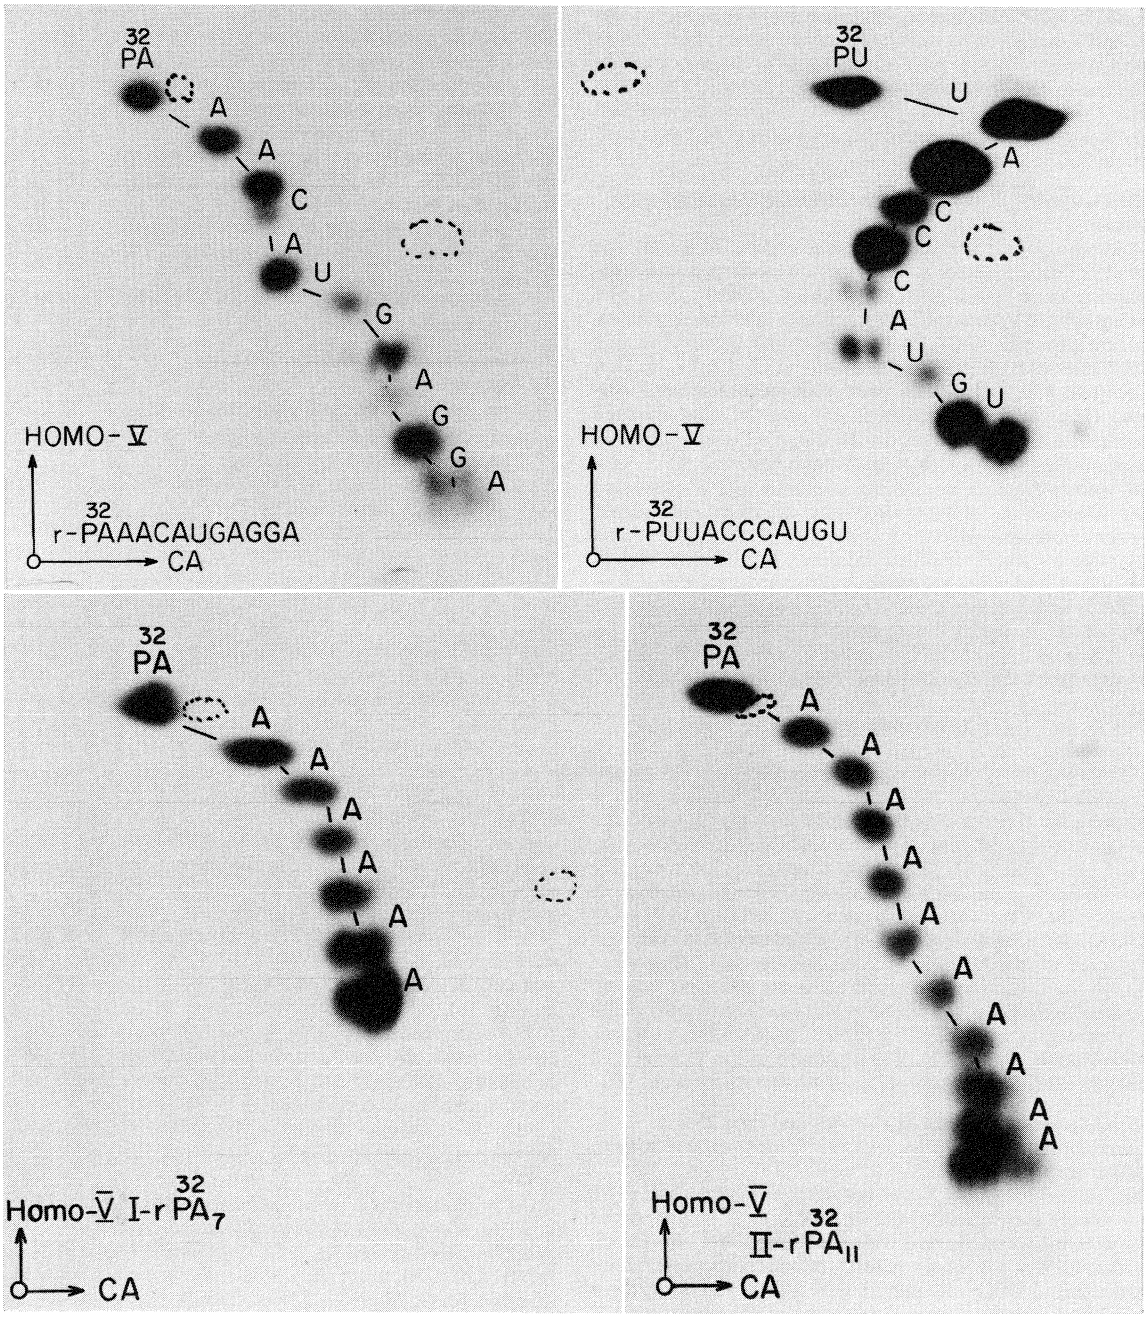

FIG. 5. Two-dimensional chromatographic fingerprints of synthetic ribooligonucleotides after partial digestion with nuclease $P_1$-enzyme. The first dimension is electrophoresis on cellulose acetate strip of pH 3.5 and the second dimension is homochromatography on 20 cm × 20 cm DEAE-cellulose plate in solvent Homo-V.

silylated derivative (16 g) was treated with triethylamine (0.5 mL) in methanol (200 mL) for 40 min at room temperature. On removing the solvent *in vacuo*, a gum was produced which was again chromatographed on a silica gel column as described above to yield a further 9 g of the 2′-protected isomer. The final isolated yields were the 2′-isomer, 39 g (66%); the 3′-isomer, 4.5 g (8%); and the 2′,3′-disilylated product, 2.0 g (4%). The structure of the 2′-protected isomer was confirmed by comparing its nmr spectral data with the literature values (13).

*5′-Dimethoxytrityl 2′-*tert*-butyldimethyl silyl uridine*

5′-Dimethoxytrityluridine (50 g, 93 mmol) in pyridine solution (150 mL) was treated with *tert*-butyldimethyl chlorosilane in the presence of imidazole according to conditions similar to those

described in ref. 13. Purification by silica gel (160 g) chromatography and subsequent isomerization of the 3′-silylated isomer and repeated chromatography (three times) as described above yielded the pure 2′-*tert*-butyldimethyl silyl isomer, 31 g (50%) and the 3′-isomer, 9 g (15%). The structure of the 2′-protected isomer was confirmed by comparing its nmr spectral data with the published values (13).

*5′-Dimethoxytrityl 2′-*tert*-butyldimethyl silyl N-benzoyladenosine*

5′-Dimethoxytrityl *N*-benzoyladenosine (50 g, 74 mmol) was silylated as described above. The reaction mixture was chromatographed on a silica gel (160 g) short column using the following solvent systems: (*i*) ethyl acetate – dichloromethane – petroleum ether (40–60°C) (1:1:3 v/v) (500 mL); (*ii*) ethyl acetate – dichloromethane – petroleum ether (40–60°C) (1:1:2 v/v) (2 L); (*iii*) acetone (800 mL). The pure 2′-protected isomer was isolated (12 g) in fraction number (*ii*) and the contaminated 2′-protected isomer (6 g) with the 3′-protected isomer (18 g) in fraction number (*iii*). Subsequent isomerization of the 3′-protected isomer fraction containing contaminated 2′-protected isomer followed by rechromatography on silica gel column under the conditions described above yielded further amounts of the pure 2′- and 3′-silylated isomers. After two cycles of isomerization and silica gel column chromatographic purification, the overall yield of the 2′-silylated protected isomer was 26 g (45%) and a slightly contaminated 3′-silylated isomer, 9 g (16%). The structure of the 2′-protected isomer was confirmed by comparing its nmr spectral data with the literature (13).

*5′-Dimethoxytrityl 2′-*tert*-butyldimethyl silyl N-isobutyrylguanosine*

5′-Dimethoxytrityl *N*-isobutyrylguanosine (50 g, 76 mmol) was silylated according to the procedure described above. Purification by column chromatography on silica gel with the following solvent systems: (*i*) petroleum ether – dichloromethane (1:1 v/v) (300 mL); (*ii*) dichloromethane (500 mL); (*iii*) dichloromethane containing 4% acetone (2 L); and, finally, (*iv*) acetone, yielded the pure 2′-silylated isomer (10 g) in fraction number (*ii*) and a mixture of the 2′-protected isomer (6 g) and the 3′-protected isomer (23 g) in fraction number (*iii*). After three cycles of isomerization and purification by silica gel column chromatography under the above conditions, the overall yields were 2′-protected isomer, 24.5 g (42%), and a slightly contaminated 3′-isomer, 10 g (17%). The structure of the 2′-protected isomer was confirmed by comparison with literature values (13).

*Attempted phosphorylation of 5′-dimethoxytrityl 2′-*tert*-butyldimethyl silyl uridine with p-chlorophenyl phosphoryl ditetrazolide*

The 5′-dimethoxytrityl 2′-*tert*-butyldimethyl silyl uridine (1.0 g, 1.5 mmol) and tetrazole (0.30 g, 4.8 mmol) in anhydrous pyridine (3 mL) was treated with *p*-chlorophenyl phosphodichloridate (0.59 g, 2.4 mmol). After 20 min at room temperature, β-cyanoethanol (0.8 g, 12 mmol) was added and kept for a further 2 h to complete the reaction. The reaction mixture was decomposed by adding a mixture of water and dichloromethane (30 mL each), then the organic layer was separated and washed with 5% aqueous sodium bicarbonate (30 mL). Evaporation *in vacuo* yielded a gummy residue which was purified on reversed phase (RP-2) (11 g) short column chromatography using the following solvents: (*i*) acetone–water (50:50 v/v) (250 mL) to remove excess β-cyanoethanol and other non-triester components; (*ii*) acetone–water (58:42 v/v) (150 mL) to elute the fully protected product. Extraction of solvent (*ii*) with dichloromethane (50 mL) and subsequent evaporation gave a mixture of two fully protected phosphotriester nucleotide compounds which were further fractionated on preparative silica gel tlc plates developed in dichloromethane–acetone (9:1 v/v) into two bands. Elution of the faster moving band with methanol–dichloromethane (3:7 v/v) and evaporation *in vacuo* yielded 4-tetrazolo-1-(β-D-5′-dimethoxytrityl-2′-*tert*-butyldimethyl silyl ribofuranosyl)-2(1*H*)-pyrimidinone 3′-*p*-chlorophenyl β-cyanoethyl phosphotriester **8** as a foamy material, 0.42 g (35%). The structure was confirmed by its ultraviolet spectra (methanol), $\lambda_{max}$: 324 nm; nmr ($CDCl_3$) δ: 9.44 (1H, s, H(5) of tetrazole), 2.48 (2H, m, $OCH_2CH_2{\cdot}CN$), 0.92 (9H, s, $(CH_3)_3CSi$). The molecular ion ($M^+$) occurs at 957 $m^+/e$ which is an increase of 52 mass units over the corresponding uridine derivative and corresponds to the addition of the tetrazole moiety (18).

On complete deblocking, the resulting product has uv spectra characteristic of cytosine.

*Phosphorylation with p-chlorophenyl phosphodichloridate and triazole*

(i) *Preparation of 5′-dimethoxytrityl 2′-*tert*-butyldimethyl silyl N-benzoyl cytidine-3′-p-chlorophenyl β-cyanoethyl phosphotriester 5*

1,2,4-Triazole (10.0 g, 145 mmol) was added to a pyridine solution (65 mL) containing the 2′-*tert*-butyldimethyl silylated cytidine **3** (33.0 g, 43.3 mmol) at room temperature. *p*-Chlorophenyl phosphodichloridate (17.7 g, 72 mmol) was then added immediately and the reaction mixture stirred for 5 min to complete the phosphorylation reaction as checked by tlc on silica gel and RP-2 plates. β-Cyanoethanol (25 g, 356 mmol) was then added and after a further 3 h at room temperature the reaction mixture was decomposed by adding water (200 mL). The solution was extracted with dichloromethane (500 mL) and the organic layer was washed with 5% aqueous sodium bicarbonate solution (100 mL). Evaporation of solvent *in vacuo* gave a gummy residue which was purified by RP-2, short column chromatography (130 g) using solvents (*i*) acetone–water (50:50 v/v) (1.5 L) to remove excess β-cyanoethanol, followed by (*ii*) acetone containing 45% water (2 L) to elute the fully protected desired product. The desired product was recovered by extracting the solvent (*ii*) with dichloromethane (500 mL), drying, and removing the solvent to produce a foamy material, 31.2 g (71%); uv (MeOH) $\lambda_{max}$: 262, 305 nm; nmr ($CDCl_3$) δ: 2.62 (2H, m, $CH_2{\cdot}CH_2{\cdot}CN$), 0.97 (9H, s, $(CH_3)_3CSi$—). *Anal.* (foamy material) calcd. for $C_{54}H_{26}N_4O_{11}ClPSi$: C 61.99, H 5.60, N 5.56; found: C 61.90, H 5.57, N 5.42.

The corresponding fully protected ribonucleoside 3′-*p*-chlorophenyl, and the β-cyanoethyl phosphotriester of uridine, *N*-benzoyladenosine, and isobutyrylguanosine were also prepared according to the above reaction conditions. The isolated yields were uridine (61%), *N*-benzoyladenosine (75%), and *N*-isobutyrylguanosine (72%). Their analytical data are given below.

(ii) *5′-Dimethoxytrityl 2′-*tert*-butyldimethyl silyl uridine 3′-p-chlorophenyl β-cyanoethyl phosphotriester*

Ultraviolet (MeOH) $\lambda_{max}$: 263 nm; nmr ($CDCl_3$) δ: 2.63 (2H, m, $CH_2CH_2CN$), 0.91 (9H, s, $(CH_3)_3CSi$). *Anal.* (foamy material) calcd. for $C_{45}H_{51}N_3O_{11}ClPSi$: C 60.25, H 5.68, N 4.64; found: C 60.12, H 5.54, N 4.56.

(iii) *5′-Dimethoxytrityl 2′-*tert*-butyldimethyl silyl N-benzoyladenosine 3′-p-chlorophenyl β-cyanoethyl phosphotriester*

Ultraviolet (MeOH) $\lambda_{max}$: 276 nm; nmr ($CDCl_3$) δ: 2.78 (2H, m, $CH_2CH_2CN$), 0.89 (9H, s, $(CH_3)_3CSi$). *Anal.* (foamy material) calcd. for $C_{53}H_{56}N_6O_{10}ClPSi$: C 61.71, H 5.47, N 8.14; found: C 61.50, H 5.57, N, 8.26.

(iv) *5′-Dimethoxytrityl 2′-*tert*-butyldimethyl silyl N-isobutyryl guanosine 3′-p-chlorophenyl β-cyanoethyl phosphotriester*

Ultraviolet (MeOH) $\lambda_{max}$: 274, 281 nm; nmr ($CDCl_3$) δ: 2.75

(2H, m, $CH_2CH_2CN$), 0.93 (9H, s, $(CH_3)_3Si$). *Anal.* (foamy material) calcd. for $C_{50}H_{58}N_6O_{11}ClPSi$: C 59.25, H 5.76, N 8.29; found: C 59.05, H 5.84, N 8.49.

*Selective removal of β-cyanoethyl group from the fully protected ribomononucleotide* **5** *on treatment with diisopropylamine – anhydrous pyridine*

Fully protected ribomononucleotide (2.5 mmol) was dissolved in anhydrous pyridine (5 mL) containing diisopropylamine (1.5 mL) and kept at room temperature. The reaction was over within an hour as monitored on reversed phase tlc and the results are documented in Table 1 for individual nucleotides. After completion of the reaction, the solvent was removed *in vacuo* and the foamy residue was reevaporated in pyridine solvent to dryness.

*General method of large-scale and rapid synthesis of sixteen fully protected ribodinucleotides* **11**

5′-Dimethoxytrityl 2′-*tert*-butyldimethyl silyl *N*-protected ribomononucleoside 3′-*p*-chlorophenylphosphate **9** (4.5 mmol) and 5′-hydroxyl ribomononucleoside, 2′-*tert*-butyldimethyl silyl, 3′-*p*-chlorophenyl, β-cyanoethyl phosphate **10** (4.0 mmol) in anhydrous pyridine (20 mL) were treated with mesitylenesulfonyl tetrazole (9 mmol) at room temperature for 15 min. The reaction mixture was taken up in dichloromethane (100 mL) and 5% aqueous sodium bicarbonate solution (100 mL). The aqueous layer was extracted twice with dichloromethane (50 mL). Evaporation of the organic solvent *in vacuo* yielded a gummy residue which was chromatographed on a reversed phase gel (40 g) packed in a short column (4 cm diameter). The column was eluted with the following solvents: (*i*) acetone containing 40% water (1.0 L) to remove the unreacted 3′-phosphodiester containing material as well as 5′-hydroxyl; (*ii*) acetone containing 25% water (300 mL) eluted the fully protected ribodinucleotide **11**. The desired product was isolated by extracting solvent (*ii*) with an equal volume of dichloromethane. Subsequent evaporation of the dichloromethane solvent *in vacuo* yielded pure fully protected dinucleotide in 50–70% yields. This purification procedure required 90 min.

*General method of ribooligonucleotide synthesis*

The synthesis of fully protected ribooligonucleotide was achieved by condensing 5′-dimethoxytrityl, 2′-*tert*-butyldimethyl silylated, *N*-protected oligonucleotides containing 3′-*p*-chlorophenylphosphate with the 5′-hydroxyl containing component in anhydrous pyridine solution in the presence of mesitylene tetrazole for 15 min at room temperature. After the usual work-up the desired product was isolated by short column chromatography on reversed phase (RP-2) silica gel as described above. The entire operation of coupling, work-up, purification, and isolation was complete within 3 h. The purity of each intermediate was 80–90% as judged by tlc on reversed phase silica gel plates as was the case also after the complete deblocking step, analysis on PEI plate, and sequence determination. The summary of reaction conditions and isolated yields are documented in Table 2.

*Final deblocking and purification step*

A fully protected undecamer containing the base sequence (r-AAACAUGAGGA) (15 mg) was treated with 2% benzenesulfonic acid in methanol–dichloromethane (3:7 v/v) (6 mL) for 1 min at room temperature followed by washing with 5% aqueous sodium bicarbonate solution (6 mL). After separating the aqueous layer, the organic solvent was evaporated *in vacuo* to dryness and then dissolved in concentrated ammonia–pyridine (2:3 v/v) (5 mL). After keeping the reaction mixture at room temperature for 48 h, it was heated to 37°C for 24 h. Subsequent evaporation *in vacuo* gave a gummy residue which was coevaporated in pyridine (1 mL) to a glassy product which was next washed with anhydrous ethyl ether (1 mL) for 15 min. Removal of ethyl ether produced a powder which was then treated with 1.0 *M* tetrabutylammonium fluoride in tetrahydrofuran (1 mL) for 4 h at room temperature. Shorter time periods, e.g. 30 min for the dimer, 2 h for the hexamer, are sufficient for the removal of all the 2′-TBDMS protected groups. The reaction mixture was applied directly on the PEI-tlc plate (~ 300 μL per plate) and the application area washed first by spraying with distilled water and then with methanol to remove excess salts and nonnucleotidic materials. The PEI plate was first developed in water (for a height of 3 cm) followed by 0.6 *M* LiCl–7 *M* urea solvent at 60°C. After 2 h, the plate was removed and then soaked in a methanol tank. The desired major band was eluted with 1 *M* triethylammonium bicarbonate pH 7.5 solution.

*Characterization*

(a) *Confirmation of 3′ → 5′ phosphodiester internucleotidic linkages in snythetic ribooligomers*

The r-AAACAUGAGGA (11-mer) acceptor (1 mmol, 100 μ*M*) and donor [r-5′-$^{32}$P]PCP (0.5 mmol, 50 μ*M*) in reaction buffer (10 μL) containing 50.0 m*M* HEPES, pH 7.5, 20 m*M* $MgCl_2$, 3.3 m*M* (dithiothreitol), 0.1 m*M* ATP, 0.25 μg bovine serum albumin, 10% v/v dimethyl sulfoxide was incubated with RNA ligase (2) (1.5 units) for 30 min at 37°C. The reaction was terminated by heating at 100°C for 2 min. The labeled compound was purified by electrophoresis on a 20% gel slab. The labeled material was then treated with spleen phosphodiesterase in 10 m*M* EDTA and 100 m*M* potassium phosphate (pH 6.5) for 30 min at 37°C. The digested material was analyzed by homochromatography using Homo-V solvent (15). All the radioactivity was found at the solvent front corresponding to mononucleotide.

(b) *Sequence analysis by mobility shift method*

(i) *5′-Labeling of synthetic ribooligonucleotides*

Each synthetic ribooligonucleotide fragment was labeled using [γ-$^{32}$P]-ATP and $T_4$-polynucleotide kinase enzyme. The labeled compound was purified by 20% gel electrophoresis according to the published procedure (22).

(ii) *Partial digest of 5′-$^{32}$P-labeled ribooligonucleotide with nuclease $P_1$ enzyme*

The 5′-labeled ribooligonucleotide in 20 μL containing 50 μg of carrier t-RNA in 50 m*M* ammonium acetate (pH 5.3) was incubated with nuclease $P_1$ enzyme (1 μg) at room temperature. Aliquots (5 μL) were removed at 0, 5, 10, and 20 min and transferred to 5 m*M* EDTA-containing diethyl pyrocarbonate (10 μL/100 mL buffer) (10 μL) and inactivation of the enzyme was accomplished by heating at 100°C for 2 min. An aliquot (1 μL) of each time interval fraction was analyzed in one dimension by homochromatography using solvent V. The appropriate aliquots were mixed, and chromatographed by the two dimensional system. The radioautograms of each oligomer are shown in Fig. 5 which confirms their individual sequences.

## Acknowledgments

We are grateful to Professor Olke Uhlenbeck, University of Illinois, Urbana, for suggesting the R-17 sequence for the chemical synthesis, and to Miss Diana Schmidt for her technical assistance.

# Copper tetrafluoroborate complexes of the potentially binucleating ligand 1,4-di(2′-pyridyl)aminophthalazine. Mononuclear and polynuclear derivatives

JOHN C. DEWAN AND LAURENCE K. THOMPSON[1]

*Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7*

Received July 31, 1981

JOHN C. DEWAN and LAURENCE K. THOMPSON. Can. J. Chem. **60**, 121 (1982).

Three different copper tetrafluoroborate complexes are obtained from the reaction of copper tetrafluoroborate and the title ligand (PAP) in water. Two crystalline modifications of a six-coordinate mononuclear protonated derivative, $[Cu(PAPH)_2(H_2O)_2](BF_4)_4$, a triclinic brown form (**I**) and a monoclinic green form (**II**), and a dark green polynuclear complex containing neutral ligand and formulated as $[Cu_3(PAP)_2(OH)_2](BF_4)(BF_3OH)_3 \cdot 5H_2O$ (**III**), are obtained from the same reaction mixture. The hydrolysis of $BF_4^-$ in water is thought to be responsible for the formation of protonated PAP. In methanol a four-coordinate protonated derivative, $[Cu(PAPH)_2](BF_4)_4$ (**IV**) and a binuclear complex $[Cu_2(PAP)_2(H_2O)_2](BF_4)_4 \cdot 0.5MeOH$ (**V**), containing neutral ligand, are obtained. The molecular structures of both forms of $[Cu(PAPH)_2(H_2O)_2](BF_4)_4$ have been determined by single crystal X-ray diffraction. The brown triclinic form (**I**) belongs to space group $P\bar{1}$ with $a = 9.856(1)$, $b = 12.724(1)$, $c = 9.401(1)$ Å, $\alpha = 101.691(8)$, $\beta = 96.717(9)$, $\gamma = 70.145(8)°$, $V = 1084.4$ Å$^3$, $Z = 1$. The green monoclinic form (**II**) belongs to space group $P2_1/n$ with $a = 12.663(4)$, $b = 9.573(3)$, $c = 18.813(4)$ Å, $\beta = 107.16(2)°$, $V = 2178.9$ Å$^3$, $Z = 2$. Both complexes have tetragonally distorted six-coordinate structures involving axially bound water molecules and two in plane bidentate protonated ligands. The major difference between the structures involves the axial Cu—O(W) bond lengths (triclinic 2.497(9) Å; monoclinic 2.426(9) Å).

JOHN C. DEWAN et LAURENCE K. THOMPSON. Can. J. Chem. **60**, 121 (1982).

On a obtenu trois complexes différents du tétrafluoroborate de cuivre par de la réaction, dans l'eau, entre du tétrafluoroborate de cuivre avec le ligand (PAP) mentionné dans le titre. Le même mélange réactionnel fournit aussi deux modifications cristallines du dérivé protoné mononucléaire hexacoordoné, $[Cu(PAPH)_2(H_2O)_2](BF_4)_4$, une forme brune triclinique (**I**) et une forme verte monoclinique (**II**) ainsi qu'un complexe polynucléaire vert foncé contenant le ligand neutre et considéré comme étant le $[Cu_3(PAP)_2(OH)_2](BF_4)(BF_3OH)_3 \cdot 5H_2O$ (**III**). On croit que l'hydrolyse de $BF_4^-$ dans l'eau est responsable de la formation du PAP protoné. Dans le méthanol, on obtient, un dérivé protoné hexacoordonné, $[Cu(PAPH)_2](BF_4)_4$ (**IV**) et un complexe binucléaire $[Cu_2(PAP)_2(H_2O)_2](BF_4)_4 \cdot 0{,}5$ MeOH (**V**) contenant le ligand neutre. On a déterminé les structures moléculaires des deux formes par diffraction des rayon-X sur un monocristal. La forme triclinique brune appartient au groupe d'espace $P1$ avec $a = 9{,}856(1)$, $b = 12{,}724(1)$, $c = 9{,}401(1)$ Å, $\alpha = 101{,}691(8)$, $\beta = 96{,}717(9)$, $\gamma = 70{,}145(8)$, $V = 1084$ Å$^3$, $Z = 1$. La forme monoclinique verte appartient au groupe d'espace $P2_1/n$ avec $a = 12{,}663(4)$, $b = 9{,}573(3)$, $c = 18{,}813(4)$ Å, $\beta = 107{,}16(2)°$, $V = 2178.9$ Å$^3$, $Z = 2$. Les deux complexes ont des structures hexacoordonnées déformées de façon tétragonale faisant intervenir des molécules d'eau liées en position axiale et deux ligands protonés bidentates dans le plan. La principale différence entre les deux structures se situe au niveau des longueurs de liaison axiale Cu—O(W); elles sont respectivement de 2,497(9) Å dans la forme triclinique, et de 2,426(9) Å dans la forme monoclinique.

[Traduit par le journal]

## Introduction

The binucleating ligand 1,4-di(2′-pyridyl)-aminophthalazine (Fig. 1, ligand abbreviated PAP) has been shown to bind preferentially to two metal centres forming binuclear complexes with copper, cobalt, nickel, and zinc salts (1–3). The metal centres are connected by multiple bridges in all cases; the bridging units include the phthalazine $N_2$ group, hydroxide, halide, and carboxylate. An X-ray study on the complex $[Cu_2(PAP)(OH)Cl_3] \cdot 1.5H_2O$ revealed a triple bridge involving hydroxide, chloride and phthalazine (4) (Fig. 2). Reaction of this complex in acetonitrile/water with 3,5-di-*tert*-butylcatechol produces a binuclear copper(I)/quinone derivative which catalytically oxidizes excess catechol to the corresponding quinone in the presence of excess oxygen (5). Other preliminary X-ray studies on the complexes $[Ni_2(PAPH)_2$-

$(PAP)(OH)_2]Br_4 \cdot 6H_2O$ (PAPH = protonated ligand) $[Co_2(PAP)_3(OH)_2]Br_4 \cdot 9H_2O$ and $[Co_2(PAP—H)_2(PAP)(OH_2](ClO_4)_2$ (PAP—H = deprotonated ligand) (6) indicate triple bridges between the cobalt(III) and nickel(II) centres involving a phthalazine $N_2$ bridge and two oxygen bridges. The identity of the oxygen bridges remains in some doubt at present but they have been formulated as hydroxides in keeping with other data. Preliminary structural details of the complex $[Co_2(PAP—H)_2(PAP)(OH)_2](ClO_4)_2$ are given in Fig. 3. The other two complexes have the same basic structure. Full details of the structures of these three complexes will be published elsewhere.

We recently reported the isolation of two mononuclear six-coordinate nickel complexes $[Ni(PAPH)_2(H_2O)_2](BF_4)_4$ and $[Ni(PAPH)_2(H_2O)_2]I_4$ (3) in which the two potentially tetradentate ligands were assumed to be bidentate and that each one was protonated. The formation of such derivatives from aqueous solution was rationalized in terms of the acidity of the solution of the metal salt, at least in the case of the tetrafluoroborate system (3).

$$BF_4^- + H_2O \rightleftharpoons BF_3(OH)^- + HF$$
$$K = 2.0 \times 10^{-3} \quad (7)$$
$$BF_3OH^- + H_2O \rightleftharpoons BF_2(OH)_2^- + HF$$
$$K = 1.8 \times 10^{-4} \quad (8)$$

We report herein that a similar mononuclear protonated system is obtained from the reaction of copper tetrafluoroborate and PAP in a 1:1 ratio in water. Initially a mixture of two different crystalline products is obtained, consisting of light brown blocks (**I**) and light green plates (**II**). Both crystalline products analyse independently as $[Cu(PAPH)_2(H_2O)_2](BF_4)_4$. X-ray analyses of these two compounds reveal the same basic tetragonally distorted six-coordinate structure involving axially coordinated water. The most significant difference between the structures involves the Cu—O(W) bond lengths, which are longer in the brown form.

In addition to the formation of the two mononuclear derivatives a polynuclear derivative is also obtained (**III**) in which the metal-to-ligand ratio appears to be 3:2. $BF_3OH^-$ ions, produced from the hydrolysis of $BF_4^-$, appear as counter ions in this product. If the pH of the copper tetrafluoroborate solution is raised to approximately 5, thus suppressing the hydrolysis of $BF_4^-$, the only product obtained is a polynuclear derivative (**VI**) analogous to **III**, which contains $BF_4^-$ and no $BF_3OH^-$.

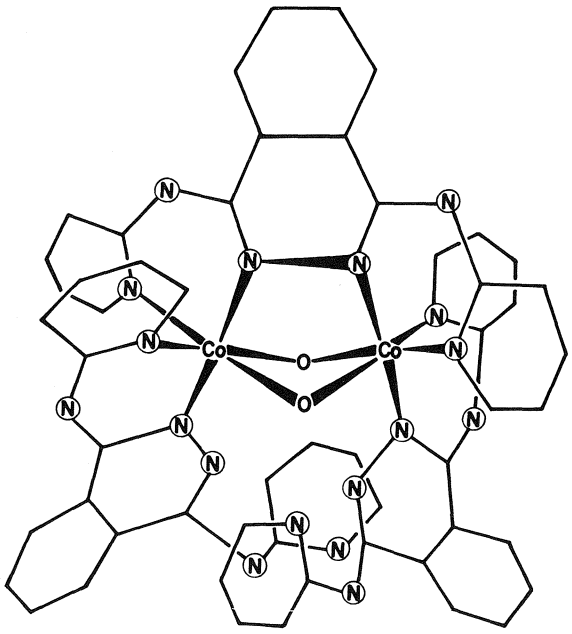

FIG. 3. Preliminary structural details for the $[Co_2(PAP—H)_2(PAP)(OH)_2]^{2+}$ cation (6).

## Experimental

Electronic spectra were recorded on a Cary 17 spectrometer, infrared spectra were obtained with a Perkin-Elmer model 283 spectrometer, and magnetic susceptibilities were obtained at room temperature by the Faraday method with a Cahn model #7600 Faraday Magnetic Susceptibility system, coupled to a Cahn gram electrobalance. Microanalyses were carried out by Canadian Microanalytical Service, Vancouver (C, H, N) and Pascher Microanalytisches Laboratorium, Bonn (F), and metal analyses were determined by Atomic Absorption with a Varian Techtron AA-5, after digestion of the samples in aqua regia.

*1,4-Di(2'-pyridyl)aminophthalazine (PAP)*

The ligand, PAP, was prepared as described previously (1).

*Copper tetrafluoroborate complexes of PAP*

*$[Cu(PAPH)_2(H_2O)_2](BF_4)_4$ (I, II), $[Cu_3(PAP)_2(OH)_2](BF_4)(BF_3OH)_3 \cdot 5H_2O$ (III)*

$Cu(BF_4)_2 \cdot 6H_2O$ (Alfa) (2.2 g; 6.4 mmol) was dissolved in water (150 mL) and the solution filtered. PAP (2.0 g; 5.8 mmol) was added and the mixture refluxed for 1 h. The resulting green solution was filtered hot and left to stand for 1 week. A mixture of brown (**I**) and light green (**II**) crystals was formed. These crystals were used directly for X-ray analysis. The product was filtered, washed with acetone, and air dried. The mother liquor was allowed to stand, open to the atmosphere, for another week. A further crop of brown and light green crystals was obtained, and was treated as before. Further reduction in volume of the mother liquor produced a third crop of mixed crystals. The relative proportions of brown and green crystals appeared to vary in that in the first crop of product the brown crystals predominated whereas, in the last crop there appeared to be more green crystals. (Total yield = 0.6 g.)

The green mother liquor was reduced in volume on a steam bath to 30 mL and ethanol (10 mL) added. On standing, dark green crystals (**III**) formed. The product was filtered, washed with ethanol, and recrystallized from $H_2O$/EtOH (75/25) (yield = 1.3 g).

*Anal.* calcd. for $[Cu(PAPH)_2(H_2O)_2](BF_4)_4$ (**I**, brown): C 40.2, H 3.09, N 15.6, F 28.2, Cu 5.89; found: C 40.0, H 2.99, N 15.5, F 28.6, Cu 6.02.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

*Anal.* calcd. for $[Cu(PAPH)_2(H_2O)_2](BF_4)_4$ (**II**, light green): C 40.2, H 3.09, N 15.6, F 28.2, Cu 5.89; found: C 40.1, H 2.92, N 15.4, F 28.6, Cu 5.91.

*Anal.* calcd. for $[Cu_3(PAP)_2(OH)_2](BF_4)(BF_3OH)_3 \cdot 5H_2O$ (**III**, dark green): C 33.6, H 3.35, N 13.1, F 19.2, Cu 14.8; found: C 33.6, H 3.31, N 13.0, F 19.1, Cu 14.8.

*$[Cu(PAPH)_2](BF_4)_4$ (IV), $[Cu_2(PAP)_2(H_2O)_2](BF_4)_4 \cdot 0.5$-MeOH (V)*

$Cu(BF_4)_2 \cdot 6H_2O$ (1.1 g; 3.2 mmol) was dissolved in methanol (80 mL) and triethylorthoformate (TEOF) (5 mL) added. PAP (1.0 g; 2.9 mmol) was added and the mixture refluxed for $2\frac{1}{2}$ h. A khaki solid (**IV**) was obtained and was filtered, washed with methanol, and dried under vacuum (yield = 0.3 g). The green mother liquor was allowed to stand for 4 days at room temperature. Dark green crystals (**V**) were formed, and were filtered, washed with methanol, and dried under vacuum at room temperature (yield = 0.6 g).

*Anal.* calcd. for $[Cu(PAPH)_2](BF_4)_4$ (**IV**): C 41.5, H 2.88, N 16.1, Cu 6.10; found: C 41.4, H 2.76, N 15.9, Cu 5.90.

*Anal.* calcd. for $[Cu_2(PAP)_2(H_2O)_2](BF_4)_4 \cdot 0.5MeOH$ (**V**): C 37.9, H 2.94, N 14.5, Cu 11.0; found: C 38.3, H 3.08, N 14.5, Cu 10.6.

*$[Cu_3(PAP)_2(OH)_2](BF_4)_4 \cdot 2H_2O$ (VI)*

$Cu(BF_4)_2 \cdot 6H_2O$ (1.0 g; 2.9 mmol) was dissolved in $H_2O$ (30 mL) and the solution filtered. The pH of this solution was about 3.5. Solid sodium fluoride was added to adjust the pH to 4.9. PAP (0.85 g; 2.7 mmol) was added and the mixture refluxed for 1 h. The green solution was filtered to remove a small amount of unreacted ligand and allowed to stand for several days. A dark khaki–green solid was obtained which was recrystallized from water to give dark green crystals. The product was filtered, washed with ethanol and diethyl ether, and dried under vacuum at room temperature.

*Anal.* calcd. for $[Cu_3(PAP)_2(OH)_2](BF_4)_4 \cdot 2H_2O$ (**VI**): C 34.9, H 2.75, N 13.6, Cu 15.4; found: C 34.9, H 2.80, N 13.4, Cu 14.7.

Only crystals of **I** and **II** proved to be suitable for X-ray analysis. Attempts were made to obtain X-ray data on crystals of compound **III** from several different preparations but in all cases the crystals were found not to diffract X-rays.

*X-ray crystallographic analyses*

*$[Cu(PAPH)_2(H_2O)_2](BF_4)_4$ (I) (triclinic modification)*

Crystal data (at 24°C) are:

$C_{36}H_{34}N_{12}B_4CuF_{16}O_2$ fw = 1077.51

Triclinic, $a$ = 9.856(1), $b$ = 12.724(1), $c$ = 9.401(1) Å, $\alpha$ = 101.691(8), $\beta$ = 96.717(9), $\gamma$ = 70.145(8)°, $V$ = 1084.4 Å$^3$, $Z$ = 1, $\rho_c$ = 1.650 g cm$^{-3}$, $F(000)$ = 543, Mo K$\alpha$ radiation ($\lambda_{\bar{\alpha}}$ = 0.71073 Å, $\mu$ = 6.2 cm$^{-1}$) graphite monochromatized. Absent reflections: none. Space group $P\bar{1}$ ($C_i^1$, No. 2) (9) from structure analysis.

The light-brown block shaped crystal used in the diffraction study was bounded by the seven faces: (100) and ($\bar{1}$00), 0.184 mm apart; (010) and (0$\bar{1}$0), 0.096 mm apart; and (001), (0$\bar{1}$1), (02$\bar{3}$) each 0.067 mm from the centre of the crystal. The quality of the data crystal was examined on the diffractometer, by taking open-counter $\omega$ scans of several strong low-angle reflections, and was judged to be acceptable. The average width of the peaks at half-height was 0.16°. Intensity data, in the range $3 \leq 2\theta \leq 55°$, were collected on an Enraf-Nonius CAD-4F $\kappa$-geometry diffractometer employing the $\omega$–$2\theta$ scan technique. Scan rates were automatically selected to make $I/\sigma(I) = 100$, and varied from 1.18 to 20.12° min$^{-1}$ in $\omega$, with a maximum scan time of 53 s being imposed. Prescans were done at 20.12° min$^{-1}$ in $\omega$ and reflections having $I/\sigma(I) < 1.5$ were considered weak and were not remeasured. Scan widths were computed according to $\Delta\omega = (0.70 + 0.35 \tan\theta)°$ and were extended 25% on either side for the measurement of backgrounds. Three standard reflections, (7$\bar{5}$4), (4$\bar{2}$5), and (22$\bar{1}$), measured after each 3600 s of X-ray exposure time (approximately after each 110 reflections) showed only random statistical fluctuations. A total of 6234 reflections ($3 \leq 2\theta \leq 30°$ ($\pm h, \pm k, -l$); $3 \leq 2\theta \leq 55°$ ($\pm h, \pm k, +l$)) were scanned. Data reduction then proceeded as detailed in ref. 10. An absorption correction was not applied. Maximum and minimum transmission factors were 0.95 and 0.92. Averaging of equivalent reflections yielded 4954 data, the 1392 having $F_o > 4\sigma(F_o)$ being used in the structure refinement. The $R$ factor for averaging (10) was 0.012. Unit-cell dimensions were obtained from a least-squares fit to the setting angles of 25 reflections with $2\theta > 30°$.

A systematic search using TRACER-II (11) failed to find any symmetry higher than triclinic and refinement, performed with SHELX-76 (12), has been completed in the centrosymmetric space group $P\bar{1}$. This choice of space group appears to be vindicated based on the successful convergence of the structure refinement. Further weight is added to this assignment of space group by the fact that, in space group $P\bar{1}$, the Cu atoms of the structure are constrained to sites of $\bar{1}$ symmetry. Compound **II** crystallizes in the centrosymmetric space group $P2_1/n$, which is uniquely defined by its systematic absences, and in this case the Cu atoms again occupy sites of $\bar{1}$ symmetry. The structure was solved by conventional heavy atom methods using Patterson and Fourier maps. Full-matrix least-squares refinement of 305 variables converged at $R_1 = 0.083$ and $R_2 = 0.104$ where $R_1 = \sum||F_o| - |F_c||/\sum|F_o|$ and $R_2 = [\sum w(|F_o| - |F_c|)^2/\sum w|F_o|^2]^{1/2}$. The function minimized in the least-squares was $\sum w(|F_o| - |F_c|)^2$ where $w = 2.2787/(\sigma^2(F_o) + 0.000941F_o^2)$. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms could not be located but those attached to carbon were placed in calculated positions and constrained to ride 0.95 Å from their respective carbon atoms (12). A common isotropic temperature factor for these hydrogen atoms converged at $U$ = 0.05(1) Å$^2$. Both tetrafluoroborate anions were refined as rigid groups (B—F, 1.37 Å; F—B—F, 109.5°) pivoting on their respective boron atoms (12).

Towards the final stages of refinement, a check was made on the assignment of N(6) and C(15). With both of these atoms vibrating isotropically and all other non-hydrogen atoms vibrating anisotropically, three cycles of least-squares refinement resulted in $R_1 = 0.083$ and $R_2 = 0.105$. The value of $U$ (Å$^2$) for N(6) was 0.053(3) and for C(15) was 0.057(4). From the same initial parameters, but with N(6) assigned a carbon atom scattering factor and C(15) a nitrogen atom scattering factor, three cycles of refinement were again performed. The residual indices were now $R_1 = 0.088$ and $R_2 = 0.110$. The isotropic temperature factor, $U$ (Å$^2$), for N(6) was 0.026(3) and for C(15) was 0.095(5). The original assignment for these two atoms was therefore considered to be correct.

Neutral atom scattering factors and anomalous dispersion corrections, for the non-hydrogen atoms, were taken from ref. 13. Scattering factors for the hydrogen atoms were those of Stewart *et al.* (14). The three largest peaks on a final difference-Fourier map were 1.10, 0.82, and 0.70 e Å$^{-3}$ located in the vicinity of the tetrafluoroborate groups. All remaining peaks were < 0.45 e Å$^{-3}$. In the final cycle of refinement no parameter shifted by more than 0.001 of its estimated standard deviation. The average $w\Delta^2$ for groups of data sectioned according to parity group, $|F_o|$, $(\sin\theta)/\lambda$, $|h|$, $|k|$, or $|l|$, showed reasonable consistency and the weighting scheme was considered to be satisfactory.

*$[Cu(PAPH)_2(H_2O)_2](BF_4)_4$ (II) (monoclinic modification)*

*Crystal data (at 24°C) are*

$C_{36}H_{34}N_{12}B_4CuF_{16}O_2$ fw = 1077.51

Monoclinic, $a$ = 12.663(4), $b$ = 9.573(3), $c$ = 18.813(4) Å, $\beta$ =

107.16(2)°, $V = 2178.9$ Å$^3$, $Z = 2$, $\rho_c = 1.642$ g cm$^{-3}$, $F(000) = 1086$, Mo Kα radiation ($\lambda_{\bar{\alpha}} = 0.71073$ Å, $\mu = 6.2$ cm$^{-1}$) graphite monochromatized. Absent reflections: $h0l, h + l \neq 2n$; $0k0, k \neq 2n$. Space group $P2_1/n$, a non-standard setting of space group $P2_1/c$ ($C_{2h}^5$, No. 14) (15) in which the general equivalent positions are $(x, y, z)$; $(\bar{x}, \bar{y}, \bar{z})$; $(\frac{1}{2} + x, \frac{1}{2} - y, \frac{1}{2} + z)$; $(\frac{1}{2} - x, \frac{1}{2} + y, \frac{1}{2} - z)$.

Except as indicated below, the details of the structure analysis for **II** are the same as those for **I**.

The light-green plate-like crystal used in the diffraction study was bounded by eight faces: (011) and (0$\bar{1}\bar{1}$), 0.234 mm apart; (01$\bar{1}$) and (0$\bar{1}$1), 0.384 mm apart; (101) and ($\bar{1}$0$\bar{1}$), 0.366 mm apart; and (10$\bar{1}$) and ($\bar{1}$01), 0.066 mm apart. Three standard reflections, ($\bar{3}$,3,$\bar{1}$0), ($\bar{3}$33), and (225) were measured after approximately every 130 data. A total of 6169 reflections ($3 \leq 2\theta \leq 30°$ ($-h, -k, \pm l$); $3 \leq 2\theta \leq 55°$ ($+h, +k, \pm l$)) were scanned. Maximum and minimum transmission factors were 0.96 and 0.84. Averaging of equivalent reflections yielded 5003 data, the 1493 having $F_o > 4\sigma(F_o)$ being used in the structure refinement. The $R$ factor for averaging (10) was 0.012. Refinement converged at $R_1 = 0.083$ and $R_2 = 0.111$ and the final weighting scheme was $w = 2.7841/(\sigma^2(F_o) + 0.000815F_o^2)$. A common isotropic temperature factor, for the hydrogen atoms attached to carbon, converged at $U = 0.04(1)$ Å$^2$. The largest peaks on a final difference-Fourier map were all < 0.73 e Å$^{-3}$ and were in the vicinity of the tetrafluoroborate groups. The check on the assignment of N(6) and C(15) performed as for **I** yielded $R_1 = 0.084$ and $R_2 = 0.111$ after three cycles of least-squares refinement. The isotropic temperature factor, $U$ (Å$^2$), was 0.053(3) for N(6) and 0.057(4) for C(15). With the scattering factors for these two atoms interchanged, three cycles of refinement from the same initial parameters resulted in $R_1 = 0.087$ and $R_2 = 0.117$. The isotropic $U$ (Å$^2$) for N(6) was now 0.026(3) and for C(15) was 0.091(5). Again, the original assignment for these two atoms was considered to be correct.

Final atomic positional parameters together with their estimated standard deviations, for **I** and **II**, are given in Table 1. Bond lengths and angles, within the cations of both structures, appear in Table 2 while interionic contacts appear in Table 3. Tables S1 and S2 list final observed and calculated structure factors for **I** and **II**, respectively. Tables S3 and S4 list final anisotropic thermal parameters while Table S5 gives a listing of least-squares planes for both structures.[2] The geometry of the cations is depicted in Figs. 5 and S1 for **I** and **II**, respectively. The atom labelling scheme for the cations of **I** and **II** is the same and is shown in Fig. 5.

## Discussion

Our previous studies with binuclear copper and cobalt complexes of PAP (1, 2) had shown that a preferred structural arrangement involved two metal centres bound simultaneously to the same ligand (Fig. 2). In all cases multiple bridging was indicated between the metal centres. Moderate to strong antiferromagnetic exchange was observed for several binuclear copper complexes ($-J = 50$–$170$ cm$^{-1}$) (1) while weaker exchange was observed for the binuclear cobalt systems ($-J < 6$ cm$^{-1}$) (2). Similar 1:2 (ligand:metal) nickel complexes were obtained but here the predominant binuclear species involved 1:1 metal:ligand ratios (3). Weak antiferromagnetic exchange ($-J < 7.3$ cm$^{-1}$) was again observed in these systems.

Since all of the binuclear copper complexes for which antiferromagnetic exchange was observed had multiple bridges between the metal centres ($N_2$ phthalazine bridge plus at least one other bridging group), attempts were made to synthesize systems in which just phthalazine bridges were involved, in order to assess the exchange pathways independently and perhaps decide which bridging groups contributed most to magnetic exchange. Consequently, 1:1 reactions between PAP and metal salts were investigated. In the case of copper tetrafluoroborate, reaction with a 1:1 stoichiometry in water resulted in the formation of three different products. Initially a mixture of brown triclinic (**I**) and green monoclinic (**II**) crystals was obtained, comprising about one third of the total product yield (see Experimental). The mixture contained approximately equal proportions of both products. On reduction of the volume of the mother liquor a dark green crystalline product (**III**) was obtained.

The brown and green crystals were separated by hand and analyzed independently. Both forms were assigned the formula $[Cu(PAPH)_2(H_2O)_2](BF_4)_4$, a system of necessity involving protonated ligand. An elemental analysis of a random sample of the mixture of **I** and **II** was found to be the same, thus supporting the individual analyses. The dark-green product (**III**) has a different elemental analysis in keeping with a product having a 2:3 (ligand:metal) ratio and is assigned a formula $[Cu_3(PAP)_2(OH)_2](BF_4)(BF_3OH)_3 \cdot 5H_2O$. A mixture of products was also obtained from the 1:1 reaction of copper tetrafluoroborate and PAP in methanol/TEOF. Initially a khaki coloured powder (**IV**) was obtained followed by dark-green crystals (**V**) on concentration of the mother liquor. The khaki product **IV** appears to be a mononuclear protonated derivative similar to **I** and **II** and is assigned the formula $[Cu(PAPH)_2](BF_4)_4$. The dark-green product **V** is a binuclear complex, $[Cu_2(PAP)_2(H_2O)_2](BF_4)_4 \cdot 0.5MeOH$.

Electronic spectra (Table 4) for compounds **I** and **II** in the solid state have major absorptions at 18 500 and 17 500 cm$^{-1}$ respectively, consistent with tetragonally distorted six-coordinate structures in which the degree of distortion may be different. Compound **IV** exhibits a weak shoulder at 16 600 cm$^{-1}$. Intense charge transfer absorption at higher energies made it impossible to pick out any further bands assignable to $d$–$d$ transitions. It seems reasonable to assume that compound **IV** is a square

[a] Values for the monoclinic modification (II) appear below those for the triclinic modification (I). Atoms are labelled as indicated in Fig. 5. Estimated standard deviations, in parentheses, occur in the last significant figure(s) for each parameter.
[b] Hydrogen atoms are labelled according to the carbon atom to which they are attached.

planar derivative. Compounds **III** and **V** exhibit three major *d–d* absorptions in the range 10 000 – 16 500 $cm^{-1}$ indicative of square pyramidal copper(II) (1). Lower energy absorptions are observed for **V**, suggesting a difference in the metal coordination sphere in these two systems. Compound **VI** has a spectrum identical to that of compound **III**. The lowest energy charge transfer absorptions, which are assigned to a $\pi-\pi^*$ transition, for all the compounds, occur at 27 400 $cm^{-1}$ or above, indicat-

ing the absence of an anionic ligand in these systems (1).

Infrared and magnetic data are recorded in Table 5. With the exception of the compound $[Cu(PAPH)_2](BF_4)_4$ (**IV**) all other derivatives exhibit infrared bands that can be assigned to coordinated and/or lattice bound water. In the case of compounds **I** and **II** two OH stretching absorptions can be clearly discerned consistent with the symmetric and antisymmetric OH stretch due to a coordinated water molecule. Single NH stretching absorptions occur in the range 3350–3390 $cm^{-1}$ for all the compounds studied, suggesting the presence of one type of NH group. These absorptions occur at somewhat higher energies than those observed for 2:1 binuclear copper complexes of PAP (1) and indicate that the two hydrogen atoms on the ligand associated with nitrogen are bound to the exocyclic nitrogen atoms. The ligand is therefore expected to exist in all the tetrafluoroborate complexes in the tautomeric form shown in Fig. 1. No other bands in this spectral region could be assigned to the protonated nitrogen site present in compounds **I**, **II**, and **IV**. The NH stretching frequency for such a group, $\overset{+}{N}H$, would be expected to occur at lower energies. Typical pyridinium salts do not have absorptions above 3000 $cm^{-1}$ which can be associated with NH stretch (16). Although compounds **I** and **II** had almost identical infrared absorptions in the OH stretching, NH stretching, and CN stretching regions, some minor differences were observed in other regions of the spectrum. However, the

complexity of the spectra in these regions prevented the rationalization of these differences in terms of a specific assignment.

One major difference between the infrared spectra of the protonated and neutral ligand complexes occurred in the aromatic CN stretching region (> 1600 $cm^{-1}$) (Table 5). Two bands associated with CN stretch are observed for PAP and compounds **III**, **V**, and **VI** which contain neutral ligand. Three major absorptions are found in this region for **I**, **II**, and **IV**, which contain protonated ligand (an additional shoulder is observed in **I** and **IV**). $[PAPH_2]Cl_2 \cdot 2H_2O$, obtained by reacting PAP with two equivalents of aqueous HCl, exhibits five bands in this region, four of which correspond with those observed for **I** and **IV**. The additional bands observed in the CN stretching region for the protonated complexes, combined with the appearance of bands associated with non-protonated exocyclic NH suggest that the possible sites of protonation are the uncoordinated phthalazine and pyridine nitrogen sites. $pK_b$ values for pyridine and for some 2-substituted pyridines fall in the range 7.2 to 8.8 at room temperature in aqueous solution (17) whereas for phthalazine a value of 10.53 is reported at 20°C (18). The pyridine nitrogen is a more basic site and although infrared data do not indicate which site is protonated the pyridine site seems most likely.

The rationale for the formation of protonated and neutral ligand complexes of PAP with copper tetrafluoroborate in water rests on the hydrolysis equilibrium involving the tetrafluoroborate ion itself. To substantiate the involvement of the tetrafluoroborate hydrolysis in the chemistry of this system would necessitate locating, for example, $BF_3OH^-$ in one of the products. It is evident from the fluorine analyses of compounds **I** and **II** that no hydroxyfluoroborate anion exists in these systems but the fluorine analysis on **III** does indicate the presence of a hydroxyfluoroborate species. However, it was not possible to identify this species by spectroscopic or crystallographic methods, although analytical and other data do suggest $BF_3OH^-$.

Magnetic moments are recorded in Table 5. Normal moments are observed for compounds **I**, **II**, and **IV**, typical of mononuclear copper(II) species. For the other complexes, which involve polynuclear structures, reduced room temperature moments are observed, indicative of systems involving antiferromagnetic exchange between the metal centres. Variable temperature magnetic studies on these systems will be reported elsewhere.

Spectroscopic and other data indicate compounds **I** and **II** to be mononuclear derivatives involving two bidentate protonated ligands and tetragonal copper with two axially coordinated water molecules (a structural description of these two compounds is to follow). Compound **III** has been formulated as a trinuclear derivative involving tetradentate ligands and possibly hydroxy bridges, with spin-exchanged metal centres. The choice of this unit is largely arbitrary and the cationic component of this system may involve a cluster of copper atoms bridged by both hydroxy and phthalazine groups. The structural identity of this compound awaits a successful X-ray analysis. Compound **VI** is assumed to have the same basic structure as **III**, while for compound **V**, in which the metal-to-ligand ratio is 1:1, a binuclear structure involving two metal centres sandwiched between two adjacent tetradentate ligands is proposed (Fig. 4). Since the ligand is neutral in this system and since no infrared absorption can be associated with a hydroxy bridge the fifth coordination site at each metal is assumed to be occupied by a water molecule. This system appears to be different from other binuclear complexes of PAP involving the metals copper, cobalt, and nickel, in which single atom bridges (e.g. halogen, hydroxide) have been found in addition to the phthalazine bridge (1–4, 6).

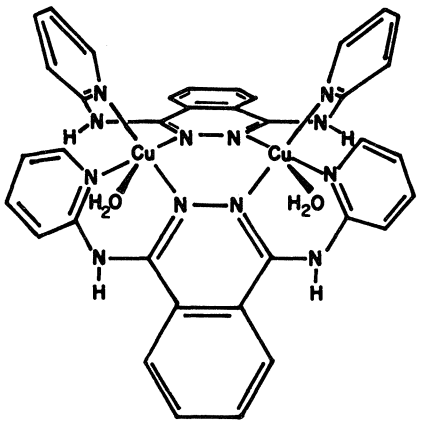

FIG. 4. Proposed structure for the $[Cu_2(PAP)_2(H_2O)_2]^{4+}$ cation in **V**.

*Description of the structures of compounds I and II*

The compound $[Cu(PAPH)_2(H_2O)_2](BF_4)_4$ crystallizes from aqueous solution yielding a brown triclinic form (**I**) and a green monoclinic form (**II**). Both structures of **I** and **II** contain $[Cu(PAPH)_2(H_2O)_2]^{4+}$ cations (Fig. 5) and $BF_4^-$ anions in a ratio of 1:4. The copper atoms of the cations in both structures occupy sites of $\bar{1}$ symmetry and are at the centre of a tetragonally distorted octahedron formed by two *trans* water molecules (Cu—O(W) = 2.497(9) Å in **I** and 2.426(9) Å in **II**) and four nitrogen atoms from two chelating bidentate protonated PAP ligands (Cu—N(pyridine) = 1.995(10) Å in **I** and 2.035(11) Å in **II**; Cu—N(phthalazine) = 1.980(9) Å in **I** and 1.997(10) Å in **II**). The Cu—N distances can be compared to similar distances in the complex $[Cu_2(PAP)(OH)Cl_3] \cdot 1.5H_2O$, **VII**, wherein PAP behaves as a bisbidentate ligand. Figure 2 shows one of the two crystallographically independent molecules of this complex, as determined in a recent X-ray study (4). The Cu—N(pyridine) distances in **I** and **II** are similar, and are comparable to the average of these distances (1.984 Å) in **VII** and to the Cu—N(pyridine) distances of 2.015(7) and 1.989(7) Å in the structure of $[Cu_2(bpim)(NO_3)_2(ClO_4)(H_2O)] \cdot H_2O$ (19). The Cu—N(phthalazine) distances in **I** and **II** are not significantly different, nor are either of them significantly different from the 2.017 Å average for this distance in **VII**. The Cu—N distances of ca. 2 Å, observed in **I** and **II**, are typical of similar distances found in a variety of copper(II) complexes (20–24). The distances and angles within the PAP ligands of both complexes are comparable, and are similar to those observed in both molecules of **VII**.

The distances and angles of **I** and **II** are generally quite comparable. One significant difference be-

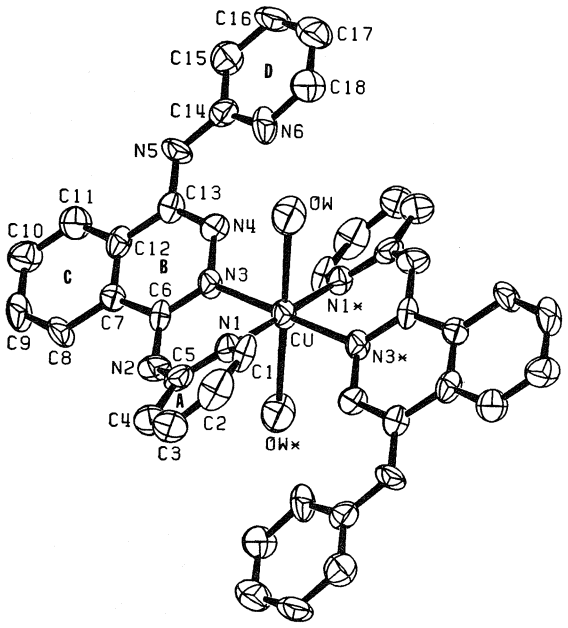

FIG. 5. Geometry and atom labelling scheme for the $[Cu(PAPH)_2(H_2O)_2]^{4+}$ cation in **I**. The geometry and atom labelling for the cation in **II** is similar. Thermal ellipsoids are depicted at the 50% probability level. Hydrogen atoms are not shown. Atoms labelled with an asterisk are related to those unlabelled by a centre of symmetry located at the Cu atom.

tween the structures, however, is the Cu—O(W) bond length which is 2.497(9) Å in **I** and 2.426(9) Å in **II**. This distance presumably reflects the fact that O(W) in **II** is involved in two H-bonding interactions of 2.77(2) and 2.79(1) Å (Table 3) to two different $BF_4^-$ groups while the closest approach to O(W) in **I** is 2.94(1) Å. Lists of interionic contacts less than 3.3 Å appear in Table 3 which summarizes the differences in packing between **I** and **II**. Packing is presumably the main difference between **I** and **II** since the geometry of the cations is quite similar in both structures. All the contacts listed in Table 3 are to fluorine atoms and close contacts to any other atoms of the structure are therefore all greater than 3.3 Å. Reference 25 lists 2.7 Å as the observed O ... F distance in O—H ... F hydrogen bonds and 2.8 Å for the N ... F distance of N—H ... F hydrogen bonds. Accordingly, the only true H-bond appears to occur in **II** between N(5)—F(11$^c$) at 2.65(1) Å but perhaps the short contacts to O(W) should be considered significant as well.

During the solution of the structures of **I** and **II**, it became apparent that there was one more tetrafluoroborate anion per ligand in the lattice of each structure than would be expected for a neutral PAP complex. It became necessary, therefore, to introduce a further positive charge into each lattice and the only plausible way of doing this was to assume that PAP had become protonated during the synthesis of the complex. Direct crystallographic evidence for this proton, however, has not been forthcoming. The possible sites for the protonation of PAP would be N(2), N(4), N(5), and N(6). Of these possibilities, N(4) and N(6) appear to be the most likely candidates (see earlier discussion). The angles at N(2) and N(5) are similar in both **I** and **II**, which suggests that neither is protonated. The location of N(6) in **I** and **II** was determined by utilizing the differences between the scattering factors for carbon and nitrogen. The position of N(6), as determined by experiment, is shown in Fig. 5. The other possibility was the interchange of N(6) with C(15). This was not found to be the case, however. The position of N(6) suggests that there may be some form of hydrogen bonding between N(4) and N(6), either of the form N(4)—H ... N(6) or N(4) ... H—N(6). The N(4) ... N(6) distances of 2.559(14) Å in **I** and 2.591(18) Å in **II** are well below the 3.1 Å indicated in ref. 25 as being the value observed for other N—H ... N hydrogen bonded systems. The small dihedral angles between plane BC and plane D of 8° in **I** and 13° in **II**, also suggest that such a hydrogen bond may exist. Normally, the PAP ligand would be expected to act as a bis-bidentate ligand interacting with two metal ions as observed in **VII** (Fig. 2). The fact that in **I** and **II**, each PAP binds to only one metal ion is also consistent with one potential chelating site being occupied by a proton, as suggested by the hydrogen bonding argument. The location of a proton on N(4) or N(6) cannot be obtained directly from the crystal structures of **I** or **II**, however. The C(14)—N(6)—C(18) angles of 120.2(13)° in **I** and 119.4(13)° in **II** fall between 125 ± 3°, for protonated nitrogen atoms, and 116 ± 3°, for unprotonated nitrogen atoms, as suggested by the empirical rule of Singh (26, 27) for six-membered nitrogen heterocycles. One possible explanation for this observation of a value lying between 125° and 116° is that the site of protonation is disordered between N(4) and N(6). That is, the situation would be N(4)—H ... N(6) approximately 50% of the time and N(4) ... H—N(6) for the remainder. This would lead to an averaging of the actual values. The angles at N(3) and N(4) are all similar to one another in **I** and **II** and reveal no information as to N(4) protonation.

The chemistry of the system described herein suggests the presence of $BF_3(OH)^-$ as well as $BF_4^-$ in aqueous solution. The possibility that $BF_3(OH)^-$ appears in the structures of **I** and **II**, or is indeed the reason for the differences between **I** and **II**, has been recognized. Tetrafluoroborate anions often

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

behave badly in the least-squares refinement, however,and the likelihood of being able to differentiate between an oxygen atom and a fluorine atom, in the same manner as was done for carbon and nitrogen (see Experimental), is quite low. Consequently, no attempt was made to explore this possibility in the present work, the tetrafluoroborate anions being refined as rigid groups. The charge balance of structures **I** or **II** would, of course, not be upset by the replacement of $BF_4^-$ by $BF_3(OH)^-$. However, the fluorine analyses on **I** and **II** indicate the absence of $BF_3(OH)^-$ in these systems. Clark and Lynton (28) determined the crystal structure of $NaBF_3OH$ and found that the hydroxyl group could not be distinguished from the isoelectronic fluorine atoms. The $BF_3OH^-$ ion has a distorted tetrahedral geometry.

The dihedral angles between plane A and plane BC (Fig. 5) in **I** and **II** are 34° and 28°, respectively. In **VII**, this angle is similar and averages 29° for the four angles involved. In **I** and **II**, the Cu atom lies 0.64 Å and 0.70 Å out of plane A. This deviation is smaller for **VII** and ranges from 0.08–0.40 Å. The dihedral angle between plane BC and plane D is small in both **I** and **II** (8° and 13°) suggesting that these two rings are more closely planar than planes A and BC which are involved in coordination to copper. Accordingly, the plane A – plane D dihedral angles in **I** and **II** (30° and 19°) are less than the average (58°) for the similar angles in **VII**.

In compound **VII**, there is a dihedral angle of 9° and 11° between planes B and C (Fig. 2) in molecules 1 and 2, respectively. In **I** and **II** the corresponding dihedral angles are only 3.5°, suggesting the phthalazine ring is almost planar in these compounds. The largest deviation of any atom from the mean plane through ring A is 0.05 Å for **I** and 0.03 Å for **II**. For ring D the largest deviations are 0.02 Å for **I** and **II**. In **VII**, the largest deviation from rings A or D is 0.03 Å. The largest deviation from plane BC is 0.08 Å in **I** and 0.07 Å in **II** and this corresponds to N(3) in both structures. The Cu atom is 0.50 Å out of this plane in **I** and 0.56 Å in **II**. For **VII**, the largest deviation from plane BC is 0.15 Å and the Cu atoms range from 0.88 to 1.03 Å out of this plane.

The phenomenon of crystals of the same compound, and having the same composition, crystallizing from the same solution in different crystalline modifications is not unknown. For example, the compound

$$[(OC)_4Mn(\mu\text{-}C_4H_5O)Pt(PMe_3)_2]$$

crystallizes from 1:1 light petroleum/ether in a red monoclinic form, space group $P2_1/n$, and a yellow triclinic form, space group $P\bar{1}$ (29). The two forms of $PdI_2(PMe_2Ph)_2$ crystallize from methanol as red needles, space group $P2_12_12_1$, and yellow plates, space group $P2_1/c$ (30). $[PtCl(NH_3)_2(C_5H_7N_3O)](NO_3)$ crystallizes from water as needles, space group $P2_1/c$, or cubic parallelepipeds, space group $C2/c$ (31). The phenomenon has also been observed before in copper coordination chemistry. Bis(1,3-diaminobutane)copper(II) perchlorate crystallizes from ethanol, methanol, or water as blue–violet prisms and plates or red violet needles (32, 33). Both forms are monoclinic, space group $P2_1/c$. Bis(*N*-*tert*-butylpyrrole-2-carbaldimino)copper(II) crystallizes from *n*-heptane as light-green needles, space group $P\bar{1}$, and dark green tetragonal-pyramids, space group $P4_12_12$ (34). With certain compounds it is possible to transform one crystalline form into another by the application of heat (30, 35–37).

# Pyrones. VIII.[1] Biosynthetic investigations of the fungal metabolite phacidin

TERRY DONALD CYR[2] AND GERALD ARTHUR POULTON[3]

*Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2*

Received July 15, 1981

TERRY DONALD CYR and GERALD ARTHUR POULTON. Can. J. Chem. **60**, 133 (1982).

Biosynthetic feeding experiments with singly and doubly $^{13}$C-labelled acetate show that phacidin (4-methoxy-6-nonanoyl-2*H*-pyran-2-one-3-carboxaldehyde) is formed from a heptaketide precursor. A similar feeding with sodium $^{13}$C-formate has shown that the methoxyl and aldehyde carbons are derived from the one-carbon pool.

TERRY DONALD CYR et GERALD ARTHUR POULTON. Can. J. Chem. **60**, 133 (1982).

Des expériences d'alimentation biosynthétique avec un acétate marqué avec un ou deux $^{13}$C révèlent que la phacidine (méthoxy-4 nonanoyl-6 2*H*-pyranone-2 carbonaldéhyde-3) se forme à partir d'un précurseur heptacétide. Une alimentation analogue avec le formate $^{13}$C de sodium montre que les carbones du méthoxy et de l'aldehyde proviennent de sources contenant un seul carbone.

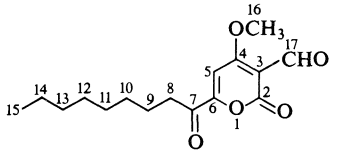
## Introduction

Phacidin, 4-methoxy-6-nonanoyl-2*H*-pyran-2-one-3-carboxaldehyde **1**, is an antibiotic (1, 2)



**1**

metabolite isolated (2) from cultures of the fungus *Potebniamyces balsamicola* Smerlis var. *boycei* Funk, whose synthesis we have recently reported (3). During our investigations, we were desirous of obtaining further supportive evidence of the structure of phacidin and information relating to its possible mode of formation by the fungus, and thus undertook to perform some simple biosynthetic experiments. The biogenetic origin of the carbon skeleton of a natural product can now be determined routinely in favourable cases by the use of $^{13}$C-enriched precursors (4). Since phacidin possessed many of the characteristics of an acetogenin (polyoxygenated ring, linear carbon skeleton, long saturated side-chain, etc.), we commenced our investigations with the feeding of singly- and doubly-labelled sodium acetate.

## Results and discussion

In order to test the predictions concerning the biosynthesis of a metabolite, the position of the labelled atom(s) in the product must be determined. The use of carbon-13 magnetic resonance, combined with the use of carbon-13 enriched precursors, has greatly simplified biosynthetic studies of secondary metabolites since chemical degradation of the product becomes unnecessary. Accurate assignment of the $^{13}$Cmr spectrum is, however, a necessity, since any misassignment may lead to false assumptions and/or conclusions about the biosynthesis.

### *(A) Assignment of $^{13}$Cmr spectrum of phacidin*

Many 4-oxy-2-pyrones are known, and the difficulties encountered in accurately assigning resonances due to C-2, C-4, and C-6 have been discussed (5). Indeed, one of the original $^{13}$C-labelled biosynthetic investigations of an α-pyrone (radicinin, **2** (6)) had to be repeated and the resonances reassigned (7). Similar studies such as the assignment (8) and reassignment (9) of the $^{13}$Cmr spectrum of Aurovertin B **3** have further emphasized the need for caution when analyzing the spectra of 2-pyrones. Considerable care was therefore taken in the assignment of the $^{13}$Cmr spectra of phacidin and its derivatives.[4]

An examination of the chemical shift values of a variety of 4-oxypyrones (see Table 1) indicates that the assignment of C-4 is straightforward, since it is consistently the most downfield signal as compared to the other ring carbons. This same trend also holds for most hydroxycoumarins (e.g. compound **12**). It has also been shown that for 2-pyrones the magnitude of the two-bond spin–spin coupling constant between C-2 and a proton at C-3 (H-3) is less than that of C-6 to H-5 or to protons on a side-chain at C-6 (12), resulting in C-6 normally

12

appearing as a multiplet, while C-2 remains as a singlet or doublet.

The signals in the $^{13}$Cmr spectrum due to the ring carbons of phacidin were thus assigned as follows:

(*i*) δ 172.9 (m), C-4, being the most deshielded ring carbon.

(*ii*) δ 160.2 (d, $^{3}J_{C-H}$ = 2.5 Hz), C-2. The chemical shift range of C-2's of similar compounds was approximately δ 160–165 ppm, and the analogous compound **5** showed a similar three-bond coupling constant of 3.3 Hz.

(*iii*) δ 158.5 (d, $^{2}J_{C-H}$ = 1.4 Hz), C-6. The chemical shifts for C-6 of a variety of analogous compounds had a relatively wide range of δ 154–175. The two extremes of this range can be represented by compounds **5** (174.4) and **4** (155.2), consistent with the donor/acceptor nature of the carbonyl substituents and its transmission via the conjugated system (13). The carbon α to the carbonyl experiences an increase in electron density (shielding), while those β or δ to it show a decrease (deshielding). In phacidin, the C-6 carbon is influenced by both the aldehyde substituent at C-3 (deshielding on C-6) and the directly attached nonanoyl group (shielding at C-6); the latter is expected to dominate, and phacidin therefore shows the C-6 resonance at δ 158.5, shielded with respect to its analogue **6** which is lacking an aldehyde substituent at C-3 (i.e. no C-17), and which has the resonance at δ 165.8 ppm.

TABLE 1. $^{13}$Cmr spectra of 4-oxy-2-pyrones

| Compound | C-2 | C-3 | C-4 | C-5 | C-6 | Reference |
|---|---|---|---|---|---|---|
| **1** | 160.2 | 105.9 | 172.9 | 97.0 | 158.5 | 3 |
| **2** | 156 | 97.8 | 174.7 | 98.2 | 162.5 | 7 |
| **3** | 163.4 | 88.6 | 170.4 | 107.4 | 154.1 | 9 |
| **4** | 162.5 | 93.7 | 170.2 | 103.8 | 155.2 | 3 |
| **5** | 162.2 | 102.1 | 174.6 | 94.3 | 174.4 | 3 |
| **6** | 165.0 | 87.5 | 171.3 | 99.6 | 165.8 | 3 |
| **7** | 164.6 | 87.3 | 171.4 | 100.3 | 162.1 | 10 |
| **8** | 161.2 | 99.9 | 181.1 | 101.4 | 169.2 | 10 |
| **9** | 161.8 | 105.1 | 170.4 | 95.2 | 166.9 | 10 |
| **10** | 159.5 | 100.0 | 178.2 | 98.3 | 166.9 | 10 |
| **11** | 160.8 | 88.4 | 166.9 | 95.2 | 162.9 | 10 |
| **12** | 161.8 | 91.0 | 165.5 | 115.7 | 153.4 | 11 |

(*iv*) δ 105.9 (dd, $^{2}J_{C-H}$ = 24.5 Hz, $^{3}J_{C-H}$ = 4.2 Hz), C-3. In the series of analogous compounds, C-3 resonated at δ 88–105 ppm. The derivative **5** likewise showed C-3 at δ 102.1 (dd, $^{2}J_{C-H}$ = 23.9 Hz, $^{3}J_{C-H}$ = 4.2 Hz), consistent with this assignment.

(*v*) δ 97.0 (d, $^{1}J_{C-H}$ = 175.3 Hz), C-5. The assignment of C-5 was trivial, since it was the only carbon directly bonded to proton. Normal chemical shift ranges and coupling constants are δ 95–108 and $^{1}J_{C-H}$ = 170–176 Hz.

In addition, it was a trivial matter to assign the nonanoyl ketone C-7 (δ 193.5, m), the 3-carboxaldehyde C-17 (δ 186.3, d, $^{1}J_{C-H}$ = 186.2 Hz), the methoxyl C-16 (δ 58.4, q, $^{1}J_{C-H}$ = 148.4 Hz), and the methylene α to the ketone, C-8 (δ 38.3, t, $^{1}J_{C-H}$ = 123.6 Hz). The remaining carbons of the nonanoyl side chain were assigned by comparison with the assignments of 2-octanone and 1-decanol (14) in Table 2.

| 9 | 23.1 | 127.5 | t |
| 8 | 38.3 | 123.6 | t |

*We were unable to distinguish C-10, C-11, and C-12 since their chemical shift values were only very slightly different from each other.

*(B) Sodium acetate-1-$^{13}C$ labelling experiment*

Labelled sodium acetate was fed to growing cultures of *P. balsamicola* and the distribution of the $^{13}C$ label in the resulting phacidin determined according to the method of McInnes *et al.* (15), by comparing the $^{13}C$mr spectra of natural abundance and enriched compounds recorded under identical instrument parameters. In order to make the comparisons more valid, the carbons to be compared should have similar substituents. Since it was known, *vide infra*, part D, that the aldehyde and methoxyl carbons were not acetate-derived, they were used as reference signals to which the unsaturated (C-2 to C-7) and saturated (C-8 to C-15) were compared.

The results (Table 3) indicate that C-2, C-4, C-6, C-8, and C-14 have been enriched by the feeding of sodium acetate-1-$^{13}C$ to *P. balsamicola*; it is obvious also that C-10 and C-12 are similarly labelled.

*(C) Sodium acetate-1,2-$^{13}C_2$ labelling experiment*

*P. balsamicola* was fed sodium acetate-1,2-$^{13}C_2$ in the same manner and for the same duration as described in the above labelling experiment. The $^{13}C$mr spectrum of labelled phacidin clearly showed the presence of coupled $^{13}C$–$^{13}C$ units (see Table 4) demonstrating the utilization of intact acetate units in the biosynthesis. In addition, the labelling pattern corroborated the chemical shift assignments discussed above.

Intact incorporation of acetate units into the phacidin skeleton was demonstrated for C-2—C-3, C-4—C-5, C-6—C-7, C-8—C-9, C-12—C-13, C-14—C-15, and was assumed for C-10—C-11, thereby indicating its probable biogenesis from an hepta-acetate precursor as indicated below.

*(D) Sodium formate-1-$^{13}C$ labelling experiment*

*P. balsamicola* cultures were fed labelled sodium formate as described below, with the incorporation of $^{13}C$ in the methoxy (C-16) and aldehyde (C-17) groups clearly being indicated by spectral examination. The extent of incorporation was so large in these two positions that it was readily detectable in

TABLE 3. Calculation of incorporation of sodium acetate-1-$^{13}C$ into phacidin

†Values not obtained due to overlapping of signals.

the 90 MHz $^1$Hmr spectrum: the methoxy protons appeared as a singlet at 4.14 ppm ($^{12}C$—H) and a doublet centred at 4.15 ppm ($^{13}C$—H, $^1J$ = 148 Hz), the ratio of intensities indicating 29% $^{13}C$ incorporation, while the aldehyde proton appeared as a singlet (10.85 ppm, $^{12}C$—H) overlapped by a doublet centred at 10.84 ($^{13}C$—H, $^1J$ = 188 Hz), the ratio of intensities indicating 36% $^{13}C$ incorporation. This was substantiated further by the 62.8 MHz $^{13}$Cmr spectrum[5] which showed dramatically increased intensities of the 186 (aldehyde) and 58 ppm (methoxyl) carbons as compared to the remaining signals. The methoxy and aldehyde carbons thus do not originate from an acetate-derived precursor, but from the C-1 metabolic pool.

*(E) Possible biogenesis*

The above feeding experiments indicate that phacidin can be formed from seven acetate units with two one-carbon insertions. This may occur via an elaboration of an enzyme-bound caprate (e.g. **13**) produced by normal fatty acid routes to a fourteen-carbon unit (**14**) which may then undergo *O*-cyclization to give a pyrone derivative. The sequence of the other necessary stages, that is, one-carbon introduction and oxidation at C-7, cannot, of course, be determined without much more extensive investigation (see Fig. 1).

## Experimental

Carbon magnetic resonance spectra were obtained on Nicolet TT-14 (15.1 MHz, Victoria), Bruker WP250 (62.8 MHz, Bruker Canada Ltd., Mississauga) and Varian XL100/15 (25.2 MHz, Atlantic Regional Laboratory, Halifax) instruments in $CDCl_3$, and are referenced to internal TMS.

[5]Kindly run by Dr. C. Roger, Bruker Spectrospin Canada, Mississauga, Ont., Canada L5L 1J9.

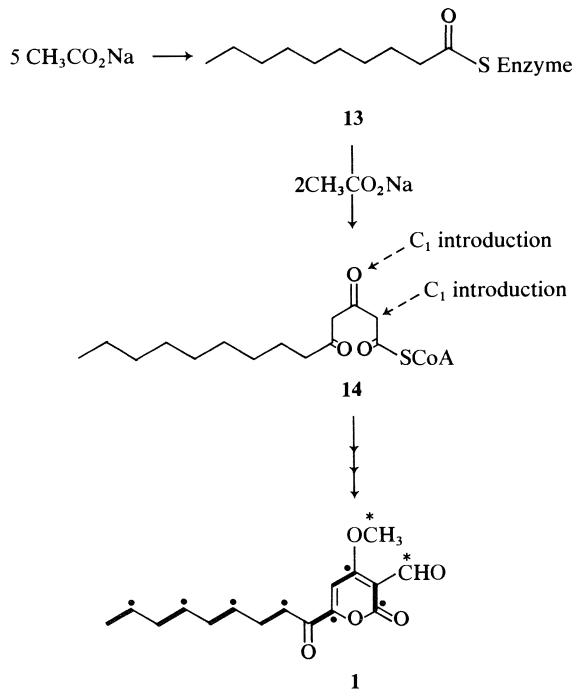

FIG. 1. Feeding of $CH_3{}^{13}\dot{C}O_2Na$, $^{13}CH_3$—$^{13}CO_2Na$, and H—$^{13}CO_2Na$ to *P. balsamicola*; possible biosynthetic route.

*Sodium acetate-1-$^{13}C$ feeding*

Cultures of *P. balsamicola* were grown at the Pacific Forest Research Centre by A. Funk. They were allowed to grow for two weeks, unshaken, at 15°C in 75 mL of 5% malt extract in water. Sodium acetate-1-$^{13}C$ (100 mg, 90% enriched, Stohler Isotope Chemicals) in water (5 mL) was added and the cultures allowed to grow for a further six weeks. Labelled phacidin was then isolated by benzene extraction, and purified by recrystallization from cyclohexane.

*Sodium acetate-1,2-$^{13}C_2$ feeding*

Cultures were grown in a manner similar to that detailed above, and sodium acetate-1,2-$^{13}C_2$ (100 mg, 90% $^{13}C$-enriched, Stohler Isotope Chemicals) added in a similar fashion. Phacidin was isolated by benzene extraction and purified by recrystallization.

*Sodium formate-1-$^{13}C$ feeding*

Cultures were grown in a manner similar to that detailed above. After 10 weeks, labelled sodium formate (90% enriched, Stohler Isotope Chemicals) was added (304 mg in four portions) over a period of two weeks. Blank feedings using unlabelled sodium formate were also carried out. After two further weeks, phacidin was isolated by hot 1,2-dichloroethane extraction and purified by recrystallization.

# Thermochromism of 1,2,5-triphenylphosphole and the formation of 1,1,2,2-tetrachloro-1,2-diphenylethane from α,α,α-trichlorotoluene

MARTIN B. HOCKING AND TREVOR A. SMYTH

*Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2*

Received March 17, 1981[1]

MARTIN B. HOCKING and TREVOR A. SMYTH. Can. J. Chem. **60**, 138 (1982).

On boiling a yellow solution of 1,2,5-triphenylphosphole in carbon tetrachloride the colour changes to red, reverting to yellow on cooling. This reversible colour change has been conducted in the presence of various additives in an attempt to determine the cause of the colour change. Boiling 1,2,5-triphenylphosphole in α,α,α-trichlorotoluene similarly showed a colour change and gave a coupling product of the solvent, 1,1,2,2-tetrachloro-1-2-diphenylethane. From this evidence and related synthetic, nmr, and esr experiments it is proposed that the colour change of the former system arises from the incipient formation of a phosphole–trichloromethide salt with carbon tetrachloride. With trichlorotoluene the phosphole undergoes more substantive formation of dichlorophenylmethide and possibly chloride salts which undergo further reaction to the observed coupling product.

MARTIN B. HOCKING et TREVOR A. SMYTH. Can. J. Chem. **60**, 138 (1982).

Une solution de triphényl-1,2,5-phosphole dans le tétrachlorure de carbone portée à ébullition devient rouge, et la couleur passe du rouge au jaune lors du refroidissement. On a réalisé ce changement réversible de couleur en présence de plusieurs additifs dans le but d'en déterminer la cause. Le triphényl-1,2,5-phosphole dans le trichloro-α,α,α-toluène porté à ébullition présente les mêmes caractéristiques et donne un produit de couplage avec le solvant; le tétrachloro-1,1,2,2 diphényl-1,2-éthane. A partir de ces observations et à partir des expériences de synthèse, de rmn et de rpe, on propose que le changement de couleur du premier système provient de la formation d'un sel phosphole-trichlorométhylure par réaction avec le tétrachlorure de carbone. Dans le cas du trichlorotoluène, le phosphole conduit à la formation plus appréciable de dichlorophénylméthylure et éventuellement de chlorures qui, par des réactions subséquentes, conduisent au produit de couplage observé.

## Introduction

Thermochromism, or a reversible colour change obtained on heating (or cooling) a substance from room temperature, has been relatively recently reviewed (1–3). More recently than these summaries and related to this study, the thermochromism demonstrated by solutions of highly arylated pyrryls (4), imidazolyl (5), or benzoquinolinium (6) heterocycles is generally ascribed to a resonance stabilized radical species analogous to that put forward for triphenylchloromethane (7). For solutions of certain spiropyrans (8), equilibrium formation of ring opened zwitterionic products has been implicated in the thermochromic effect, whereas for some anils (9) and benzophenone anthraldazine (10) "aza olefins" *E,Z* isomeric transformations are thought to be the cause. There remain, however, several examples of thermochromic compounds such as tetranisylethylene (11) and an indanedionyl dimer (12) for which no mechanistic proposal for the colour change has yet been made.

Solutions of 1,2,5-triphenylphosphole in carbon tetrachloride under ordinary conditions are yellow with a strong blue fluorescence twice the intensity of fluorescein (13). When the solution is boiled under reflux in a nitrogen atmosphere, however, it slowly changes to a bright red which rapidly reverts to the original yellow colour on cooling (14). This process, which can be repeated many times with the same sample, has now been examined in some detail to determine whether this effect is truly a thermochromic one, or an incipient but reversible reaction to a red product. An additional objective was to obtain some evidence of the probable species involved in either eventuality.

## Experimental

Unless otherwise stated, all solvents used were dried, using fresh 1.5 mm pellets of molecular sieve 4A (Union Carbide), except for α,α,α-trichlorotoluene which was dried by an azeotropic forerun and the remainder distilled.

### *1,2,5-Triphenylphosphole thermochromism in carbon tetrachloride*

A solution of yellow crystals of the phosphole (0.98 g) in carbon tetrachloride was boiled under reflux in a nitrogen atmosphere for 3.25 h during which time the solution gradually became an intense bright red. Within one minute of removing the heating mantle the solution became yellow again. Resuming heating for a further 3 h returned the red colour. The solution was cooled, washed with two small portions of water, dried, and concentrated to recover 0.91 g (93%) of the starting phosphole.

Conducting the experiment as above, but open to the air, more slowly gave the same colour change which reverted to the original yellow colour on cooling, or on the addition of a drop of water or chloroform. Also, in ordinary moist reagent grade carbon tetrachloride, either open to the air or under nitrogen, no colour change was observed.

Boiling a solution of 1,2,5-triphenylphosphole-1-*oxide* in dry

[e] Triphenylphosphine catalyst, rather than 1,2,5-triphenylphosphole.

carbon tetrachloride in the same fashion gave no colour change, and quantitative recovery of the oxide, unchanged.

*Trapping experiments for phosphole/carbon tetrachloride thermochromic species*

Prolonged interaction of benzaldehyde with a solution of the phosphole in carbon tetrachloride under nitrogen failed to demonstrate any change, either at room temperature or when boiled under reflux, by glc, and by quantitative recovery of the reactants.

Addition of a drop of dry butyric acid to a refluxing red solution obtained again as initially described caused immediate reversion to the initial yellow colour. Addition of a total of 0.30 g butyric acid and boiling for a further 24 h under $N_2$ gave no return of red colouration, near quantitative phosphole recovery, and ir bands at 1180 weak (P=O), 1715 strong (acid C=O), and 1823 weak (anhydride or acid Cl C=O) $cm^{-1}$ in the residual mother liquor. Boiling for periods as long as 16 days failed to cause any significant further change.

Repetition of the butyric acid experiment except using vacuum dried stearic, benzoic, and trichloroacetic acids, gave the same initial colour reversion, near quantitative phosphole recovery, and weak or nonexistent ir bands in the region of 1820 $cm^{-1}$ for the mother liquor after periods of boiling under reflux of 7 to 16 days.

*Phosphole coupling of α,α,α-trichlorotoluene*

A solution of 1,2,5-triphenylphosphole (0.30 g) in freshly distilled α,α,α-trichlorotoluene (40 mL) was heated at 200°C for 4 h with protection from atmospheric moisture, and then allowed to stand at room temperature for 14 h. Excess solvent was removed under reduced pressure on a rotary evaporator and the brown residue (1.03 g) sublimed (90–160°C/0.4 Torr) to yield 0.64 g of impure 1,1,2,2-tetrachloro-1,2-diphenylethane (tetrachlorotolan). Resublimation (80°C/0.4 Torr) and recrystallization of a portion of the impure material from acetone provided an analytical sample, mp 160–162°C (lit. (15) mp 162–162.5°C). *Anal.* calcd. for $C_{14}H_{10}Cl_4$: C 52.54, H 3.15; found: C 52.09, H 2.92.

The residue from the initial sublimation was an intractable brown solid that showed no ir band correspondence to the phosphole-1-oxide in the 625 to 900 $cm^{-1}$ region both from spectra obtained on mulls or from solvent-evaporated thin films. The results of other similar coupling experiments using 1,2,5-triphenylphosphole are presented in Table 1.

When triphenylphosphine (2.62 g) was boiled for 4 h in α,α,α-trichlorotoluene, 1.45 g of tetrachlorotolan was isolated by a similar sublimation technique from a tarry residue of triphenylphosphine oxide. When tri-*n*-butylphosphine and α,α,α-trichlorotoluene were boiled together under similar conditions, a residue of 8.17 g of tarry material was obtained on evaporation of the excess trichlorotoluene. Infrared spectra of fractions partially resolved by glc, fractional sublimation experiments, and $^1H$ nmr demonstrated the presence of tetrachlorotolan and traces of tri-*n*-butylphosphine oxide (16) in this residue.

A blank experiment in which 25 mL of α,α,α-trichlorotoluene was boiled under reflux on its own for 4 h left no residue on rotary evaporation under reduced pressure.

*Phosphole plus α,α,α-trichlorotoluene trapping experiments*

A solution of 1,2,5-triphenylphosphole (3.12 g) in α,α,α-trichlorotoluene was boiled under reflux for 1 h, at which time acetic acid (0.57 mL) was added. Refluxing was continued for an additional 16 h. Direct ir examination of the cooled solution, and ir and $^1H$ nmr examination of the first four fractions (1 mL total) of distillate obtained from this solution showed no trace of acetyl chloride. Rotary evaporation of the solvent from the distilland gave 6.2 g of brownish-orange semi-crystalline material from which 4.35 g of pure tetrachlorotolan, mp 158–161.5°C, was isolated. Repetition of the experiment on the same scale again gave no acetyl chloride but yielded 3.45 g of tetrachlorotolan.

Carrying out an experiment similar to the above but using butyric acid (0.86 mL) in place of acetic acid gave no acid chloride but yielded pure tetrachlorotolan (5.29 g). Benzoic acid (≈20 mg; mp 118–121°C), confirmed by ir and $^1H$ nmr, was also recovered.

α,α,α-Trichlorotoluene (15 mL) was boiled under reflux with water (4 mL) for 50 h. After cooling to room temperature, exhaustive extraction with saturated aqueous sodium bicarbonate and filtration of the cold, acidified extracts yielded 7.53 g (56% based on water) of benzoic acid.

*Electron spin resonance experiment*

A 1% solution of 1,2,5-triphenylphosphole in α,α,α-trichlorotoluene placed in a Bruker ER 200 tt esr spectrometer, was carefully scanned over 1000 G range about the free spin *g*-value, followed by a repetition over a 200 G range. No paramagnetic species were detected either at 293 K, or when repeated at 20° intervals up to 413 K or 423 K, at which temperature the solution was virtually black in colour.

*Phosphorus-31 and proton magnetic resonance experiments*

Approximately 1% solutions of twice-recrystallized 1,2,5-triphenylphosphole and its oxide were made up in carbon

[a] Spectra all taken in ethanol, or aqueous ethanol. Duplicate references given reflect very similar spectral data.
[b] Spectra of the chloride and iodide are very similar (20; plus ref. 20, page D11/5).

tetrachloride and α,α,α-trichlorotoluene, and placed in 10 mm diameter nmr tubes each with an axially-positioned, evacuated sealed capillary containing 99.8% deuterium oxide to provide an external lock signal. The tubes to be heated containing carbon tetrachloride solutions were chilled to −30°C and sealed under aspirator vacuum. Trimethyl phosphite, in a separate tube, was used for reference. The results of proton-decoupled $^{31}P$ spectra obtained on a Bruker Cryospec WM 250, Aspect 2000 instrument are summarized in Table 2. Proton spectra were also recorded.

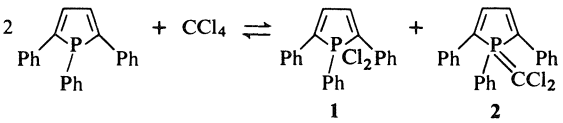
## Results and discussion

Temperature quenching of fluorescence, which has frequently been the cause of thermochromism (1), is apparently not the source of the observed colour change on heating 1,2,5-triphenylphosphole in carbon tetrachloride, both because blue fluorescence is still observed with the boiling solution, and because removing a blue component from yellow does not give a red colour.

Since no colour change was observed on prolonged boiling of a solution of 1,2,5-triphenylphosphole in benzene or xylene, evidently the chloride was a necessary feature of the solvent carbon tetrachloride to obtain the red solution. Tertiary phosphorus was also a requirement from the no-effect observation on the boiling of a solution of 1,2,5-triphenylphosphole-1-oxide in carbon tetrachloride.

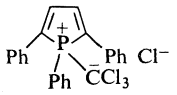
It was thought that the red colour might be the result of the bathochromic shift induced by the extension to the cross conjugated system resulting from the direct reversible formation of the dichloromethylene phosphorus compound **2**, by analogy with the triphenylphosphine system (17). Extended boiling of the red phosphole – carbon tetrachloride system in the presence of benzaldehyde, a Wittig-type substrate added to trap any potential phosphorane, only returned unchanged starting materials.

It is evident from Table 3 that phosphonium salts analogous to those postulated here uniformly show a bathochromic wavelength shift coincident with

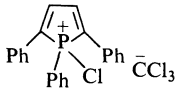


**1** **2**

hypochromic shift in intensity, as compared to the parent phosphine, the same as qualitatively observed here. Accordingly, from precedents set by the preparation of acid chlorides from analogous salts of other tertiary phosphines (22), tests were conducted with a series of carboxylic acids to interact with either of the two salt types, **3** or **4**,



**3**



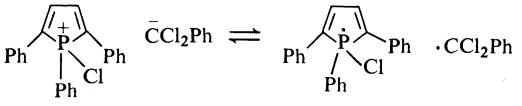
**4**

potentially present in this system. Acetic and stearic acids failed to demonstrate any significant acid chloride formation even though they caused colour reversion. Butyric acid, which was about 8% converted to acid chloride in 28 h, could not, however, be induced to react further even by extending the boiling period to 7 days. Therefore, if phosphonium salt formation was the cause of the red colour, the equilibrium must be well to the left and the colour due to very low salt concentrations, to observe such low acid to acid chloride conversions for acids which have readily afforded acid chloride with other phosphines.

Boiling 1,2,5-triphenylphosphole in α,α,α-trichlorotoluene gave a change to an orange colour in 20 min, and ultimately to a reddish-brown solution, but this solution did not revert to yellow on cooling. After as little as 4 h boiling, no trace of either phosphole or phosphole oxide was detectable in the residue obtained on evaporation of the solvent. However, significant quantities of 1,1,2,2-tetrachloro-1,2-diphenylethane (tetrachlorotolan), a coupling product, was isolated from all reactions conducted in this medium (Table 1). Crude yields ranged from 1.1 to 3.3 moles of tetrachlorotolan per mole of phosphole initially used, which decreased to the 1.4 to 2 mole range for the purified product. A control reaction in the absence of phosphole returned unchanged (although slightly coloured) α,α,α-trichlorotoluene.

The apparent novelty of this phosphine-induced coupling reaction, together with an interest in obtaining further information of potential value towards determining the pathway of this process prompted the testing of similar α,α,α-trichlorotoluene reactions with triphenylphosphine and tri-*n*-butylphosphine. With 10 mmoles of triphenylphosphine, 7.4 mmoles of pure tetrachlorotolan was obtained together with quantitative recovery of impure triphenylphosphine oxide. Tri-*n*-butylphosphine in boiling trichlorotoluene produced a difficultly resolvable mixture which was shown to contain tetrachlorotolan, traces of tri-*n*-butylphosphine oxide, and tar.

It was hypothesized at this stage that phosphonium salt formation from trichlorotoluene occurred with an associated dichlorophenylmethyl counterion **5**, which might be involved in the α,α,α-trichlorotoluene coupling reaction to tetrachlorotolan. Again, however, tests with added acetic and butyric acids in this system failed to demonstrate the formation of acid chloride and yet showed very similar tetrachlorotolan yields to tests carried out in their absence.



**5** **6**

While tertiary phosphines in the presence of methanol or ethanol have been used to reduce α,α,α-trichlorotoluene to benzal chloride, albeit sluggishly with triphenylphosphine (23), and to obtain tetraphenylethylene from dichlorodiphenylmethane (24), formation of tetrachlorotolan in this way has not been previously demonstrated. Tetrachlorotolan, however, has been obtained from trichlorotoluene using red phosphorus in the presence of hydroiodic acid (25), elemental sulfur (15), di-tertiarybutyl peroxide (26), and finely powdered tin (27), all reducing systems for the generation of radicals. Considering these examples, in the light of our own experiments, it was possible that the coloured species formed with 1,2,5-triphenylphosphole in boiling α,α,α-trichlorotoluene was the radical species **6** thermally produced in equilibrium with the phosphonium salt **5**, neither of which arise to any significant extent at ambient temperatures. But esr scanning of a 1000 G range about the free spin *g*-value failed to demonstrate the presence of any phosphoranyl radicals, which normally have $^{31}P$ coupling constants in the 800 G range (28). Thus, if any radical species was present, the concentration must have been below about $10^{-8}$ *M*, or represent less than one in $10^6$ of the phosphole molecules present, probably not a significant contribution to the colour-forming process in trichlorotoluene.

Phosphorus magnetic resonance experiments provided physical supporting evidence of the chemical evidence of phosphonium salt intermediacy in these colour-forming processes. Phosphorus shifts for 1,2,5-triphenylphosphole and its oxide were determined to be +5.1 (lit. (29) −3 ppm ($CHCl_3$), lit. (30) +3 ppm) and +39.9 ppm respectively, in carbon tetrachloride, +4.2 and +39.5 ppm in carbon

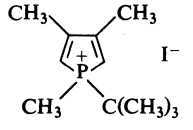
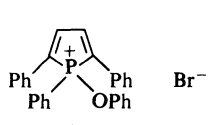
tetrachloride, and +4.2 and +39.5 ppm in α,α,α-trichlorotoluene, all at 30°C. Even room temperature measurements of the phosphole solutions, however, by the very gradual appearance of peaks at the appropriate shifts, demonstrated the formation of phosphole oxide. This appearance of phosphole oxide may have occurred via a slow progression of the process of interest, or from direct oxidation, or from a combination of both processes.

Immediately on observation of solutions of phosphole in hot trichlorotoluene, phosphole oxide was the dominant phosphorus species present, although measurable amounts of unchanged phosphole and two other phosphorus-containing species of distinctly different intermediate $^{31}P$ shifts were also present (Table 2). In hot carbon tetrachloride neither of the unknown species observed in trichlorotoluene were present, but a third phosphorus-containing component ($\delta$ = +58.2 ppm), 19 ppm downfield of the phosphole oxide, was present to a significant extent. Probably one or more of the transitory unidentified $^{31}P$ shifts at elevated temperatures in both solvents are caused by the colour-forming substances, and the rapid appearance of phosphole oxide is a strong indication that this is a product of the colour-forming process. The proton nmr spectra run in parallel with the above experiments failed to give any helpful information beyond complex, aromatic-type multiplets.

Thus, the phosphorus nmr exposes the complexity of the colour-forming reaction of the phosphole system in both carbon tetrachloride and α,α,α-trichlorotoluene solvents, the only common feature being the formation of phosphole oxide. Since the normal ranges of $^{31}P$ shifts for phosphine oxides, +20 to +50, and phosphonium salts, +20 to +45 (ref. 30, p. 199), overlap significantly, it can only be speculated that the additional intervening shifts observed in trichlorotoluene are from various possible phosphonium salts or oxidized phosphorus components other than phosphole oxide. With shifts of +52.8, and +74.6 ppm reported for the phosphonium salts **7** and **8** respectively (30), even



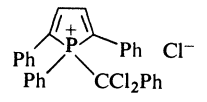
**7**



**8**

the observed +58.2 ppm shift observed for the hot carbon tetrachloride solution may well also arise from a phosphonium salt. Certainly all of the unexplained signals from hot solutions are downfield of the +20 to −62 ppm range to be expected from tertiary phosphines (ref. 30, p. 199), which can reasonably therefore be eliminated.

On the basis of the synthetic and spectroscopic evidence obtained, the single likely species responsible for the colour in the phosphole – carbon tetrachloride system is probably a phosphonium trichloromethide salt, with a significant tendency to return to phosphole and carbon tetrachloride on cooling. The combination of higher temperatures and more reactive halide in the phosphole–trichlorotoluene system involves at least two (from $^{31}P$ magnetic resonance) salt-like species which are likely to be the phosphonium dichlorophenylmethide salts, **5**, and phosphonium chloride, **9**, either of



**9**

which can reasonably participate in the coupling reaction observed at these temperatures.

# Sulfur-free penicillin derivatives. VII. Multiple functionalization of 2-azetidinyl-3-methyl-2-butenoates

SAUL WOLFE AND CHIA-CHENG SHAW

*Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6*

Received August 10, 1981

SAUL WOLFE and CHIA-CHENG SHAW. Can. J. Chem. **60**, 144 (1982).

The title compounds, substituted with chlorine in the 4′-position and with phthalimido, 2,2,2-trichloroethoxycarbonylamino, or phenoxycarbonylamino in the 3′-position of the azetidinone ring, have been converted to bis-allylic formates via bromination of both methyl groups with excess *N*-bromosuccinimide, and displacement of both bromines by formate ions in methylene chloride solvent. The diformates react smoothly with a deficit of a boron halide to form *E*/*Z* mixtures of halogeno-formates, in which the *E*-isomer predominates. Depending on the 3′-azetidinyl substituent, these halogeno-formates undergo a second displacement with acetate either with retention of olefinic geometry or inversion of olefinic geometry. The mechanisms of these reactions are discussed, along with further transformations leading to hydroxylactones, halogenolactones, halogenohydrins, and other compounds. Examination of the proton magnetic resonance spectra of twenty-one compounds reveals that methylene protons *cis* to the β-lactam nitrogen atom of a methyl 2-azetidinyl-2-butenoate are found at higher field than methylene protons *cis* to the methoxycarbonyl group. This observation appears to provide a more reliable criterion for the assignment of configuration to geometrical isomers than one based on the magnitude of the chemical shift nonequivalence of the *E* and *Z* methylene protons.

SAUL WOLFE et CHIA-CHENG SHAW. Can. J. Chem. **60**, 144 (1982).

Le composé mentionné dans le titre portant une chlore en position 4′ et un groupe phtalimido, trichloro-2,2,2 éthoxycarbonylamino ou phénoxycarbonylamino en position 3′ du cycle azétidinone, soumis à une bromation des groupes méthyles au moyen d'un excès de *N*-bromosuccinimide suivie par déplacement des bromes par des ions formiates dans le chlorure de méthylène, conduit aux formiates bis-allyliques. Les diformiates réagissent avec un défaut d'halogènure de bore en donnant les mélanges *E*/*Z* d'halogénoformiates dans lesquels l'isomère *E* est majoritaire. Dépendant du substituant en position 3′ du cycle azétidinyle, ces halogénoformiates, en présence d'un acétate, subissent une deuxième réaction de déplacement avec rétention ou inversion de la géométrie de l'oléfine. On discute des mécanismes de ces réactions ainsi que des transformation plus poussées qui conduisent à des hydroxylactones, des halogénolactones, des halohydrines et à d'autres composés. Les spectres de rmn du $^1$H de vingt et un composés révèlent que les protons méthyléniques en position 6 par rapport à l'atome d'azote du β-lactame du azétidinyl-2 butène-2 oate de méthyle, sont déplacés vers les champs forts par rapport aux protons méthyléniques en position *cis* du groupe méthoxycarbonyle. Ces observations semblent fournir des critères plus surs, que ceux fondés sur l'ordre de grandeur de la non équivalence des déplacements chimiques des protons méthyliques des isomères *E* et *Z*, pour déterminer la configuration des isomères géométriques.

[Traduit par le journal]

The first synthesis of a 1-oxacephem (**1**; $R^2 = CH_3$) from a penicillin precursor (**2**) was achieved by the sequence shown retrosynthetically in Scheme 1 (1). This approach became feasible following the development of routes from penicillins to the chloroazetidinones **3** (2, 3), and the observation that displacement of chlorine from such compounds proceeds without rupture of the β-lactam ring (2, 4, 5).

Numerous syntheses of 1-oxacephems from β-lactam natural products have since appeared in the literature (6), and two rather different strategies have evolved. One, as in Scheme 1, retains the isoprenoid moiety attached to the azetidinyl nitrogen of **3** and cognate 3-methyl-2-butenoates or 3-methyl-3-butenoates. An advantage of this approach is that these compounds possess the complete carbon skeleton of the target molecule so that,

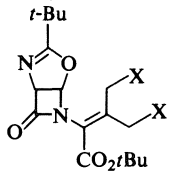
in principle, the oxacephem ring system can be reached by an oxidation and a ring closure. An alternative strategy employs methodology first devised by Woodward *et al.* (7). This approach begins with the removal of the butenoate moiety (**3** → **5**) (8); a new ring is then reconstructed by a multistep process (7). The particular advantage of this strategy is that it has allowed the ready laboratory synthesis and biological evaluation of a wide range of bicyclic systems (see, for example, ref. 9). A disadvantage is that the existing multistep sequences cannot be implemented economically on an industrial scale (10).

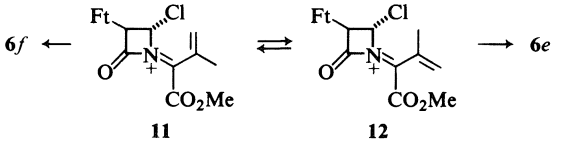
This paper is concerned with the elaboration of routes to compounds of type **4**, in which $R^2 \neq CH_3$, by functionalization of a 2-azetidinylbutenoate. Important intermediates in these sequences are the diformates **6***a*–**8***a*. A compound of this type (**9**) has been obtained by Campbell *et al.* (11) from the reaction of **10** with formate ions under phase transfer conditions. However, removal of the formate groups with bicarbonate led to loss of the β-lactam ring and concomitant rearrangement to a 1,5-oxazocine. In the present work the diformates **6***a*–**8***a* have been prepared, by a different procedure, from the dibromo precursors **6***b*–**8***b* and have been found to be convertible to the desired compounds **4** ($R^2 \neq CH_3$) under appropriate reaction conditions.

In an earlier investigation of the displacement of bromine from **6***c* and **6***d* (12), it was observed that a 1:1 mixture of these monobromides is converted in over 90% isolated yield to a 2:1 mixture of *E* (**6***e*) and *Z* (**6***f*) formates, using tetramethylguanidinium formate in chloroform solvent at room temperature. Under the same conditions, **6***a* was not obtained from the dibromide **6***b*. It has now been found that simply changing the solvent from chloroform to methylene chloride allows the isolation of **6***a* in 21–28% yield, using tetramethylguanidinium formate at −10°C, and in 42–47% yield using tetra-*n*-butylammonium formate at room temperature. Similar conditions were employed to prepare **7***a* and **8***a*.



**9** X = OCHO
**10** X = Br

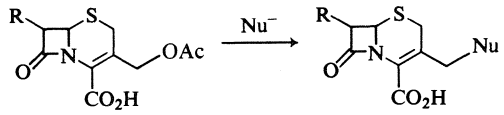
The recovery of a 2:1 mixture of **6***e* and **6***f* from the 1:1 mixture of **6***c* and **6***d* suggested (12) that both geometrical isomers react via the same intermediate, **11** (⇄ **12**), addition of formate to **11** leading to the *Z* isomer, and addition to **12** leading to the *E* isomer. There is precedent for such an elimination–addition pathway in the mechanism proposed for the process **13** → **14** (13). However, it should be noted that the latter reaction proceeds only in hydroxylic solvents, and does not occur with oxygen nucleophiles, in contrast to the observations of ref. 12.



**11** **12**

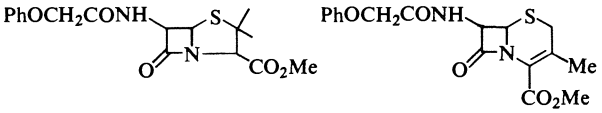
It is known that the pyramidality of the β-lactam nitrogen atom decreases in the order penicillin > cephalosporin > monocyclic azetidinones. This trend is seen in the solid state (14), and is reflected (15, 16) in the different β-lactam carbonyl stretching frequencies of these compounds (**15**: 1790 $cm^{-1}$; **16**: 1785 $cm^{-1}$; unfused β-lactams: < 1760 $cm^{-1}$).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.



13 14

The azetidinones of type **3** exhibit carbonyl absorption in the range 1773–1779 $cm^{-1}$ (17), suggesting a more nearly planar geometry at the β-lactam nitrogen than in a $\Delta^3$-cephem. Such a geometrical change can lead to an increase in the HOMO–LUMO interaction (18) between the nitrogen lone pair and the allylic halide systems of **6***c* and **6***d*, and thereby facilitate ionization to **11** (**12**).



15 16

It was thought that the conversion of a dibromide to a diformate might proceed analogously, via **17** (**18**) (X = Br), leading to a mixture of the bromo-formates **19** and **20** at an intermediate stage, but such compounds could not be isolated from any of the reactions of **6***b*–**8***b*. These multiply-functionalized butenoates were, however, accessible from the reactions of the diformates with boron halides.

Exploratory experiments with the phthalimido compound **6***a* revealed that one mol-equiv. of boron tribromide regenerated the dibromide **6***b* in quantitative yield; use of boron trichloride led to the dichloride **6***g*. With 0.6 mol-equiv. of boron tribromide, **6***a* was converted in 75% yield to a 2:1 mixture of the bromo-formates **6***h* and **6***i*, from which the major isomer **6***h*, mp 135.0–137.0°C, could be isolated in pure form. The assignment of the *E* configuration to this compound is based on the finding that deformylation under acidic conditions (HCl–MeOH–$CH_2Cl_2$) leads to the bromohydrin **6***j*, convertible to the tetrahydropyranyl ether **6***k* and the *tert*-butyldimethylsilyl ether **6***l*. Under the same deformylation conditions the minor isomer **6***i* was converted to the bromolactone **21** (R = Ft; X = Br), and the diformate **6***a* afforded the hydroxylactone **21** (R = Ft; X = OH). The hydroxylactone was convertible to the bromolactone upon further treatment with boron tribromide. The tetrahydropyranyl and *tert*-butyldimethylsilyl derivatives were also prepared.

With 0.6 mol-equiv. of boron trichloride, **6***a* gave, in 68% yield, a 3:1 mixture of the isomeric chloro-formates **6***m* and **6***n*, the assignment of configuration again being based on the deformylation of **6***m* to the chlorohydrin **6***o*, and of **6***n* to the chlorolactone **21** (R = Ft; X = Cl).

The sequences just described proved to be compatible with the TrOC (**7***a*) and PhOC (**8***a*) side chains. Deformylation of **7***a* and **8***a* led to **21** (R = TrOCNH; X = OH) (quantitative) and **21** (R = PhOCNH; X = OH) (91%), respectively. Boron tribromide afforded a separable 4:1 mixture of **7***h* and **7***i* (61%) from **7***a*, and a 4:1 mixture of **8***h* and **8***i* (61%) from **8***a*.

Thus, in the replacement of formate by halogen, as in the earlier replacement of halogen by formate (12), the *E*-geometrical isomer (**6***h*, **6***m*, **7***h*, **8***h*) is formed preferentially. However, despite their stereochemical similarities, the two reactions appear to proceed via different mechanisms. Indeed, that as many as three different mechanistic pathways may

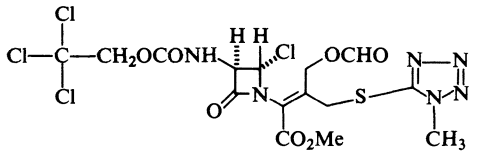
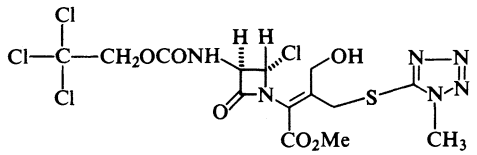
exist for the displacement of one allylic substituent by another in such compounds became apparent when the bromo-formates **6***h*, **7***h*, and **7***i* were allowed to react with tetraethylammonium acetate, to form acetoxyformates.

In the phthalimido series, this reaction proceeded *with inversion of olefinic geometry* to yield **6***p* (60%), with no trace of the geometrical isomer **6***q*. On the other hand, both TrOC compounds underwent displacement by acetate *with retention of olefinic geometry*. Thus, **7***h* afforded **7***q*, and **7***i* afforded **7***p*. In each case, the configurations of the acetoxyformates were established by deformylation experiments: **6***p* and **7***p* were converted to the acetoxylactones **21** (R = Ft, TrOC; X = OAc), but **7***q* gave the acetoxyhydrin **7***r*. The bromo-formate **7***h* was also converted to the mercaptomethyltetrazole derivative **24**, with mercaptomethyltetrazole in dimethylformamide solvent. Deformylation afforded the alcohol **25**, which appears to be a useful intermediate for further work.



**24**

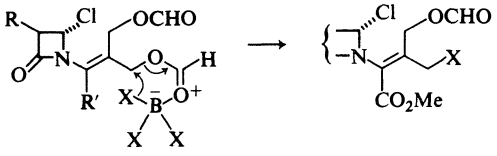


**25**

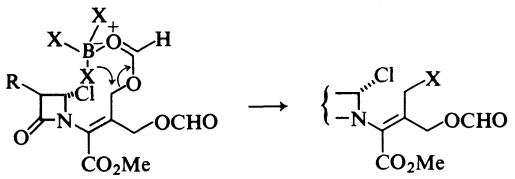
If the reaction of a diformate with boron tribromide and the reaction of a bromo-formate with a nucleophile both proceed via the elimination–addition pathway postulated earlier, then the same cationic species (**17** ⇄ **18**) (X = OCHO) must intervene in both cases. Since both reactions are conducted in methylene chloride solvent and at similar temperatures (−15° to 0°C), the partitioning of the intermediate (**17** → **22**; **18** → **23**) should not depend greatly on the nature of the entering nucleophile Y.

This behaviour is not observed in the phthalimido series, since **6***a* is converted preferentially to the *E*-bromoformate **6***h*, but **6***h* is, in turn, converted to the *Z*-acetoxyformate **6***p*. The expected behaviour is also not observed in the TrOC series, since the geometrical isomers **7***h* and **7***i* give different products upon reaction with acetate, and **7***h* is converted exclusively to **24** upon treatment with mercaptomethyltetrazole.

The most reasonable interpretation of these observations is that the displacement of bromine in the TrOC series proceeds via an $S_N2$ process and, in the phthalimido series, via the cationic intermediates **17** and **18** (X = OCHO).[1] The replacement of formate by halogen, using a boron halide, then requires a third mechanism; it is suggested that this is the $S_Ni$ process depicted in **26** and **27**.



**26** (R′ = $CO_2Me$)

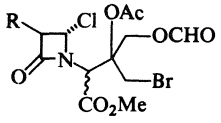


**27**

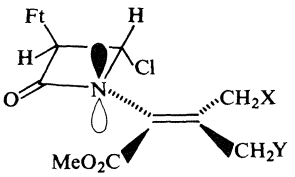
Inspection of molecular models reveals a possible conformational origin for the mechanistic difference between the phthalimido and TrOC compounds. The azetidinyl nitrogen lone pair will participate optimally in the ionization of the allylic bromine when this lone pair is oriented perpendicular to the 2-butenoate moiety (cf. **28**). Such a conformation can be achieved without difficulty in the phthalimido series. However, in the TrOC series, a hydrogen bond can exist between the TrOC N—H and the carbonyl oxygen of the ester group (cf. **29**). The resulting 90° rotation of the butenoate moiety will greatly diminish orbital interaction between the nitrogen lone pair and the allylic system.

In a recent publication dealing with compounds of type **30**, the Farmitalia group have observed (19) that, for certain combinations of E and Z, the

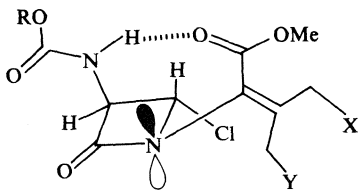
[1]A multistep process, involving Michael addition of acetate to the conjugated ester to form **i**, followed by displacement of bromine and elimination of acetate, might also be proposed. This seems unlikely for three reasons: (*i*) we have been unable to observe conjugate addition to compounds of type **3** under a variety of conditions; (*ii*) the β-elimination of acetate is expected (1) to lead to a mixture of geometrical isomers; (*iii*) the reaction mixture contains no source of protons to complete the conjugate addition.



**i**

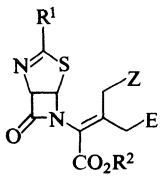


28

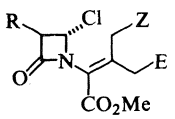


29

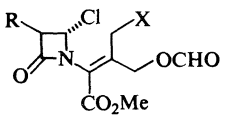
methylene protons of the $CH_2E$ moiety exhibit a larger chemical shift nonequivalence than those of the $CH_2Z$ moiety, and suggest that this observation may be useful for the assignment of configurations to such double bond isomers. Using stereochemical assignments apparently based on the generalizations of Martin and Martin (20, 21) for the proton chemical shifts of the methyl groups of compounds of type $CH_3$—CZ=CY—COX, a 0.28–0.36 ppm chemical shift difference was observed for E = Br, SPh and Z = H; and a 0.0–0.09 ppm chemical shift difference was observed for Z = Br, SPh and E = H. No chemical shift nonequivalence was observed when one of E or Z was OMe, O-*t*-Bu or OAc. For example, the bromoacetates **30** (E = Br, Z = OAc) and **30** (E = OAc, Z = Br) each showed singlets for both methylene groups. Although these latter compounds are described separately, it is not clear from the published data how the configurations were assigned.



30



31



32

The present work has led to a large number of compounds of type **31** of known stereochemistry about the double bond. It has, therefore, been possible to examine in some detail the generality of the earlier proposal concerning the use of chemical shift nonequivalence for configurational assignments. Table 1 summarizes the data for twenty-one compounds. In all cases where $Z \neq E$, $\delta^Z_{av}$ is found at higher field than $\delta^E_{av}$. This observation has been used to assign the $\delta^E_{av}$ and $\delta^Z_{av}$ resonances to compounds in which Z = E, and also to the various acetoxyformates.

Only three compounds (*6a*, *7p*, and *7r*) show no chemical shift nonequivalence in either of the methylene groups. Where nonequivalence is observed, thirteen compounds exhibit greater nonequivalence in $CH_2E$, in agreement with the Farmitalia observations. Five compounds, corresponding to structure **32** (X = Br, Cl, OAc), show the opposite behavior.

Since the reasons for the observed chemical shift nonequivalence of the diastereotopic methylene protons of these complex compounds are not known, the present results suggest that the magnitude of such nonequivalence is not a reliable criterion for the assignment of configuration. It may be more useful to base assignments on the finding that $\delta^Z_{av}$ is at higher field than $\delta^E_{av}$. This result is consistent with the data of Table 2 of ref. 20, if it is supposed that the methoxycarbonyl group of **31** has a greater effect on $\delta_{av}$ than the β-lactam nitrogen.

TABLE 1. Chemical shift data for the $CH_2Z$ and $CH_2E$ protons of compounds **31**[a,b]

## Experimental

General experimental procedures have been described previously (17). The $^1$Hmr spectra were recorded on a Varian EM360 spectrometer; infrared (ir) spectra were taken on a Perkin Elmer 180 instrument. Analyses are by Galbraith Laboratories, Knoxville, TN.

*Preparation of* **6**a

To a solution of **6***b* (2.35 g, 4.52 mmol) in methylene chloride (5 mL) was added, during 30 min, a solution of tetra-*n*-butylammonium formate (3.73 g, 13.56 mmol) in methylene chloride (20 mL). The reaction mixture was stirred for 48 h under nitrogen at room temperature and was then diluted with 10% acetone–hexane (10 mL) and chromatographed on silica gel. Graded elution with acetone–hexane afforded 919 mg (45%) of the diformate **6***a* as a pale yellow foam; ir ($CHCl_3$): 1795, 1775, 1735 cm$^{-1}$; $^1$Hmr ($CDCl_3$) δ: 3.87 (3H, s), 5.00 (2H, s), 5.23 (2H, s), 5.57 (1H, d, 2 Hz), 6.23 (1H, d, 2 Hz), 7.73 (4H, d), 7.97 (2H, s). *Anal.* calcd. for $C_{19}H_{15}N_2O_9Cl$: C 50.62, H 3.35, N 6.22; found: C 50.37, H 3.46, N 6.18.

*Hydrolysis of* **6**a *to the hydroxylactone* ***21*** *(R = Ft; X = OH)*

The diformate **6***a* (102 mg, 0.226 mmol) was dissolved in methylene chloride (4 mL), and *N* methanolic hydrogen chloride (0.2 mL) was added. The reaction mixture was stirred at 25°C for 2 h, and the solvent was then removed. The residue (89 mg) was a pale yellow foam, which appeared homogeneous on tlc. It was purified by plc (silica gel, acetone–hexane, 2:3) to give 79 mg (96%) of **21** (R = Ft; X = OH); ir ($CHCl_3$): 1790, 1770, 1725 cm$^{-1}$; $^1$Hmr ($CDCl_3$) δ: 3.00 (1H, br s, exch $D_2O$), 4.54, 4.81 (2H, ABq, $J$ = 16 Hz), 4.95 (2H, s), 5.53 (1H, d, 2 Hz), 6.57 (1H, d, 2 Hz), 7.68 (4H, br s).

*Conversion of* **6**a *to* **6**b *with excess boron tribromide*

To an ice-cold solution of the diformate **6***a* (52 mg, 0.115 mmol) in methylene chloride (3 mL) was added an ice-cold solution of boron tribromide (30 mg, 0.116 mmol) in methylene chloride (0.25 mL). The solution was stirred at 0°C for 1.5 h and then poured onto ice-cold brine (20 mL) and the layers separated. The aqueous layer was extracted with chloroform (3 × 40 mL) and the combined organic layers were washed with brine (2 × 5 mL), dried ($MgSO_4$), and evaporated to give 59 mg (100%) of **6***b* as a colourless foam. The $^1$Hmr spectrum of the product was identical with that of authentic material.

*Reaction of* **6**a *with 0.5 mol-equiv. of boron tribromide*

To an ice-cold solution of the diformate (304 mg, 0.675 mmol) in methylene chloride (5 mL) was added dropwise, with stirring, a solution of boron tribromide (86 mg, 0.34 mmol) in methylene chloride (0.8 mL). Stirring was continued for 1.5 h at 0°C, and the solution was then poured onto ice-cold 5% sodium bicarbonate. The layers were separated and the aqueous layer was extracted with methylene chloride (3 × 60 mL). The combined organic layers were washed with brine (3 × 10 mL), dried ($Na_2SO_4$), and evaporated to a colourless foam (322 mg). This was purified by plc (silica gel, acetone–hexane, 1:4) to give three products. The leading band was **6***b* (25 mg). The middle band was a 79:21 mixture of **6***h* and **6***i* (245 mg, 75%). Separation and characterization of these two compounds is described in the following experiment.

*Preparation of* **6**a *and* **6**i

To an ice-cold solution of **6***a* (937 mg, 2.08 mmol) in methylene chloride (10 mL) was added, dropwise under a nitrogen atmosphere, a solution of boron tribromide (321 mg, 1.28 mmol, 0.61 mol-equiv.) in methylene chloride (6 mL). The mixture was stirred for 1.5 h at 0°C and then poured into a large excess of saturated ice-cold sodium bicarbonate. Isolation as described above afforded a crude product which was chromatographed on silica gel. Elution with 1% acetone in hexane afforded successively the dibromide **6***b* (trace), **6***h* (343 mg, 34%), **6***i* (176 mg, 17%), unreacted **6***a* (trace), and an unidentified compound. Compound **6***h*: mp 135.0–137.0°C; ir ($CHCl_3$): 1800, 1780, 1730 cm$^{-1}$; $^1$Hmr ($CDCl_3$) δ: 4.00 (3H, s), 4.59, 4.86 (2H, ABq, 10 Hz), 5.17 (2H, s), 5.67 (1H, d, 2 Hz), 6.35 (1H, d, 2 Hz), 7.90 (4H, br s), 8.17 (1H, s). *Anal.* calcd. for $C_{18}H_{14}N_2O_7BrCl$: C 44.51, H 2.91, N 5.77, Br 16.45, Cl 7.30; found: C 44.37, H 3.02, N 5.74, Br 16.47, Cl, 7.47. Compound **6***i*: foam; $^1$Hmr ($CDCl_3$) δ, 4.05 (3H, s), 4.47, 4.64 (2H, ABq, 10 Hz), 5.53 (2H, s), 5.76 (1H, d, 2 Hz), 6.47 (1H, d, 2 Hz), 8.03 (4H, br s), 8.27 (1H, s).

*Conversion of* **6**a *to* **6**g, **6**m, *and* **6**n *with boron trichloride*

To an ice-cold solution of **6***a* (131 mg, 0.29 mmol) in methylene chloride (4 mL) was added 0.2 mL of a *M* solution of boron trichloride in methylene chloride (0.70 mol-equiv.). The resulting solution was stirred for 2 h at 0°C and then poured into ice-cold 5% sodium bicarbonate. The aqueous layer was extracted with methylene chloride (3 × 50 mL), and the combined organic extracts were washed with brine (2 × 20 mL), dried ($Na_2SO_4$), and evaporated to 133 mg of a foam. This was purified by plc (silica gel, 30% acetone in hexane) to give three products: the dichloride **6***g* (8 mg, 6%); $^1$Hmr ($CDCl_3$) δ: 3.93 (3H, s), 4.47, 4.62 (2H, ABq, 12 Hz), 4.71, 4.89 (2H, ABq, 12 Hz), 5.65 (1H, d, 2 Hz), 6.25 (1H, d, 2 Hz), 7.83 (4H, d); and a 3:1 mixture of **6***m* and **6***n* (84 mg, 68%). Compound **6***m*: $^1$Hmr ($CDCl_3$) δ: 3.93 (3H, s), 4.66, 4.78 (2H, ABq, 12 Hz), 5.07 (2H, br s), 5.61 (1H, d, 2 Hz), 6.27 (1H, d, 2 Hz), 7.80 (4H, d), 8.10 (1H, s). Compound **6***n*: $^1$Hmr ($CDCl_3$) δ: 3.91 (3H, s), 4.36, 4.53 (2H, ABq, 11 Hz), 5.37 (2H, s), 5.61 (1H, d, 2 Hz), 6.27 (1H, d, 2 Hz), 7.80 (4H, d), 8.10 (1H, s).

*Hydrolysis of* **6**h *to the bromohydrin* **6**j

The bromo-formate **6***h* (87 mg, 0.18 mmol) in methylene chloride (4 mL) was cooled to 0°C, and 0.2 mL of 3.2 *M* methanolic hydrogen chloride was added. The resulting solution was stored at 0°C for 1.5 h and then poured onto ice-cold 2.5% potassium bicarbonate (20 mL). The aqueous phase was extracted with methylene chloride (3 × 50 mL), and the combined organic layers were then washed with brine (2 × 20 mL), water (2 × 20 mL), dried ($Na_2SO_4$), and evaporated. The crude product, 73 mg of a nearly colourless foam, was purified by plc on silica gel buffered at pH 7.65 with boric acid – borax. Five developments with 20% acetone in hexane yielded 45 mg of **6***j*; $^1$Hmr ($CDCl_3$) δ: 2.87 (1H, br s, exch $D_2O$), 3.92 (3H, s), 4.43 (2H, s), 4.55, 4.72 (2H, ABq, 10 Hz), 5.60 (1H, d, 1.8 Hz), 6.27 (1H, d, 1.8 Hz), 7.83 (4H, d).

*Hydrolysis of* **6**m *to the chlorohydrin* **6**o

The chloro-formate **6***m* (53 mg, 0.12 mmol) in methylene chloride (3 mL) was cooled to 0°C and 0.15 mL of *N* methanolic hydrogen chloride was added. The resulting solution was stored for 2 h at 0°C, and then worked up as described above for **6***j* to give the chlorohydrin **6***o*, 49 mg; $^1$Hmr ($CDCl_3$) δ: 2.87 (1H, br s, exch $D_2O$), 3.90 (3H, s), 4.41 (2H, s), 4.62, 4.76 (2H, ABq, 12 Hz), 5.60 (1H, d, 1.8 Hz), 6.23 (1H, d, 1.8 Hz), 7.77 (4H, s).

*Hydrolysis of* **6**i *to the bromolactone* ***21*** *(R = Ft; X = Br)*

The bromo-formate **6***i* (59 mg, 0.122 mmol) in methylene chloride (3 mL) was cooled to 0°C and 0.15 mL of 3.2 *M* methanolic hydrogen chloride was added. The resulting solution was stored at 0°C for 1.5 h, and the product was then isolated as described above, 35 mg; $^1$Hmr ($CDCl_3$) δ: 4.41, 4.72 (2H, ABq, 12 Hz), 5.00 (2H, s), 5.67 (1H, d, 2 Hz), 6.70 (1H, d, 2 Hz), 7.87 (4H, d).

For personal use only.

*Conversion of* ***21*** *(R = Ft; X = OH) to* ***21*** *(R = Ft; X = Br)*

The hydroxylactone, prepared by deformylation of **6***a* (92 mg, 0.2 mmol), was dissolved in methylene chloride (3.5 mL) and, at 0°C, boron tribromide (0.1 mL) was added. The resulting solution was stirred at 0°C for 48 h and the product was then isolated in the usual manner to yield 80 mg (94% from **6***a*) of the bromolactone, identical to the material described above.

*Tetrahydropyranylation of* ***21*** *(R = Ft; X = OH)*

The hydroxylactone (86 mg) (prepared from 104 mg, 0.23 mmol of **6***a*) was dissolved in dry tetrahydrofuran (5 mL). To this solution were added freshly purified dihydropyran (0.5 mL) and boron trifluoride etherate (0.2 mL). The resulting solution was stirred for 2 h at room temperature and was then poured into ice-cold 5% sodium bicarbonate (20 mL). The mixture was extracted with chloroform (3 × 40 mL), and the combined organic extracts were washed with brine (2 × 20 mL), dried ($Na_2SO_4$), and evaporated to give the crude product as an oil. This was purified by plc (silica gel, acetone–hexane, 2:3) to yield the tetrahydropyranyl ether **21** (R = Ft; X = OTHP), 97 mg (94% from **6***a*); $^1$Hmr ($CDCl_3$) δ: 1.65 (6H, m), 3.67 (2H, m), 4.59, 4.79 (2H, br ABq, 12 Hz), 4.83 (1H, br, s), 5.00 (2H, br s), 5.60 (1H, d, 2 Hz), 6.67 (1H, d, 2 Hz), 7.80 (4H, d).

*Silylation of* ***21*** *(R = Ft; X = OH)*

The hydroxylactone (72 mg), prepared from **6***a* (86 mg, 0.19 mmol), was dissolved in dimethylformamide (2.5 mL), and the solution was treated successively with imidazole (30 mg, 0.44 mmol) and *tert*-butyldimethylchlorosilane (30 mg, 0.2 mmol). The reaction mixture was stirred for 1 h at room temperature, and the solvent was then removed under reduced pressure at 40–45°C. The residue was purified by plc (silica gel, 20% acetone in hexane) to yield 60 mg (65% from **6***a*) of the *tert*-butyldimethylsilyl ether; $^1$Hmr ($CDCl_3$) δ: 0.13 (6H, s), 0.92 (9H, s), 4.74, 4.98 (2H, ABq, 17 Hz), 4.93 (2H, s), 5.55 (1H, d, 2 Hz), 6.60 (1H, d, 2 Hz), 7.73 (4H, d).

*Tetrahydropyranylation of the bromohydrin* **6**j

The bromohydrin **6***j* (56 mg, 0.12 mmol) was dissolved in methylene chloride (5 mL) and to this solution were added dihydropyran (0.5 mL) and anhydrous *p*-toluenesulfonic acid (2 mg). The mixture was stirred at room temperature for 50 min and was then poured onto ice-cold 5% sodium bicarbonate (30 mL). Extraction with chloroform (3 × 40 mL), followed by washing of the chloroform extracts with brine (2 × 20 mL), drying ($Na_2SO_4$), and evaporation yielded 79 mg of an oil. This was purified by plc (silica gel, 30% acetone in hexane, two developments) to give the tetrahydropyranyl ether **6***k* (36 mg, 55%); $^1$Hmr ($CDCl_3$) δ: 1.68 (6H, m), 3.73 (2H, m), 3.90 (3H, s), 4.40, 4.64 (2H, ABq, 14 Hz), 4.52 (1H, s), 4.72 (2H, s), 5.57 (1H, d, 2 Hz), 6.25 (1H, d, 2 Hz), 7.97 (4H, d).

*Conversion of the bromo-formate* **6**h *to the acetoxyformate* **6***p*

A solution of the bromo-formate **6***h* (137 mg, 0.28 mmol) in methylene chloride (4.5 mL) was cooled to −15°C and, under nitrogen, tetraethylammonium acetate (65 mg, 0.34 mmol) was added. The reaction mixture was stirred at −15°C for 18 h and then at 0°C for 24 h. It was then poured into ice-cold brine (20 mL), the layers were separated, and the aqueous layer was extracted with methylene chloride (3 × 60 mL). The combined organic extracts were washed with brine (2 × 20 mL), dried ($Na_2SO_4$), and evaporated to 114 mg of a pale yellow foam. This was purified by plc (silica gel, acetone–hexane, 3:7) to give 79 mg (60%) of the acetoxyformate **6***p*; $^1$Hmr ($CDCl_3$) δ: 2.07 (3H, s), 3.87 (3H, s), 4.89, 5.12 (2H, ABq, 12 Hz), 5.13 (2H, s), 5.53 (1H, d, 2 Hz), 6.20 (1H, d, 2 Hz), 7.72 (4H, d), 7.97 (1H, s).

The acetoxyformate (79 mg, 0.172 mmol) was dissolved in methylene chloride (3 mL) and, at 0°C under nitrogen, *N* methanolic hydrogen chloride (0.17 mL) was added. The solution was stored at 0°C for 3 h and the solvent was then removed under reduced pressure. The residue was purified by plc (silica gel, acetone–hexane, 2:3, two developments) to give the acetoxylactone **21** (R = Ft; X = OAc), 59 mg (90%); $^1$Hmr ($CDCl_3$) δ: 2.10 (3H, s), 4.87 (2H, s), 5.20 (2H, s), 5.55 (1H, d, 2 Hz), 6.58 (1H, d, 2 Hz), 7.70 (4H, br s).

*Preparation of* ***3*** *($R^1$ = TrOC; $R^3$ = $CH_3$)*

A solution of methyl 6-trichloroethoxycarbonylaminopenicillanate (68.4 g, 0.168 mol) in methylene chloride (600 mL) was cooled to −78°C, and a precooled (−78°C) solution of chlorine (23.9 g, 0.336 mol) in methylene chloride (47 mL) was added dropwise, with stirring. Stirring was continued for 1 h at −78°C, and the reaction mixture was then brought to room temperature. Evaporation of the solvent under reduced pressure afforded a pale yellow foam, which crystallized upon trituration with ice-cold ether. The chloroazetidinone was collected, and washed with ice-cold ether: 48.7 g (70%), mp 139–140°C; $^1$Hmr ($CDCl_3$) δ: 2.03 (3H, s), 2.30 (3H, s), 3.80 (3H, s), 4.77 (2H, s), 4.93 (1H, dd, 2, 8 Hz), 5.83 (1H, br s), 6.47 (1H, br d, 8 Hz).

*Preparation of* **7**b

To a suspension of **3** ($R^1$ = TrOC; $R^3$ = $CH_3$) (49 g, 0.12 mol), in carbon tetrachloride (450 mL), were added *N*-bromosuccinimide (47 g, 0.264 mol) and benzoyl peroxide (0.5 g). The mixture was brought to rapid reflux, under nitrogen, and was then irradiated for 3 h over a Sylvania No. 2 Superflood lamp, cooled to room temperature, and filtered to remove succinimide. The filtrate was washed successively with ice-cold 5% sodium bisulfite (2 × 50 mL) and ice-cold brine (2 × 50 mL), and dried ($MgSO_4$). Evaporation afforded 72.2 g of **7***b* (100%) as a pale yellow foam which could be used directly in further reactions; $^1$Hmr ($CDCl_3$) δ: 3.90 (3H, s), 4.33 (2H, s), 4.53, 4.70 (2H, ABq, 10 Hz), 4.77 (2H, s), 4.90 (1H, dd, 2, 8 Hz), 6.00 (1H, d, 2 Hz), 6.53 (1H, d, 8 Hz).

*Preparation of* **7**a

A solution of **7***b* (2.107 g, 3.72 mmol) in chloroform (20 mL) was cooled to 0°C and, under nitrogen, treated dropwise during 5 min with a solution of tetramethylguanidinium formate (2.576 g, 16 mmol) in chloroform (8 mL). Stirring was continued for 30 min at 0°C and then overnight at room temperature. The reaction mixture was poured onto ice-cold brine (50 mL), and the layers were separated. The aqueous layer was extracted with methylene chloride (3 × 40 mL). The combined organic layers were washed with brine (3 × 20 mL), dried ($Na_2SO_4$), and evaporated to give the crude product as a light brown foam. Purification on silica gel (10% acetone in hexane) afforded 483 mg (26%) of **7***a* as a pale yellow foam; $^1$Hmr ($CDCl_3$) δ: 3.90 (3H, s), 4.77 (2H, s), 4.90 (1H, dd, 2, 8 Hz), 4.97 (2H, s), 5.17, 5.31 (2H, ABq, 12 Hz), 6.00 (1H, d, 2 Hz), 6.37 (1H, d, 8 Hz), 8.10 (2H, s). *Anal.* calcd. for $C_{14}H_{14}N_2O_9Cl_4$: C 33.89, H 2.84, N 5.65; found: C 33.53, H 2.82, N 5.86.

*Hydrolysis of* **7**a

The diformate (250 mg, 0.5 mmol) was dissolved in methylene chloride (6 mL), the solution was cooled to 0°C, and methanolic hydrogen chloride (1 mL of a 2 *M* solution, 2 mmol) was added. The reaction mixture was stirred for 1 h at 0°C by which time the starting material had disappeared. The solvent was removed under reduced pressure, and the product was taken up in methylene chloride (20 mL) and washed with cold brine (1 × 20 mL), dried ($Na_2SO_4$), and evaporated to give **21** (R = TrOC; X = OH) as a white foam which appeared homogeneous by tlc, 202 mg (100%); $^1$Hmr ($CD_3COCD_3$) δ: 4.17 (1H, br s, exch $D_2O$), 4.71, 4.86 (2H, ABq, 18 Hz), 4.90 (2H, s), 5.10 (2H, s), 5.10 (1H, dd, 2, 8 Hz), 6.47 (1H, d, 2 Hz), 7.90 (1H, d, 8 Hz).

*Conversion of* 7a *to* 7h *and* 7i

An ice-cold solution of **7*a*** (3.394 g, 6.84 mmol) in methylene chloride (40 mL) was treated dropwise, under nitrogen, with a solution of boron tribromide (1.025 g, 4.09 mmol) in methylene chloride (10 mL). The addition required 15 min, and stirring was continued at 0°C for an additional 30 min. The solution was then poured onto ice-cold 2.5% potassium bicarbonate and, after shaking, the layers were separated. The aqueous layer was extracted with methylene chloride (3 × 50 mL) and the combined organic extracts were washed with brine (2 × 10 mL) and dried ($Na_2SO_4$). Evaporation left a pale yellow foam, 3.515 g, which was subjected to silica gel chromatography. Elution with 15% acetone–hexane yielded three fractions. The first was the dibromide **7*b*** (418 mg, 11%); the second was a mixture of **7*h*** and **7*i*** (2.217 g, 61%), and the third fraction was unreacted **7*a*** (315 mg, 9%).

*Separation of* 7h *and* 7i

The above mixture of geometrical isomers (2.2 g) was rechromatographed on silica gel using 20% ethyl acetate in hexane as eluent. This afforded pure **7*h*** (1.6 g) and **7*i*** (0.4 g). For compound **7*h***, $^1$Hmr ($CDCl_3$) δ: 3.88 (3H, s), 4.47, 4.61 (2H, ABq, 11 Hz), 4.75 (2H, s), 4.88 (1H, dd, 2, 7 Hz), 5.02 (2H, s), 5.95 (1H, d, 2 Hz), 6.34 (1H, d, 7 Hz), 8.05 (1H, s). *Anal.* calcd. for $C_{13}H_{13}N_2O_7BrCl_4$: C 29.40, H 2.46, N 5.28; found: C 29.65, H 2.54, N 4.80. For compound **7*i***, $^1$Hmr ($CDCl_3$) δ: 3.88 (3H, s), 4.19, 4.35 (2H, ABq, 10 Hz), 4.73 (2H, s), 4.98 (1H, dd, 2, 6 Hz), 5.32 (2H, s), 5.98 (1H, d, 2 Hz), 6.05 (1H, d, 6 Hz), 8.05 (1H, s).

*Conversion of* 7h *to the acetoxyformate* 7q

A solution of tetramethylguanidinium acetate (300 mg, 1.73 mmol) in chloroform (5 mL) was cooled to 0°C and, with stirring, treated all at once with a solution of the bromo-formate **7*h*** (265 mg, 0.5 mmol) in chloroform (3 mL). Stirring was continued for 1 h at 0°C and then at room temperature for 5 h. The mixture was then poured onto ice-cold brine (50 mL), the layers were separated, and the aqueous layer washed with methylene chloride (3 × 40 mL). The combined organic extracts were washed with brine, dried ($Na_2SO_4$), and evaporated to a light brown foam (239 mg). Purification by plc (silica gel, ethyl acetate – hexane, 3:7) afforded recovered **7*h*** (40 mg) and the acetoxyformate **7*q*** (57 mg, 25%) as a colourless foam; $^1$Hmr ($CDCl_3$) δ: 2.08 (3H, s), 3.88 (3H, s), 4.75 (2H, s), 4.88 (1H, dd, 2, 7 Hz), 4.93 (2H, s), 5.04, 5.17 (2H, ABq, 14 Hz), 5.97 (1H, d, 2 Hz), 6.27 (1H, d, 7 Hz), 8.08 (1H, s).

*Hydrolysis of* 7q *to the acetoxyhydrin* 7r

A solution of the acetoxyformate **7*q*** (57 mg, 0.11 mmol) in methylene chloride (3 mL) was cooled to 0°C and treated with 2 *M* methanolic hydrogen chloride (0.1 mL). The resulting solution was stirred for 1 h at 0°C and was then evaporated to dryness to give a product which retained the methyl ester and acetate groups, but had lost the formate group; $^1$Hmr ($CDCl_3$) δ: 2.10 (3H, s), 3.63 (1H, br s, exch $D_2O$), 3.83 (3H, s), 4.70 (2H, s), 4.83 (2H, s), 5.15 (2H, s), 5.16 (1H, dd, 2, 6 Hz), 6.38 (1H, d, 2 Hz), 6.38 (1H, d, 6 Hz).

*Conversion of* 7i *to the acetoxyformate* 7p

The bromo-formate **7*i*** (217 mg, 0.41 mmol) was dissolved in chloroform (3 mL) and the solution was added to an ice-cold solution of tetrabutylammonium acetate (223 mg, 0.74 mmol) in chloroform (3 mL). The resulting solution was stirred at 0°C for 3 h under nitrogen, and then at room temperature for 22 h. It was then poured onto ice-cold brine (30 mL), the layers were separated, and the aqueous layer was washed with methylene chloride (3 × 40 mL). The combined organic extracts were washed with brine (2 × 20 mL), dried ($Na_2SO_4$), and evaporated. The resulting material was purified by plc (silica gel, ethyl acetate – hexane, 3:7, three developments) to give 100 mg (48%) of the acetoxyformate **7*p***; $^1$Hmr ($CDCl_3$) δ: 2.10 (3H, s), 3.90 (3H, s), 4.80 (2H, s), 4.87 (2H, s), 4.97 (1H, dd, 2, 6 Hz), 5.23 (2H, s), 5.97 (1H, d, 2 Hz), 6.52 (1H, d, 6 Hz), 8.03 (1H, s).

*Hydrolysis of* 7p *to the lactone* ***21*** *(R = TrOC; X = OAc)*

The acetoxyformate **7*p*** (100 mg, 0.20 mmol) was dissolved in methylene chloride (4 mL), the solution was cooled to 0°C, and methanolic hydrogen chloride (1 mL of a 0.8 *M* solution) was added. The resulting solution was stirred for 1.5 h, an additional 0.5 mL of *M* methanolic hydrogen chloride was added, and stirring was continued for 0.5 h. The reaction mixture was poured into cold 2.5% potassium bicarbonate (30 mL) and the layers were separated. The aqueous layer was extracted with methylene chloride (3 × 40 mL) and the combined organic extracts were washed with brine (2 × 20 mL), dried ($Na_2SO_4$), and evaporated to give the acetoxylactone as a colourless foam (74 mg, 83%), homogeneous by tlc; $^1$Hmr ($CDCl_3$) δ: 2.13 (3H, s), 4.77 (2H, s), 4.90 (2H, s), 4.95 (1H, dd, 2, 6 Hz), 5.17 (2H, s), 6.38 (1H, d, 2 Hz), 6.57 (1H, d, 6 Hz).

*Preparation of* ***24***

The bromoformate **7*h*** (133 mg, 0.25 mmol) was dissolved in dimethylformamide (6 mL), mercaptomethyltetrazole (35 mg, 0.30 mmol) was added, and the solution was stirred overnight at room temperature. The reaction mixture was then poured into ice-cold water (50 mL) and extracted with ethyl acetate (2 × 30 mL). This extract was washed successively with water (4 × 10 mL), saturated sodium bicarbonate (1 × 10 mL), and brine (1 × 10 mL), dried and evaporated to yield **24** as a colourless foam, homogeneous on tlc (125 mg, 91% yield); $^1$Hmr ($CDCl_3$) δ: 3.88 (3H, s), 3.95 (3H, s), 4.39, 4.71 (2H, ABq, 14 Hz), 4.75 (2H, s), 4.93 (1H, dd, 2, 8 Hz), 4.98 (2H, br s), 5.95 (1H, d, 2 Hz), 6.67 (1H, d, 8 Hz), 8.03 (1H, s).

*Preparation of* ***25***

Deformylation of **24** in the usual manner afforded **25**; $^1$Hmr ($CDCl_3$) δ: 3.45 (1H, br s, exch $D_2O$), 3.88 (3H, s), 3.98 (3H, s), 4.45 (2H, s), 4.62 (2H, s), 4.77 (2H, s), 4.90 (1H, dd, 2, 8 Hz), 6.02 (1H, d, 2 Hz), 6.95 (1H, d, 8 Hz).

*Preparation of* ***8***a

A slurry of 6-aminopenicillanic acid (21.6 g, 0.1 mol) in water (250 mL) was cooled to 0–5°C, and 2 *N* potassium hydroxide was added dropwise until a clear solution was obtained, and the pH was 7.5. This solution was diluted with tetrahydrofuran (200 mL). Then a solution of phenyl chloroformate (23.5 g, 19.1 mL, 0.15 mol) in dry tetrahydrofuran (40 mL) was added dropwise, with stirring at 5–10°C and simultaneous addition of 2 *N* potassium hydroxide to maintain the pH in the range 7–8. The turbid reaction mixture was extracted with ethyl acetate (2 × 300 mL), and this extract was discarded. The aqueous layer was layered with ethyl acetate (300 mL), the system cooled to 5–10°C and, with stirring, the pH was adjusted to 1 with concentrated hydrochloric acid. The layers were separated, the aqueous layer extracted with ethyl acetate (3 × 150 mL), and the combined organic extracts were washed with saturated brine, dried ($MgSO_4$), and evaporated to yield phenoxycarbonylaminopenicillanic acid (31 g, 92%), as a crisp white foam; $^1$Hmr ($CDCl_3$) δ: 1.60 (3H, s), 1.70 (3H, s), 4.47 (1H, s), 5.40–5.87 (2H, m), 6.00 (1H, br d, 10 Hz), 7.23 (5H, m). Methyl ester: $^1$Hmr ($CDCl_3$) δ: 1.53 (3H, s), 1.67 (3H, s), 3.77 (3H, s), 4.45 (1H, s), 5.38–5.70 (2H, m), 6.12 (1H, br d, 10 Hz), 7.20 (5H, m).

To the methyl ester (7.973 g, 22.78 mmol) in methylene chloride (40 mL) at −78°C was added, in one portion, a precooled solution of chlorine (3.234 g, 45.56 mmol) in methylene chloride (20 mL). The reaction mixture was stirred at −78°C for 1 h, warmed to room temperature, and evaporated. Chroma-

tography of the resulting foam (silica gel, 10–30% ethyl acetate – hexane) gave pure **3** ($R^1$ = PhOC; $R^3$ = $CH_3$) (5.867 g, 73%) as a colourless foam; $^1$Hmr ($CDCl_3$) δ: 2.00 (3H, s), 2.27 (3H, s), 3.73 (3H, s), 4.93 (1H, dd, 1.5, 8 Hz), 5.83 (1H, d, 1.5 Hz), 6.30 (1H, d, 8 Hz), 7.20 (5H, m). *Anal.* calcd. for $C_{16}H_{17}N_2O_5Cl$: C 54.47, H 4.86, N 7.94; found: C 54.18, H 4.95, N 7.62.

To a solution of **3** ($R^1$ = PhOC; $R^3$ = $CH_3$) (2.466 g, 7 mmol), in carbon tetrachloride (25 mL), were added *N*-bromosuccinimide (2.550 g, 14.2 mmol) and benzoyl peroxide (50 mg). Bromination was performed for 15 min, and the product isolated in the usual manner as a light brown foam (3.534 g). Chromatography on silica gel (ethyl acetate – hexane, 3:7) afforded pure **8***b* (2.446 g, 68%) as a colourless foam; $^1$Hmr ($CDCl_3$) δ: 3.85 (3H, s), 4.30 (2H, s), 4.53, 4.72 (2H, ABq, 10.5 Hz), 4.87 (1H, dd, 1.5, 8 Hz), 6.03 (1H, d, 1.5 Hz), 6.10 (1H, d, 8 Hz), 7.22 (5H, m). The dibromide (3.060 g, 6 mmol) was dissolved in chloroform (25 mL), the solution was cooled to 0°C and, under nitrogen, a solution of tetramethylguanidinium formate (4.0 g, 24.84 mmol) in chloroform (15 mL) was added dropwise during 5 min. The resulting solution was stirred at 0°C for 30 min and then at room temperature for 15 h. It was then poured onto a mixture of ice and water and the layers were separated. The aqueous layer was washed with methylene chloride (3 × 40 mL) and the combined organic layers were washed with saturated brine (2 × 10 mL), dried ($Na_2SO_4$), and evaporated to a pale brown foam (2.30 g). The diformate **8***a* was isolated by chromatography on silica gel (10–20% acetone–hexane); 689 mg (26%); $^1$Hmr ($CDCl_3$) δ: 3.87 (3H, s), 4.88 (1H, dd, 1.8, 8 Hz), 4.97 (2H, s) 5.23 (2H, br s), 6.05 (1H, d, 1.8 Hz), 6.23 (1H, d, 8 Hz), 7.27 (5H, m), 8.10 (2H, s).

*Hydrolysis of* **8**a

A solution of **8***a* (214 mg, 0.49 mmol) in methylene chloride (5 mL) was cooled to −10°C, and methanolic hydrogen chloride (2 mL, 29 mg/mL, 1.59 mmol) was added. The solution was allowed to stand overnight, by which time the starting material had disappeared and a single product had formed (tlc, silica gel, acetone–hexane, 3:1). The solvent was removed under reduced pressure and the residual light yellow foam was chromatographed on silica gel (30% acetone in hexane) to yield **21** (R = PhOC; X = OH), 157 mg (91%) as a colourless foam; $^1$Hmr ($CDCl_3$) δ: 3.50 (1H, br s, exch $D_2O$), 4.38, 4.68 (2H, ABq, 16 Hz), 4.85 (2H, br s), 4.95 (1H, dd, 1.8, 8 Hz), 6.32 (1H, d, 1.8 Hz), 6.48 (1H, d, 8 Hz), 7.17 (5H, m).

*Conversion of* **8**a *to* **8**h *and* **8**i

The diformate (184 mg, 0.42 mmol) was dissolved in methylene chloride (4 mL), and the solution was cooled to 0°C, under nitrogen. Then a solution of boron tribromide (61 mg, 0.24 mmol, 0.57 mol-equiv.) in methylene chloride (0.5 mL) was added dropwise during 5 min. The reaction mixture was stirred for 1 h at 0°C and was then poured onto ice-cold 2.5% potassium bicarbonate (20 mL). The layers were separated, and the aqueous layer was extracted with methylene chloride (3 × 40 mL). The combined organic extracts were washed with saturated brine (2 × 20 mL), dried ($Na_2SO_4$), and evaporated to give the crude product (188 mg) as a yellow foam. This was purified by plc (silica gel, 40% acetone–hexane) to give three bands. The leading band (10 mg) was identified as the dibromide **8***b*, and the trailing band (30 mg) was unreacted diformate. The middle band, 102 mg (61%, based on recovered starting material), was the mixture of **8***h* and **8***i*, in the ratio 4:1. For **8***h*, $^1$Hmr ($CDCl_3$) δ: 3.77 (3H, s), 4.40, 4.57 (2H, ABq, 10 Hz), 4.78 (1H, dd, 2, 8 Hz), 4.92 (2H, s), 5.92 (1H, d, 2 Hz), 6.23 (1H, d, 8 Hz), 7.10 (5H, m), 7.90 (1H, s). For **8***i*, $^1$Hmr ($CDCl_3$) δ: 3.67 (3H, s), 4.10, 4.27 (2H, ABq, 10 Hz), 4.78 (1H, dd, 2, 8 Hz), 5.23 (2H, s), 5.92 (1H, d, 2 Hz), 6.23 (1H, d, 8 Hz), 7.10 (5H, m), 7.90 (1H, s).

# Acid-catalyzed rearrangement of cyclobutanols.[1] Syntheses of chrysenes, cyclopentenophenanthrenes, and diarylmethanes

EDWARD LEE-RUFF, ALAN C. HOPKINSON, HIRA KAZARIANS-MOGHADDAM, BRIJ GUPTA, AND MORRIS KATZ

*Department of Chemistry, York University, Downsview, Ont., Canada M3J 1P3*

Received August 18, 1981

EDWARD LEE-RUFF, ALAN C. HOPKINSON, HIRA KAZARIANS-MOGHADDAM, BRIJ GUPTA, and MORRIS KATZ. Can. J. Chem. **60**, 154 (1982).

Acid-catalyzed reactions of 8-aryl or 8,8-diarylbicyclo[4.2.0]oct-2-en-7-ols lead to tetrahydrophenanthrene derivatives. For example 8-(1-naphthyl)-bicyclo[4.2.0]oct-2-en-7-ols give substituted chrysenes in methanesulphonic acid. In the case of the homologous 7-aryl or 7,7-diarylbicyclo[3.2.0]hept-2-en-6-ols a novel transformation to diarlymethanes is observed. A mechanism is proposed which accounts for the product distribution observed in these rearrangements.

EDWARD LEE-RUFF, ALAN C. HOPKINSON, HIRA KAZARIANS-MOGHADDAM, BRIJ GUPTA et MORRIS KATZ. Can. J. Chem. **60**, 154 (1982).

Les réactions des aryl-8 ou des diaryl-8,8 bicyclo[4.2.0] octène-2 ols-7, catalysées par les acides, conduisent à des dérivés tétrahydrophenanthrènes. Par exemple, les (naphtyl-1)-8 bicyclo[4.2.0] octène-2 ols-7 dans l'acide méthanesulphonique donnent des chrysènes substitués. Dans le cas des homologues aryl-7 ou diaryl-7,7 bicyclo[3.2.0] heptene-2 ols-6, on observe une nouvelle transformation en diarylméthanes. On propose un mécanisme qui tient compte de la distribution des produits observés au cours de ces transpositions.

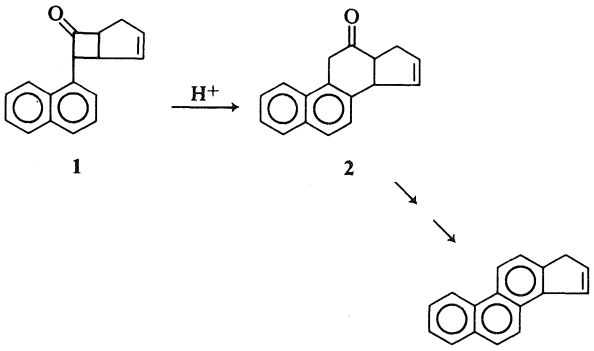
Cyclobutanones are versatile intermediates in the preparation of polycyclic compounds including steroids and aromatic derivatives (1–3). The key step in these transformations involves the ring opening of a protonated α-arylcyclobutanone and the annelation of the resultant ion to the aromatic nucleus. Thus derivatives such as **1** undergo isomerization to β-tetralones **2** under a variety of acidic



conditions. Further elaboration of these ketones permits the preparation of polycyclic aromatic hydrocarbons. It is proposed that a nonclassical 1-hydroxycyclobutyl cation is involved as an intermediate (4). However, ketones such as **2** cannot be functionalized at the carbonyl position with nucleophilic alkylating agents due to the acidic nature of the benzilic protons. On the other hand, the starting cyclobutanones can be readily alkylated at the carbonyl carbon to produce substituted cyclobutanols. Since cyclobutanols and their esters can be solvolyzed to yield similar cyclobutyl cations (5), we investigated the possibility that such ions can also undergo analogous ring annelations allowing the preparation of substituted perhydroaromatic derivatives, a number of which are of interest for the preparation of oxidized metabolites of polycyclic aromatic hydrocarbons involved in chemical carcinogenesis (6). This study reports on some of the acid-rearrangements of β-aryl cyclobutanols to substituted polycyclic aromatic hydrocarbons as well as a novel conversion of 7-arylbicyclohept-2-en-6-ols to diarylmethanes.

## Results

Cyclobutanols **3–13** were prepared from the corresponding cyclobutanones by reduction with $LiAlH_4$ or methylation with $LiCH_3$. The stereochemistry of the aryl group in **7–12** is assigned the *endo* configuration based on the benzilic-bridgehead hydrogen coupling constants of about 7–8 Hz in the $^1$Hmr spectra. The assignment is consistent with that for the aryl group configuration in the starting cyclobutanones (7). The hydroxyl group in alcohols **5–12** has been assigned the *endo* configuration, again based on the α-hydrogen bridgehead hydrogen coupling constant ($J$ = 7 Hz) as well as the slow exchange of OH hydrogen, indicating possible hydrogen bonding to the aryl group in the monosubstituted aryl alcohols **7**, **9**, and **11** (8). The assignment of the OH configuration is in accord

[1]Part VIII in a series on the acid-catalyzed rearrangement of cyclobutanones.

with nucleophilic attack occurring from the less hindered *exo* face in the bicyclic cyclobutanones.

The acid-catalyzed rearrangements were carried out using methanesulphonic acid at 0°C to 25°C or phosphorus pentoxide in benzene heated to reflux. The monocyclic alcohols **3** and **4** gave the 1,4-disubstituted 1,2-dihydronaphthalenes **14** and **15**. The structures of the hydrocarbons were confirmed by comparison with authentic samples (4) as well as the conversion by dehydrogenation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) to the 1,4-disubstituted naphthalenes **16** and **17**. The naphthalene **17** was hydrogenated to 1-phenyl-4-*n*-propylnaphthalene (**18**). The bicyclo[4.2.0]oct-2-en-7-ols **6–8** undergo dehydration and rearrangement to the tetrahydrophenanthrene **20** and tetrahydrochrysenes **24** and **25**, respectively. The structures of these derivatives were assigned based on their spectral data as well as their conversions to the known 9-phenylphenanthrene **22** (9), chrysene **26**, and 6-methylchrysene **27** (10) by dehydrogenation with DDQ. In the case of the bicyclo[3.2.0]-hept-2-en-6-ols **5**, **9–12**, in addition to formation of the ring fused derivatives **19**, **21**, **30**, and **33**, diarylmethanes **23**, **28**, **29**, **31**, and **32** respectively are produced as major products. The identity of the diarylmethanes **23** and **31** was confirmed by comparison with authentic samples. Hydrocarbons **28** and **32** were assigned structures based on comparison of spectral data with those reported in the

For personal use only.

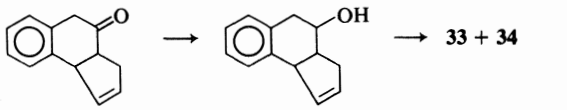
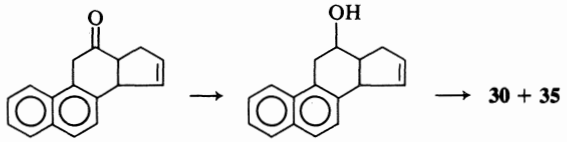
literature for these compounds (10, 11). The structure of diarylmethane **29** was based on the similarity of its spectral properties with those of **32**. Structures of the cyclopentane fused derivatives **19**, **30**, and **33** were assigned on the basis of their spectral data and conversion by strong acid to the benzoindans **21**, **34**, and **35**. The latter two compounds exhibited identical properties to those reported in the literature (12, 13). The benzoindan **34** and naphthoindan **35** were synthesized independently by dehydration of the cyclohexanols **38** and **39** with $P_2O_5$ under reflux in benzene. Alcohols **38** and **39** are derived from ketones **36** and **37** respec-



**36** **38**



**37** **39**

tively using $LiAlH_4$ (2). Yields of the rearranged hydrocarbons are given in Table 1.

## Discussion

The following scheme (Scheme 1) can be proposed to rationalize the formation of ring annelated products. Cyclobutyl cations are known to interconvert with cyclopropylcarbinyl and allylcarbinyl cations (5). Nuclear magnetic resonance data (14) of certain cyclobutyl cations indicate that these are delocalized species in which structures such as **40**, **41**, and **42** represent resonance contributors. The formation of ring annelated products such as **24** under acid dehydration conditions suggests that such ions undergo intramolecular electrophilic ar-

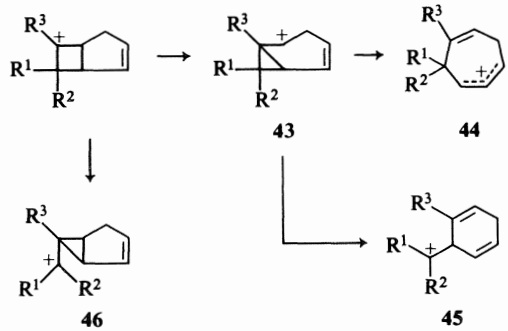
SCHEME 1

omatic substitution. The formation of diarylmethanes from bicyclohept-2-en-6-ols may involve a competitive *endo* bond cleavage (Scheme 2) of the cyclobutyl cation leading to a norcarenyl ion **43**. In the absence of positive charge stabilizing groups for $R^1$ and $R^3$ such ions are known to rearrange predominantly to products derived from cycloheptadienyl ion **44** (15). However, when $R^1$ and/or $R^2$ are positive charge stabilizing groups (e.g., aryl), *exo* cyclopropane bond scission may be expected, resulting in the formation of 2,5-cyclohexadienylmethyl cation **45**. Subsequent 1,2-hydride shift and proton loss lead to formation of the observed diarylmethanes. Both the unsubstituted bicyclohept-2-en-6-ol (**13***a*) and the β,β-dichloro derivative **13***b* were found to be inert under the same conditions in which β-aryl derivatives undergo rearrangements. Only *endo* to *exo* isomerization of the starting alcohol was observed. However, **13***a* has been reported to be transformed to 1,3,5-cycloheptatriene upon heating at 500°C in the presence of Lewis acids (16). That mono-aryl alcohols **9–12** give predominantly diarylmethanes suggests that *endo* cyclobutyl bond cleavage is preferred in this instance and that ions such as **46** derived from *exo* cleavage are probably more strained than the



**43** **44**

**46** **45**

SCHEME 2

corresponding homologues derived from bicyclooct-2-en-7-ols. In the case of β,β-diphenyl alcohol **5**, the presence of an additional phenyl group stabilizes ion **46**, making the latter pathway for rearrangement more competitive as seen from the increasing yields of ring fused products **19** and **21**.

## Summary

The present study suggests that the acid assisted dehydration of β-aryl bicyclic cyclobutanols can provide a viable route towards the synthesis of specifically substituted perhydroaromatic compounds. With the convenient availability of the starting cyclobutanones (4) this method provides a simple access to these compounds. A competing reaction in the case of β-arylbicyclohept-2-en-7-ols leads to formation of *ortho*-alkylphenylarylmethanes. Such rearrangements involve a novel pathway for the decomposition of norcar-4-en-2-yl ($C_7H_9^+$) ions. The specific structures of the intermediate ions are being investigated by low temperature nmr spectroscopy.

## Experimental

Melting points were determined on a Reichert melting point apparatus and were uncorrected. The ir spectra were recorded on a Unicam SP 1000 instrument. The nmr spectra were recorded on a Varian EM-360 spectrometer using $CDCl_3$ solutions and TMS as internal standard. Mass spectra were recorded on a V.G. Micromass 16F spectrometer. Vapour phase chromatography (vpc) was performed on a Varian Aerograph 90P instrument using a 6 ft 10% Carbowax column operating at 210°C. Microanalyses were performed by Guelph Chemical Laboratories Ltd. The starting cyclobutanones were prepared according to literature methods: 2,2,3-triphenylcyclobutanone (17), 3-(*cis*-propenyl)-2,2-diphenylcyclobutanone (18), 8,8-diphenylbicyclo[4.2.0]oct-2-en-7-one (18), 7,7-diphenylbicyclo-[3.2.0]hept-2-en-6-one (18), 8-(1-naphthyl)-bicyclo[4.2.0]oct-2-en-7-one (19), 7-(1-naphthyl)-bicyclo[3.2.0]hept-2-en-6-one (19), bicyclo[3.2.0]hept-2-en-6-one (20), 7,7-dichlorobicyclo-[3.2.0]hept-2-en-6-one (20). 7-Phenylbicyclo[3.2.0]hept-2-en-6-one was prepared by a similar synthesis as described for 7-(1-naphthyl)-bicyclo[3.2.0]hept-2-en-6-one using phenylacetyl chloride as the ketene precursor.

*Preparation of cyclobutanols* ***3–13***

The following general procedure was used for the preparation of the starting cyclobutanols. Lithium aluminum hydride (500 mg, 13 mmol) was suspended in anhydrous ether. A solution of the cyclobutanone (2–3 mmol) in anhydrous ether was added to the suspension and the solution stirred at room temperature for 1 h. The following was added to quench the excess $LiAlH_4$, 0.5 mL water, 0.5 mL 15% aqueous sodium hydroxide, and 1.5 mL water. The precipitate was filtered off and the filtrate washed neutral with water. The ether was dried over anhydrous $MgSO_4$ and evaporated. In most instances a single compound was obtained (tlc silica gel, benzene).

*Alcohol* ***3****:* nmr and ir identical with reported values (17).

*Alcohol* ***13***a: exhibited identical spectral properties with literature data (21). An 80:20 mixture of *endo–exo* alcohol was obtained.

*Alcohol* ***13***b: ir $\bar{\nu}$ ($cm^{-1}$): 3400, 1120, 725; nmr δ (ppm): 2.6 (m, 2H), 2.95 (s, 1H), 3.5 (d of q, $J$ = 3 Hz, 7 Hz, 1H), 3.9 (m, 1H), 4.6 (d of d, 1H), 5.9 (m, 2H).

*Acid rearrangements of alcohols* ***3–13***

The following general procedures were used for the acid reactions.

*Methanesulphonic acid method*

To a cooled solution (ice–water bath) of methanesulphonic acid (10–20 mL) was added dropwise a solution of 1–2 g of alcohol in 10–15 mL of ether. A deep colour developed immediately. The solution was warmed to room temperature and stirred for 1 h. This was then poured over ice and extracted with 100 mL of ether. The aqueous layer was reextracted with an additional 50 mL of ether. The combined ether extracts were washed with saturated bicarbonate (3 × 25 mL) and water, dried over $MgSO_4$, and evaporated. The residue was applied on silica gel coated preparative tlc plates, an alumina column (hexane–benzene), or on a vpc column.

*Phosphorous pentoxide method*

A benzene solution (50 mL) of the alcohol (1–2 g) containing 1 equiv. of $P_2O_5$ was heated under reflux for 1–2 h. The solution was concentrated and applied on an alumina column.

*Rearrangement products*

*Hydrocarbons* ***14*** *and* ***15***

These had identical spectral properties with those of authentic samples (4).

For personal use only.

*Hydrocarbons **16** and **17***

These were prepared from **14** and **15** using a previously reported procedure (4).

*1-Phenyl-4-*n*-propylnaphthalene (**18**)*

A solution containing 100 mg of naphthalene **17** in 50 mL of ethyl acetate and 50 mg of 5% Pd on carbon was hydrogenated in a closed system for 12 h. The catalyst was filtered off and the solvent evaporated to give an oily material; ir $\bar{\nu}$ ($cm^{-1}$): 3070, 770, 700; uv(EtOH): 295, 225 nm (similar to 1-phenylnaphthalene); nmr $\delta$ (ppm): 0.9 (t, $J$ = 6 Hz, 3H), 1.3 (m, 2H), 3.1 (t, $J$ = 7 Hz, 2H), 7.1–8.6 (m, 11 H); ms: 246 ($M^+$).

*Hydrocarbon **20***: showed identical spectral properties with that of previously prepared material (4).

*Conversion of hydrocarbon **20** to 9-phenylphenanthrene **22***

See DDQ method below. 9-Phenylphenanthrene was obtained in 70% yield. Showed identical properties with authentic sample (4).

*Hydrocarbon **24***: ir $\bar{\nu}$ ($cm^{-1}$): 3050, 680; nmr $\delta$ (ppm): 1.5–2.1 (m, 4H), 3.0 (m, 1H), 3.9 (t, $J$ = 6 Hz, 1H), 5.8–6.2 (m, 4H), 7.3–8.0 (m, 6H); ms: 232 ($M^+$).

*Conversion of hydrocarbon **24** to chrysene*

A solution containing 200 mg of **24** in 20 mL of benzene and 500 mL of DDQ was heated under reflux for two hours. The solution was concentrated to 5 mL and applied to an alumina column using benzene as the eluant. A crystalline material (180 mg) was obtained, mp 252–254°C, which was identical in all respects to chrysene.

*Hydrocarbon **25***: ir $\bar{\nu}$ ($cm^{-1}$): 3060, 700; nmr $\delta$ (ppm): 1.6–2.2 (m, 4H), 2.4 (s, 3H), 2.9 (m, 1H), 4.0 (d, $J$ = 6 Hz, 1H), 5.8 (s, 1H), 5.7–6.1 (m, 2H), 7.3–8.1 (m, 6H); ms: 246 ($M^+$).

*6-Methylchrysene (**27**)*

The same procedure was used for conversion of **25** to **27** as described above for the conversion of **24** to chrysene with DDQ. Yield 75%, mp 160–161°C (lit. (22) mp 161°C); uv (EtOH) nm: 324, 310, 298, 284, 268, 260, 244, 224; nmr $\delta$ (ppm): 2.8 (s, 3H), 7.5–8.2 (m, 7H), 8.5–8.9 (m, 4H); ms: 242 ($M^+$, base peak).

*Hydrocarbon **19***: ir $\bar{\nu}$ ($cm^{-1}$): 3050, 3010, 1600, 1500, 1450, 760, 740, 680; nmr $\delta$ (ppm): 2.1–2.7 (m, 3H), 4.1 (d of d, $J$ = 2 Hz, 8 Hz, 1H), 5.5–6.05 (m, 3H), 7.45 (s, 5H), 7.0–7.5 (m, 4H).

*Hydrocarbon **21***: ir $\bar{\nu}$ ($cm^{-1}$): 3050, 1590, 1490, 1440, 740, 685; nmr $\delta$ (ppm): 2.3 (p, $J$ = 7 Hz, 2H), 3.3 (q, $J$ = 7 Hz, 4H), 7.45 (s, 5H), 7.0–7.9 (m, 5H).

*Diarylmethane **28***: mp 54°C (lit. (10) mp 55–57°C); nmr was identical with literature reported data.

*Diarylmethane **29***: ir $\bar{\nu}$ ($cm^{-1}$): 3020, 1590, 1455, 1390, 775, 765, 725; nmr $\delta$ (ppm): 2.3 (s, 3H), 4.4 (s, 2H), 6.9–8.1 (m, 11 H); ms: 232 ($M^+$).

*Diarylmethane **32***: exhibited identical spectral values as reported in the literature (11).

*Hydrocarbon **30***: ir $\bar{\nu}$ ($cm^{-1}$): 3010, 770, 750; nmr $\delta$ (ppm): 2.1–3.4 (m, 3H), 4.0 (m, 1H), 5.7 (m, 3H), 7.0–8.0 (m, 7H); ms: 218 ($M^+$).

*Hydrocarbon **35***: exhibited identical ir and uv spectra as described in the literature (12); mp 131–133°C (lit. (12) mp 133–134°C); nmr $\delta$ (ppm): 2.3 (p, $J$ = 7 Hz, 2H), 3.25 (q, $J$ = 7 Hz, 4H), 7.4–8.0 (m, 6H), 8.6 (m, 2H); ms: 218 ($M^+$).

*Hydrocarbon **33***: ir $\bar{\nu}$ ($cm^{-1}$): 3030, 3000, 1490, 1445, 760, 750; nmr $\delta$ (ppm): 2.1–3.6 (m, 3H), 4.1 (br d, $J$ = 8 Hz, 1H), 5.8 (m, 3H), 6.4 (d of d, $J$ = 2 Hz, 8 Hz, 1H), 7.1 (m, 4H).

*Hydrocarbon **34***: showed identical spectral properties as described in the literature (13).

*Synthesis of naphthoindan **35** from ketone **37***

Ketone **37** was reduced with $LiAlH_4$ as described previously (19) to alcohol **39**. A solution of 300 mg of alcohol **39** in 20 mL benzene and 300 mg of $P_2O_5$ was heated under reflux for two hours. The solution was concentrated and applied on an alumina column. Hexane–benzene eluted 250 mg of an oily mixture containing mostly **35**. A small amount of **30** was present as evident by tlc. Ether–ethanol solution allowed crystallization of naphthoindan **35**, mp 131–132°C. Spectral data were identical in all respects with a sample prepared above.

*Synthesis of benzoindan **34** from ketone **36***

*Preparation of 7-phenylbicyclohept-2-en-6-one*

A solution of 10 g of phenylacetylchloride in 150 mL of benzene was heated to reflux in a three-neck flask containing an addition funnel and condenser in an atmosphere of nitrogen. Cyclopentadiene was rapidly added followed by dropwise addition of 7 g of triethylamine. After addition the solution was heated for a further 15 min. After cooling the resultant precipitate was filtered off and washed with ether. The ether–benzene solution was washed with 2 × 30 mL of 5% HCl, followed by 2 × 30 mL of 10% $Na_2CO_3$, water, dried over anhydrous magnesium sulphate, and evaporated to give 7.2 g of an oil which was applied to a silica gel column (hexane). Hexane eluted 1.2 g of 1,3-cyclopentadiene dimer. Benzene eluted 5.3 g of 7-phenylbicyclohept-2-en-6-one; ir $\bar{\nu}$ ($cm^{-1}$): 3020, 3000, 1780, 1490, 685; nmr $\delta$ (ppm): 2.7 (m, 2H), 3.9 (br t, 2H), 4.8 (d, $J$ = 6 Hz, 1H), 5.7 (m, 2H), 7.2 (s, 5H). *Anal.* calcd. for $C_{13}H_{12}O$: C 84.78, H 6.52; found: C 84.51, H 6.63%.

*Ketone **36***

To a cooled (ice–water bath) solution of 10 mL of methanesulphonic acid was added dropwise the above cyclobutanone (2 g). The solution turned deep red in colour. The reaction mixture was poured over ice and extracted with 50 mL of ether. The ether extract was washed with saturated aqueous $NaHCO_3$ and water, and dried over $MgSO_4$, filtered, and evaporated yielding 1.7 g of an oil. A small amount (200 mg) was purified using preparative tlc (silica gel plates 1000 Å, benzene); ir $\bar{\nu}$ ($cm^{-1}$): 3020, 3000, 1705, 720, 680; nmr $\delta$ (ppm): 2.7 (m, 2H), 3.0 (d of t, $J$ = 4 Hz, 8 Hz, 1H), 3.6 (s, 2H), 4.3 (br d, $J$ = 8 Hz, 1H), 5.8 (s, 2H), 7.2 (q, 4H). *Anal.* calcd. for $C_{13}H_{12}O$: C 84.78, H 6.52; found: C 84.43, H 6.32%.

*Synthesis of benzoindan **34** from ketone **36***

To a suspension of 500 mg of $LiAlH_4$ in 20 mL of anhydrous ether was added dropwise a solution of 1 g of ketone **36** in 10 mL of ether. The reaction mixture was stirred for 1 h. Water (0.5 mL) was carefully added followed by 0.5 mL of 15% NaOH and then by 1.5 mL of water. The resultant precipitate was filtered off and the organic filtrate washed neutral with water, dried over $MgSO_4$, and evaporated to give 0.95 g of an oil; ir $\bar{\nu}$ ($cm^{-1}$): 3600, 3400. The carbonyl peak at 1705 of ketone **36** was absent. The crude alcohol was used for the next step. A solution of 30 mL benzene, 0.8 g of crude alcohol, and 0.8 g of $P_2O_5$ was heated under reflux for 2 h. Water (1 mL) was added to the cooled solution. The benzene layer was washed with saturated $NaHCO_3$, water, dried over $MgSO_4$, and evaporated to give an oily mixture consisting of 60% **34** and 40% **33** (by vpc). The mixture was separated by preparative vpc. Both hydrocarbons **34** and **33** exhibited spectral data identical with those prepared above.

*Preparation of naphthoindan **35** from ketone **37***

The preparation of ketone **37** and alcohol **39** has been described previously (19). The dehydration of alcohol **39** was carried out under identical conditions as described above for alcohol **38**. The mixture contained 80% naphthoindan **35** which was separated by preparative tlc (10% benzene – hexane). The product obtained had properties identical to those of a sample reported above.

# Microbial hydroxylation of steroids. 8. Incubation of Cn halo- and other substituted steroids with Cn hydroxylating fungi

HERBERT L. HOLLAND AND EVERTON M. THOMAS

*Department of Chemistry, Brock University, St. Catharines, Ont., Canada, L2S 3A1*

Received June 1, 1981

HERBERT L. HOLLAND and EVERTON M. THOMAS. Can. J. Chem. **60**, 160 (1982).

A series of C-21 substituted progesterone derivatives (R = F, Cl, Br, $CH_3$) has been prepared, and incubated the C-21 hydroxylating fungus *A. niger*. No biotransformation was observed where R = Cl, Br, or $CH_3$, but a minor amount of hydroxylation occurred at an unidentified site where R = F. Two C-11β substituted progesterone derivatives (R = F, OH) were converted to the corresponding C-11 ketone by the C-11α hydroxylator *R. stolonifer*, but a C-11β hydroxylator (*C. lunata*) was unable to perform a similar transformation with a C-11α hydroxy substrate. *C. lunata* hydroxylated a C-11β fluoro substrate at C-14α and C-21 in low yield. C-7α and -7β-hydroxy androst-4-ene-3,17-diones were prepared and incubated with C-7β hydroxylating (*R. stolonifer*) and C-7α hydroxylating (*M. griseocyanus*) fungi respectively. No ketone formation was observed. Similarly, the C-6β hydroxylator *R. arrhizus* was unable to transform a C-6α-hydroxy substrate or C-6α- or C-6β-hydroxy-*B*-norsteroids. No oxidation at halogen was observed for any of the substrates used. $^{13}C-^{19}F$ coupling constants for 11β-fluoroprogesterone suggest the presence of through space interactions between fluorine and both C-18 and C-19.

---

HERBERT L. HOLLAND et EVERTON M. THOMAS. Can. J. Chem. **60**, 160 (1982).

On a préparé une série de dérivés de la progestérone substitués en position C-21 (R = F, Cl, Br, $CH_3$) et on les a incubé avec le champignon hydroxylant en C-21 *A. niger*. On n'a pas observé de biotransformation lorsque R = Cl, Br ou $CH_3$ mais une faible quantité de produit d'hydroxylation apparaît en un site inconnu lorsque R = F. On a transformé deux dérivés des progestérones substituées en C-11β (R = F, OH) en cétone C-11 correspondante à l'aide du *R. stolonifer*, un agent hydroxylant en C-11α. Toutefois le *C. lunata*, un agent hydroxylant en C-11β, ne permet pas d'effectuer une telle transformation avec des substrats hydroxylés en C-11α. Le *C. lunata* hydroxyle un substrat fluoré en C-11β au niveau de C-14α et de C-21 avec un faible rendement. On a préparé les hydroxy-7α (et 7β) androstene-4 diones-3,17 et on les a incubé avec des champignons hydroxylant respectivement en C-7β (*R. stolonifer*) et en C-7α (*M. griséocyanus*). On n'a pas observé la formation de cétone. De la même façon, le champignor *R. arrhizus*, hydroxylant en C-6β, est incapable de transformer des substrats hydroxy-6α ou des hydroxy-6α ou -6β *B*-norstéroides. On n'a pas observé d'oxydation au niveau de l'halogène dans aucun des substrats utilisés. Les constantes de couplage du $^{13}C$ et du $^{19}F$ de la fluoro-11β progestérone suggèrent la présence d'interactions spatiales entre le fluor et les deux carbones en positions 18 et 19.

[Traduit par le journal]

## Introduction

The widespread use of organohalides in both industry and medicine has led to concern about their toxic and/or carcinogenic effects (1). This in turn stimulated research into their metabolic fate, which has indicated that, in many cases, bioactivation of organohalides by a cytochrome P-450 dependant mixed-function oxygenase enzyme is a key step in their degradation, leading in some instances to the formation of toxicologically significant metabolites (2–4). Possible oxidative routes which have been considered (5) for this degradation include hydroxylation at saturated carbon, oxidation of the halogen to a hypervalent state, and epoxidation of C=C bonds. In this study, we have utilized halosteroids, and fungi known to hydroxylate steroids at specific sites, in order to investigate the first of these proposed modes of degradation.

Previous work with fluorosteroids and a series of fungi by the Oxford group (6) has demonstrated that the presence of a fluoro substituent at Cn of an androstane generally results in hydroxylation remote from that site when $C_n$ is a favoured position for hydroxylation, but has little effect in cases where the favoured hydroxylation site is remote from $C_n$. Similarly, the metabolism of a fluorogibberellin derivative by *Gibberella fugikuroi* occurred largely independently of the presence of fluorine (7), although the same group (8) found that *Aspergillus avenaceous* could not produce an ω-fluoro analog of avenaciolide when given the corresponding fluorinated precursors.

## Results and discussion

The substrates were prepared as described in the Experimental. The use of tetraethyl tin (9) to produce 21-methylprogesterone (**1***e*) from the acid chloride of **8** is preferable to the existing methods (10, 11) using diethyl cadmium. The halosteroids were prepared by unexceptional procedures. The synthesis of 11β-fluoroprogesterone (**3***a*) proceeded via the 9α-bromo compound **9** (12); we were unable to reproduce reports of the direct production of **3***a* by reaction of 11α-hydroxyprogesterone (**2***a*) with diethyl-(2-chloro-1,1,2-trifluoroethyl) amine (13, 14). In our hands the only product of this reaction was the corresponding $\Delta^{9(11)}$ olefin.

The $^{13}C$ nmr spectra of **3***a* and **9**, together with those of other steroids used in this study whose $^{13}C$ nmr spectra are hitherto unreported, are assigned in Table 2. Assignments were straightforward, those of **3***a* and **9** being simplified by the presence of $^{13}C$–$^{19}F$ coupling. The presence of significant coupling to both C-18 and C-19 in these compounds is noteworthy. Long range coupling from a C-6β fluorine to C-19 has been observed (15) and attributed to a through space interaction; a similar phenomenon is presumably operative in the present case.

The results of the incubations performed are summarized in Table 1. The 21-halosteroids **1***b*–**1***d* were incubated with *Aspergillus niger* ATCC 9142, a fungus known to hydroxylate **1***a* at C-21 in good yield (16). The 21-methyl derivative **1***e* was also studied for comparative purposes. In no case was any significant biotransformation observed; with **1***b* as substrate a minor product was obtained, mass spectrometry of which indicated a molecular weight of 348, but a quantity sufficient for structure determination could not be obtained. It is therefore apparent that the presence of halogen or methyl at the favoured site of hydroxylation of this fungus blocks hydroxylation at that site, but does not significantly direct it elsewhere. Control experiments in which **1***a* is efficiently hydroxylated at C-21 in the presence of **1***c* indicate that the failure of *A. niger* to hydroxylate **1***b*–**1***d* was unlikely to have been due to deactivation of the enzyme by the action of these α-haloketones as alkylating agents.[1]

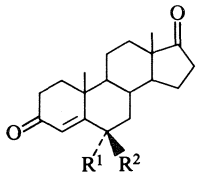
The influence of substitution at C-11β and C-11α on hydroxylation at C-11α (by *Rhizopus stolonifer*) (17) and C-11β (by *Curvularia lunata*) (18) was also examined. With *R. stolonifer*, both the C-11β alcohol **2***b* and the C-11β fluorosteroid **3***a* gave rise to the C-11 ketone **2***c*. This can be rationalized by the assumption that *R. stolonifer* hydroxylates **2***b* and **3***a* at the normal C-11α position, the products



**4**

*a* $R^1$ = $R^2$ = H
*b* $R^1$ = OH, $R^2$ = H
*c* $R^1$ = H, $R^2$ = OH
*d* $R^1$ + $R^2$ = O

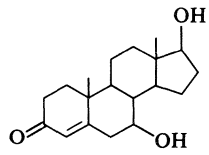
*b* $R^1$ = OH, $R^2$ = H
*c* $R^1$ + $R^2$ = O



**6**

being formed by subsequent loss of water or HF. The possibility that the alcohol **2***b* is converted to **2***c* by the action of an alcohol dehydrogenase seems unlikely in view of a lack of precedent for such conversions by *R. stolonifer* (19).

The C-11β hydroxylator *C. lunata*, although possessing a low substrate specificity with respect to substitution at sites remote from C-11 (20), is not tolerant of substitution of C-11α (hydroxyl) or

[1]We are indebted to a referee for bringing this possibility to our attention.

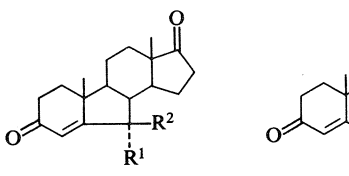
*Chemical shifts marked with asterisks may be interchanged.

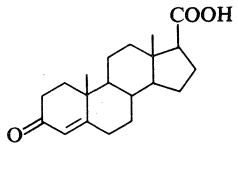
C-11β (fluoro). Incubation of 11α-hydroxyprogesterone (**2***a*) with *C. lunata* results in an almost quantitative recovery of starting material, whereas the C-11β fluorosteroid **3***a* was hydroxylated only at C-14α (a normal site of hydroxylation for this fungus (18)) and C-21. Since C-21 hydroxylation by this fungus has not previously been reported, it appears that the fluorine atom at C-11β has directed hydroxylation to this site, a finding consistent with that of previous workers (6).

In view of the apparent insensitivity of the C-11α hydroxylase of *R. stolonifer* to substitution at C-11β, we also examined the same fungus for its ability to metabolize androst-4-ene-3,17-dione-7α-ol (**5***b*); this fungus converts **4***a* to the C-7β hydroxylated product **5***a* in good yield (21). However, incubation of **5***b* with *R. stolonifer* resulted in the recovery of starting material only. The complementary incubation of the C-7β alcohol **5***a* with a C-7α hydroxylator (*Mucor griseocyanus*) (22) gave only a low yield of **6**, the product of reduction at C-17 (cf. 23).

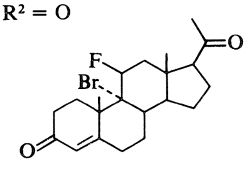


**7**

*a* $R^1 = R^2 = H$
*b* $R^1 = OH, R^2 = H$
*c* $R^1 = H, R^2 = OH$
*d* $R^1 + R^2 = O$



**8**



**9**

The C-6α alcohol **4***b* was incubated with the C-6β hydroxylator *Rhizopus arrhizus* (23), and the C-6α and C-6β *B*-nor alcohols, **7***b* and **7***c* were also incubated with the same fungus. *R. arrhizus* is capable of hydroxylation at both C-6α and C-6β of *B*-norandrostanes (24). None of the incubations with *R. arrhizus* produced detectable amounts of the ketosteroids **4***d* or **7***d*. Thus, of the fungi investigated, *R. stolonifer* is unique in its ability to perform hydroxylation at a carbon containing a substituent other than hydrogen. The difficulty of access of C-11 substituted progesterone derivatives has so far precluded a more detailed study of this reaction, but work in this direction is proceeding.

## Experimental

*Apparatus, materials, and methods*

Melting points were determined on a Kofler heating stage and are uncorrected. Infrared spectra were recorded with a Perkin-Elmer 237B, $^1H$ nmr spectra with a Bruker WP-60 or Varian A-60, and $^{13}C$ nmr with a Bruker WP-60 spectrometer using $CDCl_3$ as solvent and TMS as internal standard. Mass spectra were obtained with an AEI MS30 spectrometer. Column

chromatography was performed on silica gel (60–200 mesh), thin layer chromatography on Merck silica gel 60 F-254 (0.2 mm), and preparative layer chromatography on Merck silica gel F-254 (2.0 mm).

*Preparation of substrates*

With the exception of those listed below, the substrates used in this study were commercial samples.

*21-Methanesulphonyloxypregn-4-ene-3,20-dione (1g) (25)*

Pregn-4-ene-3,20-dione-21-ol (**1***f*) (5 g) was dissolved in dry pyridine (12 mL) and the solution cooled to −10°C. Methanesulphonyl chloride (1.73 g) was added to the solution, and the mixture stirred at −10° to −5°C for 1.25 h. The reaction was terminated by the addition of ether and water, and the white precipitate filtered and crystallized from methanol, giving 4.2 g (67%) of title compound of mp 157–160°C (lit. (26) mp 156–157°C).

*21-Fluoropregn-4-ene-3,20-dione (1b) (27)*

Potassium fluoride (4 g) and 18-crown-6 ether (1,4,7,10,13,16-hexaoxacyclooctadecane, 6 g) were suspended in freshly distilled DMF (25 mL), and **1***g* (3.5 g) added to the mixture, which was then refluxed at water aspirator pressure for 21 h. Water and ether were then added and the precipitated product filtered. Chromatography by gradient elution (benzene/ether) afforded **1***b* (1 g, 35%) mp 138–140°C (lit. (28) mp 141.5–142.2°C); $^1$H nmr included signals at δ 0.72 (3H, s, C-18H), 1.20 (3H, s, C-19H), 4.79 (2H, d, C-21H), and 5.82 (1H, s, C-4H) ppm; $^{13}$C nmr (29); *m/e* (%): 332 (100), 317 (24), 299 (26), 290 (100).

*21-Chloropregn-4-ene-3,20-dione (1c)*

The alcohol **1***f* (5 g) was dissolved in dry pyridine (10 mL) and the solution cooled to 0°C. Methanesulphonyl chloride (2.16 g) was then added, and the solution stirred and allowed to reach room temperature over a 2 h period, by which time the product **1***c* had precipitated. Water was then added and the product collected by filtration and crystallized from methanol to yield 3.8 g (73%), mp 203–205°C (lit. (30) mp 206–208°C); $^1$H nmr included signals at δ 0.71 (3H, s, C-18H), 1.20 (3H, s, C-19H), 4.12 (2H, s, C-21H), and 5.75 (1H, s, C-4H) ppm; $^{13}$C nmr (29); *m/e* (%): 350 (8), 348 (25), 333 (8), 314 (16), 312 (21), 299 (100).

*21-Bromopregn-4-ene-3,20,dione (1d) (25)*

The mesylate **1***g* (2.5 g) was dissolved in acetone (15 mL), and lithium bromide (3.5 g) added to the solution. The mixture was stirred and refluxed for 2 h, and then cooled. The precipitate was collected and dissolved in chloroform, and the resulting solution washed (water), dried (sodium sulphate), and evaporated. The residue was crystallized from acetone affording 1.8 g (76%) **1***d*, mp 159–162°C (lit. (31) mp 190–191°C); $^1$H nmr signals at δ 0.72 (3H, s, C-18H), 1.20 (3H, s, C-19H), 3.96 (2H, s, C-21H), and 5.79 (1H, s, C-4H) ppm; $^{13}$C nmr (29); *m/e* (%): 394 (16), 392 (17), 352 (28), 350 (27), 313 (53), 299 (100).

*Androst-4-ene-3-one, 17β-carboxylic acid (8) (32)*

The alcohol **1***f* (2 g) was dissolved in a mixture of acetone (25 mL) and sulphuric acid (96%, 1 drop). A solution of paraperiodic acid ($H_5IO_6$) in water (6 mL) was then added and the resulting mixture refluxed for 12 h. The acetone was then removed under reduced pressure, and chloroform (50 mL) added to the residue. The resulting solution was then extracted with aqueous sodium hydroxide (4%, 3 times). Fresh chloroform was added to the aqueous extract, which was then acidified with dilute HCl and extracted with chloroform. The extract was dried and evaporated to give 1.4 g (73%) of the title compound, mp 246–250°C (lit. (33) mp 246–250°C); $^1$H nmr included signals at δ 0.75 (3H, s, C-18H), 1.20 (3H, s, C-19), and 5.65 (1H, s, C-4H) ppm; $^{13}$C nmr, Table 2; *m/e* (%): 316 (57), 308 (18), 298 (13), 283 (14), 274 (100).

*21-Methylpregn-4-ene-3,20-dione (9, 10)*

The acid **8** (0.6 g) was suspended in dry benzene (30 mL). The mixture was flushed with dry nitrogen for 10 min, then cooled to 5°C and oxalyl chloride (2 mL) added. The mixture was then stirred and allowed to reach room temperature. After 45 min, dissolution was complete. The solvent was then removed under vacuum and the residual acid chloride dried *in vacuo* for a further 6 h. Dry hexamethylphosphoric triamide (10 mL) was added to the residue and after dissolution was complete, tetraethyl tin (0.56 g) and benzylchlorobis(triphenylphosphine) palladium II (10 mg) were added. The mixture was kept in a water bath at 80°C for 45 min, then cooled and diluted with water. The products were extracted into ether and the extract washed (2% sodium hydroxide), dried, and evaporated. The residue was separated by plc (30% ethyl acetate, 70% benzene solvent), and the resulting product crystallized from aqueous methanol, giving 0.21 g (42%), mp 139–141°C (lit. (11) mp 151–152°C); $^1$H nmr included signals at δ 0.66, (3H, s, C-18H), 1.04 (3H, t, C-22H), 1.19 (3H, s, C-19H), and 5.74 (1H, s, C-19H) ppm; $^{13}$C nmr, Table 2; *m/e* (%): 328 (64), 313 (24), 299 (59), 283 (73), 271 (100).

*9α-Bromo-11β-fluoropregn-4-ene-3,20-dione (9) (12)*

Hydrogen fluoride/pyridine reagent (70%, Aldrich Chemical Co., 50 mL) was added to dry THF (40 mL), and the mixture cooled to −50°C. *N*-Bromosuccinimide (3.5 g) was then added, followed by a solution of pregna-4,9(11)-diene-3,20-dione (5.5 g) in dry THF (10 mL). The resulting mixture was stirred at −50°C for 1 h and then allowed to remain at room temperature for 1 h. Cold saturated sodium carbonate solution was then added cautiously until the solution was basic. The product was then extracted into methylene chloride and the extract dried and evaporated. The residue was crystallized from methanol to give the title compound (6.1 g, 84%), mp 143–145°C (lit. (34) mp 145–150°C); $^1$H nmr included signals at δ 0.81 (3H, d, C-18H), 1.39 (3H, d, C-19H), 2.14 (3H, s, C-21H), 5.15 (1H, m, C-11αH), and 5.69 (1H, s, C-4H); $^{13}$C nmr, Table 2; *m/e* (%): 412 (7), 410 (8), 331 (19), 312 (100), 269 (24).

*11β-Fluoropregn-4-ene-3,20-dione (3a) (35)*

A solution of **9** (2.8 g), tri-*n*-butyltin hydride (10 mL), and azoisobutyronitrile (10 mg) in dry THF (25 mL) was allowed to stand at room temperature for 5 h, after which time several drops of water were added, and the solvent then removed under reduced pressure. The residue was crystallized from an 85% ethanol/water mixture to give 1.95 g (86%) **3***a*, mp 169–172°C (lit. (14) mp 156–158°C); $^1$H nmr included signals at δ 0.81 (3H, d, C-18H), 1.36 (3H, d, C-19H), 2.14 (3H, s, C-21H), 5.13 (1H, m, C-11αH), and 5.71 (1H, s, C-4H) ppm; $^{13}$C nmr, Table 2; *m/e* (%): 332 (54), 317 (10), 312 (100), 304 (16), 297 (46).

*Androst-4-ene-3,17-dione-7α-ol (5b)*

This was prepared from androsta-4,6,diene-3,17-dione by the procedure of Hossain *et al.* (36). Following correspondence with Professor D. N. Kirk, the $^1$H nmr spectrum of the intermediate 6,7α-epoxyandrost-4-ene-3,17-dione has been reassigned as follows: δ 0.95 (3H, s, C-18H), 1.13 (3H, s, C-19H), 3.51 (2H, br s, C-6β,7β H's), and 6.14 (1H, s, C-4H). The title compound had mp 227–230°C (lit. (36) mp 240–245°C); $^1$H nmr included signals at δ 0.92 (3H, s, C-18H), 1.22 (3H, s, C-19H), 4.10 (1H, br s, C-7βH), and 5.79 (1H, s, C-4H); $^{13}$C nmr, Table 2; *m/e* (%): 302 (15), 284 (100), 269 (29).

*Androst-4-ene-3,17-dione-7β-ol (5a)*

The alcohol **5***a* was obtained from androst-4-ene-3,17-dione (**4***a*) by fermentation with *Rhizopus stolonifer* ATCC 6227 b (see below). From 4.2 g of **4***a*, the following were obtained by column chromatography subsequent to a four day incubation with *R. stolonifer* in replacement culture. Recovered starting material (0.92 g), androst-4-ene-3,17-dione-6β-ol (**4***c*, 1.51 g), androst-4-ene-3,17-dione-11α-ol (0.21 g), and androst-4-ene-3,17-dione-7β-ol (**5***a*, 0.32 g), mp 218–220°C (lit. (21) mp 218.5–221°C); $^1$H

nmr included signals at δ 0.94 (3H, s, C-18H), 1.24 (3H, s, C-19H), 3.52 (1H, m, C-7αH), and 5.78 (1H, s, C-4) ppm; $^{13}C$ nmr, Table 2; *m/e* (%): 302 (100), 287 (16), 284 (42), 269 (31).

B-*Norandrost-4-ene-3,17-dione, 6α and 6β-ol (7b, 7c)*

These compounds were obtained by incubation of *B*-norandrost-4-ene-3,17-dione (*7a*) with *Rhizopus arrhizus* ATCC 11145 as described (24). Physical and spectral data were as previously reported (24).

*Incubations with fungi*

The fungi were grown and incubations performed according to the published procedures listed below. Details of time, products, and yields are summarized in Table 1. Data for hitherto unreported compounds are listed below.

*Aspergillus niger* ATCC 9142 (16), *Rhizopus stolonifer* ATCC 6227b (37), *Curvularia lunata* NRRL 2380 (38), *Rhizopus arrhizus* ATCC 11145 (37), and *Mucor griseocyanus* ATCC 1207 (22).

*11β-Fluoropregn-4-ene-3,20-dione-14α-ol (3b)*

Melting point 193–195°C; $R_f$: 0.77 (benzene/ethyl acetate/acetone 3:3.5:3.5), 0.81 (benzene/acetone 3:7), 0.51 (hexane/acetone 2:8); $^1H$ nmr included signals at δ 0.89 (3H, d, C-18H), 1.37 (3H, d, C-19H), 5.11 (1H, m, C-11αH), and 5.69 (1H, s, C-4H) ppm. $M^+$ calcd. for $C_{21}H_{29}O_3F$: 348.210; found: 348.210; *m/e* (%): 348 (6), 330 (36), 310 (36), 287 (43), 123 (100).

*11β-Fluoropregn-4-ene-3,20-dione-14α, 21-diol (3c)*

Melting point 175–178°C; $R_f$: 0.70 (benzene/acetone 3:7), 0.59 (benzene/ethyl acetate/acetone 3:3.5:3.5), 0.29 (hexane/acetone 2:8); $^1H$ nmr included signals at δ 0.92 (3H, d, C-18H), 1.37 (3H, d, C-19H), 4.20 (2H, d, C-21H), 5.08 (1H, m, C-11αH), and 5.70 (1H, s, C-4H) ppm. $M^+$ calcd. for $C_{21}H_{29}O_4F$: 364.205; found: 364.206; *m/e* (%): 364 (1), 346 (2), 333 (27), 315 (100), 295 (9).

# Thermal explosions with variable thermal conductivity

AVYGDOR MOISE AND HUW O. PRITCHARD

*Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3*

Received June 1, 1981

AVYGDOR MOISE and HUW O. PRITCHARD. Can. J. Chem. **60**, 165 (1982).

Numerical solutions are presented for the case of a thermal explosion in a sphere, in which the thermal conductivity varies linearly with temperature. The behaviour of the critical temperature profiles and of the other critical parameters for variations in the thermal conductivity are demonstrated.

AVYGDOR MOISE and HUW O. PRITCHARD. Can. J. Chem. **60**, 165 (1982).

On présente des solutions numériques dans le cas d'une explosion thermique dans une sphère dont la conductivité thermique varie linéairement avec la température. On démontre le comportement des profils de température critique et d'autres paramètres critiques des variations de la conductivité thermique.

## Introduction

The Frank–Kamenetskii approach to the problem of a thermal explosion has been the subject of much analytic effort in recent years (1, 2), but despite all the progress that has been made, the original simplifying assumptions of the model are unrealistic. We wish to examine in this paper the consequences of the neglect of the variation of thermal conductivity with temperature.

There have been, within the past two or three years, two studies (3, 4) of the case for which the variation of the thermal conductivity ($\kappa$) with temperature ($T$) is considered to be exponential, i.e.

$$[1] \quad \kappa(T) = \kappa(T_0) \exp [a(T - T_0)]$$

where $T_0$ is the wall temperature, and $a$ is a constant. Walker and Jackson (3) provided numerical solutions for all three class A geometries (1), whereas Wake (4) has shown that it is possible to derive isolated analytic solutions for a sphere when $b = a\boldsymbol{R}T_0^2/E = 0.2$ or 1.0, $E$ being the activation energy and $\boldsymbol{R}$ the gas constant.

We use, instead, the form

$$[2] \quad \kappa(T) = \kappa(T_0)[1 + \alpha(T - T_0)]$$

which is certainly more realistic, at least for gases.

## The basic equation

We will not re-derive the basic equation to be solved, but beginning with eq. [2] from Wake's paper (4), and by confining our attention to a first order (unimolecular) reaction taking place in a sphere, the usual manipulations lead us to

$$[1] \quad \frac{\partial^2\theta}{\partial\xi^2} + \frac{2}{\xi}\frac{\partial\theta}{\partial\xi} + \frac{\gamma}{(1+\gamma\theta)}\left(\frac{\partial\theta}{\partial\xi}\right)^2 + \frac{\delta e^{\theta}}{(1+\gamma\theta)} = 0$$

In this equation $\xi = r/R$, where $r$ is the distance from the centre and $R$ is the radius of the vessel, $\theta$, the dimensionless temperature excess (1) and $\delta$, the dimensionless heat production rate (1, 5) have their usual meanings, i.e.

$$\theta = E(T - T_0)/\boldsymbol{R}T_0^2$$

$$\delta = \frac{-\Delta H k_{\text{uni}}(T_0)}{\kappa(T_0)} \cdot \frac{P_0}{\boldsymbol{R}T_0} \cdot \frac{E}{\boldsymbol{R}T_0^2} \cdot R^2$$

and $\gamma = \kappa_0^{-1}\partial\kappa/\partial\theta$ where we now write $\kappa = \kappa(T)$ and $\kappa_0 = \kappa(T_0)$.

## Numerical solution

We have solved this equation by standard numerical methods (6, 7) for various values of $\gamma = \kappa_0^{-1}\,\partial\kappa/\partial\theta$ between zero and unity. We limited our examination to this range of $\gamma$ values because our principal interest is in gaseous explosions where $\gamma$ is rather small; we are, however, indebted to a referee for drawing to our attention a forthcoming paper by Lacey and Wake showing that a solution to [3] exists for all $\gamma$. The integration was started by the Runge–Kutta method (ref. 6, eq. 25.5.20) until sufficient points had been established to proceed with predictor–corrector method (ref. 6, eq. 25.5.21); an acceptable solution was required to fulfil the condition that at both extremities, the product $\xi\theta$ was zero to within $10^{-6}$. For each value of $\gamma$, a systematic search was made through trial values of $\delta$ until no solution could be found: the critical conditions, i.e. $\delta_c$, $\theta_c$ and $\partial\theta_c/\partial\xi|_{\xi=1}$, located in this manner are listed in Table 1.

Before discussing the significance of these solutions, we need to assure ourselves that they are accurate. For the case of $\gamma = 0$ (the standard Frank–Kamenetskii calculation) we agree with

TABLE 1. Dimensionless critical parameters for an exothermic reaction taking place in a sphere, as a function of the rate of change of thermal conductivity with temperature, i.e. $\gamma = \kappa_0^{-1}\,\partial\kappa/\partial\theta$

| $\gamma$ | $\delta_c$ | $\theta_c$ | $-\partial\theta_c/\partial\xi\|_{\xi=1}$ |
|---|---|---|---|
| 0 | 3.322 | 1.607 | 2.000 |
| 0.1 | 3.514 | 1.659 | 2.207 |
| 0.2 | 3.712 | 1.712 | 2.433 |
| 0.3 | 3.917 | 1.760 | 2.674 |
| 0.4 | 4.127 | 1.805 | 2.927 |
| 0.5 | 4.342 | 1.848 | 3.197 |
| 0.7 | 4.784 | 1.925 | 3.771 |
| 1.0 | 5.467 | 2.018 | 4.726 |

the published values (8) of $\delta_c = 3.32199$ and $\theta_c = 1.607$, and also with our own most recent values (9) of $\delta_c = 3.322640$, $\theta_c = 1.60570$ derived from a 20th order power series expansion; the slope of the dimensionless temperature excess at the wall should be exactly $-2$, and our value differs from this by 1 in the 5th figure. Another simple test we can perform is to apply the present numerical procedures to Wake's exactly soluble case (4) i.e. his $b = 0.2$ for exponential thermal conductivity variation, eq. [1]: for this case we obtain $\delta_c = 3.750$ (exact value = 15/4), $\theta_c = 1.733$ (exact value = $5 \ln \sqrt{2} = 1.73287$), and $\delta\theta_c/\partial\xi|_{\xi=1} = -2.500$ (exact value = $-5/2$); our procedure diverges, as it should, for Wake's case $b = 1$. Finally, for values of $b < 1$, we have compared our results with those of Walker and Jackson (3) for the exponential case, and we agree with their results to within the accuracy with which we can read them from their graphical presentation.

Since our work was completed, a new paper by Walker (10) has become available giving numerical solutions for the linear case, eq. [2]. Again, within the accuracy with which we can read his Fig. 4, we agree with Walker's data for the variation of $\delta_c$ with $\gamma$. However, we do not find agreement with his Fig. 1 for the variation of $\theta_c$ with $\gamma$: it appears that these temperature profiles have been misplotted — for example, the slope at the boundary for the $\gamma = 0$ case is $-2.1$ instead of $-2.0$ as is required for the standard solution.

## Discussion

The results found in Table 1 show that the neglect of the variation of thermal conductivity with temperature does not have a profound effect on the behaviour of gaseous explosions, since practical values of $\gamma$ for gases tend to be rather small: for example, for the case of methyl isocyanide for which the thermal conductivity has been measured close to the explosive temperature range (5), $\gamma \approx 0.0604$, whence $\delta_c \approx 3.437$, $\theta_c \approx 1.637$, and $\partial\theta_c/\partial\xi|_{\xi=1} \approx -2.122$. The neglect of this variation, however, may be more significant for other practical cases such as those considered by Walker and by Wake, and their co-workers (3, 4, 10).

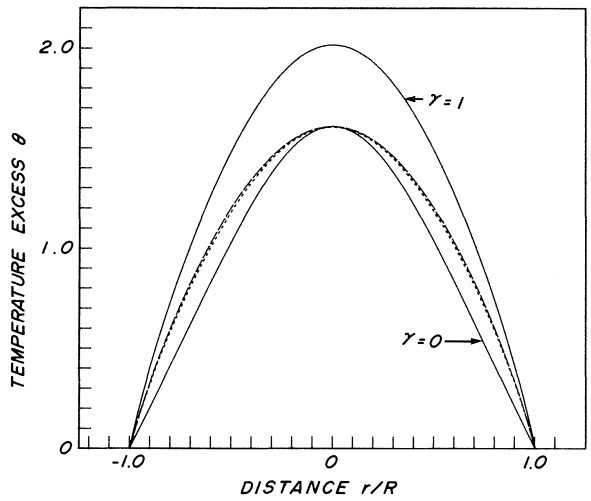

FIG. 1. Dimensionless temperature excess for an exothermic reaction in a sphere. Solid lines: critical temperature profiles for $\gamma = 1$ (top) and $\gamma = 0$ (bottom); broken lines: see Discussion.

Plots of $\delta_c$, $\theta_c$, and of $\partial\theta_c/\partial\xi|_{\xi=1}$ are almost linear over the range $0 \leq \gamma \leq 1$, making interpolation for other interesting cases quite simple. Likewise, the critical temperature profiles are of a similar form to the usual one for $\gamma = 0$, but are raised monotonically everywhere except at the wall. They are, however, of a slightly different shape, as one might expect, and this is demonstrated in Fig. 1. The two solid lines represent the calculated critical temperature profiles for $\gamma = 0$ and $\gamma = 1$: the dashed line is the case of $\gamma = 1$, $\delta = 5.31$ such that $\theta_0 = 1.605$, approximately the same as the value of $\theta_c$ for $\gamma = 0$. It can be seen that the effect of increasing thermal conduction with increasing temperature is to make the temperature profile a little flatter in the middle of the vessel, and rather steeper at the walls. The dotted curve is the critical curve for $\gamma = 1$ scaled down in the ratio of $\theta_c(\gamma = 0)/\theta_c(\gamma = 1)$: it is almost imperceptibly different in shape from that calculated for $\gamma = 1$, $\delta = 5.31$, and gives hope that it may be possible to produce simple empirical expressions for the temperature profiles as a function of $\delta, \gamma$.

# Program PKAS: a novel algorithm for the computation of successive protonation constants

RAMUNAS J. MOTEKAITIS AND ARTHUR E. MARTELL[1]

*Department of Chemistry, Texas A&M University, College Station, TX 77843, U.S.A.*

Received May 5, 1981

RAMUNAS J. MOTEKAITIS and ARTHUR E. MARTELL. Can. J. Chem. **60**, 168 (1982).

A new algorithm for the simultaneous determination of any number of protonation constants from potentiometric equilibrium data is described. This algorithm is characterized by a unique approach to the internal refinement of the constants and by the analytical nature of the numerical analysis whereby minimization is sought and achieved on the residuals between calculated and observed pH. The FORTRAN IV computer program PKAS utilizing this generalized algorithm has been written and developed and tested on 30 multidentate ligands. The details of the algorithm and the program are described and samples of its recorded usage are provided, indicating its versatility in application.

RAMUNAS J. MOTEKAITIS et ARTHUR E. MARTELL. Can. J. Chem. **60**, 168 (1982).

On décrit un nouvel algorithme qui permet de déterminer simultanément les constantes de protonation successive à partir de données d'équilibre potentiométrique. Cet algorithme se caractérise par son approche spéciale des constantes d'affinage interne et de la nature analytique des analyses numériques grâce auxquelles on a trouvé et minimisé les différences entre les pH calculé et observé. On a mis au point et vérifé, sur trente ligands multidentates, le programme PKAS en langage Fortran IV qui utilise cet algorithme généralisé. On décrit en détail l'algorithme et le programme et on fournit en même temps des exemples de calcul qui indiquent la versatilité de son application.

## Introduction

The efficient determination of the complete set of successive protonation constants of a multidentate ligand or a polyfunctional base is required for the characterization of the acid–base properties of the compound under investigation. The existing algorithms for solving mono and oligoprotic equilibria include such simple expediencies as direct algebraic calculation (1), graphical solution of intercept equations (1, 2), and the half $\bar{n}$ method (3). Such procedures are applicable for either non-overlapping or pairwise overlapping successive reaction steps. Other methodologies (3–5) for protonation constant evaluation include the refinement of initial estimates through inclusion of neighboring overlapping reactions, successive approximations, and computerization of standard graphical methods. Currently, the most common determination of successive overlapping protonation constants employs the rather widely accepted computer programs which had originally been designed for the refinement of metal–ligand formation constants. The more widely known versions include LEAST (6), LETAGROP (7), SCOGS (8), MINIQUAD (9), LETAGROP VRID (10), EQUIL (11), COMICS (12), and GAUSS (13, 14). The use (15) of these generalized programs indicates that the determination of protonation constants represents a subset of a more general problem which involves the interaction of a polyprotic ligand with metal ions. But the subset itself is important enough to merit consideration in its own right for three reasons: (*1*) for polyprotic systems the determination of protonation constants almost always involves simultaneous determination of more equilibrium constants than are needed to describe the metal–ligand systems subsequently investigated after these protonation constants are known (e.g., EDTA possesses four protonation constants, while its complexes are described by one or two formation constants (16)); (*2*) the accuracy with which these protonation constants are known directly affects any subsequent calculations which utilize these constants as parameters (e.g., formation constants, species distribution, etc.); (*3*) the equations are well-ordered and are particularly well-suited for an exact (analytical) mathematical treatment of a generalized refinement process.

Realizing the special nature of this subset (i.e., ligand–proton potentiometry vs. ligand–proton–metal potentiometry) several programs have already appeared which deal with protonation equilibrium specifically. Program TITRA (17) employed an algorithm whereby a ligand of the type $H_NL$ is replaced by $N$ monoprotonated ligands. Program ACBA (18) treats single and mixed acid systems. MUPROT (19) incorporates a technique which refines all parameters describing the titration curve, including a carbon dioxide correction. Most of the above programs utilize the minimization of $U = \sum(v_{obs} - v_{calc})^2$ or similar titer parameter, where $v$ is the volume of titrant added at each point and ($v_{obs}$

$- v_{calc}$) is the difference between the calculated and observed values (15, 20). The other frequently employed minimization parameter is the residual in one or all of the mass balance terms. An exception is a program devised by Siders and Romary (21), in which the areas between experimental and calculated titration curves are minimized. However, in this case refinement is accomplished by incremental variation of each constant and is limited to four constants. Specialized methodology has also been employed for spectral determination of protonation constants (22–25).

This algorithm for the determination of protonation constants differs from those used previously in two important ways: (*1*) the parameter computed at each titration volume is the pH and the parameter minimized is the mean sum of the squares of deviations between the calculated and observed pH values; (*2*) the final refinement of the protonation constants is based on a weighted algebraic mean of the deviations of each interval in which that protonation equilibrium is considered to dominate the reaction. In contrast, all of the previously employed programs compute and minimize either the deviation in "titer" (i.e., volume of base which must be added to achieve the observed pH) or the sums of the squared residuals of one or more of the mass balance equations, while refinement of the calculated parameters itself is based on procedures such as standard numerical analysis techniques for optimization of coefficients, gradient techniques, and Gaussian strategy. These refinement techniques serve to increase program running time as the square of parameters being fitted and can be avoided with our new algorithm.

In these laboratories, the FORTRAN program PKAS, which is based on this new algorithm, has been thoroughly tested since it was formulated more than ten years ago (26). It has evolved from its initial form on the IBM 360/5, CDC 1604A, and its latest version has been adapted as an interactive program for the Micromation CP/M microcomputer system. The algorithm is effective, fast, and very reliable. Program execution times on large computers are extremely rapid when compared to microcomputers, but for dedicated microcomputers, execution times on the order of several minutes are normal.

## The algorithm

### *Mathematical basis*

In the most general case, without making prior assumptions, there are two mass balance equations which must be satisfied at every volume addition point in a potentiometric equilibrium curve:

$$[1] \quad T_L = [L]A_1$$

$$[2] \quad T_H - B = [L]A_2$$

where

$$[3] \quad A_1 = 1 + K_1[H^+] + K_1K_2[H^+]^2 + \ldots\ldots + K_1 \ldots K_N[H^+]^N$$

$$[4] \quad A_2 = K_1[H^+] + 2K_1K_2[H^+]^2 + \ldots\ldots + NK_1 \ldots K_N[H^+]^N$$

and $T_L$ is the analytical concentration of the ligand; $T_H$ is the analytical concentration of ionizable hydrogen; $B = [H^+] - [OH^-] + [\text{titrant added}] + (\text{other corrections})$; and L is the symbol for the most deprotonated form of the ligand $H_NL$.

$$[5] \quad K_i = \frac{[H_iL]}{[H^+][H_{i-1}L]}$$

Dividing eq. [2] by eq. [1] eliminates [L] and gives eq. [6]

$$[6] \quad \frac{T_H - B}{T_L} = \frac{A_2}{A_1}$$

Given a set of protonation constants, $K_i$'s, this simple equation of order $N + 1$ in $[H^+]$ is most efficiently solved for $[H^+]$ at any degree of neutralization by the Newton–Raphson method (27) with the use of the following technique. Define a function $F$ from [6], such that $F = 0$ when the correction solution to [6] in $[H^+]$ is determined.

$$[7] \quad F = \frac{T_H - B}{T_L} - \frac{A_2}{A_1}$$

The iterative methodology involves the determination of the derivative $\partial F/\partial[H^+]$ at an initially estimated value of $[H^+]$. Explicitly stated:

$$[8] \quad F' = \frac{\partial F}{\partial[H^+]} = -\frac{1}{T_L}\frac{\partial B}{\partial[H^+]} - \frac{1}{A_1}\frac{\partial A_2}{\partial[H^+]} + \frac{A_2}{A_1^2}\frac{\partial A_1}{\partial[H^+]}$$

where

$$\frac{\partial B}{\partial[H^+]} = 1 + \frac{K_W}{[H^+]^2}$$

and $\partial A_1/\partial[H^+]$ and $\partial A_2/\partial[H^+]$ may be obtained directly from eqs. [3] and [4] by differentiation. The equation for the $j$th iteration is

$$[9] \quad [H^+]_j = [H^+]_{j-i} - \frac{F}{F'}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

When $[H^+]$ is found, the refinement is terminated, and the next experimental point is considered. In general it takes about 2–5 iterations per point for part per million convergence.

*Strategy*

The following strategy is employed in the refinement of $N$ protonation constants for the potentiometric equilibrium curve of a given ligand.

(*1*) Identify $N$ segments $S_i$ of the experimental curve according to "$a$" value, where $a$ = moles of base added to the experimental solution per mol of ligand present. Thus $0 < a \leq 1$ would constitute $S_1$; $1 < a \leq 2$ constitutes $S_2$; etc.

(*2*) Formulate initial tentative values of each $\log K_i$ corresponding to the midpoint pH value in each $S_i$. Since protonation constants are considered (not $pK_a$'s), $\log K_1 = \text{pH}(S_N)$, $\log K_2 = \text{pH}(S_N - 1)$, ..., and $\log K_N = \text{pH}(S_1)$, where $\text{pH}(S_i)$ represents the pH at the midpoint of each segment $S_i$. These values of $K_i$ are the internally determined first approximations of the protonation constants to be refined.

(*3*) Calculate a potentiometric equilibrium curve using the mathematical algorithm given above (eq. [9]).

(*4*) Determine the statistics: (*a*) calculate the standard deviation in pH residuals for the *entire curve* (SD). This is a measure of closeness of fit and is a criterion for deciding when to stop adjusting protonation constants; (*b*) calculate the (weighted) average deviation of pH residuals for *each segment* $A_i$. Since this is an average deviation, $A_i$ is a signed quantity.

(*5*) Adjust each protonation constant according to the average deviation. $\log K_1 = \log K_1 + A_N$; $\log K_2 = \log K_2 + A_{N-1}$; ...; $\log K_N = \log K_N + A_1$.

(*6*) Repeat steps *3–5* until SD for the entire curve cannot be minimized by further refinement. Experience shows that when successive SD's vary by less than one part per thousand refinement is complete.

## Discussion

The new algorithm described above is completely reliable and does not collapse under any circumstances. Furthermore, it is very easy to implement and is versatile in that it can be easily utilized for other purposes such as metal–chelate protonation or deprotonation reactions to form species such as $MLH_i$, and $ML(OH)_i$. Since this algorithm was first employed in these laboratories (26), a number of practical considerations have emerged which should be taken into account to achieve the most precise calculations.

An option should be included in order to discard points near the inflections of the potentiometric curves from consideration. On the other hand, when the compounds are pure substrates it has been repeatedly verified that the number of discarded points near integral "$a$" of neutralization values (moles of base or acid added per mole of ligand) can be kept to a minimum.

The weighting scheme during the calculation of average residual $A_i$ should favor the points near the middle of each segment of the potentiometric curves more heavily than those nearer the integral values of $a$. However, a uniform procedure of discarding values within 0.2 "$a$" values around each integral $a$ value (i.e., consider only $0.2 < a < 0.8$, $1.2 < a < 1.8$, $2.2 < a < 2.8$, etc.) without weighting also gives very rapid convergence accompanied by only a trivial increase in refinement error.

Experience has also revealed one pitfall which results mostly from employing computer programs in "black-box" style. When one considers very low protonation constants, or very high protonation constants, situations arise when the pH data may be mostly out of range of the values of the protonation constants being calculated. Thus in the former case, the ionization may be complete or virtually complete. Refinement by the above algorithm would give rise to constant ($\log K_N$ and/or $\log K_{N-1}$) which may be as much as 0.5 log value too high or two low, as the result of very slight inaccuracies in pH measurement. For alkaline solutions, $\log K_1$ could be much larger than the high pH data and the computed values would be off considerably from the correct value depending on the value of $pK_W$, which determines the concentration of free hydroxide ion. Other errors would result from the pH measurement itself and the possible presence of carbonate. In this version of PKAS, the program prints a message warning the user that the data used as the basis for the calculation may be in question for the extreme (high or low) protonation constants.

An important feature of the algorithm is that the values of pH calculated are exact for the experimental concentration of alkali hydroxide added. The fact that pH values are calculated, but not the added reagent concentration (or volume of base), results in definite advantages, because the pH in potentiometry is the measured probe for the equilibrium under investigation, and it is more natural to fit this variable with the best calculated set of protonation constants. When exact, theoretically calculated potentiometric data are submitted to the algorithm in the program PKAS, and the values of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

log $K_i$'s are reproduced exactly to $\sigma \sim 0.0003$ log units. Most of this residual error arises because the exact input is rounded to 0.001 log units, which is the pH reading limit of research pH meters. When the same input data were randomized to $\pm 0.07$ pH unit, then the protonation constants which resulted were good to $\pm 0.01$ log unit.

The program PKAS, which is the only one that currently employs this algorithm, is adapted for interactive execution. For convenience it requires a simple data file (disk in our case, card if desired) in which the first line is an identifying title card using 80 alphameric characters, while the remaining lines are pairs of volume base and pH. All of the remaining parameters are input as answers to questions as they appear on the CRT screen. These are in order:

1. Millimoles?
2. Molarity base?
3. Initial volume (mL)?
4. Number of dissociable protons on neutral ligand?
5. Number of additional protonations to be considered?
6. Fraction of "*a*" value to be excluded from computation on each end of segment?
7. Type "0" to skip remaining options. Type "1" to consider remaining options.

At this point the program goes into execution when "0" is entered and results are printed out when the calculation is finished. Otherwise, when "1" is entered, more input parameters can be entered, as follows:

8. Normality of excess acid added?
9. Volume of excess acid added?
10. Salt, such as disodium EDTA (2.0)?
11. pH correction?
12. p$K_W$?
13. Percent $CO_2$ in base?
14. First $CO_3^{2-}$ protonation constant?
15. Second $CO_3^{2-}$ protonation constant?

When the computation is complete, an option is presented to change any of the initial parameters and to rerun the program to see whether the fit can be improved or to obtain clues as to why the fit was not satisfactory. The most useful parameters to adjust are the millimoles of ligand and added excess acid. It has been observed in previous experiences that virtually all ligands possess molecular weights in general varying from ~1% to 5% higher than those computed from their molecular formulas. The source of this discrepancy is usually either interstitial (trapped) moisture or some neutral impurity such as NaCl or non-volatile solvent. Nevertheless, adjusting the calculated millimoles by the necessary amount makes possible the calculation of the exact molecular weight, which is required for exact matching of metal/ligand stoichiometry in subsequent stability constant work.

In a similar fashion, hydrochlorides or hydrobromides of bases are frequently found to contain small deficiencies or excesses of acid. This is usually the result of an interstitially trapped quantity of HX or may be caused by the cocrystallization of other sparingly soluble forms of polyhydrohalides containing one more or less hydrohalide molecule. For example, a compound bis-tren hexahydroperchlorate (28) was found to possess a formulation of $BT \cdot 6.028HClO_4$. In this case 82 titration points were considered, to give a $\sigma$ fit = 0.0008 in pH.

Finally, since the availability of self-contained microcomputers has proliferated to the point where almost all research laboratories have access to one, it was considered important to indicate how the common overflow problem was solved for the present systems. A real number $e$ accommodated in the Micromation CP/M system is limited to $10^{-38} \leq e \leq 10^{+38}$ in size. During routine scientific calculation in general, and evaluation of equilibrium expressions in particular, standard programming often gives rise to overflow. For example, at pH 10, $[H^+] = 10^{-10}$ and the last term of equations such as [3] or [4] would produce an underflow since $[H^+]^4$ in this case is $10^{-40}$ which is smaller than $10^{-38}$. A similar situation would occur in larger computer systems where often the limits are $10^{-76}$ to $10^{+76}$. Here the overflow would occur for $[H^+]^8$ at pH 10. One alternative which is practiced in the programming field is to go to logarithmic routines or other devices to maintain records of magnitudes. In order to circumvent this often fatal limitation a simple expedient was developed for this system whereby the evaluation of $A_1$ and $A_2$ in eqs. [3] and [4] and similar expressions were evaluated as if they were written:

$$[10] \quad A_1 = 1 + (K_1[H^+]) + (K_1[H^+])(K_2[H^+]) + (K_1[H^+])(K_2[H^+])(K_3[H^+]) + \ldots$$

$$[11] \quad A_2 = (K_1[H^+]) + 2(K_1[H^+])(K_2[H^+]) + 3(K_1[H^+])(K_2[H^+])(K_3[H^+]) + \ldots..$$

The products of the terms within the parentheses can very seldom exceed the CP/M number size limitation.

*Applications to multidentate ligands*

Table 1 presents a partial list of multidentate ligands of varying basicity for which the reported protonation constants were calculated with pro-

gram PKAS. The results obtained indicate that with this algorithm there is no practical limit to either the number of equilibrium constants or the degree of overlapping (closeness of p$K$'s) that may be handled. In using this method the equilibrium constants of ligands with more than six protonation constants were calculated as easily and smoothly as those of ligands containing only two or three p$K$'s. In the worst cases listed in Table 1 it was found that $\sigma = 0.017$ (log units for the entire pH fit), while in the more favorable cases $\sigma \cong 0.005$ log units. The last entry in Table 1 ("bis-tren") was calculated with the $\sigma = 0.00083$ log units. The deviations in $\sigma$ values apparently were due to the presence of small amounts of impurities in certain ligands. Indeed, the degree to which the data could be refined may be considered a measure of the analytical purity of the ligand.

Most of the ligands in Table 1 also form a series of protonated metal chelates of the type MHL, $MH_2L$, $MH_3L$, etc., as well as a number of hydrolyzed metal chelates such as MOHL and $M(OH)_2L$ with certain metal ions. In most cases cited in the table the protonation constants for the formation of these species have also been calculated with program PKAS.[2]

Received May 21, 1981

J. J. C. TEIXEIRA-DIAS, V. M. JARDIM-BARRETO, Y. OZAKI, A. C. STORER, and P. R. CAREY. Can. J. Chem. **60**, 174 (1982).

Infrared, Raman, and resonance Raman data are reported for ethyl and methyl dithioacetate together with data for their isotopically substituted analogs: $CD_3C(=S)SCH_3$, $CH_3C(=S)SCD_3$, $^{13}CH_3C(=S)SCH_3$, $CH_3{}^{13}C(=S)SCH_3$, $CD_3C(=S)SCH_2CH_3$, $CH_3C(=S)SCD_2CH_3$, and $CH_3{}^{13}C(=S)SCH_2CH_3$. Based on these data and a normal coordinate analysis of methyl dithioacetate, assignments are proposed for the majority of bands appearing in the vibrational spectra. Using excitation wavelengths in the 324–356 nm region strong intensity enhancement is observed for Raman bands near 1195, 1100, 730, and 580 $cm^{-1}$ which are assigned to stretching motions of the CCSSC skeleton. Raman excitation profiles are reported for the 1197 and 581 $cm^{-1}$ bands of ethyl dithioacetate and the electronic absorbance peak near 305 nm is identified as the source of resonance Raman intensity enhancement.

J. J. C. TEIXEIRA-DIAS, V. M. JARDIM-BARRETO, Y. OZAKI, A. C. STORER et P. R. CAREY. Can. J. Chem. **60**, 174 (1982).

On rapporte les des spectres infrarouge, Raman et de résonance Raman des dithioacétates d'éthyle et de méthyle ainsi que les données relatives à leurs analogues substitués par des isotopes: $CD_3C(=S)SCH_3$, $CH_3C(=S)SCD_3$, $^{13}CH_3C(=S)SCH_3$, $CH_3{}^{13}C(=S)SCH_3$, $CD_3C(=S)SCH_2CH_3$, $CH_3C(=S)SCD_2CH_3$, et $CH_3{}^{13}C(=S)SCH_3CH_3$. En fonction de ces données et d'une analyse des coordonnées normales du dithioacétate de méthyle, on propose une identification de la plupart des bandes qui apparaissent dans le spectre de vibration. En utilisant les longueurs d'onde d'excitation dans la région de 324–356 nm, on a observé une forte augmentation de l'intensité des bandes Raman près de 1195, 1100, 730 et 580 $cm^{-1}$ que l'on attribue à des mouvements d'élongation du squelette CCSSC. On rapporte les profils d'excitation Raman pour les bandes à 1197 et 581 $cm^{-1}$ du dithioacétate d'éthyle et on a identifé le pic d'absorption électronique près de 305 nm comme étant la cause de l'augmentation de l'intensité de la résonance Raman.

[Traduit par le journal]

## Introduction

The work presented in this series of papers (this paper and refs. 1 and 2) was motivated by our study of enzyme–substrate complexes using resonance Raman (RR) spectroscopy. In a recent report (3) it was shown that dithioesters (—C(=S)—S—) constitute an ideal RR probe for monitoring those bonds which are undergoing catalytic transformation within an enzyme's active site. The dithioester group forms a transient covalent linkage between enzyme and substrate at the instant of catalysis (4). Since the dithioester moiety has an intense $\pi \rightarrow \pi^*$ absorption band near 310 nm, excitation by 324 nm $Kr^+$ laser irradiation produces a RR spectrum of the —C(=S)—S— group while the normal Raman spectra of the enzyme (which is relatively enormous and has a MW of ~24 000 daltons) and aqueous solvent are too weak to be detected. The utility of the approach depends on our ability to interpret the RR spectrum of the dithioester function. The knowledge of the vibrational (5–10) and chemical (11) properties of dithioesters is minimal and thus we have instigated a series of spectroscopic and chemical studies which will act as a basis for understanding the spectra and properties of the enzyme–substrate intermediates.

This, the first paper in the present series, sets out to determine and assign the vibrational spectra of two of the simplest dithioesters, namely, methyl and ethyl dithioacetate. For these molecules isotopic substitutions and Raman, RR, and infrared data are used to help establish a complete description of the vibrational properties. Additionally, extensive normal coordinate analyses were undertaken for methyl dithioacetate to arrive at a quantitative understanding of the normal mode structure for the heavy atom skeleton. Detailed assignments and RR studies have not been reported hitherto. In the following paper (1) the vibrational spectra of dithioesters that are slightly more complex than methyl and ethyl dithioacetate are discussed with special attention being paid to the consequences of rotational isomerism about

C–C(=S) and —S–C

bonds. The third paper in the series (2) deals with more complex dithioesters which act, in some

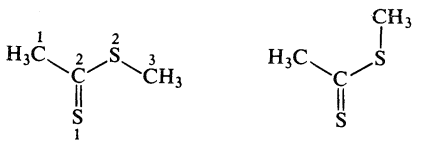

FIG. 1. The s-*cis* and s-*trans* conformers of methyl dithioacetate.

respects, as models for the catalytic region in enzyme substrate complexes.

The conformations and concomitant normal mode structures of dialkyl carboxylic acid esters have been studied in detail and some of the conclusions have been reviewed by Jones and Owen (12). In contrast, the corresponding dithioesters have been little investigated. There is, however, enough evidence in the literature to establish with reasonable certainty the preferred conformer for dithioesters. Infrared and microwave investigations (13) of methyl thiol formate ($HC(=O)SCH_3$) and infrared and Raman studies of $CH_3(=S)SCH_3$ (5) indicated that only the s-*cis* conformer (Fig. 1), with the heavy atoms in a single plane, was present in these compounds. Further support for the *cis* conformer in RC(=O)SR′, RC(=S)OR′, and RC(=S)SR′ came from dipole moment measurements (14–17). Taking this evidence into account we have assumed, unless otherwise stated, that dithioesters are in the s-*cis* conformation.

## Experimental

*Methods*

Raman measurements with visible excitation were recorded using a Jarrell-Ash 25-400 laser Raman spectrophotometer equipped with a RCA 31034A-02 photomultiplier tube and photon-counting detection. The excitation sources were Spectra-Physics model 164 $Ar^+$ and $Kr^+$ lasers. The apparatus used to obtain the Raman spectra with ultraviolet excitation consisted of a Coherent Radiation 3000 K or 2000 K $Kr^+$ laser and a Spex 0.5-m double spectrometer with direct current detection. Peak frequencies were calibrated using emission lines from Ar, Xe, Kr, and Ne lamps and are believed to be accurate to $\pm 2$ $cm^{-1}$ for well-resolved bands.

The resonance Raman spectra were recorded using a flow cell technique (18) to avoid photodecomposition or photoisomerization. A rotating cell was employed for measuring most of the Raman spectra excited by visible irradiation. The spectra showed excellent reproducibility and neither photodecomposition nor photoisomerization were observed. Band intensities were measured by band heights, and intensities reported for the excitation profiles are the average of at least two experiments. Two concentrations of ethyl dithioacetate in $CCl_4$ were prepared for the measurements of the excitation profiles. For the excitation in the range of 356.4–647.1 nm a solution containing 0.96% (v/v) ethyl dithioacetate and 5.8% (v/v) cyclohexane was used. For excitation wavelengths in the range 324.0–356.4 nm a solution containing 0.0033% (v/v) ethyl dithioacetate and 2.4% (v/v) cyclohexane was used. The cyclohexane band at 1033 $cm^{-1}$ was taken as an internal reference. Since the internal standard peak was close to the measured bands and the solutions were of low optical density neither a $\nu^4$ correction nor a self-absorption correction was necessary.

Absorption spectra were recorded using Cary 118 and 219 spectrophotometers. The infrared spectra were recorded by means of a Perkin Elmer 180 spectrophotometer. The methods used in the normal coordinate analysis of methyl dithioacetate are described below under "normal coordinate calculations for methyl dithioacetate".

*Materials*

The dithioesters were synthesised by the procedure outlined for ethyl dithioacetate by Marvel *et al.* (6). For the synthesis of methyl dithioacetate the gaseous methane thiol was liquified by passage down a column jacketed with a dry ice – acetone mixture. The addition of dry HCl to the acetonitrile – methane thiol solution was performed at −10°C. The $^{13}C$-substituted dithioesters were synthesised from acetonitrile labelled in the appropriate position. The deuterated dithioesters were synthesised from either deuterated acetonitrile, or, deuterated ethane or methane thiol prepared from the respective deuterated alkyl iodides (19) (alkyl iodides were used in place of the dialkyl sulphates in the published procedure). Purity of the samples was checked by nmr and elemental analysis of the dithioesters agreed to within 1% of the expected values.

## Results and discussion

*The absorption spectra*

The absorption spectra of methyl and ethyl dithioacetate are similar and both have intense features near 210 and 305 nm and a weak band near 450 nm. The exact positions of the $\lambda_{max}$'s and the extinction coefficients for ethyl dithioacetate in acetonitrile are 209 nm ($\log_{10} \varepsilon = 3.85$), 305.5 nm ($\log_{10} \varepsilon = 4.07$), and 452 nm ($\log_{10} \varepsilon = 1.28$) and for methyl dithioacetate the $\lambda_{max}$'s are at 208, 302, and 446 nm (the extinction coefficients for methyl dithioacetate were not measured but are very similar to those of the ethyl analog). The features near 305 and 450 nm in dithioester absorption spectra have been assigned to $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions respectively (20, 21) and it is likely that the band near 210 nm is due to a higher energy $\pi \rightarrow \pi^*$ transition. The $\pi \rightarrow \pi^*$ transition near 305 nm assumes a special importance since, in the present work, we show that this is the electronic absorbance responsible for RR enhancement. Hence, the 305 nm transition provides the basis of the specific intensity enhancement we observe in dithioester-macromolecules.

*Vibrational spectra of methyl dithioacetate*

Raman and infrared spectra of methyl dithioacetate and its isotopically substituted derivatives in the liquid phase are shown in Figs. 2 and 3 and the observed frequencies are listed in Table 1. Below 1200 $cm^{-1}$ the Raman spectrum of methyl dithioacetate is characterized by three intense bands at 1194, 864, and 580 $cm^{-1}$ while the infrared

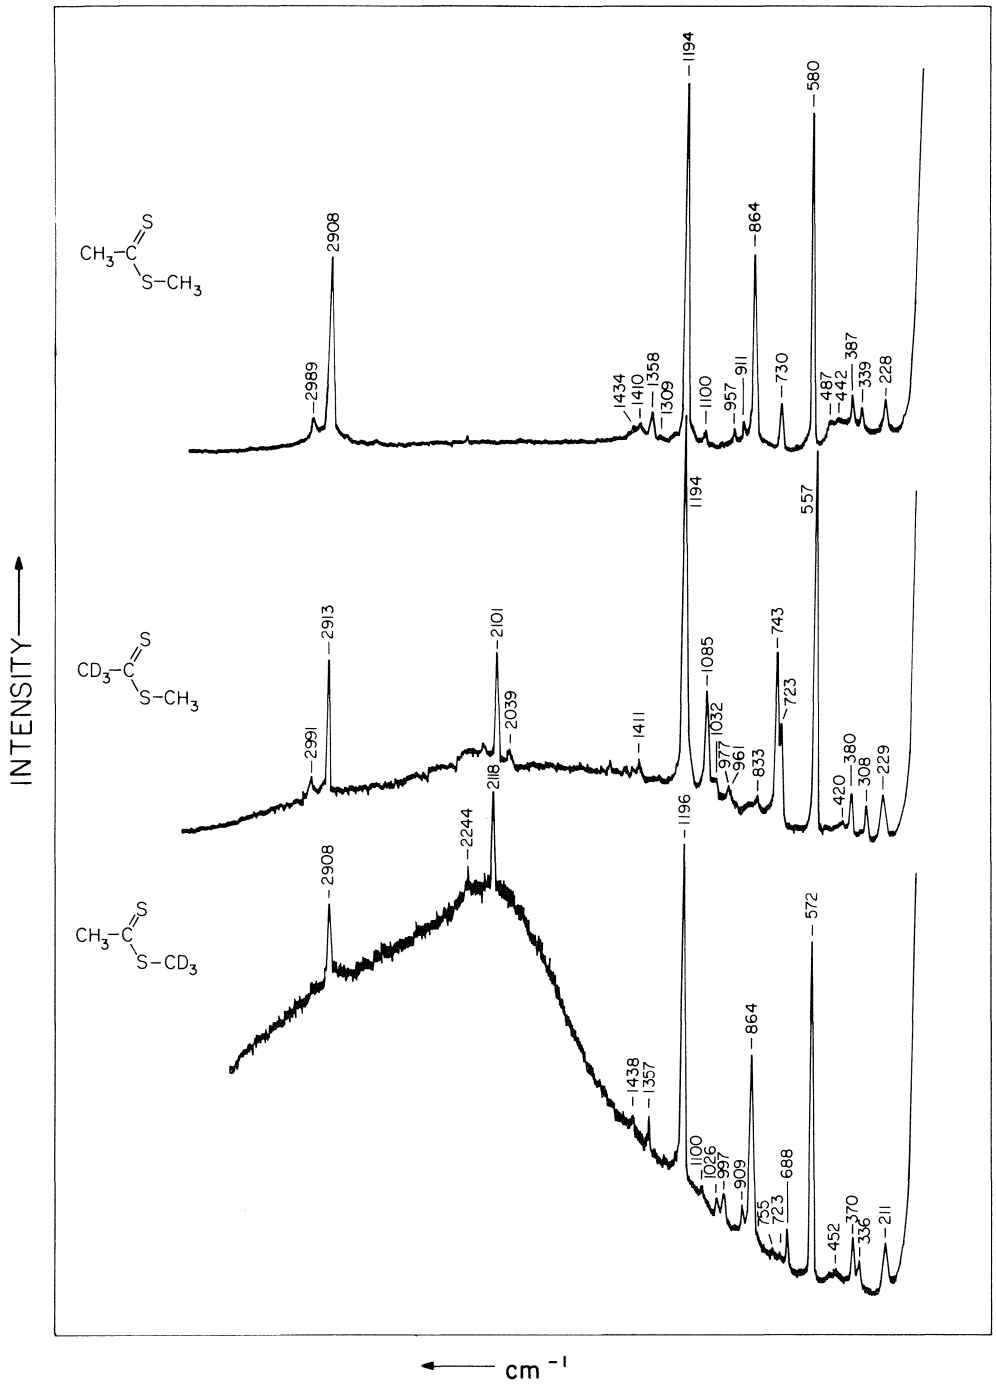

FIG. 2. The 514.5 nm excited Raman spectra of methyl dithioacetate and its isotopically substituted derivatives in the liquid state. Instrumental conditions: laser power, 50 mW; spectral slit width, 8 $cm^{-1}$; scan speed, 0.5 $cm^{-1}$ $s^{-1}$.

spectrum has four intense bands at 1195, 1100, 865, and 580 $cm^{-1}$. Almost all the Raman and infrared bands show individual shifts when various isotopic replacements are made. Upon deuterium substitution of the $CH_3$—C group, the Raman bands at 1434, 1358, and 1100 $cm^{-1}$ shift to the 1090–970 $cm^{-1}$ region while the bands at 911, 864, 730, 580, 387, and 339 $cm^{-1}$ are replaced by features at 833, 743, 723, 557, 380, and 308 $cm^{-1}$. The correspondence between the 730 and 723 $cm^{-1}$ bands in Fig. 2

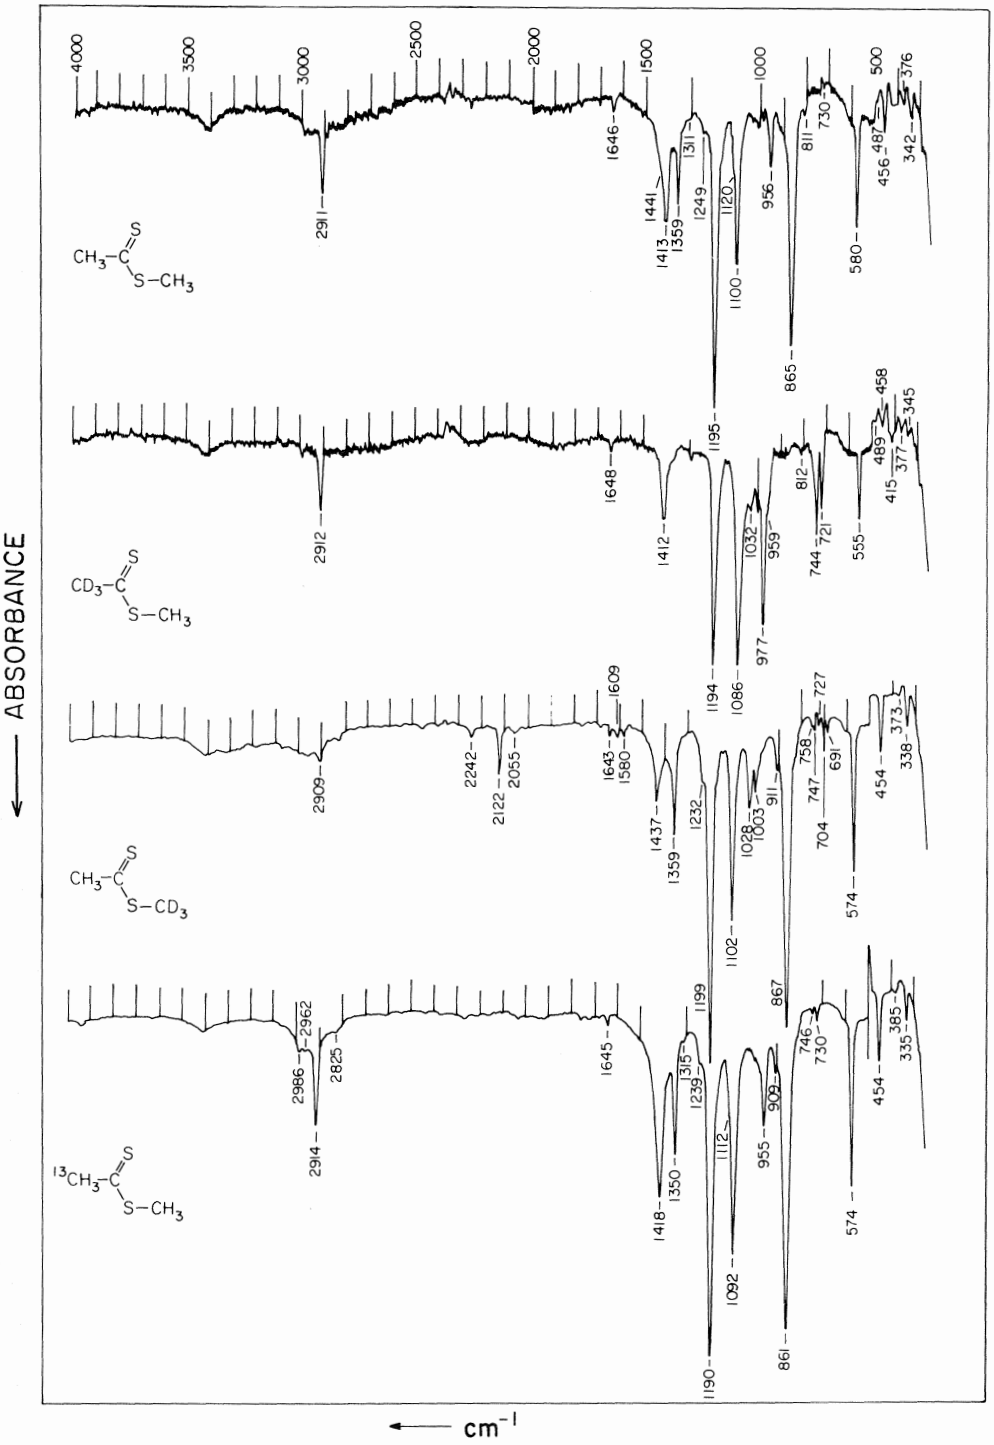

FIG. 3. The infrared spectra of methyl dithioacetate and its isotopically substituted derivatives in the liquid state.

(top and center) was confirmed by the measurement of polarized Raman spectra since only the 730 and 723 $cm^{-1}$ bands are depolarized in the 900–500 $cm^{-1}$ region. The new bands in Fig. 2 (center) at 2101 and 2039 $cm^{-1}$ result from shifts of the bands near 3000 $cm^{-1}$ in Fig. 2 (top). The infrared bands at 1441, 1359, 1100, 865, 730, and 580 $cm^{-1}$ exhibit a shift upon deuterium substitution of the $CH_3$—C

*PED contributions less than 10% are ignored. Guessed experimental frequencies are in parentheses.

group. Taking the Raman and infrared data together it is suggested that the features at 911, 864, 730, 580, 387, and 339 in the Raman spectra of the $CH_3$—C compound correspond to the features at 833, 743, 723, 557, 380, and 308 $cm^{-1}$ respectively in the spectrum of the $CD_3$—C analog.

Upon deuterium substitution of the S—$CH_3$ group the Raman bands at 730, 580, 387, and 228 $cm^{-1}$ shift to 688, 572, 370, and 211 $cm^{-1}$, respectively. The shift from 730 to 688 $cm^{-1}$ was again confirmed by the measurement of polarized Raman spectra. The bands at 1410 and 957 $cm^{-1}$ also exhibit a shift. The bands at 2244 and 2118 $cm^{-1}$ result from the shifts of the bands which appear near 3000 $cm^{-1}$ in the spectra of the parent compound. Shifts of the infrared bands at 2911, 1413, 956, 730, and 580 $cm^{-1}$ are also observed for the S—$CD_3$ analog.

Only small amounts of the $^{13}C$-substituted compounds were synthesised. Consequently, we were able to obtain just the infrared and RR spectra of $^{13}CH_3C(=S)SCH_3$ and a poor quality RR spectrum of $CH_3{}^{13}C(=S)SCH_3$. The $^{13}C$ substitution in $^{13}CH_3C(=S)SCH_3$ brought about modest shifts in the infrared spectrum with the bands at 1441, 1359, 1195, 1100, 865, and 580 moving to 1418, 1350, 1190, 1092, 861, and 574 $cm^{-1}$ respectively.

The 324 nm excited RR spectra of 0.01% (v/v) acetonitrile solutions of methyl dithioacetate and its isotopically-substituted derivatives are shown in Fig. 4. Only five RR bands are observed in the 1300–500 $cm^{-1}$ region with two bands being prominent near 1200 and 585 $cm^{-1}$. In the RR spectrum the relative intensity of the 1106 $cm^{-1}$ band increases whereas that of the 872 $cm^{-1}$ band decreases compared to the normal Raman spectrum. In fact, the 1106 $cm^{-1}$ feature undergoes the highest degree of intensity enhancement — a factor of about 9000 fold upon going from 514.5 to 324 nm excitation (c.f. Fig. 8). Some of the bands observed in the Raman spectrum were obscured by the bands of acetonitrile or became too weak to detect under resonance conditions. The bands near 2900 $cm^{-1}$, for example, could not be observed in a 0.01% (v/v) deuterated acetonitrile ($CD_3CN$) solution under the RR condition. Upon deuterium substitution of the $CH_3$—C group, the RR features at 1106, 872, 732, and 585 $cm^{-1}$ shift in frequency as in the case of the normal Raman spectrum of the neat compound. Upon deuterium substitution of the S—$CH_3$ group the 732 $cm^{-1}$ band undergoes a large shift to 694 $cm^{-1}$ while the 585 $cm^{-1}$ band shows a smaller shift to 577 $cm^{-1}$. For $^{13}CH_3C(=S)SCH_3$ the bands at 1200, 1106, 872, and 585 $cm^{-1}$ exhibit small shifts

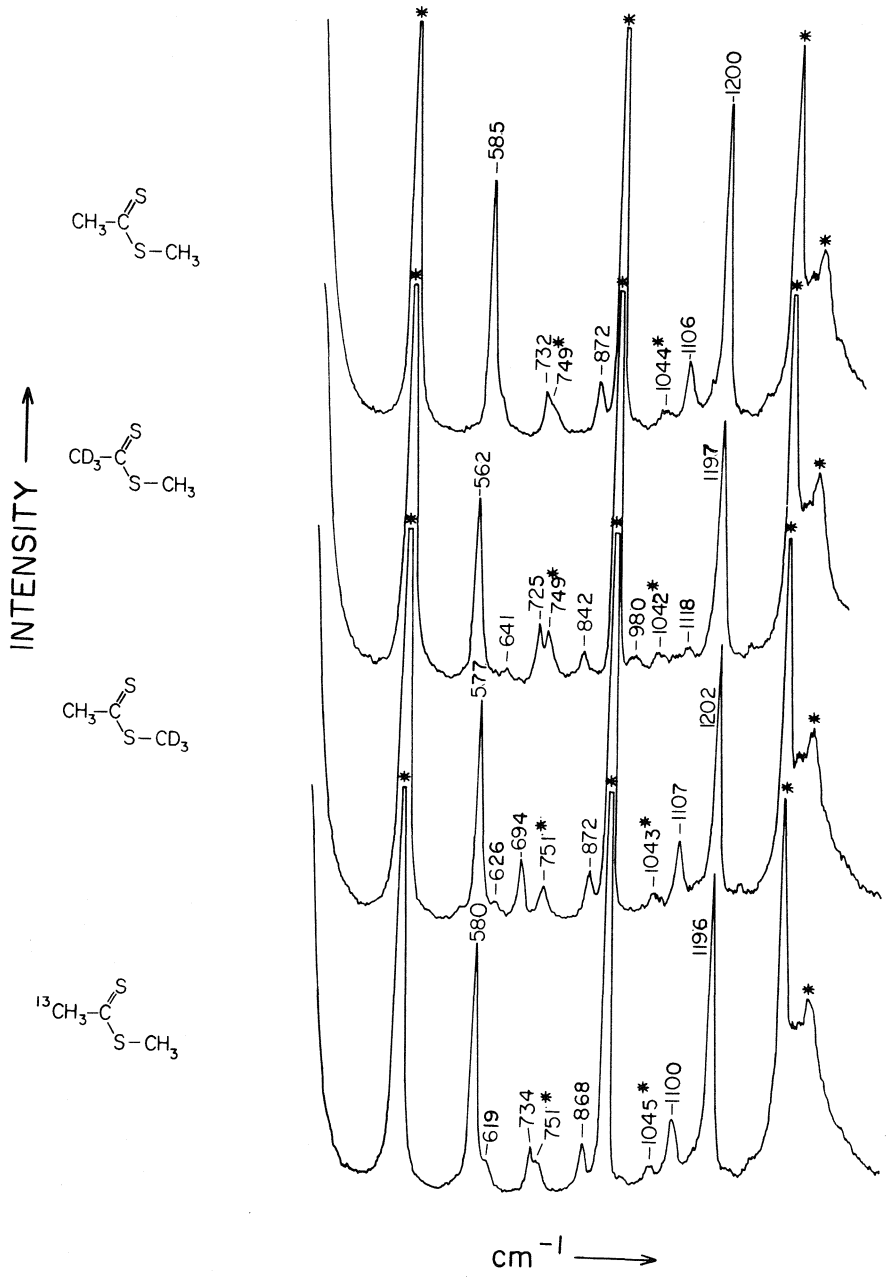

FIG. 4. The 324.0 nm excited RR spectra of methyl dithioacetate and its isotopically substituted derivatives in 0.01% (v/v) $CH_3CN$ solution. Features marked with an asterisk are due to $CH_3CN$. The RR spectrum of $CH_3$—$^{13}C$(=S)—S—$CH_3$ (not shown) has a steep base line due to strong luminescence; however, RR bands were observed at 1175, 1086, and 584 $cm^{-1}$. Instrumental conditions: laser power, 10 mW; spectral slit width, 8 $cm^{-1}$; scan speed, 0.75 $cm^{-1}$ $s^{-1}$.

compared to the parent compound (Fig. 4). However, for $CH_3{}^{13}C(=S)SCH_3$ the intense band found in the parent molecule at 1200 $cm^{-1}$ undergoes a striking shift to 1175 $cm^{-1}$ (data not shown). The band at 1106 $cm^{-1}$ also shifts to 1086 $cm^{-1}$ in the $^{13}C$=S molecule. In contrast, the band at 585 $cm^{-1}$ shifts little upon the $^{13}C$ substitution of the thiocarbonyl group. The measured value for $CH_3{}^{13}C(=S)SCH_3$ is 584 $cm^{-1}$ which, within experimental error, is identical to the value for the $^{12}C$ analog.

Raman spectra were also measured in 1.0% (v/v) acetonitrile solution using 514.5 nm excitation. The relative intensities and frequencies of the Raman bands in 1.0% (v/v) acetonitrile solution are very close to those of the Raman bands in the neat liquid. For example, the most intense band is seen at 1194

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

$cm^{-1}$ in the Raman spectrum of liquid and at 1197 $cm^{-1}$ in the Raman spectrum of 1.0% (v/v) acetonitrile solution. Therefore, it is possible to compare directly the 514.5 nm excited Raman spectra of the neat liquids with the 324.0 nm excited RR spectra of 0.01% (v/v) acetonitrile solutions.

*Normal coordinate calculations for methyl dithioacetate*

The normal coordinate analyses were performed using computer programs written by Fuhrer *et al.* (22) and adapted by two of us (J.J.C.T-D and V.M.J-B) to a Univac Sigma 5 computer. The programs were in three parts: CART which converts molecular structural parameters to cartesian coordinates, GMAT which sets up the kinetic energy matrix, and FPERT which calculates and refines the force constants using the least-squares method and the frequency data from several isotopic species.

The geometrical parameters assumed for methyl dithioacetate are listed in Table 2 and were based on previously published data for thioacetic acid (23) and dithioformic acid (24). The numbering of the C and S atoms is shown in Fig. 1. The carbon–sulfur skeleton was assumed to take up the planar S-*cis* conformation shown in Fig. 1, the methyl groups were assigned tetrahedral angles and the CH bond length fixed at the value given by Curl (25).

Table 3 shows the definition of internal coordinates for methyl dithioacetate. Apart from the usual changes in bond lengths and bond angles we have included three torsion coordinates around the C—C, C—S, and S—C bonds and an out-of-plane wagging coordinate for C=S (26).

Before starting the calculation of force constants it is necessary to eliminate any redundant coordinates. In the case of methyl dithioacetate, the internal coordinates we have defined exceed the number of vibrational degrees of freedom ($3N - 6 = 27$) by three. One can separate the redundant coordinates by taking linear combinations of the bending coordinates so that three of them correspond to the sums of the bond angle changes around the atom centres where three or more bonds are coincident (these sums are identically zero). Table 4 shows the new set of internal coordinates grouped in a vector array $S$.

Another remark about the definition of our $S$ coordinates is necessary as we did not use the molecular symmetry group ($C_s$) and preferred instead the highest local symmetry coordinates consistent with the methyl groups ($C_{3v}$ symmetry). While the particular choice of any linear and orthogonal transformation among the basis coordinates is irrelevent as regards to the calculated eigenvalues and to the information contained in the final PED matrix, our choice seems to be justified as we are mainly fitting vibrational frequencies taken from condensed phase spectra and both methyl groups should be considered, for that purpose, to display axial symmetry around the C—C and S—C bonds. Moreover, the primary objective of this work is to analyse the motions of the carbon–sulfur skeleton rather than to accurately reproduce the observed vibrational frequencies of the entire molecule.

The force field adopted in these calculations is the simplified general valence force field (SGVFF). This form of the general valence force field contains a reduced number of interaction constants compatible with a good fit of the fundamental vibrational frequencies. In addition to all the off-diagonal elements relative to the in-plane coordinates of the carbon–sulfur skeleton, we have included the off-diagonal interactions $F_{S_1S_3}$ and $F_{S_4S_{22}}$. This corresponds to having ignored the off-diagonal interactions which are not consistent with

*s = stretch; b = bend; t = torsion; w = wag; r = rock; whenever two letters are used the first stands for "symmetric" (s) or "antisymmetric" (a). For the purpose of this calculation, the skeletal and methyl coordinates are herein grouped under different headings.

the hypothesis of axial symmetry for the methyl groups. The simplicity of our force field as regards to the alkyl groups and, in particular, to the interaction elements coupling the dithioester and alkyl groups should not significantly affect the conclusions drawn for the dithioester group vibrations.

The experimental frequency data from four isotopic species, $CH_3CSSCH_3$, $CD_3CSSCH_3$, $CH_3CSSCD_3$, and $^{13}CH_3CSSCH_3$, were simultaneously entered and processed in the least-squares fitting procedure. The calculated valence force constants are reported in Table 5 and the observed and calculated frequencies and their potential energy distribution are shown in Table 1. The conclusions from the PED are also summarised in the assignments given in Table 6 for the region between 500 and 1200 $cm^{-1}$. The calculated valence force constants were subsequently used to evaluate the vibrational frequencies in $CH_3{}^{13}CSSCH_3$. The observed isotopic shifts for the RR spectral data (caption to Fig. 4) were very well reproduced, thus confirming the plausibility of the calculated force field.

*The vibrational assignments of the Raman and infrared bands of methyl dithioacetate*

The Raman band at 2989 $cm^{-1}$ probably contains a contribution from the antisymmetric C—H stretching modes of the S—$CH_3$ and $CH_3$—C groups (27). On the basis of calculations (Table 1) and the different electronegativities of the C and S atoms it is likely that the S—$CH_3$ makes a contribution at slightly higher frequencies within the band profile in this region. The symmetric C—H stretching modes of both methyl groups contribute to the intense 2908 $cm^{-1}$ Raman feature since the infrared absorbance giving rise to this band diminishes upon the deuterium substitution of the $CH_3$—C or the S—$CH_3$ group. Moreover, this conclusion is consistent with the findings in Table 1. The Raman bands at 1434 $cm^{-1}$ and 1358 $cm^{-1}$ (the infrared bands at 1441 and 1359 $cm^{-1}$) undergo a large shift in the Raman (infrared) spectrum of $CD_3$—C(=S)—S—$CH_3$ and therefore these bands may be assigned to the antisymmetric and symmetric deformation modes of the $CH_3$—C methyl group, respectively. The Raman band at 1410 $cm^{-1}$ (the infrared band at 1413 $cm^{-1}$) can be assigned to the antisymmetric deformation mode of the S—$CH_3$ methyl group since the band shifts in the Raman (infrared) spectrum of $CH_3$—C(=S)—S—$CD_3$. The weak band at 1309 $cm^{-1}$ is possibly due to the methyl symmetric deformation mode of the S—$CH_3$ group (28). Support for the $CH_3$ deformation assignments is again found in Table 1.

The band at 1194 $cm^{-1}$ is very intense in the Raman and infrared spectra and strongly enhanced in the RR spectrum. Although this band does not shift or shifts little upon the deuterium substitution of the $CH_3$—C or S—$CH_3$ groups or in the $^{13}CH_3C(=S)SCH_3$ analog, the same band does shift by 25 $cm^{-1}$ upon the $^{13}C$ substitution of the thiocarbonyl group. The intensity of the band and the results of the isotopic shifts strongly suggest that the band has a high degree of C=S stretching character. These results and conclusions are in general agreement with the normal coordinate calculations although the latter stress that the C—C stretching motion probably makes a substantial contribution to the 1194 $cm^{-1}$ mode. The band at 1100 $cm^{-1}$ is shifted in the spectra of $CD_3$—C(=S)—S—$CH_3$, $^{13}CH_3$—C(=S)—S—$CH_3$, and $CH_3$—$^{13}$C(=S)—S—$CH_3$, and it does, moreover, undergo a very high degree of intensity enhancement upon going from 514.5 to 324 nm excitation. The results of the calculations indicate that the 1100 $cm^{-1}$ mode has a high degree of C—S and some C—C stretching character (Tables 1, 6). The isotope shifts concerning this mode are faithfully reproduced in the calculations. In addition, the normal coordinate analysis explains the high degree of intensity enhancement observed under resonance conditions since the C—S bond is intimately involved in the chromophore.

The bands at 957 and 911 $cm^{-1}$ shift upon the deuterium substitution of the S—$CH_3$ or the $CH_3$—C group, respectively. This finding and the results from the calculations (Table 1) lead us to assign these bands to methyl rocking modes of the S—$CH_3$ and the $CH_3$—C groups respectively. The band at 864 $cm^{-1}$ is intense in the Raman and infrared spectra, although the relative intensity of this feature becomes weaker in the RR spectrum. Moreover, the 864 $cm^{-1}$ band exhibits a large shift to 743 $cm^{-1}$ upon the deuterium substitution of $CH_3$—C group but only a small shift in the infrared spectrum of the $^{13}CH_3$—C(=S)$SCH_3$ analog (Fig. 3). These observations suggest that the 864 $cm^{-1}$ band, too, may have a substantial degree of $CH_3$ rocking character and is due to the $CH_3$—C group. This assignment is strengthened by the results of the normal coordinate analysis (Table 1) and the fact that the 864 $cm^{-1}$ feature is absent in the spectra of $C_2H_5C(=S)SCH_3$ (1). Methyl rocking modes are prone to coupling with other vibrations in the molecule (29) and such a coupling is indicated for the 864 $cm^{-1}$ feature in the vibrational calculations. The result of the calculations show that the rocking modes at 975, 958, and 915 $cm^{-1}$ (Table 1) are essentially pure modes. However, the 864 $cm^{-1}$ band contains PED contributions of 10% from $\nu_{C-S}$ and 8% from $\nu_{C=S}$. Such coupling may be responsible for the high degree of resonance enhancement seen for this essentially hydrogenic mode. In this regard it is interesting to note that Mathies and co-workers (30) have been able to show that substantial resonance enhancement may be observed for hydrogen out-of-plane bends of certain strained conformers of the retinal molecule.

The band at 730 $cm^{-1}$ undergoes a large shift to 688 $cm^{-1}$ upon deuterium substitution of the S—$CH_3$ group. This finding, taken with the PED distribution of 87% $\nu_{S-C}$ (Tables 1 and 6) prompts us to assign the 730 $cm^{-1}$ mode to a vibration involving a very high degree S—C stretching mode of the S—$CH_3$ group. Such an assignment is in good accord with Miyazawa's finding (31) that for thioethers of the form $RCH_2SCH_3$ the S—$CH_3$ stretching vibration is observed around 725 $cm^{-1}$, and the frequency is fairly independent of the changes in molecular conformation. The band at 580 $cm^{-1}$ is intense in Raman and infrared spectra, and the fact that it is enhanced strongly in the RR spectrum indicates that this band is intimately associated with the motion of atoms in the —C(=S)—S— chromophore. The band exhibits a large shift to 557 $cm^{-1}$ upon the deuterium substitution of the $CH_3$—C group and a small shift upon the deuterium substitution of the S—$CH_3$ group or in $^{13}CH_3(=S)SCH_3$. The results suggest that the 580 $cm^{-1}$ feature contains major contributions from C—S and C—C stretching motions. These expectations are borne out by the calculations which further indicate a sizable contribution from the C=S stretch. Since the 730 $cm^{-1}$ band is weak in both Raman and infrared spectra and the 580 $cm^{-1}$ band is intense in both Raman and infrared spectra, it is not appropriate to ascribe the 730 and 580 $cm^{-1}$ bands to antisymmetric and symmetric C—S—C stretching modes, respectively, and this conclusion is substantiated by the normal coordinate analysis. The situation again parallels Nogami, Sugeta, and Miyazawa's work on thioethers (31) in which these authors found that the best description of the C—S stretches in the $RCH_2$—S—$CH_3$ group is localised $CH_2$—S and S—$CH_3$ stretches. The Raman bands at 387, 339, and 228 $cm^{-1}$ may be due to the skeletal deformation modes. Since the 228 $cm^{-1}$ bands does not show a shift upon the deuterium substitution of the $CH_3$—C group but shifts to 211 $cm^{-1}$ upon the deuterium substitution of S—$CH_3$ group, the band is probably due to a torsional or bending motion in the C—S—$CH_3$ moiety. The vibrational assign-

ments for methyl dithioacetate are summarised in Table 6.

A comparison between the diagonal stretching force constants for the CCSSC and CCOOC skeletons of methyl dithioacetate and methyl acetate reveals several interesting facets. In the case of methyl acetate the force constants for $\nu_{C=O}$ and $\nu_{C-O}$ are quite different, 10.8 and 6.1 mdyn $Å^{-1}$ respectively (J.J.C.T.-D, unpublished work), while for methyl dithioacetate the force constants for $\nu_{C=S}$ and $\nu_{C-S}$ are remarkably similar at 4.9 and 4.4 mdyn $Å^{-1}$, respectively. If we relate the ratio of the force constants to the relative degree of double bond character we can say that there is a considerably greater difference in bond order between the formal C=O and C—O bonds than between the formal C=S and C—S bonds. An additional point concerns the force constants for C—C in the dithio and dioxygen analogs. For the latter, the force constant of 4.0 mdyn $Å^{-1}$ is close to that for alkanes (32) while the force constant for C—C in methyl dithioacetate is 3.5 mdyn $Å^{-1}$. The overall similarity of the force constants within the dithioester fragment provide an ample mechanism for the observed vibrational coupling.

A comparison of the PED results and the degrees of RR enhancement shows that modes with a high degree of C=S, C—S, and S—C character are particularly intensity enhanced. Modes associated with $\nu_{C-S}$ and $\nu_{S-C}$ are at least as active as those associated with $\nu_{C=S}$ and this provides evidence for the electronic transition being delocalised over the

—C—S—C moiety rather than being confined to mainly the C=S group.

*Vibrational spectra of ethyl dithioacetate and their assignments*

The Raman, infrared, and RR spectra of ethyl dithioacetate and its isotopically substituted derivatives are shown in Figs. 5, 6, and 7, respectively. There is a striking resemblance between the spectra of methyl dithioacetate and the spectra of ethyl dithioacetate. In the RR spectrum of ethyl dithioacetate, for example, the pattern of bands between 1250 and 500 $cm^{-1}$ closely resembles the pattern of bands in the same region of the RR spectrum of methyl dithioacetate. In fact, in the RR spectrum only the band at 732 $cm^{-1}$ which was assigned to the S—$CH_3$ stretching mode showed a substantial shift upon going from methyl to ethyl ester.

Although the complete assignments of the bands in the C—H stretching vibrational region are not trivial, some comments can be made. The Raman band at 2910 $cm^{-1}$ shifts to 2100 $cm^{-1}$ upon the deuterium substitution of the $CH_3$—C moiety, thus the band can be assigned to the symmetric C—H stretching mode of the $CH_3$—C group. In the infrared spectrum, the shoulder at 2920 $cm^{-1}$ shifts upon the deuterium substitution of the S—$CH_2$

group, thus this band may be due to the antisymmetric C—H stretching mode of the S—$CH_2$ moiety. However, the mode does not make a major contribution to Raman intensity in this spectral region. The infrared bands at 2969, 2929, and 2873 $cm^{-1}$ were observed in the spectra of $CH_3$—C(=S)—S—$CH_2CH_3$, $CD_3$—C(=S)—S—$CH_2$-$CH_3$, and $CH_3$—C(=S)—S—$CD_2CH_3$, therefore

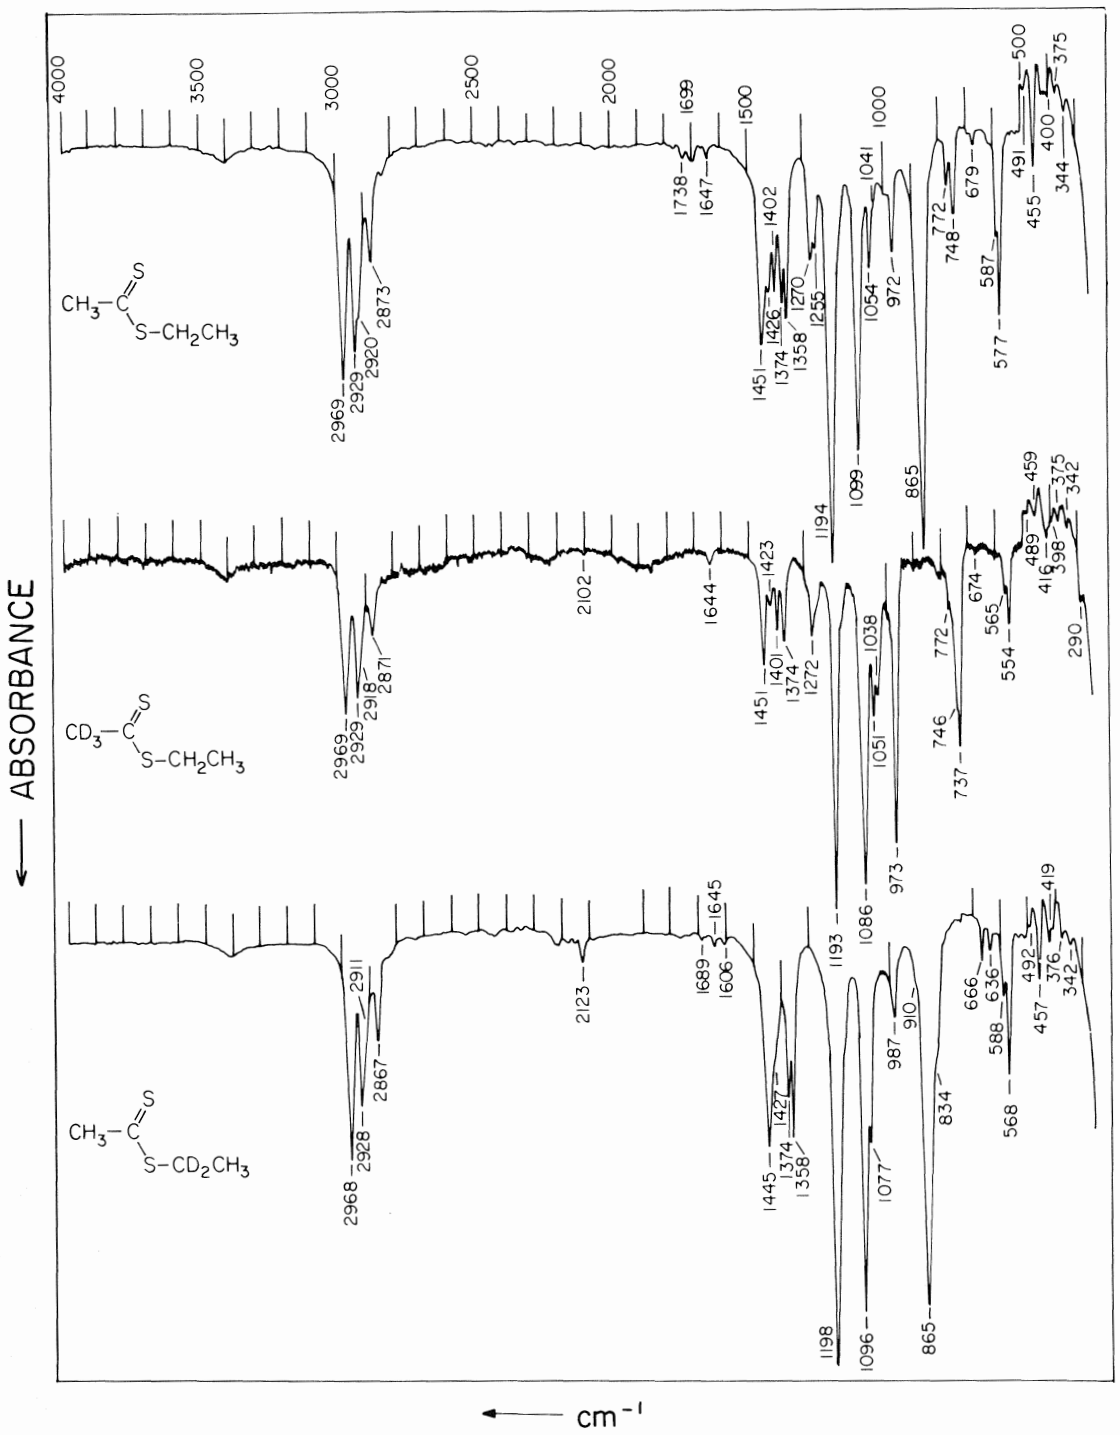

FIG. 6. The infrared spectra of ethyl dithioacetate and its isotopically substituted derivatives in the liquid state.

these bands probably include a contribution from the —$CH_3$ group. In their infrared study of ethyl acetate Nolin and Jones (33) ascribed ethyl acetate bands at 2877 $cm^{-1}$ and 2939 $cm^{-1}$ as due to the symmetrical C—H stretch and a combination band of the —$OCH_2CH_3$ methyl group with the possibility that these assignments may be reversed.

The band at 1453 $cm^{-1}$ can be assigned to the antisymmetric methyl deformation mode of the $CH_2$—$CH_3$ group since the band does not shift upon

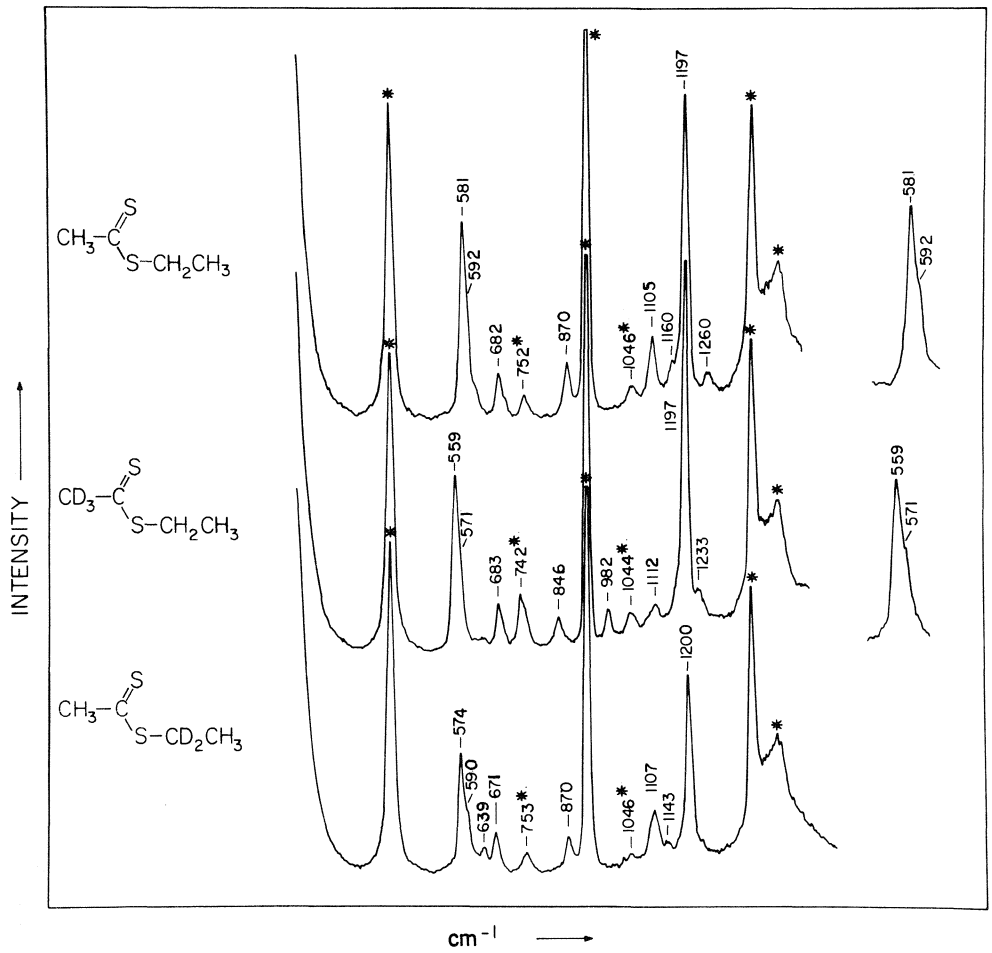

FIG. 7. The 324.0 nm excited RR spectra of ethyl dithioacetate and its isotopically substituted derivatives in 0.01% (v/v) $CH_3CN$ solution. Features marked with an asterisk are due to $CH_3CN$. The RR spectrum of $CH_3$—$^{13}C$(=S)—S—$C_2H_5$ (not shown) had a steep base line due to strong fluorescence; however, RR features were observed at 1172 and 580 $cm^{-1}$ together with a weaker band at 1092 $cm^{-1}$. Instrumental conditions are same as those in Fig. 4.

the deuterium substitution of $CH_3$—C or S—$CH_2$, whereas the infrared band at 1426 $cm^{-1}$ (seen as a shoulder on the Raman band at 1453 $cm^{-1}$) probably includes a contribution from the antisymmetric methyl deformation mode of the $CH_3$—C group, since the intensity of this band became weaker in the infrared spectrum of $CD_3$—C(=S)—S—$CH_2$-$CH_3$. Both these conclusions are in good accord with Nolin and Jones's assignments for ethyl acetate (33). The band at 1400 $cm^{-1}$ shifts upon the deuterium substitution of the methylene group, thus this band is assigned to the $CH_2$ scissoring (deformation) mode. The infrared band at 1374 $cm^{-1}$ does not shift upon the deuterium substitution of the $CH_3$—C group or the S—$CH_2$ group; however, the Raman and infrared band at 1356 $cm^{-1}$ does shift upon the deuterium substitution of the $CH_3$—C group. Thus, the 1374 and 1356 $cm^{-1}$ bands can be assigned to the symmetric methyl deformation mode of the $CH_2CH_3$ and $CH_3$—C groups, respectively. The latter assignment is in accord with the $CH_3$—C symmetric methyl deformation assignment made for methyl dithioacetate above. The infrared bands at 1270 and 1255 $cm^{-1}$ shift in the spectrum of $CH_3$—C(=S)—S—$CD_2$-$CH_3$. Moreover, methyl dithioacetate does not have a band near 1270 $cm^{-1}$, therefore it is possible to assign the feature near 1260 $cm^{-1}$ to the $CH_2$ wagging mode. The assignments concerning the $CH_2$ deformation and wagging modes are in reasonable harmony with those found in the literature (34).

The band at 1192 $cm^{-1}$ is intense in the Raman, infrared, and RR spectra. The band shifts little upon the deuterium substitution of $CH_3$—C group or S—$CH_2$ group, but as in the case of the 1194

$cm^{-1}$ band of methyl dithioacetate shows a large shift upon the $^{13}C$ substitution of the thiocarbonyl group. Therefore the 1192 $cm^{-1}$ band probably has a substantial degree of C=S stretching character. This assignment and assignment for the band at 1194 $cm^{-1}$ of methyl dithioacetate are in good agreement with the conclusions reached by several authors using mainly infrared spectroscopy (5–9).

The Raman and infrared bands at 1099, 971, 911, and 864 $cm^{-1}$ of ethyl dithioacetate correspond to those at 1100, 957, 911, and 864 $cm^{-1}$ of methyl dithioacetate, respectively, because the corresponding bands show similar frequencies, intensities, and isotopic shifts. The ethyl dithioacetate band at 1099 $cm^{-1}$, assigned to a mixed vibration involving a C—S stretching and a C—C stretching motion of the $CH_3$—C group, gains intensity under the RR condition and shifts in the spectrum of $CD_3$—C(=S)—S—$CH_2CH_3$ whereas the band at 864 $cm^{-1}$ assigned to the $CH_3$ rocking mode of the $CH_3$—C group loses intensity under the RR condition and shifts to 738 $cm^{-1}$ in the spectrum of $CD_3$—C(=S)—$CH_2CH_3$. This behaviour closely follows that noted for the methyl ester (Figs. 2, 4, 5, and 7). The ethyl ester has an additional band at 1052 $cm^{-1}$ which can be assigned to the C—C stretching mode of the ethyl group. It is marked that in the Raman spectrum, the 1052 $cm^{-1}$ band due to the C—C stretching mode of the ethyl group is much stronger than the 1099 $cm^{-1}$ band due to the C—C stretching mode of the $CH_3$—C group; however, in the RR spectrum the former is very weak or absent and the latter becomes more intense. The 747 $cm^{-1}$ band which shifts to 632 $cm^{-1}$ upon deuterium substitution of the $CH_2$ group may be due to a $CH_2$ rocking mode.

The band at 681 $cm^{-1}$ shifts to lower wavenumbers by 14 $cm^{-1}$ upon the deuterium substitution of S—$CH_2$ and the band is weak in the Raman and infrared spectra but gains intensity in the RR spectra (Figs. 5, 6, and 7). Therefore the band can be assigned to a vibration involving the S—C stretching mode. In contrast to the 681 $cm^{-1}$ band, the intense band at 579 $cm^{-1}$ undergoes a large shift by about 23 $cm^{-1}$ upon the deuterium substitution of $CH_3$—C group and shifts by only 9 $cm^{-1}$ upon the deuterium substitution of S—$CH_2$ group. Thus, by analogy with methyl dithioacetate this band can be assigned to a mode having contributions from C—C, C—S, and C=S stretching coordinates. Accordingly, for both methyl and ethyl dithioacetates the C—C + C—S + C=S stretching mode is intense and is observed near 580 $cm^{-1}$ in the Raman, infrared, and RR spectra; on the other hand, the S—C stretching mode is weak or very weak in the Raman and infrared spectra and is located at 730 $cm^{-1}$ for the methyl ester and at 680 $cm^{-1}$ for the ethyl ester. The shoulders at 697 and

590 $cm^{-1}$ of ethyl dithioacetate indicate the coexistence of the rotational isomers as discussed in the following paper (1).

The vibrational assignments for ethyl dithioacetate are summarized in Table 7.

*Excitation profiles*

The dependence of Raman intensity on excitation wavelengths (the excitation profile) can provide information on vibronic structure which lies unresolved in an absorption spectrum, information on the mechanism of Raman intensity enhancement, and provide confirmatory information on assignments of the Raman bands. In the present case excitation wavelengths in the range 647.1 to 324 nm were available and thus it was not possible to scan through the entire dithioester absorbance band centered near 307 nm. The resulting excitation profiles for the 581 and 1197 $cm^{-1}$ bands of ethyl dithioacetate are shown in Fig. 8. Compared to their intensities with 647.1 nm excitation, both bands increase in intensity by a factor of 1500–2000 upon going to 324 nm as an excitation wavelength. Although no significance is attached to the individual "dips" in the excitation profiles in the 450–500 nm region, the data taken together do suggest that a small amount of intensity enhancement is achieved by coupling to the $n \rightarrow \pi^*$ transition near 460 nm. In this region the 1197 $cm^{-1}$ feature shows markedly greater intensity enhancement compared to the 581 $cm^{-1}$ band. Importantly, the excitation profile data establish that the $\pi \rightarrow \pi^*$ transition near 307 nm is the major source of Raman intensity enhancement and, in fact, in the pre-resonance region (412 to 324 nm) there is good agreement between the experimental profile and a theoretical curve generated from an Albrecht and Hutley A type mechanism (35).

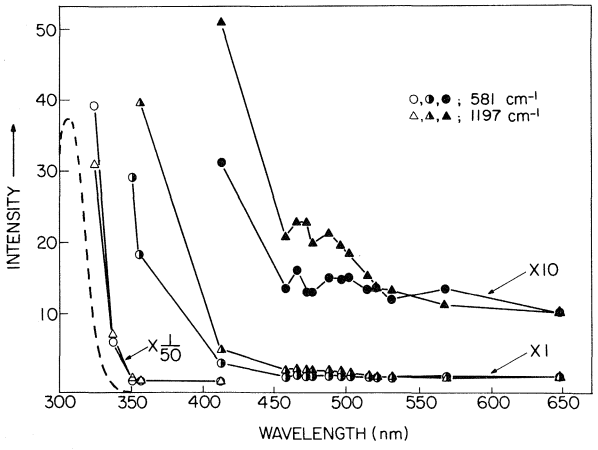

FIG. 8. The observed excitation profiles for the bands at 581 and 1197 $cm^{-1}$ of ethyl dithioacetate. (○, ◑, ● 581 $cm^{-1}$, △, ▲, ▲; 1197 $cm^{-1}$). The absorption spectrum, with an arbitrary absorbance scale, is shown as (---). The $n \rightarrow \pi^*$ transition is too weak to be observed on the same absorbance scale as the main $\pi \rightarrow \pi^*$ transition. The solution used to obtain the excitation profile in the 324 to 350.6 nm range had an O.D. of about 3 at 307 nm.

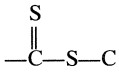
## Conclusion

By using extensive isotopic substitutions and a detailed normal coordinate treatment we have been able to form a semi-quantitative picture of the assignments of the vibrational bands due to the skeletal modes of methyl dithioacetate. Most of the conclusions can be carried over to ethyl dithioacetate. The present work also establishes that the 305 nm absorption band is the source of RR enhancement for vibrational modes of the dithioester group and indicates that the chromophore responsible for the 305 nm transition involves the entire



group. Within this group the force constants for the C=S and C—S stretching motions are very similar.

# The Raman and resonance Raman spectra of some substituted dialkyl dithioesters and their rotational isomers[1]

Y. OZAKI, A. C. STORER, AND P. R. CAREY[2]

*Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6*

Received May 21, 1981

Y. OZAKI, A. C. STORER, and P. R. CAREY. Can. J. Chem. **60**, 190 (1982).

The Raman spectra of ethyl dithioacetate, methyl dithiopropionate, and ethyl thionoacetate are presented for the liquid phase at 25°C and for the solid phase at approximately −130°C. Certain spectral features disappear upon going from the liquid to the solid phase allowing the assignment of these bands to rotational isomers which are present in the liquid state only. The consequences of placing a *tert*-butyl group proximal to the CSS moiety in dithioesters are explored by considering the absorption, Raman, and resonance Raman spectra of ethyl dithiotrimethylacetate and *tert*-butyl dithioacetate. The resonance Raman spectra of the ionized and unionized forms of dithioacetic acid are also presented. The vibrational spectra of ethyl thiolacetate, and ethyl and methyl thionoacetate are compared to the spectra of the corresponding dithioesters.

Y. OZAKI, A. C. STORER et P. R. CAREY. Can. J. Chem. **60**, 190 (1982).

On présente les spectres Raman du dithioacétate d'éthyle, du dithiopropionate de méthyle et du thionoacétate d'éthyle en phase liquide à 25°C et en phase solide à environ −130°C. Certaines caractéristiques spectrales disparaissent quand on passe de la phase liquide à la phase solide; on peut donc attribuer ces bandes aux isomères de rotation qui sont présents uniquement dans la phase liquide. On a étudié l'influence d'un groupe *tert*-butyle placé au voisinage de la portion CSS des dithioesters en se basant sur l'absorption, les spectres Raman et de résonance Raman du dithiotriméthylacétate d'éthyle et du dithioacétate de *tert*-butyle. On présente également les spectres Raman des formes ionisées et non ionisées de l'acide dithioacétique. On compare les spectres de vibration du thioacétate d'éthyle et des thionoacétates d'éthyle et de méthyle aux spectres des dithioesters correspondants.

[Traduit par le journal]

## Introduction

In the preceding paper (1) we presented data on the infrared, Raman, and resonance Raman (RR) spectra of methyl and ethyl dithioacetates and their isotopically substituted analogs. In the present work we have sought to identify the effects on the vibrational spectra of rotational isomerism about the bonds adjacent to the dithioester moiety. These data are crucial to our understanding of the spectra of more complex dithioesters (2) and, eventually, to our interpretation of the RR spectra of certain enzyme–substrate complexes containing the dithioester group (3). Specifically, we present herein the liquid and solid phase spectra of

$CH_3(C{=}S){-}S{-}CH_2{-}CH_3$,
$CH_3{-}CH_2{-}C(=S){-}S{-}CH_3$,
and $CH_3{-}C(=S){-}O{-}CH_2{-}CH_3$

which provide information on the consequences of rotational isomerism about the bonds indicated.

It is also important for us to delineate the consequences of steric hindrance about the dithioester moiety and to this end we present Raman and RR spectra of $(CH_3)_3CC(=S)SC_2H_5$ and $CH_3C(=S)SC(CH_3)_3$. Finally, our study of enzyme–substrate reactions requires characterization of the Raman and RR spectra of thiono- and thiolesters and of dithioacids; and hence, data for these compounds are presented herein and compared with the data for the corresponding dithioesters.

## Experimental

### *Materials*

Methyl dithiopropionate, *tert*-butyl dithioacetate and ethyl dithiotrimethylacetate were synthesized from their respective nitriles and mercaptans as outlined for ethyl and methyl dithioacetates in the foregoing publication (1). Methyl and ethyl thionoacetates were obtained by a procedure similar to that used for the dithioesters, the only difference being the substitution of alcohols for mercaptans. Dithioacetic acid was prepared from methyl magnesium iodide and carbon disulphide by the method of Houben and Pohl (4). Ethyl thiolacetate was prepared by the action of acetyl chloride on ethyl mercaptan. The purity of all samples was checked by nmr, and elemental analysis gave results within 2% of the calculated values.

### *Methods*

The Raman, RR, infrared, and absorption spectra were recorded using the equipment listed in the preceding paper (1). The low temperature Raman spectra were recorded using a modified Miller–Harney cell (5).

## Results and discussion

### *Absorption spectra*

The absorption maxima of the thiol-, thiono-, and dithioesters studied in the present work are listed in Table 1, where two important generalizations emerge. Firstly, by comparing the thiono- and dithioesters it is seen that the substitution of S for O brings about a very large red shift in the lowest energy $\pi \rightarrow \pi^*$ transition, from about 238 to 305 nm. This provides further support for the conclusion reached in the foregoing paper (1) that

[e] $\log_{10} \varepsilon \approx 1.25$.

the thiol sulfur in dithioesters makes an important contribution to the intense absorption band near 305 nm. Secondly, in dithioesters, the position of the lowest energy $\pi \rightarrow \pi^*$ transition is relatively insensitive to the nature of the alkyl groups. A further point is that this transition is also insensitive to change in solvent, e.g., the ethyl dithioacetate $\lambda_{max}$ is at 307 nm in $CCl_4$ and at 306 nm in $CH_3CN$.

*The vibrational spectra of ethyl thiolacetate, and ethyl and methyl thionoacetate*

The Raman spectra of the title compounds, taken as neat liquids, are shown in Fig. 1. Infrared spectra were also recorded and although the infrared data are not presented, they are mentioned wherever appropriate in the text. Table 2 lists the assignments for vibrational frequencies of ethyl dithioacetate and the corresponding thiol- and thionoacetates. The analyses for ethyl and methyl dithioacetates in the preceding paper (1) were of value in making assignments for the present compounds. Thus, the assignments of the $CH_3$ antisymmetric and symmetric deformation modes of the $CH_3$—C and —$CH_2$—$CH_3$ methyl groups, and the —$CH_2$ wagging and scissoring modes are consonant with those made for the dithioesters (1). Similarly, the assignments in Table 2 of the $CH_3$ rocking modes in the 975–850 $cm^{-1}$ region and the assignments of the C—C stretching modes between 1100 and 1050 $cm^{-1}$ parallel those for the dithioesters.

For ethyl thiolacetate the bands at 681 and 626 $cm^{-1}$ are assigned, respectively, to the S—C and C—S modes of the —C(=O)—S—$C_2H_5$ group. The band at 626 $cm^{-1}$ is very intense in the Raman spectrum and fairly intense in the infrared spectrum, while the 681 $cm^{-1}$ feature is of medium intensity in the Raman spectrum and weak in the infrared. Again, this is analogous to the situation found in the dithioesters (1) and it is unlikely that the S—C and C—S vibrations are strongly coupled. Thus the designation of the bands to the vibrations of individual bonds is preferred over an assignment to C—S—C symmetric and antisymmetric modes. A similar situation is found in dialkyl thioethers where Nogami and co-workers (6, 7) concluded that stretching vibrations within the C—S—C groups usually were not strongly coupled. This situation contrasts that found for the thionoesters in which the stretching modes of the C—O—C group do appear to be strongly coupled. Methyl thionoacetate has a feature at 701 $cm^{-1}$ which is very intense in the Raman spectrum but absent, or very weak, in the infrared spectrum. However, the mode at 1268 $cm^{-1}$ is weak in the Raman spectrum but very intense in the infrared. These observations suggest that the 701 and 1268 $cm^{-1}$ bands are most suitably described as the symmetric and antisymmetric C—O—C stretching modes, respectively. A similar situation is obtained for ethyl thionoacetate except for the appearance of two symmetric stretch bands at 692 and 724 $cm^{-1}$ due to the presence of two rotational isomers (below).

The band near 1222 $cm^{-1}$ in the Raman spectra of methyl and ethyl thionoacetate is assigned to a mode possessing a high degree of C=S stretching character. This assignment is supported by the infrared studies of several authors (8–10) and by the Raman excitation profile. The Raman spectra of ethyl thionoacetate in 1% (v/v) $CH_3CN$ were measured with 324, 337.5, 350.6, and 356.4 nm excitation. Excitation in the near-uv resulted in the intensity enhancement of the 543, 692, 724, 1103, 1222, and 1262 $cm^{-1}$ features seen in the 514.5 nm excited spectrum shown in Fig. 1. Going from 356.4 to 324 nm excitation resulted in the following enhancements with the intensity at 356.4 nm standardized to 1.0: 543 (1.2), 1103 (1.25), 692 (1.5), 724 (1.6), 1262 (1.9), and 1222 (2.6). The pronounced enhancement of the 1222 $cm^{-1}$ band with decreasing excitation wavelength supports the assignment of this band to $\nu_{C=S}$. An even more pronounced effect is seen upon going from 514.5 to 324 nm excitation: the intensity of the 1222 $cm^{-1}$ peak with 324 nm excitation is approximately twice as great as that of the 543 $cm^{-1}$ peak, whereas with 514.5 nm excitation the same intensity ratio is about 0.3 (Fig. 1). It is also apparent that the features at 1262 and 724, 692 $cm^{-1}$ which we have associated with the C—O—C antisymmetric and symmetric stretches show a high degree of intensity enhancement with uv excitation. It is likely, therefore, that vibrational coupling is prevalent and that the C=S and C—O—C bonds undergo geometric changes upon

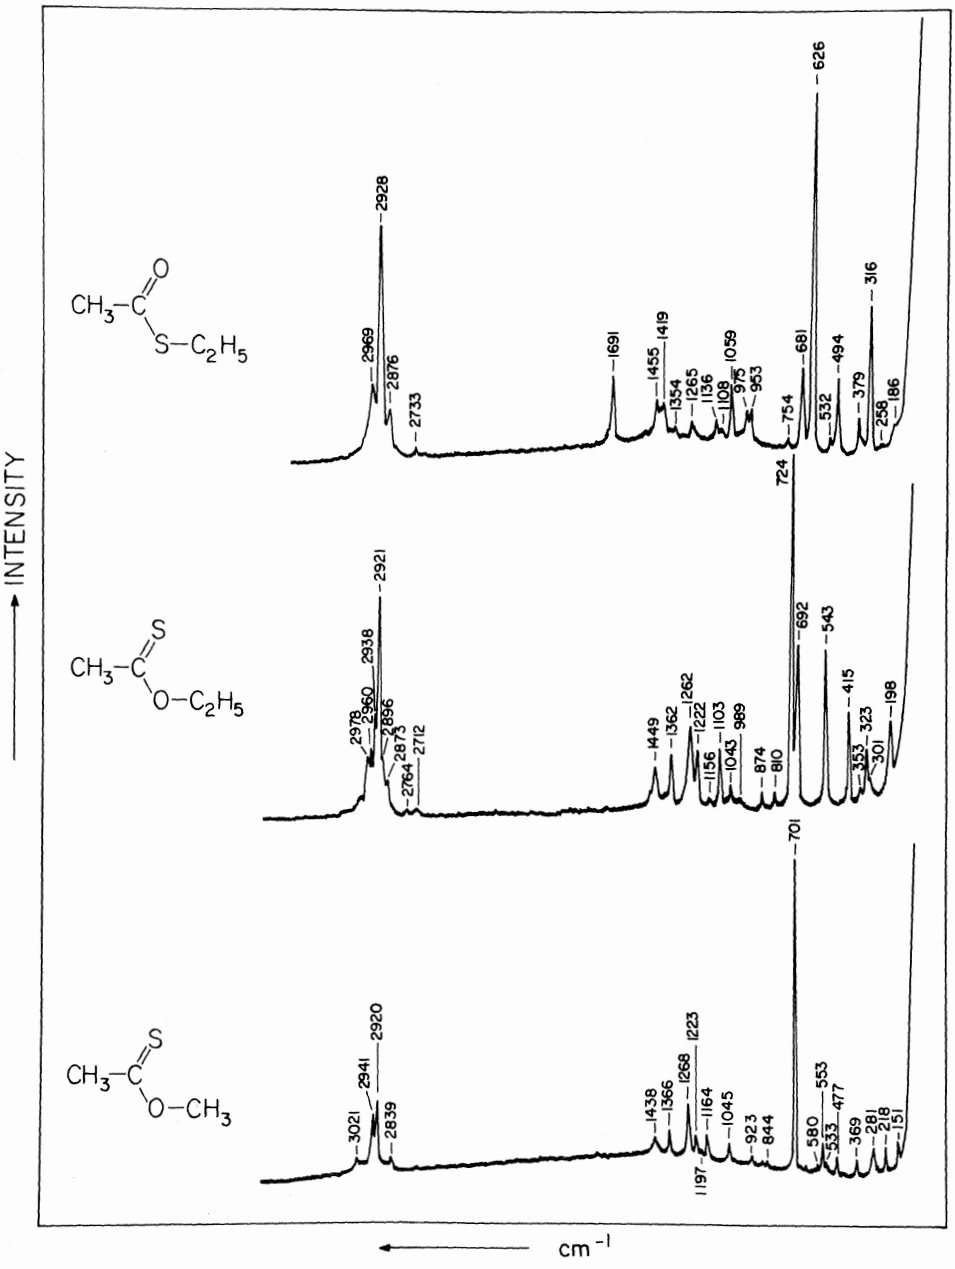

FIG. 1. The 514.5 nm excited Raman spectra of ethyl thiolacetate and methyl and ethyl thionoacetates as neat liquids. Laser power 50 mW; spectral slit width 8 $cm^{-1}$.

going from the ground to the excited electronic state.

*Comparisons between the vibrational spectra of simple dithio-, thiono- and thiolesters*

A mode having a high degree of $\nu_{C=S}$ character appears near 1195 $cm^{-1}$ in dithioesters, whereas it appears near 1222 $cm^{-1}$ in thionoesters. In both cases marked preresonance enhancement is observed. However, for dithioesters $\nu_{C=S}$ is very intense in the normal Raman spectrum and infrared whereas for thionoesters $\nu_{C=S}$ is weak in the Raman effect and intense in the infrared.

Both ethyl dithioacetate and ethyl thiolacetate have a feature near 680 $cm^{-1}$ assigned to a S—C stretching mode, whereas their C—S stretching modes are located near 580 and 626 $cm^{-1}$, respectively. Shoulders on the 580 and 680 $cm^{-1}$ features

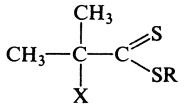
of ethyl dithioacetate provide evidence for the presence of two rotational isomers (below) but no such evidence was found for ethyl thiolacetate. For ethyl dithioacetate and ethyl thiolacetate it is probable that the S—C stretch is coupled to the C—C stretching mode of the $SCH_2$—$CH_3$ group. This C—C mode occurs near 1055 $cm^{-1}$ for ethyl dithioacetate and ethyl thiolacetate and at 1103 $cm^{-1}$ in the spectrum of ethyl thionoacetate.

*Consequences of placing bulky groups in dithioesters*

Ethyl dithiotrimethylacetate and *tert*-butyl dithioacetate were examined as examples of compounds possessing sterically large groups on the thioacetyl and thiol functions, respectively. The major interest lies in the effect of the bulky groups on the appearance of the regions between 1200 and 1050 $cm^{-1}$ and between 750 and 500 $cm^{-1}$ wherein the most intense RR features of the dithioester group occur. The Raman spectra of ethyl dithiotrimethylacetate, and *tert*-butyl dithioacetate are shown in Fig. 2 and the RR spectra of these compounds are shown in Fig. 3.

For ethyl dithiotrimethylacetate, an intense band is observed at 1103 $cm^{-1}$ in the Raman and infrared spectra and the band is strongly enhanced in the RR spectrum. No other band is observed in the 1205–1060 $cm^{-1}$ region except for a weak infrared shoulder at 1191 $cm^{-1}$. Hence, the band at 1103 $cm^{-1}$ probably has C=S stretching character. Consistent with this conclusion Mayer *et al.* (11) pointed out mainly from the results of infrared spectra that aliphatic alkyl dithiocarboxylates of type *A* have a C=S stretching mode near 1100 $cm^{-1}$.



Type *A*, R = $CH_3$, $C_2H_5$; X = $CH_3$, Cl, OH

The low frequency shifts of the C=S stretching mode in the type *A* dithioesters may result from steric hindrance changing the geometry of the dithioester group from that found in unhindered compounds. Since in *tert*-butyl groups C—C stretching vibrations coupled with $CH_3$ rocking modes are usually observed between 1250–1130 $cm^{-1}$ and 950–810 $cm^{-1}$ (12), the Raman band at 1227 $cm^{-1}$ is ascribed to a vibration mode of the *tert*-butyl group. This assignment is supported by the fact that no band is located near 1230 $cm^{-1}$ in the Raman spectrum of methyl or ethyl dithioacetate (1). The dithiotrimethylacetate Raman band at 1049 $cm^{-1}$ is very weak or absent in the RR spectrum as in the

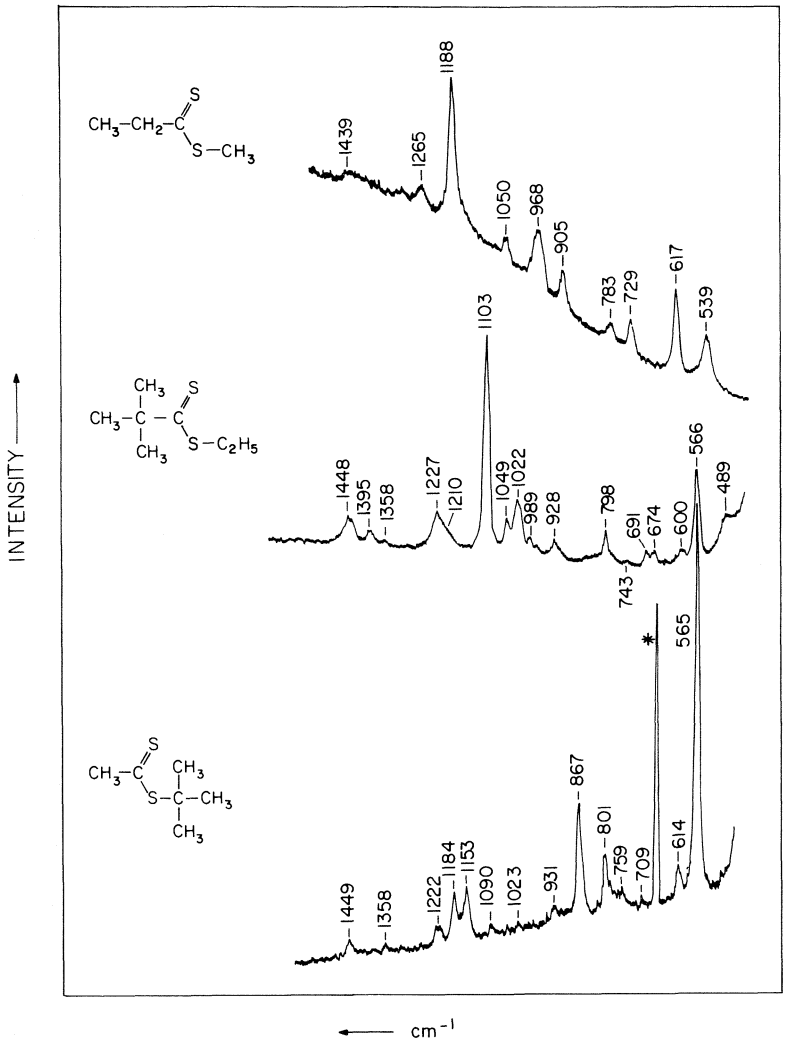

FIG. 2. The 514.5 nm excited Raman spectra of methyl dithiopropionate and ethyl dithiotrimethylacetate and the 647.1 nm excited spectrum of *tert*-butyl dithioacetate as neat liquids. Laser power 50 mW (514.5 nm), 100 mW (647.1 nm); 8 $cm^{-1}$ spectral slit. The asterisk marks a laser plasma line.

case of the 1052 $cm^{-1}$ band of ethyl dithioacetate; thus, the band at 1049 $cm^{-1}$ is ascribed to the C—C stretching mode of the $—CH_2—CH_3$ group. In contrast to the band at 1049 $cm^{-1}$, the band at 1027 $cm^{-1}$ is fairly intense in the RR spectrum; therefore, this band may be ascribed to a mode involving the C—C and C—S stretching motions of the C—C(=S)—S group. From a comparison of the spectrum of ethyl dithiotrimethylacetate with the spectrum of ethyl dithioacetate, the bands at 674 and 566 $cm^{-1}$ are assigned to the S—C and (C—S + C=S + $(CH_3)_3C$—C) stretching modes, respectively. The 681–697 $cm^{-1}$ profile in the Raman spectrum of ethyl dithioacetate has a depolarization ratio of 0.75 (1) whereas the 674–691 $cm^{-1}$ profile (Fig. 2) of dithiotrimethylacetate has a depolarization ratio of 0.60 ± 0.05.

The overall appearance of the RR spectrum of *tert*-butyl dithioacetate (Fig. 3) in the 1200–800 $cm^{-1}$ region is similar to the RR spectra of methyl and ethyl dithioacetate. The Raman band at 1184 $cm^{-1}$ is strongly intensity enhanced and is assigned to a mode possessing a high degree of C=S stretching character. The origin of the shoulder at 1159 $cm^{-1}$ in the RR spectrum of *tert*-butyl dithioacetate is not understood. The shoulder is reduced in intensity compared to the 1184 $cm^{-1}$ as excitation wavelength is reduced, and one possible source for the shoulder is the presence of more than one rotational isomer about the S—$C(CH_3)_3$ bond. Space filling

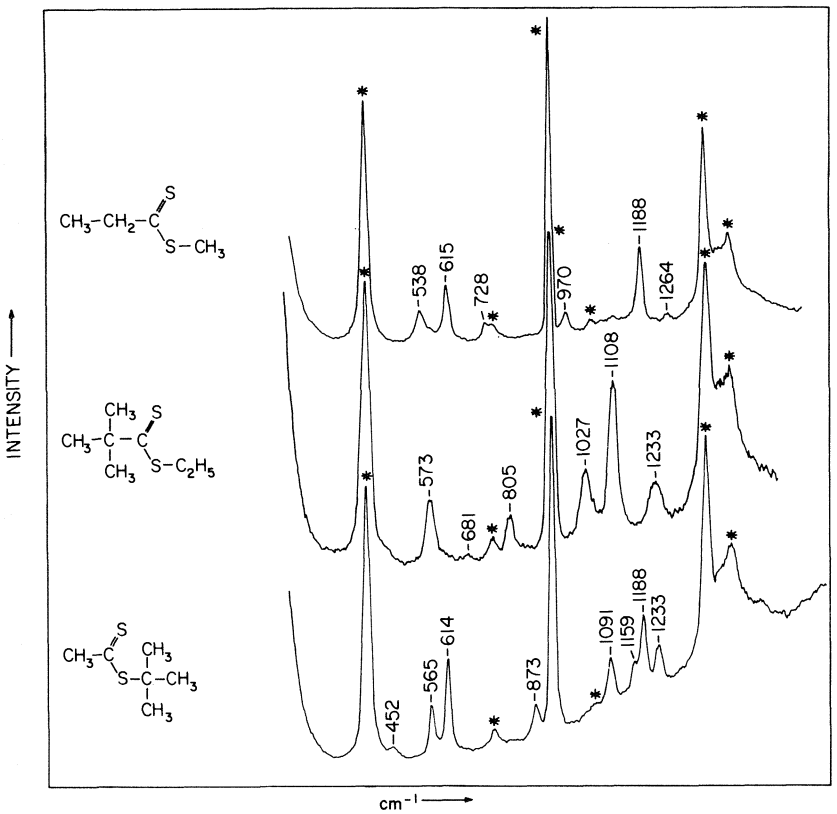

FIG. 3. The 324 nm excited RR spectra of methyl dithiopropionate, ethyl dithiotrimethylacetate and *tert*-butyl dithioacetate in 0.01% (v/v) $CH_3CN$ solutions. Laser power 10 mW; 8 $cm^{-1}$ spectral slit. $CH_3CN$ features are marked by an asterisk.

models show that in any isomer there is steric contact between the C=S sulfur and the *tert*-butyl methyl groups. The band at 1090 $cm^{-1}$ is intense in the infrared spectrum, weak in the Raman effect but becomes relatively more intense with 324 nm excitation (Figs. 2 and 3). This parallels the behaviour of the 1100 $cm^{-1}$ band of ethyl and methyl dithioacetate and, hence, the 1090 $cm^{-1}$ band is assigned to C—S + C—C stretching motions of the $CH_3$—C—S moiety. A possible origin of the 1222 $cm^{-1}$ Raman feature is a motion within the *tert*-butyl group corresponding to a C—C stretch coupled to $CH_3$ rocking modes. Interestingly, there is a band of moderate intensity at 867 $cm^{-1}$ in the Raman, RR, and infrared spectra of *tert*-butyl dithioacetate which probably corresponds to the 864 $cm^{-1}$ band of methyl and ethyl dithioacetate. Thus, the 867 $cm^{-1}$ band is assigned to a $CH_3$ rocking motion of the $CH_3$—C(=S) group. As might be expected, the 500–800 $cm^{-1}$ or "C—S stretching" spectral regions of *tert*-butyl and ethyl dithioacetates are markedly different. For the *tert*-butyl compound both bands at 614 and 565 $cm^{-1}$ can be ascribed to C—S or S—C stretching modes although we do not make specific assignments. The 614 $cm^{-1}$ band undergoes strong resonance enhancement (Fig. 3) and for this reason may be more associated with the C—S bond since the latter is more intimately involved with the chromophore.

Finally, we consider dithioacetic acid. The RR spectrum of dithioacetic acid in the $CH_3CSSH$ form (Fig. 4) strongly resembles the RR spectrum of methyl dithioacetate. The features at 1212 and 596 $cm^{-1}$ are analogous to methyl dithioacetate bands near 1194 and 580 $cm^{-1}$ (1), and the corresponding C—S + C—C (1073 $cm^{-1}$) and methyl rocking motions (845 $cm^{-1}$) are prominent too. The assignment of the 1212 $cm^{-1}$ band to essentially $\nu_{C=S}$ agrees with an earlier assignment made on the basis of Raman and infrared data (13). In the RR spectrum of the $CH_3CSS^-$ form (Fig. 4) the bands at 607 and 1103 $cm^{-1}$ are assigned to the $-CS_2^-$ symmetric and antisymmetric stretches, respectively.

*Rotational isomers of dithio- and thionoesters*

We have previously reported a Raman study on the rotational isomers of ethyl thionoacetate and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

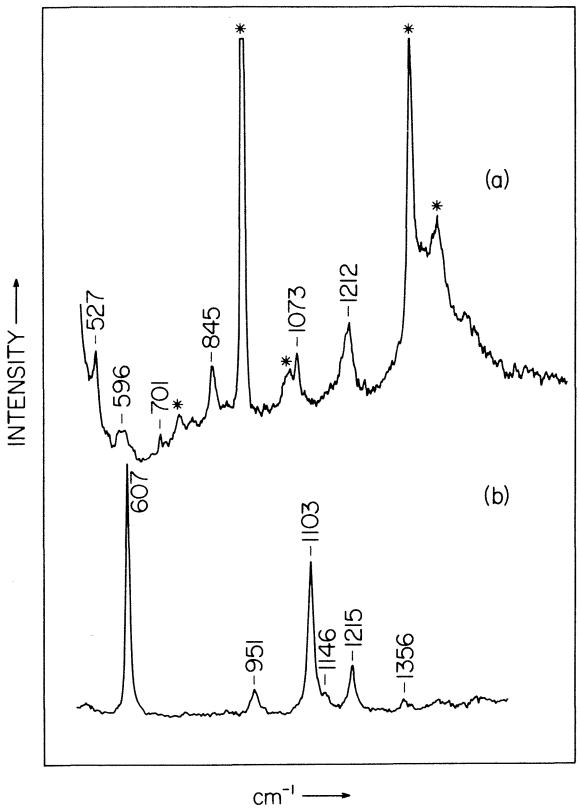

FIG. 4. The 351.6 nm excited RR spectra of dithioacetic acid in 0.01% (v/v) $CH_3CN$ solution, $CH_3CS_2H$ (*a*) and in water at pH 12.3, $CH_3CS_2^-$ (*b*). Laser power 40 mW; 8 $cm^{-1}$ spectral slit. $CH_3CN$ features are marked with an asterisk.

ethyl dithioacetate (14). However, only partial spectral data was given in ref. 14 and we now present complete Raman spectra in the 20–1500 $cm^{-1}$ range. Ethyl thiono- and dithioacetate provide information on the consequences of rotational isomerism about the O—$CH_2$ and the S—$CH_2$ bonds, respectively. In order to explore the consequences of rotational isomerism in the C—C(=S) linkage we also present data on methyl dithiopropionate, $C_2H_5C(=S)SCH_3$.

The Raman spectra of ethyl dithioacetate, methyl dithiopropionate, and ethyl thionoacetate at 25°C and approximately −130°C are shown in Fig. 5. At ~ −130°C the compounds are in the solid phase and the vibrational features which disappear upon solidification have been marked with asterisks. The disappearance of a band is ascribed to the disappearance of a rotational isomer (14); there are two isomers in solution, only one of which remains in the solid phase. For ethyl dithioacetate and ethyl thionoacetate it is thought that the low energy form (which is the one remaining upon solidification) is the *S-cis* with all the heavy atoms in a single plane (14), as shown in Fig. 6.

In the high energy form the —$CH_2CH_3$ methyl moiety rotates by 120° about the X—$CH_2$ bond. The enthalpy differences for the two forms are 598 ± 48 and 1072 ± 65 cal/mol for the ethyl dithio- and thionoacetates, respectively (14). Previously, for ethyl dithioacetate we only discussed the 579 and 589 $cm^{-1}$ bands but now the effect of solidification on the entire spectrum can be seen by referring to Fig. 5. At −132°C the only changes in the 1500–500 $cm^{-1}$ region of the Raman spectrum of ethyl dithioacetate are the disappearance of the 697 and 589 $cm^{-1}$ bands. Thus, we assign the 697 and 589 $cm^{-1}$ features to the S—C and (C—S + C=S + C—C) motions respectively, of the non-polar isomer. The 681 and 579 $cm^{-1}$ bands are the corresponding modes of the planar isomer. Similarly, for ethyl thionoacetate the "disappearing" 692 $cm^{-1}$ feature is ascribed to the C—O—C symmetric stretch of the non-planar rotamer and the 724 $cm^{-1}$ band to the planar rotamer. The situation near 1260 $cm^{-1}$ where the antisymmetric C—O—C stretch occurs is less clear due to the overlap of other spectral features. Importantly, for ethyl dithioacetate we find no evidence for rotational isomerism affecting the C=S stretching region between 1200 and 1050 $cm^{-1}$.

The spectral properties of methyl dithiopropionate have not been discussed hitherto. The Raman and RR spectra are given in Figs. 2 and 3, respectively. By analogy to the compounds discussed above and in ref. 1, the strongly enhanced features at 1188 and 615 $cm^{-1}$ may be assigned to motions involving stretching of the C=S and (C—S + C=S + C—C) bonds, respectively. Interestingly, there is no evidence for a band near 1100 $cm^{-1}$ which would be analogous to the (C—S + C—C) mode found in ethyl and methyl dithioacetate (1). The change in vibrational coupling brought about by the $CH_3CH_2C(=S)$'s methyl group and the effect of rotational isomerism about the $CH_2$—C bond on the normal modes is under active study. The 729 $cm^{-1}$ band is assigned to a mode containing a high degree of S—$CH_3$ stretching character, again by analogy with the foregoing molecules. In the Raman spectrum of the solid state (Fig. 5) the 539 $cm^{-1}$ feature disappears. This band is strongly enhanced in the RR spectrum (Fig. 3) and is therefore assigned to a C—S stretch, with additional unknown contributions from C=S and C—C stretches, for a rotational isomer different from that which gives rise to the 617 $cm^{-1}$ band. Some support for the idea that the C—S stretch is very

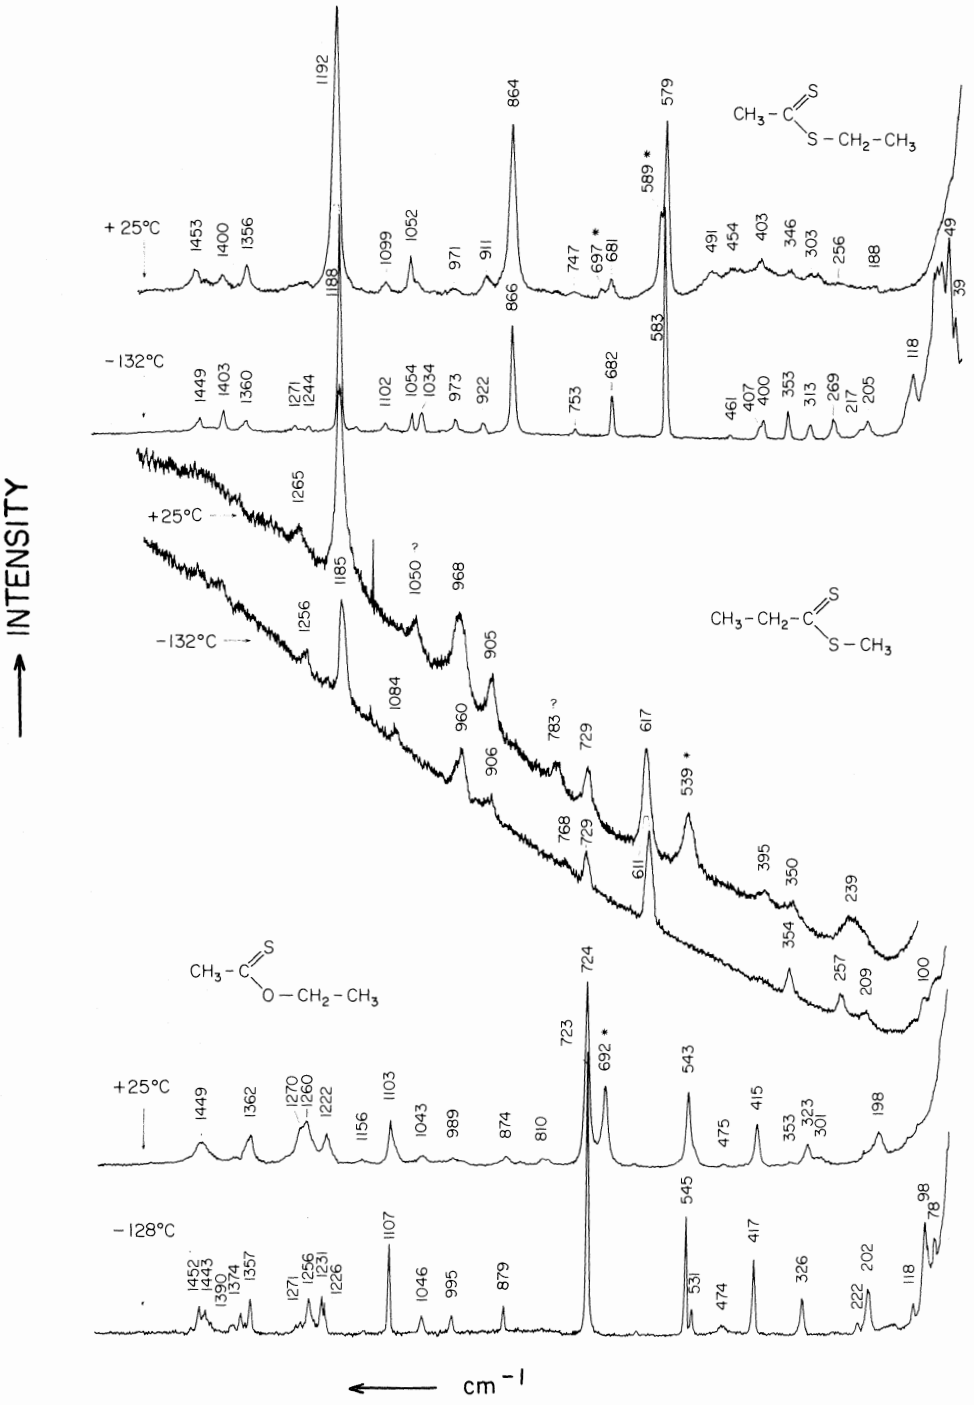

FIG. 5. The 514.5 nm excited Raman spectra of ethyl dithioacetate, methyl dithiopropionate and ethyl thionoacetate at 25°C and ≈ −130°C. Laser power 50–100 mW; 8 $cm^{-1}$ spectral slit. Bands marked with an asterisk are those which disappear in the low temperature, solid phase spectra.

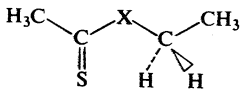

FIG. 6. The preferred conformer for ethyl dithioacetate (X = S) and ethyl thionoacetate (X = O).

sensitive to rotational isomerism comes from Nogami, Sugeta, and Miyazawa's work on dialkyl thioethers (6). These authors have documented the effect of rotational isomerism in, for example, $(CH_3)_2CHCH_2$—S—$CH_3$ on the C—S and S—C stretching modes. They found that the isomer with the H and S *trans* in a projection along the CH—$CH_2$ bond has $\nu_{C-S}$ some 70 $cm^{-1}$ lower compared to the rotamer in which the $CH_3$ and S groups are *trans* across the CH—$CH_2$ bond. In Fig. 5 it also appears that the bands in the room temperature spectrum at 1050 and 783 $cm^{-1}$ have either disappeared in the solid phase spectrum or have shifted to 1084 and 768 $cm^{-1}$, respectively. If the 783 $cm^{-1}$ band has disappeared it is possible that this feature is due to the S—$CH_3$ stretching feature of the same isomer as that giving rise to the 539 $cm^{-1}$ band. Attempts were made to measure the intensity ratio of the 617 and 539 $cm^{-1}$ bands as a function of temperature and thereby calculate the enthalpy difference between the rotamers. The ratio showed only a small change with temperature, for example $I_{617}/I_{539} \approx 1.78$ at −12°C and $\approx 1.84$ at −93°C and there were large experimental errors in the measurement of the ratio. Consequently a reliable value for $\Delta H$ could not be obtained. Similarly we were not able to identify the nature of the rotamers in solution or the preferred form in the solid state. Although measurements were hampered by the sloping baseline (Fig. 5), there appeared to be no depolarized bands in the 1300–400 $cm^{-1}$ spectral range. The band at 729 $cm^{-1}$ has the highest depolarization ratio $\approx 0.60 \pm 0.05$. Thus, we are unable to prove that either of the rotational isomers in solution is planar.

Importantly, the results for $CH_3CH_2CS_2CH_3$ show that rotational isomerism about the $CH_2$—C bond can markedly perturb bands in the 800–500 $cm^{-1}$ region but, as Fig. 5 illustrates, appear to have little or no effect on the "C=S stretching region" between 1200 and 1050 $cm^{-1}$.

# Resonance Raman spectroscopic evidence for an intramolecular interaction involving the amide and dithioester groups of *N*-acyl glycine ethyl dithioesters[1]

A. C. STORER, Y. OZAKI, AND P. R. CAREY

*Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6*

Received May 21, 1981

A. C. STORER, Y. OZAKI, and P. R. CAREY. Can. J. Chem. **60**, 199 (1982).

The synthesis and resonance Raman spectra of several new *N*-acyl glycine ethyl dithioesters RC(=O)NH—$CH_2$—C(=S)SR are reported. The resonance Raman spectra of these compounds contain at least two peaks in the "C=S stretching region" between 1050 and 1200 $cm^{-1}$. The solvent, concentration, temperature, and excitation wavelength dependencies of these features have been investigated. The results obtained are consistent with two conformations of the dithioesters co-existing in solution with the conformational differences being controlled by rotational isomerism about one or both of the NH—$CH_2$ and $CH_2$—CS bonds. Strong support for the existence of more than one conformer in solution comes from the Raman spectrum of a single crystal of *N*-acetyl glycine ethyl dithioester. In the spectrum of the single crystal several Raman bands are absent compared to the spectrum of the dithioester in solution indicating that only one of the conformers found in the solution phase is retained in the crystal. In one of the conformers found in solution there is evidence for an intramolecular interaction between the amide group and the dithioester group. The exact nature of the intramolecular interaction is uncertain, although simple H-bonding and enethiol tautomerism have been eliminated as possibilities. Possible contributors to the interaction are dipole–dipole forces and amide π-electrons interacting through space with sulfur $d_\pi$ orbitals. Both of these putative interactions would be modulated by rotational isomerism. Based on deuterium substitution experiments a resonance Raman band is identified in the 1050–1200 $cm^{-1}$ region which contains a contribution from the motion of the amide proton. The unexpected intensity enhancement of an amide mode is attributed to the amide–dithioester intramolecular interaction. The conformer exhibiting the intramolecular interaction is thought to closely resemble the conformation of the substrate in the active site of certain dithioester enzyme–substrate complexes.

A. C. STORER, Y. OZAKI et P. R. CAREY. Can. J. Chem. **60**, 199 (1982).

On rapporte la synthèse et les spectres Raman de plusieurs nouveaux dithiosters du *N*-acyl-glycine d'éthyle, RC(=O)NH—$CH_2$—C(=S)SR. Les spectres Raman de ces composés contiennent au moins deux pics dans la région d'élongation de la liaison C=S entre 1050 et 1200 $cm^{-1}$. On a étudié l'effet du solvant, de la concentration, de la température et de la longueur d'onde d'excitation sur ces caractéristiques. Les résultats obtenus sont en accord avec la présence de deux conformations des dithioesters qui co-existent en solution et dont les différences conformationnelles sont controllées par l'isomérie rotationnelle autour d'une ou des deux liaisons NH—$CH_2$, $CH_2$—CS. Le spectre Raman d'un monocristal de dithioester de *N*-acyl glycine d'éthyle fournit la meilleure preuve de l'existence de plus d'un conformère en solution. Plusieurs bandes Raman sont absentes dans le spectre du monocristal si on le compare avec le spectre du dithioester en solution, indicant ainsi que seulement un des conformères trouvés dans la solution est retenu dans le cristal. Dans l'un des conformères trouvés en solution, on rencontre des caractéristiques d'une interaction intramoléculaire entre le groupe amide et le groupe dithioester. La nature exacte de l'interaction intramoléculaire n'est pas certaine bien qu'on ait éliminé la liaison hydrogène simple et la tautomérie ènethiol comme d'éventuels responsables. L'interaction des forces dipôle–dipôle et les électrons π de l'amide interagissant à travers l'espace avec les orbitales du π du soufre sont éventuellement responsables de cette interaction. Ces deux interactions putatives peuvent être ajustées par l'isomérie rotationnelle. A partir d'expériences de substitution par du deutérium, on a identifié une bande de résonance Raman dans la région de 1050–1200 $cm^{-1}$ qui contient une contribution du mouvement du proton de l'amide. On attribue l'augmentation inattendue de l'intensité d'un mode amide à l'interaction intramoléculaire du dithioester–amide. On pense que le conformère présentant une intramoléculaire ressemble de près à la conformation du substrat dans le site actif de certains complexes enzyme dithioester substrat.

[Traduit par le journal]

## Introduction

This paper is the third of a series aimed at elucidating the vibrational spectroscopic properties of dithioesters with particular emphasis on the resonance Raman (RR) spectra of these compounds. The first paper (1) sought to define the normal modes of the simplest dithioesters, methyl and ethyl dithioacetate, while the second paper (2) dealt with the effects on the vibrational spectra of rotational isomerism about bonds in, for example, $CH_3CH_2$→C(=S)$SCH_3$ and $CH_3C$(=S)S→$CH_2$-$CH_3$. Both papers (1, 2) precede and accompany the present paper. The overall aim of this work is to aid the understanding of the RR spectra of transient dithioesters (3, 4) which are formed during enzyme substrate interactions (5, 6). The structure of the dithioester intermediates can be written as RC(=O)$NHCH_2$C(=S)S—enzyme where the thiol sulfur is from a cysteine in the enzyme's active site. We now report the synthesis and spectroscopic study of a series of six compounds of the type RC(=O)$NHCH_2$C(=S)$SC_2H_5$ which act, in some respects, as models for the enzyme–substrate intermediates. The dithioesters listed in

Table 1 can be considered to be derivatives of *N*-acyl glycine. They were prepared as described under the Methods section and, to our knowledge, only compound **1** has been reported before (7).

A major finding of the present study is that the *N*-acyl glycine ethyl dithioesters exist in more than one conformation in solution. One of these conformers, in which there appears to be strong interaction between the amide and dithioester groups, is common to all the compounds studied. This conformer assumes special importance because, based on the spectral criteria, it resembles the conformation of the corresponding substrate in the active site of enzymes such as papain.

## Methods

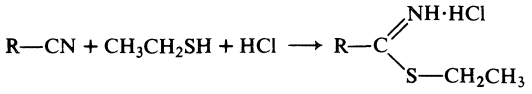
Absorption spectra were obtained using a Cary 219 spectrophotometer. The apparatus used to obtain the resonance Raman spectra consisted of either a 3000K or a 2000K Coherent Radiation krypton ion laser with a Spex 0.5 m double spectrometer and direct current detection. The near-uv laser lines were separated using two Pellin–Broca prisms and plasma lines were removed from the selected laser line using a tunable grating filter F100 (PTR Optics Corp., Waltham, MA.). Raman spectra obtained with visible excitation were recorded using a Spectra-Physics model 164 Ar ion laser with a Jarell-Ash 25-400 spectrometer.

The sampling systems consisted of a flow cell for the resonance Raman spectra and a rotating cell for the Raman spectra. The variable temperature study was conducted using a small jacketed rotating cell. Under these conditions there was no evidence for photoisomerisation or photodegradation.

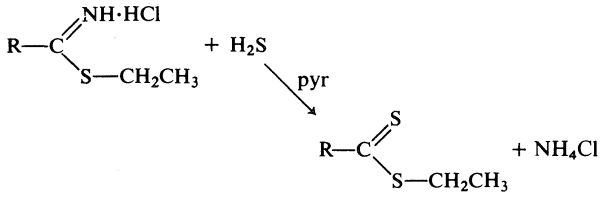
Peak frequencies were calibrated using emission lines from Ar and Ne lamps and are accurate to $\pm 2$ cm$^{-1}$. Peak heights were taken as reliable measures of band intensities for the variable temperature study.

*Synthesis*

The *N*-acyl glycine dithioesters and analogues listed in Table 1 were prepared by first treating their respective nitriles with dry HCl gas and an excess of ethanethiol using methylene chloride as solvent (the Pinner reaction) (7–10):



The thioimido ester hydrochlorides produced were treated with $H_2S$ dissolved in pyridine to give the corresponding dithioesters (7–9):



*Nitriles*

The nitriles for the synthesis of dithioesters **1**, **4**, **5**, and **6** (Table 1) were synthesised from aminoacetonitrile bisulphate and the corresponding acid chloride (**1**, **4**, and **5**) or acid chloroformate (**6**). The aminoacetonitrile bisulphate (0.1 equiv.) was dissolved in 50 mL of ice-cold water containing 0.2 equiv. NaOH. The chloride (or chlorformate) (0.1 equiv.) was added dropwise over a period of 30 min while a slightly alkaline pH was maintained by the addition of 5 *M* NaOH. The modified nitriles separated out as white solids which were collected by filtration, washed with cold water, and dried. They required no further purification. The nitriles used in the synthesis of dithioesters **2** and **3** were produced by the methods of Dinizo *et al.* (11) and Johnson and Gatewood (12), respectively.

*Thioimido esters*

The nitriles were converted to their thioimido ester hydrochloride salts by treatment for 30–60 min with dry HCl gas and excess ethanethiol in ice-cold methylene chloride. The thioimido ester salts produced were precipitated by the addition of anhydrous ether, collected by filtration, and washed with more ether. The thioimido ester salt produced for the synthesis of dithioester **3** is extremely hygroscopic and required careful handling. All the thioimido esters were stored in desiccators and used in the next synthetic step as soon as possible.

*Dithioesters*

The thioimido esters were added to pyridine saturated with $H_2S$ at 0°C and $H_2S$ was passed through the solution for 20 min after which the solution was allowed to stand 5 min. The deep yellow solution produced was then poured into sufficient ice-cold 4 *N* HCl to neutralise the pyridine and produce a slightly acidic pH. For some dithioesters crystals of the dithioester formed either immediately or on addition of ice-cold water. The crystals were collected by filtration and washed with water, then recrystallised from an acetone– water mixture. Dithioesters **2** and **4** formed orange or red oils when poured into the HCl solution. These dithioesters were extracted into ether, the ethereal solutions washed with water and dried over anhydrous $Na_2SO_4$. The ether was then removed by rotary evaporation. Dithioester **3** is soluble in water and so the HCl solution was extracted several times with ether and the combined ethereal extracts treated as above. The dithioesters were purified by passage down silica gel columns using 90% ether, 10% acetonitrile as solvent.

The results of elemental analysis of the dithioesters all agreed with the theoretical values to within 2%. The purity of all samples was checked by nmr. The yields obtained varied from about 10% for ester **3** to about 25% for ester **5**.

## Results and discussion

Aliphatic dithioesters normally possess an intense $\pi \rightarrow \pi^*$ absorption band in the range 305–310 nm (13). The $\lambda_{max}$'s and extinction coefficients of this transition, for most of the dithioesters discussed in this paper, were determined in a variety of solvents and are given in Table 2. Results obtained for ethyl dithioacetate are included in the table for comparison.

*(a) Evidence for two forms of dithioester in solution*

The RR spectra of solutions of compounds **1–6** (Table 1) are given in Figs. 1–6. Spectra, taken in several solvent systems, were obtained using 324 nm laser light excitation. The RR spectra of the compounds are more complex than those of ethyl and methyl dithioacetates discussed in the preceding paper (1). For these two simple esters in the region between 1050 and 1200 cm$^{-1}$ a single feature occurs near 1195 cm$^{-1}$. This band is assigned to a

mode possessing significant C=S and some C—C stretching character. Each of the spectra of compounds **1–6** (Table 1) is more complex in that it has more than one feature in the 1050 to 1200 $cm^{-1}$ region. The dithioester solution spectra (Figs. 1–6) all contain one feature between 1160 and 1185 $cm^{-1}$ (which we shall designate band I) and a second feature between 1115 and 1155 $cm^{-1}$ (band II), additionally compounds **3**, **4**, and **5** have a third feature between 1080 and 1100 $cm^{-1}$ (band III). The relative intensities of these three bands exhibit a strong solvent dependency (Figs. 1–6). For all the compounds tested, except dithioester **2**, band I is the most intense in $CCl_4$ solution whereas band II is the most intense in $CH_3CN$ solution. In the spectra of compound **2** in both $CCl_4$ and $CH_3CN$ solution band II is the most intense, however, band I becomes more intense, relative to band II, on changing from $CCl_4$ to $CH_3CN$ solution. This intensity change of band I for dithioester **2** is opposite in sign to that of all the other dithioesters tested. Band III, when it appears, exhibits the same solvent dependency as band II.

The relative intensities of bands I, II, and III were found to be independent of concentration. Spectra were obtained for acetonitrile solutions of dithioester **3** over a concentration range of (0.33–3.65) × $10^{-4}$ *M* and for dithioester **6** over a concentration range of (0.37–3.73) × $10^{-4}$ *M* and for both compounds the relative intensities of bands I and II (both dithioesters) and band III (dithioester **3**) remained constant. The relative intensities of the three bands do, however, exhibit a temperature dependency. Figure 7 shows the changes, in the intensities of bands I and II and where present band III, in the spectra of dithioesters **2**, **3**, and **4** as a function of temperature. In all cases, as the temperature is lowered, band I decreases in intensity relative to bands II and III. These results along with the solvent dependent changes and lack of any concentration dependency in the RR spectra point to the possibility that two forms of the dithioesters exist through some form of intramolecular rearrangement. Band I would be associated with the higher energy form, which we designate form A, and bands II and III with the lower energy form B. With the assumption that the ratio of the intensities of bands I and II is equal to the ratio of the concentrations of the two conformers, a plot of the logarithm of the intensity ratio against the reciprocal of the absolute temperature yields a $\Delta H$ value for the two forms. The $\Delta H$'s obtained for dithioesters **1**, **2**, **3**, and **4** were 1.0, 0.64, 0.89, and 0.88 kcal/mol, respectively.

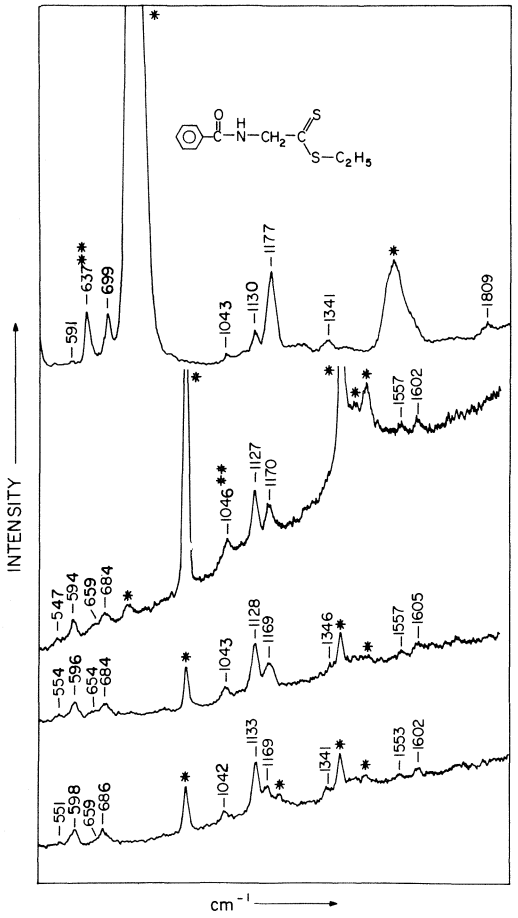

FIG. 1. Resonance Raman spectra of $4 \times 10^{-4}$ *M* solutions of ethyl dithiohippurate (**1**). The solvents used were from top to bottom: carbon tetrachloride, acetonitrile, 20% acetonitrile + 80% $H_2O$, and 20% acetonitrile + 80% $D_2O$. 10 mW of 324 nm laser excitation were used with a spectral slit width of 10 $cm^{-1}$ and a scan speed of 0.75 $cm^{-1}$/s. * denotes peaks due to solvent and ** peaks due to a combination of solute and solvent. The peaks at 637 $cm^{-1}$ in carbon tetrachloride and at 1046 $cm^{-1}$ in acetonitrile contain very weak contributions from the solvent.

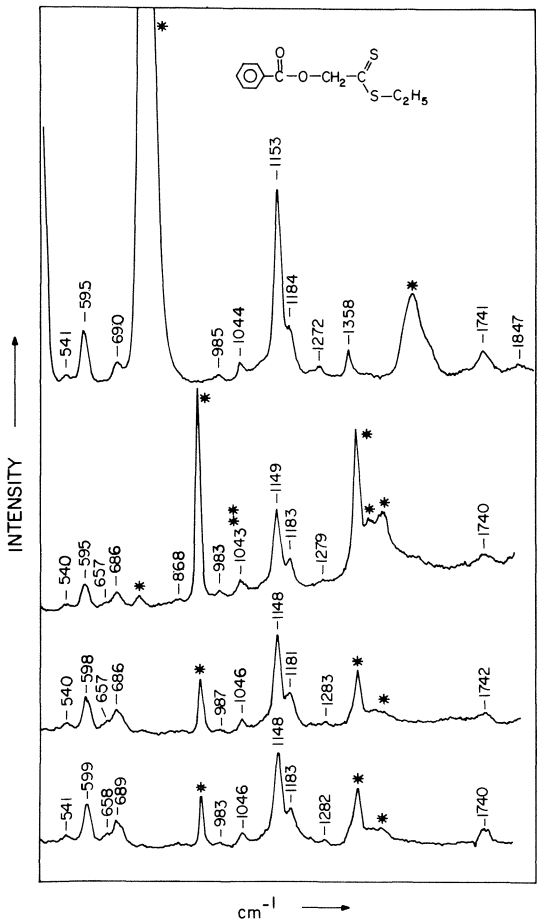

FIG. 2. Resonance Raman spectra of $4 \times 10^{-4}$ *M* solutions of benzoyl hydroxyacetyl ethyl dithioester (**2**). The solvents and other conditions were as given in Fig. 1.

A comparison of the RR spectra obtained for dithioester **3** using three near-uv laser lines (Fig. 8) shows that the intensity ratio of bands II (1145 $cm^{-1}$) and III (1096 $cm^{-1}$) is constant as a function of excitation wavelength whereas the intensity of band I (1165 $cm^{-1}$) changes with respect to bands II and III. There are several possible explanations for these data but they are consistent with the existence of two forms of the dithioester, each form having a slightly different electronic spectrum and a characteristic RR spectrum.

A Raman spectrum obtained from a single crystal of dithioester **3** contains only bands II and III at 1141 $cm^{-1}$ and 1088 $cm^{-1}$, respectively (Fig. 9). Band I is completely absent from this spectrum. Thus, dithioester **3** crystallises entirely in form B. A Raman spectrum of a concentrated acetonitrile solution of dithioester **3** contains all three bands, i.e. bands I, II, and III at 1170, 1143, and 1094 $cm^{-1}$, respectively (Fig. 9). This finding is in agreement with that of the RR study on more dilute solutions of the dithioester (Fig. 3).

The RR spectra of the dithioester solutions (Figs. 1–6) also contain many other features. In the 500–700 $cm^{-1}$ region they all contain a peak between 590 and 600 $cm^{-1}$. This peak appears to be associated with form B in that it exhibits the same solvent dependency as band II, i.e. for dithioesters **1**, and **3–6** it is more intense in acetonitrile solution than in carbon tetrachloride solution. This 590–600 $cm^{-1}$ peak has little or no $D_2O$ dependency. All the RR spectra also contain features near 690, 1045, and 1340 $cm^{-1}$. Other minor features at approximately 550 and 660 $cm^{-1}$ appear in some spectra.

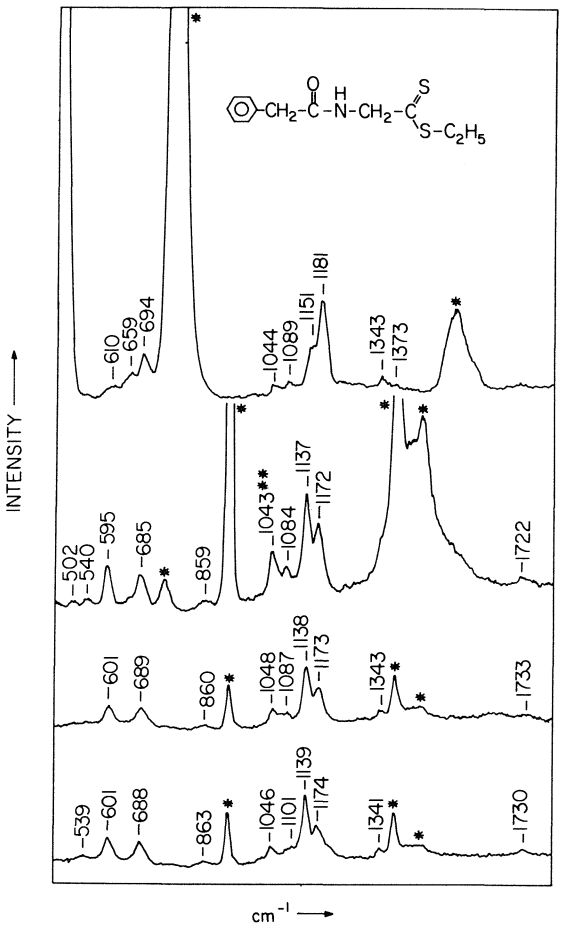

FIG. 4. Resonance Raman spectra of $4 \times 10^{-4}$ *M* solutions of *N*-phenylacetyl glycine ethyl dithioester (**4**). The solvents and other conditions were as given in Fig. 1.

*(b) The RR bands between 1050 and 1200 cm$^{-1}$*

For every *N*-acyl glycine ethyl dithioester, bands I and II appear in the region of the RR spectra associated with C=S stretching motions, and, moreover, derive from different forms of each compound. These facts suggest that bands I and II, respectively, are the corresponding normal modes of forms A and B of the dithioester and that both bands contain some C=S stretching character.

Some insight into the expected positions of C=S stretching bands may be gained by considering the infrared work of Bak *et al.* (14) on dithioesters of type R—CS—$SCH_2COOH$. The analysis of Bak *et al.* allows us to estimate the through bond inductive effect of R on the frequency of $\nu_{C=S}$. Assuming that the effect of the carboxymethyl group is constant throughout a series obtained by varying R then any correlation between R and $\nu_{C=S}$ should, after applying a constant correction for the different effects of $—CH_2COOH$ and $—CH_2CH_3$ on $\nu_{C=S}$, also be applicable to the dithioesters studied here. A plot of the p*K*'s of the series of 21 acids of the type R—COOH against the $\nu_{C=S}$ of the corresponding esters produces a straight line defined by the equation:

$$[1] \quad \nu_{C=S} = 16.8\ pK + 1143$$

The values in this equation were obtained by a regression analysis which gave a correlation coefficient of 0.79 (significant at $P = 0.05$). Using a value of 1197 cm$^{-1}$ for the $\nu_{C=S}$ of ethyl dithioacetate (**1**) and a p*K* of 4.75 for acetic acid the equation for a series of ethyl dithioesters becomes:

$$[2] \quad \nu_{C=S} = 16.8\ pK + 1116$$

A value of 1180 cm$^{-1}$ for the $\nu_{C=S}$ of ethyl dithiohippurate, **1**, can then be calculated using a

For personal use only.

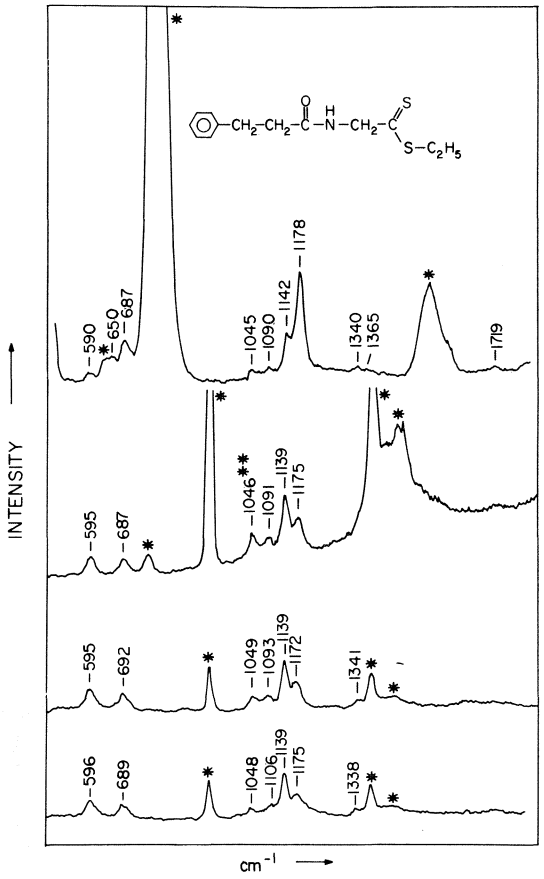

FIG. 5. Resonance Raman spectra of $4 \times 10^{-4}$ *M* solutions of *N*-β-phenylpropionyl glycine ethyl dithioester (**5**). The solvents and other conditions were as given in Fig. 1.

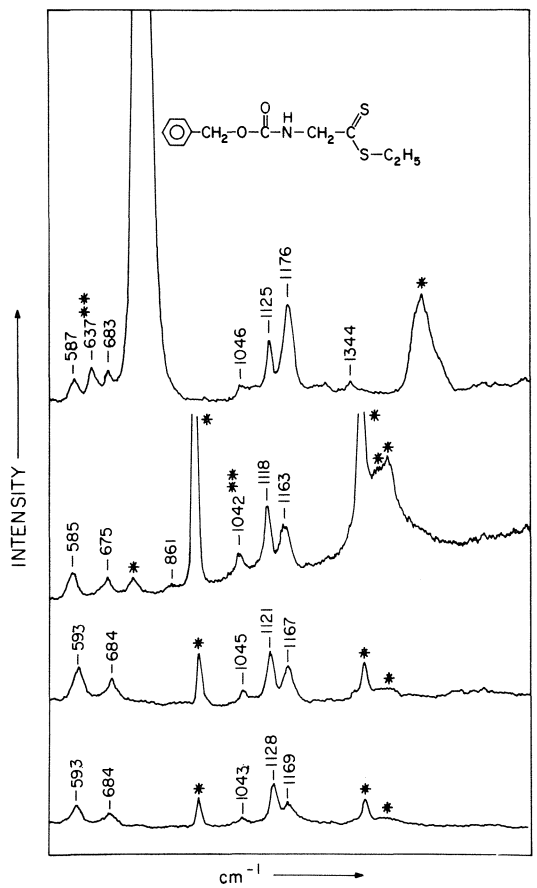

FIG. 6. Resonance Raman spectra of $4 \times 10^{-4}$ *M* solutions of *N*-carbobenzoxy glycine ethyl dithioester (**6**). The solvents and other conditions were as given in Fig. 1.

p*K* of 3.8 for hippuric acid. A similar value (i.e. approx. 1180 $cm^{-1}$) can be calculated for the other *N*-acyl glycine dithioesters studied. The position of band I of the dithioesters falls in the range 1165 $cm^{-1}$ to 1185 $cm^{-1}$, thus this band is very close to the predicted value for $\nu_{C=S}$. Therefore, it seems probable that band I of form A of the dithioesters represents a relatively unperturbed C=S stretching vibration, since it is found in the position to be expected for the C=S stretching vibration after taking into consideration only the through bond effects of the substitution of an *N*-acyl amine onto the acetyl portion of ethyl dithioacetate. By the same token the position of band II is anomalous in that it comes at a lower frequency than that predicted by eq. [2] above. It should be emphasised however that several assumptions, which have not been fully tested, have gone into deriving eq. [2]. For this reason the conclusion we have reached on the expected position for $\nu_{C=S}$ is tentative.

All the dithioesters tested, with the exception of **2**, show some band position shifts on going from solution in 80% $H_2O$, 20% $CH_3CN$, to 80% $D_2O$, 20% $CH_3CN$ (Figs. 1–6). For those compounds that do not possess a band III in their RR spectra, i.e. **1** and **6**, band II shifts to higher wavenumbers in the presence of $D_2O$, whereas band I remains fixed (Figs. 1 and 6). For compounds that do possess a band III, i.e. **4** and **5**, it is this band that shifts to higher wavenumbers, whilst bands I and II remain stationary (Figs. 4 and 5). The behaviour of the *N*-acetyl dithioester **3** is anomalous, since both bands II and III appear to shift and the shifts are also associated with intensity changes, i.e. in $D_2O/CH_3CN$ solution band III is more intense than band II, whereas in $H_2O/CH_3CN$ band II is the more intense, Fig. 3.

On examining the $H_2O/CH_3CN$ and $D_2O/CH_3CN$ dithioester solutions by nmr spectroscopy it was found that in the presence of $D_2O$ the amide proton of the *N*-acyl dithioesters is exchanged for a deuteron. On the time scale of the RR experiments no further proton–deuteron exchanges were ob-

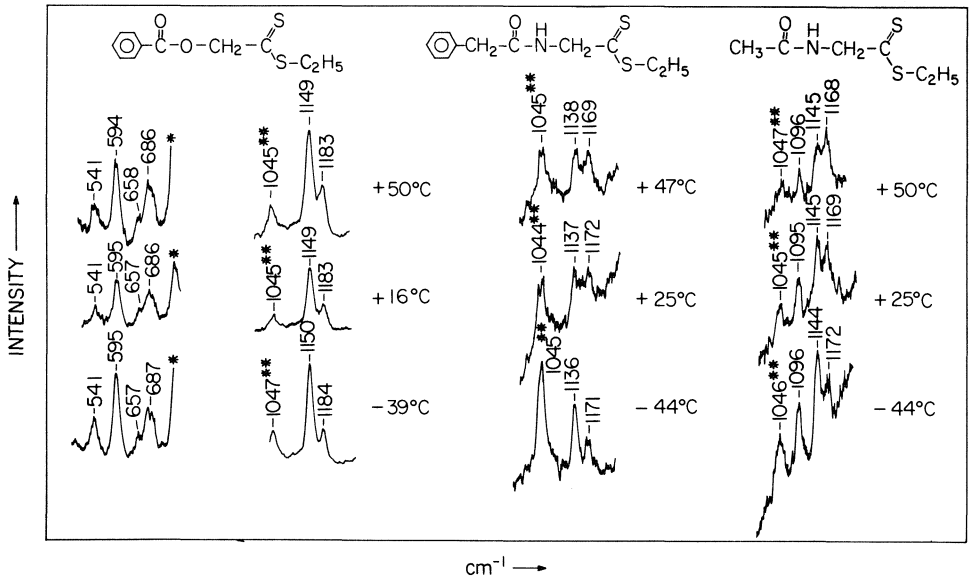

FIG. 7. Sections of the resonance Raman spectra of acetonitrile solutions of dithioesters **2** ($4.2 \times 10^{-3}$ *M*), **3** ($6 \times 10^{-3}$ *M*), and **4** ($3.1 \times 10^{-3}$ *M*) scanned at three different temperatures. 25 mW of 350.7 nm laser excitation were used with a spectral slit width of 10 $cm^{-1}$ and a scan speed of 0.75 $cm^{-1}/s$. The temperature was measured using a copper–constantan thermocouple.

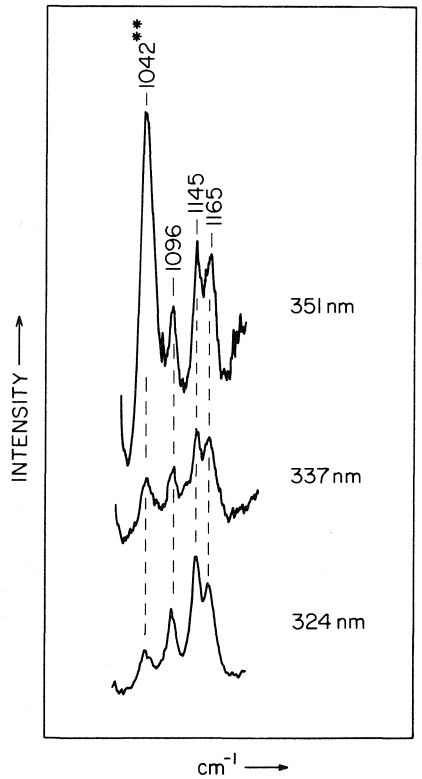

FIG. 8. The variation in the relative intensities of bands I, II, and III in the resonance Raman spectra of dithioester **3** as a function of the excitation wavelength. The concentration of the dithioester was $9.6 \times 10^{-4}$ *M* in a 1:1 acetonitrile–water mixture. The power used was 400, 40, and 15 mW for the 350.7, 337.5, and 324 nm excitation lines, respectively. A spectral slit width of 10 $cm^{-1}$ was used with a scan speed of 0.75 $cm^{-1}/s$.

served. Thus, the exchange of —NH for —ND must be related to the band position shifts in the resonance Raman spectra. Further evidence that the shifts are due to the exchange of the amide proton for a deuteron is the fact that no shift is observed for compound **2** which does not have an amide proton. The position of band I, for all the dithioesters, is not influenced by the presence of $D_2O$, thus the normal mode of form A which gives rise to band I is unaffected by —NH, —ND exchange. Form B gives rise to bands II and III in the RR spectra, and one or both of these bands is affected by deuteration of the amide groups. Band II for compounds **1** and **6** probably contains some C=S stretching character and must contain, in some way, a contribution from the motion of the amide proton. For compounds **4** and **5** band II likely contains C=S stretching character but there is no evidence for a contribution from a NH motion. However, band III in compounds **4** and **5** is sensitive to the motion of the amide proton. The situation for compound **3** is more complex and both bands II and III involve amide proton motions with possible C=S stretching contributions to one or both features.

### *(c) Nature of the two forms found in solution*

Form B, which, according to the temperature dependences of bands I, II, and III, Fig. 7, is of lower energy than form A, must differ from form A by one or more of the following possibilities: (*i*) tautomerism, (*ii*) rotational isomerism, or (*iii*) intramolecular interaction. Intermolecular interac-

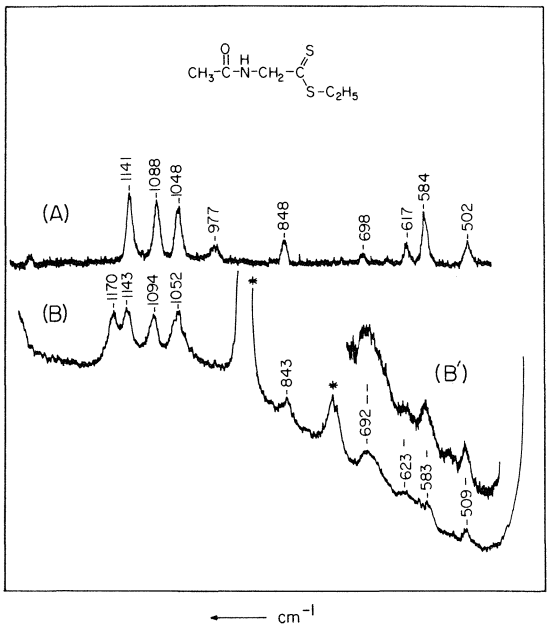

FIG. 9. Raman spectra of *N*-acetyl glycine ethyl dithioester (**3**) *A*, crystals, and *B*, a concentrated solution, 0.11 *M*, in a 1:1 acetonitrile–water mixture. *B'* is a portion of spectrum *B* recorded at higher sensitivity. The power used was 5 and 360 mW of 5145 nm laser light for spectra *A* and *B*, respectively. The spectral slit width was 10 $cm^{-1}$ with a scan speed of 0.25 $cm^{-1}$/s.

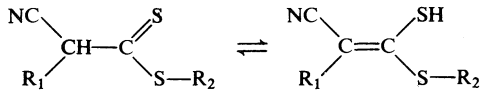
tions are ruled out by the lack of a concentration dependence in the RR spectra.

*(i) Tautomerism*

The enethiolization of thioketones is well known (15, 16). In contrast to such simple thiones dithioesters are generally stable in the thione form (17, 18). The exceptions are special dithioesters (19), for example of the type (20):

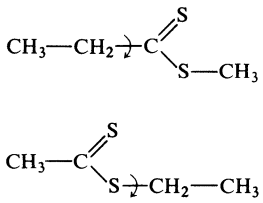


Thione Enethiol

There are three pieces of evidence against enethiolization occurring with the *N*-acyl dithioesters discussed here. Firstly, no band assignable to a C=C stretching vibration can be seen in the spectra of the dithioesters (especially in the Raman spectra of the crystals of dithioester **3** which are entirely in form B, the presumed enethiol). Secondly, if an equilibrium existed between the two tautomers this would provide a mechanism for the exchange of the glycine —$CH_2$—protons, no such exchange is observed in $D_2O$ (except at high pH). Thirdly, the dithioester chromophore would be destroyed by the formation of the enethiol and thus on going from carbon tetrachloride solution (which favours form A) to acetonitrile solution (which favours form B) a large reduction in the measured extinction coefficients should be observed. A small reduction in the extinction coefficients is seen but it is of the same magnitude as that observed for ethyl dithioacetate (Table 2) on changing solvents. Ethyl dithioacetate is known not to undergo enethiolization (17, 18).

*(ii) Rotational isomerism*

We have previously studied rotational isomers of the two dithioesters:



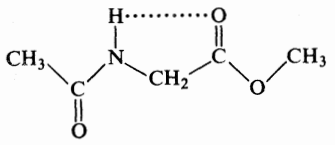
(2, 21) and determined the effect on the RR spectrum of rotations about the C—C and S—C bonds indicated. By altering the vibrational coupling in the molecules, rotational isomerism does bring about changes in the 500–700 $cm^{-1}$ spectral region. However, for ethyl dithioacetate and methyl dithiopropionate rotational isomerism appears to leave the peak near 1195 $cm^{-1}$ unchanged. Thus, it is unlikely that a simple rotation is the sole cause of the changes in the 1050–1200 $cm^{-1}$ region of the RR spectrum of form B of the present compounds. It does not rule out the possibility that the changes are caused by a rotation coupled with some form of intramolecular interaction.

*(iii) Intramolecular interaction — the difference between forms A and B*

Having argued against tautomerism and the effects of rotational isomerism and having dismissed intermolecular interactions as possible causes of the "$\nu_{C=S}$" RR peaks of form B we turn now to consider an intramolecular interaction as the source of form B's "perturbed" RR peaks. There are two examples in the literature of intramolecular interactions which have to be taken into account for the systems discussed here. However, we shall argue that neither of these two cases provides an explanation of the observed RR spectrum of form B.

The first example concerns an intramolecular interaction in *N*-acetyl glycine methylester (22). An intramolecular H-bond was proposed to explain the splitting of the N—H stretching vibration peak in the ir spectra taken in carbon tetrachloride solution, i.e.

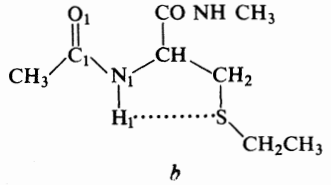
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.



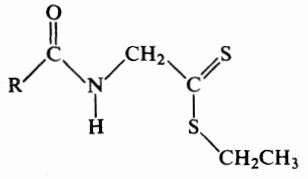
*a*

This interaction is designated $C_5$, since it involves a five-membered ring. Due to the strain in the ring the H-bond must be weak as is reflected by the small change in $\nu_{N-H}$ brought about by the interaction i.e. 24 $cm^{-1}$ (strong hydrogen bonds can change $\nu_{N-H}$ by up to 200 $cm^{-1}$). The lack of any detectable perturbation of the ester $\nu_{C=O}$ frequency (22) also supports the supposition that the $C_5$ interaction must be weak. A dipole–dipole interaction of the amide and ester groups would however help to strengthen the $C_5$ interaction (23). The $C_5$ interaction is thought to be important in the determination of protein structure since it is also present in the amides of *N*-acyl amino acids as well as the esters (22–25).

The second example concerns an intramolecular interaction between a sulfur atom and an amide group in *S*-ethylcysteine methylamide (compound *b*). The ir spectrum of this compound has a strong absorption band at 3402 $cm^{-1}$ which can be assigned to the $N_1—H_1$ stretching vibration (25). However, this frequency is too low to be ascribed to an ordinary $C_5$ interaction between the $N_1—H_1$ and $C_2=O_2$ groups. It was concluded, therefore, that the amide proton is involved in a hydrogen bond with the sulfur atom. The structural similarity between the compound and the dithioesters discussed here is shown below:



*b*



*c*

It is reported that the strength of the N—H....S interaction in *S*-ethylcysteine methylamide is such that all the molecules present in solution are in the intramolecular interacting form (25). This interaction is unusual since it was shown that the optimal ring size for the interaction is five; the equivalent methionine derivative, with its potential to form a six-membered ring, did not possess an interaction of this type. This is unexpected since a less strained H-bond could be formed in a six-membered ring. Also such a supposedly strong H-bonded N—H in *S*-ethylcysteine methylamide would be expected to have a $\nu_{N-H}$ at lower wavenumber than that observed. This suggests that the interaction in this compound is not just a simple H-bond.

In both of the literature examples just cited the formation of the hydrogen bond was proposed as the source of the free energy driving the formation of the intramolecular form. However, for the present *N*-acyl glycine ethyl dithioesters we have good evidence that a hydrogen bond is not energetically important in the intramolecular form. Firstly, compound **2** which does not have an —NH group does have a form B. Secondly, the solvent dependency of the A and B forms argues against the presence of a strong intramolecular H-bond in B. In consequence of the hydrogen-bond accepting nature of its nitrogen atom acetonitrile is a much stronger H-bond acceptor than carbon tetrachloride. Thus, it would be expected that if form B had a strong intramolecular H-bond this form would predominate in $CCl_4$. The opposite is found to be the case; for compounds **1** and **3–6** there is a higher population of form B relative to form A in $CH_3CN$ compared to $CCl_4$.

Although it seems unlikely that either structure *a* or *b*, with their crucial hydrogen bonds, is equivalent to form B, the —NH moiety is implicated in form B by the RR results. The sensitivity of the RR spectrum of form B to —NH, —ND exchange was unexpected since the —NH moiety is two bonds removed from the dithioester chromophore. The amide group itself has a $\pi-\pi^*$ transition at approximately 180 nm ($\varepsilon_{max} \simeq 10^{-4}$) and a $\pi \rightarrow \pi^*$ transition at approximately 220 nm ($\varepsilon_{max} < 100$). However, these electronic absorption bands are too far removed from the Raman excitation wavelength to obtain preresonance enhancement of normal modes of the unperturbed amide chromophore. It is likely, therefore, that the participation of the —NH motion in the RR spectrum takes place by some form of coupling between the amide and dithioester chromophores. This coupling could include both vibrational and electronic interactions and may take place through the —NH—$CH_2$—C(=S) bonds or "through space", i.e. via nonbonded contacts if the chromophores in form B are placed in close juxtaposition. The nature of the coupling is such that it occurs only in form B. Moreover, since it changes the positions of Raman peak positions (for form B compared to form A) it

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12

For personal use only.

must perturb the electron distribution in the electronic ground state. (Raman and RR peak positions reflect only electronic ground state properties). However, the coupling has only a modest effect on the electronic spectrum of the dithioester chromophore. Compared to the absorption spectrum of ethyl dithioacetate the spectra of the dithioesters in Table 1 show a red shift in $\lambda_{max}$ by 2–3 nm (Table 2) and an increase in peak width at half height of approximately 7% in $CH_3CN/H_2O$ (8:2) solution and 3% in carbon tetrachloride solution.

The nature of the coupling between the amide and dithioesters in form B is not completely understood although literature evidence (26–31) suggests that a substantial part of the coupling may occur through space. The occurrence of the coupling in form B alone suggests that the amide and dithioester chromophores are in closer contact in form B compared to form A. The preferred means of switching from form A to B would be by rotations about either or both of the NH—$CH_2$, $CH_2$—C(=S) bonds. Hence, although rotational isomerism by itself does not change the positions of peaks for form B (by altering the vibrational coupling), it is proposed that it brings the amide and dithioester groups into contact. The chromophore–chromophore interaction (which may include electronic and vibrational components) is then thought to change the position of form B's RR features with respect to those of form A. The interaction between the amide and dithioester groups can also include dipole interactions such as the field effects discussed by Bellamy and Williams (32). Field effects have been used to explain the two carbonyl bands in the ir spectra of α-halogen substituted thiolesters (33). The two bands are due to two conformers, one involving a dipole interaction between the halogen and the carbonyl oxygen (giving rise to the high wavenumber band) and the other involving a dipole interaction between the halogen and the thiol sulfur. The transition between the two forms involves a 180° rotation about a single C—C bond. Another component of the amide–dithioester interaction may be overlap between the sulfur *d*-orbitals and the π-electrons of the amide group. An interaction of this type has been suggested to occur between the π electron cloud and the empty $d_\pi$ orbitals of β,γ-unsaturated thiol esters (34).

Although we strongly favor a model in which forms A and B are different rotamers and that a strong intramolecular interaction in form B is absent in A, it is clear that the details of this interaction are speculative. However, X-ray crystallographic studies are under way and by this means we hope to provide detailed information on the geometries of forms A and B.

The dithioesters discussed in this paper are very useful models for the dithioacyl enzymes produced by the action of cysteine proteases on thiono ester substrates (3–6). The similarities between the dithioacyl enzyme resonance Raman spectra and the spectra of the B form of the dithioesters is very striking (3, 4). Thus, the knowledge obtained about the interactions that define the B form of the dithioesters is important to an understanding of the interactions controlling the catalytic properties of dithioacyl enzymes. This point will be discussed at length in a subsequent publication dealing with the resonance Raman spectra of the dithioacyl enzymes.

# Synthesis of β-chloro, β-bromo, and β-iodo α,β-unsaturated ketones

EDWARD PIERS, JOHN R. GRIERSON, CHEUK KUN LAU, AND ISAO NAGAKURA

*Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6*

Received August 11, 1981

EDWARD PIERS, JOHN R. GRIERSON, CHEUK KUN LAU, and ISAO NAGAKURA. Can. J. Chem. **60**, 210 (1982).

A new, efficient method for the preparation of β-chloro, β-bromo, and β-iodo α,β-unsaturated ketones is described. The method involves the reaction of β-diketones or α-hydroxymethylenecycloalkanones with triphenylphosphine dihalides in the presence of triethylamine. With the dichloride and dibromide reagents, the reactions are conveniently carried out in benzene at room temperature, while with triphenylphosphine diiodide the reactions are best performed in refluxing acetonitrile (β-diketones) or in acetonitrile–hexamethylphosphoramide (α-hydroxymethylenecycloalkanones). The reaction of triphenylphosphine diiodide – triethylamine with a series of 4-alkyl-1,3-cyclohexanediones provides mainly or exclusively (depending on the size of the alkyl group) 6-alkyl-3-iodo-2-cyclohexen-1-ones, while reaction of this reagent with 2-hydroxymethylenecyclohexanone and 2-hydroxymethylenecyclopentanone affords stereoselectively and regioselectively (*E*)-2-iodomethylenecyclohexanone and (*E*)-2-iodomethylenecyclopentanone, respectively.

EDWARD PIERS, JOHN R. GRIERSON, CHEUK KUN LAU et ISAO NAGAKURA. Can. J. Chem. **60**, 210 (1982).

On décrit une nouvelle méthode efficace de préparation des β-chloro, β-bromo et β-iodo cétones α,β-insaturées. La méthode fait intervenir la réaction des β-dicétones ou des α-hydroxyméthylènecycloalcanones avec les dihalogénures de triphénylphosphine en présence de triéthylamine. Les réactions ont lieu dans le benzène à la température ambiante si on utilise les dichlorures ou les dibromures comme réactifs, tandis qu'avec le diiodure de triphénylphosphine, on obtient de meilleures réactions dans l'acétonitrile au reflux (β-dicétones) ou dans un mélange d'acétonitrile–hexaméthylphosphoramide (α-hydroxyméthylènecycloalcanones). La réaction du diiodure de triphénylphosphine dans la triéthylamine avec une série d'alkyl-4 cyclohexanediones-1,3 conduit principalement ou exclusivement (dépendant de la taille du groupe alkyle) aux alkyl-6 iodo-3-cyclohexèn-2 ones-1, tandis que ce même réactif avec l'hydroxyméthylène-2 cyclohexanone et l'hydroxyméthylène-2 cyclopentanone conduit de façon stéréosélective et régiosélective aux iodométhylène-2 cyclohexanone-(*E*) et iodométhylène-2 cyclopentanone-(*E*) respectivement.

[Traduit par le journal]

## Introduction

β-Chloro α,β-unsaturated ketones have been known for a long time (1) and, over the years, have served as important and versatile intermediates in organic synthesis.[1] On the other hand, the corresponding bromo compounds, although known, do not appear to have been used a great deal by synthetic organic chemists.[2] Furthermore, prior to the initiation of our work in this area[3] reports in the chemical literature concerning the preparation and use of β-iodo α,β-unsaturated ketones were very rare.[4]

The synthesis of β-chloro α,β-unsaturated ketones from β-diketones has been carried out by treatment of the latter substances with a diversity of reagents: phosphorus trichloride (29–36), phosphorus oxychloride (29, 37), phosgene (38), acetyl chloride (39), oxalyl chloride (40, 9), and triphenylphosphine – carbon tetrachloride (41). Of these, the latter two reagents appear to be the best in terms of convenience and efficiency. Conversion of β-diketones into β-bromo enones has traditionally been accomplished by treatment of the former substrates with phosphorus tribromide (29, 36, 42), although the yield of this process does not appear to be very high. More recently, this type of conversion has been accomplished employing triphenylphosphine – carbon tetrabromide (41). To our knowledge, the direct conversion of β-diketones into β-iodo α,β-unsaturated ketones had not been accomplished prior to our work (19). We report herein the details of our study concerning the transformation of β-diketones and β-hydroxymethylenecycloalkanones into the corresponding β-chloro, β-bromo, and/or β-iodo α,β-unsaturated ketones. Subsequent publications will deal with the use of these versatile substances in organic synthesis.[5]

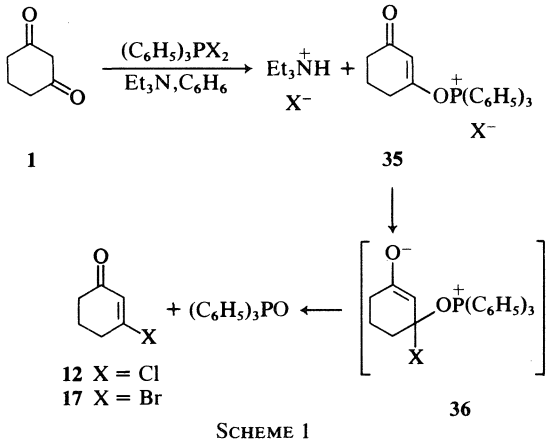
ine were added to a suspension of freshly prepared triphenylphosphine dichloride in benzene and the resulting mixture was stirred at room temperature for 1 h, 3-chloro-2-cyclohexen-1-one (**12**) was produced in 91% yield (see Chart 1). In similar fashion, reaction of **1** with triphenylphosphine dibromide in the presence of triethylamine provided (97%) 3-bromo-2-cyclohexen-1-one (**17**). It seems highly likely that these conversions proceed by way of the phosphonium salt **35**,[6] formed by reaction of the diketone with triphenylphosphine dihalide (see Scheme 1). Conjugate addition of halide ion to **35**, followed by elimination of triphenylphosphine oxide from the resulting intermediate **36** would afford the observed products **12** and **17**.

Reaction of triphenylphosphine dichloride and/or the corresponding dibromide reagent with the symmetrical β-diketones **2–4** and **6–11**, inclusive, gave results comparable to those obtained with 1,3-cyclohexanedione (**1**), and these are summarized in Table 1. Although these results are quite straightforward and require little additional comment, the following points should be noted. It was found to be important to prepare the triphenylphosphine dihalides from freshly recrystallized triphenylphosphine



SCHEME 1

[6]This type of intermediate has been proposed previously in connection with the reaction of 2-bromodimedone with triphenylphosphine (51).

and to carefully dry and distil the benzene and triethylamine used in the reactions. If these precautions were not taken, the product yields decreased significantly. However, when the reactions were carried out under the conditions prescribed in the Experimental, the yields were uniformly excellent. From the results summarized in Table 1, it is clear that this method for the conversion of β-diketones into β-chloro α,β-unsaturated ketones compares very favorably with the most recently reported methods (9, 41). Furthermore, for the preparation of β-bromo enones, our method appears to be superior to that involving the reaction of β-diketones with phosphorus tribromide (29, 36, 42) and affords yields marginally higher than those obtained from the triphenylphosphine – carbon tetrabromide method (41).

The reactions summarized in Entries 1–14 of Table 1 involved cyclic β-diketones as the starting materials and, therefore, there were no ambiguities with respect to the stereochemistry of the products. However, in the one acyclic case which was investigated, it was found that the reaction of 2,4-pentanedione (**11**) with triphenylphosphine dibromide in 5:1 acetonitrile–benzene was not totally stereoselective, since a mixture of the two geometrically isomeric β-bromo enones **26** and **27** (ratio ~87:13, respectively) was produced (88% yield). A pure sample of each of the two isomers could be obtained by preparative gas–liquid chromatography (glc) and the stereochemistry of these substances was shown to be as indicated on the basis of the $^1$H nmr spectra. Thus the major isomer, which exhibited the signal due to the vinyl methyl group at lower field (δ 2.75), was assigned structure **26**, while structure **27** could be assigned to the minor product, which showed the corresponding resonance at higher field (δ 2.45). Similarly, the olefinic protons of the two isomers exhibited the expected relative chemical shifts (**26**: δ 6.73, proton *cis* to bromine; **27**: δ 6.55, proton *trans* to bromine). It is interesting to note that the reaction of 2,4-pentanedione (**11**) with oxalyl chloride affords (50% yield) a 1:1 mixture of (*E*)- and (*Z*)-4-chloro-3-penten-2-one (40, 9), while treatment of **11** with triphenylphosphine – carbon tetrachloride has been reported (41) to yield (81%) only the (*E*) isomer.

TABLE 1. Conversion of symmetrical β-diketones into β-chloro and β-bromo α,β-unsaturated ketones[a]

| Entry | β-Diketone | Reagent[b] | Reaction time (h) | Product (yield, %)[c] |
|---|---|---|---|---|
| 1 | **1** | A | 1 | **12** (91) |

| 15 | **11** | B | 19[d] | **26** + **27**[e] (88) |

[a] All reactions were carried out at room temperature. The reaction solvent was benzene except when otherwise noted.
[b] Reagent A: triphenylphosphine dichloride. Reagent B: triphenylphosphine dibromide.
[c] Yield of distilled product(s).
[d] The solvent in this case was 5:1 acetonitrile–benzene.
[e] The ratio of **26**/**27** was approximately 87:13, respectively. Also present in the product was a minor (~5%), unidentified compound.

The infrared and $^1$H nmr spectral data derived from the β-chloro (**12–16**) and β-bromo (**17–27**) α,β-unsaturated ketones, along with appropriate references or elemental analysis data, are summarized in Table 2.

Reaction of 1,3-cyclohexanedione (**1**) with triphenylphosphine diiodide in benzene via a procedure similar to that used in the case of the dichloride or dibromide reagents (*vide supra*) failed to produce 3-iodo-2-cyclohexen-1-one (**28**) (see Chart 1). When the progress of the reaction was monitored by thin-layer chromatography (tlc) it was found that although the starting material **1** disappeared slowly, only a trace of compound **28** had formed even after a period of 20 h. Apparently, under these conditions, the dione **1** reacted with the diiodide reagent to produce the phosphonium salt **35** (X = I, see Scheme 1), but the latter species did not undergo the conjugate addition–elimination sequence (**35** (X = I) → **36** (X = I) → **28**). Some support for this conclusion was forthcoming when it was found that evaporation of the solvent, followed by heating of the residual material to 145–165°C under reduced pressure with direct distillation of product, gave the iodo enone **28** in 46% yield. In similar fashion, this procedure (Procedure A) could be used to convert other β-diketones into the corresponding β-iodo enones (see Table 3, Entries 1, 4, 9, 12). However, it is clear from the data given in Table 3 that this mode of operation did not provide high yields of the desired products.

In efforts to improve this situation, the use of a more polar reaction medium was investigated. Indeed, it was found that reaction of various β-diketones with triphenylphosphine diiodide – triethylamine in dry acetonitrile at room temperature (Procedure B) produced *directly* improved yields of the corresponding β-iodo enones (Table 3, Entries 2, 5, 7, 10). However, even when this polar solvent was used, the reactions at room temperature were slow and, typically, reaction times of ~4 days were required for complete conversion of the

TABLE 2. Spectral data for β-chloro and β-bromo α,β-unsaturated ketones

[b] Yield of distilled product.

starting materials into the desired products. Eventually, it was found that the product yields could be improved still further and that the reaction times could be reduced to a matter of hours by carrying out the reactions at elevated temperatures (refluxing acetonitrile, Procedure C). Under these conditions, it was possible to obtain consistently good to excellent yields of the β-iodo enones (Table 3, Entries 3, 6, 8, 11, 13) and this procedure, with few exceptions (*vide infra*), is the preferred one.

The infrared and $^1$H nmr spectral data derived from the β-iodo α,β-unsaturated ketones, along with elemental analysis data, are summarized in Table 4.

### *(b) Conversion of unsymmetrical 1,3-cyclohexanediones into β-iodo α,β-unsaturated ketones*

The reaction of triphenylphosphine diiodide with the unsymmetrically substituted 1,3-cyclohexanediones **37–44** (see Chart 2) was also investigated. This study was carried out in order to determine the regioselectivity of the transformations and to produce substances, more highly substituted than compounds **28–31**, which might be of use as intermediates in organic synthesis.

The substrates **37–44** necessary for this investigation were prepared in a straightforward manner (see Scheme 2). The kinetically formed (lithium diisopropylamide (LDA), tetrahydrofuran (THF), −78°C) enolate anions of the isobutyl enol ethers **63** and **64** were alkylated (52) with methyl iodide, allyl bromide and isopropyl iodide. Although alkylation (tetrahydrofuran solution) of the enolate anions with the former two alkylating agents proceeded in excellent yields (**65**: 95%, **66**: 93%, **69**: 94%, **70**: 95%), similar reactions involving isopropyl iodide gave, not unexpectedly (52), poor yields of the desired products **68** (16%) and **72** (13%), even when hexamethylphosphoramide (HMPA) was used as a cosolvent. Nevertheless, quantities of **68** and **72** sufficient to carry out the present study could be obtained quite readily by this rather simple procedure.

Hydrogenation of the allyl derivatives **66** and **70** in the presence of the homogeneous catalyst tris-(triphenylphosphine)chlororhodium (53) afforded excellent yields of the corresponding *n*-propyl compounds **67** and **71**, respectively.

Careful hydrolysis (54) of the enol ethers **65–72** with 1 *N* hydrochloric acid in acetone provided very good yields of the required 1,3-cyclohexanediones **37–44**, respectively. It is pertinent to point out that this hydrolysis should be done in the absence of oxygen and that the products should be purified carefully and stored under a dry, inert atmosphere. It is well known (55) that 1,3-diones of this type are quite prone to autoxidation, particularly when they are moist.

Treatment of 4-methyl-1,3-cyclohexanedione (**37**) with triphenylphosphine diiodide in refluxing acetonitrile in the presence of triethylamine provided, in 92% yield, a product which on the basis of glc and tlc appeared to consist of two components in a ratio of about 70:30. Separation of these components was achieved by preparative tlc. The major

product provided spectral data consistent with that expected for 3-iodo-6-methyl-2-cyclohexen-1-one (**45**), while the minor component was shown on the basis of the infrared and $^1$H nmr spectra to consist of a mixture of the isomeric iodo ketones **53** and **61** (ratio ≈8:3, respectively). Apparently, under the reaction conditions, the α,β-unsaturated ketone **53** was partially isomerized to the corresponding β,γ-unsaturated isomer **61**. Since we were unable to effect separation of compounds **53** and **61**, these substances were not individually characterized.

SCHEME 2

Reaction of triphenylphosphine diiodide with the unsymmetrical 1,3-cyclohexanediones **38–44** (see Chart 2) under conditions identical with those used for the dione **37** produced results which are summarized in Table 5. It can be seen that all of the transformations were quite efficient and, in terms of the regioselectivity of the reactions, the trends are not unexpected. For example, if one considers the series of 4-alkyl-1,3-cyclohexanediones **37–40**, it can be seen that as the alkyl group adjacent to the C-3 carbonyl function becomes larger, the regioselectivity of the reaction increases. That is, in the case of 4-methyl-1,3-cyclohexanedione (**37**), the iodine atom becomes attached to carbon atoms 1 and 3 in a ratio of ≈70:30 (Table 5, Entry 1) while in the case of the corresponding isopropyl substrate **40**, the reaction is nearly totally regioselective (Table 5, Entry 4). When the C-4 substituent is intermediate in size (allyl, *n*-propyl), the regioselectivity is between these two extremes (Table 5, Entries 2 and 3). A very similar trend is observed with the 4-alkyl-2-methyl-1,3-cyclohexanediones **41–44** (Table 5, Entries 5–8).

[a] All reactions were carried out in refluxing acetonitrile.
[b] Yield of distilled products.
[c] Ratios were determined by a combination of glc and $^1$H nmr spectroscopy.
[d] Although it was possible to separate (preparative tlc) compounds **45** and **46** from the mixtures of **53** + **61** and **54** + **62**, respectively, we were not able to effect separation of the latter two pairs of products. The ratios **53**/**61** and **54**/**62** were determined by $^1$H nmr spectroscopy and, in each case, the two compounds were characterized as a mixture (see Table 6).

The observed regioselectivity in these reactions is presumably due to steric factors. Thus, reaction of triphenylphosphine diiodide with the enolate anion **74** of the generalized 1,3-dione **73** would be expected to take place preferentially at the less hindered oxygen atom to provide mainly the phosphonium salt **75**, with species **76** being the minor intermediate (see Scheme 3). On this basis, the ratio of the final products **79** and **80** would be a reflection of the relative proportions of the intermediate phosphonium salts **75** and **76**. As R′ becomes larger, the ratio **75**:**76** should increase, thus accounting for the observed trends.

An alternative rationale is also possible. On the basis of our earlier observations, it appears that the conversion of the phosphonium salts **75** and **76** into the iodo enones **79** and **80** is the rate-determining step in the overall transformation **73** → **79** + **80**. Therefore, if under the reaction conditions the reaction **74** → **75** + **76** were to be readily reversible and a relatively fast equilibrium between **75** and **76** (via **74**) would thus be established, the ratio **79**/**80** would depend upon the relative rates of conversion of **75** and **76** (via **77** and **78**) into the final products. Clearly, attack of iodide ion on the less hindered β carbon of the enone system of **75** would be a more facile process than the corresponding reaction with intermediate **76**. Furthermore, as R′ became larger, this rate difference would be enhanced. In any case, whatever the actual course of events, the observed regioselectivities, especially in those cases where one of the carbonyl groups is quite hindered, should prove to be useful from a synthetic point of view.

The infrared and $^1$H nmr spectral data for the iodo enones listed in Table 5 are summarized in Table 6. The structural assignments for each of the isomeric pairs of compounds were based mainly on the $^1$H nmr spectra and, therefore, it is appropriate to discuss briefly how these conclusions were drawn. Firstly, we have observed that in the $^1$H nmr spectra of all of the substituted 3-iodo-2-cyclohexen-1-ones which we have prepared, the proton or protons at C-4 resonate at lower field (in the region δ 2.75–3.15) than the other ring protons and, in nearly all of the cases, this signal can be identified quite readily. Thus, for example, in the $^1$H nmr spectrum of the β-iodo enone **47**, the C-4 methylene protons give rise to a *two-proton* multiplet at δ 2.78–2.98, while the C-4 proton of the isomeric compound **55** produces a *one-proton*

| **48** | 1670, 1595 | 0.84, 0.91 (d, d, 6H, $J$ = 7 Hz), 1.70–2.48 (m, 4H), 2.76–2.98 (m, 2H), 6.67 (t, 1H, $J$ = 2 Hz) | *Exact Mass* calcd. for $C_9H_{13}OI$: 264.0011; found: 264.0005 |
| **49** | 1670, 1610 | 1.11 (d, 3H, $J$ = 6 Hz), 1.60–2.10 (m, 2H), 1.99 (t, 3H, $J$ = 2 Hz), 2.22–2.56 (m, 1H), 2.90–3.14 (m, 2H) | *Exact Mass* calcd. for $C_8H_{11}OI$: 249.9855; found: 249.9856 |
| **57** | 1680, 1600 | 1.36 (d, 3H, $J$ = 7 Hz), 1.62–2.76 (diffuse m, 4H), 2.03 (d, 3H, $J$ = 1.5 Hz), 2.80–3.12 (m, 1H) | *Exact Mass* calcd. for $C_8H_{11}OI$: 249.9855; found: 249.9858 |
| **50** | 1670, 1600 | 1.52–2.72 (diffuse m, 5H), 2.01 (t, 3H, $J$ = 2 Hz), 2.88–3.12 (m, 2H), 4.86–5.14 (m, 2H), 5.49–5.92 (m, 1H) | *Exact Mass* calcd. for $C_{10}H_{13}OI$: 276.0011; found: 276.0013 |
| **58** | 1670, 1600 | 1.74–3.02 (diffuse m, 7H), 2.01 (d, 3H, $J$ = 1.5 Hz), 4.96–5.22 (m, 2H), 5.52–5.96 (m, 1H) | *Exact Mass* calcd. for $C_{10}H_{13}OI$: 276.0011; found: 276.0024 |
| **51** | 1670, 1600 | 0.91 (t, 3H, $J$ = 6 Hz), 1.14–2.14 (diffuse m, 7H), 2.00 (t, 3H, $J$ = 2 Hz), 2.16–2.46 (m, 1H), 2.88–3.12 (m, 2H) | *Exact Mass* calcd. for $C_{10}H_{15}OI$: 278.0167; found: 278.0167 |
| **59** | 1670, 1600 | 0.98 (t, 3H, $J$ = 6.5 Hz), 1.20–2.60 (diffuse m, 8H), 2.03 (d, 3H, $J$ = 1.5 Hz), 2.70–2.98 (m, 1H) | *Exact Mass* calcd. for $C_{10}H_{15}OI$: 278.0167; found: 278.0168 |
| **52** | 1675, 1610 | 0.84, 0.91 (d, d, 6H, $J$ = 6.5 Hz), 1.62–2.48 (m, 4H), 1.99 (t, 3H, $J$ = 2 Hz), 2.84–3.10 (m, 2H) | *Exact Mass* calcd. for $C_{10}H_{15}OI$: 278.0167; found: 278.0163 |

[a] All compounds were liquids at room temperature and all exhibited one peak on glc analysis and one spot by tlc analysis.
[b] All infrared spectra were taken on liquid films.
[c] Satisfactory C, H elemental analyses were obtained on the following representative, randomly chosen compounds: **46**, **49**, **50**, **55**, **57**, **58**.
[d] We were unable to effect separation of **53** and **61** or of **54** and **62**. On the basis of careful integration of the areas under the $^1$H nmr signals due to the C-2 vinyl protons of **53** (δ 6.72) and **54** (δ 6.84) vs. the C-2 methylene protons of **61** (δ 3.38) and **62** (δ 3.46), the ratios of the two pairs of compounds were estimated to be as follows: **53/61** ≈ 8:3; **54/62** ≈ 4:1.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

multiplet at δ 2.60–2.88. Similar comparisons can be made for the other pairs of isomeric β-iodo enones. Secondly, the C-2 olefinic protons of the β-iodo enones **45–48** and **53–55** exhibit allylic coupling to the C-4 protons, while homoallylic coupling can be observed between the C-2 vinyl methyl protons and the C-4 protons of the iodo enones **49–52** and **57–59**. Thus, for example, in the $^1$H nmr spectra of the isomeric compounds **47** and **55**, the C-2 olefinic protons give rise to a *triplet* (δ 6.68, $J \approx 2$ Hz) and a *doublet* (δ 6.79, $J \approx 1.5$ Hz), clearly showing that C-4 of these two substances contains two protons and one proton, respectively. Similarly, the C-2 vinyl methyl groups of the isomeric β-iodo enones **51** and **59** produce a *triplet* (δ 2.00, $J \approx 2$ Hz) and a *doublet* (δ 2.03, $J \approx 1.5$ Hz), respectively. Analogous observations could be made for the other iodo enones.

### (c) *Conversion of 2-hydroxymethylenecycloalkanones into 2-iodomethylenecycloalkanones*

Attempts to convert 2-hydroxymethylenecyclohexanone (**81**) into 2-iodomethylenecyclohexanone by reaction of the former substance with triphenylphosphine diiodide – triethylamine under conditions previously used for 1,3-diones proved to be unsuccessful. For example, the reaction in acetonitrile at room temperature was prohibitively slow, while in refluxing acetonitrile a good deal of intractable material was formed and the yield of identifiable product was very low. Eventually it was found that the desired conversion could be carried out successfully and reproducibly by carrying out the reaction at room temperature in a mixture of acetonitrile and HMPA. Under these conditions, **81** was transformed into (*E*)-2-iodomethylenecyclohexanone (**82**) in 94% yield (see Chart 3). In similar fashion, (*E*)-2-iodomethylenecyclopentanone (**84**) could be derived in 73% yield from the corresponding hydroxymethylene compound **83**. In each case, the conversion was highly regioselective and stereoselective, since we were unable to detect the presence of isomeric products.

The assignments made regarding the stereochemistry of compounds **82** and **84** require brief comment. It seems clear that these assignments could have been made very readily if the geometric isomers of **82** and **84** had also been formed in the reactions. That is to say, the $^1$H nmr signals of the olefinic protons of the geometric isomers of **82** and **84** would have been expected to appear at higher field than the corresponding signals of **82** and **84** themselves. For example, the protons adjacent to the chlorine atoms of the β-chloro enones **85** and **86**

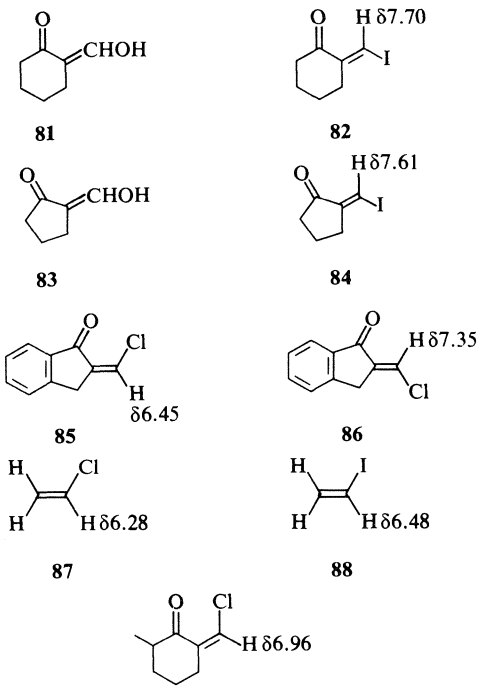

CHART 3

resonate at δ 6.45 and 7.35, respectively (9). However, since the reactions leading to the iodomethylene compounds **82** and **84** were totally stereoselective, only one of the two possible isomers was available in each case, and, therefore, direct comparisons were not possible.

The stereochemical assignments are based on the following arguments. The C-1 protons of vinyl chloride (**87**) and vinyl iodide (**88**) resonate at δ 6.28 and 6.48 respectively (Chart 3). Thus, changing the halogen from Cl to I results in a downfield shift of 0.2 ppm. On this basis, it can be argued that the olefinic protons of the *iodo* compounds corresponding to **85** and **86** (I in place of Cl in each case) should give rise to signals at about δ 6.65 and 7.55, respectively. The latter value is quite close to that of the chemical shift observed for the olefinic proton of the iodomethylenecyclopentanone derived from the reaction discussed above. Therefore, it seems reasonable to conclude that this product has the same relative stereochemistry (i.e. **84**) as that of compound **86**.

A similar argument can be used in the case of the iodomethylenecyclohexanone **82**. Clark and Heathcock (9) have reported that the $^1$H nmr spectrum of (*Z*)-2-chloromethylene-6-methylcyclohexanone (**89**) exhibits the olefinic proton at δ 6.96. The difference (0.74 ppm) between this chemical shift and that of the olefinic proton of **82** (δ 7.70) would

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12

For personal use only.

appear to be too large for the compounds to possess the same relative stereochemistry. In any case, the olefinic protons of compounds **82** and **84** show very similar chemical shifts and it is therefore highly likely that they have the same configuration.

Finally, a few comments should be made regarding the stability of 2-halomethylenecycloalkanones. It has been stated that 2-chloromethylenecyclohexanone (configuration not specified) "decomposes rapidly at room temperature and even at −20°C under nitrogen is converted into a purple oil in a matter of hours" (56).[7] Indeed, we have found that attempted preparation of 2-chloromethylenecyclohexanone by reaction of **81** with triphenylphosphine dichloride – triethylamine provides a poor yield of a very unstable product. A similar observation was made in the reaction of **81** with triphenylphosphine dibromide – triethylamine. On the other hand, the iodomethylenecycloalkanones **82** and **84**, although certainly less stable than the endocyclic β-iodo enones, can be prepared readily and can be stored in a freezer under an atmosphere of argon for a few months without substantial decomposition. If they are exposed to the air at ambient temperatures, however, they darken in color and decompose extensively in a day or two. Nevertheless, as synthetically employable intermediates, compounds **82** and **84** are certainly to be preferred to the corresponding chloro or bromo derivatives.

### *(d) Ultraviolet spectra of β-iodo α,β-unsaturated ketones*

The well-established Woodward–Fieser rules (57–59) have been employed very successfully in correlating electronic transitions with structural patterns in conjugated chromophores. For example, on the basis of the substitution pattern on the enone system of α,β-unsaturated ketones, it is possible to predict quite accurately the position of the longest wavelength $\pi \rightarrow \pi^*$ absorption band of these compounds (57–59). Since cyclic β-iodo α,β-unsaturated compounds were essentially unknown prior to execution of the work reported herein, nothing was known concerning the effect of a β-iodo substituent on the position of the $\pi \rightarrow \pi^*$ absorption maxima of enones. Therefore, the ultraviolet spectra of methanol solutions of the β-iodo enones prepared in this study were measured, with the hope of establishing the extent of the bathochromic shift caused by a β-iodo group. The results are summarized in Table 7.

The most interesting observation that one can make regarding the data given in Table 7 is that, whether or not there is an alkyl substituent at C-2, the $\pi \rightarrow \pi^*$ absorption maxima of all of the 3-iodo-2-cyclohexen-1-ones which were measured appear in nearly the same position. Thus, the average of the $\lambda_{max}$ values of the 3-iodo-2-cyclohexen-1-ones is 258 nm, with a range of 256–261 nm. The analogous values for 3-iodo-2-alkyl-2-cyclohexen-1-ones are 259 nm and 257–260 nm. Furthermore, if one compares these ultraviolet absorption maxima with those of the "parent" enones (2-cyclohexen-1-one, $\lambda_{max}$ 226 nm; 2-methyl-2-cyclohexen-1-one, $\lambda_{max}$ 234 nm), then the "increments" for a 3-iodo group should be ~32 nm for those cyclohexenones having a proton at C-2 and ~25 nm for the corresponding substances possessing a C-2 alkyl substituent.

The positions of the ultraviolet $\pi \rightarrow \pi^*$ absorption maxima of 3-iodo-2-cyclopenten-1-one (**33**) ($\lambda_{max}$ 249 nm) and the 2-methyl analog **34** ($\lambda_{max}$ 248 nm) are also very similar. Not unexpectedly (2-cyclopenten-1-one, $\lambda_{max}$ 218 nm; 2-methyl-2-cyclopenten-1-one, $\lambda_{max}$ 226 nm), these values are about 10 nm lower than those of the cyclohexenone compounds.

TABLE 7. Longest wavelength $\pi \rightarrow \pi^*$ ultraviolet absorption bands of β-iodo α,β-unsaturated ketones (methanol solution)

| Compound | $\lambda_{max}$, nm (ε) |

[7]This substance has, however, been employed subsequently as a synthetic intermediate (15). Furthermore, Clark and Heathcock (9) have reported the preparation and characterization of (*Z*)-2-chloromethylene-6-methylcyclohexanone (**89**), although no mention is made regarding the stability (or instability) of this material.

## Experimental

*General*

Melting points, which were taken on a Fisher–Johns melting point apparatus, and distillation temperatures are uncorrected. Ultraviolet (uv) spectra were recorded on methanol solutions using a Cary 15 spectrophotometer. Infrared (ir) spectra were obtained on liquid films or chloroform solutions, employing Perkin Elmer models 710 or 710B spectrophotometers. Proton magnetic resonance ($^1$H nmr) spectra (deuterochloroform solution) were measured using Varian Associates spectrometers, models T-60 and/or HA-100 or XL-100. Signal positions are given in δ units, with tetramethylsilane as the internal standard. High resolution mass spectrometric measurements were recorded on a Kratos MS-50 mass spectrometer. Gas–liquid chromatography (glc) was carried out with a Hewlett–Packard model 5832 A gas chromatograph (analytical) or with a Varian Aerograph model 90-P instrument (preparative). Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver, B.C.

Triphenylphosphine was recrystallized from ethyl acetate – methanol or from benzene. The solvents and reagents employed were freshly distilled from the following materials: benzene – potassium metal; acetonitrile – phosphorus pentoxide; triethylamine and tetrahydrofuran (THF) – lithium aluminum hydride; hexamethylphosphoramide (HMPA) and diisopropylamine – calcium hydride.

*General procedure for the conversion of β-diketones into β-chloro α,β-unsaturated ketones (Table 1, Entries 1, 3, 7, 9, 12)*

To an ice-cold, stirred solution of recrystallized triphenylphosphine (576 mg, 2.2 mmol) in 20 mL of dry benzene was added 3.7 mL of a 0.6 *M* solution of chlorine in carbon tetrachloride. After the addition was complete, tlc analysis of the mixture indicated that triphenylphosphine was absent. To the resulting suspension was added successively triethylamine (220 mg, 2.2 mmol) and the appropriate β-diketone (2.0 mmol). Stirring was continued at room temperature for the required length of time. The suspension was filtered through a short column of silica gel and the column was eluted with ether. Removal of the solvent from the combined eluate, followed by bulb-to-bulb distillation of the residual oil under reduced pressure (water aspirator, ~10–11 Torr) provided the β-chloro enone as a colorless oil. The yields of the β-chloro enones which were prepared by this procedure are summarized in Table 1, while the spectral data are given in Table 2.

*General procedure for the conversion of β-diketones into β-bromo α,β-unsaturated ketones (Table 1, Entries 2, 4–6, 8, 10, 11, 13, 14)*

To an ice-cold, stirred solution of recrystallized triphenylphosphine (576 mg, 2.2 mmol) in 20 mL of dry benzene was added dropwise 2.2 mL of a 1 *M* solution of bromine in benzene. To the resulting suspension was added successively triethylamine (220 mg, 2.2 mmol) and the appropriate β-diketone (2.0 mmol). Stirring was continued at room temperature for the indicated length of time. The reaction mixture was filtered through a short column of silica gel and the column was eluted with ether. Removal of the solvent from the combined eluate, followed by bulb-to-bulb distillation of the residual oil under reduced pressure (water aspirator, ~10–11 Torr or, in the case of product **20**, vacuum pump, 0.45 Torr) provided the β-bromo enone as a colorless oil. The yields of the β-bromo enones which were prepared by this procedure are summarized in Table 1, while the appropriate spectral data are given in Table 2.

*Conversion of 2,4-pentanedione (**11**) into a mixture of (E)- and (Z)-4-bromo-3-penten-2-one (**26**, **27**) (Table 1, Entry 15)*

To a stirred solution of recrystallized triphenylphosphine (5.76 g, 22 mmol) in dry acetonitrile (100 mL) was added successively a solution of bromine (3.52 g, 22 mmol) in 20 mL of dry benzene, triethylamine (2.2 g, 22 mmol), and 2,4-pentanedione (2.0 g, 20 mmol). The resulting mixture was stirred at room temperature for 19 h. The bulk of the solvent was removed by careful distillation (water aspirator). The residual brown material was diluted with ether (50 mL) and the resulting mixture was filtered through a short column of silica gel (~40 g). The column was washed with ether. Removal of the solvent from the combined eluate, followed by distillation (air-bath temperature 50–70°C/~25 Torr) of the residual oil (which contained some solid triphenylphosphine oxide) gave 3.02 g of a clear liquid. Gas–liquid chromatographic analysis of this material indicated that it consisted of a mixture of **26** and **27** (ratio ~87:13, respectively) along with an unidentified minor compound (~5%). A pure sample of each of the geometric isomers **26** and **27** was obtained by preparative glc, and the spectral data are summarized in Table 2.

*General procedures for the conversion of symmetrical β-diketones into β-iodo α,β-unsaturated ketones*

*(a) Benzene as solvent (Procedure A, Table 3, Entries 1, 4, 9, 12)*

To a stirred solution of recrystallized triphenylphosphine (576 mg, 2.2 mmol) in 20 mL of dry benzene was added 559 mg (2.2 mmol) of iodine and the mixture was stirred at room temperature for 16 h. To the resulting yellow-brown suspension was added successively dry triethylamine (220 mg, 2.2 mmol) and the appropriate β-diketone (2.0 mmol). The mixture was stirred at room temperature for the indicated period of time, during which a brown oil separated from the benzene solution. Examination of the latter by tlc indicated that it contained, at most, only a trace of the desired product. The entire reaction mixture was concentrated under reduced pressure and the residual material was heated at 145–180°C under reduced pressure (water aspirator, ~10–12 Torr) with direct distillation of the product. The distillate thus obtained was redistilled (bulb-to-bulb) under reduced pressure (water aspirator, 10–12 Torr or vacuum pump, 0.2–1 Torr) to provide the β-iodo enone. The yields of the latter substances which were prepared by this procedure are given in Table 3. Physical and spectral data are summarized in Table 4, while ultraviolet absorption maxima are given in Table 7.

*(b) Acetonitrile as solvent (Procedures B and C, Table 3, Entries 2, 3, 5–8, 10, 11, 13)*

To a stirred solution of recrystallized triphenylphosphine (576 mg, 2.2 mmol) in 20 mL of dry acetonitrile was added 559 mg (2.2 mmol) of iodine and the mixture was stirred at room temperature for 2 h. To the resulting orange-yellow suspension was added successively triethylamine (220 mg, 2.2 mmol) and the appropriate β-diketone (2.0 mmol). The mixture was either stirred at room temperature for 4 days (Procedure B, Table 3, Entries 2, 5, 7, 10) or was heated at reflux temperature for the indicated length of time (Procedure C, Table 3, Entries 3, 6, 8, 11, 13). The reaction mixture was concentrated under reduced pressure and the residual material was filtered through a short column of silica gel (~5 g). The column was eluted with 100 mL of ether. Removal of the solvent from the combined eluate, followed by bulb-to-bulb distillation of the residual oil under reduced pressure (water aspirator, ~10–12 Torr or vacuum pump, 0.2–1 Torr) gave the β-iodo enone. The yields of the

latter substances which were prepared by these procedures are given in Table 3, and the physical and spectral properties of the products are summarized in Table 4. Ultraviolet absorption maxima are provided in Table 7.

*General procedure for the alkylation of 3-isobutoxy-2-cyclohexen-1-one (**63**) and 3-isobutoxy-2-methyl-2-cyclohexen-1-one (**64**) with methyl iodide and allyl bromide*

To a cold (−78°C) stirred solution of LDA (22 mmol) in dry THF (80 mL) under an atmosphere of dry nitrogen was added 20 mmol of the ketone **63** or **64**. The solution was stirred for 1 h. The alkylating agent (methyl iodide or allyl bromide, 26 mmol) was added, the solution was allowed to warm slowly to room temperature, and stirring was continued for 4 h. Brine (50 mL) was added and the resulting mixture was extracted thoroughly with petroleum ether (bp 30–60°C). The combined extracts were washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by bulb-to-bulb distillation of the residual oil under reduced pressure, afforded the desired product.

The following compounds were obtained by means of this procedure.

*3-Isobutoxy-6-methyl-2-cyclohexen-1-one* (**65**): 95% yield; distillation temperature 80–90°C (air bath)/0.07 Torr; ir (film): 1690, 1610 $cm^{-1}$; uv (methanol) $\lambda_{max}$: 247 nm (ε 17 800); $^1H$ nmr δ: 0.98 (d, 6H, $J$ = 6 Hz), 1.16 (d, 3H, $J$ = 7 Hz), 1.54–2.58 (diffuse m, 6H), 3.59 (d, 2H, $J$ = 6 Hz), 5.33 (s, 1H). *Anal.* calcd. for $C_{11}H_{18}O_2$: C 72.49, H 9.95; found: C 72.70, H 9.97.

*6-Allyl-3-isobutoxy-2-cyclohexen-1-one* (**66**): 93% yield; distillation temperature 95–100°C (air bath)/0.4 Torr; mp 37–38°C (lit. mp (52) 37–38°C); ir ($CHCl_3$): 1660, 1605 $cm^{-1}$; uv (methanol) $\lambda_{max}$: 247 nm (ε 19 600); $^1H$ nmr δ: 0.98 (d, 6H, $J$ = 6.5 Hz), 1.46–2.78 (diffuse m, 8H), 3.60 (d, 2H, $J$ = 6 Hz), 4.98–5.20 (m, 2H), 5.34 (s, 1H), 5.61–6.05 (m, 1H). *Anal.* calcd. for $C_{13}H_{20}O_2$: C 74.96, H 9.68; found: C 75.05, H 9.54.

*3-Isobutoxy-2,6-dimethyl-2-cyclohexen-1-one* (**69**): 94% yield; distillation temperature 100–110°C (air bath)/0.2 Torr; ir (film): 1650, 1630 $cm^{-1}$; uv (methanol) $\lambda_{max}$: 265 nm (ε 18 800); $^1H$ nmr δ: 0.96 (d, 6H, $J$ = 7 Hz), 1.11 (d, 3H, $J$ = 6.5 Hz), 1.48–2.38 (diffuse m, 5H), 1.68 (t, 3H, $J$ = 2 Hz), 2.40–2.64 (m, 1H), 3.71 (d, 2H, $J$ = 7 Hz). *Exact Mass* calcd. for $C_{12}H_{20}O_2$: 196.1463; found: 196.1470.

*6-Allyl-3-isobutoxy-2-methyl-2-cyclohexen-1-one* (**70**): 95% yield; bp 110°C/0.35 Torr; ir (film): 1640, 1620 $cm^{-1}$; uv (methanol) $\lambda_{max}$: 265 nm (ε 18 600); $^1H$ nmr δ: 1.00 (d, 6H, $J$ = 6.5 Hz), 1.52–2.40 (diffuse m, 6H), 1.72 (t, 3H, $J$ = 1.5 Hz), 3.77 (d, 2H, $J$ = 6.5 Hz), 4.92–5.18 (m, 2H), 5.60–6.04 (m, 1H). *Exact Mass* calcd. for $C_{14}H_{22}O_2$: 222.1620; found: 222.1606.

*Hydrogenation of compounds **66** and **70**. Preparation of 3-isobutoxy-6-*n*-propyl-2-cyclohexen-1-one (**67**) and 3-isobutoxy-2-methyl-6-*n*-propyl-2-cyclohexen-1-one (**71**)*

To a solution of the ketone **66** or **70** (15 mmol) in 150 mL of dry benzene was added approximately 10% by weight of tris(triphenylphosphine)chlororhodium. The resultant solution was stirred vigorously and subjected to an atmosphere of hydrogen at room temperature for 18 h. The solvent was removed under reduced pressure and the residual material was treated with 150 mL of petroleum ether (bp 30–60°C). The mixture was filtered through Celite. Removal of the solvent from the filtrate, followed by distillation of the residual oil under reduced pressure gave the desired products.

*3-Isobutoxy-6-n-propyl-2-cyclohexen-1-one* (**67**): 95% yield; distillation temperature 95–105°C (air bath)/0.1 Torr; mp 25–28°C; ir ($CHCl_3$): 1630, 1600 $cm^{-1}$; uv (methanol) $\lambda_{max}$: 247 nm (ε 19 400); $^1H$ nmr δ: 0.82–1.06 (superimposed d, $J$ = 6.5 Hz, and poorly resolved t, 9H), 1.20–2.30 (diffuse m, 8H), 2.44 (t, 2H, $J$ = 7 Hz), 3.59 (d, 2H, $J$ = 6.5 Hz), 5.30 (s, 1H). *Anal.* calcd. for $C_{13}H_{22}O_2$: C 74.24, H 10.54; found: C 74.47, H 10.40.

*3-Isobutoxy-2-methyl-6-n-propyl-2-cyclohexen-1-one* (**71**): 94% yield; distillation temperature 100–110°C (air bath)/0.2 Torr; ir (film): 1645, 1625 $cm^{-1}$; uv (methanol) $\lambda_{max}$: 265 nm (ε 17 500); $^1H$ nmr δ: 0.91 (t, 3H, $J$ = 7 Hz), 0.98 (d, 6H, $J$ = 6 Hz), 1.14–2.24 (diffuse m, 8H), 1.68 (t, 3H, $J$ = 1.5 Hz), 2.40–2.66 (m, 2H), 3.72 (d, 2H, $J$ = 7 Hz). *Exact Mass* calcd. for $C_{14}H_{24}O_2$: 224.1776; found: 224.1786.

*Preparation of 3-isobutoxy-6-isopropyl-2-cyclohexen-1-one (**68**) and 3-isobutoxy-6-isopropyl-2-methyl-2-cyclohexen-1-one (**72**)*

To a cold (−78°C) stirred solution of LDA (55 mmol) in 60 mL of a 5:1 mixture of dry THF and dry HMPA was added 50 mmol of the ketone **63** or **64**, and the solution was stirred for 1 h. A solution of isopropyl iodide (9.35 g, 55 mmol) in 10 mL of dry THF was added, the resultant mixture was allowed to warm to room temperature, and stirring was continued for 16 h. Water (50 mL) was added and the resultant mixture was extracted thoroughly with petroleum ether (bp 30–60°C). The combined extracts were washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent produced an oil which was subjected to column chromatography on silica gel (300 g). The eluant was a 7:3 mixture of *n*-hexane – ether. In addition to minor, unidentified products and a major amount of starting material, the following desired products were obtained.

*3-Isobutoxy-6-isopropyl-2-cyclohexen-1-one* (**68**): 16% yield; distillation temperature 70–90°C (air bath)/0.2 Torr; mp 22.5–24°C; ir (film): 1650, 1605 $cm^{-1}$; uv (methanol) $\lambda_{max}$: 247 nm (ε 12 800); $^1H$ nmr δ: 0.83 (d, 3H, $J$ = 6.5 Hz), 0.94 (d, 9H, $J$ = 6.5 Hz), 1.60–2.16 (m, 4H), 2.25–2.56 (m, 3H), 3.53 (d, 2H, $J$ = 6.5 Hz), 5.26 (s, 1H). *Exact Mass* calcd. for $C_{13}H_{22}O_2$: 210.1620; found: 210.1618.

*3-Isobutoxy-3-isopropyl-2-methyl-2-cyclohexen-1-one* (**72**): 13% yield; distillation temperature 85–95°C (air bath)/0.1 Torr; ir (film): 1640, 1620 $cm^{-1}$; uv (methanol) $\lambda_{max}$: 266 (ε 18 300); $^1H$ nmr δ: 0.84 (d, 3H, $J$ = 5 Hz), 0.97 (d, 9H, $J$ = 6 Hz), 1.58 (t, 3H, $J$ = 1.5 Hz), 1.60–2.78 (diffuse m, 7H), 3.77 (d, 2H, $J$ = 6 Hz). *Exact Mass* calcd. for $C_{14}H_{24}O_2$: 224.1770; found: 224.1780.

*General procedure for the hydrolysis of compounds **65–72**. Preparation of the unsymmetrical 1,3-cyclohexanediones **37–44***

To a solution of the β-isobutoxy α,β-unsaturated ketone (**65–72**) (30 mmol) in acetone (80 mL, spectro-grade, previously purged with a stream of nitrogen for 15 min) was added with vigorous stirring 30 mL of 1 *N* hydrochloric acid (previously purged with nitrogen for 15 min). The resultant solution was stirred under an atmosphere of nitrogen for 6 h. Most of the acetone was removed under reduced pressure, the residual material was diluted with 20 mL of brine, and the resultant mixture was extracted thoroughly with dichloromethane. The combined extracts were dried over anhydrous magnesium sulfate. Removal of the solvent, followed by purification of the residual material by distillation under reduced pressure and/or by recrystallization, gave the following desired products.

*4-Methyl-1,3-cyclohexanedione* (**37**): 96% yield; distillation temperature 85–100°C (air bath)/0.03 Torr; recrystallization from ether – petroleum ether (bp 30–60°C), mp 53–57°C; ir ($CHCl_3$): 3400–2400 (broad), 1700, 1610–1580 (broad) $cm^{-1}$; $^1H$ nmr δ: 1.16 (d, 3H, $J$ = 6 Hz), 1.38–2.80 (diffuse m, 5H), 3.38 (s, ~1H, C-2 methylene of keto tautomer), 5.42 (s, ~0.5H, C-2 vinyl proton of enol tautomer). *Anal.* calcd. for $C_7H_{10}O_2$: C 66.75, H 7.99; found: C 66.79, H 7.99.

*4-Allyl-1,3-cyclohexanedione* (**38**): 90% yield; distillation temperature 90–100°C (air bath)/0.08 Torr; mp 34–36°C; ir ($CHCl_3$): 3600–2400 (broad), 1720, 1710, 1640–1590 (broad) $cm^{-1}$; $^1H$ nmr δ: 1.40–2.80 (diffuse m, 7H), 3.38 (s, ~1H, C-2 methylene of keto tautomer), 4.90–5.20 (m, 2H), 5.42 (s, ~0.5H, C-2 vinyl proton of enol tautomer), 5.52–6.00 (m, 1H). *Exact Mass* calcd. for $C_9H_{12}O_2$: 152.0838; found: 152.0845.

*4-n-Propyl-1,3-cyclohexanedione* (**39**): 60% yield; distillation temperature 110–125°C (air bath)/0.9 Torr; mp 69–71°C; ir ($CHCl_3$): 3500–2400 (broad), 1730, 1710, 1600 (broad) $cm^{-1}$; $^1H$ nmr δ: 0.91 (t, 3H, $J$ = 7 Hz), 1.16–2.72 (diffuse m, 9H), 3.40 (s, ~0.7H, C-2 methylene of keto tautomer), 5.40 (s, ~0.7H, C-2 vinyl proton of enol tautomer). *Exact Mass* calcd. for $C_9H_{14}O_2$: 154.0994; found: 154.1005.

*4-Isopropyl-1,3-cyclohexanedione* (**40**): 95% yield; distillation temperature 110–130°C (air bath)/0.07 Torr; mp 106–107°C; ir ($CHCl_3$): 1730, 1710, 1615 $cm^{-1}$; $^1H$ nmr δ: 0.80–1.14 (series of overlapping d, 6H), 1.58–2.86 (diffuse m, 6H), 3.36 (s, ~1.4H, C-2 methylene of keto tautomer), 5.42 (s, ~0.3H, C-2 vinyl proton of enol tautomer). *Exact Mass* calcd. for $C_9H_{14}O_2$: 154.0994; found: 154.0992.

*2,4-Dimethyl-1,3-cyclohexanedione* (**41**): 97% yield; distillation temperature 80–95°C (air bath)/ 0.3 Torr; mp 108–110°C; ir ($CHCl_3$): 3650–2450 (broad), 1745, 1705, 1630 $cm^{-1}$; $^1H$ nmr δ: 1.10–1.34 (series of d), 1.34–2.94 (diffuse m), 1.72 (s, vinyl methyl of enol tautomer), 3.38–3.68 (m, C-2 protons of diastereomeric keto tautomers). On the basis of the relative integrated areas of the latter two signals, the keto–enol ratio was ~1:1. *Exact Mass* calcd. for $C_8H_{12}O_2$: 140.0838; found: 140.0841.

*4-Allyl-2-methyl-1,3-cyclohexanedione* (**42**): 88% yield; distillation temperature 110–120°C (air bath)/ 0.3 Torr; mp 51–53°C; ir ($CHCl_3$): 3575, 3500–2600 (broad), 1735. 1705, 1615 (broad) $cm^{-1}$; $^1H$ nmr δ: 1.19, 1.21 (d, d, $J$ = 6.5 Hz), 1.32–2.86 (diffuse m), 1.71 (s, vinyl methyl of enol tautomer), 3.50 (q, $J$ = 6.5 Hz, C-2 proton of keto tautomers), 4.90–5.20 (m, 2H), 5.52–6.00 (m, 1H). On the basis of the relative integrated areas of the signals at δ 1.71 and 3.50; the keto–enol ratio was ~1:1. *Exact Mass* calcd. for $C_{10}H_{14}O_2$: 165.9994; found: 166.1007.

*2-Methyl-4-n-propyl-1,3-cyclohexanedione* (**43**): 95% yield; distillation temperature 100–110°C (air bath)/0.03 Torr; mp 67–69°C, ir ($CHCl_3$): 3650–2500 (broad), 1740, 1705, 1635 $cm^{-1}$; $^1H$ nmr δ: 0.82–1.04 (m, 3H), 1.18, 1.20 (d, d, $J$ = 6.5 Hz), 1.24–2.76 (diffuse m), 1.72 (s, vinyl methyl of enol tautomer), 3.36–3.68 (m, C-2 protons of diastereomeric keto tautomers). The relative integrated areas of the latter two signals was ~4:1. *Exact Mass* calcd. for $C_{10}H_{16}O_2$: 168.1150; found: 168.1146.

*4-Isopropyl-2-methyl-1,3-cyclohexanedione* (**44**): 96% yield; sublimes at 95–100°C (air bath)/0.01 Torr; mp 104–105°C; ir ($CHCl_3$): 3560, 3500–3000 (broad), 1735, 1700, 1625 (broad) $cm^{-1}$; $^1H$ nmr δ: 0.80–1.26 (series of d), 1.26–2.90 (diffuse m), 1.70 (s, vinyl methyl of enol tautomer), 3.32–3.62 (m, C-2 protons of diastereomeric keto tautomers). The relative integrated areas of the latter two signals was ~2.5:1. *Exact Mass* calcd. for $C_{10}H_{16}O_2$: 168.1150; found: 168.1151.

*General procedure for the conversion of unsymmetrical 1,3-cyclohexanediones into β-iodo α,β-unsaturated ketones (Table 5)*

To a stirred suspension of iodine (660 mg, 2.6 mmol) in 15 mL of dry acetonitrile under an atmosphere of nitrogen was added 681 mg (2.6 mmol) of recrystallized triphenylphosphine and the mixture was stirred for 30 min. To the resultant yellow suspension was added successively dry triethylamine (263 mg, 2.6 mmol) and 2.4 mmol of the appropriate 1,3-cyclohexanedione (**37**–**44**). The dark solution was stirred at room temperature for 1 h and then was heated at reflux temperature for 12 h. The solvent was removed under reduced pressure and the residue was extracted (decantation) with 6 × 25 mL of ether. Removal of the ether from the combined extracts produced a mixture of a solid and an orange oil. This material was washed with 3 × 15 mL of 7:1 *n*-pentane–ether and the combined washings were applied to a dry column consisting of a mixture of 20 g of Florisil (100–120 mesh) and 10 g of alumina (neutral, activity I). The column was eluted with 7:1 *n*-pentene–ether and the fractions containing the desired products were combined. Removal of the solvent from the combined eluate, followed by bulb-to-bulb distillation of the residual oil, provided the desired product(s). In each case, the distilled material was subjected to analysis by glc (6 ft × 0.125 in. column containing 5% OV-17 on 100–120 mesh HP Chromosorb W) and, where possible (see footnote *d*, Tables 5 and 6), the products were separated by preparative tlc on silica gel (plates developed with 7:3 *n*-pentane–ether). The results are recorded in Table 5, and appropriate characterization data and ultraviolet absorption maxima for the various products are summarized in Table 6 and Table 7, respectively.

*Preparation of (E)-2-iodomethylenecyclopentanone (84) and (E)-2-iodomethylenecyclohexanone (82)*

To a stirred solution of recrystallized triphenylphosphine (2.88 g, 11 mmol) in a mixture of dry acetonitrile (50 mL) and dry HMPA (8 mL) was added 2.79 g (11 mmol) of iodine, and the mixture was stirred at room temperature for 20 min. To the resulting yellow suspension was added successively dry triethylamine (1.1 g, 11 mmol) and the α-hydroxymethylenecycloalkanone (**83**, **81**), and stirring was continued for 72 h when the starting material was **83** and for 15 h when the starting material was **81**. Most of the solvent was removed under reduced pressure. The residual material was extracted by stirring and decantation with 5 × 50 mL of pentane. The combined extracts were washed with 3 × 30 mL of water and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by bulb-to-bulb distillation of the residual oil, provided the following products.

*(E)-2-Iodomethylenecyclopentanone* (**84**): 73% yield; recrystallized from ether, mp 31.5°C; ir ($CHCl_3$): 1720, 1608 $cm^{-1}$; uv (methanol) $\lambda_{max}$: 276 nm (ε 9 200), shoulder at 263 nm; $^1H$ nmr δ: 1.8–3.0 (diffuse m, 6H), 7.61 (t, 1H, $J$ = 2 Hz). *Exact Mass* calcd. for $C_6H_7IO$: 221.9543; found: 221.9544.

*(E)-2-Iodomethylenecyclohexanone* (**82**): 94% yield; distillation temperature 60–70°C (air bath)/ 0.4 Torr; crystallizes in refrigerator, mp ~15°C; ir (film): 1695, 1570 $cm^{-1}$; uv (methanol) $\lambda_{max}$: 265 nm (ε 7 200); $^1H$ nmr δ: 1.60–2.04 (m, 4H), 2.30–2.66 (m, 4H), 7.70 (t, 1H, $J$ = 2 Hz). *Anal.* calcd. for $C_7H_9IO$: C 35.62, H 3.84; found: C 35.65, H 3.76.

J. A. HOWARD and T. YAMADA. Can. J. Chem. **60**, 224 (1982).

The spin scavenging technique has been applied to the initial homolytic reaction between tertiary alkyl hydroperoxides and zinc and nickel complexes of dialkyldithiophosphoric acids and dialkyldithiocarbamic acids using low concentrations of Galvinoxyl and 2,2,6,6-tetramethyl-4-oxo-1-piperidinyloxyl as radical scavengers. This method has demonstrated that these transition metal complexes react with hydroperoxides at 303 K to generate free-radicals. Quantitative kinetic data have been obtained from zero-order scavenger decays and the efficiency with which the transition metal complexes generate free-radicals increases in the order $Zn[R_2NCS_2]_2 < Zn[(RO)_2PS_2]_2 < Ni[(RO)_2PS_2]_2 < Ni[R_2NCS_2]_2$. Deviations from zero-order scavenger decay have been observed, particularly at high complex concentrations, and have been attributed to reaction of the complex with transient radicals to give products which do not react rapidly with the scavenger.

J. A. HOWARD et T. YAMADA. Can. J. Chem. **60**, 224 (1982).

Utilisant de faibles concentrations de galvinoxyle et de trétraméthyl-2,2,6,6-oxo-4 pipéridinyloxy-1 comme pièges à radicaux, on a appliqué la technique de piégeage de spin à la réaction homolytique initiale entre les hydropéroxydes d'alkyles tertiaires et les acides dialkyldithiocarbamiques. Cette méthode a démontré que ces complexes de métaux de transition réagissent avec les hydroperoxydes à 303K en produisant des radicaux libres. On a obtenu des données cinétiques quantitatives à partir de la désintégration d'ordre zéro des capteurs; l'efficacité avec laquelle les complexes de métaux de transition engendrent les radicaux libres augmente dans l'ordre suivant, $Zn[R_2NCS]_2 < Zn[(RO)_2PS_2] < Ni[(RO)_2PS_2]_2 < Ni[R_2NCS_2]_2$. Toutes les désintégrations du capteur ne sont pas rigoureusement d'ordre zéro, particulièrement aux fortes concentrations du complexe. On a attribué ces déviations à la réaction du complexe avec les radicaux intermédiaires pour donner des produits qui ne réagissent pas rapidement avec le capteur.

[Traduit par le journal]

## Introduction

It has been established that reaction of transition metal complexes, $ML_x$ where M is zinc, nickel, or copper, and L is either dialkyldithiophosphate or dialkyldithiocarbamate, with alkyl hydroperoxides produces free-radicals which can be detected directly by electron spin resonance spectroscopy and indirectly by monitoring the disappearance of a free-radical scavenger such as an aromatic amine or stable free-radical (2, 3). Moreover, these radicals may initiate hydrocarbon autoxidation, induce hydroperoxide decomposition, and give rise to the chemiluminescence usually associated with autoxidation (2).

In addition to qualitatively demonstrating the production of free-radicals, the spin scavenging technique can be used to provide quantitative estimates of rates of free-radical initiation. This method does, however, appear to suffer from several distinct disadvantages which severely limit its usefulness in metal complex – hydroperoxide systems. The present paper discusses the application of this technique to a study of the initial reaction between tertiary alkyl hydroperoxides and several transition metal complexes of dialkyldithiophosphoric and dialkyldithiocarbamic acids.

## Experimental

*Materials*

2,2,6,6-Tetramethyl-4-oxo-1-piperidinyloxyl (Aldrich) was recrystallized from methanol. Galvinoxyl (Aldrich) was used as received. Zinc diisopropyldithiophosphate, nickel diisopropyldithiophosphate, zinc diethyldithiocarbamate, nickel diethyldithiocarbamate, and nickel di-*n*-butyldithiocarbamate had been prepared previously in our laboratory (4–6). *tert*-Butyl hydroperoxide, cumene hydroperoxide, diisopropyldithiophosphoryl disulphide, dimethyldithiuram disulphide, diethyldithiophosphoric acid, *tert*-butyl hyponitrite, and chlorobenzene were prepared and purified by the methods described previously in this series (4–6).

*Procedure*

In most cases runs were performed by adding 50 μL of a standard hydroperoxide solution to 250 μL of a standard solution of the metal complex and stable free-radical in chlorobenzene contained in a 4 mm od suprasil tube directly in the cavity of a Varian E-4 EPR spectrometer. Rapid mixing was achieved by passing a fine steam of argon through the reaction mixture. Before addition of the hydroperoxide the field sweep of the spectrometer was set at the magnetic field corresponding to the maximum peak height of one of the lines of the first derivative signal from the stable free-radical and was switched off. The change in the signal intensity as a function of time was

monitored immediately after addition of the hydroperoxide. All decays were recorded on the X-Y recorder provided with the spectrometer. Reaction temperatures were regulated by a Varian variable temperature accessory.

## Results

*Preliminary experiments*

Preliminary experiments demonstrated that 2,2,-6,6-tetramethyl-4-oxo-1-piperidinyloxyl (**1**) does not react with $Zn[(i\text{-}PrO)_2PS_2]_2$, $Ni[(i\text{-}PrO)_2PS_2]_2$, $Zn[Et_2NCS_2]_2$, $Ni[Et_2NCS_2]_2$, *t*-BuOOH, or $[(i\text{-}PrO)_2PS_2]_2$. It does, however, react slowly with $(EtO)_2PS_2H$ by a second-order reaction with a rate constant $\sim 3\ M^{-1}\ s^{-1}$ at 303 K.

Galvinoxyl **2**, on the other hand, reacts slowly with $Zn[(i\text{-}PrO)_2PS_2]_2$, $Zn[Et_2NCS_2]_2$, $Ni[(i\text{-}PrO)_2PS_2]_2$, and $Ni[Et_2NCS_2]_2$. Rates of reaction were, however, slow and no attempt was made to study the kinetics of these reactions. Galvinoxyl also reacts with cumene hydroperoxide and the overall rate was first-order with respect to each reactant. A value of $0.011 \pm 0.002\ M^{-1}\ s^{-1}$ was found for the second-rate constant. Spin scavenging experiments using **2** were, therefore, conducted with reactant concentrations low enough that rates of reaction of **2** with the metal complex and hydroperoxide were negligible compared to rates of destruction of **2** by the radicals produced by reaction of the metal complex with the hydroperoxide. Galvinoxyl also reacts slowly with $[(i\text{-}PrO)_2PS_2]_2$ and $(EtO)_2PS_2H$.

In experiments designed to examine the efficiency with which stable radicals scavenge the transient radicals produced by reaction of $ML_x$ with ROOH, the disappearance of **2** was monitored in the presence of *t*-$BuON_2OBu$-*t*, a thermal source of *tert*-butoxyl and a mixture of *t*-$BuON_2OBu$-*t* and *t*-BuOOH, a thermal source of *tert*-butylperoxyl.

In these experiments, it was demonstrated that **2** was completely destroyed by excess *t*-$BuON_2OBu$-*t* at 303 K and that rates of radical disappearance obeyed the rate expression

$$\frac{-d[\mathbf{2}]}{dt} = 2ek_d[t\text{-}BuON_2OBu\text{-}t]$$

where $e$, the efficiency of production of *t*-BuO$^\cdot$, = 0.9, and $k_d$, the rate constant for unimolecular decomposition of *t*-$BuON_2OBu$-*t*, $= 2.9 \times 10^{-6}\ s^{-1}$ (7). They also showed that rates of disappearance of **2** were not influenced by the presence of *t*-BuOOH (0.001 *M*).

Rates of disappearance of **2** in the presence of *t*-$BuON_2OBu$-*t* were, however, reduced by $Zn[(i\text{-}PrO)_2PS_2]_2$ and at high concentrations of this complex ($> 0.001\ M$) rates were first-order with respect to the concentration of **2**. This implies that there was a competition between **2** and $Zn[(i\text{-}PrO)_2PS_2]_2$ for *t*-BuO$^\cdot$ produced by decomposition of *t*-$BuON_2OBu$-*t* and that the products of the reaction of $Zn[(i\text{-}PrO)_2PS_2]_2$ with *t*-BuO$^\cdot$ did not react rapidly with **2**. This system can probably be described by the elementary reactions [1] to [3].

[1] $t\text{-}BuON_2OBu\text{-}t \xrightarrow{k_1} 2t\text{-}BuO^\cdot + N_2$

[2] $t\text{-}BuO^\cdot + \mathbf{2} \xrightarrow{k_2}$ non-radical products

[3] $t\text{-}BuO^\cdot + Zn[(i\text{-}PrO)_2PS_2]_2 \xrightarrow{k_3}$ unreactive products

Application of the usual steady-state assumptions indicates that the rate of disappearance of **2** should be given by [4].

$$[4] \qquad \frac{-d[\mathbf{2}]}{dt} = \frac{2ek_1k_2[\mathbf{2}][t\text{-}BuON_2OBu\text{-}t]}{k_2[\mathbf{2}] + k_3[Zn[(i\text{-}PrO)_2PS_2]_2]}$$

First-order radical decays in the presence of $Zn[(i\text{-}PrO)_2PS_2]_2$ imply that $k_3[Zn[(i\text{-}PrO)_2PS_2]_2] > k_2$ [**2**] and that the pseudo-first-order rate constant is equal to $2ek_1k_2[t\text{-}BuON_2OBu\text{-}t]/k_3[Zn[(i\text{-}PrO)_2PS_2]_2]$. This rate constant was measured at concentrations of $Zn[(i\text{-}PrO)_2PS_2]_2$ from $10^{-3}$ to $10^{-2}\ M$ and little to no dependence on $[Zn[(i\text{-}PrO)_2PS_2]_2]$ was observed.

The reaction of **2** with *t*-BuO$^\cdot$ was also retarded by $Ni[(i\text{-}PrO)_2PS_2]_2$ and at an initial complex concentration of $2 \times 10^{-3}\ M$ the rate was first-order with respect to the scavenger concentration while little or no decay of the scavenger occurred if the complex concentration was increased above $5 \times 10^{-3}\ M$.

If we assume that *t*-BuO$^\cdot$ reacts with $Zn[(i\text{-}PrO)_2PS_2]_2$ and $Ni[(i\text{-}PrO)_2PS_2]_2$ to give $(i\text{-}PrO)_2PS_2^\cdot$, e.g.,

[5] $t\text{-}BuO^\cdot + Zn[(i\text{-}PrO)_2PS_2]_2 \rightarrow t\text{-}BuOZn[(i\text{-}PrO)_2PS_2] + (i\text{-}PrO)_2PS_2^\cdot$

the results of the above experiments suggest that $(iPrO)_2PS_2^\cdot$ does not react rapidly with **2**.

We have tested this hypothesis by following the disappearance of **2** in the presence of *t*-$BuON_2OBu$-*t* and $(EtO)_2PS_2H$; a system which should give $(EtO)_2PS_2^\cdot$ by reaction [6].

[6] $t\text{-}BuO^\cdot + (EtO)_2PS_2H \rightarrow t\text{-}BuOH + (EtO)_2PS_2^\cdot$

As expected $(-d[\mathbf{2}]/dt)_0$ was slower in the presence of $(EtO)_2PS_2H$ and rates deviated from a zero-order dependence on [**2**] as it fell below one half of its initial concentration. Confirmation of this

[a] Corrected for rate of reaction of **2** with ROOH.

hypothesis at high concentrations ($> 10^{-4}$ *M*) of $(EtO)_2PS_2H$ could not be obtained because of the direct reaction between **2** and $(EtO)_2PS_2H$.

Rates of destruction of **2** by thermally generated *t*-BuO$^\cdot$ were also reduced by $Zn[n\text{-}Bu_2NCS_2]_2$ and $Ni[Et_2NCS_2]_2$. Thus at a complex concentration of $10^{-4}$ *M* the rate was still zero-order with respect to [**2**] but slower than it was in the absence of the complex, while at higher complex concentrations the usual deviations from zero-order kinetics were observed. Interestingly, dimethyldithiuram disulphide ($10^{-3}$ *M*) did not influence the kinetics for the decay of **2** although the rate was reduced by a factor of about 2. At higher concentrations of this disulphide ($\sim 10^{-2}$ *M*) the kinetics did deviate from zero-order.

*$Zn[(i\text{-}PrO)_2PS_2]_2$*

**1** and **2** began to decay immediately when a solution of *t*-BuOOH or $PhCMe_2OOH$ in chlorobenzene was added to a solution of $Zn[(i\text{-}PrO)_2PS_2]_2$ in chlorobenzene containing a low concentration of scavenger at 303 K, indicating that an initial reaction between the metal complex and hydroperoxide was forming transient free radicals.

[7] $Zn[(i\text{-}PrO)_2PS_2]_2 + ROOH \rightarrow$ free-radicals

The shape of the concentration–time profile for the scavenger did, however, depend very markedly on the initial complex concentration and zero-order decays were only obtained at low complex and low scavenger concentrations and high hydroperoxide concentrations. Under other conditions, the scavenger tended to disappear according to first-order kinetics and at high complex concentrations rates of scavenger disappearance were slower than the rates at low complex concentrations and were almost independent of the complex concentration. Clearly $Zn[(i\text{-}PrO)_2PS_2]_2$ was interfering with the radical scavenging process as it did when the transient radicals were generated by thermolysis of *t*-$BuON_2OBu$-*t*.

Kinetic data obtained under zero-order or close to zero-order conditions are given in Table 1 and initial rates of decay of **2** were approximately first-order with respect to the metal complex and hydroperoxide concentrations, i.e.,

$$\left(\frac{-d[2]}{dt}\right)_0 = nk_7[Zn[(i\text{-}PrO)_2PS_2]_2][ROOH]$$

where $n$ is the number of radicals produced by reaction [7]. The value of the second-order rate constant $nk_7$ was found to be $(5.5 \pm 1) \times 10^{-3}\ M^{-1}\ s^{-1}$.

Initial rates of disappearance of **1** in the presence of $Zn[(i\text{-}PrO)_2PS_2]_2$ and *t*-ROOH, at low initial complex concentrations, gave values of $nk_7$ in good agreement with values obtained from decay of **2**. Deviations from zero-order kinetics were, however, more pronounced with **1** than they were with **2**.

Ivanov and Kateva (8) have studied the initial homolytic reaction between $Zn[(i\text{-}PrO)_2PS_2]_2$ and

ROOH using 2,2,6,6-tetramethyl-1-piperidinyloxyl as the radical scavenger. They reported a rate constant of $3.7 \times 10^{-3}$ $M^{-1}$ $s^{-1}$ at 328 K for α-tetralin hydroperoxide (0.3 *M*) and $Zn[(i\text{-}PrO)_2PS_2]_2$ (0.05 *M*) and a value of $7.94 \times 10^{-3}$ using the same concentrations of *t*-BuOOH and metal complex. The agreement between these rate constants and our data is remarkably good considering that Ivanov and Kateva only worked at one rather high concentration of metal complex and one hydroperoxide concentration.

*$Ni[(i\text{-}PrO)_2PS_2]_2$*

Galvinoxyl disappeared completely with zero-order kinetics in the presence of $PhCMe_2OOH$ ($2 \times 10^{-3} - 0.2$ *M*) and $Ni[(i\text{-}PrO)_2PS_2]_2$ ($10^{-5} - 2 \times 10^{-3}$ *M*) at 303 K. Initial rates of radical disappearance are given in Table 2 and obey the rate expression

$$\frac{-d[2]}{dt} = nk_8[Ni[(i\text{-}PrO)_2PS_2]_2][ROOH]$$

where $k_8$ is the rate constant for production of radicals by reaction [8].

[8] $PhCMe_2OOH + Ni[(i\text{-}PrO)_2PS_2]_2 \rightarrow$ free radicals

The value of $nk_8$ at 303 K is $0.01 \pm 0.001$ $M^{-1}$ $s^{-1}$ and values of this rate constant from 293 to 343 K obey the Arrhenius equation

$$\log (nk_8/M^{-1}\ s^{-1}) = (8 \pm 1) - 10.5 \pm 0.5/\theta$$

where $\theta = 2.303RT$ kcal $mol^{-1}$.

The value of $nk_8$ at 303 K obtained by the radical scavenging technique is 2.5–3.8 times larger than rate constants obtained from rates of initiation of styrene autoxidation and rates of nickel complex disappearance (6).

**1** is completely destroyed by mixtures of $Ni[(i\text{-}PrO)_2PS_2]_2$ ($4 \times 10^{-4} - 4 \times 10^{-3}$ *M*) and *t*-BuOOH 0.06–0.6 *M*) in PhCl. In this case, however, radical decays obeyed the rate law

$$\frac{-d[1]}{dt} \propto [t\text{-BuOOH}]^{0.7 \pm 0.2} \times [Ni[(iPrO)_2PS_2]_2]^{0.9 \pm 0.1}[1]^{0.8 \pm 0.5}$$

indicating that the rates were almost first-order with respect to [1]. This suggests that $Ni[(i\text{-}PrO)_2PS_2]_2$ was competing successfully with **1** for the radicals produced by reaction [8].

*$Zn[Et_2NCS_2]_2$*

**2** ($4.8 \times 10^{-6}$ *M*) disappeared completely with zero-order kinetics when $PhCMe_2OOH$ (0.194 *M*) was added to $Zn[Et_2NCS_2]_2$ ($4.8 \times 10^{-5}$ *M*). Deviations from zero-order kinetics were, however, observed at lower hydroperoxide concentrations. Kinetic data for this system are given in Table 3 and it would appear that the rate of reaction is approximately first-order with respect to each reactant and $nk_9 = (1.8 \pm 0.4) \times 10^{-3}$ $M^{-1}$ $s^{-1}$. $Zn[Et_2NCS_2]_2$ is, therefore, only about 32% as efficient as $Zn[(i\text{-}PrO)_2PS_2]_2$ in producing free-radicals by reaction with a tertiary alkyl hydroperoxide.

**1** was completely destroyed by a mixture of $Zn[Et_2NCS_2]_2$ and *t*-BuOOH with the rate of radical disappearance depending on the initial concentration of **1** (Table 4).

*$Ni[R_2NCS_2]_2$*

Galvinoxyl ($4.8 \times 10^{-6}$ *M*) disappeared with zero-order kinetics in the presence of $Ni[Et_2NCS_2]_2$ ($2.4 \times 10^{-7} - 10^{-6}$ *M*) and $PhCMe_2OOH$ (0.005 – 0.01 *M*). Rate constants for reaction [10] are summarized in Table 5 and the average value is $1 \pm 0.5$ $M^{-1}$ $s^{-1}$ which is 6–7 times larger than values obtained from rates of initiation of styrene autoxidation and rates of nickel complex disappearance (6)

[10] $PhCMe_2OOH + Ni[Et_2NCS_2]_2 \rightarrow$ free-radicals

Decay of **1** ($2 \times 10^{-4}$ to $2 \times 10^{-5}$ *M*) in the presence of $Ni[n\text{-}Bu_2NCS_2]_2$ (0.001 to 0.0001 *M*) and *t*-BuOOH (0.02 *M*) followed first-order kinetics with respect to the radical concentration indicating that the rate expression [4] was obeyed and that $Ni[n\text{-}Bu_2NCS_2]_2$ was successfully competing with **1** for the free radicals.

## Discussion

It is clear from the present work that although the reaction of transition metal dialkyldithiophosphates and dialkyldithiocarbamates with tertiary alkyl hydroperoxides in the presence of a stable radical gives qualitative information regarding the production of transient free-radicals a great deal of care has to be exercised before rates of free-radical initiation from the metal complex – ROOH system can be obtained. This is because rates of disappearance of low scavenger concentrations are not

always zero-order in the presence of the metal complex and hydroperoxide. Thus the metal complex appears to be able to compete with the scavenger for transient free-radicals to give species which do not react rapidly with the scavenger. We have tested several types of stable radical as scavenger (phenoxyl, nitroxyl, and iminoxyl) and find that the phenoxyl is the only one which can be used to give reliable rates of free-radical production for the $ML_x$–ROOH system.

Rate constants obtained by this technique are summarized in Table 6 and indicate that the ability of the complexes to generate free-radicals increases in the order $Zn[R_2NCS_2]_2 < Zn[(RO)_2PS_2]_2 < Ni[(RO)_2PS_2]_2 < Ni[R_2NCS_2]_2$. Furthermore, where a comparison can be made these rate constants are somewhat larger than the values obtained from rates of initiated autoxidations and rates of metal complex disappearances. We do, however, feel that under conditions of zero-order scavenger decay and over a reasonable range of reactant concentrations that the spin scavenging technique gives the more reliable rate constants.

Although the initiation reactions [7] to [10] have been depicted as simple bimolecular reactions between the hydroperoxide and $ML_x$, the reaction mechanism must be more complicated than this and possibly involves the reversible formation of a co-ordination complex between the reactants followed by first-order decomposition to give radicals (2)

$$ROOH + ML_x \rightleftarrows ROOH \ldots ML_x$$

$$ROOH \ldots ML_x \rightarrow \text{radicals} + ML_x$$

Co-ordination to $ML_x$ could weaken the O—O bond of the hydroperoxide by increasing the electron density at this function. It should, however, be noted that in the case of $Cu[Et_2NCS_2]_2$ no esr evidence could be found for the formation of a co-ordination complex with ROOH (9).

A few preliminary experiments with $Cu[Et_2NCS_2]_2$ and $Cu[(i\text{-}PrO)_2PS_2]_2$ indicated that the homolytic reaction of these complexes with ROOH was either too fast to study by the spin scavenging technique or scavenger decays were too complicated to analyse.

# Lignin and related compounds. 1X. The isolation of a dimer with a benzylisochroman structure from the hydrogenolysis products of aspen lignin

KENICHI SUDO[1] AND JAMES M. PEPPER

*Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0*

Received September 25, 1981

KENICHI SUDO and JAMES M. PEPPER. Can. J. Chem. **60**, 229 (1982).

A dimer with a benzylisochroman structure, **1**, has been isolated from the products of the catalytic (Rh—C) hydrogenolysis of aspen lignin.

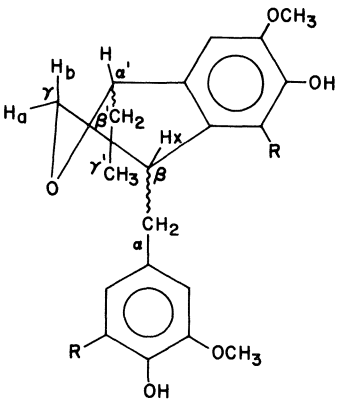
KENICHI SUDO et JAMES M. PEPPER. Can. J. Chem. **60**, 229 (1982).

Des produits résultant de l'hydrogénolyse de la lignin de peuplier catalysée par le (RH—C), on a isolé un dimêr ayant la structure du benzylisochromane (**1**).

[Traduit par le journal]

In a previous paper (1) of this series, several monomeric and dimeric lignin-derived compounds were isolated and identified from the products resulting from the hydrogenolysis of aspen wood (*Populus tremuloides*, Michx) using a rhodium-on-charcoal catalyst. The 51.6 g of chloroform-soluble lignin products (from 400 g wood) were separated into several fractions (A → P) by silica gel chromatography. Fractions C, D and L were discussed earlier. Here we discuss the characterization of a new lignin dimer isolated from Fraction E (3.2 g). Successive column chromatographic separations using silica gel (cyclohexane–acetone (6:1) as eluant), cellulose (xylene–dimethylformamide (15:1) as eluant), silica gel (petroleum ether – diethyl ether (2:1) as eluant), silica gel (cyclohexane – ethyl acetate – absolute ethanol (20:1:1) as eluant), and finally cellulose (xylene–dimethylformamide (25:1) as eluant) resulted in the isolation of pure compound **1** (34.2 mg). Each separation was monitored by thin layer chromatography, developed with toluene – formic acid – ethyl formate (5:1:4), followed by spraying with 50% sulfuric acid and heating to 105°C.

The benzylisochroman-type structure for **1** was determined as follows. The high resolution mass spectrum of the acetate of **1** indicated a molecular formula of $C_{26}H_{32}O_9$ (*m/z* 488.2036). The low resolution spectrum of **1** revealed the molecular ion and base ion peaks at *m/z* 404 and 375 ($M^+$—·$CH_2$-$CH_3$) respectively. Other prominent peaks occurred at *m/z* 237 and 167 ($C_\alpha$—$C_\beta$ cleavage) and at *m/z* 209 ($C_{\alpha'}$—$C_{\beta'}$ cleavage of fragment 237 with hydrogen rearrangement).



**1** R = $OCH_3$
**2** R = H

The $^1$HMR spectrum of **1** (as diacetate) revealed absorptions which were assigned as follows: δ0.98 (t, 3H, $H_{\gamma'}$, $J$ = 7.0 Hz); δ1.87–2.12 (m, 2H, $H_{\beta'}$); δ2.33 (s, 6H, aryl—OAc); δ2.90–3.06 (m, 2H, $H_\alpha$); δ3.57–3.68 (1H, $H_\beta$ overlapped with singlet peak of δ3.63 of aryl methoxy); δ3.63 (s, 3H, aryl—$OCH_3$); δ3.70–3.98 (m, 2H, $H_\gamma$); δ3.76 (s, 9H, aryl—$OCH_3$); δ4.82 (t, 1H, $H_\alpha$, $J$ = 4.64 Hz); δ6.09 (s, 1H, aryl—H); δ6.36 (s, 2H, aryl—H). Irradiation at the centre of the multiplet at δ1.87–2.12 reduced the triplets at δ0.98 and δ4.82 to singlets. Irradiation at the centre of the triplet at δ0.98 reduced the multiplet at δ1.87–2.12 to a doublet ($J$ = 4.64 Hz). The multiplet at δ3.70–3.98 ($H_\gamma$) would appear to be two quartets with centres at δ3.78 and 3.92 resulting from coupling of $H_a$ and $H_b$ of $C_\gamma$ with $H_x$ of $C_\beta$ ($J$ = 3.0 Hz) and of $H_a$ and $H_b$ with each other

($J$ = 11 Hz). These assignments are similar to those reported for compound **2** which Yasuda and Sakakibara (2) isolated from the products of the catalytic (copper chromite) hydrogenolysis of compression wood of Karamatsu (*Larix leptolepis* Gord.).

The present work provides evidence for the presence in normal wood lignin of the benzylisochroman structure with $C_\alpha$ and $C_\beta$ linkages. Under the reported conditions of hydrogenolysis, it is difficult to envisage its formation from other accepted structural units of lignin. Indeed, the presence in the lignin macromolecule of structural units such as **1** may be the origin of the trimethoxy-*o*-phthalic acid that has been reported by Freudenberg and Chen (3) as a product obtained by the permanganate oxidation of methylated hardwood lignin.

Received June 24, 1981

D. MÉNARD, M. ST-JACQUES, and J. F. BAGLI. Can. J. Chem. **60**, 231 (1982).

The energy barrier for the reversible substituent migration was determined for a number of 2-acyl and 2-silyl derivatives of tropolone. The energy barrier is found to be dependent on the nature of the migrating group. Asymmetric monosubstitution on the ring shifts the equilibrium in favor of one dynamic isomer. In the two cases studied (3-bromotropolone and 3-bromotropolone acetate) it is found that the equilibrium is shifted towards the isomer bearing the bromine atom at the 7-position.

D. MÉNARD, M. ST-JACQUES et J. F. BAGLI. Can. J. Chem. **60**, 231 (1982).

Nous avons mesuré la barrière énergétique pour le processus de migration réversible du substituent en position 2 de quelques dérivés acylés et silylés de la tropolone. La nature du groupe migrateur modifie l'énergie d'activation autant dans le cas des dérivés acylés que dans le cas des dérivés silylés. La présence d'une substitution asymétrique sur le cycle déplace l'équilibre vers un seul isomère dynamique. Dans les deux cas étudiés (bromo-3-tropolone et acétate de bromo-3-tropolone) nous avons montré que l'équilibre favorise l'isomère portant l'atome de brome à la position 7.

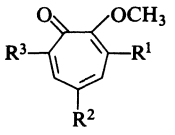
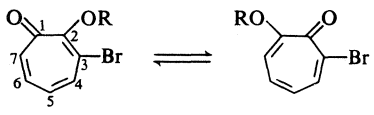
Parallel to other studies on the pharmaceutical activity of tropone and tropolone derivatives (1), we have recently reported on the additivity of substituent effects on $^{13}C$ nmr chemical shifts for a number of 2-methoxytropone derivatives **1** and have shown that $^{13}C$ nmr is quite useful to distinguish between various isomers in the 2-methoxytropone family (2). A more challenging task involves the identification of the dynamic isomer favored by nonsymmetric tropolones and tropolone derivatives for which the 2-substituent is capable of rapid migration at room temperature of the type illustrated by **2***a* ⇌ **2***b*.



**1**

$R^1, R^2, R^3$ = H, Br, $CH_3$, $OCH_3$, $CH_2CO_2CH_3$



R = H : **2***a* **2***b*
R = Ac: **3***a* **3***b*

It is well known that tropolone acetate undergoes rapid intramolecular acetyl migration at room temperature (**4***a* ⇌ **4***b*) for which $\Delta G^{\ddagger}$ is 10.8 kcal/mol (3*a*). The nonaveraging spectrum can be recorded below −60°C for which the correct line assignment was published in a previous paper in this series (3*b*). A similar exchange process has been observed in substituted tropolone acetates such as 3,7-dibenzyltropolone acetate for which $\Delta G^{\ddagger}$ was found to be 8 kcal/mol (4).

While investigating rearrangements of trialkylsilyl groups bonded to electronegative elements, Reich and Murcia (5) noted that the room temperature $^{13}C$ nmr spectrum of 2-(2-butyldimethylsiloxy)tropone contains only 4 lines, indicating a fast exchange of the trialkylsilyl group between the two oxygen atoms on the tropolone ring (**5***a* ⇌ **5***b*). In addition, they reported line broadening at about −70°C, but the slow exchange spectrum was not observed. Nevertheless, the authors estimated that $\Delta G^{\ddagger}$ for the silyl group migration is about 8.2 kcal/mol. A similar observation was reported by Hobson and co-workers (6) who prepared the trimethylsilyl ethers of tropolone (**6**) and 3-bromotropolone (**7**) and studied their $^1H$ nmr spectra down to −95°C. No significant change was observed for solutions of both trimethylsilyl ethers in toluene-$d_8$, thus indicating a significantly lower energy barrier for the exchange process.

Very few studies concerned with the identifica-

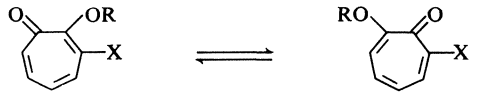
tion of the major isomer adopted by unsymmetrically substituted tropolones have been reported in the literature. In 1968, Sugiyama (7) used $^1H$ coupling constants and chemical shifts arguments to suggest that the 3-Br form (**2***a*) is favored relative to **2***b*.



R = Ac; X = H : **4***a* **4***b*

R = $-Si(CH_3)_2CH(CH_3)_2$; X = H : **5***a* **5***b*

R = TMS; X = H : **6***a* **6***b*

R = TMS; X = Br: **7***a* **7***b*

R = TBDMS; X = H : **8***a* **8***b*

R = COPh; X = H : **9***a* **9***b*

In the present work, we report the $\Delta G^{\ddagger}$ value for **6** as well as for other rapidly equilibrating 2-substituted tropolone derivatives. A quantitative description of the dynamic features of these compounds will be presented and extended to nonsymmetric derivatives such as **2** and **3**. Our results show clearly that the published conclusion (7) for **2** is wrong.

## Results and discussion

The partial 22.63 MHz $^{13}C$ nmr spectra of 2-trimethylsiloxytropone (**6**) at several temperatures are shown in Fig. 1. The room temperature spectrum is almost identical to that of the 2-(2-butyldimethylsilyl) derivative investigated by Reich and Murcia (5). At −109°C, the signals of C-3,7 and C-5 overlap but significant broadening is not yet observed. Maximum broadening takes place at −139°C, the coalescence temperature, below which a slow exchange spectrum can be recorded. At −155°C, the low field region of the spectrum of **6** contains 7 lines, one for each carbon of the tropolone ring. The splitting pattern of the C-3,7 signal is represented in Fig. 1. A $\Delta G^{\ddagger}$ of 5.7 kcal/mol was calculated at the coalescence temperature. This value is much lower than the 10.8 kcal/mol determined for the acetate derivative and it suggests that migration of a silyl group is easier than migration of an acyl group. The chemical shifts and $\Delta G^{\ddagger}$ values for all compounds investigated are summarized in Table 1.

In order to test the sensitivity of this barrier to the size of the migrating silyl group we have prepared 2-*tert*-butyldimethylsiloxytropone **8** and have studied its $^{13}C$ nmr (20 MHz) spectrum as a function of temperature. Again the room temperature spectrum contains 4 lines and is similar to the

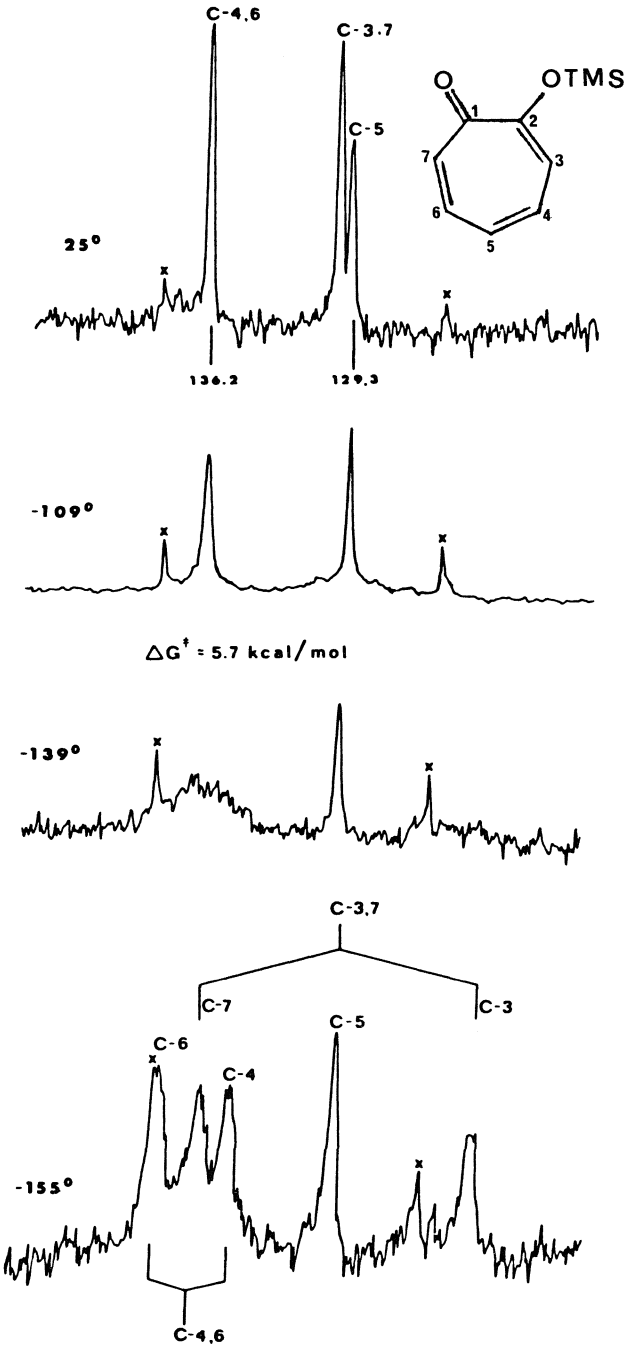


FIG. 1. The partial 22.63 MHz $^{13}C$ nmr spectra of **6** in $CHFCl_2$ at several temperatures (x denotes tropolone impurity). Flip angle = 30°; SW = 6024 Hz; data size = 8K.

spectra of **5** and **6**. As the temperature is lowered to −80°C, broadening occurs; maximum broadening is observed at −104°C, the coalescence temperature for carbons 3 and 7, and finally a well-resolved slow exchange spectrum is recorded at −130°C. A

[a] Values taken from ref. 10*b*.
[b] Values taken from ref. 10*a*.

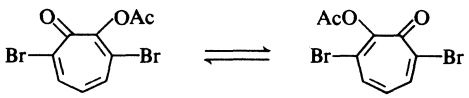
$\Delta G^{\ddagger}$ value of 7.3 kcal/mol can be calculated for **8**, indicating that increasing the size of the migrating silyl group raises the energy barrier of the process.

Studies on the lability of *O*-silyl derivatives of *cis* enols of 1,3-diketones (8) have shown that the energy barrier of the migration process is lowered as the polarity of the migrating group increases, presumably because an increase in the electron withdrawing ability of the substituent results in a greater positive charge on silicon and facilitates the use of a d-orbital in achieving the transition state. These results are consistent with a mechanism involving the formation of a five-coordinated silicon intermediate of the type proposed by Reich and Murcia (5). It appears, however, that polarity effects alone cannot account for the 1.6 kcal/mol difference in $\Delta G^{\ddagger}$ observed between **6** and **8** and that steric effects must also contribute to the energy required for the activation process.

Figure 2 illustrates the 100 MHz $^{13}C$ nmr spectrum of tropolone benzoate (**9**) recorded at 20° and −80°C. The room temperature spectrum contains only five signals while there are nine nonequivalent sites on the molecule: four belong to the tropolone ring and five to the benzoate group. Distinguishing between these two types of signals is straightforward since the latter remain unaffected by the temperature change. The slow exchange spectrum of **9** recorded at −80°C contains all 12 expected lines. The assignment of the tropolone carbons in Fig. 2 (and Table 1) respects the order of chemical shifts found for tropolone acetate and 2-methoxytropone (2). The phenyl carbons are assigned directly by comparison with the chemical shifts observed for methyl benzoate. Only the C-5 and C-12 lines cannot be assigned unambiguously because of their proximity.

From the coalescence temperature of −23°C observed for C-4,6 at 20 MHz for this compound, a $\Delta G^{\ddagger}$ of 11.5 kcal/mol is calculated. This value is 0.7 kcal/mol higher than what has been observed for tropolone acetate **4**, indicating that migration of an acetyl group is easier than migration of a benzyl group. A similar behaviour has been observed for *O*-acyl derivatives of the *cis* enols of 1,3-diketones in which replacement of acyl by benzyl raises the energy barrier from 15.4 kcal/mol to 16.3 kcal/mol (9).

The potential influence of ring substituents on the energy barrier of acetyl migration suggested from the published $^1H$ dnmr results for 3,7-dibenzyltropolone acetate (4) was investigated further through analysis of the variable temperature spectra of 3,7-dibromotropolone acetate (**10**).



**10***a* **10***b*

Under ordinary recording conditions, the room temperature 20 MHz $^{13}C$ nmr spectrum of **10** shows only three signals instead of five for the unsaturated carbons. Assignments are straightforward from intensity and chemical shifts considerations: there is an intense line at 138.9 ppm which is due to the equivalent C-4 and C-6 carbons and a less intense line at 129.0 ppm which is due to C-5. The weak line observed at 136.7 ppm is due to the nonprotonated C-3,7 carbons. At −100°C, the low field region of

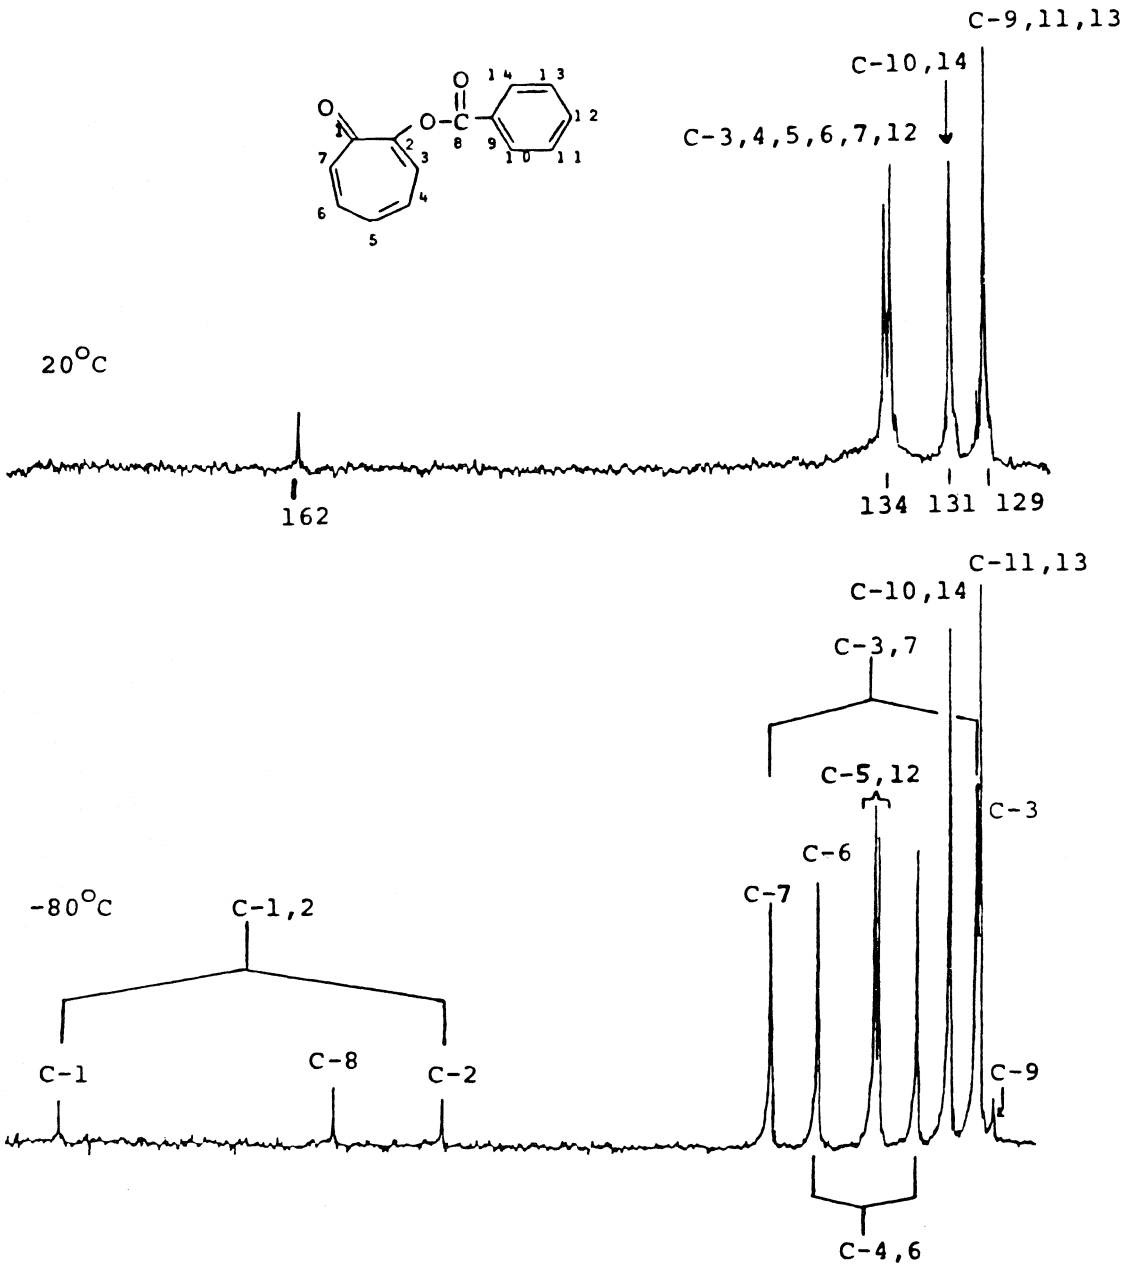

FIG. 2. The 100 MHz $^{13}C$ nmr spectra of **9** in $CHFCl_2$ at 20°C and −80°C. Flip angle = 25°; SW = 8064 Hz; data size = 8K.

the spectrum of **10** contains all expected 8 lines: the C-4,6 line has split into a doublet with components at 140.8 and 138.7 ppm while the C-3,7 line has also split into a doublet with components at 142.8 and 137.8 ppm. The C-1,2 line and the C-8 carbonyl line which were not observed at room temperature are now visible in the slow exchange spectrum: C-1 and C-2 appear at 171.8 and 153.1 ppm respectively.

A $\Delta G^{\ddagger}$ of 10.9 kcal/mol for the acetyl migration process is calculated at the coalescence temperature of −43°C observed for the C-4,6 signal. This value is very similar to that observed for tropolone acetate, indicating little influence of the two adjacent bromine substituents on the energy barrier of the migration process.

At this point it should be mentioned that the energy barrier for tautomerization in tropolone itself is too low for it to be amenable to an

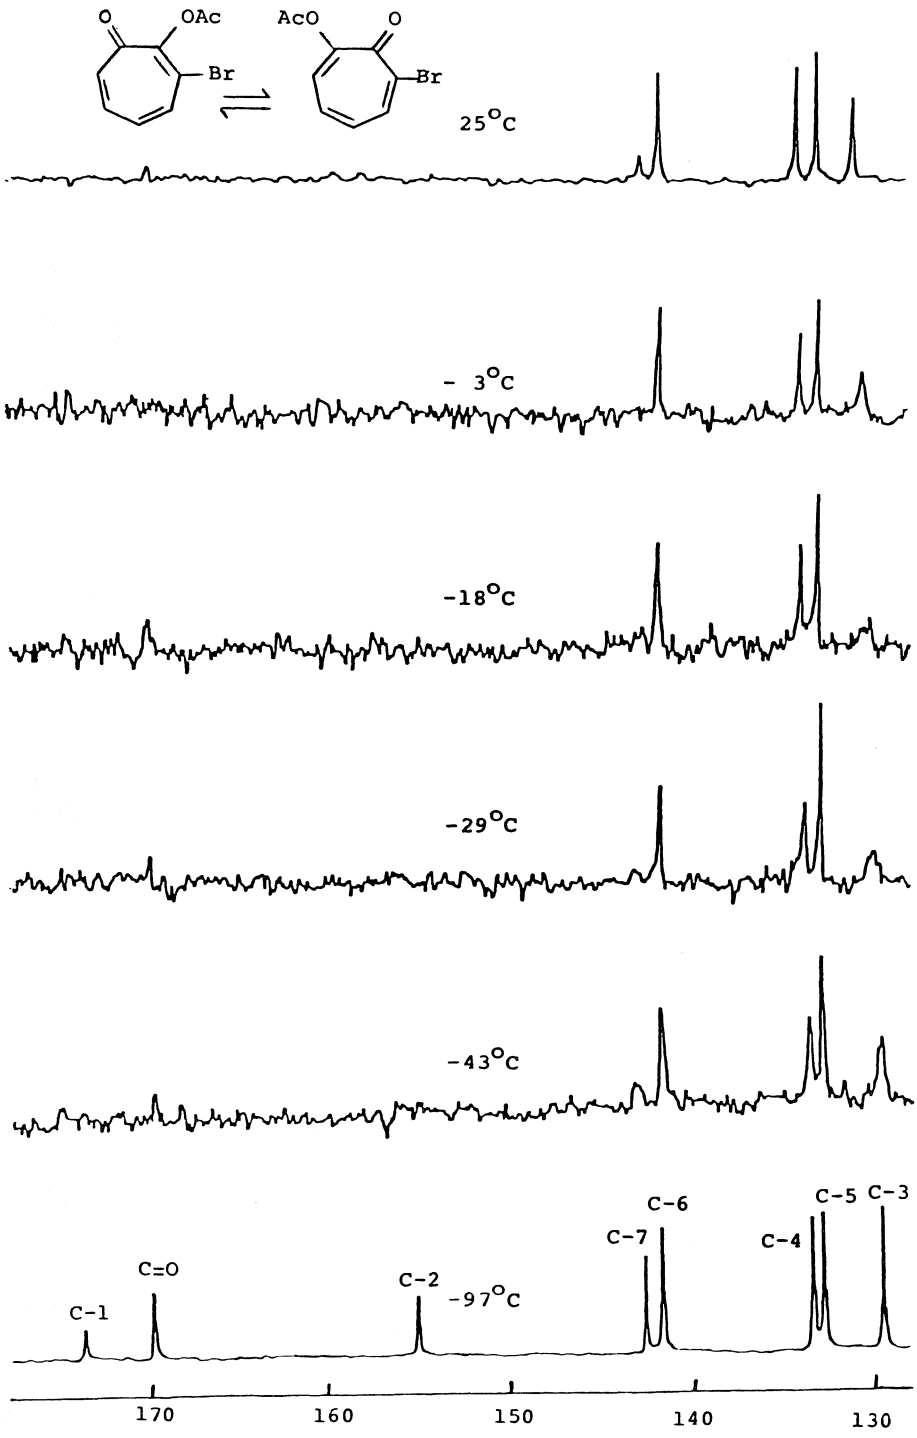

FIG. 3. The 20.15 MHz $^{13}C$ nmr spectra of **3** in $CHFCl_2$ at several temperatures. Flip angle = 35°; SW = 6024 Hz; data size = 8K.

investigation in solution by dynamic nmr techniques and our efforts to determine $\Delta G^{\ddagger}$ for tautomerization by nmr have failed. On the other hand, the 25 MHz $^{13}C$ nmr spectrum of tropolone in the solid state has recently been recorded by Fyfe (10*a*); it contains 7 lines, indicating that proton exchange is slow in the solid state. The chemical shifts of all 7 nonequivalent carbons in tropolone

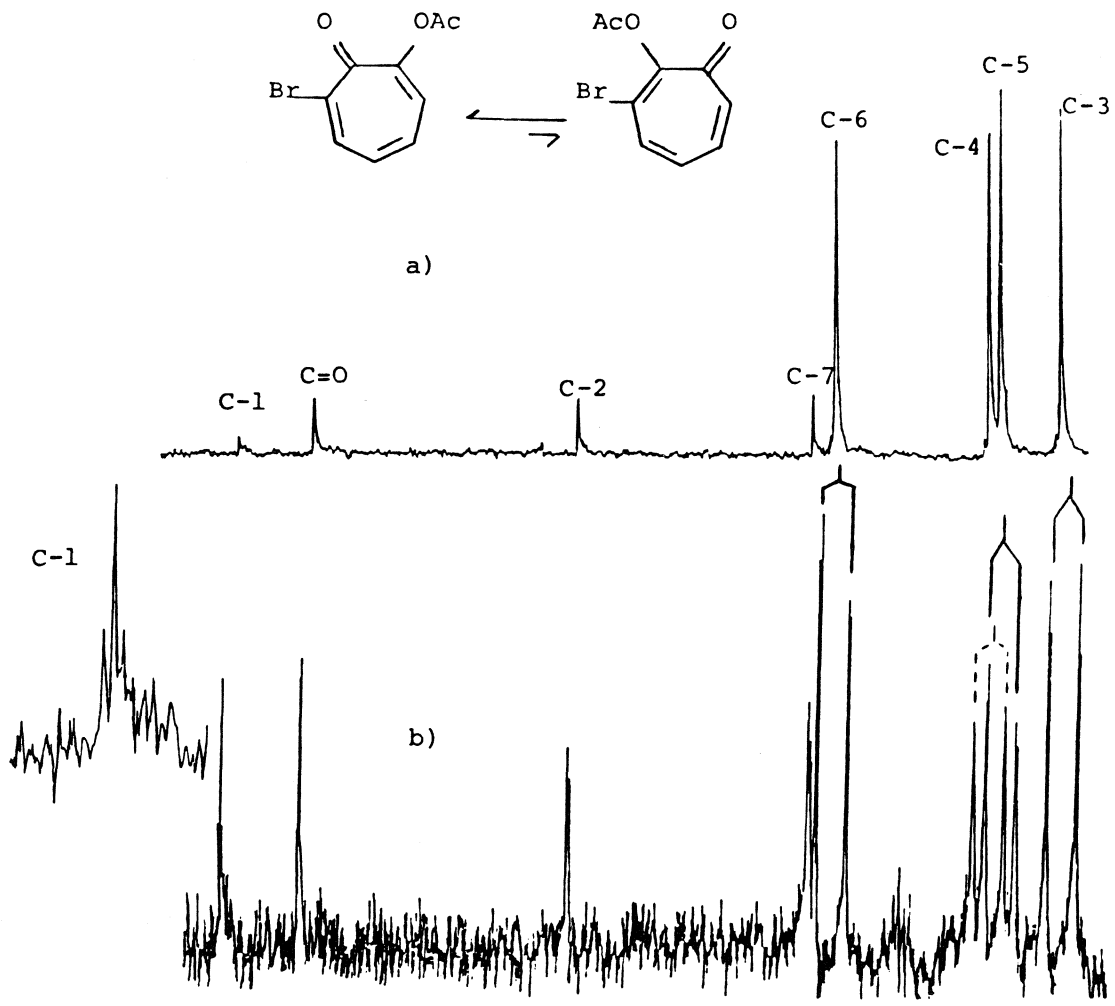

FIG. 4. The 100 MHz $^{13}C$ nmr spectra of **3** in $CHFCl_2$ at −80°C; (a) broad band decoupling; (b) gated decoupling. Flip angle = 25°; SW = 10 000 Hz; data size = 8K.

obtained from that spectrum are given in Table 1. When averaged, these chemical shifts closely match those observed in $CDCl_3$ solution (10*b*).

We now turn our attention to unsymmetrical, singly substituted derivatives at C-3 or C-7, such as **2** and **3**.

Figure 3 illustrates the variable temperature 20 MHz $^{13}C$ nmr spectra of **3** in $CHF_2Cl$ solution. It is immediately apparent that no major changes are observed in the spectrum as the temperature is lowered. At −97°C, the acetyl migration process should be slow and indeed the line broadening observed at intermediate temperatures for the smaller 142.9 and 129.6 ppm lines clearly indicates that the process has been slowed down (11). This absence of new signals suggests that the molecule exists predominantly in only one form. The total absence of weak signals at low temperature and the line broadening phenomenon at intermediate temperatures show that if a minor isomer existed it would account for less than 2% in the **3***a* ⇌ **3***b* equilibrium (11). There thus remains the task of identifying the nature of this predominant isomer, namely that which bears the bromine atom at the 3-position (**3***a*) or at the 7-position (**3***b*).

Our earlier work (2) suggested that substituent effects on $^{13}C$ chemical shifts might allow the determination of the structure of the favored isomer of **3**. Unfortunately the required substituent parameters are not available for the 2-acetoxy derivative but only for the 2-methoxy derivative. Predicted chemical shifts for **3***a* and **3***b* lead to the suggestion that **3***b* is more compatible with the observed spectrum of **3**. On the other hand, no obvious convergence is observed when this method is applied to **2**.

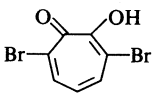
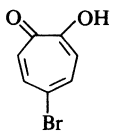
Because carbon–proton coupling constants through three bonds ($^3J_{CH}$) offered an alternate probe for locating the position of the bromine atom, proton coupled $^{13}C$ nmr spectra were recorded and analysed. It is well known (12) that in aromatic systems the magnitude of $^1J_{CH}$ coupling constants is close to 160 MHz while $^2J_{CH}$ are smaller (<3 Hz) and frequently nonresolved. Values for $^3J_{CH}$, on the other hand, usually range from 7 to 11 Hz and lead to clearly recognizable patterns in fully coupled $^{13}C$ nmr spectra (12); they therefore constitute a convenient method for determining the number of protons β to a given carbon.

The 20 MHz $^{13}C$ nmr coupled spectrum of 3,7-dibromopolone (**11**) shows that the averaged C-1,2 signal appears as a doublet ($^3J_{CH}$ = 8.8 Hz) because these equivalent carbons are coupled to only one β proton which constitutes a mean of H-6 and H-4. Similarly, the averaged C-1,2 signal in the coupled spectrum of 5-bromotropolone (**12**) appears as a triplet ($^3J_{CH}$ = 9.8 Hz) since both carbons are at all times coupled to two β protons. These results suggest that in the case of the nonsymmetric compounds **2** and **3**, if the 3-Br form was predominant, the C-1 signal should appear as a doublet (coupling with H-6) and the C-2 signal as a triplet (coupling with H-7 and H-4), while the reverse should be observed if the 7-Br form was predominant.



**11**



**12**

The 100 MHz coupled $^{13}C$ nmr spectrum of **3** at −80°C (Fig. 4) clearly shows that the C-1 signal appears as a triplet ($^3J_{CH}$ = 9.8 Hz) thereby proving unambiguously that ***3b*** is the major isomer adopted by this molecule. In this case, the C-2 signal revealed additional coupling to $^3J_{CH}$ and is therefore of little use. Similarly, the room temperature 100 MHz coupled $^{13}C$ nmr spectrum of **2** shows that the C-1 signal is a triplet ($^3J_{CH}$ = 8.3 Hz) and the C-2 signal is a doublet ($^3J_{CH}$ = 11.1 Hz), thus confirming that the 7-Br form is also favored by this molecule. This conclusion disproves the earlier claim (7), based on the interpretation of $^1H$ nmr parameters, that ***2a*** should be the more favored form.

## Experimental

Melting points are uncorrected and were determined using a Büchi melting point apparatus. The vpc analyses and separations were carried out on a Varian-Aerograph model 920 instrument using helium as carrier gas.

The variable temperature $^{13}C$ nmr spectra were recorded in the FT mode with Bruker WP-80, WH-90, or WH-400 instruments operating respectively at 20.15, 22.63, and 100.0 MHz and equipped with a Bruker variable temperature accessory. Unless otherwise mentioned, all $^{13}C$ spectra were recorded with proton noise decoupling for solutions in dichlorofluoromethane (100–150 mg in 2.2 mL of solution) containing TMS and about 19% of $CD_2Cl_2$ (for locking purposes) in standard 10 mm tubes which had been degassed and sealed. In the case of 20.15 MHz and 22.63 MHz spectra, temperatures were measured accurately with a calibrated copper–constantan thermocouple placed inside a solvent-containing dummy nmr tube. A precision of ±1°C is expected. $CDCl_3$ solutions containing TMS were used for samples studied only at room temperature. Coupled spectra were recorded using the gated decoupling technique with the decoupler on for 15 s and then switched off 0.005 s before the pulse.

The rate constants were estimated at the coalescence temperature using the equation $k = \pi\Delta\nu/\sqrt{2}$. The free energy values ($\Delta G^{\neq}$) were calculated from standard equations (13) using a transmission coefficient of one-half.

*Synthesis of compounds*

*Monobromotropolone acetate (**3**)*

To a solution of monobromotropolone (**2**) (14) (9.64 g, 48 mmol) in chloroform (12 mL) and pyridine (4.8 mL) was added a solution of acetyl chloride (4.08 mL) in chloroform (8 mL) with cooling. The mixture was stirred for 3 h at room temperature, diluted with chloroform, washed with water, and dried. The solvent was removed to yield the crude acetate. The product was purified by column chromatography to yield the pure product (5.2 g, 44.5%), mp = 72–74°C; *m/e*: 244/242 ($M^+$), 202/200 ($M - COCH_2)^+$, 174/172 [$M - (COCH_3 + CO)$]$^+$.

*2-Trimethylsiloxytropone (**6**)*

Tropolone (0.50 g, 4.1 mmol), pyridine (3 mL), hexamethyldisiloxane (2.7 mL), and chlorotrimethylsilane (1.54 mL, 12.3 mmol) were allowed to react at room temperature for 15 min. The mixture was decanted and 100 μL samples of the resulting clear solution were analysed and separated by gas chromatography. A yellow oil (250 mg) still containing tropolone impurities was obtained after separation on a SE-30 5% column (5 ft × ¼ in.). The $^1H$ nmr spectrum was similar to that already published (6) and the $^{13}C$ nmr data in Table 1 and Fig. 1 confirm the structure; *m/e*: 194 ($M^+$), 179 ($M - CH_3)^+$.

*2-tert-Butyl dimethylsiloxytropone (**8**)*

Tropolone (0.5 g, 4.1 mmol), *tert*-butyldimethylsilyl chloride (1.88 g, 12.5 mmol), and pyridine (1 mL) in hexane (13 mL) were stirred for 3 h and then refluxed for 15 h. The solution was filtered and the residue washed with hexane. Evaporation of the filtrate under reduced pressure gave 0.53 g (55%) of a pale beige solid, mp = 45°C. The structure of this compound was characterized by $^{13}C$ nmr (Table 1); *m/e*: 221 ($M - CH_3)^+$, 179 [$M - (CH_3)_3C$]$^+$.

*Tropolone benzoate (**9**)*

This compound was prepared according to the method reported by Doering and Knox (15). Yield 42.2%, mp = 130°C (lit. (15) yield 31%; mp 130°C).

*3,7-Dibromotropolone (**11**)*

A solution of tropolone (20 g, 160 mmol) in methanol (200 mL) was cooled between −10° and −15°C. Bromine (58 g, 360 mmol) was then added over a period of 30 min while keeping the temperature at −15°C. After the addition, the bath was removed and the reaction mixture was allowed to reach room temperature. Excess bromine was blown out with a stream of nitrogen. The crude product which precipitated was filtered to give a mixture (32.6 g) of 3,7-dibromo and 3,5,7-tribromotropolone.

Recrystallization from methanol gave the pure product (15.6 g, 30.3%), mp = 153–155°C (lit. (16) mp 159–160°C); *m/e*: 278/280/282 ($M^+$, 100%), 250/252/254 [$(M - CO)^+$, 75%], 199/201 [$(M - Br)^+$, 5%]. *Anal.* calcd. for $C_7H_4O_2Br_2$: C 30.04, H 1.44; found: C 30.23, H 1.5. A second crop (16.9 g), also free of tribromo impurity, was obtained on concentration of the solution. Total yield: 43.7%.

*3,7-Dibromotropolone acetate (**10**)*

To a solution of 3,7-dibromotropolone (1.68, 60 mmol) in chloroform (1.5 mL) and dry pyridine (0.6 mL) was added dropwise a solution of acetyl chloride (0.54 mL, 6.6 mmol) in chloroform (1 mL). The mixture was stirred at room temperature for 4 h. The reaction mixture was diluted with chloroform, washed with water, dried, and the solvent was removed to yield the crude product (1.71 g). This was purified by filtering through silica gel to yield the pure product (0.64 g, 33%), mp = 110–112°C; *m/e*: 320/322/324 $(M)^+$, 277/279/271 $(M - COCH_3)^+$, 249/251/253 $[M - (COCH_3 + CO)]^+$.

*5-Bromotropolone (**12**)*

To a suspension of 5-aminotropolone (17) (5 g, 36.5 mmol) in water (34 mL) was added hydrobromic acid 48% (222 mL, 1168 mmol). The mixture was cooled to −10°C and stirred for 15 min. Sodium nitrite (2.5 g) in water (17.2 mL) was added to the mixture over 5 min. The temperature was maintained at −10°C for 1.5 h. The mixture was then allowed to warm up to room temperature over one hour, heated to 45°C for one hour, and then cooled to room temperature. The mixture was then poured on crushed ice (400 g), filtered, and the solid washed with water. The crude solid (3.5 g) was dissolved in chloroform and filtered. The filtrate was treated with charcoal, dried over magnesium sulfate, and filtered. The solvent was removed and the residue (12.7 g) crystallized from chloroform–hexane to yield 1.8 g (24.5%) of pure product, mp = 189–190°C (lit. (18) mp 188°C); *m/e*: 200/202 ($M^+$, 60%), 172/174 [$(M - CO)^+$, 100%], 93 $[(M - (CO + Br)]^+$, 10%].

Reçu le 5 mai 1981

BERNARD BOYER, GÉRARD LAMATY, CLAUDE MOREAU et PATRICK GENESTE. Can. J. Chem. **60**, 239 (1982).

Les constantes de vitesse d'addition du borohydrure de sodium sur les cyclanones angulairement contraintes, tricyclo[3.3.1.$1^{3,7}$]-décanone-2 (**1**), bicyclo[3.3.1]nonanone-9 (**2**), bicyclo[3.2.1]octanone-8 (**3**) et bicyclo[2.2.1]heptanone-7 (**4**), ont été mesurées dans un mélange eau–dioxanne 50:50 en volumes à 25.0°C. Elles mettent en évidence les énergies dues à la variation de tension angulaire lorsque l'on passe de l'état initial à l'état de transition. Les énergies d'activation mesurées, représentant presque la totalité de l'énergie associée à cette variation de tension angulaire, sont significatives d'un état de transition tardif.

La comparaison des constantes de vitesse de réduction de ces cétones où le carbone siège de la réaction passe d'un état d'hybridation $sp^2$ à un état d'hybridation $sp^3$ avec les vitesses d'oxydation chromique des alcools correspondants qui impliquent le changement d'hybridation opposé montre que l'importance de la variation angulaire peut également servir de critère pour déterminer la position de l'état de transition le long du chemin réactionnel.

BERNARD BOYER, GÉRARD LAMATY, CLAUDE MOREAU, and PATRICK GENESTE. Can. J. Chem. **60**, 239 (1982).

The rate constants for addition of sodium borohydride on the angularly constrained cyclic ketones, tricyclo[3.3.1.1.$^{3,7}$]-2-decanone (**1**), bicyclo[3.3.1]-9-nonanone (**2**), bicyclo[3.2.1.])-8-octanone (**3**), and bicyclo[2.2.1.]-7-heptanone (**4**), have been determined in water/dioxane (50:50 v/v) at 25°C. These values demonstrate the energy differences caused by the changes in torsion angles on passing from the initial state to the transition state. The activation energies determined, representing almost all of the energy associated with the angular torsion, are indicative of a late transition state.

Comparison of rate constants for the reduction of these ketones where the reaction site carbon changes from $sp^2$ to $sp^3$ hybridization with the rates for chromic acid oxidation of the corresponding alcohols (opposite change of hybridization) demonstrates that the effects of the angular variations can also act as criteria for the determination of the position of transition states along the reaction pathway.

[Journal translation]

## Introduction

Dans un précédent article (1), nous avons montré que les constantes de vitesse d'addition du borohydrure de sodium sur des cyclanones stériquement encombrées et les constantes de vitesse d'oxydation chromique des cyclanols correspondants mettaient en évidence les énergies dues aux interactions diaxiales-1,3 lorsque l'on passe de l'état initial à l'état de transition. Cette mise en évidence avait été rendue possible en utilisant plus rationnellement les données conformationnelles, c'est à dire en choisissant des modèles de façon à ne faire varier qu'un seul facteur de réactivité.

Nous souhaitons présenter ici le travail que nous avons effectué afin de mettre en évidence, cette fois, les énergies dues à la variation de tension angulaire lorsque l'on passe d'un état d'hybridation $sp^2$ à un état d'hybridation $sp^3$ et inversement. Les modèles dont le squelette est une cyclohexanone chaise ou une cyclopentanone enveloppe ont été choisis de façon à maintenir constants les autres facteurs de réactivité tels que les interactions diaxiales-1,3, l'hyperconjugaison ou les barrières de torsion.

Notre étude a porté sur la réduction des cyclanones angulairement contraintes **1** à **4** et sur la comparaison avec l'oxydation chromique des cyclanols correspondants **5** à **8**, résultats obtenus dans notre laboratoire (2) ou cités par d'autres auteurs (3).

## Résultats expérimentaux

Les constantes de vitesse d'addition du borohydrure de sodium ont été déterminées à 25.0°C dans un mélange eau–dioxanne 50:50 en volumes, la phase aqueuse contenant 0.05 mol/L de soude; dans ces conditions, les solutions de $BH_4Na$ sont stables (1).

Les constantes de vitesse partielles correspondant à une attaque "équatoriale", $k_\alpha$, ont été cal-

culées à partir des constantes de vitesse totales, $k$, et des résultats stéréochimiques obtenus dans la réduction des cétones **1** à **4** ($k_\alpha = k \times \%$ alcool "axial") malgré les réserves suscitées par ce genre de calculs (4). Les résultats expérimentaux sont rassemblés dans le tableau 1.

## Interprétation des résultats et discussion

Nous admettons en première approximation que les cycles portant la fonction cétone ont la même conformation, chaise dans le cas d'une cyclohexanone, enveloppe dans le cas d'une cyclopentanone; dans ces conditions, nous pouvons supposer que, pour tous les produits étudiés, l'approche du nucléophile par la face α sera pratiquement la même et que les interactions synpériplanaires-1,3 qui se développent dans l'état de transition seront également les mêmes.[2]

Dans l'introduction de notre article, nous avons mentionné que le but de notre travail était de faire ressortir le facteur tension angulaire lorsque l'on passe d'un état initial $sp^2$ à un état de transition $sp^3$ et réciproquement; il est a priori possible d'évaluer l'énergie associée à la variation de tension angulaire entre un état d'hybridation trigonal et un état d'hybridation tétragonal à l'aide des équations énergétiques établies par Allinger *et al.* (7); les calculs ont été effectués antérieurement pour les produits que nous avons étudiés et sont rassemblés dans le tableau 2.

Le tableau 2 fait apparaitre que l'énergie associée à la variation de tension angulaire entre un état d'hybridation $sp^2$ et un état d'hybridation $sp^3$ est d'autant plus importante que le système est contraint; en d'autres termes, plus le système sera contraint, plus il tendra à se libérer de cette contrainte. Si donc la réactivité de nos produits est influencée d'une manière prépondérante par la tension angulaire, nous devrions observer une correlation entre les valeurs $\delta\Delta E$ calculées et les valeurs $\delta\Delta G_{red}^{\neq}$ expérimentales; en portant $\delta\Delta G_{red}^{\neq}$ en fonction de $\delta\Delta E$ (Fig. 1) on observe effectivement une telle correlation. Et une fois de plus, ces résultats constituent un argument en faveur d'un état de transition tétragonal dans l'addition nucléophile du borohydrure de sodium sur les dérivés carbonylés puisqu'expérimentalement on retrouve environ 80% de l'énergie calculée.

## Comparaison avec l'oxydation chromique des alcools

La comparaison de la réactivité des cyclanones vis-à-vis de $BH_4^-$, où le carbone siège de la réaction passe d'une hybridation $sp^2$ à une hybridation $sp^3$, avec l'oxydation chromique des alcools secondaires correspondants (2) qui implique le changement d'hybridation opposé, met en évidence un comportement symétrique (1, 13).

Il était donc intéressant de comparer les réactivités dans le cas de nos composés et à côté de nos résultats obtenus dans la réduction des cétones nous avons fait figurer dans le tableau 3 les résultats relatifs à l'oxydation chromique des alcools correspondants, résultats obtenus dans notre laboratoire (2) ou cités par d'autres auteurs (3).

Le tableau 3 montre qu'à une augmentation de la

[2] En toute rigueur, les liaisons impliquées dans ce type d'interactions sont axiales dans le cas d'un système cyclohexanique chaise et bissectionnelles dans le cas d'un système cyclopentanique enveloppe.

vitesse de réduction correspond une diminution de la vitesse d'oxydation. Si la tension angulaire est responsable de l'accélération observée dans la réduction des cétones **1** à **4**, elle doit être également responsable du ralentissement observé dans l'oxydation des alcools **5** à **8**; c'est effectivement ce que l'on constate en portant sur un diagramme $\delta\Delta G_{ox}^{\neq}$ en fonction de $\delta\Delta G_{red}^{\neq}$ (Fig. 2).

## Conclusion

Comme nous l'avons déja fait pour un autre facteur de réactivité, l'utilisation de systèmes rigides judicieusement choisis permet, dans le travail

que nous avons présenté, de mettre en évidence par des méthodes cinétiques l'énergie engendrée par la variation de tension angulaire aussi bien dans la réduction des dérivés carbonylés par $BH_4Na$ ($sp^2 \dashrightarrow sp^{3\ddagger}$) que dans l'oxydation chromique des alcools correspondants ($sp^3 \dashrightarrow sp^{2\ddagger}$).

## Partie expérimentale

La synthèse des cétones est décrite dans la littérature: **1** (14), **2** et **3** (5) et **4** (15).

Pour les alcools **5** et **6**, nous avons utilisé les données de laboratoire (2); pour les alcools **7** et **8**, nous avons utilisé les données de la littérature (3).

Les méthodes cinétiques ont été publiées antérieurement (2, 16).

# The preparation of some thiochroman-3-ones and derivatives

PETER D. CLARK AND DAVID M. MCKINNON[1]

*Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2*

Received May 22, 1981

PETER D. CLARK and DAVID M. MCKINNON. Can. J. Chem. **60**, 243 (1982).

The use of 2,3-dihydrobenzo[*b*]thiophene-2,3-dione as a source of 2-mercaptophenylacetic acid permits a convenient preparation of 2-carboxymethylthiophenylacetic acid or derivatives. These undergo a Dieckmann cyclization to 3-acetoxybenzothiopyrans, which may be hydrolysed to thiochroman-3-ones. The further reactions of some of these are described.

PETER D. CLARK et DAVID M. MCKINNON. Can. J. Chem. **60**, 243 (1982).

A partir de la dihydro-2,3-benzo[b]thiophènedione-2,3 on peut préparer l'acide *o*-mercaptophénylacétique permettant une synthèse convenable des acides *o*-carboxyméthylthiophénylacétiques ou de leurs dérivés. On obtient par la réaction de cyclisation de type Dieckmann des acétoxy-3-benzothiopyrrannes qui par hydrolyse conduisent aux thiochromannones-3. On décrit les réactions supplémentaires des quelques'uns de ces composés.

In contrast to thiochroman-4-ones and their derivatives (1) few derivatives of thiochroman-3-ones (1) are reported. The parent compound **1***a* may be made by a Dieckmann or modified Dieckmann cyclization of the diacid **2***a* or of derivatives (2, 3), or by photochemical rearrangement of the isomeric isothiochroman-4-one (2). This latter method was also applied to compounds bearing substituents in the aromatic ring, i.e. the 5-methyl and the 6-methoxy derivatives. In connection with another investigation we wished to prepare some examples of **1** bearing substituents in the heterocyclic ring as synthetic precursors of other heterocyclic systems. This work is reported below.

The diacids **2** may be approached in two ways, by an Arndt–Eistert homologation of ethyl 2-(carboxyphenylthioacetate) (**3**) (3), or by carboxyalkylation of 2-mercaptophenylacetic acid derivatives **4** (3). Our initial experiments using the former method to prepare a phenyl-substituted system were unsuccessful, and it appears that this method has limited value. Our experiments were therefore directed to the latter approach, i.e. from 2-mercaptophenylacetic acid (4). While this key acid may be made starting from 2-nitrophenylacetic acid (4), this approach limits the scope of the method. In fact a method starting from benzenethiol, via 2,3-dihydrobenzo[*b*]thiophene-2,3-dione (**5**) (5, 6), with certain modifications gives a very convenient preparation of the acid, as the dione **5** may be readily purified by extraction with base. This method is also capable of application to the preparation of other thiochroman-3-ones with substituents on the aromatic ring.

2-Mercaptophenylacetic acid (**4**) reacted with bromoacetic acid in base to provide the known

diacid **2***a*, previously prepared by hydrolysis of its diester (2). For cyclization to **1***a*, Mispelter *et al.* reported the use of acetic anhydride/sodium acetate, followed by aqueous sodium hydroxide, without reporting experimental conditions. In our hands, the treatment of the diacid afforded an oil, which had the properties of an enol-acetate of **1***a*. This compound was assigned the conjugated structure **6***a*, rather than the isomeric **7***a* on the following grounds.

The compound exhibited a 2H singlet at 3.59δ and a 1H singlet at 6.34δ, assigned respectively to the methylene and vinyl protons in **6***a*. Irradiation of the latter resonance produced a larger enhancement of the peak area of the aromatic protons than did the former, by a nuclear Overhauser effect,

consistent with the structure **6***a*. In addition this structure is confirmed by comparison of its nmr spectrum with that of the 2-methyl derivatives **6***b*,*c* described below. For instance, the enol-acetate **6***c*, prepared by an unambiguous synthesis, exhibits no absorption in the region 3.59δ.

The hydrolysis of **6***a* to thiochroman-3-one (**1***a*) gave some problems, but eventually it was found that dilute hydrochloric acid in acetic acid gave satisfactory results.

Likewise, treatment of **4** with ethyl-2-bromopropionate afforded the mono-ester **8***b*. This was not purified but was hydrolyzed directly to **2***b* which underwent cyclization by the above conditions to give an enol-acetate. In view of its similar spectral properties to **6***a* it is assigned the structure **6***b*, and mild acid hydrolysis gave 2-methylthiochroman-3-one (**1***b*). Also, reaction of **4** with 2-bromo-2-methylpropanoic acid afforded the acid **2***c* which cyclized to form the enol-acetate **6***c*. Hydrolysis of this afforded the ketone **1***c*.

The synthesis was then extended to produce the 2-phenyl compound **1***d*. Reaction of **4** with ethyl 2-bromophenylacetate gave the monoester **8***d* which on hydrolysis gave the diacid **2***d*. Cyclization of this afforded a mixture, which after chromatography and crystallization was separated into two components, a crystalline solid and an oil. Both of these had absorptions in the nmr corresponding to acetate methyl groups. The solid component also exhibited two singlets at 4.90 and 6.75δ, consistent with the 2- and 4-protons respectively in the enol acetate **6***d*. The other component could not be separated completely from **6***d*, but its nmr spectrum indicated a peak at 3.69δ which is consistent with the methylene protons in the isomeric enol acetate **7***b*. In contrast to the above cyclizations, i.e. to **6***a*,*b*,*c*, both enol-acetates in this case are conjugated and would be expected to be more comparable in stability.

*d* $R^1 = Ph$, $R^2 = R^3 = H$

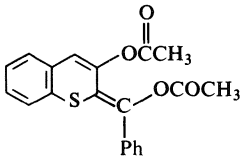
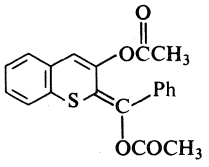
**9**



**10***a*



**10***b*

While the enol-acetate **6***d* hydrolysed cleanly to the ketone **1***d*, the isomer **7***d* gave **1***d* along with highly colored material. Consideration of hydrolysis mechanisms indicates that while for **6***d* the production of **1***d* is the most reasonable reaction, for **7***d* a competing reaction involving initial protonation at C-3 could lead to decomposition products.

When 2-phenacylthiophenylacetic acid (**9**), prepared by treatment of **4** with phenacyl bromide, was heated with the acetic anhydride/sodium acetate mixture, a dark green solution was obtained. This appeared to possess two main components, one of which was obtained as pale yellow crystals, whose analysis and properties were consistent with the *bis* enol-acetate **10***a* of the diketone **1***e*. The nmr of this exhibited two $CH_3$ singlets in the region 1.20 and 2.13δ. While the latter is in the usual range for an acetate methyl group, the former is not. However, it may be that one acetate is shielded by the extra aromatic ring. The other component of the mixture was a dark yellow oil but repeated chromatography failed to separate this from impurities. Tentatively it is assigned the structure of a geometrical isomer of **10***a*, i.e. **10***b*. A strongly colored blue component of the mixture was present in only trace amounts.

Attempted hydrolysis of the *bis* enol-acetate **10***a* gave only polymeric and highly colored material. This is not unexpected in view of its 1,3-diene structure.

The ketone **1***a* reacted smoothly with pyrrolidine to form a crystalline enamine, to which was assigned the structure **11**. The nmr spectrum was consistent with this structure rather than the isomeric nonconjugated structure. Reaction with methyl iodide followed by hydrolysis afforded a methyl derivative of **1***a* in good yield. This was not identical to the methyl derivative **1***b* prepared above, confirming its identity as 4-methylbenzothiopyran-3-one (**1***f*). Treatment of **11** with benzoyl chloride afforded, after hydrolysis, 4-benzoylthiochroman-3-one (**1***g*). Since this exhibited a two proton singlet at 3.36δ, and an acidic proton at 16.3δ, it appears to exist as an enolic tautomer, possibly structure **12**.

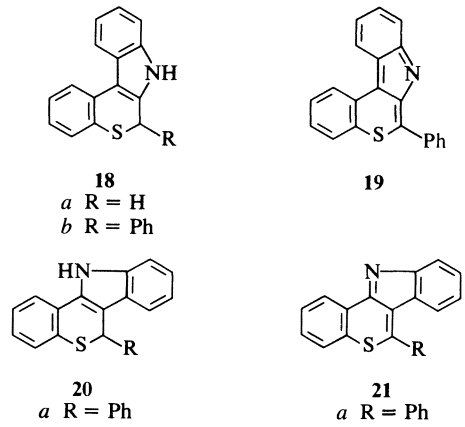
In **1***a* the 4-protons appear to be the more acidic compared to the 2-protons since on treatment with deuterium oxide in the presence of sodium carbonate only the 4-protons were exchanged as determined by nmr. Subsequent treatment with aqueous sodium carbonate regenerated the original spectrum.

When **1***a* was treated with phenylmagnesium bromide it was converted to the alcohol **13**, which dehydrated to 3-phenyl-2-*H*-1-benzothiopyran (**14**) on treatment with acid. This structure is favored over the isomeric structure **15** in view of the similarity of its nmr spectrum to 6-chloro-3-phenyl-2*H*-1-benzothiopyran (7). The compound **14** has been made (8) but no data are reported. Also, treatment with two equivalents of *m*-chloroperoxybenzoic acid afforded a sulfone **16***a*. The differences in chemical shifts of the methylene group in **14** and **16***a* are consistent with those reported for methylene protons adjacent to a sulfide and to a sulfonyl group (9). Oxidation with one equivalent afforded a sulfoxide **19***b*. When this was treated with acetic acid and perchloric acid it produced the known (10) 3-phenylbenzothiopyrylium perchlorate (**17**), although in low yield. The first two stages in a Pummerer type rearrangement of **16** would produce **17**.

While most of the aromatic protons in **12** absorbed in the region δ 7.1–7.6, an absorption at δ 6.73 was also evident, which we attribute to shielding of the 5- and/or 6-protons of the thiopyran ring by the phenyl substituent. The structure **12** has some similar steric features to 4-phenylphenanthrene because of the strong hydrogen bonding of the hydroxyl and carbonyl functions and in 4-phenylphenanthrene and derivatives similar chemical shifts have been observed (11).

The conversion of **1***a* to the condensed indole **18***a*, via a Fischer-type indolization of its phenylhydrazone is reported (2). Likewise **1***d* was converted to its phenylhydrazone which cyclized to the indole **18***b*. The related isomeric dihydrothiopyrano-[4,3-*b*]indoles **20** may be converted into the more conjugated derivatives **21** by dehydrogenation (12, 13) and this was also found for the phenyl-substituted compound **20***a*, prepared by cyclization of 2-phenylthiochromone phenylhydrazone, which formed **21***a* on treatment with chloranil. Under these conditions **18***b* could not be further dehydrogenated. Like **18***a*, **18***b* underwent atmospheric oxidation, but no definite products could be determined.



## Experimental

Unless otherwise stated, $^1$H nmr spectra were obtained in deuteriochloroform solution using tetramethylsilane as an internal standard, on a Varian model E.M. 360 spectrometer. Unless otherwise given, nmr spectra are summarized in Table 1. Mass spectra were obtained on a Finnegan model 1015 spectrometer, and ir spectra on a Perkin Elmer model 337 spectrophotometer. Thick layer chromatography (tlc) was performed on "Camag" Silica gel type D.S.F.S. supplied by Terochem Laboratories, and column chromatography (cc) on 60–200 mesh silica gel supplied by Davison Chemical. Solutions were dried over anhydrous magnesium sulfate.

*2-Mercaptophenylacetic acid (4)*

The starting 2,3-dihydrobenzo[*b*]thiophene-2,3-dione was prepared by the method of Papa *et al.* (5), with the following modifications. The crude product obtained by cyclization of 2-oxo(2-mercaptophenyl)acetyl chloride was dissolved in 20% aqueous sodium hydroxide solution. Impurities (mainly phenyl thioloxalate) were removed by extraction with dichloromethane. Acidification of the cooled solution with concentrated hydrochloric acid gave 2,3-dihydrobenzo[*b*]thiophene-2,3-dione as orange prisms, mp 119–121°C (lit. (5) mp 120–121°C). No further purification was necessary. Conversion of this to **4** was effected by the method of Glauert *et al.* (6). The material was used within one day to minimize spontaneous cyclization to 2,3-dihydrobenzo[*b*]thiophene-2-one.

*2-Carboxymethylthiophenylacetic acids (2)*

2-Mercaptophenylacetic acid (**4**) was treated with an equiva-

lent quantity of the appropriate α-haloacid or ester[2] in ethanol containing two equivalents of sodium ethoxide. The solutions were heated under reflux for 1 h under nitrogen, then the solvent was evaporated and the residues were dissolved in aqueous 2 *M* sodium hydroxide solution. This was heated at 100°C (steam bath) for 1 h. After cooling, the mixtures were acidified, and the products collected and recrystallized from a hexane – ethyl acetate 1:1 mixture. Results are summarized in Table 2.

*2-Phenacylthiophenylacetic acid (9)*

2-Mercaptophenylacetic acid (1.68 g, 0.01 mol) was added to a solution of ethanol (50 mL) containing sodium (0.23 g, 0.01 mol). To the solution was added phenacyl bromide (1.99 g, 0.01 mol) and the mixture was let stand 3 h at room temperature. The ethanol was evaporated *in vacuo* and the residue treated with dilute hydrochloric acid. The liberated oily acid was extracted with chloroform which on evaporation gave an oil which was chromatographed (cc) on silica gel using a benzene–chloroform–methanol 9:6:1 mixture as an eluent. After a yellow forerun a band was obtained which on evaporation yielded the desired ketoacid **9** as a pale yellow oil which crystallized on standing under carbon disulfide and was recrystallized from toluene as pale yellow prisms, mp 116°C (73%). The nmr spectrum in $CD_3OD$, δ: 3.81, 4.15 (two $CH_2$ singlets, the methylene protons), 7.10–7.95 (9H bands, the aromatic protons). The mass spectrum, $M^+$, found: 286, M calcd.: 286. *Anal.* calcd. for $C_{16}H_{14}O_3S$: C 67.13, H 4.89, S 11.19%; found: C 67.36, H 5.03, S 10.93%. Further elution of the column gave small quantities of another yellow oil. This was not examined further.

*3-Acetoxy-2H-1-benzothiopyran (6a)*

A mixture of **2***a* (4.52 g, 0.02 mol) and anhydrous sodium acetate (4.5 g) in acetic anhydride (50 mL) was heated under reflux under nitrogen for 15 min. The solvent was removed *in vacuo*, the residue treated with sodium carbonate solution and extracted with ether. The dried ether extract on evaporation gave a yellow oil which was distilled *in vacuo*, bp 118–120°C at

[2]The use of haloacids or haloesters gave comparable results. Use was determined simply by their availability.

0.9 Torr (82%). The ir spectrum (film): 1765 $cm^{-1}$ (C=O str.). The mass spectrum, $M^+$, found: 206, M calcd.: 206. *Anal.* calcd. for $C_{11}H_{10}SO_2$: C 61.11, H 4.63, S 14.81%; found: C 61.18, H 4.52, S 15.05%.

*3-Acetoxy-2-methyl-2*H*-1-benzothiopyran (**6**b)*

The cyclization of **2***b* was performed as above. The compound **6***b* was obtained as a pale yellow oil, bp 120°C at 0.2 Torr (85%). The ir spectrum (film): 1775 $cm^{-1}$ (C=O str.). The mass spectrum, $M^+$, found: 220, M calcd.: 220. This material was not analysed.

*3-Acetoxy-2,2-dimethyl-2*H*-1-benzothiopyran (**6**c)*

The cyclization of **2***c* was performed as above. Examination by tlc showed a mixture of two main products, identified as the enol acetate **6***c* and the ketone **1***c*. This material was not analysed. The yield, estimated as ketone, was 76%.

*3-Acetoxy-2-phenyl-2*H*-1-benzothiopyran (**6**d)*

The cyclization was performed as above except with a reaction time of 1 h. Work-up afforded a yellow oil which was examined by column chromatography using a hexane–ether 7:3 mixture as an eluent. The first major fraction eluted gave on evaporation an oil which slowly partly crystallized and was recrystallized from methanol as pale yelow needles, mp 108–109°C (40%). The ir spectrum (liquid paraffin mull): 1773 $cm^{-1}$ (C=O str.). The mass spectrum, $M^+$, found: 266, M calcd.: 266. *Anal.* calcd. for $C_{17}H_{14}SO$: C 76.69, H 5.26, S 12.03%; found: C 76.81, H 5.34, S 11.99%.

Evaporation of the methanol mother liquors afforded a viscous oil which appears to be a mixture of **6***d* and what is tentatively assigned the 3-acetoxy-2-phenyl-4*H*-1-benzothiopyran structure (**7***b*); yield 28%. This material was not analysed.

Further elution from the chromatogram yielded traces of a highly fluorescent yellow material.

*Cyclization of 2-phenacylthiophenylacetic acid (**9**)*

The acid (0.268, 1 mmol) in acetic anhydride (10 mL) and anhydrous sodium acetate (0.3 g) was refluxed 20 min. The mixture rapidly became dark green. The solution was treated cautiously with water (10 mL) and cooled. An ether extract was washed with water, then with dilute sodium carbonate solution, dried, and evaporated to give a dark green oil. This was examined by thin layer chromatography using a benzene–chloroform–methanol 8:2:1 mixture as an eluent. Two main yellow bands were obtained with an intense blue band between. Repeated chromatography afforded the first band reasonably pure and this crystallized from methanol as pale yellow needles mp 157–159°C. This is assigned the structure **10***a* (31%). The ir spectrum: 1765 $cm^{-1}$ (C=O str.). The mass spectrum, $M^+$, found: 352, M calcd.: 352. *Anal.* calcd. for $C_{20}H_{16}SO_4$: C 68.12, H 4.56, S 9.09%; found: C 68.35, H 4.31, S 8.93%.

The second yellow band could not be purified properly and was obtained as viscous yellow oil, tentatively identified as **10***b*. The blue material was present only in trace amounts.

*Hydrolyses of 3-acetoxybenzothiopyrans to thiachroman-3-ones **1**a–d*

The enol acetates (1 g) in 60% aqueous acetic acid (20 mL) containing hydrochloric acid (0.1 mL) were refluxed for 6 h under nitrogen. The mixture was diluted with water (40 mL) and ether extracted. The extracts were washed with water, saturated sodium carbonate, dried, and evaporated to give the ketones which were either purified by distillation *in vacuo* or recrystallization.

The results are summarized in Table 3.

*Preparation of 3-pyrrolidino-2-*H*-1-benzothiopyran (**11**)*

A mixture of thiochroman-3-one (1 g), pyrrolidine (2 mL), and *p*-toluenesulfonic acid (5 mg) was heated in benzene (40 mL) under nitrogen for 4 h. Water was removed by continuous azeotropic distillation. The solvent was removed and the product crystallized from hexane as pale yellow plates (91%), mp 95–96°C. The mass spectrum, $M^+$, found: 217, M calcd.: 217. *Anal.* calcd. for $C_{13}H_{15}NS$: C 71.90, H 6.90, N 6.45, S 14.75%; found: C 71.60, H 6.81, N 6.40, S 14.55%.

*4-Methylthiochroman-3-one (**1**f)*

The enamine **11** (2.17 g, 0.01 mol) was dissolved in iodomethane (10 mL) and the solution kept at 20°C for 16 h. The solvent was removed, 5% dilute aqueous acetic acid (20 mL) added, and the mixture warmed at 100°C for 1/2 h. After cooling, the mixture was extracted with dichloromethane (3 × 30 mL). The washed and dried extracts on evaporation gave an oil which was purified by distillation *in vacuo*, bp 105–106°C at 0.4 Torr (63%). The ir spectrum (film): 1720 $cm^{-1}$ (C=O str.). The mass spectrum, $M^+$, found: 178, M calcd.: 178. *Anal.* calcd. for $C_{10}H_{10}OS$: C 67.41, H 5.62, S 17.95%; found: C 67.45, H 5.40, S 17.80%.

*4-Benzoylthiochroman-3-one (**1**g)(**12**)*

The enamine **11** (0.434 g, 2 mmol) and benzoyl chloride (0.280 g, 2 mmol) in methylene chloride (20 mL) were refluxed 4 h. The solvent was removed and the crystalline material refluxed 1/2 h with 5% dilute hydrochloric acid (10 mL). The mixture was extracted with hexane and the solution was shaken with saturated aqueous cupric acetate solution. The copper complex was collected, and decomposed in dilute sulfuric acid. Final

purification was effected by chromatography in benzene. Pale yellow needles, mp 118–120°C, were obtained on evaporation (63%). The ir spectrum: 1597 $cm^{-1}$ (C=O str., strongly hydrogen bonded), 2650–3300 (OH str., hydrogen bonded). The mass spectrum, $M^+$, found: 268, M calcd.: 268. *Anal.* calcd. for $C_{16}H_{12}O_2S$: C 71.64, H 4.48, S 11.96%; found: C 71.39, H 4.61, S 12.07%.

*Preparation of 3-phenylthiochroman-3-ol (**13**)*

Into a solution of thiochroman-3-one (**1***a*) (1.64 g, 10 mmol) in anhydrous ether (10 mL) was dropped the equivalent quantity of phenyl magnesium bromide in ether (20 mL). An immediate reaction was evident. After 10 min the solution was worked up by dilution with dilute hydrochloric acid and extraction with ether. The dried extracts on evaporation gave a yellow oil which was purified by chromatography using a benzene–methanol 20:1 mixture as an eluent. A virtually colorless oil was obtained (91%). The nmr spectrum δ: 2.60–3.50 (5H bands, the two diastereotopic methylene and the hydroxy protons), 6.86–7.52 (9H bands, the aromatic protons). The mass spectrum, $M^+$, found: 242, M calcd.: 242. *Anal.* calcd. for $C_{15}H_{14}OS$: C 74.38, H 5.78, S 13.22%; found: C 74.41, H 5.69, S 12.93%.

*Preparation of 2-phenyl-2*H*-1-benzothiopyran (**14**)*

A solution of **13** (0.242 g, 1 mmol) in toluene (10 mL) with *p*-toluenesulfonic acid (10 mg) was refluxed 1 h. Evaporation gave a pale brown oil which was purified by chromatography on silica gel with benzene as an eluent and distillation *in vacuo* (81%). The mass spectrum, $M^+$, found: 224, M calcd.: 224. *Anal.* calcd. for $C_{15}H_{12}S$: C 80.35, H 5.36, S 14.29%; found: C 80.62, H 5.42, S 13.95%.

*3-Phenyl-2*H*-1-benzothiopyran-*S,S*-dioxide (**16**a)*

This was made from **14** by oxidation with two equivalents of *m*-chloroperoxybenzoic acid in acetone. After 5 min the acetone solution was diluted with water and extracted with chloroform. The extract was washed with dilute sodium hydroxide solution, dried, and evaporated to give a colorless oil which was purified by chromatography (tlc) using benzene as an eluent (86%). The mass spectrum, $M^+$, found: 256, M calcd.: 256.

*3-Phenylthiopyrylium perchlorate (**17**)*

The thiopyran **14** was treated with one equivalent of *m*-chloroperoxybenzoic acid in acetone and worked up as above. The pale oil resulting was dissolved in acetic acid, warmed briefly, and to it added perchloric acid. The yellow solution on dilution with ether gave **20** as pale yellow prisms, mp 151°C (lit. (12) mp 151°C) (20%).

*2-Phenyl-2*H*-1-benzothiopyrano[3,4-*b*]indole (**18**b)*

2-Phenylthiochroman-3-one (240 mg, 1 mmol) was treated with a slight excess of phenylhydrazine hydrochloride and sodium acetate in ethanol. After refluxing 15 min the cooled mixture was poured into water. The yellow precipitate was collected and washed with water. A small sample crystallized from ethanol afforded yellow microcrystals, mp 124–127°C. This material was dissolved in acetic acid (10 mL), saturated with hydrogen chloride, and refluxed 45 min. The mixture was poured into water and extracted with ethyl acetate (3 × 30 mL). The washed and dried extracts on evaporation gave a dark red oil which was chromatographed (cc) using a hexane–ether 1:1 mixture as an eluent. The product was obtained as pale yellow microcrystals, mp 146–147°C from hexane (56%). These turned red on standing in air. The mass spectrum, $M^+$, found: 313, M calcd.: 313. *Anal.* calcd. for $C_{21}H_{15}NS$: C 80.51, H 4.79, N 4.47, S 10.22%; found: C 80.32, H 4.03, N 4.51, S 10.25%.

*2-Phenyldihydrobenzothiopyrano[4,3-*b*]indole (**20**)*

This was prepared as **2** above, starting from 2-phenylthiochroman-4-one (14). Yellow needles, mp 182–184°C, were obtained on recrystallization from methanol (81%). The mass spectrum, $M^+$, found: 313, 312; M calcd.: 313. *Anal.* calcd. for $C_{21}H_{15}NS$: C 80.51, H 4.79, N 4.47, S 10.22%; found: C 80.63, H 5.01, N 4.48, S 10.39%.

*2-Phenylbenzothiopyrano[4,3-*b*]indole (**21**)*

A mixture of the dehydro compound **23**, (0.313 g, 1 mmol) and chloranil (0.3 g) in ethyl acetate (20 mL) was heated under reflux 1 h. The solvent was removed *in vacuo* and the residue chromatographed (tlc) on silica gel using an ethyl acetate – hexane 2:1 mixture as an eluent. The product was obtained as orange needles, mp 210–212°C from ethyl acetate (92%). The mass spectrum, $M^+$, found: 311, M calcd.: 311. *Anal.* calcd. for $C_{21}H_{13}NS$: C 81.03, H 4.18, N 4.50, S 10.29%; found: C 81.11, H 4.21, N 4.36, S 10.03%.

# Influence complexe d'additifs hydrogénés sur le craquage de substances organiques et analogie hydraulique pour la propagation des chaînes. I. Cas d'une pyrolyse à une seule stoechiométrie

GÉRARD SCACCHI, FRANÇOIS BARONNET ET MICHEL NICLAUSE

*I.N.P.L. et Université de Nancy I, Département de Chimie Physique des Réactions (E.R.A. no 136 C.N.R.S.), 1, rue Grandville, 54042 Nancy Cedex, France*

Reçu le 13 mai 1981

GÉRARD SCACCHI, FRANÇOIS BARONNET et MICHEL NICLAUSE. Can. J. Chem. **60**, 249 (1982).

Dans ce premier mémoire (I), on considère la pyrolyse homogène (à très faible avancement) d'une substance organique μH impliquant *une seule* stoechiométrie principale (μH = m + βH) et relevant d'un mécanisme où les chaînes sont propagées par des radicaux libres (β· et μ·) selon les processus:

$$[2] \quad \mu\cdot \xrightarrow{k_2} m + \beta\cdot$$
$$[3] \quad \beta\cdot + \mu H \xrightarrow{k_3} \beta H + \mu\cdot$$

Le mécanisme "μH, YH" de Niclause et coll. interprète de nombreux effets d'accélération ou d'inhibition, par des additifs hydrogénés YH, de la pyrolyse de telles substances organiques μH.

Pour représenter la *propagation* des chaînes dans ces réactions, on propose une *analogie hydraulique* originale. Elle permet tout d'abord de mieux saisir la notion d'étape limitant la vitesse de propagation dans la décomposition de μH *pur*, à savoir le processus bimoléculaire [3] dans le cas limite [A]: $k_3\,(\mu H)_0 \ll k_2$ ou le processus unimoléculaire [2] dans le cas limite [B]: $k_2 \ll k_3\,(\mu H)_0$.

Cette analogie hydraulique permet aussi de mieux comprendre pourquoi une pyrolyse relevant du cas limite [A] (*néopentane* par ex.) peut être *accélérée* par *certains* additifs hydrogénés (HCl, HBr, $H_2S$), tandis qu'une décomposition thermique relevant du cas limite [B] (*éthane* par ex.) *ne* peut être accélérée, selon ce mécanisme, par *aucun* additif hydrogéné.

Dans un second mémoire (II), on étendra les considérations précédentes au cas d'une substance organique μH se décomposant selon *plusieurs* stoechiométries primaires principales.

---

GÉRARD SCACCHI, FRANÇOIS BARONNET, and MICHEL NICLAUSE. Can. J. Chem. **60**, 249 (1982).

This first article (I) considers the homogeneous pyrolysis at very low conversion of an organic substance, μH, involving a *single* principal stoichiometry (μH = m + βH) and proceeding by a mechanism in which the chains are propagated by free radicals (β· and μ·) according to the steps:

$$[2] \quad \mu\cdot \xrightarrow{k_2} m + \beta\cdot$$
$$[3] \quad \beta\cdot + \mu H \xrightarrow{k_3} \beta H + \mu\cdot$$

The mechanism "μH, YH" of Niclause and co-workers interprets numerous effects of acceleration, or of inhibition, by hydrogenated additives YH, in the pyrolysis of such organic substances μH.

A novel *hydraulic analogy* is proposed to describe the *propagation* of chains in these reactions. This analogy immediately permits a better comprehension of the concept of a step which limits the rate of propagation in the decomposition of *pure* μH, namely the bimolecular process [3] in the limiting case [A] where $k_3[\mu H]_0 \ll k_2$, or the unimolecular process [2] in the limiting case [B] where $k_2 \ll k_3\,[\mu H]_0$. The analogy also leads to a better understanding of why a pyrolysis which follows the limiting case [A] (e.g. neopentane) may be *accelerated* by *certain* hydrogenated additives (HCl, HBr, $H_2S$), while a thermal decomposition following the limiting case [B] (e.g. *ethane*) *cannot* be accelerated by *any* hydrogenated additive according to this mechanism.

In a second article (II), the preceding considerations will be extended to the case of an organic substance μH whose decomposition involves *several* principal primary stoichiometries.

[Journal translation]

## Introduction

Niclause *et al.* (1) ont proposé et étudié théoriquement un mécanisme "μH, YH", qui conduit à attribuer à divers additifs hydrogénés YH, à la fois (dans le cas général) une influence *accélératrice* et une influence *inhibitrice* sur la pyrolyse radicalaire en chaînes d'une substance organique μH impliquant *une seule* stoechiométrie primaire principale: $\mu H = m + \beta H$. Le résultat *global* de ces deux effets cinétiques *opposés* dépend de divers paramètres qui ont été précisés.

De nombreux faits expérimentaux prévus par ce mécanisme ont été vérifiés expérimentalement: (*a*) la pyrolyse du *néopentane* est *accélérée* par $H_2S$ (2), HBr (3) et HCl (3, 4); (*b*) au contraire, $H_2S$ (5, 6) et HBr (3) *inhibent* la décomposition thermique de l'*éthane* et HCl (3) n'a pratiquement pas d'influence cinétique sur cette réaction; et (*c*) le pro-

pène, l'isobutène et les butènes-2 *inhibent* la pyrolyse du *néopentane* (7–9), celle de l'*acétaldéhyde* (10) et celle de l'*éthane* (11, 12).

Ces effets accélérateurs ou inhibiteurs ont pu être interprétés quantitativement par des lois cinétiques calculées à partir du mécanisme "μH, YH".

Mais, pour faciliter l'interprétation synthétique de ces effets et mieux comprendre qualitativement leur signification physique en termes de processus élémentaires, nous proposons et nous utilisons, dans ce qui suit, une *analogie hydraulique* pour représenter la *propagation* des chaînes dans la pyrolyse de μH, pur ou en présence d'un corps hydrogéné YH.

## 1. Pyrolyse d'une substance organique (μH) pure

### *1.1. Mécanisme "βμ"*

Considérons une réaction homogène de pyrolyse radicalaire en chaînes d'une substance organique pure, donnant naissance à deux produits primaires principaux, telle que la décomposition thermique du néopentane ou celle de l'éthane:

$$\text{néo-}C_5H_{12} = \text{i-}C_4H_8 + CH_4$$
$$C_2H_6 = C_2H_4 + H_2$$

*A très faible avancement*, le mécanisme d'une telle réaction peut souvent être schématisé de la manière suivante, en adoptant le symbolisme "βμ" usuel en cinétique chimique (13):

[1] amorçage: $\mu H \xrightarrow{k_1}$ 2 radicaux libres

suivi, éventuellement, de processus de transfert

[2] propagation: $\mu\cdot \xrightarrow{k_2} m + \beta\cdot$

[3] propagation: $\beta\cdot + \mu H \xrightarrow{k_3} \beta H + \mu\cdot$

[ββ] terminaison: $\beta\cdot + \beta\cdot \xrightarrow{k_{\beta\beta}}$ produits

[βμ] terminaison: ou $\beta\cdot + \mu\cdot \xrightarrow{k_{\beta\mu}}$ produits

[μμ] terminaison: ou $\mu\cdot + \mu\cdot \xrightarrow{k_{\mu\mu}}$ produits

μH représente la substance organique soumise à pyrolyse, μ· désigne le radical libre porteur de chaînes qui se décompose de façon *mono*moléculaire (ou unimoléculaire) par rupture d'une liaison C—C ou C—H (processus de propagation [2]) et β· désigne le radical (ou atome) libre porteur de chaînes qui réagit *bi*moléculairement avec une molécule μH en lui arrachant un atome H et en régénérant le radical libre μ· (processus de propagation [3]); enfin, m et βH représentent les produits primaires principaux de la réaction, dont l'équation stoechiométrique s'écrit schématiquement:

$$\mu H = m + \beta H$$

Si l'on suppose que la réaction est en chaînes longues, les vitesses initiales de consommation de μH et de formation de m et βH sont pratiquement égales (soit $V_0$ cette vitesse initiale commune) et l'on a: $k_2\,(\mu\cdot) \simeq k_3\,(\beta\cdot)\,(\mu H)_0$; d'où:

$$\frac{(\mu\cdot)}{(\beta\cdot)} \simeq \frac{k_3(\mu H)_0}{k_2}$$

$$= \frac{\text{réactivité de } \beta\cdot \text{ dans le processus [3]}}{\text{réactivité du } \mu\cdot \text{ dans le processus [2]}}$$

Alors, les valeurs relatives de $k_3\,(\mu H)_0$ et de $k_2$ gouvernent les concentrations relatives des porteurs de chaînes μ· et β· et, par suite, les importances relatives des trois processus possibles [ββ], [βμ] et [μμ] de terminaison des chaînes, du moins si les constantes de vitesse $k_{\beta\beta}$, $k_{\beta\mu}$ et $k_{\mu\mu}$ de ces trois processus sont du même ordre de grandeur, ce que nous supposerons ici.

Deux cas limites sont possibles selon les valeurs relatives de $k_3\,(\mu H)_0$ et de $k_2$.

*Cas limite [A]:* $k_3\,(\mu H)_0 \ll k_2$

Le processus radicalaire [3] est plus difficile que le processus radicalaire [2] et, par suite, règle la vitesse de propagation des chaînes; ón a: $[\mu\cdot] \ll [\beta\cdot]$ et le processus prépondérant de terminaison est du type [ββ].

La pyrolyse, vers 500°C, du *néopentane* (2,2-diméthylpropane) en isobutène et méthane (14–17) relève de ce premier cas limite, avec μH ≡ néo-$C_5H_{12}$, m ≡ i-$C_4H_8$ et βH ≡ $CH_4$; néo-$C_5H_{11}\cdot$ joue le rôle de radical μ· et $CH_3\cdot$ celui de radical β·; le processus [2] consiste en la décomposition unimoléculaire du radical libre néo-$C_5H_{11}\cdot$ par rupture d'une liaison C—C et est plus facile que le processus [3].

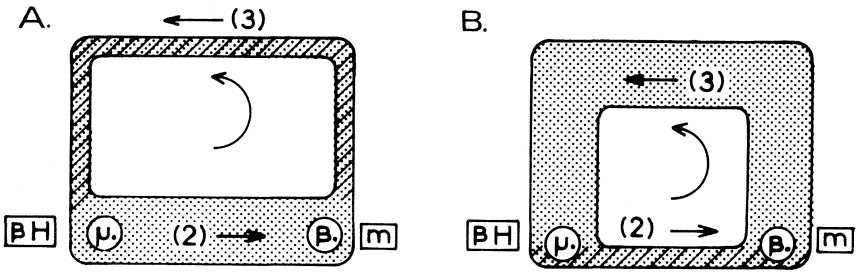

FIG. 1. Analogie hydraulique pour la propagation des chaînes dans la pyrolyse d'une substance organique μH pure.

La pyrolyse de l'*acétaldéhyde* relève également de ce premier cas limite (18).

*Cas limite [B]:* $k_2 \ll k_3 (\mu H)_0$

Le processus radicalaire [2] est plus difficile que le processus radicalaire [3] et, par suite, règle la vitesse de propagation des chaînes; on a: (β·) ≪ (μ·) et le processus prépondérant de terminaison est du type [μμ].

La pyrolyse homogène, vers 540°C, de l'*éthane* en éthylène et hydrogène (19–23) relève de ce second cas limite, avec μH ≡ $C_2H_6$, m ≡ $C_2H_4$ et βH ≡ $H_2$; $C_2H_5$· joue le rôle de radical μ· et H· celui de radical β·; le processus [2] correspond à la décomposition unimoléculaire du radical libre $C_2H_5$· par rupture d'une liaison C—H et est plus difficile que le processus [3].

### *1.2. Analogie hydraulique pour la propagation des chaînes*

Une analogie hydraulique permet de bien distinguer les deux cas limites précédents. On admet que chaque processus de *propagation* des chaînes est représenté par une *conduite*, dont le diamètre est d'autant *plus petit* que le processus est *plus difficile*. Ainsi, le diamètre de la conduite (2) sera d'autant plus petit que la constante de vitesse $k_2$ du processus unimoléculaire [2] sera plus faible; de la même façon, le diamètre de la conduite (3) sera d'autant plus petit que le produit $k_3$ $(\mu H)_0$ de la constante de vitesse $k_3$ du processus bimoléculaire [3] par la concentration initiale du réactif sera plus faible. On fait circuler un "*fluide*" dans les conduites (par exemple au moyen d'une pompe); la *vitesse* d'un processus correspond au "*débit*" du "fluide" dans la conduite correspondante et les concentrations radicalaires peuvent être assimilées à des "pressions".

Dans le *cas limite [A]*: $k_3$ $(\mu H)_0 \ll k_2$ (illustré par l'exemple du *néopentane*), c'est le processus [3] (plus difficile que le processus [2]) qui limite la vitesse de propagation. Le processus [3] sera donc représenté par une conduite (3) de plus petit diamètre que la conduite (2) correspondant au processus [2] (fig. 1A). Les deux conduites formant une boucle, le débit est le même dans (2) et (3): c'est l'équivalent de $v_2 = v_3$. Mais on voit bien que le débit global est, en fait, limité par le petit diamètre de la conduite (3), qui, dans la boucle, a une perte de charge très supérieure à celle de (2) et constitue, par suite, un "goulot d'étranglement" (la conduite (2) pourrait admettre un débit plus grand si la conduite (3) le lui fournissait); de même, la vitesse de propagation est limitée par la difficulté du processus [3] à transformer des radicaux β· en radicaux μ·, c'est-à-dire à fournir des μ· au processus [2] (qui, lui, les transforme facilement en β·). Pour assurer l'égalité des "débits" (c'est-à-dire des vitesses), la "pression" (c'est-à-dire la concentration) des espèces β· doit être très supérieure à celle des espèces μ·, en accord avec l'inégalité définissant le cas limite [A].

Au contraire, dans le *cas limite [B]*: $k_2 \ll k_3$ $(\mu H)_0$ (illustré par l'exemple de l'*éthane*), c'est le processus [2] qui est l'étape limitant la vitesse de propagation. Dans l'analogie hydraulique, le débit est encore le même dans les conduites (2) et (3), ce qui est l'équivalent de $v_2 = v_3$. Mais, cette fois, la perte de charge de la conduite (2) est très supérieure à celle de la conduite (3) et c'est donc maintenant la conduite (2) qui, dans la boucle, constitue le "goulot d'étranglement" (fig. 1B). La "pression" (concentration) des espèces μ· doit alors être très supérieure à celle des espèces β·, en accord avec l'inégalité définissant le cas limite [B].

## 2. Pyrolyse d'une substance organique (μH) en présence d'un corps hydrogéné (YH)

### *2.1. Mécanisme "μH, YH"*

Pour décrire, à très faible avancement, la pyrolyse d'une substance organique μH en présence d'un corps hydrogéné YH comportant aussi un atome (au moins) d'hydrogène "mobile", Niclause *et al.* (1) ont proposé et analysé un mécanisme symbolique "μH, YH":[1]

[1]Ce mécanisme suppose que l'additif YH n'augmente pas la vitesse d'amorçage des chaînes et que le radical (ou atome) libre Y· est thermiquement stable (ce qui est automatiquement le cas lorsque Y· est un atome libre).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

[1] amorçage: $\mu H \xrightarrow{k_1}$ 2 radicaux libres

suivi, éventuellement, de processus de transfert

[2] propagation I $\mu\cdot \xrightarrow{k_2} m + \beta\cdot$

[3] $\beta\cdot + \mu H \xrightarrow{k_3} \beta H + \mu\cdot$

[2] $\mu\cdot \xrightarrow{k_2} m + \beta\cdot$

[4] propagation II $\beta\cdot + YH \xrightarrow{k_4} \beta H + Y\cdot$

[5], [−5] $Y\cdot + \mu H \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} YH + \mu\cdot$

terminaison: processus [ββ], [βμ], [μμ], [βY], [μY] et [YY] de combinaison ou de dismutation des radicaux libres β·, μ· et Y·.

Ce mécanisme suppose essentiellement que les radicaux libres β· et μ· (qui sont porteurs de chaînes dans la décomposition de μH pur) peuvent réagir aussi avec l'additif YH en donnant naissance au nouveau radical (ou atome) libre Y· (processus [4] et [−5], Y· pouvant, à son tour, réagir avec μH (processus [5]) en régénérant YH.

En l'absence de YH, les radicaux libres β· et μ· ne peuvent propager que la décomposition en chaînes de μH selon I. Le mécanisme proposé suppose qu'*en présence de l'additif* YH, il se *propage* également *un autre type* II de décomposition en chaînes de μH, faisant participer le nouveau radical (ou atome) libre Y·, mais conduisant à la *même* stoechiométrie que I: μH = m + βH.

Enfin, ce mécanisme implique que YH tend à faire apparaître de *nouveaux* processus de *terminaison* des chaînes.

On note que, dans ce schéma réactionnel, il n'y a pas de consommation de YH dans la propagation des chaînes; une légère consommation de YH peut seulement provenir de certains processus nouveaux de terminaison.

### 2.2. *Analogie hydraulique pour la propagation des chaînes*

En présence de YH, la chaîne cinétique de la réaction globale de décomposition de μH est complexe: elle comporte un certain nombre de "maillons" représentatifs de chacun des deux types I et II de propagation. Le mode II fait intervenir les nouveaux processus [4] et ([5], [−5]) et a le processus [2] *en commun* avec le mode I de propagation. Pour traduire ceci en analogie hydraulique, il suffit d'ajouter, *en parallèle* avec la conduite (3), une nouvelle conduite constituée des éléments (4) et ((5), (−5)). Les deux schémas hydrauliques de la figure 1 se transforment alors en les schémas présentés sur la figure 2.[2] La différence essentielle entre les deux cas limites [A] et [B], en présence de l'additif YH, apparaît sur ces schémas.

Dans le *cas limite [A]*: $k_3 (\mu H)_0 \ll k_2$(*néopentane* par ex.), le nouvel assemblage de tuyaux (4) et ((5), (−5)), ajouté *en parallèle* avec la conduite (3), augmente le débit global du fluide, puisque, dans ce premier cas limite, c'était la conduite (3) qui limitait le débit global. En d'autres termes, l'additif YH a, *au niveau des propagations*, un effet *accélérateur* sur la pyrolyse de μH; il *catalyse*, par transfert d'hydrogène, la propagation de la décomposition en chaînes de μH.

Au contraire, dans le *cas limite [B]*: $k_2 \ll k_3 (\mu H)_0$ (*éthane* par ex.), le nouvel assemblage ajouté ne change pas le débit global du fluide, puisque celui-ci doit emprunter, dans les deux circuits I et II, la conduite commune (2) de faible diamètre, qui était et qui demeure le "goulot d'étranglement" dans ce second cas limite. C'est dire que, cette fois, l'additif YH *ne* peut *pas* avoir d'effet accélérateur, au niveau des propagations, sur la pyrolyse de μH (1).

### 2.3. *Influence cinétique globale de YH sur la pyrolyse de μH*

L'analogie hydraulique vient de nous montrer que, d'après le mécanisme "μH, YH", l'additif YH a, *au niveau des propagations*, un effet *accélérateur* sur la pyrolyse de μH *dans le cas limite [A]* et non dans le cas limite [B].

Mais, *dans les deux cas*, l'additif YH a aussi un

[2]Sur la figure 2, les sections des éléments (4), (5) et (−5) ont été représentées arbitrairement, cet ensemble pouvant avoir un diamètre de passage résultant très différent du diamètre de la conduite (3).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

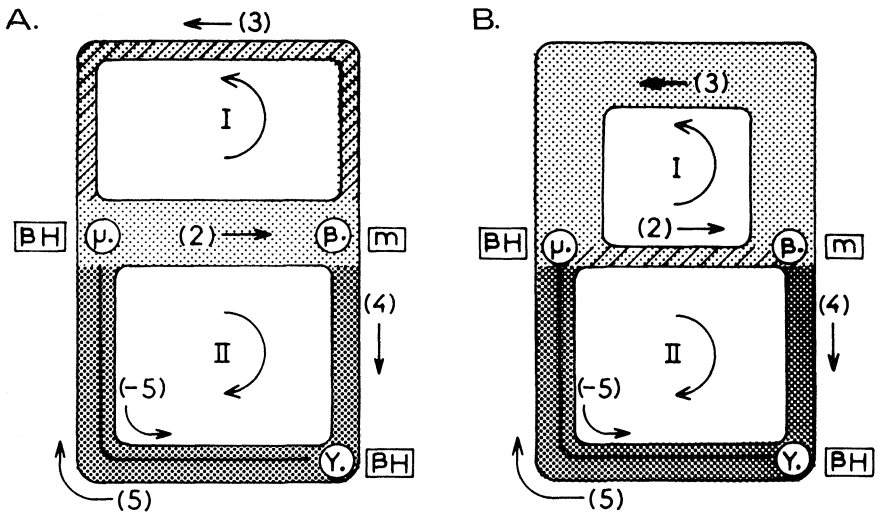

FIG. 2. Analogie hydraulique pour la propagation des chaînes dans la pyrolyse d'une substance organique μH en présence d'un corps hydrogéné YH.

effet *inhibiteur*, du fait que YH fait apparaître de nouveaux processus de *terminaison* des chaînes.

Ces prévisions qualitatives sont confirmées par le calcul, à partir du mécanisme "μH, YH", du rapport $(V_0)_{YH}/V_0$ des vitesses initiales de pyrolyse de μH en présence ou en l'absence de YH (à même concentration initiale de μH et à même température) (1, 24).

Considérons, à nouveau, les deux cas limites [A] et [B].

*Cas limite [A]:* $k_3\,(\mu H)_0 \ll k_2$ (*néopentane* par ex.)

Comme nous venons de le voir, l'additif YH exerce *simultanément deux influences cinétiques opposées* sur la pyrolyse de μH. Le résultat *global* de ces deux effets est une *accélération*, par YH, de la pyrolyse de $\mu$H si l'expression de $(V_0{}^A)_{YH}/V_0{}^A$ est supérieure à 1, une *inhibition* dans le cas contraire.

(*a*) A partir du mécanisme "μH, YH", on peut montrer (1) que si l'on a:

$$k_5 > k_3 \quad [a],$$

c'est-à-dire si le radical (ou atome) libre Y· est *plus réactif* que le radical (ou atome) libre β· vis-à-vis de $\mu$H, l'additif YH doit exercer, *globalement*, une influence *accélératrice* sur la pyrolyse de μH (l'effet accélérateur au niveau des propagations l'emporte sur l'effet inhibiteur dû aux terminaisons nouvelles).

(*b*) Si l'on a, au contraire:

$$k_5 < k_3 \quad [b],$$

c'est-à-dire si Y· est *moins réactif* que β· pour arracher un atome H de μH, l'additif YH doit, *globalement*, *inhiber* la pyrolyse de μH.

On prévoit donc qu'une décomposition relevant du *premier* cas limite [A], telle que la pyrolyse du *néopentane*, doit pouvoir être *accélérée* par certains additifs hydrogénés YH et, au contraire, *inhibée* par d'autres.

(*a*) L'expérience montre effectivement (fig. 3) que la pyrolyse du *néopentane* est *accélérée* par *HCl*, par *HBr* et par $H_2S$ (2–4). Ces effets accélérateurs indiquent donc que les radicaux (ou atomes) libres Cl·, Br· et HS· (Y·) sont *plus* réactifs que le radical libre $CH_3$· (β·) pour arracher un atome H à une molécule de néopentane ($k_5 > k_3$), en accord avec d'autres travaux indépendants.

Dans le cas de *HCl* par exemple, le rapport des vitesses initiales de pyrolyse du néopentane en présence ou en l'absence de HCl peut se mettre sous la forme (3):[3]

$$\frac{(V_0{}^A)_{HCl}}{V_0{}^A} \simeq \frac{1+ax}{1+bx} > 1,$$

avec

$$x = \frac{[HCl]_0}{[\text{néo-}C_5H_{12}]_0} \quad \text{et} \quad a = \frac{k_4{}^{HCl}}{k_3} > b$$

Le terme $1 + ax$ du numérateur traduit l'effet accélérateur de HCl par suite de l'apparition du nouveau type II de propagation; il est *supérieur* au terme $1 + bx$ du dénominateur, qui traduit l'effet inhibiteur de HCl dû aux nouveaux processus de terminaison.

[3] *b* est un paramètre dépendant de constantes de vitesse de processus élémentaires et de la concentration initiale de néopentane (cf. ref. 3).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

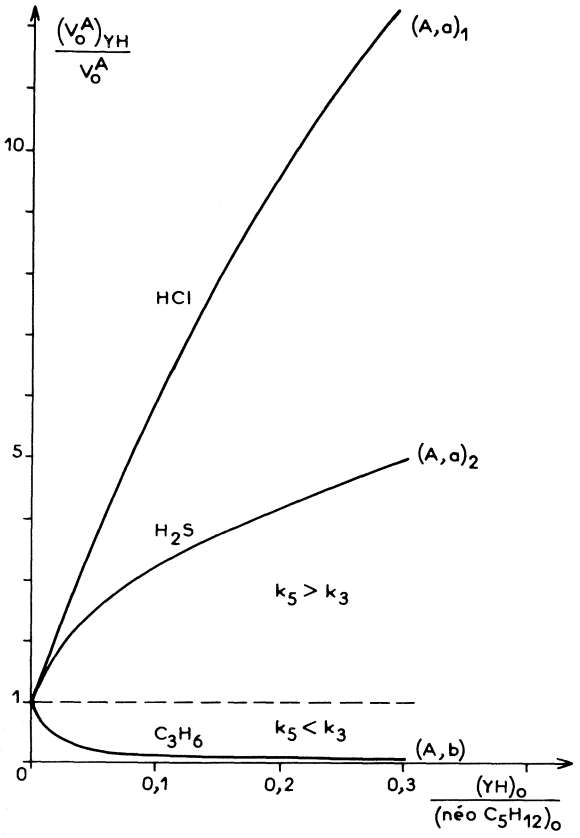

FIG. 3. Cas limite [A]: $k_3$ $(\mu H)_0 \ll k_2$. Accélération ($k_5 > k_3$) ou inhibition ($k_5 < k_3$) par YH de la pyrolyse du néopentane (μH).

| Courbe | YH | $T$ (°C) | $P_0$ (néo-$C_5H_{12}$) (Torr) | Réf. |
|---|---|---|---|---|
| (A, a)$_1$ | HCl | 480 | 100 | 3 |
| (A, a)$_2$ | $H_2S$ | 512 | 50 | 2 |
| (A, b) | $C_3H_6$ | 495 | 100 | 7 |

Rappelons que, dans la pyrolyse du néopentane pur, le processus prépondérant de terminaison des chaînes est:

[ββ] $2CH_3\cdot \rightarrow C_2H_6$

Dans la pyrolyse du néopentane *accélérée* par HCl, il apparaît les nouveaux processus de terminaison (3):

[βμ] $CH_3\cdot$ + néo-$C_5H_{11}\cdot \rightarrow CH_3—CH_2—C(CH_3)_3$

[μμ] 2 néo-$C_5H_{11}\cdot \rightarrow (CH_3)_3C—CH_2—CH_2—C(CH_3)_3$

(*b*) Par ailleurs, il a été observé (fig. 3) que la pyrolyse du *néopentane* est, au contraire, *inhibée* par le *propène* (7), par les *butènes-2* (9) et par l'*isobutène* (8). Ces effets inhibiteurs sont dus au fait que le radical libre $CH_3\cdot$ réagit avec un alcène YH (processus [4]) en donnant un radical libre allylique (Y·), qui est stabilisé par résonance et, par suite, *moins* réactif que le radical libre $CH_3\cdot$ (β·) vis-à-vis du néopentane ($k_5 < k_3$).

Le rapport des vitesses initiales de pyrolyse du néopentane en présence ou en l'absence d'alcène peut s'écrire (7, 8):[4]

$$\frac{(V_0^A)_{YH}}{V_0^A} \simeq \frac{1 + a'x}{1 + b'x} < 1,$$

avec

$$x = \frac{(YH)_0}{(néo\text{-}C_5H_{12})_0} \quad \text{et} \quad a' = \frac{k_4^{YH}}{k_3} < b'$$

Ici, le terme $1 + a'x$ du numérateur est *inférieur* au terme $1 + b'x$ du dénominateur.

(Note: Dans la pyrolyse du néopentane *inhibée* par un alcène (YH), la terminaison des chaînes implique les processus [ββ], [βY] et [YY] (7, 8).)

On peut expliquer, de façon analogue, l'allure fortement auto-inhibée (par l'isobutène formé) de la pyrolyse du néopentane (8), ainsi que l'influence inhibitrice du propène, des butènes-2 et de l'isobutène sur la décomposition thermique de l'acétaldéhyde (10).

*Cas limite [B]:* $k_2 \ll k_3$ $(\mu H)_0$ (*éthane* par ex.)

Nous avons vu que, dans ce second cas limite, l'apparition du nouveau type II de propagation ne conduit pas à un effet accélérateur de YH sur la pyrolyse de μH. L'additif YH a une influence *purement inhibitrice* (due à l'apparition de nouveaux processus de terminaison).

On prévoit donc qu'on *ne* peut *pas* accélérer, par ce mécanisme, une décomposition relevant du *second* cas limite [B], telle que la pyrolyse de l'*éthane*.

L'expérience montre effectivement (fig. 4) que *HCl*, *HBr* et $H_2S$ (qui accélèrent la décomposition du néopentane) *n'*accélèrent *pas* la pyrolyse de l'*éthane*: cette réaction est *inhibée* par *HBr* (3) et par $H_2S$ (5, 6).

Dans le cas de *HBr* par exemple, le rapport des vitesses initiales peut se mettre sous la forme (3):[4]

$$\frac{(V_0^B)_{HBr}}{V_0^B} \simeq \frac{1}{(1 + b''x)^{1/2}} < 1, \text{ avec } x = \frac{(HBr)_0}{(C_2H_6)_0}$$

La valeur 1 du numérateur indique l'absence d'effet accélérateur au niveau des propagations dans le cas limite [B]; le terme $(1 + b''x)^{1/2}$ du dénominateur traduit l'effet inhibiteur au stade de la terminaison des chaînes.

Rappelons que, dans la pyrolyse de l'éthane pur,

[4] $b'$ et $b''$ sont des paramètres dépendant de constantes de vitesse de processus élémentaires et de la concentration initiale de néopentane (cf. refs. 7 et 8 pour $b'$, ref. 3 pour $b''$).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

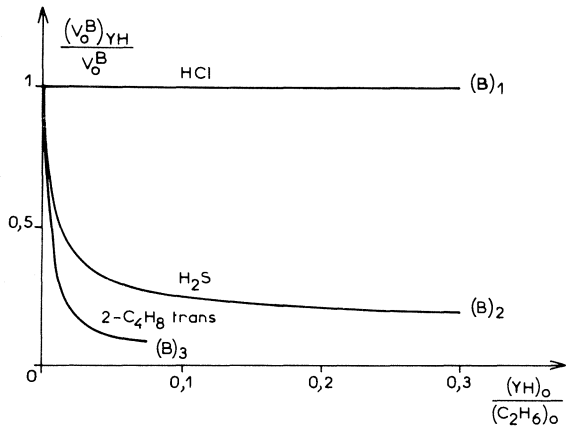

FIG. 4. Cas limite [B]: $k_2 \ll k_3$ $(\mu H)_0$. Inhibition par YH de la pyrolyse de l'éthane (μH).

| Courbe | YH | $T$ (°C) | $P_0$ ($C_2H_6$) (Torr) | Réf. |
|---|---|---|---|---|
| $(B)_1$ | HCl | 540 | 50 | 3 |
| $(B)_2$ | $H_2S$ | 540 | 50 | 5 |
| $(B)_3$ | 2-$C_4H_8$ *trans* | 520 | 100 | 12 |

le processus prépondérant de terminaison est:

$$[\mu\mu] \quad 2C_2H_5\cdot \longrightarrow \begin{matrix} C_2H_4 + C_2H_6 \\ n\text{-}C_4H_{10} \end{matrix}$$

Dans la pyrolyse de l'éthane *inhibée* par HBr, il apparaît essentiellement le nouveau processus de terminaison (3):

$$[\mu Y] \quad C_2H_5\cdot + Br\cdot \rightarrow C_2H_4 + HBr \text{ (ou } C_2H_5Br)$$

Quant à *HCl*, son influence *inhibitrice* sur la pyrolyse de l'*éthane* est *négligeable* (3) devant celle de HBr ou de $H_2S$ (fig. 4), parce que, dans le cas de HCl, le paramètre $b''$ est beaucoup plus petit.

L'expérience montre aussi (fig. 4) que la pyrolyse de l'*éthane* (comme celle du néopentane cette fois) est *inhibée* par divers *alcènes*, tels que le propène (11), les butènes-2 (12) et l'isobutène (11), par suite de l'apparition de nouveaux processus de terminaison importants.

(Note: Dans la pyrolyse de l'éthane *inhibée* par un alcène (YH), la terminaison des chaînes implique les processus $[\mu\mu]$, $[\mu Y]$ et [YY] (11).)

### 2.4. *Remarque*

L'étude théorique de l'influence cinétique globale de YH serait très complexe dans le cas général. Elle est plus simple dans les deux cas limites [A] et [B] examinés ci-dessus.

Mais, pour des raisons de continuité, on s'attend à ce que, dans le *cas intermédiaire* où $k_2$ ne serait ni très grand, ni très petit devant $k_3$ $(\mu H)_0$, l'additif YH exerce, sur la pyrolyse de μH: un effet cinétique intermédiaire au niveau des propagations, c'est-à-dire une influence *accélératrice moins marquée* que dans le cas limite [A]; et un effet *inhibiteur*, dû à l'apparition de nouveaux processus de terminaison des chaînes.

Le calcul confirme cette prévision (1).

## 3. Conclusion

Pour la pyrolyse (à très faible avancement) d'une substance organique μH impliquant *une seule* stoechiométrie principale et un mécanisme radicalaire en chaînes de type "βμ", l'*analogie hydraulique* utilisée ici pour représenter la *propagation* des chaînes nous a permis de mieux saisir la notion d'étape *limitant* la *vitesse* de *propagation*, à savoir: le processus bimoléculaire [3] dans le cas limite [A] (*néopentane* par ex.) ou, au contraire, le processus unimoléculaire [2] dans le cas limite [B] (*éthane* par ex.), bien que, dans chaque cas, les processus de propagation [2] et [3] aient la même vitesse.

L'analogie hydraulique nous a montré par ailleurs que, d'après le mécanisme "μH, YH", un additif hydrogéné YH peut avoir, *au niveau des propagations*, un effet *accélérateur* sur la pyrolyse de μH *dans le cas limite [A]* et non dans le cas limite [B]. Mais, *dans les deux cas*, l'additif YH a aussi un effet *inhibiteur*, du fait que YH fait apparaître de nouveaux processus de *terminaison* des chaînes. On comprend ainsi pourquoi une pyrolyse relevant du *cas limite [A]* (*néopentane* par ex.) peut être *accélérée* par certains additifs hydrogénés (HCl, HBr, $H_2S$) et, au contraire, *inhibée* par divers alcènes et pourquoi on *ne* peut *pas* accélérer, par ce mécanisme, une décomposition thermique relevant du *cas limite [B]* (par exemple, la pyrolyse de l'*éthane* est *inhibée* par HBr, par $H_2S$ et par des alcènes et HCl n'a pratiquement pas d'influence).

Dans un second mémoire, nous étendrons les mécanismes "βμ" et "μH, YH" et l'analogie hydraulique pour la propagation des chaînes au cas d'une substance organique μH se décomposant selon *plusieurs* stoechiométries primaires principales. Ceci nous permettra d'interpréter l'influence d'additifs hydrogénés YH sur la cinétique de la réaction et sur sa sélectivité (c'est-à-dire sur les importances relatives des stoechiométries de décomposition).

# Influence complexe d'additifs hydrogénés sur le craquage de substances organiques et analogie hydraulique pour la propagation des chaînes. II. Cas d'une pyrolyse à plusieurs stoechiométries

GÉRARD SCACCHI, CLOTILDE JUSTE-DARRAS, FRANÇOIS BARONNET ET MICHEL NICLAUSE

*I.N.P.L. et Université de Nancy I, Département de Chimie Physique des Réactions (E.R.A. no 136 C.N.R.S.), 1, rue Grandville, 54042 Nancy Cedex, France*

Reçu le 13 mai 1981

GÉRARD SCACCHI, CLOTILDE JUSTE-DARRAS, FRANÇOIS BARONNET et MICHEL NICLAUSE. Can. J. Chem. **60**, 257 (1982).

Dans un premier mémoire (I), on a considéré le cas simple d'une substance organique μH se décomposant (à très faible avancement) selon *une seule* steochiométrie principale: μH = m + βH. Pour représenter la *propagation* des chaînes dans la pyrolyse de μH, pur ou en présence d'un corps hydrogéné YH, on a introduit une *analogie hydraulique*. En se basant sur le mécanisme "μH, YH" de Niclause et coll., cette analogie a permis, en particulier, de mieux comprendre pourquoi *certains* additifs hydrogénés *accélèrent* certaines décompositions thermiques (e.g. néo-$C_5H_{12}$ = i-$C_4H_8$ + $CH_4$), tandis qu'*aucun* additif hydrogéné n'accélère d'autres pyrolyses (e.g. $C_2H_6 = C_2H_4 + H_2$).

Dans ce second mémoire (II), on étend les considérations précédentes au cas plus complexe d'une substance organique μH se décomposant selon *deux* stoechiométries primaires principales:

[A] $\mu H = m_A + CH_4$

[B] $\mu H = m_B + H_2$

On montre que le mécanisme "μH, YH" généralisé et *l'analogie hydraulique* pour la propagation des chaînes permettent d'interpréter l'influence d'additifs hydrogénés (HCl, HBr, $H_2S$, $H_2$, $C_3H_6$) sur les *vitesses* initiales des réactions [A] et [B] de la pyrolyse du *propane* ou de *l'isobutane* et sur la *sélectivité* de cette décomposition (importance de [A] par rapport à [B]).

Enfin, on examine sommairement le cas, plus complexe encore, d'une substance organique μH se décomposant selon *plus de deux* stoechiométries primaires principales.

---

GÉRARD SCACCHI, CLOTILDE JUSTE-DARRAS, FRANÇOIS BARONNET, and MICHEL NICLAUSE. Can. J. Chem. **60**, 257 (1982).

A first article (I) considered the simple case of an organic substance μH whose decomposition at low conversion follows a *single* principal stoichiometry: μH = m + βH. An *hydraulic analogy* was introduced in order to describe the *propagation* of chains in the pyrolysis of μH, either pure or in the presence of a hydrogenated substance YH. Applying the mechanism "μH, YH" of Niclause and co-workers, this analogy leads, in particular, to a better understanding of why *certain* hydrogenated additives *accelerate* certain thermal decompositions (e.g. neo-$C_5H_{12}$ = i-$C_4H_8$ + $CH_4$), whereas *no* hydrogenated additive accelerates other pyrolyses (e.g. $C_2H_6 = C_2H_4 + H_2$).

This second article (II) extends the preceding considerations to the more complex case of an organic substance μH which decomposes according to *two* principal primary stoichiometries:

[A] $\mu H = m_A + CH_4$

[B] $\mu H = m_B + H_2$

It is shown that the generalized mechanism "μH, YH" and the *hydraulic analogy* for the propagation of chains permit an interpretation of the influence of hydrogenated additives (HCl, HBr, $H_2S$, $H_2$, $C_3H_6$) on the initial *rates* of the reactions [A] and [B] in the pyrolysis of *propane* or of *isobutane* and on the *selectivity* of this decomposition (the importance of [A] relative to that of [B]).

Finally the still more complex case, in which an organic substance μH decomposes according to *more than two* principal primary stoichiometries, is briefly examined.

[Journal translation]

## Introduction

Dans un premier mémoire (1), nous avons considéré le cas simple de la décomposition thermique (à très faible avancement) d'une substance organique μH impliquant *une seule* stoechiométrie principale (μH = m + βH) et relevant d'un mécanisme radicalaire en chaînes "βμ" (2), telle que la pyrolyse du néopentane (néo-$C_5H_{12}$ = i-$C_4H_8$ + $CH_4$) ou celle de l'éthane ($C_2H_6 = C_2H_4 + H_2$).

Le mécanisme "μH, YH" (3) a permis d'interpréter de nombreux effets d'accélération ou d'inhibition, par des additifs hydrogénés YH, de la décomposition thermique de telles substances organiques μH. Pour représenter la *propagation* des chaînes dans le craquage de μH, pur ou en présence d'un corps hydrogéné YH, nous avons utilisé une *analogie hydraulique*. Grâce à celle-ci, on comprend mieux pourquoi certaines pyrolyses (*néopentane* par ex.) sont *accélérées* par certains additifs hydrogénés (HCl, HBr, $H_2S$) et, au contraire, *inhibées* par divers alcènes et pourquoi *aucun* additif hydrogéné n'accélère d'autres décom-

For personal use only.

positions thermiques (par ex., la pyrolyse de l'*éthane* est *inhibée* par HBr, par $H_2S$ et par des alcènes et HCl n'a pratiquement pas d'influence).

Dans ce second mémoire, nous allons examiner (Sect. 1 et 2) le cas, plus complexe, d'une substance organique μH se décomposant selon *deux* stoechiométries primaires principales:

[A] $\mu H = m_A + CH_4$

[B] $\mu H = m_B + H_2$

Il en est ainsi pour le *propane* et l'*isobutane*:

$C_3H_8 = C_2H_4 + CH_4$ [A] $i\text{-}C_4H_{10} = C_3H_6 + CH_4$

$C_3H_8 = C_3H_6 + H_2$ [B] $i\text{-}C_4H_{10} = i\text{-}C_4H_8 + H_2$

(Note: Remarquons que, dans chacun de ces deux exemples, la réaction [A] est du type "néopentane", la réaction [B] du type "éthane". En effet, [A] correspond à une perte de méthane, [B] à une déshydrogénation et nous verrons que la propagation des chaînes fait intervenir un processus unimoléculaire de décomposition d'un radical libre de type μ·: par rupture, relativement facile, d'une liaison C—C pour la réaction [A], comme dans le cas du néopentane; par rupture, relativement difficile, d'une liaison C—H pour la réaction [B], comme dans le cas de l'éthane.)

Niclause et coll. (4, 5) ont montré, dans le cas du *propane*, que $H_2S$, HBr et HCl *accélèrent* la réaction [A] (comme la pyrolyse du néopentane); au contraire, $H_2S$ et HBr *inhibent* la réaction [B], qui *n*'est pratiquement *pas* influencée par HCl (comme la décomposition de l'éthane). Les trois additifs précités *orientent* donc la pyrolyse du propane vers la production d'éthylène (et de méthane) au détriment de la formation de propène (et d'hydrogène). Ils *orientent* aussi la pyrolyse de l'*isobutane* vers $C_3H_6 + CH_4$ plutôt que vers $i\text{-}C_4H_8 + H_2$ (5, 6). Il est ainsi possible d'augmenter fortement la *sélectivité* (importance de [A] par rapport à [B]) de ces décompositions. Par ailleurs, l'expérience montre que des alcènes, tels que le propène, l'isobutène et les butènes-2 (qui inhibent la pyrolyse du néopentane et celle de l'éthane), *inhibent*, à la fois, les *deux* réactions [A] et [B] de décomposition du *propane* et de l'*isobutane* (4, 7–13); la sélectivité est alors peu modifiée.

Dans ce qui suit, nous nous proposons d'étendre au cas d'une substance organique μH se décomposant selon *deux* stoechiométries primaires principales [A] et [B], les mécanismes "βμ" et "μH, YH" et l'*analogie hydraulique* (pour la *propagation* des chaînes) utilisés dans le premier mémoire (1) pour une décomposition à une seule stoechiométrie. Ces considérations nous permettront d'interpréter l'influence de divers additifs hydrogénés sur les *vitesses* initiales des réactions [A] et [B] de la pyrolyse du *propane* ou de l'*isobutane* et sur la *sélectivité* de cette décomposition.

Enfin, nous examinerons sommairement (Sect. 3) le cas, plus complexe encore, d'une substance organique μH se décomposant selon *plus de deux* stoechiométries primaires principales, en tenant compte de travaux relatifs à l'influence de $H_2S$ sur la pyrolyse du *n*-butane (14, 15) ou de divers autres hydrocarbures (15, 16).

## 1. Pyrolyse distoechiométrique d'une substance organique (μH) pure

### *1.1. Mécanisme "βμ" généralisé*

Considérons la réaction de pyrolyse d'une substance organique μH se décomposant selon *deux* équations stoechiométriques primaires principales, l'une de *perte de méthane* (comme dans le cas de la pyrolyse du néopentane), l'autre de *déshydrogénation* (comme dans le cas de la pyrolyse de l'éthane):

[A] $\mu H = m_A + CH_4$

[B] $\mu H = m_B + H_2$

La généralisation du mécanisme "βμ" au cas d'une pyrolyse à deux stoechiométries permet d'écrire le mécanisme symbolique suivant (à très faible avancement):

[1] amorçage: $\mu H \xrightarrow{k_1}$ 2 radicaux libres

suivi, éventuellement, de processus de transfert

[2A] propagation Ⓐ $\mu_A\cdot \xrightarrow{k_{2A}} m_A + CH_3\cdot$

[3'A] $CH_3\cdot + \mu H \xrightarrow{k_{3'A}} CH_4 + \mu_A\cdot$

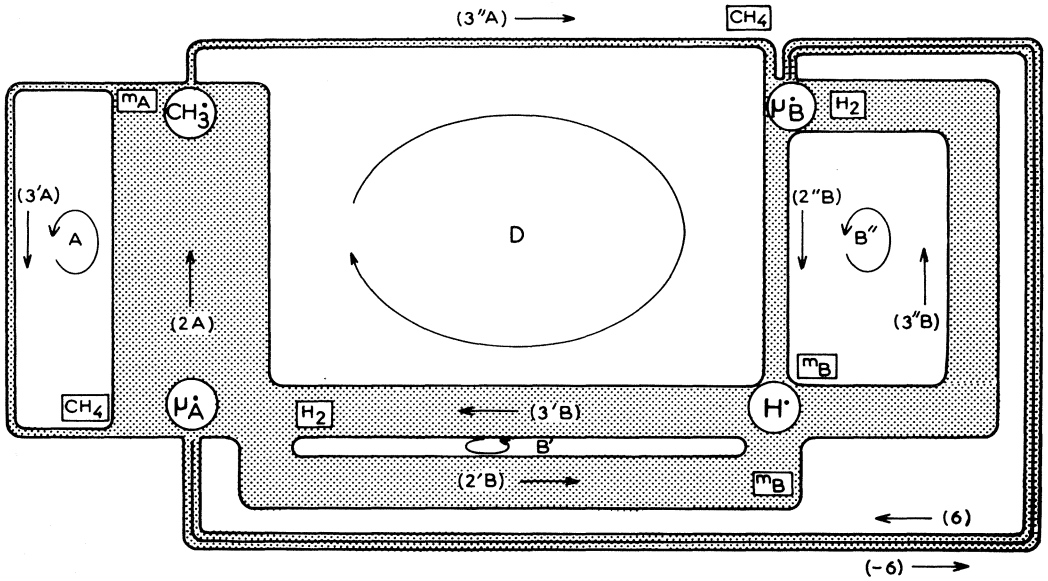

FIG. 1. Analogie hydraulique pour la *propagation* des chaînes dans la pyrolyse d'une substance organique μH pure.

[2′B] [3′B] propagation (B′)

$$\mu_A\cdot \xrightarrow{k_{2'B}} m_B + H\cdot$$
$$H\cdot + \mu H \xrightarrow{k_{3'B}} H_2 + \mu_A\cdot$$

[2″B] [3″B] propagation (B″)

$$\mu_B\cdot \xrightarrow{k_{2''B}} m_B + H\cdot$$
$$H\cdot + \mu H \xrightarrow{k_{3''B}} H_2 + \mu_B\cdot$$

[3″A] processus de croisement de chaînes: $CH_3\cdot + \mu H \xrightarrow{k_{3''A}} CH_4 + \mu_B\cdot$

[6] et [−6] processus d'isomérisation: $\mu_B\cdot + \mu H \underset{k_{-6}}{\overset{k_6}{\rightleftharpoons}} \mu H + \mu_A\cdot$

terminaison: combinaison (et dismutation éventuelle) 2 à 2 des porteurs de chaînes les plus abondants

Il existe deux types de radicaux β·: $CH_3\cdot$ et H· et deux formes isomères du radical μ·: la forme $\mu_A\cdot$, radical primaire qui peut se décomposer unimoléculairement par rupture d'une liaison carbone–carbone (processus [2A]) ou d'une liaison carbone–hydrogène (processus [2′B]); dans le cas du propane, $\mu_A\cdot \equiv$ p-$C_3H_7\cdot$ et dans celui de l'isobutane, $\mu_A\cdot \equiv$ p-$C_4H_9\cdot$ (p veut dire primaire); et la forme $\mu_B\cdot$, radical secondaire ou tertiaire qui ne peut se décomposer que par rupture d'une liaison carbone–hydrogène (processus [2′B]); dans le cas du propane, $\mu_B\cdot \equiv$ s-$C_3H_7\cdot$; dans celui de l'isobutane, $\mu_B\cdot \equiv$ t-$C_4H_9\cdot$. La propagation (A) rend compte de la stoechiométrie [A]; les propagations (B″) et (B′) rendent toutes deux compte de la stoechiométrie [B].

Le calcul des rapports des concentrations radicalaires, dans le cas de la pyrolyse du propane (4, 17) montre clairement que les radicaux libres les plus abondants dans le milieu, à très faible avancement, sont les radicaux $CH_3\cdot$ et $\mu_B\cdot$ (s-$C_3H_7\cdot$); la terminaison des chaînes implique donc essentiellement ces deux types de radicaux. De la même façon, dans la pyrolyse de l'isobutane, les radicaux libres prépondérants sont $CH_3\cdot$ et $\mu_B\cdot$ (t-$C_4H_9\cdot$).

*1.2. Analogie hydraulique pour la propagation des chaînes*

La figure 1 représente l'analogie hydraulique des divers processus de propagation, croisement de chaînes et isomérisation.

On retrouve les 3 boucles: (A) (correspondant à la stoechiométrie [A]) (B′) et (B″) (correspondant à la

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

stoechiométrie [B]). Une quatrième boucle (D) composée des processus [2A], [3″A], [2″B], [3′B] correspond à la somme des stoechiométries [A] + [B].

La stoechiométrie [A] relève du *cas limite* [A]: $(k_{3'A} + k_{3''A})\ (\mu H)_0 \ll k_{2A}$, car le processus unimoléculaire [2A] correspond à la rupture, relativement facile, d'une liaison carbone–carbone. Il est ainsi plus facile que les deux processus bimoléculaires parallèles (et de constantes de vitesse voisines) [3′A] et [3″A]. Le calcul des concentrations radicalaires dans la pyrolyse du propane (4, 17) montre que l'on a bien: $(CH_3\cdot) \gg (\mu_A\cdot)$. C'est une chaîne de ''type néopentane''.

La chaîne représentée par la boucle (B″) relève du *cas limite* [B]: $k_{2''B} < (k_{3'B} + k_{3''B})\ (\mu H)_0$, car le processus unimoléculaire [2″B] correspond à la rupture, relativement difficile, d'une liaison carbone–hydrogène (hydrogène primaire). Il est ainsi plus difficile que les deux processus bimoléculaires parallèles (et de constantes de vitesse voisines) [3′B] et [3″B]. Le calcul (4, 17) montre que l'on a bien: $(\mu_B\cdot) > (H\cdot)$. C'est une chaîne de ''type éthane''.

Dans la chaîne représentée par la boucle (B′) le processus unimoléculaire [2′B] correspond aussi à la rupture d'une liaison carbone–hydrogène, mais cette fois d'un hydrogène secondaire (dans le cas du propane) ou tertiaire (dans le cas de l'isobutane). Le processus [2′B] est donc moins difficile que le processus [2″B] et la chaîne (B′) est plutôt du type ''intermédiaire'' entre les *cas limites* [A] et [B].

(*Remarque*. Rappelons que dans l'analogie hydraulique le diamètre des conduites est fonction de la constante de vitesse (pour les processus unimoléculaires) ou de la constante de vitesse multipliée par la concentration du réactif (pour les processus bimoléculaires). Le débit de fluide (c'est-à-dire la vitesse du processus élémentaire) dépend non seulement de la taille de la conduite mais de la ''pression'' en amont, c'est-à-dire de la concentration du radical impliqué. Ceci explique pourquoi, malgré le diamètre notable de [2′B], le débit dans cette conduite est nettement inférieur à celui dans [2″B], de diamètre pourtant plus faible.)

*1.3. Echanges entre radicaux libres* $\mu_A\cdot$ *et* $\mu_B\cdot$ *et importances relatives des deux stoechiométries [A] et [B]*

Le schéma hydraulique permet de bien visualiser *les échanges entre* $\mu_A\cdot$ *et* $\mu_B\cdot$. Ce phénomène est très important et il servira plus loin de clé à l'interprétation des variations des importances relatives des stoechiométries en présence d'additif YH.

On voit que le passage $\mu_A\cdot \rightarrow \mu_B\cdot$ peut se faire par les conduites: (2A) (suivie de (3″A)), (2′B) (suivie de (3″B)), (−6); le passage $\mu_B\cdot \rightarrow \mu_A\cdot$ peut se faire par les conduites: (2″B) (suivie de (3′B)), (6). Ce sont bien ces *5 termes* que l'on retrouve dans le rapport $R = (\mu_B\cdot)/(\mu_A\cdot)$, calculé par ailleurs (17) dans le cas de la pyrolyse de μH pur:[1]

$$[I] \quad R = \frac{(1+\gamma)k_{-6}(\mu H)_0 + \gamma(k_{2A} + k_{2'B})}{(1+\gamma)k_6(\mu H)_0 + k_{2''B}}$$

L'équilibre dynamique entre $\mu_A\cdot$ et $\mu_B\cdot$ et donc *les importances relatives des stoechiométries [A] et [B]* ne dépendent *que de ces 5 conduites* (dans le cas de la pyrolyse de μH pur). Seule *l'intervention de nouvelles conduites* entre $\mu_A\cdot$ et $\mu_B\cdot$, due à la présence d'un additif YH, pourra, comme nous le verrons, déplacer l'équilibre entre $\mu_A\cdot$ et $\mu_B\cdot$ et *changer la sélectivité de la décomposition de* μH.

Ce schéma hydraulique permet également de comprendre les variations des importances relatives des deux stoechiométries en fonction des conditions expérimentales (température et pression initiale d'hydrocarbure).

Supposons d'abord, pour simplifier, que le processus [2′B] soit absent, ainsi que les processus d'isomérisation [6] et [−6].

Les conduites (3′A) et (3″A) étant de diamètres voisins, il est facile de voir que la stoechiométrie [A] provient: pour moitié environ de la boucle (A); pour moitié environ de la boucle complexe (D) composée de (2A) (3″A) (2″B) (3′B) de stoechiométrie: $2\,\mu H = m_A + CH_4 + m_B + H_2$. De la même façon, les conduites (3′B) et (3″B) ont des diamètres voisins et la stoechiométrie [B] provient: pour moitié environ de la boucle (B″); pour moitié environ de la boucle complexe (D) composée de (2A) (3″A) (2″B) (3′B). Ainsi les deux stoechiométries [A] et [B] sont sensiblement d'*égale importance* dans ce cas simple.

---

[1]On a supposé que l'on a: $\gamma = k_{3''A}/k_{3'A} \simeq k_{3''B}/k_{3'B}$. Ce rapport γ est très voisin de 1 et c'est la raison pour laquelle nous avons attribué aux conduites (3′A) et (3″A) d'une part et (3′B) et (3″B) d'autre part des diamètres très voisins. Les calculs ont été faits, en supposant, d'autre part, que les chaînes étaient longues.

*A suffisamment haute température*, l'intervention des processus d'isomérisation [6] et [−6] ne modifie pas sensiblement le résultat précédent, car les conduites (6) et (−6) sont de faible diamètre par rapport aux autres conduites d'échange entre $\mu_A$ et $\mu_B$.[2]

En revanche, l'intervention de la conduite (2′B), de taille intermédiaire entre (2A) et (2″B), transforme des $\mu_A\cdot$ en H· et tend donc à diminuer l'importance de la stoechiométrie [A] par rapport à [B].

C'est bien ce qui est observé, dans le cas du propane, pour $T \geq 600$°C. Par exemple, à 600°C: [A]/[B] ≃ 0,8 (17).

*A plus basse température* (vers 500°C), l'isomérisation [6], [−6] intervient et tend à transformer $\mu_B\cdot$ en $\mu_A\cdot$.[3] Les processus [6] et [−6] étant bimoléculaires, cet effet est d'autant plus marqué que la pression initiale d'hydrocarbure $P_0$ est plus grande. Au contraire, [2′B] tend à convertir $\mu_A\cdot$ en H· (donc en $\mu_B\cdot$).

Les importances relatives de ces deux effets opposés permettent d'interpréter les faits expérimentaux suivants: (*i*) à basse pression initiale d'hydrocarbure (par exemple: $P_0 < 300$ Torr environ pour le propane) on a: [A]/[B] < 1, aussi bien dans le cas du propane (4) que dans celui de l'isobutane (6, 11). L'influence de [2′B] l'emporte alors sur celle de l'isomérisation [6], [−6]; (*ii*) à plus haute pression initiale d'hydrocarbure (par exemple: $P_0 > 300$ Torr pour le propane) on a: [A]/[B] > 1 (4). L'influence de $P_0$ sur [6] et [−6] fait que l'effet de l'isomérisation l'emporte alors sur celui de [2′B].

## 2. Pyrolyse distoechiométrique d'une substance organique (μH) en présence d'un corps hydrogéné (YH)

### *2.1. Mécanisme "μH, YH" généralisé*

Par analogie avec le mécanisme "μH, YH" vu précédemment (cf. Premier Mémoire (1)), on peut écrire, a priori, un mécanisme "μH, YH" généralisé correspondant à l'action d'un additif YH sur la pyrolyse d'une substance se décomposant selon deux équations stoechiométriques primaires principales:

[1] amorçage: $\mu H \xrightarrow{k_1}$ radicaux libres

suivi, éventuellement, de processus de transfert

[2A], [3′A] propagation $\textcircled{A}_I$

$$\left\{\begin{array}{rl} \mu_A\cdot & \xrightarrow{k_{2A}} m_A + CH_3\cdot \\ CH_3\cdot + \mu H & \xrightarrow{k_{3'A}} CH_4 + \mu_A\cdot \end{array}\right.$$

[2A], [4A], [5A], [−5A] propagation $\textcircled{A}_{II}$

$$\left\{\begin{array}{rl} \mu_A\cdot & \xrightarrow{k_{2A}} m_A + CH_3\cdot \\ CH_3\cdot + YH & \xrightarrow{k_{4A}} CH_4 + Y\cdot \\ Y\cdot + \mu H & \underset{k_{-5A}}{\overset{k_{5A}}{\rightleftharpoons}} YH + \mu_A\cdot \end{array}\right.$$

[2′B], [3′B] propagation $\textcircled{B'}_I$

$$\left\{\begin{array}{rl} \mu_A\cdot & \xrightarrow{k_{2'B}} m_B + H\cdot \\ H\cdot + \mu H & \xrightarrow{k_{3'B}} H_2 + \mu_A\cdot \end{array}\right.$$

[2′B], [4B], [5A], [−5A] propagation $\textcircled{B'}_{II}$

$$\left\{\begin{array}{rl} \mu_A\cdot & \xrightarrow{k_{2'B}} m_B + H\cdot \\ H\cdot + YH & \xrightarrow{k_{4B}} H_2 + Y\cdot \\ Y\cdot + \mu H & \underset{k_{-5A}}{\overset{k_{5A}}{\rightleftharpoons}} YH + \mu_A\cdot \end{array}\right.$$

[2″B], [3″B] propagation $\textcircled{B''}_I$

$$\left\{\begin{array}{rl} \mu_B\cdot & \xrightarrow{k_{2''B}} m_B + H\cdot \\ H\cdot + \mu H & \xrightarrow{k_{3''B}} H_2 + \mu_B\cdot \end{array}\right.$$

[2]Les énergies d'activation des processus *bimoléculaires* [6] et [−6] sont nettement inférieures à celles des processus *unimoléculaires* [2A], [2″B] et [2′B]. Le calcul montre qu'à suffisamment haute température [6] et [−6] sont négligeables devant [2A], [2″B] et [2′B]. En revanche lorsque la température baisse, on doit tenir compte de [6] et [−6].

[3]Bien que $k_{-6}$ soit légèrement supérieur à $k_6$ (4, 10, 18), l'inégalité $(\mu_B\cdot) \gg (\mu_A\cdot)$ conduit à un flux de passage $\mu_B\cdot \rightarrow \mu_A\cdot$ plus important que le flux $\mu_A\cdot \rightarrow \mu_B\cdot$.

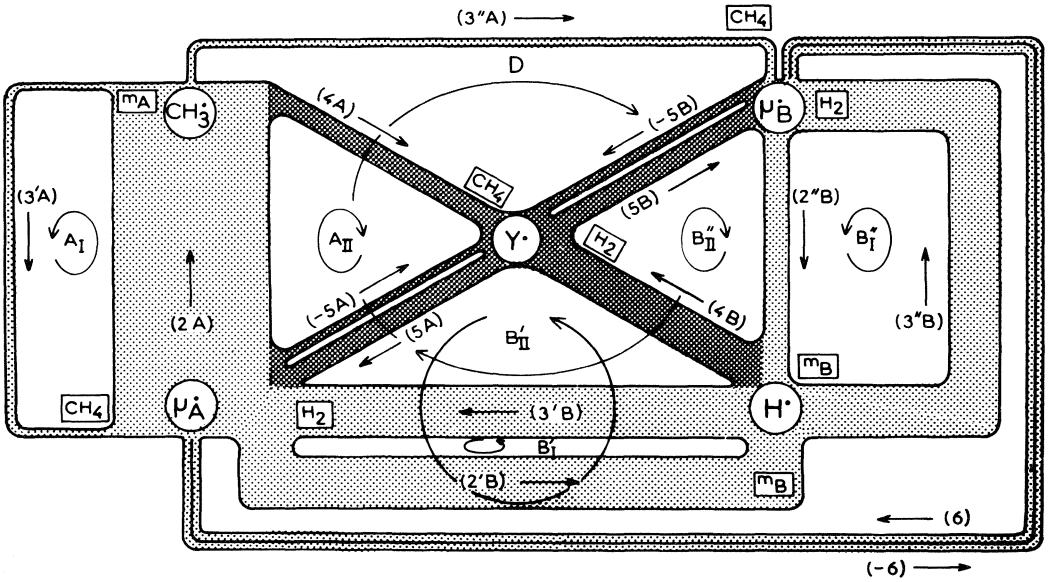

FIG. 2. Analogie hydraulique pour la propagation des chaînes dans la pyrolyse d'une substance organique μH en présence d'un additif YH.

[2″B], [4B], [5B], [−5B] — propagation $(B'')_{II}$:

$$\mu_B\cdot \xrightarrow{k_{2''B}} m_B + H\cdot$$

$$H\cdot + YH \xrightarrow{k_{4B}} H_2 + Y\cdot$$

$$Y\cdot + \mu H \underset{k_{-5B}}{\overset{k_{5B}}{\rightleftharpoons}} YH + \mu_B\cdot$$

[3″A] — processus de croisement des chaînes:

$$CH_3\cdot + \mu H \xrightarrow{k_{3''A}} CH_4 + \mu_B\cdot$$

[6], [−6] — isomérisation:

$$\mu_B\cdot + \mu H \underset{k_{-6}}{\overset{k_6}{\rightleftharpoons}} \mu H + \mu_A\cdot$$

terminaison: combinaison (et dismutation éventuelle) 2 à 2 des porteurs de chaînes les plus abondants, c'est-à-dire $CH_3\cdot$, $\mu_B\cdot$ et éventuellement, Y·, selon la nature de YH.

### 2.2. *Analogie hydraulique pour la propagation des chaînes et influence de YH sur la sélectivité de la pyrolyse de μH*

On complète le schéma de la figure 1 avec les nouvelles conduites pour obtenir le schéma global de la figure 2 représentant les processus de propagation, de croisement de chaînes et d'isomérisation.

Pour la clarté de l'exposé, nous allons d'abord supposer que la présence de YH n'*introduit pas de terminaisons nouvelles*; ceci signifie que nous allons traiter uniquement de l'*effet de YH sur les propagations*, croisement de chaînes et isomérisation, *sans nous préoccuper de l'effet global* qui, comme on l'a vu (cf. Premier Mémoire (1)), fait, en plus, intervenir les terminaisons nouvelles éventuelles.

Nous évoquerons l'influence *globale* de YH sur la pyrolyse de μH au paragraphe 2.3.

Par analogie avec les raisonnements utilisés dans le cas de l'étude des réseaux électriques complexes, nous partirons de circuits hydrauliques simples "extraits" du schéma de la figure 2 et nous les compléterons progressivement jusqu'à l'obtention du schéma complet.

#### 2.2.1. *Influence de YH sur la stoechiométrie [A]*

On a vu précédemment que la décomposition de μH pur selon la stoechiométrie [A] se fait par la boucle $(A)_I$ et la boucle complexe (D) composée de [2A] [3″A] [2″B] [3′B]. Dans ces deux boucles, les "goulots d'étranglement" sont, respectivement, les conduites (3′A) et (3″A).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

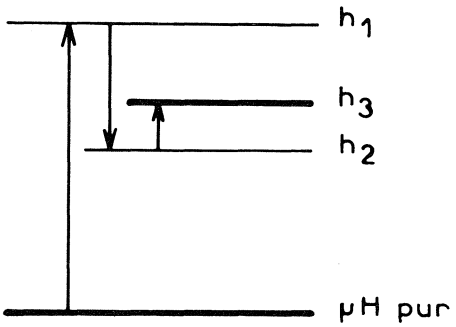

FIG. 3. Concentration de $\mu_A\cdot$ dans les différentes hypothèses.

Considérons successivement les hypothèses suivantes:

*Hypothèse* $h_1$: on suppose que le schéma de la figure 2 *se réduit* aux boucles Ⓐ$_I$, Ⓓ et Ⓐ$_{II}$ "isolées" du reste du système.

La présence de YH permet un nouveau passage de $CH_3\cdot$ vers $\mu_A\cdot$ par (4A) et (5A) (−5A), augmente le débit dans (2A) et donc accélère la stoechiométrie [A], comme dans le cas du néopentane en présence de YH. La concentration de $\mu_A\cdot$ croît (Fig. 3). Cette accélération est d'autant plus forte que la nouvelle conduite (4A) est de diamètre important par rapport aux anciennes conduites (3′A) et (3″A).

*Hypothèse* $h_2$: on suppose maintenant, en plus, que les échanges entre $\mu_A\cdot$ et $\mu_B\cdot$ sont les mêmes qu'en l'absence de YH, c'est-à-dire se font *exclusivement* par les conduites (2A) (2′B) (−6) et (2″B) (6) (cf. Sect. 1.3), aucun échange entre $\mu_A\cdot$ et $\mu_B\cdot$ n'ayant lieu par l'intermédiaire du radical Y·.

L'augmentation de $(\mu_A\cdot)$ due à la présence de YH est limitée par les échanges $\mu_A\cdot \leftrightarrow \mu_B\cdot$ puisque le rapport des concentrations $(\mu_B\cdot)/(\mu_A\cdot)$ est le même qu'en l'absence de YH. Il y a donc passage $\mu_A\cdot \rightarrow \mu_B\cdot$ et ceci bien que $(\mu_B\cdot) \gg (\mu_A\cdot)$ dans la pyrolyse de μH pur. On a indiqué la chute de la concentration $(\mu_A\cdot)$ dans l'hypothèse $h_2$, sur la figure 3.

*Hypothèse* $h_3$: cette fois, on tient compte, des nouvelles conduites d'échange: $\mu_A\cdot \rightarrow \mu_B\cdot$ par (−5A) suivi de (5B); $\mu_B\cdot \rightarrow \mu_A\cdot$ par (−5B) suivi de (5A).

Notons que ce sont bien les deux processus [−5A] et [−5B] qui apparaissent, en plus des anciens termes, dans l'expression théorique du rapport: $R_{YH} = (\mu_B\cdot)/(\mu_A\cdot)$ en présence de YH (6, 17):[4]

$$[II] \quad R_{YH} = \frac{(\mu_B\cdot)}{(\mu_A\cdot)} = \frac{\gamma k_{-5A}(YH)_0 + (1+\gamma)k_{-6}(\mu H)_0 + \gamma(k_{2A} + k_{2'B})}{k_{-5B}(YH)_0 + (1+\gamma)k_6(\mu H)_0 + k_{2''B}}$$

Ces nouvelles conduites (de tailles voisines) augmentent les échanges entre $\mu_A\cdot$ et $\mu_B\cdot$. La concentration $(\mu_B\cdot)$ étant bien supérieure à $(\mu_A\cdot)$ le débit de passage $\mu_B\cdot \rightarrow \mu_A\cdot$ est plus grand que celui de $\mu_A\cdot \rightarrow \mu_B\cdot$. La concentration relative de $\mu_B\cdot$ par rapport à $\mu_A\cdot$ diminue, ce qui tend à augmenter la concentration $(\mu_A\cdot)$ par rapport à sa valeur dans l'hypothèse $h_2$ (cf. Fig. 3).

La vitesse $V_0^A$ de décomposition de μH selon la stoechiométrie [A] s'écrit:

$$V_0^A = V_0^{CH_4} = V_0^{m_A} = k_{2A}(\mu_A\cdot)$$

La figure 3 représente donc également les variations de $V_0^A$ dans les différentes hypothèses.

Ce raisonnement qualitatif concernant l'influence de YH sur la stoechiométrie [A] est compatible avec les calculs théoriques effectués à partir du mécanisme "μH, YH" généralisé. En supposant toujours que la présence de YH ne fait pas apparaître de terminaisons nouvelles,[5] on peut calculer (17) le rapport $\Phi_{YH}^A$ des vitesses initiales de décomposition de μH selon la stoechiométrie [A], en présence de YH, $(V_0^A)_{YH}$ et en l'absence de YH, $V_0^A$:

[4]Dans l'expression de $R_{YH}$, le coefficient γ préalablement défini est aussi supposé égal à: $k_{5B}/k_{5A}$ de sorte que: $\gamma \simeq k_{5B}/k_{5A} \simeq k_{3''A}/k_{3'A} \simeq k_{3''B}/k_{3'B}$.

[5]On a supposé que la terminaison des chaînes, en l'absence de YH, impliquait les radicaux $CH_3\cdot$ et $\mu_B\cdot$: processus [ββ], [$\beta\mu_B$], [$\mu_B\mu_B$].

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

$$[III] \quad \Phi_{YH}{}^{A} = \frac{(V_0{}^{A})_{YH}}{V_0{}^{A}} = \frac{r + \left(\frac{k_{\mu_B\mu_B}}{k_{\beta\beta}}\right)^{1/2} R}{r_{YH} + \left(\frac{k_{\mu_B\mu_B}}{k_{\beta\beta}}\right)^{1/2} R_{YH}}$$

où $r_{YH} = (CH_3\cdot)/(\mu_A\cdot)$ et $R_{YH} = (\mu_B\cdot)/(\mu_A\cdot)$. $R$ et $r$ étant relatifs à la pyrolyse de μH *pur*.

*Hypothèse* $h_1$: il n'y a pas d'échange entre $\mu_A\cdot$ et $\mu_B\cdot$ autre que la boucle (D) et on suppose que la terminaison des chaînes ne fait intervenir *que* le radical $\beta\cdot \equiv CH_3\cdot$, comme dans la pyrolyse du néopentane. Le rapport $\Phi_{YH}{}^{A}$ s'écrit alors:[6]

$$[IV] \quad \Phi_{YH}{}^{A} = \frac{(V_0{}^{A})_{YH}}{V_0{}^{A}} = \frac{r}{r_{YH}} = 1 + \frac{k_{4A}}{(k_{3'A} + k_{3''A})} \frac{(YH)_0}{(\mu H)_0}$$

On retrouve, au niveau des propagations, *le terme accélérateur* qui apparaît dans la pyrolyse du néopentane en présence de YH (cf. Premier Mémoire (1) Sect. 2.3.)

*Hypothèse* $h_2$: si les échanges entre $\mu_A\cdot$ et $\mu_B\cdot$ sont les mêmes en présence de YH qu'en l'absence: $R_{YH} \equiv R$ et le rapport $\Phi_{YH}{}^{A}$ s'écrit (en faisant intervenir cette fois le radical $\mu_B\cdot$ dans les terminaisons):

$$[V] \quad \Phi_{YH}{}^{A} = \frac{(V_0{}^{A})_{YH}}{V_0{}^{A}} = \frac{r + \left(\frac{k_{\mu_B\mu_B}}{k_{\beta\beta}}\right)^{1/2} R}{r_{YH} + \left(\frac{k_{\mu_B\mu_B}}{k_{\beta\beta}}\right)^{1/2} R} < \frac{r}{r_{YH}}$$

Le terme accélérateur $r/r_{YH}$ de l'hypothèse $h_1$ est en fait diminué à cause de l'échange $\mu_A\cdot \leftrightarrow \mu_B\cdot$.

*Hypothèse* $h_3$: les échanges font intervenir de nouveaux termes au numérateur et au dénominateur de $R_{YH}$; ces nouveaux termes sont voisins et comme $R \gg 1$ on obtient $R_{YH} < R$. Le dénominateur est ainsi plus petit que dans l'hypothèse $h_2$, ce qui tend à augmenter un peu la valeur du rapport des vitesses initiales par rapport à l'hypothèse $h_2$. Le rapport $\Phi_{YH}{}^{A}$ prend alors la forme (III).

L'analogie hydraulique permet ainsi de bien mettre en évidence l'origine "physique" des différents termes apparaissant dans la formule (III).

*2.2.2. Influence de YH sur la stoechiométrie [B]*

La stoechiométrie [B] provient, en l'absence de YH, des chaînes $(B'')_I$ et $(B')_I$.

(*a*) *Considérons d'abord la boucle* $(B'')_I$. Dans cette boucle, le "goulot d'étranglement" est constitué par la conduite (2″B), comme pour la pyrolyse de l'éthane.

Considérons successivement les hypothèses suivantes:

*Hypothèse* $h_1'$: on suppose que la boucle $(B'')_I$ est *isolée*. L'adjonction de nouvelles conduites: (4B) (5B) (−5B) n'augmente pas le débit dans (2″B): YH est sans effet sur la formation de $m_B$ et $H_2$ et la concentration de $\mu_B\cdot$ reste la même qu'en l'absence de YH (cf. Fig. 4).

*Hypothèse* $h_2'$: en réalité il y a des échanges entre $\mu_A\cdot$ et $\mu_B\cdot$. Supposons qu'ils soient les mêmes qu'en l'absence de YH: échanges par (2A), (2′B), (−6) dans un sens et (2″B), (6) dans l'autre sens. Le rapport des concentrations $(\mu_B\cdot)/(\mu_A\cdot)$ reste le même qu'en l'absence de YH et comme $(\mu_A\cdot)$ augmente, $(\mu_B\cdot)$ augmente aussi, dans les mêmes proportions (cf. Fig. 4).

*Hypothèse* $h_3'$: les échanges entre $\mu_A\cdot$ et $\mu_B\cdot$ se font non seulement par les anciennes conduites, mais aussi par les nouvelles: de $\mu_A\cdot$ vers $\mu_B\cdot$ par (−5A) (5B), et de $\mu_B\cdot$ vers $\mu_A\cdot$ par (−5B) (5A).

Comme on l'a vu dans l'étude de la stoechiométrie [A], ces nouvelles conduites, de tailles voisines, tendent à faire diminuer la concentration $(\mu_B\cdot)$ et à augmenter $(\mu_A\cdot)$ et ceci d'autant plus que leurs diamètres sont gros par rapport à ceux des anciennes conduites d'échange, en l'absence de YH.

La concentration $(\mu_B\cdot)$ chute par rapport à sa valeur dans l'hypothèse $h_2'$: si les nouvelles conduites sont de très faible diamètre, $(\mu_B\cdot)$ chute très peu et la chaîne (B″) *est pratiquement autant accélérée que la*

[6]On a:

$$r_{YH} = \frac{k_{2A}}{k_{4A}(YH)_0 + (k_{3'A} + k_{3''A})(\mu H)_0} \quad \text{et} \quad r = \frac{k_{2A}}{(k_{3'A} + k_{3''A})(\mu H)_0}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

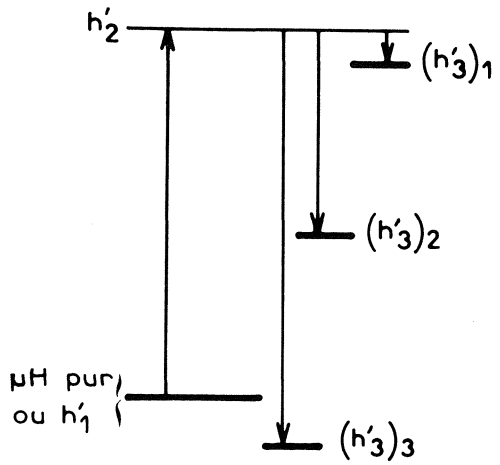

FIG. 4. Concentration de $\mu_B$· dans les différentes hypothèses.

*chaîne* (A) (Cas $(h_3')_1$); si les nouvelles conduites ont des diamètres notables, la diminution de ($\mu_B$·) est importante et la chaîne (B″) *est beaucoup moins accélérée que la chaîne* (A) (Cas $(h_3')_2$); et enfin, si les nouvelles conduites ont des diamètres importants, la diminution de ($\mu_B$·) par rapport à sa valeur $h_2'$ est telle que sa valeur en présence de YH est inférieure à sa valeur dans le cas de μH pur: *la chaîne* (B″) *est alors inhibée, alors que la chaîne* (A) *est accélérée* (Cas $(h_3')_3$).

(*b*) *Considérons maintenant la boucle* $(B')_I$. On a vu qu'elle pouvait être du type "intermédiaire" entre les *cas limites* [A] et [B] de la théorie "μH, YH". L'influence de YH sur cette chaîne est, en fait, très facile à décrire, puisque la vitesse de cette chaîne est: $V_0^{B'} = k_{2'B}(\mu_A\cdot)$. En présence de YH, on a vu que ($\mu_A$·) augmente, donc la *chaîne* (B′) *est accélérée dans les mêmes proportions que la chaîne* (A).

Ainsi, globalement, la stoechiométrie [B] provient de deux chaînes: l'une, (B′) est accélérée par YH dans les mêmes proportions que la stoechiométrie [A]; l'autre, (B″) peut être, soit accélérée comme [A], soit moins accélérée que [A], soit même inhibée.

On retrouve les résultats qualitatifs précédents en considérant la forme du rapport $(V_0^B)_{YH}/V_0^B$ des vitesses initiales de décomposition de μH selon la stoechiométrie [B], en présence et en l'absence de YH.

Avec les mêmes hypothèses concernant les terminaisons (en [ββ], [$\beta\mu_B$] et [$\mu_B\mu_B$]) on peut calculer (17):

$$[VI]\quad \Phi_{YH}{}^{B} = \frac{(V_0^B)_{YH}}{V_0^B} = \frac{r + \left(\frac{k_{\mu_B\mu_B}}{k_{\beta\beta}}\right)^{1/2} R}{r_{YH} + \left(\frac{k_{\mu_B\mu_B}}{k_{\beta\beta}}\right)^{1/2} R_{YH}} \times \frac{k_{2''B}R_{YH} + k_{2'B}}{k_{2''B}R + k_{2'B}}$$

*terme accélérateur* — *terme inhibiteur* car $R_{YH} < R$

Le terme *accélérateur* est le même que celui de la stoechiométrie [A]: on retrouve l'hypothèse $h_2'$ précédente.

Le terme *inhibiteur* contient les termes $k_{2''B}R_{YH}$ au numérateur et $k_{2''B}R$ au dénominateur; le rapport de ces deux termes est inférieur à 1, puisque $R_{YH} < R$. On retrouve l'hypothèse $h_3'$ précédente correspondant à l'effet de YH sur la chaîne (B″). Selon l'importance de l'écart entre $R_{YH}$ et $R$, le résultat *global* sera soit une accélération de [B] identique à celle de [A] (hypothèse $(h_3')_1$: $R_{YH} \simeq R$), soit une accélération moins forte que celle de [A] (hypothèse $(h_3')_2$: $R_{YH} < R$), soit enfin, une inhibition de [B] (hypothèse $(h_3')_3$: $R_{YH} \ll R$). Le terme inhibiteur comprend également au numérateur et au dénominateur le terme $k_{2'B}$. Ce terme rend compte de l'existence de la chaîne (B′) qui, comme on l'a vu, est accélérée dans les mêmes proportions que la stoechiométrie [A]. Ces termes $k_{2'B}$ tendent à rapprocher de 1 la valeur du terme inhibiteur et donc à compenser un peu l'effet inhibiteur de YH sur la chaîne (B″).

For personal use only.

*2.2.3. Influence de YH sur la sélectivité de la décomposition de* μ*H* (proportions relatives des stoechiométries [A] et [B])

L'analyse de l'influence de YH sur les stoechiométries [A] et [B] a montré que *toute variation de la sélectivité de décomposition de* μ*H*, c'est-à-dire des proportions relatives des stoechiométries [A] et [B], ne peut provenir que de *l'effet de YH sur la boucle* (B″) et que cet effet dépend de la taille des nouvelles conduites apparaissant en présence de YH et permettant de nouveaux échanges $\mu_A\cdot \leftrightarrow \mu_B\cdot$: (*a*) si ces nouvelles conduites sont de très faible diamètre, c'est-à-dire si les processus

[−5A] $\mu_A\cdot + YH \rightarrow \mu H + Y\cdot$

et

[−5B] $\mu_B\cdot + YH \rightarrow \mu H + Y\cdot$

sont difficiles, il n'y a pas de variation de la sélectivité, i.e. *(B) sera accélérée comme (A)*; (*b*) si ces nouvelles conduites ont des diamètres notables, la stoechiométrie [B] sera: soit *accélérée*, mais plus faiblement que [A] (processus [−5A] et [−5B] assez faciles); soit *inhibée* (processus [−5A] et [−5B] très faciles).

On retrouve, par le calcul, les conclusions précédentes. Le calcul théorique montre en effet que les sélectivités $S$ et $S_{YH}$ de la décomposition de μH, respectivement en l'absence et en présence de YH s'écrivent:

$$[\text{VII}] \quad S = \frac{V_0^A}{V_0^B} = \frac{k_{2A}}{k_{2''B}R + k_{2'B}} \quad \text{et} \quad S_{YH} = \frac{(V_0^A)_{YH}}{(V_0^B)_{YH}} = \frac{k_{2A}}{k_{2''B}R_{YH} + k_{2'B}}$$

Le rapport des sélectivités en présence et en l'absence de YH s'écrit donc:

$$[\text{VIII}] \quad \frac{S_{YH}}{S} = \frac{1 + \dfrac{k_{2''B}}{k_{2'B}} R}{1 + \dfrac{k_{2''B}}{k_{2'B}} R_{YH}}$$

qui est, évidemment, le rapport inverse du terme inhibiteur vu dans l'étude de la stoechiométrie [B] (cf. relation (VI)).

*La présence de YH tend donc à augmenter, à très faible avancement, la sélectivité en [A] par rapport à [B]*, l'effet étant d'autant plus marqué que $R_{YH}$ est petit par rapport à $R$, c'est-à-dire que les nouveaux processus [−5A] et [−5B] sont *faciles* par rapport aux "anciens" processus d'échange: [2A], [2′B], [−6] d'une part et [2″B], [6] d'autre part.

Pour un corps μH donné, le changement de sélectivité dû à la présence de YH dépend donc des trois facteurs suivants: (*i*) pour une même teneur et une même température, il dépend de *la nature de l'additif YH*, c'est-à-dire des constantes de vitesses des deux processus [−5A] et [−5B]; (*ii*) pour un additif YH donné, il est d'autant plus fort: que la *température est plus basse*: les énergies d'activation des processus bimoléculaires [−5A] et [−5B] étant plus faibles que celles des processus unimoléculaires [2A], [2″B] et [2′B], les nouvelles conduites d'échange (−5A) et (−5B) ne seront comparables aux anciennes ((2A), (2″B), (2′B)) que si la température n'est pas trop élevée; et (*iii*) que la *concentration de YH ajouté est plus* forte: les diamètres des conduites (−5A) et (−5B) dépendent, en effet, des produits $k_{-5A}(YH)_0$ et $k_{-5B}(YH)_0$.

*2.2.4. Changements de sélectivité observés lors de la pyrolyse du propane et de l'isobutane en présence d'additifs YH*

L'influence de YH sur la *sélectivité* des pyrolyses d'alcanes μH se décomposant selon deux équations stoechiométriques primaires principales a été étudiée expérimentalement sur les exemples suivants: pyrolyse du *propane*, étude de l'influence de $H_2$, $C_3H_6$, HCl, HBr et $H_2S$; pyrolyse de l'*isobutane*, étude de l'influence de HCl, HBr, $H_2S$ et $C_3H_6$.

*Remarque préliminaire concernant l'influence de* $H_2$

Bien que $H_2$ soit un produit primaire principal dans la pyrolyse du propane ou de l'isobutane *purs*, on peut montrer (17) que la théorie "μH, YH" généralisée exposée précédemment lui est applicable. Dans ce cas particulier, le schéma hydraulique de la figure 2 se simplifie (le radical Y· étant identique à H·), mais le

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

raisonnement général est directement transposable. On considérera donc $H_2$ comme un additif YH ordinaire.

Dans ce qui suit, nous ne nous intéresserons qu'*au changement de sélectivité* dû à la présence de YH, en faisant provisoirement abstraction de l'influence cinétique globale de cet additif, qui ne peut s'interpréter qu'en prenant en considération les terminaisons nouvelles éventuelles et qui sera traitée au paragraphe 2.3.

L'expérience confirme les prévisions du mécanisme et de l'analogie hydraulique. Comparons les sélectivités $S_{YH}$ et $S$, en reprenant, successivement, l'influence des trois facteurs précités.

*(a) Influence de la nature de l'additif YH*

Considérons l'action de $H_2$,[7] de $C_3H_6$, de HCl, de HBr et de $H_2S$ (4, 5) sur la pyrolyse du *propane* ($P_0$ = 100 Torr), à faible teneur ($x = (YH)_0/(C_3H_8)_0$ = quelques %) et dans le même domaine de température (490–550°C).

Avec $H_2$: $S_{YH} \simeq S$ ($T$ = 550°C, $x$ = 5%)
Avec $C_3H_6$: $S_{YH} \simeq 1{,}2 \times S$ ($T$ = 490°C, $x$ = 2,7%)
Avec $H_2S$: $S_{YH} \simeq 3{,}3 \times S$ ($T$ = 490°C, $x$ = 5%)
Avec HCl: $S_{YH} \simeq 4{,}1 \times S$ ($T$ = 490°C, $x$ = 5%)
Avec HBr: $S_{YH} \simeq 5{,}3 \times S$ ($T$ = 490°C, $x$ = 5%)

Ces résultats sont compatibles avec les importances relatives des nouvelles conduites par rapport aux anciennes; on a, en effet[8] (19–22):

$$(k_{-5A})_{C_3H_6} \simeq (k_{-3'B})_{H_2}{}^{9} < (k_{-5A})_{HCl} \simeq (k_{-5A})_{H_2S} < (k_{-5A})_{HBr}$$

et

$$(k_{-5B})_{C_3H_6} \simeq (k_{-3''B})_{H_2}{}^{9} < (k_{-5B})_{HCl} \simeq (k_{-5B})_{H_2S} < (k_{-5B})_{HBr}$$

L'influence relative de HCl, HBr, $H_2S$ (5, 6) et $C_3H_6$ (11, 13) sur la sélectivité de la pyrolyse de l'*isobutane* est analogue à celle observée dans le cas du propane.

*(b) Influence de la teneur en additif*

Lorsque $H_2$ est ajouté en petite quantité au propane (quelques %), vers 550°C, *on n'observé pas de changement de sélectivité*.[7]

En revanche, lorsque la teneur en $H_2$ est grande (par exemple $x = (H_2)_0/(C_3H_8)_0 = 21$), on constate, toujours vers 550°C, *un net changement de sélectivité*: $S_{YH}/S = 2{,}7$. Dans ces conditions les nouvelles conduites (−3′B) et (−3″B) ont des diamètres comparables à ceux des anciennes conduites qui assuraient les échanges $\mu_A\cdot \leftrightarrow \mu_B\cdot$ dans la pyrolyse du propane pur.

*(c) Influence de la température*

Vers 550°C l'addition de 21 fois plus de $H_2$ que de propane conduit, comme on vient de le voir à une *nette augmentation* de la sélectivité.

Vers 600°C, pour une teneur voisine en $H_2$: $x = 23$, on observe seulement une *très légère croissance de la sélectivité* par rapport à sa valeur dans la pyrolyse du propane pur (17).

Au-dessus de 650°C, l'expérience montre (17) que, pour cette même teneur, *aucun changement de sélectivité* ne se produit. Les travaux de Kunugi *et al.* (23) entre 700 et 800°C, pour $x$ = 7,5 sont compatibles avec ces observations.

*2.2.5. Remarque*

Considérons les variations de $R_{YH}$ (relation II) et de $S_{YH}/S$ (relation VIII) en fonction de la teneur en

[7]C. Richard. Résultats non encore publiés.

[8]On a supposé que le rapport des constantes de vitesse $k$ et $k'$ correspondant à:

$$R\cdot + YH \xrightarrow{k} RH + Y\cdot$$

$$R\cdot + Y'H \xrightarrow{k'} RH + Y'\cdot$$

était le même quel que soit le radical alcoyle R· attaquant YH ou Y′H. Les tables fournissent les constantes de vitesse correspondant à l'attaque du radical $CH_3\cdot$ sur différents additifs YH. Nous avons supposé que les rapports des différents $k$ sont conservés si $CH_3\cdot$ est remplacé par p-$C_3H_7\cdot$ ou s-$C_3H_7\cdot$.

[9]Dans le cas particulier où YH est $H_2$, les processus [−5A] et [−5B] deviennent, respectivement, les processus inverses [−3′B] et [−3″B] de deux processus existant dans la pyrolyse de μH pur.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

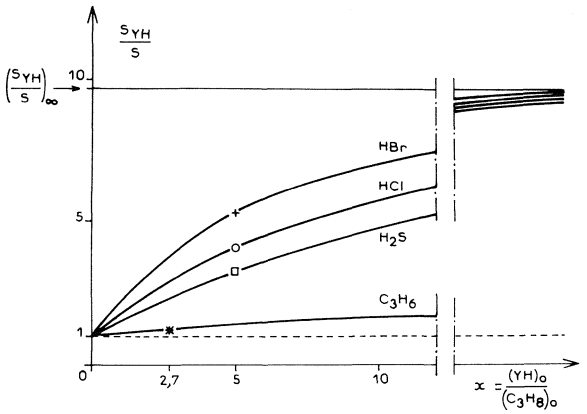

FIG. 5. Pyrolyse du propane en présence d'additifs YH. Variations, qualitatives, du rapport $S_{YH}/S$ des sélectivités en présence et en l'absence de YH en fonction de la teneur $x$ en YH. Réacteur fermé – $T$ = 490°C.

additif: $x = (YH)_0/(\mu H)_0$. Quand $x = 0$, $R_{YH} = R$ et $S_{YH}/S = 1$; quand $x \to \infty$, $R_{YH}$ se simplifie et devient: $R_\infty = \gamma(k_{-5A}/k_{-5B})$.

Compte-tenu de $\gamma = k_{5B}/k_{5A}$, $R_\infty$ s'écrit: $R_\infty = K_{5B}/K_{5A}$, où $K_{5B}$ et $K_{5A}$ sont les constantes d'équilibre des processus [5B] [−5B] et [5A] [−5A].

Ceci signifie que s'établit alors un double équilibre:

$$\mu_A\cdot + YH \underset{5A}{\overset{-5A}{\rightleftharpoons}} Y\cdot + \mu H \underset{-5B}{\overset{5B}{\rightleftharpoons}} \mu_B\cdot + YH$$

et que les radicaux $\mu_A\cdot$ et $\mu_B\cdot$ sont à l'équilibre thermodynamique: $\mu_A\cdot \overset{K}{\rightleftharpoons} \mu_B\cdot$

$$R_\infty = K = (\mu_B\cdot)/(\mu_A\cdot)$$

Les données de la littérature (24) permettent de prévoir, par exemple dans le cas du propane, que:

$$K = \frac{(\mu_B\cdot)}{(\mu_A\cdot)} \simeq 3{,}8 \text{ à } 490°C \quad \text{et} \quad 2{,}6 \text{ à } 650°C$$

Notons que ces valeurs sont compatibles avec le fait que nous avons considéré précédemment que les conduites (−5A) et (−5B) avaient des diamètres voisins (Sect. 2.2.).

Pour un corps μH donné, la valeur de $R_\infty$ est ainsi *indépendante de la nature de YH* et ne dépend que de la *température*. Il en est de même du rapport $(S_{YH}/S)_\infty$ à teneur "infinie" en YH.

La figure 5 représente ainsi, qualitativement, les courbes de variation de $S_{YH}/S$ en fonction de $x$, dans le cas du *propane*, à 490°C, pour 4 additifs: $C_3H_6$, $H_2S$, HCl et HBr. La valeur de l'asymptote $(S_{YH}/S)_\infty$ commune à ces 4 courbes est environ 9,7 à cette température;[10] seule la forme des courbes dépend de la nature de l'additif. Les 4 points expérimentaux permettent de positionner qualitativement les courbes les unes par rapport aux autres.

A 650°C l'asymptote ne correspond plus qu'à $(S_{YH}/S)_\infty = 5{,}6$. Pour un additif et une teneur $x$ donnés, le changement de sélectivité est donc d'autant plus marqué que la température est plus basse.

Ainsi le mécanisme "μH, YH" généralisé et l'analogie hydraulique pour la propagation des chaînes permettent de regrouper et d'interpréter des résultats expérimentaux variés sur les phénomènes de changement de sélectivité par action d'un additif hydrogéné.

*2.3. Influence cinétique globale de YH sur les réactions [A] et [B] de pyrolyse de μH*

Comme on l'a vu sur l'exemple de la pyrolyse du néopentane (Premier Mémoire (1)), l'effet cinétique global dépend: de l'effet cinétique au niveau des propagations (interprété par l'analogie hydraulique); de la présence de *terminaisons nouvelles éventuelles*. Selon l'importance de ces dernières, l'effet cinétique global peut être très variable.

Nous ne traiterons de l'influence de YH que sur la stoechiométrie [A], le comportement de la

[10]Les constantes de vitesses de la littérature utilisées figurent dans la référence 17.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

stoechiométrie [B] se déduisant de celui de [A] par les considérations de *sélectivité* développées précédemment.

Nous avons vu que l'*effet accélérateur au niveau des propagations* dépend de la taille de la nouvelle conduite (4A) par rapport aux conduites (3′A) et (3″A). Pour une même teneur en YH, cet effet dépend donc de la constante de vitesse du processus (4A).

Les données de la littérature (19–22) conduisent, dans le cas de la pyrolyse du *propane*, aux inégalités suivantes:

$$(k_{4A})_{HBr} > (k_{4A})_{HCl} \simeq (k_{4A})_{H_2S} > (k_{4A})_{H_2} \simeq (k_{4A})_{C_3H_6}$$

En ne prenant en compte *que le facteur accélérateur dû au processus [4A]*, on devrait observer les phénomènes suivants.

L'effet accélérateur global $\Phi_{HBr}{}^{A}$, à très faible avancement, de HBr sur la stoechiométrie [A] devrait être supérieur à ceux observés avec HCl ($\Phi_{HCl}{}^{A}$) ou $H_2S$ ($\Phi_{H_2S}{}^{A}$). Or l'expérience (4, 5) montre que, vers 500°C et pour $x = 5\%$: $\Phi_{HBr}{}^{A} \simeq 3{,}7$ (cf. Fig. 6a, courbe 1), $\Phi_{H_2S}{}^{A} \simeq 1{,}8$ (cf. Fig. 6a, courbe 2), $\Phi_{HCl}{}^{A} \simeq 4{,}9$ (cf. Fig. 6a, courbe 3). L'inversion, dans le cas de HBr et HCl, est due aux terminaisons nouvelles, plus importantes avec HBr qu'avec HCl.

HCl devrait plus accélérer la stoechiométrie [A] que $H_2$. C'est effectivement ce que l'on observe vers 500–550°C (4, 5, voir aussi la note en bas de page no 1): $\Phi_{HCl}{}^{A} \simeq 4{,}9$ alors que $\Phi_{H_2}{}^{A} \simeq 1$, pour une même teneur $x = 5\%$ (cf. Fig. 6a: courbes 3 et 4). Il faut ajouter de grosses quantités de $H_2$ pour obtenir un effet accélérateur notable sur la stoechiométrie [A]: $\Phi_{H_2}{}^{A} \simeq 4{,}5$ pour $x = 21$, vers 550°C[7] (cf. Fig. 7: courbe 1).

$H_2$ et $C_3H_6$ devraient avoir le même effet cinétique global sur la stoechiométrie [A]. En réalité $H_2$ n'a pas d'effet (à faible teneur),[7] alors que $C_3H_6$ *inhibe* fortement la stoechiométrie [A]: $\Phi_{C_3H_6}{}^{A} = 0{,}35$ pour $x = 2{,}7\%$ (4) (cf. Fig. 6a: courbes 4 et 5). Les terminaisons nouvelles importantes dues à la présence du radical allyle $C_3H_5\cdot$ peu réactif, sont responsables de cette action inhibitrice.[11]

En combinant maintenant l'effet cinétique de YH sur la stoechiométrie [A] et l'effet de changement de sélectivité, on peut imaginer les 5 cas possibles suivants:

*1er cas*: [A] est accélérée
[B] est accélérée de façon identique

C'est le cas de l'influence de $H_2$ sur $C_3H_8$ à haute température (≥650°C) (17): cf. courbes 3 et 4 de la figure 7.

*2ème cas*: [A] est accélérée
[B] est accélérée plus faiblement ou reste inchangée

C'est le cas: de l'influence de $H_2$ sur $C_3H_8$ à plus basse température (<600°C)[7]: cf.: courbes 1 et 2 de la figure 7; de l'influence de HCl sur $C_3H_8$ vers 500°C (4, 5): cf. courbes 3 des figures 6a et 6b; de l'influence de HCl sur i-$C_4H_{10}$ vers 500°C (5, 6).

*3ème cas*: [A] est accélérée
[B] est inhibée

C'est le cas: de l'influence de HBr ou $H_2S$ sur $C_3H_8$ (4, 5): cf. courbes 1 et 2 des figures 6a et 6b; de l'influence de HBr ou $H_2S$ sur i-$C_4H_{10}$ (5, 6).

*4ème cas*: [A] est inhibée
[B] est inhibée de façon identique

Nous n'avons pas actuellement d'exemple illustrant ce cas.

*5ème cas*: [A] est inhibée
[B] l'est également, mais plus fortement

C'est le cas de l'influence de $C_3H_6$ sur $C_3H_8$ (4). Les courbes 5 des figures 6a et 6b montrent que le changement de sélectivité n'est pas très important. Ce cas correspond également à l'influence de $C_3H_6$ sur i-$C_4H_{10}$ (11, 13).

[11]Rappelons que les radicaux allyle, formés à partir du propène, produit primaire principal dans la pyrolyse du propane *pur*, sont les principaux responsables de l'*auto-inhibition* de cette réaction (7, 9).

*2.4. Remarque*

Nous avons noté (cf. Introduction) que, pour le propane ou l'isobutane, la réaction [A] est du type "néopentane" et la réaction [B] du type "éthane". En raison de ces ressemblances, on pourrait être tenté de considérer comme évident le fait qu'en présence d'un corps hydrogéné YH donné, la réaction [A] se comporte cinétiquement comme la pyrolyse du néopentane et la réaction [B] comme la décomposition

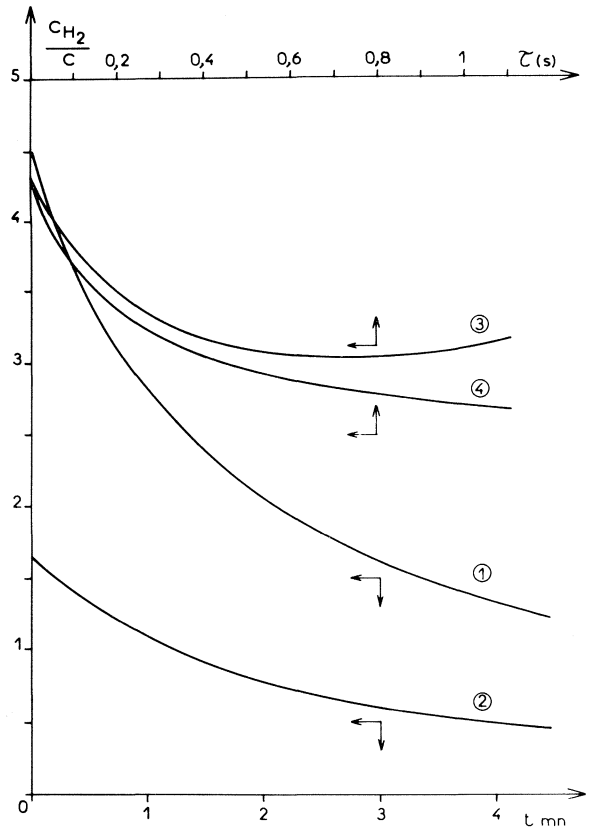

FIG. 7. Pyrolyse du propane en présence d'hydrogène. Variations du rapport $C_{H_2}/C$ de la concentration d'un produit primaire principal en présence d'hydrogène sur celle en l'absenced'hydrogène, en fonction: soit du temps de séjour $t$ (réacteur fermé, $T$ = 550°C, $x = (H_2)_0/(C_3H_8)_0 = 21$)[7], courbe 1: $C_2H_4$ (stoechiométrie [A]), courbe 2: $C_3H_6$ (stoechiométrie [B]); soit du temps de passage τ (réacteur ouvert parfaitement agité en régime permanent, $T$ = 650°C, $x = (H_2)_0/(C_3H_8)_0 = 23$ (17)), courbe 3: $C_2H_4$ (stoechiométrie [A]), courbe 4: $C_3H_6$ (stoechiométrie [B]).

de l'éthane. Mais ce raisonnement serait trop simpliste car, comme nous l'avons vu, des processus complexes de croisement de chaînes interviennent.

L'influence de $H_2$, à forte teneur, sur la pyrolyse du propane représente un contre-exemple typique du raisonnement simpliste (cf. Fig. 7). La stoechiométrie [B] est *accélérée*, aussi bien à 550°C ($\Phi_{H_2}^{B}$ = 1,65, pour $x$ = 21) qu'à 650°C ($\Phi_{H_2}^{B}$ = 4,3, pour $x$ = 23) alors que $H_2$ ne peut accélérer la pyrolyse de l'éthane (25).

### 3. Cas d'une pyrolyse à plus de deux stoechiométries

Dans le premier mémoire (1), nous avons examiné le cas simple d'une substance organique se décomposant selon *une seule* stoechiométrie primaire principale. Aux paragraphes 1 et 2 de ce second mémoire, nous avons considéré le cas, déjà plus complexe, d'une pyrolyse à *deux* stoechiométries. Examinons maintenant le cas, plus complexe encore, d'une substance organique se décomposant selon *plus de deux* stoechiométries.

La pyrolyse du n-*butane* constitue un exemple de ce type, puisqu'elle implique *trois* stoechiométries primaires principales (26, 27):

[$A_1$] $n$-$C_4H_{10} = C_3H_6 + CH_4$

[$A_2$] $n$-$C_4H_{10} = C_2H_4 + C_2H_6$

[B] $n$-$C_4H_{10} = 2C_2H_4 + H_2$

Cette réaction a été interprétée par un mécanisme de type "βμ" généralisé.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

Il a été montré (5, 14) que, vers 500°C, $H_2S$ *inhibe* la réaction [B] et, au contraire, *accélère* les réactions [$A_1$] et [$A_2$], qui tendent ainsi à devenir prépondérantes quand la concentration de $H_2S$ augmente. Ces modifications *cinétiques* et ces changements de *sélectivité* provoqués par $H_2S$ dans la décomposition thermique du *n*-butane ont été confirmés vers 600–650°C (15).

Par ailleurs, Rebick (15) a observé récemment des effets semblables de $H_2S$ sur la pyrolyse d'autres hydrocarbures (*n*-hexadécane, dodécène-1, *n*-butylbenzène, tétraline).

Tous ces effets de $H_2S$ sur des décompositions thermiques ont été expliqués essentiellement sur la base d'une extension du mécanisme "μH, YH" au cas d'une pyrolyse à plusieurs stoechiométries.

Notons enfin qu'au moins un procédé industriel utilise l'influence de $H_2S$ sur le craquage d'hydrocarbures (16).

## 4. Conclusion

Pour la pyrolyse (à très faible avancement) d'une substance organique μH (propane ou isobutane par ex.) impliquant *deux* stoechiométries principales:

[A] $\mu H = m_A + CH_4$

[B] $\mu H = m_B + H_2$

et un mécanisme radicalaire en chaînes de type "βμ" généralisé, l'*analogie hydraulique* utilisée ici pour représenter la *propagation* des chaînes nous a permis d'expliquer l'influence de la température et de la pression initiale sur la *sélectivité* de la décomposition de μH pur (importance de [A] par rapport à [B]).

Le mécanisme "μH, YH" généralisé et l'analogie hydraulique nous ont montré par ailleurs qu'un additif hydrogéné YH doit tendre à *augmenter* la *sélectivité* de la pyrolyse de μH et nous avons pu prévoir l'effet global de YH sur les *vitesses* initiales des réactions [A] et [B] de décomposition de μH. Nous avons montré que ces prévisions théoriques sont bien vérifiées expérimentalement. On rend ainsi compte de nombreuses observations faites lors de l'étude de l'influence d'additifs hydrogénés variés (HCl, HBr, $H_2S$, $H_2$, $C_3H_6$) sur la *cinétique* et la *sélectivité* de la pyrolyse du *propane* ou de l'*isobutane*.

Le mécanisme "μH, YH" généralisé permet également d'interpréter des *effets semblables* de $H_2S$ dans le cas de substances organiques se décomposant selon *plus de deux* stoechiométries primaires principales (*n*-butane, *n*-hexadécane, dodécène-1, *n*-butylbenzène, tétraline).

Rappelons aussi (cf. mémoire I) que le mécanisme "μH, YH" a déjà permis de rendre compte de phénomènes d'*accélération* ou d'*inhibition*, par des corps hydrogénés, de la pyrolyse de substances impliquant *une seule* stoechiométrie primaire principale.

En conclusion, ce mécanisme fournit une représentation synthétique et cohérente d'effets variés de divers additifs hydrogénés sur la *cinétique* et la *sélectivité* du craquage de nombreuses substances organiques; l'*analogie hydraulique* utilisée ici pour représenter la *propagation* des chaînes dans ces réactions aide à mieux saisir la signification microscopique des phénomènes observés.

# Modulation spectroscopy. Kinetics for the self-reactions of some α-aminoalkyl radicals in solution[1]

PAUL R. MARRIOTT, ARLINDO L. CASTELHANO, AND DAVID GRILLER
*Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6*

Received August 6, 1981

PAUL R. MARRIOTT, ARLINDO L. CASTELHANO, and DAVID GRILLER. Can. J. Chem. **60**, 274 (1982).

The optical spectra and reaction kinetics of some α-aminoalkyl radicals, $R\dot{C}HN(CH_2R)_2$; R ≡ H, Me, Ph, were measured in solution using the technique of modulation spectroscopy. These radicals undergo diffusion controlled self-reaction with rate constants $\simeq 10^9\ M^{-1}\ s^{-1}$. When R ≡ Ph, the absorption spectrum has a well defined maximum at 346 nm; $\varepsilon = 3390\ M^{-1}\ cm^{-1}$, while the spectra when R ≡ H or Me were less intense ($\varepsilon_{346}$ nm $\simeq 500\ M^{-1}\ cm^{-1}$) and tailed into the visible. These spectra are substantially red-shifted when compared with those of simple alkyl radicals, an effect which is thought to be due to the interaction between the unpaired electron and the lone pair of electrons on nitrogen.

PAUL R. MARRIOTT, ARLINDO L. CASTELHANO et DAVID GRILLER. Can. J. Chem. **60**, 274 (1982).

Faisant appel à la technique de spectroscopie modulée en solution, on a mesuré les spectres optiques et les cinétiques de réaction de quelques radicaux α-aminoalkyles, $R\dot{C}HN(CH_2R)_2$ où R ≡ H, Me, Ph. Ces radicaux subissent une auto-réaction, contrôlée par la diffusion, avec une constante de vitesse de $10^9\ M^{-1}\ s^{-1}$. Le spectre d'absorption, lorsque R = Ph, a un maximum bien défini à 346 nm; $\varepsilon = 3390\ M^{-1}\ cm^{-1}$. Cette absorption est moins intense quand R = H ou Me ($\varepsilon_{346\ nm}$ de $500\ M^{-1}\ cm^{-1}$) et s'étale dans le visible. Ces spectres glissent de façon marquée vers le rouge si on les compare à ceux des radicaux alkyles simples; c'est un effet que l'on attribue à l'interaction entre l'électron non apparié et le doublet libre de l'azote.

[Traduit par le journal]

## Introduction

Modulation spectroscopy has been successfully applied to the study of transient intermediates in the gas phase (see for example refs. 1 and 2). The technique involves photolytic generation of a transient using modulated initiation coupled with phase sensitive detection of that transient. This combination allows spectroscopic detection of short lived intermediates with high signal-to-noise levels and also provides information on the kinetics of their reactions.

The most recent advance in the field of modulation spectroscopy has been made by Huggenberger *et al.* (3) who have constructed a spectrometer for the study of free radicals *in solution*. With this instrument, radicals are generated using sinusoidally modulated light and are detected optically. In this work, we have used such a spectrometer in a kinetic study of the self-reactions of some α-aminoalkyl radicals.

## Experimental

*Materials*

All materials were commercially available. Iso-octane (Spectrograde) and trimethylamine were used as received. Di-*tert*-butyl peroxide was purified by chromatography through alumina which removes traces of the hydroperoxide impurity. Tribenzylamine was purified by recrystallization from ethanol. Triethylamine was purified by the standard procedure (4) and was distilled under nitrogen.

*Apparatus*

The modulation spectrometer used in this work follows closely on the design developed by Huggenberger and Fischer (3*b*). It is shown diagramatically in Fig. 1.

A fluorescence flow cell (Helma 178f-QS) was used as the sample chamber. Radicals were generated by irradiating solutions through the front window of the cell (10 mm × 10 mm) using light from a 1000 W, dc-powered mercury–xenon lamp (Hanovia 997B001; Oriel 6141 lamp housing). The irradiating light was modulated as a sine wave using a mechanical chopper (Brookdeal 9479) which was fitted with sine shaped irises.

A magnified image of the arc was brought to a focus at the sample cell which was positioned in a region of the image of fairly uniform light intensity. The quality of the sinusoidal modulation and the uniformity of light intensity were checked by manoeuvering a photomultiplier tube and housing with a small entrance slit (0.5 × 0.5 mm) throughout the region normally occupied by the sample chamber. The modulated sine wave generated by the irradiating light was compared on an

oscilloscope with one of the same amplitude and frequency produced by a sine wave generator and was indistinguishable from it. In addition, the maximum variation of light intensity across the sample cell was ± 8% of the mean.

The irradiating light was always passed through a water filter (10 cm path length) which removed much of the infrared radiation. The light could be further filtered using bandpass or cut-off filters.

Changes of optical density in the sample were followed using a monitoring beam arranged at right angles to the irradiating light path. A 100 W xenon lamp (Bausch and Lomb) provided the monitoring light which was passed through the side windows of the sample cell and then through a grating monochromator (Oriel 7240) fitted with photomultiplier tube (RCA 4840) and housing. In kinetic studies cut-off filters were always placed in the monitoring beam to prevent sample photolysis by the interrogating light.

Output from the photomultiplier tube was "terminated" by a suitable resistance. The signal at this point consisted of a large dc component and a very much smaller oscillating component which was due to the modulated absorption of starting materials, transient, and products. A ratiometer was used to divide ac by dc when recording spectra so as to correct for changes in signal intensity due to wavelength-dependent variations in the output of the monitoring light and in the sensitivity of the monochrometer/photomultiplier tube arrangement. In kinetic runs, which were carried out at fixed wavelength, the ratiometer was not used since its circuitry introduced an additional time constant into the system.

The modulated part of the signal was analysed using a lock-in amplifier (PAR 124A). The reference channel of the amplifier was driven by a photocell positioned so as to detect light from the irradiating beam. Finally, the output of the amplifier was displayed on a strip chart recorder.

*Sample preparation and analysis*

In a typical run an iso-octane solution of amine (5–10% v/v) and di-*tert*-butyl peroxide (5% v/v) was purged for ca. 20 min with a stream of nitrogen. The deoxygenated solution was taken up in a syringe and was then passed through the sample cell as ca. 1 mL/min by the use of a mechanical syringe drive.

Kinetic runs were carried out at fixed wavelength, with a 312 nm cut-off filter and an aqueous cobalt – nickel sulphate filter solution in the photolysis beam. This provides a window for photolysis of the peroxide between 312 and 340 nm. The concentration of reagents was adjusted so that > 90% of the incident light was transmitted in this wavelength range. In addition, the monitoring beam was always filtered with 316 nm or 325 nm cut-off filters. This procedure, combined with uniform irradiation at the front face of the cell, ensures a reasonably homogeneous distribution of transient which is necessary for the accurate analysis of second order kinetics. In addition, the sample flow rate was adjusted so that reagent depletion was < 1% and was further checked spectrophotometrically to ensure that the products did not absorb significantly at the photolysis wavelengths. The photolyzed mixture was analysed by vpc for *tert*-butyl alcohol using benzene as an internal standard (24 ft, 20% Carbowax 20 M).

*Electron paramagnetic resonance experiments*

A limited number of epr experiments were carried out on the amine systems using procedures which have been previously described (5).

## Results and discussion

α-Aminoalkyl radicals are formed extremely efficiently in solution by the reaction of *tert*-butoxyl radicals with amines, eq. [1] and [2]. Rate constants for these reactions are among the largest measured for H abstractions by *tert*-butoxyl with $k_2 \simeq 10^8\ M^{-1}\ s^{-1}$ (5). Only abstractions at molecules such as 1,4-cyclohexadiene, which give rise to highly stabilized radicals, proceed with rate constants of this magnitude (6). Moreover, abstractions at amines show a pronounced stereoelectronic effect. That is, H abstraction is most rapid when the C—H bond being broken is eclipsed with the axis of the lone pair orbital on nitrogen (5).

[1] $t\text{-BuO-OBu-}t \xrightarrow{\hbar\nu} 2t\text{-BuO}\cdot$

[2] $t\text{-BuO}\cdot + (RCH_2)_3N \rightarrow t\text{-BuOH} + \underset{\mathbf{1}}{R\dot{C}HN(CH_2R)_2}$

[3] $\mathbf{1} + \mathbf{1} \rightarrow$ nonradical products

**1***a* R = H; **1***b* R = Me; **1***c* R = Ph

While α-aminoalkyls can be efficiently generated they are nevertheless extremely difficult to detect in solution by using epr spectroscopy (5, 7, 8). Only the spectrum of $Me_2N\dot{C}H_2$ is easily detected and this is probably because the spectral linewidth is small, ca. 0.1 G. In all other cases, spectra are barely detectable, presumably because of the large number of hyperfine interactions and greater linewidths. This means, of course, that α-aminoalkyls cannot be studied generally using the techniques of kinetic epr spectroscopy. To overcome this problem, we have used modulation spectroscopy to characterize the uv–visible spectra of α-aminoalkyl radicals and to determine the kinetics of their self-reactions.

*Spectra*

In modulation spectroscopy the concentration of a transient species is made to oscillate at a predetermined frequency, e.g. by generating the transient using modulated photolysis. The sample is monitored optically and phase sensitive detection is used to find the signals which oscillate at the modulation frequency. These signals can be due to the disappearance of starting material, the formation of a transient intermediate, or the appearance of products. However, these three components can be differentiated by measuring the phase of the signal detected with respect to the phase of the modulated photolyzing light. The phase relationships between the signals have been previously derived (3) and are shown in Fig. 2.

In this work, we have modulated the photolyzing light as a sine wave which considerably simplifies kinetic analysis of the data. Under this condition, the rate of transient generation can be expressed as

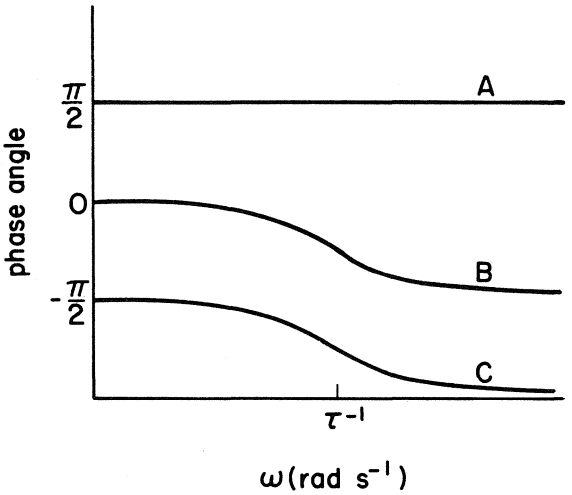

FIG. 2. Frequency dependencies of phases. A, reactant. B, radical. C, product.

a cosine function of the modulation frequency, which leads to simple solutions of the differential equations that describe the reaction kinetics (1, 3, 5, 9). By contrast, square wave or "on–off" modulation (2) requires that the rate of transient generation be expressed as a Fourier series which has obvious disadvantages.

Photolysis of an iso-octane solution of trimethylamine (5% v/v) and di-*tert*-butyl peroxide in the modulation spectrometer gave rise to a spectrum similar to that shown in Fig. 3. In the absence of trimethylamine, only very weak transient absorptions were detected. At the modulation frequencies used in these experiments (10–200 Hz), the phase of the signal lagged behind that of the modulated photolyzing light but did not reach −90° (see Fig. 2). Moreover, the shape of the spectrum was independent of the modulation frequency at which it was recorded. This behaviour implies that the signal is due to a single transient species, which we assign to radical **1***a*.

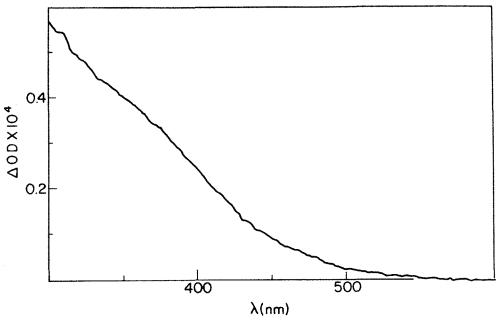

FIG. 3. Optical spectrum of radical **1***b* recorded at a modulation frequency of 43 Hz.

Photolysis of the above solution in the cavity of an epr machine gave rise to an intense spectrum of **1***a* (5), which supports the assignment of the optical spectrum. The signal intensity observed by epr was proportional to the square root of the incident light intensity when the latter was varied by a factor of 100, indicating that the radical decays with second order kinetics. In addition, prolonged photolysis of the sample gave *tert*-butyl alcohol and tetramethylethylenediamine as the major products identified by vpc analysis. Both the epr and modulation results are entirely consistent with the formation and decay of radical **1***a* according to reactions [1]–[3].

A similar optical spectrum was obtained when triethylamine was used in place of trimethylamine in the modulation spectrometer (Fig. 3). However, when tribenzylamine was used, a far more intense spectrum was obtained (Fig. 4) which had a well defined maximum at 346 nm. These spectra showed the properties associated with single transient species and we assign them to radicals **1***b* and **1***c* respectively. Similar spectra have also been obtained in laser flash photolysis experiments[2] and by gas phase modulation spectroscopy.[3]

*Kinetics*

Rate constants, $k_3$, for self-reactions of **1***a–c* were determined at a fixed wavelength. Using the lock-in amplifier, the signals due to the radicals were resolved into components which were out-of-phase and in-phase with the photolyzing light. The ratio of these components is tan $\phi$, where $\phi$ is the *phase angle*, and the vector sum of these components is directly proportional (3) to $\Delta$OD which is the modulated part of the optical density of the transient.

A plot of $-\tan\phi$ versus the modulation frequency, $\omega$, gave the lifetime, $\tau$, of the radicals, eq. [4]. The relationship between $\tau$ and the rate constant for self-reaction of the radicals, $k_3$, is given in eq. [5], where $I_0$ is the maximum rate of radical generation during the modulation cycle. An example of such a plot is given in Fig. 5.

$$[4] \quad -\tan\phi = \omega\tau$$

$$[5] \quad \tau^{-2} = 4k_3I_0$$

An alternative method of analysing the data yields the extinction coefficient for the radical, $\varepsilon$. In this approach, a plot of $(\Delta OD)^{-2}$ versus $\omega^2$ gave a straight line of slope $a$ and intercept $b$ which are related (3) to $\tau$, $\varepsilon$, $I_0$, and $l$, where $l$ is the pathlength of the cell in the monitoring direction, eqs. [6] and

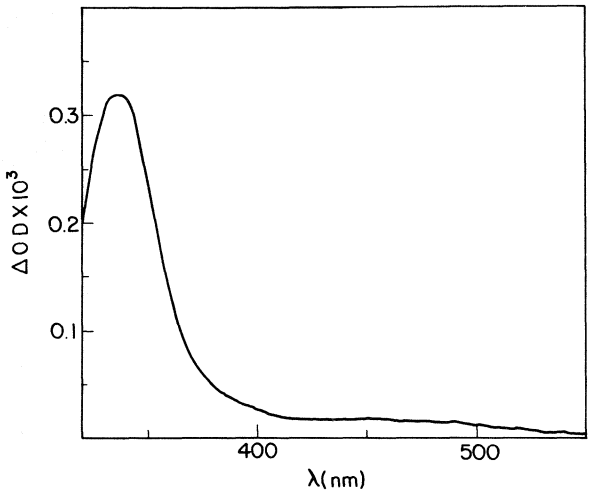

FIG. 4. Optical spectrum of radical 1*c* recorded at a modulation frequency of 43 Hz.

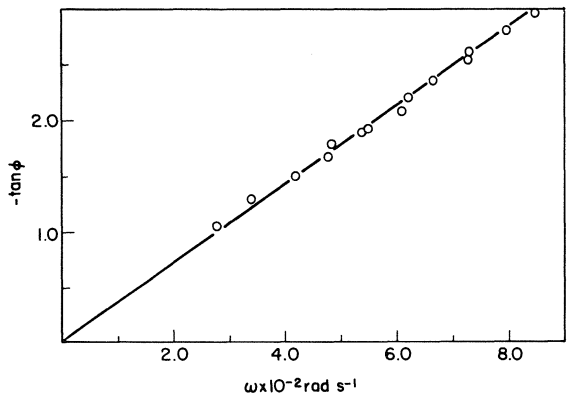

FIG. 5. Frequency dependence of ϕ for radical 1*c* in iso-octane.

[7]; Fig. 6.

[6] $a = 4(\varepsilon l I_0)^{-2}$

[7] $b = 4(\varepsilon l I_0 \tau)^{-2}$

In these experiments the mean rate of radical generation $I_0/2$ was determined by analysing the photolyzed reaction mixtures for *tert*-butanol. Values of τ obtained by the two graphical procedures were identical within experimental error. Moreover, τ was proportional to $I_0^{-\frac{1}{2}}$ when the light intensity was reduced using neutral density filters, which indicates that in all cases the radicals decay by bimolecular reactions. The data are summarized in Table 1. The experimental errors on rate constants and extinction coefficients were ca. ± 30%.

When amines were omitted from the reaction mixture the yield of *tert*-butanol obtained by photolyzing the solution under the conditions of the

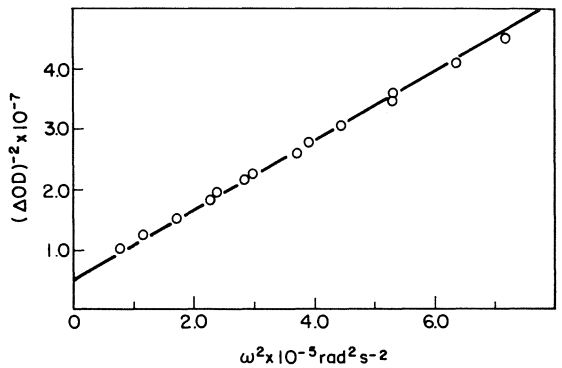

FIG. 6. Frequency dependence of ΔOD for radical 1*c* in iso-octane.

kinetic experiments was the same within experimental error as was obtained in the presence of trimethyl or triethylamine. This indicates that the α-aminoalkyl radicals do not induce decomposition of the peroxide under these experimental conditions. The slight reduction in $I_0/2$ observed when tribenzylamine was used as substrate was presumably due to slight light absorption by the amine in the region where the di-*tert*-butyl peroxide was being photolyzed.

The values of $2k_3$ measured in this work indicate that radicals 1*a–c* undergo diffusion controlled self-reaction. Indeed, $2k_3$ decreases as the size of the radicals increases which is to be expected for a diffusion controlled process. The value of $2k_3$ obtained for 1*a* is in accord with the rate constant for self-reaction of *tert*-butyl (10), i.e. $7.4 \times 10^9$ $M^{-1}$ s$^{-1}$ (294°C; octane solvent) which is a radical of similar size monitored in a solvent of similar viscosity to the iso-octane used in this work. It should be noted that *tert*-butyl has been used as a model for the study of diffusion controlled processes and the kinetics of its self-reaction have been explored in considerable detail (3*b*, 10). Thus, α-aminoalkyl radicals behave kinetically as most other small unhindered alkyls and moreover they do not appear to induce the decomposition of di-*tert*-butyl peroxide at room temperature. We therefore conclude that the failure to detect members of this class of radicals other than 1*a* by epr, in

solution, must be a consequence of the spectral characteristics of the radicals, e.g. linewidth and number of hyperfine interactions, rather than any intrinsic chemical property.

The uv–visible spectrum of radical **1***c* shows a strong absorption band at 346 nm; $\varepsilon = 3390\ M^{-1}\ cm^{-1}$. This band is typical of benzylic radicals which show strong absorption bands at ~ 316 nm with $\varepsilon_{max} \sim 9000\ M^{-1}\ cm^{-1}$ in hydrocarbon solvents.[4] By contrast, the absorption spectra of **1***a* and **1***b* show no well defined maximum in the accessible wavelength range but "tail" to ca. 500 nm. This "tail" is not generally observed in simple alkyl radicals which tend not to absorb significantly at wavelengths > 280 nm (**3***c*) and must therefore be associated with the interaction of the unpaired electron with the lone pair of electrons on nitrogen.

The electronic interaction in α-aminoalkyl radicals between the unpaired electron and the nitrogen lone pair manifests itself in a number of ways. First, the epr spectra of α-aminoalkyls isolated in matrices (for matrix isolation studies see ref. 8) indicate that there is substantial delocalization of the unpaired electron between the α-carbon and the adjacent nitrogen atom. In addition, the interaction gives rise to a stereoelectronic effect in hydrogen abstractions from amines (5) and to low ionization potentials and high stabilization energies for the radicals themselves (11). The interaction between the unpaired electron and the nitrogen lone pair can be rationalized in terms of the model of the three-electron bond (see, for example, ref. 12). In this picture, two of these three electrons reside on a bonding orbital, while the third lies in the related antibonding orbital. Electronic transitions between these orbitals in α-aminoalkyl radicals presumably give rise to the absorptions observed in the visible region.

[4]For a review of the literature data, see ref. 3*b*.

## Summary

α-Aminoalkyl radicals undergo diffusion controlled self-reaction at 298°C in iso-octane solvent. Their optical absorption spectra are substantially different to those of simple alkyl radicals in that they absorb significantly up to 500 nm. This property is thought to be a consequence of the interaction between the unpaired electron and the lone pair of electrons on the nitrogen atom.

# Solubilization sites in micellar sodium octylsulphate solutions by ultrasonic spectroscopy

DAVID J. JOBE, VINCENT C. REINSBOROUGH, AND PETER J. WHITE
*Chemistry Department, Mount Allison University, Sackville, N.B., Canada E0A 3C0*

Received August 11, 1981

DAVID J. JOBE, VINCENT C. REINSBOROUGH, and PETER J. WHITE. Can. J. Chem. **60**, 279 (1982).

Relaxation frequencies $f_c$ and amplitudes $A$ were measured ultrasonically over the 3.5–52.5 MHz range at 25°C for the fast exchange of monomer between micelles and bulk solution in micellar sodium octylsulfate solutions with solubilizates present in small amounts. The additives were cyclohexane, pyridine-2-azo-*p*-dimethylaniline (PADA), benzene, toluene, and *p*-xylene. Only cyclohexane produced no changes in $f_c$ or $A$. The variations in the relaxational parameters suggested that cyclohexane was situated within the micellar core and PADA, primarily in the surface region of the micelle. Benzene and toluene were adsorbed in minute quantities into the micelle surface but, with additive concentrations beyond a few molecules per micelle, were found principally in the micellar core. Toluene, along with *p*-xylene, showed an initial dip in $f_c$ that may indicate that the first few molecules of these additives were incorporated into the palisade layer of the micelle.

DAVID J. JOBE, VINCENT C. REINSBOROUGH et PETER J. WHITE. Can. J. Chem. **60**, 279 (1982).

On a mesuré par ultrason à des fréquences allant de 3,5 à 52,5 MHz et à 25°C les fréquences de relaxation fc et les amplitudes A de l'échange rapide de monomère entre les micelles et la solution dans des solutions micellaires d'octylsulfate de sodium ayant des petites quantités de solubilisants. On a utilisé comme additifs: le cyclohexane, la pyridine-azo-2 diméthylaniline (PADA), le benzène, le toluène et le *p*-xylène. Le cyclohexane est le seul à ne pas influencer les fréquences de relaxation et les amplitudes. Les variations des paramètres de relaxation suggèrent que le cyclohexane est situé dans la masse micellaire alors que la PADA se trouve de façon primaire dans la région de la surface de la micelle. Le benzène et le toluène sont adsorbés en petites quantités dans la surface de la micelle mais, à des concentrations croissantes de l'ordre de quelques molécules par micelle, on les a trouvé principalement dans le noyau micellaire. Le toluène ainsi que le xylène révèlent une diminution initiale de $f_c$ qui indique que les quelques premières molécules de ces additifs sont incorporées dans la couche protectrice de la micelle.

## Introduction

The location of solubilizates within micelles in aqueous solution has recently been the object of many spectroscopic studies by various techniques (1–3). The picture that is emerging from these studies is that the surface region of the micelle is much more favoured in this regard than previously thought, especially at low additive concentrations. For example, benzene, which had been reported to be chiefly absorbed into the core of sodium dodecylsulfate micelles (4), was discovered to be primarily in the surface region of the micelles when the mole fraction of benzene was less than 0.01 (1). Since these "mixed micelles" often form microemulsions of industrial, medicinal, and theoretical importance, it is of some value to determine the micellar sites of solubilization for different compounds to throw light on the interactions not only between solubilizate and micelle but also between monomer and micelle. Also, the structure of micelles is still being debated (5, 6) and further probing of these interactions could have bearing on this question.

Ultrasonic spectroscopy has not yet been employed specifically to determine solubilization sites in micelles, but since the fast relaxation observed ultrasonically in micellar solutions has been so well characterized, the technique could well prove to be a useful diagnostic tool in this regard. The process giving rise to this relaxation is the exchange of the monomeric surfactant between the micelle and bulk aqueous solution. Simplistically, one might expect that additives residing in the core of the micelle would have little effect on the dynamics of this exchange while solubilizates adsorbed into the surface region or the palisade layer should appreciably alter the entry or exit rates of the monomer.

To this end, organic compounds of various polarities were introduced in small quantities into micellar sodium octylsulfate (SOS) solutions and the ultrasonic absorptions noted. This particular surfactant, SOS, was chosen because its relaxation frequency fell within the operating frequency range of the equipment (3.5–52.5 MHz). Since some solubilizates, notably alcohols, give rise to a fast relaxation of their own accord involving exchange with the mixed micelles, care must be exercised in their selection to avoid coupling errors. Additives were screened by measuring the ultrasonic absorptions over the frequency range 3.5–52.5 MHz of their solutions in micellar sodium dodecylsulfate, in premicellar concentrations of SOS and in water. Micellar sodium dodecylsulfate solutions show a fast relaxation in the microsecond range which is far removed from the frequency range employed in this work. Thus, if no relaxation process is detectable when additive is present, it can be assumed that the relaxation process observed in additive-

micellar SOS solutions is due only to the monomer–micelle exchange. The other approach that has been already successfully used is to choose a surfactant like sodium dodecylsulphate or tetradecyltrimethylammonium bromide that does not show a relaxation in the ultrasonic range and to work with solubilizates that do (8–10). In this situation, information can be gained about the solubilizate exchange between the bulk solution and micelle.

## Experimental

The pulsed ultrasonic spectrometer has been described in detail elsewhere (11). Sodium octylsulfate (SOS) was obtained from Eastman Kodak while the additives were the highest quality obtainable. No further purifications were carried out. All ultrasonic measurements were conducted at 25.0°C.

Conductivity measurements were performed in benzene–SOS solutions at 25.0°C to determine the critical micelle concentration (cmc). The instrument used was the RC-18A Beckman conductivity bridge with a Jones–Bollinger cell.

## Results

The ultrasonic absorption data ($\alpha/f^2$) over the 3.5–52.5 MHz frequency range for various SOS solutions containing the additives were fitted by computer to the single relaxation equation:

$$[1] \quad \alpha/f^2 = A/[1 + (f/f_c)^2] + B$$

where $A$ and $B$ are relaxational parameters related to the process responsible for the excess absorption and to the background absorption respectively, and $f_c$ is the relaxation frequency. The fit was satisfactory in all instances. The experimental error in $f_c$ is about 5% except in the few cases where $f_c$ fell just outside the experimental range where these essentially extrapolated values admit of greater error, probably about 10%.

For micellar SOS solutions without additives, the $f_c$ values agree with those reported by Gettins *et al.* (12). The cmc values from conductivity measurements for two different additions of benzene, 0.010 and 0.020 *m* θ in SOS solutions, were the same as that for no additive, 0.114 mol dm$^{-3}$, which agrees with previously reported values (12–14).

The $f_c$ values for cyclohexane and pyridine-2-azo-*p*-dimethylaniline (PADA) additions to 0.397 *m* SOS solutions are shown in Figs. 1 and 2. In Fig. 3 is displayed the effect of benzene additions to various SOS solutions with $[C_6H_6]/C_M$ as the concentration co-ordinate where $C_M$ = [SOS] − cmc. $C_M$ is a measure of the micellar concentration and this ratio allows comparison between additive and micellar surfactant on a per mole basis. This same scale was employed to show the $f_c$ and $A$, the relaxation amplitude, dependencies in toluene – micellar SOS solutions (Figs. 4 and 5). Only a few $f_c$ determinations were possible with *p*-xylene in 0.300 *m* SOS solutions because of solubility limitations and these are also included in Fig. 4.

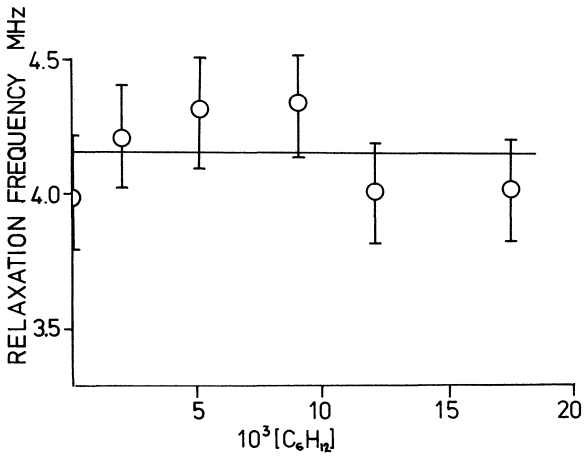

FIG. 1. Effect of cyclohexane additions on the relaxation frequency in 0.397 *m* SOS solutions.

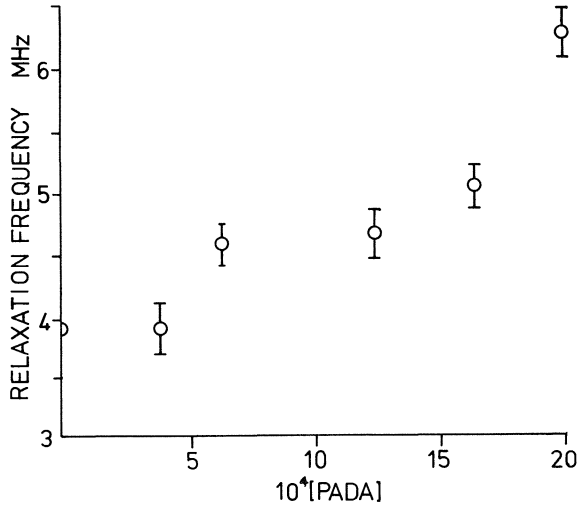

FIG. 2. Effect of PADA additions on the relaxation frequency in 0.397 *m* SOS solutions.

The solubility of benzene in SOS solutions as determined by uv spectroscopy is shown in Fig. 6. These data can be conveniently represented by means of a partitioning constant $K_{benzene}$ defined as $[benzene]_M/[benzene]_B C_M$ where the subscripts M and B refer to the micellar and bulk solution pseudo-phases respectively (15). The value of $K_{benzene}$ in SOS solutions was 30 dm$^3$ mol$^{-1}$.

## Discussion

Aniansson has developed an expression for the relaxation frequency for the fast surfactant exchange in micellar solution for mixed micelles (7), but, for small additions of solubilizate, this expres-

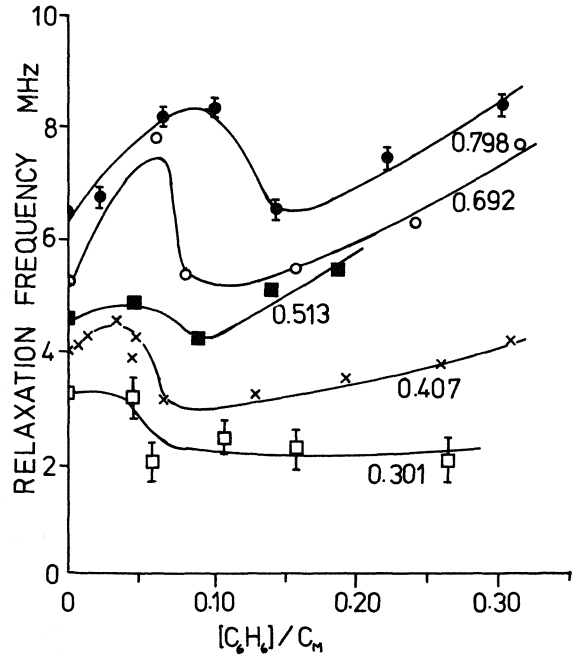

FIG. 3. Effect of benzene additions on the relaxation frequency in various micellar SOS solutions (SOS molalities are displayed).

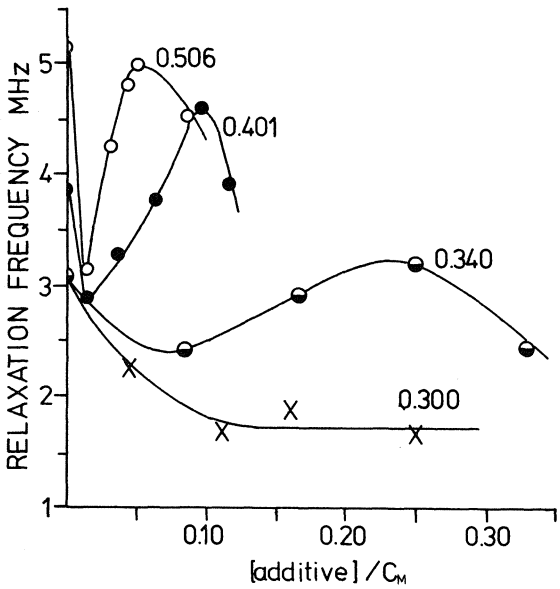

FIG. 4. Effect of toluene and *p*-xylene additions on the relaxation frequency in micellar SOS solutions. The circles represent data for toluene additions to three SOS systems while the *p*-xylene data for 0.300 *m* SOS are shown by crosses (×).

sion can be approximated by the Aniansson equation for one-component micelles (16):

[2] $2\pi f_c = k^-/\sigma^2 + (k^-/n)\,(C_M/\text{cmc})$

where $k^-$ is the rate constant for the exit of the surfactant monomer from the micelle, $\sigma^2$ is the

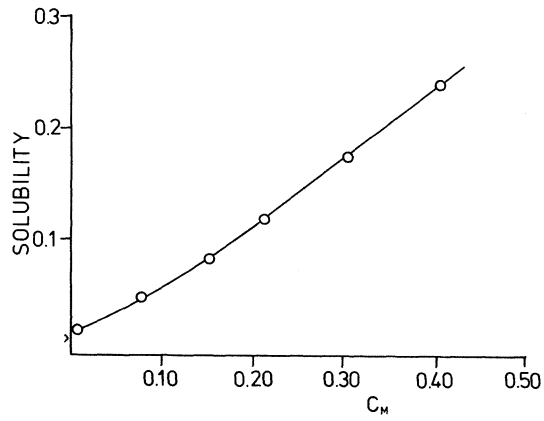

FIG. 6. Solubility of benzene in molality in micellar SOS solutions at 25.0°C. The arrow indicates the pure water solubility of benzene.

variance of the micellar distribution curve, and $n$ is the mean micellar aggregation number.

For the SOS system, $\sigma^2 = 100$ and $n = 25$ (12). Consequently, when $C_M >$ cmc,

[3] $2\pi f_c \simeq (k^-/n)\,(C_M/\text{cmc})$

Thus, for solutions of the same surfactant concentration, $f_c$ is roughly proportional to $k^-$. This assumes that $n$ and $\sigma^2$ are not changed for small additions of additive. The constancy of the cmc within experimental error when benzene was added was some assurance that this was indeed the situation. As far as $k^+$, the entrance rate of the monomers to the micelles, is concerned, this quantity is largely electrostatically controlled and, in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

solutions of high ionic strength such as in micellar SOS solutions, will not be significantly modified by small additions of organic compounds (16). Thus, changes in $f_c$ probably largely reflect changes in $k^-$ and these changes should be roughly directly proportional.

Surfactant concentrations were chosen not only to make eq. [3] more correct but also to avoid the problematical cmc-to-twice-the-cmc range with short-chained surfactants. The decrease in $f_c$ that occurs over this concentration range has never been properly characterized (12, 17).

Less attention has been paid to the relaxation amplitude $A$ which arises from the exchange of the monomers between the micellar and solution environments. Recently, Zana and Yiv (18) have developed an expression for $A$ relating it to $\Delta V_0$, the change in volume associated with the exchange per monomer, and the relaxation frequency:

$$[4] \quad A = \rho u k^- C_M (\Delta V_0)^2/2 \times 10^3 RTn f_c^2$$

where $\rho$ is the solution density and $u$ is the speed of ultrasonic sound through the solution. Teubner (19) has developed a similar expression for the intensity of the ultrasound waves.

From eqs. [3] and [4], then

$$[5] \quad A \simeq \pi \rho u(\text{cmc}) (\Delta V_0)^2/10^3 RTf_c$$

should hold for micellar SOS solutions. The amplitude then should be inversely proportional to $f_c$ where $\rho$, $u$, cmc, and $\Delta V_0$ are relatively constant. In micellar SOS solutions with or without additives, the plot of $A$ against $f_c^{-1}$ was linear (Fig. 7), giving a value of 8 cm$^3$ mol$^{-1}$ for $\Delta V_0$ calculated from the slope. This is remarkably close to 6.3 ± 1.0 cm$^3$ mol$^{-1}$, the $\Delta V_0$ value for the SOS system from density studies (20), given all the assumptions involved. Since the straight line has a non-zero intercept, the analysis may admit of a constant error which cancels when the slope is taken. Apparently, these additives are not affecting significantly the volume change that the SOS monomers undergo on micellization no matter how varied the $f_c$ values are. Thus, it appears consistent to assume that the additives are not affecting the SOS micelles, in any major way, in structure, in aggregation number, and in distribution of micelle sizes, and that the large changes in the relaxation frequency that often occur are a direct reflection of changes in the dissociation rate of the monomer from the micelle.

The $f_c$ values for 0.002–0.02 $m$ cyclohexane additions to 0.397 $m$ SOS solutions did not change within experimental error (Fig. 1). Apparently, the monomers in exchanging between micelle and solution do not "see" the cyclohexane molecules. This argues for a micellar core position for the solubilized cyclohexane which is the conclusion reached with nmr and diffusion studies with this solubilizate in other micellar systems (21–23). Other non-polar solubilizates such as $n$-decane also do not affect the $f_c$ in micellar systems even in greater concentrations (24) (ultrasound often prevents emulsions such as are found in decane (1 $m$) – soap – water systems from separating, allowing sufficient time to measure the ultrasonic absorption).

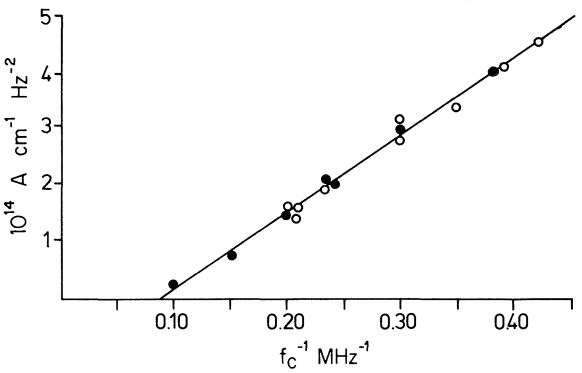

FIG. 7. Dependence of $A$ upon the inverse of the relaxation frequency in micellar SOS solutions without additive (●) and with additive (○).

Through rate enhancement studies by the stopped-flow technique, PADA is known to be preferentially adsorbed by micelles from solution where it is available for metal complexation in the surface region of the micelle (13, 25). Although the micellar-bound PADA molecules could be partitioning rapidly between core and surface in times faster than a millisecond which the stopped-flow technique would not be able to detect, there is good reason to believe from these same studies that the micellar core population of PADA is not significant. Additions of PADA to 0.002 $m$ in a 0.397 $m$ SOS solution cause a significant increase in $f_c$ which indicates, in light of eq. [3], that $k^-$ has undergone an increase of similar magnitude. If PADA were solubilized into the surface region of the micelle, the surface potential would have been lowered, accelerating the rate at which the monomers depart from the micelle. (Another explanation suggested by a referee is that PADA may have ruptured the SOS micelles so that many more but smaller micelles are present. Following his proposal, we measured the conductivity of micellar SOS solutions before and after PADA additions but could find no increase in conductivity beyond experimental error — about 0.2%.) Thus, despite the different time ranges of the techniques, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

ultrasonic and stopped-flow data agree in assigning PADA to the interfacial region of the micelles.

Concerning the effect of solubilized benzene upon the relaxation frequency in micellar SOS solutions, it is interesting to note that in one of the first ultrasonic investigations in aqueous micellar systems Yasunaga *et al.* (26) had reported that a 1% benzene addition to 0.100 mol $dm^{-3}$ sodium dodecylsulfate solutions markedly shifted the relaxation frequency to a higher value. This solitary measurement with benzene in the literature disguises the complexity in $f_c$ dependence upon additive concentration that is revealed in Fig. 3. Like PADA, benzene in amounts less than $[C_6H_6]/C_M$ values of 0.05–0.10 gives rise to an increase in $f_c$. At this concentration ratio corresponding to 1 to 2 benzene molecules per micelle ($n = 25$), $f_c$ reaches a maximum and then falls off about as rapidly to a value close to the $f_c$ value for the micellar SOS solutions without additive. Further addition of benzene beyond 2–3 molecules per SOS micelle results in a slight, leisurely increase in $f_c$. Benzene in small quantities is much more surface active than one might expect (1) and the initial increase in $f_c$ receives an easy explanation in terms of micellar surface adsorption on benzene. When one to two benzene molecules are adsorbed per micelle, surface adsorption becomes less favourable and may even cease. The $f_c$ data suggest that beyond this concentration inclusion into the micellar core becomes the chief solubilization mechanism for benzene in SOS micelles effectively negating the increase in $k^-$ brought about by the change in surface potential. Had $f_c$ measurements not been conducted in the dilute benzene range, it would have been argued from the near constancy of the $f_c$ values in the more concentrated benzene range that benzene was totally incorporated within the core. That core incorporation does not become the chief solubilization process for benzene until the concentration of benzene exceeds one to two molecules per micelle reconciles the apparently contradictory findings that solubilized benzene in micelles is found chiefly in the surface region (1) and chiefly in the core (4). It is, as Mukerjee and Cardinal (1) expected, just a matter of which site is favoured by the benzene concentration.

Although the error for the $f_c$ determinations for *p*-xylene was greater than that for benzene (Fig. 4), it is clear that *p*-xylene in 0.300 *m* SOS always caused about the same decrease in $f_c$ for $[\text{xylene}]/C_M > 0.1$ (about 2 *p*-xylene molecules per micelle). Solubility restrictions did not permit data to be taken at higher concentrations but a plateau in $f_c$ appears to be developing. This argues for core incorporation for *p*-xylene as in the cyclohexane case. The significant difference from the cyclohexane situation is that a lowering of the $f_c$ was always observed, suggesting that the first few solubilized molecules of *p*-xylene must be interacting with the surfactant monomers in the micelle so as to hinder their escape. This could be accomplished if these additive molecules were vicinal to the monomers as they would be if they were in the palisade layer or in the micellar "fjords" (27). This explanation would rule out any surface adsorption for *p*-xylene in micellar SOS solutions. Fox *et al.* had reported that *p*-xylene in sodium dodecylsulfate solutions had appeared to be solubilized throughout the hydrocarbon core of the micelle (28) with which the ultrasonic evidence does not disagree. In fact, it may be more specific in locating the solubilizate initially close to the micellar surface but then principally within the core with further *p*-xylene additions.

The toluene dependence of the $f_c$, as one might expect from its intermediate position both chemically and in water solubility between benzene and *p*-xylene, was more involved (Fig. 4). All three micellar positions: surface, palisade, and core, appear to be feasible for toluene solubilization depending upon the toluene and micellar concentration. As with *p*-xylene, the first few molecules probably are incorporated into the palisade layer. Then the next few toluene molecules per micelle are adsorbed into the surface region of the micelle as with benzene. Core solubilization, with further addition of toluene, becomes the preferred mechanism. The maxima in $f_c$ for benzene additions all occur at about the same benzene concentration but, with toluene additions, the shift in maxima to lower toluene concentration with increasing SOS concentration likely reflects complications brought about by three competing mechanisms of solubilization.

In summary, the ultrasonic absorption evidence in micellar SOS solutions at this stage suggests that cyclohexane is solubilized within the core of the micelles; PADA, the micellar surface region; benzene, in the surface for concentrations less than a molecule of benzene per micelle then principally in the core for further benzene additions; *p*-xylene, in the palisade layer for concentrations less than one or two molecules of *p*-xylene per micelle, then in the core; toluene, a more complicated pattern with all three sites, palisade, surface, and core, being populated in that order with increasing toluene addition.

The experimental frequency range of the pulse technique limits its applicability to short-chained

surfactants. More "normal" surfactants like sodium dodecylsulfate could accommodate more solubilizate in their micellar solutions but they do not show a relaxation frequency in the MHz range. Other ultasonic techniques such as the resonance or reverberation methods, although slightly less accurate, can be operated in the kHz range and may be useful in this regard. It is clear that the relaxation frequency for surfactant exchange between bulk solution and micelles can be markedly sensitive to solubilizates. From the Aniansson model and from further assumptions regarding constancy of micelle size, distribution, and structure in the presence of minute amounts of solubilizate, we interpret this observed variety of changes in $f_c$ in micellar sodium octylsulfate solutions to indicate the sites of solubilization within the micelles. Although our results appear reasonable and are in agreement with the findings of other structural determination methods where comparison is possible, it remains to be seen whether this is a more general phenomenon with micellar solutions.

# Synthèse et réactivité de quelques α-amino azocomposés: mécanisme de la cyclisation thermique en triazoles-1,2,4

PIERRE MÉTRA ET JACK HAMELIN[1]

*Groupe de Recherches de Physicochimie Structurale, Equipe de Recherche associée au C.N.R.S., U.E.R.F. "S.P.M.", Université de Rennes, Campus de Beaulieu, 35042 Rennes Cedex, France*

Reçu le 6 mars 1981[2]

PIERRE MÉTRA et JACK HAMELIN. Can. J. Chem. **60**, 285 (1982).

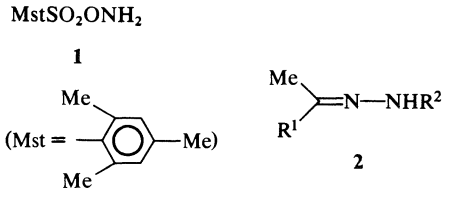
Par addition de l'*O*-mésitylènesulfonylhydroxylamine (MSH) sur des hydrazones d'aldéhydes et de cétones, on observe une amination sur le carbone avec formation d'α-amino azocomposés. La thermolyse de ces composés conduit à des triazoles-1,2,4 dont le mécanisme de formation est discuté.

PIERRE MÉTRA and JACK HAMELIN. Can. J. Chem. **60**, 285 (1982).

The reaction of *O*-mesitylenesulfonylhydroxylamine (MSH) with hydrazones leads to carbon amination with the formation of α-amino azo compounds. Thermolysis of these compounds affords 1,2,4-triazoles. The mechanism of this cyclization is discussed.

## Introduction

Les propriétés nucléophiles et électrophiles de l'*O*-mésitylènesulfonylhydroxylamine (MSH) ont été décrites et discutées dans la littérature (1, 2). En particulier par addition sur des *C*-alkyl *N*-alkyl imines la réaction conduit aux diaziridines correspondantes (1). Dans le but d'accéder aux amino diaziridines qui pouvaient être des amino ylures d'azométhine imine potentiels, nous avons étudié l'addition du MSH sur des hydrazones d'aldéhydes et de cétones **2**.



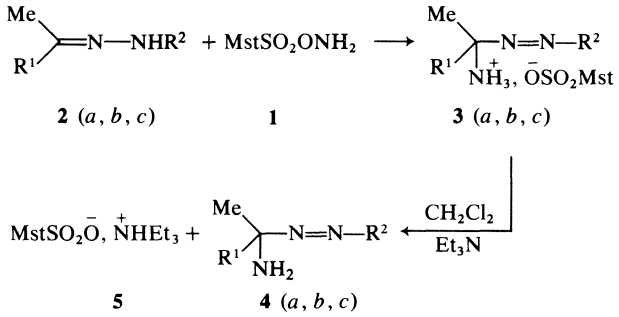
*a* $R^1 = H; R^2 = Ph$
*b* $R^1 = Me; R^2 = Ph$
*c* $R^1 = Me; R^2 = CO_2Me$
*d* $R^1 = R^2 = Me$
*e* $R^1 = H; R^2 = CO_2Me$

## Résultats et discussion

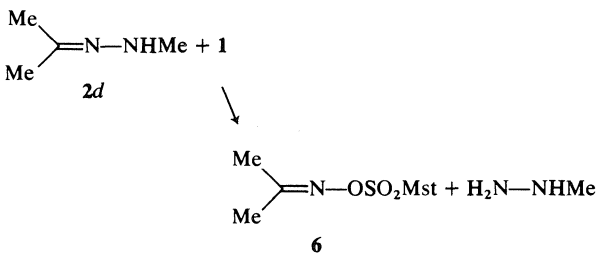
### *1. Addition du MSH sur les hydrazones*

La réaction est effectuée à température ambiante en solution dans l'éther anhydre, sous azote, les réactifs étant en proportions stoechiométriques. Avec les hydrazones **2***a*, **2***b* et **2***c* on obtient après une heure de réaction les sels de formule **3** avec un rendement pratiquement quantitatif.

Les composés **3** (*a*, *b*, *c*) en solution dans $CH_2Cl_2$ sont traités par une quanité stoechiométrique de triéthylamine, et par addition d'éther, on précipite quantitativement le composé **5**. La solution restante est lavée avec une solution aqueuse de chlorure d'ammonium à 10% puis à l'eau. Après évaporation du solvant on obtient les α-amino azocomposés avec des rendements pratiquement quantitatifs (à la précision de la rmn). Les composés **4** purifiés par distillation au four tubulaire sont caractérisés par uv, rmn $^1H$, $^{13}C$, spectrographie de masse et analyse élémentaire.



Dans les mêmes conditions de réaction, l'hydrazone **2***d* ne permet pas d'isoler de cristaux primaires analogues à **3** et après traitement à la triéthylamine, on isole avec un bon rendement l'oxime **6** caractèrisée par comparaison avec un échantillon authentique obtenu par réaction du MSH sur l'acétone (1):



Ces résultats peuvent être interprétés selon le schéma 1:

SCHÉMA 1

Il y aurait initialement attaque nucléophile du MSH **1** sur le carbone de l'hydrazone avec formation de la bétaïne (A). Lorsque $R^2$ = Ph ou $CO_2Me$, il y aurait substitution nucléophile intramoléculaire pour former le sel de diaziridinium (B), qui conduirait au sel **3** par l'intermédiaire du sel (C). Par action de la triéthylamine on libère l'azocomposé **4**. Lorsque $R^2$ = Me, l'azote négatif de (A) est plus basique que nucléophile et il y aurait prototropie avec formation de (D) qui conduirait à l'oxime **6** avec élimination de méthylhydrazine.

*2. Réactivité des azocomposés*

Quelques propriétés chimiques ont été étudiées en utilisant plus particulièrement le composé ***4a***.

*(a) Tautomérie azocomposé–hydrazone*

A température ambiante, sous azote, à l'abri de la lumière, ***4a*** se transforme quantitativement, après deux semaines, en aminohydrazone ***7a*** caractérisée par rmn $^1H$ et spectrographie de masse. Le composé ***7a*** peut également être obtenue par traitement de ***4a*** au butyllithium dans le THF (pour donner un anion dont la couleur marron résulte vraissemblablement de la complexation du lithium par l'azote), puis hydrolyse à −15°C. Si l'hydrolyse est effectuée à −90°C on récupère ***4a*** inchangé. Ces résultats sont rassemblés dans le schéma 2.

Par ailleurs, ***7a*** traitée au butyllithium à −90°C conduit à $7a^-$ qui redonne ***7a*** après hydrolyse soit à −90°C soit à −15°C. Le passage irréversible $4a^- \rightarrow 7a^-$ pourrait résulter d'un processus intermoléculaire (schématisé ci-dessous).

L'azocomposé ***4b*** traité par BuLi à −90°C conduit également à un ion marron qui ne peut donner lieu à

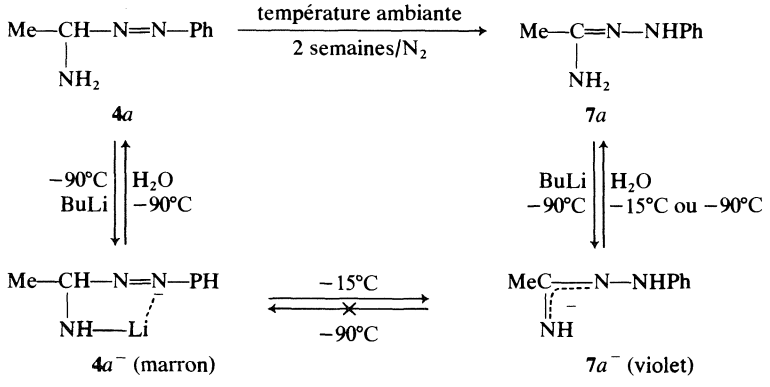

SCHÉMA 2

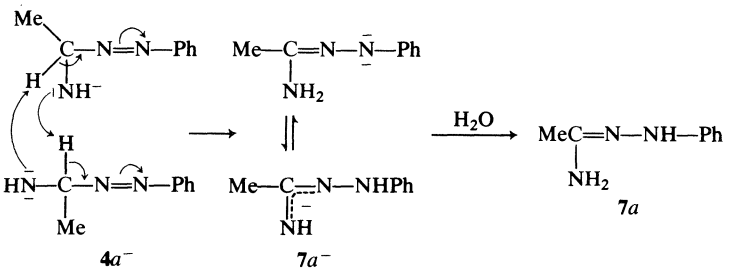
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

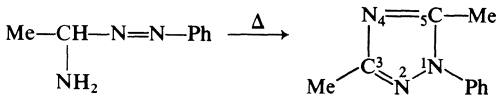


$4a^-$ $7a^-$ $7a$

l'isomérisation précédente et après hydrolyse on récupère **4***b*. Le passage **4***a* → **7***a* à température ambiante pourrait s'effectuer selon un processus analogue. La transformation azocomposé → hydrazone est déjà signalée dans la littérature et s'effectue aussi bien en milieu acide qu'en milieu basique (3), et dans le cas des α-amino azocomposés le groupement amine peut catalyser la transformation. Ce résultat est particulièrement important pour l'interprétation de la formation des triazoles-1,2,4 à partir des α-amino azocomposés ou des aminohydrazones que nous vous étudiés.

*(b) Evolution thermique*

A l'ébullition du benzène durant 24 h, **4***a* se transforme quantitativement en un composé **8***a* auquel la rmn $^1H$ et $^{13}C$ et la spectrographie de masse permettent d'attribuer la structure 1,2,4-triazole.



**4***a* **8***a*

Lorsque la thermolyse est réalisée en présence de tertiobutylcatéchol comme inhibiteur de réactions radicalaires, on retrouve après 24 h de reflux dans le benzène, 54% d'azocomposé **4***a* non transformé. Cette observation est en faveur d'un processus radicalaire auquel on pouvait s'attendre pour un azocomposé. De plus **4***a* en solution conduit également à **8***a* à température ambiante et on met en évidence la formation de benzène et un dégagement d'ammoniac.

Les observations précédentes nous conduisent à rationnaliser la formation de **8***a* de la manière suivante (schéma 3):

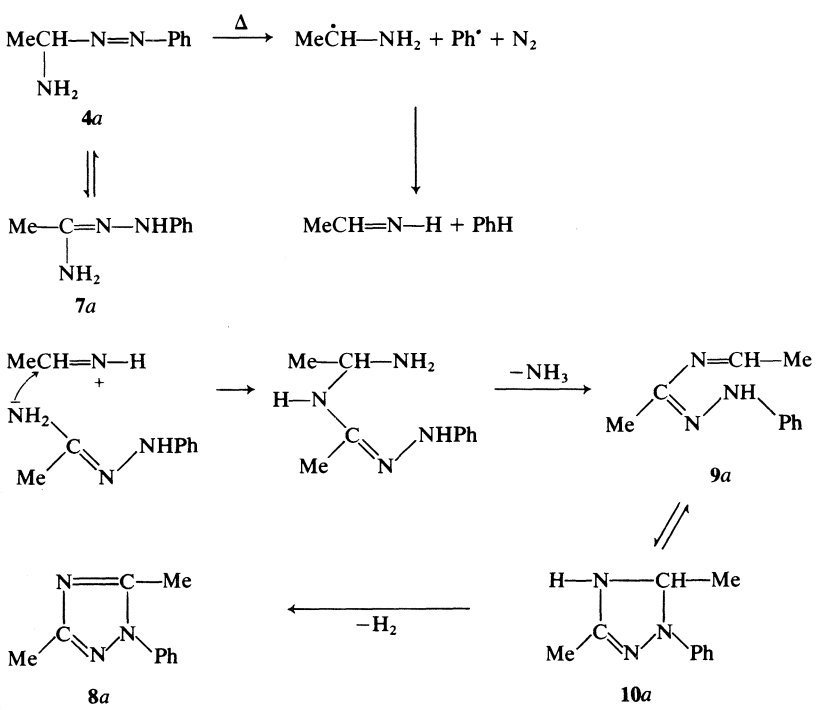


SCHÉMA 3

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

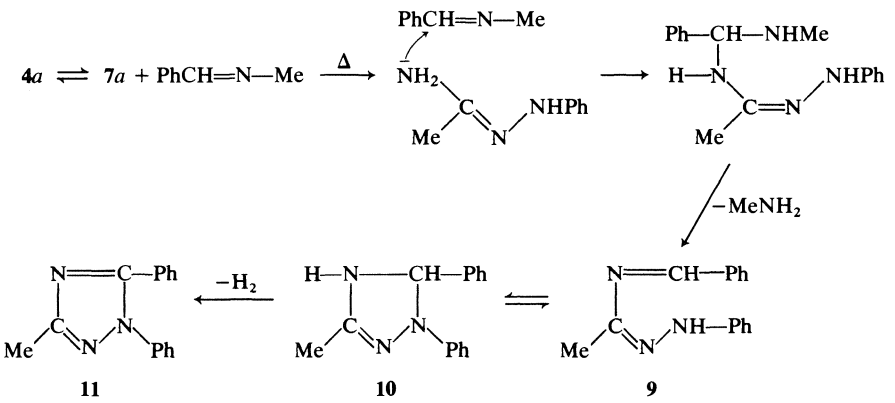

SCHÉMA 4

Il y aurait coupure radicalaire de **4***a* avec formation de deux radicaux MeĊH—$NH_2$ et Ph• et perte d'azote. Par abstraction d'hydrogène il se formerait du benzène et l'imine MeCH=N—H sur laquelle l'aminohydrazone **7***a* en équilibre avec **4***a* s'additionnerait pour former l'iminohydrazone **9***a*[3] avec perte d'ammoniac. Le composé **9***a* se cyclliserait ensuite en triazoline **10***a* dont l'aromatisation conduirait au triazole **8***a*. Il faut signaler que la thermolyse de **7***a* conduit également à **8***a* mais la réaction est plus lente et nécessite 24 h de reflux dans le toluène pour être totale, ceci résulte vraisemblablement du fait que l'équilibre **4***a* ⇌ **7***a* n'est pas en faveur de **4***a*.

Pour vérifier l'hypothèse de l'étape d'addition de l'aminohydrazone sur une imine, nous avons réalisé l'addition de **4***a* sur l'imine PhCH=N—Me. On obtient avec un rendement pratiquement quantitatif, le triazole-1,2,4 de structure **11** caractérisé par rmn $^1$H et comparaison avec un échantillon authentique (dont la synthèse univoque est décrite dans la suite). La réaction s'effectuerait selon le schéma 4, formation d'une iminohydrazone **9** avec perte de méthylamine puis aromatisation en triazole **11** via la triazoline **10**.

La thermolyse de **4***b* a également été étudiée et conduit à une décomposition avec formation de benzène et d'acétone qui ont été caractérisés par rmn et cgl, et dégagement d'azote. Le mécanisme serait initialement le même: rupture radicalaire de l'amino azocomposé avec formation d'imine $Me_2$-C=NH, de benzène et dégagement d'azote. La tautomérie azo ⇌ hydrazone n'étant pas possible dans ce cas, la réaction s'arrête avec hydrolyse de l'imine et formation d'acétone.

[3]Nous remercions l'un des rapporteurs pour son interessante suggestion relative au mécanisme de l'addition de l'aminohydrazone sur l'imine avec formation d'iminohydrazone dont l'existence est d'ailleurs confirmée par addition des aldéhydes sur les amino azocomposés.

Ainsi, l'équilibre azo ⇌ hydrazone que nous avons mis en évidence permet de rationnaliser la formation des triazoles-1,2,4 à partir des α-amino azocomposés ou des aminohydrazones, réaction dont le mécanisme, à notre connaissance, n'était pas signalé dans la littérature (4).

L'amino azocomposé **4***c* présente lors de la thermolyse un comportement particulier. En effet, au reflux du benzène sous azote, **4***c* redonne quantitativement l'hydrazone de départ, avec formellement perte de "NH". Ce résultat est vraisemblablement à l'origine de nos difficultés pour isoler l'amino azocomposé **4***e* dérivé de l'hydrazone MeCH=N—$NHCO_2$Me. En effet, lors de cette réaction on observe bien la formation quantitative du sel de triéthylammonium **5**, mais après évaporation du solvant on récupère l'hydrazone initiale et seulement 10% d'amino azocomposé **4***e*. Cette évolution est actuellement à l'étude au laboratoire.

*(c) Condensation des amino azocomposés* **4** *avec les aldéhydes*

L'amino azocomposé **4***a* donne avec les aldéhydes à température ambiante dans le chloroforme une réaction exothermique ayant pour stade ultime la formation d'un triazole selon le schéma 5.

Dans une première étape, il y a formation de l'azoimine **12** qui s'isomérise en iminohydrazone **9***a* ou **9**, ce qui confirme l'existence de cet intermédiaire postulé dans le mécanisme proposé aux schémas 3 et 4. Les composés **9***a* et **9** se cyclisent ensuite en triazolines **10***a* et **10** respectivement qui s'aromatisent en triazoles **8***a* et **11** selon la nature de R.

Dans le cas de la condensation avec le benzaldéhyde (R = Ph), la réaction à température ambiante est suivie à l'aide de la rmn $^1$H: après 12 h on observe la formation de **12** (64%), **10** (33%) accompagnés de traces de **11**. Après 48 h on obtient **12** (13%), **10** (78%) et **11** (9%), à partir de ce mélange on isole la triazoline **10** (R = Ph). Après 7 jours à

SCHÉMA 5

température ambiante le triazole **11** déjà obtenu par addition de **4***a* sur l'imine PhCH=N—Me est formé avec un rendement quantitatif.

## Partie expérimentale

Les spectres rmn $^1H$ ont été enregistrés sur un apareil JEOL MH 100 à 100 MHz et les spectres $^{13}C$ sur un appareil Brucker WP 80 à 20,115 MHz. Les échantillons sont examinés en solution dans $CDCl_3$ (sauf précision contraire) et les déplacements chimiques δ sont donnés en ppm par rapport au TMS. Les spectres de masse ont été réalisés sur un appareil Varian MAT 311, et les spectres uv sur un spectrophotomètre Beckman DB.

*1. Mésitylène sulfonyl hydroxylamine MSH*

Il est préparé selon la méthode décrite par Tamura *et al.* (1), recristallisé dans le mélange éther–pentane à 0°C ($F$ = 92°C) et conservé à −18°C.

*2. Addition du MSH 1 sur les hydrazones 2*

A une solution de l'hydrazone ($10^{-2}$ mol) dans l'éther anhydre, on ajoute goutte à goutte sous azote $10^{-2}$ mol de MSH dans l'éther à température ambiante. Après une heure sous agitation, le sel **3** généralement formé est essoré et analysé en rmn $^1H$ et $^{13}C$.

Le sel **3** brut est ensuite dissout dans $CH_2Cl_2$ et on ajoute goutte à goutte une quantité stoechiométrique de triéthylamine sous agitation. Après une heure, l'addition d'éther provoque la précipitation de **5** qui est essoré et la solution restante est lavée avec une solution de chlorure d'ammonium à 10%, puis à l'eau. Après évaporation du solvant à température ambiante on obtient l'α-amino azocomposé **4** qui est purifié par distillation au four tubulaire.

*(a) Hydrazone* **2**a

Le composé **3***a* est obtenu avec un rendement de 90% ($F$ = 264°C avec décomposition). Composé **3***a*, rmn $^1H$: 1,53 (d, 3H, *Me*CH); 2,13 et 2,50 (s, 3H, s, 6H, Me en *para* et 2 Me en *ortho* du mésitylène); 5,10 (q, 1H, Me*CH*); 6,65 (s, 2H, H du mésitylène); 8,94 (s large, échangé dans $D_2O$, $NH_3$); rmn $^{13}C$: 17,44; 20,72 et 23,01 (Me du Mésitylène et *Me*CH); 75,99 (Me*C*H, $J$ = 156 Hz) et les C aromatiques.

Le composé **3***a* traité à la triéthylamine donne **4***a* (Rdt = 46% par rapport à **2***a* après distillation au four tubulaire Eb $10^{-2}$ Torr = 70°C). Composé **4***a*, rmn $^1H$: 1,48 (d, 3H, *Me*CH); 2,05 (s, 2H, échange $D_2O$, $NH_2$); 4,58 (q, 1H, Me*CH*); rmn $^{13}C$: 20,63 (*C*$H_3$CH); 80,01 ($CH_3$*C*H, $J$ = 149 Hz) et les carbones aromatiques. Spectrographie de masse: $m/e$ = 149 ($M^+$); $m/e$ = 106 (Ph—N=$NH^+$); $m/e$ = 44 (MeCH=$NH_2^+$); uv (*n*-heptane): $\lambda_{max}$ = 261 nm, $\varepsilon_{max}$ = 7860. *Anal.* calc. pour $C_8H_{11}N_3$: C 64,43; H 7,38; N 28,19%; trouvé: C 64,58; H 7,28; N 28,14%.

*(b) Hydrazone* **2**b

Dans les mêmes conditions on isole **3***b* ($F$ = 135°C avec décomposition). Composé **3***b*, rmn $^1H$: 1,60 (s, 6H, $Me_2$C); 2,14 et 2,52 (s, 3H et s, 6H pour les Me du mésitylène); 6,66 (s, 2H, mésitylène); 8,93 (s, 3H, $NH_3$); rmn $^{13}C$: 20,72; 23,12 et 23,61 (Me en *para*, 2 Me en *ortho* du mésitylène et $Me_2$C); 81,73 ($Me_2$*C*H) et les C aromatiques. Le traitement à $Et_3N$ donne **4***b* avec un rendement de 56% par rapport à **2***b* après distillation au four tubulaire; Eb $10^{-2}$ Torr = 80°C). Composé **4***b*, rmn $^1H$: 1,44 (s, 6H, $Me_2$C); 2,13 (s, large, 2H, $NH_2$); rmn $^{13}C$: 26,75 ($Me_2$C); 80,30 ($Me_2$*C*) et les C aromatiques. Spectrographie de masse: $m/e$ = 163 ($M^+$); $m/e$ = 106 (Ph—N=$NH^+$); $m/e$ = 58 ($Me_2$C=$NH_2^+$); uv (*n*-heptane): $\lambda_{max}$ = 256 nm, $\varepsilon_{max}$ = 4990. *Anal.* calc. pour $C_9H_{13}N_3$: C 66,26; H 7,97; N 25,77%; trouvé: C 66,25; H 8.15; N 25,60%.

*(c) Hydrazone* **2**c

Formation quantitative du sel **3***c*, $F$ = 120°C (avec décomposition). Composé **3***c*, rmn $^1H$: 1,59 (s, 6H, $Me_2$C); 2,22 et 2,53 (s, 3H, s, 6H, Me du mésitylène); 3,93 (s, 3H, $CO_2$*Me*); 6,82 (s, 2H, H du mésitylène) et 9,00 (s, large, 3H, $NH_3$). Composé **4***c* (Rdt = 70% par rapport à **2***c*, non distillé); rmn $^1H$: 1,43 (s, 6H, $Me_2$C); 1,82 (s, large, 2H, $NH_2$); 4,00 (s, 3H, $CO_2$*Me*); uv (10% $CHCl_3$/90% *n*-heptane): $\lambda_{max}$ = 230 nm, $\varepsilon_{max}$ = 2250. Les résultats de l'analyse élémentaire de **3***c* et **4***c* ne sont pas satisfaisants en raison de l'instabilité des produits.

*(d) Hydrazone* **2**d

Dans ce cas on n'observe pas la formation de **3***d* et le traitement à la triéthylamine est effectué sur la solution éthérée. On obtient ainsi l'oxime **6** ($F$ = 96°C) avec un rendement quantitatif.

*(e) Hydrazone* **2**e

La précipitation du sel **3***e* n'est pas observée et après traitement à $Et_3N$ on note la précipitation quantitative de **5** et le spectre de rmn $^1H$ du mélange réactionnel brut révèle l'existence de l'hydrazone **2***e* et de 10% d'un deuxième composé, qui pourrait être **4***e* (q, 5,28 ppm), ce produit n'a pas pu être isolé à l'état pur.

*3. Tautomérie azocomposé–hydrazone*

Comme nous l'avons signalé, **4***a* se transforme quantitative-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

ment en **7***a* en deux semaines sous azote à l'abri de la lumière, sans solvant. Composé **7***a* ($F$ = 100°C, éther/*n*-hexane) est caractèrisé par comparaison avec les données de la littérature relatives au chlorhydrate (5): $F$ = 119–122°C; rmn $^1$H: 1,79 (s, 3H, Me); 5,0 (s, large échange $D_2O$, 3H, NH et $NH_2$). Spectrographie de masse: $C_8H_{11}N_3$: $m/e$ = 149 ($M^+$); $m/e$ = 132 (MeC═N═N—$PH^+$); $m/e$ = 91 (Ph—$N^+$).

*4. Evolution thermique de* **4**a

A l'ébullition du benzène durant 24 h, **4***a* se transforme avec un rendement pratiquement quantitatif en diméthyl-3,5 phényl-1 triazole-1,2,4 de formule **8***a* (Eb 2 × $10^{-2}$ Torr = 110–120°C au four tubulaire) isolé sous forme cristalline après passage au chlorhydrate et relargage; $F$ = 46°C (littérature (6) $F$ = 48°C après sublimation). Composé **8***a*, rmn $^1$H: 2,35 et 2,39 (2s, 3H et 3H, Me en 3 et 5); 7,33 (s, 5H, protons aromatiques); rmn $^{13}$C: 12,96 et 13,59 (Me en 3 et 5); 152,34 et 159,96 (*C*—Me en 3 et 5) et C aromatiques. Spectrographie de masse: $C_{10}H_{11}N_3$: $m/e$ = 173 ($M^+$); $m/e$ = 132 (Ph—N═N═C—$Me^+$); ($M^+$—MeCN); $m/e$ = 91 (PH—$N^+$).

La réaction en présence d'inhibiteur de réaction radicalaire est effectuée en présence de 5% de *para* tertiobutylcatéchol durant 24 h au reflux du benzène.

Par réaction de **4***a* sur une quantité équimoléculaire d'imine PhCH═N—Me durant 48 h au reflux du benzène sous azote on obtient, avec un rendement pratiquement quantitatif (à la précision de la rmn), le triazole **11** cristallisé après passage au chlorhydrate ($F$ = 180°C) et relargage à la soude; $F$ = 92°C. Composé **11**, rmn $^1$H: 2,51 (s, 3H, Me) et 7,36 (s, 10H, ArH). Spectrographie de masse: $C_{15}H_{13}N_3$: $m/e$ = 235 ($M^+$); $m/e$ = 132 ($M^+$—Ph—CN); $m/e$ = 91 (Ph—$N^+$). *Anal.* calc. pour chlorhydrate $C_{15}H_{14}N_3Cl$: C 66,30; H 5,16; N 15,47; Cl 13,07%; trouvé: C 66,23; H 5,19; N 15,47; Cl 13,11%.

*5. Condensation de* **4**a *avec les aldéhydes*

La condensation des aldéhydes est réalisée dans le chloroforme à température ambiante, les réactifs étant en proportions équimoléculaires.

*(a) Acétaldéhyde MeCHO*

On obtient, avec un rendement pratiquement quantitatif, le triazole **8***a* déjà formé par thermolyse de l'amino azocomposé **4***a*.

*(b) Benzaldéhyde PhCHO*

Dans les mêmes conditions, après 12 h à température ambiante, on caractérise par rmn $^1$H l'imine **12**, non isolée; rmn $^1$H: 1,64 (d, 3H, Me); 5,06 (q, 1H, MeC*H*); 8,45 (s, 1H, C*H*). Après 48 h, la triazoline **10** ($F$ = 116°C) est isolée et recristallisée dans le mélange éther/*n*-pentane; rmn $^1$H: 1,93 (s, 3H, Me); 5,95 (s, 1H, C*H*). Ce composé n'a pas pu être analysé en raison de son oxydation rapide en triazole. Après 7 jours à température ambiante, on obtient quantitativement le triazole **11** déjà décrit précédemment.

# Antitumor activity at the molecular level: binding modes in anthracycline–dinucleotide complexes as determined by optical titration and magnetic circular dichroism[1]

M. J. Bell, G. W. Buchanan,[2] B. R. Hollebone,[2] and E. D. Jones

*Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6*

Received January 29, 1981[3]

M. J. Bell, G. W. Buchanan, B. R. Hollebone, and E. D. Jones. Can. J. Chem. **60**, 291 (1982).

The first application of magnetic circular dichroism (mcd) spectroscopy to drug–dinucleotide binding is reported. The mcd spectra have been recorded for complexes of the intercalating anthracyclines carminomycin, marcellomycin, and aclacinomycin with the dinucleotide CpG. Analysis indicates that drugs having OH groups *peri* to each anthraquinone carbonyl (i.e. carminomycin and marcellomycin) bind with only one drug molecule in the central hydrophilic region of the nucleotide. By contrast, aclacinomycin, in which one of the anthraquinone carbonyls lacks a *peri*-OH, is found to cooperatively bind, and has two drug molecules present in the dinucleotide cavity. The cooperativity of binding has been elucidated via an optical titration procedure.

M. J. Bell, G. W. Buchanan, B. R. Hollebone et E. D. Jones. Can. J. Chem. **60**, 291 (1982).

On rapporte la première application de la spectroscopie du dichroisme circulaire magnétique (dcm) à la liaison médicament–dinucléotide. On a enregistré les spectres de dcm des complexes formés par les intercalants anthracycline, carminomycine, marcellomycine et aclacinomycine, avec le dinucléotide CpG. Les analyses révèlent que les médicaments qui ont des groupements OH en *péri* par rapport à chaque carbonyle de l'anthraquinone (comme la carminomycine et la marcellomycine) sont liés à une seule molécule de médicament dans la région hydrophile centrale du nucléotide. On trouve au contraire que l'aclacinomycine, dans laquelle il manque un groupement OH *péri* pour l'un des carbonyles de l'anthraquinone, est liéé coopérativement et que deux molécules de médicament sont présentes dans la cavité du dinucléotide. On a identifié la coopérativité du lien par l'intermédaire d'une méthode de titration optique.

[Traduit par le journal]

## Introduction

A number of anthracyclines are potent antitumor antibiotics, daunomycin and adriamycin being the best known (1). Several other active materials belonging to this general class of compounds have recently been isolated, among which are aclacinomycin, **1**, marcellomycin, **2**, and carminomycin, **3** (2–4) (Fig. 1).

The biological activity of these anthracyclines involves an inhibition of the cellular DNA and RNA dependent replication and transcription processes. This inhibition arises from an intercalative binding mode (5) and it is known that daunomycin and adriamycin intercalate into double-stranded DNA, although these drugs do not show any requirement for a particular base at the intercalation site (1–6).

Among the available physical methods for the study of drug–polynucleotide binding in solution, circular dichroism (cd) spectroscopy has been shown to be particularly sensitive (7). This method does not, however, give any geometrical information regarding the nature of binding. By contrast, magnetic circular dichroism (mcd) spectroscopy has recently been shown (8) to be a powerful method for monitoring subtle geometrical changes in a wide variety of chromophores.

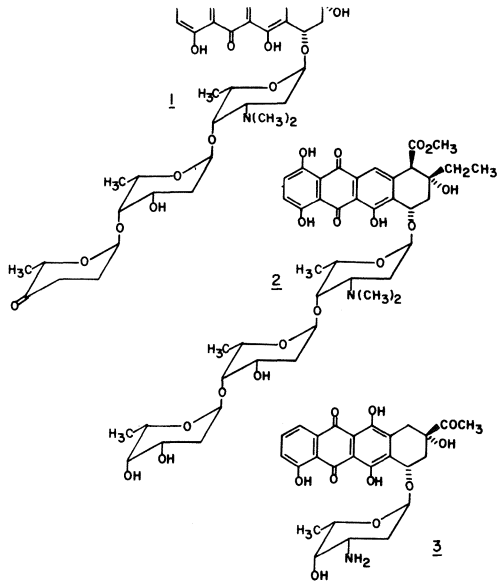

FIG. 1. Structures of aclacinomycin **1**, marcellomycin **2**, and carminomycin **3**.

Presently we have examined the solution interactions between aclacinomycin **1**, marcellomycin **2**, and carminomycin **3**, with the self-complimentary dinucleotide monophosphate CpG (2′-deoxycytidylyl-(3′ → 5′)-2′-deoxyguanosine). In studies of

DNA binding properties, the use of such self-complimentary systems has been widespread, since it has been found that these dinucleotides associate spontaneously to form a mini-helix in aqueous solution (9).

In addition to the mcd experiments, we have carried out optical titrations and, using the method of Scatchard (10), we have obtained binding isotherms and evidence for cooperativity of binding in one instance.

## Theory

(a) *General considerations of magnetic circular dichroism*

The contribution of an isolated transition to the mcd spectrum of a molecule can be expressed as the sum of three terms, which describe the three possible electronic situations which may be present (11):

$$[\theta]_M = -21.3458\ \{f_1A + f_2[B + C/kT]\}$$

where $[\theta]_M$ is the molar ellipticity per unit magnetic field, $f_1$ is the shape function for a derivative curve, $f_2$ a Gaussian shape function, and $A$, $B$, and $C$ are the Faraday constants for a particular transition.

For an $A$ term to be observed there must be degeneracy in the excited states. A $C$ term arises when the ground state is degenerate, leading to a dependence on temperature.

The mcd spectra of molecules having no 3-fold, or higher, axis of symmetry are composed entirely of $B$ terms (8, 11). These arise from the mixing of the ground state and two or more excited states. The intensities of the $B$ terms are dependent on the energy separation of the excited states and their transition moment directions. The intensities are greatest when the energy separation is small and when the transition moments to the observed and perturbing states are orthogonal.

The mcd spectra of a number of cyclic $\pi$-electron systems have been both calculated and experimentally determined (8). General rules have been derived for substituent effects. This allows the prediction of absolute mcd signs for the most prominent four low energy bands in a large number of compounds based on a simple model of the $\pi$-electron system.

The electronic transitions of aromatic chromophores are classified according to Platt's nomenclature for cata condensed polyacenes (12), based on a simple free electron model. The first excited configuration will give rise to two low energy, weak absorption bands, known as the $L$ states, plus two high energy dipole allowed bands, the $B$ states.

For aromatic ring systems, which contain some bonds parallel or perpendicular to a symmetry axis, the $L_a$, and $B_a$ transition moments will be parallel to these bonds, while the $L_b$ and $B_b$ transition moments will be perpendicular to them.

The mcd spectra of cyclic $(4n + 2)$-electron $(n)$ annulenes can be predicted based on the relative size of two orbital energy differences, ΔHOMO (highest occupied molecular orbital) and ΔLUMO (lowest unoccupied molecular orbital). In general both the HOMO and the LUMO are degenerate; however, perturbations on the parent perimeter will cause orbital splittings.

Of the four possible transitions, from a single electron HOMO → LUMO excitation, two are sense preserving of the magnetic moments and two are sense reversing of the magnetic moments. The sense preserving transitions are the electric dipole allowed $B$ bands, and yield excited configurations with small magnetic moments $\mu^-$. The sense reversing transitions, or $L$ bands, have large magnetic moment contributions $\mu^+$, but are electric dipole forbidden.

In soft chromophores (8), where ΔHOMO is equal to ΔLUMO, all $\mu^+$ contributions vanish and the mcd $B$ terms are controlled by the weaker $\mu^-$ magnetic moments. The most important odd-soft chromophores (8) are the benzenoid hydrocarbons, with the alternate pairing theorum predicting the equality of ΔHOMO and ΔLUMO. Any perturbation affecting this equality of ΔHOMO and ΔLUMO will bring in contributions from the larger $\mu^+$ quantities. This can cause substantial changes in the compound's mcd spectrum.

Substituent effects, both inductive (I) and electrometric (E), are manifested in a change in the quality of ΔHOMO and ΔLUMO. This occurs via a displacement of electrons towards regions of low potential energy, within the constraints of the Pauli exclusion principle.

Substituents presenting a positive charge to the aromatic system (+E, +I), effectively remove electrons from the ring. Conversely, −E or −I substituents will donate charge to the aromatic system.

In a dominant ring position,[4] +E and +I substituents will induce ΔHOMO < ΔLUMO while negative substituents cause ΔHOMO > ΔLUMO. Effects at sub-dominant positions are initially opposite to this, but as the substituent becomes stronger it is able to overcome any inherent molecular orbital ordering and the same changes are observed.

In the perturbed system, the larger $\mu^+$ contribu-

[4]A dominant position has Hückel coefficients $c_{k,1}^2 > c_{k,2}^2$ where $k$ refers to the atom, and 1,2 are orbitals on it (pair belonging to HOMO). In sub-dominant positions $c_{k,1}^2 < c_{k,2}^2$.

tions may affect the mcd signals. When $\Delta HOMO > \Delta LUMO$ the $\mu^+$ contributions to the mcd bands are $L_b(-)$, $L_a(+)$, $B_b(-)$, $B_a(+)$ in order of increasing energy, if $\Delta HOMO < \Delta LUMO$ then the order is $L_b(+)$, $L_a(-)$, $B_b(+)$, $B_a(-)$.

(b) *Anthracycline transition moments*

An initial step required, before the anthracycline intercalation process can be studied using mcd, is the assignment of the individual transition moments for the components involved.

In determining the transition assignments for the anthracycline drugs, we will begin with a discussion of *p*-benzoquinone and proceed to 9,10-anthraquinone.

In *p*-benzoquinone, two allowed transitions are found at accessible wavelengths, one at 282 nm, the other at 248 nm (13). The effect of OH and $CH_3$ substituents has been determined using a modified Pariser–Parr–Pople method (14).

The introduction of one OH group will red shift the first singlet absorption to 376 nm. A second OH, *ortho* to the first, will cause a further red shift to 600 nm. If the second OH is placed in any other ring position, no further changes occur.

The addition of a $CH_3$ group causes a red shift of both bands, being most pronounced for the lowest energy transition. Each additional $CH_3$ group on the ring further lowers the transition energies.

These substituent effects can be extended to both the calculated (15) and experimental (16–19) transition energies of 9,10-anthraquinone. In 9,10-anthraquinone there is a long axis polarized band at 345 nm which is assigned as the $L_b \leftarrow A$ transition. A weak band, short axis polarized, at 280 nm is the $L_a \leftarrow A$ transition. The two remaining bands at 230 and 250 nm are the $B_a$ and $B_b$ transitions, short and long axis polarized respectively (20).

The introduction of OH groups was found to red shift the low energy transition to 400–500 nm. An additional band appears at $\sim 300$ nm in most derivatives as well. The addition of $CH_3$ groups will cause slight red shifts in each of the bands.

This trend is continued in the experimental spectra of the anthracycline drugs.

(c) *Magnetic circular dichroism spectral assignments*

In considering the mcd assignments of the anthracyclines, we will begin with anthracene as the parent chromophore.

Anthracene is an odd-soft chromophore, the $^1L_b \leftarrow A$ transition having vanishing mcd intensity. Both theoretical and experimental investigations of the mcd spectrum of anthracene have been made (8, 21–26).

In anthracene the bands and their directions are $L_b(+)$, $L_a(-)$, $B_b(-)$, $B_a(+)$ in order of increasing energy (22).

When going to 9,10-anthraquinone, two strong positive electromeric substituents are placed in very dominant ring positions. This will bring in contributions from the larger $\mu^+$ values. The predicted mcd signs, in this case are $L_b(+)$, $L_a(-)$, $B_b(+)$, $B_a(-)$ in order of increasing energy. This sign sequence is observed in the experimental mcd spectra of 9,10-anthraquinone (25, 26). An $n \rightarrow \pi^*$ transition also appears, close in energy to the $L_a$ band. In fact it may split this band in some cases. The $n \rightarrow \pi^*$ band, though forbidden in the absorption spectrum, has a large magnetic moment and may overpower the weaker $L_a$ band, which is magnetically forbidden but optically allowed.

Further substituent effects are observed in going from 9,10-anthraquinone to luteoskyrin and rugulosine (26), as shown in Fig. 2. Here weaker +E and +I substituents in the form of $CH_3$ and OH are added to the anthraquinone chromophore. The effect is opposite to substitution at the 9,10 positions; here $\Delta HOMO > \Delta LUMO$ for substitution in a sub-dominant position, and the $\mu^+$ contributions are $-+-+$ in order of increasing energy. Initially such substitution will affect only the *L* bands, as is seen for luteoskyrin (Fig. 2), the mcd bands being $-++-$ in order of increasing energy.

For the anthracyclines, additional substitution at the sub-dominant positions is sufficient to bring about a sign reversal in the *B* transitions as well, the observed sign sequence being $L_b(-)$, $L_a(+)$, $B_b(-)$, and $B_a(+)$ in order of increasing energy. The $L_a$ transition is hidden under the $n \rightarrow \pi^*$ band of the same sign, as shown by marcellomycin in Fig. 3.

The transition energies (27) and mcd spectra (28) of the individual nucleosides cytidine and guanosine have been determined previously. In both cases there is no absorption of energy at wavelengths longer than 310 nm, so that contributions due to CpG absorption will not be present in the optical titrations or the mcd measurements.

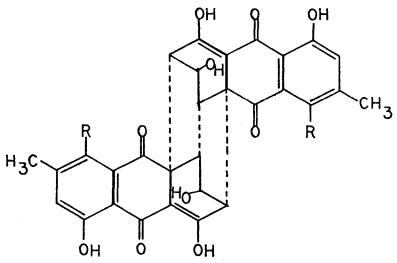
## Results and discussion

(a) *Optical titrations*

The approach taken was essentially identical to that previously used by Muller and Crothers (29) to study the binding of actinomycin to DNA. Binding was followed by measuring the decrease in the extinction coefficient of the drugs when they are mixed with a standard CpG solution. Measurements were taken in the visible region where no interference due to the dinucleotide occurs.

The concentration of the drug–dinucleotide complex, $C_k$ is given by the equation

$$[1] \quad C_k = (\varepsilon_\lambda^k C_T - A/10)/(\varepsilon_\lambda^F - \varepsilon_\lambda^k)$$



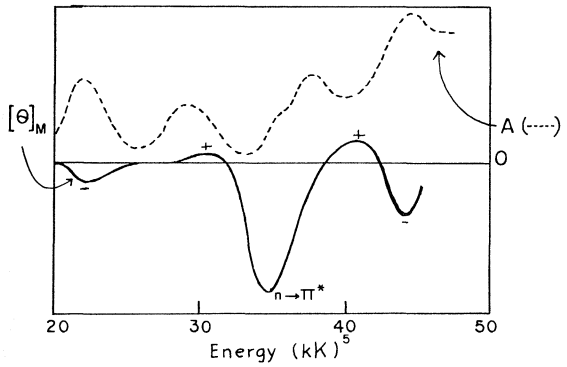


FIG. 2. Absorption (---) and mcd (———) spectra of luteoskyrin.

where $\varepsilon_\lambda^k$ is the extinction coefficient of the complex, $\varepsilon_\lambda^F$ is the extinction coefficient of the free drug, $C_T$ is the total drug concentration, and $A/10$ is the absorbance per cm path length. At very high ratios of dinucleotide to drug, it was assumed that all the drug is bound and thus one can calculate $\varepsilon_\lambda^k$.

It has been shown (30) that by rearrangement of the expression for the equilibrium between a bound and a free species, one can obtain the expression

$$[2] \quad r/m = K_{ap}(B_{ap} - r)$$

which is appropriate to a Scatchard plot (10) of binding isotherms, where $r$ is the ratio of bound drug to total CpG base pair concentration and $m$ is the concentration of the free drug. From a plot of $r/m$ vs. $r$ one can obtain the apparent binding constant, $K_{ap}$ (from the slope) and the number of binding sites per base pair, $B_{ap}$, from the extrapolated intercept at $r/m = 0$.

The results of the Scatchard plots for aclacinomycin **1** and marcellomycin **2** are depicted in Fig. 4. For carminomycin **3**, the plot is nearly identical to that of **2**. Marcellomycin and carminomycin with

[5]kK = kilokaisers, where 1 kK = $10^3$ $cm^{-1}$.

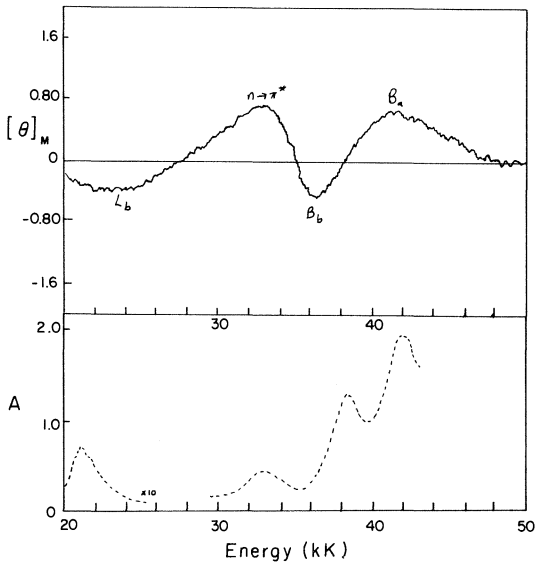

FIG. 3. Absorption (---) and mcd (———) spectra of marcellomycin.

CpG give essentially identical linear binding titrations, falling rapidly with increasing values of bound drug concentration $r$, following the Langmuir isotherm. At low values of $r$, infinity points were obtained for $r/m$, since the concentration of free drug m approaches zero. This indicates complete binding.

For marcellomycin the ratio of bound drug to CpG base pairs, $B_{ap}$, is $0.11 \pm 0.02$ and the apparent binding constant $K_{ap}$ is $4.6 \pm 0.9 \times 10^7$ $M^{-1}$. In the

case of Carminomycin, the corresponding values are $0.08 \pm 0.01$ and $1.2 \pm 0.3 \times 10^7\ M^{-1}$ respectively.

By contrast, the Scatchard plot for aclacinomycin first rises slowly to a maximum value of $r/m$, with complete binding occurring near a value of ca. 0.06 for $B_{ap}$. Subsequently there is a reversion to the Langmuir isotherm above the $r$ value of 0.06. From this portion of the plot, one can calculate $B_{ap}$ to be $0.13 \pm 0.02$ and $K_{ap}$ to be $7.3 \pm 1.0 \times 10^6\ M^{-1}$.

The slope of the plot up to the $r$ value of 0.06 is indicative of cooperative binding (31). The fact that $r/m$ increases as $r$ increases to 0.06 shows that once one drug molecule is initially bound, subsequent binding is facilitated.

(b) *Magnetic circular dichroism spectra*

As stated previously, the dinucleotide CpG has no mcd absorption in the region below 25 000 $cm^{-1}$. Thus any differences between the mcd spectra of the drug itself and the drug–nucleotide complex can be attributed to some specific change in the anthraquinone chromophore due to binding. For marcellomycin, results shown in Fig. 5a indicate little perturbation of the anthraquinone chromophore upon binding. Results for the carminomycin–CpG complex were similar. In each case ratios of dinucleotide to drug of ca. 15:1 were employed to ensure that no free drug was present. Above 25 000 $cm^{-1}$, the mcd spectrum of the excess CpG swamps that of the drug. Thus this region is not included in Fig. 5a or 5b.

In contrast to the slight perturbations in these two cases, the mcd spectrum of the aclacinomycin–CpG complex displays several strong new features. By curve resolution using Gaussian band shapes, three $B$ terms can be identified, with signs, at 18 700(+), 20 100(−), and 21 100(−) wavenumbers (Fig. 5b). The appearance of these bands, in a region of very weak absorption, suggests that a different mode of binding has occurred in this particular complex, which has stimulated forbidden transitions in the drug and the dinucleotide.

In anthraquinones, characterized by $D_{2h}$ symmetry, there is an electric dipole forbidden $\pi \rightarrow \pi^*$ transition to the $^1B_{1g}$ state (25, 26). However, this transition is allowed by an out-of-plane magnetic dipole, and if it could acquire intensity by interaction with a second similar chromophore, a strong mcd signal would be expected. Such an interaction could most easily occur through close contact of the drug chromophore with the aromatic base pairs of the dinucleotide.

(c) *Nature of the drug–dinucleotide interactions*

Clearly two distinct types of interactions are present, based on the optical titration and mcd data. The Scatchard plots for marcellomycin and carminomycin show complete but noncooperative binding when CpG is in excess. The corresponding mcd spectra are not strongly perturbed, indicating that the binding mechanism does not perturb the nature of the anthraquinone chromophore to any large extent.

On the other hand, aclacinomycin is involved in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

cooperative binding and the mcd spectrum of this drug, complexed with CpG, indicates extensive perturbation of the anthraquinone chromophore.

Previous work indicates that anthracyclines bind via an intercalative mechanism, predominantly in the minor groove of DNA (32). For CpG, this groove corresponds to a slightly displaced set of hydrophilic hydrogen bonds near the centre and hydrophobic base pairs near the edges (Fig. 6). The two drugs carminomycin and marcellomycin possess OH groups in the *peri*-position for each of the anthraquinone carbonyls (Fig. 1). Both molecules could intercalate into the hydrophilic region and be strongly bound without placing the anthraquinone chromophore near any of the bases (Fig. 7). However, aclacinomycin possesses one anthraquinone carbonyl which does not have a *peri*-OH group. Intercalation, placing the hydrophobic side between the base pairs, is therefore favoured.

This sideways shift of **1** relative to **2** and **3** implies that only one half of the CpG slot is occupied by the first molecule of aclacinomycin **1**. The observed cooperative binding strongly suggests that a second molecule of **1** can penetrate the opened slot to lie adjacent to the first (Fig. 8). The initially bound molecule of **1** probably approaches CpG via the minor groove. Intercalation will induce some uncoiling of the helix, thereby permitting the second molecule of **1** to approach via the major groove. For the sugar moieties to have the least steric interference, the two molecules of **1** are probably inverted relative to each other (Fig. 8).

This structural hypothesis is consistent with the observed features in the mcd spectrum. The proposed close association of the anthraquinone moiety between the base pairs provides a strong perturbation of the out-of-plane magnetic dipole transition and a resulting increase in observed intensity. Several new bands have appeared, the first two of which have oppositely signed *B* terms (Fig. 5b). This suggests that similar, out-of-plane, forbidden transitions in the base chromophores have been

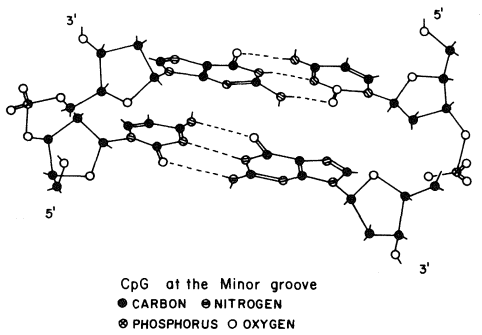

FIG. 6. CpG at the minor groove.

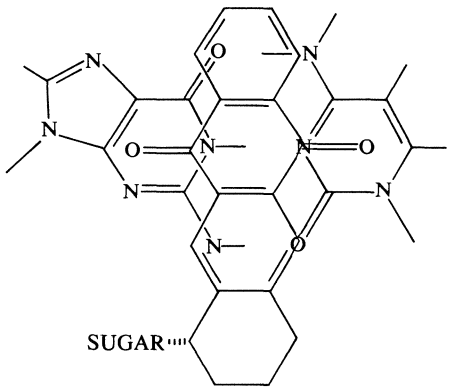

FIG. 7. Proposed interaction between intercalating marcellomycin or carminomycin and CpG base pairs.

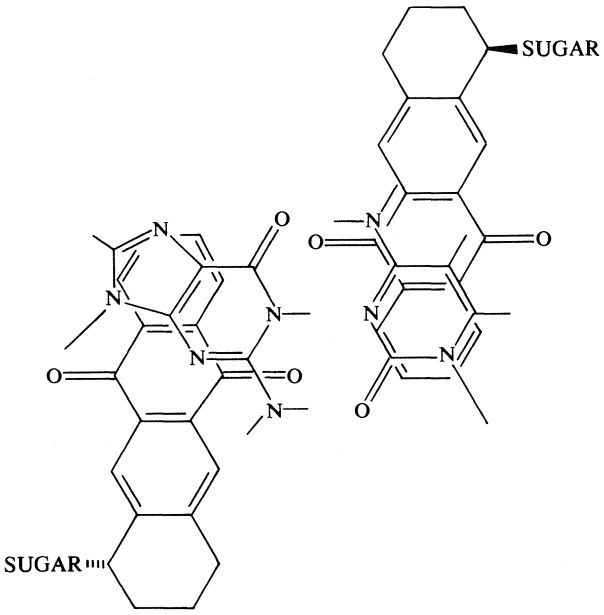

FIG. 8. Proposed interaction between intercalating aclacinomycin and CpG base pairs.

stimulated and that a substantial exiton splitting has occurred. The appearance of oppositely signed *B* terms of similar intensities is often characteristic of systems split by exitons (33).

A more detailed calculation of the orientation of the anthraquinone chromophore relative to the base pairs can be made from the relative intensities of the exiton *B* terms. These *B* terms acquire intensity through the interaction of the forbidden $^1B_{1g}$ state with either the long ($x$-polarized) axis or short ($y$-polarized) axis electric dipole allowed transitions (25, 26). Since the long axis $L_b$ states lie at much closer energy than the short axis *B* states, the $L_b$ states probably dominate the observed *B* term intensities. Thus the relevent exiton dipoles involve the interaction of long axis polarized al-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

lowed transitions in the anthraquinone with the base pair. The exiton is not directly visible in the allowed $L_b$ bands because the band width of 8 000 to 10 000 $cm^{-1}$ is much greater than the exiton splitting of approximately 1 500 $cm^{-1}$.

The equation describing the magnitude of the exiton in the classical transient point dipole model (34) is

$$V_{ab} = \frac{\rho_a \rho_b}{d^3_{ab}} [\sin\theta \sin\phi \cos(\theta-\phi) - 2\cos\theta \cos\phi]$$

where $\rho_a$ and $\rho_b$ are the electric dipole intensities for the transitions in molecules a and b, $d_{ab}$ is the intermolecular distance, and $\theta$ and $\phi$ are the angles formed by the transient dipoles with the line joining their centres.

In the present case, by assuming that the anthraquinone is inserted between the base pairs, the chromophores become stacked in coparallel fashion. The analysis thus reduces to a single orientation angle between the dipoles of the lowest $L_b$ bands in the anthraquinone and the base pair. The near equality of these intensities at 18 700 and 20 100 $cm^{-1}$ indicates that the $L_b$ dipole direction is at an angle near 45° to the $L_b$ dipole in the bases of the dinucleotide. This is quite consistent with structures proposed by Gabbay *et al.* (32).

## Conclusions

It seems clear that the two distinct binding modes are available to intercalating anthracyclines. Those compounds having both anthraquinone carbonyls *peri*-hydroxylated bind one molecule per groove in the central hydrophilic region while those having only one *peri*-hydroxylated anthraquinone carbonyl can bind two per groove and interact directly and strongly with the base pairs. This latter interaction involves a more severe perturbation of both the stereochemistry and electronic structure of the dinucleotide than the first.

This distinction could have important consequences in the understanding of the mode of action of these antitumor agents. Indeed, it has been reported (35) that aclacinomycin possesses a mode of antitumor action which distinguishes it from drugs possessing two *peri*-hydroxylated anthraquinone carbonyls, such as adriamycin, daunomycin, carminomycin, and marcellomycin. Our results indicate that these differing modes of action may reflect the presence or absence of the cooperative binding phenomena described herein.

## Experimental

(a) *Materials*

Aclacinomycin A, carminomycin, and marcellomycin were provided by Bristol Laboratories, Bristol Myers Co., Syracuse, NY. 2′-Deoxycytidylyl-(3′→5′)-2′-deoxyguanosine (CpG) was obtained as the ammonium salt from Sigma Chemical Company. Orthophosphoric acid and sodium phosphate dibasic, both reagent grade, were from Anachemia Chemical Ltd.

All samples were weighed on a Mettler H2O balance. The pH measurements were obtained using a Fisher Accumet 140 meter with a combination electrode. Calibrations were made using standard buffer solutions (pH 4.00 and 8.00), obtained from Anachemia Chemicals Ltd.

(b) *Optical titrations*

Ultraviolet and visible absorption spectra were recorded on a Cary 14 spectrophotometer (Applied Physics Corp., Monrovia, CA). Changeable potentiometers allowed measurements to be taken with 0.5 or 1.0 absorbance units corresponding to a full scale deflection.

Individual absorption spectra were measured in 1 cm quartz cells, whereas binding titrations were performed using quartz cells with a 10 cm path length.

Stock solutions of the three anthracycline drugs were prepared in 5.00 mL of millipore pure water. Binding titrations were performed against an excess of CpG, allowing 24 h for the attainment of equilibrium, during which time samples were stored in the dark. All solutions contained 0.01 *M* $Na_2HPO_4$ with the pH adjusted to 7 using $H_3PO_4$.

The binding interactions were followed at a wavelength corresponding to $\varepsilon_{max}$ for the drugs, 450 nm for aclacinomycin and 550 nm for carminomycin and marcellomycin. Similar (dilute) concentrations of the free drugs were measured under the same conditions.

(c) *Magnetic circular dichroism spectra*

The mcd spectra were obtained on an instrument built in this department. The optics of a Cary 14 spectrophotometer were modified to allow a superconducting magnet (Oxford Instruments) to be placed over the sample compartment.

The field strength was 44.7 kgauss for all experiments. Spectra of 1000 datum points were collected automatically using a scan stepper motor controlled by a Nova 4/c minicomputer (Data General Canada Ltd).

At least 16 values per datum point were collected and averaged, more values (up to 25) were taken as the noise increased. The digitized stored spectrum was then corrected for the baseline. A separate file was created containing the data for the baseline. Both files were rotated about a line connecting two points of zero mcd intensity (lock positions), bringing them to the horizontal. The baseline data were then fitted to the mcd data file and the two subtracted to produce the final spectra. This procedure minimizes the distortion caused by a badly curved baseline.

The instrument was calibrated using 0.01 *M* $CoSO_4$ giving a $[\theta]_M$ value of $-6.1 \times 10^{-3}$ deg $cm^2$ $dmol^{-1}$ $gauss^{-1}$ at 19 800 $cm^{-1}$ (36). A positive mcd signal corresponded to $\varepsilon_L > \varepsilon_R$, where these are the extinction coefficients of left and right circularly polarized light respectively.

Samples were prepared using millipore pure water, and with concentrations previously determined to provide complete binding. Free drug and dinucleotide spectra were obtained under identical conditions. Samples were run in a circular quartz cell with a 1 cm path length.

The natural cd spectra of the drugs and dinucleotide below 30 000 $cm^{-1}$ were obtained on the same instrument. With the magnet turned off, the instrument was calibrated using *d*-camphor sulfonic acid. A [θ] value of 7800 deg $cm^2$ $dmol^{-1}$ was recorded for a $2.0 \times 10^{-3}$*M* solution at 34 500 $cm^{-1}$ (37).

At $\bar{\nu}$ values lower than 30 000 $cm^{-1}$, there was negligible absorption in the cd spectra of CpG and the anthracyclines.

# Synthesis of the colitose determinant of *Escherichia coli* O111 and 3,6-di-*O*-(α-D-galactopyranosyl)-α-D-glucopyranoside[1]

TOMMY IVERSEN[2] AND DAVID R. BUNDLE

*Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6*

Received September 16, 1981

TOMMY IVERSEN and DAVID R. BUNDLE. Can. J. Chem. **60**, 299 (1982).

The syntheses of two branched trisaccharides, which constitute important elements of enterobacterial lipopolysaccharides are described. The common structural feature of each trisaccharide is α-D-glucopyranoside, upon which branching occurs at the *O*-3 and *O*-6 positions. Selective blocking of this hexoside at *O*-2 and *O*-4 by persistent blocking groups was accomplished by benzylation of 1,6-anhydro-β-D-glucopyranoside (**1**). Acetolysis of the product **2** afforded a mixture of anomeric triacetates **3** from which the corresponding 3,6-di-*O*-acetyl-2,4-*O*-benzyl-α-D-glucopyranosyl chloride (**4**) was prepared. The α and β 8-methoxycarbonyloctyl glycosides **5** and **6** were obtained in the ratio ~2:1, when **4** was reacted with 8-methoxycarbonyloctanol. Transesterification of the α-glycoside **5** gave the aglyconic intermediate **7** from which each trisaccharide could be obtained in a one step reaction. Thus glycosylation of **7** with tetra-*O*-benzyl-α-D-galactopyranosyl chloride (**8**) or 2,4-di-*O*-benzyl-3,6-dideoxy-α-L-*xylo*-hexopyranosyl chloride (**10**) gave the trisaccharides **11** and **13**. In both cases removal of blocking groups was achieved in a single hydrogenolysis step. Trisaccharide **12** represents a trisaccharide sequence present in the core saccharide of Salmonella lipopolysaccharides, while the colitose containing trisaccharide **14** is an essential element of the *E. coli* O111 *O*-antigen.

TOMMY IVERSEN et DAVID R. BUNDLE. Can. J. Chem. **60**, 299 (1982).

On décrit la synthèse de deux trisaccharides ramifiés qui constituent des éléments importants des lipopolysaccharides entérobactériens. La caractéristique structurale commune à chaque trisaccharide est l'α-D-glucopyrannoside, sur lequel s'effectue les ramification en positions *O*-3 et *O*-6. On a pu protéger sélectivement cet hexoside en positions *O*-2 et *O*-4 à l'aide de groupes protecteurs très stables en benzylant l'anhydro-1,6 β-D-glucopyrannose (1). L'acélotyse du composé **2** conduit à un mélange de triacétates **3** anomères à partir duquel on a préparé le chlorure de di-*O*-acétyl-3,6 *O*-benzyl-2,4 α-D-glucopyrannosyle (**4**). On a obtenu les α- et β-glycosides de methoxycarbonyl-8 octyle, **5** et **6**, dans un rapport de 2:1 environ en faisant réagir le composé **4** avec le méthoxycarbonyl-8 octanol. La transestérification de l'α-glycoside conduit à l'intermédiaire aglyconique **7** à partir duquel on peut obtenir chaque trisaccharide en une seule étape. Ainsi la glycosilation du composé **7** par le chlorure de tétra-*O*-benzyl α-D-galactopyrannosyle (**8**) ou par le chlorure de di-*O*-benzyl-2,4 didéoxy-3,6 α-L-xylohexopyrannosyle (**10**) donne les trisaccharides **11** et **13**. Dans les deux cas, l'hydrolyse permet d'effectuer la déprotection en une seule étape. Le trisaccharide **12** représente une suite de trisaccharides présents dans le noyau saccharique des lipopolysaccharides du type Salmonella, tandis que le trisaccharide **14** contenant la colitose est un élément essentiel de l'antigène O de l'*E. Coli* O111.

[Traduit par le journal]

## Introduction

Although antigenic determinants of *Salmonella* O-antigens containing the three 3,6-dideoxyhexoses paratose, abequose, and tyvelose have been synthesized (1–3), none of the colitose (optical antipode of abequose)-containing determinants have yet been prepared. Preliminary data indicate that colitose occurs in a "cross"-like structure as part of the repeating unit of the *E. coli* O111 O-antigen (4). Serological cross-reactions of *E. coli* O111, *Salmonella adelaide* O–35, and *Salmonella greenside* O–50 are related to the presence of colitose in the lipopolysaccharides (LPS) from each of these bacteria (5–7). In order to investigate further the dependence of these serological cross-reactions upon the colitose residues, the branched, colitose-containing trisaccharide, which is part of the *E. coli* O-antigen, was synthesized. The structurally related galactose-containing trisaccharide of *Salmonella* LPS core structures (8) was also synthesized. Since recent work has shown approximately 65% of LPS molecules to be incomplete with respect to addition of the O-chains (9, 10), the accessibility of such incomplete structures to core-specific antibodies is of renewed interest (11).

The synthesis of both trisaccharides was contingent upon an acceptable blocking strategy, which would provide an α-D-glucopyranoside with persistent blocking groups at *O*-2 and *O*-4, leaving *O*-3 and *O*-6 open for glycosylation. Branching at *O*-3 and *O*-6 of galacto- and manno-pyranosides occurs in blood-group substances (12) and glycoproteins (13). Compared with these hexoses, glucose lacks an axial–equatorial vicinal diol system that may be exploited to generate the required substitution pattern of blocking groups (14–16). A solution to this problem is described here, which facilitated the synthesis of two biologically important branched structures.

## Results

The scheme envisaged for the synthesis of branched structures was based upon the requirement

for a 8-methoxycarbonyloctyl α-D-glycopyranoside bearing persistent blocking groups, preferably benzyl ethers, at *O*-2 and *O*-4. In order to accomplish this, methyl α-D-glucopyranoside and *tert*-butyl β-D-glucopyranoside were reacted with *tert*-butyldiphenylsilyl chloride in DMF (17). Whereas the methyl glycoside gave predominantly the 2,6-disubstituted glucoside, *tert*-butyl β-D-glucopyranoside (18) gave the desired 3,6-disilyl ether. Unfortunately this product proved to be resistant to benzylation conditions, which have been reported to be compatible with the integrity of such silyl ethers (17).

A suitable derivative, 2,4-di-*O*-benzyl-1,6-anhydro-β-D-glucopyranose, has been reported in the literature (19–21). Benzylation of 1,6-anhydro-β-D-glucopyranose (**1**) with benzyl bromide and barium oxide in DMF gave **2** in 95% yield compared with the previously reported yield of 21%. Acetolysis of **2** gave an anomeric mixture of the triacetates **3** in 77% yield. This mixture was converted cleanly and quantitatively to 3,6-di-*O*-acetyl-2,4-di-*O*-benzyl-α-D-glucopyranosyl chloride (**4**), which was used without purification for the glycosylation of 8-methoxycarbonyloctanol. The desired α-glycoside **5** was obtained together with the β-anomer **6** in the ratio ~2:1. Transesterification of **5** gave the selectively blocked α-glucopyranoside **7**, which was used for the one-step syntheses of the branched trisaccharides.

Silver trifluoromethanesulphonate (triflate)-promoted glycosylation of **7** by tetra-*O*-benzyl-α-D-galactopyranosyl chloride (**8**) gave the corresponding trisaccharide **11** in 57% yield. Carbon-13 nmr revealed the presence of three anomeric carbon atoms with chemical shifts characteristic of α-anomers.

Methyl 3,6-dideoxy-α-L-*xylo*-hexopyranoside (22) was benzylated to give the benzylated glycoside **9**. Conversion of this derivative to the glycosyl chloride **10** was accomplished by reaction of the methyl glycoside **9** with dichloromethyl methyl ether in the presence of zinc chloride (23). The chlorosugar **10** was used immediately without purification. Glycosylation of the aglyconic component **7** by **10** under conditions of standard halide-ion catalysis (24) was unsuccessful. Under less conventional conditions the glycosyl chloride **10** reacted with the selectively blocked glucoside **7** in acetonitrile solution to give the required trisaccharide **13** in 53% yield.

The blocked trisaccharides **11** and **13** were hydrogenated to give the deblocked trisaccharides **12** and **14**. Proton and carbon-13 nmr chemical shifts confirm the α-configuration of the glycosidic linkages.

## Discussion

The selective protection of D-glucose residues is made difficult by the equatorial relationship of the secondary hydroxyl groups of the $^4C_1$ (D) conformer. These difficulties may be circumvented for some purposes by the use of 1,6-anhydro-β-D-glucopyranose (**1**) (20). For the purpose of generating 3,6-disubstituted glucopyranose residues, benzylation of **1** to give the 2,4-di-*O*-benzyl-glucopyranose **2** offers the most direct route (19–21), although the published yield is low (19). By comparison, an alternate route to a 2,4-di-*O*-benzyl-D-glucopyranoside was recently reported (24). Modification of the benzylation conditions of **1** gave **2** in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

good yield. Acetolysis followed by conversion to the glycosyl chloride **4** provides a rapid route via glycosylation of 8-methoxycarbonyloctanol to the desired intermediate α-glycosides **5** and **7**. The yields achieved compare favourably with previous work (19).

Methyl 2,4-di-*O*-benzyl-3,6-dideoxy-α-L-*xylo*-hexopyranoside (**9**) was efficiently converted to the corresponding glycosyl chloride **10** by dichloromethyl methyl ether with zinc chloride as the Lewis acid (23). The 3,6-dideoxyglycosyl halides are among the most labile glycosyl halides. These reaction conditions are, therefore, compatible with benzyl ether blocking groups and well suited to the lability of the product.

Throughout this study glycosyl chlorides were employed, a choice based on several considerations. The chlorides are more stable than the glycosyl bromide analogues and the reduced reactivity can be compensated for by judicious choice of promoter, according to the scheme of Paulsen and Kolář (25). Thus tetra-*O*-benzyl-α-D-galactopyranosyl chloride (**8**) readily formed α-glycosidic bonds at *O*-6 and *O*-3 with silver triflate as promoter (26).

When the glycosyl chloride **10** was reacted with 8-methoxycarbonyloctyl 2,4-di-*O*-benzyl-α-D-glucopyranoside (**7**) under conditions of halide ion catalysis, the reaction mixture contained many components from which only decomposition products of **10** and **7** could be isolated. In order to suppress side reactions which could result from the electrophilic nature of reaction intermediates (27), acetonitrile was employed as the solvent for the halide-ion catalysed reaction of **10** with **7**. The solvating action of acetonitrile served to stabilize the glycosyl chloride, the presence of which was evident from tlc examination of the reaction mixture over a five-day period. In this way an efficient yield of the trisaccharide **12** was secured.

The deblocked glycosides showed nmr parameters in agreement with the structures. The $^1$H nmr shift and $^3J$ coupling constant data for the three anomeric protons are consistent only with the presence of α-linkages in both trisaccharides **12** and **14**. The $^{13}$C nmr shifts for the anomeric carbon atoms further corroborate this conclusion.

Binding of antibody, raised against *E. coli* O111 or *Salmonella adelaide* whole cell vaccines, to the respective cell wall lipopolysaccharides was inhibited by methyl 3,6-dideoxy-α-L-*xylo*-hexopyranoside and trisaccharide **14**. In all cases the trisaccharide was at least 50–100 times more effective than the methyl α-glycoside of colitose. These results reflect the crucial spacial disposition of the two colitose residues for antibody binding. Moreover, since trisaccharide **14** inhibits the homologous *S. adelaide* system, both *S. adelaide* and *E. coli* O111 likely possess similar O-antigen structures. This conclusion based on serology is supported by independent structural studies.[3]

## Experimental

The general methods and materials employed in this work are similar to those described in other papers from this laboratory (22, 28). Carbon 13 and $^1$H nmr spectra were recorded at 20 and 79.9 MHz respectively. Proton chemical shifts are expressed relative to 1% tetramethylsilane (TMS) for deuteriochloroform solutions and, in the case of deuterium oxide, relative to sodium 3-trimethyl-silylpropionate-2,2,3,3-$d_4$ (TSP). Carbon-13 shifts are expressed relative to internal and external TMS for deuteriochloroform and deuterium oxide solutions. Medium pressure column chromatography was used for most separations and was conducted according to our published method (29).

*1,6-Anhydro-2,4-di-*O*-benzyl-β-*D*-glucopyranose (**2**)*

A mixture of 1,6-anhydro-β-D-glucopyranose (30) (**1**) (2.0 g, 12 mmol), benzyl bromide (7.5 mL), and barium oxide (7.5 g) in dimethylformamide (50 mL) was stirred at 60°C for 3 h, followed by addition of methanol (25 mL) to destroy excess benzyl bromide. After 30 min the reaction mixture was diluted with chloroform, filtered, and washed with water. Evaporation of the solvents left a syrup that was purified on a silica gel column (Skellysolve B – ethyl acetate 2:1) to give 4.0 g (95%) of **2**: $[\alpha]_D$ −28.8° (*c* 1.0, chloroform), mp 104.5–105°C (recryst. Skellysolve B – ethyl acetate) (lit. (19) $[\alpha]_D$ −28.5°; mp 106.5–107°C); $^1$H nmr ($CDCl_3$) δ: 7.34 (bs, 10H, aromatics), 5.44 (s, 1H, H-1). *Anal.* calcd. for $C_{20}H_{22}O_5$: C 70.16, H 6.48; found: C 70.04, H 6.54.

*1,3,6-Tri-*O*-acetyl-2,4-di-*O*-benzyl-*D*-glucopyranose (**3**)*

Compound **2** (3.0 g, 8.8 mmol) was dissolved in acetic anhydride (50 mL) and 3 drops of concentrated sulfuric acid were added to the stirred reaction mixture. After 30 min the solution was diluted with chloroform, washed with aqueous sodium bicarbonate and water, and evaporated. The resulting syrup was purified on a silica-gel column (Skellysolve B – ethyl acetate 2:1) to give 3.3 g (79%) of **3** as an anomeric mixture; α/β ~3; $[\alpha]_D$ +80.7° (*c* 2.0, chloroform); $^1$H nmr ($CDCl_3$) δ: 7.27 (bs, 10H, aromatics), 6.32 (d, $J_{1,2}$ = 3.6 Hz, H-1α), 5.45 (d, $J_{1,2}$ = 9.7 Hz, H-1β); $^{13}$C nmr ($CDCl_3$) $\delta_c$: 93.8 (C-1β), 89.2 (C-1α).

*3,6-Di-*O*-acetyl-2,4-di-*O*-benzyl-α-*D*-glucopyranosyl chloride (**4**)*

Dichloromethyl methyl ether (7.5 mL) was added to a solution of **3** (2.6 g, 5.3 mmol) and zinc chloride (~100 mg) in dichloromethane (50 mL). The reaction mixture was stirred for 1.5 h, filtered, evaporated, and dried under vacuum to give 2.5 g (~100%) of the syrupy chlorosugar **4**. Carbon-13 nmr and $^1$H nmr indicated the syrup to be at least 95% pure and it was used in the glycosidation step without purification; $^1$H nmr ($CDCl_3$) δ: 6.01 (d, 1-H, $J_{1,2}$ = 3.9 Hz, H-1), 5.59 (t, 1H, $J_{2,3} \approx J_{3,4}$ = 12 Hz, H-3), 2.07 (s, 3H, OAc), 2.00 (s, 3H, OAc); $^{13}$C nmr ($CDCl_3$) $\delta_c$: 92.14 (C-1).

*8-Methoxycarbonyloctyl 3,6-di-*O*-acetyl-2,4-di-*O*-benzyl-α- (**5**) and -β-*D*-glucopyranoside (**6**)*

The chlorosugar **4** (2.5 g, 5.3 mmol) dissolved in dichloromethane (5 mL) was added to a stirred mixture of 8-methoxycarbonyloctanol (31) (1.3 g, 6.9 mmol), mercuric cyanide (2.7 g,

[3]L. Kenne, private communication.

For personal use only.

11 mmol), and mercuric bromide (3.7 g, 10 mmol) in dichloromethane (10 mL) at −70°C. The reaction was allowed to warm to room temperature and stirred overnight. Filtration and evaporation gave a syrupy residue that was purified on a silica-gel column (Skellysolve B – ethyl acetate 3:1) to give 1.6 g (49%) of **5**; $[\alpha]_D$ +68.5° (*c* 1.4, chloroform); $R_f$ = 0.33 (solvent same as above); $^1$H nmr ($CDCl_3$) δ: 7.32 (bs, 10H, aromatics), 5.56 (t, 1H, $J_{2,3} = J_{3,4}$ = 9.4 Hz, H-3), 3.66 (s, 3H, OMe), 2.09 (s, 3H, AcO), 2.00 (s, 3H, AcO), 1.10–1.80 (m, 12H, —$(CH_2)_6$—); $^{13}$C nmr ($CDCl_3$) $\delta_c$: 96.6 (C-1); and 0.9 g (28%) of **6**; $[\alpha]_D$ +33.5° (*c* 1.2, chloroform); $R_f$ = 0.35 (solvent same as above); $^1$H nmr ($CDCl_3$) δ: 9.27 (bs, 10H, aromatics), 3.66 (s, 3H, OMe), 2.04 (s, 3H, AcO), 1.88 (s, 3H, AcO), 1.80–1.10 (m, 12H, —$(CH_2)_6$—); $^{13}$C nmr ($CDCl_3$) $\delta_c$: 103.5 (C-1).

*8-Methoxycarbonyloctyl 2,4-di-*O*-benzyl-α-*D*-glucopyranoside (7)*

Compound **5** (2.3 g, 3.7 mmol) in methanol (50 mL) containing a catalytic amount of sodium methoxide was left overnight. The syrup, obtained after removal of sodium ions with Rexyn 101 ($H^+$) resin, filtration, and evaporation, was purified on a silica-gel column (Skellysolve B – ethyl acetate 2:1) to give 1.6 g (83%) of **7**; $[\alpha]_D$ 79.6° (*c* 1.1, chloroform); $^1$H nmr ($CDCl_3$) δ: 7.34 (bs, 10H, aromatics), 3.65 (s, 3H, OMe), 2.0–1.0 (m, 12H, —$(CH_2)_6$—); $^{13}$C nmr ($CDCl_3$) $\delta_c$: 96.5 (C-1). *Anal.* calcd. for $C_{30}H_{42}O_8$: C 67.90, H 7.98; found: C 67.70, H 7.88.

*8-Methoxycarbonyloctyl 2,4-di-*O*-benzyl-3,6-di-*O*-[tetra-*O*-benzyl-α-*D*-galactopyranosyl]-α-*D*-glucopyranoside (11)*

A solution of tetra-*O*-benzyl-α-D-galactopyranosyl chloride (**8**) (30) (2.0 g, 3.5 mmol) in dichloromethane (10 mL) was added to a stirred mixture of compound **7** (0.40 g, 0.8 mmol), silver triflate (1.5 g, 5.8 mmol), *N*,*N*-tetramethylurea (3 mL), and molecular sieve 4 Å in dichloromethane (15 mL) at −40°C. The reaction mixture was allowed to warm to room temperature and stirred overnight. Filtration followed by evaporation left a syrup that was purified on a silica-gel column (toluene – ethyl acetate 15:1) to give 0.68 g (57%) of **8**; $[\alpha]_D$ +53.1° (*c* 1.4, chloroform); $^{13}$C nmr ($CDCl_3$) $\delta_c$: 98.3, 97.9, 96.5 (C-1″, C-1′, and C-1).

*Methyl 2,4-di-*O*-benzyl-3,6-dideoxy-α-*L*-xylo-hexopyranoside (9)*

A solution of methyl 3,6-dideoxy-α-L-*xylo*-hexopyranoside (22) (5.9 g, 36 mmol) containing sodium hydride (3.5 g, 15 mmol) in dry dimethylformamide (100 mL) was stirred at room temperature for 30 min. Benzyl bromide (20 g) in dimethylformamide (50 mL) was then slowly added to the stirred mixture and the reaction was left for 2 h at room temperature. Excess benzyl bromide was destroyed by the addition of methanol (25 mL). The reaction mixture was diluted with dichloromethane, washed with water, and evaporated to a syrup that was purified on a silica-gel column (Skellysolve B – ethyl acetate 4:1) to give 9.5 g (76%); $[\alpha]_D$ −19.8° (*c* 1.7, chloroform); $^1$H nmr ($CDCl_3$) δ: 3.90 (s, 3H, OMe), 2.20–1.70 (m, 2H, H-4), 1.28 (d, 3H, $J_{5,6}$ = 6 Hz, H-6); $^{13}$C nmr ($CDCl_3$) $\delta_c$: 98.0 (C-1), 27.9 (C-3), 16.6 (C-6). *Anal.* calcd. for $C_{21}H_{26}O_4$: C 73.66, H 7.65; found: C 73.61, H 7.66.

*2,4-Di-*O*-benzyl-3,6-dideoxy-α-*L*-xylo-hexopyranosyl chloride (10)*

Anhydrous zinc chloride (~50 mg) was added to a solution of **9** (0.53 g, 1.5 mmol) in dichloromethyl methyl ether (5 mL). The reaction mixture was stirred at room temperature for 1 h, filtered through glass wool, evaporated, and dried under high vacuum to give 0.53 g (~ 100%) of the syrupy chlorosugar **10**, which was immediately used in the glycosidation step; $^1$H nmr ($CDCl_3$) δ: 6.26 (d, 1H, $J_{1,2} \approx$ 2 Hz, H-1), 2.35–1.95 (m, 2H, H-3), 1.26 (d, 3H, $J_{5,6} \approx$ 6 Hz, H-6); $^{13}$C nmr ($CDCl_3$) $\delta_c$: 95.8 (C-1), 28.1 (C-3), 16.3 (C-6).

*8-Methoxycarbonyloctyl-2,4-di-*O*-benzyl-3,6-di-*O*-[2,4-di-*O*-benzyl-3,6-dideoxy-α-*L*-xylo-hexopyranosyl]-α-*D*-glucopyranoside (13)*

The chlorosugar **10** (0.53 g, 1.5 mmol) from the above preparation, in acetonitrile (5 mL), was added to a stirred mixture of compound **7** (0.35 g, 0.7 mmol), tetraethylammonium chloride (0.66 g, 4 mmol), diisopropylethylamine (0.25 g, 1.9 mmol), and molecular sieve 4 Å in acetonitrile (10 mL) at −40°C. The reaction mixture was allowed to reach room temperature and was stirred for 10 days, after which time the mixture was filtered and evaporated to a syrupy residue that was separated on a silica-gel column (Skellysolve B – ethyl acetate 4:1) to give 0.40 g (53%) of compound **11**; $[\alpha]_D$ −8.5° (*c* 0.7, chloroform); $^{13}$C nmr ($CDCl_3$) $\delta_c$: 96.9, 96.5, 95.9 (C-1″, C-1′, and C-1).

*8-Methoxycarbonyloctyl 3,6-di-*O*-[α-*D*-galactopyranosyl]-α-*D*-glucopyranoside (12)*

The trisaccharide **8** (0.67 g, 0.4 mmol) was dissolved in ethanol – acetic acid (1:1, 80 mL) and hydrogenolyzed for 18 h at 70 psi over 10% palladium on charcoal. Filtration and evaporation of solvents left a syrup that was purified on a silica-gel column (ethyl acetate – methanol–water 7:2:1) to give 0.18 g (63%) of the product **12**. The $^{13}$C nmr of **12** showed the presence of small amounts of disaccharide impurities and an analytically pure sample was obtained by acetylation (acetic anhydride – pyridine) and chromatography on a silica-gel column (Skellysolve B – ethyl acetate 4:1) followed by deacetylation (sodium methoxide – methanol); $[\alpha]_D$ +79.2° (*c* 0.9, in water); $^1$H nmr ($D_2O$, 90°C) δ: 5.96 (s, 1-H, H-1″), 4.97 (dd, 2-H, $J_{1,2} \approx$ 1.4, $J_{1,2}$ = 3.7 Hz, H-1′, H-1), 2.4 (t, —$CH_2CO$—), 2.0–1.1 (m, 12H, —$(CH_2)_6$—); $^{13}$C nmr ($D_2O$) $\delta_c$: 100.5, 99.6, and 99.3 (C-1″, C-1′, and C-1). *Anal.* calcd. for $C_{28}H_{50}O_{18}$: C 49.85, H 7.47; found: C 49.61, H 7.58.

*8-Methoxycarbonyloctyl 3,6-di-*O*-[3,6-dideoxy-α-*L*-xylo-hexopyranosyl]-α-*D*-glucopyranoside (14)*

The trisaccharide (**11**) (180 mg, 0.2 mmol) was dissolved in ethanol (30 mL) and hydrogenolyzed for a week at 70 psi over 10% palladium on charcoal. Filtration and evaporation of the solvent left a syrup that was purified on a silica-gel column (ethyl acetate – methanol–water 85:10:5) to give 80 mg (84%) of the product **13** $[\alpha]_D$ −17.7° (*c* 0.6, $H_2O$); $^1$H nmr ($D_2O$, 90°C) δ: 5.16 (d, 1-H, $J_{1',2'}$ = 3.6 Hz, H-1′), 4.88 (dd, 2H, $J_{1,2}$ = 3.0 Hz, $J_{1,2}$ = 4.2 Hz, H-1, H-1″); $^{13}$C nmr ($D_2O$) $\delta_c$: 100.5, 99.7, 99.5 (C-1″, C-1′, and C-1), 16.7 (C-6″), 16.6 (C-6′). *Anal.* calcd. for $C_{28}H_{50}O_{14}$: C 55.07, H 8.25; found: C 54.91, H 8.42.

## Acknowledgements

We wish to thank Dr. Klaus Bock for valuable discussions and for a generous gift of 1,6-anhydro-β-D-glucopyranose. In addition, the expert assistance of Mr. H. Seguin for microanalyses and the technical assistance of Mr. J. W. L. C. Christ are gratefully acknowledged.

# Spectral behaviour and solvent effects of some aminoanthraquinone dyes

SAFAA H. ETAIW, MORSI M. ABOU SEKKINA,[1] GAD B. EL-HEFNAWEY, AND SAMY S. ASSAR
*Department of Chemistry, Faculty of Science, University of Tanta, Tanta, Egypt*
Received October 6, 1980[2]

SAFAA H. ETAIW, MORSI M. ABOU SEKKINA, GAD B. EL-HEFNAWEY, and SAMY S. ASSAR. Can. J. Chem. **60**, 304 (1982).

The electronic absorption spectrum of each of nineteen AAQ dyes has been studied in nine different organic solvents. The acid dissociation constants of dyes containing OH, COOH, or $SO_3H$ groups have also been determined experimentally. The spectra in ethanol display five bands in the uv region and one in the visible region (450–560 nm). This band is assigned to CT transitions of the type $l$–$a_\pi$ which result from the interaction of the lone pair of the nitrogen atom with the phenyl ring of the carbonyl group. The CT nature of the band was supported theoretically and by the effect of solvent on band position.

SAFAA H. ETAIW, MORSI M. ABOU SEKKINA, GAD B. EL-HEFNAWEY et SAMY S. ASSAR. Can. J. Chem. **60**, 304 (1982).

On a étudié le spectre d'absorption électronique de chacun des 19 colorants AAQ dans neuf solvants organiques différents. On a également déterminé expérimentalement les constantes de dissociation acide des colorants contenant les groupes OH, COOH ou $SO_3H$.

Les spectres dans l'éthanol montrent cinq bandes dans la région de l'uv et une dans la région du visible (450–560 nm). On attribue cette bande à une transition TC du type $l$–$a_\pi$ qui résulte de l'interaction entre le doublet libre de l'azote et le cycle phényle du groupe carbonyle. La nature TC de la bande est établie sur des bases théoriques ainsi que par l'influence du solvent sur la position des bandes.

## Introduction

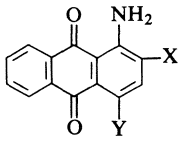
Investigations of the electronic absorption spectra of some anthraquinone derivatives have been reported (1–5). The effect of solvents on the absorption spectra of hydroxy- and aminoanthraquinone dyes have also been studied (6–8). In addition, the electronic absorption spectra of anthraquinone and its amino derivatives have been studied (3, 9, 10) by means of the polarized absorption spectra on stretched PVA sheets and by means of theoretical calculations.

In the course of our research, the major goal was to evaluate a complete band assignment for the electronic absorption spectra of six known aminoanthraquinone dyes and several newly prepared derivatives. In particular, one needs to determine the nature of their lower electronic excited states, e.g. the extent of charge transfer (CT) character, the role of the solvent, and the effect of protonation and substitution on their energy states. The acid properties of the carboxy, sulphonic, and hydroxy groups were also studied.

## Experimental

*Dye preparation and purification*

The first six aminoanthraquinone (AAQ) dyes namely, I-AAQ (**1**); 2-AAQ (**2**); 1,5-di AAQ (**3**); 1,8-di AAQ (**4**); 1-AAQ 2-$SO_3H$ (**5**), and 1-AAQ 4-OH (**6**) were obtained by purifying the Merck chemical grade through crystallization several times from the appropriate solvents. The remainder of the investigated dyes (**7–19**), as listed below, were carefully prepared for the first time and purified by methods similar to those previously recommended (11–13).



| | X | Y |
|---|---|---|
| **7** | Br | OH |
| **8** | $CH_2OH$ | H |
| **9** | $CH_2OH$ | Cl |
| **10** | $CH_2OSOCl$ | H |
| **11** | $CH_2Cl$ | Cl |
| **12** | $CH_2OCH_3$ | H |
| **13** | $CH_2OC_2H_5$ | H |
| **14** | $CH_2OC_3H_7$ | H |
| **15** | $CH_2OC_8H_{17}$ | H |
| **16** | COOH | H |
| **17** | CHO | H |
| **18** | $CH_3$ | H |
| **19** | $CH_3$ | Cl |

The solids obtained were purified by recrystallization from the appropriate solvents and their purity was checked by mp determination, nmr, and elemental analysis. The electronic absorption spectra were recorded in nine Spec. Pure (SP) organic solvents, namely ethanol, chloroform, carbon tetrachloride, *n*-hexane, cyclohexane, dioxane, dimethylformamide (DMF), 1,2-dichloroethane, and isopropylalcohol, at $4 \times 10^{-5}$ *M* concentration.

The hydrochlorides of the AAQ dyes were obtained by passing dry gaseous hydrogen chloride into solutions of the AAQ in pure dry $CCl_4$. The formation of the salts was accompanied by the deposition of an abundant white precipitate and decolourization of the solution. However, on filtration, the white precipitate rapidly acquired the colour of the initial AAQ, which indicates its decomposition. The chosen concentration of

the AAQ dyes in the different organic solvents ($4 \times 10^{-5} M$) was such that, after passing dry hydrogen chloride gas through the solution, the salts were not precipitated but the solution became decolourized. The spectra were recorded several times on a Pye Unicam SP 8000 recording spectrophotometer using 1 cm matched silica cells at 25 ± 0.1°C. The results were found to be reproducible. Universal buffer solutions were prepared (pH = 2–12) and the electronic spectra (400–650 nm) were taken soon after preparation of dye solutions. A radiometer pH-meter type 63 fitted with a combined glass electrode type GK 2301 C was used (accuracy = ±0.01 pH unit).

## Results and discussion

### *1. Electronic absorption spectra in nine different organic solvents*

The uv and visible absorption spectra of AAQ dyes (**1–19**) in ethanol display six absorption bands A, B, C, D, E, and F located near 210, 230, 245, 275, 308, and 450–560 nm respectively. The band A suffers a blue shift as the polarity of the solvent increases and disappears in HCl solution. This band has low absorptivity after background correction and corresponds to that observed at 207 nm in the spectrum of anthraquinone in ethanol (8). Thus, it was assigned to a $n-\pi^*$ transition. However, the spectra of some dyes show that the band A may be obscured by the most intense band B near 230 nm. The bands B, C, D, and E in the 230–275 nm region, corresponding to those observed in the spectra of anthracene (14) and anthraquinone (8, 15), were found to be distinctly shifted to shorter or longer wavelengths on changing the substituents. The relationships between these band shifts and the substituents are in agreement with the observations of Peters and Summer (16). These bands are polarized along Y, X, Y, and X axes respectively, where X and Y axes are perpendicular and parallel to the axis of the carbonyl bond (10) which is the main axis of the molecule. The bands B and C are due to $\pi-\pi^*$ transitions within the benzenoid system and correspond to ($1B_b \leftarrow 1A$) and ($1L_a \leftarrow 1A$) transitions respectively. The bands D and E were absent from the spectrum of anthracene, hence they are assigned to quinonoid transitions ($\pi-\pi^*$). The band D suffers a blue shift on going from aprotic to protic solvents. Also, the band suffers from splitting around 270, 276 nm in the spectra of all dyes except **9**, **11**, **12**, and **19**. Thus, the band D can be assigned to $\pi-\pi^*$ transitions within the carbonyl groups while the splitting of the band is due to the increase of the polar nature of one carbonyl group over the other, i.e. on changing the dye. On the other hand, the band E is slightly affected by the nature and position of the substituent and by the change of the solvent polarity, hence it may be attributed to $\pi-\pi^*$ transitions within the ethylenic system of the quinonoid ring. The broad band F was not observed in the spectra of either anthracene or anthraquinone. It showed a wide variation in both position and intensity under the influence of changing the solvent polarity and the type of substituents. It was previously assigned to $\pi-\pi^*$ transitions (17). Inoue *et al.* (10) assigned this band as due to intramolecular CT from the amino group to the carbonyl group without indicating the type of this CT. El-Ezaby *et al.* (8) observed this band in the spectra of hydroxy-anthraquinone dyes and attributed it to CT (from the effect of solvent on its position). To give a precise assignment of the band F, the energy of this band may be calculated theoretically and experimentally for the dyes **1** and **2** containing one amino group. The energy of the CT could be calculated using the following equation as used by Abou-Eutah and Hamed (18):

$$[1] \quad E_{CT} = I_P - (\text{E.A.} + C)$$

In this case, the coulombic forces ($C$) are estimated, to a good approximation, to be 5.6 eV (18) and the electron affinity (E.A.) of the carbonyl group equals 1.4 eV. This value was determined polarographically for dyes **1** and **2** using eq. [2] (19).

$$[2] \quad \text{E.A.} = -E_{1/2} + 2.49\,\text{eV}$$

Now, if we consider that the CT may originate either from the amino group, the aniline residue, or the benzene ring, ionization potentials of these groups were used to calculate the $E_{CT}$ (20, 21). The corresponding $E_{CT}$ values were 3.15, 0.7, and 2.245 eV, respectively. On the other hand, the experimental values of $E_{CT}$ using cyclohexane were found to be 2.77 and 3.1 eV for dyes **1** and **2**, respectively. These values closely match the value of $E_{CT}$ calculated using the value of $I_P$ of the amino group as donor. The experimental value of $E_{CT}$ for dye **2** was in better agreement with the calculated one than for the case of dye **1**. This could be attributed to the formation of an intramolecular hydrogen bond between the amino and the carbonyl group leading to growth of $s$ orbital character of the amino nitrogen atom which favours approach to the $sp^2$ state for the nitrogen atom. This is reflected in the increase of conjugation between the amino group and the anthraquinone residue. The spectra of AAQ dyes in ethanol are more or less identical with those in 0.1 $N$ HCl and after passing dry HCl gas into an ethanolic solution of the dye. However, when the spectra of these dyes are recorded in $CCl_4$ after passing dry HCl gas, the band F disappears and the solution is decolourized. In this case, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.

corresponding AAQ hydrochlorides are formed. On standing or on addition of a small amount of ethanol or water to the solution of AAQ hydrochloride, the salt solution rapidly acquires the initial colour of the AAQ dye and the band F reappears. The interaction of a proton from HCl with the amino group results in a transition of the nitrogen atom to the pure $sp^2$ state which prohibits the long wavelength CT transition due to the interaction of the lone electron pair of the nitrogen atom with the anthraquinone ring. Since ε is higher than that expected for a $n-\pi^*$ transition, the CT is of the type $l-a_\pi$ (22) resulting from the interaction of the electron pair of the nitrogen with the phenyl ring of the carbonyl group. This opinion is supported by the fact that the amino nitrogen, conjugated with a multiple bond or aromatic rings, deviates from the $sp^2$ state. The bands B, C, D, and E are slightly blue-shifted on going from polar to nonpolar solvents and this is in agreement with the general behaviour of $\pi-\pi^*$ transitions. On the other hand, the band F is highly red-shifted on going from aprotic to protic solvents, supporting its CT character.

It was noted that the spectrum of the dye **5** exhibits the band F at 478 nm in ethanol while it disappears in cyclohexane. In cyclohexane, the lone electron pair of the amino group is self protonated by the acidic hydrogen atom of the sulphonic group and the molecule has zwitterion structure. This is supported by the ir spectrum of this dye which exhibits two bonds at 3040 and 2650 $cm^{-1}$ attributed to $\nu_{NH_3}$ (23).

The addition of a very small amount of ethanol to the solution of dye **5** in cyclohexane rapidly returns the colour of the dye and the solution has the same spectrum as in ethanol, i.e. the CT band reappears. Thus the $l-a_\pi$ nature of the CT, originating from the amino group to the quinone system, is further supported. The zwitterion of dye **5** is formed only in aprotic solvent and has very low stability in protic ones. On this basis one can explain and understand why the amino group of the aminoanthraquinone dyes cannot be protonated in the protic solvents. This observation could be further clarified on the basis that, in protic solvents, the nitrogen atom is close to the $sp^2$ state. The interaction of the lone electron pair of the nitrogen with the anthraquinone ring is so pronounced that it may be regarded as incorporated in the common electronic system of the ring. This may prevent protonation of the amino group in protic solvents and hence prevent zwitterion formation, whereas the reverse case takes place in aprotic solvent.

*2. Acid ionization constants*

The acid ionization constants of dyes **6** and **7** were determined spectrophotometrically in (BR) buffers ranging from pH = 2 up to 12 at 25°C. From results obtained, the spectra are characterized by an isosbestic point around 540 nm indicating the presence of an acid–base equilibrium of the type:

$$AAQ-OH + H_2O \rightleftharpoons AAQ-O^- + H_3O^+$$

The variations of absorbance with pH at four different wavelengths are typical dissociation curves from which the p$K$ values were computed and evaluated by applying four different recommended methods (24, 25). The acid ionization constants of dyes **5** and **16** were determined potentiometrically. The p$K_a$ values can be evaluated from the titration curves using eq. [3]:

$$[3] \quad pH = pK_a + \log \frac{V}{V_0 - V}$$

where $V$ is the volume of alkali used for salt formation at the corresponding pH value and $V_0$ is the volume of alkali used to attain the end point.

A new method was introduced to calculate the ionization constants of the acids. Colleter's method (25) for the determination of the stability constant of complexes is modified to calculate the constant in the forms:

$$[4] \quad K_a = \frac{C_{H_2^+} - MC_{H_3^+}}{M - 1}$$

where

$$M = \frac{V_3 - V_1}{V_2 - V_1} \times \frac{C_{H_1^+} - C_{H_2^+}}{C_{H_1^+} - C_{H_3^+}}$$

The obtained p$K$ values were 3.79, 9.925, 9.104, and 5.74 for dyes **5**, **6**, **7**, and **16** respectively. Using $\Delta G = RT \ln K$ ($T$ = 298 K), values for p$K$ of 5.18, 13.56, 12.44, and 7.84 (kcal $mol^{-1}$) were obtained for dyes **5**, **6**, **7**, and **16** respectively.

# A synthesis of 11-nor-9-ketohexahydrocannabinol[1]

JOHN W. APSIMON,[2] ANDREW M. HOLMES,[3] AND IAN JOHNSON[4]
*Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6*
Received August 4, 1981

JOHN W. APSIMON, A. HOLMES, and IAN JOHNSON. Can. J. Chem. **60**, 308 (1982).

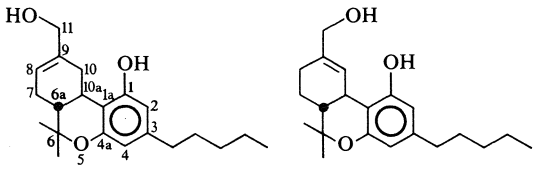
A 12-step synthesis of 11-nor-9-keto-hexahydrocannabionol (**3**) from dimethoxyolivetol (**4**) is described, together with some ancillary synthetic steps. The key step in this route is the reaction of the unsaturated dinitrile **6** with the Danishefsky diene **10**.

JOHN W. APSIMON, A. HOLMES et IAN JOHNSON. Can. J. Chem. **60**, 308 (1982).

On décrit une synthèse en 12 étapes du nor-11 céto-9 hexahydrocannabionol (**3**) à partir du diméthoxyolivétol (**4**); on décrit aussi quelques étapes connexes. La réaction du dinitrile insaturé **6** avec le diène de Danishefsky **10** est l'étape principale de cette synthèse.
[Traduit par le journal]

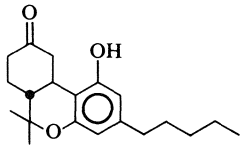
As part of a wider project aimed at the total synthesis of a variety of metabolites of cannabinoids (1) such as the 11-hydroxylated derivatives of $\Delta^8$ and $\Delta^9$ THC (**1** and **2** respectively), together with the possible requirement for the labelling of such species at nonexchangeable sites (see Scheme 1), we have examined routes proceeding via 11-nor-9-ketohexahydrocannabinol **3** (2).

In this report we describe our studies towards a direct, rational approach to the total synthesis of **3**. Although the final step in the route is of modest yield only, all of the other operations are extremely efficient.



**1**

**2**



**3**

The basis strategy of our approach is outlined in Scheme 1. The key steps foreseen in such a tactic involve a Diels–Alder reaction between a coumarin and a 2-oxygenated butadiene (3). Precedent for construction of the carbon skeleton of the basic cannabinoid system by a Diels–Alder route is reported (4), but the work described does not involve incorporation of oxygen at the 9-position. In our proposal, this oxygen atom is delivered to the correct site in the form of a trapped enol in the diene synthon. Other efficient routes to the target compound (**3**) must also be noted (3, 5).

The overall pathways studied are outlined in Schemes 2 and 3. That described first, proceeding via cyanocoumarin **7***a* or **7***b*, was not amenable to the elaboration of cannabinoid-like compounds; however, a slight modification of the strategy involved enabled **3** to be prepared.

The first synthetic plan devised for the preparation of **3** is summarized in Scheme 2. The *cis*-ring junction that would be generated in the proposed Diels–Alder reaction of 2-methoxy-1,3-butadiene **8** with the cyanocoumarin **7** presents no problem since decarboxylation (after hydrolysis of the nitrile function), proceeding through an enolate, should cause equilibration to the preferred *trans*-fusion. Both the carbocyclic ring and the requisite oxygen function would be efficiently introduced via the cycloaddition process. Incorporation of the *gem*-dimethyl grouping would involve the action of two equivalents of a methyl Grignard reagent on the lactone, affording a tertiary alcohol. Under acidic conditions, cyclization ensues, yielding the pyran ring. This sequence has been successfully performed with similar substrates, although not with the

[1]Two numbering systems are in use today. One is based on the formal chemical rules for numbering of benzopyran. The second system has a biogenetic basis, regarding cannabinoids as substituted monoterpenes. The former is used exclusively in this work. The naturally occurring enantiomer (6aR, 10aR) is shown for convenience although structures of synthetic materials described herein represent racemates.

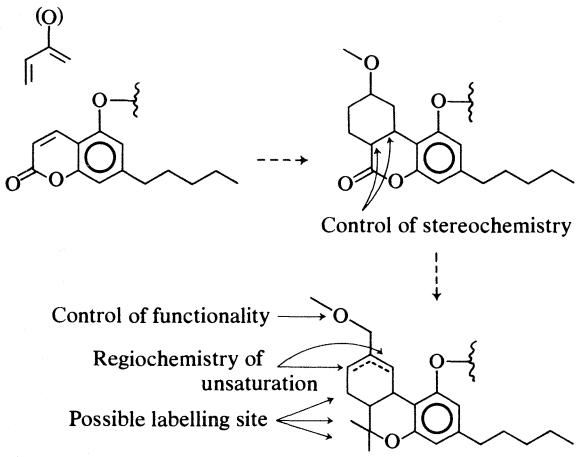


SCHEME 1. Synthetic strategy used in this study.

compounds studied in this work (For a summary of previous synthetic efforts in the cannabinoid field, see ref. 3.).

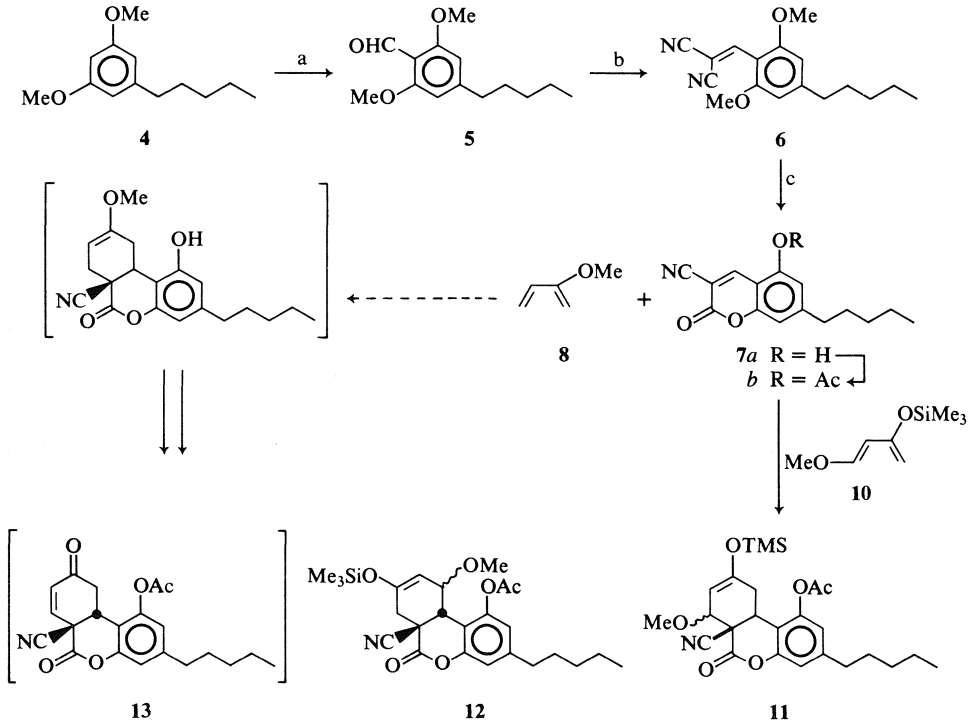
*Routes towards 11-nor-9-ketohexahydrocannabinol* ***3***

Olivetol dimethyl ether **4** was prepared via the two-step transformation developed by Bailey (6).

Introduction of the aldehyde function to give **5** was achieved through the known procedure (4, 7) involving metallation of **4** and reaction with *N*-methylformanilide. Addition of piperidine to a mixture of **5** and malononitrile initiated an exothermic reaction, producing a homogeneous mass (8) which after purification gave **6**. Cleavage of the methyl ethers of **6** was next undertaken. Refluxing of the dinitrile and aluminum chloride in chlorobenzene for 4 h (9) did not produce the dihydroxy analog of **6**, but instead yielded only the cyanocoumarin **7**. Formation of the lactone presumably occurred as outlined in Scheme 3.

The only difficulty associated with this step occurred in larger-scale preparations, when the solid mass produced during work-up interfered with complete recovery of **7**. The cyanocoumarin **7** was considered a suitable precursor for elaboration to tricyclic material, via a cycloaddition reaction with 2-methoxy-1,3-butadiene (**8**) synthesized using the two-step method of Degraw *et al.* (10).

Heating cyanocoumarin (**7**) in the presence of the substituted butadiene (**8**) failed to produce a Diels–Alder adduct as indicated by the persistence of the nmr resonance (δ 8.56) of the highly deshielded



*Reagents*: a, *n*-BuLi, *N*-methylformanilide; b, malononitrile, piperidine; c, $AlCl_3$, chlorobenzene, reflux; d, $Ac_2O$,$H_2SO_4$

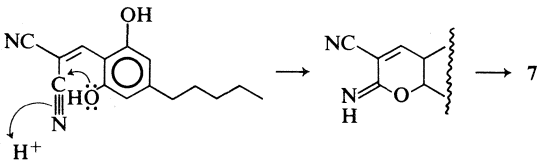
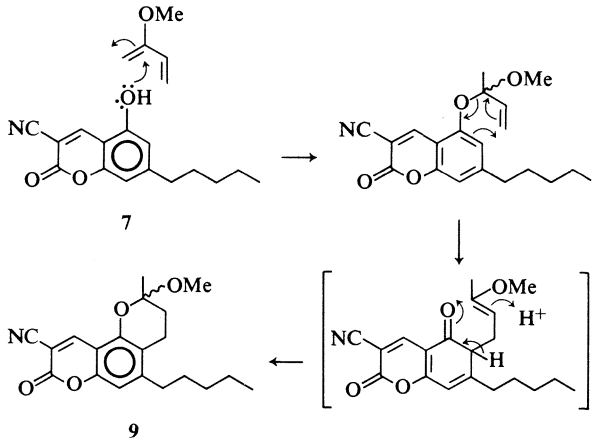


SCHEME 3

proton of the disubstituted styrene. Other features of the nmr spectrum of the product indicated that it possessed one aromatic proton (s, δ 6.76), an ether methyl group (s, δ 3.30), which was not of the enol ether variety, and another methyl group (s, δ 1.68) not coupled to other hydrogens. The ir spectrum showed no hydroxyl absorption, and the mass spectrum indicated a molecular ion of *m/e* 341. In addition, the ultraviolet (uv) absorption of the compound was in agreement with a species possessing extended conjugation to an aromatic system. All of the spectral data are in accord with structure **9**, the formation of which can be accounted for by addition of the phenol to the double bond of the diene, followed by a Claisen rearrangement as indicated in Scheme 4. Analogous processes have been cited (11).



SCHEME 4

The hydroxy function of **7** was next masked as the acetate in order to block the Claisen process, and thereby prevent competition with the Diels–Alder reaction. The acetoxycoumarin **7***b* and the diene **8** resisted all efforts to carry out the cycloaddition reaction. A sealed vessel was used to avoid loss of the relatively volatile diene (bp 74–77°C), and several attempts involved Lewis acid catalysis, known to alter the facility and regioselectivity of Diels–Alder reactions (e.g. ref. 12). The lack of reactivity of this diene–dienophile combination was rather surprising, as both compounds are activated, the former by virtue of an electron-donating function and the coumarin with two electron-withdrawing groups.

At this juncture, the Danishefsky diene (13), 1-methoxy-3-(trimethylsiloxy)-1,3-butadiene (**10**), was examined in view of its ready reaction with a variety of dienophiles, exhibiting a high degree of selectivity in the orientation of addition to unsymmetrical olefins.

Refluxing a benzene solution of the diene **10** and the acetoxycoumarin **7***b* under a nitrogen atmosphere led to complete consumption of starting material as indicated by the disappearance in the nmr spectrum of the crude reaction mixture of the olefinic proton resonance at δ 8.26. Also, the ir spectrum of the product exhibited a carbonyl absorption at 1785 $cm^{-1}$. This Diels–Alder adduct was assigned structure **11**, a conclusion based upon consideration of the "*ortho* and *para* rules".[5] Danishefsky had found that, in all reactions of **10** studied (13), there was a high degree of selectivity in the formation of the isomer in accord with these postulates. Both possible configurations of the methoxyl substituent appear to be generated, a result attributable to competition between the *exo* and *endo* modes of approach of the reactants (14). The nmr spectrum exhibited two singlets (δ 3.57, 3.61), with intensities corresponding to a product ratio of 1.0:1.4. The formation of a diastereomeric mixture in no way affects the outcome of the synthetic route, as the asymmetric centre β to the ketone would be destroyed upon hydrolysis and elimination to give the sought after enone **13**. This conversion was the next goal of the synthesis but, contrary to the previously reported (13, 15) facile hydrolyses to α,β-unsaturated systems, this step presented unforeseen difficulties. The mild conditions (0.005 *N* HCl, THF, 0°C, 10 min) employed by Danishefsky and Kitahara (15) indicated no

[5]These rules are based on the observation that an unsymmetrically substituted diene would orient itself in adding to acrolein or acrylates to produce a predominance of the adduct *a* with a 1-substituted diene, and an excess of *b* with a group at the 3-position of the diene. In the reaction of **7***b* with **10**, both these tendencies favour formation of the positional isomer **11**, rather than **12**.

*Reagents*: a, diene **10**; b, HCl, MeOH, $H_2O$; c, *p*-toluene sulfonic acid, benzene; d, $H_2$, Pd/C; e, $HOCH_2CH_2OH$, *p*-TSA; f, 10 *N* NaOH/EtOH; g, NaOH, DMF, 150°C; h, MeMgI, $Et_2O$,6 h; i, MeMgBr; j, $Ph_2PLi$, THF

SCHEME 5

reaction occurring. Attempts at forcing the process with 6 *N* hydrochloric acid in methanol or other reaction conditions produced a complex reaction mixture, with no evidence of the existence of the enone **13**.

In view of these problems, which rendered this synthetic approach unattractive, the scheme was abandoned in favour of the parallel Diels–Alder process between **10** and the unsaturated dinitrile **6** (see Scheme 5).

Reaction of **6** and **10** in dry benzene at reflux caused a high yield conversion to a crystalline bicyclic species that had a proton nmr spectrum consistent with the adduct **13**, but not with the

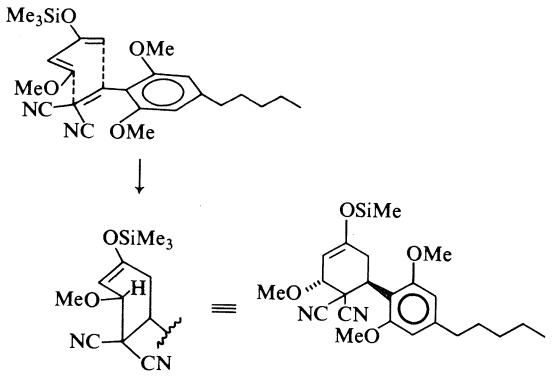
positional isomer **14**. The benzylic methine proton appears as a doublet of doublets ($J$ = 5, 12 Hz), coupled to the hydrogens of the allylic methylene group. In **14** a single splitting would be expected for this proton (coupled only to the allylic methine hydrogen). The large paramagnetic shift of the benzylic proton is likely due to the anisotropy of the neighbouring nitrile functions. The methine proton α to the ether oxygen atom is coupled solely to the olefinic hydrogen, providing further support for the assignment of **13** as the correct representation of the reaction product. The coupling constant of 6 Hz relates to a dihedral angle of 30 to 40° between the methine and olefinic hydrogens, indicating that the former is an equatorial substituent (i.e. the *O*-methyl group is axial). This is the configuration one would expect to arise from *exo* approach of the diene and dienophile (14) (see Scheme 6). Thus, structure **13** was assigned to the Diels–Alder adduct. This adduct was allowed to stand at room temperature for 30 min in a 5:3 mixture of acetone and 6 *N* hydrochloric acid. A β-methoxy ketone (**15**), rather than an enone, was again inferred from the spectral data. The infrared spectrum included a carbonyl absorption at 1735 $cm^{-1}$, and a three-proton singlet at δ 3.53 in the nmr spectrum confirmed that hydrolysis of the enol ether was not accompanied by elimination of methanol. Each methine proton β to the ketone appeared as a doublet of doublets, a result consistent with structure **15**.

Elimination of methanol to give the α,β-unsaturated ketone **16***a* was accomplished in excellent yield by refluxing **15** in benzene in the presence of *p*-toluenesulfonic acid. The $^1H$ nmr pattern of the olefinic protons reinforces the earlier statement that the orientation of the Diels–Alder cycloaddition was that required to generate **13**. The double bond hydrogens give rise to a pair of doublets centred at δ 6.32 and δ 6.90, with a coupling constant of 10 Hz. The alternative enone **16***b* would be expected to exhibit a more complex pattern for the resonance of the olefinic proton β to the ketone, as it would be coupled to the benzylic methine proton in addition to the neighbouring olefinic hydrogen.

A sharp six proton singlet at δ 3.82 in the proton nmr spectrum of **16***a* is a result of the methoxy groups. It is interesting to note that elimination of the aliphatic *O*-methyl substituent causes a collapse to this singlet from the two singlets seen for the enol silyl ether **13**, and the broad multiplet found with the β-methoxy ketone **15**. This variance is attributed to an increase in the ease of rotation about the inter-annular bond. Molecular models of



13

SCHEME 6

the compounds involved show that the axial methoxy substituent and the aromatic methoxyls experience severe steric interactions. Hydrogenation of **16***a* in ethanol at atmospheric pressure with palladium on charcoal as a catalyst gave dinitrile ketone **17** in a 99% yield as an unstable solid with a melting point of 54–55°C. The instability of **17** was probably due to aerial oxidation at room temperature leading to aromatization of the C-ring. Ketalization with ethylene glycol gave a colorless solid **18** in a yield of 93% (mp 104–106°C), which proved to be much more stable.

At this point cleavage of the methyl ether groups was, as anticipated, the major obstacle. In the earlier cannabinoid work by Adams *et al.* (4) this problem proved to be insurmountable.

In cannabinoid work, a variety of reagents have been used for this process (3) and recently a large variety of reagents have been reported for effective demethylation of phenol methyl ethers (16). In this study no satisfactory result was obtained on treatment of **17** or **18** with any of these reagents.

A variation in the synthetic route was next studied. Thus, heating **18** in 10 *N* sodium hydroxide and ethanol (1:1) resulted in the hydrolysis of only one nitrile group. The product **19** exhibited a molecular ion in its mass spectrum of *m/e* 417 as well as exhibiting the expected spectral data. This acid (**19**) was decarboxylated by stirring over ground sodium hydroxide in DMF at 150°C to give **20** in an 80% yield from **18**. After 2 h the decarboxylation was complete and analysis of the product **20** by gas chromatography (gc) showed that the two possible epimers about position 6a were present in a ratio of 2:3. After further heating of the reaction for an additional 8 h, the ratio had become 9:1. The thermodynamically more stable *trans*-isomer was assumed to predominate in the final product. The above reaction demonstrated that the nitrile **20** was relatively unreactive, so it appeared that demeth-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

ylation might again be attempted. Demethylation of **20** could lead to the intramolecular hydrolysis of the nitrile and lactonization following a route similar to that observed in the formation of **7***a*.

When **20** was treated with a variety of reagents (16) no useful reaction was observed. Finally treatment of **20** with 30 equivalents of methylmagnesium iodide in ether at gentle reflux for 6 h formed the methyl ketone **21** in a 40% conversion and 60% yield based on recovered starting material.

The methyl ketone **21** was easily methylated with methylmagnesium bromide to give alcohol **22** in a 95% yield. This represents a 28% overall yield of **22** from dimethoxyolivetol (**4**) in eleven steps with an average yield of 89% per step.

Demethylation of alcohol **22** was accomplished following the method of Ireland and Walba (16*f*) with lithium diphenylphosphide. Acidic work-up was used to invoke cyclization and deketalization when a modest yield of ketone **3** was obtained which was identical in all respects with an authentic sample of ketone **3** (prepared following the method of Archer *et al.* (5)). Thus, a total synthetic route to ketone **3** has been completed. Although existing routes would appear better suited to large scale work (3, 5) the present route reveals some useful and interesting chemistry capable of leading to a variety of modified cannabinoids.

## Experimental

Melting points were determined with a Fisher–Johns melting point block and are uncorrected. A Perkin–Elmer 237B Infracord spectrophotometer was used for recording infrared (ir) spectra. Absorptions are noted as strong (s), medium (m), weak (w), or shoulder (sh). Nuclear magnetic resonance (nmr) spectra were taken on a Varian Associates Model T-60A with deuteriochloroform solvent (unless otherwise stated), and tetramethylsilane as internal standard. The following designations are used in characterizating nmr signals: singlet (s), doublet (d), triplet (t), doublet of doublets (dd), multiplet (m), and broadened (br). Gas chromatographs were recorded using a Perkin–Elmer 990 Gas Chromatograph, with a 5.5 ft column of 3% OV-17 at 285°C, with nitrogen as the carrier gas or using a Hewlett Packard 5840B Gas Chromatograph using a 25 M, SP-2100 microcapillary column with nitrogen as the carrier gas. Mass spectra were recorded using an AEI MS12 instrument at Trent University.

Preparative hplc was done using a Waters Prep 500 with two PrepPac silica gel columns. Thin-layer and preparative thin-layer chromatography (tlc and ptlc respectively) were carried out on Merck 60 F-254 precoated silica gel plates of 0.25 mm thickness. Bands were visualized by (*i*) viewing under an ultraviolet (uv) source or (*ii*) spraying with ceric ammonium sulfate and charring the plate. Florosil (activated magnesium silicate, J. T. Baker Chemical Co., 100–200 mesh) was the adsorbent used for column chromatography.

Tetrahydrofuran (THF) was distilled from sodium and stored over 4A molecular sieves (J. T. Baker Chemical Co.) under nitrogen. Azeotropic removal of water followed by distillation afforded dry benzene which was stored over sodium. Anhydrous ether was stored under nitrogen over sodium. Anhydrous dimethylformamide was prepared by drying ACS Spec. grade solvent over molecular sieves (4A).

*((2,6-Dimethoxy-4-pentylphenyl)methylidene)malononitrile (**6**)*

Piperidine (10 mL) was added to a mixture of the 2,6-dimethoxy-4-pentylbenzaldehyde **5** (10.50 g, 44.4 mmol) and malononitrile (3.10 g, 46.9 mmol), causing the mass to become hot and homogeneous. After the red solution had cooled, it was acidified with 6 *N* hydrochloric acid, and extracted with three portions of chloroform. The combined organic solutions were washed with water (×2) and saturated aqueous sodium chloride, before being dried ($MgSO_4$) and concentrated under vacuum. Addition of a little methanol to the resultant oil, accompanied by chilling of the solution, yielded a crop of yellow crystals (2.61 g). Recrystallization from methanol afforded pure **6**, mp 64–65°C; uv: 348 nm (ε 21 500) and 203 nm (28 500); ir (KBr): 2215 (m, conjugated C═N), 1617 (s, C═C), and 825 (m, trisubstituted C═C) $cm^{-1}$; nmr (100 MHz, $CCl_4$) δ: 0.93 (br, t, $J$ = 6 Hz, 3H, terminal $CH_3$), 1.25–1.83 (m, 6H, $3CH_2$'s), 2.61 (br, t, $J$ = 7 Hz, 2H, benzylic $CH_2$), 3.90 (s, 6H, $2ArOCH_3$), 6.15 (s, 2H, aromatic), 7.74 (s, 1H, olefinic CH); *m/e* (relative intensity): 284 (40), 242 (12), 241 (10), 229 (20), 228 (100), 227 (10). *Anal.* calcd. for $C_{17}H_{20}N_2O_2$: C 71.81, H 7.09, N 9.85; found: C 71.86, H 7.05, N 9.92.

Chromatography of the mother liquors on silica gel (elution with benzene) gave a further 8.38 g of product. The total yield of **6** was 87%.

*5-Hydroxy-2-oxo-7-pentyl-2H-1-oxanapthalene-3-carbonitrile (**7***a*)

Employing the demethylation procedure of Bruce and Sutcliffe (9*b*), the dinitrile **6** (1.10 g, 3.87 mmol) was dissolved in chlorobenzene (125 mL), aluminum chloride (3.7 g, 28 mmol) was added to the solution, and the reaction mixture was refluxed under a nitrogen atmosphere for 3.5 h. 2 *N* Hydrochloric acid (100 mL) was added to the cooled flask, and the yellow solid present was removed by filtration. The aqueous layer of the filtrate was separated, and extracted with ether (×4). The pooled ethereal extracts were washed with water and aqueous sodium chloride (saturated), after which this organic solution was added to the chlorobenzene layer, previously washed in the same manner. Drying over $MgSO_4$ and evaporation of solvent afforded **7***a* as a yellow powder (570 mg).

The filter cake separated above was extracted with ether (×4). Work-up (as above) of the combined organic solutions produced a further 381 mg of material, which was combined with the product already isolated. The pooled material (951 mg, 96%) was homogeneous by tlc ($CHCl_3$/EtOAc, 80:20). Ultraviolet: 340 (ε 37 500), 250 (9 000), and 209 nm (28 000); ir (neat): 3345 (m, OH), 2230 (w, conjugated C≡N), 1695 (s, C═O), and 1625 (m, C═C) $cm^{-1}$; ir (KBr): 3270 (sh), 3205 (s, OH), 2255, 2225 (m, conjugated C≡N), 1745, 1705 (s, C═O), and 1635 (s, C═C) $cm^{-1}$; nmr (100 MHz) δ: 0.89 (br t, $J$ = 6 Hz, 3H, terminal $CH_3$), 1.13–1.83 (m, 6H, $3CH_2$'s), 2.65 (br t, $J$ = 7 Hz, 2H, benzylic $CH_2$), 6.69 (m, 2H, aromatic), and 8.61 (s, 1H, olefinic CH); *m/e* (relative intensity): 257 (33), 215 (10), 214 (11), 202 (17), 201 (100), 200 (14). The analytical sample (mp 179–181°C) was prepared by sublimation (170–175°C/0.1 Torr). Compound **7***a* recrystallized with difficulty; benzene was the most effective solvent. *Anal.* calcd. for $C_{15}H_{15}NO_3$: C 70.02, H 5.88, N 5.44; found: C 70.08, H 5.88, N 5.45.

*7,8-Dihydro-6-methoxy-6-methyl-2-oxo-9-pentyl-2H,6H-1,5-dioxaphenanthrene-3-carbonitrile (**9**)*

The cyanocoumarin **7***a* (202 mg, 0.785 mmol), 2-methoxy-1,3-butadiene (**8**, 143 mg, 1.70 mmol), and hydroquinone (53 mg) were combined with xylenes (50 mL) in a sealed pressure vessel, then heated to 165°C (sand bath). After 70 h at this temperature,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

the reaction mixture was cooled and concentrated *in vacuo*. The residue was chromatographed on silica gel. From the early benzene–ether (95:5) fractions was isolated **9** (193 mg, 72%), as white needles. Recrystallization from methanol gave the analytical sample, mp 160–160.5°C; uv: 342 (ε 18 500), 250 (4 000), and 209 nm (35 000); ir (KBr): 2855 (m, $ROCH_3$), 2230 (m, conjugated C≡N), 1745 (s, C=O), and 1625 (s, C=C) $cm^{-1}$; nmr (100 MHz) δ: 0.86 (br t, $J$ = 6 Hz, 3H, terminal $CH_3$), 1.2–1.7 (m, 6H, $3CH_2$'s), 1.68 (s, 3H, $CH_3COR$), 2.65 (br t, $J$ = 7 Hz, 2H, benzylic $CH_2$), 3.30 (s, 3H, $OCH_3$), 6.76 (s, 1H, aromatic), 8.56 (s, 1H, olefinic CH); *m/e* (relative intensity): 341 (100), 310 (57), 309 (37), 204 (42), 270 (23), 269 (92), 252 (31), 240 (24), 214 (35), 213 (24). *Anal.* calcd. for $C_{20}H_{23}NO_4$: C 70.36, H 6.79, N 4.10; found: C 70.43, H 6.69, N 4.04.

*5-(Ethanoyloxy)-2-oxo-7-pentyl-2H-1-oxanaphthalene-3-carbonitrile (7b)*

The cyanocoumarin **7***a* (1.25 g, 4.86 mmol) was covered with distilled acetic anhydride (12.41 g, 122 mmol). Concentrated sulfuric acid (0.5 mL) was added to the mixture, which immediately became hot, forming a tan paste. This material was dissolved in chloroform, and allowed to stand for 0.5 h before water was added. The aqueous layer was separated, and extracted with chloroform (×3). These extracts were combined with the original chloroform phase, which was then washed with water (×2) and saturated aqueous sodium chloride, dried ($MgSO_4$), and concentrated *in vacuo*, yielding **7***b* (1.41 g, 97%). Three recrystallizations from methanol afforded the analytical sample, mp 155–155.5°C; uv: 318 (ε 15 500) and 203 nm (32 500); ir (KBr): 2235 (m, conjugated C≡N), 1777 (s, aryl acetate), 1738 (s, C=O), and 1627 (s, C=C) $cm^{-1}$; nmr (100 MHz) δ: 0.90 (br, t, $J$, 6 Hz, 3H, terminal $CH_3$), 1.17–1.84 (m, 6H, $3CH_2$'s), 2.45 (s, 3H, acetate), 2.73 (t, $J$ = 7 Hz, 2H, benzylic $CH_2$), 7.03 (br s, 2H, aromatic), and 8.26 (s, 1H, olefinic CH); *m/e* (relative intensity): 299 (27), 258 (19), 257 (100), 215 (9), 214 (10), 202 (15), 201 (98), 200 (14). *Anal.* calcd. for $C_{17}H_{17}NO_4$: C 68.22, H 5.72, N 4.68; found: C 68.07, H 5.63, N 4.58.

*Attempted reaction of* **7**b *with 2-methoxy-1,3-butadiene (8)*

*Attempt 1*

2-Methoxy-1,3-butadiene (**8**, 19 mg, 0.23 mmol), **7***b* (68 mg, 0.23 mmol), and hydroquinone (22 mg) were dissolved in 50 mL of xylenes, and heated in a sealed vessel at 160–165°C. After 87 h, the flask was cooled to room temperature and the contents were concentrated at reduced pressure to give a solid, which was recrystallized from methanol. The spectral characteristics of the crystalline substance were identical with those of **7***b*.

*Attempt 2*

A solution of **8** (16.5 mg, 0.20 mmol) and **7***b* (62 mg, 0.21 mmol) in dry benzene (25 mL) was heated (150–152°C) in a sealed vessel for 18 h. Removal of solvent *in vacuo* afforded pure **7***b* with the same physical properties previously reported.

*Attempt 3*

To a solution of **7***b* (28.9 mg, 0.097 mmol) in anhydrous ether (25 mL), stirred under a nitrogen atmosphere, was added boron trifluoride etherate (40 μL, 0.33 mmol), followed after 15 min by the diene **8** (119 mg, 1.41 mmol). After 72 h at ambient temperature, the reaction mixture was poured into water. Extraction with chloroform (×3), washing of the combined extracts with water and aqueous sodium chloride (saturated), drying of the organic solution ($MgSO_4$), and evaporation of solvent gave a white solid that was identical with **7***b* in all respects.

*Attempt 4*

The reaction was repeated as in Attempt 3, except that it was carried out in dry benzene rather than ether. The quantities of the reactants were: **7***b* (21.5 mg, 0.072 mmol), **8** (90 mg, 1.1 mmol), boron trifluoride etherate (30 μL, 0.24 mmol). Again, only the starting coumarin was recovered.

*4-(Ethanoyloxy)-4b,5,8,8a-tetrahydro-8-methoxy-9-oxo-2-pentyl-6-(trimethylsiloxy)-9H-10-oxaphenanthrene-8a-carbonitrile (11)*

The acetoxycoumarin **7***b* (301 mg, 1.01 mmol) and the diene **10** (239 mg, 1.39 mmol) were dissolved in benzene (60 mL), then refluxed under nitrogen for 65 h. The cooled solution was concentrated *in vacuo* to give 458 mg (99%) of an oil, which eventually solidified on standing. Although tlc ($CHCl_3$) showed only one major spot, recrystallization from various solvent systems proved difficult. The product (**11**), mp 119–125°C (dec.), exhibited the following physical properties: ir (neat): 2245 (w, C≡N), 1785 (s, C=O), 1775 (s, aryl acetate), and 1662 (m, enol ether) $cm^{-1}$; nmr (100 MHz) δ: 0.23 (s, 9H, $OSi(CH_3)_3$), 0.94 (br, t, $J$ = 6 Hz, 3H, terminal $CH_3$), 1.21–1.80 (m, 6H, $3CH_2$'s), 2.39 (s, 3H, acetate), 2.64 (br t, $J$ = 7.5 Hz, 2H, benzylic $CH_2$), 2.4–2.9 (obscured m, 2H, allylic $CH_2$), 3.57, 3.61 (two s, ratio 1.0:1.4, 3H total, $OCH_3$), 3.83 (dd, $J$ = 7 Hz, $J'$ = 11 Hz, 1H, benzylic CH), 4.55 (m, 1H, $CHOCH_3$), 5.14 (m, 1H, olefinic CH), and 6.84 (m, 2H, aromatic); *m/e*: 399 ($M^+$ − 72) (relative intensity 22), 358 (24), 357 (100), 325 (10), 301 (29), 299 (15), 258 (12), 257 (40), 201 (35).

*2-(2,2-Dicyano-3-methoxy-5-(trimethylsiloxy)-4-cyclohexenyl)-1,3-dimethoxy-5-pentylbenzene (13)*

A mixture of the dinitrile **6** (515 mg, 1.81 mmol) and the diene **10** (480 mg, 2.79 mmol), in 50 mL of dry benzene, was refluxed under nitrogen for 2 h. Evaporation of the cooled solution left **13** as a solid (817 mg, 99%), which was recrystallized from hexanes. Two further recrystallizations afforded the analytical sample, mp 118.5–119.5°C; ir (KBr): 2240 (w, C≡N), 1655 (s, enol ether), and 1615 (s, C=C) $cm^{-1}$; nmr (100 MHz) δ: 0.25 (s, 9H, $OSi(CH_3)_3$), 0.91 (br t, $J$ = 6 Hz, 3H, terminal $CH_3$), 1.23–1.81 (m, 6H, $3CH_2$'s), 2.23 (dd, $J$ = 5 Hz, $J'$ = 18 Hz, 1H, allylic $CH_2$ proton), 2.58 (t, $J$ = 7.5 Hz, 2H, benzylic $CH_2$), 2.99 (dd, $J$ = 12 Hz, $J'$ = 18 Hz, 1H, allylic $CH_2$ proton), 3.58 (s, 3H, $ROCH_3$), 3.81 (s, 3H, $ArOCH_3$), 3.85 (s, 3H, $ArOCH_3$), 4.30 (d, $J$ = 6 Hz, 1H, $CHOCH_3$), 4.52 (dd, $J$ = 5 Hz, $J'$ = 12 Hz, 1H, benzylic CH), and 6.38 (s, 2H, aromatic); *m/e* (relative intensity): 456 (12), 384 (15), 353 (11), 285 (10), 284 (42), 242 (13), 234 (25), 229 (17), 228 (100), 227 (12). *Anal.* calcd. for $C_{25}H_{36}N_2O_4Si$: C 65.75, H 7.95, N 6.13; found: C 65.74, H 7.91, N 6.09.

*2-(2,2-Dicyano-3-methoxy-5-oxocyclohexyl)-1,3-dimethoxy-5-pentylbenzene (15)*

To an acetone solution (50 mL) of the adduct **13** (724 mg, 1.50 mmol) was added 6*N* hydrochloric acid (30 mL). The solution was allowed to stand at room temperature for 45 min before the organic solvent was removed *in vacuo*. Work-up of the residual liquid yielded the β-methoxy ketone **15** (577 mg, 94%), of sufficient purity (tlc ($CHCl_3$/EtOAc, 80:20)) for use in the next synthetic step. Chromatography on silica gel gave, in the benzene/ether (99:1) fractions, pure **15**, from which the analytical sample was obtained by evaporative distillation at 115–120°C (0.1 Torr); ir (neat): 2240 (w, C≡N) and 1735 (s, C=O) $cm^{-1}$; nmr (100 MHz) δ: 0.91 (br t, $J$ = 6 Hz, 3H, terminal $CH_3$), 1.24–1.81 (m, 6H, $3CH_2$'s), 2.59 (t, $J$ = 7.5 Hz, 2H, benzylic $CH_2$), 2.73–3.14 (m, 4H, $CH_2$'s α to carbonyl), 3.53 (s, 3H, $ROCH_3$), 3.61–3.86 (m, 6H, $2ArOCH_3$'s), 4.03 (dd, $J$ = 5 Hz, $J'$ = 8 Hz, 1H, $CHOCH_3$), 4.68 (dd, $J$ = 5 Hz, $J'$ = 7 Hz, 1H, benzylic CH), and 6.39 (br s, 2H, aromatic); *m/e* (relative intensity): 384 (75), 354 (13), 353 (49), 328 (10), 261 (10), 251 (10), 236 (10), 235 (57), 234 (100), 228 (14), 221 (13). *Anal.* calcd. for $C_{22}H_{28}N_2O_4$: C 68.73, H 7.34, N 7.29; found: C 68.59, H 7.46, N 7.27.

*2-(2,2-Dicyano-5-oxo-3-cyclohexenyl)-1,3-dimethoxy-5-pentylbenzene (16a)*

The ketone **15** (577 mg, 1.50 mmol) was refluxed in benzene (70 mL) under nitrogen, in the presence of a large excess of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

*p*-toluenesulfonic acid (723 mg, 3.80 mmol). After 2.5 h, water was added to the cooled reaction mixture. The benzene layer was separated, washed with water (×3) and aqueous sodium chloride (saturated), dried ($MgSO_4$), and evaporated to a white crystalline solid (481 mg, 91%). In chromatographing the product on silica gel, **16***a* (mp 84–87°C) was eluted with benzene. As recrystallization proved to be troublesome, the analytical sample was prepared by high-vacuum sublimation (134°C/0.1 Torr), ir (KBr): 2250, 2225 (w, C≡N), and 1695 (s, conjugated C=O) $cm^{-1}$; nmr (100 MHz) δ: 0.93 (br t, $J$ = 6 Hz, 3H, terminal $CH_3$), 1.22–1.83 (m, 6H, $3CH_2$'s), 2.61 (br t, $J$ = 7 Hz, 2H, benzylic $CH_2$), 2.78–2.96 (m, 2H, $CH_2$ α to carbonyl), 3.82 (s, 6H, $2ArOCH_3$'s), 4.52–4.75 (m, 1H, benzylic CH), 6.32 (d, $J$ = 10 Hz, 1H, olefinic CH α to carbonyl), 6.41 (s, 2H, aromatic), and 6.90 (d, $J$ = 10 Hz, 1H, olefinic CH β to carbonyl); *m/e* (relative intensity): 352 (26), 310 (5), 284 (8), 235 (22), 234 (100), 228 (17), 178 (28), 177 (8). *Anal.* calcd. for $C_{21}H_{24}N_2O_3$: C 71.57, H 6.86, N 7.95; found: C 71.65, H 6.72, N 7.88.

*2-(2,2-Dicyano-5-oxocyclohexyl)-1,3)-dimethoxy-5-pentylbenzene (17)*

The enone **17** (1.90 g, 5.4 mmol) in ethanol (250 mL) over 10% palladium on charcoal (50 mg) was stirred under hydrogen for 6 h. Filtration through Celite and concentration yielded a yellow oil. Column chromatography on Florisil (benzene) gave **17** as an unstable white solid (1.90 g, 99%), mp 54–55°C; ir ($CHCl_3$): 2240 (w, C≡N), 1710 (s, C=O) $cm^{-1}$; nmr δ: 0.90 (br t, $J$ = 6 Hz, 3H, terminal $CH_3$), 1.2–1.8 (m, 7H, $4CH_2$'s), 2.60 (br t, $J$ = 8 Hz, 2H, benzylic $CH_2$), 2.70–3.25 (m, 4H, $2CH_2$'s, α to carbonyl), 3.80 (s, 6H, $2ArOCH_3$'s), 4.50 (t, $J$ = 6 Hz, 1H, benzylic CH), and 6.40 (s, 2H, aromatic); *m/e* (relative intensity): $M^+$ 354 (81), 324 (100), 298 (29), 262 (41), 234 (95), 221 (47), 178 (62), 91 (35). *Anal.* calcd. for $C_{21}H_{26}N_2O_3$: C 71.16, H 7.39, N 7.90; found: C 71.05, H 7.41, N 7.72.

*2-(2,2)Dicyano-5-ethylenedioxycyclohexyl)-1,3-dimethoxy-5-pentylbenzene (18)*

Ketone **17** (1.90 g, 5.4 mmol), ethylene glycol (1.15 g, 18.5 mmol), and *p*-toluenesulfonic acid (0.2 g) were refluxed in benzene (100 mL) for 4 h with a Dean–Stark trap fitted. The reaction mixture was cooled and the solvent removed *in vacuo*. Chromatography on Florisil (benzene) yielded a yellow oil which was crystallized from hexane to give **18** (1.98 g, 93%) as a colorless solid, mp 104–106°C; ir (KBr): 2250 (w, C≡N) $cm^{-1}$; nmr δ: 0.90 (br t, $J$ = 6 Hz, 3H, terminal $CH_3$), 1.20–2.30 (m, 12H, $6CH_2$'s), 2.50 (br t, $J$ = 6 Hz, 2H, benzylic $CH_2$), 3.80 (s, 6H, $ArOCH_3$), 3.95 (4H, 2 ketal $CH_2$'s), 4.20 (dd, $J$ = 3 Hz, $J'$ = 14 Hz, 1H, benzylic CH), 6.40 (s, 2H, aromatic); *m/e* (relative intensity): 398 (68), 305 (20), 228 (13), 178 (15), 165 (31), 164 (93), 99 (24), 86 (100). *Anal.* calcd. for $C_{23}H_{30}N_2O_4$: C 69.32, H 7.59, N 7.03; found: C 69.11, H 7.52, N 7.01.

*2(2-Cyano-5-ethylenedioxy-2-cyclohexylcarboxylic acid)-1,3-dimethoxy-5-pentylbenzene (19)*

To a solution of ketal (**18**) (1.07 g, 2.7 mmol) in ethanol (200 mL) was added 10 *N* aqueous sodium hydroxide (200 mL). The mixture was refluxed for 20 h. The organic solvent was removed *in vacuo* and the aqueous residue was cooled to below 0°C. The solution was acidified to pH 3 by dropwise addition of *concentrated* hydrochloric acid, maintaining the temperature below 5°C. The aqueous layer was extracted with ether (×3) using ice to maintain the temperature at 0°C. The combined organic layers were dried ($MgSO_4$) and concentrated to give acid **19** as a white foam (1.05 g, 94%). Analysis of the product on tlc (ethyl acetate) showed one trace impurity which later proved to be **20**. The physical properties exhibited were ir (KBr): 3200 (s, acidic OH), 2240 (w, C≡N), 1750, 1720 (acid, C=O) $cm^{-1}$; nmr δ: 0.90 (br t, $J$ = 6 Hz, terminal $CH_3$), 2.60 (br t, $J$ = 6 Hz, 2H, benzylic $CH_2$), 3.80 (s, 6H, a $ArOCH_3$'s), 3.95 (s, 4H, $2CH_2$'s of ketal), 6.40 (s, 2H), aromatic, variable, $D_2O$ exchangeable (s or br s, 1H, acid OH); *m/e* (relative intensity): $M^+$ 417 (13), 373 (23), 315 (32), 234 (14), 183 (55), 139 (58), 86 (100).

*2(2-Cyano-5-ethylenedioxycyclohexyl)-1,3-dimethoxy-5-pentylbenzene (20)*

A stirred solution of acid **19** (555 mg, 1.3 mmol) in 100 mL of dimethylformamide was stirred at reflux over ground sodium hydroxide (2 pellets) under a nitrogen atmosphere for 8 h. The reaction mixture was cooled and poured into water (300 mL). The mixture was cooled to 0°C, acidified with dilute hydrochloric acid, and then extracted with ether (×3, 200 mL). The combined extracts were washed with water (×3), dried ($MgSO_4$), and concentrated *in vacuo*. Filtration through Florisil (20 g; ethyl acetate/benzene, 2:98) afforded mononitrile **20** (435 mg, 88%) as a clear oil; ir (neat): 2225 (m, C≡N) $cm^{-1}$; nmr δ: 0.90 (br t, $J$ = 6 Hz, 3H, terminal $CH_3$), 2.60 (br t, $H$ = 6 Hz, 2H, benzylic $CH_2$), 3.80 (s, 6H, $2ArOCH_3$), 4.00 (s, 4H, $2CH_2$'s of ketal), 6.40 (s, 2H, aromatic); *m/e* (relative intensity): $M^+$ 373 (51), 342 (12), 329 (15), 305 (40), 285 (48), 140 (10), 139 (94), 99 (31), 86 (100). *Anal.* calcd. for $C_{22}H_3NO_4$: C 70.75, H 8.37, N 3.75; found: C 70.51, H 8.17, N 3.54.

*2(2-Ethyloxy-5-ethylenedioxycyclohexyl)-1,3-dimethoxy-5-pentylbenzene (21)*

To oven dried magnesium turnings (0.162 g, 6.7 mmol) covered with anhydrous ether in an oven dried flask, fitted with a condenser, under a dry nitrogen atmosphere, was added methyl iodide (1.04 g, 7.3 mmol) in anhydrous ether (15 mL) via syringe. After 10 h, mononitrile **20** was added to the ice-cooled Grignard reagent. The solution was gently refluxed for 6 H. The reaction was then cooled in an ice bath and saturated aqueous ammonium chloride (10 mL) followed by water (10 mL) were added. After separation the aqueous layer was extracted with ether (×2). The combined ether layers were dried ($MgSO_4$) and concentrated *in vacuo*. Preparative tlc (ethyl acetate/benzene, 10:90) afforded the methyl ketone (28 mg, 40%) as a clear oil, and starting nitrile (18 mg). This represents a yield of 60% based on recovered starting material; ir (neat): 1700 (s, C=O) $cm^{-1}$; nmr δ: 0.90 (br t, $J$ = 6 Hz, 3H, terminal $CH_3$), 1.90 (s, 3H, methyl ketone), 3.85 (s, 6H, $2ArOCH_3$'s), 4.00 (s, 4H, 2 ketal $CH_2$'s), 6.40 (s, 2H, aromatic); *m/e* (relative intensity): $M^+$ 390 (24), 359 (39), 347 (12), 305 (21), 289 (10), 245 (12), 221 (9), 156 (22), 139 (9.4), 124 (12), 99 (31), 86 (100). *Anal.* calcd. for $C_{23}H_{34}O_5$: C 70.74, H 8.78; found: C 70.25, H 9.39.

*2(2(1-Hydroxyisopropyl)-5-ethylenedioxycyclohexyl)-1-3-dimethoxy-5-pentylbenzene (22)*

To a stirred, ice-chilled solution of methyl ketone **21** (51 mg, 0.13 mmol) in anhydrous ether (20 mL), under argon, was added methyl magnesium bromide (0.1 mL, 0.6 mmol) and the solution was refluxed 1 h. The reaction was cooled in an ice bath and saturated aqueous ammonium chloride (10 mL) was added dropwise, followed by water. The mixture was separated and the aqueous layer was extracted with ether (×2). The combined organic layers were dried ($Na_2SO_4$), and concentrated *in vacuo* before ptlc (ethyl acetate/benzene, 10:90) gave 50 mg of alcohol **22** (95%) as a clear oil; ir (neat): 3500 (OH) $cm^{-1}$; nmr δ: 0.90 (br t, $J$ = 6 Hz, 3H, terminal CH), 1.10 (s, 6H, 2CH's α to alcohol), 3.85 (s, 6H, $2ArOCH_3$), 6.40 (br s, 2H, aromatic); *m/e* (relative intensity): $M^+$ 406 (10), 305 (30), 221 (25), 178 (10), 154 (62), 152 (10), 139 (15), 99 (22), 86 (100).

*11-Nor-9-ketohexahydrocannabinol (3)*

To a solution of diphenylphosphine (0.05 mL, 0.29 mmol) in dry THC (2.5 mL) was added 0.25 mL (0.40 mmol) of cold 1.6 *M* *n*-butyllithium – hexane solution via syringe. The reaction was stirred for 15 min before the addition of alcohol **22** (32 mg, 0.08 mmol) in dry THF (2.5 mL) via syringe. The solution was

stirred at room temperature for 2 h before being added to 20 mL of 5% hydrochloric acid and stirred for an additional 2 h. The aqueous mixture was extracted with ether (×3) and the combined extracts were dried ($MgSO_4$) and concentrated *in vacuo*. Separation by ptlc (ethyl acetate/benzene, 10:90) afforded a material **16** (2 mg) identical in all respects to an authentic sample of **1**, prepared by M. Guiver following the method of Archer *et al.* (5).

ARYA K. MUKERJEE and PRADEEP KUMAR. Can. J. Chem. **60**, 317 (1982).

Schiff bases condense with 2-oxazolin-5-ones having a C-4 methylene and/or C-2 methyl group, and the reaction in glacial acetic acid, containing freshly fused sodium acetate, produces 4-arylidene- and/or 2-styryl-2-imidazoline-5-ones as a result of simultaneous introduction of arylidene and amino moieties.

ARYA K. MUKERJEE et PRADEEP KUMAR. Can. J. Chem. **60**, 317 (1982).

La condensation des bases de Schiff sur les oxazoline-2 ones-5 ayant un groupe méthylène en position C-4 et éventuellement un groupe méthyle en position C-2, conduit dans l'acide acétique glacial contenant de l'acétate de sodium fraichement fondu, aux arylidène-4 et/ou styryl-2 imidazoline-2 ones-5 provenant de l'introduction simultanée de groupe arylidène et amino.

In connection with our studies on 4-unsubstituted 2-oxazolin-5-ones, we have found that these heterocycles condense with suitable imines in benzene, affording the corresponding 4-alkylidene (arylidene) derivatives (1). In the reaction of 2-methyl-2-oxazolin-5-one with benzylideneaniline under similar conditions, the 2-styryl-2-imidazolin-5-one (**6**, $Ar^1 = Ar^2 = Ph$) was obtained in trace amount, besides the expected 4-benzylidene-2-methyl-2-oxazolin-5-one (**1**). Though several stilbenyl heterocycles have been synthesized by base-catalyzed condensation of anils with nitrogen-containing heteroaromatic systems bearing methyl groups (2, 3), simultaneous introduction of arylidene and amino moieties in suitable heterocycles does not seem to have been attempted. Therefore it was thought worthwhile to explore the possibility of using Schiff bases for the one-pot conversion of suitable O—C=N heterocycles into N—C=N heterocycles having a new exocyclic olefinic centre in conjugation with the imino group of the ring, and with this objective in mind the present investigation was undertaken.

The reaction of 4-benzylidene-2-methyl-2-oxazolin-5-ones (**1**) and Schiff bases was carried out under different conditions. When dry toluene was used as a solvent, the reaction of **1** and benzylideneaniline led to the formation of the anilide (**8**, $Ar^2 = Ph$) and the 2-styryl-2-imidazolin-5-one (**6**, $Ar^1 = Ar^2 = Ph$) in 25% and 2% yields, respectively. Addition of a catalytic amount of an acid, such as glacial acetic acid or *p*-toluenesulphonic acid to the reaction mixture raised the yield of **6** ($Ar^1 = Ar^2 = Ph$) to 10%. When 4-benzylidene-2-methyl-2-oxazolin-5-one (**1**) and Schiff bases were allowed to react in boiling glacial acetic acid in the presence of freshly fused sodium acetate, 1-substituted 4-benzylidene-2-imidazolin-5-ones (**6**) were obtained in moderate to good yields.

One of the possible reaction pathways for the conversion of **1** into **6** involves Michael type addition, followed by extrusion of the amine and subsequent aminolysis of the oxazolinone (path A, Scheme 1). The resultant amides (**5**) on cyclization afford **6**. This was verified by converting **4** into **3** ($Ar^1 = Ph$) by introducing the benzylidene moiety at the C-4 position, followed by aminolysis and subsequent cyclization (Scheme 1).

The alternative route to **6** could be through cleavage of the 1,5-bond of 2-oxazolin-5-one by the imine (path B, Scheme 1), promoted by the acid medium, and formation of **7** and the aldehyde, condensation of which ultimately affords the styryl compound. The mechanism of this route has been elaborated for the synthesis of **12** (Scheme 2). It was found that authentic 4-benzylidene-2-methyl-1-phenyl-2-imidazolin-5-one (**7**, $Ar^2 = Ph$) condenses with aromatic aldehydes in boiling glacial acetic acid to give the corresponding 2-styryl derivatives. With a view to ascertaining the authenticity of the path B, the reaction of **1** with a Schiff base was carried out in the presence of an added aldehyde different to that from which the Schiff base was derived. It was found that the imidazolone (**6**) containing the arylidene group derived from the Schiff base predominates in the reaction mixture, though its yield is considerably reduced. This finding indicates that path A has precedence over path B.

It is noteworthy that when 4-benzylidene-2-phenyl-2-oxazolin-5-one (**10**), which does not have

SCHEME 1

an active methyl group and thereby ruling out Michael type addition, was allowed to react with benzylideneaniline in glacial acetic acid, 4-benzylidene-1,2-diphenyl-2-imidazolin-5-one (**12**) and benzaldehyde were obtained (Scheme 2).

Formation of **12** by cyclodehydration of the anilide (**11**) is known in the literature, but under the reaction conditions of the present study this route is unlikely, because in that case generation of aniline from benzylideneaniline present in the reaction mixture is essential. As already indicated, the reaction is carried out strictly under anhydrous conditions and thus there is no chance of hydrolysis of the imine. Had it been so, 2-methyl-2-oxazolin-5-one (**1**) should also have produced the anilide (**8**, $Ar^2$ = Ph), on reaction with benzylideneaniline in glacial acetic acid, because it is more vulnerable to aminolysis. It should be emphasized that the excellent yield of **6** ($Ar^1$ = $Ar^2$ = Ph) rules out formation of **8** in any appreciable amount. Also, **8** does not undergo cyclodehydration, on boiling in glacial acetic acid in the presence of fused sodium acetate, and the 2-methyl-2-imidazolin-5-one (**7**) does not play the key role in the conversion of **1** into **6**, as already mentioned.

Formation of **12** by the interaction of **10** and **2** is clearly an acid-mediated reaction. For example, when **10** and **2** ($Ar^1$ = $Ar^2$ = Ph) were heated under reflux in dry toluene for about 4 h, 90% of **10** was recovered without any trace of the imidazolone (**12**). Addition of *p*-toluenesulphonic acid in catalytic amount to the reaction mixture in dry toluene led to the formation of **12** in 10% yield, the major portion of **10** remaining unaffected. On using glacial acetic acid as a solvent, the yield of the product was about 50%. The reaction of 2-phenyl-5-oxazolonium perchlorate and benzylideneaniline is known to afford the 4-imidazolone **16** (Z = $CH_2$) and the conversion obviously involves cleavage of the 1,5-bond of **9**, though the mechanism proposed is

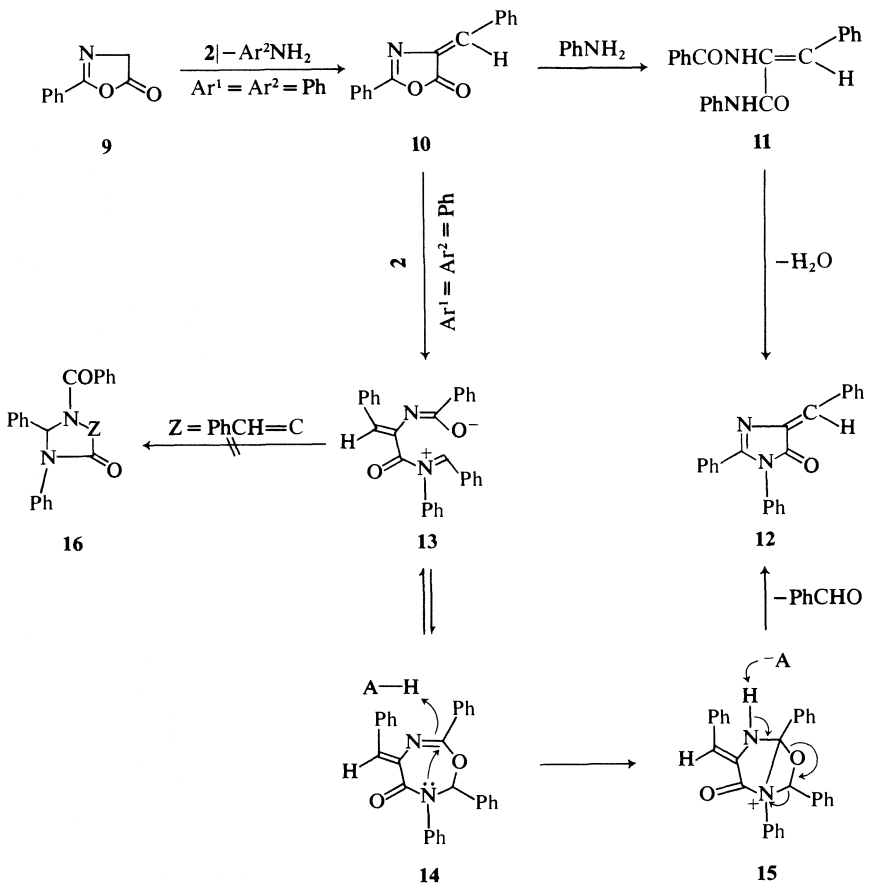

SCHEME 2

rather esoteric (4). It is noteworthy that benzylideneaniline itself does not undergo cleavage in this case. Formation of the 5-imidazolone (**12**), obtained in the present study, and 4-imidazolone (**16**, Z = $CH_2$) and other products reported in the work mentioned (4) can be adequately explained by the intermediates given in Scheme 2. It should be conceded that we could not isolate **14** and there is no precedent of the oxadiazepine in the literature. However, such a system is expected to be vulnerable to acids, and the ring closures outlined (Scheme 2) are in conformity with Baldwin's rules (5).

Simultaneous introduction of the arylidene and amine moieties seems to be advantageous. For example, synthesis of **3** and **4** in which $Ar^1$ carries a free hydroxyl group is difficult. Also, preparation of **3** and **4**, in which $Ar^1$ is a substituted phenyl group, involves several steps because substituted cinnamic acids have to be synthesized for obtaining the corresponding *N*-cinnamoyl glycines required for their synthesis. The alternative route to **3** by condensation of **1** with aromatic aldehydes gives very poor yields (6). Similarly, the condensation of 4-benzylidene-2-methyl-2-imidazolin-5-one (**7**) with aromatic aldehydes is not profitable because yields of the starting material **7** are just moderate (7) and its preparation requires a longer time (about 13 h in boiling xylene). It should be emphasized that the procedure now described overcomes these difficul-

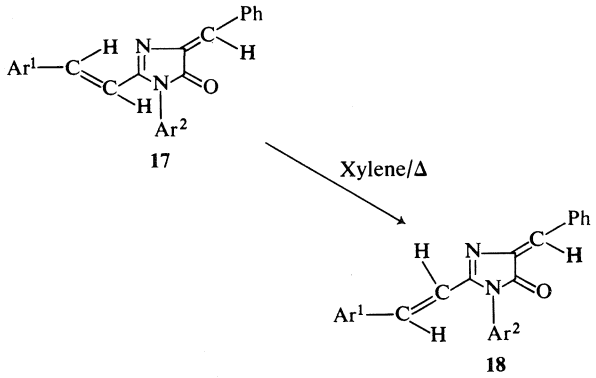
ties, affording better overall yields of the products and the time required is short.

It is noteworthy that these compounds can exist as conformers **17** and **18**. For example, condensation of **1** with 3-nitrobenzylideneaniline afforded a compound, mp 200°C. On the other hand condensation of **7** with 3-nitrobenzaldehyde led to the formation of a product, mp 225°C. Both these samples gave correct elemental analysis and they absorb near the same regions in their respective ir spectrum. But in their uv spectra, $\varepsilon_{max}$ values are different though they absorb near the same wavelengths. The sample with higher melting point has higher $\varepsilon_{max}$ values and therefore it was assigned the *transoid*-form which is thermodynamically more stable. As expected, the other conformer having lower melting point and lower $\varepsilon_{max}$ values changed



SCHEME 3

to the more stable conformation on heating in xylene for some time (Scheme 3). The compounds reported here were characterized by elemental and spectral analyses, the relevant data being presented in Tables 1 and 2, respectively. Some of the compounds obtained by the present procedure are already known in the literature and they were compared with the authentic samples.

## Experimental

All melting points are uncorrected. The uv, ir, and nmr spectra were recorded on Cary-14, Perkin-Elmer-720, and Varian A-60D spectrometers respectively.

*1-Aryl-4-benzylidene-2-styryl-2-imidazolin-5-ones (**6**); general procedures*

*Method A*

(*Z*)-4-Benzylidene-2-methyl-2-oxazolin-5-one (1, 9, 10) and a suitable Schiff base were taken in equimolar proportions in glacial acetic acid (20 mL/g of the oxazolone) containing freshly fused sodium acetate (0.48 mol) and the mixture was heated under reflux for about 4 h. The solvent was removed under reduced pressure and the pasty mass triturated with ethanol to give a solid which was filtered under suction and recrystallized from glacial acetic acid.

*Method B*

(*Z*)-4-Benzylidene-2-methyl-1-phenyl-2-imidazolin-5-one (**7**, $Ar^2$ = Ph), prepared by a published method (7), and an aromatic aldehyde were taken in equimolar proportions in glacial acetic acid (20 mL/g of the imidazolone) and the mixture was heated under reflux for about 4 h. Finally, it was worked up as in method A.

*Method C*

To a suspension of *N*-cinnamoylamino glycine (**4**, $Ar^1$ = Ph; 1.0 mol) in dry benzene (30 mL/g of the acid) containing triethylamine (1.0 mol), ethyl chloroformate (1.0 mol) was added and the mixture shaken at room temperature till the cinnamoylamino glycine crystals disappeared and triethylamine hydrochloride separated. The hydrochloride was filtered and washed twice with dry benzene. To the combined benzene solution and washings benzylideneaniline (1.0 mol) was added. The mixture was heated under reflux for 10 min and the solvent completely removed under reduced pressure.[2] To this, glacial acetic acid (20 mL/g of the Schiff base) and freshly fused sodium acetate (0.48 mol) were added and the mixture was heated under reflux for about 4 h. Finally, it was worked up as in method A.

*Method D*[3]

A mixture of (*Z*)-4-benzylidene-2-styryl-2-oxazolin-5-one (1, 6, 11) and a suitable primary amine, taken in equimolar proportions in glacial acetic acid containing freshly fused

[2] The (*Z*)-4-benzylidene-2-styryl-2-oxazolin-5-one (**3**) obtained in the reaction was not isolated. For the experimental detail of its separation and characterization see our earlier publication (1).

[3] A similar method was published earlier (12, 13).

[a]Not very distinct due to partial overlapping of the peaks of the aromatic protons.

sodium acetate (0.48 mol), was heated under reflux for about 4 h and finally worked up as in method A.

*4-Benzylidene-1,2-diphenyl-2-imidazolin-5-one (**12**)*

The title compound was obtained by starting from hippuric acid and following method C given above; yield, 60%, mp 180°C (lit. (14) mp 180°C);[4] ir (Nujol) $\nu_{max}$: 1710 (CO) and 1640 (C=C) $cm^{-1}$; nmr ($CDCl_3$/TMS) δ: 7.34 (s, 1H, 4-C=C*H*), 7.4–7.7 (m, 15H, Ar-*H*) ppm.

The same product was obtained (in 50% yield) when (*Z*)-4-benzylidene-2-phenyl-2-oxazolin-5-one (**10**) and benzylideneaniline were heated under reflux in glacial acetic acid, containing freshly fused sodium acetate, for about 4 h and worked up as in method A given above.

[4]This method involves cyclization of 2-*N*-benzoylamino cinnamanilide. The yield is just moderate. Recently, **10** and aniline, taken in the molar ratio of 1:1, and anhydrous zinc chloride in catalytic amount were fused and heated for 5 min to give **12** in 70% yield; mp 175°C (15). It was also obtained, in very poor yield, by rearrangement of 3-benzoylamino-1,4-diphenyl-2-azetidinone (16).

# Dihydropyridines in synthesis and biosynthesis. III.[1] Coupling of dihydropyridinetricarbonylchromium(0) complexes: bipyridyls[2]

JAMES P. KUTNEY, LUCAS KACZMAREK, DANUTA MOSTOWICZ, AND BRIAN R. WORTH

*Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6*

Received August 24, 1981

JAMES P. KUTNEY, LUCAS KACZMAREK, DANUTA MOSTOWICZ, and BRIAN R. WORTH. Can. J. Chem. **60**, 323 (1982).

Reaction of 1,2- and 1,6-dihydro-3-ethyl-*N*-methyl pyridine tricarbonylchromium(0) complexes with methyllithium at low temperature afforded a high yield of dimeric tricarbonylchromium(0) complexes. Structures of the latter products were established by X-ray crystallographic analysis. Some chemistry of these novel compounds is described.

JAMES P. KUTNEY, LUCAS KACZMAREK, DANUTA MOSTOWICZ et BRIAN R. WORTH. Can. J. Chem. **60**, 323 (1982).

La réaction des complexes de dihydro-1,2 et de dihydro-1,6 éthyl-3 *N*-méthyl pyridine tricarbonylchrome(0) avec le méthyl-lithium à basse température conduit avec un excellent rendement aux complexes dimères de tricarbonylchrome(0). On a établi la structure de ces dernier produits par l'analyse cristallographique aux rayons X. On décrit quelques propriétés chimiques de ces nouveaux composés.

[Traduit par le journal]

Previous work from these laboratories (1–4) described the preparation and characteristics of 1,2- and 1,6-isomers of dihydropyridinetricarbonylchromium(0) complexes. Generally, controlled reduction of pyridinium salts provided labile 1,2-dihydropyridines (e.g. **1**) which were subsequently stabilized as their chromium carbonyl complexes (**2** and **3**, Scheme 1). Facile release of the complexing metal was possible using pyridine or ethylenediamine and subsequent reaction of the enamines gave β-alkylation (5) (**5**). Alternatively, the complexes reacted with lithium salts of substituted acetonitriles to provide an overall nucleophilic substitution reaction (**6–9**, Scheme 1) (6). The stabilization of dihydropyridines as their chromium complexes has also been applied to the synthesis of various alkaloid systems (1, 7).

In order to improve the efficiency of, and/or the position of, nucleophilic substitution we attempted to prepare the cation **10** using, for example, trityl fluoroborate (8, 9). All attempts in this area were unsuccessful presumably due to the considerable electron withdrawing effect of the chromium carbonyl group and the absence of stabilization of positive charge by nitrogen electrons. By the same argument, the corresponding anion **11** seemed a plausible species and attempts were made to abstract a proton from **2** and to subsequently alkylate or acylate the expected intermediate **11**.

Initially the complex **2** was reacted with *tert*-butyllithium (1 mol equiv. at −78°C) and the mixture subsequently treated with an excess of iodomethane. The resulting solution both before and after oxidation with iodine gave mainly decomposition products together with traces of **2** and a product tentatively assigned structure **12**. Anticipated product **13** was not detected. Simply reacting **2** with *tert*-butyllithium at −78°C gave **12** in 7% yield. The major product (> 80%) was "dimeric" material with $M^+$ 382. Analogous reaction, using methyllithium as base, gave a high yield (80–92%) of "dimeric" material together with a trace (ca. 1.5%) of the substitution product **13**. Chromatography on silica gel allowed separation of the "dimeric" fraction into three bright red crystalline components **14** (32–37%), **15** (4–27%), and **16** (25–50%). Structures **14–16** were consistent with spectral data obtained and were confirmed by X-ray crystallographic analysis (2). The diastereomer **17** was not isolated, although in one reaction a low yield of a fourth product was obtained. This material rapidly decomposed in light/air. Under similar (−78°C) conditions, the 1,6-isomer **3** did not react, while at higher temperatures (up to −10°C) an intractable mixture of products was formed.

As with the simple organometallic compounds **2** and **3**, thermal isomerization was possible. In fact heating **14** in refluxing *n*-octane for twelve hours gave a 70% yield of the 1,6-isomer **18** (8% of **14** was recovered) while **16** similarly gave **18** in 41% yield (28% of **14** recovered). Thermal isomerization of either **2** or **3** had given (1) a 1:1 mixture of isomers while, here, the predominance of **18** is likely due to the release of extra steric crowding at the new $sp^3$ carbon atom. This is consistent with the configuration at C2 which is supported by $^1$Hmr data. In **18**, the C2 proton resonated as a double doublet ($J_{2,3} \simeq$ 6 Hz, $J_{2,2'} \simeq$ 8 Hz) at δ 3.18 ppm. Irradiation of the signal for C3-H (δ 3.78) collapsed the C2-H signal to

[1]For Part II, see ref. 1.

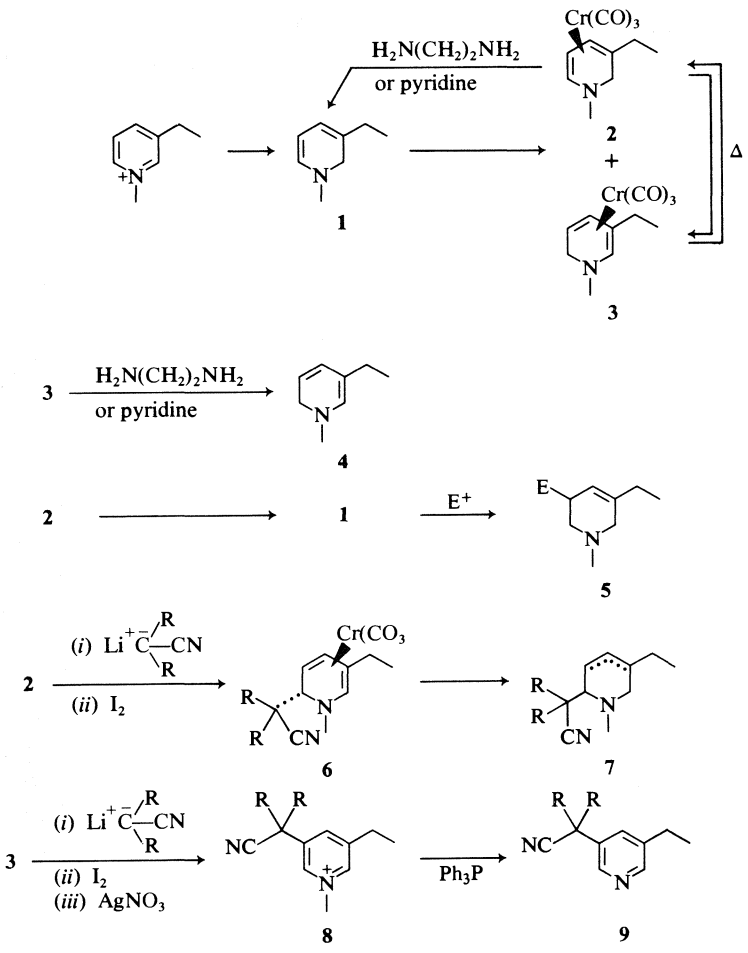
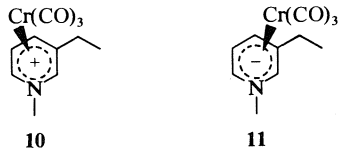


SCHEME 1

a doublet ($J$ = 8 Hz) while irradiation at δ 2.15 (C2′-H) gave a doublet ($J$ = 6 Hz) at δ 3.18. This 6 Hz coupling between C2-H and C3-H is consistent with a pseudo-equatorial orientation for C2-H

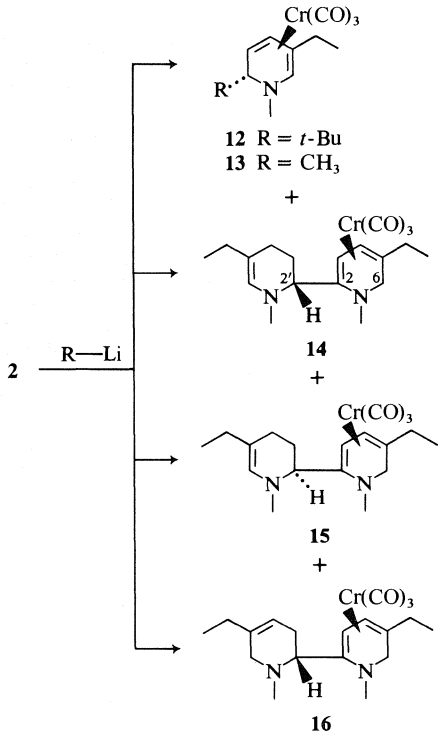


10 11

analogous to that found for **6**. The piperideine substituent is therefore *pseudo*-axial, directed away from the tricarbonylchromium group. This inherent release of steric crowding is consistent with the facile conversion of **14** to **18**. Thermal induced isomerization of **16** was accompanied by double bond migration to the enamine system in **18**.

The dimeric compounds, **14–16**, were converted to a simple bipyridyl (**21**) by two routes. Reaction of a mixture of **14–16** with pyridine at 50°C followed by reduction with sodium borohydride gave a mixture of **19** and **20** which on oxidation with selenium gave the bipyridyl **21** (27%). Direct oxidation of the mixture **14–16** with selenium gave **21** in 15% yield. Attempts to optimize these conversions or to find alternative reagents for the formation of **21** have not been made. The utility of complexes such as **14–16** and **18** was found to be limited by their steric bulk. For example, reactions with nucleophilic species (cf. **2** → **6** or **3** → **8**) were unsuccessful, giving either unreacted complex or, under more forcing conditions, intractable decomposition products.

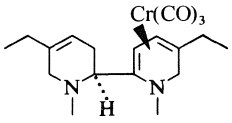
Finally, the reaction of the 1,2-dihydropyridine complex **2** with alkyllithiums at −78°C gave, rapidly, a high yield of "dimeric" compounds **14–16**, which were subsequently oxidized to the bipyridyl **21**. The mechanism of formation of the "dimers" remains ambiguous.



SCHEME 2

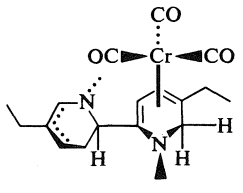
## Experimental

Melting points were determined on a Kofler block and are uncorrected. Ultraviolet (uv) spectra were recorded on a Cary 15 spectrophotometer in ethanol solution. The wavelengths of absorption maxima are reported in nanometers (nm). Infrared

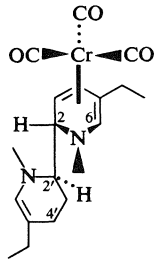


17

(ir) spectra were measured on a Perkin Elmer model 710 or 457 spectrophotometer in chloroform solution. The absorption maxima are reported in wavenumbers ($cm^{-1}$), calibrated with respect to the absorption band of polystyrene at 1601 $cm^{-1}$. Proton magnetic resonance ($^1$Hmr) spectra were measured in deuteriochloroform ($CDCl_3$) solution at ambient temperature on either a Varian HA-100 or XL-100 spectrometer or on a Nicolet



14 or 16



18

270 MHz instrument. Chemical shift values are given in the δ (ppm) scale relative to tetramethylsilane (TMS) used as internal standard. The integrated peak areas, signal multiplicities, and proton assignments are given in parentheses. Low resolution mass spectra (ms) were determined on either an AEI-MS-902 or an Atlas CH-4B spectrometer. High resolution mass spectra were measured on an AEI-MS-902 instrument. Microanalyses were carried out by Mr. P. Borda of the Microanalytical Laboratory, University of British Columbia.

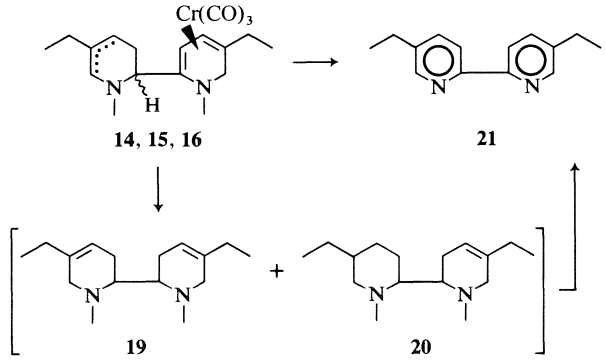
As a matter of routine, all reagents and solvents were recrystallized or distilled before use. Chromium carbonyl complexes were always handled under oxygen free nitrogen or under high vacuum.

*The complex (12)*

A solution of *tert*-butyllithium (0.66 mL of 1.6 *M* solution in *n*-pentane) was added to the complex **2** (0.276 g) in dry THF at −78°C under nitrogen. The solution was cooled to −78°C, treated with iodine (0.254 g), allowed to warm to −10°C over 1 h, concentrated *in vacuo*, and chromatographed on silica gel with petroleum ether (30–60°C)/dichloromethane, *under nitrogen* to give: (*i*) complex **12**; 23.5 mg, 7%; $^1$Hmr ($CDCl_3$) δ: 5.42 (s, 1H, C6-H), 5.20 (1H, d, $J$ = 8 Hz, C4-H), 3.77 (1H, dd, $J$ = 8, 6 Hz, C3-H), 3.26 (1H, d, $J$ = 6 Hz, C2-H), 2.73 (3H, s, $NCH_3$), 1.32 (3H, t, $J$ = 7.5 Hz, $—CH_2CH_3$), 0.70 (9H, s, $—C(CH_3)_3$); ms *m/e*: 315 ($M^+$); (*ii*) a mixture of products with *m/e* 382 ($M^+$), 173 mg (85%).

*The complexes 14–16*

A solution of methyllithium (7.5 mL of 1.43 *M*) was added to the complex **2** (2.16 g) in dry THF (50 mL) at −78°C under nitrogen. After 30 min, degassed methanol (15 mL) was added



SCHEME 3

and the solution allowed to reach 0°C. The solvents were removed *in vacuo* and the residue chromatographed *under nitrogen* on silica gel with hexane/diethyl ether to give the following.

*Compound 14* (507 mg, 32%); red crystals (dichloromethane/hexane); mp 99–101.5°C; uv $\lambda_{max}$: 402 nm (ε 3821); $\nu_{max}$: 1945, 1863, 1845 $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 5.82 (1H, d, $J$ = 5.4 Hz, C3-H), 5.79 (1H, s, C6′-H), 4.94 (1H, d, $J$ = 5.4 Hz, C4-H), 3.92 (1H, s, C2′-H), 3.33 (2H, s, C6-$H_2$), 2.87 (3H, s, $—N'CH_3$), 2.63 (3H, s, $—NCH_3$), 1.02 (3H, t, $J$ = 7.5 Hz, $—CH_2CH_3$), 0.96 (3H, t, $J$ = 7.5 Hz, $—CH_2CH_3$); ($C_6D_6$) δ: 5.50 (1H, d, $J$ = 5.4 Hz, C3-H), 5.44 (1H, s, C6′-H), 4.41 (1H, d, $J$ = 5.4 Hz, C4-H), 3.36 (1H, unresolved triplet, C2′-H), 2.62 (3H, s, $—N'CH_3$), 2.31 (2H, ABq, $\Delta\nu_{AB}$ = 12.1 Hz, $J$ = 10.8 Hz, C6-$H_2$), 1.54 (3H, s, $—NCH_3$), 0.95 (3H, t, $J$ = 7.5 Hz, $—CH_2CH_3$), 0.56 (3H, t, $J$ = 7.5 Hz, $—CH_2CH_3$); ms *m/e*: 382, 354, 326, 298, 296, 245, 122;

*Compound* ***16*** (400 mg, 25%); red crystals; mp 138–142°C; ms and uv as for **6**; $\nu_{max}$: 1945, 1870, 1845 $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 5.67 (1H, d, $J$ = 5.4 Hz, C3-H), 5.62 (1H, bs, C4′-H), 4.95 (1H, d, $J$ = 5.4 Hz, C4-H), 3.62 (1H, t, $J$ = 5.4 Hz, C2′-H), 3.36 (2H, ABq, $J$ = 10.8 Hz, C6-$H_2$), 3.19 (2H, ABq, $J$ = 17.5 Hz, C6′-$H_2$), 2.68 (3H, s, —N′$CH_3$), 2.40 (3H, s, —$NCH_3$), 1.03 (3H, t, $J$ = 7.5 Hz, —$CH_2CH_3$), 0.97 (3H, t, $J$ = 7.5 Hz, —$CH_2CH_3$); ($C_6D_6$) δ: 5.39 (1H, bs, C4′-H), 5.35 (1H, d, $J$ = 5.4 Hz, C3-H), 4.60 (1H, d, $J$ = 5.4 Hz, C4-H), 3.48 (1H, t, $J$ = 5.4 Hz, C2′-H), 2.93 (2H, ABq, $J$ = 17.5 Hz, C6′-H), 2.63 (2H, ABq, $J$ = 10.8 Hz, C6-$H_2$), 2.19 (3H, s, —N′$CH_3$), 2.06 (3H, s, —$NCH_3$), 0.94 (3H, t, $J$ = 7.5 Hz, —$CH_2CH_3$), 0.78 (3H, t, $J$ = 7.5 Hz, —$CH_2CH_3$); *Anal.* calcd. for $C_{19}H_{26}CrN_2O_3$: C 59.94, H 6.80, N 7.33; found: C 59.75, H 6.90, N 7.30.

*Isomerization of* ***14*** *to* ***18***

A solution of **14** (476 mg) in degassed *n*-octane (30 mL) was refluxed, under nitrogen, for 12 h. The solution was cooled to room temperature and chromatographed, under nitrogen, on silica gel to give **14** (37 mg, 8%); and **18** (335 mg, 70%), as red crystals (petroleum ether, ether); mp 87–88°C; ir $\nu_{max}$: 1945, 1870, 1845 $cm^{-1}$; uv $\lambda_{max}$: 405 nm (ε 3786); $^1$Hmr ($CDCl_3$) δ: 5.39 (2H, s, C6-H and C6′-H), 5.19 (1H, d, $J$ = 8 Hz, C4-H), 3.78 (1H, dd, $J$ = 8, 6 Hz, C3-H), 3.18 (1H, dd, $J$ = 8, 6 Hz, C2-H), 2.69–2.63 (5H, m, N-$CH_3$, and C5′-$CH_2CH_3$), 2.41 (3H, s, N′-$CH_3$), 2.15 (1H, dd, $J$ = 8, 6 Hz, C2′-H), 1.86 (2H, q, $J$ = 8 Hz, —$CH_2CH_3$), 1.67–1.58 (3H, m, C3′-H and C4′-$H_2$), 1.35 (3H, t, $J$ = 8 Hz, —$CH_2CH_3$), 1.16 (1H, m, C3′-H), 0.91 (3H, t, $J$ = 8 Hz, —$CH_2CH_3$); ms *m/e*: 382 ($M^+$), 354, 326, 298. High resolution molecular weight calcd. for $C_{19}H_{26}N_2O_3Cr$: 382.1349; found: 382.1347. *Anal.* calcd. for $C_{19}H_{26}N_2O_3Cr$: C 59.67, H 6.85, N 7.32; found: C 59.40, H 6.95, N 7.31.

*Isomerization of* ***16*** *to* ***18***

Similarly heating a solution of **16** (413 mg) gave **16** (115 mg, 28%) and **18** (170 mg, 41%) identical with that isolated above.

*Oxidation of* ***14–16*** *to* ***21*** *via* ***19*** *and* ***20***

A mixture of the "dimers" **14–16** (500 mg) in dry pyridine (100 mL) was refluxed under nitrogen for 3 h. The solvent was removed *in vacuo* and the residue treated with sodium borohydride (250 mg) in degassed methanol (15 mL) for 1 h, under nitrogen at room temperature. The mixture was acidified with dilute HCl, stirred for 10 min, and then made alkaline with dilute NaOH and extracted with ether. The ether extract was dried ($Na_2SO_4$) and concentrated *in vacuo* to give **19** and **20** as a clear oil. The mixture was not separated due to the number of possible diastereomeric components, but used directly for the next step.

A mixture of **19** and **20** (325 mg) and selenium (1.0 g) were heated in a sealed tube at 350°C for 15 h. The mixture was dissolved in dilute HCl and filtered. The filtrate was made basic with dilute NaOH and then extracted with ether. The ether layer was dried, concentrated, and chromatographed on silica gel to give **21** (77 mg, 27%) as colourless crystals (hexane), mp 54.5°C; ir $\nu_{max}$ ($CCl_4$): 3120–2890, 1610, 1560, 1470 $cm^{-1}$; uv $\lambda_{max}$ (MeOH): 297 (ε 20 779), 283 (29 221), 275 (27 922), 245 (21 104), 240 (19 156) nm; $^1$Hmr δ: 8.48 (2H, s, C6-H and C6′-H), 8.24 (2H, d, $J$ = 8 Hz, C3-H and C3′-H), 7.61 (2H, dd, $J$ = 8, 2 Hz, C4-H and C4′-H), 2.67 (4H, q, $J$ = 8 Hz, 2 × —$CH_2CH_3$), 1.25 (6H, t, $J$ = 8 Hz, 2 × —$CH_2CH_3$); ms *m/e*: 212 ($M^+$), 197. High resolution molecular weight determination calcd. for $C_{14}H_{16}N_2$: 212.1313; found 212.1317. *Anal.* calcd. for $C_{14}H_{16}N_2$: C 79.20, H 7.60, N 13.20; found: C 79.08, H 7.80, N 13.00.

*Oxidation of* ***14–16*** *to* ***21***

Reaction of a mixture of **14–16** (1.13 g) with selenium (2.5 g) as above gave **21** (95 mg, 15%) identical with a sample prepared earlier.

# Stereoselective synthesis of (−)-α-multistriatin from D-glucose

PHAIK-ENG SUM AND LARRY WEILER[1]

*Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6*

Received August 17, 1981

PHAIK-ENG SUM and LARRY WEILER. Can. J. Chem. **60**, 327 (1982).

D-Glucose was converted into (−)-α-multistriatin, the aggregation pheromone of the European elm bark beetle, via a highly stereoselective eighteen-step route.

PHAIK-ENG SUM et LARRY WEILER. Can. J. Chem. **60**, 327 (1982).

On a transformé le D-glucose en (−)-α-multistriatine, la phérémone d'agrégation du scolyte de l'orme européen, en utilisant une synthèse hautement stéréosélective en 18 étapes.

[Traduit par le journal]

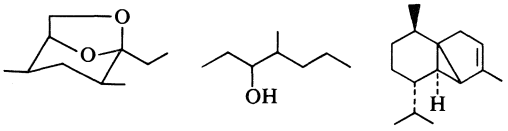
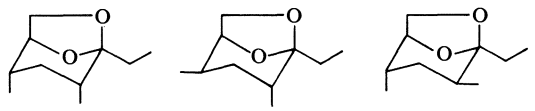
The bicyclic ketal, α-multistriatin (**1**), is one of three components of the aggregation pheromone of the European elm bark beetle, *Scolytus multistriatus*, which is the principal vector of Dutch elm disease in North America (1). The severe devastation of the elm populations in eastern North America and the steady march of the disease to the west coast have resulted in extensive studies on the use of pheromones to control this bark beetle and hence the Dutch elm disease. The volatile compounds from virgin female beetles were obtained and fractionated. The active attractant was found to be a combination of three components, α-multistriatin (**1**), 4-methyl-3-heptanol (**2**), and α-cubebene (**3**) (2). Compounds **1** and **2** were produced by the beetles, while compound **3** was produced by the host elm logs. In addition, the β-isomer **4** of multistriatin was also isolated from the beetles, but it was found to be inactive as an attractant (2). The structure of α-multistriatin was determined by extensive use of spectroscopic techniques and spectral analysis of the hydrogenolysis products from **1** (3). The natural α-multistriatin was optically active, $[\alpha]D^{25}$ −47° (hexane) (3) and subsequently the absolute configuration of (−)-α-multistriatin was found to be 1*S*,2*R*,4*S*,5*R* by a chiral synthesis (4).



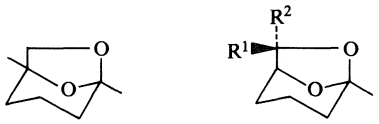
**1** **2** **3**

A nonselective synthesis of multistriatin gave the four isomers α- (**1**), β- (**4**), γ- (**5**), and δ- (**6**) (5). However, only the α-isomer **1** was active as an attractant. Subsequently one of the intermediates in this route was partially resolved and converted into the enantiomers of α-multistriatin (4). This established the absolute configuration of (−)-α-multistriatin as shown in **1**. A second synthesis of (−)-**1** was reported by Mori starting from D-mannitol (6). Cernigliaro and Kocienski have synthesized (−)-**1** from (+)-citronellol (7). Unfortunately the low optical purity of this starting material gave a product with ca. 40% optical purity. Elliott and Fried have also reported a synthesis of (−)-**1** via a resolution of one of the intermediates in their synthesis (8). Bartlett and Myerson have stereoselectively converted the readily available *meso*-2,4-dimethylglutaric anhydride into racemic α-multistriatin (9). Recently Fraser-Reid and co-workers have reported a synthesis of (−)-**1** from D-glucose (10) which has many similarities to the synthesis reported here.[2]



**4** **5** **6**

Earlier, we had developed facile synthetic routes to the 6,8-dioxabicyclo[3.2.1]octane pheromones frontalin (**7**), *exo*-brevicomin (**8**) and *endo*-brevicomin (**9**) (12). However, it was quickly apparent that this synthetic route which involved cyclization of an acyclic epoxy β-keto ester could



**7**

**8** R¹ = H, R² = Et
**9** R¹ = Et, R² = H

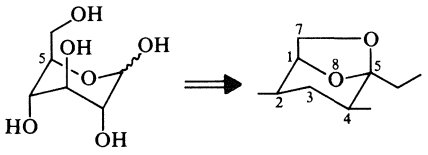
not be readily extended to a synthesis of **1**. In addition we recognized that the basic 6,8-dioxabicyclo[3.2.1]octane skeleton of all of these pheromones is present in certain anhydrohexoses (13) and we were intrigued with the potential synthesis of (−)-**1** from a readily available carbohydrate.[3] D-Glucose (**10**) shown in the unstable $^1C_4$ chair has the



**10** **1**

same absolute stereochemistry at C-5 as C-1 in (−)-α-multistriatin. Our synthetic plan to convert D-glucose into **1** involved: (*a*) deoxygenation of C-3, (*b*) introduction of methyl groups at C-2 and C-4 with "inversion" of configuration, (*c*) introduction of an ethyl group at C-1, and (*d*) formation of the C-1,6 anhydro derivative of glucose.

Methyl α-D-glucopyranoside (**11**) was protected as its benzylidine derivative **12** in 70% yield (15). The benzylidine **12** was converted into the ditosylate which on treatment with base following the procedure of Richtymer (15) gave the epoxide **13** (15) in a yield of ca. 70% for the two steps. However, we have found that we could obtain slightly higher yields (ca. 75%) but after noticeably shorter reaction periods using the dimesylate as an intermediate to epoxide **13**. Reaction of epoxide **13** with lithium dimethylcuprate according to the method of Hicks and Fraser-Reid (16) afforded the 2-deoxy sugar **14** in 75% yield. Deoxygenation of the C-3 hydroxyl group in **14** was accomplished in ca. 85% yield using the method reported by Barton and McCombie (17). The alcohol **14** was first converted into the xanthate ester **15** by treatment with sodium hydride, carbon disulfide, and iodomethane. The xanthate **15** was then heated under reflux with an excess of tri-*n*-butylstannane in toluene to yield the deoxygenated product **16**.

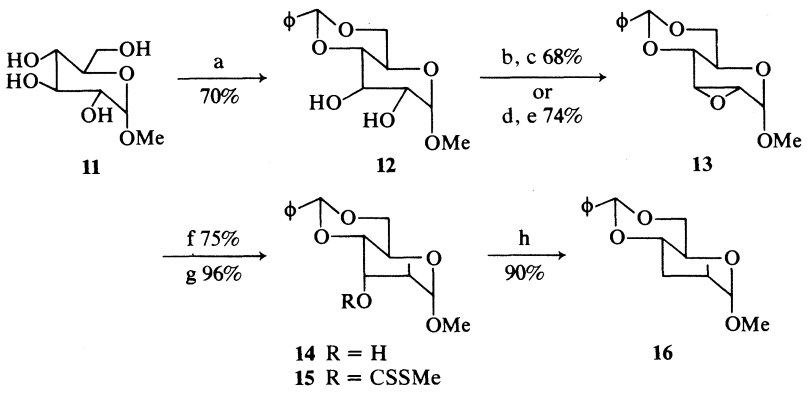
The next objective in our synthetic plan was the introduction of a β-methyl group at C-4 of the glucose derivative. A variety of catalysts was tried to effect the hydrogenolysis of the benzylidene in **16**. However, we were unsuccessful in carrying out a catalytic hydrogenolysis of **16**. We tentatively attribute the failure of this reaction in this case to the presence of trace amounts of tin–sulfur by-products derived from the previous stannane reduction. It was found that, after treatment of **16** with a catalytic amount of *p*-toluenesulfonic acid in methanol and careful work-up, the product **17** could be used directly in the preparation of the trityl ether **18** which was obtained in 77% overall yield for the two steps. The alcohol **18** gave the mesylate **19** in good yield. However, all attempts to displace this mesylate with a one carbon nucleophile failed. We had hoped to carry out a displacement with inversion at C-4 with lithium dimethylcuprate.[4] Presumably the axial methyl at C-2 provided sufficient steric interference to divert any nucleophile from approaching the backside of the mesylate at C-4.

This shielding of the top face of the molecule by the C-2 methyl group was turned to advantage in the following fashion. The alcohol at C-4 of **18** was oxidized (19) to the ketone **20** which on treatment with methylene triphenylphosphorane gave the exocyclic alkene **21** in good yield. In the crucial subsequent step the axial methyl group at C-4 was generated in a stereoselective hydrogenation of **21** using Wilkinson's catalyst (20). The stereoselectivity of this reduction was dependent on solvent and temperature. At 0°C in benzene alkene **21** was cleanly reduced to **22** and we could not detect any of the C-4 epimer by nmr or tlc. However, when ethanol was used as solvent or cosolvent (20) or if the hydrogenation was carried out at higher temperature the stereoselectivity fell. For example, hydrogenation of **21** at room temperature in anhydrous benzene gave **22** and its C-4 epimer in a ratio of 9:1. The effect of solvent (for example, ref. 21) and temperature (for example see ref. 22) on the stereoselectivity of homogeneous hydrogenations has been reported previously.

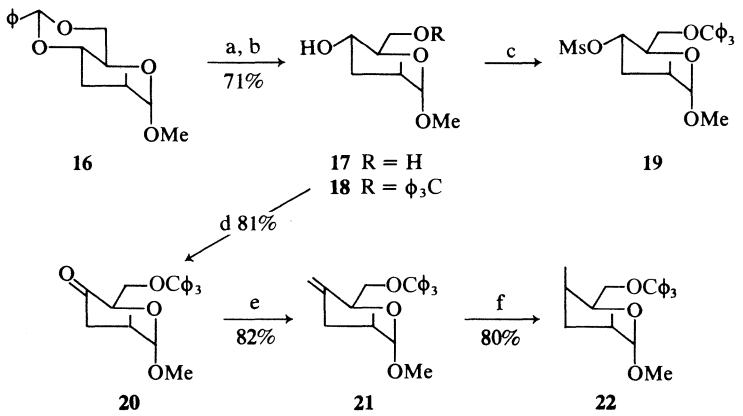
We had hoped to apply the alkylation of dithioacetal carbanions (23) to add the ethyl group at C-1 of **22** in the third phase of our synthetic plan. Compound **22** was smoothly converted into the diethyl dithioacetal **23** with concomitant cleavage of the trityl group by treatment with concentrated HCl and ethanethiol (24). The resulting diol **23** was then protected as its isopropylidene derivative **24**. Unfortunately all attempts to alkylate **24** were unsuccessful. The difficulty in this reaction was traced to our failure to generate the anion of **24**. We suspected that the methyl group at C-2 is responsible for the inertness of the dithioacetal **24**. Difficulties in alkylating α-substituted dialkyl dithioacetals have been reported (25). In contrast to our failure to alkylate **24**, the carbanion of a diethyl dithioacetal of a C-2 *unsubstituted* carbohydrate derivative has

[3]For two recent reviews on the use of carbohydrates in the synthesis of chiral natural products see ref. 14.

[4]For example (+)-2-butyl tosylate reacts with lithium diphenylcuprate to give (−)-2-phenylbutane with 100% inversion (18).

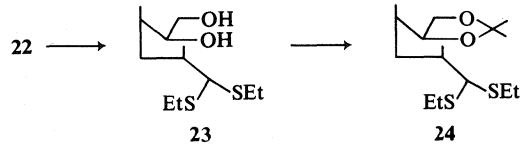


SCHEME 1. (a) $\phi$CHO, $ZnCl_2$; (b) TsCl, py, 7 days; (c) NaOMe, $CH_2Cl_2$, 6 days; (d) MsCl, py, 1 day; (e) NaOMe, $CH_2Cl_2$, $3\frac{1}{2}$ days; (f) $Me_2CuLi$, $Et_2O$; (g) NaH, $CS_2$, MeI, $Et_2O$; (h) $Bu_3SnH$, toluene, $\Delta$.



SCHEME 2. (a) TsOH, MeOH; (b) $\phi_3CCl$, py; (c) MsCl, py; (d) $CrO_3 \cdot 2py$, $CH_2Cl_2$; (e) $\phi_3P^{+}\text{-}^{-}CH_2$, $Et_2O$; (f) $H_2$, $(\phi_3P)_3RhCl$, benzene.

been alkylated in good yield (26). Several reports have indicated that the dithiane derivatives of aldehydes are less susceptible to the steric effect of an α-substituent in carbanion alkylation than the corresponding diethyl dithioacetals. For this reason we prepared the protected dithiane as shown in Scheme 3. We found that *n*-butyllithium treatment of **26** followed by a $D_2O$ quench led to partial (ca. 50%) anion formation whereas *tert*-butyllithium gave essentially quantitative formation of the desired carbanion. This carbanion was alkylated with iodoethane in HMPA–hexane to give **27** in 80% yield. A similar alkylation of another dithiane from D-glucose has recently been reported in the synthesis of the pheromone chalcogran (27).



Hydrolysis of the isopropylidene **27** afforded the diol **28** in 90% yield. Several previous syntheses of α-multistriatin involved an acid-catalyzed cyclization of epoxy ketone **29** or diol **30**. These conditions

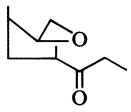
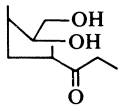
For personal use only.

usually resulted in the epimerization of the methyl group at C-4 (adjacent to the carbonyl) and the production of significant amounts of α-multistriatin (5).[5] With this in mind we attempted to cleave the thioketal of **28** with concomitant cyclization, and avoid going through the ketone **30**. Thus the



**29**



**30**

thioketal **28** in *anhydrous* acetonitrile containing mercuric chloride and mercuric oxide was cleanly converted into **1**. The structure of our synthetic material was fully confirmed by comparison of the spectral data of our synthetic material with that reported for α-multistriatin (3–8). The nmr spectrum (5) is particularly diagnostic in distinguishing the iomers of multistriatin. Our synthetic material had an optical rotation $[\alpha]_D^{25}$ −46.0° (*c* 1.00, hexane) compared with a rotation $[\alpha]_D^{25}$ −47 (*c* 0.19, hexane) for the natural material (1, 4). Finally, vpc analysis of our synthetic (−)-α-multistriatin with a 3% OV 101 column, under a variety of conditions which separated the multistriatin isomers, demonstrated that our product was 99.7% pure and no trace of the other multistriatin isomers could be detected. This confirms the absolute configuration of the natural (−)-α-multistriatin as that shown in **1** (4, 6, 7).

## Experimental

*General*

Melting points (mp) were determined on a Kofler micro heating stage or a Thomas Hoover capillary melting point apparatus and are uncorrected. Gas–liquid chromatography was performed on a Hewlett Packard Model 5831A gas chromatograph, using a 6 ft × 1/8 in. column of 3% OV 101 Chromosorb W(HP) and nitrogen as carrier gas. The 60 MHz nuclear magnetic resonance spectra were recorded on a Varian Associates Model T-60, the 100 MHz spectra were recorded on Varian Associates Model HA-100 or Model XL-100, and the 270 MHz spectra were recorded on a homebuilt high resolution nmr spectrometer consisting of an Oxford Instruments' 63.4 KG magnet. Chemical shifts in ppm are reported using the δ scale with tetramethylsilane (TMS) as internal reference. Infrared spectra were recorded on a Perkin–Elmer model 710B spectrophotometer. Optical rotations $[\alpha]_D$ were measured with a Perkin–Elmer model 241 MC polarimeter. Low resolution mass spectra were determined on a Varian/Mat model CH4B mass spectrometer. High resolution mass measurements were obtained using a Kratos-AEI model MS902 or model MS50 instrument. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver. All solvents used for nmr, ir, and optical rotations were of Spectral grade.

Analytical thin layer chromatography plates and preparative tlc plates were prepared from silica gel GF-254 from E. Merck Co. Preparative tlc plates were about 1 mm thickness. Column chromatography was carried out with 100–200 mesh ASTM silica gel from Davison Chemical. The petroleum ether used was of boiling range ca. 30–60°C. Dry solvents or reagents, where indicated, were prepared as follows: ethyl ether by refluxing over lithium aluminum hydride followed by distillation; dichloromethane and acetonitrile by distillation from phosphorus pentoxide; hexamethylphosphoramide (HMPA) by distillation from calcium hydride followed by storage over molecular sieve (Type 4A); triethylamine by distillation from and storage over potassium hydroxide pellets; pyridine by distillation from barium oxide followed by storage over potassium hydroxide pellets; benzene, toluene, and *n*-hexane by distillation from calcium hydride; and methanol by refluxing over magnesium methoxide followed by distillation.

Methyllithium (in ethyl ether) and *n*-butyllithium (in hexane) were obtained from Aldrich Chemical Company, Inc. *tert*-Butyllithium (in pentane) was supplied by Alfa Division, Ventron Corporation. The alkyllithium solutions were standardized by titration against 1.0 *M tert*-butyl alcohol in benzene using 1,10-phenanthroline as indicator.

*Methyl 4,6-O-benzylidene-α-D-gluco-pyranoside (12)*

This compound, mp 161–163°C, was prepared from methyl α-*gluco*pyranoside (**11**) in 70% yield following the procedure of Richtymer (15).

*Methyl 4,6-O-benzylidene-2,3-di-O-p-tolylsulfonyl-α-D-gluco-pyranoside*

This compound, mp 148–149°C, was prepared from **12** in 80% yield following the procedure of Richtymer (15).

*Methyl 4,6-O-benzylidene-2,3-di-O-methanesulfonyl-α-D-gluco-pyranoside*

Benzylidene diol **12** (20.0 g, 70.9 mmol) was dissolved in ca. 125 mL of dry pyridine. The solution was cooled in ice and 19.95 g (175 mmol) of methanesulfonyl chloride was added. A white heavy precipitation was observed. The reaction was stirred at room temperature for 24 h. The mixture was then poured onto ice and extracted several times with dichloromethane. The combined extracts were washed several times with dilute hydrochloric acid until no trace of pyridine could be detected. The extracts were then washed once with water and once with aqueous sodium bicarbonate, dried over anhydrous magnesium sulfate, and filtered. The solvent was removed under reduced pressure to ca. 150 mL and ethyl ether was added to induce crystallization. The yield of the recrystallized methyl 4,6-*O*-benzylidene-2,3-di-*O*-methanesulfonyl-α-D-*gluco*-pyranoside was 25.0 g (81%); mp 186–18°C. This compound was characterized by ir ($CHCl_3$): 1100, 1130, 1180, and 1420 $cm^{-1}$; nmr ($CDCl_3$) δ: 2.87 (s, 3H), 3.17 (s, 3H), 3.48 (s, 3H), 3.6–4.8 (m, 5H), 4.8–5.2 (m, 2H), 5.51 (s, 1H), and 7.1–7.6 (m, 5H); mass spectrum: (*a*) high resolution calcd. for $C_{16}H_{22}O_{10}S_2$: 438.0655 amu; found: 438 0655; (*b*) low resolution *m/e* (relative intensity): 47(13), 49(100), 69(4), 79(4), 107(8), 116(6), 121(4), 149(3), 157(4), 185(4), 193(7), 229(3), 289(3), 299(8), 359(3), 437(11), and 438(7).

*Methyl 2,3-anhydro-4,6-O-benzylidene-α-D-allo-pyranoside (13)*

(a) *From the ditosylate of* **12**

Compound **13**, mp 198–200°C, was prepared from the ditosylate of **12**, in 85% following the procedure of Richtymer (15).

[5]Recently Rao and co-workers (28) have suggested that ketal formation of five-membered rings may involve enol ether intermediates which would explain the epimerization of the C-4 methyl in **29** or **30**.

(b) *From the dimesylate of* ***12***

A solution of sodium methoxide was prepared using 12.7 g (552 mmol) of sodium and 188 mL of dry methanol. Methyl 4,6-*O*-benzylidene-2,3-di-*O*-methanesulfonyl-α-D-*gluco*-pyranoside from above (48.18 g, 110 mmol) in 780 mL of dichloromethane was added to the sodium methoxide solution at 0°C. The reaction mixture was kept at 0°C for 3 days and stirred at room temperature for 10 h. The reaction mixture was diluted with water and the dichloromethane layer separated. The aqueous layer was extracted several times with dichloromethane. The combined organic extracts were washed with water, dried over anhydrous magnesium sulfate, and solvents were removed under reduced pressure. The product crystallized readily, and was filtered and washed with ether. The crude product was recrystallized from a mixture of dichloromethane and ethyl ether to give 26.40 g (91%) of pure epoxide **13**, mp 198–200°C. The spectral data were identical to the epoxide prepared from the ditosylate.

*Methyl 4,6-*O*-benzylidene-2-deoxy-2-*C*-methyl-α-D-*altro*-pyranoside (**14**)*

This compound, mp 112–113°C, was prepared in 75% from **13** using the procedure of Hicks and Fraser-Reid (16).

*Methyl 4,6-*O*-benzylidene-2-deoxy-2-*C*-methyl-3-*O*-[(thiomethyl)-thiocarbonyl]-α-D-*altro*-pyranoside (**15**)*

Compound **15** was prepared in 96% crude yield from **14** using the procedure of Hicks and Fraser-Reid (16). The crude product was used directly in the next step. A small amount of compound **14** was purified by preparative tlc ($CCl_4$–$Et_2O$, 4:1 v/v) and characterized by the following spectral data. Infrared ($CHCl_3$): 950, 1005, 1040, 1060, 1100, 1140, and 2950 $cm^{-1}$; nmr ($CDCl_3$) δ: 1.18 (d, $J$ = 7 Hz, 3H), 2.55 (s, 3H), 2.4–2.8 (m, 1H), 3.33 (s, 3H), 3.5–4.5 (m, 5H), 5.55 (br s, 1H), 5.75 (m, 1H), and 7.1–7.6 (m, 5H); mass spectrum *m/e* (relative intensity): 41(29), 43(30), 55(21), 57(29), 69(23), 85(44), 91(38), 105(56), 113(44), 121(32), 125(25), 131(29), 149(100), 150(14), 231(20), 262(47), 263(24), and 370(11).

*Methyl 4,6-*O*-benzylidene-2,3-dideoxy-2-*C*-methyl-α-D-*arabino*-hexopyranoside (**16**)*

A solution of 22.2 g (60.0 mmol) of the *S*-methyl dithiocarbonate compound **15** in 260 mL of dry toluene was added over 1.5 h to 34.92 g (120 mmol) of tri-*n*-butylstannane in 240 mL refluxing dry toluene under dry nitrogen. Refluxing was continued overnight, and the solvent was removed under reduced pressure. Purification was achieved by column chromatography using silica gel (100–200 mesh) and a mixture of petroleum ether and ethyl ether (9.5:1, v/v, then 1:1, v/v) to yield 14.30 g (90%) of pure compound **16** as a syrup, $[\alpha]_D^{28}$ +82.7° (*c* 14.2, ethyl ether); ir ($CHCl_3$): 930, 950, 1005, 1050, 1100, 1120, 1140, 1380, and 1460 $cm^{-1}$; nmr ($CDCl_3$) δ: 1.13 (d, $J$ = 7 Hz, 3H), 1.4–2.3 (m, 3H), 3.33 (s, 3H), 3.5–4.3 (m, 4H), 4.33 (s, 1H), 5.50 (s, 1H), and 7.0–7.5 (m, 5H); mass spectrum: (*a*) high resolution calcd. for $C_{15}H_{20}O_4$: 264.1362 amu; found: 264.1374; (*b*) low resolution *m/e* (relative intensity): 55(15), 73(12), 83(19), 105(21), 115(100), 116(11), 149(11), 221(10), and 264(22).

*Methyl 2,3-dideoxy-2-*C*-methyl-α-D-*arabino*-hexopyranoside (**17**)*

To a solution of 12.41 g (47.0 mmol) of compound **16** in ca. 30 mL of methanol was added 0.40 g of *p*-toluenesulfonic acid monohydrate. The reaction mixture was stirred at room temperature and followed by tlc. After the reaction was complete (2.5 h), solid sodium carbonate was added to neutralize the acid. The reaction mixture was filtered, and the methanol was removed under reduced pressure. The residue was dissolved in water and ethyl ether, and extracted several times with water. The combined aqueous extracts were concentrated under reduced pressure and the residue dissolved in dichloromethane, dried over anhydrous magnesium sulfate, and filtered. The dichloromethane was removed under reduced pressure to give a thick oil, 6.81 g (82%) of which was pure enough for the next step. Compound **17** was characterized by the following spectral data. Infrared ($CHCl_3$): 960, 1050, 1100, 1150, 2975, 3500, and 3650 $cm^{-1}$; nmr ($CDCl_3$) δ: 1.03 (d, $J$ = 7 Hz, 3H), 1.5–2.2 (m, 3H), 2.83 (br s, 2H), 3.33 (s, 3H), 3.6–4.2 (m, 4H), and 4.3 (br s, 1H); mass spectrum: (*a*) high resolution calcd. for $C_8H_{16}O_4$: 176.1049 amu, found: 176.1047; (*b*) low resolution *m/e* (relative intensity): 41(24), 43(27), 55(28), 56(29), 57(27), 72(100), 74(55), 83(23), 113(26), 115(27), 145(33), and 176(1).

*Methyl 2,3-dideoxy-2-*C*-methyl-6-*O*-triphenylmethyl-α-D-*arabino*-hexopyranoside (**18**)*

Compound **17** (3.17 g, 18 mmol) was treated with 7.5 g (27 mmol) of trityl chloride in 30 mL of anhydrous pyridine. The reaction mixture was stirred at room temperature for 3 days. It was then poured onto ice cold water, acidified, and extracted several times with dichloromethane. The combined extracts were washed with dilute sodium bicarbonate and brine, dried over anhydrous magnesium sulfate, filtered, and the solvents were removed under reduced pressure. Purification was achieved by column chromatography using silica gel (100–200 mesh) and a mixture of carbon tetrachloride and ethyl ether (4:1, v/v) as eluent to yield 6.465 g (86%) of **18**, mp 147–149°C, $[\alpha]_D^{26}$ +26° (*c* 20.0, chloroform); ir ($CHCl_3$): 1600 and 3570 $cm^{-1}$; nmr ($CDCl_3$) δ: 0.99 (d, $J$ = 7 Hz, 3H), 1.4–2.1 (m, 3H), 2.39 (br s, 1H), 3.31 (s, 3H), 3.0–3.7 (m, 4H), 4.26 (s, 1H), and 6.7–7.4 (m, 15H); mass spectrum *m/e* (relative intensity): 43(4), 55(5), 72(4), 77(6), 83(6), 105(13), 113(13), 127(5), 165(27), 175(21), 183(15), 243(100), 244(27), 258(4), 259(7), 260(5), 309(5), 386(4), and 418(3). *Anal.* calcd. for $C_{17}H_{30}O_4$: C 77.48, H 7.22; found: C 77.61, H 7.21.

*Methyl 2,3-dideoxy-2-*C*-methyl-6-*O*-triphenylmethyl-α-D-*threo*-hexopyranosid-4-ulose (**20**)*

A sample of 6.0 g (60 mmol) of chromium trioxide was added to a magnetically stirred solution of 9.5 g (120 mmol) of anhydrous pyridine in ca. 150 mL anhydrous dichloromethane. The flask was stopped with a drying tube, and the deep burgundy solution stirred for 15 min at room temperature. At the end of this period, a solution of 4.18 g (10 mmol) of alcohol **18** in 5 mL of dry dichloromethane was added in one portion. A tarry, black deposit separated immediately. After stirring for 18 h at room temperature, the solution was decanted and the dichloromethane removed under reduced pressure. The residue was dissolved in ethyl ether and the reaction flask was rinsed several times with ethyl ether. The ether layers were combined and filtered through a bed of Celite. The slight yellow filtrate was washed with dilute hydrochloric acid and aqueous sodium bicarbonate solution, dried over anhydrous magnesium sulfate, filtered, and the solvents were removed under reduced pressure to give 3.99 g (96%) of ketone **20** which was homogeneous from tlc. The crude product was purified by column chromatography using silica gel (100–200 mesh) and a mixture of carbon tetrachloride and ethyl ether (8:1, v/v) as eluent to give 3.35 g (81%) of pure **20**, mp 88–89°C; $[\alpha]_D^{28}$ +98.8° (*c* 20.0, chloroform), which was characterized by ir ($CHCl_3$): 1600, 1730, and 2960 $cm^{-1}$; nmr ($CDCl_3$) δ: 1.14 (d, $J$ = 7 Hz, 3H), 1.9–2.6 (m, 3H), 3.2–3.6 (m, 2H), 3.5 (s, 3H), 3.83 (m, 1H), 4.6 (d, $J$ = 4 Hz, 1H), and 7.0–7.7 (m, 15H); mass spectrum: (*a*) high resolution calcd. for $C_{27}H_{28}O_4$: 416.1988 amu; found: 416.1989; (*b*) low resolution *m/e* (relative intensity): 43(4), 45(6), 55(4), 59(7), 71(6), 72(8), 105(7), 157(6), 165(20), 173(5), 183(5), 243(100), 244(24), 259(6), 339(4), and 416(4).

For personal use only.

*Methyl 2,3,4-trideoxy-2-C-methyl-4-methylene-6-O-triphenylmethyl-α-D-*threo*-hexopyranoside (**21**)*

A 250-mL 3-necked round bottom flask containing ca. 120 mL of anhydrous ethyl ether was fitted with a reflux condenser, an addition funnel, a septum stopper, and a nitrogen outlet. *n*-Butyllithium (8.86 mL of 1.58 *M*, 14 mmol) was added to the flask and 5.00 g (14 mmol) of triphenylmethylphosphonium bromide was added in portions to the *n*-butyllithium solution. The orange reaction mixture was refluxed for 4 h and 5.82 g (14 mmol) of ketone **20** in 30 mL of ethyl ether was added slowly. The orange color discharged and a white precipitate was observed. The reaction mixture was then refluxed for 24 h, cooled, and the precipitate was filtered off. The ether filtrate was washed with water and brine, dried over magnesium sulfate, filtered, and the solvents were evaporated under reduced pressure. Purification of the crude product by column chromatography using silica gel (100–200 mesh) and a mixture of carbon tetrachloride and ethyl ether (10:1, v/v) as eluent gave 4.53 g (78%) of compound **21**, mp 153–154°C, $[\alpha]_D^{22}$ +45.4° (*c* 7.4, chloroform), and 0.5 g of recovered **20**. Thus, the yield was 82% based on recovered starting material **20**. The olefin **21** was characterized by the following spectral data. Infrared ($CHCl_3$): 1600, 1660, 2960, 3040, and 3100 $cm^{-1}$; nmr ($CDCl_3$) δ: 0.93 (d, $J$ = 7 Hz, 3H), 1.6–2.8 (m, 3H), 3.30 (d, $J$ = 6 Hz, 2H), 3.43 (s, 3H), 4.2–4.4 (m, 2H), 4.62 (m, 2H), and 6.8–7.6 (m, 15H); mass spectrum: (*a*) high resolution calcd. for $C_{28}H_{30}O_3$: 414.2195 amu; found: 414.2214; (*b*) low resolution *m/e* (relative intensity); 41(2), 43(2), 77(2), 81(4), 105(5), 109(14), 139(2), 141(50), 142(5), 165(21), 166(4), 183(2), 215(2), 228(3), 241(3), 243(100), 244(21), and 414(1).

*Hydrogenation of compound **21***

A 100-mL round bottom flask containing 50 mL of anhydrous benzene, 0.7 g of tris(triphenylphosphine)rhodium chloride (20), and 3.31 g (8.0 mmol) of alkene **21** was fitted with a magnetic stirrer and connected to an atmospheric pressure hydrogenation apparatus equipped with a graduated burette to measure the uptake of hydrogen. The system was evacuated and filled with hydrogen. After 24 h, about 1 equiv. of hydrogen was absorbed. The solvent was removed under reduced pressure and the product was purified by column chromatography using silica gel (100–200 mesh) and a mixture of ethyl acetate and petroleum ether (10:1, v/v) as eluent. Two components were isolated from this chromatography, and these were, in order of elution: methyl 2,3,4-trideoxy-2,4-di-*C*-methyl-α-D-*arabino*-hexopyranoside (0.29 g, 9%), and methyl 2,3,4-trideoxy-2,4-di-*C*-methyl-α-D-*lyxo*-hexopyranoside (**22**) (2.74 g, 80%).

Methyl 2,3,4-trideoxy-2,4-di-*C*-methyl-α-D-*arabino*-hexopyranoside was characterized by ir ($CHCl_3$): 1600 $cm^{-1}$; nmr ($CDCl_3$) δ: 0.58 (d, $J$ = 6 Hz, 3H), 1.05 (d, $J$ = 7 Hz, 3H), 1.3–2.0 (m, 4H), 2.9–3.6 (m, 3H), 3.38 (s, 3H), 4.4 (br s, 1H), and 6.9–7.6 (m, 15H); mass spectrum: (*a*) high resolution calcd. for $C_{28}H_{32}O_3$: 416.2351 amu; found: 416.2328; (*b*) low resolution *m/e* (relative intensity): 83(10), 85(25), 105(15), 111(17), 141(9), 143(60), 165(40), 173(48), 243(100), 244(31), 258(8), and 416(5).

Methyl 2,3,4-trideoxy-2,4-di-*C*-methyl-α-D-*lyxo*-hexopyranoside (**22**) had mp 153–154°C and $[\alpha]_D^{24}$ +27.0° (*c* 6.6, chloroform) and was characterized by ir ($CHCl_3$): 1600 $cm^{-1}$; nmr ($CDCl_3$) δ: 0.70 (d, $J$ = 7 Hz, 3H), 0.95 (d, $J$ = 7 Hz, 3H), 1.3–2.0 (m, 4H), 3.0–3.3 (m, 2H), 3.45 (s, 3H), 3.8–4.1 (m, 1H), 4.2 (d, $J$ = 5 Hz, 1H), and 6.9–7.6 (m, 15H); $^{13}C$ nmr ($CDCl_3$) δ: 15.93, 18.3, 30.61, 33.75, 34.73, 55.35, 63.10, 71.96, 104.34, 126.98, 127.77, 128.83, and 144.21; mass spectrum: low resolution *m/e* (relative intensity): 55(7), 72(7), 83(8), 85(20), 105(13), 111(16), 115(4), 141(8), 143(65), 144(7), 165(25), 166(6), 173(63), 174(9), 183(7), 229(5), 243(100), 244(36), 258(3), and 416(1). *Anal.* calcd. for $C_{28}H_{32}O_3$: C 80.73, H 7.74; found: C 80.51, H 7.55.

*(2S, 4S, 4'S)-1,1-Diethylthio-2-methyl-4-(2',2'-dimethyl-1',3'-dioxacyclopent-4'-yl)pentane (**24**)*

To a mixture of 0.83 g of **22** and 1.80 mL of concentrated hydrochloric acid at 0°C was added 1.80 mL of ethanethiol. The reaction mixture was stirred for 24 h at 0°C. Ice and water were added to the reaction mixture and the mixture extracted several times with ethyl acetate. The organic extract was washed with brine and saturated aqueous sodium bicarbonate, dried over anhydrous sodium sulfate, filtered, and the solvent was removed under reduced pressure. The crude product was purified by column chromatography (silica gel 100–200 mesh) using a mixture of petroleum ether and ethyl ether (3:1, v/v); after the side-product had completely eluted, the solvent was changed to ethyl ether. The yield of compound **23** from this chromatography was 0.44 g (83%). The nmr ($CDCl_3$) of compound **23** had absorptions at δ: 0.92 (d, $J$ = 7 Hz, 3H), 1.16 (d, $J$ = 7 Hz, 3H), 1.25 (t, $J$ = 7 Hz, 6H), 1.4–2.3 (m, 4H), 2.2–3.0 (m, 4H), 3.26 (br s, 2H), 3.4–3.7 (m, 3H), and 3.75 (d, $J$ = 3 Hz, 1H).

To a solution of diol **23** (0.43 g, 1.60 mmol) in 9 mL of 2,2-dimethoxypropane was added ca. 20 mg of *p*-toluenesulfonic acid. After stirring at room temperature for 2 h, the reaction mixture was diluted with chloroform, washed with 5% aqueous sodium bicarbonate, dried over anhydrous magnesium sulfate, filtered, and solvents were removed under reduced pressure. The crude product was distilled (Kugelrohr, bath temperature 100°C/0.2 Torr) to give 0.40 g (82%) of **24**. A small sample was purified by tlc using a mixture of petroleum ether and ethyl ether (4:1, v/v) to give pure **24** and was characterized by ir ($CHCl_3$): 860, 1060, 1160, 1260, 1280, 1380, and 1460 $cm^{-1}$; 270 MHz nmr ($CDCl_3$) δ: 0.98 (d, $J$ = 6 Hz, 3H), 1.04 (d, $J$ = 6 Hz, 3H), 1.25 (t, $J$ = 7 Hz, 3H), 1.35 (s, 3H), 1.40 (s, 3H), 1.5–1.7 (m, 3H), 2.0–2.2 (m, 1H), 2.5–2.8 (m, 4H), and 3.6–4.2 (m, 4H); mass spectrum: (*a*) high resolution calcd. for $C_{15}H_{30}O_2S_2$: 306.1687 amu; found: 306.1690; (*b*) low resolution *m/e* (relative intensity): 43(38), 55(18), 75(27), 103(19), 107(55), 115(56), 125(29), 135(30), 169(19), 187(100), and 306(30).

*(2'S, 4'R, 5'S)-2-(2',4'-Dimethyl-5',6'-dihydroxyhex-2'-yl)-1,3-dithiane (**25**)*

To a solution of 2.08 g (5.0 mmol) of compound **22** in ca. 40 mL of dry dichloromethane was added 1.63 g (15 mmol) of 1,3-dithiolpropane and 1.4 mL of distilled boron trifluoride etherate at 0°C. The reaction was stirred at 0°C for 18 h. It was then diluted with ethyl acetate, washed with aqueous sodium bicarbonate, dried over anhydrous magnesium sulfate, filtered, and the solvents were removed under reduced pressure. Purification of the crude product was achieved by column chromatography using silica gel (100–200 mesh) and a mixture of petroleum ether and ethyl ether (9:1, v/v) as eluent. After the side product had completely eluted, the eluting solvent was changed to ethyl acetate. The yield of compound **25** from this chromatography was 1.0 g (80%) and this product was characterized by ir ($CHCl_3$): 3500 and 3660 $cm^{-1}$; nmr ($CDCl_3$) δ: 0.98 (d, $J$ = 6 Hz, 3H), 1.1 (d, $J$ = 6 Hz, 3H), 1.5–2.5 (m, 8H), 2.7–3.1 (m, 4H) 3.4–3.7 (m, 3H), and 4.12 (d, $J$ = 4 Hz, 1H); mass spectrum: (*a*) high resolution calcd. for $C_{11}H_{22}O_2S_2$: 250.1061 amu; found: 250.1085; (*b*) low resolution *m/e* (relative intensity): 41(10), 43(7), 55(6), 73(5), 119(100), 120(8), 121(10), 143(5), 219(5), and 250(16).

*(2'S, 4'R, 4"S)-2-[4'-(2",2"-Dimethyl-1", 3"-dioxacyclopent-4"-yl)pent-2'-yl]-1,3-dithiane (**26**)*

To a solution of 1.0 g (4.0 mmol) of diol dithiane **25** in 20 mL of 2,2-dimethoxypropane was added a catalytic amount of *p*-toluenesulfonic acid (0.10 g). The reaction was stirred at room temperature for 1.5 h. It was then diluted with chloroform, washed with aqueous sodium bicarbonate, dried over anhydrous magnesium sulfate, filtered, and the solvents were removed

under reduced pressure. The crude product was purified by column chromatography using silica gel (100–200 mesh) and a mixture of petroleum ether and ethyl ether (9:1, v/v) as eluent. From this chromatography 1.02 g (88%) of compound **26** was isolated. Kugelrohr distillation (bath temperature 120°C/0.1 Torr) of **26** isolated from this column had $[\alpha]_D^{25}$ −6.2° (*c* 15.0, ethyl ether), and was characterized by ir ($CHCl_3$): 920, 1070, 1380, 1390, and 2975 $cm^{-1}$; 270 MHz nmr ($CDCl_3$) δ: 0.98 (d, $J$ = 7 Hz, 3H), 1.07 (d, $J$ = 7 Hz, 3H), 1.35 (s, 3H), 1.41 (s, 3H), 1.5–1.9 (m, 4H), 1.95–2.2 (m, 2H), 2.75–3.0 (m, 4H), 3.65 (t, $J$ = 7 Hz, 1H), 3.85 (q, $J$ = 7 Hz, 1H), 4.01 (t, $J$ = 7 Hz, 1H), and 4.16 (d, $J$ = 4 Hz, 1H); mass spectrum *m/e* (relative intensity): 41(22), 43(38), 72(21), 119(100), 159(31), 161(18), 232(24), 275(44), and 290(58). *Anal.* calcd. for $C_{14}H_{26}O_2S_2$: C 57.89, H 9.02; found: C 57.70, H 9.00.

*(2'S, 4'R, 4"S)-2-Ethyl-2-[4'-(2",2"-dimethyl-1",3"-dioxacyclopent-4"-yl)pent-2'-yl]-1,3-dithiane (**27**)*

A solution of 0.58 g (2.0 mmol) of compound **26** in ca. 8 mL of dry *n*-hexane was placed in a 25-mL round bottom flask fitted with a magnetic stirrer and nitrogen outlet. The flask was cooled to ca. −20°C (Dry Ice and carbon tetrachloride) and 1.5 mL (2.0 *M* in pentane, 3 mmol) of *tert*-butyllithium was added dropwise. The reaction was stirred at ca. −20°C for 2 h, then kept in the freezer (ca. −10°C) for 16 h. The temperature of the reaction mixture was then raised to 0°C and 0.4 mL (0.78 g, 5 mmol) of iodoethane in 1.74 mL (5 equiv.) of hexamethylphosphoramide was added; a white precipitate formed immediately. The reaction was stirred for 5 h, diluted with ethyl ether, washed with ice cold dilute hydrochloric acid, sodium bicarbonate solution, and brine, dried over anhydrous sodium sulfate, filtered, and the solvents were removed under reduced pressure. The crude product was purified by column chromatography using silica gel (100–200 mesh) and a mixture of petroleum ether and ethyl ether (9:1, v/v) as eluent to yield 0.506 g (80%) of compound **27**. Kugelrohr distillation (bath temperature 128°C/0.1 Torr) of **27** isolated from this column had $[\alpha]_D^{25}$ −28.0° (*c* 5.0, ethyl ether), and was characterized by ir ($CHCl_3$): 860, 1060, 1160, 1380, 1480, and 2970 $cm^{-1}$; 270 MHz nmr ($CDCl_3$) δ: 0.98 (t, $J$ = 7 Hz, 3H), 1.01 (d, $J$ = 7 Hz, 3H), 1.1 (d, $J$ = 7 Hz, 3H), 1.34 (s, 3H), 1.41 (s, 3H), 1.5–2.2 (m, 8H), 2.6–3.0 (m, 2H), 3.7 (t, $J$ = 7 Hz, 3H), and 3.9–4.1 (m, 2H); mass spectrum *m/e* (relative intensity): 41(12), 43(16), 134(15), 147(100), 148(13), 149(15), 303(18), and 320(16). *Anal.* calcd. for $C_{16}H_{30}O_2S_2$: C 60.30, H 9.49; found: C 60.20, H 9.53.

*(2'S, 4'R, 5'S)-2-Ethyl-2-(2',4'-dimethyl-5',6'-dihydroxyhex-2-yl)-1,3-dithiane (**28**)*

To a solution of 0.35 g (1.1 mmol) of compound **27** in ca. 15 mL of methanol was added a catalytic amount of *p*-toluenesulfonic acid monohydrate (0.02 g). The reaction mixture was stirred at room temperature for 24 h. Solid sodium carbonate was added to neutralize the acid. The mixture was filtered and the filtrate concentrated under reduced pressure. The residue was dissolved in ethyl acetate, dried over anhydrous magnesium sulfate, filtered, and the solvents were removed under reduced pressure. Purification was achieved by column chromatography using silica gel (100–200 mesh) and a mixture of petroleum ether and ethyl ether (9:1, v/v) as eluent to yield 0.20 g (90%) of compound **28**, $[\alpha]_D^{24}$ −42.6° (*c* 5.0, ethyl ether). This compound was characterized by the following spectral data. Infrared ($CHCl_3$): 900, 1005, 1050, 1280, 1380, 1460, 2970, 3500, and 3650 $cm^{-1}$; nmr ($CDCl_3$) δ: 0.87 (d, $J$ = 7 Hz, 3H), 1.08 (d, $J$ = 7 Hz, 3H), 1.02 (t, $J$ = 7 Hz, 3H), 1.7–2.3 (m, 8H), 2.38 (br s, 2H), 2.6–3.0 (m, 4H), and 3.4–3.8 (m, 3H); mass spectrum: (*a*) high resolution calcd. for $C_{13}H_{26}O_2S_2$: 278.1374 amu; found: 278.1358; (*b*) low resolution *m/e* (relative intensity): 41(8), 47(11), 83(36), 85(23), 147(100), 148(12), 149(13), and 278(12).

*(−)-α-Multistriatin (**1**)*

To a stirred solution of 0.43 g (1.6 mmol) of mercuric chloride and 0.17 g (0.80 mmol) of mercuric oxide in ca. 5 mL of dry acetonitrile was added a solution of 0.197 g (0.71 mmol) of dithiane **28** in 5 mL of anhydrous acetonitrile under nitrogen. The reaction mixture was refluxed for 4 h with stirring. After cooling, the reaction mixture was filtered and the solid washed with pentane. An equal amount of saturated brine solution was added to the filtrate and this solution was extracted several times with pentane. The organic extracts were washed with aqueous ammonium acetate, dried over anhydrous sodium sulfate, filtered, and the solvents were removed under reduced pressure. Kugelrohr distillation (bath temperature 110°C/20 Torr) of the crude produce gave 0.096 g (80%) of α-multistriatin (**1**), $[\alpha]_D^{24}$ −46.0° (*c* 1.0, hexane) (lit. (3) bp 90°C/20 Torr, bath temperature), and all the spectral data were identical to those reported (3–8). Gas–liquid chromatographic analysis showed a major component (> 98%). This was further identified by comparison with a sample of (±)-α-multistriatin kindly provided by Dr. J. W. Peacock; **1** was characterized by ir ($CHCl_3$): 895, 920, 1035, 1130, 1180, 1255, 1460, 2925, and 2980 $cm^{-1}$; nmr ($CDCl_3$) δ: 0.81 (d, $J$ = 7 Hz, 3H), 0.81 (d, $J$ = 7 Hz, 3H), 0.93 (t, $J$ = 7 Hz, 3H), 1.4–2.2 (m, 6H), 3.68 (m, 1H), 3.89 (m, 1H), and 4.20 (m, 1H); mass spectrum: (*a*) high resolution calcd. for $C_{10}H_{18}O_2$: 170.1307 amu; found: 170.1298, (*b*) low resolution *m/e* (relative intensity): 41(8), 43(6), 54(9), 55(22), 57(100), 71(20), 81(16), 96(25), 99(11), 128(25), and 170(19).

# Enzymes in organic synthesis. 22.[1] Effects of organic solvents on horse liver alcohol dehydrogenase-catalyzed reduction

J. Bryan Jones and Harold M. Schwartz

*Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1*

Received July 30, 1981

J. Bryan Jones and Harold M. Schwartz. Can. J. Chem. **60**, 335 (1982).

The effects have been evaluated of up to 30% (v/v) of *methanol*, *ethanol*, 2-propanol, tert-*butyl alcohol*, dimethylsulfoxide, sulfolane, *acetonitrile*, dimethylformamide, N-*methyl-2-pyrrolidone*, hexamethylphosphoramide, tetrahydrofuran, *dimethoxymethane*, *diglyme*, and *dioxane* on horse liver alcohol dehydrogenase-catalyzed reduction of the representative ketone cyclohexanone. The most viable solvents are those shown in italics on the above list.

J. Bryan Jones et Harold M. Schwartz. Can. J. Chem. **60**, 335 (1982).

On a étudié l'effet du *méthanol*, de l'*éthanol*, du propanol-2, du tert-*butanol*, du diméthylsulfoxide, du sulfolanne, de l'*acétonitrile*, du diméthylformamide, de la N-*méthyl pyrolidone-2*, de l'hexaméthylphosphoramide, du tétrahydrofuranne, du *diméthoxyméthane*, du *diglyme* et du *dixoanne*, à des compositions allant jusqu'à 30% sur la réduction de la cyclohexanone, comme substrat type, catalysée par la déhydrogénase de l'alcool du foie de cheval. Les solvants les plus efficaces sont en italique.

[Traduit par le journal]

## Introduction

The advantages of using enzymes as chiral catalysts in organic synthesis are becoming increasingly recognized (1*b*, *c*). However, many of the organic substrates of current or potential interest are hydrophobic in nature and are effectively insoluble in the aqueous solutions preferred for enzyme-catalyzed reactions. In such cases, it is usually necessary to add organic cosolvents to the enzyme-containing medium in order to attain at least a minimal solubility of the substrate. The problem can become acute when immobilized enzymes are used in flow systems (2), when complete solubility of the substrate becomes a requirement.

Significant proportions of organic cosolvents, which often exert deleterious effects on enzymic catalyses, may be needed to achieve the desired levels of substrate concentrations. While some organic cosolvent effects have been documented for a few enzymes (1, 3), few data are available on their influence on the oxidoreductase enzymes of greatest current asymmetric synthetic value. In this paper we report on the effect of a broad range of commonly used, water-miscible, protic and aprotic organic solvents on the horse liver alcohol dehydrogenase (HLADH[2])-catalyzed reduction of the representative organic ketone substrate cyclohexanone.

## Results

A range of common protic and aprotic water-miscible solvents of different polarities was evaluated. The solvents selected were: protic – methanol, ethanol, 2-propanol, and *tert*-butyl alcohol; aprotic – DMSO, sulfolane, acetonitrile, DMF, NMP, HMPA, THF, dimethoxyethane, diglyme, and dioxane. The effects of up to 30% of each cosolvent on HLADH-catalyzed reduction were evaluated using cyclohexanone as substrate. The reductions were performed in 0.1 *M* phosphate buffer pH 7.0 at 0.175 m*M* NADH and 0.2, 1, and 5 m*M* cyclohexanone concentrations. The relative activities observed, based on initial reaction velocities, are recorded in Table 1. The activity of the enzyme is seen to be progressively lowered to a greater or lesser extent by each solvent.

While not as complete as from a thorough kinetic study, the Table 1 data did permit satisfactory basic Lineweaver–Burk (3) plots to be derived. With the exception of the data obtained in 2-propanol, ethanol, DMF, HMPA, THF, and dioxane, the double reciprocal plots obtained were linear up to the highest cosolvent concentrations evaluated. The Lineweaver–Burk data indicated that the majority of the solvents were acting as reversible inhibitors of the noncompetitive or mixed type. Further analysis of the Table 1 data by the method of Dixon (3) permitted the $K_I$ values of most cosolvents to be estimated. These are summarized in Table 2.

[1]For Part 21, see ref. 1*a*. Abstracted from the Ph.D. thesis, University of Toronto (1979) of H.M.S.

[2]Abbreviations used: HLADH, horse liver alcohol dehydrogenase; NADH, nicotinamide adenine dinucleotide, reduced form; DMSO, dimethylsulfoxide; DMF, dimethylformamide; NMP, *N*-methyl-2-pyrrolidone; HMPA, hexamethylphosphoramide; THF, tetrahydrofuran.

[a]Determined in 0.1 *M* phosphate buffer pH (app) 7.0, 0.175 m*M* in NADH at 25°C.
[b]Relative to initial velocity of 100 in absence of organic cosolvent.
[c]Intermediate activities were observed at 2 and 3% organic solvent levels.

## Discussion

The solvents were chosen on the basis of their complete water miscibility, their ready availability, and their common use in organic chemistry. Representative solvents of both protic and aprotic character possessing varying protogenic, protophilic, or amphiprotic (4) properties were included. A broad range of polarity was selected using dielectric constant as the guide. No acyclic ketone solvents could be included because they are substrates, albeit often poor ones (1*b*).

Cyclohexanone was picked as the substrate

TABLE 2. $K_I$ values estimated for cosolvent inhibition of HLADH[a]

| Cosolvent | $K_I$(m$M$) |
|---|---|
| Methanol | 720 |
| Sulfolane | 600 |
| Acetonitrile | 210 |
| DMF | 15 |
| NMP | 130 |
| THF | 15 |
| Dimethoxyethane | 200 |
| Diglyme | 400 |

[a]Estimated from the Table 2 data using Dixon plots (3).

since its behaviour and properties are representative of those of organic interest (1*b*) and its mechanism of reduction is well documented (5, 6). Many ketone substrates of HLADH possess large Michaelis constants and have limited aqueous solubilities at high substrate concentrations. Consequently, kinetic analyses of ketone substrates are generally performed at concentrations well below $K_m$ levels. Concentrations in the 1 m$M$ range are the most common (1*f*). Thus cyclohexanone levels of 0.2, 1.0, and 5 m$M$, spanning this common concentration region, were evaluated, despite the fact that the $K_m$ of cyclohexanone is 17 m$M$ (5). A saturating concentration (0.175 m$M$) of the NADH coenzyme was used for each assay.

The initial reaction rates were measured for each cosolvent level in phosphate buffer at the pH optimum for reduction of 7.0. Although the pH of phosphate buffers is known to be affected by the addition of organic solvents (7), no corrections were made since, with the exception of HMPA, the apparent pH's of the solutions were not significantly altered by the levels of organic solvents used. For each solvent, the concentration was raised until the observed activity was $\lesssim$ 10% of that in aqueous solution. This level of activity represents the practical lower limit for effective preparative scale applications of HLADH. For the two solvents with the least deactivating effects, HMPA and diglyme, up to 30% (v/v) of organic solvents were required before this lower activity limit was reached (Table 1).

The assays were performed by monitoring the coenzyme absorbance change at 340 nm. With methanol, acetonitrile, HMPA, THF, and dioxane as cosolvents, a change in the 340 nm absorbance was observed on their addition to the assay medium even when cyclohexanone was omitted to preclude the enzyme-induced reaction. These effects are attributed to nucleophilic attack of NADH to form addition products (8) in the case of methanol and HMPA and to oxidation of NADH by the peroxides present in THF and dioxane.[3] The nature of the acetonitrile-induced NADH transformation is not known and was not investigated.[3] The relative rates of reduction cited in Table 1 have been corrected for these solvent effects.

As Table 1 shows, all the cosolvents evaluated are strongly inactivating towards HLDAH at their highest concentrations. However, at the lower organic solvent levels, HLADH retains significant activity in a number of cases. For example, with 5% of sulfolane, HMPA, or dimethoxyethane present, the enzyme retains >40% of its original catalytic power. In fact, when 1% of HMPA is added, the activity of HLADH is actually slightly enhanced, possibly due to induction of a catalytically more effective protein conformation (9).

Identification of a solvent as being protic or aprotic in character is clearly of no benefit with respect to predicting its effect on HLADH catalysis. Furthermore, while the two groups of solvents are arranged in Table 1 in order of decreasing dielectric constant, it is evident from the lack of correlation of inactivation power with polarity that this parameter is of little guidance value either.

Lineweaver–Burk and Dixon plot analyses of the Table 1 data show that the cosolvents are acting as reversible inhibitors, with most (Table 2) being of the noncompetitive (3) type. The linear Dixon plot obtained suggest the addition of only one molecule of cosolvent per subunit in the inactive complex. For the solvents omitted from Table 2, the Lineweaver–Burk or Dixon analyses gave nonlinear plots for the highest organic cosolvent concentration runs. However, the patterns for methanol, HMPA, and dioxane were strongly indicative of mixed (3) inhibition. The strong inactivations by DMSO, known to be a competitive inhibitor, and DMF are due to coordination of their respective functional groups with the catalytically vital active site zinc ion (10). From the $K_I$ values of Table 2, it is seen that none of the cosolvents is a particularly powerful reversible inhibitor, particularly when compared with the better competitive inhibitors such as pyrazoles, some of which have $K_I$'s as low as $10^{-6}$ m$M$ (11).

For the cosolvents acetonitrile, NMP, HMPA,

[3]Although freshly distilled solvents were used, rigorous steps to remove peroxides were not taken. The nonenzymic rate of NADH oxidation was much increased when undistilled THF and dioxane were employed. A referee, to whom we are grateful, has drawn our attention to the fact that Sanyal and Maren (University of Florida) have found that even doubly distilled acetonitrile contains trace quantities of cyanide. Nucleophilic attack of NADH by $CN^-$, in a manner analogous to that of methanol addition (8), may well occur with acetonitrile as solvent.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

and THF, increasing the substrate concentration affords some protection against inactivation. With methanol, ethanol, 2-propanol, dimethoxyethane, and diglyme, no such trend can be seen while in the presence of *tert*-butyl alcohol and sulfolane, the catalytic activity of the enzyme is reduced as the cyclohexane concentration is raised.

For HLADH-catalyzed reductions, the cosolvent with the least deleterious effect is clearly HMPA. Unfortunately, however, the aqueous solubilities of hydrophobic organic substrates are not greatly enhanced by this solvent. DMSO and DMF are not recommended since they eliminate 97% of the enzyme's activity even in 1% (v/v) solutions. The remaining Table 1 solvents should all be preparatively viable, with the best prospects being *tert*-butyl alcohol, acetonitrile, NMP, dimethoxyethane, diglyme, and dioxane.[4] With the ethereal solvents, care must be taken to remove peroxides prior to, and prevent their build-up during, the reaction. The results of the analogous study on solvent effects on HLADH-catalyzed oxidations will be reported shortly.

## Experimental

HLADH, prepared by the method of Roy and Nishikawa (17), was a gift from Hoffmann-La Roche. It is also available from Sigma. Enzyme stock solution was prepared containing 1 mg HLADH/mL of 0.1 *M* Tris buffers pH 7.4. NADH was purchased from Sigma. Cyclohexanone and all solvents were redistilled immediately prior to use, with dimethoxyethane and diglyme being distilled over potassium hydroxide. Dioxane was purified over stannous chloride prior to distillation over lithium aluminum hydride. Acetonitrile was distilled over calcium hydride. Kinetics were performed on a Unicam SP 1800 uv spectrophotometer equipped with a Unican AR 25 linear recorder.

*Relative rate studies*

All kinetic runs were carried out in 3 mL volume uv cuvettes at 25°C in 0.1 *M* potassium phosphate buffer pH 7.0, $1.75 \times 10^{-4}$ *M* in NADH, and with cyclohexanone concentrations of 0.2, 1.0, and $5.0 \times 10^{-3}$ *M*. The volume of buffer was varied so that addition of between 30 μL and 0.9 mL of cosolvent would bring the total volume to 2.95 mL. The solution was then allowed to equilibrate at 25°C in the spectrophotometer and the catalysis initiated by the addition of 50 μL of enzyme stock solution giving a final [HLADH] of $9.92 \times 10^{-8}$ *M*. The initial rates of reduction were determined by monitoring the rate of decrease in optical density at 340 nm. The rates, which are recorded in Table 1, were corrected for the solvent-induced rates when methanol, HMPA, acetonitrile, dioxane, and THF were used as cosolvents. The levels of organic solvents used had no effect on the pH of the buffer solutions except for HMPA. In 30% HMPA, the pH(app) of the solution was 7.6, but the reduction rates were unaltered when pH(app) 7.0 solutions (prepared from aqueous buffer pH 6.45) were used.

[4]The limited preparative-scale data in the literature are in accord with these recommendations. Use of up to 3% methanol or ethanol has been reported (1) as has up to 2.5% of dioxane (12–14). The inhibitory problems reported for dioxane (15) may have been due to the inadvertent presence of peroxides. Dimethoxyethane has been used successfully at 1.66% (v/v) (15); again the inhibitory properties reported in other work (16) could have been due to peroxide contaminants.

# Triplet energies of fumaronitrile and maleonitrile[1]

PO CHEONG WONG[2]

*Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6*

Received June 17, 1981

PO CHEONG WONG. Can. J. Chem. **60**, 339 (1982).

The triplet energies of fumaronitrile and maleonitrile measured by laser flash photolysis technique using the Herkstroeter–Hammond method are both 59 ± 2 kcal mol$^{-1}$. Our results show that these olefins are classical triplet energy acceptors for non-electron donating sensitizers. With electron donating sensitizers, quenching through a charge-transfer mechanism also occurs in benzene solution.

PO CHEONG WONG. Can. J. Chem. **60**, 339 (1982).

Les énergies du triplet du fumaronitrile et du maléonitrile, telles que mesurées par la technique de photolyse flash au laser en utilisant la méthode de Hekstroeter-Hammond, sont toutes les deux égales à 59 ± 2 kcal mol$^{-1}$. Nos résultats révèlent que ces oléfines sont des accepteurs classiques d'énergie de triplet pour des sensibilisateurs qui ne sont pas des donneurs d'électrons. Dans le cas des sensibilisateurs donneurs d'électrons, le piégeage par l'intermédiaire d'un mécanisme par transfert de charge se produit également dans une solution de benzène.

## Introduction

In recent years, there has been a substantial increase in the use of fumaronitrile (FN) and maleonitrile (MN) in photochemical reactions. Unfortunately, the mechanisms postulated for these reactions often require the knowledge of the accurate vertical triplet energies ($E_T$) of this olefin pair which are so far unavailable (1).

In our previous study (1*a*), we attempted to measure the triplet energies for FN and MN by the well-known Saltiel method (2). The estimated $E_T$'s were both ca. 50 kcal mol$^{-1}$ since the efficiency of sensitized isomerization dropped significantly when sensitizers of $E_T < 49$ kcal mol$^{-1}$ were used. In the present study, we employed a more accurate method developed by Hammond and Herkstroeter (3) to measure the triplet energies of these olefins. The quenching rates of the triplet sensitizers were measured by using the laser flash photolysis technique. The triplet energies thus measured are both about 9 kcal mol$^{-1}$ higher than our previous estimate.

## Experimental

Fumaronitrile (K & K) was freshly sublimed before use. Maleonitrile was prepared and purified as reported before (1*a*) (vpc pure). All the sensitizers were commercially available and were purified by either recrystallization or distillation. Benzene (Aldrich, Gold Label) was treated with concentrated sulfuric acid, washed, and neutralized before being distilled from calcium hydride. All the sample solutions were deaerated by nitrogen purging.

The laser flash photolysis equipment has been described in detail elsewhere (4). Briefly, pulses (337.1 nm, 8 ns, 1–10 mJ) from the Molectron nitrogen laser were used for sample excitation. The transient absorbances in the sample were monitored by using a detection system with nanosecond response at a preselected wavelength. Signals from the detector system were processed through a R7912 Tektronix transient digitizer and were analyzed by using a dedicated PDP 11 computer.

## Results and discussion

All our experiments involving triplet quenching have been carried out by using laser flash photolysis technique. Quenching of the triplets of a series of sensitizers in benzene by the olefins was observed by monitoring the triplet–triplet absorptions in the presence of various concentrations of the olefin (5). At sufficiently low excitation doses and sensitizer concentrations, all the triplets underwent clean first order decay. The pseudo-first order rate constants of triplet decay ($k_d = \tau_T^{-1}$) are linearly related to the olefin concentrations according to eq. [1].

$$[1] \quad k_d = k_d^0 + k_q[\text{olefin}]$$

Here $k_d^0$ is the rate constant of decay for the triplet in the absence of olefin and $k_q$ is the rate constant of quenching the triplet by the olefin. The reverse triplet energy transfer reaction is probably unimportant here due to the short lifetimes of the olefin triplets.

Figure 1 shows a typical plot according to eq. [1] and the corresponding triplet decay trace (insert). The quenching rate constants ($k_q$) obtained by using this approach are summarized in Table 1. Our $k_q$ values for quenching of high energy triplet sensitizers by fumaronitrile are in good agreement to those reported by Loutfy, Dogra, and Yip using

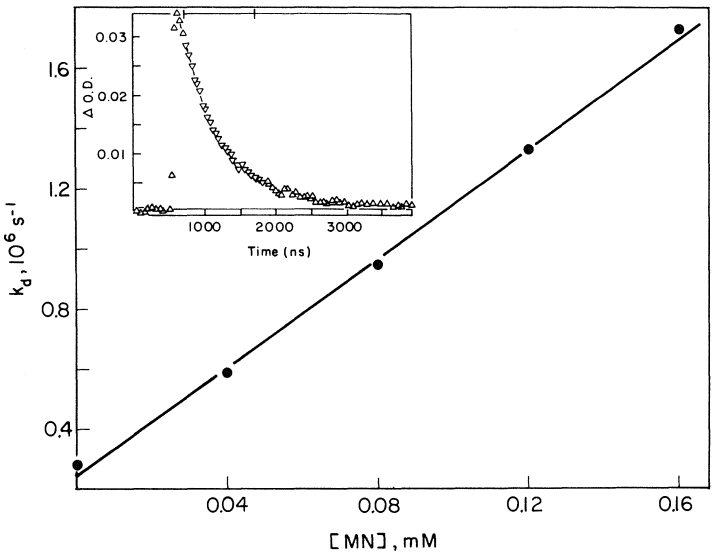

FIG. 1. Determination of $k_q$ for benzophenone in benzene, according to eq. [1]. Insert: trace obtained for maleonitrile, [MN] = 0.16 m$M$ (average of twenty laser shots).

TABLE 1. Quenching rate constants ($k_q$) of sensitizer triplets by fumaronitrile and maleonitrile in benzene

| Sensitizer | Triplet energy (kcal $mol^{-1}$) | $k_q$[a] | |
|---|---|---|---|
| | | Fumaronitrile | Maleonitrile |
| Acetone | 76.0 | $6.50 \times 10^{9}$[b] | — |
| Butyrophenone | 74.5 | $5.80 \times 10^{9}$[b] | — |
| Acetophenone | 74.0 | $4.10 \times 10^{9}$ | $5.46 \times 10^{9}$ |
| *p*-Methoxyacetophenone | 71.8 | $1.44 \times 10^{10}$ | $1.38 \times 10^{10}$ |
| Benzophenone | 69.2 | $7.95 \times 10^{9}$ | $9.10 \times 10^{9}$ |
| Phenanthrene | 62.0 | $7.17 \times 10^{9}$ | $8.38 \times 10^{9}$ |
| 2-Acetonaphthone | 59.0 | $4.55 \times 10^{8}$ | $6.73 \times 10^{8}$ |
| Chrysene | 57.3 | $5.41 \times 10^{8}$ | $6.08 \times 10^{8}$ |
| 1-Nitronaphthalene | 54.9 | $3.51 \times 10^{6}$ | $5.16 \times 10^{6}$ |
| 9-Fluorenone | 53.0 | $8.54 \times 10^{4}$ | $1.36 \times 10^{5}$ |
| Benzil | 50.9 | $3.80 \times 10^{4}$ | $3.25 \times 10^{4}$ |
| Pyrene | 48.2 | [c] | [c] |

[a]In $M^{-1}$ $s^{-1}$, at 25°C, with an error limit of ±10% for $k_q > 10^5$ and ±50% for $k_q < 10^5$.
[b]Taken from ref. 6.
[c]Too slow to be conveniently measured by our instrument.

flash emission technique (6). They claimed that the quenching of acetone, butyrophenone, and benzophenone by FN were purely triplet energy transfer since the quenching rates are faster when using sensitizers of higher $E_T$'s. This is also the general trend observed in Table 1. However, some exceptions are encountered for sensitizers with low oxidation potentials (good electron donors) e.g. *p*-methoxyacetophenone, benzophenone, and chrysene. The quenching rates for these sensitizers are higher than the nonelectron donating sensitizers with the same or even higher $E_T$'s. Such phenomenon has also been observed earlier by other workers (6, 7). The faster quenching rates are probably due to charge-transfer from the excited donors (sensitizers) to the ground state acceptors. Our observation is also in line with the electron-transfer quenching of triplets in aqueous acetonitrile solution (8).

The plot of log $k_q$ versus triplet energies of the sensitizers for both quenching by FN and MN (Fig. 2) are typically saturation curves as observed in the case of *trans*-stilbene (3). From Fig. 2, FN quenches efficiently all triplet sensitizers with $E_T$ greater than 60 kcal $mol^{-1}$. Therefore, the vertical triplet energy for FN is 59 ± 2 kcal $mol^{-1}$. With lower energy sensitizers, the quenching efficiency drops in accord with the Arrhenius equation (3).

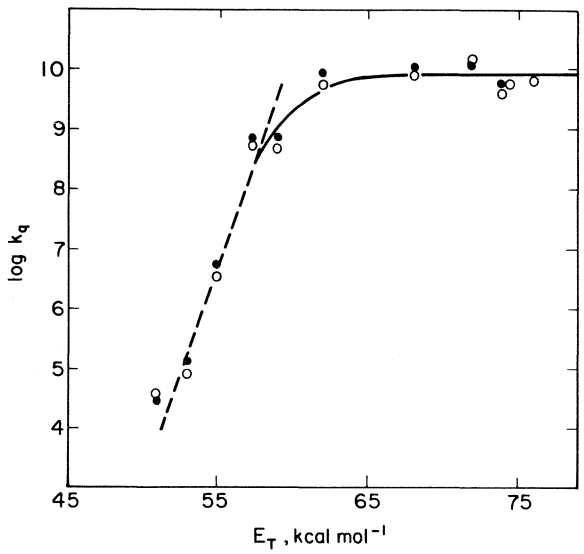

FIG. 2. Dependence of log $k_q$ for fumaronitrile (circles) and maleonitrile (dots) on the triplet energy of the sensitizers. The dotted line represents the slope expected on the basis of the Arrhenius equation.

When plotting the log $k_q$ vs. the sensitizer triplet energy, $E_T$, a slope of $+1/(2.30RT)$ (0.74 at 22°C) is predicted by the Arrhenius equation; a straight line with the slope has been drawn in Fig. 2. Our results in this region are uncomplicated by the charge-transfer mechanism because ketones with low $E_T$ and 1-nitronaphthalene are less likely to donate an electron than the aromatic hydrocarbon sensitizers. Since the slope of the plot in Fig. 2 matches closely the predicted line, this part of our data can be treated the same as the classical triplet quencher like *trans*-stilbene to extract $E_T$.

The behaviour of maleonitrile is very similar to FN as shown in Fig. 2. The triplet energy for MN thus estimated is also $59 \pm 2$ kcal mol$^{-1}$. Therefore, our earlier explanation (1*a*) for the Saltiel plot being a flat line for FN–MN is confirmed. By comparing the quenching rates listed in Table 1, the $k_q$'s for MN are consistently larger than those for FN by a factor of ca. 1.3, except for *p*-methoxyacetophenone. Assuming that the twisted triplet state has equal probability in decaying to FN and MN, the photostationary state concentration ratios can then be deduced from the inverse of the $k_q$ ratios (i.e. FN:MN = 57:43). The agreement between the observed and the photostationary state concentration ratios thus predicted is fairly good (1*a*). The assumption for the 1:1 decay is more or less justified since the heats of formation for FN and MN are almost identical (1*a*, 9).

The higher triplet energies found for FN and MN in the present study are in accord with most of the previous results and interpretations. For example, in the irradiation of *trans*-stilbene and fumaronitrile, there was very little MN formation and no CIDNP signal for MN (1*b*, *d*, *e*).

The triplet energy of *trans*-stilbene is now 9 kcal mol$^{-1}$ below the fumaronitrile triplet. Therefore, when back electron transfer occurs in the radical ion pair, the triplet of *trans*-stilbene will be formed exclusively which will account for the CIDNP signal of *cis*-stilbene upon isomerization.

# Conformational consequences of intramolecular hydrogen bonding by OH to the directional lone-pair of sulfur in derivatives of methyl phenyl sulfide, diphenyl sulfide, and diphenyl disulfide

TED SCHAEFER, SALMAN R. SALMAN[1], TIMOTHY A. WILDMAN, AND PETER D. CLARK[2]

*Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2*

Received August 7, 1981

TED SCHAEFER, SALMAN R. SALMAN, TIMOTHY A. WILDMAN, and PETER D. CLARK. Can. J. Chem. **60**, 342 (1982).

Complete spectral parameters for the $^1$H nmr spectra of 2-hydroxyphenyl methyl sulfide, **2**, 2-hydroxyphenyl phenyl sulfide, **3**, bis(2-hydroxy-3-*tert*-butyl-5-methylphenyl) sulfide, **4**, and bis(2-hydroxyphenyl) disulfide, **5**, are reported for $CCl_4$ solutions at 305 K. For **2** the parameters are consistent only with a conformation in which the C—S—C plane is roughly perpendicular to the aromatic plane. The conformational determinant is the OH···3*p* hydrogen bond which forces the mainly 3*p* orbital on sulfur into the benzene plane. In **3** a similar arrangement is found about the sulfur atom, with the phenyl group lying in the C—S—C plane and therefore perpendicular to the hydroxyphenyl plane (skew conformation). In **4** two OH···3*p* hydrogen bonds exist, yielding a gable (twist) conformation. Compound **5** exists in the axial conformation with probable $C_2$ symmetry, the CSSC dihedral angle and the CCSS torsion angles all being near 90°. For none of the compounds is there any evidence for OH···π interactions.

TED SCHAEFER, SALMAN R. SALMAN, TIMOTHY A. WILDMAN et PETER D. CLARK. Can. J. Chem. **60**, 342 (1982).

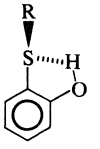
On rapporte les paramètres spectraux complets des spectres de rmn du $^1$H des composés suivants en solution, dans le $CCl_4$, à 305 K: sulfure de l'hydroxy-2 phényle et de méthyle, **2**, sulfure de hydroxy-2 phényle et de phényle, **3**, sulfure du bis(hydroxy-2 *tert*-butyl-3 méthyl-5 phényle), **4** et du disulfure de bis(hydroxy-2 phényle), **5**. Les paramètres du composé **2** sont uniquement en accord avec une conformation dans laquelle le plan C—S—C est approximativement perpendiculaire au plan du noyau aromatique. Le déterminant conformationnel est la liaison hydrogène OH···3*p* qui oblige l'orbitale principale 3*p* du soufre à passer dans le plan du benzène. Dans le cas du composé **3**, on trouve un arrangement semblable autour de l'atome de soufre avec le groupe phényle oriente dans le plan C—S—C et par conséquent perpendiculaire au plan de l'hydroxyphényle (conformation *gauche*). Deux liaisons hydrogènes OH···3*p* existent dans le composé **4**, donnant une conformation gable (twist). Le composé **5** existe dans une conformation axiale avec une symétrie probable $C_2$, l'angle dièdre CSSC et les angles de torsion CCSS étant tous deux pratiquement à 90°. On n'a pas pu établir l'existence d'interactions OH···π dans aucun de ces composés.

[Traduit par le journal]

## Introduction

The existence of intramolecular OH···π hydrogen bonds in 2-phenylphenol and in derivatives of 2-benzylphenol is attested by infrared spectroscopy (1) and by X-ray crystallography (2). Furthermore, infrared, ultraviolet, and nmr data in $CCl_4$ solution are interpreted in terms of predominant intramolecular OH···π bonding in *ortho* hydroxy derivatives of diphenyl sulfide and diphenyl disulfide (3). Apparently, the $^1$H nmr data are not useful in the deduction of the conformations adopted as a consequence of the OH···π bonds (3). A $^{13}$C nmr study concludes that $^{13}$C shifts are insensitive to the intramolecular hydrogen bonding but assumes the OH···π intramolecular interaction as proven (4).

It is interesting, therefore, that a detailed $^1$H nmr investigation of 2-hydroxythiophenol, **1**, in $CCl_4$ shows its conformation as one in which the SH bond prefers to lie perpendicular to the benzene plane (5). In the absence of the hydroxyl group the SH bond prefers the molecular plane by 3.2 kJ/mol (6), the mainly 3*p* orbital conjugating with the π system. Also, the hydroxyl group in phenol shows a preference of 14.6 kJ/mol for the benzene plane (7, 8*a*). The most favorable conformation, **1** (R=H), is therefore a consequence of a stereospecific electrostatic attraction between the directional 3*p* lone pair on the polarizable sulfur atom and the O—H dipole (5).



**1** R = H
**2** R = $CH_3$
**3** R = $C_6H_5$

When R=$CH_3$, the preferred conformation may still be determined by the OH···3*p* attraction. Furthermore, the latter may well play an important role in the conformations adopted for R = $C_6H_5$ and perhaps also for R = $SC_6H_5$.

In this paper, chemical shifts and spin–spin coupling constants are used in arguments about the conformations of **2**, **3**, bis(2-hydroxy-3-*tert*-butyl-

5-methyl) sulfide, **4**, and of bis(2-hydroxyphenyl) disulfide, **5**. No evidence for OH···π bonding is found.

## Experimental

*Compounds*

The 2-hydroxyphenyl methyl sulfide, **2**, was prepared from the 2-amino derivative (Parish) via diazotization (8*b*) and **3** was prepared as follows. A mixture of 2-bromophenol (5 g, 0.029 mol), benzenethiol (3.2 g, 0.029 mol), and sodium ethoxide (4.8 g, 0.06 mol) in dry dimethylformamide (100 mL) was heated under reflux for 8 h in a nitrogen atmosphere. The reaction mixture was cooled, poured into 2 *M* HCl solution (200 mL), and the resultant milky solution was extracted with $CH_2Cl_2$ (3 × 50 mL). The combined organic extract (diphenyldisulfide, 3.2 g, 50%, was isolated from these extracts after basic extraction) was washed with water (6 × 100 mL) and then was extracted with 2 *M* NaOH (3 × 30 mL). These basic extracts were acidified with 2 *M* HCl and the mixture was extracted with $CH_2Cl_2$ (3 × 30 mL). Evaporation of the washed ($H_2O$) and dried ($MgSO_4$) organic extracts left an oil which was distilled to give **3** (1.4 g, 20%) as a clear oil, bp 95–103°C at 0.5 Torr. No attempt was made to maximize the yield. $C_{12}H_{10}OS$ requires M 202, found $M^+$202. Compound **4** came from Aldrich and **5** was formed in the presence of air in a $CCl_4$ solution of **1**.

*$^1$H nuclear magnetic resonance measurements*

Samples were prepared as dilute solutions in $CCl_4$ and contained about 4 mol% of tetramethylsilane (TMS). The solutions were degassed by the freeze–pump–thaw method and were then flame-sealed into 5 mm od nmr sample tubes. Care (9) was taken to retard intermolecular hydroxyl proton exchange.

The $^1$H nmr spectra were recorded on an HA100 spectrometer in the frequency sweep mode at a probe temperature of 305 K. Calibrations of peak positions were performed by the reading of sweep and manual oscillator frequencies for markers placed at ca. 5 Hz intervals with a dispersion of 1 Hz/cm and sweep rates of 0.02 and 0.01 Hz/s. Repetition of this procedure and interpolation yielded peak frequencies with a typical rms deviation of ≤ 0.02 Hz.

## Results and discussion

*Spectral analyses*

These used the computer program LAME (10, 11). The derived $^1$H nmr spectral parameters for **2**, **3**, and **5** are presented in Table 1. The $C_6H_5$ spectrum of **3** also yields to analysis; all but a few of its peaks could be unequivocally identified. Figure 1 provides evidence for the high spectral quality obtained in this work.

*The conformation of 2-hydroxyphenyl methyl sulfide, 2*

In **2**, $^5J_m^{H_4,OH}$ is 0.45 ± 0.01 Hz (assuming an accuracy of three times the standard deviation in Table 1), whereas in 2-hydroxythiophenol it is 0.42 ± 0.01 Hz (5). As discussed in detail for the latter compound (5), this stereospecific coupling and the absence of significant coupling to H-5 and H-6 means that at least 95% of **2** exists in a conformation containing an OH···S hydrogen bond (compare **1**); and this interaction involves a negligible out-of-plane twist about the C—O bond.

The conformation about the C—S bond in **2** can be reasonably deduced as follows. Temperature-dependent photoelectron spectra imply that the

For personal use only.

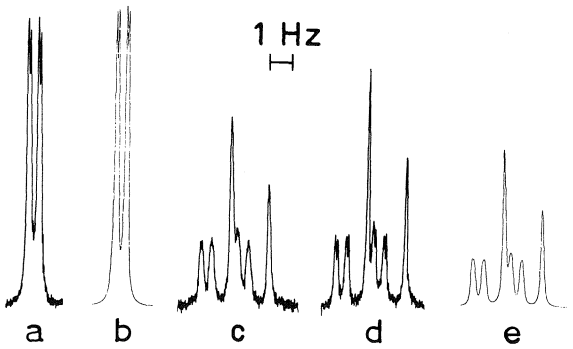

FIG. 1. In (a) is shown the hydroxyl proton spectrum of a 5 mol% solution of **2** in $CCl_4$ at 305 K and 100.001 MHz (centerband). In (b) the calculated spectrum assumes the parameters in Table 1 and a linewidth at half height of 0.10 Hz. *Parts* of the multiplets from H-3 *and* H-5 are displayed in (c), whereas (d) has the same region under conditions of methyl proton decoupling. The small coupling (0.11 Hz) of H-3 to the hydroxyl proton is apparent. In (e) the calculated spectrum assumes that H-3 and H-5 are also coupled to the methyl protons by 0.04 Hz (compare (c)). Altering this coupling by 0.02 Hz produced disagreement. It should be noted that the linewidths of all peaks from H-4 and H-6 were 0.10 ± 0.01 Hz ("spectrometer" or "sample" linewidth) and these protons are coupled to the methyl protons by ≤ 0.02 Hz.

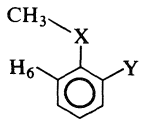
planar ($C_2C_1SC = 0°$) form of thioanisole is favored by 3.5 kJ/mol over the (probably) perpendicular conformer (12). This number is close to the twofold barrier in thiophenol, suggesting $3p\cdots\pi$ conjugation as a major contributor to the stability of the planar forms. MO calculations are also available (13, 14). Therefore it is reasonable that in both **1** and **2** the polar O—H bond seeks the directional lone pair on sulfur, twisting it into the molecular plane and causing the S—H and S—$CH_3$ bonds to move into the perpendicular plane. This conformation of **2** should have three consequences: (*i*) the chemical shift of the methyl protons should show evidence for a perpendicular form, (*ii*) as should the ring proton shifts, and (*iii*) no proximate coupling of $CH_3$ and H-6 protons should exist.

Taking the coupling evidence first, a comparison with *ortho* substituted anisoles, **6** (X = O), is in



**6**

order. Because of the relatively strong conjugation when X = O, the anisoles usually favor a conformation with a zero angle of twist (15, 16) about the C—O bond (planar). As a consequence (17, 18) a proximate coupling of −0.30 ± 0.02 Hz between the methyl protons and H-6 exists. INDO MO FPT calculations (19) reproduce this phenomenon (20), which has its origin in the close approach of the coupled nuclei and/or the relevant bond orbitals. The coupling is observed also for 2-hydroxyanisole, in which an intramolecular hydrogen bond exists (18).

Now, in *ortho* substituted thioanisoles, such a coupling also occurs (21). Contrary to ref. 21, there is a $^5J_o^{H_6,CH_3}$ of (−) 0.24 Hz in 2-methoxythioanisole and of −0.36 Hz in 2,5-dichlorothioanisole.[3] These numbers and their signs are again consistent with a proximate (through-space) coupling mechanism for a preferred **6** (X = S). However, in **2**, $^5J_o^{H,CH_3}$ is not larger than 0.02 Hz in magnitude (see Fig. 1) indicating that **2**, in which the hydrogen atoms containing the coupled protons are separated by more than their Van der Waals radii, and not **6** (X = S) is the stable conformation.

Furthermore, in **2** the methyl protons resonate at $\delta_{CH_3}$ = 2.27 ppm (Table 1). In 4-hydroxythioanisole, $\delta_{CH_3}$ is 2.41 ppm and is 2.44 ppm in thioanisole (22*a*). The upfield shift in **2** is analogous to that observed for the SH proton in the corresponding hydroxythiophenol (5) and can be attributed to the magnetic anisotropy of the benzene nucleus. Similar calculations to those in refs. 5 and 22*b*, taking reasonable geometries (5, 12) for **2** and **6** (X = S), predict an upfield shift of ca. 0.3 ppm for the methyl protons in **2** relative to **6** (X = S). This is an extreme value because in 4-hydroxythioanisole the relatively low barrier to rotation about the C—S bond implies that the methyl protons sample conformations other than **6**. Therefore an upfield shift of less than 0.3 ppm is anticipated. Accordingly, the observed shift of 0.14 ppm for the methyl protons is consistent with a perpendicular conformation of **2**.

Turning to the ring proton shifts, their equality in **2** and **1** is striking (Table 2). Because the latter exists as the perpendicular **1**, the equalities suggest the same conformation for **2**. A comparison with 2-hydroxyanisole is also useful. In Table 2, two sets of predicted shifts are given, based on the shifts observed for the corresponding phenyl derivatives. One set assumes that the $SCH_3$ and $OCH_3$ substituents do not contribute to the shifts in the two disubstituted compounds. The other set assumes additive contributions from both substituents in a compound. A comparison of the mean deviations between observed and calculated shifts, $\langle\Delta\delta\rangle$, implies that the $SCH_3$ group in **2** is no longer conjugated with the $\pi$ system of the benzene nucleus.

Of course, it is known (25, 26) that a simple

[a]In ppm relative to internal TMS; different concentrations will cause variations of ca. 0.02 ppm for various measurements.
[b]On an additive basis, $\delta_{C_6H_6} = 7.25$ in $CCl_4$.
[c]Assuming only OH contributes to the shifts.
[d]The mean deviation between observed and calculated shifts for all four protons.

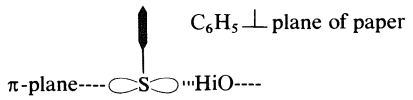
additivity scheme for the ring proton shifts in *ortho* disubstituted benzenes somewhat lacks predictive power, particularly for protons next to the substituents. Therefore, centering attention on $\delta_4$, i.e., for the proton placed *para* to $SCH_3$ or $OCH_3$, note that a shift to low field occurs in going from methyl phenyl sulfide to **2** whereas a high field shift occurs for the corresponding anisoles (OH causes a high field shift at a *meta* position). Accordingly, conjugation between the 3*p* orbital of the sulfur atom and the $\pi$ system has been decreased in **2**, but not between the corresponding oxygen orbitals and the $\pi$ system in 2-hydroxyanisole. In fact, a detailed comparison of $\delta_4$ in the various compounds suggests almost no conjugative electron donation by $SCH_3$ in **2**.

Note also the marked shift to low field of H-6, the proton *ortho* to the $SCH_3$ group in **2**. The so-called "heavy-atom" perturbation (27, 28) is accentuated in **2**. We attribute this shift to the proximity of the directional, mainly 3*p*, lone-pair in **2**. It should also be noted that H-6 in thiophenol or thioanisole resonates farther to low field than expected for a $\pi$ donor (compare phenol), also a "heavy-atom" effect, observable because the barrier to internal rotation in these two compounds is not large compared to thermal energies.

It seems clear that the ring proton shifts in **2** are compatible with a perpendicular conformation and not with a "planar" conformation as found for 2-hydroxyanisole. Taken together, the present $^1$H nmr data are consistent only with a relatively strong OH···3*p* hydrogen bond in **2**. Because no coupling between the hydroxyl proton and H-6 is observed, the perpendicular conformer **2** must exist to the extent of at least 95% in $CCl_4$ at 305 K. The photoelectron spectrum and a crystal structure of **2** should confirm the $^1$H nmr work. The photoelectron spectrum of thioanisole (29) is describable in terms of a 3*p* model for the delocalization of the sulfur lone pair.

*2-Hydroxyphenyl phenyl sulfide, 3*

The chemical shift of the hydroxyl proton, 6.36 ppm, and its coupling to H-4, 0.47 Hz (Table 1), imply the same conformation at sulfur and oxygen as in **2**, as does the large $\delta$ value for H-6. The four ring protons are all deshielded relative to the corresponding protons in **2**. The largest deshielding occurs for H-4, the proton most distant from the phenyl ring. If the deshielding for **3** relative to **2** arises from the magnetic anisotropy of the phenyl ring, the *only* conformation consistent with the observed $\Delta\delta_3 \sim \Delta\delta_5 < \Delta\delta_4$ is one in which the phenyl group lies roughly perpendicular to the substituted benzene plane, i.e., with a conformation **7**. For this conformation, the anisotropy model



**7**

and reasonable CSC angles and C—S bond lengths (30, 31) predicts $\Delta\delta_4 > \Delta\delta_3 = \Delta\delta_5$, with $\Delta\delta_4 \sim 0.07$ ppm. $\Delta\delta_{OH}$ is calculated as 0.04 ppm. Any other conformation, reached by twisting about the $C_1$—S bond in **7**, involves striking contradictions between model and observation.

In **7** the 3*p* orbital can conjugate most effectively with the second phenyl $\pi$ system and may be favored (by about 3 kJ/mol) for this reason. Because of partial delocalization into the second phenyl, the OH···3*p* bond may also be somewhat weaker than in **2** and could account for the observed shift to high field of 0.14 ppm in **3**. An empirical relationship (32) suggests this weakening as only 0.4 to 0.8 kJ/mol. The partial delocalization

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

might also help to account for the $\Delta\delta_6$ of 0.06 ppm (calculated as 0.10 ppm). Of course, **7** is an idealized structure. The real conformation undergoes torsional motions, among others. Nevertheless, no other conformation is expected to display the low field shifts given in Table 1.

A further test involves $\delta_o$, $\delta_m$, and $\delta_p$ in the $C_6H_5$ group. These are 6.996, 7.133, and 7.039 ppm, respectively, from a full analysis (rms error of 0.014 Hz). Diphenyl sulfide itself may have $C_s$ or $C_2$ symmetry (30) or a twisted (33) conformation. The experimental uncertainties imply marked freedom of motion about the C—S bonds. In $CS_2$ solution, $\delta_o$, $\delta_m$, $\delta_p$ are 7.264, 7.235, 7.170 ppm (33). The striking shift in **3** is $\delta_o$, which now lies at highest field. Indeed, structure **7** places an *ortho* proton into the shielding region of the other benzene ring, so that, on average, the anisotropy model predicts an upfield shift of ca. 0.5 ppm. The observed value relative to diphenyl sulfide is 0.27 ppm. The $C_6H_5$ group is constrained to **7** by only 3 kJ/mol. Therefore it will sample other conformations as well and these have lower anisotropy shifts for the *ortho* protons. Considering the approximate nature of the anisotropy model and the $CS_2$ solvent for diphenyl sulfide, the agreement is satisfactory. Further, $\Delta\delta_m$ is calculated as 0.12 ppm (observed 0.10 ppm) and $\Delta\delta_p$ as 0.05 ppm (observed 0.13 ppm). $\Delta\delta_p$ is independent of the orientation about the $C_1$—S bond. Therefore the additional shift to high field is very likely due to the enhanced $3p,\pi$ conjugation relative to diphenyl sulfide. In fact, in benzenethiol $\delta_p$ is 7.05 ppm (Table 2).

Taken together, the shift and coupling data for **3** firmly imply **7** as the low energy conformation in solution, with the provision that the $C_6H_5$ group is relatively weakly constrained in its motion about the C—S bond. Conformation **7** is usually called a skew conformation (34).

*Bis(2-hydroxy-3-*tert*-butyl-5-methyl) sulfide, 4*

This compound was examined for two reasons. First, its infrared spectrum has been interpreted in terms of two different intramolecular OH···π bonds, together with simultaneous OH···π and OH···O interactions for one hydroxyl group and out-of-plane twisting of both hydroxyl groups (3). Second, these interpretations have been used in $^1H$ and $^{13}C$ nmr studies of related compounds (4).

The most interesting spectral parameters are $\delta_{OH} = 6.42_0$ ppm (3 mol% in $CCl_4$) and $^5J_m^{OH,H_4} = 0.59 \pm 0.04$ Hz (three times the standard deviation). The magnitude of $^5J_m$ is that expected for a trisubstituted phenol (35) and indicates a conformation in which the OH···S bond predominates. No coupling between the hydroxyl and methyl protons was observed. A finite coupling is expected if **4** takes on conformations in which the hydroxyl groups are rotated away from the planes of their respective benzene rings. Again, the hydroxyl proton shift agrees with an OH···S hydrogen bond (compare numbers in Table 1) but not with extensive OH···π interaction. In comparison, the analogous parameters (36) for 2-benzyl-4-chlorophenol imply an intramolecular OH···π interaction of about 1 kJ/mol in free energy, but note that there $\delta_{OH}$ is 4.43 ppm (3 mol% in $CCl_4$ and 305 K).

Characteristic broadening of the H-4 peaks ($6.94_5$ ppm) by small couplings with the *tert*-butyl protons gave an unequivocal assignment of the ring proton shifts with H-6 at $6.90_3$ ppm. In a 2 mol% solution in $CCl_4$ of 2-*tert*-butylphenol, $\delta_3$ is 7.16 ppm and $\delta_5$ is 6.94 ppm. A methyl group causes an upfield shift of 0.18 ppm at an *ortho* position (25). In the absence of sulfur, additivity of shifts predicts $\delta_4$ as 6.98 and $\delta_6$ as 6.76 ppm in **4**. In the gable (butterfly) conformation, in which two OH···3*p* interactions exist (on either end of the 3*p* orbital), the anisotropy of the phenyl groups should cause $\delta_6 = 6.89$ and $\delta_4 = 6.93$ ppm, effectively identical to the observed shifts.[4]

In other words, the present model implies that the low-field shift caused by a coplanar 3*p* orbital at an *ortho* proton, as discussed above for **1** to **3**, is *absent* if the 3*p* orbital is involved in two OH···3*p* hydrogen bonds. This implication is intriguing in terms of chemical shift theory (note that the electronegativity of a $C_6H_5S$ group is thought to be 2.0, i.e., probably the same as that of hydrogen (30)). A first test demands a structure determination of **4** or of 2,2′-dihydroxydiphenyl sulfide.

The detailed $^1H$ nmr data provide no evidence for other than OH···S preferences in **4**.

*Bis(2-hydroxyphenyl) disulfide, 5*

The conformations of diphenyldisulfides have received much experimental (37–39) and theoretical (40–43) attention. Here we take a simple view designed to rationalize the observed chemical shifts in terms of one conformation.

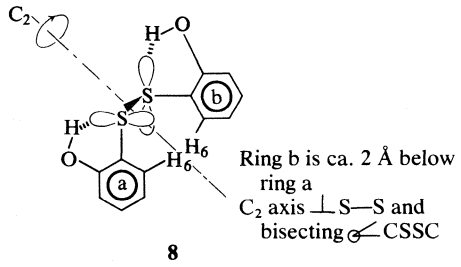
The dihedral angle in $H_2S_2$ is ca. 90° and the HSS angle is also near 90° (44). The filled 3*p* lone pair electrons minimize their mutal repulsion by a twist of 90° to give the observed conformation. If hydrogen atoms are replaced by phenyl groups, the CSSC dihedral angle remains near 90° (38, 45, 46). Furthermore if $3p,\pi$ conjugation is to be maintained, then the CCSS torsion angles are favored at 0°, yielding the observed *equatorial* (47) conformation. In the latter, an *ortho* proton again lies near a

[4]If $\delta_{OH} = 6.03$ ppm from **1** is taken as a reference, the anisotropy model predicts $\delta_{OH}$ as 6.35 ppm (6.42 observed).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

3*p* orbital of the *other* $SC_6H_5$ fragment. The closest H···S distance of about 2.3 Å is much smaller than that of 3.0 Å in **2**. In terms of the discussion in previous sections, this proximity accounts for the large $\delta_o$ of 7.44 ppm in equatorial diphenyl disulfide (the phenyl rings reorient rapidly about the C—S bonds and S—S bonds on this shift scale).

Now, for **5**, $\delta_{OH}$ is 6.13 ppm (similar to the 6.04 ppm in 2-hydroxythiophenol) and $^5J_m^{OH,H_4}$ is 0.48 Hz. Intramolecular hydrogen bonds exist, therefore. The equatorial form of **5** would imply hydrogen bonding to the diffuse 3*s* lone pair on the *ortho* sulfur atom. However, a further twist of 90° about each C—S bond produces the *axial* form in which OH···3*p* bonds can exist. In this form **8**, the hydroxyl groups lie on one side of the molecule, which brings the H-6 protons close to the neighbouring rings but outside each other's contact distance. 3*p*,π conjugation is largely lost and there is a $C_2$ axis perpendicular to the S—S bond.



**8**

The anisotropy model for the benzene ring and reasonable geometry about sulfur (37) predicts that for **8**, O—H, H-3, and H-4 should shift (downfield) by 0.09, 0.04, and 0.02 ppm, respectively; whereas H-5 and H-6 should shift (upfield) by −0.03 and −0.36 ppm, respectively. In the above order, the observed shifts relative to **1** are 0.10, 0.04, 0.10, −0.03, and −0.22 ppm. Considering that **8** is not rigid and that the reference compound is not ideal, the agreement is satisfactory. A number of other possible conformers produced much larger discrepancies between observed and calculated shifts. Anisotropy models are semiquantitative at best, of course. The present results provide *no* evidence for OH···π interactions (3). It is of interest that the corresponding diamino compound has this conformation in the crystal, i.e., axial with the amino groups on the same side of the molecule (38, 45). From our viewpoint, this conformation is expected. Again, the corresponding dinitro compound has an equatorial form (48), as anticipated because of the absence of a stereospecific hydrogen bond and probably also because the nitro groups enhance the 3*p*,π conjugation (37, 49).

3,3′-Dihydroxy-2-pyridyl disulfide adopts the equatorial conformation (37) in the crystal. There is one *inter*molecular OH···N hydrogen bond and the other hydroxyl group in the molecule is not involved in hydrogen bonding. Conformation **8** would bring the (negatively charged) nitrogen atoms to within about 3 Å (they replace the C—$H_6$ bonds in **5**). It is quite possible that the N,N electrostatic repulsion, together with the lack of 3*p*,π conjugation, in a conformation **8** is higher in energy than the observed conformation in which 3*p*,π conjugation is retained and one OH···N intermolecular hydrogen bond occurs.

The model used for all the molecules in this paper distinguishes between mainly *s* and mainly *p* type lone-pair orbitals on sulfur. The model rationalizes the approximately perpendicular conformation deduced for **1** (5). The pressure to keep 3*s* orbitals fully occupied (50) supports the simple viewpoint taken in the present discussion. Furthermore, equilibrium bond electron densities can be bent away from the corresponding internuclear axes in a variety of molecules (51). There is also considerable evidence for a nonspherical shape of sulfur in crystals, giving rise to directional preferences in interactions with divalent sulfur (52). In particular, electrophiles approach sulfur in a plane roughly perpendicular to the X—S—Y plane.

The present model is similar to one which would be based on canonical molecular orbitals obtained from, say, single-determinant molecular orbital calculations. An alternative approach would invoke localized molecular orbitals giving equivalent, roughly $sp^3$, lone-pairs on sulfur. This approach could not account in a straightforward way for the observed conformation of **1**, for example, simply because of the equivalency of the lone-pairs (see ref. 53 for a nice discussion of canonical and localized molecular orbitals). An X-ray investigation of **2** would decide the quality of the model used in this paper.

## Acknowledgments

We are grateful to Dr. L. Kruczynski and Dr. R. Laatikainen for their help with the synthesis of 2-hydroxyphenyl methyl sulfide and with the analysis of the phenyl $^1$H nmr spectrum of 2-hydroxyphenyl phenyl sulfide. The Natural Sciences and Engineering Research Council of Canada gave essential financial support. We thank a referee for useful criticism.

Received June 9, 1981

JOSEPH ARMAND, CLAUDETTE BOIS, MICHÈLE PHILOCHE-LEVISALLES, MARIE-JOSÉ POUET, and MARIE-PAULE SIMONNIN. Can. J. Chem. **60**, 349 (1982).

It is shown by X-ray crystallography that the 1,4-dihydropyrazine skeleton of 1,4-diacetyl-1,4-dihydro-2,3-diphenylpyrazine **2** has a boat shape. The C(2)–C(3) and C(5)–C(6) double bonds are localized; therefore **2** does not exist as an azahomoaromatic entity with 6 electrons delocalized on the ring and two electrons localized on one nitrogen atom. In the solid state **2** is in a *Z,Z* conformation. The $^1H$ and $^{13}C$ nmr spectra indicate that **2** exists as an equilibrium mixture of *Z,E*, *E,E*, and *Z,Z* conformers in $CD_2Cl_2$ at −80°C. An unambiguous assignment of the different sets of signals has been obtained by nOe experiments performed at −80°C. The conformer distribution is the following: 65% (*Z,E*), 22% (*E,E*), and 13% (*Z,Z*). The relatively low barrier to rotation about the carbonyl nitrogen bonds of the two amide groups ($\Delta G_c^{\neq} \sim 13$ kcal/mol) is in line with a rather large C—N bond length (~1.37$_5$ Å) in the crystal.

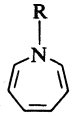
---

JOSEPH ARMAND, CLAUDETTE BOIS, MICHÈLE PHILOCHE-LEVISALLES, MARIE-JOSÉ POUET et MARIE-PAULE SIMONNIN. Can. J. Chem. **60**, 349 (1982).

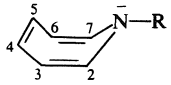
Les données cristallographiques obtenues par diffraction des rayons X montrent que le noyau de la 1,4-diacetyl-1,4-dihydro-2,3-diphenylpyrazine **2** se présente sous la forme d'un bateau sensiblement symétrique. Les doubles liaisons C(2)–C(3) et C(5)–C(6) sont localisées: **2** n'a donc pas une structure de type azahomoaromatique comprenant un ensemble de 6 électrons π délocalisés et une paire d'électrons localisée sur un atome d'azote. A l'état solide **2** adopte une conformation *Z,Z*. Les spectres rmn $^1H$ et $^{13}C$ de **2** indiquent que les trois conformations *Z,E*, *E,E* et *Z,Z* coexistent à −80°C dans $CD_2Cl_2$. Des expériences de nOe effectuées à −80°C ont permis d'attribuer sans ambiguité les différents signaux à chacun de ces conformères. Leurs populations sont respectivement de 65% (*Z,E*), 22% (*E,E*) et 13% (*Z,Z*). La barrière à la rotation autour des liaisons carbone–azote des groupes amides est relativement faible ($\Delta G^{\neq} \sim 13$ kcal/mol), en accord avec la longueur des liaisons C—N (~1.37$_5$ Å) dans le cristal.

## Introduction

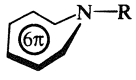
The replacement of an ethylene group of cyclooctatetraene by a >N–R group leads to derivatives of 1-*H*-azepine which are potential 8π-electron systems with antiaromatic character (1). But, like cyclooctatetraene (2, 3), these compounds are not planar. X-ray crystallographic study of **1** has shown (4) that the N(1), C(4), and C(5) atoms lie above the best plane through the atoms C(2), C(3), C(6), and C(7) (structure **1***a*). The double bonds are localized at C(2)–C(3), C(4)–C(5), and C(6)–C(7). These results show that 1-*H*-azepines exhibit little propensity to exist as an azahomoaromatic entity (structure **1***b*).



**1**, R = $SO_2C_6H_4pBr$

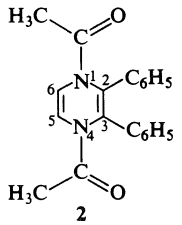


**1***a*

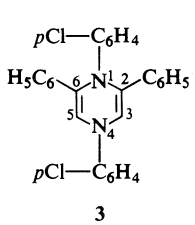


**1***b*

Replacing two opposite ethylene groups in cyclooctatetraene by two N—R groups yields derivatives of 1,4-dihydropyrazine which are also potential 8π-electron systems. 1,4-Dihydropyrazines are very easily oxidized and cannot in general be isolated (5). Only a few stable *N,N'*-substituted derivatives are known: *N,N'*-dialkyl- and *N,N'*-diaryl-1,4-dihydro-2,6-diphenylpyrazines (e.g. **3**) (6) and 1,4-diacetyl-1,4-dihydro-2,3-diphenylpyrazine **2** (7).



**2**



**3**

An X-ray structural analysis of **3** has already been made (8). Its skeleton was found to be an

unsymmetrical boat and this led Schmidt *et al.* (9) to propose that its structure would be similar to that of **1***b*, namely that the 8π system would be divided into two parts, a delocalized 6π system and a lone pair localized on a nitrogen. This asymmetry could be caused by the two phenyl groups on carbon atoms α to one nitrogen.

We report in the first part of this paper an X-ray structure analysis of **2**. This molecule was selected since, if Schmidt's hypothesis is correct, the skeleton of **2** should be a half-boat because it has a plane of symmetry perpendicular to the N–N axis. On the other hand, it is possible that the presence of the electron-withdrawing substituents on the nitrogen atoms might cause the skeleton to be nearly planar, i.e. antiaromatic in character.

In the second part of this paper we report a conformational study of **2** in solution using $^1H$ and $^{13}C$ nmr. While an extensive study of monoamides (10) and a conformational study of diacetamide (11) have been made, there is to our knowledge no report regarding *N,N'*-diacetyl derivatives of *N*-heterocyclic compounds. Compound **2** appears to be a good model for such studies since there is no apparent steric interaction with the acetyl groups and we have been able to compare the solid state and solution results.

## 1. Structure in the solid state

Tables of atomic positions, bond lengths, bond angles, of some selected dihedral angles, of observed and calculated structure factor amplitudes, and of temperature factors were put on deposit.[1] Figures 1 and 2 give some crystallographic results of **2** and **3**. Figures 3 and 4 are ORTEP diagrams of the crystal structure of **2**.

The carbon atoms of the 1,4-dihydropyrazine ring are nearly coplanar, as indicated by the dihedral angle C(6)C(5)C(3)C(2) (2.6°).

The conformation of the 1,4-dihydropyrazine ring corresponds to a boat form displaying a good mirror symmetry as shown by the values of the α and β angles (Fig. 2) as well as by the similarity of the N(1)C(2) and N(4)C(3), N(1)C(6) and N(4)C(5) distances. In the same way, the values of the C(3)C(2)N(1), C(2)N(1)C(6), and N(1)C(6)C(5) angles are nearly equal to that of the C(2)C(3)N(4), C(3)N(4)C(5), and N(4)C(5)C(6) angles. Points N(1),A, B,N(4) are nearly coplanar, this mediating plane is nearly perpendicular to the C(2)C(3)C(5)C(6) plane (angle equal to 88.5°).

[1]A complete set of tabular data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

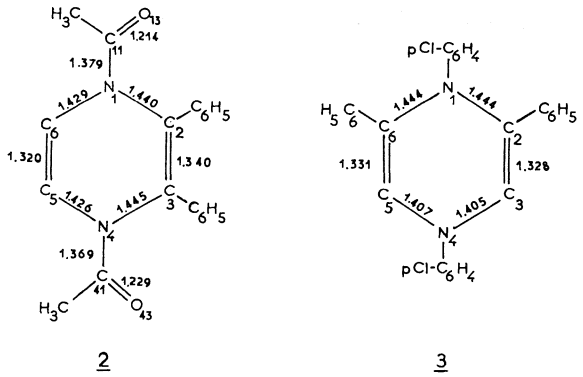

FIG. 1. Bond lengths within **2** and **3**.

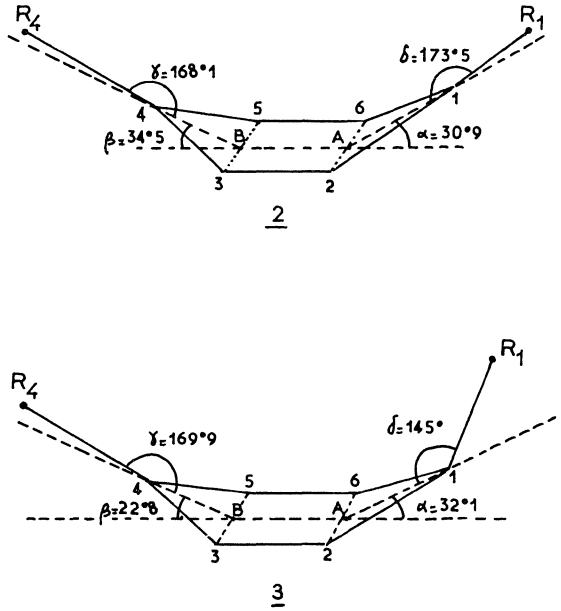

FIG. 2. Angles α, β, γ, and δ within **2** and **3**.

Both phenyl rings make an angle with the mean C(2)C(3)C(5)C(6) plane which precludes any conjugation with the C(2)C(3) double bond. Thus the dihedral angle is 34.2° in the case of $\phi_2$ and 80.3° in the case of $\phi_3$. The angle between $\phi_2$ and $\phi_3$ is 73°.

As could be expected for this diamide, atoms N(1), C(11), C(12), and O(13) on one side and N(4), C(41), C(42), and O(43) on the other side are coplanar. The angles between these planes and the mediating plane of the cycle N(1)ABN(4) are respectively 78.9° and 85.5°. As shown in Fig. 3, both amide groups present a *Z* conformation. These conformations correspond to a minimum of steric hindrance as the methyl groups lie on the less hindered side of the molecule. For each of these

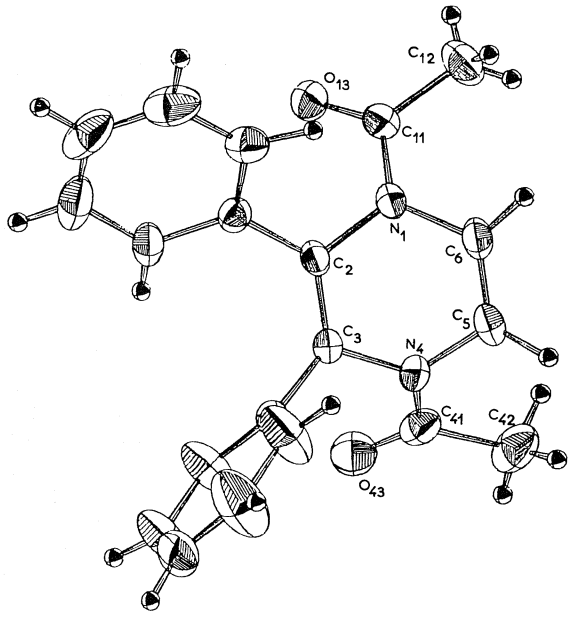

FIG. 3. ORTEP diagram of the crystal structure of **2**.

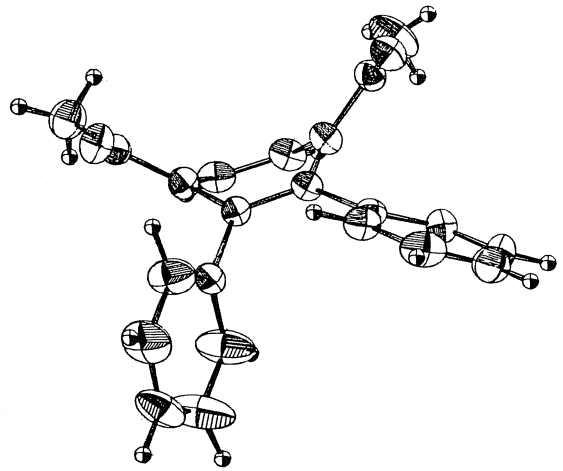

FIG. 4. ORTEP diagram of the crystal structure of **2**.

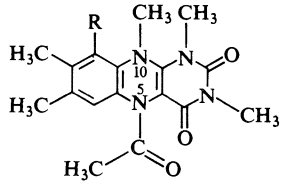
amide groups the C—O length is slightly shorter than for the open chain alkylamides (~1.24 Å), but the C—N length is somewhat longer (~1.32 Å). The large values of the γ and δ angles (Fig. 2) should be noticed, together with the valency angles around N(1) and N(4) implying a substantial $sp_2$ character for the nitrogen atoms (C(2)N(1)C(11): 121.8°; C(6)N(1)C(11): 122.6°; C(2)N(1)C(6): 115.1°; C(3)N(4)C(41): 121.2°; C(5)N(4)C(41): 123.0°; C(3)-N(4)C(5): 114.3°).

*Discussion*

The main feature of this structure is that the skeleton of this heterocycle is not planar as had been supposed (7). Its nearly symmetrical boat shape rules out the hypothesis of the separation of the eight π electrons into 6 electrons delocalized on the ring and two electrons localized on one of the nitrogen atoms. This hypothesis is also disproved by the values of the C(2)C(3) and C(5)C(6) bond length. In the case of **2** as well as in the case of **3** a mean value of 1.33 Å is obtained; these values correspond to localized ethylenic bonds as the C=C length is 1.34 Å in ethylene and 1.35 Å in cyclooctatetraene (12).

Structures **2** and **3** are thus similar to that of azepine **1** and cyclooctatetraene. They feature localized double bonds and absence of conjugation with the lone pairs of the nitrogen atoms. The difference between the α and β angles in **3** may be assigned to the disymmetry of the molecule (two hydrogens in the 3- and 5-positions, two phenyls in the 2- and 6-positions). The 1,4-dihydropyrazines escape the instability related to antiaromaticity in the same way as cyclooctatetraene and 1-*H*-azepines through the nonplanarity of the heteroaromatic ring.

Another interesting point should be brought forward. The dihedral angle between the mean N(1)C(2)C(3)N(4) and N(1)C(5)C(6)N(4) planes is equal to 38.2° and it has been shown that the 1,5-dihydroalloxazines **4** and **5** present an angular shape (13, 14), the analogous angles being 32° and 35.5° respectively. In the case of **4**, it has been



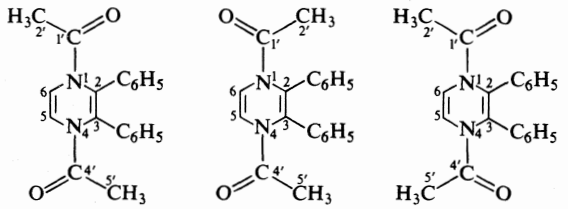
**4** R = H **5** R = Br

shown that the observed interannular angle is at an energy minimum (13). The central ring of **4** and **5** is a 1,4-dihydropyrazine; a good agreement is thus observed between the values of this angle for compounds **2**, **4**, and **5**.

### 2. Conformational study in solution

A variable temperature $^1H$ and $^{13}C$ nmr study of 1,4-diacetyl-1,4-dihydro-2,3-diphenylpyrazine **2** was performed to determine which of the three possible conformers *Z,E*, *E,E*, or *Z,Z* is preferred in solution.

Symmetry arguments allow us to predict that two distinct methyl signals should be observed for the *Z,E* conformer, while only one methyl signal is expected for each of the *E,E* and *Z,Z* conformers. Similarly, the ethylenic protons H(5) and H(6) are



*Z,E* *E,E* *Z,Z*

anisochronous in the *Z,E* conformation and may give rise to an AB system, while they become isochronous in the *E,E* and in the *Z,Z* conformers and their resonance should be a singlet in both cases. Moreover, the aromatic rings bonded to the carbons C(2) and C(3) lie out of the plane of the double bond C(2)–C(3) and it can be anticipated that the $^1$H methyl signal of the *E,E* conformer and one of the methyl signals of the *Z,E* conformer will be shielded by the aromatic ring current.

*$^1$H nuclear magnetic resonance spectra*

At ambient probe temperature (31°C), the 100 MHz $^1$H spectrum of **2** dissolved in $CD_2Cl_2$ showed only one methyl signal (δ 1.80 ppm) and one singlet for the ethylenic protons (δ 6.60 ppm). This spectrum indicates that rotation around the N—CO bond is fast on the nmr time scale at 31°C. Broadening of the signals occurred on decreasing the temperature and a well resolved spectrum was obtained at −80°C. The methyl resonance was split into four lines, two of which had the same intensity, thus showing that the three conformers *Z,E*, *E,E*, and *Z,Z* coexist at −80°C. A five-line pattern was observed at low field instead of the six lines expected for the resonances of the ethylenic H(5)/H(6) protons in the three conformers, i.e. a singlet was superimposed on the low field component of the AB system due to the *Z,E* conformer.

Nuclear Overhauser enhancement (nOe) experiments were performed at −80°C to identify the ethylenic protons which are located spatially close to a methyl group, i.e. in a *Z* conformation. Successive irradiation of the two upfield methyl signals (δ 1.59 and 1.62 ppm) did not produce any detectable enhancement of the ethylenic resonances, while irradiation of the two downfield methyl signals (δ 2.15 and 2.17 ppm) resulted respectively in about 15% and 28% enhancement of the upfield part of the ethylenic resonances. This result indicates that the two methyl groups at low field are *syn* to the upfield ethylenic protons (*Z* conformation) and allows an unambiguous assignment to be made of the low temperature spectrum (Table 1).

The relative populations of the three conformers were obtained by integration of the ethylenic and of the methyl signals at −80°C: *Z,E*: 65%; *E,E*: 22%; *Z,Z*: 13%.

TABLE 1. The $^1$H nmr parameters of the *Z,E*, *E,E*, and *Z,Z* conformers of **2**[a]

| Conformer | $\delta_{H(5)}$ | $\delta_{H(6)}$ | $\delta_{H(2')}$ | $\delta_{H(5')}$ | $^3J_{H(5)H(6)}$ |
|---|---|---|---|---|---|
| *Z,E* | 7.05 | 6.58 | 2.15 | 1.59 | 4.5 |
| *E,E* | 7.07 | | 1.62 | | |
| *Z,Z* | 6.54 | | 2.17 | | |

[a] Temperature −80°C, solvent $CD_2Cl_2$. Chemical shifts in ppm from internal TMS; *J* in Hz. Averaged chemical shifts at ambient probe temperature: H(5)/H(6): 6.80; H(2')/H(5'): 1.80 ppm.

Upon increasing the temperature, a reversible coalescence of the methyl signals and of the ethylenic lines was observed. Three coalescence temperatures were determined for the coalescence of the methyl signals: −38°C for the two lowfield resonances ($\Delta\nu$ = 1.8 Hz), −29°C for the two high-field resonances ($\Delta\nu$ = 3.1 Hz), and −2°C for the two partially coalesced signals ($\Delta\nu$ = 52.5 Hz). A free energy of activation $\Delta G_c^{\ddagger} \sim 13$ kcal/mol was calculated from these three sets of data, using the approximate Gutowsky–Holm formula (15).

*$^{13}$C nuclear magnetic resonance spectra*

At ambient probe temperature, the 25.17 MHz proton noise decoupled $^{13}$C spectrum of **2** was averaged and the assignment of the observed eight lines was straightforward. Below −50°C the rotation around the N—CO bonds becomes slow enough to allow an individual set of signals to be observed for each of the three conformers. Between −50° and −80°C, the resonances of C(2)/C(3) and of carbonyl carbons C(1')/C(4') gave four distinct lines, while only three lines were observed for C(5)/C(6) and for the methyl carbons C(2')/C(5') (Table 2).

Selective proton irradiation and off-resonance decoupling experiments (16) were performed to assign the low temperature $^{13}$C signals. Due to the existence of a two bond $^2J_{CH}$ coupling constant, the carbonyl resonances could be assigned unambiguously.

The four CO resonances observed in the low temperature proton noise decoupled $^{13}$C spectrum indicate that shielding of $^{13}$CO increases in the order: C(1') (*Z,E*) < C(1')/C(4') (*E,E*) < C(4') (*Z,E*) < C(1')/C(4') (*Z,Z*).

The relative populations of the three conformers were calculated from the intensities of the four carbonyl signals and the results are identical to those obtained from low temperature $^1$H spectra.

## Discussion

While assignments deduced from chemical shifts are not reliable, nOe has been shown to be the method of choice in conformational studies of tertiary amides (17). However, it was emphasized that these experiments have to be performed at a sufficiently low temperature ($T \ll T_c$) to avoid

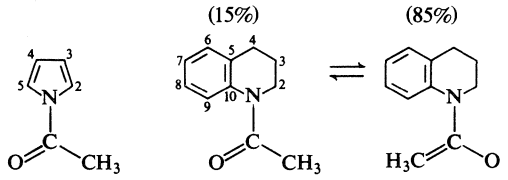
[a] Temperature −80°C, solvent $CD_2Cl_2$. Chemical shifts in ppm from internal TMS. Averaged chemical shifts at ambient probe temperature:

$C_i$: 135.4$_5$ $C_o$: 130.9$_9$ $C_p$: 128.4$_3$ $C_m$: 127.9$_3$
C(1')/C(4'): 167.8$_5$ C(5)/C(6): 119.8$_3$ C(2)/C(3): 132.7$_3$ C(2')/C(5'): 23.9$_8$ ppm.

spin-saturation transfer (18, 19). In this study, the nOe experiments were performed at −80°C and the first coalescence process was observed at −38°C, so that the condition $T \ll T_c$ is fulfilled. The absence of nOe effect on irradiating the upfield methyl signals shows that, effectively, no saturation transfer occurs at this temperature so that the assignments deduced from nOe are unequivocal.

Due to the lack of data regarding *N,N'*-diacetyl derivatives of *N*-heterocyclic compounds, $^1H$ and $^{13}C$ chemical shifts can only be compared to those previously reported for *N*-acetyl heterocycles. We selected *N*-acetylpyrrole **6** and *N*-acetyltetrahydroquinoline **7** for model compounds because assignments were deduced from low temperature nOe experiments (18). However, such a comparison has to take into account differences in the geometry of these compounds. *N*-acetylpyrrole is planar (18) and the low barrier to rotation around the amide bond, $\Delta G_{298}^{\neq} = 12.1$ kcal/mol indicates that "the lone pair on the nitrogen is to a great extent localized in the pyrrole ring" (20). On the other hand, it was suggested that the acetyl group of *N*-acetyltetrahydroquinoline lies out of the mean molecular plane corresponding to a low steric interaction between the methyl group and the methylene group α to the nitrogen. This hypothesis is in line with the low barrier determined for this compound, $\Delta G_c^{\neq} = 12.8$ kcal/mol.

(Acetone, −45°C)



**6** **7a** **7b**

The main factor determining the $^1H$ methyl chemical shifts in the $E,E$ and $Z,Z$ conformers of **2** is the orientation of the $CH_3$ relative to the phenyl substituents, which lie out of the plane of the C(2)–C(3) double bond ($\delta_{CH_3}$ $E,E$: 1.62 ppm; $Z,Z$: 2.17 ppm). A similar result is observed for **7** ($\delta_{CH_3}$ **7***a*: 2.30 ppm, **7***b*: 2.20 ppm) but the difference between these shifts is greater for **2** (0.55 ppm) than for **7** (0.1 ppm). The large difference observed for **2** indicates that the twist angles of the phenyl substituents are significant in solution, suggesting a geometry similar to the one found in the solid state. Such a geometry explains the high shielding observed in the $E,E$ conformer and the $E$ part of the $Z,E$ one.

The ethylenic protons H(5)/H(6) are less shielded when they are *syn* to the carbonyl oxygen ($E$ conformation) than when they are *anti* ($Z$ conformation). Similarly, in *N*-acetylpyrrole **6**, H(5) is deshielded relative to H(2) ($\delta_{H(5)}$: 7.41, $\delta_{H(2)}$: 7.12 ppm).

On going from $^1H$ to $^{13}C$ spectra, a quite different sequence is observed for the methyl groups. While $^1H$ shielding shows an increase in the following order: $Z,Z <$ $Z$ part of $Z,E < E,E <$ $E$ part of $Z,E$, the corresponding $^{13}C$ sequence is: $E,E <$ $E$ part of $Z,E <$ $Z,Z =$ $Z$ part of $Z,E$. Additionally only three signals are observed in the $^{13}C$ spectra instead of four in the $^1H$ spectra. The differences between the above sequences are due to the great sensitivity of proton chemical shifts to anisotropy effects and to the minor importance of these effects on $^{13}C$ shifts.

Four distinct $^{13}C$ resonances are observed for the carbonyl groups and the corresponding carbon is more shielded when the carbonyl oxygen is oriented towards the Ph-substituted C(2)/C(3) $sp^2$ carbons than when the oxygen is oriented towards the nonsubstituted C(5)/C(6) $sp^2$ carbons. Although this behavior seems difficult to explain at first sight, a similar trend is observed in **7**. The carbonyl carbon is more shielded in **7***a* (δ 169.8 ppm) where the oxygen is directed towards the aromatic ring than in **7***b* (δ 169.6 ppm) where the oxygen is oriented towards the unsubstituted $sp^3$ carbon C(2). This suggests that a repulsive interaction could exist between the aromatic ring and the oxygen of the carbonyl group.

The chemical shifts of the $sp^2$ C(5)/C(6) carbons are dependent upon their orientation relative to the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

carbonyl group; this carbon is more shielded when *syn* to the carbonyl oxygen (*E* conformation) than when *anti* to the oxygen (*Z* conformation). Identical results have been reported (18) for **6** (C(2): 120.2 ppm, C(5): 118.5 ppm) and for the $sp^3$ and $sp^2$ carbons of **7** (C(2): **7***b*, 42.8, **7***a*, 46.7 ppm; C(10): **7***a*, 138.8; **7***b*, 140 ppm) and for various acyclic amides (21–23). This effect, which has been attributed to the electric field of the carbonyl (21), seems to be general in the absence of steric compression (18).

It can be noted that $^1H$ and $^{13}C$ chemical shifts of the *Z* or *E* part of **2** are slightly different in the *Z*,*E* conformer and in the *Z*,*Z* or *E*,*E* conformers. Two hypotheses can explain this result; either the chemical shifts are not only dependent on their close but also on their remote surroundings, or geometry of the *Z*,*E* conformer is not exactly identical to the geometry obtained in joining one half of the *Z*,*Z* and one half of the *E*,*E* conformer.

Although the structure of **2** in the solid state indicates that the nitrogen lone pairs are not delocalized towards the 1,4-dihydropyrazine ring, the barrier to rotation about the carbonyl–nitrogen bonds in **2** is rather low ($\Delta G_c^{\ddagger} \sim 13$ kcal/mol) relative to that observed in *N*,*N*-dimethylacetamide ($\Delta G^{\ddagger} \sim 18.1$ kcal/mol) (27). This result is in line with a C—N bond longer in **2** ($\sim 1.37_5$ Å) than in *N*,*N*-dimethylacetamide ($\sim 1.32$ Å).

## Experimental

The 1,4-diacetyl-1,4-dihydro-2,3-diphenylpyrazine has been prepared according to ref. 24. The monocrystal used in the crystallographic study was obtained by slow evaporation of an ethanolic solution.

*Crystallographic study*

Crystal data are used as follows:

$C_{20}H_{18}N_2O_2$ f.w. = 318

Triclinic, $a = 5.684(1)$, $b = 9.299(2)$, $c = 16.516(3)$ Å, $\alpha = 89.62(2)$, $\beta = 90.16(2)$, $\gamma = 107.29(2)°$, $V = 833.49$ Å$^3$, $Z = 2$, $\rho_c = 1.27$ g cm$^{-3}$, $\rho_o = 1.26(2)$ g cm$^{-3}$ (20°C, MoK$_\alpha$ $\lambda = 0.707$ Å, $\mu = 0.86$ cm$^{-1}$). Preliminary X-ray photographs showed triclinic diffraction symmetry; a statistical analysis of the intensity data indicated the centrosymmetric space group $P\bar{1}$. A crystal ($0.7 \times 0.4 \times 0.2$ mm) was mounted with the *a* axis parallel to the $\phi$ axis of a Philips automated diffractometer equipped with a graphite monochromator. The intensities of all reflections having $2\theta$ less than 50° were measured using the variable $\omega$–$2\theta$ scan technique. During the course of the data collection three standard reflections were measured every 54 reflections. A total of 2676 reflections were measured, 2114 of which had $I \geq 4\sigma(I)$. The data were reduced to $|F_o|$ by the routine procedure. Lorentz and polarization but no absorption or extinction corrections were applied. The scattering factors for neutral atoms were taken from ref. 25. The structure was determined by direct methods (MULTAN) (26) and refined by large block least squares $\Sigma\omega(|F_o| - |F_c|)^2 = \min$ with $\omega = 1/6^2$. The refinement with anisotropic thermal parameters on the non-hydrogen atoms converged to $R = 0.126$. At this stage, a difference Fourier map revealing the positions of all the hydrogen atoms was calculated; refinement of their positional parameters was carried out, using the thermal parameters of the corresponding heavy atoms at the end of isotropic refinement. The refinement converged with $R = 0.043$ and $R_w = 0.048$.

*Conformational study in solution*

The $^1H$ and $^{13}C$ spectra were recorded on a Varian XL-100-12-W.G. spectrometer. The $^1H$ and $^{13}C$ chemical shifts were measured relative to TMS as an internal reference. The nOe experiments were performed using carefully degassed solution by three freeze–pump–thaw cycles.

# Synthesis and incorporation of [3-$^3$H, U-$^{14}$C]-L-valine into penicillin V using *Penicillium chrysogenum*

SAUL WOLFE AND RAYMOND JOHN BOWERS
*Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6*
AND
DAVID A. LOWE[1] AND ROBERT B. MORIN[1]
*Raylo Chemicals Limited, Edmonton, Alta., Canada T6C 4A9*

Received May 26, 1981

SAUL WOLFE, RAYMOND JOHN BOWERS, DAVID A. LOWE, and ROBERT B. MORIN. Can. J. Chem. **60**, 355 (1982).

The title compound was synthesized by exchange of dimethylpyruvic acid with NaOH–HTO, followed by reductive amination using cyanoborohydride in methanol solvent, resolution of the *N*-chloroacetyl derivative, and admixture with [U-$^{14}$C]-L-valine. Degradation of the compound revealed that 94.5% of the tritium was attached to C3, and 5.5% was located on the methyl groups. Incorporation of this doubly labelled valine into penicillin V, purified as the dibenzylamine salt, proceeded with 100.7% loss of the tritium originally present at C3. Commercial [2,3-$^3$H, U-$^{14}$C]-L-valine, which was found to have 12% of the tritium on the methyl groups, was also incorporated into penicillin V, purified as its methyl ester. Degradation to remove the hydrogen attached to C3 of this ester revealed that no tritium was present at this position. Therefore, in agreement with an earlier result and other related studies, the β-hydrogen of valine is not transferred to C3 of penicillin during the biosynthesis of the latter compound.

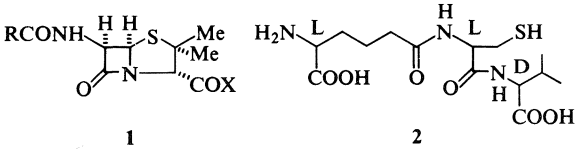
SAUL WOLFE, RAYMOND JOHN BOWERS, DAVID A. LOWE et ROBERT B. MORIN. Can. J. Chem. **60**, 355 (1982).

On a synthétisé le composé mentionné dans le titre grâce à un échange de l'acide diméthylpyruvique avec une solution de NaOH–HTO, suivi d'une amination réductrice utilisant le cyanoborohydrure dans le méthanol, d'une résolution du dérivé *N*-chloroacétyle et finalement d'un mélange avec la [U-$^{14}$C]-L-valine. La dégradation du composé a révélé que 94,5% du tritium est attaché au carbone en position 3 et 5,5% se retrouve au niveau des groupes méthyles. L'incorporation de cette valine doublement marquée dans de la pénicilline V, purifié sous forme de sel de dibenzylamine, se fait avec une perte de 100,7% du tritium originalement présent au niveau du carbone en position 3. On a également incorporé la [$^3$H-2,3, U-$^{14}$C] L-valine commerciale qui contient 12% de tritium dans les groupes méthyles à la péniciline V purifiée sous forme d'ester méthylique. La dégradation en vue d'enlever le tritium du carbone en position 3 a révélé qu'il n'y en avait pas dans cette position. Par conséquent, en accord avec un résultat antérieur et d'autres études apparentées, l'hydrogène en position β de la valine n'est pas transférré sur le carbone en position 3 de la pénicilline pendant la biosynthèse de ce dernier composé.

[Traduit par le journal]

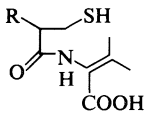
Both eukaryotic (1) and prokaryotic (2) organisms synthesize the penicillin nucleus (**1**, X = OH) from the tripeptide precursor **2**, δ-L-(α-aminoadipyl)-L-cysteinyl-D-valine (ACV). The overall process **2** → **1** includes a two-equivalent oxidation in the cysteinyl moiety, and a two-equivalent oxidation in the valinyl moiety of ACV. Although the stereochemical consequences of these processes at the β carbon atoms of cysteine and valine are known (3), their relative timing and detailed chemical mechanisms are not, despite much effort and ingenious speculation.

It has been known for some time that L-valine is a more efficient precursor of the D-valinyl moiety of penicillin than is D-valine (4), and that both enantiomers are incorporated with loss of their α-hydrogen atoms. More recently, it has been found that this loss occurs during the attachment of valine to an aminoadipylcysteine dipeptide, since some (5) or all (6) of the α-valinyl hydrogen of ACV is retained during the oxidative stages of the biosynthesis. This fact suggests (7) that the oft-considered dehydrovalinyl-containing peptide **3** (8) can no longer be regarded as a viable post-ACV intermediate in the overall process.



**1**

**2**



**3**

The present work originated from some mechanistic considerations, based on literature precedents, which suggested that retention of the α-valinyl hydrogen of ACV need not be incompatible with the postulate of **3** as a post-ACV intermediate.

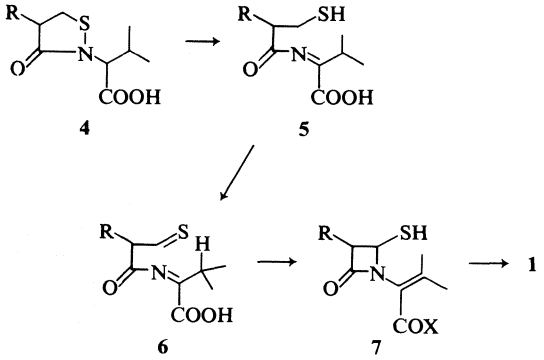
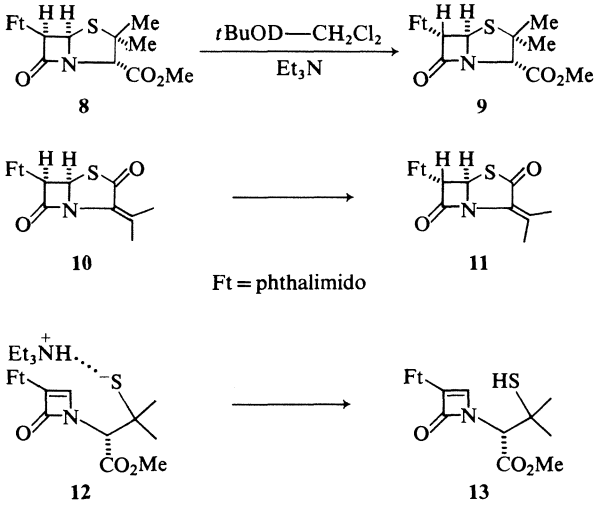
In one version of the Morin–Baldwin hypotheses (9–11), oxidation of ACV at sulfur, followed by intramolecular dehydration, leads to the isothiazolidinone **4**. A β-elimination to the acylimine **5** (12), followed by a second oxidation at sulfur, then affords **6** which, by an ene reaction, is transformed to the mercaptoazetidinone **7**, which cyclizes to penicillin. Although the reported examples of the latter reaction (13, 14) have not been confirmed (15), such cyclizations are known in model systems (16), and the reverse reaction, i.e., **1** (X = Cl, $OCH_3$, OCOR) → **7** (X = Cl, $OCH_3$, OCOR) also exists (17, 18).

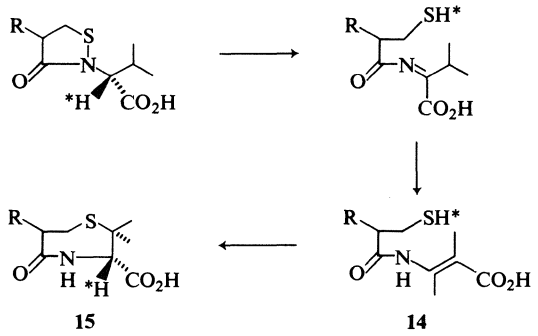


During an investigation of the C6 epimerization of the penicillin derivative **8** (19), it was observed that exposure of this compound to triethylamine in a mixture of *tert*-butanol-*d* and methylene chloride led to **9** *without incorporation of deuterium from the solvent*. Under the same conditions, the anhydropenicillin **10** was epimerized to **11**, again without incorporation of deuterium. To account for these observations, it was proposed that triethylamine promotes a β-elimination to form an ion-pair (e.g., **12**), which is transformed to the mercaptan **13**. This corresponds to an intramolecular 1 → 3 shift of hydrogen from C6 to sulfur. Ring closure by a concerted *cis*-addition of S—H to the β-face of the C5—C6 double bond would then explain the labelling results. The role of ion-pairs in base-catalyzed intramolecular 1,3-proton transfer reactions has since been examined in some detail (20). In addition, there is now good evidence for intramolecular 1,3-hydrogen shifts under enzymatic control, e.g., the C4 to C6 hydrogen transfer during the conversion of cholesterol into cholestenone (21), and the intramolecular hydrogen transfer observed during the enzymatic conversion of 3-carboxymuconolactone into 3-oxoadipic acid (22).

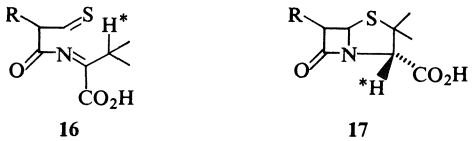
On the basis of these precedents, it was considered that the postulated conversion of **4** to **5** might proceed with transfer of hydrogen from the α-valinyl carbon to sulfur. Prototropic rearrangement



to **14**, followed by *cis*-addition to the carbon–carbon double bond would then lead to the thiazepine **15** (23) with retention of some or all of the α-valinyl hydrogen. This mechanism is consistent with the labelling results, predicts that the β-hydrogen of the valinyl moiety is lost, and provides a new route to the putative (23) intermediate **15**.



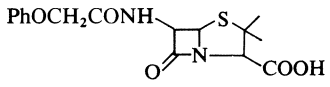
Alternatively, an intramolecular hydrogen transfer during the step **6** → **7**, followed by *cis*-addition of S—H* to the carbon–carbon double bond (*cf.* **16** → **17**) would lead to penicillin, with loss of the α-valinyl hydrogen of ACV, and a transfer of the β-valinyl hydrogen of ACV to the α-valinyl carbon atom of penicillin.



Although this latter pathway is inconsistent with the observations of refs. 5–7, it seemed desirable to reexamine the fate of the β hydrogen atom of valine during the incorporation of this amino acid into penicillin by the eukaryotic *P. chrysogenum*. An experiment of this type has been reported previous-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

ly by Adriaens *et al.* (24). In the latter work, DL-[3-$^3$H]valine was prepared by racemization of L-[2,3-$^3$H]valine, and was found to contain 0.46% tritium on the methyl groups; after admixture with DL-[4,4′-$^{14}$C]valine to a $^3$H/$^{14}$C ratio of 3.0103, the compound was incorporated into penicillin V (**18**), using *P. chrysogenum*. The latter compound exhibited a $^3$H/$^{14}$C ratio of 0.05184 (average of four runs), somewhat higher than the value (0.01385) expected for complete loss of the 3-$^3$H and retention of only the 0.46% tritium on the methyl groups (25). The specific objectives of the present work were, therefore, to develop an alternative synthesis of DL-[3-$^3$H]valine, and a degradation of the labelled penicillin to locate the position(s) of any residual tritium.



**18**

## Experimental

General experimental procedures have been summarized in ref. 23. Enzymes used in the present work were purchased from Sigma Chemical Company. [2,3-$^3$H]-L-valine was supplied by Schwarzmann, Inc., Division of Medisciences, Spring Valley, NY 10977, U.S.A.

*[3-$^3$H]-Dimethylpyruvic acid*

A solution of dimethylpyruvic acid (1.06 g, 9.1 mmol), sodium hydroxide (600 mg, 15 mmol), and HTO (5.0 mL, specific activity 4 mCi/mmol) was stirred at room temperature for 17 h. The solution was then acidified by addition of concentrated hydrochloric acid (1.6 mL) and was continuously extracted with methylene chloride for 3 h. The organic extract was evaporated and the residual oil dissolved in methanol (40 mL) to exchange the carboxylic acid proton. This solution was evaporated and the residue was again dissolved in methanol (40 mL). After evaporation of the solvent a colourless oil (994 mg) was obtained, with specific activity 25.5 μCi/mmol.

*Reductive amination of dimethylpyruvic acid (26)*

A solution of dimethylpyruvic acid (106 mg, 0.9 mmol) and ammonium acetate (385 mg, 50 mmol) in methanol (20 mL) was treated with sodium cyanoborohydride (126 mg, 2.0 mmol) and stirred at 20°C for 46 h. The reaction was quenched by addition of concentrated hydrochloric acid (5.0 mL), and the solvent was removed under reduced pressure. The white, solid residue was dissolved in water (3.0 mL) and added to an ion exchange column, which had been prepared as follows: Rexyn RG50 (H+) (24 g, 100 mequiv.) was stirred with water (50 mL) and decanted. This process was repeated several times to remove small particles of resin. The slurry was then poured into a glass column and washed with 2 *N* hydrochloric acid (150 mL), followed by water until the eluate was neutral.

The solution of the product (3 mL) was added to the column. The acidic impurities were removed by a distilled water wash (500 mL), after which the product was eluted with 1 *N* ammonium hydroxide (300 mL). Evaporation of the eluate gave a light brown solid (60 mg, 50%), which gave a purple colour with ninhydrin. Analysis by paper chromatography (Whatman 3M; *n*-butanol – acetic acid – water; 27:10:33) showed a single spot, $R_f$ 0.73, identical to that of an authentic sample of valine; ir (Nujol): 3360–1830 (s, br, $NH_3^+$), 2140 (s, $NH_3^+$), 1620 (s, br, $CO_2^-$) cm$^{-1}$; $^3$Hmr ($D_2O/D_2SO_4$) δ: 0.97 (3H, d, $J$ = 7 Hz, $CH_3$), 1.03 (3H, d, $J$ = 7 Hz, $CH_3$), 1.80–2.52 (1H, m, C3 methine), 3.57 (1H, d, $J$ = 5 Hz, C2 methine).

A similar experiment employing ammonium chloride (268 mg, 5.0 mmol) in place of ammonium acetate as the nitrogen source afforded only a 10% yield of valine.

A further experiment with methanol-*d* (99.5 at.%) in place of methanol gave a 50% yield of valine. Analysis of this product by $^1$Hmr indicated that no deuterium had been incorporated into the product. This material was then converted to *N*-acetyl-D,L-valine, mp 149.5–151°C, with *p*-nitrophenyl acetate, and esterified with diazomethane to form *N*-acetyl-D,L-valine methyl ester as a colourless syrup which, on standing, crystallized slowly as large needles, mp 59–60°C; ir (film): 3400 (br, sh, NH), 3290 (s, br, NH), 1735 (s, ester C=O), 1650 (s, amide C=O), 1535 (s, amide II) cm$^{-1}$; $^1$Hmr ($CDCl_3$) δ: 0.93 (3H, d, $J$ = 6.5 Hz, $CH_3$), 0.95 (3H, d, $J$ = 6.5 Hz, $CH_3$), 2.05 (3H, s, $COCH_3$), superimposed on 1.80–2.47 (1H, m, C3 methine), 3.74 (3H, s, $CO_2CH_3$), 4.55 (1H, q, $J$ = 5, 8 Hz, C2 methine), 6.14 (1H, br d, $J$ = 8 Hz, N*H*); ms (70 eV) *m/e* (relative intensity) taking *m/e* 114 ($M^+ - CO_2CH_3$) as the base peak: 116 (3.0), 115 (4.7) 114 (100). A sample prepared from D,L-valine (Aldrich) had: 116 (2.9), 115 (8.8), 114 (100).

*[3-$^3$H]-D,L-Valine*

In the same manner, the reductive amination of [3-$^3$H]-dimethylpyruvic acid (0.99 g, 8.6 mmol) (specific activity 25.5 μCi/mmol) gave [3-$^3$H]-D,L-valine (499 mg, 50%). The product was converted immediately to *N*-chloroacetyl-[3-$^3$H]-D,L-valine (27), mp 126–130°C, specific activity 27.9 μCi/mmol.

*[3-$^3$H, U-$^{14}$C]-L-Valine*

The *N*-chloroacetyl-[3-$^3$H]-D,L-valine (197 mg, 1.013 mmol), specific activity 28 μCi/mmol, was resolved, using hog kidney acylase (28) to give [3-$^3$H]-L-valine (12.19 μCi, 85.5%). A solution of [3-$^3$H, U-$^{14}$C]-L-valine was prepared by mixing a solution of [3-$^3$H]-L-valine (41.72 mg, 9.986 μCi) in water (9.5 mL) with a solution of [U-$^{14}$C]-L-valine (2.28 mg, 3.359 μCi, New England Nuclear) in water (3.0 mL). The solution showed $^3$H/$^{14}$C = 2.91. Aliquots (3.0 mL) of this solution were used for the incorporation experiments.

*Distribution of tritium in [2,3-$^3$H, U-$^{14}$C] or [3-$^3$H, U-$^{14}$C]-L-valine*

Eighty μmoles of doubly labelled L-valine containing approximately 1 μCi $^3$H and 0.3 μCi $^{14}$C were absorbed onto Dowex 50 ($H^+$) at neutral pH, eluted with 2 *M* ammonium hydroxide solution, and the eluate was lyphilized. The eluate was reconstituted at pH 8.0 in 6 mL of a solution containing 500 μmol Tris-HCl and 500 μmol KCl, and shaken with L-amino acid oxidase (10 mg) and catalase (1 mg) at 37°C for 18 h. A further 80 μmol aliquot of unlabelled L-valine was added to the reaction mixture and the incubation was continued for 6 h. The pH of the final solution was adjusted to 5.0 with dilute acetic acid. The solution was then passed through Dowex 50 ($H^+$), and the resin was washed with four volumes of water. The combined eluate and wash were dried by lyophilization, and reconstituted with water. Lyophilization was repeated to ensure the complete removal of tritiated water. The resultant dimethylpyruvic acid was dissolved in water (5 mL) and the pH adjusted to 13 by the addition of 1 *N* ammonium hydroxide (1.5 mL), and the solution was maintained overnight in a sealed tube at 37°C. The alkaline solution was neutralized with dilute hydrochloric acid and dried by lyophilization. The exchange procedure was repeated to ensure the complete removal of tritium from the 3-position.

*Production of penicillin V by* Penicillium chryosogenum *ATC-C26818*

Surface spores were developed on tube slants on an agar

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

medium containing 0.75% glycerol, 0.75% molasses, and 0.5% Bactopeptone. Spores from a 10 day culture were suspended in distilled water and inoculated at a density of $10^4$/mL into a seed medium of composition 3% corn steep liquor, 1% distillers' solubles, 2% sucrose, and 0.5% calcium carbonate adjusted to pH 6.5 before sterilization. The seed was cultured in 100 mL volume in a 500 mL Erlenmeyer flask by shaking at 250 rpm at 24°C for 72 h. Production medium consisted of 6% corn steep liquor, 6% lactose, 1.0% $CaCO_3$, 0.3% $MgSO_4 \cdot 7H_2O$, 0.5% $KH_2PO_4$, 0.5% soybean oil, and 0.2% phenoxyacetic acid, adjusted to pH 6.5 before sterilization. Production fermentations were carried out in 100 mL of medium in 500 mL Erlenmeyer flasks shaken at 250 rpm at 24°C for 72 h. A 10% cross volume from the third day of seed was used to inoculate the production medium. Bioassay results using *Bacillus subtilis* indicated that penicillin V was produced at a titre of 1.1 mg/mL filtrate at 72 h.

*Incorporation of doubly labelled* L-*valine into penicillin V*

Doubly labelled L-valine (10 mg) was dissolved in distilled water (15 mL) and sterilized by membrane filtration. Equal aliquots were added to *P. chrysogenum* growing in three flasks of production medium at 52 h and the fermentation was continued for a further 20 h, after which time the contents of the flasks were pooled, unlabelled penicillin V (1.5 g) was added, and the whole broth filtered. The pH of the filtrate was adjusted to 2.5 with dilute sulfuric acid and the mixture was then extracted with an equal volume of ethyl acetate. The organic phase was separated, washed with water, and dried over sodium sulfate. Crude penicillin V was precipitated from the ethyl acetate as the potassium salt by titration to pH 7.5 with 2 *M* potassium 2-ethylhexanoate in *n*-butanol, collected by filtration, and finally washed with ethyl acetate.

*Separation of penicillin V from phenoxyacetic acid via the dibenzylamine salt*

A solution of potassium penicillin V (646 mg, 1.67 mmol) and potassium phenoxyacetate (253 mg, 1.33 mmol), in water (10 mL), was stirred vigorously at room temperature, and a warm solution of dibenzylamine hydrochloride (767 mg, 3.3 mmol), in water (23 mL), was added to give a thick white paste. The mixture was cooled overnight at 5°C and then filtered, washed with ice-cold water (6 mL), and air-dried. Drying under high vacuum gave 894 mg of material. This was suspended in acetonitrile (5.0 mL) and water (8.0 mL), and it dissolved readily upon heating. The hot solution was filtered through a short stemmed, preheated filter funnel, containing a small plug of tissue paper, into a flask containing hot water (8.0 mL). The product crystallized smoothly as the solution cooled. After cooling of the mixture overnight, the product was collected to give a white microcrystalline solid (692 mg) mp 98–100°C; ir (Nujol): 3442, 3355, 3218 (s, NH), 2615, 2445 (s, $NH_2^+$), 1770 (s, β-lactam C=O), 1675 (s, amide C=O), 1628 (s, $CO_2^-$), 1576 (s, amide II and $NH_2^+$) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 1.56 (3H, s $CH_3$), 1.46 (3H, s, $CH_3$), 3.83 (4H, s, $PhCH_2$), 4.49 (2H, s, $PhOCH_2$), 4.23 (1H, s, C3 methine), 5.36 (1H, d, $J$ = 4 Hz, C5 methine), 5.56 (1H, q, $J$ = 4, 8 Hz, collapses to a doublet, $J$ = 4 Hz on exchange of NH with $D_2O$, C6 methine), 5.99–6.39 (3H, exch $D_2O$, N*H* and $NH_2^+$), 7.28 (10H, s, Ph) overlapping with 6.76–7.49 (5H, m, PhO). *Anal.* calcd. for $C_{30}H_{33}N_3O_5S$: C 65.79, H 6.07, N 7.67, S 5.85; found: C 65.78, H 6.04, N 7.51, S 5.70.

*Isolation of [$^3$H, $^{14}$C]-penicillin V dibenzylamine salt from the crude penicillin isolate obtained after incubation of [3-$^3$H, U-$^{14}$C]-*L-*valine*

In a similar manner, the crude penicillin V isolate (824 mg) from the incubation of [3-$^3$H, U-$^{14}$C]-L-valine ($^3$H/$^{14}$C 2.91) with *Penicillium chrysogenum* was dissolved in water (9.0 mL) and treated with a solution of dibenzylamine hydrochloride (700 mg) in hot water (24.0 mL). The precipitated [$^3$H, $^{14}$C]-penicillin V dibenzylamine salt was collected and dried under high vacuum, mp 91–95°C; specific activity: $^3$H, 0.0043; $^{14}$C, 0.031 μCi/mmol. Recrystallization from aqueous acetonitrile gave a fluffy white microcrystalline solid, mp 97–100°C; specific activity: $^3$H, 0.0052; $^{14}$C, 0.0355 μCi/mmol ($^3$H/$^{14}$C 0.146, 5.03% retention of tritium).

A second penicillin V isolate (751 mg) was also treated with dibenzylamine hydrochloride (640 mg) in water. The precipitated salt was recrystallized twice from aqueous acetonitrile to give a fluffy white microcrystalline solid, mp 98.5–100.5°C (mixture mp with an authentic sample, 98–100°C). Specific activity: $^3$H, 0.0045; $^{14}$C, 0.033 μCi/mmol ($^3$H/$^{14}$C 0.136, 4.7% retention of tritium).

*Isolation of [$^3$H, $^{14}$C]-penicillin V methyl ester from the incubation of [2,3-$^3$H, U-$^{14}$C]-*L-*valine with* Penicillium chrysogenum

The crude penicillin V isolate (401.5 mg) was dissolved in water (4.0 mL), and the solution was cooled to 0°C. The pH was adjusted to 2.0 with 6 *N* hydrochloric acid and the product was extracted into ethyl acetate (4 × 10 mL). The combined extracts were dried and evaporated to leave a pale yellow gum (340 mg). The product was dissolved in absolute ether (20 mL and esterified at 0°C with alcohol-free diazomethane. The excess diazomethane was destroyed by the dropwise addition of acetic acid and the solvent was evaporated. The residue was dissolved in methylene chloride (20 mL) and washed with 7% sodium bicarbonate (10 mL). The organic layer was dried and evaporated to leave a golden yellow syrup (363 mg). Chromatography on silica gel (7.0 g) (methylene chloride – ethyl acetate, 19:1) separated methyl phenoxyacetate from the penicillin V methyl ester, which was isolated as two samples; the first, 195.5 mg, was homogenous on tlc, $R_f$ 0.58 (methylene chloride – ethyl acetate, 19:1) and identical by $^1$Hmr with an authentic sample. Specific activity: $^3$H, 0.011; $^{14}$C, 0.023 μCi/mmol; $^3$H/$^{14}$C 0.46.

*Rearrangement of methyl 6-phenoxyacetamido-[$^3$H, $^{14}$C]-penicillanate-1β-oxide (29)*

Methyl 6-phenoxyacetamidopenicillanate-1β-oxide (118 mg, 0.311 mmol, specific activity: $^3$H, 0.011 μCi/mmol; $^3$H/$^{14}$C 0.46) was reacted with trimethyl phosphite (40 mg, 0.32 mmol) in benzene (10 mL). The crude product was purified by column chromatography on 5 g silica gel (methylene chloride – ethyl acetate, 1:1) to give 56 mg of material that was homogenous on tlc ($R_f$ 0.55), and identical by $^1$Hmr with an authentic sample (29). Specific activity: $^3$H, 0.008; $^{14}$C, 0.027 μCi/mmol; $^3$H/$^{14}$C 0.3.

*Isomerization of the β,γ-isomer (29)*

A solution of the β,γ-isomer (173 mg, 0.5 mmol) in methanol (2.5 mL) was stirred with triethylamine (0.07 mL, 51 mg, 1 equiv.) at room temperature for 20 min. The solvent was then evaporated and the residue dissolved in methylene chloride (15 mL) and reevaporated. Repetition of this process with methylene chloride (15 mL) gave a syrup which was dried under high vacuum (174 mg); ir ($CDCl_3$): 1769 (s, β-lactam C=O), 1720 (s, ester C=O) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 1.77 (3H, s, $CH_3$), 2.23 (3H, s, $CH_3$), 3.74 (3H, s, $CO_2CH_3$), 4.95 (2H, s, $PhOCH_2$), 5.83 (1H, d, $J$ = 4 Hz, β-lactam *H*), 6.03 (1H, d, $J$ = 4 Hz, β-lactam *H*), 6.77–7.43 (5H, m, Ar*H*).

*Isomerization in methanol-*d

A similar experiment using methanol-*d* (99.5 at.%) in place of methanol gave the α,β-isomer containing one atom of deuterium by nmr integration; $^1$Hmr ($CDCl_3$) δ: 1.77 (2.8H, s, vinyl $CH_3$), 2.23 (2.2H, s, vinyl $CH_3$).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

*Isomerization of the β,γ-isomer at high dilution*

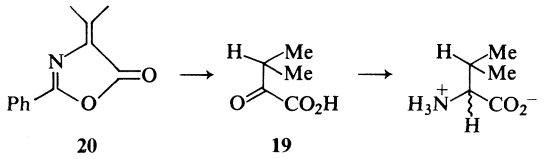
Triethylamine (0.70 mL) was dissolved in redistilled methanol and the solution was diluted to 50.0 mL in a volumetric flask. An aliquot of this solution (5.0 mL, 0.5 mmol of triethylamine) was added to a solution of the β,γ-isomer (17.3 mg, 0.05 mmol) in redistilled methanol (345 mL). After 5 h the solvent was evaporated and the residue dissolved in methylene chloride (15 mL), filtered, and evaporated to leave a pale yellow oil (17 mg) which was identical ($^1$Hmr) to material prepared previously.

*Isomerization of the [$^3$H, $^{14}$C]-β,γ-isomer*

In the same way, the [$^3$H,$^{14}$C]-β,γ-isomer (27.0 mg, 0.078 mmol), was isomerized using triethylamine (10 equiv.) in redistilled methanol (500 mL). The product (27.0 mg) was purified on silica gel (1.0 g), (methylene chloride – ethyl acetate, 19:1) to give 19.0 mg of the α,β-isomer which was identical ($^1$Hmr, tlc) to material prepared previously; specific activity: $^3$H, 0.007; $^{14}$C, 0.026 μCi/mmol; ($^3$H/$^{14}$C 0.27).

## Results and discussion

Dimethylpyruvic acid **19** was prepared by hydrolysis (30) of 2-phenyl-4-isopropylidene-5-oxazolone **20** (31), and was converted to valine in 50% yield using ammonium acetate as the nitrogen source in the reductive amination. Interestingly, the yield of valine decreased to only 10% when ammonium chloride was employed in place of ammonium acetate.



**20** **19**

Exchange of **19** with 1 *M* NaOD–$D_2O$ was complete within 5 min at room temperature. Because of the facility of this exchange, it was necessary to check for loss of isotope to the solvent during the reductive amination step. Therefore, **19** was converted to D,L-valine with cyanoborohydride and ammonium acetate in methanol-*d*. The resulting product showed no incorporation of deuterium by $^1$Hmr and mass spectral examination of the derived *N*-acetyl methyl ester (see Experimental).

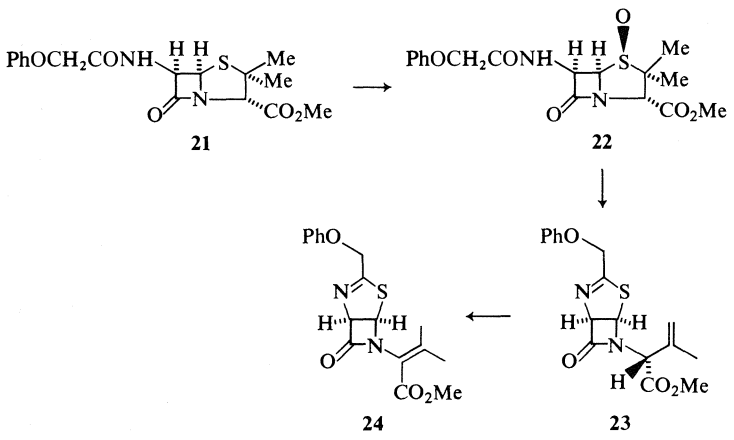
Tritiation of **19** was performed in 1 *M* NaOH–HTO and the resulting **19**-*t* was converted to [3-$^3$H]-D,L-valine in 49% yield. The *N*-chloroacetyl derivative of this compound, specific activity 28.0 μCi/mmol, was resolved, using hog kidney acylase, and the product was mixed with [U-$^{14}$C]-L-valine, $^3$H/$^{14}$C = 2.91. The distribution of tritium in this compound was then determined. Incubation with L-amino acid oxidase afforded [3-$^3$H,U-$^{14}$C]-dimethylpyruvic acid, which was exposed to 1 *M* ammonium hydroxide. Reacidification, followed by repetition of the exchange procedure, afforded doubly labelled **19**, $^3$H/$^{14}$C = 0.161. These results indicated that, in the doubly labelled L-valine, 94.5% of the tritium was attached to C3, and 5.5% was located in the methyl groups. The presence of tritium in the methyl groups was unexpected, and is indicative of homoenolization (32) during the exchange of **19** with NaOH in a tritiated medium.

Incorporation of the doubly labelled L-valine into penicillin V was achieved using *P. chrysogenum* in a medium supplemented with phenoxyacetic acid. The crude penicillin was isolated as the potassium salt by filtration of the broth, acidification to pH 2.5, extraction with ethyl acetate, and treatment with potassium 2-ethylhexanoate. Three experiments were performed, with an average incorporation of L-valine of 5.5%, based on recovered $^{14}$C. These crude potassium penicillin V isolates exhibited an average $^3$H/$^{14}$C ratio of 0.407, and suggested retention of 14% of the tritium originally present in the valine, corresponding to ca. 8.5% of the tritium originally located at C3 of the precursor.

Since $^1$Hmr examination of unlabelled crude potassium penicillin V isolates indicated some contamination with potassium phenoxyacetate, separation and purification of the penicillin was necessary. This was accomplished by treatment of the mixture, in water, with a hot aqueous solution of dibenzylamine hydrochloride. The dibenzylamine salt of penicillin V precipitated virtually quantitatively, and could be recrystallized to analytical purity from aqueous acetonitrile. Similar treatment of the labelled material yielded pure dibenzylamine salt of penicillin V having an average $^3$H/$^{14}$C ratio of 0.136, corresponding to 100.7% loss of the tritium originally present at C3 of the valine.

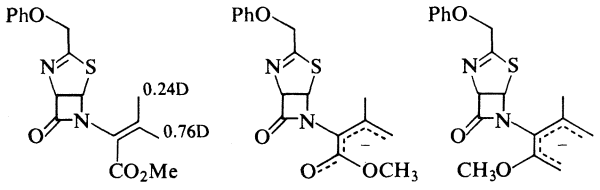
A further set of experiments was performed using commercially available [2,3-$^3$H]-L-valine. Degradation of this material, using L-amino acid oxidase as described above, revealed 12% tritium in the methyl groups. The compound was mixed with [U-$^{14}$C]-L-valine ($^3$H/$^{14}$C = 5.1) and incorporated into Penicillin V as before. Three experiments were performed. In this case, the crude potassium salts were acidified to pH 2, extracted into ethyl acetate, and treated with alcohol-free diazomethane. The pure methyl ester of penicillin V ($^3$H/$^{14}$C = 0.46) was isolated by column chromatography. Although this radioactivity corresponds to ca. 103% loss of tritium from the C3 position of the valine precursor, the methyl ester (**21**) was degraded to the thiazoline **24** via the known sequence **21** → **22** → **23** → **24** (29), to allow the removal of the hydrogen attached to C3.

To validate this degradative sequence, it was necessary to demonstrate that the rearrangement **23** → **24** proceeds in an intermolecular manner, with incorporation of hydrogen from the solvent.



Therefore, **23** was converted to **24**-*d* with triethylamine in methanol-*d*. The product was found, by $^1$Hmr, to contain one deuterium atom, distributed unequally between the two methyl groups, as indicated in **25**. The assignments of the chemical shifts of these methyl groups are based on literature precedents (33). These observations indicate that the conversion of **23** to **24** in methanol solvent is intermolecular, and proceeds via a carbanionic intermediate which protonates most readily in the sickle (**26**) or U (**27**) conformations (34).

In the radioactive series, the conversion of **23** to **24** was performed with triethylamine in a large excess of methanol. The $^3$H/$^{14}$C ratios were found to be: **21**, 0.46; **23**, 0.31; **24**, 0.27. This corresponds to loss of 23% tritium in the sequence **21** → **22** → **23**, slightly higher than the expected 17% and, within the experimental error, no further loss of tritium in the formation of **24**.



The two sets of experiments confirm the conclusions of Adriaens *et al.* (24), and provide no support for our hypothesis that the β-hydrogen of valine is transferred to C3 of penicillin during the biosynthesis of the latter compound. As has been reported elsewhere (35), the thiazepine **15** (R = δ-L-α-aminoadipyl) (23) is not converted to penicillin by a cell-free preparation of *C. acremonium*.

# The crystal and molecular structure of *syn*-2,11-diselena[3,3]metacyclophane and comparison with the dithia-analogue

GORDON W. BUSHNELL AND REGINALD H. MITCHELL

*Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2*

Received April 30, 1981

GORDON W. BUSHNELL and REGINALD H. MITCHELL. Can. J. Chem. **60**, 362 (1982).

The crystal structure of *syn*-2,11-diselena[3,3]metacyclophane, **1***a*, has been determined by single crystal X-ray diffraction and refined to an *R*-value of 0.039. The crystal structure is monoclinic with $a = 1926(1)$, $b = 801.4(3)$, $c = 924(1)$ pm, $\beta = 98.9(1)°$, and is isomorphous with that of the analogous sulphur compound. The space group is $P2_1/n$ with 4 molecules per cell, $D$(meas) = 1.733 g cm$^{-3}$, $D$(calcd) = 1.726 g cm$^{-3}$. The molecule has the *syn*-conformation with the largest possible Se—Se distance of 721.8 pm. The benzenoid rings form a dihedral angle of 19.1°. The distance between the internal aryl hydrogen atoms on rings **1** and **2** is 285.1 pm. The internal aryl C atoms are 314.6 pm apart. The $^1$Hmr solution spectra of **1***a* are consistent with the solid state structure, and can be explained without involving equilibration with an *anti*-conformer.

GORDON W. BUSHNELL et REGINALD H. MITCHELL. Can. J. Chem. **60**, 362 (1982).

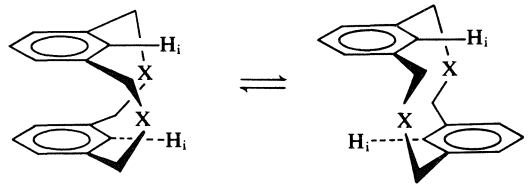
On a déterminé la structure cristalline du *syn*-diséléna-2,11[3,3]métacyclophane (**1***a*) par diffraction de rayons X sur un monocristal et on l'a affinée jusqu'à une valeur de $R = 0{,}039$. Le cristal est monoclinique avec $a = 1926(1)$, $b = 801{,}4(3)$, $c = 924(1)$ pm, $\beta = 98.9(1)°$, et il a la même forme que le composé sulfuré analogue. Le cristal appartient au groupe d'espace $P2_1/n$ avec 4 molécules par maille, $D$(mesuré) = 1,733 g cm$^{-3}$, $D$(calculé) = 1,726 g cm$^{-3}$. La molécule a une conformation syn avec la plus grande distance possible Se—Se égale à 721,8 pm. Les noyaux benzéniques forment un angle dièdre de 19.1°. La distance entre les atomes d'hydrogène aryles internes des cycles 1 et 2 est égale à de 285,1 pm. Les atomes de C aromatiques internes sont à 314,6 pm les uns des autres. Les spectres de rmn du $^1$H en solution du composé **1***a* sont en accord avec la structure à l'état solide et peuvent être expliqués sans faire intervenir l'équilibre avec le conformère *anti*.

[Traduit par le journal]

## Introduction

We have recently reported (1) the preparation and properties of 2,11-diselena[3,3]metacyclophane, **1**.[1] On the basis of its $^1$Hmr spectrum, in which the internal aryl hydrogens ($H_i$) appear at δ6.46, we assigned the solution molecular structure of **1** to be that of the *syn*-conformer **1***a*, or a rapidly equilibrating mixture of *syn*-**1***a* and the *anti*-conformer **1***b*, in which *syn*-conformer predominates. These conclusions were made by comparison to the analogous thiaphane, **2**, which we have previously (2) shown exists as the *syn*-conformer in both the solid state and in solution. However, because the $H_i$ protons of **1***a* (δ6.46) were shielded from those of **2***a* (δ6.82), which *a priori* might not be expected (see below), and because no evidence for *anti*-conformer participation in **2** could be observed, we decided to determine the crystal structure of **1** in order to illuminate these observations, and also to allow the first detailed comparison between the structures of thia- and selenacyclophanes.

This paper reports the results of this study.



X = Se **1***a* **1***b*
X = S **2***a* **2***b*

## Experimental

*X-ray measurements*

Preliminary X-ray photographs gave space group $P2_1/n$ with equivalent positions; $x, y, z$; $0.5 + x, 0.5 - y, 0.5 + z$; $-x, -y, -z$; and $0.5 - x, 0.5 + y, 0.5 - z$. Measurements were obtained on a Picker 4-circle diffractometer, using Zr filtered Mo$K_{\bar{\alpha}}$ radiation ($\lambda = 71.069$ pm). The crystal was mounted approximately along the *b*-axis within a glass capillary, and the crystal shape was specified by the following indices and perpendicular distances ±(1,0,−1), 0.132 mm; ±(1,0,0), 0.100 mm; ±(0,1,0), 0.321 mm; ±(1,0,1), 0.130 mm. The crystal data at 26°C were:

$C_{16}H_{16}Se_2$ mw = 366.22

$a = 1926(1)$, $b = 801.4(3)$, $c = 924(1)$ pm, $\beta = 98.9(1)°$, $V$(cell) = 1.409(2) nm$^3$, $D$(meas) = 1.733 Mg m$^{-3}$ (flotation in $CCl_4$/$CHBr_3$ solution). $D$(calcd) = 1.726 Mg m$^{-3}$, $Z = 4$.

Intensity measurements were completed over two octants up to $2\theta = 50°$, (~2480 reflections). A set of three standards 5,0,−5; 0,6,0; and 10,0,0 was used. An instrument instabilty constant of 0.017 (3) was evaluated from the standards. Lorentz and polarisation corrections were applied to the reflections and those for which $I < \sigma(I)$ were eliminated. Absorption corrections were carried out by numerical integration using a 6 × 14 × 6 Gaussian grid ($\mu$ for Mo$K_\alpha$ = 55.65 cm$^{-1}$). After sorting and the merging of a few duplicate measurements there were 2044 independent reflections in the dataset.

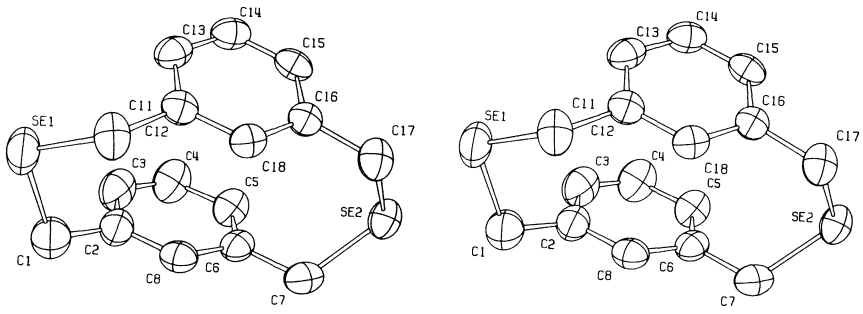

FIG. 1. A stereoview of the molecular structure of *syn*-2,11-diselena[3,3]metacyclophane.

*Structure determination*

A set of programs supplied by Penfold was used, based on ORFLS, FORDAP, ORTEP, and ORFEE (4). From the cell dimensions the crystal structure was seen to be approximately isomorphous with $C_{16}H_{16}S_2$ (2). Atomic scattering curves were taken from International Tables (5), and Se was treated as an anomalous scatterer. The carbon atom co-ordinates were found by means of a difference map. The refinement was by full-matrix least-squares minimisation of $\Sigma w(|F_o| - |F_c|)^2$. The hydrogen atoms were placed at calculated positions using a C—H length of 97 pm, and were given isotropic temperature parameters. The weights derived from counting statistics and experimental considerations did not give constant $w\Delta^2$ when analysed as a function of $|F_o|$, and a weighting scheme was therefore devised: $w = (A + Bx + Cx^2 + Dx^3)^{-1}$ where $x = |F_o|$, $A = 48.7703$, $B = -2.50651$, $C = 0.046833$, $D = -1.63 \times 10^{-4}$. The final agreement factors were $R = 0.039$, $R_w = 0.041$ where $R_w = (\Sigma w\Delta^2/\Sigma w|F_o|^2)^{1/2}$. The final difference map had a maximum of $0.385 \times 10^{-6}$ e pm$^{-3}$, and a minimum of $-0.450 \times 10^{-6}$ e pm$^{-3}$, and $\sigma(\rho) = 0.089 \times 10^{-6}$ e pm$^{-3}$. The fractional atomic co-ordinates for the Se and C atoms are given in Table 1. Supplementary tables have been deposited containing the hydrogen atom and the anisotropic temperature parameters, and the magnitudes of the structure factors.[2]

## Crystal structure description

A stereoscopic view of a single molecule with atom labels and the thermal ellipsoids containing 50% of the atom probability density is given in Fig. 1. The molecule has an approximate two-fold axis of symmetry passing through the midpoints of C(8)—C(18) and C(4)—C(14). The bond lengths are given in Table 2. There is agreement between columns 1 and 2 within 3 esds, the mean lengths are: Se—C = 196.4 pm, C—C(exocyclic) = 150.3 pm, C—C(aromatic) = 138.5 pm. The bond angles are given in Table 3, in which columns 1 and 2 are related by the approximate two-fold axis of the molecule, and agree satisfactorily. The mean plane results given in Table 4 show that benzene rings are planar and form a dihedral angle of 19.1°. Table 4(*b*) has columns 1 and 2 related by the approximate two-fold molecular axis. The exocyclic C-atoms, C(1) and C(17), lie out of planes *1* and *2* respectively on the inner (Se) sides. A similar displacement for C(7) and C(11) is less definite.

In our previous paper (2) on the isomorphous structure of *syn*-2,11-dithia[3,3]metacyclophane, **2***a*, the emphasis was on the unexpected *syn*-conformation of the compound. Magnetic reso-

*Estimated standard deviations in parentheses.

nance results were used to extend the scope of the argument in favour of many other related dithia[3,3]metacyclophanes with internal aryl hydrogens, also having the *syn*-conformation. This paper establishes beyond doubt the *syn*-conformation of the diselena[3,3]metacyclophane, **1***a*, and now enables us to discuss in detail the relationship between nmr parameters and structure for the sulphur and selenium analogs.

Table 5 summarises the structural differences between the sulphur and selenium compounds. A difference of 15.3 pm in the bond length C—X (X = S or Se) is accompanied by the selenium atom having a smaller C—X—C bond angle by 3.0°. The strain in the molecules is examined through the X—C—C bond angles and the distortions of the methylene C atoms out of the benzene ring planes on the same side as the S or Se atoms. Averaging over all four X—C—C angles we find that the total distortion is the same in the two compounds. In Table 5 we have averaged pairs of X—C—C bond angles related by the approximate two-fold axis of the molecule. Summing the methylene out-of-plane distortions we come to the conclusion that the sulphur compound is slightly more strained than the selenium one.

Turning our attention now to the distances of the S and Se atoms from the planes of the benzene rings, we find long and short perpendiculars in each compound. These distances are in pairs and related by the approximate two-fold symmetry. A longer perpendicular is associated with a C—C—C—X torsion angle closer to 90°. The strain is then more directly out of the benzene plane, which produces a larger out-of-plane methylene displacement.

The two-fold molecular symmetry approximation is quite good in both compounds, as may be seen by inspecting the groups of four numbers given in the central of part of Table 5. The first and second entries are similar, as are the third and fourth. Both molecules are twisted so that the aromatic rings are not directly one above the other, and the twist is greater for the selenium compound. The various differences in bond lengths and angles combine to give a sizeable increase in the intramolecular X—X distance of 24.4 pm in changing from S to Se. It may be seen from Fig. 1 that this increase in molecular size in the X—X direction is probably responsible for the *a*-axis of the Se compound being 28 pm larger than that of the S compound, a major difference between the unit cell parameters. In the lower section of Table 5 the numbers show that the intramolecular ring-to-ring distances are only slightly larger for the selenium compound, and that the dihedral angle is 1.5° smaller, an almost negligible difference.

We can now amplify our previous statement (2), that in the dithiametacyclophane, **2***a*, the deviations of the benzene ring angles from 120° are collectively greater than the differences between corre-

TABLE 4. The mean planes of the aromatic rings*, plane *1* is through C(2)—C(6) and C(8); plane *2* is through C(12)—C(16) and C(18); the angle between planes *1* and *2* = 19.1°

sponding angles in the two rings. A comparison of the diselena and dithia compounds reinforces our confidence in the estimated standard deviations derived from the full-matrix least-squares procedure, and shows that the angles are the same in the two compounds as well as between rings *1* and *2*. The angles at the internal carbon atoms such as C(2)—C(8)—C(6) have a mean value of 122.2°. The angles internal to the benzene rings at the bridge junctions have a mean value of 118.4°, and the angles such as C(1)—C(2)—C(3) which are external to both the 6- and 12-membered rings have a mean value of 121.7°.

### Discussion of the nuclear magnetic resonance data relative to the crystal structures of 1 and 2

The pertinent magnetic resonance data are given in Table 6. Whilst there have been a number of studies of $^1H$ and $^{77}Se$ nmr shifts in organoselenium compounds (see for example refs. 8 to 10), apart from correlations to electronegativity, not much has been said about $^1H$ shifts of organosulfur relative to organoselenium compounds. However, as might be expected on the basis of the very similar electronegativities (ref. 11, p. 82) of sulfur and selenium, the $^1H$mr shifts of analogous compounds are very similar. This is also quite clear from Table 6 in which many of the chemical shift differences for the compounds listed there are negligible.

For $H_i$ of **1**, **2** and —$CH_3$ of **5**, **6**, however, the chemical shift difference $\Delta(\delta_S - \delta_{Se})$ is larger and requires some explanation. In the case of **1***a*, **2***a* there are several possible explanations as to why $H_i$ for the selenium analogue **1***a* might be more shielded than $H_i$ of **2***a*. One of the well known (12) consequences of bringing two benzene rings face-

to-face is that one benzene ring shields the protons of the opposite ring. If the geometry of the molecule is known, the degree of shielding can be calculated using the tables of Johnson and Bovey (ref. 13, ref. 14, p. 595). When this calculation is carried out for H(8) and H(18) (i.e. $H_i$) of **1***a* and **2***a* using the geometry of the crystal (data given in Table 5), the average shielding of $H_i$ for the sulfur analogue (ca. 0.17 ppm) is actually less than for the selenium analogue (ca. 0.19 ppm), but the difference between these two values of only 0.02 ppm is marginal. As well, although the deshielding effect of a benzene ring on its own hydrogens changes rapidly as the distance of a hydrogen varies from the center of the ring, the difference between the calculated distances of H(8) and H(18) from the centers of their own rings in **1***a* and **2***a* is very small and has no significant effect (< 0.01 ppm) on the chemical shift differences of $H_i$.

Thus the observed difference of chemical shift of $H_i$ for **1** and **2** of 0.36 ppm is probably caused by a through space heteroatom anisotropy effect. Whilst the exact calculation of the shielding of a hydrogen close to a heteroatom is rather complex (see, for example, ref. 14, p. 130), certainly it is reasonable that such shielding would be distance dependent. As can be seen from Table 5, the $H_i$–Se distance of **1***a* is notaby greater than the corresponding $H_i$–S distance of **2***a*, and this may explain the observed chemical shift difference, without the necessity of invoking participation of an *anti*-conformer such as **1***b* to account for the shielding of $H_i$ of **1**. This would then be consistent with the results found (2) for **2**.

Further support for this suggestion can be found by considering the C(8)–C(18) and H(8)–H(18) distances given in Table 5. In both cases these are greater for the selena compound, which should result in less strain for the latter, and less need to invoke *anti*-conformer involvement. However, as the size of the substituent (Z) on C(8) and C(18) grows then the compression between Z(8) and Z(18) becomes of paramount importance (for a review see ref. 15 and the *anti*-conformer is generally preferred, e.g. in the case of **5**, the *anti:syn* ratio observed experimentally in their preparation is about 7:1 (6). Thus in *syn*-**5** the $CH_3(8)$–$CH_3(18)$ distance measured (16) is 352 pm, considerably less than the normally expected distance of closest approach of about 400 pm (ref. 11, p. 109). In the case of **1***a* and **2***a* however, the H(8)–H(18) distances are greater than the closest approach values of ca. 240 pm, and hence the preference for *syn*-conformation.

The $^{13}$Cmr spectra (1) of **1***a* and **2***a* are very similar to each other with the exception of the methylene bridge carbons (C-1, 7, 11, 17) which for **1***a* appear at δ27.8 whereas for **2***a* are at δ37.7. The shielding in the selenium case is probably due to the neighbour anisotropy shielding term (17) which would be expected to be larger for selenium than sulfur. Presumably this must be counteracted to some extent by any steric effect, since the thia-compound **2***a* is the more strained, and much of this occurs by bending these particular carbon atoms out of the planes of the benzene rings (see Table 5) which would be expected (17) to shield the carbon atoms in their $^{13}$Cmr spectra.

Unfortunately the crystal structures of the *anti*-compounds **5** and **6** are not yet available. Nevertheless, from the data observed in this comparison between **1** and **2** it would seem reasonable to expect that because of the longer C—Se bonds (196.4 pm) relative to C—S (181.1 pm), the internal methyl groups of **6** will not be projected so far into the shielding cavity of the opposite benzene ring, and hence would be expected to be less shielded than those of **5** as observed. We hope to be able to comment further on this in due course.

COMMUNICATION

# Biogenetic type solid phase phenol coupling synthesis of alkaloids. Prelycorane species

J. W. APSIMON[1] AND D. M. DIXIT

*Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6*

Received August 4, 1981

J. W. APSIMON and D. M. DIXIT. Can. J. Chem. **60**, 368 (1982).

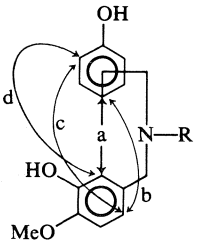
The coupling of a norbelladine derivative supported on a modified styrene – 1% divinylbenzene copolymer proceeds in modest yield to provide a coupled product whose structure corresponds to the presently undescribed precursors to the Lycorane alkaloids. The orientation of phenol coupling (*o–o*-) is different to that observed (*o–p*-) on oxidation of the nonsupported substrates.

J. W. APSIMON et D. M. DIXIT. Can. J. Chem. **60**, 368 (1982).

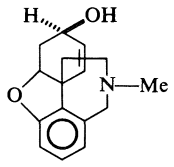
Le couplage d'un dérivé de la norbelladine fixé sur un copolymère modifié de styrène – 1% divinylbenzène se fait avec un rendement modeste et conduit à un produit couplé dont la structure correspond au précurseur d'alcaloïdes du Lycorane qui ne sont pas encore décrits. L'orientation du couplage du phénol (*o–o*) est différente de celle observée (*o–p*) lors de l'oxydation des substrats non fixés sur un support.

[Traduit par le journal]

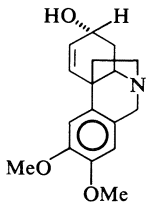
Oxidative coupling of phenols (1) plays an important role in the biosynthesis of a large variety of natural products. Alkaloids present in the Amaryllidaceae demonstrate beautifully the varied operations of phenol coupling (2). These compounds are present in three skeletal types (**2**, **3**, and **4**) all derived from a single biogenetic precursor, related to 4′-*O*-methylnorbelladine (**1***b*) by the coupling modes a, b, and c, shown.



**1***a* R = H
*b* R = Ⓟ

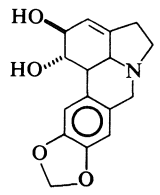


Golanthamine **2** (via a)

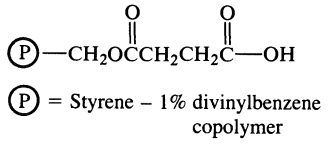


Crinine **3** (via b)

Barton and Cohen (3) outlined a mechanism whereby these three major structural types among these alkaloids were derivable from this parent compound by intramolecular oxidative coupling of two phenolic rings, a hypothesis that has been supported by radioactive tracer evidence (4). In vitro oxidations of norbelladine derivatives have yielded both crinane (**3**) (5) and galanthamine (**2**) (6) type compounds but to date we are unaware of a phenolic coupling route that has led to the lycorane type species (mode c or d), although several



Lycorine **4** (via c)



**5**

stepwise syntheses of this type of compound have been recently reported (7). With a couple of exceptions, in vitro biomimetic phenolic coupling reactions have been unsatisfactory because of low yields. Some while ago we became interested in the possibility of solving this problem by examining the oxidation of phenolic precursors supported on a solid phase (8). In this manner we felt that the intermolecular coupling reactions (polymerization) of the phenolic radicals would be reduced and, hopefully, the products of intramolecular reaction would be increased. Although this goal is still not completely realised we have been successful in accomplishing coupling on a polymer support, and our preliminary results are reported here suggesting mode d outlined above.

4′-*O*-methylnorbelladine **1***a* has three sites (2 phenol, 1 amine) available for anchoring onto a polymer support, although bonding at the amino group appears to be preferable since at the same time as leaving two phenolic groups required for the oxidative experiments, the nitrogen atom is also protected from oxidation. Of the many polymers examined as a suitable support (9) for the

diphenol, only one was found to be suitable in both specific amine anchoring and deanchoring reactions. This polymer **5** is prepared by the esterification of hydroxymethylated styrene – 1% divinylbenzene polymer with succinic anhydride in DMF and pyridine (ir $\nu_{max}$ (KBr): 1730 (ester), 1710 (acid) $cm^{-1}$ (10)).

Reaction of **1***a* and **5** in the presence of dicyclohexylcarbodiimide provided the supported diphenol **1***c* (ir $\nu_{max}$ (KBr): 1730 (ester), 1645 (amide) $cm^{-1}$) in a concentration of about 0.05 mmol of diphenol per gram of resin. Anchoring appears to have occurred only on nitrogen. Oxidation of **1***c* with a variety of one-electron oxidizing agents, followed by deanchoring of the reaction products from the resin with potassium carbonate in methanol, was disappointing until we chose vanadium oxytrichloride (5, 11) in methylene chloride at −55°C. After deanchoring and tlc purification a product was obtained (approx. 30% yield) to which we assign structure **6***a* (isolated as its methylated derivative **6***b* after treatment of the reaction mixture with diazomethane).[2]

The structure of **6***b* follows from spectroscopic data. The high resolution mass spectrum indicates that coupling has occurred ($M^+$ 399.1697, $C_{22}H_{25}O_6N$ requires $M^+$ 399.1682) and its infrared spectrum shows strong intramolecular hydrogen bonding (3420 $cm^{-1}$) together with ester (1730 $cm^{-1}$) and amide (1645 $cm^{-1}$) absorptions. The uv spectrum ($\lambda_{max}$ EtOH, 225 nm (log ε 3.32), 277.5 (log ε 1.07) suggests a skewed diphenyl. The $^1H$ nmr spectrum (100 MHz FT JEOL) indicates a mixture of conformers at room temperature, but at 120°C in DMSO-$d_6$ simplification is observed (together with thermal decomposition), revealing the two AX aromatic proton systems (centred at 6.95 and 7.28 ppm) together with the single *m*-proton signal (6.98 ppm, $J$ = 1 Hz). The *o*–*m*-cyclophane system and the *o*,*o*′-substituents of **6** presumably lead to this conformational barrier.

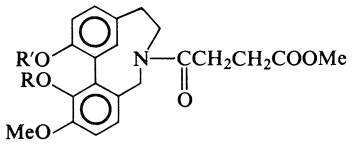
It is apparent that **6***a* represents the primary cyclization product leading to the lycorane-type alkaloids (e.g. **4**). Its formation in this case is in distinct contrast to Schwartz's $VOCl_3$ oxidation of the trifluoroacetyl derivative of **1***b* (5) and Tobinaga's electrochemical cyclization of the same compound (12). Both of these reactions yielded *p*–*p*′ coupling products.

Probably the solid matrix used immobilizes the diphenyl system in some way to restrict the previously observed in vitro coupling mode. The vanadium oxytrichloride may also help in the efficient cyclization by the intervention of a cyclic coupling mode as shown in **7**.

The data presented for **6***b*, while indicating that coupling has occurred ($M^+$) and that a diphenyl system is present (nmr, uv, ir), do not distinguish between this structure and the alternate structures **8**, **9**, and **10**. Of these, the proton nmr data eliminated **9** and **10** (2 AX systems in aromatic region) and all are eliminated from consideration by the observation of strong intramolecular hydrogen bonding in the infrared spectrum of **6***b*.

The dibenzo[*c*,*e*]azocine system present in **8** has been reported (13); amongst other spectral data this system displays that are not consistent with the proposed **6***b*, it is to be noted that the $ArCH_2N$ protons are of substantially different chemical shift (~ 2.2 ppm) and show a geminal coupling constant of 14 Hz. No such signals can be detected in the nmr spectrum of **6***b*. Further, work from this laboratory[3] has led to a synthesis of **8***b*, a compound which is far more stable than **6***b* and whose nmr spectrum can be analysed in a first-order manner at room temperature.

A natural product, Nivaldine (14), is also known which possesses the basic structure of **8** (minus the hydroxyl group on the topmost ring). The mass spectral fragmentation of this species is reportedly (15) characteristic for the dibenzazocine ring sys-



**6***a* R = R′ = H

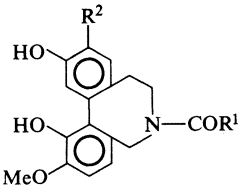
[2]Compound **1***b* (200 mg) was anchored to resin **5** (5 g) and suspended in dry methylene chloride (40 mL). The suspension was treated at −55°C under argon with an excess of $VOCl_3$ (2.4 mL) for 48 h. The resin was then filtered, washed successively with $CH_2Cl_2$, $H_2O$, 6 *N* $H_2SO_4$, $H_2O$, and acetone, and dried *in vacuo*. The resin was then transesterified with methanol and $K_2CO_3$ and the product obtained was treated with ethereal-diazomethane. Preparative tlc provided **6***b* (47 mg) which slowly crystallized from ether as conglomerates of fine needles, mp 132–134°C.

[3]J. W. ApSimon and D. M. Dixit. Unpublished data.

tem. The mass spectrum of **6***b* exhibits none of the reported major fragmentation patterns of Nivaldine.

The intriguing possibility of modifying hitherto observed reaction pathways by solid phase conformational restriction, the conversion of **6** to known lycorane alkaloids, and parallel reactions in the benzylisoquinoline field are presently in progress in our laboratories.



**8***a* $R^1 = COCH_2CH_2COOMe$; $R^2 = H$
**8***b* $R^1 = COCH_2CH_2COOMe$; $R^2 = OMe$

# The biosynthesis of cyclopropane fatty acids. II. Mechanistic studies using methionine labelled with one, two, and three deuterium atoms in the methyl group

PETER H. BUIST AND DAVID B. MACLEAN
*Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1*

Received May 26, 1981

PETER H. BUIST and DAVID B. MACLEAN. Can. J. Chem. **60**, 371 (1982).

The mechanism of formation of monodeuterated cyclopropane fatty acids on administration of L-methione-methyl-$d_3$ to *L. plantarum* has been investigated. It has been found that the extent of exchange is not affected by the presence of oxygen in the medium, that neither formate-$d_0$ nor formaldehyde-$d_2$ is significantly incorporated into the fatty acid, and that methionine reisolated from the intracellular pool does not contain any exchanged species. These experiments militate against any mechanism involving exchange prior to methyl group transfer. Parallel feeding experiments using methionine labelled in the methyl group with one, two, or three deuterium atoms were carried out and in this way that extent of exchange was quantitated. It was found that at least one-third of the cyclopropane fatty acid from methionine methyl-$d_3$ experiments is derived from an exchanged methyl group. The intramolecular and intermolecular primary deuterium isotope effects for biological cyclopropane ring formation were measured and found to be 3.2 ± 0.5, and 1.01 ± 0.04, respectively. These results are consistent with a mechanism in which a methyl group is transferred in a slow step which is followed by a fast, partially reversible, protonation–deprotonation step.

PETER H. BUIST et DAVID B. MACLEAN. Can. J. Chem. **60**, 371 (1982).

On a étudié le mécanisme de formation du cyclopropane monodeutéré d'acides gras contenant un cyclopropane monodeutéré en administrant de la L-méthionine-méthyl-$d_3$ au *L. plantarum*. On a trouvé que le taux d'échange n'est pas affecté par la présence de l'oxygène dans le milieu et que ni le formiate-$d_0$ ni la formaldéhyde-$d_2$ ne s'incorporent de façon significative dans l'acide gras et que la méthionine réisolée du bain intracellulaire ne contient aucune espèce inchangée. Ces expériences militent contre tout mécanisme impliquant un échange avant le transfert du groupe méthyle. On a réalisé des expériences parallèles d'alimentation utilisant de la méthionine marquée au niveau du groupe méthyle avec un, deux ou trois atomes de deutérium et dans cette voie on a pu mesurer le taux d'échange. A partir des expériences avec la méthionine-méthyl-$d_3$ on a trouvé qu'au moins un tiers du cyclopropane de l'acide gras provient du groupe méthyle échangé. On a mesuré que les effets isotopiques primaires intra et intermoléculaires du deutérium lors de la formation biologique du cyclopropane sont respectivement de 3,2 ± 0,5 et de 1,01 ± 0,4. Ces résultats sont en accord avec un mécanisme dans lequel il y a transfert d'un groupe méthyle dans l'étape lente qui est suivi par une rapide étape de protonation–déprotonation qui est partiellement réversible.

[Traduit par le journal]

The biosynthesis of cyclopropane fatty acids involves the construction of a methylene bridge across the *cis* double bond of an unsaturated precursor. The methylene group is derived from *S*-adenosyl-L-methionine (SAM) which in turn is formed by reaction of L-methionine with adenosine triphosphate (1). Recently, we reported the results of methionine-methyl-$d_3$ feedings, to *Lactobacillus plantarum*, where up to 17% of a monodeuterated cyclopropane fatty acid was formed along with the expected $d_2$ species (2). Clearly, substantial amounts of label had been exchanged out at some stage in the biosynthetic pathway. A similar exchange phenomenon had been observed in biological exomethylene group formation, a process thought to involve the same initial carbocationic intermediate as that postulated for cyclopropane group biosynthesis (Scheme 1) (3). Reversible 1,3 $H^+$ elimination would lead to exchanged product. Lederer has shown quite conclusively that, in methionine-methyl-$d_3$ feedings leading to exomethylene group formation, the methyl group had not undergone exchange prior to the methyl transfer step (3). Here we report experiments designed to investigate whether exchange had occurred in our feeding experiments, by processes unrelated to the cyclopropanation reaction. Furthermore, by carrying out parallel feeding experiments using methionine labelled with one, two, or three deuterons in the methyl group, the extent of exchange could be quantitated. The data from these experiments allowed the calculation of an intramolecular primary deuterium isotope effect for the proton abstraction step in the cyclopropanation reaction. Comparison of this value with the

*All culture media contained biotin at 10 μg/L.

results of an intermolecular isotope effect experiment yielded further mechanistic information.

One possible mechanism for methyl group exchange would be the degradation of methionine to formaldehyde or formate followed by resynthesis of methionine. Liu and Hofman (4) were able to obtain low levels of incorporation of formate-$^{14}$C into the bridgehead position of cyclopropane fatty acids and low levels of methionine biosynthesis have been detected in *L. casei* (5), a closely related microorganism, also capable of performing the cyclopropanation reaction. A series of experiments, designed to test for methionine degradation and resynthesis, was carried out. Since oxygen might be involved in the oxidative degradation of methionine, two methionine-methyl-$d_3$ feedings, one under anaerobic and one under aerobic conditions, were carried out (Experiments 1 and 2, Table 1). In another experiment, formaldehyde-$d_2$ (Experiment 3) along with L-methionine-methyl-$d_0$ was administered to the organism. Two further experiments were performed in which nonlabelled formate was fed at 0.7 × (Experiment 4) and at 1.3 × (Experiment 5) the concentration of methionine-methyl-$d_3$ to the organism. Finally, intracellular methionine was isolated from the aerobically grown cells (Experiment 1) and the bis-TMS derivative examined by gc-ms (Table 2).

From examination of Tables 1 and 2, it is evident that *de novo* methionine biosynthesis from formaldehyde-$d_2$ is not involved in $d_1$-cyclopropane fatty acid formation.

Removal of oxygen from the culture medium did not reduce $d_1$-cyclopropyl fatty acid formation (Experiments 1, 2). Neither formate or formaldehyde was incorporated into the cyclopropane fatty acid (Experiments 3, 4, 5). Finally, reisolated methionine contained no $d_1$ or $d_2$-species within experimental error (Table 2).

TABLE 2. Intracellular methionine isolation experiment

| Compound analyzed | % $d_0$ | % $d_1$ | % $d_2$ | % $d_3$ |
|---|---|---|---|---|
| Methionine administered | 14.0 | 0 | 1.0 | 85.0 |
| Cyclopropane fatty acid isolated | 16.4 | 11.6 | 72.0 | |
| Methionine isolated | 51* | 1.0 | 0 | 48.0 |

*The large amount of $d_0$-methionine was derived from the methionine tracer used to isolate the intracellular methionine.

It is also possible that SAM-methyl-$d_3$ loses deuterium by a simple exchange process. This seems unlikely for a number of reasons. Firstly, the pH inside fermenting cells of *L. plantarum* has been shown to be approximately 5.4 (6). These slightly acidic conditions would not favor rapid exchange of a methyl sulfoniun salt. Nuclear magnetic resonance experiments have shown that *S*-methyl-methionine does not exchange its methyl protons in neutral medium. Secondly, SAM-methyl-$d_3$ has been isolated from yeast (Fleischmann, Standard Brands, Inc.) and shown to have the same deuterium content, within experimental error, as that of the methionine from which it was biosynthesized (7). Thirdly, natural products, containing methyl groups derived from SAM-methyl-$d_3$ via simple methyl transfer to electron-rich centres, do not contain any significant $d_2$ or $d_1$-species (8–15).

Notes to Table:
1. The results of Experiment II are included to show that even though these cells grew out more slowly than those in Exp. I, the resulting distribution of deuterium in the cyclopropyl product was similar. The results of Exp. I are used for the calculations.
2. Isotopic compositions of the cyclopropane fatty acid were corrected for both the isotopic composition of the labelled methionine (which in all cases did not consist of one isotopic species) and for endogenous $d_0$-methionine and $d_0$-cyclopropane fatty acid in the inoculum. The latter value was estimated to contribute ca. 2% to the $d_0$ content of the cyclopropyl product. The corrected isotopic compositions are given in parentheses to an accuracy of ±2%.

If exchange is actually occurring at the active site of cyclopropane synthetase, it would be of interest to quantitate this process, namely, to determine the percentage of methyl groups that go through the reaction sequence irreversibly. Our approach was to carry out three parallel feeding experiments, using methionine labelled with one, two, or three deuterons in the methyl group, and then determine by mass spectrometry the deuterium distribution in the resulting biosynthetic cyclopropane fatty acid. The results are shown in Table 3.

The extent of exchange at the methyl group in the methionine-methyl-$d_3$ feedings was calculated in the following manner. In the feeding using methionine-methyl-$d_3$ (Table 3, hereafter referred to as Experiment A), a $d_3$-methyl group must have exchanged to give a $d_2$-methyl group which in turn might have exchanged to give a $d_1$ and eventually a $d_0$-methyl group species. In the feeding using methionine-methyl-$d_2$ (Table 3, hereafter referred to as Experiment B), a $d_2$-methyl group might have exchanged to give a $d_1$ and eventually a $d_0$-methyl group species. Assuming, for the moment, that the extent to which a $d_2$-methyl group exchanged was the same in both experiments A and B, then one can calculate the amount of cyclopropyl product derived directly or indirectly from such a species in Experiment A. Thus, associated with the 11.5% of $d_1$-product obtained in Experiment A was a certain amount of $d_2$-product which also arose from a $d_2$-methyl species. This amount can be calculated by taking the ratio of the $d_1$ content obtained in Experiments A and B and multiplying this value by the $d_2$ content obtained in Experiment B. This is $(11.5/35.1 \times 63.8) = 20.9$. Adding this number to the $d_1$ and $d_0$ content obtained in Experiment A gives the total amount of cyclopropane fatty acid derived from an exchanged methyl group species. The extent of this exchange was $(20.9 + 11.5 + 0.8) = 33.2\%$.

However, the extent of exchange of a $d_2$-methyl group in Experiment B may have been greater (never less) than in Experiment A. The ratio of $\%\, d_2/\%\, d_1$ used in the above calculation might, therefore, be too low and thus the above calculated value for the extent of exchange is a minimum value. From the above discussion it is clear that, typically, at least one-third of the cyclopropane fatty acid is derived from an exchanged methyl group species in a methionine-methyl-$d_3$ feeding experiment.

The results of the feeding experiments using methionine-methyl-$d_2$ (Experiment B) and methionine-methyl-$d_1$ (Experiment C) can be used to obtain primary intramolecular isotope effects for the proton abstraction step in the biological cyclopropanation reaction.

Since the extent of exchange at the methyl group in the methionine-methyl-$d_1$ and methionine-methyl-$d_2$ feedings could not be determined, only a minimum intramolecular isotope effect was calculated. This value was calculated to be $k_H/k_D = 2(\%\, d_2/\%\, d_1) = 2(63.8 \pm 2/35.1 \pm 2) = 3.6 \pm 0.2$, for the methionine-methyl-$d_2$ feeding and $k_H/k_D =$

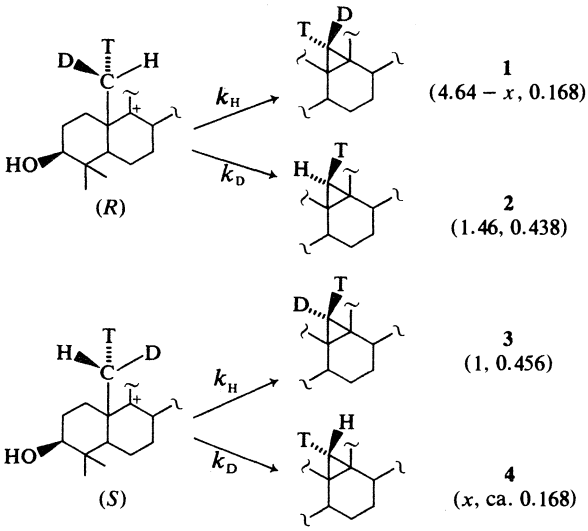
$\frac{1}{2}(\%\, d_1/\%\, d_0) = \frac{1}{2}(86.5 \pm 2) = 3.2 \pm 0.5$, for the methionine-methyl-$d_1$ feeding.[1] Exchange in the methionine-methyl-$d_1$ feeding would be less than in the methionine-methyl-$d_2$ feeding and thus the calculated $k_H/k_D$ from the former experiment would be more accurate. This value is, therefore, used in the following discussion.

From the experiments of Pohl *et al.* (16), it is possible to extract an approximate intramolecular tritium isotope effect of 5.3 for the biological cyclopropanation reaction.[2] Applying the Swain relationship (17) to the $k_H/k_D$ obtained in the methionine-methyl-$d_1$ experiment gives an intramolecular tritium isotope effect of $(3.2 \pm 0.5)^{1.44} = 5.4 \pm 0.4$, in good agreement with that obtained above.

An enzymic reaction which has been taken as the model for biological cyclopropane ring formation is the 1,3-elimination of a proton to form cycloartenol. The stereochemistry of this reaction has been studied using chiral methyl-labelled oxidosqualene containing 30% tritium enrichment to allow examination of the product by $^3$H nmr (18) (see Scheme 2).



SCHEME 2

From the intensities of the tritium nmr signals corresponding to the two tritiated products,[3] it was possible to calculate an intramolecular deuterium isotope effect of 2.8 which compares reasonably closely to the value of $3.2 \pm 0.5$ obtained from the methionine-methyl-$d_1$ feeding.

The intramolecular isotope effect obtained above are independent of the degree to which proton (deuteron) abstraction is rate limiting. It was of interest to compare these results with a primary intermolecular deuterium isotope effect in order to measure the extent to which the proton removal step is rate limiting.

A 1:1 mixture of nondeuterated L-methionine and L-methionine-methyl-$d_3$ was fed to *L. plantarum*

[1]For the loss of one hydrogen (deuteron) from a methyl-$d_1$ group, the following kinetic scheme obtains:

$$CH_2D\text{—}X \xrightarrow{2k_H} CHD\text{—}Y \qquad CH_2D\text{—}X \xrightarrow{k_D} CH_2\text{—}Y$$

The rate of $d_1$ and $d_0$ cyclopropane formation is given by $d[d_1]/dt = 2k_H[CH_2D\text{—}X]$, $d[d_0]/dt = k_D[CH_2D\text{—}X]$. Taking the ratio of the rates yields the expression for the intramolecular deuterium isotope effect: $d[d_1]/d[d_0] = 2k_H/k_D$. Integration yields: $d_1/d_0 = 2k_H/k_D$. Since $d_1 + d_0 = 1$, $\%d_1/\%d_0 = 2k_H/k_D$. Rearranging, $k_H/k_D = \%\, d_1/2(\%\, d_0)$.

For the conversion of a methyl-$d_2$ group into a methylene group, the following kinetic scheme obtains:

$$CHD_2\text{—}X \xrightarrow{k_H} CD_2\text{—}Y \qquad CHD_2\text{—}X \xrightarrow{2k_D} CHD\text{—}Y$$

The rate of $d_2$ and $d_1$ cyclopropane formation is given by $d[d_2]/dt = k_H[CHD_2\text{—}X]$, $d[d_1]/dt = 2k_D[CHD_2\text{—}X]$. Taking the ratio of the rates, integrating, and rearranging yields the expression for the intramolecular deuterium isotope effect: $d_2/d_1 = k_H/2k_D$. Thus, $k_H/k_D = 2(\%\, d_2)/(\%\, d_1)$.

[2]The above workers fed a mixture of methionine-methyl-$^3$H, and methionine-methyl-$^{14}$C in the ratio of 0.427 to 1. They isolated a biosynthetic cyclopropane which had a $^3$H/$^{14}$C ratio of 0.39 to 1. The following kinetic scheme applies if there is no intermolecular isotope effect where the amount of $^{14}CH_2$—Y formed is equal to the amount of $CH_2$—Y *and* CHT—Y formed:

$$^{14}CH_3\text{—}X \xrightarrow{k_H} {}^{14}CH_2\text{—}Y$$

$$CH_2T\text{—}X \xrightarrow{k_T} CH_2\text{—}Y \qquad CH_2T\text{—}X \xrightarrow{2k_H} CHT\text{—}Y$$

Thus $d[(CHT)]/dt = 2k_H[CH_2T\text{—}X]$ and $d[(CH_2)]/dt = k_T[CH_2T\text{—}X)$. Using similar arithmetic manipulations as in Footnote 1, one arrives at an expression for $k_H/k_T = \%\,(CHT)/2\%(CH_2) = 0.39/(0.427 - 0.39) \times \frac{1}{2} = 0.39/0.037 \times \frac{1}{2} = 5.3$.

[3]The above workers fed chiral-methyl labelled oxidosqualene (80% (*R*)-methyl and 20% (*S*)-methyl) which when cyclized gave the following distribution of products (see Scheme 2; the figures in parentheses represent $^3$H nmr intensities and the chemical shift in ppm).

The value of $x$ could be calculated by assuming identical rates of formation of compounds **2** and **4**. Since the (*R*)-methyl compound was present at four times the concentration of the (*S*)-methyl compound, then $x = 1.46/4 = 0.365$. Thus, the contribution of compound **1** to the intensity of the signal at 0.168 ppm was $4.64 - 0.365 = 4.275$ (this represents an error of 7% from the expected value of 4.0). By taking the ratios $4.275/1.46 = 2.93$ and $1/0.365 = 2.74$, one arrives at an average intramolecular deuterium isotope effect of 2.84.

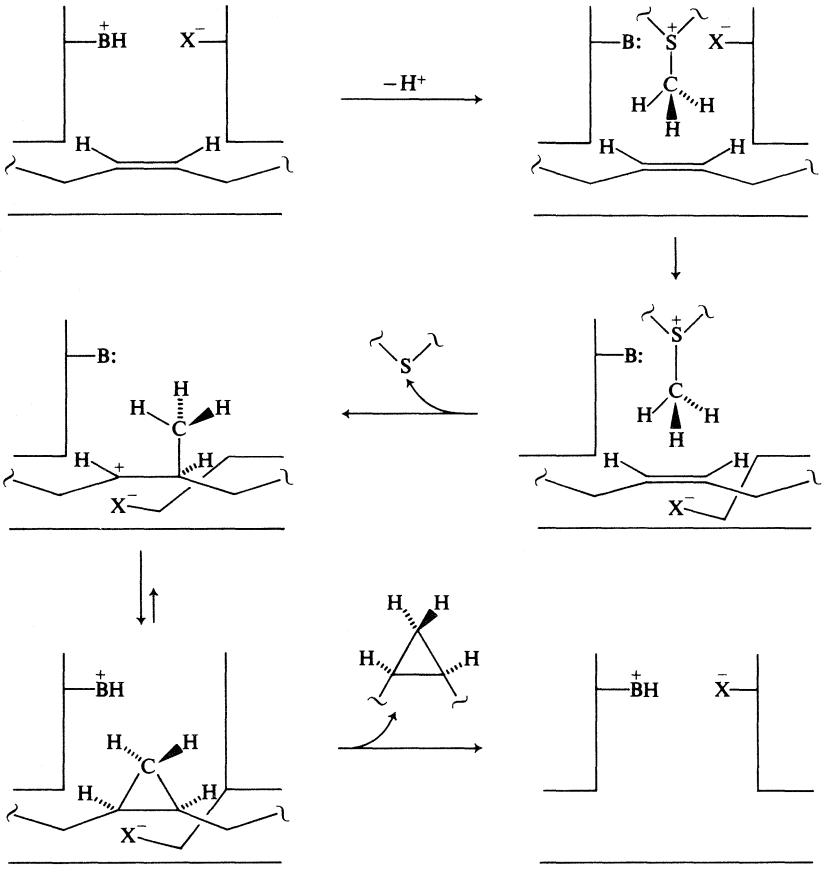

SCHEME 3

and the distribution in the resulting biosynthetic cyclopropane fatty acid measured to be: $d_0$, 51.6%; $d_1$, 5.9%; $d_2$, 42.5%. Analogous feeding experiments using only methionine-methyl-$d_3$ of the same isotopic composition as used in this experiment ($d_0$, 1.9%; $d_1$, 0.9%; $d_2$, 1.4%; $d_3$, 95.8%) gave rise to a biosynthetic cyclopropane fatty acid with the following isotopic composition: $d_0$, 1.5%; $d_1$ 13.8%; $d_2$, 84.7%. Thus in the intermolecular isotope effect study described above the amount of $d_0$ material, "derived from the methionine-methyl-$d_3$", would be ca. 0.8%. Also the mole ratio of methionine-methyl-$d_0$ to methionine-methyl-$d_3$ as calculated by the weights (cf. Experimental) was 1.02. Taking these two corrections into account one arrives at a calculated intermolecular primary deuterium isotope effect, $k_H/k_D$, of $(50.8 \pm 1.4)/(1.02(0.8 + 5.9 + 42.5) \pm 1.7) = (50.8 \pm 1.4)/(50.2 \pm 1.7) = 1.01 \pm 0.04$. The lack of any significant intermolecular isotope effect means that proton–carbon bond cleavage is not a rate-determining step in the cyclopropanation reaction. (This interpretation assumes that biological cyclopropanation does not deplete the cell of SAM, in which case no isotope effect would be observed. The results of Cronan *et al.* suggest that cyclopropanation is not a means of disposing of excess SAM (19).)

It is tempting to account for the negligible intermolecular isotope effect in terms of a carbonium ion mechanism (Scheme 1) where deprotonation of a carbonium ion intermediate would be expected to be a more facile process than methyl transfer to an unactivated double bond. Akhtar and Jones (20) have postulated that biological methylation of isolated double bonds is initiated by an enzymic conformational change which separates the methyl sulfonium cation from its anionic counterion. (Scheme 3).[4] It is possible that a third group (B), such as the ε-amino group from a lysine residue, plays an important role in these reactions.

[4]Bringing the $X^-$ group below the olefinic plane as shown in our scheme could enhance the nucleophilicity of the olefin due to steric compression. (The postulation of an $X^-$ group has recently gained some experimental support from the inhibition studies of P. Benveniste and co-workers using sterols carrying an ammonium group at C-25 (21).)

In the absence of SAM, it could serve as the counterion to the $X^-$ group. In its deprotonated form B could abstract a proton from the carbocationic intermediate (formed on transfer of methyl) resulting in a second charge-separated state which could partition via one of two possible pathways: (1) reprotonation of the cyclopropane ring; (2) release of product to form the original ion pair. (The 9β,19 cyclopropane ring cleavage reaction in phytosterol biosynthesis (22) is presumably also initiated by protonation using an unsolvated acid in analogy to the postulated protonation of isolated double bonds in biochemical hydrogenation reactions (20).) The results presented in this paper indicate that approximately one-third of the total cyclopropyl fatty acid is derived from an exchanged methyl group species and thus the ratio of the rate of reprotonation to the rate of product release is at least 1:2. We have also observed that the exchange increases with cell growth or decreasing pH (2). It is not inconceivable that the reprotonation reaction could be favoured at decreased pH. Further work with buffered cell-free systems is needed to clarify this point.

## Experimental

*Apparatus, methods, and materials*

L-Methionine-methyl-$d_3$, methyl iodide-$d_1$, and methyl iodide-$d_2$ were purchased from Merck Sharpe and Dohme, Point Claire, Quebec. L-Methionine-methyl-$^{14}$C was obtained from New England Nuclear. Paraformaldehyde-$d_2$ was a generous gift from Professor D. Moule, Brock University, St. Catharines, Ontario.

Deuterium determinations were performed by mass spectrometry using either a CEC model 21-110-B mass spectrometer at 70 eV, using a direct introduction probe, or a VG micromass 7070 F instrument at 70 eV, coupled to a Varian model 3700 gas chromatograph. The experimental error in the deuterium content measurements was estimated to be ±1% for each isotopic species expressed as a percentage, unless otherwise stated. The mass spectrometry methods were described in detail earlier (2).

The methionine isolation experiment was carried out using a Beckman Model 119 automatic amino acid analyzer, equipped with a single column (32 cm × 0.9 cm id) packed with Durrum DC-6A cation exchange resin.

The microorganism used in this study was *Lactobacillus plantarum* ATC 8014, available from the American Type Culture Collection. The basal medium used for each feeding experiment was that of Henderson and Snell (23). The details of the microbiological aspects of this work have already been described elsewhere (2). The fatty acids were isolated from the microorganism as previously described (2).

*Methionine-methyl-*$d_3$ *feeding under aerobic and anaerobic conditions (Experiments 1 and 2)*

The basal medium (1.65 L), containing biotin (17.0 μg) and methione-methyl-$d_3$ (165.0 mg), was filter sterilized and distributed among 11 × 250 mL Erlenmeyer flasks (150 mL each). A saline cell suspension (1 mL) was used to inoculate each flask. Three flasks were fitted with 2-hole rubber stoppers and sterile argon passed through the medium for 0.5 h. The remaining flasks were fitted with disposable plugs to allow growth under aerobic conditions. The anaerobic and aerobic cultures were grown for 48 h. The anaerobically grown cells were harvested, dried, weighed (542 mg), and extracted to obtain the fatty acids (9.5 mg). The relative proportion of the three major fatty acids was as follows: *cis* vaccenic acid ($C_{18}$), 28%; palmitic acid ($C_{16}$), 38%; lactobacillic acid ($C_{19}$) 34%.

The aerobically grown cells were used to isolate methionine as well as fatty acids and a different procedure was used in the work-up. The cells were harvested, washed with water (2 × 150 mL), and resuspended in water (50 mL) in a round bottomed flask. The mixture was heated to boiling over 0.5 h and kept at 100°C for a further 10 min, with stirring. The mixture was cooled and centrifuged to obtain a pale yellow supernatant. The cells were dried, weighed (994 mg), and extracted to obtain the fatty acids (9.5 mg, $C_{18}$, 29%; $C_{16}$, 35%; $C_{19}$, 36%). The supernatant was reduced in volume to 10 mL and an aliquot (100 μL) subjected to automatic amino acid analysis to determine the methionine present.

*Isolation of methionine*

Automatic amino acid analysis showed that there were ca. 950 μg of methionine present in the 10 mL extract of 994 mg of dry cells. Thus, the intracellular pool of methionine was 0.65 μmol per 100 mg of dry cell weight. To an aliquot of the extract (2.5 mL) was added sulfosalicylic acid to precipitate the protein present in the sample. The sample was concentrated to 500 μL, filtered through a 20 μm Millipore filter, and ca. 0.1 μcurie of methionine-methyl-$^{14}$C was added. The sample was injected onto the automatic amino acid analyzer and the effluent collected at the column exit in 2.5 mL fractions, using a Gilson automatic fraction collector. Each fraction was checked for radioactivity by counting an aliquot (50 μL) which had been dissolved in A.C.S. aqueous counting scintillant. All the radioactivity was contained in 3 fractions, collected at a retention time of ca. 148 min, using a flow rate of 70 mL/h.

The three fractions were individually cleaned up to remove lithium citrate buffer. The procedure used was as follows. Dowex 1 × 8-200 (100–200 mesh) ion exchange resin (6 g) was washed with 2 *M* NaOH (50 mL) by stirring for 15 min, filtered, and washed with water (100 mL). (All water used in this procedure was deionized and passed through a charcoal filter.) The process was repeated with 2.5 *M* HCl and the cycle repeated once more. Two more cycles were carried out with warm 2 *M* NaOH (50°C) and 2 *M* acetic acid. The resin was then suspended in water and a 1.4 cm × 7 cm column made up. The column was washed with 2 *M* NaOH at 45°C (25 mL). (The NaOH solution was made up in $CO_2$-free water and the washing procedure was carried out under a KOH drying tube.) The column was washed with water (20 mL) until the pH of the effluent was ca. 7.0. The 2.5 mL fraction containing methionine and buffer was then placed on the column and the column washed with water (20 mL) until the effluent was neutral. Acetic acid (1 *M*) was added to elute the methionine and one 50 mL fraction collected and evaporated and dissolved in water (2 mL). The column was regenerated by washing with 1 *M* HCl (20 mL) and then water (20 mL).

By tlc (70% ethanol, ninhydrin spray detection), it was estimated that only 1–10 μg of methionine was present in all the fractions combined. This was about 25 times less than anticipated and may have been caused by decomposition of methionine in the extract, which had been kept in the dark for 4 months at 5°C.

The aqueous methionine solution obtained from the Dowex column was evaporated under nitrogen in a 2.0 mL reactivial which had previously been treated with a 5% dimethyldichlorosilane in toluene solution to render the surface hydrophobic. The sample was dried *in vacuo* for several hours. A mixture of

| Flask | Dry cell wt-(mg) | Cell yield (mg/100 mL) | Total fatty acid (mg) | % $C_{18}$* | % $C_{16}$* | % $C_{19}$* |
|---|---|---|---|---|---|---|
| $A_1$–$A_4$ | 640 | 110 | 14.2 | 27 | 38 | 35 |
| $B_1$–$B_4$ | 646 | 111 | 8.1 | 37 | 36 | 27 |
| $C_1$, $C_2$ | 308 | 106 | 5.8 | 29 | 28 | 43 |
| $A_5$ | 176 | 121 | 2.5 | 20 | 40 | 40 |
| $B_5$ | 177 | 122 | 1.9 | 21 | 41 | 38 |

*$C_{18}$: *cis*-vaccenic acid; $C_{16}$: palmitic acid; $C_{19}$: lactobacillic acid.

acetonitrile/BSTFA (1:3, 100 μL) was added via syringe, the mixture heated at 100°C for 10 min, and the sample analyzed by gc-ms using the following gc conditions: 3% OV-1 on Gas Chrom Q (110/120), 6 ft × 2 mm id, glass, temperature programmed from 50°–250°C at 10°/min. The $M - 117$ ion (loss of carbosiloxy) from the bis-TMS derivative of methionine was monitored at *m/e* 176–179 and the deuterium content calculated from the ion intensities.

*Formaldehyde-*$d_2$ *feeding (Experiment 3)*

Paraformaldehyde-$d_2$ (3.75 mg) was suspended in water (6 mL) and heated under reflux, at which time the white solid had disappeared. To one-half of this solution was added the basal medium (100 mL) which also contained L-methionine (10 mg) and biotin (1 μg). The medium was filter sterilized and placed in a 250 mL Erlenmeyer flask. A saline cell suspension (0.7 mL) was used to inoculate the 2 flasks. After 80 h the cells were harvested, dried, weighed (55 mg), and the fatty acids (1.3 mg) extracted. The relative proportion of the three major fatty acids was as follows: $C_{18}$, 13%; $C_{16}$, 45%; $C_{19}$, 42%.

*Methionine-methyl-*$d_3$*/formate feedings (Experiments 4 and 5)*

The basal medium (290 mL) containing biotin (2.9 μg) was distributed in two flasks (145 mL) each, supplemented with the components listed below and filter sterilized. Flask A contained methionine-methyl-$d_3$ (13.0 mg) and sodium formate (4.0 mg) (Experiment 4), flask B contained methionine-methyl-$d_3$ (6.5 mg) and sodium formate (4.0 mg) (Experiment 5). Each of the above flasks was inoculated with a saline cell suspension (1.0 mL, Klett reading of 400). Growth was monitored by measuring the pH of 5 mL aliquots. After 29 h of growth, the two flasks were harvested, the cells dried and weighed, and the fatty acids extracted.

In Experiment 4, 2.2 mg of total fatty acids were obtained from 175 mg of cells. The relative proportion of the three major fatty acids was as follows: $C_{18}$, 18%; $C_{16}$, 48%; $C_{19}$, 34%.

In Experiment 5, 3.2 mg of total fatty acids were obtained from 232 mg of cells. The relative proportion of the three major fatty acids was as follows: $C_{18}$, 35%; $C_{16}$, 32%; $C_{19}$, 33%.

L-*Methionine-methyl-*$d_2$

*S*-Benzyl-L-homocysteine (Sigma) was converted to the title compound in 80% yield by treatment with methyl iodide-$d_2$ according to the method of Nelville *et al.* (24); $^1$H nmr ($D_2O$): 2.1 (3 H, m, $CH_2CH(NH_2)CO_2H$ + $CHD_2$—S), 2.6 (2 H, m, $CH_2$—S), 3.8 (1 H, t, $NH_2CH$—COOH). Mass spectrum: the bis-TMS derivitive of the title compound was prepared by heating 1 mg of the amino acid with acetonitrile (200 μL) and bis-(trimethylsilyl)-trifluoroacetamide (BSTFA) (200 μL) at 100°C for 5 min; 1 μL of the resulting solution was injected into the gc-ms system. The gc conditions were as follows: 3% OV-1 on Gas Chrom Q (110/120), 6 ft × 2 mm id, glass, temperature programmed from 50°–250°C at 10°/min. The molecular ions at *m/e* 293 ($M^+$, $d_0$), *m/e* 294 ($M^+$, $d_1$), and *m/e* 295 ($M^+$, $d_2$) were scanned and the deuterium distribution was calculated to be: $d_2$, 96.7%; $d_1$ 2.7%; $d_0$ 0.6%.

L-*Methionine-methyl-*$d_1$

The title compound was prepared by a method identical with that described above, except that methyl iodide-$d_1$ was used; $^1$H nmr ($D_2O$): 2.1 (4 H, m, $CH_2CH(NH_2)COOH$, $CH_2D$—S). Mass spectrum: by a similar analysis to that described above, the following deuterium content was calculated: $d_1$, 97%; $d_0$, 3%.

*Intermolecular isotope effect study*

L-Methionine (49.475 mg), L-methionine-methyl-$d_3$ (49.460 mg), and biotin (10 μg) were dissolved in basal medium (1 L). The complete medium, after filter sterilization, was distributed among 14 culture tubes (10 mL each) and among 7 × 250 mL Erlenmeyer flasks (125 mL each). A saline cell suspension (0.05 mL) was used to inoculate each of 14 culture tubes. After 24 h of growth, the resulting cultures (2 × 10 mL each) were used to inoculate each of the 250 mL flasks. The cells were allowed to grow for 24 h, after which they were harvested and the fatty acids extracted. The total fatty acid content was 9.3 mg ($C_{18}$, 9%, $C_{16}$, 34%; $C_{19}$, 57%).

*Intramolecular isotope effect study*

Basal medium (1.75 L) containing biotin(17.5 μg) was supplemented with the components listed below, filter sterilized, and distributed in 145 mL portions among 12 × 250 mL Erlenmeyer flasks ($A_1$–$A_5$, $B_1$–$B_5$, $C_1$, $C_2$). Flasks $A_1$–$A_5$ contained methionine-methyl-$d_2$ (14.5 mg each); flasks $B_1$–$B_5$ contained methionine-methyl-$d_1$ (14.5 mg each); flasks, $C_1$, $C_2$ contained methionine-methyl-$d_3$ (14.5 mg each). Each of the above flasks was inoculated with a saline cell suspension (1.0 mL, Klett reading of 400). Growth was monitored by measuring the pH of 5 mL aliquotes. After 29 h of growth, flasks $A_1$–$A_4$, $B_1$–$B_4$, $C_1$, $C_2$ were harvested, the cells dried and weighed, and the fatty acids extracted. After 48 h of growth, the same procedure was carried out with Flasks $A_5$, $B_5$. The analytical data of the above experiment are listed in Table 4.

Received May 11, 1981

PIERRE BABIN, PAULETTE LAPOUYADE, and JACQUES DUNOGUÈS. Can. J. Chem. **60**, 379 (1982).

A simple route to chalcone ethynylogues, convenient even in the presence of alkoxy or acyloxy substituents, is proposed. This method is based on the use of ethynylsilanes, the involved trimethylsilyl group being recovered during the course of the reaction.

PIERRE BABIN, PAULETTE LAPOUYADE et JACQUES DUNOGUÈS. Can. J. Chem. **60**, 379 (1982).

Une méthode simple de synthèse d'éthynylogues de chalcones, utilisable même avec des substituants alcoxy ou acyloxy, est proposée. Cette méthode met en jeu la voie organosilicique, le groupe triméthylsilyle engagé étant récupérable en fin d'opération.

Several chalcone derivatives have found pharmaceutical uses. Thus, some flavonoids having a chalcone skeleton exhibit anti-aldose reductase properties (1) and a trimethoxy derivative of chalcone (2) is currently used as a qualitative and quantitative choleretic for biliary secretion (commercial name: Vesidryl (3)). Moreover a chalcone vinylogue, the divanillidene cyclohexanone, also is a commercially available choleretic (Vanilone[2]). In the context of our studies concerning the obtention of drug ethynylogues (4, 5) we have focused our interest on the synthesis of chalcone ethynylogues having potential pharmacological properties (products with aryl groups substituted by one or several alkoxy or acyloxy substituents).

In this series only Ph—C≡C—CO—CH=CH—Ph has been described to our knowledge (6–9). It has been made according to three synthetic methods which offer possibilities of comparison.

(*a*) Condensation of Ph—C≡C—Na with cinnamic anhydride, which does not afford chalcone in high yields (~33%) (6) and raises problems with acetoxy substituents (6*b*).

(*b*) Quantitative preparation of Ph—C≡C—Cu used as precursor of chalcone (7) presents danger (9).

(*c*) Chalcone is afforded by the direct condensation of Ph—C≡CH with a stoichiometric amount of cinnamoyl chloride in the presence of triethylamine and $(Ph_3P)_2PdCl_2$ and CuI as the catalyst (9):

$$Ph—C{\equiv}C—H + Ph—CH{=}CH—COCl + Et_3N \xrightarrow[CuI]{(Ph_3P)_2PdCl_2} Ph—C{\equiv}C—CO—CH{=}CH—Ph$$
$$-Et_3N, HCl \qquad 80\%$$

Despite the formation of triethylamine hydrochloride and the use of an expensive catalyst we attempted this process for the synthesis of **13** and **7**, both previously undescribed: we obtained 55% yields in the first case but lower than 20% yield in the presence of the acyloxy substituent after 48 h, while most of the unreacted phenyl acetylene was recovered.

The proposed routes are not generally adaptable to the preparation of alkoxy or acyloxy substituted structures. For all these reasons we decided to investigate the synthesis of chalcone ethynylogues from alkynylsilanes and aryl substituted cinnamoyl chlorides since alkynylsilanes react with electrophiles (10, 11) such as acyl chlorides under Friedel–

TABLE 1. Synthesis of chalcone ethynylogues

| Ar | Ar′ | Yields % crude products | Yields % after recrystallization | Number |
|---|---|---|---|---|
| Ph- | Ph- | 55 | 40 | **6** |
| Ph- | | 60 | 40 | **7** |
| | Ph— | 50 | 30 | **8** |
| | | 38 | 38[a] | **9** |
|  |  | 40 | 30 | **10** |
|  |  | 60 | 40 | **11** |
|  | | 50 | 30 | **12** |

[a]Liquid product.

Crafts conditions, at least in the absence of alkoxy and acyloxy substituents.

Several routes were used for the preparation of ethynylsilanes. Ethynyltrimethylsilane was obtained by silylation of trichloroethylene (12); (*p*-methoxyphenylethynyl)trimethylsilane (15, 16) **5** was synthesized by condensation of ethynyltrimethylsilane on *p*-methoxy iodobenzene (13); (phenylethynyl)-trimethylsilane **1** was prepared from phenylacetylene (14), whereas the other substituted (phenylethynyl)trimethylsilanes (*o*-RO—$C_6H_4$—C≡C—$SiMe_3$, R = H, **2**, $SiMe_3$, **3**, COMe, **4**), also new compounds, were easily obtained from *o*-$Me_3SiO$—$C_6H_4$—C≡CH described in one of our previous publications (4).

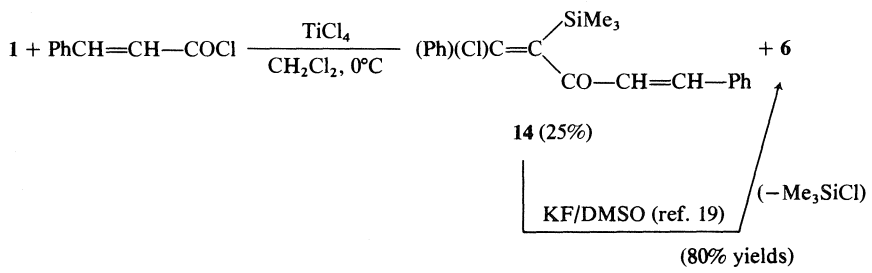
Chalcone ethynylogues were formed according to:

$$Ar—C{\equiv}C—SiMe_3 + Ar'—CH{=}CH—COCl \xrightarrow[CH_2Cl_2;\ 0°C]{AlCl_3} Ar—C{\equiv}C—CO—CH{=}CH—Ar' + Me_3SiCl$$

Results are summarized in Table 1. These results require the following comments.

(*i*) All the chalcone ethynylogues have a *trans* structure ($AlCl_3$ isomerizes *cis* to *trans* α,β-ethylenic ketones) (17).

(*ii*) In an attempt to improve the results we replaced $AlCl_3$ by $TiCl_4$, which often limits the formation of degradation products (18). The ethynylogue of the nonsubstituted chalcone was obtained in only 20% yields but the silylated intermediate **14** could be isolated. The stereochemistry of the reaction was not determined.



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

The route we propose for the synthesis of chalcone ethynylogues appears to be synthetically convenient even in the presence of acyloxy substituents since the involved trimethylchlorosilane was recovered during the acylation reaction.

## Experimental

All the new compounds exhibit satisfactory C, H analyses. Microanalytical data are available on request.

*Ethynylsilanes*

H—C≡C—$SiMe_3$, **1**, and **5** were prepared according to refs. 12, 14, and 13 respectively. Compounds **2**, **3**, and **4** were synthesized from *o*-$Me_3SiO$—$C_6H_4$—C≡C—H (4) by classical replacement of the acetylenic proton by a $Me_3Si$ group followed by hydrolysis or acetylation. Infrared $cm^{-1}$: 1250, 840, and 755 ($SiMe_3$); 2170 ($\nu_{C\equiv C}$) and 3500 ($\nu_{OH}$) for **2**; 1760 ($\nu_{C=O}$) for **4**.

*(2-Hydroxyphenylethynyl)trimethylsilane* **2**

Boiling point: 80°C/1 Torr; nmr ($CCl_4$, TMS) δ ppm: 0.30 (s, 9H, $SiMe_3$), 6.1 (s, 1H, OH which disappears when added $D_2O$), 7.0–7.8 (m, 4 arom H).

*(2-Trimethylsiloxyphenylethynyl)trimethylsilane* **3**

Boiling point: 80–83°C/1 Torr; nmr δ ppm: 0.24 (s, 9H, $SiMe_3$), 0.30 (s, 9H, $SiMe_3$), 7.3–7.8 (m, 4 arom H).

*(2-Acetoxyphenylethynyl)trimethylsilane* **4**

Boiling point: 105°C/1 Torr; nmr δ ppm: 0.25 (s, 9H, $SiMe_3$), 2.23 (s, 3H, OCOMe), 6.9–7.5 (m, 4 arom H).

*Chalcone etynylogues*

The general procedure given by Birkofer *et al.* (10) was modified as follows: ethynylsilane (15 mmol in 20 mL $Ch_2Cl_2$) was added dropwise at −30°C to the complex formed from acyl chloride (15 mmol) and $AlCl_3$ (15 mmol) in 40 mL $CH_2Cl_2$ under $N_2$ atm. After 1 h at −30°C, the reaction mixture was left 2 h at 0°C, then poured into ice-cold water containing $NH_4Cl$ and $NaHCO_3$. Products were extracted with $CH_2Cl_2$ and the organic layer washed, dried with $Na_2SO_4$, and the solvent and $Me_6Si_2O$ evolved. Then the products were purified on a silica column (Kieselgel 60, 70–230 mesh ASTM) using benzene, benzene–ether, or methylene chloride as the eluent (as specified below).

Compound **6** also was synthesized from PhCH=CH—COCl/$TiCl_4$ according to a similar procedure ($TiCl_4$ replacing $AlCl_3$). Dechlorosilylation of **14** was carried out according to ref. 19 (3 h at 70°C); **7** and **13** also were prepared according to the method of Tohda *et al.* (9) starting from phenylacetylene (15 mmol).

Except for the nonsubstituted chalcone ethynylogue **6** previously described (9), all the other ethynylogues are new compounds.

*5-(2'-Acetoxyphenyl) 1-phenyl pent-1-yn 4-enone* **7**

Melting point (ether/pentane, 1:1 vol) 88°C; eluent: $CH_2Cl_2$; ir $cm^{-1}$: 2225 and 2195 (C≡C), 1775 (C=O ester), 1640 (C=O ketone), 1610 (C=C); nmr δ ppm: 2.23 (s, 3H, OCOMe), 6.56, 6.84, 7.72, 8.00 (AB spectr, $J \simeq 16.5$ Hz, 2H, CH=CH), 6.80–7.75 (m, 9 arom H).

*1-(2'-Acetoxyphenyl) 5-phenyl pent-1-yn 4-enone* **8**

Melting point (pentane) 72°C; **8** was purified by hplc (Jobin–Yvon Chromatospac Prep 100, silica column H 60 10–40 mesh, $CH_2Cl_2$ as the eluent); ir $cm^{-1}$: 2230 (C≡C), 1770 and 1750 (C=O ester), 1640 (C=O ketone), 1600 (C=C); nmr δ ppm: 2.31 (s, 3H, OCOMe), 6.66, 6.94, 7.80, 8.08 (AB spectr, $J \sim 16.5$ Hz, 2H, CH=CH), 7.05–7.80 (m, 9 arom H).

*1,5-Bis(2'-acetoxyphenyl) pent-1-yn 4-enone* **9**

Eluent: $CHS_2Cl_2$; ir $cm^{-1}$: 2220 (C≡C), 1765 (C=O ester), 1635 (C=O ketone), 1605 (C=C); nmr δ ppm: 2.23 (s, 6H, 2 OCOMe), 6.56, 6.83, 7.76, 8.03 (AB spectr, $J \sim 16$ Hz, 2H, CH=CH), 6.80–7.75 (m, 8 arom H).

Compounds **10**, **11**, **12**, and **13** were studied by 90 MHz nmr spectrometry with expansion of the aromatic region to specify some couplings.

*1,5-Bis(4'-methoxyphenyl) pent-1-yn 4-enone* **10**

Melting point ($C_6H_{12}/Et_2O$, 1:1 vol) 106°C; eluent: $C_6H_6/Et_2O$, 19:1 vol; ir $cm^{-1}$: 2220 and 2200 (C≡C), 1685 (C=O ketone), 1610 (C=C); nmr δ ppm: 3.70 (s, 6H, 2MeO), 6.36, 6.63, 7.45, 7.72 (AB spectr, 2H, $J \sim 16.5$ Hz), 6.69, 6.83, 7.36, 7.50 (AA'BB' spectr, $J \sim 9$ Hz, 4 arom H), 6.70, 6.84, 7.37, 7.51 (AA'BB' spectr, $J \sim 9$ Hz, 4 arom H).

*5-(3',4'-Dimethoxyphenyl) 1-(4'-methoxyphenyl) pent-1-yn 4-enone* **11**

Melting point ($C_6H_{12}/Et_2O$, 1:1 vol) 96°C; eluent: $Et_2O/C_6H_6$, 1:1 vol; ir $cm^{-1}$: 2220 and 2195 (C≡C), 1680 (C=O), 1605 (C=C); nmr δ ppm: 3.80 (s, 9H, 3MeO), 6.41, 6.68, 7.50 and 7.77 (AB spectr, $J \sim 16$ Hz, 2H, CH=CH), 6.71, 6.86, 7.40, 7.56 (AA'BB' spectr, $J \sim 9$ Hz, 4H of the disubstituted arom ring), 6.55–7.70 (m, 3 other arom H).

*5-(2'-Acetoxyphenyl) 1-(4'-methoxyphenyl) pent-1-yn 4-enone* **12**

Melting point ($C_6H_{12}/Et_2O$, 1:1 vol) 109°C; eluent: $C_6H_6/Et_2O$, 9:1 vol; ir $cm^{-1}$: 2230 and 2200 (C≡C), 1770 (C=O ester), 1645 (C=O ketone), 1616 (C=C); nmr δ ppm: 2.25 (s, 3H, OCOMe), 3.75 (s, 3H, MeO), 6.46, 6.73, 7.63, 7.90 (AB spectr, $J \sim 16$ Hz, 2H, CH=CH), 6.68, 6.83, 7.36, 7.51 (AA'BB' spectr, $J \sim 9$ Hz, 4H of the disubstituted arom ring), 6.65–7.65 (m, 3 other arom H).

*5-(4'-Methoxyphenyl) 1-phenyl pent-1-yn 4-enone* **13**

Melting point ($Et_2O$/*n*-$C_6H_{14}$, 1:1 vol) 105°C; no elution; ir $cm^{-1}$: 2220 (C≡C), 1640 (C=O), 1610 (C=C); nmr δ ppm: 3.76 (s, 3H, MeO), 6.38, 6.66, 7.48, 7.76 (AB spectr, $J \sim 16.5$ Hz, 2H, CH=CH), 6.70, 6.84, 7.36, 7.50 (AA'BB' spectr, $J \sim 8.5$ Hz, 4H of the disubstituted arom ring), 6.70–7.70 (m, 5 other arom H).

*1,5-Diphenyl 1-chloro 2-trimethylsilyl penta-1,4-dienone* **14**

# Pyrrole chemistry. XXIV. The Vilsmeier formylation and the cyanation of pyrrole acetals. A synthesis of pyrrole-2,3,5-tricarboxaldehyde

CHARLES E. LOADER, GRAHAM H. BARNETT, AND HUGH J. ANDERSON

*Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7*

Received July 15, 1981

CHARLES E. LOADER, GRAHAM H. BARNETT, and HUGH J. ANDERSON. Can. J. Chem. **60**, 383 (1982).

The preparation of the acetals of a number of pyrrole mono- and dicarboxaldehydes is described. It is shown that, provided the reactivity of the unsubstituted ring positions on the pyrrole nucleus is not too low, a carboxyaldehyde or a carbonitrile group may be substituted onto the pyrrole ring using the Vilsmeier reaction or chlorosulfonyl isocyanate respectively. Vilsmeier formylation of the diacetal, 2,4-di(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole, followed by hydrolysis gave pyrrole-2,3,5-tricarboxaldehyde.

CHARLES E. LOADER, GRAHAM H. BARNETT et HUGH J. ANDERSON. Can. J. Chem. **60**, 383 (1982).

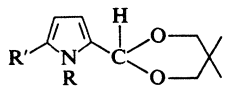
On décrit la préparation des acétals d'un certain nombre de pyrroles mono et de dicarboxaldéhydes. On montre, en admettant que la réactivité des positions non substituées du noyau pyrrole n'est pas trop faible, que l'on peut substituer un groupe carboxaldéhyde ou carbonitrile du cycle pyrrole en utilisant soit la réaction de Vilsmeier ou l'isocyanate de chlorosulfonyle. La formylation de Vilsmeier du diacétal, di (diméthyl-5,5 dioxanne-1,3 yl-2)-2,4 pyrrole, suivie d'une hydrolyse donne le pyrroletricarboxaldéhyde-2,3,5.

[Traduit par le journal]

## Introduction

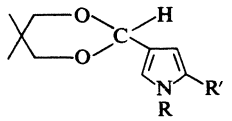
We recently reported the synthesis of 2-(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole (**1***a*) (1), and noted that it was formylated by the Vilsmeier reaction in very good yield and without appreciable hydrolysis of the acetal group, to give 5-(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole-2-carboxaldehyde (**1***b*). We have now synthesized a wide variety of substituted pyrrole acetals to assess the scope of this reaction.

The unsubstituted pyrrole 2- and 3-acetals can be prepared directly from the corresponding aldehydes and 2,2-dimethylpropane-1,3-diol but are obtained in better overall yields using indirect methods. When the 1-position on the pyrrole ring is blocked by a methyl group, excellent yields of both the 1-methyl-2- and 1-methyl-3-pyrrole acetals can be obtained directly from the aldehydes. We were also able to prepare, using similar methods, the diacetals (**1***d*) and (**2***d*) and their 1-methyl analogs. In some cases the most convenient starting material was the dialdehyde, and in others, the monoaldehyde/monoacetal (e.g. **1***d* was prepared from **1***b* rather than from the dialdehyde). Attempts to prepare the diacetal, 2-(5,5-dimethyl-1,3-dioxan-2-yl)-4-(2,5,5-trimethyl-1,3-dioxan-2-yl)-pyrrole, from 4-acetylpyrrole-2-carboxaldehyde gave much lower yields and the product was much less stable than **2***d*. Other acetals prepared directly from the corresponding aldehydes are listed in Table 1.



**1**

*a* R = R′ = H
*b* R = H, R′ = CHO
*c* R = $CH_3$, R′ = H



**2**

*d* R = H, R′ = *e* R = $CH_3$, R′ = CHO
*f* R = H, R′ = $COOCH_3$

Like the monoacetals reported earlier (1) the diacetals prepared in this work are fairly stable compounds. They can be stored at room temperature for long periods without visible change provided that they are protected from acid. Decomposition is usually attended by discoloration and the sublimation of the free diol onto the sides of the container.

Pyrrole-2-carboxaldehyde has not been formylated successfully by direct methods. Direct formylation of 1-methypyrrole-2-carboxaldehyde using the Friedel and Crafts reaction has been reported (2) to give mainly the 2,4-dialdehyde. Formylation using the Vilsmeier reaction gives a very poor yield of a mixture of 2,4- and 2,5-dialdehydes.

Vilsmeier formylation of 1-methyl-2-(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole (**1***c*) using the method that we reported for the corresponding 2-(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole (**1***a*) (1), gave an excellent yield of 1-methyl-5-(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole-2-carboxaldehyde (**1***e*) in a much cleaner reaction than that given by the 1-*H* pyrrole 2-acetal. The reaction was very selective and there was no significant amount of 2,4-substitution observed. Hydrolysis of the formylated 1-methyl-2-acetal gives 1-methylpyrrole-2,5-dicarboxaldehyde in almost quantitative yield. Although other syntheses are available (3) this

[b]Centroid of AB quartet.

procedure provides an additional convenient route to this 2,5-dialdehyde.

The acetal grouping on the pyrrole ring appears to behave as a very weakly electron-withdrawing group. Evidence for this is provided by the formation of traces (detected by $^1$H nmr) of the 4-substituted product in the Vilsmeier formylation of the 2-acetal. There is also a greater deshielding effect on the 5-position of the pyrrole ring by the acetal group as shown in both the $^1$H nmr and the $^{13}$C nmr chemical shifts compared to those for 2-methylpyrrole (4*a*, 5*a*). The $^{13}$C nmr spectra of the 5,5-dimethyl-1,3-dioxan-2-yl ring of the 2-acetal and its *N*-methyl derivative were found to be in close agreement with those reported for similar compounds as assigned by Jones *et al.* (5*b*). The observed chemical shifts are shown in Figure 1.

Electrophilic attack on 3-alkyl pyrroles reportedly gives a high proportion of 2,3-disubstituted products relative to the yield of 2,4- and 3,4-disubstituted products (4*b*). We hoped that formylation of the 3-acetals **2***a* and **2***c* would afford primarily the 2-substituted products providing a new route to some 2,3-difunctionalized pyrroles. However, formylation of the 3-(5,5-dimethyl-1,3-doxan-2-yl)-pyrrole (**2***a*) gave a mixture, which was separated by fractional recrystallization. Hydrolysis of the crude mixture of acetals gave a mixture containing 2,3- (54%) and 2,4- (46%) dialdehydes which were separated by chromatography on silica gel. Similarly, Vilsmeier formylation of 1-methyl-3-(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole (**2***c*) gave 2,3- (~34%) and 2,4- (~62%) substitution with traces of the 3,4- (~4%) disubstituted product.

Other routes available for the synthesis of the 2,3-dialdehyde involve ring synthesis followed by several steps to the desired product (6,7), and poor overall yields. The procedure described here al-

**1***a* **1***c*

FIG. 1. $^{13}$C nmr chemical shifts for **1***a* and **1***c* with shifts for pyrrole and *N*-methylpyrrole in parentheses. Assignments of resonances for C(3) and C(4) of **1***a* and **1***c* may be interchanged.

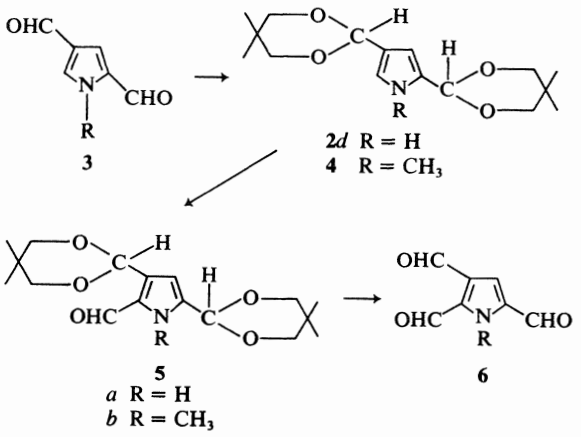
lows a stepwise synthesis from pyrrole and is thus of synthetic interest.

The acetals, methyl 5-(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole-2-carboxylate (**1***f*) and methyl 4-(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole-2-carboxylate (**2***f*) are readily prepared directly from the corresponding aldehyde-esters and we hoped that formylation of them would lead to interesting trisubstituted pyrroles. In both cases there was evidence (nmr spectrum) that some formylation took place but no product was isolated. Most of the starting material was recovered unchanged, hydrolysed to the aldehyde, or destroyed. The reactivity of the pyrrole ring in both cases is apparently too low to permit reaction with the Vilsmeier reagent under conditions where the acetal can survive.

We found that both pyrrole-2,4-dicarboxaldehyde (**3***a*) and 5-(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole-2-carboxaldehyde (**1***b*) formed their corresponding diacetals (**2***d* and **1***d* respectively) in good yields. Both of the diacetals were fairly stable crystalline solids so the Vilsmeier reaction was attempted on them. The 2,4-diacetal gave an excellent yield of the formylated product **5***a* (77%). However, the 2,5-diacetal gave only a trace of what appeared to be the desired formylation product. The unreacted 2,5-diacetal could not be recovered because it was partially hydrolysed in the work-up and the main product isolated was 5-(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole-2-carboxaldehyde (**1***b*). The failure of the 2,5-diacetal (**1***d*) to formylate can be attributed to the relatively low reactivity of the 3- and 4-positions of the pyrrole ring. In contrast, the 2,4-diacetal (**2***d*) has a reactive 5-position still available. This again emphasizes the electron withdrawing and deactivating effect on the pyrrole ring of the acetal group.

The successful formylation of the 2,4-diacetal (**2***d*) gives a route (Scheme 1) to the previously unknown pyrrole-2,3,5-tricarboxaldehyde (**6***a*). The hydrolysis of the formylated acetal (**5***a*) proved to be very difficult. Mild hydrolysis gave a mixture of monoacetals which required long and rather vigorous hydrolysis. Prolonged hydrolysis eventually gave the trialdehyde (**6***a*) in 67% yield. The $^1$H nmr spectrum of the trialdehyde showed resonances for the aldehydic protons at 9.81, 10.22, and 10.25, and for the ring proton at 7.48 ppm. Long range coupling between the ring proton and the aldehydic proton was too small to be resolved by the spectrometer used, indicating that the ring proton was in the 4-position rather than the 2-position. A ring proton in the 2-position would have produced a larger long range coupling to the 5-aldehydic proton (6). Other spectral properties were in accord with the assigned structure.



SCHEME 1

A similar series of reactions on 1-methyl-2,4-di(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole (**4**) gave 1-methyl-2,3,5-tricarboxaldehyde (**6***b*), a known compound. The melting point of our product was much higher and some of the spectral properties differed slightly from those reported by Severin and Krönig (8).[1] Direct comparison of the spectra of authentic material and our product showed them to be the same in all essential details and those differences present could be attributed to concentration effects since the original spectra had been obtained for very dilute solutions. The low melting point previously reported (8) can probably be attributed to the difficulties associated with purifying the small amount of material that was available to the original workers.

The Vilsmeier formylation of the acetals formed from 3-acetylpyrrole and from 4-acetylpyrrole-2-carboxaldehyde was also attempted but led only to extreme decomposition of the acetals. None of the desired products could be isolated from the tarry mass produced in the reaction.

We have lately reported (9) the cyanation of some substituted pyrroles using chlorosulfonyl isocyanate (CSI) in fairly good yield where the pyrrole was not too deactivated by electron-withdrawing substituents. Since the reaction can be carried out under quite mild conditions we attempted this reaction on some of the acetals. The best results were obtained by treating a solution of the acetal in *N*,*N*-dimethylformamide (DMF), with CSI at low temperature (solid $CO_2$/acetone bath) and then allowing the reaction mixture to warm near 0°C, depending on the acetal (cf. the preparation of pyrrole-2-carbonitrile (9)). Cyanation of the

[1]In a private communication Dr. Severin kindly provided additional information including copies of some of the original spectra but he was unable to provide a sample of the authentic compound.

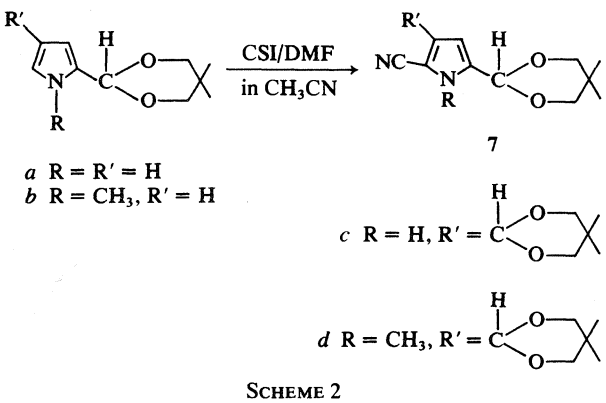
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

pyrrole-2-acetal (**1***a*) in this way gave a good yield (~85%) of a mixture of 4- (~10%) and 5- (~75%, ~63% isolated yield) cyanated product. The mixture of cyanoacetals was hydrolysed and separated by fractional crystallization to give 5-cyanopyrrole-2-carboxaldehyde (~75%) and 4-cyanopyrrole-2-carboxaldehyde (~9%). When the 1-methyl homologue (**1***c*) was cyanated in a similar fashion, only the product of 5-cyanation, **7***b*, was isolated (65% yield). Although the cyanation of **1***c* might have been expected to give more 4-substitution than **1***a*, there were no more than trace amounts of the 4-substituted product present in the crude product. This result probably does not indicate abnormal selectivity in the substitution reaction but is more likely a result of the lability of the 2-acetal (**1***a*) towards hydrolysis and other side reactions. Attempts at the cyanation of the 2,5- (**1***d*) and 2,4- (**2***d*) diacetals with CSI gave a very small yield of the 3,5-di(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole-2-carbonitrile (**7***c*) (Scheme 2) from the 2,4-diacetal but no isolable product from the 2,5-diacetal. When the nitrogen is blocked by a methyl group we again found that the yield in the reaction was greatly improved, so that the 1-methylpyrrole-2,4-di(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole (**4**) gave a 18% yield of 1-methyl-3,5-di(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole-2-carbonitrile (**7***d*).

While there is considerable scope for the use of the Vilsmeier reaction for the formylation of pyrrole acetals where the pyrrole ring is reactive towards electrophilic substitution, cyanation using CSI seems to be limited by the lability of the acetal function towards decomposition under the reaction conditions required for substitution.

## Experimental

Melting points are uncorrected. Elemental analyses were by Atlantic Microlabs, GA, U.S.A., or by Memorial University Water Analysis Facility. The ir spectra were recorded on a Perkin–Elmer 237B grating spectrophotometer as Nujol mulls or as liquid films. The $^1$H nmr spectra were determined using a Varian EM 360 instrument and are recorded on the δ scale with tetramethylsilane as internal reference. Mass spectra were recorded on a Hitachi–Perkin–Elmer RMU-6E spectrometer using a direct inlet system. The $^{13}$C nmr spectra were determined at 25.2 MHz in $CDCl_3$ on a Varian Associates XL-100/15 Fourier transform instrument.



SCHEME 2

*Preparation of acetals*

The acetals were prepared by the method reported earlier for related acetals (1) and are listed in Table 1.

*Vilsmeier formylation of pyrrole monoacetals*

For (1) to (3) below the method given for the formylation of 2-(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole in ref. 1 was used.

(1) *1-Methyl-2-(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole-2-carboxaldehyde (1e)*

1-Methyl-2-(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole gave the product, 1-methyl-5-(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole-2-carboxaldehyde (**1***e*), (95% yield), as an oil; nmr ($CDCl_3$) δ: 0.77, 1.24 (each 3H, s), 3.67 (4H, dd, $J_{AB}$ = 12 Hz), 3.99 (3H, s), 5.40 (1H, s), 6.29, 6.77 (each 1H, d), 9.47 (1H, s); $J_{3,4}$ = 4.0 Hz.

The product was immediately hydrolysed using the method described for hydrolysis of **1***e* in ref. 1 to give 1-methylpyrrole-2,5-dicarboxaldehyde (94%), mp 96–97°C (lit. (3b) mp 97°C); nmr ($CDCl_3$) δ: 4.25 (3H, s), 6.90 (2H, s), 9.78 (2H, s); *m/e*: 137.

(2) *4- and 3-(5,5-Dimethyl-1,3-dioxan-2-yl)-pyrrole-2-carboxaldehyde*

3-(5,5-Dimethyl-1,3-dioxan-2-yl)-pyrrole gave a mixture (78% yield) which was separated by fractional crystallization from ether/petroleum mixtures to give: (*i*) 4-(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole-2-carboxaldehyde (**2***b*) (46% of total product), mp 131–132°C; nmr ($CDCl_3$) δ: 0.76, 1.24 (each 3H, s), 3.64 (4H, dd, $J_{AB}$ = 12 Hz), 5.35 (1H, s), 6.97, 7.13 (each 1H, m), 9.41 (1H, s), 9.8 (1H, broad, N—H), *m/e*: 209. *Anal.* calcd. for $C_{11}H_{15}NO_3$: C 63.14, H 7.23, N 6.69; found: C 63.34, H 7.35, N 6.66; and (*ii*) 3-(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole-2-carboxaldehyde (54%), mp 105–106°C; nmr ($CDCl_3$) δ: 0.77, 1.26 (each 3H, s), 3.68 (4H, dd, $J_{AB}$ = 12 Hz), 5.62 (1H, s), 6.33, 6.93 (each 1H, m), 9.83 (1H, d); $J_{5,CHO}$ = 1.0 and $J_{3,5}$ = 1.5 Hz. *Anal.* calcd. for $C_{11}H_{15}NO_3$: C 63.14, H 7.23, N 6.69; found: C 63.40, H 7.17, N 6.58.

The mixture of acetals was also hydrolysed before purification in the usual way (1) affording a mixture of aldehydes which could be separated by fractional crystallization or by chromatography on silica gel (see ref. 6) to give: pyrrole-2,4-dicarboxaldehyde, mp 151.5–152°C (lit. (6) mp 152°C), the mixture melting point with authentic material was undepressed; and pyrrole-2,3-dicarboxaldehyde, mp 118–120°C (lit. (6) mp 123°C); ir ν: 3260 (N—H), 1660 (C=O) cm$^{-1}$; nmr ($CDCl_3$) δ: 6.72 (1H, d), 7.23 (1H, unresolved dd), 10.06 (1H, d), 10.20 (1H, s); $J_{4,5}$ = 3.0, $J_{2\text{-CHO},5}$ = 0.7 Hz.

(3) *1-Methyl-3-(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole carboxaldehyde (mixture of isomers)*

1-Methyl-3-(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole gave a mixture of monoformylated products (~53% yield). The reaction mixture was hydrolysed (1) and then the mixture of aldehydes was chromatographed on a silica gel column. Elution with benzene/ethyl acetate mixtures gave (in order) the following. 1-Methylpyrrole-2,3-dicarboxaldehyde, mp 78°C (lit. (7*a*) mp 77°C); ir ν: 1740 (C=O), 1670 (C=O) cm$^{-1}$; nmr ($CDCl_3$) δ: 3.97 (3H, s), 6.63 (1H, d), 6.80 (1H, unresolved dd), 10.22 (1H, s), 10.38 (1H, d), $J_{4,5}$ = 3.0, $J_{2\text{-CHO},5}$ = 0.7 Hz. 1-Methylpyrrole-2,4-dicarboxaldehyde, mp 96–97°C (lit. (2) mp 95°C); nmr ($CDCl_3$) δ: 3.97 (3H, s), 7.26 (1H, d), 7.40 (1H, unresolved dd), 9.56 (1H, d), 9.67 (1H, s). 1-Methylpyrrole-3,4-dicarboxaldehyde, mp 166–167°C (lit. (7*b*) mp 169°C). ir ν: 1680, 1665 (each C=O) cm$^{-1}$; nmr ($CDCl_3$) δ: 3.73 (3H, s), 7.21 (2H, s), 10.07 (2H, s).

For personal use only.

*3,5-Di(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole-2-carboxaldehyde (5a)*

*N,N*-Dimethylformamide (20 mL) was cooled in an ice bath and phosphorus oxychloride (3.0 mL) was added to the stirred liquid. The very pale yellow liquid was stirred for 10 min at room temperature and then cooled in an ice bath. Solid 2,4-di(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole (1.04 g) was added fairly rapidly to the cooled mixture and the red solution formed was stirred in the ice bath for 100 min. The reaction mixture was then poured onto a stirred mixture of 6 mol $L^{-1}$ NaOH/ice/water (~200 mL). The yellow solution was extracted with ether until the aqueous layer was almost colourless. The ether extracts were washed with 10% aqueous $NaHCO_3$ and dried ($K_2CO_3$). Removal of the solvent gave a brown gum which rapidly crystallized (1.14 g after removal of as much DMF as possible under high vacuum). The product was recrystallized from $CH_2Cl_2$/petroleum as light brown crystals (0.877 g, 77%), mp 126–127°C; nmr ($CDCl_3$) δ: 0.76 (6H, s), 1.17, 1.23 (each 3H, s), 3.64 (8H, broad s), 5.37, 5.56 (each 1H, s), 6.31 (1H, d), 9.39 (1H, broad s), 9.79 (1H, s); *m/e*: 323. *Anal.* calcd. for $C_{17}H_{25}NO_5$: C 63.14, H 7.79, N 4.33; found C 63.18, H 7.79, N 4.33.

*1-Methyl-3,5-di(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole-2-carboxaldehyde (5b)*

Using the same method described above for 3,5-di(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole-2-carboxaldehyde, 1-methyl-2,4-di(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole gave the product as colourless crystals (80%), from heptane, mp 168.5°C; nmr ($CDCl_3$) δ: 0.77, 1.24 (each 6H, s), 3.67 (8H, broad s), 3.97, (3H, s), 5.37, 5.59 (each 1H, s), 6.40 (1H, s), 9.90 (1H, s); *m/e*: 337. *Anal.* calcd. for $C_{18}H_{27}NO_5$: C 64.07, H 8.07, N 4.15; found C 64.15, H 8.08, N 4.11.

*Pyrrole-2,3,5-tricarboxaldehyde (6a)*

3,5-Di(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole-2-carboxaldehyde (200 mg) was added to water (10 mL), ethanol (1 mL), and *p*-toluenesulfonic acid (100 mg), and the mixture was heated first under reflux for 1 h and then open to the atmosphere for 3.3 h with the solvent level maintained by the addition of water. Water (50 mL) was then added and the solution was extracted very thoroughly with chloroform. The extracts were dried ($MgSO_4$) and the solvent was removed to leave a solid residue of the almost pure product (93 mg, 67%), mp 185–187°C; ir ν: 3120 (N—H), 1676, 1660 (each broad C=O) $cm^{-1}$; nmr (acetone-$d_6$) δ: 7.48, 9.81, 10.22, 10.25 (each 1H, s); *m/e*: 151. *Anal.* calcd. for $C_7H_5NO_3$: C 55.64, H 3.34, N 9.27; found: C 55.58, H 3.38, N 9.25.

*1-Methylpyrrole-2,3,5-tricarboxaldehyde (6b)*

Using the method described above for pyrrole-2,3,5-tricarboxaldehyde, 1-methyl-3,5-di(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole-2-carboxaldehyde gave the product, mp 125.5–126°C; ir ν: 1670 (broad C=O) $cm^{-1}$; nmr ($CDCl_3$) δ: 4.25 (3H, s), 7.28, 9.73, 9.98, 10.35 (each 1H, s); *m/e*: 165. *Anal.* calcd. for $C_8H_7NO_3$: C 58.18, H 4.27, N 8.48; found: C 58.41, H 4.39, N 8.51.

*5-(5,5-Dimethyl-1,3-dioxan-2-yl)-pyrrole-2-carbonitrile (7a)*

2-(5,5-Dimethyl-1,3-dioxan-2-yl)-pyrrole (500 mg) was dissolved in a mixture of $CH_3CN$ (2 mL) and DMF (3 mL) and cooled in a solid $CO_2$/acetone bath. Chlorosulfonyl isocyanate (CSI) (0.43 mL) dissolved in $CH_3CN$ (3 mL) was added to the stirred mixture dropwise over about 5 min. The stirred mixture was held in the cooling bath for about 1 h as it was allowed to warm slowly to −5°C. During this period the solution, yellow at the start of the reaction, became dark red. The reaction mixture was poured into a rapidly stirred mixture of aqueous NaOH (5 mL, 3 mol $L^{-1}$), aqueous $NaHCO_3$ (50 mL, 5% aqueous), and ice (~25 g). The aqueous mixture was extracted with $CH_2Cl_2$, the extracts washed with water, dried ($K_2CO_3$), and the solvent was removed to leave the crude product containing some 4-substituted material (nmr) as a red oil. Molecular distillation of the red oil gave the product as a colourless oil which crystallized very slowly. The product was purified by repeated sublimation (60°C/0.5 Torr) to give colourless crystals, mp 72–73.5°C (360 mg. 63%); ir ν: 3200 (N—H), 2215 (CN) $cm^{-1}$; nmr ($CDCl_3$) δ: 0.77, 1.24 (each 3H, s), 3.64 (4H, dd, $J_{AB}$ = 12 Hz), 5.40 (1H, s), 6.18, 6.72 (each 1H, m), 9.25 (1H, broad); *m/e*: 206. *Anal.* calcd. for $C_{11}H_{14}N_2O_2$: C 64.06, H 6.84, N 13.58; found: C 64.05, H 6.88, N 13.58.

When the reaction mixture was poured into 1.5 mol $L^{-1}$ HCl/ice (200 mL) and then stirred at room temperature for 1 h the acetal group was completely hydrolysed. Extraction with ether gave a solid mixture of 5- and 4-cyanopyrrole-2-carboxaldehyde ($^1H$ nmr). The mixture was easily separated by fractional recrystallization from ethyl acetate/petroleum (bp 60–80°C) to give: 5-cyanopyrrole-2-carboxaldehyde (249 mg, 75%), mp 162–163°C; ir ν: 3170 (N—H), 2233 (CN), 1670 (C=O) $cm^{-1}$; nmr ($CDCl_3$) δ: 6.82, 6.91 (each 1H, d, $J_{3,4}$ = 3.8 Hz), 9.57 (1H, s); *m/e*: 120. *Anal.* calcd. for $C_6H_4N_2O$: C 60.00, H 3.33, N 23.33; found: C 60.19, H 3.18, N 23.37; and the much less soluble 4-cyanopyrrole-2-carboxaldehyde (31 mg, 9%), mp 175.5–177°C (from ethyl acetate/petroleum (bp 80–100°C)) (lit. (9) mp 177°C) was also isolated. The mixture melting point with authentic material was undepressed.

*1-Methyl-5-(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole-2-carbonitrile (7b)*

1-Methyl-2-(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole (500 mg) was dissolved in a mixture of $CH_3CN$ (2 mL) and DMF (13 mL) and cooled in a solid $CO_2$/acetone bath. Chlorosulfonyl isocyanate (CSI) (0.4 mL) dissolved in $CH_3CN$ (3.0 mL) was added to the stirred mixture dropwise over about 5 min. The solution became yellow and thickened due to the formation of solid. After 10 min the solid $CO_2$ bath was removed and the mixture was allowed to warm to room temperature (~15 min) and then poured onto ice-cold $NaHCO_3$ (5% aqueous, 100 mL). The aqueous mixture was extracted with chloroform (all of the colour was extracted into the organic layer). The combined chloroform extracts were washed twice with $NaHCO_3$ solution (5% aqueous), dried ($K_2CO_3$), and evaporated. The oily residue was pumped at high vacuum (0.1 Torr) to remove residual DMF and gave the almost pure product (500 mg) as a brownish oil. The oil was subjected to molecular distillation along a glass tube (0.1 Torr, 130°C) and the colourless distillate which slowly crystallized was recrystallized from an ethyl ether/petroleum (bp 60–80°C) mixture (364 mg, 65%), mp 49.5–51°C; ir ν: 2200 (CN) $cm^{-1}$; nmr ($CDCl_3$) δ: 0.80, 1.28 (each 3H, s), 3.67 (4H, dd, $J_{AB}$ = 12 Hz), 3.83 (3H, s), 5.37 (1H, s), 6.19, 6.63 (each 1H, d, $J_{AB}$ = 4.2 Hz); *m/e*: 220. *Anal.* calcd. for $C_{12}H_{16}N_2O_2$: C 65.43, H 7.32; found: C 65.47, H 7.35.

The reaction product was hydrolysed using a dilute HCl/methanol mixture (1) to give 1-methyl-5-cyanopyrrole-2-carboxaldehyde (83% yield), mp 66–67°C; ir ν: 2226 (CN), 1670 (C=O) $cm^{-1}$; nmr ($CDCl_3$) δ: 4.03(3H, s), 6.75, 6.87 (each 1H, d, $J_{AB}$ = 4.3 Hz), 9.62 (1H, s); *m/e*: 134. *Anal.* calcd. for $C_7H_6N_2O$: C 62.68, H 4.52; found C 62.67, H 4.53.

*3,5-Di-(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole-2-carbonitrile (7c)*

Cyanation of 2,4-di(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole gave a ~2% yield of the product, which was recrystallized from petroleum (bp 60–80°C), mp 113–115°C; ir ν: 3255 (N—H), 2235 (CN) $cm^{-1}$; nmr ($CDCl_3$) δ: 0.77, 0.77, 1.19, 1.26 (each 3H, s), 3.61 (8H, dd, $J_{AB}$ = 12 Hz), 5.33, 5.39 (each 1H, s), 6.29 (1H, d), 8.87 (1H, broad); *m/e*: 320. *Anal.* calcd. for $C_{17}H_{24}N_2O_4$: C 63.71, H 7.55; found: C 63.67, H 7.56.

*1-Methyl-3,5-di(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole-2-carbonitrile (7d)*

Cyanation of 1-methyl-2,4-di(5,5-dimethyl-1,3-dioxan-2-yl)-pyrrole as above for **1***a* gave the product in 18% yield after sublimation, mp 162.5–163°C; ir ν: 2202 (CN) $cm^{-1}$; nmr ($CDCl_3$) δ: 0.79, 1.27, (6H, each s), 3.67 (8H, dd), 3.81, (3H, s), 5.34, 5.43 (each 1H, s), 6.36 (1H, s); *m/e*: 334. *Anal.* calcd. for $C_{18}H_{26}N_2O_4$: C 64.65, H 7.84; found: C 64.67, H 7.85.

WALTER A. SZAREK, B. MARIO PINTO, ALAN H. HAINES, and T. BRUCE GRINDLEY. Can. J. Chem. **60**, 390 (1982).

The intramolecular aldol condensation of 2,2′-*O*-methylene-bis-D-glycerose has been found to yield only two of the four possible diastereomeric products. At higher base concentration or prolonged reaction times, these products undergo a Cannizzaro reaction. The stereochemistry of the products derived from the aldol condensation has been established by means of labelling experiments and by examination of the products by $^1$Hmr and $^{13}$Cmr spectroscopy. The major and minor products of the reaction have been identified as being 2-*C*-hydroxymethyl-2,4-*O*-methylene-D,L-ribose (**7**) and 2-*C*-hydroxymethyl-2,4-*O*-methylene-D,L-xylose (**8**), respectively. The preferential stabilization of these products in the reaction by means of intramolecular hemiacetal formation is proposed as a driving force for the high degree of stereoselectivity; this possibility is supported by the isolation of the bicyclic systems expected from such a reaction. Conditions have been chosen such that **7** is formed exclusively.

WALTER A. SZAREK, B. MARIO PINTO, ALAN H. HAINES et T. BRUCE GRINDLEY. Can. J. Chem. **60**, 390 (1982).

On a trouvé que la condensation aldolique intramoléculaire du *O*-méthylène bis-2,2′ D-glycérose donne seulement deux des quatres diastéroisomères possibles. Ces produits subissent une réaction de Cannizaro si la concentration de la base est plus élevée ou si on prolonge les temps de réaction. On a établi la stéréochimie des produits issus de la condensation aldolique à l'aide d'expériences de marquage et de la spectroscopie de rmn du $^1$H et du $^{13}$C. Les produits majoritaires et secondaires de la réaction sont respectivement le *C*-hydroxyméthyl-2 *O*-méthylène-2,4 D,L ribose (**7**) et le *C*-hydroxyméthyl-2 *O*-méthylène-2,4 D,L xylose (**8**). On croit que le haut degré de stéréosélectivité est dû à la stabilisation préférentielle de ces produits au cours de la réaction par l'intermédiaire de la formation d'un hémiacétal intramoléculaire; on envisage cette possibilité par suite de l'isolement de systèmes bicycliques caractéristiques pour de telles réactions. On a choisi des conditions de façon à obtenir exclusivement le composé **7**.

[Traduit par le journal]

## Introduction

In 1943 Hudson and co-workers (1) reported the formation of a di-*O*-acetoxymethyl-di-*O*-acetyl-*O*-methylene-D-mannitol when tri-*O*-methylene-D-mannitol was subjected to mild acetolysis. In order to characterize this compound it was first deacylated, and the resulting *O*-methylene-D-mannitol was subjected to periodate oxidation. Since one mole of periodate was consumed for every mole of compound, and formaldehyde was not generated, it was concluded that the compound contained a 2,5-*O*-methylene acetal (see **1**). Interestingly, the addition of a slight excess of hot saturated barium hydroxide solution in order to remove iodate and periodate from the reaction mixture resulted in the formation of a new compound, as evidenced by a change in sign of the optical rotation of the solution. Concentration of the solution and reduction of the resulting syrup with Raney nickel and hydrogen afforded a product which partially crystallized. Elemental analyses of the reduced compound and of its acetylated derivative were consistent with those of an *O*-methylene mannitol and its tetraacetate, and a molecular-weight determination indicated that the compound was monomeric. Furthermore, the compounds

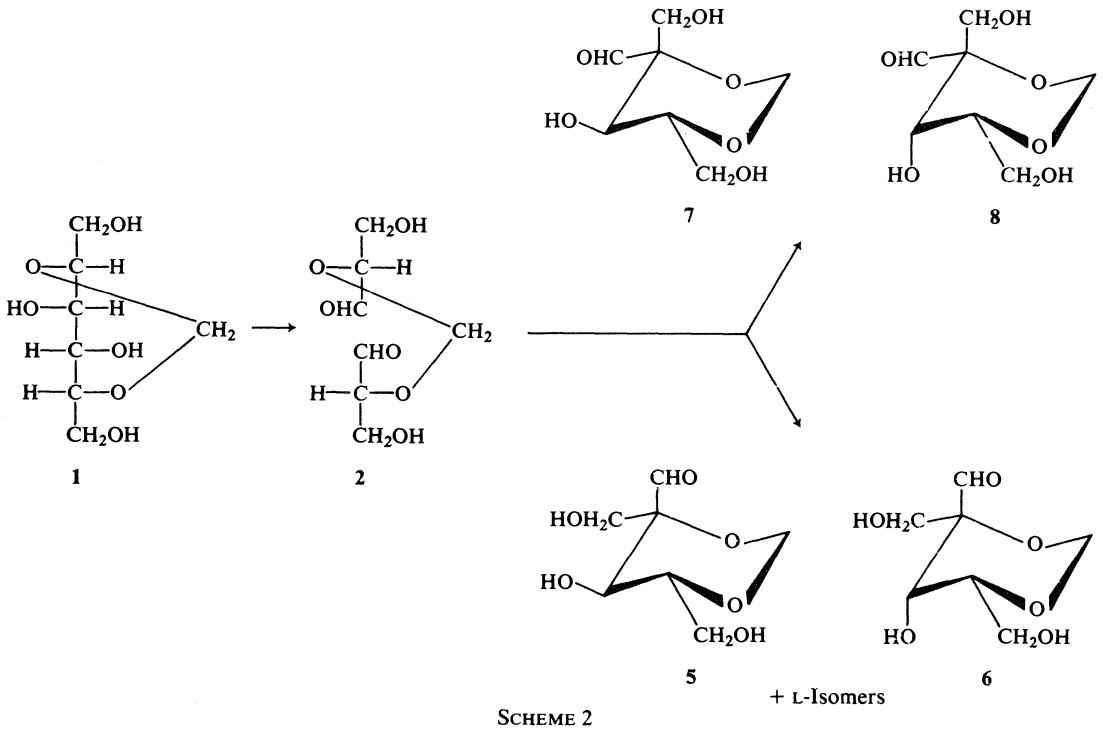
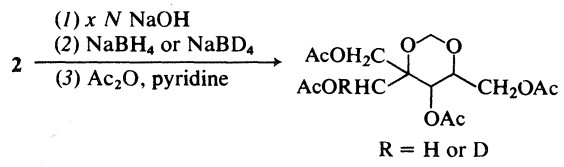


SCHEME 2

were not oxidized by sodium periodate or lead tetraacetate. On the basis of these results, it was concluded that, under the slightly alkaline conditions of the experiment, the primary oxidation product, namely 2,2′-*O*-methylene-bis-D-glycerose (**2**), was converted by an intramolecular aldol condensation into the isomeric cyclic aldehyde, namely 4-formyl-5-hydroxy-4,6-di(hydroxymethyl)-1,3-dioxane (**3**), which was then reduced to form 5-hydroxy-4,4,6-tri(hydroxymethyl)-1,3-dioxane (**4**), as indicated in Scheme 1.

The intramolecular aldol condensation reaction of 2,2′-*O*-methylene-bis-D-glycerose can potentially result in the formation of four enantiomeric pairs of products (**5**, **6**, **7**, and **8** and their enantiomers), as indicated in Scheme 2. Moreover, each of these products can undergo a Cannizzaro reaction to give the corresponding acid and alcohol. It was anticipated that the stereochemistry at C-5 and C-6 of the products would be deducible by examination



SCHEME 3

of the $^1$Hmr spectra but that the determination of the stereochemistry at the quaternary centre (C-4) would require more sophisticated methods. In order to solve the latter problem, the following strategy was implemented. The products of the reaction were subjected to reduction with sodium borodeuteride followed by acetylation (see Scheme 3). The *gem*-di-(acetoxymethyl) derivatives obtained in this manner were then examined by means of $^{13}$Cmr spectroscopy; the introduction of a deuterium label onto one of the carbon atoms attached to C-4 was expected to result in a change in multiplicity and intensity of the signal attributable to the labelled carbon atom. The unambiguous assignment of the $^{13}$Cmr spectra of the nondeuterated derivatives together with the information obtained from the spectra of the deuterated derivatives would then result in the assignment of stereochemistry at C-4 of the latter compounds and, hence, in the assignment of stereochemistry of the products of the aldol condensation reaction. An alternative route employing the sequence: periodate oxidation, aldol condensation, sodium borohydride reduction, and acetylation, using 2,5-*O*-methylene-D-mannitol-1-*d* (**9**) as starting material, was designed to provide complementary information; in this case, the deuterium label would be present in the diastereotopic counterpart of the

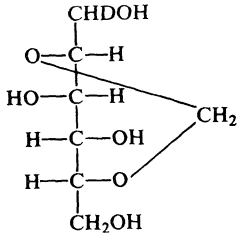
For personal use only.



9

acetoxymethyl group at C-4 that was labelled by the first route.

The question of stereochemistry is of some interest, since **7** represents a simple derivative of the naturally occurring branched-chain sugar, hamamelose, and **5**, **6**, and **8** represent isomers of this compound. The intramolecular aldol condensation offers, therefore, an interesting route to this class of compounds.

## Results and discussion

Treatment of 2,2′-*O*-methylene-bis-D-glycerose (**2**) with sodium hydroxide followed by borohydride reduction and subsequent acetylation afforded only two products which were isolated by fractional crystallization. Interestingly, the ratio of the two products was found to be dependent on the conditions of the aldol condensation reaction, namely the base concentration and the reaction time. Thus, for example, when the reaction mixture was 0.3 *N* in sodium hydroxide and the reaction time was 4.5 h, the lower-melting isomer (Isomer 1) and the higher-melting isomer (Isomer 2) were present in a ratio of 63:37. In contrast, treatment of compound **2** with 0.05 *N* sodium hydroxide for 3.5 h afforded Isomer 1 exclusively. The ratio of Isomer 1/Isomer 2 obtained using a base concentration of 0.2 *N* and a reaction time of 24 h was 92:8 and that obtained using a base concentration of 0.1 *N* and a reaction time of 3.5 h was 93:7 (see Table 1). Isomer 1 corresponds to that obtained by Hudson and co-workers (1); these workers utilized a base concentration of 0.1 *N* sodium hydroxide and a reaction time of 3.5 h in order to effect the aldol condensation reaction. Treatment of 2,2′-*O*-methylene-bis-D-glycerose (**2**) under the four conditions described above followed by sodium borodeuteride reduction of the resulting mixtures also furnished some interesting results (see Table 2). Thus, treatment of **2** under the first set of conditions (0.3 *N* NaOH, 4.5 h) followed by borodeuteride reduction and subsequent acetylation afforded Isomer 1 and Isomer 2 as before. Examination of the $^{1}H$-decoupled $^{13}C$mr spectrum of Isomer 1 indicated the presence of a 1:1:1 triplet for one of the signals, attributable to a carbon of an acetoxymethyl group, and the absence of the signal attributable to the corresponding carbon in the nondeuterated derivative (see later). Surprisingly, the $^{13}C$mr spectrum of Isomer 2 showed neither the 1:1:1 triplet for one of the signals nor a reduction in intensity of any of the signals attributable to the carbons of the acetoxymethyl groups relative to those in the spectrum of the nondeuterated derivative. Clearly, deuterium incorporation was unsuccessful in this case. However, when the aldol-condensation reaction was performed at a lower base concentration (0.1 *N* NaOH, 3.5 h), and the products obtained after sequential borodeuteride reduction and acetylation were subjected to analysis by $^{13}C$mr spectroscopy, Isomer 1 was found to have incorporated deuterium as before but Isomer 2 was now found to have partially incorporated deuterium (evidenced by a reduction in intensity of one of the signals, attributable to a carbon of an acetoxymethyl group, relative to that in the nondeuterated derivative). When the aldol-condensation reaction was performed for prolonged reaction times (0.2 *N* NaOH, 24 h), neither of the two isomers obtained after sequential borodeuteride reduction and acetylation showed the incorporation of deuterium. Finally, treatment of **2** at a low base concentration (0.05 *N* NaOH, 3.5 h) afforded Isomer 1 which was shown to have incorporated deuterium.

The production of only two of the four possible diastereomers in the aldol-condensation reaction is noteworthy. Moreover, the observed stereospeci-

ficity of the reaction at low base concentration is remarkable in view of the fact that the reaction proceeds through a carbanion. The results of the deuterium incorporation experiments (Table 2) suggest that under certain conditions the formyl group in the products of the aldol-condensation reaction undergoes reduction, presumably by a Cannizzaro reaction, prior to the addition of sodium borodeuteride. Examples of crossed-aldol condensations followed by Cannizzaro reactions to give branched-chain sugars are well documented (2). Apparently, the Cannizzaro reaction occurring in the present study is substrate selective, since, under certain conditions, the aldehyde precursor of Isomer 2 undergoes preferential reduction. For example, at a base concentration of 0.3 *N* or 0.1 *N* and short reaction times, the aldehyde precursor of Isomer 2 undergoes exclusive and partial reduction, respectively, by means of a Cannizzaro reaction, whereas the aldehyde precursor of Isomer 1 is either unaffected by these conditions or serves as the reducing agent and is itself oxidized to the acid. With prolonged reaction times, this selectivity is lost and both compounds undergo reduction by means of a Cannizzaro reaction to furnish, after acetylation, Isomer 1 and Isomer 2. Presumably, the acids that are also formed in these reactions are retained on the basic ion-exchange resin during the processing of the reaction.

The assignment of the relative stereochemistry at C-5 and C-6 of Isomer 1 and Isomer 2 was performed by examination of $^1$Hmr spectra obtained at 220 MHz. The spectra are shown in Figs. 1–8. All spectral assignments were confirmed by means of systematic spin-decoupling experiments. Initially, the spectra were measured in chloroform-*d* solution and later in benzene-$d_6$ solution since it was anticipated that benzene-induced shifts of the proton resonances would result in greater spectral dispersion and thus facilitate assignment of the spectra. The solvent shifts of proton resonances induced by benzene, relative to carbon tetrachloride or chloroform, are well documented, and have been used to advantage in the solution of a variety of structural, stereochemical, and conformational problems (3). These shifts have been attributed (3*a*) to the interaction of the $\pi$-system of the benzene ring with polar sites in solute molecules by way of an induced dipole–dipole mechanism. The nature of the collision complex in various alkyl-substituted 1,3-dioxanes has been considered previously (4, 5). In particular, Carlson *et al.* (5) have postulated a collision complex in which the benzene molecule lies above the solute molecule and in which the plane of the aromatic ring is perpendicular to the molecular dipole moment. However, the presence of additional polar sites in these derivatives (for example, acetates) was found (5) to modify this shielding pattern.

The partial $^1$Hmr spectrum of Isomer 1 (obtained from compound **2** by application of the sequential reactions aldol condensation, borohydride reduction, and acetylation) in chloroform-*d* is shown in Fig. 1. An outstanding feature of this spectrum is the appearance of the H-5 signal as a doublet having a coupling constant of 10.3 Hz; this value for a vicinal coupling constant is only consistent with the existence of an antiperiplanar relationship between H-5 and H-6. Isomer 1, obtained as described above, is, therefore, identified as being 2-*C*-acetoxymethyl-1,3,5-tri-*O*-acetyl-2,4-*O*-methylene-D,L-*erythro*-pentitol (**10**).[2] Another noteworthy feature in the spectrum of **10** is the marked chemical-shift difference between the diastereotopic protons of one of the acetoxymethyl groups. The signal at lower field is attributed to the hydrogen atom of the axial acetoxymethyl group which is directed "inwards" towards the axial hydrogen atoms at C-2 and C-6. The wide separation of the H-4′ and H-4″ signals is indicative of restricted rotation about the $C_4$—$C_{4'}$ bond which results in the preponderance of one rotational conformation. The spectrum of Isomer 1 in benzene-$d_6$ exhibits similar features to those observed in the spectrum measured in chloroform-*d* although greater spectral dispersion obtains (see Fig. 2). It is interesting to note that the H-6 signal is shifted upfield and the H-5 signal is shifted downfield relative to the corresponding signals in the spectrum measured in chloroform-*d* (see Table 3). Since the model proposed by Carlson *et al.* (5) for the benzene – 2-methyl-1,3-dioxane collision complex predicts that both H-5 and H-6 should be shielded in benzene solution relative to chloroform solution, it would appear that the additional sites available for benzene complexation, namely the ester functions, also play an important role in inducing chemical-shift changes. The deshielding of H-5 is most likely caused by the complexation of a benzene molecule with the carbonyl function of the acetoxy group at C-5. In rigid systems, methine protons of secondary acetates are usually deshielded in benzene relative to inert solvents ($\Delta$ = 0.10–0.27 ppm) (3*h*, 3*i*, 3*k*, 6). Similarly, the shielding of H-2, H-2′, H-4′, and H-4″ and the deshielding of H-4‴ and H-4⁗ in benzene relative to chloroform (see Table 3) reflects the

[2]Although the descriptor D,L is used here and elsewhere in this paper, it does not signify in these instances that a racemic mixture of a compound was obtained, but rather that a mixture (not necessarily equimolar) of D- and L-isomers was obtained.

balance of interactions as a result of benzene complexes with the dipole of the 1,3-dioxane ring and with the dipoles of the acetate-carbonyl functions.

The $^1$Hmr spectra of the deuterated derivatives of Isomer 1 (obtained by application of the sequential reactions aldol condensation, borodeuteride reduction, and acetylation to compound **2**) in chloroform-*d* and benzene-$d_6$ are shown in Figs. 3 and 4, respectively. The noteworthy feature of these spectra is the absence of the doublets attributable to H-4‴ and H-4⁗ that are observed in the spectra of the nondeuterated derivative and the presence of two singlets for the H-4‴ signals; the

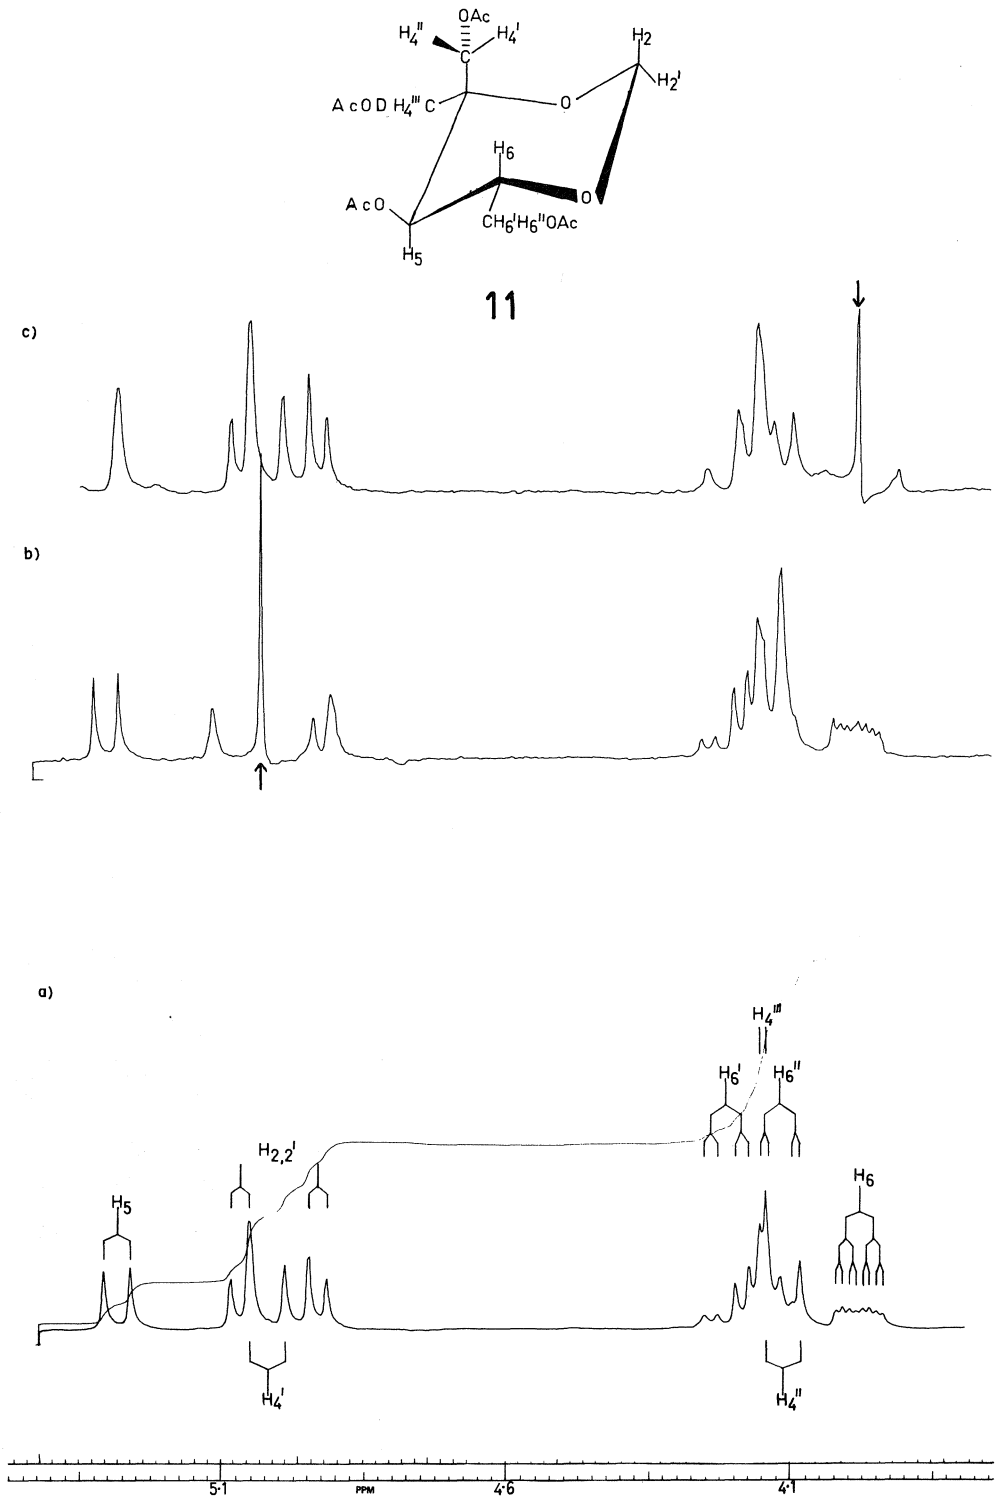

FIG. 3. (a) Partial $^1$Hmr spectrum at 220 MHz of 2-*C*-acetoxymethyl-1,3,5-tri-*O*-acetyl-1-(*R*,*S*)-deuterio-2,4-*O*-methylene-D,L-ribitol (**11**) in chloroform-*d*; (b) with irradiation at $\nu_{H\text{-}4'}$; (c) with irradiation at $\nu_{H\text{-}6}$.

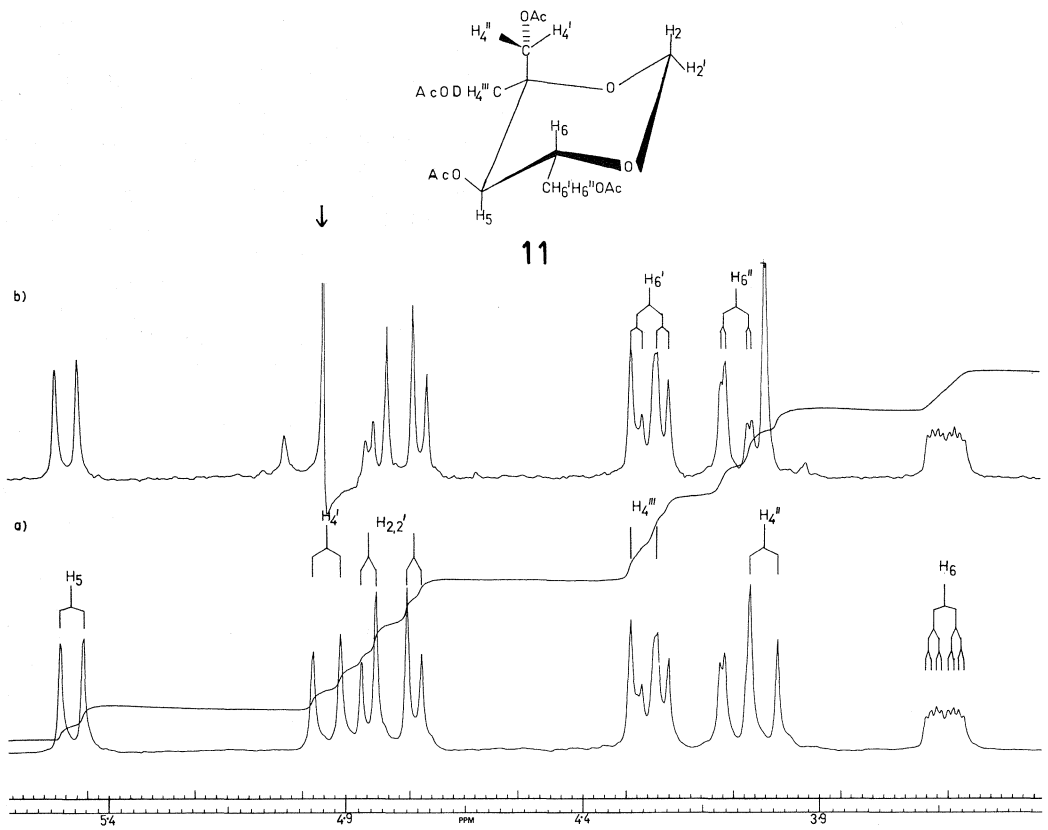

FIG. 4. (a) Partial $^1$Hmr spectrum at 220 MHz of 2-*C*-acetoxymethyl-1,3,5-tri-*O*-acetyl-1-(*R*,*S*)-deuterio-2,4-*O*-methylene-D,L-ribitol (**11**) in benzene-$d_6$; (b) with irradiation at $\nu_{H\text{-}4'}$.

latter two signals are attributed to the methylene proton of the acetoxymethyl group also bearing a deuterium atom in the two diastereomers resulting from generation of a new chiral centre by deuterium substitution. Since the H-4′ and H-4″ signals were tentatively assigned to those belonging to the axial acetoxymethyl group, the acetoxymethyl group bearing a deuterium atom is assigned to the equatorial orientation. The deuterated derivative of Isomer 1 is, therefore, tentatively identified as being 2-*C*-acetoxymethyl-1,3,5-tri-*O*-acetyl-1-(*R*,*S*)-deuterio-2,4-*O*-methylene-D,L-ribitol (**11**). This suggests, therefore, that the aldehyde precursor of **11** contains a formyl group that is equatorially oriented; the major product derived from the aldol-condensation reaction can thus be tentatively identified as being 2-*C*-hydroxymethyl-2,4-*O*-methylene-D,L-ribose (**7**).

The $^1$Hmr spectra of the nondeuterated derivative of Isomer 2 in chloroform-*d* and in benzene-$d_6$ are shown in Figs. 5 and 6, respectively. The signal for H-5 appears as a broadened singlet, signifying a *gauche* relationship of H-5 and H-6 in Isomer 2. The small coupling between these two protons may be attributed to the antiperiplanar arrangement of these protons with vicinal electronegative oxygen atoms (that is, H-5 with O-1; H-6 with O-5) since this is known (7–9) to reduce the magnitude of vicinal coupling constants markedly. The nondeuterated derivative of Isomer 2 is, therefore, identified as being 2-*C*-acetoxymethyl-1,3,5-tri-*O*-acetyl-2,4-*O*-methylene-D,L-*threo*-pentitol (**12**). It is interesting to note that Angyal and James (10) have obtained the L-isomer of **12** in low yield by lead tetraacetate oxidation of 2,4-*O*-methylene-D-glucitol; under the conditions of the processing, namely treatment with barium hydroxide, 2,4-*O*-methylene-L-xylose, the product of oxidation, evidently undergoes a mixed-aldol condensation with formaldehyde, followed by a crossed-Cannizzaro reaction. Another distinctive feature of the spectra of **12** is the appearance of the H-4′ and H-4″ signals as an AK pattern with a substantial chemical-shift difference between signals; this result is interpre-

12

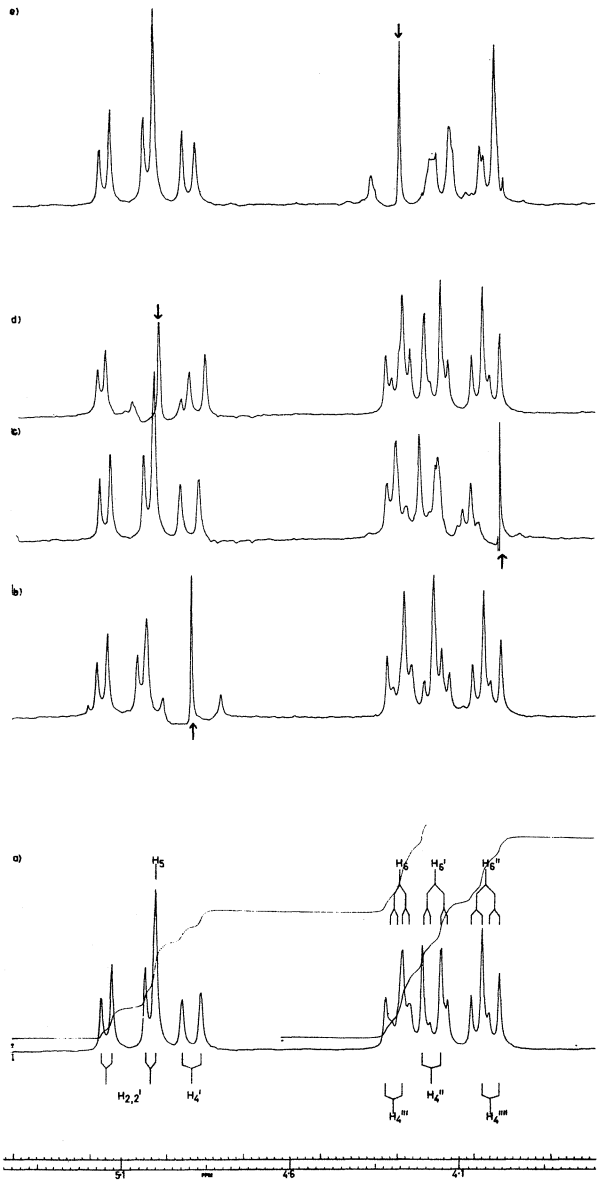

FIG. 5. (a) Partial $^1$Hmr spectrum at 220 MHz of 2-*C*-acetoxymethyl-1,3,5-tri-*O*-acetyl-2,4-*O*-methylene-D,L-*threo*-pentitol (**12**) in chloroform-*d*; (b) with irradiation at $\nu_{H\text{-}4'}$; (c) with irradiation at $\nu_{H\text{-}4'''}$; (d) with irradiation at $\nu_{H\text{-}5}$; (e) with irradiation at $\nu_{H\text{-}4''}$ and $\nu_{H\text{-}6}$.

ted in the same manner as that proposed earlier to account for a similar chemical-shift difference between H-4′ and H-4″ signals in the spectra of Isomer 1. The benzene-induced shifts for the proton resonances of **12** are presented in Table 3. The benzene-induced shift of the H-6 signal is of similar magnitude to that observed in the spectra of Isomer 1. However, the H-5 signal in the spectrum of Isomer 2 in benzene-$d_6$ is only shifted upfield by 0.02 ppm relative to that in the spectrum measured in chloroform-*d*, and is probably indicative of a cancellation of the shielding effect of the benzene molecule associated with the dipole of the 1,3-dioxane ring and the deshielding effect of the benzene molecule associated with the carbonyl function of the acetoxy group at C-5. That H-5 in Isomer 1 should be shielded more than H-5 in Isomer 2 by the benzene – 1,3-dioxane collision complex is evident from the greater benzene-induced shielding of the equatorial proton or equatorial methyl group at C-5, as compared to their axial counterparts, in 2-methyl-1,3-dioxane and 2,5,5-trimethyl-1,3-dioxane, respectively (4). The benzene-induced shifts of the other proton resonances in the spectra of Isomer 2 also probably reflect some balance in the effects of the ring-dipole – benzene complex and the carbonyl-dipole – benzene complexes.

The $^1$Hmr spectra of a mixture of the deuterated and nondeuterated derivatives of Isomer 2 (obtained by application of the sequential reactions aldol condensation, borodeuteride reduction, and acetylation) in chloroform-*d* and benzene-$d_6$ are shown in Figs. 7 and 8, respectively. The spectra are more complicated than those of Isomer 2 owing to the presence of three compounds. Nevertheless, analysis of the spectra indicates that two diastereomers containing a deuterium atom at one of the acetoxymethyl groups are present, in addition to the nondeuterated derivative; the proton resonances corresponding to the remaining proton of each of these acetoxymethyl groups in the two diastereomers appear as singlets, and are labelled as H-4* in the spectra. As was the case with Isomer 1, the acetoxymethyl group that is tentatively assigned to the equatorial orientation bears the deuterium label; this suggests that the formyl group in the aldehyde precursor, obtained from the aldol condensation reaction, is also equatorially oriented. The minor product of the aldol condensation reaction is, therefore, tentatively identified as being 2-*C*-hydroxymethyl-2,4-*O*-methylene-D,L-xylose (**8**).

It thus appears that the two diastereomers obtained in the aldol-condensation differ in configuration only at the newly formed asymmetric centre and that the reaction proceeds with complete

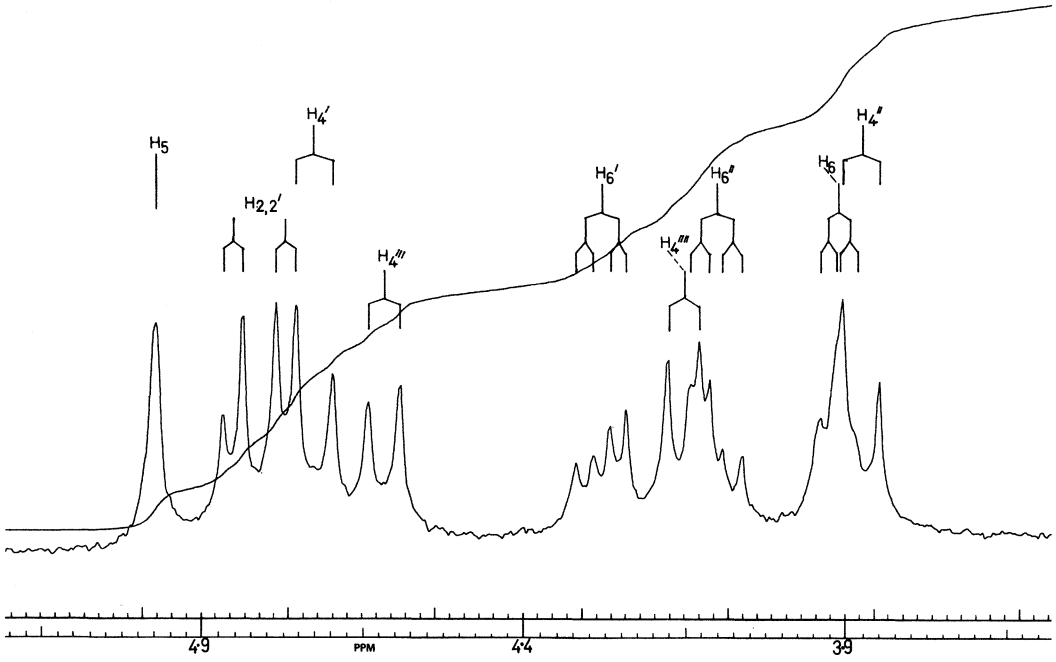

FIG. 6. Partial $^1$Hmr spectrum at 220 MHz of 2-*C*-acetoxymethyl-1,3,5-tri-*O*-acetyl-2,4-*O*-methylene-D,L-*threo*-pentitol (**12**) in benzene-$d_6$.

inversion of configuration at the quaternary centre (see **5** and **6** in Scheme 2). In order to unequivocally establish the stereochemistry at the quaternary centre, however, the products obtained as described in the preceding section were examined by means of $^{13}$Cmr spectroscopy (see Table 4).

Initially, it was necessary to assign unambiguously the $^{13}$Cmr resonances in the $^1$H – noise-decoupled spectra of the nondeuterated derivatives of Isomer 1 and Isomer 2, namely, **10** and **12**. The spectral assignments were made by examination of the coupled spectra, by means of single-frequency off-resonance decoupling (sford) experiments, and by consideration of the effects of substituents on $^{13}$Cmr chemical shifts. The spectra of Isomer 2 will be discussed first. Since the $^{13}$Cmr sford experiments were performed at a spectrum frequency of 20.0 MHz, a description of the $^1$Hmr spectrum at 80 MHz is necessary. The $^1$Hmr spectrum of **12** consisted of two groups of signals; the downfield group consisted of an AB quartet attributable to H-2 and H-2′ (δ 5.02, Δν 0.13 ppm, $J$ = 6.9 Hz), a broadened singlet attributable to H-5 (δ 4.97), and a doublet for one of the six C-methylene protons (δ 4.82, $J$ = 12.3 Hz). The upfield group of signals (δ 3.88–4.33) contained the remainder of the proton resonances (excluding methyl resonances) and could not be assigned. The $^{13}$Cmr signal assignments in the spectrum measured in chloroform-*d* were performed as follows. The signals appearing at 88.0

12 13

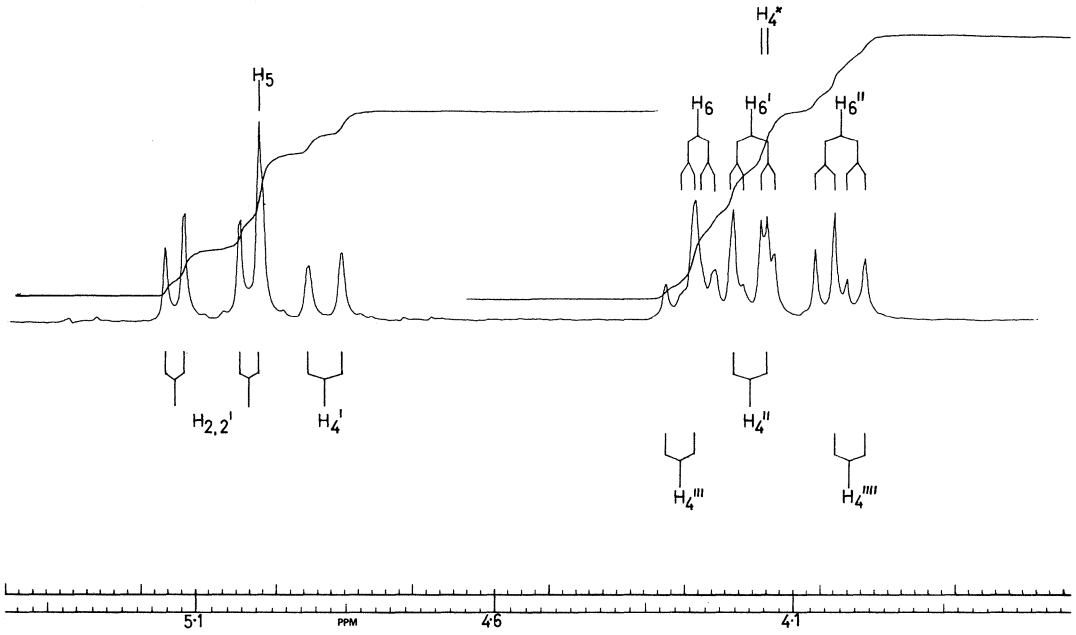

FIG. 7. Partial $^1$Hmr spectrum at 220 MHz of a mixture of 2-*C*-acetoxymethyl-1,3,5-tri-*O*-acetyl-2,4-*O*-methylene-D,L-*threo*-pentitol (**12**) and 2-*C*-acetoxymethyl-1,3,5-tri-*O*-acetyl-1-(*R*,*S*)-deuterio-2,4-*O*-methylene-D,L-xylitol (**13**) in chloroform-*d*.

and 75.6 ppm downfield from tetramethylsilane appeared, in the coupled spectra, as a quartet ($J$ = 162.4 and 170.3 Hz) and a broad singlet, respectively, and were therefore assigned to C-2 and C-4, respectively.[3] The signal at 72.6 ppm appeared as a doublet in the coupled spectrum and collapsed to a singlet upon irradiation at 4.19 ppm in the $^1$Hmr spectrum. Similarly, the signal at 63.7 ppm appeared as a doublet ($J$ = 149.0 Hz) in the coupled spectrum and collapsed to a singlet upon irradiation at 4.94 ppm in the $^1$Hmr spectrum. On the basis of the sford experiments, the signal at 63.7 ppm was assigned to C-5 while that at 72.6 ppm was assigned to C-6. The coupled spectrum of **12** exhibited three triplets at 62.6, 61.8, and 58.4 ppm having coupling constants of 150.0, 151.7, and 147.9 Hz, respectively. The triplet appearing at 62.6 ppm exhibited further splitting into doublets ($J$ = 6.0 Hz) of narrow line width (~2 Hz) while the other two triplets appeared as broad signals (line widths ~9 Hz). Since C-6′ is α to a carbon atom bearing one hydrogen and is also β to a carbon bearing one hydrogen, the signal at 62.6 ppm was assigned to C-6. On the other hand, both C-4′ and C-4″ are β to two carbon atoms, one of which bears two hydrogens and the other one hydrogen, and the signals attributable to C-4′ and C-4″ might not be expected to show individual resolved couplings to these protons. The signals at 62.6 and 61.8 ppm appeared

[3]The numbering of carbon atoms is designated in the formula for **10** in Table 4.

[b]The signal appeared as a 1:1:1 triplet in the $^1$H decoupled spectrum.

as singlets upon irradiation at 4.19 or 4.32 ppm in the $^1$Hmr spectrum. The appearance of the signal at 58.4 ppm varied from a triplet to a quartet to a sextet in the $^{13}$C sford spectrum depending on the frequency of irradiation in the $^1$Hmr spectrum. This behaviour is typical of that of the X portion of an ABX pattern in which A and B exhibit strong chemical-shift nonequivalence, and irradiation is applied at the A or B portion of the spectrum (11). Hagaman (11) has observed such "deviant" $^{13}$C–

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

[$^1$H] multiplets in the sford spectra of C–H systems which show strong geminal-proton nonequivalence. Thus, the signal at 58.4 ppm was assigned to the carbon that is directly coupled to the two methylene protons which exhibit a large chemical-shift difference in the $^1$Hmr spectrum. Nikiforova and co-workers (12) have reported the $^{13}$Cmr spectra of a variety of 2-alkyl-4,4-dimethyl-1,3-dioxanes; in every case, the signal attributable to the axial methyl carbon resonated at higher field (~ 10 ppm) than its equatorial counterpart. Moreover, the carbon atom of an axial hydroxymethyl substituent in the *E*-isomer of 4-*tert*-butyl-1-hydroxymethylcyclohexanol is reportedly shielded (by 6.0 ppm) with respect to its equatorial counterpart in the *Z*-isomer (13), and a similar result has been reported (14) for the $^{13}$Cmr shifts of the axial and equatorial hydroxymethyl carbon atoms in the isomers of 4-*tert*-butyl-1-hydroxymethylcyclohexane. On the basis of these results, one might have expected a substantial chemical-shift difference between the signals for C-4′ and C-4″ in the spectrum of **12**. However, in this case, the anticipated shielding of C-4′ relative to that of C-4″ is offset by the shielding of the C-4″ carbon by virtue of the γ-*gauche* effect of the acetoxy substituent at C-5. Moreover, the shielding of C-4″ by the γ-*gauche* effect is expected to be of greater magnitude than the corresponding shielding of C-4′[4] by virtue of the γ-*anti* effect of the acetoxy substituent at C-5 (15). Since a quantitative estimate of these various effects was not available, it was considered hazardous to assign the signals at 58.4 or 61.8 ppm to the carbons of either the axial or equatorial acetoxymethyl groups at C-4 solely on the basis of anticipated substituent effects on the chemical shifts. However, the assignment of the geminal methylene group showing strong chemical-shift nonequivalence in the $^1$Hmr spectra of **12** to the axially oriented acetoxymethyl group[5] and the demonstration, by means of $^{13}$C sford experiments, that the signal at 58.4 ppm in the $^{13}$Cmr spectrum is indeed attributable to the carbon atom directly coupled to this set of methylene protons, left no doubt that the high-field signal at δ 58.4 was that belonging to the carbon of the axially oriented acetoxymethyl group. The peak at δ 61.8 was then assigned to the carbon of the equatorially oriented acetoxymethyl group.

The $^{13}$Cmr spectral assignments in the spectrum of the nondeuterated derivative of Isomer 1, namely **10**, were made in an analogous manner to that already described for the spectral assignment of **12**. The $^1$Hmr spectrum at 80 MHz of **10** showed the presence of two groups of signals. The group at lower field consisted of an AB quartet (δ 4.97, Δν 0.16 ppm, $J$ = 6.7 Hz) that was assigned to H-2 and H-2′, a doublet at δ 5.26 ($J$ = 10 Hz) that was assigned to H-5, and a doublet at δ 4.98 ($J$ = 12.7 Hz) that was assigned to the methylene proton on the axially oriented acetoxymethyl group. The upfield group of signals (δ 4.0–4.2) appeared as a complex multiplet and contained the remainder of the proton resonances (excluding methyl resonances). The $^{13}$Cmr signal assignments in the spectrum measured in chloroform-*d* were performed as follows. The signals appearing at 87.8 and 75.1 ppm were readily assigned to C-2 and C-4, respectively, on the basis of their appearance in the coupled spectrum. The signal at 72.8 ppm appeared as a doublet in the coupled spectrum and collapsed to a singlet upon irradiation at the high-field group of signals in the $^1$Hmr spectrum. The signal at 64.7 ppm also appeared as a doublet in the coupled spectrum but remained unchanged upon irradiation of the high-field group of signals in the $^1$Hmr spectrum. The signal at 64.7 ppm was assigned to C-5 while that at 72.8 ppm was assigned to C-6. The coupled spectrum of **10** exhibited three triplets at 58.3, 62.7, and 65.0 ppm. The signal at 62.7 ppm was readily assigned to C-6′ on the basis of its appearance in the coupled spectrum, as described for the case of **12**. The assignment of the remaining two signals to the carbons of the axial or equatorial acetoxymethyl groups was also made by analogy with the assignments in the spectrum of **12**. Thus, the upfield signal at 58.3 ppm exhibited the "deviant" $^{13}$C–[$^1$H] multiplets expected of a carbon that was directly bonded to two protons showing strong chemical-shift nonequivalence. This signal was, therefore, assigned to the carbon (C-4′) of the axial acetoxymethyl group at C-4 (see earlier discussion) and the signal appearing at 65.0 ppm was assigned to the carbon (C-4″) of the equatorial acetoxymethyl group. In contrast to the situation with **12**, the C-4′ and C-4″ signals in the spectrum of **10** showed a substantial chemical-shift difference between peaks. This is understandable since the effect of the acetoxy substituent at C-5 on C-4′ and C-4″ should be the shielding of both of these carbons to about the same extent by virtue of the γ-*gauche* effect. The observed chemical-shift difference between the C-4′ and C-4″ signals should then reflect the intrinsic shielding of axial substituents relative to their equatorial counterparts in 1,3-dioxane rings

[4]Since the γ-*anti* effect is transmitted through a quaternary centre, it is also conceivable that the effect of the 5-acetoxy group on C-4′ will be weakly deshielding (16).

[5]It is noteworthy that Angyal and James (10) have made similar assignments in the $^1$Hmr spectra of the L-isomer of **12** and of a closely related compound, namely, 2-*C*-hydroxymethyl-1,3,5-tri-*O*-acetyl-2,4-*O*-benzylidine-L-*threo*-pentitol.

(12). The $^{13}$Cmr spectral assignments for compounds **10** and **12** are summarized in Table 4.

Having unambiguously assigned the $^{13}$Cmr spectra of the nondeuterated derivatives of Isomer 1 and Isomer 2, it is now possible to settle the question of stereochemistry at the quaternary centre in these compounds by examination of the $^{13}$Cmr spectra of the corresponding deuterated derivatives. The $^{13}$C chemical-shift data for the deuterated derivative of Isomer 1, namely **11**, are presented in Table 4. The distinctive feature of the $^{13}$Cmr spectrum of **11** is the absence of the peak at 65.0 ppm attributed to C-4″, and the presence of a 1:1:1 triplet at 64.7 ppm ($J_{^{13}C-^{2}H}$ = 22.5 Hz), as indicated in Fig. 9. The latter resonance is assigned to the carbon of the equatorial acetoxymethyl group in **11**. Therefore, the product of the aldol-condensation reaction which served as an intermediate to **11** must have had the stereochemistry represented by **7** (see Scheme 2). Another noteworthy feature of the $^{13}$Cmr spectrum of **11** is the displacement of the C-4″ resonance by about 0.3 ppm to higher field and the displacement of the C-4 signal by 0.06 ppm to higher field relative to the corresponding signals in the spectrum of **10**. These shifts are attributed to α- and β-deuterium isotope shifts, respectively.

Examination of the $^{13}$Cmr spectrum of a mixture of the nondeuterated and deuterated derivatives of Isomer 2, namely **12** and **13**, indicated only a reduction in intensity of one of the carbon signals, namely the C-4″ signal (see Fig. 10); this is caused by the partial deuterium incorporation into the sample. Therefore, compound **13** is labelled with deuterium on the carbon of the equatorial acetoxymethyl group. The result suggests that the product of the aldol-condensation reaction which served as an intermediate to **13** must have the stereochemistry represented by **8** (see Scheme 2).

An alternative approach that was intended to provide complementary information about the stereochemistry at the quaternary centre of the aldol-condensation products is discussed below. Thus, D-mannose was converted into D-mannitol-1-*d* (**14**) by simple reduction with sodium borodeuteride and the latter compound was converted by means of the usual reaction sequence into 2,5-*O*-methylene-D-mannitol-1(or 6)-*d* (**9**). Periodate oxidation of **9** to the dialdehyde (**15**), followed by the aldol-condensation reaction and successive borohydride reduction and acetylation, afforded two separable isomers, as before. Owing to the symmetry of the starting material, one would expect that 50% of the molecules of each isomer would contain a deuterium label on C-6′ and that the other 50% of the molecules would be labelled on one of the acetoxymethyl groups attached to C-4 (see Scheme 4). Moreover, the deuterium label in the C-4′ or C-4″ acetoxymethyl group should reside on the opposite carbon to that observed in the previous deuterium-labelling study since the formyl group in the products of the aldol-condensation reaction was subjected to borohydride reduction in this study. One would predict, therefore, that 50% of the molecules should be labelled with deuterium on the *axial* acetoxy group at C-4 in the products of the above reaction sequence.

The $^{13}$Cmr spectral data for the derivatives obtained in this manner are presented in Table 4. The spectrum of Isomer 1 (lower melting point) shows the presence of two species **16** and **17**, as expected, one of which contains deuterium at C-6′ and the other of which contains deuterium at C-4′ (see Fig. 9c). Thus, as predicted, it is the axial acetoxymethyl group at C-4 which contains the deuterium label. Similarly, the spectrum of Isomer 2 shows the presence of two species, **18** and **19**, labelled at C-6′ or C-4′ with deuterium (see Fig. 10c). Once again it is the *axial* acetoxymethyl group at C-4 which bears the deuterium label. The results suggest that the formyl group in both products of the aldol-condensation reaction is equatorially oriented. Another noteworthy feature of the spectra of **16–19** is the manifestation of an α-deuterium isotope shift of about 0.25 ppm and a β-deuterium isotope shift of about 0.05 ppm. Interestingly, the α-deuterium isotope shift of the C-6′ signals in the spectra of **17** and **19** serves to verify the earlier assignments of the signals at 62.7 ppm and 62.6 ppm in the spectra of **10** and **12**, respectively, to the C-6′ carbons.

The remarkable stereoselectivity exhibited by the aldol-condensation reaction, in particular, the total inversion or total retention of configuration at the quaternary centre, strongly suggests the existence of some other controlling influence since a reaction proceeding through a carbanion with 100% inversion or 100% retention, in the absence of such an influence, seems unlikely. Indeed it seems more likely that an enolate anion is formed, and that the products resulting from the reaction are then directed by some other factor. Given that the aldol condensation is an equilibrium reaction, the preferential stabilization of one of the products could be an important factor in directing the equilibrium towards the formation of that product exclusively.

In 1973 Lloyd and Harrison (17) reported the conversion of 2,2′-*O*-methylene-bis-D-glycerose (**2**) into 5-hydroxy-4,4,6-tri(hydroxymethyl)-1,3-dioxane (**4**) by treatment with sodium borohydride.

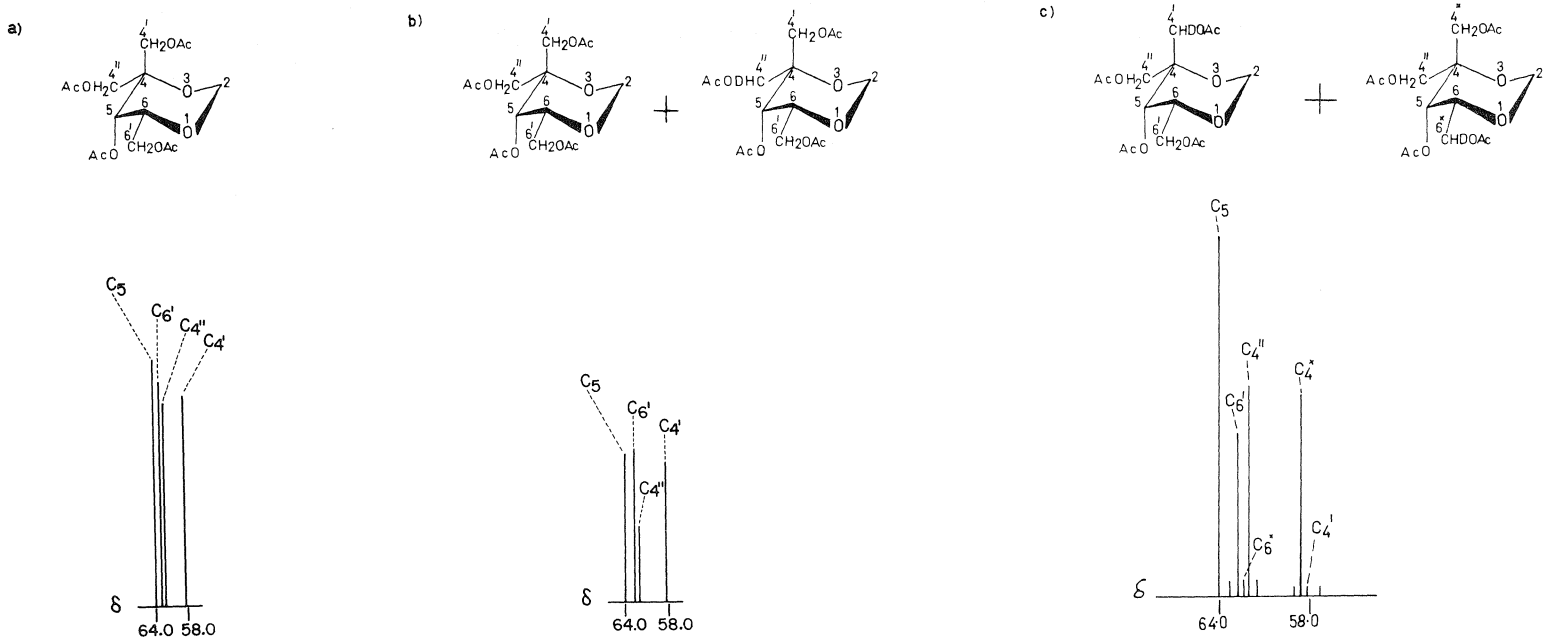

FIG. 10. (a) Partial $^{13}$Cmr spectrum ($^{1}$H-decoupled) of Isomer 2 derived from the products of the intramolecular aldol condensation of 2,2′-*O*-methylene-bis-D-glycerose; (b), (c) the effects of deuterium substitution on the chemical shifts, intensities, and multiplicities of the signals.

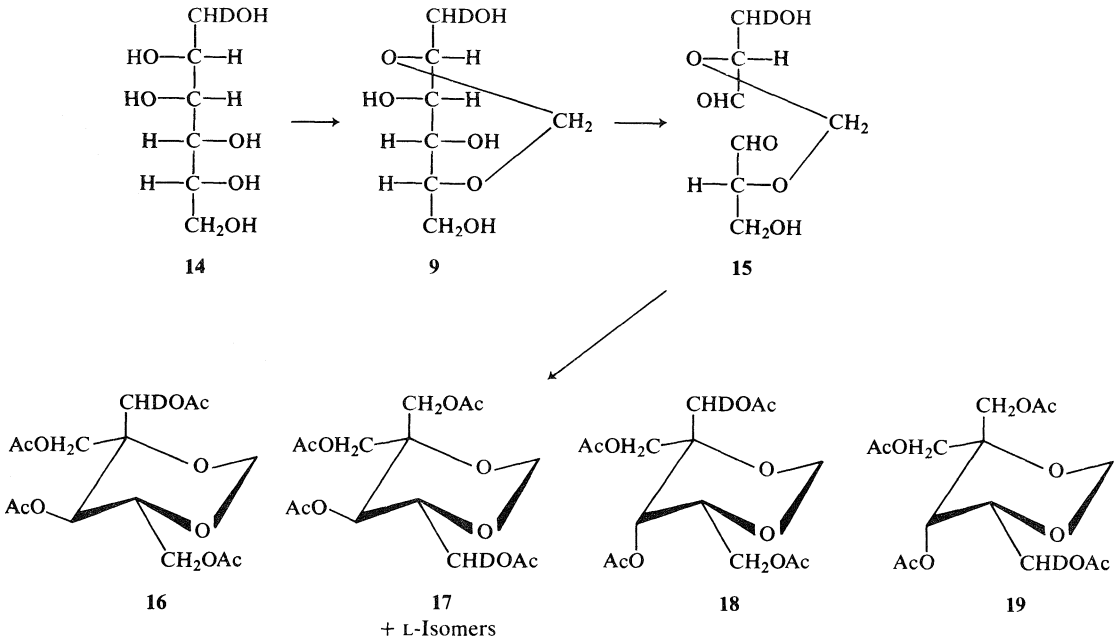
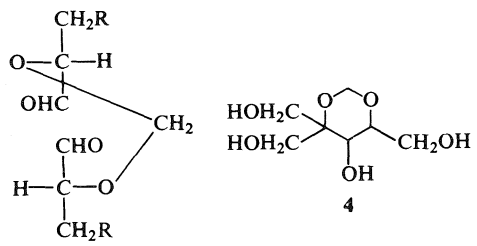


SCHEME 4

Apparently, the intramolecular aldol condensation of **2** proceeds under the conditions of the reaction. Since that time, Jordaan and co-workers (18) have also reported an aldol condensation taking place during sodium borohydride reduction of a furanosidulose. Lloyd and Harrison (17) also observed that sodium borohydride reduction of dialdehyde (**20**) afforded the expected product, namely 2,2′-*O*-methylene-bis(1-deoxy-1-fluoro-L-glycerol) (**21**), and not the reduced aldol product. In order to account for this difference in behaviour, these workers postulated (17) that the base-catalyzed cyclization of the dialdehyde **2** was more facile than that of the difluoride **20** because of greater product stabilization in the former case. Specifically, it was suggested that the product of the aldol condensation derived from **2** might be stabilized by the formation of a cyclic hemiacetal (**22**), provided that its formation was allowed by the relative configuration at C-4 and C-6. The product of the aldol condensation derived from **20** could not, of course, form a cyclic hemiacetal. Harrison also later suggested that the stereochemistry of the products of the aldol-condensation reaction of **2** might be directed by the possibility of later hemiacetal ring closure.[6] The exclusive formation of aldol-condensation products (**7** or **8**) in which the hydroxymethyl group at C-6 and the formyl group at C-4 are *syn* to one another, as demonstrated in the present work, is certainly in accord with Harrison's hypothesis since only these products can undergo internal hemiacetal formation.



**2** R = OH
**20** R = F

**4**

The possible aldol-condensation products and the hypothetical reaction routes giving rise to these products are shown in Scheme 5. Thus, retention of configuration at the carbon centre bearing the formyl group that is attacked by the enolate ion can give rise to the species labelled as A and B, and inversion of configuration at this centre can give rise to the corresponding enantiomeric species labelled as A′ and B′, respectively. According to Harrison's hypothesis, only A and A′ will be stabilized by intramolecular hemiacetal formation, yielding C and C′, respectively (see Scheme 6); B and B′ should then re-enter the equilibrium to give either A or A′.

The data obtained in the present study suggest that both A and A′ are formed in the aldol-

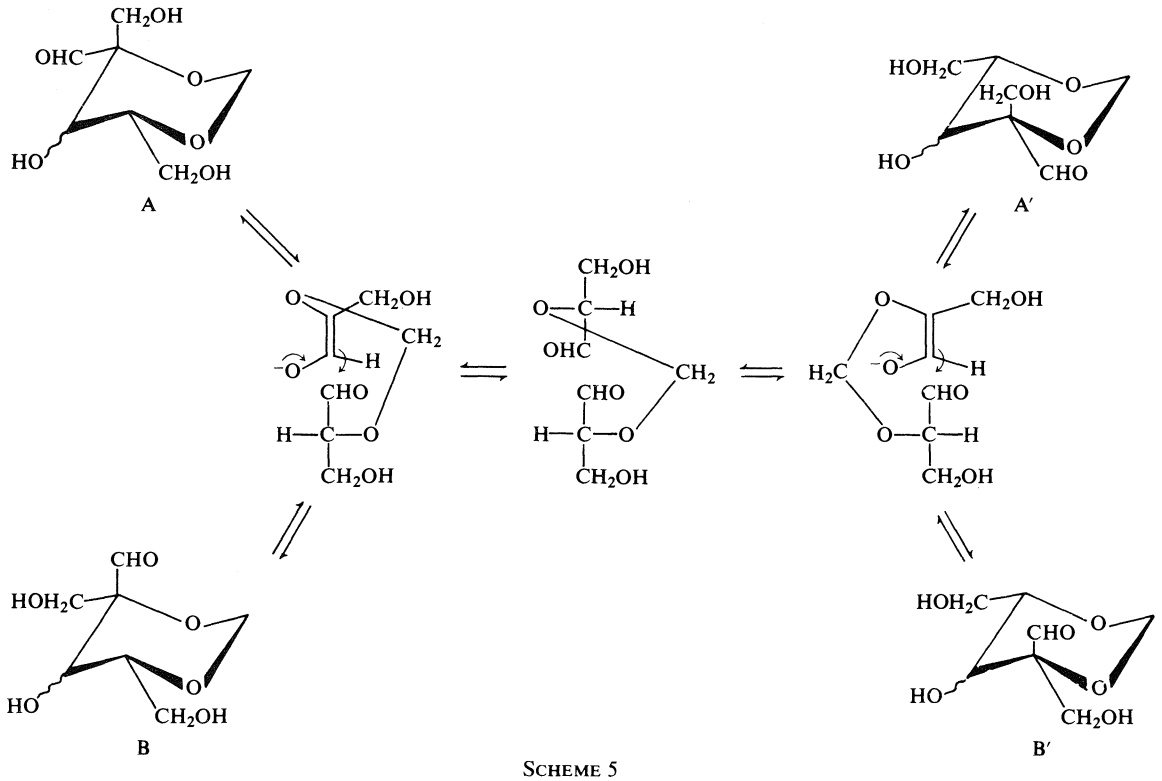
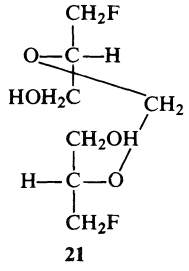
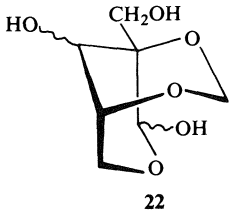


SCHEME 5

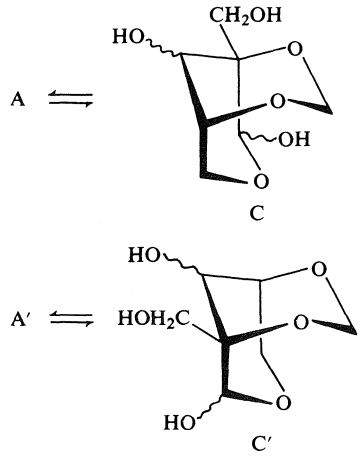
condensation reaction, but in a non-equimolar ratio. Thus, for example, variable optical rotations were obtained for the products derived from A or A′, depending on the conditions of the aldol-condensation reactions. Moreover, one of the products of the aldol condensation has been converted into a mixture of 2-*C*-hydroxymethyl-D- and L-ribose (19). Angyal and James (10) have reported an optical rotation of +1.6° for 2-*C*-acetoxymethyl-1,3,5-tri-*O*-acetyl-L-*threo*-pentitol (**23**). In one preparation, the enantiomer of this compound was presumably obtained ($[\alpha]_D = -1.8°$). However, under the particular conditions of the aldol condensation that preceded the formation of this compound, it is likely that this product arose by means





of a Cannizzaro reaction. Therefore, in this case, it would appear that one of the species represented by A in Scheme 5 was reduced before it could re-enter the equilibrium.

The possibility that internal hemiacetal formation provides the driving force for controlling the stereochemistry of the aldol-condensation products is further supported by the fact that the products of the aldol condensation exist to a great extent in aqueous solution as the bicyclic compounds. Thus, examination of the $^1$Hmr spectrum at 220 MHz in deuterium oxide of the aldol-condensation product, obtained under conditions that had previously been shown to yield only one isomer, namely **7**,



SCHEME 6

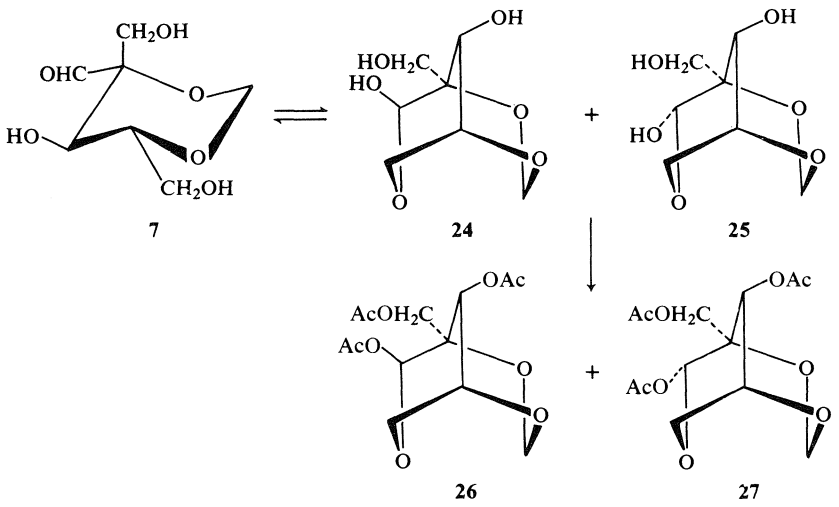
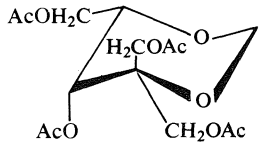


SCHEME 7

indicated the presence of mainly two compounds, one being present in greater proportion. A distinctive feature of the spectrum was the presence of



23

two singlets at δ 5.39 (major) and δ 5.19 (minor); these were assigned to the protons at the hemiacetal centres of the bicyclic compounds **24** and **25**, respectively (see Scheme 7), on the basis of the expected shielding of the quasi-axial H-6 proton relative to its quasi-equatorial counterpart. The preponderance of **24** is in agreement with expectations based on the anomeric effect. Interestingly, the signals for the geminal acetal protons displayed substantial chemical-shift nonequivalence. Hence, these signals appeared as AX doublets at δ 5.77 and δ 5.07 ($J$ = 5.2 Hz) for the major isomer and at δ 5.80 and δ 5.01 ($J$ = 5.2 Hz) for the minor isomer. The significance of this result will be discussed later. The H-8 and H-8′ signals for the major isomer appeared as AB doublets at δ 3.84 and 3.71 ($J$ = 12 Hz) and the rest of the $^1$H resonances appeared as complex multiplets at δ 4.33–3.52 and at δ 4.88–5.15. The presence of the bicyclic compounds was corroborated by the appearance of a signal at 96.3 ppm in the $^{13}$Cmr spectrum in deuterium oxide which was assigned to the hemiacetal carbon, C-6. Only the peaks attributable to the major isomer could be assigned unambiguously (see Experimental).

Acetylation of the mixture obtained from the aldol condensation, as described above, afforded, after chromatography, five components. The least polar of these components was identified as being a mixture of the two isomeric bicyclo[3.3.1]nonanes, **26** and **27** derived from **24** and **25** (see Scheme 7). The $^1$Hmr spectrum at 220 MHz of the mixture of **26** and **27** in toluene-$d_8$ is shown in Fig. 11. The distinctive feature of this spectrum is the appearance of the H-6 signals of the major and minor isomers as singlets at δ 6.52 and 6.03, respectively. As before, the major isomer is assigned the structure in which the acetoxy group at C-6 is quasi-axial. The signals for H-3 and H-3′ appear once again as AX doublets for both isomers. The $^{13}$Cmr spectral data for **26** and **27** (see Experimental) are also in accord with the assignment of the stereochemistry at C-6 in the major and minor isomers. Thus, the C-6 signals for both the major and minor isomers appear at 92.94 ppm. However, in the gated-decoupled spectrum, the signal for the major isomer shows a one-bond coupling constant of 177 Hz while that for the minor isomer shows a one-bond coupling constant of about 166 Hz. It is well known that $^1J_{^{13}C_2-H}$ for equatorially oriented protons in 2-substituted tetrahydropyrans is about 10 Hz greater than $^1J_{^{13}C_2-H}$ for axially oriented protons in the analogously substituted isomeric compound (20). Thus, the major isomer **26** is assigned a configuration at C-6 in which the acetoxy group is quasi-axial.

The strong chemical-shift nonequivalence displayed by the geminal methylene protons, H-3 and H-3′, in compounds **24–27** (Δν 0.71–0.97 ppm) may be interpreted in terms of the deshielding of one of the set of protons as a result of the repulsion of electrons in the vicinity of this proton by a proximal

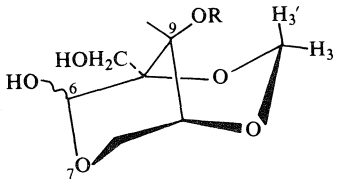
substituent atom (21). If it is assumed that these derivatives exist preponderantly in the chair,chair conformation, as shown, then the substituent atom in question may be assigned as O-7. However, if the boat,chair conformation **28** is preferred, then the substituent atom in question is O-9. It is noteworthy that 2,4-dioxabicyclo[3.3.1]nonane has been assigned the boat,chair conformation on the basis of coupling-constant data, nuclear Overhauser effects, and the $T_1$-relaxation times (22). However, it is difficult to rationalize the observed differences in $\Delta\nu_{AX}$ for the major and minor isomers (which differ in configuration only at C-6) if **28** is indeed

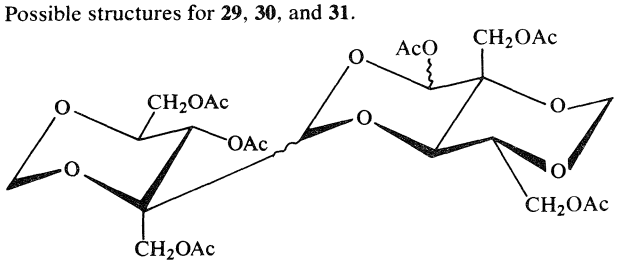


**28** R = H or Ac

the predominant conformation. In particular, $\Delta\nu_{AX}$ in the minor acetylated derivative **27** is 0.2 ppm greater than that in the corresponding major isomer **26**. If the chair,chair conformation is favoured, then this difference might reflect the effect of the anisotropy of the carbonyl group of the equatorially oriented acetoxy group at C-6 in **27** on the chemical shift of H-3. It must be noted that $\Delta\nu_{AX}$ in the minor isomer of the non-acetylated derivative **25** is slightly greater (0.08 ppm) than that in the corresponding major isomer **24**. The choice of the chair conformation for the derivatives obtained in the present work also seems reasonable in view of the fact that the internuclear distance between O-7 and H-3 in the chair,chair conformation is considerably less than the internuclear distance between O-9 and H-3′ in the boat,chair conformation, and should, therefore, result in greater van der Waals shielding in the former case. The magnitude of this effect decreases very rapidly with increasing internuclear distance (21). More definitive conclusions regarding the preponderant conformation of these derivatives must, however, await further studies.

The second component isolated from the acetylation reaction was present in small quantity; it was identified as being 2-*C*-acetoxymethyl-1,3,5-tri-*O*-acetyl-2,4-*O*-methylene-D,L-*threo*-pentitol (**12**), the product of a Cannizzaro reaction. The other three components isolated from this reaction mixture were much more polar in nature and were identified as being the acetylated dimers **29–31** derived from the self-condensation of **7** (see Scheme 8). The condensation of β-hydroxy aldehydes with

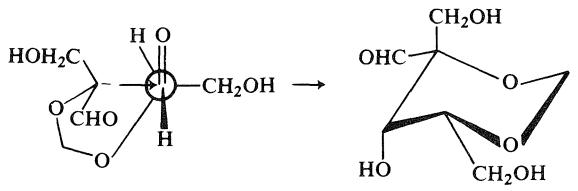
Possible structures for **29**, **30**, and **31**.



SCHEME 8

themselves and with other aldehydes is well documented (10, 23, 24). Of particular relevance are the dimers derived from 2,4-*O*-ethylidene-D-erythrose (23) and the 2,4-acetals of L-xylose (10) which have analogous structures to those of **29–31**. The proposed structures for **29–31** were supported by the mass-spectral data.

Under the conditions of the aldol-condensation reaction employed in the present work, it is almost certain that the products obtained are under thermodynamic control. Hence, the thermodynamically most stable isomer of the four possible 1,3-dioxanes is that in which the formyl group at C-4, the hydroxymethyl group at C-6, and the hydroxyl group at C-5 are equatorial, as represented by **7** in Scheme 2. It is noteworthy that consideration of the favoured transition state **32** for the aldol-condensation reaction according to Felkin's model (25) or the model proposed by Anh and Eisenstein (26) for 1,2-asymmetric induction on the basis of *ab initio* calculations suggests that the kinetically controlled product should be that in which the hydroxyl group at C-5 adopts the axial orientation (see **8** in Scheme 9). The formation of a substantial



**32** **8**

SCHEME 9

amount of the reduced product derived from **8** (in which the 5-hydroxyl group is axial) at higher base concentration is likely to result from the distortion of the true equilibrium of the aldol condensation by the Cannizzaro reaction of **8**.

## Experimental

Melting points were determined with a Fisher–Johns melting-point apparatus and are uncorrected. Mass spectra were recorded on a CEC21-104 mass spectrometer under electron-impact conditions at 70 eV ionizing voltage. Proton magnetic resonance

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

($^1$Hmr) spectra were recorded on a Bruker HX-60, Varian CFT-20, or Varian HR-220 spectrometer. Carbon-13 magnetic resonance ($^{13}$Cmr) spectra were recorded on a Bruker HX-60 spectrometer equipped with a FT60M Fourier transform accessory at 15.09 MHz, a Varian CFT-20 spectrometer at 20.0 MHz, or a JEOL FX-100 spectrometer at 25.05 MHz. Spectra were measured in chloroform-*d* with tetramethylsilane (TMS) as internal standard, unless otherwise stated. Chemical shifts are given in ppm downfield from TMS. Spectra recorded in deuterium oxide solution were measured with respect to internal acetone whose chemical shift was taken as being 2.225 ppm relative to TMS for the $^1$Hmr spectra and 32.78 ppm relative to TMS for the $^{13}$Cmr spectra. Chemical shifts and coupling constants were obtained from first-order analyses of the nmr spectra. Optical rotations were determined on a Perkin–Elmer 141 polarimeter.

Analytical thin-layer chromatography (tlc) was performed on precoated glass plates with Merck silica gel 60F-254 as the adsorbent (layer thickness 0.25 mm). The developed plates were air-dried and exposed to uv light and/or sprayed with a solution of cerium sulfate (1%) and molybdic acid (1.5%) in 10% aqueous sulfuric acid, and heated at 150°C. Column chromatography was performed on Brinkman silica gel (70–325 mesh, E. Merck). The chromatographic solvent systems (v/v) employed in this work are as follows: (A) benzene – ethyl acetate, 1:1; (B) 4:1; (C) toluene – ethyl acetate, 4:1; (D) 1:4; (E) ethyl acetate.

Solvents were evaporated under reduced pressure and below 40°C.

For convenience, the numbering of compounds according to the convention for heterocyclic derivatives has been employed for the presentation of nmr data. However, in order to identify the compounds unequivocally, the names of the compounds are based on accepted carbohydrate nomenclature.

*2,2′-O-Methylene-bis-D-glycerose (**2**)*

To a solution of 2,5-*O*-methylene-D-mannitol (**1**) (10 g), prepared in three steps from D-mannitol by the method of Ness *et al.* (1), in water (50 mL), was added a solution of sodium metaperiodate (12 g) in water (100 mL). After 5 h the solution was carefully neutralized with 0.1 *N* sodium hydroxide, and a solution of barium chloride dihydrate (6.5 g) in water (70 mL) was added. The mixture was refrigerated for 3 h and then filtered to remove the precipitated salts. The filtrate was concentrated to afford a syrup (**2**) (8.6 g), $[\alpha]_D^{24}$ +11.4° (*c* 1.1, water), lit. (1) $[\alpha]_D$ + 10.5°.

In subsequent experiments the filtrate was directly subjected to the conditions of the aldol-condensation reaction, reduction, and acetylation, as follows. The filtrate was diluted with water and the solution was adjusted to the desired pH by dropwise addition of 1 *N* sodium hydroxide. The mixture was let stand at room temperature for the alloted time and was then treated with Amberlite IR-120 (H), followed by Amberlite IR-45 (OH). The neutral solution was treated directly with either sodium borohydride or sodium borodeuteride as required. After 12 h at room temperature the mixture was acidified by addition of Amberlite IR-120 (H) and was subsequently neutralized with Amberlite IR-45 (OH). The solution was concentrated and the residue was acetylated in the usual manner.

A typical procedure is outlined below.

*2-C-Acetoxymethyl-1,3,5-tri-O-acetyl-1-(R,S)-deuterio-2,4-O-methylene-D,L-ribitol (**11**), 2-C-acetoxymethyl-1,3,5-tri-O-acetyl-2,4-O-methylene-D,L-threo-pentitol (**12**), and 2-C-acetoxymethyl-1,3,5-tri-O-acetyl-1-(R,S)-deuterio-2,4-O-methylene-D,L-xylitol (**13**)*

To a solution of 2,5-*O*-methylene-D-mannitol (**1**) (0.5 g) in water (2.5 mL) was added a solution of sodium metaperiodate (0.6 g) in water (5 mL). After 5 h the solution was carefully neutralized with 0.1 *N* sodium hydroxide and a solution of barium chloride dihydrate (0.34 g) in water (3.5 mL) was added. The mixture was refrigerated for 2.5 h and then filtered to remove the precipitated salts. The filtrate was diluted to 40 mL and 1 *N* sodium hydroxide (3.3 mL) was added. The mixture was let stand at room temperature for 3.25 h and was then acidified (pH 4) with Amberlite IR-120 (H), and finally neutralized with Amberlite IR-45 (OH). The resulting solution was made up to a volume of 125 mL, and sodium borodeuteride (0.11 g) was added in small portions. After 12 h at room temperature the mixture was acidified (pH 2) with Amberlite IR-120 (H) and was subsequently neutralized with Amberlite IR-45 (OH). The solution was concentrated to afford a syrup which was repeatedly reconcentrated from methanol to remove boric acid. The resulting syrup was treated with pyridine (10 mL) and acetic anhydride (7.5 mL) and the mixture was shaken to effect complete dissolution. After 12 h the mixture was poured into cold saturated sodium hydrogen carbonate solution (200 mL) and was shaken for 2 h. The mixture was extracted with methylene chloride (4 × 50 mL). The extracts were washed with water (2 × 50 mL) and dried over magnesium sulfate. Evaporation of the solvent afforded a syrup (0.561 g). Thin-layer chromatography (Solvent B) indicated the presence of one component having an $R_f$ value of 0.24. The syrup was dissolved in ethanol and the solution was allowed to stand at room temperature for 12 h. The white needles that deposited were collected and were identified as being a mixture of 2-*C*-acetoxymethyl-1,3,5-tri-*O*-acetyl-2,4-*O*-methylene-D,L-*threo*-pentitol (**12**) and 2-*C*-acetoxymethyl-1,3,5-tri-*O*-acetyl-1-(*R*,*S*)-deuterio-2,4-*O*-methylene-D,L-xylitol (**13**) (0.04 g, 4.3%), mp 145.5–146.5°C, $[\alpha]_D^{33}$ −2.4° (*c* 1.2, $CHCl_3$); $^1$Hmr (220 MHz, $CDCl_3$) δ: 2.04, 2.09, 2.14, 2.16 (12 H, s's, 4 OAc), 3.99 (1H, *J* = 11.2 Hz, H-4‴), 4.01 (1H, d of d, *J* = 11.8, 7.2 Hz, H-6″), 4.13, 4.14 (1H, s's, H-4*'s), 4.16 (1H, d, *J* = 12.2 Hz, H-4″), 4.16 (1H, d of d, *J* = 11.5, 5.1 Hz, H-6′), 4.25 (1H, d of d, *J* = 7.2, 5.2 Hz, H-6), 4.28 (1H, d, *J* = 11.2 Hz, H-4‴), 4.87 (1H, d, *J* = 12.2 Hz, H-4′), 4.98 (1H, br s, H-5), 4.99, 5.12 (two 1H d's, *J* = 6.9 Hz, H-2, H-2′); (220 MHz, $C_6D_6$) δ: 3.85 (1H, d, *J* = 12.6 Hz, H-4″), 3.88 (1H, d of d, *J* = 6.6, 6.0 Hz, H-6), 4.09, 4.10 (1H, s's, H-4*'s), 4.07 (1H, d of d, *J* = 11.0, 6.6 Hz, H-6″), 4.13 (1H, d, *J* = 10.5 Hz, H-4‴), 4.25 (1H, d of d, *J* = 11.0, 6.0 Hz, H-6′), 4.59 (1H, d, *J* = 10.5 Hz, H-4‴), 4.70 (1H, d, *J* = 12.6 Hz, H-4′), 4.74, 4.83 (two 1H d's, *J* = 6.4 Hz, H-2, H-2′), 4.94 (1H, br s, H-5). The filtrate was refrigerated for 12 h upon which orthorhombic crystals deposited. These were collected and were identified as being 2-*C*-acetoxymethyl-1,3,5-tri-*O*-acetyl-1-(*R*,*S*)-deuterio-2,4-*O*-methylene-D,L-ribitol (**11**) (0.164 g, 18%), mp 88–89°C, $[\alpha]_D^{33}$ + 12.2° (*c* 1.4, $CHCl_3$); $^1$Hmr (220 MHz, $CDCl_3$) δ: 2.08 (3H, s, OAc), 2.11 (9H, br s, 3 OAc), 3.96 (1H, d of q, *J* = 2.6, 5.3, 10.4 Hz, H-6), 4.10 (1H, d, *J* = 13.2 Hz, H-4″), 4.10 (1H, d of d, *J* = 12.0, 2.6 Hz, H-6″), 4.13, 4.14 (1H, s's, H-4‴'s), 4.20 (1H, d of d, *J* = 12.0, 5.3 Hz, H-6′), 5.00 (1H, d, *J* = 13.4 Hz, H-4′), 4.91, 5.05 (two 1H d's, *J* = 7.0 Hz, H-2, H-2′), 5.27 (1H, d, *J* = 10.3 Hz, H-5); (220 MHz, $C_6D_6$) δ: 1.64, 1.71, 1.76, 1.79 (12 H, s's, 4 OAc), 3.63 (1H, d of q, *J* = 2.1, 5.0, 10.8 Hz, H-6), 4.01 (1H, d, *J* = 12.5 Hz, H-4″), 4.07 (1H, d of d, *J* = 2.1, 12.7 Hz, H-6″), 4.25 (1H, d of d, *J* = 5.0, 12.7 Hz, H-6′), 4.24, 4.29 (1H, s's, H-4‴'s), 4.75, 4.84 (two 1H d's, *J* = 6.4 Hz, H-2, H-2′), 4.93 (1H, d, *J* = 12.5 Hz, H-4′), 5.47 (1H, d, *J* = 10.8 Hz, H-5). The mother liquor was concentrated to afford a partially crystalline syrup (0.34 g, 36%) which was shown to consist of only compound **11** by $^1$Hmr and $^{13}$Cmr spectroscopy.

*2-C-Acetoxymethyl-1,3,5-tri-O-acetyl-2,4-O-methylene-D,L-erythro-pentitol (**10**) and 2-C-acetoxymethyl-1,3,5-tri-O-acetyl-2,4-O-methylene-D,L-threo-pentitol (**12**)*

When 2,2′-*O*-methylene-bis-D-glycerose (**2**) was subjected to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

the conditions of the aldol condensation, followed by sodium borohydride reduction and then acetylation, as described for the synthesis of compounds **11**, **12**, and **13**, two isomers were obtained by fractional crystallization. Compound **12** was obtained as white needles, mp 147–148°C, lit. (10) mp 147–148°C, $[\alpha]_D^{33}$ −1.8° (*c* 0.8, $CHCl_3$), lit. (10) $[\alpha]_D$ +1.6° (*c* 1, $CHCl_3$) for the L-isomer; $^1$Hmr (220 MHz, $CDCl_3$) δ: 2.04, 2.09, 2.14, 2.16 (12H, s's, 4 OAc), 3.99 (1H, d, *J* = 11.2 Hz, H-4‴), 4.01 (1H, d of d, *J* = 11.5, 7.0 Hz, H-6″), 4.16 (1H, d of d, *J* = 11.5, 4.2 Hz, H-6′), 4.17 (1H, d, *J* = 12.0 Hz, H-4″), 4.26 (1H, d of d, *J* = 7.0, 4.2 Hz, H-6), 4.28 (1H, d, *J* = 11.2 Hz, H-4‴), 4.88 (1H, d, *J* = 12.0 Hz, H-4′), 4.98 (1H, br s, H-5), 4.99, 5.13 (two 1H d's, *J* = 7.0 Hz, H-2, H-2′); (220 MHz, $C_6D_6$) δ: 3.87 (1H, d, *J* = 12.5 Hz, H-4″), 3.90 (1H, d of d, *J* = 6.6, 5.8 Hz, H-6), 4.09 (1H, d of d, *J* = 11.1, 6.6 Hz, H-6″), 4.15 (1H, d, *J* = 11.0 Hz, H-4‴), 4.27 (1H, d of d, *J* = 11.1, 5.8 Hz, H-6′), 4.61 (1H, d, *J* = 11.0 Hz, H-4‴), 4.72 (1H, d, *J* = 12.5 Hz, H-4′), 4.76, 4.84 (two 1H d's, *J* = 6.8 Hz, H-2, H-2′), 4.96 (1H, br s, H-5). *Anal.* calcd. for $C_{15}H_{22}O_{10}$: C 49.72, H 6.12; found: C 49.82, H 6.12.

Compound **10** was obtained as white crystals, mp 91–93°C, lit. (1) mp 93–94°C, $[\alpha]_D^{33}$ +13.9° (*c* 0.44, $CHCl_3$), lit. (1) $[\alpha]_D^{20}$ +12.4° (*c* 1.0, $CHCl_3$); $^1$Hmr (220 MHz, $CDCl_3$) δ: 2.09 (3H, s, OAc), 2.11 (9H, br s, 3 OAc), 3.96 (1H, d of q, *J* = 3.0, 5.4, 10.3 Hz, H-6), 4.10 (1H, d, *J* = 13.5 Hz, H-4″), 4.10 (1H, d of d, *J* = 12.2, 3.0 Hz, H-6″), 4.11 (1H, d, *J* = 12.2 Hz, H-4‴), 4.17 (1H, d, *J* = 12.2 Hz, H-4‴), 4.20 (1H, d of d, *J* = 12.2, 5.4 Hz, H-6′), 5.01 (1H, d, *J* = 13.5 Hz, H-4′), 4.92, 5.05 (two 1H d's, *J* = 7.0 Hz, H-2, H-2′), 5.27 (1H, d, *J* = 10.2 Hz, H-5); (220 MHz, $C_6D_6$) δ: 1.60, 1.69, 1.74, 1.78 (12H, s's, 4 OAc), 3.58 (1H, d of q, *J* = 2.3, 5.0, 10.4 Hz, H-6), 3.98 (1H, d, *J* = 13.0, H-4″), 4.05 (1H, d of d, *J* = 12.3, 2.3 Hz, H-6″), 4.23 (1H, d of d, *J* = 12.3, 5.0 Hz, H-6′), 4.24, 4.31 (two 1H d's, *J* = 11.4 Hz, H-4‴, H-4‴), 4.71, 4.81 (two 1H d's, *J* = 7.2 Hz, H-2, H-2′), 4.91 (1H, d, *J* = 13.0 Hz, H-4′), 5.47 (1H, d, *J* = 10.4 Hz, H-5).

*D-Mannitol-1-*d *(14)*

To a solution of D-mannose (10 g) in water (30 mL) was added dropwise, with stirring, a solution of sodium borodeuteride (1 g) in water (25 mL) over a period of 0.5 h. After 48 h at room temperature, an acidic ion-exchange resin (30 mL of Amberlite IR-120 (H)) was added, and the solution was stirred for 0.5 h, after which the solution had pH 3. The resin was removed by filtration and the filtrate was evaporated to give a residue that was repeatedly reconcentrated from methanol (5 × 30 mL) to remove boric acid as methyl borate. The residue was dissolved in water (15 mL) and to the warmed solution was added methanol (50 mL). A seed crystal of D-mannitol was added and the solution was stored at room temperature. Collection of the crystalline material afforded D-mannitol-1-*d* (**14**) (7.52 g, 74%), mp 166–168°C. This material was, presumably, a mixture of the two diastereomers resulting from the two possible configurations at C-1.

*l-*(R,S)*-Deuterio-2,2′-O-methylene-bis-D-glycerose (15)*

2,5-*O*-Methylene-D-mannitol-1-*d* (**9**), prepared in three steps from D-mannitol-1-*d* (**14**) by the method of Ness *et al.* (1), was treated with sodium metaperiodate, as described for the synthesis of the unlabelled compound **2**, to yield the title compound.

*2-C-Acetoxymethyl-1,3,5-tri-*O*-acetyl-1-*(R,S)*-deuterio-2,4-O-methylene-D,L-arabinitol (16), 2-C-acetoxymethyl-1,3,5-tri-*O*-acetyl-5-*(R,S)*-deuterio-2,4-O-methylene-D,L-*erythro*-pentitol (17), 2-C-acetoxymethyl-1,3,5-tri-O-acetyl-1-*(R,S)*-deuterio-2,4-O-methylene-D,L-lyxitol (18), and 2-C-acetoxymethyl-1,3,5-tri-O-acetyl-5-*(R,S)*-deuterio-2,4-O-methylene-D,L-*threo*-pentitol (19)*

When 1-(*R,S*)-deuterio-2,2′-*O*-methylene-bis-D-glycerose (**15**) was subjected to the conditions of the aldol condensation, followed by sodium borohydride reduction and then acetylation, as described for the synthesis of compounds **11**, **12**, and **13**, two fractions were obtained. The first fraction was shown by $^{13}$Cmr spectroscopy at 25.05 MHz to consist of a mixture of compounds **18** and **19**, mp 144–146°C. Similarly, the second fraction was shown to consist of a mixture of compounds **16** and **17**, mp 90–93°C.

*2-C-Hydroxymethyl-2,4-*O*-methylene-D,L-ribose (7)*

2,2′-*O*-Methylene-bis-D-glycerose (**2**) (12 g) was subjected to the conditions of the aldol condensation that were previously shown to yield compound **7** and at most a trace of compound **8**, namely a 0.05 *N* sodium hydroxide solution for 3.5 h. The mixture was acidified (pH 3) by addition of Amberlite IR-120 (H) and was subsequently neutralized by addition of Amberlite IR-45 (OH). Filtration of the resin and concentration of the solution afforded a hygroscopic foam (12 g). The $^1$Hmr and $^{13}$Cmr spectra of the product in $D_2O$ solution indicated that the major species present were those resulting from intramolecular hemiacetal formation in compound **7**, namely, 6(*S*),9(*R*)-dihydroxy-5(*R*)-hydroxymethyl-2,4,7-trioxabicyclo[3.3.1]nonane (**24**) and 6(*R*),9(*R*)-dihydroxy-5(*R*)-hydroxymethyl-2,4,7-trioxabicyclo[3.3.1]nonane (**25**); the latter compound was present as the minor component. $^1$Hmr (220 MHz, $D_2O$) δ: 3.71, 3.84 (two 1H d's, *J* = 12 Hz, H-5′, H-5″ for **24**), 3.52–4.33 (m's), 4.88–5.15 (m's), 5.01 (1H, d, *J* = 5.2 Hz, H-3 for **25**); 5.07 (1H, d, *J* = 5.2 Hz, H-3 for **24**), 5.19 (1H, s, H-6 for **25**), 5.39 (1H, s, H-6 for **24**), 5.77 (1H, d, *J* = 5.2 Hz, H-3′ for **24**), 5.80 (1H, d, *J* = 5.2 Hz, H-3′ for **25**); $^{13}$Cmr (for **24**, $D_2O$) δ: 64.7 (C-9), 65.4 (C-5′), 67.1 (C-8), 73.5 (C-1), 77.7 (C-5), 90.7 (C-3), 96.3 (C-6).

*5(R)-Acetoxymethyl-6(S),9(R)-diacetoxy-2,4,7-trioxabicyclo-[3.3.1]nonane (26) and 5(R)-acetoxymethyl-6(R),9(R)-diacetoxy-2,4,7-trioxabicyclo[3.3.1]nonane (27)*

A portion of the foam that was obtained in the preceding experiment (0.38 g) was treated with pyridine (20 mL) and acetic anhydride (2.5 mL) for 72 h. The mixture was processed in the usual manner to yield a syrup; tlc (Solvent B) indicated the presence of two components having $R_f$ values of 0.32 and 0.18 as well as a component at the origin. The sample was chromatographed on silica gel using Solvent C as eluant initially and then Solvent E as eluant. The component having an $R_f$ value of 0.32 was obtained as a partially crystalline syrup which was identified as being a mixture of compounds **26** and **27**, present in a ratio of 2.6:1 (0.15 g). $^1$Hmr (220 MHz, toluene-$d_8$) for compound **26**, δ: 1.70, 1.74, 1.75 (three 3H s's, 3 OAc), 3.71 (1H, br d, *J* = 13.2 Hz, H-8), 3.82 (1H, d of d, $J_{8,8'}$ = 13.2 Hz, $J_{1,8'}$ = 2 Hz, H-8′), 3.82 (1H, br d, $J_{1,9}$ = 2 Hz, H-1), 4.18 (1H, d, *J* = 11.8 Hz, H-5″), 4.36 (1H, d, *J* = 11.8 Hz, H-5′), 4.94 (1H, d, *J* = 4.3 Hz, H-3′), 5.10 (1H, d, $J_{9,1}$ = 2 Hz, H-9), 5.72 (1H, d, *J* = 4.3 Hz, H-3), 6.52 (1H, s, H-6); $^1$Hmr (220 MHz, toluene-$d_8$) for compound **27**, δ: 1.74, 1.75, 1.76 (three 3H s's, 3 OAc), 3.33 (1H, d, *J* = 12.5 Hz, H-8), 3.64–3.94 (m's including H-8′ and H-1 signals), 4.10 (1H, d, *J* = 11.2 Hz, H-5″), 4.42 (1H, d, *J* = 11.2 Hz, H-5′), 4.93 (1H, d, *J* = 4.3 Hz, H-3′), 4.96 (1H, d, *J* = 2 Hz, H-9), 5.90 (1H, d, *J* = 4.3 Hz, H-3), 6.03 (1H, s, H-6); $^{13}$Cmr data (toluene-$d_8$) for **26**, δ: 20.24 (Me), 64.35 (C-5′), 65.71 (C-1), 66.81 (C-8), 68.42 (C-9), 72.76 (C-5), 88.86 (C-3), 92.94 ($^1J_{C-H}$ = 177 Hz, C-6), 167.8, 169.6, 169.9 (CO); $^{13}$Cmr (toluene-$d_8$) for **27**, δ: 20.24 (Me), 59.82 (C-5′), 66.29, 67.52, 68.10 (C-5, C-8, C-9), 88.86 (C-3), 92.94 ($^1J_{C-H}$ = 165 Hz, C-6), 168.4, 169.6, 169.9 (CO); mass spectral data: M calcd. for $C_{13}H_{18}O_9$: 318; found: *m/e* 259 ($M^+$ − OAc). *Anal.* calcd. for $C_{13}H_{18}O_9$: C 49.06, H 5.70; found: C 48.97, H 6.18.

The compound having an $R_f$ value of 0.18 was obtained as a solid and was identified as being one of the products derived from the Cannizzaro reaction of compound **8**, namely, 2-*C*-acetoxymethyl-1,3,5-tri-*O*-acetyl-2,4-*O*-methylene-D,L-

*threo*-pentitol (**12**) (0.016 g). The component migrating at the origin in Solvent B was eluted with Solvent E and was shown to consist of three components having $R_f$ values of 0.56, 0.50, and 0.44. The mixture was rechromatographed using Solvent D as eluant to yield each component as a white foam. All three compounds were identified as being the acetylated dimers **29**, **30**, and **31** derived from the self-condensation of **7**; mass spectral data: M calcd. for $C_{26}H_{36}O_{18}$: 636.5; found for **29** ($R_f$ = 0.56, 0.048 g): *m/e* 348, 289 ($M^+ - C_{12}H_{17}O_8$), 275 (348 − $CH_2OAc$), 259 (289 − $CH_2O$), 245 (275 − $CH_2O$), 229 (259 − $CH_2O$), 215 (245 − $CH_2O$), 203 (276 − $CH_2OAc$), 199 (229 −$CH_2O$); found for **30** ($R_f$ 0.50, 0.042 g): *m/e* 577 ($M^+$ − OAc), 563 ($M^+$ − $CH_2OAc$), 461 (563 − $CH_3CO$ − OAc), 445 (563 − 2 OAc); found for **31** ($R_f$ 0.44, 0.029 g): *m/e* 348, 289 ($M^+ - C_{12}H_{17}O_8$), 305 (348 − $CH_3CO$), 275 (348 − $CH_2OAc$), 259 (289 − $CH_2O$), 245 (275 − $CH_2O$). A mixture of compounds **29**, **30**, and **31** was also obtained (0.046 g).

# Quadricyclane–norbornadiene isomerizations on alumina

DOUGLAS N. BUTLER AND INDRANIL GUPTA

*Department of Chemistry, York University, Downsview, Ont., Canada M3J 1P3*

Received August 25, 1981

DOUGLAS N. BUTLER and INDRANIL GUPTA. Can. J. Chem. **60**, 415 (1982).

Standard synthetic steps have been used to convert 7-methylenequadricyclane into the spiro-cyclopropene **1** and the allene **2**. These (and other) quadricyclanes are cleanly isomerized on alumina to the respective bicyclo[2.2.1]hepta-2,5-dienes **3** and **4**.

DOUGLAS N. BUTLER et INDRANIL GUPTA. Can. J. Chem. **60**, 415 (1982).

Faisant appel à des méthodes usuelles de synthèse, on a transformé le méthylène-7 quadricyclane en un spiro cyclopropène **1** et en allène **2**. Ce quadricyclane (ainsi que d'autres), par une isomérisation sur alumine, se transforment respectivement, d'une façon très propre, en bicyclo[2,2,1]heptadiènes-2,5 **3** et **4**.

Interest has recently been shown in the quadricyclane–norbornadiene isomerization using polymer supported catalysts in relation to energy-storage systems (1). Conventionally, noble metal complexes of Ru, Pd, Cu, and Rh have been used (2) and reviewed (3) with respect to the mechanisms of transition metal-catalysed isomerizations of these highly condensed systems. Herein we report the synthesis of novel spiro-annelated norbornadienes via *alumina promoted* cyclo-reversions of quadricyclanes.

The isomeric hydrocarbons **1** to **4** have not been previously reported, though an analysis of through-space and through-bond interactions in these molecules would be of interest in relation to their constitution and properties (4).

The key intermediate **5** (from methylenequadricyclane (5)) was the precursor for all of the isomers **1** to **4**. The synthetic sequences and interconversions are shown in Scheme 1 with the only deviations from standard procedures being the quadricyclane–norbornadiene isomerizations **1** → **3**, **2** → **4**, **5** → **7**, and **9** → **10** which were all brought about by simple passage in pentane through ice-cooled columns of neutral alumina. In each case, the alumina turned orange or pink and in larger samples (~ 3 g) the local heat of reaction disturbed the column packing. In the case of the isomerization of **1** → **3**, these spiro-cyclopropenes slowly reacted on the column to produce uncharacterized products (possibly alcohols by hydration of the strained olefin) and we experienced poor recoveries until we cooled the columns.

It seems indeed surprising to us that this alumina promoted isomerization has not been observed before, but we were not able to find it mentioned in the literature (6). Quadricyclane itself was also shown to be isomerized to norbornadiene but required about three times as much alumina when compared to the more strained cases described above. Also, methylenequadricyclane was cleanly isomerized to 7-methylenenorbornadiene (5). Although it was not tried, we have no reason to doubt that the conversion **6** → **8** could also be effected on alumina in pentane. This cycloreversion phenomenon seems to be associated with the fresh surface of the alumina since once having been used, a column loses its capacity to bring about the isomerization. It should be noted that the thermally sensitive compounds of this study could not be prepared using the conventional noble metal cycloreversion catalysts due to decomposition under the conditions used, and thus this alumina method, being cheap, facile, and applicable to sensitive quadricyclanes, should find ready utilization.

The structures of these new hydrocarbons and their precursors all follow from their mode of synthesis and their consentaneous $^1H$ and $^{13}C$ nuclear magnetic resonance spectra (see Experimental). Isomers **1** to **4** all show very similar mass spectra with a strong P-1 peak at $m/e = 115$ as their most interesting feature.

The stability of the spiro-cyclopropene hydrocarbons **1** and **3** as compared to other 3,3-dialkyl substituted cyclopropenes is noteworthy in relation to the novel type of spiro-conjugation inherent in the constitution of these isomers. Thus, although **1** or **3** polymerized when we attempted to distil them under vacuum (14 Torr), they can be stored at 0°C for weeks without serious loss. This stability contrasts with that of the heretofore unknown norbornane **14** (see Scheme 1 for synthesis) which rapidly polymerized at 0°C on attempted isolation from pentane solution. In turn, this instability should be contrasted with the successful isolation of the spiro-cyclopropene **16** (7) as a stable, crystal-

SCHEME 1

line solid. This spiro-conjugation is also evident in the uv spectrum of **3** which shows a pronounced bathochromic shift of the $\lambda_{max}$ (pentane) = 220.5 nm as compared to norbornadiene ($\lambda_{max}$ (pentane) = 205 nm) (8) or the spiro-cyclopropanenorbornadiene **17** (4*a*) ($\lambda_{max}$ (pentane) = 207 nm) (9). A fuller discussion of the orbital interactions involved must await an analysis of the photo-electron spectra currently under way.

## Experimental

The ir spectra were recorded on a Unicam SP1000 spectrophotometer as liquid films or Nujol mulls. The $^1H$ and $^{13}C$ nmr spectra were taken respectively on Varian EM360 or CFT20 instruments in the solvents indicated. The uv spectra were run on a Unicam SP800A spectrophotometer. Mass spectra were taken at 70 eV using a Hitachi–Perkin–Elmer RMU-6E instrument. Vapour phase chromatographic analyses were carried out using a Varian Aerograph instrument, Model 1700, on a 7 ft × 1/4 in. glass column packed with Chromosorb W (60–80 mesh) loaded with a mixture of 6% SE30 and 4% QF1. All melting points are uncorrected.

*Dibromocarbene addition to 3-methylenetetracyclo-[3.2.0.0$^{2,7}$,0$^{4,6}$]heptane. Spiro-tetracyclo[3.2.0.0$^{2,7}$,0$^{4,6}$]-heptane-3:1′-(2′,2′-dibromocyclopropane), 5*

A solution of bromoform (10.04 g, 40 mmol) in hexane (25 mL) was added dropwise over 15 min to a stirred mixture of 3-methylenetetracyclo[3.2.0.0$^{2,7}$,0$^{4,6}$]heptane (2.08 g, 20 mmol) (5) and freshly prepared potassium *tert*-butoxide (11.2 g, 100 mmol) in hexane (50 mL) at 0°C under $N_2$. This mixture was stirred for a further 30 min and then poured into water (200 mL) and the hexane layer separated. The aqueous phase was extracted with hexane (3 × 50 mL) and the combined hexane extracts were washed with ice-water (3 × 50 mL). The organic extract was dried ($Na_2SO_4$) and evaporated to a white solid which was recrystallized from pentane to give the adduct **5** (4.03 g, 72%), mp 54°C; $^1H$ nmr ($CDCl_3$) δ: 1.33 (t, $J$ = 4.5 Hz, 2H), 1.90 (m, 4H), and 2.11 (s, 2H); $^{13}C$ nmr ($CDCl_3$) δ: 16.6 (d), 17.6 (d), 28.6 (t), 31.2 (s + d), and 46.4 (s); mass spectrum *m/e*: 274, 276, 278 ($M^+$). Anal. calcd. for $C_9H_8Br_2$: C 39.17, H 2.92; found: C 38.88, H 2.83.

*Spiro-tetracyclo[3.2.0.0$^{2,7}$,0$^{4,6}$]heptane-3:1′-(2′-bromocyclo-propane), 6*

Tri-*n*-butyl tin hydride (3.5 g) was added to a solution of the dribromide **5** (3.3 g) in dry tetrahydrofuran (20 mL) and the mixture heated to reflux for 3/4 h. The solvent was then removed

under vacuum and the residue distilled with the fraction bp 50–52°C /0.1 Torr being collected as the colorless liquid **6** (2.05 g, 84%); $^1$H nmr ($CDCl_3$) δ: 0.9 (m, 1H), 1.1–2.0 (complex multiplets, 7H), and 3.41 (dd, 1H); $^{13}$C nmr ($CDCl_3$) δ: 15.3 (d), 15.6 (d), 15.9 (t), 16.4 (d), 17.8 (d), 22.9 (d), 28.9 (d + d), and 36.7 (s); mass spectrum *m/e*: 196, 198 ($M^+$).

*Spiro-tetracyclo[3.2.0.0$^{2,7}$,0$^{4,6}$]heptane-3:1′-(cyclopropene), **1***

Freshly prepared potassium *tert*-butoxide (2.7 g) was added to a magnetically stirred solution of the monobromide **6** (2.4 g) in dry dimethyl sulfoxide (7 mL) at 10°C. This mixture was stirred at room temperature for 1 h and then worked up by the addition of ice-water (50 mL) followed by extraction with pentane (3 × 50 mL). The combined pentane extracts were washed with water (3 × 50 mL), dried ($Na_2SO_4$), and carefully rotated in an evaporator at water pump pressure using ice-water in the bath until the pentane was removed. The remaining oil (1.1 g, 77%) could not be distilled or vacuum transferred without polymerizing and spectroscopic data were collected directly on this crude reaction product. On standing overnight in the freezer it crystallized, mp approximately 16°C; $^1$H nmr ($CDCl_3$) δ: 0.63 (t, $J$ = 4.3 Hz, 2H), 1.70 (d, $J$ = 2.4 Hz, 4H), and 7.74 (s, 2H); $^{13}$C nmr ($CDCl_3$) δ: 15.1 (d, $J$ = 186 Hz), 26.9 (d, $J$ = 167 Hz), 33.9 (s), and 121.0 (d, $J$ = 221 Hz); mass spectrum *m/e*: 116 ($M^+$).

*Spiro-tetracyclo[3.2.0.0$^{2,7}$,0$^{4,6}$]heptane-3:1′-(cyclopropane), **9***

The hydrocarbon **1** (50 mg) was shaken in pentane (10 mL) in a hydrogen atmosphere with 10% palladium-on-charcoal catalyst (5 mg) until rapid gas uptake stopped. After filtration and careful evaporation the crude product **9** (43 mg) remained as a clear liquid, $^1$H nmr ($CDCl_3$) δ: 0.83 (s and t, $J$ = 4.2 Hz, 6H) and 1.78 (d, $J$ = 4.2 Hz, 4H); $^{13}$C nmr ($CDCl_3$) δ: 5.3 (t, $J$ = 159 Hz), 15.8 (d, $J$ = 183), 28.9 (d, $J$ = 168 Hz), and 29.3 (s); mass spectrum *m/e*: 118 ($M^+$).

*Spiro-bicyclo[2.2.1]hepta-2,5-diene-7:1′(2′,2′-dibromocyclopropane), **7***

A solution of the adduct **5** (700 mg) in hexane (5 mL) was run onto a neutral alumina (Activity Grade 1) (10 g) column (1 cm diameter) packed in hexane and cooled with an ice-jacket. The column was eluted with hexane (100 mL) and the solvent removed from the eluate in a rotary evaporator under vacuum to provide a solid which was recrystallized from pentane to give **7** (554 mg, 79%), mp 42°C; $^1$H nmr ($CDCl_3$) δ: 1.69 (s, 2H), 3.50 (p, $J$ = 2 Hz, 2H), 6.89 (t, $J$ = 2 Hz, 2H), and 7.03 (t, $J$ = 2 Hz, 2H); $^{13}$C nmr ($CDCl_3$) δ: 31.5 (s), 31.9 (t), 54.9 (d), 76.9 (s), 141.5 (d), and 141.7 (d); mass spectrum *m/e*: 274, 276, 278 ($M^+$).

*Spiro-bicyclo[2.2.1]hepta-2,5-diene-7:1′(2′-bromocyclopropane, **8***

Prepared from **7** as described for **6**, monobromide **8** was obtained as a colorless oil (66%), bp 43–47°C/0.1 Torr; $^1$H nmr ($CDCl_3$) δ: 0.8–1.5 (m, 2H), 2.91 (q, 1H), 3.06 (m, 1H), 3.47 (m, 1H), and 6.87 (m, 4H); $^{13}$C nmr ($CDCl_3$) δ: 19.8 (t, $J$ = 161.0 Hz), 23.9 (d, $J$ = 185.6 Hz), 53.8 (d, $J$ = 148.7 Hz), 54.0 (d, $J$ = 148.7 Hz), 71.7 (s), 141.5 (d, $J$ = 176.0 Hz), and 142.6 (d, $J$ = 176.0 Hz); mass spectrum *m/e*: 196. 198 ($M^+$).

*Spiro-bicyclo[2.2.1]hepta-2,5-diene-7,1′-cyclopropene, **3***

Prepared by isomerization of **1** (0.3 g) as described for **7**, hydrocarbon **3** was obtained as an oil which polymerized on attempted distillation (81 mg, 27%); uv (pentane)$\lambda_{max}$: 220.5 nm (ε = 1090); $^1$H nmr ($CDCl_3$) δ: 3.18 (p, $J$ = 2.1 Hz, 2H), 6.80 (t, $J$ = 2.1 Hz, 4H), and 7.41 (s, 2H); $^{13}$C nmr ($CDCl_3$) δ: 58.4 (d, $J$ = 146.4 Hz), 76.0 (s), 126.6 (d, $J$ = 218.4 Hz), and 139.0 (d, $J$ = 168.9 Hz); mass spectrum *m/e*: 116 ($M^+$).

*Spiro-bicyclo[2.2.1]hepta-2,5-diene-7:1′-(cyclopropane), **10***

Prepared from **9** (0.01 g) as described for **1** as an unstable oil (78 mg, 78%) (*4b*); $^1$H nmr ($CDCl_3$) δ: 0.48 (s, 4H), 3.05 (p, $J$ = 2 Hz, 2H), and 6.91 (t, $J$ = 2 Hz, 4H); $^{13}$C nmr ($CDCl_3$) δ: 9.5 (t, $J$ = 159.5 Hz), 55.1 (d, $J$ = 148.4 Hz), 69.7 (s), and 142.5 (d, $J$ = 172.1 Hz); mass spectrum *m/e*: 118 ($M^+$).

*Spiro-bicyclo[2.2.1]heptane-7:1′(2′,2′-dibromocyclopropane), **11***

Prepared from 7-methylenebicyclo[2.2.1]heptane (1.08 g) (5) as for **5** as a white solid (1.98 g, 71%), mp 47°C; $^1$H nmr ($CDCl_3$) δ: 0.75–2.3 with singlets at 1.43, 1.68 and 1.90 (bd); $^{13}$C nmr ($CDCl_3$) δ: 28.3 (t), 28.6 (t), 29.4 (t), 31.0 (s), 43.3 (d), and 48.0 (s); mass spectrum *m/e*: 278, 280, 282 ($M^+$).

*Spiro-bicyclo[2.2.1]heptane-7:1′-(2′-bromocyclopropane), **13***

From the dibromide **11** (0.98 g) as described for **6**, the monobromide **13** was obtained as a liquid (0.525 g, 75%), bp 50–55°C/0.1 Torr; $^1$H nmr ($CDCl_3$) δ: 0.8–2.0 (complex, 12H) and 3.02 (dd, 1H); $^{13}$C nmr ($CDCl_3$) δ: 15.8 (t), 22.9 (d), 28.6 (t), 28.7 (t), 28.8 (t), 29.9 (t), 39.7 (s), 41.2 (d), and 41.3 (d); mass spectrum *m/e*: 200, 202 ($M^+$).

*Spiro-bicyclo[2.2.1]heptane-7:1′-(cyclopropene), **14***

Prepared from mono-bromide **13** (0.56 g) as described for **1**, hydrocarbon **14** was obtained as an unstable oil which rapidly polymerized on warming (180 mg, 54%); $^1$H nmr ($CDCl_3$) δ: 0.75–1.9 (complex, 10H) and 7.43 (s, 2H); $^{13}$C nmr ($CDCl_3$) δ: 28.1, 37.3, 41.1, and 120.8; mass spectrum *m/e*: 120 ($M^+$).

*Spiro-bicyclo[2.2.1]heptane-7:1′-(cyclopropane), **15***

Prepared by hydrogenation of **10** or **14** as described for **9**, liquid (*4b*); $^1$H nmr ($CDCl_3$) δ: 0.40 (s, 4H) and 1.1–1.9 (complex, 10H); $^{13}$C nmr ($CDCl_3$) δ: 4.9 (t, $J$ = 161.0 Hz), 29.4 (t, $J$ = 135.8 Hz), 32.5 (s), and 41.4 (d, $J$ = 138.3 Hz); mass spectrum *m/e*: 122 ($M^+$).

*3-Ethenylidenetetracyclo[3.2.0.0$^{2,7}$,0$^{4,6}$]heptane, **2***

The dibromide **5** (0.46 g) was dissolved in dry ether (15 mL) and the reaction mixture stirred and cooled in an ice-bath under $N_2$ with moisture exclusion. An approximately 1 *N* solution of methyl lithium in ether (6 mL) was added via syringe over 5 min and the mixture kept stirring for 1 h before pouring into water (50 mL) and extraction with pentane (3 × 10 mL). After drying the combined organic extracts and careful evaporation of the solvents, the oily residue (0.16 g, 83%) was shown by gas chromatography to be one major product comprising 90% of the mixture. For characterization, a pure sample was obtained by preparative gas chromatography at 130°C. Compound **2**, colorless liquid, $^1$H nmr ($CDCl_3$) δ: 1.89 (s + m, 6H) and 4.94 (s, 2H); $^{13}$C nmr ($CDCl_3$) δ: 18.4 (d, $J$ = 187.6 Hz), 26.6 (d, $J$ = 168.7 Hz), 77.2 (t, $J$ = 167.2 Hz), 107.0 (s), and 200.5 (s); mass spectrum *m/e*: 116 ($M^+$).

*7-Ethenylidenebicyclo[2.2.1]hepta-2,5-diene, **4***

The dibromide **7** (0.23 g) was reacted with methyl lithium in ether as described for **2**. The hydrocarbon **4** was collected by vacuum transfer at 43–47°C and 0.05 Torr as a colorless oil (0.074 g, 76%); $^1$H nmr ($CDCl_3$) δ: 4.05 (p, $J$ = 2 Hz, 2H), 4.90 (s, 2H), and 6.90 (t, $J$ = 2 Hz, 4H); $^{13}$C nmr ($CDCl_3$) δ: 52.2, 82.4, 142.2 – dilute sample, two lines missing, no coupling constants taken; mass spectrum *m/e*: 116 ($M^+$).

The same allene **4** was also formed by passage of **2** in pentane over alumina as described for **3**.

*7-Ethenylidenebicyclo[2.2.1]heptane, **12***

The dibromide **11** (0.28 g) was reacted with methyl lithium in ether as described for **2**. The hydrocarbon **12** was collected by vacuum transfer at 50°C and 0.05 Torr as a colorless liquid (0.097 g, 81%); $^1$H nmr ($CDCl_3$) δ: 1.1–2.03 ($A_2B_2$ pattern, 8H), 2.66 (m, 2H), and 4.67 (s, 2H); $^{13}$C nmr ($CDCl_3$) δ: 29.7 (t),

40.6 (d), 75.1 (t), 107.4 (s), and 193.6 (s); mass spectrum *m/e*: 120 ($M^+$).

G. W. BRYAN REED, PETER T. W. CHENG, and STEWART MCLEAN. Can. J. Chem. **60**, 419 (1982).

The cyclohexanone **3** and the cyclohexenone **13** have been prepared, converted to their phenylhydrazones, and subjected to the Fischer indole synthesis under conditions ranging from 7% to 60% sulfuric acid in methanol. The tetrahydrocarbazoles **4** and **5** were isolated in a 2:1 ratio in the sequence starting from **3** and no significant variation in the ratio was observed through the range of conditions used. In the sequence starting with **13**, the dihydrocarbazoles **14** and **15** were isolated in a 1:1 ratio when 7% or 15% sulfuric acid was used; when more concentrated acid was used, normal Fischer products were not obtained but some transformation products were isolated from the complex mixture of products obtained. The observed regioselectivity of these reactions is not predicted from mechanistic considerations, and no mechanistic explanation for the results is apparent. As part of the proof of structure of **4** and **14**, their *N*-benzyl derivatives were prepared from 1-benzyl-2-vinylindole by Diels–Alder reactions.

G. W. BRYAN REED, PETER T. W. CHENG et STEWART MCLEAN. Can. J. Chem. **60**, 419 (1982).

On a préparé la cyclohexanone **3** et la cyclohexènone **13**, ainsi que leurs phénylhydrazones qui subissent la synthèse de l'indole de Fisher lorsque mises en solution dans de l'acide sulfurique à des concentrations de 7 à 60% dans le méthanol. On a recueilli les tétrahydrocarbazoles **4** et **5** dans un rapport 2:1 en partant du composé **3** et ce rapport reste invariable dans les conditions utilisées. Dans le cas du composé **13**, on pu isoler les tétrahydrocarbazoles **14** et **15** dans un rapport de 1:1 lorsqu'on utilise des solutions d'acide sulfurique à 7 ou 15%. En solutions plus concentrées, on n'obtient pas les produits normaux de Fisher, mais on a isolé quelques produits de transformation à partir d'un mélange complexe de produits obtenus. la régiosélectivité observée pour ces réactions n'est pas prévue à partir des mécanismes connus, et on n'a aucun mécanisme apparent qui permette d'expliquer ces résultats. On établit la structure des composés **4** et **14** en préparant leurs dérivés *N*-benzyle à partir du benzyl-1 vinyl-2 indole par des réactions de Diels–Alder.

[Traduit par le journal]

Tetrahydrocarbazoles carrying reactive substituents at assigned locations could serve as intermediates in syntheses of more complex structures, including a range of indole alkaloids. The classical Fischer indole synthesis (1) offers a convenient route to such tetrahydrocarbazoles, provided that the appropriate cyclohexanone is available as a precursor and that a reasonable degree of regioselectivity can be established when an unsymmetrically substituted cyclohexanone is taken through the Fischer sequence. The regioselectivity observed experimentally and the question of whether it can be controlled by varying the reaction conditions are matters of practical importance in such cases, and are the subject of the present study. It is also of interest to see whether mechanistic considerations can be used to predict and explain the results obtained.

We studied first the simple case using the cyclohexanone **3**, which was conveniently prepared (70% yield) by the Diels–Alder reaction of the trimethylsiloxybutadiene **1** (2) with *N*-methylmaleimide followed by methanolysis of the adduct **2** (see Scheme 1). The phenylhydrazone of **3** was isolated (90% yield) and subjected to the Fischer indole reaction under a range of acidic conditions (see Table 1). The crystalline adducts **4** and **5** were isolated in the yields shown in the table; the overall yields diminished as the concentration of acid used increased, but the **4**/**5** ratio remained close to 2:1 until yields were significantly lowered.

Although the structures assigned to **4** and **5** on the basis of their spectroscopic properties appeared secure, confirmation of the structure of **4** was obtained by the synthesis of a derivative by the unambiguous route outlined in Scheme 2. Indole-2-carboxylic acid (**6**) was converted by diazomethane to its methyl ester, which was *N*-benzylated to provide **7**. The ester was converted by the action of hydrazine in ethanol to the hydrazide, which was tosylated with tosyl chloride, and then subjected to a McFadyen–Stevens reduction. Yields at each step were excellent and the aldehyde **8** was obtained from **6** in 83% overall yield. The vinyl compound **9** was obtained in 85% yield from **8** by a Wittig reaction. A Diels–Alder reaction of **9** with *N*-methylmaleimide then led to the isolation of **10**, the *N*-benzyl derivative of **4**, in 52% yield. Unfortunately, the benzyl group of **10** resisted hydrogenolysis and attempts to *N*-benzylate **4** led to a complex mixture of products none of which was **10**. Nevertheless, comparison of the critical spectroscopic properties of **4** and **10** served to demonstrate that they possessed the same tetracyclic skeleton. Fur-

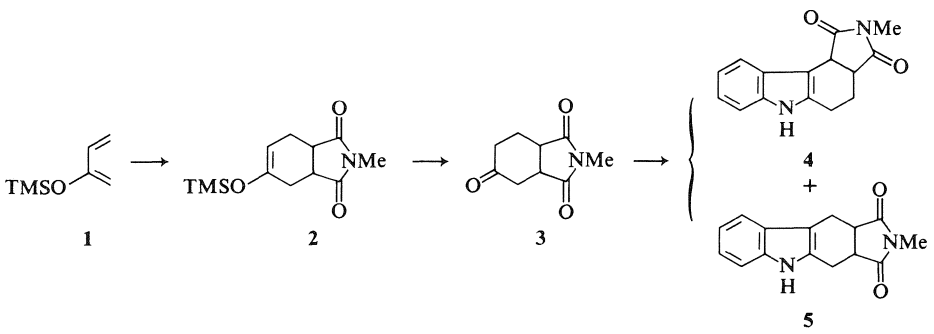

SCHEME 1

thermore, the major product isolated (albeit in only 35% yield) from the treatment of **4** with sodium hydride (1 equiv.) and benzyl chloride in HMPT was a dibenzyl compound. The probable structure of this compound is shown as **11**. Its uv spectrum strongly resembles that of **10** and both compounds show the same carbonyl ir absorptions, but there are key differences in their proton nmr spectra: a one-proton doublet at $\tau$ 5.69 in the spectrum of **10**, assigned to the C-4 proton, is absent in **11**, and a two-proton AB quartet centred at $\tau$ 6.35 appears instead and is assigned to the *C*-benzyl methylene protons; the *N*-benzyl methylene protons have the same chemical shift in both spectra, but those of **10** appear as a singlet, while in the spectrum of **11**, the signal is split. For present purposes, the main importance of this compound obtained from **4** is that it could also be obtained from **10** (in 25% yield) by benzylation, and so demonstrates that **4** and **10** have the same tetracyclic skeleton.

The Diels–Alder reaction of diene **1** with dimethyl acetylenedicarboxylate led to an oily product in 86% yield, the spectroscopic properties of which were consistent with the structure **12** expected for the adduct. Conversion of **12** to a ketone (Scheme 3) even under the mildest conditions (stirring with methanol at room temperature), led to the formation of the conjugated cyclohexenone **13** in excellent yield; this compound showed $\lambda_{max}$ 223 nm ($\varepsilon$ 10 500) in its uv spectrum, a one-proton doublet with $J = 1.5$ Hz at $\tau$ 3.20 in its proton nmr spectrum, and other features in its ir and nmr ($^1$H and $^{13}$C) spectra in accord with the assigned structure. Compound **13** was converted to its crystalline phenylhydrazone which was then subjected to the Fischer indole reaction under the range of acidic conditions used previously. In this series the yields of the Fischer products were lower even from reactions carried out in 7% or 15% sulfuric acid in methanol (see Table 1), and the use of more strongly acidic conditions led to the formation of very complex mixtures of products which afforded none of the normal Fischer products, the dihydrocarbazoles **14** and **15**. The carbazole **16**, presumably an oxidation product of **15**, was isolated from the mixture obtained from reactions in concentrated acids. (It was also detected in some runs even when the reaction was carried out in 15% sulfuric acid.) The corresponding oxidized derivative of **14**, the carbazole **17**, was not identified in the mixture, but a compound that appeared to be **18**, its reduction product, was isolated. (Reference samples of **16** and **17** were prepared by treatment of the corresponding dihydrocarbazole with dichlorodicyanoquinone.) A considerable amount of polymeric material was also evident, and consequently it was deemed unwise to attempt to quantify the regioselectivity of the Fischer reaction under these

TABLE 1. Product distributions in Fischer reactions

| Conditions | Products* from Phenylhydrazone of **3** | | Products* from Phenylhydrazone of **13** | |
|---|---|---|---|---|
| | **4** | **5** | **14** | **15** |

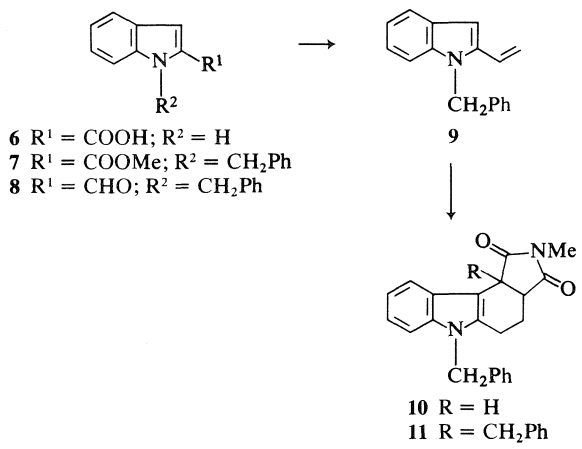

SCHEME 2

circumstances; undoubtedly the reaction of interest is accompanied by undesired competitive and consecutive reactions and even if all of the products from the complex mixture formed could be isolated in the hope of throwing light on any regioselectivity in the Fischer reaction, the procedure under these conditions is of no preparative value. We may note, however, that in the more restricted range of 7% to 15% sulfuric acid, there was no apparent regioselectivity and the **14**/**15** ratio remained 1:1.

As with the previous series, the *N*-benzyl derivative **19** of the diester **14** was prepared by the Diels–Alder reaction of the vinylindole **9** with dimethyl acetylenedicarboxylate. In this case, however, the yield of adduct was only 25%; a complex mixture of by-products was also obtained, some of which appeared to result from oxidation–reduction reactions involving **19** that took place under the Diels–Alder conditions (in the presence of hydroquinone) since the carbazole **20** was isolated from the mixture. Confirmation of the structure assigned to Fischer product **14** was obtained by its *N*-benzylation; in this case monobenzylation could be effected and **19** was isolated in 30% yield. Once again, there was evidence that some of the product had undergone aromatization during the reaction, providing at least a partial explanation for the poor yield.

The mechanism of the Fischer indole synthesis has been the subject of several investigations (1). It is generally agreed that a complex series of events occurs, in which the phenylhydrazone is converted to its enehydrazine tautomer which undergoes a reaction corresponding to a [3,3] sigmatropic rearrangement to form the new C—C bond and cleave the N—N bond; subsequently the indole ring is formed with the elimination of one nitrogen. Normally the reaction is acid-catalyzed, but neither its kinetic dependence on the acid catalyst nor the identity of the rate-determining step has been established unequivocally. In most proposed mechanisms it is a protonated enehydrazine that undergoes rearrangement, and it is the rearrangement step that is probably rate-determining.

The phenylhydrazone of an unsymmetrically substituted cyclohexanone can clearly form two enehydrazine tautomers (e.g. **21** and **22**) and the regioselectivity of the overall Fischer reaction will depend on which of these preferentially undergoes the rearrangement process (Scheme 4). It appeared, *a priori*, that any electronic effects of the substituents ($R^1$, $R^2$) in this case should have a negligible influence on the **21**/**22** ratio; steric effects, if of any significance, would appear to disfavor bond development in the rearrangement of **21**, and consequently favor reaction through **22**. In the case of a cyclohexenone derivative, however, the electronic effects of substituents may be expected to be significant in determining the ratio of enehydrazines (e.g. **23** and **24**) formed; it can also

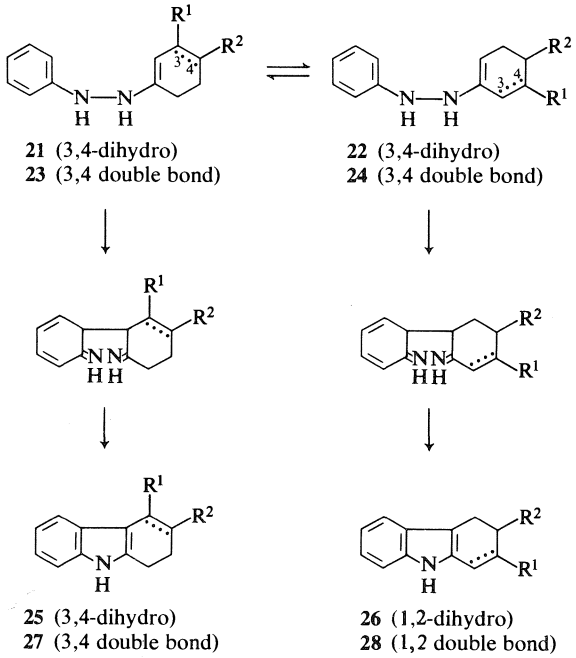
be seen, however, that the ratio under kinetic control may differ from that under thermodynamic control, and that each isomer may undergo the rearrangement at a different rate. In any event, these factors seem likely to lead to some degree of regioselectivity, and this would probably be sensitive to reaction conditions.

In practice, the distribution of isomers isolated from the Fischer reaction of our cyclohexanone **3** was not approximately 1:1 as predicted, but 2:1 in favor of the route through **21**, and the ratio was not sensitive to the conditions of the reaction. There is a report (3) that only products corresponding to **25** were isolated from the Fischer reaction of a series of compounds corresponding to our **3** but with other substituents on the nitrogen atom; the reaction through **21** again seemed to be favored. However, in another case that appears to be similar, two groups of workers (4) have obtained the opposite regioselectivity; in this case the starting material was cyclohexanone-3-carboxylic acid and only **26** ($R^1$ = COOH; $R^2$ = H) was isolated, indicating that the route through **22** was strongly preferred. It seems clear from these results that the reaction is influenced by effects more subtle than those we have already considered.

In the sequence starting from the cyclohexenone **13**, no regioselectivity was observed when the Fischer reaction was carried out in solutions containing 7% or 15% sulfuric acid, and a 1:1 ratio of isomers was obtained. When more concentrated sulfuric acid was used, no regioselectivity was observable because normal Fischer products were not isolated. Undoubtedly the dihydrocarbazoles are subject to further transformations in the strongly acidic media and they probably undergo some degradation even when the conditions are less acidic. If the two products underwent degradation at different rates, the 1:1 ratio observed for the isolated products could reflect the selective destruction of the major isomer. However, the absence of any significant change in yield or product ratio when the conditions were varied from 7% to 15% sulfuric acid provides some evidence against this possibility, although it does not exclude it. The results in this series must consequently be treated with circumspection but, with the reservations stated, they indicate that reactions through **23** and **24** are equally favored.



SCHEME 4

In summary then, some regioselectivity (2:1) was observed in the Fischer reaction starting with cyclohexanone **3**, but none was observed in the case of cyclohexenone **13**. These results are not those expected from mechanistic considerations, and we can present no mechanistic explanation for them.

## Experimental

Melting points were determined on a calibrated Thomas–Kofler micro hot stage. A Perkin–Elmer 237B infrared spectrometer was used; the wavelengths (μ) of selected ir absorptions of solutions in chloroform are reported. A Unicam SP 1800 ultraviolet spectrometer was used. The $\lambda_{max}$ values (nm) followed by the extinction coefficients (ε) in parentheses of principal uv absorptions of solutions in methanol are reported. Varian T-60, HA 100, XL 100, and HR 220 nmr spectrometers were used. Unless otherwise indicated, the $^1$Hmr spectra reported were obtained at 100 MHz with solutions in $CDCl_3$; chemical shifts are reported on the τ scale, followed in parentheses by an indication of the multiplicity (initial letter) of the signal, the coupling constant (in Hz units) when available, and the number of protons associated with the signal. Unless otherwise indicated, $^{13}$Cmr spectra were obtained with solutions in $CDCl_3$ and chemical shifts are reported on the $\delta_C$ scale (ppm relative to TMS = 0) followed in parentheses by an indication of the multiplicity of the signal. An AEI MS-902 mass spectrometer was used to make accurate mass measurements.

*The cyclohexanone 3*

A solution of 2-trimethylsiloxy-1,3-butadiene (2) (2.00 g; 0.014 mol) and *N*-methylmaleimide (1.56 g; 14.0 mmol) in 10 mL of dry benzene was heated at 65°C for 24 h. Benzene was removed on a rotary evaporator and adduct **2** (2.99 g) was obtained as an oily residue. The residue was dissolved in 20 mL of methanol and stirred at room temperature for 48 h. Evaporation on a rotary evaporator provided the oily ketone **3** (1.92 g; 11.0 mmol) which was purified by vacuum distillation; ir: 5.66, 5.75, 5.85; $^1$Hmr (220 MHz): 6.62–6.87 (m, 2), 6.98 (s, 3), 7.26 (d, $J$ = 6; 2), 7.56–7.94 (m, 4); $^{13}$Cmr: 207.63 (s), 178.34(s), 177.98(s), 37.96(d), 37.11(d), 36.89(t), 36.14(t), 24.66(q), 21.49(t);

*Fischer indole syntheses*

*Standard procedure*

The phenylhydrazone (1.0 g) was dissolved in 5 g of methanolic sulfuric acid of the required composition (w./w.), and the solution was heated in an oil bath at 80°C for 6 h. The solution was cooled and poured into about 100 mL of water, neutralized with sodium carbonate, and extracted thoroughly with dichloromethane. The combined extracts were washed with water and brine, dried, and evaporated. The residue was chromatographed on silica gel with elution by 1:1 ethyl acetate – hexane, and the separated products were isolated.

*Cyclohexanone* ***3*** *series*

The results obtained by the standard procedure are reported in Table 1. For preparative purposes, the procedure using 15% methanolic sulfuric acid was scaled up. Compound **4** was eluted first, followed by compound **5**, and no other identifiable material was obtained.

Tetrahydrocarbazole **4** was recrystallized from benzene–cyclohexane and obtained as crystals, mp 180–183°C; ir: 2.88, 5.61, 5.88; uv: 223 (30 000), 273 (6040), 278 (6100), 282 (6040), 289 (5150); $^1$Hmr: 2.05 (complex, 2, $D_2O$ reduces to 1), 2.66–2.94 (m, 3), 5.73 (d, $J$ = 8; 1), 6.66 (m, 1), 7.10 (s, 3), 7.26–7.58 (m, 3), 8.05 (m, 1); $^{13}$Cmr: 179.07(s), 177.35(s), 135.56(s), 134.30(s), 126.76(s), 122.03(d), 120.18(d), 119.69(d), 110.59(d), 103.61(s), 40.18(d), 39.58(d), 24.74(q), 21.32(t), 19.79(t). *Anal.* calcd. for $C_{15}H_{14}N_2O_2$: C 70.85, H 5.55, N 11.02; found: C 70.98, H 5.66, N 11.06.

Tetrahydrocarbazole **5** was recrystallized from benzene–methanol and obtained as crystals, mp 219–223°C; ir: 2.89, 5.63, 5.89; uv: 224 (28 000), 274 (6450), 282 (6740), 290 (5500); $^1$Hmr: 1.78 (broad s, 1, $D_2O$ removes), 2.45–3.05 (m, 4), 6.50–6.65 (m, 4), 6.85–7.05 (m, 2), 7.15 (s, 3); $^{13}$Cmr: ($CDCl_3$/DMSO-$d_6$): 181.04(s), 180.80(s), 136.55(s), 133.54(s), 127.51(s), 121.46(d), 119.61(d), 118.16(d), 112.07(d), 107.15(s), 25.81(q), 22.91(t), 21.33(t). *Anal.* calcd. for $C_{15}H_{14}N_2O_2$: C 70.85, H 5.55, N 11.02; found: C 70.75, H 5.71, N 11.13.

*Cyclohexenone* ***13*** *series*

The results obtained by the standard procedure with 7% and 15% methanolic sulfuric acid are reported in Table 1. The reactions in 30%, 45%, and 60% methanolic sulfuric acid produced complex mixtures which were not successfully separated by the standard chromatographic procedure. The material obtained from the 60% sulfuric acid was subsequently subjected to preparative tlc on alumina with elution by 95:5 benzene–methanol; the carbazole **16** (20%) and a trace of material considered to be the tetrahydrocarbazole **18** were isolated in this way. For preparative purposes the procedure using 15% methanolic sulfuric acid was scaled up. Compound **15** was eluted first followed by compound **14**; very small amounts of **16** and **18** were also obtained by a combination of chromatographic and fractional crystallization procedures.

Dihydrocarbazole **14** was recrystallized from benzene and obtained as crystals, mp 223–225°C; ir: 2.88, 5.78, 5.89; uv: 233 (20 750), 272 (8950), 278 (8700), 305 (3550), 369 (12 050); $^1$Hmr (220 MHz): 1.38 (br s, 1), 2.50–2.94 (m, 4), 5.97 (s, 3), 6.21 (s, 3), 7.17 (narrow m, 4; in $C_6D_6$ soln. becomes 7.41 (t, 2), 7.95 (t, 2), $J$ = 8). *Anal.* calcd. for $C_{16}H_{15}NO_4$: C 67.36, H 5.30, N 4.91; found: C 67.49, H 5.31, N 4.81.

Dicarbazole **15** was recrystallized from benzene–cyclohexane and obtained as crystals, mp 192–193°C; ir: 2.79, 5.79, 5.90; uv: 214 (end absorption; 15 350), 258 (10 200), 374 (13 600); $^1$Hmr (220 MHz): 2.33 (br s, 1), 2.44 (s, 1), 2.48–2.95 (complex, 4), 5.97 (dd, $J$ = 9, 2.5; 1), 6.29 (s, 3), 6.36 (s, 3), 6.38 (dd, $J$ = 17, 2.5; 1), 6.88 (dd, $J$ = 17, 9; 1). *Anal.* calcd. for $C_{16}H_{15}NO_4$: C 67.36, H 5.30, N 4.91; found: C 67.03, H 5.51, N 5.17.

Carbazole **16** was recrystallized from benzene and obtained as crystals, mp 136–137°C; ir: 2.89, 5.83; uv: 220 (end absorption; 20 000), 236 (23 600), 245 (25 000), 270 (45 500), 297 (12 800), 305 (11 500), 341 (3750); $^1$Hmr (60 MHz): 0.99 (br s, 1), 1.52–2.96 (complex, 6), 6.06 (s, 3), 6.10 (s, 3). *Anal.* calcd. for $C_{16}H_{13}NO_4$: C 67.84, H 4.63, N 4.95; found: C 67.88, H 4.69, N 5.04. Compound **16** was also prepared by stirring a solution of the dihydrocarbazole **15** (150 mg; 0.53 mmol) and dichlorodicyanoquinone (125 mg; 0.55 mmol) in 10 mL of dioxane at 80°C for 1 h. Filtration and evaporation afforded a residue which was chromatographed on alumina with elution by benzene to provide **16** (110 mg; 0.39 mmol). The same method was used to convert dihydrocarbazole **14** to carbazole **17**, mp 224–225°C; ir: 2.89, 5.80, 5.85; uv: 226 (end absorption; 27 200), 243 (19 200), 264 (25 400), 279 (44 000), 314 (5250), 323 (4800); $^1$Hmr (60 MHz): 2.40–2.80 (complex, 6), 5.83 (s, 3), 6.05 (s, 3). *Anal.* calcd. for $C_{16}H_{13}NO_4$: C 67.84, H 4.63, N 4.95; found: C 67.89, H 4.57, N 4.96.

Compound **18** was recrystallized from benzene in cyclohexane and obtained as crystals, mp 139–142°C; ir: 2.89, 5.79; uv: 225 (13 000), 274 (3050), 278 (3050), 282 (3050), 290 (2400); $^1$Hmr (60 MHz): 2.05 (broad s, 1), 2.44 (m, 1), 2.74–3.06 (complex, 3), 5.70 (d, $J$ = 6; 1), 6.26 (s, 3), 6.33 (s, 3), 6.68 (m, 1), 7.13–8.10 (complex, 4); *Exact Mass* calcd. for $C_{16}H_{17}NO_4$: 287.1157; found: 287.1157.

*Methyl 1-benzylindole-2-carboxylate (****7****)*

A solution of methyl indole-2-carboxylate (12.0 g; 68.6 mmol) in 60 mL of dry hexamethylphosphoric triamide (HMPT) was added over 2 h to a stirred slurry of sodium hydride (83 mmol) in 40 mL of HMPT maintained at 0°C. The reaction mixture was stirred at 0°C for a further hour and then allowed to warm to room temperature. Benzyl chloride (9.1 g; 72 mmol) was added over 0.5 h and the reaction mixture was stirred for a further 2 h. The mixture was poured into 700 mL of water containing 20 mL of concentrated hydrochloric acid and extracted with ether. The ether extract afforded **7** (16.4 g; 61.7 mmol), which was recrystallized from cyclohexane–acetone and obtained as crystals, mp 84–86°C; ir: 5.86; uv: 230 (end absorption, 20 000), 248 (4500), 293 (20 500); $^1$Hmr: 2.31 (dd, $J$ = 6.5, 1.5; 1), 2.61–3.05 (complex, 9), 4.18 (s, 2), 6.17 (s, 3). *Anal.* calcd. for $C_{17}H_{15}NO_2$: C 76.96, H 5.70, N 5.28; found: C 76.94, H 5.79, N 5.22.

*1-Benzylindole-2-carboxaldehyde (****8****)*

A solution of ester **7** (8.2 g; 30.9 mmol) and hydrazine hydrate (15 mL; 0.309 mol) in 25 mL of absolute ethanol was refluxed for 3 h and then allowed to stand. Crystals separated and were collected; the mother liquor afforded a further crop of crystals on evaporation (total yield 95%). Recrystallization from metha-

nol provided a sample, mp 186–189°C; ir: 2.90, 3.00, 6.00, 6.15; uv: 214 (end absorption; 28 800), 292 (16 100); $^1$Hmr: 2.33 (dd, $J$ = 7, 2; 1), 2.47 (broad m, 1), 2.64–3.10 (complex, 9), 4.22 (s, 2), 6.43 (broad m, 2). *Anal.* calcd. for $C_{16}H_{15}N_3O$: C 72.43, H 5.70, N 15.84; found: C 72.62, H 5.72, N 15.88.

Tosyl chloride (5.7 g; 30.0 mmol) was added to a stirred solution of the hydrazide (7.8 g; 29.4 mmol) in 90 mL of pyridine at 0°C; after 0.5 h at 0°C, the cooling bath was removed, and the stirring was continued for 2 h. The reaction mixture was poured into a mixture of ice and concentrated hydrochloric acid and the product was obtained as a solid which was collected by filtration and washed with dilute hydrochloric acid and water. The partially dry material was dissolved in methylene chloride and dried (magnesium sulfate). The methylene chloride afforded the crystalline tosylhydrazide (97% yield); recrystallization from ethanol provided a sample, mp 231–230°C; ir: 2.99, 5.98, 6.04; uv: 218 (end absorption; 30 200), 294 (17 700); $^1$Hmr: 0.55 (d, $J$ = 4; 1), 1.24 (m, 1), 2.13–3.22 (complex, 14), 4.46 (s, 2), 7.69 (s, 3); *Exact Mass* calcd. for $C_{23}H_{21}N_3SO_3$: 419.1304; found: 419.1304.

The tosylhydrazide (3.0 g; 7.1 mmol) was dissolved in a minimum (about 300 mL) of ethylene glycol at 150°C in a wide-mouthed vessel, and potassium carbonate (2.1 g; 15 mmol) was added in one lot. As soon as the vigorous effervescence ceased (about 1 min), the solution was poured into a large volume of ice. Ether extraction afforded the aldehyde **8** (1.6 g; 6.8 mmol); recrystallization from methanol provided a sample, mp 68–70°C; ir: 3.54, 5.99, 6.04, 6.19; uv: 210 (end absorption; 18 900), 231 (12 100), 307 (18 400); $^1$Hmr: 0.19 (s, 1), 2.33 (dd, $J$ = 8, 1; 1), 2.65–3.00 (complex, 9), 4.27 (s, 2). *Anal.* calcd. for $C_{16}H_{13}NO$: C 81.68, H 5.57, N 5.95; found: C 81.77, H 5.69, N 6.01.

*1-Benzyl-2-vinylindole (9)*

Methyltriphenylphosphonium bromide (3.4 g; 9.5 mmol) and butyllithium (9.5 mmol) in 50 mL of dry ether were stirred at reflux under a nitrogen atmosphere for 1.5 h, and then cooled to 0°C. An ether solution of aldehyde **8** (2.12 g; 9.0 mmol) was added and the mixture was refluxed for 1.5 h. The mixture was cooled and then treated with a solution of sodium sulfate (6.8 g) in 100 mL of water. The organic layer was washed with water, dried, and evaporated. The residue obtained was repeatedly triturated with petroleum ether (30–60°C); the petroleum ether solution was filtered and evaporated to provide the product as a yellow oil (1.78 g; 7.7 mmol): ir: 6.22; uv: 225 (16 000), 242 (10 900), 306 (12 900), 345 (1350); $^1$Hmr: 2.24–3.29 (complex, 10), 3.39 (dd, $J$ = 17.5, 11; 1), 4.31 (dd, $J$ = 17.5, 1.5; 1), 4.80 (s, 2), 4.85 (dd, $J$ = 11, 1.5; 1); *Exact Mass* calcd. for $C_{17}H_{15}N$: 233.1204; found: 233.1204.

*Diels–Alder adduct **10***

A solution of the vinylindole **9** (1.60 g; 6.9 mmol) and *N*-methylmaleimide (0.76 g; 6.9 mmol) in 35 mL of benzene was heated at 70°C for 21 h. Concentration of the solution and addition of cyclohexane caused the product **10** to separate as crystals; several crops were collected (total yield 52%). Recrystallization from benzene–cyclohexane provided a sample, mp 186–188°C; ir: 5.64, 5.86; uv: 224 (21 600), 276 (4100), 283 (4400), 292 (4000); $^1$Hmr: 1.97 (dd, $J$ = 6, 2; 1), 2.60–3.10 (complex, 8), 4.80 (s, 2), 5.69 (d, $J$ = 8; 1), 6.72 (m, 1), 7.10 (s, 3), 7.3–8.0 (complex, 4). *Anal.* calcd. for $C_{22}H_{20}N_2O_2$: C 76.72, H 5.85, N 8.13; found: C 76.77, H 6.04, N 8.06.

*Diels–Alder adduct **19***

A solution of the vinylindole **9** (2.0 g; 8.6 mmol), dimethyl acetylenedicarboxylate (1.2 g; 8.5 mmol), and hydroquinone (50 mg) in 50 mL of benzene was heated at 60°C for 1 h and at 40°C for 20 h. Evaporation of the solvent left a red oily residue; chromatography on an alumina column gave a fraction (1.0 g) that contained adduct **19** and some oxidized material **20**. This mixture of products (about 9:1) was separated by preparative tlc on alumina. Recrystallization of **19** from benzene–cyclohexane gave a sample, mp 151–153°C; ir: 5.75, 5.88; uv: 219 (end absorption; 19 000), 234 (24 900), 274 (11 600), 306 (5600), 369 (16 100); $^1$Hmr: 2.44–3.14 (complex, 9), 4.74 (s, 2), 5.95 (s, 3), 6.22 (s, 3), 7.16 (s, 4; in benzene forms symmetrical complex multiplet centred ~τ 7.5). *Anal.* calcd. for $C_{23}H_{21}NO_4$: C 73.58, H 5.64, N 3.73; found: C 73.74, H 5.76, N 3.76.

The carbazole **20** was also prepared by heating a solution of adduct **19** (250 mg; 0.67 mmol) and dichlorodicyanoquinone (160 mg; 0.70 mmol) in 5 mL of dioxane to 90°C for 25 min. Evaporation, chromatography on alumina, and recrystallization from benzene–cyclohexane provided **20**, mp 164–165°C; ir: 5.80, 5.85; uv: 216 (end absorption; 17 200), 231 (21 600), 247 (17 200), 266 (19 000), 281 (34 000), 316 (3750), 330 (3000), 342 (1500); $^1$Hmr: 1.94–2.10 (complex, 2), 2.57–3.16 (complex, 9), 4.64 (s, 2), 5.85 (s, 3), 6.10 (s, 3). *Anal.* calcd. for $C_{23}H_{19}NO_4$: C 73.98, H 5.13, N 3.75; found: C 74.11, H 4.96, N 3.85.

*Benzylation of **4***

A solution of compound **4** (100 mg; 0.39 mmol) in 5 mL of dry HMPT was added to a stirred slurry of sodium hydride (0.56 mmol) in 3 mL of HMPT maintained at 0°C. After 10 min the mixture was allowed to warm to room temperature, benzyl chloride (55 mg; 0.44 mmol) was added, and stirring was continued for 3 h. The reaction mixture was poured into water and extracted with methylene chloride. The extract afforded the product (**11**) as a white solid (42 mg; 0.10 mmol); recrystallization from benzene provided a sample, mp 264–265°C; ir: 5.63, 5.88; uv: 225 (end absorption; 25 800), 286 (5700), 293 (5750); $^1$Hmr: 1.33 (m, 1), 2.60–3.20 (m, 13), 4.81 (two peaks, 3 Hz separation; 2), 6.19 (d, $J$ = 14; 1), 6.50 (d, $J$ = 14; 1), 6.92 (m, 1), 7.15 (s, 3), 7.48–7.82 (complex, 4).

Compound **11** (31 mg; 0.07 mmol) was also prepared by treating compound **10** (101 mg; 0.29 mmol) with sodium hydride (0.31 mmol) in 5 mL of HMPT and benzyl chloride (45 mg; 0.35 mmol) in the manner just described.

*Benzylation of **14***

Compound **14** (60 mg; 0.20 mmol) was treated with sodium hydride (0.25 mmol) and benzyl chloride (30 mg; 0.26 mmol) in the manner described above, and converted to the compound **19** (20 mg; 0.70 mmol) described previously.

The possible application in synthesis of a micellar solution as a medium in the photocycloaddition of enones to alkenes has been examined. It is found that the micelles are useful in increasing the effective concentration of reactants, have some ability in directing reaction regiochemistry, and may reduce hydrogen atom transfer in intermediate biradicals.

NADER BERENJIAN, PAUL DE MAYO, MARY-ELLEN STURGEON, LEIV K. SYDNES et ALAN C. WEEDON. Can. J. Chem. **60**, 425 (1982).

On a étudié la possibilité d'utiliser en synthèse une solution micellaire comme milieu réactionnel lors de l'addition photochimique des énones sur les alcènes. On a trouvé que les micelles servent à augementer la concentration effective des réactifs, qu'elles sont capables de diriger la régiochimie de la réaction et qu'elles peuvent réduire le transfert d'atome d'hydrogène dans les biradicaux intermédiaires.

## Introduction

Photochemical cycloaddition between an alkene and an α,β-unsaturated ketone has proved to be a useful tool in synthesis (1–5). The process has been extensively employed for the preparation of cyclobutanes per se (2, 3, 5–8) and the method has also proved to be valuable for the generation of reactive four-membered rings that can undergo subsequent transformations (5, 9). However, the reaction suffers from the disadvantage that a large excess of alkene must be used to avoid enone dimerization and also, since it is bimolecular, reasonably high concentrations of both components are required. The latter can present a technical problem if a small scale reaction is performed,[2] whilst the former represents a source of inefficiency if the alkene used is accessible only with difficulty.

Another problem in the synthetic application of enone photocycloaddition is control of regiochemistry in the reaction between an α,β-unsaturated ketone and a nonsymmetrically substituted olefin. It has been known for some time that the regioselectivity is influenced by the substitution pattern of enone and alkene (8) as well as by the interactions of the overall dipoles of the reacting molecules (7, 10). Since the latter effect is strongly affected by the dielectric constant of the reaction medium, it has been possible, in some cases, to control the regioselectivity to some extent by solvent variation (7, 10). It has recently been demonstrated that photochemical cycloaddition between an enone and an alkene as well as enone photodimerization can occur between species solubilized in aqueous micelle solutions (11, 12). For example, photodimerization of 3-*n*-butylcyclopent-2-en-1-one, **1**, proceeds readily in aqueous potassium dodecanoate micelles (12). Furthermore, the regiochemistry of the addition is reversed as compared with the reaction in homogeneous solution. Thus, in the micellar environment the head-to-head dimer **3** is formed almost exclusively, whilst in benzene the head-to-tail dimer **2** is the major product.

TABLE 1. Relative yields[a] of photoadducts **4** and **3** as a function of enone and alkene concentration in potassium dodecanoate micelles.

| Average number of enone molecules per micelles | Average number of alkene molecules per micelle | Alkene | Yield of adduct **4** × 100 / combined yield of **4** + **3** |
|---|---|---|---|
| 0.55 | 0.54 | Cyclohexene | 74 |
| 0.55 | 0.82 | Cyclohexene | 82 |
| 0.55 | 1.09 | Cyclohexene | 88 |
| 0.55 | 2.18 | Cyclohexene | 94 |
| 0.51 | 0.50 | 1,2-Dimethyl cyclohexene | 48 |
| 0.51 | 1.00 | 1,2-Dimethyl cyclohexene | 68 |
| 0.51 | 2.00 | 1,2-Dimethyl cyclohexene | 88 |
| 0.51 | 4.00 | 1,2-Dimethyl cyclohexene | 93 |

[a]All irradiations taken to ca. 30% conversion. Absolute yields of adduct and dimer were determined by glc using *n*-docasane as an internal standard.

We describe here the results of our work[3] concerning the mixed photochemical cycloaddition of α,β-unsaturated ketones with alkenes in aqueous micellar solutions, which show that the micellar environment has potential utility as a medium for overcoming the problems described above.

## Results and discussion

### *Photochemical cycloaddition of 3-*n*-butylcyclopent-2-en-1-one, **1**, to cyclohexene and 1,2-dimethylcyclohexene in micelles; examination of the effect of reactant stoichiometry upon product distribution*

Irradiation of a cyclopentenone in the presence of cyclohexene results in the formation of cyclobutane ring-containing adducts, e.g., **4** (1–3). If the concentration of alkene is low, cyclopentenone dimers (e.g., *syn* and *anti* isomers of **2** and **3**) are also formed; in the absence of alkene, dimers are formed exclusively. It was of interest to us to determine if the reaction could be performed in a micellar environment and to determine the minimum alkene concentration required to prevent appreciable enone dimer formation. Solutions of cyclohexene and 3-*n*-butylcyclopentenone, **1**, in aqueous potassium dodecanoate (0.08 *M*) were irradiated to approximately the same conversion to give the "head-to-head" enone photodimer **3** (12) and the photoadducts **4**. The yields of the products were determined as a function of the mean concentrations of the reactants in the micelles. The study was repeated using 1,2-dimethylcyclohexene and the results are given in Table 1 and expressed graphically in Fig. 1. The mean concentrations of reactants in the micelles were calculated assuming a critical micelle concentration (CMC) for surfactant of 0.024 *M* (13) and an aggregation number of 47 (14). The concentration of micelles is then given by eq. [1]:

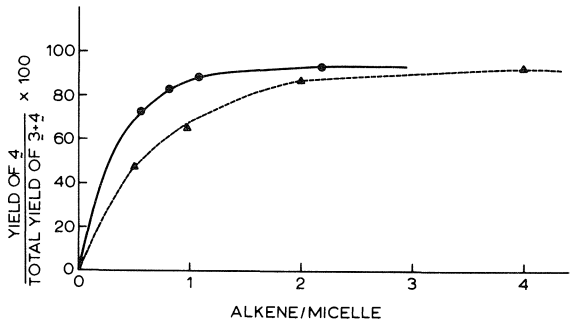

FIG. 1. Relative yield of photoadduct against average number of alkene molecules in each micelle for an average of half an enone/micelle. —●—●—● reaction with cyclohexene; --●-----●--- reaction with dimethylcyclohexene.

$$[1]\quad \text{micelle concentration} = \frac{M - \text{CMC}}{47}$$

Avogadro's number of micelles/L

where *M* is the concentration of potassium dodecanoate. If it is assumed that all alkene and cyclopentenone are dissolved within the micelles and essentially none remains in the aqueous exterior (12), then an average number of molecules of each reactant in each micelle can be calculated. The probability of finding a given number of molecules in each micelle can be determined assuming a Poisson distribution (15). 3-*n*-Butylcyclopentenone

[3]For a preliminary account of part of this work see ref. 12*c*.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

was used in order to ensure that most of the enone would be dissolved in the micelles rather than in the aqueous phase.

The results shown in Table 1 and Fig. 1 indicate that the cycloaddition, to give mixed adducts **4** or dimers, proceeds selectively with respect to mixed adduct formation if the cyclohexene enone ratio is 2:1 or greater, whilst the more hindered 1,2-dimethylcyclohexene requires a ratio of 4:1 for the same selectivity. It was also found that increasing enone and alkene concentration together (i.e., from 1/2 enone/micelle and 1/2 alkene/micelle to 2 enone and 2 alkene/micelle) did not greatly alter the observed photodimer/adduct ratio. These results suggest that micelles are not serving to isolate enone molecules from one another but rather are concentrating the enone and alkene molecules so that their effective concentrations are high even though the bulk concentrations are low. Also, since potassium dodecanoate concentration can be raised as high as 0.5 *M* without drastically altering the aggregation number of the micelle (16), in principle it is possible to handle anywhere from submilligram to gram quantities of reactants.

*Irradiation of 3-*n*-butylcyclopentenone, **1**, in micelles in the presence of nonsymmetrical alkenes; examination of product regiochemistry*

Recently it was demonstrated that the photochemical dimerization of 3-*n*-butylcyclopentenone can be performed in micelles as well as in organic solvents and that the micellar medium greatly affected the regiochemistry of the products. Thus, whereas in nonpolar solvents mainly the head-to-tail dimer **2** was observed and in polar solvents a mixture of head-to-tail and head-to-head dimers **3** and **2** in roughly equal amounts, in micellar potassium dodecanoate the head-to-head dimer **3** was formed almost exclusively (12). The alteration of the reaction regiochemistry is greater than can be reasonably ascribed to change in dielectric constant of the medium (which appears to be the controlling factor in solution (7)) and is possibly owing to some orienting effect of the micelle in which a solubilized molecule containing hydrophilic and hydrophobic components will align itself with the surfactant molecules to maximize hydrophilic and hydrophobic interactions.

Described here are the results of an examination of the stereochemistry of products obtained by mixed photochemical cycloaddition of 3-*n*-butylcyclopentenone and nonsymmetrical olefins in potassium dodecanoate micelles.

*Reactions with simple alkenes*

Photocycloaddition of 3-*n*-butylcyclopentenone in the presence of an excess of 1-hexene and 1-octene in organic solvents proceeded smoothly to afford mixtures of the corresponding adducts **5** and **6**. Regioisomers **5**, resulting from head-to-head[4] attack of the enone to the olefin, could in both cases be unequivocally distinguished from isomers **6**, derived from head-to-tail attack, by comparing the $^{13}C$ nmr spectra of pure samples of the regioisomers obtained by preparative vapour phase chromatography. Thus, in structure **5**, C-5 experiences an α-shielding effect whilst in **6** C-5 experiences a β-deshielding effect from the *n*-butyl substituent at C-7 (17). Similarly C-1 in structure **6** experiences an α-shielding effect and in **5** a β-deshielding effect from the butyl group. Consequently in the head-to-head regioisomer **5** the resonances assigned to C-1 and C-5 should be shifted to lower and higher fields respectively, whilst in the head-to-tail regioisomer **6** the resonances assigned to C-1 and C-5 should be shifted to higher and lower fields respectively. Applying these predictions to the data compiled in Table 2 for the cycloadducts obtained with 1-hexene and 1-octene in organic solvents, it is clear that the major isomer in both cases is formed by head-to-head attack to give **5**. It is also noteworthy that **5** in both cases consists almost exclusively of a single isomer, the stereochemistry of which is unknown, whilst in **6** both possible isomers, epimeric at C-7, are observed.

The photocycloaddition of 3-*n*-butylcyclopentenone to 1-hexene and 1-octene gave the corresponding adducts in near quantitative yield in a variety of solvents, but in both cases the regioisomeric composition of the product mixture was solvent dependent. Thus, with 1-hexene the ratio of **5***a*/**6***a* changed from 51:49 in cyclohexane to 57:43 in diethyl ether. When the reaction was performed in micellar potassium dodecanoate a ratio of 78:22 was obtained. A more pronounced variation was observed with 1-octene; the ratio of **5***b*/**6***b* changed from 53:47 in cyclohexane to 63:38 in acetonitrile (Table 3). When the reaction was performed in micellar potassium dodecanoate a ratio of 88:12 was obtained.

It has been reported (7, 10) that dipole–dipole interactions between reactants in photochemical cycloadditions can control the reaction regiochemistry. These interactions are sensitive to variations in solvent polarity and have been related to the dielectric constant of the medium by the Kirkwood–Onsager equation (18). In Fig. 2, the logarithm of the ratio of cycloadducts, **5***b*/**6***b*, is plotted against

[4]In this context, the more hydrophobic end of the molecule is termed the tail.

TABLE 2. $^{13}C$ nmr chemical shifts of selected carbon atoms in photoadducts **5** and **6** produced from cycloaddition of 1-hexene and 1-octene to 3-*n*-butylcyclopentenone **1** in organic solvents

|---|---|---|
| Cyclohexane | 2.02 | 53:47 |
| Diethylether | 4.34 | 47:43 |
| Ethyl acetate | 6.02 | 59:41 |
| Methanol | 32.63 | 62:38 |
| Acetonitrite | 37.50 | 63:37 |
| 0.08 *M* Aqueous potassium dodecanoate | — | 88:12 |

[a]Dielectric constant at 20°C.
[b]Determined by glc; expressed as a ratio of noncalibrated areas of peaks assigned to each regioisomer.

the Kirkwood–Onsager function; a linear relationship appears to hold for the organic solvents used and the maximum value of the dielectric term (0.5) predicts a value of 64:36 for the maximum ratio of **5***b* to **6***b*. The ratio obtained in micellar potassium dodecanoate (88:12), therefore, suggests factors other than the bulk dielectric constant of the medium are controlling the regiochemistry of the cycloaddition. This was confirmed when the photocycloaddition between 3-*n*-butylcyclopentenone and 1-octene was performed in aqueous potassium dodecanoate below the critical micelle concentration; a ratio of **5***b* to **6***b* of 62:38 was obtained which is similar to that obtained in polar organic solvents even though submicellar aggregates may be present.

These results are consistent with the simplified micelle model shown in Fig. 3 in which the cyclopentenone is oriented in the micelle with the polar carbonyl function in the water–micelle interface and the hydrophobic butyl tail in the micelle interior. Similarly, the hydrophobic alkene is mainly incorporated into the relatively nonpolar micelle

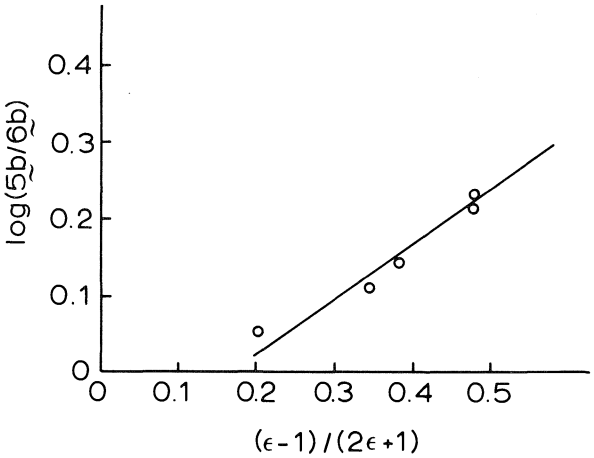

FIG. 2. Variation of the ratio of **5***b* to **6***b* with the solvent dielectric constant (Kirkwood–Onsager plot).

interior; as a result the most likely orientation for reaction between the photoexcited enone and the alkene is that shown in Fig. 3, leading to an increase in the proportion of head-to-head regioisomers **5**.

*Reactions with alkenyl acetates*

If the model suggested above correctly describes the origin of the regioselectivity observed in the irradiation experiments in micelles, then the presence of a polar group on the alkene would be expected to enhance the effect. For example, a 1-acetoxy-1-alkene would orient in a micelle with the polar acetate at the micelle–water interface and the hydrophobic alkyl chain in the nonpolar interior; interaction with a similarly oriented, photoexcited 3-*n*-butylcyclopentenone molecule would afford the head-to-head isomer at the expense of the head-to-head isomer at the expense of the head-to-tail isomer.

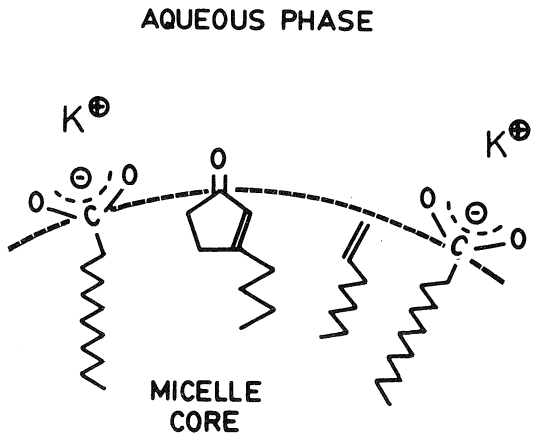

FIG. 3. Representation of proposed model showing orienting effect of micelle upon enone **1** and an alkene.

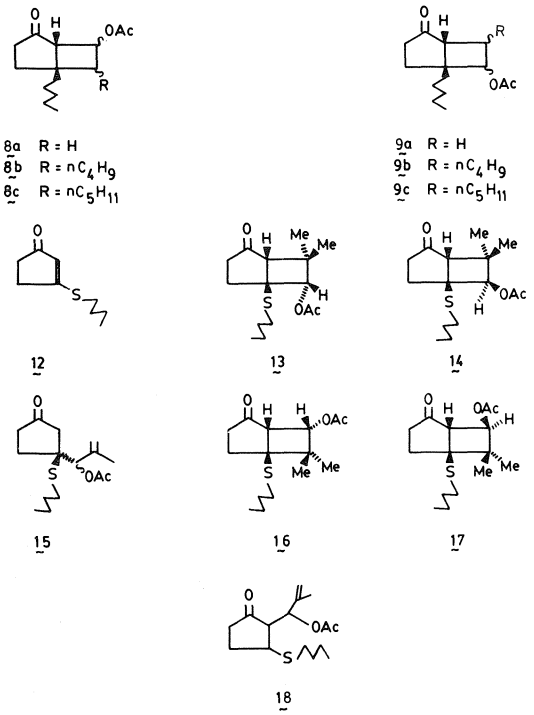
Experimentally, this was found to be the case; irradiation of 3-*n*-butylcyclopentenone in the presence of 1-alkenylacetates, **7**, gave a mixture of regioisomers **8** and **9**, and when the reaction medium was changed from organic solvent to



aqueous micellar potassium dodecanoate the proportion of **8** increased relative to **9**. The effect was even discernable in the photoaddition between enone **1** and vinyl acetate which has a very short hydrophobic chain. Thus, the ratio of **8***a* to **9***a* changed from 1:3 in organic solvents to 1:1 in micellar potassium dodecanoate (Table 4).

As was the case with compounds **5** and **6**, the regioisomers derived from reaction of 3-*n*-butylcyclopentenone with vinyl acetate could be conveniently distinguished by their $^{13}C$ nmr spectra, and the results are summarized in Table 5. The assignments were confirmed by hydrolyzing a 1:3 mixture of the acetates **8***a* and **9***a* and oxidizing the alcohols obtained to the corresponding ketones (Scheme 1). Comparison of the $^{13}C$ nmr spectrum of the major component of the mixture of ketones with that of bicyclo[3.2.0]heptan-2,6-dione[5] (Table 6) demonstrates, taking into account $\alpha$, $\beta$, and $\gamma$ shielding and deshielding effects, that the major product is 5-*n*-butylbicyclo[3.2.0]heptan-2,6-dione, **11***a*.

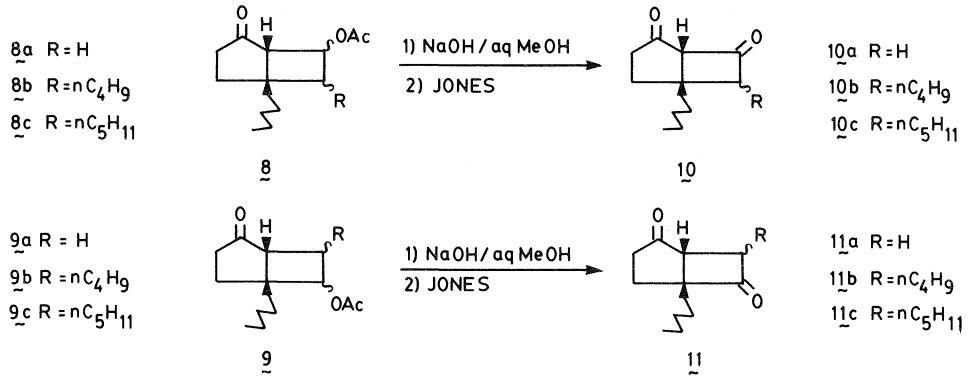
| minor stereoisomer | 57.7 | 41.3 | **8***a* |

A more pronounced effect of the micellar environment upon cycloaddition regiochemistry was observed in the reaction of 3-*n*-butylcyclopentenone with 1-hexenyl acetate and 1-heptenyl acetate. Thus, irradiation of 3-*n*-butylcyclopentenone with 1-heptenyl acetate in organic solvents gave four adducts in the ratio 50:20:20:10 as judged by uncalibrated peak areas on glc, whilst in aqueous micellar potassium dodecanoate six adducts were observed in the ratio 10:5:25:35:20:5. Because of the large number of products, and the difficulty of their separation, identification of individual isomers and assignment of relative stereochemistries and regiochemistries was not possible. Instead the adducts were converted to the ketones via hydrolysis and oxidation as depicted in Scheme 1.

Two mixtures of cycloadducts, one obtained by photoaddition of enone to 1-hexenyl acetate in diethyl ether and the other from enone and 1-heptenyl acetate in cyclohexane, were subjected to the hydrolysis/oxidation sequence. The only compounds detected by glc were the stereoisomers **11***b* and **11***c*, and none of the regioisomers **10***b* and **10***c*. Both stereoisomeric mixtures were isolated in good yield (> 80%), and their infrared spectra exhibited the expected strong absorption bands at 1775 $cm^{-1}$ and 1735 $cm^{-1}$ assigned to the cyclobutanone and cyclopentanone carbonyl groups respectively. The



SCHEME 1

$^{13}C$ nmr spectra of the diketones were compared with those of bicyclo[3.2.0]heptan-2,6-dione and 5-*n*-butylbicyclo[3.2.0]heptan-2,6-dione, **11***a*, (Table 6), and allowing for shielding and deshielding effects of alkyl substituents clearly indicate that the products are 2,6-diketones, and not 2,7-diketones (Table 7). The assignment was supported by the failure to observe the formation of ketoacids when the diketones were treated with aqueous potassium hydroxide (8). The cycloaddition between enone **1** and 1-hexenyl and 1-heptenyl acetates in organic solvents appears to be highly regioselective, giving only the head-to-tail adducts.

In the light of this result, a reaction mixture from photocycloaddition between 1-heptenyl acetate and enone **1** in aqueous micellar potassium dodecanoate was treated with base followed by oxidation according to Scheme 1. The base hydrolysis of the acetate adducts proceeded smoothly, but the oxidation of the resulting alcohols, which was followed by glc, proceeded at varying rates for different components of the mixture. Initially, the main product was diketone **11***c*, followed by slower formation of a second product identified as **10***c*. At extended reaction times a secondary process became evident which caused depletion of **10***c* to an unidentified product. Thus, after three hours reaction, uncalibrated glc analysis indicated a mixture of **11***c* (16%), peaks assigned to **10***c* (49%), and unreacted alcohols (35%), whilst after six hours oxidation a mixture of **11***c* (15%), **10***c* (29%), unconverted alcohol (11%), and unidentified secondary product 44% was observed. Work-up gave a mixture of **11***c* and **10***c* in a ratio of approximately 1:2. Attempted separation and purification of **10***c* failed because of decomposition and the structure was deduced from the spectroscopic data of the mixture allowing for the presence of **11***c*. In the infrared spectrum, the expected strong absorptions assigned to the cyclobutanone and cyclopentanone carbonyls were observed at 1775 $cm^{-1}$ and 1745 $cm^{-1}$ respectively. In the $^1H$ nmr spectrum, as well as a complex multiplet in the region 0.50–2.93 ppm, two triplets at 3.20 and 3.23 ppm were observed in a ratio of approximately 1:2. These signals are assigned to the proton at the C-1 position between the carbonyls of the isomeric β-diketones **10***c* epimeric at C-6 and the splitting arises from 1,3 coupling across the cyclobutane ring. The coupling constant of the major triplet was 1.5 Hz, that of the minor 0.5 Hz, suggesting that the predominant stereoisomer of **10***c* has the butyl group and pentyl group *trans* to each other (19). The $^{13}C$ nmr spectrum of regioisomers **10***c* confirmed the structural assignment; the data are given in Table 8 and are substantially different from those for the 2,6-diketones **11***c* given in Tables 6 and 7.

Thus photolysis of 3-*n*-butylcyclopentenone with 1-heptenyl acetate in organic solvents, followed by hydrolysis and oxidation, yields stereoisomeric

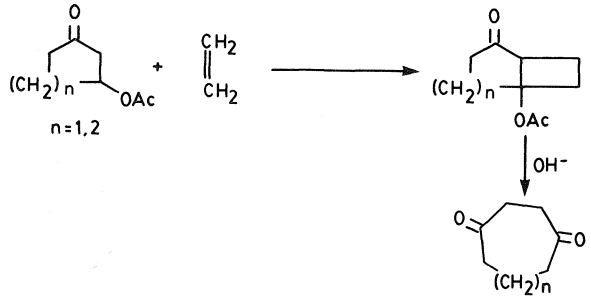
bicyclo[3.2.0]heptan-2,6-diones **11***c* as the only cycloaddition products whereas, if the irradiation is performed in aqueous micellar potassium dodecanoate, a mixture of the 2,6-diones and the regioisomeric bicyclo[3.2.0]heptan-2,7-diones **10***c* are obtained, in which the latter comprises at least 70% of the total. Consequently, whereas head-to-tail addition is the only mode of photochemical cycloaddition in organic solvents, in the micelle the proportion of head-to-head addition rises from zero to a minimum of 70% of the total. This strong directing effect exerted by the micellar environment is greater than in the case of vinyl acetate, possibly because of the relatively long hydrophobic alkyl chain of the heptenyl acetate. This is consistent with the model proposed in Fig. 3.

*Photochemical cycloaddition of 3-(*n*-butylthio)-cyclopent-2-en-1-one,* ***12***

Photochemical additions between alkenes and the enolic derivatives of cyclic β-diketones have been much used in synthesis because of the ability of the intermediate cyclobutanol derivative to open to give a larger ring (4, 9) (Scheme 2). However, inability to control the regiochemistry of this reaction represents a limitation. The directing effect of aqueous potassium dodecanoate micelles described above suggested a method of controlling regiochemistry in this synthetically useful reaction.

Reported here are the results of an investigation of the photochemical cycloaddition reactions of 3-(*n*-butylthio)cyclopent-2-en-1-one **12**. This molecule was chosen in preference to an oxygen analogue because of the relative nonpolarity of the sulphur substituent; it was hoped that the carbonyl function would control the orientation of the molecule in a micellar environment in a similar manner to that observed for 3-*n*-butylcyclopent-2-en-1-one.



SCHEME 2

The enone **12** was irradiated in the presence of isobutenyl acetate in cyclohexane to 76% conversion to give a mixture of five products as judged by glc. A combination of thin-layer chromatography and preparative glc allowed the isolation of four of these compounds which were assigned the structures **13**, **14**, **15**, and **16**. The fifth component of the mixture was present in too small a quantity to allow isolation.

Repetition of the reaction to 52% conversion in aqueous potassium dodecanoate micelles using concentrations of enone, enol acetate, and surfactant such that on average each micelle contained less than one enone and more than three enol acetate molecules gave five products, four of which were isolated by preparative hplc. The fifth was present in too small a quantity to be isolated. The four products were assigned structures **13**, **14**, **16**, and **17**.

The structures of the products were deduced from their mass spectra and $^1H$ nmr spectra. Compounds **13** and **14** both exhibited weak molecular ions and fragments corresponding to sequential loss of carbon monoxide, an acyl group, and propene, to give base peaks at 161 mass units. The molecular ions of **16** and **17** were not observed, but the fragmentation patterns were consistent with those expected.

Head-to-head adducts **16** and **17** were differentiated from head-to-tail adducts **13** and **14** by comparison of the magnitudes of the coupling constants of the protons geminal to the acetoxy functions. In **16** and **17** these protons experience vicinal coupling with the adjacent methines ($J$ = 9 and 7 Hz respectively) and in **13** and **14** the isolated acetoxyl protons are weakly coupled across the cyclobutane ring ($J$ = 0.9 and 1.1 Hz respectively) (19).

The relative stereochemistries of compounds **13** and **14** were determined by nuclear Overhauser enhancement of the acetoxyl substituted methines following selective irradiation of the adjacent methyls. In structure **13** (Fig. 4) $Me_A$ appears at 0.90 ppm and $Me_B$ appears at lower field (1.40 ppm) owing to a deshielding effect by the carbonyl group. Selective irradiation of $Me_B$ caused a nuclear Overhauser enhancement of $H_A$ which was not observed when $Me_A$ was irradiated. Similarly in **14** (Fig. 4), $Me_A$ appeared at 1.03 ppm and $Me_B$ 1.34 ppm; irradiation of $Me_A$ caused an enhancement of $H_B$,

For personal use only.

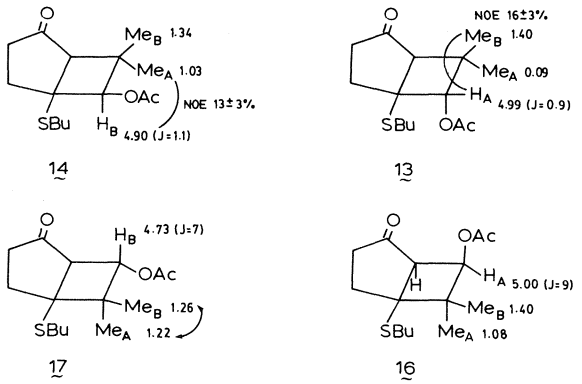

FIG. 4. Structures **13**, **14**, **16**, and **17** with relevant $^1$H nmr data. The assignments for methyls A and B in **17** may be reversed.

which was not observed when Me$_B$ was irradiated. These results are summarized in Table 9.

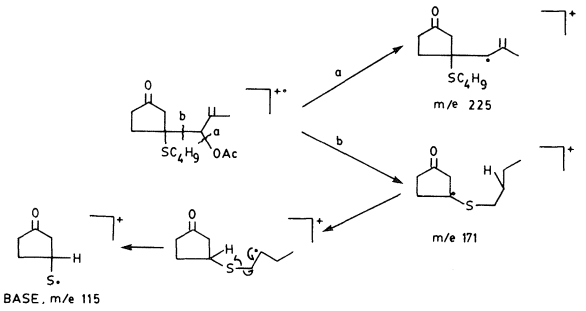
The assignment of relative stereochemistries to **16** and **17** is based upon a comparison of the chemical shifts of the acetoxyl-substituted methine protons. In compounds **13**, **14**, and **16**, this proton appears at 4.99, 4.90, and 5.00 ppm respectively; in **17** it has been shifted upfield to 4.74 ppm. This is ascribed to the shielding effect of the adjacent carbonyl (Fig. 4).

Compound **15** presumably arises from intramolecular abstraction in the diradical initially formed from the addition of the photoexcited enone **13** to the isobutenyl acetate (3). The mass spectrum of **15** showed a weak molecular ion and a consistent fragmentation pattern in which peaks corresponding to loss of the acetoxy group and the whole acetoxy-containing side chain followed by loss of butene to give the base peak were seen (Scheme 3). The $^1$H nmr spectrum contained a multiplet at 5.07 ppm corresponding to the vinylic methylene and a peak at 5.31 ppm assigned to the acetoxyl-substituted methine. This signal appeared as a broadened singlet, unambiguously distinguishing **15** from the alternative possible structure **18**, where a doublet would be observed.

Compounds **13**, **14**, and **15** are derived from head-to-tail addition of the enol acetate to enone **13**, whilst compounds **16** and **17** derive from head-to-head addition. The relative yields of each product from the reaction performed in cyclohexane, and in aqueous potassium dodecanoate micelles, were determined by glc, and the results are shown in Table 10. It can be seen that whereas in cyclohexane solution the reaction gives predominantly head-to-tail products with considerable amounts of olefinic by-product (compound **15**), in the micellar medium the production of the latter is completely quenched and the proportion of head-to-head adduct is greatly increased.

TABLE 9. Nuclear Overhauser enhancement for cyclobutane ring methines in cycloadducts **13** and **14**

| Proton observed in Fig. 3 | δ (ppm) | Protons irradiated | δ (ppm) | Observed increase in intensity (%) |
|---|---|---|---|---|
| **13** H$_A$ | 4.99 | Me$_A$ | 0.90 | 0 |
| | | Me$_B$ | 1.40 | 16±3 |
| **14** H$_B$ | 4.90 | Me$_A$ | 1.03 | 13±3 |
| | | Me$_B$ | 1.34 | 0 |



SCHEME 3

## Conclusion

From the foregoing, we conclude that the use of micelles in photocycloaddition has, in special cases, synthetic utility. These are: (a) as a means of increasing effective concentration when small amounts of reactants are available, (b) where head-to-head regioisomers are desired, and (c) when it is desirable to suppress hydrogen transfer in the intermediate biradicals (leading to alkenes).

## Experimental

All proton and carbon nmr spectra were recorded in $CDCl_3$. Carbon spectra were obtained on a Varian XL-100-15 system and assignments were made by comparison of decoupled and off-resonance spectra. All chemical shifts are in δ values relative to tetramethylsilane internal standard. Irradiations were performed using a 450 W Hanovia medium pressure mercury lamp suspended in a water cooled Pyrex jacket, unless otherwise stated. Small scale irradiations in organic solvents were carried out in sealed tubes which had been degassed to a residual pressure of $2 \times 10^{-5}$ Torr by at least three freeze–pump–thaw cycles. Preparative irradiations and micelle solution irradiations were performed under oxygen-free nitrogen using solutions which had been deoxygenated by purging with nitrogen for at least 30 min. Micelle solutions were prepared using triply distilled water and organic substrates were dissolved by immersing solutions in an ultrasonic bath.

*Irradiation of 3-*n*-butylcyclopent-2-en-1-one, 1, with cyclohexene*

3-*n*-Butycyclopentenone, **1**, was prepared by the method of Buchi and Egger (20) and had $\lambda_{max}$ (95% EtOH): 228 nm (ε = 13 500)

| Cyclohexane[d] | 61 | 27 | 9 | —[c] | 88:9 |
| Potassium dodecanoate micelles[e] | 41 | —[c] | 35 | 14 | 41:49 |

[a]Determined by glc; expressed as a ratio of uncalibrated areas of peaks assigned to each isomer.
[b]For this purpose the olefinic product **15** is designated as a head-to-tail product as it is derived from initial head-to-tail interaction of enone and alkene.
[c]Too small to be measured.
[d]3% unidentified compounds.
[e]9% unidentified compounds.

and 297 nm (ε = 49). Cyclohexene was distilled from calcium hydride under nitrogen.

3-*n*-Butylcyclopentenone (271 mg) was dissolved in cyclohexene (20 mL) and irradiated for 3 h, after which time tlc showed almost complete disappearance of the enone. The glc analysis of the mixture (3% SE 30 at 130°C, and 5% FFAP at 130–170°C) indicated clean formation of two products, in approximately equal amounts. A sample of the reaction mixture was purified by preparative glc (15% FFAP, 180°C). The component with the shorter retention time was a colourless oil and was shown by $^{13}C$ nmr to be a mixture of two isomers of **4**, whilst the component with the longer retention time, which was also a colourless oil, was a single isomer of **4**.

The faster component had the following data: $\nu_{max}$ (film): 2920, 2860, 1730, 1450 $cm^{-1}$; $\lambda_{max}$ (95% EtOH): 289 nm (ε = 35); $^1H$ nmr ($CDCl_3$) (100 MHz): 2.63–2.23 (3H, m), 1.9–1.1 (18H, m), 0.93 (3H, t, 6 Hz), 0.90 (3H, t, 6 Hz); $^{13}C$ nmr ($CDCL_3$): 14.1 (2 methyl groups), 23.3, 23.5, 24.4, 26.1, 26.3, 26.5, 26.7, 27.2, 27.6, 27.8, 28.5, 28.6, 30.5, 31.2, 32.6, 39.3, 40.4, 40.5 (all $CH_2$ groups), 41.7 (methine) 42.5 (methine), 48.3 (methine), 51.2 (quaternary), 51.5 (methine), 53.5 (quaternary), 55.0 (methine), 59.8 (methine), 219.4, 222.5 (carbonyls) ppm; *m/e* (25 eV): 220 ($M^+$, 3%), 191 (3%), 149 (100%); *Mol. Wt.* calcd. for $C_{15}H_{24}O$: 220.1827; found: 220.1825.

The component with the longer retention time had the following data: $\nu_{max}$ (film): 2940, 2870, 1730, 1460 $cm^{-1}$; $\lambda_{max}$ (95% EtOH): 287 nm (ε = 44); $^1H$ nmr ($CDCl_3$) (100 MHz): 2.7–1.9 (6H, m), 1.85–1.05 (15H, m), 0.90 (3H, t, 6 Hz); $^{13}C$ nmr ($CDCl_3$): 14.1 (methyl), 22.0, 22.1, 23.4, 23.5, 26.4, 26.8 (all methylenes), 32.6 (methine), 32.9, 34.9, 39.2 (all methylenes), 40.7 (methine), 46.5 (quaternary), 55.4 (methine), 221 (carbonyl) ppm; *m/e* (25 eV): 220 ($M^+$, 3%), 191 (1%), 149 (100%), *Mol. Wt.* calcd. for $C_{15}H_{24}O$: 220.1827; found: 220.1825.

Repetition of the reaction in potassium dodecanoate solution gave the same cycloadduct products in the same proportions, along with varying quantities of the head-to-head adduct **3** resulting from dimerization of the enone. The ratio of cycloadduct to dimer was determined in a series of reactions where the concentration of cyclohexene was varied. The procedure used was as follows.

A series of stock solutions was prepared. Potassium dodecanoate (9.527 g) was dissolved to 500.0 mL in triply distilled water to give a 0.0800 *M* solution. This solution was deoxygenated by purging with nitrogen gas for one hour to give a stock micelle solution.

3-*n*-Butylcyclopentenone, **1**, (0.0424 g) was dissolved by sonication in 50.0 mL of the potassium dodecanoate solution, to give a solution $6.15 \times 10^{-3}$ *M* in enone.

Cyclohexene (0.0626 g) was dissolved in sonication in 100 mL of the potassium dodecanoate solution, to give a solution $7.63 \times 10^{-3}$ *M* in cyclohexene.

These three solutions were mixed in varying proportions to give solutions $6.15 \times 10^{-4}$ *M* in enone, 0.0800 *M* in potassium dodecanoate, and between $6.11 \times 10^{-4}$ and $2.59 \times 10^{-3}$ *M* in alkene. Total solution volumes were 50.0 mL. All transfers were carried out under nitrogen to minimize dissolution of oxygen in the reaction mixtures. Micelle solutions were irradiated in quartz tubes to allow monitoring of the uv spectrum. Conversion was determined by observing disappearance of the $\pi \rightarrow \pi^*$ band of the enone. Typically, reaction times were in the order of 20 min. Irradiated mixtures were poured into water (500 mL) and extracted with ether (5 × 100 mL). Salt was added carefully in portions to break emulsions; addition of too much salt caused the dodecanoate to come out of solution as a nonfilterable precipate. Combined ether extracts were washed with aqueous $Na_2CO_3$, dried ($MgSO_4$), and concentrated. The concentrate was analysed by glc (3% SE 30, 100–200°C) for cycloadduct **4** and dimer **3** using *n*-docosane as an internal standard. Calibrations of *n*-docosane against **3** and **4** were obtained using purified samples of dimer (12) and the adducts. The results are given in Table 1.

*Irradiation of 3-*n*-butylcyclopent-2-en-1-one, 1, with 1,2-dimethylcyclohexene*

3-*n*-Butylcyclopentenone (166 mg) and 1,2-dimethylcyclohexene (0.554 g) were irradiated together. The progress of the reaction was monitored by recording the $^1H$ nmr spectrum at intervals; disappearance of the olefinic proton of the enone was observed and the reaction was terminated at 70% conversion. Small amounts (< 10%) of olefinic reaction products from intramolecular hydrogen abstraction by the intermediate diradical were observed (3). A glc analysis (3% SE 30) of the reaction mixture showed the presence of a single major peak (> 80% of the total) and four minor peaks travelling closely together. These were assumed to be cycloadduct isomers and small amounts of olefinic by-products. The reaction products we isolated as a mixture by preparative glc (15% SE 30 at 210°C) and used for calibration against *n*-docosane.

Repetition of the reaction in aqueous potassium dodecanoate solution gave a similar result, as indicated by glc analysis of the worked-up reaction mixture. A series of experiments were performed as described above for the reaction of cyclohexene with enone **1** in order to examine the effect of dimethylcyclohexene concentration upon the ratio of cycloadduct to enone dimer. The results are given in Table 1.

*Irradiation of 3-*n*-butylcyclopent-2-en-1-one, 1, with 1-hexene*

A nitrogen purged solution of enone **1** (0.151 g) and 1-hexene (2.77 g) in dry ether (350 mL) was irradiated at room temperature until all enone had been consumed as shown by glc (3% SE 30, 100–175°C). Evaporation gave an isomeric mixture of adducts **5***a* and **6***a* (0.235 g, 97%). Bulb-to-bulb distillation (65°C/0.7 Torr) gave an oil which had $\nu_{max}$ (neat): 1738, 1467, 1457, 1167 $cm^{-1}$; $^1H$ nmr: 0.6–2.8 (complex multiplet) ppm. The glc

For personal use only.

analysis (5% FFAP, 140°C) of the oil showed the presence of two peaks with areas in the ratio 43:57 (flame ionization detector); separation by preparative glc gave the minor component (shorter retention time) which was identified as the head-to-tail regioisomers **6***a* and had *m/e*: 222 ($M^+$, 3%), 193(3), 165(8), 152(6), 140(3), 139(50), 138(3), 112(100), 111(12), 110(17), 97(66), 96(25), 95(4); *Mol. Wt.* calcd. for $C_{15}H_{26}O$: 222.1984; found: 222.1979; $^{13}C$ nmr, see Table 2. The $^{13}C$ nmr indicated that **6***a* was a mixture of stereoisomers in which one predominated.

The major component was identified as the head-to-head regioisomer **5***a* and had *m/e*: 222 ($M^+$, 2%), 193(2), 165(4), 140(10), 139(100), 138(10), 111(13), 110(18), 97(11), 96(81), 95(22); *Mol. Wt.* calcd. for $C_{15}H_{26}O$: 222.1984; found: 222.1986; $^{13}C$ nmr, see Table 2. The $^{13}C$ nmr indicated that **5***a* was a mixture of stereoisomers present in approximately equal amounts.

*Irradiation of 3-*n*-butylcyclopent-2-en-1-one, **1**, with 1-octene*

A deoxygenated solution of enone **1** (0.168 g) and 1-octene (3.05 g) in dry ether (350 mL) was irradiated for five hours after which time glc indicated all of the enone had been consumed. Evaporation gave a mixture of adducts **5***b* and **6***b* (0.300 g, 99%) which was distilled bulb-to-bulb, 70°C/0.6 Torr) to give an oil which had $\nu_{max}$ (film): 1739, 1470, 1460, 1162 $cm^{-1}$; $^1H$ nmr: 0.6–2.9 (complex multiplet) ppm. The glc analysis (5% FFAP, 150°C) of the mixture indicated two peaks with areas in the ratio 43:57 (flame ionization detector). Separation by preparative glc gave the minor component (shorter retention time) which was identified as regioisomers **6***b*. The $^{13}C$ nmr spectrum (Table 2) indicated that **6***b* was a mixture of isomers present in approximately equal amounts. The major component was identified as regioisomers **6***a* in which one stereoisomer predominated, as indicated by the $^{13}C$ nmr spectrum (Table 2).

*Irradiation of 3-*n*-butylcyclopent-2-en-1-one, **1**, with vinyl acetate, **7**a*

A deoxygenated solution of enone **1** (0.311 g) and freshly distilled vinyl acetate (2.09 g) in dry ether (350 mL) was irradiated until glc (3% SE 30, 100–140°C) indicated no enone remained (4.5 h). Evaporation gave a glassy residue which was triturated with hot pentane (5 × 50 mL) to give a yellow oil (0.51 g). Bulb-to-bulb distillation (92°C/0.3 Torr) yielded a mixture of **8***a* and **9***a* (0.43 g, 85%) as an oil which had $\nu_{max}$ (film): 1739, 1373, 1288, 1070, 1046 $cm^{-1}$; $^1H$ nmr: 0.63–2.93 (19H, m), 4.95 (1H, m) ppm. The glc analysis of the mixture (5% FFAP, 100–180°C, flame ionization detector) showed 3 peaks with areas in the ratio 74:15:11. The $^{13}C$ nmr of the mixture (Table 5) showed the presence of all four possible isomers of **8***a* and **9***a*.

A portion of the mixture of **8***a* and **9***a* (0.20 g) was dissolved in methanol (2.0 mL) and aqueous sodium hydroxide (2.5 *M*, 0.5 mL) was added. The solution was stirred at room temperature for 20 min, hydrochloric acid (0.5 *M*) was added to pH 8, and the products were extracted with ether, dried ($MgSO_4$), and evaporated to give a mixture of alcohols (0.15 g, 90%) which had $\nu_{max}$ (film): 3430, 1730, 1468, 1458, 1240, 1175, 1090 $cm^{-1}$; $^1H$ nmr: 0.57–3.03 (16H, m), 3.17–4.77 (2H, m) ppm. This mixture was dissolved in acetone (2.0 mL) and treated with Jones reagent (0.70 mL) at 3°C. Aqueous work-up gave a yellow oil (0.13 g) which contained (glc analysis; 3% SE 30, 85–150°C) some unreacted alcohols. Chromatography on neutral alumina with ether as eluent followed by bulb-to-bulb distillation (80°C/0.3 Torr) gave 5-*n*-butylbicyclo[3.2.0]heptane-2-6-dione, **11***a*, (0.099 g, 69%) as an oil which had $\nu_{max}$ (film): 1784, 1744, 1468, 1458 $cm^{-1}$; $^1H$ nmr: 0.58–3.80 (complex multiplet) ppm; $^{13}C$ nmr: 13.9 (methyl), 23.0, 27.1, 28.2, 33.2, 37.1 (all methylenes), 41.4 (methine), 50.0 (methylene), 73.3 (quaternary), 211.1 (carbonyl), 216.8 (carbonyl) ppm; *m/e*: 152 $M^+ - 28$, 3%) 151(23), 141(6), 140(3), 139(30), 97(100), 95(27), 81(39), 73(37).

*Irradiation of 3-*n*-butylcyclopent-2-en-1-one, **1**, with 1-hexenyl acetate, **7**b*

1-Hexenyl acetate was synthesized as a mixture of *cis* and *trans* isomers (21), bp 64°C/12 Torr. A deoxygenated solution of enone **1**, (0.443 g) and hexenyl acetate (2.47 g) in dry ether (350 mL) was irradiated until glc (3% SE 30, 100–175°C) indicated that no enone remained (10 h). Bulb-to-bulb distillation (116°C/0.4 Torr) gave a mixture of cycloadducts **8***b* and **9***b* (0.76 g, 85%) which on glc (3% SE 30, 100–175°C) showed four peaks with areas in the ratio 46:18:26:10 (flame ionization detector). The mixture had $\nu_{max}$ (film): 1738, 1467, 1458, 1373, 1236 $cm^{-1}$; $^1H$ nmr: 0.62–2.96 (27H multiplet), 3.10–5.00 (1H, multiplet) ppm. A sample (0.31 g) was dissolved in methanol (3.0 mL) and treated with aqueous NaOH (0.60 mL, 2.5 *M*) at room temperature for 20 min. Dilution with water and extraction into ether gave a mixture of alcohols (0.24 g, 92%), following drying ($MgSO_4$) and evaporation. The alcohol mixture had $\nu_{max}$ (film): 3435, 1735, 1465, 1085 $cm^{-1}$; $^1H$ nmr: 0.50–2.87 (24H, m), 2.93–4.27 (2H, m) ppm. Most of this mixture (0.23 g) was dissolved in acetone (3.0 mL) and treated with Jones reagent (0.75 mL) at 3°C for 1.5 h. The mixture was diluted with water and extracted with ether; the ether extracts were washed (aqueous sodium bicarbonate) and dried ($MgSO_4$). Evaporation gave mainly (glc analysis; 3% SE 30, 100–175°C) 5,7-dibutylbicyclo[3.2.0]heptane-2,6-dione, **11***b*, (0.212 g) as a mixture of isomers. Further purification was unsuccessful. The dione had $\nu_{max}$ (film): 1777, 1738, 1468, 1458 $cm^{-1}$; $^1H$ nmr: 0.50–3.82 (complex multiplet) ppm; $^{13}C$ nmr, see Tables 6 and 7; *m/e*: 222 (0.5%), 221(0.5), 220(1), 205(2), 181(2), 165(4), 140(12), 139(100), 97(5), 96(5), 95(4), 83(12), 73(26).

*Irradiation of 3-*n*-butylcyclopent-2-en-1-one, **1**, with 1-heptenyl acetate, **7**c*

1-Heptenyl acetate was synthesized as a mixture of *cis* and *trans* isomers (21) and had bp 82–88°C/15 Torr. A deoxygenated solution of enone **1** (0.120 g) and heptenyl acetate (1.01 g) was irradiated in dry cyclohexane (65 mL) until all enone was consumed. Distillation (94°C/0.2 Torr) gave a mixture of cycloadducts (0.136 g, 53%). Gas-liquid chromatography (3% SE 30, 100–175°C) indicated four peaks with areas in the ratio 47:22:22:9. The mixture had $\nu_{max}$ (film): 1740, 1471, 1460, 1375, 1236, 1062 $cm^{-1}$; $^1H$ nmr: 0.55–2.92 (29H, m), 4.58–5.25 (1H, m) ppm.

The major part of the cycloadduct mixture (0.124 g) was dissolved in methanol (0.30 mL) and treated with aqueous sodium hydroxide (0.10 mL, 5.0 *M*) at room temperature for 30 min. Neutralization with dilute HCl and extraction with ether gave, after drying ($MgSO_4$), a mixture of alcohols (0.109 g, 99%) which had $\nu_{max}$ (film): 3460, 1730, 1473, 1465, 1100 $cm^{-1}$; $^1H$ nmr: 0.53–3.00 (27H, m), 3.53–4.30 (1H, m) ppm. Most of this mixture (0.100 g) was dissolved in acetone (2.5 mL) and oxidized with Jones Reagent (0.55 mL) at 3°C. Aqueous work-up gave an oil which was a mixture of 5-butyl-7-pentylbicyclo[3.2.0]-heptane-2,6-dione, **11***c*, and the starting alcohols in a ratio of approximately 9:1 as shown by glc (3% SE 30, 100–175°C). Chromatography on neutral alumina followed by bulb-to-bulb distillation (90°C/0.3 Torr) gave **11***c* as an oil (0.088 g, 89%) which had $\nu_{max}$ (film): 1775, 1735, 1469, 1460 $cm^{-1}$; $^1H$ nmr: 0.55–2.94 (25H, m), 2.94–3.78 (1H, m) ppm; $^{13}C$ nmr, see Table 7; *m/e*: 222(1%), 221(5), 220(23), 206(14), 205(95), 177(22), 145(14), 140(8), 139(82), 97(12), 96(43), 95(28), 81(40), 68(36), 58(100).

*Irradiation of 3-*n*-butylcyclopent-2-en-1-one, **1**, with 1-heptenyl acetate in potassium dodecanoate micelles*

A solution (500 mL) of enone **1** and 1-heptenyl acetate in aqueous potassium dodecanoate was made up so as to be $2.5 \times 10^{-3}$ *M* in enone, $1.7 \times 10^{-2}$ *M* in heptenyl acetate, and 0.142 *M*

in potassium dodecanoate. Under these conditions, each micelle before irradiation contained on average one enone molecule and approximately seven heptenyl acetate molecules. Irradiation followed by aqueous work-up gave a mixture of adducts **8***c* and **9***c* (0.250 g, 68%). The spectroscopic properties of the mixture were identical with those of the product obtained by irradiation in cyclohexane. The mixture of adducts was hydrolysed and oxidized as described in the previous procedure; the extent of the oxidation was monitored by glc (5% FFAP and 3% SE 30, 100–175°C) and the reaction was given an aqueous work-up after six hours to yield an oil (0.149 g). Gas–liquid chromatography (3% SE 30, 90–165°C) showed the presence of 3 products in addition to starting material. Bulb-to-bulb distillation gave a mixture of diones **10***c* and **11***c* (0.072 g) in a ratio of approximately 2:1. Attempted chromatographic separation of these two compounds resulted in decomposition; consequently the isomeric mixture of head-to-head diones **10***c* was characterized spectroscopically allowing for the presence of **11***c* and had $\nu_{max}$ (film): 1775, 1745, 1465 $cm^{-1}$; $^1H$ nmr: 0.50–2.93 (25H, m), 3.20 and 3.23 (total 1 H, two triplets in the ratio of approximately 1:2 with $J$ = 0.5 and 1.5 Hz, respectively) ppm; $^{13}C$ nmr spectrum, see Table 8; *m/e*: 236(2%), 235(1), 234(5), 219(3), 205(9), 179(9), 140(11), 139(100), 97(8), 96(12), 95(12), 81(15), 79(15), 57(42), 54(35).

*Irradiation of 3-(*n*-butylthio)cyclopent-2-en-1-one, **12**, with isobutenyl acetate*

The enone **12** was prepared according to published procedures (22) and was irradiated with the alkenyl acetate in cyclohexane and in aqueous potassium dodecanoate solution.

(a) *In cyclohexane*

A deoxygenated solution of enone **12** (2.00 g) and isobutenyl acetate (10.0 g) in cyclohexane (180 mL) was irradiated in a Rayonet Reactor (300 nm lamps) to 76% conversion. The reaction was followed by monitoring the disappearance of the enone $\pi \rightarrow \pi^*$ absorption at 267 nm. The glc analysis of the reaction mixture (10% SE 30, 170°C) following removal of solvent showed four product peaks in the ratio 61:27:9:3 (flame ionization detector). The major product was found to be a mixture of two compounds (glc 10% FFAP, 200°C). A portion of the mixture (0.10 g) was separated by a combination of tlc, hplc, and glc; the fifth, smallest component of the mixture was present in too small a quantity to allow identification. The isolated compounds were identified as adducts **13**, **14**, **15**, and **16**.

For **13**: $^1H$ nmr: 4.99 (1H, d, $J$ = 1.8 Hz), 2.7–2.0 (7H, m), 2.12 (3H, s), 1.6–1.2 (4H, m), 1.40 (3H, s), 1.1–0.75 (3H, m), 0.90 (3H, s) ppm; *m/e* (25 eV): 284 ($M^+$, 4%), 224(7), 213(67), 171(100), 114(32); *Mol. Wt.* calcd. for $C_{15}H_{24}O_3S$: 284.1448; found: 284.1448.

For **14**: $^1H$ nmr: 4.90 (2H, d, $J$ = 2.4 Hz), 2.7–2.1 (7H, m), 2.16 (3H, s), 0.90 (3H, t, $J$ = 6 Hz) ppm; *m/e* (20 eV): 284 ($M^+$, 2%), 213(24), 171(100), 114(5), 72(7); *Mol. Wt.* calcd. for $C_{15}H_{24}O_3S$: 284.1448; found: 284.1448.

For **15**: $^1H$ nmr: 5.31 (1H, s), 5.07 (2H, m), 2.6–2.3 (6H, m), 2.25–2.0 (2H, m), 2.07 (3H, s), 1.88 (3H, broadened s), 1.63 (4H, m), 0.88 (3H, t, $J$ = 6 Hz) ppm; *m/e*: 284 (2%), 225(23), 171(57), 115(100); *Mol. Wt.* calcd. for $C_{15}H_{24}O_3S$: 284.1448; found: 284.1443.

For **16**: $^1H$ nmr: 4.8 (1H, d, $J$ = 7 Hz), 2.8–2.0 (7H, m), 2.1 (3H, s), 1.7–1.1 (4H, m), 1.28 (3H, s), 1.24 (3H, s), 0.95 (3H, t, $J$ = 6 Hz) ppm; *m/e*: 215(1), 214(3), 213(26), 173(4), 172(8), 171(100), 153(3), 114(5), 72(7).

(b) *In aqueous potassium dodecanoate*

Potassium dodecanoate (75 g) was dissolved to 1200 mL in triply distilled deoxygenated water. Enone **12** (0.761 g) and isobutenyl acetate (3.45 g) were added and the suspension was sonicated to dissolve the reactants. The solution obtained was 0.26 $M$ in dodecanoate, $3.41 \times 10^{-3}$ $M$ in enone, and $3.03 \times 10^{-2}$ $M$ in alkene; the average number of enone and alkene molecules was therefore 0.7 and 6 respectively. The irradiation was performed in a Rayonet reactor using 300 nm lamps and was followed by monitoring the disappearance of the uv absorption of the enone. At 52% conversion the reaction mixture was diluted below the cmc with water and extracted with ether to yield the cycloadducts (0.67 g) which were purified by chromatography on silica. The glc analysis of the adduct mixture (10% SE 30, 170°C) showed four peaks whose areas were in the ratio 41:35:14:9 (flame ionization detector). As in the previous experiment, the major peak was a mixture of compounds **13** and **14**, and the second largest component was compound **16**. The smallest component was not isolated in sufficient quantity to allow identification and the remaining component was identified as **17**.

For **17**: $^1H$ nmr: 5.0 (1H, d, $J$ = 8.8), 2.8–2.2 (7H, m), 2.05 (3H, s), 1.8–1.1 (4H, m), 1.4 (3H, s), 1.08 (3H, s), 0.90 (3H, t, $J$ = 6 Hz) ppm; *m/e*: 213(16), 205(5), 171(100).

# An improved procedure for the preparation of 3-carbomethoxy-4-oxotetrahydrothiopyran, 2- and 4-carbomethoxy-3-oxotetrahydrothiophene

HSING-JANG LIU AND TENG KO NGOOI

*Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2*

Received September 16, 1981

HSING-JANG LIU and TENG KO NGOOI. Can. J. Chem. **60**, 437 (1982).

An improved procedure for the preparation of the title compounds **1–3** has been developed. Direct condensation of methyl 3-mercaptopropionate with methyl acrylate using sodium hydride as a base gave compound **1** in good yield. The reaction of methyl thioglycolate and methyl acrylate at 0°C gave compound **2** as the major product whereas at lower temperature (−40°C) isomer **3** was found as the major product. The condensation reactions of methyl thioglycolate with methyl methacrylate and crotonate were also carried out.

HSING-JANG LIU et TENG KO NGOOI. Can. J. Chem. **60**, 437 (1982).

On a développé une méthode efficace de préparation des composés **1–3** mentionnés dans le titre. La condensation directe du mercapto-3 propionate de méthyle sur l'acrylate de méthyle en présence de l'hydrure de sodium conduit au composé **1** avec un bon rendement. La réaction du thioglycolate de méthyle avec l'acrylate de méthyle à 0°C donne le composé **2** comme produit majoritaire tandis qu'à basse température (−40°C) l'isomère **3** est le produit majoritaire. On a également étudié les réactions de condensations du thioglycolate de méthyle sur le méthacrylate de méthyle et sur le crotonate de méthyle.

[Traduit par le journal]

The title compounds **1–3** are useful synthetic intermediates (1–3) leading to compounds which are of current interest. The conventional methods for their preparation require the formation of the diesters of 3-thioadipic acid and 4-thiopimelic acid followed by a Dieckmann condensation (1, 4–8). Apart from the operational complexity, these procedures often suffer from unsatisfactory yields of the products due to the rather severe conditions required to induce Dieckmann reaction. We wish to report a convenient procedure leading directly to the title compounds with improved yields.

The *S*-anions derived from 3-mercaptopropionate and thioglycolate are expected to undergo conjugate addition to acrylate and the resulting carbanion can conceivably proceed to cyclization under appropriate conditions.[1] This was realized experimentally as follows. Treatment of methyl 3-mercaptopropionate with 1.2 equiv. each of sodium hydride and methyl acrylate in 1,2-dimethoxyethane at 0°C for 4 h gave directly 3-carbomethoxy-4-oxotetrahydrothiopyran (**1**) in 75% yield. In the case of the reaction of methyl thioglycolate and methyl acrylate, the intermediate carbanion resulting from the 1,4-addition can in principle undergo two different modes of cyclization via proton exchange. As a result both compounds **2** and **3** could be produced. Although we were unable to find conditions to facilitate the exclusive formation of either compound, a reasonable selectivity could be achieved by merely adjusting the reaction temperature. At lower temperature (−40°C) the two isomers **2** and **3** were formed in near-quantitative yield and in a ratio of ca. 2:3, whereas at 0°C the former was isolated as the major product in 67% yield along with a lesser quantity (32% yield) of the latter isomer.

The described direct procedure could be further extended to the preparation of derivatives of the title compounds by suitable choice of the two reactants. For example, the reaction of methyl thioglycolate and methyl methacrylate afforded a 94% yield of 3-oxotetrahydrothiophene **4**[2] (12), whereas treatment of methyl thioglycolate with methyl crotonate gave rise to a 1:1 mixture of two isomeric compounds **5** and **6**[3] (13) in 82% yield.

[1]For examples of two related processes, i.e. mercaptide ion induced Wittig reaction and alkoxide induced Dieckmann condensation, see refs. 9 and 10 respectively.

[2]The exclusive formation of this compound is in accordance with the known regioselectivity of Dieckmann condensation (11).

[3]Compounds **5** and **6** were further characterized by acetylation (acetyl chloride in pyridine; 20°C; 5 h) to give the corresponding enol acetates **7** (94% yield; ir (neat): 1775, 1720, and 1660 $cm^{-1}$; nmr ($CCl_4$) δ: 4.34 (q, 1H, $J = 7, J' = 2$ Hz, —CH—), 3.71 (s, 3H, $—COOCH_3$), 3.53–4.01 (complex, 2H, $—CH_2—$), 2.17 (s, 3H, $CH_3COO—$), and 1.51 (d, 3H, $J = 7$ Hz, $—CH_3$); ms $M^+$ 216.0455 (calcd. for $C_9H_{12}O_4S$: 216.0456)) and **8** (92% yield; ir (neat): 1780, 1720, and 1630 $cm^{-1}$; nmr ($CCl_4$) δ: 3.71 (s, 3H, $—COOCH_3$), 3.55 (m, 1H, —CH—), 3.14 (dd, 1H, $J = 17, J' = 9$ Hz, —C*H*H—), 2.51 (dd, 1H, $J = 17, J' = 5$ Hz, —CH*H*—), 2.16 (s, 3H, $CH_3COO—$), and 1.38 (d, 3H, $J = 7$ Hz, $—CH_3$); ms $M^+$ 216.0456 (calcd. for $C_9H_{12}O_4S$: 216.0456)).

[a]All the products exist partially in the corresponding enol form. In cases of compounds **4–6**, inseparable diastereomers are present.
[b]Melting point 36–37°C.
[c]*Anal.* calcd. for $C_7H_{10}O_3S$: C 48.28, H 5.75, S 18.39.
[d]Found: C 48.19, H 5.61, S 18.15.
[e]Found: C 48.25, H 5.67, S 18.57.
[f]Found: C 48.49, H 5.89, S 18.58.
[g]Except where otherwise stated, the ir spectra were obtained on neat liquid and only diagnostic signals are cited.
[h]Obtained in carbon tetrachloride.
[i]The nmr spectra were obtained on solutions in carbon tetrachloride with tetramethylsilane as internal reference.
[j]Molecular ions are given with calculated values in parentheses.
[k]The spectral data were shown to be identical with those of an authentic sample.

Results of this investigation and the spectral data for products are summarized in Table 1.

## Experimental

*General and material*

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. Infrared spectra were recorded on a Perkin–Elmer model 457 spectrophotometer. Nuclear magnetic resonance spectra were recorded on a 90 MHz Perkin–Elmer 32 spectrometer. Mass spectra were recorded using an A.E.I. Model MS 50 mass spectrometer. Elemental analyses were performed by the microanalytical laboratory of this department. Methyl 3-mercaptopropionate and methyl thioglycolate (Aldrich) were used without purification. 1,2-Dimethoxyethane was freshly distilled over lithium aluminum hydride. Methyl acrylate, methacrylate, and crotonate were distilled prior to use.

*Preparation of 3-carbomethoxy-4-oxotetrahydrothiopyran (**1**), 4-carbomethoxy-3-oxotetrahydrothiophene (**2**), 2-carbomethoxy-3-oxotetrahydrothiophene (**3**), and derivatives **4–6***

The general procedure used for the preparation of these compounds is illustrated below with the reaction of methyl 3-mercaptopropionate and methyl acrylate. Temperature and time of reactions as well as spectral data and yields of products are compiled in Table 1. Separation of the two isomeric pairs, **2** (faster-moving) and **3**, and **5** (faster-moving) and **6**, was effected by flash column chromatography (14) on silica gel, eluting with a solution of 5% ethyl acetate in petroleum ether.

At 0°C, to a solution of methyl 3-mercaptopropionate (490 mg, 4.1 mmol) and methyl acrylate (430 mg, 5 mmol) in 1,2-dimethoxyethane (15 mL), was added sodium hydride (50% dispersion in oil; 240 mg, 5 mmol). The reaction mixture was stirred at 0°C under an atmosphere of nitrogen for 4 h. The mixture was acidified with 1 *N* hydrochloric acid and extracted with methylene chloride. Drying ($MgSO_4$), filtration, and concentration gave the crude product which was purified by column chromatography on silica gel. Elution with ethyl acetate – petroleum ether (1:20) afforded compound **1** (540 mg; 75% yield).

# Nucleophilic attack on 2,1-benzisothiazolium salts

DAVID M. MCKINNON[1], K. ANN DUNCAN, AND LESLEY M. MILLAR

*Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2*

Received August 10, 1981

DAVID M. MCKINNON, K. ANN DUNCAN, and LESLEY M. MILLAR. Can. J. Chem. **60**, 440 (1982).

2,1-Benzisothiazolium salts react with several stabilized carbanions to give products that are derived by attack at the carbon atom of the heterocyclic ring.

DAVID M. MCKINNON, K. ANN DUNCAN et LESLEY M. MILLAR. Can. J. Chem. **60**, 440 (1982).

Les sels de benzisothiazolium-2,1 réagissent avec plusieurs carbanions stabilisés en donnant des produits qui proviennent de l'attaque au niveau de l'atome de carbone de l'hétérocycle.

[Traduit par le journal]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

Although the site of nucleophilic attack of carbanions on monocyclic isothiazolium salts and the 1,2-benzisothiazolium cation appears to be at ring sulfur rather than at a carbon atom (1–4), little work is reported of the attack of carbanions on 2,1-benzisothiazolium salts. It is known that nucleophilic attack occurs at a ring carbon, i.e. the 3-position by certain oxygen (5), sulfur (6), and nitrogen (7) nucleophiles, and by *N*,*N*-dimethylaniline (on its *para* position) (6). For this investigation we used the salts **1** *a*–*e* which were available from reported syntheses (5–7) or simple modifications. For the reactions of cations of type **1**, a number of reaction possibilities may be envisaged by analogies with other isothiazoles or related heterocyclic species: reaction at ring sulfur with subsequent ring opening (1, 2) as for the isothiazolium (1, 2) and 1,2-benzisothiazolium system (2–4); addition at carbon 3 followed by ring fission or replacement of a reactive substituent with retention of the isothiazole ring (5, 7); dealkylation by nucleophilic displacement at an *N*-alkyl substituent (8), or removal of a C-3 proton giving a carbene (or zwitterion) or further acyclic derivative as for the monocyclic system (9). Other possible reactions of the salts, involving deprotonation of a C-3 alkyl substituent (10), are not possible with the examples we used.

The reaction of the anion of diethyl malonate with **1***a* afforded a mixture of products, from which 2-methylaminobenzaldehyde (**2***a*) and diethyl 1-methyl-2,1-benzisothiazol-3-ylidenemalonate (**3***a*) were isolated. The formation of the latter may be rationalized in terms of nucleophilic attack at carbon to form a saturated derivative **4***a* which is then oxidized by possibly unreacted **1***a* to form **3***a*. The reduction of **1***a* would provide 2-methylaminobenzaldehyde which might be expected to convert to **2***a* under the reaction conditions. It is known (11, 12) that the structurally related 1,2-dithiolium salts react with ketones to produce 3-acylmethylene-1,2-dithioles. On the other hand, if malonate were displaced from **4** by water during the work-up process, ring opening reactions would lead to **2***a*, as described (5). The ester **3***a* was obtained in much better yield by reaction of **1***b* with diethyl malonate. This is again obviously formed by nucleophilic attack at carbon to form **4***b*, which then eliminates methanethiol.

When **1***a* was treated with triethylamine or pyridine and the product worked up, the only products obtained were the thione **5** and **2***a*. No products derived from proton abstraction were isolated. The formation of **5** and **2***a* represents a dismutation reaction of a product formed by nucleophilic attack of water on **1***a*, with sulfur being transferred between two molecules. This could have arisen by the mechanism shown (Fig. 1). The addition of extra sulfur to the reaction mixture did not affect the relative yield of the products and therefore this reaction would then appear to pro-

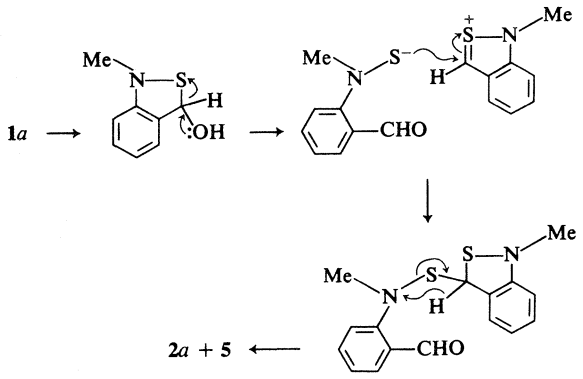

FIG. 1.

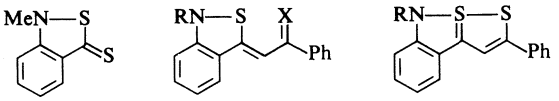
ceed via a different mechanism to the base catalysed sulfurizations of 1,2-dithiolium salts to 1,2-dithiole-3-thiones (13) and of isothiazolium salts to isothiazoline 3- and 5-thiones (9). Davis *et al.* (5) obtained **2***a* by treatment of **1***a* with sodium bicarbonate, without reporting the isolation of **5**. In our hands a repeat of this reaction did also yield some thione. The treatment of **1***b* with sodium benzoylacetate in ethanol yielded the ketone **6***a* as a yellow oil. This reaction is analogous to the reactions of sodium benzoylacetate with 3-alkylthio-1,2-dithiolium salts to form 3-phenacylidene-1,2-dithioles (14). The product **6***a* upon thionation with phosphorus pentasulfide yielded the thione **6***b* which is probably best represented by the hypervalent sulfur structure **7**. The product **6***a* was accompanied by small amounts of a red oil, whose properties are consistent with methyl 2-methylaminodithiobenzoate **8***a*, likely formed by reduction of **1***b* with methanethiolate eliminated in the reaction, as for monocyclic isothiazolium salts (1).

Also, treatment of **1***b* with the anion of 2,2-dimethyl-1,3-dioxane-4,6-dione (Meldrum's Acid) afforded the cyclic ester **9***a*. When this was treated with perchloric acid in acetic acid it rapidly converted to the acid derivative **1***f* by ketal hydrolysis and decarboxylation of the malonic acid derivative **1***g*. We were unsuccessful, however, in converting this further to the 1,3-dimethyl-2,1-benzisothiazolium salt **1***h* by further decarboxylation as is described for 1,2-dithioles (15). Similarly **1***d* reacted with Meldrum's acid to form **9***d*.

Reactions of **1***c* or *d* with various anions proceeded similarly with little difference, other than in side products. Thus **1***c* reacted with diethyl malonate or sodium benzoylacetate to yield **3***b* and **6***c* respectively. A side product in these reactions was methyl 2-(*N*-phenylamino)dithiobenzoate (**8***b*) produced by reduction of **1***c* with eliminating methanethiolate. To check this, a sample of **1***c* was treated with methanethiol, giving **8***b* in excellent yield. This product was contaminated, however, with a small amount of 9-methylthioacridine (**10**). This does not appear to arise from **8***b* by base catalysed cyclization since its prolonged treatment with methanethiolate gave no acridine **10**. It therefore may be that it is some initial reduction product of **1***c*, possibly a radical species, that is the direct percursor of **10**. Alternatively it may be formed by initial nucleophilic attack at carbon, with subsequent production of the species **11**, which eventually cyclizes to **10**.[2]



**5** **6** **7**

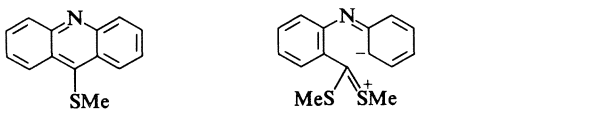
*b* $R^1$ = Ph; $R_2$ = 2-Py; $R_3$ = OMe
*c* $R^1$ = Ph; $R_2$ = OMe; $R_3$ = 2-Py
*d* $R^1$ = Ph; $R_2$, $R_3$ = $-C(=O)-O-CMe_2-O-$



**10** **11**

The treatment of **1***d* with sodium benzoylacetate also afforded **6***c*, and reaction with methyl pyridyl-2-acetate gave a dark yellow oil which could not be separated, but appears to be a mixture of the ester **9***b* and its geometrical isomer **9***c*. With the anion of 2,2-dimethyl-1,3-dioxane-2,6-dione, **9***d* was obtained. Attempted hydrolysis and decarboxylation of this gave only brown polymeric material. Both **9***a* and **9***d* exhibited low field absorptions at ~9.3 δ, no doubt due to the shielding effect of a dioxane-ring carbonyl group on the neighboring aromatic proton. These are in close proximity, due to the steric constraints of the conjugated ring systems.

[2]We are indebted to one of the referees for this suggestion.

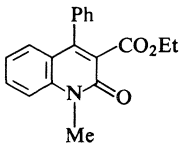
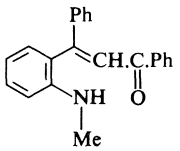
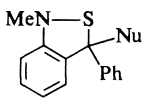
Treatment of 1-methyl-3-phenyl-2,1-benzisothiazolium perchlorate (**1***e*) with diethyl malonate under a number of conditions gave only 3-phenyl-2,1-benzisothiazole and 2-methylaminobenzophenone (**2***b*). Only a trace of material was isolated whose mass spectrum corresponded to the quinolone **12**, formed by nucleophilic attack on carbon, ring opening, and recyclization. Likewise treatment of **1***e* with sodium benzoylacetate gave 3-phenyl-2,1-benzisothiazole and **2***b*, along with what appear to be traces of the aminoketone **13**, or a tautomer, formed by nucleophilic attack of a phenacyl ion, actual or potential at ring carbon, followed by ring opening, and extrusion of a sulfur atom.



**12**



**13**



**14**

The low yields of the reaction products with the nucleophiles may be rationalized in terms of initial production of 1:1 addition products which are relatively resistant to ring opening. Nakagawa and co-workers (7) report the isolation of initial products of amines on 2,1-benzisothiazolium salts. Redissociation of adducts of type **14**, with dealkylation, or attack of water on the regenerated cation as alternate reaction pathways could produce the main products isolated. Indeed when **1***e* was treated with sodium bicarbonate, 2-methylaminobenzophenone was isolated. This is comparable to earlier reactions of simpler 2,1-benzisothiazoles (5). Two other unstable products were formed in lesser amounts which may represent side reactions.

Thus all of the products obtained in these reactions, other than dimethylation products, are consistent with nucleophilic attack at ring carbon, in contrast to isothiazolium and 1,2-benzisothiazolium salts which give products by attack of carbanions at sulfur. In terms of "Hard and Soft" acid and base theory, it implies that in the 2,1-system the carbon is "softer," and the sulfur is the "harder" in the latter systems. The low frequencies of the carbonyl stretching frequencies in **6***a* and **6***c*, as well as the two greatly different carbonyl frequencies in **3***a* and **3***c*, are indicative of partial bonding between carbonyl oxygen and sulfur atom. Similar data are available for closely related 1,6,6a$S^{iv}$ trithiapentalenes (16).

## Experimental

The $^1$H nmr spectra were obtained in deuteriochloroform solution, unless otherwise stated, on a Varian model EM 360 spectrometer using tetramethyl silane as an internal standard. Mass spectra were obtained on a Finnegan 1015 spectrometer. Chromatography was performed on Camag silica gel type D.S.F. 5, supplied by Terochem Laboratories, and elution, unless otherwise stated, was by benzene with varying proportions of chloroform. Unless otherwise stated, solutions were dried over anhydrous magnesium sulfate.

*2,1-Benzisothiazolium salts (1*a–e)

These were prepared by literature methods (5–7) or simple modifications of them.

*Reaction of 1-methyl-2,1-benzisothiazolium iodide (1*a) *with sodium bicarbonate*

This was performed as described (5). Examination of the product obtained by tlc afforded 2-methylaminobenzaldehyde (**2***a*) (34%) and 1-methyl-2,1-benzisothiazoline-3-thione (**5***a*) (22%) identical with an authentic sample (6)

*Reaction of 1-methyl-3-phenyl-2,1-benzisothiazolium perchlorate (1e) with sodium bicarbonate*

The perchlorate (326 mg, 1 mmol) was stirred in a warm mixture of ether and saturated sodium bicarbonate. After 30 min the red ether layer was separated, washed with water, dried, and evaporated to give a red oil which on chromatography yielded a broad yellow band. On elution this yielded 2-methylaminobenzophenone (**2***b*) as bright yellow needles from hexane (73%), mp 69°C (lit. (17) mp 69°C).

Two other bands gave small amounts of oily material which appeared to be unstable.

*Reaction of 1-methyl-2,1-benzisothiazolium iodide (1*a) *with triethylamine*

The salt (277 mg, 1 mmol) was added to dry triethylamine and stirred for 30 min. The solution was filtered and partitioned between dilute hydrochloric acid (10%) and ether. The ether layer on evaporation yielded a red oil which on examination by chromatography yielded 2-methylaminobenzaldehyde (36%) and 1-methyl-2,1-benziothiazoline-3-thione (21%), both identical (mixture mp) with authentic specimens (refs. 5 and 6 respectively). Use of pyridine gave similar results.

*Reaction of 1-methyl-2,1-benzisothiazolium iodide (1*a) *with diethyl malonate to form 3*a

The salt (277 mg, 1 mmol) was added to the equivalent quantity of sodium diethyl malonate in ethanol. On stirring, an orange solution resulted which was evaporated and examined by chromatography. Two main bands were evident. A yellow band was found to be 2-methylaminobenzaldehyde (20%), and a slower moving band was isolated as an orange oil which crystallized on standing under ethanol and was recrystallized from hexane as pale orange needles, mp 78–80°C. This is assigned the structure **3***a* (28%). The ir spectrum: 1611, 1702 $cm^{-1}$ (C=O str, the two different carbonyl groups) (in liquid paraffin). The nmr spectrum, δ: 1.20–1.53 (6H, two superimposed methyl triplets), 3.49 (3H, s, the N methyl), 4.12–4.65 (4H, two superimposed methylene quartlets), 6.95–8.02 (4H bands, the aromatic protons). The mass spectrum $M^+$ 307, M calcd. 307.

*Anal.* calcd. for $C_{15}H_{17}NO_4S$: C 58.63, H 5.54, N 4.56, S 10.42; found: C 58.51, H 5.61, N 4.59, S 10.53%.

*Reactions of 3-methylthio- or 3-chloro-2,1-benzisothiazolium salts 1*b, c, d *with diethyl malonate, 2,2-dimethyl-1,3-dioxane-4,6-dione, or benzoylacetic acid*

These were performed under similar conditions. The salts

were added to slight excesses (1.1 equiv.) of the anions in anhydrous ethanol (prepared by adding the ester or acid to a solution of sodium ethoxide in ethanol). The mixtures were warmed gently until homogeneous, then diluted with water, extracted with chloroform, dried, and examined by chromatography. Products from 2,2-dimethyldioxane-4,6-dione crystallized on dilution of the ethanol with water and were collected. Results of individual experiments are summarized below.

*1-Methyl-3-methylthio-2,1-benzisothiazolium iodide (1b) and sodium benzoyl acetate to form 6a*

Chromatography gave a dark yellow strongly adsorbed material and small amounts of 1-methyl-2,1-benzisothiazoline-3-thione. Separation of the dark yellow material gave an oil which could not be crystallized but had properties consistent with **6a** (76%). It was not analysed.

The ir spectrum: 1000 $cm^{-1}$ (C=O str) (as a liquid film). The nmr spectrum: δ: 3.46 (3 H, s, the *N* methyl protons), 6.85–8.25 (10H bonds, the aromatic and methine protons). The mass spectrum $M^+$ 267, M calcd. 267.

*1-Phenyl-3-methylthio-2,1-benzisothiazolium iodide (1c) and sodium benzoylacetate to form 6c*

Chromatography of the reaction mixture afforded two main products. A dark yellow band on elution and evaporation gave a viscous oil which crystallized on standing under ethanol. Compound **6c** was recrystallized from ethanol as orange prisms, mp 148–50°C (49%). The ir spectrum: 1604 $cm^{-1}$ (C=O str) (in liquid paraffin). The nmr spectrum only exhibited complex bands between δ 7.0 and 8.35. The mass spectrum, $M^+$ 329, M calcd. 329.

*Anal.* calcd. for $C_{21}H_{15}NOS$: C 76.60, H 4.50, N 4.26, S 9.73; found: C 76.73, H 4.31, N 4.28, S 9.80.

A dark orange band on elution and evaporation gave a viscous red oil whose properties were consistent with **8b** (15%). This was identical ($R_f$, nmr) to the product of a preparation described below.

*1-Phenyl-3-chloro-2,1-benzisothiazolium chloride (1d) and sodium benzoylacetate*

This reaction was performed as above. A yellow band obtained on chromatography yielded **6c** as an oil which crystallized under ethanol and was identical to that obtained above (62%).

*Reaction of 1-methyl-3-methylthio-2,1-benzisothiazolium iodide (1b) with 2,2-dimethyl-1,3-dioxane-4,6-dione to form 9a*

The reaction mixture diluted with water gave red needles which recrystallized from ethanol as pale orange needles, mp 165–166°C (43%). The aqueous filtrate on extraction with chloroform yielded more product (19%). The ir spectrum: 1610, 1699 $cm^{-1}$ (C=O str, the two different carbonyl groups) (in liquid paraffin). The nmr spectrum, δ: 1.90 (6H, s, the two C methyl groups), 3.84 (3H, s, the *N*-methyl). The aromatic protons were evident as groups at 7.05–7.83 and 9.15–9.45. The mass spectrum $M^+$ 291, M calcd. 291.

*Anal.* calcd. for $C_{14}H_{13}NO_4S$: C 57.73, H 6.47, N 4.81, S 11.00; found: C 57.62, H 4.48, N 4.90, S 11.13.

*Reaction of 3-chloro-1-phenyl-2,1-benzisothiazolium chloride (1d) with 2,2-dimethyl-1,3-dioxane-4,6-dione to form 9d*

This was performed as above. Dilution with water afforded a dark yellow precipitate which was recrystallized from ethanol as dark yellow prisms, mp 189–190°C (65%). The ir spectrum: 1609, 1699 $cm^{-1}$ (C=O str, the two carbonyl groups) (in liquid paraffin). The nmr spectrum, δ: 1.91 (6H, s, the two methyl groups). The aromatic protons were evident as groups at 7.01–7.86 and 9.13–9.41. The mass spectrum $M^+$ 352, M calcd. 353.

*Anal.* calcd. for $C_{19}H_{15}NO_4S$: C 64.59, H 4.25, N 3.97, S 9.07; found: C 64.81, H 4.26, N 3.83, S 8.94.

*Reaction of 1-methyl-3-methylthio-2,1-benzisothiazolium iodide (1b) with diethyl malonate*

On chromatography a broad yellow band was obtained which on evaporation and standing under ethanol gave **3a** as orange needles from hexane (56%) identical to above.

A faster running orange band gave ~10 mg of a red oil, assigned tentatively to the dithioester **8a**; $M^+$ 197, M calcd. 197.

*Reaction of 3-methylthio-1-phenyl-2,1-benzisothiazolium iodide (1c) with diethyl malonate to form 3b*

Chromatography of the reaction mixture gave a broad strongly absorbed yellow band which on elution gave **3b** as a yellow oil which crystallized from hexane as yellow needles, mp 80°C (42%). The ir spectrum: 1621, 1701 $cm^{-1}$ (C=O str) (in liquid paraffin). The nmr spectrum, δ: 1.31–1.62 (6H, two superimposed methyl triplets), 4.20–4.73 (4H, two superimposed methylene quartets), 6.95–8.11 (9H bands, the aromatic protons). The mass spectrum $M^+$ 369, M calcd. 369.

*Anal.* calcd. for $C_{20}H_{19}NO_4S$: C 65.04, H 5.15, N 3.79, S 8.67; found: C 64.97, H 5.23, N 3.88, S 8.53.

The reaction also yielded **8b** (10%) and small amounts of 1-phenyl-2,1-benzisothiazoline-3-thione as side products.

*Reaction of 3-chloro-1-phenyl-2.1-benzisothiazolium chloride (1d) with methyl 2-pyridylacetate*

The isothiazolium salt (282 mg, 1 mmol) and methyl 2-pyridylacetate (151 mg, 1 mmol) in anhydrous pyridine (10 mL) were refluxed 3 h. The mixture was diluted with water and partitioned between 10% dilute hydrochloric acid and chloroform. The chloroform layer was dried and evaporated to give a dark oil. Chromatography gave a broad yellow band which on elution gave an orange oil. This failed to crystallize and could not be further separated. It was not analysed but its spectral properties are consistent with a mixture of **9b** and **9c**.

The nmr spectrum, δ: 3.78, 4.01 (two singlets of the two isomers). Other protons were evident as bands between 6.95 and 8.85. The mass spectrum $M^+$ 360, M calcd. 360.

*Reaction of 1-methyl-3-phenyl-2,1-benzisothiazolium perchlorate (1e) with diethyl malonate*

The isothiazolium salt (**1e**) (32.6 mg, 1 mmol) and diethyl malonate (~0.2 g) were refluxed together in pyridine for 1.5 h. The pyridine was evaporated under reduced pressure and the product partitioned between dilute hydrochloric acid and chloroform. Examination of the chloroform solution by tlc afforded 3-phenyl-2,1-benzisothiazole (38%) and 2-methylaminobenzophenone (26%), both identical with authentic specimens (refs. 7 and 18, respectively) and only traces of a pale yellow material, mp 135°C, tentatively assigned to **12**.

The mass spectrum $M^+$ 307, M calcd. 307. The use of other reaction conditions gave poorer results.

*Reaction of 1-methyl-3-phenyl-2,1-benzisothiazolium perchlorate (1e) with sodium benzoylacetate*

The perchlorate (326 mg, 1 mmol) was added to a solution of sodium benzoylacetate, prepared from benzoylacetic acid (164 mg, 1 mmol) added to a solution of sodium (23 mg, 1 mmol) in ethanol (10 mL). The mixture was warmed until homogeneous, evaporated under reduced pressure, and examined by chromatography.

The reaction yielded only 3-phenyl-2,1-benzisothiazole, 2-methylaminobenzophenone, and traces of pale orange crystals, mp 68°C, tentatively assigned to **13**.

The mass spectrum $M^+$ 313, M calcd. 313.

*1-Methyl-2,1-benzisothiazole[2,3-b]-5-phenyl-1,2-dithiole (7)*

1-Methyl-3-phenacylidene-2,1-benzisothiazole (**6***a*) (133 mg, 0.5 mmol) in toluene (10 mL) was refluxed with phosphorus pentasulfide (0.5 g) for 30 min. The mixture was cooled and treated with saturated sodium bicarbonate solution and extracted with chloroform. Evaporation yielded a red oil which was separated by chromatography. Elution of the crimson band gave a red oil which crystallized on trituration with ethanol. Dark red prisms, mp 152–153°C, were obtained (61%). The nmr spectrum, δ: 3.60 (3H, s, the *N*-methyl), 6.95–8.29 (9H bands, the aromatic protons), 8.51 (1H, s, the methine proton). The mass spectrum $M^+$ 283, M calcd. 283.

*Anal.* calcd. for $C_{16}H_{13}NS_2$: C 67.84, H 4.59, N 4.95, S 22.61%; found: C 67.91, H 4.66, N 4.61, S 22.89%.

*1-Methyl-3-carboxymethyl-2,1-benzisothiazolium perchlorate (1f)*

The dioxane **9***a* (145 mg, 0.5 mmol) in acetic acid (3 mL) was treated with 70% perchloric acid (0.05 mL) and warmed briefly. The red solution turned pale yellow with gas evolution and separation of a crystalline precipitate. This was recrystallized from acetic acid containing a trace of perchloric acid as buff needles, mp 155°C (dec.).

The ir spectrum: 1710 $cm^{-1}$ (C=O str). It also exhibited a broad absorption between 2800 and 3200 $cm^{-1}$. *Anal.* calcd. for $C_{10}H_{10}ClNO_6S$: C 39.02, H 3.25, Cl 11.54, N 4.55, S 10.41; found: C 39.31, H 3.51, Cl 11.60, N 4.62, S 10.59%.

Further heating of this gave dark yellow polymeric material.

*Methyl 2-phenylaminodithiobenzoate (8b)*
