It is interesting to compare this approach with alternative approaches which could have been used. To begin, we could have used a relayed coherence experiment (7) in place of the homonuclear correlated experiment (6). The former approach also establishes $^1H-^1H$ connectivities between vicinal hydrogens but detects these connectivities via ^{13}C spectral peaks, taking advantage of the much greater resolution in the ^{13}C spectrum (7, 10). This would have avoided the need to carry out measurements in more than one solvent. However, due to the significantly lower sensitivity of this experiment (7), the total measuring time would have been longer than for the homonuclear correlated spectra, negating the advantages of increased resolution in this particular case.

The main advantage of the approach we have used over the use of $^{13}C-^{13}C$ connectivity (INADEQUATE) experiments is sensitivity. For example, the actual spectra in Figs. 2–4 were obtained using 200 mg of **1** and 5-h acquisition times (in view of the high signal-to-noise ratios, 1- to 2-h runs probably would have been sufficient). By contrast, when we carried out a $^{13}C-^{13}C$ connectivity experiment using the same sample, signal-to-noise was still "inadequate" after 36 h. In addition, the long range heteronuclear correlated experiment can be used to establish connectivities even through heteroatoms (e.g. $^1\underline{H}—C—O—^{13}\underline{C}(10)$). Finally, as partially illustrated in Figs. 3 and 4, it provides much redundant information which can be used to confirm the spectral assignments. There are, however, at least two potential limitations to this experiment. First, there must be resolved peaks in the ^1H spectra which can be used to unambiguously assign geminal and vicinal $^1H-^{13}C$ connectivities. This will be a problem particularly for large molecules with complex ^1H spectra but can be partially overcome by increasing digitization for the ^1H spectral domain. There may

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

also be sensitivity problems for larger molecules because their very short ^1H relaxation times result in very significant loss of ^1H magnetization during Δ_1, prior to transfer to ^{13}C. However, subsequent to submission of this manuscript, Kessler *et al.* published a modified heteronuclear correlation pulse sequence (COLOC (16)) which is specifically designed to minimize this problem. Consequently, we conclude that these limitations are not serious and that "long range" heteronuclear correlated experiments, either as used above or as modified by Kessler (16), can often provide a viable alternative to $^{13}C-^{13}C$ connectivity experiments, particularly in cases where sensitivity limitations make INADEQUATE impossible.

Experimental

Full details of the isolation of **1** have been presented elsewhere (17). 2D experiments were performed on a Varian XL-200 spectrometer at a probe temperature of ca. 20°C. Standard Varian software (G and H release) were used.

Homonuclear correlated experiments were carried out using a spectral width of 1000 Hz in each domain (ca. δ 0.5−5.5), a 512 × 512 data matrix, 256 time increments, and 16 transients for each FID. The second mixing pulse in the homonuclear (Jeener) pulse sequence (6) was set at 60° (5.2 μs), as recommended by Bax and Freeman (18). Free induction decays were subjected to "pseudo-echo" processing (18) and diagonal folding (5*b*) was applied to the final spectrum. Normal heteronuclear correlated experiments were carried out using a spectral width of 5500 Hz in the first domain (^{13}C, ca. δ 10−120) and 1000 Hz in the second domain (^1H, ca. δ 0.5−5.5), a 2048 × 512 data matrix, 128 time increments, and 128 transients per FID 2.5-Hz exponential line broadening was applied in each case. Long range heteronuclear correlated experiments were carried out in $CDCl_3$, using $\Delta_1 = 0.05$ s and $\Delta_2 = 0.033$ s. The first experiment used a ^{13}C spectral width of 2500 Hz (ca. δ 10−60) and 500 Hz in the ^1H domain (ca. δ 0.5−3.0) and a 2048 × 512 data matrix, while the second experiment differed only by using a ^{13}C spectral width of 9000 Hz (ca. 10−190) to include CO_2H and quaternary $C(sp^2)$ carbons. It should be noted that the first of the two modified heteronuclear experiments was not strictly necessary and was carried out mainly for esthetic purposes, i.e. to get a spectrum with excellent ^{13}C digital resolution for the aliphatic region (see Fig. 4).

All heteronuclear experiments were carried out in 10-mm tubes, using 200 nmg of **1** in ca. 2 mL of $CDCl_3$ or C_6D_6. Homonuclear experiments were carried out in 5-mm tubes, using aliquots of the samples from the heteronuclear experiments.

On Worrall's dilactams. Structural corrections

DOUGLAS N. BUTLER AND SUSHIL DATTA
Department of Chemistry, York University, Toronto, Ont., Canada M3J 1P3

Received March 21, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

DOUGLAS N. BUTLER and SUSHIL DATTA. Can. J. Chem. **62**, 2426 (1984).

The structures of a number of polycyclic diamides available via the action of ammonia on *exo,exo*-5,6-dibromonorbornane-*endo,endo*-2,3-dicarboxylic anhydride have been shown to be incorrectly reported. These substances all possess a nortricyclyl skeleton, e.g. **8**, **9**, and **10**.

DOUGLAS N. BUTLER et SUSHIL DATTA. Can. J. Chem. **62**, 2426 (1984).

On a démontré que les structures proposées antérieurement pour un certain nombre de diamides polycycliques disponibles par le biais de l'action de l'ammoniac sur l'anhydride dibromo-5,6 *exo,exo* norbornane dicarboxylique-2,3 *endo,endo* ne sont pas correctes. Le squelette fondamental de chacune de ces substances est le nortricyclyle, comme dans les produits **8**, **9** et **10**.
[Traduit par le journal]

For a number of years we have designed, synthesized, and studied rigid molecules which exhibit specific, intramolecular functional group proximities (2). Recently we observed that the basicity of certain diethers (eg. **1**) was markedly enhanced by the proximity of the two oxygen atoms (3) and we therefore sought to extend this concept to the equivalent diamine **2**. A survey of the literature for potential starting points revealed that the obviously desirable dilactam **3** was apparently known.

The carefully described, though somewhat tedious procedure of Worrall (1) for the "ammonolysis" of *exo,exo*-5,6-dibromonorbornane-*endo,endo*-2,3-dicarboxylic anhydride (4) was repeated and a solid isolated which by melting point, yield (28%), and infrared spectrum corresponded to the compound for which he ascribed the hydroxy-amide-lactam structure **4**. No evidence was presented by Worrall (or by us) as to the fate of the remainder of the starting material. In our hands, repeated recrystallization from methanol of this product raised the melting point considerably – perhaps because water was the solvent originally used. However, the combustion analysis, the mass spectrum, the infrared spectrum, and subsequent chemistry were all consistent with this product being the same as that isolated by Worrall. In particular, thermal deamination to a

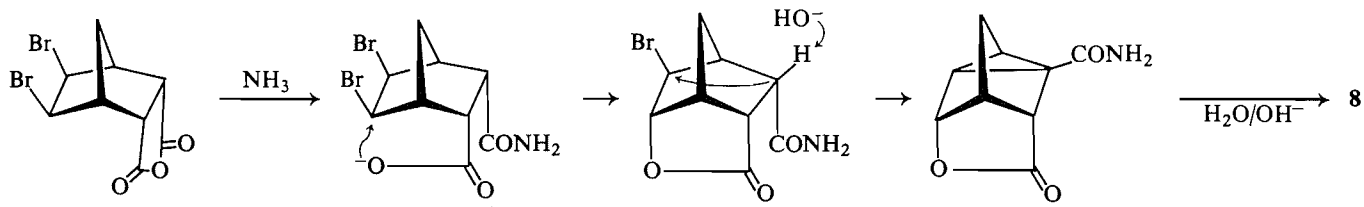
For personal use only.



SCHEME 1

lactone-lactam assigned as structure **5** (or **5′**) was readily repeated, giving a product having an identical melting point and infrared spectrum to that described. It also showed the appropriate parent-ion in its mass spectrum. Further, permanganate oxidation to a keto-amide-lactone (given as structure **6**) and its derived oxime (given as structure **7**) was easily followed using the published procedure, once again giving products of like melting points and infrared spectra and again for which appropriate parent-ions were observed. Thus there is little doubt that the compounds that we have made do indeed correspond to those originally prepared.

An examination of the compound given structure **4** by 2D FT nuclear magnetic resonance techniques quickly revealed that the assigned structures were wrong. Structure **4** is reassigned as **8** with **5**, **6**, and **7** becoming **9**, **10**, and **11** respectively. In particular, the 2D $^1H-^1H$ homonuclear shift and $^{13}H-^1H$ heteronuclear shift correlated plots were obtained in DMSO-d_6 solution and these analysed to provide the assignments given herein. Along with the two-proton AB quartet for the 7-methylene protons at δ = 1.32 and 1.48 ppm with ^2J = 10.5 Hz there were two other coupled protons (^3J = 6 Hz) at δ = 1.61 and 1.96 ppm. These correlated with the highest-field carbon lines at δ = 22.5 and 25.64 ppm, both of which showed a $J(^{13}C-^1H)$ = 179 Hz. Such large couplings for high-field carbon resonances are consistent with cyclopropyl structures and similar pairs of such proton coupled high-field carbon resonances were seen in **9**, **10**, and **11** (see Experimental). For compound **8** at 10°C, five D_2O exchangeable protons were all resolved in the ^1H spectrum in DMSO-d_6. After the exchange for deuterium, the ^1H doublet at δ = 3.75 ppm now appeared as a slightly broadened singlet and thus must be assigned as H_5. This was corroborated in the COSY plot (5) which showed the coupled —OH at δ = 5.74 ppm. At room temperature, two of the four NH lines observed upon cooling coalesced into a broad singlet (δ = 6.81 ppm) whilst the remaining two at δ = 7.27 and 7.79 coalesced upon heating to 90°C into a very broad resonance centred near δ = 7.4 ppm. Since, from the thermal cyclization (with ammonia evolution) by which **9** is produced, the *endo–endo* disposition of the functionalities involved is obligatory, we propose that hydrogen bonding between these functions (i.e. 5-hydroxyl and 3-carboxamido) is responsible for the differential behaviour of the pairs of amido protons. The remaining ^1H assignments of δ = 1.98 and 2.69 ppm, as H_4 and H_3 respectively, whilst showing only small coupling in the normal ^1H spectrum, did show weak correlations in the COSY plot with H_3 only coupling to H_4 but H_4 coupling to H_3, H_5, and to both H_7 protons. With these proton assignments in hand, the $^{13}C-^1H$ shift correlation readily allowed the carbon assignments with C_2 δ = 31.08 ppm unattached to any proton and C_7 δ = 31.70 ppm being attached to two protons ($J(^{13}C-^1H)$ = 134 Hz), confirming the corresponding ^1H resonances detailed above and C_3 and C_4 respectively at δ = 50.49 and 40.74 ppm.

These assignments allowed fully consistent analysis of the ^1H and ^{13}C routine spectra of compounds **9**, **10**, and **11** (see Experimental) and thus support our revised structures for these molecules.

Further structural proof was indirectly provided from the literature. Zalkow and Kennedy (6) repeated Worrall's preparations and found that when the lactone-lactam **5** (actually **9**) was heated with 5% hydrochloric acid, an "unusual" *N*-alkyl cleavage took place to give the known tricyclic lactone-acid **12**. Likewise, under the same conditions the ketone **6** (actually **10**) was converted to the known keto-diacid **13**. Since the structures of **12** and **13** were secure (7), the revised tricyclic structures for the starting materials, viz. **9** and **10**, of these reactions were in fact already present and no "unusual" chemistry was involved at all.

The literature preparation (7) of **12**, from alkali treatment of the same dibromo-anhydride as used in Worrall's aqueous ammonia procedure, provided an insight to the formation of **8** as rationalized in Scheme 1.

Although we did not proceed beyond the oxime **11** of Worrall's route, we have little reason to doubt that his reported dilactam **3** is, in fact, compound **14**. We have synthesized diamine **2** via an alternative route and will shortly report this chemistry.

Experimental

General

Melting points were determined an a Fisher–Johns apparatus and are uncorrected. Infrared spectra were recorded on a Unicam SP1000A instrument as Nujol mulls and mass spectra taken at 70 eV on a V. & G. Micro-mass 16F spectrometer. The ^1H and ^{13}C nuclear magnetic resonance spectra were recorded on Varian Associates EM360 (60 MHz), CFT80, or Bruker AM250 (250 MHz) instruments.

*2,3-Bis-carboxamido-5-*endo*-hydroxy tricyclo[2.2.1.0^{2,6}]heptane,* **8**

To saturated ammonium hydroxide (750 mL) was added *exo,exo*-5,6-dibromobicyclo[2.2.1]heptane-*endo,endo*-2,3-dicarboxylic anhydride (4) (76.5 g) and this stoppered mixture was allowed to stand with occasional shaking at room temperature for two weeks (solid goes into solution after 3 days). The solution was partially concentrated under vacuum at 40°C to 500 mL, diluted with an equal volume of water, and then passed through a 125 × 3.8 cm column of Amberlite IRA-400 (approx. 500 g) in the OH^- form in two halves, with the exchange column being regenerated to the OH^- form between each half. The combined effuents and washings (approx. 3 L) were evaporated under vacuum (0.05 Torr; 1 Torr = 133.3 Pa) with the bath at 40–45°C, and the residue recrystallized from hot water to give the product (12.3 g), mp 183–184°C. Four recrystallizations from methanol produced colorless crystals of **8**, mp 219–220°C; ir: 3190, 3300, 1665, 1610 cm^{-1}; ^1H nmr (DMSO-d_6) δ = 1.32 (d, J = 10.5 Hz, 1H = H_{7s}), 1.48 (d, J = 10.5 Hz, 1H = H_{7a}), 1.61 (d, J = 6 Hz, 1H = H_1), 1.96 (d, J = 6 Hz, 1H = H_6), 1.98 (narrow m, 1H = H_4), 2.69 (d, J = 2 Hz, 1H = H_3), 3.75 (d, J = 10 Hz, 1H = H_5), 5.74 (d, J = 10 Hz, 1H = OH), 6.81 (bd s, 2H = NH_2), 7.27 (bd s, 1H = NH), 7.79 (bd s, 1H = NH); ^{13}C nmr (DMSO-d_6) δ: 22.50 (d, J = 179 Hz, C_1), 25.64 (d, J = 179 Hz, C_6), 31.08 (s, C_2), 31.70 (t, J = 134 Hz, C_7), 40.74 (d, J = 149 Hz, C_4), 50.49 (d, J = 138 Hz,

Preparation and transformations of allenic ketones and 3(2*H*)-furanones

STEVEN WOLFF AND WILLIAM C. AGOSTA
Laboratories of The Rockefeller University, New York, NY 10021, U.S.A.

Received March 8, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

STEVEN WOLFF and WILLIAM C. AGOSTA. Can. J. Chem. **62**, 2429 (1984).

Swern oxidation of allenic alcohols **7** and **10** gives the corresponding ketones **3** and **12**. Reaction of **3** with ruthenium tetroxide yields the stable acyl ketene **17** and the acyloxy α-diketone **20** as well as pivalil (**4**). Formation of **20** by way of the 3(2*H*)-furanone **22** is suggested, since oxidation of **3** and **12** with osmium tetroxide followed by dehydration provides the corresponding furanones **22** and **26** in good yield. Epoxidation of **3** furnishes some **20** as well as **27** and **29**, the first stable keto allene oxide and bisepoxide, respectively. On thermolysis **27** rearranges to furanone **22**. The double bond of **22** is cleaved by peracid to form **20**; similar treatment of **31***a, b* leads to cleavage of the double bond accompanied by Baeyer–Villiger oxidation, with formation of the carboxylic acids corresponding to methyl esters **33***a, b* as the major products.

STEVEN WOLFF et WILLIAM C. AGOSTA. Can. J. Chem. **62**, 2429 (1984).

Une oxydation de Swern des alcools alléniques **7** et **10** conduit aux cétones correspondantes **3** et **12**. La réaction de **3** avec le tétroxyde de ruthénium fournit l'acyl cétène stable (**17**), l'acyloxy α-dicétone (**20**) ainsi que le pivalile (**4**). On suggère que la formation de **20** se produit probablement via la (2*H*)-furanone-3 (**22**) puisque l'oxydation des composés **3** et **12** par le tétroxyde d'osmium, suivie d'une déshydratation, conduit aux furanones correspondantes **22** et **26** avec de bons rendements. L'époxydation du composé **3** conduit à un peu de composé **20** aux côtés des composés **27** et **29**, respectivement les premiers céto allène oxyde et bisépoxyde stables. La thermolyse du produit **27** provoque une transposition en furanone **22**. On a coupé la double liaison du composé **22** par traitement avec un peracide et on a ainsi obtenu le composé **20**; un traitement semblable des composés **31***a, b* conduit à une coupure de la double liaison qui est accompagnée d'une réaction d'oxydation de Baeyer–Villiger conduisant à la formation, comme produits majeurs, des acides carboxyliques correspondants aux esters méthyliques **33***a, b*.

[Traduit par le journal]

Irradiation of the α,β-acetylenic ketone **1** and tetramethylethylene in wet benzene leads to efficient formation of the cyclopropenol **2**, a reaction we have explained by the path shown in [1] (1). Part of the evidence for the constitution of **2** is its thermal fragmentation to form conjugated allenic ketone **3** and dimethylcarbene or its equivalent (1). In the course of securing the structure of **3** we treated it with excess ruthenium tetroxide and obtained pivalil (**4**) (1) along with two other oxidation products not yet described in detail. Investigation of these two compounds led us to examine the preparation and reactions both of allenic ketones and of the 3(2*H*)-furanones that were found to be important oxidation products of the allenes. Overall, we have found new routes to both allenic ketones and furanones; we have observed several novel oxidations of both these types of ketones; and we have encountered the first examples of an acyl ketene, an acyl allene oxide, and an acyl allene bisepoxide that are isolable by virtue of steric stabilization. Details are given below.

Investigation of the reactions of **3** with any convenience required a more suitable source of this ketone. This was available through reaction (2) of pivalaldehyde with the lithium derivative **5** of 1,1-dimethyl-3-*tert*-butylallene (**6**) (3), which yielded a 4:1 mixture of alcohol **7** and its acetylenic isomer **8**. Oxidation of these alcohols using oxalyl chloride in dimethyl sulfoxide (4) converted them into **3** and **9**, respectively, in high yield. The properties of **3** prepared in this fashion were identical with those of the compound formed thermally from **2**. Difficulties in oxidation of allenic alcohols to the corresponding ketones are well known (5) and this convenient application of Swern's conditions (4) appeared attractive. We found that they worked equally well on the trisubstituted allenic alcohol **10** to furnish **12**. Alcohol **10**, accompanied by a small amount

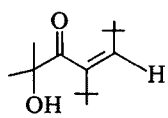
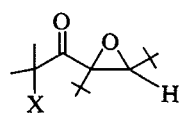
12

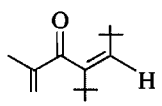
of its prototropic isomer **11**, was available from addition of the lithium derivative of 1,1-dimethylallene to pivalaldehyde. In keeping with the previous difficulties mentioned, oxidation of **7** by other methods, including Jones's reagent (6), Collins's reagent (7), and pyridinium chlorochromate (8), gave no allenic ketone. We did, however, isolate pivalil (**4**) and varying amounts of five other products from these attempts. These latter compounds were identified as **13**–**16** from their spectroscopic properties. The assignment of geometry to **13** and **15** follows from comparison of their nuclear magnetic resonance (nmr) spectra with data reported for *E*- and *Z*-3-methyl-3-penten-2-one (9). The stereochemical assignments for **14** and **16** are tentative but supported by nmr data for related systems (10). Related oxidations of hindered secondary allylic alcohols are known, and their possible mechanisms have been discussed (11). Efforts to reach **3** more directly by reaction of **5** with either pivalyl chloride or *N*,*N*-dimethylpivalamide (12) gave mixtures containing little or none of the desired product.



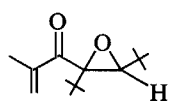
13



14
a, X = OH; *b*, X = H

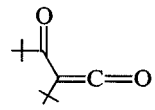


15

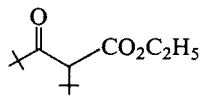


16

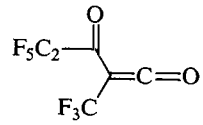
We turn now to the two oxidation products from **3**. The simpler of these is formed in very low yield and was recognized from its spectroscopic properties as *tert*-butyl pivalyl ketene (**17**). We confirmed this structure through slow reaction of **17** with warm ethanol to furnish the known (13) β-ketoester **18**. Acyl ketenes have been recognized as transient intermediates for years, but they typically dimerize unless trapped by some dienophile (14). More recently, perfluoro methyl propionyl ketene (**19**) has been isolated; this inductively stabilized ketene does not dimerize but is quite reactive in [4 + 2] cycloadditions (15). Ketene **17** appears to be the first isolable acyl ketene stabilized only by bulky substituents, and its kinetic stability is similar to that of di-*tert*-butyl ketene (16).



17

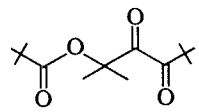


18

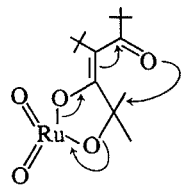


19

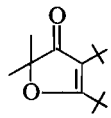
The remaining compound formed on oxidation of **3** with ruthenium tetroxide was a yellow oil with surprising spectroscopic properties that were compatible only with ester α-diketone **20**. In justifying this unexpected transformation we reasoned that, if ruthenium tetroxide initially oxidized **3** to **21**, this intermediate might well cyclize to the furanone, **22**. The related cyclization of α′-hydroxy β-diketones to furanones occurs readily under mild conditions (17). Cleavage of **22** at the double bond by ruthenium tetroxide could then furnish **20**.



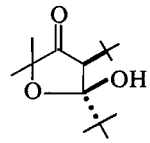
20



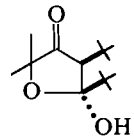
21



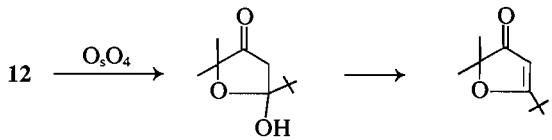
22



23



24

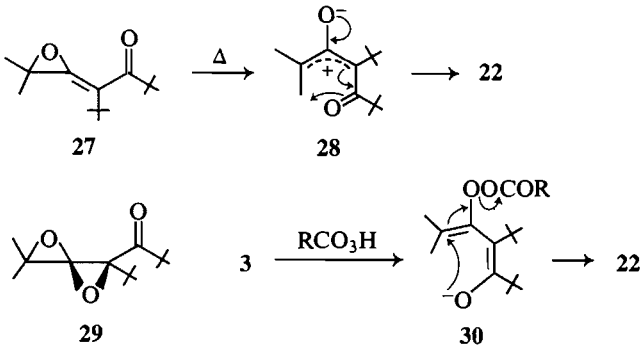


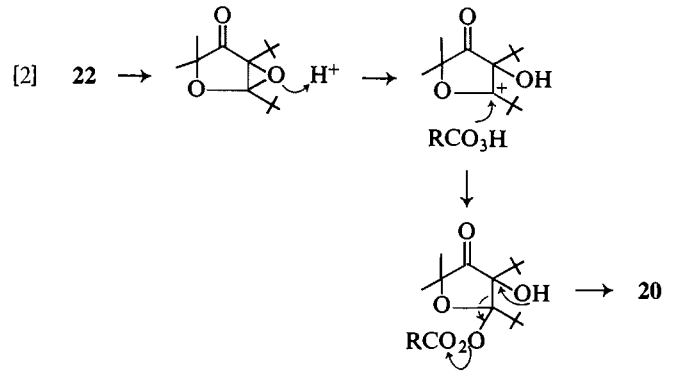
25 26

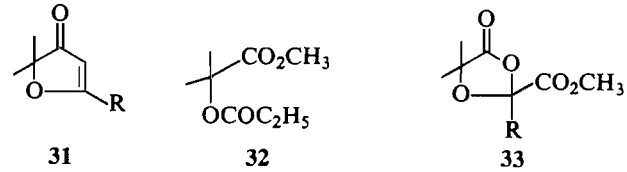
Support for this explanation came from treatment of **3** with osmium tetroxide (18). Oxidation proceeded smoothly with this milder reagent and furnished the cyclic hemiketals **23** and **24**. Only a few percent of the latter, very congested isomer was obtained, and it lost water to give **22** on attempted purification. Treatment of the crude hemiketal mixture with acid furnished **22** in high yield. The spectroscopic properties of **22** are appropriate for a 3(2*H*)-furanone; especially noteworthy are the characteristic (19) ^{13}C nmr signals for the olefinic carbon atoms at 118 and 190 ppm. Oxidation of **22** with ruthenium tetroxide in carbon tetrachloride yielded the yellow diketone **20**, thus completing experimental support for the suggested path from **3**.

Conversion of **3** into **22** is interesting, since synthesis of 3(2*H*)-furanones has commanded considerable attention in recent years (17). Similar oxidation of **12** with osmium tetroxide gave hemiketal **25**, and subsequent dehydration furnished the known (17) furanone **26** in good yield.

In exploring oxidation of **3** we also examined its reaction with *m*-chloroperbenzoic acid in methylene chloride. This gave two new products along with some **20**. The first of these new compounds was the keto allene oxide **27**, which was sufficiently stable for complete characterization. A particularly distinctive spectroscopic feature of **27** is the infrared (ir) band at 1786 cm^{-1}, an absorption typical of allene oxides (20, 21). Epoxidation of allenes is known to be sensitive to steric hindrance (22) and the effective bulk of peracids is enhanced in







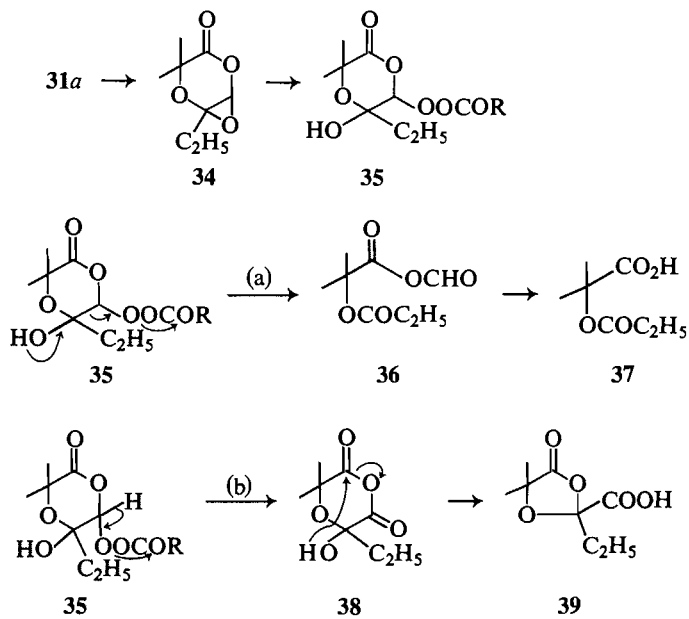
31 32 33

a, R = C_2H_5; *b*, R = $CH(CH_3)_2$

methylene chloride as solvent (23); for these reasons the single allene oxide obtained is considered to be the isomer shown as **27**. Although allene oxides have been known for some time (20, 21), **27** is the first characterized epoxide derived from a conjugated allenic ketone (5). On heating to 125°C it smoothly isomerizes to **22**, presumably by way of zwitterion **28** (21) or the corresponding biradical. This result lends support to the earlier suggestion (24) of an unisolated acyl allene oxide intermediate in conversion of an allenic ketone to a 3(2*H*)-furanone (5–10%) on reaction with hydrogen peroxide in hot formic acid. Related oxidative cyclizations of allenic alcohols and esters are also known (25). The second product from peracid oxidation of **3** was also formed on resubmission of **27** to the conditions of oxidation. This fact, together with previous observations on the oxidation of hindered allenes (22), suggests that the second product is spiro bisepoxide **29**, an assignment supported by the presence of an ir absorption at 1616 cm^{-1} characteristic of such systems (22), carbonyl absorption typical of an ordinary *tert*-butyl ketone (1693 cm^{-1}), and ^{13}C nmr absorption at 90.5 ppm attributable to the spiro carbon atom bearing two oxygen atoms.

The third product from treatment of **3** with peracid was **20**. Since exposure of **27** to mild acid in methylene chloride leads to no reaction and reexposure of **27** to peracid yields only **29**, it appears that neither of these epoxides is an intermediate in oxidation of **3** to **20**. A reasonable possibility is that Michael addition of *m*-chloroperoxybenzoate anion to **3** competes with epoxidation. Cyclization of the resulting enolate **30** with expulsion of *m*-chlorobenzoate anion would then give the furanone **22**, oxidative cleavage of which by peroxy acid could furnish **20**. The last step of this proposed sequence was demonstrated experimentally; **22** undergoes smooth reaction with *m*-chloroperbenzoic acid to give **20**. As depicted in [2], this transformation can be understood as initial epoxidation, followed by ring opening, attack of a second molecule of peracid on the derived alkoxy-stabilized carbonium ion, and subsequent elimination of *m*-chlorobenzoic acid, all in analogy with the long-known scission of simple enol ethers by peroxyacids (26).

We have also investigated this oxidation in two other 3(2*H*)-furanones, **31***a* and *b* (17). Treatment of **31***a* with *m*-chloroperbenzoic acid yielded a mixture of two acidic products that were conveniently isolated and purified after esterification with ethereal diazomethane. The first of these (~10%) was identified as the propionate ester of methyl α-hydroxyisobutyrate (**32**) from its composition and spectroscopic properties. The characteristics of the accompanying major ester (~50%) were most consistent with its formulation as the 1,3-dioxolan-4-one **33***a*. Especially significant in this regard was intense carbonyl absorption in the ir spectrum at 1814 cm^{-1}, since both the high frequency and the intensity of the carbonyl band in such dioxolanones have been noted (27). This structural assignment was verified by independent synthesis of **33***a* through acid-catalyzed ketalization (27) of methyl α-ketobutyrate with α-hydroxyisobutyric acid. Reaction of **31***b* with peroxyacid led to analogous transformations, but in this case too little of the minor product was obtained for characterization. Although various mechanisms may be entertained for these oxidations, in the absence of additional evidence it seems appropriate to write the most economical sequence, and this is shown for **31***a* in the accompanying scheme. Baeyer–Villiger reaction accompanied by epoxidation gives **34** in a process that has analogy in the quantitative conversion of a cyclopentenone into an epoxy δ-lactone (28). Subsequent opening of the epoxide by peroxyacid furnishes the key intermediate **35**. Fragmentation of this along path (a) (see [2] above) (26) leads to the unstable mixed formyl anhydride **36**, which should decompose to product **37**. Alternatively, oxidative elimination of *m*-chlorobenzoate from **35** by path (b) (29) should provide the hydroxyanhydride **38**. Intramolecular acyl transfer through the



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

boat form of **38** could then furnish **39**. Subsequent esterification of **37** and **39** with diazomethane yields the observed products **32** and **33***a*. Thus, peracid oxidation of **31***a* and *b* leads to the Baeyer–Villiger reaction as well as the epoxidation that occurs with **22**. Presumably Baeyer–Villiger attack on the carbonyl group of **22** is prevented by the adjacent *tert*-butyl substituent at C(4). These rather clean oxidations of **22** and **31***a* and *b* with peracid stand in contrast to previous observation of the "massive decomposition" of 3(2*H*)-furanones on exposure to a variety of oxidizing agents (30).

Experimental

Materials and equipment

General procedures have been previously described (1). All vapor phase chromatography (vpc) was carried out by using a Varian Aerograph Model 920 gas chromatograph with one of the following columns: A, 25% QF-1, 10 ft; B, 22.5% Carbowax 20 M, 7 ft; C, 25% QF-1, 3 ft; D, 22.5% Carbowax 20 M, 8 ft; E, 25% Carbowax 20 M, 4 ft. All columns were packed in 0.25-in. aluminum tubing with 45/60 Chromosorb W except column B which used 60/80 Chromosorb P. In addition to a Varian T-60A nmr spectrophotometer, a Nicolet/Oxford NT-300 (300 MHz for ^{1}H) instrument was also employed. Unless otherwise noted, all pure compounds were obtained as colorless oils; melting points are corrected; boiling points are uncorrected; products are usually listed in order of their elution upon column or vapor phase chromatography.

*Reaction of 1,1-dimethyl-3-*tert*-butylallene-3-lithium (**6**) with trimethylacetaldehyde*

To a solution of **6** (3) (1.242 g, 10 mmol) in THF (25 mL), cooled to −40°C under a N_2 atmosphere, was added *tert*-butyllithium (5 mL of a 2 *M* solution, 10 mmol) (12). The mixture was maintained at this temperature for 21 h, then cooled to −78°C before the addition of trimethylacetaldehyde (1.0 g, 11.6 mmol). The reaction was allowed to warm to 25°C, poured into ice/H_2O, and was extracted with Et_2O. The residue obtained after removal of solvent by distillation through a Vigreux column was distilled with a short-path apparatus to give an oil (1.084 g, 52%), bp 95–104°C (12 Torr; 1 Torr = 133.3 Pa) which vpc analysis (column A, 140°C) indicated to be a mixture of 2 components in the ratio of 1:4. These were separated by preparative vpc. The minor, first eluted compound was 2,2,4,4,7,7-hexamethyl-5-octyn-3-ol (**8**); ir: 3645 (w), 3540 (w), 2975 (s), 1469 (m), 1357 (m), 1040 (m), 998 (m) cm^{-1}; nmr (60 MHz) δ: 2.90 (d, J = 8 Hz, 1H), 1.58 (d, J = 8 Hz, 1H), 1.24 (s, 6H), 1.18 (s, 9H), 1.02 (s, 9H). *Anal.* calcd. for $C_{14}H_{26}O$: C 79.93, H 12.46; found: C 80.07, H 12.48. The second compound was 4-*tert*-butyl-2,2,6-trimethyl-4,5-heptadien-3-ol (**7**); ir: 3615 (w), 2960 (s), 1387 (m), 1360 (m), 988 (s), 891 (w) cm^{-1}; nmr (60 MHz) δ: 3.57 (br d, $J \cong$ 8 Hz, 1H) 1.68 (s, 6H), 1.05 (s, 9H), 0.92 (s, 9H), 0.83 (br d, 1H). *Anal.* calcd. for $C_{14}H_{26}O$: C 79.93, H 12.46; found: C 79.99, H 12.41.

Swern oxidation of 7 and 8

A mixture of crude alcohols **7** and **8** (3.766 g, 17.9 mmol) was oxidized with $(COCl)_2$ (2.614 g, 20.6 mmol) and DMSO (3.22 g, 41.2 mmol) in CH_2Cl_2 according to the method of Swern and co-workers (4). Bulb-to-bulb distillation afforded an oil (2.627 g, 70%), bp 90–100°C (20 Torr) which vpc analysis (column A, 140°C) indicated to be a mixture of 2 components in the ratio of 1:4. These were separated by preparative vpc. The first, minor component was 2,2,4,4,7,7-hexamethyl-5-octyn-3-one, mp 35–36°C; ir: 2960 (s), 1697 (s), 1362 (m), 1277 (m), 1050 (m), 986 (m) cm^{-1}; nmr (300 MHz) δ: 1.34 (s, 9H), 1.31 (s, 6H), 1.19 (s, 9H); ^{13}C nmr δ: 215.25, 92.60, 83.25, 45.96, 41.46, 30.90, 29.63, 27.51, 27.27; mass spectrum m/z: 208.1763 (M^+, calcd. for $C_{14}H_{24}O$: 208.1826). The second component was **3**, identical in all respects to the compound obtained previously (1).

Oxidation of 7 with chromium reagents

The allenic alcohol **7** (50.8 mg) in acetone (4 mL), cooled to 5°C, was treated with excess Jones's reagent for 1 h. Standard work-up yielded an oil (46.6 mg, 92%) which vpc analysis indicated to be a mixture of four major components. The first component (10%) was pivalil (**4**). The second component was a mixture of **15** (4%) and **16** (27%). These were separated by flash chromatography with 98:2 hexanes/Et_2O. First eluted was **16**; ir: 2960 (s), 2865 (m), 1664 (s), 1364 (s), 1081 (m), 952 (s), 877 (m), 842 (w) cm^{-1}; nmr (60 MHz) δ: 6.45 (br s, 1H), 5.88 (m, 1H), 2.53 (s, 1H), 1.80 (br s, 3H), 0.93 (s, 9H), 0.83 (s, 9H); mass spectrum m/z: 224.1772 (M^+, calcd. for $C_{14}H_{24}O_2$: 224.1776). The second compound was **15**; ir: 2960 (s), 2860 (m), 1657 (s), 1475 (m), 1360 (m), 1110 (m), 955 (w), 937 (w), 730 (w) cm^{-1}; nmr (60 MHz) δ: 5.88 (br s, 2H), 5.40 (s, 1H), 1.87 (br s, 3H), 1.03 (s, 9H), 0.93 (s, 9H); mass spectrum m/z: 208.1832 (M^+, calcd. for $C_{14}H_{24}O$: 208.1828). The third component (10%) was **14***b*; ir: 2965 (s), 1698 (s), 1475 (s), 1395 (w), 1382 (w), 1365 (s), 910 (m) cm^{-1}; nmr (60 MHz) δ: 3.00 (septet, J = 6.5 Hz, 1H), 2.60 (s, 1H), 1.15 (d, J = 6.5 Hz, 3H), 0.98 (d, J = 6.5 Hz, 3H), 0.97 (s, 9H), 0.90 (s, 9H); mass spectrum m/z: 226.1925 (M^+, calcd. for $C_{14}H_{26}O_2$: 226.1933). The fourth component was a mixture of **13** (14%) and **14***a* (35%); these were separated by flash chromatography using 85:15 hexanes/Et_2O. First eluted was **14***a*, mp 56.5–57°C; ir: 3575 (m), 2955 (s), 1710 (s), 1464 (m), 1366 (m), 1192 (s), 969 (m), 899 (m) cm^{-1}; nmr (60 MHz) δ: 3.07 (br s, 1H), 2.62 (s, 1H), 1.36 (br s, 6H), 1.03 (s, 9H), 0.98 (s, 9H); ^{13}C nmr δ: 212.94, 79.75, 73.04, 68.99, 34.63, 31.59, 31.18, 27.49, 27.24. *Anal.* calcd. for $C_{14}H_{26}O_3$: C 69.38, H 10.81; found: C 69.53, H 10.86. The second eluted compound was **13**, mp 62–63°C; ir: 3560 (w), 2960 (s), 1680 (s), 1475 (m), 1360 (m), 965 (m) cm^{-1}; nmr (60 MHz) δ: 5.37 (s, 1H), 2.28 (br s, 1H), 1.42 (s, 6H), 1.13 (s, 9H), 1.03 (s, 9H). *Anal.* calcd. for $C_{14}H_{26}O_2$: C 74.28, H 11.58; found: C 73.98, H 11.67.

Oxidation of **7** (69.5 mg, 0.33 mmol) in CH_2Cl_2 (3 mL) with pyridinium chlorochromate (172.6 mg, 0.80 mmol) yielded a mixture (60.8 mg, 87%) of **4** (5%), **15** (5%), **14***a* (5%), and **13** (85%).

Oxidation of **7** (60.0 mg, 2 mmol) with the complex prepared from CrO_3 (200 mg, 2 mmol) and pyridine (323 mL) in CH_2Cl_2 (5 mL) yielded an oil (56.4 mg, 94%) consisting of **15** and **16** (18%), **13** (65%), and **14***a* (17%).

Reaction of 1,1dimethylallene-3-lithium with trimethylacetaldehyde

To a solution of dimethylallene (1.362 g, 20 mmol) in THF (30 mL), cooled to −40°C under a N_2 atmosphere, was added *tert*-butyllithium (10 mL of a 2 *M* solution, 20 mmol). The mixture was stirred at −40°C for 2.5 h. It was then cooled to −78°C and trimethylacetaldehyde (1.72 g, 20 mmol) in THF (5 mL) was added. The mixture was allowed to warm to 25°C and was worked up as described above. Short-path distillaiton yielded an oil (2.081 g, 67%) which vpc analysis (column A, 120°C) showed to be a mixture of two components. The first component (12%) was 2,2,6-trimethyl-4-heptyn-3-ol (**11**); ir: 3625 (m), 3475 (w), 2975 (s), 2870 (m), 2235 (w), 1363 (m), 1318 (m), 995 (s) cm^{-1}; nmr (60 MHz) δ: 3.55 (d, J = 1.5 Hz, 1H), 2.58 (m, 1H), 1.43 (br s, 1H), 1.18 (d, J = 7 Hz, 6H), 0.95 (s, 9H). *Anal.* calcd. for $C_{10}H_{18}O$: C 77.86, H 11.76; found: C 77.78, H 11.80. The second component (88%) was 2,2,6-trimethyl-4,5-heptadien-3-ol (**10**); ir: 3625 (w), 3570 (w), 2970 (s), 1958 (w), 1628 (w), 1475 (m), 1358 (s), 1086 (m), 993 (m) cm^{-1}; nmr (60 MHz) δ: 5.08 (septet, J = 3.5 Hz, 1H), 3.63 (d, J = 6 Hz, 1H), 1.72 (d, J = 3.5 Hz, 6H), 1.33 (br s, 1H), 0.88 (s, 9H). *Anal.* calcd. for $C_{10}H_{18}O$: C 77.86, H 11.76; found: C 77.92, H 11.70.

*Swern oxidation of **10** and **11***

A mixture of **10** and **11** (1.137 g, 7.4 mmol) was oxidized with $(COCl)_2$ (0.74 mL) and DMSO (1.25 mL) in CH_2Cl_2 according to the published procedure (4). Short-path distillation gave an oil (884 mg, 78%), bp 79–85°C (16 Torr). Preparative vpc (column B, 135°C) gave 2,2,6-trimethyl-4-heptyn-3-one (18%); ir: 2975 (s), 2930 (s), 2865 (s), 2250 (m), 2200 (s), 1667 (s), 1474 (m), 1362 (w), 1312 (m), 1181 (s), 1127 (s), 918 (s) cm^{-1}; nmr (60 MHz) δ: 2.73 (septet, J = 7 Hz, 1H), 1.28 (d, J = 7 Hz, 6H), 1.15 (s, 9H); mass spectrum m/z: 95.0495 ((M − t-Bu)$^+$, calcd. for C_6H_7O: 95.0497). The second eluted component (82%) was **12**; ir: 2970 (s), 1955 (m), 1668 (s),

1388 (m), 1124 (s), 1066 (m), 975 cm^{-1}; nmr (60 MHz) δ: 5.77 (septet, J = 3.5 Hz, 1H), 1.81 (d, J = 3.5 Hz, 6H), 1.17 (s, 9H). *Anal.* calcd. for $C_{10}H_{16}O$: C 79.93, H 12.46; found: C 79.99, H 12.41.

Oxidation of 4-tert-butyl-2,2-6-trimethyl-4,5-heptadien-3-one (3) with ruthenium tetroxide

Oxidation of **3** was carried out as previously described (1). In addition to pivalil (**4**), *tert*-butyl pivalyl ketene (**17**, ~5%) was detected; ir: 2105 (s) and 1658 (m) cm^{-1}; nmr (60 MHz) δ: 1.22 (s) and 1.2 (s). A mixture of **4** and **17** in CCl_4 (4 mL) containing ethanol (1 mL) was allowed to stand at 25°C overnight; no reaction was detected. The mixture was heated at 50°C for 4 h to afford **18**, which was isolated by preparative vpc and whose ir and nmr spectral characteristics were identical to those reported (13). The third compound isolated from this reaction was **20**, a yellow oil: uv λ_{max}: 402 nm (ε = 23.5); ir: 3000 (m), 1711 (s), 1477 (m), 1297 (m), 1132 (m), 900 (w) cm^{-1}; nmr (60 MHz) δ: 1.56 (s, 6H), 1.23 (s, 9H), 1.15 (s, 9H). *Anal.* calcd. for $C_{14}H_{24}O_4$: C 65.59, H 9.44; found: C 66.12, H 9.42.

Osmium tetroxide oxidation of 3

To a solution of OsO_4 (657 mg, 2.58 mmol) in pyridine (10 mL) was added allene **3** (511 mg, 2.45 mmol). The mixture was stirred for 2 days at 25°C. Hydrolysis of the osmate ester was accomplished by the addition of $NaHSO_3$ (1.3 g) in 2:1 H_2O/pyridine (15 mL) and stirring for 5 h. Dilution with H_2O and extraction with Et_2O afforded an oil (635 mg) which vpc analysis (column C, 130°C) indicated to be a mixture of 2 components in a 1:10 ratio. The major component was collected by preparative vpc and was identified as **23**, mp 78–79°C; ir: 3600 (m), 2955 (s), 1750 (s), 1480 (m), 1464 (m), 1390 (m), 1374 (m), 1365 (m), 1095 cm^{-1}; nmr (60 Mz) δ: 2.30 (s, 1H), 2.17 (br s, 1H), 1.30 (s, 6H), 1.20 (s, 9H), 1.02 (s, 9H). *Anal.* calcd. for $C_{14}H_{26}O_3$: C 69.49, H 10.71; found: C 69.38, H 10.81. Attempted purification of the first eluted minor component resulted in partial dehydration to **22**, but the following nmr data were obtained, permitting identification of this material as **24**; nmr (60 MHz) δ: 5.1 (s, 1H), 2.03 (br s, 1H), 1.40 (s, 3H), 1.28 (s, 3H), 1.25 (s, 9H), 1.08 (s, 9H).

Preparation of 2,2-dimethyl-4,5-di-tert-butyl-3(2H)-furanone (22)

A mixture of **23** and **24** (592 mg, 2.44 mmol) in benzene (50 mL) containing a trace of *p*-toluenesulfonic acid was heated to reflux for 4 h with removal of H_2O in a Dean–Stark trap. The reaction mixture was cooled, washed with aqueous $NaHCO_3$, and dried. Removal of solvent yielded a semi-solid (458 mg, 84%); vpc analysis (column C, 120°C) indicated the absence of starting materials and the formation of one product. This was collected preparatively and identified as **22**, mp 51–52°C; uv λ_{max}: 275 (log ε = 3.92); ir: 2995 (s), 1687 (s), 1532 (m), 1339 (m), 1176 (m), 1057 (m), 992 (m) cm^{-1}; nmr (60 MHz) δ: 1.37 (s, 9H), 1.32 (s, 9H), 1.20 (s, 6H); ^{13}C nmr δ: 209.97, 190.25, 118.41, 81.73, 36.86, 31.28, 29.90, 27.08, 23.07; mass spectrum m/z: 224.1775 (M^+, calcd. for $C_{14}H_{24}O_2$: 224.1776).

Oxidation of 2,2,6-trimethyl-4,5-heptadien-3-one (12) with osmium tetroxide

The allenic ketone (**12**) (154 mg, 1.01 mmol) was added to a pyridine solution (4 mL) of OsO_4 (311 mg, 1.22 mmol). The mixture was stirred for 45 h at 25°C and was worked up as above to yield an oil (119 mg); vpc analysis (column A, 140°C) indicated one component which was collected and identified as 2,2-dimethyl-5-*tert*-butyl-3(2*H*)-furanone on the basis of its nmr (60 MHz) and ir spectra, which were identical to those reported (17).

Oxidations of furanone 22

Furanone **22** (~6 mg) in CCl_4 (0.5 mL) was added to RuO_4 (from RuO_2, 10 mg) in CCl_4 (2 mL). Precipitation of black RuO_2 was instantaneous. Excess oxidant was destroyed by the addition of 2-propanol; vpc analysis (column B, 150°C) indicated complete disappearance of starting material and the formation of one product with the retention time of **20**. This was collected and identified spectroscopically as **20**.

The reaction of **22** (47 mg) with *m*-chloroperbenzoic acid (49.2 mg) in CH_2Cl_2 (1 mL) was complete in 1 h as monitored by vpc analysis. The mixture was diluted with Et_2O, washed with aqueous $NaHSO_3$, $NaHCO_3$, and brine, and was dried. After removal of solvent, the residue was purified by preparative vpc to afford **20**, whose nmr and ir spectra were identical to those obtained previously.

Oxidation of allene 3 with m-chloroperbenzoic acid

Allene **3** (111.4 mg, 0.54 mmol) in CH_2Cl_2 (5 mL) was treated with *m*-chloroperbenzoic acid (175.2 mg, 1.0 mmol) for 24 h at 25°C. Work-up as before yielded a residue that vpc analysis (column D, 150°C) indicated to be a mixture of 3 components. These were collected and identified as (in order of elution) **3** (50%), **20** (10%), and **22** (25%).

Similar treatment of **3** (166 mg) with MCPBA (414 mg) in CH_2Cl_2 (4 mL) gave, after flash chromatography with 95:5 hexanes/Et_2O, in addition to small amounts of **3** and **20**, two new products. The first of these was **27** (35 mg, 20%); ir: 2980 (s), 2890 (s), 1786 (w), 1663 (s), 1475 (s), 1387 (m), 1372 (m), 1358 (m), 1261 (m), 1161 (m), 1050 cm^{-1}; nmr (60 MHz) δ: 1.55 (s, 6H), 1.13 (s, 18H); mass spectrum m/z: 224.1782 (M^+, calcd. for $C_{14}H_{24}O_2$: 224.1776). The second eluted new compound was bisepoxide **29** (84 mg, 44%); ir: 2970 (s), 2930 (s), 2875 (m), 1693 (s), 1616 (m), 1477 (s), 1394 (m), 1378 (m), 1366 (m), 1144 (m), 961 (m), 915 (m), 856 (s) cm^{-1}; nmr (60 MHz) δ: 1.50 (s, 6H), 1.21 (s, 9H), 1.05 (s, 9H); ^{13}C nmr nmr δ: 210.49, 90.53, 77.37, 63.17, 45.47, 34.91, 27.33, 27.01, 22.11, 19.92. *Anal.* calcd. for $C_{14}H_{24}O_3$: C 69.96, H 10.07; found: C 70.00, H 9.84.

Treatment of allene oxide 27 with MCPBA

To a solution of **27** (~60 mg, 0.27 mmol) in CH_2Cl_2 (3 mL) was added MCPBA (140 mg, 0.81 mmol). The mixture was stirred at 25°C overnight. The usual work-up afforded an oil (59 mg, 92%) whose nmr and ir spectra indicated it to be **29**.

Thermolysis of allene oxide 27

Preparative vpc (column D, 150°C) of **27**, isolated by flash chromatography, afforded furanone **22**. Alternatively, a benzene solution of **27** was heated at 100°C for 5.5 h. A nmr spectrum of the residue after removal of solvent indicated the formation of **22** (~85% purity).

Oxidation of 2,2-dimethyl-5-ethyl-3(2H)-furanone (31a) with MCPBA

A mixture of **31***a* (167 mg, 1.19 mmol) and MCPBA (653 mg, 3.78 mmol) in CH_2Cl_2 (10 mL) was stirred at 25°C for 3 days; vpc analysis (column E, 135°C) indicated the presence only of starting material. The mixture was filtered and treated with excess diazomethane. After removal of solvent, vpc analysis indicated the presence of 3 additional peaks. The first component was **32** (18 mg, 9%); ir: 2995 (m), 2950 (m), 1748 (s), 1183 (m), 1193 (s), 1168 (s), 1129 (s) cm^{-1}; nmr (60 MHz) δ: 3.65 (s, 3H), 2.26 (q, J = 7 Hz, 2H), 1.48 (s, 6H), 1.10 (t, J = 7 Hz, 3H). *Anal.* calcd. for $C_8H_{14}O_4$: C 55.16, H 8.10; found: C 55.07, H 8.15. Eluted second was unreacted **31***a*. The third component was **33***a* (114 mg, 51%); ir: 3010 (m), 2970 (w), 1814 (s), 1761 (s), 1378 (w), 1175 (m) cm^{-1}; nmr (60 MHz) δ: 3.82 (s, 3H), 1.99 (q, J = 7 Hz, 2H), 1.46 (s, 6H), 0.97 (t, J = 7 Hz, 3H); ^{13}C nmr δ: 174.70, 168.54, 105.20, 77.93, 53.07, 29.07, 25.85, 24.12, 6.22. *Anal.* calcd. for $C_8H_{14}O_5$: C 53.46, H 6.98; found: C 53.66, H 6.94. The last component was methyl *p*-chlorobenzoate.

Oxidation of 2,2-dimethyl-5-isopropyl-3(2H)-furanone (31b) with MCPBA

Similar treatment of **31***b* (72 mg, 0.5 mmol) in CH_2Cl_2 (5 mL) with MCPBA (711 mg, 3.5 mmol) for 45 h at 25°C and then with diazomethane yielded **33***b* (47 mg, 44%); ir: 3005 (m), 1812 (s), 1758 (s), 1262 (m), 1175 (m), 1032 (m) cm^{-1}; nmr (60 MHz) δ: 3.80 (s, 3H), 2.02 (septet, J = 7 Hz, 1H), 1.45 (s, 3H), 1.4 (s, 3H), 0.96 (d, J = 7 Hz, 6H). *Anal.* calcd. for $C_{10}H_{16}O_5$: C 55.54, H 7.46; found: C 55.73, H 7.40.

Preparation of 2-carbomethoxy-2-ethyl-5,5-dimethyl-1,3-dioxolan-4-one (33a)

A mixture of methyl α-keto butyrate (1.78 g, 15.3 mmol), α-hydroxybutyric acid (1.33 g, 12.8 mmol), and *p*-TsOH (371 mg, 1.95 mmol) in benzene (40 mL) was heated to reflux with removal of

H_2O by a Dean–Stark trap for 5 h according to the literature procedure (26). Work-up yielded an oil (2.34 g, 89%) which was further purified by vpc (column C, 120°C) to give **33***a*, having identical nmr and ir spectra with material derived from **31***a*.

Acknowledgments

We thank Professor Amos B. Smith III for generous samples of **31***a*, *b*, Francis Picart for 300-MHz nmr spectra, Phyllis Wilson for technical assistance, and S. T. Bella for microanalyses. This research was supported by the National Science Foundation and the donors of the Petroleum Research Fund, administered by the American Chemical Society. Purchase of the 300-MHz nmr spectrometer was facilitated by funds from the National Science Foundation and from the Camille and Henry Dreyfus Foundation.

Synthesis of some 3-arylisochromene, 3-arylisoquinoline, 6*H*-5-oxachrysene, and benzo[*c*]phenanthridine analogs of some naturally occurring alkaloids

ANTOINE CARTY, I. WESLEY ELLIOTT,[1] AND GREFONDA M. LENIOR
Department of Chemistry, Fisk University, Nashville, TN 37203, U.S.A.

Received March 19, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

ANTOINE CARTY, I. WESLEY ELLIOT, and GREFONDA M. LENIOR. Can. J. Chem. **62**, 2435 (1984).

A 2-benzopyrylium perchlorate **6** was prepared from the keto ester **5**. Reduction of **6** followed by dilute HCl affords 6*H*-5-oxachrysene **10**. Reaction of **6** with ammonia solution gives the isoquinoline acid **13**. By a short series of steps **13** is cyclized to the dihydrobenzo[*c*]phenanthridine **16**.

ANTOINE CARTY, I. WESLEY ELLIOT et GREFONDA M. LENIOR. Can. J. Chem. **62**, 2435 (1984).

On a préparé le perchlorate du benzopyrylium-2 **6** à partir du céto-ester **5**. La réduction de **6**, suivie d'une hydrolyse par du HCl dilué, conduit au 6*H*-oxo-5 chrysène **10**. La réaction de **6** avec une solution d'ammoniac conduit à l'acide isoquinoléique **13**. Faisant appel à une courte série de réactions, on peut cycliser le composé **13** en dihydrobenzo[*c*] phénanthridine **16**.

[Traduit par le journal]

In early schemes for the biogenesis of isoquinoline alkaloids Robinson boldly proposed that benzo[*c*]phenanthridines **3** (e.g., chelerythrine and sanguinarine) arose from berberine alkaloids **1** (1). The structural change from a dibenzo[*a*,*g*]quinolizine **1** to a benzo[*c*]phenanthridine **3** required a bond cleavage in **1** to form an intermediate 3-arylisoquinoline derivative **2** which subsequently recyclized to **3**. At that time there were no known examples of 3-arylisoquinoline alkaloids. The hypothesis that compounds of type **1** could give rise to related alkaloids of type **3** was shown by Battersby *et al.* to be substantially correct by the biosynthesis of several benzo[*c*]phenanthridine alkaloids from the proposed biogenetic precursors, exemplified by the formation of chelidonine from labeled (−)-stylopine (2). Although the exact sequence for these conversions has not been established, nor all of the specific intermediates identified, there is general agreement that a 3-arylisoquinoline (cf. **2**) is required. Battersby suggested an intermediate with an aldehyde side chain (**2**, Y = O=) and the heterocyclic ring at the 1,2-dihydroisoquinoline stage. Following the discovery of 3-arylisoquinoline alkaloids in nature, labeled (±)-tetrahydrocoptisine, a berberine alkaloid, was shown to be converted in *Corydalis incisa* to the 3-arylisoquinoline alkaloids, corydamine and corydalic acid methyl ester, as well as to corynoline, which is a reduced benzo[*c*]phenanthridine alkaloid (3). Moreover, laboratory syntheses that parallel the biogenetic sequence **1** → **2** → **3** have been reported for chelerythrine and sanguinarine from canadine and protopine respectively (4).

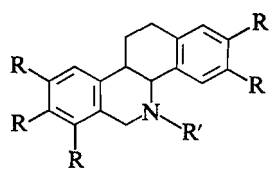
2



3

In our program of syntheses of structurally diverse, but biogenetically related, isoquinoline alkaloids from 6-homoveratroylhomoveratric acid (the keto acid, **4**), tetrahydropapaverine (5), laudanosine (5), *O*-methylthalisopavine (6), and *O*-methylcryptaustoline iodide (7) have been prepared. Other workers have used **4** to synthesize the aporphine alkaloid, pontevedrine (8), and berberine-type alkaloids (9). We now report the syntheses of some 3-arylisochromene and 3-arylisoquinoline derivatives from **4** and the conversion of these tricyclic compounds to the corresponding 5-oxachrysene and benzo[*c*]phenanthridine compounds (Schemes 1 and 2).

We chose to investigate the preparation and reactions of a 2-benzopyrylium salt derived from **4**, along the lines explored by Dorofeenko and Kuznetsov with aryl benzyl ketones (10), and after our work was in progress Dorofeenko and co-workers reported studies with the keto acid **4** and a derivative of **4** that are similar to ours in some aspects but also differ significantly in others (11).

The oxygen series

Attempted reactions of the keto acid **4** with acetic anhydride and perchloric acid (Scheme 1) did not readily afford a benzopyrylium salt, but when the keto ester **5** was used in place of **4**, a benzopyrylium perchlorate **6** was rapidly formed in good yield. The 2-benzopyrylium perchlorate **6**, and an analogous one **7** derived from desoxyveratroin, were reduced by sodium borohydride in alcohol to the corresponding 3-aryl-1*H*-2-benzopyrans (3-arylisochromenes, **8** and **9**). The 2-benzopyrylium ring was only partially reduced to the dihydro stage

by sodium borohydride in aqueous alcohol, in contrast to *N*-alkylisoquinolinium salts which are really reduced to the 1,2,3,4-tetrahydroisoquinolines under these conditions (12).

When the isochromene **8** was warmed briefly with EtOH–HCl a new, higher-melting product was obtained that was identified as a difficulty separable mixture of 6*H*-5-oxachrysene derivatives **10** and **11** in which the phenol **10** predominated. The ethyl ether **11** was not detected in the 60-MHz ^{1}H nmr spectrum, probably because of its low concentration and the limited solubility of the tetracyclic compounds, but the presence of both **10** and **11** in the reaction product, even after several recrystallizations, was suggested from the mass spectrum of the product, which showed molecular ion peaks at 382 and 410 for **10** and **11** respectively and parallel fragmentation patterns from each of the parent molecular ions. Liquid chromatographic separation of the product showed two peaks in the approximate ratio of 10 to 1, and when these fractions were examined separately by mass spectral analysis, the two samples showed the peaks matching those for **10** and **11** in the composite spectrum. The reaction mixture of **10** with **11** was treated with Ac_2O–pyridine, and the 11-acetoxy-6*H*-5-oxachrysene **12** was obtained as a useful derivative for further characterization. Attempts to regain the phenol **10** by hydrolysis of **12** were generally accompanied by extensive oxidation to afford dark colored products and were abandoned.

The formation of the 5-oxachrysenes **10** and **11** from **8** under mild acid catalysis can be explained by a push–pull effect in which the β-position of the vinyl ether in **8** serves as a nucleophile that adds to the protonated ethoxycarbonyl group. The mixture of the phenol **10** and the ethyl ether **11** can arise from competing loss of water or ethanol from an intermediate hemiketal. Alternatively, the reaction mixture of **10** and **11** can be rationalized through a series of equilibria involving the keto tautomer of **10** and a hemiketal in a manner similar to the polynuclear phenols studied by Newman *et al.* (13).

The isoquinoline derivatives

Reaction of the 2-benzopyrylium salt **6** with alcoholic am-

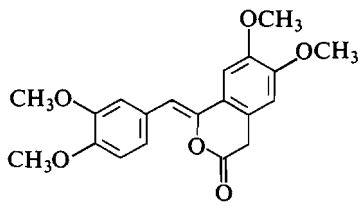
monium hydroxide solution afforded the isoquinoline derivative **13** (Scheme 2). Surprisingly, hydrolysis of the ester occurred readily and possibly conjunctively under the very mild conditions used for ammonolysis of the 2-benzopyrylium ring of **6** and recyclization of the isoquinoline system. The structure of the isoquinoline acid **13** was supported by both chemical and spectroscopic evidence. Loss of the ethyl group was first suspected by the disappearance of an ir band for the ester carbonyl stretching vibration near 1730 cm^{-1} and the appearance of a medium intensity band at 1620 cm^{-1}, assigned to the carboxyl group. The low frequency for the carboxyl group absorption band suggests that the isoquinoline acid may exist in the zwitterionic form. Initially the mass spectrum showed the highest peak at 379 amu and a base peak at 353, but when spectra were obtained under more careful temperature controls, a weak peak was observed at 397; the presence of this molecular ion peak at 397 was confirmed from a field desorption spectrum. The repeated elemental analyses showed that the compound tenaciously retained solvents, especially water, but eventually recrystallization of **13** from xylene gave analytical samples that provided satisfactory combustion data for $C_{22}H_{23}NO_6$. The ^{13}C nmr spectrum showed the presence of five doublets in the aromatic region and a singlet at 172.4 which is assigned to the carboxyl carbon. Other data from both the ^{13}C and ^{1}H nmr spectra support the structure **13** (see Experimental).

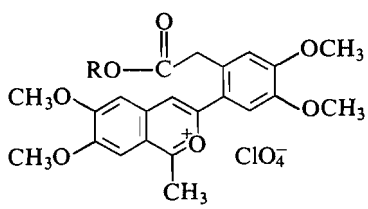
The isoquinoline acid **13** was esterfied to **14** by methyl iodide and potassium carbonate in acetone or alternatively by addition of a sulfuric acid solution of **13** to methanol. The methyl ester **14** was a more tractable compound than **13** for analysis, and both elemental composition and spectral data for **14** fit the assigned constitution. The ester **14** provides access to other isoquinoline derivatives structurally analogous to alkaloids of the 3-arylisoquinoline and benzo[*c*]phenanthridine types.

A methiodide **15** was readily obtained from the ester **14**. Controlled reduction of **15** by sodium borohydride in cold THF, followed by treatment with warm EtOH–HCl solution gave the salt **16**. A 1,2-dihydroisoquinoline derivative, analogous to **8**, is a probable intermediate in the formation of **16** from **15**. The parent ion in the mass spectrum of **16** was at 395 amu, corresponding to the formula $C_{23}H_{25}NO_5$. An ester carbonyl band was not present in the ir, but a broad band appeared at 3400 cm^{-1}, corresponding to an OH. Since the hydrochloride **16** tended to darken on exposure to light and retain hydroxylic solvents, **16** was allowed to react with acetic anhydride in excess pyridine to give a stable crystalline acetyl derivative **17**.

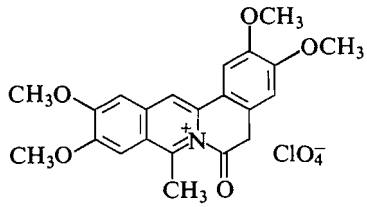
As indicated earlier, Dorofeenko and co-workers (11) used an 1-benzylidene-3-isochromanone **18**, which is obtained from the keto acid **4** by an intramolecular cyclodehydration, to prepare a 2-benzopyrylium perchlorate **19**, and **19** is simply the parent acid of the ester **6**. When **19** was heated with ammonia solution, followed by perchloric acid, these investigators isolated a product to which they assigned the constitution **20**. In more recent papers, this group has offered further support for the oxoberberinum structure (14) and also reported that **4** was successfully converted to a benzopyrylium perchlorate (15).



18



19



20

Our attempts to prepare a perchlorate **20** from **13** were unsuccessful; although a perchlorate salt was obtained from **13**, it was heavily solvated and apparently not in the tetracyclic, acyliminium form **20**; efforts to dehydrate the perchlorate from **13** resulted in extensive decomposition and no useful products, with the properties described for **20**, could be isolated. However, when our experimental protocol for benzopyrylium salt formation and ammonolysis was applied to **18**, we were able to isolate **13**, but the yields were small and inferior to the results from **5**.

In addition to providing new compounds in the 5-oxachrysene and benzo[*c*]phenanthridine series, this work includes practical examples of intramolecular acylation of a vinyl ether and an enamine with an ester group.

Experimental

General

Melting points were determined on a Mel-Temp apparatus and are uncorrected. Spectra were recorded as indicated: ir on a Perkin Elmer 727 spectrophotometer as paraffin oil mulls; uv on a Carey 14 spectrophotometer; ^{1}H nmr on Varian A60 or EM390 and ^{13}C nmr on a Varian CFT-20 spectrometer as $CDCl_3$ solutions, except where other solvents are specified, with Me_4Si as internal reference; mass spectra on LKB9000 spectrometer. Analyses were performed by Schwarzkopf Microanalytical Laboratory, Woodside, NY. or by MicAnal, Tucson, Arizona.

Ethyl 6-[(3,4-dimethoxyphenyl)acetyl]-3,4-dimethoxyphenylacetate (5)

Compound **5** was prepared from **4** as previously described (5); the preparation of the keto acid **4** in 60% yield was modified as follows: 20 g of 3,4-dimethoxyphenylacetic acid was allowed to react at room temperature in 200 g of polyphosphoric acid for 48 h.

1-Methyl-3-[2-(ethoxycarbonylmethyl)-4,5-dimethoxyphenyl]-6,7-dimethoxy-2-benzopyrylium perchlorate (6)

A suspension of 5 g of the keto ester **5** in 15 mL of acetic anhydride was cooled in an ice bath, and 5 mL of cold 70% $HClO_4$ was added dropwise with stirring over a 20-min period. The reaction mixture immediately developed an orange color, and after 1.5 h the cold paste was filtered and the salt **6** was washed with ether. For routine reductions or aminolyses, the damp perchlorate was used immediately without drying or recrystallizing.[2]

An analytical sample of **6** was recrystallized from acetic acid – nitromethane, with two drops of $HClO_4$, as deep orange prisms; mp 268–270°C (dec.); ir: 1725 cm^{-1} (ester C=O); ^{1}H nmr (trifluoro-

[2] The perchlorates prepared in this work have been stable to shock or heat (**6** decomposes gently at its mp), but organic perchlorates are often unpredictably explosive and should be handled with care.

acetic acid) δ: 1.21 (t, 3H, J = 6.0 Hz), 3.28 (s, 3H), 3.92 (s, 6H, $2CH_3O$), 4.11 (s, 3H, CH_3O), 4.18 (s, 3H, CH_3O), 4.20 (q, 2H, J = 6.0 Hz), 7.05 (s, 1H), 7.26 (s, 1H), 7.48 (s, 1H), 7.62 (s, 1H), 8.07 (s, 1H). *Anal.* calcd. for $C_{24}H_{27}O_{11}Cl$: C 54.70, H 5.17; found: C 54.30, H 5.20.

1-Methyl-3-[2-(ethoxycarbonylmethyl)-4,5-dimethoxyphenyl]-6,7-dimethoxyisochromene (8)

To the perchlorate salt **6**, freshly prepared from 5 g of **5**, was added 20 mL of methanol, 1 mL of water, and, in portions, 1 g of $NaBH_4$. After 1 h, more water was added to precipitate a gum which was recrystallized from aqueous ethanol as a colorless crystalline solid (2.1 g, 35% from **5**); mp 85–86°C; ir: 1740 cm^{-1}; uv (EtOH), λ_{max} (log ε): 215 (4.82), 270 (4.42), 300 nm (4.18); ^1H nmr δ: 1.24 (t, 3H, J = 7.0 Hz), 1.67 (d, 2H, J = 6.4 Hz), 3.78 (s, 2H), 3.87 (s, 12H, $4CH_3O$), 4.15 (q, 2H, J = 7.0 Hz), 5.31 (q, 1H, J = 6.4 Hz), 5.96 (s, 1H, =CH), 6.82–7.97 (m, 4H, ArH); mass spectrum, m/e: 428 (M^+, base peak), 413 ($M^+ - 15$, 80%); 399 ($M^+ - 29$, 11%). *Anal.* calcd. for $C_{24}H_{28}O_7$: C 67.28, H 6.59; found: C 67.22, H 6.46.

1-Methyl-3-(3,4-dimethoxyphenyl)-6,7-dimethoxyisochromene (9)

To an ice cold suspension of 5 g of desoxyveratroin in 25 mL of acetic anhydride was added 6 mL of 70% $HClO_4$ over a 20-min period. The orange perchlorate was collected by suction filtration, washed with ether, and directly reduced by the addition of 3 g of $NaBH_4$ to an ethanolic mixture of the salt. After standing overnight, the organic product was isolated by the addition of water and recrystallization from ethanol as a colorless solid (4.8 g); mp 141–142°C; ir: 1610 cm^{-1}; uv (EtOH), λ_{max} (log ε): 215 (4.55), 270 (4.23), 300 nm (3.98); mass spectrum, m/e: 342 (17%), 341 ($M^+ - 1$, 62%), 327 ($M^+ - 15$, 100%), 311 ($M^+ - 31$, 5%). *Anal.* calcd. for $C_{20}H_{22}O_5$: C 70.16, H 6.48; found: C 70.45, H 6.48.

2,3,8,9-Tetramethoxy-6-methyl-11-hydroxy-6H-5-oxachrysene (10) and ethyl ester 11

A solution of 1.60 g of **8** in 40 mL of ethanol and 2 mL of concentrated HCl was allowed to reflux 45 min. The red-brown solution was concentrated to yield a tan solid that was recrystallized from ethanol–benzene as a colorless solid (0.95 g, 73%); mp 223–225°C; ir: 3550 and 1638 cm^{-1}; uv (EtOH), λ_{max} (log ε): 215 (4.88), 260 (4.51), 300 nm (4.30); ^1H nmr: ($CDCl_3$ – DMSO-d_6) δ: 1.74 (d, 3H, J = 7.0 Hz), 3.94–3.97 (m, 12H, $4CH_3O$), 5.28 (q, 1H, J = 7.0 Hz), 6.78 (s, 1H), 682 (s, 1H), 6.86 (s, 1H), 7.20 (s, 1H), 8.29 (s, 1H), 9.59 (s, 1H, ArOH); mass spectrum, m/e: 410, 395, 382, 367, 351. *Anal.* found: C 66.48, H 6.63. High-pressure liquid chromatography (hplc) was performed on Radial Pak A (Waters C_{18} reverse phase column) using acetonitrile–water (80:20) as the solvent. The sample separated into two peaks (relative areas 10 to 1), and each fraction was collected, evaporated, and reextracted in $CHCl_3$ for mass spectrometry (LKB9000 probe); fraction 1, m/e: 382 (M^+, 51%); 367 ($M^+ - 15$, 100%), 351 ($M^+ - 13$%); fraction 2, m/e: 410 (M^+), 395 ($M^+ - 15$), 379 ($M^+ - 31$).

2,3,8,9-Tetramethoxy-6-methyl-11-acetoxy-6H-5-oxachrysene (12)

A solution of 0.75 g of the oxychrysene **10** in 7.5 mL of pyridine and 2.5 mL of acetic anhydride was heated on a water bath for 40 min and poured into excess 10% HCl solution. The precipitate was collected and recrystallized from ethanol–benzene as a colorless solid (0.61 g); mp 235–236°C; ir: 1785 cm^{-1}; uv (EtOH), λ_{max} (log ε): 230 (4.46), 280 (4.42), 320 nm (3.96); ^1H nmr δ: 1.65 (d, 3H, J = 6.0 Hz), 2.32 (s, 3H), 3.90–3.99 (m, 12H, $4CH_3O$), 5.28 (q, 1H, J = 6.0 Hz), 6.72 (s, 1H), 6.99 (s, 1H), 7.05 (s, 1H), 7.48 (s, 1H), 7.62 (s, 1H); mass spectrum, m/e: 424 (M^+, 93%), 409 ($M^+ - 15$, 31%), 395 ($M^+ - 29$, 20%), 382 ($M^+ - 42$, 28%), 368 ($M^+ - 56$, 100%). *Anal.* calcd. for $C_{24}H_{24}O_7$: C 67.91, H 5.70; found: C 68.19, H 5.98.

1-Methyl-3-(2-carboxymethyl-4,5-dimethoxyphenyl)-6,7-dimethoxyisoquinoline (13)

2-Benzopyrylium perchlorate **6**, freshly prepared from 10 g of keto ester **5**, was dissolved in 20 mL of ethanol and 20 mL of ammonium hydroxide with loss of orange color. On heating 40 min on a water bath, the solution first became reddish amber and then a tan solid precipitated. The solid was collected from the cooled mixture after 2 h and re-suspended in 150 mL of 10% acetic acid solution for 30 min. The solid was filtered off and recrystallized from pyridine–ethanol as a colorless solid (4.2 g, 43% from **5**); mp 229–230°C; ir: 3450, 1680 sh, 1620, 1520 cm^{-1}; ^1H nmr δ: 2.99 (s, 3H), 3.65 (s, 2H), 3.94 (s, 6H, $2CH_3O$), 4.08 (s, 6H, $2CH_3O$), 7.02 (s, 1H), 7.04 (s, 1H), 7.20 (s, 1H), 7.36 (s, 1H), 7.69 (s, 1H); ^{13}C nmr (DMSO-d_6) δ: 172.42, 154.32, 153.44, 150.28, 148.89, 147.84, 133.74, 131.01, 125.75, 121.35, 118.21, 114.34, 113.86, 105.82, 104.10, 79.13, 55.78, 41.66, 20.26; mass spectrum, m/e: field desorption spectrum 397 (M^+), electron impact spectrum 379 ($M^+ - 18$, 8%), 353 ($M^+ - 44$, 100%), 353 (83%), 338 (64%). *Anal.* calcd. for $C_{22}H_{23}NO_6$: C 66.48, H 5.83, N 3.52; found: C 66.34, H 5.74, N 3.45.

A *perchlorate salt* of **13** was prepared in acetic acid as an ivory solid: mp 164–166°C (dec.); ir: 3480, 1680, 1655, 1610 cm^{-1}. *Anal.* calcd. for $C_{22}H_{24}NO_{10}Cl \cdot 2H_2O$: C 49.51, H 5.29, N 2.62; found: C 49.23, H 5.49, N 2.29.

1-Methyl-3-(2-carbomethoxymethyl-4,5-dimethoxyphenyl-6,7-dimethoxyisoquinoline (14)

(a) *From methyl iodide – K_2CO_3*

A suspension of 4.2 g of the isoquinoline acid **13** in 100 mL of acetone was treated with 6 g of anhydrous potassium carbonate and, with vigorous stirring, 7 mL of methyl iodide was added in portions over a 30-min period. The mixture was warmed and stirred for 1.5 h longer, during which time the solid phase changed in appearance. The solid was filtered by suction and the acetone solution was evaporated. The residual syrup was diluted with methanol and, on scratching and standing, the ester **14** was obtained in three crops and recrystallized from aqueous methanol as a colorless solid (3.5 g, 81%); mp 126–128°C; ir: 1740 cm^{-1} (C=O); ^1H nmr δ: 2.88 (s, 3H, $ArCH_3$), 3.61 (s, 3H, CH_3O), 3.78 (s, 2H), 3.93–4.04 (12H, $4CH_3O$), 6.87 (s, 1H), 7.08 (s, 2H), 7.30 (s, 1H), 7.52 (s, 1H); mass spectrum, m/e: 411 (M^+, 100%), 396 (46%), 354 (92%). *Anal.* calcd. for $C_{23}H_{25}NO_6$: C 67.14, H 6.12, N 3.40; found: C 66.88, H 6.10, N 3.34.

(b) *Alternative preparation of 14*

To 10 mL of cold sulfuric acid was added 4 g of **13**, and after 30 min the acid solution was stirred slowly into 30 mL of cold methanol. A pale yellow solid separated on standing and, after 24 h, 30 mL of ether was added. The salt was collected after 2 h and added to 200 mL of saturated sodium bicarbonate solution. The organic base was extracted with three 30-mL portions of dichloromethane, and evaporation of the organic solvent left an oily residue that was dissolved in hot methanol. The ester **14** was obtained in several crops from aqueous methanol as a colorless solid (3.5 g); mp 126–127°C. This product was identical with the ester **14** from part (a) by ir and nmr comparisons.

1-Methyl-3-(2-carbomethoxymethyl-4,5-dimethoxyphenyl)-6,7-dimethoxyisoquinoline methiodide (15)

The methiodide **15** was obtained from 0.3 g of **14**, 3 mL of methyl iodide, and 2 drops of DMF, after 18 h at room temperature, as a yellow crystalline solid (0.18 g); mp 194–195°C. *Anal.* calcd. for $C_{24}H_{28}NO_6I$: C 52.09, H 5.10, N 2.53, I 22.93; found: C 51.73, H 5.19, N 2.66, I 22.94.

2,3,8,9-Tetramethoxy-5,6-dimethyl-11-hydroxy-5,6-dihydrobenzo[c]phenanthridine hydrochloride (16)

Into an ice cold solution of 2.6 g of **15** in 60 mL of dry THF was stirred 0.2 g of $NaBH_4$ over a 5-min period. After 20 min an additional 0.1 g of $NaBH_4$ was introduced, and the reaction mixture was stirred 20 min longer at 0°C. The mixture was filtered to remove insoluble salts, and the filtrate was treated with 20 mL of a 1:1 solution of methanol – concentrated HCl. A solid precipitated immediately, but this redissolved when the mixture was heated on a water bath for 30 min. Addition and evaporation of two 20-mL portions of benzene, followed by dilution of the residue with ether, gave a solid (1.2 g, 44%) that was recrystallized from benzene–ethanol as a colorless solid; mp 274–276°C; ir: 3400, 1620, 1520, 1475 cm^{-1}; mass spec-

trum, *m/e*: 395 (M^+ − HCl, 21%), 380 (100%). *Anal.* calcd. for $C_{23}H_{26}NO_5Cl$: C 63.96, H 6.07, N 3.32, Cl 8.21; found: C 63.58, H 6.18, N 3.22, Cl 8.15.

2,3,8,9-Tetramethoxy-5,6-dimethyl-11-acetoxy-5,6-dihydrobenzo-[c]phenanthridine (17)

A solution of 0.8 g of the hydrochloride **16** in 3 mL of pyridine and 2 mL of acetic anhydride was warmed on a water bath 30 min and diluted with water to give a precipitate. Recrystallization of the product from ethanol–benzene gave colorless needles (0.65 g, 82%); mp 187–188°C; ir: 1760 cm^{-1}; ^1H nmr δ: 1.20 (d, 3H, J = 2.0 Hz), 2.33 (s, 3H), 2.56 (s, 3H), 3.45 (q, 1H, J = 2.0 Hz), 4.00 (m, 12H, $4CH_3O$), 6.77 (s, 1H), 7.06 (s, 1H), 7.30 (s, 1H), 7.64 (s, 1H), 7.70 (s, 1H); mass spectrum, *m/e*: 437 (M^+, 76%), 422 (100%), 380 (64%). *Anal.* calcd. for $C_{25}H_{27}NO_6$: C 68.63, H 6.22, N 3.20; found: C 68.71, H 6.42, N 3.16.

Acknowledgements

We thank Dr. Helen Lloyd, National Institute of Health, for some of the mass spectral data and assistance with the hplc experiment, Dr. Edward White, National Bureau of Standards, Analytical Chemistry Division, for the field desorption mass spectrum, and Professor Peter Yates for mass and ^{13}C nmr spectra and useful interpretations of them. This research was supported by a grant (RR08062) from the National Institute of Health.

Received February 15, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

THÉOPHILE TSCHAMBER, JACQUES STREITH, HENRI STRUB, HANS FRITZ, and DAVID J. WILLIAMS. Can. J. Chem. **62**, 2440 (1984).

Ultraviolet irradiation of the azetidinodiazepines **3** leads in good yield to the expected tricyclic isomers **4** which represent potential precursors for the synthesis of 3-azacarbapenam derivatives. The rigid boat-shaped topology of the photoisomers **4** could be ascertained by detailed ^1H and ^{13}C nmr measurements, and in particular by the determination of nuclear Overhauser effects. That only the *syn* stereoisomers **4** are formed is most likely due to the conformation of the precursors **3** in which the convex side of the seven-membered ring is *syn* with respect to the β-lactam ring. Triplet sensitized irradiation of **3**, which should specifically give a $\pi^* \leftarrow n$ transition of the azetidinocarbonyl function, leads to the highly strained anti-Bredt isomers **5** whose structures were determined by ^1H and, especially, by ^{13}C nmr measurements. The structure of **5***a* was also established by an X-ray analysis which shows, in particular, that the bridgehead imine double bond is twisted out of plane by about 20°. Thermal activation of the anti-Bredt compound **5***a* leads to a mixture of the two isomers **8** and **9** which are more stable than **5***a* by about 40 kcal/mol as determined by differential scanning calorimetry.

THÉOPHILE TSCHAMBER, JACQUES STREITH, HENRI STRUB, HANS FRITZ et DAVID J. WILLIAMS. Can. J. Chem. **62**, 2440 (1984).

L'irridation ultraviolette des azétidinodiazépines **3** conduit, avec de bons rendements, aux isomères tricycliques attendus **4** qui représentent des précurseurs potentiels pour la synthèse de dérivés aza-3 carbapénames. Des mesures de rmn du ^1H et du ^{13}C et, en particulier, des mesures d'effet Overhauser nucléaire permettent d'établir que le photoisomère **4** possède une topologie de forme bateau rigide. Le fait que seuls les stéréoisomères *syn* **4** se forment est probablement dû à la conformation des précurseurs **3** dans lesquels la portion convexe du cycle à sept chaînons est en position *syn* par rapport au cycle du β-lactame. L'irradiation, sensibilisée par un triplet, du composé **3**, qui devrait conduire d'une façon spécifique à une transition $\pi^* \leftarrow n$ de la fonction azétidinocarbonyle, conduit plutôt aux isomères **5** qui sont fortement tendus et qui n'obéissent pas à la règle de Bredt; on a déterminé leurs structures en faisant appel à la rmn du ^1H et plus encore à la rmn du ^{13}C. On a également établi la structure du composé **5***a* par diffraction des rayons-X qui montre, en particulier, que la double liaison de l'imine sur la tête de pont est tordue hors du plan d'environ 20°. L'activation thermique du produit anti-Bredt **5***a* conduit à un mélange des deux isomères **8** et **9**. La calorimétrie différentielle à balayage montre que ces derniers sont plus stables que leur précurseur **5***a* d'environ 40 kcal/mol.

[Traduit par le journal]

Introduction

The pharmacologically active β-lactam antibiotics, such as penicillins, cephalosporins, or monobactams, are produced by microorganisms. Starting from these naturally occurring products, slightly modified molecules have been synthesized in the pharmaceutical industry; these play an ever-increasing role in modern medicine (1). On the other hand, medicinal chemists are focusing their attention and efforts towards the total synthesis of non-natural monocyclic or bicyclic β-lactams, which would hopefully have some antimicrobial activity.

Although to our knowledge none of the "artificial" β-lactams synthesized so far have made their way to the market, major pharmaceutical companies are striving to find new β-lactam antibiotics by total synthesis (2–5).

Azetidinodiazepines **3** can be prepared easily by cycloaddition of methylketene with the imino double bond of the corresponding 1,2-diazepines (6). We surmised that the conjugated diene moiety of **3** would undergo a facile photochemical ring closure, leading to the new tricyclic system **4**. These latter compounds represent annelated azacarbapenam derivatives whose partial structure (azetidinone and five-membered ring) is similar to that of the penicillin and the thienamycin skeleton.

We describe herein some experimental data, which agree with the above mentioned expectation, as well as some unexpected results which were obtained during photosensitized uv irradiation of the four azetidinodiazepines **3***a*–**3***d*.

Direct ultraviolet irradiation of azetidinodiazepines 3*a*–3*d*

Ultraviolet irradiation of the diazepine **1***a* has been shown to lead in moderate yield to the bicyclic isomer **2** (7). Similar results have been obtained by us (7, 8) and by others (9) during uv irradiation of a series of diazepines which gave the corresponding bicyclic isomers having the same skeleton as **2**. We expected, therefore, that the azetidinodiazepines **3** would undergo a similar disrotatory ring closure during direct ultraviolet irradiation of their conjugated diene moiety.

Ultraviolet irradiation of **3***a* through Corex glass – which permits the specific electronic excitation of the diene portion – gives the expected tricyclic isomer **4***a* in 69% yield. A minor photoisomer **5***a* also forms in this experiment (yield: 14%); the

2

	R	Y
a	CH_3	CO_2Et
b	CH_3	$CONH_2$
c	CH_3	COPh
d	H	CO_2CH_2Ph

The structure and relative configuration of **4***a* follow from its spectral data. The ir spectrum shows a band at 1785 cm^{-1} which is indicative of a β-lactam ring; this means that the four-membered ring stayed intact during uv excitation. In Table 1 chemical shifts and coupling constants of the ^1H nmr spectrum of **4***a* are reproduced. We notice, in particular, that the $J_{6,7}$ coupling constant of 6.5 Hz is in favour of a *cis* configuration for H-6 and H-7, and therefore of a rigid boat-shaped topology for this tricyclic molecule. The ^{13}C nmr spectrum of **4***a* (Table 2) fits the proposed structure, although the β-lactam carbonyl function appears at an unexpectedly low field (180.06 ppm). In the starting material **3***a* the carbonyl of the β-lactam moiety appears at 164.64 ppm (6); the β-lactam carbonyls show up between 165 and 168 ppm for penicillins (10, 11), at about 165 ppm for cephalosporin (12), and at 166.1 ppm for thienamycin (13). The low-field chemical shift we observe for the β-lactam carbonyl of **4***a* clearly indicates that there is very little amide character in the four-membered ring and that the N-1 nitrogen atom is likely to have a pronounced pyramidal geometry.

	R	Y
a	CH_3	CO_2Et
b	CH_3	$CONH_2$
c	CH_3	COPh
d	H	CO_2CH_2Ph

The ^{13}C spectrum of **4***a* agrees well with a *syn* configuration for this tricyclic molecule: the coupling constants $J_{Me\text{-}8,H\text{-}7}$ (3 Hz) and $J_{C\text{-}6,H\text{-}8}$ (2.5 Hz) indicate that Me-8 and H-7 on the one hand, and C-6 and H-8 on the other hand, are both *cis* to each other (14). Together with the ^1H nmr data cited above, these findings are good evidence in favour of the relative configuration as shown in formula **4***a* (Table 2).

That the structure of the tricyclic compound is indeed as shown in formula **4***a* — not considering stereochemistry — is demonstrated by the $^{13}C—^{13}C$ coupling constant parameters which were obtained from satellites observed in the broad-band-decoupled ^{13}C nmr spectra of a concentrated solution of **4***a* in $CDCl_3$ (14). Table 3 gives the values of the one-bond

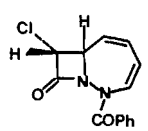
TABLE 4. Nuclear Overhauser effect measurements determined at 360 MHz by selective irradiation of several protons of compound **4***a*

Irradiated protons	Intensity enhancements observed with neighbourhood protons
H-3	H-4: +10.3%; H-6: +10.8%
H-6	H-3: +17% ; H-7: +14.9%
H-7	H-6: +13.4%; H-8: no change
Me-8	H-7: +14.6%; H-8: +19.4%
Me-5	H-4: +9.7% ; H-6: +5.8%; H-8: +15.5%

coupling constants and of the $^{13}C-^{13}C$ isotope effects on the chemical shifts.

The results obtained with nuclear Overhauser effect (nOe) measurements fully agree with the proposed relative configuration as shown in formula **4***a* (Table 4). The most pronounced nOe effects are those observed for H-8, during irradiation of the methyl group Me-5, and for H-3 and H-7 during irradiation of H-6. On the other hand, no nOe effect could be detected for H-8 when H-7 was irradiated. These data clearly indicate that H-7 and H-8 are in a *trans* configuration and that H-3, H-6, and H-7 are all three located on the convex side of the rigid boat-shaped molecule **4***a*.

The exclusive formation of stereoisomer **4***a* can be accounted for as follows. The X-ray diagram of the azetidinodiazepine **6** (15), a compound whose topology is similar to that of **3***a*, shows that the boat-shaped conformation of the seven-membered ring and the plane of the β-lactam ring are *syn*. It also shows that the H-3 and H-6 hydrogen atoms point towards the "backside" of the azetidinodiazepine. A photochemical disrotatory ring closure, starting from this *syn* conformation, would then lead to the stereoisomer **4***a*.



6

Ultraviolet irradiation of the azetidinodiazepines **3***b*–**3***d* leads likewise to the corresponding tricyclic isomers **4***b*–**4***d* (see Experimental).

Triplet-sensitized irradiation of the azetidinodiazepine 3*a*

In the above unsensitized photochemical experiments there was always formed a minor photoisomer **5** together with **4**. When the uv irradiation of **3***a* is carried out in the presence of fluorenone as triplet-sensitizer (E_T = 53.3 kcal/mol), **4***a* is no longer formed. Instead, the compound **5***a*, which was obtained as a minor by-product during the direct irradiation, is now the major photoproduct. These results show that the products **4***a*–**4***d* are most likely produced starting from an excited singlet state of the corresponding educts **3***a*–**3***d*, whereas the by-products are formed from an excited triplet state.

Determination of the structure of the by-products **5** could be achieved with the usual spectrophotometric methods, except for the relative configuration of the two asymmetric centres. The ir spectrum of **5***a* shows a strong carbonyl band at 1708 cm^{-1} which indicates the absence of a β-lactam ring in this photoproduct. The 360-MHz ^1H nmr spectrum, measured in $CDCl_3$, shows a single two-proton band at δ 5.74 ppm which could be resolved by using a solvent mixture ($CDCl_3/C_6D_6$ 1:1): these two vinylic protons have a coupling constant of 9.2 Hz. Two additional vinylic protons appear at δ 6.90 and 4.94 ppm (AB spectrum) with a coupling constant of 9.5 Hz. Clearly neither of these two pairs of olefinic protons can be attached to unsaturated five-membered rings. The ^{13}C nmr spectral data, which are reproduced in the experimental part, led us to postulate the bicyclic "anti-Bredt" structure **5***a* for this unexpected photoproduct.[2] To be noted in particular is a fully substituted sp^3 carbon atom giving rise to a singlet at δ 86.49 ppm; such a low-field chemical shift seemed to indicate that this doubly allylic carbon atom is attached to an oxygen atom. An X-ray investigation of **5***a* confirmed the postulated structure (see below) and led to the determination of the relative configuration of the two asymmetric centres.

For the time being, there is no clear-cut mechanistic interpretation for the triplet-photosensitized formation of the "anti-Bredt" isomer **5***a*. Formally, **5***a* results from a Cope-type rearrangement. Nevertheless it is obvious that this photoproduct cannot be formed in a concerted fashion, starting from **3***a* in its triplet state: Cope-rearrangements are initiated from a singlet ground state!

Whatever the real mechanism for the formation of **5***a*, a diradical intermediate of type **10** – first in its triplet state and thence in its singlet ground state – must be ruled out, since it is precisely this singlet ground state **10** which seems to be the obvious intermediate during the thermal rearrangement of **5***a* (*vide infra*).

Refined unit cell parameters were obtained by centering 15 reflections on a Nicolet R3m diffractometer. 1529 independent reflections were measured ($\theta \leq 55°$) with Cu-$K\alpha$ radiation (graphite monochromator) using the ω-scan measuring technique. 1447 reflections had $|F_o| > 3\sigma(|F_o|)$ and were considered to be ob-

[2]Some so-called anti-Bredt compounds have been synthesized; some of them could be isolated at room temperature as stable entities, provided that the two-bridged cycles were sufficiently large rings, so that the bridgehead double bonds are only slightly twisted out of plane (16). For the evaluation and prediction of the stability of bridgehead olefinic compounds, see ref. 17; for a review, see ref. 18.

served. The data were corrected for Lorentz and polarisation factors. No absorption correction was applied.

The structure was solved by direct methods and the non-hydrogen atoms refined anisotropically. All the hydrogen atoms were clearly located in a difference electron density map. The hydrogen positions were idealized (C—H = 0.96 Å), assigned isotropic thermal parameters, $U(H) = 1.2U_{eq}(C)$ and allowed to ride on their parent carbon atoms. The methyl groups were refined as rigid bodies. Refinement was by block-cascade full matrix least-squares to $R = 0.040$, $R_w = 0.051$, ($w^{-1} = \sigma^2(F) + 0.00065F^2$). The maximum residual electron density in the final ΔF map was 0.17 e A^{-3}, and the mean and maximum shifts/error in the final refinement cycle were 0.03 and 0.25 respectively. Computations were carried out on an Eclipse S140 computer using the SHELXTL program system.

Tables 5–7 list the fractional atomic coordinates, some selected torsion angles, bond lengths, and bond angles, respectively. The anisotropic thermal parameters, the structure factors, and the hydrogen coordinates and temperature factors (tables) have been placed in the Depository of Unpublished Data.[3]

The X-ray analysis of **5***a* has confirmed the postulated structure (Fig. 1) and showed that this highly strained arrangement can only be achieved by sacrificing the planarity of the C(1)—N(2), C(4)—C(5), and C(7)—C(8) double bonds. This is most

[3]Data are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

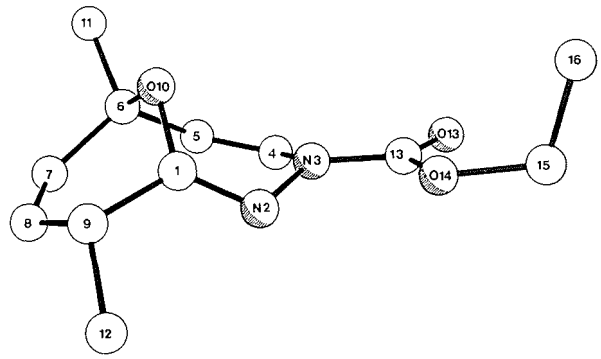

FIG. 1. Perspective view of the anti-Bredt compound **5***a* as determined by X-ray analysis.

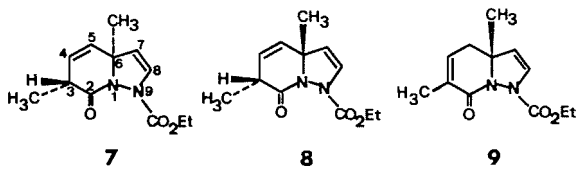
pronounced for the bridgehead imine double bond which is twisted out of plane by 20°. This is accompanied by a pyramidal distortion of C(1) which lies 0.066 Å (in the direction of H(9)) from the plane of N(2), C(9), and O(10). N(3) is also slightly pyramidilized, being displaced 0.156 Å above the plane formed by N(2), C(4), and C(13). Table 6 lists selected torsion angles and Table 7 the bond lengths and valence angles. There are no short intermolecular contacts.

Thermal rearrangement of the anti-Bredt photoproduct 5*a*

Thermolysis of the strained photoproduct **5***a* leads to the more stable isomers **7** (85%) and **8** (7%), whose structures follow from their nmr data (see Experimental). To be noted in particular are two close peaks (δ 5.83) corresponding to H-4 and H-5 on **7**. The corresponding protons in **8** appear respectively at δ 5.60 and 5.85 ppm with a coupling constant of 9.6 Hz. The H-7 and H-8 protons show coupling constants of 4.4 Hz for **7** and 4.3 Hz for **8**; the magnitude of these coupling constants is compatible with olefinic protons in a five-membered ring.



7 **8** **9**

The ^{13}C nmr spectra agree with the stereostructures which are assigned to the diastereomers **7** and **8**. For example Me-3 of **9** shows two coupling constants of 6.5 and 4.0 Hz, respectively with H-3 and with H-4, whereas Me-3 of **7** shows coupling only with H-3 (^2J = 7 Hz) but no coupling constant with H-4. The absence of any coupling with H-4 is due to the fact that the dihedral angle between the C-3—Me-3 and the C-4—H-4 bonds is close to 90°: according to the Karplus equation, ^3J for such a dihedral angle should indeed be close to zero. These data show that the two methyl groups of diastereomer **7** are located on the same side of the molecule: they are *cis* to one another. To be noted, furthermore, are the Me-3 chemical shifts of **7** (δ = 29.2) and of **8** (δ = 14.55): this large difference is not due to a so-called δ-effect between Me-3 and Me-6! It is rather the result of the steric interaction, in **8**, between Me-3 and one of the carbonyl lone electron pairs. A Dreiding model shows that the carbonyl double bond and the C-3—Me-3 bond are indeed quasi coplanar.

Differential scanning calorimetry of the reaction **5***a* → **7** + **8** gave an enthalpy of 40.5 kcal/mol for this rearrangement.

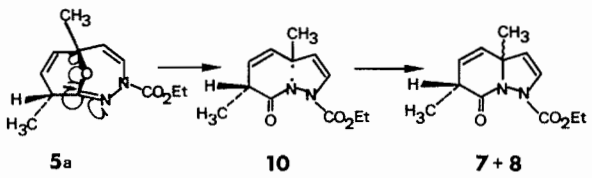

SCHEME 1. Proposed mechanistic scheme for the thermal rearrangement of the anti-Bredt compound **5***a* to the isomers **7** and **8**.

Such a large exothermic value is to be attributed to relief of the ring strain present in the bridged anti-Bredt compound **5***a*. Treatment of the DSC (differential scanning calorimetry) curve using Ellerstein's method (19) leads to the determination of the activation energy (E_a = 31.1 kcal/mol) and the pre-exponential factor ($\ln A$ = 32.0 s^{-1}) of the Arrhenius equation for this thermal isomerization.

The mechanism of this latter ground-state rearrangement seems to be straightforward: homolytic fragmentation of the C_6—O_{10} bond leads to a singlet diradical **10** which is doubly allylic at carbon, and of the "push-pull" type (20) or of the capto-dative type (21) at nitrogen (Scheme 1). Recombination of these two delocalized radicals leads to compounds **7** and **8**, which are thermodynamically more stable than their strained precursor **5***a*.

That **7** and **8** are diastereoisomers can easily be demonstrated: both lead, after equilibration, to the same conjugated enamide **9** when treated with DBU in boiling chloroform (about 65°C) for 15 h. A similar experiment with **7** in the presence of DBU but in boiling methylene chloride (ca. 43°C), under equilibrating conditions when no **9** was formed, gave mainly **8**, suggesting that it is the thermodynamically more stable isomer of the two. Yet, in the thermolysis of **5** leading to **7** and **8**, the latter – though more stable – is the minor isomer formed.

This may indicate that the carbon radical of **10** combines with its neighbouring nitrogen radical in a very fast intramolecular process, thereby retaining to a large degree its original configuration.

Ultraviolet irradiation of the azetidinodiazepines **3***a*–**3***d* led to the expected tricyclic isomers **4***a*–**4***d* as the major photoproducts. Taking advantage of these model reactions, one should now be in a position (*i*) to attach an acid, other than carboxyl, to the nitrogen atom N-2; (*ii*) to induce a fragmentation reaction between C-3 and C-4 and between C-5 and C-6 of products having the overall structure **4**. This synthetic planning would ultimately yield 3-azacarbapenam derivatives.

The photochemical formation of the highly strained anti-Bredt isomers **5***a*–**5***d* was rather unexpected. It shows once more how specific photochemical reactions can be, when compared to thermally induced ones, provided that the proper wavelengths and spin multiplicities are chosen.

Experimental

Microanalyses were carried out by the Service Central de Microanalyses of the C.N.R.S. Melting points were taken with Büchi SMP-2 and Mettler FP5 apparatus and are not corrected. The uv spectra (λ_{max} nm (ϵ)) were recorded on a Varian Techtron 635 spectrophotometer. The ir spectra (cm^{-1}) were determined on a Perkin–Elmer 157 G spectrophotometer. The ^1H and ^{13}C nmr spectra were obtained with Varian T-60 (60 MHz), Bruker WP 80 (80 MHz), Bruker WH 360 (360 MHz), and Bruker WM 400 (400 MHz) instruments, with Me_4Si as an internal reference (δ ppm, J Hz). Normal ms as well as high resolution ms were measured with a MAT 311 mass spectrometer by the Centre de Mesures Physiques of the University of Rennes. Differential Scanning Calorimetry was performed with the fully automated Perkin–Elmer DSC-2C apparatus. Flash chromatographies (22) were carried out with silica gel (Merck 60; 230–400 mesh) and thin-layer chromatographies on aluminium roll (Merck 60 F_{254}). The photochemical experiments were carried out under an argon atmosphere in a Pyrex glass vessel using a water-cooled Hanovia immersion well (Corex glass) equipped with a Philips HPK 125 medium pressure mercury vapour lamp.

Synthesis of 1-benzoyloxycarbonyl 1,2-diazepine **1**d

(*i*) To a stirred solution of hydroxylamin-O-sulfonic acid at 0°C (14.13 g; 0.125 mol) in water (31 mL) are successively added potassium hydroxide (8.8 g) in water (13 mL) and pyridine (18.8 mL) over 30 min at about 5°C. After 2 days of continuous stirring at room temperature, potassium carbonate (8.75 g) is slowly added. After 2 h the precipitated solids are filtered off; ethanol is added to the solution, leading to additional precipitates which are filtered. The resulting solution is diluted with ethanol (250 mL) and stirred at 10°C. To this stirred solution potassium carbonate (25 g) and benzyl chloroformate (18 mL) are added, the latter dropwise, and the reaction mixture is kept at room temperature for 24 h and then filtered over sinter glass. The resulting solution is evaporated to dryness *in vacuo*. The resulting crude pyridinium ylide is purified by column chromatography (AcOEt/EtOH 8:2) followed by crystallization in toluene; the resulting brown crystals are further purified by dissolution in a mixture of acetone and petrol ether, whereby a brown product precipitates; after filtration, the mother liquors lead to the pure pyridinium ylide (4.60 g; 16% overall yield) as colourless crystals (toluene), mp 113°C; ir (KBr): 1630, 1605 cm^{-1}; uv (MeOH) λ_{max} (ϵ): 312 nm (6400); ^1H nmr ($CDCl_3$ at 60 MHz) δ: 8.87 (dm, J = 7 Hz, H-2 and H-6), 7.8–7.2 (m, H-3, H-4, H-5, and H-arom.), and 5.20 ppm (s, CH_2). *Anal.* calcd. for $C_{13}H_{12}N_2O_2$ (228.24): C 68.41, H 5.30, N 12.27; found: C 68.30, H 5.25, N 12.46.

(*ii*) A solution of the above described pyridinium ylide (4.60 g; 20.2 mmol) in toluene (2.0 L) is irradiated for 7 h under nitrogen in a "falling-film" type photoreactor (23) equipped with a 700-W medium pressure mercury vapour lamp, the reaction being followed by uv spectroscopy and by tlc until complete disappearance of the pyridinium ylide absorption band. After evaporation of the solvent *in vacuo* and column flash chromatography (AcOEt/cyclohexane 3:7) of the crude reaction mixture, diazepine **1***d* is obtained as an orange oil which solidifies in the cold; mp 67–68°C (hexane); ir (KBr): 1701 cm^{-1}; uv (MeOH) λ_{max} (ϵ): 216 nm (15 200) and 357 nm (280); ^1H nmr ($CDCl_3$ at 60 MHz) δ: 7.40 (m, H-3 and H-arom.), 6.52 (ddd, J = 11, 5, and 1 Hz, H-5), 6.24 (d, J = 7.2 Hz, H-7), 6.20 (partly hidden by H-7; resolved when determined in C_6D_6: dd, J = 11 and 3.5 Hz, H-4), 5.72 (ddd, J = 7.2, 5, 1.5 Hz, H-6), and 5.33 ppm (s, CH_2). *Anal.* calcd for $C_{13}H_{12}N_2O_2$ (228.24): C 68.41, H 5.30, N 12.27; found: C 68.32, H 5.27, N 12.17.

[7α,8α] 8-Methyl 2-benzoyloxycarbonyl 9-oxo 1,2-diazabicyclo-[5.2.0] 3,5-nonadiene **3**d

Through a solution of diazepine **1***d* (3.27 g; 14.3 mmol) in 200 mL toluene is passed the pyrolysis gas of butanone which is produced in a ketene lamp (3) for about 3 h at room temperature, until disappearance of **1***d* as shown by tlc. After evaporation of the solvent *in vacuo*, the crude reaction mixture is separated into its components by flash chromatography (AcOEt/cyclohexane 2:8), which gives mainly the expected β-lactam **3***d* (3.42 g; 84%) as a colourless solid (ether); mp 78°C; ir (KBr): 1773, 1728 cm^{-1}; uv (MeOH) λ_{max} (ϵ): 274 nm (9600); ^1H nmr ($CDCl_3$ at 60 MHz) δ: 7.40 (s, H-arom.), 6.88 (d, J = 9 Hz, H-3), 5.93 (s, H-6), 5.87 (m, H-5), 5.27 (s, CH_2), 5.12 (ddd, J = 9, 7, and 2 Hz, H-4), 4.17 (m, H-7), 2.68 (qd, J = 7.5 and 2.0 Hz, H-8), and 1.38 ppm (d, J = 7.5 Hz, Me-8). *Anal.* calcd. for $C_{16}H_{16}N_2O_3$ (284.30): C 67.59, H 5.67, N 9.85; found: C 67.63, H 5.75, N 9.89.

[3α,6α,7α,8α] 5,8-Dimethyl 2-ethoxycarbonyl 9-oxo 1,2-diazatricyclo[5.2.0.0^{3,6}] 4-nonene **4**a *and [1α,6α,9β] 6,9-dimethyl 3-ethoxy-carbonyl 10-oxa 2,3-diazabicyclo[4.3.1] 1,4,7-decatriene* **5**a

A solution of the azetidinodiazepine **3***a* (3) (3.10 g; 13.1 mmol) in 400 mL methylene chloride is irradiated by uv light until complete consumption of the starting material, the reaction medium being monitored by tlc. Two photoproducts appear which are separated by column flash chromatography (AcOEt/cyclohexane 2:8). Compound **5***a* (435 mg; 14%), being the less polar one, is eluted first; it is followed by its isomer **4***a* (2.127 g; 69%).

Photoisomer **4**a: colourless crystals (ether/petrol ether), mp 92°C; ir (KBr): 1785, 1695 cm^{-1}; uv (MeOH) λ_{max} (ϵ): 238 nm (770); ms: 236 (M^+; 11%); 180 (100%). *Anal.* calcd. for $C_{12}H_{16}N_2O_3$ (236.26): C 61.00, H 6.83, N 11.86; found: C 61.15, H 6.76, N 12.32.

Photoisomer **5**a: colourless crystals (*n*-hexane), mp 54°C; ir (KBr): 1708, 1700, and 1635 cm^{-1}; uv (MeOH) λ_{max} (ϵ): 240 nm (8400); ^1H nmr ($CDCl_3$ at 360 MHz) δ: 6.90 (d, J = 9.5 Hz, H-4), 5.74 (s, H-7 and H-8), 4.94 (d, J = 9.5 Hz, H-5), 4.34 and 4.28 (two ABX systems; twice dq, J_{AB} = 11 Hz, J_{AX} = J_{BX} = 7 Hz, OCH_2CH_3), 3.31 (qd, J = 7 Hz and J < 1 Hz; H-9), 1.50 (s, Me-6), 1.35 (t, J = 7 Hz, OCH_2CH_3), 1.27 (d, J = 7 Hz, Me-9); ^1H nmr ($CDCl_3/C_6D_6$ 1:1 at 360 MHz) δ: 5.52 (d, J = 9.2 Hz, H-7) and 5.50 ppm (d, J = 9.2 Hz, H-8); ^{13}C nmr ($CDCl_3$ at 100.6 MHz) δ: ($^1J_{i,j}$) 167.40 (s, C-1), 153.90 (s, CO), 132.36 (ddq, 167 Hz, C-8), 131.86 (dm, 163 Hz, C-7), 125.91 (dd, 180.5 Hz, C-4), 115.61 (d, 162 Hz, C-5), 86.49 (s, C-6), 63.10 (tq, 149 Hz, CH_2CH_3), 35.94 (dm, 133 Hz, C-9), 28.06 (qs, 129 Hz, Me-6), 14.45 (qt, 127 Hz, CH_2CH_3), 14.45 (q, about 130 Hz, Me-9); ^{13}C nmr ($CDCl_3$ at 100.6 MHz) ^1J ($^{13}C_i - ^{13}C_j$) coupling constants ± 0.3 Hz: J(1, 9) = 55.9 Hz; J(9, Me-9) = 35.9 Hz; J(9, 8) = 36.8 Hz; J(6, Me-6) = 39.7 Hz; J(6, 5) = 47.5 Hz; J(6, 7) = 45.3 Hz; J(5, 4) = 80 Hz; ms: 236 (M^+, 12%), 121 (100%). *Anal.* calcd. for $C_{12}H_{16}N_2O_3$ (236.26): C 61.00, H 6.83, N 11.86; found: C 61.00, H 6.89, N 11.78.

Fluorenone-sensitized formation of the bicyclic product **5**a

A stirred solution of the azetidinodiazepine **3***a* (1.416 g; 6.00 mmol) and of fluorenone (270 mg; 1.5 mmol) in 250 mL acetone is irradiated by uv light (Philips HPK 125) through Pyrex for 9 h, the disappearance of the starting material being determined by tlc. After evaporation of the solvent *in vacuo*, the crude reaction mixture is separated into its components by column flash chromatography (AcOEt/cyclohexane 1:9). The main compound proved to be the photoisomer **5***a* (1.041 g; 73%).

[3α,6α,7α,8α] 5,7-Dimethyl 2-carboxamido 9-oxo 1,2-diazatricyclo-[5.2.0.0^{3,6}] 4-nonene **4**b *and [1α,6α,9β] 6,9-dimethyl 3-carboxamido 10-oxa 2,3-diazabicyclo[4.3.1] 1,4,7-decatriene* **5**b

A solution of azetidinodiazepine **3***b* (3) (995 mg; 4.80 mmol) in 300 mL methylene chloride is irradiated by uv light for 6 h until complete disappearance of the starting material. After evaporation of the solvent *in vacuo* the crude reaction mixture is dissolved in a mixture of ethyl acetate and cyclohexane 6:4 whereby compound **4***b* (368 mg) crystallizes out. Flash chromatography of the remaining mother liquors (AcOEt/cyclohexane 6:4) leads to the successive isolation of the photoisomers **5***b* (130 mg; 13%) and **4***b* (193 mg; combined yield of **4***b*: 56%).

Photoisomer **4**b: colourless crystals (methylene chloride/petrol ether), mp 160–161°C (dec.); ir (KBr): 1779, 1690 cm^{-1}; uv (MeOH) λ_{max} (ϵ): 241 nm (720); ^1H nmr ($CDCl_3$ at 80 MHz) δ: 5.83 (m, H-4), 5.45 (m, H-3), 3.70 (dm, H-6), 3.44 (dd, H-7), 3.07 (qd, H-8), 1.82 (m, Me-5), 1.50 (d, Me-8), 5.4 (s large, NH_2); ^1H-J (i, j) mostly determined by selective irradiation experiments: 3,6 = 3 Hz; 3, Me-5 = 1.5 Hz; 4,6 = 1.5 Hz; 4,Me-5 = 1.5 Hz; 6,7 = 7 Hz; 6,Me-5 = 1.5 Hz; 7,8 = 1.8 Hz; 8,Me-8 = 7 Hz. *Anal.* calcd. for $C_{10}H_{13}N_3O_2$ (207.23): C 57.96, H 6.32, N 20.28; found: C 57.65, H 6.18, N 20.24.

Photoisomer **5**b: colourless crystals (methylene chloride/petrol ether), mp 110–111°C (turns yellow); ir (KBr): 1695 cm^{-1}; uv (MeOH) λ_{max} (ϵ): 243 nm (8800); ^1H nmr ($CDCl_3$ at 80 MHz) δ : 7.07 (d, J = 9.5 Hz, H-3), 5.75 (s, H-6 and H-7), 5.8 (s large, exchangeable with D_2O; NH_2), 4.91 (d, J = 9.5 Hz, H-4), 3.31 (qd, J = 7 and 1 Hz, H-8), 1.54 (s, Me-5), 1.24 (d, J = 7 Hz, Me-8). *Anal.* calcd. for $C_{10}H_{13}N_3O_2$ (207.23): C 57.96, H 6.32, N 20.28; found: C 57.97, H 6.51, N 21.07.

[3α,6α,7α,8α] 5,8-Dimethyl 2-benzoyl 9-oxo 1,2-diazatricyclo-[5.2.0.0^{3,6}] 4-nonene **4**c *and [1α,6α,9β] 6,9-dimethyl 3-benzoyl 10-oxa 2,3-diazabicyclo[4.3.1] 1,4,7-decatriene* **5**c

A solution of azetidinodiazepine **3***c* (3) (2.005 g; 7.47 mmol) in 250 mL methylene chloride is irradiated by uv light for 14 h until

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

complete disappearance of the starting material. After evaporation of the solvent *in vacuo*, the crude reaction mixture is separated into its components by flash chromatography (AcOEt/cyclohexane 2:8). The two isomers **5***c* (55 mg; 3%) and **4***c* (402 mg; 20%) are isolated in that order.

Photoisomer **4**c: colourless crystals (ether), mp 138−139°C; ir (KBr): 1775, 1655 cm^{-1}; uv (MeOH) λ_{max} (ϵ): 228 nm (14 100); ^1H nmr ($CDCl_3$ at 60 MHz) δ: 7.93 (m, H-arom.), 7.47 (m, H-arom.), 5.95 (m, H-4), 5.77 (m, H-3), 3.72 (dm, J = 7 Hz, H-6), 3.37 (dd, J = 7 and 1.5 Hz, H-7), 3.07 (qd, J = 7.5 and 1.5 Hz, H-8), 1.85 (m, Me-5), 1.37 (d, J = 7.5 Hz, Me-8); ms: 268 (M^+; 4%), 105 (100%). *Anal.* calcd for $C_{16}H_{16}N_2O_2$ (268.30): C 71.62, H 6.01, N 10.44; found: C 71.50, H 5.84, N 10.41.

Photoisomer **5**c: colourless crystals (methylene chloride, petrol ether), mp 115−117°C (dec.); ir (KBr): 1670, 1640 cm^{-1}; uv (MeOH) λ_{max} (ϵ): 280 (8000), 227 (7400), and 204 nm (14 900); ^1H nmr ($CDCl_3$ at 60 MHz) δ: 7.77 (m, H-arom.), 7.45 (m, H-arom.), 7.30 (d, J = 10 Hz, H-4), 5.78 (s, H-7 and H-8), 5.13 (d, J = 10 Hz, H-5), 3.30 (q, J = 7 Hz, H-9), 1.53 (s, Me-6), and 1.10 ppm (d, J = 7 Hz, Me-9); ms: 268 (M^+; 8%), 105 (100%). *Exact Mass* calcd. for $C_{16}H_{16}N_2O_2$ (ms): 268.121169; found: 268.1217.

[3α,6α,7α,8α] 8-Methyl 2-benzyloxycarbonyl 9-oxo 1,2-diazatricyclo[5.2.0.0^{3,6}] 4-nonene **4**d *and [1α,6α,9β] 9-methyl 3-benzyloxycarbonyl 10-oxa 2,3-diazabicyclo[4.3.1] 1,4,7-decatriene* **5**d

A solution of azetidinodiazepine **3***d* (1.11 g; 3.89 mmol) in 150 mL methylene chloride is irradiated with uv light for 9 h until consumption of the starting material. After evaporation of the solvent *in vacuo*, the crude reaction mixture is separated into its components by flash chromatography (AcOEt/cyclohexane 2:8). The two isomers **5***d* (144 mg; 13%) and **4***d* (785 mg; 71%) are isolated in that order.

Photoisomer **4**d: yellow oil; ir ($CHCl_3$): 1785, 1718 cm^{-1}; uv (MeOH) λ_{max} (ϵ): 242 nm (770); ^1H nmr ($CDCl_3$ at 60 MHz) δ: 7.40 (s, H-arom.), 6.18 (s, H-4 and H-5), 5.45 (dm, J = 3 Hz, H-3), 5.22 (s, CH_2), 3.93 (dd, J = 6.5 and 3 Hz, H-6), 3.43 (dd, J = 6.5 and 1.5 Hz, H-7), 3.04 (qd, J = 7.5 and 1.5 Hz, H-8), 1.45 (d, J = 7.5 Hz, Me-8); ms: 284 (M^+; less than 1%), 91 (100%). *Exact Mass* calcd. for $C_{16}H_{16}N_2O_3$ (ms): 284.116083; found: 284.1153.

Photoisomer **5**d: colourless oil; ir ($CHCl_3$): 1715, 1645, 1395, 1325, 1305 cm^{-1}; uv (MeOH) λ_{max} (ϵ): 229 (10 700) and 207 nm (13 500); ^1H nmr ($CDCl_3$ at 60 MHz) δ: 7.4 (s, H-arom.), 7.02 (dd, J = 10 and 2 Hz, H-4), 5.80 (m, H-7 and H-8), 5.37 (dd, J = 4 and 2 Hz, H-6), 5.30 (s, CH_2), 5.01 (dd, J = 10 and 4 Hz, H-5), 3.34 (qm, J = 7 Hz, H-9), and 1.27 (d, J = 7 Hz, Me-9); ms: 284 (M^+; 6%); 91 (100%). *Exact Mass* calcd. for $C_{16}H_{16}N_2O_3$ (ms): 284.116084; found: 284.1162.

[3α,6α] And [3α,6β] 3,6-dimethyl 9-ethoxycarbonyl 2-oxo 1,9-diazabicyclo[4.3.0] 4,7-nonadiene 7 and 8

The anti-Bredt compound **5***a* (2.10 g; 8.89 mmol) is heated under an argon atmosphere for 30 min at 140°C; tlc shows that the starting material has disappeared and that two new products have formed. Flash chromatography of the reaction mixture (AcOEt/cyclohexane 3:7) leads to the isolation of compound **8** (146 mg; 7%) and thence of its diasteroisomer **7** (1.78 g; 85%).

Diastereoisomer **7**: colourless crystals (ether/petrol ether), mp 68°C; ir (KBr): 1740, 1718, 1680 cm^{-1}; uv (MeOH) λ_{max} (ϵ): 230 nm (9200); ^1H nmr ($CDCl_3$ at 80 MHz) δ: 6.79 (d, J = 4.4 Hz, H-8), 5.83 (d, J = 2.2 Hz, H-4 and H-5), 5.36 (d, J = 4.4 Hz, H-7), 4.30 (q, J = 7 Hz, CH_2CH_3), 3.04 (qt, J = 7.3 and 2.2 Hz, H-3), 1.46 (d, J = 7.3 Hz, Me-3), 1.43 (s, Me-6), 1.35 (t, J = 7 Hz, CH_2CH_3); ^{13}C nmr ($CDCl_3$ at 100.6 MHz) δ ($^1J_{C-H}$): 172.44 (s, C-2), 152.80 (s, CO_2Et), 127.24 (dd, 194 Hz, C-8), 126.98 (d, 163 Hz, C-4 or C-5), 126.96 (d, 163 Hz, C-5 or C-4), 116.22 (ddq, 181 Hz, C-7), 71.71 (sm, C-6), 62.72 (tq, 149 Hz, CH_2CH_3), 38.63 (dm, 134 Hz, C-3), 29.12 (qs, 129 Hz, Me-6), 20.52 (qd, 130 Hz, Me-3), 14.38 (qt, 128 Hz, CH_2CH_3); ^{13}C nmr ($CDCl_3$ at 100.6 Hz) ^1J ($^{13}C-^{13}C$) coupling constants ± 0.3 Hz: J(2,3) = 50.8 Hz; J(3,4) = 38.7 Hz; J(3,Me-3) = 31.6 Hz; J(6,Me-6) = 36.6 Hz; $J(CH_2,CH_3)$ = 38.3 Hz; J(6,7) = 40.2 Hz; J(7,8) = 76.8 Hz; ms: 236 (M^+; 7%); 121 (100%). *Anal.* calcd. for $C_{12}H_{16}N_2O_3$ (236.26): C 61.00, H 6.83, N 11.86; found: C 61.25, H 6.92, N 11.96.

Diastereoisomer **8**: colourless crystals (ether/petrol ether), mp 83°C; ir (KBr): 1740, 1683 cm^{-1}; uv (MeOH) λ_{max} (ϵ): 230 nm (8800); ^1H nmr ($CDCl_3$ at 80 MHz) δ: 6.75 (d, J = 4.3 Hz, H-8), 5.85 (dd, J = 9.6 and 3.2 Hz, H-4), 5.60 (dd, J = 9.6 and 1.4 Hz, H-5), 5.27 (d, J = 4.3 Hz, H-7), 4.28 (q, J = 7 Hz, CH_2—CH_3), 3.25 (qdd, J = 7.3, 3.2, and 1.4 Hz, H-3), 1.38 (s, Me-6), 1.31 (t, J = 7 Hz, CH_2—CH_3), 1.30 (d, J = 7.3 Hz, Me-3); ^{13}C nmr ($CDCl_3$ at 20.1 MHz) δ($^1J_{C-H}$): 171.29 (sm, C-2), 152.09(st, CO_2Et), 128.20 (dm, 167 Hz, C-4 or C-5), 127.38 (ddq, 168 Hz, C-5 or C-4), 126.74 (dd, 196 Hz, C-8), 114.99 (dm, 180 Hz, C-7), 72.26 (sm, C-6), 62.29 (tq, 148.5 Hz, CH_2CH_3), 34.28 (ddq, 128 Hz, C-3), 27.31 (qs, 130 Hz, Me-6), 14.55 (qdd, 129 Hz, Me-3), 14.05 (qt, 128 Hz, CH_2CH_3); ms: 236 (M^+; 6%); 121 (100%). *Anal.* calcd. for $C_{12}H_{16}N_2O_3$ (236.26): C 61.00, H 6.83, N 11.86; found: C 60.97, H 6.79, N 12.02.

Base-catalyzed equilibration of the two diastereoisomers 7 and 8

(*i*) A solution of compound 7 (945 mg; 4.00 mmol) in 5 mL methylene chloride, to which is added DBU (0.30 mL; 2.00 mmol), is heated at reflux temperature for 90 min, the reaction being followed by tlc. After cooling to room temperature and addition of silicic acid (4 g), the solvent is evaporated *in vacuo*. Flash chromatography of the reaction mixture (AcOEt/cyclohexane 3:7) leads to the isolation of isomer **8** as the major product (530 mg; 56%) and of isomer 7 (388 mg; 41%).

(*ii*) A solution of compound **8** (590 mg; 2.50 mmol) is treated with identical reaction conditions whereby **8** is again isolated as the major product (330 mg; 56%) and 7 as the minor isomer (207 mg; 35%). In addition, compound **9** also forms in low yield (22 mg; 4%).

3,6-Dimethyl 9-ethoxycarbonyl 2-oxo 1,9-diazabicyclo[4.3.0] 3,7-nonadiene **9**

A solution of compound 7 (472 mg; 2.00 mmol) in 8 mL chloroform, to which is added DBU (0.30 mL; 2.00 mmol), is heated at reflux temperature for 15 h. The reaction is followed by tlc which shows that the equilibration between 7 and **8** occurs rapidly. After a few hours a new compound appears which is the sole product at the end of the reaction. After addition of some silicic acid (2 g) the solvent is evaporated *in vacuo* and the crude reaction mixture separated by flash chromatography (AcOEt/cyclohexane 3:7). Compound **9** is obtained (408 mg; 86%) as colourless crystals (ether/petrol ether), mp 62°C; ir (KBr): 1745, 1675, 1642, 1615 cm^{-1}; uv (MeOH) λ_{max} (ϵ): 212 (13 400) and 273 nm (1700; shoulder); ^1H nmr ($CDCl_3$ at 80 MHz) δ: 6.71 (d, J = 4.5 Hz, H-8), 6.10 (m, H-4), 5.30 (d, J = 4.5 Hz, H-7), 4.27 (q, J = 7 Hz, CH_2CH_3), 2.70 (ddq, J = 16, 2.5, and 2.5 Hz, H-5), 2.37 (dd, J = 16 and 6 Hz, H-5), 1.98 (m, Me-3), 1.39 (s, Me-6), and 1.34 ppm (t, J = 7 Hz, CH_2CH_3); ^{13}C nmr ($CDCl_3$ at 20.1 MHz) δ ($^1J_{C-H}$): 160.17 (sm, C-2), 153.61 (st, $CO_2CH_2CH_3$), 131.02 (sm, C-3), 128.24 (dm, 163 Hz, C-4), 128.10 (dd, 195 Hz, C-8), 116.35 (dm, 179 Hz, C-7), 66.84 (sm, C-6), 62.47 (tq, 149 Hz, CH_2CH_3), 33.77 (tm, 131 Hz, C-5), 25.57 (qdd, 129 Hz, Me-6), 16.24 (qdd, 128 Hz, Me-3), 13.91 (qt, 128 Hz, CH_2CH_3); ms: 236 (M^+; 13%), 82 (100%). *Anal.* calcd. for $C_{12}H_{16}N_2O_3$ (236.26): C 61.00, H 6.83, N 11.86; found: C 61.13, H 6.87, N 11.85.

Differential scanning calorimetry of the thermal isomerization of **5**a *into the mixture of 7 and 8*

The thermal rearrangement of the neat anti-Bredt compound **5***a* to its isomers **7** and **8** (melt process) was determined by DSC with a Perkin−Elmer DSC-2C apparatus coupled with a Perkin−Elmer TADS-computer. This latter permits one to memorize and to process the DSC curve according to the standard Perkin−Elmer DSC program. Measurements were determined in a dynamic mode, with a constant heating rate of 80°/min. Results: reaction enthalpy: ΔH = 169 ± 2.0 kJ/mol (40.5 kcal/mol); order of the reaction: n = 1.09 ± 0.02; activation energy: E_a = 130 ± 2.8 kJ/mol (31.1 kcal/mol); logarithm of the Arrhenius pre-exponential factor: ln (A) = 32.0 ±

0.7 (A in s^{-1}). According to the ^1H nmr (80-MHz FT) and to the tlc analysis of the reaction mixture, compound **7** is by far the major thermoisomer formed at the end of the DSC experiment with educt **5***a*.

Received June 22, 1983[1]

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

JOHN T. EDWARD, SIN CHEONG WONG, A. J. KRESGE, and M. POWELL. Can. J. Chem. **62**, 2448 (1984).

Tritium was incorporated into the 11-position of strychnine, and of strychninesulfonic acids-I, -II, and -III, and the rate of detritiation from the four compounds in 0.5 *M* sodium hydroxide at 25°C was measured. Rates were reduced by the negative sulfonate groups, the extent of reduction varying inversely with the distance of the sulfonate group from the negative oxygen of the enolate intermediate. Experimental rates were in reasonable agreement with values expected at zero ionic strength from the Kirkwood–Westheimer equation. The problem of correcting experimental values for the effect of ionic strength is discussed.

JOHN T. EDWARD, SIN CHEONG WONG, A. J. KRESGE et M. POWELL. Can. J. Chem. **62**, 2448 (1984).

On a incorporé du tritium en position 11 de la strychnine et des acides strychninesulfoniques-I, II et III et on a mesuré la vitesse de détritiation des quatre composés, dans l'hydroxyde de sodium 0,5 *M*, à 25°C. Les groupes sulfonates négatifs réduisent la vitesse; le taux de la réduction varie de façon inverse avec la distance du groupe sulfonate par rapport à l'oxygène négatif de l'énolate intermédiaire. Les vitesses expérimentales sont raisonablement en accord avec les valeurs attendues à partir de l'équation de Kirkwood–Westheimer pour une force ionique de zéro. On discute de la façon de corriger les valeurs expérimentales pour tenir compte de l'effet de la force ionique.

Strychnine (**1***a*), brucine, and their derivatives condense readily with benzaldehyde (1) and amyl nitrite (2) in alkaline solution. It may be assumed that these reactions involve the enolate ion **2** as an intermediate. The same ion must be involved in the incorporation of tritium from TOH into strychnine, which we find to take place readily under alkaline conditions. This reaction is reversible. In the present paper we report on the rate of removal in alkali of tritium from tritiated strychnine and from the tritiated anions derived from strychninesulfonic acids-I (**1***b*), -II (**1***c*), and -III (**1***d*). The structures of these acids have been elucidated only recently (3, 4). The anions **3***b*–**3***d*, with the charged SO_3^- group at various distances from the developing negative centre of **2**, would seem good model compounds for testing the validity of Kirkwood–Westheimer theory (5) for the kinetics of detritiation.

Experimental

Materials

Tritiated strychnine was prepared by stirring a suspension of strychnine in tetrahydrofuran and tritiated water with a small amount of sodium hydroxide added as a catalyst. After 24 h, the tritium exchange was quenched by acid. The solid was filtered, washed thoroughly with ordinary water, and dried under high vacuum to remove any unreacted TOH. It was then used for detritiation studies without further purification.

Tritiated strychninesulfonic acids-I, -II, and -III were similarly prepared, except that sulfonic acid-III was not washed with water because of its high water solubility.

Detritiation of strychnine

A small amount of tritiated strychnine was added to a 50 mL volumetric flask containing aqueous sodium hydroxide solution of an appropriate concentration (and KCl to keep the ionic strength at 0.5), thermally pre-equilibrated to 25.0°C in a thermostatted water bath. The flask was shaken vigorously and placed back in the water bath. Five-milliliter aliquots of the solution were removed at regular intervals and quenched with acid in a separatory funnel; 30 mL of carbonate buffer (pH 10) and exactly 7 mL of toluene were added. The funnel was vigorously shaken and the aqueous layer was discarded. The toluene layer was washed 3 more times with 30-mL portions of carbonate buffer and 5 mL of th toluene solution was pipetted into a scintillation counting vial containing 15 mL of Bray's solution (6). The residual radioactivity of the tritiated strychnine was then counted by a Packard Tricarb Model 314 EX scintillation counter.

Detritiation of strychninesulfonic acids

Due to their low solubilities in toluene as well as in Bray's solution, the above procedure used for strychnine had to be modified. Five-milliliter aliquots of the substrate in aqueous sodium hydroxide were again removed at regular intervals and quenched in acid. They were

[1] Revision received April 3, 1984.

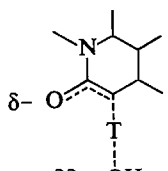
left in round bottom flasks and evaporated to dryness, and then kept several hours under high vacuum to remove any TOH formed in the detritiation process. The residue was redissolved in 5 mL of dilute aqueous sodium hydroxide, and 3 mL of it was the pipetted into a scintillation counting vial containing 15 mL of the water-tolerant scintillation solution due to Kennedy (7) and counted.

Results and discussion

Order of reaction

In the large excess of sodium hydroxide employed, detritiation of strychnine (**3***a*) followed pseudo-first-order kinetics. Over the range 0.1–0.5 *M* sodium hydroxide, the rate constant k_ψ was roughly linear with hydroxide ion concentration, but was somewhat higher than predicted by a linear relationship in the highest concentrations of hydroxide.

Such behaviour is consonant with a mechanism having a transition state **4**, in which δ− of the carbonyl oxygen approaches a unit electronic charge, and breaking of the



4

C(11)—T bond to form T—OH is largely complete (δδ− very small). For such a mechanism the Bronsted–Bjerrum treatment gives

$$[1] \quad k_\psi = k_0[OH^-] f_{ST} f_{OH^-}/f_{S^\ddagger}$$

where ST stands for **3***a*, $S^\ddagger$ for the transition state **4**, k_0 for the rate constant at zero ionic strength, and the *f*'s are activity coefficients. If the equilibrium ionization of **3***a* in sodium hydroxide solution is governed by the h_- function established with thioacetamide (8) (which is likely to be only approximately true), then we can write

$$[2] \quad f_{ST} f_{OH^-}/f_{S^-} = K_w/h_- [OH^-]$$

where K_w is the autoprotolysis constant for water. Since **4** is close to **2** in structure, $f_{S^\ddagger} \approx f_{S^-}$, and we obtain from [1] and [2]

$$[3] \quad k_\psi = k_0 K_w/h_-$$

Values of k_ψ thus calculated are given in Table 1 and are in fair agreement with experimental results.

Effect of negatively-charged groups

The presence of negatively-charged sulfonate groups in **3***b–d* depresses k_ψ, as shown by the positive values of $\Delta\log k_\psi$ ($\equiv \log k_\psi^P - \log k_\psi$, where k_ψ^P is the rate constant for the "parent" compound, strychnine) in Table 2. This is in agreement qualitatively with Kirkwood–Westheimer theory: the negative charges of the sulfonate groups will make the change from the formally uncharged carbonyl group of **3** to the negatively charged group of the transition state **4** more difficult. Furthermore, this electrostatic effect diminishes as the distance of the sulfonate groups from the carbonyl group increases, in going from strychninesulfonic acid-I to -II to -III.

Calculation of the electrostatic effect by the Kirkwood–Westheimer equation

According to Kirkwood and Westheimer (9), the change in rate of hydrolysis brought about by the variously-placed sulfonate groups is given by

$$[4] \quad \Delta\log k_0 = \log k_0^P - \log k_0 = e^2/2.3\ kTRD_{eff}$$

where k_0 stands for rate constants obtained by extrapolation of $k_\psi/[OH^-]$ to zero ionic strength, *e* is the electronic charge, *k* Boltzmann's constnat, *T* the absolute temperature, *R* the intercharge distance, and D_{eff} the effective dielectric constant.

To obtain *R* we assumed that in the transition state the negative charge resides completely on the carbonyl oxygen, i.e. that the transition state **4** is very close to **2**. *R* was obtained by measurements on scale models of **2** set up using the Tacoma flexible molecular model kit,[2] and is given in Table 2. From *R* the eccentricity λ_0 of a prolate ellipsoid modelling the transition state was calculated according to Tanford (10), and D_{eff} thence obtained from the published $D_{eff} - \lambda_0$ relation (9).

The $\Delta\log k_0$ values given by eq. [4] were as follows ($\Delta\log k_\psi$ from Table 2 in parentheses):

Strychninesulfonic acid-I	0.60	(0.68)
Strychninesulfonic acid-II	0.41	(0.50)
Strychninesulfonic acid-III	0.38	(0.34)

These results are surprising, since the k_ψ values were obtained in 0.5 *M* sodium hydroxide. In a solution of this ionic strength $\Delta\log k_\psi$ might be expected to be considerably lower than $\Delta\log k_0$ because shielding of the negative sulfonate groups by counterions should reduce the electrostatic effects of these groups. However, the estimate of this shielding effect is uncertain in concentrated solutions because of the limitations of Debye–Hückel theory (11). Westheimer *et al.* (5) found that

TABLE 1. Effect of concentration of sodium hydroxide on the rate of detritiation of strychnine-C(11)-t

	$10^4\ k_\psi(s^{-1})$

II	**1***c*	8.4	7.75 ± 0.11	0.50
III	**1***d*	8.9	11.1 ± 0.12	0.34

[2] These models are more convenient than the Dreiding models when models of strained cage molecules must be constructed.

the second-order rate constant k for the hydrolysis of the negative monoethyl adipate ion by hydroxide ion in water at 20°C in solutions having ionic strength μ up to 0.273 obeyed the equation:

$$[5] \quad \text{Log } k = \log k_0 + 2\alpha\sqrt{\mu} + \beta\mu$$

where α is the Debye–Hückel constant and β is an empirically-determined constant (obtained as the slope of the straight line given by plotting ($\log k - 2\alpha\sqrt{\mu}$) against μ). For the hydrolysis of monoethyl adipate ion β was -1.03. On the other hand, the second-order rate constant for the hydrolysis of the uncharged diethyl adipate molecule by hydroxide ion under the same conditions was almost independent of ionic strength. If we assume similar relationships to hold for the detritiation by hydroxide ion of the neutral strychnine molecule and the negatively charged sulfonate ions in 0.5 *M* sodium hydroxide, the fairly close correspondence between $\Delta\log k_\psi$ and $\Delta\log k_0$ can be accounted by a value for β of about -1.4. This would seem a reasonable value, and could be confirmed experimentally by obtaining rates of detritiation at several lower values of μ. However, the counting methods for the water-soluble sodium salts of the sulfonic acids are tedious, and the accuracy of measurements would drop for the slower reactions in more dilute alkali. Consequently, it was decided that it would be more profitable to look for more simply monitored reactions of salts of strychnine sulfonic acids. However, the present work does suggest that Kirkwood–Westheimer calculations may indicate trends for reaction rates even in solutions of high ionic strength.

Addition initiated ring closure: synthesis of substituted spiro[2.4]hepta-4,6-dienes via cyclopentadiene intermediates from fulvene precursors

KAZIMIERZ ANTCZAK, JOHN F. KINGSTON, AND ALEX G. FALLIS

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received March 20, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

KASIMIERZ ANTCZAK, JOHN F. KINGSTON, and ALEX G. FALLIS. Can. J. Chem. **62**, 2451 (1984).

The reactivity of the epoxy-fulvene **1**, prepared by pyrrolidine catalyzed condensation of cyclopentadiene and epoxybutanone, has been examined with various nucleophiles. It is a versatile intermediate for the preparation of spiro[2.4]hepta-4,6-diene synthons via nucleophilic addition to the C_6 position of the fulvene followed by intramolecular cyclization of the substituted cyclopentadiene anion generated *in situ*.

KASIMIERZ ANTCZAK, JOHN F. KINGSTON et ALEX G. FALLIS. Can. J. Chem. **62**, 2451 (1984).

On a étudié la réactivité de l'époxy-fulvène **1**, préparé par une condensation catalysée par la pyrrolidine du cyclopentadiène sur l'époxybutanone, avec divers nucléophiles. C'est un intermédiaire versatil dans la préparation de synthons spiro[2,4]-heptadiènes-4,6 accessibles par le biais d'une addition nucléophile en position C_6 du fulvène qui est suivie d'une cyclisation intramoléculaire de l'anion cyclopentadiène substitué, généré *in situ*.

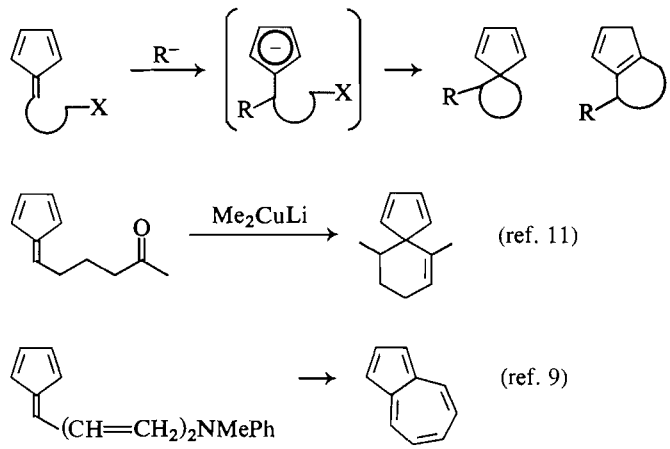
Introduction

Synthetic routes involving sequential nucleophilic addition with the generation of a new nucleophilic centre that can react intramolecularly with another electrophile have particular appeal. These schemes require intermediates bearing several electrophilic sites and, in principle, offer rapid synthetic access to an array of bridge, fused, conjoint, and spiro ring systems. This strategy holds considerable potential and is frequently initiated by a Michael addition (Michael initiated ring closure) (1–3). Recently Danishefsky *et al.* reported a stereospecific 2 + 2 + 2 annulation which involves two sequential Michael additions followed by an aldol reaction (4, 5).

Cyclopentadiene is an economical and readily available cyclopentane unit; however, the use of substituted cyclopentadienes in natural product synthesis has frequently been complicated by the facile 1,5-sigmatropic rearrangements which these species undergo. One solution we have developed is to block the rearrangement with a cyclopropyl unit which may serve as a source of latent functionality (6, 7). In the course of these investigations we have devised a general route to spiro[2.4]-hepta-4,6-dienes ("blocked cyclopentadienes") from fulvene intermediates via *in situ* generation of substituted cyclopentadiene anions. It is well established that the exocyclic double bond in fulvenes is polarized and of similar reactivity to a carbonyl group (8). Thus fulvenes have served as a source of substituted cyclopentadienes by both hydride reduction (9–11) and nucleophilic addition (11, 12). However, with the exception of work by Büchi *et al.* (13) leading to the spiro-sesquiterpenes hinesol and β-vetivone, they have been underutilized in total synthesis. As illustrated in Scheme 1, after nucleophilic addition intramolecular alkylation may proceed to give spiro and (or) fused ring systems (more than one cyclopentadiene isomer is possible but only one is illustrated). The major products will depend upon the relative ease of cyclization for the competing pathways and in most instances should be predictable, based on the nature of the electrophiles and the chain lengths involved. The system studied by Büchi *et al.* (13), in which the electrophilic site was four carbons removed from the fulvene, gave spiro[4.5]deca-1,3-dienes and no hydroazulenes were formed. This is in contrast to earlier results of Hafner (10), who found that spiro ring formation was



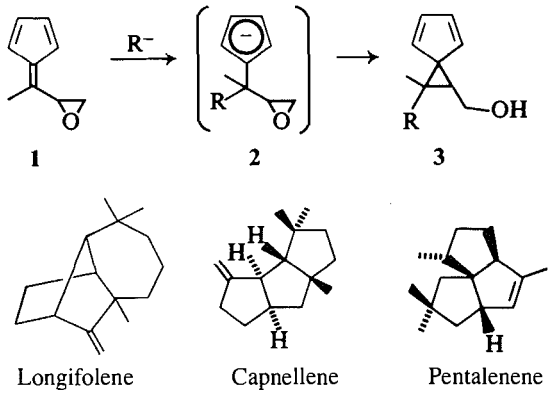
SCHEME 1

inhibited by the presence of unsaturation in the connecting chain and afforded azulene exclusively.

We wish to report the results of our initial studies, which permit the introduction of diverse functionality into the epoxy-fulvene **1**. These investigations have established that the preferred mode of intramolecular cyclization affords the spiro[2.4]hepta-4,6-diene system **3** (Scheme 2), a key intermediate in our approach to longifolene. These addition initiated ring closures provide direct access to useful bicyclic synthons for subsequent Diels–Alder reactions, as synthetic equivalents for 5,5-disubstituted cyclopentadienes (14), and in cases where the cyclopropane contains olefinic substituents for subsequent vinyl cyclopropane type rearrangements to diverse ring systems. The extension of this approach to polyquinanes such as capnellene (15) and pentalenene (16) also appears feasible.

Results and discussion

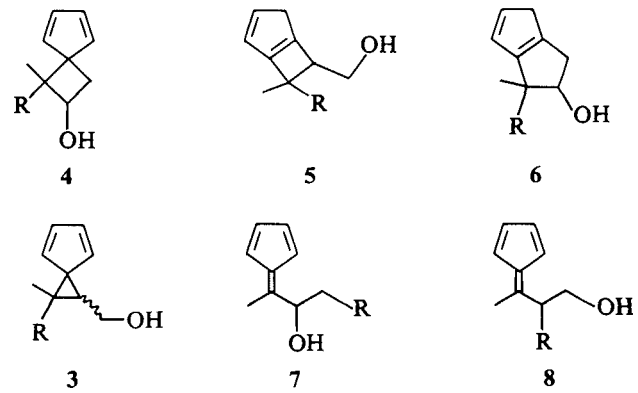
A variety of bases have been employed for fulvene preparation (8) from carbonyl compounds, although the mildest and most efficient tend to be amines (17). In these studies a significant improvement in yield was achieved by using pyrrolidine as the catalyst. Thus condensation of cyclopentadiene with the epoxide derived from 3-butenone (30% H_2O_2, CH_3OH,



SCHEME 2

60–71%) in the presence of pyrrolidine (0°C, 2 h) afforded the epoxy-fulvene **1** in 86% yield.[1] The ^{1}H nmr spectrum of this material displayed a characteristic four-proton multiplet at δ 6.35 for the vinyl protons, a vinyl methyl singlet at 1.91, a multiplet at 2.82 for the methylene hydrogens, and a doublet of doublets (J = 1.5, 1 Hz) at 3.90 due to the methine hydrogen. These features support the assigned structure.

In principle, nucleophilic attack may occur at any of the three major electrophilic sites present in **1** and the epoxide may be opened at either end to generate several different structures.



The carbocyclic skeletons **3**–**6** and the fulvene alcohols **7**–**8** are all possible. However, in the majority of cases nucleophilic addition occurred preferentially at the C_6 fulvene centre to generate the cyclopentadiene intermediate **2** which cyclized to form the cyclopropyl unit by *exo* cleavage of the epoxide. These results are summarized for a variety of lithio nucleophiles in Table 1. The alternative cyclization to form the cyclobutane **4** requires an *endo-tet* ring opening which is disfavoured (18–21), as is the spiro[3.4]octa-1,3-diene system itself (22–24). In a typical example, addition of methyllithium to the fulvene-epoxide **1** at −78°C in tetrahydrofuran followed by warming to 0°C afforded the spiro-alcohol **9** as the sole product after work-up and chromatography. The ^{1}H nmr spectrum displayed methyl singlets at δ 1.38 and 1.40, the cyclopropyl hydrogen appeared as a triplet (J = 7 Hz) at 2.22, the methylene protons as a doublet (J = 7 Hz) at 3.71, and the four cyclopentadienyl hydrogens as two overlapping multiplets at

TABLE 1. Addition of lithium nucleophiles to fulvene **1**

Nucleophile	Product	Yield
MeLi	 **9**	55%
*n*BuLi	 **10**	52% (~1:1)
*s*BuLi	 **11**	40% (~3:1)
VinylLi	 **12**	46%

6.30, all of which were consistent with the assigned structure. There was no evidence for any of the fused ring structures **5** or **6**. In all cases 10–15% of the unreacted fulvene was recovered even in the presence of excess nucleophile. Thus, based on reacted starting material, the yields are 10–15% higher than listed.

Lithium reagents were the most efficient although their use is influenced by their steric bulk. These results were consistent with related studies on Michael initiated ring closure of methyl 4-bromocrotonate (3), where it was also found that the better nucleophiles afforded the best yields of cyclopropanes. In contrast to the results for methyllithium, methyl Grignard and related reagents were unreactive towards both the fulvene and the epoxide. Apparently as a consequence of its size, *tert*-butyllithium also failed to add. In this case most of the fulvene-epoxide decomposed and the major product was the fulvene-alcohol **13** (35%). This unexpected product resulted, formally at least, from the net addition of hydrogen to **1**. The exact mechanism is uncertain, but it appears, as recommended by a referee, that the fulvene-alcohol arose via electron transfer from *tert*-butyllithium to epoxyfulvene **1** followed by protonation on work-up, rather than from deprotonation, rearrangement, and bond cleavage. Analogy for this electron transfer pathway (Scheme 3) is provided by the work of Ashby and Wiesemann (25) with *tert*-butylmagnesium chloride, where it was established that the Grignard addition to benzophenone involved a radical anion – radical cation pair which collapsed to addition products or dissociated to form *tert*-butyl radical and benzopinacol. Similarly, the synthesis of carbocyclic rings upon treatment of diiodoalkanes with *tert*-butyllithium (26) is assumed to proceed via initial metal–halogen interchange, a reaction for which the intermediacy of anion radicals, formed by electron transfer, is implicated (27).

Sodium dimethyl malonate did not add to the fulvene, but after prolonged reflux (3 h) a low yield (<10%) of alcohols was obtained. In contrast, 2-lithio-1,3-dithiane occupied an intermediate position, since it reacted at both the fulvene terminus to give **14** and the primary epoxide centre to generate the secondary alcohol **15** (Table 2). Some control over the relative

[1]Since acceptance of this manuscript Stone and Little (30) have reported similar observations in a detailed account of pyrrolidene induced fulvene preparation.

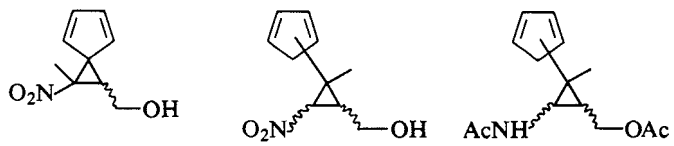
13

SCHEME 3

amounts of these two products was achieved by varying the temperature and the *cis* and *trans* cyclopropane isomers were separated by chromatography. These results are summarized in Table 2. The spiro compound **14** was the major product (31%) and the fulvene **15** the minor one (16%) when the reaction was conducted for 10 min at −60°C followed by 2 h at 22°C.

A number of other reagents, including the lithium salt of nitromethane and alkoxymethyllithiums (28, 29), which should serve to introduce a functionalized carbon atom, did not add in useful yields. In contrast, the potassium anion of nitromethane was generated with potassium hydride but addition to the fulvene occurred only in the presence of 18-crown-6 ether (Table 2). However, unlike the examples above, the reaction stopped at the cyclopentadiene stage to give **16** as a mixture of interconverting double bond isomers (~1:2). The 400-MHz ^{1}H nmr spectrum displayed four separate methyl singlets at δ 0.90, 0.96, 1.00, and 1.05 due to the individual isomers. Subsequent base treatment (KH, MeLi) of the isolated cyclopentadiene failed to produce any of the corresponding spiro compound **17**. This appears to be a consequence of the similarity in acidity of the two potential anionic centres, so that intramolecular proton exchange takes precedence over nucleophilic displacement. Treatment of **16** with two equivalents of methyllithium formed the dianion by proton abstraction from both the cyclopentadiene and the nitromethylene centres but instead of the spiro product the conjoint system **18** resulted. This material was a mixture of positional (~1:1) and stereochemical isomers. The methyl singlets were shifted downfield (δ 2.16−2.18) compared to the starting material, reflecting their rigid anisotropic environment. The cyclopropyl hydrogen adjacent to the nitro function appeared as a multiplet at 3.46, while the other cyclopropyl proton gave rise to a broadened triplet (J ~ 7 Hz) at 1.75. The structure of **18** was further established by conversion into the diacetate **19**. This involved reduction of the nitro group with lithium aluminum hydride (86%) followed by acetylation with acetic anhydride in pyridine.



17 18 19

Work is in progress to prepare the fulvene-epoxide **1** in chiral form, both for use in the asymmetric total synthesis of sesquiterpenes and to provide insight into the diastereofacial selection of these reactions. In addition, these investigations are being extended to other fulvenes bearing electrophilic centres for the preparation of various spiro and fused rings.

TABLE 2. Addition of functionalized nucleophiles to fulvene **1**

	46% (~1:2)	

Experimental

Infrared spectra were recorded on a Perkin−Elmer 237B or 451 grating spectrophotometer, and were calibrated with the 2850 and 1601 cm^{-1} bands of polystyrene film. Ultraviolet spectra were recorded on a Perkin−Elmer 202 uv−visible spectrophotometer and were calibrated with the 279.4-nm band of a Holmium oxide filter. Proton magnetic resonance spectra were measured at 80 MHz with a Bruker WP80 spectrometer employing a chloroform lock or at 60 MHz with a Varian EM 360 spectrometer or at 400 MHz with a Bruker WH 400 spectrometer at the University of Alberta. Signal positions are reported in ppm downfield from tetramethylsilane (δ scale) as an internal standard; the number of protons, multiplicity, coupling constants, and proton assignments are indicated in parentheses. Mass spectra were determined on a V.G. Micromass 7070 HS instrument using an ionization energy of 70 eV.

Gas−liquid chromatographic analyses were conducted on a Hewlett Packard 402B gas chromatograph equipped with a column (3 m × 6 mm id) containing 1.5% OV-17 supported on Gas Chrome Q using helium as the carrier gas. Thin-layer chromatographic analyses were carried out on commercial precoated silica gel plates with a fluorescent indicator (Eastman Kodak silica gel 13181). Preparative thin-layer chromatography was conducted on 20 × 20 cm glass plates coated with silica gel $PF_{254+366}$ type 60 (E. Merck). Flash chromatography using BDH silica gel Kieselgel 60, 230−400 mesh, was employed for all column chromatography.

Petroleum ether refers to a fraction with boiling range 30−60°C. Anhydrous diethyl ether (ether), tetrahydrofuran (THF), dimethoxyethane (DME), and dioxane were obtained by distillation from lithium aluminum hydride or potassium/benzophenone. Absolute ethanol and methanol were dried by distillation from magnesium. Dry hexamethylphosphoramide (HMPA), dimethylformamide (DMF), dimethyl sulfoxide (DMSO), and diisopropylamine were prepared by distillation from calcium hydride. Solutions in organic solvents were dried over anhydrous magnesium sulphate and stripped of solvent with a Büchi rotary evaporator connected to a water aspirator. Unless otherwise indicated all reactions were conducted under an atmosphere of dry nitrogen.

1,2-Epoxy-3-butanone

3-Butenone (56 g, 0.8 mol, Aldrich) was dissolved in methanol (400 mL) containing 30% hydrogen peroxide (230 mL) and the solution cooled to 0°C with an external ice bath. Aqueous sodium hydroxide (2 *M*, 200 mL) was added dropwise to the stirred solution (caution: initially the reaction is very exothermic) maintaining the temperature

below 20°C. Stirring was continued for a further 2 h at 22°C after addition was complete, the reaction was extracted with dichloromethane (5×), the extracts dried, filtered, concentrated, and the product purified by distillation to give the epoxy-ketone, 42 g (60%), bp 45–46°C/12 Torr (1 Torr = 133.3 Pa) (the yield was 71% on a smaller scale); ir (film): 1715 (C=O), 1260, 865 (C—O) cm^{-1}; ^1H nmr (CCl_4) δ: 1.99 (s, 3H, CH_3), 2.92 (m, 2H, CH_2-O), 3.28 (dd, 1H, J = 1.5, 1 Hz, O=C-CH-O). *Exact Mass* calcd. for $C_4H_6O_2$: 86.0368; found: 86.0352.

6-Methyl-6-oxiranyl fulvene (1)

A stirred, methanol solution (12 mL) of cyclopentadiene (3.30 g, 0.05 mmol, Aldrich) and 1,2-epoxy-3-butanone (4.30 g, 0.05 mol) was cooled to 0°C and pyrrolidine (0.25 mL) added. The yellow colour due to the fulvene was immediately observed and stirring was continued for 2 h at 0°C, 2 h at 22°C, and the reaction poured into cold, dilute aqueous HCl and extracted with petroleum ether. The combined organic layers were washed with saturated aqueous sodium bicarbonate, followed by brine, dried, filtered and concentrated to give the fulvene (**1**), 5.8 g (86%). The fulvene was sufficiently pure for direct use; upon storage at −20°C it formed yellow crystals, and it was kept anhydrous by addition and evaporation of anhydrous benzene; ir (film): 3060 (H-C=), 1635 (s, C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 1.91 (s, 3H, CH_3), 2.82 (m, 2H, CH_2-O), 3.90 (dd, 1H, J = 1.5, 1 Hz, CH-O), 6.35 (m, 4H, H-C=C). *Exact Mass* calcd. for $C_{10}H_{10}O$: 134.0732; found: 134.0708.

General procedure for the addition of lithium reagents to fulvene (1)

The appropriate lithium reagent (Aldrich or ROC/RIC, 1.2 equiv.) was added dropwise to a stirred tetrahydrofuran (20 mL) solution containing the fulvene (**1**) (2.01 g, 15 mmol) maintained at −78°C by an external solid CO_2/acetone bath. After stirring for 10 min at −78°C, it was allowed to warm to 0°C and saturated aqueous ammonium chloride was added. The mixture was extracted with ether, the combined ether extracts dried, filtered, concentrated, and the product purified by chromatography (25% ethyl ether/*n*-hexane) to give the spiro-alcohols **9**–**14**. In each case 10–15% of the fulvene **1** was also recovered.

2,2-Dimethyl-1-hydroxymethylspiro[2.4]hepta-4,6-diene (9): 1.24 g (55%); ir (film): 3350 (br, OH), 3090, 3060 (H-C=), 1650 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 1.38 (s, 3H, CH_3), 1.40 (s, 3H, CH_3), 2.22 (t, 1H, J = 7 Hz, cyclopropyl H), 3.18 (br s, 1H, OH), 3.71 (d, 2H, J = 7 Hz, CH_2-O), 6.20 (m, 2H, H-C=), 6.36 (m, 2H, H-C=C). *Exact Mass* calcd. for $C_{10}H_{14}O$: 150.1044; found: 150.1025.

2-Methyl-2-(1-butyl)-1-hydroxymethylspiro[2.4]hepta-4,6-diene (10): 1.50 g (52%, ~1:1 isomer ratio); ir (film): 3330 (br, OH), 3085, 3060 (H-C=), 1630 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 0.91 (br t, 3H, CH_2CH_3), 1.38 (s, 3H, CH_3), 2.21 (t, 1H, J = 7 Hz, cyclopropyl H), 3.22 (br s, 1H, OH), 3.73 (d, 2H, J = 7 Hz, CH_2-O), 6.18 (m, 2H, HC=C), 6.39 (m, 2H, H-C=C). *Exact Mass* calcd. for $C_{13}H_{20}O$: 192.1514; found: 192.1511.

2-Methyl-2-(1-methyl-1-propyl)-1-hydroxymethylspiro[2.4]hepta-4,6-diene (11): 1.15 g (40%), the major isomer (~3:1) was separated by tlc although the minor isomer could not be fully resolved; major, ir (film): 3325 (br, OH), 3070 (sh), 3055 (H-C=), 1645 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 0.80 (d, 3H, J ~ 6 Hz, CH_3-CH), 1.05 (m, 3H, CH_2CH_3), 1.21 (s, 3H, CH_3), 2.23 (t, 1H, J = 7 Hz, cyclopropyl H), 2.78 (br s, 1H, OH), 3.71 (d, 2H, J = 7 Hz, CH_2-O), 6.20 (m, 2H, H-C=C), 6.40 (m, 2H, H-C=C). *Exact Mass* calcd. for $C_{13}H_{20}O$: 192.1514; found: 192.1516; minor, ir (film): 3350 (br, OH), 3080 (sh), 3055 (H-C=), 1650 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 0.70–1.08 (m, 6H, overlapping CH_3's), 1.22 (s, 3H, CH_3), 2.20 (m, 1H, cyclopropyl H), 3.70 (m, 2H, CH_2-O), 6.17 (m, 2H, H-C=C), 6.39 (m, 2H, H-C=C). *Exact Mass* calcd. for $C_{13}H_{20}O$: 192.1514; found: 192.1516.

2-Methyl-2-vinyl-1-hydroxymethylspiro[2.4]hepta-4,6-diene (12): 1.12 g (46%); ir (film): 3340 (br, OH), 3060 (H-C=), 1665 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 1.50 (s, 3H, CH_3), 2.53 (t, 1H, J = 7 Hz, cyclopropyl H), 3.10 (br s, 1H, OH), 3.80 (d, 2H, J = 7 Hz, CH_2-O), 4.93 (m, 1H, H-C=), 5.15 (m, 1H, H-C=), 5.7–6.1 (m, 1H, C=CH-C), 6.28 (m, 4H, cyclopentadiene H). *Exact Mass* calcd. for $C_{11}H_{14}O$: 162.1044; found: 162.1050.

6-Methyl-6-(1-ethyl-2-hydroxy)fulvene (13): 35%; ir (film): 3325 (br, OH), 3085, 3060 (H-C=), 1635 (s, C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 1.12 (s, 3H, CH_3), 2.54 (t, 2H, J = 7 Hz, =C-CH_2-), 3.28 (br s, 1H, OH), 3.63 (t, 2H, J = 7 Hz, CH_2-O), 6.32 (s, 4H, H-C=C). *Exact Mass* calcd. for $C_9H_{12}O$: 136.0888; found: 136.0873.

Addition of 2-lithio-1,3-dithiane to fulvene 1

A solution of tetrahydrofuran (6 mL) containing 1,3-dithiane (0.96 g, 8 mmol, Aldrich) was cooled to −60°C with an external solid CO_2/methanol bath. *n*-Butyllithium (0.74 mL, 9.5 *M*, 7 mmol, Aldrich) was added dropwise, after 5 min the reagent was warmed to 0°C, recooled to −60°C, fulvene **1** (0.804 g, 6 mmol) in tetrahydrofuran (3 mL) added dropwise, and the reaction stirred for 10 min at −60°C followed by 2.5 h at 22°C. Aqueous saturated ammonium chloride (10 mL) was added, the mixture extracted with ether, the combined ether extracts dried, filtered, concentrated, and the product purified by chromatography (20% ethyl ether/*n*-hexane) to give **14**, 0.470 g (31%, ~1:2) and **15**, 0.240 g (16%); when the reaction was conducted for 5 h at −60°C the relative amounts changed, **14**, 0.310 g (20%, ~2:3) and **15**, 0.430 g (28%); when the reaction was conducted for 2.5 h at −60°C followed by 40 min at 22°C the products were **14**, minor isomer 0.140 g (10%), major isomer 0.230 g (15%) and **15**, 0.390 g (26%).

2-Methyl-2-(2-(1,3-dithianyl)-1-hydroxymethylspiro[2.4]hepta-4,6-diene (14): major, ir (film): 3380 (br, OH), 3070 (sh), 3055 (H-C=), 1635 (C=C), cm^{-1}; ^1H nmr (CCl_4) δ: 1.45 (s, 3H, CH_3), 1.91 (m, 2H, ring CH_2), 2.28 (t, 1H, J = 7 Hz, cyclopropyl H), 2.73 (m, 4H, CH_2-S), 3.91 (s, 1H, S-CH-S), 6.14 (m, 2H, H-C=C), 6.39 (m, 2H, H-C=C). *Exact Mass* calcd. for $C_{13}H_{18}OS_2$: 254.0799; found: 254.0808; minor, ir (film): 3420 (br, OH), 3055 (H-C=), 1635 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 1.53 (s, 3H, CH_3), 1.97 (m, 2H, ring CH_2), 2.41 (m, 1H, cyclopropyl H), 2.73 (m, 4H, CH_2-S), 3.76 (m, 2H, CH_2-O), 4.36 (s, 1H, S—CH—S), 6.14 (m, 2H, H-C=C), 6.44 (m, 2H, H-C=C). *Exact Mass* calcd. for $C_{13}H_{18}OS_2$: 254.0799; found: 254.0813.

6-Methyl-6-(1-propyl-1-hydroxy-3-(2-(1,3-dithianyl)fulvene (15): ir (film): 3415 (OH), 3090, 3060 (H-C=), 1640 (s, C=C), cm^{-1}; ^1H nmr (CCl_4) δ: 2.08 (m, 4H, CH_2), 2.18 (s, 3H, CH_3), 2.87 (m, 4H, CH_2-S), 4.15 (dd, 1H, J = 6, 8 Hz, S-CH-S), 5.23 (m, 1H, CH-O), 6.52 (s, 4H, H-C=C). *Exact Mass* calcd. for $C_{13}H_{18}OS_2$: 254.0799; found: 254.0800.

Addition of potassium nitromethane to fulvene 1: preparation of (1-nitro-2-oxiranylpropyl)cyclopentadiene (16)

Potassium hydride (7.43 g, 65 mmol, 35% suspension in oil, Aldrich) after washing with dry hexane, was suspended in tetrahydrofuran (100 mL) and nitromethane (6.5 mL, 120 mmol) added to the stirred mixture. Stirring was continued at 22°C until all the potassium hydride has dissolved. The solution was cooled to 0°C, 18-crown-6 ether (0.2 g, Aldrich) added, followed by the fulvene **1** (8.04 g, 60 mmol) in tetrahydrofuran (20 mL) which was added dropwise. After 1 h at 0°C saturated aqueous ammonium chloride (30 mL) was slowly added, the mixture was extracted with ether, the combined ether extracts were dried, filtered, concentrated, and the product purified by chromatography (25%–50% ethyl ether/*n*-hexane) to give recovered fulvene (1 g) plus **16**, 5.4 g (46%), ~1:2 isomer ratio; ir (film): 3040 (H-C=), 1535 (NO_2), 1565 (NO_2) cm^{-1}; ^1H nmr (CCl_4) δ: 1.16, 1.28 (s, 3H, CH_3), 2.59 (m, 2H, CH_2-O), 3.01 (m, 2H, C=C-CH_2-C=C), 3.11 (m, 1H, CH-O), 4.54 (m, 2H, CH_2NO_2), 6.15–6.65 (m, 3H, H-C=C); (400 MHz, $CDCl_3$) δ: 0.90, 0.96, 1.00, 1.05 (s, 3H, CH_3's), 2.00 (overlapping m, 2H, CH_2-O), 2.58, 2.70 (m, 2H, C=C-CH_2-C=C), 2.70, 2.89 (m, 1H, CH-O), 3.80–4.09 (overlapping m, 2H, CH_2NO_2), 5.83, 6.03, 6.19, 6.40 (m, 3H, H-C=C). *Exact Mass* calcd. for $C_{10}H_{13}NO_3$: 195.0895; found: 195.0880.

*Treatment of cyclopentadiene-epoxide **16** with methyllithium: preparation of (1-methyl-2-nitro-3-hydroxymethylcyclopropyl)-cyclopentadiene (**18**)*

The cyclopentadiene-epoxide **16** (1.95 g, 10 mmol) was dissolved in THF (5 mL) and added dropwise to a stirred THF (30 mL) solution containing methyllithium (14 mL, 22 mmol, 1.56 *M*, Aldrich) maintained at −78°C with an external solid CO_2/acetone bath. Stirring was continued for a further 10 min after addition was complete, the reaction was allowed to warm to 22°C, and saturated aqueous ammonium chloride added slowly. The mixture was extracted with ether, the combined ether extracts washed with brine, dried, filtered, concentrated, and the product purified by chromatography (50% ether/*n*-hexane) to give the cyclopropyl alcohol **18**, 1.37 g, (70%); ir (film): 3300−3500 (OH), 3050 (H-C=), 1630 (C=C), 1540 (sh), 1515 (NO_2), 1365 (sh), 1335 (NO_2) cm^{-1}; ^1H nmr (360 MHz, $CDCl_3$) δ: 1.75 (br t, 1H, $J \sim 7$ Hz, cyclopropyl H), 2.16, 2.17, 2.18 (overlapping s, 3H, CH_3), 2.88, 3.04 (m, 2H, C=C-CH_2-C=C), 3.46 (m, 1H, cyclopropyl H-C-NO_2), 3.94 (m, 2H, CH_2-O), 6.22, 6.37, 6.46 (m, 3H, H-C=), 7.08 (m, 1H, OH).

*(1-Methyl-2-amino(*N*-acetoxy)-3-acetoxymethylcyclopropyl)-cyclopentadiene (**19**)*

The nitro compound **18** (2.34 g, 12 mmol) dissolved in ether (20 mL) was added dropwise to a stirred suspension of lithium aluminum hydride (1.14 g, 30 mmol) in ether (100 mL) maintained at 0°C by an external ice bath. Stirring was continued at 0°C for 2 h after addition was complete and water (2 mL) was added carefully to the reaction mixture, followed by aqueous 20% sodium-potassium tartrate (80 mL). The mixture was extracted with ether, the combined ether extracts washed with brine, dried, filtered, and concentrated to give the amino-alcohol, 1.7 g (86%). This material was dissolved in pyridine (15 mL), the solution cooled to 0°C with an external ice bath, and acetic anhydride (6 mL) added. The reaction was stirred at 0°C overnight, poured into 3 *N* HCl at 0°C, extracted with ether, the combined ether extracts dried, filtered, concentrated, and the product purified by chromatography (100% ethyl ether to 5% 2-propanol/ether) to give **19**, 0.55 g (18%); ir (film): 3275 (NH), 3050 (H-C=), 1735 (C=O), 1650 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 0.96 (m, 2H, cyclopropyl H), 1.95 (s, 3H, CH_3), 2.00 (s, 6H, CH_3C=O), 2.98 (m, 2H, C=C-CH_2-C=C), 4.30 (m, 2H, CH_2-OAc), 6.18−6.53 (m, 3H, H-C=), 7.79 (br, 1H, NH).

Photolysis of 4-diazo-2-pyrazolin-5-ones in methanol gives a mixture of stereoisomeric methyl 3-aryl-(or alkyl-)azo-2-alkenoates. A study of the absorption spectra of the species generated upon steady-state photolyses in glasses at 77 K, in solution at 296 K, and by laser and lamp flash photolysis experiments suggests that a long-lived heterocyclic intermediate that we formulate as a carbene or its valence isomer, as well as a ketene generated by ring opening, are precursors to the esters.

PESI UMRIGAR, GARY W. GRIFFIN, SEYHAN N. EGE, ALAN D. ADAMS et PARITOSH K. DAS. Can. J. Chem. **62**, 2456 (1984).

La photolyse des diazo-4 pyrazoline-2 ones-5 dans le méthanol conduit à un mélange des stéréoisomères des aryl-3 (ou alkyl-3) azo-2 alcènoates de méthyle. Sur la base d'une étude des spectres d'absorption des espèces générées dans les états stationnaires de photolyses réalisées dans des verres à 77 K et en solution à 296 K ainsi que ceux des espèces générées lors d'expériences de photolyse éclair provoquées par des lampes ou des laser, on suggère que les précurseurs des esters sont d'une part un intermédiaire hétérocyclique à longue vie que l'on formule sous forme de carbène ou de son isomère de valence et d'autre part un cétène généré par son ouverture de cycle.

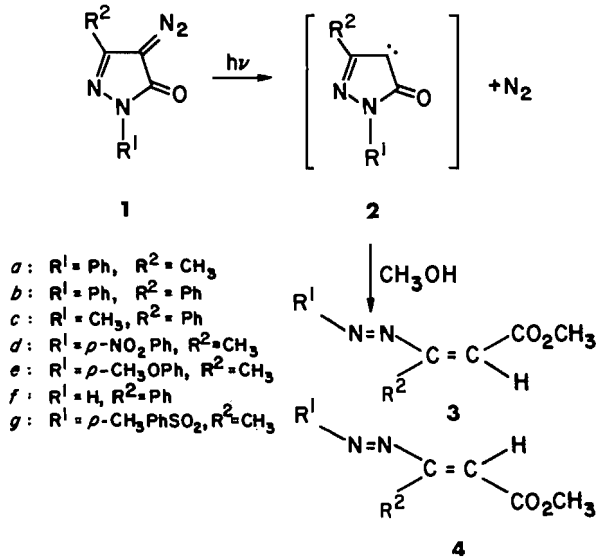
Introduction

Diazo compounds are classical thermal and photochemical precursors of carbenes (1). We became interested in 4-diazo-2-pyrazolin-5-ones (**1**) as possible sources of heterocyclic carbenes **2** (Scheme 1) when we failed to find products derived from such carbenes during experiments on the photochemical fragmentation of 1-oxa-5,6-diazaspiro[2.4]hept-6-ene-4-ones, pyrazolinone spirooxiranes (**5***b*), even when aryl aldehydes **7** were isolated in high yields (2) (Scheme 2). The intervention of another reactive intermediate, carbonyl ylides **6**, in the photochemical reactions of oxiranes **5***b* complicates the search for carbenes **2**, hence we attempted to create **2** in an alternative and more conventional manner by photolysis of diazopyrazolinones **1**, prepared by diazo transfer reactions (3) from the corresponding pyrazolinones (Table 1).

Results and discussion

No carbene addition products, as have been observed upon photolysis of 1-methyl-3-diazooxindole (4) in alkenes, are found when diazopyrazolinone **1***a* is photolyzed in 2,3-dimethyl-2-butene or cyclohexene. The mixture of products is not separable by chromatography, an outcome that was not surprising in light of similar mixtures obtained when oxiranes **5***b* are photolyzed in the presence of alkenes (2). Nor do we have evidence of cycloaddition of the diazopyrazolinones to the alkenes as has been observed in a thermal reaction of **1***a* with an electron-deficient alkene (5).

Photolysis of **1***a* in acetone, attempted to see whether carbene **2***a* may have been intercepted by acetone (6) to give oxirane **5***a* (isolated as the chief photoproduct when 5-methyl-2-phenyl-3-pyrazolidinone is irradiated in acetone (7)), also gave no isolable products and no chromatographic evidence of the formation of **5***a*.



SCHEME 1. Esters isolated from **1***a*, **1***b*, **1***c*, and **1***e*.

Diazopyrazolinone **1***a* upon photolysis in methanol gives chiefly methyl (*Z*)-3-phenylazo-2-butenoate (**3***a*), which, upon standing in deuteriochloroform, is converted over a week to the thermodynamically more stable (*E*)-isomer, **4***a*. A similar acid-catalyzed isomerization of (*Z*)-3-phenylazo-2-butenenitrile to the (*E*)-isomer has been reported (8). Experimentally, we determined that the isomerization did not occur thermally in the photolysis mixture and that the two stereoisomers were not photochemically interconvertible. Thus it is certain that the photochemical reaction leads predominantly to the thermodynamically less stable isomer.

The assignment of the phenylazo ester structures **3***a* and **4***a*

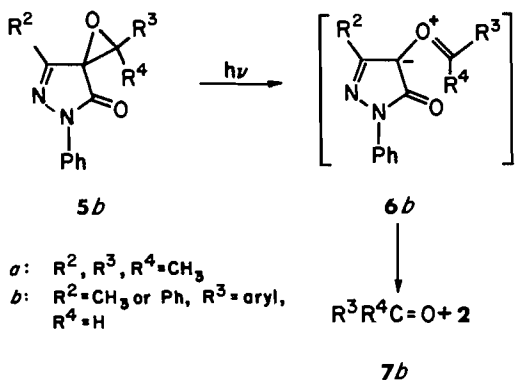
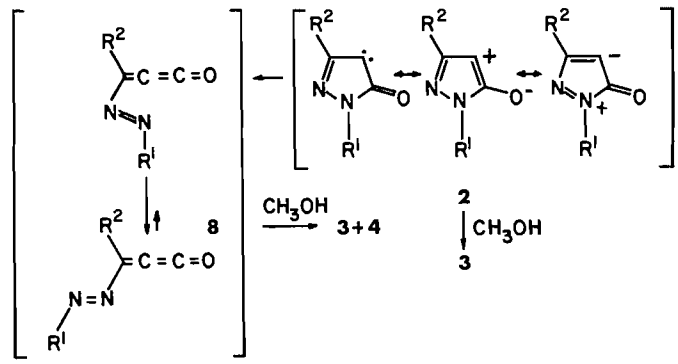


SCHEME 2



SCHEME 3

to the photoproducts of **1***a* was based on the formation of the known (9) ethyl (*E*)-3-phenylazo-2-butenoate when **1***a* was photolyzed in ethanol. In both sets of stereoisomeric esters, as well as in the case of the stereoisomeric phenylazobutenenitriles (8), the methyl group on the carbon–carbon double bond has the smaller chemical shift: δ 2.04 for **3***a*, δ 2.05 for the (*Z*) ethyl ester, δ 2.13 for the nitrile, as compared to δ 2.41 for **4***a*, δ 2.40 for the (*E*) ethyl ester, and δ 2.28 for the (*E*)-nitrile. Similarly for both sets of esters, the vinylic hydrogen in the (*Z*)-ester is upfield, δ 6.20 for **3***a* and δ 6.24 for the ethyl ester compared to δ 6.77 for **4***a* and the (*E*)-isomer of the ethyl ester. These values were also used to assign stereochemistry to the azoesters obtained as photoproducts from other diazopyrazolinones **1**. Along with the esters **3***a* and **4***a*, polymeric materials were separated from the photolysis mixture.

Similar mixtures of (*Z*)- and (*E*)-arylazoalkenoic acid esters **3** and **4**, as well as polymeric material, have been obtained from **1***b* and **1***e*, and an unstable yellow oil having the ^1H nmr spectrum expected of methyl (*Z*)-3-methylazo-3-phenylpropenoate (**3***c*) was obtained when **1***c* was photolyzed in methanol. The two diazopyrazolinones bearing electron-withdrawing groups on the ring nitrogen atom, **1***d* with a *p*-nitrophenyl group and **1***g* with a tosyl group, do not give such esters as photoproducts, and **1***f*, which is unsubstituted on the nitrogen atom, gives only polymeric material. These findings are summarized in Scheme 1. The photochemical reactivity of **1***f* is in direct contrast to its thermal stability (10). It withstands refluxing xylene, but heating of **1***f* in benzyl alcohol to reflux gives 4-benzyl-3-phenyl-2-pyrazolin-5-one, an unusual reduction reaction (10).

Two mechanisms account for the formation of open-chain azoesters **3** and **4**, as depicted in Scheme 3. The electronic charge distribution in **2** may be such that this transient has zwitterionic character. Concerted or non-concerted nucleophilic attack and protonation of **2** in methanol results in the formation of the (*Z*)-esters **3**, but fails to account for the presence of the (*E*)-isomers **4** unless we assume tht rotation of the carbonyl function about the carbon-3 – carbon-4 axis is possible in the transition state.

In the alternate mechanism shown in Scheme 3, carbene **2**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

undergoes ring opening to ketene **8**, which subsequently is intercepted by methanol to give **3** and **4**. The stereochemical outcome of the photolyses of the diazopyrazolinones described above is difficult to rationalize on the basis of a ring-opened ketene intermediate, which should give approximately equal quantities of **3** and **4**, if not indeed an excess of the thermodynamically more stable **4**. The formation of the (*Z*)-ester **3***c* exclusively from the photolysis of diazopyrazolinone **1***c*, especially, points to a direct attack of the nucleophilic solvent on carbene **2**. In this case, the presence of the electron-donating methyl group on the nitrogen atom of the pyrazolinone ring facilitates the development of positive charge on the nitrogen, precluding ring opening of the carbene to ketene.

It might be argued that if an electron-donating substituent at the 1-position of the pyrazolinone ring system provides additional driving force for the formation of the azoesters, then the reverse should also hold true; that is, an electron-withdrawing substituent at this position should inhibit the conversion of diazopyrazolinones **1** to azoesters by this mechanism. In fact, because this mechanism appears to be the more important one, even in the case of **1***a* and **1***b*, a powerful electron-withdrawing substituent at the 1-position of the ring may destabilize the transition state for the ring opening of the carbene to such an extent that the reaction path is altered. Indeed, the two diazopyrazolinones **1***d* and **1***g* that have substitution on the ring nitrogen atom that would destabilize one zwitterionic form of **2** do not give esters as products upon photolysis.

Ketenes have been proposed as reactive intermediates in the ring contraction reactions of a number of heterocyclic α-diazoketones. Among these are 3-diazo-4-oxo-3,4-dihydroquinolines, which give derivatives of 3-indolecarboxylic acids (11, 12) as well as 3-diazo-4-oxo-3,4-dihydropyridine (12) and diazopyridazine derivatives (13). The ring contraction reaction is also seen for analogs of 3-diazo-4-oxoindanes in which the methylene group of the five-membered ring is replaced by sulfur or oxygen, but not in 3-diazooxoindoles (4, 14). To our knowledge, however, ring opening of heterocyclic carbenes has been reported only for thermolysis reactions of 3-diazoindazoles (15) and of 3-diazopyrazole (16), in which products are postulated to arise from such rearrangement of a carbene to a cyanonitrene. Photolysis of these compounds gives primarily carbene insertion products (16, 17), though the carbenes derived from diazopyrazoles are reported to be electrophilic enough to react with the oxygen atom of ethers giving products interpreted to arise from the ionic cleavage of the resulting oxonium ions (16).

Carbenes usually react with alcohols to give ethers; the reactivity of an alcohol with a carbene in this manner depends upon the acidity of the alcohol and upon the electronic character of the carbene (18). Photolysis of diazoimidazoles in alcohols, however, gives, along with ethers, significant amounts of products derived from insertion into carbon–hydrogen bonds (19), a reaction seen previously only at low temperatures in alcohol matrices (20). The reaction that we see differs from both of these modes of reactivity.

In contrast to the reactions we observed, photolyses of 3-carbethoxy-4-diazo-1-phenyl-2-pyrazolin-5-one in dioxane, ethanol, benzene, or tetrahydrofuran are reported (21) to give a variety of decomposition products, the only isolable one being a compound derived from insertion of the terminal nitrogen atom of the diazo group in a carbon–hydrogen bond in tetrahydrofuran. Thus 4-diazo-2-pyrazolin-5-ones appear to have a range of thermal (5, 10) and photochemical (21) reactions that depends heavily on the substituents on the pyrazolinone ring.

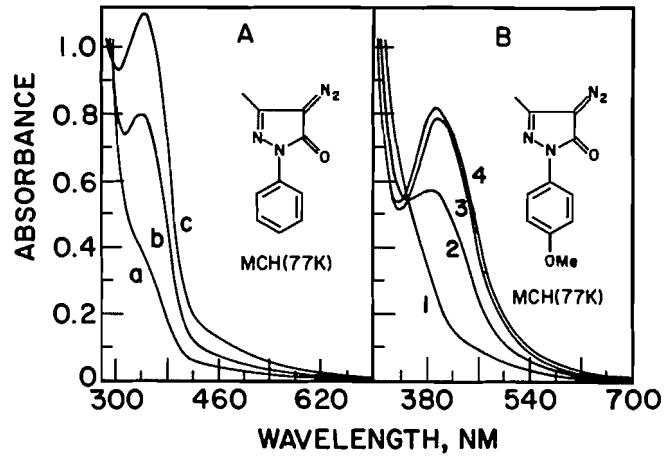


FIG. 1. Absorption spectral changes from steady-state photolysis of **1***a* (A) and **1***e* (B) at 366 nm in methylcyclohexane glass at 77 K. Irradiation times are: 0, 5, and 15 min for the spectra marked a, b, and c, respectively in Fig. A and 0, 2.5, 5, and 7.5 minutes for the spectra marked 1, 2, 3, and 4, respectively, in Fig. B.

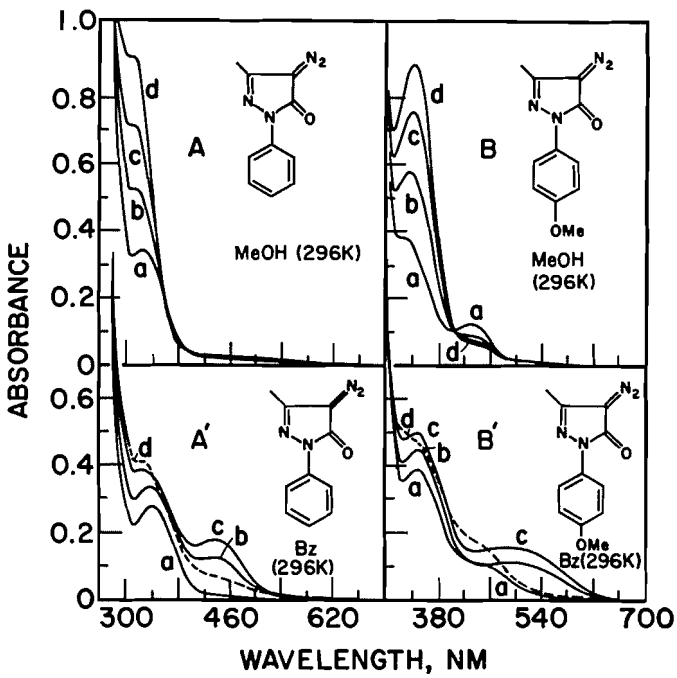

FIG. 2. Absorption spectral changes from steady-state photolysis (366 nm) of **1***a* and **1***e* at 296 K. **1***a* (A) in methanol; irradiation times: 0, 1, 2, and 3 min for a, b, c, and d, respectively. **1***e* (B) in methanol; irradiation times: 0, 1, 2, and 3 min, respectively. **1***a* in benzene (A′); irradiation times: 0, 1, and 3 min for a, b, and c, respectively; the spectrum d (dotted line) was obtained 25 min after adding methanol to the irradiated solution (to make 0.6 *M* in MeOH). **1***e* in benzene (B′); irradiation times: 0, 2, and 3 min for a, b, and c, respectively; the spectrum d (dotted line) was recorded at 10 min, following the addition of methanol to the irradiated solution (to make 0.6 *M* in MeOH).

The nature of the intermediates formed from diazopyrazolinones **1** was further investigated by studying the absorption spectra of the species generated upon steady-state photolyses in glasses at 77 K (Fig. 1), in solution at 296 K (Fig. 2), and by laser (Figs. 3 and 4) and conventional lamp flash

TABLE 2. Absorption maxima (λ_{max}, nm) observed upon photolyses of diazopyrazolinones under different conditions

Diazopyrazolinone	Steady-state irradiations		Flash photolyses	
	77 K (solvent glasses)[a]	296 K (solvent)[a]	Laser (solvent, lifetime)[a,b]	Lamp (solvent, lifetime)[a]
1*a*	342 (MCH) 350 (MTHF)	314,460 (MeOH) 327,442 (ϕH) 322,435 (MCH)	345 (MeOH, >150 μs) 345 (CH, >150 μs) 350 (ϕH, >150 μs)	
1*c*			315–320 (ϕH, >150 μs) 315–320 (MeOH, 90 μs) 315–320 (*i*-PrOH, >1 ms)	
1*e*	394 (MCH)	340,520 (MeOH) 350,495 (ϕH)	400 (MeOH, >150 μs) 400 (CH, >150 μs) 405 (ϕH, >150 μs)	400 (CH, >100 ms) 400,450 (MeOH, 2 ms)[c]
1*f*			305–310 (ϕH, >150 μs) 305–310 (MeOH, 18 μs) 305–310 (EtOH, 75 μs) 305–310 (*i*-PrOH, 700 μs)	
1*g*			No transient absorption in ϕH, MeOH	

[a] MCH = methylcyclohexane; MTHF = 2-methyltetrahydrofuran; CH = cyclohexane.
[b] The lifetimes of the transients formed here are not affected by cyclohexene and dimethyl acetylenedicarboxylate (for **1***c*, **1***e*, and **1***f*).
[c] Absorption at 340 nm, corresponding to the photoproduct seen upon steady-state irradiation in MeOH, develops.

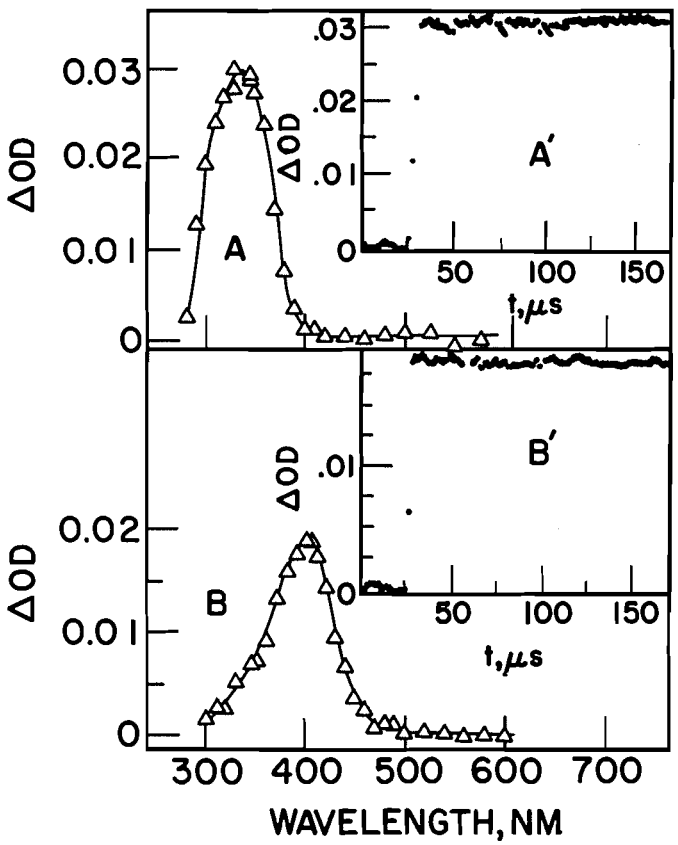

FIG. 3. Transient absorption spectra observed at 10 μs following 337.1-nm laser flash photolysis of **1***a* (A) and **1***e* (B) in degassed methanol. Insets: typical experimental traces in degassed methanol for **1***a* at 350 nm (A′) and **1***e* at 400 nm (B′).

photolysis experiments. The most significant findings of these experiments are summarized in Table 2. Two findings correlate directly with the preparative scale steady-state experiments described above. First, diazopyrazolinone **1***g*, which gives no isolable product, also exhibits no absorption attributable to a transient upon laser flash photolysis. Second, the absorption spectrum developed upon steady-state irradiation of **1***a* in methanol at room temperature (Fig. 2A, λ_{max} 314 nm) corresponds closely with those of the product azoesters (λ_{max} 308 nm for **3***a*; 311 nm for **4***a*). This second finding is significant because two other species with different transient absorption spectra have also been observed for diazopyrazolinones **1***a* and **1***e*. In methylcyclohexane glass at 77 K, steady-state irradiation of **1***a* and **1***e* at 366 nm leads to the formation of photoproducts with absorption maxima at 342 and 394 nm and isobestic points at 298 and 345 nm, respectively (Figs. 1A and B). When the glass from the photolysis of **1***a* is allowed to warm up, bands at 322 and 435 nm develop. This same spectrum is obtained when **1***a* is subjected to steady-state irradiation at 296 K in methylcyclohexane.

The species observed in matrix have spectra similar to those observed upon laser flash photolysis of **1***a* and **1***e* in methanol, benzene, and cyclohexane. Diazopyrazolinone **1***a* in methanol, for example, gives a photoproduct with λ_{max} 345 nm that does not decay over 100–150 μs. A similar intermediate, λ_{max} 400 nm, is observed for **1***e*. These experimental results, including insets A′ and B′ showing the persistence over time of the species formed, are shown in Figs. 3A and 3B. Observation of transient phenomena within ~20 ns following the laser pulse shows that the products are formed within that time period. Experiments with **1***e* in methanol at temperatures as low as −100°C indicate no formation or decay process that can be attributed to a precursor of the long-lived photoproduct observed at 400 nm.

Conventional flash photolysis of diazopyrazolinone **1***e* allows us to observe the intermediate over longer periods of time. The same transient with λ_{max} 400 nm is observed in cyclohexane and does not decay over 100 ms. In methanol, however, we observe that the intermediate has a lifetime of 2 ms and that decay is coincident withe the development of a band at 340 nm, corresponding to the absorption maximum seen when **1***e* is subjected to steady-state irradiation in methanol at 296 K (Fig. 2B).

In contrast to the results obtained at 77 K and upon flash photolysis, diazo compound **1***a* gives rise to another species with significant absorption at 327 and 442 nm when subjected

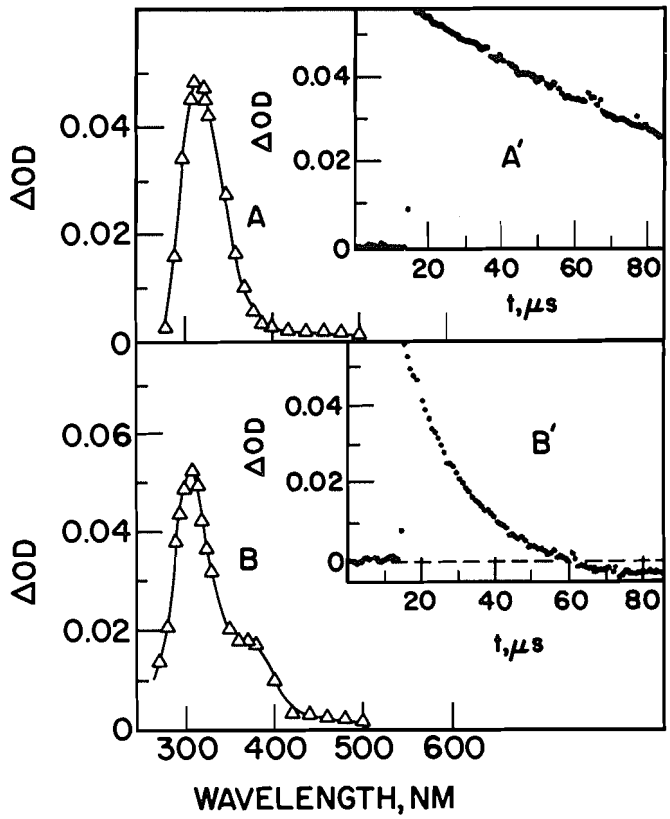

FIG. 4. Transient absorption spectra observed at 10 μs following 337.1-nm laser flash photolysis of **1***c* (A) and **1***f* (B) in degassed benzene. Insets: experimetnal decay curves in degassed methanol for **1***c* at 320 nm (A′) and **1***f* at 310 nm (B′).

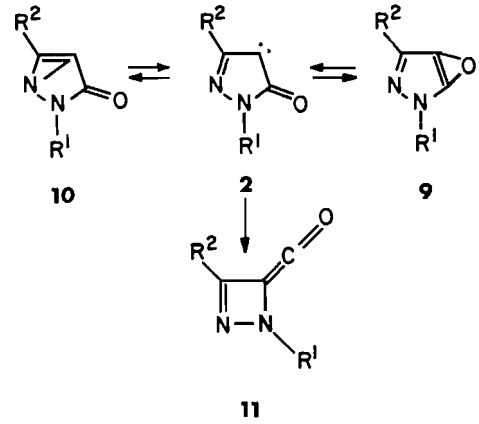
to steady-state irradiation at 296 K in benzene (Fig. 2A′). The corresponding experiment in benzene for **1***e* gives a spectrum (Fig. 2B′) with absorption at 350 and 495 nm. When methanol is added to these benzene solutions in the dark, the species observed appear to be converted into the products seen when **1***a* and **1***e* are irradiated in methanol (cf. traces d in Figs. 2A′ and 2B′ with Figs. 2A and 2B).

Laser flash photolyses (Fig. 4) of diazopyrazolinones **1***c* and **1***f*, which do not have phenyl groups on nitrogen, give transients that have shorter lifetimes and an interesting sensitivity to the alcohol used in quenching experiments. The transient from **1***c* has a lifetime of 90 μs in methanol, but over 1 ms in 2-propanol. That from **1***f* has a lifetime of 18 μs in methanol, 75 μs in ethanol, and 70 μs in 2-propanol. If the transients observed are carbenes, they show a much larger range of reactivity with different alcohols than has been previously observed (18*b*).

Upon the photolysis of compounds **1***a* and **1***e*, we appear to observe three distinct species. The spectra generated upon steady-state irradiation at 296 K in methanol are assigned to the azoesters **3** and **4**. The species with the long-wavelength absorption that are generated in benzene and methylcyclohexane at 296 K and that are converted to azoesters upon the addition of methanol are assigned arylazoketene structures **8**.

Assignment of structure to the third species, observed at low temperatures and in laser flash photolysis experiments, is more difficult. These species, absorbing at ~342–345 nm when generated from **1***a* and at ~394–400 nm for **1***e*, are very long-lived with lifetimes extending into milliseconds. While lifetimes for many carbenes have not been determined, the ones



SCHEME 4

reported vary from 27 ns for triplet fluorenylidene (22) to values in the μs range for triplet diphenylmethylene (23), *p*-nitrophenylmethylene (2*b*), and 10,11-dihydrobenzo[*a*,*d*]-cycloheptenylidene (24). Dimesitylcarbene, with a lifetime of ~200 μs, has been recently characterized as a particularly long-lived carbene (25).

In view of the isolation of the (*Z*)-azoesters **3** as the major photoproducts in methanol, we are inclined to assign a cyclic structure to the species observed upon flash photolysis. The species from **1***e*, for example, seems to react directly with methanol to give the azoester.

The observed lifetimes of the transients and their lack of conventional carbenoid reactivity suggest alternative structures for the species. Valence isomers such as oxirenes **9**, well-known intermediates in the photochemistry of α-diazocarbonyl compounds (26), azirenes **10**, or diazetine-ketenes **11** derived from contraction of the ring in carbene **2** are possibilities (Scheme 4). Such formulations require, however, that the precursor of these species, carbene **2**, be very short-lived ($\tau < 5$ ns) for all of the systems that we have examined under different conditions.

The data now available do not allow us to distinguish among the several possibilities. Infrared spectroscopy of matrix-isolated species at low temperatures may permit a more definitive assignment of structure to the unusual heterocyclic intermediate observed. We continue to investigate the properties of these interesting species.

Experimental

The photolyses from which products were isolated were carried out in 17 cm × 2.5 cm id Pyrex test tubes, which were then sealed with rubber serum caps wired into place. The samples were deoxygenated by nitrogen sparging for 30 min prior to irradiation. Irradiations were conducted in a Rayonet Photochemical Reactor (Southern New England Ultraviolet Co., Middletown, Conn.) employing, unless otherwise specified, sixteen 8-W G8T5 (254 nm) or F8T5/BLB (350 nm) low-pressure mercury lamps (General Electric Company). Solutions were usually stirred magnetically during irradiation.

In experiments to measure the spectral changes that occur upon steady-state irradiation at 366 nm, the excitation source was a Bausch and Lomb SP-200 medium pressure mercury lamp coupled with a Bausch and Lomb 33-86-07 monochromator and a Corning filter (CS 0-54). Photolyses at room temperature were performed on degassed solutions (4 mL, ~10–4 *M*) contained in quartz cells (1 cm^2). Solutions (~10–4 *M*) contained in rectangular quartz cells with a path-length of ~3 mm were immersed in liquid nitrogen in a Dewar fitted with flat-faced quartz windows for the experiments at 77 K.

Ultraviolet and visible spectra were obtained on a Cary Model 17 spectrophotometer. Mass spectra were determined with a Hitachi Perkin–Elmer RMU-6E spectrometer. Infrared spectra were recorded on Beckman and Perkin–Elmer 237B spectrometers. The ^{1}H nmr were obtained on Varian A-60, T-60, or Hitachi Perkin–Elmer R-20B spectrometers or a JEOL FX-90Q spectrometer. Deuteriochloroform was generally used as the solvent with 1% tetramethylsilane as the internal standard.

Fischer spectroscopic grade solvents were used as received for irradiation experiments, except when otherwise indicated. Solutions were evaporated on a rotary evaporator under vacuum. Melting points were obtained in capillary tubes on a Thomas–Hoover apparatus and are uncorrected. Silica Gel G (PF 254; Brinkman Co.) on glass plates was used for thick-layer, Eastman Kodak No. 6060 sheets for thin-layer chromatography (tlc). Oils recovered by chromatography were further purified by bulb-to-bulb distillation under vacuum before elemental analysis. Elemental analyses were performed by Galbraith Laboratories, Inc., Knoxville, Tennessee, or Spang Microanalytical Laboratory, Eagle Harbor, Michigan.

Flash photolyses

All laser flash photolysis experiments (27*a*) were carried out in rectangular quartz cells (3 mm × 7 mm) using pulses (337.1 nm, 8 ns, 3 mJ) from a Molectron UV-400 nitrogen laser system for excitation. The transients were monitored by a kinetic spectrophotometer consisting of an Eimac 150-W xenon lamp (pulsed), a high-intensity Bausch and Lomb monochromator, and an RCA 4840 photomultiplier tube. The signal from the photomultiplier tube was terminated via 93 ohm into a Tektronix transient digitizer, which, in turn, was interphased with a multiuser PDP 11/55 computer system that controlled experiments, processed data, and stored information. Electromechanical shutters in the paths of exciting and analyzing lights, as well as suitable Corning filters, were used to minimize undue exposure of samples to actinic lights. The response of the detector system was ≤1 ns. The apparatus used for conventional flash photolyses is described elsewhere (27*b*). Solutions used for laser flash photolyses experiments were $0.5–1 \times 10^{-3}$ *M*; those for conventional flash photolyses were $1–3 \times 10^{-6}$ *M*.

Preparation of 4-diazo-2-pyrazolin-5-ones

Method A

The pyrazolinone (0.01 mol) was dissolved in dimethylformamide (25 mL) and triethylamine (0.005 mol) was added to the stirred solution. Tosyl azide (28) (0.01 mol) was added in one portion and the solution stirred rapidly for 0.25 h. Hydrochloric acid (6 *N*, 50 mL) was then added to the solution and the resultant brown mixture was diluted with water (500 mL) and twice extracted with benzene (500 mL). The benzene layer was washed with water (300 mL) containing silica gel (20–25 g), dried over magnesium sulfate, and the benzene removed under reduced pressure for **1***c* and **1***f*. Alternatively, for **1***a* and **1***b*, the original benzene extracts were dried, then filtered through silica gel (dry column, 6 in. × 1 in.). The column was eluted with benzene (100–200 mL), and the benzene evaporated to give the product.

Method B

In the preparation of diazopyrazolinone **1***d*, acetonitrile (100 mL) was the solvent and triethylamine was increased to 0.01 mol. The reaction with tosyl azide took 1 h, after which the solvent was removed and the residue triturated with ether (100 mL). The ether solution was shaken with sodium hydroxide (3%, 25 mL) and the aqueous layer extracted twice more with ether (100 mL). The combined ether extracts were washed successively with hydrochloric acid (6 *M*, 200 mL) and water. Drying of the ether (magnesium sulfate) and removal of the solvent gave the product.

Method C

A solution of the pyrazolinone (0.01 mol) in dimethylformamide/water (50 mL, 4:1) was adjusted to pH 3–4 with a hydrochloric acid – sodium acetate (1 *M* in each component) buffer. To this was added a similarly pH-adjusted solution of 2-azido-3-ethylbenzo-1,3-thiazolium tetrafluoroborate (29) (0.01 mol) in the same solvent (50 mL). The mixture was allowed to stand in the dark for 1 h. It was then diluted with water (400–500 mL) and extracted with benzene (500–1000 mL). The benzene layer was washed successively with hydrochloric acid (1 *M*, 300 mL) and water, dried (mganesium sulfate), and evaporated.

*Photolysis of 4-diazo-3-methyl-1-phenyl-2-pyrazolin-5-one (1*a*) in alkenes or acetone*

Diazopyrazolinone **1***a* (200 mg, 1.00 mmol) was dissolved in acetone (distilled from anhydrous calcium sulfate), 2,3-dimethyl-2-butene, or cycloehexene (45 mL) and irradiated at 350 nm for 24 h. Removal of solvent yielded a dark tarry residue that proved unresolvable upon chromatography (silica gel; benzene; chloroform; benzene/chloroform; ethyl acetate/hexane). In the case of acetone, no chromatographic evidence was found for the presence of oxirane **5***a* (7).

*Photolysis of 4-diazo-3-methyl-1-phenyl-2-pyrazolin-5-one (1*a*) in alcohols*

Diazopyrazolinone **1***a* (200 mg, 1.00 mmol) in absolute methanol (50 mL) was irradiated at 350 nm for 24 h. Removal of the solvent, trituration of the residue with ether (5 mL), and preparative thick-layer chromatography (benzene/petroleum ether, 3:2) of the ether-soluble portion of the product, after removal of the ether, gave two fractions. Fraction I was *methyl* (E)*-3-phenylazo-2-butenoate*, red oil, (**4***a*) (13 mg, 6%); λ_{max} (methanol): 540 (ε 94), 433 (ε 3.9×10^2), 311 nm (ε 2.1×10^4); ^{1}H nmr ($CDCl_3$): 2.41 (d, J = 1.2 Hz, 3H), 3.82 (s, 3H), 6.77 (q, J = 1.2 Hz, 1H), 7.40–7.92 (m, 5H) ppm; *m/z* 204. *Anal.* calcd for $C_{11}H_{12}N_2O_2$: C 64.69, H 5.92, N 13.72; found: C 64.76, H 6.04, N 13.61.

Fraction II was methyl (*Z*)-3-phenylazo-2-butenoate, red oil, (**3***a*) (87 mg, 43%); λ_{max} (methanol): 549 (ε 57), 440 (ε 2.4×10^2), 308 (ε 1.6×10^4); ^{1}H nmr ($CDCl_3$): 2.04 (d, J = 0.8 Hz, 3H), 3.76 (s, 3H), 6.20 (q, J = 0.8 Hz, 1H), 7.35–7.91 (m, 5H) ppm; *m/z* 204.

The ether-insoluble residue was a brownish-white solid that decomposed without melting at 212–215°C; ^{1}H nmr ($CDCl_3$): 1.0–2.8 (br), 7.0–7.7 (br); not volatilized in the mass spectrometer.

Diazopyrazolinone **1***a* was photolyzed again under identical conditions, but allowed to stand in the dark for two days before work-up. The ratio of (*Z*)- to (*E*)-esters **3***a* and **4***a* obtained was the same as that above. When the nmr sample of the (*Z*)-ester was allowed to stand for 1 week and the spectrum taken again, the solution contained only (*E*)-isomer.

An identical photolysis experiment was carried out with **1***a* in absolute ethanol (distilled from magnesium in the presence of iodine). The products were ethyl (*E*)-3-phenyl-azo-2-butenoate (16 mg, 7%), mp 48°C (lit. (9) mp 50°C); ^{1}H nmr ($CDCl_3$): 1.37 (t, J = 6.0 Hz, 3H), 2.40 (d, J = 1.2 Hz, 3H), 4.28 (q, J = 6.0 Hz, 2H), 6.77 (q, J = 1.2 Hz, 1H), 7.39–7.94 (m, 5H) ppm; *m/z* 218; and ethyl (*Z*)-3-phenyl-azo-2-butenoate, red oil (92 mg, 42%), ^{1}H nmr ($CDCl_3$): 1.30 (t, J = 6.3 Hz, 3H), 2.05 (d, J = 0.8 Hz, 3H), 4.25 (q, J = 6.3 Hz, 2H), 6.24 (q, J = 0.8 Hz, 1H), 7.38–7.95 (m, 5H) ppm; *m/z* 218.

Investigation of the photochemical interconvertability of (Z)*- and* (E)*-phenylazobutenoates* 3a *and* 4a

(*E*)-Ester **4***a* (30 mg) in methanol (10 mL) was irradiated at 350 nm for 24 h. The ^{1}H nmr analysis of the oil after removal of solvent showed some deterioration of the sample, but no conversion to (*Z*)-isomer **3***a*. Similarly, a mixture of the two isomers **3***a* and **4***a* (30 mg) in methanol (10 mL) was irradiated at 350 nm for 24 h, with no nmr evidence, as judged by the relative intensities of bands at δ 2.41 and δ 2.04, that one isomer had been photochemically converted to the other.

*Photolysis of 4-diazo-1,3-diphenyl-2-pyrazolin-5-one (1*b*) in methanol*

Diazopyrazolinone **1***b* (262 mg, 1.00 mmol) in absolute methanol (50 mL) was irradiated at 350 nm for 24 h. Removal of the solvent, trituration of the residue with ether (5 mL), and preparative thick-layer chromatography (benzene/petroleum ether, 1:1) of the ether-soluble

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

portion after removal of the ether gave two fractions. Fraction I was *methyl* (E)-*3-phenyl-azo-3-phenylpropenoate* (**4***b*), red oil (11 mg, 4%); ^{1}H nmr ($CDCl_3$): 3.79 (s, 3H), 6.87 (s, 1H), 7.35–7.95 (m, 10H) ppm; *m/z* 266. *Anal.* calcd for $C_{16}H_{14}N_2O_2$: C 72.15, H 5.31, N 10.52; found: C 72.32, H 5.28, N 10.66.

Fraction II was methyl (*Z*)-3-phenylazo-3-phenylpropenoate (**3***b*), red oil (104 mg, 39%); ^{1}H nmr ($CDCl_3$): 3.67 (s, 3H), 6.03 (s, 1H), 7.39–8.00 (m, 10H) ppm; *m/z* 266.

Photolysis of 4-diazo-1-methyl-3-phenyl-2-pyrazolin-5-one (1c) in methanol

Diazopyrazolinone **1***c* (285 mg, 1.42 mmol) in absolute methanol (45 mL) was irradiated at 350 nm for 24 h. Removal of the solvent, trituration with ether (5 mL), and preparative thick-layer chromatography (benzene/petroleum ether, 3:2) of the ether-soluble portion after removal of solvent gave a yellow oil (78 mg, 27%), assigned structure as methyl (*Z*)-3-methylazo-3-phenylpropenoate (**3***c*) on the basis of spectroscopic evidence; ^{1}H nmr ($CDCl_3$): 3.66 (s, 3H), 4.06 (s, 3H), 5.95 (s, 1H), 7.35 (s, 5H) ppm; *m/z* 204.

Photolysis of 4-diazo-3-methyl-1-(p-nitrophenyl)-2-pyrazolin-5-one (1d) in methanol

Diazopyrazolinone **1***d* (245 mg, 1.00 mmol) in methanol (50 mL) was irradiated at 350 nm for 24 h. Removal of the solvent gave a dark brown residue that could not be resolved by chromatography (silica gel; benzene; chloroform; benzene/chloroform; ethyl acetate/hexane).

Photolysis of 4-diazo-1-(p-methoxyphenyl)-3-methyl-3-pyrazolin-5-one (1d) in methanol

Diazopyrazolinone **1***e* (70 mg) in absolute methanol (70 mL) was irradiated (eleven 350-nm lamps in use) for 12.5 h. Removal of solvent gave an oil, the ^{1}H nmr spectrum of which indicated that methyl (*Z*)-3-(*p*-methoxyphenyl)azo-2-butenoate (**3***a*), ($CDCl_3$) δ 2.10 and 6.20 ppm, is the major product, and the (*E*)-isomer **4***e*, ($CDCl_3$) δ 2.39 and 6.65 ppm, is the minor one. The nmr sample was inspected at intervals of 1, 3, 5, 7, and 13 days, during which time a decrease in the intensity of the bands at δ 2.10 and 6.20 and a corresponding increase at δ 2.39 and 6.65 ppm could be observed.

A small sample (15 mg) of a red oil with ^{1}H nmr ($CDCl_3$): 2.39 (d, 3H), 3.79 (s, 3H), 3.86 (s, 3H), 6.65 (m, 1H), 6.8–7.8 (m, 4H) ppm, consistent with an assignment of structure as methyl (*E*)-3-(*p*-methoxyphenyl)azo-2-butenoate (**4***e*), was obtained by preparative thick-layer chromatography (ether).

Photolysis of 4-diazo-3-phenyl-2-pyrazolin-5-one (1f) in methanol

Diazopyrazolinone **1***f* (313 mg, 1.68 mmol) in absolute methanol (45 mL) was irradiated at 350 nm for 24 h. Trituration with ether (5 mL) of the residue from the removal of the solvent gave a white precipitate (278 mg) that was polymeric, mp > 200°C with decomposition; ^{1}H nmr ($CDCl_3$): 2.1–3.0 (br), 4.5 (br), 7.3–7.9 (m) ppm; *m/z* >500. Analysis of the ether-soluble portion by tlc (silica gel; benzene; chloroform; chloroform/petroleum ether; ethyl acetate/petroleum ether) showed only intractable material present.

Photolysis of 4-diazo-3-methyl-1-tosyl-2-pyrazolin-5-one (1g) in methanol

Diazopyrazolinone **1***g* (278 mg, 1.00 mmol) in methanol (50 mL) was irradiated at 350 nm for 24 h. Trituration with ether (5 mL) of the residue from the removal of the solvent gave a white precipitate (201 mg), mp 167–168°C, which was not further characterized. The tlc of the ether-soluble portion of the residue failed to yield any azoesters.

Acknowledgments

The work described herein was supported in part by the Office of Basic Energy Sciences of the Department of Energy (P.K.D.) and the National Science Foundation (G.W.G.). This is Document NDRL 2565 from the Notre Dame Radiation Laboratory. We are grateful to Dr. G. Ferraudi for giving us access to his conventional flash photolysis set-up and for his assistance in using it. We thank Professor A. M. Trozzolo for helpful discussions.

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

HARRY M. WALBORSKY and MARTHA PASS MURARI. Can. J. Chem. **62**, 2464 (1984).

The 1,3-elimination of methoxide by carbanions generated from the reaction of (±)-1,3-dimethoxy-1,1-diphenylbutane with the alkali metals, lithium, sodium, and potassium, in various solvents was studied to determine the significance of cation–methoxyl coordination due to decreasing charge/radius ratio of the cations and also the cation complexing ability of the solvent. The stereochemistry of cyclization in the reaction of (*S*)-(−)-1,3-dimethoxy-1,1-diphenylbutane with lithium metal in tetrahydrofuran and with sodium metal in methylcyclohexane to yield 1-methyl-2,2-diphenylcyclopropane was determined. The reaction proceeded by an intramolecular S_N2-type displacement to yield optically pure product of inverted configuration.

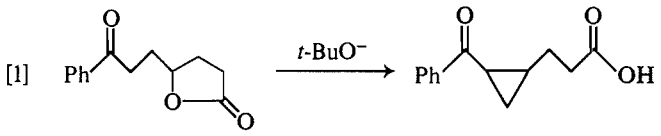
HARRY M. WALBORSKY et MARTHA PASS MURARI. Can. J. Chem. **62**, 2464 (1984).

Dans le but de déterminer l'importance de la coordination du méthoxyle par le cation dû à une diminution du rapport charge à rayon des cations ainsi que l'habilité du solvant à complexer le cation, on a étudié la réaction d'élimination 1,3 du méthylate par des carbanions générés par la réaction, dans divers solvants, du (±)-diméthoxy-1,3 diphényl-1,1 butane avec les métaux alcalins, lithium, sodium et potassium. On a déterminé la stéréochimie de la réaction du (*S*)-(−)-diméthoxy-1,3 diphényl-1,1 butane avec le lithium métallique dans le tétrahydrofuranne et avec le sodium métallique dans le méthylcyclohexane qui conduit, par cyclisation, au méthyl-1 diphényl-2,2 cyclopropane. La réaction se produit par un mécanisme, de type déplacement S_N2- intramoléculaire, qui conduit à une produit optiquement pur dont la configuration est inversée.

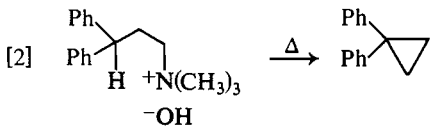
[Traduit par le journal]

Introduction

An established method for preparation of cyclopropane compounds is the use of the base-induced 1,3-elimination reaction. Two examples, *inter alia*, of this process are the conversion of **1** to **2** by Yates and Anderson (1) (eq. [1]) and **3** to **4** by Bumgardner (2) (eq. [2]).



1 **2**

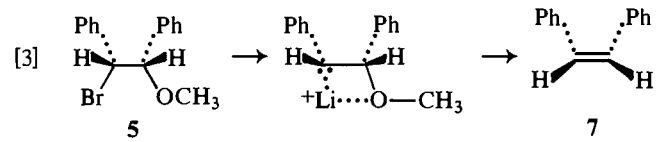


3 **4**

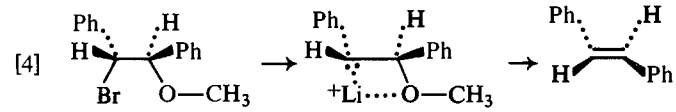
Some general features of base-induced 1,3-elimination reactions have been covered in an early review (3), and various mechanistic aspects, conformational and stereochemical, have also been discussed (4, 5). Considerable experimental evidence has accumulated to support the view that for base-induced 1,3-elimination reactions a two-step reaction process is preferred and a one-step concerted reaction is rare, if it exists at all. A consequence of this two step process is inversion of confuguration at the carbon atom that is the object of nucleophilic attack.

The two-step process is enhanced by relatively unreactive leaving groups. A leaving group which belongs to that classification is alkoxyl. The nucleophilic displacement of alkoxide has been studied in some detail by Köbrich and Baumann (6) and observed on several other occasions (7–9).

A stereochemical study of cyclopropane formation by displacement of an alkoxide has not been made but, in view of some interesting results obtained by Sugita *et al.* (10) in a 1,2-elimination of methoxide, such a study is warranted. The 1,2-elimination of methoxide in the reaction of *erythro-* and *threo*-1-bromo-2-methoxy-1,2-diphenylethane (**5** and **6**) with *n*-butyllithium in diethyl ether gave *cis*- (**7**) and *trans*-stilbene (**8**), respectively (eqs. [3] and [4]). These results show that a



5 **7**



6 **8**

stereospecific *syn*-elimination has occurred. The factor expected to be the driving force for the production of **7** from the *erythro* isomer (**5**), even against the large thermodynamical instability of the product, is the coordination between the lithium cation and the oxygen of the methoxyl group. This was indicated by the observation that the stereospecificity decreased on changing the solvent from the low polarity solvents, diethyl ether and benzene, to the more polar, cation complexing solvents, tetrahydrofuran and diglyme. Table 1 summarizes the relevant data of Sugita *et al.* (10).

The binding energies of lithium cations with the nonbonding electrons of the oxygen in ethers is substantial (~38 kcal/mol) (11). Such bonding plays an important role in Cram's cyclic model (12) for asymmetric syntheses, Meyers (13) asymmetric syntheses model (chiral lithio-oxazoline), Helmchen's (14) chiral lithium enolates of esters, and Masamune's (15) lithium enolates of aldehydes and ketones which lead to directed aldol condensations. This type of binding also

accounts for the stability of 2-lithio-7-*syn*-methoxy-norbornane which, although a secondary organolithium, is more stable than the primary *n*-butyllithium (16). A similar effect accounts for the stabilization of α-halocyclopropyllithium reagents (carbenoids) (17).

Moreover, for reactions believed to involve intramolecular coordination of alkali metal cations with ligands containing heteroatoms, it is found that the reaction course is specific for lithium (18). Changing the cation from lithium to sodium or potassium or adding solvents capable of complexing with lithium competitively with internal complexation can critically affect the course of the reaction.

This investigation into 1,3-elimination is designed to study the parameters known to affect internal lithium–alkoxyl coordination. The effects of varying the solvent and the cation will be presented, as will the stereochemistry of the reaction.

Results and discussion

Synthesis of substrate

The choice of substrate to study the effect of lithium–alkoxyl coordination on 1,3-elimination reactions was determined by the scope of the investigation. To make a systematic study, the substrate was required to have structural features that would (1) permit generation of a carbanionic nucleophile with lithium, sodium, or potassium as cation, (2) have an alkoxyl group attached to an asymmetric center capable of being displaced, and (3) allow cyclization to a cyclopropane with known absolute configuration. The molecule 1,3-dimethoxy-1,1-diphenylbutane (9) fulfilled these requirements. As can be seen in eq. [5], **9** possesses the diphenylcarbinylmethyl ether moiety

[5] 
9 **10** **11**

M = Li, Na, K

which can be cleaved (19) with alkali metals to form **10**. The 2° carbon to which the methoxyl group is attached can be chiral and nucleophilic attack is possible since it is not sterically hindered. Cyclization of **10** would give 1-methyl-2,2-diphenylcyclopropane (**11**) whose absolute configuration was determined many years ago (20). (±)-1,3-Dimethoxy-1,1-diphenylbutane (**9**) was simply prepared by the reaction of the dilithium derivative of benzophenone (21) with racemic propylene oxide to form (±)-1,1-diphenyl-1,3-butanediol (**12**), which upon treatment with sodium hydride and methyl iodide (eq. [6]) produced the desired substrate.

Chiral **9** was prepared by the same reaction sequence illustrated in eq. [6] but using chiral (*S*)-(−)-propylene oxide (22) to yield (*S*)-(+)-**12** in 84% yield. The chiral diol produced (*S*)-(−)-**9** in 95% yield upon treatment with sodium hydride and methyl iodide.

[6] 
Effect of solvent and cation

To determine the effect of solvent on the lithium–methoxyl coordination, three solvents were chosen that represent a range of polarities. Nonpolar methylcyclohexane, tetrahydrofuran (THF) with intermediate polarity, and the very polar hexamethylphosphoramide (HMPA) were used. Finely dispersed lithium was prepared and was allowed to react with racemic 1,3-dimethoxy-1,1-diphenylbutane (**9**). In each solvent sufficient time was allowed to cleave the diphenylcarbinyl ether and for subsequent cyclization to occur. The main products observed in these reactions were 1-methyl-2,2-diphenylcyclopropane (**11**) and 2-methoxy-4,4-diphenylbutane (**13**) (eq. [7]). The product of interest (**11**) was not stable under

[7] 
9 **11** **13**

[8] 
11 **14**

these conditions and reacted with excess metal to form 1,1-diphenylbutane (**14**) (23) (eq. [8]). The yields of 1-methyl-2,2-diphenylcyclopropane (**11**) and 1,1-diphenylbutane (**14**) for this series of reactions are given in Table 2.

As is evident from the data in Table 2, fair yields of cyclization product were observed in methylcyclohexane and THF but not in HMPA. In hydrocarbon solvents, it is known that the ion pair consisting of a lithium cation attached to a delocalized carbanion exists as an unreactive contact ion pair, whereas in THF the ion pair exists as a reactive solvent-separated ion pair (24). By analogy, the observed cyclization in THF would be expected to take place from a solvent-separated ion pair in which the diphenylcarbinyl anion is a reactive nucleophile. However, it would seem that in methylcyclohexane the diphenylcarbinyl anion would not have been a reactive nucleophile and cyclization should not have occurred. The fact that cyclization did occur in methylcyclohexane indicates that the lithium–methoxy coordination produced a reactive solvent-separated lithium diphenylcarbinyl anion ion pair (**15**).

If a reactive nucleophile is the only prerequisite for obtaining cyclization, then HMPA should have promoted cyclization in-

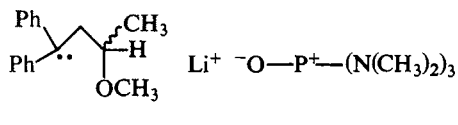
15



16

stead of diminishing cyclization since HMPA is known to dissociate ion pairs into free ions (25). For the reaction in HMPA, a species such as **16** in which the lithium cation is out of binding distance can be envisioned. Both intermediates, **15** and **16**, have the diphenylcarbinyl anion as a reactive nucleophile but only **15** has the lithium–methoxy coordination. Therefore it appears that the displacement of the methoxyl group is facilitated by coordination with the lithium cation (Lewis acid) and is retarded when the lithium cation is unable to coordinate. The coordination of the lithium cation to the methoxyl group weakens the C—OCH_3 bond. Furthermore, cyclization in THF must be occurring through **15** and this conclusion indicates that the internal solvation of the lithium cation by the methoxyl group competes effectively with the external solvation of the lithium cation by THF.

The tendency for ligand attraction decreases for other alkali metal ions like sodium and potassium due to decreasing charge/radius ratio (26) and, for the same reason, the fraction of reactive solvent-separated ion pairs decreases according to the sequence Li > Na > K (27). Thus it was of interest to determine the existence of a species corresponding to **15** for the reaction of 1,3-dimethoxy-1,1-diphenylbutane (**9**) with sodium and potassium in both methylcyclohexane and THF.

The reaction of **9** with sodium in methylcyclohexane gave 1-methyl-2,2-diphenylcyclopropane (**11**) and 2-methoxy-4,4-diphenylbutane (**13**) as the main products but the reaction of **9** with potassium in methylcyclohexane gave mainly **13**. The yields of the cyclization product **11** for these two reactions and for the previously discussed reaction of lithium with **9** in methylcyclohexane are given in Table 3. In the reactions of **9** with sodium and potassium in tetrahydrofuran mainly **13** was obtained. However, the reaction of **9** with potassium in THF to form intermediate **10**, followed by cation exchange with anhydrous lithium perchlorate ($LiClO_4$), gave both **11** and **13**. The yields of cyclization product **11** for these three reactions and for the previously discussed reaction of lithium with **9** in THF are given in Table 4. It was noted that longer reaction times were necessary for the reaction of **9** with lithium because the lithium metal floats and contact with solution is not very good.

Inspection of Tables 2 and 4 shows that for the reaction of **9** with sodium in methylcyclohexane, an intermediate, **17**,

TABLE 3. Reactions of 1,3-dimethoxy-1,1-diphenylbutane with metals in methylcyclohexane[a, b]

Time (h)	T (°C)	Metal	% Yield[c] 11	14[d]

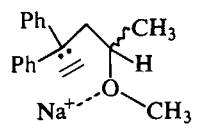
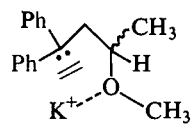
[e] Yield determined by glc analysis.

corresponding to **15** for lithium, must be present. In **17** the sodium cation is internally solvated by the methoxyl group so that the diphenyl carbinyl anion is not part of a contact ion pair with the sodium cation but instead is reactive and able to initiate nucleophilic attack. Since the unit positive charge on the sodium cation is dispersed over a larger area than that for the lithium cation, the sodium cation cannot effectively coordinate to the methoxyl group in the presence of external solvation by THF. Hence **17** cannot form and cyclization does not occur.



17



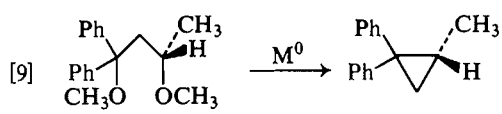
18

For the reaction of potassium with **9** in both methylcyclohexane and THF, intermediate **18**, corresponding to **15** for lithium, must not be present to any large extent. Thus, for the potassium cation in which the unit positive charge is dispersed over an area greater than that for either lithium or sodium cations, ligand coordination is ineffective even in the absence of external solvation (methylcyclohexane). An ion pair consisting of the potassium cation and the diphenylcarbinyl anion must be the predominant species in the reactions with potassium. This is unreactive and does not cyclize.

The significance and existence of the lithium–methoxyl coordination is further substantiated by the cation exchange reaction. As shown in Table 4, in the addition of excess lithium cation (from $LiClO_4$), the diphenylcarbinyl–potassium exchanges potassium cation for lithium cation and cyclization can then occur through the intermediate, **15**.

Stereochemistry

The solvent and cation studies showed that lithium in THF and sodium in methylcyclohexane resulted in reasonable yields of **11** from **9** and these conditions were chosen to evaluate the stereochemistry of the reaction (eq. [9]).



[9]

(*S*)-(−)-**9** (*R*)-(−)-**11**

Reaction of (*S*)-(−)-**9** with lithium metal in THF at 25°C gave a 20% yield of (*R*)-(−)-**11** with 99% optical purity. The same reaction of sodium metal in methylcyclohexane at 100°C

gave a 63% yield of (*R*)-(−)-**11** with 96% optical purity. Thus the overall reaction (eq. [9]) proceeds in a stereospecific manner with complete inversion of configuration at C-3 of **9**.

(*S*)-(+)-2-Methoxy-4,4-diphenylbutane (**19**) was prepared by reaction of lithium diphenylmethide with (*S*)-1-(*p*-toluenesulfonoxy)-2-(tetrahydro-2-pyranoxy) propane (22), hydrolysis to remove the tetrahydropyranyl blocking group, and the resulting (*S*)-(+)-4,4-diphenyl-2-butanol etherified with sodium hydride and methyl iodide. The metalation of (*S*)-(+)-**19** with *n*-butyllithium in methylcyclohexane/THF (35:1) at 25°C resulted in a 28% yield of (*R*)-(−)-**11** with 99% optical purity (eq. [10]).

[10] 
(*S*)-(+)-**19** (*R*)-(−)-**11**

The foregoing results show that in all cases inversion of configuration has occurred and speak strongly for an intermediate like **15** in which the cation is strongly coordinated with the oxygen of the leaving methoxyl group and in which the cation is solvent separated from the diphenylcarbanion moiety. The ring closure then proceeds as depicted in eq. [11].

[11] 
Experimental

Melting points were measured in open capillaries with a Mel-Temp apparatus. Melting points and boiling points are uncorrected. The ir spectra were recorded on a Perkin–Elmer Model 257 spectrophotometer; band positions are reported in wave numbers (cm^{-1}). The nmr spectra were recorded as $CDCl_3$ solutions on Varian Associates Model A-60 and on JEOL Model C-60 HL spectrometers unless specified otherwise; chemical shifts are reported in δ (ppm) downfield from internal tetramethylsilane and coupling constants are in hertz (Hz). Low resolution mass spectra were obtained on a Nuclide Model 12-90 G electron impact mass spectrometer. Microanalyses were performed by the Beller Laboratories, Göttingen, Germany.

Optical rotations were measured at either the 546.1-nm mercury line or at the 589.3-nm sodium line using a Bendix–Ericsson Model 987 ETL/NPL polarimeter with a digital display attachment. The cell length was 0.4 dm and all solvents used were spectrophotometric grade. Error limits for rotations were calculated by multiplying the relative standard deviation by the specific rotation. The relative standard deviation was determined by dividing the standard deviation (0.002) by the observed rotation. Percent optical purity was determined as follows: (observed specific rotation ÷ maximum specific rotation) multiplied by 100. The maximum specific rotation for (*R*)-(−)-1-methyl-2,2-diphenylcyclopropane is $[\alpha]_{Hg}^{25}$ −150.6° (*c* 1.18, $CHCl_3$) or, as reported, $[\alpha]_D^{26}$ −127° (28).

Qualitative gc analyses were performed on a Hewlett Packard Model 5710A gas chromatograph (thermal conductivity detectors with helium as carrier gas) using packed columns (column A, 15% Carbowax-20 M on acid-washed 80/100 Chromosorb P, 10 ft × 1/8 in., 220°C; and column B, 15% Lexan on acid-washed 60/80 Chromosorb P, 4 ft × 1/8 in., 200°C) and on a Varian Model 1200 Series gas chromatograph (flame ionization detector with nitrogen as carrier gas) using a J & W Scientific, Inc., glass capillary column (column C, wall coated SE 30, 30 m × 0.2415 mm, 165°C). Quantitative glpc analyses were performed on column A using diphenylmethane as internal standard. Peak areas were measured as height × width at half-height.

Product separations obtained by high-pressure liquid chromatography (hplc) were conducted on Waters Associates ALC 202 Liquid Chromatograph equipped with an Instrument Specialities Co. "Golden Retriever" automatic sample collector and a Rikadenki recorder (dfifferential refractometer detection) using two Porasil B columns (4 ft × 3/8 in. each) under the conditions described. Thin-layer chromatography (tlc) and preparative thick-layer chromatography (ptlc) were performed using glass plates coated with Merck silica gel 60 PF-254 + 366. Flash chromatography was carried out on a 20 × 5 cm column of silica gel 60 (400–230 mesh, E. Merck No. 9385).

(±)-1,1-Diphenyl-1,3-butanediol (12)

A modification of the procedure of Askinazi and Ioffe (21) was used. To a cooled (0°C) purple solution of the dilithium dianion of benzophenone prepared (*vide supra*) from 9.1 g (0.050 mol) benzophenone, 1.3 g (0.010 mol) of naphthalene, and 0.85 g (0.12 g-atom) of lithium in 63 mL of dry THF under an argon atmosphere was added slowly a solution of 3.8 g (0.065 mol) racemic propylene oxide in 15 mL dry THF. The reaction mixture was stirred at 25°C for 3 h as it decolorized, cooled, and was cautiously quenched with 20 mL saturated ammonium chloride. After removing the THF *in vacuo*, the basic aqueous layer was extracted with 100 mL ether and the ether extract was washed with saturated ammonium chloride, dried over anhydrous sodium sulfate, and evaporated to leave an oil (14.1 g) which crystallized to a white solid upon scratching. The solid was refluxed overnight with low boiling petroleum ether to dissolve the naphthalene and leave the insoluble product. After cooling and filtering, there was obtained 9.3 g (77%) of (±)-1,1-diphenyl-1,3-butanediol: mp 80–82°C; ir ($CHCl_3$): 3571 (s), 3531–3111 (s, br), 3091–2791 (s), 1981–1721 (w), 1596 (w), 1491 (s), 1451 (s), 1376 (s), 1131 (s), 1066 (s) cm^{-1}; nmr ($CDCl_3$) δ: 1.10 (3H, d, *J* 6 Hz), 2.30 (2H, m), 3.23 (1H, br d, *J* 3 Hz), 3.73 (1H, br m), 4.85 (1H, s), 7.30 (10H, m). *Anal.* calcd. for $C_{16}H_{18}O_2$: C 79.31, H 7.49; found: C 79.46, H 7.55.

(S)-(+)-1,1-Diphenyl-1,3-butanediol (12)

The procedure is identical to that for the preparation of (±)-1,1-diphenyl-1,3-butanediol except that (*S*)-(−)-propylene oxide (22), $[\alpha]_D^{29}$ −8.7 was used. The yield of (*S*)-(+)-1,1-diphenyl-1,3-butanediol was 84% and gave mp 105–107°C; $[\alpha]_{Hg}^{24}$ +65.4 ± 0.5 (*c* 1.02, $CHCl_3$). The ir and nmr spectra were identical with those of racemic diol. *Anal.* calcd. for $C_{16}H_{18}O_2$: C 79.31, H 7.49; found: C 79.34, H 7.36.

(±)-1,3-Dimethoxy-1,1-diphenylbutane (9)

To a slurry of 19.7 g (0.821 mol) of sodium hydride in 250 mL of dry THF at 25°C was added dropwise (30 min) a solution of 25.6 g (0.106 mol) of (±)-1,1-diphenyl-1,3-butanediol in 250 mL of dry THF. After a 2-h reflux, the reaction mixture was cooled (0°C) and 106 mL (1.70 mol) of freshly distilled methyl iodide was added dropwise (15 min). The reaction mixture was stirred at 25°C for an additional 15 h, poured slowly with stirring onto 2000 g of ice, and extracted twice with ether. The combined ethered extracts were washed with saturated ammonium chloride, water, saturated sodium chloride, dried over anhydrous sodium sulfate, and concentrated *in vacuo* to afford 27.9 g of product. The tlc analysis with hexane–ether (1:1) showed two components. The mixture was separated into two portions by flash chromatography (hexane bed). Eluting first with hexane and then with 10% ether in hexane gave 20.8 g (73%) of 1,3-dimethoxy-1,1-diphenylbutane. Elution continued with ether gave 5.0 g of impure 1,3-dimethoxy-1,1-diphenylbutane. Distillation of the 20.8-g portion gave 19.0 g of (±)-1,3-dimethoxy-1,1-diphenylbutane; bp 116–119°C (0.25 Torr (1 Torr = 133.3 Pa); mp 54–56°C; ir ($CHCl_3$): 3001–2791 (m), 1901–1745 (w), 1446 (m), 1059, 1036 (s) cm^{-1}; 270-MHz nmr ($CDCl_3$) δ: 0.96 (3H, d, $J(CH_3—H_x)$ 6 Hz), 2.34 ($1H_B$, dd, J(AB) 15 Hz, J(BX) 8 Hz), 2.67 ($1H_A$, dd, J(AB) 15 Hz, J(AX) 6 Hz), 3.03 (3H, s), 3.05 (3H, s), 3.17 ($1H_X$, m), 7.29 (10H, m). *Anal.* calcd. for $C_{18}H_{22}O_2$: C 79.96, H 8.20; found: C 80.06, H 8.31.

(S)-(−)-1,3-Dimethoxy-1,1-diphenylbutane (9)

(*S*)-(−)-**9** was prepared in an identical manner to (±)-**9**. The yield was 95% and gave bp 118–120°C (0.2 Torr); mp 52–54°C; $[\alpha]_{Hg}^{24}$ −15.4 g ± 0.7 (*c* 0.770, $CHCl_3$). The ir and nmr spectra were identical with those of (±)-**9**. *Anal.* calcd. for $C_{18}H_{22}O_2$: C 79.96, H 8.20; found: C 80.02, H 8.09.

(S)-4,4-Diphenyl-2-(tetrahydro-2-pyranoxy)butane

To a solution of lithium diphenylmethide (15°C) prepared from 50.5 g (0.301 mol) of diphenylmethane was added 34.9 g (0.301 mol) of TMEDA, 300 mL of dry ether, and 139 mL (0.30 mol) of (*S*)-1-(*p*-toluenesulfonoxy)-2-(tetrahydro-2-pyranoxy)propane in 150 mL of anhydrous ether under nitrogen. The reaction mixture was stirred at 25°C overnight, refluxed 4 h, cooled, and hydrolyzed with 100 mL of cold water. The ether layer was separated, washed with cold 3 *N* hydrochloric acid, saturated sodium bicarbonate, and saturated sodium chloride, dried over anhydrous sodium sulfate, and concentrated *in vacuo* to give an oil (80.6 g). A portion of this oil (13.9 g) was chromatographed on a column of alumina. Elution with pentane removed diphenylmethane and pentane–chloroform (1:1) gave 10.9 g of (*S*)-4,4-diphenyl-2-(tetrahydro-2-pyranoxy)butane; ir (CCl_4): 3051–3021 (w), 2938–2849 (s), 2000–1670 (w), 1596, 1491, 1451, 1376 (s), 1138, 1080, 1036, 1025 (s), 696 (s) cm^{-1}; nmr ($CDCl_3$) δ: 1.10 and 1.20 (3H, doublets, *J* 3 Hz and *J* 3 Hz), 1.37–1.93 (5H, br), 2.0–2.5 (3H, m), 3.17–4.77 (5H, m), 7.32 (10H, s). *Anal.* calcd. for $C_{21}H_{26}O_2$: C 81.25, H 8.44; found: C 81.31, H 8.42.

The remaining 66.7 g of the oil was used without further purification as described below to prepare (*S*)-(+)-4,4-diphenyl-2-butanol.

(S)-(+)-4,4-Diphenyl-2-butanol

To 66.7 g of crude (*S*)-4,4-diphenyl-2-(tetrahydro-2-pyranoxy)butane from the above experiment dissolved in 250 mL of anhydrous methanol was added 3 mL of 12 *N* hydrochloric acid. After standing 48 h, the solution was brought to neutral pH with 30 mL of saturated sodium bicarbonate. The methanol was evaporated and replaced with ether. The ether solution was dried over anhydrous sodium sulfate and concentrated *in vacuo* to give 51.4 g of product which was purified by alumina chromatography. Diphenylmethane was eluted with pentane and chloroform eluted the alcohol which was distilled to give 37.0 g of (*S*)-(+)-4,4-diphenyl-2-butanol; bp 103–105°C (0.025 Torr); $[\alpha]_{Hg}^{24}$ +33.1 ± 0.17° (*c* 2.95, $CHCl_3$). The values reported for (*R*)-(−)-4,4-diphenyl-2-butanol are bp 107–109°C (0.1 Torr); $[\alpha]_D$ −27.1 ± 0.9° (*c* 2.77, $CHCl_3$); the nmr spectrum reported is identical with that of (*S*)-(+)-4,4-diphenyl-2-butanol prepared here.

(S)-(+)-2-Methoxy-4,4-diphenylbutane (19)

To 1.4 g (0.058 mol) of sodium hydride was added a solution of 6.6 g (0.029 mol) of (*S*)-(+)-4,4-diphenyl-2-butanol in 50 mL of dry THF at 25°C and the mixture was refluxed for 2 h. The reaction mixture was cooled (25°C) and 17 g (0.12 mol) of freshly distilled methyl iodide was added. After stirring overnight, the reaction mixture was poured slowly with stirring onto ice and extracted twice with ether.The combined ethereal extracts were washed with saturated ammonium chloride, water, saturated sodium chloride, dried over anhydrous sodium sulfate, and concentrated *in vacuo* to give 7.2 g of product which was distilled to yield 5.5 g (79%) of (*S*)-(+)-2-methoxy-4,4-diphenylbutane; bp 150–151°C (3.0 Torr); mp 39–40°C $[\alpha]_{Hg}^{25}$ +19.2 ± 0.2° (*c* 2.10, $CHCl_3$); ir (CCl_4): 3098–3038 (m), 2978–2838 (s), 1946–1754 (w), 1598, 1496, 1453, 1377 (s), 1143, 1083 (s), 693 (s) cm^{-1}; nmr ($CDCl_3$) δ: 1.12 (3H, d, *J* 6 Hz), 2.17 (2H, m), 2.83–3.47 (1H, m), 3.20 (3H, s), 4.2 (1H, dd, *J* 6.3, 7 Hz), 7.2 (10H, s). *Anal.* calcd. for $C_{17}H_{20}O$: C 84.96, H 8.39; found: C 85.03, H 8.35.

General procedure for preparing metal dispersions (ref. 29)

The desired amount of metal was rinsed with heptane to remove mineral oil, cut into small pieces, and placed in a dry 500-mL Morton-type flask along with 25 mL of a dry hydrocarbon solvent (methylcyclohexane was used in the case of potassium, decane was used for sodium, and dodecane was used for lithium) under an atmosphere of dry argon. The flask was heated until the solvent boiled and the metal was molten. The heating mantle was quickly replaced by a metal pail loosely packed with glass wool and the contents of the flask were stirred at high speed (7500 rpm) for 1 min. The flask was then allowed to cool slowly. A change of solvent was made by removing the hydrocarbon solvent with a syringe attached to a long needle. The high-speed stirrer was replaced by a glass-enclosed magnetic stirring bar.

Reaction of (±)-1,3-dimethoxy-1,1-diphenylbutane (9) with lithium in methylcyclohexane

A lithium dispersion was made from 0.104 g (0.0151 g-atom; 2.45 cm of 1/8-in. diameter wire) of lithium in dodecane under an argon atmosphere. The dodecane was replaced with 25 mL dry methylcyclohexane. To this dispersion was added 0.405 g (0.0015 mol) of (±)-1,3-dimethoxy-1,1-diphenylbutane as a solid and the mixture was stirred at reflux for 72 h. The progress of the reaction was monitored by glpc on column C at 24-h intervals to check for the disappearance of starting material and for an increase in the amount of product, 1-methyl-2,2-diphenylcyclopropane. The starting material disappeared within 48 h and there was no further increase in the amount of 1-methyl-2,2-diphenylcyclopropane during the next 24 h, as shown by a constant area ratio between 1-methyl-2,2-diphenylcyclopropane and 2-methoxy-4,4-diphenylbutane. The color of the reaction solution throughout reflux varied from an initial yellow or green to gray. After the usual work-up procedure, the product mixture (0.880 g) was separated by hplc using 5% ether in heptane into 0.529 g of a hydrocarbon mixture containing dodecane and 1-methyl-2,2-diphenylcyclopropane, 0.159 g (44%) of 2-methoxy-4,4-diphenylbutane, and 0.0585 g (15%) of 3-methoxy-1,1-diphenyl-1-butanol. The 0.529-g hydrocarbon fraction was resubmitted to hplc separation with heptane as eluant to give 0.102 g (33%) of 1-methyl-2,2-diphenylcyclopropane. Products present in trace amounts were not identified. The nmr spectrum for each was identical with that of an authentic sample.

Reaction of (S)-(−)-1,3-dimethoxy-1,1-diphenylbutane with sodium in methylcyclohexane

A sodium dispersion was made from 0.240 g (0.0104 g-atom) of sodium in decane under an argon atmosphere. The decane was replaced with 17 mL of dry methylcyclohexane. To this dispersion was added 0.272 g (0.0010 mol) of (*S*)-(−)-1,3-dimethoxy-1,1-diphenylbutane as a solid and the mixture was refluxed 24 h. During this time, an orange color developed and disappeared. After the usual work-up procedure, the product mixture (0.215 g) was analyzed by gc on column C and found to contain two components which were separated by hplc using 5% ether in heptane to give 0.131 g (63%) of (*R*)-(−)-1-methyl-2,2-diphenylcyclopropane and 0.0451 g (19%) of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

(*S*)-(+)-2-methoxy-4,4-diphenylbutane. The (*R*)-(−)-1-methyl-2,2-diphenylcyclopropane was further purified by Kugelrohr distillation (120°C bath, 0.4 Torr) and gave $[\alpha]_{Hg}^{24}$ −144.5 ± 0.8° (*c* 0.628, $CHCl_3$), 96% optical purity. The (*S*)-(+)-2-methoxy-4,4-diphenylbutane, without further purification, gave $[\alpha]_{Hg}^{24}$ +20.2 ± 0.8° (*c* 0.60, $CHCl_3$), 100% optical purity. The nmr spectrum for each was identical with that of an authentic sample.

Reaction of (±)-1,3-dimethoxy-1,1-diphenylbutane (9) with potassium in methylcyclohexane

A potassium dispersion was made from 0.660 g (0.0169 g-atom) of potassium in 25 mL of dry methylcyclohexane under an argon atmosphere. To this dispersion was added 0.412 g (0.0015 mol) of (±)-1,3-dimethoxy-1,1-diphenylbutane as a solid and the mixture stirred at reflux for 24 h. The reaction mixture became dark red immediately and the color was maintained during reflux. After the usual work-up procedure, the product mixture (0.359 g) was separated by hplc using 5% ether in heptane into 0.0257 g of a hydrocarbon mixture, 0.217 g (60%) of 2-methoxy-4,4-diphenylbutane, 0.0414 g (11%) of 3-methoxy-1,1-diphenyl-1-butanol, and two minor components which were not identified. Analysis of the hydrocarbon mixture by gc on columns A and C showed three components that gave enhancement with authentic samples of 1-methyl-2,2-diphenylcyclopropane, 1,1-diphenylbutane, and 1,1-diphenyl-1-butene. Quantitative glpc analysis on column A with diphenylmethane as internal standard gave the following yields: <1% of 1-methyl-2,2-diphenylcyclopropane, 1.5% of 1,1-diphenylbutane, and 4.0% of 1,1-diphenyl-1-butene. The nmr spectrum for each pure component was identical with that of an authentic sample.

Reaction of (S)-(−)-1,3-dimethoxy-1,1-diphenylbutane (9) with lithium in tetrahydrofuran

A lithium dispersion was made from 0.069 g (0.010 g-atom; 1.6 cm of 1/8-in. diameter wire) of lithium in dodecane under an argon atmosphere. The dodecane was replaced with 17 mL of dry THF. To this dispersion was added 0.271 g (0.0010 mol) of (*S*)-(−)-1,3-dimethoxy-1,1-diphenylbutane as a solid and the mixture was stirred at 25°C for 27 h. A red color developed and persisted after 2 h of rapid stirring. After the usual work-up procedure, the product mixture (0.282 g) was analyzed by gc on column C and found to contain five components which were separated by hplc using 5% ether in heptane into 0.217 g of a hydrocarbon mixture, 0.0796 g (33%) of (*S*)-(+)-2-methoxy-4,4-diphenylbutane with $[\alpha]_{Hg}^{24}$ +19.0 ± 0.3° (*c* 1.59, $CHCl_3$) and 99% optical purity, and 0.0115 g (4.5%) of (*S*)-(+)-3-methoxy-1,1-diphenyl-1-butanol with $[\alpha]_{Hg}^{24}$ +34.7 ± 2° (*c* 0.230, $CHCl_3$) and unknown optical purity. Analysis of the hydrocarbon mixture by gc on columns A and C showed four components that gave enhancement with authentic samples of 1-methyl-2,2-diphenylcyclopropane, 1,1diphenylbutane, 1,1-diphenyl-1-butene, and dodecane. The dodecane was removed by preparative tlc with heptane to give 0.0629 g of an aromatic hydrocarbon mixture which was distilled by the Kugelrohr method to yield 0.0387 g which gave $[\alpha]_{Hg}^{24}$ −100.4 ± 0.8° (*c* 0.610, $CHCl_3$), 66.7% optical purity. Quantitative gc analysis on column A with diphenylmethane as internal standard showed the mixture to be composed of 67.5% (*R*)-(−)-1-methyl-2,2-diphenylcyclopropane, 17.3% of 1,1-diphenylbutane, and 15.1% of 1,1-diphenyl-1-butene, and the corrected specific rotation for (*R*)-(−)-1-methyl-2,2-diphenylcyclopropane is $[\alpha]_{Hg}^{24}$ −148.7 ± 0.8° (99% optical purity). The yields based on internal standardization are 20% of (*R*)-(−)-1-methyl-2,2-diphenylcyclopropane, 5.2% of 1,1-diphenylbutane, and 4.6% of 1,1-diphenyl-1-butene. The nmr spectrum for each pure component was identical with that of an authentic sample.

Reaction of (±)-1,3-dimethoxy-1,1-diphenylbutane (9) with lithium in tetrahydrofuran

A lithium dispersion was made from 0.104 g (0.0151 g-atom; 2.45 cm of 1/8-in. diameter wire) of lithium in dodecane under an argon atmosphere. The dodecane was replaced with 25 mL of dry THF. To this dispersion was added 0.405 g (0.0015 mol) of (±)-1,3-dimethoxy-1,1-diphenylbutane as a solid and the mixture stirred at 25°C, becoming red and decoloring in 72 h. After the usual work-up procedure, the product mixture (0.391 g) was separated by hplc using 5% ether in heptane into 0.149 g of a hydrocarbon mixture, 0.124 g (34%) of 2-methoxy-4,4-diphenylbutane, 0.0160 g (4.2%) of 3-methoxy-1,1-diphenyl-1-butanol, and a minor component which was not identified. Analysis of the hydrocarbon mixture by gc on columns A and C showed four components that gave enhancement with authentic samples of 1-methyl-2,2-diphenylcyclopropane, 1,1-diphenylbutane (under these conditions, in a separate experiment, it was found that **11** formed 1,1-diphenylbutane), 1,1-diphenyl-1-butene, and dodecane. Quantitative gc analysis on column A with diphenylmethane as internal standard gave the following yields: 32% of 1-methyl-2,2-diphenylcyclopropane, 4.8% of 1,1-diphenylbutane, and 5.7% of 1,1-diphenyl-1-butene. The nmr spectrum for each pure component was identical with that of an authentic sample.

Reaction of (±)-1,3-dimethoxy-1,1-diphenylbutane (9) with sodium in tetrahydrofuran

A sodium dispersion was made from 0.350 g (0.0152 g-atom) of sodium in decane under an argon atmosphere. The decane was replaced with 25 mL of dry THF. To this dispersion was added 0.407 g (0.0015 mol) of (±)-1,3-dimethoxy-1,1-diphenylbutane as a solid and the mixture stirred at 25°C for 40 h and at reflux for 24 h, since gc analysis on column A of a sample showed minor conversion to 1-methyl-2,2-diphenylcyclopropane at 25°C. After the usual work-up procedure, the product mixture (0.338 g) was separated by hplc using 5% ether in heptane into 0.0415 g of a hydrocarbon mixture, 0.131 g (50%) of 2-methoxy-4,4-diphenylbutane, 0.114 g (28%) of 1,3-dimethoxy-1,1-diphenylbutane, 0.0232 g (8.2%) of 3-methoxy-1,1-diphenyl-1-butanol, and a minor component which was not identified. Analysis of the hydrocarbon mixture by gc on columns A and C showed three components that gave enhancement with authentic samples of 1-methyl-2,2-diphenylcyclopropane, 1,1-diphenylbutane, and 1,1-diphenyl-1-butene. Quantitative gc analysis on column A with diphenylmethane as internal standard gave the following yields: 7.7% of 1-methyl-2,2-diphenylcyclopropane, <1% of 1,1-diphenylbutane, and 2.6% of 1,1-diphenyl-1-butene. The nmr spectrum for each pure component was identical with that of an authentic sample.

Reaction of (±)-1,3-dimethoxy-1,1-diphenylbutane (9) with potassium in tetrahydrofuran

A potassium dispersion was made from 0.590 g (0.0151 g-atom) of potassium in methylcyclohexane under an argon atmosphere. The methylcyclohexane was replaced with 25 mL of dry THF. To this dispersion was added 0.407 g (0.0015 mol) of (±)-1,3-dimethoxy-1,1-diphenylbutane as a solid and the mixture stirred at 25°C for 40 h and at reflux for 24 h, since gc analysis on column A of a sample showed minor conversion to the 1-methyl-2,2-diphenylcyclopropane at 25°C. After the usual work-up procedure, the product mixture (0.339 g) was separated by hplc using 5% ether in heptane into 0.0313 g of a hydrocarbon mixture, 0.223 g (62%) of 2-methoxy-4,4-diphenylbutane, 0.0132 g (3.4%) of 3-methoxy-1,1-diphenyl-1-butanol, and a minor component which was not identified. Analysis of the hydrocarbon mixture by gc on columns A and C showed three components that gave enhancement with authentic samples of 1-methyl-2,2-diphenylcyclopropane, 1,1-diphenylbutane, and 1,1-diphenyl-1-butene. Quantitative gc analysis on column A with diphenylmethane as internal standard gave the following yields: <1% of 1-methyl-2,2-diphenylcyclopropane, 2.0% of 1,1-diphenylbutane, and 4.5% of 1,1-diphenyl-1-butene. The nmr spectrum for each pure component was identical with that of an authentic sample.

Reaction of (±)-1,3-dimethoxy-1,1-diphenylbutane (9) with potassium in tetrahydrofuran and cation exchange with lithium perchlorate

A potassium dispersion was made from 0.600 g (0.0153 g-atom) of potassium in methylcyclohexane under an argon atmosphere. The methylcyclohexane was replaced with 25 mL of dry THF. To this dispersion was added 0.405 g (0.0015 mol) of (±)-1,3-dimethoxy-1,1-diphenylbutane as a solid and the mixture stirred at 25°C for 3 h, becoming deep red. The red solution was filtered through a Schlenck apparatus (medium frit; 0.25-Torr vacuum) into a receiving

flask containing a glass-covered magnetic stirrer and anhydrous $LiClO_4$ which was prepared by treating under vacuum (250°C bath, 0.25 Torr) of 1.0 g (0.009 mol) of $LiClO_4 \cdot 3H_2O$ for 20 min, resolidifying, and storing under an argon atmosphere. The reaction flask and Schlenck apparatus were rinsed with 5 mL of dry THF and the receiving flask was maintained under argon as the reaction mixture stirred for 23 h and complete decolorization occurred. After the usual work-up procedure, the product mixture (0.341 g) was analyzed by gc on column C and found to contain four main components which were separated by hplc using 5% ether in heptane into 0.0820 g (28%) of 1-methyl-2,2-diphenylcyclopropane, 0.137 g (41%) of 2-methoxy-4,4-diphenylbutane, 0.0193 g (4.8%) of 1,3-dimethoxy-1,1-diphenylbutane, 0.0187 g (5.2%) of 3-methoxy-1,1-diphenyl-1-butanol, and a minor component which was not identified. The nmr spectrum for each pure component was identical with that of an authentic sample.

Controlled coupling of aminoglycoside antibiotics to proteins for use in homogeneous enzyme immunoassays

PRITHIPAL SINGH,[1] MARCEL PIRIO, DANTON K. LEUNG, AND YUH-GENG TSAY
Syva Company,[2] Palo Alto, CA 94303, U.S.A.

Received March 23, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

PRITHIPAL SINGH, MARCEL PIRIO, DANTON K. LEUNG, and YUH-GENG TSAY. Can. J. Chem. **62**, 2471 (1984).

Selective *N*-acylation of aminoglycoside antibiotics with the *N*-hydroxysuccinimide ester of methyldithioacetic acid, followed by reaction with methanethiol or dithioerythritol, gives sulfhydryl labeled antibiotics. Alternatively, the nucleophilic sulfhydryl group is incorporated into an antibiotic by treatment with *N*-acetyl-*d,l*-homocysteine thiolactone. These derivatives couple readily with proteins that have previously been modified with bromoacetylglycyl groups to provide conjugates for use in the development of homogeneous enzyme immunoassays.

PRITHIPAL SINGH, MARCEL PIRIO, DANTON K. LEUNG et YUH-GENG TSAY. Can. J. Chem. **62**, 2471 (1984).

La *N*-acylation sélective d'antibiotiques aminoglycosidiques, à l'aide de l'ester *N*-hydroxysuccinimide de l'acide méthyldithioacétique, suivie d'une réaction avec du méthanethiol ou du dithioérythritol conduit à des antibiotiques portant des groupes sulfhydryles marqués. On peut aussi incorporer le groupe sulfhydryle nucléophile dans un antibiotique en le faisant réagir avec de la *N*-acétyl *d,l*-homocystéine thiolactone. Grâce à un couplage facile de ces dérivés avec des protéines qui auraient préalablement été modifiées à l'aide de groupes bromoacétylglycyles, on peut obtenir des dérivés conjugués qui peuvent être utilisés pour développer des méthodes immunologiques homogènes de détermination des enzymes.

Aminoglycoside antibiotics, products of mold metabolites, are commonly given intravenously to patients suffering from severe infection of Gram-negative bacteria. Serious oto- and nephrotoxic side effects are often encountered during the course of therapy (1, 2). This generally happens when the concentration of an antibiotic in patient blood is kept abnormally high for an extended period of time. The optimum therapeutic window for these antibiotics, which differs somewhat from drug to drug, is narrow (3). For example, in serum the therapeutic range of the two most commonly used drugs, gentamicin and tobramycin, is between 2–8 μg/mL while that of amikacin, a semi-synthetic antibiotic, is between 5–25 μg/mL. Titration of the plasma concentration of these antibiotics is often practiced as an aid to therapy and to decrease the risk of undesirable side effects during the course of treatment.

A number of analytical methods based on chromatographic, microbiological, and immunochemical techniques have been used to monitor blood level concentration of aminoglycosides (4, 5). Homogeneous enzyme immunoassay (EMIT®)[3] (6, 7), one of the more versatile immunochemical methods, has found wide acceptance by commercial clinical laboratories for routine monitoring of drugs in biological fluid. It utilizes drug specific antibodies and drug enzyme conjugate as the key reagents. The antidrug antibodies are generally harvested from animals injected at regular intervals with immunogens (drugs coupled to proteins). The conjugates are readily prepared by reacting an activated carboxylic acid derivative of an appropriately functionalized drug with the amino groups of enzymes and carrier proteins. Since the aminoglycoside antibiotics, **1**–**6**, are polyamino compounds (Fig. 1), this coupling method is of limited application for preparation of their protein conjugates. Activation of their carboxylic acid derivatives would result in polymerization. During the course of development of EMIT assays for these antibiotics, we solved this problem by application of a novel three-stage heterobifunctional coupling method (8, 9). It involves (*a*) selective modification of an antibiotic with a nucleophilic sulfhydryl group, (*b*) labeling of the protein with electrophilic bromoacyl groups, (*c*) coupling under gentle experimental conditions.

Although a host of nucleophilic and electrophilic groups can be considered (10), the sulfhydryl and bromoacyl groups were preferred for ease of their reactivity at 0°C in aqueous buffered media.

Appropriately derivatized antibiotics (haptens)[4] are required to achieve their chemical attachment to proteins. Preparation of gentamicin, amikacin, and tobramycin haptens requires only subtle chemical modifications in such a way that most of the structural integrity of these drugs is kept intact. Only a limited chemistry of these aminoglycosides has been reported in the literature. This is presumably due to their complex structures and insolubility in most of the organic solvents. Our approach to preparing their haptens rests on modification of the antibiotic amines with a sulfhydryl group. Because of the general lability of sulfhydryl groups to aerial oxidation, the antibiotic was selectively acylated with methyldithioacetic acid. Cleavage with dithioerythritol or methanethiol gave the desired drug hapten. Alternatively, the nucleophilic suflhydryl group was generated by controlled reaction of an antibiotic with *N*-acetyl-*d,l*-homocysteine thiolactone.

Proteins were modified with a number of bromoacetylglycyl groups. Coupling with the sulfhydryl haptens afforded the desired drug immunogens and the drug enzyme conjugates (Scheme 1).

Gentamicin hapten

Perhaps the most commonly utilized antibiotic of its class, gentamicin is available as a mixture of at least three components, **1**–**3**. It is commonly resolved through liquid–liquid partition chromatography (11). This method is both tedious and time consuming. Because of the quantities of material needed,

we considered this procedure to be less attractive and developed a more practical high-pressure liquid chromatographic method for separation. Gram quantities of the pure, individual components are readily available by using this technique.

Each of the antibiotic components **1**–**3** has a number of amino and hydroxyl functionalities. Since gentamicin C_1, **1**, has the least number of primary amino groups and the design of a hapten involved selective *N*-acylation, it was chosen as a starting material. The more reactive $R^{4'}$ amino group was protected by reaction with *S*-ethyl trifluorothioacetate (12). Careful acylation of the product **7** with the *N*-hydroxysuccinimide

monoacylated product failed. The bismethyldithioacetyl derivative was cleaved to hapten **9** with methanethiol for *in situ* coupling to the bromoacetylglycyl modified enzyme, glucose-6-phosphate dehydrogenase (G6PDH) (8).

Amikacin hapten

A relatively new member in its class for treatment of Gram-negative bacteria, amikacin is particularly useful for patients having strains resistant to all other aminoglycosides (13). Hapten **14** was designed so that most of the structural topology of the drug would remain intact and exposed after coupling to proteins. Such a conjugate should produce drug specific antibodies.

Our synthetic approach for amikacin hapten **14** followed that of the parent drug from kanamycin A (14, 15). The order of reactivity for acylation of amino groups in kanamycin A, **5**, has been determined as C-6′ > C-1 > C-3 > C-3″, which makes its direct transformation to **14** by reaction with **10** less attractive. A more involved route, utilizing the protection of amino groups before acylation, was therefore followed. The C-1 and C-3″ amino groups of **5** were first protected by reacting it with nickel acetate in dimethyl sulfoxide. Treatment of the nickel complex with *p*-methoxybenzyl-5-(4,6-dimethylpyrimidine-2-yl)thiocarbonate, followed by removal of the metal with hydrogen sulfide, gave 3,6′-di-*N*-*p*-methoxybenzyloxycarbonyl kanamycin A, **11**, identical in all respects to an authentic sample (16). Based on the findings of Hanessian and Patel (17) that the vicinal C-3″ amino and C-4″ hydroxyl groups selectively complex with the Group II transition metals such as Cu^{2+} in protic media, **11** was stirred with Ni^{2+} acetate in a 1:1 mixture of tetrahydrofuran and water. The resulting nickel complex, which now has a free C-1 amino group, was then condensed with the activated methyldithioacetic acid **10**. Removal of the metal with Chelex-100® resin gave **12**, which after cleavage of the *p*-methoxybenzyloxycarbonyl protecting groups with trifluoroacetic acid afforded the desired pro-hapten **13** in an overall yield of 15% from kanamycin A. The hapten **14** was readily obtained by stirring it with dithioerythritol under an inert atmosphere for *in situ* coupling to modified proteins. The pure hapten could not be isolated, presumably due to its sensitivity to aerial oxidation.

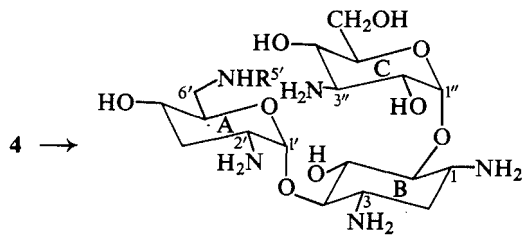
The chemical structure **13** of the amikacin pro-hapten is in accord with its elemental analysis and spectral data. The exact site of acylation was determined from the pH-dependent ^{13}C nmr chemical shift of its carbon nuclei β to amino groups (Table 1). A change in pH from 4 to 11 caused 2,5′, 2″, and 4″ carbon nuclei to experience downfield shifts of ~4 ppm, similar to the ones observed for amikacin (18). As expected, the C-6 nucleus showed insignificant change and the shift of approximately 4 ppm in the C-2 nucleus, one half the value of the same carbon atom in kanamycin A (7.6 ppm shift), is in accord with acylation only at the C-1 amino group.

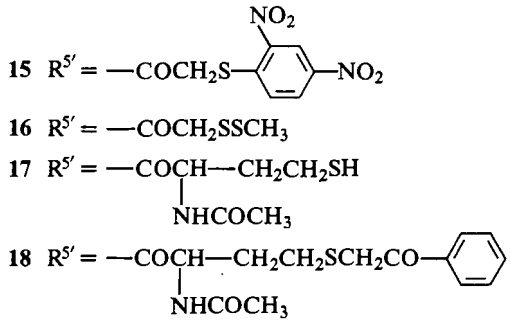
Tobramycin hapten

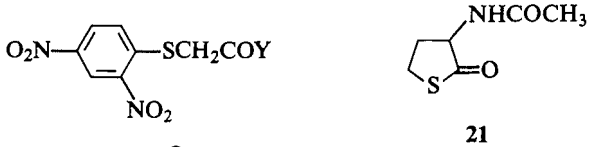
Our strategy to prepare its hapten directly from the parent drug by selective acylation of the C-6 amino group of **4** relied heavily on the relative basicities of the five amino groups of tobramycin, which by pH-dependent nmr studies have been reported in the order C-6′ > C-3 > (C-2′, C-3″) > C-1 (19). Such a hapten would furthermore provide the maximum exposure of the antibiotic ring C after attachment to proteins, the part of structures at which tobramycin differs substantially from gentamicins **1**–**3**. More selective anti-tobramycin antibodies are therefore expected.

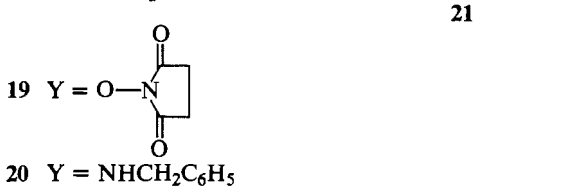
Reaction of tobramycin (**4**) with the *N*-hydroxysuccinimide ester of 2,4-dinitrophenylthioglycolic acid afforded monoacylated product **15**. Analysis of its ultraviolet spectrum at 331 nm and comparison with the benzamide derivative **20** of 2,4-dinitrophenylthioglycolic acid as a model compound clearly showed that only one 2,4-dinitrophenyl moiety had been incorporated into a molecule of **4**. That the monoacylation had indeed taken place only at the C-6 amino group was in accord with the mass spectral fragmentation of the derivative **15**. As expected, appropriate fragments attributed to the cleavage of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.









unmodified glycosidic rings B and C were observed (20).

Formation of **15** as the sole monoacylated product established that the selective acylation of tobramycin at the C-6′ amino group was indeed achievable. Our attempt to extend this reaction further by acylation with **10**, with the object of preparing the pro-hapten **16**, failed. The product had an amide carbonyl infrared absorption at 1650 cm^{-1} and showed complete absence of an SCH_3 signal in it proton nmr spectrum. We rationalize these observations as due to the presumed instability of the disulfide group in the product to the experimental conditions.

Amines are reported to open *N*-acetyl-*d,l*-homocysteine thiolactone, **21**, quantitatively (21). Our attention was therefore turned to using this thiolactone as a potential synthon for introduction of a mercapto group into tobramycin. Indeed, when aqueous tobramycin, under high dilution, was stirred under argon, with 0.5 mol-equivalents of the thiolactone **21**, a new compound **17** was obtained as the sole product by tlc analysis. That it is the monoacylated derivative **17** was proven by reaction, without further purification, with ω-bromoacetophenone and by comparing the spectral data of the product **18** with 2-hydroxyethylmercaptophenone as a model compound.

The tobramycin hapten **17**, prepared *in situ*, was used directly for coupling to bromoacetylglycyl modified G6PDH and bovine serum albumin.

Modification of proteins for coupling to aminoglycosides

Development of an EMIT® assay for an aminoglycoside antibiotic requires drug specific antibodies and active drug enzyme conjugates. The immunogens needed for raising the antibodies to antibiotics are often prepared by coupling an aminoglycoside with a carrier protein in the presence of 1-ethyl-3(3-dimethylaminopropyl)carbodiimide (EDAC). Such a method would lead to random coupling of antibiotics, resulting in an heterogeneous mixture of immunogens. This not only leads to a lot-to-lot variation for preparation of immunogens but, in our experience, elicits poor quality (low titer) antisera. As an attempt to solve this problem, the antibiotic immunogens were prepared by using a more controlled heterobifunctional coupling procedure, shown in Scheme 1. For example, the amikacin and tobramycin immunogens were readily prepared by coupling at pH ~ 8 bovine serum albumin, modified with a number of bromoacetylglycyl groups, with the sulfhydryl labeled antibiotic haptens **14** and **17**. Selective reaction of the modified proteins with the sulfhydryl groups of antibiotics is expected because of more than hundred-fold greater reactivity of thiols as compared to amino groups with bromoacyl groups (22). This is in agreement with the observation that only a single product **18** is formed upon reacting **17** with ω-bromoacetophenone under similar conditions. Use of radiolabeled drugs showed that 8–12 haptens could be readily incorporated into proteins using this procedure. Superior titer antibodies were obtained from sheep injected with these immunogens.

Labeling of the enzyme, glucose-6-phosphate dehydrogenase, with aminoglycosides using the direct EDAC coupling procedure turned out to be a more serious problem. The method afforded enzyme conjugates which were generally found inactive, presumably due to extensive polymerization, and therefore could not be used in EMIT® assays. Extension of the protocol similar to the one used for the preparation of antibiotic immunogens afforded useable enzyme conjugates. The procedure has been described previously in detail for preparation of the G6PDH–gentamicin conjugates (8). The method has now been extended for preparation of the G6PDH conjugates of other aminoglycosides, including tobramycin, netilmicin, and amikacin. These conjugates are found useful for development of their EMIT® assays (23, 24).

A brief mention of the method for preparation of the enzyme–amikacin conjugate for use in development of its EMIT® assay is provided as an example. The enzyme, G6PDH, was labeled with a number of bromoacetyl groups by reaction in a buffer at pH ~6, with bromoacetylglycyl-*N*-hydroxysuccinimide ester. The modified enzyme was then treated at 0°C, under an inert atmosphere, with the freshly prepared amikacin hapten **14** in a buffered medium at pH 8. The amikacin–G6PDH conjugate, with a residual activity of ~25% of the native enzyme, was readily inhibited by anti-amikacin antibodies. The conjugate was used to develop its EMIT® assay in the range of 2.5–50 μg/mL. The assay has the usual convenient protocol like other EMIT® assays and provides patient sample quantitation in less than a minute (6, 7).

Experimental

Melting points are uncorrected and were determined with a Thomas–Hoover capillary apparatus. The ir spectra were measured on a Perkin–Elmer 297 spectrometer and the proton nmr spectra were recorded on a 90 MHz Varian EM-390 instrument using tetramethylsilane as an internal standard. The ^{13}C nmr were taken on a Bruker WM-300 with dioxane as an internal standard and uv spectra were recorded on a Cary-15 instrument. Enzyme activity of drug–enzyme conjugates was measured on a Gilford Stasar III spectrometer. Analytical tlc analyses were performed on Analtech silica gel GF and E Merck silanized silica gel 60 plates, using 5% ammonium molybdate – sulfuric acid or 0.1% ninhydrin in isopropanol as sprays for viewing of the developed plates. Preparative tlc work was carried using Analtech 1000-μm thick silica G plates.

Separation of gentamicin isomers 1–3

Ammonia gas was bubbled through a stirring suspension of gentamicin sulfate (60 g) in 750 mL of methanol. After 3 h, the slurry was filtered and the filtrate was evaporated to give 35 g of gentamicin-free base as a white foam. The tlc analysis ($CHCl_3/CH_3OH/NH_4OH$, 10:10:3) showed two major and one minor spots.

Two silica cartridges (Waters preparative 500), in series, were equilibrated with the lower phase of a 2:1:1 mixture of chloroform, isopropanol, and 14% aqueous ammonium hydroxide. A solution of gentamicin-free base (10 g) in methylene chloride (total volume, 15 mL) was loaded onto the first column. Elution with the same mixture of solvents at 300 mL/min afforded fractions which after evaporation gave tlc pure gentamicin C_1 (**1**, 3.39 g). The elution solvent was then made more basic by changing it to the lower layer of a 2:2:1 mixture of chloroform, isopropanol, and concentrated ammonium hydroxide. The fractions were continuously monitored by analytical tlc. Pooling of the like fractions followed by evaporation afforded the remaining two components, namely gentamicin C_2 (**3**, 1.5 g) and gentamicin C_{1a} (**2**, 2.1 g).

N-*Hydroxysuccinimide ester of methyldithioacetic acid (10)*

Into a 50-mL round-bottom flask was placed 1.2 g (8.86 mmol) of methyldithioacetic acid (8), 35 mL of dichloromethane, and 1.09 g (9.54 mmol) of *N*-hydroxysuccinimide (crystallized from ethyl acetate). The solution was cooled in an ice bath, to which was then added 1.96 g (9.54 mmol) of freshly distilled *N,N'*-dicyclohexylcarbodiimide. The reaction mixture was stirred, and after 4 h the solution was filtered through a sintered glass funnel. Precipitated urea was washed with dichloromethane. The light brown filtrate was concentrated under vacuum at ambient temperature. The residue was dissolved in 10 mL of methylene chloride and applied to the top of a 2.5 × 43 cm dry glass column packed with 110 g of silanized silica gel (70–230 mesh, E Merck reagent). Elution with a mixture of hexane/methylene chloride (1:1) afforded **10** as a white solid (1.2 g, 60%). Recrystallization from methylene chloride/hexane afforded crystals, mp 79–81°C; ir (KBr): 1760, 1790, 1830 cm^{-1}; nmr ($CDCl_3$) δ: 2.5 (s, 3H, SCH_3), 2.85 (s, 4H), and 3.74 (s, 2H, CH_2); ms, *m/e*: 235 (M^+), 120, 93. *Anal.* calcd. for $C_7H_9NO_4S_2$: C 35.73, H 3.85, N 5.95, S 27.25; found: C 36.22, H 4.02, N 6.18, S 27.25.

*Preparation of 3-*N*-methyldithioacetyl-2'-*N*-trifluoroacetyl gentamicin C_1 (8)*

Into a 250-mL 3-necked round-bottom flask, equipped with an argon inlet, rubber septum, and magnetic stirrer, was placed 2'-*N*-trifluoroacetyl gentamicin C_1 (**7**, 1.5 g, 2.6 mmol), prepared from gentamicin C_1 according to the literature procedure (11), in 80 mL of dry tetrahydrofuran. To this was added dropwise over 2 h the activated ester **10** of methyldithioacetic acid (560 mg, 2.8 mmol) (8) in 15 mL dimethylformamide. The mixture was allowed to stir overnight at room temperature and the solvent was removed under reduced pressure at 40°C. Careful chromatography of the crude product on a column of silica gel using chloroform/methanol (2:1) followed by chloroform/methanol/17% NH_4OH (2:1:1) yielded two products.

The minor product, R_f 0.3 ($CHCl_3/CH_3OH$/17%NH_4OH, 2:1:1), considered to be a monoacylated derivative, exhibited the following spectral data: ir (KBr): 3300 (NH_2,OH), 1720 (CF_3CO), and 1660 (amide CO) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.1 (d, $CHCH_3$ J = 6 Hz), 1.2 (s, CH_3), 2.4 (s, $NHCH_3$), 2.5 (s, S—CH_3), 2.7 (s, $NHCH_3$), 3.4 (s, CH_2SS). The major product, identified as **8**, had its R_f 0.6 and showed bands in its ir spectrum identical to the monoacylated derivative mentioned above. It showed signals in its nmr ($CDCl_3$) spectrum at δ: 1.1 (d, J = 6 Hz, $CHCH_3$), 1.26 (s, $C(OH)CH_3$), 3.40 (s, SCH_2CO). *Anal.* calcd. for $C_{29}H_{50}N_5O_{10}F_3S_4$: C 42.80, H 6.15, N 8.61, F 7.01, S 15.72; found: C 42.47, H 6.17, F 6.90, N 8.32, S 15.98.

*3,6'-Di-*N*-p-methoxybenzyloxycarbonyl kanamycin A (11)*

A solution of 1 *N* sodium hydroxide in deionized water was passed through a column (35 cm × 4 cm) packed with 350 mL of Bio-Rad Ag1X8 resin (20–50 mesh, chloride form) until the eluent showed a negative test for chloride ions. An aqueous solution of kanamycin A sulfate (23 g, Sigma Company) in 2 L of deionized water was then passed through the column at 8 mL/min and the solution collected. The column was further washed with 3 L of deionized water. The total eluent was concentrated under vacuum at 45°C to approximately 400 mL. Methanol (400 mL) was added to the concentrate, which was kept stirring and maintained at about 45°C. A white amorphous precipitate of the free kanamycin A (**5**), mp >245°C (dec.), was formed and collected by filtration. Treatment of the filtrate with an additional 400 mL of methanol afforded a second crop of **5**.

A solution of the kanamycin free base **5** (4.6 g, 9.5 mmol) and nickelous acetate (15 g, 60 mmol) in anhydrous DMSO was stirred in a round-bottomed flask for 30 min. A deep green solution was formed, to which was added dropwise, with stirring, *p*-methoxybenzyl-*S*-(4,6-dimethylpyrimidine-2-yl)thiocarbonate (7.22 g, 23.7 mmol) in 60 mL of DMSO. After stirring overnight the green solution was placed in a 2-L Erlenmeyer flask and treated with a liter of diethylether. The mixture was swirled vigorously, allowed to settle, and the ethereal phase decanted. This was repeated three more times, when a green semisolid material was obtained. The semisolid residue was dissolved in methanol (300 mL) and filtered. Hydrogen sulfide was slowly bubbled through the filtrate for 30 min and the reaction set aside with stirring for 24 h.

The mixture was filtered through a bed of Celite and washed with methanol. To the concentrated filtrate (~300 mL) was added an excess of ethyl acetate and the pH adjusted to 9.0 with ammonium hydroxide. The crude aminoglycoside product **11** separated out as an oily solid. The semisolid material was redissolved in a minimum amount of methanol and reprecipitated with a 1:1 mixture of acetonitrile and ethyl acetate. The solid was filtered, washed with ethyl acetate, and dried under vacuum over P_2O_5. The title compound **11** was obtained as a white solid (5.1 g, 65%), mp 220–235°C (dec.); ir (KBr): 3395 (br), 1700, 1620 cm^{-1}. Its R_f value on a silica tlc plate (CH_3OH/NH_4OH, 9.5:05) and infrared spectrum were identical to those of the authentic sample (16). *Anal.* calcd. for $C_{36}H_{52}N_4O_{17}$: C 53.19, H 6.44, N 6.89; found: C 52.99, H 6.29, N 6.90.

*1-*N*-Methyldithioacetyl-3,6'-di-*N*-p-methoxybenzyloxycarbonyl kanamycin A (12)*

A mixture of **11** (2.5 g, 3 mmol) and nickelous acetate (4 g, 16 mmol) in 100 mL of 1:1 tetrahydrofuran–water was stirred for 1 h. A deep green solution was formed. To the stirring green solution was added dropwise a solution of the activated ester **10** of methyldithioacetic acid (1 g, 4.5 mmol) in tetrahydrofuran (30 mL). The reaction mixture was stirred for 16 h and treated with an excess of Bio-Rad Chelex-100 resin. The mixture was stirred overnight and filtered. The resin was washed with a mixture of tetrahydrofuran–water (1:1) until the filtrate was free of aminoglycoside by tlc analysis. The colorless filtrate was concentrated under vacuum at 20°C, when a white suspension was formed. The mixture was centrifuged. The supernatant was removed and made alkaline to pH 9.5 with ammonium hydroxide. A white precipitate was formed and removed by centrifugation. The precipitate was washed twice with deionized water and once with methanol by repeatedly suspending and centrifuging it in these liquids. The white solid was lyophilized, affording **12** as a tlc pure white powder (1.4 g, 50%), mp 200–205°C (dec.). Its proton nmr spectrum (DMF-d_7) showed signals at δ: 2.46 (s, 3H, S—CH_3), 3.2–4.2 (m), 3.8 (s, OCH_3) 5.0 (br s, 4H, —O—CH_2 Ar), and AA'XX' doublet of a doublet centered at 7.1 (aromatics, 8H) and ir absorption bands (KBr) at 3350 (br), 1700, 1645 cm^{-1}. *Anal.* calcd. for $C_{39}H_{56}N_4O_{18}S_2$: C 50.20, H 6.05, N 6.00, S 6.87; found: C 50.50, H 6.12, N 5.90, S 6.89.

*Amikacin pro-hapten, 1-*N*-methyldithioacetyl kanamycin A, (13)*

Into a dry two-necked flask was placed 1.5 g (1.50 mmol) of **12** (previously dried at 60°C/0.1 Torr over P_2O_5 (1 Torr = 133.3 Pa) and a stream of argon was passed over it. The contents of the flask were cooled in an ice bath and 25 mL ice-cooled trifluoroacetic acid (distilled from P_2O_5) was added with swirling. After 5 min the acid, from the deep purple colored mixture, was removed at room temperature under vacuum (0.1 Torr). The residual solid material was pulverized

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

and washed with diethyl ether. This was repeated twice with ether and twice with dichloromethane, leaving **13** as an off-white solid. Chromatography on a 250-g silanized silica gel RP-2 column using a gradient of 0–20% of methanol in methylene chloride afforded the pure hapten as a white solid (670 mg, 45%), mp > 185°C (dec.). It showed signals in its ^{1}H nmr spectrum (CD_3OD) at δ: 2.46 (s, 3H, S—CH_3), 5.15 (br s, 1H, —O*CH*O—), 5.5 (br s, 1H, O*CH*O), along with multiplets for other protons between δ 2.8–4.4. *Anal.* calcd. for $C_{21}H_{40}N_4O_{12}S_2 \cdot 3CF_3CO_2H \cdot H_2O$: C 33.60, H 4.69, N 5.80, F 17.70, S 6.64; found: C 33.25, H 4.66, N 5.78, F 17.40, S 6.53.

The ^{13}C nmr spectrum of **13** (D_2O–dioxane) exhibited its carbon signals at the following chemical shifts: for pH ≤4.0, δ: 49.94 (C-1), 30.98 (C-2), 48.60 (C-3), 79.98 (C-4), 73.15 (C-5), 81.70 (C-6), 96.33 (C-1′), 72.86 (C-2′), 71.59 (C-3′ and C-4′), 69.54 (C-5′), 41.09 (C-6′), 98.99 (C-1″), 68.73 (C-2″), 55.98 (C-3″), 66.39 (C-4″), 73.15 (C-5″), 60.57 (C-6″), 22.76 (S—CH_3), 41.65 (S—CH_2), and 173.15 (C=O); for pH ≥11.0, δ: 50.39 (C-1), 35.02 (C-2), 49.51 (C-3), 87.62 (C-4), 75.23 (C-5), 82.02 (C-6), 99.51 (C-1′), 72.69 (C-2′), 71.82 (C-3′ and C-4′), 73.73 (C-5′), 42.27 (C-6′), 100.26 (C-1″), 72.69 (C-2″), 54.42 (C-3″), 70.29 (C-4″), 73.25 (C-5″), 61.0 (C-6″), 42.27 (S—CH_2), and 179.0 (C=O).

2,4-Dinitrophenylthioglycolic acid N-*hydroxy succinimide ester (**19**)*

To a mixture of 2,4-dinitrophenylthioglycolic acid (0.774 g, 3 mmol) and *N*-hydroxysuccinimide (0.345 g, 3 mmol) in 25 mL of freshly distilled THF at 0°C under nitrogen was added *N,N′*-dicyclohexylcarbodiimide (DCC) (0.927 g, 4.5 mmol). The mixture was stirred. After 4 h, a white precipitate was formed and was filtered. The solvent was removed from the filtrate under reduced pressure and the solid residue was triturated with 10% dichloromethane in hexanes. The solid which remained undissolved was collected by filtration. Recrystallization of the solid from ethyl acetate – DMF gave **19** as a light yellow solid (0.854 g, 80% yield), mp 198–199°C; ir (KBr): 1820, 1775, 1740 cm^{-1}; ^{1}H nmr (DMSO-d_6) δ: 8.88 (d, J = 1.5 Hz, 1H), 8.47 (q, J_1 = 5.0, J_2 = 1.5, 1H), 7.90 (d, J = 5.0 Hz, 1H), 4.85 (s, 2H), 2.83 (s, 4H). *Anal.* calcd. for $C_{12}H_9N_3O_8S$: S 40.51, H 2.55, N 11.58, S 9.17; found: C 40.56, H 2.53, N 11.83, S 9.00.

*Reaction of tobramycin with 2,4-dinitrophenylthioglycolic acid NHS ester (**19**)*

To a stirring solution of tobramycin (**4**, 0.92 g, 2 mmol) in 200 mL of water at 0°C, pH 10.76, was added very slowly a solution of 2,4-dinitrophenylthioglycolic acid NHS ester **18** (0.365 g, 1 mmol) in 25 mL of anhydrous DMF. The pH of the solution was maintained at 10.5–10.9 throughout the reaction (10% sodium hydroxide). After addition, the mixture was stirred at 0°C for 2 h and filtered. The filtrate was washed several times with ethyl acetate. The aqueous layer was evaporated to dryness under reduced pressure to give a solid residue. The solid residue was chromatographed on preparative silica gel plates, using chloroform/methanol/ammonium hydroxide (v/v 1:2:1) for elution, to give **15** as an orange solid (0.2 g, 28.3%), mp 210°C (dec.); ir (KBr): 3700–2400, 1645 cm^{-1}; uv (H_2O): 331 nm (ε 6532); EI ms, *m/e* (relative abundance): 163(8), 203(2), 306(1.5), 323(3), 351(2), 407(2.5). *Anal.* calcd. for $C_{26}H_{41}N_7O_{14}S$: S 4.53; found: S 4.74.

*Preparation of benzamide derivative **20***

To a solution of 2,4-dinitrophenylthioglycolic acid NHS ester **18** (0.19 g, 0.54 mmol) in 5 mL of anhydrous DMF at 0°C under nitrogen, was added dropwise a solution of benzylamine (0.06 g, 0.54 mmol). After addition, the mixture was stirred at 0°C for 3 h. The solvent was removed under reduced pressure to give an orange solid residue. Preparative tlc on silica plates using chloroform/methanol (95:5) gave **20** (0.16 g, 85%), which upon recrystallization from methanol gave deep yellow needles, mp 148–151°C; ir (KBr): 3300, 1640 cm^{-1}; uv (50% THF in water): 335 (ε 9000); nmr (DMSO-d_6) δ: 8.78 (d, 1H), 8.35 (q, 1H), 7.80 (d, 1H), 7.20 (s, 5H), 4.28 (d, 2H), 4.05 (s, 2H); *Anal.* calcd. for $C_{15}H_{13}N_3O_5S$: C 51.60, H 3.80, N 12.00, S 9.32; found: C 51.72, H 3.80, N 12.69, S 9.20.

*Reaction of tobramycin with activated methyldithioacetic ester (**10**)*

To a stirring solution of tobramycin (0.723 g, 1.55 mmol) in 20 mL of dimethylformamide, 20 mL of water, and 10 drops of triethylamine at 0°C and under nitrogen was added very slowly a solution of methyldithioacetic acid NHS ester (**10**, 0.364 g, 1.55 mmol) in 4 mL of anhydrous DMF. After addition, the mixture was stirred at 0°C for 2 days. The solvent was removed under reduced pressure to give a white residue. The solid residue was chromatographed on silica plates, elution with methanol/acetic acid/water (3:1:1) or methanol/chloroform/ammonium hydroxide (2:1:1) gave a solid product which showed in its ir spectrum an amide band at 1650 cm^{-1}. Its ^{1}H nmr spectrum, however, showed the absence of an S—CH_3 signal.

Reaction of tobramycin with N-*acetyl*-d,l-*homocysteine thiolactone (**21**)*

A steady stream of dry nitrogen was bubbled through a solution of tobramycin (0.934 g, 2 mmol) in 75 mL of water at pH 10.12 for 30 min. To this stirring solution was added slowly (15 drop/s) a solution of the homocysteine thiolactone **20** (0.159 g, 1 mmol, Sigma Chemicals) in 5 mL of oxygen-free tetrahydrofuran. The pH of the mixture was maintained at 10.12–10.25 throughout the addition with 10% sodium hydroxide. After addition, the mixture was stirred for 1 h. The pH of the solution was adjusted to 7 with 5% hydrochloric acid. The solution was washed carefully with oxygen-free ethyl acetate (4 × 30 mL) and the aqueous layer was collected. The pH of the solution was adjusted to 10.12 with 10% sodium hydroxide. Lyophilization of the solution gave a white solid (ca. 800 mg). The analytical silica gel tlc showed a single new product (R_f 0.39) and the unreacted starting tobramycin (R_f 0.10) using methanol/chloroform/ammonium hydroxide (2:1:1) as the solvent system.

The mixture obtained by the addition of tobramycin to *N*-acetylhomocysteine thiolactone (**4** + **17**, 700 mg) was dissolved in 25 mL of oxygen-free water. The pH of the solution was adjusted to 7.5 with 5% hydrochloric acid. To this solution was added slowly a solution of ω-bromoacetophenone (0.1 g, 0.5 mmol) in 5 mL of THF at 0°C under nitrogen. The pH of the reaction mixture was maintained at 7.1–7.5 with 10% sodium hydroxide solution. After addition, the mixture was stirred for 2 h and filtered. The filtrate was washed with ethyl acetate and lyophilized to give a white solid residue. The solid was chromatographed on silica tlc plates; elution with chloroform/methanol/ammonium hydroxide (1:2:1) gave **18** as a white solid (60 mg); ir (KBr): 3700–2400, 1640 cm^{-1}; uv (H_2O): 250 nm (ε 10 496). The 2-hydroxyethylmercaptoacetophenone, prepared in 91% yield by condensing bromoacetophenone with 2-mercaptoethanol, had its ultraviolet maxima in ethanol at 242 nm (ε 10 014).

Bromoacetylglycine N-*hydroxysuccinimide ester*

To a solution of bromoacetylglycine (463 mg, 2.37 mmol) and *N*-hydroxysuccinimide (273 mg, 2.37 mmol) in 15 mL of anhydrous tetrahydrofuran at 0°C, under nitrogen, was added *N,N′*-dicyclohexylcarbodiimide (DCC) (732 mg, 50% excess). The resulting solution was stirred at 0°C for 4 h, when a white precipitate had formed. The precipitate was removed by filtration and the filtrate evaporated to dryness under vacuum. The solid residue was triturated with a 1:4 mixture of dichloromethane in hexanes. The solid was collected by filtration, and recrystallization from dichloromethane – ethyl acetate – hexanes gave the title compound as ten colored crystals (400 mg, 58%), mp 122–123°C; ir (KBr); 3270, 1830, 1780, 1650 cm^{-1}; ^{1}H nmr ($CDCl_3$ – DMSO-d_6) δ: 2.88 (s, 4H), 3.90 (s, 2H), 4.55 (d, 2H), 8.50 (m, 1H). *Anal.* calcd. for $C_8H_9NO_5Br$: C 32.76, H 3.07, N 9.56, Br 27.30; found: C 32.62, H 2.99, N 9.42, Br 27.53.

Labeling of bromoacetylglycine–NHS ester to bovine serum albumin (BSA)

To a solution of BSA (644 mg, 0.01 mmol) in 32 mL of 0.1 *M* borate buffer, pH 8.44, at 0°C was added dropwise a solution of bromoacetylglycine–NHS ester (293 mg, 1 mmol) in 5 mL of dry DMF. All solutions were saturated with argon before use. The addition took 20 min. The conjugation was closely monitored by pH meter. While the initial pH of the protein solution was 8.44, it dropped

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

to around 8.0 and was maintained to ±0.5 pH units with 0.1 *N* sodium hydroxide or 0.1 *N* hydrochloric acid. The pH, after additions of the NHS ester, was adjusted to 8.04; the solution was allowed to stir in an ice bath for 40 min, after which time the pH had changed to 7.15. This pH was again adjusted to 6.8 with the acid. The bromoacetylglycyl labeled BSA conjugate, about 50 mL, was purified by passing through a 100-ml G-50 Sephadex column using deionized water as eluent. Appropriate fractions were pooled and used either immediately or the following day (stored in cold room).

Conjugation of amikacin hapten ***14*** *to BSA. Formation of an immunogen*

The amikacin pro-hapten **13** (44 mg) was dissolved in 2 mL of methanol and taken into a 10-ml round-bottomed (or a pear shaped) flask. A slow stream of argon was bubbled through the solution for 30 min. To this stirring solution under argon was now added dithioerythritol (180 mg) in degassed methanol (6 mL), along with a drop of triethylamine. Progress of the reaction was continuously monitored by using silica tlc plates. After completion of the reaction (ca. 2 h), the solution was dried by evaporation and the residue stored under nitrogen.

The bromoacetylglycyl-labeled BSA solution (ca. 10 mL) prepared from 60 mg of BSA was degassed by bubbling a slow stream of argon. The pH of the solution was maintained around 7.3 using 0.2 *M* phosphate buffer. To this solution at 0°C was now added dropwise the cleaved amikacin hapten **14** in 0.5 mL of DMF (degassed with argon). The reaction mixture was stirred overnight in the cold room. The BSA–amikacin conjugate was dialyzed in a Spectropor membrane tubing (mol. wt. cutoff 6000–8000), dialyzed against 4 L of deionized water, and adjusted to pH 8.0 with ammonium hydroxide. The dialyzing medium was changed three times after every 3 h. The residual conjugate in the membrane tube was centrifuged at ~10,000 rpm (to remove any suspended material) and the liquid was lyophilized to give 56 mg of the conjugate.

*Conjugation of tobramycin-*N*-acetyl-*d,l*-homocysteine thiolactone (17) with bromoacetylglycine-labeled G6PDH*

To a solution of bromoacetylglycine-labeled G6PDH (3.3 mL, 0.0245 μmol of G6PDH) prepared as described elsewhere (8), at 0°C, pH 7.7 (adjusted with 10% NaOH), was added in 5-μL portions a solution of **17** (36.8 mg, only 25% of which is assumed to be the desired mercaptotobramycin) in 0.5 mL of 0.01 *M*, pH 6.8 phosphate buffer. The pH of the reaction solution was maintained at around 7.5–7.7 throughout the reaction with 5% hydrochloric acid. The reaction was constantly followed by checking the enzyme activity on a Gilford spectrophotometer. The reaction was stopped when a total of 240 μL of the tobramycin sulfhydryl derivative **17** had been added. No loss of the enzyme activity was noticed throughout the reaction. The solution of tobramycin–G6PDH conjugate was stored at 0°C for 5 days and chromatographically purified by a Sephadex G-50 column (eluting with 0.01 *M*, pH 6.8 phosphate buffer) for use in an EMIT® assay.

Conjugation of amikacin hapten ***14*** *to glucose-6-phosphate dehydrogenase*

The amikacin hapten **14**, freshly prepared by cleaving the disulfide linkage of **13** as described above, was coupled to bromoacetylglycine-labeled G6PDH by a procedure identical to the one described for the preparation of gentamicin–G6PDH conjugates (8). The amikacin–G6PDH conjugate, with 25–30% of the native enzyme activity, was ~75% inhibitable by addition of anti-amikacin antibodies. Most of the inhibited activity was reversible by addition of the drug.

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

JOSEPH POULIQUEN, VÉRONIQUE WINTGENS, VICENTE TOSCANO, BRAHIM BEN JAAFAR, SADHANA TRIPATHI, JEAN KOSSANYI, and PIERRE VALAT. Can. J. Chem. **62**, 2478 (1984).

The photochemical behaviour of *N,N'*-disubstituted indigo dyes has been investigated. The *trans* to *cis* and *cis* to *trans* photoisomerization quantum yields are found to be of the order of 0.25 or less (down to 0.03). These dyes, which fluoresce only weakly in solution and at room temperature, show a drastic increase in their fluorescence when inserted into a polymer matrix or at 77 K in butyronitrile glass. This has been interpreted in terms of the inhibition of formation of a twisted excited intermediate as well as of the rotation of the substituent on the nitrogen atom. An important electron transfer occurs from the singlet excited state when the indigo dyes are placed in the presence of electron-donating molecules. When irradiating with visible light, the photostationary state is always in favour of the *trans* isomers. This, and kinetic as well as thermodynamic considerations, excludes these compounds as candidates for solar energy storage.

JOSEPH POULIQUEN, VÉRONIQUE WINTGENS, VICENTE TOSCANO, BRAHIM BEN JAAFAR, SADHANA TRIPATHI, JEAN KOSSANYI et PIERRE VALAT. Can. J. Chem. **62**, 2478 (1984).

Le comportement des indigos substitués **1**–**4** a été examiné. On trouve que les rendements quantiques de photoisomerisation sont faibles (de l'ordre de, ou inférieurs à, 0,20). Ces composés qui fluorescent faiblement en solution et à 20°C, présentent une augmentation considérable de leur fluorescence quand ils sont inclus dans un polymère ou bien lorsque la température est abaissée à 77 K dans le butyronitrile. Ceci a été interprêté comme un empêchement à la rotation autour de la double liaison centrale, et comme une gêne à la rotation du substituant sur l'azote ainsi que de l'inversion de cet atome. L'irradiation en lumière blanche est toujours en faveur des isomères *trans*. Ceci, ainsi que des considérations cinétiques et thermodynamiques excluent ces composés pour le stockage de l'énergie solaire.

Introduction

In the search for new sources of energy, photochemical transformations have been examined as a potential means of obtaining energy-rich stable products. Criteria for efficient photochemical conversion of solar energy are: absorption in the visible or near-ultraviolet region, high quantum efficiencies, large positive ground state enthalpies, and stable photoproducts. In addition, the reactant must be inexpensive and not dangerous.

The importance of dyes has been widely recognized in different converting systems related to photobiology (1, 2), photoelectrochemistry (3, 4), and photochemistry (5).

Photochemical systems mostly involve (Fig. 1) absorption of visible light by a reagent R to produce a high energy content product P which can later release the stored energy while reverting to the starting material. Among the systems reported thus far, one finds intramolecular cycloadditions (the best system investigated seems to be the norbornadiene-quadricyclane one (6) which can store about 26 kcal/mol (7)) and valence isomerization (such as the photochemical transformation of 1-methyl 5-phenyl Δ-2 pyrazoline into 2-phenylcyclopropylazomethane (8).

E/Z isomerizations have been recognized for a long time as efficient photochemical reactions which can occur by either direct irradiation or triplet sensitization. These reactions, which have been investigated in great detail, include the cases of azobenzene (9) and stilbene derivatives (10), but they usually suffer from the fact that the materials absorb mainly in the uv region. The use of *E/Z* isomerization for energy storage has been proposed tentatively (11) for cyanines and indigos as well. These two series of compounds have the advantage of absorbing light in the visible region but the difference in energy between the excited states of the geometrical isomers is around 10 kcal/mol in the 500-nm region (*vide infra*) and decreases as the molecules absorb at longer wavelengths.

In several cases, the reactivity of the compounds towards oxygen or their low solubility in both organic solvents and water put a limit to the feasibility of their isomerization as a source of energy storage. In addition, a compromise must be found between two opposing requirements: to absorb visible light and to gain enough energy for the isomerization. Such an energy gain will depend on the energy gap between the singlet (or triplet) excited states of the two isomers and on the height of the energy barrier between them. A gain of 10 kcal/mol or more seems to be a reasonable goal. This can be obtained when the excited states are separated by 150 nm in the 600–750 nm region or by 100 nm in the 500–600 nm region. Trying to store 15 kcal/mol is only reasonable for the 400–500 nm region and this explains why the best results are given by systems which absorb light in the near-uv region. A reasonable compromise can be achieved when the singlet excited states are localized in the 500–600 nm range. This is precisely the case of the *N,N'*-diacyl substituted indigos.

Experimental

Melting points were determined with a Mettler FP1 automatic appa-

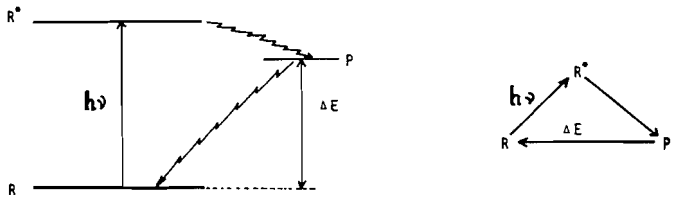

FIG. 1. Photochemical conversion (by direct irradiation or by triplet energy transfer) of a reagent R into the product P. ΔE is the stored energy which can be released in the back reaction P → R.

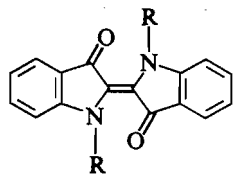
ratus. Infrared spectra were obtained with a Perkin–Elmer 357 model spectrophotometer and uv–visible absorption spectra were recorded on a Varian Cary 219 model. Emission spectra were performed using a Perkin–Elmer MPF 44B spectrofluorimeter; the spectra are corrected with a DCS 2U unit and a calibrated tungsten lamp.

A. *Materials*

The amines used as electron donors were purified by distillation with the exception of triphenylamine which was used without purification, of *N,N'*-diphenylparaphenylenediamine which was chromatographed on silica gel (elution with benzene), and of phenothiazine which was purified in the same way but using a 50:50 mixture of benzene with petroleum ether (60–80°C) as eluent. Naphthalene (scintillation grade), 1,4-dimethoxybenzene, and 1,3,5-trimethoxybenzene were used without purification. 1,2-Dimethoxybenzene was distilled.

The *trans* isomers of *N,N'*-disubstituted indigos were prepared according to the procedure of Blanc and Ross (12) for the *N,N'*-diacetyl derivative **1***t* and by Posner's method (13) for the *N,N'*-dibenzoyl **2***t*, *N,N'*-diparachlorobenzoyl **3***t*, and *N,N'*-diparamethoxybenzoyl **4***t* derivatives.



trans-Indigos: **1***t* R = CH_3—C(=O)— **2***t* R = C_6H_5—C(=O)—

3*t* R = *p*-Cl—C_6H_4—C(=O)— **4***t* R = *p*-CH_3O—C_6H_4—C(=O)—

The purity of the compounds was verified by thin-layer chromatography on silica gel (elution with benzene/ethylacetate 80:20).

(a) trans *Derivatives*

The chemical yields and characteristics of the *trans* derivatives were the following.

trans-N,N'-*diacetylindigo* (**1***t*): yield 57%; mp 269°C (lit. (12*a*) mp 263–264°C); ir (KBr): 1700, 1685, 1600, 1472, 1460, 1362, 1320, 1300, 1278, 1250, 1200, 1170, 1064, 925, and 755 cm^{-1}; uv λ_{max} (toluene) (ϵ): 560 nm (6,400 L mol^{-1} cm^{-1}).

trans N,N'-*dibenzoylindigo* (**2***t*): yield 79%; mp 254°C (lit. (14) mp 256–257°C); ir (KBr): 1705, 1670, 1600, 1472, 1460, 1320, 1270, 1240, 1187, 1105, 1070, 1040, 1020, 912, 800, 790, 758, 750, and 740 cm^{-1}; uv λ_{max} (toluene) (ϵ): 577 nm (7,700 L mol^{-1} cm^{-1}).

trans-N,N'-*diparachlorobenzoylindigo* (**3***t*): yield 42%; mp 254°C; ir (KBr): 1710, 1690, 1660, 1605, 1476, 1460, 1320, 1300, 1290, 1255, 1187, 1175, 1043, 1010, 877, 847, 830, 760, and 750 cm^{-1}; uv λ_{max} (toluene) (ϵ): 575 nm (8,350 L mol^{-1} cm^{-1}).

trans-N,N'-*diparamethoxybenzoylindigo* (**4***t*): yield 52%; mp 255°C; ir (KBr): 1690, 1665, 1600, 1575, 1510, 1455, 1420, 1320, 1295, 1250, 1183, 1165, 1065, 1040, 1020, 872, 860, 840, 760, and 750 cm^{-1}; uv λ_{max} (toluene) (ϵ): 580 nm (8,900 L mol^{-1} cm^{-1}).

(b) *Irradiation; general procedure*

The *cis* isomers were prepared by photochemical isomerization of the *trans* isomers, according to the procedure already described (14). Irradiations were carried out with a Philips HPLN 400 medium-pressure mercury arc in a water-cooled Pyrex jacket; the light emitted by the mercury lamp was filtered with a circulating solution of 80 g cobalt sulphate, 4.3 g potassium chromate, and 16 g sodium carbonate dissolved in 1 L of water.

The general procedure consisted of the irradiation of a 1:1 benzene – *n*-hexane solution saturated with the *trans* isomer and cooled at a temperature between 0° and 10°C by an external cooling jacket. As the *cis* isomer was formed, additional aliquots of the *trans* isomer were introduced into the irradiated solution. After several hours of irradiation, the solution was enriched in the *cis* isomer which began to crystallize.

This procedure enabled the *cis* isomer to be separated in a pure form. Only for the *N,N'*-diparamethoxybenzoyl indigo did this procedure fail, as the *cis* isomer reverted rapidly in the solution to the *trans* isomer when the light was switched off, even at −5°C.

(c) cis *Derivatives*

The characteristics of the isolated *cis* isomers were the following.

cis-N,N'-*diacetylindigo* (**1***c*): mp 266°C (lit. (14) mp 244–246°C);[3] ir (KBr): 1725, 1695, 1600, 1560, 1472, 1460, 1370, 1325, 1300, 1268, 1260, 1210, 1168, 1100, 1085, 1000, 885, 750, and 740 cm^{-1}; uv λ_{max} (toluene) (ϵ): 432 nm (4,050 L mol^{-1} cm^{-1}).

cis-N,N'-*dibenzoylindigo* (**2***c*): mp 260°C (lit. (14) mp 246°C);[3] ir (KBr): 1724, 1670, 1595, 1560, 1460, 1445, 1325, 1285, 1227, 1170, 1087, 1050, 1020, 1010, 922, 900, 855, 782, 750, and 740 cm^{-1}; uv λ_{max} (toluene) (ϵ): 460 nm (4,800 L mol^{-1} cm^{-1}).

cis-N,N'-*diparachlorobenzoylindigo* (**3***c*): mp 257°C; ir (KBr): 1720, 1675, 1597, 1585, 1560, 1460, 1395, 1325, 1285, 1230, 1180, 1167, 1085, 1050, 1008, 902, 845, 830, 780, 760, and 746 cm^{-1}; uv λ_{max} (toluene) (ϵ): 460 nm (2,600 L mol^{-1} cm^{-1}).

(d) *Solvents*

Solvents for absorption, emission, and quantum yield measurements were of spectrograde (Merck) quality and used without further purification. Experiments for the photochemical preparation of the *cis* isomers of the indigo derivatives were carried out in distilled benzene – *n*-hexane 1:1 solution.

B. *Emission*

(a) *Spectra*

All four *trans* isomers fluoresced when excited in their long-wavelength charge transfer band; the excitation spectra matched the absorption bands. No phosphorescence emission could be detected from them, even at liquid nitrogen temperature.

The *cis* isomers showed no fluorescence or phosphorescence.

(b) *Lifetimes*

The fluorescence decay of the *trans* isomers **1***t*–**4***t* was measured with a YAG laser from Quantel.

Frequency doubling of the fundamental light (1064 nm) by a prism gave a 532-nm light beam which passed through a diaphragm before traversing a quartz cell of dimensions 1 cm × 1 cm which contained the sample in chloroform solution. The emitted light was received at right angles by the photocathode of a high-speed photodiode (type S 11; rise time less than 150 ps). A gelatin filter (Kodak nb 21) was inserted between the photocathode and the cell, in order to eliminate the Rayleigh scattering. The photodiode signal was transmitted to a Tektronix 7104 oscilloscope with a risetime of about 350 ps and the oscilloscope trace was recorded on a Polaroid film. A 30-ps laser pulse produced an electronic echo in the detection system about 1 ns

[3]The mp of the *cis* isomers might be higher than the one given here since they can revert thermally to more stable *trans* isomers. This would be more pronounced for **1***c* (which has a lower mp than **1***t*) than for **2***c* and **3***c* (which melt at higher temperature than **2***t* and **3***t*).

after the signal; treatment of the data enabled this perturbation to be removed.

The light beam was split before passing through the cell and one part was focused on a GenTec pyroelectric detector; the signal obtained was proportional to the energy of the excitation light. A linear relationship between the fluorescence intensity and the excitation energy was obtained for all the compounds studied. The power density at the sample was less than 1 MW cm^{-2}.

(c) *Quantum yields*

The fluorescence quantum yields were determined using the Perkin–Elmer MPF-44B spectrofluorometer coupled to the DCS-2U device. The optical density of the solutions of the indigo derivatives in chloroform solution (Uvasol quality) was adjusted to 0.05 at the excitation wavelength. Fluorescein was used as the standard under the following experimental conditions: buffer solution at pH 10, optical density 0.05 at an excitation wavelength of 436 nm. A value of 0.85 has been reported (15) for the fluorescence quantum yield at this wavelength.

C. *Isomerization quantum yields*

The quantum yields of the *trans* to *cis* and *cis* to *trans* isomerizations of the indigo derivatives were measured using a 150-W Xenon lamp, the light being focused on a 1 cm × 1 cm quartz cell through a water filter and a Jobin–Yvon H 20 monochromator adjusted at 580 nm. The second-order spectra of the grating were removed by a 400-nm cut-off glass filter.

All the measurements were carried out at 20°C, the optical density of the toluene solution of the sample being adjusted to 0.13 at 580 nm. Under these conditions, the irradiation time varied from 0.3 to 0.6 h, depending on the starting material.

In the case of the *cis* to *trans* isomerization quantum yield measurements, a blank was run simultaneously in the dark to take into account the amount of isomerization which occurs thermally.

D. *Photostationary equilibrium*

The photostationary state equilibrium was determined for each couple of the *cis–trans* isomeric indigo derivatives. The irradiations were carried out with a 150-W Xenon lamp using an optical bench; the light beam was focused through a Pyrex lens and a diaphragm into a 1 cm × 1 cm Pyrex cuvette held firmly by a holder and containing the solution of the sample to be analyzed. A 400-nm cut-off filter was put between the lamp and the cuvette. Experiments were carried out at both 10°C and 22°C, starting from pure *cis* or *trans* isomers (10^{-4} *M* in chloroform) except for **4***c* where a 60% *cis*-rich mixture was used.

Degassed and undegassed solutions were used for comparison. Direct irradiations in the presence or in the absence of triplet inhibitors (oxygen-saturated solution, or perylene) as well as sensitized irradiations (benzophenone, anthracene, xanthone, thioxanthone) were performed for the sake of comparison, but aromatic ketones react rapidly with the indigo derivatives and form addition products (*vide infra*).

E. *Fluorescence quenching*

The quenching of the fluorescence of the indigo derivatives **1***t*, **2***t*, and **3***t* was carried out in acetonitrile solution at 20°C. The indigo derivative concentration was adjusted to about a 0.1 optical density at the excitation wavelength which was chosen at the maximum of the visible absorption band. The apparent rate constant K_{CT} for the quenching of the fluorescence by the electron donor was deduced from the slope of the Stern–Volmer plot. The process was repeated for all the electron-donor molecules. The quenching rate constant can be evaluated, as the lifetime of the singlet excited state was known (*vide supra*). The decimal logarithm of this constant is plotted vs. the free energy ΔG of the charge-transfer complex formation (Fig. 2).

F. *Electrochemistry*

Redox potentials were obtained by cyclic voltammetry using a P.A.R. model 173 potentiostat monitored by a P.A.R. model 175 programmer coupled to a TGM X-Y Sefram recorder. The electrochemical measurements were performed in acetonitrile solution using 0.1 *M* tetrabutylammonium perchlorate as supporting electrolyte. The reference electrode was a calomel electrode saturated with KCl and separated from the main solution by a bridge consisting of a glass tube closed by a medium-porosity glass frit and containing the supporting electrolyte. The working electrode was a platinum gauze and the counter electrode was a 1 cm × 1 cm platinum surface.

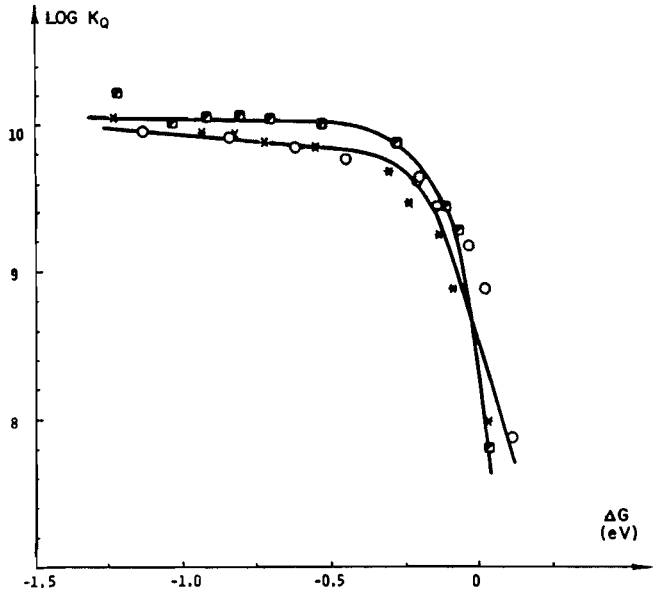

FIG. 2. Plot of the logarithm of the quenching rate constant versus ΔG for **1***t* (◪◪◪), **2***t* (○○○○○), and **3***t* (*****).

Results and discussion

A. *Excited state involved in the isomerization*

Knowledge of the excited state(s) from which the $t \rightarrow c$ and $c \rightarrow t$ isomerizations of the substituted indigos originate is of importance since it governs the thermodynamic data and the energy content of the process.

It is known that the isomerization of stilbenes results from a singlet excited state (10, 16) and that for thioindigo derivatives, molecules which are closely related to the series studied here, it depends on the geometry of the starting material with the *trans* isomer undergoing a photoisomerization via the triplet excited state (17–19), while the reverse photochemical reaction occurs from the singlet state (20, 21). When the $c \rightarrow t$ isomerization of thioindigo derivatives was studied in a toluene-containing solution, the isomerization quantum yield was found to vary with the temperature and to reach a maximum value (ca. 0.9) at 180 K; this effect could be rationalized (22) on the basis of the formation of an exciplex between the excited *cis*-indigos and toluene. The multiplicity of the excited state involved in the $t \rightarrow c$ isomerization has been questioned by Haucke and Paetzold (20) who found that oxygen quenches this process, but not completely (about 90%); such a quenching was already described by Kirsch and Wyman (17).

All the *trans N*-substituted indigo dyes **1***t*–**4***t* studied here fluoresce weakly at room temperature (Table 1) but do not phosphoresce. On the other hand, the *cis* isomers **1***c*–**4***c* show no emission at all, even at liquid nitrogen temperature; when a weak fluorescence was observed for a *cis* derivative, it had to be attributed to a trace of the corresponding *trans* isomer (the method described in the experimental part for preparing the *cis* isomers appears to be particularly well adapted for obtaining them in a pure form). Radiative lifetimes of the *trans* isomers are reasonable for singlet excited states (Table 1); if one com-

pares with the thioindigos, one would expect the latter to show a shorter singlet lifetime and a smaller fluorescence quantum yield than the corresponding indigo derivatives; simultaneously, the intersystem crossing efficiency should be larger due to the heavy atom effect from the sulphur atom. In fact, the intersystem crossing efficiency value is (19) reasonably high (0.42) for thioindigo, but its singlet lifetime (13.4 ns) and fluorescence efficiency (0.56) are both unexpectedly high (23) compared to the indigo derivatives and are not consistent with a heavy atom effect from sulphur in the thioindigo derivatives.

When the temperature is decreased from room temperature to 77 K, the fluorescence efficiency increases by a factor of 16, 110, and 140 respectively for compounds **1***t*, **2***t*, and **3***t* in butyronitrile solution. Under the same conditions, the singlet lifetime increases by factors of only 4.4, 5.4, and 7.1 respectively. Such a decrease in lifetime when the temperature increases is not uncommon and can be attributed to several processes which already have precedents in the literature. One is a hindrance to the rotation around the central double bond as a result of the increased viscosity of the medium; this is usually the case for *cis*–*trans* isomerization which involves a twisted intermediate state (24). Another, which has been reported already for a few rigid aromatic molecules (25), is a modification of the singlet to triplet intersystem crossing which is found to increase with the temperature; if this is effectively the case, both the *cis* to *trans* and *trans* to *cis* isomerizations could have a double singlet and triplet origin. A third process could be a net decrease of the rotation of the substituents linked to the nitrogen atom.

A similar increase, although less pronounced than the one found in liquid nitrogen, of the fluorescence quantum yields is observed at room temperature when the compounds are inserted in a poly(methyl methacrylate) matrix. The factor by which ϕ_f increases is now 2, 28, and 23 for **1***t*, **2***t*, and **3***t* respectively, by comparison with the values in glycerol triacetate (GTA) solution. More striking, just as at 77 K, is the absence of isomerization to the *cis* isomers after prolonged irradiation of the *trans* isomers in their absorption band. This can be interpreted in terms of a steric hindrance to the formation of the twisted intermediate by the rigid medium.

Different processes can contribute to the deactivation of the singlet excited state: fluorescence (rate constant k_f), intersystem crossing (k_{isc}), formation of a twisted intermediate (k_{tw}) by a 90° rotation of one moiety of the molecule around the central double bond, and rotation of the substituents on the nitrogen atoms (k_{rot}) as well as radiationless internal conversion (k_{nr}).

In a fluid liquid medium, all five processes are competitive. Inversion at the level of the nitrogen might occur also in the excited state although the N atom is expected to be planar in the ground state.[4] Argument for a change in the excited state is obtained with the Stokes shift of the fluorescence. This process, if it occurs, should be strongly restricted at 77 K (26). Its rate constant has been included in k_{rot}. In the polymeric matrix the twisted intermediate is no longer formed since no photoisomerization is then observed. At 77 K the rotation of the R—CO substituents becomes considerably hindered, as is the formation of the twisted intermediate; fluorescence, intersystem crossing, and radiationless internal conversion become the principal deactivation paths of the singlet excited state.

At room temperature, in fluid solution, the inverse of the singlet excited lifetime τ_s^{293} can be written as:

$$[1]\quad \frac{1}{\tau_s^{293}} = k_f + k_{isc} + k_{tw} + k_{nr} + k_{rot}$$

In the polymeric matrix the twisting around the central double bond of the two bulky moieties is considerably restricted as no *trans* to *cis* isomerization occurs under irradiation. Since this observation is made at room temperature, the rotation of the acyl groups around the N—C single bond must still take place.

The lifetime τ_s^{PMMA} of the singlet excited state of the *trans* indigo dyes **1***t*–**3***t* in PMMA can be expressed, then, by the relation [2]:

$$[2]\quad \frac{1}{\tau_s^{PMMA}} = k_f + k_{isc} + k_{rot} + k_{nr}$$

At liquid nitrogen temperature, one would expect the rotation around the N—C single bond to be strongly hindered; the quantum yield of the other processes would consequently increase, since the rate constants of the intrinsic deactivation processes are not expected to vary appreciably. If one considers

[4]We thank one of the referees for pointing out the planarity of the nitrogen atom in the ground state.

the lifetime of the singlet excited state to be subordinated mainly to k_f, k_{nr}, and k_{isc}, the knowledge of k_f and that of τ_s^{77} (relation [3]) can give ($k_{nr} + k_{isc}$) and, consequently, the upper limit of

$$[3] \quad \frac{1}{\tau_s^{77}} \simeq k_f + k_{isc} + k_{nr}$$

the singlet to triplet intersystem crossing quantum yield, if no radiationless transition occurs.

Thus, measurement of the fluorescence quantum yield and singlet lifetime under the different conditions can give a reasonable idea of the various deactivation process rate constants. These are listed in Table 2.

In the case of *trans*-thioindigo, different mechanisms have been postulated for the rotation process; in the first one, the isomerization occurs from the singlet excited state through the twisted state which subsequently can undergo the intersystem crossing to the triplet excited state (20); in the second one, the planar singlet excited state crosses over to the triplet excited state which then undergoes the internal rotation to the twisted form (27).

If a triplet excited state has to be involved in the isomerization of the indigo derivatives **1***t*−**3***t*, this process could be both sensitized and inhibited. The isomerization of thioindigos has been claimed to be sensitized by tin(IV) tetraphenylporphyrin (E_T = 36.1 kcal/mol) in benzene or toluene solution, and argument has been taken from this to postulate a double singlet and triplet origin to the isomerization (28); it has been verified also that the ratio of the *cis* to *trans* isomers is different in the sensitized reaction compared to its value for direct irradiation.

Sensitizing the isomerization of **1***t*−**3***t* has been tried, using tetraphenylporphine (TPP) as sensitizer. Unfortunately, no triplet sensitization could be characterized, but rather a very efficient quenching of the fluorescence of TPP by the *N*,*N*′-disubstituted indigos has been observed; the rate constant for the quenching process is found to be of the same order as that of the diffusion. As will be discussed later, an electron-transfer mechanism has been put forward for this process.

Inhibition of the *trans* to *cis* isomerization of **1***t*−**3***t* by oxygen failed, the quantum yield for the isomerization process being the same whether oxygen is present or absent.

Thus, unlike the thioindigo derivatives for which the *trans* to *cis* isomerization could be partly quenched by oxygen (20), compounds **1***t*−**3***t* apparently isomerize solely from the singlet excited state.

Similarly, no quenching of the isomerization occurs when perylene (E_T = 36 kcal/mol) or anthracene (E_T = 42 kcal/mol) are used as triplet quenchers in degassed toluene solution, the irradiation ($\lambda > 450$ nm) being carried out at the temperature of +10°C.

That the singlet excited state is the only one involved in the *trans* to *cis* photoisomerizations has been verified by additional experiments: (*i*) the photostationary state between the two isomers is the same, whether the solution is degassed or enriched with oxygen; this holds as long as the excitation wavelength is higher than 400 nm; (*ii*) attempts to sensitize the *trans* to *cis* isomerization by perylene (E_T = 36 kcal/mol) in degassed toluene solution with monochromatic light at 435 nm were unsuccessful; under such conditions the sensitizer absorbs more than 97% of the light, but after 2 h irradiation, only 4% of the *trans* isomer had disappeared; (*iii*) the same failure was experienced when sensitization by anthracene (E_T = 42 kcal/mol) was carried out under 360-nm irradiation.

However, a weak isomerization, resulting from direct ab-

sorption (ca. 3% of the light) by the indigo derivatives could not be excluded in the last two cases. In the presence of *N*,*N*-diethylaniline, the photoisomerization of compounds **1***t* and **2***t* was totally inhibited; no singlet or triplet energy transfer from the indigo derivatives ($E_s \sim 49$ kcal/mol) to *N*,*N*-diethylaniline ($E_s \sim 95$ kcal/mol; $E_T \sim 73$ kcal/mol) could be involved in this deactivation process, as the energies of the excited states do not match each other.

This effect could be attributed to an electron donor–acceptor interaction between the two species, since the oxidation potential of diethylaniline is +0.76 V vs. SCE. That there is effectively such an effect is supported by the fact that the irradiation ($\lambda > 500$ nm) of a (**1***t* + **1***c*) or (**2***t* + **2***c*) mixture reduces rapidly the percentage of the *cis* isomer in the mixture.

No characterization of the triplet of the *trans* isomers could be obtained, even by laser flash photolysis using a ruby laser, although the *T*–*T* absorption spectra of **1***t* has already been found (27). Indeed, as we have discussed above on the basis of the kinetics, intersystem crossing to the triplet state should apparently occur,[5] the most striking result that we found being the absence of quenching or sensitization of this excited state.

That an electron transfer reaction occurs in most cases is evidenced in the subsequent discussion.

B. *Electron-acceptor behaviour*

As has been discussed above, no quenching of the triplet excited state of the *trans* indigo derivatives **1***t*–**3***t* could be characterized, in contrast to thioindigo derivatives which show triplet quenching by oxygen (17, 20) as well as triplet sensitization by tin(IV) tetraphenylporphyrin (28).

Thioindigo derivatives have been found to interact with hydroxyl compounds such as phenols (29) and alcohols (30); they have been reported also to behave like electron acceptors (22) in donor–acceptor interactions. This prompted us to investigate the effect of electron donors on the excited state of the indigo derivatives **1***t*, **2***t*, and **3***t*.

The voltamogram curves of these *trans* isomers show two distinct reversible reduction waves (at −0.58 V and −1.18 V vs. SCE for **2***t*) and an oxidation wave (at +0.64 V vs. SCE for **2***t*) in acetonitrile solution. This oxidation wave, 1.22 V above the first reduction wave, lies below the reduction potential of the corresponding excited states. Consequently, a serious effect on the photochemical behaviour of the indigo derivatives might be expected.

The reduction potentials of the ground (E_{red}) and singlet (E^*_{red}) excited states of an acceptor molecule can be related to each other by relation [4]:

$$[4] \quad E^*_{red}(A^*/A^{\cdot-}) = E_{red}(A/A^{\cdot-}) + E_s$$

where E_s is the energy of the singlet excited state. This relation neglects the work functions of ion-pair and encounter-complex formation.

For compounds **1***t*–**3***t*, E_s is about 2.1 eV, as deduced from the fluorescence emission. Irradiation of an acetonitrile solution of the *trans* indigo derivatives, in the long-wavelength absorption band, yields the lowest excited state which fluoresces weakly. Addition of an electron-donor molecule to the solution yields an encounter complex which can revert to the ground-state starting molecules or form a charge-transfer complex. The electron transfer can be viewed as irreversible at the very early stage, since then the reverse reactions are negligible (31). Usually, quenching of the lowest singlet excited state by an electron donor–acceptor exchange process forms no detectable separate ions, in contrast to the ion pairs arising from the triplet state, thus showing an expected spin selection rule (32).

The absorption spectra of mixtures of the indigo derivatives with the electron-donor molecules proved to be additive with respect to the acceptor and quencher component spectra. Furthermore, the weak fluorescence and fluorescence excitation spectra of **1***t*–**3***t* show no change in the presence of the quencher but only a decrease of the emission intensity. This process, which increases with the concentration of the electron donor, gives a linear Stern–Volmer plot according to relation [5]:

$$[5] \quad \phi^0_f/\phi_f = 1 + K_q\tau_s[\text{quencher}]$$

If the quenching process occurs from an electron acceptor–donor exchange, as is the case for the thioindigo derivatives (22), then the rate constant K_q should vary with the oxidation potential of the donor E^{ox}_D. According to the pioneering work of Leonhard and Weller (33), the rate constant K_q for the fluorescence quenching process should increase with decreasing E^{ox}_D of the donor, until a plateau is reached when K_q is equal to the diffusion rate constant of the solvent (34, 35).

The oxidation potentials of the electron donors used as quenchers lie between 0.35 and 1.60 V versus the saturated calomel electrode. No quenching by toluene ($E^{ox}_D = 1.97$ V) has been observed, in contrast to the thioindigo compounds (22), the reduction potentials (−0.5 V) of which are slightly less negative than that of the indigo derivatives (−0.58 V).

The quenching of the fluorescence of compounds **1***t*–**3***t* in acetonitrile solution gives a linear Stern–Volmer plot for all the series of electron donors used as quencher. Since the lifetime of the singlet excited state of the *trans* derivatives has been measured directly by fluorescence decay after excitation by a frequency-doubled YAG laser, it was possible to calculate the quenching rate constant from the slope of the linear plot. The decimal logarithms of the values thus obtained are reported in Table 3.

No new luminescence has been detected, in different solvents, which could be attributed to an exciplex or a charge-transfer complex emission. Consequently, it must be ensured that the standard free energy change ΔG^0 of the exciplex formation varies with the oxidation potential of the electron donor.

The energy of the charge-transfer complex E_e in solution is related to the energy of the pure charge-transfer complex E^0_e in the gaseous phase by a relationship which includes the solvation enthalpy of the complex. This involves several factors including the radius ρ of the solvent spherical cavity occupied by the complex in the Kirkwood and Onsager model. By taking ρ = 9 Å for the cavity radius, as deduced from molecular volume calculations (36), and by assuming that the distance between the electron donor and electron acceptor in the complex is 5 Å, one obtains the value 0.35 for the solvation term in acetonitrile solution. This leads to expression [6] for the variation of the free energy change ΔG:

$$[6] \quad \Delta G = E^{ox}_D - E^{red}_A - E_s \ (\pm 0.10 \text{ eV})$$

The rate constant K_q for the charge-transfer complex formation is correlated to ΔG by an expression of the type

$$[7] \quad K_q = A \exp(-\Delta G^{\neq}/RT)$$

[5] Further studies for characterizing the triplet excited state of **1**–**3** are in progress.

TABLE 3. Values of the oxidation potential of the electron-donor molecule, of the reduction potential of the electron-accepting indigo derivatives **1***t*, **2***t*, and **3***t*, and of the logarithm of the quenching rate constant log k_q for the different values of the free energy change ΔG of the charge-transfer complex formation

which assumes that the electron-transfer process occurs according to an outer-sphere mechanism, $\Delta G^{\neq}$ being the standard free activation energy. Since ΔG can be measured for a thermodynamically reversible electron-transfer reaction, and as $\Delta G^{\neq}$ can be expressed, in principle, as a function of ΔG, the quenching rate constant will vary only with ΔG. Thus, plotting log K_q versus ΔG yields a curve which increases as ΔG decreases and which should reach a maximum value equal to the diffusion-controlled rate constant $2.7 \times 10^{10}\ M^{-1}\ s^{-1}$ in acetonitrile solution (37) whatever ΔG may be. The variation of log K_q versus ΔG is depicted in Fig. 2.

The results obtained by this method agree with an electron-transfer mechanism in which the excited singlet state of the *trans* indigo derivatives behaves like an electron acceptor.

Porphyrins are known to be good electron donors in EDA complex formation, their oxidation potential (versus SCE) being of the order of 1 V (38*a*, as quoted in ref. 38*b*). Thus, in benzene solution, the fluorescence of tetraphenylporphine has been found to be quenched by the *trans* indigo derivatives **1***t* and **2***t* with a rate constant ($6 \times 10^9\ M^{-1}\ s^{-1}$) close to that for diffusion ($1.5 \times 10^{10}\ M^{-1}\ s^{-1}$ for benzene), while with the parachlorobenzoyl derivative **3***t* this rate constant is $1.8 \times 10^{10}\ M^{-1}\ s^{-1}$. By analogy with this result and in accord with the recently reported electron-acceptor behaviour of thioindigos (22), one should consider the possibility that isomerization of thioindigos in the presence of tin tetraphenylporphyrin (28) is the result of an electron transfer mechanism rather than a triplet−triplet energy transfer.

C. *Photostationary state*

The photostationary equilibrium has been determined in chloroform solution at 10° and 20°C. Due to the tendency of the *cis* isomers to revert thermally to the corresponding *trans* isomer, better results are obtained at 10°C. A Corning 3-74 glass filter was placed between the 150-W Xenon lamp and the cuvette containing the sample in order to eliminate the λ < 400 nm uv light. The photostationary state was reached starting from both the pure *cis* and pure *trans* isomers; the evolution of the *trans*/*cis* ratio is shown in Fig. 3 and the values at the steady state are tabulated in Table 2. In each case, the same equilibrium is obtained whether or not the solution is flushed through with argon for 15 min prior to the experiment.

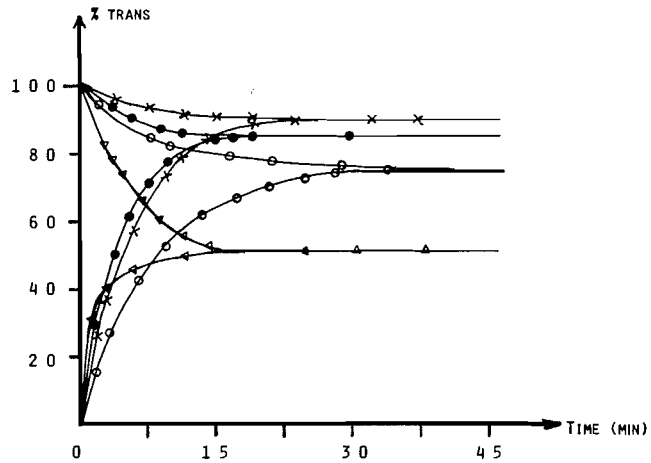

FIG. 3. Photostationary state composition versus time, obtained by irradiation of the indigo derivatives **1** (ΔΔΔΔ), **2** (○○○○), **3** (●●●●), and **4** (××××) with visible light (λ > 400 nm).

No change in the *trans*/*cis* ratio was observed when the well-degassed photostationary equilibrium was irradiated with visible light (λ > 400 nm) in the presence of anthracene or with λ > 440 nm in the presence of perylene. Under these conditions neither anthracene nor perylene absorbs light. Consequently, there seems to be no triplet quenching by *T*−*T* energy transfer from the excited indigo dyes to anthracene or perylene. We have indicated already that no sensitization could be observed using either tetraphenylporphine, anthracene, or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

perylene.

As indicated in Table 1, the photostationary state is always in favor of the *trans* isomer when the irradiation is carried out with polychromatic light of wavelength > 400 nm. The *N,N'*-diacetyl derivative **1** is the only compound for which the *cis* isomer is present in equal quantity with the *trans* one at the steady state under these conditions.

When the irradiation is extended in order to include the uv region, a slow disappearance of the dyes is observed. If, in addition, the irradiation is carried out in toluene solution, then a very rapid bleaching of the dye is observed; thus irradiation, using exclusively the 330−380 nm region (Corning band-pass 7-37), causes a degassed 6×10^{-5} *M* toluene solution of **2***t* to fade in less than 1 h while, under the same conditions but in acetonitrile solution, 25% of **2***t* is transformed into **2***c*. A rapid bleaching is observed also when irradiating a deaerated acetone solution (Merck, spectroscopic quality) of **2***t* at 254 nm.

Formation of a charge-transfer complex between the excited dye and toluene can hardly be put forward as an explanation for this bleaching since the same solution gives the normal *trans*−*cis* isomerization when the excitation wavelength is limited to the long-wavelength absorption band of the dye, or if the irradiation is carried out in benzene solution instead of toluene. We believe that the indigo dye, in its second excited singlet state S_2, abstracts a hydrogen atom from the solvent and adds subsequently to the formed $C_6H_5CH_2$· radical. At this stage, a more efficient intersystem crossing to the triplet state from S_2 cannot be excluded completely, but we have observed no phosphorescence of the compounds when excited at 77 K with 360-nm light.

Bleaching of the indigo dyes was also observed during the attempts at sensitization by xanthone, thioxanthone, or benzophenone in toluene solution using the Corning 7-37 band-pass filter (360 nm).

If a trace of tertiary amine, such as *N,N*-diethylaniline (E_D^{ox} = +0.76 V), is added to the photostationary equilibrium between the two isomers, the *cis* reverts rapidly to the *trans*; in the same way, the *trans* derivatives do not isomerize to their corresponding *cis* derivatives when irradiated at their long-wavelength maximum in the presence of a tertiary amine. If this is relevant to an intermediate charge-transfer complex formation, the oxidation potential of the donor must be critical since neither TPP (E_D^{ox} = +0.97 V) nor perylene (+0.85 V) are effective under the same conditions.

D. *Energy storage feasibility*

As already mentioned, the *trans* → *cis* photoisomerization of *N,N'*-disubstituted indigo derivatives has been proposed as a potential system for solar energy conversion and storage (11). The practical efficiency of the process has been discussed also (39). It appears that one of the disadvantages of the system overcomes its advantages, the main drawback being the low amount of the stored energy: 34 kJ mol^{-1} for *N,N'*-diacetyl indigo **1**, and from 14 to 24 kJ mol^{-1} for various *N,N'*-dibenzoyl derivatives (11, 39). Increasing the bulk of the *N*-substituent does not increase the energy difference (and so the stored energy) between the *cis* and the *trans* isomers: ΔH = 13.4 kJ mol^{-1} for *N,N'*-dibenzoyl derivatives and 8 kJ mol^{-1} for *N,N'*-di-(1-naphthoyl) derivatives. *N,N'*-diacetylindigo is also the more suitable compound for the stored energy content per gram of compound: 100 J g^{-1}, but only 29 J g^{-1} for compound **2**. The amount stored in this way corresponds at the most to an increase by 25° of the temperature of 1 g of water.

In solution, the *cis* isomers exhibit a low kinetic stability since the activation free energy is about 100 kJ mol^{-1} (14); for instance, the lifetime of **1***c* in benzene solution and at 42.5°C is 0.55 h if we assume a first-order kinetics; this kinetic stability increases slightly from **1***c* to **2***c*, the relative isomerization rate being 7.9:1. This observation implies that the *cis*-rich solution should be stored or handled at low temperature, and the ir part of the solar spectrum eliminated during the irradiation process.

In addition to these unfavourable thermodynamic and kinetic data, the photochemical results do not look much better. Our results show that the isomerization quantum yields $\phi_{t\rightarrow c}$ are rather low, although no by-product can be detected when irradiating with $\lambda > 400$ nm. As mentioned already, decomposition occurs slowly if the irradiation is carried out with an irradiation light which includes the uv part. Also, it has been demonstrated that minute amounts of amines or alcohols quench the *trans* to *cis* photoisomerization and catalyze the reverse reaction. Consequently, this point implies high purity and expensive solvents which forbid the proposed energy extraction process (11*b*).

Catalysis by the amines, which speeds up the $c \rightarrow t$ reaction, allows one to gather the stored energy in a reasonable time but prevents any recycling of the system. And, finally, it should be recognized that at best the photostationary state is 1:1 (in the case of **1**) when exciting with visible light, so that, in order to get *cis*-rich mixtures, one has to use filtered light ($\lambda >$ 580 nm), and this results in long and inconvenient irradiation times.

Thus, although the indigo dyes show interesting photochemical behaviour, and are claimed as ranking among the best photochemical energy storage systems, we believe from our study that, even ignoring their cost, they show little promise as a convenient system.

Received April 2, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

OTTORINO DE LUCCHI, VITTORIO LUCCHINI, MORENO ZAMAI, GIORGIO MODENA, and GIOVANNI VALLE. Can. J. Chem. **62**, 2487 (1984).

The cycloaddition of (*E*)-1,2-bis(benzenesulfonyl)ethylene (**2**) to 2-acetoxy- and 2-silyloxy-1,3-cyclodienes occurs in high yields and with high steroselectivity. Structure assignment has been based largely on ^{1}H nmr nuclear Overhauser effect (nOe) experiments on the isolated products. The cycloadducts **4***a* and **4***b* derived from the 2-oxa substituted cyclopentadienes have been further elaborated to the parent norbornenone, to the respective unsaturated sulfones **5**, and to the β-hydroxy substituted sulfone **6**. The vinyl sulfones **5** have also been independently synthesized via cycloaddition of benzenesulfonyl acetylene. The sulfones obtained are potentially important starting molecules for the preparation of more complex targets.

OTTORINO DE LUCCHI, VITTORIO LUCCHINI, MORENO ZAMAI, GIORGIO MODENA et GIOVANNI VALLE. Can. J. Chem. **62**, 2487 (1984).

La cycloaddition du (*E*)-bis(benzènesulfonyl)-1,2-éthylène (**2**) sur les acétoxy-2 et silyloxy-2 cyclodiènes-1,3 se produit avec des rendements élevés et avec une stéréosélectivité élevée. La détermination des structures repose principalement sur des expériences d'effet Overhauser nucléaire (eOn) et rmn du ^{1}H qui ont été réalisées sur les produits isolés. De plus, une filiation a pu être établi entre les cycloadduits **4***a* et **4***b*, obtenus à partir des oxa-2 cyclopentadiènes, et la norbornénone apparentée ainsi qu'avec la sulfone insaturée **5** et la β-hydroxysulfone **6**. Faisant appel à une cycloaddition du benzènesulfonylacétylène, on a également synthétisé les vinylsulfones **5** d'une façon indépendante. Les sulfones obtenues peuvent éventuellement être d'importantes molécules de départ dans la synthèse de composés plus complexes.

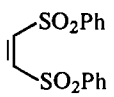
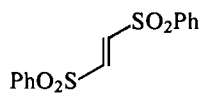
We have recently reported on the high dienophilic reactivity of (*Z*)- and (*E*)-1,2-bis(benzenesulfonyl)ethylenes **1** (1) and **2** (2) towards cyclic 1,3-dienes and on the reductive elimination of the two sulfonyl groups from the adducts with the formation of the corresponding carbon–carbon single (3) or double (1, 2) bond, depending upon the reaction conditions.



1



2

Lately we became interested in utilizing these reagents for the synthesis of polycyclic ketones in order to exploit fully their synthetic potential. Preparation of polycyclic saturated and especially unsaturated ketones has in fact remarkable importance because of their verstatility as building blocks for the preparation of complex natural products (4) and especially of prostaglandins (5).

As represented in Scheme 1, two possible approaches to bicyclic unsaturated ketones of type **3** are practicable. Path (a) entails the reaction of a ketene equivalent (as ketenes usually undergo [2+2]-cycloadditions) with a 1,3-diene, while path (b) takes advantage of the easy hydrolysis of the products derived by the acetylene equivalent cycloaddition to 2-oxa substituted 1,3-dienes. While there are a number of reagents capable of performing path (a) (6), and even **1** and **2** have been shown to be potential ketene equivalents (3), maleic anhydride is so far the only acetylene equivalent that can realize path (b), as shown by Yates and co-workers (7) as well as by others (8).

Herewith we report on the use of (*E*)-1,2-bis(benzenesulfonyl)ethylene (**2**) for the synthesis of bicyclic unsaturated ketones of type **3** through path (b), with a procedure that entails reductive processes, as an alternative to the strong oxidative conditions necessary with the use of maleic anhydride. The isomeric dienophile **1** behaves similarly, but in the present study **2** was preferred for its greater reactivity.

The cycloaddition of a *trans* dienophile to an asymmetric diene necessarily leads to a mixture of isomers of type **4**; they have been obtained in variable ratios and their structure determined by nuclear Overhauser effect (nOe) experiments.

Finally, in view of the growing interest in sulfones as building blocks of complex molecules (9), we provide access to vinyl sulfones of type **5** and to the β-hydroxy sulfone **6**, which are polyfunctionalized molecules amenable to a variety of more complex transformations.

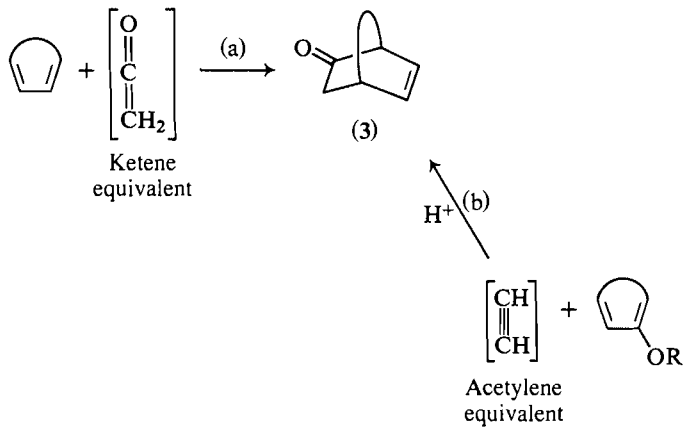


SCHEME 1

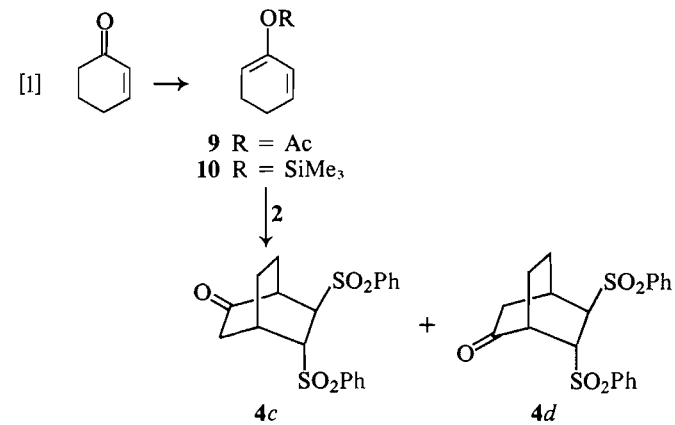
Results

Ketones **4***a* and **4***b* are obtained via cycloaddition of (*E*)-1,2-bis(benzenesulfonyl)ethylene (**2**) to *in situ* generated 2-acetoxycyclopentadiene (**7**) or 2-silyloxycyclopentadiene (**8**) (routes (a) and (b) in Chart 1). Route (a) is performed by refluxing an isopropenyl acetate solution of 2-cyclopentenone and **2** with catalytic amounts of *p*-toluenesulfonic acid for 2 h (8). After silica gel low pressure chromatography, adducts **4***a* and **4***b* are obtained in ca. 50 and 20% yields respectively. Alternatively (route (b)), the cycloaddition of **2** to 2-silyloxycyclopentadiene, generated *in situ* from 2-cyclopentenone and trimethylsilyl chloride with zinc chloride in triethylamine (10), furnishes a 9:1 mixture of adducts **4***a* and **4***b* in ca. 90% yield with respect to the dienophile. Similarly as above, the resulting isomeric adducts can be separated by silica gel column chromatography. The generation of **8** by other different procedures as, for example, with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) (11), is less efficient, and also the isolation of **8** upon quenching of the 2-cyclopentenone anion with trimethylsilyl chloride (12) prior to cycloaddition gives poorer results.

No attempts were undertaken for the isolation of the intermediate enol-acetate adducts derived from route (a) or the silyl enol-ethers from route (b).

Beside the correct C,H composition by combustion analysis, the ^1H, ^{13}C nmr, ir spectral data, and especially nOe experiments were essential for the structure elucidation and for the determination of their relative stereochemistry (see below).

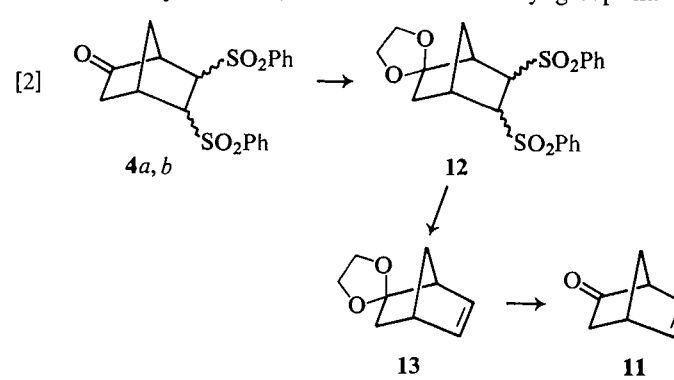
The same set of reactions of Chart 1 can be accomplished with 2-cyclohexenone with some differences in the product distribution. The isopropenyl acetate route leads with 2-cyclohexenone mainly to products derived from the cycloaddition of **2** to the thermodynamically more stable isomer 1-acetoxy-1,3-cyclohexadiene, while products of type **4***c* and **4***d* derived from cycloaddition to 2-acetoxy-1,3-cyclohexadiene (**9**) are obtained only in low yields. The cycloaddition of **2** to the more reactive 2-trimethylsilyloxy-1,3-cyclohexadiene (**10**) (13) (eq. [1]) affords adduct **4***c* almost exclusively. The isomeric **4***d* is produced in such a small quantity that it could not be isolated from runs carried out with ca. 1.5 mmol of dienophile.



In contrast to the 2-cyclopentenone case, the *in situ* generation of **10** is of little convenience for the preparation of **4***c*, and good results are obtained only when pure **10** is reacted.

The structures of **4***c* and **4***d* have been determined by C,H composition and by spectral data. The relative stereochemistry has been assigned on the basis of nOe experiments.

The isomeric adducts **4***a* and **4***b* from cyclopentenone have been transformed into 5-norbornen-2-one (**11**) with the set of reactions shown in eq. [2]. After protection of the ketone function as the ethylene ketal, the two benzenesulfonyl groups have



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

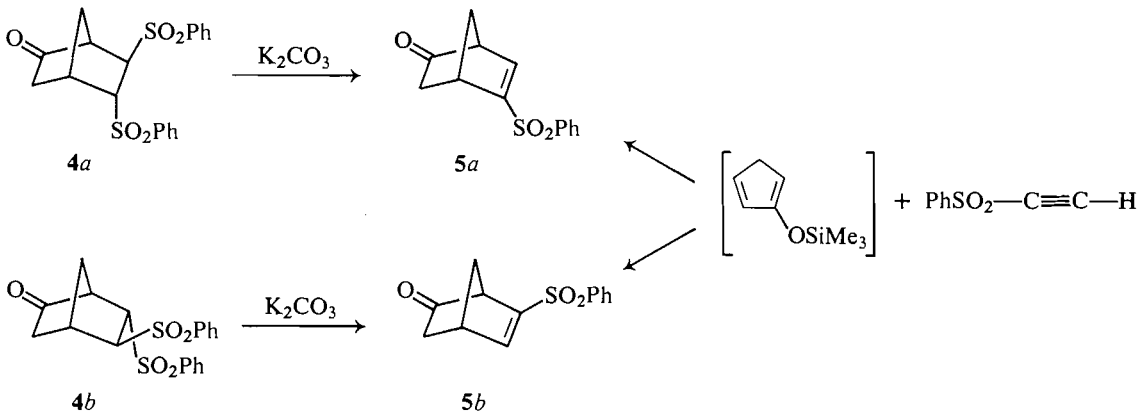

CHART 2

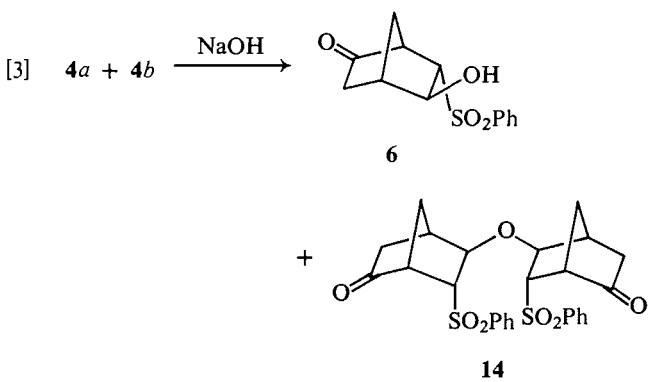
been efficiently removed with the recently reported method of sodium amalgam in buffered methanol (1), to give protected norbornenone (**13**) in 94% overall yield. Acidic deprotection furnishes **11**, whose structure has been confirmed by independent synthesis (14).

A mixture of **4***a* and **4***b* treated with potassium carbonate in aqueous dioxane gives a mixture of isomeric vinyl sulfones **5** in a ratio comparable to that of the starting adducts. This fact suggested that the reaction is stereo- and regiospecific in each isomer. Consequently **4***a* and **4***b* were independently reacted with potassium carbonate and transformed into the isomeric vinyl sulfones **5***a* and **5***b* respectively as single products (Chart 2). A mixture of the same vinyl sulfones **5***a* and **5***b* in a ratio of ca. 8:2 was also obtained via addition of benzensulfonylacetylene to the *in situ* generated 2-trimethylsilyloxycyclopentadiene, thus confirming by chemical means the structure of the products.

The individual structure assignment has been made on the basis of ^{1}H nmr spectral data. In fact, in both isomers the bridgehead proton 4, which couples with four methylenic protons,is readily distinguishable from the other bridgehead proton in 1, which couples only with two methylenic protons. In the isomer **5***a*, proton 1 shows a further coupling (confirmed by decoupling experiments) with the vinylic proton, which is not observed in the case of isomer **5***b*.

The reaction of adducts **4***a* and **4***b* with sodium hydroxide is remarkably different. On treatment of a mixture of **4***a* and **4***b* in dioxane with a ca. 0.5 *N* sodium hydroxide solution, a mixture of β-hydroxyalcohol **6** and ether **14** is obtained in ca. 50% yield.



The two products have been separated through low pressure column chromatography and identified by elemental analysis and spectral data. The stereochemistry of the functional groups in **6** has been determined by nOe experiments. The relative position of the alcoholic and sulfonyl functionalities with respect to the carbonyl one was confirmed with an X-ray structure determination.

Treatment of pure adduct **4***a* with sodium hydroxide gives, in low yields (ca. 10%), alcohol **6** plus lower yields of unidentified products. In contrast, adduct **4***b* furnishes upon the same treatment both **6** and **14** in 40 and 10% yield respectively. A mixture of **6** and **14** is also obtained in comparable yields via hydroxide ion reaction with vinyl sulfone **5***b*, but only low yields of unidentified products are obtained from **5***a* under the same conditions. Work is in progress to gain a better understanding of this reaction.

Determination of the absolute configurations by the nOe technique

Isomers **4**a *and* **4**b

In these isomers the two *endo* protons are either in the 1,3 or in the 1,4 reciprocal position, so that the measurement of the nOe enhancements between them should allow the assignment of the absolute stereochemistry. To this aim, the resonances of the 3-*endo* proton and of the *endo* proton α to the sulfonyl group should be predetermined.

The ^{1}H nmr spectra are given in Figs. 1 and 2, while the nOe enhancements induced by individual saturation of all the alkyl resonances are reported in Tables 1 and 2.

In both spectra, the two multiplets at low field are to be attributed to the α-sulfonyl protons. Other safe assignments are those of the methylenic protons at the 7 position (isomer **4**: multiplets at δ 2.48 and 1.87; isomer **4***b*: multiplets at δ 2.47 and 1.76) and of the methylenic protons at the 3 position (separated multiplets for the isomer **4***a*, resonating at δ 3.09 and 2.18; almost coincident resonances at δ 2.27 for the isomer **4***b*).

In the case of **4***a*, the saturation of the low field α-sulfonyl resonance at δ 4.36 brings about positive and negative enhancements of the multiplets at δ 2.48 and 1.87, which are therefore attributed to protons 7′ and 7 in that order, while the α-sulfonyl proton is *exo* oriented.

Analogously, in the isomer **4***b* the resonance at δ 4.19 belongs to the *exo* α-sulfonyl proton since its saturation causes positive and negative nOe enhancements of the multiplets at δ 2.47 and 1.76 (respectively 7′ and 7 protons). These attributions are confirmed, for both isomers, by the reverse nOe experiments.

The other α-sulfonyl proton is necessarily *endo* and resonates in the isomer **4***a* at δ 3.78. Its saturation allows us to

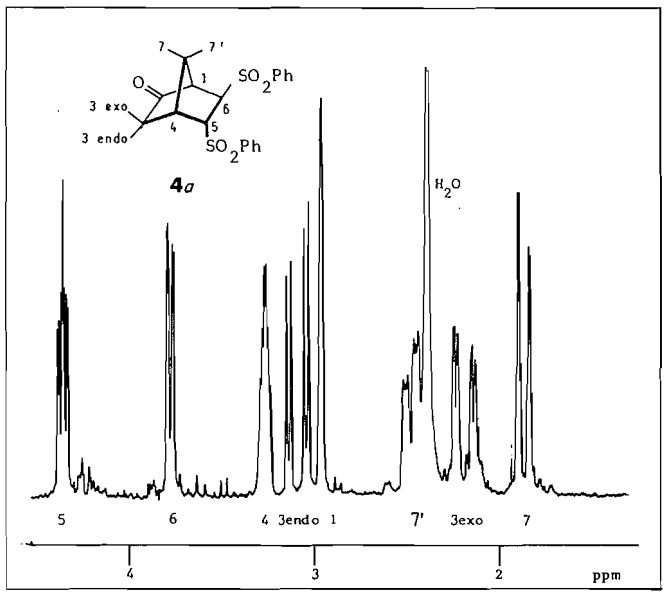

FIG. 1. 200-MHz ^{1}H nmr spectrum of the aliphatic region of cycloadduct **4***a*.

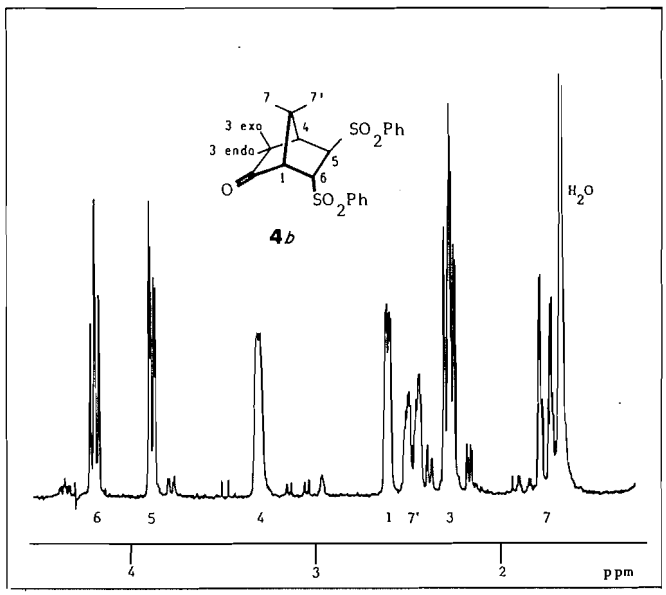

FIG. 2. 200-MHz ^{1}H nmr spectrum of the aliphatic region of cycloadduct **4***b*.

individuate the 3-*endo* resonance at δ 3.09. The nOe enhancement is small (1.4%), because of the relatively efficient relaxation induced by the nearby 3-*exo* proton. The reverse experiment gives a more significant 4.3% enhancement of the *endo* α-sulfonyl proton.

This result is to be compared with the outcome of the similar experiment carried out on the isomer **4***b*. The irradiation of the multiplet at δ 2.27 induces the contemporary saturation of both 3-*exo* and 3-*endo* protons; the result is a 13.4% enhancement of the *endo* α-sulfonyl proton resonating at δ 3.88. It is evident from this comparison that the 3 and α-sulfonyl protons with *endo* orientation are in the 1,4 position in isomer **4***a* and in the 1,3 position in isomer **4***b*.

Isomers **4**c *and* **4**d

The ^{1}H nmr spectra and the results of nOe experiments are reported in Fig. 3 and Table 3 for isomer **4***c* and in Fig. 4 and Table 4 for isomer **4***d*. The criterion for the structure assignment is, also for this pair of isomers, the measurement of the nOe enhancements between the two *endo* protons.

From the onset, only the α-sulfonyl protons can be safely attributed to the two low field multiplets (isomer **4***c*: δ 4.09 and 4.03; isomer **4***d*: δ 4.09 and 3.96). The protons in position 3 are easily identifiable, in the case of **4***c*, with the relatively isolated doublets at δ 3.11 and 2.26. The assignment is less certain for the other isomer **4***d*, where the methylenic 3 protons resonate around δ 2.5, together with one bridgehead and one ethano resonance.

It is therefore relatively easy, in the case of the first isomer **4***c*, to establish that the 3-*exo* proton is that at δ 2.26, since its saturation causes a small but significant 1.2% enhancement of the ethano resonance at δ 1.87 (proton 8); the saturation of this two-proton resonance causes positive and negative enhancements of the 3-*exo* and 3-*endo* resonances respectively, because of the obtuse angle between the 3-*exo*, 3-*endo*, and 8 protons. From the saturation of the 3-*endo* resonance at δ 3.11 follows a rather small (1.6%) enhancement of the α-sulfonyl proton resonating at δ 4.09 (therefore in the *endo* orientation). The modesty of this value suggests that the relative position of the *endo* protons is 1,4 and that the structure of the isomer is that reported in formula **4***c*.

TABLE 1. Nuclear Overhauser effect enhancements of compound **4***a*

	Observed

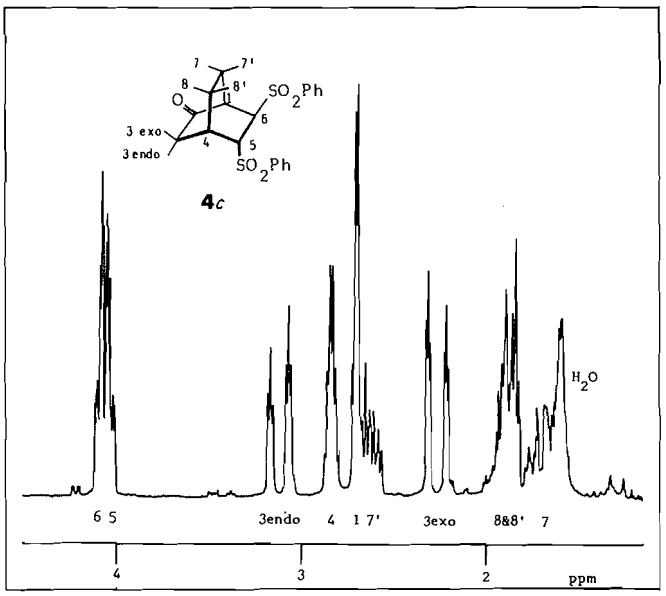

FIG. 3. 200-MHz ^{1}H nmr spectrum of the aliphatic region of cycloadduct **4***c*.

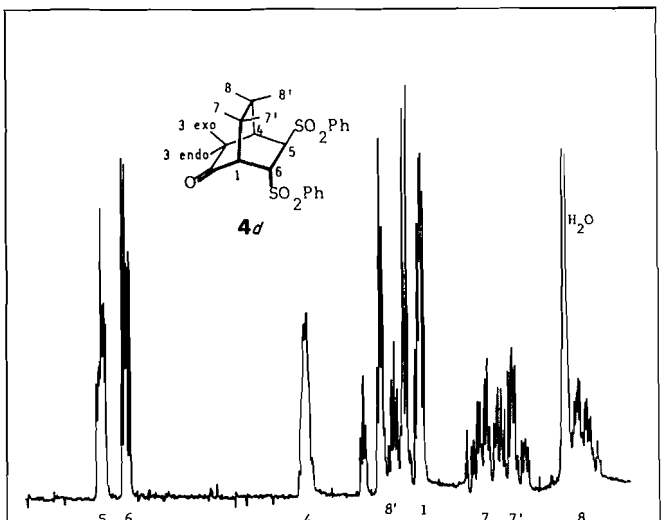

FIG. 4. 200-MHz ^{1}H nmr spectrum of the aliphatic region of cycloadduct **4***d*.

Regarding the isomer **4***d*, it is more convenient to determine firstly the orientation of the α-sulfonyl protons, since protons 3 resonate in a crowded region. The saturation of the high field part of the two-proton ethano resonance at δ 1.9 induces a nOe enhancement of the α-sulfonyl proton resonating at δ 3.96, which is therefore in the *exo* orientation. The perturbation of the other α-sulfonyl proton at δ 4.09 (necessarily *endo*) allows the identification of the 3-*endo* resonance at δ 2.61. The enhancement is a modest 3.3% (because of efficient relaxation induced by the geminal proton), while the reverse experiment brings about a 9.8% enhancement of the *endo* α-sulfonyl resonance. This value is indicative of a 1,3 relative position of the *endo* protons and a proof for the structure of the isomer as reported in formula **4***d*.

*Adducts **6** and **14***

The ^{1}H nmr spectra for alcohol **6** and ether **14** (reported in Figs. 5 and 6 respectively) are very similar, as are the results of nOe experiments (Table 5 and 6), except for one significant point to be dealt with later.

In both spectra the methylenic 3 protons resonate at the same frequency (**6**: δ 2.19; **14**: δ 2.24); furthermore, in the alcohol **6** the resonance of one methylenic 7 proton overlaps with that of proton 3. All that makes the discussion of nOe results rather difficult. It is, however, possible to assign, by saturation of the *ortho* protons in the phenyl ring, the α-sulfonyl proton to the resonance at δ 3.44 (alcohol **6**) or 3.61 (ether **14**).

Regarding the alcohol **6**, the saturation of the high field 7 methylenic doublet at δ 1.77 has the effect of a 0.7% negative enhancement of the α-sulfonyl proton resonance, so that this latter is almost collinear with the 7 methylenic protons, and *exo* oriented. No such effect is noted for the resonance at δ 4.78, to be attributed to the α-hydroxy proton, with *endo* orientation. Actually, the small (2.5%) mutual nOe which is observed between the α-sulfonyl and the α-hydroxy protons is indicative of a *trans* reciprocal orientation. A significant (9.8%) nOe is induced on the α-hydroxy resonance from saturation of the methylenic 3 resonance, suggesting the 1,3 reciprocal position of the *endo* protons and the structure given in formula **6**.

Exactly the same perturbational pattern holds for the ether **14**, except that the nOe reciprocal enhancements between α-sulfonyl 6 and α-hydroxy 5 protons are noticeably greater (5{6}: 9.8%; 6{5}: 11.8%). Because the saturation of the 7 methylenic resonances affects only the α-sulfonyl resonance 6, their orientation is again *trans*. The greater nOe is due to the fact that the 5 (or 6) proton in one monomeric unit can come very close to the 6 (or 5) proton in the second unit.

*X-ray analysis of hydroxysulfone **6***

Positional parameters are given in Table 7. Table 8 lists bond lengths and Table 9 bond angles. The perspective drawing is represented in Fig. 7. As independently shown by nOe experiments, the hydroxy group is *exo* oriented, while the sulfonyl group is *endo* on the same side of the carbonyl group. No intramolecular hydrogen bonding is effective between the hydroxy and the sulfonyl group (O(2)—O(4) = 3.60 Å) but it is observed intermolecularly. Each O(2) atom binds reciprocally with an inversion centre with an O(4) of another molecule (O(2)—O(4) $(1-x, -y, 1-z)$ = 2.763 Å). It is, however, likely that in solution the hydrogen bonding is actually intramolecular.

Discussion

The method of choice for the preparation of **4***a* and **4***b* is based on the acid-catalyzed reaction of 2-cyclopentenone with isopropenyl acetate and simultaneous reaction with **2** (route (a) in Chart 1). This method has already been used by several other authors (8) for the *in situ* generation of 2-acetoxy dienes and their reaction with maleic anhydride. Indeed this procedure is convenient for the reaction with **2** when reactive dienic substrates such as 2-acetoxycyclopentadiene are formed, but it fails to give good yields of the expected cycloadducts when 2-acetoxy-1,3-cyclohexadiene is the intermediate diene. In this case, in fact, the need of a higher temperature to promote the cycloaddition of the dienophile favours the allowed 1,5-sigmatropic proton shift in **9**, with formation of the thermodynamically more stable (and probably more reactive) isomer **15**.

[e]Not discernible from the enhancement of nearby resonances.

[4] 
9

The desired cycloadduct of type **4** from 2-cyclohexenone is, however, readily obtainable from the reaction of **2** with the 2-silyloxy-1,3-cyclohexadiene **10**, because of the higher activation given by the ether functionality with respect to the acetoxy one. This trend of reactivity has also been observed in the reaction with maleic anhydride (12), although in this case the observation of the preferential stereoselectivity exerted by a *trans* dienophile was precluded. To the best of our knowledge, no studies on the stereoselectivity in the cycloaddition to 2-oxy substituted 1,3-cyclodienes have been reported (15).

Our results indicate that the reaction of a *trans* dienophile such as (*E*)-1,2-bis(benzenesulfonyl)ethylene (**2**) with 2-oxy substituted 1,3-cyclodienes leads with high stereoselectivity to the isomer in which the activating group of the dienophile is *endo* with respect to the unsubstituted part of the molecule. The observed steric course of addition can be easily explained by the rules of secondary orbital interaction associated with the consideration of the magnitude of the orbital coefficients that usually controls regioselectivity (16). The effect exerted by the silyloxy group to the atomic orbital coefficients in the HOMO of the diene, as compared to that of the acetoxy one, is the probable cause of the higher stereoselectivity. Furthermore, an added steric contribution caused by the trimethylsilyl group may play some role in determining the observed stereopreference. A more in-depth investigation of the real factors that govern the stereoselectivity of these reactions is in progress and it will be published in due time.

For the preparation of norbonenone (**11**) it has been shown that there is no need to use separated isomers and that the overall yield of the reaction is reasonably comparable with that of other routes to the same molecule (14). However, it is to be pointed out that the present method, engaging a very powerful dienophile, may be broader in scope and can be used when functional groups sensitive to oxidants are present in the

molecule, since it requires reductive conditions.

The preparation of vinyl sulfones **5***a* and **5***b* represents an example of synthetic transformation of the adducts. Vinyl sulfones are continuously receiving remarkable interest in organic synthesis, and recent work in a number of laboratories witnesses their importance (9). The regioselective formation of **5***a* from **4***a* and **5***b* from **4***b* can be explained on the basis of the stereochemistry of the molecules and of the higher exposure of the *exo* hydrogen to the base attack.

Finally, the preparation of β-hydroxysulfone **6** is a further example of synthetic modification of the adducts derived from cycloaddition of (*E*)-1,2-bis(benzenesulfonyl)ethylene (**2**), where three versatile functional groups have been stereo- and regiospecifically constituted in a single molecule.

Experimental

Melting points are uncorrected. The nmr spectra were recorded on a Bruker WP 200SY, operating at 200 MHz or 50.3 MHz respectively for ^{1}H and ^{13}C. Alternatively a Varian EM 360A or a Bruker WP 60, both operating at 60 MHz, were used. All nmr spectra were recorded in $CDCl_3$ solution. The ir spectra were recorded on a Perkin Elmer 580B spectrophotometer and were taken in $CHCl_3$ solution. Microanalyses were performed by Mr. G. Biasioli of Prof. E. Celon "Laboratorio di Microanalisi" staff. Commercial reagents and solvents were purified to match reported physical and spectral data. Known compounds used in this research were either purchased from standard chemical suppliers or prepared according to literature procedures and purified to match the reported physical and spectral data.

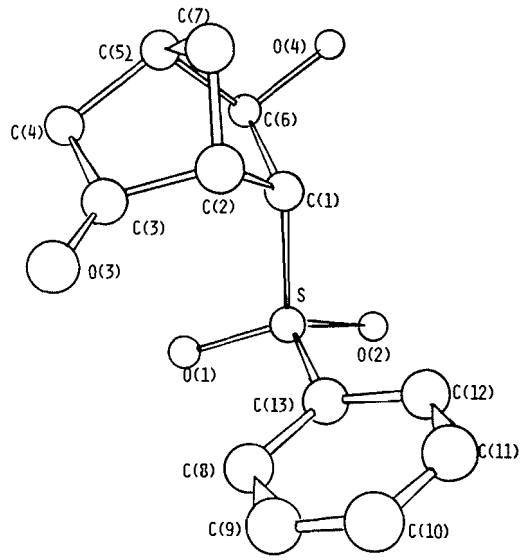

FIG. 7. Perspective drawing of the crystal structure of β-hydroxysulfone **6**.

*Nuclear Overhauser effect measurements (17*a)

The measurement tubes were freed from oxygen by repeated freeze–thaw cycles and then sealed under vacuum.

The usual pulse sequence for differential nOe experiments was adopted (17*b*); as the only modification, a multiplet was saturated with the least decoupling power by a 5-s cyclic perturbation of all multiplet lines. The percent enhancements were obtained from the coefficients of the reference spectrum when it was brought to exact matching with the perturbed spectrum. Errors are estimated as about 1%.

Preparation of 5,6-bis(benzenesulfonyl)bicyclo[2.2.1]heptan-2-one **4***a and* **4***a*

(a) *Through cycloaddition of* **2** *to* in situ *generated 2-acetoxycyclopentadiene*

(*E*)-1,2-bis(benzenesulfonyl)ethylene (**2**) (18) (2.7 g, 8.8 mmol) is added to a solution of 2-cyclopentenone (2.6 g, 31.9 mmol) and *p*-toluenesulfonic acid (30 mg) in 6.0 mL of isopropenyl acetate, and the reaction mixture is refluxed for 2 h with stirring. The cooled, clear yellow solution is concentrated on the rotatory evaporator and the residue is flash chromatographed through a silica gel column (>230 mesh, weight ratio adsorbant/substrate ca. 15:1) eluting with a 9:1 mixture chloroform – ethyl acetate. The first eluted product is ketone **4***a* (1.81 g, 53%); mp 204–206°C; ir ν_{max}: 1759, 1449, 1310, 1293, 1154, 1085 cm^{-1}; ^{1}H nmr δ: 1.87 (H_7, dq, $J_{7,7'}$ = 11.5, $J_{6,7}$ = $J_{1,7}$ = $J_{4,7}$ = 1.5, 1H), 2.18 ($H_{3\text{-}exo}$, dd, $J_{3\text{-}endo,3\text{-}exo}$ = 18.9, $J_{3\text{-}exo,4}$ = 4.3, 1H), 2.48 ($H_{7'}$, dm, 1H), 2.96 (H_1, bs, 1H), 3.09 ($H_{3\text{-}endo}$, dd, $J_{3\text{-}endo,4}$ = 4.6, 1H), 3.26 (H_4, m, 1H), 3.78 (H_6, dd, $J_{5,6}$ = 5.5, 1H), 4.36 (H_5, m, 1H), 7.53–7.82, 7.91–7.97 (C_6H_5, series of m, 10H); ^{13}C nmr δ: 36.59 (t), 39.54 (d), 40.49 (t), 54.34 (d), 62.40 (d), 65.23 (d), 128.51 (d), 128.62 (d), 129.43 (d), 129.71 (d), 134.40 (d), 134.61 (d), 137.83 (s), 139.30 (s), 209.25 (s); *m/e*: 249, 125, 107, 79, 77, 66, 51, 39. *Anal.* calcd. for $C_{19}H_{18}O_5S_2$: C 58.44, H 4.65; found: C 58.10, H 4.59.

The second product eluted is ketone **4***b* (0.77 g, 23%); mp 205–206°C; ir ν_{max}: 1761, 1449, 1310, 1154, 1084 cm^{-1}; ^{1}H nmr δ: 1.76 (H_7, dq, $J_{7,7'}$ = 11.6, $J_{5,7}$ = $J_{1,7}$ = $J_{4,7}$ = 1.8, 1H), 2.23 and 2.31 ($H_{3\text{-}endo}$ and $H_{3\text{-}exo}$, split AB quartet, $J_{3\text{-}endo,3\text{-}exo}$ = 18.0, $J_{3\text{-}endo,4}$ = 3.7, $J_{3\text{-}exo,4}$ = 4.3, 2H), 2.47 ($H_{7'}$, dm, 1H), 2.61 (H_1, m, 1H), 3.30 (H_4, m, 1H), 3.88 (H_5, dd, $J_{5,6}$ = 4.9, 1H), 4.19 (H_6, t, $J_{1,6}$ = 4.9, 1H), 7.57–7.80, 7.89–8.02 (C_6H_5, series of m, 10H); ^{13}C nmr δ: 36.40 (t), 38.29 (d), 42.43 (t), 51.77 (d), 65.37 (d), 65.43 (d), 128.88 (d), 129.03 (d), 129.53 (d), 129.57 (d), 134.52 (d), 134.61 (d), 137.47 (s), 138.32 (s), 208.51 (s); *m/e*: 249, 125, 107, 79, 77, 51.

(b) *Through cycloaddition to* in situ *generated 2-silyloxacyclopentadiene*

A 100-mL, three-necked, round-bottomed flask is charged with 2.3 mL (16.8 mmol) of freshly distilled triethylamine and ca. 3 mg (0.22 mmol) of anhydrous zinc chloride (10). The mixture is stirred 1 h under nitrogen at room temperature and then added through a rubber septum, via syringe, to 0.59 g (7.7 mmol) of 2-cyclopentenone in 4 mL of dry benzene, followed by 1.9 mL (14.4 mmol) of trimethylchlorosilane with a drop of triethylamine. After 12 h at 40°C under vigorous stirring, the mixture is cooled to room temperature and 0.5 g (1.62 mmol) of **2** are added. The mixture is further stirred at room temperature for 1 day, then rotoevaporated. The residue is chromatographed through silica gel (70–230 mesh, weight ratio adsorbant/substrate ca. 10:1), eluting with dichloromethane. The first eluted product is ketone **4***a* (0.52, 82.2%), the second is ketone **4***b* (52 mg, 8.2%).

Preparation of 5,6-bis(benzenesulfonyl)bicyclo[2.2.2]octan-2-one **4**c *and* **4**d

(a) *Through cycloaddition of* **2** *to* in situ *generated 2-acetoxy-1,3-cyclohexadiene*

(*E*)-1,2-bis(benzenesulfonyl)ethylene (**2**) (0.45 g, 1.46 mmol), 2-cyclohexenone (0.19 g, 1.97 mmol), and *p*-toluenesulfonic acid (6 mg) in 1 mL of isopropenyl acetate are refluxed 90 min into a Pyrex vial sealed with a screw cap. The resulting reaction mixture is concentrated on the rotatory evaporator and the residue chromatographed through silica gel (>230 mesh, weight radio adsorbant/substrate ca. 20:1), eluting with dichloromethane. Except for products probably derived from cycloaddition of **2** to the isomeric acetate **15**, **4***c* is the first eluted adduct (0.10 g, 14%); mp 179–180.5°C (EtOH); ir ν_{max}: 2955, 1735, 1449, 1322, 1150, 1086 cm^{-1}; ^1H nmr δ: 1.70 (H_7, m, 1H), 1.87 (H_8 and $H_{8'}$, m, 2H), 2.26 ($H_{3\text{-}exo}$, dm, $J_{3\text{-}exo,3\text{-}endo}$ = 19.8, 1H), 2.63 ($H_{7'}$, m, 1H), 2.70 (H_1, m, 1H), 2.84 (H_4, m, 1H), 3.11 ($H_{3\text{-}endo}$, dm, 1H), 4.03 and 4.09 (H_5 and H_6, split AB quartet, $J_{5,6}$ = 5.5, 2H), 7.52–7.95 (C_6H_5, series of m, 10H). *Anal.* calcd. for $C_{20}H_{20}O_5S_2$: C 59.39, H 4.98; found: C 59.50, H 5.11.

As second adduct, **4***d* is eluted (30 mg, 5%); mp 215°C (EtOH); ir ν_{max}: 2929, 1738, 1451, 1328, 1153, 1088, cm^{-1}; ^1H nmr δ: 1.51 (H_8, m, 1H), 1.87 (H_7, m, 1H), 2.04 ($H_{7'}$, m, 1H), 2.36 (H_1, m, 1H) 2.50 ($H_{8'}$, m, 1H), 2.41 and 2.61 ($H_{3\text{-}exo}$ and $H_{3\text{-}endo}$, split AB quartet, $J_{3\text{-}endo,3\text{-}exo}$ = 18.6, 2H), 2.99 (H_4, m, 1H), 3.96 (H_6, dd, $J_{5,6}$ = 4.6, $J_{1,6}$ = 2.7, 1H), 4.09 (H_5, m, 1H), 7.55–7.82, 7.98–8.04 (C_6H_5, series of m, 10H). *Anal.* calcd. for $C_{20}H_{20}O_5S_2$: C 59.39, H 4.98; found: 59.09, H 4.82.

(b) *Through cycloaddition of* **2** *to 2-silyloxy-1,3-cyclohexadiene*

(*E*)-1,2-bis(benzenesulfonyl)ethylene (**2**) (0.5 g, 1.62 mmol), 2-trimethylsilyloxy-1,3-cyclohexadiene (0.5 g, 2.97 mmol), and 1.5 mL of toluene are deposited into a screw-capped vial and sealed under nitrogen. After heating at 120°C for 90 min, the reaction mixture is cooled and the precipitated, unreacted **2** is filtered off. The filtrate is concentrated on the rotatory evaporator and chromatographed through silica gel (70–230 mesh, weight ratio adsorbant/substrate ca. 15:1), eluting with dichloromethane to obtain **4***c* as the only recognizable product (0.44 g, 67%).

*Preparation of 5,6-bis(benzenesulfonyl)bicyclo[2.2.1]heptan-2-one ethylene ketal (***12***)*

A mixture of the isomeric ketone **4***a* and **4***b* (0.8 g, 2.05 mmol), ethylene glycol (0.3 g, 4.83 mmol), and *p*-toluenesulfonic acid (70 mg) in 30 mL of anhydrous toluene is refluxed with azeotropic water removal (Dean Stark apparatus) for 7 h. The resulting reaction mixture is rotoevaporated to dryness, dissolved in a few drops of dichloromethane, and ether added to form colorless crystals of ketal (**13**: 0.86 g, 97%); mp 203–205°C; ^1H nmr δ: 1.62–2.00 (series of m, 3H), 2.52–2.80 (series of m, 3H), 3.38–4.29 (series of m, 6H), 7.49–8.05 (C_6H_5, series of m, 10H). *Anal.* calcd. for $C_{21}H_{21}O_6S_2$: C 58.05, H 5.10; found: C 57.62, H 5.12.

Desulfonylation and hydrolysis of ketal **12**. *Preparation of 5-norbornen-2-one (***11***)*

A mixture of ketals **12** (0.5 g, 1.15 mmol), obtained as above, was suspended in methanol (20 mL) containing ca. 2.5 g of sodium dihydrogenphosphate and ca. 4.8 g of finely grounded sodium amalgam (ca. 4%, 8.5 mg-atoms of sodium). The reaction mixture is kept under continuous stirring at room temperature overnight, filtered, water added, and extracted with dichloromethane (3 × ca. 20 mL). The organic phase is washed with brine (3 × ca. 30 mL), dried over anhydrous sodium sulfate, and carefully concentrated on the rotatory evaporator. The residue (**13**, 0.16 g, 91%; ^1H nmr δ: 1.43 (H_7, dd, $J_{7,7'}$ = ca. 13 and 3, 1H), 1.62 (H_6, dm, $J_{6\text{-}endo,6\text{-}exo}$ = ca. 10, 1H), 1.69 (H_6, d, 1H), 1.80 (H_7, dd, J_d = ca. 3, 1H), 2.61 ($H_{1(4)}$, m, 1H), 2.80 ($H_{1(4)}$, m, 1H), 6.05 ($H_{2(3)}$, dd, $J_{2,3}$ = ca. 6 and 3, 1H), 6.28 ($H_{2(3)}$, dd, J_d = ca. 3, 1H)) has been directly submitted to hydrolysis.

The crude ketal is dissolved in dichloromethane (ca. 10 mL) and a few drops of concentrated hydrochloric acid are added with stirring. After 30 min water is added, and the organic phase is separated and washed to neutrality. Rotoevaporation of the dried (Na_2SO_4) resulting solution and Kugel-rohr distillation of the residue affords an oil (0.08 g, 80%) whose ir and ^1H nmr spectral data are identical to those of an authentic sample of **11** independently synthesized as described (14).

Potassium carbonate treatment of ketones **4**a and **4**b

(a) *Preparation of 5- and 6-benzenesulfonylnorbornen-2-one* **5**a *and* **5**b *as a mixture*

Potassium carbonate (0.96 g, 6.91 mmol) in ca. 6 mL of water is added, while stirring, to a solution of a mixture of **4***a* and **4***b* (0.45 g, 1.15 mmol) in ca. 13 mL of dioxane. After 45 min at 45°C, dichloromethane (ca. 15 mL) is poured into the reaction mixture and the organic phase is separated. The aqueous layer is neutralized by addition of 1 *N* hydrochloric acid and thoroughly extracted with dichloromethane (3 × 20 mL). The combined organic extracts are dried over anhydrous sodium sulfate and rotoevaporated to dryness to afford a pale yellow oily residue of the two isomeric vinylsulfones (**5***a* and **5***b*; 0.25 g, 88%). Though it is possible to separate them by silica gel chromatography (see later), this specific mixture has not been further purified since **5***a* and **5***b* can be prepared as single products from the separated isomers **4***a* and **4***b*.

(b) *Preparation of vinylsulfone* **5**a *from adduct* **4**a

To a solution of ketone **4***a* (0.7 g, 1.79 mmol) in ca. 16 mL of dioxane 1.49 g (10.8 mmol) of potassium carbonate in ca. 9 mL of water are added with stirring at 45°C. After 1 h, dichloromethane (ca. 15 mL) is added and the aqueous layer neutralized with dilute hydrochloric acid. After separation of the two layers, the aqueous phase is extracted with more dichloromethane (2 × 10 mL) and the organic extracts washed with brine (3 × 30 mL), dried over anhydrous sodium sulfate, and rotoevaporated to dryness to afford an oil (**5***a*; 0.4 g, 90%) that was crystallized from ethanol; mp 74.5–76°C; ir ν_{max}: 2953, 1750, 1579, 1308, 1172, 1150, 1091 cm^{-1}; ^1H nmr δ: 1.61 (H_8, dd, $J_{7,8}$ = 17.1, $J_{8,3\text{-}endo}$ = 4.6, 1H), 2.01 (H_7, dd, $J_{4,7}$ = 3.4, 1H), 2.08 ($H_{3\text{-}exo}$, dm, $J_{3\text{-}exo,3\text{-}endo}$ = 9.8, 1H), 2.39 ($H_{3\text{-}endo}$, dm, 1H), 3.33 (H_1, m, 1H), 3.40 (H_4, m, 1H), 6.83 (H_6, m, 1H), 7.53–7.74, 7.87–7.95 (C_6H_5, series of m, 5H); *m/e*: 248, 206, 141, 125, 97, 81, 77, 53, 51, 39. *Anal.* calcd. for $C_{13}H_{12}O_3S$: C 62.89, H 4.87; found: C 63.40, H 4.93.

(c) *Preparation of vinylsulfone* **5**b *from adduct* **4**b

On treatment of adduct **4***b* (0.9 g, 2.30 mmol) in 12 mL of dioxane with potassium carbonate (1.79 g, 13.0 mmol) in 11 mL of water, at 45°C for 30 min and work-up as before, there was obtained 0.52 g (90%) of vinylsulfone **5***b* that was recrystallized from ethanol; mp 81°–82.5°C; ir ν_{max}: 2947, 1765, 1579, 1320, 1170, 1150, 1071 cm^{-1}; ^1H nmr δ: 1.83 (H_8, dd, $J_{7,8}$ = 17.09, $J_{3\text{-}endo,8}$ = 4.6, 1H), 2.04 (H_7, dd, $J_{4,7}$ = 3.4, 1H), 2.08 ($H_{3\text{-}exo}$, dm, $J_{3\text{-}endo,3\text{-}exo}$ = 10.1, 1H), 2.45 ($H_{3\text{-}endo}$, dm, 1H), 3.29 (H_1, m, 1H), 3.39 (H_4, m, 1H), 7.39 (H_5, d, $J_{4,5}$ = 3.0, 1H), 7.50–7.71, 7.84–7.92 (C_6H_5, series of m, 5H); *m/e*: 248, 206, 141, 125, 97, 81, 77, 53, 51, 39. *Anal.* calcd. for $C_{13}H_{12}O_3S$: C 62.89, H 4.87; found: C 62.24, H 4.80. Depending on the runs, this sample may be contaminated with ether **14** (see below).

(d) *Cycloaddition of benzenesulfonyl acetylene to* in situ *generated 2-acetoxycyclopentadiene. Preparation of a mixture of vinylsulfones* **5**a *and* **5**b

A 10-mL Pyrex vial equipped with a screw cap and a rubber septum, containing benzenesulfonyl acetylene (19) (0.5 g, 3.01 mmol), 2-cyclopentenone (0.32 g, 3.9 mmol), and *p*-toluenesulfonic acid (30 mg) in 2 mL of isopropenyl acetate is sealed under nitrogen and heated at reflux for 2 h. The reaction mixture is rotoevaporated and the resulting dark residue is chromatographed through a silica gel column (70–230 mesh, weight ratio adsorbant/substrate ca. 10:1) eluted with dichloromethane. The products are eluted in the sequence **5***a* (0.48 g, 64%) and **5***b* (0.12 g, 12%), as determined by comparison of the tlc and ^1H nmr spectral data with those of the previously obtained samples.

Sodium hydroxide treatment of adducts **4**a *and* **4**b. *Preparation of ketohydroxysulfone* **6**

To a solution of 1.10 g (2.82 mmol) of ketones **4***a* and **4***b*, as obtained from cycloaddition of **2** to 2-acetoxycyclopentadiene in 23 mL of dioxane, is added, while stirring, a 0.5 *N* solution (30 mL) of sodium hydroxide. The mixture is stirred at room temperature for 30 min and extracted with dichloromethane (20 mL). The aqueous phase is neutralized with 1 *N* hydrochloric acid and further extracted with dichloromethane (2 × 20 mL). The organic extracts are washed with brine (3 × 30 mL), dried over anhydrous sodium sulfate, and rotoevaporated. The residue is flash chromatographed through a silica gel column (>230 mesh, weight ratio adsorbant/substrate ca. 15:1), eluting with a 8:2 mixture chloroform – ethyl ether. The first eluted product is the ketohydroxysulfone **6** (0.3 g, 40%); mp 263–267°C; ir ν_{max}: 3601, 3493, 2983, 1754, 1448, 1311, 1290, 1153, 1084 cm^{-1}; ^1H nmr δ: 1.77 ($H_{7'}$, dm, $J_{7,7'}$ = 11.0, 1H), 2.19 ($H_{3\text{-}endo}$, $H_{3\text{-}exo}$, and $H_{7'}$, m, 3H), 2.47 (H_1, m, 1H), 2.74 (H_4, m, 1H), 4.78 (H_5, m, 1H), 7.56–7.72, 7.94–7.80 (C_6H_5, series of m, 5H); *m/e*: 267, 249, 125, 107, 79, 77. *Anal.* calcd. for $C_{13}H_{14}O_4S$: C 58.63, H 5.30; found: C 58.48, H 5.31.

Crystal data of **6** are as follows:

$C_{13}H_{14}O_4S$ fw = 266

Monoclinic, a = 19.314(7), b = 6.001(3), c = 11.348(5) Å, β = 98.7(3)°, V = 1300 $Å^3$, ρ_o = 1.35(1), ρ_c = 1.359 g cm^{-3} (20°C, MoKα, λ = 0.71069 Å), space group $P2_{1/\alpha}$ (N. 14).

3116 independent reflections were collected on a Philips PW1100 four-circle diffractometer, θ–2θ scan mode up to 2θ = 50°. 2005 reflections were considered observed with $I > 3\sigma(I)$. The structure solution was obtained by the direct method using the "Multan" program. All non-hydrogen atoms were refined anisotropically by full-matrix least-squares ($w = 1/(\sigma^2 F + 0.0102 F^2)$). Hydrogen atoms were located on a ΔF map, but not refined. The final agreement index R = 0.064. The scattering factors and all the calculations were obtained by Shelx-76 programs (G. M. Sheldrick, Cambridge).

The second eluted product is ether **14** (0.15 g, 20%); mp 150–152°C (EtOH); ir ν_{max}: 2938, 1756, 1448, 1321, 1155, 1076 cm^{-1}; ^1H nmr δ: 1.77 (H_7, dm, $J_{7,7'}$ = 11.0, 2H), 2.06 ($H_{7'}$, dm, 2H), 2.24 ($H_{3\text{-}endo}$ and $H_{3\text{-}exo}$, m, 4H), 2.46 (H_1, m, 2H), 2.85 (H_4, m, 2H), 3.61 (H_6, m, 2H), 4.76 (H_5, m, 2H), 7.54–7.73, 7.97–8.04 (C_6H_5, series of m, 10H); *m/e*: 372, 267, 249, 125, 107, 79, 77, 55, 41. *Anal.* calcd. for $C_{26}H_{22}O_7S_2$: C 60.68, H 5.09; found: C 60.70, H 5.10.

Under the same reaction conditions adduct **4***a* and vinyl sulfone **5***a* give, with sodium hydroxide, ca. 10% yield of **6**, while a mixture of **6** (ca. 40%) and **14** (ca. 10%) is produced from pure **4***b* or **5***b*. Work is in progress to gain a better understanding of these reactions.

Stereospecific cyclization of β-hydroxy aryl amides to β-lactams[1]

AJAY K. BOSE, M. S. MANHAS, D. P. SAHU, AND V. R. HEGDE
Department of Chemistry and Chemical Engineering, Stevens Institute of Technology, Hoboken, NJ. 07030, U.S.A.

Received January 17, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

AJAY K. BOSE, M. S. MANHAS, D. P. SAHU, and V. R. HEGDE. Can. J. Chem. **62**, 2498 (1984).

N-Aryl-β-lactams can be prepared conveniently by an intramolecular reaction of β-hydroxyarylamides under the influence of diethyl azodicarboxylate (DEAD) and triphenylphosphine (TPP). Optically active 3-amino-2-azetidinone derivatives can be prepared by this method starting with a suitably protected α-amino-β-hydroxy carboxylic acid amide. This cyclization involves the retention of configuration at C2 and complete inversion at C3 of the starting acid. In some cases diamides of azodicarboxylic acid have been used by replacing TPP with the more reactive tributyl phosphine. Other phosphorus reagents such as phosphite esters and hexamethyl phosphorus triamide could also be used.

AJAY K. BOSE, M. S. MANHAS, D. P. SAHU et V. R. HEGDE. Can. J. Chem. **62**, 2498 (1984).

Grâce à une réaction intramoléculaire des β-hydroxyarylamides, qui se produit sous l'influence de l'azodicarboxylate de diéthyle (DEAD) et de la triphénylphosphine (TPP), on peut facilement préparer des *N*-aryl β-lactames. Utilisant cette méthode, on peut préparer des dérivés optiquement actifs de l'amino-3 azètidone-2 en partant de l'amide d'un acide α-amino β-hydroxy carboxylique convenablement protégé. Cette cyclisation implique une rétention de configuration en C2 et une inversion complète en C3 de l'acide de départ. Dans quelques cas, on a utilisé les diamides de l'acide azodicarboxylique en remplacant la TPP par la tributyl phosphine qui est plus réactive. On pourrait aussi utiliser d'autres réactifs phosphorés comme les esters de phosphites et le HMPT (hexaméthyl phosphore triamide).

In recent years monocyclic β-lactams have become a center of attention in many laboratories. This type of heterocycle has been found in nature (2); also, suitably substituted moncyclic β-lactams can be converted to bicyclic (or polycyclic) β-lactams including naturally occurring penicillins, cephalosporins, cephamycins, and their analogs (3). In a preliminary communication (4) we have reported some aspects of our studies on the conversion of α-amino-β-hydroxy acid derivatives to optically active β-lactams by an intramolecular Mitsunobu type reaction (5). We present here details of these studies as well as new observations made by us.

Characteristics of the Mitsunobu reaction

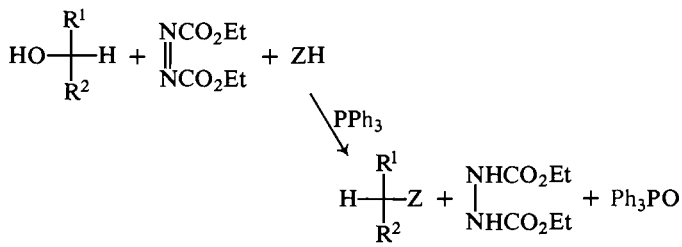
In essence the Mitsunobu reaction (5) is the replacement of a hydroxyl group by an anion under the influence of triphenylphosphine (TPP) and diethyl azodicarboxylate (DEAD) (6); the elements of water are removed by combining hydrogen with DEAD to form the hydrazine derivative and by converting TPP to its oxide (Scheme 1). The replacement of the hydroxyl group is stereospecific and occurs with complete inversion.

Even such weak acids as active methylene compounds can undergo reactions with alcohols under the influence of DEAD/TPP. For example, ethyl cyanoacetate and propyl alcohol have been reported to produce mono- and dipropylcyanoacetate (6*c*).

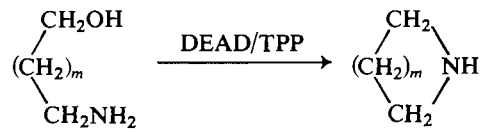
Carlock and Mack (7) have shown that intramolecular dehydration of diols to cyclic ethers (8) and amino alcohols to cyclic amines takes place under the conditions of the Mitsunobu reaction (Scheme 2).

Synthesis of 1-aryl-3-carbamato-2-azetidinones

In the light of the successful synthesis by Carlock and Mack of azacyclic compounds by an internal Mitsunobu reaction, and of our earlier work (9), we attempted the cyclization of the *p*-toluidide **1** of N-Cbz serine (Scheme 3). Under the influence of DEAD/TPP at room temperature, **1** was converted in 53% yield to the desired β-lactam **2** (4). The clearest indication of



SCHEME 1



SCHEME 2

β-lactam formation was the infrared absorption of **2** at 1770 cm^{-1} and the ^1H nmr spectrum.

While this research was in progress, Miller and co-workers (10,11) reported the synthesis of β-lactams **4** from β-hydroxyhydroxamic acids **3** under the Mitsunobu reaction conditions (Scheme 3). According to these authors, the key to their success in cyclization was the acidity ($pK_a \sim 6-10$) of the —CO—NH— bond of the hydroxamic acid.

In a later publication Townsend and Nguyen (12) have reported the formation of the *N*-alkyl-β-lactam **6** from the dipeptide **5**, the —CO—NH bond of which is not expected to be particularly acidic (Scheme 4).

Our detailed studies on the internal Mitsunobu reaction of arylamides of β-hydroxy-α-amino acids disclosed that the acidity of the —CO—NH— bond is but one of several factors that affect the course of the reaction. Our findings are discussed below.

Steric course of β-lactam formation

The reaction of the *p*-toluidide **7***c* of phenylserine with DEAD and TPP led to two products, in about equal amounts,

SCHEME 5

which could be separated by chromatography. Loss of the elements of water from **7***c* could possibly lead to four different types of compounds (Scheme 5). The ^1H nmr spectra of the two products obtained were incompatible with the oxazoline (**8***c*) and the eneamide (**9**) structures, but these spectra were in agreement with the four-membered and three-membered ring structures **10** and **11**, respectively.

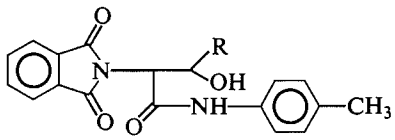
Of the two products, one showed infrared absorption peaks at 1740, 1730, 1620 cm^{-1} and the other at 1730, 1665, 1600 cm^{-1}. Clearly, the former is the β-lactam **10***c* and the latter the aziridine **11***c*. The ^1H nmr spectrum of **10***c* showed signals δ ($CDCl_3$): 7.4–6.9 (m, 14H), 6.1 (bd, J = 9 Hz, 1H), 5.03 (s, 2H), 4.9 (bs, 1H), 4.45 (bd, J = 8 Hz, 1H), 2.2 (s, 3H). The broad singlet at δ 4.9 could be resolved into a doublet (J = 2 Hz) by adding the shift reagent $Eu(fod)_3$ to the nmr sample.

The J value of 2 Hz for the coupling of C3 and C4 protons in **10***c* is evidence for the *trans* stereochemistry of the β-lactam. Since the starting compound **7***c* had the *erythro* or (2*SR*,3*RS*) configuration, the internal Mitsunobu-type reaction must proceed with inversion at C3 of **7***c*. The *cis* or *trans* configuration of the β-lactam, therefore, can be controlled by selecting a *threo*- or *erythro*-β-hydroxy-α-amino acid as the

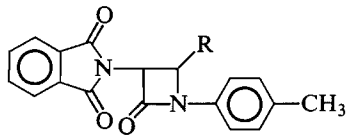
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

starting material.

The second product, **11***c*, which is isomeric with **10***c*, is best described by the aziridine structure **11**. The two ring protons of **11***c* which resonate at 3.6 and 4.0 ppm show a coupling constant of 7 Hz and are therefore *cis* to each other. During cyclization to the 3-membered ring, inversion must have occurred at C3 of the starting material **7***c*.



12

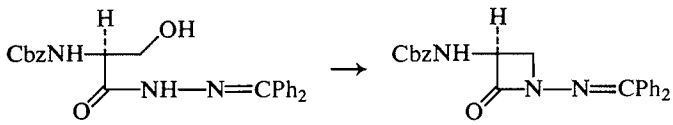


13

a = H
b = CH_3
c = Ph

A simple way of preventing the formation of aziridine is to use the *N*-phthaloyl derivative of a β-hydroxy-α-amino acid. Thus, the phthalimido derivative **12** was smoothly converted to the β-lactam **13** under the DEAD/TPP reaction conditions.

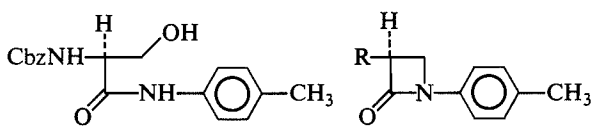
Previously we (4) have reported that the acyl hydrazide **14** can be cyclized to the β-lactam **15** – although in low yield – under the influence of DEAD/TPP at room temperature. It should be possible to prepare an *N*-unsubstituted β-lactam by taking advantage of N—N bond scission under dissolving metal reduction conditions.



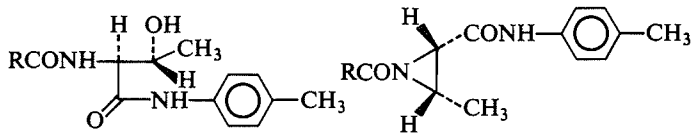
14 **15**

Chiral synthesis

The chiral nature of the synthesis described here was established by converting the *p*-toluidide **7***a* of *N*-carbobenzyloxy-L-serine to the β-lactam **10***a*. Attempts to determine the optical purity of **10***a* by using the chiral shift reagent Eu(tfac)$_3$ for nmr spectral studies were unsuccessful. To induce stronger binding with the shift reagent, the β-lactam **14** containing a free amino group was then generated by catalytic hydrogenation of **10***a*. The shift in the signal for the 4H proton *trans* to the 3H proton (shown by J = 1.5 Hz) in the ^{1}H nmr spectrum of **10***a* was studied. The quartet pattern for this proton in DL-**10***a* derived from DL-serine was shifted to form two sets of quartets of equal area. Under the same conditions **10***a* from L-serine showed only the quartet at lower field. Hence, in the course of β-lactam formation there was retention of the chirality of the α-amino acid.



7*a* **10***a* R = CbzNH
16 R = NH_2



7 **11**

R = OCH_2Ph
R = $OC_4H_9^t$

Influence of various parameters

The L-threonine amides **7***b* and **7***g* on DEAD/TPP reaction gave no β-lactam; the aziridine derivatives **11***b* and **11***g* were formed instead. This indicates the importance of the group attached to the carbinol carbon in directing the course of the reaction. The *cis*-stereochemistry of the C2 and C3 protons in **11***b* and **11***g* was as expected.

2′,4′-Dimethoxybenzamide of carbobenzyloxyserine failed to undergo any reaction with DEAD/TPP under similar conditions. The nature of the group attached to the amide nitrogen also appears to play a significant role in this reaction. Thus, the 2′,4′-dimethoxylbenzamide **7***d* and the *p*-methoxybenzamide **7***b* produced only dehydration products of the type **9** under the influence of DEAD and tributylphosphine or triethyl phosphite.

We have studied the effect of changing the nature of the phosphorus and the hydrazine compounds used in our β-lactam synthesis. Table 1 shows the conversion of **7***a* to **10***a* using various phosphorus compounds and diethyl azodicarboxylate. Triphenylphosphite failed to produce any β-lactam in 2 h at room temperature. In the light of later work (11, 12), that 2 h appears to have been inadequate reaction time. Morrison and Miller (11) have shown that β-lactam formation using triphenylphosphite and DEAD requires several days at room temperature.

The effect of changing the azo reagent was also studied. Several azo reagents were prepared by heating diethyl azodicarboxylate with secondary amines in ether (13). These reagents were tested for the cyclization of **7***a* to **10***a* (Table 2). It was found that **17**, **18**, and **19** failed to produce **10***a* when triphenylphosphine was used as the phosphorus compound. However, these compounds reacted with **7***a* in the presence of tri-n-butyl phosphine. Table 2 shows the yields of β-lactam **10***a* obtained with these reagents.

3-Unsubstituted-2-azetidinones

We have found that an α-carbamato or α-phthlimido group is not necessary for cyclization to β-lactams. Thus, benzoylacetanilide (**20**) was reduced with sodium borohydride in methanol to the corresponding β-hydroxy derivative (**21**) which on treatment with DEAD/TPP gave the β-lactam **22** (15) in 61% yield. The structure of this compound was established

through its spectral analysis. Acetoacetanilide **23**, under similar conditions, gave a mixture of the expected β-lactam **25** and crotonanilide **26**. The β-lactams obtained are unsubstituted on C3 and are thus similar in structure to a series of naturally occurring β-lactams, a representative example of which is clavulanic acid **27**.

Conclusions

The reaction of a phosphine and an azo compound with an arylamide of a β-hydroxycarboxylic acid constitutes a convenient synthesis of substituted β-lactams under mild conditions. This method involves the retention of the configuration at C2 and total inversion of the configuration at C3 of the β-hydroxy-α-amino acid starting material. Therefore, knowledge about the steric disposition of the starting compound permits one to predict the absolute and relative configuration of the β-lactam formed. Extension of the scope of this reaction is possible (16); further studies are in progress in our laboratory.

Experimental

The melting points are uncorrected. The ^1H nmr spectra were recorded on a Varian EM-390 nmr spectrometer. Chemical shifts are reported in parts per million from tetramethylsilane as internal standard, with the downfield direction taken as positive. Mass spectra were taken with a Hitachi RMU-7 mass spectrometer and a CIMS-Biospec instrument. The infrared spectra were recorded on a Perkin–Elmer 1310 infrared spectrophotomer. Microanalyses were performed by Schwarzkopf Microanalytical Laboratory, Inc., Woodside, N.Y.

Formation of amides from protected amino acids

To a mixture of carbobenzyloxyamino acid (0.05 *M*) and dicyclohexylcarbodiimide (0.055 *M*) in 100 mL of chloroform, was added *p*-toluidine (0.05 *M*) and the solution was stirred at room temperature for about 5 h. The cooled solution was filtered to remove precipitated dicyclohexylurea. The filtrate was washed successively with 0.5 *N* hydrochloric acid, 5% sodium bicarbonate, and water. The solution was then dried ($MgSO_4$). Removal of the solvent under reduced pressure gave the crude amide as a gummy solid which on crystallization from chloroform and petroleum ether afforded the pure product. The compounds listed in Table 3 were synthesized by using this procedure.

Preparation of diazenecarboxamides

To a solution of 2 g of diethyl azodicarboxylate in 20 mL of dry ether at 0°C was added dropwise with stirring 2 g of the secondary amine in 20 mL dry ether. After 2 h at 0°C the crystallized product was filtered, dried, and recrystallized from ether and petroleum ether to obtain pure diazenecarboxamide. Compounds **17** and **19** were prepared by this method (13).

Cyclization of β-hydroxy-α-amino acid amides

To a mixture of carbobenzyloxyamino acid amide (0.003 *M*) and triaryl (or trialkyl) phosphine (0.004 *M*) in 30 mL of dry tetrahydrofuran, was added diethyl azodicarboxylate (or diazenecarboxamide) in 15 mL of tetrahydrofuran, dropwise with stirring, over a period of 30 min. The course of the reaction was monitored with thin-layer chromatography. The reaction mixture was stirred at room temperature for 2 h. Removal of the solvent afforded a gummy mass which on passing through silica gel column gave the pure product. The compounds shown in Table 4 were obtained by this method.

Sodium borohydride reduction of β-keto acid anilides

To a cold (5°C) solution of β-keto acid anilide (0.01 *M*) in methanol was added sodium borohydride (0.015 *M*) in small portions with stirring. After 2 h of stirring, methanol was removed under reduced pressure. To the resulting solid were added ethyl acetate and water and the mixture was well shaken. The contents (ethyl acetate and water layers) were slowly neutralized with dilute hydrochloric acid. The ethyl acetate layer was separated, dried, and solvent evaporated to get a white solid which was further crystallized from ethyl acetate and hexane to obtain the β-hydroxyanilides. Compounds **21** and **24** were prepared by this method.

Cyclization of β-hydroxy acid anilides

Cyclizations of β-hydroxy acid anilides were effected using the DEAD/TPP reaction. The method is similar to the one explained in the case of cyclization of β-hydroxy-α-amino acid amides. Compounds **22**, **25**, and the amide **26** were obtained by using this procedure.

cis-*1-Carbobenzyloxy-2-methyl-3-(*N-p-*tolyl)amidoaziridine* (**11***b*) was obtained as an oily liquid in 66% yield; ir (neat): 3300, 1715, 1660 cm^{-1}; nmr ($CDCl_3$) δ: 1.26 (d, 3H, J = 6 Hz), 2.3 (s, 3H), 2.83 (quintet, 1H, J = 6 Hz), 3.30 (d, 1H, J = 6 Hz), 5.26 (s, 2H), 7.08 (d, 2H, J = 9 Hz), 7.28 (s, 5H), 7.52 (d, 2H, J = 9 Hz), 9.11 (b, 1H).

cis-*1-*tert-*butoxycarbonyl-2-methyl-3-(*N-p-*tolyl)amidoaziridine* (**11***g*) was obtained as a viscous liquid in 54% yield; ir (neat): 3300, 1715, 1635 cm^{-1}; nmr ($CDCl_3$) δ: 1.30 (d, 3H, J = 6 Hz), 1.52 (s, 9H), 2.26 (s, 3H), 2.28 (quintet, 1H, J = 6 Hz), 3.16 (d, 1H, J = 6 Hz), 7.15 (d, 2H, J = 9 Hz), 7.45 (d, 2H, J = 9 Hz), 8.20 (s, H).

cis-*1-Carbobenzyloxy-2-phenyl-3-(*N-p-*tolyl)amidoaziridine* (**11***h*) was isolated in 39% yield, mp 107°C; ir (Nujol): 1730, 1665, 1600 cm^{-1}; nmr ($CDCl_3$) δ: 2.2 (s, 3H), 3.6 (d, 1H, J = 7 Hz), 4.0 (d, 1H, J = 7 Hz), 5.2 (s, 2H), 6.9–7.5 (m, 14H), 7.64 (b, 1H); mass spectrum (CIMS, NH_3 reagent gas) m/z: 387 ($M^+ + 1$). *Anal.* calcd. for $C_{24}H_{22}N_2O_3$: C 74.59, H 5.74, N 7.25%; found: C 74.57, H 5.74, N 7.31%.

α-*Carbobenzyloxyamino-*N-*(2,4-dimethoxyphenyl)acrylamide* (**9***d*) was isolated as a white crystalline solid in 48% yield, mp 101°C; ir (Nujol); 3300, 1710, 1660 cm^{-1}; nmr (DMSO-d_6) δ: 3.66 (s, 6H), 4.98 (s, 2H), 5.40 (s, 1H), 5.55 (s, 1H), 6.42 (m, 2H), 7.20 (s, 5H), 7.42 (m, 1H) 8.60 (b, 1H), 8.96 (b, 1H); mass spectrum (CIMS, NH_3 reagent gas) m/z: 357 ($M^+ + 1$). *Anal.* calcd. for $C_{19}H_{20}N_2O_5$: C 64.04, H 5.61, N 7.86%; found: C 65.03, H 5.71, N 7.87%.

α-tert-*Butoxycarbonylamino-*N-*(*p-*anisyl)acrylamide* (**9***e*) was obtained in 55% yield, mp 153–155°C; nmr ($CDCl_3$) δ: 1.50 (s, 9H), 3.47 (s, 3H), 5.2 (b, 1H), 6.06 (b, 1H), 6.90 (d, 2H, J = 9 Hz), 7.30 (b, 1H), 7.40 (d, 2H, J = 9 Hz), 7.90 (b, 1H). *Anal.* calcd. for $C_{15}H_{20}N_2O_4$: C 61.64, H 7.53, N 9.58%; found: C 61.62, H 7.46, N 9.53%.

Crotonanilide (**28**) was formed in 21% yield from **24**, mp 112°C;

Dipolar cycloaddition reactions of diazoindene and the thermal behavior of the cycloadducts

ALBERT PADWA[1] AND STEVEN I. GOLDSTEIN
Department of Chemistry, Emory University, Atlanta, GA 30322, U.S.A.

Received February 7, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

ALBERT PADWA and STEVEN I. GOLDSTEIN. Can. J. Chem. **62**, 2506 (1984).

A study of the dipolar cycloaddition behavior of diazoindene toward electron-deficient acetylenic and olefinic dipolarophiles has been carried out. Reactions with alkynes afford transient 1,3-dipolar cycloadducts. Product formation can be attributed to a substituent-dependent partitioning between spiro 3*H*-pyrazole adducts and ring opened diazoalkenes. The initially formed cycloadducts lose nitrogen to give a spirocyclopropene derivative or undergo the van Alphen – Huttel rearrangement. When olefinic dipolarophiles are used, nitrogen deficient 1 : 1 adducts are isolated. The formation of the product involves the further loss of nitrogen from the initially formed spiropyrazoline adduct.

ALBERT PADWA and STEVEN I. GOLDSTEIN. Can. J. Chem. **62**, 2506 (1984).

On a réalisé une étude du comportement, lors de réactions de cycloadditions dipolaires, du diazoindène vis-à-vis de dipolarophiles oléfiniques et acétyléniques déficients en électrons. Les réactions avec les alcynes fournissent des cycloadduits 1,3-dipolaires intermédiaires. On peut attribuer la formation de ces produits à une partition, qui dépend des substituants, entre les adduits spiro 3*H*-pyrazoles et les diazoalcènes à cycle ouvert. Les cycloadduits qui se forment initialement peuvent soit perdre de l'azote pour conduire à un dérivé spirocyclopropène ou subir une transposition de van Alphen – Huttel. Lorsqu'on utilise des dipolarophiles oléfiniques, on isole des adduits 1 : 1 déficients en azote. La formation du produit implique une perte subséquente d'azote par l'adduit spiropyrazoline qui se forme initialement.

[Traduit par le journal]

Higher order dipolar cycloadditions of diazo compounds can occur when the diazo system contains more than four π-electrons (1–12). The use of extended diazoalkanes with six or more electrons has received little attention despite the obvious synthetic and theoretical interest in such processes. Selection rules for higher order dipolar cycloadditions are similar to those of the corresponding isoelectronic polyenes and are allowed in the suprafacial-suprafacial mode when the total number of participating electrons is $4n + 2$ (13, 14). Derivatives of the diazocyclopentadiene and certain diazoazole ring systems are ideally suited to a study of the various possible modes of extended dipolar cycloaddition. As part of a general program to study profiles of reactivity of diazoalkanes (15–17), we became interested in determining whether diazoindene (**1**) could undergo a higher order dipolar cycloaddition reaction. This paper summarizes our observations in this area.

Results and discussion

Diazoindene **1** could in principle react with acetylenic dipolarophiles via several plausible pathways: by either or both of two competing modes (1,3 or 1,7) of cycloaddition giving respectively **2** or **3**, or via loss of nitrogen to give the carbene derived product **4**. Previous work in this area has shown that while the analogous diazacyclopentadiene system reacts almost exclusively by 1,3-addition to acetylenes (7–10), the aza-heterocyclic analogues give products resulting from 1,7-cycloaddition (1, 2). In an effort to establish the preferred mode of cycloaddition, we allowed diazoindene **1** to react with dimethyl acetylenedicarboxylate. The cycloaddition was carried out in benzene solution and the reaction was monitored qualitatively by the disappearance of the diazo compound according to both infrared and tlc analyses. The reaction of **1** with dimethyl acetylenedicarboxylate furnished (94%) dimethyl *Z*-diazo-1*H*-

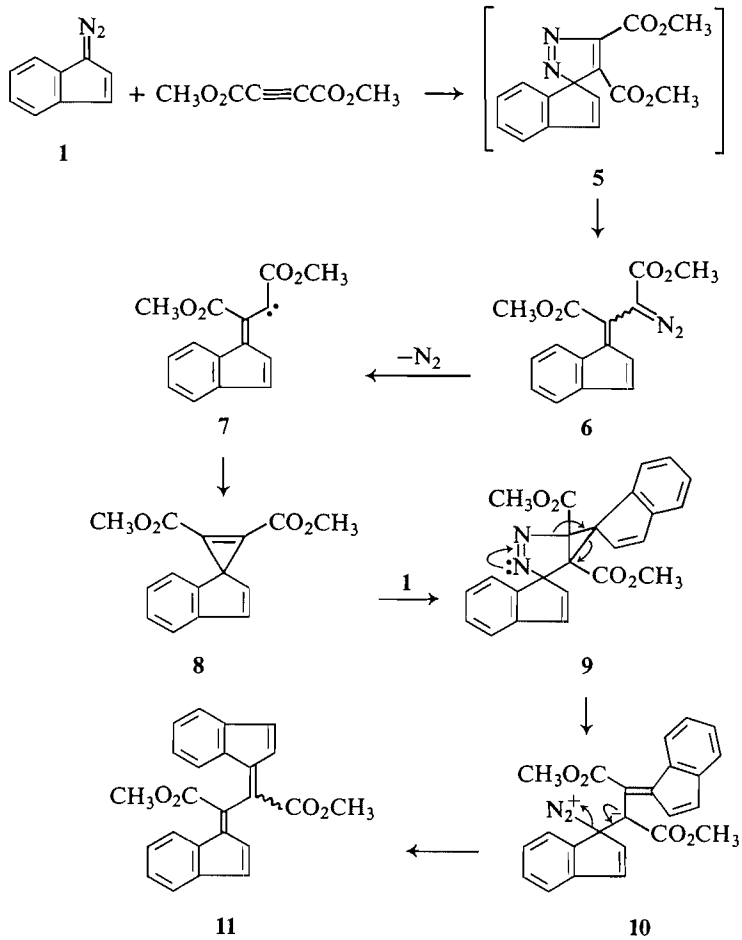

SCHEME 1

inden-1-ylidenebutanedioate (**6**). The formation of **6** can be regarded as proceeding by an initial 1,3-dipolar cycloaddition followed by a thermally allowed (3+2)-cycloreversion (for a review of 1,3-dipolar cycloreversions, see ref. 18). The conversion of **1** to **6** represents an interesting example of a 1,3-dipole metathesis process since the diazoalkane obtained is different from the one used initially (19).[2]

Structure **6** liberated nitrogen on heating in benzene to give spirocyclopropene **8**. This reaction undoubtedly involves cyclization of the initially formed vinylcarbene intermediate **7**. The thermolysis of vinyldiazomethanes is well known to give cyclopropenes as products, thereby providing a good analogy for this process (20). Heating a sample of diazoindene **1** and dimethyl acetylenedicarboxylate at 80°C for longer periods of time produced a 2:1 adduct (i.e. **9**, 92%) in addition to spiroindene **8**. The formation of **9** is believed to proceed by cycloaddition of **1** onto spirocyclopropene **8**. This could be confirmed by allowing **1** to react with a sample of **8** at 25°C. When diazabicyclohexene **9** was heated at 160°C, nitrogen was lost and the major product obtained corresponded to diene **11**. The formation of **11** can be viewed in terms of a process involving initial carbon–nitrogen bond cleavage to yield zwitterion **10** followed by loss of nitrogen to give diene **11**. This reaction is similar to that encountered on thermal or photochemical decomposition of related derivatives of 2,3-diazabicyclo[3.1.0]hex-2-enes (21, 22).

There are a number of reports in the literature which describe 1,3-dipolar cycloadditions to cyclopropene derivatives (21–43). The rates of these 1,3-dipolar cycloadditions are quite high, indicating that considerable strain in the olefin is relieved in the transition state for addition (43). The initial cycloadducts often rearrange by valence bond tautomerization, and secondary products are frequently isolated. In view of our interest in the cycloaddition behavior of cyclopropene derivatives (44), we initiated a study dealing with the reaction of **8** with several dipoles. When spirocyclopropene **8** was treated with diazomethane in ether solution at 25°C, a clean cycloaddition reaction occurred to give diazabicyclohexene **12**. Thermolysis of a sample of **12** at 110°C in benzene or photolysis in benzene resulted in the formation of the isomeric diazabicyclohexene **13**. Interestingly, structure **13** could not be isomerized back to **12** on heating or on irradiation. The stereochemistry of the individual isomers could be readily discerned by examination of their nmr spectra. The appearance of the 6-*endo* proton in **12** (δ 3.98) at high field relative to proton H6 in **13** (δ 5.13) is compatible with the anisotropic shielding of this proton by the adjacent aromatic ring. As is the case with most 1,3-dipolar cycloadditions (45), the 1,3-dipole added from the least hindered side of the π-bond to give structure **12**. An attractive rationale for the interconversion of **12** to **13** (Path A) involves an initial cycloreversion to give **14** followed by a subsequent intramolecular cycloaddition. An alternate mechanism (Path B) consists of cleavage of the cyclopropane ring to give diradical **15**, which undergoes ring flipping followed by ring closure. This path seems less likely since diazabicyclohexenes are

[2]No signs of the initially formed cycloadduct **5** could be detected in the crude reaction mixture.

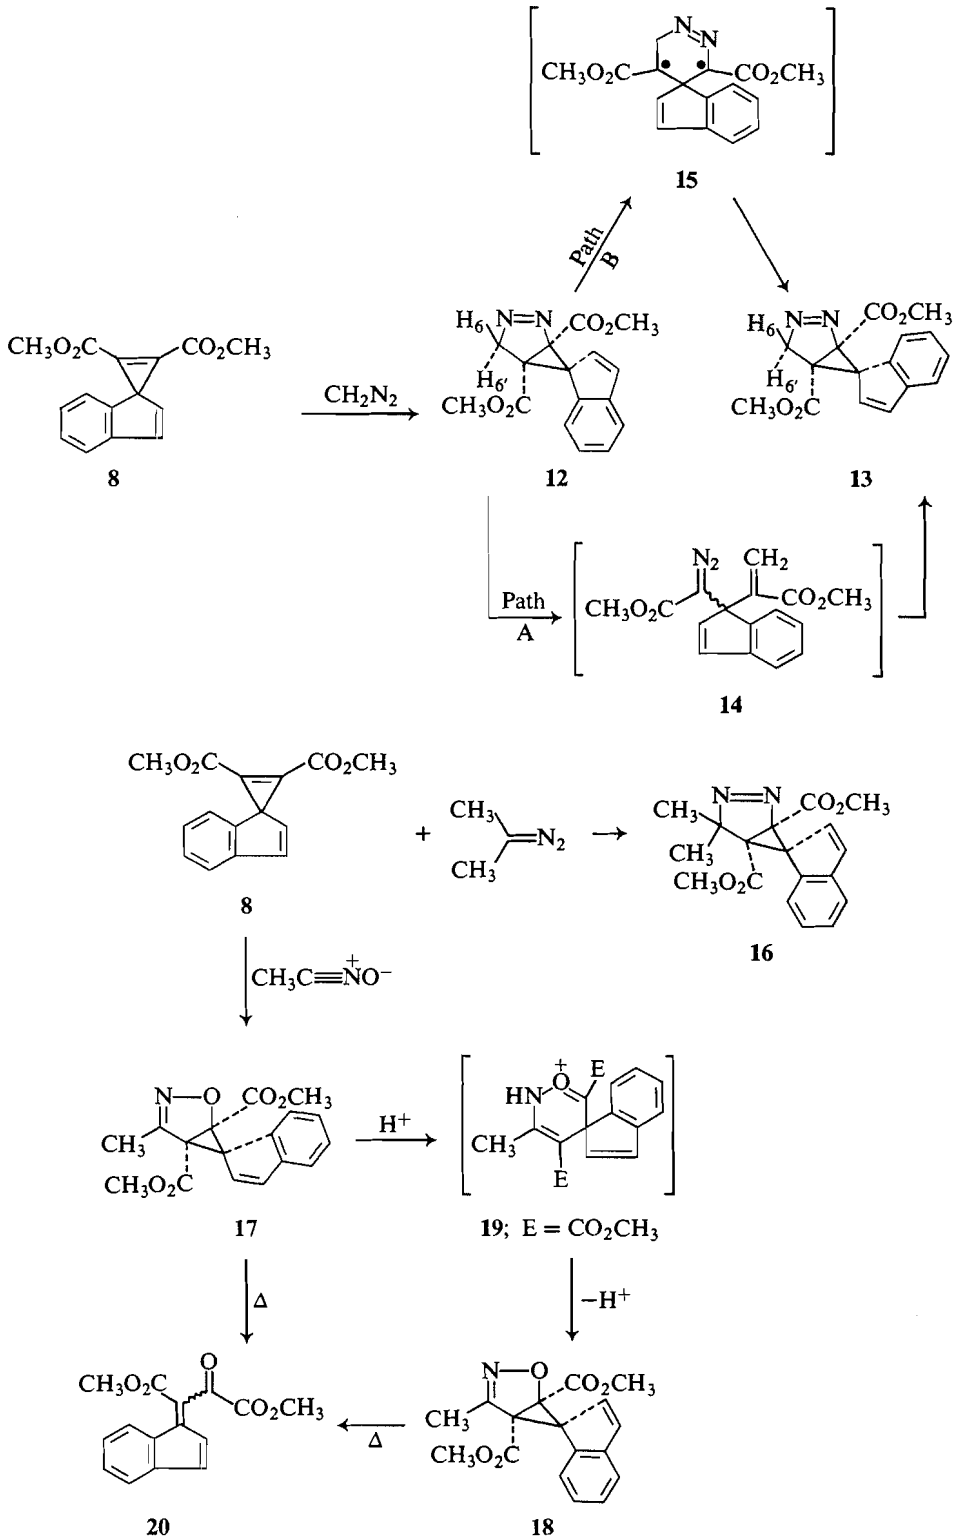
For personal use only.



known to produce β,γ-unsaturated diazoalkenes on heating (21, 22). In fact, the thermolysis of a sample of **12** at 145°C produced diazoalkene **14**. The nmr absorptions due to **14** disappeared on standing at room temperature, cleanly reproducing the spectrum of **13**. These results clearly indicate that the intramolecular dipolar cycloaddition reaction of **14** is highly stereoselective and produces the thermodynamically more stable diazabicyclohexene isomer.

A related set of results was encountered when spirocyclopropene **8** was allowed to react with 2-diazopropane. We also found that **8** gave the dipolar cycloadduct **17** when treated with α-chloroacetaldoxime in the presence of triethylamine. Silica gel chromatography of **17** produced the isomeric oxadiazabicyclohexene **18**. A similar rearrangement occurred when **17** was stirred in benzene with a trace of *p*-toluene sulfonic acid. The stereochemistry of cycloadduct **17** was easily assigned on the basis of its nmr spectrum. The appearance of the indenyl proton in **17** at a higher field (δ 5.80) than the corresponding proton in **18** (δ 6.57) is consistent with the expected shielding effect of the C=N double bond. Thermolysis of **17** (or **18**)

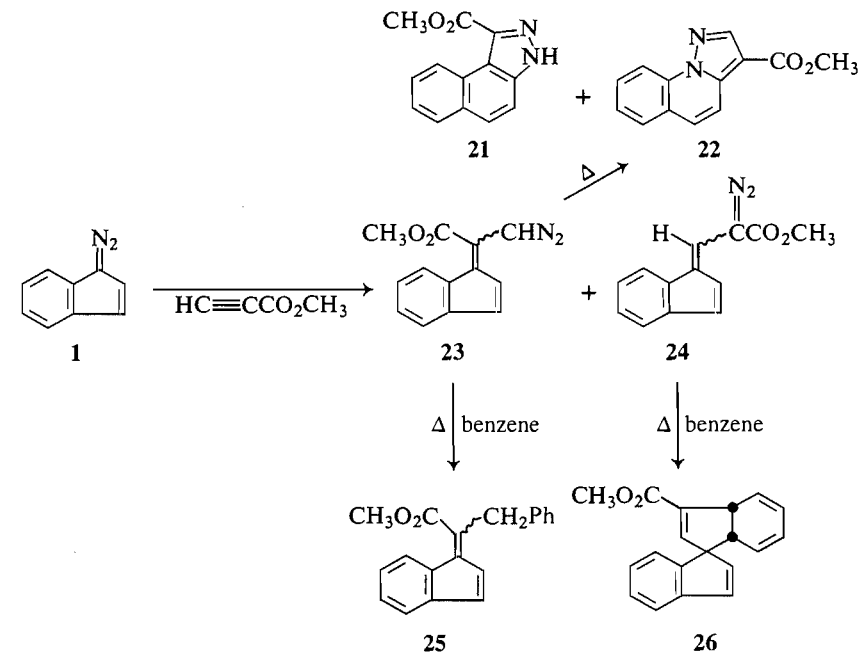
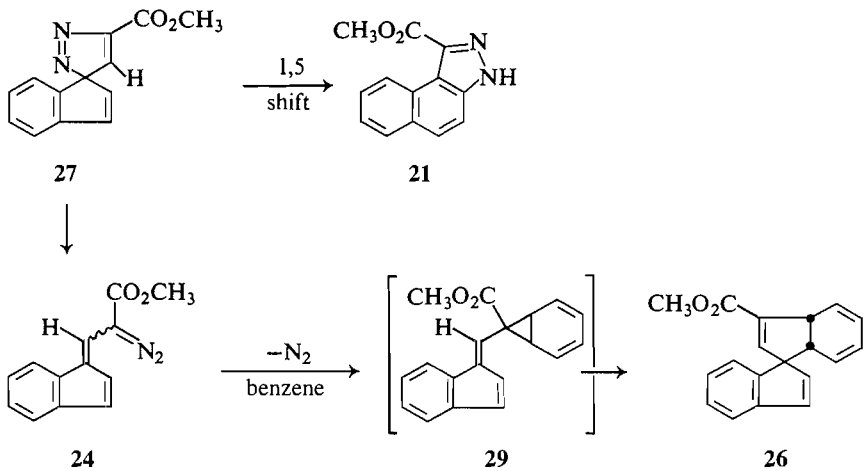


SCHEME 2



results in the loss of acetonitrile and formation of enone **20**. The isomerization of **17** to **18** is an interesting transformation and merits some discussion. The reaction most likely involves cleavage of the central bond of the cyclopropane ring to give **19**, which undergoes ring flipping followed by a subsequent ring closure.

In an effort to establish the regiochemical cycloaddition behavior of diazoindene, the reaction of **1** with methyl propiolate was investigated. In this case the cycloaddition produced a complex mixture of products which could be separated by silica gel chromatography. The products were assigned as indazole **21**, pyrazoloquinoline **22**, and diazoalkenes **23** and **24** (*E*,*Z*-mixture). The structures of **21**–**24** were in accord with the nmr, uv, ir, and mass spectral data (see experimental section). Heating diazoalkenes **23** and **24** in a sealed tube in benzene at 160°C produced pyrazole **22**, benzylidene indene **25**, and spiroindene **26**, respectively (see Scheme 2).

The mechanism by which these reactions proceed is worthy of comment in view of the diversity of structures obtained. We believe that the initial reaction involves a 1,3-dipolar cycloaddition of **1** with methyl propiolate to give a mixture of regioisomeric cycloadducts (i.e. **27** and **28**). The reactions of simple diazoalkanes are generally HO (1,3-dipole) – LU (dipolarophile) controlled (46) (Type I process (47)). 3-Substituted pyrazolines are the major products produced, a result of union of the larger diazoalkane HO coefficient on carbon with that of the larger dipolarophile LU coefficient on the unsubstituted carbon (46). We suspect that the formation of a mixture of regioisomers (*vide infra*) is a result of the Type II dipolar cycloaddition behavior of diazoindene **1** (Sustmann's classification (47)). Introduction of an aryl group onto diazomethane is known to result in a mixture of regioisomeric cycloadducts (45). The initially formed cycloadduct **27** aromatizes under the reaction conditions via a thermally allowed 1,5-sigmatropic shift of the phenyl group to give compound **21**. Interestingly, this type of isomerization (van Alphen – Huttel rearrangement), for which ample precedence exists (48, 49), proceeds by exclusive migration of the phenyl bond to the carbon atom. The major path followed by **27** involves a 3+2-cycloreversion to give diazoalkene **24**. Further heating of this material in benzene results in the formation of spiroindene **26**. The formation of **26** involves loss of nitrogen followed by carbene addition across

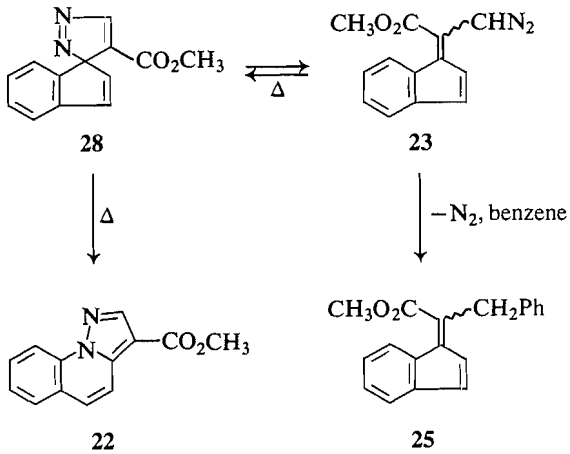
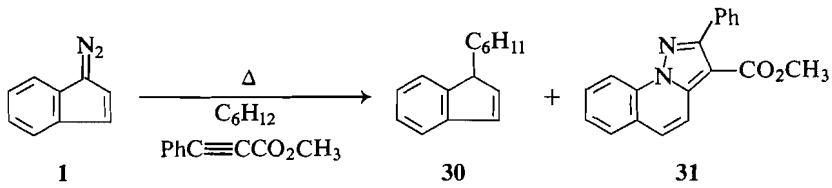
the π-bond of benzene to give a transient norcaradiene intermediate (i.e. **29**) which rearranges to **26** via a vinylcyclopropane–cyclopentene rearrangement.

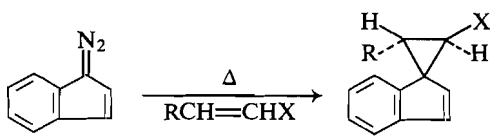
The isomeric cycloadduct (i.e. **28**) obtained from the initial 1,3-dipolar cycloaddition could not be isolated. It is assumed that this species is converted into diazoalkene **23** by means of a 3+2-cycloreversion. A control experiment showed that **23** is stable at room temperature but is converted into pyrazoloquinoline **22** upon heating in a sealed tube at 178°C. This transformation can be rationalized in terms of an intramolecular electrocyclization reaction to produce **28** followed by a van Alphen – Huttel rearrangement. The exclusive migration of the phenyl group to the nitrogen atom in this case is probably associated with stabilization of the developing negative charge by the carbomethoxy group in the transition state. Steric factors may also play a role in the migration. Structure **23** also undergoes the loss of nitrogen and the resulting carbene inserts into the carbon–hydrogen bond of benzene to give **25**.



We also examined the thermal cycloaddition of diazoindene **1** with methyl phenylpropiolate in cyclohexane. From the reaction two products were isolated by preparative thick layer chromatography. The major species (34%) corresponded to 1-cyclohexylindene (**30**). This material is formed by insertion of the carbene derived from diazoindene into the C—H bond of solvent. In addition to **30**, the minor component obtained was a white solid whose structure was assigned as methyl pyrazolo[1,5-*a*]quinoline-2-phenyl-3-carboxylate (**31**) on the basis of its spectral properties. Here again the formation of **31** can be most conveniently rationalized as arising from a simple 1,3-dipolar cycloaddition followed by a van Alphen – Huttel rearrangement of the initial spiro adduct.



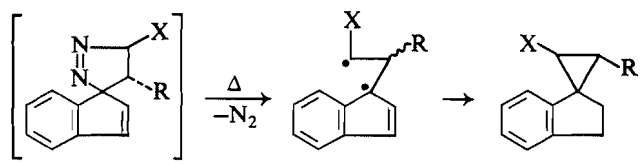
As an extension of our studies with diazoindene **1**, we also investigated its cycloaddition behavior with electron deficient alkenes. In each case, nitrogen deficient 1:1 adducts, the structures of which have been assigned as the spiro-cyclopropylindenes **32–36**, were isolated in yields of 80–95%. Whereas the reaction of **1** with methyl acrylate (or nitroethylene) afforded a mixture of stereoisomers, diazoindene gave rise to a single product when diethyl fumarate was used as the trapping agent. This same adduct was also obtained when diethyl maleate was used as the alkene. The isomer in which the cyclopropyl methoxycarbonyl group is *syn* to the aromatic ring (i.e. **33**) has been assigned on the basis of a comparison of resonances due to the ester methoxyls. Specifically, the appearance of a high-field signal at δ 2.52 can only be rationalized by assuming a configuration in which shielding due to the anisotropic properties of the aromatic benzene ring is invoked. The isomer to which the *anti* configuration has been assigned (i.e. **32**) exhibits the same signal at δ 3.63. Because only minimal steric and anisotropic interactions are likely to be incurred with spiro adducts **35** and **36**, it is not possible to establish the stereochemistry of substitution on the cyclopropane ring.



32 and **33** R = H; X = CO_2CH_3
34 R = X = CO_2CH_3
35 and **36** R = H; X = NO_2

It is of some interest to note that diazoindene **1** is stable under the reaction conditions used for the cycloadditions. This would suggest that the reaction of **1** with electron deficient alkenes does not proceed by initial loss of nitrogen from diazoindene followed by carbene addition to the olefinic π-bond. Instead, the formation of cycloadducts **32–36** can be thought of as resulting from a thermally induced extrusion of nitrogen from intermediate spiro pyrazoline adducts (**37**) which are formed in a manner analogous to those derived from propiolate cycloadditions.

Since the theory of spiroconjugation was formulated over fifteen years ago (50, 51), a number of spiroconjugated compounds have been prepared and their spectral data and chemical reactivity have been evaluated. Several dialkyl derivatives of spiro[2.4]heptatriene (**39**) have been experimentally isolated and spectroscopically studied with particular emphasis on the stability of the system (52–54). Spiroconjugation theory suggests that the HOMO level of **39** should be stabilized (50). Using MINDO/3 calculations, Gordon *et al.* (54) concluded

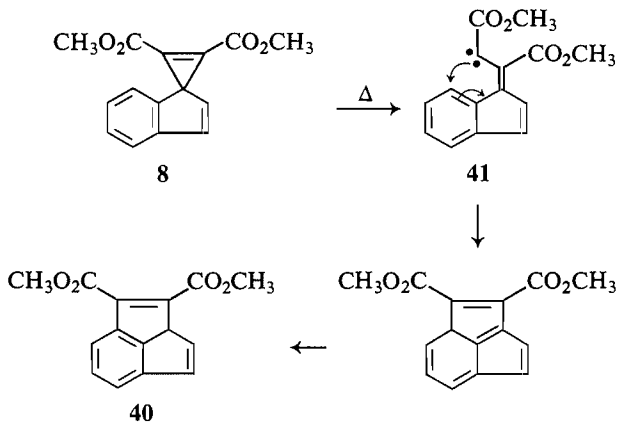


39

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

that spiroconjugation adds little, if any, contribution to the stabilization of molecules like **39**. On the other hand, Kao and Radom argued that the spiroconjugated stabilization of spiro-[2.4]heptatriene is reflected in the calculated strain (55). This comes out to 58.5 kcal/mol, which is less than the sum of the strains of the cyclopropene and cyclopentadiene rings despite the deformed bond angles about the spiro carbon. This result was interpreted as being consistent with a favorable orbital interaction (56).

As a continuation of our interest in this area, we decided to study the thermal chemistry of spiroindene **8**. Heating a sample of **8** at 160°C gave dimethyl 2a*H*-cyclopent[*c*,*d*]inden-1,2-dicarboxylate (**40**) in good yield. The rate of reaction of **8** is very similar to related cyclopropenes (57) and it does not appear that this molecule is stabilized by spiroconjugation. The rearrangement can be interpreted in terms of an initial ring opening to produce a vinylcarbene intermediate (**41**) which



undergoes 1,5-electrocyclization followed by a 1,5-sigmatropic hydrogen shift. Other mechanisms are also conceivable and can not be ruled out without further evidence.

Experimental[3]

Reaction of diazoindene (1) with dimethyl acetylenedicarboxylate

To a solution containing 220 mg of diazoindene **1** in 10 mL of anhydrous benzene was added 250 mg of dimethyl acetylenedicarboxylate. After stirring for 17 h at 25°C, the solvent was removed under reduced pressure and the residue was chromatographed on a silica gel column using a 10% acetone–hexane mixture as the eluent to give 413 mg (94%) of a red oil which was identified as dimethyl *Z*-diazo-1*H*-inden-1-ylidenebutanedioate (**6**); ir (neat): 2990, 2100, 1700, 1435, 1340 cm^{-1}; nmr (CCl_4, 90 MHz) δ: 3.88 (s, 3H), 3.92 (s, 3H), 6.92 (d, 1H, J = 6.0 Hz), 6.96 (d, 1H, J = 6.0 Hz), and 7.00–7.34 (m, 4H). *Anal.* calcd. for $C_{15}H_{12}N_2O_4$: C 63.38, H 4.26, N 9.86; found: C 63.19, H 4.17, N 9.84.

A solution containing 400 mg of **6** in 10 mL of benzene was heated at reflux for 20 min. The solvent was removed under reduced pressure and the residue was chromatographed on a silica gel column using a 10% acetone–hexane mixture to give 256 mg (71%) of a pale yellow solid, mp 86–87°C, whose structure was assigned as dimethyl spiro[2-cyclopropene-1,1-[1*H*]indene]-2,3-dicarboxylate (**8**); ir (KBr): 3000, 1870, 1730, 1430, 1260, 1050 and 750 cm^{-1}; uv (95% ethanol): 292 (ε 1,470), 266 (7,330), and 227 nm (16 660); nmr (CCl_4, 90 MHz) δ: 3.81 (s, 6H), 6.16 (d, 1H, J = 7.0 Hz), 6.96 (d, 1H, J = 7.0 Hz), and 7.00–7.46 (m, 4H); *m/e*: 256 (M^+), 226, 225, 224 (base), 197, 166, 139, and 138. *Anal.* calcd. for $C_{15}H_{12}O_4$: C 70.30, H 4.72; found: C 70.44, H 4.75.

Reaction of dimethyl spiro[2-cyclopropene-1-1′-[1H]indene]-2,3-dicarboxylate (8) with diazoindene (1)

To a solution containing 26 mg of **8** in 20 mL of benzene was added 30 mg of diazoindene. The solution was heated at reflux for 15 min. At the end of this time the solvent was removed under reduced pressure and the residue was chromatographed on a silica gel column using a 10% acetone–hexane mixture as the eluent. The first component isolated contained 55 mg (92%) of a white crystalline solid, mp 137–138°C, whose structure was assigned as dimethyl dispiro-[indene-1,4′-[2,3]diazabicyclo[3.1.0]hexane-6′,1′-indene]-1′,5′-dicarboxylate (**9**); ir (KBr): 3020, 1740, 1450, 1430, 1280, 1260, 1190, and 1090 cm^{-1}; uv (95% ethanol): 229 nm (ε 26 840); nmr (CCl_4, 90 MHz) δ: 3.06 (s, 3H), 3.96 (s, 3H), 5.69 (d, 1H, J = 6.0 Hz), 6.18 (d, 1H, J = 6.0 Hz), 7.00 (d, 1H, J = 6.0 Hz), 7.03 (d, 1H, J = 6.0 Hz), 7.10–7.37 (m, 8H); *m/e*: 370, 339, 311, 296, 280, and 252 (base). *Anal.* calcd. for $C_{24}H_{18}N_2O_4$: C 72.35, H 4.55, N 7.03; found: C 72.06, H 4.73, N 6.98.

A solution containing 31 mg of **9** in 20 mL of anhydrous benzene was heated in a sealed tube for 2.5 h at 128°C. The solvent was removed under reduced pressure leaving behind a red oil which was chromatographed on a silica gel column using a 10% acetone–hexane mixture as the eluent to give 26 mg (88%) of an orange oil which was identified as dimethyl bimethyleneindene-1,1′-dicarboxylate (**11**);[4] ir (neat): 3100, 3000, 1730, 1600, 1450, 1220, and 750 cm^{-1}; uv (95% ethanol): 355 (ε 4,320) and 250 nm (14 530); nmr (CCl_4, 90 MHz) δ: 3.73 (s, 3H), 3.76 (s, 3H), 6.20 (d, 1H, J = 6.0 Hz), 6.63 (d, 1H, J = 6.0 Hz), 6.80 (d, 1H, J = 6.0 Hz), 6.73–7.26 (m, 6H), 7.33 (d, 1H, J = 6.0 Hz), 7.70–8.00 (m, 1H), and 8.25–8.40 (m, 1H); *m/e*: 370 (M^+), 229, 227, 311, 310, 308, 280, 279, 252, and 125. *Anal.* calcd. for $C_{24}H_{18}O_4$: C 77.82, H 4.90; found: C 77.72, H 4.94.

Reaction of dimethyl spiro[2-cyclopropene-1,1′-[1H]indene]-2,3-dicarboxylate (8) with diazomethane

To a solution containing 286 mg of dimethyl spiro[2-cyclopropene-1,1′-[1*H*]indene]-2,3-dicarboxylate (**8**) in 20 mL of ether was added an excess of diazomethane. This mixture was allowed to stir for 8 h and the solid that formed was filtered to give 90 mg of a colorless crystalline material, mp 152–153°C, whose structure was assigned as *endo* dimethyl spiro[2,3-diazabicyclo[3.1.0]hex-2-ene-6,1′-indene]-1,5-dicarboxylate (**12**); ir (KBr): 3000, 1740, 1430, 1300, 1250, 1200, and 1110 cm^{-1}; uv (95% ethanol): 236 nm (ε 14 300) and 220 nm (16 250); nmr ($CDCl_3$, 90 MHz) δ: 3.76 (s, 3H), 3.85 (s, 3H), 3.98 (d, 1H, J = 18.0 Hz), 5.25 (d, 1H, J = 7.0 Hz), 5.48 (d, 1H, J = 18.0 Hz), 6.93 (d, 1H, J = 7.0 Hz), and 7.10–7.56 (m, 4H). *Anal.* calcd. for $C_{16}H_{14}O_4N_2$: C 64.42, H 4.73, N 9.39; found: C 64.52, H 4.71, N 9.20.

Thermolysis of dimethyl spiro[2,3-diazabicyclo[3.1.0]hex-2-ene-6,1′-indene]-1,5-dicarboxylate (12) in benzene

A solution containing 80 mg of **12** in 25 mL of anhydrous benzene was heated in a sealed tube at 110°C for 10 min. The solvent was removed under reduced pressure and the residue was chromatographed on a silica gel column using a 10% acetone–hexane mixture as the eluent. The first material to be eluted from the column contained 443 mg of a pale yellow oil whose structure was assigned as *exo*-dimethyl spiro[2,3-diazabicyclo[3.1.0]hex-2-ene-6,1′-indene]-1,5-dicarboxylate (**13**); ir (neat: 2990, 1730, 1530, 1450, 1430, 1260, 1120, and 780 cm^{-1}; uv (95% ethanol): 242 (ε 14 420) and 215 nm (22 050); nmr (CCl_4, 90 MHz) δ: 3.73 (s, 3H), 3.87 (s, 3H), 5.13 (d, 1H, J = 18.0 Hz), 5.47 (d, 1H, J = 18.0 Hz), 6.20 (d, 1H, J = 7.0

[3]All melting points and boiling points are uncorrected. Elemental analyses were performed by Atlantic Microlabs, Atlanta, GA. The infrared absorption spectra were determined on a Perkin–Elmer 467 infrared spectrophotometer. The ultraviolet absorption spectra were measured with a Cary Model 14 recording spectrophotometer by using 1-cm matched cells. The proton magnetic resonance spectra were determined at 90 MHz by using a Varian EM-390 spectrometer. Mass spectra were determined with a Finnegan 4000 mass spectrometer at an ionizing voltage of 70 eV.

[4]The sterochemistry of **11** is plausible but not proven.

Hz), 6.60–7.30 (m, 5H); *m/e*: 298 (M^+), 270, 211, 210, and 152. *Anal.* calcd. for $C_{16}H_{14}N_2O_4$: C 64.42, H 4.73, N 9.39; found: C 64.40, H 4.75, N 9.30.

A solution containing 100 mg of **12** in 10 mL of benzene was also heated in a sealed tube at 145°C for 35 min. The solvent was removed under reduced pressure and the residue was chromatographed on a medium pressure chromatography column using a 10% acetone–hexane mixture as the eluent. The first fraction contained 80 mg of a yellow oil whose structure was assigned as 1-(methyl diazoacetate)-1-(methyl ethylene-1-acetate)indene (**14**); ir (neat): 3400, 2130, 1720, 1440, 1315, 1210, 1180, 1130, and 860 cm^{-1}; uv (95% ethanol): 250 (ε 11 030) and 210 nm (26 530); nmr (CCl_4, 90 MHz) δ: 3.70 (s, 3H), 3.76 (s, 3H), 5.70 (s, 1H), 6.03 (s, 1H), 6.73 (d, 1H, J = 5.0 Hz), 6.83 (d, 1H, J = 5.0 Hz), 7.06–7.33 (m, 3H), and 7.60–7.77 (m, 1H); *m/e*: 270, 212, 180, 179, 168, 167, 146 (base), and 145. *Anal.* calcd. for $C_{16}H_{14}O_4N_2$: C 64.42, H 4.73, N 9.39; found: C 64.62, H 4.78, N 9.16.

Reaction of dimethyl spiro[2-cyclopropene-1-1′-[1H]indene]-2,3-dicarboxylate (8) with diazopropane

To a solution containing 40 mg of **8** in 20 mL of anhydrous ether at 0°C was slowly added an ether solution of diazopropane until the orange color persisted. The mixture was allowed to stir for 12 h and the solvent was removed under reduced pressure. The residue was chromatographed on a silica gel column using a 10% acetone–hexane mixture as the eluent. The major fraction contained 51 mg (98%) of a white crystalline solid, mp 114–115°C, whose structure was assigned as dimethyl spiro[2,3-diazo-4,4-dimethylbicyclo[3.1.0]hex-2-ene-6,1′-[1*H*]indene]-1,5-dicarboxylate (**16**); ir (KBr): 3000, 1740, 1450, 1430, 1270, 1240, 1200, and 1080 cm^{-1}; uv (95% ethanol): 232 nm (ε 19 010); nmr (CCl_4, 90 MHz) δ: 1.33 (s, 3H), 1.60 (s, 3H), 3.62 (s, 3H), 3.83 (s, 3H), 5.49 (d, 1H, J = 6.0 Hz), 6.90 (d, 1H, J = 6.0 Hz), and 7.10–7.40 (m, 4H). *Anal.* calcd. for $C_{18}H_{18}N_2O_4$: C 66.24, H 5.56, N 8.58; found: C 66.18, H 5.63, N 8.31.

Thermal rearrangement of dimethyl spiro[2-cyclopropene-1,1′-[1H]-indene]-2,3-dicarboxylate (8) in benzene

A solution containing 60 mg of **8** in 100 mL of anhydrous benzene was heated in a sealed tube at 176°C for 30 min. The solvent was removed under reduced pressure and the residue was chromatographed by hplc on a Zorbax-Cn preparative column using a 3% acetone–hexane mixture. The major component contained 28 mg of a yellow oil whose structure was assigned as dimethyl 2a*H*-cyclopent[*c,d*]-inden-1,2-dicarboxylate (**40**); ir (neat): 2990, 1720, 1700, 1430, 1280, 1100, 900, 770, and 720 cm^{-1}; uv (95% ethanol): 320 (ε 4,100), 275 (6,160), 245 (8,210), 238 (8,360), and 215 nm (10 560); nmr (CCl_4, 90 MHz) δ: 3.69 (s, 3H), 3.83 (s, 3H), 5.18 (s, 1H), 6.75 (d, 1H, J = 5.5 Hz), and 7.15–7.46 (m, 4H); *m/e*: 256 (M^+), 241, 225, and 166. *Anal.* calcd. for $C_{15}H_{12}O_4$: C 70.30, H 4.72; found: C 70.15, H 4.69.

Reaction of dimethyl spiro[2-cyclopropene-1,1-[1H]indene]2,3-dicarboxylate (8) with chloroacetaldoxime

To a solution containing 200 mg of **8** and 80 mg of α-chloroacetaldoxime and 20 mL of anhydrous ether at 0°C was slowly added 100 mg of triethylamine. The mixture was stirred at 0°C for 1 h and the solution was filtered in order to remove the triethylamine hydrochloride salt. The solvent was removed under reduced pressure, leaving behind 240 mg of a pale yellow oil which was identified as dimethyl spiro[4-methyl-2-oxa-3-azabicyclo[3.1.0]hex-3-ene-6,1′-indene]-1,5-dicarboxylate (**17**); ir (neat): 3000, 1760, 1450, 1390, 1280, 1240, 1210, 1110, 1090, 940, 870, and 750 cm^{-1}; uv (95% ethanol): 247 (ε 13 770) and 210 nm (14 910); nmr (CCl_4, 90 MHz) δ: 2.03 (s, 3H), 3.70 (s, 6H), 5.80 (d, 1H, J = 6.0 Hz), 6.90 (d, 1H, J = 6.0 Hz), and 6.98–7.23 (m, 4H); ^{13}C nmr ($CDCl_3$, 30 MHz) δ: 12.28 (q), 42.80 (s), 53.16 (q), 58.54 (s), 79.10 (s), 122.31 (d), 124.87 (d), 125.19 (d), 127.68 (d), 129.29 (d), 134.75 (d), 137.00 (s), 145.27 (s), 157.32 (s), and 162.70 (s); *m/e*: 272, 213 (base), 154 and 114. *Anal.* calcd. for $C_{17}H_{15}NO_5$: C 65.17, H 4.82, N 4.47; found: C 65.09, H 4.76, N 4.53.

Chromatography of this material on a silica gel column using a 10% acetone–hexane mixture as the eluent resulted in an epimerization reaction to give *endo*-dimethyl spiro[4-methyl-2-oxa-3-azabicyclo-[3.1.0]-hex-3-ene-6,1′-indene]-1,5-dicarboxylate (**18**); ir (neat): 3000, 1750, 1440, 1380, 1280, 1240, 1110, 870, and 730 cm^{-1}; uv (95% ethanol): 242 (ε 11 050) and 221 nm (10 730); nmr (CCl_4, 90 MHz) δ: 2.1 (s, 3H), 3.80 (s, 3H), 3.83 (s, 3H), 6.57 (d, 1H, J = 6.0 Hz), 6.83 (d, 1H, J = 6.0 Hz), and 7.00–7.45 (m, 4H); ^{13}C nmr ($CDCl_3$, 20 MHz) δ: 12.46 (q), 40.26 (s), 53.40 (q), 58.87 (s), 84.49 (s), 122.31 (d), 122.72 (d), 125.50 (d), 128.18 (d), 131.18 (d), 132.27 (d), 136.12 (s), 145.51 (s), 154.67 (s), 163.51 (s), and 164.72 (s); *m/e*: 272, 213 (base), 154, and 114. *Anal.* calcd. for $C_{17}H_{15}NO_5$: C 65.17, H 4.82, N 4.47; found: C 65.10, H 4.68, N 4.31.

A solution containing 100 mg of **17** (or **18**) in 10 mL of anhydrous benzene was heated at 160°C for 10 min. The solvent was removed under reduced pressure leaving behind a pale oil whose structure was assigned as pyruvate **20**;[5] ir (neat): 3000, 1730, 1700, 1600, 1450, 1380, 1310, 1240, 1150, 1050, and 750 cm^{-1}; uv (95% ethanol): 245 (ε 5,900) and 247 nm (16 550); nmr (CCl_4, 90 MHz) δ: 3.83 (s, 3H), 3.87 (s, 3H), 6.87 (d, 1H, J = 6.0 Hz), 7.00–7.20 (m, 4H), and 7.35 (d, 1H, J = 6.0 Hz); ^{13}C nmr ($CDCl_3$, 20 MHz) δ: 52.77 (q), 53.61 (q), 126.31 (s), 126.88 (d), 127.04 (d), 127.44 (s), 131.36 (d), 131.78 (d), 133.30 (s), 140.37 (d), 141.32 (d), 144.54 (s), 152.89 (d), 154.25 (d), 182.92 (s), and 185.15 (s); *m/e*: 272 (M^+), 213 (base), 154, and 114. *Anal.* calcd. for $C_{15}H_{12}O_5$: C 66.17, H 4.44; found: C 66.03, H 4.27.

Reaction of diazoindene (1) with methyl propiolate

To a solution containing 200 mg of diazoindene **1** in 20 mL of anhydrous benzene was added 200 mg of methyl propiolate. The mixture was allowed to stir at 25°C for 18 h and the red solution was filtered to give 75 mg of a white crystalline material, mp 254–255°C, whose structure was assigned as methyl-1*H*-benz[*e*]indazole-3-carboxylate (**21**); ir (KBr): 3250, 1730, 1470, 1440, 1270, 1220, 1060, 1020, 980, 820, and 760 cm^{-1}; uv (95% ethanol): 333 (ε 6,340), 317 (6,890), 292 (12 410), 281 (12 690), 270 (15 720), 255 (17 930), 237 (48 000), and 230 nm (41 380); nmr (C_5D_6, 90 MHz) δ: 4.0 (s, 3H), 7.63–7.80 (m, 3H), 8.10–8.30 (m, 2H), 8.45–8.65 (m, 1H), and 14.5 (s, 1H); *m/e*: 266 (M^+), 195, 140, and 138 (base). *Anal.* calcd. for $C_{13}H_{10}N_2O_2$: C 69.01, H 4.46, N 12.38; found: C 69.21, H 4.47, N 12.40.

The solvent was removed from the mother liquor and the residue was chromatographed on a medium pressure silica gel column using a 5% acetone–hexane mixture as the eluent. The major diazo compound isolated from the column (120 mg) was assigned the structure of methyl (*Z*)-diazo-1*H*-inden-1-ylidenepropanoate (**24**) on the basis of its spectral data; ir (neat): 3300, 2110, 1720, 1620, 1440, 1400, 1310, 1250, 1220, and 1100 cm^{-1}; uv (95% ethanol): 363 (ε 15 790), 298 (12 680), 287 (12 620), 252 (14 660), 245 (14 150) and 210 nm (28 990); nmr (CCl_4, 90 MHz) δ: 3.83 (s, 3H), 6.56 (d, 1H, J = 6.0 Hz), 6.66 (s, 1H), 6.86 (s, 1H, J = 6.0 Hz), 7.00–7.33 (m, 3H), and 7.46–7.66 (m, 1H).

A solution containing 150 mg of the above oil in 10 mL of benzene was heated in a sealed tube at 178°C for 12 h. The solvent was removed under reduced pressure and the residue was chromatographed to give 135 mg of methyl spiro[3a,7a-dihydroindene-1,1′-indene]-3-carboxylate (**26**); ir (neat: 2990, 2900, 1720, 1620, 1440, 1330, 1230, 1110, 1090, and 960 cm^{-1}; uv (95% ethanol): 258 (ε 11 240) and 218 nm (27 720); nmr (CCl_4, 90 MHz) δ: 3.45 (dd, 1H, J = 12.0, J = 5.0 Hz), 3.72 (s, 3H), 4.11 (brd, 1H, J = 12.0 Hz), 5.10–5.26 (m, 1H), 5.66–5.86 (m, 3H), 6.16 (d, 1H, J = 6.0 Hz), 6.22 (brs, 1H), 6.58 (d, 1H, J = 6.0 Hz), and 7.00–7.30 (m, 4H); ^{13}C nmr ($CDCl_3$, 20 MHz) δ: 43.83 (d), 44.86 (d), 51.54 (q), 70.96 (s), 121.16 (d), 121.72 (d), 122.47 (d), 123.01 (d), 124.22 (d), 125.51 (d), 127.45 (d), 131.10 (d), 139.64 (d), 139.87 (s), 144.29 (s), 147.50 (d), 148.87 (s), 164.69 (s). *Anal.* calcd. for $C_{19}H_{16}O_2$: C 82.58, H 5.84; found: C 82.20, H 5.80.

The next component isolated from the chromatography of the resi-

[5]The stereochemistry of **20** is unknown.

due derived from diazoindene with methyl propiolate contained 26 mg of methyl pyrazolo[1,5-*a*]quinoline-3-carboxylate (**22**): ir (neat): 1710, 1540, 1450, 1380, 1320, 1280, 1220, 1200, 1170, 1100, 800, and 770 cm^{-1}; uv (95% ethanol): 335 (ε 8,500), 320 (6,860), 265 (29 410), 258 (28 100), and 208 (25 000); nmr (CCl_4, 90 MHz) δ: 3.90 (s, 3H), 7.1 (d, 1H, J = 7.0 Hz), 7.60–7.80 (m, 3H), 8.25 (d, 1H, J = 7.0 Hz), 8.33 (s, 1H), and 9.80–9.93 (m, 1H); *m/e*: 226 (M^+), 195 (base), 167, 141, and 180. *Anal.* calcd. for $C_{13}H_{10}N_2O_2$: C 69.01, H 4.46, N 12.38; found: C 68.87, H 4.31, N 12.46.

The third component isolated from the column contained a mixture of isomeric diazo compounds (**23**, *Z* and *E*) which could not be separated. A solution containing 80 mg of this oil in 10 mL of benzene was heated at 178°C for 10 min. Removal of the solvent left a yellow oil which was chromatographed on a silica gel column to give 55 mg of methyl β-benzylindenylindene-β-carboxylate (**25**)[6]; ir (neat): 3090, 2980, 1720, 1460, 1440, 1240, 1040, and 760 cm^{-1}; uv (95% ethanol): 310 (ε 4,090) and 250 nm (20 460); nrm (CCl_4, 90 MHz) δ: 3.16 (brs, 2H), 3.70 (s, 3H), 5.8–6.4 (2H), 7.00–7.50 (m, 9H), ^{13}C nmr ($CDCl_3$, 20 MHz) δ: 39.16 (t), 52.36 (q), 119.17 (d), 123.89 (d), 125.25 (d), 126.31 (d), 127.80 (d), 128.51 (d), 128.39 (d), 132.01 (d), 134.85 (s), 144.20 (s), and 168.05 (s); *m/e*: 276 (M^+), 245, 217 (base), and 215. *Anal.* calcd. for $C_{19}H_6O_2$: C 82.58, H 5.84; found: C 82.70, H 5.83.

In addition, 25 mg of pyrazoloquinoline **22** was also isolated.

Reaction of diazoindene with methyl phenylpropiolate

To a solution containing 100 mg of diazoindene (**1**) in 10 mL of anhydrous cyclohexane was added 124 mg of methyl phenylpropiolate. The mixture was heated in a sealed tube at 160°C for 1 h. At the end of this time the solvent was removed under reduced pressure and the residual oil was chromatographed on a medium pressure chromatography column using a 10% acetone–hexane mixture as the eluent. The first compound isolated from the column contained 65 mg of a pale yellow oil which was identified as 1-cyclohexylindene (**30**); ir (neat): 3070, 2930, 2860, 1460, 1450, 800, 760, 750, and 720 cm^{-1}; nmr (CCl_4, 90 MHz) δ: 0.53–2.20 (m, 11H), 3.25–3.40 (m, 1H), 6.40 (dd, 1H, J = 6.0, J = 1.5 Hz), 6.20 (dd, 1H, J = 6.0, J = 2.0 Hz), and 6.90–7.43 (m, 4H); *m/e*: 198 (M^+), 116 (base), 115, and 83. *Anal.* calcd. for $C_{15}H_{18}$: C 90.85, H 9.15; found: C 90.81, H 9.10.

The next compound isolated from the column contained 30 mg of a white solid, mp 109–110°C, whose structure was assigned as methyl pyrazolo[1,5-*a*]quinoline-2-phenyl-3-carboxylate (**31**); ir: 1370, 1330, 1160, and 1110 cm^{-1}; uv (95% ethanol): 337 (ε 6,400), 321 (5,700), and 265 nm (40 515); nmr (CCl_4, 90 MHz) δ: 3.70 (s, 3H), 6.93 (d, 1H, J = 8.0 Hz), 7.20–7.63 (m, 8H), 8.16 (d, 1H, J = 8.0 Hz), and 9.10–9.30 (m, 1H); *m/e*: 302 (M^+), 271 (base), 244, 243, and 140. *Anal.* calcd. for $C_{19}H_{14}N_2O_2$: C 75.48, H 4.67, N 9.27; found: C 75.36, H 4.72, N 9.20.

Reaction of diazoindene with methyl acrylate

To a 100-mg sample of diazoindene (**1**) was added 129 mg of methyl acrylate. After stirring for 6 h at 25°C, the reaction mixture was chromatographed on a medium pressure column using a 5% acetone–hexane mixture as the eluent. The first compound isolated contained 88 mg (63%) of a colorless oil whose structure was assigned as methyl *cis*-spiro[cyclopropane-1,1′-[1*H*]indene]-2-carboxylate (**32**); ir (neat): 3050, 2975, 1740, 1460, 1440, 1390, 1320, 1280, 1180, 1090, 1070, 1000, 960, 940, 850, and 820 cm^{-1}; uv (95% ethanol): 290 (ε 960), 272 (1,330), 245 (5,790), and 227 nm (26 060); nmr (CCl_4, 90 MHz) δ: 1.80 (dd, 1H, J = 8.5 Hz, J = 5.5 Hz), 2.23 (dd, 1H, J = 6.5 Hz, J = 5.5 Hz), 2.60 (dd, 1H, J = 8.5 Hz, J = 6.5 Hz), 3.63 (s, 3H), 6.53 (d, 1H, J = 6.0 Hz), 6.83 (d, 1H, J = 6.0 Hz), and 6.90–7.40 (m, 4H); ^{13}C nmr ($CDCl_3$, 20 MHz) δ: 19.37 (t), 28.46 (d), 40.20 (s), 51.68 (qd), 117.45 (d), 121.45 (d), 124.61 (d), 135.36 (d), 143.47 (s), 145.56 (s), and 171.82 (s); *m/e*: 200 (M^+), 185, 169, 168, 141 (base), 128, and 115. *Anal.* calcd. for $C_{13}H_{12}O_2$: C 77.98, H 6.04; found: C 77.82, H 6.09.

The next component isolated from the column contained 48 mg (32%) of a colorless oil whose structure was assigned as methyl *trans*-spiro[cyclopropane-1,1′-[1*H*]indene]-2-carboxylate (**33**); ir (neat): 3100, 3000, 1730, 1400, 1390, 1360, 1280, 1210, 1170, 1090, 1020, 940, 840, 810, 760, and 720 cm^{-1}; uv (95% ethanol): 300 (ε 1,500), 290 (1,880), 263 (5,640), and 230 nm (21 430); nmr (CCl_4, 90 MHz) δ: 1.80 (dd, 1H, J = 8.5 Hz, J = 4.5 Hz), 2.19 (dd, 1H, J = 7.5 Hz, J = 4.5 Hz), 2.60 (dd, 1H, J = 8.5 Hz, J = 7.5 Hz), 2.52 (s, 3H), 5.89 (d, 1H, J = 5.7 Hz), 6.78 (d, 1H, J = 5.7 Hz), and 6.97–7.48 (m, 4H); ^{13}C nmr ($CDCl_3$, 20 MHz) δ: 17.66 (t), 27.76 (d), 40.21 (s), 51.26 (q), 121.35 (d), 121.45 (d), 124.57 (d), 126.28 (d), 130.00 (d), 139.07 (d), 142.20 (s), 144.44 (s), and 169.90 (s); *m/e*: 200 (M^+), 169, 168, and 115 (base). *Anal.* calcd. for $C_{13}H_{12}O_2$: C 77.98, H 6.04; found: C 77.73, H 6.09.

Reaction of diazoindene with diethylfumarate

To a solution containing 200 mg of diazoindene in 10 mL of anhydrous benzene was added 240 mg of diethylfumarate. After stirring for 53 h at 25°C, the solvent was removed under reduced pressure and the resulting residue was chromatographed on a silica gel column using a 1% acetone–hexane solution as the eluent. The first compound isolated from the column contained 320 mg (82%) of a white solid, mp 91–92°C, whose structure was assigned as diethyl *trans*-spiro[cyclopropane-1,1′-indene]-2,3-dicarboxylate (**34**); ir (KBr): 3010, 1730, 1450, 1370, 1330, 1310, 1280, 1210, 1160, 1080, 1020, and 850 cm^{-1}; uv (95% ethanol): 295 (ε 1,420), 260 (2,960), and 232 nm (25 800); nmr (CCl_4, 90 MHz) δ: 1.15 (t, 3H, J = 6.0 Hz), 1.23 (t, 3H, J = 6.0 Hz), 3.25 (s, 2H), 4.07 (q, 2H, J = 6.0 Hz), 4.16 (q, 2H, J = 6.0 Hz), 6.46 (d, 1H, J = 6 Hz), 6.83 (d, 1H, J = 6.0 Hz), and 7.00–7.52 (m, 4H); *m/e*: 286 (M^+), 241, 240, 213, 168, and 139 (base). *Anal.* calcd. for $C_{17}H_{18}O_4$: C 71.31, H 6.34; found: C 71.21, H 6.28.

Reaction of diazoindene with nitroethylene

To a solution containing 215 mg of diazoindene in 10 mL of benzene was added 200 mg of nitroethylene. After stirring for 4 h the solvent was removed under reduced pressure and the residue was chromatographed on a medium pressure chromatography column using a 1% acetone–hexane solution as the eluent. The first component contained 169 mg (67%) of a colorless oil whose structure was assigned as 2-nitrospiro[cyclopropane-1,1′-[1*H*]indene] (**35**); ir (neat): 3230, 1560, 1460, 1420, 1370, 1220, 1090, 1080, 1000, 960, 880, 820, and 740 cm^{-1}; uv (95% ethanol): 298 (ε 1,990) and 242 nm (17 340); nmr (CCl_4, 90 MHz) δ: 2.00 (t, 1H, J = 6 Hz), 2.86 (t, 1H, J = 6 Hz), 4.93 (brd, 1H, J = 6 Hz), 6.45 (d, 1H, J = 5.7 Hz), 6.80–7.45 (m, 5H); *m/e*: 187 (M^+), 158, 144, 141, 139 (base), 128, and 115. *Anal.* calcd. for $C_{11}H_9NO_2$: C 70.58, H 4.85, N 7.48; found: C 70.35, H 4.87, N 7.33.

The second component to be eluted from the column contained 70 mg (28%) of a colorless oil whose structure was assigned as the isomeric 2-nitro-spiro[cyclopropane-1,1[1*H*]indene] (**36**); ir (neat): 3040, 1560, 1470, 1430, 1370, 1210, 1100, 960, 860, 820, and 770 cm^{-1}; uv (95% ethanol): 301 (ε 2,190) and 246 nm (11 700); nmr (CCl_4, 90 MHz) δ: 2.01 (dt, 1H, J = 6.5 Hz, J = 2.0 Hz), 2.63 (dt, 1H, J = 6.5 Hz, J = 2.0 Hz), 4.83 (brt, 1H, J = 6.5 Hz), 5.80 (brd, 1H, J = 6.5 Hz), 6.82 (d, 1H, J = 6.5 Hz), and 7.00–7.40 (m, 4H); *m/e*: 187 (M^+), 158, 141 (base), and 115. *Anal.* calcd. for $C_{11}H_9NO_2$: C 70.58, H 4.85, N 7.48; found: C 70.30, H 4.86, N 7.33.

Acknowledgments

We wish to thank the National Institute of Health for generous support of this work. A.P. also wishes to thank the organic faculty at the University of Wurzburg for their gracious hospitality during his stay at the Institute as an Alexander von Humboldt Senior Awardee. Use of the high field nmr spectrometer used in these studies was made possible through a NSF equipment grant.

[6]The stereochemistry of compounds **23–25** is unknown.

Structural effects on reactivity in intramolecular catalysis. The hydrolysis of *N*-alkylated monoamides derived from norbornene-2,3-dicarboxylic acid

RONALD KLUGER AND MICHAEL BRANDL

Lash Miller Laboratories, Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received April 27, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

RONALD KLUGER and MICHAEL BRANDL. Can. J. Chem. **62**, 2515 (1984).

Monoamides of 2,3-*endo-cis*-5-norborene dicarboxylic acid (compounds **1**–**5**) were prepared by addition of primary alkyl amines (*n*-propyl-, 2-methoxyethyl-, 2-fluoroethyl-, 2,2-difluoroethyl-, 2,2,2-trifluoroethyl-) to 2,3-*endo-cis*-5-norborene dicarboxylic anhydride. The rates of hydrolysis of each compound in solutions whose acid concentration ranged from 0.01 *M* to 9 *M* were determined. Rates increase with acidity above 0.1 *M* until a maximum rate is achieved in strong acid. The results are consistent with a mechanism involving intramolecular catalysis of the hydrolysis of the amide by the adjacent carboxylic acid. The dependence of rate on acidity can be interpreted in terms of a multistep mechanism involving formation of an intramolecular tetrahedral adduct, tautomerization of the adduct, and expulsion of the amine to give the anhydride. The identity of the rate-determining step is a function of the basicity of the substrate and the acidity of the medium. Analysis of the data in terms of the proposed mechanism suggests that the effective molarity of the groups involved in tautomerization of the tetrahedral internal addition intermediate is higher than in other rigid systems which lack the norbornene structure. It is proposed that ring strain and rotational entropy control cyclization and elimination steps. Interactions of the solvent with the entire substrate control reorganization of the intermediate. Conjugation of the interacting functional groups does not appear to have a significant effect upon their reactivity.

RONALD KLUGER et MICHAEL BRANDL. Can. J. Chem. **62**, 2515 (1984).

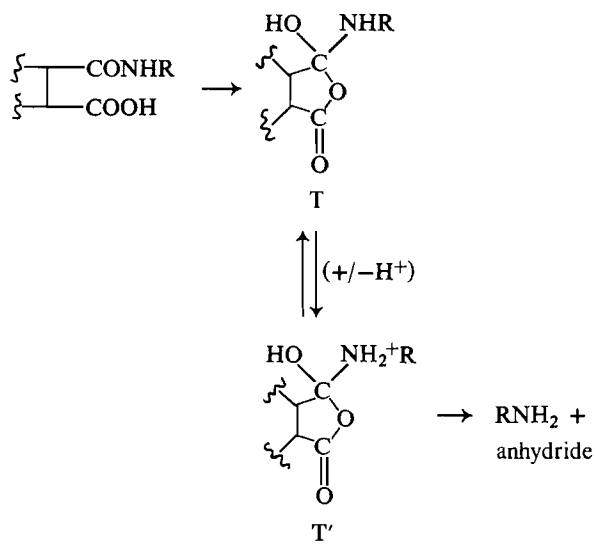
Faisant réagir des amines aliphatiques primaires (*n*-propyl-, méthoxy-2 éthyl-, fluoro-2 éthyl-, difluoro-2,2 éthyl- et trifluoro-2,2,2 éthyl-) sur l'anhydride de l'acide norbornène-5 dicarboxylique-2,3 (*endo, cis*), on a préparé les monoamides de l'acide norbornène-5 dicarboxylique-2,3 (*endo, cis*) (composés **1** à **5**). On a déterminé les vitesses d'hydrolyse de chacun de ces composés dans des solutions dont la concentration en acide variait de 0,01 à 9 *M*. Les vitesses augmentent avec une augmentation de l'acidité (au-dessus de 0,1 *M*) jusqu'à ce qu'elles atteignent un maximum en milieu fortement acide. Ces résultats sont en accord avec un mécanisme impliquant une catalyse intramoléculaire, due à l'acide carboxylique voisin, lors de l'hydrolyse de l'amide. On peut interpréter la relation qui existe entre les vitesses et l'acidité en faisant appel à un mécanisme en plusieurs étapes impliquant la formation d'un adduit tétraédrique intramoléculaire, une tautomérisation de l'adduit et l'expulsion de l'amine pour donner l'anhydride. La nature de l'étape déterminante est une fonction de la basicité du substrat et de l'acidité du milieu. L'analyse des données en relation avec le mécanisme proposé suggère que la molarité efficace des groupes impliqués dans la tautomérisation de l'intermédiaire tétraédrique provenant d'une addition interne est plus élevée que dans d'autres systèmes rigides qui ne comportent pas la structure norbornène. On suggère que les tensions de cycle et l'entropie de rotation sont les facteurs qui contrôlent les étapes de cyclisation et d'élimination. Les interactions du solvant avec l'ensemble du substrat contrôleraient la réorganisation de l'intermédiaire. Il ne semble pas que la conjugaison entre les groupes fonctionnels qui interagissent ait un effet important sur leur réactivité.

[Traduit par le journal]

Carboxylic acids may promote the hydrolysis of an adjacent amide through a mechanism involving intermediate formation of an anhydride (1, 2). The mechanism of this type of reaction has been investigated in detail and a number of factors which contribute to the effectiveness of the intramolecular participation phenomenon have been identified. The geometric relationship of the functional groups has been shown to be a key factor in determining the efficiency of the reaction (3). In addition, steric effects due to substituents on the departing amine cause variations in reactivity (4). The basicity of the departing amine may also have an observable effect which can be related to the detailed mechanism of the formation of the anhydride (5).

A key part of the mechanism involves conversion of an uncharged tetrahedral intermediate (**T**) to the zwitterion (**T′**) by net internal transfer of a proton. This transfer may occur with or without acid catalysis (3, 5, 6).

Kinetic analysis of the hydrolysis of amides derived from rigid systems containing neighboring amide and carboxylic acid groups has provided valuable information on the reactivity of tetrahedral intermediates. In particular, substrates which have provided information about proton transfer have been derived from acyclic conjugated monoamide monocarboxylic



acids (maleamic acids (3, 6) and 2,3-dimethylmaleamic acids (3, 5)). Since interactions between functional groups are affected by conjugation, it is important to examine in detail the kinetics of similar reactions in rigid but nonconjugated sub-

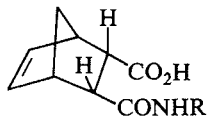
For personal use only.

strates. This allows the effects on reactivity of the structure connecting the interacting functional groups in each step to be determined. We have now determined the reactivity in acidic solutions of a series of sterically similar monoamides derived from norbornene-2,3-dicarboxylic acid (structures **1**–**5**).



1 R = $—CH_2CH_2CH_3$
2 R = $—CH_2CH_2OCH_3$
3 R = $—CH_2CH_2F$
4 R = $—CH_2CHF_2$
5 R = $—CH_2CF_3$

In this series, the groups are held in proximity while the connection does not cause the interacting groups to be conjugated. The reactivities can be analyzed in terms of the mechanisms established for related conjugated compounds. Our results indicate that the reactivity patterns of these compounds are affected by the structure of the hydrocarbon connecting the amide and acid at each stage of the reaction process. No specific effects due to conjugation of the interacting functional groups are apparent.

Materials and methods

All chemicals used for which preparations are not given were obtained from the Aldrich Chemical Company or Fisher Scientific. All inorganic materials were reagent grade.

endo-cis-5-Norbornene-2,3-dicarboxylic acid monoamides were prepared by addition of the appropriate amine to *endo-cis*-5-norbornene-2,3-dicarboxylic anhydride in ether. Amines which are available as free bases (propylamine, 2-methoxyethylamine, and 3-hydroxypropylamine) were purified by distillation and added directly to a solution of 1 equivalent of the anhydride. The amides precipitated as they formed and were collected by filtration. For the other amines, the free base was generated by stirring the hydrochloride salt (which had been recrystallized prior to use) with triethylamine in tetrahydrofuran for several hours. The mixture was then filtered and the filtrate reacted with the anhydride in ether as above. 2,2-Difluoroethylamine was prepared from 2,2-difluoroacetic acid by a procedure which has previously been reported (5). All amides thus prepared gave satisfactory nmr and ir spectra as well as elemental analyses (Galbraith Laboratories). The uv spectra of the amides, products, and intermediate anhydride were determined under the reaction conditions, and extinction coefficients were determined at 220 nm (the wavelength at which kinetic data were collected).

Kinetics

The amides were subjected to hydrolysis in aqueous solutions at 38.0°C. Dilute acid solutions (less than 1.0 *M*) were prepared by adding aqueous potassium chloride to concentrated hydrochloric acid, maintaining ionic strength at 1.0. The diluted solutions were used as standards for measurement of empirical pH values. The pH values of the solutions were determined with a glass electrode and Fisher 119 pH meter based on the calibration from diluted hydrochloric acid solutions. For solutions of acid strength 1 *M* and more, concentrated sulphuric acid was diluted with distilled water, with acidity measured by the Hammett acidity function. Solutions of phosphoric acid – sodium phosphate buffers were prepared by neutralizing 1 *M* phosphoric acid with 1 *M* sodium hydroxide solutions and diluting with 1 *M* KCl. Buffer concentrations refer to the total phosphate concentration. Phosphoric acid solutions of 1 *M* and higher concentrations were prepared by adding distilled water to 85% phosphoric acid.

Hydrolysis reactions were initiated by adding the amide, dissolved in a minimal volume of methanol or water, to the acid solution at the reaction temperature in a cuvette contained in a jacketed holder in the spectrophotometer. Temperature in the sample compartment was kept constant at 38.0 (+/− 0.1)°C with a Neslab Exacal EX-100 Circulator.

Hydrolysis reactions were followed by monitoring the decrease in absorbance at 220 nm for all compounds studied. The measurements were performed with a Varian Cary 210 spectrometer and the data were collected through a digital interface and microprocessor with a Commodore 2001 computer. The data were transferred to diskettes for storage and retrieval using a Commodore 2031 disk drive. The microprocessor-based controller for the interface was built by Comspec Communications. In all cases the reactions were followed for at least three half-lives. Observed first-order rate constants were determined from the data using a computer program based on the method of "over-relaxation" as described by Swain *et al.* (7).

Results

Kinetic data were obtained from observations of changes in absorbance due to the conversion of the amides (**1**–**5**) to norbornene dicarboxylic acid and the corresponding amine at 220 nm. Since the amides are not conjugated, there is no significant change in absorbance at longer wavelengths. The initial product of the reaction is the anhydride, which is converted to an equilibrium mixture with the dicarboxylic acid (see Scheme 1). The rate of hydrolysis of the anhydride (rate constant k') is comparable to the rate of conversion of the amide to the anhydride and amine (rate constant k_0). The observed process is also first order ($v = k_{obs}$[amide]).

$$\text{Amide} \xrightarrow{k_0} \text{amine} + \text{anhydride} \overset{k'}{\rightleftharpoons} \text{dicarboxylic acid}$$

SCHEME 1

The value of k' was determined independently, as were the extinction coefficients for each species in Scheme 1 at 220 nm. These data were substituted into the integrated rate law for consecutive first-order reactions, following the procedure reported by Wiberg and Lepse (8) for their analysis of the oxidation of benzaldehyde by chromyl acetate. We find that the observed rate constant for the hydrolysis of the anhydride, k' ($= 4.5 \times 10^{-3}\ M^{-1}\ s^{-1}$), is independent of acidity. Our first trial value for k_0 for each amide at each acidity is the observed rate constant, k_{obs}. We then computed a best fit (least squares) of the observed absorbance changes to that predicted from the Wiberg–Lepse treatment by varying k_0. The absorbance change for the anhydride to acid conversion is small compared to that for the amide cleavage. Since the difference between k_{obs} and k_0 depends on the relative degree of spectral change in the two steps, the final values of k_0 were close to each k_{obs}.

The kinetic results for the hydrolysis of amides **1**–**5** are summarized in Fig. 1 and Table 1. The plot relates the first-order rate constant for cleavage of the amides (k_0) to the acidity of the solution. Since the study involves strongly acidic media as well as dilute acids, acidity is reported as measured by the Hammett acidity function, H_0 (9), in strongly acidic solutions. The rates increase with acidity to varying extents and reach maxima. For **5**, which is the least basic substrate, the maximum appears just to be reached at $H_0 = -3$. Data collected for the reaction of **5** in 9 *M* sulfuric acid (beyond the scale of Fig. 1, presented in Table 1) were used to determine the maximum. The maxima are clearly attained for the other amides.

Since the reactions of the least basic compounds are subject to hydronium catalysis, we wished to determine if other Bronsted acids will accelerate the reaction. We note that catalysis is observable only at hydronium ion concentrations near

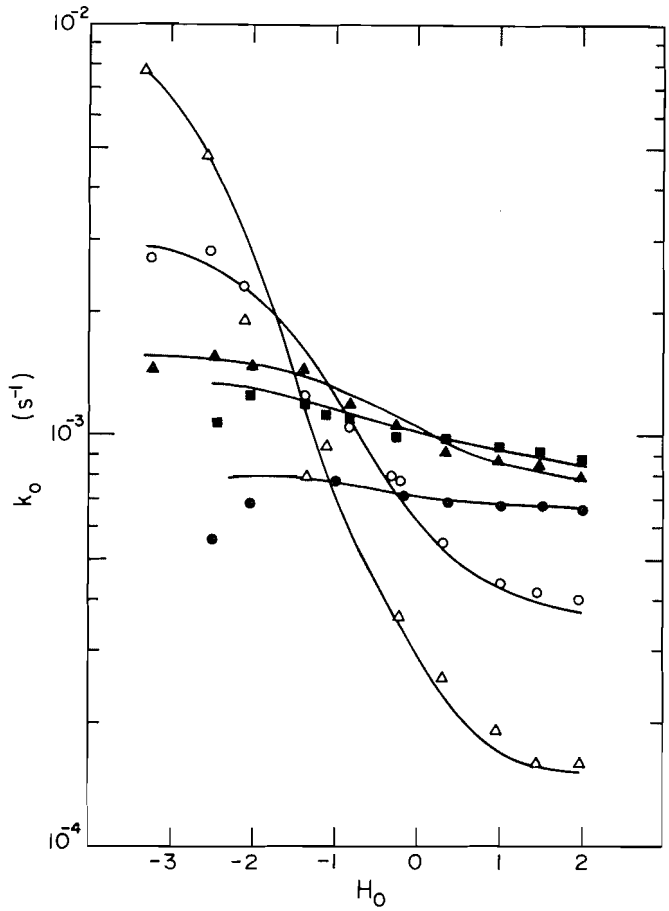

FIG. 1. Dependence on acidity of first-order rate constant for conversion of **1** (●), **2** (■), **3** (▲), **4** (○), and **5** (△) to norbornene-2,3-dicarboxylic acid anhydride and the corresponding amine at 38°C. The acidity scale is the Hammett acidity function at acid concentrations above 1 *M*. The lines are plots of eq. [1] using parameters in Tables 2 and 3.

1 *M* and above, indicating that the "uncatalyzed" mechanism competes very effectively. Since the hydrolysis of **5** shows the largest susceptibility to hydronium ion catalysis, we studied the effects of phosphoric acid and phosphate buffers on its hydrolysis. The results of these experiments are presented in Table 1. The rates do not increase at low phosphoric acid concentrations. At higher concentrations, the rates follow the H_0 correlation as in Fig. 1.

The data in Fig. 1 are consistent with the mechanism in Scheme 2. This mechanism is similar to mechanisms for other reactions in which an adjacent carboxylic acid promotes the hydrolysis of an amide (3, 5).

This mechanism involves a branch via specific acid − general base catalysis (k_5k_4) as well as a direct equivalent of intramolecular proton transfer (k_2). These branches were proposed by Kirby and co-workers to explain the observation of buffer catalysis in reactions of alkylated maleamic acids (3).

An expression for observed first-order rate constants based on Scheme 2 is presented in eq. [1], which depends explicitly on hydrogen ion activity.

$$[1] \quad k_0 = (k_2k_3K_1 + k_3k_4K_5[H^+]K_1)/(k_3 + k_{-2} + k_{-4}[H^+])$$

Equation [1] contains seven dependent variables (rate constants and equilibrium constants). Many of these parameters can be estimated independently. The equilibrium constants K_5 and K_2 (that is, k_2/k_{-2}) are dissociation constants which can be estimated using linear free energy relationships following the procedure used in an earlier study (5). The value of K_4 is the product of the other two equilibria. The rate constant k_{-4} is for a diffusion-controlled proton transfer and therefore should have a value of about $10^{10}\ M^{-1}\ s^{-1}$ (10). The resulting values are presented in Table 2.

TABLE 1. First-order rate constants (k_0) for conversion of **5** to norbornene dicarboxylic acid anhydride and trifluoroethylamine at 38°C[a]

Buffer or acid	Concentration	H_0 or pH[b]	$k_0 \times 10^4$, s^{-1}
HCl	0.01 *M*	2.15	1.65
H_3PO_4/NaH_2PO_4	0.2 *M*	2.15	1.64
	0.4 *M*	2.15	1.66
	0.8 *M*	2.15	1.68
	1.0 *M*	2.15	1.67
	0.3 *M*	0.8	1.97
	0.5 *M*	0.8	1.96
	0.7 *M*	0.8	1.90
H_3PO_4	10%	0.75	2.24
	20%	0.3	2.85
	30%	−0.12	4.03
	44%	−0.6	4.86
	52%	−1	8.08
H_2SO_4	9 *M*	−4.5	200

[a]Rate constants listed are for data that does not duplicate results presented in Fig. 1. Ionic strength was maintained at 1.0 for all concentrations of buffers and acids less than 1.0 *M*.

[b]"pH" as measured by glass electrode for first eight points. H_0 values are from ref. 17.

Other rate and equilibrium constants can be obtained by fitting the data to appropriate versions of eq. [1]. At low acidity, we observe that the rate for all substrates is independent of acidity. Thus, the pathway involving the protonated intermediate, $\mathbf{TH}^+$ does not make a significant contribution under these conditions.

$$[2] \quad k_0 = K_1k_2k_3/(k_3 + k_{-2})$$

In more acidic solutions, terms containing proton concentrations become dominant so that eq. [1] simplifies to eq. [3].

$$[3] \quad k_0 = K_1K_2k_3$$

As acidity is increased, the observed rate constants for each substrate increase to varying extents. At the point where the rate is twice that at low acidity, flux through the protonated and neutral intermediates is equal. Using eq. [1] with the data for compound **5**, we derive the acidity at which the fluxes through the two pathways are equal. This acidity gives the ratio of rate constants.

$$[4] \quad [H^+] = k_2/k_4K_5 = k_{-2}/k_{-4}$$

The terms k_{-2} and k_{-4} are thermodynamically favorable proton transfers. Since k_{-4} represents an intermolecular process, we set its value at $10^{10}\ M^{-1}\ s^{-1}$ (10). The values of k_{-2} and k_{-4} should be independent of the amine substituent since the rest of the molecule remains unchanged. We find k_{-2} by noting the acidity at which rates are twice the low acid minimum for **5**. The rate at this acidity must be made up of equal contributions from the acid catalysis pathway and the uncatalysed route ($k_{-2} = k_{-4}[H^+]$). Our data suggest the acidity at which rates are equal is that produced by 1 *M* sulfuric acid. Therefore, k_{-2}/k_{-4} is 1 *M*. The data in Fig. 1 were fitted to eq. [1] using K_1 and

5	3.4×10^{2}	4.4×10^{-7}	9×10^{11}

k_3 as adjustable parameters within the restrictions we have presented. The values giving the best fit to the data are presented in Table 3. The curves in Fig. 1 are plots of these parameters substituted into eq. [1].

Discussion

Reactivity patterns

The amides derived from the least basic amines are less reactive than those derived from the more basic amines in dilute acid; the order of reactivity is reversed in strong acid. This is consistent with the mechanisms presented in Scheme 2. The intermediate formed by the addition of the carboxyl group (**T**) must become protonated on its nitrogen atom and its hydroxyl group must be deprotonated in order for the amine to be expelled (**T′**). In solutions of low acidity, the tautomeric shift of a proton from the hydroxyl group to the amino group is the most effective route for generating the alkyl ammonium ion. If expulsion of the amine from the zwitterionic intermediate is completely rate determining for a particular substrate, then addition of acid to the solution will not further increase the rate of reaction. Therefore, we observe very little acid catalysis for the derivatives with the most basic leaving groups. However, if proton transfer, k_2, is rate determining or partly rate determining, then addition of acid can produce a more effective reaction through the conjugate acid of T. This will lead to an increase in rate with acidity until the rate-determining step becomes elimination, k_3. At this point, the rate should not increase with additional acidity, which is consistent with the patterns in Fig. 1.

The rate-determining step in the acid-catalyzed process in Scheme 2 is removal of the hydroxyl proton of the protonated intermediate by water to give the zwitterion. This step is a thermodynamically unfavourable proton transfer and should be subject to general base catalysis with β near unity for weak bases (3, 10). Since a prior protonation is involved, the observed phenomenon should be general acid catalysis with α near zero. As we have noted in the Results section, we do not observe buffer catalysis although the mechanism involves a step which should be subject to such catalysis. However, the uncatalysed process (k_2) is very efficient so that high acid concentrations are needed to see catalysis by acid. Furthermore, since hydronium ion is much more effective than predicted by Bronsted plots in related cases (3), it overwhelms any catalysis that we might have observed from other Bronsted acids.

Alternatively, one could interpret our results as indicating that the hydronium ion catalysis we observe is the result of a mechanism involving specific acid catalysis. However, we find that a less likely possibility. Since decomposition of the tetrahedral intermediate, rather than cyclization, is rate deter-

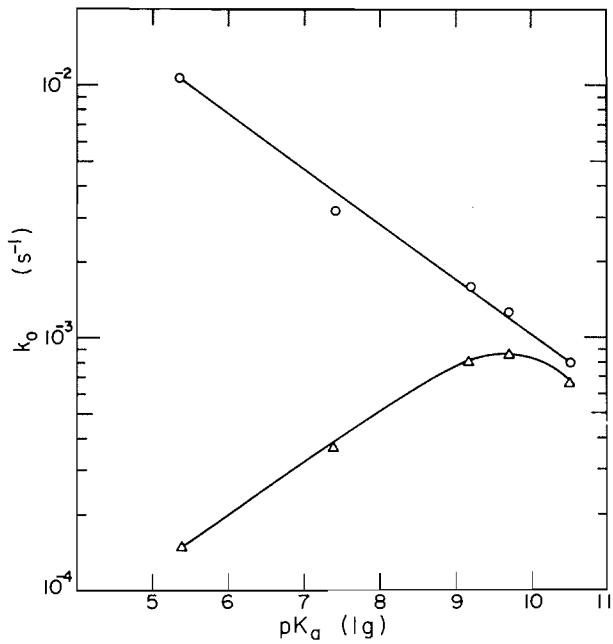

FIG. 2. The dependence of the maximal (○) and minimal (△) rate constants (k_0) upon the pK_a of the conjugate acid of the leaving amine ("lg" = leaving group) for compounds **1**–**5**. The pK_a values are listed in Table 2.

mining (3, 5), a mechanism involving specific acid catalysis must provide a means for direct decomposition of the protonated tetrahedral intermediate, $\mathbf{TH}^+$. In Fig. 2, a pK_a vs. rate plot for the rates at low acid concentration is concave downward, indicating that there is a change in rate-determining step within a common mechanism amongst the substrates. The plot for the rate maxima in high acid concentration is a straight line with the high pK_a portion in common with the plot for the minima. This suggests that acid catalysis is enhancing the rate within a mechanism involving the same intermediates as in the uncatalysed process. A specific acid catalysis route involving direct decomposition of $\mathbf{TH}^+$ would provide an alternative mechanism, resulting in all rates at high acid concentration being significantly above those at low acidity, with the greatest effect on the substrate with the poorest leaving group (**1**). This is contrary to the observed results.

Effective molarities

Effective molarity measures the relative concentrations of interacting functional groups within a molecule as the ratio of the intramolecular rate or equilibrium constant to the analogous quantity for a bimolecular reaction (11). It is a useful calibration of the efficiency of intramolecular catalysis.

The addition of a carboxylic acid to an amide in water, the bimolecular analogue of the equilibrium between **S** and **I**, has not been observed. However, an appropriate bimolecular analogue has been estimated in an earlier study from our laboratory, based on methods that have been developed by Guthrie (5, 12). Thus, it was estimated that the equilibrium constant for addition of acetic acid to dimethyl acetamide is $10^{-18}\,M^{-1}$. The equilibrium constant for the conversion of **S** to **I** can be estimated from the kinetic data we have obtained. The closest analogy to the dimethyl acetamide case is that in which n-propylamine is the leaving group in the intramolecular reaction. Since K_1 is 10^{-10}, the effective molarity of the carboxyl group in these reactions is about $10^8\,M$.

The effective molarity for the proton transfer step, k_{-2}, in the tautomerization of the intermediate, **T**, can also be estimated. The analogous bimolecular process is a thermodynamically favorable proton transfer. The rate should be diffusion controlled with a rate constant of $10^{10}\,M^{-1}\,s^{-1}$. This is k_4 in Scheme 2. Since k_{-2} is $10^{10}\,s^{-1}$, the effective molarity of the internal ammonium ion is 1 M.

These effective molarities differ from values that have been obtained for the similar hydrolysis reactions of *N*-alkyl maleamic acids and *N*-alkyl 2,3-dimethylmaleamic acids (5, 6). The effective molarity of the cyclization equilibrium, K_1, is two orders of magnitude smaller than that for the maleamic acids and four orders of magnitude smaller than for the 2,3-dimethylmaleamic acids. Intramolecular processes are most effective when there is a minimal amount of rotational entropy lost upon cyclization (11). The norbornene system should equal the maleamic acids in this respect since the interacting functional groups are held *cis* and coplanar in both systems. Beyond this, the norbornene system is subject to additional steric strain upon cyclization, due to the fusing of the additional ring onto the bicyclic system, while the maleamic acid systems will be monocyclic, relieving interactions between other substituents on the carbon–carbon double bond. It is also apparent that there is no special effect due to the conjugation of the functional groups in the maleamic acids since the norbornene derivatives, in which the connection between functional groups is saturated, show similar reaction patterns.

The effective molarity for the proton transfer step is much larger than in the monocyclic cases by about three orders of magnitude. Bernasconi *et al.* have considered the general question of effective molarities in formal 1,3-proton transfers between nitrogen and oxygen (13). The transfer in these cases involves intermediate participation by the solvent. The value of 1 M is in the upper range of possibilities that was considered. Our results suggest that the structure of the nonreacting portion of the substrate has a significant influence on the effective molarities in the reacting portion with respect to the proton transfer step.

Since the solvent is an essential participant in the 1,3 prototopic shift, it is likely that any effect that disrupts the structure of the solvent will have an effect on the rate of this process. The norbornenyl derivatives contain large hydrocarbon regions which do not fit into the hydrogen-bonded water lattice. By comparison, derivatives of maleic acid contain no large hydrocarbon region and will better accommodate themselves to aqueous solvation. The norbornenyl derivatives then may effectively direct the proton transfer away from the backbone and reduce the entropic barrier to the proton shift associated with smaller substrates.

Amine expulsion

A plot of the maximum rate constants versus pK_a of the leaving group is linear (Fig. 2). As stated earlier, this is evidence that these rates involve a common mechanism with a common rate-limiting step. The slope of the plot of log k vs. pK_a for the maximum rate constants is −0.27. This value suggests that the amine has about 0.27 units less positive charge associated with it in the transition state of the rate-determining step than it does in the initial amide (14). This is consistent with a transition state for the expulsion step in which considerable bond breaking has occurred. In the product, the amine is uncharged while in the intermediate it has a charge of +1. In the starting amide, we expect a charge of about 0.5 to 0.6 on nitrogen (14, 15).

Conclusions

Our results illustrate how the interactions of functional groups involved in intramolecular reactions are influenced by the chain which connects them. However, for amides and carboxylic acids, conjugation of the interacting functional groups appears to have no significant effect on reactivity. The principal enthalpic effects in these systems are widely recognized and can be considered in terms of buttressing and ring strain (16). However, we now see that additional complications, probably arising from perturbations of the solvent, also affect observed rates by affecting the reactivity of intermediates. As a result, we feel that further generalizations concerning rate constants for reactive intermediates must describe ranges rather than specific values of rate constants.

Received May 31, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

BRIAN A. DAWSON, ASHIM K. GHOSH, JEFFREY L. JURLINA, ARTHUR J. RAGAUSKAS, and J. B. STOTHERS. Can. J. Chem. **62**, 2521 (1984).

A simple sequence from dicyclopentadiene to the *cis,anti,cis*-tricyclopentanoid carbon skeleton of the hirsutanes is described. A key step employs a β-enolate rearrangement to generate the ring system having the desired stereochemistry. The route to the requisite ketone for this rearrangement utilizes efficient ring expansion via homoketonization.

BRIAN A. DAWSON, ASHIM K. GHOSH, JEFFREY L. JURLINA, ARTHUR J. RAGAUSKAS et J. B. STOTHERS. Can. J. Chem. **62**, 2521 (1984).

On décrit une série simple de réactions qui permettent de transformer le dicyclopentadiène en squelette carboné tricyclopentanoïde-*cis,anti,cis* des hirsutanes. L'étape clé fait intervenir une transposition β-énolique qui permet de générer le système cyclique comportant la stéréochimie appropriée. Afin d'obtenir la cétone requise pour cette transposition, on utilise une méthode efficace d'extension de cycle par le biais d'une homocétonisation.

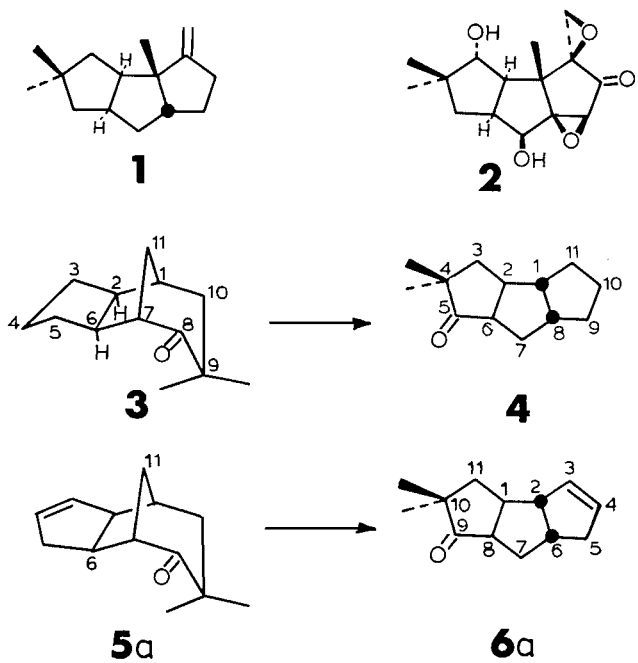
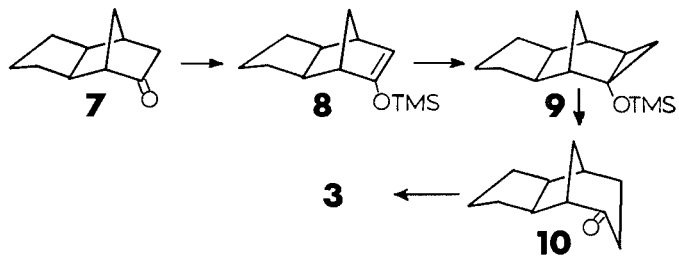
The linearly fused tricyclopentanoid ring system of *cis,anti,cis*-tricyclo[6.3.0.0^{2,6}]undecane constitutes the skeleton of several naturally occurring sesquiterpenes having antibiotic and (or) antitumor activity (1) and consequently has attracted considerable attention in recent years. Representative examples of this group of compounds are hirsutene (**1**) and coriolin (**2**). Several different syntheses have been devised for (±)-**1** (2–5), which has been considered the biosynthetic precursor of **2** and hirsutic acid (2) as originally suggested from results of study of the synthesis of the latter (6) even though **1** had not been isolated and characterized at the time. We describe here a simple stereocontrolled sequence leading from





SCHEME 1

dicyclopentadiene to **1** which employs ring expansion by ketonization of a cyclopropoxide and skeletal rearrangement through a β-enolate. A major feature of this synthesis is that the stereochemistry at three of the four chiral centres is established essentially at the outset of the sequence and the constraints are such that the β-enolate rearrangement specifically generates the correct configuration at the fourth centre exclusively. A preliminary report of this sequence has appeared (5).

The notion that the key β-enolate rearrangement could provide the desired ring system arose from our earlier results for 3,3-dimethylbicyclo[3.2.1]octan-2-one which had been found to rearrange unidirectionally to the isomeric 3,3-dimethylbicyclo[3.3.0]octan-2-one (7). As an exploratory case, the potential isomerization of 9,9-dimethyltricyclo[5.3.1.0^{2,6}]undecan-8-one (**3**) to *cis,anti,cis*-4,4-dimethyltricyclo[6.3.0.0^{2,6}]-undecan-5-one (**4**) through β-enolate formation at C-11 of **3** was examined initially. Upon finding that the conversion of **3** → **4** indeed occurs, we turned our attention to an examination of the behavior of **5***a* under the same reaction conditions, namely, *t*-BuO$^-$/*t*-BuOH at 185°C, since the transformation of **5***a* → **6***a* provides the needed functionality in the third cyclopentane ring for generation of the appropriate substitution for the hirsutene molecule.

For the initial case, ketone **3** was prepared from commercially available tricyclo[5.2.1.0^{2,6}]decan-8-one (**7**) as outlined in Scheme 1, utilizing ring expansion via ketonization of the cyclopropoxide analog (8). Treatment of **7** with lithium diisopropylamide (LDA) at −78°C followed by reaction with trimethylsilyl chloride and triethylamine gave silyl enol ether **8** in 98% yield. Cyclopropanation of **8** using a zinc–silver couple and CH_2I_2 provided the tetracyclic ether **9** in 94% yield. On the

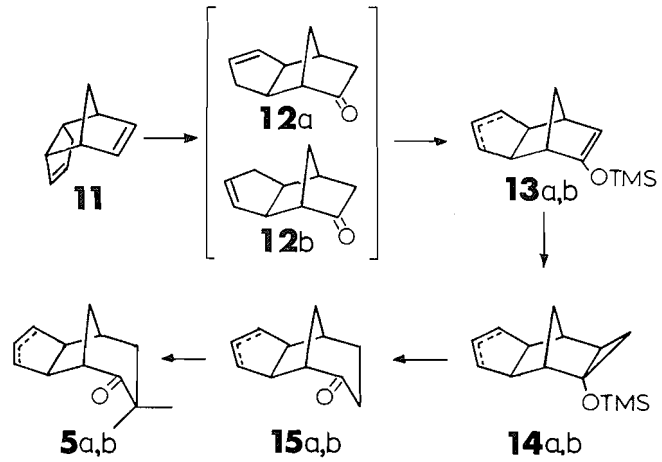

SCHEME 2

basis of our earlier results for the homoketonization of polycyclic cyclopropoxides (8), we anticipated that base-catalyzed cleavage of **9** would strongly favor ring expansion to the desired ketone **10** rather than generation of the 9-methyl derivative of **7**. This was indeed the case; upon treatment of **9** with NaOH–MeOH at 0°C a single ketone lacking methyl absorption in both its ^{1}H and ^{13}Cmr spectra was obtained in 96% yield. Dimethylation of **10** with $NaNH_2$–Et_2O–MeI (9) furnished the required ketone **3**. The ^{13}Cmr spectra of **3** and **7**–**10** have been reported previously (10).

Treatment of **3** with *t*-BuO^-/*t*-BuOH at 185°C for extended reaction times gave a neutral fraction in >90% yield which, by glc analysis, consisted of two components, readily separable by preparative glc. The ratio of the two compounds was a function of reaction time, with equal quantities apparent after ca. 120 h. One was easily identified as recovered starting material **3** while the second was a new ketone, containing a cyclopentanone moiety on the basis of its carbonyl absorption (1737 cm^{-1}, δ_C 224.6) which was distinctly different from that of **3** (1710 cm^{-1}, δ_C 218.0). Furthermore, its ^{13}Cmr spectrum contained signals for two methyl, five methylene, four methine, and one quaternary carbon which are entirely consistent with structure **4**. Although the formation of β-enolates can be envisaged by proton abstraction from C-6, -10, -11, and the methyl carbons of **3**, rearrangement via cleavage of each of these intermediates leads to a different isomeric ketone, each of which has different numbers of methyl, methylene, methine, and quaternary carbons. Only the β-enolate formed by 11-proton abstraction yields a ketone fitting the observed data. The parent system, 3,3-dimethylbicyclo[3.2.1]octan-2-one, undergoes β-enolization at the centres corresponding to C-6 and -11 in **3** (7). If rearrangement of **3** proceeded by proton abstraction at C-6, the product, 8,8-dimethyltricyclo[4.3.2.$0^{1,5}$]undecan-9-one, would have six methylene and each of two methyl, methine, and quaternary signals, contrary to the spectral data. Structure **4** was confirmed by Wolff–Kishner reduction to the corresponding hydrocarbon, as discussed later.

Experiments at 200°C revealed that the conversion of **3** → **4** is >95% complete after 140 h and the half-life for the transformation is ca. 30 h.

With clear evidence that **3** is smoothly transformed to **4** under homoenolization conditions, we turned our attention to the preparation of ketone **5** (see Scheme 2) as the key intermediate for our planned sequence leading to **1**. Dicyclopentadiene (**11**) was readily converted to **12** by reaction with HCOOH and alkaline hydrolysis (11) followed by oxidation (12); this product is a 30:70 mixture of the Δ^3- and Δ^4-isomers, **12***a* and *b*, respectively. It should be noted that, at this stage, three of the chiral centres (C-1, -2, and -6) have the stereochemistry required in the target skeleton. Treatment of **12** with LDA at −78°C followed by Me_3SiCl afforded a 30:70 mixture of **13***a*,*b*, in 95% yield, cyclopropanation of which gave **14***a*,*b* in 82% yield. For the latter step, the mole ratio of CH_2I_2/**13***a*,*b* was reduced to 1.1 from 1.7 used for the cyclopropanation of **8** → **9**; this was done to avoid reaction at the second double bond in the unsaturated series that occurs if a larger excess of CH_2I_2 is used. As in the case of **9**, ether cleavage and ketonization of **14***a*,*b* in methanolic NaOH at 0°C furnished a "single" product in the sense that a 30:70 mixture of **15***a*,*b* was obtained exclusively. It may be mentioned that with relatively short reaction times (1–2 h) and (or) at higher temperatures glc analysis reveals the presence of small amounts of the 9-methyl derivative of **12** in the ketonization product. Since these derivatives were prepared in another project (10), their identification was straightforward. While higher reaction temperatures are known to increase the proportion of the α-methyl isomers in closely related homoketonizations (8), the α-methyl derivatives can also arise from thermal decomposition of the cyclopropanols formed from TMS ethers analogous to **14**. We have found that although the TMS ethers are generally stable to glc analysis the corresponding cyclopropanols decompose on the column to give the α-methyl products exclusively. To avoid this complication, the ketonizations were performed at 0°C for relatively long reaction times (24 h). Dimethylation of **15***a*,*b* ($NaNH_2$–Et_2O–MeI) furnished the required ketone **5** as the expected 30:70 mixture of Δ^3- and Δ^4-isomers. For all products in this sequence, **5** and **12**–**15**, the mixtures of *a* and *b* isomers gave a single band in the glc traces; the composition of the mixtures was judged from the ^{13}Cmr spectra of each product, which have been reported previously (10).

The behavior of **5***a*, *b* upon reaction with *t*-BuO^-/*t*-BuOH at 185°C was very similar to that found for **3**, in that glc analysis of the neutral product indicated the presence of only two "components", each of which, of course, is a mixture of two double bond isomers. One of the components was easily shown to be the initial ketone **5**, differing from the starting material only in the proportion of *a* and *b* isomers. With increasing reaction times, the proportion approached 50:50 but a detailed study of the rate of change was not done. Since proton abstraction from C-5 (**5***a*) and C-3 (**5***b*) generates the same allylic carbanion, one can expect equilibration of the Δ^3- and Δ^4-isomers to occur under these strongly basic conditions. Because of this, separation of the isomeric mixtures **5** and **12**–**15** is unwarranted. The new component generated under these reaction conditions was also found to be an approximately 50:50 mixture of isomers (by ^{13}Cmr) which contain a five-membered ring ketone (1736 cm^{-1}, δ_C 224.7). By analogy with the results discussed earlier, β-enolate **16** could be envisaged to arise by proton abstraction from C-11 in **5** and cleavage, as indicated, to form **6**. The ^{13}C spectrum of this product contain-

For personal use only.

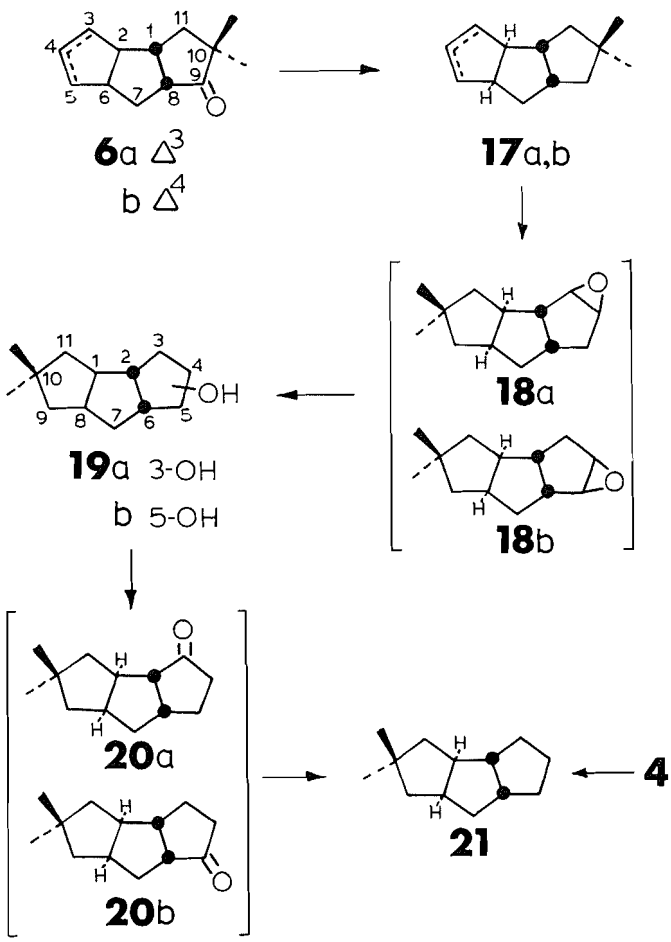
ed the expected signals for an approximately 1:1 mixture of **6***a*,*b* although there were four accidental equivalencies with two methyl, the two quaternary, both carbonyls, and a methylene and methine carbons exhibiting the same shieldings. To confirm the presence of two isomeric ketones a small sample of **6***a*,*b* was treated with LAH and the resulting mixture of alcohols, giving a single major spot on tlc, was isolated and examined by ^{13}Cmr. The ^{13}C spectrum contained two sets of thirteen signals in a ratio of ca. 55:45 with each set consisting of two methyl, three methylene, five methine, one quaternary, and two olefinic CH signals. These results are entirely consistent with the reduction of **6***a*,*b* to the corresponding alcohols, presumably having *endo*-hydroxyl groups, but their orientation was not established. At 185°C, the half-life for the conversion of **5** → **6** is ca. 225 h. A few runs were also performed at 205–210°C and exhibited a half-life of ca. 70 h; in the longest runs (150 h) at this temperature the neutral product contained 80% of **6** whereas even after >300 h at 185°C the maximum amount of **6** was ca. 65%.



Wolff–Kishner reduction of **6***a*,*b* gave **17***a*,*b* in 90% yield after isolation by column chromatography and, upon treatment with *m*-chloroperbenzoic acid, furnished a 50:50 mixture of **18***a*,*b* in 85% yield after bulb-to-bulb distillation. This mixture was treated with LAH to furnish an oily product which on the basis of its ^{13}C spectrum consisted mainly of a 1:1 mixture of the 3- and 5-alcohols together with a small amount (<5%) of a third alcohol. The total product was subsequently oxidized in 92% yield to the corresponding mixture of ketones from which samples of the ketones **20***a* and *b* were isolated by preparative hplc. For the series **6** and **17**–**20**, all attempts with glc failed to effect a separation of the isomers. Spectral data (ir, ^{1}Hmr, ^{13}Cmr) for **20***a* were found to be identical to those for the same ketone described by Little and Muller (3). Wolff–Kishner reduction of the mixture of ketones furnished a single hydrocarbon **21**, confirming that **20***b* had the same carbon skeleton. As mentioned earlier, ketone **4** also gave **21** exclusively upon Wolff–Kishner reduction, thus confirming the transformation of **3** → **4**.

Since **20***a* has previously been converted into (±)-hirsutene (3), our synthesis is complete, demonstrating the utility of a stereocontrolled β-enolate rearrangement for the generation of the *cis,anti,cis*-tricyclopentane ring system of the hirsutanes. As noted earlier, the configuration at three of the four chiral sites is established at an early stage in the sequence and the constraints of the β-enolate rearrangement are such that only the correct configuration is realized at the fourth centre upon the conversion of **5** → **6**. It can be mentioned that, in principle, resolution of the enantiomeric intermediates could be performed at an early stage in the sequence, thereby providing an asymmetric synthesis of this ring system.

Experimental

Thin-layer chromatography (tlc) was done on Kiesel gel 60 F_{254} plates. Gas–liquid chromatography (glc) was performed using a 6% FFAP on Chromosorb W (3 m × 0.6 cm) with a Varian 920 or 3700 instrument. Tetrahydrofuran (THF) and ether were distilled from Na/benzophenone before use. Pyridine and *tert*-butyl alcohol were distilled from CaH_2 and stored over 4A molecular sieves. Dicylopentadiene and *exo*-tricyclo[5.2.1.$0^{2,6}$]decan-8-one were obtained commercially (Aldrich).

Infrared spectra were recorded with a Beckman 4250 spectrophotometer and mass spectra with a Varian MAT-311A system at 70 eV (direct inlet). Routine ^{1}Hmr spectra were recorded on Varian T-60 or EM-360 instruments, while the data for pure samples were obtained using a Varian XL-200 spectrometer. The latter instrument was employed for the ^{13}C spectra (50.3 MHz) and comparison of the fully decoupled spectra with those obtained with either the APT (13) or INEPT (14) sequences served to identify the methyl, methylene, methine, and quaternary signals.

Trimethylsilyl enol ether of tricyclo[5.2.1.$0^{2,6}$]decan-8-one (8)

A solution of diisopropylamine (5.22 mL) in THF (22 mL) was cooled to −78°C and, after stirring for 10 min, n-butyllithium (12.78 mL, 2.5 *M* in hexane) was added dropwise. After the slow addition of **7** (4.0 g, 7 mmol) in THF (10 mL), the solution was stirred for 0.5 h. A quenching solution (triethylamine (1.86 mL), THF (8 mL), and chlorotrimethylsilane (5.4 mL)) was prepared in a flame-dried centrifuge tube, sealed with a syringe cap, and purged with nitrogen. After centrifugation for 10 min, the clear solution was transferred to the reaction mixture using a syringe and the mixture stirred for 1 h at −78°C before it was allowed to warm to room temperature and stirred for 3 h. The mixture was cooled to 0°C, cold saturated Na_2CO_3 solution (60 mL) was added with vigorous stirring, and the product isolated by pentane extraction (4 × 40 mL). The combined extracts were washed with saturated Na_2CO_3, then with saturated NaCl solution, dried over $MgSO_4$, and the solvent removed by evaporation. Short path distillation of the residue gave **8** (5.81 g, 98%), bp ~ 92–94°C/0.4 Torr (1 Torr = 133.3 Pa); ir ($CHCl_3$): 1610, 1315, 1250, 850 cm^{-1}. *Exact Mass* calcd. for $C_{13}H_{22}OSi$: 222.1440; found: 222.1445.

Cyclopropanation of 8 and (9)

Anhydrous ether (5 mL) and methylene iodide (2.05 g, 7.7 mmol) were added to a flame-dried flask containing Zn/Ag couple (0.88 g) and the mixture refluxed for 15 min before the addition of **8** (1.00 g, 4.5 mmol) in anhydrous ether (5 mL). After heating under reflux for 18 h, the mixture was cooled to 0° and pyridine (2 mL) was added

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

slowly. The solids were removed by filtration and washed with ether (20 mL). The ether solution was dried over Na_2SO_4 before removal of the solvent by evaporation. Bulb-to-bulb distillation of the residue gave a single product, **9** (bp ~ 70°C/0.2 Torr, 1.00 g, 94%); ir ($CHCl_3$): 1250, 840 cm^{-1}. *Exact Mass* calcd. for $C_{14}H_{24}OSi$: 236.1596; found: 236.1596.

*Tricyclo[5.3.1.0^{2,6}]undecan-8-one (**10**)*

A solution of **9** (3.47 g, 14.7 mmol) in methanolic NaOH (66 mL, 3.13 *M* in NaOH) was stirred at ice temperature for 26 h, after which time 10% NaCl solution (50 mL) was added and the product extracted with pentane (4 × 40 mL). The pentane extracts were washed with 10% NaCl (2 × 30 mL), and water (2 × 30 mL). The aqueous extracts were extracted again with pentane (2 × 50 mL) and the combined extracts dried over $MgSO_4$. Removal of the pentane gave a clear oil (2.31 g, 96%) which was >99% pure **10** by glc analysis; ir ($CHCl_3$): 1705 cm^{-1}. *Exact Mass* calcd. for $C_{11}H_{16}O$: 164.1201; found: 164.1199.

*9,9-Dimethyltricyclo[5.3.1.0^{2,6}]undecan-8-one (**3**)*

To a stirred suspension of $NaNH_2$ (1.78 g, 46 mmol) in dry Et_2O (50 mL) under nitrogen was added **10** (1.50 g, 9.2 mmol) and the mixture gently refluxed for 3 h. Methyl iodide (1.14 mL, 18 mmol) was added slowly and three further additions of CH_3I (1.14 mL) were made after 2, 9, and 5-h reflux periods; finally the mixture was gently refluxed for 3 h. After cooling to 0°C and the addition of 10% NaCl solution (40 mL) slowly, the product was isolated by pentane extraction (4 × 35 mL) as a viscous colorless liquid (1.56 g, 89%), >99% pure by glc analysis; ir ($CHCl_3$): 1710 cm^{-1}. *Exact Mass* calcd. for $C_{13}H_{20}O$: 192.1514; found: 192.15135.

*Rearrangement of **3** to* cis,anti,cis-*4,4-dimethyltricyclo[6.3.0.0^{2,6}]-undecan-5-one (**4**)*

Our general procedure for homoenolization studies (7) was employed whereby a solution of **3** in *t*-BuO^-/*t*-BuOH (H_2O content ~ 30 μg/mL, made by dissolving potassium metal in dry *t*-BuOH) was prepared under nitrogen having a molar ratio of ketone/*t*-BuO^-/*t*-BuOH of 1:4:40. Aliquots were quickly transferred to predried, thick-walled glass tubes which were degassed and sealed under vacuum before heating. After cooling, the reaction mixture was diluted with 10% NaCl and the neutral product isolated by ether extraction. The extracts were washed with 10% NaCl, dried over $MgSO_4$, and the solvent evaporated to afford a pale yellow oil which was examined by glc (6% FFAP). The product was a two-component mixture, separable by preparative glc, containing **3** and a new ketone **4**; ir ($CHCl_3$): 1738 cm^{-1}; ^{13}Cmr ($CDCl_3$) δ_C: 24.8, 25.2 (2 × CH_3), 26.7, 33.7, 34.2, 35.5, 43.8 (5 × CH_2), 44.2, 46.1, 51.4, 52.0 (4 × CH), 47.1 (quat C), 224.6 (C=O). *Exact Mass* calcd. for $C_{13}H_{20}O$: 192.1514; found: 192.1519.

Experiments at 185°C indicated the half-life for the conversion of **3** → **4** to be ca. 120 h, which was reduced to ca. 30 h at 200°C. After 140 h at 200°C only traces of **3** were detectable by glc.

*Trimethylsilyl enol ethers of Δ^3- and Δ^4-**12** (**13**a,b)*

A 30:70 mixture of **12***a* and *b* (3 g, 20 mmol), prepared in 72% yield from dicyclopentadiene following literature procedures (11, 12), was dissolved in THF (5 mL) and added by syringe to a stirred solution of diisopropylamine (3.6 mL) in THF (10 mL) containing *n*-butyllithium (9 mL, 2.3 *M* in hexane), maintained at −78°C. Stirring was continued for 0.5 h during which time a quenching solution (Et_3N (2.4 mL), THF (18 mL), and trimethylsilyl chloride (4.8 mL)) was prepared in a flame-dried centrifuge tube as described for **8**, and then the clear solution was added to the reaction mixture. After isolation of the crude product as above for **8**, bulb-to-bulb distillation furnished a 30:70 mixture of **13***a,b* (4.2 g, 95%); ir ($CHCl_3$): 1610, 1320, 1250, 850 cm^{-1}. *Exact Mass* calcd. for $C_{13}H_{20}OSi$: 220.1284; found: 220.1280.

*Cyclopropanation of **13**a,b (**14**a,b)*

Following the procedure described above for **9**, the reagent was prepared in dry ether (15 mL) using 4.15 g of Zn/Ag couple and 9.4 g of CH_2I_2 and cooled to room temperature before the addition of the mixture of **13***a,b* (7.0 g). The reaction mixture was stirred at room temperature for 18 h and cooled to 0°C before pyridine (5.5 g) was added. Bulb-to-bulb distillation (75°C/0.2 Torr) of the crude product afforded **14***a,b* (6.13 g, 85%); ir ($CHCl_3$): 1240, 865, 830 cm^{-1}. *Exact Mass* calcd. for $C_{14}H_{22}OSi$: 234.1440; found: 234.1432.

*Δ^3- and Δ^4-tricyclo[5.3.1.0^{2,6}]undecan-8-one (**15**a,b)*

Ketonization of **14***a,b* (6.1 g) was accomplished with aqueous NaOH (10 mL, 2 *M*) and methanol (50 mL) at 0°C for 24 h and the product isolated as described for **10**. The glc analysis indicated a single product and bulb-to-bulb distillation (80°C/0.3 Torr) furnished 3.68 g (87%) of **15***a,b*; ir ($CHCl_3$): 1700 cm^{-1}. *Exact Mass* calcd. for $C_{11}H_{14}O$: 162.1045; found: 162.1042.

*Δ^3- and Δ^4-9,9-dimethyltricyclo[5.3.1.0^{2,6}]undecan-8-one (**5**a,b)*

To a stirred suspension of $NaNH_2$ (6.0 g, 0.154 mol) in dry Et_2O (50 mL) under nitrogen was added **15***a,b* (5.0 g, 0.031 mol) and the mixture refluxed for 3 h. After cooling to room temperature, methyl iodide (27 g, 0.19 mol) was added slowly along with more Et_2O (20 mL) and this mixture refluxed for 15 h before cooling to room temperature. Methyl iodide (8 g, 0.056 mol) was added and then refluxing continued for 3 h. The product was isolated by ether extraction as described for **3**. Bulb-to-bulb distillation (80°C/0.3 Torr) furnished **5***a,b* (4.89 g, 83%); glc analysis indicated the presence of a single component; ir ($CHCl_3$): 1705 cm^{-1}. *Exact Mass* calcd. for $C_{13}H_{18}O$: 190.1358; found: 190.1349.

*Rearrangement of **5**a,b (**6**a,b)*

Our general procedure for homoenolizations, described above, was employed using 30:70 mixtures of **5***a,b* and the neutral product, isolated by pentane extraction in 70–80% yield, was examined by glc. Two prominent bands, the ratios of which varied with reaction time, were evident. One was found, by ^{13}Cmr, to contain a mixture of the initial ketones differing only from the starting material in terms of the ratio of **5***a/b*; with increasing reaction times the ratio approached 50:50 but the rate of approach was not determined. The second band also contained a mixture of two ketones on the basis of its ^{13}Cmr spectrum; ir ($CHCl_3$): 1736 cm^{-1}; ^{13}Cmr ($CDCl_3$) δ: 24.8, 25.1(2), 25.2 (4 × CH_3), 33.3, 36.6, 40.5, 41.4, 43.6, 44.1 (6 × CH_2), 41.4, 44.1, 47.6, 48.4, 51.4, 51.6, 52.4, 58.5 (8 × CH), 129.5, 130.1, 133.5, 133.9 (4 × —CH=), 47.1 (2 quat C), 224.7, (2C=O). *Exact Mass* calcd. for $C_{13}H_{18}O$: 190.1358; found: 190.1351. The ratio of these two ketones (**6***a,b*) was close to 50:50 but was not precisely determined. The half-life for conversion of **5** → **6** was ca. 225 h at 185°C and ca. 75 h at 205°C. All attempts to separate **6***a* and *b* by glc were uniformly unsuccessful.

Additional evidence that the carbon skeleton is as assigned was provided by the ^{13}C spectrum of the alcohol mixture produced by LAH reduction. A sample of **6***a,b* (39 mg) was added to a mixture of LAH (39 mg) in THF (3 mL) and the mixture refluxed for 8 h. After isolation by ether extraction the product (39 mg) was examined by tlc (n-pentane/EtOAc, 95:5) which showed one major and one very minor spot. Bulb-to-bulb distillation (85°C/0.3 Torr) gave a colorless oil (34 mg, 87%) and the ^{13}C spectrum indicated the presence of two alcohols in a 55:45 ratio giving rise to the following signals ($CDCl_3$). δ: (major component) 19.8, 26.6 (2 × CH_3), 36.9, 38.4, 46.5 (3 × CH_2), 40.9, 42.7, 51.2, 60.0, 85.6 (5 × CH), 42.6 (quat C), 128.3, 135.3 (2 olefinic CH); (minor component): 20.7, 27.3 (2 × CH_3), 36.5, 39.8, 45.9 (3 × CH_2), 47.4, 51.1, 52.3, 52.6, 87.4 (5 × CH), 44.0 (quat C), 129.0, 135.4 (2 olefinic CH).

*Δ^3- and Δ^4-*cis,anti,cis-*10,10-dimethyltricyclo[6.3.0.0^{2,6}]undecane (**17**)*

A mixture of **6***a,b* (250 mg, 1.3 mmol), hydrazine hydrate (705 mg, 13 mmol), KOH (1.11 g), and diethylene glycol (10 mL) was placed in a thick-walled glass tube; the tube was sealed and heated at 182°C for 64 h. After cooling and dilution with H_2O (10 mL), the reaction mixture was extracted with Et_2O (3 × 10 mL) and the extracts washed with water before drying over $MgSO_4$. Evaporation of the ether gave an oil (228 mg) which was purified by chromatography on silica gel,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

elution with n-pentane, to furnish a colorless oil (206 mg, 90%) characterized as **17***a,b*; ^{13}Cmr ($CDCl_3$) δ: 27.8, 29.2, 29.6, 30.6 (4 × CH_3), 39.0, 39.1, 39.8, 40.9, 47.5, 47.9, 48.3, 49.6 (8 × CH_2), 40.9, 44.0(2), 48.0, 48.7, 52.9, 53.9, 59.3 (8 × CH), 128.1, 129.1, 135.3, 135.6 (4 × —CH=), 41.6, 41.0 (2 × quat C). *Exact Mass* calcd. for $C_{13}H_{20}$: 176.1565; found: 176.1562.

Preparation of ***18***a,b

The mixture of **17** isomers (200 mg, 1.14 mmol) was dissolved in CH_2Cl_2 (10 mL) and cooled in an ice-bath before the addition of *m*-chloroperbenzoic acid (237 mg, 1.37 mmol). This mixture was stirred at room temperature for 16 h, at which point tlc indicated the absence of starting material. Excess peracid was destroyed by the addition of 10% sodium sulfite solution (negative starch–iodide test) before washing with 10% $NaHCO_3$ solution (3 × 20 mL), water, and finally with saturated NaCl solution. The organic layer was dried over $MgSO_4$ and the solvent evaporated to leave an oil which was purified by bulb-to-bulb distillation (70°C/1 Torr) to furnish a 50:50 mixture of **18***a,b* (185 mg, 85%) which was used directly for the next step; ^{13}Cmr ($CDCl_3$) δ: 26.7, 28.4, 29.0, 29.8 (4 × CH_3), 33.3, 33.4, 33.5, 39.2, 47.8, 48.2, 48.7, 49.6 (8 × CH_2), 42.9, 43.5, 44.4, 44.5, 45.7, 45.9, 48.2, 52.2, 56.6, 58.4, 60.0, 61.1 (12 × CH), 41.1(2) (2 quat C).

Cleavage of ***18***a,b *(****19****a,b)*

The mixture of epoxides **18***a,b* (175 mg, 0.9 mmol) was added to a solution of LAH (171 mg, 4.5 mmol) in dry Et_2O (25 mL) and the reaction mixture was refluxed overnight. After the cautious destruction of the excess LAH with 5% NaOH solution, the ether layer was separated, washed with H_2O (3 × 10 mL), and dried over $MgSO_4$. Removal of the ether gave a clear oil (175 mg, 99%) which was judged to consist mainly of two major alcoholic components (**19***a,b*) in equal amounts together with a small amount (<5%) of a third alcohol on the basis of its ^{13}C spectrum; ^{13}Cmr ($CDCl_3$) δ: 28.1, 28.5, 29.9, 30.1 (4 × CH_3), 29.3, 30.0, 30.7, 34.8, 35.1, 36.7, 40.9, 47.7, 48.0, 48.7 (10 × CH_2), 42.8, 43.8, 44.1, 48.8, 49.7, 51.4, 53.6, 60.8 (8 × CH), 79.1, 80.0 (2 × —CHOH), 41.1, 41.6 (quat C). The total product was used directly for the next step.

Oxidation of ***19***a,b *(****20****a,b)*

The above mixture of alcohols **19***a,b* (175 mg, 0.9 mmol) was dissolved in acetone (5 mL) and titrated with Jones' reagent until the brown color persisted. Isolation by ether extraction afforded a crude product (160 mg, 92%) consisting of a mixture of isomeric ketones; ir ($CHCl_3$): 1735 cm^{-1}. *Exact Mass* calcd. for $C_{13}H_{20}O$: 192.1514; found: 192.1512. All attempts to separate this mixture by glc were unsuccessful but hplc examination indicated the presence of two major components and a minor one in an approximate ratio of 10:10:1. Although poorly resolved, hplc on a semipreparative scale (Prep LC 500 system, semiprep column, silica gel, hexane/CH_2Cl_2 60:1, flow rate 0.1 L/min) furnished small samples of the two major components which, on the basis of their ^{13}Cmr spectra, were reasonably pure (>98%). Fraction 1, **20***a* (49 mg), ir ($CHCl_3$): 1735 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.9 (s, 3H), 1.04 (s, 3H), 1.0–3.0 complex absorption, 14H with discernible multiplets centred at 1.4 (1H), 2.2 (1H), 2.28 (3H), 2.69 (1H), 2.85 (1H), 2.95 (1H); ^{13}Cmr ($CDCl_3$) δ: 26.6, 28.9 (2 × CH_3), 23.8, 35.8, 37.0, 48.0, 49.1 (5 × CH_2), 40.6, 43.9, 45.9, 61.3 (4 × CH), 41.1 (quat C), 222.7 (C=O). Fraction 2, **20***b* (32 mg), ir ($CHCl_3$): 1735 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.92 (s, 3H), 1.04 (s, 3H), 1.0–1.15 (m, 2H), 1.5–3.0 (multiplets, 12H); ^{13}Cmr ($CDCl_3$) δ: 27.1, 29.1 (2 × CH_3), 26.9, 34.9, 38.1, 48.4, 48.5 (5 × CH_2), 44.1, 49.6, 50.4, 53.0 (4 × CH), 41.6 (quat C), 222.1 (C=O).

cis, anti, cis-*4,4-Dimethyltricyclo[6.3.0.0^{2,6}]undecane (****21****)*

A sample (21 mg, 0.109 mmol) of the product from the preceding reaction, hydrazine hydrate (54 mg, 1.1 mmol), KOH (108 mg, 1.91 mmol), and diethylene glycol (0.5 mL) were placed in a thick-walled glass tube; the tube was sealed and heated at 182°C for 60 h. After cooling and dilution with H_2O (5 mL), the reaction mixture was extracted with Et_2O (3 × 10 mL) and the extracts washed with H_2O before drying over $MgSO_4$. After removal of the ether, the residual oil was passed through a short column (1 × 5 cm) of SiO_2 with n-pentane (30 mL) as eluent to furnish **21** (13 mg, 65%) as a colorless oil; ^{1}Hmr ($CDCl_3$) δ: 0.84 (s, 3H, Me), 1.00 (s, 3H, Me), 1.0–2.8 (complex absorption, 16H); ^{13}Cmr ($CDCl_3$) δ_C: 28.1, 29.9 (2 × CH_3), 25.8, 32.0, 33.3, 39.8, 49.1, 49.0 (6 × CH_2), 44.0, 44.2, 50.9, 52.1 (4 × CH), 41.2 (quat C); *m/e* relative intensity): 178 (M^+, 10), 163 (42), 122 (100), 95 (26), 93 (31), 81 (49), 67 (33). *Exact Mass* calcd. for $C_{13}H_{22}$: 178.17215; found: 178.17227.

In an analogous experiment, a sample of **4** (63 mg, 0.33 mmol) was heated at 185°C for 57 h with hydrazine hydrate (170 mg, 3.4 mmol), KOH (280 mg, 5 mmol), and diethylene glycol (3.5 mL) in a sealed, thick-walled Pyrex tube. After cooling to 0°C, the tube was opened and the contents washed from the tube with 10% aqueous NaCl (6 mL). This solution was acidified with 50% aqueous HCl and extracted with pentane (3 × 10 mL). The combined extracts were washed with 10% aqueous NaCl solution (2 × 8 mL) and dried over $MgSO_4$. Removal of the pentane by distillation gave a colorless oil (58 mg, 99%) which was identical to **21** described above.

Evidence for molecular complexes in the mechanism of additions of iodine monochloride to alkenes

GEORGE H. SCHMID[1] AND JAMES W. GORDON

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received February 8, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

GEORGE H. SCHMID and JAMES W. GORDON. Can. J. Chem. **62**, 2526 (1984).

Immediately upon mixing ICl and 2,3-dimethyl-2-butene in CCl_4 at 25°C a new absorption band due to an alkene−ICl molecular complex appears at 295 ± 5 nm and decreases rapidly with time. The rate law under conditions of $(alkene)_0 \gg (ICl)_0$ for the electrophilic addition of ICl to 2,3-dimethyl-2-butene, *E*- and *Z*-2-butene, and *E*- and *Z*-1-phenylpropene is $-d(ICl)/dt = k_{expt}(alkene)(ICl)^3/\{1 + K_{AD}(alkene)\}^3$ where K_{AD} is the equilibrium constant for the formation of a 1:1 alkene−ICl molecular complex. The addition of ICl to the *Z* and *E* isomers of 2-butene and 1-phenylpropene occurs by *anti*-stereospecific addition. The negative enthalpy of activation for the addition of ICl to 2,3-dimethyl-2-butene is evidence that one or more complexes are involved on the reaction coordinate prior to the rate-determining step. On the basis of analysis of the enthalpy changes during the reaction, it is proposed that both a 1:1 and a 1:2 alkene−ICl molecular complex is involved in the mechanism prior to the rate-determining step.

GEORGE H. SCHMID et JAMES W. GORDON. Can. J. Chem. **62**, 2526 (1984).

Dès que l'on mélange du ICl et du diméthyl-2,3 butène-2 dans du CCl_4 à 25°C, il y a apparition, à 295 ± 5 nm, d'une nouvelle bande d'absorption qui est due à un complexe moléculaire alcène−ICl; l'intensité de cette bande diminue rapidement avec le temps. La loi de vitesse qui s'applique, si $(alcène)_0 \gg (ICl)_0$, pour l'addition électrophile de ICl sur le diméthyl-2,3 butène-2, sur les butènes-2 (*E* ou *Z*) ou sur les phényl-1 propènes (*E* ou *Z*) est $-d(ICl)/dt = k_{expt}(alcène)(ICl)^3/\{1 + K_{AD}(alcène)\}^3$, où K_{AD} est la constante d'équilibre pour la formation d'un complexe moléculaire 1:1 alcène−ICl. La stéréochimie de l'addition du ICl sur les isomères *E* et *Z* du butène-2 et du phényl-1 propène est stéréospécifiquement *anti*. Le fait que l'enthalpie d'activation de l'addition du ICl sur le diméthyl-2,3 butène-2 soit négative est une preuve qu'un ou plusieurs complexes sont impliqués dans les coordonnées de la réaction avant d'atteindre l'étape déterminante. Sur la base d'une analyse des changements d'enthalpie au cours de la réaction, on propose que des complexes moléculaires alcène−ICl 1:1 ainsi que 1:2 sont impliqués dans le mécanisme avant d'atteindre l'étape déterminante.

For personal use only.

The stoichiometry of the addition of iodine monochloride (ICl) to alkenes is 1:1 in a number of solvents (1−5). Because of this fact, solutions of ICl in acetic acid (Wijs' solution) are used to determine iodine values of fats and oils (6). Despite such widespread use, little work has been done on the kinetics and mechanism of this addition of ICl to alkenes and some of the work is contradictory. White and Robertson (1) reported that the addition of ICl to allyl acetate in acetic acid follows an overall third-order rate law, first order in alkene and second order in ICl. A similar rate law was reported by Viswanathan and co-workers (2) for ICl addition to some allyl and vinyl compounds in acetic acid, and by Sergeev and Smirnov (3) for the addition of ICl to both cyclohexene and 1-hexene in CCl_4. In contrast, Heublein (4) reported a second-order rate law, first order in both ICl and alkene, for the addition of ICl to *trans*-stilbene in acetic acid, dibutyl ether, and acetonitrile.

The products of addition of ICl to alkenes are sometimes formed by *anti*-stereospecific addition (4−7), while in other cases by *anti*-stereoselective addition (8). Regiospecific addition to styrene (9) is reported, while nonregiospecific addition occurs to 1-hexene (10). Furthermore, solvent incorporated (10) and rearranged products have also been reported (11).

The work reported in the literature is fragmented, with each worker or group of workers employing different compounds and different solvent systems. Frequently only the rates of addition with no product study are carried out or vice versa. It is clear that a systematic study of both the rates and products of this reaction is long overdue. We have undertaken such a study. In this first paper we report the rate law, the effect of temperature on the rate, and the stereo- and regiochemistry of the addition of ICl to 2,3-dimethyl-2-butene, *E*- and *Z*-1-phenylpropene, and *E*- and *Z*-2-butene.

Results and discussion

Kinetic and thermochemical study

The rate of addition of ICl to 2,3-dimethyl-2-butene in CCl_4 at 25°C was measured by monitoring the disappearance with time of ICl at 460 nm by means of a Durrum−Gibson stopped-flow spectrophotometer. The rate measurements were made with $(alkene)_0 \gg (ICl)_0$.

Immediately on mixing ICl and 2,3-dimethyl-2-butene a new absorption band, absent in either reactant or product, appears at 295 ± 5 nm and decreases rapidly with time. This new band is attributed to the presence of an intermediate ICl−alkene molecular complex. Reversible formation of labile molecular complexes between alkenes and halogens are well documented (2). While fewer data are available for alkene−interhalogen complexes, cyclohexene and 1-hexene are known to form molecular complexes with ICl in CCl_4 at room temperature, characterized by absorbances at 267 and 257 nm respectively (3). The molecular complexes of ICl and several allyl and vinyl compounds have characteristic absorbances in dry acetic acid in the region 290−310 nm (2). The position of the band for the complex of ICl and 2,3-dimethyl-2-butene at longer wavelength (295 nm), compared to the complexes of ICl and cyclohexene (267 nm) and 1-hexene (257 nm), is expected for the more highly substituted alkene (12*a*). Thus we conclude that the band at 295 nm in CCl_4 at 25°C is consistent with the formation of a molecular complex between ICl and 2,3-dimethyl-2-butene.

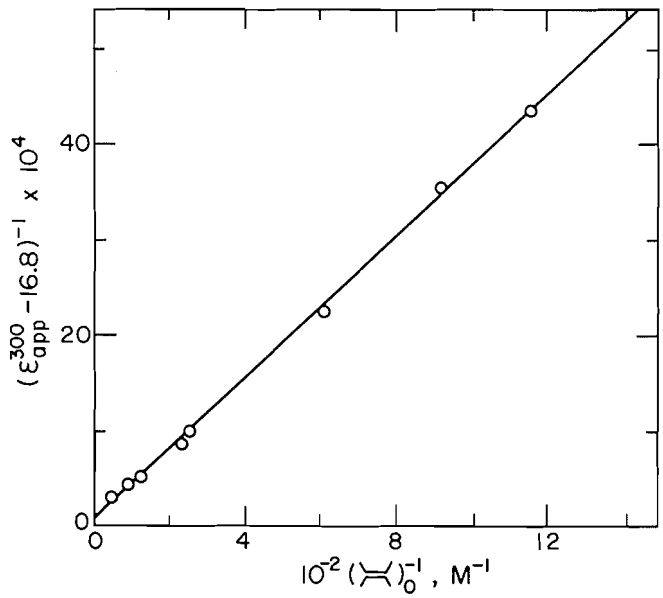

FIG. 1. Ketelaar plot for the 2,3-dimethyl-2-butene-ICl system measured at 300 nm in CCl_4 at 25°C.

The Ketelaar equation (13) was used to obtain the equilibrium constant for the formation of the molecular complex, K_{AD}. Briefly, the method is to measure the variation of initial absorbance values with varying initial concentrations of alkene under conditions where $(\text{alkene})_0 \gg (\text{ICl})_0$. The analysis was carried out in CCl_4 at 25°C and at 300 nm. The equation is as follows:

$$[1] \quad \frac{1}{\epsilon_{app} - \epsilon_{ICl}} = \frac{1}{\epsilon_{AD} - \epsilon_{ICl}} + \frac{1}{K_{AD}(\epsilon_{AD} - \epsilon_{ICl})(\text{alkene})_0}$$

where ϵ_{app} is the apparent extinction coefficient and ϵ_{AD} is the extinction coefficient of the molecular complex. The apparent extinction coefficient is defined by eq. [2].

$$[2] \quad \epsilon_{app} = \text{Abs}_0\, l^{-1}\, (\text{ICl})_0^{-1}$$

The straight line obtained by plotting $1/(\epsilon_{app} - \epsilon_{ICl})$ versus $1/(\text{alkene})_0$ is shown in Fig. 1. Values of $K_{AD} = 19 \pm 6\ M^{-1}$ and $\epsilon_{AD} = 1.4 \pm 0.5 \times 10^4\ M^{-1}\ \text{cm}^{-1}$ are obtained from the values of the slope, intercept with the ordinate axis, and their ratio. The value of K_{AD} obtained in this study is larger than the value of $2\ M^{-1}$ for the equilibrium constant of the formation of the molecular complex in the reaction of 1-hexene and ICl in CCl_4 at 25°C obtained by Sergeev *et al.* (14*a*).

If it is assumed that the ICl–alkene molecular complex is rapidly established relative to the rate of addition of ICl (14*b*), then Beer's law (eq. [3]) will be valid for the total or stoichiometric ICl concentration at all times t under the conditions $(\text{alkene})_0 \gg (\text{ICl})_0$.[2]

$$[3] \quad \text{Abs}_t - \text{Abs}_\infty = \epsilon_{app} l (\text{ICl})_t$$

The pseudo-order rate law, eq. [4], is third order with respect to ICl.

$$[4] \quad -\text{d(ICl)}/\text{d}t = k_{app}(\text{ICl})_t^3$$

Substituting eq. [3] into the integrated form of eq. [4] and rearranging gives the pseudo-order experimental rate equation [5].

$$[5] \quad (\text{Abs}_t - \text{Abs}_\infty)^{-2} = \{\epsilon_{app} l (\text{ICl})_0\}^{-2} + \{2k_{app}/(\epsilon_{app} l)^2\}t$$

The plot of a typical run is given in Fig. 2. The apparent pseudo-order rate constant is readily calculated from the intercept, slope, and $(\text{ICl})_0$. As shown by the data in Table 1, there is no apparent trend in the values of the slope as required by eq. [4] for a series of solutions of constant $(\text{alkene})_0$ and varying $(\text{ICl})_0$. Furthermore, the values of K_{app} are not dependent on the wavelength used to follow the kinetics.

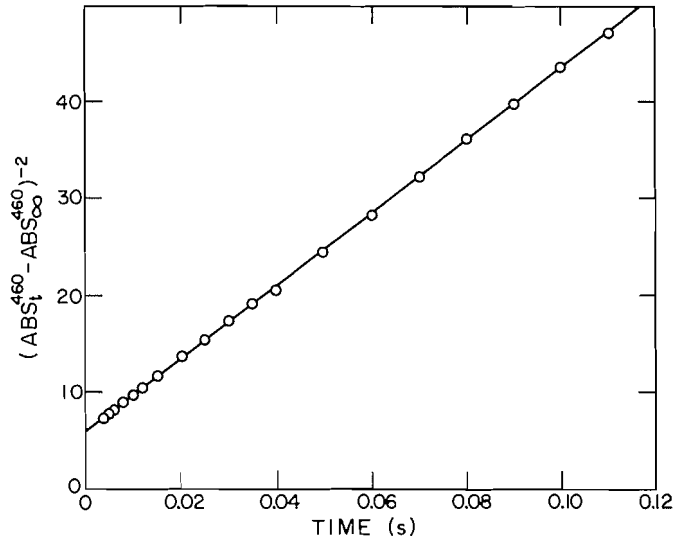

FIG. 2. Third-order kinetic plot for the addition of ICl to 2,3-dimethyl-2-butene in CCl_4 at 25°C.

TABLE 1. Slope and intercept obtained by fitting eq. [4] to the data from the reactions of a series of solutions of constant $(2,3\text{-dimethyl-2-butene})_0 = 0.1188\ M$ and varying $(\text{ICl})_0$ in CCl_4 at 25°C

$(\text{ICl})_0$ $(M) \times 10^3$	Intercept	Slope
5.59	2.74	620
3.31	7.55	415
2.24	15.8	500
1.68	19.3	396
1.33	32.9	425
1.12	51.1	410

The initial concentration of alkene was varied over the range from $3.33 \times 10^{-3}\ M$ to $4.25 \times 10^{-1}\ M$ to determine the dependence of alkene in the rate law. Equation [6] describes the experimentally observed variation of the pseudo-third-order rate constant k_{app} with initial alkene concentration where C_1 and C_2 are constants.

$$[6] \quad \frac{C_1(\text{alkene})_0}{\{1 + C_2(\text{alkene})_0\}^3} = k_{app}$$

The linear plot of $\{(\text{alkene})_0/k_{app}\}^{1/3}$ versus $(\text{alkene})_0$ is shown in Fig. 3. From the intercept and the ratio of slope to intercept, values of $C_1 = 9 \pm 1 \times 10^8\ M^{-3}\ \text{s}^{-1}$ and $C_2 = 17.8 \pm 0.8\ M^{-1}$ are obtained.

The complete rate law describing the rate of addition of ICl to 2,3-dimethyl-2-butene in CCl_4 at 25°C in terms of their total

[2]The symbol (X) represents the total, stoichiometric, or analytical concentration of X in solution in mol/L; [X] represents the free, uncomplexed concentration of X in solution in mol/L.

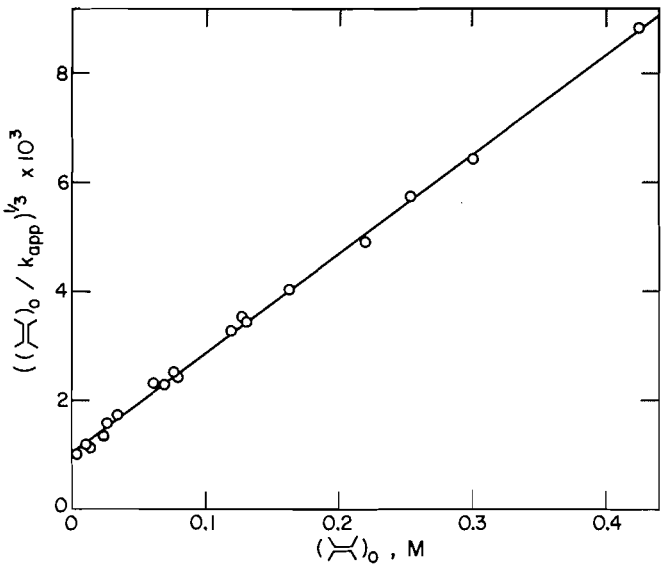

FIG. 3. Experimental test of eq. [6] for the addition of ICl to 2,3-dimethyl-2-butene in CCl_4 at 25°C.

or stoichiometric concentrations is given in eq. [7] for $(\text{alkene})_0 \gg (\text{ICl})_0$. The constants C_1 and C_2 can be identified as a rate

$$[7] \quad -\text{d(ICl)}/\text{d}t = \frac{C_1(\text{alkene})_0(\text{ICl})^3}{\{1 + C_2(\text{alkene})_0\}^3}$$

constants k and K_{AD} respectively in the following way. Equations [8] and [9] relate the stoichiometric and free concentrations of both 2,3-dimethyl-2-butene and ICl at time t under the condition $(\text{alkene})_0 \gg (\text{ICl})_0$. Comparison of eqs. [7] and [9]

$$[8] \quad [\text{alkene}] = (\text{alkene})_0$$

$$[9] \quad [\text{ICl}] = \frac{(\text{ICl})}{1 + K_{AD}(\text{alkene})_0}$$

strongly suggests that the experimental parameter C_2 be identified as the equilibrium constant K_{AD}. This assignment is further substantiated by the fact that the value of C_2 is identical within experimental error with the value of K_{AD} obtained independently from analysis of the initial absorbance data.

The experimental rate law can now be written in terms of the actual, free or uncomplexed, concentrations of ICl and 2,3-dimethyl-2-butene as given in eq. [10].

$$[10] \quad -\text{d(ICl)}/\text{d}t = k[\text{alkene}][\text{ICl}]^3$$

In eq. [10], the experimental parameter C_1 has been redefined as rate constant k. Since C_1 and C_2 are identified, the complete rate law when $(\text{alkene})_0 \gg (\text{ICl})_0$ can be written as given in eq. [11].

$$[11] \quad -\text{d(ICl)}/\text{d}t = \frac{k(\text{alkene})_0(\text{ICl})^3}{\{1 + K_{AD}(\text{alkene})_0\}^3}$$

The rate law given in eq. [11] is not unique to 2,3-dimethyl-2-butene since the additions of ICl to *E*- and *Z*-2-butene and *E*- and *Z*-1-phenylpropene in CCl_4 at 25°C follow exactly the same rate law. Treating the rate data in the same way as described for 2,3-dimethyl-2-butene allows us to determine the values of k and K_{AD} for both pairs of *Z* and *E* isomers. The data are summarized in Table 2.

The structure–reactivity pattern of these five compounds

TABLE 2. Values of k and K_{AD} for the addition of ICl to selected alkenes in CCl_4 at 25°C

Alkene	k (M^{-3} s^{-1})	K_{AD} (M^{-1})
E-$CH_3CH{=}CHCH_3$	$(2.27\pm0.06)\times10^7$	3.7±0.1
Z-$CH_3CH{=}CHCH_3$	$(7.1\pm0.4)\times10^7$	5.8±0.1
E-$C_6H_5CH{=}CHCH_3$	$(5.2\pm0.2)\times10^6$	1.4±0.1
Z-$C_6H_5CH{=}CHCH_3$	$(3.1\pm0.1)\times10^6$	1.4±0.1
$(CH_3)_2C{=}C(CH_3)_2$	$(9\pm1)\times10^8$	17.8±0.8

given in Table 2 is consistent with a reaction that occurs by an electrophilic addition mechanism (15). Further evidence for an ionic mechanism is the fact that the rate of addition is unaffected by the presence of small amounts of I_2. Furthermore, chlorocyclohexane is not formed when the addition of ICl to 2,3-dimethyl-2-butene is carried out in cyclohexane.

The product of the addition of ICl to alkenes reacts further with ICl to form a vicinal dichloro compound. This subsequent reaction has been shown to be much slower and does not compete with the fast addition of ICl to any of the alkenes reported here under conditions where $(\text{alkene})_0 \gg (\text{ICl})_0$ (16).

The observation of a molecular complex in the reaction of ICl and alkenes does not necessarily mean that it is on the reaction coordinate. In order to establish that the molecular complex is involved in the reaction, variation in k and K_{AD} with temperature was determined for the addition of ICl to 2,3-dimethyl-2-butene. The data are given in Table 3. The rate of the addition actually *decreases* with increasing temperature. Furthermore, the value of the enthalpy of activation is an extremely large negative value. Such temperature dependence of the rate of reaction is good evidence for a complex reaction mechanism (17). Thus the negative enthalpy of activation observed for this reaction may be taken as kinetic proof that a complex or several complexes are involved *on the reaction coordinate prior* to the rate determining transition site.

Product stereo- and regiochemistry

The products of the addition of ICl to *E*- and *Z*-2-butene and *E*- and *Z*-1-phenylpropene were examined to establish the stereo- and regiochemistry of this reaction in CCl_4 at 25°C. The addition to *Z*-2-butene forms a single adduct while addition to the *E* isomer also forms only one product whose ^1H nmr, given in Table 4, is different from that of the product of addition to the *Z* isomer. Such a result is consistent with a stereospecific addition of ICl. The *vicinal* methine H—H coupling constants (J_{ab}) of the products can be used to determine the stereochemistry of the adducts. Usually the *vicinal* methine H—H coupling constant in 1,2-disubstituted-1,2-dihaloethanes is larger for the *erythro* (or *meso*) than the corresponding *threo* (or *dl*) isomer (18). On this basis we can assign the *threo* configuration to the product of addition of ICl to *Z*-2-butene and the *erythro* configuration to the product formed by addition of ICl to *E*-2-butene.

To verify this stereochemical assignment the two adducts were independently synthesized by the series of reactions shown in Fig. 4. The addition of iodine to a mixture of *Z*-2-butene and yellow mercuric oxide in 80% aqueous acetonitrile forms *threo*-3-iodo-2-butanol. The *threo* configuration of the product was established by means of a base-induced ring closure reaction to form the epoxide. This reaction is known to occur with a single inversion of configuration at the carbon atom bearing the halogen atom (19). Thus treatment of *threo*-3-iodo-2-butanol with moist sodium aluminate in methylene

chloride forms the known *cis*-2,3-dimethyloxirane (19*c*).

Reaction of *threo*-3-iodo-2-butanol with neat thionyl chloride forms 2-chloro-3-iodobutane whose ^{1}H nmr spectrum is identical to the product formed by addition of ICl to *Z*-2-butene. The configuration of the product of the thionyl chloride reaction is assigned on the basis of the mechanism of this reaction (20). In neat thionyl chloride, replacement of the hydroxy group by chloride occurs with retention of configuration. Retention of configuration is also expected because of the involvement of the iodine atom as a neighboring group (21). Consequently the product of the reaction of *threo*-3-iodo-2-butanol with neat thionyl chloride has the *threo* configuration.

The *erythro*-3-iodo-2-butanol was synthesized by an identical series of reactions starting with *E*-2-butene as shown in Fig. 4. The ^{1}H nmr spectrum of 2-chloro-3-iodobutane prepared in this way is identical to the product formed by the addition of ICl to *E*-1-butene. Thus these results are conclusive evidence that the addition of ICl to *Z*- and *E*-2-butene occurs in an *anti* stereospecific manner.

To determine the regiochemistry as well as the stereochemistry, the addition of ICl to *E*- and *Z*-1-phenylpropene was carried out. As in the case of the 2-butenes, the ^{1}H nmr spectrum of the product of addition to *Z*-1-phenylpropene is different than that of the product obtained by addition of *E*-1-phenylpropene as shown in Table 4. To unambigously determine the stereo- and regiochemistry of addition in this system,

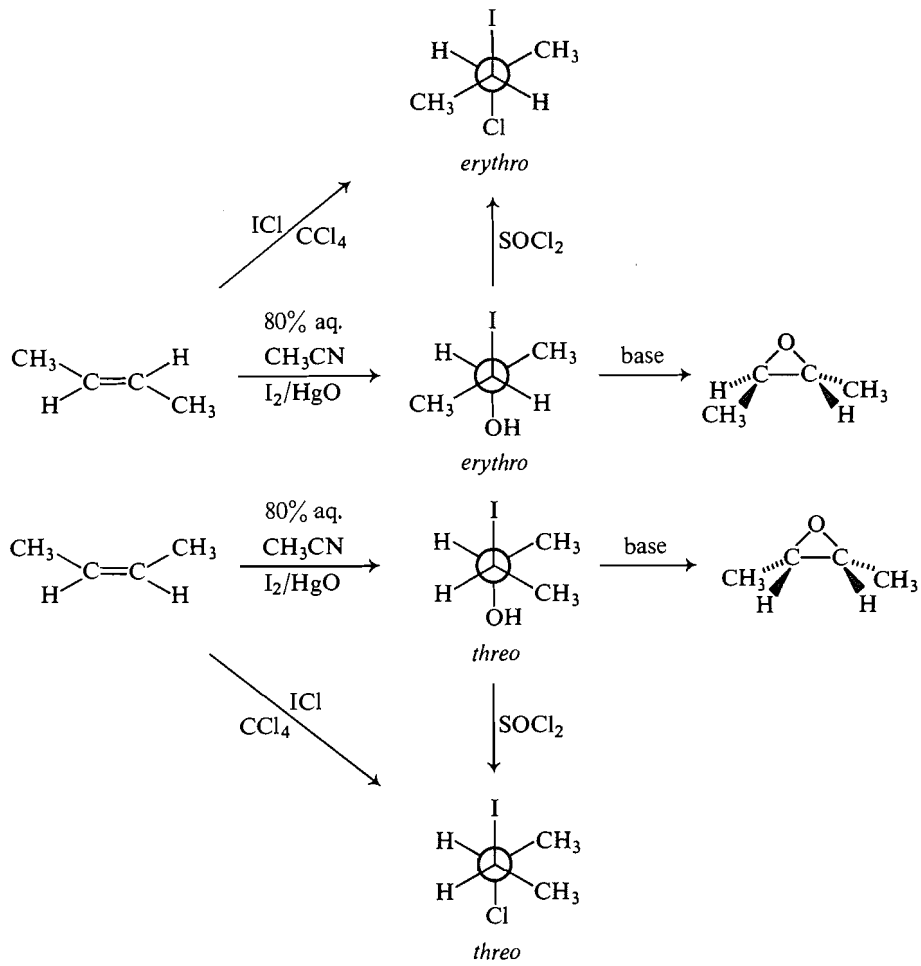

FIG. 4. Synthetic scheme for preparation of *erythro*- and *threo*-2- chloro-3-iodobutane.

it is necessary to prepare authentic samples of the four possible adducts: *erythro*- and *threo*-1-chloro-2-iodo-1-phenylpropane and *erythro*- and *threo*-2-chloro-1-iodo-1-phenylpropane. The synthesis of the two stereoisomers of 1-chloro-2-iodo-1-phenylpropane has been reported (16). The *threo* and *erythro* isomers of 2-chloro-1-iodo-1-phenylpropane were synthesized as shown in Fig. 5.

erythro-1-Chloro-1-phenyl-2-propanol was prepared from *E*-1-phenylpropene by using the oxymercuration reaction (22) followed by a chlorodemercuration reaction (23). Reaction of the chlorohydrin product with base forms *trans*-2-methyl-3-phenyloxirane. This reaction again establishes the configuration of the chlorohydrin as being *erythro*. The position of the chlorine atom in the chlorohydrin was established by means of the ring opening of *trans*-2-methyl-3-phenyloxirane by HCl. Such acid-catalyzed ring opening reactions of oxiranes are known to form the product resulting from the more stable carbonium ion (24). Thus the reaction of *trans*-2-methyl-3-phenyloxirane with aqueous concentration HCl forms a mixture of 45% *erythro*- and 55% *threo*-1-chloro-1-phenyl-2-propanol.

The treatment of *erythro*-1-chloro-1-phenyl-2-propanol with *o*-phenylene phosphorochloridite in pyridine followed by iodine in CCl_4 forms a mixture of 41% *threo*- and 59% *erythro*-2-chloro-1-iodo-1-phenylpropane (25). The same mixture of products could be prepared by the same series of reactions starting with *Z*-1-phenylpropene as shown in Fig. 5. The ^1H nmr spectra of these two compounds are different than those of *erythro*- and *threo*-1-chloro-2-iodo-1-phenylpropane. The data are summarized in Table 4.

The value of preparing all four stereo- and regioisomers is that we can now use well-established ^1H nmr relationships to verify their structure and stereochemistry. For a pair of *threo*–*erythro* stereoisomers, it is known that the methyl protons of the *threo* isomer of 1,2-disubstituted-2-arylpropanes are found at higher field than those of the *erythro* isomer (26). Thus the methyl protons of *threo*-1-chloro-2-iodo-1-phenylpropane are found at δ 1.87 while those of its *erythro* isomer are found further downfield at δ 2.12 ppm. A similar relationship exists between the *threo* (δ 1.48 ppm) and the *erythro* (δ 1.85 ppm) isomers of 2-chloro-1-iodo-1-phenylpropane. As well, the $J_{H,H}$ coupling constant of the *erythro* isomer is larger than that of the *threo* isomer. Thus the proton magnetic resonance spectra are in accord with our assignment of stereochemistry.

The chemical shift of a proton next to iodine is further downfield than the same proton next to chlorine (27). We can make use of this relationship to verify the regiochemistry of the four compounds. Compare the methyl protons first. In *erythro*-1-chloro-2-iodo-1-phenylpropane, the methyl protons are found at δ 2.12 ppm downfield from the methyl protons of the isomeric *erythro*-2-chloro-1-iodo-1-phenylpropane at δ 1.85 ppm. The same relationship exists for the *threo* isomers ($ICHCH_3$ δ 1.87 ppm; $ClCHCH_3$ δ 1.48 ppm). A similar relationship exists for protons at benzylic carbons bonded to

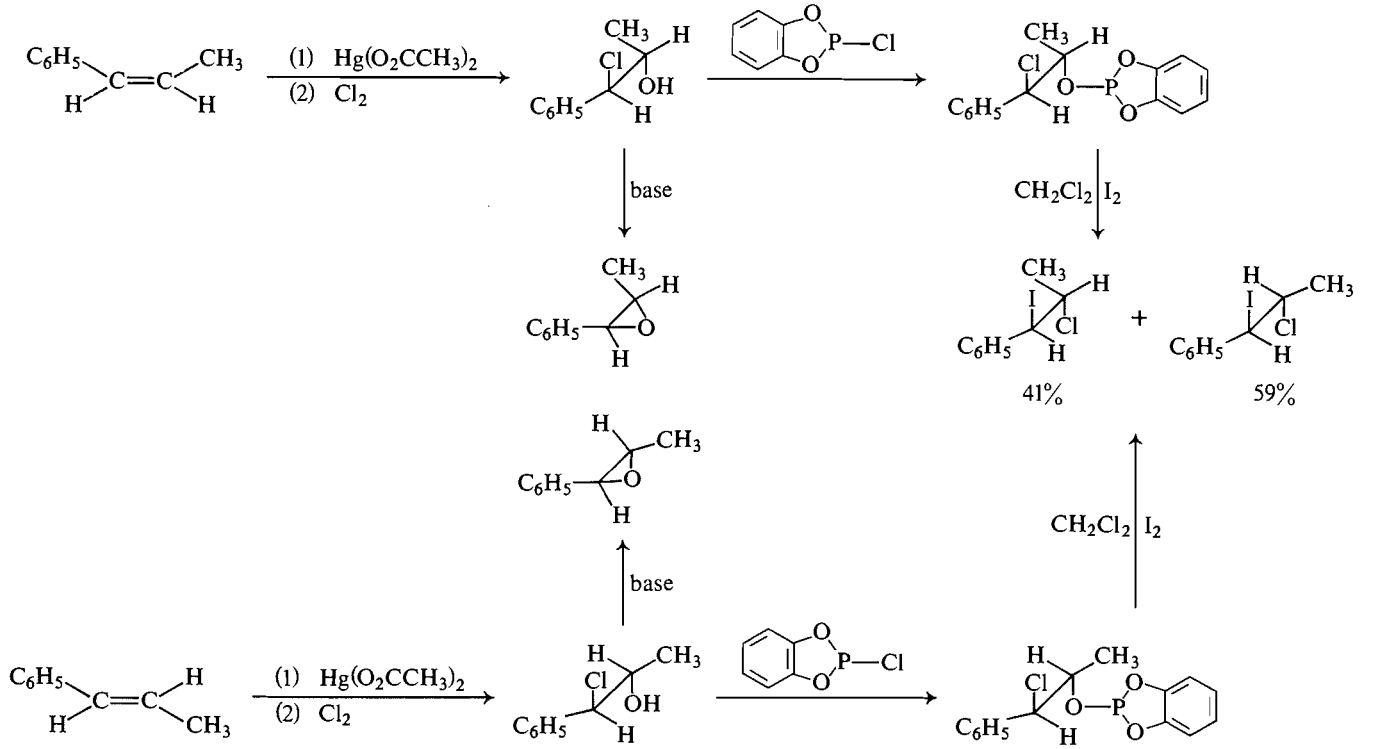

FIG. 5. Synthetic scheme for the preparation of *erythro*- and *threo*-2-chloro-1-iodo-1-phenylpropane.

chlorine and iodine. Thus the proton magnetic resonance spectra of these four isomers are in accord with our assignment of both the stereochemistry and regiochemistry of the compounds.

In summary, addition to all four alkenes is *anti*-stereospecific. Furthermore, addition to the 1-phenylpropenes is regiospecific: only the product of Markownikoff orientation is formed. No Markownikoff to *anti*-Markownikoff isomerization of the products of addition to *Z*- or *E*--1phenylpropene has been observed (28).

Proposed mechanism

Two possible mechanisms for this reaction are shown in Fig. 6. Both mechanisms involve only bimolecular processes, a rate-determining step that contains 3 molecules of ICl and one of alkene, and two equilibria prior to the rate-determining step. The first equilibrium in both mechanisms is the formation of a 1:1 alkene−ICl molecular complex. Formation of an ICl dimer is the second equilibrium in mechanism A while formation of a 1:2 alkene−ICl molecular complex is the second equilibrium in mechanism B. Both mechanisms are consistent with our data. Johnson and Bowen (29) have shown that linear Benesi−Hildebrand (B−H) or Ketelaar plots can be obtained for reactions that involve both 1:1 and 1:2 molecular complexes. Thus both mechanisms are in accord with our linear Ketelaar plot.

When $(\text{alkene})_0 \gg (\text{ICl})_0$, the concentration of the product of the second equilibrium in either mechanism (ICl dimer in mechanism A or 1:2 alkene−ICl molecular complex in mechanism B) will always be small compared to the concentration of the 1:1 alkene−ICl complex.[3] As a result, the stoichiometric concentration of ICl can be approximated within experimental error by eq. [9]. The predicted rate law for both mechanisms is then given by eq. [10] where $k = k_3 K_{AD} K_{A_2}$ (for mechanism A) or $k = k_3 K_{AD} K_2$ (for mechanism B). Again substituting for $[\text{ICl}]_t$ in eq. [10], we obtain the rate law given in eq. [11]. Thus both mechanisms are in accord with the experimentally determined rate law.

Mechanism A.

$$A + D \rightleftharpoons AD \quad (K_{AD})$$
$$A + A \rightleftharpoons A_2 \quad (K_{A_2})$$
$$AD + A_2 \xrightarrow{k_3} \text{Product}$$

A = ICl D = Alkene
AD = 1:1 Alkene−ICl molecular complex
A_2D = 1:2 Alkene−ICl molecular complex
A_2 = ICl dimer

Mechanism B.

$$A + D \rightleftharpoons AD \quad (K_{AD})$$
$$A + AD \rightleftharpoons A_2D \quad (K_2)$$
$$A + A_2D \xrightarrow{k_3} \text{Product}$$

FIG. 6. Two proposed mechanisms for the addition of ICl to alkenes in CCl_4 at 25°C.

The assumption of two equilibria can be substantiated by quantitative consideration of the enthalpy changes in the reaction as shown in Fig. 7. It is clear that the enthalpy change, ΔH_{AD}, for the formation of a 1:1 alkene−ICl complex (−9 kcal/mol) cannot account for the large negative enthalpy of activation (−17 kcal/mol). Another intermediate is needed whose value of $\Delta H_x \leq -8$ kcal/mol.[4]

Dimers of halogens are known and the equilibrium constants

[3]For example, when the ratio K_{A_2D}/K_{AD} is 100, the ratio $[A_2D]/(AD)$ will be less than 0.01.

[4]If the enthalpy of activation for step 3 is taken into account, ΔH_x becomes even more negative than −8 kcal/mol.

and enthalpies of formation for the dimers of several halogens in solution and in the gas phase have been determined (30). The most common method for determining these quantities is to examine deviations from the Beer–Lambert Law (31). If ICl and its dimer both contribute to the uv absorbance, eq. [12] can be written.

$$[12]\quad \mathrm{Abs}^{\lambda} l^{-1} = \epsilon^{\lambda}_{ICl}[ICl] + \epsilon^{\lambda}_{A_2}[\mathrm{dimer}]$$

where $\epsilon^{\lambda}_{A_2}$ is the extinction coefficient of the dimer. If the extent of dimer formation is very small than eq. [12] becomes

$$[13]\quad \epsilon^{\lambda}_{app} = \frac{\mathrm{Abs}^{\lambda}}{l(ICl)} = \epsilon^{\lambda}_{ICl} + K_{A_2}\epsilon^{\lambda}_{A_2}(ICl)$$

From linear plots of ϵ^{λ}_{app} versus (ICl), values of $K_{A_2}\epsilon^{\lambda}_{A_2}$ were obtained and are given in Table 5.

From our data, it is impossible to determine K_{A_2} from the product $K_{A_2}\epsilon_{A_2}$. It is possible, however, to obtain an upper limit to K_{A_2} in the following way. If K_{A_2} were appreciable, the exact equation for ϵ^{λ}_{app} is as follows:

$$[14]\quad \epsilon^{\lambda}_{app} = \epsilon^{\lambda}_{ICl} + (\epsilon^{\lambda}_{A_2} - 2\epsilon^{\lambda}_{ICl})\{1 + 4K_{A_2}(ICl) - [1 + 8K_{A_2}(ICl)]^{1/2}(8K_{A_2})^{-1}$$

Synthetic data were generated from eq. [14] using values of $\epsilon^{\lambda}_{ICl} = 10$ and $\epsilon_{A_2}K_{A_2} = 100$, which correspond closely to the experimental values obtained in CCl_4 at 290 to 310 nm. Sets of values of ϵ^{λ}_{app} were calculated for various values of K_{A_2} (0.1 to 5.0 M^{-1}). The values of ϵ^{λ}_{app} obtained for a particular value of K_{A_2} were then plotted according to eq. [13]. Any value of K_{A_2} greater than 0.5 M^{-1} causes a definitive curvature of plots of eq. [13]. Thus the value of $K_{A_2} \leq 0.5\ M^{-1}$ in order to account for the experimentally observed linear plots of eq. [13].

The enthalpy of formation of the ICl dimer was estimated by the method of Keefer and Allen (32). Literature values of ΔH_{AD} and ΔG_{AD} for a wide range of donor–ICl complexes in CCl_4 at 25°C are given in Table 6. When ΔG_{AD} is plotted against ΔH_{AD} the following linear relationship is obtained:

$$[15]\quad \Delta G_{AD} = 2.8 + 0.77\ \Delta H_{AD}$$

Equation [15] should be valid for the ICl dimer. A K_{AD} value of 0.5 M^{-1} predicts a value of ΔH_{A_2} of −3 kcal/mol, very similar to the literature values of ΔH_{A_2} for the iodine dimer in CCl_4 at 25°C (−1.0 ± 0.2 kcal/mol (41); −1.96 kcal/mol (42); −1.52 ± 0.29 (43). We may state with some confidence that ΔH_{A_2} for the ICl dimer is more positive than −4 kcal/mol. Returning to Fig. 7, it is clear that ΔH_{A_2} is not sufficient to account for the value of ΔH_x. On this basis, it is concluded that the ICl dimer, while present in CCl_4, is not involved on the reaction coordinate of the addition of ICl to 2,3-dimethyl-2-butene.[5]

Mechanism B, Fig. 6, involves successive equilibria for the formation of 1:1 and 1:2 alkene–ICl molecular complexes. There is no experimental evidence for such 1:2 alkene–ICl molecular complexes. However, experimental data are available for 1:2 alkene–Br_2 complexes. Kimer'fel'd *et al.* (44) have observed both 1:1 and 1:2 cyclohexene-Br_2 complexes in solid solutions at −185°C in ir and Raman spectroscopy. Sergeev *et al.* and Lishnevskii *et al.* have demonstrated the existence of a 1:1 and 1:2 propene–Br_2 complexes at low temperatures by thermographic (45), uv (46), and ir (46) studies. Sergeev *et al.* (47) have also postulated a 1:2 cyclohexene–Br_2 complex in Freon 113 at ambient temperature on the basis of a uv study in the range 250–270 nm. A structure of these 1:2 alkene–Br_2 complexes has been proposed in which the two bromine molecules are on opposite sides and perpendicular to the plane of the double bond (44). A similar structure would be expected for a 1:2 alkene–ICl complex. While it seems reasonable to propose the existence of a 1:2 alkene–ICl complex on the reaction coordinate of ICl additions to alkenes, its verification awaits further data.

Summary

Observation of a negative activation enthalpy for the reaction of ICl and 2,3-dimethyl-2-butene in CCl_4 at 25°C provides strong evidence for the existence of one or more molecular complexes on the reaction coordinate. The rate law requires a rate-determining step that contains one molecule of alkene and three of ICl. Quantitative analysis of the enthalpy change in the reaction rules out the involvement of the ICl dimer on the reaction coordinate. The involvement of a 1:2 alkene–ICl complex in the mechanism is proposed.

Experimental

All boiling and melting points are uncorrected. The glc analysis was carried out using a Varian Aerograph Series 2740 analytical instrument equipped with a FID. Proton magnetic resonance spectra were recorded on a Varian T-60 or HA-100 spectrometer in $CDCl_3$ containing $(CH_3)_4Si$ as internal standard. ACS grade CCl_4, CH_2Cl_2, and CH_3CN were used without further purification. *E*- and *Z*-1-phenylpropene, *E*- and *Z*-2-butene, and 2,3-dimethyl-2-butene were

[5]We estimate the errors in $\Delta H^{\ddagger}$(expt) and ΔH_{AD} to be ±10% using the method of Benson (17*a*).

obtained commercially and used without further purification. Iodine monochloride was purified by fractional crystallization from the melt, discarding the remaining liquid portion (48).

threo-*3-Iodo-2-butanol* was prepared by adding 8.0 g (0.035 mol) of finely ground iodine in several portions over 5−10 min to a vigorously stirred solution of 40 g (0.0185 mol) of yellow mercuric oxide and excess *Z*-2-butene in 15 mL of 80% aqueous acetonitrile at room temperature. After an additional 10−15 min, the reaction mixture was filtered by suction to remove the red mercuric iodide using a small amount of acetonitrile as a rinse solution. The filtrate was poured into a separatory funnel containing a two-fold excess of ether. The resulting solution was washed successively with a 5% aqueous KI solution, a 5% aqueous $NaHSO_3$ solution, and a saturated NaCl solution. The organic layer was separated, dried over anhydrous $MgSO_4$, filtered, and solvent removed at reduced pressure to yield 3.28 g (0.0164 mol, 52%), bp 45−47°C/5 Torr (1 Torr = 133.3 Pa) (lit. (49) bp 43.0°C/2.5 Torr); ^{1}H nmr δ: 1.23 (d, J = 6.0 Hz, 3H), 1.92 (d, J = 7.0 Hz, 3H), 3.20 (dq, J = 4.5, 6.0 Hz, 1H), 4.15 (dq, J = 3.5, 7.0 Hz, 1H).

erythro-*3-Iodo-2-butanol* was prepared in 80% yield by the same method as the *threo* isomer but using *E*-2-butene as the starting alkene, bp 50−52°C/5 Torr (lit. (49) bp 34.3−34.9°C/0.9 Torr); ^{1}H nmr δ: 1.21 (d, J = 6.0 Hz, 3H), 1.82 (d, J = 7.0 Hz, 3H), 4.31 (dq, J = 3.5, 7.0 Hz, 1H), 3.32 (dq, J = 3.5, 6.0 Hz, 1H).

cis-*2,3-Dimethyloxirane* was prepared by adding excess moist sodium aluminate to 2.00 g (0.010 mol) of *threo*-3-iodo-2-butanol in 10 mL CS_2. The sodium aluminate was prepared by adding with stirring 1 mL of 10 *N* NaOH solution per 5 g of chromatographic grade alumina. A three-fold excess of base was used. The reaction mixture was allowed to stand for 10 h with occasional stirring. The mixture was filtered and the solid was thoroughly washed with CH_2Cl_2. The solvent was removed at reduced pressure to yield 0.56 g (80% yield) of product, bp 55−57°C (lit. (53) bp 53.5−53.7°C); ^{1}H nmr δ: 1.22 (d, J = 6 Hz, 3H), 2.91 (m, 1H).

trans-*2,3-Dimethyloxirane* was prepared in 67% yield by the same method as the *cis* isomer except that *erythro*-3-iodo-2-butanol was used as the starting iodohydrin, bp 55−56°C (lit. (49) bp 53.5−54.0°C); ^{1}H nmr δ 1.27 (d, J = 5Hz, 3H), 2.62 (m, 1H).

threo-*2-Chloro-3-iodobutane* was prepared by adding 16.6 g (0.014 mol) $SOCl_2$ to 20 g (0.010 mol) *threo*-3-iodo-3-butanol. After copious evolution of HCl, the solution was stirred for 30 min at room temperature. The reaction mixture was transferred to a separatory funnel containing a 10-fold excess of CH_2Cl_2. The organic layer was washed with a 5% aqueous $NaHCO_3$ solution, a 5% aqueous $NaHSO_3$ solution, and a saturated NaCl solution. The organic layer was dried over K_2SO_3, filtered, and the solvent removed at reduced pressure to give 1.5 g (68%) of product, bp 35−37°C/5 Torr (lit. (49) bp 32.2−33.5/4 Torr).

erythro-*2-Chloro-3-iodobutane* was prepared in 88% yield by the same method as the *threo* isomer except that *erythro*-3-iodo-2-butanol was used as the starting iodohydrin; bp 35−37°C 5 Torr (lit. (49) bp 34.8−35.3°C/5 Torr).

threo-*1-Chloro-1-phenyl-2-propanol* was prepared by adding 4.72 g (0.040 mol) of *Z*-1-phenylpropene to a stirred ice-cold solution of 15.9 g (0.050 mol) of mercuric acetate in 200 mL of 50% aqueous acetonitrile. Stirring was continued for 4 days at room temperature. To the reaction mixture was added 50 mL of a saturated NaCl solution. Stirring was continued for an additional 15 min. The resulting mixture was poured into 200 mL of water and extracted with 3 × 125 mL portions of ether. The combined ether extracts were washed with 2 × 100 mL portions of water and 100 mL of saturated NaCl solution. The ether layer was dried over $MgSO_4$, filtered, and the ether removed to give 9.6 g of *threo*-2-hydroxy-1-methyl-2-phenylethyl mercuric chloride. A solution of 1.60 g (4.31 mmol) of the organomercurial in 25 mL of dry pyridine in a 50-mL flask fitted with a magnetic stirrer, $CaCl_2$ drying tube, and a gas bubbler was cooled to between −50 and −60°C and Cl_2 was bubbled through for 5 min. The reaction mixture was poured into 150 mL of ether. The ether solution was washed with 2 × 50 mL 5% aqueous HCl solution, 2 × 50 mL 5% aqueous $NaHCO_3$ solution, 25 mL of a 1% aqueous $NaHSO_3$ solution, and 50 mL saturated NaCl solution. The ether layer was dried over anhydrous $MgSO_4$, filtered, and the solvent removed at reduced pressure to give 0.60 g (81%) of product; ^{1}H nmr δ: 1.05 (d, J = 6.0 Hz, 3H), 4.00 (dq, J = 6.0, 7.0 Hz, 1H), 4.68 (d, J = 7.0 Hz, 1H), 7.27 (s, 5H).

erythro-*1-Chloro-1-phenyl-2-propanol* was prepared in 75% yield by the same method as the *threo* isomer except that *E*-1-phenylpropene was used as the starting alkene; ^{1}H nmr δ: 1.22 (d, J = 6.0 Hz, 3H), 4.04 (dq, J = 6.0 Hz, 1H), 4.74 (d, J = 6.0 Hz, 1H), 7.27 (s, 5H).

Reaction of the 2-methyl-3-phenyloxirane and HCl

A solution of epoxide in CH_2Cl_2 cooled in an ice bath was treated with enough concentrated HCl solution so that a 1.5 to 2.0-fold excess of HCl was present. After stirring for 1 h, the reaction mixture was diluted with an equal volume of CH_2Cl_2. The CH_2Cl_2 layer was separated and washed with 3 portions of H_2O and one portion of saturated NaCl solution. The organic layer was dried over anhydrous $MgSO_4$,

filtered, and the solvent removed at reduced pressure to give the crude chlorohydrin. The product of the reaction of the *trans* isomer was determined to be 45% *erythro*- and 55% *threo*-1-chloro-1-phenyl-2-propanol. The *cis* isomer formed 57% *threo*- and 17% *erythro*-1-chloro-1-phenyl-2-propanol and 26% *threo*-2-chloro-1-phenyl-1-propanol (16). The ratios of products were determined from the areas of non-overlapping methyl peaks in the ^{1}H nmr spectrum (26).

erythro- *And* threo-*2-chloro-1-iodo-1-phenylpropane* were prepared from the corresponding *erythro* or *threo*-1-chloro-1-phenyl-2-propanol using the method of Corey and Anderson (25*b*). Starting with either isomer, a mixture containing 59% *erythro*- and 41% *threo*-2-chloro-1-iodo-1-phenylpropane was obtained as determined from the relative areas of the non-overlapping methyl peaks in the ^{1}H nmr spectrum. Anal. ($C_9H_{10}ICl$)C,H.

A general route to the synthesis of 3-alkylidene derivatives of 4-thiochromanone 1,1-dioxide

IAN W. J. STILL[1] AND FRED J. ABLENAS

J. Tuzo Wilson Research Laboratories, Erindale Campus, University of Toronto in Mississauga, Mississauga, Ont., Canada L5L 1C6

Received May 1, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

IAN W. J. STILL and FRED J. ABLENAS. Can. J. Chem. **62**, 2535 (1984).

The reactions of the trimethylsilyl enol ethers of both 4-thiochromanone and 4-thiochromanone 1,1-dioxide with various carbonyl compounds complexed with titanium tetrachloride give moderate yields of the previously unknown 3-alkylidene condensation products under mild conditions. Other Lewis acids, with the exception of boron trifluoride, were found to be ineffective in this transformation.

IAN W. J. STILL et FRED J. ABLENAS. Can. J. Chem. **62**, 2535 (1984).

Opérant sous des conditions expérimentales douces, les réactions des éthers énoliques triméthylsilylés de la thio-4 chromanone et de la thio-4 chromanone dioxyde-1,1 avec divers composés carbonylés complexés avec du tétrachlorure de titane conduisent, avec des rendements modérés, à des produits de condensation alkylidène-3 qui étaient inconnus antérieurement. On a trouvé que les autres acides de Lewis, à l'exception du trifluorure de bore, sont inefficaces pour cette transformation.

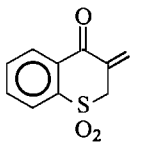
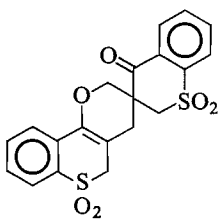
Introduction

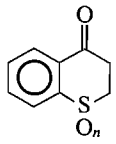
The synthesis of 3-methylene-4-thiochromanone 1,1-dioxide **1** has been reported for the first time in a recent paper by Holshouser and Loeffler (1). This compound was synthesized as part of a systematic investigation (2) of the effectiveness of various α-methylene carbonyl compounds as anti-tumor agents and was shown to be marginally active in this respect. Of more immediate chemical interest, **1** was also found to undergo very facile dimerization at 25°C, via a Diels–Alder reaction to the pentacyclic compound **2**, this process being reversible at 250°C.



1



2



3*a*, $n = 0$
b, $n = 2$

Given our previous interest in 4-thiochromanone chemistry (3–6), we wished to undertaken a more general investigation of synthetic routes to higher homologs of **1**. Somewhat surprisingly, very few analogs of **1** have been reported in the literature to date, although 3-arylidene deivatives derived from 4-thiochromanone **3***a* itself have been known for many years (7, 8). The dichloromethylene derivative of **3***a* was also obtained earlier by us (3) in an unusual reaction of 4-thiochromanone with carbon tetrachloride. The Mannich procedure (1) used to prepare **1** and the acid-catalyzed route to the arylidene derivatives of **3***a* employed by Orlov *et al.* (8) proved to be incapable of extension to the condensation of **3***a*, or its dioxide **3***b*, with ketones. In addition, the well-documented (8, 9) tendency for the α-carbanions of **3***a* and **3***b* to undergo ring-opening reactions in preference to alkylation at the C-3 carbon meant almost certain failure for any approach to the condensation along these lines. The use of milder reaction conditions seemed to offer the only hope of success and constitutes the subject of this paper.

Results and discussion

In the light of the difficulties mentioned above, it seemed to us that an approach to the condensation of **3***a* (or **3***b*) with ketones would be most effective if an additional electron-withdrawing group were present at C-3 to facilitate carbanion formation at this site under mild conditions. The 3-hydroxymethylene compound **4**, reported by Tilak and co-workers (10), seemed ideal for this purpose and was readily prepared in 95% yield by reaction of **3***a* with ethyl formate, using sodium hydride as the base. (In contrast to the earlier report (10), sodium methoxide was found to be ineffective as a catalyst for the formylation and compound **4**, when pure, is a reasonably stable compound which can be stored for several weeks without appreciable decomposition.) Unfortunately, **4** did not react under acid- or base-catalyzed Knoevenagel reaction conditions at room temperature with cyclopentanone or cyclohexanone, and attempts to ensure reaction by resorting to higher temperatures led only to the destruction of the keto-aldehyde.

Compound **4** did undergo successful alkylation with chloromethyl phenyl sulfide in the presence of sodium hydride to produce **5**, albeit in only 24% yield. We had thought that it might be possible to selectively oxidize the acyclic sulfur atom in **5** to the corresponding sulfoxide or sulfone and then carry out a combined deformylation and elimination of benzenethiolate ion with alkali to provide an alternative route to the 3-methylene derivative of **3***a*, but the low yield of the alkylation step discouraged further exploration of this route. Attempted alkylation of **4** with chloromethyl phenyl sulfone directly to avoid the awkward selective oxidation step was completely without success, again presumably for steric reasons.

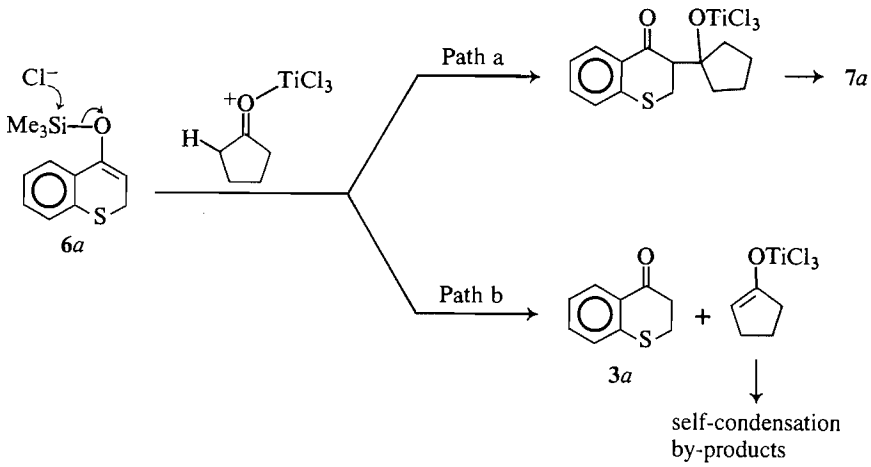
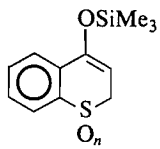
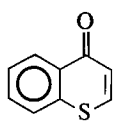


SCHEME 1

An alternative approach which presented itself was to use the enol silyl ether of **3***a* or **3***b* for the condensation with the appropriate ketone, in the presence of a Lewis acid catalyst, by the procedure developed recently by Paterson and Fleming (11). Here an immediate difficulty presented itself in that one of the most commonly employed routes to enol silyl ethers is via the (lithium) enolate and we have already noted the propensity of the enolates derived from **3***a* and **3***b* to undergo preferential ring cleavage reactions. The enol silyl ether **6***a* of 4-thiochromanone had been reported earlier by Hellberg and Juarez (12) as resulting from the reaction of 4-thiochromanone with dimethylaminotrimethylsilane. We have found, however, that a recent modification to the lithium enolate procedure by Fleming *et al.* (13), whereby the ketone and the chlorotrimethylsilane are added *simultaneously* to the strong base used (here LDA) instead of treating the preformed enolate with the silylating agent, works very well and affords **6***a* in 94% yield and the corresponding enol silyl ether **6***b* derived from **3***b* in 96% yield. Compound **6***a* may be purified by short-path distillation but the higher-boiling **6***b* was used directly for the condensation reactions without purification. Both compounds were found to be stable towards water and brief exposure to 1 *M* hydrochloric acid.

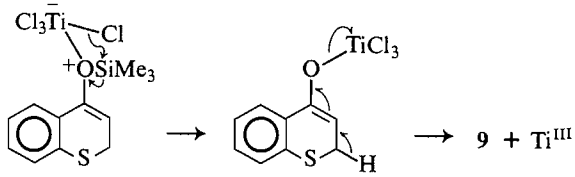


6*a*, *n* = 0
b, *n* = 2



9

The enol silyl ethers **6***a*,*b* were initially reacted with cyclopentanone and cyclohexanone in dichloromethane at −78°C, with titanium tetrachloride as the catalyst, to establish the potential of this method. The reaction of **6***a* with cyclopentanone is illustrative. Three compounds could be isolated: the desired 3-cyclopentylidene-4-thiochromanone **7***a* (22%), accompanied by 4-thiochromaone **3***a* (24%) and thiochromone **9** (20%). Since **3***a* can be recycled via the enol silyl ether, the corrected figure for the isolated yield of the alkylidene derivative **7***a* is 29%. Initially it was felt that the 4-thiochromanone was being formed from the enol silyl ether during work-up, or possibly because of contamination of the titanium tetrachloride used by traces of hydrogen chloride, but the latter cause can now be



SCHEME 2

eliminated. It is quite possible, however, that proton transfer from cyclopentanone to the enol silyl ether, with concomitant formation of the cyclopentanone enolate, is responsible, since in almost all of the reactions which we have carried out significant amounts of ketone self-condensation products were found. A plausible mechanistic rationale for these reactions is shown in Scheme 1, where path a accounts for the formation of the desired aldol product and path b for the unproductive trans-enolization process.

The formation of thiochromone **9** is more surprising, since this formally involves an oxidation step, but Kuwajima and co-workers (14) have very recently noted the rapid (5−15 min) conversion of enol silyl ethers from cyclohexanones into the corresponding trichlorotitanium enolates, with $TiCl_4$ in halocarbon solvents at 20−35°C. While this process is unlikely to be complete under our reaction conditions (−78°C), a significant amount of the trichlorotitanium enolate must be formed which could then react, given the particularly stable, quasi-aromatic nature of the thiochromone produced, by the redox mechanism shown in Scheme 2 to give **9**. The formation of a violet color, perhaps indicative of Ti^{III}, is observed during the reaction. Once again, modification of the conventional reaction conditions was instrumental in eliminating this problem. It was found that by pre-coordinating the ketone with titanium tetrachloride at −78°C, *followed by* addition of the enol silyl ether, the amount of thiochromone formed became negligible and no violet coloration was observed during the reaction. Conversion yields of the alkylidene derivatives did not change dramatically but the corrected yields were higher (see Table 1).

In one experiment the *tert*-butyldimethylsilyl ether analog of **6***a* was used but the conversion to **7***a* achieved (26 vs. 22%) was only marginally better. The remaining aspect which we examined in our preliminary investigation was the importance of the Lewis acid catalyst used. The results of a number of reactions of enol silyl ethers **6***a*,*b* with cyclopentanone or cyclohexanone using a variety of Lewis acids and, in one

[a]Isolated yields, uncorrected for recovered **3***b*.

instance, tetrabutylammonium fluoride as catalyst have been summarized in Table 1. The yields of the condensation products have been corrected to allow for substantial recovery (0–95%) of **3***a* or **3***b* in almost all cases. It is quite clear from these results that, while the list of Lewis acids is not exhaustive, only $TiCl_4$ and BF_3 are effective in catalyzing this difficult condensation reaction. The use of triethylamine in conjunction with the titanium tetrachloride appeared to have little effect on the success of the reaction.

Returning to our original goal of establishing a viable synthetic route to 3-alkylidene-4-thiochromanone 1,1-dioxide analogs, we have now successfully extended our investigation of the utility of the method to a fairly large variety of ketones and aldehydes, as shown by Table 2. Since the purpose of these reactions is primarily synthetic, the yields shown in this table are *uncorrected* and represent conversion to isolated products in each case. The yields are modest but represent the only viable general route so far reported to these novel derivatives of 4-thiochromanone, a ring system of continuing biological interest (1, 2, 15). Benzophenone did not react with **6***b* under these conditions, while acetophenone gave only a trace of the expected product.

The application of a modern variant of the classical aldol reaction described in this study has revealed once again the impressive ability of enolate equivalents to overcome serious problems arising from the use of strongly basic, or acidic, reaction conditions. A convenient route to the otherwise difficulty accessible 3-alkylidene-4-thiochromanones is thereby revealed.

Experimental

Infrared spectra were recorded in chloroform on a Perkin–Elmer 298 grating spectrophotometer. The ^{1}H nmr spectra were obtained on a EM-360 spectrometer in $CHCl_3$-*d* solution unless otherwise indicated. Routine (low-resolution) mass spectra were obtained with a Du Pont 21-490 spectrometer and the high-resolution data on the AEI-MS 3074 instrument. Column chromatography and tlc (analytical and preparative) were carried out on silica gel supplied by E. Merck (Darmstadt). Elemental analyses were performed by the Scandinavian Microanalytical Laboratory, Box 25 DK2730, Herlev, Denmark. Melting points are uncorrected.

DME (1,2-dimethoxyethane) was dried from sodium benzophenone ketyl. Triethylamine, diisopropylamine, and toluene were dried by distillation over sodium. Chloroform and dichloromethane were dried with calcium chloride. Carbonyl compounds were routinely distilled on a Büchi–Brinkmann Kugelrohr apparatus. Titanium tetrachloride, if yellow, was distilled from zinc, although this additional precaution did not appear to affect the product yields obtained.

Preparations of enol silyl ethers **6**a,b

(a) *4-Trimethylsilyloxy-3-thiochromene,* **6**a

Potassium iodide (7.52 g, 45 mmol) was stirred in dry chloroform (25 mL), cooled to 0°C under N_2, and chlorotrimethylsilane (2.0 mL, 16 mmol) added, followed by the slow addition of a solution of 4-thiochromanone (**3***a*) (1.13 g, 6.9 mmol) and triethylamine (2.0 mL, 27 mmol) in dry chloroform (25 mL). The solution was allowed to warm to 25°C, then refluxed 16 h in the dark. Filtration and removal of solvent yielded crude **6***a* (1.47 g, 94%). This was distilled (Kugelrohr) at 130–140°C/0.9 torr (1 Torr = 133.3 Pa) (lit. (12) bp 115–118°C/0.75 Torr); ir ν: 1255 (C—O), 1640 (C=C) cm^{-1}; ^{1}H nmr δ: 0.2 (s, 9H), 3.4 (d, J = 6 Hz, 2H), 5.13 (t, J = 6 Hz, 1H), 6.8–7.3 (m, 3H), 7.3–7.6 (m, 1H) ppm (lit. (12) δ 5.12 (t, J = 5.1 Hz) ppm).

(b) *4-Trimethylsilyloxy-3-thiochromene 1,1-dioxide,* **6**b[2]

Dissopropylamine (3.02 mL, 22 mmol) was dissolved in dry DME (40 mL) and cooled to −78°C under N_2. 2.5 *M* n-Butyllithium (8.40 mL, 22 mmol) was added, followed 30 min later by the addition of a solution of 4-thiochromanone 1,1-dioxide **3***b* (4.01 g, 21 mmol) and chlorotrimethylsilane (6.50 mL, 51 mmol) in DME (40 mL). The red solution was allowed to warm to room temperature, then filtered and the solvent removed. The solid was redissolved in dichloromethane (60 mL) and the solution washed with saturated sodium bicarbonate solution (50 mL). The organic layer was dried ($MgSO_4$), filtered, and evaporated to yield **6***b* as a red oil (5.16 g, 96%). This crude product was satisfactory for further use and was not amenable to further purification by recrystallization, distillation, or chromatography (silica gel or alumina); ir ν: 1155 (SO_2), 1260 (C—O), 1320 (SO_2), 1642 (C=C) cm^{-1}; ^{1}H nmr δ: 0.2 (s, 9H), 3.85 (d, J = 6 Hz, 2H), 5.3 (t, J = 6 Hz, 1H), 7.4–7.7 (m, 3H), 7.8–8.0 (m, 1H) ppm.

3-Hydroxymethylene-4-thiochromanone, **4**

The procedure of Tilak (10) was modified by substituting an equimolar quantity of sodium hydride for sodium methoxide and an equal volume of toluene for benzene. Compound **4** was obtained in 95% yield and was distilled (Kugelrohr) at 140°C/1.5 Torr; ^{1}H nmr δ: 3.5 (s, 2H), 7.0–7.3 (m, 3H), 7.8–8.0 (m, 1H), 8.3 (s, 1H), 14.7 (s, 1H, disappears in D_2O) ppm. The red oil was stable and storable at 0°C.

3-Formyl-3-phenylthiomethyl-4-thiochromanone, **5**

Sodium hydride (0.27 g, 9.0 mmol) was slurried in dry DME (5.0 mL) and a solution of 3-hydroxymethylenethiochromanone **4** (1.71 g, 8.9 mmol) in DME (5.0 mL) added slowly at 0°C. Chloromethyl phenyl sulfide (1.20 mL, 8.9 mmol) was slowly added and the red slurry warmed to 25°C for 13 h, then refluxed a further 5 h, by which time the red color had disappeared. The solution was cooled and water added (1.0 mL) before evaporation of the solvent. The resultant red oil was dissolved in dichloromethane (50 mL) and washed with 1 *M* hydrochloric acid (20 mL). The acid layer was washed twice with dichloromethane (30 mL), the organic layers combined, dried ($MgSO_4$), filtered, and solvent removed to yield a red oil (2.80 g). This was chromatographed on a silica-gel thick-layer plate (dichloromethane) wtih a "pre-concentration" zone to yield **5** as a yellow oil (24%); ^{1}H nmr δ: 3.75 (s, 2H), 3.8 (s, 2H), 7.0–7.5 (m, 8H), 7.9–8.1 (m, 1H), 9.85 (s, 1H) ppm; ms *m/z*: 314(M^+, 1), 284(32), 175(100).

General procedures for Lewis acid catalyzed reactions of **6**a,b *with ketones/aldehydes*

Method A

3-Cyclohexylidene-4-thiochromanone, **8**a

4-Trimethylsilyloxy-3-thiochromene **6***a* (1.02 g, 4.3 mmol) and cyclohexanone **11** (0.50 mL, 4.9 mmol) were dissolved in dry dichloromethane (10 mL) and cooled to −78°C under N_2. Titanium tetrachloride (0.50 mL, 4.6 mmol) was added, turning the yellow solution black. The solution was allowed to warm to 25°C and stirred 18 h, before diluting with dichloromethane (50 mL) and washing with 1 *M* hydrochloric acid (50 mL), followed by saturated sodium bicarbonate (50 mL). Drying ($MgSO_4$), filtration, and evaporation yielded a dark oil which was chromatographed on silica gel. Dichloromethane/carbon tetrachloride (50:50) eluted **8***a* as a yellow oil (0.34 g, 32%); ir ν: 1682 (C=O) cm^{-1}; ^{1}H nmr δ: 1.4–2.1 (m, 6H), 2.3 (t, 2H), 2.6 (t, 2H), 4.3 (s, 2H), 7.6–8.0 (m, 3H), 8.0–8.2 (m, 1H) ppm; ms *m/z*: 244(100), 163(33), 136(53). *Exact mass* calcd. for $C_{15}H_{16}OS$: 244.0918; found (high resolution ms): 244.0925.

Dichloromethane/carbon tetrachloride (75:25) eluted 4-thiochromanone **3***a* (0.45 g, 63%).

3-Cyclopentylidene-4-thiochromanone, **7**a

Compound **6***a* (1.03 g, 4.4 mmol) and cyclopentanone **10** (0.40 mL, 4.5 mmol) were dissolved in dry dichloromethane (10 mL), cooled to −78°C under N_2, and titanium tetrachloride (0.38 mL, 3.5 mmol) added.

Work-up as above yielded a black oil (0.91 g) which was chromatographed on a silica gel thick-layer plate (dichloromethane) to yield **7***a* as a pale yellow oil (0.22 g, 22%); ^{1}H nmr δ: 1.5–1.8 (m, 4H), 2.4 (t, 2H), 2.75 (t, 2H), 3.7 (s, 2H), 7.0–7.3 (m, 3H), 7.9–8.2 (m, 1H) ppm; ms *m/z*: 230(100), 201(22), 197(26), 136(57).

4-Thiochromanone **3***a* was also recovered (0.24 g, 24%), as well as thiochromone **9** (0.14 g, 20%).

Method B

3-Cyclohexylidene-4-thiochromanone 1,1-dioxide, **8**b

Titanium tetrachloride (0.35 mL, 3.2 mmol) was added to a solution of cyclohexanone (0.33 mL, 3.2 mmol) at 0°C in chloroform (15 mL) under N_2. The addition of triethylamine (0.80 mL) turned the yellow solution red. A solution of 4-trimethylsilyloxy-3-thiochromene 1,1-dioxide **6***b* (0.80 g, 3.0 mmol) in dichloromethane (3 mL) was slowly added and the solution allowed to warm up to 25°C. After 18 h, the solution was diluted with dichloromethane (50 mL) and washed with 1 *M* hydrochloric acid (50 mL), saturated sodium bicarbonate (50 mL), dried ($MgSO_4$), filtered, and evaporated to yield a brown oil (0.75 g) which was chromatographed on silica gel. Dichloromethane/carbon tetrachloride (50:50) eluted **8***b* (0.28 g, 33%). This was recrystallized from 95% ethyl alcohol to yield pale yellow crystals, mp 138–139°C. (No 4-thiochromanone 1,1-dioxide was recovered in this case.) *Anal.* calcd. for $C_{15}H_{16}O_3S.\frac{1}{2}C_2H_5OH$: C 64.21, H 6.35, S 10.70; found: C 64.55, H 6.08, S 10.71.

3-Isopropylidene-4-thiochromanone 1,1-dioxide, **12**

Method B was used, with acetone (0.39 mL, 5.3 mmol) and titanium tetrachloride (0.57 mL, 5.3 mmol) in dichloromethane (5 mL) at −78°C, followed by the addition of **6***b* (1.39 g, 5.2 mmol) in dichloromethane (5.0 mL). Work-up afforded a brown oil (0.85 g) from which **12** (42%) was isolated by chromatography on a silica-gel thick-layer plate, mp 107–108°C. *Anal.* calcd. for $C_{12}H_{12}O_3S$: C 61.00, H 5.12, S 13.57; found: C 61.01, H 5.32, S 13.41.

[2]Silyl ether **6***a* could also be made conveniently using this procedure.

3-Isobutylidene-4-thiochromanone 1,1-dioxide, 13

Method B was used, with isobutyraldehyde (0.41 mL, 4.5 mmol), titanium tetrachloride (0.48 mL, 4.5 mmol) in dichloromethane (10 mL) at −78°C, followed by the addition of **6***b* (1.18 g, 4.4 mmol) in dichloromethane (10 mL). Work-up afforded a brown oil (0.95 g) from which pure **13** was isolated (0.32 g, 30%) as a yellow solid, mp 98°C (95% EtOH); ms *m/z*: 250(20), 186(72), 171(52), 132(100). *Exact Mass* calcd. for $C_{13}H_{14}O_3S$: 250.0646; found (high resolution ms): 250.0663.

3-Benzylidene-4-thiochromanone 1,1-dioxide, 14

Method B was used, with a solution of **6***b* (1.39 g, 5.2 mmol) in dichloromethane (5 mL) being added to a solution of titanium tetrachloride (0.58 mL, 5.3 mmol) and benzaldehyde (0.54 mL, 5.3 mmol) at −78°C. Chromatography of the oil (0.34 g) resulting from work-up afforded pure **14** (0.27 g 18%) on elution with dichloromethane/carbon tetrachloride (50:50), as a solid, mp 172°C (95% EtOH); ir *ν*: 1155, 1320 (SO_2), 1675 (C=O) cm^{-1}; ms *m/z*: 284(82), 220(85), 192(100). *Exact Mass* calcd. for $C_{16}H_{12}O_3S$: 284.0503; found (high resolution ms): 284.0510.

3-(2-Heptylidene)-4-thiochromanone 1,1-dioxide, 15

Method B was used, with a solution of **6***b* (1.39 g, 5.2 mmol) in dichloromethane (7 mL) being added to a solution of 2-heptanone (0.75 mL, 5.3 mmol) and titanium tetrachloride (0.58 mL, 5.3 mmol) in dichloromethane. Work-up afforded a dark oil (1.40 g) from which pure **15** (0.17 g, 11%) was obtained by column chromatography with dichloromethane/carbon tetrachloride (75:25) as eluant. Attempted recrystallization from 95% ethanol yielded only a tan oil; ir *ν*: 1150, 1318 (SO_2), 1677 (C=O) cm^{-1}; ms *m/z*: 292(5), 166(11), 149(100). *Exact Mass* calcd. for $C_{16}H_{20}O_3S$: 292.1127; found (high resolution ms): 292.1140.

Method C

*3-Cyclopentylidene-4-thiochromanone 1,1-dioxide, 7*b

Silyl ether **6***b* (1.14 g, 4.3 mmol) and **10** (0.38 mL, 4.3 mmol) were dissolved in dry dichloromethane (25 mL) and cooled to −78°C. A slow stream (1 bubble/s) of boron trifluoride was passed through the solution in a N_2 stream (3 bubbles/s) until fuming was observed in the sodium hydroxide solution exit trap. The flow of gases was continued for an additional 15 min before the reaction flask was allowed to warm to room temperature and stirred a further 16 h. The mixture was then poured into saturated sodium bicarbonate solution (50 mL) and extracted three times with dichloromethane (30 mL). The organic layers were combined, dried ($MgSO_4$), filtered, and evaporated to yield a brown oil (1.07 g), from which **7***b* was obtained (0.28 g, 25%), mp 126.7°C (95% EtOH); ir *ν*: 1155, 1322 (SO_2), 1670 (C=O) cm^{-1}; ms *m/z*: 262(100), 197(48), 169(40). *Exact Mass* calcd. for $C_{14}H_{14}O_3S$: 262.0660; found (high resolution ms): 262.0664.

Hydrogenation of phenol at 2.8 MPa pressure with $MoO_3-NiO-Al_2O_3$ catalyst at 450°C gave 60% benzene, 16% cyclohexane, and 7% methylcyclopentane, while anisole under the same conditions gave 60–70% less of each of these products and 52% methylated benzenes. In the presence of added methanol either phenol or anisole give 47–63% of methylbenzenes and 22% of methylated phenols. At 350–400°C significant yields of cyclohexylbenzene and cyclohexylphenol were formed. The reactions are interpreted as involving electrophilic methylation or cyclohexylation of phenol concurrent with ring hydrogenation and hydrogenolysis of C—O bonds. Cyclohexyl cations are proposed as reactive intermediates that act as cyclohexylating agents or rearrange to methylcyclopentyl cations, and the methylating species is derived from methanol or the methyl group of anisole. When phenol was reacted with H_2 and CD_3OH the methylated aromatic products were only partially deuterated, indicating exchange with the H_2 atmosphere was occurring. Control experiments involving possible intermediates in the reaction are consistent with these conclusions. Nickel catalysts favour ring saturation over C—O bond cleavage.

R. K. M. R. KALLURY, T. T. TIDWELL, D. G. B. BOOCOCK et D. H. L. CHOW. Can. J. Chem. **62**, 2540 (1984).

L'hydrogénation du phénol à une pression de 2,8 MPa, à 450°C et utilisant un catalyseur de $MoO_3-NiO-Al_2O_3$ fournit un mélange formé de 60% de benzène, 16% de cyclohexane et 7% de méthylcyclopentane; dans les mêmes conditions, l'anisole fournit de 60 à 70% de moins de chacun de ces produits et 52% de benzènes méthylés. Si on ajoute du méthanol au milieu réactionnel, le phénol ainsi que l'anisole conduisent à 47–63% de méthylbenzènes et 22% de phénols méthylés. A des températures de 350 à 400°C, il se forme des quantités importantes de cyclohexylbenzène et de cyclohexylphénol. On suppose que ces réactions impliquent que, concurrement avec l'hydrogénation du cycle et l'hydrogénolyse des liaisons C—O, il se produit des réactions de méthylation ou de cyclohexylation électrophiles du phénol. On propose les cations cyclohexyles comme intermédiaires réactionnels qui agissent comme agents cyclohexylants ou qui se transposent en cations méthylcyclopentyles; les espèces méthylantes proviendraient soit du méthanol soit du groupe méthyle de l'anisole. Lorsqu'on fait réagir du phénol avec du H_2 et du CD_3OH, les produits aromatiques méthylés qui se forment ne sont que partiellement deutérés; ceci indique qu'il se produit un échange avec le H_2 du milieu. Des réactions de contrôle impliquant des intermédiaires réactionnels possibles sont en accord avec ces conclusions. Les catalyseurs de nickel favorisent la saturation du cycle plutôt que la rupture de la liaison C—O.

Introduction

The thermal liquefaction of wood is a process for biomass conversion that has recently been the object of study in many different laboratories (1–7). Analysis of the chemical composition of the liquefaction products has revealed the presence of alkylphenols as well as cyclic ketones that may be derived at least in part from phenols (8–11). The present investigation was undertaken for the purpose of understanding some of the chemical pathways that may occur during liquefaction and also for studying the reactivity of the phenols themselves in processes that might form upgraded products with increased value as fuels. Increased yields of aromatics and decreased oxygen content would be particularly desirable for the latter goal.

Previous studies on the hydrogenolysis of phenol indicate that under most conditions for removal of the OH function saturation of the ring also occurs (12–14). However, it has been demonstrated that the use of molybdenum-based catalysts gives significant yields of aromatic hydrocarbons (15). Accordingly this study has concentrated on hydrogenation in the presence of a molybdenum catalyst.

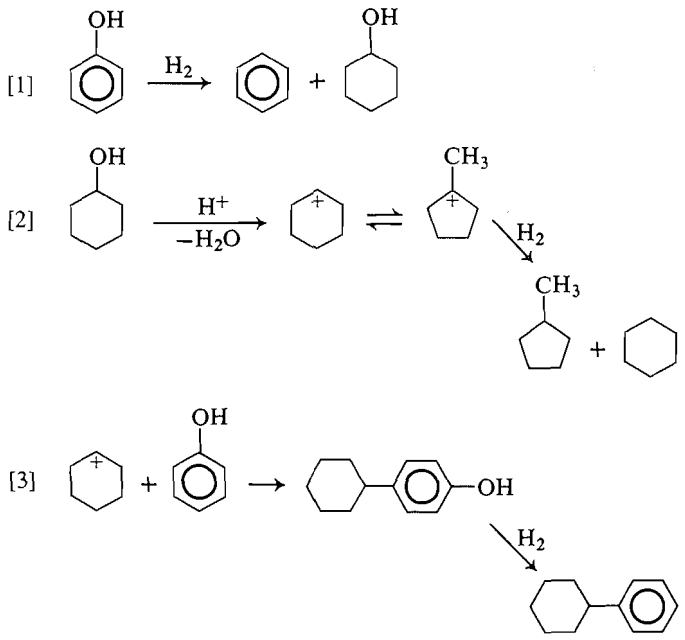
Experimental

A. Procedure for hydrogenolysis

Approximately 10 g of the substrate was placed in a 1 L stirred autoclave reactor (AE Autoclave of Canada Ltd.) with approximately 1.5 g of BASF catalyst M 8-21 (15% MoO_3, 3% NiO on activated alumina) enclosed in two stainless steel mesh baskets suspended in the vapour region of the reactor. The autoclave was sealed, hydrogen-flushed twice, and charged with hydrogen to the desired cold pressure (2.8–9.8 MPa). The autoclave was heated to the desired temperature (350–450°C) at the rate of approximately 5°/min, with the reported reaction time commencing from the point of reaching the desired temperature. After the contemplated reaction period the heaters were removed and the reactor cooled. After venting of the gases the reactor was opened and the liquid product collected and weighed.

B. Analysis of the liquid products

The dried ($MgSO_4$) liquid was analyzed by a three-step procedure: (*i*) initially, the product mixture from each reaction was subjected to analytical gas chromatography and peak retention times compared with those of standards (which include commercial or synthesized methylcyclopentane, cyclohexane, cyclohexene, benzen, toluene, *o*-, *m*-, and *p*-xylenes, 1,2,4- and 1,3,5-trimethylbenzenes, 1,2,4,5-tetramethylbenzene, phenol, *o*-, *m*-, and *p*-cresols, 2,4- and 2,6-dimethylphenols, and *o*- and *p*-cyclohexylphenols, diphenyl, and cyclohexylbenzene); (*ii*) each product mixture was then subjected to gc–ms and comparison of each peak from the resulting mass chromatogram (a plot of the total ion current against time/scan number) with the analytical gc of the same product mixture confirmed the structure of the substance corresponding to each peak; and finally (*iii*) the reaction product from each substrate was subjected to preparative gas chromatography and the structures of individual products isolated there



SCHEME 1

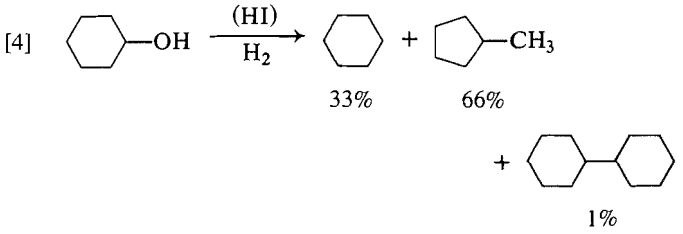
from unequivocally established by ^{1}H-nmr and mass spectra. The instrumentation used has been described previously (11).

Results and discussion

The reaction of phenol using the MoO_3-NiO catalyst at 450°C and 2.8 MPa gave essentially complete conversion of the reactant after 45 min reaction time, with formation of benzene (60%), cyclohexane (16%), and methylcyclopentane (7%) as the major products. In addition, a group of products were formed that were presumably derived from coupling of two phenol-derived units, namely, cyclohexylcyclohexane (2%), diphenyl (3%), and cyclohexylbenzene (2%). These results indicate that benzene is essentially inert to these reaction conditions and this was confirmed experimentally (Table 1).

A mechanism to explain these observations is shown in Scheme 1 (reactions [1]–[3]).[1] A key feature of this proposed pathway is the intermediacy of cyclohexanol as the precursor to cyclohexane, methylcyclopentane, and the C_{12}-products, so this was tested by examining the reactivity of various cyclic C_6 compounds under the same conditions (Table 1). The failure of benzene, cyclohexane, cyclohexene, or cyclohexanone to form major amounts of methylcyclopentane or the C_{12}-products indicates that these reactants are not major participants as reactive intermediates in phenol reduction, whereas the observed formation of methylcyclopentane and cyclohexane from cyclohexanol is in accord with Scheme 1. The isomerization of cyclohexane to methylcyclopentane has been observed on heating with catalysts (16), but, as shown in Table 1, is not significant under our reaction conditions. The intervention of a cyclohexyl cation as shown in Scheme 1 can accommodate this product, as the rearrangement of the cyclohexyl cation to the methylcyclopentyl system is a known process (17). The intervention of the cyclohexyl cation provides a reasonable pathway for formation of the C_{12}-products as well by the known electrophilic aromatic substitution on phenol (18). Free radical intermediates are excluded on the basis that rearrangement of the cyclohexyl radical to the methylcyclopentyl system is not normally observed (19). The failure to form C_{12}-products from cyclohexanol itself is expected in the absence of phenol.

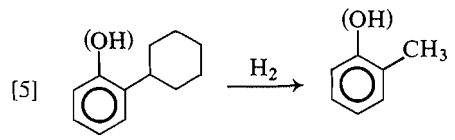
In an interesting analogue of this reaction cyclohexanol was reacted with hydrogen and iodine at 7 MPa at 300°C to give a 40% yield of hydrocarbons in the ratio shown (reaction [4]) (20).



This process was shown to involve alkyl iodides and while the mechanism of their reaction was left open, the formation of cyclohexylcyclohexane was attributed to a free radical dimerization. As already noted, free radical intermediates would not provide a route to the large amounts of methylcyclopentane, whereas the alkyl iodides should be good sources of carbonium ions so such intermediates are strongly implied in this reaction. The similarity of the products observed in our work and in this latter study also suggests that our MoO_3-NiO catalyst does not play a crucial role in the cyclohexyl/methylcyclopentyl interconversion.

At lower temperatures (350 or 400°C, Table 2) the conversion of phenol is not complete even after 2 h, and the proportion of saturated products has increased at the expense of the benzene. Evidently the reaction mechanism for the hydrogenolysis of phenol to benzene and the ring saturation to cyclohexanol are quite different, and the former process becomes much more favourable at higher temperatures. This effect has been observed before by Cawley (21) who found that ammonium molybdate on charcoal converted phenol to cyclohexane and benzene in 37 and 25% yields at 400°C, and 35 and 44%, respectively, at 450°C.

The reaction of *o*-cyclohexylphenol under comparable conditions (Table 1) provides a further insight into this reaction sequence. The product mixture resembled that from phenol itself, and the formation of methylbenzenes provides a clue to the origin of these products from phenol. Degradation of the cyclohexylarene to a methylarene (reaction [5]) evidently occurs as one of the reaction pathways, although it cannot be specified whether this reaction precedes hydrogenolysis of the phenolic OH. This reaction also explains why significant yields of cyclohexylphenols are observed at 350–400°C but not at 450°C (Table 2). Evidently these products do not survive the higher temperature.



Anisole was 98% consumed on reaction with the MoO_3-NiO catalyst at 450°C and 2.8 MPa (Table 1), but in comparison to phenol gave only about a third of the amounts of methylcyclopentane, cyclohexane, and benzene. Instead tolu-

[1]This description of a mechanism for a reaction at high temperature in the presence of inhomogeneous catalysts in terms of specific reaction intermediates familiar from reactions in solution near room temperature is surely naive. Nevertheless, a consistent and useful rationalization does emerge from this analysis.

ene, xylenes, and tri- and tetramethylbenzenes constituted 52% of the volatile product, along with 20% of phenol and mono- and dimethylphenols. If methanol was added to the reaction of either phenol or anisole then the formation of C_6 products decreased still further and methylated benzenes and phenols made up at least 80% of the product.

Evidently phenol is methylated by a reactive species derived from methanol, and the methyl group of anisole is also active in ring methylation. The alkylation of the phenol nucleus must precede cleavage of the OH group, as benzene is unreactive under these conditions and xylene gives only 15% conversion to other products (Table 1). The much greater reactivity of phenol compared to benzene and xylene is consistent with an electrophilic attack on the phenol to give methylated phenols, which then undergo hydrogenolysis to the methylbenzenes (reaction [6]).

[6] 
There have been previous reports of methylation of phenol by methanol and MoO_3 catalysts, for example, that of Inoue and Enomoto shown in reaction [7] (22). A similar preference for *o*-methylation was observed for reaction of phenol and methanol with ThO_2 (23).

[7] 
The preference for substitution *ortho* to the OH group was ascribed by these latter authors (23) to coordination of phenol and methanol to neighboring sites on the catalyst surface and delivery of the methyl group in an electrophilic attack to the nearby *ortho* position (reaction [8]). Inoue and Enomoto (22) also suggested that electrophilic attack on the ring by an alkyl cation on the catalyst surface could occur. The *p*-position of the phenol ring would also be accessible for such a process and this mechanism provides a satisfactory explanation of our results.

[8] 
The details of the alkylation process were elucidated further in an experiment in which phenol was reacted with CD_3OH (Table 1). The product distribution resembled that for the comparable reaction with CH_3OH, but in the former case the conversion of phenol dropped to 75% instead of 90%, and the yield of polymethylated benzenes was greatly reduced (18% vs. 56%) while the amount of methylphenols was significantly greater (15% vs. 3%). The lower extents of methylation and hydrogenolysis are presumably due to the proportionally lower amount of methanol and the somewhat lower pressure used in the CD_3OH experiment.

The deuterium contents[2] of the products in the CD_3OH experiment were monitored using CIMS and gc–ms, with the following results: benzene (d_0/d_1 = 1/0.3), toluene ($d_0/d_1/d_2/d_3$ = 1/0.6/0.5/0.4), phenol (d_0/d_1 = 1/0.3), cyclohexane (d_0/d_1 = 1/0.5), xylenes ($d_0/d_1/d_2/d_3/d_4/d_5/d_6$ = 1/0.6/0.3/0.2/0.1/0.05/0.03). The alkylphenols showed comparable deuterium incorporation.

These results show that there has been considerable isotopic exchange by hydrogen for deuterium in the methylated aromatic products. One plausible pathway for this exchange would be isotopic exchange of the methanol through dedeuteration to a formaldehyde intermediate on the catalyst surface which is then hydrogenated to methanol which attacks the aryl ring as depicted in reaction [8]. An alternative pathway would involve attack by the formaldehyde unit (reaction [9]), and is similar to

[2]Corrected for natural isotopic abundance.

a process proposed by Inoue and Enomoto for MgO catalyst (22). A third alternative would be the exchange of the aryl-methyls by hydrogen after ring-substitution has occurred; there is evidence for such a reaction using Ni catalysts (24). However, under these latter conditions exchange of the aryl hydrogens in both benzene and alkylbenzenes occurred, whereas under our conditions this is evidently not the case.

[9] 
The benzene and cyclohexane formed had each undergone monodeuteration to the extent of about 30%, with very little, if any, higher deuteration. This result indicates that the deuterium is incorporated in the hydrogenolysis of the OH group and not in the hydrogenation of the ring. This reaction could occur by nucleophilic substitution with concomitant formation of formaldehyde as shown in reaction [10].

[10] 
The recovered phenol was shown by its mass spectrum to have the deuterium incorporated as PhOD. This result shows that deuterium originally present as CD_3OH has been converted to part of the hydroxylic hydrogen pool.

The reaction of cyclohexanone with MoO_3–NiO catalyst (Table 1) gives a product composition significantly different from that of cyclohexanol, so it is apparent that reduction of cyclohexanone to cyclohexanol is not a major reaction pathway under these conditions. In particular 36% of cyclohexene is observed, as well as 4% of phenol and 11% of cyclohexylbenzene and biphenyl which are evidently derived from phenol. The formation of phenol from cyclohexanone on catalytic treatment has been observed before (25) and presumably occurs via enolization of the cyclohexanone (reaction [11]). A metal enolate (**1**) could undergo hydrogenolysis to provide the observed cyclohexene (reaction [12]). This suggestion is related to the proposal of a "π-allylic intermediate" (**2**) in the reaction of cyclohexanol on platinum (25), and similar oxo-π-allylpalladium complexes have been reported (26) and provide an alternative to the enolate **1**.

[11] 
[12] 
The strong effect of MoO_3-based catalysts in removing oxygen from organic molecules appears in the conversions of both phenol to benzene, and cyclohexanone to cyclohexene. The active molybdenum species under the reaction conditions of high temperatures and hydrogen atmosphere has been shown to be Mo(IV) (27), and evidently this species has a high affinity for oxygen which facilitates cleavage of the C—O bond by hydrogen.

The reduction of anisole with nickel catalysts (Table 3) gave quite different results from the reaction with the molybdenum-based catalyst. Raney nickel without solvent was the most active catalyst, and the predominant reaction was saturation of the aromatic ring. No ring methylated products were observed.

The NiO in the BASF catalyst clearly does not have the catalytic activity of the nickel catalysts surveyed in Table 3, for even at the higher temperatures used in the former reactions the extent of benzene hydrogenation is low. The specificity of this MoO_3–NiO on alumina catalyst is emphasized by the observation that MoO_2 supported on nickel is an effective catalyst for the hydrogenation of benzene to cyclohexane (28).

In summary, the use of MoO_3-NiO catalyst is quite effective for the hydrogenation of phenol to benzene and this process shows promise for the upgrading of wood oils. The conversion of anisole or of phenol and methanol to methylated aromatics by the catalyst indicates that this process will also occur in wood oils because of the presence of aryl methyl ethers in the original lignin. The observations of the degradation of o-cyclohexylphenol and the isotopic exchange of the CD_3OH-

derived products demonstrate the severity of the reaction conditions and the complexity of the processes which occur.

Spectroscopic studies of the compatibility of small molecules in polymers

RAFIK O. LOUTFY AND BENG S. ONG
Xerox Research Centre of Canada, 2660 Speakman Drive, Mississauga, Ont., Canada L5K 2L1

Received March 16, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

RAFIK O. LOUTFY and BENG S. ONG. Can. J. Chem. **62**, 2546 (1984).

A spectroscopic technique has been developed to study the compatibility and stability of small molecules in polymers. The technique was applied to investigate the compatibility of an electron-acceptor molecule, *n*-butyl 9-dicyanomethylene fluorene-4-carboxylate (BDFC), **1**, in six different polymers. The electronic absorption of the small molecule **1** in polymer films as a function of concentration and temperature was examined. The deviation in the absorption of **1** from the molecular absorption properties was taken to indicate the degree of incompatibility (phase separation). The small molecule **1** was found to be most compatible with halogenated and electron-donating polymers.

In general, our results indicated the existence of very strong intermolecular interaction between the small molecules and weaker small molecule – polymer interaction, which lead to the small molecule aggregation, i.e., incompatibility. The extent of aggregation of **1** in various polymers varied with the concentration of **1**, the speed of drying the film, and the post-casting heat treatment. Aggregation of **1** in polycarbonate was drastically suppressed by incorporating a donor molecule into the matrix.

RAFIK O. LOUTFY et BENG S. ONG. Can. J. Chem. **62**, 2546 (1984).

On a développé une technique spectroscopique permettant d'étudier la compatibilité et la stabilité des petites molécules dans des polymères. On a appliqué la technique pour étudier la compatibilité d'une molécule acceptrice d'électrons, le dicyanométhylène-9 fluorènecarboxylate-4 de *n*-butyle (BDFC) (**1**), dans six polymères différents. On a aussi évalué, en fonction de la concentration et de la température, l'absorption électronique de la petite molécule **1** dans des films de polymère. On a utilisé la déviation dans l'absorption de **1**, par rapport aux propriétés moléculaires d'absorption, comme mesure de l'incompatibilité (séparation de phase). On a trouvé que la compatibilité de la petite molécule **1** est maximale avec les polymères halogénés et les polymères donneurs d'électrons.

D'une façon générale, nos résultats indiquent qu'il existe de très fortes interactions intermoléculaires entre les petites molécules et des interactions plus faibles entre la petite molécule et les polymères; ceci conduit à une aggrégation des petites molécules, donc à une incompatibilité. Le taux d'aggrégation de **1** dans divers polymères varie avec la concentration de **1**, la vitesse de séchage du film et avec les traitements par la chaleur opérés après le moulage. L'incorporation d'une molécule donneur dans la matrice supprime d'une façon dramatique l'aggrégation de **1** dans le polycarbonate.

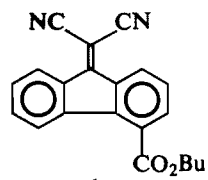
Introduction

The idea of dispersing or dissolving small electron-acceptor or -donor molecules into solid polymer matrices has attracted a great deal of interest in industry, mainly because such devices are simple to fabricate, economical, and have wide technological applications. Xerographic applications in charge carrier generation layer (1, 2), and charge transport layer (3, 4) have been documented. The unique feature of stable molecularly-doped polymer systems is that the reactants are held apart at fixed distance which is controlled by the concentration and the molecular size of the charge rely molecule. In practice, it has been shown that the microscopic structure of these small molecules in the matrix has a profound effect on the performance of these devices. Inhomogeneity due to microcrystallization or aggregation of the small molecule in the polymer matrix can dramatically change the electrical properties of such layers. The crystallization and aggregation phenomena are dominated by intermolecular interaction forces between the small molecules (molecule–molecule interaction) and with the host polymer (molecule–polymer interaction). In order to have better control over the properties of a given device, knowledge of the microscopic characteristics of the material package is essential.

In this work the photophysical properties of an electron-acceptor molecule butyl 9-dicyanomethylene fluorene-4-carboxylate (BDFC) **1** (5) in different polymer matrices were studied. This material when incorporated into a polymer matrix was shown to exhibit good electron mobility (5).

We used spectroscopic techniques to probe the microscopic properties of BDFC **1** in six different polymers and to monitor the stability of the small molecules in these matrices. We observed broadening and decrease in the absorption coefficient as the concentration of **1** increased or the polymer films were heated for extended periods above 60°C.



1

Experimental section

Materials

n-Butyl 9-dicyanomethylene fluorene-4-carboxylate was synthesized (5) via the condensation of *n*-butyl fluorenone-4-carboxylate with malononitrile in methanol in the presence of piperidine. The product was purified by recrystallization from acetone/methanol. Polyvinylcarbazole, polyvinylchloride, and copolyvinylidene chloride – vinylacetate (10%) were obtained from Poly Science; polyvinyl butyral was obtained from Aldrich; polyvinylidene chloride – acrylonitrile (SF-310) from Dow Chemical Company; and bisphenol – a polycarbonate, (Makrolon) obtained from Bayer. All polymers except polyvinylcarbazole were used as received. Polyvinylcarbazole was purified by dissolving in methylene chloride and precipitating with methanol. Glass substrates were obtained from Corning (7059) and were washed with soapy water and distilled water (twice) in an ultrasonic bath; they were then dried before use. Methylene chloride (glass distilled) was from BDH.

Preparation of the small molecule-in-polymer films

Various concentrations of the polymers and **1** in methylene chloride

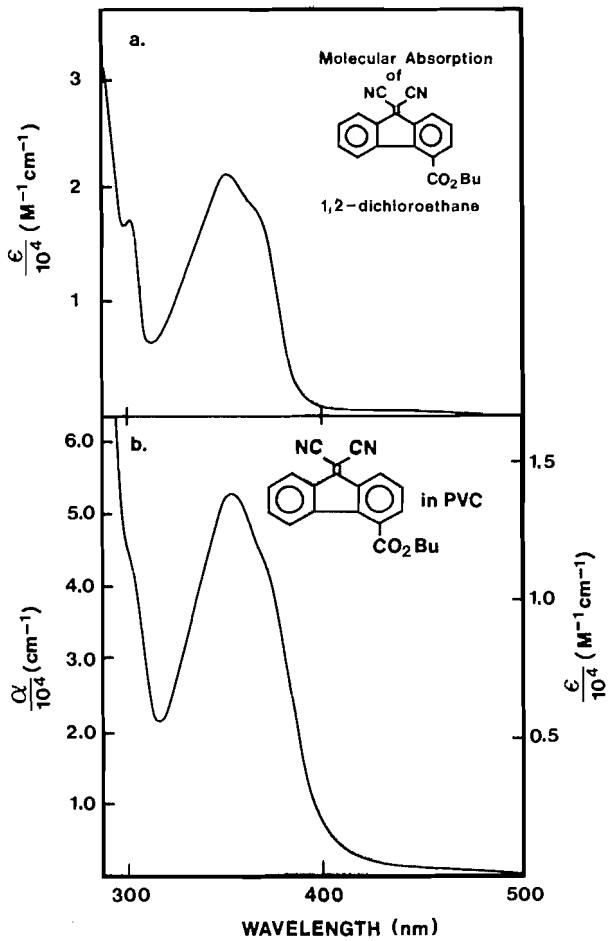


FIG. 1. Molecular electronic absorption of **1**, (*a*) in 1,2-dichloroethane and (*b*) at low concentration (21% by weight) in polyvinylchloride.

were prepared by vibrating in an ultrasonic bath until a clear solution was achieved. The solutions were filtered through 1 μm Millipore filters and then spin coated onto precleaned 2 in. × 2 in. glass substrate, using a Model 1-EC-101 Headway Research photoresist spinner. Uniform and optically clear films were obtained. The film thickness was controlled by the spin rate, typically between 500–4000 rpm. The optical density and the thickness of the resulting films were measured with a Cary 17 spectrophotometer and a Talystep instrument, respectively. The heat treatment studies were carried out by placing the samples in a forced air oven Delta Design 2300 at 60°C for 30 min.

Results and discussion

Absorption spectroscopy

Figure 1*a* shows the molecular electronic absorption spectrum of **1** in 1,2-dichloroethane. The electron acceptor molecule **1** exhibits an intense uv absorption (ϵ_{max} 2.15 × 10^4 M^{-1} cm^{-1}) at λ_{max} 352 nm. The width of the absorption band at half-height is approximately 55 nm. The cause of the yellow–orange color of this material is a weak visible absorption band centred around 440 nm. In Fig. 1*b* the absorption spectrum of a solid-solution of **1** at low concentration (21% by weight) in polyvinyl chloride is shown. The spectrum resembles closely the molecular absorption of **1** in solution, indicating that the small molecules are randomly dispersed into the polymer. The density of the film is about 1.36 g/mL. The molarity, C_m, of **1** in the polymer was calculated accordingly:

TABLE 1. The decadic absorption of **1** at 352 nm (3 mmol/g polymer) in various polymers

Number	Polymer	$\alpha_{352}/10^4$ cm^{-1}
1	Polyvinyl butyral	3.93
2	Polyvinyl carbazole	4.2
3	Polycarbonate	4.7
4	Polyvinyl chloride	4.9
5	Copolyvinylidene chloride – vinyl acetate	5.13
6	Co-polyvinylidene chloride – acrylonitrile	5.6
7	Polycarbonate/TPB	7.8

$$[1]\quad C_m = \frac{\rho W_f \times 1000}{\text{M.wt.}}$$

where M.wt. is the molecular weight of **1** (328 g/mol), W_f is the weight fraction of **1** ($\omega_1/(\omega_1 + \omega_2)$), and ρ is the density of the film. The density of **1** (1.25 g/mL) is very close to the density of most polymers used (1.1–1.39 g/mL). The decadic absorption coefficients, α, were calculated from the optical density, O.D., according to:

$$[2]\quad \alpha = \frac{\text{O.D.}}{LV_f}$$

where L is the film thickness and V_f is the volume fraction of **1** in the polymer. The decadic absorption coefficient α is related to the molar extinction coefficient ε (ε = O.D. × M.wt./$L\rho W_f$ 1000) according to:

$$[3]\quad \alpha(\lambda) = \epsilon(\lambda)C_M$$

where C_M is the molar concentration of **1** (for pure **1**, C_M = 3.808).

The solid absorption coefficient, α of **1** in PVC at 352 nm is 5.3 × 10^4 cm^{-1} which corresponds to an ϵ_{max} of 1.39 × 10^4 M^{-1} cm^{-1}. This value is only slightly lower than the molecular absorption coefficient in solution, 2.15 × 10^4 M^{-1} cm^{-1}. Similar results were obtained for the absorption coefficient of **1** at low concentration in other polymers.

For most practical applications the concentration of the electroactive species molecularly dispersed into polymers is usually high, > 35%. Therefore, we determined the absorption characteristic of films consisting of 50% by weight of **1** in the various polymers. Figure 2*a–f* show the electronic absorption of **1** at the 50% by weight (3.1 mmol/g polymer) in polyvinyl butyral, polyvinylcarbazole, polyvinyl choride, polycarbonate, copolyvinylidene chloride – acrylonitrile, and copolyvinylidene chloride – vinylacetate, respectively. In contrast to the absorption at low concentrations, the absorption bands become broader and less intense. In Table 1 the decadic absorption coefficient of **1** at λ_{max} (352 nm) in the various polymers studied is listed. The values of α_{max} vary from 3.9 to 5.6 × 10^4 cm^{-1}; depending on the host polymer. In general, higher absorption coefficients were observed in halogenated polymers. The lowest α value of **1** was obtained in polyvinyl butyral.

The loss of absorption intensity and broadening of the electronic absorption band of **1** can be attributed to aggregation and phase separation of the small molecule from the polymer. It is evident that at high concentration **1** is incompatible with polyvinyl butyral, polyvinyl carbazole and polycarbonate, however, it is more compatible with polyvinyl chloride copolyvinylidene chloride – vinylacetate and most compatible with

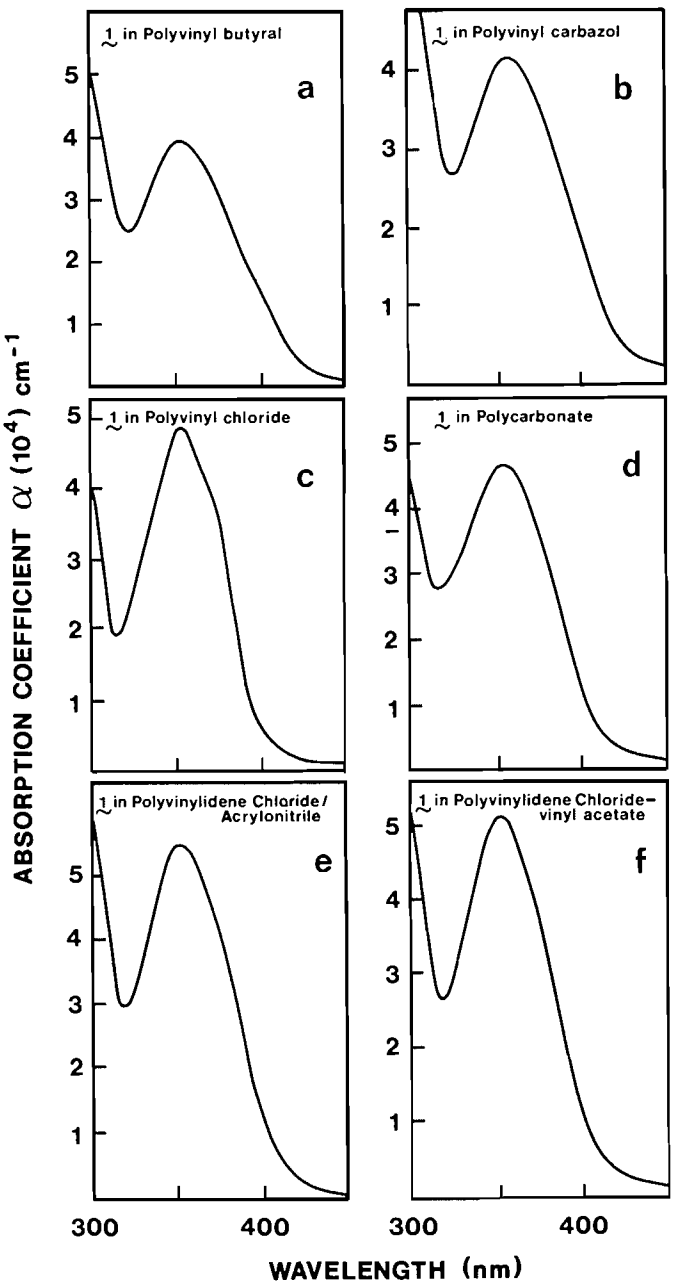

FIG. 2. The electronic absorption spectra of **1** at 50% by weight in (*a*) polyvinyl butyral, (*b*) polyvinylcarbazole, (*c*) polyvinyl chloride, (*d*) polycarbonate, (*e*) copolyvinylidene chloride – acrylonitrile, and (*f*) copolyvinylidene chloride – vinylacetate.

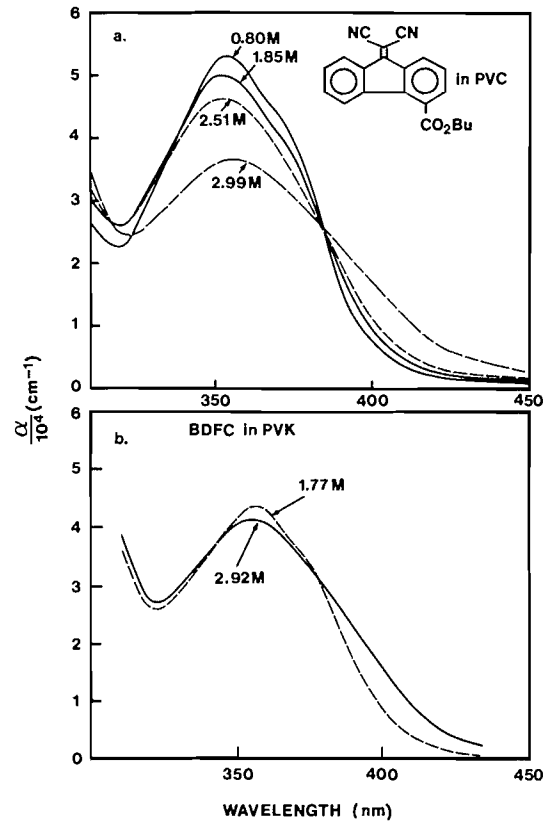

FIG. 3. The concentration-dependent uv absorption of **1** in (*a*) PVC and (*b*) PVK.

copolyvinylidenechloride – acrylonitrile. It, thus, appears that the electron-acceptor small molecule is more compatible with polymers possessing electronegative atoms such as chlorine.

The aggregation of the small molecule **1** in polymer matrices was further studied by investigating the dependence of the absorption spectra on the concentration of **1** in polyvinylchloride and polyvinyl carbazole. Figure 3 (*a* and *b*) shows the concentration-dependent uv absorption coefficients of **1** in PVC and PVK, respectively. The absorption band became broader, less intense, and shifted slightly to the red as the concentration of **1** in the polymer increases. The spectroscopic results for PVC are summarized in Table 2. An isosbestic point at ~380 nm was observed, indicating a specific stoichiometry of aggregates. The aggregates must have absorption bands to the red and blue of the monomer absorption and exhibit lower absorption coefficients. The large difference between the molecular absorption of many small molecules and that of their

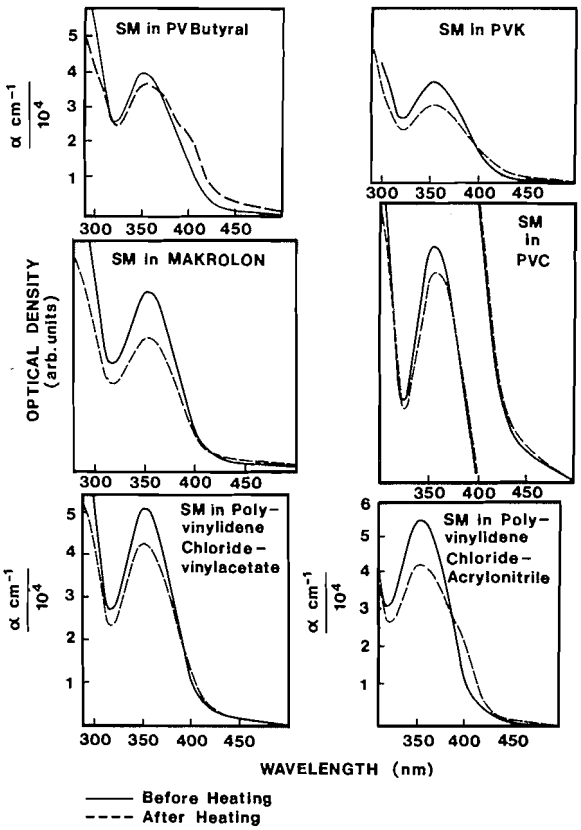

FIG. 4. Test of the stability of **1** in various polymers. Effect of heating the films for 30 min at 60°C (—) before heating, (- - -) after heating.

aggregates permit the use of electronic absorption spectroscopy as a tool to probe the compatibility of the small molecule in polymers.

For xerographic applications the concentration of the small molecule in polymer is typically 3 mmol/g or about 50% by weight, which corresponds to molar concentration of ~1.95 *M* depending on the density of the polymer. At such concentration **1** appears to exhibit significant aggregation in all polymers studied.

Stability of 1 in polymer matrices

The thermal stability of **1** in the six polymers chosen was investigated by heating films of **1** at 50% by weight in polymers for 30 min at 60°C. This temperature is below the glass transition, T_g, of all polymeric solid-solutions studied. During the thermal treatment the diffusion of the small molecule in the matrix is greatly accelerated. Figure 4*a–f* shows the electronic absorption spectra of **1** in polymers before and after heat treatment. Again, it is evident that the absorption coefficient of **1** decreases and the absorption bands broaden, indicating increase in aggregate level upon heat treatment. The magnitude of absorption band broadening and loss of absorption intensity depend on the host polymer. The absorption spectra of **1** in polyvinyl butyral and copolyvinylidene chloride – acrylonitrile after heating show a distinct shoulder around 400 nm, indicating the increase in aggregate concentration.

In the other polymer matrices, namely, polyvinylcarbazole, polycarbonate, polyvinylchloride, and copolyvinylidene chloride-vinylacetate, the effect of heating is much less severe. This test is an extremely mild test of stability of the small molecule in the polymer and the results indicate that none of the chosen polymers is a good host for the small molecule. This is in a large part due to the strong affinity of the small molecule to aggregate, i.e., strong molecule–molecule interaction force.

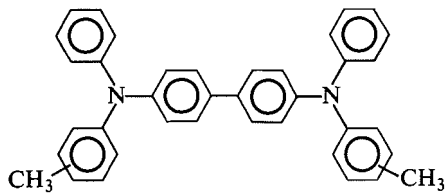
[a] 0.1363 g **1** and 0.1035 g polycarbonate.
[b] λ_{max} = 350 nm.

Stabilization of 1 in polymer matrices

It has been noted that the addition of donor molecules to **1** in polymer matrices generally increases the absorption coefficient. This can be attributed to the formation of charge-transfer complexes between the electron acceptor, **1**, and the electron donor which minimize acceptor–acceptor interactions. We investigated the effect of the electron-donor molecule tetraphenyl benzidene derivative (TPB) (6), **2**, on the dispersability and stability of **1** in polycarbonate. To solutions of 0.136 g of **1**, 0.104 g of polycarbonate in 5 mL methylene chloride various amounts of **2**, ranging from zero to 0.118 g was added. The solutions were then spin coated onto 2 in. × 2 in. precleaned glass slides. Analysis of the absorption spectra of the resulting films are complicated by the absorption of **2** in the same wavelength region as **1**. We have previously determined the absorption coefficient of **2** in polycarbonate and found that $\alpha_{350} = 4.5 \times 10^4$ cm^{-1}. Knowing α_{350} for **2**, its volume fraction V_f (2), and film thickness *L*, the contribution of **2** to the optical absorption can be determined from eq. [2] and subtracted to get the absorption due to **1**.

Table 3 lists the results of the effect of **2** on the absorptivity of **1** in polycarbonate. It is evident that the addition of **2** to



2

1/PC matrix increases the absorption coefficient of **1**, which approaches the molecular absorption values at the **2**-to-**1** molar ratio of 1:4. Figure 5 shows the correlation between **1** absorption coefficient onto **2**:**1** ratio. The highest α values obtained at molar ratio of 1:3 to 1:4. These results indicate that one molecule of the electron donor **2** forms a charge transfer complex with four molecules of the electron acceptor **1**. This charge transfer complexation diminishes the interaction force between the acceptor molecules and results in an absorption curve very closely similar to molecular absorption. An additional absorption band at 600 nm was also observed, this can be assigned to the charge-transfer complex (CT state), see Fig. 6. Figure 7 shows the effect of heat treatment on the absorption characteristics of a polycarbonate film containing ~50% by weight of **1**

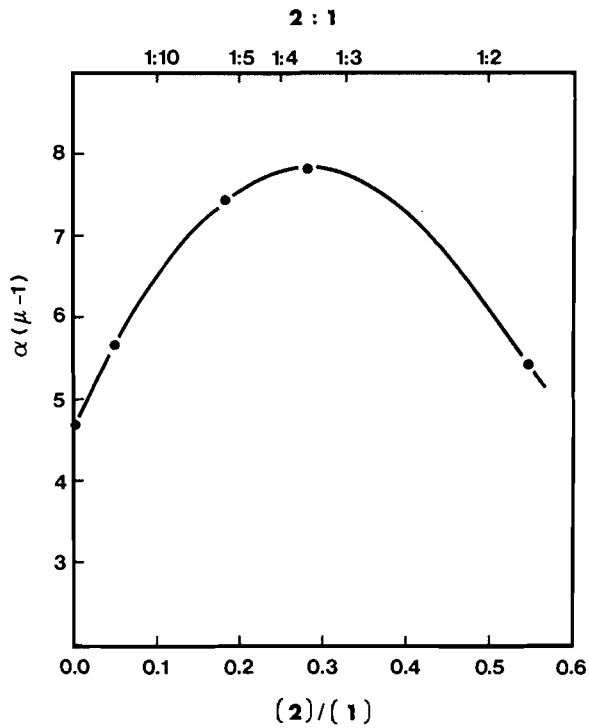


FIG. 5. Effect of **2** on the absorption coefficient of **1** in polycarbonate.

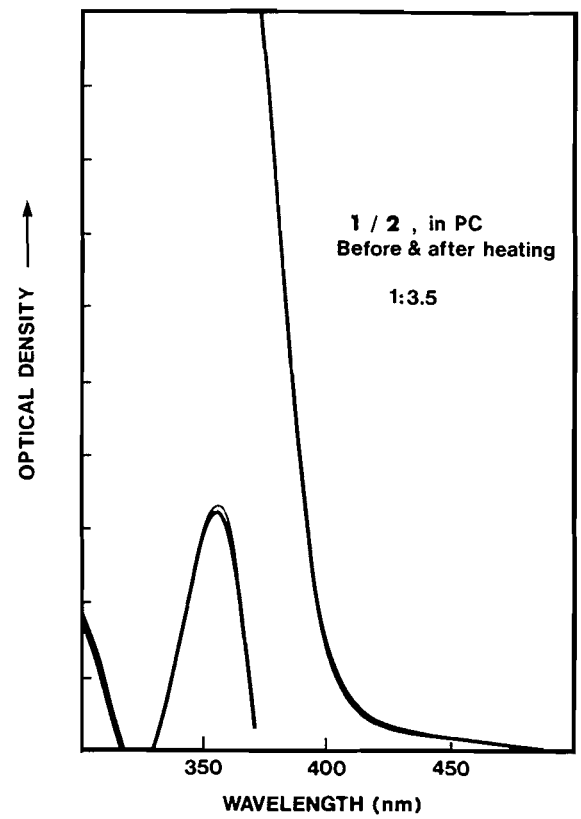

FIG. 7. Effect of heating on the absorption characteristics of **1** in PC in presence of **2**.

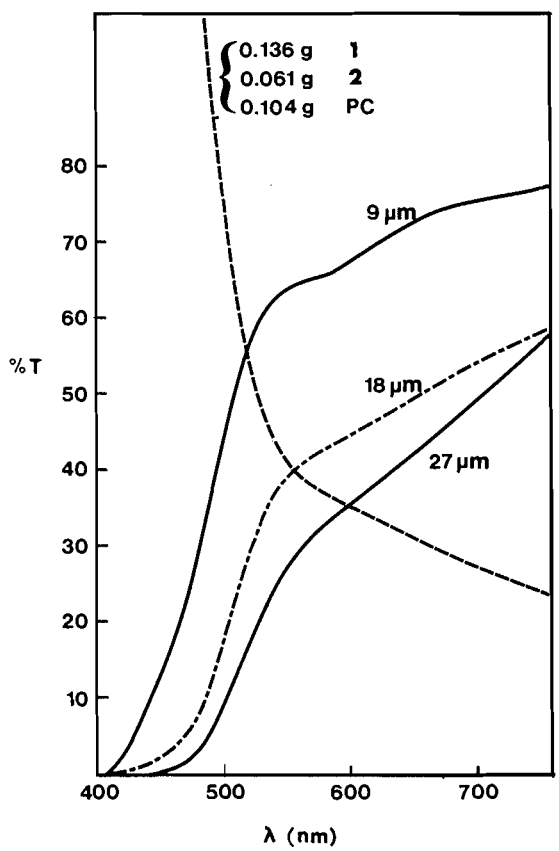

FIG. 6. The absorption spectra of thick polycarbonate film containing **1** and **2** at a molar ratio of 3.5:1.

and also incorporates **2** (**2**:**1** molar ratio 1:3.5). The absorption spectra before and after heat treatment are virtually identical (cf. Fig. 4*c*). The presence of the electron donor **2** had a dramatic stabilizing effect on the diffusion and aggregation of the electron acceptor **1**.

Conclusion

We have utilized electronic absorption spectroscopy to study the compatibility and stability of a small molecule, *n*-butyl 9-dicyanomethylene fluorene-4-carboxylate, **1**, in polymer matrices. At low concentration the electronic absorption of **1** in various polymers closely resembled the molecular absorption, indicating random distribution. As the concentration of **1** increases the absorption bands become broader, less intense, and red-shifted. These results implied aggregation and phase separation of **1** from the polymer (incompatibility). The small molecule **1** was found to be more compatible with halogenated polymers than with polyesters of polyvinyl carbazole. Heating the film causes diffusion of the small molecules and enhances aggregation and phase separation.

The addition of electron donor molecules to the matrix of **1** in polycarbonate caused dramatic increase in the absorptivity and the stability of **1**. This was attributed to the formation of large charge transfer complexes.

Electron transfer from anthracenes. Comparison of photoionization, charge-transfer excitation and electrochemical oxidation

J. M. MASNOVI, E. A. SEDDON, AND J. K. KOCHI[1]

Departments of Chemistry, Indiana University, Bloomington, IN 47405, U.S.A.; University of Houston, University Park, Houston, TX 77004, U.S.A; and School of Molecular Sciences, University of Sussex, Brighton BN1 9QJ, England

Received March 26, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

J. M. MASNOVI, E. A. SEDDON, and J. K. KOCHI. Can. J. Chem. **62**, 2552 (1984).

Quantitative measures of electron detachment from anthracene and various *meso*-substituted derivatives (D) are examined in the gas phase and in solution. The photoelectron spectra show well-resolved bands for E_I corresponding to the first ionization (i.e., $D \rightarrow D^{+\cdot} + e$) from a π-molecular orbital (HOMO) with maximum electron density at the 9,10-positions. The same series of anthracenes form 1:1 electron donor–acceptor complexes with tetracyanoethylene [D,TCNE], which exhibit distinctive colors associated with charge transfer transitions $h\nu_{CT}$ to the ion pair $[D^{+\cdot},TCNE^{-\cdot}]$. These measures of the gas phase energetics of electron transfer from the anthracenes are compared with their standard oxidation potentials E^0_{Ar} determined from the reversible cyclic voltammograms in methylene chloride and trifluoroacetic acid solutions. Although there are direct, linear free energy relationships between E_I and $h\nu_{CT}$ as well as E_I and E^0_{Ar}, the best correlation is observed between E^0_{Ar} and $h\nu_{CT}$. The validity of the latter is discussed in terms of offsetting effects arising from differences in solvation energy and steric effects attendant upon 9,10-substitution in anthracenes.

J. M. MASNOVI, E. A. SEDDON et J. K. KOCHI. Can. J. Chem. **62**, 2552 (1984).

Opérant en phase gazeuse ainsi qu'en solution, nous avons effectué des mesures quantitatives d'enlèvement d'électrons de l'anthracène et de divers dérivés substitués en position méso (D). Les spectres photoélectroniques présentent des bandes bien résolues pour E_I qui correspondent à la première ionisation (soit $D \rightarrow D^{+\cdot} + e$) d'une orbitale moléculaire π(OM-HO) avec une densité électronique maximale aux positions 9 et 10. La même série d'anthracènes forme des complexes électroniques donneur–accepteur 1:1 avec le tétracyanoéthylène [D,TCNE] qui présentent des couleurs caractéristiques associées avec des transitions de transfert de charge $h\nu_{CT}$ conduisant à la paire d'ions $[D^{+\cdot},TCNE^{-\cdot}]$. Nous comparons les énergies impliquées en phase gazeuse lors du transfert d'électrons provenant d'anthracènes avec leurs potentiels standard d'oxydation E^0_{Ar} déterminés, en solutions dans le chlorure de méthylène et dans l'acide trifluoroacétique, à partir de voltammogrammes cycliques réversibles. Quoique les relations linéaires d'énergie libre entre E_I et $h\nu_{CT}$ ainsi qu'entre E_I et E^0_{Ar} soient directes, la meilleure corrélation est celle qui relie E^0_{Ar} et $h\nu_{CT}$. Nous discutons de la validité de cette dernière en fonction d'effets qui se compensent et qui découlent de différences dans les énergies de solvatation et dans les effets stériques qui sont reliées à la présence de substituants dans les positions 9 et 10 des anthracènes.

Introduction

Electron transfer from aromatic hydrocarbons to form such reactive intermediates as arene cation radicals is playing an increasingly important role in various oxidative processes in organic chemistry (1–3). In these situations, the quantitative evaluation of the feasibility of electron transfer as a reaction pathway depends critically on the knowledge of the energetics of electron detachment from the aromatic compound ArH (4). Such information *in the gas phase* can be obtained as vertical or adiabatic ionization energies

$$[1] \quad ArH \xrightarrow{E_i} ArH^{+\cdot} + e$$

which are readily evaluated by photoelectron spectroscopy (5). A more convenient, although less direct, method is based on the charge transfer absorption energy $h\nu_{CT}$ for electron donor–acceptor or EDA complexes (6). For a series of aromatic hydrocarbons with an electron acceptor (A) in common, the charge transfer excitation of the EDA complex leads to the ion pair (7), i.e.,

$$[2] \quad [ArH,A] \xrightarrow{h\nu_{CT}} [ArH^{+\cdot},A^{-\cdot}]$$

According to the Mulliken theory (8), the value of $h\nu_{CT}$ for weak complexes is directly proportional to the first vertical ionization energy E_I (or equivalently the ionization potential I_P) of ArH according to the relationship

$$[3] \quad h\nu_{CT} = I_P - E_A - \omega$$

where E_A is the electron affinity of the common acceptor. The term ω is to first order the electrostatic energy of the ion pair formed in eq. [2], and is commonly considered to be invariant in such a series of related donors.

The assessment of electron transfer from aromatic compounds *in solution* requires knowledge of the standard or reversible oxidation potential for the process

$$[4] \quad ArH_s \overset{-E^0_{Ar}}{\rightleftharpoons} ArH^{+\cdot}_s + e$$

where subscript s refers to the solvated species (9). Electrochemical methods, particularly cyclic voltammetry, offer the most direct and convenient access to oxidation potentials. When electron transfer in reaction [4] is reversible, the cyclic voltammogram consists of anodic and cathodic waves with current maxima of equal magnitudes at potentials E^a_P and E^c_P, respectively. Under these circumstances the standard potential E^0_{Ar} is within 0.030 V of the average, namely $(E^a_P + E^c_P)/2$. Unfortunately, most aromatic hydrocarbons do not afford reversible cyclic voltammograms at sweep rates attainable with standard instrumentation. Therefore we focused our attention in this study on anthracene and its derivatives substituted in the 9- and 10- or *meso* positions to represent structurally related

compounds in which the energetics of electron detachment can be systematically varied by appropriate substituents. This series of aromatic compounds is particularly well suited to study the relationships among the various measures of electron detachment both in the gas phase and in solution. Thus the anthracenes are sufficiently volatile for the photoelectron spectra to be measured directly in the gas phase (10). Moreover, they form an extensive series of EDA complexes with tetracyanoethylene or TCNE, in which the charge transfer absorption bands are exceptionally well resolved from those of the components (11). Most importantly, the cyclic voltammograms of these anthracenes are reversible (12), which allows a direct relationship to be established between values of E^0_{Ar} in solution and E_1 or I_P in the gas phase. The latter will permit an evaluation of solvation effects on electron transfer from this aromatic system (12, 13).

Results

Photoelectron spectra of anthracene and its derivatives

The comparison of the He(I) and He(II) photoelectron spectra of anthracene with those of benzene and naphthalene has established the first ionization E_1 at 7.43 eV to occur from a π-orbital (HOMO according to Koopmans' theorem) of b_{2g} symmetry with maximum electron density at the 9- and 10-positions (10). The second ionization E_2 at 8.53 eV occurs from the subjacent π-orbital (SHOMO) of b_{1g} symmetry with a node at the 9- and 10-positions. In order to examine the polar effects of substituents at both of these positions, we measured the photoelectron spectra of the series of anthracene derivatives included in Table 1. Uniformity in the PES measurements was ensured by recording all the spectra under a single set of standard conditions using a small amount of methyl iodide as an internal calibrant (with E_1 9.53_8 eV and E_2 10.16_5 eV (5*b*)).

The lowest energy bands of the photoelectron spectra for most anthracenes are well resolved — the adiabatic and vertical ionization energies being within ~0.02 eV of one another, and showing a progression of vibrational fine structure, as typically illustrated in Fig. 1 for 9-acetoxy, 9-bromo, and 9,10-dibromoanthracene. The reliability in the values of E_1 and that of the second ionization energy E_2 listed in Table 1 was established by a comparison with those obtained independently by Klasinc and co-workers (10). The trend, as reported earlier, is for both E_1 and E_2 to generally increase with values of the Hammett σ constant — that is, the presence of electron-attracting substituents leads to the stabilization of the HOMO as well as the SHOMO.

Charge transfer transitions in electron donor–acceptor complexes of substituted anthracenes with tetracyanoethylene

When a methylene chloride solution of anthracene is mixed with tetracyanoethylene or TCNE, a transient blue coloration is observed immediately (11), and it persists for slightly longer times if the reactants are cooled prior to mixing (14). Analogously, 9-cyanoanthracene and tetracyanoethylene afford a green solution which lasts for a prolonged period. The other substituted anthracenes yield similarly colored solutions of varying shades of blue and green as illustrated by the absorption spectra in Fig. 2. These broad, featureless absorption bands are characteristic of weak intermolecular electron donor–acceptor or EDA complexes, and the visible absorptions have been assigned to charge transfer transitions in the 1:1 EDA complex (11), e.g.

[5] 
The color as such is a measure of the electron donor property of the particular anthracene (see eq. [3]), and it is quantitatively indicated in Table 2 by the value of $h\nu_{CT}$, i.e., the absorption maximum. Since neither the parent anthracenes (see Fig. 3) nor tetracyanoethylene absorb beyond 500 nm, the charge transfer transitions in this series of EDA complexes are unambiguously indicated by these clearly resolved visible absorptions. With some of the anthracene–tetracyanoethylene complexes, a second absorption band was apparent in the far uv region. More often, the second band was obscured by the long wavelength tail of the parent anthracene absorption. The CT transition energy of the visible band (I) and that of the uv band (II), when resolved, are included in Table 2. Since the splittings between bands I and II are the same as the first and second bands E_1 and E_2 in the PE spectra (see Table 1), band II is most likely to be associated with charge transfer transitions from the SHOMO (14*b*).

Electrochemical oxidation of substituted anthracenes. Evaluation of the standard oxidation potential E^0_{Ar}

The cyclic voltammogram of a 5×10^{-3} *M* solution of 9,10-diphenylanthracene in methylene chloride (containing 0.1 *M* tetrabutylammonium perchlorate as supporting electrolyte) is reversible at a platinum electrode at sweep rates less

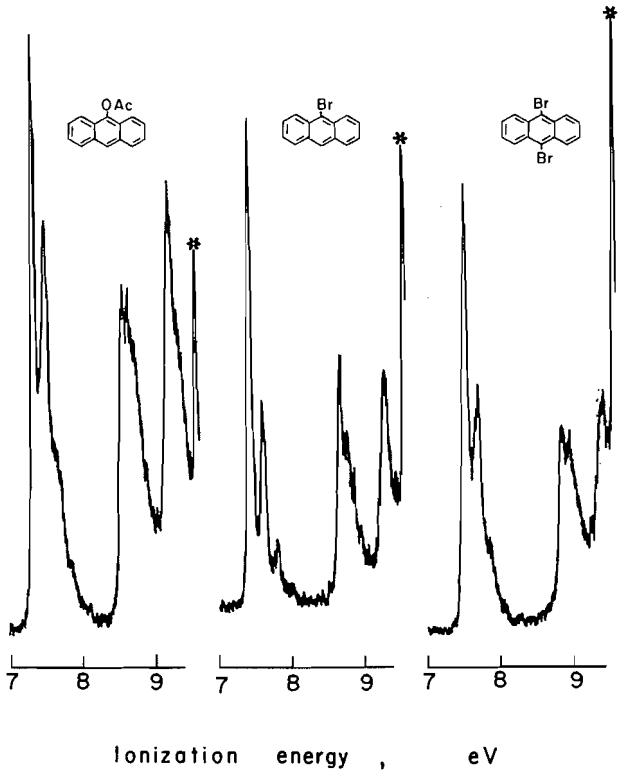

FIG. 1. Low energy portion of the He(I) photoelectron spectra of 9-acetoxy-, 9-bromo-, and 9,10-dibromoanthracene with methyl iodide* as calibrant (E_1 9.53$_8$ eV).

than 0.05 V s^{-1}. Under the same conditions, the cyclic voltammogram of 9,10-dimethylanthracene is irreversible (the cathodic wave on the return sweep simply being unobserved), but it becomes reversible at a higher sweep rate of 0.20 V s^{-1} (see Fig. 4). Although the cyclic voltammogram of the parent anthracene remains irreversible in methylene chloride up to sweep rates exceeding 100 V s^{-1}, the addition of trifluoroacetic acid is sufficient to promote reversibility in the cyclic voltammogram (CV), even at a sweep rate of 1 V s^{-1}. The CV waves correspond to a one-electron process (as in reaction [6]), based on the calibration of the peak current with ferrocene.

[6]  + e

Thus for each anthracene derivative, the CV reversibility can be achieved by the appropriate adjustment of the sweep rate and/or by the addition of trifluoroacetic acid. Both of these factors relate directly to the varying lifetimes of the respective anthracene cation radicals which are known to be more persistent in acidic media such as trifluoroacetic acid (15, 16).[2] (Note also that the intrinsic heterogeneous rate constant k_s appears to be fast for aromatic hydrocarbons (13).) Indeed, each of the substituted anthracenes in Table 3 shows distinctive CV behavior as indicated by the sweep rate v at which reversibility is observed in a standard medium consisting of methylene chloride and 20 %v trifluoroacetic acid. Most importantly for each anthracene, the average of the anodic and cathodic peak potentials, i.e. $(E_P^a + E_P^c)/2$, remains constant with variations in the

scan rate (17). The values of E^0_{Ar} obtained in this manner are listed in Table 3, and they show a marked dependence on the presence of *meso* substituents.

The effect of solvent on the values of the standard oxidation potentials of substituted anthracenes was also examined in methylene chloride (without added trifluoroacetic acid), trifluoroacetic acid alone, and in acetonitrile. Each solvent system contained 0.1 *M* tetra-*n*-butylammonium perchlorate as the supporting electrolyte. The values of E^0_{Ar} in these pure solvents are presented in Table 4. The standard oxidation potentials of the anthracenes are not always reported for each solvent owing to difficulties in attaining reversibility of the cyclic voltammogram.

Direct evidence for the formation of anthracene cation radicals according to reaction [6] was obtained by a spectroelectrochemical examination of anthracene oxidation. For example, the absorption spectrum of the radical cation of anthracene shown in Fig. 5 represents the average of the multiple accumulation of spectra (>50) measured through a 0.1 mm gold minigrid electrode maintained at constant potential in 30 %v trifluoroacetic acid – methylene chloride containing 0.1 *M* tetra-*n*-butylammonium perchlorate. Figure 5 emphasizes the pronounced red spectral shift which accompanies the oxidation of the anthracene to its radical cation. (The absorption spectrum of anthracene cation radical in Fig. 5 is the same as that generated independently by γ-irradiation of the parent hydrocarbon immobilized in a polymer matrix (18).) The absorption spectra of 9-nitro and 9-carbomethoxyanthracene as well as their radical cations are also included in Fig. 5 for comparison. The radical cations of 9-methoxy-, 9,10-dimethoxy-, 9-cyano-, 9,10-dicyano-, 9-formyl-, 9-formyl-10-chloro-, and 9,10-diphenylanthracene were also generated in sufficient concentrations to observe by the same spectroelectrochemical method.

Discussion

The availability of the independent measures for effecting electron detachment from the anthracenes listed in Tables 1–4 allows us to examine the relationships between various gas phase and solution processes. Let us first examine how the vertical ionization energy E_1 of anthracenes obtained from the photoelectron spectrum relates to the charge transfer transition energy $h\nu_{CT}$ of their EDA complexes with tetracyanoethylene. The linear correlation of $h\nu_{CT}$ and E_1 shown in Fig. 6 includes

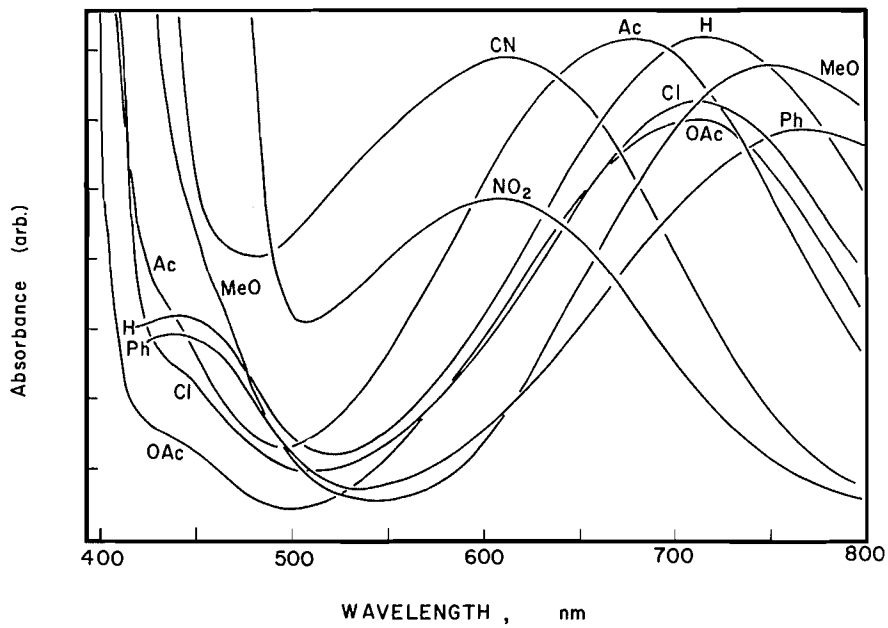

FIG. 2. Charge transfer spectra of a series of EDA complexes of 9-substituted anthracenes (~0.05 *M*) with tetracyanoethylene (0.05 *M*) in methylene chloride.

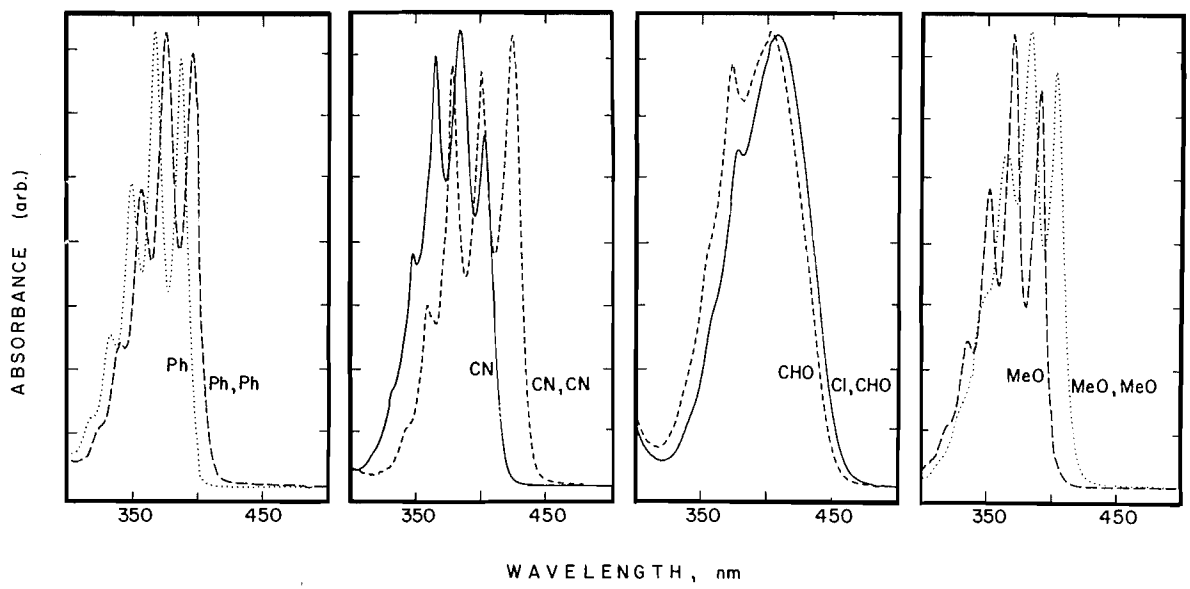

FIG. 3. Absorption spectra of representative pairs of 9,10-mono- and disubstituted anthracenes (~10^{-4} *M*) in methylene chloride.

all eighteen of the 9-monosubstituted as well as the 9,10-disubstituted anthracenes. The least-squares line in the graph describes the relationship

$$[7] \quad h\nu_{CT} = 0.63E_I - 2.93$$

with a correlation coefficient of 0.97. Since the photoionization of an anthracene and the charge transfer excitation of its EDA complex both represent vertical transitions, the slope of the correlation should be close to unity if the interaction energy ω in eq. [3] were invariant in the series. Thus a slope of only 0.6 in eq. [7] suggests that ω actually decreases in proportion to the donor property of the anthracene. Such a trend could arise from increasing steric hindrance at the *meso* positions attendant upon disubstitution required for better donor properties. The adverse steric effect would be expected to decrease the magnitude of ω owing to its large electrostatic component which is inversely proportional to the mean separation *r* of the anthracene and TCNE in the EDA complex.[3]

The comparison of the vertical ionization energy E_I and the standard oxidation potential E^0_{Ar} is illustrated in Fig. 7. The line in the graph describes the relationship

$$[8] \quad E^0_{Ar} = 0.86E_I - 4.91$$

with a correlation coefficient of 0.98 for fourteen mono- and disubstituted anthracenes. A slope of considerably less than unity indicates that the energetics of the gas phase ionization are not completely mirrored in the solution oxidation. In partic-

[3] For a discussion of steric effects on the charge transfer transition energy of EDA complexes, see ref. 19.

ular, the contribution from solvation is implicit in the values of E^0_{Ar}, whereas it is not in the values of E_1. Furthermore, values of the vertical E_1 do not include any reorganization energy arising from a Jahn–Teller distortion. Inclusion of these terms (13) leads to

$$[9] \quad E^0_{Ar} = E_1 + (\Delta G^0_s + \Delta G^0_r)/F + C$$

TABLE 4. Solvent effects on the standard oxidation potentials of substituted anthracenes[a]

[a] In the pure solvent, each containing 0.1 *M* tetraalkylammonium perchlorate.

where ΔG^0_s and ΔG^0_r represent the free energies of solvation and reorganization of the radical ion $ArH^{\ddagger}$, respectively.[4] (*F* is the Faraday constant and *C* is a constant determined by the particular working and reference electrode.) Comparison of eq. [9] with the experimental relationship in eq. [8] indicates that $(\Delta G^0_s + \Delta G^0_r)$ cannot be considered as a constant term for the series of anthracenes under consideration. Instead, it varies with E_1 or E^0_{Ar}, as given by the combination of eqs. [8] and [9], i.e.

$$[10] \quad \Delta G^0_s + \Delta G^0_r = -0.14FE_1 + \text{constant}$$

From the limited difference observed between the magnitudes of the vertical and adiabatic ionization energies for the first photoelectron band E_1 (see Results section), we infer that the reorganization energies of the anthracene cation radicals are rather small and constant (5*b*). If so, the relationship in eq. [10] suggests that the solvation energy decreases by about 0.2 eV or ~5 kcal mol^{-1} in covering the gamut of anthracenes from 9-nitroanthracene to 9,10-dimethoxyanthracene at the extremes. Interestingly, this trend also parallels the structural changes of increasing size of the anthracene moiety resulting from disubstitution of both *meso* positions. Furthermore, the point for 9,10-diphenylanthracene falls furthest off the line in Fig. 7, in accord with an expected large decrease in the solvation energy associated with extensive delocalization of the charge in the corresponding radical cation.

Steric size thus appears to be a common factor which diminishes the slope of the correlation in Fig. 6 as well as that in Fig. 7. The limited slopes in both instances suggest that a reasonable correlation would be found between the standard oxidation potential E^0_{Ar} and the charge transfer transition energy $h\nu_{CT}$. Indeed, the result shown in Fig. 8 includes the least-squares line which describes the relationship

$$[11] \quad E^0_{Ar} = 1.22\, h\nu_{CT} - 0.67$$

with a correlation coefficient of 0.98 for thirteen substituted anthracenes. It is interesting to note that all the points (includ-

[4] For a discussion of these energy terms as they relate to aromatic cation radicals, see refs. 12 and 13. Note the contribution arising from the neutral arenes is negligible owing to their much smaller solvation energies; see ref. 20.

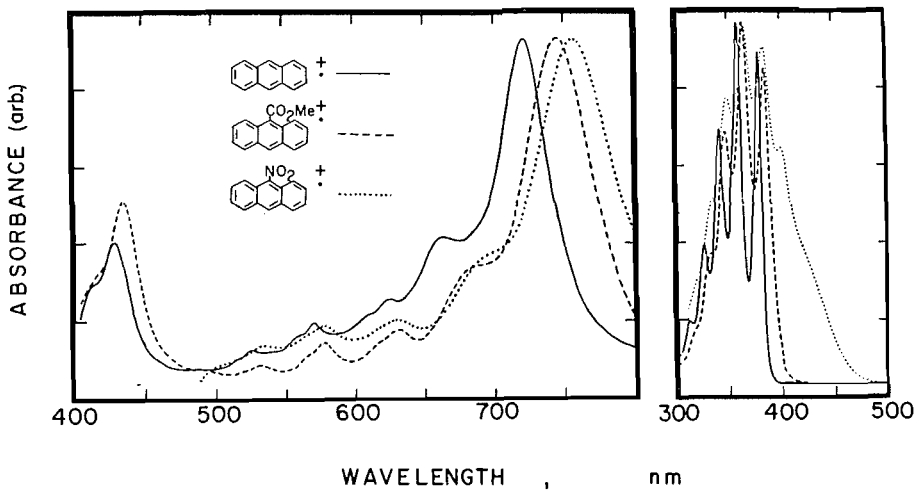

FIG. 5. Left: absorption spectra of the radical cations of 9-nitro- (···), 9-carbomethoxy- (- - -), and anthracene (—) generated at a gold minianode at constant potentials of 2.0, 1.8, and 1.7 V vs. sce, respectively, in 30 %v trifluoroacetic acid – methylene chloride containing 0.1 *M* tetra-*n*-butylammonium perchlorate. Right: absorption spectra of the parent anthracenes ($\sim 10^{-4}$ *M*). Absorbance units are arbitrary.

ing those for the disubstituted anthracenes) are better accommodated by this correlation than those presented in either Fig 6 or 7. (Note especially the points for 9,10-diphenylanthracene in these comparisons.) The reason could lie in the partial offset of steric factors in the measurements of E^0_{Ar} (owing to differences in the solvation energy) and $h\nu_{CT}$ (owing to changes in the mean separation). In any case, the validity of this type of correlation is supported in Fig. 9 which utilizes the recent electrochemical data obtained for the homologous methylbenzenes (13). The least-squares line in Fig. 9 has a slope close to unity, viz., $E^0_{Ar} = 0.99h\nu_{CT} - 0.58$. Indeed, the foregoing correlations of E^0_{Ar} and $h\nu_{CT}$ may be a general one applicable to other electron donors. If so, it would provide a very convenient method for the evaluation of standard oxidation potentials of organic compounds which are otherwise not directly measurable.[5]

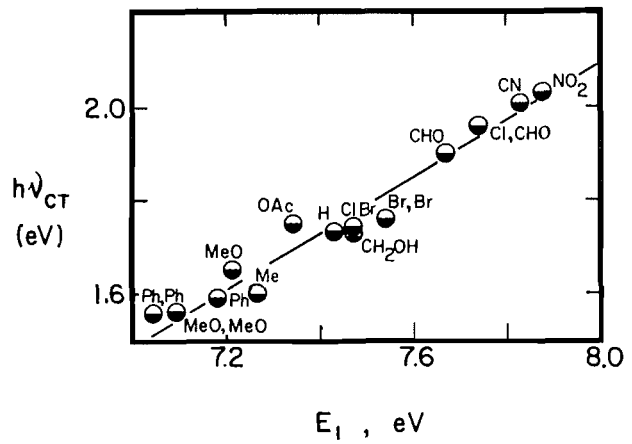

FIG. 6. Correlation of the vertical ionization energy E_i of various anthracenes with the charge transfer transition energy $h\nu_{CT}$ of their EDA complexes with tetracyanoethylene.

Experimental section

Materials

Tetracyanoethylene (Aldrich) was purified by repeated sublimation, first *in vacuo* and then several times at atmospheric pressure. 9-Cyanoanthracene, 9-anthraldehyde, 10-chloro-9-anthraldehyde, 9-methylanthracene, 9,10-dimethylanthracene, 9-acetylanthracene, 9-bromoanthracene, and 9-anthracenemethanol (Aldrich) were each purified by three recrystallizations from ethanol. 9-Chloroanthracene (Pfaltz and Bauer) was recrystallized from alcohol. Anthracene, 9-phenylanthracene, and 9,10-diphenylanthracene (Aldrich, Gold Label) were used without further purification. 9-Nitroanthracene (23), 9-methoxyanthracene (24), 9,10-dimethoxyanthracene (25), 9-anthryl acetate (24), methyl 9-anthroate (26), and 9,10-dibromoanthracene (27) were synthesized according to the procedures in the literature indicated. 9,10-Dicyanoanthracene was a gift from Professor N. C. Yang and was used as received.

Methylene chloride (Aldrich, Gold Label) was distilled from P_2O_5 under argon prior to use and was stored under argon in a Schlenk flask. Trifluoroacetic acid was a gift from Halocarbon Corporation and was distilled from a small amount of trifluoroacetic anhydride. The middle half was collected under argon in a Schlenk flask. Manipulation of trifluoroacetic acid was carried out with a platinum needle attached to an all-glass syringe under an argon atmosphere. Acetonitrile (HPLC grade from Fisher Scientific) was further purified by distillation from CaH_2 through a 15-plate Oldershaw column, followed by stirring overnight with $KMnO_4$ and Na_2CO_3 (5 g of each per liter). The mixture was filtered, distilled under reduced pressure, and finally fractionated from P_2O_5 under an argon atmosphere and stored in a Schlenk flask.

Tetra-*n*-butylammonium perchlorate (G.F. Smith Co.) was recrystallized from an isooctane – ethyl acetate mixture, and was dried *in vacuo* for 2 days prior to use. Tetraethylammonium perchlorate (G.F. Smith Co.) was further dried under vacuo.

Instrumentation

Photoelectron spectra were measured for gaseous compounds using a Perkin-Elmer PS 16/18 photoelectron spectrometer fitted with an Helectros lamp capable of generating both He(I) and He(II) radiation. Spectra were calibrated with respect to methyl iodide and the He (1s) band. The photoelectron spectra of the anthracenes demonstrate sharp peaks with well-resolved vibrational fine structure for ionizations involving the lower energy π-orbitals (Fig. 1). The vibrational progressions for the first (E_1) ionization energies of the anthracenes were measured as reported below (in cm^{-1}): *H*, 1300; *9-Me*, 1400; *9-OCOMe*, 1300; *9-Br*, 1500; *9-Cl*, 1500; *9-CH_2OH*, 1200; *9-CHO*, 1300; *9-COOH*, 1300; *9-CN*, 1400; *9-COOMe*, 1400; *9-COMe*, 1400; *9,10-DCN*, 1400; *9,10-DMe*, 1400; *9,10-DPh*, 1400; *9,10-DBr*, 1400; *9-CHO-10Cl*, 950. The sharpness of the bands and the similarity

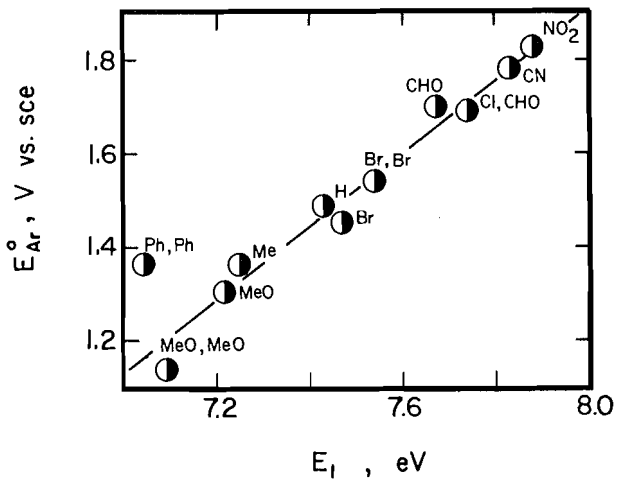

FIG. 7. Correlation of the standard oxidation potentials E^0_{Ar} of various anthracenes with the first vertical ionization energies E_I.

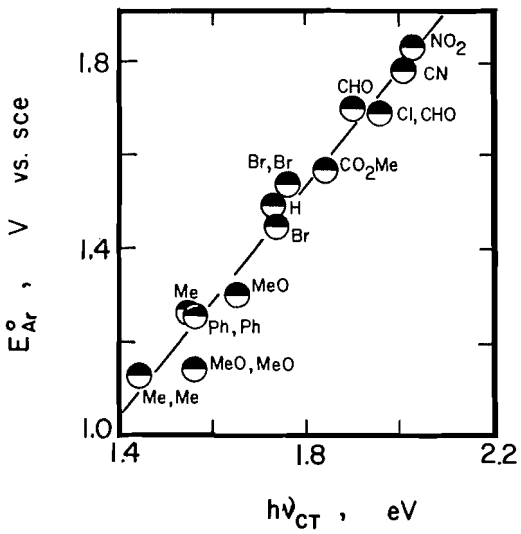

FIG. 8. Correlation of the standard oxidation potential E^0_{Ar} of 9,10-substituted anthracenes with the charge transfer transition energy $h\nu_{CT}$ of the corresponding EDA complex with tetracyanoethylene.

of the energies of the vibrational progression to those observed in the absorption spectra of the neutral, uncomplexed arenes (~1400 cm^{-1}, see Figs 3 and 5) indicates that a similarity exists in the geometries of the ground and excited states of the anthracene chromophore and the respective cation radical. That is, excitation or ionization generates a species in which the equilibrium geometry has not changed greatly, so that the internal reorganization energy is very small.

Electronic spectra were obtained on a Hewlett-Packard 8450A diode-array spectrometer. Absorption spectra of the anthracenes were measured on ~10^{-4} *M* solutions in methylene chloride and were normalized at their maxima to facilitate comparison (see Figs. 3 and 5). The absorption of the electron donor–acceptor complexes of anthracenes with TCNE were measured on solutions ~0.05 *M* in arene and in TCNE. The relative intensities in Fig. 2 are on an arbitrary scale.

Cyclic voltammetry was conducted with 5 × 10^{-3} *M* solutions of arene containing 0.1 *M* electrolyte (tetra-*n*-butylammonium perchlorate in methylene chloride or trifluoroacetic acid solvent systems and tetraethylammonium perchlorate in acetonitrile). All electrochemical experiments were performed using a flame-dried, air-tight cell under an atmosphere of argon. The instrumentation consisted of a Princeton Applied Research (PAR Model 173) potentiostat equipped with a current-to-voltage converter (PAR Model 176) for suitable

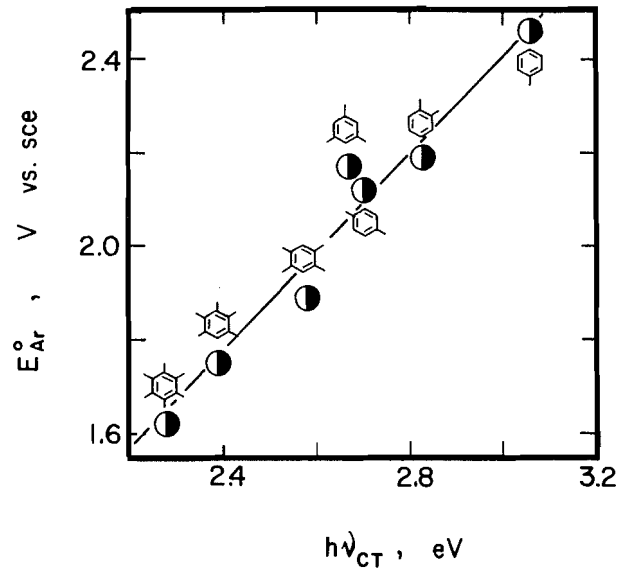

FIG. 9. Correlation of the standard oxidation potentials E^0_{Ar} for the homologous methylbenzenes with the charge transfer transition energy $h\nu_{CT}$ of the corresponding EDA complex with tetracyanoethylene.

ohmic drop compensation and a high impedance voltage amplifier (PAR model 178). The working electrode consisted of a 1 mm diameter platinum disc embedded in a cobalt glass seal. The counter electrode was a grid of platinum mesh with a 1 cm^2 surface area. The reference electrode was a saturated calomel electrode (sce) which was contained in a separate compartment separated by a cracked-glass tip capillary. Prior to use it was immersed in solvent of the same composition as that contained within the cell. However, methylene chloride was used in the reference cell compartment for cyclic voltammograms taken in trifluoroacetic acid solvent in order to limit exposure to this solvent. The system was calibrated relative to an anthracene standard (28). To obtain E^0_{Ar} relative to ferrocene, subtract 0.14_5 from each value. The addition of trifluoroacetic acid to methylene chloride solutions was found to be particularly effective in the stabilization of the cation radicals of monosubstituted anthracenes (15). The values of the standard oxidation potentials for the homologous methylarenes (see Fig. 9) are from ref. 13 after correction by 0.06 V for the change in solvent to 20 %v trifluoroacetic and in methylene chloride.

The absorption spectra of the anthracene radical cations were the result of electronically averaging multiple accumulations of spectra measured through a 0.1 mm gold minigrid (Buckbee-Mears Co., St. Paul, MN) electrode maintained at a constant potential ~0.2 V more positive than the E_0 determined by cyclic voltammetry. Spectroelectrochemistry was carried out by positioning the working electrode in a bulk electrolysis cell fused to a 1.0 cm Pyrex uv cuvette. The interrogating beam of the Hewlett-Packard 8450A spectrometer was directed through the gold minigrid electrode and was balanced prior to oxidation. Spectra were accumulated every 1 s starting simultaneously with the application of an oxidizing potential to the minigrid. The spectra of the immediately formed transients were the result of 40–100 balance-accumulation measurements.

The Py scale of solvent polarities

DAO CONG DONG[1] AND MITCHELL A. WINNIK[2]

Lash Miller Laboratories, Department of Chemistry and Erindale College, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received March 26, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday and to Professor J. T. Edward on the occasion of his 65th birthday

DAO CONG DONG and MITCHELL A. WINNIK. Can. J. Chem. **62**, 2560 (1984).

The relative intensities I_1/I_3 of the vibronic bands of pyrene fluorescence in 94 solvents and the vapor phase are reported. These values, ranging from 0.47 (vapor) to 1.95 (dimethyl sulfoxide) form the Py scale of solvent polarities. This scale is compared to other scales of solvent polarity, particularly the π^* scale of Kamlet and Taft in order to assess the contributions of various factors (dipolarity/polarizability, hydrogen bonding, etc.) to the solute–solvent interaction.

DAO CONG DONG et MITCHELL A. WINNIK. Can. J. Chem. **62**, 2560 (1984).

On rapporte les intensités relatives I_1/I_3 des bandes vibroniques de la fluorescence du pyrène dans 94 solvants et en phase vapeur. Ces valeurs, qui s'étalent de 0,47 (vapeur) à 1,95 (diméthyl sulfoxyde) forment l'échelle Py des polarités de solvant. Dans le but d'évaluer les contributions de divers facteurs (dipolarité/polarisabilité, liaison hydrogène, etc) sur l'interaction soluté–solvant, on compare cette échelle à d'autres échelles de polarité de solvants, en particulier avec l'échelle π^* de Kamlet et Taft.

Introduction

Empirical solvent polarity parameters represent simple and straightforward means for characterizing and ranking the polarity of solvent media (1–5). When these media are structured or anisotropic, as in micelles, biological membranes, polymer blends, or swollen polymer resins, they provide unique insights into the effective polarity within individual microdomains (6, 7). The problem is that there are now many such parameters. Among the more well known are Kosower's Z parameter (5), the Dimroth E_T30 scale (3), Hildebrand's δ_H parameter (8), the Py scale (9), and the (π^*, α, β) treatment of Kamlet and Taft (1, 10). These parameters tend to be differently sensitive to various aspects of solvent–solute interactions.

Important progress has been made over the last ten to fifteen years in understanding the relationships between these various scales. While the early dream has vanished that a single parameter would somehow serve to describe a solvent, one still believes that there are a small number of identifiable classes of interactions between solvents and solutes (1). These can in principle be identified and measured, and through them the magnitude of any solvent-sensitive process can be understood. It is particularly noteworthy that all attempts to understand solvent sensitivity in terms of the bulk properties of the solvent — its dielectric constant and its index of refraction — have in the end failed. One now recognizes that interactions between molecules must be treated at the molecular level (1). The molecular theory of solvent–solute interactions is not very advanced but progress can be anticipated.

Among the most significant discoveries was the recognition that all solvent polarity scales can be expressed as linear combinations of other polarity parameters (1). This is in accord with the simple concept of linear free energy relationships and also supports the belief that the different scales are simply sensitive to different combinations of fundamental interactions between solutes and solvents. The current problem is one of identifying those interactions and separating experimental observations into the contributions of each of the individual components.

Kamlet and Taft (1, 10) and co-workers have played a leading role in this development. They write an equation which describes any observable XYZ as a linear combination of individual components

$$[1] \quad XYZ = XYZ_0 + S(\pi^* + d\delta) + a\alpha + b\beta + h\delta_H + e\xi$$

where π^* is an index solvent dipolarity/polarizability. The α scale is an index of hydrogen bond donor capability; β, of hydrogen bond acceptor basicities; and ξ, a coordinate covalency measure for electron pair donors. The δ_H term is the Hildebrand solubility parameter (8), a measure of solvent/solvent interactions which are interrupted in creating a cavity for the solute. The S, a, b, h, and e coefficients describe the sensitivity of a process to each of the individual contributions. Their hope is that each of the parameters in eq. [1] describe a truly fundamental aspect of solute–solvent interactions. For any given process, the coefficients of these parameters would measure the relative importance of each type of interaction.

Our concern is with the Py scale of solvent polarity. Py values are obtained in a very simple manner, either as the ratio of two absorbances within the fine structure of the uv spectrum of pyrene (6, 9, 11), or as the ratio of two intensities within the vibrational bands of pyrene fluorescence. Pyrene is readily available. One introduces it into a sample in only trace amounts. Detection by fluorescence means that one can examine optically awkward systems such as powders, suspensions, and other turbid mixtures. Values obtained by different laboratories agree to within a few percent (6, 9, 11).

In this paper we report Py values for 95 solvents. We review the origin of the phenomena underlying this effect and compare the Py scale to other measures of solvent polarity. Because of the extensive studies of Kamlet, Taft, and co-workers, we examine in more detail the relationship between the Py values and their π^* scale. Both are suggested to be independent of the hydrogen bonding nature of solvent media.

Results

The fluorescence spectra of pyrene at 1 μm in hexane and in

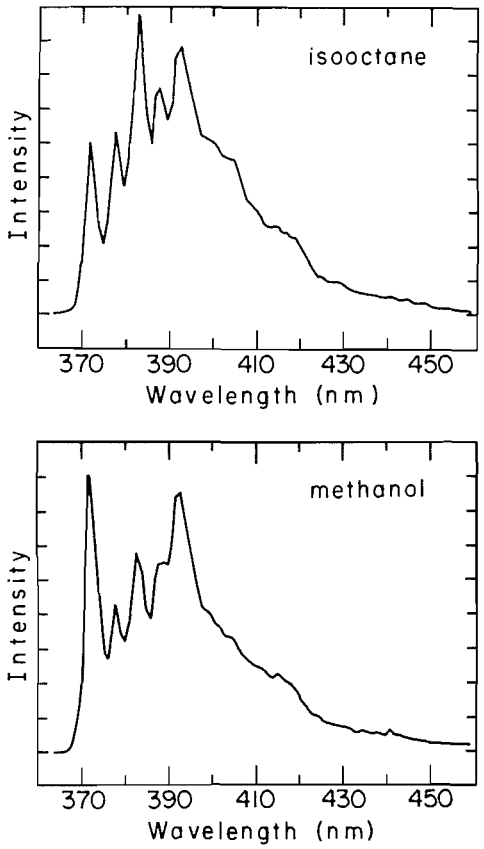

FIG. 1. Fluorescence spectra of pyrene in hexadecane and methanol showing differences in the fine structure of the spectra due to solvent change.

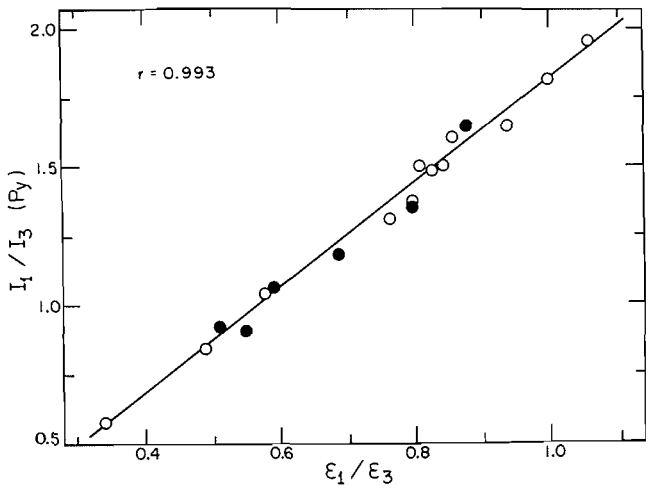

FIG. 2. Plot of Py values vs. extinction coefficients ratio ϵ_1/ϵ_3. Protic solvent (●); aprotic solvents (○).

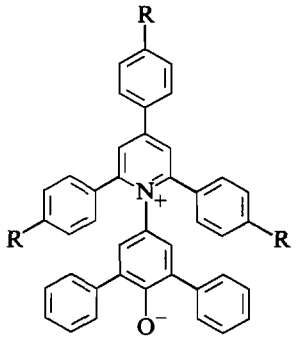
methanol are shown in Fig. 1. Following Nakajima (11) these are normalized at the (0,2) band. One notices a pronounced enhancement of the intensity (I_1) of the (0,0) peak at 375 nm relative to that (I_3) of the (0,2) peak at 384 nm. Values of "Py" = I_1/I_3 range from 0.41 in the gas phase (11*a*) and 0.58 in hexane to 1.95 in dimethyl sulfoxide. Measurements are reproducible typically to ±0.02, and the results from different laboratories tend to fall within this range. Table 1 contains I_1/I_3 values measured for 95 solvents.

Pyrene fluorescence is suceptible to quenching by certain solvents such as amines and carbon tetrachloride. Py values in these solvents can be obtained by measuring the Beer's law extinction coefficient of the lowest energy peak (the (0,0) band) at 374 nm in the uv absorption spectrum of pyrene. These ϵ values increase linearly with I_1/I_3 (12). We have found it operationally less tedious to measure the ratio of the peak absorbance at ca. 374 nm to that at ca. 362 nm; which we denote as ϵ_1/ϵ_3. These are related to I_1/I_3 values (for 18 solvents, Fig. 2) by the equation

$$[2] \quad \frac{I_1}{I_3} = 1.84\frac{\epsilon_1}{\epsilon_3} - 0.054 \qquad \text{corr. } 0.991$$

Empirical correlations of Py with other solvent polarity scales are described below.



I, R = H
II, R = CH_3

Dimroth et al.*'s betaine*

E_T scale of Dimroth, Reichardt, Siepmann, and Bohlmann (3*a*) is based on the solvatochromic band of the pyridinium-*N*-phenolbetaines, **I** and **II**. The E_T value is the transition energy (in kcal mol^{-1}) of the intramolecular charge transfer band of **I**.

Compound **I** is insoluble in aliphatic and aromatic hydrocarbons, but the scale may be extended using the more soluble compound **II**. An excellent correlation exists between the transition energies of **I** and **II**, and the E_T scale has been extended to include value for *n*-hexane (13). As has been described in previous papers (9), plotting Py values against E_T values gives separate correlations for aprotic and protic solvents (Fig. 3). Py values for 37 aprotic solvents (except dioxane (solvent 73) and *o*-dichlorobenzene (solvent 24)) are nicely linear with corresponding E_T values. The correlation, represented by the regression line in Fig. 3, is as shown in eq. [3] with r (the correlation coefficient) = 0.946 and sd (the standard deviation) = 0.34. If the data for dioxane and *o*-dichlorobenzene are included, n = 39 solvents, r becomes 0.924, sd = 0.36. The

$$[3] \quad \text{Py} = 0.080E_T - 1.74$$

correlation equation for 19 protic solvents (except 2-methoxyethanol (solvent 80)), represented by the regression line in Fig. 3, is as shown in eq. [4] with r = 0.921, sd = 0.28. If the data for 2-methoxyethanol is included r becomes 0.892, sd = 0.28

$$[4] \quad \text{Py} = 0.0584E_T - 1.750$$

Different correlations for protic and aprotic solvents can be explained by the fact that solvent polarity and polarizability are dominant effects influencing E_T values in aprotic solvents whereas in protic solvents, in addition to polarity and polarizability, there are contribution from hydrogen bonding inter-

actions (4) on E_T values. Hydrogen bonding to phenoxide oxygen should stabilize the ground state relative to electronic state, and the effect in protic solvents should be hypsochromic (14) as is observed.

Kosower's 1-ethyl-4-carbomethoxypyridinium iodide

Kosower's Z scale (5) is based on the pronounced solvatochromism of 1-ethyl-4-carbomethoxypyridinium oxide. The Z value is calculated from the position of the absorption maximum. The stronger the stabilization effect of the solvent on the ion-pair relative to that in the less polar excited state, the higher the transition energy and the Z value.

Correlation equation of Py value of 18 aprotic solvents (except benzene (solvent 31) and dimethoxyethane (solvent 72)) with Z values represented by the regression line in Fig. 4, is shown in eq. [5] with $r = 0.920$, sd = 0.25. If the data for benzene and dimethoxyethane are included $n = 25$, r becomes 0.896, sd = 0.25

$$[5] \quad \text{Py} = 0.0671Z - 2.870$$

The Z value for water was reported by Kosower (5*a*) to be 94.6, but it was later proposed by Griffiths and Pugh (5*c*) to be 91.8.[3] The correlation of Py values with Z values for 17 protic solvents (except 2-ethoxyethanol (solvent 61) and *N*-methylacetamide (solvent 69)) is represented by the regression

[3] The Z value could not be obtained directly as the charge transfer band is masked by the intense absorption band of the pyridinium cation. It was obtained by extrapolating from the correlation with Winstein's Y value (15) of binary solvent mixtures (5*a*).

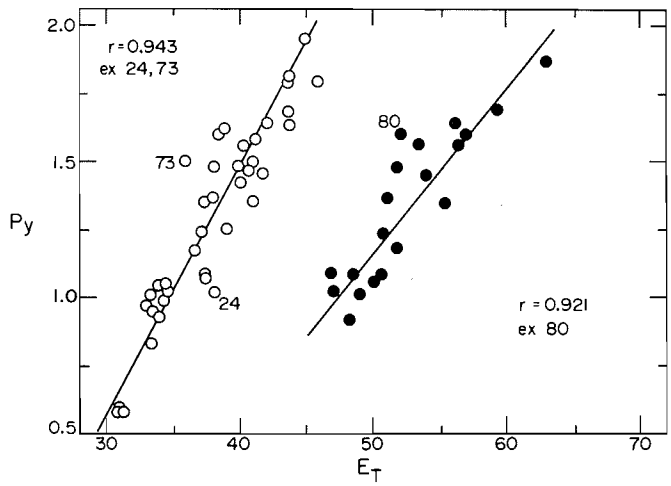

FIG. 3. Plot of Py values vs. Dimroth's E_T values. Protic solvents (●); aprotic solvents (○).

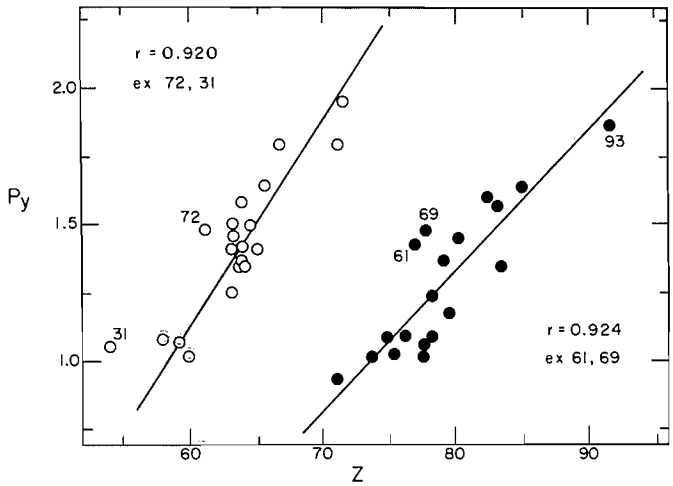

FIG. 4. Plot of Py values vs. Kosower's Z values. Protic solvents (●); aprotic solvents (○).

line in Fig. 4, and is given by eq. [6] with $r = 0.924$, sd = 0.27 when the value 91.8 is used for water.

[6] $\quad Py = 0.052Z - 2.82$

If the results for solvents 61, 69 are included r becomes 0.866, sd = 0.26.

The contribution of hydrogen bonding on Z values of protic solvents was recognized by Kosower (5*a*) in agreement with our separate correlation with aprotic and with protic solvents (Fig. 4).

Smith, Fainberg, and Winstein's log k_{ion} *values*

Fainberg and Winstein (15) introduced the ionization of *p*-methoxyneophenyl-*p*-toluenesulphonate as a standard reaction for characterizing the polarity of solvents. The rate of this reaction at 75°C was termed the log k_{ion} value.

Py values for eight aprotic solvents (Et_2O, THF, EtOAc, Ac_2O, acetone, CH_3CN, DMF, Me_2SO; excluding pyridine (solvent 60)) are nicely linear with their correlation equation represented by

[7] $\quad Py = 0.250 \log k_{ion} + 2.85$

with $r = 0.987$, sd = 0.30. If value for pyridine is included one obtains $r = 0.939$, sd = 0.29, slope = 0.239, intercept = 2.77.

For six protic solvents (*n*-octanoic acide, EtOH, MeOH, AcOH, HCOOH, H_2O) against log k_{ion} values, the correlation equation obtained is $r = 0.969$, sd = 0.34:

[8] $\quad Py = 0.27 \log k_{ion} + 2.08$

Taft's P *value*

Taft's *P* parameter (16) is defined as the chemical shift (in ppm) of the fluorine resonance in the nmr spectrum of *p*-nitrosofluorobenzene in a given solvent relative to the same quantity in the standard solvent cyclohexane. The *P* values appear to be related to the ability of the solvents to form specific 1:1 complexes with the polar nitroso group. Py gives only a very poor correlation with *P* values, i.e. for 23 aprotic and 3 protic solvents

[9] $\quad Py = 0.46P + 0.6$

with $r = 0.79$ and sd = 0.31.

Allerhand and Schleyer's G *values*

The *G* value (17) is based on the relative wave number difference in the gas phase and in solution of ir stretching vibration absorption of X=O and X—H . . . B groups (X = C, S, N, O, P; B = solvent). A plot of Py vs. *G* gives the regression equation

[10]. $\quad Py = 0.0165G - 0.16$

with $r = 0.858$, $S = 0.36$, $n = 13$. If the results for chloroform (high Py value) and acetonitrile (low Py value, but similar *G* values) are excluded, r becomes 0.938.

Kamlet, Abboud, and Taft's π^* *scale*

Recently Kamlet, Abboud, and Taft introduced the π^* solvent polarity scale (10) on the basis of the average solvatochromic behavior of a large number of indicator solutes rather than on a single one. A plot of Py vs. π^* values for 44 solvents is shown in Fig. 5. The correlation equation is as shown in eq. [11], with $r = 0.832$ and sd = 0.32.

[11] $\quad Py = 0.64 + 1.109\pi^*$

Interestingly, if solvents are divided by classes: aprotic aliphatics, protic aliphatics, aprotic aromatic, each class gives excellent correlation of Py vs. π^* values as shown in eqs. [12]–[14]:

[12] $\quad Py = 0.64 + 1.329\pi^*$

for aprotic aliphatic solvents ($n = 23$, $r = 0.976$, sd = 0.37)

[13] $\quad Py = 0.46 + 1.304\pi^*$

for protic aliphatic solvents ($n = 9$, $r = 0.982$, sd = 0.28)

[14] $\quad Py = 0.54 + 0.972\pi^*$

for aprotic aromatic solvents ($n = 8$, $r = 0.979$, sd = 0.16)

For chlorinated aliphatics (three solvents) and protic aromatic solvents (one solvent), data are insufficient for correlation.

Discussion

Spectroscopy

The variation of I_1/I_3 with solvent polarity is one of many examples of intensification of symmetry-forbidden bands in polar solvents. The effect was first observed in benzene by Ham (18) and later studied by Durocher and Sandorfy (19). It is frequently referred to as the Ham effect. This effect is partic-

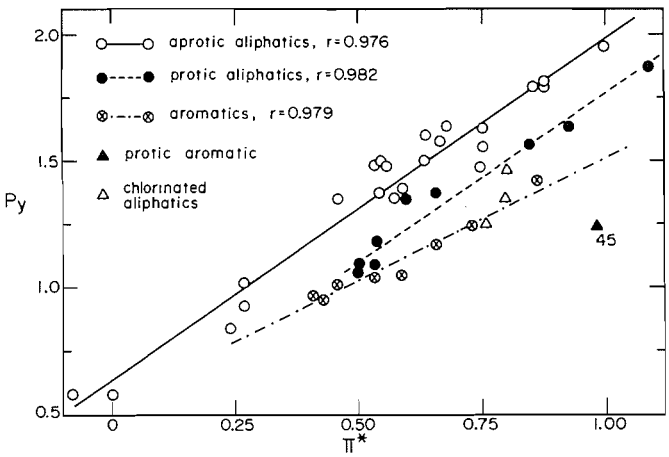

FIG. 5. Plot of Py values vs. Taft's π^* values.

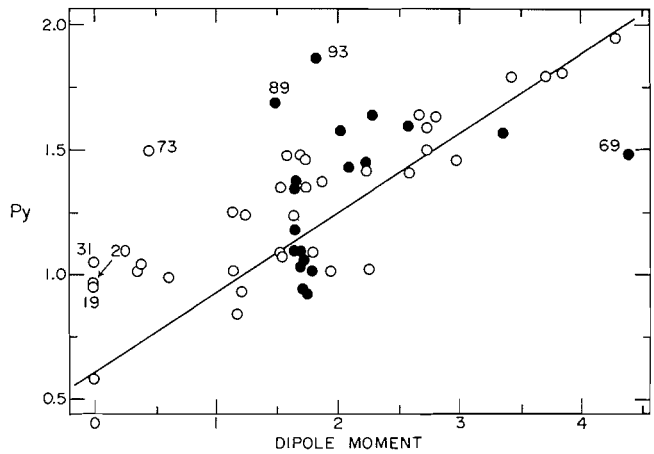

FIG. 6. Plot of Py values vs. dipole moment. Protic solvents (●); aprotic solvents (○).

ularly pronounced in pyrene where it has been studied by several research groups including those of Nakajima (11), Kalyanasundaram and Thomas (6), Hara and Ware (12), Lianos and Georghiou (20), and ourselves (9). Hara and Ware (12) demonstrated that polar solvents effected an increase of the radiative transition rate of the (0,0) band in fluorescence. This is the most compelling of many indications that polar solvents enhance the oscillator strength of symmetry-forbidden transitions. Other factors indicate that they do so through a reduction of local symmetry.

Lianos and Georghiou (20) compared pyrene with 1-methylpyrene and noted that the I_1/I_3 value of the latter in heptane was comparable to that of the former in water. Furthermore, the vibrational fine structure in 1-methylpyrene is broadened and much less sensitive to solvent polarity than that of pyrene itself. These symmetry-breaking features of the local field about the pyrene group ought also to affect the selection rules for vibronic transitions in pyrene. Solvent-enhancement of weakly allowed infrared bands in pyrene were also reported. Polar solvents cause peak broadening and intensity enhancements comparable in magnitude to those caused by methyl substitution.

The origin and nature of the local field is still not clear. Four factors can be cited. (*i*) Dipole interactions between the transition moment of the pyrene and the permanent dipole moment of the solvent molecules; (*ii*) inductive interactions with the quadrupole moment of the solvent molecules; (*iii*) dispersive interactions, and (*iv*) hydrogen bonding interactions. The first three effects have been discussed by Nakajima (11) and by Hara and Ware (12). If (*i*) were dominant, one would anticipate a correlation by Py with molecular dipole moment μ. As Fig. 6 emphasizes, this correlation is rather poor. Kamlet and Taft (1, 10) report a correlation of their π^* scale with μ for *select solvents*. Their presumption is that for these solvents, other factors affecting π^* are relatively unimportant.

Lianos and Georghiou (20) believe that molecular complex formation is the major factor. For protic solvents they see pyrene as a hydrogen bond acceptor with alcohols and even solvents as weakly acidic as CH_2Cl_2 acting as hydrogen bond donors. To substantiate this point of view he finds from infrared studies that pyrene forms weakly-bound 1:1 complexes with simple alcohols in dilute solution in CCl_4, and that these complexes have red-shifted O—H stretching frequencies. On the other hand we find only very small H/D isotope effects on I_1/I_3. Thus we obtain Py values of 1.20 in EtOD (1.18 in EtOH), 1.36 in CD_3OD (1.35 in CH_3OH), 1.44 in CH_3CO_2D (1.44 in CH_3CO_2H),[4] and 1.91 in D_2O (1.87 in H_2O).

Comparison with eq. [1]

According to eq. [1], π^* is an index of solvent dipolarity and polarizability. Under some circumstances, it overcompensates for the additional polarizability of aromatic and halogenated solvents, so that a correction term $d\delta$ is introduced. We noted in discussing Fig. 5 that Py correlated poorly with π^* but that there were indications of local correlations within families of solvents. This observation suggests that a correlation of Py ≡ XYZ ought to be possible in terms of eq. [1].

$$[15]\quad XYZ = XYZ_0 + S(\pi^* + d\delta) + a\alpha$$

Equation [1] can be simplified since pyrene is not a hydrogen bond donor: $b = 0$. We also assume that h and e are likewise zero, although the neglect of the $h\delta_H$ term is based only on the observation of similar Py values in alkanes that differ by about 1 unit in δ_H. With these assumptions we find an excellent correlation, Fig. 7, to the expression

$$[16]\quad Py^{calcd} = 0.64 + 1.33(\pi^* - 0.24\delta) - 0.25\alpha$$

with certain exceptions. The perfluorodecalin, perfluoromethylcyclohexane (Py = 0.52), and gas phase (Py = 0.41) points fall far off the line and are not included in the correlation. For the gas phase, eq. [16] predicts a Py^{calcd} value of −0.8. Trifluoroethanol has a Py^{calcd} value substantially smaller than its actual Py value, with the difference exacerbated by the -0.25α term ($\alpha[CF_3CH_2OH] = 1.51$). Acetonitrile and formamide also seem conspicuously far from the correlation line. These differences are particularly striking since dimethylformamide, dimethyl acetamide, and dimethylsulfoxide fall directly on the correlation line.

We suggest the possibility that the π^* values for fluorocarbons, acetonitrile, and formamide may need revision. For acetonitrile, where the $a\alpha$ term is very small, a π^* value of 0.90 (rather than 0.75) is in better accord with our data. In treating the fluorocarbons, we have set $\delta = 0$ in our correlation using eq. [15]. To improve the fit, we would suggest $\pi^* = -0.09$ instead of −0.33. For formamide, we question whether a somewhat smaller π^* value coupled with a larger value of a α might not also accommodate the other data from which the

[4] In freshly dried (glacial) acetic acid, Py = 1.37, as reported in Table 1.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

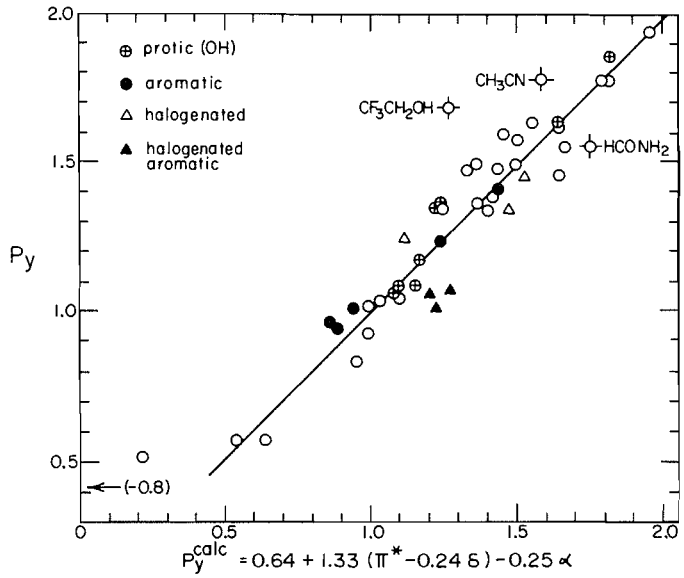

FIG. 7. Plot of Py values vs. Py^{calcd} values obtained from the Kamlet and Taft parameters and the correlation equation (15): $Py^{calcd} = 0.64 + 1.33\ (\pi^* - 0.24\delta) - 0.25\alpha$; slope = 0.988, intercept = 0.02, corr. = 0.959.

original values were derived.

It is curious that the coefficient of the α-term in eq. [14] is negative. This implies that solvent hydrogen bond donor ability acts to *lower* Py values over those inferred from ($\pi^* + 0.24\delta$) values (see Fig. 5). Yet in Table 1 it appears that solvents which are strong hydrogen bond donors have larger Py values (e.g. water, formic acid, trifluoroethanol) than those which are weaker hydrogen bond donors (e.g. ethanol, methanol). The small absolute value of the coefficient of the α-term indicates that the Py scale is much less sensitive to hydrogen bonding effects than to dipolarity–polarizability effects of the solvent. Its negative sign raises the question of whether there might be some residual hydrogen-bond-acceptor sensitivity contained within Kamlet and Taft's π^* scale for protic solvents.

Summary and future directions

The Py scale of solvent polarities is an empirical scale. Its values are easily determined with good precision. They span a significant range, varying from 0.41 in the gas phase to 1.95 in dimethylsulfoxide. Comparison with eq. [1] based upon the work of Kamlet, Taft, and co-workers (1, 10) emphasizes that the Py scale is relatively insensitive to the hydrogen bonding capability of protic solvents. Under other circumstances, these values might have served to parameterize the π^* scale for protic solvents.

In the spirit of Kamlet and Taft's research (1, 10), one would like a series of independent measurements which could be used to parameterize a solvent polarity scale in which dipolarity–polarizability terms were indeed separated from those describing hydrogen bond donor or acceptor capabilities. This is of course the aim of eq. [1]. This ought to be possible by examining solvent-induced emission intensity and absorption enhancements for other aromatic molecules. Mukhopadhyay and Georghiou (21) report enhancement factors (DMSO vs. *n*-heptane) of 2.93 (fluorescence) and 3.84 (absorption) for 1,12-benzoperylene, 2.10 (fluorescence) and 3.47 (absorption) for naphthalene, with somewhat smaller enhancements for 1-methylnaphthalene. Nakajima reported a value of 3.95 (fluorescence) for coronene (11*b*). Each of these molecules could serve as a probe for its own independent solvent polarity scale.

Experimental

Pyrene was purified as described previously (9). Solvents used were either reagent grade or spectral grade and were purified further by distillation. Fluorescence spectra were run at 22° on an SLM model 4800 spectrometer using 0.5 nm slits. Details were as previously reported (9).

Restricted rotation about arene–oxygen bonds in some 1,3-di-*tert*-butyl-2-methoxyarenedicarbonylphosphorus(III)chromium compounds

EVA M. CAMPI, BRYAN M. K. GATEHOUSE, W. ROY JACKSON, IAN D. RAE,[1] AND MARGARET G. WONG
Department of Chemistry, Monash University, Clayton, Victoria, Australia 3168

Received March 6, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

EVA M. CAMPI, BRYAN M. K. GATEHOUSE, W. ROY JACKSON, IAN D. RAE, and MARGARET G. WONG. Can. J. Chem. **62**, 2566 (1984).

The ^{1}H nmr spectra of 1,3-di-*tert*-butyl-2-methoxybenzenedicarbonyltriphenylphosphinechromium (**5**) and some related compounds at low temperatures show the presence of two species which interconvert with free energy of activation near 50 kJ mol^{-1}. The species differ in the orientation of the methoxy with respect to the chromium, since the same type of process is observed in a chelate complex in which a phosphinite ligand on chromium is also attached to the arene. Hindered rotation about the arene–chromium axis is not involved. The crystal structure of **5** shows the Ph_3P *anti* to the methoxy and the O-methyl group proximal to chromium.

EVA M. CAMPI, BRYAN M. K. GATEHOUSE, W. ROY JACKSON, IAN D. RAE et MARGARET G. WONG. Can. J. Chem. **62**, 2566 (1984).

Les spectres rmn du ^{1}H, obtenus à basse température, du di-*tert*-butyl-1,3 méthoxy-2 benzènedicarbonyltriphénylphosphinechrome (**5**) et de quelques composés apparentés démontrent l'existence de deux espèces qui se convertissent l'une dans l'autre avec une énergie libre d'activation de près de 50 kJ mol^{-1}. Considérant que l'on observe le même type de processus dans le chélate complexe dans lequel un ligand phosphinite du chrome est aussi attaché à l'arène, on en conclut que la différence entre les espèces se manifeste dans l'orientation du groupe méthoxyle par rapport au chrome. L'empêchement à la rotation autour de l'axe arène–chrome n'est pas impliquée. La structure cristalline du composé **5** démontre que le Ph_3P est en position *anti* par rapport au groupe méthoxyle alors que le groupe O-méthyle est proximal par rapport au chrome.

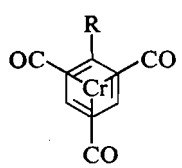
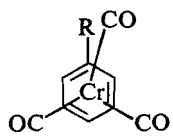
Introduction

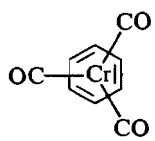
Arenetricarbonyl chromium compounds (**1**) are believed to exist in solution as equilibrium mixtures of eclipsed conformers (**1***a*, **1***b*) (1, 2), although staggered conformers (**2**) are often observed in the solid state, e.g. for benzenetricarbonylchromium itself (3). The position of equilibrium is determined by the steric and electronic properties of substituents on the arene ring, with **1***b* being favoured when R is electron releasing, but **1***a* if R is large and (or) electron withdrawing (1).



1*a*



1*b*



2

The interchange between these two eclipsed conformations is extremely rapid, with an electron diffraction study indicating that there was practically unhindered motion about the arene–Cr axis in gaseous benzenetricarbonylchromium (4). In the solid state a phase change at 108 K was attributed to the freezing-out of this motion (5). Nonetheless there have been numerous attempts to prepare arenechromium compounds in which this rotation would be sufficiently hindered to permit the observation of individual conformers by low-temperature nmr spectroscopy. We had great hopes (6) for 1,3,5-tri-*tert*-butylbenzenedicarbonyltriphenylphosphinechromium, but no evidence for restricted rotation could be found above 183 K, the lowest temperature at which we could keep the compound in solution. Others have succeeded in demonstrating restricted rotation about an arene–metal bond in the complexes (*p*-*t*-$BuC_6H_4Me)Ru(CO)(SiCl_3)_2$ (7) and (*p*-*t*-$BuC_6H_4Me)_2Cr$ (8).

When hexaethylbenzenetricarbonylchromium was studied at low temperature (9), the arene ligand was found to be eclipsed with respect to the carbonyls and alternate methyl groups were distal and proximal to the chromium. The ethyl groups changed orientation by a complex series of rotations having, overall, $\Delta G‡$ about 48 kJ mol^{-1}. When one of the carbonyls was replaced by Ph_3P, however, the crystal structure showed a staggered conformation with all of the methyls distal to the chromium, and solutions of the complex showed no dynamic nmr behaviour down to 148 K (9).

More recently McGlinchey *et al.* have reported low-temperature nmr studies of hexaethylbenzenedicarbonylthiocarbonylchromium (10) in which it is proposed that arene–Cr rotation is slow at 163 K and that $\Delta G‡$ for the rotation is 48 kJ mol^{-1}. This attribution has been challenged by Hunter and Mislow (11), who feel that changes in the nmr spectrum at low temperatures can be explained by permutation among the side-chains as described above.

In pursuing this same goal of restricted arene–Cr rotation we have used as ligands some 1,3-di-*tert*-butyl-2-methoxyarenes in which the three contiguous arene substituents were expected to buttress each other and increase the hindrance they offer to rotation of the $Cr(CO)_3$, $Cr(CO)_2P(OPh)_3$, and $Cr(CO)_2PPh_3$ moieties. Theoretical work had indicated (12) that electron donation by the arene substituents would increase the barrier to rotation, and the methoxy substituent was expected to help in this regard.

Experimental

Synthesis

The arenetricarbonylchromium complexes were prepared from hexacarbonylchromium and the appropriate arenes in a mixture of butyl ether and tetrahydrofuran (13) and purified by flash chro-

Cyclic phosphinite (8)

A solution of 3,5-di-*tert*-butyl-4-methoxytoluene (17.6 g, 0.075 mol), recrystallized *N*-bromosuccinimide (13.35 g, 0.075 mol), and benzoyl peroxide (100 mg) in carbon tetrachloride (100 mL) was stirred and refluxed for 18 h while under irradiation from a photoflood lamp. The mixture was cooled and filtered, the precipitated succinimide being washed with a little CCl_4 which was added to the filtrate. The solvent was then removed on the rotary evaporator and the residue distilled at reduced pressure to give the *bromomethyl compound* as an oil (14.7 g, 62%), bp 126–128°C/0.5 Torr (1 Torr = 133.3 Pa), which solidified to a yellowish solid with mp 41–43°C and was sufficiently pure for use in the next step.

The bromomethyl compound (13.5 g, 0.043 mol) and sodium acetate (10.2 g, 0.125 mol) were dissolved in glacial acetic acid (50 mL) and the solution refluxed for 9 h. The cooled mixture was partitioned between water (150 mL) and diethyl ether (150 mL) and the ether layer was separated, washed with aqueous $NaHCO_3$ and then water (2 × 50 mL), dried over Na_2SO_4, and finally evaporated to give crude *acetoxymethyl compound* (11.2 g) which was shown by nmr to contain some aldehyde impurity.

The acetoxymethyl compound (10 g, 0.034 mol) was dissolved in dry methanol (30 mL) and treated at room temperature with a solution of sodium methoxide prepared from sodium (0.80 g, 0.035 mol) in methanol (15 mL). The solution was stirred under a N_2 atmosphere for 18 h and then diluted with concentrated NaCl solution (80 mL). Extraction with diethyl ether (4 × 50 mL) and a conventional work-up gave the crude product as a liquid, which slowly solidified. Recrystallization from ethyl acetate – hexane gave 3,5-di-*tert*-butyl-4-methoxybenzenemethanol (5.09 g, 59%) as white crystals, mp 101.5–102.5°C; infrared (KBr) ν_{max}: 3300, 1120 cm^{-1}; ^{1}Hmr ($CDCl_3$/TMS) δ: 1.43 (s, 18), approx. 1.4 (br, 1), 3.69 (s, 3), 4.62 (br d, 2, J = 4 Hz), 7.26 (s, 2). *Anal.* calcd. for $C_{16}H_{26}O_2$: C 76.75, H 10.47; found: C 76.82, H 10.80.

This alcohol (2.33 g, 9 mmol) and hexacarbonylchromium (2.0 g, 9 mmol) reacted in dibutyl ether – tetrahydrofuran as described (13, 14) for 18 h, and the solvent was removed at reduced pressure. Recrystallization of the residue from ether–hexane gave several crops of the *tricarbonylchromium complex* (0.95 g, 26%) as bright yellow crystals, mp 144–146°C; infrared (KBr) ν_{max}: 3440, 1950, 1870, 1815 cm^{-1}; ^{1}Hmr ($CDCl_3$/TMS) δ: 1.47 (s, 18), approx. 1.4 (br, 1), 3.86 (s, 3), 4.25 (d, 2, J = 7 Hz), 5.9 (s, 2). *Anal.* calcd. for $C_{19}H_{26}CrO_5$: C 59.06, H 6.78; found: C 58.76, H 6.82.

The above complex (0.68 g, 1.8 mmol) in diethyl ether (25 mL) with triethylamine (0.27 g, 2.7 mmol) was treated with $ClPPh_2$ (0.409 g, 1.8 mmol) under a N_2 atmosphere at 0°C. After stirring for 1 h, the solution was filtered through a glass sinter into a quartz test tube. The precipitate was washed with C_6H_6 (30 mL) and then cyclohexane (30 mL), which were added to the filtrate. This solution was then irradiated for 7 h with annular discharge lamps (254, 310 nm) and then evaporated to dryness. The residue was taken up in toluene – light petroleum (1:4) and flash chromatographed on silica gel, the product eluting as an orange band. Evaporation of the solvents and recrystallization from light petroleum gave the *chelate complex* **8** (140 mg, 15%) as orange needles, mp 180–182°C; infrared (KBr) ν_{max}: 1875, 1820 cm^{-1}; ^{1}Hmr (CD_2Cl_2/TMS) δ: 1.36 (s, 18), 3.90 (s, 3), 4.39 (d, 2, J = 13.8 Hz), 4.97 (d, 2, J = 2.6 Hz), 7.2–7.7 (m, 10). *Anal.* calcd. for $C_{30}H_{35}CrO_4P$: C 66.41, H 6.50; found: C 66.45, H 6.83.

Deuterated complex 6

2,6-Di-*tert*-butyl-1-methoxybenzene (11.23 g, 0.051 mol) was stirred for 24 h at room temperature with bromine (8.16 g, 0.051 mol) and anhydrous $FeCl_3$ (0.2 g) in methylene chloride (50 mL). The reaction mixture was then washed with water (2 × 50 mL), dried over sodium sulfate, and evaporated. Distillation under reduced pressure gave 4-bromo-2,6-di-*tert*-butyl-1-methoxybenzene (12.2 g, 80%) as a colourless liquid, bp 130°C/2 Torr, which soon solidified, mp 48–49°C (lit. (15) bp 149–150°C/9 Torr). The bromo compound (7.0 g, 0.023 mol) in anhydrous ether (50 mL) was added dropwise to a Grignard reagent prepared from iodoethane (0.85 g, 0.005 mol) and magnesium (0.85 g, 0.036 mol). The solution was refluxed for 2 h, the D_2O (2 mL) was added, and the mixture was worked up to give the neutral product.

Flash chromatography on silica gel with pentane gave the 4-deutero compound as a liquid whose spectroscopic properties were similar to those of the protio-analogue. Mass spectrum m/z: 221 (mol. ion), 206 (base peak). Conversion to the complex **6** was accomplished in the usual way (14) and the product had mp 179–180°C.

Nuclear magnetic resonance spectra

^{1}H and ^{13}C nmr spectra were recorded at 90 MHz and 22.62 MHz respectively with Bruker WH90 and HX90 spectrometers operating in the pulse-FT mode. Digital resolution was 0.15 or 0.3 Hz for ^{1}H and 0.75 or 1.5 Hz for ^{13}C spectra and probe temperatures were measured with the Bruker temperature controller. Theoretical spectra were calculated using the computer program DMNR5 (16) assuming a two-site exchange from unequally populated sites, and the exchange rates derived from visual matching were used in the Eyring equation to calculate $\Delta G\ddagger$ values. Error limits are ±2 kJ mol^{-1}.

Crystal structure determination

Diffraction data for compound **5** were collected for Mo-Kα radiation on a Phillips PW1100 automated diffractometer and the structure solved by conventional methods. Details are given in our preliminary communication (17) and atomic coordinates are available on request from the Cambridge Crystallographic Data Centre. The structure is shown in Fig. 1.

Results

The ^{1}H nmr spectra of the tricarbonyl (**3**) and dicarbonyltriphenylphosphite (**4**) complexes did not change over the temperature range 303–183 K, and we deduce that all possible intramolecular rotations in these molecules remain very fast at the lowest temperature. The triphenylphosphine complexes **5**–**7** did show temperature-variable spectra, those of the latter two being easier to analyze because of the simpler aromatic region. In the spectra of **6** taken below 223 K in CD_2Cl_2, the signals of the methoxy group, the *tert*-butyl groups, and the aromatic hydrogens were all doubled. The two solute species were in the ratio 6:5 with the major one giving the more shielded methoxy signal ($\Delta\nu$ 56 Hz) and the less shielded aromatic ($\Delta\nu$ 52 Hz). The $\Delta G\ddagger$ for interconversion was 48.2 kJ mol^{-1}. Some ^{13}C spectra were also recorded but, because of the concentrated solutions required for these measurements, we were unable to maintain solutions below 233 K, at which temperature only the methoxy carbon and the ring carbon Cl signals had broadened extensively. Complex **5** had $\Delta G\ddagger$ 47.2 ($CDCl_3$) and 48.1 (CD_2Cl_2) and complex **7** 48.0 ($CDCl_3$) and 48.3 (CD_2Cl_2) kJ mol^{-1}.

The chelate complex **8** was synthesized from 3,5-di-*tert*-butyl-4-methoxytoluene and it also showed temperature dependent ^{1}H nmr spectra in CD_2Cl_2, with $\Delta G\ddagger$ 49.7 kJ mol^{-1}.

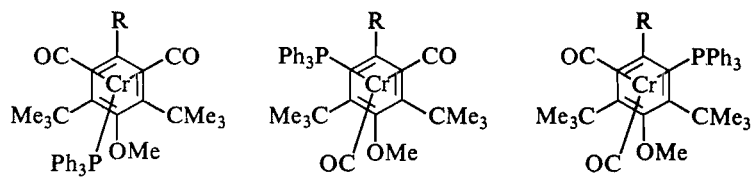
8 **10*a*** **10*b***



9a ***9b*** ***9c***

Discussion

Two intramolecular rotations need to be considered as causes of the temperature dependence of the nmr spectra: rotation about the arene–chromium axis and hindered rotation of the methoxy group about the arene–oxygen bond. These alternatives are depicted in formulae **9***a–c* and **10***a,b*, and the second was initially unattractive because of the difference in behaviour between the $Cr(CO)_2PPh_3$ compound **5** and its less bulky analogues **3** and **4**. It was only in the bulkiest of these compounds, complex **5**, that we observed restricted rotation, whereas in other cases, where the side chain rotates about a complexed arene, the free energies of activation normally lie in the reverse order: free ligand > ligand$(CO)_3Cr$ > ligand$(CO)_2P(OPh)_3Cr$ > ligand$(CO)_2PPh_3Cr$ (18).

In the first proposal, the two species giving rise to nmr spectra at low temperatures would be **9***a*, which has a mirror plane, and a 1:1 mixture of **9***b* and **9***c*, which interconvert rapidly when PPh_3 passes the substituent R. The energy maximum is the movement of PPh_3 past a *tert*-butyl group. This scheme became less likely, however, when the X-ray crystal structure (Fig. 1) showed the PPh_3 ligand eclipsing R, i.e. *trans* to the methoxy and as far as possible from the *tert*-butyls. Similar conformations probably exist in solution because we had previously noted (14) some shielding of groups at R which we now ascribe to the anisotropic effects of the aromatic rings on the PPh_3 ligand.

Other possible explanations are that rotation about the arene–Cr bond is very slow, with the preferred conformation being **9***a* or the one shown in Fig. 1 (with the phosphorus in the C1—C4—Cr plane), and that rotation about the aryl–oxygen bond is being observed. Rapid rotation about the arene–chromium axis and slow aryl–oxygen rotation would also produce this result.

A final decision in favour of methoxy group rotation was made on the basis that the chelate compound **8** also showed restricted rotation at low temperatures, and the arene–Cr rotation in this compound is prevented by attachment of the phosphinite ligand to the arene. There remains the anomaly of the steric considerations discussed above: we are unable to explain why our series should show the opposite behaviour to those in the literature. Significantly though, the $\Delta G\ddagger$ values for all of our complexes and for Mislow's hexaethylbenzene complex (9) were close to 50 kJ mol^{-1}. The McGlinchey work (10) produced a $\Delta G\ddagger$ of about this size, too, and it seems possible that all of these cases involve restricted rotation of the side chain in the complexed arene.

Crystal structure

The crystal structure (Fig. 1) shows the chromium atom to be almost centered with respect to the aromatic ring, and at a distance of 173.6(2) pm from the mean ring plane. The average Cr—C(arene) distance is 223.6 pm, similar to the 219.8 pm

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

found in (methylbenzoate)dicarbonyltriphenylphosphinechromium (19) and slightly longer than the 220.2 pm for the only other chelate complex (a phosphite) studied by X-ray crystallography (20). The Cr—P bond distance is even shorter than that found in the methyl benzoate complex above, 231.5 vs. 233.7 pm, but not as short as that in the chelate complex, 220.1 pm.

The carbonyls and the phosphorus are approximately eclipsed with aromatic ring carbons, the angle defined by C1, the ring centre and the C17 carbonyl being 16.4(5)°. The importance of this structure is that the PPh_3 ligand is *anti* to the methoxy, as far as possible from the *tert*-butyls, and in a position where its aromatic rings can shield C5 (Fig. 1).

An interesting feature of the structure is that the methoxy methyl group is proximal to the chromium, the torsion angle C3, C2, 3, C11 being −98.0(9)°. This places it in the apparently more crowded region of the molecule, and a similar preference has been observed for the central methoxy group in the crystal structure of (1,2,3-trimethoxybenzene)tricarbonylchromium (21). There might be some stereoelectronic reason for this seemingly contra-steric preference, but the nature of it is not apparent to us and invites further investigation.

Acknowledgments

A definitive synthesis of 2-[(5-methyl-*s*-triazolo[4,3-*c*]quinazolin-3-yl)thio]-*N*-benzylacetanilide and other reactions of its precursors[1]

ELLI SMAKULA HAND AND DAVID C. BAKER
Department of Chemistry, University of Alabama, Tuscaloosa, AL 35486, U.S.A.

Received May 2, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

ELLI SMAKULA HAND and DAVID C. BAKER. Can. J. Chem. **62**, 2570 (1984).

Treatment of 2-methyl-4-chloroquinazoline **2** with hydrazine gave 2-methyl-4-hydrazinoquinazoline **3** which was converted to 5-methyl-3-mercapto-*s*-triazolo[4,3-*c*]quinazoline **4**, followed by *S*-alkylation with chloro-*N*-benzylacetanilide to give **6**. The hydrazine **3** was converted to the hydrazone **9** with acetone, to 3,5-dimethyltriazolo[4,3-*c*]-quinazoline **10** with acetic anhydride, and to 5-methyl-*s*-tetrazolo[1,5-*c*]-quinazoline **12** via a nitroso intermediate **11** with nitrous acid. Compound **3** and its derivatives **4**, **6**, **10**, and **12** differed from those alleged to have these structures. The previously reported compounds cannot have these structures since X-ray diffraction studies established that the structure of the common precursor is **3**. The mercaptotriazole **4** was air oxidized to the disulfide **20** and hydrolyzed to 2-methyl-3-hydrazinothiocarbonyl-4(3*H*)-quinazolinone **19**. The reaction of **4** with carbon disulfide gave a side-product for which the 5-methylquinazolino[3,4-*c*]-1,2,4-thiadiazol-2-thione **21** is suggested. The ^{1}H nmr chemical shifts of the quinazoline methyl substituent are near δ 3 ppm in the fully aromatic compounds and at higher field when the heterocycle is non-aromatic.

ELLI SMAKULA HAND et DAVID C. BAKER. Can. J. Chem. **62**, 2570 (1984).

La réaction de la méthyl-2 chloro-4 quinazoline **2** avec de l'hydrazine conduit à la méthyl-2 hydrazino-4 quinazoline **3** que l'on a transformée en méthyl-5 mercapto-3-*s*-triazolo[4,3-*c*] quinazoline **4**; une *S*-alkylation de ce dernier composé, à l'aide de la chloro--benzylacétanilide, conduit au produit **6**. L'hydrazine **3** est transformée en hydrazone **9** par réaction avec de l'acétone, en diméthyl-3,5 triazolo[4,3-*c*] quinazoline **10** par réaction avec de l'anhydride acétique et en méthyl-5-*s*-tétrazolo[1,5-*c*]quinazoline **12**, via l'intermédiaire nitroso **11**, par réaction avec de l'acide nitreux. Le composé **3** et ses dérivés **4**, **6**, **10** et **12** diffèrent de ceux qui seraient censés posséder ces structures. Les composés rapportés antérieurement ne peuvent pas posséder les structures qui leur ont été attribuées puisque des études de diffraction des rayons-X ont permis d'établir la structure du composé **3** qui est un précurseur commun. Le mercaptotriazole **4** a été oxydé par l'air en disulfure **20** et son hydrolyse conduit à la méthyl-2 hydrazinothiocarbonyl-3 (3*H*)-quinazolinone-4 **19**. La réaction du composé **4** avec le bisulfure de carbone fournit un produit secondaire pour lequel on suggère la structure méthyl-5 quinazolino[3,4-*c*] thiadiazole-1,2,4 thione-2 **21**. Dans les spectres rmn du ^{1}H, les déplacements chimiques des substituants méthyles sont de l'ordre de 3 ppm dans les composés complètement aromatiques et à des champs plus élevés lorsque l'hétérocycle n'est pas aromatique.

[Traduit par le journal]

The reactions shown in Scheme 1 are reported (1) to give the alkylthiotriazoloquinazoline **6**, a compound of interest to our program in the synthesis and evaluation of heterocyclic compounds as potential anti-tumor agents. Our attempted synthesis of **6** by the published procedure (1), however, led to products distinctly different from **6** and its precursors **3** and **4**. We describe here a definitive synthetic route to **6** and show that the hydrazine previously obtained (1) cannot have structure **3**.

4-Chloro-2-methylquinazoline, 2

2-Methyl-4(3*H*)-quinazolinone (**1**) was converted to **2** by the reported procedure (2). Since other workers reported (3) that **2**, prepared according to ref. 2, gave **1**·HCl upon standing for 1 week at refrigerator temperatures, and since other 4-chloroquinazolines are heat-sensitive as well (4), we modified the procedure (2) by keeping both work-up time and temperatures to a minimum and immediately purifying crude **2** by chromatography on neutral alumina. Such preparations of **2** were stable at room temperature for at least 1 month.

The reactions of 4-chloro-2-methylquinazoline (2) with hydrazine

Hydrazinolysis of **2** has been reported by two research groups (1, 5) to give in ≥80% yield compounds (**A** and **B**, Table 1) of decidedly different characteristics to which, however, the same structure, **3***a*, was assigned. Our attempts to repeat these procedures led to conflicting results, intractable mixtures, or both. (See parts (a) and (b) in the experimental section.) The conditions advocated by one group (5), for instance, gave the hydrochloride **7**, formed by ethanolysis of **2**,[2] as the major product (45%), along with **3** (10%) and small amounts of **8** (Scheme 2.)

Gradual addition of an ethanolic solution of **2** to a 10-fold excess of aqueous 85% hydrazine hydrate at 0°C gave the desired hydrazine **3** in 80% yield. Its structure was established by (a) elemental analysis; (b) a ^{1}H nmr spectrum (Table 2) which shows the presence of a methyl group, four aromatic protons, and protons that exchanged with deuterium oxide; (c) a mass spectrum which gave the expected molecular ion ($M^{\ddagger}$ = 174) as the base peak; and (d) formation of the hydrazone **9** on treatment with acetone.

Inasmuch as the physical properties of our preparation differed from those reported (1, 5), and **3** was essential to our scheme, its structure was unequivocally established by single-crystal X-ray analysis (Fig. 1). The diffraction study also shows that the N1—C2 and N3—C4 bond lengths are equal (1.36 Å); the crystalline solid, obtained from chloroform, therefore has the aromatic structure **3***a* (Scheme 1). Solution ^{1}H nmr data (Table 2) are in better accord with the 4-(3*H*)quinazolinone structure **3***b* (Scheme 2) or an equilibrium mixture of both forms (*vide infra*).

The hydrazine **3**, which is stable at −15°C in the dark,

[1] Aspects of this work have been presented in preliminary form. See ref. 16.

[2] Similarly, when the parent 4-chloroquinazoline is dissolved in absolute methanol, the HCl salt of 4-methoxyquinazoline is formed (6).

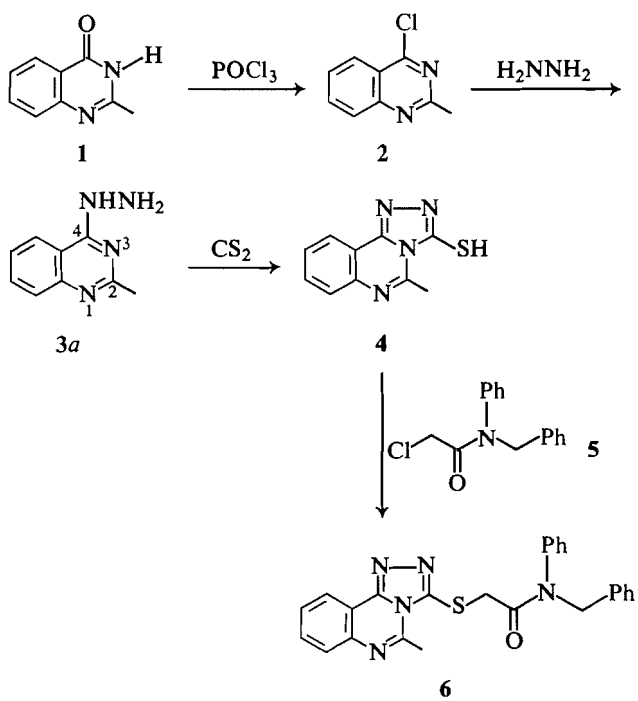
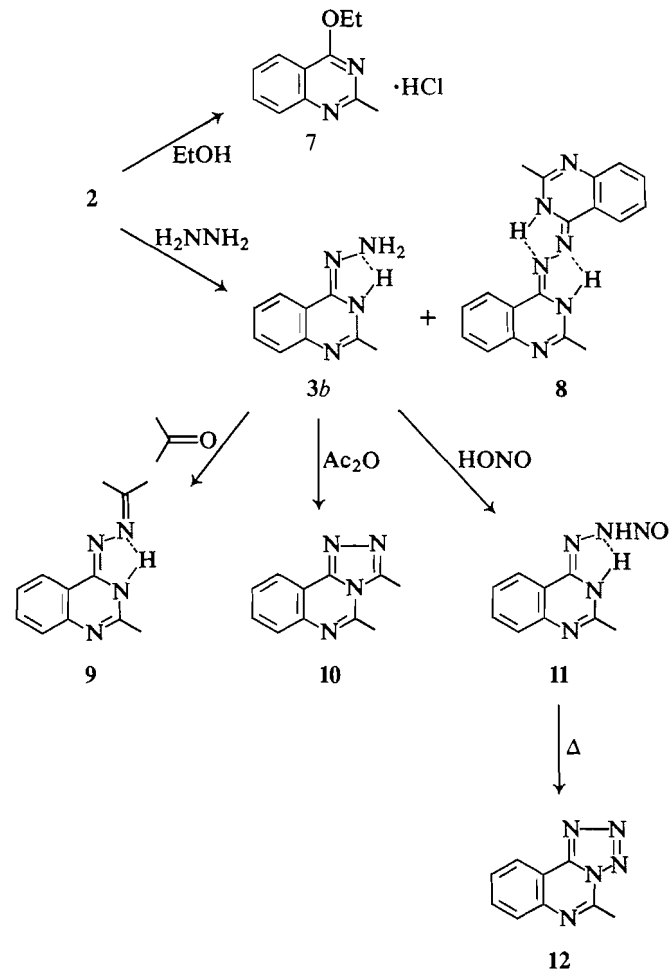
13 172 (7)	196 (7)		151 (7)



SCHEME 1

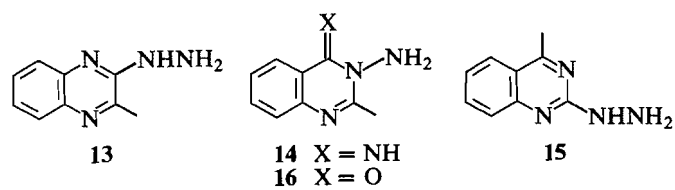


SCHEME 2

gradually forms the *N,N'*-disubstituted compound **8** on exposure to air and light. Compound **8** is also formed when **2** is treated with hydrazine under various conditions (see Experimental). The symmetrical structure **8** shown (Scheme 2) conforms to elemental analysis data, a mass spectrum (*m/z* 316 $M^{\ddagger}$, 100%), and ^1H nmr data which indicate the presence of a non-aromatic 4-(3*H*)-pyrimidone system.[3] The N3—H (**8**) rather than the tautomeric N1—H structure is shown, since in this arrangement internal hydrogen bonding is possible.

The identity of our compound **3** with **B** (5) and its dissimilarity to **A** (1) is established by comparison of the properties of some derivatives (Table 1). Compound **3** was converted by nitrous acid to a nitroso compound **11** that was in turn converted to the tetrazoloquinazoline **12** by heating at its melting point (~190°C). Compounds **3**, **11**, and **12** have melting points similar to those reported (5). The melting point and ir spectrum of the tetrazoloquinazoline prepared in ref. 1 differ from those of both **11** and **12**. Treatment of **3** with acetic anhydride gave the triazoloquinazoline **10**, which also differed from that reported (1). The structures of **10**–**12** are supported by ^1H nmr (Table 2) and ms data (Experimental).

The question of the structure of the hydrazine compound **A** (1) remains unresolved. As possible candidates for **A** one might consider the three isomers, **13**, **14**, and **15**, which could undergo reactions analogous to those of **3**. Compound **13** is excluded on the basis of its melting point and those of the derivatives (Table 1). Neither **14** nor **15** has been reported. It seemed plausible that **3** might have rearranged to give **14** under the conditions employed for the preparation of **A** (1). Alternatively, the precursor of **3**, i.e. **2**, could have decomposed to give the quinazolinone hydrochloride **1**·HCl (3), which upon treatment with hydrazine might have given **14**. Neither hypothesis was substantiated by experiment. Thus, attempts to induce the rearrangement of **3** to **14** by refluxing ethanolic solutions of **3** with hydrazine or hydrazine and acid failed, and the reaction



13 **14** X = NH **15**
16 X = O

[3] The ^1H nmr data thus exclude the alternate unsymmetrical structure, in which the system must be aromatic.

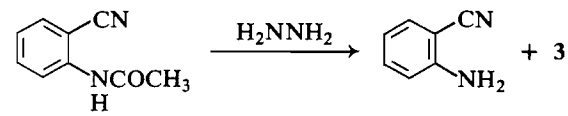
of **1**·HCl with hydrazine gave instead another rearrangement product, **16**, identified by its melting point (8)[4] and spectral data. An attempt to produce **14** from 2-acetamidobenzonitrile gave 2-aminobenzonitrile (**18**) and **3** in 42 and 35% yield, respectively.[5]



17 **18**

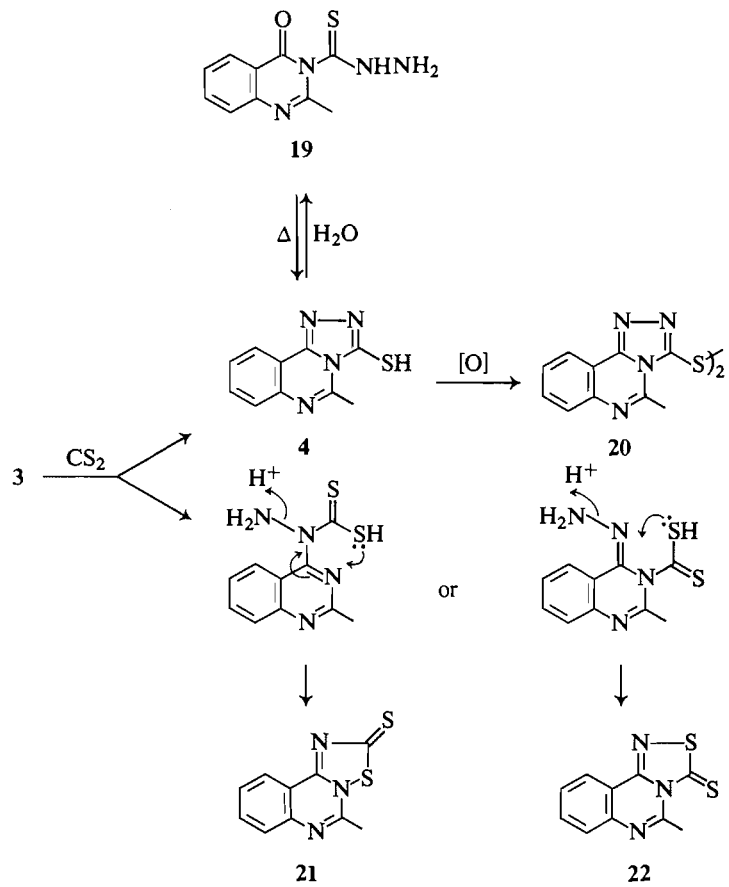
*The reaction of 4-hydrazino-2-methylquinazoline **3** with carbon disulfide*

Treatment of **3** with carbon disulfide in *N*,*N*-dimethylformamide gave **4** as the major product (in ~50% yield),[6] along

[4] The previous synthesis of **16** from **1** was achieved in the absence of acid (8).

[5] Although the yield of **3** from commercially available **18** (via the *N*-acetyl derivative **17**) is low, the process, based on a single experiment, is recommended since the work-up is simpler and the compounds do not have the tenacious unpleasant odor associated with **2**.

[6] Other methods, including the use of potassium trithiocarbonate/acetic acid, carbon disulfide/pyridine, or carbon disulfide/potassium hydroxide (1), gave much lower yields of **4**, in part expected, since **3** is known to decompose in the presence of air and base (5) and since the 2-methyl group in other quinazolines undergoes condensation reactions in the presence of even weak bases, such as sodium acetate or piperidine (9).



SCHEME 3

with at least nine other products, including **19**, **20**, and **21** (Scheme 3).

The structure of the unstable **4** is assigned on the basis of (a) spectral data, and conversion to stable derivatives by (b) oxidation to **20**, and by (c) hydrolysis to **19**, as well as by alkylation to give **6**.

(a) The elemental composition of $C_{10}H_8N_4S$ is indicated by the mass and isotopic distribution of the molecular ion, *m/z* 216, 217, 218 (100, 13, 4.3%; calcd. 100, 13.2, 5.1%). The presence of an aromatic methyl group and four aromatic protons is established by a ^{1}H nmr spectrum (Table 2), and a broad band in an ir spectrum at 2600 cm^{-1} is attributable to the stretch of the SH function.

(b) On exposure to air and light, **4** was converted to a compound that displays neither —NH nor —SH absorption in its ir spectrum, contains only aromatic and methyl protons in a ratio of 4:3 as shown by a ^{1}H nmr spectrum, and has a molecular weight of 430 as indicated by the molecular ion (base) peak in its mass spectrum. These data, together with an elemental analysis, establish the disulfide structure **20**.[7]

(c) Compound **4** was converted to **19** by refluxing a solution of **4** in 95% ethanol for 1 h. The spectral evidence for **19** includes broad —NH ir absorption from 2600 to 3300 cm^{-1}; a molecular ion *m/z* 234 (1.6%) and a low-mass fragmentation pattern which is the same as that of **4**; and ^{1}H nmr signals corresponding to one methyl group, four aromatic protons, and three protons exchangeable with deuterium oxide (Table 2). Elemental analysis data are in accord with structure **19**.

A fourth product isolated from the reaction of carbon disulfide and **4** must have structure **21** or **22** on the basis of the following data. Its ^{1}H nmr spectrum shows only four aromatic protons and a methyl group, its ir spectrum lacks —NH, —OH, and —SH absorption, and a mass spectrum has molecular ion isotopic distribution peaks, *m/z* 233, 234, 235 (53, 8, 5.5%), in accord with a formula $C_9H_7N_3S_2$ (calcd. 53, 6.6, 4.7%). This formula is supported by elemental analysis of a derivative (**24**, *vide infra*). Of the two possible strutures, **21** is preferred on mechanistic grounds. Reaction of **3** at H_2N—*N*== or the *N*3 ring nitrogen with CS_2 would give initial adducts (Scheme 3) in equilibrium with **3** and CS_2. Such reactions may well have similar energy requirements. Subsequent cyclization to **21** or **22**, however, should be energetically more favorable from the former adduct since an sp^3 rather than an sp^2 bond must be broken. It is estimated that ~15% of **3** was converted to the thiadiazole.

*Alkylation of **4** to give 2-[(5-methyl-*s*-triazolo[4,3-c]quinazolin-3-yl)thio]-N-benzylacetanilide **6***

Reaction of the mercaptotriazole **4** with chloro-*N*-benzylacetanilide in ethanolic sodium hydroxide gave a product ($C_{25}H_{21}N_5SO$) in 63% yield to which the structure **6** is assigned, in accord with predominant *S*-alkylation observed with other mercaptotriazoles (11). The similarity of the ^{1}H nmr chemical shifts of the protons of **6** and the corresponding protons of the disulfide **20** provides strong evidence that the ring systems and the substitution patterns are the same in both of these compounds. Since in **20** the ring system must be aromatic, possible *N*-alkylation of **4**, which gives a non-aromatic system, is ex-

[7] For other examples of oxidation of mercaptotriazoles to the disulfides, see ref. 10.

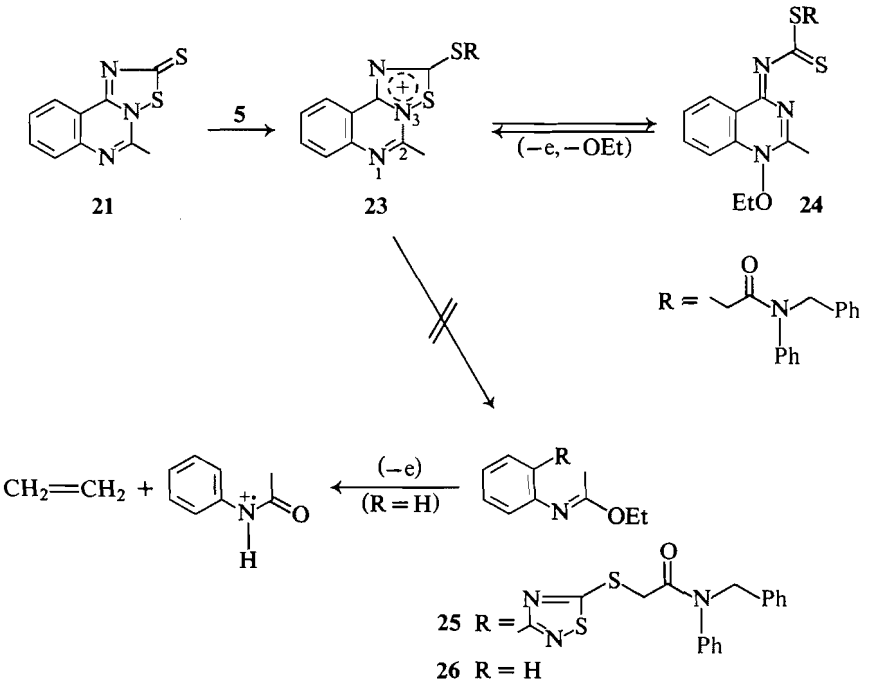
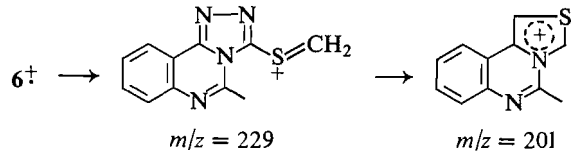


SCHEME 4

cluded. Further, the mass spectrum of **6** has a fragment,[8] m/z 201, which indicates the alkyl group is bonded to sulfur. This fragment, which has the same intensity (16%) as the parent ion, can arise by loss of $OCN(Ph)CH_2Ph$ and N_2. A possible path via the fragment m/z 229 (56%) is shown below.



Since **4** was contaminated with small amounts of **19**, **20**, and **21**, and attempted purification led to increased amounts of **19** and **20**, the alkylation with **5** was carried out on crude **4**. From that mixture another alkylation product **24** was obtained. The ^1H nmr spectrum (Table 2) showed the presence of the $—CH_2CON(Ph)CH_2Ph$ group, four additional aromatic protons, plus a methyl and an ethyl group. Elemental analysis gave a composition of $C_{27}H_{26}N_4O_2S_2$. These data indicate that **24** was formed from **21** (or **22**) by addition of the elements $CH_3CH_2O—$ and $—CH_2CON(Ph)CH_2Ph$. This was confirmed by tlc analysis of the alkylation reaction of pure **21**.

Structure **24**, which is derived by *S*-alkylation of **21**, followed by nucleophilic attack of solvent ethanol at N1 and cleavage of the N3—S bond (Scheme 4), is suggested for this product. The alternative imido ester structure **25**, obtained by reaction of ethanol at C2, is contraindicated by ir and mass spectral data. Compound **24** shows a single ir absorption band in the 1600–1700 cm^{-1} region at 1640 cm^{-1}, attributable to the amide function of the alkyl side chain. The model imido ester **26** absorbs at 1670 cm^{-1}. In its mass spectrum compound **24** gave no detectable fragment attributable to loss of $CH_2=CH_2$, the expected product of McLafferty rearrangement of an ethyl imido ester.[9] The high-mass region is characterized by the molecular ion (11%), a fragment due to the loss of $\cdot CH_3$ (3%), and an intense fragment due to loss of $\cdot OEt$ (76%). The latter fragmentation is expected for **24** since it results in the formation of a resonance-stabilized species, **23**. The ^1H nmr data are also in accord with structure **24**. The low-field chemical shift (δ 4.45) of the methylene protons of the $—OCH_2CH_3$ group suggests that this group is attached to an electron-withdrawing moiety,[10] and the high-field chemical shift of one of the aromatic doublets (δ 6.77) is indicative of the presence of an NR_2 function.[11] Attempts to formulate a corresponding derivative from **22** led to no reasonable postulates.

Proton magnetic resonance spectra

The chemical shifts of the 2-methyl substituents in the above compounds tend to fall in two general ranges (Table 2). When the ring system is aromatic, as in the simple 4-substituted compounds (**2** and **7**) or in those fused with a five-membered aromatic heterocycle (**6**, **10**, **12**, and **20**), the 2-methyl protons exhibit signals near δ 3 ppm. Similar low-field resonances of the 2-methyl groups in **4** and **21** suggest that the mercaptotriazole **4** exists as the SH tautomer as shown (Scheme 1) and that the thiadiazole **21** (Scheme 3) is also a fully aromatic system.

The methyl signals of the quinazolinones **1**, **16**, and **19**, in which the heterocycle is not aromatic, are observed at higher field (δ 2.35, 2.61, and 2.07, respectively). Since compounds

[8] Other fragments of potential diagnostic value, i.e., those containing sulfur and the alkyl side chain or portions thereof, coincidentally have the same masses as fragments containing the heterocycle. The position of alkylation cannot be inferred from such fragments. For example m/z 256 can be due to both RS^+ and $ArSCHCO^+$ and m/z 257 can be due to both RSH^+ and $ArSCH_2CO^+$

[9] The $(M - CH_2=CH_2)^+$ fragment of the model imido ester, $PhN=C(CH_3)OEt$ (**26**), has half the intensity (19%) of the parent ion (39%); other high-mass peaks are attributable to the loss of $\cdot OEt$ (20%) and $CH_2=CH_2 + \cdot CH_3$ (20%).

[10] Compare with δ 3.48 for $—CH_2CH_3$ in diethyl ether and δ 4.21 for $PhN=C(CH_3)OCH_2CH_3$.

[11] Compare with δ 6.7 for the *ortho* protons in $PhNR_2$.

For personal use only.

3, **8**, **9**, and **11** exhibit methyl signals in the higher-field region, it is suggested that the heterocyclic ring of these compounds exists predominantly as the non-aromatic tautomer in solution.

Experimental

General

Melting points were taken on a Thomas–Hoover capillary melting point apparatus or, if >250°C, on a Mel-Temp capillary block; both are uncorrected. Thin-layer chromatography (tlc) was carried out on E. Merck's silica gel plates (60F-254 aluminum-backed plates, catalog no. 5539). Column chromatography was carried out as indicated using either Woelm neutral alumina (activity grade III) or E. Merck Silica Gel 60 (70–230 mesh, catalog no. 7734). Spectra were determined as follows: infrared (ir) on a Beckman IR-33 double-beam spectrophotometer as Nujol mulls; proton nuclear magnetic resonance (^{1}H nmr) at 200 MHz on ~1% solutions (tetramethylsilane, internal standard) using a Nicolet NT-200 FT-NMR instrument; mass spectra (ms) at 70 eV using the direct-inlet probe on a Hewlett–Packard 5985A GLC–MS instrument. Elemental analyses were performed by Atlantic Microlab, Inc., Atlanta, Georgia.

Preparation of 4-chloro-2-methylquinazoline (2)

A mixture of 2-methyl-4(3*H*)-quinazolinone (**1**, Aldrich, mp 232.5–233°C, 4.8 g, 30 mmol), *N*,*N*-dimethylaniline (5.5 g, 45 mmol), and dry benzene (100 mL) was briefly boiled to remove water; aged phosphorus oxychloride (3.7 g, 24 mmol) was added, and the mixture was stirred and refluxed for 2 h under protection of a Drierite-filled tube. The mixture was then filtered, and the insoluble material was extracted with benzene (100 mL). The combined solutions were rapidly extracted sequentially with ice water, 20% sodium hydroxide (2 × 50 mL) diluted with ice, ice water, saturated sodium chloride, and then dried over sodium sulfate. Evaporation of solvent at ~30°C under reduced pressure gave a liquid which was directly applied to a column of alumina (300 g) packed in hexane. Hexane eluted dimethylaniline. 50% Hexane–benzene gave **2** (3.2 g, 60%), pure by tlc (chloroform), mp 78–79°C (lit. (2) mp 81.5–83°C); ms *m/z* (%): 178, 180 ($M^{\ddagger}$, 25, 9).

Reactions of 4-chloro-2-methylquinazoline (2) with hydrazine

(a) When 85% hydrazine hydrate (0.90 g, 15 mmol) was added to a solution of **2** (1.25 g, 7.0 mmol) in absolute ethanol (10 mL) (1), **2** was consumed at once (tlc, chloroform). After the solution had been refluxed for the requisite 5 h, 4 major and 7 minor products were present (tlc, ~10% absolute ethanol – chloroform). Attempted work-up according to ref. 1 gave a mixture (0.45 g) that was not further investigated.

(b) An attempt to duplicate the formation of **3** in 80% yield by stirring an emulsion of **2** (500 mg, 2.8 mmol) with 5 equivalents of hydrazine hydrate (0.75 g, 13.8 mmol) in benzene (15 mL) for two h (5), gave a benzene-insoluble gum which was treated with water (8 mL) to give **3** (50 mg, 10%, mp 171–174°C (dec)). Evaporation of solvent from the benzene-soluble fraction gave a residue which was rinsed with water and air dried (0.4 g). An ir spectrum displayed all of the bands present in the starting material **2**. Crystallization of the residue (90 mg) from absolute ethanol (10 mL) afforded a mixture (20 mg) which contained **8** according to a mass spectrum (*m/z* (%) 316 ($M^{\ddagger}$, 100)). Evaporation of the ethanolic mother liquor, extraction of the resulting residue with chloroform, evaporation of the solvent, and treatment of the residue with ether gave 4-ethoxy-2-methylquinazoline hydrochloride (**7**, 65 mg, 45%); ir: ~2350 and 1880 (both broad) cm^{-1}; ms *m/z* (%): 188, 189 ((M-HCl)‡, 28, 4.4), 173 ((M-HCl-CH_3)$^+$, 51), 160 ((M-HCl-CH_2=CH_2)‡, 100). The presence of halogen was verified by a green flame with a copper wire.

(c) To a stirred solution of 85% aqueous hydrazine hydrate (11.5 g, 200 mmol) in absolute ethanol (15 mL), cooled in ice, was added dropwise during 15 min a freshly prepared solution of pure **2** (3.2 g, 18 mmol) in absolute ethanol (60 mL). The ice bath was then removed, and stirring was continued for 1.75 h. After the mixture was clarified by filtration, the filtrate was concentrated *in vacuo*. The residual oil dissolved in water (35 mL) and then suddenly set to a crystalline mass. Filtration, rinsing with water, and air drying gave a hydrate of nearly pure **3** as pale yellow needles (3.05 g), mp (partial melting) 80°C, gas evolution, resolidification, partial melting 165°C, resolidification with gas evolution 168°C.

A chloroform solution (100 mL) of the hydrate (2.54 g) was boiled down (to 40 mL) to give off-white needles of **3** (1.92 g). Treatment of the mother liquor with charcoal, followed by concentration to ~10 mL yielded a second crop of **3** (0.23 g, 81% total). An analytical sample had mp 175–176.5°C (dec.); another sample had mp 179–180°C; on occasion the melt resolidified on further heating; other times resolidification occurred prior to complete melting (lit. (1) mp 199°C; lit. (5) mp 180–182°C); ms *m/z* (%): 174, 175 ($M^{\ddagger}$, 100, 12). *Anal.* calcd. for $C_9H_{10}N_4$: C 62.05, H 5.79, N 32.16; found: C 61.97, H 5.82, N 32.12. The compound became contaminated with **8** (tlc, chloroform), gradually in the presence of air, rapidly in the presence of air and light, but was stable at −15°C in the dark.

(d) In other experiments, when hydrazine was added to **2**, or when **2** was added rapidly to hydrazine, or when the latter was not cooled, varying amounts of the disubstituted hydrazine **8** were formed. Treatment with water of the residue obtained after evaporation of ethanol led to selective dissolution of **3**. Rapid filtration gave the solid **8**; the filtrate then either spontaneously or upon seeding deposited the hydrate of **3**.

N,*N*′-di(2-methylquinazolin-4-yl)-hydrazine (**8**) crystallized from 2-propanol as fine, bright yellow needles; mp 287°C (dec.) (depends on rate of heating) (lit. (5) mp 280°C); ms *m/z* (%): 316, 317 ($M^{\ddagger}$, 100, 22). *Anal.* calcd. for $C_{18}H_{16}N_6 \cdot 0.42\ C_3H_7OH$: C 67.78, H 5.63, N 24.62; found: C 67.95, H 5.82, N 24.67. The presence of 2-propanol was confirmed by a ^{1}H nmr spectrum.

(e) Refluxing an ethanolic solution (3 mL) of **3** (200 mg, 1.15 mmol) and aqueous 85% hydrazine hydrate (100 mg, 1.7 mmol) for 5 h, evaporation of solvent, and treatment of the residue with water gave starting material **3** (130 mg), contaminated with **8** (tlc, 15% absolute ethanol – chloroform). A similar experiment, in which ~90% of the hydrazine was present as its hydrochloride salt, gave a ten-component mixture (tlc).

*Acetone 2-methyl-4(3*H*)-quinazolinone azine (9)*

A solution of crude **3** (0.65 g) in acetone was left to stand for several days when the solvent had evaporated to give a solid form which the hydrazone **9** (0.50 g) was isolated by chromatography on silica gel (30 g, 2.5% absolute ethanol – chloroform). Crystallization from hexane, followed by sublimation (80°C/0.1 Torr) (1 Torr = 133.3 Pa), gave **9** as a colorless solid, mp 118.5–120.5°C; ms *m/z* (%): 214, 215 ($M^{\ddagger}$, 22, 3.4), 199 ((M − CH_3)$^+$, 100). The compound turned deep yellow on exposure to light and air. *Anal.* calcd. for $C_{12}H_{14}N_4$: C 67.27, H 6.59, N 26.15; found: C 67.07, H 6.61, N 26.09.

*3,5-Dimethyl-*s*-triazolo[4,3-*c*]quinazoline (10)*

A solution of **3** (100 mg, 0.58 mmol) in acetic anhydride (0.7 mL, 7.5 mmol) was heated for 1 h in a 150°C oil bath. The solvents were evaporated in a stream of nitrogen, and the residual solid was crystallized from ethyl acetate to give colorless needles of **10** (80 mg, 73%). Two recrystallizations gave an analytical sample, mp 200–201°C (lit. (1) mp 155°C); ms *m/z* (%): 198, 199 ($M^{\ddagger}$, 100, 22), 197 ((M − H)$^+$, 22). *Anal.* calcd. for $C_{11}H_{10}N_4$: C 66.66, H 5.08, N 28.27; found: C 66.73, H 5.09, N 28.23.

*5-Methyltetrazolo[1,5-*c*]quinazoline (12) via 11*

Compound **3** (120 mg, 0.69 mmol) was treated with aqueous hydrochloric acid (2.9 *N*, 3 mL). A small amount of orange material was removed by filtration, and the colorless filtrate, stirred in ice, was treated dropwise with aqueous (~0.3 mL) sodium nitrite (~50 mg, 0.73 mmol). A solid which separated almost at once was filtered after 50 min and rinsed with water to give colorless **11** (135 mg, 96%, pure by tlc (~30% absolute ethanol – chloroform)) which crystallized from ethanol as a light yellow powder, mp 190–191°C (dec.) (lit. (5) mp 197–198°C); ms *m/z* (%): 203, 204 ($M^{\ddagger}$, 100, 11).

Compound **11** (55 mg, 0.27 mmol) was heated for 2 min at its

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

For personal use only.

melting point in a beaker covered with a watch glass when no further gas evolved. The mixture was cooled, treated with ethanol and charcoal, and filtered through Celite. Evaporation of the filtrate to ~1 mL afforded **12** (20 mg, 40%) as off-white needles; mp 157–158°C (lit. (5) mp 162–163°C); ms *m/z* (%): 185, 186 (M^+, 40, 4.7), 157 ($(M - N_2)^+$, 90), 156 (100).

*Reaction of 2-methylquinazolinone (**1**) with hydrazine*

A solution of **1** (1.6 g, 10 mmol), concentrated HCl (0.83 mL, 10.4 mmol), and 95% hydrazine hydrate (1 mL, ~20 mmol) in absolute ethanol (60 mL) was refluxed for 2 h. Since tlc indicated the presence of only **1**, another portion of hydrazine (2 mL, ~60 mmol, total) was added, and refluxing was continued overnight when some of the product had formed (tlc, 5% methanol–chloroform). Most of the solvent was then boiled off, and heating was continued for 2 h. On cooling, the residue set to a solid mass which was treated with ice and water. Insolubles were filtered and rinsed with water to give **16** (0.63 g, 36%). When the remaining ethanol in the filtrate was evaporated under reduced pressure, a second crop of **16** (0.67 g) contaminated with **1** separated. A third crop (0.34 g) was obtained by extraction of the aqueous filtrate with chloroform (2 × 20 mL). Crystallization of the combined latter crops from benzene gave a solid (0.48 g) enriched in **1**. The material remaining in the benzene was recrystallized from aqueous 60% ethanol to give pure **16** (0.38 g, 58% total), mp 144–145.5°C (lit. (8) mp 146–148°C); ms *m/z* (%): 175, 176 (M^+, 100, 11.3), 146 ($(M - COH)^+$, 72).

*Reaction of 2-acetamidobenzonitrile (**17**) and hydrazine*

A solution of 2-acetamidobenzonitrile (11) (640 mg, 4 mmol) and aqueous 85% hydrazine hydrate (3.4 g, 55 mmol) in absolute ethanol (10 mL) was refluxed overnight. Since tlc (20% absolute ethanol – chloroform) indicated the presence of starting material, ethanol was boiled off, and the residual liquid was heated for an additional 1.5 h at 100°C. The cooled solution was diluted with water (5 mL) and extracted with chloroform (3 × 15 mL). The extracts were dried over sodium sulfate and stripped of solvent under reduced pressure to give a light brown liquid (660 mg) which partially solidified. Treatment with hot hexane (2 × 60 mL) gave an insoluble solid, **3** (240 mg, 35%), which after crystallization from chloroform (charcoal) was nearly colorless (180 mg, 25%), mp 179–180°C (dec.).[5] The hexane-soluble fraction was subjected to chromatography on alumina (35 g). Elution with chloroform afforded 2-aminobenzonitrile (0.20 g, 42%) which, after sublimation (50°C/0.1 Torr), had mp 47–48°C and the same ir spectrum (melt) as a commercial (Aldrich) sample (mp 45–47.5°C).

*Reaction of 4-hydrazino-2-methylquinazoline with carbon disulfide: formation of **4**, **19**, **20**, and **21***

After a solution of **3** (1.4 g, 8 mmol), carbon disulfide (20 mL, 330 mmol), and dry *N,N*-dimethylformamide (2 mL) was refluxed overnight, a solid had separated. Carbon disulfide was boiled off, the mixture was cooled, and the yellow solid was filtered and rinsed with small amounts of *N,N*-dimethylformamide (filtrate A) and absolute ethanol. The insoluble product **4** (0.90 g, 52%) was contaminated (tlc, 15% absolute ethanol – chloroform) with sulfur (ms: S–S8, e.g., S8 *m/z* (%) 256, 258 (M^+, 100, 34)), the disulfide **20**, and the yellow compound **21**.

Crystallization of **4** from ethanol gave less pure product (tlc), larger amounts of **20**, as well as the hydrolysis product **19** being formed. Subsequent treatment of **4** (80 mg) with hot chloroform gave a colorless insoluble solid **19**, 2-methyl-3-hydrazinothiocarbonyl-4(3*H*)-quinazolinone (25 mg). Compound **19** was also isolated from the filtrate A, above, as follows. The filtrate was diluted with water (20 mL), and the insoluble materials (0.16 g, ten components (tlc, 10% absolute ethanol – chloroform)) were filtered and discarded. After standing for 2 weeks, the filtrate had deposited a five-component mixture (0.33 g) from which colored materials (0.01 g) were removed by extraction with hot benzene (10 mL). Subsequent crystallization from ethanol failed to give separation; the recombined mixture was then triturated with boiling chloroform (15 mL), cooled, and filtered to give **19** (0.16 g, 8.5% total). Two crystallizations from absolute ethanol afforded colorless crystals, mp 249.5–250°C (dec.) (depends on rate of heating); ir: 3290 (br), 3100 (br), 1680 (s), 1620 (s), 1590 (s), 1535 (s), 1310 (s) cm^{-1}; ms: same as mass spectrum of **4**, except for the additional molecular ion peak, *m/z* (%) 234 (1.6). *Anal.* calcd. for $C_{10}H_{10}N_4OS \cdot 0.25\ H_2O$: C 50.30, H 4.43, N 23.47, S 13.43; found: C 50.30, H 4.41, N 23.45, S 13.49.

A pure sample of the disulfide **20** was obtained as follows. After refluxing a solution of **3** (250 mg, 1.4 mmol) in carbon disulfide (2.5 mL, 41 mmol) and dry *N,N*-dimethylformamide (0.3 mL) for 19 h, the carbon disulfide was boiled off and the cooled residual mixture was triturated with ether. Filtration of the mixture gave a yellow solid (300 mg) which was heated with chloroform (5 mL) and then cooled. The chloroform-soluble fraction (170 mg) was treated with water (5 mL) and 2.5 *N* sodium hydroxide (pH ~ 10) to give an insoluble yellow solid (20 mg), which was primarily **21** according to its ^1H nmr spectrum. Treating the filtrate with 1 *N* hydrochloric acid (to pH ~3) gave a precipitate of primarily **4**, **19**, and **20** (tlc, ~5% absolute ethanol – chloroform). A similar mixture precipitated upon standing overnight. On further standing, the aqueous solution deposited colorless needles of **20** (25 mg, 15% total). An analytical sample, prepared by dissolving **20** (45 mg) in chloroform (3 mL), filtering, adding absolute ethanol (5 mL) to the filtrate, and boiling the solution down to incipient crystal formation, cooling, and filtering, had mp 244–245°C; ir: 1625 (s), 1525 (m), 1285 (s) cm^{-1}; ms *m/z* (%): 430, 431, 432, (M^+, 100, 28, 13), 216 (8), 215 (17). *Anal.* calcd. for $C_{20}H_{14}N_8S_2$: C 55.80, H 3.28, N 26.05, S 14.89; found: C 55.52, H 3.29, N 25.94, S 14.75.

*Interconversion of **4** and **19***

(a) Compound **19** (35 mg, 0.15 mmol) was heated in a beaker at its melting point for ~3 min. The nearly colorless crystals of **4** (15 mg, 46%), which deposited on the walls, had mp 210–211.5°C and displayed in an ir spectrum all of the major bands present in the spectrum of crude **4** (obtained from **3** and carbon disulfide, *vide supra*): 2650 (br); 1640 (s), 1530 (s), 1310 (s) cm^{-1}; ms *m/z* (%): 216, 217, 218 (M^+, 100, 13, 4.3), 215 (12).

(b) When a solution of crude **4** (12.2 mg, 0.056 mmol) in aqueous 70% ethanol (0.7 mL) was refluxed for 1 h, none of 4 remained and **19** had formed (tlc, 15% absolute ethanol – chloroform). Ethanol was boiled off and the mixture was cooled and filtered to give a solid (8.3 mg, 63%). After crystallization from absolute ethanol, the colorless solid had an ir spectrum identical to that of the analytical sample of **19** (*vide supra*).

*Reaction of crude **4** with 2-chloro-*N*-benzylacetanilide, **5**; formation of **6** and **24**; isolation of 5-methyl-1,2,4-thiadiazolo[2,3-c]-quinazolin-2-thione, **21***

The chloroamide **5**, prepared by a general method (12), was treated with several portions of hexane to remove unreacted benzylaniline. The product was then pure according to its ^1H nmr spectrum and had mp 64–66°C (lit. (13) mp 75–76°C); ^1H nmr δ ($CDCl_3$): 3.85 (s, 2), 4.90 (s, 2), 6.99–7.36 (m, 10); ms *m/z* (%): 259, 261 (M^+, 5.2, 1.6), 91 (100).

A stirred mixture of crude **4** (0.9 g, ~4.2 mmol) and absolute ethanol (40 mL) was treated with aqueous 2.5 *N* sodium hydroxide (1.67 mL, 4.2 mmol) to give a green solution to which the chloroamide **5** (1.08 g, 4.2 mmol) was added. Shortly after the latter had dissolved, a colorless solid began to precipitate. The solid was filtered after 2 h (filtrate A), rinsed with absolute ethanol, and then triturated with water to give **6** (1.15 g, 63%). After recrystallization from absolute ethanol, **6** had mp 149.5–150.5°C (lit. (1) mp 89°C); ir: 1665 (s), 1620 (s), 1520 (s), 1385 (s), 1190 (s) cm^{-1}. *Anal.* calcd. for $C_{25}H_{21}N_5SO$: C 68.31, H 4.82, N 15.93, S 7.29; found: C 68.20, H 4.85, N 15.90, S 7.19.

The combined green-blue filtrate A and rinse liquid were concentrated *in vacuo* to give a solid (0.37 g), primarily **6** and **24** (tlc, chloroform), which was fractionated by elution with chloroform from silica gel (40 g). Early fractions gave **24** (0.17 g, 8% based on crude **4**), which after crystallization from ethanol had mp 156.5–157.5°C; ir: 1640 (s), 1590 (m), 1490 (m), 1390 (m), 1290 (m), 1280 (m) cm^{-1};

ms m/z (%): 502, 503 (M^{+}, 11, 3), 487 ($(M - CH_3)^{+}$, 3.3); 457, 458, 459 ($(M - OC_2H_5)^{+}$, 76, 19, 11), 91 (100). *Anal.* calcd. for $C_{27}H_{26}N_4S_2O_2$: C 64.52, H 5.21, N 11.15, S 12.76; found: C 64.33, H 5.22, N 11.13, S 12.80.

In a similar experiment less than one equivalent of sodium hydroxide (1.9 mmol for 0.57 g, (2.6 mmol) of crude **4**) was used. As above, the initially green solution (pH ~ 10) deposited a solid, but the supernatant solution turned bright yellow (pH ~ 6). Filtration of the mixture and rinsing of the solids with ethanol and water gave a mixture of **21** and **6** (0.75 g) which was treated with hot ethanol (75 mL). An insoluble, bright yellow solid, **21** (~20 mg, 3%), was filtered. Concentration of the filtrate to ~15 mL gave impure **6** (0.50 g) which was subjected to chromatography on alumina (40 g). 40% Chloroform–ether eluted colorless **6** (0.42 g, 35%).

Compound **21** had mp 275°C (sudden dec.); ir: 1600 (s), 1550 (w), 1400 (s), 1040 (s) cm^{-1}; ms m/z (%): 233, 234, 235 (M^{+}, 53, 8, 5.5), 201 ($(M - S)^{+}$, 2), 175 ($(M - NCS)^{+}$, 5). Its R_f (chloroform) was the same as that of the yellow contaminant in crude **4**. According to tlc analysis (chloroform), reaction of a chloroform–ethanol (1:2) solution of **21** (~1 mg) with **5** in the presence of sodium hydroxide gave **24**.

Ethyl N-*phenylacetimidate (26)*

The imido ester **26** (14) had bp 119°C/40 Torr (lit. (14) bp 94.5°C/12.5 Torr); ^{1}H nmr δ ($CDCl_3$): 1.32 (t, 3), 1.80 (s, 3), 4.25 (q, 2), 6.65–7.45 (m, 5) ppm; ms, see footnote 9.

Crystallographic structure determination of **3**[12]

$C_9H_{10}N_4$ fw = 174.2

Monoclinic, space group $P2_1/n$, a = 4.941(2), b = 15.008(6), c = 11.928(5) Å, β = 100.20(4)°, V = 870.5 Å^3, Z = 4, ρ_c = 1.33 g cm^{-1}, MoK_α radiation, λ = 0.71069 Å, $\mu(MoK_\alpha)$ = 0.51 cm^{-1}.

Data were collected on an Enraf–Nonius CAD-4 diffractometer out to a 2θ value of 40°. A total of 408 observed reflections were obtained, and the structure was refined to a conventional R value of 0.044. Details of data collection are given in ref. 15.

Acknowledgments

The authors are grateful to W. E. Hunter and J. L. Atwood for the X-ray crystallographic study of **3**. This work was supported in part by contract no. NO1-CM-07355 from the National Cancer Institute of the National Institutes of Health.

Enzymes in organic synthesis. 32.[1] Stereospecific horse liver alcohol dehydrogenase-catalyzed oxidations of *exo*- and *endo*-oxabicyclic *meso* diols

J. Bryan Jones and Christopher J. Francis
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received March 7, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

J. Bryan Jones and Christopher J. Francis. Can. J. Chem. **62**, 2578 (1984).

Preparative-scale horse liver alcohol dehydrogenase-catalyzed oxidation of *meso exo*- and *endo*-7-oxabicyclo[2.2.1]heptane diols provides a direct one-step route to enantiomerically pure chiral γ-lactones of the oxabicyclic series.

J. Bryan Jones et Christopher J. Francis. Can. J. Chem. **62**, 2578 (1984).

L'oxydation préparative, catalysée par l'alcool déshydrogénase du foie de cheval, des oxa-7 bicyclo[2.2.1] heptanediols-*exo* et -*endo méso* s'avère être une route directe en une étape conduisant aux γ-lactones chirales énantiomériquement pures de la série oxabicyclique.

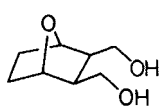
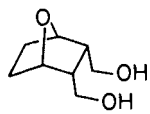
The abilities of enzymes to discriminate between enantiotopic groups of compounds that possess prochiral centres or that are *meso* compounds are being exploited to an ever-increasing extent in asymmetric synthesis (2). Horse liver alcohol dehydrogenase (HLADH),[2] a commercially available NAD-dependent alcohol dehydrogenase that catalyzes CH(OH) ⇌ C=O oxidoreductions of a wide range of substrates, is one of the most versatile enzymes in this regard. In its oxidative mode, it has been shown to operate stereospecifically on only one of the enantiotopic hydroxyl groups of acyclic and monocyclic *meso*-diols (1, 3). In this paper we report that preparative-scale HLADH-catalyzed oxidations are also enantiotopically specific for *meso* oxabicyclic diols such as **1** and **2**.



1



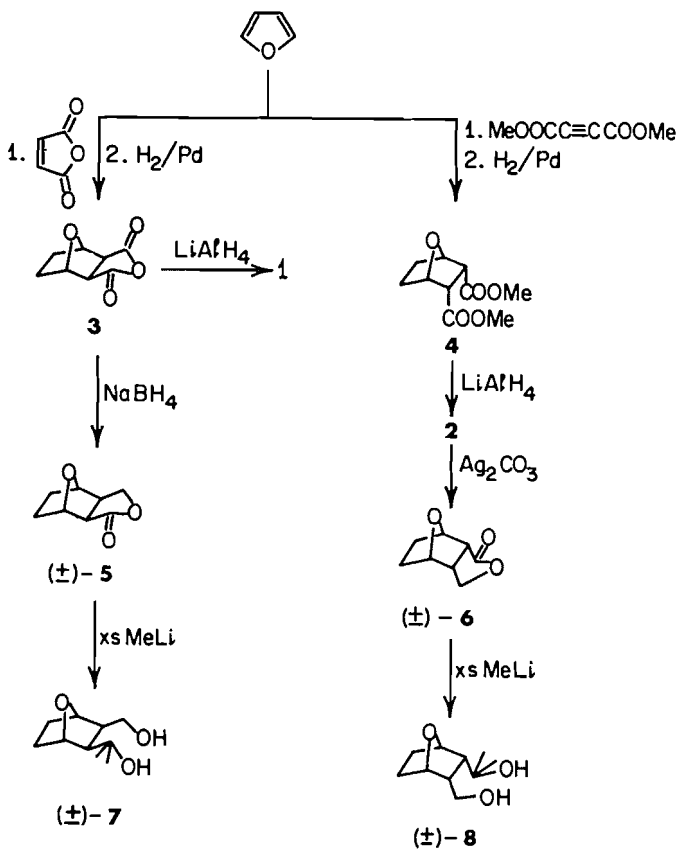
2

Results

The *exo*- and *endo*-diol substrates **1** and **2**, the racemic lactones **5** and **6**, and racemic diols **7** and **8** required as reference compounds were obtained as shown in Scheme 1.

Both **1** and **2** were found to be excellent substrates of the enzyme. Their rates of HLADH-catalyzed oxidations, relative to the usual benchmark of cyclohexanol = 1.0 under equivalent assay conditions, were found to be 0.63 for **1** and 0.21 for **2**. Such oxidation rates indicate that multi-gram HLADH-catalyzed oxidations will be viable.[3] The results of the preparative-scale enzyme-mediated oxidations are summarized in Scheme 2.

The enantiomeric excesses of the *exo*-(+)-**5** and *endo*-(+)-**6** lactones of Scheme 2 were determined by ^{1}H nmr spectroscopic



SCHEME 1

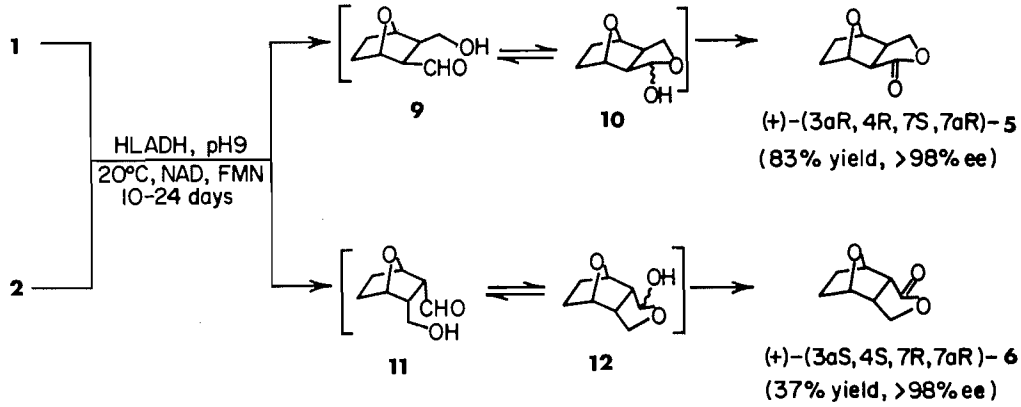
examination (4) of the dimethyl diols, (+)-**7** and (+)-**8** respectively, obtained using excess methyllithium as shown for the racemic series in Scheme 1. In the presence of 0.4 equivalents of Eu(hfc)$_3$, the protons of the *gem*-dimethyl groups of the racemic reference diols *exo*-(±)-**7** and *endo*-(±)-**8** were cleanly resolved into two doublets with ΔΔδ values of 0.03 and 0.11 ppm respectively. The spectra of (+)-**7** and (+)-**8** showed no trace of splitting under the same conditions, thereby demonstrating that their precursor lactones (+)-**5** and (+)-**6** respectively were enantiomerically pure.[4]

[1]For Part 31, see ref. 1.

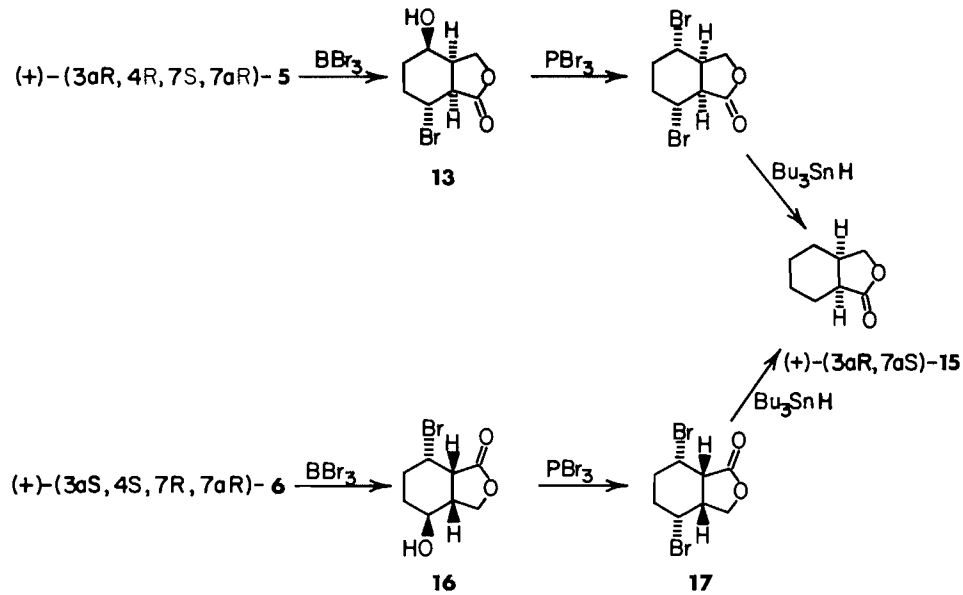
[2]Abbreviations used: HLADH, horse liver alcohol dehydrogenase; NAD, nicotinamide adenine dinucleotide; FMN, flavin mononucleotide (riboflavin phosphate); Eu(hfc)$_3$, tris[3-(heptafluoropropylhydroxymethylene)-*d*-camphorato]europium^{III}; PLE, pig liver esterase.

[3]Good preparative-scale oxidations can be expected when the rate of oxidation of a new substrate is >0.05 of that of cyclohexanol under the same assay conditions.

[4]The nmr ee (enantiomeric excess) determination method is considered accurate to <±2%.



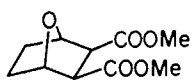
SCHEME 2



SCHEME 3

The absolute configurations of (+)-**5** and (+)-**6** were established by their conversion to the known (3*a*) (+)-(3a*R*,7a*S*)-perhydroisobenzofuranone (**15**) by the methods summarized in Scheme 3.

In view of the stereospecificities reported for pig liver esterase-catalyzed hydrolyses of *meso*-diesters (5), the ability of PLE to exert enantiotopic discrimination in its hydrolyses of diesters within the oxabicyclic series was evaluated on the *meso* diesters *exo*-**18** and *endo*-**4**. The diester **4** had been prepared earlier (Scheme 1) and **18** was readily produced from **3** by Fischer esterification in methanol. Disappointingly, neither diester was a substrate of PLE.[5]



18

Discussion

The substrates and required reference compounds were readily prepared by the Scheme 1 routes. The *exo*- and *endo*-diols **1** and **2** were both very good substrates for HLADH under the preliminary assay conditions, exhibiting very high relative oxidation rate values of 0.63 and 0.21 respectively.[3] In view of this, the 2−3 week reaction times required for the preparative-scale reactions were unexpectedly lengthy. For such excellent substrates, HLADH-catalyzed oxidations on the 2-g scale of the Scheme 2 reactions should have been complete in a few hours and the enzyme may be experiencing product inhibition by one or all of the hydroxy aldehydes **9** and **11** formed initially, their hemiacetal isomers **10** and **12**, or the hydroxyacid precursors of **3** and **4** that are the final products before work-up of the pH 9 reaction medium. In contrast to previous *meso*-diol oxidations, in which some hemicaetal intermediates were isolated (3), only the lactone products (+)-**3** and (+)-**4** were obtained from the Scheme 2 reactions.

Both HLADH-derived lactones were shown to be enantiomerically pure within the accuracy limits of the nmr method used. The absolute configuration determinations (Scheme 3) were straightforward. While only one bromoalcohol structure is shown for each of **13** and **16**, the positions of the hydroxyl and bromo substituents could be reversed. In fact, the ^{1}H nmr spectrum of **16** indicated that it was a mixture of isomers. In contrast, **13** appeared to be a single stereoisomer. The spectral data did not permit unequivocal isomeric

[5]The experimental conditions applied were those described by Chen *et al.* in ref. 5.

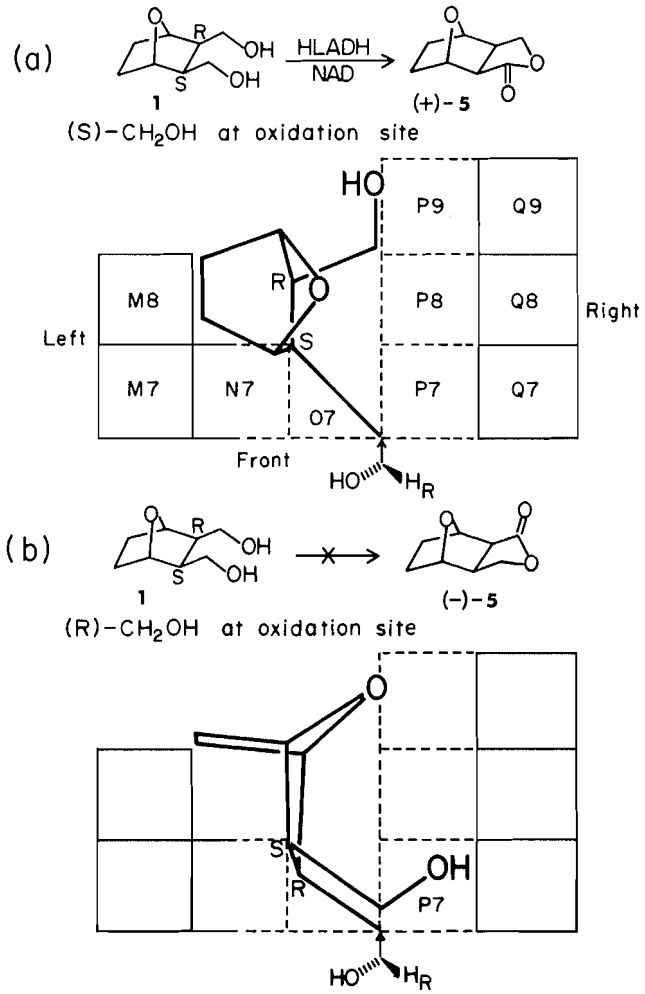

FIG. 1. Cubic active-site section analysis of the stereospecificity of HLADH-catalyzed oxidation of the *exo*-diol **1**. The model, the analytical procedure applied, and the alphanumeric assignments of the cube locations are as described previously (6). In this analysis, the top elevation perspective is used to depict the substrate orientations. The orientations shown are the most favourable for the reactive ES-complex and the least unfavourable for the unreactive orientations. Cubes bounded by solid lines are "forbidden" regions where substrate groups cannot be accommodated because the space is filled with amino-acid residues or by coenzyme. The regions in front, underneath, and above the defined cubic section are forbidden for the same reason. Cubes bordered by broken lines represent "limited access" spaces where substrate binding is possible, but not favoured owing to their proximity to forbidden locations. The negative effects of limited region binding are synergistic. Violation of two limited regions is equivalent to a forbidden location. The open areas are "allowed" space where substrate can be freely accommodated. For oxidation to occur the alcohol moiety must locate at the enzymic oxidation site, indicated by ↑. HLADH-catalyzed oxidations of primary alcohols require abstraction of the *pro-R* hydrogen (3, 7). This ensures a unique —CH_2OH group orientation. In (a) oxidation of the —CH_2OH group attached to the (*S*)-centre is considered. All of the substrate can be accommodated in allowed space. Productive ES-complex formation is therefore possible and oxidation to (+)-**5** occurs via the Scheme 2 pathway. In (b), the consequences of placing the (*R*)-CH_2OH group at the oxidation site are considered. No orientations are possible that do not involve unfavourable interactions. In the best fit shown, the (*S*)-CH_2OH would penetrate limited region **P7**, an interaction that would be particularly adverse because **P7** is a hydrophobic region that would accept a polar OH function with great reluctance. Productive ES-complex formation is therefore precluded and (−)-**5** is not produced.

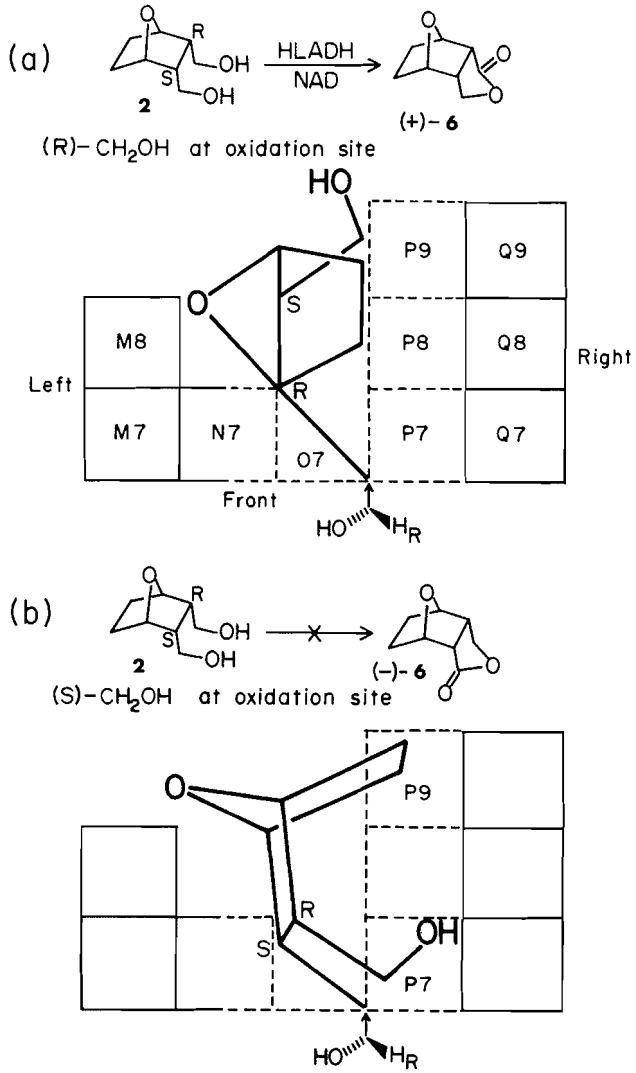

FIG. 2. Cubic active-site section analysis of the stereospecificity of HLADH-catalyzed oxidation of the *endo*-diol **2**. Again, the top elevation perspective (6) is used. (a) With (*R*)-CH_2OH correctly positioned at the oxidation site, all substrate groups can locate in allowed space and oxidation to (+)-**6** therefore occurs readily. (b) A productive ES-complex cannot form for (*S*)-CH_2OH oxidation and (−)-**6** is therefore not produced. The least unfavourable orientation shown would require penetration of two limited regions, **P7** and **P9**, an energetically prohibitive combination.

structure distinctions to be made.

The active site model employing cubic space descriptors developed recently (6) enables the stereospecificities of the enzyme-catalyzed oxidations of **1** and **2** to be readily interpreted. The analyses are depicted in Figs. 1 and 2.

The results of this study provide a further demonstration of the value of the approach for the preparation of useful chiral synthons. Lactones **5** and **6**, which are of potential value as oxaprostaglandin precursors, are not easily available in enantiomerically pure form by any other route.

Experimental

Analytical and instrumental procedures and sources of materials were as described previously (3*a*). All distillations were performed in a Kugelrohr apparatus.

cis-exo-*2,3-(Bishydroxymethyl)-7-oxabicyclo[2.2.1]heptane (1)*

exo-4,7-Epoxyisobenzofuran-1,3-dione (**3**, 5 g, 30 mmol, obtained

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

by the literature (8, 9) method) in dry THF (300 mL) was reduced with lithium aluminum hydride (2.5 g, 66 mmol) in the usual way to yield the *exo*-diol **1** (2.7 g, 57% yield after recrystallization from ethyl acetate/ether (1:2)), mp 63°C (lit. (9) mp 62°C); ^{1}H nmr ($CDCl_3$) δ: 2.18 (2H, d of t, J = 5 Hz, 1.5 Hz), 3.4−3.8 (4H, m), 4.1 (2H, broad s, OH), and 4.35 (2H, t, J = 3 Hz) ppm.

cis-endo-*2,3-(Bishydroxymethyl)-7-oxabicyclo[2.2.1]heptane (2)*

cis-endo-2,3-(Biscarbomethoxy)-7-oxabicyclo[2.2.1]heptane (**4**, 5.35 g, 25 mmol, prepared by the method of Eberbach *et al.* (10)) in dry THF (300 mL) was reduced with lithium aluminum hydride (2.1 g, 55 mmol) to give the *endo*-diol **2** (2.6 g, 66% yield), bp 120°C (0.4 Torr (1 Torr = 133.3 Pa)), mp 49−51°C (lit. (11) mp 49−50°C); ^{1}H nmr ($CDCl_3$) δ: 1.55 (4H, s), 2.2−2.6 (2H, m), 3.4−3.82 (4H, m), 4.1 (2H, broad s, OH), and 4.5 (2H, broad s) ppm.

exo-*Perhydro-4,7-epoxyisobenzofuranone ((±)-5)*

The anhydride **3** was reduced with sodium borohydride by the procedure of Eggelte *et al.* (11) to give the *exo*-lactone (±)-**5** (63% yield after recrystallization from acetone), mp 113°C (lit. (11) mp 112−113°C); ir ($CHCl_3$): 1770 cm^{-1}, ^{1}H nmr ($CDCl_3$) δ 1.4−1.9 (4H, m), 2.6−2.9 (2H, m), and 3.9−4.9 (4H, m) ppm.

endo-*Perhydro-4,7-epoxyisobenzofuranone ((±)-6)*

Using the method of Fetizon and Golfier (12), *cis-endo*-2,3-(bishydroxymethyl)-7-oxabicyclo[2.2.1]heptane (**2**, 1.0 g, 6.3 mmol) was refluxed in the dark for 16 h in benzene (60 mL) containing freshly prepared silver carbonate on Celite (16 g). Filtration followed by rotary evaporation gave the *endo*-lactone (±)-**6** (0.92 g, 91% yield), mp 108−109°C (lit. (11) mp 108−109°C); ir ($CHCl_3$): 1765 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.8 (4H, broad s), 3.1−3.3 (2H, m), 4.0−4.3 (2H, m), and 4.5−4.9 (2H, m) ppm.

Relative rates of HLADH-catalyzed oxidations of diols 1 and 2

The oxidation rates were determined by monitoring the change in the 340-nm absorption of NAD as in the general HLADH kinetic assay method (13). The assays were performed at 25°C at pH 9.0 with the following stock solutions: HLADH, 1 mg mL^{-1} in 0.05 *M* Tris−HCl buffer, pH 7.4; NAD, 10 mg mL^{-1} in 0.1 *M* glycine−NaOH buffer, pH 9.0; diols, 2×10^{-2} *M* solutions in 0.05 *M* glycine−NaOH buffer, pH 9.0. A reference assay was performed under the same conditions with cyclohexanol. The rates observed, relative to cyclohexanol = 1.0, were 0.63 for **1** and 0.21 for **2**.

Preparative-scale HLADH-catalyzed oxidations

(a) *Of the* exo-*diol 1*

The *exo*-diol **1** (2.0 g, 12.7 mmol), NAD (720 mg, 1.1 mmol), and FMN[6] (9.72 g, 20 mmol) were dissolved in 0.1 *M* glycine−NaOH buffer (600 mL, pH 9.0) at room temperature (20°C) and the pH adjusted to 9.0 by the addition of 15% aqueous NaOH. HLADH (50 mg) was then added and the mixture kept at room temperature (20−25°C). The clear, orange solution soon turned black as the reaction proceeded, and the pH was readjusted periodically to 9.0 with 15% aqueous NaOH. The course of the reaction was monitored by glc analysis and, when no more **1** remained (10 days), the mixture was acidified to pH 3 with 5 *N* hydrochloric acid and continuously extracted with $CHCl_3$ for 2 days. The $CHCl_3$ extract was dried ($MgSO_4$), decolourized with Norite, and rotoevaporated to a pale yellow oil (2 g) which was purified by column chromatography on silica gel (60−200 mesh, 50 g) with ethyl acetate elution. (+)-(3a*R*,4*R*,7*S*,7a*R*)-perhydro-4,7-epoxyisobenzofuranone (**5**) was obtained as a white crystalline solid (1.62 g, 83% yield, >98% ee), mp 112°C; $[\alpha]_D^{25}$ +91.9° (*c* 0.1, $CHCl_3$); ir ($CHCl_3$) and ^{1}H nmr ($CDCl_3$) as for (±)-**5** above. *Anal.* calcd. for $C_7H_{10}O_3$: C 62.34, H 6.49; found: C 62.51, H 6.53%.

(b) *Of the* endo-*diol 2*

The *endo*-diol **2** (2.0 g, 12.7 mmol) was oxidized as described above for 12 days. At this time, glc analysis indicated only 16% conversion of **2**. More NAD (720 mg, 1.1 mmol) and HLADH (50 mg) were added and the reaction was continued for a further 14 days, by which time ~50% of **2** had disappeared. The reaction mixture was terminated at this stage and worked up as described above to give (+)-(3a*S*,4*S*,7*R*,7a*R*)-4,7-epoxyisobenzofuranone (**6**, 712 mg, 37% yield, >98% ee); $[\alpha]_D^{25}$ +31.3° (*c* 0.1, MeOH); ir ($CHCl_3$) and ^{1}H nmr ($CDCl_3$) as for (±)-**6** above. *Anal.* calcd. for $C_7H_{10}O_3$: C 62.34, H 6.49; found: C 62.15, H 6.24%.

Enantiomeric excess determinations

The ee's of the (+)-lactones **5** and **6** were determined by reacting 100 mg of each with excess MeLi as described previously (4) and examining the ^{1}H nmr spectra of the *gem*-dimethyl groups of the product diols **7** and **8** respectively in CCl_4 solution in the presence of 0.4 equivalents of Eu(hfc)$_3$. For the racemic references diols (±)-**7** and (±)-**8**, ΔΔδ values of 0.03 and 0.11 ppm respectively were observed. Only one enantiomer was detectable for the (+)-**7** and (+)-**8** diols obtained from the enzyme-derived lactones.[4] The properties of the dimethyl diols **7** and **8** were as follows. *cis-exo*-2-Hydroxymethyl-3-(1′-hydroxy-1′-methyl)ethyl-7-oxabicyclo[2.2.1]heptane ((±)-**7**, 84% yield from (±)-**3**), mp 89−91°C; ir ($CHCl_3$): 3700−3780 cm^{-1}; ^{1}H nmr (CCl_4) δ: 1.3 (6H, *gem*-diMe) ppm; (+)-**7** (82% yield from (+)-**3**), mp 88−89°C; $[\alpha]_D^{25}$ +21.3°C (*c* 0.1, MeOH). *cis-endo*-2-Hydroxymethyl-3-(1′-hydroxy-1′-methyl)ethyl-7-oxabicyclo[2.2.1]-heptane ((±)-**8**, 85% yield from (±)-**4**), mp 76−77°C; ir ($CHCl_3$): 3710−3100 cm^{-1}; ^{1}H nmr (CCl_4) δ: 1.15 (6H, *gem*-diMe) ppm; (+)-**8** (90% yield from (+)-**4**), mp 77−78°C; $[\alpha]_D^{25}$ +12.8°C (*c* 0.1, MeOH).

Absolute configuration determinations

(a) *Of (+)-(3a*R*,4*R*,7*S*,7a*R*)-Perhydro-4,7-epoxyisobenzofuranone ((±)-5)*

Based on the procedure of McOmie *et al.* (15), boron tribromide (0.42 g, 1.7 mmol) was added dropwise with stirring to the *exo*-lactone (+)-**5** (1.54 g, 0.01 mol) in dry CH_2Cl_2 (25 mL) at −78°C and the resulting light brown solution stirred for 1 h. The mixture was then allowed to warm slowly to room temperature during 2 h and was then washed with brine (2 × 25 mL). The brine solution was reextracted with CH_2Cl_2 (2 × 25 mL) and the combined CH_2Cl_2 solutions (75 mL) washed successively with saturated aqueous $NaHCO_3$ (2 × 30 mL), water (25 mL), and brine (2 × 20 mL) and then dried ($MgSO_4$). Rotoevaporation gave 7-bromo-4-hydroxyperhydroisobenzofuranone (**13**, or its 4-bromo-7-hydroxy isomer) as a white solid (842 mg, 75% yield), mp 90−91°C; $[\alpha]_D^{25}$ +31.3° (*c* 0.1, MeOH); ir ($CHCl_3$): 3500, 1760 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.4−2.6 (4H, m), 2.6−3.12 (2H, m), 3.9 (1H, broad s, OH), and 3.4−4.38 (4H, m) ppm.

Using the methodology of Noller and Dinsmore (16), phosphorous tribromide (100 mg, 0.34 mmol) was added dropwise with stirring to the bromohydroxy lactone (+)-**13** (235 mg, 1 mmol) in dry CH_2Cl_2 (10 mL) at −78°C. The mixture was kept at −78°C for 90 min, then allowed to warm slowly to room temperature and stirred for a further 3 h. The mixture was then washed with water (2 × 10 mL), saturated aqueous $NaHCO_3$ (2 × 10 mL), and finally with brine (2 × 10 mL). The dried ($MgSO_4$) CH_2Cl_2 solution was rotoevaporated to give the dibromo lactone **14** as a viscous oil (300 mg, ir (film): 1770 cm^{-1}). This was dissolved immediately in dry benzene (20 mL) and, based on the method of van der Kerk *et al.* (17), freshly prepared (18) tri-n-butyltin hydride (1.4 g, 5 mmol) was added. The mixture was kept at 20°C in the dark for 40 h and then refluxed for 30 min. The mixture was rotovaporated and the residual oil chromatographed on silica gel (75 g, 60−200 mesh, ethyl acetate/hexane (1:1) elution) to give, after Kugelrohr distillation at 120-C (0.3 Torr), (+)-(3a*R*,7a*S*)-perhydroisobenzofuranone (**15**, 63 mg, 50% yield); $[\alpha]_D^{25}$ +43.8° (*c* 0.1, MeOH) (lit. (3*a*) $[\alpha]_D^{25}$ +48.8° (*c* 0.5, $CHCl_3$)).

(b) *Of (+)-(3a*S*,4*S*,7*R*,7a*R*)-perhydro-4,7-epoxyisobenzofuranone ((+)-6)*

Using the same procedures as described above, the *endo*-lactone (+)-**6** (500 mg, 3.3 mmol) was treated with boron tribromide (270 mg, 1.1 mmol) to give a C-4,C-7-mixture of isomers of the

[6]FMN is used to recycle the catalytic amount of NAD used (14).

bromohydroxy lactone **16** (600 mg), mp 69–71°C; ir ($CHCl_3$): 3650, 1765 cm^{-1}, ^1H nmr ($CDCl_3$) δ: 1.0–2.6 (4H, m), 2.6–3.0 (2H, m), and 3.3–4.95 (5H, m, includes OH) ppm. This mixture was converted to the dibromolactone **17** (ir (film): 1760 cm^{-1}) with phosphorus tribromide (230 mg, 0.86 mmol) and the product (500 mg) immediately reduced with tri-n-butyltin hydride (1.95 g, 10 mmol) to give (+)-(3a*R*,7a*S*)-perhydroisobenzofuranone (**15**, 60 mg, 13% overall yield from (+)-**6**), bp 120°C (0.2 Torr); $[\alpha]_D^{25}$ +21.2° (*c* 0.1, MeOH) (lit. (3*a*) $[\alpha]_D^{25}$ +48.8° (*c* 0.5, $CHCl_3$)).

Amino derivatives of anhydrotetracycline

MARY D. MENACHERY AND MICHAEL P. CAVA[1]
Department of Chemistry, University of Pennsylvania, Philadelphia, PA 19104, U.S.A.

Received March 7, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

MARY D. MENACHERY and MICHAEL P. CAVA. Can. J. Chem. **62**, 2583 (1984).

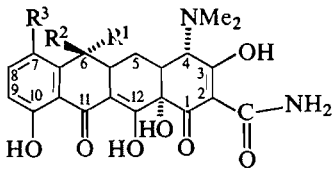
Nitrosation of anhydrotetracycline (**5**) affords 9-nitrosoanhydrotetracycline (**6**), which is converted by sodium dithionite into 9-aminoanhydrotetracycline (**7**). Alkaline coupling of anhydrotetracycline with diazotized sulfanilic acid gives an azo dye which is reduced by sodium dithionite to give 7-aminoanhydrotetracycline (**9**). Reductive methylation of amines **7** and **9** with formaldehyde and sodium cyanoborohydride yields 9-dimethylaminoanhydrotetracycline (**8**) and 7-dimethylaminoanhydrotetracycline (**10**), respectively.

MARY D. MENACHERY et MICHAEL P. CAVA. Can. J. Chem. **62**, 2583 (1984).

La nitrosation de l'anhydrotétracycline (**5**) conduit à la nitroso-9 anhydrotétracycline (**6**) qui, par réaction avec le dithionite de sodium, peut être transformée en amino-9 anhydrotétracycline (**7**). Un couplage en milieu alcalin de l'anhydrotétracycline avec l'acide sulfanilique diazoté conduit à un colorant azo qui, par réduction avec du dithionite de sodium, fournit l'amino-7 anhydrotétracycline (**9**). Des méthylations réductrices des amines **7** et **9**, par réaction avec le formaldéhyde et le cyanoborohydrure de sodium, fournissent respectivement les diméthylamino-9 anhydrotétracycline (**8**) et diméthylamino-7 anhydrotétracycline (**10**).

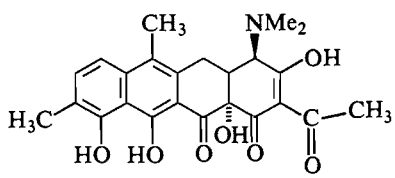
[Traduit par le journal]

Tetracycline (**1**) is one of the most widely used of all antibiotics. Its bacteriostatic properties are usually decreased by structural modification, but this is not always the case. Thus, the mutant-derived analog sancycline (**2**) has activity similar to that of tetracycline; chemical introduction of a 7-dimethylamino group into sancycline yields minocycline (**3**), an expensive but valuable antibiotic which is clinically active against



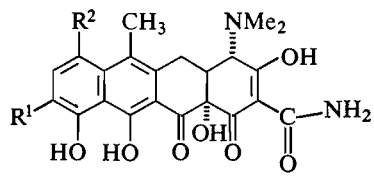
1 R^1 = OH; R^2 = CH_3; R^3 = H
2 R^1, R^2, R^3 = H
3 R^1, R^2 = H; R^3 = NMe_2

a number of tetracycline-resistant organisms. By contrast, anhydrotetracycline (**5**), the acid-catalyzed dehydration product of tetracycline, is clinically useless. Anhydrotetracycline-type structures are not, however, necessarily inactive per se, as shown by the broad-spectrum antibiotic properties of the naturally-produced compound chelocardin (cetotetrin, **4**). In



4

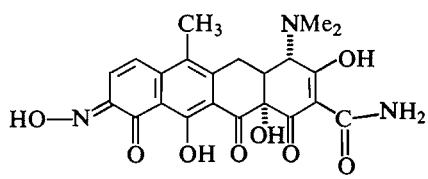
view of the facts outlined above, we felt that it would be of interest to attempt the synthesis of several amino and dimethylamino derivatives of anhydrotetracycline, in the hope that these compounds might show enhanced biological activity over the parent substance. No compounds of this type have been



5 R^1 = R^2 = H
7 R^1 = NH_2; R^2 = H
8 R^1 = NMe_2; R^2 = H
9 R^1 = H; R^2 = NH_2
10 R^1 = H; R^2 = NMe_2

reported previously.[2]

Anhydrotetracycline reacted rapidly with nitrous acid in a cold aqueous solution to give a single nitroso derivative, which was easily isolated in almost quantitative yield as its red-orange hydrochloride. Its nmr spectrum indicated the absence of any appreciable chemical shift difference for the C-6 methyl, indicating that substitution had taken place at C-9 rather than C-7. The absence of a green nitroso chromophore and the observed red end-absorption were consistent with its formulation as the *o*-quinone oxime tautomer **6**, as in the case of 2-nitroso-1-naphthol (2). It may be noted that several tetracyclines have been found previously to undergo degradative nitrosation with the formation of dimethylnitrosamine, but no aromatic nitrosation products were detected (3).



6

The "nitroso" compound **6** was easily reduced by excess sodium dithionite in a dilute alkaline solution. The resulting 9-aminoanhydrotetracycline (**7**) was isolated in good yield by

chloroform extraction at pH 4.5, followed by conversion to the dihydrochloride. The nmr spectrum of this salt showed the aromatic protons as an AB system (J = 9 Hz) centered at δ 7.89 and 7.63, attributable to the C-7 *peri* proton and the C-8 proton deshielded by a protonated amino group. Reductive alkylation of **7** by aqueous formaldehyde and sodium cyanoborohydride afforded 9-dimethylaminoanhydrotetracycline (**8**), isolated as the dihydrochloride.

In contrast to nitrosation, diazonium coupling of anhydrotetracycline led to substitution at C-7. Thus, coupling of anhydrotetracycline with diazotized anthranilic acid in an alkaline solution, followed by sodium dithionite reduction of the resulting dye, afforded 7-aminoanhydrotetracycline (**9**), isolated in good (57%) overall yield as its dihydrochloride. The nmr spectrum of this salt was in accord with the assigned structure. Thus, the C-9 proton of the aromatic AB system appeared at δ 6.88, due to the absence of a strongly deshielding *ortho* substituent. In addition, the C-6 methyl protons were deshielded by the adjacent protonated amino group of the extent of 0.17 ppm as compared to the 9-substituted isomer. Reductive methylation of **9** was carried out as described for the 9-isomer to give, in low yield, 7-dimethylaminoanhydrotetracycline (**10**).

The nmr spectra of all compounds studied showed only one peak for the 4-dimethylamino group at around δ 3, indicating no appreciable contamination by 4-*epi* isomers.

The new anhydrotetracycline derivatives were much less active than tetracycline, and showed no useful activity against a number of gram-negative bacteria which were either tetracycline-susceptible or tetracycline-resistant. Minimum inhibitory concentrations (MIC, 18 h, 35°C, mcg/mL) of ≧128 were observed for all five compounds against strains *Escherichia coli*, *Klebsiella pneumoniae*, *Enterobacter aerogenes*, *E. cloacae*, *Serratia marcescens*, *Proteus morganii*, *P. rettgeri*, *Salmonella sp.*, *Acinetobacter calcoaceticus*, and *Pseudomonas aeruginosa*. The 9-amino derivative (**7**) was the only member of the series to show significant activity among a few gram-positive strains tested. It gave m.i.c. values of ≦0.06 and 8 for *Staphyloccuus aureus* (Smith) and *Micrococcus lutea*, respectively; the tetracycline values against the same organisms were 0.06 and 0.25, respectively.

Experimental

The nmr spectra were obtained on a Bruker 250 nmr spectrometer with tetramethylsilane as internal standard. Ultraviolet spectra were determined using a Perkin Elmer 202 spectrometer. Analyses were carried out at Galbraith Labs, Knoxville, Tennessee.

9-Nitrosoanhydrotetracycline (6)

To a solution of anhydrotetracycline hydrochloride (2.15 g, 4.65 mmol), in distilled water (70 mL) at 0°C, was added a solution of $NaNO_2$ (0.38 g, 5.62 mmol) in a few mL of water. Concentrated HCl was added to lower the pH to 1. The precipitated red-orange nitroso salt was filtered and further purified by dissolving in methanol and precipitating with ether to give the hydrochloride of **6** (2.25 g, 98%); uv (MeOH): 225 (log ε 4.46), 242 sh (4.53), 258 (4.64), 275 (4.63), 292 sh (4.28), 298 sh (4.17), 322 (4.00), 341 (3.91), and 445 nm (4.14); nmr (CD_3OD) δ: 7.00, 6.94 (d, 1H each, J = 10 Hz), 4.22 (s, 1H, C_4-H), 3.22 (s, 6H, NMe_2), 2.34 (s, 3H, C6Me). *Anal.* calcd. for $C_{22}H_{27}N_3O_8Cl.2H_2O$: C 50.03, H 5.15, N 7.96, Cl 6.71; found: C 49.59, H 5.10, N 7.89, Cl 6.57.

9-Aminoanhydrotetracycline (1)

Excess $Na_2S_2O_4$ was added to a solution of 9-nitrosoanhydrotetracycline hydrochloride (1.82 g, 3.70 mmol) in 0.1 *N* aqueous NaOH (150 mL). The 9-amino compound was extracted into chloroform at pH 4.5. The red-orange solution was washed with a little distilled water and the chloroform layer was then acidified with concentrated HCl to give the dihydrochloride on evaporation to dryness (1.61 g, 84%); uv (MeOH): 226 (log ε 4.37), 244 sh (4.42), 274 4.62), 305 sh (4.22), 315 sh (4.13), 327 sh (4.00), 4.18 (3.70), 474 sh (3.40), and 494 nm sh (3.31); nmr (CD_3OD) δ: 7.89, 7.63 (d, 1H each, J = 9 Hz), 4.36 (s, 1H, C4-H), 3.13 (s, 6H, NMe_2), 2.46 (s, 3H, C6Me). *Anal.* calcd. for $C_{22}H_{25}N_3O_7Cl_2.3H_2O$: C 46.47, H 5.49, N 7.39, Cl 12.4; found: C 46.32, H 5.46, N 7.17, Cl 11.78.

9-Dimethylaminoanhydrotetracycline (8)

9-Aminoanhydrotetracycline dihydrochloride (0.038 g, 0.07 mmol) was dissolved in 3 mL of water, and to this solution was added one drop of aqueous HCHO followed by excess $NaBH_3CN$. The 9-dimethylamino derivative was extracted into $CHCl_3$ at pH 6.0, the solution washed with a little distilled water, and the chloroform layer acidified with concentrated HCl and evaporated to dryness, giving the dihydrochloride of **8** (0.017 g, 42%); uv (MeOH): 244 (log ε 4.38), 278 (4.68), 320 sh (3.74), and 408 nm (3.77); nmr (CD_3OD) δ: 8.01, 7.44 (d, 1H each, J = 9 Hz), 4.32 (s, 1H, C4-H), 3.37 (s, 6H, C9-NMe_2), 3.09 (s, 6H, C4-NMe_2), 2.51 (s, 3H, C6-Me). High resolution mass spectrum (Cl) calcd. for $C_{24}H_{27}N_3O_7$: 469.1839; found: 469.1853.

7-Aminoanhydrotetracycline (9)

To a solution of sulfanilic acid (0.347 g, 2.00 mmol) and sodium carbonate (0.08 g, 0.75 mmol), in a few mL of cold distilled water, $NaNO_2$ (0.107 g, 1.55 mmol) was added. To about 10 g of ice, 0.3 mL of concentrated HCl was added, followed by the sodium sulfanilate solution. The anhydrotetracycline hydrochloride (0.462 g, 1 mmol) was dissolved in 40 mL of 0.1 *N* NaOH and the cooled solution was added to the cold diazonium compound solution. After stirring for 15 min, excess $Na_2S_2O_4$ was added to reduce the azo dye and the 7-amino derivative was extracted into chloroform, as in the case of 9-amino derivative, at pH 4.7 and converted into the dihydrochloride (0.29 g, 57%); mp 220−223°C (dec); uv (MeOH): 230 sh (og ε 4.44), 268 (4.88), 340 sh (3.53), and 408 nm (3.89); nmr (CD_3OD) δ: 7.75, 6.88 (d, 1H each, J = 8 Hz), 4.32 (s, 1H, C4-H), 3.18 (s, 6H, NMe_2), 2.63 (s, 3H, C6-H_3). *Anal.* calcd. for $C_{22}H_{25}N_3O_7Cl_2.H_2O$: C 49.61, H 5.11, N 7.89, Cl 13.3; found: C 49.49, H 5.89, N 7.44, Cl 13.68. High resolution mass spectrum (Cl). calcd. for $C_{22}H_{23}N_3O_7$: 441.1527; found: 441.1535.

7-Dimethylaminoanhydrotetracycline (10)

To 7-aminoanhydrotetracycline dihydrochloride (0.065 g, 0.126 mmol) in 3 mL distilled water, excess formaldehyde was added and the solution was stirred for 2 min. Excess sodium cyanoborohydride was then added and the solution was stirred for 30 min. The 9-dimethylamino derivative was extracted into chloroform at pH 4.7−5.0 (0.008 g, 12%); uv (MeOH): 230 sh (log ε 4.38), 270 (4.81), 329 (3.55), and 410 nm (3.43). High resolution mass spectrum (Cl) calcd. for $C_{24}H_{27}N_3O_7$: 469.1839; found: 469.1880.

Chromatographic characterization

The new aminoanhydrotetracycline hydrochlorides were characterized by chromatography on Analtech Micropolyamide plates (ML = 1515) using acetonitrile−water (45:55) as developer. The R_f values were as follows: 0.65 (**1**), 0.53 (**8**), 0.50 (**9**), and 0.79 (**10**).

Acknowledegments

Partial support of this work by NIH grant AI 14717 is gratefully acknowledged. We also thank Dr. R. Wilkinson, Lederle Laboratories, for the antibacterial assay results.

Adriamycin analogues. Synthesis of the α and β anomers of 7-*O*-(3-amino-3,5-dideoxy-D-ribofuranosyl)adriamycinone and some related compounds[1]

NARENDRA KUMAR AND MERVYN ISRAEL[2]

Department of Pharmacology, University of Tennessee Center for the Health Sciences, Memphis, TN 38163, U.S.A.

Received March 26, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

NARENDRA KUMAR and MERVYN ISRAEL. Can. J. Chem. **62**, 2585 (1984).

2-*O*-Acetyl-3,5-dideoxy-3-trifluoracetamido-D-ribofuranosyl bromide, prepared by an improved 10-step synthesis from 1,2-isopropylidene-D-xylofuranose, was coupled under Koenigs–Knorr glycosidation conditions with a side-chain protected aglycone derivative of the antitumor antibiotic adriamycin. Complete removal of the blocking groups from the anomeric coupling products afforded glycoside ring-contracted analogs of adriamycin. Selective removal of blocking groups resulted in analogs of *N*-trifluoroacetyladriamycin-14-valerate (AD 32), an non-DNA binding analog of adriamycin with clinical activity and reduced toxicity. Anomeric assignment of coupling products was derived from nmr spectral data consistent with Karplus equation considerations. In vitro growth-inhibition and DNA binding assays were performed with a number of the target compounds. Of interest is the observation that, although binding to calf thymus DNA to a lesser extent than adriamycin, the isosteric 7-*O*-(3-amino-3,5-dideoxy-β-D-ribofuranosyl)adriamycinone produced a greater inhibition of growth of CCRF–CEM human-derived lymphoblastic leukemic cells in culture.

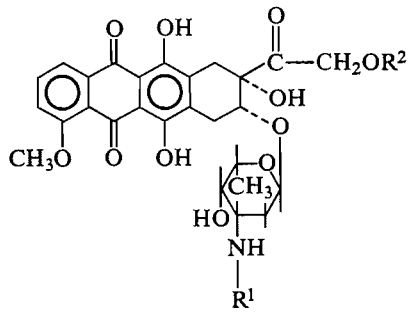
NARENDRA KUMAR et MERVYN ISRAEL. Can. J. Chem. **62**, 2585 (1984).

Le 2-*O*-acetyl-3,5-trifluoroacetamido-D-ribofuranosyl de bromure, preparé de 1,2-isopropylidene-D-xylofuranose en 10 étapes, était attaché, sous les conditions de la glycosidation de Koenings–Knorr, à la chaîne de côté protégée d'une aglycone dérivée de l'antitumeur antibiotique adriamycine. L'enlèvement complet des groupes de stoppage des produits anomériques fournit des analogues d'adriamycine dont l'anneau de la glycoside est réduit. Le déplacement sélective d'un groupe de stoppage produit l'analogues *N*-trifluoroacetyladriamycine-14-valerate (AD 32), même qui se ne réagit pas avec les ADN, manifeste une activité supérieure en clinique, et en même temps moins toxique. L'anomérique assignée de ces produits qui était dérivée de data de spectre de rmn est compatible aux considérations de l'équation de Karplus. L'inhibition de croissance de la culture, in vitro, et l'essai de l'attachement à ADN, étaient exécutés avec plusieurs produits d'objectif; et c'était intéressant d'observer que malgré l'attachement aux ADN de thymus de veau est moins que cel d'adriamycine, il inhibe considérablement la croissance des cellules lymphoblastiques leucémiques (CCRF–CEM) d'origine humaine en culture.

For some time, these laboratories have been engaged in a broad program of anthracycline pharmacology, including new drug development. The anthracyclines are a diverse family of antibiotic substances containing hydroxylated anthraquinone chromophores connected to one or more glycosidic units. Adriamycin (doxorubicin, **1**), the prototypical anthracycline antitumor agent, continues to be of major importance in cancer medicine because of its broad spectrum of activity against leukemias, lymphomas, and a range of solid tumors, including soft-tissue sarcomas, otherwise refractory towards chemotherapeutic intervention (1). Dose-limiting toxicities (acute myelosuppression and chronic accumulated dose-related cardiomyopathy), however, complicate its use, and the desire for reduced toxicity and enhanced activity, particularly against advanced carcinomatous disease, has led to a variety of efforts to develop analogs with improved therapeutic properties.

Mechanistically, based upon early evidence, adriamycin has generally been considered to exert its antitumor effects through DNA binding, with resultant steric interference of DNA polymerase action (2). Thus, with respect to the synthesis of analogs, many investigators have adhered closely to this mechanistic hypothesis and the published restriction that the glycosidic amino group must be unsubstituted in order for DNA binding and antitumor effects to be expressed. At the outset of our program, we were not entirely convinced of these arguments, and so, in addition, sought to explore structure–activity relationships among semisynthetic analogs with reduced or absent DNA binding capability. This approach has led to the development of *N*-trifluoroacetyladriamycin-14-valerate (AD 32, **2**), a non-DNA binding analog with experimentally superior in vivo antitumor activity and significantly reduced toxicity compared to **1** (3–8). Compound **2** continues in Phase II clinical trial, with documented activity against a number of different human tumor types (9, 10). Recently, we described the synthesis and biological evaluation of *N*-trifluoroacetyladriamycin-14-*O*-hemiadipate (**3**), a second-generation analog of **2** with improved water solubility (11, 12); this agent is currently in late preclinical development.

The profound biological effects exhibited by **2** and **3**, to-



1 $R^1 = R^2 = H$ (adriamycin)
2 $R^1 = COCF_3$, $R^2 = CO(CH_2)_3CH_3$
3 $R^1 = COCF_3$, $R^2 = CO(CH_2)_4COOH$
4 $R^1 = COCF_3$, $R^2 = H$

gether with other evidence, have done much to alter the overly simplistic DNA-binding hypothesis for **1** and related compounds, and has encouraged us to explore other more diverse structural variants in the search for novel analogs. Since the activity of the system appears to be inherent in the chromophore, with the natural daunosamine sugar possibly serving as a carrier, we have also been examining various analogs of **1** containing fraudulent glycosidic units, which agents have been shown to exhibit significant in vivo antitumor activity in murine tumor systems despite greatly altered DNA binding capability (13, 14).

We now wish to report on the synthesis and in vitro biological evaluation of the anomeric 7-*O*-(3-amino-3,5-dideoxy-D-ribofuranosyl)adriamycinones, **29** and **30**, and their trifluoroacetamides, **25** and **26**, compounds which may be viewed as glycoside ring-contracted isosteres of **1** and **4**, respectively. Compound **4** (*N*-trifluoroacetyladriamycin) is the initially-formed metabolite of **2** and **3**, and has been shown to be biologically active in its own right.

Chemistry

The synthesis of the target compounds was accomplished utilizing the following stepwise approach: (*a*) preparation of an appropriately protected bromosugar; (*b*) preparation of a side-chain protected adriamycin aglycone; (*c*) coupling of the aglycone and bromosugar under Koenings–Knorr conditions; (*d*) separation of the anomeric coupling products; and (*e*) selective removal of protecting groups, in each instance, to give the trifluoroacetamide and the fully-deblocked anomeric product.

The requisite bromosugar, 2-*O*-acetyl-3,5-dideoxy-3-trifluoroacetamido-D-ribofuranosyl bromide (**17**), was prepared in 10 steps from commercially available 1,2-*O*-isopropylidene-D-xylofuranose (**5**), as shown in Scheme 1. This sequence is similar to the route previously developed by us (14), but with a number of significant improvements. Deoxygenation at C-5 via tosylation, followed by iodide displacement and reductive deiodination, was adapted from a procedure used by Almquist and Vince (15). Previously, the iodination step was accomplished under pressure in a sealed Pyrex pressure bottle. However, in attempts to prepare larger amounts of the 5-deoxyxylofuranoside **8** for our current and future needs, we found this pressure reaction to be both arduous and hazardous.[3] The use of elevated temperature instead of pressure for the conversion of **6** into **7** proved highly successful, with a quantitative yield of product being formed when the reaction was carried out at 100°C in HMPA (the reaction did not go when attempted in hot DMF). The iodide was then reduced to **8** in the same flask by means of sodium cyanoborohydride.

Similarly, the use of the earlier described (15) DMSO-based oxidizing system for the conversion of **8** into **9**, in connection with placing an amino function in the *ribo* configuration at C-3, proved inadequate for larger scale reactions because of a complex work-up and the formation of accompanying thioethers, which made isolation of **9** difficult and resulted in poor yields. As an alternative for situating the riboamino function at C-3, we considered the preparation of an azide precursor, which had the attraction of allowing, after coupling, for a novel anthracycline azide derivative for evaluation as a new analog type, as well as providing for an intact glycoside precursor for reduction to the corresponding amine.

Although reports exist of failure in displacing the 3-xylotosyloxy function by azide (16), the possibility of displacing a triflyl group appeared worth attempting in view of the greater leaving character of this function. Unfortunately, only very poor yields of the 3-azidoribofuranose were produced when the 3-triflyl ester of **8** was treated with excess lithium azide in DMF at 100°C. Instability of **8** triflyl ester precluded the possibility of success at higher temperature; attempts led to extensive decomposition and a complex mixture of products, of which the elimination product was most prominent. Attention was then redirected to improving the oxidation of the C-3 hydroxyl. This was successfully accomplished by an adaptation of a procedure described by Lawton *et al.* (17), involving as oxidant ruthenium tetraoxide derived from catalytic amounts of ruthenium dioxide. Ketone **9**, obtained in excellent yields by this

method, was then converted into the 3-riboamine **11** in quantitative yield by LAH reduction of the corresponding oxime **10**. The amino group of **11** was trifluoroacetylated, and the acetonide group removed by treatment with ion-exchange resin, to give a mixture of the anomeric diols **13** and **14**, which were not separable by tlc. Following acetylation, the anomeric diacetates **15**(α) and **16**(β) could be separated by preparative hplc. Anomeric bromination of **15** and **16** separately, or of the mixture **15/16**, was accomplished by means of the TMS bromide procedure developed earlier in these laboratories (18); this conversion was done just prior to use, because of the instability of **17** on storage.

Adriamycinone, the aglycone of **1**, is easily obtained from the parent antibiotic by mild acid hydrolysis. Protection of the C-14 primary alcohol function prior to coupling was essential, both to eliminate this function as an alternate site for glycosidation and to preserve the base-labile but biologically important dihydroxyacetone side-chain during subsequent operations to remove glycosidic protecting groups after coupling. For this purpose, the *p*-anisyldiphenylmethyl ether (19, 20) was preferred over the dioxolane (13) or other acid-sensitive side-chain protecting groups (21), based upon (*a*) the ease of its formation in high purity without recourse to chromatography, (*b*) its lipophilic character, imparting to the molecule the desired solubility in organic solvents for extraction from aqueous media, (*c*) its inability to produce overlapping proton signals in the diagnostically crucial region in the nmr spectrum of the coupled products, and (*d*) the ease of removal under mild acidic conditions. In contrast to the *p*-anisyldiphenylmethyl function, the otherwise unsubstituted trityl function was found to be less desirable as a protecting function because it required, for removal, acidic conditions drastic enough to produce a significant degree of hydrolytic cleavage of the glycoside.

The coupling of the bromosugar **17** onto the C-7 hydroxyl of the protected adriamycinone **18** was accomplished under Koenigs–Knorr conditions in dry methylene dichloride (Scheme 2). The progress of the reaction was monitored by a combination of tlc and analytical hplc. Maximum conversion of **18** into the product mixture **19/20** was conveniently determined by injecting aliquots withdrawn from the reaction mixture from time to time onto the hplc column and measuring the quantitative ratios of the integrated peak areas of starting material and products on the recorder trace of the detector response. Best results were obtained when a ratio of 2:1 of **17** to **18** was employed. The anomeric products, **19**(β) and **20**(α), were formed in a ratio of 2:3, a relationship which varied only slightly from the results obtained in different small-scale practice runs. Separation of the anomeric coupling products and removal, in each instance, of the *p*-anisyldiphenylmethyl protecting group produced the doubly-blocked ribofuranosyl adriamycinones **21**(β) and **22**(α). When the acidic removal of the *p*-anisyldiphenylmethyl group was effected after removal of the sugar *O*-acetyl function, the desired ribofuranoside analogs of **4** (**25** and **26**) were obtained. Removal of *p*-anisyldiphenylmethyl groups after sequential hydrolysis of both the *O*- and *N*-acyl blocking groups afforded the glycoside ring-contracted adriamycin analogs **29** and **30**. Samples of **25** and **26** made by trifluoroacetylation of **29** and **30** were identical to those derived, as shown, from **23** and **24**, respectively.

The appearance of the C-1′ proton in the nmr spectra (Table 1) of the coupled products **19** and **20** as a singlet in one instance, and a doublet (J = 4 Hz) in the other, provided

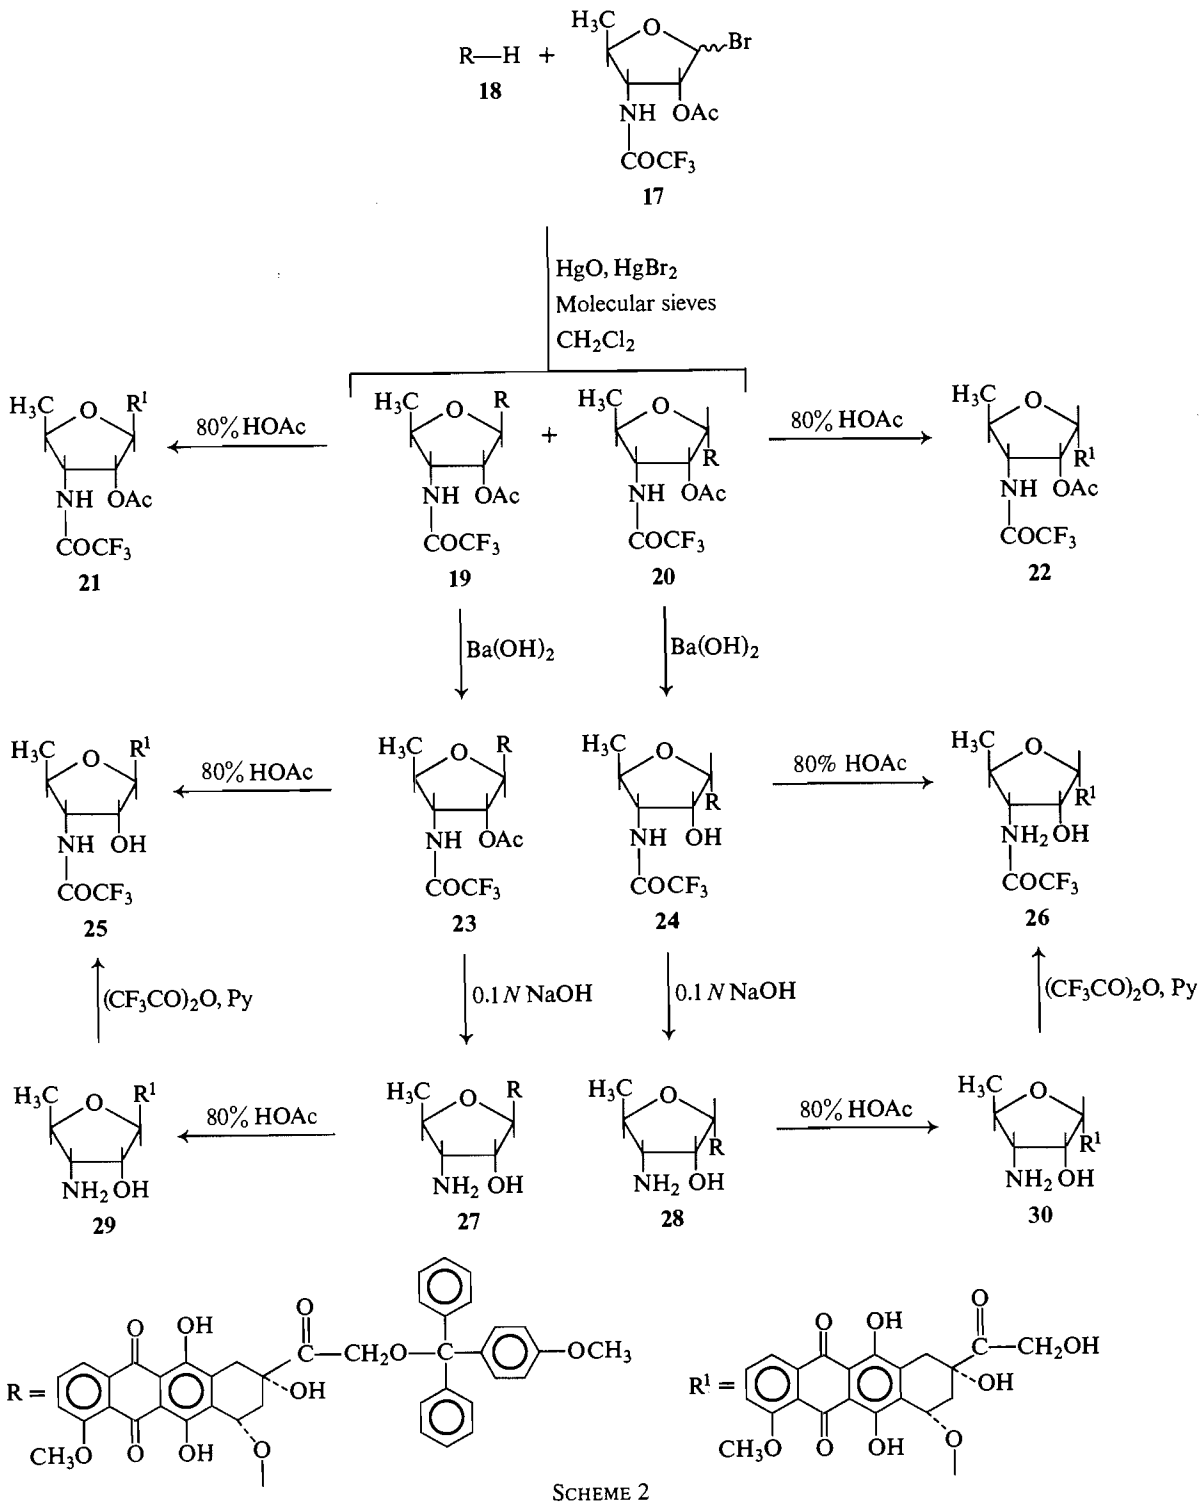

SCHEME 2

evidence for the β- and α-anomeric stereochemical assignments, as depicted in Scheme 2. The assignments are in agreement with the Karplus calculations (22), which require that the observed coupling constants involving H-1′ and H-2′ ($J_{1',2'}$) be in the range of 3.5−8.0 Hz for the α-glycoside and 0.0−8.0 Hz for the β anomer. Dreiding models for **20** showed a dihedral angle for H-1′—H-2′ of about 30°, whereas for **19** the value was closer to 90°. The stereochemical assignments were also consistent with the doublet and double−doublet nature of the H-2′ proton of the anomeric glycosides, and with the relative chemical shifts of the proton under the glycosidic bond (H-7), as described in Table 1 (21). Removal of the protecting groups in the side-chain and in the sugar produced expected proton shifts in the nmr spectra of the deprotected products.

Biological evaluation

Compounds **21**, **22**, **25**, **26**, **29**, and **30** were evaluated in vitro for growth-inhibitory activity against human leukemic cells. Compounds **29** and **30**, which possess an unaltered adriamycin aglycone and an unsubstituted aminoglycoside, were additionally assayed for their DNA binding capability. The results of these assays are summarized in Table 2, which also

TABLE 2. In vitro properties of some ribofuranosyladriamycinones

Compound	ID_{50},[a] μM	Extent of DNA binding: A/A_0[b] (λ 480 nm)
Adriamycin (**1**)	0.05	0.62
AD 32 (**2**)	0.23	0.98
21 (β)	1.0	
22 (α)	>1.0	
25 (β)	0.28	
26 (α)	>1.0	
29 (β)	0.04	0.70
30 (α)	>1.0	0.76

[a]Versus CCRF–CEM cells in culture; 48-h continuous drug exposure.

includes corresponding values for key reference compounds.

The growth-inhibition assay (23, 24) utilized CCRF–CEM cells, a lymphoblastic leukemic cell line of human origin, maintained as suspension cultures. The ID_{50} value represents the concentration of drug which results in a 50% inhibition of growth of treated (48 h) cultures, compared to untreated controls. Adriamycin (**1**) is highly growth inhibitory in this system, the ID_{50} generally being in the range of 0.05–0.06 μM. In an internally consistent test system, **29**, which is isosteric with **1**, actually proved to be more growth inhibitory. Just as **1** shows anomeric specificity in its biological action, the α anomer **30** shows greatly reduced activity compared to the β anomer. A similar structure–activity relationship as exists between **1** and **2**, or **4** (ID_{50} 0.23 μM), is seen for **29** and its trifluoroacetamide **25**; again, activity is greater in the β-anomeric configuration than in the α configuration. The sugar-diprotected analogs (*O*-acetoxy-*N*-trifluoroacetamido) **21** and **22** were inactive, regardless of anomeric configuration.

The extent of DNA binding of **29** and **30** was determined by a spectral method (25). This procedure measures the ratio of the absorbances of drug–DNA mixtures, under defined conditions, to drug alone at 480 nm. By this technique, A/A_0 values close to unity represent little or no drug–DNA interaction, while values significantly less than 1.0 represent extensive interaction. A/A_0 values in our laboratories for adriamycin in the range 0.60–0.65 are in close agreement with other published data (26); values for AD 32 (**2**) indicate essentially no drug–DNA interaction. Both **29** and **30** by this procedure show significant DNA binding, but not nearly to the extent of adriamycin. More DNA interaction is shown by **29** and **30** than by the corresponding (14) ribofuranosyldaunomycinones (9-methylketone side-chain in place of the adriamycin 9-hydroxymethylketone), thus providing further support for the importance of the C-14 hydroxyl function of **1** as an additional site for hydrogen bonding. Somewhat greater DNA interaction is exhibited by the β anomer **29** (anomerically equivalent to **1**) than by the α anomer, in which the amino function is somewhat buried beneath the chromophore.

Interestingly, **29**, which is isosteric with **1** and is more growth inhibitory than **1** in the CEM assay, does not interact with DNA to as great an extent as **1**. Compound **30**, on the other hand, interacts to a reasonable extent with DNA, but is not active in the growth-inhibition assay. These findings continue to support our general considerations that cytotoxicity and antitumor effects among anthracyclines may have much less to do with direct DNA binding than has generally been regarded. We hope that other adriamycin analogs under development in our laboratories, including those with more drastically altered glycosidic functions, will help to further probe these structure–activity relationships.

Experimental

Melting points were recorded on a Kofler hot stage with microscope and are uncorrected. The ir spectra were determined as KBr disks on Perkin–Elmer Model 137B and Model 1320 spectrophotometers. The uv spectra were recorded on a Perkin–Elmer Model Lambda 3 system linked with their Model 3600 Data Station. Proton nmr spectra were recorded on a Varian Associates Model T60-A system spectrometer, with tetramethylsilane as internal standard, and are expressed as δ values. Elemental analyses were performed by Galbraith Laboratories, Inc., Knoxville, TN. Thin-layer chromatography (tlc) was done using analytical silica gel G glass-backed plates (Analtech), with chloroform–methanol (9:1 by volume, System A), chloroform–methanol (19:1, System B), or chloroform–methanol–water (120:20:1, System C) as irrigant. Analytical hplc determinations utilized a Waters Associates Model 202 chromatograph, with a U6K universal loop injector and dual Model M6000-A solvent delivery pumps controlled by a Model 660 Programmer. The column material was μ-Bondapak/phenyl, operating in reverse phase, with linear gradient elution (32% to 65% acetonitrile in ammonium formate buffer, pH 4.0, at 3.5 mL/min over 6 min). Signals were monitored by means of flow fluorescence detection (Schoeffel Model FS970 fluorescence detector, excitation wavelength 484 nm, emission cut-off at 580 nm). Preparative separations were done by gravity-flow column chromatography on silicic acid (Bio-Sil A, Bio-Rad), by preparative tlc using silica gel G Uniplates (Analtech) and by hplc, using a preparative (1-in. od × 1 ft) column packed with silica gel mounted in the above Waters Associates instrument and operating in normal phase, with signal detection by uv and refractive index. Moisture or oxygen-sensitive reactions were carried out in flame-dried glassware in a nitrogen atmosphere.

1,2-O-Isopropylidene-5-deoxy-D-xylofuranose (8)

1,2-*O*-Isopropylidene-5-xylofuranose (**5**), purchased from Pfanstiehl, was converted into 1,2-*O*-isopropylidene-5-tosyloxy-α-D-xylofuranose (**6**), as previously described (15). Reaction of **6** (5 g), dissolved in HMPA (150 mL), with NaI (10 g) at 100°C for 12 h, with stirring, afforded **7** *in situ*. To the flask was added $Na(CN)BH_3$ (7.5 g) and heating was continued for an additional 15 h. The mixture was cooled, diluted with H_2O, and extracted with ether. The ether extract was washed with H_2O, dried, and evaporated *in vacuo* to give a syrup, which was crystallized from $CHCl_3$ – petroleum ether to give **8** (3 g, 60% yield), identical to previously obtained samples (14, 15).

1,2-O-Isopropylidene-5-deoxy-α-D-erythropentofuran-3-ulose (9)

Compound **8** (3 g) was dissolved in alcohol-free CH_2Cl_2 (40 mL), and to this solution was added 30 mL of H_2O. Powdered KIO_4 (5 g), K_2CO_3 (0.5 g), and RuO_2 (Engelhardt Industries; 0.1 g)[4] were added simultaneously and the mixture was stirred vigorously for 2 h. At that time, additional quantities of KIO_4 (0.15 g), K_2CO_3 (0.22 g), and RuO_2 (0.05 g) were added and vigorous stirring was continued for another hour or until tlc no longer showed the presence of starting material. Residual RuO_4 was destroyed by isopropyl alcohol (5 mL) and the mixture filtered. The filtrate was evaporated under reduced pressure and the residue taken into $CHCl_3$. The $CHCl_3$ solution was washed with H_2O, dried, and the solvent removed to give **9** as a syrup (2.7 g, 90%). The spectral properties of this material were identical with those previously reported (15) for **9**.

[4]Best yields were obtained with ruthenium dioxide supplied by Engelhardt Industries; use of material from other supplies gave unsatisfactory results.

2-O-Acetyl-3,5-dideoxy-3-trifluoroacetamido-α- and β-D-ribofuranosyl bromide 17

Ketone **9** (5 g) was converted into 3-amino-3,5-dideoxy-1,2-*O*-isopropylidene-α-D-ribofuranose (**11**) in 2 steps (3.75 g, 75%), according to the procedure of Almquist and Vince (15). Bromosugar **17** was obtained from **11** in 4 steps, as previously described (14).

7-O-(2-Acetoxy-3,5-dideoxy-3-trifluoroacetamido-α- and β-D-ribofuranosyl)-14-O-p-anisyldiphenylmethyladriamycinones (19 and 20)

14-*O*-*p*-Anisyldiphenylmethyladriamycinone (**18**) was prepared according to the published procedure (19); mp 192°C; tlc (system B) R_f 0.78. To a solution of **18** (500 mg) dissolved in dry and alcohol-free CH_2Cl_2 (70 mL) was added finely-ground preignited type 3A molecular sieves (3.0 g), moisture-free yellow HgO (0.75 g), and $HgBr_2$ (0.25 g). Freshly prepared bromosugar (900 mg) was dissolved in dry CH_2Cl_2 (10 mL). Half of this solution was added, dropwise in a N_2 atmosphere, to the solution of **18**. After stirring for 30 min, another batch of molecular sieves (1.0 g), yellow HgO (0.25 g), and $HgBr_2$ (0.015 g) was added, followed by the dropwise addition of the remainder of the bromosugar solution. The mixture was stirred at room temperature for an additional 0.5 h, at which time no further conversion of **18** into **19**/**20** could be detected (hplc). The mixture was filtered and the solvent removed under reduced pressure to give a red residue, which was dissolved in CH_2Cl_2 (10 mL). Addition of petroleum ether (70 mL) precipitated an orange solid, which was collected and dried under vacuum. This crude product showed 3 major red spots on tlc (System B), R_f 0.8, 0.78, and 0.64; hplc analysis showed 2 peaks, corresponding to **19** and **20** in a ratio of 3:2, and a third small signal corresponding to unchanged **18**. Chromatography on silica gel afforded 350 mg of **19**, 210 mg of **20**, and 30 mg of starting material.

Compound **19**: mp 133–34°C; tlc (System B) R_f 0.80; hplc, retention time (RT) 12.89 min; ir (KBr): 3450 (br), 1740, 1730, 1720, 1620, 1580, 1510, and 1225 cm^{-1}; nmr given in Table 1. *Anal.* calcd. for $C_{50}H_{44}F_3NO_{14}$: C 63.90, H 4.68, F 6.07, N 1.49; found: C 63.56, H 5.13, F 5.60, N 1.29.

Compound **20**: mp 145°C; tlc (System B) R_f 0.64; hplc, RT 12.17 min; ir (KBr): 3460, 1750, 1730, 1615, 1515, and 1230 cm^{-1}; nmr Table 1. *Anal.* calcd. for $C_{50}H_{44}F_3NO_{14}\cdot 2H_2O$: C 61.50, H 4.71, F 5.84, N 1.43; found: C 61.83, H 4.92, F 6.16, N 1.42.

Final elution of the column with $CHCl_3$–CH_3OH (9:1) gave a mixture of products (**21**/**22**) which were separated by preparative tlc (System B); R_f 0.46 and 0.36. These materials, which arose as a result of loss of the *p*-anisyldiphenylmethyl group during chromatography, were identical with samples of **21** and **22** obtained by hydrolysis of **19** and **20** respectively, as described below.

7-O-(2-Acetoxy-3,5-dideoxy-3-trifluoroacetamido-β-D-ribofuranosyl)-adriamycinone (21)

Compound **19** (50 mg) was dissolved with stirring in 80% HOAc (5 mL) at 0°C, and the solution was let stand overnight in the refrigerator. Lyophilization, followed by crystallization of the residue from $CHCl_3$ – petroleum ether, afforded **21** as a red powder (30 mg), mp 138–139°C; tlc (System B) R_f 0.46; hplc, RT 6.10 min; ir (KBr): 3500, 1725 (br), 1620, 1580, and 1230 cm^{-1}; nmr Table 1. *Anal.* calcd. for $C_{30}H_{28}F_3NO_{13}\cdot H_2O$: C 52.55, H 4.37, F 8.31, N 2.04; found: C 52.96, H 4.39, F 7.77, N 2.03.

7-O-(2-Acetoxy-3,5-dideoxy-3-trifluoroacetamido-α-D-ribofuranosyl)-adriamycinone (21)

The hydrolysis procedure was identical to that described for the preparation of **21** from **19**. Hydrolysis of **20** (10 mg) gave 28 mg of **22**, mp 146°C after crystallization from $CHCl_3$ – petroleum ether; tlc (System B) R_f 0.36; hplc, RT 6.23 min; ir (KBr): 3500, 1730 (br), 1625, and 1590 cm^{-1}; nmr Table 1. *Anal.* calcd. for $C_{30}H_{28}F_3NO_{13}\cdot 2H_2O$: C 51.10, H 4.55, F 8.10, N 1.99; found: C 50.61, H 4.20, F 8.65, N 2.11.

7-O-(3,5-Dideoxy-3-trifluoroacetamido-β-D-ribofuranosyl)-14-O-p-anisyldiphenylmethyladriamycinone (23)

A solution of **19** (0.63 g) in 30 mL of acetone was cooled in an ice bath and to it was added dropwise an ice-cold solution of $Ba(OH)_2$ $8H_2O$ in CH_3OH (6 mL of a 10 g/100 mL solution). The resulting violet solution was stirred at 0°C for 1–5 h, then treated with dry CO_2 until the red color returned, and extracted with $CHCl_3$. The $CHCl_3$ layer was washed with H_2O, dried, and the solvent removed. The product was purified by preparative tlc to give **23**, which gave, from $CHCl_3$ – petroleum ether, an orange-red amorphous powder (0.36 g); mp 156–157°C; tlc (System B) R_f 0.70; hplc, RT 0.61 min; ir (KBr): 3450, 1728, 1720, 1615, and 1580 cm^{-1}; nmr Table 1. *Anal.* calcd. for $C_{48}H_{42}F_3NO_{13}\cdot H_2O$: C 62.95, H 4.80, F 6.35, N 1.53; found: C 62.94, H 5.01, F 6.42, N 1.53.

7-O-(3,5-Dideoxy-3-trifluoroacetamido-α-D-ribofuranosyl)-14-O-p-anisyldiphenylmethyladriamycinone (24)

Compound **20** (500 mg) was converted into **24** using the above described procedure for **23**. The product was purified by preparative tlc to give 200 mg of red powder after crystallization from $CHCl_3$ – petroleum ether, mp 161–162°C; tlc (System B) R_f 0.52; ir (KBr): 3440, 1740, 1616, and 1580 cm^{-1}; nmr Table 1. *Anal.* calcd. for $C_{48}H_{42}F_3NO_{13}$: C 64.20, H 4.68, F 6.35, N 1.56; found: C 64.01, H 4.64, F 6.12, N 1.35.

7-O-(3,5-Dideoxy-3-trifluoroacetamido-β- and α-D-ribofuranosyl)-adriamycinone (25 and 26)

Compounds **23** and **24** (50 mg each) were treated separately with 80% HOAc, as described before for the preparation of **21**. Crystallization of the products from $CHCl_3$ – petroleum ether gave **25** (32 mg, mp 148–149°C; tlc (System B) R_f 0.35; ir (KBr): 3400, 1720 (br), 1618, and 1578 cm^{-1}; nmr Table 1. *Anal.* calcd. for $C_{28}H_{26}F_3NO_{12}\cdot H_2O$: C 52.24, H 4.35, F 8.86, N 2.17; found: C 52.08, H 4.06, F 8.92, N 1.95); and **26** (35 mg, mp 165–166°C; tlc (System B) R_f 0.40; ir (KBr): 3450, 1720 (br), 1618, and 1580 cm^{-1}; nmr Table 1. *Anal.* calcd. for $C_{28}H_{26}F_3NO_{12}\cdot H_2O$: C 52.45, H 4.35, F 8.86, N 2.17; found: C 52.47, H 4.54, F 8.59, N 1.99.

7-O-(3-Amino-3,5-dideoxy-β-D-ribofuranosyl)-14-O-p-anisyldiphenylmethyladriamycinone (27)

Compound **23** (250 mg) was dissolved in 50 mL of acetone and the solution cooled to 0°C. NaOH solution (0.1 *N*, 2.5 mL) was added dropwise under N_2 with stirring. The blue solution was allowed to stir at 0°C for 1 h, at which time the hplc trace (reverse phase) of an aliquot of the solution showed the total replacement of the signal from **23** by a new one. The pH of the solution was adjusted to 8.5 by dropwise addition of 0.1 *N* HCl at 0°C, acetone (20 mL) was added, and the mixture was evaporated at 0°C. The concentrate was repeatedly extracted with $CHCl_3$–CH_3OH (9:1) until no orange color was further extracted. The combined $CHCl_3$–CH_3OH extracts were washed with 5 mL of H_2O and the water washings were extracted back. The colored organic layers were combined, dried, and evaporated. The residue was chromatographed on preparative tlc and the pure **27** was crystallized from $CHCl_3$ – petroleum ether (100 mg), mp 161–162°C; tlc (System A) 0.50; ir (KBr): 3450, 1730, 1720, 1615, and 1579 cm^{-1}; nmr Table 1. *Anal.* calcd. for $C_{46}H_{43}NO_{12}$: C 68.91, H 5.36, N 1.74; found: C 68.61, H 5.44, N 1.67.

7-O-(3-Amino-3,5-dideoxy-α-D-ribofuranosyl)-14-O-anisyldiphenylmethyladriamycinone (28)

Compound **28** was obtained from **24** in a manner similar to that used to prepare **27** from **23**. Thus, 200 mg of **24** afforded, after preparative tlc, 75 mg of **28**, mp 169–170°C; tlc (System A) 0.62; ir (KBr): 3450, 1730, 1617, and 1580 cm^{-1}; nmr Table 1. *Anal.* calcd. for $C_{46}H_{43}NO_{12}\cdot H_2O$: C 67.39, H 5.49, N 1.70; found: C 67.05, H 5.40, N 1.53.

7-O-(3-Amino-3,5-dideoxy-β- and α-D-ribofuranosyl)adriamycinones (29 and 30)

Compounds **27** and **28** (50 mg of each), from above, were dissolved separately in ice-cold 80% HOAc (5 mL) and the solutions stored at 0°C for 10 h. Lyophilization, followed by chromatography of the residues on silica gel, afforded pure **29** and **30** as deep-red amorphous powders from $CHCl_3$–ether. Compound **29** (25 mg): mp 232–233°C;

tlc (System C) R_f 0.22; ir (KBr): 3400, 3220, 1720, 1612, and 1580 cm^{-1}. *Anal.* calcd. for $C_{26}H_{21}NO_{11} \cdot 4H_2O$: C 55.91, H 5.82, N 2.32; found: C 55.78, H 5.57, N 2.17. Compound **30** (20 mg): mp 209–210°C; tlc (System C) R_f 0.40; ir (KBr): 3440, 3240 (br), 1724, 1718, 1618, and 1578 cm^{-1}. *Anal.* calcd. for $C_{26}H_{27}NO_{11} \cdot 2H_2O$: C 55.24, H 5.48, N 2.47; found: C 55.78, H 5.57, N 2.17.

Hydrochloride salts of **29** and **30** were prepared by adding equivalent amounts of methanolic HCl to their $CHCl_3-CH_3OH$ solutions, evaporating the solutions below 0°C, and precipitating the hydrochloride salts. The two hydrochlorides had the same tlc behavior and hplc retention times as the free amines **29** and **30**.

N-*Trifluoracetylation of* ***29*** *and* ***30****: alternate preparation of* ***25*** *and* ***26***

Free amines **29** and **30** (3 mg each) were separately dissolved in 1 mL of pyridine and cooled to −78°C. An ice-cold solution of 0.1 mL of trifluoroacetic anhydride in 2 mL of ether was added to each of the above solutions, and the mixtures stirred at −78°C for 0.5 h. Ice-cold water (5 mL) was then added, and the solutions extracted with $CHCl_3$. The $CHCl_3$ extracts were washed with H_2O (2 mL), dried, and evaporated. Methanol (5 mL) was added to each residue and the solutions heated at reflux for 0.5 h. Removal of the methanol in each instance gave products identical with **25** and **26** (tlc, hplc).

Some photochemical rearrangements of vinylcyclopentadienes. Mechanistic and exploratory organic photochemistry[1,2]

HOWARD E. ZIMMERMAN AND WILLIAM D. RAMSDEN
Department of Chemistry, University of Wisconsin, Madison, WI 53706, U.S.A.

Received March 8, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

HOWARD E. ZIMMERMAN and WILLIAM D. RAMSDEN. Can. J. Chem. **62**, 2592 (1984).

The photochemistry of 2,3-diphenyl-1,4,5-trimethyl-5-vinylcyclopentadiene and 1,2-diphenyl-3,4,5-trimethyl-5-vinylcyclopentadiene was studied. The triplet of the 2,3-diphenyl isomer was found to undergo a 1,5-vinyl migration; in contrast, the 1,2-diphenyl diene was unreactive. On direct irradiation, in addition to vinyl migration, four photoproducts were formed from the cyclopentadienes. These were shown to be 5,6-diphenyl-1,2,7-trimethylbicyclo[3.2.0]hepta-2,6-diene, 1,5-diphenyl-2,6,7-trimethylbicyclo[3.2.0]hepta-2,6-diene, 6,7-diphenyl-1,2,5-trimethylbicyclo[3.2.0]hepta-2,6-diene, and 1,7-diphenyl-2,5,6-trimethylbicyclo[3.2.0]hepta-2,6-diene. A number of experimental observations led to a mechanism involving: (*a*) electrocyclic closure of the vinylcyclopentadienes to give vinyl housenes, (*b*) bicycling which interconverts isomeric housenes, and (*c*) thermal Cope rearrangement of the vinyl housenes to afford bicyclo[3.2.0]hepta-2,6-dienes. In addition, evidence was adduced for 1,5-vinyl shifts occurring in the vinylcyclopentadiene reactants.

HOWARD E. ZIMMERMAN et WILLIAM D. RAMSDEN. Can. J. Chem. **62**, 2592 (1984).

On a étudié la photochimie du diphényl-2,3 triméthyl-1,4,5 vinyl-5 cyclopentadiène et du diphényl-1,2 triméthyl-3,4,5 vinyl-5 cyclopentadiène. On a trouvé que l'état triplet de l'isomère diphényl-2,3 subit une migration 1,5 du vinyle; par opposition, le diphényl-1,2 diène n'est pas réactif. Par irradiation directe, les cyclopentadiènes conduisent, en plus du produit de migration du groupe vinyle, à quatre photoproduits; on a démontré qu'ils ont les structures suivantes: diphényl-5,6 triméthyl-1,2,7 bicyclo[3.2.0] heptadiène-2,6; diphényl-1,5 triméthyl-2,6,7 bicyclo[3.2.0] heptadiène-2,6; diphényl-6,7 triméthyl-1,2,5 bicyclo[3.2.0] heptadiène-2,6 et diphényl-1,7 triméthyl-2,5,6 bicyclo[3.2.0] heptadiène. Sur la base d'un certain nombre de données expérimentales, on propose un mécanisme impliquant: (*a*) une cyclisation électrocyclique des vinylcyclopentadiènes conduisant aux vinyl housènes; (*b*) des réactions de bicyclisation permettant de provoquer des interconversions entre les divers housènes isomères; (*c*) une transposition thermique de Cope qui transforme les vinyl housènes en bicyclo[3.2.0] heptadiènes-2,6. De plus, on a obtenu des données permettant de supposer qu'il se produit des déplacements 1,5 de groupes vinyles dans les réactifs vinylcyclopentadiènes.

Introduction

One of our main research objectives has been the elucidation of new photochemical organic reactions. It is clear that the number of ground state organic reactions is immense, a result of a century and a half of intensive efforts. In comparison, the number of photochemical reactions is minuscule. Nevertheless, the known photochemical reactions are often fascinating, primarily because of their departure from intuitive ground state expectation, and promising, primarily because patterns of behavior demonstrate the presence of understandable mechanistic factors.

In recent years we have uncovered some unique rearrangements of vinylcyclopropenes affording cyclopentadienes (1*c*, 2; note also work by Padwa *et al.* (3)). We thus proceeded to investigate the photochemical behavior of the homologous vinylcyclopentadienes.

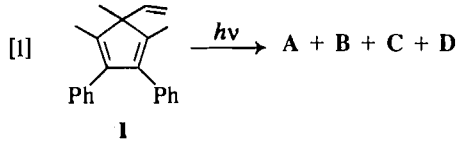
Results

Synthesis of reactants of interest

For our study we selected 2,3-diphenyl-1,4,5-trimethyl-5-vinylcyclopentadiene **1**. The synthesis of this compound is outlined in Scheme 1. Also included in Scheme 1 is the synthesis of 1,2-diphenyl-3,4,5-trimethyl-5-vinylcyclopentadiene **2** whose photochemistry proved to be intimately intertwined with that of vinylcyclopentadiene **1**.

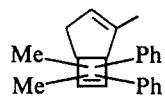
*Reactivity of vinylcyclopentadiene **1** on direct irradiation and structure elucidation of photoproducts*

Irradiation of vinylcyclopentadiene **1** afforded four photoproducts **A**, **B**, **C**, and **D** in a ratio of 8:4:1:2 as outlined in eq. [1].



1

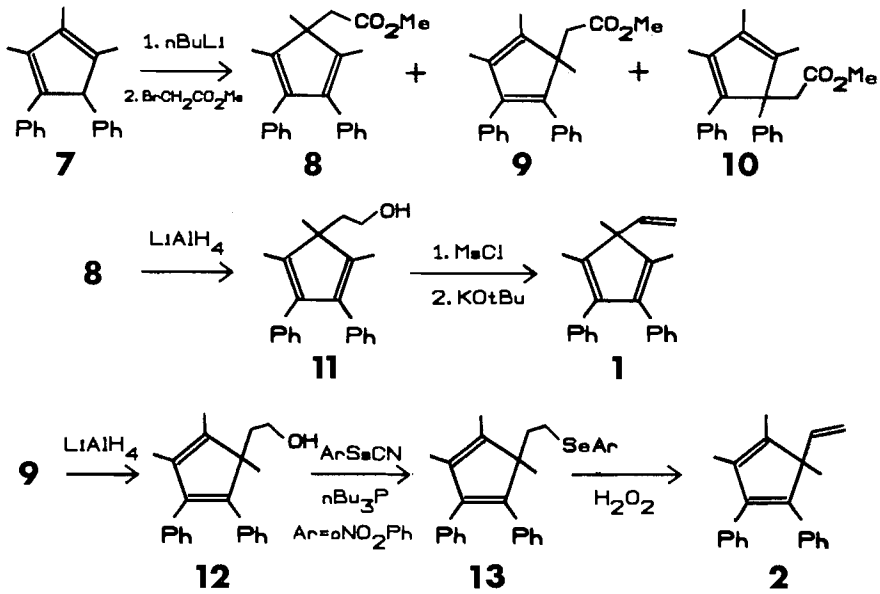
The nmr spectra of these photoproducts revealed a three-hydrogen pattern attributable to a $CH_2CH=$ moiety. Additionally, one methyl peak was weakly coupled with these hydrogens, and the chemical shift was suggestive of a vinyl methyl group, thus further defining the group as $CH_2CH=CCH_3$ in all four photoproducts. Further, the proton nmr spectra showed two additional methyl peaks in each photoproduct. Beyond this, the Cmr spectra of each photoproduct had two absorbances in the range of δ 50–75 ppm, characteristic of quaternary ring junction carbon atoms. At this point we considered the basic structure **14** for the four photoproducts. The ultraviolet spectrum of **A** suggested the presence of a styryl moiety, that of **B** only unconjugated phenyl groups, the uv of



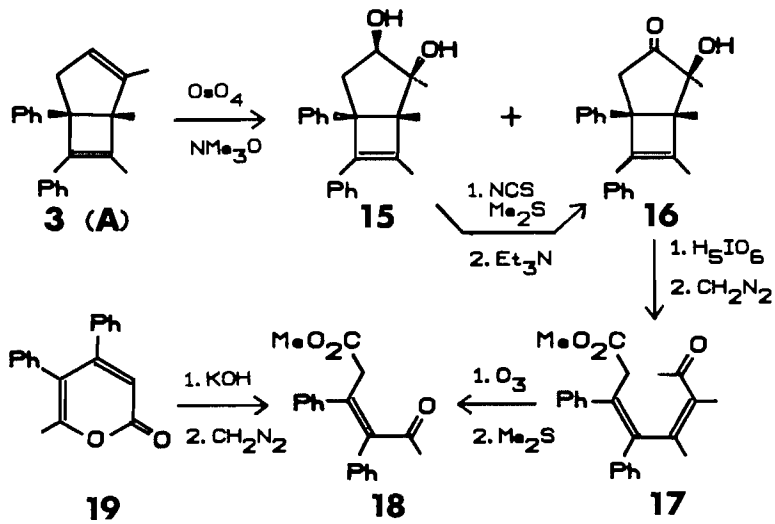
14

[1] This is paper 141 of our photochemical series.

[2] For paper 140, note ref. 1*a*. For paper 139, see ref. 1*b*, and for paper 138, see ref. 1*c*.



SCHEME 1. Synthesis of photochemical reactants.



SCHEME 2. Structure elucidation of photoproduct A by degradation.

C a stilbenyl chromophore, and that of **D** a styryl group as in **A**. Since rigorous structural assignments seem a necessary requisite to mechanistic understanding (4), we proceeded to establish the structures of the photoproducts by degradation and X-ray determination.[3]

The structure of photoproduct **A** was established by a degradation beginning with osmium tetroxide oxidation, which afforded a vicinal diol **15** as well as a ketol **16**. For simplicity in presentation, the degradation is outlined in Scheme 2 with final structural assignments.

Surprisingly, periodic acid oxidation of ketol **16** afforded a ketoester which, after esterification, possessed *two* double bonds while the ketol reactant had only *one*. This resulted from the remarkably facile electrocyclic ring opening of the cyclobutene oxidation product (*vide infra*). The degradation scheme led ultimately to enone ester **18** which was independently prepared from pyrone **19**.

The validity of the degradation scheme was established by an X-ray determination of the structure of ketol **16** derived from photoproduct **A**. Figure 1 provides the ORTEP drawing. Hence photoproduct **A** is assigned structure **3**.

A degradation of photoproduct **B**, beginning in similar fashion, led as depicted in Scheme 3 to the terphenyl aldehyde **22**. Routine X-ray structure determination of terphenyl **22** confirmed its structure. Note Fig. 2. This led to formulation of photoproduct **B** as **4**.

We next turned our attention to photoproduct **D**. Hydroboration–oxidation of **D** led to hydroxylated product **23**. With the strong implication of a bicyclo[3.2.0] skeleton for **D**, coupled wih nmr evidence suggesting the placement of all substituents except for possible interchange of phenyl and methyl

[3] Currently X-ray has become a routine tool for structure elucidation in our group. Such powerful programs as MULTAN 80 (*5a*) and SHELX 76 (*5b*) coupled with a VAX/750 provide unrefined structures in 15–20 min; refinement does take some additional time. The X-ray structure determinations are to be published by K. J. Haller and W. D. Ramsden.

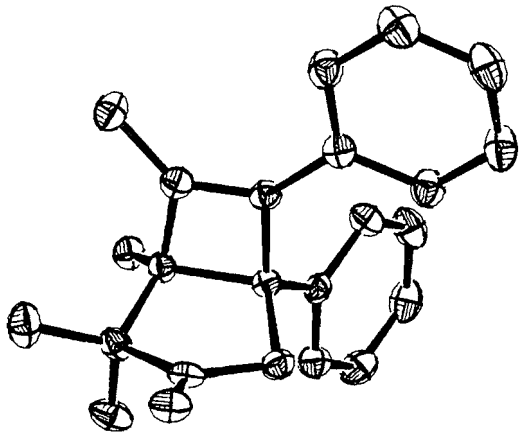

FIG. 1. ORTEP drawing for ketol **16**.

groups, we independently synthesized the hydroxylated product **23** as outlined in Scheme 4. The most critical step involved the useful cyclopropene cycloaddition of van Tilborg *et al.* (6). Finally, we note that photoproduct **D** was assigned structure **6**.

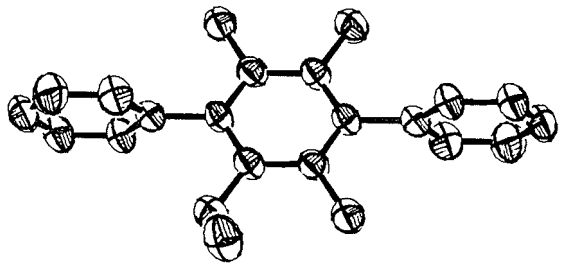

FIG. 2. ORTEP drawing for terphenyl **22**.

Photoproduct **C** was the most minor photoproduct and thus the least available for study. Its structure derived from the presence of two junction methyl groups (δ 1.36 and 1.38 singlets), the usual $CH_2CH{=}CCH_3$ moiety as determined by nmr, and the presence of a *cis*-stilbenyl chromophore as evidenced in the ultraviolet spectrum. This led to formulation of **C** as **5**.

As a consequence of the structure elucidations, one may describe the photochemical transformation of vinylcyclopentadiene **1** as in eq. [2]. Additionally, the product distribution at 8°C is included and is discussed below.

[2] 
	1	**3 (A)**		**4 (B)**		**5 (C)**		**6 (D)**
Temperature: 30°C		8	:	4	:	1	:	2
8°C		4	:	13	:	1	:	2

Reactivity of vinylcyclopentadiene 2 on direct irradiation

Irradiation of vinylcyclopentadiene **2** rapidly led to vinylcyclopentadiene **1** with very minor formation of **3**, **4**, **5**, and **6**. The irradiation was carried out with a solution filter preventing absorption of light by product vinylcyclopentadiene **1**. This transformation is depicted in eq. [3]. The significance of this is considered below in connection with the reaction mechanism.

[3] 
Reactivity of the vinylcyclopentadienes on sensitized irradiation

When the corresponding photolysis of vinylcyclopentadiene **2** was carried out with sensitization, using *p*-dimethylaminobenzophenone (E_T 62 kcal/mol (7)[4]), no reaction occurred. In contrast, when the same sensitization was carried out with vinylcyclopentadiene **1** as the reactant, a facile conversion to diene **2** was observed. Note eq. [4]. Here, the energy of vinylcyclopentadiene **1** triplet should be no higher than the 58 kcal/mol reported (8) for cyclopentadiene itself and E_T for vinylcyclopentadiene **2** should be no higher than the 57 kcal/mol reported (9) for *cis*-stilbene.

[4] 
[4]The estimated triplet energy is taken as that of *p*-aminobenzophenone as in ref. 7*a* and 7*b*.

Labeling studies necessary for mechanistic understanding

Since two different mechanisms – a 1,5-vinyl shift and a bicycle migration (10) – seemed plausible possibilities for the interconversion of vinylcyclopentadienes **1** and **2**, it was necessary to have available these molecules properly labeled to differentiate between these pathways. Reaction of vinylcyclopentadiene **1** with Streitwieser's base (11, 12), however containing deuterium (12), led to selective deuteration of the C-1 and C-4 methyl groups as shown in eq. [5].

[5] 
Direct irradiation of **1***d* to appreciable conversion (77%) led to the expected formation of the usual bicyclic photoproducts. In addition, a very minor (3%) amount of vinylcyclopentadiene **2** was isolable. Interestingly, the nmr spectrum showed the methyl groups to be statistically scrambled, each being 1/3 CH_3 and 2/3 CD_3. The recovered starting material (i.e. vinylcyclopentadiene **1**) also had its methyl groups close to statistically scrambled. Note eq. [6]. As might be surmised, the bicyclic photoproducts **3**, **4**, **5**, and **6** each possessed nmr spectra showing that two-thirds of the methyl groups in each location were replaced by CD_3. Note eq. [7]. Clearly, scrambling of the

deuterium labeled methyl groups in vinylcyclopentadiene **1** and the product vinylcyclopentadiene **2** accounts of the scrambling of the bicyclic photoproducts. In lower conversion runs, vinylcyclopentadiene **2** was formed in too minor amounts to be isolated. However, scrambling methyl groups could be monitored by observing distribution of the deuterated methyl groups in recovered vinylcyclopentadiene **1** and in the bicyclic photoproducts **3**, **4**, **5**, and **6**. Note eqs. [6] and [7].

In another study of labeled reactant, methyl deuterated vinylcyclopentadiene **1***d* was irradiated under sensitized conditions to afford vinylcyclopentadiene **2***d′* but no bicyclic products. Strikingly, and in contrast to the direct irradiation, not only was reactant not scrambled, but also the photoproduct consisted of one isomer resulting from a simple vinyl migration with no methyl scrambling. Note eq. [8].

With specifically labeled **2** (i.e. **2***d*′) available it was of interest to investigate its photochemistry. Direct irradiation of **2***d*′ led to partially scrambled **1** (i.e. **1***d* and **1***d*′). Recovered reactant was unscrambled. In addition the usual photoproducts were observed. Of most interest were **3** and **4**. In **3**, the C-2 methyl group was completely deuterated while the remaining label was equally distributed between C-1 and C-7. In product **4** C-2, again, was completely deuterated while the remaining label was unequally distributed between C-6 and C-7. The photolysis of labeled **2** is described in eq. [9]. The significance of these labeling studies is considered in the section on Discussion of results.

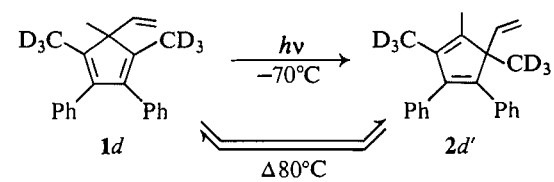
Equation [2] includes the effect on the distribution of photoproducts resulting from lowering the irradiation temperature from 30 to 8°C. Although the overall conversion was not appreciably affected, the ratio of photoproducts **A** to **B** was decreased by a factor of ca. 6. This suggested a still lower temperature run, and at −70°C, in place of the bicyclic photoproducts, there was observed the vinyl shifted cyclopentadiene **2**. Note eq. [10].

[10]



1*d* **2***d*′

Beyond this simple low temperature run, we used deuterium labeled **1***d* to check on the nature of the rearrangement process. This, too, is included in eq. [10]. It is seen that the low temperature photolysis affords **2***d*′ which is derived from vinylcyclopentadiene **1***d* by a simple 1,5-vinyl shift rather than by a bicycle process.

Quantum yields, quenching experiments, and product photostability

Quantum yields for the reactions of interest were obtained (note Experimental section) and are detailed in Table 1. These include the direct irradiation efficiencies for photolysis of vinylcyclopentadiene **1** and for the sensitized irradiation of this compound.

A related item of consequence is the very low photoreactivity of the four photoproducts **3**, **4**, **5**, and **6**, coupled with the observation that these compounds neither interconvert nor afford any of the compounds of the present study.

Finally, it was of some importance to test for the presence of triplet species in the direct irradiation of vinylcyclopentadiene **1**, since intersystem crossing was a possibility and any such triplets would be candidates for the rearranging excited state. At 0.002 *M*, 3,3,4,4-tetramethyl-1,2-diazetine-1,2-dioxide (E_T 40 kcal/mol) did not quench the rearrangement to photoproducts **3**, **4**, **5**, and **6** (note Experimental section for details).

Observation of ground state chemistry

It seemed necessary to establish the limits of thermal stability of the photochemical reactants **1** and **2**. At 30°C these proved quite stable. However, at 80°C in benzene facile equilibration was encountered, the steady-state distribution being 1:1. Furthermore, deuterium labeling showed that the rearrangement derived from a vicinal vinyl shift rather than a bicyclic step. Note eq. [10], which includes the deuterium substitution.

Interpretative discussion

The overall mechanism of bicyclic photoproduct formation

The two phenyl groups and three methyl groups provided markers which clarified the nature of the skeletal transformation on direct irradiation of vinylcyclopentadiene **1**. Even more definitive was the photolysis of the di-deuteriomethyl reactant **1***d*. Note eq. [7]. For the transformation of vinylcyclopentadiene **1** or **1***d* into photoproduct **A** (i.e. **3**) or its deuterated counterpart, an electrocyclic closure of **1** to afford housene **29**, followed by a Cope rearrangement, leads nicely to the skeletal pattern of phenyl, methyl, and trideuteriomethyl substitution in photoproduct **A** (**3**). This mechanism is outlined as eq. [11] in Scheme 5.

Also, the same mechanistic process accounts for the conversion of vinylcyclopentadiene **2** into the observed bicyclic photoproduct **B** (i.e. **4**) with the correct disposition of phenyl and methyl groups. This route proceeds via housene **30** as depicted in eq. [12] of Scheme 5. Additionally, the alternative Cope regiochemistry can be seen to lead to photoproduct **C** (i.e. **5**).

Thus far we have considered just two mechanistic processes, namely electrocyclic closure of the vinylcyclopentadiene reactants to afford housenes and the Cope rearrangement of the housenes thus formed. It is clear that more than these two processes are occurring. We see, for example, that irradiation

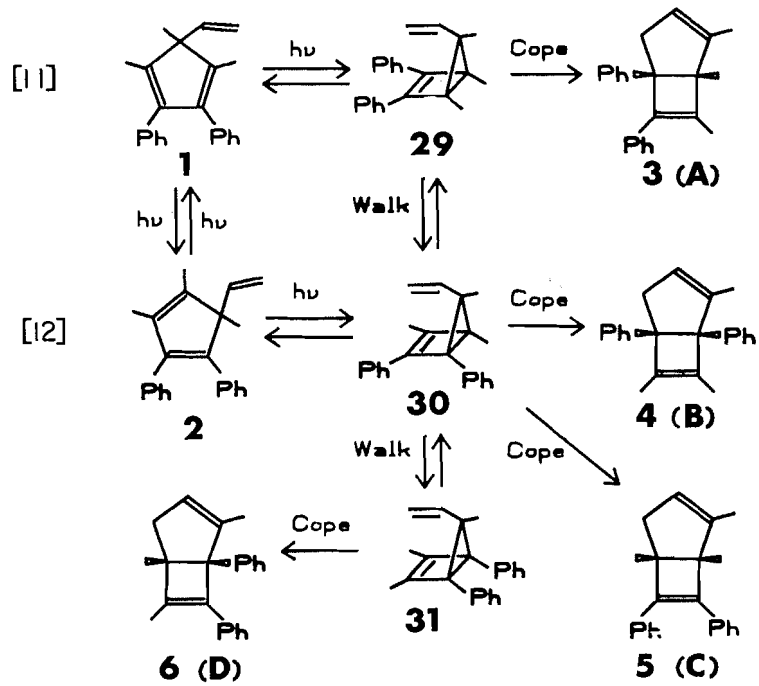
For personal use only.



SCHEME 5. Mechanism of conversion of vinylcyclopentadienes **1** and **2** into photoproducts.

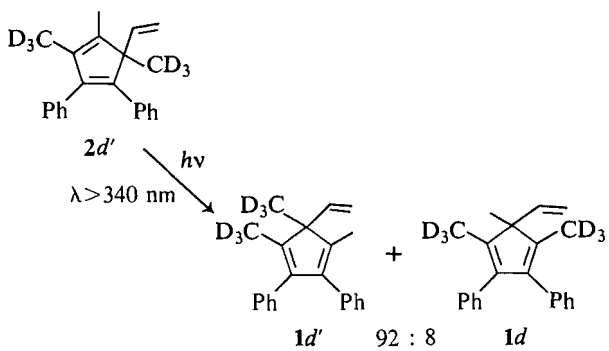
of vinylcyclopentadiene **1** affords all four of the photoproducts – **A**, **B**, **C**, and **D** – rather than just **A** as predicted by the above. Similarly, photolysis of **2** leads to more photoproducts than just **B** and **C**.

It appears that two additional mechanistic processes are operating and account for the additional products observed in each case. The first is a vinyl shift in which a vinyl moiety moves to the adjacent carbon of the five-membered ring. An illustration of the process is found in Scheme 5 in the interconversion of **1** and **2**.

A second mechanistic process which seems to be operating is a bicycle rearrangement (10, 13) in which the out-of-plane carbon atom of the housene molecule moves to the adjacent bond. This is illustrated in Scheme 5 in the conversion of housene **29** to **30** and the conversion of **30** to **31**.

Clear evidence for these processes came from irradiation of the deuterated vinylcyclopentadiene **2***d*′ (note eq. [13]) where the major (86% of the converted reactant) photoproduct is vinylcyclopentadiene **1** with labeling demonstrating 92% bicycling to give **1***d*′ and 8% vicinal (i.e. 1,5) vinyl shifting to give **1***d*.

[13]



Thus four basic processes – (*a*) electrocyclic closure to afford the vinylcyclopentadienes, (*b*) bicycling of C-5 of the housenes, (*c*) vicinal vinyl shifting, and (*d*) Cope rearrangement of the housenes – permit formulation of the overall mechanistic pathways in Scheme 5 leading from reactant vinylcyclopentadienes to bicyclic photoproducts.

A check on the mechanisms leading to bicyclic photoproducts provided by deuterium labeling

As noted above, the bistrideuteriomethyl vinylcyclopentadienes **1***d* and **2***d*′ promised to shed light on the mechanisms of both the vinylcyclopentadiene interconversions and on the conversions to bicyclic photoproducts **3**–**6**. The latter require discussion first. Referring to Scheme 6, we note that bis-deuteriomethyl vinylcyclopentadiene **1***d* affords primarily bicyclic photoproduct with the deuteriomethyl groups in locations in accordance with the proposed mechanism; as a consequence of the plane of symmetry in the housene precursor **29***d*, the subsequent Cope rearrangement affords only one bicyclic product (i.e. **3***d*). The competitive 1,5-vinyl shift to afford **2***d*′ does not obscure the results, since the formation of bicyclic products **3***d*′ and **3***d*″ is of lower efficiency. Similarly, scrambling of reactant **1***d* is a lower efficiency process.

More informative is the photolysis of the bis-deuteriomethyl vinylcyclopentadiene **2***d*′, also shown in Scheme 6, which portrays the relevant transformations. Here the irradiation wavelength was such that any vinylcyclopentadiene **1***d* formed would not absorb light and thus would not mar the simplicity of the experiment. The formation of the two bicyclic regioisomers **3***d*′ and **3***d*″ in a 1:1 ratio confirms the mechanism. Thus, housene intermediate **29***d*′ has a pseudo plane of symmetry, and the two Cope rearrangements depicted have equal probability, barring any minor secondary deuterium isotope effects.

Nature of the bicycle and Cope rearrangement steps

A priori, it appeared possible that the bicycle rearrangements were either thermal or photochemical, since both have precedent (12–14). Scheme 7 depicts the photochemistry relevant to this question. Housene **31***d* has no extended chromophore and should not absorb under the conditions of the irradiation of **2***d*′.

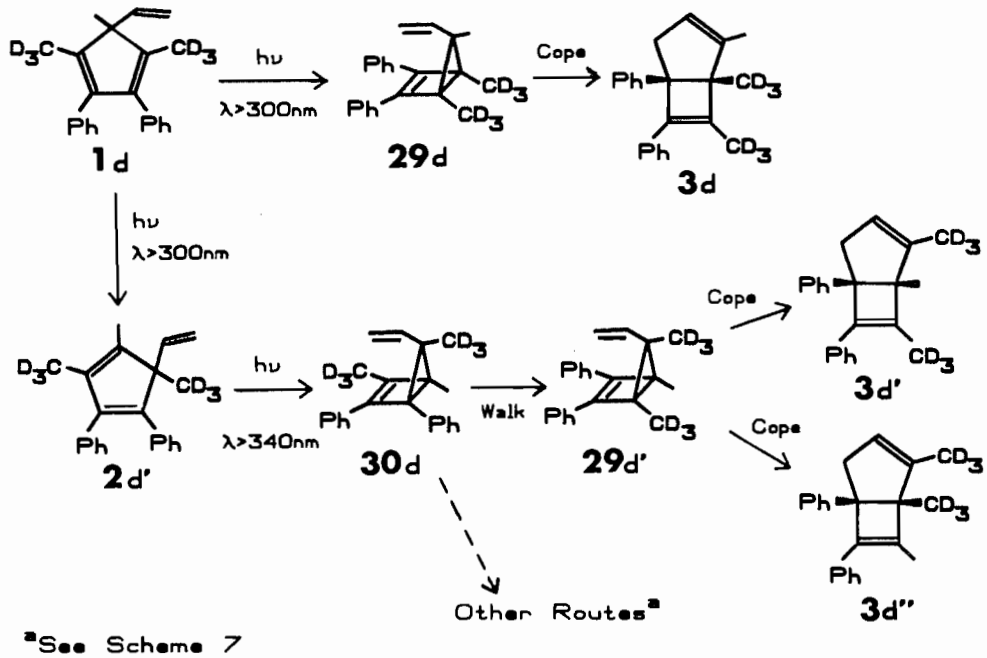
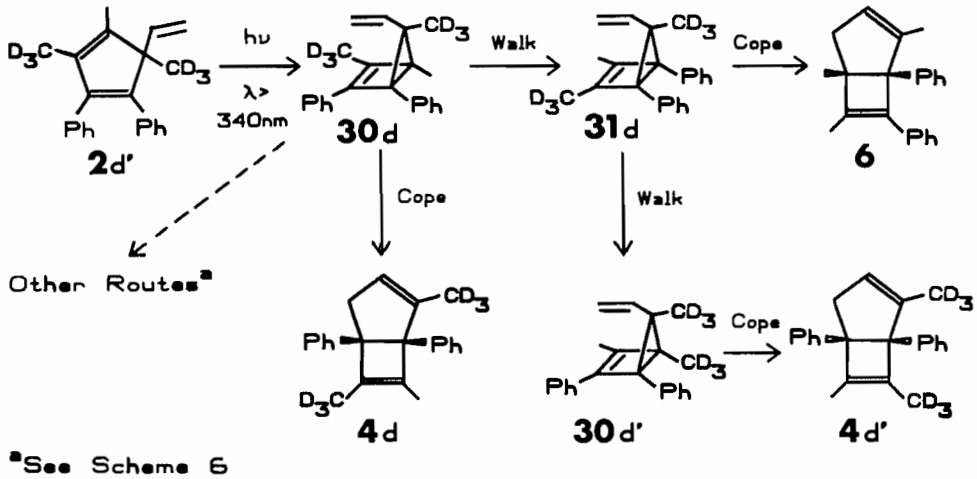


SCHEME 6. Selected transformations in the photochemistry of bis-deuteriomethyl vinylcyclopentadienes 1*d* and 2*d'* giving product A.



SCHEME 7. Selected transformations in the photochemistry of bis-deuteriomethyl vinylcyclopentadiene 2*d'* giving photoproducts B and D.

Nevertheless, experimentally, housene **31***d* leads onwards by bicycle and Cope rearrangements to afford bicyclic photoproduct **4***d'*. In absence of light absorption by **31***d*, the bicycle rearrangement must thus be thermal.

A similar point derives from the observation of photoproduct **D** (i.e. **6**) under these conditions. This means that the Cope rearrangement step converting **31** (or **31***d*) must be occurring under conditions where no light is absorbed by the housene precursor **31***d*, and the Cope rearrangement also must be occurring thermally.

Since the various bicycle steps are similar structurally, the thermal nature of one step strongly suggests that all of the bicycle rearrangements observed are thermal. Similarly, the observation of one thermal Cope step provides evidence that the remaining Cope rearrangements are thermal rather than photochemical.

Regarding the reaction stereochemistry, we note that an *endo*-vinyl configuration in the housenes is required for each Cope rearrangement. The simplest rationale is that the electrocyclic closure of the vinylcyclopentadienes **1** and **2** gives rise to some *endo* stereoisomer. The *endo* stereoisomer (e.g. **30**), then, would be capable of undergoing either the Cope rearrangement to afford product (e.g. **4**) or a stereospecific bicycle rearrangement, giving rise to product housene (e.g. **31**) still having an *endo*-vinyl group. The low quantum yields, in the range of 0.03 and lower, imply that some *exo*-vinyl stereoisomer might be formed and revert to initial reactant, being unable to undergo the Cope rearrangement. Reversion of the housenes to afford vinylcyclopentadienes is quite likely in view of the reported[5] (15) thermal instability of housenes, coupled with our not finding nmr indication of the presence of housenes surviving at 0°C (note Experimental section).

In much simpler systems the thermal walk reaction of housenes is known from the work of Klärner and Adamsky (13), who have shown these to proceed in a thermally allowed fashion with retention of the *endo* vs. *exo* configuration, that is,

[5] Housenes tend to revert to cyclopentadienes at 0–50°C (13, 15).

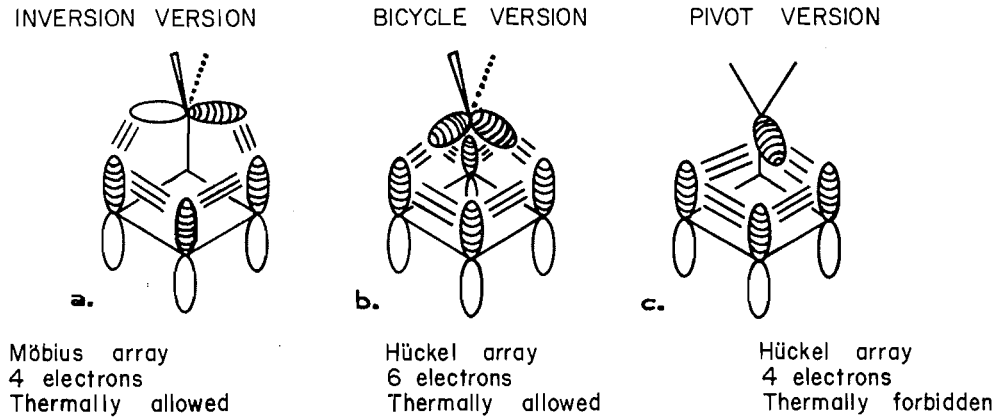

FIG. 3. Electronics of the bicycle (walk) rearrangement for bicyclo[2.1.0]pentenes.

with stereochemistry corresponding to our photochemical bicycle rearrangements (13) and ground state bicycle walk rearrangements of Type A zwitterions[6–8] (16–18). The reaction is seen to be allowed in the Woodward–Hoffmann sense (19), being a 1,3-suprafacial rearrangement with inversion of configuration of the bicycling carbon.

An alternative and useful analysis of this type of "walk rearrangement" (20) has been presented in connection with the rearrangement of Type A zwitterions. This uses the Möbius–Hückel treatment (21). Applied to the case in hand, we consider Figs. 3a and 3b and see that, with bicycling (i.e. inversion of migrating carbon configuration), there are 4 delocalized electrons in a Möbius system (21). With 4N electrons and a ground state Möbius array, a closed shell is predicted by the Zimmerman circle mnemonic (21). This contrasts with pivoting as in Fig. 3c where there are 4N electrons in a Hückel array (21), which predicts a higher energy and open shell transition state using the Frost counterpart mnemonic (22).

The bicycle description of the mechanism, as in Fig. 3b, depends on our recognition (21*e*) that two sp^5 orbitals are precisely equivalent to an sp^2 and a *p*-orbital (Fig. 3a). When we use the bicycle equivalent, we again apply the Möbius–Hückel treatment by including the six delocalized orbitals.

Unusual Cope selectivity[9]

The rather interesting regioselectivity observed in the preferential conversion of vinyl housene **30** to afford photoproduct **4** (i.e. **B**) over photoproduct **5** (i.e. **C**) needs consideration. A simple rationale might be applicable if the phenyl group at C-1 is selectively twisted into a conformation not permitting full overlap with σ bond 1–5, and thus not able to stabilize the transition state leading to photoproduct **5** (i.e. **C**). The ORTEP drawing in Fig. 1 for the analogous bicyclic ketol **16** does show the ring junction phenyl group as conformationally twisted, while the remaining phenyl is not. This explanation is less than ideal, since crystal lattice forces may control the phenyl conformation in solid ketol **16**.

A more intriguing possibility is found in an analysis which considers the effect of a phenyl group substituted in each of two locations in a Cope transition state. Figure 4 poses the problem of two alternative transition states and thus the question of which location for phenyl substitution is most helpful energetically. The Cope rearrangement under discussion is a special case of the 1,2-divinylcyclopropane rearrangement which is known to be particularly facile (23) as a result of release of three-ring strain energy. Hence the rearrangement under consideration is one which should have an early transition state compared to that for the usual acyclic systems[10] which have received attention.

The two cyclic arrays included in Fig. 4 correspond to the two modes of rearrangement of vinylhousene **30**. For a divinylcyclopropane, a model is selected which assumes an early transition state, and thus has appreciable residual 3,4-σ bonding compared with new π–π (i.e. 1,6) overlap. We consider two types of effects. The first is inclusion of *s*-character in the orbitals of the original 3,4-σ bond; the second is inclusion of *s*-character in the bond itself. Dissection of the two effects – on the diagonal matrix element and on the off-diagonal matrix elements – is artificial but does reveal the consequence of inclusion of the two independently. From even simple Hückel calculations we find that it is the phenyl group remote from the site of σ-bond fission which has the greater stabilizing effect. This is quite different from the situation[10] observed where 1,6-σ-bond formation is more complete than 3,4-σ-bond fission as in the ordinary Cope cases and where phenyl substitution on the central carbon of each allylic moiety has a dominating effect.

Temperature control of vinylcyclopentadiene reactivity

Two effects were noted on lowering temperature. One was seen at −70°C (note eq. [10]) where vinylcyclopentadiene **1** isomerization still occurred and the Cope rearrangement was inhibited. The second effect is the changed product distribution on photolysis of **1** (note eq. [2]) where the trend is toward inhibition of the Cope rearrangement of the initially formed housene **9** relative to processes which lead to the isomeric housene **30**. The overall reaction efficiency did not appear to be

[6] The stereochemistry of the zwitterion rearrangement by motion of two bonds rather than pivoting of one was first outlined in refs. 16*a* and 16*b*.

[7] The first non-photochemically generated bicyclo[3.1.0] system rearranging was described in ref. 16*c*.

[8] The equivalence of the "inversion" and "bicycling" mechanisms was shown in refs. 17*a–c*.

[9] Subsequent examples of bicycling of ground state bicyclo[3.1.0]-hexyl species are described in refs. 18*a–c*.

[10] Literature experiment (24*a–d*) reveals that phenyl at the central carbon of the allylic moiety in the Cope rearrangement accelerates the reaction by ca. 17-fold, while phenyl substitution at the σ-bonded end causes an acceleration of ca. 69-fold. However, it has already been noted by Gajewski and Conrad (24*d*) that a divinylcyclopropane is likely to have an early transition state.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

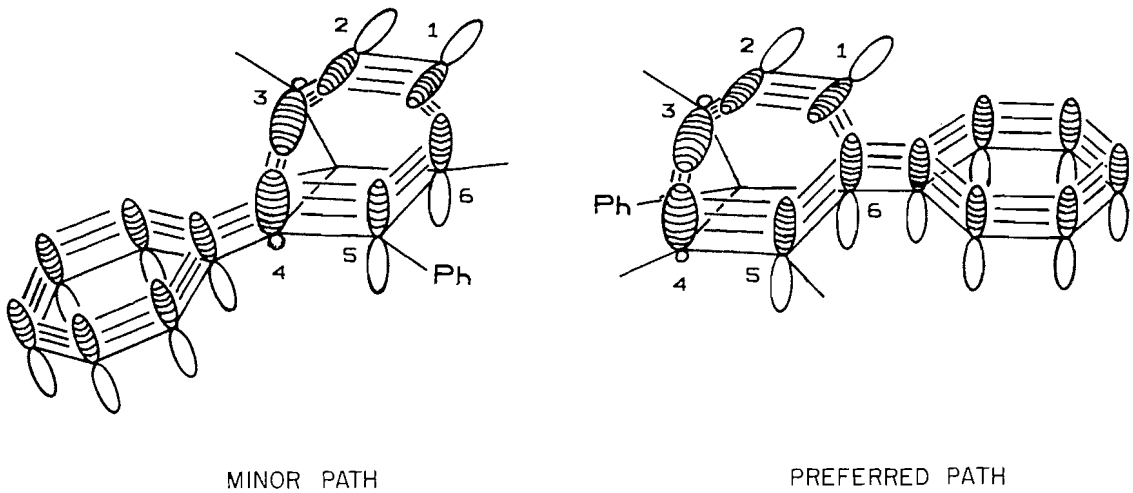

FIG. 4. The effect of phenyl substitution on Cope rearrangements of divinylcyclopropanes.

inhibited, at least qualitatively, and thus the initial electrocyclic closure seems to be relatively temperature independent. In contrast to such a photochemical process, one might expect a ground state Cope rearrangement to be inhibited at lower temperature in accord with these observations.

Finally, relative to the low temperature photochemistry we see from the deuterium labeling (note eq. [10]) that the rearrangement of vinylcyclopentadiene **1***d* to afford **2***d'* involved a 1,5-vinyl sigmatropic rearrangement rather than bicycling which also was an a priori possibility. Hence low temperature inhibits both the Cope rearrangement, as noted above, and also the bicycling, leaving the vinyl shift process.

Multiplicity control of reactivity. Differing triplet behavior

In recent years we have been particularly interested in examples where a given reactant exhibits different photochemistry depending on multiplicity. The major challenge here is development of a mechanistic framework which eventually may predict such dependences.

In the present study, sensitization of vinylcyclopentadiene **1** led exclusively to vinylcyclopentadiene **2** as initially described in eq. [4]. The use of the tagged methyl groups as described in eq. [8] permitted description of the rearrangement as a vicinal 1,5-vinyl shift rather than a bicycle process.

The exact counterpart direct irradiation experiment is not available, since direct irradiation of vinylcyclopentadiene **1** affords both primary and secondary photoproducts. However, direct irradiation of **2** should be quite similar mechanistically, and here the long wavelength chromophore permits selective light absorption by reactant only. This direct irradiation of vinylcyclopentadiene **2** affords primarily (86%) isomeric vinylcyclopentadiene **1** (note eq. [9]), and the deuterium label showed that this arose 92% by electrocyclic closure followed by a bicycle process and only 8% by vicinal vinyl shifting. In addition, the 14% of bicyclic photoproducts **3** and **4** have been shown to arise by bicycling of the vinylhousene **30**.

Hence there is a dramatic difference, wherein T_1 vinylcyclopentadienes prefer vicinal vinyl shifting while S_1 vinylcyclopentadienes prefer electrocyclic closure. This appears to be still another example of the exchange integral (i.e. K) control of photochemical reactions. In this work (12*g*, 25, 26) and related early discussions (27–29), the type of reactions undergoing triplet processes was postulated to be quite different than those undergoing singlet transformations. Figure 5 outlines the

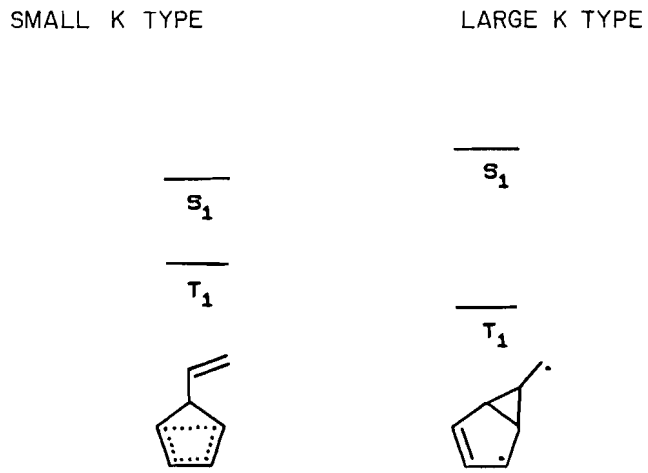

FIG. 5. Exchange integral control of vinylcyclopentadiene reactivity.

present situation. As in our general postulate, singlets prefer the small K mechanism while triplets prefer the large K route. As has been noted earlier, pericyclic processes are small K type reactions while large K reactions include diradical rearrangements in which the odd electrons are distributed over a delocalized system.[11]

Electronic nature of the 1,5-vinyl shift

The 1,5-vinyl shift process, observed both thermally and photochemically, is reminiscent of the MO Following description (21*c*, 32) of the 1,2-vinyl shift for cations, radicals, and carbanions. In that case (e.g. the radical) an odd-electron containing *p*-orbital was on a carbon adjacent to the vinyl group and was left in the new *p*-orbital generated by the 1,2-shift. In the current system, there is a string of three *p*-orbitals con-

[11] (a) Large K photochemical reactions include 1,3-vinyl shifts in di-π-methane systems (26), triplet di-π-methane rearrangements of bicyclics (30) and reactive acyclics (12*g*, 25), stereoisomerization of vinylcyclopropanes via ring opening to diradicals (28), *cis–trans* isomerization of styrenes (27). (b) Small K reactions include such pericyclic processes as electrocyclic ring closure as in the present study, cycloaddition (26), electrocyclic ring opening (e.g.) of cyclohexadienes (28), and concerted di-π-methane rearrangements (12*a*, *b*, *d*, *e*, 27, 31).

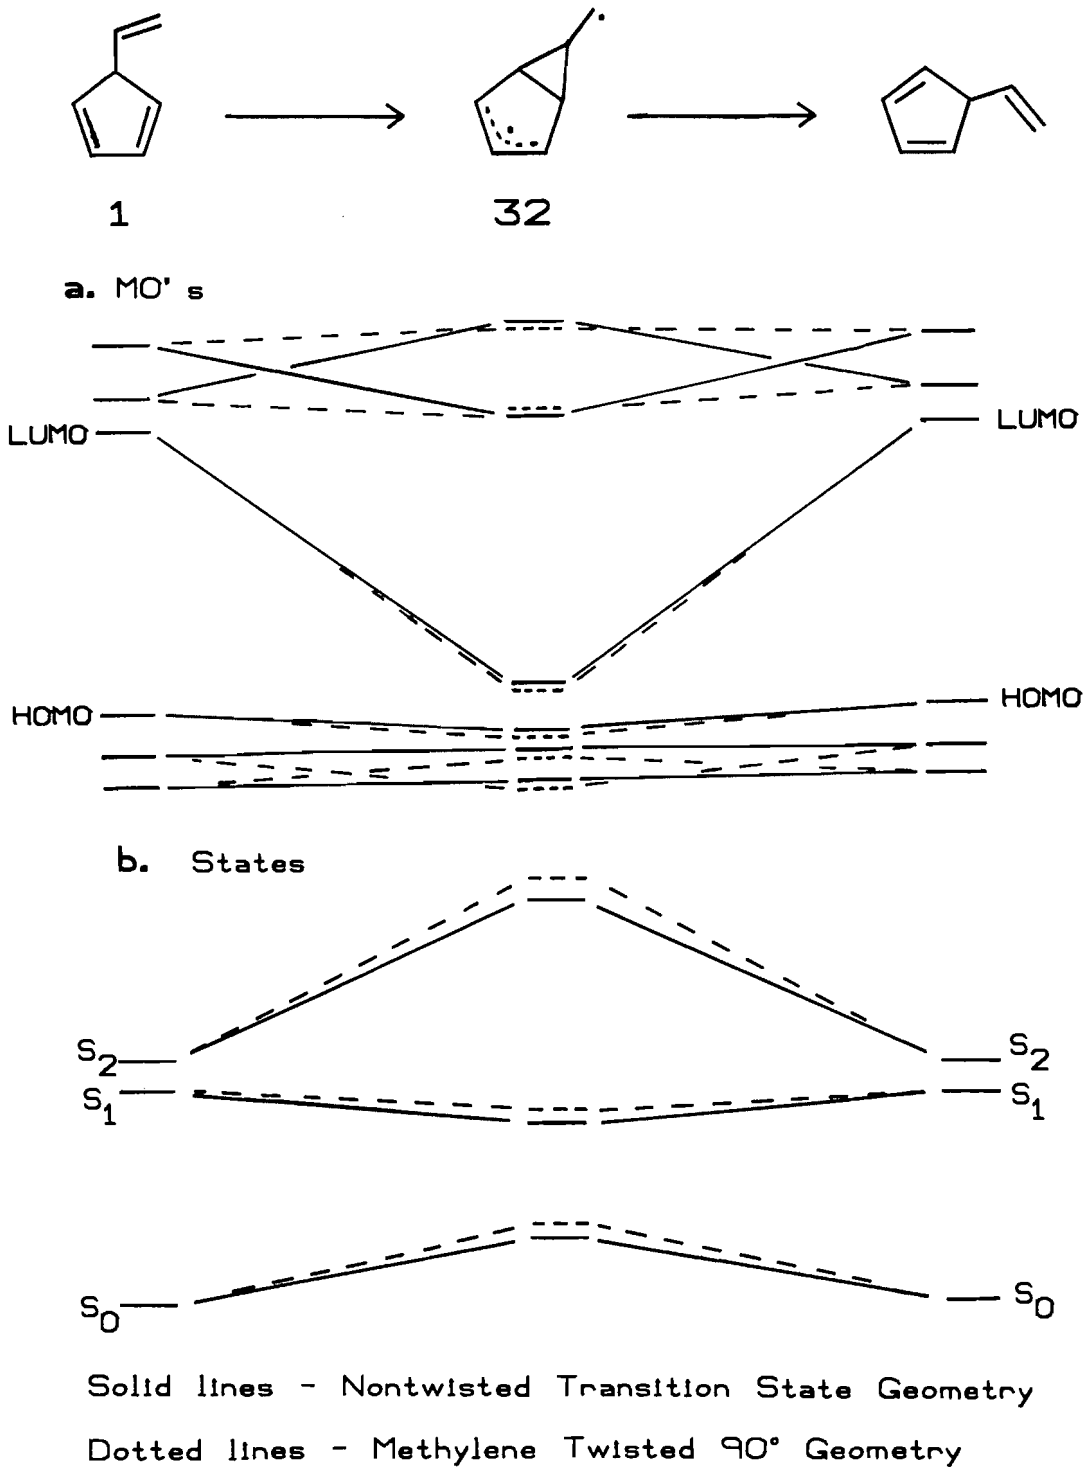

FIG. 6. Correlation diagram for 1,5-vinyl migration.

necting the two *p*-orbitals constituting the origin and terminus of the vinyl shift.

The present case is considerably more complex, and was analyzed by quantum mechanical calculation[12] of the starting vinylcyclopentadiene **1**, the diradical **32**, and the product vinylcyclopentadiene. For simplicity, the calculations were performed on a truncated model with phenyl and methyl groups removed; note Fig. 6a which depicts only the highest few bonding MO's and lowest few antibonding MO's. Figure 6b provides the results of configuration interaction and the state surfaces.

It is seen that there is no crossing of bonding and antibonding MO's although there is a near degeneracy with approach of bonding and antibonding MO's. The situation is quite reminiscent of the correlation obtained in our earlier treatment (32)

[12] (a) All calculations were run on a Digital Equipment VAX/750; (b) To obtain geometry of the species, "Tribble", D. Pensak and J. J. Wendoloski, was employed; (c) SCF and CI calculations were run on "Gamess", as written by M. DuPuis, D. Spangler, and J. J. Wendoloski, NRCC, Berkeley, and modified by M. W. Schmidt and S. T. Elbert, Iowa State University.

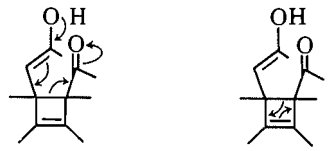

FIG. 7. Equivalency of reverse Michael and electrocyclic processes.

of phenyl migration where the bonding MO rose in energy transiently. The net result in the present system is a correlation diagram which provides an approach of excited and ground state surfaces to provide the bifunnel (12*f*, 12*i*, 12*j*, 29) required for a successful photochemical reaction with decay of the reacting excited state to the S_0 surface. Furthermore, the conclusions appear independent of any terminal twisting of the carbinyl carbon (i.e. the terminal methylene).

One interesting point is that the bridged species is precedented in the cyclopropyldicarbinyl diradicals of the di-π-methane and bicycle rearrangements. In any case, it appears that the reaction is also photochemically allowed.

Finally, the correlation provides a sufficiently low barrier to permit successful thermal rearrangement in a situation quite similar to that observed in the phenyl migration study (32). Hence the reaction is predicted to be thermally allowed, consonant with the experimentally observed facile vinyl migration compared with alkyl shifts (33) and in agreement with literature conclusions.

Interpretation of interesting ground state chemistry encountered

Several observations made in the synthetic portions of this endeavor deserve comment. Both deal with the oxidative degradation of the bicyclic photoproducts **3** (i.e. **A**) and **4** (i.e. **B**); note Schemes 2 and 3. The cyclobutene openings proceeded under very mild conditions.[13] While the ring openings of ketol **16** and diol **20** seem formally to be electrocyclic processes, they also may be considered to be reverse Michael reactions which by precedent are also facile (note Fig. 7). With these two views of the same process, it is clear that an electrocyclic cyclobutene opening should be facile when there is a capable electron donor attached to one sp^3 hybridized ring carbon and an electron withdrawing group attached to the other as in these examples. This point has literature precedent (35).

Finally, selective formation of the tautomers of **17** and **21** in this reaction seems likely to derive from a preferential protonation of the resulting, ring-opened enolate at a site α to the carbonyl, a kinetic preference noted by us (36) quite some years ago.

Experimental

Melting points were determined using a calibrated hot-stage apparatus. Elemental analyses were performed by Galbraith Laboratory, Inc., Knoxville. TE.

All reactions were run under dry nitrogen. High-pressure liquid chromatography (hplc) was performed on a liquid chromatograph employing a LDC 254 nm detector, a LDC 6000 psi minipump, and a 0.95 × 50 cm polished stainless steel column packed with 5–15 μm porous silica micro beads.[14] Column chromatography was performed on silica gel (Matheson, Coleman, and Bell, grade 62, 60–200 mesh) mixed with Sylvania 2282 phosphor and slurry packed into quartz columns permitting monitoring by a hand uv lamp. Preparative thick-layer chromatography was carried out with MN-Kieselgel G/UV 254 silica gel. Acetonitrile and *tert*-butanol utilized for irradiation experiments were distilled from calcium hydride before use. Pentane utilized for irradiation experiments was washed with concentrated sulfuric acid, water, saturated $NaHCO_3$, brine, dried over anhydrous magnesium sulfate, and distilled from calcium hydride. THF was purified by storage over KOH, followed by successive distillation under a nitrogen atmosphere from calcium hydride, lithium aluminium hydride, and sodium/benzophenone ketyl.

Neutral work-up refers to dilution with ether, washing with water and brine, drying over anhydrous magnesium sulfate or sodium sulfate, filtering, and concentration *in vacuo*. Acidic work-up added an initial 5% HCl wash after dilution. Basic work-up added an initial saturated Na_2CO_3 wash after dilution. Basic–acidic work-up used both the acid and base washes after dilution.

5-(Carbomethoxymethyl)-2,3-diphenyl-1,4,5-trimethyl-1,3-cyclopentadiene, 5-(carbomethoxymethyl)-1,2-diphenyl-3,4,5-trimethyl-1,3-cyclopentadiene, and 5-(carbomethoxymethyl)-1,5-diphenyl-2,3,4-trimethyl-1,3-cyclopentadiene

To 33.6 g (0.130 mol) of 4,5-diphenyl-1,2,3-trimethyl-1,3-cyclopentadiene (37) in 200 mL of THF at 0°C was added 90 mL (0.135 mol) of a 1.5 *M* solution of *n*-BuLi in hexane. After 0.5 h, 22.7 g (0.127 mol) of HMPA was added, followed by 19.5 g (0.130 mol) of methyl bromoacetate dropwise. After 18 h at room temperature, acidic work-up gave 49 g of an oil. Trituration with 150 mL of pentane and cooling gave 13.9 g of ester, mp 79–82°C. Recrystallization from ether–hexane gave 10.3 g (24%) of 5-(carbomethoxymethyl)-2,3-diphenyl-1,4,5-trimethyl-1,3-cyclopentadiene, mp 89–89.5°C. The mother liquors were treated as below.

The spectral data were: ir ($CHCl_3$): 3012, 2967, 2932, 2924, 2873, 2857, 1760, 1613, 1577, 1497, 1443, 1324, 1280, 1163, 1090, 1080, 1024 cm^{-1}; H nmr ($CDCl_3$) δ: 6.80–7.35 (m, 10H, arom), 3.52 (s, 3H, —O—CH_3), 2.64 (s, 2H, CH_2), 1.91 (s, 6H, 2 vinyl CH_3), 1.20 (s, 3H, CH_3); Cmr ($CDCl_3$) δ: 170.56, 143.61, 139.90, 136.42, 129.62, 127.52, 126.06, 55.48, 51.04, 40.91, 21.46, 10.80; ms, *m/e*: 332.1777 (calcd. for $C_{23}H_{24}O_2$, *m/e*: 332.1775). *Anal.* calcd. for $C_{23}H_{24}O_2$: C 83.10, H 7.28; found: C 83.26, H 7.29.

Chromatography of 1.68 g of the mother liquors (34.0 g) on a 3 × 230 cm silica gel column eluted with 2 L hexane and 17 L 1% ether–hexane, collecting 40-mL fractions, was monitored at 252 nm to give: fractions 339–368, 248 mg of 5-(carbomethoxymethyl)-1,2-diphenyl-3,4,5-trimethyl-1,3-cyclopentadiene as an oil; 369–373, 16.8 mg of overlap as an oil; 374–388, 129 mg of 5-(carbomethoxymethyl)-2,3-diphenyl-1,4,5-trimethyl-1,3-cyclopentadiene as an oil; 389–398, 89.7 mg of overlap as an oil; 399–413, 90.2 mg of 5-(carbomethoxymethyl)-1,5-diphenyl-2,3,4-trimethyl-1,3-cyclopentadiene as an oil.

Trituration and cooling of fractions 339–368 gave crystals, mp 25–55°C, which were recrystallized from ether–hexane to give 161 mg of 5-(carbomethoxymethyl)-1,2-diphenyl-3,4,5-trimethyl-1,3-cyclopentadiene, mp 54–55°C.

The spectral data were: ir ($CHCl_3$): 3160, 3010, 2970, 2930, 2870, 1725, 1605, 1578, 1498, 1440, 1389, 1327, 1280, 1200, 1150, 1100, 1076, 1020, 910, 693 cm^{-1}; 200-MHz H nmr ($CDCl_3$) δ: 7.00–7.20 (m, 10H, arom), 3.43 (s, 3H, OCH_3), 2.61 (d, J = 13.5 Hz, 1H, —C*H*H—), 2.44 (d, J = 13.5 Hz, 1H, —CH*H*—), 1.81 (bs, 3H, vinyl CH_3), 1.68 (bs, 3H, vinyl CH_3), 1.13 (s, 3H, CH_3); Cmr ($CDCl_3$) δ: 170.63, 147.00, 143.64, 142.20, 137.02, 136.58, 133.45, 130.25, 129.42, 127.50, 126.12, 56.14, 51.02, 40.16, 21.71, 12.07, 10.36; ms, *m/e*: 332.1777 (calcd. for $C_{23}H_{24}O_2$, *m/e*: 332.1775). *Anal.* calcd. for $C_{23}H_{24}O_2$: C 83.10, H 7.28; found: C 83.25, H 7.45.

[13] Phenyl substitution on the cyclobutene double bond seems not to affect the facility of electrocyclic opening, while such substitution on the sp^3 carbons markedly lowers the activation energy (34*a–e*) by ca. 5–6 kcal/mol per phenyl group (34*e*). Thus the 1,2,3,4-tetraphenylcyclobutene stereoisomers open at room temperature (34*b–d*).

Fractions 388–413 were further purified by hplc, eluting with 20% ether–pentane at 1.8 mL/min collecting the major band, k' 0.84, cutting fronts and tails to give 71.5 mg of 5-(carbomethoxymethyl)-1,5-diphenyl-2,3,4-trimethyl-1,3-cyclopentadiene as an oil.

The spectral data were: ir (thin film): 3085, 3060, 3025, 2975, 2950, 2917, 2858, 1740, 1727, 1592, 1485, 1435, 1368, 1317, 1270, 1220, 1178, 1155, 1080, 1060, 1039, 1020, 998, 940, 918, 898, 840, 810, 772, 746, 728, 685, 625 cm^{-1}; 270-MHz H nmr ($CDCl_3$) δ: 6.75–7.25 (m, 10H, arom), 3.46 (s, 3H, —OCH_3), 2.99 (d, J = 12.2 Hz, 1H, —C*H*H—), 2.87 (d, J = 12.2 Hz, 1H, —CH*H*—), 1.95 (s, 3H, C-2 CH_3), 1.89 (bs, 3H, vinyl CH_3), 1.64 (bs, 3H, vinyl CH_3); Cmr ($CDCl_3$) δ: 170.25, 145.41, 143.38, 140.07, 139.63, 136.33, 136.16, 129.12, 128.23, 127.35, 126.14, 125.98, 63.43, 50.88, 37.06, 12.66, 11.12, 10.46; ms, *m/e*: 332.1770 (calcd. for $C_{23}H_{24}O_2$, *m/e*: 332.1775). *Anal.* calcd. for $C_{23}H_{24}O_2$: C 83.10, H 7.28; found: C 82.93, H 7.24.

2,3-Diphenyl-5-(2-hydroxyethyl)-1,4,5-trimethyl-1,3-cyclopentadiene

To 12.3 g (37.0 mmol) of 5-(carbomethoxymethyl)-2,3-diphenyl-1,4,5-trimethyl-1,3-cyclopentadiene in 250 mL of ether at 0°C was added 0.920 g (24.2 mmol) of LAH. After stirring 3.5 h, 150 mL of 10% HCl was slowly added, and neutral work-up gave 11.0 g of alcohol, mp 88–100°C. Decolorization with charcoal and recrystallization from ether–hexane gave 8.67 g (77%) of 2,3-diphenyl-5-(2-hydroxyethyl)-1,4,5-trimethyl-1,3-cyclopentadiene, mp 117–118°C.

The spectral data were: ir ($CHCl_3$): 3154–3700, 3058, 3003, 2958, 2932, 1949, 1859, 1742, 1709, 1642, 1558, 1495, 1445, 1385, 1360, 1340, 1241, 1060, 1012, 943 cm^{-1}; H nmr ($CDCl_3$) δ: 6.80–7.35 (m, 10H, arom), 3.36 (t, J = 6.9 Hz, 2H, CH_2—C*H*$_2$—O), 2.04 (t, J = 6.9 Hz, 2H, C*H*$_2$—CH_2—O), 1.90 (s, 6H, 2 vinyl CH_3), 1.60 (bs, 1H, —OH), 1.18 (s, 3H, C-5 CH_3); Cmr ($CDCl_3$) δ: 144.81, 139.72, 136.18, 129.60, 127.61, 126.15, 60.268, 56.030, 38.698, 22.502, 10.992; ms, *m/e*: 304.1828 (calcd. for $C_{22}H_{24}O$, *m/e*: 304.1826). *Anal.* calcd. for $C_{22}H_{24}O$: C 86.80, H 7.95; found: C 87.00, H 8.02.

2,3-Diphenyl-5-(2-methanesulfonylethyl)-1,4,5-trimethyl-1,3-cyclopentadiene

To 9.78 g (32.1 mmol) of 2,3-diphenyl-5-(2-hydroxyethyl)-1,4,5-trimethyl-1,3-cyclopentadiene and 6.5 g (64 mmol) of triethylamine in 150 mL methylene chloride at 0°C was added 5.51 g (48.1 mmol) of methanesulfonyl chloride dropwise. After 2 h, acidic work-up gave a semi-solid. Chromatography on a 5 × 35 cm silica gel column eluted with 500 mL of 20% methylene chloride – hexane, 500 mL of 30% methylene chloride – hexane, and 7 L of 50% methylene chloride – hexane gave 11.25 g (92%) 2,3-diphenyl-5-(2-methanesulfonylethyl)-1,4,5-trimethyl-1,3-cyclopentadiene, mp 103–117°C, as the first band. Recrystallization from ether–hexane brought the mp to 116–117°C.

The spectral data were: ir ($CHCl_3$): 3021, 2958, 2924, 2865, 1751, 1721, 1698, 1639, 1610, 1492, 1462, 1445, 1360, 1339, 1230, 1181, 1080, 1055, 1024, 980, 961 cm^{-1}; H nmr ($CDCl_3$) δ: 6.80–7.40 (m, 10H, arom), 3.84 (t, J = 6.6 Hz, 2H, CH_2—C*H*$_2$—O), 2.89 (s, 3H, SCH_3), 2.20 (t, J = 6.6 Hz, 2H, C*H*$_2$—CH_2—O), 1.89 (s, 6H, 2 vinyl CH_3), 1.20 (s, 3H, C-5 CH_3); ms, *m/e*: 382.1601 (calcd. for $C_{23}H_{26}O_3S$, *m/e*: 382.1601). *Anal.* calcd. for $C_{23}H_{26}O_3S$: C 72.22, H 6.85; found: C 72.30, H 6.85.

2,3-Diphenyl-1,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene

To 11.1 g (29.1 mmol) of 2,3-diphenyl-5-(2-methanesulfonylethyl)-1,4,5-trimethyl-1,3-cyclopentadiene in 125 mL of DMSO at 0°C was added 5.60 g (50.0 mmol) of potassium *tert*-butoxide. After 8 h at room temperature, an additional 5.60 g of potassium *tert*-butoxide was added. After 2.5 h more, 100 mL of saturated NH_4Cl was added, and neutral work-up gave 8.13 g of an oil which crystallized on standing, mp 66–79°C. Chromatography on a 3 × 30 cm silica gel column eluted with hexane gave 6.75 g of product, mp 78–80°C, as the first band. Recrystallization from pentane gave 5.16 g (62%) of 2,3-diphenyl-1,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene, mp 79.5–80.0°C.

The spectral data were: ir ($CHCl_3$): 3077, 3003, 2967, 2932, 2907, 2849, 1631, 1608, 1492, 1445, 1195, 1080, 1015, 917 cm^{-1}; uv (EtOH): 226 (sh, ε 15 700), 234 (ε 17 200), 256 (sh, ε 5160) nm; 200-MHz H nmr ($CDCl_3$) δ: 6.95–7.40 (m, 10H, arom), 5.40 (dd, J = 18.5, 10.0 Hz, 1H, C*H*=CH_2), 5.10–5.30 (m, 2H, —CH=C*H*$_2$), 1.82 (s, 6H, 2 vinyl CH_3), 1.25 (s, 3H, C-5 CH_3); Cmr ($CDCl_3$) δ: 144.35, 140.93, 139.77, 136.29, 129.56, 127.46, 126.02, 113.66, 60.72, 17.20, 12.20; ms *m/e*: 286.1722 (calcd. for $C_{22}H_{22}$, *m/e*: 286.1720). *Anal.* calcd. for $C_{22}H_{22}$: C 92.26, H 7.74; found: C 92.06, H 7.82.

1,2-Diphenyl-5-(2-hydroxyethyl)-3,4,5-trimethyl-1,3-cyclopentadiene

To 773 mg (2.32 mmol) of 5-(carbomethoxymethyl)-1,2-diphenyl-3,4,5-trimethyl-1,3-cyclopentadiene in 25 mL of ether at 0°C was added 66.3 mg (1.74 mmol) of LAH. After 3 h, 5.0 g (14 mmol) of sodium sulfate decahydrate was added. After 2 h more, acidic work-up gave 710 mg of an oil; hplc eluting with 20% ether – 40% pentane – 40% methylene chloride gave a major band, k' 3.1, 381 mg of an oil. Trituration and cooling with pentane gave 342 mg (48%) of 1,2-diphenyl-5-(2-hydroxyethyl)-3,4,5-trimethyl-1,3-cyclopentadiene, mp 106–107°C.

The spectral data were: ir ($CHCl_3$): 3610, 3300–3580, 3055, 3000, 2960, 2920, 2860, 1605, 1578, 1500, 1450, 1390, 1373, 1347, 1110, 1082, 1060, 1042, 1023, 1009, 999, 975, 920, 704 cm^{-1}; 270-MHz H nmr (C_6D_6) δ: 6.90–7.20 (m, 10H, arom), 3.41 (ddd, J = 14.1, 8.55, 5.70 Hz, 1H, CH_2—C*H*H—OH), 3.29 (ddd, J = 14.3, 8.30, 6.17 Hz, 1H, CH_2—CH*H*—OH), 2.03 (ddd, J = 13.7, 8.18, 5.64 Hz, 1H, C*H*H—CH_2OH), 1.78 (m, 1H, —CH*H*—CH_2OH), 1.76 (bs, 3H, vinyl CH_3), 1.73 (bs, 3H, vinyl CH_3), 1.15 (s, 3H, C5-CH_3); ms *m/e*: 304.1828 (calcd. for $C_{22}H_{24}O$, *m/e*: 304.1826). *Anal.* calcd. for $C_{22}H_{24}O$: C 86.80, H 7.95; found: C 86.62, H 7.91.

1,2-Diphenyl-5-(2-(2-nitroselenophenyl)ethyl)-3,4,5-trimethyl-1,3-cyclopentadiene

Following the general method of Grieco *et al.* (38), to 396 mg (1.30 mmol) of 1,2-diphenyl-5-(2-hydroxyethyl)-3,4,5-trimethyl-1,3-cyclopentadiene and 352 mg (1.55 mmol) of 2-nitrophenylselenocyanate (39) in 5.0 mL of THF at room temperature was added, dropwise, 313 mg (1.55 mmol) of tri-*n*-butylphosphine. After 3 h, concentration *in vacuo* gave 1.13 g of a red oil which was chromatographed on a 1 × 60 cm silica gel column eluted with 100 mL of hexane, 100 mL of 5% ether–hexane, and 400 mL of 10% ether–hexane collecting the initial band to yield 467 mg of an oil. Crystallization from hexane gave 427 mg (67%) of 1,2-diphenyl-5-(2-(2-nitroselenophenyl)ethyl)-3,4,5-trimethyl-1,3-cyclopentadiene, mp 136–138°C.

The spectral data were: ir (thin film): 3060, 3030, 2970, 2930, 2870, 1599, 1572, 1520, 1510, 1468, 1460, 1450, 1440, 1340, 1314, 1260, 1180, 1109, 1083, 1048, 920, 861, 792, 761, 740, 710 cm^{-1}; 200-MHz H nmr ($CDCl_3$) δ: 8.16–8.30 (m, 1H, *o*-NO_2 H), 7.00–7.30 (m, 13H, arom), 2.63 (td, J = 13.0, 5.0 Hz, 1H, CH_2—C*H*H—Se), 2.35 (td, J = 13.0, 5.0 Hz, 1H, —CH_2—CH*H*—Se), 1.90–2.20 (m, 2H, C*H*$_2$—CH_2—Se), 1.89 (bs, 3H, vinyl CH_3), 1.88 (bs, 3H, vinyl CH_3), 1.30 (s, 3H, C-5 CH_3); ms, *m/e*: 489.1208 (calcd. for $C_{28}H_{27}NO_2Se$, *m/e*: 489.1205). *Anal.* calcd. for $C_{28}H_{27}NO_2Se$: C 68.84, H 5.57; found: C 68.70, H 5.76.

1,2-Diphenyl-3,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene

Following the general method of Reich *et al.* (40), to a rapidly stirred solution of 410 mg (0.839 mmol) of 1,2-dimethyl-5-(2-(2-nitroselenophenyl)ethyl)-3,4,5-trimethyl-1,3-cyclopentadiene and 130 mg (1.70 mmol) of pyridine in 5.0 mL of methylene chloride at room temperature was added 250 mg (2.24 mmol) of 30% H_2O_2. After 36 h, basic–acidic work-up gave 362 mg of an oil which was chromatographed on a 1 × 70 cm silica gel column eluted with hexane in 100-mL fractions. Fraction 1, nil; 2, 66.1 mg of colorless product, mp 55–73°C; 3, 69.1 mg of more product as an orange oil (total crude yield 56%). Recrystallization of fraction 2 from pentane gave 48.1 mg of 1,2-diphenyl-3,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene, mp 78–79°C.

The spectral data were: ir ($CHCl_3$): 3775, 3445, 2990, 2960, 2915,

General procedure for exploratory photolysis

All direct and sensitized exploratory irradiations were performed using a 450-W medium-pressure mercury lamp immersion apparatus fitted with a Pyrex filter sleeve and cooled with a recirculating filter solution. The filter solutions employed were: Filter A, 0.0020 *M* sodium metavanadate in 0.1 *M* NaOH; transmission, 0% below 300 nm, 40% at 328 nm, 90% above 370 nm; Filter B, 0.020 *M* sodium metavanadate in 0.10 *M* NaOH; transmission, 0% below 340 nm, 90% above 380 nm; Filter C, 0.010 *M* $FeCl_3$ in 0.5 *M* HCl; transmission, 0% below 380 nm, 3.0% at 420 nm, 55% above 460 nm. The filter solutions remained unchanged after photolysis. All runs were purged with purified nitrogen (41) for at least 1 h before and during photolysis and the temperature was monitored during the run using a calibrated thermistor.

Exploratory direct photolysis of 2,3-diphenyl-1,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene

Run A, at 30°C

Using the general photolysis procedure, 300 mg (1.05 mmol) of 2,3-diphenyl-1,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene in 230 mL of *tert*-butanol was irradiated through Filter A for 17 h at 30 ± 2°C. Concentration *in vacuo* gave 311 mg of a yellow oil which was chromatographed on a 3 × 100 cm 7% (by weight) silver nitrate – silica gel column, gradient eluted with ether–hexane, collecting 40 mL fractions and monitoring at 240 nm. Column fraction compositions were determined by integration of their 200-MHz nmr spectra. Fractions 1–280, 0% (per cent ether–hexane), nil; 281–331, 0.5%, 4.8 mg of an unidentified oil; 332–338, 0.5%, 7.0 mg of an oil, nearly pure photoisomer **D**; 339–346, 0.5%, 24.9 mg of an oil, 65% photoisomer **D** and 35% photoisomer **A**; 347–394, 0.5%, 96.0 mg, mp 77–94°C, nearly pure photoisomer **A**; 395–414, 1%, 24.6 mg of an oil, 72% photoisomer **A** and 27% photoisomer **C**; 415–442, 1%, 27.6 mg, mp 35–62°C, 87% recovered starting material, 9% photoisomer **C**, and 5% photoisomer **A**; 443–460, 1%, 9.5 mg, mp 65–77°C, nearly pure recovered starting material; 461–506, 3%, 29.9 mg, mp 47–66°C, 52% recovered starting material and 37% photoisomer **B**; 507–540, 5%, 31.7 mg, mp 30–62°C, nearly pure photoisomer **B**; 541–601, 5%, 30.7 mg of an oil, 50% photoisomer **B** and 50% unidentified material. Results: 52.0 mg of recovered starting material, 123.8 mg of photoisomer **A**, 58.1 mg of photoisomer **B**, 23.2 mg of photoisomer **D**, and 9.1 mg of photoisomer **C**. Mass balance: 89%.

Recrystallization of fractions 347–394 from pentane gave 51.2 mg of 5,6-diphenyl-1,2,7-trimethylbicyclo[3.2.0]hepta-2,6-diene (photoisomer **A**), mp 98–99°C.

Recrystallization of fractions 507–540 from ether–pentane gave 19.5 mg of 1,5-diphenyl-2,6,7-trimethylbicyclo[3.2.0]hepta-2,6-diene (photoisomer **B**), mp 90–91°C.

High-pressure liquid chromatography, using 1% isopropanol–pentane, of fractions 332–338 combined with the corresponding fractions from 2 identical photolysates (total of 27.1 mg), collecting the center of the major band, gave 19.8 mg of 1,7-diphenyl-2,5,6-trimethylbicyclo[3.2.0]hepta-2,6-diene (photoisomer **D**) as an oil.

High-pressure liquid chromatography of fractions 395–414 eluting with 6% methylene chloride – pentane at a flow rate of 2.4 mL/min yielded fraction 1, k' 1.75, 4.2 mg of 6,7-diphenyl-1,2,5-trimethylbicyclo[3.2.0]hepta-2,6-diene (photoisomer **C**) as an oil; 2, k' 2.47, photoisomer **A**.

The spectral data for 5,6-diphenyl-1,2,7-trimethylbicyclo[3.2.0]-hepta-2,6-diene were: ir ($CHCl_3$): 3085, 3062, 3008, 2965, 2920, 2850, 1600, 1493, 1447, 1583, 1572, 1520, 1495, 1208, 1133, 1095, 1082, 1070, 1038, 1021, 1008, 998, 945, 910, 812, 690 cm^{-1}; uv (EtOH) 217 (sh, ε 15 900), 268 (ε 10 900) nm; 200-MHz H nmr ($CDCl_3$) δ: 6.60–7.20 (m, 10H, arom), 5.40 (bs, 1H, vinyl), 2.90 (qd, J = 2.21, 1.10 Hz, 2H, CH_2), 2.08 (s, 3H, C-7 CH_3), 1.75 (td, J = 2.40, 1.47 Hz, 3H, C-2 CH_3), 0.647 (s, 3H, C-1 CH_3); Cmr ($CDCl_3$) δ: 149.84, 144.23, 143.06, 137.96, 134.22, 128.90, 127.80, 127.07, 126.24, 125.59, 124.88, 65.78, 59.98, 39.59, 14.94, 13.17; ms, m/e: 286.1713 (calcd. for $C_{22}H_{22}$, m/e: 286.1720). *Anal.* calcd. for $C_{22}H_{22}$: C 92.26, H 7.74; found: C 92.31, H 7.90.

The spectral data for 1,5-diphenyl-2,6,7-trimethylbicyclo[3.2.0]-hepta-2,6-diene were: ir ($CHCl_3$): 3040, 3004, 2918, 2853, 1606, 1497, 1450, 1382, 1314, 1158, 1122, 1085, 1040, 1030, 973, 954, 840, 830, 903; uv (EtOH) 254 (ε 182), 261 (ε 208), 267 (ε 156), 272 (ε 113) nm; 200-MHz H nmr ($CDCl_3$) δ: 6.77–7.06 (m, 10H, arom), 5.61 (m, 1H, vinyl), 2.85 (ddq, J = 18.0, 2.2, 2.2 Hz, 1H, CHH), 2.63 (ddq, J = 18.0, 2.2, 2.2 Hz, 1H, CHH), 1.86 (bs, 3H, C-7 CH_3), 1.84 (bs, 3H, C-6 CH_3), 1.73 (bq, J = 2.16 Hz, 3H, C-2 CH_3); Cmr ($CDCl_3$) δ: 145.90, 143.08, 139.77, 139.16, 128.44, 127.50, 127.34, 127.22, 126.51, 125.40, 125.12, 75.52, 65.80, 37.84, 15.80, 11.60, 9.45; ms, m/e: 286.1722 (calcd. for $C_{22}H_{22}$, m/e: 286.1720. *Anal.* calcd. for $C_{22}H_{22}$: C 92.26, H 7.74; found: C 92.33, H 7.79.

The spectral data for 1,7-diphenyl-2,5,6-trimethylbicyclo[3.2.0]-hepta-2,6-diene were: ir ($CHCl_3$): 3070, 3045, 2990, 2950, 2900, 2850, 2830, 1645, 1595, 1492, 1445, 1375, 1305, 1170, 1105, 1080, 1025, 995, 960, 945, 910, 830, 695 cm^{-1}; uv (EtOH): 216 (ε 25 000), 266 (ε 17 000), 295 (sh, ε 1300) nm; 200-MHz H nmr ($CDCl_3$) δ: 7.05–7.40 (m, 10H, arom), 5.46 (bs, 1H, vinyl), 2.42 (bd, J = 16 Hz, 1H, CHH), 2.05 (bd, J = 16 Hz, 1H, CHH), 2.05 (s, 3H, C-6 CH_3), 1.78 (bs, 3H, C-2 CH_3), 0.67 (s, 3H, C-5 CH_3); Cmr ($CDCl_3$) δ: 145.30, 143.54, 143.38, 140.13, 134.84, 128.40, 127.79, 127.57, 126.86, 126.69, 126.09, 125.54, 70.588, 56.822, 38.377, 20.041, 16.462, 11.287; ms, m/e: 286.1722 (calcd. for $C_{22}H_{22}$, m/e: 286.1720). *Anal.* calcd. for $C_{22}H_{22}$: C 92.26, H 7.74; found: C 91.96, H 8.02.

Run B, at 8°C

Using the general photolysis procedure, 305 mg (1.06 mmol) of 2,3-diphenyl-1,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene in 270 mL of acetonitrile was irradiated through Filter A for 18.25 h. The photolysis well was externally cooled with recirculating ice-water. The temperature inside the well during the run was found to be 8–9°C. Concentration *in vacuo* gave 318 mg of a yellow oil which was chromatographed on a 2.5 × 100 cm 10% (by weight) silver nitrate – silica gel column, collecting 40 mL fractions monitoring at 244 nm. Column fraction compositions were determined by integration of their 200-MHz H nmr spectrum. Fractions 1–383, 0% (per cent ether–hexane), nil; 384–408, 0%, 10.6 mg of an oil, nearly pure photoisomer **D**; 409–429, 1%, 15.1 mg of an oil, 25% photoisomer **D** and 75% photoisomer **A**; 430–441, 1%, 8.2 mg, mp 38–70°C, 16% photoisomer **C** and 84% photoisomer **A**; 442–470, 1%, 43.5 mg, mp 25–42°C, 12% photoisomer **C**, 25% photoisomer **A**, and 62% recovered starting material; 471–494, 1%, 17.9 mg, mp 46–65°C, recovered starting material; 495–518, 1%, 6.3 mg, mp 52–68°C, recovered starting material; 519–541, 1%, 15.4 mg, mp 37–54°C, 18% recovered starting material and 82% photoisomer **B**; 542–589,

1.5%, 42.1 mg, mp 34–59°C, photoisomer **B**; 590–663, 1.5%, 45.1 mg, mp 28–51°C, photoisomer **B** and 20% unidentified material; 664–686, 2%, 1.5 mg, mp 25–34°C, 60% photoisomer **B** and 40% unidentified material; 687–738, 2%, 12.0 mg of an oil containing some photoisomer **B**. Results: 54.0 mg recovered starting material, 29.1 mg of photoisomer **A**, 91.7 mg of photoisomer **B**, 14.4 mg of photoisomer **D**, and 6.5 mg of photoisomer **C**. Mass balance: 64%.

Run C, at −70°C

Using a low temperature photolysis apparatus (consisting of a toroidal 100-mL Pyrex vessel with two ground-glass joint openings fused to a Pyrex cyclinder of the same id, closed on the bottom with dimensions such that a Hanovia lamp well fit down the center of the apparatus with the lamp center coincident with the toroid's center, note Figure 8), 91.1 mg (0.318 mmol) of 2,3-diphenyl-1,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene in 100 mL of pentane was irradiated for 2.6 h in a −78°C bath using the general photolysis procedure through Filter A. After photolysis, the solution was kept at −78°C for 1.5 h with continued nitrogen purging, then at room temperature for 5 h. Concentration *in vacuo* gave 93.4 mg of an oil; hplc eluting with 6% methylene chloride – pentane at 2.4 mL/min gave: fraction 1, k' 1.8, 47.1 mg (52%) of recovered starting material, mp 64–73°C; 2, k' 2.1, 20.0 mg (22%) of a 4:1 mixture of 1,2-diphenyl-3,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene (16 mg, 17.6%) and starting material as an oil; 3, k' 2.6, 8.3 mg (9.1%) of an oil containing small amounts of 1,2-diphenyl-3,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene and photoisomer **A**, along with at least two unknown products.

Exploratory p-*dimethylaminobenzophenone sensitized photolysis of 2,3-diphenyl-1,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene*

Using the general photolysis procedure, 100 mg (0.349 mmol) of 2,3-diphenyl-1,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene and 0.391 g (1.74 mmol) of *p*-dimethylaminobenzophenone in 260 mL of *tert*-butanol was irradiated through Filter B at 31°C for 25 min. After concentration *in vacuo*, the residue was chromatographed on a 3 × 50 cm silica gel column eluted with 1 L of hexane, 500 mL of 1% ether–hexane, 500 mL of 2% ether–hexane, 1 L of 5% ether–hexane, and 500 mL of 10% ether–hexane collecting 500-mL fractions. Fraction 2 gave 94.8 mg (95%) of product, mp 69–72°C, fractions 8 and 9 gave 397 mg recovered *p*-dimethylaminobenzophenone, mp 70–86°C. Other fractions contained no material. Recrystallization of fraction 2 from hexane gave 48.2 mg of 1,2-diphenyl-3,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene, mp 77–78.5°C, whose spectral data were identical with those of independently synthesized material (*vide supra*).

Exploratory direct photolysis of 1,2-diphenyl-3,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene

Using the general photolysis procedure, 300 mg (1.046 mmol) of 1,2-diphenyl-3,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene in 270 mL of acetonitrile was irradiated through Filter B at 31°C for 20 min. After concentration *in vacuo*, 305 mg, mp 53–68°C, were obtained. 200-MHz H nmr analysis showed 95% 2,3-diphenyl-1,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene and ca. 5% bicyclics. Recrystallization from ether–pentane gave 173 mg (58%) of 2,3-diphenyl-1,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene, mp 77–79°C, identical in all respects to independently synthesized material (*vide supra*).

Exploratory sensitized photolysis of 1,2-diphenyl-3,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene

Using the general photolysis procedure, 63.0 mg (0.220 mmol) of 1,2-diphenyl-3,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene and 295 mg (1.10 mmol) of *p*-dimethylaminobenzophenone in 260 mL of acetonitrile were irradiated through Filter C at 31°C for 6 h. After concentration *in vacuo*, 375.5 mg, mp 152–162°C, were obtained. Chromatography on a 1 × 65 cm silica gel column eluted with 250 mL 5% ether–hexane, and 1 L ether, collecting 75-mL fractions: 1, nil; 2, 58.0 mg of starting material; 3, nil; 4–13, 295 mg of recovered sensitizer, mp 148–162°C.

Photolysis apparatus for quantum yield determinations

All quantum yield determinations were run on the microoptical bench (42). Light output was measured for each run by digital electronic actinometer (43) calibrated by ferrioxalate actinometry (44). Photolyses employed an Osram HBO 200-W high-pressure mercury lamp and a Bausch and Lomb Model 33-86-79 high intensity monochromator. All quantum yield photolyses were in 40 mL of *tert*-butanol, were purged with purified nitrogen (41) for 1 h before and during each run, and were maintained at 30°C using a jacketed cell and a recirculating constant temperature apparatus. Runs were analyzed by 200-MHz H nmr, expanded peaks being integrated using a Summagraphics Bit Pad interfaced with a PDP-11/T55 computer. The internal standard employed was methyl diphenylglycolate.

Summary of direct quantum yield results for 2,3-diphenyl-1,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene

All runs were conducted at 315 nm with a 3.6-mm entrance slit and 2.0-mm exit slit (half-height band pass, 15 nm). All runs are reported in Table 2.

Summary of p-*dimethylaminobenzophenone sensitized quantum yield results for 2,3-diphenyl-1,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene*

Photolyses were conducted at 370 nm with a 3.6-mm entrance slit and 4.0-mm exit slit (band pass, 0% transmittance beyond ±30 nm). *p*-Dimethylaminobenzophenone, absorbing ≥ 99% of the light, was used as the sensitizer. After concentrating the photolysates *in vacuo*, the sensitizer was removed by column chromatography on a 2 × 40 cm silica gel column using pentane and collecting all of the intial band. Runs are reported in Table 3.

Thermolysis of 2,3-diphenyl-1,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene

A solution of 103 mg (0.360 mmol) of 2,3-diphenyl-1,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene in 15 mL of benzene was refluxed for 23 h. Concentration *in vacuo* gave 127 mg of an oil. 200-MHz H nmr analysis revealed a 1:1 mixture of starting material and 1,2-diphenyl-3,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene. High-pressure liquid chromatography eluting with 6% methylene chloride – pentane at a flow rate of 2.3 mL/min gave: 1, k' 2.18, 39.6 mg of recovered starting material, mp 64–74°C; 2, k' 2.48, 52.1 mg of 1,2-diphenyl-3,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene, mp 54–63°C. crystallization of fraction 1 from pentane gave 30.3 mg of recovered starting material (29%), mp 78–80°C. Recrystallization of fraction 2 from ether–pentane gave 42.2 mg of product (41%), mp 77–78°C.

Thermolysis of 1,2-diphenyl-3,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene

A solution of 41.7 mg (0.146 mmol) of 1,2-diphenyl-3,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene in 1.0 mL of benzene was refluxed for 24 h. Concentration *in vacuo* gave 44.0 mg of an oil. 200-MHz H nmr analysis revealed a 1.1:1 mixture of starting material and 2,3-diphenyl-1,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene.

2,3-(exo,exo)-Dihydroxy-5,6-diphenyl-1,2,7-trimethylbicyclo[3.2.0]hept-6-ene

Using a modification of the general method of Ray and Matteson (45), a mixture of 142 mg (0.495 mmol) of photoproduct **A**, 95 mg (0.86 mmol) of trimethylamine *N*-oxide dihydrate, 2 mg (0.008 mmol) of osmium tetroxide, 0.15 mL of pyridine, 0.3 mL of water, and 2 mL of *tert*-butanol were heated with stirring at 80°C for 6 h. After cooling, 5 mL of saturated sodium bisulfite solution were added, and neutral work-up gave 179 mg of an oil, which was chromatographed on a 7 × 20 cm silica gel thick-layer plate eluted with 50% ether–hexane to give: 1, R_f 0.8, 15.2 mg of an unidentified oil; 2, R_f 0.5, 21 mg (13%) of crude 5,6-diphenyl-2-*exo*-hydroxy-1,2,7-trimethylbicyclo[3.2.0]hept-6-en-3-one (note below for identification), as an oil; 3, R_f 0.2, 102.3 mg (64%) of diol as an oil. Recrystallization of fraction 3 from ether–hexane gave 84.1 mg (53%) of 2,3-*exo,exo*-dihydroxy-5,6-diphenyl-1,2,7-trimethylbicyclo[3.2.0]hept-6-ene, mp 116–117°C.

The spectral data were: ir (thin film): 3610, 3542, 3440 (br), 3080, 3058, 3000, 2960, 2925, 2885, 1602, 1497, 1450, 1382, 1371, 1235, 1117, 1082, 1060, 1038, 1010, 960, 915, 885, 828, 704 cm^{-1}; H nmr ($CDCl_3$) δ: 6.80–7.40 (m, 10H, arom), 4.02 (dd, J = 6.3, 10.0 Hz, 1H, —C*H*OH—), 2.20–2.60 (bs, 2H, 2—OH's), 2.48 (dd, J = 6.3, 12.0 Hz, 1H, C*H*H), 2.26 (dd, J = 10.0, 12.0 Hz, 1H, CH*H*), 1.87 (s, 3H, C-7 CH_3), 1.20 (s, 3H, C-2 CH_3), 0.67 (s, 3H, C-1 CH_3); Cmr ($CDCl_3$) δ: 141.56, 141.42, 139.02, 133.74, 128.25, 127.87, 127.69, 126.99, 126.61, 125.73, 77.85, 76.44, 61.23, 57.96, 36.35, 21.58, 12.91, 11.51; ms, *m/e*: 320.1776 (calcd. for $C_{22}H_{24}O_2$, *m/e*: 320.1775). *Anal.* calcd. for $C_{22}H_{24}O_2$: C 82.46, H 7.55; found: C 82.68, H 7.64.

5,6-Diphenyl-2-exo-hydroxy-1,2,7-trimethylbicyclo[3.2.0]hept-6-en-3-one

Using the general method of Corey and Kim (46), to a slurry of 147 mg (1.10 mmol) of *N*-chlorosuccinimide in 3.0 mL of toluene at 0°C, 143 mg (2.30 mmol) of dimethyl sulfide was added. After cooling to −20°C, 133 mg (0.146 mmol) of 2,3-*exo,exo*-dihydroxy-5,6-diphenyl-1,2,7-trimethylbicyclo[3.2.0]hept-6-ene in 1 mL of toluene was added dropwise. After 2 h, 110 mg (1.10 mmol) of triethylamine was added dropwise, the mixture stirred 1 h at −20°C, then warmed to room temperature over 2 h. Neutral work-up gave 154 mg of an oil which was chromatographed on a 20 × 20 cm silica gel thick-layer plate eluted twice with 30% ether–hexane to give: 1, R_f 0.9, 11.2 mg of an unidentified oil; 2, R_f 0.6, 94 mg of product, mp 51–53°C; 3, R_f 0.1, 19.0 mg of recovered starting material as an oil. Recrystallization of fraction 2 from 20% ether–hexane gave 76.7 mg (58%) of 5,6-diphenyl-2-*exo*-hydroxy-1,2,7-trimethylbicyclo[3.2.0]-hept-6-en-3-one, mp 160.5–161.5°C.

The spectral data were: ir ($CHCl_3$): 3575, 3450 (br), 3078, 3050, 3012, 3000, 2980, 2960, 2920, 2858, 1742, 1651, 1600, 1495, 1445, 1408, 1380, 1370, 1322, 1292, 1183, 1130, 1112, 1080, 1070, 1009, 998, 939, 922, 883, 810, 697 cm^{-1}; uv (EtOH): 216 (sh, ε 12 000), 224 (sh, ε 9100), 256 (sh, ε 8900), 265 (ε 10 400), 277 (sh, ε 6900), 292 (sh, ε 550) nm; H nmr ($CDCl_3$) δ: 7.00–7.60 (m, 10H, arom), 3.54 (d, J = 18.0 Hz, 1H, C*H*H), 2.83 (d, J = 18.0 Hz, 1H, CH*H*), 2.50 (bs, 1H, —OH), 2.04 (s, 3H, C-7 CH_3), 1.35 (s, 3H, C-2 CH_3), 0.83 (s, 3H, C-1 CH_3); ms, *m/e*: 318.1619 (calcd. for $C_{22}H_{22}O_2$, *m/e*: 318.1619). *Anal.* calcd. for $C_{22}H_{22}O_2$: C 82.99, H 6.94; found: C 82.70, H 7.04.

Single-crystal X-ray structures of 5,6-diphenyl-2-(exo)-hydroxy-1,2,7-trimethylbicyclo[3.2.0]hept-6-en-3-one and 3,5,6-trimethyl-1,4-terphenyl-2-carboxaldehyde[15]

Preliminary examinations and collection of the diffraction data were carried out on a Syntex–Nicolet P_1 diffractometer equipped with a graphite monochromated MoK_α radiation source (and a modified LT-1 low temperature device.) Structure amplitudes and their standard deviations were calculated from the intensity data by procedures similar to those described previously (47). Crystal data and details of the intensity data collections are given in Table 4.

The structures were solved by direct methods using the MULTAN (48) package and refined by full-matrix least-squares refinement. The final cycles of the least-squares refinement[15] assumed the non-hydrogen atoms to vibrate anisotropically and the hydrogen atoms to vibrate isotropically. Final electron density difference maps showed no significant features. Final discrepancy indices are included in Table 4.

[15] (a) Atomic form factors were from ref. 49. (b) The atomic factor for hydrogen was from ref. 50.

Discrepancy index, R_1	0.054	0.056
R_2	0.055	0.065
Goodness of fit	1.37	1.71

Degradation of 5,6-diphenyl-2-(exo)-hydroxy-1,2,7-trimethylbicyclo[3.2.0]hept-6-en-3-one to methyl 3,4-diphenyl-5-oxo-3-hexenoate

To 61.0 mg (0.191 mmol) of 5,6-diphenyl-2-*exo*-hydroxy-1,2,7-trimethylbicyclo[3.2.0]hept-6-en-3-one in 1.0 mL of *tert*-butanol and 0.25 mL of ethyl acetate at room temperature was added 43.5 mg (0.191 mmol) of periodic acid in 1.5 mL of water. After 18 h, ether was added, the solution extracted with saturated sodium bicarbonate, the water layers acidified to Congo red with 10% HCl, then ether extracted, dried over anhydrous sodium sulfate, and concentrated *in vacuo* to yield 31.4 mg (0.094 mmol, 49%) of one isomer of 5,6-dimethyl-3,4-diphenyl-6-oxo-3,5-octadienoic acid as a slightly yellow oil.

The spectral data were: ir ($CHCl_3$): 3600–2500 (br), 1710 (br), 1670 cm^{-1}; H nmr ($CDCl_3$) δ: 7.00–7.70 (m, 10H, arom), 3.48 (s, 2H, CH_2), 1.78 (s, 3H, CH_3), 1.70 (s, 6H, 2 CH_3).

The acid in 3 mL of ether was added to 2 mmol of diazomethane[16] in 20 mL of ether at 0°C. After 10 min, the excess diazomethane was removed with a stream of nitrogen. Concentration *in vacuo* gave 31.1 mg (0.0892 mmol, 95%) methyl 5,6-dimethyl-3,4-diphenyl-6-oxo-3,5-octadienoate as a slightly yellow oil.

The spectral data were: ir ($CHCl_3$): 1735, 1690 cm^{-1}; H nmr ($CDCl_3$) δ: 7.00–7.70 (m, 10H, arom), 3.57 (s, 3H, OCH_3), 3.46 (s, 2H, CH_2), 1.76 (s, 3H, CH_3), 1.70 (s, 3H, CH_3), 1.64 (s, 3H, CH_3).

The methyl ester in 10 mL of ethyl acetate in a −23°C bath was treated with a stream of ozone in dry oxygen (0.05 mmol/min, Welsbach Ozonator) for 4.3 min, followed by addition of 0.25 g (4.1 mmol) of dimethyl sulfide. After 2 h, concentration *in vacuo* gave 33.4 mg of a yellow oil, which was chromatographed on a 5 × 20 cm thick-layer silica gel plate eluted with 50% ether–hexane to give 9.4 mg, R_f 0.5, methyl 3,4-diphenyl-5-oxo-3-hexenoate as a yellow oil. Crystallization from hexane gave 9.0 mg (32% from the acid, 16% overall) crystals, mp 94–105°C. The spectral data proved identical with those of independently synthesized material (*vide supra*).

4,5-Diphenyl-6-methyl-2-pyrone

To 0.25 g (1.6 mmol) of methyl phenylpropiolate and 0.21 g (1.6 mmol) of phenylacetone in 2 mL of ether at room temperature was added 0.084 g (1.6 mmol) of sodium methoxide. After 3 h, 5.0 mL of saturated NH_4Cl was added, and neutral work-up gave an oil which was chromatographed on a 3 × 40 cm silica gel column eluted with 1 L 2% ether–hexane and 1 L 10% ether–hexane collecting 500 mL fractions. Fraction 1, nil; 2, recovered phenylacetone; 3, nil; 4, 0.170 g of product as a yellow oil. Recrystallization from methanol gave 31.0 mg of 4,5-diphenyl-6-methyl-2-pyrone (7.6%), mp 137–138°C (lit.[17] mp 135°C).

The spectral data were: ir ($CHCl_3$): 2996, 1720, 1633, 1621, 1602, 1580, 1533, 1490, 1448, 1394, 1380, 1295, 1266, 1156, 1080, 1028, 1011, 998, 927, 908, 868, 845 cm^{-1}; H nmr ($CDCl_3$) δ: 7.00–7.40 (m, 10H, arom), 6.34 (s, 1H, vinyl), 2.23 (s, 3H, CH_3).

Methyl 3,4-diphenyl-5-oxo-3-hexenoate

A 140-mg (0.534 mmol) sample of 4,5-diphenyl-6-methyl-2-pyrone was dissolved in 4.0 mL of 5% KOH in CH_3OH by warming for 10 min and then kept at room temperature for 18 h. The solution was poured into water, acidifed with 10% HCl, ether extracted, dried over anhydrous magnesium sulfate, and concentrated *in vacuo* to give 116.4 mg of the two product acids as an oil.

The acids in 6.0 mL of ether were added to 2.0 mmol of diazomethane[16] at 0°C in 20 mL of ether. After 10 min, excess diazomethane was removed with a stream of nitrogen, and the solution concentrated *in vacuo* to give 93.0 mg of a yellow oil. Column chromatography on a 1 × 30 cm silica gel column eluted with 10% ether–hexane, collecting the initial band, gave 65.2 mg of an oil which was further purified by hplc, eluting with 45% methylene chloride – 45% pentane – 10% ether to give: 1, *k'* 0.71, 6.2 mg of unidentified oil; 2, *k'* 0.88, 24.4 mg of the major product isomer, mp 78–95°C; 3, *k'* 1.83, 9.0 mg of the minor product isomer as an oil. Recrystallization of fraction 2 gave 19.7 mg, mp 99–100°C, (13%) of the major isomer of methyl 3,4-diphenyl-5-oxo-3-hexenoate, identical in all respects to the ester obtained from degradation of photoproduct **A**.

The spectral data were: ir ($CHCl_3$): 3000, 2956, 1739, 1692, 1495, 1447, 1440, 1418, 1359, 1340, 1267, 1165, 1081, 1028, 706 cm^{-1}; uv (EtOH): 248 (ε 8300) nm; 200-MHz H nmr ($CDCl_3$) δ: 7.00–7.30 (m, 10H, arom), 3.56 (s, 3H, OCH_3), 3.40 (s, 2H, CH_2), 1.92 (s, 3H, CH_3); Cmr ($CDCl_3$) δ: 204.08, 170.81, 145.28, 139.89, 136.64, 136.25, 128.65, 128.45, 128.19, 51.719, 40.478, 30.667; ms, *m/e*: 294.1256 (calcd. for $C_{19}H_{18}O_3$, *m/e*: 294.125). *Anal.* calcd. for $C_{19}H_{18}O_3$: C 77.53, H 6.16; found: C 77.59, H 6.37.

Crystallization of fraction 3 from pentane gave 6.2 mg of the minor isomer of methyl 3,4-diphenyl-5-oxo-3-hexenoate, mp 67–68°C. The spectral data were: ir ($CHCl_3$): 3080, 3060, 3030, 3005, 2955, 1740, 1688, 1617, 1600, 1580, 1497, 1449, 1441, 1420, 1360, 1345, 1242, 1200, 1176, 1090, 1077, 1038, 1023, 1010, 955, 704 cm^{-1}; 200-MHz H nmr ($CDCl_3$) δ: 6.90–7.20 (m, 10H, arom), 3.76 (s, 2H, CH_2), 3.69 (s, 3H, OCH_3), 2.10 (s, 3H, —C=O—CH_3); ms, *m/e*: 294.126 (calcd. for $C_{19}H_{18}O_3$, *m/e*: 294.125).

2,3-(exo,exo)-Dihydroxy-1,5-diphenyl-2,6,7-trimethylbicyclo-[3.2.0]hept-6-ene

To 175 mg (0.61 mmol) of photoisomer **B** in 3.0 mL of pyridine at 0°C was added 140 mg (0.550 mmol) of osmium tetroxide. After 5 h, the pyridine was removed *in vacuo* and 50 mL of sodium bisulfite-saturated 95% ethanol added. After stirring 15 h, the solvent was removed *in vacuo*, and neutral work-up gave 282 mg of an oil. Chromatography on a 8 × 20 cm thick-layer silica gel plate eluted twice with 20% ether–hexane, twice with 30% ether–hexane, and twice with ether gave: 1, R_f 1.0, 56.3 mg of recovered starting material as an oil; 2, R_f 0.2, 77.4 mg of diol as an oil. Recrystallization from ether gave 48.3 mg (25%) of 2,3-*exo*,*exo*-dihydroxy-1,5-diphenyl-2,6,7-trimethylbicyclo[3.2.0]hept-6-ene, mp 167–167.5°C.

The spectral data were: ir ($CHCl_3$): 3550–3600, 3090, 3060, 3005,

[16] Generated by distillation from 0.70 g of *N,N'*-dinitroso-*N,N'*-dimethyl terephthalamide (Du Pont EXR-101), 1.24 g KOH, 2.5 mL ethoxyethoxyethanol, 25 mL ether, and 4.0 mL water.

[17] 4,5-Diphenyl-6-methyl-2-pyrone has been previously reported (51) but the details of its preparation are not readily available, nor is the preparation a straightforward one.

3,5,6-Trimethyl-1,4-terphenyl-2-carboxaldehyde

To 50.5 mg (0.158 mmol) of 2,3-*exo,exo*-dihydroxy-1,5-diphenyl-2,6,7-trimethylbicyclo[3.2.0]hepta-6-ene in 1.0 mL of benzene at room temperature was added 69.8 mg (0.158 mmol) of lead tetraacetate. After 10 min, neutral work-up gave 54.7 mg of 4,5-dimethyl-3,6-diphenyl-3,5-ocatadien-7-one-1-carboxaldehyde as an oil. This material was used below without further purification.

The spectral data were: ir (thin film): 1713, 1677 cm^{-1}; 200-MHz H nmr ($CDCl_3$) δ: 9.70 (t, J = 2.2 Hz, 1H, CHO), 6.70–7.50 (m, 10H, arom), 3.49 (d, J = 2.2 Hz, 2H, CH_2), 2.05 (s, 3H, —CO—CH_3), 1.62 (s, 3H, CH_3), 1.60 (s, 3H, CH_3); ms, *m/e*: 318.1619 (calcd. for $C_{22}H_{22}O_2$, *m/e*: 318.1618).

To the crude aldehyde in 1 mL of methanol was added 3.4 mg (0.061 mmol) of KOH at room temperature. After 15 min, neutral work-up gave 69.4 mg of solid, mp 106–211°C. Recrystallization from ether–hexane gave 30.3 mg of 3,5,6-trimethyl-1,4-terphenyl-2-carboxaldehyde, (64%), mp 217–220°C (sealed tube).

The spectral data were: ir ($CHCl_3$): 3067, 3017, 2880, 2778, 1683, 1603, 1568, 1557, 1498, 1464, 1445, 1411, 1387, 1320, 1290, 1075, 1032, 1004, 993, 920, 848, 820, 697 cm^{-1}; uv (EtOH): 222 (ε 36 000), 267 (ε 13 000), 307 (ε 3700) nm; 200-MHz H nmr ($CDCl_3$) δ: 9.77 (s, 1H, CHO), 7.07–7.53 (m, 10H, arom), 2.24 (s, 3H, CH_3), 2.02 (s, 3H, CH_3), 2.01 (s, 3H, CH_3); Cmr ($CDCl_3$) δ: 195.55, 145.19, 143.04, 141.27, 140.54, 138.87, 134.75, 132.90, 131.75, 130.01, 129.22, 128.62, 128.33, 127.42, 126.88, 19.06, 18.33, 17.06; ms, *m/e*: 300.1514 (calcd. for $C_{22}H_{20}O$, *m/e*: 300.1513). *Anal.* calcd. for $C_{22}H_{20}O$: C 87.96, H 6.71; found: C 88.04, H 6.80.

2,5-Dimethyl-3,4-diphenylthiophene

Using a modification of the general method of Dabard and Le Bihan (52), to a suspension of 3.22 g (84.7 mmol) of LAH in 120 mL of ether, with mechanical stirring in an ice-bath, was slowly added, 11.3 g (84.7 mmol) of aluminum trichloride. After 1 h, 4.28 g (12.1 mmol) of 2,5-bis(carbomethoxy)-3,4-diphenylthiophene (53) suspended in 200 mL of ether was added, and the solution refluxed 9 h. After recooling in an ice-bath, 30 mL of ethyl acetate was slowly added, followed by 100 mL of 10% HCl. Basic work-up gave 3.9 g of an oil, which was chromatographed on a 3 × 33 cm silica gel column eluted with hexane to give 1.8 g of product as the initial band as an oil. Recrystallization from hexane gave 1.38 g (43%) of 2,5-dimethyl-3,4-diphenylthiophene, mp 101–102°C.

The spectral data were: ir ($CHCl_3$): 3060, 3000, 2922, 2860, 1610, 1492, 1450, 1285, 1175, 1140, 1084, 1025, 928, 708 cm^{-1}; 270-MHz H nmr ($CDCl_3$) δ: 6.90–7.30 (m, 10H, arom), 2.36 (s, 6H, $2CH_3$); Cmr ($CDCl_3$) δ: 138.99, 136.74, 131.28, 130.20, 127.66, 126.20, 13.90; ms, *m/e*: 264.0973 (calcd. for $C_{18}H_{16}S$, *m/e*: 264.0972). *Anal.* calcd. for $C_{18}H_{16}S$: C 81.77, H 6.10; found: C 81.84, H 6.19.

2,5-Dimethyl-3,4-diphenylthiophene-1,1-dioxide

To 1.38 g (5.23 mmol) of 2,5-dimethyl-3,4-diphenylthiophene, in 20 mL of chloroform at room temperature was added dropwise 198 g (11.5 mmol) of *meta*-chloroperbenzoic acid in 15 mL of chloroform. After 2 h, basic work-up gave 1.70 g of crude product, mp 150–190°C (dec.). Recrystallization from chloroform–ether gave 0.642 g (41%) of 2,5-dimethyl-3,4-diphenylthiophene-1,1-dioxide, mp 209–210°C.

The spectral data were: ir ($CHCl_3$): 3080, 3060, 3024, 2910, 2844, 1595, 1580, 1497, 1448, 1383, 1293, 1235, 1199, 1180, 1114, 1082, 1024, 1010, 1001, 983, 929, 913, 870, 846, 702 cm^{-1}; 270-MHz H nmr ($CDCl_3$) δ: 7.20–7.50 (m, 6H, arom), 6.85–7.00 (m, 4H, arom), 2.15 (s, 6H, 2 CH_3); Cmr ($CDCl_3$) δ: 133.67, 131.24, 130.19, 128.93, 128.49 (C4 Ph), 127.99, 8.264 (CH_3); ms, *m/e*: 296.0872 (calcd. for $C_{18}H_{16}O_2S$, *m/e*: 296.0960). *Anal.* calcd. for $C_{18}H_{16}O_2S$: C 72.94, H 5.44; found: C 72.95, H 5.50.

3,4-Diphenyl-1,2,5-trimethyl-1,3,5-cycloheptatriene

Using the general method of van Tilborg *et al.* (6), to 800 mg (2.72 mmol) of 2,5-dimethyl-3,4-diphenylthiophene-1,1-dioxide in 5 mL of methylene chloride at room temperature was added a solution of 370 mg (6.8 mmol) of 1-methylcyclopropene (54) in 2.0 mL of methylene chloride at −78°C in a stoppered flask. The mixture was stirred at room temperature for 4 h. Concentration *in vacuo* gave 1.2 g of an oil, which was chromatographed ona 3 × 33 cm alumina column eluted with hexane to yield: 1, 500 mL, nil; 2, 1 L, 0.575 g of product, mp 71–76°C. Recrystallization from ether–pentane gave 0.4127 g (53%) of 3,4-diphenyl-1,2,5-trimethyl-1,3,5-cycloheptatriene, mp 86–87°C.

The spectral data were: ir ($CHCl_3$): 3085, 3063, 3016, 2963, 2935, 2892, 2863, 1600, 1490, 1450, 1440, 1378, 1310, 1072, 840, 696, 645 cm^{-1}; 270-MHz H nmr ($CDCl_3$) δ: 6.80–7.20 (m, 10H, arom), 5.60 (t, J = 8.1 Hz, 1H, vinyl), 2.52 (bs, 2H, CH_2), 1.98 (s, 3H, CH_3), 1.68 (s, 3H, CH_3), 1.54 (s, 3H, CH_3); Cmr ($CDCl_3$) δ: 145.62, 141.98, 141.71, 141.43, 134.00, 131.40, 130.47, 130.30, 126.83, 125.40, 122.98, 35.10, 21.49, 20.66, 17.08; ms, *m/e*: 286.1722 (calcd. for $C_{22}H_{22}$, *m/e*: 286.1720). *Anal.* calcd. for $C_{22}H_{22}$: C 92.26, H 7.74; found: C 92.08, H 7.94.

*3,4-Diphenyl-*trans*-2,5,6-trimethylcyclohepta-3,5-dienol*

Using the general method of Zweifel and Brown (55), to 288 mg (1.00 mmol) of 3,4-diphenyl-1,2,5-trimethylcyclohepta-1,3,5-triene in 2.0 mL of THF at 0°C was added 6.9 mg (0.50 mmol, 0.51 mL) of 0.98 *M* borane in THF) of borane. After 30 min, 1.5 mL of 5 *N* NaOH solution was added, followed by 1.0 mL of 30% H_2O_2 solution. After 3 h, neutral work-up gave an oil which nmr analysis showed as approximently 50% converted starting material. This material was again treated with borane as above to yield 317 mg of an oil, which was chromatographed on two 5 × 20 cm silica gel thick-layer paltes eluted once with 10% ether–hexane and once with 20% ether–hexane to give: 1, R_f 0.71, 43.2 mg of recovered material as an oil; 2, R_f 0.50, 5.8 mg of an unidentified oil; 3, R_f 0.21, 133.9 mg of alcohol, mp 114–118°C; 4, R_f 0.00, 82.0 mg of an unidentified solid, mp 70–100°C. Recrystallization of fraction 3 from ethyl acetate – pentane gave 129.2 mg (42%) of 3,4-diphenyl-*trans*-2,5,6-trimethylcyclohepta-3,5-dienol, mp 122–123°C.

The spectral data were: ir ($CHCl_3$): 3590, 3300–3500, 3075, 3055, 2998, 2956, 2922, 2865, 1603, 1494, 1454, 1445, 1385, 1330, 1245, 1190, 1160, 1136, 1110, 1077, 1045, 1032, 996, 867, 705 cm^{-1}; uv (EtOH): 234 (ε 14 000/, 269 (sh, ε 6800) nm; 270-MHz H nmr ($CDCl_3$) δ: 6.80–7.20 (m, 10H, arom), 4.07 (m, 1H, —C*H*OH—), 2.77 (dd, J = 13.3, 4.3 Hz, 1H, C*H*H), 2.67 (p, J = 7.22 Hz, 1H, —C*H*CH_3—), 2.31 (dd, J = 13.3, 4.0 Hz, 1H, CH*H*), 2.02 (s, 3H, vinyl CH_3), 1.56 (s, 3H, vinyl CH_3), 1.05 (d, J = 7.06 Hz, 3H, —CHCH_3—); Cmr ($CDCl_3$) δ: 142.84, 142.29, 141.91, 140.62, 131.28, 132.51, 130.11, 129.85, 127.25, 125.79, 87.453, 45.962, 43.072, 21.408, 16.852, 16.561; ms, *m/e*: 304.1828 (calcd. for $C_{22}H_{24}O$, *m/e*: 304.1826). *Anal.* calcd. for $C_{22}H_{24}O$: C 86.80, H 7.95; found: C 87.14, H 7.96.

*1,7-Diphenyl-*endo*-2,5,6-trimethylbicyclo[3.2.0]hept-6-ene-2-*exo*-ol*

*Method A, photolysis of 3,4-diphenyl-*trans*-2,5,6-trimethylcyclohepta-3,5-diene-1-ol*

Using the general photolysis procedure, 75.1 mg (0.247 mmol) of 3,4-diphenyl-*trans*-2,5,6-trimethylcyclopheta-3,5-diene-1-ol in 185 mL of acetonitrile was irradiated for 5 h through Filter A at 30°C. Concentration *in vacuo* yielded 79.5 mg of an oil, which was chromatographed on a 1 × 60 cm silica gel column eluted with 20% ether–hexane, collecting 50-mL of fractions to give: 1, nil; 2, 5.6 mg of an unidentifid oil; 3–4, 29.3 mg of product as an oil. Recrystallization from ether–pentane gave 19.1 mg (25%) of 1,7-

diphenyl-*endo*-2,5,6-trimethylbicyclo[3.2.0]hept-6-ene-2-*exo*-ol, mp 112–113°C.

The spectral data were: ir ($CHCl_3$): 3620, 3300–3550, 3093, 3064, 3015, 2972, 2940, 2882, 1603, 1500, 1450, 1378, 1210, 1120, 1086, 1052, 1028, 1008, 968, 725, 699 cm^{-1}; 270-MHz H nmr ($CDCl_3$) δ: 7.10–7.40 (m, 10H, arom), 3.82 (td, J = 9.5, 6.0 Hz, 1H, —C*H*OH—), 2.40 (dq, J = 9.0, 6.8 Hz, 1H, —C*H*CH_3—), 2.20 (dd, J = 12.5, 6.0 Hz, 1H, C*H*H), 1.98 (s, 3H, vinyl CH_3), 1.56 (bs, 1H, —OH), 1.25 (dd, J = 12.4, 9.9 Hz, 1H, CH*H*), 1.00 (d, J = 6.8 Hz, 3H, —CHC*H*$_3$—), 0.65 (s, 3H, C-5 CH_3); Cmr ($CDCl_3$) δ: 145.03, 141.12, 136.22, 135.69, 128.01, 127.86, 127.75, 126.38, 126.14, 63.74, 53.88, 44.30, 41.11, 17.96, 13.96, 10.75; ms, m/e: 304.1828 (calcd. for $C_{22}H_{24}O$, m/e: 304.1826). *Anal.* calcd. for $C_{22}H_{24}O$: C 86.80, H 7.95; found: C 86.92, H 8.02.

Method B: Hydroboration–oxidation of photoproduct D

Using the general method of Zweifel and Brown (55), to 28.8 mg (0.100 mmol) of photoproduct D in 0.6 mL of THF at room temperature was added 1.4 mg (0.10 mmol, 0.010 mL of 0.98 *M* borane in THF) of borane. After 12 h, 0.20 mL of 5.0 *N* NaOH was added, followed by 0.2 mL of 30% H_2O_2, stirred for 10 h, and neutral work-up gave 39.4 mg of an oil. High-pressure liquid chromatography eluting with 1:1 ether–pentane at a flow rate of 4.5 mL/min gave: 1, k' 0.0, 2.9 mg of an unidentified oil; 2, k' 1.0, 0.4 mg of an unidentified oil; 3, k' 2.47, 3.6 mg of an unidentified oil; 4, k' 8.05, 12.8 mg of product as an oil. Recrystallization of fraction 4 from ether–pentane gave 6.7 mg of 1,7-diphenyl-*endo*-2,5,6-trimethylbicyclo[3.2.0]hept-6-ene-2-*exo*-ol, mp 112–113°C, whose spectral data were identical to those of independently synthesized material.

1,4-Bis(trideuteriomethyl)-2,3-diphenyl-5-methyl-5-vinyl-1,3-cyclopentadiene

Using the general method of Zimmerman *et al.* (12*b*), to 1.0 g (3.5 mmol) of 2,3-diphenyl-1,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene in 8.80 g (8.80 mmol) of *N,N*-dideuteriocyclohexyl amine (12*b*) (>98% D) at room temperature was added 2.4 mL of 1.5 *M* (3.5 mmol) *n*-BuLi in hexane. After 12 h, 0.40 mL of D_2O was added, the solution poured into 220 mL of 5% HCl, and neutral work-up gave 1.01 g, mp 74.5–78°C, 90% deuterated (nmr). The above procedure was repeated to yield 0.988 g, mp 74.5–78°C, 94% deuterated, and once more repeated to yield 0.982 g, mp 38–65°C. Recrystallization from pentane gave 0.702 g (70%) of 1,4-bis(trideuteriomethyl)-2,3-diphenyl-5-methyl-5-vinyl-1,3-cyclopentadiene, mp 77.5–78°C, 96.5% deuterated (nmr).

Direct photolysis of 1,4-bis(trideuteriomethyl)-2,3-diphenyl-5-methyl-5-vinyl-1,3-cyclopentadiene

High conversion run

Using the general photolysis procedure, 82.0 mg (0.281 mmol) of 1,4-bis(trideuteriomethyl)-2,3-diphenyl-5-methyl-5-vinyl-1,3-cyclopentadiene in 170 mL of acetonitrile was irradiated for 3 h through Filter A at 31–33°C. Concentration *in vacuo* gave 80.8 mg of an oil, which was chromatographed using hplc eluting with 6% methylene chloride – pentane at a flow rate of 2.4 mL/min. Fraction compositions were determined by integration of their 200-MHz H nmr spectra. Fraction 1, k' 1.48, 1.8 mg of an unidentified oil; 2, k' 1.67, 2.5 mg of an oil, 60% photoisomer **D** and 40% photoisomer **C**; 3, k' 1.87, 19.0 mg of recovered starting material, mp 51–67°C; 4, k' 2.03, 8.5 mg of an oil, 67% photoisomer **B** and 33% 1,2-diphenyl-3,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene; 5, k' 2.33, 27.1 mg of an oil, 43% photoisomer **B** and 57% photoisomer **A**. Results: 19.0 mg (23%) of recovered starting material, 15.4 mg (18.8%) of photoisomer **A**, 17.3 mg (21.1%) of photoisomer **B**, 1.5 mg (1.8%) of photoisomer **D**, 1.0 mg (1.2%) of photoisomer **C**, and 2.8 mg (3.4%) of 1,2-diphenyl-3,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene. The recovered starting material had 36% CH_3 on C-5 (1.25 ppm) and 64% CH_3 on the vinyl positions (1.82 ppm). All the products had 33 ± 1% CH_3 in all positions.

Low conversion run

Using the general photolysis procedure, 30.3 mg (0.104 mmol) of 1,4-bis(trideuteriomethyl)-2,3-diphenyl-5-methyl-5-vinyl-1,3-cyclopentadiene in 170 mL acetonitrile was irradiated through Filter A for 22 min at 27°C. Concentration *in vacuo* gave 28.9 mg of a semi-solid. High-pressure liquid chromatography eluting with 6% methylene chloride – pentane at 1.1 mL/min gave: 1, k' 1.47, 0.1 mg of an unidentified oil; 2, k' 2.38, 24.5 mg (81%) of recovered starting material, 95% CH_3 on C-5 (1.25 ppm) and 5% CH_3 on the vinyl positions (1.82 ppm); 3, k' 3.75, 2.0 mg (6.6%) of a mixture of 78% photoisomer **A** (5.1%) and 22% photoisomer **B** (1.5%). Photoisomer **A** had 89% CH_3 on C-2 (1.75 ppm), 6% CH_3 on C-1 (0.65 ppm), and 5% CH_3 on C-7 (2.08 ppm). Photoisomer **B** had 77% CH_3 on C-2 (1.73 ppm), 16% CH_3 on C-7 (1.86 ppm), and 7% CH_3 on C-6 (1.84 ppm).

At −70°C

Using the low temperature photolysis apparatus described above (note Fig. 8), 47.7 mg (0.163 mmol) of 1,4-bis(trideuteriomethyl)-2,3-diphenyl-5-methyl-5-vinyl-1,3-cyclopentadiene in 100 mL pentane was irradiated for 164 min in a −78°C bath using the general photolysis procedure through Filter A. The solution was kept at −78°C with continued nitrogen purging for an additional 1.5 h, followed by 4 h at room temperature. Concentration *in vacuo* gave 47.3 mg of a yellow solid, mp 23–43°C, which 270-MHz nmr analysis showed consisted of a 3.75:1 mixture of recovered starting material and 3,5-bis(trideuteriomethyl)-1,2-diphenyl-4-methyl-5-vinyl-1,3-cyclopentadiene, with small amounts (<5%) of unidentified material. Neither component showed detectable scrambling of the methyl groups.

Sensitized photolysis of 1,4-bis(trideuteriomethyl)-2,3-diphenyl-5-methyl-5-vinyl-1,3-cyclopentadiene

Using the general photolysis procedure, 42.1 mg (0.114 mmol) of 1,4-bis(trideuteriomethyl)-2,3-diphenyl-5-methyl-5-vinyl-1,3-cyclopentadiene and 162.4 mg (0.721 mmol) of *p*-dimethylaminobenzophenone in 250 mL acetonitrile were irradiated through Filter C for 40 min at 30°C. Concentration *in vacuo* gave 217 mg of an oil which was chromatographed on a 1 × 28 cm silica gel column eluted with 100 mL 1% ether–pentane and 500 mL ether collecting 50-mL fractions to give: 1, nil; 2, 41.2 mg of a mixture of starting material and product; 3–4, nil; 5–6, 171.8 mg of recovered sensitizer, mp 80–87°C. High-pressure liquid chromatography of fraction 2 eluting with 6% methylene chloride – pentane at a flow rate of 2.2 mL/min gave: 1, k' 1.9, 4.2 mg of recovered starting material as an oil, retaining its label on the vinyl methyl groups; 2, k' 1.95, 3.3 mg of overlap; 3, k' 2.0, 27.0 mg of 3,5-bis(trideuteriomethyl)-1,2-diphenyl-4-methyl-5-vinyl-1,3-cyclopentadiene, mp 66–73°C.

Direct photolysis of 3,5-bis(trideuteriomethyl)-1,2-diphenyl-4-methyl-5-vinyl-1,3-cyclopentadiene

Using the general photolysis procedure, 23.0 mg (0.0788 mmol) of 3,5-bis(trideuteriomethyl)-1,2-diphenyl-4-methyl-5-vinyl-1,3-cyclopentadiene in 160 mL acetonitrile was irradiated through Filter A for 10 min at 27°C. Concentration *in vacuo* gave 21.0 mg of an oil; hplc eluting with 6% methylene chloride – pentane at a flow rate of 2.2 mL/min gave: 1, k' 2.29, 14.2 mg of 2,3-diphenyl-1,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene, mp 61–72°C, 92% CH_3 on the vinyl positions (1.82 ppm), and 8% CH_3 on C-5 (1.25 ppm); 2, k' 2.78, 4.1 mg of recovered starting material as an oil, labeled as before the photolysis; 3, k' 3.21, 2.3 mg of a mixture of 59% photoisomer **A** and 41% photoisomer **B** as an oil. Photoisomer **A** had 0% CH_3 on C-2 (1.75 ppm), 50% CH_3 on C-1 (0.65 ppm), and 50% CH_3 on C-7 (2.08 ppm). Photoisomer **B** had 0% CH_3 on C-2 (1.73 ppm), 68% CH_3 on C-7 (1.86 ppm), and 32% CH_3 on C-6 (1.83 ppm).

Thermolysis of 1,4-bis(trideuteriomethyl)-2,3-diphenyl-5-methyl-5-vinyl-1,3-cyclopentadiene

A solution of 16.1 mg of 1,4-bis(trideuteriomethyl)-2,3-diphenyl-5-methyl-5-vinyl-1,3-cyclopentadiene in 1 mL of benzene was re-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

fluxed 23 h. Concentration *in vacuo* gave 15.5 mg of an oil, which 200-MHz H nmr analysis showed consisted of a 1:1 mixture starting material, labeled unchanged, and 3,5-bis(trideuteriomethyl)-1,2-diphenyl-4-methyl-5-vinyl-1,3-cyclopentadiene.

Photolysis of 2,3-diphenyl-1,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene in the presence of 3,3,4,4,-tetramethyl-1,2-diazetine-1,2-dioxide

Using the general photolysis procedure, 120 mg (0.419 mmol) of 2,3-diphenyl-1,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene and 46.9 mg (0.326 mmol, 2.03×10^{-3} *M*) of 3,3,4,4-tetramethyl-1,2-diazetine-1,2-dioxide (56) in 160 mL of acetonitrile was irradiated through Filter A for 3 h at 31–33°C. Concentration *in vacuo* gave 152.2 mg of an oil. 200-MHz H nmr analysis revealed 84.5% recovered starting cyclopentadiene, 9.3% photoisomer **A**, 5.0% photoisomer **B**, and 1.1% photoisomer **D**. An identical run was conducted using 122.9 mg (0.4291 mmol) of 2,3-diphenyl-1,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene, but omitting the quencher. Concentration *in vacuo* gave 119.7 mg of an oil. Analysis by 200-MHz H nmr revealed 81.4% recovered starting material, 10.4% photoisomer **A**, 6.2% photoisomer **B**, and 1.9% photoisomer **D**. Within experimental error, the two runs provided photoproducts in the same ratios.

Photolysis of 2,3-diphenyl-1,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene at −20°C in an nmr tube

In a 5-mm od nmr tube was put 1.5 mg of 2,3-diphenyl-1,4,5-trimethyl-5-vinyl-1,3-cyclopentadiene in 0.5 mL trideuterioacetonitrile. After purging with purified nitrogen (41) for 0.5 h, the nitrogen inlet was raised above the surface of the solution ca. 3 cm, and the tube placed inside a Pyrex tube through which nitrogen cooled to −20°C (via a coil immersed in liquid nitrogen) was continually blown. The tube was then placed ca. 1 cm from a 450-W medium-pressure mercury lamp and irradiated through Filter A for 4 h. Analysis by 200-MHz H nmr at −40°C revealed only recovered starting material.

Investigation of the secondary photochemistry

Photoisomer A

Using the general photolysis procedure, 15.3 mg (0.0534 mmol) of photoisomer **A** in 170 mL *tert*-butanol was irradiated at 30°C for 11.7 h. Concentration *in vacuo* gave 17.1 mg of an oil; nmr analysis showed ca. 20% remaining starting material, along with several unknown products. None of the other bicyclic photoproducts were present.

Photoisomer C

After purging with purified nitrogen (41) for 1 h prior to and during photolysis, 4.4 mg (0.015 mmol) of photoisomer **C** in 40 mL acetonitrile was irradiated at 28°C on the microoptical bench (42) at 330 nm with an entrance slit of 3.6 mm and an exit slit of 4.0 mm (band pass: 100% transmittance at ±15 nm, decreasing to 0% transmittance at ±30 nm) until digital actinometry (43) indicated 0.322 mEinsteins (20.9 equivalents) of light had been absorbed. Concentration *in vacuo* gave 4.6 mg of an oil, to which 3.3 mg (0.014 mmol) of methyl diphenylglycolate was added as internal standard; nmr analysis showed 79% recovered starting material for a quantum yield of disappearance of 0.0098. None of the unidentified products were the other bicyclic photoproducts.

Photoisomer D

Using the general photolysis procedure, 27.4 mg (0.0957 mmol) of photoisomer **D** in 170 mL acetonitrile was irradiated for 5.7 h at 30°C. Concentration *in vacuo* gave 25.0 mg of an oil; nmr analysis showed 21% remaining starting material, along with several unknown products. None of the other bicyclic photoproducts were present.

Quantum mechanical calculations

All quantum mechanical calculations were performed using the "GAMESS" program package (12*c*). The geometry of 5-vinyl-1,3-cyclopentadiene was obtained using the molecular mechanics portion of the "Tribble" program package (12*b*) and was optimized using the MNDO program contained therein. The geometry for the transition states was constructed using standard bond lengths and angles and was not optimized. In all cases, an STO-3G basis set was used. For 5-vinyl-1,3-cyclopentadiene, the Restricted Hartree–Fock method yielded MO's which, after configuration interaction involving the two highest energy HOMO's and the two lowest energy LUMO's, yielded the energies of the three lowest energy singlet states. For the non-twisted transition state geometry and the 90-deg methylene twisted transition state geometry, the Restricted Open Shell Hartree–Fock method yielded MO's which, after configuration interaction involving the three highest energy HOMO's and the three lowest energy LUMO's yielded the energies of the three lowest energy singlet states.

Received April 4, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

PHILIP E. EATON, WILLIAM H. BUNNELLE, and PETER ENGLE. Can. J. Chem. **62**, 2612 (1984).

Phenylsulfenylation of 2-alkyl-1,3-cyclopentanediones followed by oxidation and elimination is shown to give easy access to 2-alkylidene-1,3-cyclopentanediones, a heretofore rare class of highly reactive compounds with good synthetic potential as dienophiles, Michael acceptors, etc. The synthesis of 2-phenylthio-1,3-cyclopentanedione is given and its use as synthon for introduction of the 2-alkylidene-1,3-cyclopentadione group into other systems is described. The methodology is applied to the preparation of a substituted peristylane containing a complete complement of carbons, proper functionality, and correct stereochemistry for closure to a dodecahedrane. The X-ray structure analysis of an example of this ring system is given. Efforts to effect the closure are described.

PHILIP E. EATON, WILLIAM H. BUNNELLE et PETER ENGLE. Can. J. Chem. **62**, 2612 (1984).

On démontre que la phénylsulfénylation des alkyl-2 cyclopentanediones-1,3, suivie d'une oxydation et d'une élimination, s'avère une voie d'accès facile aux alkylidène-2 cyclopentanediones-1,3, une classe de composés qui était jusqu'à maintenant rare, qui sont très réactifs et qui présentent beaucoup de potentiel en synthèse soit comme diénophiles, comme accepteurs dans les réactions de Michael, etc. On rapporte la synthèse de la phénylthio-2 cyclopentanedione-1,3 et on l'utilise comme synthon pour introduire le groupe alkylidène-2 cyclopentanedione-1,3 dans d'autres systèmes. On a appliqué la méthodologie pour préparer un péristylane substitué contenant un complément complet de carbones, la fonctionalité appropriée et la bonne stéréochimie pour effectuer une fermeture conduisant à un dodécaédrane. Faisant appel à la diffraction des rayons-X, on a déterminé la structure d'un composé faisant partie de ce système cyclique. On décrit les essais effectués en vue de réaliser la fermeture désirée.

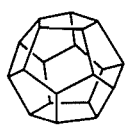
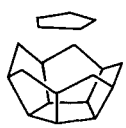
Introduction

Dodecahedrane (**1**) is an exceptional molecule. Its symmetry, rigidity, and near lack of angular strain provide a special opportunity for the study of fundamental chemistry (for a general overview, see Eaton (1)). The synthesis of dodecahedrane continues to be pursued with great vigor both here and elsewhere (1), even in view of the recent fine achievement of its first preparation by Paquette *et al.* (2). The challenge and importance of the system are sufficient to merit development of other synthetic methodologies. We report here some of our continuing efforts along these lines (3).



1



2

We view dodecahedrane as a peristylane (**2**) roofed by a five-membered ring. In 1972 we reported the first synthesis of the peristylane ring system (3*a*,*b*), and have since modified and improved this synthesis to the point that the peristylane **3** can now be considered a fairly readily accessible material (3*d*). We have examined the chemistry of this peristylane at some length and have presented detailed methodology for its further functionalization at carbons 8 and 15, and for substitution at carbon 4 (3*c*). These methods depend on the preparation of unsaturated peristylenones and the high reactivity of these strained olefins. We have shown also how certain *exo*-substituents on the peristylane frame, particularly at C-4, can be transformed into the corresponding *endo*-substituents positioned properly for ultimate integration into the dodecahedrane frame (3*c*). A proposal is sketched out in Scheme 1 to bring these successes together into a tactical synthesis of a peristylane substituted and suited functionally, at least in theory, for closure into a dodecahedrane. This paper describes the real-world travails by which the ideas in Scheme 1 were brought to fruition and then some of our attempts to carry on further toward dodecahedrane.

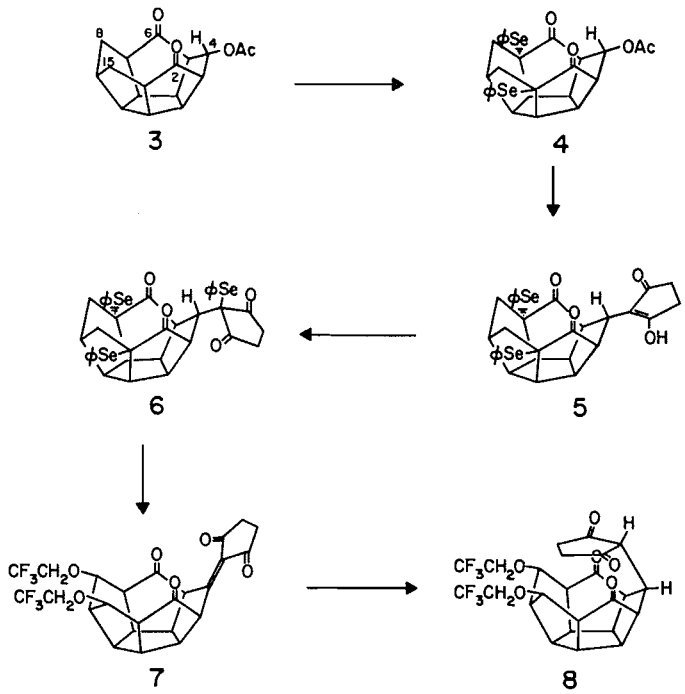
Results and discussion

The roof: initial attachment

The 1,7-bisselenide **4** can be made readily from **3** by reaction with phenylselenenyl chloride in ethyl acetate (3*c*). Heating **4** with 1,3-cyclopentanedione in basic 2,2,2-trifluoroethanol gave the expected *exo*-adduct **5**. The material, like most 1,3-cyclopentanedione derivatives, was an equilibrating mixture of the enolized forms, as evidenced by the single absorption for the four methylene protons in its ^{1}Hmr spectrum, as well as ir bands characteristic of β-hydroxycyclopentenones (2700, 1580 cm^{-1}). As a result of this enolization, **5** was quite insoluble in most organic solvents; as an organic acid, however, it was readily soluble in basic solutions.

Selenenylation of **5** was easily achieved by reaction of its

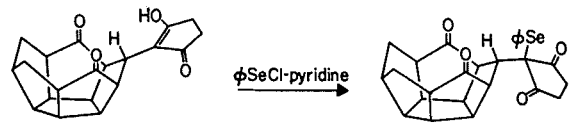
[1]Author to whom correspondence may be addressed.



SCHEME 1

solution in pyridine with phenylselenenyl chloride.[2] Substitution took place at the nucleophilic carbon of the 1,3-dione system, and not at the oxygen of the enolate, providing the trisselenide **6**. As enolization of the β-dione was now blocked, **6** was easily handled as a typical hydrophobic compound. Its ^{1}Hmr spectrum was consistent with the plane of symmetry in the molecule.

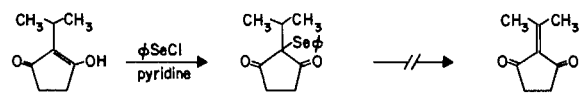
With the successful preparation of trisselenide **6**, it seemed that functionalization of the remote peristylane methylenes (C-8 and C-15) as well as part of an *exo* → *endo* inversion sequence at C-4 could be attempted, all in one fell swoop, following the methods developed here previously. However, treatment of **6** at −70°C with ozone, conditions appropriate to selenoxide formation, followed by warming to room temperature in basic trifluoroethanol, gave a hopeless mixture of products. The addition of ethyl vinyl ether as a selenenic acid trap, a useful technique developed here (*3c*), failed to improve the situation. Even gross simplification of the system failed to help: although condensation of acetoxyperistylanedione **3** and 1,3-cyclopentanedione gave adduct **9** easily enough, and selenenylation produced the C-selenide **10**, oxidation/elimination gave only low yields of unidentified products.



2-Alkylidene-1,3-cyclopentanediones

Faced with this, it was prudent to backtrack and investigate the chemistry of simple 2-alkylidene-1,3-cyclopentanediones (6). A search of the literature revealed that very little was known about such compounds (7). Although the "parent" 2-alkyl-1,3-cyclopentanediones are accessible by a variety of routes, the conceptually simple transformation to the unsaturated 2-alkylidene compounds had never been reported. With this rather puzzling lack of precedent, work on the formal dehydrogenation of 2-isopropyl-1,3-cyclopentanedione (**11**) was begun. The compound was prepared as described by Hiraga (8). The ^{1}Hmr spectrum of **11** in pyridine-d_5 solution showed the anticipated four-proton singlet for the ring methylene hydrogens and the heptet−doublet pair characteristic of an isopropyl group. The relative simplicity of this spectrum and the spectra of the reaction products from **11** proved a great asset in subsequent structural assignments.

Selenenylation of **11** in pyridine with phenylselenenyl chloride gave, after chromatographic work-up, a good yield of a product whose ir and ^{1}Hmr spectra were consistent with the *C*-selenenylated structure **12**. Confirmation of this structure was obtained by ^{13}Cmr spectroscopy. There were nine lines in the proton-decoupled spectrum, consistent in number and position with the *C*-selenide, but not the alternative enol *O*-selenenylated isomer. As samples of **12** degraded upon



[2]The conditions of this selenenylation are worthy of comment. When these experiments were first carried out in 1978, literature precedent for selenenylation of β-dicarbonyl compounds dictated very much more drastic conditions (4). Typically, the β-dicarbonyl system would first be deprotonated with a strong base (potassium hydride or lithium diisopropylamide) and the enolate then quenched with phenylselenenyl chloride. When other enolizable carbonyl groups were present, as in **5**, the amount of base had to be controlled carefully to avoid over-selenenylation. We found here that pyridine was a strong enough base to allow selenenylation of the β-diketone via the enolate, while isolated carbonyl groups were quite inert. The use of pyridine/phenylselenenyl chloride as a general reagent for effecting selenenylation of β-dicarbonyl compounds has since been developed independently by Liotta *et al.* (5).

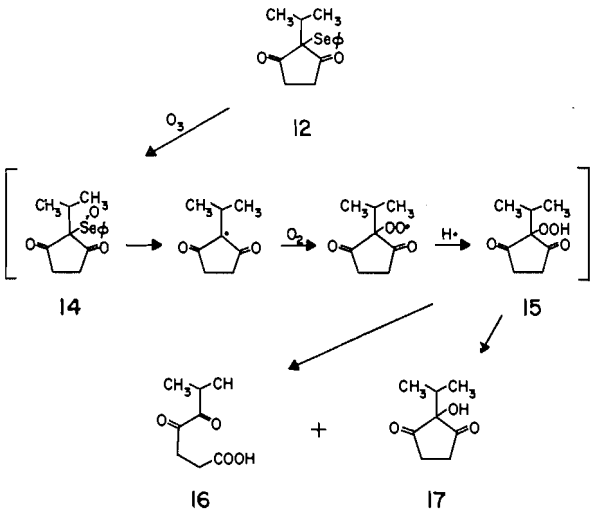
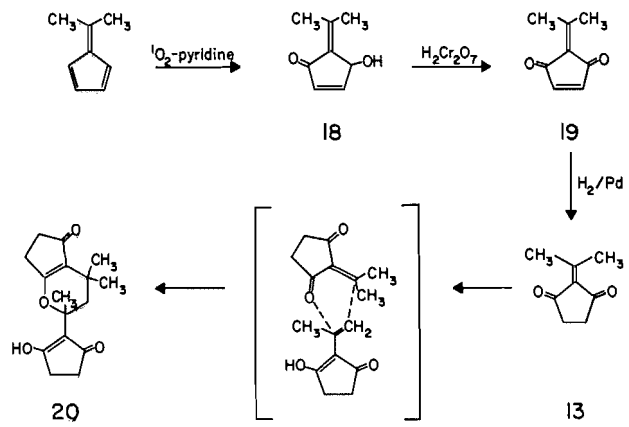


SCHEME 2

standing, attempts to convert it to **13** had to be done with freshly prepared material. Even so, although a variety of oxidation–elimination conditions were tried, in no case could any of the desired ene-dione **13** be isolated. Instead, more or less complex mixtures of products were obtained. The cleanest reaction occurred on low-temperature ozonization of a methylene chloride solution of **12**, followed by warming to room temperature. In addition to deselenenylated material **11**, two major products were obtained in a 3:1 ratio (see Scheme 2). The major component, shown by mass spectroscopy to have molecular formula $C_8H_{12}O_{14}$, was assigned structure **16** on the basis of the spectral evidence (isopropyl group methine at 3.36 ppm, AA′BB′ pattern centered at 2.80 ppm in ^{1}Hmr; CO_2H band in ir). The minor product was likewise identified as the tertiary alcohol **17** ($C_8H_{12}O_3$; isopropyl methine at 2.15 ppm, AA′BB′ pattern centered at 2.84 ppm in the ^{1}Hmr). Low-temperature ^{1}Hmr studies indicated that these products were formed rapidly even at −60°C. We believe (Scheme 2) that selenoxide **14** was formed initially but then fragmented, not in the desired pericyclic sense, but rather homolytically at the carbon–selenium bond to give the stabilized cyclopentanedione radical.[3] This in turn could have captured oxygen to give a peroxide radical and then, through hydrogen abstraction, the hydroperoxide **15**. This compound finally could have decomposed along two pathways: the major product **16** arising from fragmentation of the peroxide (11); the minor product **17** resulting from reduction of the peroxide (by available selenium species?) to the observed tertiary alcohol.

By now it seemed certain that a selenenylation–oxidation–elimination route to compounds like **13** would not work. We looked for alternative routes. Partial hydrogenation of the known 2-isopropylidene-4-cyclopenten-1,3-dione **19** appeared promising. This compound was prepared by the procedure of Skorianetz *et al.* (10); sensitized photooxygenation of dimethylfulvene (Rose Bengal, O_2, pyridine) gave (in part) the ketodienol **18**, which was converted to the bright yellow crystalline diene-dione **19** on oxidation with Jones reagent.

Catalytic hydrogenation of **19** over palladium-on-carbon at 0°C using methylene chloride as solvent, gave fairly selective reduction of the disubstituted double bond. The ^{1}Hmr spectrum of the crude yellow product showed only two lines, a four-proton singlet at 2.64 ppm and a six-proton singlet at 2.54 ppm, completely consistent with the formation of enedione **13**. The uv spectrum could not be determined precisely as the material was unstable, converting to a dimeric compound, isolated as colorless crystals from ether–hexanes.



The mass spectrum of the dimer gave a parent ion corresponding to $C_{16}H_{20}O_4$ and a major fragment ion for the monomer $C_8H_{10}O_2$. The presence of an enolized 1,3-cyclopentanedione was indicated in the ir by bands at 2700, 1693, and 1636 cm^{-1}, and in the uv by an absorption at 250 nm (ϵ = 24 300) that shifted to 260 nm (ϵ = 26 000) in base. The ^{1}Hmr spectrum of the dimer showed the presence of three methyl group (singlets), as well as one isolated geminal methylene proton pair. Taken with knowledge of the compound's origin, this spectroscopic information was sufficient to assign structure **20** to the dimer, a formal Diels–Alder adduct between the heterodiene system of one molecule of **13** and the terminal olefin of the dienol form of a second.[4] A few attempts were made to intercept these components (maleic anhydride as dienophile for the former; furan as diene for the other), but these were not successful. Only dimer **20** was isolated.

With the knowledge that 2-alkylidene-1,3-cyclopentanediones could be handled and characterized (albeit requiring some speed), new attempts were made to obtain them directly from the much more readily available 2-alkyl-1,3-cyclopentanedione precursors. As proposed in Scheme 2, the problem with the initial approach is thought to be the homolytic frangibility of the carbon–selenium bond. Carbon–sulfur bonds are stronger than those to selenium (11), it seemed therefore that substitution of sulfur for selenium might be exploited with success. With this change, the desired pericyclic elimination might be able to compete successfully with the homolytic bond cleavage pathway.

The sulfenylation of ketones has generally been achieved by reaction of the ketone enolate with diphenyl disulfide (12). To this end, the potassium enolate of 2-isopropyl-1,3-cyclopentanedione was prepared by reaction with potassium hydride in tetrahydrofuran. However, this stabilized β-dione enolate did not react with diphenyl disulfide or even the more electrophilic phenyl benzenethiosulfonate. 1,3-Cyclopentanediones have been sulfenylated with phenylsulfenyl chloride (13), but the

[3]Cyclic 1,3-diketones are easily peroxygenated without basic catalysts (9).

[4]Its regioisomer was excluded based on the high field position of the methylene protons of the dihydropyran sub-unit.

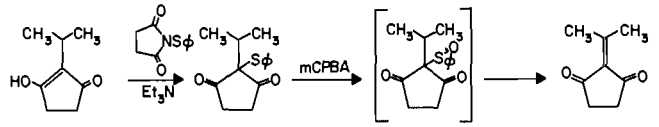
For personal use only.

instability of this reagent makes it impractical for general use. On the other hand, sulfenimides are stable, crystalline solids and have been shown to be effective sulfenylating reagents for active methylene compounds (14). Indeed, treatment of 2-isopropyl-1,3-cyclopentanedione with *N*-phenylthiosuccinimide in triethylamine and benzene resulted in its efficient conversion to the desired phenyl sulfide **21**. The ^{1}Hmr and ir spectral data for **21** were certainly consistent with this structure but, as before with the corresponding selenide **12**, it was ^{13}Cmr spectroscopy that permitted unambiguous determination that sulfenylation had occurred on carbon and not on oxgyen.

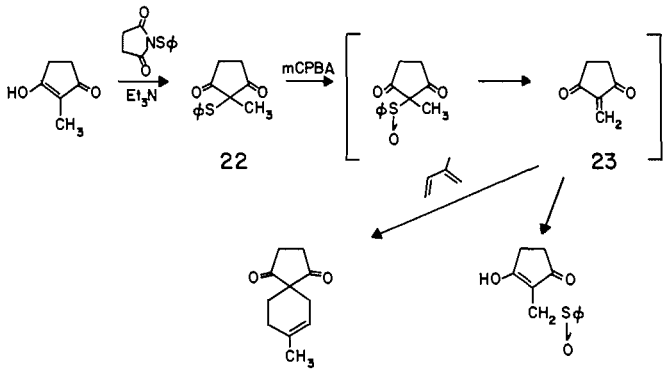


11 21 13

Oxidation of **21** was carried out with *m*-chloroperoxybenzoic acid (mCPBA). Experimentally, it was most convenient to add the peracid to a cold (−70°C) solution of **21**. Oxidation was sluggish at this temperature, but proceeded smoothly as the mixture was warmed toward room temperature. The presumed intermediate sulfoxide was not isolated, but was taken to 40°C, effecting elimination of phenylsulfenic acid and clean generation of the desired ene-dione **13**. This route gave for the first time a simple and direct conversion of a 2-alkyl-1,3-cyclopentanedione to the corresponding 2-alkylidene-1,3-cyclopentanedione.

Although it was outside our purpose to explore fully the application of this sulfenylation−oxidation−elimination to compounds not on the path to dodecahedrane, we did consider briefly the synthesis of the simplest 2-alkylidene-1,3-cyclopentanedione, the 2-methylene compound **23** (see Scheme 3). Phenylsulfenylation of the readily available 2-methyl-1,3-cyclopentanedione with *N*-phenylthiosuccinimide in benzene with triethylamine as base proceeded smoothly to give **22** in 90% yield. Reaction of **22** with *m*-chloroperoxybenzoic acid, as in the conversion **21** → **13**, gave (presumably) 2-methylene-1,3-cyclopentanedione. It was not possible to isolate this compound. Apparently, this unhindered, cross-conjugated enedione is exceptionally reactive. In the case at hand, it was trapped by Michael addition of cognate phenylsulfenic acid (15) to give a crystalline adduct assigned the sulfoxide structure **24**, consistent with the AB quartet in the ^{1}Hmr spectrum arising from the diastereotopic protons on the sulfoxide methylene group.

The exceptional reactivity of 2-alkylidene-1,3-cyclopentanediones can be put to very good use, for not only are the compounds active Michael acceptors, they are reactive dienophiles. Thus, when **23** was generated at 40°C in the presence of isoprene the major product (70% isolated yield overall from **22**) was a Diels−Alder adduct, the [4.5]spirocycle **25**.[5] Such spiro systems are common elements in the acorane and spirovetivane sesquiterpenes, etc. Clearly, this chemistry could be developed



22 23 25 24

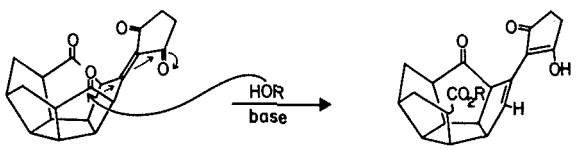
SCHEME 3

fruitfully with such goals in miond. Here, however, we turn to apply it to elaboration of peristylane.

2-(Peristylylidene)-1,3-cyclopentanediones

With the simple model work completed satisfactorily, we were able to apply sulfoxide elimination methodology successfully to the preparation of the peristylane ene-tetraone **27**. Phenyl sulfenylation of the peristylanedione-cyclopentanedione **9** with *N*-phenylthiosuccinimide gave **26**. Oxidation to the sulfoxide with *m*-chloroperoxybenzoic acid followed by warming to 40°C produced the desired ene-tetraone **27** as the major product (Scheme 4).

The important features of the ^{1}Hmr spectrum of **27** were the obvious simplifications due to symmetry, the broadened doublet at 5.15 ppm for the allylic methines (H-3 and H-5), and the absence of a signal for a proton at C-4. The molecular formula was confirmed by high resolution mass spectroscopy. This yellow, microcrystalline 2-alkylidene-1,3-cyclopentadione was completely stable to dimerization, no doubt due to the steric effects of the bulky peristylane substituent. The enedione chromophore could now be characterized precisely (see Experimental). The compound was, however, exceptionally sensitive to nucleophilic attack. If aqueous base were used in its work-up, substantial amounts of a by-product were formed. This is thought to have structure **28***a* (R = H) on mechanistic grounds supported by ^{1}Hmr and mass spectral evidence. Even carefully controlled attempts to perform Michael additions (CF_3CH_2OH, Et_3N) to the conjugated olefin of **27** resulted instead in facile, vinylogous retrograde-Claisen reaction, probably initiated by attack of the nucleophile at a carbonyl center on the peristylane ring as shown for the formation of **28***b* (R = CH_2CF_3).



27 28

The overall yield of ene-tetraone **27** from peristylanedione-cyclopentanedione **9** by the sulfenylation−oxidative elimination was 50%. It was good finally to have the material in hand, but this first synthesis was not altogether satisfying. There was, *ex post facto*, no reason to sulfenylate compound **9**, which was difficult to make and handle efficiently (enolized β-dicarbonyl). Why not instead have the sulfur substituent already attached to the cyclopentanedione ring at the time this

[5]The expected "*para*" regiochemistry was confirmed by converting **25** (ketalization, photochemical olefin migration, ketal hydrolysis) to its exocyclic double bond isomer, the nmr spectrum of which was in complete accord with the C_{2v} symmetry: δ 4.72 (2H, s), 2.81 (4H, 2), 2.41 (4H, t, $J \sim 5$ Hz), and 1.73 ppm (4H, t, $J \sim 5$ Hz), *quod erat demonstrandum*.

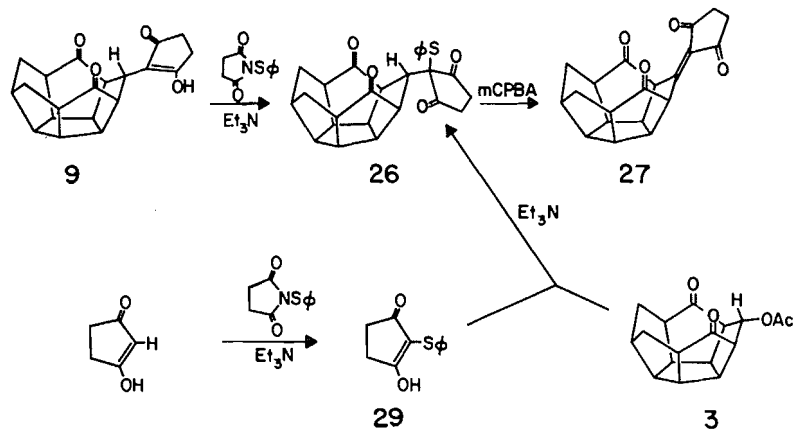


SCHEME 4

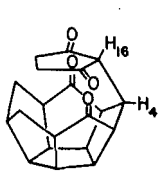
is put on the readily available peristylane **3**? The synthetic scheme would be more convergent, and **9** could be bypassed altogether.

The previously unknown 2-phenylthio-1,3-cyclopentanedione **29** was easily prepared in 90% yield by phenylsulfenylation of 1,3-cyclopentanedione with one equivalent of *N*-phenylthiosuccinimide. It was isolated as stable, colorless needles from ethyl acetate. Initial alkylation experiments using 4-acetoxyperistylane-2,6-dione (**3**) in methylene chloride with triethylamine afforded mainly the *O*-alkylated product. A simple change of solvent, from methylene chloride to benzene, resulted in exclusive *C*-alkylation; 80–85% yields of the crystalline (phenylthiocyclopentanedionyl)-peristylanedione **26** were then obtained from **3** in this single laboratory operation. This compound was taken as before to be **27**. A 70% yield of pure material was obtained directly. The major by-product was the desulfenylated material **9**, which could be recovered and recycled, bringing the total yield for this step to 80–85%. Overall then, ene-tetraone **27** could be prepared from **3** in 60–70% yield using just two simple laboratory operations on this most available peristylane. This sequence was altogether satisfactory for the preparation of multigram quantities of the ene-tetraone.

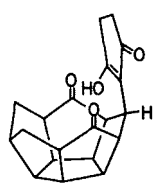
Before moving on to the next section the point should be made that 2-phenylthiocyclopentane-1,3-dione is easily made and should, in turn, make readily available a large variety of 2-alkylidene cyclopentane-1,3-diones to whose utility we have already alluded.

Stereochemistry at C-4

Hydrogenation of the olefin bond in ene-tetraone **27** from the outer, less-hindered face can be imagined to give the *endo* roofed compound **30***a*. The close geometrical relationship between this product and dodecahedrane is obvious. However, this conceptual drawing is illusory. It does not give proper weight to the steric congestion of groups about the peristylane rim nor to the ways that simple changes can minimize these interactions. Enolization and slight rotation about the peristylane–cyclopentane connecting bond (C-4, C-16) would move the "roof" out from close proximity to the peristylane rim (→ **30***b*). It was obvious therefore from the start that some conformational difficulties would pertain to further closures of **30** towards dodecahedrane.

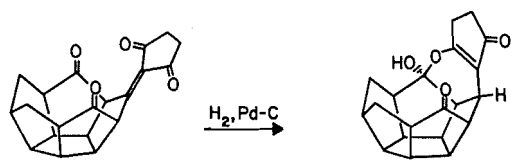


30*a*

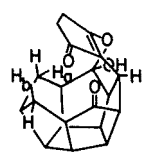


30*b*

Ene-tetraone **27** smoothly absorbed hydrogen over a palladium catalyst to give an equilibrating mixture of dihydro isomers, from which one eventually crystallized from chloroform solution. This compound was assigned structure **31**, formed via enolization of the hydrogenation product **30** and then internal hemiketalization. Molecular models of **31** suggest a low-energy conformation in which the dihydropyran so formed exists in a flattened half-chair conformation **31***a*. Minimization of steric interactions about the peristylane cavity would put one of the *endo*-peristylane protons (H_a) within the shielding region of the enone sub-system; the dihedral angles to the vicinal protons would be about 160°. Consistent with this, the ^{1}Hmr spectrum of **31** showed a signal for one proton unusually upfield at 0.38 ppm, appearing appropriately as a doublet of triplets (J_{gem} = 15 Hz, J_{vic} = 12 Hz). Complementarily, the other *endo* proton (H_b) appeared as a slightly broadened doublet at 2.08 ppm. In conformation **31***a* the dihedral angles for this proton to its vicinal neighbors are close to 90°, so only geminal coupling is observable.



27 **31**



31*a*

A sample of **31** was heated in acetic acid-d_4 with sodium acetate. At 50°C, exchange of deuterium for protium occurred over a period of hours at the four sites adjacent to carbonyls and potential carbonyls on the peristylane ring (C-1,3,5,7 by

For personal use only.

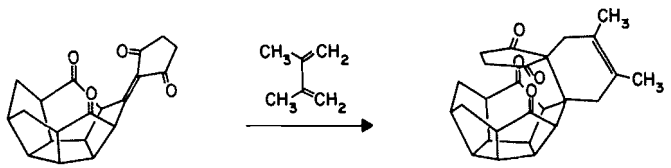
peristylane numbering).[6] The exchange was monitored conveniently by ^{1}Hmr, following the loss of vicinal spin coupling to the protons at C-4, C-8, and C-15. We interpret this exchange to mean that **31** under these conditions was in equilibrium with its open forms.

These results showed that the ready enolization of the β-diketone of the roof fragment would be little more than a nuisance. Conformational flexibility about the C-4, C-16 bond was surely to be more troublesome as there was no reason for the roof to assume a conformation consistent with the required bonding ahead. Our plan from the beginning therefore was to set in the appropriate conformation by Diels–Alder addition to (rather than reduction of) the electron deficient olefin of **27**. This incidentally would also solve the enolization problem. We were encouraged in this with the results from simple model systems, e.g. **23** → **25**. Indeed, reaction of **27** with excess 2,3-dimethylbutadiene in a sealed tube at 130°C gave the crystalline, 1:1 Diels–Alder adduct **32** in 85% yield. Examination of its ^{1}Hmr and ^{13}Cmr spectra confirmed this assignment of structure fully.



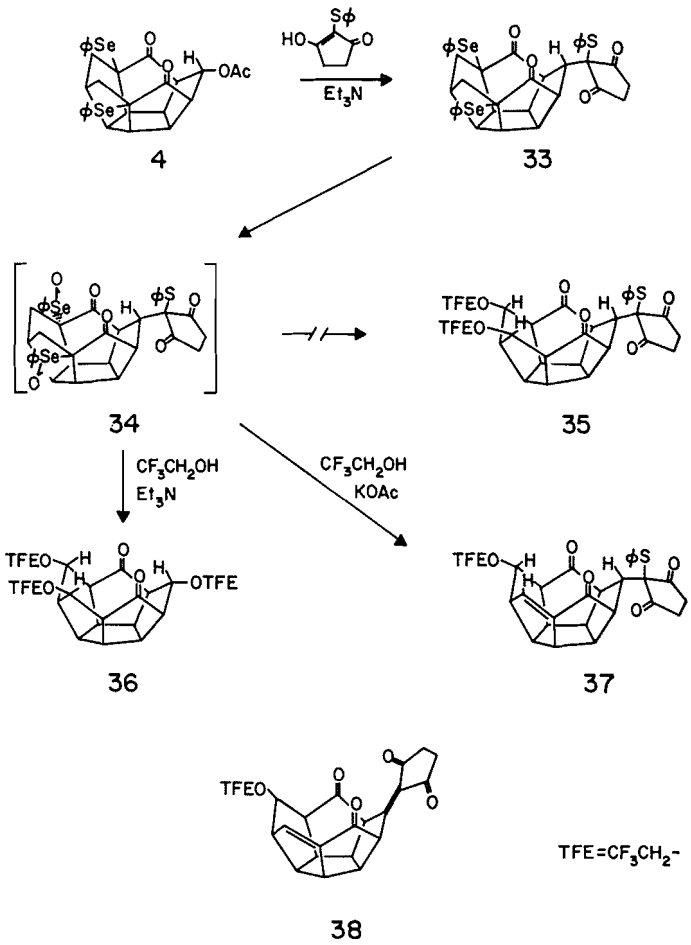
27 32

Further functionalization

Compound **32**, available in just three synthetic steps from acetoxyperistylanedione **3**, is a very attractive dodecahedrane intermediate. All twenty carbon atoms are there and are suitably arranged for incorporation into the dodecahedrane skeleton. The nuisance enolization of the β-dione system has been blocked, and rotation around the peristylane–cyclopentane connective bond (C-4, C-16) has at least been partially restricted. Construction of only four carbon–carbon bonds would complete the dodecahedrane cage. On paper, all that seems necessary for two of these bonds is the introduction of leaving groups at C-8 and C-15, followed by intramolecular alkylation α to each carbonyl group of the roof.

Methodology for the functionalization of the C-8 and C-15 positions had been described in our earlier paper (3*c*, cf. Scheme 1); now it was a matter of integrating it into the evolving scheme. Reaction of the known (3*c*) 1,7-bis(phenylselenenyl)-4-*exo*-acetoxyperistylane-1,5-dione (**4**) with 2-thiophenyl-1,3-cyclopentanedione and triethylamine in benzene formed the desired C-4 alkylated product **33** in 84% yield (Scheme 5). Low temperature ozonization of **33**, as expected, oxidized the selenide groups cleanly and selectively without affecting the sulfide portion of the molecule. No attempts was made to isolate this bisselenoxide-sulfide (**34**); it was allowed instead to decompose in the presence of triethylamine and trifluoroethanol. The expected eliminations of phenylselenenic acid and the Michael additions of trifluoroethanol to the transient enones so formed occurred smoothly, but (distressingly)

[6]The methylene protons of the enolized cyclopentanedione underwent exchange at a substantially slower rate; extended enolization of an already enolized system is not easy. Exchange of two of these cyclopentane protons (presumably those in the *exo*-position) was eventually effected by raising the temperature to 100°C.

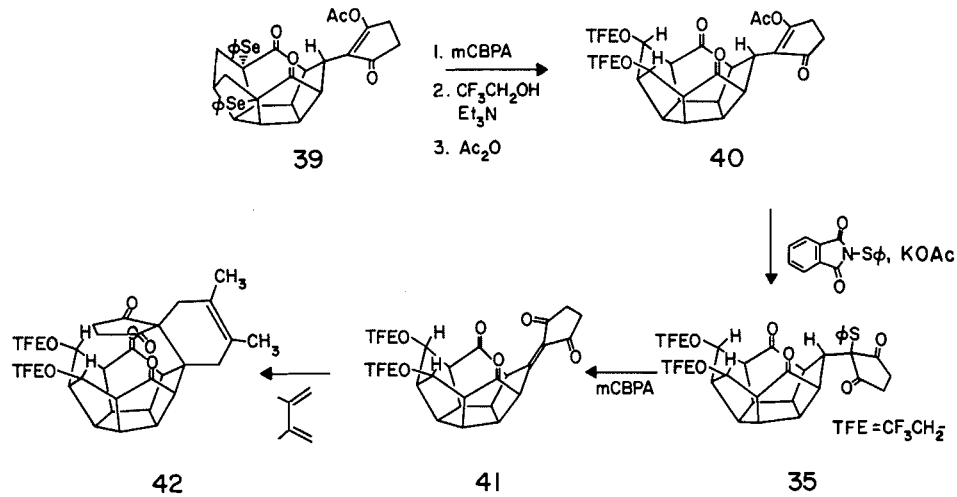


4 33 34 35 36 37 38

SCHEME 5

the product finally isolated was the tris(trifluoroethyl ether) **36** (3*c*). None of the desired compound **35** could be isolated.

Apparently, under the conditions of the reaction, reverse Michael loss of the highly-stabilized anion of 2-thiophenyl-1,3-cyclopentanedione occurred to give the familiar peristyl-3(4)-enone system, which then added the third trifluoroethanol unit. We thought it should be possible to suppress this retro-Michael elimination by using a weaker base than triethylamine. To test this, the simpler phenylthiocyclopentanedione-peristylanedione **26** was put through a series of model experiments to determine the range of conditions compatible with the thiophenylcyclopentanedione moiety. Alkyl amines, alkali metal carbonates, and bicarbonate bases in trifluoroethanol all promoted retro-Michael reactions at ambient temperature. Pyridine and alkali metal carboxylate salts were unreactive under these conditions, meriting further consideration for use in the conversion **33** → **35**. Pyridine proved unsuitable in the real case – intractable mixtures were produced. Potassium acetate was used somewhat more successfully. When **33** was ozonized in methylene chloride at −70°C, and the solution then allowed to warm to room temperature in the presence of added trifluoroethanol and potassium acetate, the thiophenylcyclopentanedione moiety remained intact, and the elimination–addition chemistry on the rest of the molecule went well, if somewhat astray. The major product isolated was now the ene-trifluoroethyl ether **37**. A bit, but not enough, of the more desirable bis(trifluoroethyl ether) **35** could be detected spectroscopically.



SCHEME 6

Although the ene-ether **37** might at first be considered functionally equivalent to **35** with regard to the projected enolate closure reactions, there are some unfortunate problems with this idea. The alkylidene cyclopentanedione **38**, of which **37** could be parent, would certainly react first in a Diels–Alder addition at the peristylenone double bond rather than at the ene-dione; we have shown already that such strained, twisted olefins are exceptionally reactive in these diene additions (3*c*). On the other hand, there is no possibility of being able to achieve selective Michael addition to the peristylenone double bond in the presence of the much more Michael-receptive enedione moiety; recall the reverse Claisen cleavage of **27** → **28**. The only remaining remedy is to effect addition to the peristylenone **37** before oxidative elimination of the phenylthio group. Disappointingly, all attempts to do this, extending over a wide variety of nucleophiles, were without significant reward.

More devious ways around this stalemate were sought. If the sulfide group in **33** could be oxidized to the exclusion of the selenide groups, then elimination and Diels–Alder addition at C-4 could be carried out first, without interference from sensitive groups on the peristylane ring. Unfortunately, no method to achieve such selectivity is known; on the contrary, selenides are oxidized much more easily than sulfides. But if the sulfur group were to be oxidized prior to its introduction into the molecule, the presence of the selenides would offer no problem. To this end, 2-phenylthio-1,3-cyclopentanedione was oxidized to the corresponding sulfoxide with 2-hydroperoxyhexafluoroisopropanol (16). The sulfoxide was heated in benzene with triethylamine and 4-acetoxyperistylanedione. Under the conditions of the experiment, had any of the *C*-alkylated adduct formed, it would have immediately suffered thermolysis to the known ene-tetraone **27**. Unfortunately, none of this material was obtained.

Since the development of proper substitution at the C-8 and C-15 positions of peristylane required nucleophilic conditions incompatible with a fragile group or good nucleofuge at C-4, we turned to placing the enolate ion of a 1,3-cyclopentanedione at C-4. The negative charge on this ion would effectively prevent it from being attacked by nucleophiles or behaving as a leaving group. The plan (Scheme 6), unhappily less convergent than before, was to carry out the selenoxide elimination – Michael addition sequence to functionalize C-8 and C-15 on compound **5** (from **39**)[7] in which cyclopentane-1,3-dione was already in place as the C-4 appendage. Under the basic conditions of the reaction the β-diketone would of course be in its ionized, enolic form. After functionalization of the peristylane methylenes had been completed, sulfenylation, oxidative elimination, and Diels–Alder addition should then provide the desired, fully-developed dodecahedrane precursor **42**.

Condensation of cyclopentane-1,3-dione with bis(phenylselenenyl)acetoxyperistylanedione **4** in triethylamine and benzene, followed by treatment of the crude adduct with acetic anhydride, gave the beautifully crystalline enol acetate **39** in 95% overall yield. Oxidation of the selenide groups of **39** with ozone, even at low temperature, also gave substantial oxidation at the enol double bond. Fortunately, the use of *m*-chloroperoxybenzoic acid at −70°C avoided this complication and provided the bisselenoxide with a minimum of side reactions. When trifluoroethanol and triethylamine were added to the cold solution of the (unisolated) bisselenoxide, and the mixture was allowed to warm to room temperature, sequential elimination and Michael addition occurred without interference. Of course, these conditions were sufficient to take the enol acetate of the dione to the desired enolate anion, shielding the group from displacement or attack. Work-up and reacetylation (Ac_2O) gave the enol acetate **40**. This was then subjected to a very mild deprotection–sulfenylation sequence with *N*-phenylthiosuccinimide, trifluoroethanol, and potassium acetate. Isolation by preparative thin-layer chromatography provided finally the elusive sulfenylated bis(trifluoroethyl ether) **35** in 45–50% overall yield from **39**.

Oxidative elimination of phenyl sulfenic acid from **36** was effected smoothly as before with *m*-chloroperoxybenzoic acid. Buffered work-up followed by trituration with diethyl ether gave a 73% yield of the bright yellow ene-tetraone **41**, whose identity followed from its ^{1}Hmr spectrum. After so much frus-

[7]In practice, it was much more satisfactory to work with this enol acetate than with the free β-diketone **5**. The derivative had the advantage of high solubility in common organic solvents and under the reaction conditions to be used for C-8/C-15 functionalization, trifluoroethanol and triethylamine (or even potassium acetate), the enol acetate was rapidly converted to the enolate anion. Thus, **39** served as a synthetic equivalent of **5**, while conferring the convenience of solubility.

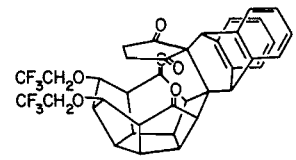
tration, this was indeed a pleasing result.

Reaction of **41** with 2,3-dimethylbutadiene in a sealed tube at 100°C gave the desired Diels–Alder adduct **42**. The reaction proved capricious; yields ranged, without apparent reason, from 0 to 100%. It proved wise therefore to do only small-scale runs.[8] Nevertheless, it was possible to prepare and characterize **42** and to bring up sufficient material to investigate the chemistry of this crucial intermediate. The mass spectrum was in agreement with the assigned structure, and the ^{1}Hmr spectrum was readily recognizable as that of an 8,15-substituted peristylane.

The conformation problem

At this point our synthetic plan called for generation of an enolate anion in the roof five-membered ring and its bonding into the peristylane portion via one of two possible mechanisms: the first, simply S_N2 displacement of the appropriately sited trifluoroethoxy group in an intramolecular alkylation; alternatively, base-induced elimination of trifluoroethanol would give a peristylenone to which the roof enolate could add in Michael fashion. Done twice over, either of these internal alkylations would produce the desired bissecododecahedrane, from which a dodecahedrane could then be obtained by, for example, pinacol closure. This plan requires a proper orientation of the reactive sites within the molecule (C-8 must bond with C-18; C-15 with C-19). The necessary stereochemical alignment is possible, but by no means comfortable. The required conformation in **42** involves significant non-bonded interactions between opposing *endo*-oriented protons. At this point in our work the solid-state structure of the closely related Diels–Alder adduct **32** was obtained by single crystal X-ray analysis. The drawings in Fig. 1 generated from this analysis clearly show the fused 6-membered ring of **32** in its half-chair conformation and the cyclopentanedione unit in an orientation skewed to the peristylane mirror plane. Thus, even with the extra rigidity provided by the annulated cyclohexene ring, the molecule can still flex away from the necessary conformational arrangement.

A molecule with a yet more rigid skeleton was needed. Diels–Alder adducts of ene-tetraone **41** to cyclic rather than



43

acyclic dienes would, with the extra bridge, have much less conformational flexibility. For example, in the anthracene adduct **43** the cyclopentanedione "roof" would be locked into position symmetrically over the peristylane bowl with very little torsional movement possible.

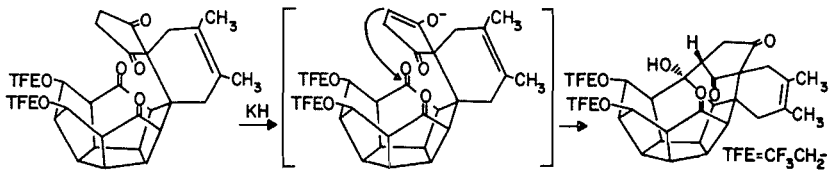
Exploratory reactions were carried out with the readily available ene-tetraone **27**. Even with prolonged reaction times at 100–200°C, none of the desired adduct could be obtained with anthracene or the more highly reactive 9,10-dimethylanthracene. Under forcing conditions, charring of the ene-tetraone occurred. Attempted catalysis with Lewis acids gave only unreacted starting materials, even after long reaction times. Tries at additions of cyclic, non-aromatic dienes (e.g. cyclohexa-1,3-diene) were equally without reward. Even furan at very high pressures failed to add. Diels–Alder reactions are often easily reversible, and here it now seems probable that the steric congestion enforced in the desired adduct sets the equilibrium position well to the side of the starting materials.

A variety of other attempts was made to provide locks on the conformation of the roof: light-induced 2+2 cycloadditions (e.g. cyclopentene) and thermal 2+2 and 1,3-dipolar cycloadditions (e.g. 1,1-dimethoxyethylene, diazomethane). These reactions often gave interesting chemistry, but none proved useful for solution of the problem at hand.

Attempts at closure

Although it was clear that the conformational preferences of **42** were not ideal for the necessary bond-forming reactions, neither were they forbidding. With little other choice available we proceeded to examine the reactions of **42** under enolate-generating conditions. Heating it under equilibrating conditions in trifluoroethanol with potassium carbonate caused loss of trifluoroethanol from the peristylane rim. Escalation of the reaction conditions to higher temperatures or longer reaction times caused only unproductive destruction of starting material. Use of amine bases (triethylamine or 1,4-diazabicyclo-[2.2.2]octane led to similar results. Potassium *tert*-butoxide in *tert*-butyl alcohol caused resinification. Many other systems were tried. In one, on the supposition that a complexing cation might favor bond-closing conformations by association

[8]Much effort was expended to bring the reaction under control, but this was not achieved. In one case, the two major wayward products had molecular formula $C_{38}H_{44}O_4$, implying double elimination of trifluoroethanol and net uptake of three equivalents of dimethylbutadiene. One product gave a ^{1}Hmr spectrum indicative of a time average plane of symmetry, consistent with a tris Diels–Alder adduct. The isomeric product quite likely resulted from at least one ene-type addition.

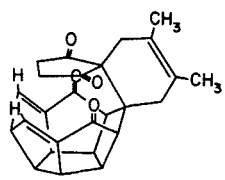


42 44

with the carbonyl oxygens, the reaction was attempted with magnesium methoxide as the base; only starting material was recovered.

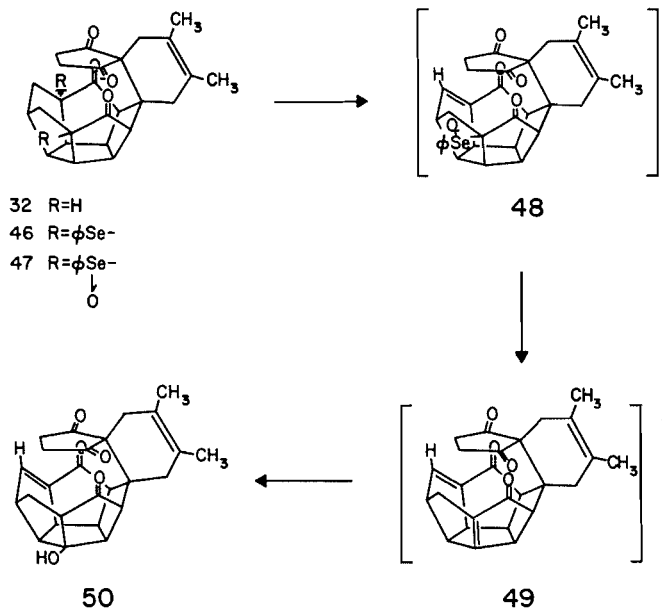
Kinetic deprotonation conditions were tried next. When a tetrahydrofuran solution of **44** was added to a slurry of potassium hydride in tetrahydrofuran at −70°C, there was no reaction at all. Quenching with acetic acid-*O-d* gave only starting material without any deuterium incorporation. When the reaction mixture was allowed to warm to −45°C, a yellow color developed, signaling some kind of reaction. Quenching with acetic acid-*O-d*, followed by work-up with H_2O at room temperature, gave a new compound. Prominent peaks in the mass spectrum were observed at *m/e*'s corresponding to loss of water and to loss of trifluoroethanol from the starting material. No deuterium incorporation was evident. By ^{1}Hmr, the compound was clearly non-symmetric; both trifluoroethoxy groups were intact; one D_2O-exchangeable proton could be detected. The ir spectrum showed a weak band consistent with the presence of a tertiary alcohol and obvious carbonyl group absorptions. The structure was assigned as **44**, the product of an internal aldol reaction between a cyclopentanedione enolate at C-19 and a peristylane carbonyl group at C-6. Reference to Fig. 1 provides rationalization for this product without lengthy comment; the juxtaposition of the peristylane carbonyl center with the cyclopentanedione methylene group permits facile intramolecular reaction.

The conformation of **42** works against the desired bond closure reactions. The *endo*-oriented hydrogens at C-8 and C-15 are responsible, at least in part, for the conformational difficulty. This would be eliminated by conversion of **42** to the bis olefin **45**. We thought this very highly strained molecule might be made available transiently by oxidative elimination from bisselenide **46** done *in the absence of nucleophiles*. If this worked, then if the cyclopentanedione enolate could be formed (non-nucleophilic base), the desired intramolecular Michael addition might subsequently occur spontaneously.



45

The necessary bisselenide **46** was prepared in good yield by selenenylation of tetraketone **32**. Low temperature oxidation with *m*-chloroperoxybenzoic acid gave (presumably) the corresponding bisselenoxide **47**. The reaction mixture was allowed to warm to room temperature in the presence of a large excess of triethylamine. The product (80% yield!) was the extraordinary ene-alcohol **50**, the first peristylane with a basal plane substituent. Its molecular formula was established by mass spectroscopy, and the structure was deduced from extensive ^{1}Hmr decoupling experiments which established the connectivity in the system. As proposed in the progression **47** → **50**, the first selenoxide elimination probably occurred along the peristylane rim as normal, giving enone **48**. All previous eliminations of peristylane bisselenoxides had been performed under conditions of high nucleophile concentration wherein this kind of enone would have undergone Michael addition prior to the second elimination. In the case at hand, with only adventitious water available as nucleophile, this sub-unit can survive. Apparently its presence alters markedly the elimination pathway of the second selenoxide. Probably the conformation of the peristylenone is such that the *syn* arrangement necessary for concerted loss of phenylselenenic acid along the rim is less available, whereas that for loss toward the basal position is not. By default, then, elimination would occur towards the base giving the very strained olefin **49** which in turn would hydrate readily. Further discussion of such compounds will be reserved for a later paper, with less complex examples.



A brief excursion with another approach

Bonding reactions of the kind anticipated clearly require more rigid geometric control than we have yet achieved. A small torsional displacement at the single connective bond between roof and peristylane in **42** causes a drastic misalignment of the bonding positions C-8 and C-18, C-15 and C-19. This distortion is much less severe between the pairs of carbonyl positions. Geometrically, it might be easier to construct bonds between these carbonyl centers. Two-fold pinacol coupling within **32** would provide a bissecododecahedrane. (Of course, the loss of the carbonyl groups would necessitate a new strategy for closure of the final bonds.) Unfortunately, tetraketone **32** proved completely inert to treatment with magnesium amalgam

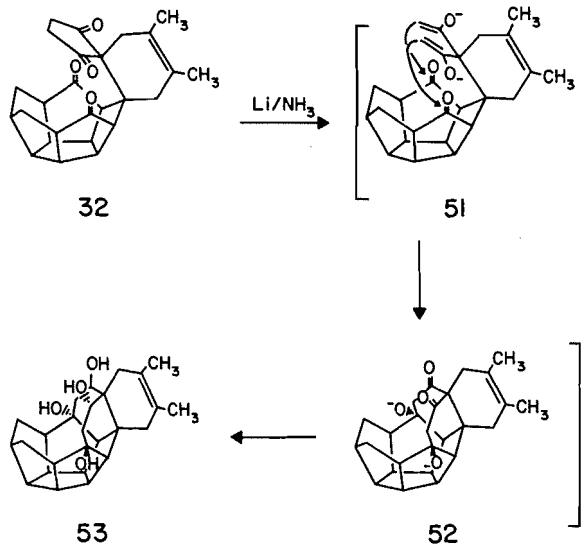
in refluxing dioxane and variations on such classical pinacol coupling conditions. Suffice it to say, although many reagents and conditions were tried, none of them – from simple zinc and magnesium metal systems to the more exotic low-valent titanium species – led to any of the desired pinacol product.

Only one reduction system ever gave an identifiable, symmetrical material. Lithium – liquid ammonia reduction of tetraketone **32** provided a 30–40% yield of a crystalline material, tentatively assigned tetraol structure **53** on the basis of nmr and mass spectroscopy. Under these reducing conditions, the 1,4-diketone bonding within the cyclopentanedione was apparently cleaved reductively to the bisenolate **51**. Two-fold intramolecular aldol reaction (→**52**) and subsequent reduction of the ketones would account for the observed product. Although a very interesting ring system of highly convex topology, tetraol **53** is not especially well suited for development to dodecahedrane. The twenty-carbon framework has been effectively scrambled.



Conclusion

The cyclopentanedione-peristylanedione route to dodecahedrane has been examined from many different angles in this work; much has been learned, but our goal has not yet been reached. One point in particular has been driven home repeatedly – the effect of steric congestion around the peristylane cavity is to discourage much more dramatically than expected those reactions originally projected to complete the scheme.

Experimental

Proton nmr spectra of solutions in deuteriochloroform were taken in pulsed-Fourier mode at 500 MHz unless indicated otherwise and were referenced to internal chloroform (δ = 7.26 ppm). Chemical shifts are reported to a precision of ±0.02 ppm and coupling constants to ±1 Hz. Carbon-13 nmr spectra of solutions in deuteriochloroform were obtained in pulsed-Fourier mode at 22.63 MHz. Chemical shifts, referenced to the center line of deuteriochloroform (δ = 77.0 ppm), are reported to the nearest 0.1 ppm.

High-resolution mass spectra were obtained at an ionizing potential of 50–70 eV with perfluorokerosene as an internal reference. In most cases samples were homogeneous by tlc.

Infrared spectra were referenced to the 1602 cm^{-1} band of polystyrene for calibration. Spectra were recorded as solutions in chloroform unless otherwise noted. Absorptions are reported to a precision of ±3 cm^{-1} for bands of importance.

Analytical thin-layer chromatography (tlc) was performed on fluorescent-indicating silica gel on plastic sheets precoated to a thickness of 0.25 mm (Machery–Nagel Co.). Visualization was accomplished under ultraviolet light or with iodine vapor. Preparative thin-layer chromatography was performed on silica gel precoated on glass plates to a thickness of 1 mm (Brinkman Instruments, Inc.). Column chromatography was done using slurry-packed columns of 60–200 mesh silica gel (J. T. Baker Chemical Co.). Eluting solvents are reported as volume-to-volume mixtures, with the minor component given first.

Reactions were generally run under an inert atmosphere of either dry nitrogen or argon. Concentration of solutions during work-up procedures refers to the evaporation of solvent on a rotary evaporator under house vacuum (about 40 Torr; 1 Torr = 133.3 Pa) at 20–30°C. Pumping down of a sample refers to initial removal of solvent on the rotary evaporator, followed by removal of residual volatiles on a vacuum line at 20 mTorr.

Solvents were bulk reagent grade and were dried and distilled before use: methylene chloride and ethyl acetate were distilled from phosphorous pentoxide; hexane and pentane were distilled over concentrated sulfuric acid; benzene was dried azeotropically, then distilled; methanol was distilled over magnesium metal and a catalytic amount of iodine.

Ozone was generated to a concentration of ca. 5% in a stream of oxygen using an Orec Model E3V5-O Ozonator. The effluent stream was dried with sulfuric acid before use.

Melting points are uncorrected. Microanalyses were performed by MicAnal Laboratories.

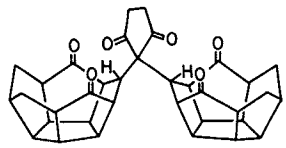
exo-*4-(1-Phenylselenenocyclopentyl-2,5-dione)-1,7-bis(phenylselenenyl)hexacyclo[7.5.1.$0^{3,13}$.$0^{5,12}$.$0^{7,11}$.$0^{10,14}$]pentadecane-2,6-dione* (**6**)

Compound **4** (100 mg, 0.17 mmol), prepared as described previously (3*c*), and 1,3-cyclopentanedione (60 mg, 0.61 mmol) were put into a resealable Carius tube with potassium carbonate (100 mg, 0.72 mmol) and 2,2,2-trifluoroethanol (3 mL). The tube was sealed and the mixture stirred at 70°C for 40 h. After cooling, the contents of the tube were rinsed into a separatory funnel with 1 *M* HCl (10 mL) and the whole extracted with methylene chloride (6 × 10 mL). The extract was dried ($MgSO_4$), filtered, and concentrated to leave a yellow solid contaminated with 1,3-cyclopentanedione. Trituration with cold isopropanol (2 mL), followed by drying under vacuum, left **5** as a white solid (75 mg, 70%). (This material was characterized as its enol acetate, compound **39**, *vide infra*.)

A solution of crude **5** (32 mg, 0.05 mmol) in methylene chloride (11 mL), ethyl acetate (3 mL), and pyridine (5.5 mL) was stirred at room temperature as solid phenylselenenyl chloride (29 mg, 0.151 mmol) was added. The resulting pale yellow solution was stirred 4 h, then pumped down to leave an orange-yellow residue. The product was purified by column chromatography, eluting first with methylene chloride to remove diphenyl diselenide, then 5% ethyl acetate – methylene chloride to elute the tris(phenylselenide) **6** (32 mg, 80%). Purification of this material could not be effected satisfactorily but, as its ^{1}Hmr spectrum was sufficiently in accord with expectation, it was used as it was; ^{1}Hmr δ: 7.8–7.3 (15H), 3.77 (1H, q, *J* = 10 Hz), 3.53 (1H, br s), 3.38 (2H, m), 3.27 (2H, m), 2.94 (2H, d of d, *J* = 7, 17 Hz), 2.90 (1H, m), 2.79 (2H, br d, *J* = 9 Hz), 2.45 (2H, d of d, *J* = 7, 17 Hz), 2.24 (2H, d of d, *J* = 10, 15 Hz), 2.04 (2H, d of d, *J* = 4, 15 Hz) ppm.

exo-*4-(Cyclopentyl-2,5-dione)-hexacyclo[7.5.1.$0^{3,13}$.$0^{5,12}$.$0^{7,11}$.$0^{10,14}$]-pentadecane-2,6-dione* (**9**)

Acetoxyperistylanedione (**3**, 57 mg, 0.20 mmol), 1,3-cyclopentanedione (20 mg, 0.20 mmol), and triethylamine (0.20 mL, 1.4 mmol) were refluxed together in benzene (8 mL) for 4 h. The mixture was then cooled; the volatiles were removed *in vacuo*. Water (4 mL) and a trace of phenolphthalein were added. Aqueous 1 *M* NaOH was added to the suspension very slowly with good agitation until a just pink endpoint was sustained. Filtration gave a white powder (3 mg)



54

identified spectroscopically as the double adduct **54**; ^{1}Hmr δ: 3.64 (4H, m), 3.58 (2H, q, J = 10 Hz), 3.37 (2H, br s), 3.30 (4H, m), 2.84 (4H, br d, J = 9 Hz), 2.74 (4H, s), 2.75–2.65 (6H, m), 2.30 (4H, d of t, J = 15, 10 Hz), 1.75 (4H, d of t, J = 15, 4 Hz) ppm.

Acidification of the filtrate with excess 10% hydrochloric acid gave a white precipitate which was extracted into methylene chloride (3 × 10 mL). The extract was dried (Na_2SO_4), filtered, and evaporated to dryness. Trituration with ether left 55 mg (85%) of **9** of reasonable quality; this was usually taken on without further purification. Crystallization (with difficulty) of a small sample from methanol gave a bit better material, mp >290°C; ir (KBr) ν: 2700, 1730, 1575 cm^{-1}; ^{1}Hmr ($CDCl_3$ with a drop of C_5D_5N) δ: 3.89 (3H, m), 3.43 (1H, q, J = 9 Hz), 3.20 (2H, q, J = 10 Hz), 2.76 (2H, m), 2.61 (2H, m), 2.54 (1H, m), 2.33 (4H, s), 1.88 (2H, d of t, J = 13, 9 Hz), 1.54 (2H, d of t, J = 13, 5 Hz) ppm; m/e: 324.1411 ($C_{20}H_{20}O_4$ requires 324.1362).

*exo-4-(1-Phenylselenenocyclopentyl-2,5-dione)-hexacyclo[7.5.1.0^{3,13}.0^{5,12}.0^{7,11}.0^{10,14}]pentadecane-2,6-dione (**10**)*

Crude compound **9** (32 mg, 0.1 mmol) was dissolved in pyridine (500 μL) and ethyl acetate (1 mL). Solid phenylselenenyl chloride (21 mg, 0.11 mmol) was added. The yellow solution was stirred for 2 h at room temperature under nitrogen. The reaction mixture was diluted with methylene chloride (10 mL) and washed with 1 *M* sulfuric acid (10 mL). The organic phase was dried ($MgSO_4$), filtered, and concentrated. The residue was purified by trituration with pentane, followed by quick chromatography on silica gel with ethyl acetate. Evaporation left a yellow-orange crystalline solid which could not be purified further efficiently, but was of sufficient quality to use in trial oxidations; ^{1}Hmr δ: 7.7–7.3 (5H, aromatics), 3.77 (1H, q, J = 10 Hz), 3.53 (1H, br s), 3.38 (2H, m), 3.27 (2H, m), 2.94 (2H, d of d, J = 7, 17 Hz), 2.90 (1H, m), 2.79 (2H, br d, J = 9 Hz), 2.45 (2H, d of d, J = 7, 17 Hz), 2.24 (2H, d of d, J = 10, 13 Hz), 2.04 (2H, d of d, J = 4, 15 Hz) ppm.

Preparation and oxidation of 2-isopropyl-2-(phenylselenenyl)-1,3-cyclopentanedione

A stirred solution of 2-isopropyl-1,3-cyclopentanedione (**11**, 100 mg, 0.70 mmol) in ethyl acetate (10 mL) and pyridine (60 μL) was treated with phenylselenenyl chloride (160 mg, 0.83 mmol, added as a solid). The yellow solution was stirred for 2 h, then poured into 25 mL of 0.04 *M* H_2SO_4. The layers were separated, and the aqueous phase was extracted twice with methylene chloride (10 mL total). The combined organic phase was dried (Na_2SO_4) and concentrated to a yellow oil which was purified by column chromatography (methylene chloride). Selenide **12** (200 mg, 95%) was obtained as a pale yellow oil and used directly without further purification; ^{1}Hmr (350 MHz) δ: 7.55 (2H, d, J = 8 Hz), 7.44 (1H, t, J = 8 Hz), 7.34 (2H, t, J = 8 Hz), 2.65 (2H, m), 2.46 (2H, m), 2.26 (1H, heptet, J = 7 Hz), 1.17 (6H, d, J = 7 Hz) ppm; ^{13}Cmr δ: 208.2 (s), 137.6 (d), 130.2 (d), 129.2 (d), 125.7 (s), 64.8 (s), 34.8 (t), 29.9 (d), 18.4 (q) ppm.

A stream of ozone in oxygen was bubbled through a cold (−70°C) solution of selenide **12** (50 mg) in methylene chloride (5 mL) until the bright blue color of ozone developed. Excess ozone was removed in a nitrogen stream until the effluent gave a negative starch–iodide test. The cold bath was removed, and the solution was stirred at room temperature for 2 h. The yellow solution was concentrated. By ^{1}Hmr analysis the residue was shown to contain three aliphatic products in a 6:3:2 ratio. These were identified as diketo acid **16**, deselenenylated dione **11**, and tertiary alcohol **17**, respectively. Although rather sensitive to chromatography, pure samples of **16** and **17** could be isolated by preparative tlc (10% ethyl acetate − methylene chloride); **16** (R_f = 0.4); ir ν: 3100, 1720 cm^{-1}; ^{1}Hmr (270 MHz) δ: 3.30 (1H, heptet, J = 7 Hz), 2.97 (2H, m), 2.53 (2H, m), 1.04 (6H, d, J = 7 Hz) ppm; m/e: 172.0743 ($C_8H_{12}O_4$ requires 172.0735); **17** (R_f = 0.3); ^{1}Hmr δ: 3.05 (2H, m), 2.70 (2H, m), 2.15 (1H, heptet, J = 7 Hz), 0.95 (6H, d, J = 7 Hz) ppm; m/e: 156.0826 ($C_8H_{12}O_3$ requires 156.0786).

*2-Isopropylidene-1,3-cyclopentanedione (**13**) and 3-(cyclopentyl-2,5-dione)-3,5,5-trimethyl-2-oxabicyclo[4.3.0]non-1,6-en-7-one (**20**)*

Method A

Palladium catalyst (38 mg, 10% on carbon support) which had been washed free of carbonate was suspended in methylene chloride (15 mL). The flask was attached to an atmospheric pressure hydrogenator and agitated vigorously (Vibromixer shaking) for 30 min under hydrogen. The suspension was then cooled to 0°C; diene-dione **18** (136 mg, 1.00 mmol) was added as a solid. The mixture was shaken at 0°C for 1 h, at which time hydrogen uptake had reached 24 mL (1.1 equiv.). The reaction mixture was filtered through a pad of Celite, then concentrated to leave a yellowish semi-solid consisting mostly of ene-dione **13**; uv (CH_2Cl_2) λ_{max}: 239 (ε ~7,900), 264 (~3,200) and 390 nm (~12), cf. text; ^{1}Hmr (270 MHz) δ: 2.64 (4H, s), 2.54 (6H, s) ppm.

The ene-dione **13**, on standing in the concentrated state for several hours at room temperature, converted to dimer **20**. This was purified by crystallization from ether–hexanes to give colorless prisms (96 mg, 70% from **18**), mp 200–202°C (dec.); ir ν: 2800, 1692, 1635 cm^{-1}; uv (ethanol) λ_{max}: 250 nm (ε = 24 300), shifts to λ_{max} = 260 nm (ε = 26 000) upon addition of a small amount of 10% aqueous K_2CO_3; ^{1}Hmr δ: 9.04 (1H, br s), 2.62–2.30 (5H, m), 1.99 (1H, d, J = 16 Hz), 1.63 (3H, s), 1.29 (3H, s), 1.11 (3H, s) ppm; ^{13}Cmr ($CDCl_3$ + py-d_5) δ: 204.0, 193.2 (2 carbons), 183.1, 121.2, 118.2, 82.3, 43.1, 33.6, 30.8 (2 carbons), 28.8, 28.4, 27.6, 26.3, 25.6 ppm; m/e: 276.1383 ($C_{16}H_{20}O_4$) requires 276.1361).

Method B

A solution of 2-isopropyl-2-phenylthio-1,3-cyclopentanedione **21** (*vide infra*, 248 mg, 1.0 mmol) in methylene chloride (10 mL) was prepared in a 25-mL round-bottomed flask equipped with a stirring bar and addition funnel. The mixture was cooled in a Dry Ice/methanol bath; a solution of *m*-chloroperoxybenzoic acid (216 mg, 80% titre, 1.0 mmol) in methylene chloride (5 mL) was added dropwise over 5 min. The cold bath was removed, and the mixture allowed to warm toward room temperature. After 5 min, a reflux condenser was fitted to the system, and the white suspension was warmed to reflux on a steam bath. The solids quickly dissolved, and a bright yellow color developed. After 30 min, the yellow solution was cooled, diluted with methylene chloride (10 mL), and washed with 20 mL of 0.15 *M* phosphate buffer (pH 7.5) to remove *m*-chlorobenzoic acid (17). After drying ($MgSO_4$), the solvent was removed *in vacuo*. Analysis of the residue by ^{1}Hmr showed only signals for **13** and its dimer **20** in the aliphatic region.

*2-Isopropyl-2-phenylthio-1,3-cyclopentanedione (**21**)*

2-Isopropyl-1,3-cyclopentanedione (280 mg, 2.00 mmol) and *N*-phenylthiosuccinimide (414 mg, 2.00 mmol) were stirred together in benzene (10 mL). Triethylamine (0.6 mL) was added, and the solution was heated at reflux for 2 h. The mixture was then cooled to room temperature and concentrated. The brown semi-solid residue was extracted with hot hexane (4 × 10 mL). Concentration of the extract left **21** (480 mg, 97%) as a light yellow oil of reasonable purity by ^{1}Hmr; ^{1}Hmr (270 MHz) δ: 7.45 (2H, d, J = 8 Hz), 7.41 (1H, t, J = 8 Hz), 7.33 (2H, t, J = 8 Hz), 2.48 (4H, s), 2.27 (1H, heptet, J = 7 Hz), 1.14 (6H, d, J = 7 Hz) ppm; ^{13}Cmr δ: 209.7 (s), 136.7 (d), 130.0 (d), 128.6 (d), 128.0 (s), 35.6 (t), 31.0 (d), 17.9 (q) ppm; m/e: 248.0870 ($C_{14}H_{16}O_2S$ requires 248.0870). This material was used without further purification.

*2-Methyl-2-phenylthio-1,3-cyclopentanedione (**22**)*

A mixture of 2-methyl-1,3-cyclopentanedione (1.12 g, 10 mmol),

For personal use only.

N-phenylthiosuccinimide (2.07 g, 10 mmol), and triethylamine (1.1 g, 11 mmol) in benzene (50 mL) was heated at reflux for 2 h. The solution was cooled to room temperature, washed with 1 *M* H_2SO_4, dried over Na_2SO_4, and concentrated. The residue was taken up in CCl_4 (10 mL) and filtered to remove succinimide. After removal of the solvent, the crude product was crystallized from ether–hexanes to give 2.0 g (90%) of **22** as white needles, mp 67–68°C (lit. (14) mp 69–70°C); ir ν: 1765, 1730 cm^{-1}; ^{1}Hmr δ: 7.47 (3H, m), 7.37 (2H, t, J = 8 Hz), 2.95 (2H, m), 2.61 (2H, m), 1.38 (3H, s) ppm. *Anal.* calcd. for $C_{12}H_{12}O_2S$: C 65.41, H 5.49; found: C 65.45, H 5.54.

2-(Phenylsulfoxymethyl)-1,3-cyclopentanedione (24)

A solution of 2-methyl-1,3-cyclopentanedione (**22**, 220 mg, 1.0 mmol) in ether (7 mL) was prepared in a 25-mL round-bottomed flask equipped with a stirring bar and addition funnel. The stirred solution was cooled in an ice-water bath as *m*-chloroperoxybenzoic acid (216 mg, 80% titre, 1.0 contained mmol) in ether (8 mL) was added dropwise over a period of 5 min. The cold solution was stirred for 5 min more at 0°C. The flask was fitted with a reflux condenser, and the clear, colorless solution was warmed to reflux on a steam bath for 30 min. A white crystalline precipitate began forming almost immediately. The mixture was cooled overnight at 0°C. The precipitate was isolated by filtration to give 215 mg (91%) of **24**, mp >200°C (dec.); ir (KBr) ν: 2900, 1620, 1020, 985 cm^{-1}; ^{1}Hmr (acetone-d_6) δ: 7.58 (5H, m), 4.08 and 3.76 (2H, AB quartet, J = 14 Hz), 2.38 (4H, br, s) ppm; *m/e*: no parent ($C_{12}H_{12}O_3S$), major fragments at 110.0368 (P − C_6H_5 − SOH requires 110.0368) and 126.0182 (P − $C_6H_6O_2$ requires 126.0139). *Anal.* calcd. for $C_{12}H_{12}O_3S$: C 61.00, H 5.12, S 13.57; found: C 60.77, H 5.42, S 11.61. Attempts to purify the material further were thwarted by its ready disproportionation.

8-Methylspiro[4.5]dec-7-ene-1,4-dione (25)

A solution of 1.10 g (5 mmol) of sulfide **22** in methylene chloride (10 mL) was prepared in a 100-mL, round-bottomed flask fitted with a stirring bar and addition funnel. The mixture was cooled in an ice bath and stirred as a solution of *m*-chloroperoxybenzoic acid (1.10 g, 80% titre, 5 mmol) in methylene chloride (10 mL) was added dropwise over 15 min. Isoprene (25 mL) was then added in one portion. A reflux condenser was fitted to the top of the addition funnel; the cold bath was removed, and the mixture was warmed to reflux on a steam bath for 1 h. After cooling, the light yellow solution was diluted with methylene chloride (10 mL) and washed with saturated aqueous $NaHCO_3$ (25 mL). The organic phase was dried ($MgSO_4$) and concentrated. The residue was crystallized from hexanes (3 crops) to give 620 mg (70%) of spirodiketone **25**, mp 81.5–83°C; ir ν: 1730 cm^{-1}; ^{1}Hmr δ: 5.41 (1H, m), 2.89 (2H, m), 2.69 (2H, m), 2.14 (2H, m), 2.03 (2H, m), 1.75 (2H, t, J = 6 Hz), 1.70 (3H, br, s) ppm; *m/e*: 178.0999 ($C_{11}H_{14}O_2$ requires 178.0994).

exo-*4-(1-Phenylthiocyclopentyl-2,5-dione)hexacyclo[7.5.1.$0^{3,13}$.$0^{5,12}$.$0^{7,11}$.$0^{10,14}$]pentadecane-2,6-dione (26)*

A solution of acetoxyperistylanedione **3** (3.04 g, 10.6 mmol) and 2-phenylthio-1,3-cyclopentanedione (**29**, 2.62 g, 12.7 mmol) in benzene (750 mL) and triethylamine (9 mL) was stirred and heated at reflux for 40 h. (This reaction must be run under dilute conditions to suppress formation of compound **54**; cf. the procedure for **5**.) After cooling, the yellow solution was washed with 1 *M* H_2SO_4 (100 mL), dried (Na_2SO_4), and concentrated. The brownish residue was absorbed on a small column of silica gel which was then eluted with 30% ethyl acetate − methylene chloride (200 mL) to give, after concentration, 4.20 g of an off-white solid. Crystallization from ethyl acetate (400 mL, 4 crops) gave colorless plates of **26** (3.72 g, 81%), mp 215–217°C (dec.); ir ν: 1720 cm^{-1}; ^{1}Hmr δ: 7.61 (2H, d, J = 8 Hz), 7.40 (1H, t, J = 8 Hz), 7.35 (2H, t, J = 8 Hz), 3.88 (2H, m), 3.69 (1H, q, J = 10 Hz), 3.46 (1H, s), 3.44 (2H, q, J = 10 Hz), 3.14 (2H, br d, J = 10 Hz), 2.75 (3H, m), 2.69 (4H, m), 2.09 (2H, d of t, J = 15, 9 Hz), 1.71 (2H, d of t, J = 15, 4 Hz) ppm; ^{13}Cmr δ: 223.3, 206.8, 136.9, 130.4, 129.4, 64.0, 58.5, 55.6, 55.5, 53.9, 51.8, 47.3, 38.1, 34.9 ppm (one phenyl carbon not observed, two aliphatic carbons overlapping); *m/e*: 432.1472 ($C_{26}H_{24}O_4S$ requires 432.1393).

4-(Cyclopentyliden-2,5-dione)hexacyclo[7.5.1.$0^{3,13}$.$0^{5,12}$.$0^{7,11}$.$0^{10,14}$]-pentadecane-2,6-dione (27)

A solution of 1.76 g sulfide **26** (4.08 mmol) in methylene chloride (80 mL) was placed in a 250-mL, round-bottomed flask with stirring bar and fitted with an addition funnel. The stirred solution was cooled to −70°C. A solution of *m*-chloroperoxybenzoic acid (880 mg, 80% titre, 4.08 contained mmol) in methylene chloride (50 mL) was added dropwise over 5 min. The cold bath was then removed, and succinic anhydride (1.0 g, 2.5 equiv.) in 35 mL of methylene chloride was added rapidly to the reaction mixture according to the method of Schlessinger and co-workers (18). The flask was warmed on a steam bath, and the contents gently refluxed for 30 min. The solution developed a bright yellow color during this time. After cooling to room temperature, the solution was washed with aqueous sodium phosphate buffer (100 mL, 0.15 *M*, pH 7.5) and dried (Na_2SO_4). It was concentrated to leave a yellow solid. This, on trituration with ethyl acetate (30 mL), gave 970 mg (74%) of yellow, microcrystalline ene-tetraone **27**. A small sample was crystallized from ethyl acetate, mp >290°C (dec.); ir ($CHCl_3$) ν: 1750, 1692, 1608 cm^{-1}; uv (methylene chloride) λ_{max}: 286 (ϵ = 12 200), 310 (8,700), and 415 nm (225); ^{1}Hmr δ: 5.09 (2H, br d, J = 10 Hz), 3.69 (3H, m), 3.46 (2H, q, J = 10 Hz), 2.98 (2H, t of d, J = 10, 3 Hz), 2.90–2.60 (5H, m), 2.17 (2H, d of t, J = 16, 10 Hz), 1.73 (2H, d of t, J = 16, 4 Hz) ppm; *m/e*: 322.1214 ($C_{20}H_{18}O_4$ requires 322.1204).

2-Phenylthio-1,3-cyclopentanedione (29)

Triethylamine (0.4 mL) was added to a stirred suspension of 1,3-cyclopentanedione (326 mg, 3.69 mmol) and *N*-phenylthiosuccinimide (764 mg, 3.69 mmol) in benzene (10 mL). The mixture was heated at reflux for 3 h, during which time all of the solids dissolved and the *N*-phenylthiosuccinimide reacted (tlc analysis; 5% ethyl acetate − methylene chloride). The solution was cooled to room temperature and concentrated. The brown residue was taken up in methylene chloride (10 mL), and this solution poured into 0.5 *M* H_2SO_4 (4 mL). The mixture was cooled in an ice bath for 15 min to complete precipitation of the product, which was isolated by filtration. Crystallization from ethyl acetate (60 mL) gave 690 mg (90%) of **29** as white needles, mp 191–192°C; ir (KBr) ν: 2900, 2600, 1665, 1560, 1400 cm^{-1}; ^{1}Hmr ($CDCl_3$ with a drop of C_5D_5N, 350 MHz) δ: 7.05 (2H, t, J = 8 Hz), 6.93 (3H, m), 6.55 (1H, br s), 2.65 (4H, s) ppm. *Anal.* calcd. for $C_{11}H_{10}O_2S$: C 64.03, H 4.89; found: C 63.68, H 5.01.

Reduction of enetetraone 27. Formation of 31

A 10-mL flask containing a suspension of neutralized 10% palladium-on-carbon (10 mg) in acetone (3 mL) under a hydrogen atmosphere was shaken vigorously for 2 h. A solution of ene-tetraone **27** (7 mg, 0.022 mmol) in acetone (1 mL) and methylene chloride (2 mL) was added, and agitation under hydrogen was continued for 2 h longer. At the end of this time, tlc analysis (30% ethyl acetate − methylene chloride eluent) indicated complete consumption of starting material. The hydrogen atmosphere was replaced by nitrogen in the usual way, and the mixture was filtered through a pad of Celite. The solvents were removed under vacuum, and the residue taken up in $CDCl_3$ (400 μL). Hemiketal **32** separated as fine white needles (4 mg, 57%), mp 213–217°C (dec.); ir (KBr) ν: 3440, 1725, and 1625 cm^{-1}; *m/e*: 324.1339, $C_{20}H_{20}O_4$ requires 324.1362. The key features of the otherwise uselessly complex ^{1}Hmr spectrum are discussed in the text.

Hexacyclo[7.5.1.$0^{3,13}$.$0^{5,12}$.$0^{7,11}$.$0^{10,14}$]pentadecane-2,6-dione-4-spiro-1′-4′,5′-dimethylcyclohex-4′-ene-2′-spiro-2″-cyclopentane-1″,3″-dione (32)

Ene-tetraone **27** (285 mg, 0.88 mmol), dimethylbutadiene (17 mL), and a small stirring bar were placed in a resealable Carius tube (Fischer and Porter Co.). The sealed tube was immersed in a 130°C oil bath, and the yellow suspension heated with stirring for 19 h. By the end of this time, the yellow color had faded leaving a colorless mixture with a lot of white solid present. The mixture was cooled to room temperature, the tube opened, and the solid collected. Purification by column chromatography on silica gel (30% ethyl acetate −

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

methylene chloride) gave 285 mg of adduct **33**. An additional 25 mg was obtained from the dimethylbutadiene solution after concentration and column chromatography to remove substantial quantities of polymeric material (methylene chloride, then 30% ethyl acetate – methylene chloride). The total yield was 310 mg (87%). Crystallization from 1,2-dimethoxyethane gave small prisms of **32**, mp 247–252°C (dec.); ir ν: 1720 cm^{-1}; ^{1}Hmr δ: 3.61 (2H, m), 3.52 (1H, q, J = 9 Hz), 3.26 (2H, m), 2.93 (2H, m), 2.82–2.68 (4H, m), 2.67–2.60 (3H, m), 2.50–2.35 (4H, br m), 2.01 (2H, d of t, J = 15, 8 Hz), 1.82 (2H, br m), 1.66 (3H, s), 1.63 (3H, s) ppm; ^{13}Cmr δ: 221.0, 211.1, 124.3, 121.4, 64.2, 61.9, 57.8, 56.2, 55.3, 52.9, 51.3, 48.4, 48.0, 37.3, 36.4, 33.9, 18.9, 18.4 ppm; m/e: 404.2030 ($C_{26}H_{28}O_4$ requires 404.1986).

X-ray crystal structure analysis of ***32***

Small colourless crystals of **32**, 0.1–0.5 mm in size, were used. The shape is prismatic, elongated along the a-axis with prominent monoclinic prism {0.23} and pinacoid {101}. Preliminary Weissenberg photographs with CuK_α radiation indicated that the crystals belong to the monoclinic system. Systematic extinctions are $h0l$, $h+l = 2n+1$, and $0k0$, $k = 2n+1$, thus defining the space group $P2_1/n$. The determination of the lattice parameters and the intensity measurements were made with the Nonius CAD4-diffractometer, with graphite monochromatized $MoK_{\bar{\alpha}}$ radiation. A small crystal fragment with approximate dimensions 0.22 × 0.22 × 0.25 mm was used. 25 reflections determined with the Nonius peak-hunting procedure in the range $10° < 2\theta < 25°$ were carefully centered. Cell parameters were calculated by a least-squares procedure. All independent reflections in the range $2° \leq 2\theta \leq 54°$ were measured at T = 20(1)°C by the $\omega-2\theta$ scan technique. Every 200 reflections the orientation of the crystal was controlled and every 2.5 h the intensities of the $6\bar{3}2$ and $7\bar{1}4$ reflections were checked. During the measurement no significant deviation (less than 3σ) could be observed. A total of 4587 reflections were measured. After averaging multiple measurements 4142 independent reflections remained, of which 1235 were unobserved with $I < 2.58\,\sigma(I)$. The intensities were corrected for Lorentz and polarization effects but no absorption correction was applied ($\mu(MoK_{\bar{\alpha}})$ = 1.010 cm^{-1}).

Crystal data:

$C_{26}H_{28}O_4$ fw = 404.5

Monoclinic, $P2_1/n$, a = 10.260(5), b = 11.583(5), c = 16.004(7) Å, β = 90.7(1)°, V = 1901.7 $Å^3$, Z = 4, ρ_c = 1.41 gcm^{-3} (20°C; $MoK_{\bar{\alpha}}$, λ = 0.71069 Å). Statistical tests are in good agreement with a centrosymmetric structure viz. $\langle E\rangle$ = 0.791, $\langle E^2\rangle$ = 1.0, $\langle E^2-1\rangle$ = 0.968. The structure was solved with direct phasing according to the symbolic addition procedure. The E-map clearly showed 28 out of the 30 non-hydrogen atoms. The complete molecule was then determined with structure factor and successive Fourier calculations. The hydrogen atoms could all be seen in a difference Fourier synthesis. The structure was refined with block-diagonal least-squares calculations. In the last few cycles of refinement the hydrogen atoms were included with isotropic temperature factors, and anisotropic temperature factors for the C and O atoms were applied. The function minimized being $\Sigma w(|F_o| - |F_c|)^2$ and $w = 1/\sigma^2$ (F). The atomic scattering factors were taken from ref. 19. The final agreement index was R = 0.048 for observed reflections and R = 0.084 for all reflections.[8] A final difference Fourier synthesis did not show any peak higher than $\mp$ 0.3 e/A^3. All calculations and drawings were done using the program system KRIPROG (20).

exo-*4-(1-Phenylthiocyclopentyl-2,5-dione)-1,7-bis(phenylselenenyl)-hexacyclo[7.5.1.0^{3,13}.0^{5,12}.0^{7,11}.0^{10,14}]pentadecane-2,6-dione* (***33***)

Compound **4** (176 mg, 0.29 mmol), described previously (3*c*), and 2-(phenylthio)-1,3-cyclopentanedione (70 mg, 0.34 mmol) were combined in benzene (10 mL) in a 25-mL, round-bottomed flask. Triethylamine (0.5 mL) was added, and the resulting solution was heated at reflux for 40 h. The amber solution was cooled to room temperature and concentrated. The crude residue was taken up in methylene chloride and filtered through a short column of silica gel with 10% ethyl acetate – methylene chloride (30 mL). Evaporation of the eluate gave the solid bisselenide-sulfide **33** (187 mg, 84%); ir ν: 1730 cm^{-1}; ^{1}Hmr δ: 7.66 (2H, d, J = 8 Hz), 7.52 (4H, d, J = 8 Hz), 7.42 (1H, t, J = 8 Hz), 7.35 (6H, t, J = 8 Hz), 7.28 (2H, t, J = 8 Hz), 3.87 (1H, q, J = 10 Hz), 3.46 (1H, s), 3.39 (2H, m), 3.26 (2H, t, J = 11 Hz), 2.91 (3H, m), 2.78 (2H, m), 2.54 (2H, m), 2.24 (2H, d of d, J = 16, 10 Hz), 1.99 (2H, d of d, J = 16, 3 Hz) ppm. *Anal.* calcd. for $C_{38}H_{32}O_4Se_2S$: C 61.46, H 4.34; found: C 61.87, H 4.34. Further purification was ineffective; the phenylthio group suffered easy nucleophilic displacement.

exo-*4-(1-Phenylthiocyclopentanyl-2,5-dione)*-exo-*15-(2,2,2-trifluoroethoxy)hexacyclo[7.5.1.0^{3,13}.0^{5,12}.0^{7,11}.0^{10,14}]pentadec-7-ene-2,6-dione* (***37***)

A solution of bisselenide-sulfide **34** (60 mg, 0.081 mmol) in methylene chloride was cooled to −70°C. A stream of ozone in oxygen was bubbled through the solution until a bright blue color developed. The excess ozone was removed in a nitrogen purging stream until the effluent gas did not color moistened starch–iodide test paper. A solution of potassium acetate (100 mg, 1.02 mmol) in trifluoroethanol (5 mL) was added to the cold mixture along with 1 mL of ethyl vinyl ether. The cold bath was removed, and the reaction mixture was allowed to stir at ambient temperature for 8 h. The yellow solution was concentrated, and the residue purified by preparative tlc (10% ethyl acetate – methylene chloride) to give as the major peristylane-based product, ene-ether **37** (R_f = 0.55, 20 mg, 39%); ir ν: 1730, 1625, 1285, 1180 cm^{-1}; ^{1}Hmr δ: 7.57 (2H, d, J = 8 Hz), 7.42 (1H, t, J = 8 Hz), 7.36 (2H, t, J = 8 Hz), 5.63 (1H, s), 4.49 (1H, s), 3.90–3.50 (8H, m), 3.22 (1H, s), 3.16 (1H, d, J = 12 Hz), 3.06 (1H, d, J = 7 Hz), 3.01 (1H, d, J = 10 Hz), 2.86 (2H, m), 2.62 (2H, m) ppm; m/e: 528.1193 ($C_{28}H_{23}O_5F_3S$ requires 528.1218).

exo-*4-(2-Acetoxycyclopentyl-1-en-5-one)-1,7-bis(phenylselenenyl)-hexacyclo[7.5.1.0^{3,13}.0^{5,12}.0^{7,11}.0^{10,14}]pentadecane-2,6-dione* (***39***)

The bisselenide acetate **4** (700 mg, 1.17 mmol), 1,3-cyclopentanedione (142 mg, 1.45 mmol), benzene (21 mL), and triethylamine (1 mL) were combined in a 50-mL, round-bottomed flask equipped with a stirring bar and reflux condenser. The mixture was stirred at reflux for 4 h, then cooled to room temperature and treated with acetic anhydride (2 mL). After being stirred for 20 min at room temperature, all of the solids had dissolved. The stirring was continued for 40 min more. Concentration of this mixture left a dark residue which was filtered through silica gel with 5% ethyl acetate – methylene chloride (120 mL). This eluate was pumped down to leave a light yellow, crystalline solid. Crystallization from ethyl acetate provided fine white needles of **39** (730 mg, 92%), mp (206–208°C (dec.); ir ν: 1775, 1730, 1705, 1650, 1180 cm^{-1}; ^{1}Hmr δ: 7.49 (4H, d, J = 8 Hz), 7.35 (2H, t, J = 8 Hz), 7.27 (4H, t, J = 8 Hz), 3.88 (1H, s), 3.76 (1H, q, J = 10 Hz), 3.67 (2H, m), 3.23 (2H, t of m, J = 10 Hz), 2.91 (1H, m), 2.89 (2H, d, J = 9 Hz), 2.80 (2H, m), 2.46 (2H, m), 2.35 (3H, s), 2.24 (2H, d of d, J = 15, 10 Hz), 1.96 (2H, d of d, J = 15, 4 Hz) ppm; ^{13}Cmr δ: 216.7, 204.4, 176.2, 136.6, 133.6, 129.2, 128.9, 127.9, 63.3, 63.0, 59.2, 59.0, 54.2, 45.3, 34.8, 26.9, 21.0 ppm (one aromatic and one aliphatic signal are not accounted for, presumably due to fortuitous overlap with neighboring lines); m/e: 678.0336 ($C_{34}H_{30}O_5Se_2$ requires 678.0424). *Anal.* calcd. for $C_{30}H_{30}O_5Se_2$: C 60.36, H 4.47; found: C 60.25, H 4.53.

exo-*4-(2-Acetoxycyclopentyl-1-en-5-one)*-exo,exo-*8,15-bis(2,2,2-trifluoroethoxy)hexacyclo[7.5.1.0^{3,13}.0^{5,12}.0^{7,11}.0^{10,14}]pentadecane-2,6-dione* (***42***)

A solution of bisselenide **39** (156 mg, 0.23 mmol) in methylene chloride (6 mL) was placed with a stirring bar in a 25-mL round-

[8]Tables of observed and calculated structure factor amplitudes, of bond length and bond angles, and of torsion angles are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

bottomed flask fitted with two 10-mL addition funnels, arranged one atop the other. The lower funnel contained a solution of *m*-chloroperoxybenzoic acid (153 mg, 60% titre, 0.53 contained mmol) in methylene chloride (5 mL); the upper, a mixture of trifluoroethanol (9 mL) and triethylamine (1 mL). The reaction solution was cooled to −70°C; oxidizing solution was added dropwise with stirring over 3 min. The cold reaction mixture was stirred for 2 min more, whereupon the contents of the upper addition funnel were added all at once. The cooling bath was removed, and the reaction mixture was allowed to warm to room temperature. After 16 h, the yellow-orange solution was concentrated; the residue was taken up in methylene chloride (5 mL) and acetic anhydride (2 mL). The reddish-brown mixture was stirred for 2 h at room temperature. This solution was then pumped down, and the dark brown residue was dissolved in methylene chloride (15 mL). The solution was washed with 0.1 *M* H_2SO_4 (15 mL), then 10% aqueous Na_2CO_3 (10 mL), dried (Na_2SO_4), and concentrated to give crude enol acetate **40**, contaminated chiefly with diphenyl diselenide. This was conveniently removed by partitioning the crude between trifluoroethanol (4 mL) and pentane (3 mL). The alcohol solution contained the enol acetate in reasonable purity as shown by ^{1}Hmr analysis; ^{1}Hmr δ: 3.97 (2H, br s), 3.95 (4H, m), 3.84 (4H, q, J = 8 Hz), 3.58 (2H, q, J = 11 Hz), 2.93 (2H, d, J = 11 Hz), 2.82 (3H, m), 2.76 (2H, d, J = 11 Hz), 2.50 (2H, m), 2.41 (3H, s) ppm. This was used directly in the next step.

exo-*4-(1-Phenylthiocyclopentanyl-2,5-dione)*-exo,exo-*bis(2,2,2-trifluoroethoxy)hexacyclo[7.5.1.0^{3,13}.0^{5,12}.0^{7,11}.0^{10,14}]pentadecane-2,6-dione (**35**)*

The trifluoroethanol solution of **40** as just obtained was heated at 70°C with potassium acetate (48 mg, 0.49 mmol) and *N*-phenylthiophthalimide (69 mg, 0.27 mmol). The progress of the reaction was most conveniently followed by ^{1}Hmr analysis of aliquots. Deprotection of the enol acetate was rapid; the free, enolized cyclopentadione gave rise to a signal at 2.4 ppm for the methylene protons. Subsequently this disappeared to be replaced by the AA′BB′ pattern for the methylene protons of **35**. The conversion was complete after 8 h. The mixture was cooled, diluted with methylene chloride (30 mL), and the solution was washed with 0.1 *M* H_2SO_4. The organic layer was dried (Na_2SO_4) and concentrated. The dark brown residue was purified by preparative tlc (10% ethyl acetate − methylene chloride, R_f = 0.7) to yield 74 mg of **35** (51% overall from bisselenide **39**). A small sample was crystallized from benzene − petroleum ether, mp 185.5−187°C; ir ν: 1730, 1280, 1170 cm^{-1}; ^{1}Hmr δ: 7.67 (2H, d, J = 8 Hz), 7.45 (1H, t, J = 8 Hz), 7.39 (2H, t, J = 8 Hz), 3.95 (2H, s), 3.94 (1H, q, J = 10 Hz), 3.84 (6H, m), 3.58 (2H, q, J = 11 Hz), 3.44 (1H, s), 3.15 (2H, br d, J = 10 Hz), 2.93 (2H, d, J = 11 Hz), 2.80 (3H, m), 2.65 (2H, m) ppm; *m/e*: 628.1336 ($C_{30}H_{26}O_6F_6S$ requires 628.1354).

4-(Cyclopentyliden-2,5-dione)-exo,exo-*8,15-bis(2,2,2-trifluoroethoxy)hexacyclo[7.5.1.0^{3,13}.0^{5,12}.0^{7,12}.0^{10,14}]pentadecane-2,6-dione (**41**)*

A solution of sulfide **35** (100 mg, 0.16 mmol) in methylene chloride (15 mL) was placed with a stirring bar in a 50-mL, round-bottomed flask equipped with an addition funnel. The stirred solution was cooled to −70°C. A solution of *m*-chloroperoxybenzoic acid (58 mg, 60% titre, 0.20 contained mmol) in methylene chloride was added dropwise over 30 min. The cold mixture was stirred for 1 h more, then the cold bath was removed and the reaction warmed to reflux on the steam bath for 20 min. A bright yellow color developed over this time. The solution was cooled, diluted with methylene chloride (50 mL), and washed with sodium phosphate buffer solution (40 mL, 0.15 *M*, pH 7.5). The organic layer was dried (Na_2SO_4) and concentrated to leave a yellow semisolid (110 mg). Trituration with ether (3 mL) left 60 mg (73%) of yellow, microcrystalline ene-tetraone (**41**), mp 199−201°C (dec.); ir ν: 1750, 1690, 1610, 1280, 1170 cm^{-1}; uv (CH_2Cl_2) λ_{max}: 281 (ε = 8,800), 315 (4,500) 420 nm (~150); ^{1}Hmr δ: 5.07 (2H, d, J = 8 Hz), 4.06 (1H, q, J = 11 Hz), 3.95 (2H, s), 3.81 (4H, q, J = 8 Hz), 3.75 (4H, m), 3.12 (2H, d, J = 11 Hz), 2.87 (3H, m), 2.68 (2H, m) ppm; *m/e*: 518.1216 ($C_{24}H_{20}O_6F_6$ requires 518.1164). *Anal.* calcd. for $C_{24}H_{20}O_6F_6$: C 55.19, H 3.89; found: C 55.61, H 3.80.

exo,exo-*8,15-Bis(2,2,2-trifluoroethoxy)hexacyclo[7.5.1.0^{3,13}.0^{5,12}.0^{7,11}.0^{10,14}]pentadecane-2,6-dione-4-spiro-1′-4′,5′-dimethylcyclohex-4′-ene-2′-spiro-2″-cyclopentane-1″,3″-dione (**42**)*

Ene-tetraone **41** (17 mg, 0.033 mmol) and dimethylbutadiene (1 mL) were placed in a resealable Carius tube (7-mL capacity, Fischer and Porter Co.) containing a small stirring bar. The sealed tube was immersed in a 100°C oil bath and stirred for 3 h. The initial yellow color faded to give a colorless solution. The tube was cooled; the solution was concentrated to give a semi-solid residue. This was freed of polymeric material by preparative tlc (10% ethyl acetate − methylene chloride, R_f = 0.55) and gave 15 mg of adduct **42**. A sample was crystallized from hexane, mp 221−222°C (dec., bubbling); ir ν: 1723, 1280, 1170 cm^{-1}; ^{1}Hmr δ: 4.19 (2H, br s), 4.03 (2H, m), 3.95 (2H, m), 3.83 (1H, q, J = 11 Hz), 3.66 (2H, m), 3.51 (2H, br q, J = 10 Hz), 2.90−2.78 (7H, m), 2.67 (2H, br d, J = 10 Hz), 2.42 (4H, br m), 1.66 (3H, s), 1.63 (3H, s) ppm; *m/e*: 600.2008 ($C_{30}H_{30}O_6F_6$ requires 600.1944).

*3,4-Dimethyl-20-hydroxy-16,18-bis(2,2,2-trifluoroethoxy)nonacyclo[19.2.1.0^{1,6}.0^{6,13}.0^{7,20}.0^{8,12}.0^{9,19}.0^{10,17}.0^{11,15}]tetracos-3-ene-14,23,24-trione (**44**)*

Oil-free potassium hydride (20 mg, 0.50 mmol) and tetrahydrofuran (2 mL, freshly distilled from sodium-benzophenone ketyl) were placed in a dry, 10-mL, pear-shaped flask with a septum inlet and a magnetic stirring bar. The stirred suspension was cooled to −70°C under a nitrogen atmosphere. A solution of **42** (13 mg, 0.022 mmol) in dry tetrahydrofuran (1.5 mL) was added via syringe over 10 min. After 5 min more, the mixture was allowed to warm to −45°C (Dry Ice/acetonitrile bath). The suspension slowly turned yellow, then orange. After 2 h at −45°C the cold reaction mixture was quenched by rapid addition of acetic acid (0.3 mL, 5 mmol). The color was discharged to light yellow during the quench. The mixture was warmed to room temperature and concentrated. The residue was taken up in methylene chloride (7 mL) and washed with saturated aqueous $NaHCO_3$ (7 mL). The organic phase was dried (Na_2SO_4) and concentrated to a pale yellow oil. Preparative tlc (5% ethyl acetate − methylene chloride) gave, at R_f = 0.23, the aldol product **44** (8 mg, 62%); ir ν: 3510, 1740 cm^{-1}; ^{1}Hmr δ: 4.17 (1H, s, disappeared on treatment with D_2O), 3.99 (1H, s), 3.94 (2H, m), 3.83 (1H, s), 3.78 (2H, q, J = 9 Hz), 3.38 (1H, br t, J = 6 Hz), 3.04 (1H, q, J = 7 Hz), 2.98 (1H, br d, J = 5 Hz), 2.90 (2H, m), 2.71 (1H, q, J = 8 Hz), 2.55 (3H, m), 2.40 (1H, t, J = 10 Hz), 2.35 (1H, m), 2.25−2.02 (4H, m), 1.75 (1H, d, J = 18 Hz), 1.63 (3H, s), 1.59 (3H, s), 1.49 (1H, d, J = 18 Hz) ppm; *m/e*: 582.1862, 500.1837 ($C_{30}H_{30}O_6F_6$ minus H_2O requires 582.1840, $C_{30}H_{30}O_6F_6$ minus CF_3CH_2OH requires 500.1809).

*1,7-Bis(phenylselenenyl)hexacyclo[7.5.1.0^{3,13}.0^{5,12}.0^{7,11}.0^{10,14}]pentadecane-2,6-dione-4-spiro-1′-4′,5′-dimethylcyclohex-4′-ene-2′-spiro-2″-cyclopentane-1″,3″-dione (**46**)*

Diels−Alder adduct **32** (285 mg, 0.705 mmol) was dissolved in ethyl acetate (15 mL), and the solution was stirred at 50°C as solid phenylselenenyl chloride (325 mg, 1.70 mmol) was rinsed in with 4 mL of ethyl acetate. The orange mixture was stirred at 50°C for 2 h; the color gradually faded to yellow. The solution was cooled to room temperature and concentrated. The residue was purified by column chromatography (5% ethyl acetate − methylene chloride). Crystallization from 20 mL of isopropyl ether − ethyl acetate (3:1, v/v) gave 2 crops of bisselenide **46** (300 mg, 60%), mp 136.5−139°C; ir ν: 1720 cm^{-1}; ^{1}Hmr δ: 7.55 (4H, d, J = 8 Hz), 7.36 (2H, t, J = 8 Hz), 7.28 (4H, 1, J = 8 Hz), 3.67 (1H, q, J = 9 Hz), 3.27 (2H, m), 3.22 (2H, m), 2.90 (2H, m), 2.70 (2H, m), 2.63 (2H, br d, J = 9 Hz), 2.58 (1H, m), 2.30 (2H, br s, $w_{\frac{1}{2}}$ = 12 Hz), 2.2 (2H, br s, $w_{\frac{1}{2}}$ = 20 Hz), 2.05 (4H, m), 1.63 (3H, s), 1.57 (3H, s) ppm; *m/e*: 716.1019 ($C_{38}H_{36}O_4Se_2$ requires 716.0944).

11-Hydroxyhecacyclo[7.5.1.0^{3,13}.0^{5,12}.0^{7,11}.0^{10,14}]pentadec-7-ene-2,6-dione-4-spiro-1'-4',5'-dimethylcyclohex-4'-ene-2'-spiro-2"-cyclopentane-1",3"-dione (50)

Bisselenide **46** (49 mg, 0.069 mmol) and methylene chloride were placed with a stirring bar in a 10-mL, round-bottomed flask equipped with an addition funnel. The solution was cooled to −70°C, and a solution of *m*-chloroperoxybenzoic acid (37 mg, 80% titre, 0.17 contained mmol) in methylene chloride (2.5 mL) was added dropwise over 5 min. The cold reaction mixture was stirred for 3 min more, then triethylamine (2 mL) was added and the cold bath was removed. The reaction was allowed to warm to room temperature with stirring overnight (10 h). In the morning, the solution was pumped down and the residue redissolved in fresh methylene chloride (25 mL). This was washed with 1 *M* H_2SO_4 (10 mL), then 10% aqueous Na_2CO_3 (10 mL). The organic phase was dried (Na_2SO_4) and concentrated to a yellow oil which was purified by preparative tlc (30% ethyl acetate − methylene chloride, R_f = 0.19) to give ene-alcohol **52** (23 mg, 79%): ir *ν*: 3590, 1720 cm^{-1}; ^{1}Hmr δ: 5.58 (1H, br s), 3.70 (1H, m), 3.64 (1H, t, *J* = 8 Hz), 3.55 (1H, m), 3.43 (1H, t, *J* = 11 Hz), 3.21 (1H, t, *J* = 7 Hz), 3.03 (1H, br d, *J* = 17 Hz), 2.95 (1H, d of d, *J* = 11, 2 Hz), 2.90−2.60 (7H, m), 2.59 (1H, d, *J* = 8 Hz), 2.48 (2H, m), 1.95 (1H, d, *J* = 17 Hz), 1.68 (1H, d, *J* = 17 Hz), 1.64 (3H, s), 1.61 (3H, s) ppm; *m/e*: 418.1757 ($C_{26}H_{26}O_5$ requires 418.1779).

1,13,15,24-Tetrahydroxy-18,19-dimethynonacyclo[14.6.2.0^{2,9}.0^{4,8}.0^{6,13}.0^{7,11}.0^{10,22}.0^{12,21}.0^{16,21}]tetracos-18-ene (52)

Diels−Alder adduct **32** (28 mg, 0.069 mmol) was placed with a stirring bar in a 50-mL, three-necked flask fitted with a Dry Ice condenser. Tetrahydrofuran (7 mL, freshly distilled from sodium-benzophenone ketyl) was added. The flask was cooled in a Dry Ice/methanol bath, and the condenser was filled with Dry Ice and methanol. Ammonia was distilled directly into the flask from a blue solution of lithium in ammonia (about 25 mL transferred). The cold bath was removed, and the contents of the flask were stirred at reflux. Lithium wire (12 mg, 1.7 mmol, low sodium, Foote Mineral Company) was added. A deep blue color developed immediately. The reaction was allowed to proceed for 90 min, after which the deep blue solution was quenched by cautious addition of solid ammonium chloride (220 mg, 4.0 mmol). The white mixture was allowed to warm to room temperature overnight with evaporation of most of the ammonia. The residual slurry was pumped down, suspended in boiling methylene chloride (25 mL), and filtered hot. The residue was washed with hot methylene chloride (15 mL), and the combined filtrate was evaporated. The crude product (20 mg) was purified by preparative tlc (30% ethyl acetate − methylene chloride). The component at *Rf* = 0.18 was crystallized from benzene as feathery crystals of tetraol **52** (12 mg, 42%), mp 243−244°C; ir *ν*: 3400, 2960, 1075 cm^{-1}; ^{1}Hmr δ: 4.81 (2H, m), 3.11 (1H, q, *J* = 8 Hz), 2.90 (2H, m), 2.60 (1H, q, *J* = 8 Hz), 2.54 (2H, t, *J* = 8 Hz), 2.48 (2H, m), 2.28 (2H, t, *J* = 2 Hz), 2.23 (4H, br s), 1.84 (2H, m), 1.76 (4H, m), 1.69 (3H, s), 1.63 (2H, d, *J* = 13 Hz), 1.57 (3H, s) ppm; ^{13}Cmr δ: 127.4, 125.8, 88.2, 77.6, 60.2, 59.7, 57.4, 54.1, 52.5, 48.4, 44.1, 41.2, 38.8, 32.3, 30.7, 17.9 ppm (2 lines not resolved); *m/e*: 392.2343 ($C_{26}H_{34}O_4$ minus H_2O requires 392.2350).

COMMUNICATION

A construction of the angularly hydroxylated *cis* 1,8-naphthalenedione system typical of the tetracyclines

GILBERT STORK[1] AND YING K. YEE
Department of Chemistry, Columbia University, New York, NY 10027, U.S.A.

Received March 30, 1984

This article is dedicated to Professor Peter Yates on the occasion of his 60th birthday

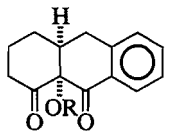
GILBERT STORK and YING K. YEE. Can. J. Chem. **62**, 2627 (1984).

This paper demonstrates the feasibility of constructing the angularly hydroxylated 1,8-decalindione system typical of the tetracycline group of antibiotics. The α-hydroxy-β-diketone structure is constructed by the action of fluoride ion on an enediol disilyl ether. The siloxyketone enolate thus generated is then intramolecularly trapped by an appositely placed ester.

GILBERT STORK et YING K. YEE. Can. J. Chem. **62**, 2627 (1984).

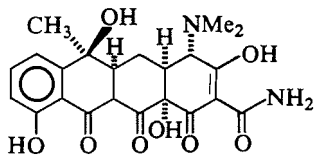
Cet article montre qu'il est possible de construire le système d'une 1,8-décalinedione portant un hydroxyle dans l'angle qui est typique du groupe d'antibiotiques apparentés à la tétracycline. La fonctionalité α-hydroxy β-dicétone est formée par l'action de l'anion fluorure sur le bis-silyl ether d'un ènediol. L'énolate de siloxy cétone ainsi formé est alors piégé intramoléculairement par un ester approprié.

This communication reports the construction of a molecule **1** (as its trimethylsilyl ether **1***a*) embodying the α-hydroxy-β-diketone array which is a common feature of the a/b ring system of antibiotics such as tetracycline, **2** (1). Our goal was to develop a process which would specifically produce the *cis*-fused 8a-hydroxy-1, 8-napthalenedione arrangement rather than the mixture of *cis* and *trans* isomers which results when the hydroxydiketone construction depends, as it classically has (2), on the hydroxylation of a precursor enolic β-diketone system.

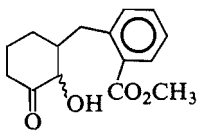


1 R = H

1*a* R = Si



2

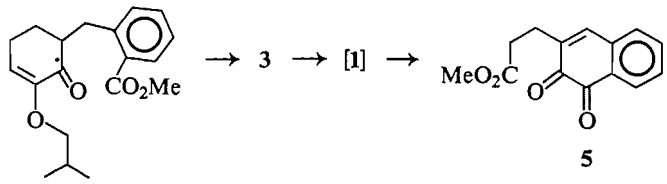


3

We envisaged that a cyclization formally represented by **3** → **1** would, if feasible, lead to the required structure and stereochemistry, as a result of well-understood geometric constraints on the transition state for the cyclization process.

Our initial attempts were centered on the possibility of achieving base-catalyzed cyclization of some enolate species derivable from ketols like **3**. The ketol **3** was simply constructed by alkylation of the isobutyl enol ether of cyclohexane-1,2-dione with methyl 2-bromomethylbenzoate (LDA–THF; HMPA, 1 h, −20°C) to **4** (61% yield), which was then transformed to the desired **3** by reduction with sodium borohydride followed by hydrolysis of the enol ether with 50% acetic acid.

[1] Author to whom correspondence may be addressed.

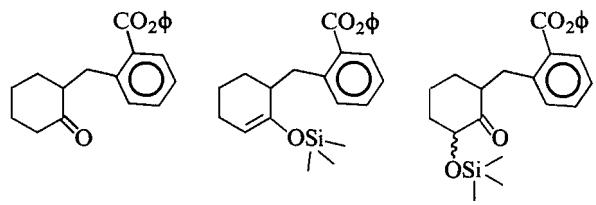


4 → **3** → [1] → **5**

Treatment of the ketol **3** with 1 equiv. of sodium hydride in THF for 2 h at room temperature resulted in the isolation, after flash chromatography, of the α-naphthoquinone **5** as orange crystals, mp 89.5–91.5°C; ir ($CHCl_3$): 1735 (s), 1695 (w), 1662 (s), 1627 (w) cm^{-1}; nmr (δ): 1.67–2.02 (m, 2H), 2.10–2.55 (m, 4H), 3.60 (s, 3H), 6.85–7.65 (m, 4H), 7.87–8.06 (m, 1H); ms (EI): 258. This result strongly suggests that the desired cyclization (**3** → **1**) had taken place but had been followed by cleavage of the β-diketone system and air oxidation (the latter, presumably, during chromatography).

The desired cyclization was finally achieved by a modification of the general scheme above.

Alkylation of cyclohexanone (LDA/THF/−78°C) with phenyl-2-bromomethylbenzoate (HMPA, −10°C) gave **6**, mp 70–71.5°C in 76% yield. The silyl enol ether **7** (75%) obtained via kinetic deprotonation with LDA[2] was converted to the ketol TMS ether **8** (*m*-CPBA; TMSCl, NEt_3; ~2:1 mixture of stereoisomers, 82% yield) (3).



6 **7** **8**

After various attempts at cyclization of the kinetic lithium enolate of **8** had met with failure, success was finally achieved

[2] About 20% of the tricyclic enol lactone, mp 104.5°C, derived from the enolate precursor of **7** was also obtained.

by the use of the crucial silylated enediol **9**[3] obtained from the kinetic enolate of **8**: Treatment of **9** with a dry (molecular sieves) THF solution of tetrabutylammonium fluoride at −78 to −20°C, followed by quenching with *N*-trimethylsilylimidazole, gave **1***a* in 74% yield (mp 69.5–70°C from hexane; ir (neat): 1735 (s), 1725 (s), 1690 (s), 1677 (s), 1603 (m) cm^{-1}; nmr (δ): 0.13 (s, 9H), 1.53–2.15 (m, 4H), 2.35–2.70 (m, 3H), 2.77 (db of db, incompletely resolved, J = 6.3, 16.2 Hz, 1H), 3.47 (db, J = 4.5, 16.2 Hz, 1H), 7.15–7.67 (m, 3H), 7.90–8.07 (m, 1H); ms (EI): 302 (M^+). The identity of **1***a* was further established by conversion (Zn/AcOH) to the β-diketone **10**, mp 74–76°C, identical with an unambiguously synthesized sample. The ring fusion in **1***a* is shown as *cis*, as it is in the tetracyclines, for mechanistic reasons.[4] It is of some interest that the conditions which were successful with the phenyl ester **9** were unsuccessful with the corresponding methyl ester.

[3] For related reactions, see ref. 4.

[4] This is a consequence of geometric requirements for the cyclization reaction (cf. "Baldwin rules").

Received February 16, 1984

R. E. CLEMENT, A. C. VIAU, and F. W. KARASEK. Can. J. Chem. **62**, 2629 (1984).

The extraction efficiencies of various solvents for toxic organic compounds on municipal incinerator flyash were examined. Soxhlet extraction by the solvent was followed by benzene Soxhlet extraction for determination of the non-extracted material. Benzene was found to be the best solvent when considering purity and extraction of hazardous compounds.

R. E. CLEMENT, A. C. VIAU et F. W. KARASEK. Can. J. Chem. **62**, 2629 (1984).

On a étudié l'efficacité de divers solvants pour extraire des composés organiques toxiques qui sont présents dans les jets de cendre d'incinérateurs municipaux. L'extraction par le solvant se fait à l'aide d'un appareil Soxhlet et, dans le but de déterminer les quantités de produits qui n'ont pas été extraits, on procède à une autre extraction par du benzène, à l'aide d'un appareil Soxhlet. On a trouvé que le benzène est le meilleur solvant lorsqu'on veut déterminer la pureté ou extraire des composés dangereux.

[Traduit par le journal]

Introduction

Toxic compounds found on flyash from combustion of waste are a recognized problem (1). Among the toxic compounds found worldwide on flyash are polychlorinated dibenzo-*p*-dioxins (PCDD). The toxicological implications of PCDD on flyash are being elucidated (2). It has been found that rats fed flyash particles containing PCDD absorb all the congeners and isomers into their livers (2). A similar mechanism of absorption could occur in humans.

The precision of PCDD quantitation has increased with the methods of analysis. It is common to see solvent extraction with some form of clean-up procedure involving hplc and analysis with gc–ms. More recently, attention has focussed on the extraction of PCDD from flyash. Various solvents have been reported for extraction of PCDD but the use of acid treatment prior to solvent extraction has gained popularity (3). The original work used 1 *N* HCl; however, researchers are now using 12 *N* HCl in an attempt to puncture the flyash particulate releasing the PCDD found in the interior of the particle for extraction (4). This approach has been found satisfactory if PCDD are the only compounds of interest, but acid treatment ultimately will decompose many other organic compounds. As a result the original composition of organic compounds found on the flyash has been altered and no conclusions can be reached with respect to formation mechanisms and the presence of other toxic compounds such as PAH on flyash particles.

An extraction procedure is needed where the maximum amount of organic compounds including PCDD are extracted unaltered in composition. Such a procedure is proposed in this study. It consists of sequential soxhlet extraction with two solvents. It is found that methanol followed by benzene results in extraction efficiencies which are equal to toluene or benzene for total screening of PAH and PCDD. However, this sequential extraction resulted in better extraction of selected PAH and tetrachlorodibenzo-*p*-dioxins than toluene or benzene.

Experimental

Sample preparation

Three flyash grab samples, from municipal incinerators located in southern Ontario, were combined in equal weights, approximately 50 g each, in a large flint glass jar. The jar was shaken and rotated prior to the removal of each sub-sample, to minimize heterogeneity of the bulk composite.

Sample extraction and concentration

Approximately 10 g samples of the composite flyash were extracted in medium porosity glass fritted extraction thimbles, for 20 filling and draining cycles with 200 mL of each of five solvents; benzene, toluene, and methanol ("Distilled in Glass" grade, Caledon Laboratories Ltd., Georgetown, Ont.) and cyclohexane and dichloromethane ("Distilled in Glass" grade, Burdick and Jackson, Inc., Muskegon, MI) in a soxhlet apparatus. Duplicate extracts for each solvent were prepared in this matter.

Each extract was concentrated to approximately 5 mL by rotary evaporation at 56–69°C under water aspirator vacuum. The extract was transferred, with three washings of 1–2 mL, to a 25 mL pear-shaped flask for further concentration. The concentrated extract was transferred, with three washings of 50–100 μL, to a 1 mL "Mini-Vial" (Alltech Associates, Inc., Arlington Heights, IL) equipped with screw-caps fitted with Teflon-faced liners. A final volume reduction to approximately 100 μL was achieved by direction of a slow stream of high purity argon or nitrogen onto the surface of the extract in the vial. All concentrated extracts were stored in a freezer at approximately −5°C.

After the first extraction with a particular solvent, each flyash sample was subjected to a second extraction with 200 mL of benzene under the same conditions outlined above. The benzene re-extract of each sample was concentrated in the same manner as the original solvent extract.

In addition to the flyash samples, a procedure blank for each solvent was prepared by carring 200 mL of the solvent through each extraction and concentration step, using an empty extraction thimble in a soxhlet apparatus. No contamination could be detected upon gc/fid and gc/ms/sim analysis.

All glassware, vials, and Pasteur pipets were cleaned via the following procedure: ultrasonic agitation in an aqueous solution of Alconox detergent (Alconox, Inc., New York, NY.) for a minimum of 30 min, rinsed with copious quantities of tap water, followed by

rinsing with deionized water, and heated in a laboratory oven for 1 h at 350°C.

Measurement of final extract volume

The following final extract volume calculation was used to reduce measurement errors: 100 μL of pure solvent was dispensed into a vial with a 1000 μL syringe, the weight of the pure solvent in the vial was obtained. The volume of the extract was obtained by multiplying a weight ratio; the weight of extract divided by the weight of the 100 μL of pure solvent, times 100 μL. The assumption that the extract density may be approximated by the density of the pure solvent was justified by the fact that approximately 98% of the peak area, determined via gc/fid, of each extract was attributable to the solvent.

Due to the excessive amount of polar inorganic material co-extracted by methanol, the methanol extracts were successively concentrated by gaseous evaporation until a milky white precipitate formed and centrifuged at 3000 rpm for 10 min. The supernatant was transferred to another vial and the process repeated two more times. The final volume of the methanol extracts was estimated by the graduated vials markings, as any inorganic material still dissolved in the extract would have altered the density of the extract and invalidated the mass ratio technique.

Gas chromatographic analysis

A Hewlett-Packard 5830A digital gas chromatograph (gc) was equipped with a 2.6 m long, 2 mm id column packed with Aue packing, 0.2% w/w Carbowax 20M deposited on 100/120 mesh acid wash Chromosorb W (5). A flame ionization detector (fid) was employed for the determination of the total organic carbon (toc) content of each extract. Chromatographic conditions were as follows: initial temperature, 50°C; program rate, 4°C/min; final temperature, 250°C; time at final temperature, 15 min; helium carrier gas flow, 45 mL/min; attenuation 32; slope sensitivity, 0.01 mV/min, and area reject, 500.

Gas chromatography/mass spectrometry analysis

A Hewlett-Packard 5992A gas chromatograph/mass spectrometer (gc/ms), equipped with a single floppy disk and an X−Y plotter was employed for the selected ion monitoring (sim) analysis of each extract. The glass-packed column employed in the gc/fid analysis was transferred to the gc/ms and identical chromatographic conditions were used. Selected ion monitoring areas generated by the gc/ms were used for quantification. Three standards were employed for the sim analyses. An *n*-alkane standard was employed for the evaluation of response factors for all of the *n*-alkanes from C14 to C30 which were observed in the extracts. A standard containing 1,2,3,4-TCDD was employed for the quantitation of all the PCDD's, assuming all isomers had a relative response factor of one. Although this assumption is not exact, this method is valid for comparative evaluations (6). The third standard contained six *n*-alkanes, three PAH compounds which were employed for the quantitation of the appropriate compounds in each extract. Table 1 lists the components, concentration, and selected ions for all standards. Anthracene was assumed to have a response factor intermediate to fluorene and fluoranthene. A response factor similar to fluoranthene was used for pyrene.

Before operating in sim, the mass spectrometer was tuned daily by the manufacturer-supplied program AUTOTUNE using a perfluorotributylamine calibration standard.

Results and discussion

The gc/ms/sim analysis for *n*-alkanes are shown in Fig. 1. The various solvents used for primary extraction are denoted with each reconstructed ion chromatogram. All chromatograms are plotted to the same full scale for a more direct comparison. This can be done since all the variables such as sample weight are approximately equal. It is seen that benzene, toluene, and cyclohexane extract all of the *n*-alkanes. Dichloromethane extracts other unidentified components which prohibits confident identification and quantitation of some of the *n*-alkanes. It is found that methanol extracts a substantially lower amount of alkanes than any of the other solvents.

The benzene re-extraction of the flyash following the respective solvent extraction indicates that benzene and toluene primary extraction is efficient since relatively little alkanes are extracted. This is not true for the cyclohexane extraction. The re-extract from dichloromethane extraction shows that some alkanes are recovered. The benzene re-extraction of methanol extraction expectedly has the *n*-alkanes since previously little was removed from the flyash by the methanol.

An arbitrary division of the alkanes into low (14−19), medium (20−25), and high (26−30) concentration (ng/g) was done to compare the concentrations extracted with each procedure. These values are listed in Table 2. These data show that primary extraction with benzene extracts more alkanes than any other solvent. Cyclohexane and toluene extract approximately

TABLE 1. Concentration of standard components and ions monitored during selected ion monitoring mass spectrometry

equal amounts while the more polar dichloromethane and methanol extract substantially less than the other solvents. The re-extraction with benzene shows that the alkanes are not totally recovered if the primary solvent was very polar.

The sim chromatogram for two selected PAH, fluoranthene and pyrene, are shown in Fig. 2. Different extraction efficiencies for each primary solvent are seen as compared to alkanes. Benzene and toluene extract those components fairly readily but the other solvents do not. The benzene re-extraction confirms this observation since these compounds are recovered from the cyclohexane, dichloromethane, and methanol but are not evident in the benzene, toluene re-extracts.

The quantitative data for other PAH are shown in Table 3. The trends observed in Fig. 2 are also seen for other PAH. Furthermore, unlike the alkanes, the PAHs are almost totally recovered from flyash following benzene re-extraction. The

best second extraction recovery is seen with the methanol primary extract. Primary benzene extraction is found to remove the most total PAH than any other solvent. Toluene does not extract any fluorene and a lower amount of biphenyl and anthracene than benzene. The total PAH extracted by toluene is less than that of the sequential methanol–benzene extract which has all the PAHs. Sequential methanol–benzene extraction is also seen to extract more fluorene than any other method. The reason for the differential solvent extraction observed for PAH may lie in π-electron interactions. Thus, cyclohexane would not be as efficient as benzene, toluene, or dichloromethane. This may also help to explain why benzene extracts fluorene better than toluene.

It is to be noted that the concentrations obtained from duplicate extracts are often very close. This is especially observed with solvents which are efficient extractors.

The sim total ion (sti) current chromatogram for PCDD is plotted for all the extracts in Fig. 3. The sim total ion is a program developed for this gc/ms system which allows the user to plot the summed abundances of all the ions monitored (7). The elution times for each PCDD isomeric group are identified in Fig. 3 from the single ions previously plotted. The PCDD are easily identified because of previous work done with flyash from this site (6). It is evident that the extraction of PCDD follows the extraction behaviour of PAH on flyash. Benzene and toluene can extract most of the PCDD while dichloromethane is less efficient in this process. Cyclohexane and methanol extract very little PCDD. The benzene re-extraction only recovers PCDD from the cyclohexane, dichloromethane, methanol primary extracts. The π-electron interactions may again be responsible for the efficient removal of the PCDD from the flyash particle.

The concentrations of PCDD are given in Table 4. It is ascertained that toluene extracts the most PCDD. However, the greatest difference between benzene and toluene is with OCDD; otherwise toluene extracts slightly more than benzene. Cyclohexane virtually does not extract PCDD and benzene re-extraction does not recover all the PCDD. Dichloromethane extracts approximately one-half the benzene amount. It is interesting that although methanol essentially does not extract PCDD, benzene re-extraction results in more PCDD being extracted than by benzene extraction alone. The total amount of PCDD extract by this sequential method is close to that extracted by toluene. An important difference is noted. Whereas toluene extracted a greater amont of OCDD, sequential methanol–benzene extracts more TCDD. The other PCDD concentrations approach the values obtained for toluene.

One of the objectives in the study of toxic compounds on flyash is to extract the components of interest while minimizing interferant and nontoxic compounds. Benzene is found to extract all of the PAH and PCDD sought but many alkanes are also extracted. Toluene extracts less alkanes but does not extract all the PAH compounds and the improvement in PCDD extraction is not very substantial. Cyclohexane and dichloromethane are found to be unsuitable for extraction of the PAH and PCDD from flyash. Sequential extraction of flyash with methanol followed by benzene allows the extraction of all PAH and PCDD. Enhancement of certain compounds such as TCDD and fluorene is found. It can be ascertained that benzene and sequential methanol–benzene extraction of flyash yields the best results for specific trace analysis of the PAH and PCDD compounds. The other solvent methods are found to be less satisfactory.

Etude structurale et thermodynamique des interactions entre des dérivés chlorés et bromés du méthane et des amides tertiaires

J. M. DUMAS, C. GERON, A. R. KRIBII ET M. LAKRAIMI

Laboratoire de Physicochimie des diélectriques, Université de Poitiers, 40, avenue du Recteur Pineau, 86002 Poitiers Cedex, France

Reçu le 23 janvier 1984

J. M. DUMAS, C. GERON, A. R. KRIBII et M. LAKRAIMI. Can. J. Chem. **62**, 2634 (1984).

Une étude par polarisation diélectrique, microcalorimétrie et spectrométrie infrarouge a permis de mettre en évidence le rôle joué par l'halogène dans les interactions entre une série de dérivés chlorés et bromés du méthane, pris comme représentants d'anesthésiques halogénés et deux amides tertiaires prises comme modèle de constituant de la membrane des cellules nerveuses. Cette étude a eu lieu en solution diluée dans un solvant organique inerte, le cyclohexane. Les interactions sont de type liaison hydrogène et/ou liaison halogène.

J. M. DUMAS, C. GERON, A. R. KRIBII, and M. LAKRAIMI. Can. J. Chem. **62**, 2634 (1984).

A study by dielectric polarization, microcalorimetry, and infrared spectrometry has allowed us to demonstrate the role played by the halogen in interactions between a series of chlorinated and brominated derivatives of methane (considered as types of halogenated anesthetics) and two tertiary amides taken as models for an element of the membranes of the nervous cells. The inert organic solvent used was cyclohexane. The interactions are of the hydrogen bonding and (or) halogen bonding types.

Introduction

L'activité biologique et, en particulier, les propriétés anesthésiques des dérivés halogénés ont retenu notre attention. Le mécanisme de l'anesthésie générale semble pouvoir être lié à des phénomènes d'interactions entre les anesthésiques volatils et différents sites d'action au sein de la membrane des cellules nerveuses (1–3). Aussi, les résultats des études sur la recherche des interactions entre les dérivés halogénés et des molécules simples prises pour modèle d'un site d'action possible, paraissent donc importants.

Des études effectuées par Sandorfy et coll. (4–8) ont montré que les dérivés halogénés peuvent entraver la formation de liaison hydrogène. D'autre part, les résultats des recherches menées dans notre laboratoire (9) ont permis de signaler l'existence très générale d'interactions moléculaires de type liaison hydrogène et/ou liaison halogène entre des bases organiques et des dérivés halogénés et d'étudier l'évolution de ces interactions en fonction de l'halogène. Notre contribution à une meilleure connaissance de ces interactions repose sur une étude structurale et thermodynamique de systèmes formés par des dérivés halogénés du méthane (essentiellement chlorés et bromés) et par des amides tertiaires (*N*,*N*-diméthylacétamide et *N*-méthylpyrrolidone) utilisées comme modèle de constituant de la membrane et choisies pour leur caractère polaire (une part importante de notre étude s'appuyant sur la polarisation diélectrique).

Pour cette étude nous avons suivi une démarche méthodologique rigoureuse qui s'appuie sur une sélection de techniques physicochimiques: (*i*) la polarisation diélectrique qui permet de conduire simultanément à la stabilité (constante d'équilibre) et à des informations sur la structure des complexes formés. Tous les systèmes ont été étudiés par cette technique; (*ii*) la microcalorimétrie qui procure des valeurs d'enthalpie accompagnant les interactions étudiées et permet de comparer ces valeurs à celles habituellement mises en jeu dans le cas d'interactions non spécifiques (de l'ordre de 2 à 5 kJ mol^{-1}). Seuls quelques systèmes sont concernés; (*iii*) la spectrométrie d'absorption infrarouge qui, par l'intermédiaire d'une étude à basse température, apporte des compléments d'information sur la structure des complexes. Cette étude est très partielle.

Techniques et méthodes utilisées

En polarisation diélectrique

Nous avons adopté la méthode de Cleverdon *et al.* (10) qui, dans le cadre de la théorie de Debye, permet d'accéder simultanément à la constante d'association K_{AB}, à l'incrément de polarisation ΔP et au moment dipolaire global μ_{AB}, liés à la formation du complexe AB. Cette méthode consiste à déterminer la polarisation molaire du soluté A extrapolée à dilution infinie au sein d'un solvant inerte S (le cyclohexane) et dans une série de solvants mixtes BS.

La relation fondamentale sur laquelle repose la détermination de la polarisation molaire du complexe AB de stoechiométrie 1:1 est

$$\frac{1}{P'_{A_\infty/BS} - (P_{A_\infty/BS})_{cal.}} = \frac{1}{K_{AB}\,\Delta P} \cdot \frac{M_B\,V_{BS}}{W'_B} + \frac{1}{\Delta P}$$

où K_{AB}: constante de formation du complexe AB; V_{BS}: volume massique de la solution BS; M_B: masse molaire du soluté B; W'_B: fraction massique du soluté B dans le solvant S; ΔP: incrément de polarisation lié à la formation du complexe AB tel que $\Delta P + P_{A/S} + P_{B/S} = P_{AB/S}$; $P'_{A_\infty/BS}$: polarisation molaire apparente, à dilution infinie, de A dans BS. L'expression précédente tient compte de l'effet normal de solvant lorsque le soluté A en solution dans un solvant inerte S, se trouve en solution dans un solvant mixte BS.

$(P_{A_\infty/BS})_{cal.}$ représente la polarisation molaire, à dilution infinie, de A dans un solvant inerte fictif de même permittivité que BS. Elle est calculée à partir de l'expression suivante:

$$(P_{A_\infty/BS})_{cal.} = \frac{\left[1 + \frac{\epsilon_{BS} - 1}{\epsilon_{BS} + 2}\,e^{\epsilon^2} - \frac{n_{BS}^2}{n_A^2}\right]\left[P_{A_\infty/S} - \frac{n_A^2 - 1}{n_A^2 + 2} \cdot \frac{M_A}{\rho_A}\right]}{1 + \frac{\epsilon_S - 1}{\epsilon_S + 2}\left(e^{\epsilon^2} - \frac{n_S^2}{n_A^2}\right)} + \frac{n_A^2 - 1}{n_A^2 + 2} \cdot \frac{M_A}{\rho_A}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

$P_{A_\infty/S}$: polarisation molaire à dilution infinie du soluté A dans un solvant S; n_A, n_{BS}: indices de réfraction respectifs du soluté A et du solvant mixte BS; M_A: masse molaire du soluté A; ρ_A: masse volumique du soluté A; ϵ_S, ϵ_{BS}: constantes diélectriques respectives du solvant S et du solvant mixte BS; e^{x^2}: caractéristique du soluté A; $x^2 = \frac{c^2 - a^2}{a^2}$ si $a > b > c$; $x^2 = \frac{c^2 - a^2}{b^2}$ si $b > a > c$; $x^2 = \frac{c^2 - a^2}{c^2}$ si $b > c > a$; a, b, c: dimensions de la molécule de soluté A; a: dimension suivant la direction du moment dipolaire; b, c: dimensions suivant les directions perpendiculaires à celle du moment.

Il a été vérifié par l'étude de systèmes témoins: dérivés halogénés (tétrahalogénés (18), trihalogénés (15)), chlorocyclohexane, cyclohexane, que la méthode utilisée corrige de toutes les interactions type van der Waals. Le graphe

$$\frac{1}{P'_{(A_\infty/BS)} - P_{(A_\infty/BS)cal.}} = f\left(\frac{M, v}{w}\right)$$

conduit alors aux valeurs de K_{AB} et du ΔP (11).

Les mesures diélectriques ont été effectuées à l'aide d'un dipolemètre de type DMO1 "Wissenshaftlich-Technische Werkstatten" équipé soit d'une cellule DFL1 (capacité 20 cm^3) soit d'une cellule DFL2 (capacité 8 cm^3) thermorégularisées. Les masses volumiques des corps purs et des solutions ont été mesurées à l'aide d'un densimètre digital AP.PAAR.DMA45 thermorégularisé.

En microcalorimétrie

Nous avons utilisé la relation de Lamberts et Zeegers-Huyskens (12) qui fournit simultanément les valeurs des constantes d'équilibre et les variations d'enthalpie au cours de la formation des complexes. Nous nous sommes placés dans les conditions expérimentales proches de celles préconisées par Deranleau (13) qui permettent de mesurer des valeurs de constantes d'association très faibles (<1 L mol^{-1}).

$$\Delta H = \frac{2Q_C}{V\left[C_A^0 + C_B^0 + \frac{1}{K_{AB}} - \sqrt{\left(C_A^0 + C_B^0 + \frac{1}{K_{AB}}\right)^2 - 4C_A^0 C_B^0}\right]}$$

où V: volume total de la solution; C_A^0, C_B^0: concentrations initiales en A et B en mol L^{-1}; Q_C: chaleur de complexation obtenue à partir des chaleurs de dilution de A (dont la concentration C_A^0 est fixe dans le solvant mixte BS à plusieurs concentrations C_B^0) corrigées de la chaleur de dilution de A dans le solvant S et de celle de S dans le solvant mixte BS pour les concentrations C_B^0 précédemment utilisées.

Les graphes $\Delta H = f(C_B^0)$ établis pour diverses valeurs de K_{AB} permettent de trouver la valeur de K_{AB} liée à une valeur de ΔH constante.

Le calorimètre utilisé est un calorimètre CRMT (SETARAM), avec une cellule de 80 cm^3, couplé à un intégrateur.

En spectrométrie infrarouge

Nous avons étudié la bande d'absorption caractéristique du vibrateur C=O des amides tertiaires (nombre d'onde de vibration de l'ordre de 1680 cm^{-1}) à basse température, sur un spectrophotomètre Perkin Elmer 621. Le principe a été décrit par Asselin et Sandorfy (14). L'intervalle de température était compris entre 30°C et −80°C. Le solvant utilisé était le méthylcyclohexane afin de pouvoir atteindre les basses températures souhaitées.

Purification des produits

Le cyclohexane, produit de très grande pureté pour spectroscopie, a été utilisé sans traitement préalable. Tous les autres produits ont été distillés sous pression réduite d'azote et à l'abri de la lumière, puis conservés sur tamis moléculaire. Le trichlorométhane a été lavé avec un mélange de H_2SO_4 + H_2O et séché sur $MgSO_4$ préalablement à la distillation. Le tétrabromométhane a été sublimé sous vide.

Résultats et interprétation

D'une façon générale, les valeurs de ΔP, ΔH et K_{AB} déterminées dans l'hypothèse d'un complexe 1:1 (cf. tableau 1) pour les systèmes étudiés, mettent en évidence l'existence d'interactions spécifiques entre les deux amides et les dérivés halogénés. Les composés tétrahalogénés en particulier donneraient lieu à des interactions de type liaison halogène. L'étude des systèmes témoins dérivés halogénés (tétrahalogénés (18), trihalogénés (15)), chlorocyclohexane, cyclohexane a montré que toutes les interactions type liaison de van der Waals étaient corrigées.

I. *Informations structurales sur le type de complexe formé*

I. 1. *Par polarisation diélectrique*

En nous appuyant sur des travaux déjà publiés (15, 16) nous avons suivi dans les complexes formés de A et B l'évolution de l'incrément de moment dipolaire $|\vec{\Delta\mu}|$ (noté par la suite $\Delta\mu$) défini vectoriellement comme $\vec{\mu}_{AB} = \vec{\Delta\mu} + (\vec{\mu}_A + \vec{\mu}_B)$.

La figure 1 relative à un complexe formé entre la *N,N*-diméthylacétamide, et un trihalogénométhane, illustre le fait que: (*i*) la direction de $\vec{\Delta\mu}$ est celle de la liaison intermoléculaire; (*ii*) son sens correspond aux exigences du modèle (c'est-à-dire que le déplacement des charges positives doit avoir lieu du site accepteurs d'électrons vers le site donneur: il est vraisemblablement positif dans tous les cas considérés). L'ordre de grandeur de $\Delta\mu$ doit être comparable à celui trouvé pour des complexes présentant des liaisons intermoléculaires semblables et pour lesquels la structure est bien établie. Dans le cas d'un complexe de type liaison hydrogène, nous avons retenu comme valeur probable de référence ($\Delta\mu_{réf}$), celle qui concerne les complexes formés par le pyrrole et les cétones (17): 0,1 D pour une interaction avec les électrons π, 0,6 D pour une interaction avec les électrons n. Dans le cas d'un complexe de type liaison halogène, la valeur de $\Delta\mu_{réf}$ pour les dérivés chlorés a été calculée à partir des systèmes étudiés ici et mettant en jeu le tétrachlorométhane ($\Delta\mu_{réf}$ voisin de 0,5 D). Les mélanges de tétrabromométhane et d'amides tertiaires menant à la formation de combinaisons solides insolubles dans le cyclohexane, il est impossible d'accéder à une valeur sûre de $\Delta\mu_{réf}$ pour les dérivés bromés. Des études faites sur les interactions entre les dérivés tétrahalogénés du méthane (18) et diverses bases organiques ont montré que $\Delta\mu(CBr_4) > \Delta\mu(CCl_4)$, on peut donc estimer, dans le cas d'une interaction par liaison halogène dont l'atome de brome est responsable, une valeur de $\Delta\mu_{réf}$ supérieure à celle calculée précédemment pour CCl_4.

Compte tenu de nos résultats expérimentaux, nous avons éliminé tous les modèles fournissant des valeurs de $\Delta\mu$ trop éloignées des valeurs de référence. Nous ne présentons que les résultats afférant au modèle que nous avons considéré comme le plus probable car permettant de calculer des valeurs de $\Delta\mu$ les plus rapprochées des valeurs de référence.

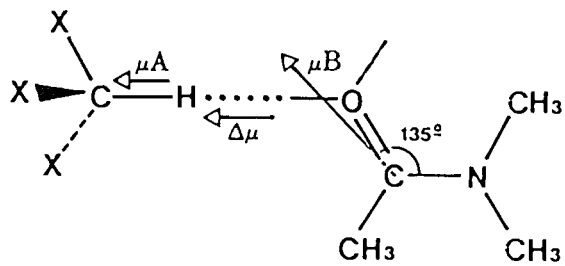
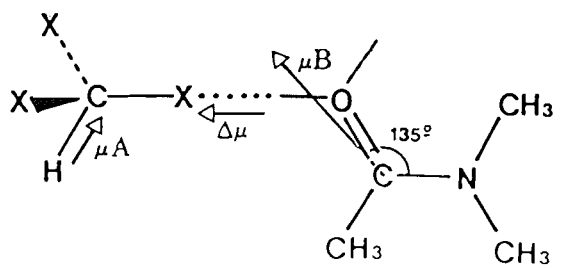
[a] NNDMA est l'abréviation de *N,N*-diméthylacétamide; NMP est l'abréviation de *N*-méthylpyrrolidone.
[b] Le solvant utilisé est le benzène.



Liaison hydrogène



Liaison halogène

FIG. 1. Modèle structural le plus probable dans le cas d'une liaison hydrogène et dans celui d'une liaison halogène.

Pour le système *N,N*-diméthylacétamide (B), trihalogénométhane (A), le modèle le plus probable est schématisé fig. 1. La liaison intermoléculaire se fait suivant l'axe de l'orbitale occupée par une paire d'électrons *n* qui est du côté du groupement CH_3. Le modèle retenu correspond, dans le cas d'une libre rotation autour de l'axe, au cas particulier où les dipôles s'orientent de manière à ce que l'énergie électrostatique du système soit minimisée. Sur la figure 1, il est indiqué le sens des moments de A et de B. La direction du moment de la *N,N*-diméthylacétamide est celle donnée par Nasyrov *et al.* (19).

Les valeurs de $\Delta\mu$ calculées pour ce modèle (cf. tableau 2) sont comparées aux valeurs de $\Delta\mu_{réf}$ retenues et précisées ci-dessus. La comparaison de ces valeurs mène aux remarques suivantes: dans le cas de $CHCl_3$ il est vraisemblable que la liaison soit de type hydrogène, dans celui de $CHBr_3$ une liaison halogène rendrait compte de nos résultats expérimentaux, dans ceux de CH_2Cl_2 et CH_2Br_2 il faudrait envisager une compétition entre les deux modes de liaison intermoléculaire.

En conclusion, pour le modèle structural retenu (le seul pouvant mener à des valeurs d'incrément de moment dipolaire susceptibles de rendre compte de nos résultats expérimentaux) seul le dérivé chloré $CHCl_3$ présente des résultats compatibles avec l'hypothèse d'une liaison hydrogène, et seul le dérivé bromé $CHBr_3$ présente des résultats compatibles avec l'hypothèse d'une liaison halogène. Compte tenu des grandes incertitudes rattachées aux valeurs de $\Delta\mu$ et de l'interprétation donnée aux résultats obtenus sur des systèmes voisins (9, 15, 16), il nous paraît préférable d'émettre, pour tous les cas envisagés ici, l'hypothèse d'une compétition entre les deux modes d'interaction: l'interaction par liaison hydrogène étant prépondérante lorsque l'halogéne est le chlore, l'interaction par liaison halogène devenant prépondérante lorsque l'halogène est le brome.

Les électrons *n* de l'amide seraient les seuls concernés dans cette interaction.

I. 2. *Par spectrométrie infrarouge*

La région spectrale comprise entre 1630 et 1680 cm^{-1}, dans laquelle se trouve la bande caractéristique du vibrateur C=O de la *N,N*-diméthylacétamide, a été explorée. Les spectres des mélanges *N,N*-diméthylacétamide (NNDMA) – dérivés halogénés ($CHCl_3$, $CHCl_2Br$, CCl_4), obtenus dans le solvant méthylcyclohexane pour différentes températures ou différentes concentrations en dérivé halogéné sont comparés au spectre de la NNDMA en solution dans ce même solvant (cf.

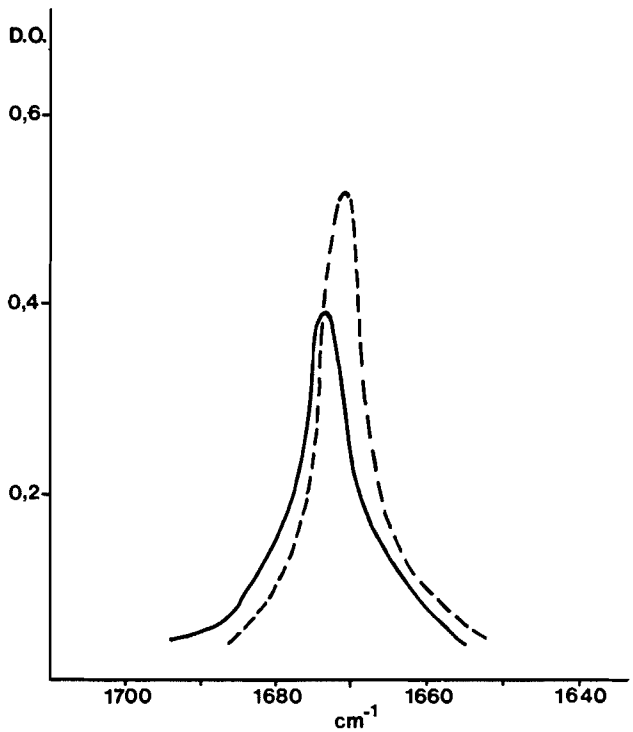

FIG. 2. Région de la vibration CO du spectre infrarouge de la *N*,*N*-diméthylacétamide en solution dans le méthylcyclohexane. c = 0,0084 mol L^{-1}; e = 0,425 mm; — t = 30°C; - - - - t = −56,6°C.

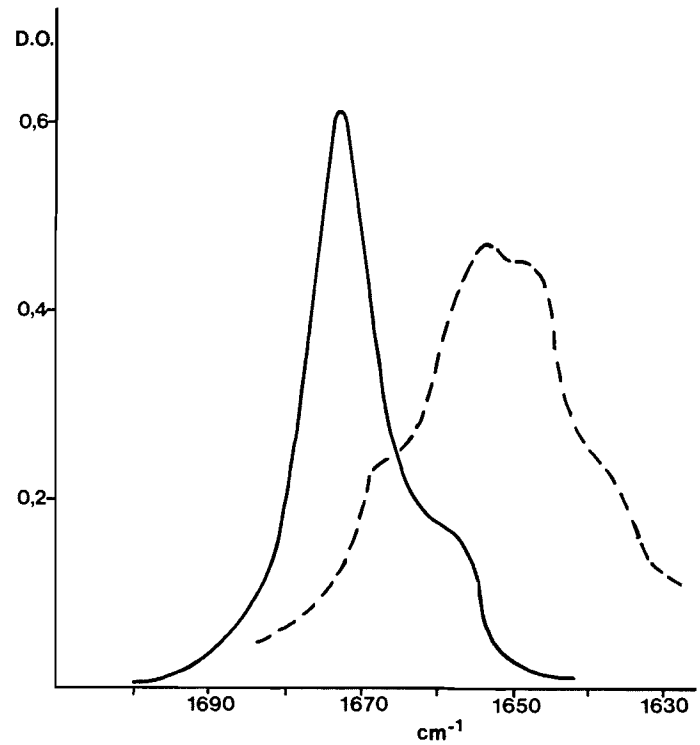

FIG. 3. Région de la vibration CO du spectre infrarouge de la *N*,*N*-diméthylacétamide (c = 0,00239 mol L^{-1}) dans une solution de trichlorométhane (c = 0,0455 mol L^{-1}) et de méthylcyclohexane. e = 0,225 mm; — t = 28,9°C; - - - t = −73,3°C.

fig. 2). Cette comparaison mène aux remarques suivantes.

À 30°C et pour des concentrations pour les deux solutés (NNDMA et dérivé halogéné) peu différentes, c'est-à-dire dans des conditions expérimentales proches de celles des études en polarisation diélectrique et en microcalorimétrie, une bande aux environs de 1655 cm^{-1} apparaît (cf. figs. 3–5). Suivant les résultats obtenus en polarisation diélectrique cette bande pourrait être attribuée à l'existence d'un seul type de complexe de stoechiométrie 1 : 1 dont la liaison intermoléculaire se ferait par l'intermédiaire des électrons *n* de la NNDMA.

À basse température ou à forte concentration en dérivé halogéné, c'est-à-dire loin des conditions expérimentales utilisées en polarisation diélectrique ou en microcalorimétrie, on note un déplacement de la bande du CO "libre" vers les faibles nombres d'onde. D'autre part la bande vers 1655 cm^{-1} se dédouble et une nouvelle bande vers 1640 cm^{-1} apparaît pour les plus fortes concentrations en dérivés halogénés ou pour les plus basses températures (cf. fig. 6). Ces conditions expérimentales particulières favoriseraient la formation de complexes de stoe-

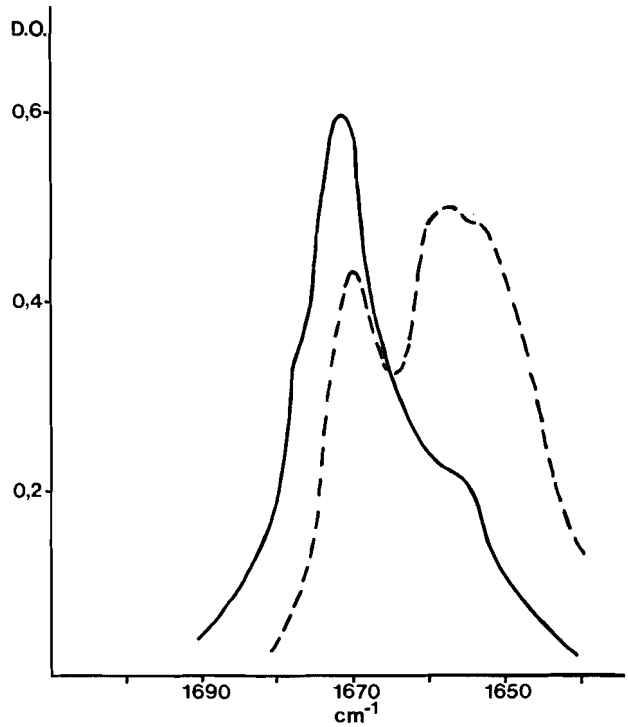

FIG. 4. Région de la vibration CO du spectre infrarouge de la *N,N*-diméthylacétamide (c = 0,0145 mol L^{-1}) dans une solution de bromodichlorométhane (c = 0,0634 mol L^{-1}) et de méthylcyclohexane. e = 0,403 mm; — t = 28,9°C; ---- t = −51,6°C.

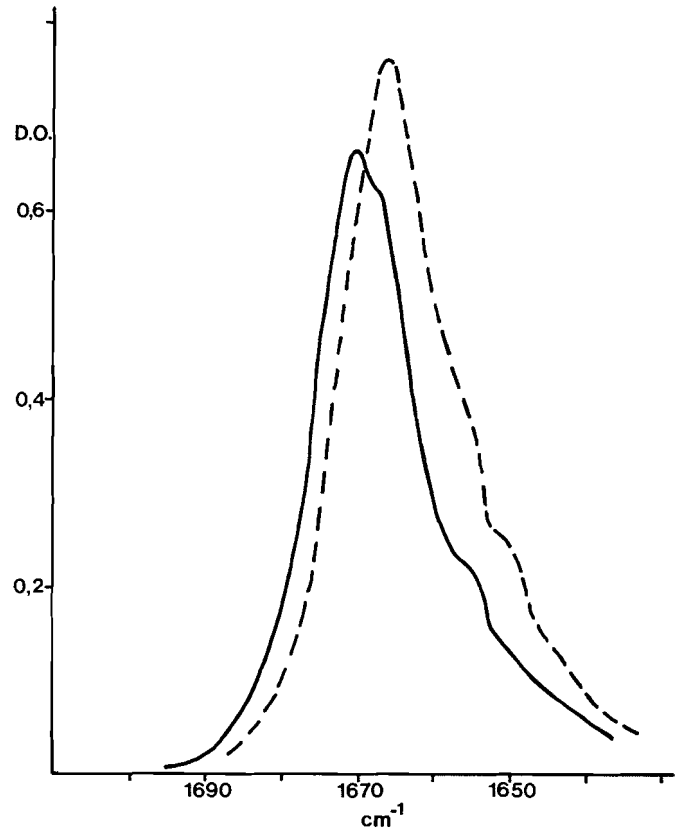

FIG. 5. Région de la vibration CO du spectre infrarouge de la *N,N*-diméthylacétamide (c = 0,0241 mol L^{-1}) dans une solution de tétrachlorométhane (c = 2,076 mol L^{-1}) et de méthylcyclohexane. e = 0,393 mm; — t = 31,0°C; ---- t = −36,6°C.

chiométrie différente de 1:1 ou de complexes présentant différents types de configuration (par l'intermédiaire des électrons n et/ou π de la NNDMA). Ce fait est révélé à l'extrême dans le cas du composé CF_2Br-CF_2Br, qui a pu être étudié jusqu'à la température de −80°C (cf. fig. 7).

II. *Comparaison des valeurs de* K *et* ΔH

Les résultats de l'analyse structurale précédente nous ont conduit à postuler, pour l'interaction décelée entre les amides tertiaires et les dérivés CH_qX_r étudiés, dans le domaine expérimental utilisé, l'existence de complexes de type 1:1 formés par liaison hydrogène (LH) et/ou liaison halogène (LX). Il est donc nécessaire, pour interpréter des résultats issus de techniques différentes, d'élucider la signification des grandeurs à interpréter.

Un développement des équations utilisées en polarisation diélectrique (pd) et en calorimétrie (cal) pour i complexes de type 1:1 en équilibre compétitif mène aux résultas suivants (15):

$$K_{pd} = K_{cal} = \Sigma K_i \ (= \text{par exemple } K_{LH} + K_{LX})$$

$$\Delta H = \frac{\Sigma n_i \Delta H_i}{\Sigma n_i} \left(= \text{par exemple } \frac{K_{LH}}{K_{LH} + K_{LX}} \Delta H_{LH} + \frac{K_{LX}}{K_{LH} + K_{LX}} \Delta H_{LX} \right)$$

LH: interaction par liaison hydrogène; LX: interaction par liaison halogène.

Les résultats portés dans le tableau 1 montrent qu'il apparaît bien une similitude entre les valeurs des constantes d'équilibre issues de ces deux techniques confirmant ainsi que les corrections d'effets secondaires ont été correctement faites. Mais une comparaison des valeurs de K ou de ΔH s'avère difficile car elle nécessite la connaissance de ces grandeurs thermodynamiques pour chaque équilibre mis en jeu. On peut toutefois envisager cette comparaison dans les deux cas extrêmes c'est-à-dire dans l'hypothèse d'une interaction unique par liaison hydrogène ou par liaison halogène. Dans ce cas, lors du passage du dérivé chloré au dérivé bromé on peut prévoir une décroissance de K et de $|\Delta H|$ pour une interaction unique par liaison hydrogène et une croissance de K et de $|\Delta H|$ pour une interaction unique par liaison halogène (15).

Suivant nos résultats expérimentaux (cf. tableau 1), on constate que les valeurs des constantes d'équilibre, qui augmentent lorsque le numéro atomique de l'halogène augmente, ne permettent pas d'admettre l'existence d'un unique mode d'interaction par liaison hydrogène mais elles ne seraient pas incompatibles avec celle d'un unique mode d'interaction par liaison halogène. Ces constatations, dans les quelques cas expérimentaux étudiés, sont inversées pour les valeurs de $|\Delta H|$. Les valeurs de ΔS n'ont pas été notées, car les domaines d'incertitude sont tels que ces valeurs n'ont pas de signification. Toutefois, les résultats de l'analyse structurale nous ont amené à faire intervenir l'existence compétitive de ces deux modes d'interaction. Dans ce cas, pour expliquer une quelconque variation des valeurs de ΔH il est nécessaire de connaitre les valeurs respectives de K_{LH}, ΔH_{LH} et K_{LX}, ΔH_{LX} (voir ci-dessus). Par contre, un sens de variation des valeurs de K, représentant une somme de constantes ($K_{LH} + K_{LX}$), peut être interprété suivant le sens de variation probable de chacune des constantes d'équilibre (18): une augmentation de K lorsque le

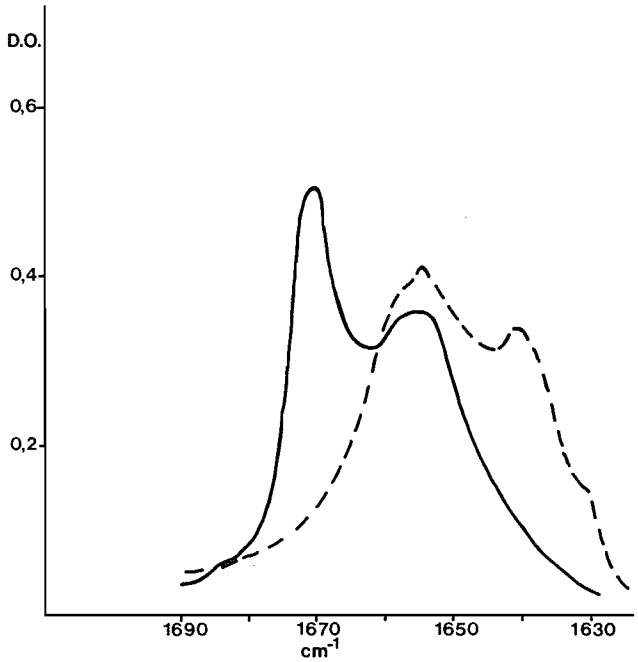

FIG. 6. Région de la vibration CO du spectre infrarouge de la *N,N*-diméthylacétamide (c = 0,023 mol L^{-1}) dans deux solutions de trichlorométhane (— c = 0,0455 mol L^{-1}, ---- c = 0,4511 mol L^{-1}) et de méthylcyclohexane. e = 0,225 mm; t = −36,6°C.

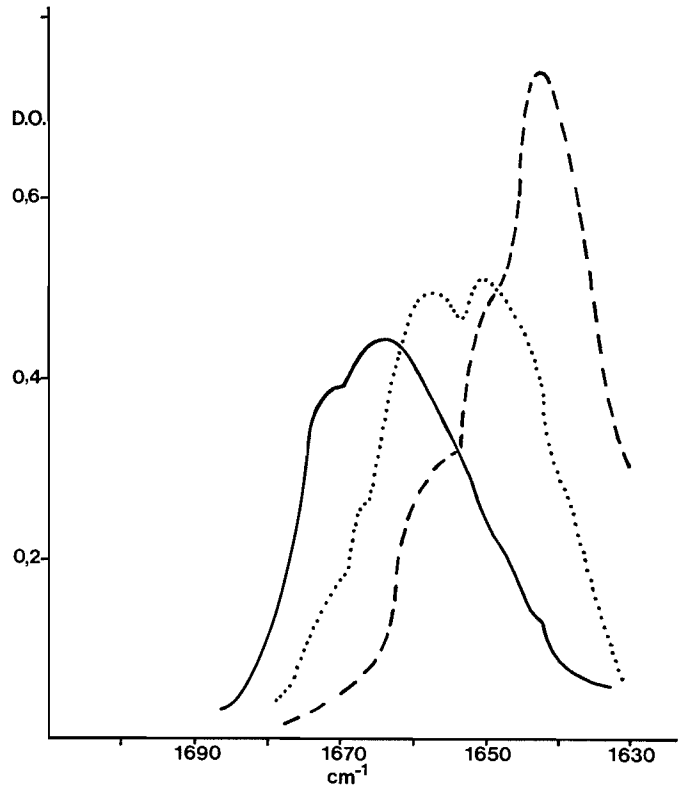

FIG. 7. Région de la vibration CO du spectre infrarouge de la *N,N*-diméthylacétamide (c = 0,0145 mol L^{-1}) dans une solution de tétrafluoro-1,1,2,2 éthane (c = 1,498 mol L^{-1}) et de méthylcyclohexane. e = 0,393 mm; — t = 28,9°C, ... t = −37°C; ---- t = −80,5°C.

numéro atomique de l'halogène croît indique que K_{LX} croît plus vite que K_{LH} ne décroît.

Conclusion

Une étude menée par trois techniques différentes (polarisation diélectrique, spectrométrie infrarouge, microcalorimétrie) nous a permis de mettre en évidence l'existence d'interactions moléculaires faibles entre les dérivés halogénés du méthane et des amides tertiaires.

L'étude structurale par polarisation diélectrique, à partir de modèles structuraux caractéristiques faisant intervenir les électrons n et les électrons π des amides tertiaires, a permis d'une part, de minimiser le rôle des électrons π et maximaliser le rôle des électrons n, d'autre part, de préciser la nature de l'interaction. Les résultats plaident en faveur d'une compétition entre deux modes d'interaction (par liaison hydrogéne et par l'intermédiaire d'un atome d'halogène ou liaison halogène), à l'exception de $CHCl_3$ et $CHBr_3$, pour lesquels respectivement une liaison hydrogène seule et une liaison halogène seule pourrait suffire à expliquer les résultats expérimentaux.

L'étude vibrationnelle par spectrométrie infrarouge a montré que dans les conditions expérimentales sélectionnées pour les deux autres techniques (25°C; concentrations molaires de l'ordre de 0,05 M), les liaisons intermoléculaires (hydrogène ou halogène) donneraient lieu à un complexe de stoechiométrie 1:1, d'autres types de complexes n'apparaissant qu'à basse température.

Les valeurs identiques des grandeurs thermodynamiques déterminées par polarisation diélectrique et microcalorimétrie, dans le domaine d'incertitude considéré, confirment la validité des corrections d'effets secondaires apportées dans chacune des méthodes adoptées. La stoechiométrie des complexes étant postulée 1:1, la variation de ces grandeurs thermodynamiques en fonction du numéro atomique de l'halogène au sein d'une même molécule est incompatible avec une interaction unique par liaison hydrogène et pourrait être interprétée par une interaction par liaison halogène seule. Ce résultat associé aux résultats de notre analyse structurale et à ceux obtenus par ailleurs (9, 15, 16) nous permettent en fait, d'émettre l'hypothèse de l'intervention compétitive de ces deux types d'interaction, l'une ou l'autre devenant plus ou moins prépondérante suivant le type d'halogène porté par le dérivé halogéné.

En conclusion, cette étude des interactions entre une série de composés organohalogénés pris pour représentants d'anesthésiques halogénés et deux amides tertiaires prises comme modèles d'un constituant de la membrane des cellules nerveuses, nous a permis de mettre en évidence, en particulier, le rôle joué par l'halogène dans ces interactions (liaison halogène). Les systèmes simples utilisés dans cette étude sont, bien sûr, loin des systèmes biologiques mais nous proposons l'intervention de ce type d'interaction dans ces milieux plus complexes et sa prise en compte dans un classement des anesthésiques généraux (1–3) suivant le type d'interactions principales auquel ils peuvent participer.

Remerciements

Les spectres infrarouge ont été réalisés par l'un d'entre nous dans le laboratoire du Professeur Sandorfy (Université de Montréal) que nous tenons ici, à remercier. Ce séjour à Montréal a été rendu possible grâce à un programme d'échange scientifique France–Québec.

Permanganate peroxidation of cyclohexene. II. Temperature, solvent, and concentration effects

JAY. E. TAYLOR
Department of Chemistry, Kent State University, Kent, OH 44242, U.S.A.

Received December 23, 1983

JAY E. TAYLOR. Can. J. Chem. **62**, 2641 (1984).

An investigation of the peroxidation of cyclohexene to form *cis*-1,2-cyclohexanediol has been continued using an improved turbulent stirring apparatus. Varying conditions of temperature, methanol concentration, dilution, and permanganate/cyclohexene ratios have been evaluated by the method of comparative product yields. The temperature effect was quite modest since only at the extremes of −20 and 40°C were decreases in yields noted. Added methanol in low concentrations, >10%, gave slightly increased yields, but decreased yields were observed when methanol was added in 75% concentration. Under the new stirring conditions, 83−86% yields were obtained with ~0.05 *M* added potassium permanganate, but only 70−74% yields were obtained at higher concentrations. This effect appeared to relate to the increased viscosity of the mixture which results from the formation of gelatinous manganese oxides. Ratios of cyclohexene to permanganate ion greater than 2:1 gave no significant yield increases, based on permanganate utilization. All of the above data have been interpreted with the assumption of an intermediate alkene − permanganate ion addition complex. Preparative scale syntheses of *cis*-1,2-cyclohexanediol have produced 83−87% yields with either 0.2 or 0.5 molar quantities of cyclohexene.

JAY E. TAYLOR. Can. J. Chem. **62**, 2641 (1984).

Utilisant un appareil à agitation turbulente amélioré, on a poursuivi l'étude de la peroxydation du cyclohexène conduisant au cyclohexanediol-1,2-*cis*. Faisant appel à la méthode des comparaisons des rendements en produits, on a pu évaluer l'effet d'une variation des conditions de la température, de la concentration en méthanol, de la dilution et des rapports permanganate/cyclohexène. L'influence de la température est faible puisque les rendements ne diminuent qu'aux températures extrêmes, soit à −20 et à 40°C. L'addition de faibles concentrations, <10%, de méthanol provoque une légère augmentation des rendements; toutefois, on observe une diminution des rendements lorsque la concentration de méthanol ajouté est égale ou supérieure à 75%. Les nouvelles conditions d'agitation permettent d'obtenir des rendements de l'ordre de 83 à 86% pour une concentration de permanganate de potassium de 0,05 *M*; toutefois, le rendement n'est que de 70 à 74% pour des concentrations plus élevées. Cet effet semble être relié à une augmentation de la viscosité du mélange qui résulte de la formation d'oxydes de manganèse gélatineux. En tenant compte de l'utilisation du permanganate, des rapports de cyclohexène/permanganate supérieurs à 2:1 ne provoquent pas d'augmentation appréciable des rendements. On interprète tous ces résultats en faisant l'hypothèse qu'il y a formation d'un intermédiaire complexe provenant de l'addition de l'alcène sur l'ion permanganate. A une échelle préparative, impliquant de 0,2 − 0,5 moles de cyclohexène, on peut obtenir le cyclohexanediol-1,2-*cis* avec des rendements de 83 à 87%.

Yields of *cis*-1,2-cyclohexanediol formed by the permanganate peroxidation of cyclohexene (1) may vary from >0 to <88% as a result of stirring efficiency. This unusual stirring effect appears to be the result of competing reactions, one of which is minimized under turbulent stirring conditions.

It is the purpose of this paper to elucidate further the conditions and the mechanism by which this stirring effect occurs. The paper, as was its predecessor (1), is concerned primarily with the peroxidation reaction. Comparative product yields have provided a convenient method of evaluation of a reaction for which many of the classical procedures are inapplicable.

Experimental

A revised stirring arrangement is shown in Fig. 1. The addition of cross bars to the stirring shaft and a baffle in the 1-L bottle reactor enhanced the stirring efficiency of the previously described "Lightnin" stirrer (1). Also an ice water condenser, through which methanol was added, minimized cyclohexene vapor loss. Varying flow rates were attained by using selected lengths of 0.5-mm id tubing at appropriate heights. It was found that the flow rates of $KMnO_4$ solutions and water were essentially the same, but methanol was quite different. Calibrations were done, (s/5 mL) with methanol and with water. Mixtures of methanol and water have significantly slower flow rates (higher viscosities) than either water or methanol (2).

The same general set-up using an enlarged baffle and the same stirrer, but without the cross pieces, has been used in 5-L and 12-L reactors. See Fig. 2.

The cyclohexene (Aldrich Chemical Co.) was redistilled and the product boiling over a range of 0.3°C was used. However, in a duplicate run the unpurified cyclohexene gave the same yield of *cis*-1,2-cyclohexanediol as the redistilled reagent. The cyclohexene was preserved at −20°C.

Descriptions of typical experiments follow.

cis-*1,2-Cyclohexanediol. Procedure A*

The reactor was set up as in Fig. 1. Methanol, 125 mL, was placed in flask A; 7.78 g (0.0492 *m*) $KMnO_4$ in 375 mL water were added to flask B; and 140 mL water, 10 mL of 1 *M* sodium hydroxide, 4.036 g (0.0492 *m*) cyclohexene from a 5-mL pipet (20.0°C) calibrated by weighing the cyclohexene delivered at 20.0°C, followed by 50 mL methanol were placed in reactor J. With the ice water condenser and stirrer in operation, flask A was inverted into C and flask B into D to start the reaction. The length of capillaries and (or) heights of C and D had been previously adjusted to allow the delivery of both the $KMnO_4$ solution and methanol in 1 h. The temperature in J was maintained at 20 ± 2°C. Five minutes after completion of the additions, sulfur dioxide was bubbled in to just dissolve the precipitated manganese dioxide. The stirring was then stopped, and sodium bicarbonate was added to attain pH 8 (slow). The resulting slowly-formed precipitate of manganese sulfites and carbonates was allowed to settle, the solution was decanted and filtered and then extracted continuously over a period of 1−4 days with dichloromethane as previously described (1). The dichloromethane−glycol solution was then concentrated to 25−30 mL, cooled to room temperature, and then to ~4°C. The resulting crystals were filtered and washed twice with CH_2Cl_2 precooled to −15°C. Yield 4.513 g, mp 98−98.5°C (uncorrected). The filtrate was further concentrated and treated as above. Yield 0.230 g, mp 97−98°C. Total yield 83.1%.

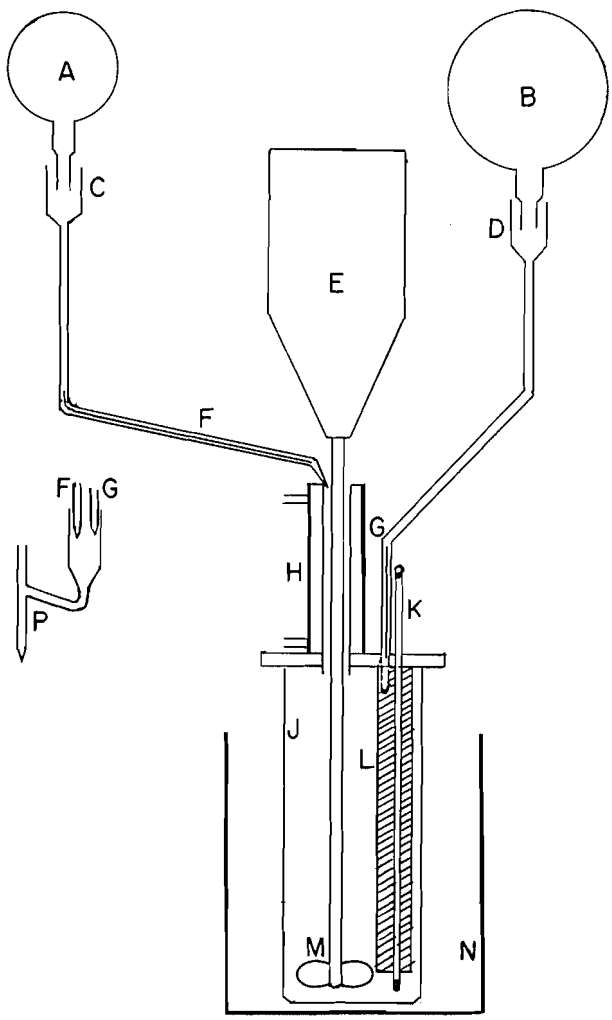

FIG. 1. Small scale reactor. A, methanol reservoir; B, $KMnO_4$ solution reservoir; C and D, liquid leveling devices; E, 1/30-hp, 1600-rpm Lightnin stirrer; F and G, 0.5-mm capillary tubing for liquid flow control; H, ice water condenser; J, 1-L square bottle reactor with a 3/8-in. thick Plexiglas top and rubber tubing seals around inlets G and K; K, thermometer; L, stainless steel baffle; M, 5-cm diameter, 3-blade, 45° angle stirrer; N, water or ice bath; P, auxiliary addition tube for addition of methanol and permanganate solutions as a unit mixture whereby P is substituted for G.

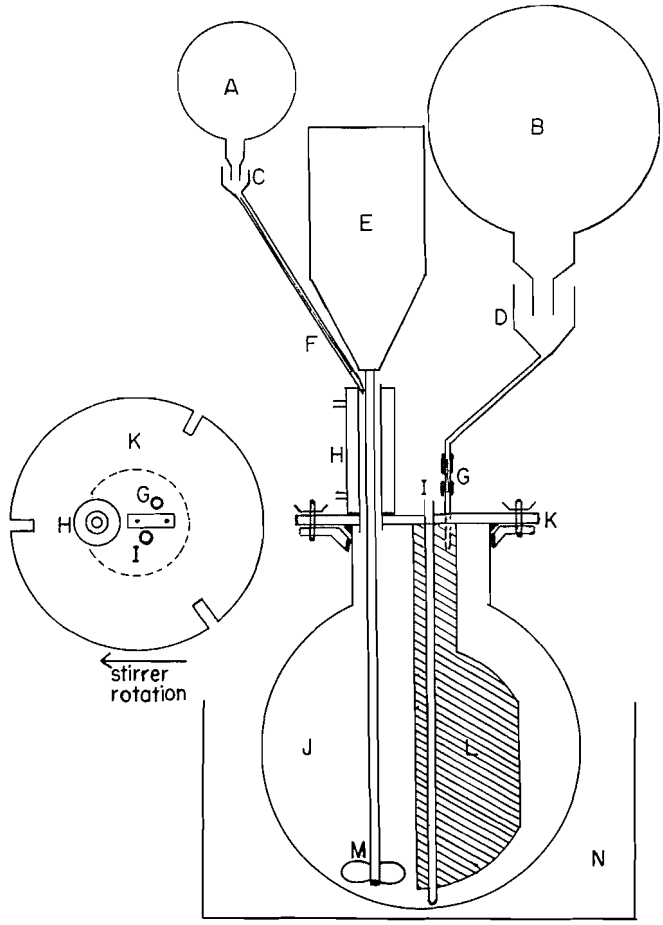

FIG. 2. Preparatory scale reactor. A, methanol reservoir; B, $KMnO_4$ solution reservoir; C and D, liquid leveling devices; E, 1/30-hp, 1600-rpm Lightnin stirrer; F and G, 0.5-mm capillary tubes for flow control; H, ice water condenser; I, thermometer; J, 12-L wide mouth reactor and extension support (Ace Glass Co.); K. 1/2-in. thick Plexiglas top for the reactor with rubber tubing seals around inlets I and G; L, baffle; M, 5-cm diameter, 3-blade, 45° angle stirrer; N, ice bath.

Variations on the above procedure included changes in temperature, methanol concentration, and reactant concentrations. In all experiments described, unless otherwise indicated, the methanol concentrations were continuously maintained by adding methanol at the appropriate rate concurrent with the potassium permanganate solution. Extractions with dichloromethane were made directly on solutions containing up to 50% methanol. With the 75% methanol experiments, it was necessary to remove part of the methanol by vacuum distillation.

Not all experiments used the apparatus precisely as shown in Fig. 1. For certain experiments, indicated in the tables, the methanol was added without passing through the condenser. Through-the-condenser addition was found to increase yields significantly only for the most dilute solutions.

In another set of experiments in which the effect of premixing the potassium permanganate and methanol was investigated, the alternate addition tube, P, shown in Fig. 1 was employed. With this set-up, the potassium permanganate solution and methanol or methanol–water mixtures, each flowing at prescribed rates, dripped into a receiver which then emptied into the reactor. In this manner the concentration of potassium permanganate, as added, was always constant, but the solvent varied in relative concentrations of methanol and water. The reason for the use of the flow mixing arrangement was to minimize the oxidation of methanol by the permanganate ion.

cis-1,2-Cyclohexanediol. Procedure B, for preparative utility

The reactor was set up as in Fig. 2. Methanol, 1 L, was placed in reservoir A; 79 g (0.5 *m*) $KMnO_4$ dissolved in 6 L water were added to reservoir B; then 3 g sodium hydroxide, 1.0 L water, 50.75 mL at 20.0°C (0.500 *m*) cyclohexene followed by 100 mL methanol were placed in reactor J. With the temperature in J at about 12°C and with the ice water condenser and stirrer activated, A and B were inverted into C and D to initiate the reaction. Since C and D served as automatic leveling devices, no further attention, except to replenish ice, was needed until the $KMnO_4$ addition was complete. The temperature remained at 12 ± 2°C, during the time of addition, 3.3 h. A and B, as shown, may be substituted by 2-L and 6-L stoppered separatory funnels with 6-mm and 12-mm bore stopcocks, respectively.

Upon completion of the $KMnO_4$ addition plus 5 min additional stirring, sulfur dioxide was bubbled in to reduce the manganese oxides. The solution was then neutralized (pH 8) with $NaHCO_3$ and extracted with dichloromethane. Using a 120-cm long vertical extraction tube, the extraction was continued until no more product was obtained. Yield 44.36 g, mp 97.5–98.5°C, plus 4.69 g, mp 96–98°C, total yield 85%.

[a]In all experiments 0.0492 m $KMnO_4$ was reacted with 0.0492 m cyclohexene by procedure A except that the methanol was not added through the condenser. All yields are based on cyclohexene.

[b]The specific volumes added were 75% methanol = 375 mL methanol, 125 mL $KMnO_4$, 50% methanol = 250 mL methanol, 250 mL $KMnO_4$; 25% methanol = 125 mL methanol, 375 mL $KMnO_4$; 0% methanol = 500 mL $KMnO_4$.

For personal use only.

Using 0.2-m reactants in a 5-L reactor similar to Fig. 2, 83−87% yields were obtained.

All yields are based on the initial charge of cyclohexene except for experiments 7−9, Table 3, where excesses of cyclohexene were used. The two yields given are based on unrecovered cyclohexene and on potassium permanganate assuming a 1:1 reaction ratio.

Based on duplicate runs which were made, the average deviation of yields was ±1%.

Discussion

Variations in yields of *cis*-1,2-cyclohexanediol have been evaluated under a variety of conditions including alterations in temperature, methanol concentrations, dilution of reactants, and permanganate/cyclohexene ratios.

Since the existence of the permanganate−alkene complex for alkenes other than cyclohexene has been established by Lee and Brownridge (3) and Wiberg *et al.* (4), with further support by Ogino and Mochizuki (5), the concept was also applied to cyclohexene in the form of the following proposed mechanism.

[1] $MnO_4^- +$ $\xrightarrow{\text{rapid}}$  or Q^-

[2] $Q^- + H_2O \longrightarrow$  $+ MnO_3^-$

[2a] $3MnO_3^- + H_2O \longrightarrow MnO_4^- + 2MnO_2 + 2OH^-$

[3] $Q^- + MnO_4^- \longrightarrow {}^-O_2C(CH_2)_4CO_2^- + MnO_2$

other oxidations

Temperature

The effects of alterations in temperature were surprisingly minimal. See Table 1, comparing experiments at the same methanol concentrations. Only at the extremes of temperature (−20°C and 40°C) were detectable variations in yields observed. This small temperature coefficient may be attributed to the rapidity of formation of Q^- by reaction [1] followed by conversion to glycol by reaction [2] in the absence of excess MnO_4^-. However, at the low temperature of −20°C, the rate of Q^- formation appeared to decrease sufficiently so that presumably excess MnO_4^- accumulated and reacted with the previously formed Q^- by reaction [3]. This is further supported by the observation of a significant induction period in initial MnO_4^- uptake at −20°C. It is possible therefore that very

[b]The methanol and $KMnO_4$ solution were mixed continuously before addition using the auxiliary device of Fig. 1. The 0.0492 *m* $KMnO_4$ reacted with 0.0492 *m* (5.00 mL) cyclohexene).

slow addition at −20°C may increase the yield. This has not been tried. Also yields were not as reproducible as at higher temperatures.

In contrast, the modest decrease in yield noted at the high temperature of 40°C may have been the result of other oxidative side reactions or possibly cyclohexene vapor loss.

Methanol

The effect of methanol on yields is not large, as may be seen in Table 1. In the total absence of methanol, the percent yields were 3 to 9% less than with added methanol. With methanol absent, a distinctly greenish color of the reaction mixture (indicating the presence of MnO_4^{2-}) persisted as long as 15 min, particularly at the lower temperatures. In the presence of methanol, this greenish color was seen for only 1–2 min or less. There did appear, therefore, to be some minor effect of the added methanol on the mechanism of the reaction. The methanol also appeared to enhance dispersion of the cyclohexene in the aqueous suspension, and this was probably its major effect.

For the data of Table 1 the permanganate solutions and methanol were added separately. To attain the different concentrations, the amount of water dissolving a given amount of potassium permanganate was varied as shown in note *b*, Table 1. There was then the possibility that the decreased yields at high methanol concentrations were due to the high concentration of added permanganate ion. In view of this possibility, another set of experiments, described in Table 2, was done so that each permanganate solution had the same concentration, 0.098 *M*, as it contacted the surface of the reaction mixture. The only differences were in the methanol content. The concentrated permanganate solutions were diluted continuously with methanol or methanol–water mixtures as described in the Experimental section using the mixing tube, P, shown in Fig. 1.

Essentially the same yields under corresponding conditions were obtained for experiments 8–10, Table 1, and those of Table 2. It is therefore concluded that the stirring was sufficiently adequate and that the direct addition of either dilute or concentrated permanganate solutions had no effect on yields. Therefore, the 75% methanol data of Table 1 are a direct reflection of the influence of that substance.

The explanation of the decrease in yields at 75% methanol concentration appears to relate to the decrease in activity of water with increased concentration of methanol. Since by reaction [2], water is a reactant, any decrease in its activity must correspondingly influence the rate of reaction [2]. In summary, there are then two opposing factors by which methanol may affect yields: rate enhancement of reaction [1] by improved dispersion of the cyclohexene, and retardation of reaction [2] by decreased water activity.

Dilution

In Table 3, experiments 1–6, lower yields were obtained at 0.0985 *m* added permanganate, but roughly equal yields resulted with either 0.0492 or 0.0197 *m*. This apparent optimization of yields with ~0.05 *m* permanganate suggests that factors other than stirring efficiency were operative. If there were inadequacies in mixing of simple aqueous solutions, these should have been evident at all concentration ranges.

As previously noted, adding either a dilute or a concentrated permanganate solution to the reaction mixture made no difference in yields under otherwise equal conditions. Compare again Tables 1 and 2. Thus, it was demonstrated that the specific concentration of the added potassium permanganate did not affect yields, providing the final product concentrations were the same. This observation also is supportive of the above conclusion that mixing efficiency for a low viscosity solution was optimal.

The lowered yields at higher concentrations as seen in Table 3 (experiments 1, 2, 4, 5) may then be attributed to the increased viscosity of the reaction mixture due to the greater concentrations of accumulated manganese dioxide. Since from the outset of any given reaction the cyclohexene distribution was obviously consistent, each drop of added permanganate provided a localized excess of that reagent. Under initial conditions, or dilute concentrations, the viscosity effect was minimal, the permanganate reacted with the available cyclohexene by reaction [1], and the excess was rapidly dispersed. But in the presence of greater accumulations of gelatinous manganese dioxide, the apparent viscosity was significantly increased, the rate of dispersion of excess permanganate ion was retarded, and the undispersed MnO_4^- reacted with the available complex Q by reaction [3], thereby decreasing the glycol yield. Entrainment of a combination of permanganate ions and the complex in a manganaese dioxide matrix may also have been a contributing factor. The stirring efficiency was adequate to overcome the effect of roughly 0.05 *m* of gelatinous manganese dioxide per 700 mL of solution. Yields obtained in either the apparatus of Fig. 1 or of Fig. 2 were equal.

Varying cyclohexene ratios

In another series of experiments, the permanganate concentration was held constant and the cyclohexene concentrations were increased. See Table 3, experiments 7–9. The excess cyclohexene was recovered, and yields were calculated on the basis of unrecovered cyclohexene and on initial potassium permanganate. Due to cyclohexene vapor losses and solubility in the water–alcohol mixture, the yields based on cyclohexene were of little significance. However, the permanganate yields were relevant since these experiments indicated that a 1:1 ratio of MnO_4^-/cyclohexene was the most effective ratio. The yields based on 1:1 $KMnO_4$ utilization (assuming one mole C_6H_{10} consumed 1 mole MnO_4^-) were 93%, 94%, 94% with 2:1, 4:1, and 8:1 ratios respectively. If, however, a 3:2 ratio by the equation

$$[4]\quad 3C_6H_{10} + 2MnO_4^- + 4H_2O \rightarrow 3C_6H_{12}O_2 + 2MnO_2 + 2OH^-$$

is assumed, the yields correspondingly become 62%, 63%, 62%. It is clear, therefore, that if the stoichiometry of equation

[a]Procedure A was followed except as indicated. Final volume for each experiment was 700 mL plus cyclohexene on which yields were based.
[b]The methanol was not added through the condenser.
[c]Initial concentration. No methanol was added during the course of the reaction.
[d]The yield was based on unrecovered cyclohexene.
[e]The yield was based on $KMnO_4$ assuming a 1:1 reaction ratio with cyclohexene.

[4] is applicable, other side reactions must decrease its efficiency. Previously, it was shown (1) that *at lesser stirring efficiencies*, where the 1:1 ratio gave a yield of 15%, increased cyclohexene/MnO_4^- ratios did give greatly increased yields, ~42%. It appears, therefore, that these increases were the result of better reactant contact efficiencies as the cyclohexene concentration was increased, and were not due to a mass action effect on some phase of the mechanism.

Received March 29, 1984

GEORGE I. BIRNBAUM, MIROSLAW CYGLER, and DAVID SHUGAR. Can. J. Chem. **62**, 2646 (1984).

Crystals of acyclovir belong to the space group $P2_1/n$, and the cell dimensions are a = 25.459(1), b = 11.282 (1), c = 10.768(1) Å, β = 95.16(1)°. Intensity data were measured on a diffractometer and the structure was determined by direct methods. The asymmetric unit was found to contain three independent molecules of acyclovir and two molecules of water. Least-squares refinement, which included all hydrogen atoms, converged at R = 0.053 for 3970 observed reflections. In two of the molecules the side chain is partially folded, while in the third one it is fully extended. The glycosidic torsion angles are in the range 91.4−104.3°. The conformational features are compared with those in other known acyclonucleosides. They are also examined in relation to the behavior of acyclonucleosides and acyclonucleotides in various enzymatic systems, including those related to antiviral activities.

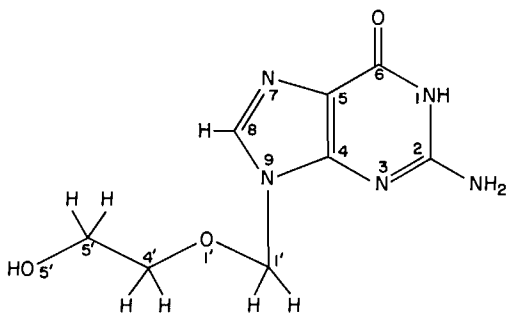
GEORGE I. BIRNBAUM, MIROSLAW CYGLER et DAVID SHUGAR. Can. J. Chem. **62**, 2646 (1984).

Les cristaux d'acyclovir appartiennent au groupe d'espace $P2_1/n$ et les dimensions de maille sont a = 25,459(1), b = 11,282(1), c = 10,768(1) Å, β = 95,16(1)°. On a mesuré les intensités à l'aide d'un diffractomètre et on a déterminé la structure par des méthodes directes. On a trouvé que l'unité asymétrique comporte trois molécules indépendantes d'acyclovir et deux molécules d'eau. Un affinement par la méthode des moindes carrés, qui inclut tous les atomes d'hydrogène, converge vers une valeur de R = 0,053 pour 3970 réflexions observées. Dans deux des molécules, la chaîne latérale est partiellement repliée alors qu'elle est totalement allongée dans la troisième. Les angles de torsion autour des liaisons glycosidiques s'étalent de 91,4 à 104,3°. On compare les caractéristiques conformationnelles à celles d'autres acyclonucléosides connus. On les examine aussi en relation avec les comportements des acyclonucléosides et des acyclonucléotides dans divers systèmes enzymatiques, y compris ceux reliés aux activités antivirales.

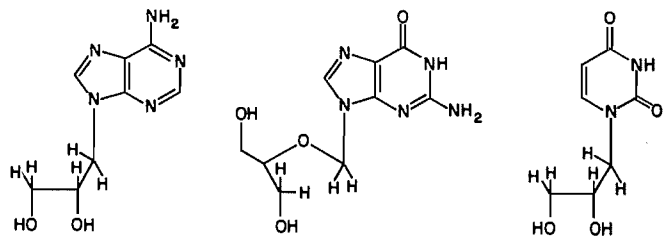
[Traduit par le journal]

Introduction

It was initially demonstrated by Elion *et al.* (1) that replacement of the ribose moiety of guanosine by an acyclic chain corresponding to the "upper" portion of the ribose ring led to an analogue, 9-[(2-hydroxyethoxy)methyl]guanine (acycloG, acyclovir, ACV), with potent antiherpes activity. Interest in this compound, now licensed for clinical use, was further enhanced by the finding that, in HSV-infected cells, its mechanism of action was due to its specific phosphorylation by the viral-encoded (but not cellular) thymidine kinase to acyclo-GMP (1), followed by further phosphorylation by cellular GMP and GDP kinases to the triphosphate, acycloGTP, which is a selective and potent inhibitor of the HSV DNA polymerase (2).



Concurrently it was found that an acyclic analogue of adenosine, in which the sugar ring is replaced by its "lower" fragment, 9-(2,3-dihydroxypropyl)adenine (DHPA), also exhibits significant antiviral activity (3), although the mechanism of action in this instance remains to be clarified. More recently a new analogue of acyclovir has been reported from several laboratories, 9[(1,3-dihydroxy-2-propoxy)methyl]guanine (DHPG), which is an even more active antiherpes agent than acyclovir and is more rapidly phosphorylated by the viral thymidine kinase than acyclovir (4−6).



DHPA DHPG DHPU

The foregoing findings have stimulated widespread interest in, and led to the synthesis of a large number of, purine and pyrimidine acyclonucleosides (7). Their antiviral activities and, in some instances, their substrate/inhibitor properties towards both viral and cellular enzymes involved in the anabolism (or "activation") and catabolism of nucleoside analogues with chemotherapeutic activities have been evaluated (7).

Crystal structures have now been reported for the *S* form of DHPA and of its *RS* racemate (8), as well as that of the 2′,3′-*O*-isopropylidene derivative of the *S* form of 1-(2,3-di-

hydroxypropyl)uracil (DHPU) (9); a preliminary account of the solid state structure of acyclovir has also appeared (10). We present here full details of the solid state structure and conformation of acyclovir and several examples of its relevance to the role of such compounds in various enzyme systems and in chemotherapy.

Experimental

Acyclovir was crystallized from aqueous dimethylformamide to give thin plates of a hydrate. Precession photographs indicated space group $P2_1/n$. A crystal fragment measuring 0.550 × 0.125 × 0.025 mm was mounted on an Enraf–Nonius CAD4 diffractometer; it provided the following data:

$C_8H_{11}N_5O_3.2/3H_2O$ fw = 237.23

Monoclinic, a = 25.459(1), b = 11.282(1), c = 10.768(1) Å, β = 95.16(1)°, V = 3080.3 Å^3, ρ_c = 1.53 g cm^{-3}, Z = 12 (20°C; CuKα$_1$, λ = 1.54056 Å); $F(000)$ = 1496, μ(CuKα) = 10.1 cm^{-1}.

Cell dimensions were determined from angular settings of 22 reflections. Intensities were measured with Ni-filtered CuKα radiation, using ω/2θ scans with variable scan ranges and speeds. Of the 6343 unique reflections with 2θ ≤ 150°C, there were 3978 with $I \geq 1.5\sigma(I)$ which were considered observed. The intensities were corrected for Lorentz and polarization factors; absorption corrections were considered unnecessary in view of the low value of μ.

The statistics of normalized structure factors indicated a hypercentric distribution, particularly for the $h0l$ zone, and the E values ranged up to 5.60. Repeated attempts to determine the structure with MULTAN (11) and SAP (12) programs were unsuccessful. Removal of $h0l$ reflections also produced uninterpretable E maps. Success was finally achieved when 60 reflections with $E > 3.03$ were removed from the dataset. The MULTAN solution with the highest combined figure of merit gave rise to an E map on which three molecules of acyclovir (48 nonhydrogen atoms) could be located. In addition, the asymmetric unit was found to contain two molecules of water. The difficulties in the structure determination can be attributed to the parallel stacking of all guanine residues (see below). Atomic parameters were refined by block-diagonal least squares with anisotropic thermal parameters for the 50 nonhydrogen atoms and isotropic ones for 34 hydrogen atoms. Three hydrogen atoms were placed in calculated positions and their parameters were not refined. All scattering factors were taken from the "International tables for X-ray crystallography" (13). A weighting scheme was chosen which made the average values of $w(\Delta F)^2$ almost independent of $|F_o|$ and $\sin^2\theta$. Eight strong reflections suffered from extinction effects and were given zero weights. After the final least-squares cycle the average parameter shift equalled 0.03σ and the final value of R was 0.053 (R' = 0.064) for 3970 observed reflections. The coordinates and equivalent isotropic temperature parameters of nonhydrogen atoms are listed in Table 1. Their anisotropic temperature parameters as well as lists of hydrogen atom parameters and of observed and calculated structure factors are available.[2]

Results and discussion

Solid state conformation

The conformations of molecules A and B are fairly similar while that of molecule C is different. The two types of conformations can be seen in the stereoscopic views (Fig. 1) and the details are given in Table 2. In molecule C, the bonds in the side chain attached to N(9) are all in the *trans* conformation, giving rise to an almost planar, zig-zag, arrangement. The *trans* orientation of the C(4′)—O(1′) and C(5′)—O(5′) bonds, corresponding to the gauche$^-$ rotamer in nucleosides, is energetically the least stable one (14). In the other two molecules, these two bonds are in the preferred *gauche* conformation, but the increased stability is estimated to be only 0.65 kcal/mol (15). If the 2:1 equilibrium found in the crystal structure existed in solution as well, the energy difference between the two conformers would amount to about 0.4 kcal/mol. In *S*-DHPA the two C—OH bonds were found to be *trans* to one another, while in the crystal of the racemate (*RS*-DHPA) they were *gauche* oriented (8). In DHPG there are two C—O/C—OH interactions which may be viewed as corresponding to C(4′)—O(1′)/C(5′)—O(5′) and C(4′)—O(1′)/C(3′)—O(3′). Again, one of these interactions is *gauche* and the other *trans* (16). The conformation resembles a xylofuranosyl nucleoside with a *gauche*$^-$ side chain. These examples demonstrate the flexibility of such side chains which is a consequence of the previously mentioned small energy difference between the

[2]These tables may be obtained, at a nominal charge, from the depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1S 0S2.

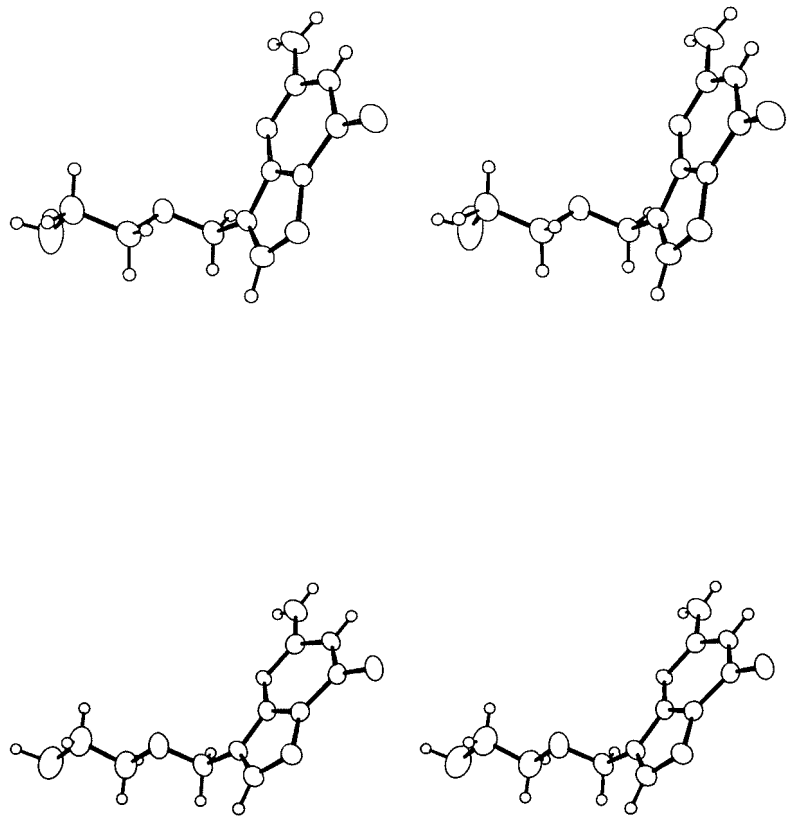

FIG. 1. (Top) Stereoscopic view of molecule B, showing the partially folded conformation of the side chain. Molecule A has essentially the same conformation. (Bottom) Stereoscopic view of molecule C, showing the extended conformation of the side chain.

TABLE 2. Torsion angles (in degrees)

Angle	Molecule A	Molecule B	Molecule C
C(8)—N(9)—C(1′)—O(1′) (χ_{CN})	97.3	104.3	91.4
C(4)—N(9)—C(1′)—O(1′)	−76.5	−74.4	−90.5
N(9)—C(1′)—O(1′)—C(4′)	−76.9	−66.3	−173.3
C(1′)—O(1′)—C(4′)—C(5′)	173.2	−176.2	−171.9
O(1′)—C(4′)—C(5′)—O(5′)	60.6	73.5	−174.4

various possible conformers (see also below). In the crystal structure, the conformation is likely to be dominated by intermolecular hydrogen bonds (see below), while in solution these molecules will easily adopt a conformation in which they can serve as substrates for the appropriate kinase.

In all three molecules of acyclovir the glycosidic torsion angle χ_{CN}[C(8)—N(9)—C(1′)—O(1′)] is in the range 91.4−104.3°. It should be noted that these are absolute values, because in centrosymmetric space groups the signs of torsion angles may be reversed. In DHPG χ_{CN} was found to have a value of 109.3°. In DHPA χ_{CN} cannot be determined owing to the absence of O(1′). We note, however, that the torsion angles C(8)—N(9)—C(1′)—C(2′) are −69.1 and 87.4° in *S*-DHPA and in *RS*-DHPA, respectively. In the DHPU derivative the C(6)—N(1)—C(1′)—C(2′) torsion angle is 85° (9). Thus, all acyclonucleosides in which C(1′) is a secondary carbon atom adopt a conformation about N—C(1′) in which the C(1′)—X bond (X = O or C) is approximately perpendicular (90 ± 20°) to the aglycon. In this conformation the bonds adjoining N—C(1′) are maximally staggered, giving rise to a minimum of steric interactions.

Bond lengths and bond angles

With two exceptions, all bond lengths (Table 3) in the guanine residues are in very good agreement with recently published "standard" values derived from crystal structure analyses (17). The exceptions are in molecule C, where N(3)—C(4) is 0.016 Å shorter, and C(4)—C(5) is 0.015 Å longer, than normal. We do not observe any unique features in the environment of this molecule which would explain what seems to be abnormal electron distribution in part of its ring system. We also note a significant difference between the lengths of the glycosidic bond N(9)—C(1′) in molecules A and B and that in molecule C. This bond can be expected to be somewhat shorter in acyclonucleosides because of decreased substitution at C(1′). Furthermore, its length is influenced by backbonding from the nitrogen p_z-orbital to the antibonding (σ*) orbital of C(1′)—O(1′), an interaction which is at an optimum for χ_{CN} = 90°. The bond length can also be correlated with the torsion angle N(9)—C(1′)—O(1′)—C(4′) as a result of backbonding from the oxygen lone pair to the antibonding orbital of N(9)—C(1′). This torsion angle, approximately *trans* in normal nucleosides, is *gauche* in molecules A and B and *trans*

TABLE 3. Bond lengths (in Ångströms)[a]

Bond	Molecule A	Molecule B	Molecule C
N(1)—C(2)	1.368	1.374	1.372

[a]Esd's are 0.2° unless otherwise indicated.

in molecule C. We can infer that this accounts for the observed differences in the lengths of N(9)—C(1′). In DHPG, where the corresponding torsion angle is *trans* (16), the glycosidic bond has the same length, 1.441(5) Å, as the one found in molecule C.

Most bond angles (Table 4) in the guanine moiety agree very well with normal values (17). Again, the exception is at C(4) in molecule C where the C(5)—C(4)—N(9) angle is more acute than in the other molecules. Attempts have been made in the past to correlate the relative values of C(4)—N(9)—C(1′) and C(8)—N(9)—C(1′) in purine nucleosides with the conformation about the glycosyl bond (18, 19). The limited data available to date (six independent molecules) suggest that in acyclonucleosides there is a preference for C(8)—N(9)—C(1′) being slightly larger (0–3°) than C(4)—N(9)—C(1′). In molecules A and B the bond angles at C(1′) and O(1′) are considerably larger than in molecule C. This can be attributed to a 1,3-interaction between a C(4′)—H bond and the C(1′)—N(9) bond. The opening of these angles is necessary in order to reduce the nonbonded N(9)···H distance.

Planarity of the guanine residue

As shown in Table 5, the planarity of the guanine residue varies from molecule to molecule. The deviations from planarity are statistically significant, even in molecule B. The χ^2 values are 171.3, 41.1, and 418.6 for A, B, and C, respectively. In most of the cases in which the displaced atom or its substituent participates in a hydrogen bond, the donor, or acceptor, atom in the other molecule is on the same side of the mean plane. This supports our recent conclusion (20) that deviations from planarity in nucleic acid bases, often observed in crystal structure determinations, can be attributed to intermolecular hydrogen bonds.

TABLE 5. Deviations (in Ångströms) from guanine least-squares planes[a]

Atom	Molecule A	Molecule B	Molecule C

[b]Atoms not included in the calculations of the planes.

Hydrogen bonding and packing

Each molecule of acyclovir has four protons capable of participating in hydrogen bonds. With the two molecules of water, there are thus 16 possible hydrogen bonds in the crystal structure. Table 6 lists 15 such bonds, all of them intermolecular, and only H(22A) is missing from this list. Although the latter has O(W1) as its nearest intermolecular neighbour, we do not regard this contact as a proper hydrogen bond because the distance between them is rather long (2.61 Å) and because the H—O—H angles at O(W1) indicate a planar coordination, with only one proton, H(5′B), being accepted. As commonly observed in X-ray analyses, the O—H and N—H bonds appear shorter than their true values of 0.97 and 1.04 Å, respectively. By extending the covalent bond lengths to their nominal values, one obtains corrected H···*A* distances which reflect more accurately the strengths of these hydrogen bonds. It can be seen that most hydrogen bonds are fairly linear and of medium strength. Two of them, however, deviate considerably from linearity and are therefore much weaker. On the basis of the hydrogen bonds involving the two water molecules, one can postulate that the O(6) and O(5′) atoms play an important role

TABLE 6. Distances and angles for hydrogen bonds

			Distances (Å)			Angles (deg)
D	*A*	*A* at	*D*···*A*	H···*A*	H···A_{corr}	*D*—H···*A*
N(1A)—H···N(7A)	$3/2-x, \frac{1}{2}+y, 3/2-z$	2.809	1.96	1.78	173
N(2A)—H(21A)···O(6A)	$3/2-x, \frac{1}{2}+y, 3/2-z$	2.874	2.01	1.88	160
N(1B)—H···N(7C)	$\frac{1}{2}-x, \frac{1}{2}+y, 3/2-z$	2.846	2.05	1.83	166
N(2B)—H(21B)···O(6C)	$\frac{1}{2}-x, \frac{1}{2}+y, 3/2-z$	2.910	2.13	1.91	162

O(5′A)—H···N(3B)	$\bar{x}, 2-y, 1-z$	2.852	2.07	1.96	154
N(1C)—H···N(7B)	$\frac{1}{2}-x, \frac{1}{2}+y, 3/2-z$	2.864	2.02	1.83	177
N(2C)—H(21C)···O(6B)	$\frac{1}{2}-x, \frac{1}{2}+y, 3/2-z$	2.927	2.10	1.93	161
N(2C)—H(22C)···O(W2)	$\bar{x}, \bar{y}, 1-z$	2.995	2.41	2.28	129
O(W2)—H(W21)···O(6A)	$-\frac{1}{2}+x, 3/2-y, \frac{1}{2}+z$	2.949	1.98	1.99	168
O(W2)—H(W22)···O(5′B)	x, y, z	2.844	2.03	1.88	171
O(5′B)—H···O(W1)	$-\frac{1}{2}+x, 3/2-y, \frac{1}{2}+z$	2.660	1.72	1.69	174
O(W1)—H(W11)···O(6C)	x, y, z	2.742	1.91	1.84	155
O(W1)—H(W12)···O(5′C)	$\frac{1}{2}+x, 3/2-y, \frac{1}{2}+z$	2.892	2.10	1.96	162
O(5′C)—H···O(6B)	$-\frac{1}{2}+x, 3/2-y, -\frac{1}{2}+z$	2.827	1.79	1.87	170

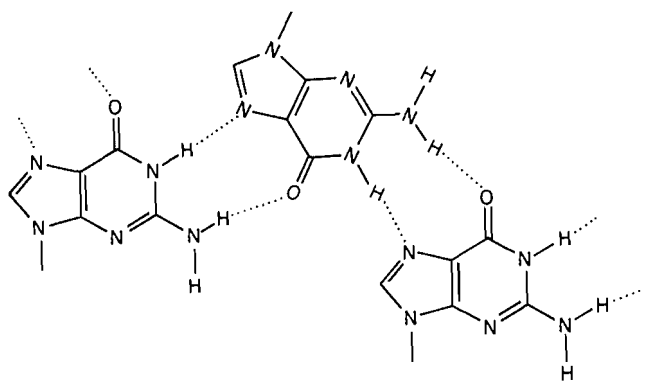

FIG. 2. Hydrogen bonding network in acyclovir.

in acyclovir's interaction with its receptor.

The hydrogen bonding scheme is remarkable, as it joins all guanine bases into infinite sheets. Each base is connected to the next one by two hydrogen bonds: N(1)—H···N(7) and N(2)—H···O(6) (Fig. 2). There are two such sheets in the crystal structure, one formed by symmetry-related A molecules and the other by alternating B and C molecules. The geometry of these hydrogen bonds is very similar: all H···N distances are 1.80 ± 0.03 Å and all H···O distances are 1.90 ± 0.03 Å. The packing diagram (Fig. 3) shows that the ···A···A··· and the ···B···C··· sheets are almost parallel to each other. The dihedral angles between the three guanines in the asymmetric unit are 2.8° for A/B, 3.9° for A/C, and 4.6° for B/C.

Stacking interactions between bases contribute substantially to the stability of nucleic acid structures. The crystal structure of acyclovir is also stabilized by stacking which is illustrated in Fig. 4. A remarkable feature of this arrangement are the continuous dipole–dipole interactions of the carbonyl groups, the electron-rich oxygen atoms overlapping the electron-deficient carbon atoms. This arrangement is maintained despite the fact that the orientation of the A molecules is different from that of the B and C molecules. There is considerable overlapping of bases, particularly between the A/C and B/A pairs. The distances between the successive bases are 3.37 Å for A/C, 3.34 Å for C/B, and 3.37 Å for B/A. These distances are essentially the same as those found between adjacent base pairs in DNA.

Solution conformation and biological activity

In view of the anticipated extensive flexibility of the acyclic chains in acyclonucleosides, it is not unexpected that the standard ^1H and ^{13}C nmr data hitherto reported for such compounds (4, 21) are inadequate for determination of preferred solution conformations. This is further underlined by the results of quantum mechanical calculations of preferred conformation(s) in *S*-DHPA (22), which revealed only the existence of several close energy minima, with no single conformation explicitly favoured. Preliminary attempts to determine some features of the solution conformation of acyclovir by ^1H nmr spectroscopy revealed only free rotation about the terminal C(5′)—O(5′) bond with comparable populations of the three classical rotamers, as compared to the observed *gauche*$^-$ rotamer for molecule C, and *gauche*$^+$ for molecules A and B, in the solid state. Clearly, the use of long-range couplings and, possibly, of nOe methods will be required to obtain more explicit data. The conformation about C—O bonds, which determines the conformation of the entire chain, might be resolved by measurements of carbon–proton coupling constants.

In contrast to the conformational flexibility of the isolated acyclic nucleosides and nucleotides in solution, the biological activities of some of them point to the adoption of defined conformations on interaction with specific enzymes, e.g. the preferential phosphorylation of acyclovir by herpes virus thymidine kinase (see above), and the weak substrate/inhibitor properties of acycloGMP in the 5′-nucleotidase system (10). In tubulin polymerization, which is accompanied by hydrolysis of exchangeably bound GTP to GDP, the former is replaced by acycloGTP with only minimal loss of activity (23). A number of pyrimidine acyclonucleosides are specific reversible inhibitors of mammalian uridine phosphorylase, the most potent being 1-[(2-hydroxyethoxy)methyl]thymine, with a K_i of 3 μM (24, 25). Several bacterial ribonucleases cleave the 2′,3′-cyclic phosphates of DHPU, and of its corresponding thymine analogue, when these are in the *S*, but not *R*, configuration (26), consistent with the fact that only the *S* derivatives imitate the conformation of the natural β-D-ribofuranosyl nucleosides. Investigations of the foregoing enzyme/substrate/inhibitor reactions, and associated conformational changes, should be facilitated with the aid of solid state and solution data for these acyclic nucleoside analogues.

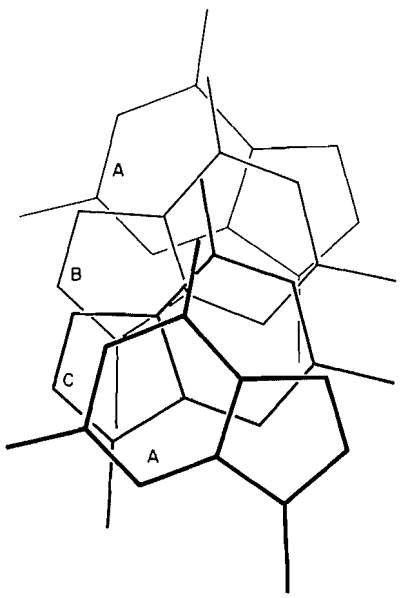

FIG. 4. Guanine stacking in acyclovir; note the dipole–dipole interactions of the carbonyl groups.

Acknowledgments

Apart from MULTAN 78 (11), all crystallographic computations were carried out with programs written by Ahmed *et al.* (12). We are grateful to Dr. G. B. Elion for the gift of a sample of acyclovir and to Dr. R. L. Tolman for providing us with the results of the X-ray analysis of DHPG. Part of this investigation was supported by the Polish National Cancer Research Program (PR-6/1701).

Proton transfer reactions from 4-X-phenyl-4-nitrophenylcyanomethanes to tetramethylguanidine in acetonitrile solvent

MAHMOOD HOJATTI AND KENNETH T. LEFFEK
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4H6

Received December 14, 1983

MAHMOOD HOJATTI and KENNETH T. LEFFEK. Can. J. Chem. **62**, 2653 (1984).

The reactions of 4-X-phenyl-4-nitrophenylcyanomethanes with tetramethylguanidine in acetonitrile solvent give carbanionic products absorbing in the range λ_{max} 580–650 nm. The equilibrium constants are all large, in excess of 6000 $dm^3\ mol^{-1}$. For a series of deprotonation reactions with X = NO_2, Cl, Br, H, and OCH_3, the Hammett ρ value is 2.03 ± 0.03. For the same compounds, the primary deuterium isotope effect, k_H/k_D, varies from 8.9 for X = NO_2 to 14.0 for X = OCH_3 at 25°C.

MAHMOOD HOJATTI et KENNETH T. LEFFEK. Can. J. Chem. **62**, 2653 (1984).

Les réactions des X-4 phényl nitro-4 phénylcyanométhanes avec la tétraméthylguanidine dans l'acétonitrile comme solvant fournissent des produits carbanioniques qui absorbent à des longueurs d'onde allant de 580 à 650 nm. Les valeurs des constantes d'équilibre, qui sont toutes très grandes, dépassent toutes 6000 $dm^3\ mol^{-1}$. Pour une série de réactions de déprotonation, alors que X = NO_2, Cl, Br, H et OCH_3, la valeur ρ de Hammett est égale à 2,03 ± 0,03. Pour les mêmes composés, l'effet isotopique primaire du deutérium, k_H/k_D, varie de 8,9 pour X = NO_2 à 14,0 pour X = OCH_3 à 25°C.

Introduction

The reaction of 4-nitrophenylphenylcyanomethane with tetramethylguanidine in acetonitrile solvent was shown to be a proton transfer with a large equilibrium constant (1). The reaction, shown in eq. [1],

[1] $NO_2C_6H_4\underset{\displaystyle C_6H_4X}{\underset{|}{C}}HCN + HN{=}C(N(CH_3)_2)_2 \underset{k_f}{\overset{k_b}{\rightleftharpoons}} NO_2C_6H_4\overset{-}{\underset{\displaystyle C_6H_4X}{\underset{|}{C}}}CN\ldots H_2\overset{+}{N}{=}C(N(CH_3)_2)_2$

where X = H, was found to have characteristics quite similar to the proton transfer reaction to the same base from 4-nitrophenylnitromethane studied by Caldin and Mateo (2). The cyanomethane reaction gave a primary deuterium isotope, k_H/k_D = 10.7 at 25°C, slightly less than the 11.8 found for the nitromethane. The observed solvent effect on the second-order rate constant between benzonitrile and acetonitrile led to the postulate (1) that the transition state must come early along the reaction coordinate, before much charge development has taken place.

In this paper, further insight into the nature of the transition state is sought by the study of the correlation of the second-order rate constants with the σ value of the substituent, for a series of substrates with different *para*-substituted phenyl groups.

Results and discussion

The reaction of each 4-substituted phenyl-4-nitrophenylcyanomethane with tetramethylguanidine (TMG) in acetonitrile solvent gave a blue–violet product λ_{max} = 582 ± 2 nm, except for bis(4-nitrophenyl)cyanomethane which gave an absorption peak at λ_{max} = 646 nm. An attempt to determine the equilibrium constants by the Hildebrand–Benesi method (3) showed that these constants were all large, greater than 6000 $dm^3\ mol^{-1}$, since the absorption remained virtually unchanged when the base concentration was varied. However, the reaction of 4-nitrophenylphenylcyanomethane with TMG in benzonitrile solvent was previously shown (1) to react as in reaction [1] to give an ion-pair product.

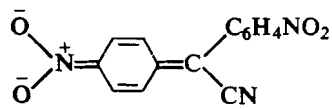
Pseudo first-order rate constants were obtained for each reaction by monitoring the growth of the product peak with time using a stopped-flow spectrophotometer. Each reaction was followed at the wavelength corresponding to the absorption maximum. Initial carbon acid concentrations of $1 \times 10^{-5}\ M$ were used, except for the bis(4-nitrophenyl)cyanomethane reaction for which this had to be reduced to $0.25 \times 10^{-5}\ M$ because of the very rapid rate of the reaction. A range of base concentrations was used with the base always in large excess over the acid to maintain pseudo first-order conditions.

The pseudo first-order rate constants, k_{obs}, were fitted to eq. [2] by a least-squares calculation to yield k_f and k_b, the rate constants for the forward and backward reactions of eq. [1],

[2] $k_{obs} = k_f[\text{base}] + k_b$

which are collected in Table 1. The rate constants at 25°C for the unsubstituted carbon acid (1) are included for comparison purposes.

The second-order rate constants give a very good Hammett plot when the $\log_{10} k_f$ values are plotted against σ^0, the scale appropriate for reactions in which through conjugation is either absent or does not change on going from the initial state to the transition state. The σ^0 values determined for aqueous solutions (4) give a correlation coefficient of 0.9997, whereas σ^0(non-aq) values give a slightly poorer correlation with a coefficient of 0.994. The correlation is poor when σ^- is used for the *p*-nitro substituted compound. A good correlation with σ^0 rather than σ^- was also observed by Boyle (5) for *p*-substituted phenylnitromethane substrates in aqueous solutions. Thus, resonance structures such as **I** may not be important in the transition state of the deprotonation.



I

TABLE 1. Rate constants for the reaction of 4-X-phenyl-4-nitrophenylcyanomethanes with tetramethylguanidine in acetonitrile solvent

X	T (°C)	10^4 [Base] (M)	k_{obs} (s^{-1})	10^{-3} k_f (dm^3 mol^{-1} s^{-1})	k_b (s^{-1})
NO_2	20.0	0.5–2.5	77.4–129	258 ± 25	61 ± 4
	25.0	0.5–2.5	89.8–166	389 ± 26	66 ± 4
	30.0	0.5–2.5	95.2–203	539 ± 45	69 ± 7
	35.0	0.5–2.5	114–275	824 ± 54	64 ± 9
	40.0	0.5–2.5	137–339	1020 ± 60	76 ± 10
Cl	20.0	1.0–9.0	3.67–15.6	21.2 ± 0.6	2.1 ± 0.3

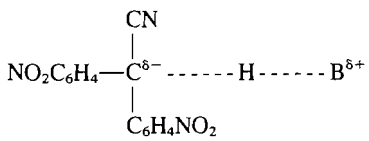
	35.0	10.0–50.0	4.8–27.8	5.97 ± 0.3	−1.5 ± 0.8
	40.0	10.0–50.0	5.1–30.1	6.39 ± 0.2	−1.7 ± 0.6

* Reference 1.

This could be either because the transition state comes very early along the reaction path or that the developing negative charge remains localized on the carbon atom. Since the ρ value for σ^0(aq) is 2.03 ± 0.03 at 25°C, quite large compared to those observed by Boyle in the range 1.0 to 1.4 in aqueous solution, it appears that there is some amount of negative charge developed in the transition state. Thus, the transition state must have the structure **II** in which the developing charge is mostly localized on the carbon atom.



II

The better correlation coefficient with σ^0(aq) than that obtained for σ^0(non-aq) is unexpected. The two scales differ for the substituents used in this study in that σ^0(aq) for NO_2 is 0.82 compared to 0.73 for σ^0(non-aq) and also σ^0(aq) for OCH_3 is −0.12 compared to −0.16 for σ^0(non-aq). The better correlation with σ^0(aq) may be merely an artifact arising from the fact that σ_{NO_2} for this reaction is slightly higher than the standard value of 0.78 but well below the σ^- value for NO_2 of 1.25. If σ_{NO_2} = 0.82 is the best value for this reaction, then the substrate molecule is stabilized by some through conjugation, but this amount of through conjugation increases only very slightly during the activation process.

A correlation $\log_{10} k_f$ may also be made using the dual substituent parameter treatment of Taft (6). This treatment uses eq. [3] in which both σ and ρ values are separated into polar (I)

$$[3] \quad \log_{10} k_f = \log k_{f0} + \sigma_I\rho_I + \sigma_R\rho_R$$

and π delocalization (R) effects. The best fit was obtained when the σ_I and σ_R^0 scales were used with log k_{f0} equal to 3.90, the value corresponding to the observed k_f for the unsubstituted compound from Table 1. This gave ρ_I = 2.1 ± 0.1 and ρ_R = 1.9 ± 0.1, indicating that the substituent effect on the rate constant arises roughly equally from inductive and resonance interactions.

TABLE 2. Activation parameters for the reaction of 4-X-phenyl-4-nitrophenylcyanomethanes with tetramethylguanidine in acetonitrile solvent

X	$\Delta H^{\ddagger}$ (kcal mol^{-1})	$\Delta S^{\ddagger}$ (cal mol^{-1} deg^{-1})
NO_2	12.2 ± 0.6	7.8 ± 2.0
Cl	6.0 ± 0.4	−18.4 ± 1.2
Br	6.9 ± 0.4	−15.1 ± 1.3
H	3.7 ± 0.2	−28.3 ± 0.7
OCH_3	4.0 ± 0.4	−28.4 ± 1.2

The activation parameters, derived from the second-order rate constants of Table 1, are shown in Table 2. All substrates, except the bis-4-nitrophenyl compound, show low enthalpies of activation and negative entropies of activation, typical of proton transfer reactions. The *p*-nitro substituent substantially increases $\Delta H^{\ddagger}$ and brings about a positive $\Delta S^{\ddagger}$. The less powerful electron-withdrawing substitutents Cl and Br exert the same type of influence to a lesser extent, but the electron-releasing substituent OCH_3 has an effect which is not significantly different from that of the unsubstituted substrate.

The most likely explanation of these changes is that the major contribution to $\Delta H^{\ddagger}$ is the energy required to break the initial state solvation shell. Electron withdrawal towards the nitro groups in the bis-4-nitrophenyl compound gives a strongly bound solvation shell in the initial state relative to that of the other substrates. More energy is required to break it and allow

TABLE 3. Primary deuterium isotope effects for the reaction of 4-X-phenyl-4-nitrophenylcyanomethanes with tetramethylguanidine in acetonitrile solvent at 25°C

X	$10^{-3}\ k_{fD}$ ($dm^3\ mol^{-1}\ s^{-1}$)	k_{fH}/k_{fD}
NO_2	43.7 ± 1.6	8.9 ± 0.7
Cl	2.06 ± 0.2	12.3 ± 0.1
Br	2.10 ± 0.04	11.9 ± 0.6
H	0.73 ± 0.03	10.7 ± 0.5
OCH_3	0.318 ± 0.026	14.0 ± 1.2

proton transfer. The positive ΔS^* arises from a decrease in the strength of solvation between the initial and transition states. This phenomenon is much reduced for the halogen-substituted compounds, resulting in a smaller ΔH^* and a transition state more strongly solvated than the initial state, yielding a negative ΔS^*.

The primary deuterium isotope effects on the second-order rate constants for the reactions are given in Table 3. In order to verify that the k_{fD} values were not in error due to exchange between the deuterated acid and the proton of TMG, a series of experiments was carried out with the *p*-chloro-substituted acid and TMG-*d*. The deuterated TMG was prepared by repeated exchange with D_2O and redried in the usual manner. The second-order rate constants obtained for TMG and TMG-*d* were the same within experimental error.

The value of k_H/k_D appears to increase with the electron-releasing power of the substituent, although the change is not smooth in that the unsubstituted compound has a low value (1) compared to those observed in the present work. However, the standard errors in the k_f values are in some cases quite large, so only the general trend in the isotope effect may be interpreted. It was concluded previously (1) that the unsubstituted compound probably reacted with a significant contribution from proton tunnelling. However, it is not possible to deduce from the present results whether the variation in k_H/k_D arises from changes in the tunnelling contribution or changes arising from vibrational frequency sources. Nevertheless, the variation in k_H/k_D can be qualitatively correlated with the ΔpK for the reactions. The isotope effect is at a maximum when $\Delta pK \sim 0$ and decreases with both positive and negative ΔpK (7). The pK_a of the OCH_3-substituted substrate will be larger than that of the NO_2-substituted substrate. Thus, for a strong base, ΔpK will be smaller for the OCH_3-substituted compound than for the NO_2-substituted compound. Thus, it is expected that k_H/k_D will be larger for the OCH_3 than for the NO_2 compound. Therefore, the change of isotope effect with substrate could arise from vibrational frequency sources with a constant contribution from tunnelling combined with it, although there is no theoretical reason why the tunnelling contribution should not also change with substrate structure.

The suggestion was considered (8) but rejected, that the residual water remaining after very careful drying of TMG, about 1% (9), might give rise to ^-OH base in the form of an ion-pair, which could be the proton-abstracting base rather than TMG. This conclusion was supported when it was shown in a previous publication (1) that replacing this ^-OH by ^-OD gave rise to no isotope effect. Since an isotope effect of 50 to 80% would be expected for these two bases it was concluded that $TMG^+{}^-OH$ contributed to the proton abstraction in a negligible amount.

Tetra-*n*-butylammonium hydroxide was prepared and reacted with 4-chlorophenyl-4-nitrophenylcyanomethane at 25°C under pseudo first-order conditions. This gave $k_f = 3.6 \pm 0.2 \times 10^5\ dm^3\ mol^{-1}\ s^{-1}$, about 15 times greater than that with TMG. Caldin and Mateo (9) determined that equilibrium constant for the reaction of water with TMG to yield the ^-OH ion-pair to be 1.4 in toluene solvent.

If the reactivity of $(C_4H_9)_4N^+{}^-OH$ is assumed to be the same as $TMG^+{}^-OH$, the residual water does not interfere significantly with the TMG reaction, even if the equilibrium constant for $TMG^+{}^-OH$ is as high as 1000 in acetonitrile.

Experimental

Materials

4-Chlorophenyl-4-nitrophenylcyanomethane, 4-bromophenyl-4-nitrophenylcyanomethane, and 4-methoxylphenyl-4-nitrophenylcyanomethane were prepared according to the procedure of Davis and Pizzini (10). The melting points of the compounds were 110–111°C (lit. (10) 110–112°C), 96–97°C, and 69–70.5°C (lit. (10) 69–71°C), respectively.

Bis(4-nitrophenyl)cyanomethane was prepared by nitrating 4-nitrophenylphenylcyanomethane (11) with fuming nitric acid as described by Minch *et al.* (12). The resulting gum was triturated under dry ether at dry ice temperature to yield a yellow powder. After crystallization from ethanol, the slightly yellow crystals melted at 93–94.5°C (lit. (12) 40–45°C). Nmr $CDCl_3$ δ: 5.4 (1H, s), 7.5 (4H, d, J = 9.0 Hz), 8.2 (4H, d, J = 9.0 Hz).

The deuterated analogues of the substrates were prepared as previously described (1). The deuterated materials showed no nmr peak for the aliphatic proton and were, therefore, at least 98% deuterated.

Acetonitrile was purified by the method of O'Donnell *et al.* (13), fractionally distilled over P_2O_5, and collected at 81.5–82.0°C.

Tetramethylguanidine (TMG) was dried over KOH, fractionally distilled over BaO under nitrogen, and collected at 161°C.

Deuterated TMG was made according to the method described by Caldin *et al.* (2). The nmr spectrum showed an isotopic purity of about 98%.

Tetra-*n*-butylammonium hydroxide was prepared from the iodide with Dowex-1-X8 Resin using the method of Harlow (14).

Kinetic measurements

The reaction rates were measured with a Durrum–Gibson stopped-flow spectrophotometer. One hundred optical density measurements were taken for each run using a Hewlett Packard multiprogrammer. Six consecutive trials were made for each set of reactant concentrations and the average value for each of the hundred points was calculated. The first-order rate constant was then calculated using a least-squares fit by a Pet microcomputer from the six-trial-averaged points using the Guggenheim method (15).

Synthesis of aminoalcohol compounds of platinum and crystal structure of *trans*-[Pt(2-amino-2-methyl-1-propanol)$_2$Cl$_2$]

F. D. ROCHON, P. C. KONG, AND R. MELANSON

Département de chimie, Université du Québec à Montréal, C.P. 8888, Succ. A, Montréal, (Qué.), Canada H3C 3P8

Received October 6, 1983[1]

F. D. ROCHON, P. C. KONG, and R. MELANSON. Can. J. Chem. **62**, 2657 (1984).

Three types of complexes, *trans*-[Pt(LH)$_2$Cl$_2$], [Pt(L)$_2$], and [Pt(LH)$_2$(SR)$_2$] where LH = NH_2—$C(CH_3)_2(CH_2OH)$ and NH_2—$C(CH_2OH)_3$ and L are the deprotonated ligands, have been synthesized.

The crystal structure of *trans*-[Pt(NH_2—$C(CH_3)_2CH_2OH)_2Cl_2$] has been determined by X-ray diffraction methods. The crystals are monoclinic, space group $P2_1/c$, with a = 6,282(3), b = 20,901(13), c = 10,769(10) Å, β = 92,64(6)°, and Z = 4. The structure was refined by full-matrix least-squares analysis to a conventional R factor of 0.049 and R_w = 0.042. The coordination around the platinum atom is square planar. The Pt—Cl distances are 2.306(2) and 2.309(3) Å and the Pt—N bonds are 2.060(8) and 2.071(7) Å. The hydroxyl oxygen atoms are disordered; the disorder is different for each organic ligand. The structure is stabilized by an extensive hydrogen bonding system.

F. D. ROCHON, P. C. KONG et R. MELANSON. Can. J. Chem. **62**, 2657 (1984).

Trois types de composés *trans*-[Pt(LH)$_2$Cl$_2$], [Pt(L$_2$)] et [Pt(LH)$_2$(SR)$_2$] où LH = NH_2—$C(CH_3)_2CH_2OH$ et NH_2—$C(CH_2OH)_3$ et L sont les mêmes ligands déprotonés, ont été synthétisés.

La structure cristalline de *trans*-[Pt(NH_2—$C(CH_3)_2CH_2OH)_2Cl_2$] a été déterminée par diffraction des rayons-X. Les cristaux sont monocliniques, groupe d'espace $P2_1/c$, a = 6,282(3), b = 20,901(13), c = 10,769(10) Å, β = 92,64(6)° et Z = 4. Les coordonnées et les facteurs thermiques anisotropes ont été affinés par moindres-carrés (matrice entière) jusqu'à R = 0,049 et R_w = 0,042. La coordination autour de l'atome de platine est plane. Les distances Pt—Cl sont 2,306(2) et 2,309(3) Å et les liens Pt—N sont 2,060(8) et 2,071(7) Å. Les atomes d'oxygène des ligands sont désordonnés, le désordre étant différent sur chacun des deux ligands organiques. La structure est stabilisée par de nombreux ponts hydrogènes.

Introduction

Stetsenko *et al.* (1, 2) prepared *trans*-[Pt(LH)$_2$Cl$_2$] (LH = NH_2—$C(CH_2OH)_3$) in a 30% yield from the hot aqueous reaction of Na_2PtCl_4 + 2LH. By heating this product with LH in a Pt:LH ratio of 1:2 in water, the authors obtained [Pt(L)$_2$].2.5-H_2O where L = NH_2—$C(CH_2OH)_2CH_2O^-$. On repeating these experiments, we have found that the yield in the first reaction depends critically on the amount of LH and the heating time, while in the second, the amount of LH is not important and an excess of LH can be used. Furthermore, we found a different content of hydration water in [Pt(L)$_2$].

We have modified these methods to prepare *trans*-[Pt(LH)$_2$-Cl_2] and [Pt(L)$_2$]. Compounds of NH_2—$C(CH_3)_2CH_2OH$ (identified below as L'H) were also synthesized. Organic sulphur compounds R—SH (thiophenol and thiouracil) can react with [Pt(L)$_2$] or [Pt(L')$_2$] to form [Pt(LH)$_2$(SR)$_2$] (or L'H).

The three types of complexes [Pt(LH)$_2$Cl$_2$], [Pt(L)$_2$], and [Pt(LH)$_2$(SR)$_2$] (or L'H) are believed to be *trans*-isomers. In order to confirm these hypotheses, we wanted to determine the crystal structures of one compound of each type. Unfortunately, up to now, only [Pt(L'H)$_2$Cl$_2$] gave suitable crystals for X-ray diffraction. Its crystal structure is reported below.

Experimental

[Pt(L$_2$)] and [Pt(L')$_2$]

K_2PtCl_4 and LH or L'H were dissolved in water in a ratio of LH:Pt > 5. The mixture was heated to 50−70°C for about 1 h and then cooled to room temperature. The light yellow precipitate was filtered, washed with water, and dried with a vacuum pump overnight. The compounds crystallized with one (L) and two (L') molecules of water (Table 1). Yield: 80%.

trans-*[Pt(LH)$_2$Cl$_2$] and* trans-*[Pt(L'H)$_2$Cl$_2$]*

The compounds [Pt(L$_2$)] or [Pt(L')$_2$] were slightly heated in 1 *M* hydrochloric acid until completely dissolved. Upon cooling, yellow crystals slowly formed and they were washed with water and dried under vacuum overnight. Yield: 90%.

[Pt(LH)$_2$(SR)$_2$] and [Pt(L'H)$_2$(SR)$_2$]

[Pt(L)$_2$] or [Pt(L')$_2$] and thiophenol (or thiouracil) were suspended in water in a ratio of RSH:Pt = 2. The mixture was stirred overnight. The precipitate was then filtered, washed with water, and dried under vacuum. The yield was quantitative.

The crystals of *trans*-[Pt(L'H)$_2$Cl$_2$] used for X-ray diffraction were obtained by slow crystallization from a solution of [Pt(L')$_2$] in 1 *M* HCl.

A set of precession photographs showed that the crystals belong to the $P2_1/c$ space group. The cell parameters were calculated by least-squares refinement from the setting angles of 15 centered reflections on a Syntex P$\bar{1}$ diffractometer using graphite-monochromatized MoKα radiation.

Crystal data

$C_8H_{22}N_2O_2Cl_2Pt$ mw = 444.27

Monoclinic, $P2_1/c$, a = 6.282(3), b = 20.901(13), c = 10.769(10) Å, β = 92.64(6)°, V = 1412.5(2) Å^3, Z = 4, D_x × 2.089, D_m = 2.10(2) Mg m^{-3}, λ(MoKα) = 0.71069 Å, μ(MoKα) = 10.40 mm^{-1}, and T = 295 K.

A total of 4140 independent reflections were measured with 2θ < 60° by the θ−2θ scan technique using MoKα radiation. The scan rate was 1° (2θ) min^{-1} for most reflections, but rates as high as 24° min^{-1} were selected for strong reflections by the autocollection program. A 2θ scan range of 1° below $K\alpha_1$ and 1° above $K\alpha_2$ was chosen. The background time to scan time ratio was 0.50. Reflections with I_{net} < 2.5σ(I) were considered as unobserved, where σ(I) was calculated as already described (3). An absorption correction based on the equations of the crystal faces was applied to all reflections. The transmission factors varied from 0.197 to 0.263. The data were then corrected for Lorentz-polarization effects. This set of 2372 observed reflections was used for the structure determination.

The atomic scattering factors of Cromer and Waber (4) were used for Pt, Cl, O, N, and C atoms and those of Stewart, Davidson, and Simpson (5) were used for H. The anomalous-dispersion terms (6) of Pt and Cl were included in the calculations.

The position of the Pt atom was found from the three-dimensional Patterson map. The positions of all other non-hydrogen atoms were

obtained by a series of full-matrix least-squares refinements followed by electron density difference syntheses. The two oxygen atoms were found to be disordered. Each oxygen atom was located at two different positions. The occupancy factors of the four different positions were refined, keeping the isotropic thermal parameters at 3.0 Å^2. The occupancy factors were then fixed at 0.415, 0.585, 0.386, and 0.614 for O(1), O(1′), O(2), and O(2′), respectively, and the thermal parameters refined. An isotropic secondary-extinction correction (7) was included in the calculations. Individual weights $w = 1/\sigma^2(F)$ were finally applied. The H atoms on the —NH_2 groups were fixed at their calculated positions (N—H = 0.85 Å) and assigned isotropic temperature factors β = 6.0 Å^2. The refinement of the scale factor, the coordinates and anisotropic temperature factors of all non-hydrogen atoms converged to $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.049$ and a weighted $R_w = \{\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2\}^{1/2} = 0.042$.

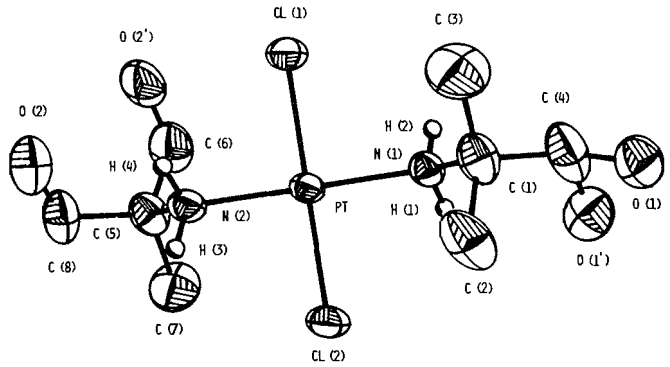

FIG. 1. Labelled diagram of the molecule *trans*-$[Pt(NH_2—C(CH_3)_2CH_2OH)_2Cl_2]$.

The calculations were carried out with a Cyber 171 computer using previously described programs (3). Tables of observed and calculated structure factors and anisotropic thermal parameters are available from the Depository of Unpublished Data.[2]

Results and discussion

The $[Pt(L \text{ or } L')_2]$ compounds have been prepared by heating K_2PtCl_4 with an excess of LH or L′H in water. The light yellow compounds were identified as $[Pt(L)_2].H_2O$ and $[Pt(L')_2].2H_2O$ after drying with a vacuum pump overnight. The syntheses were repeated several times and the elemental analyses were always identical. Stetsenko *et al.* (1, 2) reported $[Pt(L)_2].2.5H_2O$ which was prepared by a different method. They obtained a higher hydration content because they did not dry their compound. They washed it with ethanol and ether and determined its hydration content by thermal analysis.

When $[Pt(L \text{ or } L')_2]$ was dissolved in warm hydrochloric acid solution, yellow crystals of *trans*-$[Pt(LH \text{ or } L'H)_2Cl_2]$ were gradually formed. The reactions are as follows:

$$K_2PtCl_4 + 2LH \text{ or } 2L'H \xrightarrow[H_2O]{50-70°C} [Pt(L \text{ or } L')_2].xH_2O + 2KCl + 2HCl$$

$$[Pt(L \text{ or } L')_2].xH_2O \xrightarrow{1\ M\ HCl} trans\text{-}[Pt(LH \text{ or } L'H)_2Cl_2]$$

[2]Lists of structure factors and anisotropic thermal parameters are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

		C(6)—C(5)—C(8)	110.7(10)
		C(7)—C(5)—C(8)	108.6(10)
		C(1)—C(4)—O(1)	119.0(13)
		C(1)—C(4)—O(1′)	113.6(13)
		C(5)—C(8)—O(2)	114.7(12)
		C(5)—C(6)—O(2′)	113.9(15)

where $x = 1$ (L) or 2 (L′).

The compounds [Pt(L or L′)$_2$] can react with organic sulphur compounds R—SH (thiophenol and thiouracil) to form [Pt(LH or L′H)$_2$(SR)$_2$]. The reactions are as follows:

$$[\text{Pt(L or L')}_2] + 2\text{RSH} \xrightarrow{H_2O} [\text{Pt(LH or L'H)}_2(\text{RS})_2]$$

The results of the elemental analysis of the [Pt(L or L′)$_2$] and [Pt(LH or L′H)$_2$(SR)$_2$] compounds are shown in Table 1.

The three types of compounds, [Pt(L or L′)$_2$], [Pt(LH or L′H)$_2$Cl$_2$], and [Pt(LH or L′H)$_2$(SR)$_2$] are probably *trans*-isomers. The infrared spectrum of [Pt(L′H)$_2$Cl$_2$] showed only one ν_{Pt-Cl} band at 329 cm^{-1} (vs), which is typical of *trans*-compounds. The ν(N—H) vibrations appeared at 3360 (vs br) and 3210 cm^{-1} (vs br) and the $\delta(NH_2)$ deformation absorbed at 1572 cm^{-1} (vs). Since the Pt—N bonds are fairly strong and stable in the conditions used for the preparation of the three types of compounds, we can reasonably assume that [Pt(L or L′)$_2$] and [Pt(LH or L′H)$_2$(SR)$_2$] have the same configuration as *trans*-[Pt(L′H)$_2$Cl$_2$].

The crystal structure analysis of [Pt(L′H)$_2$Cl$_2$] confirmed its *trans* configuration. The refined atomic parameters are listed in Table 2. A labelled diagram of the molecule is shown in Fig. 1. The coordination around the Pt is square planar. The deviations from the least-squares weighted plane are as follows: Pt, −0.0002(3); Cl(1), 0.007(3); Cl(2), 0.008(3); N(1), −0.010(8); and N(2), −0.010(8) Å. The bond lengths and angles are given in Table 3. The angles around the Pt atom are close to the expected values of 90° and 180°.

The Pt—Cl bond lengths (2.306(2) and 2.309(3) Å) are normal and agree well with published values on *trans*-dichloroplatinum(II) compounds (8–11).

The Pt—N bond lengths (2.071(7) and 2.060(8) Å) are also normal and agree with published values on similar compounds (10–12). For example, the Pt—N distances in *trans*-[Pt(NH_2—CH_2—CH_2—$OH)_2I_2$] are 2.05 and 2.08 Å (12). In *trans*-[Pt(NH_2—$C(CH_3)_2CH_2OH)_2Cl_2$], the two organic ligands are arranged so that one ligand is above the platinum plane and the second below it (Fig. 1). The bond lengths and angles in L′H seem normal except that the oxygen atoms are disordered. The disorder is different on each of the two ligands. The disorder of C(4)—O(1) and C(4)—O(1′) is due to redirection of the ROH group while C(6)—O(2) and C(8)—O(2′) are due to disordered —CH_2OH groups. The occupancy ratio for each oxygen atom is about 2:3.

The structures of several copper(II) compounds with this ligand (L′H) has been determined (13–15) where L′H is either neutral or deprotonated. In all these structures, the ligand is

bidentate forming a chelate with the metal. Platinum is a soft metal, and is not expected to form strong Pt—O bonds with alcohols or other neutral oxygen ligands as do most first row transition metals. For example, DMSO coordinates to platinum through the sulphur atom (3, 16, 17) and not through the oxygen atom like most transition metals of the first row. Therefore L′H does not form a chelate with platinum unless it is deprotonated.

The packing of the molecules is shown in Fig. 2. The crystal is stabilized by an extensive hydrogen bonding system. The most favorable hydrogen bonds are shown in Table 4. All the amine groups are hydrogen bonded to the chlorine atoms. The hydroxy groups are also hydrogen bonded between themselves or possibly to one chlorine atom.

Linear oligopeptides. 118.[1] Preferred conformations and modes of self-association of the fluoren-9-ylmethoxycarbonyl amino acid derivatives

GIOVANNI VALLE, GIAN MARIA BONORA, AND CLAUDIO TONIOLO[2]

Biopolymer Research Centre, C.N.R., Institute of Organic Chemistry, University of Padova, 35131 Padova, Italy

Received December 20, 1983

GIOVANNI VALLE, GIAN MARIA BONORA, and CLAUDIO TONIOLO. Can. J. Chem. **62**, 2661 (1984).

An analysis of the preferred conformations and modes of self-association of the *N*-fluoren-9-methoxycarbonyl derivatives of L-alanine and α-aminoisobutyric acid was performed in solution and in the solid state using infrared absorption, ^{1}H nuclear magnetic resonance, and X-ray diffraction. In a solvent of low polarity (deuterochloroform) non-associated and self-associated species (involving predominantly the hydroxyl and carbonyl groups of the carboxylic acid moiety) simultaneously occur. At high dilution, where self-association is absent, the amount of intramolecularly H-bonded forms, if any, should be extremely small. *Z*(*trans*) $\rightleftharpoons$ *E*(*cis*) isomerism about the amide bond of the secondary urethane moiety was observed only for the less bulky L-alanine derivative. In the solid state all H-bonding donors and acceptors of the L-alanine and α-aminoisobutyric acid derivatives take part to complex schemes of intermolecular H-bonds. In the L-alanine derivative, crystallized as monohydrate, most of the intermolecular H-bonds involve the water molecule. Intramolecular H-bonds are not observed in either compound. The conformation about the secondary urethane CO—NH bond is *Z*(*trans*) in both compounds. Both L-alanine and α-aminoisobutyric acid residues are partially folded. The observation of the long C(sp^3)—O bond of the fluoren-9-ylmethoxycarbonyl moiety might contribute to explain the unexpected experimental result that this protecting group can be removed by catalytic hydrogenation.

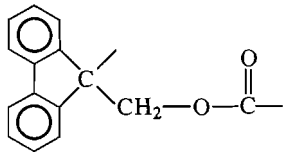
GIOVANNI VALLE, GIAN MARIA BONORA et CLAUDIO TONIOLO. Can. J. Chem. **62**, 2661 (1984).

Opérant en solution ainsi qu'à l'état solide et faisant appel à la spectroscopie d'absorption infrarouge, à la résonance magnétique nucléaire du ^{1}H et à la diffraction des rayons-X, on a effectué une analyse des conformations priviligiées et des modes d'auto-association des dérivés *N*-fluorèneméthoxycarbonyle-9 de la L-alanine et de l'acide α-aminoisobutyrique. Dans un solvant de faible polarité (deutérochloroforme), les espèces non associées et auto-associées (impliquant d'une façon prépondérante les groupes hydroxyle et carbonyle de la portion acide carboxylique) se forment simultanément. A grande dilution, alors qu'il n'y a pas d'auto-association, le nombre de molécules liées par des liaisons hydrogènes intramoléculaires, s'il y en a, doit être extrêmement faible. Ce n'est que dans le cas du dérivé le moins encombré de la L-alanine que l'on a pu observer une isomérisation *Z*(*trans*) $\rightleftharpoons$ *E*(*cis*) autour de la liaison amide de l'unité uréthane secondaire. A l'état solide, tous les groupes des dérivées de la L-alanine et de l'acide α-aminoisobutyrique qui peuvent agir comme donneurs ou comme accepteurs de liaisons hydrogènes participent à des formes complexes de liaisons hydrogènes intermoléculaires. Dans le dérivé de la L-alanine, qui cristallise sous forme de monohydrate, la plupart des liaisons hydrogènes intermoléculaires impliquent la molécule d'eau. On n'a pas observé de liaisons hydrogènes intramoléculaires ni dans l'un ni dans l'autre de ces composés. La conformation autour de la liaison uréthane secondaire CO—NH est *Z*(*trans*) dans les deux composées. Les résidus L-alanine et acide α-aminoisobutyrique sont partiellement repliés. La présence, dans la portion fluorèneméthoxycarbonyle-9, d'une liaison C(sp^3)—O qui est plus longue que prévue peut contribuer à expliquer le fait inattendu que l'on peut éliminer ce groupe protecteur par hydrogénation catalytique.

[Traduit par le journal]

Introduction

This work is part of our continuing study on the preferred conformations and modes of self-association of amino acids protected at the amino function with urethane-type groups (2, 3). The fluoren-9-ylmethoxycarbonyl (Fmoc) (**1**) group, currently adopted for routine use in peptide synthesis as a N^{α}-protecting group (4, 5), is most attractive because of the following favorable properties: (*i*) the ready preparation of



1

crystalline Fmoc-amino acids (5, 6), active esters (7*a*, 7*b*, 8), symmetrical anhydrides (5*b*), 5(4*H*)-oxazolones (9), and oxazolidinones (10); (*ii*) the rapid, quantitative cleavage under racemization-free, nonhydrolytic, mild base treatment via a β-elimination process (abstraction of the acidic benzylic hydrogen atom on the β-carbon of the bulky fluorenyl annular system by the base is the rate-limiting step) (4–7); and (*iii*) the strong uv absorption maxima (11), particularly advantageous for a facile reaction monitoring (5).

In addition: (*i*) the blocking of N^{ω}-amino groups with Fmoc (7*a*, 7*b*) and the blocking of the C-terminal —COOH and side-chain —SH functions in the form of fluoren-9-ylmethyl esters (7*c*, 7*d*) and thioethers (7*e*), respectively, have also been found useful in peptide synthesis; (*ii*) a Fmoc-amino acid derivative containing an isothiocyanate function has been synthesized and assessed for potential application as a chiral Edman reagent to test for racemization after peptide coupling (12); and (*iii*) the 2-sulpho derivative of Fmoc has been proposed as a N^{α}-protecting group for the elimination of side products from the peptides synthesized by the solid-phase method (13).

In this paper we describe the results of an ir absorption, ^{1}H nmr, and X-ray diffraction investigation of Fmoc-Aib-OH (Aib, α-aminoisobutyric acid) and Fmoc-L-Ala-OH in a solvent of low polarity and in the solid state. This study represents *inter alia* the *first* X-ray diffraction analysis of the electronic structure, preferred conformation, and mode of self-association of Fmoc-amino acid and peptide derivatives. The combined in-

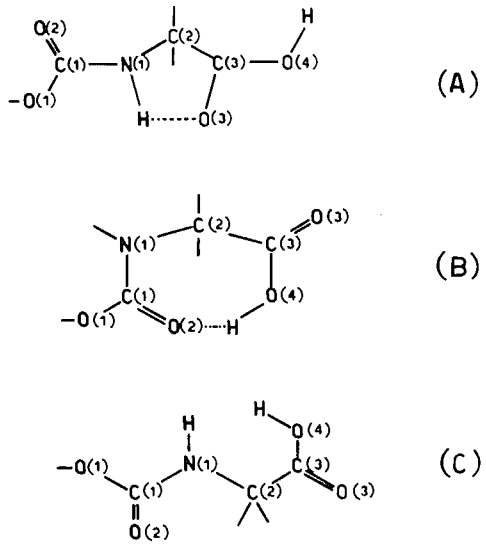

FIG. 1. (*A*) The C_5 conformer of an urethane-protected α-amino acid residue stabilized by the N—H...O=C (carboxylic acid) intramolecular H-bond. (*B*) An oxy-C_7 conformer of an urethane-protected α-amino acid residue stabilized by the O—H...O=C (urethane) intramolecular H-bond. (*C*) The open (no intramolecular H-bond), extended conformer.

vestigation of the Aib and L-Ala derivatives was expected to be particularly relevant, since the former amino acid exhibits severe restrictions to its conformational freedom due to the presence of *gem*-dimethylation at the α-carbon (14), whereas the latter amino acid is free to assume a wide range of conformations owing to the presence of a single, small, side chain (15).

In particular this study could allow us to obtain more information on the following points: (*i*) What are the conformational preferences about the O—C (=O) and (O=) C—N bonds of the secondary urethane moieties (2, 3)? (*ii*) Are the molecules extended (Fig. 1*A* and *C*), e.g. with the formation of the N—H...O=C (carboxylic acid) intramolecular H-bond of the C_5-type (Fig. 1*A*) (16), or rather, folded up to adopt the oxy-analogs of the C_7 conformation (Fig. 1*B*) with the formation of the O—H...O=C (urethane) intramolecular H-bond (16)? Is folding facilitated by the presence of *gem*-dimethylation (Aib derivative) (14)? (*iii*) In the absence of intramolecular H-bonding do these achiral compounds containing a —COOH group form cyclic dimers, as most of the carboxylic acids do (17, 18)? Are the urethane N—H and C=O groups involved in the intermolecular H-bonding schemes? (*iv*) Can the results of this study provide a contribution to explain the unexpected experimental observation that the Fmoc group is completely removed by hydrogenolysis giving 9-methylfluorene in quantitative yield (7*f*)?

Concerning the N-blocked derivatives of these two amino acid residues, it is pertinent to recall that the molecular and crystal structures of *t*-Boc-Aib-OH (*t*-Boc, *tert*-butyloxycarbonyl) (19, 20), *t*-Boc-D-Ala-OH·½H_2O (21), and *t*-Boc-DL-Ala-OH (21) have already been determined by X-ray diffraction.

Experimental

Materials

Fmoc-L-Ala-OH (6*b*, 6*d*, 22) was obtained from Fluka (Büchs, Switzerland).

Fmoc-Aib-OH was prepared as described by Meienhofer *et al.* (22). Mp 179–180°C (from ethyl acetate – petroleum ether). *Anal.* calcd. for $C_{19}H_{19}NO_4$ (325.3): C 70.1, H 5.9, N 4.3; found: C 69.8, H 5.9, N 4.4.

Infrared absorption

Infrared absorption spectra were recorded using a Perkin-Elmer Model 580 spectrophotometer. For the solid-state measurements the KBr disk technique was employed. For the solution measurements 0.1-mm and 1.0-mm cells with CaF_2 windows were used. Deuterochloroform (99.8% *d*) was purchased from Merck, (Darmstadt, West Germany). The band positions are accurate to ±1 cm^{-1}.

^1H Nuclear magnetic resonance

The ^1H nuclear magnetic resonance spectra were recorded using a Bruker WP200SY spectrometer. Measurements were carried out in deuteriochloroform (99.96% *d*; Merck), with tetramethylsilane as the internal standard.

X-ray diffraction

Colorless crystals of Fmoc-L-Ala-OH monohydrate were obtained from an acetone–water solution. Crystal data are:

$C_{18}H_{17}NO_4$ fw = 311.3

Orthorhombic, a = 25.054(4), b = 9.226(6), c = 7.360(6) Å, V = 1701.25 Å^3, ρ_o = 1.20(1), ρ_c = 1.21, Z = 4 (20°C; MoK_α, λ = 0.7107 Å). Space group $P2_12_12_1$.

Colorless crystals of Fmoc-Aib-OH were obtained from an acetone solution. Crystal data are:

$C_{19}H_{19}NO_4$ fw = 325.3

Orthorhombic, a = 29.785(9), b = 12.119(4), c = 9.556(4) Å, V = 3449.37 Å^3, ρ_o = 1.24(1), ρ_c = 1.25, Z = 8 (20°C; MoK_α, λ = 0.7107 Å). Space group *Pbcn*.

A total of 1401 (Fmoc-L-Ala-OH·H_2O) and 2921 (Fmoc-Aib-OH) independent reflections, respectively, were collected on a Philips PW 1100 four-circle diffractometer, using graphite monochromatized MoK_α radiation at $4° < 2\theta < 50°$ with the $\theta-2\theta$ scan mode. The structures were solved by direct methods using MULTAN (23), and refined by full-matrix least-squares with anisotropic thermal parameters for all non-hydrogen atoms. All hydrogen atoms of Fmoc-L-Ala-OH.H_2O were found on the difference Fourier map and refined. Part of the hydrogen atoms of Fmoc-Aib-OH were found on the difference Fourier map; the others were calculated, but not refined. The final R values for 1326 (Fmoc-L-Ala-OH.H_2O) and 1124 (Fmoc-Aib-OH) observed reflections with $I \geq 3.0\sigma(I)$ were 0.047 and 0.086, respectively. For Fmoc-Aib-OH the low (38.5) percentage of observed reflections might tentatively be attributed to the tiny crystals obtained and to the peculiar hypercentricity of the structure. The final atomic coordinates and thermal parameters for the two structures are presented in Tables 1 and 2, respectively. Lists of observed and calculated structure factors are available from the Depository of Unpublished Data.[3]

Results and discussion

Solution conformational analysis

In a diluted (6×10^{-4} M) $CDCl_3$ solution only two bands, at about 3510 cm^{-1} and 3440 cm^{-1}, are visible in the 3550–3300 cm^{-1} region of the ir absorption spectrum of both Fmoc-L-Ala-OH and Fmoc-Aib-OH. They are assigned to absorptions of free (solvated) carboxylic acid —OH and urethane —NH groups, respectively (21, 24, 25). At higher concentration (3×10^{-2} M), conversely, the intensity of the 3510 cm^{-1} band is markedly reduced relative to the 3440 cm^{-1} band. These is no evidence for bands below 3400 cm^{-1}, where H-bonded N—H groups are expected to absorb (21, 25, 26). For

both compounds this trend is paralleled by an analogous trend in the carbonyl stretching region (1800−1600 cm^{-1}). Upon increasing concentration, a considerable decrease in intensity of the 1755 cm^{-1} band (free C=O of the un-ionized carboxylic acid group) (21, 24−26) is seen, relative to the band near 1720 cm^{-1} (free C=O of the urethane group) (21, 25, 26). These results, taken together, indicate that the modes of self-association of the Fmoc-L-Ala-OH and Fmoc-Aib-OH molecules in $CDCl_3$ solution involve primarily the —OH and C=O groups of the carboxylic acid moiety. In addition, at high dilution the amount of the intramolecularly H-bonded C_5-form (16) (Fig. 1*A*) and oxy-C_7 form (16) (Fig. 1*B*), if any, should be extremely small.

In $CDCl_3$ (1.8×10^{-2} *M* concentration) the ^1H nmr spectrum of Fmoc-L-Ala-OH shows two peaks for the NH proton (at 5.29 ppm and 6.32 ppm, respectively) (6*c*, 27*a*). The approximate ratio is 5:1. The low-field peak tends to disappear upon heating. The effects of decreasing concentration (to 1.7×10^{-3}) and heating on the chemical shift of the high-field peak are negligible, again suggesting that the mode of self-association of Fmoc-L-Ala-OH in $CDCl_3$ solution does not involve the NH group as the H-bonding donor. According to Branik and Kessler (25, 27*b*), the two NH peaks exhibited by amino acids protected at the N^α-atom as a secondary urethane group have to be related to the *E*(*cis*) ⇌ *Z*(*trans*) conformational equilibrium about the CO—NH bond. Conversely, in the ^1H nmr spectrum of Fmoc-Aib-OH only the high-field peak (5.34 ppm) is observed. This finding is not unexpected in view of the results obtained on N^α-benzyloxycarbonyl Aib derivatives and peptides, and should be related to the enhanced bulkiness and conformational restrictions characteristic of α,α-dialkylated amino acid residues (14).

Solid-state conformational analysis

We started our conformational analysis of Fmoc-L-Ala-OH and Fmoc-Aib-OH in the solid state using ir absorption. Interestingly, the H-bonding schemes in the solid state for both compounds are more complex than those observed in $CDCl_3$ solution. For Fmoc-L-Ala-OH three bands are seen in the region corresponding to the O—H and N—H stretching vibrations (3550−3300 cm^{-1}): two weak bands at 3516 cm^{-1} (free OH) and 3419 cm^{-1} (weakly H-bonded N—H), and an intense band at 3344 cm^{-1} (N—H involved in a H-bond of moderate strength) (21, 24). In the C=O stretching region (1800−1600 cm^{-1}) three bands of comparable intensities are visible, at 1720, 1703, and 1688 cm^{-1}. They are attributed to complex contributions arising from H-bonded C=O of the carboxylic acid group, and free and H-bonded C=O of the urethane group (21, 24, 26, 28). As for Fmoc-Aib-OH, the ir absorption spectrum resembles qualitatively that of Fmoc-L-Ala-OH. Minor differences are as follows. (*i*) The band of the —OH group is absent, suggesting an H-bonded state for this proton. (*ii*) The intensity of the band associated with weakly H-bonded N—H is even furtherly reduced. (*iii*) The intense band of H-bonded N—H falls at 3303 cm^{-1}, suggesting an enhancement in the strength of the corresponding H-bond. (*iv*) The three bands in the C=O stretching region are seen at 1720, 1701, and 1692 cm^{-1}, with an enhancement in the relative intensity of the low-frequency band (H-bonded C=O of the urethane group). It is safe to conclude that the molecules of both Fmoc-protected amino acids tend to self-associate in the solid state. Most of the H-bonding donor and acceptor group seem to be involved in the aggregation process. The molecules of Fmoc-Aib-OH appear to be held together by stronger H-bonds than those of Fmoc-L-Ala-OH.

The solid-state conformational analysis of Fmoc-L-Ala-OH and Fmoc-Aib-OH was extended to X-ray diffraction. This investigation, *inter alia*, allowed us to solve the ambiguity of the assignment of the modes of self-association made on the

basis of the ir absorption properties. The molecular structures of Fmoc-L-Ala-Aib-OH.H_2O and Fmoc-Aib-OH are illustrated in Figs. 2 and 3, respectively. Bond lengths and bond angles of the two compounds are listed in Tables 3 and 4, respectively.

Bond lengths and bond angles of the two Fmoc-amino acids compare well with those found in other fluorene (29), urethane (2, 3), alanine (30), and Aib derivatives (19, 31). In particular, we note the following points. (*i*) The C(6)—C(7), C(12)—C(13), and C(1)—C(13) bond lengths of the fluorene system are 1.440 and 1.453 Å, 1.512 and 1.500 Å, and 1.531 and 1.519 Å for Fmoc-L-Ala-OH.H_2O and Fmoc-Aib-OH, respectively. (*ii*) The tetrahedral bond angles about the C(13) atom are considerably spread (101.9° to 113.7° and 103.1° to 114.1° for Fmoc-L-Ala-OH.H_2O and Fmoc-Aib-OH, respectively) to help to relieve the unfavorable interactions between the tricyclic moiety and the methoxycarbonylaminoacyl chain. (*iii*) The C(13)—C(14) bond lengths (1.506 Å for Fmoc-L-Ala-OH.H_2O and 1.492 Å for Fmoc-Aib-OH) are significantly shorter than that quoted as standard for a paraffinic C—C single bond, 1.541(3) Å (32); in contrast, the C(14)—O(1) bond lengths (1.447 Å for Fmoc-L-Ala-OH.H_2O and 1.441 Å for Fmoc-Aib-OH) are longer than that quoted as standard for an ether C—O single bond, 1.430(5) Å (32). The corresponding C—O bond length in N^{α}-benzyloxycarbonyl amino acid and peptide derivatives is on the average 1.454 Å (3).

The fluorene ring system, and the urethane and carboxylic acid groups are close to planarity. The dihedral angle between the average planes of the two aromatic rings of the fluorene system is 3.35° for Fmoc-L-Ala-OH.H_2O and 3.47° for Fmoc-Aib-OH. The dihedral angles between the average plane of the urethane group and the average planes of the fluorene system and the carboxylic acid group are 61.5° and 106.1°, re-

spectively, for Fmoc-L-Ala-OH.H_2O, while 89.2° and 73.1°, respectively, for Fmoc-Aib-OH. The secondary urethane linkage in both compounds adopt one of its most common conformations (*trans*, *trans*, or *b* (2, 3)), the corresponding torsional angles being 178.1° and 179.1° for Fmoc-L-Ala-OH.H_2O, and ±168.2° and ∓173.6° for Fmoc-Aib-OH (33). The L-Ala and Aib moieties are partially folded, the sets of ϕ, ψ_T torsional angles (−65.5° and 150.2°, respectively, for Fmoc-L-Ala-OH.H_2O and ±78.6° and ∓158.6°, respectively, for Fmoc-Aib-OH) falling in the *F* region (or in the enantiomeric *F** region for Fmoc-Aib-OH) (34) of the conformational energy map. The carboxylic acid group in both compounds adopts a conformation with respect to the C(16)—N(1) bond intermediate between the *synplanar* and *synclinal* conformations (35), the N(1)—C(16)—C(17)—O(3) torsional angle being −32.2° for Fmoc-L-Ala-OH.H_2O and the corresponding N(1)—C(16)—C(19)—O(3) torsional angle being ±25.2° for Fmoc-Aib-OH.

There are no *intramolecular* H-bonds in either Fmoc-L-Ala-OH.H_2O or Fmoc-Aib-OH. Rather, all potential donors and acceptors of Fmoc-L-Ala-OH.H_2O are involved in a complex scheme of *intermolecular* hydrogen bonds, most of them involving the water molecule: (*i*) O(2)...H_1—O(W) (x, y, $1 + z$), O...O distance 2.754 Å; (*ii*) O(3)...H_2—O (W) (x, y, z), O...O distance 2.773 Å; (*iii*) O(W)...H—O(4) ($2 - x$, $y - 1/2$, $1/2 - z$), O...O distance 2.554 Å; and (*iv*) O(3)...H—N(1) ($2 - x$, $1/2 + y$, $1/2 - z$), O...N distance 3.000 Å. These results are in line with the observation that, in molecules containing the —CONH— moiety, hydration of the C=O group occurs more frequently than hydration of the N—H group (21). Conversely, in the Fmoc-Aib-OH molecules an intermolecular H-bond is seen between the urethane N—H and C=O groups, the O(2)...N(1) (x, $2 - y$, $z - 1/2$) distance being 2.942 Å. Two additional intermolecular distances shorter than 3.0 Å involve the un-ionized carboxylic acid group: (*i*) O(3)...O(3) ($1 - x$, y, $3/2 - z$) = 2.636 Å, and O(4)...O(4) ($1 - x$, y, $3/2 - z$) 2.599 Å.

Conclusion

In this work we have shown that in a solvent of low polarity (deuteriochloroform) non-associated and self-associated species simultaneously occur for both Fmoc-L-Ala-OH and Fmoc-Aib-OH. Self-association involves primarily the hydroxyl and carbonyl groups of the carboxylic acid moiety. The extent of self-association decreases with dilution. At high dilution, where self-association is absent, the amount of intramolecularly H-bonded C_5-form and oxy-C_7 form, if any, should be extremely small. *Z(trans)* ⇌ *E(cis)* isomerism about the amide bond of the secondary urethane moiety was observed only for the less bulky L-Ala derivative.

In the solid state all H-bonding donors and acceptors of the L-Ala and Aib derivatives take part to complex schemes of intermolecular H-bonds. In the L-Ala derivative, crystallized as monohydrate, most of the intermolecular H-bonds involve the water molecule. Intramolecular H-bonds are not observed in either compound, thereby excluding the formation of the C_5-and oxy-C_7 forms. The conformation of the secondary urethane —CONH— group is *Z(trans)* in both compounds. Both L-Ala and Aib residues are partially folded. The observation of the long C(14)—O(1) bond might contribute to explain the unexpected experimental result that the Fmoc group can be removed by catalytic hydrogenation.

The chloroindolenine – imino ether – oxindole sequence. A reexamination[1]

DENNIS V. C. AWANG,[2] ANDRÉ VINCENT, AND DARYL KINDACK
Bureau of Drug Research, Health and Welfare Canada, Sir Frederick G. Banting Research Centre, Ottawa, Ont., Canada K1A 0L2

Received July 15, 1983[3]

DENNIS V. C. AWANG, ANDRÉ VINCENT, and DARYL KINDACK. Can. J. Chem. **62**, 2667 (1984).

The chloroindolenines of deserpidine and reserpine, and the isomeric chloroindolenines derived from yohimbine – characterized for the first time – have been treated with methanol and methoxide ion under a variety of conditions. In the traditional medium of methanolic hydroxide, chlorodeserpidine partially undergoes rearrangement to imino ether, whereas chlororeserpine suffers only substitution of chloride by methoxide; only the α-isomer of the two yohimbine chlorides undergoes rearrangement to a methyl imino ether, the β-isomer being degraded to an intractable mixture. In refluxing neat methanol, the α-chloride of yohimbine rearranges readily and cleanly to imino ether at a rate comparable to that of chlorodeserpidine rearrangement, but vastly greater than that of the β-chloride. However, under silver oxide catalysis all the chloroindolenines rearrange at closely similar rates. The rearrangement of chloroindolenine to methyl imino ether is stereospecific, α-chloride leading to α-spiro imino ether and β-chloride to β-spiro imino ether. The results are rationalized on the basis of stereoelectronic considerations applied to a process of addition of methanol to the imine bond, followed by elimination of hydrogen chloride from the methanol adduct.

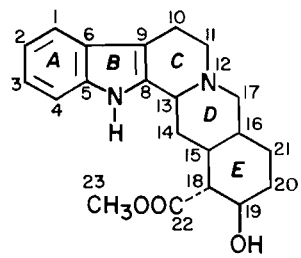
DENNIS V. C. AWANG, ANDRÉ VINCENT et DARYL KINDACK. Can. J. Chem. **62**, 2667 (1984).

Opérant sous diverses conditions, on a traité les chloroindolénines de la déserpidine et de la réserpine ainsi que les chloroindolénines isomères dérivées de la yohimbine – que l'on a caratérisées pour la première fois – avec du méthanol et avec l'ion méthanolate. Traitée dans des conditions traditionnelles par l'ion hydroxyde dans le méthanol, la chlorodéserpidine subit une transposition partielle en iminoéther tandis que la chlororéserpine subit uniquement une substitution du chlore par le méthanolate; seul l'isomère α des deux chlorures de yohimbine se transpose en iminoéther méthylique alors que l'isomère β est décomposé en un mélange que l'on ne peut séparer. Par reflux dans du méthanol pur, le chlorure α de la yohimbine se transpose facilement et proprement en un iminoéther; la vitesse de cette réaction est comparable à celle de la transposition de la chlorodéserpidine, mais cette vitesse est de beaucoup supérieure à celle de la transposition du chlorure β. Cependant, lors de la réaction catalysée par l'oxyde d'argent, toutes les chloroindolénines se transposent avec des vitesses très voisines. La transposition de la chloroindolénine en iminoéther méthylique est stéréospécifique, le chlorure α conduit à un spiroiminoéther α alors que le chlorure β conduit à un spiroiminoéther β. On rationalise les résultats en faisant appel à des considérations stéréoélectroniques intervenant dans la réaction d'addition du méthanol sur la liaison de l'imine qui est suivie par une élimination de chlorure d'hydrogène à partir de l'adduit.

[Traduit par le journal]

The most common route to oxindoles from indole alkaloids of the tetrahydro-β-carboline variety involves an initial reaction with *tert*-butyl hypochlorite which produces highly reactive chloroindolenines (1).

Finch and Taylor (2) developed a two-step procedure whereby the crude product of indole chlorination is treated first with aqueous methanolic hydroxide and then hydrolyzed under acidic conditions.[4] The initial phase of this procedure was viewed as producing a unique imino ether (**10**) from *one* of the two epimeric chloroindolenines (see Scheme 1); acid hydrolysis of the rearranged ether yielded the corresponding oxindole which then underwent isomerization to the observed mixture of oxindoles **A** and **B**. Finch and Taylor depicted the isomeric chloroindolenines as having chlorine in axial and equatorial dispositions, and further suggested that it is only in the product of a postulated methanol addition[5] to the *equatorially chlorinated* β-*isomer* that the stereochemistry is appropriate for their suggested four-centred rearrangement to imino ether. It was also claimed that chlorodeserpidine was resistant to methanolysis (except for loss of the trimethoxybenzoyl group), and that therefore this unique product of deserpidine chlorination bore axially oriented chlorine.



1

In the study here reported, the epimeric chloroindolenines derived from yohimbine (**1**) have been separated and characterized, then treated with aqueous methanolic hydroxide, as have the unique chlorides obtained from reserpine and deserpidine.

Under such conditions, 9-chloro-9*H*-reserpine[6] (**4***a*) is efficiently converted into 9-methoxy-9*H*-reserpine, identical with the product of reaction of reserpine with iodosobenzene diacetate (IBD) in methanol (6). These reserpine derivatives are

[1] Presented in part at the 62nd Annual Conference of the Chemical Institute of Canada. Vancouver, B.C., June 3–6, 1979.

[2] Author to whom all correspondence should be addressed.

[3] Revision received May 23, 1984.

[4] Zinnes and Shavel (3) effected the conversion of chloroindolenines into oxindoles by refluxing in aqueous methanol which had been adjusted to pH 6 by addition of acetic acid, a process which clearly obviates imino ether formation.

[5] Kuehne and Hafter (4) also favour methanol addition to the imine function as a prerequisite to rearrangement.

[6] The numbering system is that used by Wehrli (5), which seems more suitable to general application than the older systems which would designate such compounds as 7-substituted indolenines.

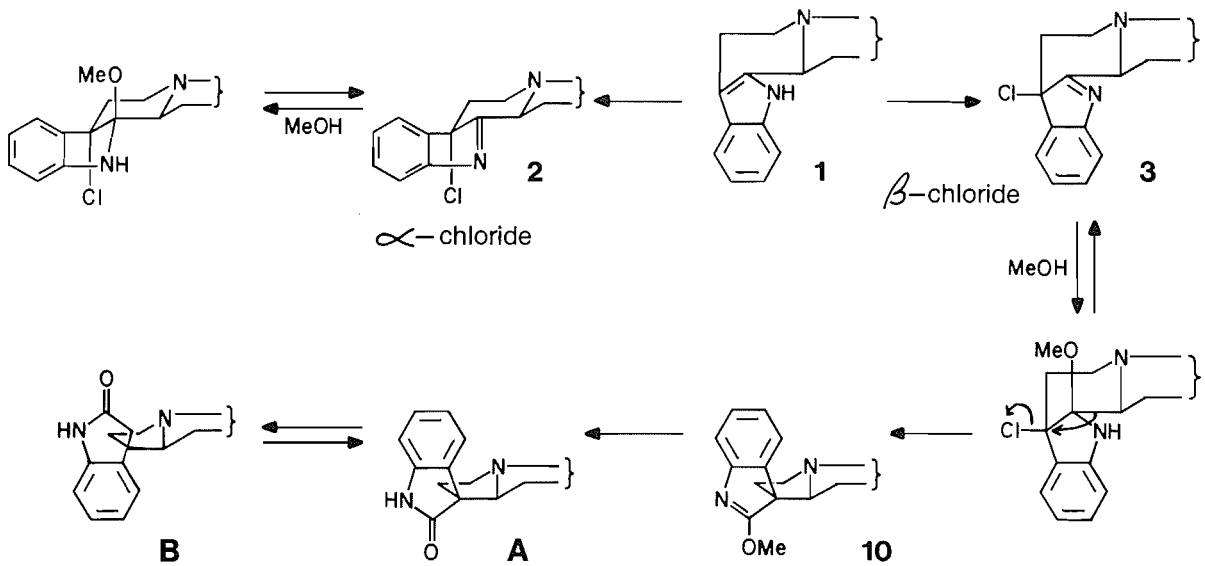
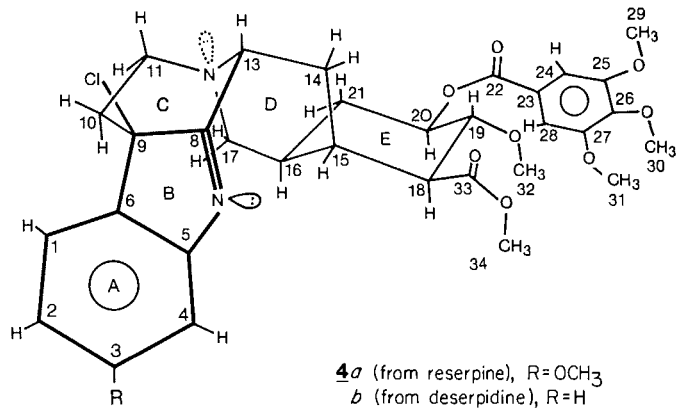


SCHEME 1. Formation of oxindoles from indoles via chloroindolenines (ref. 2).

unquestionably of β configuration,[7] and this methanolysis almost certainly proceeds by way of a benzylic carbonium ion, and not by an S_N2 mechanism as suggested by Owellen (7) for the analogous reaction of the chloroindolenine of tetrahydrocarbazole. The chlororeserpine reaction produced no spiro imino ether, the expected product of rearrangement for which Owellen indicated a carbonium ion intermediate. 9-Chloro-9*H*-deserpidine (**4***b*), under the same conditions, was readily converted to a mixture of methyl 9-methoxy-9*H*-deserpidate and the pair of methyl imino ethers of methyl 13-isodeserpidate, isomeric at C-9.[8]

Treatment of yohimbine (**1**) with *tert*-butyl hypochlorite in the presence of triethylamine (1) produced a mixture of the epimeric 9-chloro-9*H*-yohimbines, the α isomer (**2**) predominating. These chlorides, illustrated as three-dimensional line diagrams in Scheme 2, were separated by column chromatography in roughly a 4:1 ratio of α/β isomers, and subjected to detailed spectroscopic analysis, which is offered later in the text.

The corresponding 9-methoxy derivatives of yohimbine were synthesized, for comparison, by the IBD–methanol reaction (6) and separated by preparative tlc on silica gel in the ratio



35α:65β.[9] The isomeric chlorides and methyl ethers showed closely corresponding R_f's in the tlc system used, the α-chloro and α-methoxy derivatives having values of 0.27 and 0.30 and the β-isomers, 0.16 and 0.17, respectively. It is interesting to note that lower R_f in silica gel chromatography of epimeric chlorindolenines has been associated with greater basicity, and led Dolby and Gribble (9) to an assignment of epimer configuration contrary to ours. These authors isolated "about equal amounts" of epimeric chlorides from the tetracyclic base, 1,2,3,4,6,7,12,12b-octahydroindolo[2,3-*a*]quinolizine (**5**) and assigned the β configuration (see **3**) to the faster-moving *trans*-chloroindolenine,[10] on the basis that the isomer bearing chlorine *trans* to the N-5 nitrogen would have a less-hindered N-5

[7] The absolute configuration of 9α-acetoxy-9*H*-yohimbine has been established by X-ray crystallographic analysis of its methiodide salt (10). Comparison of the C^{13} nmr spectrum of this acetoxy yohimbine with those of the two epimeric methoxy derivatives leaves no doubt as to their relative configurations. The choice between chlorides seems easy when one makes a similar comparison between methoxy and chloro derivatives, supported by close correspondence of R_f values upon thin-layer chromatography of the chloro and methoxy pairs.

[8] The protons of the methoxyl group attached to the saturated C-9 carbon of 9-methoxyindolenines are easily distinguishable in the ^1H nmr spectrum, giving rise to a methyl spike in the vicinity of δ_{TMS} ($CDCl_3$) 3 ppm (reserpine, 2.78; deserpidine 2.96). The protons of the methoxyl group attached to the C=N carbon resonate much farther downfield, at δ 4.07 and 4.14 ppm, in the imino ethers of methyl 13-isodeserpidate. In the case of 9-chloro-9*H*-reserpine, attack by methanol at C-9 is so rapid that 9-methoxy-9*H*-reserpine precipitates out of solution, thus preventing the hydrolysis of the benzoate group which occurs in the deserpidine case.

[9] Contrary to the claim of Finch and Taylor (2) no quantitation of the isomeric ratio has hitherto been published for the products of chlorination of either yohimbine or yohimbane; these authors reported a "50:50 mixture" for the former and made an unsubstantiated claim that "equal amounts" (of epimers) have been "proved conclusively" in the case of the chloroyohimbanes by Shavel and Zinnes (8). In this study, the ratios of epimers in the crude reaction products from yohimbine were estimated from peak areas of chromatograms following hplc analysis; the ratios of α/β were observed to be 3:1 for the chlorides and 1:3 for the methyl ethers.

[10] *Cis* and *trans* refer to the spatial arrangement of the chlorine atom and the C-12b methine hydrogen.

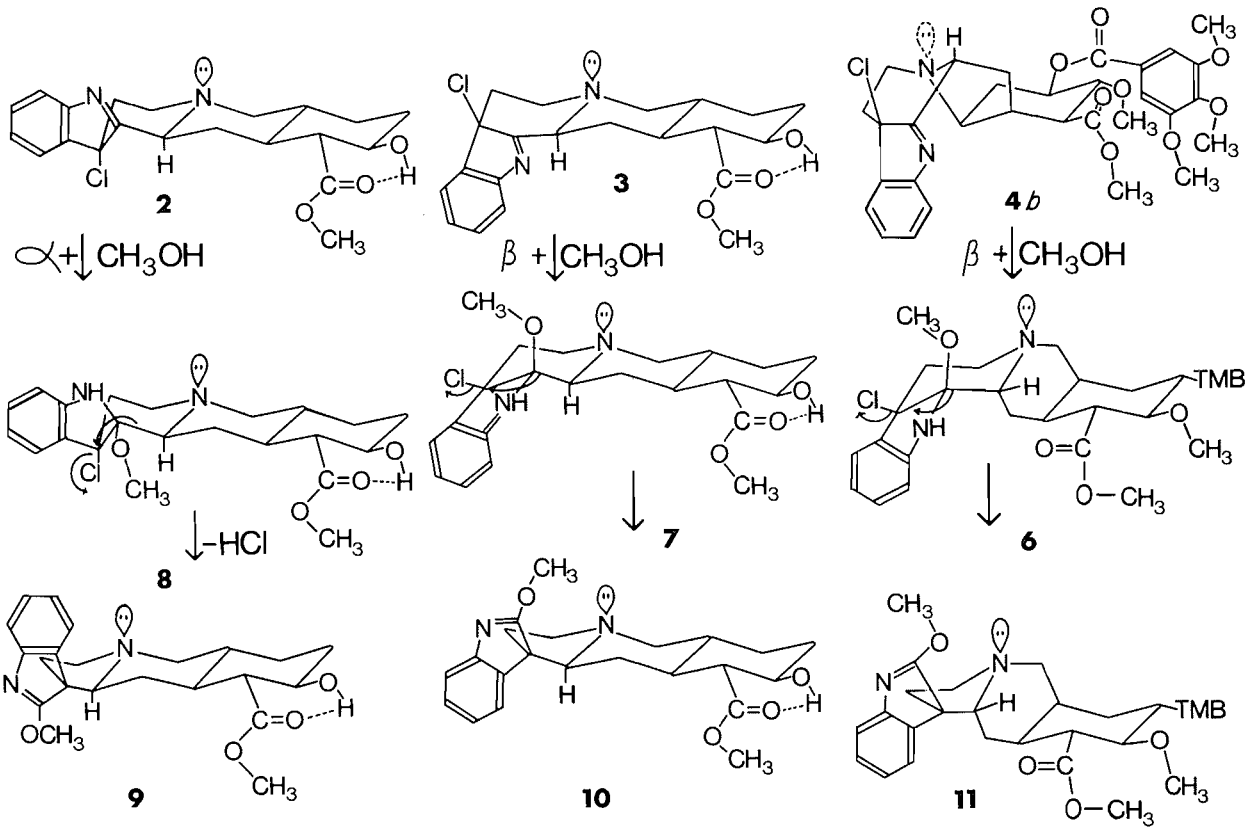
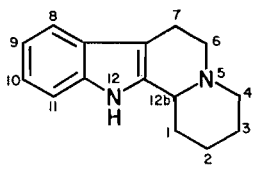


SCHEME 2. Mechanism of formation of imino ethers from chloroindolenines.



5

lone pair, resulting in stronger adherence to silica gel and enhanced reactivity towards methyl iodide;[11] these authors also cite ^{1}H nmr evidence to support their stereochemical assignments. On the other hand, Finch *et al.* (10) conclude that the epimer of chloroyohimbane that moves faster on silica gel tlc plates – and is positively rotating of polarized light – has the α configuration, parallel to positively rotating 9-acetoxyyohimbine, whose structure and stereochemistry have been established by X-ray crystallography.[12]

The ^{13}C nmr spectra of 9-acetoxyyohimbine, and the epimeric chloro- and methoxyyohimbines, illustrated as bar graphs in Figure 1,[13] confirm the α configuration for the epimers of greater R_f on silica gel and provide a ready means of differentiating indolenine epimers. Comparison of the generally closely similar spectral patterns for the indolenines with that of yohimbine reveals the marked changes that take place in the resonances of ring A and B carbon atoms upon alteration of the indole ring B. The most pronounced effect (of the order of 50 ppm) is observed in the chemical shift of C-8, the imine carbon, undoubtedly due to the highly polar character of the C=N bond; the appreciably reduced chemical shift (by about 10 ppm) of the acetoxyyohimbine C-8 resonance is attributed to shielding by the acetoxy carbonyl group.

It appears clear from models of the indolenine epimers that the C-9 substituents of the β-isomers would have the greater effect, interspatially, on the tertiary nitrogen lone pair and on the carbon electrons of ring D. Compared with the α-isomers, it is observed that C-16 and C-17 of the β-isomers are significantly shielded, whereas the β-carbons-13 are comparably deshielded; as well, β-carbons-10 and especially carbons-11 in ring C are notably shielded, probably a result of transannular influence of the imine double bond.

The mechanism of rearrangement of chloroindolenines to spiro imino ethers

All published accounts (2, 3, 14) of rearrangement of chloroyohimbine to yohimbine oxindoles in basic medium, so far discovered, indicate that the unresolved amorphous *mixture* of epimeric chlorides, the product of yohimbine – *tert*-butyl hypochlorite reaction, was not purified before treatment with methanolic hydroxide. In this study, the pure crystalline epimeric chlorides were separately refluxed in the basic medium and the products of reaction analyzed. It was observed that *only the α-chloro isomer underwent rearrangement to the imino ether*

[11] The anchimeric participation of chlorine in nitrogen lone-pair binding to acidic sites appears not to have been considered.

[12] This stereochemistry could now have been more readily deduced by measuring the nuclear Overhauser effect (nOe) between acetoxy methyl protons and the C-13 methine proton. Our experiments indicate an increase of more than 20% in the integrated intensity of the signal due to H-13 (4.19 ppm) upon irradiation of the acetoxy methyl protons. Also, selective on-resonance decoupling dictates a reversal of the published (11) assignments of ^{13}C resonances for C-13 and C-19 in yohimbine: irradiating the cleanly separated H-13 methine proton at 4.22 ppm resulted in collapse of the *downfield* doublet.

[13] Chemical shifts are listed in Table 1.

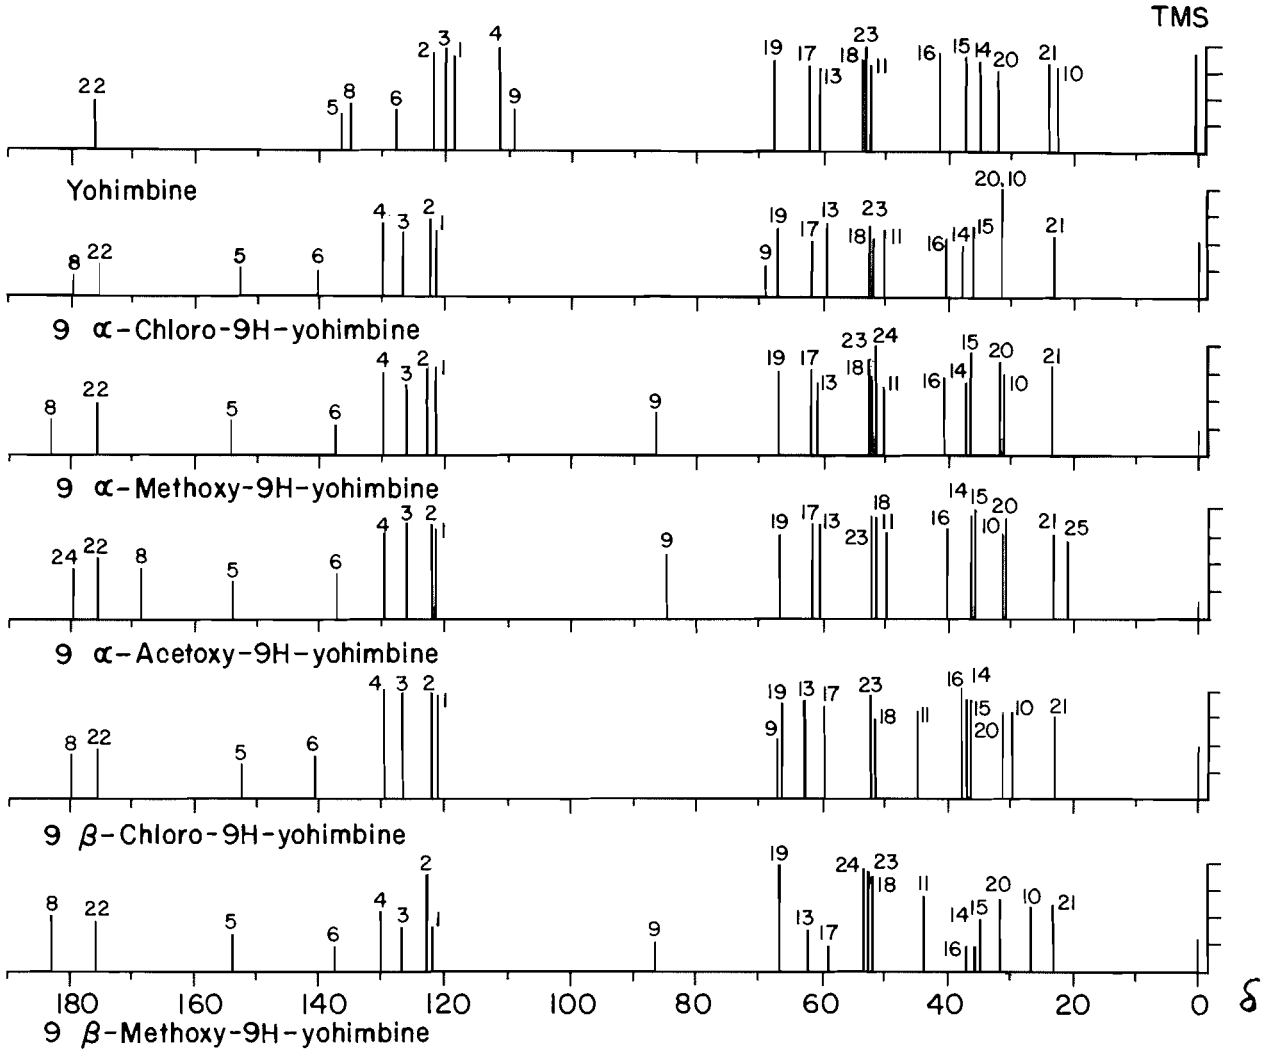


FIG. 1. Bar graphs of ^{13}C spectra of yohimbine and derivatives.

precursor of yohimbine oxindoles. The β-chloride yielded neither imino ether nor the epimeric methoxy yohimbine substitution products formed by IBD reaction in methanol; tlc of the intractable reaction product indicated a predominance of polar (probably polymeric) material close to the origin, accompanied by traces of at least three other compounds.

The fact that under these conditions *only* the α-chloro isomer from yohimbine (**2**) undergoes rearrangement to imino ether further discredits the proposal by Owellen (7) of a carbonium ion mechanism for the rearrangement: one would expect that *both* isomers of 9-chloro-9*H*-yohimbine would yield the same carbonium ion at C-9 even if at different rates, and lead to the same product.

The presence of hydroxide in the traditional reaction medium suggested the possibility of an intermediate cyclopropimine bridging C-9 and C-13, produced by elimination of hydrogen chloride (Fig. 2); such an intermediate would be analogous to the cyclopropanone intermediate widely supported for the Favorskii rearrangement of α-chloroketones under basic influence. Owellen and Hartke (12) discounted such a mechanism for analogous rearrangements of tetrahydrocarbazole derivatives on the plausible grounds that such structures would demand too much distortion – and attendant strain – in the five-membered indole B ring. *No other authors have considered any*

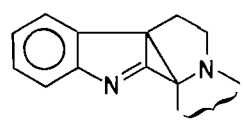

FIG. 2

mechanistic role for hydroxide ion. In view of this apparent oddity, the popularity of the methanol-addition mechanism, and the relatively recent support of Dmitrienko *et al.* (13) for methanol addition to imine being an *acid-catalysed* process, the reaction of neat methanol with the chloroindolenines of yohimbine, deserpidine, and reserpine was examined.

In neat refluxing methanol, α-chloroyohimbine underwent ready rearrangement to methyl imino ether; hplc analysis of the reaction mixture indicated that all substrate disappeared within 90 min. By comparison, after the same period of refluxing, 89% of β-chloroyohimbine was left unreacted; overnight refluxing was needed to complete the rearrangement. Chlorodeserpidine (**4***b*) rearranged to methyl imino ether (without loss of benzoate) almost as readily as α-chloroyohimbine, taking just over 2 h reflux for completion of reaction; at the 1-h mark there were, respectively, 25% and 11% of unreacted chloride. However, as was the case in methanolic hydroxide medium, chlororeserpine underwent quantitative conversion to methoxy-

*$CDCl_3$ solution, internal TMS.

†C-24 refers to C-9 methoxy and imino ether methyl carbons and, in the case of acetoxyyohimbine, C-24 and C-25 correspond to the acetoxy carbonyl and acetoxy methyl carbons, respectively.

reserpine. The failure of chlororeserpine to yield a rearranged product is attributed to activation of S_N1 substitution at the C-9 position by the C-3 methoxyl group.

The above results are consistent with addition of methanol to the imine bond of the chloroindolenines. Hydroxide ions are clearly unnecessary to the rearrangement, as are protons (since the rearrangement also proceeds under strongly basic conditions), although in the case of neat methanol its addition may be catalysed by hydrogen chloride produced in the course of the reaction. Addition of methanol to the imine bond of 9α- and 9β-chloro-9*H*-yohimbine may occur from α and β faces of the plane of the ring network, with strikingly different results. In the case of each of the three substrates which undergo rearrangement, only one of the two possible addition products (as illustrated in Scheme 2) provides the appropriate *anti* alignment of the C8—C13 and C—Cl bonds,[14] namely the products of β addition of methanol to 9β-chloro-9*H*-deserpidine and 9β-chloro-9*H*-yohimbine (**6** and **7**, respectively) in which the alignment is almost ideal for a planar four-centred transition state, and the product of α addition of methanol to 9α-chloro-9*H*-yohimbine (**8**) in which only relatively unencumbered rotation about the C8—C9 bond is needed to optimize alignment of the skewed C—Cl bond. However, in the first two cases, the benzene ring attached to C9 must adopt an *axial* configuration, a factor which would be expected to disfavour their rearrangement relative to the third substrate (**2**) for which the benzene ring in the addition compound (**8**) is *equatorially* oriented. The dramatic difference in the rates of rearrangement of **4***b* and **3** is likely due to the additional steric hindrance to approach of methanol presented by the C14 methylene group in **3**: the C—Cl and C13—C14 bonds almost coplanarly flank the route to the imine nitrogen orbital; this judgement implies that both methanol addition and bond migration contribute to the rate-determining process.

While the mechanism of Dmitrienko *et al.* (13) involving acid-catalysed addition of methanol to the imine bond of chloroindolenines followed by S_N1 ionization of chloride to form a benzylic carbonium ion seems plausible under those conditions, S_N2 displacement of chloride would appear more likely in strongly basic medium such as employed by Owellen (7). The fact that under Owellen's optimum "substitution" conditions (sodium methoxide in methanol at −10°C)[15] the chloroindolenines of yohimbine undergo rearrangement, exclusively, suggests that their rigid fused ring system militates against the S_N2 mechanism that is dominant in the simpler 2,3-dimethylindole and tetrahydrocarbazole derivatives.

The fact that, in our experiments, no products derived from substitution of chloride by methoxide were observed in refluxing methanol, whereas Dmitrienko *et al.* (13) reported exclusive substitution when methylene chloride solutions of chloroindolenines from 2,3-dimethylindole and tetrahydrocarbazole were treated with methanol at −5°C, prompted ex-

[14] α-Addition of methanol to 9β-chloro-9*H*-yohimbine (**3**) and chlorodeserpidine (**4***b*) produces boat conformations of ring C and unfavourable *syn* alignment of C8—C13 and C—Cl bonds; β-addition of methanol to 9α-chloro-9*H*-yohimbine (**2**) produces a chair conformation of ring C, but also a *syn* alignment of the critical bonds.

[15] Under these conditions the chloroindolenine of tetrahydrocarbazole yielded 80% substitution product vs. 20% rearranged, whereas refluxing methanolic sodium hydroxide (65°C) produced 87% rearrangement and 13% substitution, in both cases after only 30 min.

amination of the behaviour of the yohimbine chloroindolenines at low temperature. Under the conditions employed by Dmitrienko *et al.*, the β-chloroindolenine of yohimbine (**3**) is inert, no change being observed after 72 h at −5°C. After 2 weeks all of the β-chloride (**3**) was eventually transformed to the pair of methyl imino ethers, without a trace of substitution products being observed. By contrast, all α-chloroindolenine (**2**) disappears in just over a day, yielding 80% of rearranged product (**9**) in the ratio 6:1::**9**/**10** and 20% 9α-methoxy-9*H*-yohimbine, *uncontaminated by any 9β-methoxy-9*H*-yohimbine*. The predominance of the α imino ether (**9**) indicates a stereospecific rearrangement which also finds support in the methanolic methoxide reaction data later reported. The only rationale suggested for the retention of configuration in the substitution product involves α attack of methanol on the benzylic carbonium ion derived from the product of β addition of methanol to the α chloride. Chlorodeserpidine also degrades completely after 24 h at −5°C in methanol, but no trace of substitution product is observed either by hplc or nmr analysis.

The relative rates of α- and β-chloride rearrangement under the influence of methoxide ion paralleled those observed in refluxing methanol, but the reactions are considerably slower than reported by Owellen for the chloroindolenine of tetrahydrocarbazole. After 2 h at −10°C, 82% and 94% of α- and β-chlorides, respectively, were left unreacted. The reaction mixtures were stored in the refrigerator (15°C) and analyzed by hplc daily. After 1 day at 15°C, 38% and 72% respectively of the α- and β-chlorides remained, at which time both reaction vessels were stored at room temperature; it took fully 2 further days to complete the rearrangement of α-chloride (30% β-chloride remaining), and roughly another 3 days for disappearance of all the β-chloride.

A most interesting result was obtained from treatment of methanolic solutions of the yohimbine chloroindolenines with silver oxide at room temperature.[16] Whereas the exclusive product of reaction is that of rearrangement to spiro methyl imino ether, as in refluxing methanol and low-temperature methanolic sodium methoxide, in this case the rates of reaction of α- and β-chlorides are virtually identical, in contrast with the vast superiority of the α-isomer in the other media; after 2 h 50 and 51% of the α- and β-chlorides, respectively, had been consumed. This result may be rationalized on the basis that complexation of chloride with silver on the surface of silver oxide leads to polarization of the C—Cl bond and facilitation of C8—C13 bond migration; distortion of the half-boat conformation of ring C as a result of unfavourable 1,4-interaction between chlorine and nitrogen lone-pair electrons of the β-chloride would also be relieved as a result. Attack of methanol from the opposite face of the ring planes could take place *in concert* with C8—C13 bond migration, a mechanism which would afford no particular advantage to either of the isomeric chlorides, since both bear chlorine in pseudo-axial conformation relative to the equatorial C8—C13 bond. This silver oxide procedure should be particularly useful where temperature-sensitive indolenine chlorides are involved and where product requirements do not render use of silver economically prohibitive.

The stereochemistry of spiro imino ether formation and the isomerization of spiro imino ethers

Finch and Taylor (2) reported the formation of a single "imido" (imino) ether from rearrangement of the mixture of chloroyohimbines and deduced its structure from a consideration of their proposed mechanism of its formation (Scheme 1), coupled with their judgement that the ether was stereochemically related (via its methiodide) to the less basic oxindole **A**; the more basic oxindole **B** predominated after acid treatment, presumably on account of stabilization of its conjugate acid by hydrogen bonding to the oxindole carbonyl group (see Scheme 1). During the course of this investigation, our observation of *two* epimeric imino ethers was confirmed by Herlem and Khuong-Huu (14) who reported ^{13}C nmr spectra of both imino ether and oxindole pairs; one imino ether, which crystallized from a methanolic solution of the isomeric pair, had a melting point similar to that reported for Finch and Taylor's ether and was likewise dextrorotatory; the other ether was separated by preparative tlc but did not crystallize.[17] Herlem and Khuong-Huu express support for the stereochemistry of Finch and Taylor's imino ether and oxindoles, the structures of the latter pair having been earlier reinforced by Zinnes and Shavel (3).

In this study both imino ethers were obtained pure by preparative tlc and examined by nmr. While excellent ^1H nmr spectra[18] could be obtained from freshly prepared solutions of the imino ethers, it was found difficult to get clean ^{13}C nmr spectra using normal concentration and number of scans: invariably one observed the spectrum of the mixture of epimeric ethers, obviously readily isomerized in solution. However, the use of high concentrations and a relatively low number of scans allowed identification of the respective resonances, their relative growth and decay easily observed with the passage of time and leading to the ascendancy of the isomer of higher R_f in $CDCl_3$ and CD_3OD solution.

The isomeric methyl imino ethers **9** and **10** exist at equilibrium in $CDCl_3$ in a ratio of 1.8:1::**9**/**10**, ether **A** (**9**) predominating presumably because of the destabilizing influence of the methoxy–nitrogen lone-pair interaction in ether **B** (**10**).[19] Under acid conditions at room temperature the rapidity of isomerization makes it difficult to observe the kinetic product of chloride-to-ether rearrangement, but data obtained from the reaction in methanolic methoxide medium support the stereospecificity and concerted character of the rearrangement of both isomeric chlorides, α-chloride leading to ether **A** and

[16] We are grateful to Dr. A. J. Bell for suggesting this procedure and for performing preliminary experiments with it.

[17] It seems curious to note that Herlem and Khuong-Huu generate oxindole **A** by refluxing the crystalline imino ether in trifluoroacetic acid, and oxindole **B** by refluxing the same compound in acetic acid. Finch and Taylor found **B** to predominate after acid treatment while **A** was ascendant after reflux in pyridine.

[18] Our observations are at variance with Herlem and Khuong-Huu, who cite values of 3.53 and 3.90 ppm for the chemical shifts of the respective carbomethoxy protons, 4.06 ppm for the imino ether protons, in $CDCl_3$ solution. We find values of 3.56 and 3.52 for carbomethoxy and 4.07 and 4.03, respectively, for imino ether protons. Their reported value of 3.90 (3.49?) is close to that for the carbomethoxy protons of yohimbine (3.96) and would not be consistent with the appreciably greater shielding by the aromatic ring A which is attendant with such significant departure from the plane of rings B, C, and D as obtains in the indolenines and spiro derivatives; the observed difference in chemical shift for β- and α-substituted indolenines (β, 0.7 ppm > α) is not helpful in assigning configuration in the spiro derivatives on account of the smaller shift differences and not strictly analogous stereochemistry.

[19] This rationale is supported by the relative shielding of the imine methoxy protons of ether **B** (**10**); in the ^1H nmr spectrum, **B** protons appear 0.04 ppm upfield.

TABLE 2. High pressure liquid chromatography retention times of yohimbine and its derivatives

Compound	Time (min)
Spiro imino methyl ether A	3.9
9-α-Chloro-9*H*-yohimbine	5.3
9-α-Methoxy-9*H*-yohimbine	7.6
9-β-Chloro-9*H*-yohimbine	9.8
Spiro imino methyl ether B	12.0
Yohimbine	17.6
9-β-Methoxy-9*H*-yohimbine	18.7

β-chloride to ether **B**; for the α-chloride a ratio of as high as 6:1::**A**/**B**[20] was observed at the outset of the reaction while for the β-isomer the initial ratio observed was as low as 0.6, both ratios gradually approaching the equilibrium value as the reaction progressed.

Consistent with the stereochemistry indicated in the mechanistic outline of Scheme 2, rearrangement of chlorodeserpidine in refluxing methanol yielded predominantly imino ether **B** (**11**); ^{1}H nmr examination of the total crude product, soon after completion of the reaction, indicated a ratio of 4:1 for the integrated intensities of proton resonances (4.11 and 4.19 ppm) due to methoxyl groups attached to the C=N bond, the more highly shielded dominant. Preparative tlc allowed separation of the major reaction product (the pair of imino ethers, in their equilibrium ratio of 4:3) from a minor product of lesser R_f, which is probably the pair of corresponding oxindoles[21] resulting from degradation by hydrogen chloride liberated in the course of the rearrangement.

Experimental

Melting points were determined on a Thomas–Hoover capillary melting point apparatus and are uncorrected. Nuclear magnetic resonance spectra were recorded on a Bruker Spectrospin WP-80 spectrometer (chloroform-*d* solvent and tetramethylsilane internal standard) and chemical shifts reported in parts per million on the δ scale, followed by multiplicity, associated number, and assignment of protons, in parenthesis. Mass spectrometry (ms) was performed on a Hewlett–Packard 5985 gc/ms system using the EI mode at 70 eV. Precise mass determinations were performed on a Kratos MS50 system.

High pressure liquid chromatography (hplc) was done on a Laboratory Data Control (LDC) solvent delivery system fitted with a Valco valve and a 20-μL injection loop. An LDC variable-wavelength detector, set at 254 nm, a Honeywell Electronik 196 recorder, and a Spectraphysics Minigrator completed the system. Yohimbine products were chromatographed on a Brownlee Laboratories SI-5A silica column (4.6-mm id × 25 cm) with a mobile phase of hexane, methylene chloride, and 97% aqueous isopropyl alcohol in the ratio 30:7:3. Reserpine and deserpidine products were chromatographed on a Brownlee Laboratories RP-18 column (4.6-mm id × 25 cm) with an 80% aqueous methanol mobile phase. In every case the flow rate was 2 mL/min. Representative hplc retention times for yohimbine and its derivatives are recorded in Table 2.

Satisfactory elemental analyses were obtained for all individual products isolated as well as ms highest mass peaks consistent with their molecular formulation.

Indoles

Yohimbine hydrochloride, reserpine, and deserpidine were obtained commercially and their purity checked by thin-layer chromatography (tlc); yohimbine free base was generated from the hydrochloride by neutralization with bicarbonate and standard work-up, to yield chromatographically pure material whose physical constants were in agreement with literature values.

Chloroindolenines

Chloroindolenines were prepared from indoles using the procedure of Godtfredsen and Vangedal (1) by reaction with commercial *tert*-butyl hypochlorite in the presence of triethylamine. Unique monochlorinated products were obtained from reserpine and deserpidine: 9-chloro-9*H*-reserpine (**4***a*) had mp 178–183°C, ^{1}H nmr: 7.4–6.8 (m, 5H, aromatic H), 3.92 (s, 9H, benzoate-OCH_3), 3.87, 3.85 (s, s, 6H, ring E-OCH_3 and ring E-$COOCH_3$), 3.54 (s, 3H, ring E-OCH_3); ^{13}C nmr: C-1 122.98, C-2 112.31, C-3 161.57, C-4 107.43, C-5 132.21, C-6 154.20, C-8 178.84, C-9 70.32, C-10 37.77, C-11 50.13, C-13 (C-34?) 51.85 (52.08?), C-14 22.23, C-15 34.57, C-16 31.44, C-17 47.06, C-18 53.66, C-19 (C-20?) 77.94 (78.14?), C-21 29.65, C-22 165.48, C-23 125.47, C-24 106.98, C-25 153.03, C-26 142.44, C-27 153.03, C-28 106.98, C-29 56.33, C-30 60.89, C-31 56.33, C-32 60.89, C-33 172.48, C-35 55.70. 9-Chloro-9*H*-deserpidine (**4***b*) had mp 190–196°C (lit. (1) mp 191–196°C); ^{1}H nmr: 7.6–7.2 (m, 6H, aromatic H), 3.92 (s, 9H, benzoate-OCH_3), 3.84 (s, 3H, ring E-$COOCH_3$), 3.54 (s, 3H, ring E-OCH_3); ^{13}C nmr: C-1 126.54, C-2 129.92, C-3 122.57, C-4 121.62, C-5 140.27, C-6 152.60, C-8 177.40, C-9 70.21, C-10 37.49, C-11 50.13, C-13 (C-34?) 51.84 (52.05?), C-14 22.24, C-15 34.55, C-16 31.40, C-17 49.02, C-18 53.60, C-19 (C-20?) 77.91 (78.06?), C-21 29.62, C-22 165.48, C-23 125.48, C-24,28 106.97, C-25,27 153.03, C-29,31 56.33, C-30,32 60.89, C-33 172.44.

*Separation of isomeric 9-chloro-9*H*-yohimbines*

Generally 5.0 g of the crude chlorinated product were applied to a 3 × 50 cm glass column containing 150 g of neutral alumina (Bio-rad AG7), activity III (6% water, by weight). One of two eluent systems was used, namely, methylene chloride followed by methylene chloride – methanol (19:1), or benzene followed by benzene–ether (9:1).

A Büchler Fractomette 200 automatic fraction collector was used to collect the eluent in 10–15-mL portions. The composition of the fractions was monitored by tlc on silica gel GF 254 precoated plates (0.25 mm) using benzene–ether–methanol (7:2:1) as the developing solvent system. Representative yields of chromatographically pure α- and β-chloroyohimbines from such a run were 2.4 g and 0.8 g, respectively.

*9α-Chloro-9*H*-yohimbine* (**2**) had mp 78–82°C; ^{1}H nmr: 7.7–7.0 (m, 4H, aromatic H), 3.77 (s, 3H, OCH_3). (See Table 1 for ^{13}C nmr chemical shifts of yohimbine derivatives.) *Anal.* calcd. for $C_{21}H_{25}N_2O_3Cl$: C 64.86, H 6.48, N 7.20, Cl 9.12; found: C 65.14, H 6.65, N 6.63, Cl 8.69.

*9β-Chloro-9*H*-yohimbine* (**3**) had mp 85–90°C; ^{1}H nmr: 7.7–7.2 (m, 4H, aromatic H), 3.71 (s, 3H, OCH_3). *Anal.* calcd. for $C_{21}H_{25}N_2O_3Cl$: C 64.86, H 6.48, N 7.20, Cl 9.12; found: C 64.22, H 6.49, N 6.76, Cl 9.41.

Methoxyindolenines

The procedure developed by Awang and Vincent (6) was applied to the synthesis of methoxyindolenines from reserpine and yohimbine. Reserpine yielded pure 9β-methoxy-9*H*-reserpine.

*Separation of 9-methoxy-9*H*-yohimbines*

The methoxyyohimbines were separated by preparative tlc on silica gel GF 254 precoated glass plates (1 mm, 20 × 20 cm) using benzene–ether–methanol (7:2:1) as developing solvent system. The resulting discrete bands were eluted with methanol and the extracts

[20] In one freak instance the initial chromatogram for α-chloride reaction showed only ether **A** and none of ether **B**. This is consistent with the results of α-chloride reaction with methanol at −5°C, discussed earlier in the text.

[21] Cleavage of the C9—C13 bond of spiro imino ethers and oxindoles according to Finch and Taylor's mechanism (2), affords the opportunity for isomerization at C-13. However, in the case of deserpidine such isomerization would lead to unstable boat forms of ring C.

evaporated to dryness. Representative yields of chromatographically pure α- and β-methoxyyohimbines were 125 mg and 225 mg, respectively, from 500 mg of the crude mixture.

9α-Methoxy-9H-yohimbine had mp 70–74°C; ^{1}H nmr: 7.8–7.0 (m, 4H, aromatic H), 3.76 (s, 3H, $COOCH_3$), 2.83 (s, 3H, OCH_3); ms M^+: 384.2051 (calcd. for $C_{22}H_{28}N_2O_4$: 384.2049).

9β-Methoxy-9H-yohimbine had mp 88–92°C; ^{1}H nmr: 7.8–7.0 (m, 4H, aromatic H), 3.69 (s, 3H, $COOCH_3$), 2.83 (s, 3H, OCH_3); ms M^+: 384.2051 (calcd. for $C_{22}H_{28}N_2O_4$: 384.2049).

9α-Acetoxy-9H-yohimbine

To 0.25 g (1.4 mmol) of yohimbine dissolved in 25 mL of methylene chloride was added 0.626 g (1.4 mmol) of lead tetraacetate, with stirring. After a couple of minutes the contents of the reaction vessel were filtered and the filtrate passed through 13.0 g of neutral alumina, activity III, in a 6 × 15 cm glass column. The column was eluted with 4 × 50-mL portions of methanol, and the collected fractions (5 mL) analyzed by tlc. All fractions containing only reaction product were combined and the solvent removed under reduced pressure. The resultant colourless crystalline residue had mp 118–120°C (lit. (15) mp 123–124°C); ^{1}H nmr: 7.8–7.0 (m, 4H, aromatic H), 3.76 (s, 3H, $COOCH_3$), 2.05 (s, 3H, CH_3—COO).

Reaction of chloroindolenines with methanolic hydroxide

*Chloroyohimbines (**2**, **3**)*

A solution of 400 mg of chloroyohimbine in 10 mL of methanol was treated with 2.25 mL of 0.43 *N* potassium hydroxide. The resulting solution was refluxed under nitrogen for 90 min, at the end of which it was allowed to cool to room temperature, diluted with a roughly equivalent volume of water, and extracted with methylene chloride. The organic layer was dried over anhydrous sodium sulphate and the dried filtrate evaporated to dryness under reduced pressure.

*Chlorodeserpidine (**4**b)*

A solution of 1.30 g of chlorodeserpidine in 80 mL of methanol was treated with 18.0 mL of 0.43 *N* potassium hydroxide. The resulting solution was refluxed for 90 min under nitrogen and worked up as described above for the chloroyohimbines.

*Chlororeserpine (**4**a)*

A solution of 1.0 g of chlororeserpine in 30 mL of methanol was treated with 4.0 mL of 0.43 *N* potassium hydroxide. The resulting solution was refluxed under nitrogen for 1 h (after approximately 45 min some precipitation was noticeable). At the end of the refluxing period the reaction vessel was cooled in an ice bath, the precipitate filtered, washed with a minimum of cold methanol, and left to dry in the open air.

Separation of isomeric methyl spiro imino ethers of yohimbine

The product of methanolysis of 9α-chloro-9*H*-yohimbine was chromatographed as previously described for the separation of methoxyyohimbines. The separated isomers assessed by analytical tlc were chromatographically pure just after separation but isomerized rapidly in solution. As observed by previous workers, the faster-moving α isomer (N=OCH_3 group *below* the plane of the yohimbine skeleton) had mp in the vicinity of 200°C (194–198°C), whereas the β isomer did not crystallize (14).

*α-Iminoether (**9**)*: ^{1}H nmr: 7.6–7.0 (m, 4H, aromatic H), 4.06 (s, 3H, N=C—OCH_3), 3.55 (s, 3H, $COOCH_3$) (ref. 14).

*β-Iminoether (**10**)*: ^{1}H nmr: 7.4–6.9 (m, 4H, aromatic H), 4.09 (s, 3H, N—C—OCH_3), 3.58 (s, 3H, $COOCH_3$) (ref. 14).

Reaction of chloroindolenines with neat methanol

A solution of 50–200 mg of chlorindolenine was dissolved in 5 mL methanol and the solution refluxed under nitrogen. Aliquots were withdrawn periodically, evaporated to dryness under reduced pressure, dissolved in methylene chloride, and analyzed by hplc. When reaction was complete the reaction vessel was cooled and the product isolated from solvent. In the case of chlororeserpine the product precipitated upon cooling and was filtered off, washed with cold methanol, and dried in the open air prior to hplc analysis; in all other cases the solution was treated in the same manner as the periodic aliquots.

Reaction of chloroyohimbines with silver oxide

To 25 mg (0.064 mmol) of chloroyohimbine dissolved in 1 mL of methanol was added 25 mg (0.11 mmol) of silver oxide. The reaction mixture was sampled periodically, the sample filtered through glass wool, and the filtrate evaporated to dryness under a stream of dry nitrogen. The residues were dissolved in methylene chloride and analyzed by hplc.

Reaction of chloroyohimbines with sodium methoxide at low temperature

A 50-mg (0.13 mmol) sample of chloroyohimbine dissolved in a minimum of cold methanol was added to 10 mg (0.19 mmol) of sodium methoxide, dissolved in 5 mL of methanol and cooled to −10°C in an ice–salt bath. After 3 h at −10°C the reactions were transferred to a refrigerator (15°C). Aliquots taken from the reaction medium were quenched with water, extracted with methylene chloride, dried, and analyzed by hplc.

Reaction of chloroindolenines with methanol at −5°C

Chloroyohimbines

To 200 mg of chloroyohimbine, dissolved in 5 mL of methylene chloride and cooled to −5°C in an ice bath, was added dropwise, over a period of roughly 10 min, 10 mL of cold methanol. After 5 h at −5°C the reaction solution was transferred to the freezing compartment of a refrigerator (−5°C). Periodic aliquots of the solution were withdrawn, evaporated to dryness, dissolved in methylene chloride, and analyzed by hplc. Upon completion of the reaction, solvent was removed under reduced pressure, the residue dissolved in chloroform, washed with saturated aqueous sodium bicarbonate, dried over anhydrous sodium sulphate, and evaporated to dryness.

Chlorodeserpidine

By a procedure essentially similar to that outlined above for the chloroyohimbines, 20 mL of cold methanol were added dropwise to 150 mg of chlorodeserpidine dissolved in 5 mL of methylene chloride at −5°C, under nitrogen, an additional 5 mL of methylene chloride being required to maintain solution of chlorodeserpidine.

Acknowledgements

The authors acknowledge the technical assistance of Mssrs. H. Avdovich, H. D. Beckstead, J.-C. Ethier, and D. Legault, and helpful discussions with Drs. A. By, G. A. Neville, and N. Beaulieu, all of the Bureau of Drug Research, Health and Welfare Canada, Ottawa. Special thanks are due to Dr. A. Bell for her contribution to the silver oxide aspect of our studies, Mr. H. Séguin of the National Research Council of Canada for conducting elemental analyses, and Mr. W. Miles of Agriculture Canada for conducting precise mass determinations.

The total synthesis of (±)-petasitolone

HSING-JANG LIU AND TENG KO NGOOI
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received March 5, 1984

HSING-JANG LIU and TENG KO NGOOI. Can. J. Chem. **62**, 2676 (1984).

The total synthesis of petasitolone (**1**), a sesquiterpenoid of the eremophilane family, has been accomplished. The key step of this efficient synthesis is the Lewis acid catalyzed Diels–Alder addition of 2-carbomethoxy-2-cyclohexenone (**3**) to diene **9**. The cycloaddition, which gives adduct **16** in good yield, facilitates the rapid construction of the parent ring system of the target molecule and allows an excellent control of the required stereochemistry.

HSING-JANG LIU et TENG KO NGOOI. Can. J. Chem. **62**, 2676 (1984).

On a réalisé la synthèse totale de la pétasitolone (**1**), un sesquiterpène de la famille de l'érémophilane. L'étape fondamentale de cette synthèse efficace est une addition de Diels–Alder, catalysée par un acide de Lewis, de la carbométhoxy-2 cyclohexène-2 one (**3**) sur le diène **9**. La cycloaddition, qui conduit à l'adduit **16** avec un bon rendement, facilite l'édification rapide du système cyclique parent de la molécule recherchée et permet un excellent contrôle de la stéréochimie requise.

[Traduit par le journal]

We wish to report the first total synthesis, in racemic form, of petasitolone (**1**), a sesquiterpene of the eremophilane family which has been isolated from *Petasites japonicus* Maxim (1). The synthesis also demonstrates a new approach to eremophilane sesquiterpenes which are widely distributed in nature (2). These naturally occurring compounds have attracted a great deal of synthetic effort during the past two decades (3). Although a rapid construction of the required decalin framework can conceivably be achieved by an intermolecular Diels–Alder reaction, the difficulty[1] in controlling the desired *cis* stereochemistry of the vicinal methyl groups has hampered the efficient use of such an approach to the synthesis of eremophilanes. During a recent study of the dienophilicity of 2-carbomethoxy-2-cyclohexenone (**3**) (5), it was observed that the Diels–Alder reactions of this enone ester with 1-substituted and 1,3-disubstituted dienes led, in each case, to the preferential formation of the adduct that arose from secondary orbital overlap between the diene and the ester moeity of **3**. For example, its reaction with *trans*-piperylene at −78°C and under stannic chloride catalysis gave a 5:3 mixture of adducts **4** and **5**. The major adduct **4**, which has the all-*cis* stereochemistry for the three contiguous chiral centers, was formed by *endo* addition of the diene to the ester group of **3**. It was also observed that addition of *trans*-2-methyl-1,3-pentadiene to enone ester **3** under the same conditions led to a mixture of adducts **6** and **7**. In this case, an improved stereoselectivity of 13:1 in favor of adduct **6** was obtained. The remarkable ability of the ester group to reverse the course of stereoselectivity normally observed for 2-cyclohexenones makes possible the direct control of the eremophilane stereochemistry using a Diels–Alder reaction. This is illustrated with the efficient total synthesis of petasitolone described below.

Although the Diels–Alder reaction of enone ester **3** and *trans*-piperylene resulted in the preferential formation of adduct **4** possessing the desired stereochemistry, the degree of selectivity was rather unsatisfactory. Since 1,3-disubstituted dienes were shown to be more stereoselective (*vide supra*), two such dienes **8** (6) and **9**[2] were chosen as the diene component

[1] The reaction of 2-methyl-2-cyclohexenone with *trans*-piperylene, for instance, gave predominantly adduct **2** (4). With the far less reactive *cis*-piperylene, no significant reaction was observed (unpublished results of this laboratory).

[2] Diene **9** was prepared in 44% yield by trapping the kinetic enolate of *trans*-3-penten-2-one, generated *in situ* in tetrahydrofuran at −78°C using lithium diisopropylamide as a base, with diethylchlorophosphate. This diene is rather stable and can be purified by silica gel chromatography.

in the reaction. In each case, the additional substituent at C-2, after serving as an element for stereochemical control, could be easily removed.

Treatment of enone ester **3** with diene **8** (5 equiv.) in ether–dichloromethane (1:1) in the presence of stannic chloride (0.5 equiv.) at −50°C for 6 h gave, after aqueous work-up, an inseparable mixture of diketones **10** and **11** in 46% yield and in 7:1 ratio (^{1}Hmr analysis). The mixture was treated with 5 equiv. of 1,2-ethanedithiol and 1 equiv. of boron trifluoride etherate in methylene chloride at 0°C for 30 min to effect the selective thioketalization of the less hindered ketone carbonyl. Desulfurization of the resulting thioketals **12** and **13** (7:1; 90% yield) with W-2 Raney nickel (7) in refluxing ethanol gave, after chromatographic separation, a 60% yield of the desired keto ester **14** along with a small amount (~9%) of its epimer **15**[3].

A shorter and more efficient route leading to the desired keto ester **14** involves the stannic chloride catalyzed addition of enone ester **3** to diene phosphate **9**[4]. When the reaction was carried out in ether at −30°C for 6 h using 1.5 equiv. of the diene and 0.5 equiv. of the catalyst, it afforded a 6:1 mixture of adducts **16** and **17** in 66% yield. Treatment of the mixture with Adams catalyst in ethyl acetate at 1 atmosphere (101.3 kPa) of hydrogen pressure resulted in the reduction of the double bond as well as the cleavage of the phosphoryloxy group (9) to give keto esters **14** and **15** in 76% and 11% yield respectively.

Reduction of keto ester **14** with sodium bis(2-methoxyethoxy)aluminum hydride in ether at 0°C gave almost quantitatively a single crystalline diol (mp 97–99°C) showing 12 lines in the ^{13}Cmr spectrum. Assuming that the reduction of the ketone carbonyl occurred from the sterically less-hindered convex face of the molecule, the resulting diol would have the relative stereochemistry as shown in structure **18** in which the proton adjacent to the secondary hydroxyl group would be axial. This was confirmed by the presence, in the ^{1}Hmr spectrum, of a doublet of doublets at δ 3.83 with a large diaxial coupling constant of 14 Hz and a small axial–equatorial coupling constant of 6 Hz.

Selective mesylation of the primary hydroxyl group of diol **18** was effected by treatment with 1 equiv. of methanesulfonyl chloride in pyridine–dichloromethane (1:10) at −20°C. Jones oxidation of hydroxy mesylate **19** thus obtained in 86% yield afforded the corresponding keto mesylate **20** (85% yield). This compound was subjected to reduction with zince dust and sodium iodide (10) in refluxing *N*,*N*-dimethylformamide (DMF). Two isomeric products were obtained. The major isomer isolated in 60% yield was characterized as the expected ketone **21** and the minor isomer (21% yield) was found to possess the interesting structure of cyclopropanol **22**. This compound was readily converted into ketone **21** upon treatment with aqueous sodium hydroxide in refluxing DMF.

Carbomethoxylation of ketone **21** with dimethyl carbonate and sodium hydride in refluxing benzene gave an 88% yield of two epimeric keto esters **23** existing partially in the corresponding enol form. Sodium borohydride reduction of this mixture furnished two isomeric alcohols, **24** in 20% yield and **25** in 69% yield. The stereochemical assignments were made based on the following spectral data. In the ^{1}Hmr spectrum of the minor alcohol, a signal appearing at δ 3.62 as a doublet of doublets with coupling constants of 6 and 5 Hz was assigned to the proton adjacent to the hydroxyl group. Another signal, due to the methine proton on the α-carbon of the methyl ester, appeared at δ 2.83 as a multiplet. It showed discernible coupling constants of 10 and 5 Hz. A third signal due to the hydroxyl proton appeared at δ 3.35 as a doublet (J = 6 Hz). On deuterium exchange with D_2O, this latter signal disappeared and the signal at δ 3.62 collapsed to a doublet with a coupling constant of 5 Hz. This observation indicated that the proton on the carbon bearing the hydroxyl group was equatorially disposed. Together with the presence of a diaxial coupling constant of 10 Hz for the signal at δ 2.83, it led to the assignment of the structure **24** for the minor alcohol, where the methine proton (at δ 2.83) on the α-carbon of the methyl ester would be axial. The major isomer showed, in the ^{1}Hmr spectrum, a

[3] Compounds **14** and **15** were found to be identical respectively with the products obtained from the hydrogenation of unsaturated keto esters **4** and **5** carried out with W-2 Raney nickel in ethanol.

[4] It is worth noting that very few phosphoryloxy-substituted dienes have been used in Diels–Alder reactions. The only known example is that derived from methyl vinyl ketone (8).

signal at δ 2.73 which was assigned to the methine proton on the α-carbon of the methyl ester. It appeared as a doublet of doublets of doublets with coupling constants of 13, 11, and 4.5 hz. The presence of two large coupling constants of 13 and 11 Hz indicated that this proton was axial and further coupled to two adjacent axial protons. One of these axial protons had to be on the carbon bearing the hydroxyl group. That this was so, was confirmed by the presence of a signal at δ 3.53 with coupling constants of 11 and 4.5 assigned to the proton adjacent to the hydroxyl group. On deuterium exchange with D_2O, this signal collapsed to a doublet with a coupling constant of 11 Hz and the doublet at δ 2.46 (J = 4.5 Hz) disappeared.

Treatment of a mixture of alcohols **24** and **25** (~2:7) with dicyclohexylcarbodiimide in refluxing DMF in the presence of a small amount of copper(I) chloride (11) afforded unsaturated ester **26** in 75% yield. Introduction of an oxygen functionality to the allylic carbon of this compound was achieved with selenium dioxide oxidation. When **26** was reacted with an excess of selenium dioxide in refluxing acetic acid for two days, the crystalline acetate **27** (mp 119–120°C) was isolated in 61% yield. The stereochemistry of the newly created asymmetric center was assigned on the basis of the ^{1}Hmr spectrum in which the allylic proton appeared at δ 5.74 as a doublet of doublets with small coupling constants of 4 and 1.5 Hz indicating the equatorial disposition of this proton.

Acetate **27** was converted into petasitolone (**1**) as follows. Treatment of **27** with excess methyllithium in tetrahydrofuran at −78°C resulted in the formation of diol **28** in 93% yield. Oxidation of this diol with 8 *N* Jones reagent (12) gave rise to a 79% yield of (±)-petasitolone (**1**) whose ir, ^{1}Hmr, and ^{13}Cmr spectral data were found to be in agreement with those of the natural material.

Experimental

General

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. Elemental analyses were performed by the microanalytical laboratory of this department. Infrared (ir) spectra were recorded on a Perkin–Elmer model 457 or Nicolet 7-199 FT-IR spectrophotometer and, except where otherwise stated, were obtained on solutions in carbon tetrachloride. Proton nuclear magnetic resonance (^{1}Hmr) spectra were recorded on Varian HA-100, HA-100/Digilab, Bruker WH-200 and WH-400 spectrometers. Unless otherwise stated, deuterochloroform was used as solvent and tetramethylsilane as internal standard. Carbon-13 nuclear magnetic resonance (^{13}Cmr) spectra were recorded on a Bruker WH-200, WH-400, or Bruker HFX-90/Nicolet 1085 system and were obtained on solutions in deuterochloroform using tetramethylsilane as internal reference. Mass spectra (ms) were recorded using A.E.I. model MS9, MS12, or MS50 mass spectrometers. Chemical ionization mass spectra (cims) were recorded on an AEI-MS12 spectrometer using ammonia gas as the ionizing medium. Unless otherwise stated, anhydrous magnesium sulfate was used for drying organic solutions.

Materials

Benzene, ether, and tetrahydrofuran were freshly distilled over lithium aluminum hydride. Pyridine was distilled over barium oxide and stored over potassium hydroxide pellets. Methylene chloride used for reactions was washed with an equal volume of 10% aqueous sodium carbonate and distilled over powdered calcium chloride. Acetone was treated with potassium permanganate, dried over anhydrous potassium carbonate, and distilled. Diisopropylamine was distilled over calcium hydride. *N,N*-Dimethylformamide was distilled over phosphorus pentoxide. Methanol and ethanol were dried over magnesium turnings at elevated temperature and distilled. Enone ester **3** was prepared from 2-carbomethoxycyclohexanone according to the reported procedure (13).

*8aβ-Carbomethoxy-8β-methyl-2,3,4,4aβ,5,7,8,8a-octahydro-1,6-naphthalenedione (**10**) and 8aβ-carbomethoxy-8α-methyl-2,3,4,4aβ,5,7,8,8a-octahydro-1,6-naphthalenedione (**11**)*

At −50°C, anhydrous stannic chloride (261 mg, 1 mmol) was added to a solution of enone ester **3** (369 mg, 2 mmol) and *trans*-2-trimethylsilyloxy-1,3-pentadiene (**8**) (936 mg, 6 mmol) in ether and methylene chloride (2.5 mL each). An additional amount of **8** (624) mg, 4 mmol) in a 1:1 mixture of ether and methylene chloride (5 mL) was added. After stirring under an atmosphere of argon for 6 h, the reaction mixture was warmed to room temperature and water was added. The resulting mixture was extracted with methylene chloride. The organic extracts were dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 10–15% ethyl acetate in *n*-hexane, gave an impure mixture of **10** and **11**. Another purification by flash chromatography on silica gel, eluting with 10% ethyl acetate in *n*-hexane, gave a 7:1 mixture (by ^{1}Hmr integration) of diketones **10** and **11** (218 mg; 46% yield). The mixture of diketones **10** and **11** showed the following spectral data: ir: 1740 (ester C=O) and 1714 (ketone C=O) cm^{-1}; ms: M$^+$ 238.1205 (calcd. for $C_{13}H_{22}O_4$: 238.1205). The ^{1}Hmr spectrum showed two sets of signals in an integral ratio of 7:1. The major set, assignable to **10**, showed signals at δ 3.73 (s, 3H, —$COOCH_3$) and 0.90 (d, 3H, J = 7 Hz, —CH_3) and the minor set, attributed to **11**, showed signals at δ 3.82 (s, 3H, —$COOCH_3$) and 1.15 (d, 3H, J = 7 Hz, —CH_3).

*8aβ-Carbomethoxy-6,6-ethylenedithio-8β-methyl-3,4,4aβ,5,6,7,8,8a-octahydro-1(2H)-naphthalenone (**12**) and 8aβ-carbomethoxy-6,6-ethylenedithio-8α-methyl-3,4,4aβ,5,6,7,8,8a-octahydro-1(2H)-naphthalenone (**13**)*

At 0°C, 1,2-ethanedithiol (333 mg, 3.54 mmol) and boron trifluoride etherate (104 mg, 0.73 mmol) were sequentially added to a solution of a 7:1 mixture of diketones **10** and **11** (167 mg, 0.7 mmol) in methylene chloride (10 mL). After stirring under an atmosphere of argon for 30 min, the reaction mixture was poured into ice-cold 2 *N* aqueous sodium hydroxide and extracted with methylene chloride. The organic extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 5% ether in *n*-hexane, gave a 7:1 mixture of thioketals **12** and **13** (198 mg; 90% yield) which showed the following spectral data: ir: 1740 (ester C=O) and 1713 (ketone C=O) cm^{-1}; ms: M$^+$ 314.1008 (calcd. for $C_{15}H_{22}O_3S_2$: 314.1010). The ^{1}Hmr spectrum of the mixture showed two sets of signals in an integral ratio of 7:1. The major set, attributed to **12**, consisted of signals at δ 3.74 (s, 3H, —$COOCH_3$) and 1.02 (d, 3H, J = 7.5 Hz, —CH_3). The minor set, attributed to **13**, showed signals at δ 3.80 (s, 3H, —$COOCH_3$) and 1.10 (d, 3H, J = 7.5 Hz, —CH_3).

Diethyl trans*-1,3-pentadien-2-yl phosphate (**9**)*

To a solution of diisopropylamine (4.1 g, 40.3 mmol) in tetrahydrofuran (50 mL) at −78°C and under an atmosphere of argon, was added a 1.1 *M* solution of methyllithium in *n*-hexane (36.3 mL, 40.3 mmol) with stirring. After 10 min, a solution of *trans*-3-penten-2-one (3.1 g, 36.7 mmol) in tetrahydrofuran (20 mL) was added dropwise over 10 min. After another 15 min, diethylchlorophosphate (13.8 g, 80 mmol) was added. The reaction mixture was allowed to warm up to room temperature. Ice-cold water was added and the resulting mixture extracted with *n*-pentane. The organic extracts were washed with water, dried, filtered, and concentrated. Flash chromatography of the resulting dark yellow oil, eluting with a solution of 50% ether in petroleum ether, gave diene **9** (3.5 g, 44% yield); ir: 1275 and 1270 (P=O) cm^{-1}; ^{1}Hmr δ: 5.70–6.32 (m, 2H, —CH=CH—), 4.82, 4.60 (both m, 1H each, =CH_2), 4.17 (dq, 4H, $J = J'$ = 7 Hz, 2 × —CH_2—), 1.80 (d, 3H, J = 5.5 Hz, =CH—CH_3), and 1.35 (t, 6H, J = 7 Hz, 2 × —OCH_2CH_3); ms: M$^+$ 220.0865 (calcd. for $C_9H_{17}O_4P$: 220.0865).

*8aβ-Carbomethoxy-6-diethylphosphoryloxy-8β-methyl-3,4,4aβ,5,8,8a-hexahydro-1(2H)-naphthalenone (**16**) and 8aβ-carbomethoxy-6-diethylphosphoryloxy-8α-methyl-3,4,4aβ,5,8,8a-hexahydro-1(2H)-naphthalenone (**17**)*

At −30°C, anhydrous stannic chloride (294 mg, 1.13 mmol) was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

added to a solution of enone ester **3** (348 mg, 2.26 mmol) and diene phosphate **9** (698 mg, 3.17 mmol) in ether (10 mL). After stirring under an atmosphere of nitrogen for 6 h, the reaction mixture was warmed to room temperature. Water was added and the resulting mixture extracted with methylene chloride. The organic extracts were combined, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with 50% ethyl acetate in *n*-hexane, gave diene **9** (180 mg; 26% recovery). Continued elution gave a mixture of enol phosphates **16** and **17** (555 mg; 66% yield) in a ratio of 6:1. The mixture showed the following spectral data: ir: 1750 (ester C=O) and 1720 (ketone C=O) cm^{-1}; ms: M^+ 374.1495 (calcd. for $C_{17}H_{27}O_7$: 374.1495). The ^{1}Hmr spectrum of the mixture of adducts showed two sets of signals in an integral ratio of 6:1. The major set, assignable to **16**, showed signals at δ 5.47 (m, 1H, =CH—), 4.15 (m, 4H, 2 × —OCH_2—), 3.75 (s, 3H, —$COOCH_3$), 1.37 (t, 6H, J = 7 Hz, 2 × —OCH_2CH_3), and 0.92 (d, 3H, J = 7 Hz, —CH_3); the other set, assignable to **17**, showed signals at δ 5.34 (m, 1H, =CH—), 4.15 (m, 4H, 2 × —OCH_2—), 3.80 (s, 3H, —$COOCH_3$), 1.37 (t, J = 7 Hz, 6H, 2 × —OCH_2CH_3), and 1.24 (d, 3H, J = 7 Hz, —CH_3).

*aβ-Carbomethoxy-8β-methyl-3,4,4aβ,5,6,7,8,8a-octahydro-1(2H)-naphthalenone (**14**) and 8aβ-carbomethoxy-8α-methyl-3,4,4aβ,5,6,7,8,8a-octahydro-1(2H)-naphthalenone (**15**)*

*From thioketals **12** and **13***

Raney nickel (ca. 2 g; grade W-2) was added to a solution of a 7:1 mixture of thioketals **12** and **13** (181 mg, 0.58 mmol) in ethanol (10 mL). The resulting mixture was heated to reflux under a nitrogen atmosphere for 2.5 h. Filtration and concentration gave a light yellow oil which was purified by column chromatography on silica gel. Elution with 1–2% ether in *n*-hexane gave keto ester **15** (11 mg; 9% yield) as a colorless oil; ir (neat): 1739 (ester) and 1712 (ketone) cm^{-1}; ^{1}Hmr δ 3.79 (s, 3H, —$COOCH_3$) and 1.18 (d, 3H, J = 7 Hz, —CH_3); ms: M^+ 224.1410 (calcd. for $C_{13}H_{20}O_3$: 224.1407). Continued elution gave the keto ester (78 mg; 60% yield) which crystallized on standing, mp 37–39°C; ir: 1740 (ester) and 1714 (ketone) cm^{-1}; ^{1}Hmr δ 3.72 (s, 3H, —$COOCH_3$) and 0.86 (d, 3H, J = 7 Hz, —CH_3); ms: M^+ 224.1411 (calcd. for $C_{13}H_{20}O_3$: 224.1407). *Anal.* calcd. for $C_{13}H_{20}O_3$: C 69.91, H 8.99; found: C 69.77, H 9.01.

*From enol phosphates **16** and **17***

A 6:1 mixture of enol phosphates **16** and **17** (528 mg, 1.41 mmol) was dissolved in ethyl acetate (20 mL) and platinum oxide (52 mg) was added. The reaction mixture was hydrogenated at 1 atmosphere of hydrogen pressure for 1 h. Filtration and concentration gave an oil which was purified by flash chromatography on silica gel. Elution with 10% ether in petroleum ether gave keto ester **15** (35 mg; 11% yield). Continued elution gave the isomeric keto ester **14** (241 mg; 76% yield).

*1α-Hydroxy-8aβ-hydroxymethyl-8β-methyl-1,2,3,4,4aβ,5,6,7,8,8a-perhydronaphthalene (**18**)*

At 0°C, a 3.5 *M* solution of sodium bis(2-methoxyethoxy)-aluminium hydride in toluene (2.5 mL, 8.75 mmol) was added to a solution of keto ester **14** (340 mg, 1.53 mmol) in tetrahydrofuran (20 mL). After stirring under an atmosphere of nitrogen for 8 h, the reaction mixture was cooled to 0°C and ice-cold water was added to destroy excess reducing agent. Ice-cold aqueous 2 *N* hydrochloric acid was added and the resulting mixture extracted with ether. The ethereal extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 50% ether in *n*-hexane, gave diol **18** (289 mg; 96% yield). Recrystallization from a solution of ether and petroleum ether gave white needles of pure **18**, mp 97–99°C; ir: 3317 (—OH) cm^{-1}; ^{1}Hmr δ: 4.35 (d, 1H, J = 12 Hz, —CH*H*—OH), 3.83 (dd, 1H, J = 14, J' = 6 Hz, —C*H*—OH), 3.71 (d, 1H, J = 12 Hz, —C*H*H—OH), 2.74, 2.26 (both br s, 1H each, 2 × —OH), and 1.17 (d, 3H, J = 7 Hz, —CH_3); ^{13}Cmr δ: 79, 66, 44, 38, 32, 30, 29, 27, 26, 25, 21, and 19; ms *m/e*: 180.1517 (M^+ − 18; calcd. for $C_{12}H_{20}O$: 180.1515). *Anal.* calcd. for $C_{12}H_{22}O_2$: C 72.68, H 11.18; found: C 72.58, H 11.06.

*1α-Hydroxy-8aβ-methanesulfonyloxymethyl-8β-methyl-1,2,3,4,4aβ,5,6,7,8,8a-perhydronaphthalene (**19**)*

Diol **18** (215 mg, 1.08 mmol) was dissolved in methylene chloride (10 mL) and cooled to −10°C. Pyridine (1 mL) and methanesulfonyl chloride (120 mg, 1.08 mmol) were sequentially added. After stirring under an atmosphere of argon for 28 h, the reaction mixture was warmed to 0°C. A solution of 2 *N* aqueous hydrochloric acid was added and the resulting mixture extracted with methylene chloride. The organic extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 50% ether in *n*-hexane, gave mesylate **19** (274 mg; ~86% yield based on consumed starting material) which was contaminated with a small amount (~10%) of the regioisomer. Continued elution gave diol **18** (11 mg, 5% recovery). The following spectral data were recorded for **19**: ir: 3550 (—OH), 2357 and 1173 (S=O) cm^{-1}; ^{1}Hmr δ: 4.73, 4.48 (both d, 1H each, J = 10 Hz each, CH_2O—), 3.68 (m, 1H, —C*H*OH), 3.08 (s, 3H, —OSO_2CH_3), and 1.01 (d, 3H, J = 7 Hz, —CH_3); ms *m/e*: 180.1514 (M^+ − 96; calcd. for $C_{12}H_{20}O$: 180.1515) and 162.1408 (M^+ − 114; calcd. for $C_{12}H_{18}$: 162.1409).

*8aβ-Methanesulfonyloxymethyl-8β-methyl-3,4,4aβ,5,6,7,8,8a-1(2H)-naphthalenone (**20**)*

Mesylate **19** (260 mg, ~90% pure, ~0.85 mmol) was dissolved in acetone (8 mL) and cooled to 0°C. Jones reagent (2 mL of 8 *N*, 16 mmol) was added. After stirring for 30 min, the reaction mixture was diluted with ice-cold water and extracted with methylene chloride. The organic extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 30% ether in *n*-hexane, gave pure keto mesylate **20** (199 mg, ~85% yield); ir (neat): 1703 (C=O), 1356 and 1175 (S=O) cm^{-1}; ^{1}Hmr δ: 4.70, 4.33 (both d, 1H each, J = 9 Hz each, —CH_2O—), 3.10 (s, 3H, —OSO_2CH_3), and 0.68 (d, 3H, J = 7 Hz, —CH_3); ms: M^+ 274.1233 (calcd. for $C_{13}H_{22}O_4S$: 274.1233).

*8β,8aβ-Dimethyl-3,4,4aβ,5,6,7,8,8a-octahydro-1(2H)-naphthalenone (**21**) and 1α-hydroxy-1β,8aβ-methano-8β-methyl-1,2,3,4,4aβ,5,6,7,8,8a-perhydronaphthalene (**22**)*

Keto mesylate **20** (170 mg, 0.62 mmol), anhydrous sodium iodide (930 mg, 6.20 mmol), and zinc dust (811 mg, 12.4 mmol) were placed in *N,N*-dimethylformamide (10 mL). The resulting mixture was heated to reflux under a nitrogen atmosphere for 52 h. After cooling to room temperature, the reaction mixture was filtered. The organic filtrate was washed with ice-cold 2 *N* aqueous hydrochloric acid and water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 2% ether in *n*-hexane, gave ketone **21** (67 mg; 60% yield); ir: 1706 (C=O) cm^{-1}; ^{1}Hmr δ: 1.08 (s, 3H, —CH_3) and 0.67 (d, 3H, J = 7 Hz, —C*H*CH_3); ^{13}Cmr δ: 216.0, 51.0, 45.0, 38.0, 31.7, 30.0, 26.8, 26.4, 21.0, 16.0, and 14.6; ms: M^+ 180.1515 (calcd. for $C_{12}H_{20}O$: 180.1509). Further elution with 5% ether in *n*-hexane gave cyclopropanol **22** (23 mg; 21% yield); ir: 3443 (—OH) cm^{-1}; ^{1}Hmr δ: 1.07 (d, 3H, J = 7 Hz, —C*H*CH_3), 0.69 (d, 1H, J = 5.5 Hz, cyclopropyl H), and 0.25 (dd, 1H, J = 5.5, J' = 1.5 Hz, cyclopropyl H); ms: M^+ 180.1521 (calcd. for $C_{12}H_{20}O$: 180.1509).

*Conversion of cyclopropanol **22** to ketone **21***

A solution of cyclopropanol **22** (21 mg, 0.12 mmol) and sodium hydroxide (25 mg, 0.63 mmol) in water and *N,N*-dimethylformamide (1:2; 2 mL) was heated to reflux under a nitrogen atmosphere. After 8 h, the reaction mixture was cooled to room temperature and diluted with *n*-hexane. A saturated aqueous ammonium chloride solution was added and the resulting mixture separated. The aqueous phase was extracted with *n*-hexane. The organic extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 2% ether in *n*-hexane, gave the ketone **21** (10 mg; 48% yield).

*2-Carbomethoxy-8β,8aβ-dimethyl-3,4,4aβ,5,6,7,8,8a-octahydro-1(2H)-naphthalenones (**23**)*

Sodium hydride (60% dispersion in oil, 0.57 g, 14.3 mmol) was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

added to a solution of dimethyl carbonate (4.3 g, 47.8 mmol) in benzene (50 mL) under a nitrogen atmosphere. The resulting mixture was heated to reflux. A solution of ketone **21** (733 mg, 4.07 mmol) in benzene (20 mL) was added dropwise over 20 min. After refluxing for 50 h, the reaction mixture was cooled to 0°C and methanol was added with vigorous stirring to destroy excess sodium hydride. An ice-cold aqueous 10% solution of acetic acid was added. The resulting mixture was extracted with methylene chloride. The organic extracts were washed with water, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with 2% ether in petroleum ether, gave a mixture of two epimeric keto esters **23** and the corresponding enol (890 mg; 88% yield). The ^{1}Hmr spectrum showed three sets of signals corresponding to the three compounds. Signals appeared at δ 12.72 (s, ~0.5H, enolic H), 3.74, 3.73, 3.70 (each s, total 3H, —$COOCH_3$), 1.15, 1.11, 1.05 (each s, total 3H, —CH_3), 0.95, 0.73, and 0.66 (each d, total 3H, —$CHCH_3$); ir: 1748, 1702, 1640 and 1604 (β-keto ester) cm^{-1}; ms: M^+ 238.1572 (calcd. for $C_{14}H_{22}O_3$: 238.1563). *Anal.* calcd. for $C_{14}H_{22}O_3$: C 70.56, H 9.30; found: C 70.27, H 9.31.

*2β-Carbomethoxy-1β-hydroxy-8β,8aβ-dimethyl-1,2,3,4,4aβ,5,6,7,8,8a-perhydronaphthalene (**24**) and 2β-carbomethoxy-1α-hydroxy-8β,8aβ-dimethyl-1,2,3,4,4aβ,5,6,7,8,8a-perhydronaphthalene (**25**)*

A mixture of keto esters **23** and the corresponding enol (65 mg, 0.27 mmol) obtained from the preceding experiment was dissolved in methanol (2 mL). The solution was cooled to 0°C and sodium borohydride (33 mg, 0.87 mmol) was added with stirring. After 30 min, water and then saturated aqueous ammonium chloride were introduced. The resulting mixture was extracted with methylene chloride. The organic extracts were washed with water, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with 10% ether in petroleum ether, gave alcohol **24** (13 mg, 20% yield) as a colorless oil; ir: 3480 (—OH) and 1728 (C=O) cm^{-1}; ms: M^+ 240.1720 (calcd. for $C_{14}H_{24}O_3$: 240.1726); ^{1}Hmr δ: 3.76 (s, 3H, —$COOCH_3$), 3.62 (dd, 1H, J = 6, J' = 5 Hz, —$CHOH$), 3.35 (d, 1H, J = 6 Hz, —OH), 2.83 (ddm, 1H, J = 10, J' = 5 Hz, —$CHCOOCH_3$), 1.00 (s, 3H, —CH_3), and 0.91 (d, 3H, J = 7 Hz, —$CHCH_3$). After D_2O exchange, the signal at δ 3.35 disappeared and the dd at δ 3.62 collapsed to a doublet (J = 5 Hz). Continued elution gave alcohol **25** (45 mg, 69% yield), mp 82–84°C (ether – petroleum ether); ir: 3510 (—OH) and 1719 (C=O) cm^{-1}; ms: M^+ 240.1723 (calcd. for $C_{14}H_{24}O_3$: 240.1726); ^{1}Hmr δ 3.74 (s, 3H, —$COOCH_3$), 3.53 (dd, 1H, J = 11, J' = 4.5 Hz, —$CHOH$), 2.73 (ddd, 1H, J = 13, J' = 11, J'' = 4.5 Hz, —$CHCOOCH_3$), 2.46 (d, 1H, J = 4.5 Hz, —OH), 1.12 (s, 3H, —CH_3), and 0.98 (d, 3H, J = 7 Hz, —$CHCH_3$). After D_2O exchange, the doublet at δ 2.46 disappeared and the signal at δ 3.53 changed to a doublet (J = 11 Hz). *Anal.* calcd. for $C_{14}H_{24}O_3$: C 69.96, H 10.66; found: C 70.10, H 10.15.

*2-Carbomethoxy-8β,8aβ-dimethyl-3,4,4aβ,5,6,7,8,8a-octahydronaphthalene (**26**)*

A mixture of alcohols **24** and **25** (~2:7, 217 mg, 0.9 mmol) was dissolved in *N*,*N*-dimethylformamide (5 mL) under an atmosphere of nitrogen. Dicyclohexylcarbodiimide (279 mg, 1.36 mmol) and copper(I) chloride (43 mg, 0.43 mmol) were added. The reaction mixture was heated under reflux for 10 h, then cooled to room temperature and diluted with methylene chloride (10 mL). An aqueous 10% solution of acetic acid was added. After stirring for 1.5 h, the mixture was diluted with water and extracted with methylene chloride. The organic extracts were washed with water, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with 5% ether in petroleum ether, gave unsaturated ester **26** (150 mg; 75% yield) as a colorless oil; ir: 1717 (C=O) and 1642 (C=C) cm^{-1}; ^{1}Hmr δ: 6.90 (dd, 1H, J = 2, J' = 1.5 Hz, =CH—), 3.76 (s, 3H, —$COOCH_3$), 2.43 (dddd, 1H, J = 17, J' = 6, J'' = 3, J''' = 1.5 Hz, =C—CHH—), 2.19 (dddd, 1H, J = 17, J' = 10, J'' = 6, J''' = 2 Hz, =C—CHH—), 1.04 (s, 3H, —CH_3), and 0.91 (d, 3H, J = 7 Hz, —$CHCH_3$); ms: M^+ 222.1618 (calcd. for $C_{14}H_{22}O_2$: 222.1625). *Anal.* calcd. for $C_{14}H_{22}O_2$: C 75.63, H 9.97; found: C 75.75, H 10.06.

*3β-Acetoxy-2-carbomethoxy-8β,8aβ-dimethyl-3,4,4aβ,5,6,7,8,8a-octahydronaphthalene (**27**)*

Selenium dioxide (63 mg, 0.57 mmol) was added to a solution of unsaturated ester **26** (105 mg, 0.47 mmol) in glacial acetic acid (4 mL) under a nitrogen atmosphere. The resulting mixture was heated at reflux with stirring. After 24 h, an additional batch of selenium dioxide (63 mg, 0.57 mmol) and glacial acetic acid (2 mL) were added. After heating for an additional period of 25 h, the reaction mixture was cooled to room temperature and potassium acetate (200 mg) was added. The resulting mixture was filtered and the residue washed thoroughly with methylene chloride. The filtrate was washed with water, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with 10% ether in petroleum ether, gave acetate **27** (81 mg; 61% yield), mp 119–120°C (ether – petroleum ether); ir: 1737 (acetate) and 1723 (α,β-unsaturated ester) cm^{-1}; ^{1}Hmr δ: 7.22 (s, 1H, =CH—), 5.74 (dd, 1H, J = 4, J' = 1.5 Hz, —CHO—), 3.75 (s, 3H, —$COOCH_3$), 2.03 (s, 3H, —$OCOCH_3$), 1.10 (s, 3H, —CH_3), and 0.89 (d, 3H, J = 7 Hz, —$CHCH_3$); ms: M^+ 280.1650 (calcd. for $C_{16}H_{24}O_4$: 280.1675). *Anal.* calcd. for $C_{16}H_{24}O_4$: C 68.55, H 8.63; found: C 68.54, H 8.59.

*8β-Hydroxy-2-(2-hydroxy-2-propyl)-8β,8aβ-dimethyl-3,4,4aβ,5,6,7,8,8a-octahydronaphthalene (**28**)*

At −78°C, a 1.6 *M* solution of methyllithium in ether (0.77 mL, 1.22 mmol) was added to a solution of acetate **27** (57 mg, 0.2 mmol) in tetrahydrofuran (5 mL) under an atmosphere of argon. The reaction mixture was allowed to warm up to room temperature. Ice-cold water was slowly added to destroy excess methyllithium. The resulting mixture was extracted with methylene chloride. The organic extracts were washed with water, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with 25% ethyl acetate in petroleum ether, gave diol **28** (45 mg; 93% yield); ir: 3480 and 3377 (—OH) cm^{-1}; ^{1}Hmr δ: 5.74 (s, 1H, =CH—), 4.51 (dd, 1H, J = 4.5, J' = 2 Hz, —$CHOH$), 1.47, 1.39 (both s, 3H each, —$C(CH_3)_2$), 1.00 (s, 3H, —CH_3), and 0.84 (d, 3H, J = 7 Hz, —$CHCH_3$); cims M^+: 238 ($C_{15}H_{26}O_2$).

*Petasitolone (**1**)*

Diol **28** (12.9 mg, 0.05 mmol) was dissolved in acetone (2 mL) and cooled to 0°C. Jones reagent (0.5 mL of 8 *N*, 4 mmol) was added. After stirring for 10 min, the reaction mixture was poured into water and extracted with methylene chloride. The organic extracts were washed with water, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with 20% ethyl acetate in petroleum ether, gave petasitolone (**1**) (10.1 mg, 79% yield); ir: 3450 (—OH) and 1719 (C=O) cm^{-1}; ^{1}Hmr δ: 6.73 (s, 1H, =CH—), 4.55 (s, 1H, —OH), 2.73 (dd, 1H, J = 16, J' = 12 Hz, —$COCHH$—), 1.46 (s, 6H, —$C(CH_3)_2$), 1.07 (s, 3H, —CH_3), and 0.97 (d, 3H, J = 7 Hz, —$CHCH_3$); ^{13}Cmr δ: 202.6, 154.7, 141.3, 71.7, 40.7, 39.4, 38.6, 35.8, 30.2, 29.3, 29.1, 26.9, 20.7, 20.4 and 15.8; ms: M^+ 236.2141 (calcd. for $C_{15}H_{24}O_2$: 236.2142).

Received April 13, 1984

RICHARD MARSDEN, DAVID B. MACLEAN, and LAJOS FODOR. Can. J. Chem. **62**, 2682 (1984).

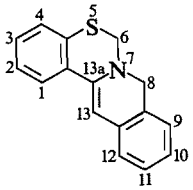
6,7-Dimethoxy-(2*H*)-1,3-benzothiazine undergoes reaction with phthalide anions yielding 13-hydroxy-8-oxo-5-thiaprotoberberines. The latter dehydrate readily to thia analogues of 8-oxoprotoberberines and in one case have been reduced to 5-thiaprotoberberines by treatment with phosphorus oxychloride followed by sodium borohydride. These compounds are members of a new heterocyclic ring system.

RICHARD MARSDEN, DAVID B. MACLEAN et LAJOS FODOR. Can. J. Chem. **62**, 2682 (1984).

La diméthoxy-6,7 (2*H*)-benzothiazine-1,3 réagit avec les anions phtalides en fournissant les hydroxy-13 oxo-8 thia-5 protoberbérines qui se déshydratent facilement pour conduire aux analogues thia des oxo-8 protoberbérines et qui, dans un cas, ont pu être réduites en thia-5 protoberbérines par un traitement avec de l'oxychlorure de phosphore suivi par une réaction avec du borohydrure de sodium. Ces composés font partie d'un nouveau système hétérocyclique.

[Traduit par le journal]

The reaction of phthalide anions with cylic imines in the form of 3,4-dihydroisoquinolines (1, 2) and with acyclic imines (2–4) has been described in several recent publications. Here we report the reaction of 6,7-dimethoxy-(2*H*)-1,3-benzothiazine **1** (5, 6) with anions derived from phthalide **2***a* and 5,6-dimethoxyphthalide **2***b*. The condensation products and their various transformation products are 5-thia analogues of the protoberberine ring system and represent a new heterocyclic ring system. A different approach to this ring system has recently been discovered and communicated (7). The ring system is systematically named and numbered as shown below.[3]



6*H*,8*H*-Isoquino[2,3-*c*][1,3]benzothiazine

A single product of condensation **3***a* was obtained when **1** and **2***a* were condensed together as shown in Scheme 1. Spectroscopic examination of the product and its *O*-acetate led to the structure shown in the formula. The ir spectrum supported the presence of an OH group and a lactam carbonyl in **3***a*. In the aliphatic region of the ^{1}H nmr spectrum the signals at δ 4.27 and δ 5.72 are assigned, respectively, to the protons at H-6_{ax} and H-6_{eq}. The shielding of the equatorial proton is in keeping with similar observations made for protons in the same environment in the 8-oxoprotoberberines (2). A two-proton signal at δ 4.8–4.9 has been assigned to H-13 and H-14, in **3***a*. Upon acetylation of **3***a* to **3***c* these protons now appeared at 4.99 and 6.39 as doublets (J = 8.0 Hz) and are assigned to H-14 and H-13, respectively. The observed coupling constant is compatible with a *trans* relationship between the two hydrogens. Other signals in the nmr spectra of **3***a* and **3***c* corroborate the assigned structures.

The condensation of **1** with **2***b* provided **3***b* as a single product of the reaction. The ir and ^{1}H nmr spectra of **3***a* and **3***b* are very similar. In the nmr, it is noteworthy that the signals associated with the protons at C-6, C-13, and C-14 show analogous behaviour to those in **3***a*, while the differences in the aromatic region are associated with the introduction of the two methoxy groups. It is evident therefore that the two compounds have the same structure and the same stereochemistry about C-13 and C-14.

The ^{13}C nmr spectra of **3***a* and **3***b* confirm the conclusions drawn from the other spectroscopic data, supporting as they do the substitution pattern in each case, and the presence of the lactam carbonyl. No attempt was made to assign the signals attributed to the aromatic carbon atoms other than to separate them on the basis of their coupling into two groups, one bearing hydrogen, and the other quaternary.

Both **3***a* and **3***b* suffer dehydration readily to the compounds **4***a* and **4***b*. The ir, ^{1}H nmr, and ^{13}C nmr spectra of these compounds support the structures assigned to them. The signals associated with H-13 and H-14 in the precursor molecules have disappeared and a new signal of area one attributed to H-13 has appeared in the aromatic region of the ^{1}H nmr but has not been specifically assigned.

Several unsuccessful attempts were made to reduce the lactam function of **3***a*. Complex mixtures, as judged by tlc, were obtained with lithium aluminum hydride in tetrahydrofuran, or with diborane in THF. When triethyloxonium fluoroborate followed by $NaBH_4$ was employed (8) the product was **4***a* and a similar result was observed when tetra-n-butyl ammonium borohydride was used (9).

The reduction of **4***b* with $POCl_3$–$NaBH_4$ (10) proceeded normally, however, yielding **5***b* in a 65% yield. The product lacked lactam absorption in its ir spectrum and displayed nmr properties that are compatible with the assigned structure. Unfortunately, in both the ^{13}C and ^{1}H nmr spectra the presence of several overlapping signals did not allow the unambiguous assignment of the structure, although the weight of evidence is in accord with the proposed structure.

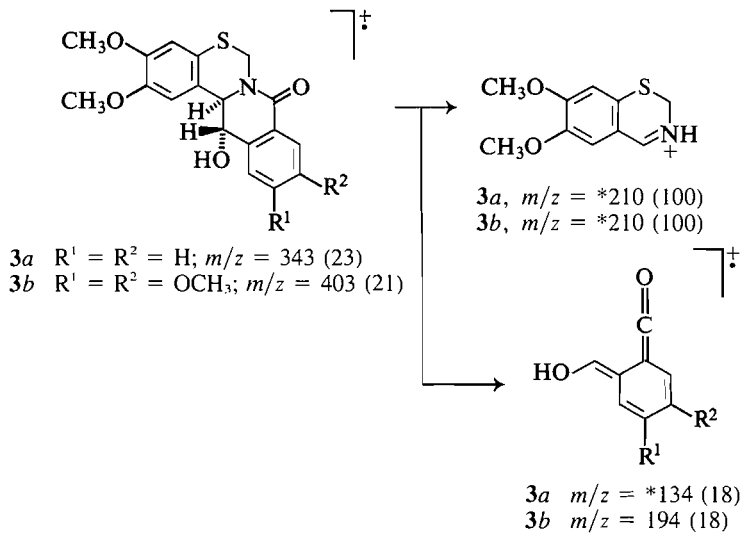
(a) THF, −35°C; (b) TsOH, C_6H_6; (c) $POCl_3$, $NaBH_4$ in MeOH

SCHEME 1



*Compositions verified by accurate mass analysis

SCHEME 2

Compound **4***a* failed to undergo reduction under conditions similar to those used successfully for **4***b*; the reaction product was mainly starting material, based on tlc examination, although a small amount of material of slightly higher R_f value was present. Under forcing conditions (refluxing $POCl_3$, 2 h, followed by $NaBH_4$) the starting material had disappeared, but we were unable to identify the product. Presumably the $POCl_3$–$NaBH_4$ procedure involves formation of a quaternary intermediate, bearing either Cl or $OPOCl_2$ at C-8, which then undergoes reduction by sodium borohydride. The formation of this intermediate would be aided by the methoxyl group at C-11 and this may account for the successful reduction of **4***b* but not of **4***a*.

The mass spectra of these compounds have been recorded and compared with similar structures in the protoberberine series. In the case of **3***a* and **3***b* the spectra are strictly analogous to the spectra of 13-hydroxy-8-oxoprotoberberines of similar substitution pattern (2). The fragmentation pattern is illustrated in Scheme 2. The composition of the fragment ions was established by accurate mass measurement. Compounds **4***a* and **4***b* both display strong molecular ions in their spectra and only a single intense fragment ion at $M - 33$. In both compounds this ion arises by loss of SH from the molecular ion as established by accurate mass measurement. Compound **5***b* behaves much as a tetrahydroprotoberberine alkaloid with a methoxyl substituent at C-10 and C-11 (11). It has, as shown

*Compositions verified by accurate mass analysis

SCHEME 3

in Scheme 3, a molecular ion of moderate intensity and a single intense fragment ion at m/z 164 which on further fragmentation yields an ion of low intensity at m/z 149. Ions of low intensity at m/z 208 and 209 represent the benzothiazine portion of the molecule and again the low intensity of these ions strictly parallels the situation with the protoberberines of comparable substitution pattern (11). It is proposed that the peak at m/z 204 may arise by fission of the S—C-6 bond followed by extrusion of the phenyl group by breaking of the bond between C-14 and C-14a. A comparable ion is not found in the spectra of the protoberberines. The mass spectral fragmentation patterns of the compounds studied show many similarities to those of the protoberberines and lend further support to the proposed structures.

It is apparent that **3***a* and **3***b* are formed stereoselectively in the same way that the 13-hydroxy-8-oxoprotoberberines are derived from lithium phthalides and 3,4-dihydroisoquinolines (2).

Experimental

Apparatus, materials, and methods

Unless otherwise stated, the ^{1}H nmr spectra were continuous wave, run at 90 MHz on a Varian EM 390 spectrometer. The samples were dissoved in $CDCl_3$ using tetramethylsilane (TMS) as the internal standard. Chemical shifts, quoted as δ values, were measured in relation to TMS. The symbols s, singlet, d, doublet, t, triplet, q, quartet, and m, multiplet are used in reporting spectra. The Fourier transform spectra were run on either a Bruker WP80 (80 MHz) or WM250 (250 MHz) spectrometer. The ^{13}C nmr spectra were run at 62.9 MHz on a Bruker WM250 FT spectrometer or at 20.115 MHz on a Bruker WP80 FT spectrometer, both at ambient temperature.

Mass spectra were recorded on a V.G. Micromass 7070 F mass spectrometer at 70 eV. Infrared spectra were recorded on a Perkin–Elmer 283 spectrometer in $CHCl_3$ solution. Melting points were determined using a Gallenkamp apparatus and are uncorrected. The microanalyses were performed by the Guelph Chemical Laboratories Ltd., Guelph, Ontario.

Thin-layer chromatography (tlc) was performed using Polygram Sil G/UV$_{254}$ plates. Flash column chromatography (12) was employed using Kieselgel 60 (230–400 mesh).

All reactions involving lithiation steps were carried out in flame-dried apparatus under a blanket of argon, using septa and syringes for transfer of reagents. Diisopropylamine was refluxed over calcium hydride and distilled onto molecular sieves (4A). THF was dried by distillation from Na/benzophenone under a nitrogen atmosphere just prior to use.

The following compounds were prepared by standard methods and gave satisfactory physical data: *m*-meconin (13) and 6,7-dimethoxy-(2*H*)-1,3-benzothiazine (5, 6).

trans-*13-Hydroxy-2,3-dimethoxy-8-oxo-5-thia-tetrahydroproto-berberine* **3***a*

To a stirred solution of diisopropylamine (0.14 mL, 1 mmol) in dry THF (5 mL) at −10°C was added n-BuLi (0.67 mL of a 1.65 *M* solution in hexane, 1.1 mmol). After 5 min the LDA solution was cooled to −70°C and treated dropwise with a solution of phthalide **2***a* (0.134 g, 1 mmol) in dry THF (5 mL), producing initially an orange solution. Towards the end of the addition a suspension was observed; homogeneity was restored by adjusting the temperature to −35°C. After stirring the solution at this temperature for 20 min, imine **1** (0.21 g, 1 mmol) in dry THF (5 mL) was added and the mixture stirred at −35°C for 1 h, allowed to warm to room temperature, and stirred overnight. Evaporation of solvent gave a yellow solid which was crystallized from EtOH following treatment with activated charcoal, yielding **3***a* as a cream colored crystalline powder (190 mg, 55.4%), mp 250–252°C (EtOH); ir: ν_{max}: 3600, 1655 cm^{-1}; ^{1}H nmr (DMSO-d_6) δ: 3.71 (3H, s, —OCH_3), 3.74 (3H, s, —OCH_3), 4.27 (1H, d, J = 12.0 Hz, H-6$_{ax}$), 4.8–4.9 (2H, d (collapsed AB quartet), H-13 and H-14), 5.72 (1H, d, J = 12.0 Hz, H-6$_{eq}$), 6.87 (1H, s, H-1 or H-4), 7.03 (1H, s, H-1 or H-4), 7.25–7.75 and 7.85–8.0 (4H, m, H-9, H-10, H-11, and H-12); ^{13}C nmr: 43.4 (C-6), 55.5, 55.7 (2 × OCH_3), 61.7 (C-14), 67.4 (C-13), 112.0, 114.4, 125.6, 127.1, 127.6, 132.1 (ArCH), 124.1, 124.7, 126.6, 141.0, 146.0, 148.0 (ArC), 161.7 (C-8); ms, m/z (%): 343 (23) M$^+$, 210 (100), 134 (18). *Anal.* calcd. for $C_{18}H_{17}NO_4S$: C 62.97, H 4.96, N 4.08; found: C 63.04, H 4.93, N 4.12%.

The 13-acetoxy derivative **3***c* was prepared by heating **3***a* under reflux in acetic anhydride and pyridine overnight. The solvent was

evaporated under high vacuum and the residue analysed by ^{1}H nmr ($CDCl_3$) δ: 2.10 (3H, s, $OCOCH_3$), 3.80 (3H, s, —OCH_3), 3.85 (3H, s, —OCH_3), 4.23 (1H, d, J = 12.0 Hz, H-6_{ax}), 4.99 (1H, d, J = 8.0 Hz, H-14), 5.87 (1H, d, J = 12.0 Hz, H-6_{eq}) 6.39 (1H, d, J = 8.0 Hz, H-13), 6.74 (1H, s, H-1 or H-4), 6.80 (1H, s, H-4 or H-1), 7.2–7.7 (3H, m, H-10, H-11, and H-12), 8.05–8.25 (1H, m, H-9).

trans-*13-Hydroxy-2,3,10,11-tetramethoxy-8-oxo-5-thiatetrahydroprotoberberine* **3**b

An LDA solution (1.5 mmol), prepared by the procedure described above, was treated dropwise at −70°C with a solution of *m*-meconin **2***b* (0.291 g, 1.5 mmol) in dry THF (15 mL). The resulting clear orange solution was stirred at −70°C for 20 min and treated with a solution of imine **1** (0.314 g, 1.5 mmol) in dry THF (10 mL). After stirring the solution at −70°C for 1 h the mixture was allowed to warm to room temperature and stirred overnight. The solvent was evaporated, water added, and the whole extracted with $CHCl_3$. Drying the extract (Na_2SO_4) and evaporation gave a yellow oil. Flash chromatography (silica, eluting with $CHCl_3$ + 0.5% MeOH) furnished **3***b* as a white powder (305 mg, 50.5%), mp 219–221°C (EtOH); ir: ν_{max}: 3610, 1650 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 3.79 (3H, s, —OCH_3), 3.85 (3H, s, —OCH_3), 3.93 (3H, s, —OCH_3), 3.97 (3H, s, —OCH_3), 3.96 (1H, d (partially obscured by methoxy signal), H-6_{ax}), 4.77 (2H, s, H-13 and H-14), 5.78 (1H, d, J = 13.0 Hz, H-6_{eq}), 6.77 (1H, s, aromatic), 6.91 (1H, s, aromatic), 7.22 (1H, s, aromatic), 7.52 (1H, s, H-9); ^{13}C nmr: 44.5 (C-6), 56.4 (4 × OCH_3), 63.6 (C-14), 70.2 (C-13), 107.2, 111.2, 113.2, 114.0 (ArCH), 119.9, 123.8, 127.2, 134.5, 147.3, 149.0, 149.3, 153.2 (ArC), 163.2 (C-8); ms, *m*/*z* (%): 403 (21) M$^+$, 210 (100), 194 (18). *Anal.* calcd. for $C_{20}H_{21}NO_6S$: C 59.55, H 5.21, N 3.47; found: C 59.45, H 5.35, N 3.32%.

13,14-Didehydro-2,3-dimethoxy-5-thiaberbin-8-one, **4**a

Lactam **3***a* (145 mg) in benzene was treated with *p*-toluenesulfonic acid (50 mg) as in the case of **3***b*. Evaporation of solvent and crystallization of the residue from EtOH gave **4***a* as a white crystalline powder (125 mg, 91%), mp 222–224°C; ir: ν_{max}: 1640 cm^{-1}; ^{1}H nmr δ: 3.93 (3H, s, —OCH_3), 4.00 (3H, s, —OCH_3), 5.39 (2H, s, H-6_{ax} and H-6_{eq}), 6.80 (1H, s, aromatic H), 6.90 (1H, s, aromatic H), 7.30 (1H, s, aromatic H), 7.35–7.80 (3H, m, H-10, H-11, and H-12), 8.48 (1H, d, J = 8 Hz, H-9); ms, *m*/*z* (%): 325 (89) M$^+$, 292 (100). *Mol. wt.* calcd. for $C_{18}H_{15}NO_3S$: 325.077; found (hrms): 325.074.

13,14-Didehydro-2,3,10,11-tetramethoxy-5-thiaberbin-8-one, **4**b

Lactam **3***b* (120 mg) in benzene (40 mL) was heated under reflux in a Dean–Stark apparatus overnight over *p*-toluenesulfonic acid (50 mg). The cooled solution was washed with water (3 × 50 mL), evaporated to dryness, and crystallized from EtOH as a pale green powder (100 mg, 87.2%), mp 212–214°C; ir ν_{max}: 1650 cm^{-1}; ^{1}H nmr δ: 3.94 (3H, s, —OCH_3), 4.00 (3H, s, —OCH_3), 4.03 (6H, s, 2 × —OCH_3), 5.39 (2H, s, —SCH_2N—), 6.75 (1H, s, aromatic), 6.90 (1H, s, aromatic), 6.96 (1H, s, aromatic), 7.27 (1H, s, aromatic), 7.83 (1H, s, aromatic); ^{13}C nmr: 43.0 (C-6), 56.3, 56.4, 56.7 (4 × OCH_3), 104.1, 106.6, 108.3, 110.3, 111.4 (ArCH), 118.7, 124.0, 126.6, 132.2, 135.9, 148.6, 149.6, 150.4, 154.4 (ArC), 160.3 (C-8); ms, *m*/*z* (%): 385 (100), 352 (62). *Mol. wt.* calcd. for $C_{20}H_{19}NO_5S$: 385.098; found: 385.092.

2,3,10,11-Tetramethoxy-5-thiatetrahydroprotoberberine, **5**b[4]

The didehydro compound **4***b* (100 mg, 0.26 mmol) was dissolved in dry, ethanol-free chloroform (6 mL), treated with $POCl_3$ (4.5 mL, 48 mmol), and refluxed under argon for 1 h. The orange solution was evaporated to dryness, dry methanol (30 mL) was added, and the cooled stirred methanolic suspension was treated with $NaBH_4$ (120 mg, 3.2 mmol) in portions. The mixture was stirred for 0.5 h at room temperature, the solvent evaporated, water (15 mL) was added, and the crude product extracted with $CHCl_3$. The dried (Na_2SO_4), evaporated extract yielded a yellow oil which was subjected to flash chromatography (silica, eluting with $CHCl_3$). Crystallization of the major fraction from EtOH furnished white needles of **5***b* (63 mg, 65%), mp 171–173°C; ir ν_{max}: 2840 cm^{-1}; ^{1}H nmr (250 MHz) δ: 3.1–3.35 (2H, m, H-13_{ax} and H-13_{eq}), 3.75 (3H, s, —OCH_3), 3.80 (3H, s, —OCH_3), 3.82 (3H, s, —OCH_3), 3.85 (3H, s, —OCH_3), 4.05 (1H, t, J = 5.4 Hz, H-14), 4.22 (1H, d, J = 11.4 Hz, H-6_{ax}), 4.64 (1H, d, J = 11.4 Hz, H-6_{eq}), 6.47 (1H, s, aromatic), 6.65 (1H, s, aromatic), 6.67 (2H, s, 2 × aromatic). The integral of the 4 × —OCH_3 protons suggests an additional two protons, H-8_{ax} and H-8_{eq}, are present in the region δ 3.7–3.9; ^{13}C nmr: 33.0 (C-13), 51.7 (C-6 and C-8), 56.1 (C-14), 56.1, 56.3, 56.5, 56.9 (4 × OCH_3), 109.8, 111.2, 111.4, 111.9 (ArCH), 124.8, 125.0, 126.1, 126.2, 146.9, 147.9, 148.1, 148.5 (ArC); ms, *m*/*z* (%): 373 (38) M$^+$, 209 (6), 208 (9), 204 (15), 164 (100), 149 (6). *Anal.* calcd. for $C_{20}H_{23}NO_4S$: C 64.34, H 6.17, N 3.75; found: C 64.26, H 6.21, N 3.69%.

The free energy barrier to internal rotation about the Csp^2—N bond in 4-bromo-2,6-difluoro-N-methylaniline in dimethylether solution is 23.1 ± 0.4 kJ/mol at 120 ± 2 K, as determined by demagnetization (lineshape) measurements of ^{19}F nmr spectra. In the same solvent, $\Delta G^{\ddagger}$ is some 7 kJ/mol higher for N-methylaniline. STO 3G MO calculations of the barrier in 2,6-difluoro-N-methylaniline are compared with calculations for the parent compound and its 2,6-dichloro derivative. The calculated barriers can be fit to a twofold potential and are V (kJ/mol) = (19.1 ± 0.9) $\sin^2$ (ϕ − 141.5 ± 0.7°) for N-methylaniline and V (kJ/mol) = (22.2 ± 0.8) $\sin^2$ (ϕ − 120.9 ± 0.8°) for the 2,6-difluoro derivative. The errors are given for the 95% confidence intervals. The angle ϕ is the C_2C_1NC dihedral angle. The barrier in the title compound is presumably a subtle compromise between opposing components consisting of conjugation, intra and intermolecular hydrogen bonding, and steric interactions. For 2,6-dimethyl-N-methylaniline in dimethyl ether no relative broadening of the ^{13}C nmr peaks was observed at 130 K, consistent with a very low barrier or with a ground state conformation in which, via inversion at nitrogen, the C-2 and C-6 relative chemical shift is averaged to zero. The computed geometry of an analogous compound implies that the N—H and N—(CH_3) bonds lie on opposite sides of the benzene plane in the conformation of lowest energy, so that inversion can coalesce the C-2 and C-6 shifts; the methyl group does not have to pass through the benzene plane for inversion to occur.

TED SCHAEFER, GLENN H. PENNER, KIRK MARAT et RUDY SEBASTIAN. Can. J. Chem. **62**, 2686 (1984).

Opérant à 120 ± 2 K et faisant appel à des mesures de démagnétisation (forme des raies) des spectres rmn du ^{19}F, on a trouvé que la barrière (énergie libre) à la rotation interne autour de la liaison Csp^2—N dans la bromo-4 difluoro-2,6 N-méthylaniline, en solution dans l'éther diméthylique, est de 23,1 ± 0,4 kJ/mol. Dans le même solvant, le $\Delta G^{\ddagger}$ de la N-diméthylaniline est environ 7 kJ/mol plus élevé. On compare des calculs d'orbitales moléculaires, sur la base STO 3G, de la barrière dans la difluoro-2,6 N-méthylaniline avec ceux effectués sur le composé de base et sur son dérivé dichloro-2,6. On peut adapter les barrières calculées à un potentiel binaire; pour la N-méthylaniline, V (kJ/mol) = (19,1 ± 0,9) $\sin^2$ (ϕ − 141,5 ± 0,7°), alors que pour le dérivé difluoro-2,6, V (kJ/mol) = (22,2 ± 0,8) $\sin^2$ (ϕ − 120,9 ± 0,8°). On rapporte les erreurs pour les intervalles de confiance de 95%. L'angle ϕ est l'angle dièdre C_2C_1NC. La barrière observée dans le composé mentionné dans le titre est probablement un compromis subtil entre des composantes qui s'opposent comme la conjuguaison, les liaisons hydrogènes intra- et intermoléculaires et les interactions stériques. Dans le cas de la diméthyl-2,6 N-méthylaniline en solution dans l'éther diméthylique que l'on a examinée par rmn du ^{13}C à 130 K, on n'a pas observé d'élargissement relatif des raies; ce résultat est en accord avec la présence d'une barrière à la rotation qui serait très faible ou avec l'existence d'une conformation dans l'état fondamental de laquelle la moyenne des déplacements chimiques relatifs des carbones C-2 et C-6 est égale à zéro. La géométrie que l'on a calculée pour un composé analogue implique que, dans la conformation de plus basse énergie, les liaisons N—H et N—(CH_3) se trouvent de part et d'autre du plan du benzène de façon à ce que l'inversion puisse provoquer une coalescence des déplacements des carbones en C-2 et en C-6; il n'est pas nécessaire que le groupe méthyle passe à travers le plan du benzène pour que l'inversion se produise.

Introduction

The free energy of activation, $\Delta G^{\ddagger}$, for rotation about the Csp^2—N bond in N-methylaniline in dimethylether solution is 30.29 ± 0.08 kJ/mol, somewhere between 147 and 160 K (1). Substitution at the *para* position by a π electron donor (acceptor) leads to decreases (increases) in $\Delta G^{\ddagger}$, as expected if the barrier to rotation depends on the mobile bond order of the C—N bond (2). It also appears that there is a substantial solvent effect on the internal rotational barrier (2–4). Vapour phase infrared experiments (4), together with an assumption of a twofold cosine potential, yield 14.5 ± 2.0 kJ/mol as the magnitude of the barrier, to be compared with 25.5 kJ/mol for $\Delta G^{\ddagger}$ in $CHFCl_2$–CHF_2Cl solution and with the 30.3 kJ/mol in ether solution. An STO 3G MO computation gave 37.9 kJ/mol (1).

The heavy atoms in N-methylaniline are unlikely to be coplanar in the minimum-energy conformation (4–6), aniline having a pyramidal arrangement at nitrogen (7, 8). Large *ortho* substituents could possibly produce a conformation of lowest energy in which the N—C(H_3) bond tends towards a plane perpendicular to the benzene plane, thereby relieving steric repulsions between the methyl group and the *ortho* substituents. Thus, for 2-methyl-N-methylaniline and for its 4-nitro derivative (2), only the one conformer, that with the two methyl groups in a *trans* orientation, could be detected. Substitution by two *ortho* substituents might therefore lead to a perpendicular conformation.

Such is *not* found for derivatives of N-methylaniline with two *ortho* nitro groups (9, 10), the Arrhenius activation energy, E_a, rising to 52.3 ± 0.8 kJ/mol in 2,6-dinitro-Nmethylaniline and to 60.7 ± 1.3 kJ/mol in the presence of an additional nitro substituent at the *para* position (CD_2Cl_2 solution). These relatively large barriers probably arise from intramolecular hydrogen bonding in the ground state, suggested as 21 to 29 kJ/mol (9, 10), together with the decrease in the C—N double bond character as the transition state is approached. A *para* nitro substituent increases $\Delta G^{\ddagger}$ for N-methylaniline by about 17 kJ/mol (2, 3). *Ortho* nitro substituents should induce similar changes in the C—N mobile bond order, so that the barrier in these picrates may also include destabilization of the ground

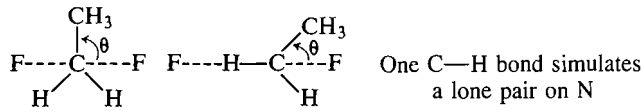
state by steric repulsions between the nitro groups and the *N*-alkyl substituent. In that way the much smaller barrier in the *N-tert*-butyl picrate, too small to be measurable by the lineshape methods employed for the smaller alkyl groups (11, becomes plausible.

Now, a *para* fluorine substituent decreases the internal barrier by 1.4 ± 0.3 kJ/mol (2) in dimethylether solution, no doubt because fluorine is a π electron donor. As an *ortho* substituent, fluorine may again reduce the C—N mobile bond order, but it may also act as a hydrogen bond acceptor in the form C—F . . . H—N (an electrostatic interaction). Furthermore, a C—F bond presents a larger van der Waals volume to a methyl group than does a C—H bond. For example, the twofold barrier to rotation about the Csp^2—Csp^3 bond for the ethyl group in ethylbenzene is raised by as much as 20 kJ/mol when hydrogen is replaced by fluorine to yield the 2,6-difluoro derivatives (11). This increase may well be predominantly steric in origin.

Of course, in 2,6-difluoro-*N*-methylaniline the geometry about nitrogen deviates rather more from tetrahedral (including the lone pair as a direction) than it does about the α carbon in ethyl benzene. Consequently, the ground state conformation will not be analogous to **1**, the preferred conformation of the



1 **2**

latter, with θ = 90°, but will have θ rather less than 60°, similar to **2**. In fact, the N—H and C—CH_3 bonds are later calculated to lie above the benzene plane for the 2,6-difluoro-*N*-methylaniline (see **3** below), yet do fall on opposite sides of this plane for the 2,6-dichloro derivative (see **5** below).

The actual barrier to internal rotation could be smaller or larger than in *N*-methylaniline, depending on the interplay of the opposing factors mentioned above. Of course, if the steric repulsions were large enough to overcome the conjugation energy, then the conformation might resemble **1** and perhaps lead to only very small Larmor frequency differences for nuclei acting as marker sites in a dynamic nuclear magnetic resonance experiment (dnmr).

In this paper, dnmr experiments are reported for 4-bromo-2,6-difluoro-*N*-methylaniline in dimethylether solution. The bromine substituent, like a chlorine substituent in 4-chloro-*N*-methylaniline (2), serves to raise the barrier sufficiently so as to be measurable with the technology available in this laboratory. The barrier in 2,6-difluoro-*N*-methylaniline is computed at the STO 3G level of *ab initio* molecular orbital theory (12) and is compared with calculations on *N*-methylaniline and its 2,6-dichloro derivative. These calculations give *some* insight into the ground and transition state geometries.

Experimental

The 2,6-difluoroaniline (Aldrich) was brominated in acetic acid solution in the usual way to yield its 4-bromo derivative. *N*-methylation was carried out exactly as described by Johnstone *et al.* (13), giving a compound with the expected ^1H nmr spectrum and mass peaks.

A solution in dimethylether, containing 0.11 g of the aniline, 0.11 g of acetone-d_6, 1.5 mL of dimethylether, and 1 drop of C_6F_6 was transferred on a vacuum line to a 5-mm od nmr sample tube. The latter was flame sealed and stored in a refrigerator while not in use. The

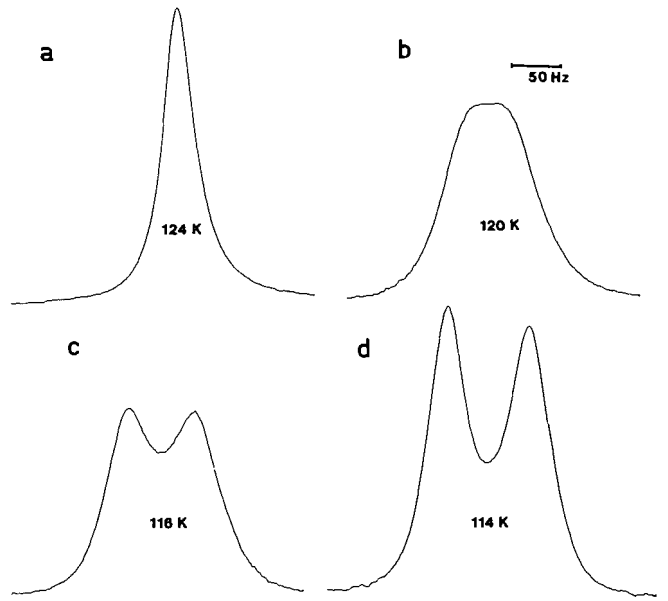


FIG. 1. The ^{19}F nmr spectrum of 2,6-difluoro-*N*-methylaniline in dimethyl ether solution at 84.700 MHz. The spectra were accumulated as described in the text. The coalescence temperature is very near 120 K and complete separation of the doublet has not occurred at 114 K, the lowest temperature attained.

acetone-d_6 was used for internal locking purposes and C_6F_6 served as a linewidth standard.

The ^{19}F nmr spectra were recorded in the FT mode on a WH90 nmr spectrometer at 84.700 MHz (centerband), under conditions of ^1H noise decoupling. The amplitude of the decoupling field was kept low enough to prevent significant sample heating. The pulse width was 5 μs, roughly a 90° pulse, the digitized response was accumulated for 1.02 s into 4 K and the sweep width was 2000 Hz. These conditions applied at temperatures where the peak widths were rather large. As many as 64 scans were performed. At the lowest temperatures, shimming was performed on the FID of the C_6F_6 and the sample was not spun. A very high flow rate of cooling gas was necessary in order to reach 114 K and the temperature was checked by means of a copper–constantan thermocouple. Spectra were accumulated at a given temperature reached from lower as well as from higher temperatures, so that a check on lineshapes obtained near and at coalescence temperatures was possible.

STO 3G MO computations employed an Amdahl 470/V8 system.

Results and discussion

The free energy barrier, $\Delta G^{\ddagger}$

Some typical ^{19}F spectra are displayed in Fig. 1. At 114 K a distinct asymmetry in the unresolved doublet is observable. It is conceivable that stereospecific coupling over three bonds between ^{14}N and ^{19}F nuclei causes a slight broadening of one of the peaks in the doublet. As the temperature increases, the ^{14}N quadrupolar relaxation rate would increase and the asymmetry would decrease. More likely is the presence of a small impurity also yielding a broad peak and lying under the taller peak. A weak impurity peak, lying near the main band, was noticeable at higher temperatures. It was not observable at the low temperatures used during the experiment and may have broadened and moved in the spectral region of interest. In any event, although the source of the peak was not identified, our estimate is that the observed asymmetry caused a negligible contribution to the error quoted for $\Delta G^{\ddagger}$ below.

It is quite clear that the available range of temperatures, 114 K to 135 K, in which a noticeable linewidth difference exists

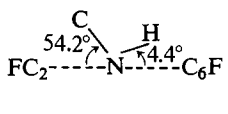
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

between reference and substrate peaks, is too small for a reliable decomposition of $\Delta G^{\ddagger}$ into $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ parameters, particularly as a complete separation into two peaks could not be achieved at the lowest attainable temperature, 114 K. From the repeated experiments at 118 to 120 K, together with thermocouple measurements of the temperatures indicated by the dial settings on the Bruker B-VT-1000 variable temperature controller, it is safe to state that the coalescence temperature, T_c, is 120 ± 2 K. Furthermore, a conservative estimate of $\delta\nu$, the peak separation at zero exchange rate, is 96 ± 5 Hz. The total width at half height at coalescence is the sum of the static splitting and the natural width (14). The width at coalescence was 100 ± 2 Hz and the reference peak had a width of 4 ± 1 Hz. Accordingly, the value of $\Delta G^{\ddagger}_{120}$ can be written (15) as $\Delta G^{\ddagger}_{120}$ (kJ/mol) = $1.914 \times 10^{-2} T_c[9.972 + \log (T_c/\delta\nu)]$ or 23.1 ± 0.4 kJ/mol, using eq. 7.13 of ref. 15. As in the previous studies (2, 3), a transmission coefficient of unity was assumed. This $\Delta G^{\ddagger}_{120}$ is 7 kJ/mol lower than for *N*-methylaniline in the same solvent (1, 3) at 138 K, presumably too large a difference to account for by differences in $\Delta S^{\ddagger}$ for the two compounds.

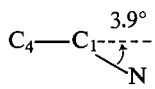
Molecular orbital calculations

It would be preferable to use a basis set larger than minimal, the one employed in the present STO 3G computations. It would also be very expensive. It may be noted, however, that a recent set of geometry optimizations (16) with STO 3G for benzoyl X compounds (X = H, F, CH_3) gave internal rotational barriers 3.1 kJ/mol too high but in the correct order, and that for phenol the STO 3G barrier was 4.0 kJ/mol too large.

For 2,6-difluoro-*N*-methylaniline, geometry optimization of the sidechain, as well as of the exocyclic bond angles and lengths (keeping the benzene carbon skeleton as a regular hexagon) gave the geometry in Fig. 2, as well as the dihedral angles in **3**. The C_1—N bond direction is tilted 3.9° from the benzene plane, **4**. Furthermore, the methyl group is calculated to be

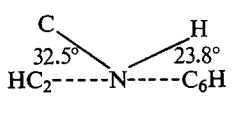


3

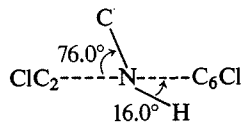


4

almost exactly staggered with respect to the C_1—N bond (61.4, 181.4, and 301.4°). With reference to **3**, the corresponding calculated angles for *N*-methylaniline are 32.5 and 23.8°, whereas they are 76.0 and −16.0° for the 2,6-dichloro derivative, as in **5** and **6**. With reference to **4**, the tilt angles are 3.7° and 2.7° for the compounds depicted in **5** and **6**, respectively. The H—C—N—C_1 dihedral angles are 72.6, 192.6, 312.6° and 58.5, 178.5, and 298.5° (methyl protons constrained to define an equilateral triangle) for **5** and **6**.



5



6

Comparison of **3**, **5**, and **6** implies increasing steric repulsion between the methyl group and the *ortho* C—X bond. As X changes from H to F to Cl, the CNC_1C_2 dihedral angle increases from 32.5 to 54.2 to 76.0°. The Csp^2—N bond is also calculated to increase from 1.449 to 1.451 to 1.454 Å (1 Å ≡ 100 pm). In going from **5** to **3**, the HNC_1C_6 dihedral angle decreases by nearly 20°, probably because of twisting about the Csp^2—N bond and increased electrostatic interaction between the N—H^+ and C—F^- dipoles (hydrogen bonding). In the 2,6-dichloro derivative, the N—H and N—$C(H_3)$ bonds lie on opposite sides of the benzene plane. Considerable loss of conjugation between the lone pair on nitrogen and the π orbitals is implied on stepping from H to F to Cl as *ortho* substituents.

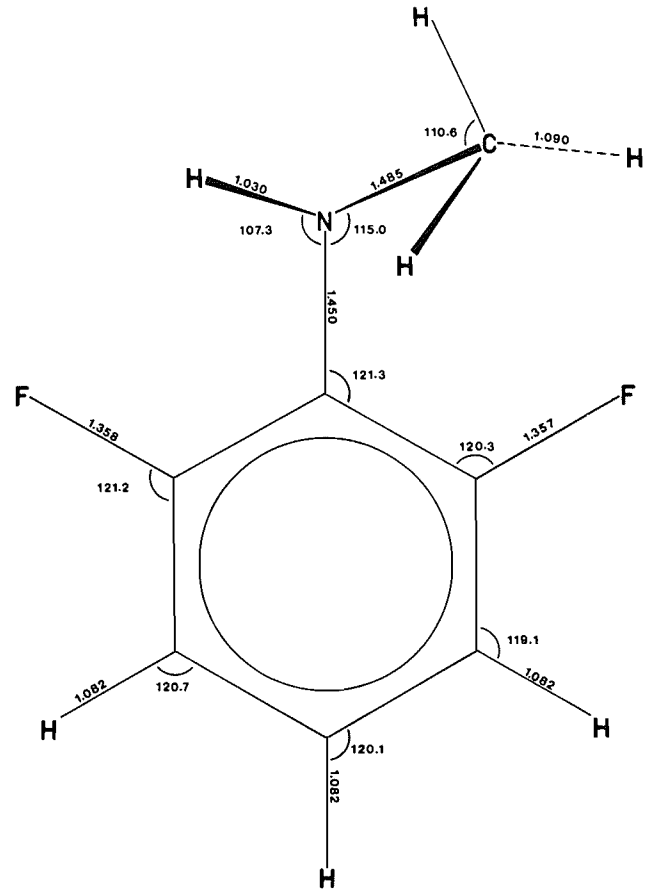


FIG. 2. The computed ground-state structure of 2,6-difluoro-*N*-methylaniline at the STO-3G level of molecular orbital theory. A regular hexagon was assumed for the carbon atom arrangement in the benzene ring. Dihedral angles can be found in the text. One C—H bond of the methyl group lies in a plane at 11° to the ring plane.

The computed barriers

In Figs. 3 and 4 the STO 3G MO energies, relative to their respective ground states, are plotted for *N*-methylaniline and its 2,6-difluoro derivative. The curves represent least-squares fits to the computed points for twofold barriers of the form *V* (kJ mol) = (19.1 ± 0.9) $\sin^2$ (ϕ − 141.5 ± 0.7°) for the parent molecule and *V* (kJ mol) = (22.2 ± 0.8) $\sin^2$ (ϕ − 120.9 ± 0.8°) for the fluorinated compound. The errors are given for 95% confidence intervals. Part of the error arises from difficulties experienced in the geometry optimizations insofar as the computed energies at ϕ = 0° and 180° are unequal. The optimization procedure, sequential variation of bond angles and lengths, proceeded by 15° increments from ϕ = 0° to 180°. The final energy depended somewhat on the starting geometry for ϕ = 180°, which was that for ϕ = 165°. It must therefore be true that at least some of the computed points in the figures

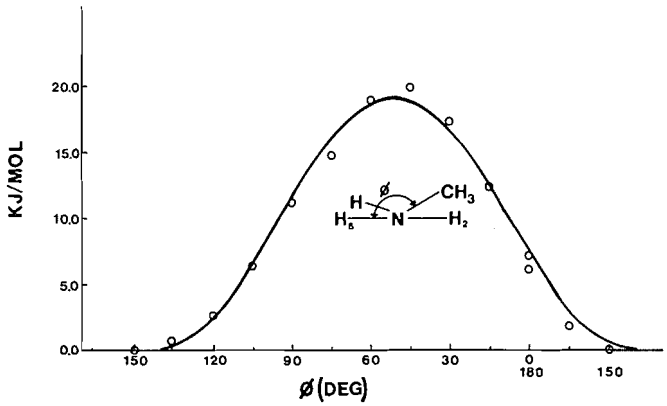

FIG. 3. The computed energies for *N*-methylaniline are plotted as a function of the dihedral angle, ϕ. The solid curve represents a twofold potential fit to the points and is given by V (kJ mol) = (19.1 ± 0.9) $\sin^2$ (ϕ − 141.5 ± 0.7°). The quoted errors are for a 95% confidence interval. The ground-state energy is −320.78804 au for the STO 3G MO computation.

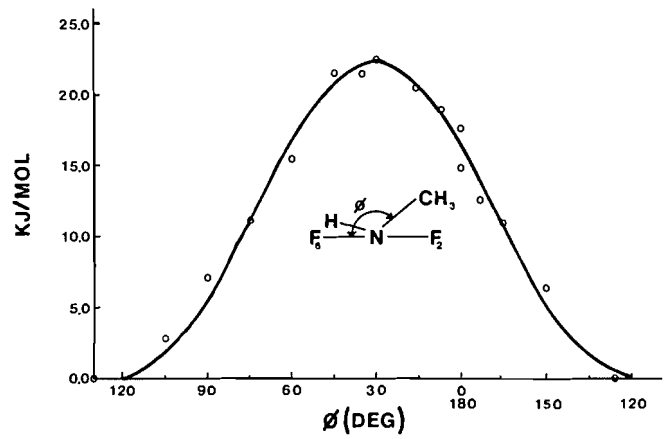

FIG. 4. As for Fig. 3, for 2,6-difluoro-*N*-methylaniline and V (kJ mol) = (22.2 ± 0.8) $\sin^2$ (ϕ − 120.9 ± 0.8°). The STO 3G MO energy for the ground state is −515.70377 au.

have an uncertainty[1] of perhaps as large as 1 kJ/mol. The ground state energies of *N*-methylaniline and 2,6-difluoro-*N*-methylaniline were computed as −320.788044 and −515.703773 au, respectively, at ϕ values of 147.5° and 125.8°.

Comparison of these angles with the fitted twofold potentials above shows that the latter are not exact representations of the computed barriers, as expected. However, they are a good approximation and support the assumption of twofold barriers in the treatment of torsion data (4). Such data imply that the barrier to C_1—N rotation in *N*-methylaniline is 9.8 ± 2.5 kJ/mol lower than in aniline (4, 17). A lower barrier is likely due to steric repulsion between the methyl group and the *ortho* C—H bond, leading to destablization of the ground state in *N*-methylaniline. The shielding of the C-4 nucleus in *N*-methylaniline is very nearly that of C-4 in aniline (18), implying very similar $2p \ldots \pi$ conjugation in the two compounds. That CH_3 repulsive interactions are present is made plausible by the twofold steric barrier of 5.0 kJ/mol in ethylbenzene (19), where the top of the barrier is reached when the methyl group lies in the benzene plane.

Turning to the 2,6-difluoro derivative, an augmented repulsive interaction between the methyl group and the *ortho* C—F bond is expected. This expectation is supported by the smaller calculated ϕ value in the ground state relative to the parent compound and by the observation that the repulsive barrier in 2,6-difluoroethylbenzene (11) is 20 ± 8 kJ/mol higher than in ethylbenzene. That the computed barrier in 2,6-difluoro-*N*-methylaniline is about 3 kJ/mol *higher* than in *N*-methylaniline can be attributed partly to the breaking of the attractive N—$H^+ \ldots {}^-F$—C interaction (the internal hydrogen bond in planar 2-fluorophenol has an energy of about 6 kJ/mol (20)), but also to the fact that the phases and amplitudes of the repulsive and attractive components of the barriers in the two compounds are different. The nitrogen lone pair also has steric requirements (21). At present a further decomposition of the calculated torsion barriers seems infeasible.

However, the inversion barriers are also of interest. In *N*-methylaniline, the inversion barrier is 2.3 ± 0.5 kJ/mol (4); our calculation gives 16 kJ/mol, an overestimate similar to that found for aniline itself (8). Clearly, a larger basis set is needed, as demonstrated for aniline (8). Presumably the inversion barrier in 2,6-difluoro-*N*-methylaniline will be larger than in *N*-methylaniline.

Our calculations for the barrier to rotation of the methyl group in the latter gave 11.7 kJ/mol, the methyl torsion data yielding 12.9 ± 0.2 kJ/mol on the assumption of a threefold potential (4).

Correlations of $\Delta G^{\ddagger}$ *with* V_2 *in* para *substituted thiophenols*

For thiophenol and its *para* substituted derivatives, the *J* method (22, 23) has been used to derive twofold potentials, V_2, for rotation about the C—S bonds. The preferred conformation is planar for thiophenol. V_2 decreases for π electron donors. Indeed, in the *para* amino and methoxy derivatives the preferred conformations have the S—H bond in a plane perpendicular to the benzene plane.

For the five *para* substituents (H, OCH_3, F, Cl, NO_2) common to the thiophenol (23) and *N*-methylaniline (2) derivatives, the correlation between V_2 and $\Delta G^{\ddagger}$ is reasonably good, having a correlation coefficient of 0.965, significant at the 95% confidence level. The V_2 values are derived from data for CCl_4 solutions and assume a twofold cosine potential. In view of the solvent effects on $\Delta G^{\ddagger}$ for the *N*-methylaniline derivatives and the fact that $\Delta G^{\ddagger}$ *may* contain an entropy contribution, the correlation is perhaps as good as could be expected. The correlation is here offered as evidence that both sets of barriers are a reflection of the changes induced in the mobile bond orders of the C—S and C—N bonds by the *para* substituents and that a *para* methoxy substituent does indeed change the ground state conformational preference of the sulfhydryl group.

Furthermore, the correlation can be used to estimate the increase in the $\Delta G^{\ddagger}$ value caused by a *para* bromine substituent in *N*-methylaniline as 2.1 ± 0.3 kJ/mol; the V_2 for the corresponding bromothiophenol being known (23). This estimate may be compared with the increase of 1.9 ± 0.3 kJ/mol in $\Delta G^{\ddagger}$ measured for the 4-chloro substituent (2) in *N*-methylaniline. Consequently, the $\Delta G^{\ddagger}$ for 2,6-difluoro-*N*-methylaniline in dimethyl ether solution could well be as low as 21 kJ/mol and would not be measurable at 114 K and 84.7 MHz because the rate constant would be about 600 s^{-1} instead of near 60 s^{-1} for the title compound.

[1] An automatic geometry optimization procedure is now available to us and gives a ground state geometry for the 2,6-difluoro compound insignificantly different from that in Fig. 2.

[c] From torsion data (4).
[d] The 4-bromo-2,6-difluoro-*N*-methylaniline in ether solution has 23.1 ± 0.4 kJ/mol; see text for an estimate of 21.0 kJ/mol for the 2,6-difluoro-*N*-methylaniline.
[e] Estimated as explained in the text.
[f] For geometry optimized conformations.

The barriers in solution and the gas phase

In dimethyl ether solution, the free energy barrier in 2,6-difluoro-*N*-methylaniline is definitely smaller than in the parent compound, contrary to the computed values above. One may reason as follows. In the gas phase, V_2 is 14.5 ± 2.0 kJ/mol for *N*-methylaniline (4). As mentioned, for a series of benzoyl X compounds (X = H, F, CH_3) and for phenol (16) the computational methods employed here yielded barriers between 3 and 4 kJ/mol higher than experimental, estimated in the gas phase. Comparison of V_2 with the STO 3G MO number for *N*-methylaniline suggests a similar situation, in that the computed barrier is 4.6 ± 2.9 kJ/mol too high. Application of this number to the computed barrier of 22.2 kJ/mol for 2,6-difluoro-*N*-methylaniline implies a gas phase barrier of 17.6 ± 3.7 kJ/mol, that is, higher than for the parent compound. A gas phase torsion study would be of interest.

Turning to the ether solutions, the solvent increases the barrier of *N*-methylaniline by 15.8 ± 2.1 kJ/mol, that is by more than its gas phase magnitude.[2] In the previous section, an estimate for 2,6-difluoro-*N*-methylaniline was made as 21.0 ± 0.7 kJ/mol. Therefore, the ether solvent appears to have increased the internal barrier by only 3.4 ± 3.3 kJ/mol, as expected if the *ortho* fluorine substituents with their polar $^{+}C—F^{-}$ bonds severely restrict hydrogen bonding between N—H and the lone pairs on the solvent oxygen atoms, $^{-}O—C_2^{+}$, or, at least, interfere with the approach of the solvent molecules to the $NHCH_3$ moiety.

Table 1 contains data summarizing the reasoning employed in the last few paragraphs.

Because the computed dipole moments of the ground and transition states of *N*-methylaniline differ by only 0.14 D, being 1.35 and 1.49 D, respectively,[3] it appears unlikely that dielectric continuum models (24) could account for the large increase in the barrier in ether solution, at least at the dipole level. In fact, the transition state would be stabilized by such an interaction (unless, of course, quadrupole interaction energies were to reverse this expectation).

All these comparisons are based on the assumption that $\Delta S^{\ddagger}$ is unimportant. The sparse data on *N*-methylaniline in ether solution (1) indicate as much.

*Concerning 2,6-dimethyl-*N*-methylaniline*

The methyl group is larger than a fluorine substituent. The following experiments and calculations were performed on 2,6-dimethyl-*N*-methylaniline (Bader, Aldrich). The ^{13}C nmr spectra at 23.63 MHz were recorded from a solution containing 1 g of the compound, 3 mL of dimethyl ether, and 0.5 g of acetone-d_6. At 130 K, the temperature at which precipitation of the compound became marked, no relative broadening of the C-2, C-6 peak was observable. In *N*-methylaniline itself the shift difference between C-2 and C-6 is 6.0 ppm at 140 K. If this were also true for the dimethylaniline, then it would follow that an upper limit to $\Delta G^{\ddagger}$ would be 24.6 kJ/mol. However, in *N-tert*-butylaniline, the corresponding shift difference is only 3.6 ppm, presumably because the conformation of the ground state is one in which the *tert*-butyl group lies nearer a plane perpendicular to the benzene ring than does the methyl group in the ground state of *N*-methylaniline. If the C-2,C-6 internal shift in the 2,6-dimethyl-*N*-methylaniline is only 3.6 ppm, then an upper limit to $\Delta G^{\ddagger}$ for rotation about the C_1—N bond becomes 25.2 kJ/mol.

These conclusions may well be vitiated by the following arguments. STO-3G MO computations gave 75° for the $C_2C_1N(CH_3)$ dihedral angle in the minimum energy conformation (see **6**), that is, a geometry near that of the 2,6-dichloro derivative. Repeated attempts at full geometry optimizations, as done for *N*-methylaniline and the 2,6-difluoro derivative, resulted in nonconvergence even after 9-h runs. In any event, it seems likely that the ground state is strongly destabilized by the two *ortho* methyl substituents.

This supposition is supported by the chemical shift of C-4. After a correction for the presence of the two methyl substituents, δ_4 is 122.0 at 200 K. In *N*-methylaniline in the same solvent at 200 K, δ_4 is 115.8(3). δ_C in benzene is 128.5. The high-field shift due to π electron donation by the lone pair on nitrogen is therefore reduced by a factor of one half in the presence of the *ortho* methyl groups.

The photoelectron spectrum (26) of 2,6-dimethyl-*N*-methylaniline may in interpreted to mean that the angle between the lone-pair direction and the plane perpendicular to the benzene ring is as large as 44°. Referring to **3** to **6**, it seems reasonable that the angle between the N—(CH_3) bond and ring plane is therefore near 75°.

Now, if the N—(CH_3) bond were in a plane perpendicular to the benzene ring, inversion at nitrogen, as in **7** ⇌ **8**, would lead to a coalescence of the chemical shifts of C-2 and C-6. Even if the N—(CH_3) bond direction deviates somewhat from the perpendicular but leaves the N—H bond on the opposite side of

[2] In view of the experimental errors, any discrimination between V_2 and other barrier forms (questions of ground state energies and the difference between $\Delta H^{\ddagger}$ and V_2, etc) is immaterial at present.

[3] The dipole moment of *N*-methylaniline is 1.67 D in benzene solution (25).

7 8

the benzene plane, as appears probable for 2,6-dimethyl-*N*-methylaniline from the STO-3G MO computations, then inversion will average the C-2 and C-6 relative shift to zero because the N—(CH_3) bond need only move a little near its energy minimum. However, when the N—H and N—(CH_3) bonds lie on the same side of the benzene plane, inversion will not cause such an averaging process.

Although the C_1—N rotational barrier could not be computed for 2,6-dimethyl-*N*-methylaniline, some calculations were done for the 2,6-dichloro derivative, in which the N—H and N—(CH_3) bonds apparently also sit on opposite sides of the benzene plane in the low-energy conformation (see **6**). For example, as the dihedral angle in **6**, C_2C_1NC, decreases to zero, the energy of the molecule increases by 24.2 kJ/mol and this value is still below the maximum barrier. However, torsion by 20° from the equilibrium conformation requires only about 7 kJ/mol, so that a concerted motion to yield the mirror image of **6** is very likely much faster than rotation by 180° about the C_1—N bond.

It appears, therefore, that inversion at nitrogen causes coalescence of the C-2 and C-6 chemical shifts in 2,6-dimethyl-*N*-methylaniline and that, in general, barriers to rotation about the C_1—N bond in *ortho* disubstituted *N*-methylaniline derivatives will not be available from dnmr experiments if the N—H and N—(CH_3) bonds are situated on opposite sides of the benzene plane; the inversion rate will then always be much larger than the rotation rate and too large for the measurement of the dephasing of magnetization due to Larmor site exchange.

Further molecular orbital calculations

For aniline itself, the STO-3G geometry is reasonably good, having an angle of 51° between the NH_2 and benzene plane (8); the experimental value is 38° (27). At the 4-21G level of theory, our calculations yield a planar aniline geometry and a very similar result for *N*-methylaniline, the H—N—C(H_3) plane lying within a degree or two of the benzene plane. Clearly, the introduction of other orbital-type functions (28) is necessary if an improvement over the STO 3G geometries in this paper is to be achieved.

The phenyl group as a hydrogen bond acceptor in 2-phenylphenol derivatives. Substituent comparisons

TED SCHAEFER, TIMOTHY A. WILDMAN, RUDY SEBASTIAN, AND DAVID M. MCKINNON
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received April 13, 1984

TED SCHAEFER, TIMOTHY A. WILDMAN, RUDY SEBASTIAN, and DAVID M. MCKINNON. Can. J. Chem. **62**, 2692 (1984).

The disagreement about the free energy of formation, ΔG, of the intramolecular O—H . . . π bond in 2-phenylphenol is resolved by the measurement of stereospecific spin–spin coupling constants between ring protons and the hydroxyl proton. In CCl_4 solution at 305 K, ΔG is $5.1_5 \pm 1.06$ kJ/mol, in reasonable agreement with a value from hydroxyl stretching band studies. The free energy preferences of the phenyl group relative to chlorine, iodine, and the allyl group are also estimated from long-range couplings in the appropriate derivatives of 2-phenylphenol. A ranking of free energy preferences is given for twelve *ortho* substituents in phenol derivatives in CCl_4 solution. Relative to a methyl group, the free energy difference favoring the O—H . . . π interaction is 1500 ± 350 J/mol for an allyl and is 6500 ± 1030 J/mol for a phenyl group.

TED SCHAEFER, TIMOTHY A. WILDMAN, RUDY SEBASTIAN et DAVID M. MCKINNON. Can. J. Chem. **62**, 2692 (1984).

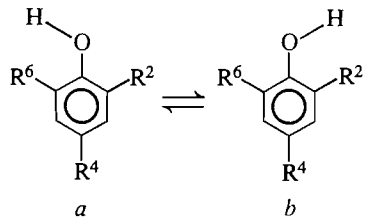
On a résolu le désaccord qui existait relativement à l'énergie libre de formation, ΔG, de la liaison intramoléculaire O—H . . . π dans le phényl-2 phénol, en mesurant les constantes de couplage spin–spin stéréospécifiques entre les protons du cycle et le proton hydroxyle. A 305 K et en solution dans le CCl_4, le ΔG est égal à $5,1_5 \pm 1,06$ kJ/mol; cette valeur est en bon accord avec une valeur obtenue en étudiant les bandes de vibration de la liaison hydroxyle. Utilisant les couplages à longue distance dans les dérivés appropriés du phényl-2 phénol, on a aussi évalué les préférences, du point de vue de l'énergie libre, du groupe phényle par rapport au chlore, à l'iode ou au groupe allyle. On a établi un ordre, du point de vue de l'énergie libre, des préférences de douze groupes *ortho* dans des dérivés phénoliques en solution dans le CCl_4. Par rapport à un groupe méthyle, la différence d'énergie libre favorisant l'interaction O—H . . . π est égale à 1500 ± 350 J/mol pour un groupe allyle et elle est égale à 6500 ± 1030 J/mol pour un groupe phényle.

[Traduit par le journal]

Introduction

The intramolecular OH . . . π hydrogen bond in 2-phenylphenol, **1** (R^2 = phenyl, $R^4 = R^6$ = H), has been examined by means of hydroxyl stretching (1–4) and torsional (5) frequencies, and by dipole moment measurements (6). Over a range of 50°C in CCl_4 solution, the temperature dependence of the intensities of the hydroxyl stretching bands assigned to **1***b* and **1***a* yielded an enthalpy difference, ΔH, of -6070 ± 1130 J/mol favoring **1***b*. The entropy difference, ΔS, was reported as -1.4 ± 3.5 J/mol K (2), implying a free energy difference, ΔG, of -5640 ± 2200 J/mol at 305 K. For reasons given in an examination of errors inherent to such studies (7), it may well be that this ΔS value is uncertain. Repetition of such experiments indicated ΔH as either greater than 10.4 kJ/mol or smaller than 2.1 kJ/mol (5). Another investigation (3) also reports infrared measurements for **1** in CCl_4 solution, presumably near room temperature. The ratio of the intensities of the hydroxyl stretching bands is 6.4, interpretable as a free energy difference of 4700 J/mol at 305 K or 4600 J/mol at 298 K if the absorptivities of the two bands are equal. There is some evidence for their equality to within about 5% (8). The most recent infrared measurements (4) on **1** in various solvents report an intensity ratio of 6.7, at 35°C, but it is unclear in which solvent this value was found.

Although there were difficulties with the assignment of the torsional frequencies of the hydroxyl group in cyclohexane solution, a potential energy of 11.4 kJ/mol (roughly equivalent to ΔH) favoring **1***b* was tentatively suggested. The dipole moment of **1** was consistent with a preferred OH . . . π interaction (6).



1: R^2 = phenyl, $R^4 = R^6$ = H
2: $R^2 = R^6$ = phenyl, R^4 = H
3: R^2 = phenyl, R^6 = allyl, R^4 = H
4: R^2 = phenyl, $R^4 = R^6$ = I
5: R^2 = phenyl, R^4 = H, R^6 = Cl
6: R^2 = phenyl, R^4 = I, R^6 = H

The existence of an attractive OH . . . π interaction is supported by the crystal structure of 2,6-diphenylphenol, **2** ($R^2 = R^6$ = phenyl, R^4 = H), in which to within experimental error the hydrogen atom of the hydroxyl group lies above the C_1—C_2 bond of R^2 at a distance of 2.42 Å from the two carbon atoms. The hydroxyl group appears to be twisted by 5° away from coplanarity with its own phenyl group. The 6-phenyl group is twisted by 44° and the other phenyl group, involved in the OH . . . π bond, by 52° out of the plane of the phenol ring (9). The latter angle is substantiated by ultraviolet spectra, interpreted to yield 50° in **1** (3).

Ultraviolet and infrared spectra (3) indicate an increased OH . . . π interaction as the dihedral angle between the two benzene rings increases. One conclusion (3) has it that the interaction depends mainly on the π orbital of C-1 on the phenyl ring, giving rise to a charge transfer between the antibonding orbital of the hydroxyl group and the donating occupied π orbital. This conclusion is at variance with the geometry of **2**, with the very similar infrared absorbances of phenol and **1** (8), and very likely also with some recent photoelectron spectroscopy data (10) on OH . . . π systems. These imply a predominantly electrostatic OH . . . π hydrogen bonding energy, requiring little charge transfer.

Now, it has been shown (11–13) that the stereospecific spin–spin coupling constant over five formal bonds between the hydroxyl proton and the ring protons in the *meta* position, $^5J_m^{OH,H}$, yields reliable free energy differences between *a* and *b* conformers of phenol derivatives in solution.[1] This approach

[1] An exception is 2-*tert*-butylphenol (14), but not its 6-substituted derivatives.

TABLE 1. The ^{1}H nmr spectral parameters for 2-phenylphenol at 100.001 MHz in CCl_4 solution at 305 K

Parameter	1.9 mol%	4.6 mol%	Parameter	1.9 mol%	4.6 mol%
ν_{OH}	497.938(13)[a]	499.750(5)[b]	$^3J_{45}$	7.357(11)	7.366(8)
ν_3	711.805(9)	710.495(5)	$^3J_{56}$	8.132(13)	8.136(8)
ν_4	686.677(9)	685.567(5)	$^4J_{35}$	1.718(10)	1.732(6)
ν_5	714.813(10)	713.065(5)	$^4J_{46}$	1.182(2)	1.183(5)
ν_6	687.280(7)	685.384(4)	$^5J_{36}$	0.437(13)	0.419(8)
$^5J_m^{OH,3}$	0.05(2)[c]	0.06(2)[c]	rms deviation	0.0151	0.0153
$^5J_p^{OH,4}$	[d]	[d]			
$^5J_m^{OH,5}$	0.434(11)	0.403(6)	Observed peaks	33	42
$^4J_o^{OH,6}$	[d]	[d]	Assigned transitions	35	75
$^3J_{34}$	7.610(11)	7.614(7)	Calculated transitions	79[e]	81[e]

[a] In Hz at 100.001 MHz to low field of internal tetramethylsilane.
[b] Numbers in parentheses are standard deviations in the last one or two significant figures.
[c] Estimated from linewidth changes in H-3 and H-5 peaks and spectral simulations while decoupling the hydroxyl protons.
[d] No evidence found for finite magnitudes.
[e] Above a relative intensity of 0.05; note that the signal-to-noise ratio for the 1.9 mol% solution was poor, leading to fewer assigned transitions and larger errors in the spectral parameters.

assumes $^5J_m^{OH,5} \equiv {}^5J_m^{OH,H\text{-}5} = 0$ in *a* and $^5J_m^{OH,3} \equiv {}^5J_m^{OH,H\text{-}3} = 0$ in *b*, so that ΔG can be found from $-RT \ln ({}^5J_m^{OH,5}/{}^5J_m^{OH,3})$. Because of the disagreements among the techniques mentioned above, it was decided to use $^5J_m^{OH,H}$ as an indicator of ΔG for **1** in CCl_4 solution. Furthermore, because the allyl group and the halogens had previously been examined by this method as hydrogen bond acceptors in phenol derivatives (12, 15), **3** (R^2 = phenyl, R^6 = allyl, R^4 = H), **4** (R^2 = phenyl, $R^4 = R^6$ = I), **5** (R^2 = phenyl, R^6 = Cl, R^4 = H), and **6** (R^2 = phenyl, R^6 = H, R^4 = I) were also studied in an attempt to rank the phenyl group as a hydrogen bond acceptor. Compound **2** was also examined. Full analyses of the ^{1}H nmr spectra were performed.

This paper reports the results of these experiments and concludes that the phenyl group ranks below the halogens but above allyl, trifluoromethyl, and saturated hydrocarbon groupings as a hydrogen bond acceptor. No evidence is found for a significant decrease in entropy on formation of the intramolecular OH . . . π bond in 2-phenylphenol.

Experimental

Compounds **1**, **2**, and **5** came from Aldrich Chemical Co. Compounds **4** and **6** were minor and major products, respectively, of a standard iodination procedure. Thin-layer chromatography on silica gel with 10 v/v% $CHCl_3$ in CCl_4 gave 2-phenyl-4-iodophenol, **6**, and 2-phenyl-4,6-diiodophenol, **4**, which yielded satisfactory ^{1}H nmr and mass spectra. Compound **3**, 6-allyl-2-phenylphenol, was prepared via 2-allyloxybiphenyl. The latter was made by reaction of equimolar quantities of **1**, allyl chloride, and NaOH in ethanol. This mixture was heated at reflux for 3 h and worked up by dilution with water. The material was purified by chromatography on silica gel in petroleum ether. The compound (1 g) was heated at 230°C under nitrogen for 1 h. The crude product, **3**, was dissolved in 1:1 v/v benzene/petroleum ether and chromatographed on silica gel. A fast-running colorless band was removed and purified by rechromatography (thick-layer) in benzene/petroleum ether. Compound **3** was obtained as a viscous colorless oil.

Samples for ^{1}H nmr spectroscopy were prepared in 5-mm od Pyrex tubes and were degassed by eight freeze–pump–thaw cycles before being flame sealed. Intermolecular hydroxyl proton exchange was retarded by procedures previously described (15). Concentrations of **1** to **6** in various solvents are given in the tables below. The ^{1}H nmr spectra were calibrated on an HA100 nmr spectrometer at a probe temperature of 305 K. The calibration procedures for this instrument have been described in detail and yield typical standard deviations of the peak frequencies of $\leq$0.02 Hz (16).

Results and discussion

1. *Spectral analyses*

These were performed with the computer program LAME (17, 18). The protons of the phenyl groups in all but **5** were too tightly coupled for an analysis. For **5** an analysis of the complete spectrum was made. Table 1 presents the spectral parameters obtained for two different samples of **1** in CCl_4 solution. Table 2 gives only those spectral parameters of immediate interest to the discussion for **1** to **6**. Figure 1 demonstrates the spectral quality obtained for those compounds. Some inter-ring proton coupling may have contributed to the observed linewidths. Certainly for **6**, some coupling exists between the hydroxyl proton and the phenyl ring protons. The allyl spectrum for **3** was analyzed, yielding coupling parameters very similar to those found for 2-allylphenol and some derivatives (12).

2. *The phenyl group as an acceptor of and competitor for the hydrogen bond*

In the following discussion, $^5J^{OH,H}$ numbers are used: first, to establish the free energy preference of **1***b* in 2-phenylphenol; second, to show the phenyl group in competition with other hydrocarbon substituents for the hydrogen bond; third, to make similar comparisons with halogen substituents. Finally, based on $^5J^{OH,H}$ values, there is given a ranking of the phenyl group as a hydrogen bond acceptor for a variety of substituents.

(i) 2-Phenylphenol, 1

It has been successfully argued previously (11–15) that the free energy difference, ΔG, between conformers *a* and *b* is given simply by $-RT \ln ({}^5J_m^{OH,5}/{}^5J_m^{OH,3})$. For **1**, dilution from 4.6 to 1.9 mol% in CCl_4 causes a highfield shift of 0.02 ppm in δ_{OH}, implying negligible intermolecular self-association at

[b] In Hz at 100.001 MHz to low field of internal tetramethylsilane.
[c] Long-range couplings from the methylene protons to the ring protons are $^4J_o = -0.609(5)$, $^5J_m = 0.282(5)$, and $^6J_p = -0.413(5)$ Hz.
[d] Simulation of peak widths obtained under single resonance and double resonance (decoupling of hydroxyl proton) conditions.
[e] In CS_2 solution, $^5J_m^{OH,5}$ not measured.
[f] In C_6D_6 solution.

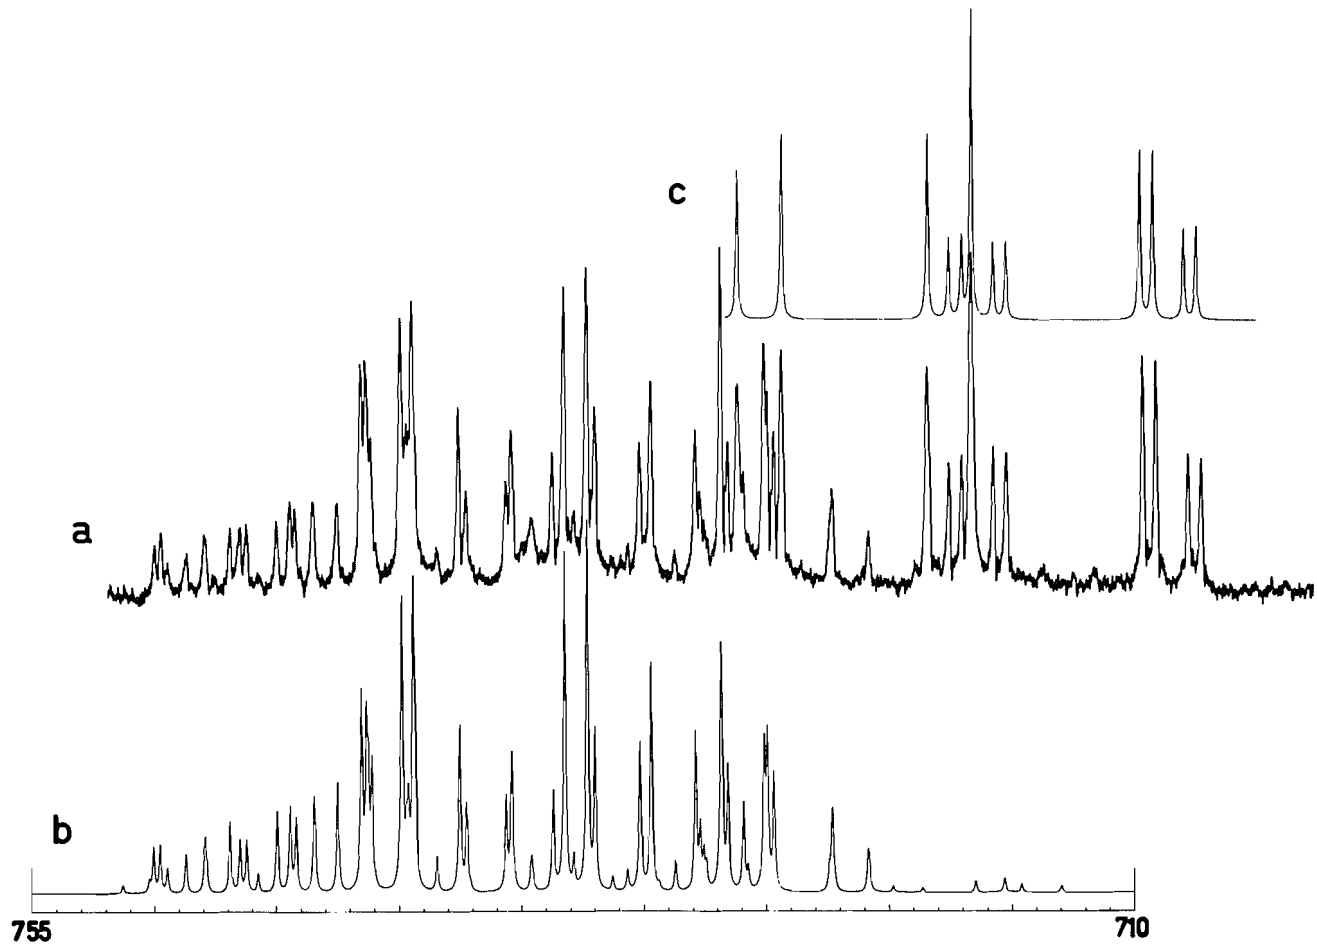

FIG. 1. In (a) a region of the aromatic ^1H nmr spectrum at 100 MHz and 305 K is shown for 2-phenyl-6-chlorophenol, **5**, as a 4.5 mol% solution in CCl_4. The spectrum of H-4 does not occur in this region. In (b) the computed spectrum of the phenyl protons is displayed, and in (c) the computed spectrum of H-3 and H-5 is given. Some impurity peaks are evident in the experimental spectrum. The linewidths at halfheight, $\Delta\nu_{1/2}$, are substantial for some peaks, indicating unresolved coupling to the hydroxyl proton. Thus, the four peaks due to H-3, centered at 717 and 725 Hz relative to internal TMS, decrease in width from 0.22 to 0.15 Hz upon strong irradiation of the hydroxyl proton peaks, while the doublets due to H-5 collapse to single peaks having $\Delta\nu_{1/2}$ as 0.15 Hz. Many of the peaks from the phenyl protons also sharpen under these conditions.

these concentrations. It may also be noted that a detailed dilution study of 2-methyl-4-chlorophenol (11) showed that at these concentrations intermolecular association does not alter the free energy differences calculated for the intramolecular equilibrium from $^5J_m^{OH,H}$. For **1** at 1.9 mol% in CCl_4, signal-to-noise problems lead to higher errors in $^5J_m^{OH,H}$ than for the 4.6 mol% solution (Tables 1 and 2). Nevertheless, the data for the more dilute solution are included in the calculation of ΔG,

leading to 5150 ± 1060 J/mol at 305 K favoring conformation *b*, the intramolecularly hydrogen bonded form. The relatively large error in ΔG has its origin in the small magnitude of ${}^5J_m^{OH,3}$ and the concomitant large relative error in this parameter.

Comparison with the infrared data, discussed above, clearly favors the initial results from the hydroxyl stretching band intensities (2) over the estimates obtained from torsional frequencies. The former gave ΔG as 5640 ± 2200 J/mol, in agreement with the coupling constant data, although, to within experimental error, the latter also agree with the ΔH of 6070 ± 1130 J/mol found from the temperature dependence of the intensities of the stretching bands. Our numbers do not affirm the existence of a negative entropy of formation for the OH . . . π bond in **1**.

(ii) 2-Phenyl-6-allylphenol, 3

In 2-allylphenol, the free energy favoring conformer *a* in CCl_4 solution is 90 ± 190 J/mol (12), based on ${}^5J_m^{OH,H}$. On an additive basis, it follows that ΔG in 2-phenyl-6-allylbenzene, **3**, is 5240 ± 1250 J/mol, whereas the coupling data in Table 2 yield 5010 ± 680 J/mol favoring *b*, that is, a hydrogen bond to the phenyl group.

Now, comparison of ${}^5J_m^{H,OH}$ values in 2-allylphenol, 2-methylphenol, and 2-allyl-6-methylphenol shows, first, that ΔG for the last of these three compounds is obtained by addition of the ΔG values for the first two compounds and, second, that the OH . . . π bond in 2-allylphenol has a free energy preference of 1500 ± 350 J/mol at 305 K (12). This number is based on the assumption that the increased population of the conformer with the OH bond *cis* to the substituent in 2-allyphenyl *relative to* 2-*methylphenol* is a consequence of the OH . . . π bond to the allyl substituent.

Because the internal equilibrium constants in the 2- and the 2,6-disubstituted phenols vary substantially for allyl, methyl, and phenyl substituents, the self-consistent additivity schemes above provide no support for substantial negative entropies of formation (2, 5) of the O—H . . . π bond in 2-allylphenol or 2-phenylphenol, unless the entropy differences coincidentally cancel for all these substituents. This coincidence seems unlikely.

It has been suggested (5) that in 2-phenylphenol an entropy decrease of about 18 J/mol K could occur on formation of the OH . . . π hydrogen bond. In our opinion a decrease of less than I J/mol K is more likely. Thus, the internal barrier to rotation in biphenyl is not less than 8 kJ/mol (19–23). Insertion of a 2-hydroxy substituent raises the internal barrier even in the absence of the OH . . . π interaction. An estimate of this increase is available from a comparison of the increased internal rotational barriers in some biphenyl derivatives (Table 3 of ref. 22) caused by 2-fluoro and 2-hydroxy substituents, suggesting a *minimum* value of 11 kJ/mol. Formation of the OH . . . π bond will contribute a further increase of at most 6 kJ/mol. Accordingly, the decrease in entropy on formation of *b* from *a* can be estimated[2] as 1.3 J/mol K on the basis of a hindered rotor model (24). An estimate based on the harmonic oscillator model (25) yields 1.2 J/mol K. The infrared data gave 1.4 ± 3.5 J/mol K for **1***a* ⇌ **1***b* (2). The experimental estimate of the internal entropy of biphenyl itself is 0.9 J/mol K (23), so that these numbers are probably too large. See also ref. 26.

The infrared studies also found ΔS as 3.8 ± 1.8 J/mol K for the equilibrium in 2-allylphenol. In view of the remarks in the introduction concerning the reliability of such numbers, and because of our present results for ΔG, it seems that very small values for ΔS are more likely. Unfortunately, simple calculations show that a temperature change of 50°C, the useful range for CCl_4 solutions, will not yield a reliable ΔS via measurements of ${}^5J_m^{OH,H}$.

In any event, relative to a methyl group, the present results yield free energy differences favoring an OH . . . π interaction of 1500 ± 350 J/mol for allyl and 6500 ± 1030 J/mol for phenyl. The comparison with a methyl group as a 2-substituent seems more appropriate than with hydrogen as a 2-substituent.

(iii) 2-Phenyl-4,6-diiodophenol, 4, and 2-phenyl-6-chlorophenol, 5

In **4** the free energy difference is 1670 ± 150 J/mol to the advantage of the OH . . . I hydrogen bond. Note that for **6**, 2-phenyl-4-iodophenol, in CCl_4 solution (Table 2), ΔG is 5250 ± 1140 J/mol, implying that a 4-iodo substituent does not perturb the equilibrium for **1** or **4**.

Turning to **5**, one has a free energy of 4660 ± 770 J/mol favoring the OH . . . Cl interaction. Now, in a study of halophenol derivatives it was established that the ΔG value to the advantage of Cl over I was 1920 ± 250 J/mol (15). Proceeding as before, one has (4660 ± 630) − (1920 ± 250) or 2740 ± 890 J/mol as a prediction for the OH . . . I over the OH . . . π bond in **4**. The observed value is 1670 ± 150 J/mol.

Clearly, for the chlorine, iodine and phenyl substituents, combined as pairs of 2,6-substituents, an additivity scheme is much less satisfactory than for the allyl, methyl, phenyl triplet. For the latter, the ΔG values for the 2-substituents alone also fit into the additivity scheme. Unfortunately, the equilibrium for 2-iodophenol in CCl_4 solution is shifted so far to the intramolecularly hydrogen bonded conformer that a ΔG value is not available from ${}^5J_m^{OH,H}$ (27).

(iv) Ranking of the phenyl group as a hydrogen bond acceptor

${}^5J_m^{OH,H}$ values are now available for a substantial number of phenol derivatives. Table 3 gives a tabulation of the derived free energy preferences of the hydroxyl group for twelve relatively weak hydrogen-bond acceptors or repellors. The fourth column represents experimental data and the other columns follow directly from it. The first column arranges these preferences relative to the *tert*-butyl group as zero, purely for convenience. Other columns in Table 3 compare free energy preferences for pairs of *ortho* substituents, also derived from ${}^5J_m^{OH,H}$, with the appropriate differences taken from the first column. In general, the agreement is satisfactory, indicating the validity of an additive scheme which includes hydrogen as a substituent.

However, one discrepancy is unsatisfactory and occurs for iodine as a substituent competing with the phenyl group (footnote *e* in Table 3). The iodine substituent provides an entry into the hydrocarbon substituent series, the latter forming a self-consistent set ranging from phenyl, preferring the hydroxyl group by about 5.0 kJ/mol, to *tert*-butyl, repelling the hydroxyl group by about 6.6 kJ/mol. According to Table 3, iodine should have a free energy preference of 2.7 kJ/mol over phenyl, yet the observed value is only 1.7 kJ/mol. Chlorine, on the other hand, does not misbehave in such a comparison. One possibility, unprovable here, is that the *relatively* large iodine substituent causes an increased OH . . . π overlap in **4**.

Table 3 does not contain comparisons of certain other substituents, also studied by nmr. For example, mercapto and chlorine as competing *ortho* substituents (29) yield ${}^5J_m^{OH,H}$ val-

[2] The reduced moment of inertia of 2-phenylphenol is 1.00×10^{-38} g cm^2.

[f] From infrared band intensities (33).

ues which suggest that SH falls between I and CF_3 in Table 3. However, formation of the OH . . . S bond twists the mercapto group into a perpendicular conformation, causing a loss of 3.3 kJ/mol in $3p,\pi$ conjugation (29, 30), perhaps implying that the OH . . . S bond strength is as large as the OH . . . Cl interaction. Again, in salicylaldehyde, the OH . . . O=C bond strength is estimated as 29.7 kJ/mol on the basis of δ_{OH} (31), in rough agreement with molecular orbital calculations. The 2-methoxy substituent has also been studied by nmr (32) and by far infrared techniques (5). $^5J_m^{OH,H}$ did not yield ΔG values (32) but is consistent with an energy (enthalpy) preference of 8.4 kJ/mol for the OH . . . O bond derived from the torsional frequencies.

Conclusions

In CCl_4 solution the OH . . . π bond in 2-phenylphenol has a free energy preference of $5.1_5 \pm 1.0_6$ kJ/mol at 305 K. In a ranking of substituents as intramolecular hydrogen bond acceptors in phenol derivatives, the phenyl group falls below the halogens but above the CF_3 group. Comparison with other hydrocarbon groupings does not support the notion of a significant decrease in entropy on formation of the OH . . . π bond, but does show that the OH . . . π bond in 2-phenylphenol is appreciably stronger than in 2-allyl and 2-benzylphenols, in which the nonbonded conformers are actually most abundant at 305 K.

A new efficient synthesis of the 16-epimers of (±)-3-hydroxy-16,17-butanomorphinan

JOHN DIMAIO
Clinical Research Institute of Montreal, Department of Chemical Biology and Peptide Research, 110 Pine Avenue West, Montreal, P.Q., Canada H2W 1R7

AND

BERNARD BELLEAU
Department of Chemistry, McGill University, 801 Sherbrooke Street West, Montreal, P.Q., Canada H3A 2K6

Received February 7, 1984

JOHN DIMAIO and BERNARD BELLEAU. Can. J. Chem. **62**, 2697 (1984).

A novel synthetic route to the 16α- and 16β-epimers of (±)-3-hydroxy-16,17-butanomorphinan is described. The method involves the key intermediate 4a-(2-piperidinylmethylene)-1,2,3,4,4a,9-hexahydro-6-methoxyphenanthrene **9**. Deprotection of the intermediate epoxy trifluoroacetamide **10** with sodium borohydride provides exclusively the 9α-hydroxyhasubanan which is rearranged to the 14-dehydromorphinan with PBr_3. Hydrogenation of the intermediate olefin followed by *O*-demethylation afforded th desired (±)-3-hydroxy-16,17-butanomorphinan epimers which were separated by crystallization. Single crystal X-ray crystallography confirmed the 16β configuration and chair conformation of ring D in **1***b* which contrasts with the 16α configuration and boat conformation for ring D in **1***a*, a compound identical to that previously synthesized using an extension of the Grewe-type methodology.

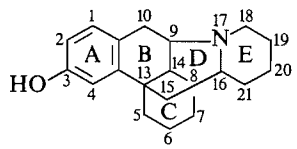
JOHN DIMAIO et BERNARD BELLEAU. Can. J. Chem. **62**, 2697 (1984).

On décrit une nouvelle voie de synthèse des épimères 16α et 16β des (±)-hydroxy-3 butano-16,17 morphinanes. La méthode implique le (pypéridinyl-2 méthylène)-4a hexahydro-1,2,3,4,4a,9 méthoxy-6 phénanthrène **9** comme intermédiaire clé. La déprotection de l'intermédiaire époxy trifluoroacétamide **10** par le borohydrure de sodium conduit exclusivement à l'hydroxy-9α hasubanane qui se transpose en déhydro-14 morphinane sous l'action du PBr_3. L'hydrogénation de l'oléfine intermédiaire, suivie d'une *O*-déméthylation, conduit aux épimères (±)-hydroxy-3 butano-16,17 morphinanes désirés que l'on peut séparer par cristallisation. Une étude par diffraction des rayons-X sur des cristaux uniques a permis de confirmer la configuration de l'isomère 16β pour le composé **1***b* et d'établir que son cycle D existe dans une conformation chaise; ceci est en opposition avec une configuration 16α et une conformation bateau du cycle D pour l'isomère **1***a*, un composé identique à celui synthétisé antérieurement en faisant appel à une extension d'une méthodologie du type Grewe.

[Traduit par le journal]

Among the many parameters that contribute to the agonistic activity of rigid opiates of the morphinan and benzomorphan type (1), the spatial orientation of the *N* lone pair plays a role which has formed the basis of much controversy (2, 3). Douglas and Meunier (4) described the synthesis of one of two possible epimers of (±)-3-hydroxy-16,17-butanomorphinan (Fig. 1) and reported that it was inactive either as an agonist or as an antagonist. Recently we reported (5) that this inactive epimer has the structure **1***a* (Fig. 1). The 16α-configuration rigidly locks ring D in the boat conformation. It is difficult to force ring D into the chair form because of the severe steric interactions that are created between the butano bridge and the aromatic ring.[1] As a result, the *N* lone pair of this latter epimer can only be oriented toward the phenyl ring in a manner analogous to the lone pair of an inactive ring D normorphinan described previously (6).

In order to provide additional evidence for the relevance of the *N* lone pair orientation to productive in vivo opiate receptor interactions, we sought a method to invert the *N* lone pair into the favoured orientation (away from the phenyl ring). In order to achieve this, we oxidized the *O*-acetyl-16α,17-butanomorphinan derivative of **1***a* with mercuric acetate (Scheme 1) and obtained the enamine **2** which was reduced with sodium cyanoborohydride followed by hydrolytic removal of the *O*-acetyl group to give the morphinan **1***b*. Single crystal X-ray analysis of the latter established (7) the 16β-configuration and the chair conformation for ring D. This arrangement fixes the



1

1*b*

FIG. 1

N lone pair orientation in the direction opposite to that of **1***a* (away from the phenyl ring). It was gratifying to discover that this epimer displayed analgesic activity in mice (writhing assay, ED_{50} (mean effective dose) 3 ± 0.5 mg/kg sc) at a level comparable to that of pentazocine as the standard, but was inactive as an antagonist (oxymorphone Straub tail test).[2] The

[1] Using the SCRIPT computer programme, Dr. N. C. Cohen of Roussel–UCLAF estimated this chair form to be disfavored by 2.9 kcal/mol over the boat form.

[2] We are indebted to Dr. Anthony W. Pircio of Bristol Laboratories, Syracuse, New York, for providing us with this data.

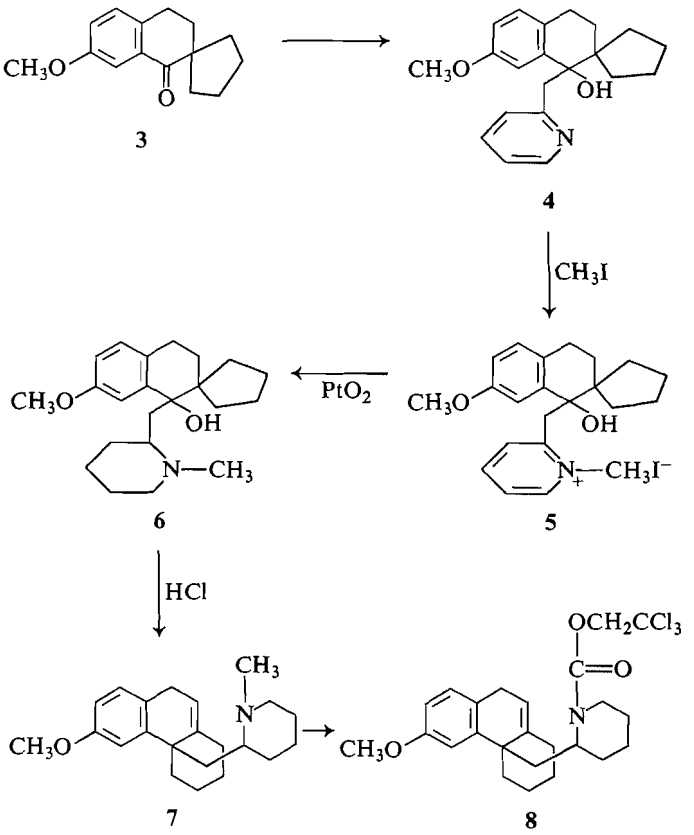
SCHEME 1

original synthesis of Douglas and Meunier generated a single but inactive epimer **1***a* and did not permit access to analogs functionalized at or near the 14-position, although it allowed us to generate (albeit inefficiently) the desired 16β-epimer **1***b* as outlined above. In order to overcome these limitations and acquire a complete pharmacological profile for this and related analogs, access to a more versatile and efficient synthesis became necessary. In this communication we described an alternative strategy which satisfies our requirements.

Results and discussion

Our synthetic approach to (±)-3-hydroxy-16,17-butanomorphinan is shown in Scheme 2 and begins with the known spiro ketone **3** (8). The latter was reacted with the carbanion of α-picoline (generated with phenyllithium) and the adduct **4** quaternized to give the methiodide **5**. Catalytic hydrogenation of the latter over PtO_2 proceeded smoothly to afford **6** without affecting the sensitive benzylic hydroxyl group. It is noteworthy that **6** consisted of a mixture of diastereomers that were readily separable by fractional crystallization of the hydrochloride salts. However, this exercise is obviously superfluous because Wagner–Meerwein rearrangement of each isomer generates the same mixture of racemic diastereomers **7** nonstereospecifically. The resulting tertiary amine **7** was *N*-demethylated using trichloroethyl chloroformate and the resulting carbamate **8** decomposed by the method of Just and Grozinger (9) to yield secondary amine **9** (Scheme 3). As the hydrochloride salt, the latter is soluble in chloroform and in that solvent unequivocal evidence for the expected presence of diastereomers was adduced by nmr spectroscopy which revealed chemical shift differences arising from the olefinic and methoxy protons.

The next step involved oxidation followed by cyclization through the secondary amine nitrogen. However, we attempted initially to isomerize the double bond to the benzylic position with the hope of generating the desired morphinan directly through a subsequent base-catalyzed cyclization (10). Unfortunately, migration of the double bond to the conjugated position did not occur in this instance, no matter the nature of



3 4 5 6 7 8

SCHEME 2

the base used (*tert*-butoxide/DMSO, dimsyl sodium/DMSO, n-butyllithium/THF, LDA). Presumably the electron-donating properties of the aromatic methoxy group are counter productive. An alternative strategy involved the direct oxidative cyclization of **9** with mercuric acetate (11). However, the only product isolated using this method was the hasubanan analog, a not unprecedented result (12).

A different route was therefore adopted where the *N*-trifluoroacetyl epoxide **10** served as the key intermediate. It was generated by reaction of the diastereomeric **9** with trifluoroacetic anhydride, followed by epoxidation using *m*-chloroperbenzoic acid, which proceeded in a regiospecific fashion (*trans* relative to the piperidinemethyl face) to afford **10**. Deprotection of the amine with K_2CO_3 or $NaBH_4$ induced cyclization to give exclusively the 9α-hydroxy-16,17-butanohasubanan **11** as a mixture of two diastereomers.[3] The latter readily underwent rearrangement to the desired ring system simply by treatment with excess phosphorus tribromide in boiling ether. After neutralization, the $\Delta^{8,14}$-morphinan **12** was isolated as a mixture of diastereomers, as evidenced by nmr spectroscopy (two triplet signals for the olefinic protons at 5.25 and 5.75 ppm). This mixture of olefins was hydrogenated over PtO_2 and the *O*-methyl group removed with BBr_3. After workup the 16β-epimer **1***b* separated spontaneously from ethanol while the more soluble 16α-isomer remained in the mother liquors. The two isomers thus obtained were characterized by

[3] The two isomers of this 9α-hydroxyhasubanan co-crystallize as their hydrochloride salts. However, subsequent experiments on reversed phase liquid chromatography, in the solvent system 1:1 0.1% trifluoroacetic acid/methanol, revealed two peaks in a one-to-one ratio.

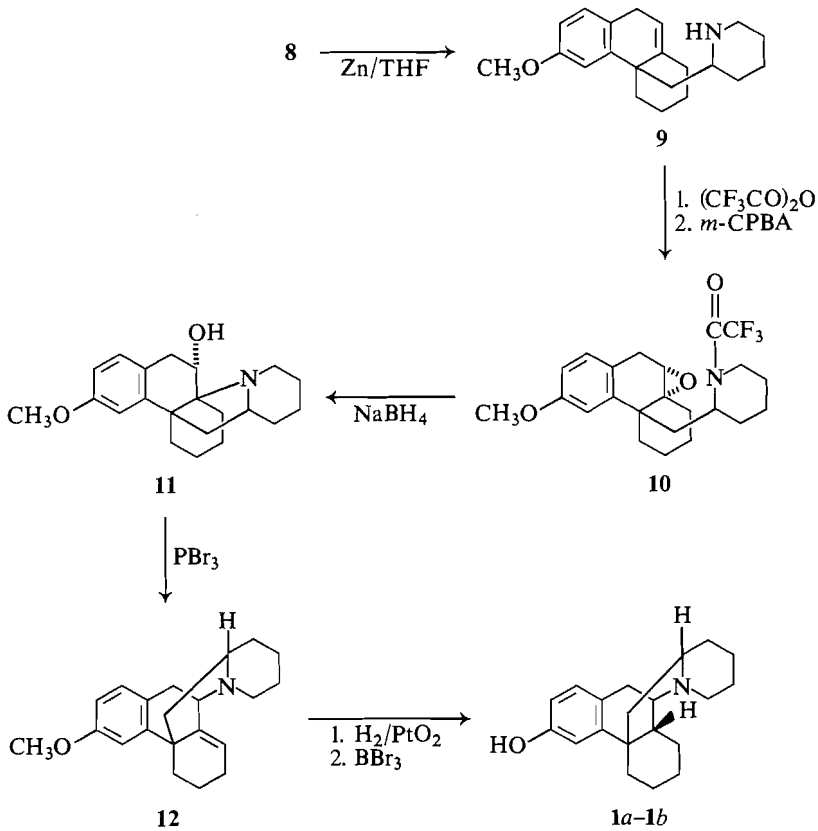

SCHEME 3

ir, hplc, and X-ray crystallography. Their properties were identical to those already observed for the previously synthesized (±)-3-hydroxy-16,17-butanomorphinans, the 16-epimers of which were characterized by X-ray analysis (7).

This new synthetic method also provides entry into analogs as yet unknown, such as 3,14-dihydroxy-16,17-butanomorphinans. Our results along this line will be described later, together with the detailed pharmacological properties of these interesting morphinans.

Experimental

The nmr spectra were recorded on a Varian EM-390 spectrometer using $CDCl_3$ as solvent. The chemical shifts are expressed as values relative to tetramethylsilane. Melting points were determined on a Gallenkamp apparatus and are uncorrected. The tlc analyses were done on Merck Kieselgel $60F_{254}$ silica gel and column chromatography was done on an equivalent Merck Kieselgel 60 gel 230–400 mesh. The ir spectra were recorded on a Beckman ir 4240 spectrophotometer. The hplc experiments were performed on a Waters model 600 A solvent delivery system equipped with a model 450 variable wavelength detector and U6K injector. Microanalyses were performed by Canadian Micro Analytical Services Ltd., Vancouver, B.C.

1-(2-Pyridylmethylene)-7-methoxy-1,2,3,4-tetrahydro-2,2-tetramethylene-1-naphthol (4)

In a 1-L three-neck flask (under nitrogen) containing 100 mL of anhydrous ether was added phenyllithium 2.4 *M* (150 mL) followed by the dropwise addition of 19.4 mL (200 mmol) of α-picoline. After stirring for 15 min, the solution was cooled (MeOH – Dry Ice) and treated dropwise with 57.5 g (240 mmol) of **3**. The solution was stirred at room temperature for 24 h and the reaction quenched with H_2O. The organic layer was separated and the aqueous phase extracted several times with ether. The combined extracts were extracted with cold 6 *N* HCl and the acidic solution made basic with ammonium hydroxide and extracted several times with ether. The combined extracts were dried (Na_2SO_4) and evaporated *in vacuo*. A pure product was obtained (50 g, 80% yield) by crystallization from petroleum ether 80–60°C, mp 63–65°C; ir (KBr): 3400 cm^{-1}; nmr ($CDCl_3$) δ: 5.8–9.7 (7H, m), 3.5 (3H, s), 2.8–3.3 (4H, m), 1.0–2.2 (1H, m). *Anal.* calcd. for $C_{21}H_{25}NO_2$: C 77.96, H 7.81, N 4.33; found: C 77.97, H 7.97, N 4.35.

1-(2-N-methylpyridylmethylene-7-methoxy-1,2,3,4-tetrahydro-2,2-tetramethylene-1-naphthol iodide (5)

To a solution of 4.64 g of **4** (10 mmol) in 30 mL of absolute ethanol was added a three-fold excess of methyl iodide. The solution was allowed to stand for 24 h. Crystalline material deposited, was collected by filtration, and the crystals washed with cold ethanol followed by ether, yield 3.2 g (73%), mp 211–213°C. An analytical sample was prepared by recrystallization from methanol; nmr ($CDCl_3$/DMSO) δ: 1.2–2.4 (10H, m), 2.7–3 (2H, m), 3.3 (3H, s), 3.8 (3H, s). *Anal.* calcd. for $C_{22}H_{28}NO_2I$: C 56.75, H 6.08, N 3.01; found: C 56.51, H 5.95, N 3.05.

1-(2-N-methylpiperidinylmethylene)-7-methoxy-1,2,3,4-tetrahydro-2,2-tetramethylene-1-naphthol (6)

A mixture of 13.6 g of **5** (32 mmol) and 1 g of PtO_2 in 300 mL of methanol was shaken in a Parr instrument (40 psi; 1 psi = 6.89 kPa) until uptake of hydrogen ceased (about 2 h). The catalyst was removed (Celite) and the filtrate evaporated *in vacuo*. The residue was suspended in water, and the mixture made basic with ammonium hydroxide and extracted several times with ether. The combined extracts were washed with 6 *N* HCl and the ether layer discarded. The aqueous phase was made basic with NH_4OH while cooling, the mixture extracted with ether, and the organic phase dried and evaporated *in vacuo*. The residue was dissolved in 200 mL of anhydrous ether and dry HCl introduced into the solution, whereupon a white solid deposited. The hydrochloride salt was collected and dried, yield 9.8 g (90%); nmr free base ($CDCl_3$) δ: 1.85 (N—CH_3, s, 3H), 2.3

(N—CH_3, s, 3H), diastereomers. Fractional crystallization from ethanol ether of this product yielded two compounds, one with mp 270–273°C and the other 219–220°C. *Anal.* calcd. for $C_{22}H_{34}N_1O_2Cl$: C 69.69, H 9.06, N 3.70; found: C 69.35, H 9.20, N 3.56.

*4a-(2-*N*-methylpiperidinylmethylene)-1,2,3,4,4a-9-hexahydro-6-methoxyphenanthrene (7)*

The preceding mixture of isomers (4.6 g, 12 mmol) was added to 50 mL of concentrated aqueous HCl and 100 mL of ether and the mixture refluxed for 24 h after which time the layers were separated. The acidic phase was diluted with 50 mL of H_2O, made basic with ammonium hydroxide, and extracted with ether. The combined organic extracts were dried (Na_2SO_4) and evaporated *in vacuo* affording 3.8 g (98% yield) of a clear viscous oil; nmr ($CDCl_3$) δ: 7.1–6.6 (3H, m), 5.7 (1H, m), 3.8 (3H, s), 3.3 (2H, m), 2.2 (1.4H, s), 1.8 (1.5H, s). For purposes of analysis, the HBr salt was prepared and had mp 219–220°C. *Anal.* calcd. for $C_{22}H_{32}NOBr$: C 64.99, H 7.96, N 3.45; found: C 64.42, H 8.08, N 3.39.

*4a-(2-*N*-trichloroethoxycarbonylpiperidinylmethylene)-1,2,3,4,4a,9-hexahydro-6-methoxyphenanthrene (8)*

To a solution of 1.3 g (4 mmol) of **7** in 50 mL of benzene was added 500 mg (6 mmol) of $NaHCO_3$ and 1 mL (6 mmol) of trichloroethyl chloroformate. The solution was heated to reflux while monitoring the reaction by tlc. After 18 h the reaction was complete. The mixture was extracted sequentially with H_2O, 6 *N* HCl (3×), 10% NaOH (3×), and then water again. The organic phase was dried ($MgSO_4$) and evaporated to give a thick oil. The product was purified by flash chromatography eluting with chloroform. The clear viscous oil (1.5 g, 75% yield) resisted crystallization and was used as such in the next step.

4a-(2-Piperidinylmethylene)-1,2,3,4,4a,9-hexahydro-6-methoxyphenanthrene (9)

To a solution of 9.3 g (19 mmol) of **8** in 200 mL of THF was added 20 g of granular Zn, followed immediately by a 50-mL portion of 1 *M* KH_2PO_4. The solution was stirred at room temperature for 4 h, filtered over Celite, the filtrate evaporated *in vacuo*, the residue suspended in water, and the mixture extracted with ether. The combined extracts were washed with 6 *N* HCl and the organic layer discarded. The acidic phase was extracted with chloroform several times, and the extract dried (Na_2SO_4) and evaporated *in vacuo*. A crystalline pure material was obtained from ethanol/ether, yield 4 g (60%), mp 244–245°C; nmr ($CDCl_3$) δ: 5.75 (1H, t, CH=C), 5.55 (1, t, CH=C), 3.8 (3H, s, OCH_3), 3.60 (3H, s, OCH_3). An analytical sample was prepared by recrystallization from ethanol/ether. *Anal.* calcd. for $C_{21}H_{28}NOCl$: C 72.47, H 8.71, N 4.03; found: C 72.08, H 8.96, N 3.97.

*10,10a-α-Epoxy-4a-[2-(*N*-trifluoroacetylpiperidine)methyl]-1,2,3,4,4a,9,10,10a-octahydro-6-methoxyphenanthrene (10)*

To a solution of 1.6 g (5.2 mmol) of **9** in 50 mL of anhydrous ether was added 1.5 g (7 mmol) of trifluoroacetic anhydride and the solution stirred at room temperature overnight. The clear solution was cooled and neutralized with aqueous bicarbonate. The organic phase was extracted with 1 *N* HCl, washed with H_2O, dried, and evaporated *in vacuo* to give 2.1 g (91% yield) of a clear viscous oil; tlc, ($CHCl_3$): two spots R_f 0.4 and 0.45 corresponding to the diastereomeric mixture.

The compound was dissolved in CH_2Cl_2 (50 mL) and treated at 0°C with 1.2 g (7 mmol) of *m*-CPBA. The ice bath was removed and the solution stirred for 2 h and extracted with 5% sodium sulfite, 2 *N* NaOH (3×), 1 *N* HCl (3×), H_2O, and dried. Removal of the solvent *in vacuo* gave 2.2 g of a yellow viscous oil which was submitted to flash chromatography (Merck silica gel). The $CHCl_3$ eluent yielded 1.8 g (90%) of a clear viscous oil that resisted crystallization.

9α-Hydroxy-3-methoxy-16,17-butanohasubanan (11)

The preceding epoxy trifluoroacetamide (2.1 g, 5 mmol) in 50 mL of ethanol was treated with 378 mg (10 mmol) of $NaBH_4$. The solution was heated under reflux for 24 h after which time the reaction had reached completion (tlc). The mixture was concentrated *in vacuo*, diluted with 50 mL of H_2O, and extracted with ether. The combined extracts were re-extracted with 2 *N* HCl and the aqueous phase made basic with NH_4OH followed by extraction with chloroform. After drying (Na_2SO_4) and evaporation of the solvent, a brownish viscous oil consisting of a single component (tlc) was obtained.[3] Yield: 1.5 g (94%); ir (neat): 3400 cm^{-1}; nmr ($CDCl_3$) δ: 6.6–7.1 (3H, m), 3.9 (1H, t), 3.7 (3H, s, OCH_3). A portion was converted to the hydrochloride salt and the solid dried over P_2O_5. Crystallization from ethanol–ether afforded colorless crystals, mp 153–155°C. *Anal.* calcd. for $C_{21}H_{30}NO_2Cl$: C 69.46, H 8.35, N 3.86; found: C 69.20, H 8.61, N 3.80.

3-Methoxy-16,17-butano-$\Delta^{8,14}$-morphinan (12)

To a solution of 654 mg (2 mmol) of the hydroxyhasubanan **11** in 30 mL of anhydrous ether was added 1.6 g (6 mmol) of phosphorus tribromide. The mixture was heated under reflux for 24 h, cooled in an ice bath, and subjected to a dropwise addition of 2 *N* NaOH while maintaining the temperature between 60–70°C. The mixture was then extracted with ethyl acetate and the combined extracts re-extracted with 3 *N* HCl. The aqueous phase was made basic with NH_4OH and extracted with chloroform. The combined extracts were dried (Na_2SO_4) and evaporated *in vacuo*, affording 400 mg of a reddish oil; nmr ($CDCl_3$) δ: 7.1–6.6 (3H, m), 5.7 (0.5H, t), 5.2 (0.5H, t), 3.8 (3H, s, OCH_3). The product appeared sufficiently pure (tlc) for use in the next step.

(±)-3-Hydroxy-16,17- and 16,17-butanomorphinan (1a, 1b)

The preceding $\Delta^{8,14}$-morphinan **12** (324 mg, 1 mmol) was dissolved in 20 mL of ethanol and hydrogenated over PtO_2 in a Parr instrument. After 8 h the catalyst was removed and the filtrate evaporated *in vacuo*, yielding 320 mg of a clear viscous oil. After drying over P_2O_5, the oil was dissolved in 10 mL of CH_2Cl_2 and treated with 750 mg (3 mmol) of BBr_3 to give a clear solution which was stirred at room temperature for 2 h. After quenching with water, it was made strongly basic with 2 *N* NaOH and extracted several times with methylene chloride. The combined extracts were dried (Na_2SO_4), evaporated *in vacuo*, and the residue treated with 15 mL of warm ethanol. The suspended material was collected and washed with some cold ethanol. The hydrobromide salt of this fraction was prepared by suspending the solid in methanol containing aqueous HBr (48%) and the resulting solution evaporated *in vacuo* and the residue dried over P_2O_5. Crystallization from ethanol–ether gave pure crystals (50 mg, 34%), mp 209–210°C; ir (KBr): 3400 cm^{-1}.

The ethanol filtrate was evaporated *in vacuo* to yield a viscous oil which was purified by flash chromatography using the solvent system 20:1 chloroform/0.1% NH_4OH in MeOH. The eluted product was crystallized by slow evaporation of an ethyl acetate solution, yielding 20 mg (15% yield), mp 250°C; ir (KBr): 3400 cm^{-1}.

The two isomers proved identical in every respect (ir, hplc, nmr, X-ray diffraction) to the 16,17-butanomorphinans previously synthesized.

Synthesis of antiviral compounds. Preparation and rearrangement of 6-methoxyglyceropurines

KELVIN K. OGILVIE[1] AND H. RIZK HANNA
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received January 9, 1984

KEVIN K. OGILVIE and H. RIZK HANNA. Can. J. Chem. **62**, 2702 (1984).

The synthesis of 6-methoxypurine (**4**) and 6-methoxyguanine (**11** and **12**) derivatives of the glyceropurine series is described. The N-7 guanine derivatives rearrange to the N-9 isomers under certain conditions. The 6-methoxyguanine derivative **12** was found to have a remarkably specific activity against equine herpesvirus.

KEVIN K. OGILVIE and H. RIZK HANNA. Can. J. Chem. **62**, 2702 (1984).

On décrit les synthèses des méthoxy-6 purine (**4**) et méthoxy-6 guanines (**11** et **12**) dérivées de la série de la glycéropurine. Sous certaines conditions, les dérivés de la N-7 guanine se transposent en isomères N-9. On a trouvé que le dérivé **12** de la méthoxy-6 guanine possède une activité spécifique remarquable contre le virus herpès de cheval.

Introduction

In our development of the "glycerosides" as a novel class of nucleoside analogues (1–5) having antiviral activity, we have found that some of the glyceropurines have powerful antiherpes activity. In particular, the guanine derivative 9-[[2-hydroxy-1-(hydroxymethyl)ethoxy]methyl]guanine (BIOLF-62) has perhaps the strongest and widest activity against herpesviruses of any reported compound (6–8). The 6-chloroguanine derivative also has significant activity against herpesviruses (4). Because substitution at C-6 of other purine nucleosides has led to a range of biological activity (4,9,10), we sought selective changes at C-6 in the glyceropurine series. In this report we wish to describe the preparation of the 6-methoxypurine and 6-methoxyguanine compounds **4**, **11**, and **12**. In the latter case we have found that the N-7 isomer rapidly rearranges to the more stable N-9 isomer under specific conditions. The 6-methoxy compounds **4**, **11**, and **12** have been tested for activity against a range of herpesviruses with only the N-9 guanine derivative **12** having activity and, in this case, only against equine HSV-2.

The 6-chloropurine (**1**) and 6-chloroguanine (**6**, **7**) derivatives were chosen as starting materials. Alkaline displacement of chlorine at C-6 of purines has led to mixed results, according to the literature. In some reports, ring opening has been the major result (11–14) while in others smooth displacement of chlorine has been observed (15–17). The general trend indicates that 9-alkyl-6-chloropurines are smoothly converted under alkaline conditions, while the nucleosides of 6-chloropurines often lead to ring opening (18). Conversion of 6-methoxy to 6-hydroxypurines with aqueous base has been established (11).

The 6-chloropurine **1** (4) was converted to the 6-methoxypurine **2** in 93% yield using sodium methoxide in methanol for 30 min at room temperature. Interestingly, the same result is obtained when **1** is treated with sodium hydroxide in methanol–water at room temperature for 15 min. However, if the latter reaction is carried out at reflux temperature the hypoxanthine derivative **3** is produced. Compound **2** can be converted to **3** on refluxing with sodium hydroxide in methanol–water. Both compounds, **2** and **3**, are easily deprotected to **4** and **5** respectively using boron trichloride solution.

In the preparation of the 6-chloroguanine derivative a mixture of the N-7 (**6**) and N-9 (**7**) isomers is obtained (ref. 4, ratio 2:3 by nmr). The mixture can be separated at this stage or (and generally more easily) after conversion of the chlorine. The 6-chlorine of the guanine derivative (2-amino-6-chloropurine derivative) is more difficult to displace than in the 6-chloropurine **1**. However, after reflux with sodium methoxide in methanol for 1.5 h, the 6-methoxy products **8** and **9** were obtained in virtually the same ratio as the starting mixture.

When the mixture of **6** and **7** was heated at reflux with sodium hydroxide in methanol–water (1.5 h) only the N-9 guanine derivative **10** was obtained. Furthermore, pure **6** (the N-7 isomer) yielded only the N-9 isomer **10** when subjected to the same conditions. Pure compound **8** and pure compound **9** are each completely converted to the guanine derivative **10** under reflux with sodium hydroxide in methanol–water.

The pure 6-methoxy derivative **9** was smoothly deprotected using boron trichloride (19) giving only the guanine derivative **12**. The N-7 isomer **8** was more sensitive to the conditions used. While tlc indicated that only the N-7 isomer **11** was produced during the actual reaction with boron trichloride, the product was affected by work-up conditions. With heating or during concentration of the reaction mixture, **11** was converted to **12** to varying degrees. Once isolated, **11** was quite stable and was unaffected by most solvents including hot ethanol. However, if after the removal of solvents during the work-up of the reaction the residue was heated in ethanol, significant conversion of **11** to the N-9 isomer occurred. Complete conversion of **11** to **12** could be achieved in this manner. It has previously been reported that the N-7 isomers of purine derivatives can be converted to the more stable N-9 isomers on heating in the presence of salts (20, 21). Pure compound **11** is stable in ethanolic sodium hydroxide (0.05 *N*) for at least 1.5 h at room temperature. However, pure **11** is rapidly converted to the N-9 isomer **12** in 0.05 *N* HCl in ethanol (aqueous) at room temperature.

The new compounds described in this manuscript were tested against a number of herpesviruses including human HSV-1, HSV-2, and CMV, canine herpesvirus, feline herpesvirus, bovine herpesvirus type 4, and equine herpesvirus type 1. In general, **4**, **11**, and **12** were inactive against all of these viruses at a level less than 100 μg/mL. However, the exception was compound **12** which was uniquely active against equine herpesvirus with an ED-50 of 2.8 μg/mL.

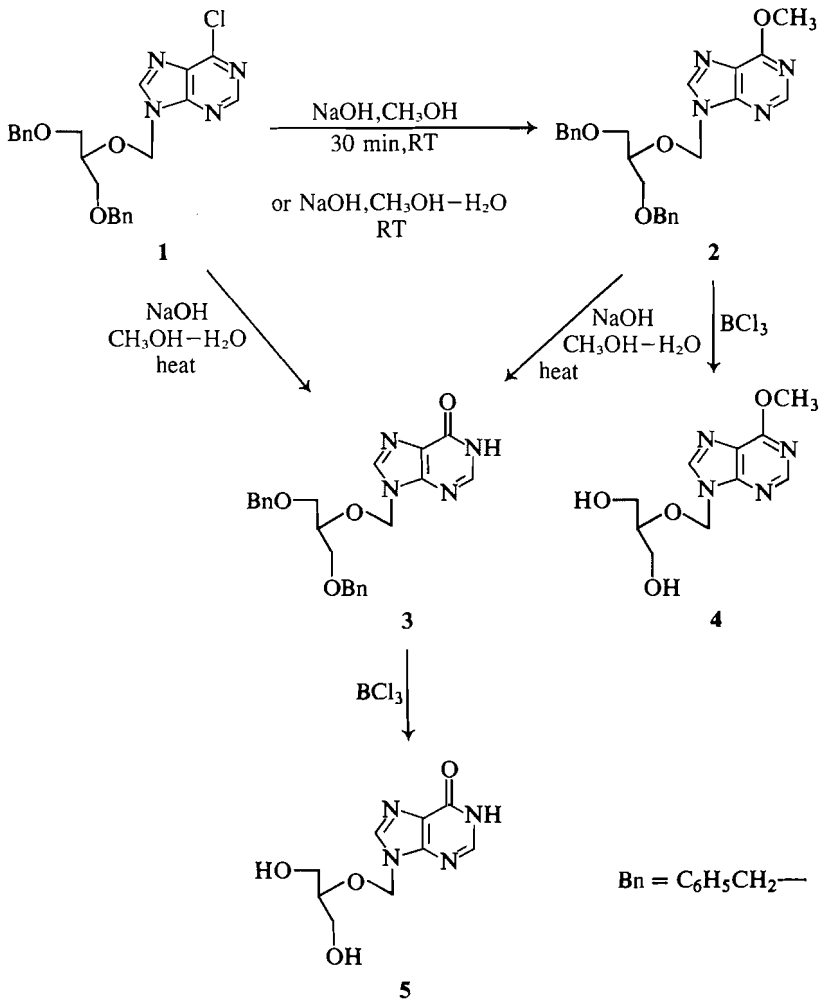

SCHEME 1

Experimental

General methods

Products from preparative scale reactions were isolated by column chromatography using Merck silica gel 60 (230–400 mesh) packed in glass columns (15 g of silica per gram of crude material). Thin-layer chromatographic data (R_f values) are recorded from Merck Kieselgel 60F254 analytical sheets. Purine bases were purchased from Sigma Chemical Co. The uv spectra were recorded on a Cary 17 spectrometer. Nuclear magnetic resonance spectra were recorded using a Bruker WH-90, a Varian XL-200, and a Varian T60A spectrometer.

The 6-chloropurine derivatives 9-[[2-benzyloxy-1-(benzyloxymethyl)ethoxy]methyl]-6-chloropurine **1** and the N-7 and 9-[[2-benzyloxy-1-(benzyloxymethyl)ethoxy]methyl]-2-amino-6-chloropurines **6** and **7** were prepared as previously described (4). Compounds **6** and **7** were obtained as a mixture in a ratio of ~2:3 as judged by nmr (4).

9-[[2-Benzyloxy-1-(benzyloxymethyl)ethoxy]methyl]-6-methoxypurine 2

A. Compound **1** (1 g) was dissolved in methanol (25 mL) containing sodium (0.3 g). The solution was stirred at room temperature for 30 min at which point tlc (EtOAc–hexane, 5:2) indicated complete conversion of **1** (R_f 0.5) to a new compound of R_f 0.2. The solvent was removed at reduced pressure and the residue was dissolved in dichloromethane. The organic layer was washed twice with water followed by drying over magnesium sulfate. The solution was collected by filtration and concentrated. The residue was chromatographed over silica gel eluted with ethyl acetate – hexane (5:7). The product **2** was obtained in 93% yield (0.92 g). The ^{1}Hpmr spectrum of **2** in DMSO-d_6 showed signals (δ, ppm) at 3.49 (m, 4H), 4.0 (m, 1H), 4.17 (s, 3H, OCH_3), 4.43 (s, 4H), 5.8 (s, 1H), 7.28 (10H, aromatic), 8.05 (s, 1H), and 8.56 (s, 1H). The uv characteristics for **2** were λ_{max} in nm(ε) at pH 1: 247 (8200); pH 7: 247 (8800); pH 13: 247 (8500).

B. Compound **1** (0.5 g) was dissolved in methanol (38 mL) to which water (4 mL) and sodium hydroxide (10.5 g) were added. After 5 min at room temperature tlc showed complete conversion of **1** to **2**. After a total of 15 min the solution was diluted with cold water (20 mL) and the solution was carefully neutralized (with cooling) with HCl (3*N* solution). The product was extracted into ether which was dried over magnesium sulphate. Evaporation of the ether gave 0.48 g (97%) of remarkably pure **2**.

9-[[2-Benzyloxy-1-(benzyloxymethyl)ethoxy]methyl]-6-hydroxypurine 3

A. Compound **1** (1 g, 2.3 mmol) was treated with sodium hydroxide (21 g) in methanol (75 mL) to which water (9 mL) had been added. A tlc taken immediately showed only a compound having the same R_f as **2**. The solution was heated at reflux for 1 h at which point tlc indicated the presence of a single spot of R_f 0.06 (ethyl acetate – methanol, 10:0.1). The solution was concentrated at reduced pressure, the residue was dissolved in water, and the solution was neutralized with acetic acid whereupon a precipitate formed. The precipitate was collected by filtration and was allowed to crystallize from ethyl acetate to yield **3** (0.57 g, 60%), mp 131–132°C. Compound **3** had uv properties (λ_{max} in nm (ε)) as follows: pH 1, 247 (9100); pH 7, 247 (10 100); pH 13, 253 (10 700). The ^{1}Hpmr spectrum in DMSO-d_6 showed signals at δ(ppm) of 3.42 (m, 4H), 4.03 (m, 1H), 4.38 (s, 4H), 5.64 (s, 1H), 7.24 (10H, aromatic), 8.06 (s, 1H), and 8.21

(s, 1H). The ^{13}C spectrum of **3** (DMSO-d_6) showed signals at δ(ppm) of 148.47 (C-2), 145.99 (C-4), 124.14 (C-5), 156.73 (C-6), 140.6 (C-8), 72.25 (C-1′), 76.94 (C-3′), 69.71 (C-4′), and 72.25 (—$CH_2\phi$). *Anal.* calcd. for $C_{23}H_{24}N_4O_4$: C 65.70, H 5.75, N 13.32; found: C 65.52, H 5.64, N 13.34.

Compound **3** was further characterized by treatment with boron trichloride in the standard way (ref. 4, see below) to give the known 6-hydroxypurine derivative **5** in 60% isolated yield. The properties of **5** were identical to those of an authentic sample (4).

B. Compound **2** (1.3 g) was heated in methanol (75 mL) containing water (9 mL) and sodium hydroxide (21 g) at reflux for 30 min. The reaction mixture was worked up as above to yield **3** in 60% yield. No other uv-absorbing material was detected.

*9-[[2-Hydroxy-1-(hydroxymethyl)ethoxy]methyl]-6-methoxypurine **4***

Compound **2** (0.9 g) was dissolved in dichloromethane (50 mL, spectrograde) and boron trichloride (8 mL, 1 *N* in dichloromethane) was added to the solution maintained at −78°C under a nitrogen atmosphere. A tlc showed that after 1 h all of **2** (R_f 0.7, methanol − ethyl acetate (1:3)) had been converted to a new compound of R_f 0.3. The solution was then neutralized with triethyl amine in methanol and the pH was raised to between 8 and 9. The solvents were removed at reduced pressure and the residue was chromatographed on silica gel (eluting first with hexane (500 mL), ethyl acetate (1 L), and ethyl acetate − methanol (18:1, 2 L). The product **4** was collected and after crystallization from methanol−dichloromethane pure crystals of **4** were obtained (70%, mp 135−136°C). The uv properties showed λ_{max} (nm, (ε)) at pH 1: 247 (11 100); pH 7: 247 (12 000); pH 13: 247 (12 100). The ^{1}Hpmr spectrum of **4** in DMSO-d_6 showed signals at δ(ppm) of 3.31 (m, 4H), 3.58 (m, 1H), 4.08 (s, 3H, —OCH_3), 4.58 (t, 2H, —OH), 5.72 (s, 1H), 8.48 (s, 1H), and 8.55 (s, 1H). The ^{13}C spectrum (DMSO-d_6) showed signals at δ(ppm) of 152.19 (C-2), 151.87 (C-4), 120.53 (C-5), 160.34 (C-6), 144.05 (C-8), 72.25 (C-1′), 80.88 (C-3′), 60.97 (C-4′), and 53.96 (—OCH_3). *Anal.* calcd. for $C_{10}H_{14}N_4O_4$: C 47.24, H 5.55, N 22.04; found: C 47.17, H 5.64, N 22.01.

*Conversion of **6** and **7** to the guanine derivative **10***

A. A mixture of **6** and **7** (5.5 g, 2:3 by ^{1}Hpmr) was dissolved in methanol (300 mL) to which water (21 mL) and sodium hydroxide (84 g) were added. The solution was heated at reflux and after 1.5 h, tlc (methanol − ethyl acetate − dichloromethane, 1:3:3) showed that the starting material (R_f 0.75) had been completely converted to material having R_f 0.3. The solution was concentrated at reduced pressure and the residue was dissolved in water. The solution was neutralized with acetic acid whereupon a precipitate formed that was collected by filtration. The material gave, after crystallization from ethanol−water, 3.8 g (70%) of **10**, which was identical in all respects (mp, ^{13}C, ^{1}Hpmr, R_f, uv) to authentic material previously described (2,4)).

B. Pure N-7 isomer **6** (280 mg) was subjected to the above conditions. The sole product was compound **10** isolated in 95% yield (256 mg).

*Conversion of the mixture of **6** and **7** into the 6-methoxyguanine derivatives **8** and **9***

A mixture of **6** and **7** (2.5 g, 2:3 by ^{1}Hpmr) was added to a solution of sodium (0.7 g) in methanol (50 mL). The solution was heated at reflux for 1.5 h at which point tlc (ethyl acetate − hexane, 3:1) showed the starting material (R_f 0.5) had been completely converted to two materials having R_f 0.3 and 0.1. The solvent was removed at reduced pressure and water (50 mL) was added. The pH was adjusted to ~5.5 with acetic acid. The product was extracted into dichloromethane. After drying over magnesium sulfate the solvent was evaporated to leave a dark syrup (2.56 g) which was chromatographed on silica gel. The column was eluted with ethyl acetate − hexane (1:1, 1 L; 2:1, until the first product was completely eluted; 3:1, to collect the second product). The first product, **9**, had R_f 0.3 in ethyl acetate − hexane (3:1) and was obtained as a viscous oil. The material crystallized from ethyl acetate − hexane (mp 83−84°C, 0.87 g, 44%). Compound **9** had λ_{max} (nm (ε)) at pH 1: 289 (8600), 244 (8600); pH 7: 282 (10 100), 247 (11 300); pH 13: 282 (9700), 247 (11 300). The ^{1}Hpmr spectrum in $CDCl_3$ showed signals at 3.49 (m, 4H), 3.97 (m, 1H), 4.05 (s, 3H), 4.44 (s, 4H), 5.60 (s, 2H), 4.92 (NH_2), 7.26 (10H, aromatic), 7.7 (s, 1H). The ^{13}C spectrum (DMSO-d_6) showed signals at δ(ppm) of 160.72 (C-2), 154.24 (C-4), 113.78 (C-5), 160.08 (C-6), 139.79 (C-8), 71.60 (C-1′), 76.56 (C-3′), 69.66 (C-4′), 53.09 (—OCH_3), and 72.19 (—$CH_2\phi$). *Anal.* calcd. for $C_{24}H_{27}N_5O_4$: C 64.13, H 6.05, N 15.58; found: C 64.42, H 6.18, N 15.32.

The second fraction (R_f 0.1) was obtained as a viscous oil (**8**, 0.53 g, 27%). Compound **8** had λ_{max} (nm (ε)) at pH 1: 288 (6600), 247 (7200); pH 7: 283 (7200), 253 (9900); pH 13: 283 (6800), 253 (9700). The ^{1}Hpmr spectrum in $CDCl_3$ showed signals at 3.5 (m, 4H), 3.96 (s, 3H), 4.05 (m, 1H), 4.44 (s, 4H), 5.65 (s, 2H), 6.27 (NH_2), 7.23 (10H, aromatic), 7.7 (s, 1H). *Anal.* calcd. for $C_{24}H_{27}N_5O_4$: C 64.13, H 6.05, N 15.58; found: C 63.96, H 5.95, N 15.41.

*Conversion of **9** to **10***

Compound **9** (0.5 g) was dissolved in methanol (30 mL) and water (3 mL) and sodium hydroxide (10.5 g) were added. The solution was heated at reflux for 1.5 h whereupon tlc showed complete conversion to **10**. The solvents were removed at reduced pressure and the residue was dissolved in water (80 mL). The solution was acidified with acetic acid whereupon a precipitate formed. The solid was collected by filtration, washed with water, and dried to yield 0.41 g (85%) of pure **10**.

*Conversion of **8** to **10***

The above procedure was repeated using 400 mg of **8**. Compound **8** was converted to **10** in 88% isolated yield.

*Conversion of **8** to 7-[[2-hydroxy-1-(hydroxymethyl)ethoxy]methyl]-2-amino-6-methoxypurine (**11**)*

Compound **8** (500 mg) was treated with boron trichloride in the usual manner. After 1 h, tlc (methanol − ethyl acetate, 1:2) showed complete conversion of **8**, R_f 0.7, to a new material of R_f 0.2. The solution was neutralized with triethyl amine in methanol and the pH was adjusted to 8. The solvent was removed at reduced pressure to give a solid that was dissolved in methanol. Dichloromethane was added and a fine precipitate was obtained. This material was identified as compound **11** (0.17 g, 57%, mp 211−212°C). The mother liquor contained both **11** and **12**.

In a repeat of the above reaction the solid obtained directly from the reaction was dissolved in ethanol and allowed to stand; tlc showed that **11** was completely converted to **12** with time and the process was hastened by heating the solution. However, once isolated pure, **11** is stable on heating in ethanol.

Compound **11** showed λ max (nm (ε)) at pH 1: 287 (5900), 246 (6800); pH 7: 283 (7200), 253 (9700); pH 13: 283 (7100), 253 (9700). The ^{1}Hpmr spectrum of **11** in DMSO-d_6 showed signals at 3.33 (m, 4H), 3.6 (m, 1H), 3.98 (s, 3H), 4.62 (OH), 5.58 (s, 2H), 7.40 (NH_2), and 8.01 (s, 1H). *Anal.* calcd. for $C_{10}H_{15}N_5O_4 \cdot \frac{1}{2}H_2O$: C 43.16, H 5.79, N 25.17; found C 43.37, H 5.66, N 24.91.

*Stability of **11** in acid and base*

Compound **11** was dissolved in (a) 0.05 *N* HCl in ethanol (aqueous) and (b) 0.05 *N* NaOH in ethanol (aqueous). Both solutions were stirred at room temperature. After 1.5 h compound **11** had been completely converted to **12** under the acid conditions (a) but was unaffected by the basic conditions (b).

*Conversion of **9** to **12***

Compound **9** (3 g) was treated with boron trichloride solution in the normal manner. The product was isolated pure following chromatography on silica gel using methanol − ethyl acetate (1:6). Compound **12** (mp 167−168°C) was obtained in 63% yield (1.1 g). Compound **9** showed λ max (nm (ε)) at pH 1: 288 (5800), 245 (6100); pH 7: 282 (6600), 247 (7500); pH 13: 282 (6500), 247 (7700). The ^{1}Hpmr spectrum in DMSO-d_6 showed signals δ(ppm) at 3.35 (m, 4H), 3.54 (m, 1H), 3.97 (s, 3H), 4.62 (OH), 5.52 (s, 2H), 6.48 (NH_2), and 7.98 (s, 1H). The ^{13}C spectrum (DMSO-d_6) showed signals at δ (ppm)

of 160.88 (C-2), 154.35 (C-4), 113.78 (C-5), 160.18 (C-6), 140.11 (C-8), 71.65 (C-1′), 80.28 (C-3′), 61.02 (C-4′), and 53.31 (—OCH_3). *Anal.* calcd. for $C_{10}H_{15}N_5O_4 \cdot \frac{1}{2}H_2O$: C 43.16, H 5.79, N 25.17; found C 43.65, H 5.71, N 25.34.

Correlation of nuclear magnetic resonance spectra and structure of *trans*-camphane-2,3-diols

M. S. ALLEN, J. H. HUTCHINSON, AND T. MONEY
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received March 8, 1984

M. S. ALLEN, J. H. HUTCHINSON, and T. MONEY. Can. J. Chem. **62**, 2707 (1984).

Evidence is provided to demonstrate that a recent correction in the published nmr spectra of *trans*-camphane-2,3-diols is unjustified.

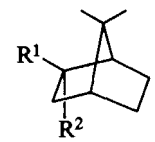
M. S. ALLEN, J. H. HUTCHINSON et T. MONEY. Can. J. Chem. **62**, 2707 (1984).

On démontre, évidences à l'appui, qu'une correction parue récemment pour les spectres de rmn de *trans*-camphanediols-2,3 est injustifiée.

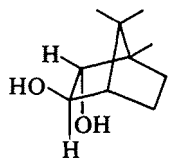
[Traduit par le journal]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

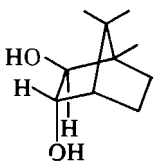
In a recent paper (1) it was suggested that the nmr spectra previously assigned by Anet (2) to the *trans*-camphane-2,3-diols, **4** and **5** (3–5), should be reversed. During our investigations (6) on the chemical and microbiological oxidation or bornyl acetate, **1**, we found that a minor product in the microbiological transformation of this compound was 3-*exo*-hydroxyborneol, **4**. In addition, chemical oxidation of bornyl acetate produced a small amount of 3-oxobornyl acetate which was subsequently reduced to 3-*exo*-hydroxyborneol, **4**. The ir and nmr spectra of our *trans*-diol (**4**) (δ ($CDCl_3$): 3.55 (d, $J \sim 2$ Hz), 3.97 (m); δ (C_5H_5N, D_2O): 1.95 (d, $J = 4.5$ Hz), 4.05 (d, $J = 2.5$ Hz), 4.45 (m)) was very similar to that reported by Takeshita and Kitajima (4) and Anet (2) respectively. Furthermore the published nmr spectra (7) for borneol **2**, isoborneol **3**, epiborneol **6**, and epiisoborneol **7** lead to the expectation that Δδ for the C(2) and C(3)-hydrogens in 2-*exo*-3-*endo*-camphanediol (**5**) would be significantly greater than that for the 2-*endo*-3-*exo*-diol (**4**). Anet's recorded spectra (2) for the *trans*-2,3-camphanediols are consistent with this prediction. In addition, the C(4) bridgehead hydrogen in our *trans*-diol (**4**) (2-*endo*-3-*exo*) appears as a doublet at δ 1.95 ($J = 4.5$ Hz) in the 100-MHz spectrum (pyridine-d_5/D_2O). By comparison, the corresponding hydrogen in camphor (**8**) is a triplet ($J = 4.5$ Hz) while in 5-*exo*-hydroxycamphor,[1]



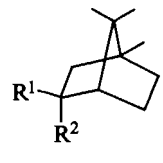
1 R^1 = H, R^2 = OAc
2 R^1 = H, R^2 = OH (δ3.95)
3 R^1 = OH, R^2 = H (δ3.55)



4



5



6 R^1 = H, R^2 = OH (δ4.55)
7 R^1 = OH, R^2 = H (δ3.75)

iii Br_2–dioxane/C_5H_5N/CH_2Cl_2 *iv* O_3/CH_2Cl_2/−78°C

SCHEME 1

5-*exo*-hydroxyborneol (3, 8), 5-*exo*-acetoxybornyl acetate (6), and 5-*exo*-deuterioborneol (9) it appears as a doublet ($J \sim 4.5$ Hz).

The proposed correction (1) in the nmr spectra (2) of *trans*-camphane-2,3-diols was based on the assumption that hydroboration of camphor enol trimethylsilyl ether **11** would occur preferentially on the "less hindered" *endo* face of this compound. In recent studies we have established that kinetic methylation of camphor enolate occurs preferentially on the *exo* face to provide a mixture (~4:1) of 3-*exo*-methylcamphor **9** and 3-*endo*-methylcamphor **10** (12). In addition we have shown that treatment of camphor enol trimethylsilyl enol ether **11** (10) with Br_2–dioxane/C_5H_5N (11) produces a mixture (~1:1) of 3-*exo* and 3-*endo* bromo derivatives, **12** and **13**. It has also been reported (13, 14) that ozone reacts with camphor enol trimethylsilyl ether **11** to give a mixture (1.3:1) of 3-*exo*-trimethylsilyloxycamphor **14** and its 3-*endo* epimer **15**. Thus the assumption that the reactions of camphor enolate in camphor enolate derivatives occur preferentially on the *endo* face of the enolate system is not supported by experimental evidence.

On the basis of the chemical and spectroscopic evidence cited above we suggest that the proposed correction (1) of Anet's original assignment (2) of nmr spectra to the *trans*-camphane-2,3-diols is unwarranted.

A synthesis of 2-deoxy-2-{^{18}F}fluoro-D-glucose using accelerator-produced ^{18}F-fluoride ion generated in a water target

PHILIP A. BEELEY, WALTER A. SZAREK, GEORGE W. HAY, AND MILTON M. PERLMUTTER

Carbohydrate Research Institute and Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received March 13, 1984

PHILIP A. BEELEY, WALTER A. SZAREK, GEORGE W. HAY, and MILTON M. PERLMUTTER. Can. J. Chem. **62**, 2709 (1984).

A synthesis of 2-deoxy-2-{^{18}F}fluoro-D-glucose (2-{^{18}F}DFG) from 1,2-anhydro-3,4:5,6-di-*O*-isopropylidene-1-*C*-nitro-D-mannitol has been developed. The procedure employed ^{18}F produced by the $^{16}O(^3He,p)^{18}F$ reaction using a water target. The label was introduced using KH{^{18}F}F_2 dried by microwave heating; the ^{18}F-labeled derivative, upon treatment with 80% trifluoroacetic acid, afforded 2-{^{18}F}DFG in a radiochemical yield of 10%. The total time of the synthesis was less than 110 min.

PHILIP A BEELEY, WALTER A. SZAREK, GEORGE W. HAY et MILTON M. PERLMUTTER. Can. J. Chem. **62**, 2709 (1984).

On développé une méthode de synthèse du déoxy-2 {^{18}F}fluoro-2 D-glucose ({^{18}F}-2 DFG) à partir de l'anhydro-1,2 di-*O*-isopropylidène-3,4:5,6 *C*-nitro-1 D-mannitol. La méthode implique l'utilisation de ^{18}F produit par une réaction $^{16}O(^3He,p)^{18}F$ faisant appel à une cible aqueuse. On a introduit le marqueur en utilisant du KH{^{18}F}F_2 qui avait été séché par micro-ondes; la réaction du dérivé marqué au ^{18}F avec de l'acide trifluoroacétique à 80% fournit le {^{18}F}-2 DFG avec un rendement radiochimique de 10%. Le temps total de la synthèse est inférieur à 110 min.

Introduction

The use of 2-deoxy-2-{^{18}F}fluoro-D-glucose (2-{^{18}F}DFG) for the measurement of regional cerebral glucose metabolism by positron emission tomography (PET) is now well established (1–3) and has generated a widespread interest in the application of this technique. Concomitantly, there has been expended a substantial effort to find alternative routes for the synthesis of this radiopharmaceutical. The first synthesis (4) of 2-{^{18}F}DFG, involving the addition of ^{18}F-labeled F_2 to tri-*O*-acetyl-D-glucal, gave a radiochemical yield of 10%. Recently, this yield has been increased by the use of {^{18}F}-acetyl hypofluorite (5) or {^{18}F}-xenon difluoride (6, 7). However, these syntheses employ molecular fluorine, thereby restricting the theoretical incorporation of ^{18}F to 50%; these methods involve the production of isotope by the $^{20}N(d,\alpha)$ ^{18}F reaction. In contrast, synthetic procedures based on ^{18}F-fluoride ion would, in principle, allow all of the radioisotope to be incorporated into the required product, and would allow a choice from a wider range of nuclear reactions. For example, Levy *et al.* (8) have synthesized 2-{^{18}F}DFG in a radiochemical yield of 10%, by the displacement of the trifluoromethanesulfonyloxy group in methyl 4,6-*O*-benzylidene-3-*O*-methyl-2-*O*-trifluoromethanesulfonyl-β-D-mannopyranoside. The low yield obtained by Levy *et al.* (8) is attributable in part to the low yield of CsH{^{18}F}F_2 obtained by trapping H^{18}F on CsF, and in part to the difficulties in effecting the quantitative hydrolysis of the 1-*O*- and 3-*O*-methyl groups of the substrate. More recently Tewson (9) has synthesized the same compound in a radiochemical yield of 40% by a nucleophilic reaction at C-2 in methyl 4,6-*O*-benzylidene-β-D-mannopyranoside 2,3-cyclic sulfate. Tewson (9) reported an excellent (>90%) incorporation of ^{18}F into the required fluorosulfate, a value approaching the theoretical maximum. However, hydrolysis of the glycoside resulted in a considerably reduced yield of 2-{^{18}F}DFG. Nevertheless, the radiochemical yield obtained is the highest reported at present.

In this laboratory, a synthesis of 2-deoxy-2-fluoro-D-glucose has been achieved (10) in high yield by the reaction of KHF_2 with the acyclic α-nitroepoxide, 1,2-anhydro-1-deoxy-3,4:5,6-di-*O*-isopropylidene-1-*C*-nitro-D-mannitol (**1**). We now report the reaction of KH{^{18}F}F_2 with **1** (see Fig. 1), followed by the removal of the blocking groups to afford 2-{^{18}F}DFG in a radiochemical yield of 10%; the overall synthesis time was less than one half-life of ^{18}F.

Experimental

Production of ^{18}F and labeling of KHF_2

The production of ^{18}F was achieved by the $^{16}O(^3He,p)^{18}F$ reaction using the Queen's University 4-MeV Van de Graaff accelerator. Beam degradation in this low energy accelerator was circumvented by the use of a windowless ice target. The target consisted of a gold-plated, liquid nitrogen-cooled, cold finger located in the vacuum beam line of the accelerator. An external reservoir containing high purity water[1] supplied a constant jet of water vapor to the cold finger, and the ice layer thus formed was bombarded with the 4-MeV ^{3}He beam. This arrangement afforded approximately 0.5 mCi of ^{18}F per μA, accompanied by the production of a similar quantity of ^{15}O from the $^{16}O(^3He,\alpha)^{15}O$ reaction. Normally a 2-μA beam was used and approximately 1 mCi of ^{18}F could be recovered from the target at the end of bombardment. A stoichiometric quantity of ^{19}F-fluoride ion-carrier in the form of KHF_2 (0.5 mole per mole of **1**) was added as a 0.1 *M* aqueous solution to the $^{18}F-H_2O$ (~3 mL) in a Teflon vial and the solution evaporated to dryness in a microwave oven.[2]

*Reaction of the α-nitroepoxide **1** with KH{^{18}F}F_2*

The α-nitroepoxide **1** was synthesized by the method of Szarek *et al.* (10). A weighed amount of **1** (40–60 μmol) was dried over P_2O_5 in a vacuum desiccator for 1 h prior to reaction. The solvent employed in this reaction, namely ethylene glycol, was initially treated with CaO and distilled under reduced pressure; it was then heated at reflux temperature in the presence of 4A molecular sieves and distilled. The distillate was stored over 4A molecular sieves; immediately prior to its use it was treated with Na under N_2 and distilled under reduced pressure. The sample of **1** was added to the KH{^{18}F}F_2 (20–30 μmol) and the vial was sealed with a septum. The freshly distilled ethylene glycol (1 mL) was added to the vial and the solution heated, under N_2, at 135°C for 20–25 min. Thin-layer chromatography[3] (tlc)

[1]HPLC-grade water; Fisher W5.

[2]CEM Corporation; model MDS-81.

[3]Thin-layer chromatography was performed using Merck plates precoated with silica gel 60 F-254. The developed plates were dried and compounds located by heating the plates at ~150°C after they had been sprayed with 10% aqueous sulfuric acid containing 1% cerium sulfate and 1.5% molybdic acid.

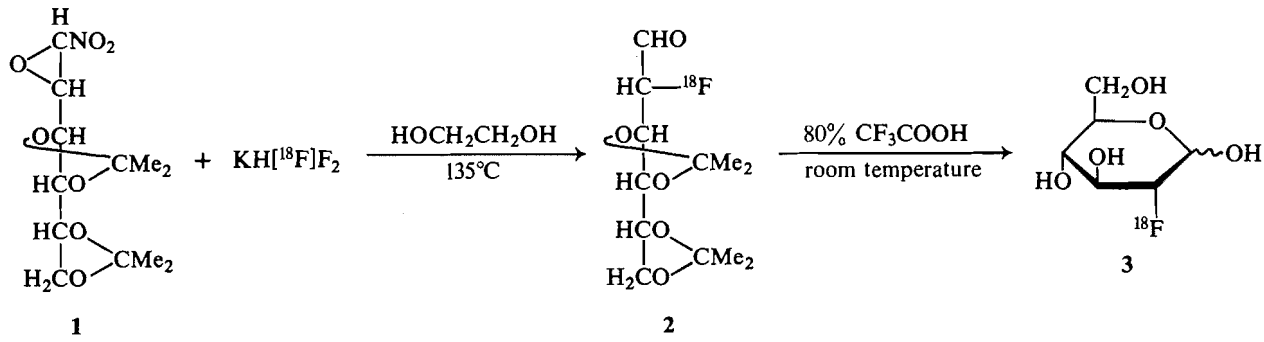

FIG. 1. Synthesis of 2-deoxy-2-{^{18}F}fluoro-D-glucose.

(toluene – ethyl acetate, 1:1 (v/v)) indicated the presence of a trace of starting material **1** (R_f 0.8), and of a component (R_f 0.42) containing 15% (mean value obtained from 8 runs) of the total activity on the plate, the remainder of the activity being at the origin. The reaction mixture was cooled rapidly, diluted with distilled water (10 mL), and the solution was extracted with dichloromethane (3 × 5 mL). The activity distribution between the organic and aqueous layers was comparable to that observed above by tlc; this thin-layer chromatographic examination indicated that more than 90% of the activity present in the organic extracts was attributable to the product having R_f 0.42, the remainder arising from a minute amount of non-migrating material carried over in the extraction procedure. The combined organic extracts were dried over anhydrous Na_2SO_4 and concentrated under reduced pressure.

*Deprotection of 2-deoxy-2-{^{18}F}fluoro-3,4:5,6-di-O-isopropylidene-*aldehydo-*D-glucose (2)*

Method (a)

Trifluoroacetic acid (80% (v/v), 2 mL) was added to the residue obtained from the organic extracts, and the solution was heated to 50°C for 5 min. The acid was removed under reduced pressure (bath temperature < 50°C) and the residue was dissolved in aqueous acetonitrile (0.3% water (v/v), 2 mL). Thin-layer chromatography (acetonitrile–water, 95:5 (v/v)) indicated that the major radioactive product migrated at the same rate as an authentic sample of 2-deoxy-2-fluoro-D-glucose[4] (R_f 0.43). The component giving rise to the most intense spot in tlc (R_f 0.11) did not contain any radioactivity. The presence of a minor component having R_f 0.32 was observed occasionally; this component migrated at the same rate as the product resulting from the treatment of the α-nitroepoxide **1** with trifluoroacetic acid. Thin-layer chromatography indicated the following activity distribution: 2-deoxy-2-fluoro-D-glucose, 80%; solvent front, 15%; origin, 5%.

Method (b)

Trifluoroacetic acid (80% (v/v), 2 mL) was added to the residue obtained from the organic extracts, and the solution was stirred at room temperature for 10 min; the reaction mixture was processed as described in Method (a). Thin-layer chromatography indicated the following activity distribution: 2-deoxy-2-fluoro-D-glucose, ~86%; solvent front, 8%; origin ~6%.

Column chromatography and high performance liquid chromatography (hplc) analysis

The aqueous acetonitrile solution (0.3% water (v/v)) of 2-{^{18}F}DFG was chromatographed on a column (0.7 × 10 cm) of dry silica gel 60 using the same solvent as eluent. The initial 6-mL portion of the eluate was discarded and the product was obtained from the subsequent 10-mL portion. The solvent was removed under reduced pressure; hplc-grade water (~2.5 mL) and washed alumina (~50 mg) were added and the solution filtered through a 0.2-μm Millipore membrane. The product was analyzed by hplc (Bio-Rad Carbohydrate Column HPX-87; Varian 5000 Liquid Chromatograph; 85°C, water, flow rate 0.6 mL/min; differential refractometer and NaI (Tl) well counter detectors). The retention time of the product, detected by the refractometer, was 9.7 min, corresponding to that of an authentic sample[4] of 2-deoxy-2-fluoro-D-glucose. Only one major radioactive component was detected; this had a retention time of 10.0 min and a radiochemical purity greater than 97%. The retention times indicated by the two detectors corresponded to those obtained using a sample of 2-{^{18}F}DFG provided by the Montreal Neurological Institute. Chemical and radiochemical yields of 2-deoxy-2-fluoro-D-glucose were of a comparable value, namely ~10% (mean value obtained from 8 runs).

Activity measurements

Activity distribution on the plates was measured by fractional counting after charring using 10% H_2SO_4 in methanol. The activities in aqueous and organic solutions were measured by counting 100-μL samples at a fixed geometry to the detector system. For relative activity distributions, a 7.62 × 7.62 cm NaI (Tl) detector coupled to a single-channel analyzer, or an intrinsic Ge detector coupled to a multichannel analyzer, was used. The absolute activity of ^{18}F-fluoride ion and of 2-{^{18}F}DFG was measured by counting 100-μL samples at a fixed geometry to the calibrated Ge detector.

Results and discussion

This article described a new synthesis of 2-{^{18}F}DFG in a radiochemical (decay-corrected) yield of 10%. Although this yield is lower than some of those recently reported, nevertheless the synthetic method is a viable alternative for the "in-house" production of 2-{^{18}F}DFG. Because the chemical yield of 2-deoxy-2-fluoro-D-glucose was comparable to the radiochemical yield, it was considered to be unnecessary to treat the accelerator-derived ^{18}F-H_2O with a cation-exchange resin, as was necessary in the method of Tewson (9). Such treatment may result in a loss of ^{18}F, thereby reducing the radiochemical yield of the radiopharmaceutical when based on the starting activity of ^{18}F. The starting material, 1,2-anhydro-3,4:5,6-di-*O*-isopropylidene-1-*C*-nitro-D-mannitol (**1**), has been isolated (10) in crystalline form in 72% yield from a mixture of 1,2-anhydro-3,4:5,6-di-*O*-isopropylidene-1-*C*-nitro-D-mannitol and -D-glucitol which was obtained in 80% yield by treatment of 1,2-dideoxy-3,4:5,6-di-*O*-isopropylidene-1-*C*-nitro-D-*arabino*-hex-1-enitol with 30% hydrogen peroxide; this nitroolefin can be obtained from D-arabinose in a good overall yield. The substrate **1** is a crystalline solid that is stable when stored at 0°C. Full details of the carbohydrate synthesis will be published separately.

In the reaction of the α-nitroepoxide **1** with KHF_2 it has been found that a 12-fold molar-equivalent excess of KHF_2 affords 2-deoxy-2-fluoro-D-glucose in a yield greater than 30% based on **1** and that further increasing the concentration of the fluoride salt enhances the yield. However, reactions using up to 2.5

For personal use only.

molar equivalents of KHF_2 did not afford yields of 2-deoxy-2-fluoro-D-glucose beyond 10%, in experiments leading to either labeled or unlabeled product. A decrease in the amount of KHF_2 carrier to 5 μmol per 50 μmol of **1** resulted in a 15% incorporation of ^{18}F into the fluoro aldehyde **2**; thus the use of less than 1 molar equivalent of KHF_2 allows the specific activity of the product to be increased, if so desired.

The use of ethylene glycol as the solvent in the reaction of the α-nitroepoxide with fluoride ion resulted in the formation of a component the R_f of which was similar to that of the product, fluoro aldehyde **2**; however, treatment of the mixture of products with 80% trifluoroacetic acid converted this component into one (R_f 0.11, acetonitrile–water, 95:5 (v/v)) which was well separated from 2-deoxy-2-fluoro-D-glucose (R_f 0.43). Competing reactions with ethylene glycol have been observed (11–13) previously with carbohydrate substrates. The use of a variety of other solvents, together with a number of different fluoride salts as well as crown-ether systems (14), has been investigated and the results will be reported in the separate publication.

In the present study the fluoro aldehyde **2** has also been obtained by treatment of the α-nitroepoxide **1** with ^{18}F-labeled tetra-*n*-butylammonium fluoride in ethylene glycol; the reagent salt was dried by the repeated addition of acetonitrile and distillation using a rotary evaporator. In these experiments the yields (~10%) of **2** that were obtained were lower than was the case with KHF_2 and were less reproducible. The use of the technique of microwave drying (15) combined with the performance of the reactions in Teflon vials greatly reduce the loss of ^{18}F prior to its reaction and give better reproducibility.

The deprotection of the fluoro aldehyde **2** was originally accomplished using boron trichloride in dichloromethane. However, the time required for the efficient removal of boron salts during processing prompted the use of 80% trifluoroacetic acid. On the small scales employed in the experiments no epimerization of the fluoro aldehyde to the *manno* epimer was observed with the use of this reagent. If the reaction were performed at room temperature for 10 min, rather than at 50°C for 5 min, less radioactivity was observed at the solvent front in tlc; however, there was slightly more radioactivity at the origin, possibly resulting from the liberation of ^{18}F-fluoride ion. Nevertheless, the room-temperature reaction provided a higher radiochemical purity of the final product **3**.

The use of the α-nitroepoxide substrate **1** is currently being adapted for the synthesis of 2-{^{18}F}DFG employing ^{18}F produced with the McMaster University nuclear reactor.

Conclusion

The methodology described in this article provides an alternative route to 2-{^{18}F}DFG using a water target. Although the beam-energy constraints of the accelerator employed necessitated the use of an unconventional target, it seems reasonable to assume that the method is applicable to any PET facility employing a conventional target. The amounts of radioactivity incorporated, of course, depend upon the concentrations of ^{18}F achieved by the accelerator.

Six analogs of ACV, the biosynthetic precursor of the penicillin nucleus, have been synthesized, in which the δ-(L-α-aminoadipyl) moiety has been replaced by : β-(L-aspartyl), γ-(L-glutamyl), δ-(D-α-aminoadipyl), adipyl, glycyl-δ-(L-α-aminoadipyl), and *N*-acetyl-δ-(L-α-aminoadipyl) side chains have also been synthesized. Several improvements have been made in earlier routes to ACV and related peptides, including a simplified preparation of a dipeptide precursor, and a new synthesis of α-aminoadipic acid from lysine. A new reagent, 2-acetoximino-2-phenylacetonitrile, has been synthesized, which allows ready *N*-acetylation of amino hydroxyacids in aqueous acetone at room temperature. The peptide analogs have been examined as substrates of the enzyme isopenicillin N synthetase, which converts ACV to isopenicillin N in the presence of oxygen, ferrous ions, and ascorbate. The enzyme has been isolated from the prokaryotic organism *Streptomyces clavuligerus*, and has been employed either as a crude salt precipitate or in semi-purified form, freed from other enzymes of the penicillin–cephalosporin pathway. With the crude enzyme preparation, three of the analogs are active substrates, viz., adipyl, glycyl-δ-(L-α-aminoadipyl), and *N*-acetyl-δ-(L-α-aminoadipyl), but the latter two are converted, only via ACV, to isopenicillin N, the normal cyclization product. That the crude enzyme preparation contains a protease that deacylates *N*-substituted ACV analogs to ACV is confirmed, *inter alia*, by the behaviour of the purified enzyme; of the various analogs, only the adipyl compound is an active substrate, but the conversion of this analog to carboxybutylpenicillin proceeds with only 1–2% efficiency, compared to the natural substrate.

SUSAN E. JENSEN, DONALD W. S. WESTLAKE, RAYMOND J. BOWERS, CHRISTOPHER F. INGOLD, MARC JOUANY, LEAH LYUBECHANSKY et SAUL WOLFE. Can. J. Chem. **62**, 2712 (1984).

On a synthétisé six analogues de l'ACV, le précurseur biosynthétique du noyau de la pénicilline, dans lesquel on a remplacé l'unité δ-(L-α-aminoadipyl) par les unités suivantes: β-(L-aspartyl), γ-(L-glutamyl), δ-(D-α-aminoadipyl), adipyl, glycyl-δ-(L-α-aminoadipyl) et *N*-acétyl-δ-(L-α-aminoadipyl). On a également synthétisé des pénicillines ayant des groupes adipyl, glycyl-δ-(L-α-aminoadipyl) et *N*-acétyl-δ-(L-α-aminoadipyl) comme chaînes latérales. On a apporté plusieurs améliorations aux voies d'accès à l'ACV et aux peptides apparentés que nous avions décrites antérieurement; ces améliorations comprennent entre autre une préparation simplifiée d'un dipeptide précurseur ainsi qu'une nouvelle synthèse de l'acide α-aminoadipique à partir de la lysine. On a synthétisé un nouveau réactif, l'acétoxymino-2 phényl-2 acétonitrile, qui permet d'effectuer facilement une *N*-acétylation des hydroxy-acides aminés en opérant dans l'acétone aqueuse et à la température ambiante. On a étudié le comportement des analogues peptidiques comme substrats de l'enzyme isopénicilline *N*-synthétase qui transforme l'ACV en isopénicilline N en présence d'oxygène, d'ions ferreux et d'ions ascorbate. On a isolé l'enzyme à partir de l'organisme prokaryotique *Streptomyces clavuligerus* et on l'a utilisé soit sous la forme d'un sel précipité brut ou sous une forme semi-purifiée, alors que l'enzyme a été débarassé des autres enzymes de la voie pénicilline–céphalosporine. Avec la préparation brute de l'enzyme, les trois analogues portant les groupes adipyl, glycyl-δ-(L-α-aminoadipyl) et *N*-acétyl-δ-(L-α-aminoadipyl) sont des substrats actifs; toutefois, les deux derniers composés ne sont transformés en isopénicilline N, le produit normal de la cyclisation, que via l'ACV. Le fait que la préparation brute de l'enzyme contient un protéase qui peut enlever les groupes acétyles de l'ACV pour les transformer en ACV est confirmé, entre autre, par le comportement de l'enzyme purifié; des divers analogues, seul le composé portant un groupe adipyl s'avère un substrat actif, mais l'efficacité de la transformation de cet analogue en carboxybutylpénicilline n'est que de 1 à 2% par rapport au substrat naturel.

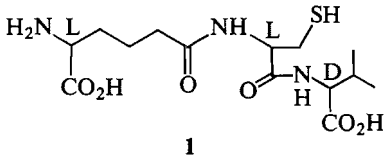
[Traduit par le journal]

Introduction

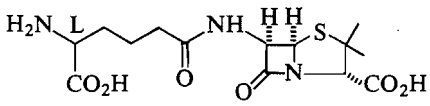
Streptomyces clavuligerus is a Gram positive, filamentous bacterium which produces a variety of β-lactam compounds including penicillin N, cephamycin C, and clavulanic acid (1, 2). The biosynthetic versatility of this organism, in terms of the synthesis of β-lactam compounds, has prompted an investigation of the enzymatic steps involved in the natural production of these antibiotics (3–5). Concurrent studies on the penicillin and cephalosporin-producing enzymes of *Cephalosporium acremonium* have been undertaken by several groups, and continue at the present time (6–8). One of these enzymes, variously referred to as cyclizing enzyme (3), cyclase (9), or isopenicillin N synthetase (10), leads to oxidative cyclization of the linear tripeptide δ-(L-α-aminoadipyl)-L-cysteinyl-D-valine (**1**) (ACV) into isopenicillin N (**2**). This enzymatic step constitutes the single β-lactam ring forming reaction which leads from the amino acid oxidation level to penicillins and cephalosporins (cephamycins).

In both the prokaryotic (*S. clavuligerus*) and eukaryotic (*C. acremonium*) systems, this oxidative cyclization is carried out by an enzyme with remarkably similar characteristics. In both cases, the enzymes are soluble, require iron and ascorbate as cofactors, and consume molecular oxygen (3, 6, 9, 11).

As noted above, *S. clavuligerus* also produces clavulanic

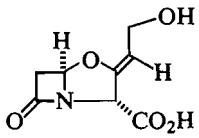


1



2

acid (**3**), a non-classical β-lactam compound which contains oxygen in the nucleus. The nature of the β-lactam ring forming enzyme associated with clavulanic acid biosynthesis is not known. It is conceivable that a single cyclizing enzyme of broad specificity could lead to the synthesis of penicillin–cephalosporin type compounds and also clavulanic acid (12). It seems more likely, however, that clavulanic acid biosynthesis involves a different pathway (13). Investigations into the substrate specificity of the cyclizing enzyme of *C. acremonium* have already indicated this enzyme to have a narrow substrate specificity (6, 9, 14).



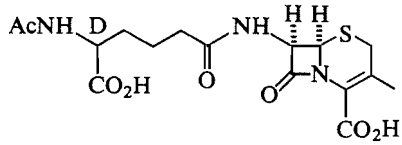
3

The present work is concerned with the behaviour of the cyclizing enzyme of *S. clavuligerus* towards analogs of ACV modified in the aminoadipyl residue. Certain specific modifications were of particular interest, because some β-lactam producing organisms also synthesize peptides, penicillins, and cephalosporins with side chains other than aminoadipyl. For example, ACV was first isolated from the mycelium of *Penicillium chrysogenum* (15), but was later found (16) to be contaminated with an additional peptide containing glycine. The structure and stereochemistry of ACV were established by Loder and Abraham (17) who isolated the peptide from the mycelium of *Cephalosporium* sp. C91, together with a tetrapeptide containing glycine, in addition to aminoadipic acid, cysteine, and valine. The constitution Aad-Cys-Val-Gly was suggested for this tetrapeptide, but a shortage of material prevented proof of this sequence. A peptide, apparently identical to Loder and Abraham's tetrapeptide, has been isolated from the β-lactam producing organism *Paecilomyces persicinus* P10 (18), and found to have the constitution Gly-Aad-Cys-Val (GACV). It was suggested that ACV is a precursor of penicillins, and that GACV may be a precursor of cephalosporins.

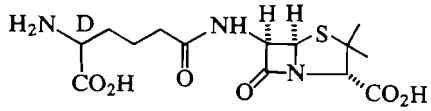
However, it has since become clear (3–5) that ACV is a precursor of both penicillins and cephalosporins. The biosynthetic significance of GACV therefore remains unknown.

N-Acetyldesacetoxycephalosporin C (**4**) has been isolated from a mutant of *C. acremonium* which is blocked in the synthesis of cephalosporin C (19). More recently, *N*-acetylisopenicillin N has been isolated from the culture broth of *Streptomyces tokunonensis* sp. nov., an organism that also produces isopenicillin N, penicillin N (**5**), and several carbapenems (20). The compound is considered in this case to be a shunt metabolite of isopenicillin N.

Cephalosporins containing fewer than six carbons in the side



4



5

chain, or lacking an amino group in the side chain, have been isolated from *Cephalosporium* spp. (21) and *Streptomyces* spp. (22). The side chains of these compounds are thought to be derived from the aminoadipyl side chains of cephalosporin precursors.

In view of these various observations, analogs of ACV were synthesized in which the δ-(L-α-aminoadipyl) moiety was replaced by: β-(L-aspartyl) (**6**), γ-(L-glutamyl) (**7**), δ-(D-α-aminoadipyl) (**8**), adipyl (**9**), *N*-acetyl-δ-(L-α-aminoadipyl) (**10**), and glycyl-δ-(L-α-aminoadipyl) (**11**). Each of these peptides was then subjected to the action of the cyclizing enzyme of *S. clavuligerus*. To facilitate the identication of possible cyclization products, glycyl-isopenicillin N (**12**), *N*-acetylisopenicillin N (**13**), and carboxybutylpenicillin (**14**) were also synthesized. All of the peptides were supplied for enzymatic experiments in the disulfide form. Reduction to the monomeric peptides was performed immediately prior to assays, using dithiothreitol (3).

During the course of the work, two improvements were made in the published synthesis of ACV (23): a technically simpler preparation of *S*-trityl-L-cysteinyl-D-valine benzhydryl ester (**15**) was developed, based on preferential removal of a *tert*-butoxycarbonyl protecting group in the presence of a benzhydryl ester; and a new synthesis of L-α-aminoadipic acid from L-lysine was found. Difficulties encountered in the conversion of α-aminoadipic acid to *N*-acetyl-α-aminoadipic acid led to the development of a new reagent for *N*-acetylation under mild conditions in aqueous media. Details of all of these syntheses are provided.

Experimental

Materials

S-Trityl-L-cysteinyl-D-valine benzhydryl ester (15)

N-tert-Butoxycarbonyl-*S*-trityl-L-cysteinyl-D-valine benzhydryl ester (23) (2.00 g, 2.74 mmol) was dissolved in ethyl acetate (2.0 mL) to give a mobile yellow oil. To this was added 98% formic acid (200 mL) and the resultant solution was stirred vigorously at room temperature. After 15 min the reaction mixture was frozen using liquid nitrogen and then freeze-dried. The residual oil was azeotroped twice with methylene chloride, under reduced pressure, to leave a white foam. The crude formate salt was dissolved in ethyl acetate (100 mL) and washed with saturated sodium bicarbonate (2 × 80 mL, with brine added to minimize the formation of an emulsion), followed by saturated brine (80 mL). The solvent was dried over sodium sulfate and evaporated to leave a syrup which, after azeotroping with methylene chloride and drying under high vacuum, afforded a white foam, 1.49 g (87.5%).

A portion (724 mg) of the product was dissolved in chloroform (1.5 mL), diluted with hexane to the cloud point, and seeded to give white microprisms (517 mg), mp 155–156°C, $[\alpha]_D$ +34.7° (*c* 1.0, CH_2Cl_2); ir (KBr): 3355 (m), 3290 (w), 3160 (m, NH, NH_2), 1726, 1662 (s, ester, amide carbonyl) cm^{-1}; ^{1}Hmr (200 MHz, $CDCl_3$) δ:

0.74 (3H, d, J = 7 Hz, $CHCH_3$), 0.84 (3H, d, J = 7 Hz, $CHCH_3$), 1.46 (2H, br, NH_2), 2.17 (1H, m, collapses to quintet, J = 7 Hz, on irradiation at 4.55 ppm; valine C3 methine), 2.47 (1H, q, J = 9, 12 Hz) and 2.75 (1H, q, J = 4, 12 Hz, A and B quartets for cysteine methylene which collapse to two doublets, J = 12 Hz, on irradiation at 2.90 ppm), 2.90 (1H, q, J = 4, 9 Hz, cysteine methine), 4.55 (1H, q, J = 5, 9 Hz, collapses to doublet, J = 9 Hz, on irradiation at 2.17 ppm, valine C2 methine), 6.87 (1H, s, benzhydryl methine), 7.16–7.53 (~26H, aromatic and amide NH). *Anal.* calcd. for $C_{40}H_{40}N_2O_3S$: C 76.40, H 6.41, N 4.45; found: C 75.98, H 6.48, N 4.30.

Bis-β-(L-aspartyl)-L-cysteinyl-D-valine (6)

This compound was synthesized from **15** and N-BOC-L-aspartic acid-α-benzhydryl ester as described for ACV (23), except that the final deprotection was accomplished with formic acid (16 h). Thin-layer chromatography (tlc): R_f 0.12 (butanone – acetic acid – water, 4:1:1); ^{1}Hmr (D_2O) δ: 0.95 (12H, t, 6 Hz), 2.17 (2H, m), 2.99 (4H, m), 3.05 (2H, q, 8, 14 Hz), 3.18 (2H, q, 6.5, 14 Hz), 4.05 (2H, q, 6.5, 8 Hz), 4.20 (2H, d, 6.4 Hz), 4.8 (2H, m).

Bis-γ-(L-glutamyl)-L-cysteinyl-D-valine (7)

This compound was synthesized from **15** and N-BOC-L-glutamic acid-α-benzhydryl ester as described for **6**; tlc: R_f 0.12 (butanone – acetic acid – water, 4:1:1); ^{1}Hmr (D_2O) δ: 2.17 (4H, m), 2.51 (4H, m), 3.00 (2H, q, 8, 14 Hz), 3.18 (2H, q, 6, 14 Hz), 3.77 (2H, t), 4.17 (2H, d), 4.78 (2H, m).

Bis-δ-(D-α-aminoadipyl)-L-cysteinyl-D-valine (8)

This compound has $[\alpha]_D^{20}$ −35.8 (*c* 0.8, 2 *N* HCl); tlc: 0.18 (butanone – acetic acid – water, 4:1:1); ^{1}Hmr (D_2O) δ: 0.92 (12H, t, 7 Hz), 1.73 (4H, m), 1.88 (4H, m), 2.18 (2H, m), 3.00 (2H, q, 8.2, 15 Hz), 3.20 (2H, q, 6.5, 15 Hz), 3.78 (2H, br t), 4.21 (2H, d, 6 Hz), 4.81 (2H, m).

Bis-adipyl-L-cysteinyl-D-valine (9)

Adipic acid (730 mg, 5 mmol) was dissolved in a mixture of methanol (5 mL) and methylene chloride (30 mL), and a solution of diphenyldiazomethane (970 mg, 5 mmol) was added in portions during 8.5 h. When the addition was complete, the solvent was removed and the residue was triturated with ethyl acetate (15 mL) and filtered to give 220 mg of unreacted adipic acid. The filtrate was evaporated, ether (2 mL) was added, and this solution was treated with dicyclohexylamine (519 mg, 3.49 mmol). Hexane was then added to the cloud point and the mixture was chilled overnight. The crystals were then collected (1.1 g, mp 101–104°C) and recrystallized from ethyl acetate – ether (0.92 g, mp 103.5–105°C). The salt (420 mg) was partitioned between ethyl acetate (15 mL) and 10% potassium bisulfate (5 mL), and the organic layer was washed successively with 10% potassium bisulfate (2 × 5 mL) and brine (5 mL), dried, and evaporated. The residue crystallized from hexane (279 mg). Recrystallization from methylene chloride – hexane afforded 197 mg (mp 84.5–85.5°C) of the monobenzhydryl ester of adipic acid. Coupling of this ester with **15**, and further treatment as described for **6** led to **9**, R_f 0.66 (95% ethanol – acetic acid, 20:1).

Conversion of pipecolic acid to α-aminoadipic acid

Thionyl chloride (50.3 mL) was added dropwise, with cooling at 0°C, to a solution of pipecolic acid (50 g, 0.387 mol) in absolute methanol (400 mL). The reaction mixture was allowed to warm to room temperature, stirred for 12 h, and the solvent was then removed under reduced pressure. The crystalline residue was dissolved in dry methylene chloride (900 mL), the solution was cooled to 0°C, stirred, and dry triethylamine (110 mL, 0.785 mol) was added during 15 min followed, dropwise, by a solution of acetyl chloride (28 mL, 0.39 mol) in methylene chloride (100 mL). This mixture was stirred for 12 h, allowed to warm to room temperature, and water (750 mL) was added. The aqueous phase was extracted with methylene chloride (2 × 250 mL), and the combined organic phases were dried and evaporated. The residual oil was distilled (bp 100–110°C/2 Torr; 1 Torr = 133.3 Pa).

A mixture of methyl *N*-acetylpipecolate (46.4 g, 0.25 mol), ruthenium trichloride trihydrate (5 g), sodium periodate (1.073 L of 10% solution), and chloroform (1 L) was stirred vigorously. After 4 h the mixture turned black and was filtered through glass wool. The organic phase was separated, dried, and evaporated. The residue (47.1 g, 0.24 mol) was refluxed for 10 h in 8 *N* hydrochloric acid (1.41 L) and the resulting solution was then cooled to room temperature and concentrated under reduced pressure to a volume of 150 mL. The pH was adjusted to 2.9 with 10 *N* sodium hydroxide and the mixture was stored at 0°C overnight. Subsequent filtration afforded α-aminoadipic acid (24 g), identified by ir, nmr, and tlc.

Conversion of L-α-amino-ω-hydroxycaproic acid (24) to N-BOC-L-α-aminoadipic acid benzhydryl ester

To the amino acid alcohol **18** (92.5 mg, 0.63 mmol) in 50% acetone–water (1 mL) containing triethylamine (95.4 mg, 0.94 mmol) was added BOC-ON (155 mg, 0.63 mmol). The resulting yellow solution was stirred for 2 days and the solvent was then removed. The semi-solid residue was dissolved in water (40 mL) and this solution was extracted with ether (3 × 10 mL). These ether extracts were discarded. The aqueous phase was acidified with 10% potassium bisulfate and extracted with ethyl acetate (3 × 30 mL). The organic phase was dried and evaporated to afford the N-BOC derivative (135 mg, 87%) as a colourless oil. This oil (94.5 mg, 0.38 mmol) was dissolved in methylene chloride (2.5 mL) and treated with diphenyldiazomethane (74 mg, 0.38 mmol). After 5 min, the solvent was evaporated, and the residue was chromatographed (methylene chloride – ethyl acetate 5:1) to give the N-BOC benzhydryl ester (157 mg, 100%). A suspension of platinum oxide (100 mg) in water (1 mL) was stirred under a hydrogen atmosphere for 30 min, purged with nitrogen for 30 min, and then placed under an oxygen atmosphere. Sodium bicarbonate (32 mg, 0.38 mmol) was added, followed by the N-BOC benzhydryl ester (157 mg) in 66% acetone (5 mL). Stirring was continued under oxygen for 16 h and the mixture was then centrifuged and the supernatant acidified with 2% potassium bisulfate. Extraction with methylene chloride, followed by drying and evaporation of the organic extract, yielded N-BOC-L-α-aminoadipic acid benzhydryl ester (156 mg, 96%) as a semi-solid. Dicyclohexylamine salt: mp 156–158°C (lit. (23) mp 156.5–157.5°C); $[\alpha]_D^{25}$ −21.6° (*c* 2, methanol) (lit. (23) $[\alpha]_D$ −20.5 (*c* 2, methanol)).

2-Acetoximino-2-phenylacetonitrile

To 2-oximino-2-phenylacetonitrile (25) (3.1 g, 0.021 mol) in pyridine–benzene (10 mL of a 1:2 mixture) was added acetyl chloride (1.5 mL, 2.08 g, 0.026 mol). The reaction mixture was stirred at 0°C for 3 h, and the solvent was then removed under reduced pressure. The residue was dissolved in a mixture of water and ether and the organic layer was separated, dried, and evaporated. The crystalline residue was recrystallized from ether–hexane to give 3.1 g, mp 70–71°C; ^{1}Hmr ($CDCl_3$) δ: 2.28 (3H, s), 7.35–7.72 (5H, m). *Anal.* calcd. for $C_{10}H_8N_2O_2$: C 63.82, H 4.38, N 14.89; found: C 63.95, H 4.44, N 14.63.

Conversion of L-α-amino-ω-hydroxycaproic acid to N-acetyl-L-α-aminoadipic acid benzhydryl ester (21)

The amino acid alcohol **18** (73.5 mg, 0.5 mmol) was dissolved in 50% acetone (1.5 mL), and triethylamine (1.5 equiv., 100 μL) and 2-acetoximino-2-phenylacetonitrile (113 mg, 0.77 mmol) were added. The resulting solution was stirred at room temperature for 4 h, and the solvent was then removed under reduced pressure. The residue was dissolved in dry methanol (3 mL) and a solution of diphenyldiazomethane (100 mg, 0.52 mmol) in methylene chloride (0.5 mL) was added. The mixture was stirred for 30 min, concentrated, and the residue was chromatographed on silica gel. Elution with methylene chloride – methanol (10:1) gave 110 mg (62%) of **25**; $[\alpha]_D^{24}$ − 9.5° (*c* 2, chloroform); ir (KBr): 3270, 1730, 1650 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.02–1.95 (6H, m, $CH_2CH_2CH_2$), 1.96 (3H, s, $COCH_3$), 3.51 (2H, t, 6 Hz, CH_2), 4.75 (1H, sextet, 5.5, 7.5 Hz, CH), 6.1 (1H, d, 7.5 Hz, NH), 6.9 (1H, s, CH), 7.33 (10H, s).

Platinum oxide (1 g) was suspended in 50% aqueous acetone (10 mL), containing sodium bicarbonate (168 mg, 2 mmol), and the suspension was stirred under hydrogen for 30 min, purged with nitro-

For personal use only.

gen, and then placed under an oxygen atmosphere. The protected alcohol **25** (510 mg, 1.44 mmol) was added, and vigorous stirring was continued, under oxygen, for 12 h. The mixture was then centrifuged, the residue washed with water (2 × 2 mL), and the combined supernatant was evaporated under reduced pressure. The residue was dissolved in water, the pH was adjusted to 3.0, and the resulting precipitate was extracted with ethyl acetate. This extract was washed successively with 10% potassium bisulfate (10 mL), water (10 mL), and brine (10 mL), then dried and evaporated to yield **21** (340 mg, 64%) as a foam; $[\alpha]_D^{25}$ −7.8° (*c* 2, chloroform); ir (KBr): 1720, 1705, 1660 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.35−1.95 (4H, m), 1.97 (3H, s), 2.27 (2H, m), 4.75 (1H, sextet, 5.5, 7.5 Hz), 6.29 (1H, d, 7.5 Hz), 6.88 (1H, s), 7.33 (10H, s).

N-Acetylation of L-α-aminoadipic acid-α-benzhydryl ester

The ester **22** (60 mg, 0.18 mmol) was suspended in 50% acetone (1.5 mL), and 2-acetoximino-2-phenylacetonitrile (36 mg, 0.19 mmol) and triethylamine (1.5 equiv.) were added. The suspension dissolved and the resulting solution was stirred for 4 h and then evaporated. Chromatography on silica gel (methylene chloride − methanol, 4:1) afforded 60 mg (90%) of **21**.

*Bis-N-acetyl-δ-(L-α-aminoadipyl)-L-cysteinyl-D-valine (**10**)*

This compound was synthesized from **15** and *N*-acetyl-L-α-aminoadipic acid-α-benzyhydryl ester; tlc: R_f 0.56 (butanone − acetic acid − water, 4:1:1); ^{1}Hmr (DMSO-d_6) δ: 0.96 (6H, d, 7.5 Hz), 0.98 (6H, d, 7.5 Hz), 1.76 (8H, m), 2.00 (6H, s), 2.22 (2H, m), 2.34 (4H, br t), 2.97 (2H, q, 9, 14 Hz), 3.20 (2H, q, 6, 14 Hz), 4.33 (2H, m), 4.38 (2H, m).

*Bis-glycyl-δ-(L-α-aminoadipyl)-L-cysteinyl-D-valine (**11**)*

This compound was synthesized from N-BOC-glycyl-L-α-aminoadipic acid-α-benzhydryl ester (26) and **15**: tlc: R_f 0.1 (butanone − acetic acid − water, 4:1:1), ^{1}Hmr (D_2O) δ: 0.89 (6H, d, 7 Hz), 0.94 (6H, d, 7 Hz), 1.70−2.30 (10H, m), 2.39 (4H, m), 2.98 (2H, q, 8.6, 14 Hz), 3.21 (2H, q, 5.5, 14 Hz), 3.87 (4H, s), 4.16 (2H, d, 6 Hz), 4.28 (2H, m), 4.76 (2H, q, 5.5, 8.6 Hz). *Anal.* calcd. for $C_{34}H_{58}N_8S_2O_{18}\cdot H_2O$: C 43.03, H 6.37, N 11.81; found: C 43.00, H 6.84, N 12.30.

*Glycylisopenicillin N (**12**)*

A solution of L-α-aminoadipic acid-α-benzhydryl ester (321 mg, 0.98 mmol) and dicyclohexylamine (0.4 mL) in methanol (16 mL) and dimethoxyethane (5 mL) was treated with *N*-carbobenzoxyglycine succinimidyl ester (306 mg, 1.0 mmol) (27), and then stirred at room temperature for 72 h. The solvent was removed, and the residue was redissolved in methylene chloride (25 mL), washed with 10% potassium bisulfate (3 × 30 mL) and brine (20 mL), dried, and evaporated. The resulting syrup (565 mg) was redissolved in methylene chloride (10 mL), and the solution was filtered and reevaporated to give a yellow foam (504 mg). A portion of this carbobenzoxyglycyl-L-α-aminoadipic acid-α-benzhydryl ester was purified by rapid chromatography; ^{1}Hmr ($CDCl_3$) δ: 1.58 (4H, m), 2.19 (2H, m), 3.87 (2H, m), 4.71 (1H, m), 5.08 (2H, s), 5.89 (1H, m), 6.86 (1H, s), 7.30 (16H, m), 9.45 (1H, br s). This compound was then converted to glycyl-isopenicillin N, as described for the syntheses of isopenicillin N and penicillin N (4); ir (KBr): 1768 cm^{-1}; ^{1}Hmr (D_2O) δ: 1.52 (3H, s), 1.65 (3H, s), 1.76 (4H, m), 2.40 (2H, m), 3.91 (2H, s), 4.26 (1H, s), 5.49 (1H, d, 4 Hz), 5.57 (1H, d, 4 Hz).

*N-Acetylisopenicillin N (**13**)*

This compound was synthesized from *N*-acetyl-L-α-aminoadipic acid-α-benzhydryl ester and the benzhydryl ester of 6-aminopenicillanic acid (4), as described for **12**, ir (KBr): 1767 cm^{-1}; ^{1}Hmr (D_2O) δ: 1.49 (3H, s), 1.62 (3H, s), 2.03 (3H, s), 1.65−2.45 (6H, m), 4.24 (1H, s), 5.47 (1H, d, 4.0 Hz), 5.57 (1H, d, 4.0 Hz).

*Carboxybutylpenicillin (**14**)*

This compound was synthesized from the monobenzhydryl ester of adipic acid and the benzhydryl ester of 6-aminopenicillanic acid, as described for **12**; ir (KBr): 1765 cm^{-1}; ^{1}Hmr (D_2O) δ: 1.49 (3H, s), overlapping with 1.56 (4H, br m), overlapping with 1.63 (3H, s), 2.17 (2H, m), 2.37 (2H, m), 4.25 (1H, s), 5.66 (1H, d, 3.6 Hz), 5.75 (1H, d, 3.6 Hz).

Organism and cultural conditions

Streptomyces clavuligerus NRRL 3585 was maintained and cultivated as previously described (3). Cells from 40-h cultures were harvested by filtration, washed, and resuspended to 1/10 of the original culture volume (approximately 1.8 mg dry weight/mL) in 0.05 *M* Tris-HCl buffer, pH 7.0, containing 0.1 m*M* dithiothreitol (TD buffer) for preparation of cell-free extracts.

Enzyme preparations

Washed cell suspensions were broken, in 25-mL aliquots, by sonic oscillation for 2 × 15 s at setting 5 with a Sonifier Cell Disruptor 350, Branson Sonic Power, using a standard flat-tipped probe (1.9 cm diameter). Broken cell suspensions were centrifuged 30 min at 25 000 × *g* to remove unbroken cells and cell envelope material. The resulting supernatant, termed cell-free extract, was partially purified by ammonium sulfate precipitation. Solid ammonium sulfate was gradually added to cell-free extract (typically 100 mL) with gentle stirring at 4°C. Material which precipitated between 40% and 70% saturation was collected by centrifugation (15 min at 25,000 × *g*) and resuspended to 1/10 of the original culture volume in TD buffer. This salt-precipitated cell-free extract was concentrated tenfold by ultrafiltration (PM-10 filter, Amicon Corporation), returned to its original volume with TD buffer, and again concentrated tenfold to remove residual ammonium sulfate. The resulting crude enzyme concentrate contained 40−60 mg protein/mL.

Partially purified cyclizing enzyme was prepared by anion exchange chromatography of the crude enzyme concentrate using DEAE-trisacryl resin, as described in ref. 5. This partially purified cyclizing enzyme is functionally pure, since it contains none of the other enzyme activities associated with penicillin/cephalosporin biosynthesis.

Assays

Cyclization activity was measured in a 0.4-mL standard cyclization assay system containing: ascorbic acid 2.8 m*M*, $FeSO_4$ 45 μ*M*, Tris HCl buffer (pH 7.0) 50.0 m*M*, and enzyme 0.1 mL. One hundred micrograms of each peptide substrate was reacted with 25 μL of 66.7 m*M* dithiothreitol for 15 min at 21°C before addition to the standard assay system. The mixtures were incubated for 2 h at 20°C and the reactions were then terminated by the addition of 0.4 mL of methanol. Under these conditions this corresponds to >90% consumption of ACV. Antibiotic formation was monitored by biological assay of reaction mixtures and by hplc analysis.

Biological assays of reaction mixtures were conducted using the agar diffusion procedure with *Micrococcus luteus* ATCC 9341 as the indicator organism.

The protein contents of cell-free extract and salt precipitated cell-free extract were determined by the method of Bradford (28).

High pressure liquid chromatographic analysis of reaction mixtures

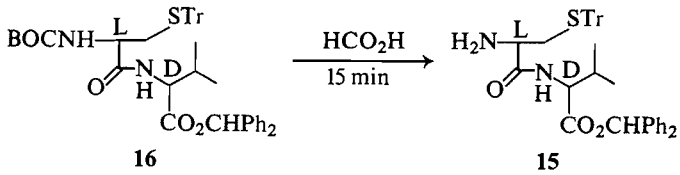
Methanol-inactivated reaction mixtures were centrifuged for 5 min at 12 000 × *g* before analysis. Equipment used for hplc analyses consisted of: an M6000 A pump, a WISP Model 710B automatic injector, and M-480 variable wavelength detector, an M420 data module, a Model 720 systems controller, and a C_{18} column (RadPak A in a Z module). All equipment was from Waters Scientific Ltd. The mobile phase consisted of methanol−KH_2PO_4 (0.05 *M* adjusted to pH 4.0 with H_3PO_4) in proportions which varied with the particular separation. The flow rate was 2 mL/min for 5 min and then 3 mL/min for the remaining analysis time. Detection of uv-absorbing materials was at 220 nm at a sensitivity of 0.02 absorbance units full scale.

Results

Syntheses of substrates

A. *Improved synthesis of* S-*trityl-L-cysteinyl-D-valine benzhydryl ester (**15**)*

In an earlier synthesis of ACV (23), **15** was prepared by *N*-detritylation of a *N*,*S*-ditritylated precursor. It has now been

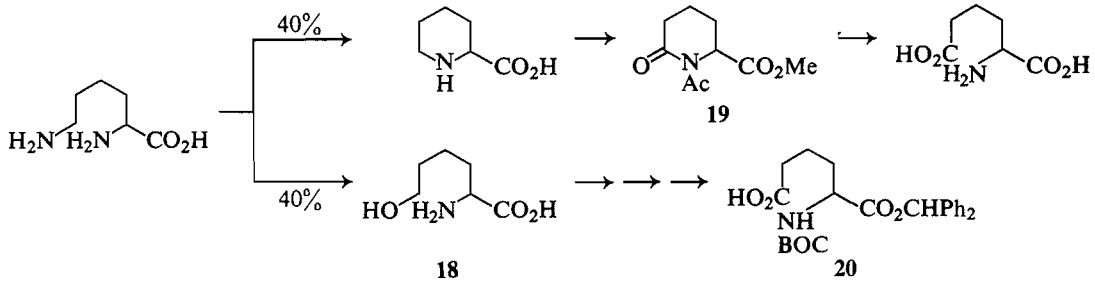


found that a 15-min treatment with a 98–100% formic acid leads to selective removal of the *tert*-butoxycarbonyl protecting group of **16** (23), and provides the intermediate **15** as a crystalline compound in over 80% yield. This is an improvement over the earlier sequence, because of the higher yield in the introduction of the nitrogen protecting group, and the greater ease of coupling of the cysteinyl and valinyl moieties when *N*-*tert*-butoxycarbonyl is employed in place of *N*-trityl.

B. *A new synthesis of* L-α-*aminoadipic acid*

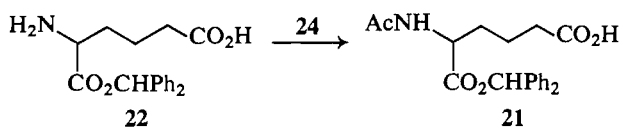
Hungarian workers have recently observed deamination of amino acids, using sodium nitroprusside as the formal source of NO^+ (24). Applied to L-lysine, this reaction leads to L-pipecolic acid (**17**) (40%), and the amino acid alcohol **18** (40%). In the present work, oxidation of *N*-acetylpipecolic acid methyl ester with ruthenium tetroxide (29) led smoothly to **19**. Hydrolysis of this lactam provided α-aminoadipic acid.

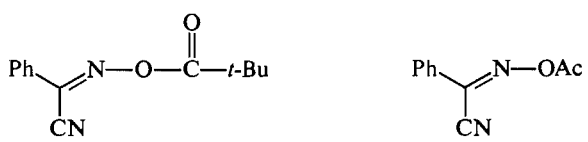
However, since α-aminoadipic acid is normally employed in our peptide syntheses in the form of the diprotected derivative **20**, the preparation of **20** from **17** requires six steps. The alcohol **18** is, therefore, a more useful intermediate since only three steps are then needed. In practice, these consisted of reaction with BOC-ON, reaction with diphenyldiazomethane, and oxidation with Pt/O_2. The yield of **20** from **18** was 83%.

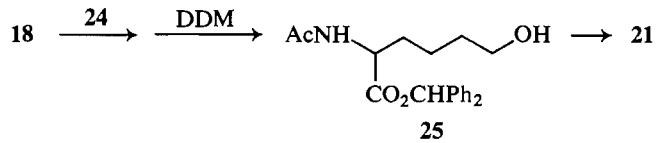


C. *A new reagent for* N-*acetylation in aqueous media*

For the syntheses of the peptide **10** and the penicillin **13**, the *N*-acetylated α-aminoadipic acid derivative **21** was required. However, several attempts to acetylate **22** led to piperidone formation, and **21** could not be detected. Since BOC-ON (**23**) reacts smoothly with **22**, the analog **24** was synthesized from 2-oximino-2-phenylacetonitrile. This compound solved the problem. In aqueous acetone it acetylated **22** in 90% yield, and also *N*-acetylated the amino alcohol **18**.

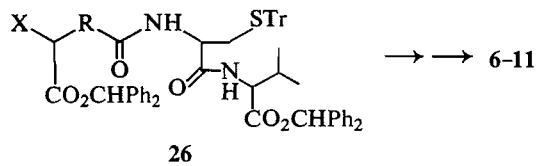






D. *Syntheses of peptides*

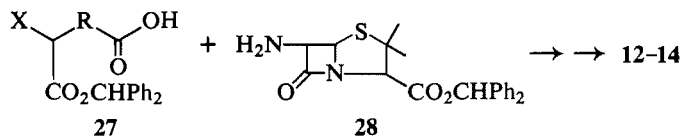
These followed the general strategy of ref. 23, with the modifications noted above. Condensation of **15** with the appropriately protected diacid or amino acid led to compounds of the general structure **26**. These were deprotected in two steps: detritylation with iodine in methanol; and removal of *tert*-butoxycarbonyl and benzhydryl protecting groups by overnight treatment with formic acid.



X = BOC-GLY, BOC-NH, AcNH, H

E. *Syntheses of penicillins*

These followed the strategy devised in ref. 4 for the syntheses of isopenicillin N and penicillin N. Condensation of the appropriately protected diacid or amino acid **27** with **28**, the benzhydryl ester of 6-APA (4) afforded the fully protected penicillins. These were deprotected by hydrogenolysis.



X = Z-GLY, AcNH, H

Cyclization of unnatural peptide substrates

A. *Biological assays*

In control reaction mixtures, none of the peptide substrates **1**, **6**–**11** exhibited antibacterial activity. Reaction mixtures containing enzyme, but no peptide substrate, also showed no activity.

Table 1 summarizes the results of experiments conducted under identical conditions for test reaction mixtures containing both substrate and enzyme. The L-aspartyl (**6**), L-glutamyl (**7**),

and D-α-aminoadipyl (**8**) containing peptides are inactive substrates. However, antibacterial activity is observed when the adipyl (**9**), *N*-acetyl-L-α-aminoadipyl (**10**), and glycyl-L-α-aminoadipyl (**11**) containing peptides are employed as substrates.

B. *High pressure liquid chromatographic analyses*

The retention times of all monomeric peptide substrates and the putative cyclization products of the active substrates **1**, **9**−**11** were established prior to the analysis of test reaction mixtures. These are summarized in Table 2. Two sets of conditions were necessary because **9**, **10**, **13**, and **14** are retained by the stationary phase under the optimum conditions for elution of the other substrates and penicillins. For **1**, **6**, **7**, **8**, **11**, and **12**, the mobile phase consisted of 5% methanol − 95% KH_2PO_4 (0.05 *M* adjusted to pH 4.0 with H_3PO_4) (method A). For **9**, **10**, **13**, and **14**, the methanol content of the mobile phase was increased to 20% (method B).

Figure 1 shows hplc data obtained using method A, for a no-substrate control and for reaction mixtures containing ACV and **9**−**11**. In the case of the natural substrate ACV, the unreacted peptide is observed at 19.9 min, and there is a large peak at 5.4 min, corresponding to an unresolved mixture of isopenicillin N and penicillin N ((iso)penicillin N) (3−5). In the cases of the inactive substrates **6**−**8**, (data not shown in Fig. 1), hplc profiles of reaction mixtures are identical to the no-substrate control, with the addition of the peaks corresponding to unreacted peptide substrate. These peptides are, therefore, not undergoing transformation to biologically inactive products.

With GACV (**11**) as the substrate, unreacted peptide is observed at 21.7 min, and *(iso)penicillin N is observed at 5.4 min*. In addition, there is a minor peak, corresponding to ACV, at 19.9 min. The latter peak is not seen in control GACV reaction mixtures incubated without enzyme. Since no peak corresponding to glycyl-isopenicillin N is seen at 8.0 min, these observations represent a first indication (confirmed below) that GACV is converted in part to ACV under these conditions, and that the antibacterial activity reported in Table 1 refers to the cyclization of the latter compound.

A similar result is obtained with acetyl-ACV (**10**). The chromatogram shows a small ACV peak at 19.9 min, and a large (iso)penicillin N peak at 5.4 min. No peak is observed at 19.9 min in control reaction mixtures incubated without enzyme. However, the presence or absence of *N*-acetyl-ACV and *N*-acetylisopenicillin N in the reaction mixture cannot be established using method A, because of their retention by the stationary phase. For the same reason, the chromatogram, obtained using method A, of the reaction mixture containing adipyl-CV (**9**) is identical to that of the no-substrate control.

Figure 2 shows the hplc data obtained by method B for reaction mixtures containing **9** and **10**. With **10** as the substrate, all of the substrate is consumed, an ACV peak is seen at 5.0 min, but no penicillin peak corresponding to **13** can be found at 2.9 min. As will be seen below, the acetyl-ACV substrate has been converted completely to ACV *prior to* cyclization in the normal manner.

On the other hand, with **9** as the substrate, a considerable amount of the substrate remains unreacted, and is observed at 14.1 min. A new peak, corresponding to the penicillin **14**, is observed at 8.3 min. The low conversion of **9** that is observed in Fig. 2 is consistent with the low antibacterial activity noted in Table 1. Since zones of inhibition are related exponentially to the concentration of antibiotic, zones of 31.5 mm and 12 mm from ACV and from **9** would have suggested an antibiotic concentration about eighty times lower in the latter case, assuming the two antibiotics to have equal activity.

To check the conclusion that GACV (**11**) and acetyl-ACV (**10**) do not cyclize directly to (iso)penicillin N but, rather, undergo prior deacylation to ACV, cyclization assays were performed on these substrates in mixtures lacking iron and ascorbate. These are the essential cofactors for cyclization activity to be observed (3). Figure 3 shows the hplc data, using method A, obtained from such reactions. The no-substrate control differs in this case from that seen in Fig. 1, because the relative amounts of the oxidized and reduced forms of dithiothreitol (14.3 min and 9.3 min, respectively) are not the same in the absence of the cofactors. In particular, absence of ferrous ions permits the reduced form of dithiothreitol to persist for much longer times.

With **10** as the substrate for this experiment, the chromatogram shows a large ACV peak at 19.9 min, but no (iso)penicillin peak is observed at 5.4 min (and the reaction mixture shows no antibacterial activity). The chromatogram obtained using method B shows no residual **10**. On the other hand, GACV is somewhat more stable. The chromatogram obtained using method A shows unreacted GACV at 21.7 min,

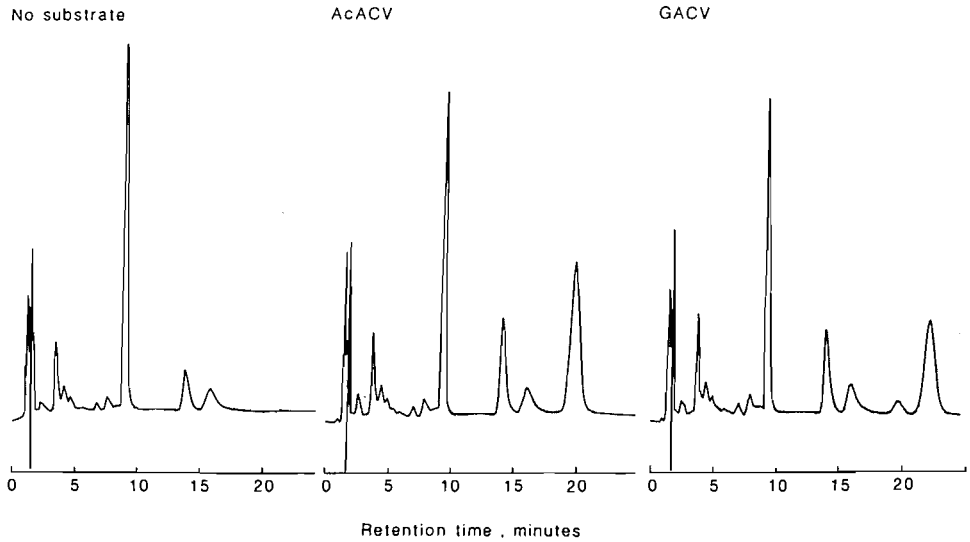

FIG. 3. The hplc analysis of cyclization reaction mixtures lacking iron and ascorbate using method A.

and ACV at 19.9 min. Again, no (iso)penicillin N is observed (and the reaction mixture shows no antibacterial activity).

It is clear that the activities observed from **10** and **11** in Table 1 reflect the extent to which these peptides were converted to ACV under the conditions of those experiments. Once formed, ACV resists further degradation, and there is no evidence that ACV is converted to CV or to free amino acids, either by *S. clavuligerus* cell-free extract or by non-specific proteases. Proteolytic activity, as measured by degradation of azocasein, was not detectable in cell-free extracts or semi-purified enzyme preparations. Similarly, addition of benzylsulfonyl fluoride to reaction mixtures at a final concentration of 1 m*M* had no effect on activity.

C. *Behaviour of functionally purified cyclizing enzyme*

The zones of inhibition shown in parentheses in Table 1 refer to cyclization experiments conducted with functionally purified enzyme. These data demonstrate that only ACV and adipyl-CV (**9**) are true substrates for the cyclizing enzyme, and confirm the conclusions reached in the preceding section.

Discussion

The present study has revealed that the cyclizing enzyme of *S. clavuligerus* has a high degree of specificity for the α-aminoadipyl moiety of ACV. Although this portion of the peptide is well removed from the sites of bond formation, and has no known role in the formation of the penicillin nucleus, modifications to this residue have a profound effect upon the activity of the peptide. A change in the configuration of the α-aminoadipyl residue from L to D or a decrease in the chain length by one or two carbons abolishes cyclizing activity. Although *N*-acylated derivatives of ACV exhibit some cyclization activity, the antibiotic produced in such cases is (iso)penicillin N, the natural product of ACV cyclization. That *N*-deacylation precedes cyclization with these substrates was demonstrated by the formation of ACV following preincubation of reaction mixtures under iron- and ascorbate-free conditions.

Of the analogs tested, only AdCV, which lacks the α-amino group of ACV, is an active substrate, but it is only 1−2% as active as ACV. All of these observations concerning the substrate specificity of the cyclizing enzyme of *S. clavuligerus* are very similar to those reported previously for the cyclizing enzyme of *C. acremonium* (6, 9).

Study of electrolytic solution process using the scaled particle theory. 4. Standard free energy of transfer from aqueous to mixed aqueous binary solvent systems

UTPAL SEN

Central Electrochemical Research Institute, Karaikudi – 623 006, Tamil Nadu, India

Received February 7, 1984

UTPAL SEN. Can. J. Chem. **62**, 2721 (1984).

A unified approach which considers the electrolyte solution process as a combination of two steps, viz. (*1*) creation of a cavity of suitable size to accommodate the ionic solute species in the solvent system and (*2*) introduction of the ionic solute species into the cavity which interacts with the solvent system, proposed earlier along with the assumption that the overall ion–solvent interaction is the resultant of the electrostatic field and structural contributions, has been extended to study the free energy of transfer of electrolytes from water to a number of mixed aqueous binary solvent systems. The results of such theoretical analysis suggest that electrolytes can possibly be solvated preferentially by water molecules, particularly in the water-rich regions of the binary solvent system, with comparatively more ease in the solvent systems with dipolar aprotic co-solvents rather than in the binary solvent systems with protic co-solvents. This may be attributed to the possibility of strong interactions of water molecules with the protic co-solvent molecules through the hydrogen bonding. Dipolar aprotic co-solvents do not provide the facility for such hydrogen bonding. This observation seems to be consistent with most of the present day understandings about ion-solvent interactions in different binary solvent systems.

UTPAL SEN. Can. J. Chem. **62**, 2721 (1984).

Dans le but d'étudier l'énergie libre de transfert d'électrolytes de l'eau vers un certain nombre de systèmes de solvants binaires aqueux mixtes, on a essayé de rendre plus générale l'hypothèse selon laquelle l'interaction globale ion–solvant est la résultante de contributions structurales et de contributions du champ électrostatique ainsi que l'approche unifiée proposée antérieurement qui considère le processus de dissolution des électrolytes comme une combinaison de deux étapes, soit (*1*) la création d'une cavité ayant une dimension suffisante pour accomoder les espèces ioniques dissoutes dans le système de solvant et (*2*) l'introduction de l'espèce ionique dissoute dans la cavité qui interagit avec le système de solvant. Les résultats de telles analyses théoriques suggèrent qu'il est possible que les électrolytes puissent être solvatés préférentiellement par les molécules d'eau (en particulier dans les régions riches en eau du système de solvant binaire) et avec une facilité relativement plus grande dans les systèmes de solvant ayant des co-solvants aprotiques dipolaires plutôt que dans les systèmes ayant des co-solvants protiques. On peut attribuer ce comportement à la possibilité qu'ont les molécules d'eau de créer des interactions fortes avec les molécules de co-solvants protiques au moyen de liaisons hydrogènes. Par ailleurs, avec les co-solvants aprotiques dipolaires il n'est pas possible de former de telles liaisons hydrogènes. Cette observation semble être en accord avec la plupart des connaissances actuelles portant sur les interactions ion–solvant dans différents systèmes de solvants binaires.

Introduction

Studies of the interaction of electrolytes (ions) in various binary solvent systems are of considerable current interest (1–3). Covington and Newman (4) visualized solvation around an ion in a mixed solvent as a competition between the solvent components for available solvation sites. They also identified this competition to be a useful measure of the solvating ability of the different solvents. Thus for many aqueous binary solvent mixtures it has frequently been suggested that water is the dominant hydrogen bond donor in aqueous solutions, leaving little or no chance for other hydrogen bond donors to compete with water for available acceptor sites as the solute species (5). Consequently, the idea of preferential solvation comes into picture (3). On the other hand, many binary mixtures, particularly of strongly interacting solvent components, may form an entirely new solvent system as the result of the overall interactions among different solvent molecules present (in the absence of the solute species). The behavior of the new solvent system thus formed with respect to the electrolyte solute may be quite different from that of any of the pure components. Consequently, the idea of preferential solvation of ions in such particular mixed solvent systems may get somewhat confused except probably in regions where one particular component in the solvent mixture is so much in excess that almost all the molecules just do not feel at all that there might be any other type of solvent molecules in the system. Obviously, at such given conditions only one component is available for solvation free from the influence of any other type of solvent molecules. As such there would be no competition between the components as they are in the same conditions as in the pure single component solvent state. With this kind of dual understanding in the background a theoretical look into the interaction phenomenon of ions in various mixed solvent systems may be worthwhile.

Calculation of various thermodynamic properties of electrolytes in solution from purely theoretical consideration has long been one of the important objectives of various theories of electrolytes. Many such theoretical approaches are based on various models. Frank and Evans (6), Gurney (7) and others developed their chemical model according to which changes in the water properties are assumed when the water passes from the bulk region far from an ion into a small region (cosphere) next to an ion. The attractive proposal of multilayer hydration zones around a solute ion in solution due to Frank and Wen (8) came almost simultaneously. Many subsequent attempts to theoretically account for the thermodynamic and other behaviours of ions in solution are based on those concepts in one way or another. Excellent recent reviews are available on this subject (9–11).

In our recent work, we have found that the overall interaction phenomenon in electrolyte–solvent systems can be conveniently split into two additive parts, viz. (*i*) the interaction due to the presence of an ionic species of finite size into a uniform dielectric solvent system, and (*ii*) the so-called specific interactions occurring at various distances apart from the incorporated ion which may result in the formation of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

so-called multilayer solvation zones around the solute ion (12). The free energy involved in the first part of the interaction process as mentioned above may be conveniently estimated with the help of the Born charging equation (13). A prior fixation of the value of the interaction free energy for the second part (denoted as ΔG^*), on the other hand, seems to be difficult and may require various kinds of speculation. It has, however, been realized that ΔG^*, which apparently has its major contribution in the strong interactions in the vicinity of a dissolved ion, would be relatively insensitive to temperature variations (14). Consequently, some interesting possibilities arise for accurate theoretical predictions of the related thermodynamic properties of the system at different temperatures (14, 15).

According to the above theory (16) proposed on the basis of the scaled particle approach (12) the solvation process of electrolytes (or ions) can be seen as the simple combination of two steps, viz. (*a*) the formation of a cavity of appropriate size in the solvent system for the accommodation of the solute species, and (*b*) the introduction of the solute ion into the cavity which interacts with the surrounding solvent. Consequently, when this interaction process is again subdivided as stated above into the (*i*) Born-type electrostatic interaction and (*ii*) the sum of the other various kind specific interactions occurring in the various regions around the incorporated solute ion, which the Born continuum model cannot recognise, the standard free energy of solvation, ΔG_s^0, for electrolytes can be represented as

$$[1] \quad \Delta G_s^0 = \Delta G_c^0 + \Delta G_i^0 + \Delta G_x^0$$

$$[2] \quad \Delta G_s^0 = \Delta G_c^0 + (\Delta G_{Born}^0 + \Delta G^*) + \Delta G_x^0$$

where ΔG_c^0, ΔG_{Born}^0, ΔG^*, and ΔG_x^0 are the Gibbs free energy of cavity formation, of Born type electrostatic interaction, of specific interactions which the Born equation cannot recognise, and the free energy change due to the standard state conversion, respectively.

In a slightly different approach Roseman and Jencks (17) divided the solution process into three parts: (*1*) the formation of cavities in the solvent, (*2*) the development of relatively "nonpolar" solvent–solute interactions in which they included dispersion, dipole – induced-dipole and quadrupole forces, and (*3*) the development of "polar" interactions that involve the polarity of both the solvent and the solute species, i.e., primarily the strong solvent–solute interactions. The overall Gibbs free energy of transfer of a solute from the gas phase to the solvent (in the solvation process) is thus given by eq. [3]

$$[3] \quad \Delta G_{tr} = \Delta G^{cav} + \Delta G_{nonpolar}^{int} + \Delta G_{polar}^{int}$$

The free energy of transfer for a solute from water to a water cosolvent binary mixture, ΔG_{tr} (h $\rightarrow$ c) is given by the difference between the values of ΔG_{tr} (g $\rightarrow$ l) from eq. [3] for two solvents and may be expressed in forms of eq. [4]

$$[4] \quad \Delta G_{tr}\,(h \rightarrow c) = \delta\Delta G^{cav} + \delta\Delta G_{nonpolar}^{int} + \delta\Delta G_{polar}^{int}$$

in which each $\delta\Delta G$ term represents the difference in the free energy of that component in the two solvents. The cavity free energy term in eq. [3] may be estimated by assuming the solute and solvent molecules to be hard spheres. None of the two interaction free energy terms, however, can be estimated without difficulty. Moreover, eq. [3] has apparently been formulated to deal with nonelectrolytic solutes. Another matter to be considered is the free energy change due to the changes of standard states of solutes in different solvent systems, the magnitude of which may not be always considered as negligible when other than molar scale are used (10).

Scaled particle theory (SPT) (18) alone has been used by several workers (19–25) for predicting some thermodynamic functions of transfer from water to mixed and other aqueous solvent systems. Most of the cases solutes involved are nonpolar and it was assumed that the similarity of the solvents for each transfer could cause a cancellation of the interaction terms which was by any means comparatively less significant in magnitude because of nonpolar nature of the solute involved. It was thus implied that a good prediction of the transfer properties may be possible from the cavity formation contribution alone which may be calculated from the SPT. Desrosiers and Desnoyers (23) used the SPT to predict the signs, magnitudes, and the trends on the co-solvent concentration dependence of the enthalpies, volumes, and heat capacities of transfer of Bu_4N^+ from water to aqueous *tert*-butanol binary solvent mixtures considering the cavity formation contributions only.

In the present paper eq. [2] has been used for the theoretical prediction of the Gibbs free energy transfer of electrolytes from water to the mixed aqueous solvent systems. Here, unlike earlier occasions involving nonpolar or hydrophobic solutes where all other interaction contributions were ignored, only a part of the overall interaction for energy contributions (viz., the specific interaction term, ΔG^*) has been probingly assumed to be more or less the same in both the aqueous and mixed aqueous solvent systems. Aqueous mixtures of some typical protic solvent such as methanol (MeOH) and of some typical dipolar aprotic solvents such as dimethyl sulfoxide (Me_2SO) and acetonitrile (MeCN) have been chosen and found convenient for the comparison of the experimentally available and theoretically predicted values of free energy of transfer for electrolytes because the required experimental data related to the free energy transfer values as well as the essential physical parameters of this binary aqueous mixtures required for the theoretical computations may be obtained from literature (26–28).

Method of calculations

Following eq. [1] the standard free energy for transfer of electrolytes from one solvent (S_1) to another (S_2) can be expressed as

$$[5] \quad \Delta G_{tr(S_1-S_2)}^0 = \Delta G_{c(tr)}^0 + \Delta G_{Born(tr)}^0 + \Delta G_{tr}^* + \Delta G_{x(tr)}^0$$

$$[6] \quad \Delta G_{S_2}^0 - \Delta G_{S_1}^0 = [\Delta G_{c(2)}^0 - \Delta G_{c(1)}^0] + [\Delta G_{Born(2)}^0 - \Delta G_{Born(1)}^0] + [\Delta G_2^* - \Delta G_1^*] + [\Delta G_{x(2)}^0 - \Delta G_{x(1)}^0]$$

The first term inside the square brackets on the right side can be calculated by computing the standard free energy for cavity formation for ions in individual solvents and taking the difference. The cavity free energy expressions according to the scaled particle theory (11) are as follows:

$$[7] \quad \Delta G_c^0 = K_0 + K_1 d_{12} + K_2 d_{12}^2 + K_3 d_{12}^3$$

$$[8] \quad K_0 = RT[-\ln(1-y) + 4.5\{y/(1-y)^2\}] - PN\pi d_1^3/6$$

$$[9] \quad K_1 = -(RT/d_1)[\{6y/(1-y)\} + 18\{y/(1-y)\}^2] + PN\pi d_1^2$$

$$[10] \quad K_2 = (RT/d_1^2)[\{12y/(1-y)\} + 18\{y/(1-y)\}^2] - 2PN\pi d_1$$

$$[11] \quad K_3 = 4PN\pi/3$$

where $d_{12} = (d_1 + d_2)/2$ and d_1 and d_2 are the hard sphere

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

diameters of solvent and solute molecules, respectively, and $y(=\pi N d_1^3/6V_1)$ is the corresponding compactness factor of the solvent. The details of cavity free energy calculations with the help of SPT have been reported elsewhere (12). The solute species and the solvent molecules have been assumed to be hard spheres. The problem of selecting the so-called hard sphere diameter of a mixed solvent system has been discussed by Desrosiers and Desnoyers (23). In one of the methods they suggested the use of the experimental isothermal compressibility value of the mixed solvent has been recommended for the calculation of the solvent diameter using the Mayer's equation (29). Obviously, the mixed solvent system is assumed to be a uniform solvent system having average molecular diameter d_1. We have followed the same technique and used the average values of molecular weight (M) and molar volume (V) along with the experimental values of dielectric constant (D) for the SPT calculation for cavity free energy contributions. The Born free energy transfer contribution and that of the standard states conversion may be calculated using the following equations:

$$[12]\quad \Delta G^0_{\text{Born(tr)}} = \frac{N(Ze)^2}{2T}\left[\frac{1}{D_2} - \frac{1}{D_1}\right]$$

$$[13]\quad \Delta G^0_{\text{x(tr)}} = RT \ln \frac{RTM_2}{V_2} - RT \ln \frac{RTM_1}{V_1}$$

$$= RT \ln (M_2V_1/M_1V_2) = RT \ln (\rho_2/\rho_1)$$

where r $(= d_2/2)$ is the radius of the solute ion which is assumed to be equal to the Pauling's crystal radius of the ion (30). D_1, D_2; M_1, M_2; V_1, V_2, and ρ_1, ρ_2 are the static dielectric constants, molecular weights, molar volumes, and densities of the solvent systems S_1 and S_2, respectively. Other symbols have the usual significance. To estimate the value of the transfer free energy for specific interactions, which could include many complicated interaction terms theoretically according to the presently known ion–solvent interactions, may be a difficult task. In some earlier attempts of theoretical predictions of thermodynamic functions of transfer of mostly uncharged or feebly charged solutes, the overall interaction contribution as a whole was ignored by assuming the same interaction (which is presumably weak) in both the pure solvent and in mixed solvent systems. With electrolyte solute, as in the present case, one perhaps cannot do the same. However, one may assume that the part of the interaction free energy which the classical Born equation cannot recognise will be approximately the same in pure water as in mixed solvent system containing water. Therefore, the magnitude of $(\Delta G_2^* - \Delta G_1^*)$ in eq. [2] may be considered to be negligible. Consequently, the value of ΔG^0_{tr} $(S \leftarrow W)$ where S_1 is water (W) and S_2 is the corresponding mixed aqueous solvent systems (S), can be calculed theoretically as

$$[14]\quad \Delta G^0_{tr}(S \leftarrow W) = [\Delta G^0_c + \Delta G^0_{\text{Born}} + \Delta G^0_x]_{tr}(S \leftarrow W)$$

Results

As we have seen in the above section, the theoretical estimation of the various contributions of the free energy of transfer for ions from one solvent to the other needs a number of physical parameters, relating particularly to the solvent systems under study and the actual value of such parameters used in these calculations will largely determine the magnitude of each free energy contribution. It is therefore important to define

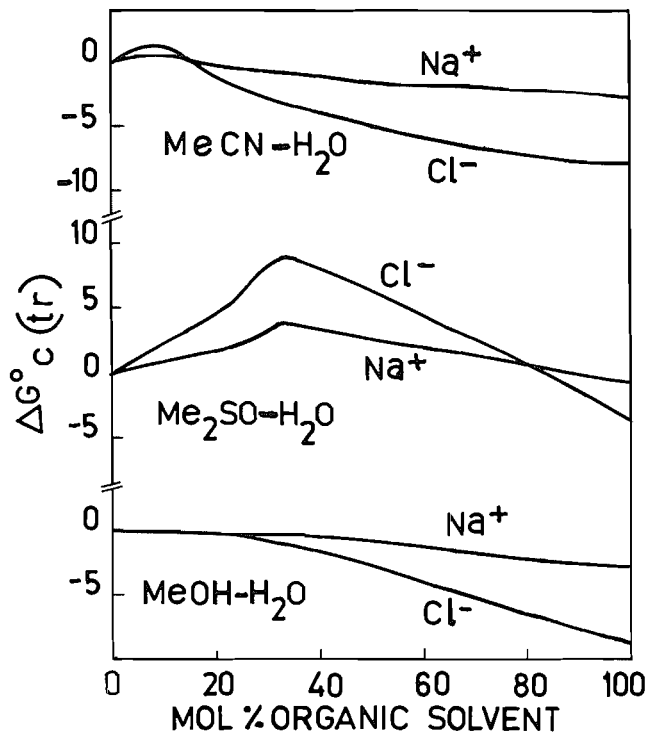

FIG. 1. Variation of transfer free energy due to cavity formation ($\Delta G^0_{c(tr)}$, kJ mol^{-1}) for typical ions with solvent composition.

those parameters which have been actually used. Table 1 shows such parameters. Overall effective average parameters such as molar volume (V), molecular diameter (d_1), compactness factor (y), etc., are calculated from the respective experimental values of the corresponding physical properties such as density (ρ_T), isothermal compressibility (β_T), etc., of the aqueous binary solvent mixtures and hence would be assumed to represent the effective behaviour of the mixed solvent systems with respect to the solute ions. The average molecular diameter (d_1) for the different solvent systems have been estimated from the corresponding isothermal compressibility data (β_T). For the MeOH–H_2O and Me_2SO–H_2O solvent systems, direct experimental values of β_T are not available (22) for the entire range of the solvent compositions where the components of the binaries would be present in the mixture from zero to 100%. Hence the available experimental values of β_T are plotted against the corresponding solvent composition and the values of β_T at all the desired solvent compositions have been generated by interpolation from the smooth master curves. The same β_T values (see Table 1) for solvent mixtures were used for the calculation of the corresponding d_1 values of the solvent mixture. For the Me_2SO–H_2O systems β_T values at 35°C and not at 25°C are available (27). In this case the d_1 values have been calculated for 35°C and subsequently been corrected for 25°C using the available value of the corresponding temperature coefficient $(\delta d_1/\delta T)_P$ of water and of Me_2SO (31). One of the coefficients (K_3) of the equations representing free energy for cavity formation has the same value ($K_3 = 0.2556$ J mol^{-1} Å^{-3}), irrespective of the solvent systems used and is given at the bottom of Table 1.

The free energy of cavity formation is by definition a function of the actual size of the solute ion and not of the charge on it. Figure 1 which plots the calculated cavity free energy of transfer for Na^+ ($r = 0.95$ Å) and Cl^- ($r = 1.81$ Å) from water to the corresponding mixed solvents would give an idea how

the magnitude of the cavity free energy transfer for ions changes with the change of the solvent compositions. The electrostatic contributions of free energy of transfer for ions which has been calculated with the help of Born charging equation essentially depends on the respective static bulk dielectric constants (D) of the solvent systems involved. Figure 2 may give an idea how, for monovalent ions (Na^+ and Cl^-), the value of $\Delta G^0_{Born}(tr)$ changes with the solvent compositions of the three particular solvent systems in this study. Table 2 lists the magnitude of the free energy change due to the change of the standard states in these three different aquo-organic solvent systems.

In their excellent review Cox and Waghorne (1) listed the experimental values of free energies of transfer for several electrolytes from water to a number of mixed solvent binaries, obtained by various workers using different experimental techniques. All these experimental values from different sources, which are reported in molar scale, have been converted to the corresponding values in the molal scale (15) and graphically plotted against the respective solvent compositions in mol%. From the smooth average master curves subsequently drawn from the plot the experimental values of free energy of transfer for different electrolytes have been obtained by interpolation at regular intervals of solvent compositions. These ΔG^0_{tr} values in MeOH–H_2O, Me_2SO–H_2O, and MeCN–H_2O binary solvent systems have been listed in Table 3. The values of free energies of transfer for NaCl (a typical electrolyte) from water to the corresponding mixed solvent systems calculated using eq. [14], i.e., by assuming ΔG^*_{tr} to be negligible are plotted along with the corresponding experimental values from Table 3 have been plotted against the corresponding solvent composition in Fig. 3 for comparison.

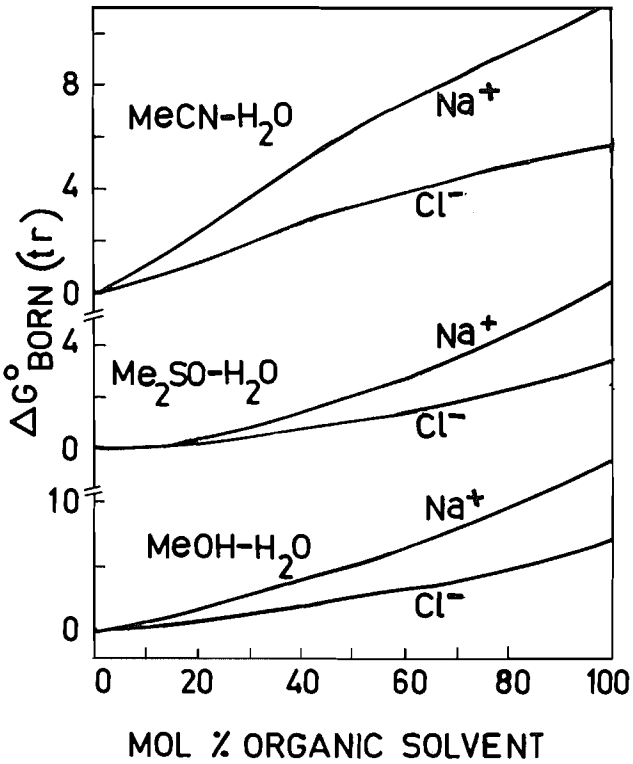

FIG. 2. Variation of transfer free energy due to electrostatic field effect ($\Delta G^0_{Born(tr)}$, kJ mol^{-1}) for typical ions with solvent composition.

Discussion

In mixed aqueous binary solvent systems, the water molecules understandably interact with different kinds of available solvent molecules including those of the cosolvent. The presence of a solute ion in the system obviously disturbs the equilibrium and eventually the ion becomes solvated in one way or other. Normally interactions of water molecules with those of some protic co-solvent (such as alcohols) is believed to be strong due to hydrogen bonding (2). From Fig. 3 it is evident that the value of ΔG^*, free energy of specific interaction, of electrolytes with the methanol–water binary solvent systems is different from that in water. This is true for almost all the different compositions of the binary mixtures. This probably suggests that due to strong interactions between water and methanol molecules in the binary systems there may not be much chance that the solute ions would get preferentially solvated by water molecules as they are present in pure water as solvent. From detailed nmr studies Symons recently reported similar conclusion for ions in alcohol–water binary systems (32).

Interactions of water molecules with dipolar aprotic co-solvents (such as dimethyl sulfoxide, acetonitrile, etc.) are comparatively weaker obviously due to the lack of facilities for hydrogen bonding. Figure 3 shows that in dimethyl sulfoxide – water binary systems, the value of ΔG^* of NaCl is not much different from that in pure water, at least, upto around 50 mol% of dimethyl sulfoxide in the mixture. This probably suggests that solute ions may be getting preferentially solvated by water molecules making the value of the specific interaction free energy, ΔG^*, more or less unchanged. However, when the proportion of dimethyl sulfoxide becomes more than 50 mol% or so the solvation picture becomes complicated and the so-called preferential solvation of electrolytes with water molecules becomes confused with progressively more and more dimethyl sulfoxide molecules interfering with the solvation process. Solvation experience of ions in acetonitrile and its aqueous binary mixtures has been found to be somewhat puzzling (33). Solvation free energy of individual cations and anions obtained from some experimental results through the help of some kind or other extrathermodynamic assumption also did not solve the puzzle (33, 34). Conflicting reports are available stating some cations being preferentially solvated by water and some other by the co-solvent acetonitrile molecules (34), whereas halide anions are thought not to be preferentially solvated by water in acetonitrile–water binary mixtures (33). Considering this somewhat confusing background the present analysis probably (Fig. 3) can only say that the value of the specific interaction free energy in acetonitrile water binary mixtures is different from that in pure water when the propor-

tion of acetonitrile in the mixture is more than ~20 mol%. This suggests that the so-called preferential solvation of electrolytes by water molecules in the present binary systems may be possible only when the mixture contains a high percentage (~80 mol%) of water. Further experimental and theoretical studies involving different approaches with electrolytes in aqueous mixtures of various dipolar aprotic co-solvents seem to be necessary to have a clearer picture of ion–solvent interactions in those systems and to know whether a generalized picture can be drawn.

The above approach no doubt is essentially associated with some approximations such as the assumptions of hard sphere molecules of particular dimension for the binary solvent mixtures. The corresponding average diameters have been estimated from the experimental values of the respective isothermal compressibility in order to calculate the free energy contribution for cavity formations in the solvent systems to accommodate the solute ions. Nevertheless, it appears that the splitting of the ion–solvent interaction phenomenon into the electrostatic field and the structural contributions which is the basis of eq. [2] may be useful to study the so-called preferential solvation and related aspects of behaviours of electrolytes in mixed binary solvent systems. The theory seems to go along well with most of the recent concepts and understandings.

Received April 23, 1984

GERALD OLIVER ASPINALL, DELPHI CHATTERJEE, and LEV KHONDO. Can. J. Chem. **62**, 2728 (1984).

The Bernet–Vasella reaction of 6-deoxy-6-halohexopyranosides with zinc dust to give hex-5-enoses has been explored as the basis for a new procedure for the selective cleavage of glycosidic linkages in complex oligo- and polysaccharides. The overall reaction sequence involves: (a) the generation of primary hydroxyl groups in otherwise fully methylated oligo- or polysaccharides; (b) the formation of 6-deoxy-6-iodohexopyranosides by iodide displacement of reactive sulfonate esters; and (c) treatment with zinc dust followed by the formation of suitable derivatives from the liberated hex-5-enoses. Oligosaccharides carrying β-D-xylopyranosyl substituents at the 2-*O*- (**4**), 3-*O*- (**17**), 4-*O*- (**12**), and both 3-*O*- and 4-*O*- (**8**) positions have been converted into otherwise fully methylated derivatives, each containing methyl 6-deoxy-6-iodo-α-D-galactopyranoside residues, to serve as model substrates for different structural environments. In each case the derived 5,6-dideoxy-hex-5-enoses formed on treatment with zinc dust have been characterized by conversion into the corresponding 1,2-dideoxy-hex-1-enitol acetates. During preparations of 6-deoxy-6-iodo-α-D-galactopyranosides from the corresponding 6-sulfonate esters, solvolytic side reactions have been observed which may include the formation of 3,6-anhydro-α-D-galactopyranosides with intramolecular participation of 3-*O*-methyl or 3-*O*-glycosyl substituents and subsequent loss of such substituents.

GERALD OLIVER ASPINALL, DELPHI CHATTERJEE et LEV KHONDO. Can. J. Chem. **62**, 2728 (1984).

On a examiné la possibilité d'utiliser la réaction de Bernet–Vasella, qui permet de transformer des désoxy-6 halogéno-6 hexopyrannosides en hexène-5 oses par action de la poudre de zinc, comme base d'une nouvelle méthode pour cliver d'une façon sélective les liaisons glycosidiques d'oligo- et de polysaccharides complexes. Dans l'ensemble, la série de réactions implique: (a) qu'il faut générer des groupes hydroxyles primaires dans des oligo- et des polysaccharides qui sont par ailleurs complètement méthylés; (b) la formation de désoxy-6 iodo-6 hexopyrannosides grâce à un déplacement de sulfonates réactifs par de l'iode et (c) un traitement par de la poudre de zinc qui est suivi par la formation de dérivés appropriés des hexène-5 oses libérés. On a pu transformer les oligosaccharides portant des substituants β-D-xylopyrannosyles en positions 2-*O*- (**4**), 3-*O*- (**17**), 4-*O*- (**12**) et 3-*O*- ainsi que 4-*O*- (**8**) en dérivés qui sont par ailleurs complètement méthylés, qui contiennent chacun des résidus désoxy-6 iodo-6 α-D-galactopyrannosides de méthyle et qui peuvent servir de substrats modèles pour différents environnements structuraux. Dans chaque cas, on a caractérisé les didésoxy-5,6 hexène-5 oses qui se forment par traitement avec de la poudre de zinc en les transformant en acétates des didésoxy-1,2 hexène-1 itols correspondants. Lors de la préparation des désoxy-6 iodo-6 α-D-galactopyrannosides à partir des sulfonates-6 correspondants, on a observé des réactions de solvolyses secondaires qui peuvent conduire à la formation des anhydro-3,6 α-D-galactopyrannosides par le biais d'une participation intramoléculaire des substituants 3-*O*-méthyles ou 3-*O*-glycosyles et d'une perte subséquente de ces substituants.

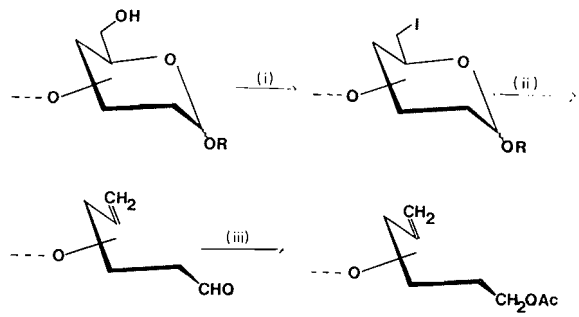
Bernet and Vasella (1) have shown that 6-deoxy-6-halo-glycosides react with zinc dust under mild conditions with glycoside cleavage and formation of hex-5-enoses. In order to assess this reaction for the selective cleavage of glycosidic linkages in polysaccharide derivatives we have examined reactions of selected oligosaccharides. Methylated oligosaccharide glycosides, each of which contained a single primary hydroxyl group, were synthesized in standard reaction sequences. The reactions shown in Scheme 1 were studied, (*i*) the formation of 6-deoxy-6-iodohexopyranosides, and (*ii*) the zinc dust cleavage reaction followed by derivative formation suitable for the characterization of hex-5-enose residues thus generated. The oligosaccharides were all α-D-galactopyranosides, which were chosen as models for different structural regions in carboxyl-reduced methylated pectins and related α-D-galacturonans. Since nucleophilic displacements at C-6 occur least readily in galactopyranosides (2), it is likely that transformations which proceed satisfactorily for these glycosides will take place without difficulty for the corresponding gluco- and mannopyranosides. Two recent methods for halogenation at C-6 involve the formation of highly reactive sulfonates followed by halide displacement under mild conditions (3, 4). These reactions



SCHEME 1. Generation of hex-5-enoses and formation of derivatives: (i) sulfonylation, followed by displacement of sulfonate ester with $Bu_4N^+ I^-$; (ii) Zn dust; and (iii) $NaBH_4$, followed by Ac_2O/Pyr (unchanged substituents are omitted).

appeared to offer the greatest chance for the successful introduction of 6-halo substituents into sterically hindered galactopyranose residues in even less reactive environments in polysaccharides where polymer chain conformations may impose additional restrictions. Displacement by iodide ion was chosen as the reaction least likely to be accompanied by competing elimination (3, 4).

Oligosaccharide syntheses

The most readily accessible (1 → 2)-linked disaccharide glycoside (**4**) was synthesized without ambiguity as to linkage type. Condensation of 2,3,4-tri-*O*-acetyl-α-D-xylopyranosyl

bromide with methyl 6-*O*-benzyl-3,4-*O*-isopropylidene-α-D-galactopyranoside (5) afforded methyl 2-*O*-(2,3,4-tri-*O*-acetyl-β-D-xylopyranosyl)-6-*O*-benzyl-3,4-*O*-isopropylidene-α-D-galactopyranoside (**1**), which was successively treated with trifluoroacetic acid for de-isopropylidenation and sodium methoxide for de-*O*-acetylation to give crystalline methyl 6-*O*-benzyl-2-*O*-(β-D-xylopyranosyl)-α-D-galactopyranoside (**2**). The disaccharide benzyl ether (**2**) furnished a fully methylated derivative (**3**) which was hydrogenolyzed to give methyl 3,4-di-*O*-methyl-2-*O*-(2,3,4-tri-*O*-methyl-β-D-xylopyranosyl)-α-D-galactopyranoside (**4**).

In order to have available derivatives of linkage types likely to be encountered in tragacanthic acid (6) and related galacturonan derivatives, syntheses were extended to the isomeric (1 → 3)- and (1→4)-linked disaccharide and the (1 → 3)- and (1 → 4)- linked branched trisaccharide series using generally similar reaction sequences. In each series of reactions all crystalline compounds including end products (**8**, **12**, and **17**) were obtained in analytically pure form. The syrupy intermediates were isolated in chromatographically homogeneous form, gave nmr spectra in accord with the structures shown, and were used directly for the next stages of the syntheses. Methyl 6-*O*-benzyl-2-*O*-methyl-α-D-galactopyranoside (7) was a convenient starting material for each synthetic sequence. When 2,3,4-tri-*O*-acetyl-α-D-xylopyranosyl bromide was condensed with this compound, regardless of the molar ratios of glycosyl halide to aglycone, two products only, although in varying proportions, were observed on tlc and these were separated by preparative chromatography. The first product was methyl

3,4-di-*O*-(2,3,4-tri-*O*-acetyl-β-D-xylopyranosyl)-6-*O*-benzyl-2-*O*-methyl-α-D-galactopyranoside (**5**), which on deacetylation, methylation, and debenzylation afforded the trisaccharide derivative, methyl 2-*O*-methyl-3,4-di-*O*-(2,3,4-tri-*O*-methyl-β-D-xylopyranosyl)-α-D-galactopyranoside (**8**). Surprisingly, the second compound from mono-*O*-glycosylation was shown to be methyl 4-*O*-(2,3,4-tri-*O*-acetyl-β-D-xylopyranosyl)-6-*O*-benzyl-2-*O*-methyl-α-D-galactopyranoside (**9**), whose structure was established by methylation–deacetylation, debenzylation, remethylation, and methylated sugar analysis to give *inter alia* 2,3,6-tri-*O*-methylgalactose, identified by glc–ms of the derived partially methylated alditol acetate. In contrast to the preferential glycosylation of equatorial 3-hydroxyl over 4-axial hydroxyl groups in α-D- (8) and β-D-galactopyranosides (9), the present observation provides an example of the opposite selectivity. The methylated disaccharide derivative (**12**) was then prepared in the same way as for the trisaccharide derivative (**8**). Entry was gained to the (1 → 3)-linked disaccharide series by reaction of methyl 6-*O*-benzyl-2-*O*-methyl-α-D-galactopyranoside (7) with trimethyl orthobenzoate followed by acid-catalyzed rearrangement to give the axial 4-benzoate (**13**) (10). Condensation of this compound with 2,3,4-tri-*O*-acetyl-α-D-xylopyranosyl bromide gave methyl 3-*O*-(2,3,4-tri-*O*-acetyl-β-D-xylopyranosyl)-4-*O*-benzoyl-6-*O*-

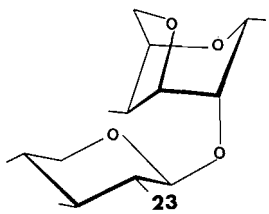
benzyl-2-*O*-methyl-α-D-galactopyranoside (**14**). The linkage position in this disaccharide was confirmed, as for the (1 → 4)-linked disaccharide, by methylation analysis which gave 2,4,6-tri-*O*-methylgalactose from the galactose moiety. The disaccharide benzoate (**14**) was then converted into the methylated derivative (**17**).

Preparation of 6-deoxy-6-iodo oligosaccharides via sulfonate esters and competing 3,6-anhydrogalactopyranoside formation

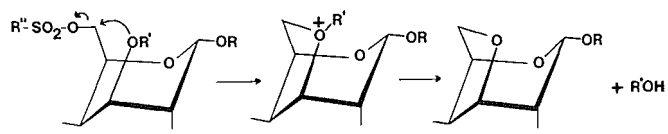
The 2-linked methylated disaccharide glycoside (**4**) was reacted with sodium hydride and *N,N'*-sulfuryldiimidazole in oxolane, as described by Hanessian and Vatèle (4), and gave the crystalline imidazolylsulfonate (imidazylate) (**18**) which was quite stable provided that care was taken to minimize contact with polar solvents. The imidazylate was converted smoothly into methyl 6-deoxy-6-iodo-3,4-di-*O*-methyl-2-*O*-(2,3,4-tri-*O*-methyl-β-D-xylopyranosyl)-α-D-galactopyranoside (**19**) on heating with tetrabutylammonium iodide in benzene. Alternatively, the iodo disaccharide derivative (**19**) was prepared in comparable yield by reaction of the methylated disaccharide glycoside (**4**) with triflic anhydride in pyridine (3) followed by direct iodide displacement. This procedure was adopted as the method of choice and was used for the conversion of trisaccharide **8** and disaccharides **12** and **17** into the respective 6-deoxy-6-iodo derivatives **20**, **21**, and **22** in good yield.

When an attempt was made to prepare the iododisaccharide (**19**) from the imidazylate (**18**) by activation on nitrogen by reaction with methyl iodide in *N,N'*-dimethylformamide (4), a second product was formed in almost equal amount. The formation of this compound, methyl 3,6-anhydro-4-*O*-methyl-2-*O*-(2,3,4-tri-*O*-methyl-β-D-xylopyranosyl)-α-D-galactopyranoside (**23**), was difficult to suppress entirely in any reaction

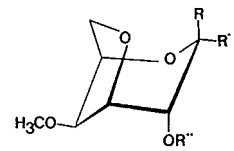


23

involving formation or further reaction of either reactive sulfonate ester unless extreme precautions were taken to exclude moisture and avoid contact with polar solvents. The compound (**23**) was isolated as the major product when the imidazylate (**18**) was allowed to solvolyze in DMF at room temperature. Fragment ions observed in the mass spectrum and ^{1}Hmr data showed loss of sulfonate ester and of a methoxyl group consistent with anhydride formation. The Cmr data showed a downfield shift for C-6 (δ_C 69.69) indicative of etherification, and the alteration in the signal for the anomeric carbon (δ_C 97.52, $J_{^{13}C_1\text{-}^1H_1}$ = 161.6 Hz) was consistent with change from the $^4C_1$ to a $_4C^1$ conformation for the α-D-galactopyranoside residue. In support of these assignments methyl 3,6-anhydro-2,4-di-*O*-methyl-α-D-galactopyranoside (**24**) showed signals for C-6 at δ_C 69.08 and for C-1 at δ_C 98.63 with $J_{^{13}C_1\text{-}^1H_1}$ = 161.1 Hz. Compound **23** may therefore be assigned the structure, methyl 3,6-anhydro-4-*O*-methyl-2-*O*-(2,3,4-tri-*O*-methyl-β-D-xylopyranosyl)-α-D-galactopyranoside. Supporting chemical evidence for the formation of the 3,6-anhydro derivative was obtained by glc–ms analysis of the products of methanolysis



SCHEME 2. Formation of 3,6-anhydro-α-D-galactopyranosides during solvolysis of 6-sulfonates with intramolecular participation and subsequent loss of 3-*O*-methyl or 3-*O*-glycosyl (R') substituent (other substituents are not specified).



24 R = H, R' = OMe, R'' = Me
25 R = R'' = H, R' = OMe

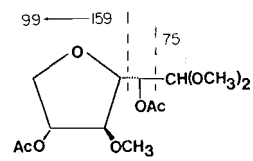
followed by acetylation which showed the formation *inter alia* of the same mixture of anomeric methyl glycoside acetates (**26** and **27**) and acetylated dimethyl acetal (**28**) that was obtained from synthetic methyl 3,6-anhydro-4-*O*-methyl-α-D-galactopyranoside (**25**) (11). The formation of 3,6-anhydro-D-galactopyranose derivatives by intramolecular displacement of 6-sulfonate esters with alkoxyl group participation was first shown by Brimacombe and Ching (12). Volkova *et al.* (13) have previously reported 3,6-anhydride formation during the reaction of benzyl 2,3,4-tri-*O*-benzyl-6-deoxy-6-tosyl-β-D-galactopyranoside with sodium iodide in both acetone and *N,N*-dimethylformamide.



28

Further examination of the solvolysis products from the imidazylate (**18**) showed the formation of a second compound (**29**). Although the anhydride (**23**) was still the major product, the second compound was formed in relatively greater yield when the triflate ester of disaccharide **4** was treated in the same way. Spectroscopic data, including the typical mass spectral fragment ions at *m/z* 293 and 233 for the galactosyl moiety, a characteristic one proton singlet in the ^{1}Hmr spectrum at δ 8.15, and a carbonyl band in the ir spectrum at 1730 cm^{-1}, coupled with characterization of otherwise unaltered sugar constituents on hydrolysis, showed that this second product was the disaccharide 6-formate (**29**). *N,N*-Dimethylformamide used as solvent has been observed to be the source of formylation as a side reaction in other transformations (14, 15).

In order to assess the extent to which variously substituted galactopyranoside 6-sulfonate esters were susceptible to solvolytic side reactions, and in particular to see if 3,6-anhydride formation could occur with participation of a 3-*O*-glycosyl substituent and liberation of that substituent on collapse of an intermediate oxonium ion (Scheme 2), the solvolysis products

from the triflate esters of disaccharides **12** and **17** and trisaccharide **8** were examined. In the case of derivatives of disaccharide **12** and the branched trisaccharide **8**, where participation by the 3-*O*-substituents might be expected to lead to the formation of the same 3,6-anhydro derivative, with liberation of 2,3,4-tri-*O*-methylxylose in the latter instance, no evidence was obtained for the formation of such a compound. The major product from the trisaccharide (**8**) was the corresponding 6-formate (**30**). Solvolysis of the triflate ester of disaccharide **17** also led to formation of the disaccharide 6-formate (**31**) as the major product. However, the occurrence of 3-*O*-glycosyl participation in 3,6-anhydride formation was clearly established. Direct examination of the solvolysis products by glc – mass spectrometry showed the formation of methyl 3,6-anhydro-2,4-di-*O*-methyl-D-galactopyranoside (**24**) (in 30% yield based on 1,6-anhydro-2,3,4-tri-*O*-methyl-β-D-galactopyranose as internal standard), together with the disaccharide 6-formate (**31**). When a portion of the solvolysis products was treated with sodium borohydride and then acetylated, glc – mass spectrometry showed the presence of the anhydride (**24**), together with 2,3,4-tri-*O*-methylxylitol diacetate from the liberated glycosyl substituent and a disaccharide derivative now converted into the 6-acetate (**32**).

Cleavage of 6-deoxy-6-iodo-oligosaccharide glycosides with zinc dust and characterization of 5,6-dideoxy-hex-5-enoses

Each of the methylated 6-deoxy-6-iodo oligosaccharides was treated for short periods with freshly prepared activated zinc dust in boiling ethanol or 1-propanol and furnished the corresponding 5,6-dideoxy-hex-5-enose. In the case of the 4-linked 6-deoxy-6-iodo disaccharide glycoside (**21**), extended reaction time or the use of the higher-boiling solvent resulted in the liberation of 2,3,4-tri-*O*-methylxylose to a much greater extent than with the corresponding 2- and 3-linked disaccharide derivatives (**19** and **22**). It is possible that sufficient acidity, not otherwise detected, was generated from the basic zinc iodide formed in the reaction to cause hydrolysis of the resulting 5,6-dideoxy-hex-5-enose, proceeding by a mechanism involving O-allyl rather the normal glycosyl-oxygen cleavage during glycoside hydrolysis. Each 5,6-dideoxy-hex-5-enose-terminated oligosaccharide was conveniently characterized by reduction and acetylation to give the corresponding 1,2-dideoxy-hex-1-enitol acetate (**33**–**36**). These derivatives in the di- and trisaccharide series were amenable to analysis by glc–ms as for the corresponding saturated oligosaccharide alditol derivatives (16). The accompanying structures for these derivatives show the most important fragment ions in the mass spectra, including those which clearly establish the substitution patterns of the methylated 1,2-dideoxy-hex-1-enitol acetate residues. In the case of the trisaccharide derivative (**34**) the V ion at m/z 215 pointed to the presence of vicinal glycosyl substituents (17). Additionally, the ^{1}Hmr spectra of the oligosaccharide derivatives showed characteristic signals for the allyl group of 1,2-dideoxy-hex-1-enitol residues. Furthermore, the oligosaccharide derivatives were hydrolyzed without detectable rearrangement of the 1,2-dideoxy-hex-1-enitol residues so that normal methylated sugar analysis by glc–ms of the partially methylated alditol acetates (18) could be performed. The various partially methylated 1,2-dideoxy-hex-1-enitol acetates gave fragment ions indicative of substitution patterns.

These results clearly show that 5,6-dideoxy-hex-5-enose formation by zinc dust cleavage of 6-deoxy-6-iodo-α-D-galactopyranosides, and presumably of other hexopyranose derivatives, may be used for the selective cleavage of glycosidic linkages. It is necessary that care should be exercised in the introduction of the halo substituent. In the examples studied to date, glycosyl substituents at all positions in the ring are retained in hexenose formation. An application of this non-hydrolytic degradative procedure to a polysaccharide substrate is described in the accompanying paper (6).

Experimental

Evaporations were carried out under diminished pressure at temperatures of 40°C or less. Optical rotations were measured with a Perkin–Elmer model 141 polarimeter at 20 ± 2°C. The ir spectra were measured on a Unicam SP 200 spectrophotometer. The nmr spectra were recorded in deuteriochloroform with tetramethylsilane as internal standard with Varian EM 360 (for ^{1}H), Varian CFT 80A (for ^{13}C), and Bruker WH 400 (for both ^{1}H and ^{13}C) spectrophotometers. Gas–liquid chromatography (glc) was performed on a Perkin–Elmer Sigma 3B chromatograph using (A) a packed column of 3% of silicone gum Silar 10 CP on Chromosorb W-HP (100/200 mesh) or (B) a S.C.O.T. column coated with silicone gum OV-225. For glc – mass spectrometry, capillary columns of (C) silicone gum DB225-15N and (D) DB5-15N (permanently bonded OV-54) were attached by a jet separator to a VG Micromass 16F mass spectrometer operated with an inlet temperature of 250°C, an ionization potential of 70 eV, and an ion-source temperature of ~250°C. Preparative tlc (thin-layer chromatography) was performed on precoated silica gel plates (Baker tlc plate silica gel 60-F (250 μm)). For column chromatography silica gel 60, 0.05–0.2 mm/70–270 mesh ASTM (Macherey Nagel), was used without activation. Zinc dust was activated by the procedure of Frank and Smith (19).

Methyl 6-O-benzyl-2-O-(β-D-xylopyranosyl)-α-D-galactopyranoside (2)

Drierite (pre-dried, 25 g) was added to methyl 6-*O*-benzyl-3,4-*O*-isopropylidene-α-D-galactopyranoside (5) (6.8 g, 20.9 mmol) in dry benzene and nitromethane (500 mL, 1:1) and solvent (200 mL) was removed by distillation with exclusion of moisture. Mercuric cyanide (6 g, 23.7 mmol) was added to the reaction flask at room temperature, followed by 2,3,4-tri-*O*-acetyl-α-D-xylopyranosyl bromide (8 g, 23.5 mmol). The reaction mixture was stirred for 12 h, further quantities of mercuric cyanide (1.5 g, 2.5 mmol) and glycosyl bromide (2.1 g, 2.5 mmol) were added, and the mixture was stirred for another 8 h. The filtrate from the reaction mixture was diluted with dichloromethane, extracted with *M* potassium bromide solution (2 × 50 mL) and water (3 × 50 mL), dried, and concentrated to a syrup (14 g). The syrup was chromatographed on silica gel in chloroform–ether (1:1) to give methyl 2-*O*-(2,3,4-tri-*O*-acetyl-β-D-xylopyranosyl)-6-*O*-benzyl-3,4-*O*-isopropylidene-α-D-galactopyranoside (**1**) (9 g, 77%) as a syrup, R_f 0.51; $[\alpha]_D$ +21.3° (*c*, 1.37 in chloroform); nmr δ: 7.25–7.37 (m, 5H, Ph), 3.39 (s, 3H, CO_2CH_3), 2.07 (s, 3H, OAc), 2.05 (s, 6H, 2 × OAc), 1.33 and 1.50 (2s, 2 × 3H, Me_2C); δ_C: 101.6 ($J_{1',2'}$ 165.4 Hz (C-1')), 99.1 ($J_{1,2}$ 169.5 Hz (C-1)).

This isopropylidene compound **1** (3.1 g) was kept in trifluoroacetic acid (30 mL, 90%) for 1 h, the solution was diluted with water, concentrated, and repeatedly concentrated after further addition of water to ensure removal of trifluoracetic acid. The crude product was treated with 0.1 *M* methanolic sodium methoxide. When deacetylation was complete the solution was treated with Amberlite IR-120 (H) resin to remove sodium ions, and the filtrate was concentrated to a crystalline residue which was recrystallized from ethanol and then chloroform–methanol (10:1) to give the disaccharide glycoside **2** (1.8 g, 80%), mp 180–182°C; $[\alpha]_D$ +53° (*c*, 4.3 in methanol). *Anal.* calcd. for $C_{19}H_{28}O_{10}$: C 54.80, H 6.73; found: C 54.60, H 6.55.

Methyl 3,4-di-O-methyl-2-O-(2,3,4-tri-O-methyl-β-D-xylopyranosyl)-α-D-galactopyranoside (4)

Sodium hydride (0.93 g, 38.7 mmol) was added to disaccharide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

glycoside **2** (1.2 g, 2.9 mmol) in dry oxolane (50 mL), the mixture was stirred for 4 h at room temperature, cooled to 0°C, methyl iodide (4 mL) was added, and the mixture was stirred overnight. Excess of sodium hydride was destroyed by the addition of methanol (0.3 mL), solvent was removed, and the residue was partitioned between water and chloroform. The dried organic layer was concentrated to a syrup which was chromatographed on silica gel in chloroform–ether (1:1) to give methyl 6-*O*-benzyl-3,4-di-*O*-methyl-2-*O*-(2,3,4-tri-*O*-methyl-β-D-xylopyranosyl)-α-D-galactopyranoside (**3**) (0.9 g, 65%), mp 68–71°C; nmr δ: 4.85 (d, 1H, $J_{1,2}$ 3.7 Hz, H-1), 4.41 (d, 1H, $J_{1',2'}$ 6.9 Hz, H-1′); δ_C: 105.92 (C-1′), 100.08 (C-1). *Anal.* calcd. for $C_{24}H_{38}O_{10}$: C 59.24, H 7.87; found: C 58.74, H 8.00. The fully etherified disaccharide glycoside **3** (0.587 g) in ethanol (50 mL) was hydrogenolyzed over 10% palladium-on-charcoal (0.17 g) for 16 h, the solution was filtered, and the filtrate was concentrated to a residue which was crystallized from ether–hexane to give the disaccharide glycoside **4** (0.458 g, 96%), mp 125–126°C. *Anal.* calcd. for $C_{17}H_{32}O_{10}$: C 51.51, H 8.14; found: C 51.41, H 8.21.

*Methyl 3,4-di-*O*-(2,3,4-tri-*O*-acetyl-β-D-xylopyranosyl)-6-*O*-benzyl-2-*O*-methyl-α-D-galactopyranoside (**5**) and methyl 4-*O*-(2,3,4-tri-*O*-acetyl-β-D-xylopyranosyl-6-*O*-benzyl-2-*O*-methyl-α-D-galactopyranoside (**9**)*

Powdered Drierite (15 g) and mercuric cyanide (4.72 g, 18.7 mmol) were added to methyl 6-*O*-benzyl-2-*O*-methyl-α-D-galactopyranoside (7) (4.3 g, 14.4 mmol) in benzene–nitromethane (350 mL, 1:1) and solvent (100 mL) was removed by distillation at atmospheric pressure to remove moisture. 2,3,4-Tri-*O*-acetyl-α-D-xylopyranosyl bromide (5.58 g, 18.7 mmol) was added and the mixture was stirred at room temperature for 3 h; tlc (chloroform–acetone, 5:1) showed the formation of two products, R_f 0.75 and 0.48, together with some starting material, R_f 0.25. Further portions of acetobromoxylose (3.0 g, 10.1 mmol) and mercuric cyanide (2.55 g, 10.1 mmol) were added, and the mixture was stirred for 2 h, at which time tlc showed complete disappearance of starting material. The reaction mixture was filtered through Celite and the filtrate was concentrated to a residue which was extracted with chloroform. The extract was washed with *M* potassium bromide solution and water alone, dried, and concentrated to a syrup which was chromatographed on silica gel in benzene – ethyl acetate (2:1) to give (*i*) trisaccharide glycoside **5** (5.3 g, 45%) as a syrup, R_f 0.75, $[\alpha]_D$ −0.3° (*c*, 1.0 in chloroform); nmr δ: 7.34 (s, 5H, Ph), 4.85 (d, 1H, $J_{1,2}$ 3.57 Hz, H-1), 4.70 (d, 1H, $J_{1',2'}$ 7.62 Hz, H-1′ or H-1″), 4.55, 4.51 (ABq, 2H, J_{AB} 11.7 Hz, CH_2-Ph), 3.41, 3.40 (s, each 3H, 2 × OMe), 2.07, 2.05, 2.02 (s, each 3H, 3 × OAc); δ_C: 102.4 (C-1″, 4-linked), 100.0 (C-1′, 3-linked), 97.4 (C-1); and (*ii*) disaccharide glycoside **9** (2.65 g, 33%), mp 128–129°C (from ether), R_f 0.48; $[\alpha]_D$ +9.1° (*c*, 1.0 in chloroform); nmr δ: 7.38 (s, 5H, Ph), 4.60 (s, 2H, CH_2-Ph), 3.53, 3.45 (s, each 3H, 2 × OMe), 2.10 (m, 9H, 3 × OAc); δ_C: 103.2 (C-1′), 98.2 (C-1). *Anal.* calcd. for $C_{26}H_{36}O_{13}$: C 56.11, H 6.52; found: C 55.84, H 6.07. A sample of the disaccharide glycoside **9** was subjected to the following series of reactions: debenzylation, deacetylation, methylation, hydrolysis, reduction ($NaBD_4$), and acetylation. The derived partially methylated alditol acetates were characterized by glc–ms on column C (180°C) as formed from 2,3,4-tri-*O*-methylxylitol and 2,3,6-tri-*O*-methylgalactitol (fragment ions at *m/z* 233, 173, 162, 131, 118, and 102).

*Methyl 2-*O*-methyl-3,4-di-(2,3,4-tri-*O*-methyl-β-D-xylopyranosyl)-α-D-galactopyranoside (**8**)*

Acetylated trisaccharide glycoside **5** (4.9 g, 6.0 mmol) in methanol (50 mL) was treated with a catalytic quantity of sodium methoxide for 1 h. Sodium ions were removed by treatment with Dowex 50W-X8 (H^+) resin and the filtrate was concentrated to syrupy methyl 6-*O*-benzyl-2-*O*-methyl-3,4-di-*O*-β-D-xylopyranosyl-α-D-galactopyranoside (**6**) (2.91 g, 86%), $[\alpha]_D$ +44.5° (*c*, 1.0 in methanol). Sodium hydride (0.51 g, 21 mmol) was added to the trisaccharide glycoside **6** (1.97 g, 3.5 mmol) in oxolane (60 mL). The mixture was stirred at room temperature for 2 h, cooled to 0°C, and, after addition of methyl iodide, stirred at room temperature overnight. Excess sodium hydride was destroyed by careful addition of methanol to a stirred pre-cooled solution, the solution was concentrated, and the residue was extracted with chloroform. The extract was washed with water, dried, and concentrated to a syrup which was chromatographed on silica gel in chloroform–ether (3:1) to give methyl 6-*O*-benzyl-2-*O*-methyl-3,4-di-*O*-(2,3,4-tri-*O*-methyl-β-D-xylopyranosyl)-α-D-galactopyranoside (**7**) as a syrup (1.67 g, 74%), $[\alpha]_D$ +10.6° (*c*, 1.6 in chloroform); nmr δ: 7.33 (s, 5H, Ph), 4.91 (d, 1H, $J_{1,2}$ 3.61 Hz, H-1), 4.71 (d, 1H, $J_{1',2'}$ 7.36 Hz, H-1′), 4.59, 4.52 (ABq, 2H, J_{AB} 11.8 Hz), 4.52 (d, 1H, $J_{1'',2''}$ 7.52 Hz, H-1″), 3.44–3.62 (8s, each 3H, 8 × OMe); δ_C: 104.4 (C-1′, 3-linked), 103.4 (C-1″, 4-linked), 97.9 (C-1). Trisaccharide glycoside **7** (1.62 g, 2.5 mmol) in ethanol (25 mL) was hydrogenolyzed over 10% palladium-on-charcoal (1.1 g) for 2 h at 505 kPa. The filtered solution was concentrated to a syrup which was crystallized from isopropyl ether to give trisaccharide glycoside **8** (1.15, 83%), mp 129–130°C, $[\alpha]_D$ +20.5° (*c*, 1.0 in chloroform); nmr δ: 4.86 (d, 1H, $J_{1,2}$ 3.10 Hz, H-1), 4.67 (d, 1H, $J_{1',2'}$ 7.53 Hz, H-1′), 4.51 (d, 1H, $J_{1'',2''}$ 7.51 Hz, H-1″), 3.42–3.62 (8s, each 3H, 8 × OMe); δ_C: 104.7 (C-1′, 3-linked), 104.4 (C-1″, 4-linked), 98.1 (C-1). *Anal.* calcd. for $C_{24}H_{44}O_{14}$: C 51.79, H 7.97; found: C 52.01, H 8.14.

*Methyl 2,3-di-*O*-methyl-4-*O*-(2,3,4-tri-*O*-methyl-β-D-xylopyranosyl)-α-D-galactopyranoside (**12**)*

Acetylated disaccharide glycoside **9** (2.5 g, 4.5 mmol) was de-*O*-acetylated as described for compound **5** and crystallization of the product from chloroform–methanol gave methyl 6-*O*-benzyl-2-*O*-methyl-4-*O*-β-D-xylopyranosyl-α-D-galactopyranoside (**10**) (1.76 g, 91%), mp 172–173°; $[\alpha]_D$ +75.5° (*c*, 0.6 in methanol). *Anal.* calcd. for $C_{20}H_{30}O_{10}$: C 55.80, H 7.03; found: C 55.84, H 7.05. Compound **10** was methylated as described for compound **6** and column chromatography afforded methyl 6-*O*-benzyl-2,3-di-*O*-methyl-4-*O*-(2,3,4-tri-*O*-methyl-β-D-xylopyranosyl)-α-D-galactopyranoside (**11**) (1.53 g, 90%) as a syrup, $[\alpha]_D$ +29.0° (*c*, 1.1 in chloroform); nmr δ: 7.34 (s, 5H, Ph), 4.89 (d, 1H, $J_{1,2}$ 3.62 Hz, H-1), 4.65 (d, 1H, $J_{1',2'}$ 7.23 Hz, H-1′), 4.59, 4.53 (ABq, 2H, J_{AB} 11.7 Hz, CH_2Ph), 3.62–3.46 (6s, each 3H, 6 × OMe); δ_C: 103.2 (C-1′), 98.1 (C-1). The foregoing disaccharide glycoside **11** (1.46 g, 3 mmol) was hydrogenolyzed as described for compound **7** and recrystallization of the solid product from isopropyl ether furnished disaccharide glycoside **12** (1.07 g, 90%), mp 69–70°C; $[\alpha]_D$ +47.5° (*c*, 1.0 in chloroform); nmr δ: 4.83 (d, 1H, $J_{1,2}$ 2.81 Hz, H-1), 4.55 (d, 1H, $J_{1',2'}$ 7.41 Hz, H-1′), 3.63–3.39 (6s, each 3H, 6 × OMe); δ_C: 104.2 (C-1′), 98.3 (C-1). *Anal.* calcd. for $C_{17}H_{32}O_{10}$: C 51.51, H 8.14; found: C 51.30, H 7.95.

*Methyl 4-*O*-benzoyl-6-*O*-benzyl-2-*O*-methyl-α-D-galactopyranoside (**13**)*

Methyl 6-*O*-benzyl-2-*O*-methyl-α-D-galactopyranoside (2.0 g, 6.7 mmol), trimethyl orthobenzoate (2.3 mL, 13.4 mmol) and toluene-*p*-sulfonic acid (15 mg) were dissolved in dry benzene and solvent was removed under diminished pressure. Thin-layer chromatography (chloroform–ether, 1:1) showed disappearance of starting material and formation of a new compound of R_f 0.72. The residue was kept in 80% acetic acid (10 mL) for 0.5 h at room teperature and tlc showed disappearence of the compound of R_f 0.72 and formation of a new compound, R_f 0.50. The solution was concentrated several times with toluene to a residue which was chromatographed on silica gel in hexane – ethyl acetate (1:1) and recrystallized from isopropyl ether to give the *O*-benzoyl glycoside **13** (1.99 g, 74%), mp 75°; $[\alpha]_D$ +66.3° (*c*, 1.0 in chloroform); nmr δ: 8.08–7.25 (m, 10H, 2 × Ph), 5.68 (m, 1H, H-4), 5.05 (d, 1H, $J_{1,2}$ 3.52 Hz, H-1), 4.52, 4.42 (ABq, 2H, J_{AB} 11.8 Hz, CH_2Ph), 3.52, 3.48 (s, 3H each, 2 × OMe); δ_C: 97.4 (C-1). *Anal.* calcd. for $C_{22}H_{26}O_7$: C 65.66, H 6.51; found: C 65.45, H 6.59.

*Methyl 2,4-di-*O*-methyl-3-*O*-(2,3,4-tri-*O*-methyl-β-D-xylopyranosyl)-α-D-galactopyranoside (**17**)*

Powdered Drierite (5 g) and mercuric cyanide (1.35 g, 5.3 mmol) were added to the foregoing galactoside **13** (1.65 g, 4.1 mmol) in benzene–nitromethane (150 mL, 1:1) and solvent (50 mL) was removed by distillation. 2,3,4-Tri-*O*-acetyl-α-D-xylopyranosyl bromide (1.81 g, 5.3 mmol) was added and the mixture was stirred at room temperature for 4 h. The filtrate from the reaction mixture was concen-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

trated to a residue which was dissolved in chloroform, and the extract was washed with *M* potassium bromide solution and water alone, dried, and concentrated to a syrup. The syrup was chromatographed on silica gel in chloroform–ether (3:1) to give syrupy methyl 3-*O*-(2,3,4-tri-*O*-acetyl-β-D-xylopyranosyl)-4-*O*-benzoyl-6-*O*-benzyl-2-*O*-methyl-α-D-galactopyranoside (**14**) (1.97 g, 73%); $[\alpha]_D$ +35.8° (*c*, 1.0 in chloroform); nmr δ: 8.08–7.29 (m, 10H, 2 × Ph), 5.72 (m, 1H, H-4), 4.53, 4.48 (ABq, 2H, J_{AB} 11.8 Hz, CH_2Ph), 3.53, 3.50 (s, each 3H, 2 × OMe), 2.07, 1.97, 1.77 (s, each 3H, 3 × OAc); δ_C: 100.9 (C-1′), 97.7 (C-1). The linkage type in compound **14** was confirmed as described for disaccharide glycoside **9**, by methylation analysis which furnished *inter alia* 2,4,6-tri-*O*-methylgalactitol triacetate which was characterized by glc–ms on column C (180°C) with fragment ions at *m/z* 277, 245, 234, 203, 202, 174, 161, 129, 118, and 101. Acetylated disaccharide glycoside **14** (1.92 g, 2.9 mmol) was de-*O*-acylated with sodium methoxide for 48 h and chromatography on silica gel by elution with a chloroform–methanol gradient afforded syrupy methyl 6-*O*-benzyl-2-*O*-methyl-3-*O*-β-D-xylopyranosyl-α-D-galactopyranoside (**15**) (1.15 g, 92%), $[\alpha]_D$ +76° (*c*, 1.4 in methanol). Disaccharide glycoside **15** (1.08 g, 2.5 mmol) was methylated as described for compound **6** and chromatography on silica gel in chloroform–ether (4:1) afforded methyl 6-*O*-benzyl-2,4-di-*O*-methyl-3-*O*-(2,3,4-tri-*O*-methyl-β-D-xylopyranosyl)-α-D-galactopyranoside (**16**) (0.95 g, 78%), $[\alpha]_D$ +34.0° (*c*, 1.0 in chloroform); nmr δ: 7.34 (s, 5H, Ph), 4.88 (d, 1H, $J_{1,2}$ 3.60 Hz, H-1), 4.60, 4.52 (ABq, 2H, J_{AB} 11.8 Hz, CH_2Ph), 4.56 (d, 1H, $J_{1',2'}$ 7.42 Hz, H-1′), 3.61–3.42 (6s, each 3H, 7 × OMe); δ_C: 104.4 (C-1′), 97.8 (C-1). Disaccharide glycoside **16** (0.90 g, 1.85 mmol) in ethanol (15 mL) was hydrogenolyzed as described for compound **7** and recrystallization of the solid product from isopropyl ether furnished disaccharide glycoside **17** (0.58 g, 79%), mp 83–84°C; $[\alpha]_D$ +40.8° (*c*, 0.9 in chloroform); nmr δ: 4.93 (d, 1H, $J_{1,2}$ 3.63 Hz, H-1), 4.54 (d, 1H, $J_{1',2'}$ 7.43 Hz, H-1′), 3.61–3.43 (6s, each 3H, 6 × OMe); δ_C: 104.5 (C-1′), 97.9 (C-1). *Anal.* calcd. for $C_{17}H_{32}O_{10}$: C 51.51, H 8.14; found: C 51.81, H 8.32.

*Methyl 6-deoxy-6-iodo-3,4-di-*O*-methyl-2-*O*-(2,3,4-tri-*O*-methyl-β-D-xylopyranosyl)-α-D-galactopyranoside (**19**)*

A. *Synthesis via imidazolylsulfonate (**18**)*

Sodium hydride (0.048 g, 2 mmol) was added to methylated disaccharide glycoside **4** (0.397 g, 1 mmol) in freshly distilled dry oxolane (10 mL) at 0°C, the suspension was stirred for 2 h, cooled to −40°C, and *N,N′*-sulfuryldiimidazole (0.619 g, 3 mmol) in oxolane (5 mL) was added. The reaction mixture was kept at −40°C for 20 min and then stirred at room temperature for 2 h. Thin-layer chromatography showed complete disappearance of starting material and formation of a single product, and excess of sodium hydride was destroyed by the addition of dry methanol (0.2 mL) to the reaction mixture at 0°C. The reaction mixture was diluted with dichloromethane (15 mL), and the solution was extracted with water until the aqueous extracts were neutral (pH 6.5). The dried organic extract was concentrated to a syrup which crystallized on storage at 0°C and was recrystallized from ether to give methyl 6-*O*-imidazolysulfonyl-3,4-di-*O*-methyl-2-*O*-(2,3,4-tri-*O*-methyl-β-D-xylopyranosyl)-α-D-galactopyranoside (**18**) (0.500 g, 95%), mp 95–99°C. *Anal.* calcd. for $C_{20}H_{34}N_2O_{12}S$: C 45.60, H 6.46, N 5.32, S 6.08; found: C 45.63, H 6.43, N 5.18, S 6.16.

The imidazylate **18** (0.229 g, 0.435 mmol) was heated in boiling benzene (10 mL) with tetrabutylammonium iodide (0.5 g, 1.35 mmol) for 25 min. Solvent was removed, the residue was diluted with dichloromethane, and the organic solution was extracted with aqueous sodium thiosulfate, washed with water, dried, and concentrated to a crystalline residue. Purification by chromatography on silica gel in chloroform–ether (1:1) afforded the iododisaccharide **19** (0.179 g, 81%), mp 120–121°C. The mass spectrum showed prominent fragment ions at *m/z* 415, 375, 315, 175, and 143. *Anal.* calcd. for $C_{17}H_{31}O_9I$: C 40.31, H 6.12, I 25.0; found: C 40.26, H 6.39, I 25.0.

B. *Synthesis via trifluoromethanesulfonate*
(with V. Puvanesarajah)

Trifluoromethanesulfonic anhydride (50 μL) in dichloromethane (0.5 mL) was added dropwise with stirring to dry pyridine (25 μL) in dichloromethane (0.5 mL) at −10°C. Methylated disaccharide glycoside **4** (50 mg) in dichloromethane (1 mL) was added dropwise and the mixture was stirred at −10°C for 2 h. Thin-layer chromatography (dichloromethane–acetone, 10:1) showed complete disappearance of starting material. The reaction mixture was poured into ice-water, and the combined separated organic layer and dichloromethane extracts were washed with aqueous sodium hydrogen carbonate and then with water until free from pyridine, dried, and concentrated to a syrup which showed strong absorption at 1420 cm^{-1} (sulfonate) but none at 3400 cm^{-1} (OH). The triflate ester was heated in boiling benzene (4 mL) with tetrabutylammonium iodide (100 mg) for 2 h. After removal of solvent the residue was chromatographed on silica gel in dichloromethane–acetone (10:1) to yield iododisaccharide **19** (45 mg, 70%) which was identical (mp and glc – mass spectrometry) to the previous sample. A polar component (~2 mg) was also isolated from the column and shown to be indistinguishable (glc – mass spectrometry) from the anhydro disaccharide **23**.

C. *Synthesis from imidazolylsulfonate (**18**) in* N,N-*dimethylformamide*

Imidazylate **18** in *N,N*-dimethylformamide containing imidazole (0.5 equiv.) was treated with methyl iodide and kept for 24 h at room temperature. Thin-layer chromatography showed complete disappearance of starting material with formation of iododisaccharide **19** as the major product with a second component, later identified as the anhydrodisaccharide **23**. The mixture was chromatographed on silica gel in chloroform–acetone (4:1) to give crystalline iododisaccharide **19** (65%), which was identical to the previously isolated sample, and syrupy anhydrodisaccharide **23** (20%). The latter compound gave a single peak on glc on column B (210°C) and the mass spectrum showed fragment ions at *m/z* 233, 175, 173, and 143.

*Solvolysis of imidazolylsulfonate (**18**) in* N,N-*dimethylformamide*

Imidazylate **18** (36 mg) was kept in dry *N,N*-dimethylformamide (2 mL) for 36 h. The acidic solution was neutralized with sodium hydrogen carbonate, diluted with water, and extracted with chloroform. Examination of the chloroform extract by glc – mass spectrometry (column C, 170°C, 1 min, 170 → 200°C, 6°/min) showed anhydrodisaccharide **23** as the major component with a second minor component, later identified as methylated disaccharide 6-formate **29**, which showed fragment ions at *m/z* 293, 233, 201, 175, and 143. The extract was chromatographed on silica gel in chloroform–acetone (4:1) to give syrupy methyl 3,6-anhydro-4-*O*-methyl-2-*O*-(2,3,4-tri-*O*-methyl-β-D-xylopyranosyl)-α-D-galactopyranoside (**23**) (16 mg); nmr δ: 4.84 (d, 1H, $J_{1,2}$ 2.85 Hz, H-1), 3.46–3.70 (5s, each 3H, 5 × OMe); δ_C: 102.84 ($J^{13}C_{1'}\text{-}^{1}H_{1'}$ 160.5 Hz, (C-1′)), 97.52 ($J^{13}C_{1}\text{-}^{1}H_{1}$ 161.1 Hz (C-1)), 69.69 (C-6). A sample was boiled under reflux with methanolic 2% hydrogen chloride for 2 h, and the cooled solution was neutralized and concentrated to a syrup which was treated with acetic anhydride in pyridine. Examination of the products by glc on column B (150 → 180°C, 5°/min, hold) showed the presence of methyl glycosides of 2,3,4-tri-*O*-methylxylose together with three components which were identical (glc – mass spectrometry on column C) to those (**26**–**28**) similarly formed from methyl 3,6-anhydro-4-*O*-methyl-α-D-galactopyranoside (**25**).

*Solvolysis of trifluoromethanesulfonate esters of methylated oligosaccharides (**4**, **8**, and **17**) in* N,N-*dimethylformamide*

Samples (~20 mg) of methylated oligosaccharides were converted into triflate esters using procedure B, and the esters were kept in dry *N,N*-dimethylformamide (1 mL) for 1 h at which time tlc (benzene–methanol, 5:1) showed complete disappearance of starting material. Solutions were diluted with dichloromethane (10 mL), washed several times with water, dried, and concentrated.

Examination of the solvolysis products from the triflate ester of methylated disaccharide **4** by glc – mass spectrometry (as above) showed the formation of anhydro disaccharide **23** and methylated disaccharide 6-formate (**29**) in the molar ratio of 1.3:1. A sample of compound **29** was isolated by preparative tlc; ν_{max} 1730 cm^{-1}; nmr δ: 8.15 (s, 1H, —O—CHO). Hydrolysis of the disaccharide derivative,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

followed by reduction and acetylation, afforded acetates of 2,3,4-tri-*O*-methylxylitol and 3,4-di-*O*-methylgalactitol which were characterized by glc–ms on column C and shown to be identical to derivatives formed similarly from methylated disaccharide **4**.

The solvolysis products from the triflate ester of methylated disaccharide **17** were formed in the presence of 1,6-anhydro-2,3,4-tri-*O*-methyl-β-D-galactopyranose as an internal standard. The glc analysis of the products on column B (130 → 180°C, 4°/min, hold) showed the formation of methyl 3,6-anhydro-2,4-di-*O*-methyl-α-D-galactopyranoside (**24**) in 30% yield. The identity of the latter compound was confirmed by glc – mass spectrometry on column C (180 → 200°C, 6°/min, hold) with fragment ions at *m/z* 173, 113, 101, 71 as for a synthetic sample. The major reaction product had a high retention time and fragment ions at *m/z* 293, 175, 143, 101, and 88 were consistent with those of the 6-formate (**31**) of the methylated disaccharide **17**. A sample of the 6-formate **31** was isolated by preparative tlc and methylated sugar analysis gave the same products as from the parent disaccharide **17**. A sample of the solvolysis mixture was treated with sodium borohydride and then with acetic anhydride in pyridine. Analysis of the products by glc – mass spectrometry as for the solvolysis mixture showed the presence of 2,3,4-tri-*O*-methylxylitol diacetate, anhydro derivative **24**, and a disaccharide derivative identical to a synthetic sample of the 6-acetate of methylated disaccharide **17** (fragment ions at *m/z* 307, 187, 175, 143, 127).

The reaction mixture from solvolysis of the triflate ester of methylated trisaccharide **8** afforded a single major product, a sample of which was isolated by preparative tlc. The ^{1}Hmr spectrum of this compound (**30**) showed signals at δ 8.08 (s, 1H, —O—CHO), 4.90 (d, 1H, $J_{1,2}$ 3.56 Hz, H-1), 4.65 (d, 1H, $J_{1',2'}$ 7.39 Hz, H-1′), 4.51 (d, 1H, $J_{1'',2''}$ 7.37 Hz, H-1″) and the mass spectrum (direct insertion) showed fragment ions at *m/z* 453, 393, 247, 175, 143 which were consistent with its formulation as the 6-formate of methylated trisaccharide (**12**).

*Methyl 6-deoxy-6-iodo-2-*O*-methyl-3,4-di-*O*-(2,3,4-tri-*O*-methyl-β-D-xylopyranosyl)-α-D-galactopyranoside (20)*

The iodo trisaccharide (**20**) was synthesized in 73% yield from methylated trisaccharide glycoside **8** by method B as described for compound **19**, and had $[\alpha]_D$ +19.6° (*c*, 0.7 in chloroform); nmr δ_C: 104.6 (C-1′, 3-linked), 103.6 (C-1″, 4-linked), 98.0 (C-1), 4.8 (C-6); *m/z*: 535, 475, 329, 269, 253, 175, 143.

*Methyl 6-deoxy-6-iodo-2,3-di-*O*-methyl-4-*O*-(2,3,4-tri-*O*-methyl-β-D-xylopyranosyl)-α-D-galactopyranoside (21)*

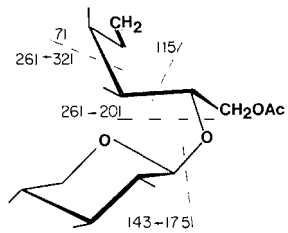
The iodo disaccharide (**21**) was synthesized in 74% yield from methylated disaccharide glycoside **12** by method B as described for compound **19**, and after recrystallization from hexane had mp 115–116°C; $[\alpha]_D$ +55.3° (*c*, 0.8 in chloroform); nmr δ_C: 103.4 (C-1′), 98.2 (C-1), 4.6 (C-6). *Anal.* calcd. for $C_{17}H_{31}O_9I$: C 40.32, H 6.17, I 25.06; found: C 40.33, H 6.37, I 24.91.

*Methyl 6-deoxy-6-iodo-2,4-di-*O*-methyl-3-*O*-(2,3,4-tri-*O*-methyl-β-D-xylopyranosyl)-α-D-galactopyranoside (22)*

The iododisaccharide (**22**) was synthesized in 75% yield from methylated disaccharide glycoside **17** by method B as described for compound **19**, and after recrystallization from hexane had mp 111–112°C; $[\alpha]_D$ +41.1° (*c*, 1.6 in chloroform); nmr δ: 4.86 (d, 1H, $J_{1,2}$ 3.65 Hz, H-1), 4.56 (d, 1H, $J_{1',2'}$ 7.54 Hz, H-1′), 3.47–3.65 (6s, each 3H, 6 × OMe); δ_C: 104.4 (C-1′), 97.9 (C-1), 2.6 (C-6); *m/z*: 375, 315, 255, 223, 195, 175, 143. *Anal.* calcd. for $C_{17}H_{31}O_9I$: C 40.32, H 6.17, I 25.06; found: C 40.15, H 6.05, I 24.51.

*1,2-Dideoxy-3,4-di-*O*-methyl-5-*O*-(2,3,4-tri-*O*-methyl-β-D-xylopyranosyl)-L-*lyxo*-hex-1-enitol acetate (33)*

Methylated iododisaccharide **19** (169 mg, 0.33 mmol) in 1-propanol – water (5 mL, 14:1) was boiled under reflux with freshly activated zinc dust (0.4 g, 6.1 mmol). After 1 h tlc showed formation of a single product and complete disappearance of starting material. The cooled mixture was filtered through Celite, the filtrate was concentrated, and the residue in oxolane–water (2:1) was treated with sodium borohydride for 4 h at room temperature. The reaction mixture was worked up in the usual way, and the product was acetylated with

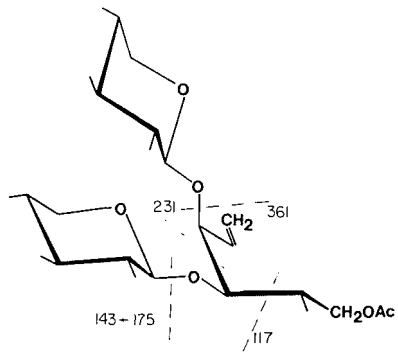


33

acetic anhydride in pyridine. The resulting acetylated derivative (**33**) was chromatographed on silica gel in chloroform–ether (1:1) to give the title compound as a syrup (90 mg, 69%); nmr δ: 5.85 (ddd, 1H, $J_{5,6(trans)}$ 17 Hz, $J_{5,6(cis)}$ 10.3, $J_{4,5}$ 7.9 Hz, —C*H*=CH$_2$), 5.50 (m, 2H, —CH=C*H*$_2$), 4.28 (d, 1H, $J_{1',2'}$ 7.3 Hz, H-1′), 3.60–3.20 (5s, each 3H, 5 × OMe), 2.10 (s, 3H, OAc). Examination by glc–ms on column D (140°C, 1 min, 140 → 200°C, 8°/min, hold) showed a single peak with fragment ions at the *m/z* values shown in structure **33**. *Anal.* calcd. for $C_{18}H_{32}O_9$: C 55.10, H 8.16; found: C 55.24, H 8.15. A portion of the unsaturated disaccharide alditol was hydrolyzed as in methylation analysis, reduced, and acetylated to give two compounds which were characterized by glc–ms on column C as 2,3,4-tri-*O*-methylxylitol diacetate and 1,2-dideoxy-3,4-di-*O*-di-*O*-methyl-L-*lyxo*-hex-1-enitol diacetate (fragment ions at *m/z* 189, 129, 115, 87, and 71).

*1,2-Dideoxy-5-*O*-methyl-3,4-di-*O*-(2,3,4-tri-*O*-methyl-β-D-xylopyranosyl)-L-*lyxo*-hex-1-enitol acetate (34)*

Methylated iodotrisaccharide **20** (67 mg, 0.1 mmol) was reacted with zinc dust in 1-propanol – water as above for 30 min. Thin-layer chromatography indicated a single product which was reduced with sodium borohydride and then acetylated to give the trisaccharide hex-1-enitol acetate **34**; nmr δ: 5.98 (ddd, 1H, $J_{5,6(trans)}$ 17.3 Hz, $J_{5,6'(cis)}$ 10.7 Hz, $J_{4,5}$ 6.1 Hz, H-5), 5.32 (d, 1H, $J_{5,6(trans)}$ 17.26 Hz, H-6), 5.17 (d, 1H, $J_{5,6'(cis)}$ 10.66 Hz, H-6′), 3.60 (s, 6H, 2 × OMe), 3.58–3.45 (5s, each 3H, 5 × OMe), 2.07 (s, 3H, OAc). Analysis by glc–ms on column D (180°C, 2 min, 180 → 230°C, 4°/min, hold) showed a single peak with fragment ions at the *m/z* values shown with structure

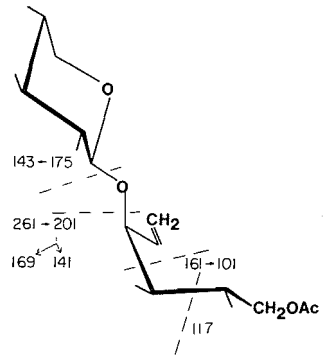


34

34. Hydrolysis etc. as described for compound **33** gave 2,3,4-tri-*O*-methylxylitol diacetate and 1,2-dideoxy-5-*O*-methyl-L-*lyxo*-hex-1-enitol 3,4,6-triacetate (fragment ions at *m/z* 215, 189, 155, 129, and 99).

*1,2-Dideoxy-4,5-di-*O*-methyl-3-*O*-(2,3,4-tri-*O*-methyl-β-D-xylopyranoxyl)-L-*lyxo*-hex-1-enitol acetate (35)*

Methylated iododisaccharide **21** was treated with zinc dust in ethanol–water (14:1) at a bath temperature of 85°C for 30 min. Under these conditions essentially a single product was observed and reduction followed by acetylation afforded the disaccharide hex-1-enitol acetate **35** which was analyzed by glc–ms on column C (180°C, 1 min, 180 → 200°C, 4°/min, hold). Hydrolysis etc. as described for compound **33** gave 2,3,4-tri-*O*-methylxylitol diacetate and 1,2-

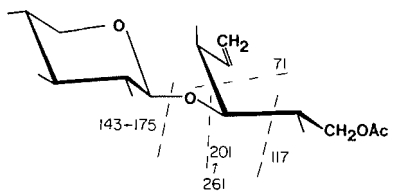


35

dideoxy-4,5-di-*O*-methyl-L-*lyxo*-hex-1-enitol diacetate (fragment ions at *m/z* 161, 143, 127, 117, 101, and 99). When the zinc dust treatment was performed in 1-propanol for longer periods a second product was detected by tlc and was shown to be 2,3,4-tri-*O*-methylxylose by conversion into the corresponding partially methylated alditol acetate.

*1,2-Dideoxy-3,5-di-*O*-methyl-4-*O*-(2,3,4-tri-*O*-methyl-β-D-xylopyranosyl)-L-*lyxo*-hex-1-enitol acetate (36)*

Methylated iododisaccharide **22** was treated with zinc dust in 1-propanol – water as described for compound **19** to give a single product which was reduced and acetylated to furnish the disaccharide 1,2-dideoxy-hex-1-enitol acetate **36** whose structure was confirmed by glc–ms on column C (100°C, 2 min, 100 → 200°C, 8°/min, hold). Hydrolysis etc. for compositional analysis afforded 2,3,4-tri-*O*-methylxylitol diacetate and 1,2-dideoxy-3,5-di-*O*-methyl-L-*lyxo*-hex-1-enitol diacetate (fragment ions at *m/z* 189, 187, 129, 127, 117, and 71.



36

Derivatives of methyl 3,6-anhydro-α-D-galactopyranoside

Samples of the 2,4-di-*O*-methyl (**24**) and 4-*O*-methyl (**25**) derivatives of methyl 3,6-anhydro-α-D-galactopyranoside were prepared by incomplete methylation as described by Anderson *et al.* (11). The ^{13}C nmr spectrum of **24** included signals at δ_C 98.63 ($J_{^{13}C_1\text{-}^1H_1}$ 161 Hz) and 69.08 (C-6). The acetylated derivative (**26**) of compound **25** when examined by glc – mass spectrometry on column C showed fragment ions at *m/z* 201 (M − OCH_3), 129, 116, 103, and 71. A sample of glycoside **25** was treated with boiling methanolic 2% hydrogen chloride for 2 h and the products were acetylated; glc – mass spectrometry showed the presence of 3 components, the first indistinguishable from **26**, the second well separated but giving a similar mass spectrum (presumably the β-D-glycoside **27**), and a third and major component for which the acetylated dimethylacetal structure (**28**) may be proposed in the light of prominent fragment ions at *m/z* values shown (compare Chizhov *et al.* (20)).

GERALD OLIVER ASPINALL and VELUPILLAI PUVANESARAJAH. Can. J. Chem. **62**, 2736 (1984).

Reduction of galacturonic acid residues in permethylated tragacanthic acid, followed by transformation of the resulting galactose residues to those of 6-deoxy-6-iodogalactose, affords a modified polysaccharide which undergoes depolymerization by the Bernet–Vasella reaction on treatment with zinc dust. The two main products of depolymerization have been characterized, after reduction and acetylation, as 3,6-di-*O*-acetyl-1,2-dideoxy-5-*O*-methyl-4-*O*-(2,3,4-tri-*O*-methyl-β-D-xylopyranosyl)-L-*lyxo*-hex-1-enitol (**1**) and *O*-(2,3,4-tri-*O*-methyl-α-L-fucopyranosyl)-(1 → 2)-*O*-(3,4-di-*O*-methyl-β-D-xylopyranosyl)-(1 → 4)-3,6-di-*O*-acetyl-1,2-dideoxy-5-*O*-methyl-L-*lyxo*-hex-1-enitol (**2**). The fragmentation provides the first example of a chemical degradation of an α-D-galacturonan to furnish oligosaccharides in which side-chain units remain attached to modified galacturonic acid residues. Under the conditions used for the introduction of iodo substituents no evidence could be obtained for loss of 3-*O*-glycosyl substituents through side reactions involving solvolysis of 6-sulfonates.

GERALD OLIVER ASPINALL et VELUPILLAI PUVANESARAJAH. Can. J. Chem. **62**, 2736 (1984).

La réduction de résidus d'acide galacturonique dans de l'acide tragacanthique, suivie par une transformation des résidus de galactose qui en résultent en désoxy-6 iodo-6 galactose, fournit un polysaccharide modifié qui subit une dépolymérisation, sous l'influence de la poudre de zinc, par une réaction de Bernet–Vasella. Après la réduction et une acétylation, on a caractérisé les deux produits principaux de la réaction de dépolymérisation comme étant le di-*O*-acétyl-3,6 didésoxy-1,2 *O*-méthyl-5 *O*-(tri-*O*-méthyl-2,3,4 β-D-xylopyrannosyl)-4 L-*lyxo*-hexène-1 itol (**1**) et le *O*-(tri-*O*-méthyl-2,3,4 α-L-fucopyrannosyl)-(1 → 2)-*O*-(di-*O*-méthyl-3,4 β-D-xylopyrannosyl)-(1 → 4)-di-*O*-acétyl-3,6 didésoxy-1,2 *O*-méthyl-5 L-*lyxo*-hexène-1 itol (**2**). Cette fragmentation est le premier exemple d'une dégradation chimique d'un α-D-galacturonane qui conduit à des oligosaccharides dans lesquels les unités des chaînes latérales restent attachées à des résidus d'acide galacturonique modifiés. Sous les conditions utilisées pour l'introduction des substituants iodo, on n'a pas pu observer de pertes de substituants *O*-glycosyles-3 provenant de réactions de solvolyses secondaires des sulfonates-6.

[Traduit par le journal]

Methods developed recently for the selective cleavage of non-terminal glycosiduronic acid or glycosiduronamide linkages in permethylated polysacharides have been based on structural modifications to yield altered sugar residues at which controlled depolymerization may be carried out with no detectable hydrolysis of normal glycosidic linkages. Thus treatment of glycosiduronic acids with lead tetraacetate effects decarboxylation–acetoxylation to give 5-acetoxypentopyranosides which may be cleaved reductively with sodium borohydride (1). Alternatively, Curtius rearrangements of glycosiduronamides furnish carbamates, 5-*tert*-butyloxycarbonylamino- or 5-benzyloxycarbonylamino-pentopyranosides, which may be cleaved respectively by mild acid treatment or hydrogenolysis (2). The procedures have been applied successfully to the fragmentation of both exterior (1, 2) and interior (3) chains containing β-D-glucosiduronic acid units with the formation of xylitol-terminated oligosaccharides carrying unaltered neutral sugar residues. In this way it is now possible to obtain information on difficultly accessible or previously inaccessible regions of polysaccharide structure. However, the corresponding reactions involving scission of α-D-galactopyranosiduronic acid linkages proceed with difficulty. Even for mono- (4) and disaccharides (2), extended reaction times are often required and (or) products from competing reactions are detected. To an even greater extent (5, 6), derivatives of α-D-galacturonans either fail to react significantly or give rise to incompletely characterized products other than the desired pentitol-terminated fragments.

Bernet and Vasella (7) showed that the reaction of 6-deoxy-6-halohexopyranosides with zinc dust under mild conditions results in glycoside cleavage with the formation of hex-5-enoses. In the accompanying paper (8) it has been shown that permethylated oligosaccharides containing various *O*-substituted methyl 6-deoxy-6-iodo-α-D-galactopyranosides undergo selective glycoside cleavage on treatment with zinc dust and that the resulting hex-5-enoses are conveniently characterized as the derived hex-1-enitol acetates. In principle, the reaction could be initiated through conversion of primary hydroxyl groups at C-6 of hexopyranose residues, however generated, to 6-deoxy-6-halohexopyranose residues in otherwise protected polysaccharides. We describe here an application of this reaction to the selective fragmentation of a permethylated polysaccharide in which the primary hydroxyl groups are formed from the reduction of hexuronic acid residues in a methylated α-D-galacturonan. Although this use of the hex-5-enose-forming reaction involves an indirect approach to structure determination of glycuronans, the overall sequence achieves an objective not otherwise obtained for α-D-galacturonans by chemical degradation, namely, the formation of modified sugar units originating from hexuronic acid residues with neutral glycosyl substituents still attached.

Tragacanthic acid has one of the more completely established structures amongst pectins and structurally related α-D-galacturonans. The 4-linked main chain, which is interrupted only infrequently by the insertion of 2-linked L-rhamnopyranose residues, carries side chains through O-3 of D-galacturonic acid residues (9, 10). These side chains are of D-xylopyranose residues, some of which are further substituted at O-2 by α-L-fucopyranose or, less frequently, β-D-galactopyranose residues. In an earlier study (9), assignments of anomeric configurations for glycosidic linkages of side-chain units were made for terminal α-L-fucopyranose and β-D-xylo-

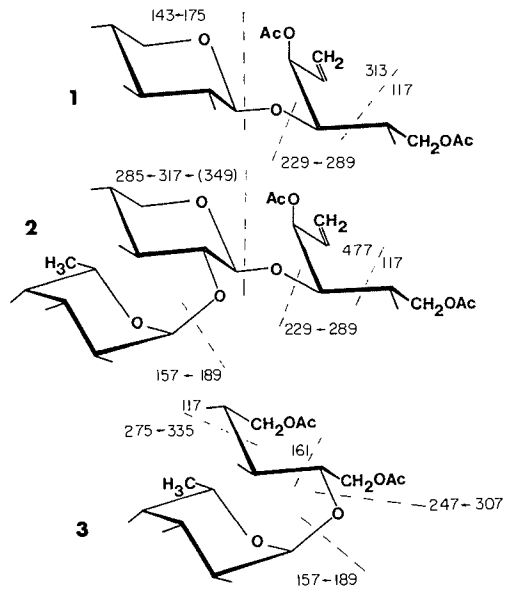
pyranose residues on the basis of optical rotations of oligosaccharides formed on partial fragmentation, but no specific information was available in respect of the non-terminal D-xylopyranose units.

Fractional precipitation of the water-soluble portion of gum tragacanth afforded a sample of tragacanthic acid whose sugar composition (galacturonic acid, 50%; xylose, 27%; fucose, 20%; galactose and arabinose, traces) was qualitatively similar to, but differed slightly in the proportions of sugar constituents from, those of a previously studied sample of the polysaccharide (9).

Lithium aluminum hydride treatment of permethylated tragacanthic acid afforded the carboxyl-reduced derivative. A sample of the reduced polysaccharide was further alkylated with trideuteriomethyl iodide, and methylated sugar analysis by glc–ms of the derived partially methylated alditol acetates showed the following relative proportions of the main constituents: 2,3,4-tri-*O*-methylxylose and 2,3,4-tri-*O*-methylfucose (28%), 3,4-di-*O*-methylxylose (21%), 2,3,6-tri-*O*-methylgalactose (15%), and 2,6-di-*O*-methylgalactose (36%). The last two sugars contained trideuteriomethyl groups at O-6 in confirmation of their origin in galacturonic acid residues. The small proportions of galactose-terminated side chains found in the earlier sample of tragacanthic acid were apparently absent from the present material.

Carboxyl-reduced permethylated tragacanthic acid was treated carefully with triflic anhydride in pyridine (11) and, as soon as ir examination showed virtual disappearance of hydroxyl absorption at 3600 cm^{-1} together with appearance of sulfonate ester absorption at 1420 cm^{-1}, the reaction mixture was worked up and the product reacted with tetrabutylammonium iodide. Completeness of reaction was ascertained by disappearance of the sulfonate ester band at 1420 cm^{-1}. Reaction of the 6-deoxy-6-iodogalactose residues in the modified polysaccharide with zinc dust in boiling 1-propanol was followed by treatment of the products with sodium borohydride and acetylation to give a mixture of partially methylated oligosaccharide alditol acetates. The two main products were separated chromatographically. Fraction T1 gave on hydrolysis 2,3,4-tri-*O*-methylxylose and a 1,2-dideoxy-5-*O*-methylhex-1-enitol, both of which were characterized by glc–ms of the derived alditol acetates. The ^{1}Hmr spectrum of T1 showed a single anomeric signal at δ 4.42 (doublet, $J_{1,2}$ = 7.26 Hz) characteristic of a β-D-xylopyranose residue. The structure, 3,6-di-*O*-acetyl-1,2-dideoxy-5-*O*-methyl-4-*O*-(2,3,4-tri-*O*-methyl-β-D-xylopyranosyl)-L-*lyxo*-hex-1-enitol (**1**), may therefore be advanced for this compound. Fraction T2 gave on hydrolysis 2,3,4-tri-*O*-methylfucose, 3,4-di-*O*-methylxylose, and the same hexenitol derivative, and the ^{1}Hmr spectrum showed two anomeric signals at δ 5.46 (doublet, $J_{1,2}$ = 3.7 Hz) and 4.51 (doublet, $J_{1,2}$ = 7.3 Hz), assignable to α-L-fucopyranose and β-D-xylopyranose residues respectively. Structure **2**, *O*-(2,3,4-tri-*O*-methyl-α-L-fucopyranosyl)-(1 → 2)-*O*-(3,4-di-*O*-methyl-β-D-xylopyranosyl)-(1 → 4)-3,6-di-*O*-acetyl-1,2-dideoxy-5-*O*-methyl-L-*lyxo*-hex-1-enitol, may be proposed for oligosaccharide alditol T2.

The glc–ms examination of the mixture of partially methylated oligosaccharide alditol acetates provided supporting evidence for structures **1** and **2** for the two main components and *m/z* values are shown for the more significant fragment ions in the mass spectra. A third minor component T3 was observed, whose retention time and mass spectrum were consistent with those of an *O*-(2,3,4-tri-*O*-methylfucopyranosyl)-(1 → 2)-3,4-di-*O*-methylxylitol (**3**), which presumably resulted from a side reaction that involved breakdown of a segment otherwise generating oligosaccharide **2**.



Unless otherwise specified, substituents are OCH_3

The successful application of the hex-5-enose degradation to carboxyl-reduced permethylated tragacanthic acid provides the first example of a chemical (as opposed to enzymic) fragmentation of an α-D-galacturonan derivative which furnishes oligosaccharides containing the full complement of unaltered neutral glycosyl substituents. Since the oligosaccharides are terminated by hex-5-enose units originating from former galacturonic acid residues, the characterization of these substances defines the nature and sites of attachment of side chains, as in structure **4**. The degradative procedure should be applicable to

structure determination of otherwise inaccessible regions of pectins and structurally-related galacturonanas and rhamnogalacturonans.

In the accompanying paper (8) evidence was presented for 3,6-anhydro-α-D-galactopyranoside formation through intramolecular participation of 3-*O*-methyl or 3-*O*-glycosyl substituents and subsequent loss of such substituents when the corresponding α-D-galactopyranoside 6-sulfonates undergo solvolysis. Such a solvolytic reaction competes with iodide displacement when reaction is performed in *N,N'*-dimethylformamide, but is of no detectable significance when α-D-galactopyranoside 6-sulfonates are treated with tetrabutylammonium iodide in benzene. Under these latter conditions 6-deoxy-6-iodogalactosides are isolated in high preparative yields. In order to assess whether 3,6-anhydride formation with accompanying loss of 3-*O*-glycosyl substituents would be of any significance in polysaccharide studies, either as an unfavourable side reaction or as an alternative degradation which might be turned to advantage in structural analysis, the solvolysis of methylated carboxyl-reduced tragacanthic acid 6-imidazylate was examined. Chromatographic separation of the products gave modified methylated polysaccharide as the major fraction with a minor fraction containing some material which migrated on tlc. In order to detect the formation of derivatives of 3,6-anhydrogalactose, samples of carboxyl-reduced methylated tragacanthic acid and the methylated polysaccharide recovered from the solvolysis were methanolyzed and the resulting methyl glycosides were acetylated. The glc–ms analysis of the methyl glycoside acetates from the latter polysaccharide sample showed the presence *inter alia* of methyl 3,6-anhydro-2-*O*-methyl-β-D-galactopyranoside 4-acetate. Quantitative estimation placed an upper limit of 2% for the proportion of anhydrogalactose residues in the modifed polysaccharide and for the proportion of 3-*O*-glycosyl side chains which could have been lost in the solvolysis reaction. Furthermore, at least some of the anhydrogalactose residues could have been formed from methoxy rather than glycosyloxy participation in the sulfonate solvolysis. Attempts to detect glycosyl substituents liberated during the solvolysis were unsuccessful. We conclude that, for this 4-linked polysaccharide derivative, sulfonate solvolysis, even under the most favourable conditions, does not result in degradation with liberation of 3-*O*-glycosyl substituents in amounts which could be used to gain structural information. It is even less likely that such a side reaction will compete significantly during the introduction of iodo substituents when sulfonate displacement by iodide ion is performed in a nonpolar solvent in the key step preceding the hex-5-enose degradation.

Experimental

General experimental methods were as described in the preceding paper (8).

Carboxyl-reduced methylated tragacanthic acid

Tragacanthic acid was isolated by fractional precipitation of the water-soluble part of gum tragacanthic acid by graded addition of ethanol. The precipitated polysaccharide was dispersed in water and freeze-dried to give a sample which contained 50% of galacturonic acid residues (12) and gave on hydrolysis (13) xylose (27%), fucose (20%), and traces of galactose and arabinose, which were converted into alditol acetates (14) for analysis by glc on column A. Methylated tragacanthic acid was prepared by the Hakomori procedure (15) in dimethylsulfoxide using sodium methylsulfinylmethanide in ~30% excess of the quantity required to ensure ionization of carboxyl and hydroxyl groups present, as checked with triphenylmethane (16), with subsequent addition of methyl iodide (2 molar proportions). Methylated tragacanthic acid (150 mg) was heated with lithium aluminum hydride (400 mg) in boiling oxolane (10 mL). Excess hydride was destroyed by addition of ethyl acetate and the solution was neutralized to pH 4 by dropwise addition of dilute sulfuric acid. The mixture was diluted with water, concentrated to remove organic solvent, and then extracted with dichloromethane. Concentration of the dried extract afforded carboxyl-reduced methylated tragacanthic acid (125 mg). A portion of the methylated polysaccharide was realkylated using trideuteriomethyl iodide, the product was hydrolyzed, and the resulting sugars were converted into partially methylated alditol acetates which were analyzed by glc – mass spectrometry (15) using column B. The results indicated the presence of derivatives of 2,3,4-tri-*O*-methylxylose and 2,3,4-tri-*O*-methylfucose (28% combined from incompletely separated components), 3,4-di-*O*-methylxylose (21%), 2,3-di-*O*-methyl-6-*O*-($^2H_3$)methylgalactose (15%), and 2-*O*-methyl-6-*O*-($^2H_3$)methylgalactose (36%).

Formation and selective cleavage of 6-deoxy-6-iodogalactopyranosyl residues in carboxyl-reduced methylated tragacanthic acid

Trifluoromethanesulfonic anhydride (300 μL) in dichloromethane (2 mL) was added dropwise, with stirring, to dry pyridine (150 μL) in dichloromethane (1 mL) at −10°C. After 15 min, carboxyl-reduced methylated tragacanthic acid (100 mg) in dichloromethane (2 mL) was added dropwise and the mixture was stirred at −10°C for 2.5 h. The reaction mixture was poured into ice-water (5 mL), the organic layer was separated, and the aqueous layer was extracted with dichloromethane. The combined organic layers were washed with cold dilute sodium hydrogen carbonate and then water until free of base. Concentration of the dried solution yielded polysaccharide sulfonate which showed ir absorption (NaCl) at 1420 cm^{-1} (—SO_2—) but none at 3600 cm^{-1} (OH). The polysaccharide sulfonate was heated in boiling benzene (4 mL) containing tetrabutylammonium iodide (200 mg) for 24 h. After removal of solvent the residue was chromatographed on Sephadex LH-20 in dichloromethane to furnish iodinated methylated polysaccharide (60 mg) whose ir spectrum showed absence of sulfonyl absorption at 1420 cm^{-1}. Iodinated methylated polysaccharide was heated in boiling 1-propanol – water (3 mL, 14:1) with freshly activated zinc (100 mg) for 15 h. The filtered solution combined with methanol washings was concentrated, and the residue in oxolane–water (1:1, 3 mL) was treated with sodium borohydride (75 mg) for 15 h. After normal work-up the product was acetylated with acetic anhydride in pyridine. Examination of a portion of the resulting mixture of partially methylated oligosaccharide alditol acetates by glc – mass spectrometry on column D (180°C, 4°/min → 230°C, hold) showed two major components T1 and T2, eluted at 6.0 and 20.2 min, which were isolated preparatively, together with a minor component T3, eluted at 7.9 min, whose mass spectrum and retention time were consistent with those of an *O*-(2,3,4-tri-*O*-methylfucopyranosyl)-(1 → 2)-3,4-di-*O*-xylitol diacetate. The major part of the above mixture was chromatographed on silica gel with dichloromethane–acetone (10:1) to give samples of hex-1-enitol-terminated oligosaccharides T1 and T2 whose structures were established from the ^{1}Hmr and mass spectra and by methylated sugar analysis. The 1,2-dideoxy-5-*O*-methylhex-1-enitol triacetate formed from both oligosaccharides was identical (glc – mass spectrometry) to the derivative reported in the preceding paper (8).

Solvolysis of carboxyl-reduced methylated tragacanthic acid 6-imidazylate (with L. Khondo)

Carboxyl-reduced methylated tragacanthic acid (30 mg) in dry oxolane (1 mL) was added to sodium hydride (6 mg) in dry oxolane (0.5 mL) and the suspension was stirred for 4 h at room temperature. *N,N'*-Sulfuryldiimidazole (45 mg) was added to the reaction mixture at −40°C, and the mixture was stirred at −40°C for 20 min and at room temperature for 2 days. Progress of reaction was monitored from the ir spectra of isolated polysaccharide samples which showed appearance of a band at 3120 cm^{-1} (imidazole C—H) and the corresponding disappearance of absorption at ~3500 cm^{-1} (OH). Methanol

(0.1 mL) was added to destroy residual sodium hydride, the reaction mixture was concentrated, the residue was extracted with dichloromethane, and the extract was washed several times with water, dried, and concentrated to give modified polysaccharide (36 mg).

The methylated polysaccharide imidazylate (36 mg) was kept in dry *N,N'*-dimethylformamide at room temperature for 5 days. Progress of the solvolysis was monitored by disappearance of ir absorption at 3120 cm^{-1} (imidazole C—H). On completion of reaction the solution was diluted with dichloromethane, washed with water, dried, and concentrated. The residue in *N,N'*-dimethylformamide – water (2 mL, 1:1) was absorbed on a Waters C_{18} reverse-phase Sep-Pak cartridge (17, 18). Elution of the cartridge with methanol–water (1:1) afforded a minor fraction (1.6 mg) which showed traces of chromatographically mobile carbohydrate on tlc in benzene–methanol (5:1). Elution of the cartridge with methanol furnished as a major fraction modified methylated polysaccharide (20 mg). A portion of this material was boiled with methanolic 2.5% hydrogen chloride for 2.5 h and the methanolysate was acetylated. The resulting mixture of methyl glycosides and methyl glycoside acetates was examined by glc–ms on column C, and shown to contain derivatives of 2,3,4-tri- and 3,4-di-*O*-methylxylose, and 2,3,4-tri-*O*-methylfucose, together with small amounts of methyl 4-*O*-acetyl-3,6-anhydro-2-*O*-methyl β-D-galactopyranoside. A parallel experiment showed that this latter compound comprised 67% of the mixture of products formed when methyl 3,6-anhydro-2-*O*-methyl-α-D-galactopyranoside (19) was methanolysed and acetylated under identical conditions. Under these conditions of analysis derivatives of 2,3-di- and 2-*O*-methylgalactose (from caboxyl-reduced galacturonic acid residues) were not conveniently estimated. Based on the above-determined composition of carboxyl-reduced methylated tragacanthic acid and on the ratio of methyl 4-*O*-acetyl-3,6-anhydro-2-*O*-methyl-β-D-galactopyranoside to the above-mentioned methyl glycosides, it is calculated that residues of 3,6-anhydro-D-galactose are present in the modified polysaccharide in an amount not exceeding 2%. The minor fraction from the polysaccharide solvolysis was treated with sodium borodeuteride and then acetylated. The glc–ms analysis of the products showed some non-carbohydrate impurities but neither 2,3,4-tri-*O*-methylxylitol nor the disaccharide alditol **3** could be detected.

Received March 2, 1984

HERBERT L. HOLLAND, P. CHINNA CHENCHAIAH, EVERTON M. THOMAS, BEATRIX MADER, and MICHAEL J. DENNIS. Can. J. Chem. **62**, 2740 (1984).

A series of Δ^6-3-ketosteroids has been incubated with the C-6β hydroxylating fungus *Rhizopus arrhizus* ATCC 11145. Ring A aromatic steroids are not metabolized by this fungus, nor are 3-chloro- and 3-(*N*-pyrrolideno)-androsta-3,5-dienes. $\Delta^{4,6}$-3-Ketosteroids are epoxidized at the 6,7 position by *R. arrhizus* with β stereochemistry; in contrast, both 5α- and 5β-Δ^6-3-ketosteroids are epoxidized with α stereochemistry by fungal and peracid reagents. The results of this and previous studies now make it possible to define the nature of the hydroxylating/epoxidizing species of the 6β hydroxylase enzyme of *R. arrhizus*. Evidence is presented for a stepwise reaction mechanism in both cases. Improved methods of synthesis are described for 6-methylene-testosterone and estra-4,6-dien-17β-ol-3-one.

HERBERT L. HOLLAND, P. CHINNA CHENCHAIAH, EVERTON M. THOMAS, BEATRIX MADER et MICHAEL J. DENNIS. Can. J. Chem. **62**, 2740 (1984).

On a procédé à l'incubation d'une série de Δ^6 céto-3 stéroïdes en présence du champignon *Rhizopus arrhizus* ATCC 11145 qui provoque des réactions d'hydroxylation en C-6β. Les stéroïdes comportant un cycle A aromatique ainsi que les chloro-3 ou (*N*-pyrrolidéno)-3 androstadiènes-3,5 ne sont pas métabolisés par ce champignon. Sous l'influence du *R. arrhizus*, les $\Delta^{4,6}$ céto-3 stéroïdes subissent une réaction d'époxydation en position 6,7 et la stéréochimie de la réaction est β; par opposition, les Δ^6 céto-3 stéroïdes tant de la série 5α que de la série 5β subissent des réactions d'époxydation dont la stéréochimie est α tant sous l'action des champignons que des peracides. Grâce aux résultats de la présente étude ainsi que ces obtenus antérieurement, il est maintenant possible de définir la nature des espèces, présentes dans l'enzyme hydroxylase 6β du *R. arrhizus*, qui provoquent les réactions d'hydroxylation et d'époxydation. Dans chacun de ces cas, on présente des données qui suggèrent un mécanisme réactionnel par étapes. On décrit des méthodes améliorées de synthèse pour la méthylène-6 testostérone ainsi que pour l'estradiène-4,6 ol-17β one-3.

Introduction

The enzymic introduction of a hydroxy group at the C-6β position of Δ^4-3-ketosteroids (the conversion of **1** to **2**) is a common example of a biotransformation which can be carried out efficiently by mammalian (1) or microbial (2) systems. We have studied the latter reaction, performed by the fungus *Rhizopus arrhizus*, and have demonstrated that the substrate is hydroxylated in its $\Delta^{3,5}$-dienol form (eq. [1]) (3–8).

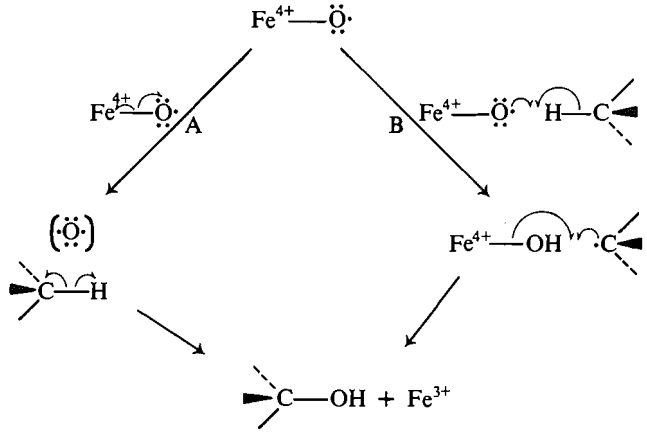
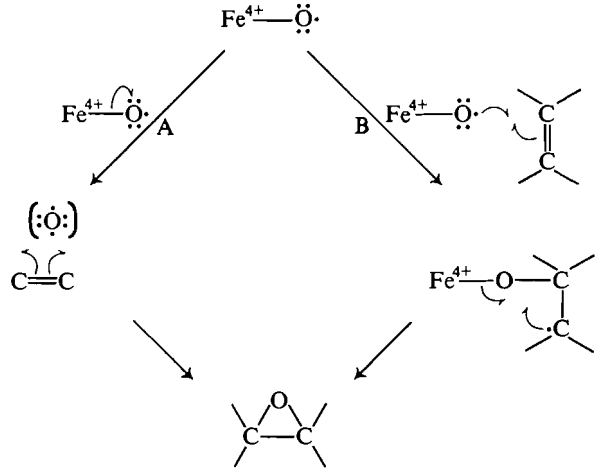
6

The mammalian enzyme which carries out this reaction is a cytochrome P-450 dependent mono-oxygenase (1, 9). Steroid hydroxylating enzymes from microbial sources appear to have similar cofactor requirements (10), and to function by a similar mechanism (2). Analogous enzymes from mammalian or microbial sources are also responsible for the detoxification by hydroxylation of endogenous organic material (11), and are implicated in the metabolism of arenes to arene oxides (12).

The nature of the active site oxidizing species has been formulated as the iron–oxygen complex shown in Scheme 1 (13); the weight of available evidence favours a non-concerted, radical mechanism (pathway B, Scheme 1) for its reaction with a saturated C—H bond (2). A closely related reaction, also carried out by cytochrome P-450 dependent mono-oxygenases (14), is the epoxidation of olefinic substrates (2). This reaction may proceed via one of the mechanisms of Scheme 2, anal-



SCHEME 1. Possible routes for hydroxylation at saturated carbon by cytochrome P-450 dependent mono-oxygenases.



SCHEME 2. Possible routes for epoxidation of olefins by cytochrome P-450 dependent mono-oxygenases.

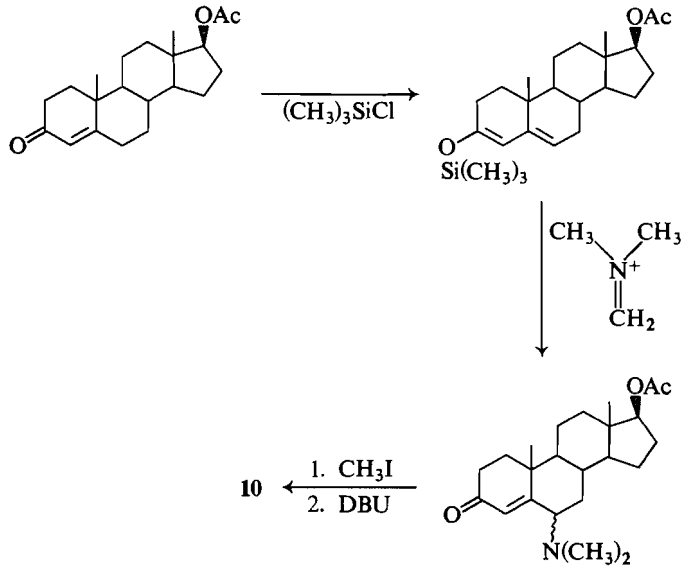
ogous to the corresponding concerted (path A) or stepwise (path B) routes of Scheme 1; little discriminating evidence is available in support of either pathway (14, 15, and references therein).

We have now extended our study of the microbial hydroxylation of Δ^4-3-ketosteroids at C-6β to include the epoxidation of $\Delta^{4,6}$-diene-3-ones and Δ^6-3-ketosteroids, and propose herein that both processes occur via stepwise rather than a concerted reaction pathway.

Results

Of the substrates used in this study, only 6-methylene-testosterone (10) was synthesized by a new route (Scheme 3), that developed by Danishefsky *et al.* for the synthesis of 6-methylene-progesterone (16).

The determination of the structure of biotransformation products in this study relied heavily on the interpretation of ^{13}C nmr spectral data. For this reason, the ^{13}C nmr spectra of the Δ^6 androstenes used as substrates are reported in Table 1. The resonances assigned to carbons 4 and 6, and to carbons 9 and 14, respectively, of **4***a* and **4***c* represent a reversal of the literature values (17). Our assignments of the carbons 9 and 14 resonance positions of **4***a*–*c*, **5***a*, **5***b*, and **13** reflect the anticipated effects of substitution at C-10 and C-16 (18), while the chemical shifts of C-4 and C-6 of the same compounds were



SCHEME 3. Synthesis of 6-methylene testosterone (**10**) (ref. 16).

reassigned following a consideration of the spectra of the 6,7β-epoxides **12** (see below) in which C-4 and C-5 chemical shifts are essentially unchanged from those of the corresponding olefins **4** and **5**. The assignments of the carbon resonances of the Δ^6 estrogens **8***a* and **8***b* were straightforward, while those of the 5α- and 5β-Δ^6-androstenes **11***a*, **11***b*, and **17** follow readily from the spectra of the corresponding saturated compounds (18) and a consideration of the effect of the introduction of unsaturation in the 6,7 position (19).

Following the successful use of $\Delta^{3,5}$ enol acetates as substrates for C-6β hydroxylation by *Rhizopus arrhizus* (4, 7) the $\Delta^{3,5}$-3-chloro steroid **9***a* and the $\Delta^{3,5}$ dienamine **9***b* were

For personal use only.

incubated with this fungus. The former was not metabolized by *R. arrhizus*, and the latter gave only those products produced by rearrangement and auto-oxidation following its hydrolysis to androst-5-ene-3,17-dione (6, 20). The successful use of testosterone acetate (**1***c*) as a substrate, giving the 6β and 11α hydroxy derivatives **2***c* and **3**, respectively, confirms that the 6β hydroxylase enzyme can accept a 17-acetoxy steroid substrate, so that the presence of this functional group in the substrate cannot account for the failure of *R. arrhizus* to metabolize **9***a*.

The 6-methylene steroid **10** and the Δ^6 estrogens **8***a* and **8***b* were recovered unchanged from incubation with *R. arrhizus*. This fungus also fails to hydroxylate estrone (**7**), so its failure to metabolize **8***a* and **8***b* is not unexpected.

The $\Delta^{4,6}$-diene-3,17-dione **4***a* gave two products on incubation with *R. arrhizus*, the 6,7β epoxide **12***a* and the 17β-hydroxy-16-ketone **13**. The structure of **12***a* follows from a comparison of its carbon nmr spectral properties (Table 2) with those of the corresponding 6,7α epoxide (**20**) prepared by chemical synthesis or by incubation of **4***a* with the C-7α hydroxylator *Mucor griseocyanus*. The upfield position of the resonances assigned to carbons 9 and 14 in the latter compound with respect to those reported for **12***a* confirm the respective stereochemistry of substitutions in ring B (γ-*gauche* effects). The assignment of the C-8 resonance of **12***a* at δ 36.1 ppm with respect to that of **20** at 35.6 ppm is in accord with the presence of a γ-*gauche* effect (ca −5 ppm) in the former moderated by a change from axial to equatorial oxygen substitution at C-7 (ca +4 ppm at C-8) (18). A similar effect occurs at C-12 in 9(11) epoxides.[1] Other spectral data (^1H nmr, ir, uv, mass spectra) for **12***a* are in agreement with the proposed structure. The structure proposed for the metabolite **13** is in accord with its proton and carbon nmr data. The assignment of the C-17α hydrogen resonance to the singlet at δ 3.81 and the appearance of the C-18

*Chemical shifts marked with asterisks may be interchanged.

methyl signal at δ 0.83 are characteristic of the substitution pattern proposed for ring D, as are the resonances of carbons 12–18 (Table 1).

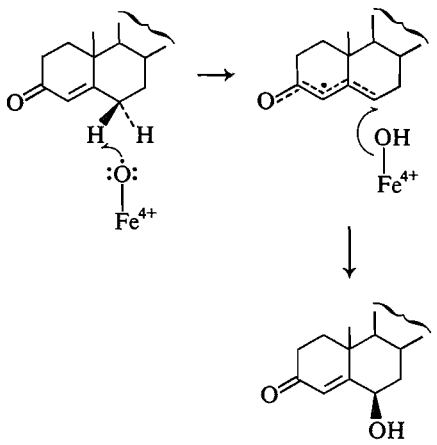
Androsta-4,6-dien-17β-ol-3-one (**4***b*) gave only the product of 6,7β epoxidation on incubation with *R. arrhizus*, as did the corresponding diol **6** (following oxidation at C-3). Comparison of carbon spectral data for this product (**12***b*), that for **12***a*, and the epoxide **12***c* (derived from **5***a*) with that for **20** (Table 2) confirms the common β stereochemistry of epoxide in **12***a–c*. The only differences within this series are those anticipated for substitution at C-10 and C-17 (18).

The 19-nor-steroid **5***a* gave, in addition to the epoxide **12***c* as described above, a product **5***b* resulting from hydroxylation at C-10. The structure of **5***b* is entirely in accord with that predicted from application of the ^{13}C nmr shift parameters for a C-10β hydroxy group (22) to **5***a*, and with other spectral data.

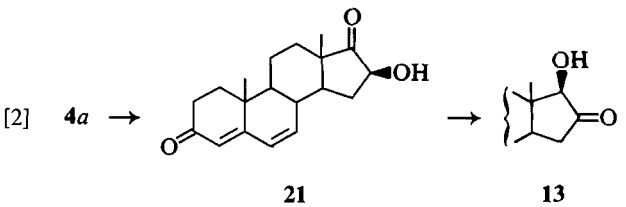
The 5α and 5β-androst-6-enes **11***a* and **11***b* each gave a single product on incubation with *R. arrhizus*. These products were identical with those obtained by peracid oxidation of the corresponding olefins, and were assigned the 6,7α epoxy structures **15***b* and **14***b* respectively. The stereochemistry of the epoxide grouping in these compounds can be readily deduced from their ^{13}C nmr spectra (Table 2), the γ upfield shifts of carbons 9 and 14 with respect to those of the corresponding saturated diones being particularly diagnostic (18).

Discussion

The formation of the minor products **13** (from **4***a*) and **5***b* (from **5***a*) may be rationalized as follows. The 16-ketone **13** can arise via the 16β-hydroxy-17-ketosteroid **21** (eq. [2]); steroids with the latter functionality rearrange readily under acidic or basic conditions to the more stable 17β-hydroxy-16-one (23). The pH of the incubation medium is 5.2. Hydroxylation of **5***a* at C-10β parallels the observed hydroxylation of 19-nortestosterone (22) and the corresponding dione (5) at C-10β by *R. arrhizus*. Both **13** and **5***b* may therefore be the result of the enzyme's predilection for axial hydroxylation at



SCHEME 4. Mechanism of C-6β hydroxylation of Δ^4-3-ketosteroids by *R. arrhizus*.



enolizable carbon.

The enzymic formation of the β epoxides **12***a–c* from $\Delta^{4,6}$-diene-3-ones **4**, and the β hydroxylation at C-6 of Δ^4-3-ketosteroids (1) is in contrast to the α epoxidation of **11** reported herein, the stereospecific α epoxidation of the Δ^5 bond in *B*-norsteroids (8), and the C-6α hydroxylation of 5α-androstan-17β-ol-3-one by *R. arrhizus* (24).

Inspection of models of **1**, **4**, and **11**, with the assumption of a fixed relationship between the sites of substrate binding (C-3 and C-17(2)) and oxidation, fails to provide any plausible explanation for the observed changes in the stereochemistry of oxidation at C-6 noted above. In the absence of any clearly definable effect due to substrate binding, we suggest that the reason for these stereochemical changes may be attributable to steric and (or) stereoelectronic effects associated with the individual substrates themselves.

We have previously argued that the β stereochemistry of oxidation at C-6 in the conversion of **1** to **2** is not necessarily a restraint of enzyme specificity, but can be a result of stereoelectronic factors inherent in the conversion of the $\Delta^{3,5}$-dienol intermediate to product (6) (eq. [1]). This reaction has been shown to involve a product-like transition state with the C-6β bond approaching an axial position (25, 26).

If our previous argument is correct, then the enzymic 6β hydroxylation of **1** is most satisfactorily represented as the stepwise process (analogous to route B of Scheme 1) presented in Scheme 4. The alternative concerted proposal (analogous to route A of Schemes 1 and 2) requires a stereospecific β epoxidation at the 5,6 position, followed by rearrangement to give the product (eq. [3]). The data presented herein demonstrate, however, that in the absence of stereoelectronic contraints, enzymic oxidation at C-6 occurs with only α stereochemistry. We therefore conclude that, since the concerted epoxidation of eq. [3] would occur independently of stereoelectronic factors, this reaction pathway is not consistent with the available data.

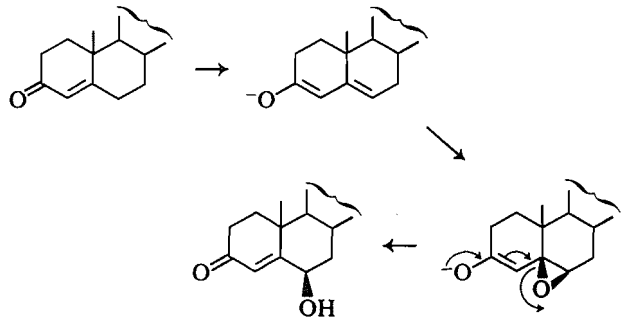
[3]

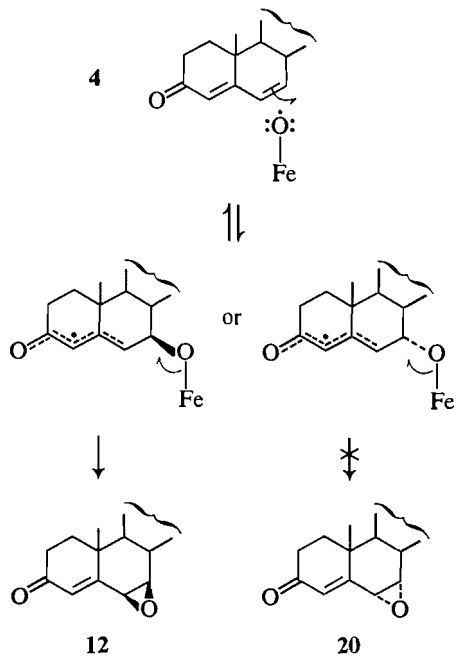


The β stereochemistry of enzymic epoxidation observed for the $\Delta^{4,6}$-dien-3-ones (**4**) can also be rationalized in terms of a stepwise process whose stereochemistry is dictated, not by enzyme specificity, but by the steric and stereoelectronic properties of the substrate. By analogy with the enzymic and chemical conversions of **11** to **14***b* and **15***b*, simple concerted epoxidation of the Δ^6 bond of **4** by *R. arrhizus* should proceed with α stereochemistry. Such is indeed the case for the peracid oxidation of **4** (21). The observed β epoxidation of **4** by *R. arrhizus*, however, in the absence of any discernable effects due to substrate binding (*vide supra*) cannot be attributed simply to enzyme specificity (cf. the α epoxidation of **11**).

Scheme 5 proposes a route for this reaction which is consistent with both the known features of the enzyme (Schemes 1 and 2), and the known steric and stereoelectronic properties exhibited during the epoxidation of the substrate and related molecules (27). The route proposed involves addition of the enzymes active site specie at C-7 of **4**, a process parallel to that of route B, Scheme 2. This process may give either resonance stabilized intermediate **22** or **23** but, by analogy with the preferred addition at C-5 of Δ^4-3-ketosteroids (20, 27), should proceed mainly from the β face to produce **22** whose subsequent closure to **12** would proceed without appreciable steric hindrance (27). In any event, the alternative C-7α intermediate **23** would, if formed, experience severe 1,3-diaxial interactions with the C-14 and C-15 hydrogens when correctly oriented for subsequent epoxide ring closure. An entirely analogous state of affairs prevents the formation of 4,5α epoxides from Δ^4-3-ketosteroids when bulky oxidants are used (27).

The enzymic 6,7α epoxidation of **4***a* to give **20** does in fact proceed with the C-7α hydroxylating fungus *Mucor griseocyanus*. This finding accords with the general observation (28) that fungi capable of introducing an axial hydroxyl group into a saturated steroid epoxidize analogous olefinic steroids with corresponding stereochemistry. In the case of *M. griseocyanus* and other fungi which epoxidize remote from existing functionality in the substrate, however, this effect follows from a spatial similarity of axial C—H and π electron density (2); such cannot be the case for the 6β hydroxylase of *R. arrhizus*, in view of the preferred α stereochemistry of epoxidation in the absence of the Δ^4 bond. The epoxidation of **11***a* and **11***b*, either chemical or enzymic, provides only the α epoxides **14***b* and **15***b*.

For the reasons discussed above, the results of the incubations of the Δ^6-3-ketosteroids **4** and **11** with *R. arrhizus* described herein are therefore most consistent with a stepwise oxidation mechanism for the enzymes as outlined in Schemes 4 and 5. This conclusion adds additional weight to the evidence now accumulating that the cytochrome P-450 mono-oxygenase enzymes act by the non-concerted one-electron pathways outlined in route B, Schemes 1 and 2.



SCHEME 5. Mechanism of 6,7β epoxidation of Δ^4-3-ketosteroids by *R. arrhizus*.

Experimental

Apparatus, materials, and methods

Melting points were determined on a Kofler heating stage and are uncorrected. Infrared spectra were recorded with a Perkin–Elmer 237B spectrometer. The nmr spectra were obtained with a Bruker WP 60, WP80 CW, or WH 400 (at the Southwestern Ontario NMR Centre, Guelph) using $CDCl_3$ as solvent and TMS as internal standard. Mass spectra were obtained with an AEI MS 30 spectrometer fitted with a Kratos DS-55 data system. Thin-layer chromatography was performed on Merck silica gel 60 F-254, and column chromatography on silica gel (60–200 mesh) or alumina. Elemental analyses were performed by Guelph Chemical Laboratories, Guelph, Ontario.

Incubations with fungi

Incubations with *Rhizopus arrhizus* ATCC 11145 (3) or *Mucor griseocyanus* ATCC 1207 (29) were performed as reported, unless otherwise stated.

Preparation of substrates

The following were prepared by published methods and gave satisfactory analytical data: androsta-4,6-diene-3,17-dione (**4***a*) (30), androsta-4,6-dien-17β-ol-3-one (**4***b*) (30), 17β-acetoxy-3-chloroandrosta-3,5-diene (**9***a*) (31), 3-(*N*-pyrrolideno)-androsta-3,5-dien-17-one (**9***b*) (32), 5β-androst-6-ene-3,17-dione (**11***b*) (33), and 5α-androst-6-ene-3β,17β-diol (**17**) (34). The following compounds were commercial samples: **1***a*, **1***b*, **1***c*, **7**, **8***a*, and **8***b*. Hitherto unpublished ^{13}C nmr spectra are presented in Table 1.

*Estra-4,6-dien-17β-ol-3-one (5*a*)*

This was prepared by a modification of the published method (35). A solution of estr-4-ene-17β-ol-3-one (5 g) and chloranil (3.35 g) in ethanol (500 mL) was stirred at 50°C for 2 h, and then evaporated to dryness under reduced pressure. The residue (8.3 g) was dissolved in chloroform (100 mL) and the solution allowed to stand until precipitation of the phenolic by-product was complete. The solution was then filtered, and the filtrate evaporated *in vacuo*. The residue so obtained comprised the desired product and starting material in approximately equal amounts. It was therefore redissolved in ethanol (500 mL) and the above reaction procedure repeated. The final residue from the evaporation of the chloroform solution was filtered through a column of basic alumina (150 g) in chloroform (200 mL). Evapo-

For personal use only.

ration of the resulting solution gave crude **5***a* (3.06 g) which was crystallized from ethyl acetate – hexane to give a sample (2.1 g) of mp 168–170°C; ^{1}H nmr included signals at δ 0.82 (3H, s, C-18 H), 3.70 (1H, t, J = 8 Hz, C-17α H), 5.78 (1H, br s, C-4 H), 6.20 (2H, s, C-6 and -7 H's) ppm; ^{13}C nmr: see Table 1.

*Androsta-4,6-diene-3β,17β-diol (**6**)*

A slurry of lithium tri-*tert*-butoxy aluminum hydride (2.5 g) in THF (100 mL) was added to a stirred solution of **4***b* (1 g) in THF (75 mL), and the mixture heated under reflux for 1 h. Following the usual work-up, the product **6** (0.8 g) was isolated, mp 192–195°C (lit. (36) mp 194–196°C); ^{1}H nmr include signals at δ 0.79 (3H, s, C-18 H), 0.98 (3H, s, C-19 H), 3.5–3.8 (1H, t, C-17α H), 4.0–4.4 (1H, m, C-3α H), 5.46 (1H, m, C-4 H), 5.62 and 5.96 (2H, AB q, J = 9 Hz, C-6 and C-7 H's) ppm.

*6-Methylene androst-4-en-17β-ol-3-one (**10**)*

This was prepared using synthetic methodology developed by Danishefsky *et al.* (16), and outlined in Scheme 3.

3-Trimethylsilyloxyandrosta-3,5-diene-17β-ol, acetate

Freshly distilled chlorotrimethylsilane (25 mL) followed by triethylamine (5 mL) were added to a stirred solution of testosterone acetate (**1***c*) in dry DMF (30 mL) and the resulting mixture refluxed with stirring for 48 h. The mixture was then cooled, diluted with pentane (100 mL), and washed with sodium bicarbonate solution. The aqueous washings were back extracted with pentane and the combined organic extracts washed rapidly with HCl (1.5 *M*) and aqueous sodium bicarbonate. The organic extract was then dried and evaporated to give a residue (1.6 g) which was dissolved in ether–hexane (1:3) and filtered through a short column of silica gel (60 g). In this way was obtained 1.35 g of the title compound, mp 86–88°C, which was used directly in the next step.

6ξ-Dimethylaminoandrost-4-en-17β-ol-3-one, 17 acetate

Working under a nitrogen atmosphere, Eshenmosher's salt (1 g, Aldrich) was dissolved in dry chloroform (20 mL, acid free) by heating for 10 min, after which time the enol silyl ether (above) (1.3 g) was added in three portions at 2-min intervals. The resulting mixture was stirred and refluxed for 45 min, cooled, and then acidified (concentrated HCl, 20 mL). The reaction mixture was stirred for a further 10 min, and the aqueous layer then separated. The organic layer was washed (dilute HCl, water), and the combined aqueous washings were basified and then extracted with ether (2 × 50 mL). The ethereal extract was evaporated to give a thick oil (1.1 g), ^{1}H nmr of which indicated the presence of the dimethylamino group (δ 2.24 ppm). This material was used directly in the next step.

*6-Methylene androst-4-ene-17β-ol-3-one (**10**)*

To a solution of the above Mannich base (1 g) in dry ether (20 mL) was added methyl iodide (7 mL). The resulting mixture was refluxed for 1h, cooled, filtered, and concentrated to half-volume, and refiltered. The quaternary iodide thus obtained (1.19 g) was dried *in vacuo* and used directly in the next step.

A mixture of the above salt (0.99 g) and DBU (0.1 g) in dry THF (5 mL) was refluxed for 1 h. The solvent was then removed by filtration, and the residue washed twice with ether. The combined organic extracts were evaporated to give a residue which was redissolved in ether. The resulting solution was washed (water), dried, and evaporated to give the product **10** (0.465 g). Recrystallization from chloroform–hexane gave a sample (0.4 g) of mp 167–168°C (lit. (37) mp 175°C; lit. (38) mp 110–112°C); ^{1}H nmr included signals at δ 0.81 (3H, s, C-18 H), 1.12 (3H, s, C-19 H), 3.65 (1H, t, C-17α H), 5.0 (2H, br d, =CH_2), and 5.9 (1H, s, C-4 H) ppm; ^{13}C nmr: see Table 1. *Anal.* calcd. for $C_{20}H_{28}O_2$: C 79.96, H 9.39%; found: C 80.06, H 9.03%.

*5α-Androst-6-ene-3,17-dione (**11**a)*

This was prepared by Jones' oxidation of 5α-androst-6-ene-3β,17β-diol (**17**) (34) (1.3 g). Conventional work-up afforded **11***a* (0.95 g from ethyl acetate), mp 156–158°C; ^{1}H nmr included signals at δ 1.06 (3H, s, C-18 H), 1.2 (3H, s, C-19 H), and 5.5 (2H, ABq, C-6 and -7 H's) ppm; ^{13}C nmr: see Table 1. *Anal.* calcd. for $C_{19}H_{26}O_2$: C 79.68, H 9.15%; found: C 79.79, H 9.32%.

Incubations with R. arrhizus

*Androst-4-en-17β-ol-3-one, acetate (**1**c)*

Incubation of **1***c* (4 g) gave extracts from the growth medium (3.4 g) and mycelia (2.8 g).

Starting material (1.34 g) was recovered from the latter extract as the only isolable steroid. Chromatography of the medium extract (silica gel, benzene/ether gradient) afforded further **1***c* (0.22 g) followed by androst-4-ene-11α,17β-diol-3-one, 17 acetate (**3**) (0.48 g), mp 153–155°C (ethyl acetate/hexane); ^{1}H nmr included signals at δ 0.88 (3H, s, C-18 H), 1.34 (3H, s, C-19 H), 2.06 (3H, s, OAc), 3.8–4.25 (1H, m, C-11β H), 4.66 (1H, t, C-17α H), and 5.77 (1H, s, C-4 H) ppm. *Anal.* calcd. for $C_{21}H_{30}O_4$: C 72.80, H 8.73%; found: C 72.89, H 8.91%. Further elution gave androst-4-ene-6β,17β-diol-3-one, 17 acetate (**2***c*) (0.53 g), mp 206–209°C (ethyl acetate/hexane) (lit. (39) mp 206–208°C); ^{1}H nmr included signals at δ 0.88 (3H, s, C-18 H), 1.50 (3H, s, C-19 H), 2.07 (3H, s, OAc), 4.34 (1H, br s, C-6α H), 4.68 (1H, t, C-17α H), and 5.80 (1H, s, C-4 H) ppm.

*Androsta-4,6-diene-3,17-dione (**4**a)*

Incubation of **4***a* (1.7 g) gave an extract from the growth medium (1.8 g) which was chromatographed as described above. Purification of intermediate fractions by preparative tlc afforded the following quantities of product. 6,7β-Epoxyandrost-4-ene-3,17-dione (**12***a*) (0.23 g), mp 210–213°C. ^{1}H nmr included signals at δ 0.97 (3H, s, C-18 H), 1.25 (3H, s, C-19 H), 3.46 (2H, br s, C-6,7 H's), and 6.18 (1H, s, C-4 H) ppm; ^{13}C nmr: see Table 2. *Anal.* calcd. for $C_{19}H_{24}O_3$: C 75.97, H 8.05%; found: C 75.82, H 7.87%. Androsta-4,6-diene-3,16-dione-17β-ol (**13**) (0.16 g), mp 178–180°C; ^{1}H nmr included signals at δ 0.83 (3H, s, C-18 H), 1.15 (3H, s, C-19 H), 3.81 (1H, s, C-17α H), 5.71 (1H, s, C-4 H), and 6.08 (2H, br s, C-6,7 H's) ppm; ^{13}C nmr: see Table 1. *Anal.* calcd. for $C_{19}H_{24}O_3$: C 75.97, H 8.05%; found: C 75.90, H 8.04%, and androsta-4,6-dien-17β-ol-3-one (**4***b*) (0.16 g), identical with an authentic sample.

*Androsta-4,6-dien-17β-ol-3-one (**4**b)*

Incubation of **4***b* (2 g) afforded extracts from medium (0.85 g) and fungal mycelia (3.01 g). The latter extract gave starting material (1.35 g) on column chromatography. Chromatography of the growth medium extract afforded **4***b* (0.28 g) followed by 6,7β-epoxyandrost-4-ene-17β-ol-3-one (**12***b*) (0.41 g), mp 197–199°C (ethyl acetate–hexane); ^{1}H nmr included signals at δ 0.82 (3H, s, C-18 H), 1.22 (3H, s, C-19 H), 3.34 (2H, s, C-6,7 H's), 3.65 (1H, t, C-17α H), and 6.14 (1H, s, C-4 H) ppm; ^{13}C nmr: see Table 2. *Anal.* calcd. for $C_{19}H_{26}O_3$: C 75.46, H 8.66%; found: C 75.26, H 8.70%.

*Estra-4,6-diene-17β-ol-3-one (**5**a)*

Incubation of **5***a* (1 g) gave extracts from the growth medium (0.85 g) and fungus (0.52 g). The latter afforded recovered **5***a* (0.18 g), while the former extract gave, following chromatography as described above, the following steroids.

Recovered **5***a* (0.48 g), followed by 5,6β-epoxyestr-4-en-17β-ol-3-one (**12***c*) (0.295 g), mp 194–197°C (ethyl acetate/hexane); ^{1}H nmr included signals at δ 0.82 (3H, s, C-18 H), 3.32 and 3.45 (2H, ABq, J = 4 Hz, C-6 and 7 H's), 3.72 (1H, t, C-17α H), and 6.25 (1H, d, J = 1.8 Hz, C-4 H) ppm; ^{13}C nmr: see Table 2. *Anal.* calcd. for $C_{18}H_{24}O_3.H_2O$: C 70.58, H 8.5%; found: C 70.67, H 8.0%. Mass spectrum indicated a molecular ion at m/z 288 of composition $C_{18}H_{24}O_3$. Also eluted was estra-4,6-diene-10β,17β-diol-3-one (**5***b*), mp 237–240°C (dec.) (ethyl acetate); ^{1}H nmr included signals at δ 0.77 (3H, s, C-18 H), 3.55 (1H, t, C-17α H), 5.57 (1H, s, C-4 H), and 6.10 (2H, s, C-6 and 7 H's) ppm; ^{13}C nmr: see Table 1. *Anal.* calcd. for $C_{18}H_{24}O_3$: C 74.97, H 8.39%; found: C 74.97, H 8.57%.

*Androsta-4,6-diene-3β,17β-diol (**6**)*

Incubation of **6** (0.5 g) for 36 h gave extracts from the medium (0.35 g) and fungus (0.2 g). Compound **6** (0.19 g) was recovered from the latter, and the former extract chromatographed to give 6,7β-epoxyandrost-4-en-17β-ol-3-one (**12***b*) (0.11 g), identical with the sample described above.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

*3-(*N*-pyrrolideno)-androsta-3,5-dien-17-one (**9***b*)

Incubation of **9***b* (2.0 g) for 36 h gave **1***a* (0.88 g) from the mycelial extract, and an extract of growth medium (1.54 g) which was chromatographed in the usual way to yield further **1***a* (0.21 g), androst-4-ene-3,6,17-trione (**16**) (0.09 g), androst-4-en-6β-ol-3,17-dione (**2***a*) (0.04 g), and androst-4-en-6α-ol-3,17-dione (**19**) (0.04 g). These compounds were all identical with authentic samples (5). A similar distribution of products was obtained from an incubation in which the *R. arrhizus* enzymes were denatured by autoclaving prior to the addition of substrate.

*5α-Androst-6-ene-3,17-dione (**11**a)*

Incubation of **11***a* (0.9 g) for 64 h gave an extract from the medium (1.3 g) from which **11***a* (0.7 g) was recovered. The medium extract was chromatographed to give 6,7α-epoxy-5α-androstane-3,17-dione (**15***b*) (0.04 g). Crystallization from chloroform–hexane gave a sample of mp 174–176°C; ^{1}H nmr included signals at δ 1.1 (3H, s, C-18 H), 1.16 (3H, s, C-19 H), and 2.8 and 3.2 (2H, m, 6β, 7β H's) ppm; ^{13}C nmr see Table 2. *Anal.* calcd. for $C_{19}H_{26}O_3$: C 75.50, H 8.61%; found: C 75.47, H 8.79%.

*5β-Androst-6-ene-3,17-dione (**11**b)*

Incubation of **11***b* (1 g) for 72 h gave an extract of fungus (0.35 g) from which **11***b* (0.27 g) was recovered, and an extract of growth medium (0.8 g) which was chromatographed to afford further **11***b* (0.23 g) followed by 6,7α-epoxy-5β-androstane-3,17-dione (**14***b*) (0.4 g), mp 165–166°C; ^{1}H nmr included signals at δ 0.86 (3H, s, C-19 H), 0.90 (3H, s, C-18 H), and 3.1 and 3.2 (2H, m, C-6β,7β H's) ppm; ^{13}C nmr: see Table 2. *Anal.* calcd. for $C_{19}H_{26}O_3$: C 75.50, H 8.61%; found: C 75.37, H 8.80%.

The following compounds, on incubation with *R. arrhizus*, gave no detectable trace of biotransformation. Only starting material was recovered in all cases. Estrone (**7**), estra-1,3,5(10),6-tetraene-3-ol-17-one (**8***a*), estra-1,3,5(10),6-tetraene-3,17β-diol (**8***b*), 3-chloro-androsta-3,5-diene-17β-ol, acetate (**9***a*), and 6-methyleneandrost-4-en-17β-ol-3-one (**10**).

Incubations with M. griseocyanus

*Androsta-4,6-dien-17β-ol-3-one (**4**b)*

Incubation of **4***b* (1.2 g) gave an extract of fungus from which **4***b* (0.8 g) was recovered, and a growth medium extract (0.2 g) which by spectral analysis (ir, ^{1}H nmr) was shown to consist of a mixture of starting material (**4***b*) and androsta-4,6-diene-3,17-dione (**4***a*) in approximately equal amounts. This mixture proved difficult to separate and was therefore not investigated further.

*Androsta-4,6-diene-3,17-dione (**4**a)*

Incubation of **4***a* (1 g) gave an extract of growth medium (0.82 g) which was chromatographed to give **4***a* (0.34 g) and 6,7α epoxy-androst-4-ene-3,17-dione (**20**), identical in all respects with an authentic sample (21); ^{13}C nmr: see Table 2.

Epoxidations of Δ^6 steroids

*5α-Androst-6-ene-3β,17β-diol (**17**)*

To an ice-cold, stirred solution of **17** (0.112 g) in dichloromethane (5 mL) was added a solution of *m*-chloroperoxybenzoic acid (0.1 g) in dichloromethane (5 mL). The reaction mixture was stirred overnight and then worked up in the usual manner to give **18** (0.94 g), mp 211–212°C; ^{1}H nmr included signals at δ 0.78 (6H, s, C-18 and -19 H's), 2.65 and 2.88 (2H, m, C-6β,7β H's), and 3.4–3.8 (2H, m, C-3α and 17α H's); ^{13}C nmr: see Table 2. *Anal.* calcd. for $C_{19}H_{30}O_3.H_2O$: C 70.33, H 9.94%; found: C 70.32, H 9.64%.

*5α-Androst-6-ene-3,17-dione (**11**a)*

Reaction of **11***a* (0.112 g) with *m*-chloroperoxybenzoic acid (0.1 g) as described above gave 6,7α-epoxy-5α-androstane-3,17-dione (**15***b*) (0.094 g), identical in all respects with the sample obtained by fungal oxidation of **11***a*.

*5β-Androst-6-ene-3,17-dione (**11**b)*

Reaction of **11***b* (0.286 g) with *m*-chloroperoxybenzoic acid (0.22 g) as described above gave 6,7α-epoxy-5β-androstane-3,17-dione (**14***b*) (0.27 g), identical in all respects with the sample obtained by fungal oxidation of **11***b*.

Charge distributions and chemical effects. XXXV. Polyunsaturated hydrocarbons, energy calculations from C-13 nmr spectra

S. FLISZÁR AND G. CARDINAL

Department of Chemistry, Université de Montréal, C.P. 6210, Succ. A, Montreal, Quebec, H3C 3V1

Received March 30, 1984

S. FLISZÁR and G. CARDINAL. Can. J. Chem. **62**, 2748 (1984).

Conjugated and nonconjugated dienes are well described in terms of bond energies featuring explicitly the electronic charges of the bond forming atoms. Using charges deduced from ^{13}C nuclear magnetic resonance shifts, this approach evaluates, ultimately, enthalpies of formation of conjugated molecules from ^{13}C nmr spectra, with an accuracy comparable to that achieved for nonconjugated molecules. The examples include typical dienes (like 1,3-butadiene, isoprene, dimethyl-1,3-butadiene, and 1,3-cyclohexadiene) which permit comparisons with experimental results, as well as predictions for larger systems (e.g., *trans*-1,4,9-decatriene and squalene).

S. FLISZÁR et G. CARDINAL. Can. J. Chem. **62**, 2748 (1984).

Les dienes conjugués et non conjugués sont bien décrits par l'utilisation d'énergies de liaison dépendant explicitement des charges électroniques des atomes liés. Les charges déduites de spectres de résonance magnétique nucléaire du carbone-13 conduisent, finalement, à des enthalpies de formation d'hydrocarbures conjugués avec une précision comparable à celle obtenue pour des molécules non conjuguées. Les systèmes étudiés comprennent des dienes typiques (tels que le butadiène-1,3, l'isoprène, le diméthyl butadiène-1,3 et le cyclohexadiène-1,3) permettant des vérifications expérimentales, ainsi que des prédictions pour des molécules plus complexes (le *trans* décatriène-1,4,9 et le squalène, par exemple).

Introduction

The theoretical evaluation of molecular energies in terms of electron distributions offers a vivid insight into fundamental, basically simple aspects relating to the nature of chemical bonding. This approach has the merit of permitting calculations at the level of experimental accuracy. Here we describe conjugated and non-conjugated double bond systems, and their energies, using charges deduced from ^{13}C nmr shifts — an approach leading, ultimately, to a calculation of enthalpies of formation from ^{13}C nmr spectra. Of course, the derivation of enthalpies also requires an adequate knowledge about vibrational energy. This, however, is another probem. Let us first look at chemical bonding.

The energy of atomization, ΔE_a^*, of a molecule in its hypothetical vibrationless state at 0 K is well described by a sum of individual bond energy terms,

$$[1] \quad \Delta E_a^* \simeq \sum_{j>i} \epsilon_{ij}$$

This approximation yields valid results because the omitted nonbonded Coulomb-type contributions are small in the first place (typically ~0.02−0.05% of ΔE_a^*), nearly additive and, finally, differ little between structural isomers so that they can easily (although not exactly) be incorporated in the ϵ_{ij}'s (1). For a representative group of 19 alkanes, for example, the average deviation between calculated and experimental ΔE_a^*'s is 0.16 kcal mol^{-1} when nonbonded terms are explicitly taken into account and 0.22 kcal mol^{-1} otherwise (1).

Structural effects are included in the *ij*-bond energy terms through the charges carried by atoms *i* and *j* (1, 2),[1]

$$[2] \quad \epsilon_{ij} = \epsilon_{ij}^0 + a_{ij}\Delta q_i + a_{ji}\Delta q_{ji}$$

So, for example, in ethane and cyclohexane the ϵ_{CC}'s are 69.633 and 72.783 kcal mol^{-1}, respectively, because the C atoms are somewhat electron richer in the latter molecule. It follows from eqs. [1] and [2] that

$$[3] \quad \Delta E_a^* \simeq \Sigma\epsilon_{ij}^0 + \Sigma_i\Sigma_j a_{ij}\Delta q_j$$

where $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ clearly describes the role of atomic charges, showing that structural isomers differing in their electron distributions (as a consequence of changes in their molecular wave functions) differ in the overall stability of their chemical bonds. This approach has proven highly successful in over 120 comparisons with experimental energies (1).

The present study concerns unsaturated hydrocarbons, particular attention being focussed on conjugated dienes, in an analysis involving only the basic physical content summarized in eqs. [2] and [3]. Equation [2] results primarily from an effort in developing simplified realistic models that capture the essence of the phenomena: that bond energies should depend on the charges of the bond-forming atoms comes as no surprise. The question asked here is one regarding the applicability of this approach to conjugated systems, and the way conjugation is perceived in a scheme essentially constructed in terms of localized bonds.

Outline of calculations

To begin with, let us describe the steps involved in numerical applications of eq. [3]. The proper evaluation of atomic charges may often enough turn into a problem (1). Luckily, on many occasions, carefully established correlations between theoretical charges and nuclear magnetic resonance shifts (3) provide the required information. Numerical details are given in Appendix 1, showing that the evaluation of the Δq_i's is straightforward, indeed, for the molecules considered in this work.

The next step consists in a calculation of the appropriate a_{ij}'s. This is done following the methods explained elsewhere (1, 2) and which are summarized in Appendix 2. Table 1 indicates the numerical a_{ij}'s which are required in this study.

The $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ term of eq. [3] is most efficiently evaluated as follows. Using the a_{ij}'s of Table 1, we begin with a calcu-

[1] In eq. [2], ϵ_{ij}^0 is the energy contribution of the bond formed by atoms *i* (with net atomic charge q_i^0) and *j* (with net atomic q_j^0); ϵ_{ij} is the energy of the same type of bond in which, however, the net charges of atoms *i* and *j* differ by Δq_i and Δq_j, respectively, from those of the "reference" bond with energy ϵ_{ij}^0. The a_{ij}'s indicate by how much a bond energy is affected by a unitary change in net charge at atom *i* bonded to *j*.

TABLE 1. Theoretical a_{ij} parameters, kcal mol^{-1} me^{-1}*

Bond i–j	a_{ij}
C(sp^3)—C(sp^3)	−0.488
C(sp^3)—C(sp^2)	−0.488
C(sp^2)—C(sp^3)	0.275
C(sp^2)—C(sp^2)	0.258
C(sp^2)=C(sp^2)	−0.183
C(sp^3)—H	−0.247
C(sp^2)—H	0.454
H—C(sp^3, sp^2)	−0.632

*Conversion factor: 1 au = 627.51 kcal mol^{-1}.

TABLE 2. Numerical evaluation of $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ for (*E*)-1,3-pentadiene*

Atom i	δ^{TMS}	Δq_i	$\Sigma_j a_{ij}$	$\Sigma_j a_{ij}\Delta q_i$
C-1	113.90	−1.335	0.725	−0.968
C-2	137.45	2.198	0.529	1.162
C-3	132.93	1.520	0.529	0.804
C-4	129.03	0.935	0.546	0.510
C-5	17.55	−1.769	−1.229	2.174
$\Sigma\Delta q_H$		26.152	−0.632	−16.528

*Charges and energies are in me and kcal mol^{-1}, respectively. The sum of all the $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ terms gives $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ = = −12.846 kcal mol^{-1}.

TABLE 3. Reference energies, kcal mol^{-1}, of bonds formed by atoms i and j with net charges as indicated in me*

Bond i—j	Reference charge i	Reference charge j	ϵ_{ij}^0
C(sp^3)—C(sp^3)	35.1	35.1	69.633
C(sp^3)—C(sp^2)	35.1	7.7	77.69
C(sp^2)—C(sp^2)	7.7	7.7	89.70
C(sp^2)=C(sp^2)	7.7	7.7	139.27
C(sp^3)—H	35.1	−11.7	106.806
C(sp^2)—H	7.7	−11.7	110.68

*Results extracted from refs. 1, 2, and 4, except for the C(sp^2)—C(sp^2) bond.

lation of $\Sigma_j a_{ij}$ for each individual carbon atom. (A methyl-C atom attached to another carbon, for example, gives $\Sigma_j a_{ij}$ = 3(−0.247) + (−0.488) = −1.229 kcal mol^{-1} me^{-1}.) By means of the Δq_C's deduced from nmr shifts (Appendix 1), we now obtain $\Delta q_i\Sigma_j a_{ij} = \Sigma_j a_{ij}\Delta q_i$. The sum of these atomic terms over all carbon centers i gives the corresponding part of $\Sigma_i\Sigma_j a_{ij}\Delta q_i$. The contribution of the hydrogens is included in the final result by adding the appropriate $\Sigma_i a_{HC}\Delta q_{Hi} = a_{HC}\Sigma\Delta q_H$ term, where $\Sigma\Delta q_H$ is deduced from charge normalization (Appendix 1). A detailed numerical example is worked out in Table 2, illustrating the simplicity of this approach.

The final step consists in the evaluation of the sum of reference bond energies, $\Sigma\epsilon_{ij}^0$. All the ϵ_{ij}^0's (Table 3) are known from previous work on alkanes (1, 2) and alkenes (1, 4) with one exception, namely, the ϵ_{CC}^0 describing the CC "single" bond formed by two sp^2 carbons at a distance of ~1.46 Å (like the central CC bond in 1,3-butadiene). For the latter, a theoretical estimate (Appendix 3) suggests a value in the neighborhood of ~93 kcal mol^{-1} in a planar conjugated system. This sort of result from SCF data, however, is limited in precision. It turns out, from a comparison with experimental energies, that 89.70 kcal mol^{-1} represents a more realistic estimate, at the very demanding level of experimental accuracy. The agreement with its theoretical counterpart is surely acceptable, considering the uncertainties associated with the latter (Appendix 3).

There is one final point to be considered. Energy calculations (1, 4) indicate that the results for *cis*-, *gem*-disubstituted and trialkylsubstituted ethylenes deviate slightly but consistently from experimental ΔE_a^*'s, quite unlike what is observed for mono-alkyl- and *trans*-dialkylsubstituted ethylenes, and tetramethylethylene. This effect is possibly due to differences in local geometries about the ethylenic carbons (3*b*) and the ensuing changes in hydridization (5) affecting charge-shift relationships (1, 4). Presently, small effects of this sort unfortunately resist their theoretical evaluation, at least at the degree of accuracy required in the present work. For mono-olefins, the simplest way of handling this problem is to treat all olefins as indicated above and to include a correction of +0.56 kcal mol^{-1} into $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ for each double bond presenting a *cis*-, *gem*-disubstitution, or trisubstitution situation (4) — an approach which is followed also in the present study of poly-olefins. This correction is primarily made to accommodate possible users of our methods in thermochemical problems: it does not alter the basic tenet of this theory, i.e., the charge dependence of the individual bond energy contributions which is predicted by eq. [2].

We can now proceed with applications and assess the validity of the methods outlined in this section.

Results

In order to offer valid comparisons with theoretical results, we must first deduce "experimental" atomization energies from experimental enthalpies of formation, ΔH^0_f (gas, 298.15 K), zero-point and heat-content energies, ZPE + H_T − H_0, and from the enthalpies of formation, ΔH^0_f(A), of the atoms. The latter are taken from literature (6), i.e., ΔH^0_f(C) = 170.89 and ΔH^0_f(H) = 52.09 kcal atg^{-1}. The appropriate equation is, for nonlinear molecules, at 298.15 K,

$$[4]\quad \Delta E_a^* = \Sigma n_i[\Delta H^0_f(A_i) - \tfrac{5}{2}RT] + \mathrm{ZPE} + H_T - H_0 - \Delta H^0_f$$

Vibrational energy data are relatively scarce, however. Fortunately they can be constructed to a good approximation by means of additivity rules (1), e.g., ZPE + H_T − H_0 ≃ 33.35 + 18.213(n − 2) − 0.343n_{br} for mono-olefins with n carbon atoms and n_{br} = number of branchings. Similar equations are also found to apply in other homologous series of compounds. Along these lines, we use the following appoximation for dienes, based on the experimental ZPE + H_T − H_0 value (55.19 kcal mol^{-1}) deduced for 1,3-butadiene in the harmonic oscillator approximation (1):

$$[5]\quad \mathrm{ZPE} + H_T - H_0 \simeq 55.19 + 18.213(n-4) - 0.343n_{br}\ \text{kcal mol}^{-1}$$

While this type of estimate usually carries an uncertainty not exceeding ~0.2 kcal mol^{-1}, it remains that for the dienes (as for mono-olefins) no spectroscopic information is presently available which would discriminate ZPE + H_T − H_0 energies of *cis* and *trans* isomers in a reliable manner. It is thus possible that part of the correction of 0.56 kcal mol^{-1} discussed pre-

TABLE 4. Energy analysis of selected diolefins (kcal mol^{-1})*

Molecule	ΔH^0_f	ZPE+$H_T - H_0$	$\Sigma\epsilon^0_{ij}$	$\Sigma_i\Sigma_j a_{ij}\Delta q_i$	ΔE^*_a Calcd.	ΔE^*_a Exptl.
1 1,3-Butadiene	26.33	55.19	1032.32	−22.41	1009.9	1010.1
2 (*Z*)-1,3-Pentadiene	19.77	73.40	1319.75	−14.09	1305.7	1305.6
3 (*E*)-1,3-Pentadiene	18.77	73.40	1319.75	−12.85	1306.9	1306.6
4 Isoprene	18.06	73.06	1319.75	−13.09	1306.7	1306.9
5 1,4-Pentadiene	25.25	73.40	1311.61	−11.61	1300.0	1300.1
6 1,5-Hexadiene	20.11	91.60	1594.86	−0.99	1593.9	1594.0
7 DiMe-1,3-butadiene	10.78	90.93	1607.18	−4.20	1603.0	1602.7
8 1,3-Cyclohexadiene	25.38	77.80	1463.20	10.98	1474.2	1473.7

*The ΔH^0_f values are taken from ref. 7 (**1**–**3**) and ref. 8 (**4**–**8**). The ZPE + $H_T - H_0$ values are deduced following the rules given in ref. 1, as indicated in the text. The appropriate ^{13}C nmr shifts are literature values (see Appendix 1).

NOTE ADDED IN PROOF. From experimental Raman and infrared vibrational frequencies given by Compton *et al.* (27), we find in the harmonic oscillator approximation that ZPE + $H_T - H_0$ = 73.32 kcal mol^{-1} for **3**. Similarly, we find for **2** that ZPE + $H_T - H_0$ = 73.28 kcal mol^{-1}, using experimental frequencies given by the same authors and results calculated by Panchenko *et al.* (28). Finally, using frequencies calculated by the latter authors and, whenever available, experimental results from Durig and Compton (29), we find for **7** that ZPE + $H_T - H_0$ = 91.08 kcal mol^{-1}.

TABLE 5. Predicted energies (kcal mol^{-1}) of selected di- and polyolefins*

Molecule	$\Sigma\epsilon^0_{ij}$	$\Sigma_i\Sigma_j a_{ij}\Delta q_i$	ΔE^*_a	ZPE+$H_T - H_0$	ΔH^0_f

*The ^{13}C nmr spectra used in these calculations are from ref. 10 (**1**–**3**), ref. 11 (**4**–**11**), and ref. 12 for **12**.

viously covers, in fact, an incomplete description of vibrational energy contributions. Additional spectroscopic analyses would be highly desirable in this area.

With these (minor) reservations in mind, we can now compare atomization energies derived from experimental data with their counterparts deduced from eq. [3]. The results are indicated in Table 4. The average deviation (0.23 kcal mol^{-1}) between calculated and experimental results is well within experimental uncertainty limits and resembles the outcome of earlier energy analyses presented for paraffins, six-membered cycloalkanes, olefins, ethers, and carbonyl compounds (1).

The quality of these results certainly encourages us to offer predictions for related systems (Table 5). The validity of calculated enthalpies rests, of course, largely with the approximations involved in the estimate of ZPE + $H_T - H_0$ energies. The use of vibrational energies constructed on the basis of regular group increments may be regarded acceptable in simple cases like those investigated here (1). However, one should refrain from extrapolations in very large or highly crowded systems until these are adequately supported by spectroscopic evidence. Reversing the approach, one could profit from additional experimental enthalpies of formation obtained by traditional thermochemical methods and/or from appropriate enthalpies of hydrogenation and thus gain access to a new generation of ZPE + $H_T - H_0$ energies using eq. [4] and calculated atomization energies. This type of information would be valuable because it would extend our knowledge concerning ZPE + $H_T - H_0$ energies, and their construction from empirical rules, to classes of compounds which are presently beyond what can be safely inferred from the body of "small" molecules considered in this study. This being said, the predicted ΔH^0_f values given in Table 5 should represent reasonably good estimates.

In selecting the conjugated hydrocarbons indicated in Tables 4 and 5, attention was given to their geometry, essentially planar in their preferred conformations, in order to avoid situations disrupting conjugation. The exception is offered by 1,3-cyclohexadiene, in which a slight departure from planarity (~12–18°) appears to be real for the double bond system (9), thus allowing a staggered conformation for the CH bonds of the two CH_2 groups. Indeed, our calculation appears to overestimate the stability of this compound by a small margin: this could perhaps be taken as an indication for a partial loss in conjugation although, evidently, only limited weight should be given to the numerical value (~0.5 kcal mol^{-1}) describing this discrepancy. Comments on the disruption of conjugation due to changes in geometry are offered further below.

First, it appears interesting to draw attention on a simple method which, besides being instructive in its own way, per-

TABLE 6. Charge effects in saturated and unsaturated hydrocarbons, the $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ results (kcal mol^{-1}) are "reduced" values*

Parent alkane	$\Sigma_i\Sigma_j a_{ij}\Delta q_i$	Unsaturated hydrocarbon	$\Sigma_i\Sigma_j a_{ij}\Delta q_i$
C_4 Butane	20.82	1-Butene	19.57
		(*Z*)-2-Butene	20.84
		(*E*)-2-Butene	22.01
		1,3-Butadiene	20.90
C_5 Pentane	31.25	1-Pentene	30.18
		(*Z*)-2-Pentene	31.65
		(*E*)-2-Pentene	32.49
		(*Z*)-1,3-Pentadiene	33.41
		(*E*)-1,3-Pentadiene	34.65
		1,4-Pentadiene	27.75
C_{10} Decane	81.31	1-Decene	82.34
		(*E*)-5-Decene	85.06
		1,9-Decadiene	79.76
		(*E*)-1,4,9-Decatriene	80.88
C_6 Cyclohexane	60.60	Cyclohexene	60.59
		1,3-Cyclohexadiene	62.66
		1,4-Cyclohexadiene	59.90

*The value quoted for 1,4-cyclohexadiene is for $\Delta E_a^* = 1471.42$ kcal mol^{-1}, calculated from the ^{13}C nmr spectrum given in ref. 11; assuming ZPE + $H_T - H_0 = 77.8$ kcal mol^{-1} (1), this result corresponds to $\Delta H^0_f = 27.7$ kcal mol^{-1} (1) (gas, 298.15 K). The value for 1-decene was obtained from the experimental ΔE_a^*, eq. [4], using $\Delta H^0_f = -29.48$ kcal mol^{-1} (8) and that for (*E*)-5-decene was deduced from its ^{13}C nmr spectrum (11). The result indicated for decane corresponds to $\Delta H^0_f = -59.64$ kcal mol^{-1} (8). The results for butane, pentane, cyclohexane, and the butene and pentene isomers are extracted from ref. 1. Numerous additional examples follow from $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ results for alkanes and alkenes (1, 2, 4, 13) and those indicated in Tables 4 and 5.

mits a back-of-the-envelope check of ΔE_a^* energies calculated from eq. [3].

Dehydrogenation of hydrocarbons

Up to this point, the appropriate $\Sigma\epsilon_{ij}^0$ sums were deduced from the set of reference bond energies indicated in Table 3. The $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ terms given in Tables 4 and 5 were calculated accordingly. However, one could have selected a simpler set of reference bond energies, namely, the 69.633 value for all CC single bonds, 139.27 for the CC double bond, and 106.806 kcal mol^{-1} for all CH bonds. The latter reference set was, indeed, used in earlier work on olefins (1, 4). Its use renders energy calculations somewhat more involved than those presented in this study because the changes from 69.633 to 77.69 and from 106.806 to 110.68 kcal mol^{-1} for CC and CH bonds, respectively, accompanying the replacement of an sp^3 by an sp^2 carbon, become part of the $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ term. It is instructive to examine the latter $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ term, identified here as "reduced" term. In order to derive it, we calculate ΔE_a^* as shown in this work (which is the "easy" way) and subtract the appropriate $\Sigma\epsilon_{ij}^0$ part involving only $\epsilon_{CC}^0 = 69.633$ (for any single CC bond), $\epsilon_{CH}^0 = 106.806$ (for any CH bond), and $\epsilon_{C=C}^0 = 139.27$ kcal mol^{-1} for each double bond. The results are indicated in Table 6.

The results are self-explanatory. It appears, indeed, that dehydrogenation does not affect the "reduced" $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ energy contribution if we are ready to accept, at this rough level of approximation, discrepancies of a few kcal mol^{-1}. The "quasi constancy" of the "reduced" $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ term during dehydrogenation draws attention on the $\Sigma\epsilon_{ij}^0$ part of eq. [3]: the removal to two CH bonds (-2×106.806) and the replacement of a single CC bond (-69.633) by a double bond ($+139.27$ kcal mol^{-1}) translates into a decrease of $\sim$144 kcal mol^{-1} in ΔE_a^* energy. Briefly, it suffices to subtract $\sim$144 kcal mol^{-1} from the atomization energy of a hydrocarbon in order to obtain a rough estimate for the ΔE_a^* of the corresponding dehydrogenated parent compound. For example, *n*-decane ($\Delta E_a^* = 3057.74$ kcal mol^{-1}) yields estimates of 2769.7 kcal mol^{-1} for decadiene and 2625.7 kcal mol^{-1} for decatriene, in satisfactory agreement with the results given in Table 5. This regularity enables a rapid cross-checking of ΔE_a^* results. More generally, however, it shows the link relating to one another the various classes of saturated and unsaturated hydrocarbons, including allenic, acetylenic, and aromatic hydrocarbons (13).

Conjugation

The electron diffraction investigation of the molecular structure of 1,3-butadiene vapor indicates that the planar *trans* form is predominating: no signs of other conformations were observed (14), a result which is convincingly suported by *ab initio* MO theory (15), at the level of minimal (STO-3G) and extended (4−31G, 6-31G, 6-31G*, (7*s*3*p*|3*s*), and larger) basis set calculations. Structural parameters were determined (14, 16), namely, r(C—C) = 1.463 ± 0.003, r(C=C) = 1.341 ± 0.002, and r(C—H) = 1.090 ± 0.004 Å. While the double bond is, in essence, that of ethylene itself (a fact which led us to treat all double bonds on the same footing), the single CC bond of 1,3-butadiene is significantly shorter than the "usual" single bonds, i.e., those formed by two sp^3 carbon atoms. The short CC single bond and the planar equilibrium conformation have been attributed to π-electron delocalization which gives the single bond some amount of double bond character and is most effective in the planar molecule (17). It became apparent, however, that delocalization was less than predicted by the simple Hückel method (18) and the CC bond shortening was then attributed to the change in hybridization of the bond-forming atoms (19). These points merit attention in the interpretation of anticipated energy effects resulting from steric constraints which would force non-coplanarity of the two double bond systems.

Extended basis set SCF MO calculations indicate that, indeed, resonance is the main factor responsible for the shortening of the CC single bond in the planar *s-trans* conformation of 1,3-butadiene (20, 21). In this conformation the distinction between σ and π electrons is evident. For the perpendicular case, on the other hand, it is always possible to define one localized π MO on each C=C fragment. The SCF localized π MO located on one of the C=C moieties has σ tails on the other C=C fragment and the σ MO's of each C=C moiety have components on the $2p_y$ atomic orbitals associated with the other fragment. This effect which is known as hyperconjugation has been found to stabilize the perpendicular form, largely compensating the lack of π conjugation, and leads to a similar shortening of the central CC bond (21).

Ab initio analyses thus substantiate the concept of π conjugation in the planar conformation and extend it to hyperconjugation in perpendicular forms. Direct calculations of resonance energies lead to estimates in the neighborhood of $\sim$10 kcal mol^{-1} (20, 21). Here, resonance energy is defined in its original sense as the energy difference between the conjugated system and its reference state without resonance, the latter being represented by a model wave function consisting of strictly localized nonresonating π molecular orbitals. Hyperconjugation energy is defined in similar manner (21). The hyperconjugative stabilization in the perpendicular form at

its SCF optimum distance (~1.5 Å) turns out to be almost as large (~8.0 kcal mol^{-1}) as the π conjugation energy in the equilibrium planar conformation (~10.4 kcal mol^{-1} at ~1.48 Å) (21). This change from resonance to hyperconjugative stabilization of the central CC bond, however, is not reflected in the $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ term because the latter considers only the effects of varying electron populations at the bond-forming atoms under otherwise identical conditions. Rather, the change in geometry from a planar to a nonplanar form which is at the origin of the loss in conjugation in favor of a hyperconjugative stabilization should be contained in an appropriate change in the reference bond energy ϵ^0_{CC}.

The extent of the change in ϵ^0_{CC}, however, is difficult to evaluate theoretically. A valuable rough estimate is offered by the SCF results discussed above (21) indicating that hyperconjugative stabilization is less effective (by ~2.4 kcal mol^{-1}) than π conjugation. This estimate is similar to the familiar thermochemical resonance energy of some 3 kcal mol^{-1} (22) and suggests that the reference bond energy ϵ^0_{CC} in a markedly nonplanar situation should be lower by approximately that amount relative to that applicable in a planar resonating arrangement.

While π conjugation and/or hyperconjugation are certainly important contributions to the thermochemical stability of CC single bonds embedded in double bond systems, molecules featuring this arrangment (e.g., 1,3-butadiene) still appear to be strongly localized (i.e., poorly conjugated). Of course, this fact is well known from simple π-Hückel theory with equal CC resonance integrals leading to alternating π bond orders. In this sense, keeping in mind the features linked to π conjugation vs. hyperconjugation revealed by SCF theory, it remains valid to apply our bond energy scheme, eqs. [1]–[3], to conjugated systems. The understanding, however, is that π conjugation and/or hyperconjugation effects must be adequately included in the appropriate ϵ^0_{CC} terms.

Conclusion

It is concluded that our bond energy scheme featuring explicitly the charges of the bond-forming atoms can be applied successfully to conjugated hydrocarbons, with an accuracy comparable to that achieved for nonconjugated molecules. In essence, the calculations are carried out in precisely the same manner as for monoolefins. The only new term involved is that of the bond energy contribution, ϵ^0_{CC} = 89.7 kcal mol^{-1}, describing a conjugated CC bond in planar arrangement of the unsaturated moieties. Extention of these views to aromatic hydrocarbons is to be presented shortly.

Appendix 1

Evaluation of atomic charges

For typical sp^3 carbons (such as in linear and branched paraffins and six-membered cycloalkanes), the change in net charge (Δq_C) with reference to the ethane-C atom is deduced from eq. [A1] (1)

$$[A1] \quad \Delta q_C(sp^3) = -0.148\delta^{C_2H_6} \text{ me}$$

where $\delta^{C_2H_6}$ is the ^{13}C nmr shift relative to ethane (~5.6 ppm from TMS). Similarly, for ethylenic sp^2 carbons, we use (1, 4)

$$[A2] \quad \Delta q_C(sp^2) \simeq 0.15\delta^{C_2H_4} \text{ me}$$

where $\delta^{C_2H_4}$ is the shift relative to ethylene (taken at 122.8 ppm from TMS) and Δq_C is the change in net charge relative to the ethylene-C atom. The validity of eq. [A1] is well supported by theoretical charges (1, 3) and by numerous energy calculations relying on charges derived from this expression. Its accuracy is important because the saturated hydrocarbon part of organic molecules usually controls a major portion of $\Sigma_i\Sigma_j a_{ij}\Delta q_i$. Unfortunately, the validity of eq. [A2] is presently not assessed as firmly as desired. However, charge contributions of sp^2 carbons generally turn out to be relatively modest so that calculated $\Delta E_a^{\ddagger}$s are not invalidated by uncertainties associated with eq. [A2] — as illustrated by the results obtained for mono-olefins (4).

As regards the hydrogen atoms, we proceed as follows. First, the carbon net charges are calculated from $q_C(sp^3) = 35.1 - 0.148\delta^{C_2H_6}$ and $q_C(sp^2) = 7.7 + 0.15\delta^{C_2H_4}$ me, where 35.1 = C net charge in ethane (1, 2) and 7.7 = ethylene-C net charge (4), in me units. Using these results, the sum (over all C atoms) Σq_C is formed, giving

$$\Sigma q_H = -\Sigma q_C$$

Next, we calculate what the *total* net charge of all the hydrogen atoms of the molecule would have been, had each H net charge been taken at its reference value, −11.7 me (i.e., the H net charge in ethane). Briefly, we calculate $-11.7n_H$, with n_H = number of H atoms in the molecule under scrutiny. (This selection of a reference H charge imposes a constraint in the definition of reference CH bond energies, ϵ_{CH}^0, which is properly taken into account). Finally, we obtain

$$[A3] \quad \Sigma\Delta q_H = \Sigma q_H + 11.7n_H \text{ me}$$

for use in the calculation of $\Sigma_i a_{HC}\Delta q_{Hi} = a_{HC}\Sigma\Delta q_H$.

For the readers' convenience, we indicate in Table [A1] selected ^{13}C nmr results which are used in this work.

Appendix 2

The a_{ij} parameters are deduced from the expression (1, 2)

$$a_{ij} = \frac{1}{\nu_i}\frac{3/7}{K_i^{mol}}\left[\left(\frac{\partial E_i^{vs}}{\partial N_i}\right)^0 - \frac{1}{2}\left(\frac{\partial^2 E_i^{vs}}{\partial N_i^2}\right)^0 \Delta q_i\right] - \frac{3}{7}Z_i^{eff}\langle r_{ij}^{-1}\rangle^0$$

For small Δq_i's (as for C and H), the second order derivative of E_i^{vs} (the valence state energy of atom i) with respect to N_i (the electron population of i) can be safely neglected. The first derivatives $(\partial E_i^{vs}/\partial N_i)^0$ are (from SCF-Xα calculations) −0.735 for C(sp^3), −0.244 for C(sp^2)-π electrons, −0.375 for C(sp^2)-σ electrons and −0.195 au (hartrees) for hydrogen (1, 2, 4). The other quantities are: ν_i = number of atoms bonded to i; K_i^{mol} = constant for each atomic species (= 1/2 for H, ~3/7 for any other atom); Z_i^{eff} = effective nuclear charge of atom i (1 for H, 4 for C); $\langle r_{ij}^{-1}\rangle^0$ = average inverse distance between the electrons of i and nucleus Z_j, corresponding to r_{CH} = 1.08 (σ electrons of sp^3 or sp^2C), r_{CH} = 1.10 (π electrons of sp^2 carbon), r_{CC} = 1.53 (sp^3—sp^3), r_{CC} = 1.34 (sp^2—σ electrons) and r_{CC} = 1.30 (sp^2—π electrons) for double bonds, r_{CC} = 1.46 (sp^2—sp^2 single bond) for σ electrons, viz. 1.48 for π electrons, r_{CC} (sp^2—sp^3) = 1.53 for σ electrons, and 1.55 Å for π electrons of the sp^2 carbon atom. The conversion factors 1 bohr = 0.529 Å and 1 hartree = 627.51 kcal mol^{-1} were used. For ethylenic sp^2 carbons, the appropriate average a_{ij}'s (Table 1), accounting for the fact that electron populations vary at both the σ and π levels, are deduced from the equation (4)

$$a_{ij} = (ma_{ij}^{\sigma} + a_{ij}^{\pi})/(m + 1)$$

with $m = -0.955$. These parameters are precisely those which were described and used in earlier calculations of saturated and unsaturated hydrocarbons.

Appendix 3

The reference bond energies are deduced from the equation (1, 2)

$$[A4] \quad \epsilon_{ij} = K_i^{mol}Z_i\left(\frac{\partial\epsilon_{ij}}{\partial Z_i}\right) + K_j^{mol}Z_j\left(\frac{\partial\epsilon_{ij}}{\partial Z_j}\right) + (K_i^{at} - K_i^{mol}) \times V_{ne}(\text{at } i)/\nu_i + (K_j^{at} - K_j^{mol})V_{ne}(\text{at } j)/\nu_j$$

where V_{ne} (at i) and V_{ne} (at j) are the nuclear−electronic potential energies of the isolated atoms i and j, respectively, and ν_i, ν_j the number of bonds these atoms form in the molecule. The constants K_i^{mol} (=0.4287 for C and 1/2 for H atoms in the molecule) and K_i^{at} (= 0.4276 for C and 1/2 for H, referring to isolated ground-state atoms) were deduced (1, 2) from near Hartree−Fock results. The derivatives $(\partial\epsilon_{ij}/\partial Z_i)$ are obtained from the equation (1, 2)

TABLE A2. Optimized structure of *trans*-1,3-butadiene in the $[5s3p|3s]$ basis set

Parameter	Calculated value	
	$[5s3p\|3s]$	Skaarup (19)
r(C—C)	1.4704 Å	1.453 Å
r(C=C)	1.3249	1.320
r(C$_2$—H)	1.0758	1.074
r(C$_1$—H)(Z)	1.0741	1.073
r(C$_1$—H)(E)	1.0717	1.071
∠C—C=C	124.34°	124.7°
∠C=C—H(E)	121.85	121.8
∠C=C—H(Z)	121.91	121.8
∠C=C$_2$—H	119.65	119.6

[A5] $$Z_i\Sigma_j\left(\frac{\partial\epsilon_{ij}}{\partial Z_i}\right) \simeq V_{ne}(\text{at } i) - V(i, \text{mol})$$

where, in conventional notations,

$$V(i, \text{mol}) = -Z_i\int\frac{\rho(\boldsymbol{r})}{|\boldsymbol{r} - \boldsymbol{r}_i|}d\boldsymbol{r} + Z_i\sum_{j\neq i}Z_j/r_{ij}$$

is the total (nuclear−electronic and nuclear−nuclear) potential energy involving Z_i, where r_{ij} is the ij internuclear distance.

From $[5s3p|3s]$ SCF results we obtain V_{ne}(at C) = −87.9315 au as well as $\partial\epsilon_{CH}/\partial Z_C \simeq 0.026$ au (1, 2, 13). For 1,3-butadiene in its optimized geometry (using the same basis set), it is found that $V(i, \text{mol}) = -88.42836$ and −88.34076 au for carbons 1 and 2, respectively. Applying eq. [A5] it follows that $\partial\epsilon_{C=C}/\partial Z_C \simeq 0.0308$ au (C-1) and $\partial\epsilon_{C=C}/\partial Z_C + \partial\epsilon_{C-C}/\partial Z_C \simeq 0.0422$ au (C-2). Using these results and eq. [A4] it is found that the sum of the two double bonds plus the CC single bond in butadiene amounts to ~357 kcal mol^{-1}. On the other hand, the ethylenic double bond is ~133.7 kcal mol^{-1} in this basis set (1, 2, 13), giving an estimate of ~89.6 kcal mol^{-1} for the central CC bond. This bond energy is thus 1.343 times that of the ethane CC bond calculated in the same way (66.7 kcal mol^{-1}). Finally, referring now to the appropriate CC bond in ethane (69.633 kcal mol^{-1}), present results lead to an estimate of ~93.5 kcal mol^{-1} for the central CC bond in butadiene. This estimate, however, is not yet the final one. Using eq. [2] and the appropriate a_{ij}'s of Table 1, the charges deduced from $\delta^{C_2H_4} = -6.2$ and 14.4 ppm for C-1 and C-2, respectively, indicate that each butadiene double bond energy is 0.225 kcal mol^{-1} less than that of ethylene (which was used in this evaluation), whereas the central CC bond in butadiene is 1.11 kcal mol^{-1} larger than what would be the case for two sp^2 carbons having the same charge as in ethylene. Taking these corrections into consideration, the final estimate of ϵ^0_{CC} must be lowered by 1.11−0.45 = 0.66 kcal mol^{-1}, giving ~92.9 kcal mol^{-1}. This sort of theoretical prediction is perforce limited in precision. It appears nonetheless to be a realistic one, as indicated by its empirical counterpart, 89.70 kcal mol^{-1}. Possible slight changes of the corresponding C(sp^2)—C(sp^2) bond distance in higher polyenes should not affect the validity of this estimate because any anticipated effect would only be minor (1, 26).

In the $[5s3p|3s]$ contracted basis set, the optimized geometry is as indicated in Table A2. The virial theorem is reasonably well satisfied ($V/T = -1.9989$), which is important because this theorem, as well as the Hellmann−Feynman theorem applied to molecules at equilibrium, are part of the derivation of eqs. [A4] and [A5].

Received January 26, 1984

LAURENCE KENNETH THOMPSON, FREDERICK W. HARTSTOCK, PHILLIP ROBICHAUD, and A. W. HANSON. Can. J. Chem. **62**, 2755 (1984).

The synthesis and study of a series of copper(II) complexes of a biologically relevant binucleating ligand, 1,4-di(1′-methyl-2′-imidazolyl)phthalazine (MIP) is reported. The binuclear complex $[Cu_2(MIP)(OH)Cl_3(H_2O)]H_2O$ has been characterized by single crystal X-ray diffraction and belongs to the space group $P2_1/n$ with $a = 10.063(1)$, $b = 20.967(1)$, $c = 9.919(1)$ Å, $\beta = 96.48(1)°$, $V = 2079.4$ Å^3, $Z = 4$. The copper coordination geometry is square pyramidal and the two copper(II) centres are bridged by two groups: N_2 (phthalazine) and hydroxide. A large metal–metal separation (3.425 Å) and Cu—O—Cu bridge angle (126.2°) are considered to be a dominant factor responsible for the very large antiferromagnetic exchange present in this system ($-2J = 800$ cm^{-1}). A comparison of $-2J$ and the Cu—O—Cu bridge angle shows that for a related series of complexes with the same basic binuclear centre and a $d_{x^2-y^2}$ copper ion ground state an approximately linear relationship exists.

LAURENCE KENNETH THOMPSON, FREDERICK W. HARTSTOCK, PHILLIP ROBICHAUD et A. W. HANSON. Can. J. Chem. **62**, 2755 (1984).

On rapporte la synthèse et l'étude d'une série de complexes de cuivre(II) d'un ligand bidentate présentant un intérêt du point de vue biologique, soit la di(méthyl-1′ imidazolyl-2′)-1,4 phthalazine (MIP). Faisant appel à la diffraction des rayons-X sur un cristal unique, on a caractérisé le complexe binucléaire $[Cu_2(MIP)(OH)Cl_3(H_2O)]H_2O$ qui appartient au groupe d'espace $P2_1/n$ avec $a = 10{,}063(1)$, $b = 20{,}967(1)$, $c = 9{,}919(1)$ Å, $\beta = 96{,}48(1)°$, $V = 2079{,}4$ Å^3, $Z = 4$. Le cuivre a une géométrie de coordination pyramidale à base carée et les deux ions cuivriques sont reliés par un pont formé de deux groupes: N_2 (phtalazine) et hydroxyde. On considère que la grande distance métal–métal (3,25 Å) et l'angle du pont Cu—O—Cu (126,2°) sont les facteurs les plus responsables de l'échange ferromagnétique important qui est présent dans ce système ($-2J = 800$ cm^{-1}). Si on compare les valeurs de $-2J$ et les angles du pont Cu—O—Cu d'une série de complexes apparentés possédant le même centre binucléaire de base et un état fondamental $d_{x^2-y^2}$ pour l'ion cuivrique, on peut démontrer qu'il existe une relation approximativement linéaire pour ces valeurs.

[Traduit par le journal]

Introduction

Single hydroxy bridges have been shown to mediate strong antiferromagnetic exchange between copper(II) centres, depending on the oxygen bridge angle and the ground state of the metal ion (1–4) and in some cases very large exchange integrals are observed ($-2J > 800$ cm^{-1}) (2, 3) approaching the range observed for binuclear copper protein centres (5, 6). For dihydroxy bridged systems exchange integrals are somewhat smaller, with a linear variation of exchange with oxygen bridge angle (7), and for systems with small oxygen bridge angles ferromagnetic exchange is observed.

Although there appears to be no correlation between oxygen bridge angle and exchange integral for the few systems reported for which X-ray structural evidence indicates a "single hydroxy bridge" (refs. 1–4, 8, and Table 10), it should be emphasized that structurally these compounds are unrelated. In other papers these compounds have been referred to as if they contain just one bridge group, which is a hydroxide bridge, whereas, in reality, most of them contain additional "ligand" bridges. The complex $[Cu_2(bipy)_4(OH)](ClO_4)_3$ has been shown by X-ray crystallography to have just a single hydroxide bridge and other related systems $[Cu_2(phen)_4(OH)](ClO_4)_3$ and $[Cu_2(tren)_2(OH)]X_3$ (X = ClO_4^-, PF_6^-) are expected to be bridged similarly based on other data (8).

In an attempt to correlate the magnetic properties of a binuclear multibridged copper(II) system with a single hydroxy bridge and such variables as oxygen bridge angle and metal–metal separation we have examined the structure and magnetism of a series of closely related binuclear copper(II) compounds based on the phthalazine subunit as a binucleating building block (9, 10). An approximately linear relationship is observed between the exchange integral and the oxygen bridge angle for the compounds $[Cu_2(PAP)(OH)X_3].1.5H_2O$ (X = Cl, Br), $[Cu_2(PAP)(OH)Cl(SO_4)].2H_2O$ and $[Cu_2(PAP4Me)(OH)(H_2O)_2(NO_3)_2]NO_3$ (PAP = 1,4-di-(2′-pyridyl)aminophthalazine, PAP4Me = 1,4-di-(2′-pyridyl-4′-methyl)aminophthalazine). In each case the two copper centres are bridged by a diazine group (=N—N=), a hydroxide, and a variable bridging anion (Cl^-, Br^-, SO_4^{2-}, NO_3^-). Approximately square pyramidal stereochemistries were found for the copper centres in these complexes with $d_{x^2-y^2}$ ground states. The complex $[Cu_2(PAP)(OH)(IO_3)_3].4H_2O$ did not fit the trend and has an exchange much lower than expected based on its oxygen bridge angle. This was attributed to a distorted five-coordinate stereochemistry at the copper centres which approached a trigonal bipyramid, thus indicating a possible d_{z^2} ground state and a possibly different relationship between exchange and bridge angle.

In this report we describe a series of copper(II) complexes of the ligand MIP (1,4-di(1′-methyl-2′-imidazolyl)phthalazine (Fig. 1), which is previously unreported, and which bears a

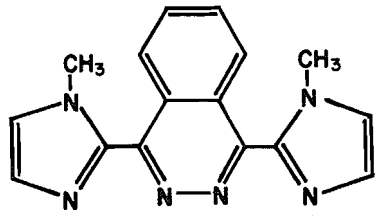

FIG. 1. MIP (1,4-di(1′-methyl-2′-imidazolyl)phthalazine.

resemblance to the ligand 3,6-di(2′-pyridyl)pyridazine (DPPN) (11–13). Also full structural details and a variable temperature magnetic study for the complex $[Cu_2(MIP)(OH)Cl_3(H_2O)].H_2O$ are reported which show that even with structurally different, but related, systems that involve $d_{x^2-y^2}$ ground states, the relationship between exchange integral and bridge angle still appears to hold. The variable temperature magnetism of the complex $[Cu_2(PAP)(OH)(IO_3)_3].4H_2O$ has also been re-examined since the original Gouy data were rather limited.

Experimental

Electronic spectra were recorded with a Cary 17 spectrometer and infrared spectra with a Perkin-Elmer Model 283 spectrometer. Magnetic susceptibilities were obtained at room temperature by the Faraday method using a Cahn Model #7600 Faraday Magnetic Susceptibility system, coupled to a Cahn gram electrobalance. Nuclear magnetic resonance spectra were run as solutions in deuterochloroform using a Bruker WP80 spectrometer and mass spectra were run using a V.G. Micromass 7070 HS spectrometer with a direct insertion probe. Microanalyses were carried out by Canadian Microanalytical Service, Vancouver (C, H, N). Metal analyses were determined by atomic absorption with a Varian Techtron AA-5, after digestion of the samples in concentrated HNO_3 or aqua regia.

Variable temperature magnetic susceptibility data (77–340 K) were obtained courtesy of Mr. B. Van der Griendt, Department of Chemistry, Gorlaeus Laboratories, State University Leiden, Netherlands, using a PAR 150A vibrating sample magnetometer. The data were corrected for underlying diamagnetism and temperature-independent paramagnetism ($N_\alpha = 60 \times 10^{-6}$ cgsu/mol Cu).

Synthesis of 1,4-di(1′-methyl-2′-imidazolyl)phthalazine (MIP)

n-BuLi (37.5 mL of 2.0 *M* solution in hexane) was added to dry (distilled over sodium benzophenone ketyl) THF (300 mL) in an atmosphere of dry nitrogen and the mixture cooled to −70°C. *N*-Methylimidazole (5.8 mL; 0.070 mol) dissolved in dry THF (75 mL) was added dropwise to the solution of *n*-butyllithium in THF over a period of 1/2 h and the mixture stirred for a further 3 h at −70°C. 1,4-Dichlorophthalazine (14) (7.0 g; 0.035 mol) dissolved in dry THF (100 mL) was added dropwise over a period of 1/2 h and the mixture allowed to warm to room temperature overnight. The solvent was removed using a rotary evaporator and the resulting solid extracted into dichloromethane, treated with decolourising charcoal, filtered, and the volume reduced to induce crystallization. The buff solid formed was filtered and recrystallized from 50/50 toluene/ethanol to produce yellow-buff crystals (yield 6 g, 60%) (mp 165–167°C). *Anal.* calcd. for $C_{16}H_{14}N_6.0.75EtOH$: C 64.7, H 5.70, N 25.9; found: C 65.0, H 5.50; N 26.1. Mass spectrum, major mass peaks (*m/e* (relative intensity)) 291(62), 290(100)P, 289(100), 262(87), 248(79), 235(19), 209(51), 183(87), 156(29), 145(26), 129(32), 102(11); ^{1}H nmr ($CDCl_3$) (σ (relative intensity)) 4.08(9) (singlet, CH_3), 7.16(3) (doublet, imidazole, H), 7.34(3) (doublet, imidazole, H), 7.94(3), 9.04(3) (AA′BB′ phthalazine, 2H).

$[Cu_2(MIP)(OH)Cl_3(H_2O)].H_2O$ (I)

$CuCl_2.2H_2O$ (1.0 g; 5.9 mmol) was dissolved in hot water (50 mL) and MIP (0.85 g; 2.9 mmol) dissolved in a minimum volume of hot ethanol. The two solutions were mixed with the formation of a dark green solution. The volume of the solution was reduced by half on a steam bath and allowed to stand. Bright green crystals formed and the product was recrystallised from water.

Compound **III** was prepared in a similar manner while compounds **II** and **V** were prepared using absolute ethanol as solvent for both the ligand and the metal salt. Compound **IV** was obtained as an insoluble green precipitate by addition of excess thiocyanate to an aqueous solution of the green precipitate obtained by reacting MIP and copper nitrate (1:2) in ethanol. The hygroscopic nature of the copper nitrate product prevented adequate characterization of this compound and so it is not described.

Satisfactory analytical data have been obtained for all compounds and are reported in Table 1, which is available from the Depository of Unpublished data.[2]

X-ray crystallographic analysis for $[Cu_2(MIP)(OH)Cl_3(H_2O)].H_2O$

Crystal data (at 24°C) are:

$C_{16}H_{19}N_6O_3Cl_3Cu_2$ fw = 576.82

Monoclinic, $P2_1/n$ (C_{2h}^5; absences $h0l$ for $h + l$ odd, $0k0$ for k odd), $a = 10.063(1)$, $b = 20.967(1)$, $c = 9.919(1)$ Å, $\beta = 96.48(1)°$, $V = 2079.4$ Å^3, $Z = 4$ (CuKα, $\lambda\alpha_1 = 1.54056$ Å); $\mu = 6.4$ mm^{-1}, $D_x = 1.842$ g cm^{-3}.

The crystals were green parallelepipeds with edges corresponding to the unit-cell axes. The specimen used for all measurements was of extreme dimensions 0.04 and 0.20 mm. The cell dimensions were derived from least-squares fitting of the diffractometer settings of 35 well centred reflections for which $111 < 2\theta < 129°$. The relative intensities of the independent reflections with $2\theta < 130°$ were measured with a Picker four-circle diffractometer, using Ni-filtered CuKα radiation. The $\theta-2\theta$ scan method was used, and individual reflection profiles were analysed as described by Grant and Gabe (15). The standard deviations of the measured intensities were evaluated from counting statistics, and those for which $I_{net} < 3\sigma(I_{net})$ were considered to be unobserved, and were omitted from the analysis. The observed reflections numbered 2442, of a possible 3544. Absorption corrections (ranging from 1.30 to 2.58) were applied to the measured intensities.

The structure was solved by the heavy-atom method, and refined by block-diagonal least squares, minimizing $\Sigma w\Delta F^2$, where $w^{-1} = \sigma^2(F_o) + 0.001F_o^2$. Most hydrogen atoms were included in the refinement, with initial positions reasonably assumed, or determined from a difference-Fourier synthesis, and isotropic temperature factors fixed at reasonable values. However, the hydrogen atoms of one water molecule (O(3)) could not be reliably located, and were omitted. The parameters refined were scale factor, secondary extinction coefficient, coordinates of all atoms, and anisotropic temperature parameters of the non-hydrogen atoms. The refinement converged at $R = 0.034$ (observed reflections only; $R_w = 0.046$). Except in the neighbourhood of O(3), where there is a peak of 0.6 e/Å^3, the residual election density lies between the limits −0.4 and 0.3 e/Å^3. The computer program system is specified in ref. 16, and the source of atomic scattering factors in ref. 17. The final atomic coordinates are given in Tables 2 and 3, thermal parameters in Table 4, and observed and calculated structure factors in Table 5.[3]

Results and discussion

Structure description of μ-[1,4-di(1′-methyl-2′-imidazolyl)-phthalazine-N^1,N^3,N^4,N^6]-μ-hydroxotrichloroaquodicopper(II) hydrate

The molecular structure of $[Cu_2(MIP)(OH)Cl_3(H_2O)].H_2O$ (**I**) is shown in Fig. 2 and consists of a pair of copper(II) centres bound simultaneously to the tetradentate phthalazine ligand and bridged by two groups: the phthalazine N_2 and a hydroxide.

[a]An esd of zero denotes a parameter not refined; H atoms bound to carbon are given in Table 3;[2] equivalent positions: $\pm(x, y, z; 1/2 + x, 1/2 - y, 1/2 + z)$.

Selected intramolecular bond distances and angles are given in Table 6. (Other interatomic distances and angles are given in Table 7[2].) The stereochemistry at each copper centre is approximately square pyramidal with the same arrangement of donor atoms in the basal plane. A basal corner is shared at oxygen O(1) by both copper centres. A chlorine atom, Cl(3), is the apical donor to Cu(2) while a water molecule occupies the apical site at Cu(1). A hydrogen bonding contact between Cl(3) and a hydrogen atom of this water molecule is apparent (H....Cl 2.32 Å), while the other hydrogen atom interacts with a corresponding chlorine atom in an adjacent molecule.

The Cu---Cu separation (3.425 Å) is much larger than those found in other monohydroxy bridged systems involving pyridyl aminophthalazine ligands, in which the substituent donor groups are separated from the diazine entity by an additional (nitrogen) atom (9, 10, 18). This has been attributed to the presence of five-membered chelate rings involving MIP as opposed to six-membered chelate rings in the other systems. The geometrical consequence of the five-membered ring is that larger Cu—N—N angles to the diazine group occur in this system (120−121°) than in the others (114−117°). The result of this effect is that the metal−metal separation and the metal−oxygen separations are larger in the MIP complex.

A comparison of the structure of $[Cu_2(MIP)(OH)Cl_3(H_2O)].H_2O$ with that of a related complex $[Cu_2(DPPN)(OH)Cl_3(H_2O)]$ (DPPN = 3,6-bis(pyridyl)pyridazine) reveals a basically similar structure but with some significant differences (13). Bond angles and bond lengths in the coordination sphere of each metal centre and at the diazine function are comparable implying that the basic binuclear centres in each system are very similar but the Cu...Cu separation and the copper−oxygen bridge separations are slightly longer in the MIP complex. Whereas in the DPPN complex the ligand itself is roughly planar (the two pyridyl rings are twisted with respect to the pyridazine moiety by 3.3 and 3.0°, respectively) in the MIP complex significant twisting of the imidazole groups occurs with respect to the mean plane of the phthalazine group. The imidazole rings (A, B) are inclined at 33° to each other and at 31 and 40°, respectively, to the mean plane of the phthalazine entity (*E*). Also this group is bent by 12° about the fused bond C(6)—C(11) (Table 8).[2] This twisting of the ligand is, no doubt, due to steric interactions between the methyl groups on the imidazole rings and protons HC(7) and HC(10) on the "fused" benzene ring of the phthalazine group. This effect would be absent in DPPN and comparable steric interactions would be minimal. The steric effect and the resultant twisting of the ligand in **I** do not significantly alter the overall dimensions of the binuclear centre in this system, when compared with the DPPN complex, other than to create a slightly longer metal−metal separation and copper−oxygen bridge separations. The two copper centres Cu(1) and Cu(2) are displaced by 0.261 and 0.176 Å, respectively, above the mean planes *F* and *G* which describe the basal planes of their square pyramids (Table 8).[2]

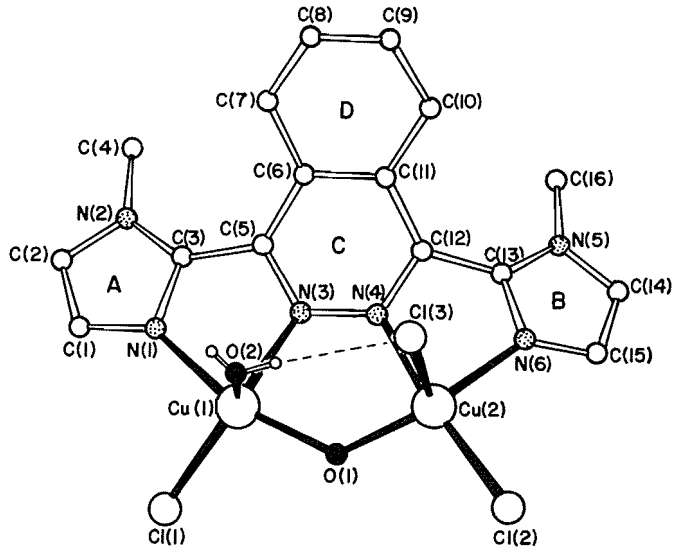

FIG. 2. Molecular structure and labelling scheme for $[Cu_2(MIP)(OH)Cl_3(H_2O)].H_2O$.

Synthesis and characterization of the complexes

Infrared, electronic spectral, and magnetic data are given in Table 9.

Compounds **I** and **III** were prepared from aqueous ethanol while **II** and **V** were prepared from absolute ethanol. On recrystallization of compound **II** from aqueous solvent **I** is obtained. **IV** is obtained by reacting a crude product, obtained from the reaction of copper nitrate and MIP in ethanol, dissolved in water with excess thiocyanate. The copper nitrate complex was, itself, not characterized. While compounds

[a]Exchange integral $-2J = 800 \pm 40$ cm^{-1}; $g = 2.00 \pm 0.02$.

I–**IV** are clearly binuclear, **V** is a mononuclear, bis-ligand derivative and no binuclear complex could be isolated.

Compound **I** exhibits $d-d$ bands in the visible region which can be associated with square pyramidal copper(II) and infrared bands indicative of the presence of terminal copper–chlorine bonds, a hydroxy bridge, and water. This compound exhibits a very low room temperature magnetic moment indicative of strong antiferromagnetic exchange. Reaction of copper chloride and MIP in an essentially non-aqueous medium produces a different complex, **II**, which does not have a hydroxy bridge. A lower energy $d-d$ absorption is consistent with a weaker ligand field associated with more coordinated chlorine atoms and a much higher magnetic moment may indicate the presence of a halogen bridge or perhaps no bridge other than the diazine. In the absence of such a bridge two coordinated chlorines per metal seem likely with the possible presence of a coordinated water also at each metal centre. It is of interest to note that an analogous compound involving DPPN has also been reported (13) and a recent X-ray study (19) shows that in $[Cu_2(DPPN)Cl_4(H_2O)]$ the two copper(II) centres are bridged by a chlorine, in addition to the pyridazine bridge, two chlorine atoms are bound to one copper and one chlorine and a water molecule to the other. The structure is similar to that of the μ-hydroxo-bridged analogue and suggests that a similar structure may well exist for **II**.

Compound **III** appears to be the bromo-analogue of **I** with slightly lower energy $d-d$ absorption and similar infrared bands indicative of a hydroxy bridge and the presence of water. However, the room temperature magnetic moment is much lower, which may indicate a more strongly coupled system. Compound **IV** has no discernible $d-d$ absorption in the visible and it is presumably hidden within the intense charge transfer absorption at 27800 cm^{-1}. The stereochemistry at copper is likely, therefore, to be close to square planar. Only one thiocyanate band is observed in the infrared due to CN stretch and this is associated with a terminal nitrogen bound group. The apparent lack of splitting of this absorption does not rule out the presence of two terminal thiocyanates per copper and this seems to be the most likely structure. Since no bridging group other than the diazine, N_2, appears to be present in **IV** the reduction in magnetic moment can be attributed to exchange via the diazine bridge alone.

Compound **V** is clearly anomalous in that it is mononuclear, presumably involving bidentate ligands. A similar situation has been observed with other phthalazine ligands (20–22) although in these cases, in aqueous solution, the pH of the system

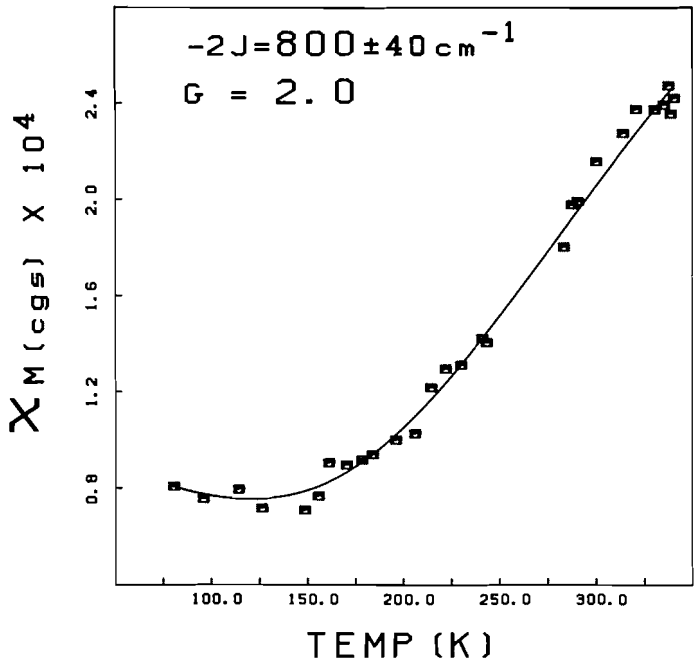

FIG. 3. Magnetic susceptibility data for $[Cu_2(MIP)(OH)Cl_3(H_2O)].H_2O$. The solid line was calculated from eq. [1] with g = 2.00 ± 0.02, $-2J$ = 800 ± 40 cm^{-1}, and $N\alpha$ = 120 × 10^{-6} cgsu/binuclear centre.

turned out to be the controlling factor. A tetragonally distorted six-coordinate structure is proposed for this system involving axially bound water molecules.

Magnetic measurements

Magnetic susceptibility measurements were carried out on powdered samples of **I** and $[Cu_2(PAP)(OH)(IO_3)_3].4H_2O$ (**VIII**; Table 10) in the range 77−340 K. A best fit of the experimental data was obtained using the Van Vleck equation (23) for exchange coupled pairs of copper(II) ions (eq. [1]).

$$[1]\quad \chi_M = \frac{N\beta^2 g^2}{3kT}\left[1 + \frac{1}{3}\exp(-2J/kT)\right]^{-1} + N\alpha$$

In this expression $2J$ (in the spin Hamiltonian $H = -2J\hat{S}_1.\hat{S}_2$) is the singlet−triplet splitting or exchange integral and other symbols have their usual meaning. The parameters giving the best fit were obtained by minimizing the function

$$E = \Sigma_i W_i(\chi_i^{obsd}\chi_i^{calcd})^2$$

(where $W_i = (\chi_i^{obsd})^{-1}$) using a Simplex non-linear fitting routine (24, 25). The results of this fit gave the parameters g = 2.00 ± 0.02 and $-2J$ = 800 ± 40 cm^{-1} (0.5% monomeric paramagnetic impurity) for **I** and g = 2.21 ± 0.02 and $-2J$ = 290 ± 10 cm^{-1} for **VIII**. Figures 3 and 4 illustrate the experimental and theoretical susceptibility curves for **I** and **VIII**, respectively. At temperatures less than 200 K several susceptibility measurements were taken at each temperature for **I**. In some cases significant scatter in these data points were observed. Some of these points have been removed from Fig. 3 for clarity but the best fit of data and error limits were determined using the complete data point set.

Table 10 summarises magnetic and structural data for a number of binuclear copper(II) compounds (including **I** and **VIII**) containing single hydroxy bridges which have been published recently. Figures 5 and 6 illustrate plots of exchange integral ($-2J$) and magnetic moment (RT), respectively, versus oxygen bridge angle for these systems and compound **I**. Reasonable straight lines can be drawn, in both cases, to include compounds **I**, **VI**, **VII**, **IX**, and **X**. For complexes **VI**, **VII**, **IX**, and **X** three bridging entities exist between the copper centres, including the diazine bridge and the hydroxide bridge, and since this feature occurs in **I**, which also falls on the straight line plots, it is this pair of bridges and the $d_{x^2-y^2}$ ground

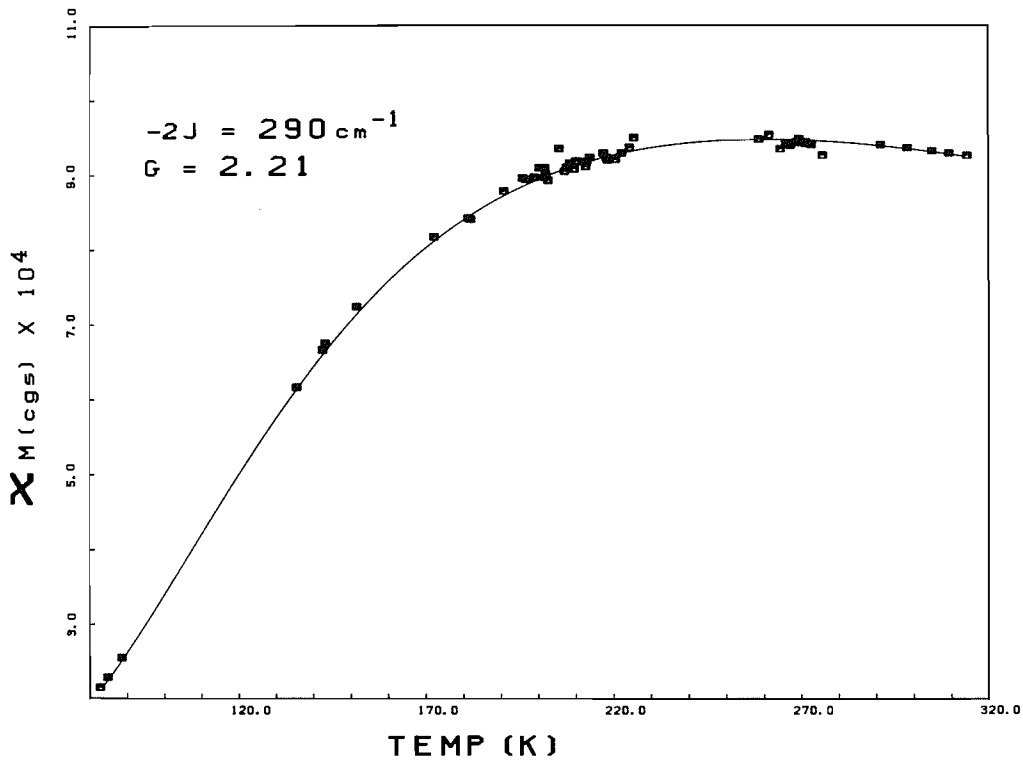

FIG. 4. Magnetic susceptibility data for $[Cu_2(PAP)(OH)(IO_3)_3].4H_2O$. The solid line was calculated from eq. [1] with $g = 2.21 \pm 0.02$, $-2J = 290 \pm 10$ cm^{-1}, and $N\alpha = 120 \times 10^{-6}$ cgsu/binuclear centre.

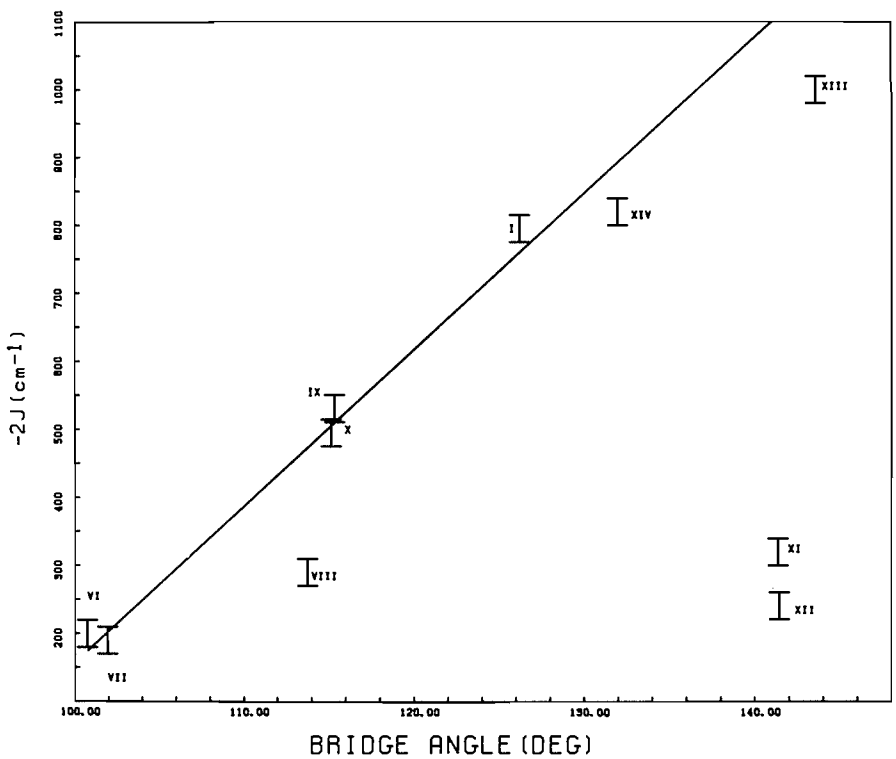

FIG. 5. Plot of $-2J$ against oxygen bridge angle for compounds **I**, **VI**–**XIV** (error bars set arbitrarily).

state which appears to group these five compounds together. The exchange data quoted for **VIII**, $[Cu_2(PAP)(OH)(IO_3)_3].4H_2O$ (26), were obtained originally from a limited set of Gouy measurements. The variable temperature magnetism for this compound has been remeasured because the original data for this compound did not fit the plot of exchange and bridge angle. However, rather than the exchange increasing, as might have been expected, the new data indicate somewhat weaker exchange, confirming the unique position of this compound in the series. The stereochemistry at each copper centre in **VIII**

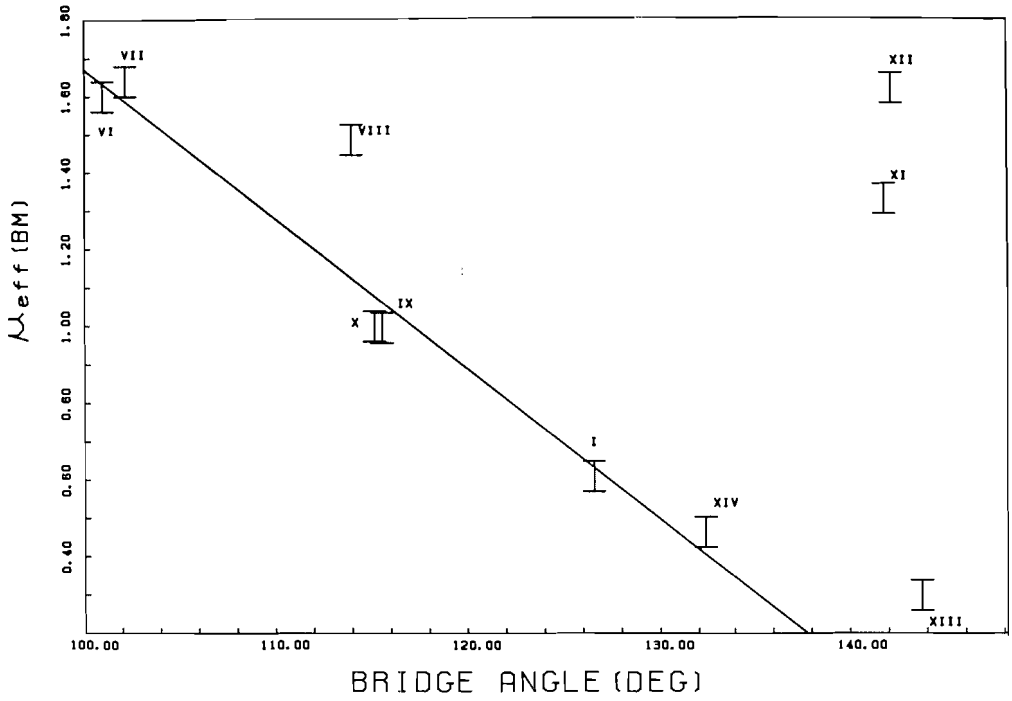

FIG. 6. Plot of μ (RT) against oxygen bridge angle for compounds **I**, **VI**–**XIV** (error bars set arbitrarily).

(9) is in between a square pyramid and a trigonal bipyramid and so the ground state representation may not be $d_{x^2-y^2}$. Such a situation may lead to a different relationship between exchange and bridge angle.

Including data for compounds **XI**–**XIV** in Figs. 5 and 6 shows that compounds **XIII** and **XIV** lie close to the straight line plots but the other two compounds do not. However, the uncertainty of the measurements for compounds **XIII**, **XIV** could place these systems closer to the line generated by compounds **I**, **VI**, **VII**, **IX**, **X**. Compound **XI**, $[Cu_2(bipy)_4(OH)](ClO_4)_3$, has a distorted trigonal bipyramidal structure at the copper centres and orbital overlap with the bridging oxygen atoms occurs via an equatorial metal orbital. d_{z^2} orbital overlap with the oxygen bridge would be much more favourable with an axially bound system, as is expected for $[Cu_2(tren)_2(OH)](ClO_4)_3$ (8), and this leads to much stronger exchange. Surprisingly compound **XII** has a copper ion stereochemistry close to square pyramidal and it is not obvious why this system should display such weak exchange. However, unlike all the other single hydroxide bridged species in which the copper centres are related to each other approximately by a plane of symmetry through the oxygen bridge, the square pyramidal centres in **XII** are twisted with respect to each other by about 90° along the copper–oxygen bonds.

Within the limited scope of this survey most systems with $d_{x^2-y^2}$ ground states and approximately square pyramidal structures relate antiferromagnetic exchange and hydroxide bridge angle in a roughly linear manner. However, within a series of related complexes, with the same copper ion ground state, a much better linear relationship is observed. It is clear that more examples are required to better substantiate these relationships, and that distortions at the copper centres be documented in a systematic way in order to evaluate the molecular orbital situation in the Cu—O—Cu framework.

We have observed that by varying certain bridging groups, X, in the binuclear unit $Cu_2N_2(OH)X$, the dimensions of the binuclear centre, and especially the oxygen bridge angle, can be "tuned" according to the size of X (9, 10). A limit of about 116° for the Cu—O—Cu bridge angle is reached with large bridges, e.g. sulphate, but, on changing from a system with three bridge groups to one with two and decreasing the chelate ring size, enhanced exchange is observed as a result of increased metal–metal separation and bridge angle. Further studies of this sort are ongoing, in which we are attempting to "tune" these systems further by the use of bigger groups, X, and by examining other molecular constraints which might impose, through, e.g., steric factors, other perturbing influences on the dimensions of the binuclear centres. Preliminary structural data indicate that by placing 6-methyl groups on the pyridine rings in ligands like PAP the oxygen bridge angle can be opened up dramatically.

Formation and reactivity of transannular sulphur–sulphur bonds in cyclothiazenes and related compounds. A molecular orbital analysis

RICHARD T. OAKLEY

Guelph–Waterloo Centre for Graduate Work in Chemistry, Guelph Campus, Department of Chemistry and Biochemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received March 27, 1984

RICHARD T. OAKLEY. Can. J. Chem. **62**, 2763 (1984).

The structural dichotomy exhibited by heterocyclic thiazenes of the type $E(NSN)_2E$ (E = CR, SR) is analyzed in the light of MNDO molecular orbital calculations on a variety of model structures. For $RS(NSN)_2SR$ molecules the activation energies for inversion at sulphur have been estimated, and the formation of *exo–endo* and *exo–exo* isomers is discussed in terms of the frontier orbitals involved in the free radical and electrophilic oxidation of transannular S—S bonds.

RICHARD T. OAKLEY. Can. J. Chem. **62**, 2763 (1984).

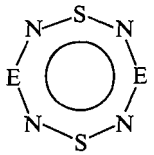
En se basant sur des calculs d'orbitales moléculaires du type MNDO, effectués sur une variété de structures modèles, on a analysé la dichotomie de structure que présentent les thiazènes hétérocycliques du type $E(NSN)_2E$ (E = CR, SR). Dans le cas des molécules $RS(NSN)_2SR$, on a évalué les énergies d'activation pour l'inversion au niveau du soufre et on discute de la formation des isomères *exo–endo* et *exo–exo* en fonction des orbitales frontières impliquées dans les oxydations radicalaire et électrophile des liaisons S—S transannulaires.

[Traduit par le journal]

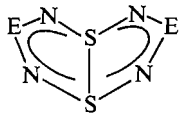
Introduction

The structural diversity of binary sulphur nitride derivatives has evoked continued debate over the electronic factors which control their shape. The cage-like molecule of S_4N_4 has attracted the most attention (see, for example, ref. 1), and the results of recent structural and theoretical (molecular orbital) studies on the protonated form $S_4N_4H^+$ have illustrated how the energetic balance between different structural modifications can be shifted by a seemingly minor chemical change (2).

In addition to the simple binary molecule, S_4N_4, a variety of heterocyclic derivatives of the type $E(NSN)_2E$ have recently been synthesized and structurally characterized (E = CPh, $CNMe_2$, PMe_2, PPh_2, SCl, $SNMe_2$, $SNPPh_3$) (3–8). The molecular structures of these derivatives fall into two distinct categories exhibiting either an essentially planar shape, e.g. **1**, or a puckered conformation with a close (2.50–2.60 Å) transannular sulphur–sulphur contact, e.g. **2**. Although the reasons



1



2

for the occurrence of the two structural modifications for different E groups have been investigated by molecular orbital methods (4, 9), no quantitative correlation of electronic structure with observed geometry has been attempted. In addition, for those molecules in which E represents an SR moiety three distinct ligand orientations, here designated as *exo–exo* **3***a*, *endo–endo* **3***b*, and *exo–endo* **3***c*, are possible, but to date no theoretical investigation has been made of the relative stabilities of these isomers, the ease of their interconversion, or the mechanistic factors which might influence the formation of one rather than another.

In the present paper the electronic and energetic criteria underlying the structural reorganization **1** to **2** are evaluated in the light of MNDO molecular orbital calculations on a number of key model compounds. For molecules of the type $RS(NSN)_2SR$ and $S_4N_4R_4$ the observed range of ligand orientations

is discussed in terms of the stereochemical characteristics of the free radical and electrophilic oxidation of S_4N_4.

Theoretical method and models

The use of the M(odified) N(eglect) of D(iatomic) O(verlap) method (10) and the DFP geometry optimizing algorithm has been used extensively for the study of the conformational characteristics of sulphur nitride compounds. Although the method is somewhat deficient in assessing sulphur(III)–sulphur(III) σ-interactions (11) it has, in many cases, provided reliable predictions of ground state geometries (e.g. S_4N_2, S_3N-, S_4N-, S_4N_4H+) (2, 12–14). In the present study calculations on planar models **1** were carried out with full optimization of the endocyclic bond lengths and angles (within the constraints of D_{2h} symmetry). Bond lengths to the exocyclic ligands (C—H, C—N, S—Cl, S—F, S—N) were also optimized, but for NH_2 ligands, an idealized geometry (planar configuration with d(N—H) = 1.0 Å and ∠NHN = 120°) was used. For the calculations on the puckered models **2**, the transannular S—S distance was fixed at 2.6 Å and each of the ES_2N_2 rings was held planar. Outside of these restrictions, full geometry optimization (within C_{2v} symmetry) was invoked. Bond orders (ρ_{NS}) were calculated as described in ref. 15.

Calculations on the ligand orientations of $RS(NSN)_2SR$ were performed using a restriction of planarity on the two five-membered $(R)SN_2S_2$ rings, the parameters of each being optimized independently (with the exception of the transannular

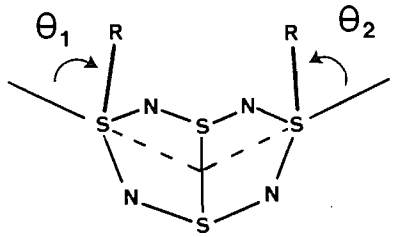

FIG. 1. Definition of ligand orientations in $S_4N_4R_2$ molecules by the two angles θ_1 and θ_2.

S—S distance, which was fixed at 2.6 Å). The two ligand positions were varied by means of the two angles θ_1 and θ_2 defined in Fig. 1.

Results and discussion

$E(NSN)_2E$ isomers

In a recent analysis of the effect of protonation on the shape of the S_4N_4 molecule we emphasized how the redistribution of the π-molecular orbitals following protonation resulted in a net stabilization of the planar conformation relative to the cage structure (2). The structural dichotomy observed for molecules of the type $E(NSN)_2E$ can be interpreted using similar reasoning, and to this end it is useful to compare their electronic structures with that of the unperturbed 10 electron π-system of $S_4N_4^{2+}$. For this latter species the results of extended Hückel, CNDO and *ab initio* Hartree-Fock-Slater molecular orbital studies have confirmed that the π-network of the planar conformation is sufficiently robust to offset the potential gains in σ-bonding occasioned by a puckering of the ring into C_{2v} or D_{2d} symmetry (16, 17). Table 1 summarizes the bond orders obtained from MNDO calculations on a series of $E(NSN)_2E$ molecules, all with a planar skeletal geometry imposed. It is readily apparent that the incorporation of heteroatoms (E = CH, CNH_2) or the covalent attachment of ligands to $S_4N_4^{2+}$ (E = SCl, SF, SNH_2) induces a substantial electronic reorganization, as a result of which the NS bonds of all the $E_2S_2N_4$ molecules are, to varying extents, weakened relative to those of $S_4N_4^{2+}$. Analysis of the π-molecular orbital distributions of the planar models with E = CH, CNH_2 provides an insight into the reasons for this trend.

Figure 2 illustrates the energies and distributions of the π-molecular orbitals of $HC(NSN)_2CH$ and $H_2NC(NSN)_2CNH_2$ (in D_{2h} symmetry). It is evident that while most of the occupied orbitals transform from one molecule to the other with little change in energy or composition, the π-HOMO is altered significantly. In $S_4N_4^{2+}$ the π-HOMO ($2b_{1u}$) is a non-bonding distribution centred on the four sulphur atoms (16, 17) and in $RC(NSN)_2CR$ it evolves progressively under the influences of electronegativity changes and exocyclic conjugation (4) into one ($2b_{1u}$ in R = H and $3b_{1u}$ in R = NH_2) exhibiting strong antibonding characteristics with respect to the SN linkages. Thus of the various orbital modifications which occur in the sequence $S_4N_4^{2+} \rightarrow HC(NSN)_2CH \rightarrow H_2NC(NSN)_2CNH_2$ the changes in this particular orbital are dominant in causing the decrease in ρ_{NS} (Table 1). As a result of the weakening of the planar framework, some deformation should be expected in those molecules with particularly low NS bond orders. The distortion coordinate that transforms the π-HOMO of **1** into the cross ring S—S bond of **2**, and thereby reduces its antibonding character over the NS linkages, has been discussed elsewhere (1*d*, 4, 16, 17). In order to assess the overall energy changes

CH	137.3	154.7	17.4
CNH_2	146.6	151.2	4.6
SCl[b]	218.4	221.1	2.7
SF[b]	236.6	221.8	−14.8
SNH_2[b]	303.2	282.4	−20.8

[a]d(S—S) = 2.6 Å.
[b]$\theta_1 = \theta_2 = -60°$.

associated with such a deformation, a series of calculations of the heats of formation of $E(NSN)_2E$ molecules as a function of d(S—S) has been performed. The results are shown in Table 2, which lists the absolute and relative energies of the planar versus the puckered conformations (with d(S—S) set at 2.6 Å) of different models. In a relative sense the trend in ΔH_f(**2**) − ΔH_f(**1**) corresponds remarkably well with the observed structures of $E(NSN)_2E$ derivatives — all are puckered, i.e. **2**, save for $PhC(NSN)_2CPh$ and $S_4N_4^{2+}$, which are both planar. The apparent stability of **1** versus **2** for E = CNH_2 reflects the deficiency of the MNDO method in underestimating the transannular S—S bond of **2** with respect to the π-bonds of **1** (11). Indeed all of the differences ΔH_f(**2**) − ΔH_f(**1**) should probably be adjusted by at least 10 kcal/mol in favour of **2**. Nonetheless the difference in ΔH_f(**2**) − ΔH_f(**1**) for E = CH and CNH_2 illustrates the magnitude of the weakening effect of exocyclic conjugation on the π-system of **1**. The absence of a molecular plane of symmetry in the $R_2S_4N_4$ molecules precludes a rigorous π-orbital analysis. However, the effects of conjugation are still apparent in the relative stabilities of **2** versus **1** for R = Cl, F, and NH_2, the ordering following the expected trend in π-donor capabilities or R (NH_2 > F > Cl).[1]

$RS(NSN)_2SR$ isomers

The preceding analysis focussed attention on the electronic factors which control the skeletal shape of $E(NSN)_2E$ derivatives. In the case of $RS(NSN)_2SR$ compounds, all the known examples of which exhibit puckered geometries (type **2**) in the solid state, the possibility of different orientations (i.e. **3***a*, **3***b*, **3***c*) also exists. X-ray crystallographic studies on $S_4N_4Cl_2$ (6),

[1]Calculations on $E(NSN)_2E$ with E = PH_2 reveal a large preference (33 kcal/mol) for the puckered configuration **2**. However, the planar model converges to a "non-10π" ground state (i.e., the $3b_{1u}$ orbital becomes virtual), indicative of the inability of the restricted MNDO basis set to handle the P(V) valence state.

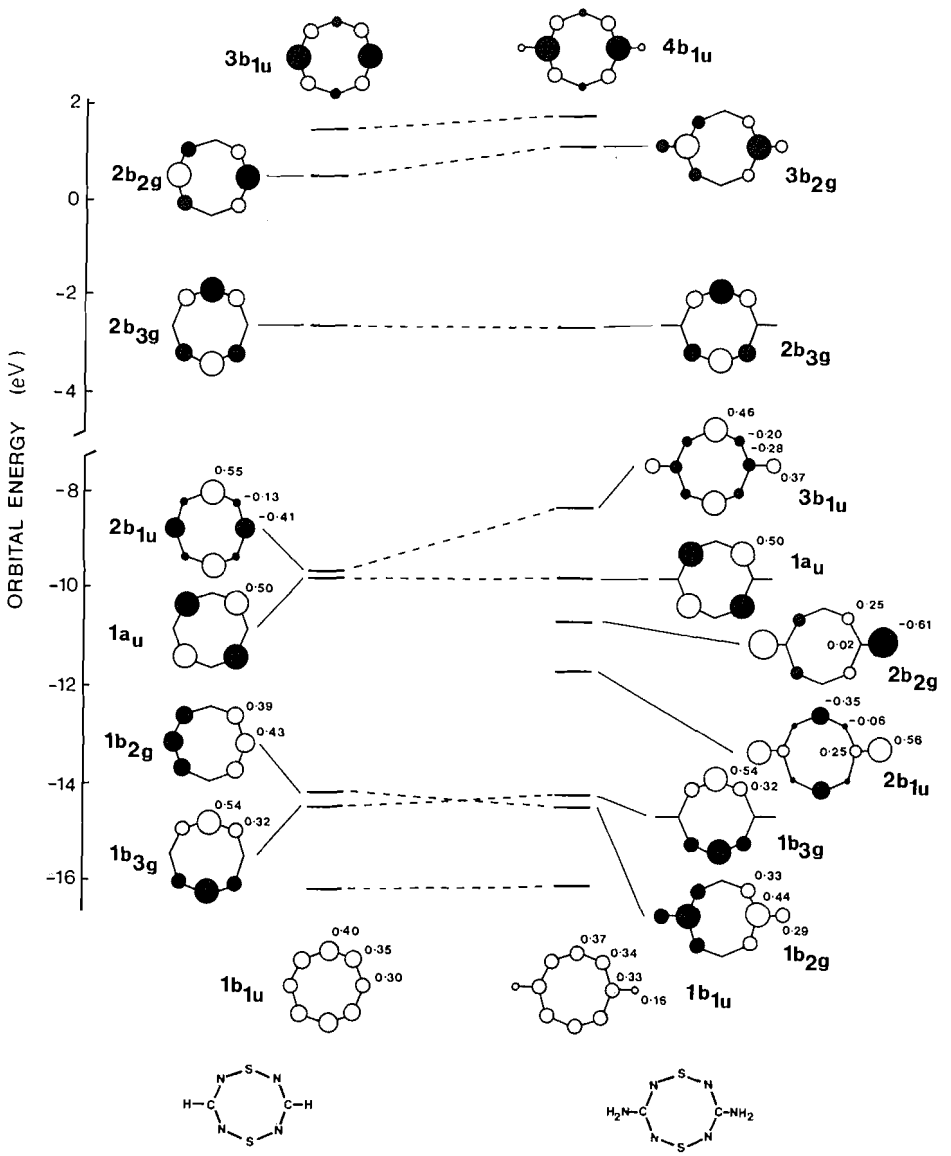

FIG. 2. π-Molecular orbital (MNDO) distributions and energies for $HC(NSN)_2CH$ and $H_2NC(NSN)_2CNH_2$, both in D_{2h} symmetry. Eigenvalue coefficients are indicated for occupied levels.

$S_4N_4(NMe_2)_2$ (7), and $S_4N_4(NPPh_3)_2$ (8) have established the unsymmetrical *exo–endo* ligand orientation **3***c* in the solid state, and nmr studies on all three of these systems (7, 8, 18) have confirmed the non-equivalence of the ligand environments in solution at ambient temperatures.[2] By contrast, the ^{19}F nmr spectra of **3** (R = F and $ON(CF_3)_2$) reveal a single fluorine environment, indicative of one of the two symmetrical isomers **3***a* or **3***b* (19, 20). The interpretation of these observations requires (*i*) an understanding of the energetics of the isomer equilibration process and (*ii*) a consideration of the stereochemistries associated with the preparation of $RS(NSN)_2SR$ compounds.

MNDO calculations on the heats of formation of model $RS(NSN)_2SR$ compounds as a function of the two angles θ_1 and θ_2 (see Fig. 1) provide an estimate of the relative stabilities of the three isomers and the activation barriers which restrict their interconversion. The results of a typical calculation are illustrated in Fig. 3, which shows a plot of the potential energy hypersurface (ΔH_f) for $S_4N_4F_2$. As expected there are three independent minima corresponding to the *exo–exo* ($\theta_1 \simeq \theta_2 \simeq -60°$), *endo–endo* ($\theta_1 \simeq \theta_2 \simeq +60°$) and *exo–endo* ($\theta_1 \simeq \pm 60°$, $\theta_2 \simeq \mp 60°$) geometries. The absolute energies of the three minima and of the transition states between them are listed in Table 3 for a number of different models. The energies of the three "invertomers" **3***a*,*b*,*c* are all very similar, the symmetrical modifications both being slightly more stable than the *exo–endo* form. However, the relative stabilities should not be given too great a significance, since the energy differences are smaller than the limit of reliability of the theoretical model. Of more importance are the barriers to the interconversions (e.g. **3***c* → **3***a*: 27, 47, and 45 kcal/mol for R = Cl, F, and NH_2, respectively), that for R = F being effectively identical to the barrier recently calculated for inversion at sulphur in S_4N_5F, **4** (46.7 kcal/mol) (21).

In view of the thermal instability of all $RS(NSN)_2SR$ derivatives, it seems unlikely that experimental data will be obtained to compare with these calculated values. Nonetheless, the bar-

[2]The ^{15}N nmr spectra of $S_4N_4Cl_2$ shows two distinct resonances at −60°C, consistent with the *exo–endo* geometry **3***c* (see ref. 18). On warming to room temperature the signals broaden but do not coalesce (18*b*).

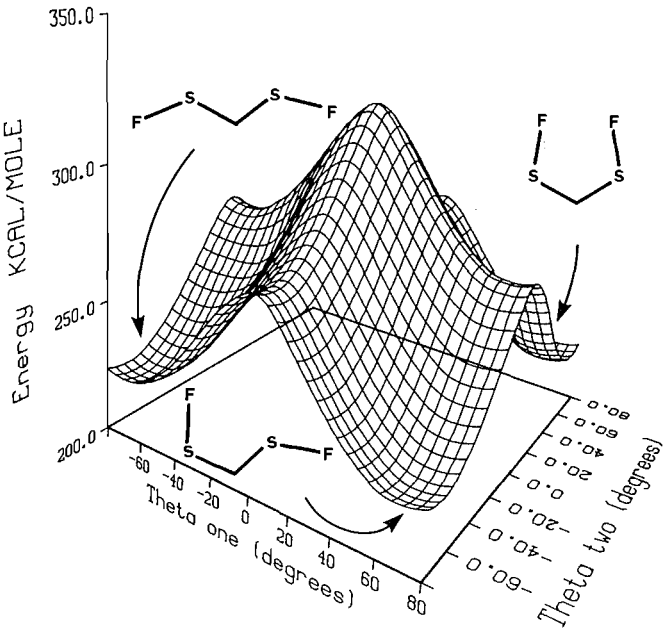

FIG. 3. Heat of formation (kcal/mol) of $S_4N_4F_2$ (d(S—S) = 2.6 Å) as a function of θ_1 and θ_2.

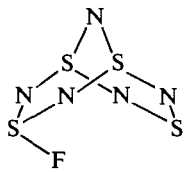
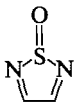
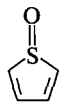


4

riers observed for simpler but related systems provide a useful basis for discussion. Thus, for example, the measured barrier for 1,2,5-thiadiazole-1-oxide **5** (33 kcal/mol) (22) is higher than that found for thiophene-1-oxide **6** (14.8 kcal/mol) (23), but considerably less than that calculated for $(NH_2)_2SO$ (66.5 kcal/mol) (22). For these systems, it has been suggested that conjugation in the cyclic molecules stabilizes the planar transition state, but that this is partially offset in the thiadiazole oxide **5** by the electronegativity effect of nitrogen (which stabilizes



5



6

the pyramidal structure relative to the transition state). In $RS(NSN)_2SR$ derivatives the latter influences are likely to be even more pronounced, while the effects of conjugation are probably diminished.[3] Consistently the increase in the barrier height along the series R = Cl < NH_2 < F parallels the trend in ligand electronegativity.

[3]The π-electron-rich character of cyclothiazenes inhibits their acceptor capability. This concept is well illustrated by the orbital changes shown in Fig. 2, and is substantiated in the structures of $(Me_2N)_2S_4N_4$ (7) and $(Ph_8P_4N_6S_2)(NMe_2)_2$ (24), both of which exhibit rather long S—N_{exo} distances and pyramidalized nitrogen atoms. Cyclophosphazenes, on the other hand, are better π-acceptors, and aminophosphazene structures are characterized by short P—N_{exo} distances and planar geometries at nitrogen (25).

[a]d(S—S) fixed at 2.6 Å.

On the basis of the above estimates the stereochemical rigidity of $S_4N_4R_2$ derivatives with respect to inversion at sulphur is to be expected. Moreover, in view of the lack of thermal equilibration of invertomers at ambient temperatures, the range of stereochemistries exhibited by such compounds must reflect fundamental mechanistic differences in the reactions used to prepare them. Scheme 1 summarizes the pertinent synthetic routes to $S_4N_4R_2$ and $S_4N_4R_4$ compounds, i.e. those which involve a direct oxidative addition to the transannular S—S bonds of S_4N_4. It is worth noting that the stereochemistries for $S_4N_4F_4$ (26) and $S_4N_4(ON(CF_3)_2)_4$ (27) support the above assignments, based on nmr evidence, of *exo*−*exo* geometries for the corresponding $S_4N_4R_2$ derivatives, i.e., the ligand orientation patterns of the tetra-substituted products correspond to the sequential oxidation of both S—S bonds of S_4N_4, each step occurring with *exo*−*exo* stereochemistry. While double *endo*−*endo* addition would provide the same $S_4N_4R_4$ geometries, the steric constraints of this pathway make it less attractive. A mechanistic analysis of these reactions further substantiates the *exo*−*exo* geometry.

The stereochemistry of oxidative additions to the transannular S—S bonds of S_4N_4 (and those of $E_2S_2N_4$ derivatives) can be interpreted using the frontier orbital concepts that are commonly used in rationalizing the stereochemistry of organic reactions (28). Indeed recent studies on the electrocyclic additions of olefins to cyclothiazenes have already demonstrated the applicability of these ideas in inorganic thiazyl chemistry

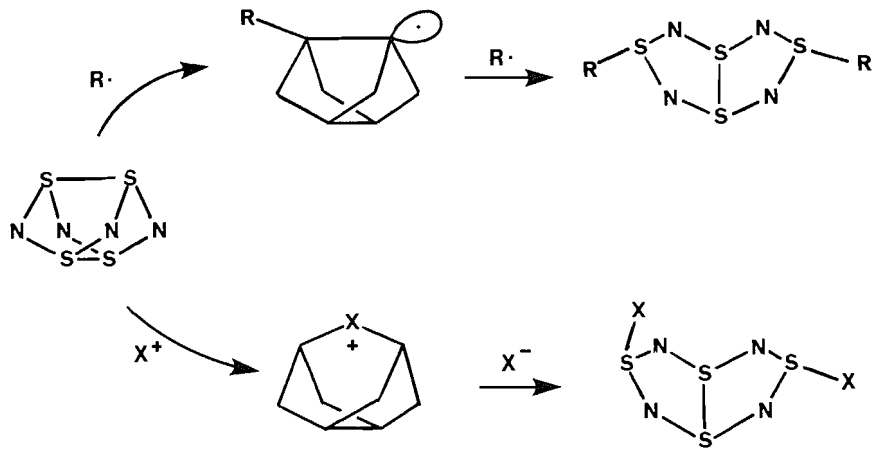

SCHEME 2

(29, 30). In the present instance the interpretation relies on a consideration of the symmetries and spatial distributions of the frontier orbitals of S_4N_4 that are associated with the S—S interactions. The results of many theoretical studies all concur that the high-lying occupied orbital $4b_2$ and the LUMO $6e$ possess overlap and symmetry properties that are characteristic of S—S σ and σ* orbitals (1). The interactions of these orbitals with the corresponding frontier orbitals of an approaching oxidant will determine the stereochemistry of the ensuing product. Thus oxidations involving a polar mechanism, e.g. chlorination, will proceed through the preliminary attack of an electrophilic species, e.g. Cl^+, on the occupied S—S σ-orbital, producing an intermediate with the symmetrical structure shown in Fig. 4. Subsequent attack of Cl^- can then only occur in an *exo* S—S σ-orbital,[4] producing an intermediate with the symmetrical structure shown in Fig. 4. Subsequent attack of Cl^- can then only occur in an *exo* fashion, thereby yielding the *exo–endo* product **3***c* (Scheme 2). By contrast, the reaction of nucleophilic radical oxidants (e.g. AgF_2 and $ON(CF_3)_2$) will be stereochemically coupled to the interaction of the high-lying SOMO of the radical and the low-lying LUMO of S_4N_4.[5] As is illustrated in Fig. 4, such an interaction will lead to attack of the oxidant on the *exo* side of the molecule. Subsequent reaction of a second radical will also be directed *trans* to the S—S bond, resulting in the *exo–exo* isomer **3***a* (Scheme 2).

Finally, some comments on the substitution behaviour of $S_4N_4Cl_2$ are warranted. The stereochemistry of the product $Me_2NS(NSN)_2SNMe_2$ obtained from the reaction of $S_4N_4Cl_2$ with Me_3SiNMe_2 (7) is readily accounted for in terms of a four-centre transition state which retains the configuration of each sulphur atom (31). By contrast, its reaction with ionic nucleophiles should yield the thermodynamically most stable isomer which, according to the above calculations, should be one of **3***a* or **3***b*. Consistently the conversion of $S_4N_4Cl_2$ to

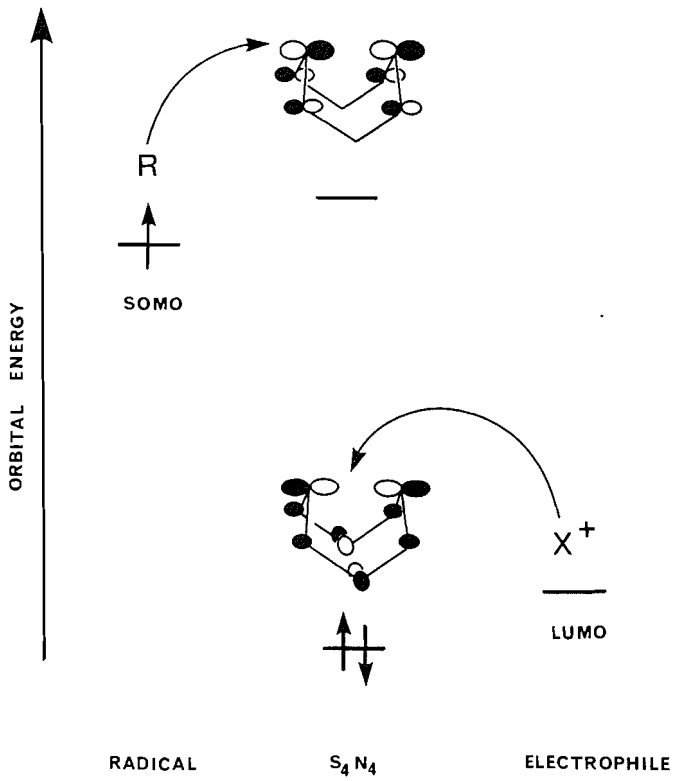

FIG. 4. Dominant interactions between the S—S σ($4b_2$) and σ*($6e$) orbitals of S_4N_4 and the frontier orbitals of radical and polar oxidants.

$S_4N_4F_2$ using excess NaF yields a product whose ^{19}F nmr spectrum is identical to that obtained from S_4N_4 and AgF_2 (19).

Summary

Heteroatom incorporation into the 10 π-electron perimeter of $S_4N_4^{2+}$ transforms its nonbonding π-HOMO into an antibonding orbital localized over the NSN linkages. Puckering of the molecules alleviates the weakness in these bonds by redistributing the orbital into a transannular S—S σ-interaction. The stereochemistry associated with the oxidation of the S—S bonds of S_4N_4 depends on the nature of the oxidants, and the consequent frontier orbital (S—S σ or σ*) with which they interact. Dipolar oxidation proceeds through initial electrophilic attack on the S—S σ-orbital, while the low-lying

[4]There are many occupied orbitals in the molecular orbital stack of S_4N_4 that have non-zero overlap populations between transannular sulphur atoms (1*a*). The cumulative effects (bonding and antibonding) give rise to a very weak but positive interaction, i.e. a partial bond, between cross-ring sulphurs. The $4b_2$ orbital, which is referred to herein as the S—S σ-orbital, is a major contributor to this bond. Energetically, it is the most readily disposed to interact with an approaching electrophile.

[5]The degeneracy of the $6e$ orbitals will be broken upon the approach of an oxidant. In Fig. 4 only one of these orbitals (the one that will interact most strongly with the radical SOMO) is illustrated.

Evidence for a di-π-methane rearrangement in the photoisomerization of 2,3-benzo-7,8-dimethylbicyclo[4.2.0]octa-2,4,7-triene to 6,7-dimethylbenzotricyclo[3.3.0.0^{2,8}]octa-3,6-diene

CHRISTOPHER OWEN BENDER, IRENE MARIE CASSIS, DOUGLAS DOLMAN, LOUIS DENNIS HEERZE, and FRANCES LINDA SCHULTZ

Department of Chemistry, University of Lethbridge, Lethbridge, Alta., Canada T1K 3M4

Received February 27, 1984

CHRISTOPHER OWEN BENDER, IRENE MARIE CASSIS, DOUGLAS DOLMAN, LOUIS DENNIS HEERZE, and FRANCES LINDA SCHULTZ. Can. J. Chem. **62**, 2769 (1984).

The direct and sensitized (Michler's ketone) irradiations of 2,3-benzo-7,8-dimethylbicyclo[4.2.0]octa-2,4,7-triene (**7**) yield 6,7-dimethylbenzotricyclo[3.3.0.0^{2,8}]octa-3,6-diene (**3**, $\Phi = 0.030$ and 0.093, respectively) and naphthalene ($\Phi = 0.10$ and 0.16, respectively). Deuterium labelling studies suggest that **3** derives from a Zimmerman di-π-methane rearrangement of **7**, and that 1,8-dimethyl-1a,2,7,7a-tetrahydro-1,2,7-metheno-1*H*-cyclopropa[*b*]naphthalene is not an intermediate en route to **3**.

CHRISTOPHER OWEN BENDER, IRENE MARIE CASSIS, DOUGLAS DOLMAN, LOUIS DENNIS HEERZE et FRANCES LINDA SCHULTZ. Can. J. Chem. **62**, 2769 (1984).

La photolyse directe et sensibilisée par le cétone de Michler du benzo-2,3-diméthyl-7,8-bicyclo[4.2.0]octa-2,4,7-trième (**7**) conduit au diméthyl-6,7-benzotricyclo[3.3.0.0^{2,8}]octa-3,6-diène (**3**, $\Phi = 0.030$ et 0.093, respectivement) et au naphtalène ($\Phi = 0.10$ et 0.16, respectivement). Des études de marquages au deuterium suggèrent que **3** dérive d'un réarrangement di-π-méthane de Zimmerman, et que diméthyl-1,8-tetrahydro-1a,2,7,7a-métheno-1,2,7-cyclopropa-1*H*-naphtalène[*b*] n'est pas un composé intermédiaire en route à **3**.

Introduction

Recently we reported the formation of the mixture of semibullvalenes (SB's) **2** and **3** from the sensitized irradiation of the barrelene **1** (1). The isomers proved difficult to separate (prep. glc). Based on the observations of Sasse and co-workers (2) that the diene **4** could be converted to the SB **6** via the [2 + 2] cycloadduct **5**, we had envisioned that an alternative and perhaps cleaner route to **2** might be available from photoisomerization of the dimethyldiene **7** (i.e., **7** → **8** → **2**, Scheme 1). Here we report that **3** and not the anticipated semibullvalene **2** is the only photoproduct isomeric with reactant **7**, and provide evidence that **3** is formed by a Zimmerman di-π-methane (DPM) rearrangement without the involvement of a symmetric intermediate such as **8**.

Results

2,3-Benzo-7,8-dimethylbicyclo[4.2.0]octa-2,4,7-triene (**7**) was conveniently prepared from the photolysis of 6,7-dimethylbenzocyclooctatetraene (COT **9**) by a modification of the previous method (1). The use of 1-acetonaphthone as sensitizer, instead of chlorobenzene, gave **7** in almost quantitative yield (Scheme 2). Compound **7** was less successfully prepared from the direct irradiation (Pyrex filter) of COT **9** due to secondary photochemistry of initially formed **7** (*vide infra*); at low conversions **7** was the dominant product but naphthalene and 6,7-dimethylbenzotricyclo[3.3.0.0^{2,8}]octa-3,6-diene (**3**) became the major components as the photolysis progressed.

On direct (Pyrex filter) and on sensitized (Michler's ketone) irradiations, **7** gave naphthalene and **3** in the ratio of 3:1 (direct) and 1.7:1 (sensit.). Both COT **9** and SB **2** were absent in photolysates (glc evidence), and **3** was inert under the irradiation conditions used here.

Since the structure of SB **3** was previously assigned on the basis of spectroscopic data alone, the diimide reduction of **3** was carried out in order to provide some chemical support. The reduction of **3** proceeded in a highly stereoselective manner to give **10** quantitatively (Scheme 3). The interpretation of the ^{1}H 400-MHz nmr spectrum of **10** is straighforward. The aliphatic ring protons occur as six distinctly separated one-proton resonances; couplings between protons were confirmed by double irradiation techniques (see Experimental). The stereochemistry of **10** was assigned on the basis that $J_{5,6} = 5$ Hz (cf. $J_{5,6} = 5.4$ Hz in **12** (2), whereas $J_{5,6'} = 0$ Hz in **13** (3)).

Singlet and triplet energies of 7 and quantum yields

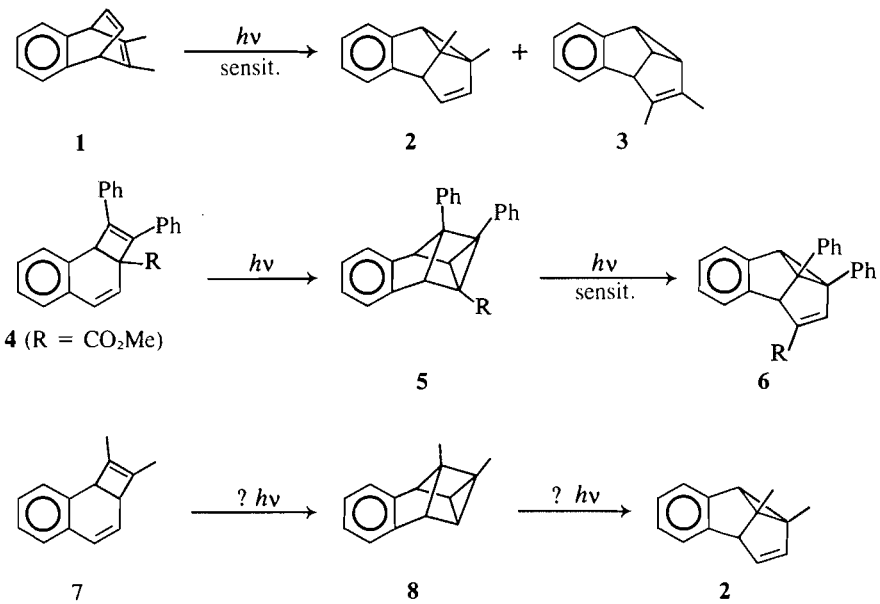
The singlet energy of **7** in cyclohexane at room temperature was determined to be 94 kcal/mol from intersection of the absorption and fluorescence spectra. The triplet energy of **7** could not be obtained spectrometrically since no phosphorescence in isopentane–methylcyclohexane glass at 77 K could be detected. However, an "effective" triplet energy at room temperature in cyclohexane solution of $61 \geq E_T \geq 59$ kcal/mol (cf. 61 kcal/mol for styrene) is suggested by triplet sensitization experiments: the conversion of **7** to naphthalene and SB **3** can be sensitized by Michler's ketone ($E_T = 61$ kcal/mol), but not by 2-acetonaphthone ($E_T = 59$ kcal/mol) nor by 1-acetonaphthone ($E_T = 56$ kcal/mol).

The fluorescence quantum yield of **7** at room temperature was determined to be 0.50 by the relative quantum yield method using naphthalene as standard ($\phi_f = 0.23$ (4)) (see Experimental). Product quantum yields for all the transformations observed in this study are summarized in Table 1.

Mechanistic considerations

Unlike the case of **4** → **5** → **6**, the formation of a [2 + 2] cycloadduct in the photoconversion of diene **7** to SB **3** was not detected (glc and nmr monitoring of photolysates). The non-observation of possible intermediate **8** does not, however, preclude its involvement in the production of SB **3**, since **8** may be photo-labile. In order to study this point further, irradiations of the doubly deuterated diene **7***a* (ca. 15%-d_1 at C-4; ca. 90%-d_1 at C-5) were undertaken. The synthesis of **7***a* is outlined in Scheme 4. The structures of compounds **14** and **18** follow from the synthetic route and spectral properties (see Experimental).

The direct and sensitized photolysis of **7***a* led to semibullvalene product **3***a* with deuterium at C-2 (15%-d_1) and at



SCHEME 1

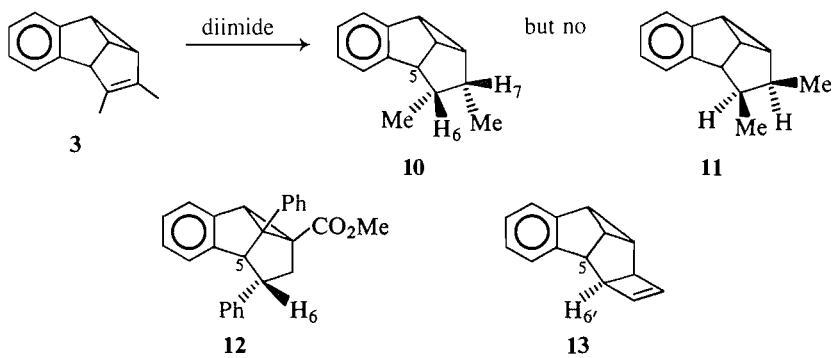
direct (a)	19%	57%
sensit. (b)	24%	41%

SCHEME 2



SCHEME 3

C-8 (90%-d_1), as determined by ^{1}H nmr analysis. Recovered reactant showed no label scrambling after >85% consumption.

Three plausible mechanistic routes which rationalize the conversion of diene **7** to SB **3** are given in Scheme 5. A consequence of semibullvalene formation via route ii (Scheme 5), the [2 + 2] cycloaddition pathway, is that both **3***a* and **3***b* should be formed in approximately equal amounts because of the symmetry of the carbon skeleton of **8** (assuming small secondary deuterium isotope effects). Thus the finding that **7***a* gave **3***a* but no **3***b* is persuasive evidence that cycloadduct **8** is not an intermediate en route to **3**.

Inspection of the other pathways shown in Scheme 5 (i.e., routes i and iii) reveals that only route iii can provide the observed labelling pattern of product **3***a*. Route iii is formally equivalent to the ubiquitous Zimmerman di-π-methane rearrangement.

Another aspect of mechanistic interest concerns the formation of SB **3** during the direct irradiations of COT **9** (*vide supra*). By analogy with the isomerization of cyclooctatetraenes to semibullvalenes (5, 6) there exists the possibility that some **3** may derive from 5,9 + 8,10 bonding of an excited state stereoisomer of COT **9** (i.e., **22**; Scheme 6, route i), rather than all of it being produced as a result of secondary photolysis of diene **7** (Scheme 6, route ii).

A means of determining competition between route i and route ii was provided by examining the photolysis of the la-

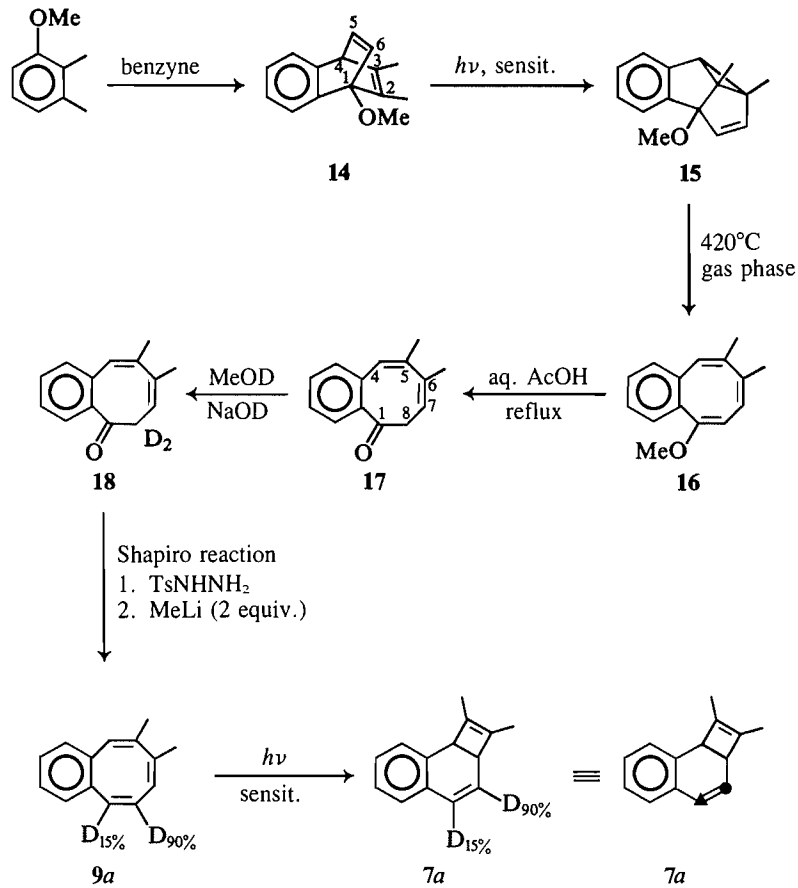
TABLE 1. Quantum yield data[a]

Compound	Light wavelength (nm)	Sensitizer	Φ (Product appearance) 7	3	Naphthalene
9	366	1-Acetonaphthone	0.36	—	—
9	300	None	0.04	—	—
7	300	None	—	0.030	0.10
7	335	Michler's ketone	—	0.093	0.16
7	335	1- or 2-acetonaphthone	—	<0.01	<0.01

[a]Ferrioxalate actinometry; cyclohexane solvent. Φ's given are extrapolated to zero conversion; product analyses by glc (internal hydrocarbon standard) at several conversions ≤ 8%. Experimental error of Φ's is ±10%. For sensitized runs, sensitizers absorb >95% of incident light.



SCHEME 4

belled COT **9***a*. The semibullvalene product isolated from the direct irradiation of **9***a* showed hydrogen distributions consistent with those anticipated for route ii, and which were the same as those found for the conversion of diene **7***a* to SB **3***a* (*vide supra*). Thus **3** is not produced by the traditional 5,9 + 8,10 bonding pathway (route i) usually invoked to rationalize semibullvalene formation in the cases of non aro-fused COT's.

Discussion

The excited state of diene **7** yielding SB **3** and naphthalene upon sensitization with Michler's ketone is assumed to be the triplet, since the products are formed with greater efficiency than when generated from direct irradiation. The multiplicity assignment(s) in the case of the direct irradiation is much less certain. Interpretation of the quantum yield data (Table 1) in terms of the Zimmerman "ratio bracketing rule" (7) indicates that at least ca. 50% of the naphthalene must be singlet derived (i.e., $0.05 \lesssim {}^1\Phi_{Nap} \lesssim 0.1$). But the percentage of singlet involvement in the production of SB **3** cannot be gleaned from this approach. We note, however, that a general preference for triplet initiation of DPM rearrangements has been observed for rigid systems (8), and this situation will hold in the present case if $\Phi_{isc} = 0.33$. This value is not inconsistent with what we know of the fate of excited singlet **7** (i.e., since $\phi_f = 0.5$ and ${}^1\Phi_{Nap} \gtrsim 0.05$, then $\Phi_{isc} \lesssim 0.45$).

With regard to the photoreactions observed for **7**, i.e., cleavage to naphthalene and rearrangement to SB **3**, only the former is well precedented in benzobicyclo[4.2.0]octa-2,4,7-triene derivatives (2). For the latter reaction there may be at least two analogous literature examples.

The first concerns the formation of SB **24** from the photoreaction between naphthalene and dimethyl acetylene-

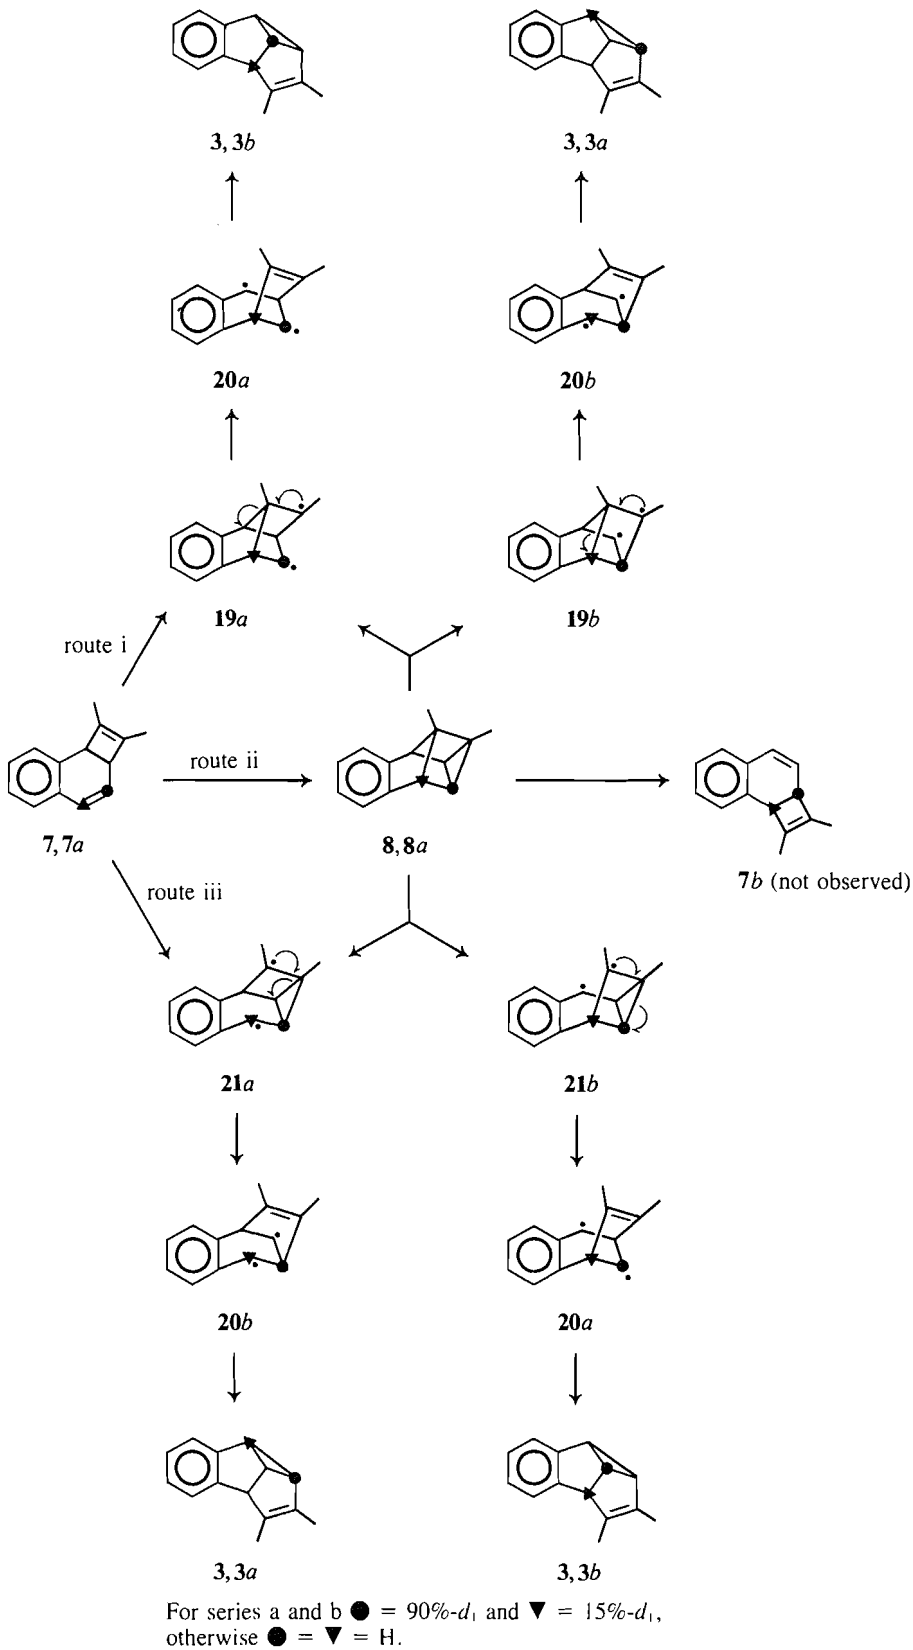
For personal use only.



SCHEME 5

dicarboxylate (9). Addition of the acetylene to the diradical species **23** was the suggested product rationalization (Scheme 7). However, naphthalenes are well known to undergo [2 + 2] photocycloadditions with acetylenes (2) (and with alkenes (10)). In light of the present work a plausible alternative pathway to SB **24** is via a DPM rearrangement of initially formed [2 + 2] adduct **25** (Scheme 7).

The second example is the photoconversion of COT **26** to SB

30. No previous rationalization of the reaction was given (11). It is readily seen that formation of SB **30** is conveniently accounted for in terms of a DPM rearrangement of initially formed diene **27** (Scheme 8). Note that the mechanism depicted in Scheme 8 predicts the observed location of the cyano group in **30** and both deuterium labels in **30***a*. The photochemistry of COT **26** is presently being reinvestigated,[1] and we report here that diene **27** is indeed an intermediate, and that it further photoisomerizes to SB **30**.

Experimental

The nmr spectra were recorded on a Bruker 400-MHz instrument or on a Varian (EM-360) 60-MHz instrument, with TMS as internal standard. The chemical shifts are in δ units and the coupling constants (J) in Hz. The abbreviations s, d, t, q, and m refer to singlet, doublet, triplet, quartet, and multiplet, respectively. The ir spectra were recorded on a Perkin–Elmer 337 spectrometer and are given in cm^{-1}. The uv spectra (run in cyclohexane solvent) were measured on a Cary 15 spectrometer; maxima are given in nm, with ϵ_{max} values in parentheses; sh = shoulder. Mass spectra were recorded on an MS 9 (A.E.I.) instrument at 70 eV. All melting points are uncorrected. Elemental analyses were performed by Galbraith Labs. Inc., Knoxvil-

le, TN. The glc analyses were made on a Varian 3700 instrument (FID) coupled to a Varian CDS 111 computing integrator, and fitted with an OV-101 glass capillary column, 50 m, with helium as carrier gas. Column chromatography was performed with Silica Gel 60 (230–400 mesh; Merck) or Silica Gel H (100–200 mesh; Grace). Cyclohexane for photolyses was prepared by scrubbing with 10% of its volume of 30% fuming sulfuric acid, followed by washing with 10% aqueous sodium hydroxide, drying ($MgSO_4$), and finally distilling from calcium hydride. Sensitizers were distilled or recrystallized prior to use.

General procedures for preparative photolyses

The apparatus consisted of a 450-W Hanovia medium pressure mercury arc surrounded by a water cooled quartz immersion well. For direct irradiations the light was filtered through a cylindrical Pyrex sleeve. For irradiations at wavelengths >340 nm the light was passed through an aqeuous filter jacket (10-mm path length) containing a solution prepared from 750 g NaBr and 8 g $Pb(NO_3)_2$ per 1 L of water. Before irradiations, solutions (35 mL) of reactants contained in 2 cm × 15 cm quartz test-tube-like photolysis cells were deoxygenated by flushing with argon. The tubes were sealed under a positive pressure of argon which was maintained over the stirred solutions throughout the course of the irradiations. The progress of photolyses was followed by glc analyses.

Sensitized irradiation of COT ***9***

A solution of 80.0 mg (0.44 mmol) of **9** (1) and 209.2 mg (1.23 mmol) of 1-acetonaphthone in 35 mL of cyclohexane was photolysed at >340 nm for 1 h (100% conversion by glc). The photolysate was concentrated and the residue chromatographed on Silica Gel 60 (2 cm × 25 cm) with cyclohexane solvent. The first band gave 77.6 mg (97%) of known **7** (1) after short-path distillation at 55°C/0.1 Torr (1 Torr = 133.3 Pa).

Direct irradiation of diene 7

A solution of 45.6 mg (0.25 mmol) of **7** in 35 mL of cyclohexane was photolysed with Pyrex-filtered light for 6 h (100% conversion by glc). The yields of naphthalene and SB **3** were 18.3 mg (57%) and 8.7 mg (19%), respectively, as determined by glc after addition of a known amount of standardized tridecane. The photolysate was concentrated and the residue chromatographed on Silica Gel 60 (2 cm × 45 cm) with cyclohexane solvent. The first band gave 9.6 mg (30%) of naphthalene, mp 78–80°C, after recrystallization from ethanol. The second band gave 7.2 mg (16%) of known SB **3** (1) after short-path distillation at 55°C/0.1 Torr.

Sensitized irradiation of diene 7

A solution of 96.3 mg (0.53 mmol) of **7** and 4.7 mg (0.02 mmol) of Michler's ketone in 35 mL of cyclohexane was photolysed at >340 nm for 2 h (100% conversion by glc). The yields of naphthalene and SB **3** were 27.8 mg (41%) and 23.1 mg (24%), respectively, as determined by glc after addition of a known amount of standardized tridecane. The photolysate, after work-up as in the case of the direct irradiation of **7**, gave 21.3 mg (31%) of naphthalene, mp 78–80°C, and 20.3 mg (21%) of SB **3**.

Diimide reduction of SB ***3***

To a stirred mixture of 47.9 mg (0.26 mmol) of **3** and 3.45 g (17.8 mmol) of potassium azodicarboxylate in 20 mL of methanol at −30°C, 2 mL of acetic acid was added in one portion. The reaction mixture was allowed to warm to room temperature during 1.5 h after which time the solution was added to 200 mL of cyclohexane and was washed with 5% aqueous potassium hydroxide (200 mL) followed by water (2 × 200 mL). The cyclohexane solution was dried ($MgSO_4$), concentrated, and the residue chromatographed on Silica Gel 60 (2 cm × 35 cm) with cyclohexane solvent. The first band gave 47.9 mg (99%) of *endo*-3,4-benzo-6,7-dimethyltricyclo[3.3.0.$0^{2,8}$]oct-3-ene (**10**) as a colourless oil (glc purity >99%) after short-path distillation at 55°C/0.1 Torr; uv: 230 (5 060), 261.5 sh (600), 267 (970), 273 sh (1 300), 275 (1 420), and 282.5 (1 660); nmr (400 MHz, $CDCl_3$): 6.90–7.21 (m, 4**H**, aromatics), 3.34 (t, 1H, **H**-5, $J_{5,1} = J_{5,6} = 5.5$), 2.98 (q, 1H, H-1, $J_{1,2} = J_{1,8} = 6.5$, $J_{1,5} = 5.5$), 2.78–2.88 (m, 1H, H-6, $J_{6,5} = 5.5$, $J_{6,7} = 10.0$, $J_{6,C6\text{-}Me} = 7.0$), 2.47–2.57 (m, 1H, H-7, $J_{7,6} = 10.0$, $J_{7,8} = 6.5$, $J_{7,C7\text{-}Me} = 7.5$), 2.25 (d × d, 1H, H-2, $J_{2,1} = 6.5$, $J_{2,8} = 7.5$), 2.01 (q, 1H, H-8, $J_{8,1} = J_{8,7} = 6.5$, $J_{8,2} = 7.5$), 0.78 (d, 3H, C6-methyl, $J_{C6\text{-}Me,6} = 7.0$), and 0.36 (d, 3H, C7-methyl, $J_{C7\text{-}Me,7} = 7.5$); spin decoupling experiments: irradiation of H-5 collapsed H-1 to a t ($J_{1,2} = J_{1,8} = 6.5$) and modified the H-6 m; irradiation of H-1 collapsed H-5 to a d ($J_{5,6} = 5$), H-2 to a d ($J_{2,8} = 7.5$), and H-8 to a br t ($J_{8,2} = 7.5$, $J_{8,7} = 6.5$); irradiation of H-6 collapsed H-5 to a d ($J_{1,5} = 5.5$), the C6-methyl to an s, and modified H-7; irradiation of H-7 collapsed H-8 to a br t ($J_{8,2} = 7.5$, $J_{8,1} = 6.5$), the C7-methyl to an s, and modified H-6; irradiation of H-2 collapsed H-1 to a br t ($J_{1,5} = 5.5$, $J_{1,8} = 6.5$), and H-8 to a t ($J_{8,1} = J_{8,7} = 6.5$); irradiation of H-8 collapsed H-2 to a d ($J_{2,1} = 6.5$), H-1 to a d × d ($J_{1,2} = 6.5$, $J_{1,5} = 5.5$), and modified H-7; irradiation of the C7-methyl collapsed H-7 to a d × d ($J_{7,8} = 6.5$, $J_{7,6} = 10.0$); irradiation of the C6-methyl collapsed H-6 to a d × d ($J_{6,5} = 5.5$, $J_{6,7} = 10.0$). Mass spectrum showed molecular ion at m/e = 184.1250 (100%), $C_{14}H_{16}$ requires 184.1253.

Quantum yield determinations

Quantum yields were performed on an apparatus previously described (1), which includes an optical bench arranged for beam splitting into ferrioxalate actinometer (12). Sample solutions (4 mL) of reactants (ca. 1×10^{-2} *M*) and sensitizer, if any (1- and 2-acetonaphthone, 3×10^{-2} *M*; Michler's ketone, 0.57×10^{-3} *M*), were deoxygenated prior to irradiation by flushing with argon. A positive pressure of argon was maintained over the stirred solutions throughout the course of the irradiations. For Φ's, and further experimental details, see Table 1.

Fluorescence studies of diene 7

The fluorescence spectrum of **7** was measured in cyclohexane solution at room temperature on an Aminco–Bowman Spectrometer, and showed a maxima at 335 nm. Intersection of emission and absorption spectra occurred at 305 nm corresponding to a singlet energy of 94 kcal/mol. The approximate fluorescence quantum yield of **7** was measured relative to naphthalene as standard. The absorption and emission spectra of these two compounds are similar in the 280–320 nm and 300–400 nm range, respectively. The optical densities of both compounds in cyclohexane solution were matched at 283 nm, the fluorescence excitation λ employed. The fluorescence intensities of the naphthalene and **7** solutions were integrated by cutting and weighing the recorded spectra. Since the ratio was 1.00:2.16, respectively, and $\phi_f = 0.23$ for naphthalene (4), then $\phi_f = 0.50$ for diene **7**.

*2,3-Dimethyl-1-methoxy-4-hydro-1,4-ethenonaphthalene (****14****)*

A mixture of benzene diazonium carboxylate, prepared from 3.5 g (25.6 mmol) of anthranilic acid (1) and 500 mL of 2,3-dimethylanisole was stirred at 50°C overnight under a dry nitrogen atmosphere, and then concentrated. The residue was dissolved in acetone (50 mL), diluted with cyclohexane (500 mL), filtered, and the filtrate concentrated. The residue was chromatographed on Silica Gel H (2.5 cm × 60 cm) with 2% ether–cyclohexane. The first band was residual dimethylanisole. Concentration of the second band gave a yellow residue which yielded 2.90 g (62%) of colourless **14**, mp 83–85°C, after two recrystallizations from ethanol; uv: 248 sh (845), 256.5 (710), 263 (805), 271 (1 040), and 278 (1 000); nmr (60 MHz, CCl_4): 6.56–7.24 (m, 6H, aromatics and vinyls), 4.27 (d × d, 1H, bridgehead, $J_{4,5} = 6$, $J_{4,6} = 1.5$), 3.78 (s, 3H, methoxyl), 1.73 (s, 3**H**, methyl), and 1.66 (s, 3H, methyl). *Anal.* calcd. for $C_{15}H_{16}O$: C 84.87, H 7.60; found: C 84.81, H 7.76.

Sensitized photolysis of barrelene ***14***

A solution of 506.2 mg (2.39 mmol) of **14** and 10 mL of acetone in 250 mL of cyclohexane was irradiated with Pyrex-filtered light for 50 min. The photolysate was concentrated and the residue taken up in 3 mL of 80% aqueous acetic acid. The solution was refluxed for 1 h with stirring, cooled, basified with aqueous KOH, and extracted with cyclohexane. The extract was washed with water, dried ($MgSO_4$),

For personal use only.

concentrated, and the residue chromatographed on Silica Gel H (3 cm × 50 cm) with 2% ether–cyclohexane. The first band gave 82.5 mg (16%) of recovered **14**, and the second band gave 101.2 mg (20%) of 3,4-benzo-1,8-dimethyl-5-methoxytricyclo[3.3.0.$0^{2,8}$]octa-3,6-diene (**15**) (glc purity > 99.5%) as a colourless oil after short-path distillation at 55°C/0.1 Torr; uv: 231 sh (9 000), 269 sh (750), 275 (930), and 282 (810); nmr (60 MHz, CCl_4): 6.63–6.92 (m, 4H, aromatics), 5.30 (d, 1H, H-6, $J_{6,7}$ = 5.0), 4.74 (d, 1H, H-7, $J_{7,6}$ = 5.0), 3.30 (s, 3H, methoxyl), 2.46 (s, 1H, H-2), 1.48 (s, 3H, methyl), and 1.28 (s, 3H, methyl); spin decoupling experiment: irradiation of H-7 collapsed H-6 to an s. Mass spectrum showed molecular ion at m/e = 212.1198 (77%); $C_{15}H_{16}O$ requires 212.1201.

Gas phase thermolysis of SB 15

Over a 45-min period 132.9 mg (0.63 mmol) of **15** was distilled into a Pyrex tube (2 cm × 30 cm) packed with glass beads (0.5 cm diameter) maintained at 420°C. The pressure in the system was kept at 3.5 Torr by the passage of nitrogen. The thermolysis product, collected in a cooled U-trap (Dry Ice – acetone), was chromatographed on Silica Gel 60 (3 cm × 70 cm) with 5% ether–cyclohexane. Crystallization from ethanol of the first band gave 110.0 mg (83%) of colourless 6,7-dimethyl-10-methoxybenzocyclooctatetraene (**16**), mp 68.5–70.5°C; ir (melt): 810, 825, and 840, trisubstituted vinyls; uv: 230 sh (13 300), 253 sh (5 550), and 270 sh (1 650); nmr (400 MHz, $CDCl_3$): 7.18–7.28 (m, 3H, aromatics), 6.97–7.03 (m, 1H, aromatic), 6.35 (br s, 1H, H-5, $J_{5,C6\text{-}Me}$ = 1.5), 5.56 (sym. m, 1H, H-8, $J_{8,9}$ = 3.7, $J_{8,C7\text{-}Me}$ = 1.5), 5.14 (sym. m, 1H, H-9, $J_{9,8}$ = 3.7, $J_{9,C7\text{-}Me}$ = 1.5), 3.68 (s, 3H, methoxy), 1.94 (d, 3H, C6-methyl, $J_{C6\text{-}Me,5}$ = 1.5), and 1.75 (t, 3H, C7-methyl, $J_{C7\text{-}Me,8}$ = $J_{C7\text{-}Me,9}$ = 1.5); spin decoupling experiments: irradiation of H-5 collapsed the C7-methyl to an s; irradiation of H-8 collapsed the C7-methyl to a d ($J_{C7\text{-}Me,9}$ = 1.5) and H-9 to a q ($J_{9,C7\text{-}Me}$ = 1.5); irradiation of H-9 collapsed the C7-methyl to a d ($J_{7,C7\text{-}Me}$ = 1.5) and H-8 to a q ($J_{8,C7\text{-}Me}$ = 1.5); irradiation of the C6-methyl modified H-5 to a sharp s; irradiation of the C7-methyl collapsed H-8 to a d ($J_{8,9}$ = 3.7) and H-9 to a d ($J_{9,8}$ = 3.7). Mass spectrum showed molecular ion at m/e = 212.1200 (90%). *Anal.* found: C 85.02, H 7.69.

Ketone 17

A solution of 287.8 mg (1.45 mmol) of **16** in 3 mL of 80% aqueous acetic acid was refluxed for 1 h, cooled, basified with aqueous KOH, and extracted with cyclohexane. The extract was washed with water, dried ($MgSO_4$), concentrated, and the residue crystallized from ethanol to give 218.5 mg (81%) of 5,6-dimethyl-2,3-benzo-2,4,7-cyclooctatrienone (**17**), mp 72–74°C; ir (KBr): 1670, C=O; uv: 232 (29 800), 304 (3 000), 335 sh (960), 349 sh (600), and 367 sh (195); nmr (60 MHz, CCl_4): 8.01–8.26 (m, 1H, aromatic closest to C=O), 6.97–7.52 (m, 3H, remaining aromatics), 6.53 (br s, 1H, H-4), 5.40 (br t, 1H, H-7, $J_{7,8}$ = $J_{7,8'}$ = 8.0), 3.05–3.52 (m (temperature sensitive), 2H, C8-methylene), 2.07 (d, 3H, C6-methyl, $J_{C6\text{-}Me,7}$ = 1.5), and 1.77 (d, 3H, C5-methyl, $J_{C5\text{-}Me,4}$ = 1.5); spin decoupling experiments: irradiation of C8-methylene collapsed H-7 to a br s; irradiation of C5-methyl modified H-4 to a sharp s. Mass spectrum showed molecular ion at m/e = 198.1046 (100%); $C_{14}H_{14}O$ requires 198.1045. *Anal.* calcd. for $C_{14}H_{14}O$: C 84.81, H 7.12; found: C 84.95, H 7.20.

COT 9 from ketone 17 via the Shapiro reaction (ref. 13)

A solution of 1.0153 g (5.1 mmol) of **17**, 50 mg (0.26 mmol) of *p*-toluenesulfonylchloride, and 1.30 g (7.0 mmol) of *p*-toluenesulfonylhydrazide in 25 mL methanol was stirred at room temperature for 24 h and then cooled to −12°C for 12 h. The precipitate was filtered, washed with cold methanol, and dried *in vacuo* to give 1.7335 g (93%) of the tosylhydrazone as a white solid, mp 166–168°C dec. A solution of 3 mL (0.48 mmol) of 1.6 *M* methyllithium in ether was slowly (1 min) titrated into an ice-cooled, stirred slurry of 345.0 mg (0.95 mmol) of the tosylhydrazone in 20 mL of dry ether under argon until the mixture just maintained an orange colour. A second 3-mL aliquot of the methyllithium was added during 1 min. The orange solution was stirred at room temperature for 2 h, refluxed for 2 h, cooled, and then made slightly acidic by the careful addition of aqueous ammonium chloride solution. The ether layer was extracted with brine, dried ($MgSO_4$), concentrated, and chromatographed on Silica Gel 60 (1.5 cm × 40 cm) with cyclohexane solvent. Short-path distillation (55°C/0.1 Torr) of the first band gave 83.9 mg (49%) of a colourless oil, identical (glc, nmr) to COT **9**.

Labelled COT 9a from ketone 17

To a solution of 200.0 mg (0.94 mmol) of ketone **17** in 20 mL of methanol-d_1 was added 0.15 mL of a 1.43 *M* solution of sodium methoxide in methanol-d_1. The solution was stirred at room temperature for 21.5 h, after which time 2 mL of a 0.72 *M* solution of *p*-toluenesulfonylchloride in methanol-d_1 was added, followed by 260.7 mg (1.40 mmol) of dry *p*-toluenesulfonylhydrazide. The solution was stirred at room temperature for a further 24 h and then cooled to −12°C for 12 h. The precipitate was filtered and washed with cold methanol. The solid was dissolved in 10 mL of acetone and was precipitated by the addition of 30 mL of water. The solid was rapidly filtered, and the precipitation procedure repeated. The tosylhydrazone, after drying *in vacuo*, gave 264.3 mg (74%) of white powder, mp 166–168°C dec. The procedure described above for the preparation of COT **9** was used to convert 234.2 mg (0.67 mmol) of the labelled tosylhydrazone to 61.7 mg (55%) of COT **9***a* (glc purity > 99%); nmr (400 MHz, $CDCl_3$; CW mode): 6.95–7.22 (m, 4.05H, aromatics), 6.52 (br s, 0.85H, H-10), 6.28 (br s, 0.97H, H-5), 6.03 (m, 0.10H, H-9), 5.56 (br s, 0.96H, H-8), 1.94 (d, 3.00H, C6-methyl, $J_{C6\text{-}Me,5}$ = 1.5), and 1.78 (d, 3.00H, C7-methyl, $J_{C7\text{-}Me,8}$ = 1.5), i.e., COT **9***a* is 90%-d_1 labelled at C-9 and 15%-d_1 labelled at C-10. See Table 2, entry 1, for further hydrogen integration details.

Sensitized irradiation of labelled COT 9a

A solution of 97.8 mg (0.53 mmol) of **9***a* and 197.6 mg (1.16 mmol) of 1-acetonaphthone in 35 mL of cyclohexane was photolysed at >340 nm for 1 h (complete conversion by glc). The photolysate was worked up as in the case of the sensitized irradiation of COT **9** to give 96.2 mg (98%) of diene **7***a* (glc purity > 99%); nmr (60 MHz, CCl_4): 6.67–7.06 (m, 4.09H, aromatics), 6.06 (s, 0.83H, H-4), 5.76 (m, 0.09H, H-5), 3.65 (br s, 0.96H, H-1), 3.33 (br s, 0.97H, H-6), 1.40 and 1.63 (two br overlapping singlets, 6.00H, methyls). See Table 2, entry 2, for further hydrogen integration details.

Direct irradiation of labelled diene 7a

A solution of 86.7 mg (0.47 mmol) of **7***a* in 35 mL of cyclohexane was photolysed with Pyrex-filtered light for 4.5 h (85% conversion by glc). The photolysate was worked up as in the case of the direct irradiation of unlabelled diene **7**. Column chromatography gave: 15.1 mg (27%) of labelled naphthalene (from the first band); 12.9 mg (15%) of recovered diene **7***a* (from the second band; see Table 2, entry 3, for hydrogen integration details); and 10.7 mg (14%) of SB **3***a* (from the third band); nmr (60 MHz, CCl_4): 6.72–7.24 (m, 4.10H, aromatics), 3.50 (d, 1.02H, H-5, $J_{5,1}$ = 6.5), 3.15 (t, 0.99H, H-1, $J_{1,5}$ = $J_{1,2}$ = 6.5), 2.77 (d, 0.89H, H-2, $J_{2,1}$ = 6.5), 2.36 (m, 0.13H, H-8), and 1.49 (s, 6.00H, methyls). See Table 2, entry 5, for further hydrogen integration details.

Sensitized irradiation of labelled diene 7a

A solution of 94.9 mg (0.52 mmol) of **7***a* and 4.7 mg (0.02 mmol) of Michler's ketone in 35 mL of cyclohexane was photolysed at >340 nm for 1.75 h (87% conversion by glc). The photolysate was worked up as in the case of the sensitized irradiation of diene **7**. Column chromatography gave: 17.2 mg (30%) of labelled naphthalene (from first band); 10.3 mg (11%) of recovered diene **7***a* (from second band; see Table 2, entry 4, for hydrogen integration details); and 16.0 mg (19%) of SB **3***a* (from third band; see Table 2, entry 6, for hydrogen integration details).

Direct irradiation of labelled COT 9a

A solution of 132.1 mg (0.73 mmol) of **9***a* in 35 mL of cyclohexane was photolysed with Pyrex-filtered light for 25 h (100% conversion by glc). The photolysate was concentrated and the residue chromatographed on Silica Gel 60 (1.7 cm × 45 cm) with cyclohexane

The vibrational spectra of thioketene and deuterothioketenes

MANUEL TORRES, IMRE SAFARIK, ALLAN CLEMENT, RATNAKAR K. GOSAVI, AND OTTO P. STRAUSZ
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada, T6G 2G2

Received January 3, 1984

MANUEL TORRES, IMRE SAFARIK, ALLEN CLEMENT, RATNAKAR K. GOSAVI, and OTTO P. STRAUSZ. Can. J. Chem. **62**, 2777 (1984).

The FTIR spectra of low temperature argon matrix isolated thioketene-d_0, thioketene-d_1, and thioketene-d_2 molecules from the flow thermolysis of the corresponding 1,2,3-thiadiazoles have been recorded and analyzed. Assignment of the normal frequencies has been made by a normal coordinate analysis. Alternatively, vibrational frequencies were computed by *ab initio* MO calculations and the predicted values compared to the experimentally observed ones.

MANUEL TORRES, IMRE SAFARIK, ALLEN CLEMENT, RATNAKAR K. GOSAVI et OTTO P. STRAUSZ. Can. J. Chem. **62**, 2777 (1984).

Opérant à basse température, on a enregistré et analysé les spectres FTIR de molécules, isolées dans des matrices d'argon, de thiocétène-d_0, de thiocétène-d_1 et de thiocétène-d_2 provenant de la thermolyse à flux des thiadiazoles-1,2,3 correspondantes. On a attribué les fréquences normales en se basant sur une analyse normale des coordonnées. On a aussi calculé les fréquences vibrationnelles en faisant appel à des calculs *ab initio* d'orbitales moléculaires et on a alors comparé les valeurs calculées avec les valeurs expérimentales.

Thioketene **1** was first prepared by Howard in 1962 (1) in the thermolysis of *tert*-butylthioacetylene, which produces **1** together with isobutene. Thioketene was described as unstable in solution above −80°C and characterized by a strong ir absorption at 1750 cm^{-1}. Stable substituted thioketenes were subsequently reported by Raasch (2), Elam *et al.* (3), and Seybold (4), and they all feature a characteristic strong ir band at ~1750 cm^{-1}. In 1974 Krantz and Laureni (5) observed the formation of thioketene **1** together with ethynylthiol in the λ>290-nm photolysis of argon-matrix 1,2,3-thiadiazole and reported the observed ir bands of **1** and its deuterated isotopomers assigned on the basis of the similarity of the absorption intensity versus irradiation time plots, Table 1. Each of the observed thioketene absorptions was assigned, presumably intuitively, to a normal mode (Table 1). A subsequent paper by the same authors published in 1981 (6) reports somewhat revised spectral assignments belonging to **1** and its deutero and ^{13}C isotopomers, but none of the normal mode assignments with the exception of the trivial C=C and C—H/D stretching modes, Table 2.

Substituted thioketenes have also been prepared by the flash thermolysis of 1,2,3-thiadiazoles and 1,3-dithietanes (7–9), by the reaction of alkylidene-phosphoranes and α-monosubstituted phosphonate carbanions with CS_2 (10), and by argon-matrix photolysis of 1,2,3-thiadiazoles (11). Unsubstituted thioketene **1** has also been detected in the thermolysis of 1,2,3-thiadiazole and dithioacetic acid (12) and in the argon-matrix photolysis of vinylene trithiocarbonate (13).

The microwave (14, 15) and photoelectron (12) spectra of **1** have been investigated and, although some of the thioketene ir absorptions have been reported (5, 6), to date no serious attempt has been made to assign the thioketene vibrational spectra. Encouraged by the results obtained in the study of the vibrational spectra of argon matrix isolated thiirene (16) and thioformaldehyde (17), we have carried out a study of the vibrational spectra of thioketene and its deuterated isotopomers obtained by flow thermolysis of 1,2,3-thiadiazole **2**, 4-*d*- and 5-*d*-1,2,3-thiadiazole, and 4,5-d_2-1,2,3-thiadiazole, Figs. 1, 2, and 3.

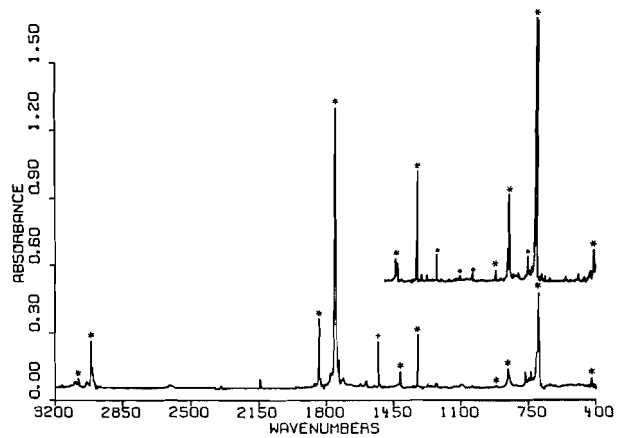

FIG. 1. FTIR spectrum of thioketene-d_0 argon matrix isolated obtained by flow thermolysis of 1,2,3-thiadiazole. Inset: the thioketene-d_0 spectrum isolated in a nitrogen matrix. (*) bands assigned to thioketene-d_0, (+) band assigned to CS_2, (●) bands assigned to unthermolyzed 1,2,3-thiadiazole.

Experimental

An Air-Products and Chemical Inc. Model CS-202 Displex closed-cycle helium refrigeration system coupled to a high vacuum line was employed. The matrix deposit was made on a cesium iodide plate kept at 10 K and the typical host-to-guest ratios were 1:300 with an average deposition time of 30 min at a typical flow rate of 0.2–0.3 μmol/min. Flow thermolyses were carried out in a 6 mm id × 100 mm quartz tube wrapped with a heating filament, maintained at the thermolysis temperature, and placed before the cryostat. The temperature was monitored by an iron versus constantan thermocouple. The residence time at the deposition rate was measured to be ~0.7 s. Alternatively, photolyses were carried out with a Hanovia 30620 medium pressure mercury arc equipped with a 7910 Vycor filter.

1,2,3-Thiadiazole (18), 4-*d*- and 5-*d*-1,2,3-thiadiazole (17, 19), and 4,5-d_2-1,2,3-thiadiazole (17) were prepared as reported before and 4000–400 cm^{-1} ir spectra of matrix isolated species were obtained on a Nicolet 7199 FT infrared spectrophotometer at 1 cm^{-1} resolution and with baseline correction. The ir spectra below 400 were obtained on a Perkin Elmer model 457 spectrophotometer. The MO calculations were carried out on the AMDAHL 5860 computer at the University of Alberta.

Results and discussion

Flow thermolysis of 1,2,3-thiadiazole **2** at 450–520°C resulted in the formation of **1** and nitrogen. Small amounts of

[a] When the band was split, due to matrix effects, only the strongest band was used in the calculation.

[b] $\left[\frac{\nu_{calcd} - \nu_{obs}}{\nu_{obs}} \times 100\right]$

[c] Tentative, not used for calculation.

unthermolyzed **2** and CS_2, probably resulting from secondary decomposition of the thioketene, were also observed but ethynylthiol was notably absent and this made it possible to obtain the ir spectrum of essentially pure thioketene **1**, Fig. 1. Similarly, flow thermolysis of 4-*d*- or 5-*d*-1,2,3-thiadiazole and 4,5-d_2-1,2,3-thiadiazole resulted in the formation of thioketene-d_1, Fig. 2, and thioketene-d_2, Fig. 3. Owing to the weakness of some of the thioketene bands, assignment of the thioketene d_0, d_1, and d_2 bands was based on the criterion that they be observable in both the flow thermolysis and the λ>210-nm photolysis of **2** under argon-matrix conditions. In addition, bands assigned to thioketene-d_1 were also observed when either 4-*d*- or 5-*d*-1,2,3-thiadiazole was used as source compound. Some of the bands assigned to thioketene appear as doublets but the split is not affected by dilution (200:1 to 500:1), whereas it changes or disappears by changing the matrix environment and therefore has been attributed to different matrix trapping sites (17, 20). In general, ir bands of **1** are found to be sharper and better resolved in nitrogen than in argon matrices and nitrogen causes a hypsochromic shift of 0–10 cm^{-1} as compared to argon, Fig. 1.

As has been established by microwave spectroscopy (14, 15), the thioketene molecule has a planar geometry, and C_{2v} symmetry. The nine normal vibrations form the representation: $4a_1 + 2b_1 + 3b_2$ and the same considerations should apply to thioketene-d_2, whereas thioketene-d_1 has a C_s symmetry and forms the representation: $7a' + 2a''$. In all cases the nine normal vibrations are ir active. The ir spectra of thioketene-d_0, d_1, and d_2, Figs. 1, 2, and 3, respectively, were obtained as described above and the observed frequencies and assignments are listed in Table 3.

C—H stretchings

Two broad bands have been observed for thioketene-d_0 in the C—H stretching region, one at 3012 and a doublet at 3068 and 3097 cm^{-1}, whereas thioketene-d_2 features a single clear absorption at 2229 cm^{-1} and a weak absorption, tentatively assigned to **1**-d_2, at 2330 cm^{-1}. These are assigned to the symmetric and asymmetric C—H stretchings of thioketene-d_0 and thioketene-d_2, respectively. On the other hand, thioketene-d_1 exhibits absorptions at 2274 and 3060 cm^{-1} which are assigned to the two a' C—H stretchings.

C=C and C=S stretchings

The very intense band at 1755 cm^{-1}, which has long been assigned to the C=C stretch of thioketene, shifts upon deuteration to 1738 cm^{-1} for thioketene-d_2. The unusually high wave number for the C=C stretch must be attributed to its coupling with the C=S stretch in a similar manner as observed in ketene for the coupling between the C=O and C=C stretchings, which causes a shift to higher wave numbers for the C=O st, to 2140 cm^{-1} from its normal value of ~1700 cm^{-1}, and at the same time shifts the C=C stretch, usually at ~1650 cm^{-1}, to 1380 cm^{-1} (21). Consequently, the C=S stretch expected in the broad region of 1000–1300 cm^{-1} (22) should be found at substantially lower wave numbers. The next bands identified in the thioketene spectrum appear at 918 and 858 cm^{-1}. These have their counterparts in thioketene-d_2 at 755 and 775 cm^{-1}, respectively. The very weak intensity and larger isotopic shift of the 918-cm^{-1} band made the 858 and 775-cm^{-1} bands a better choice for the C=S stretchings of thioketene-d_0

TABLE 4. Theoretical versus observed product rule ratios[a]

Species	Theoretical	Observed
a_1	0.509	0.515
b_1	0.762	0.744
b_2	0.543	0.540

[a] When the band was split, due to matrix effects, only the strongest band was used in the calculation.

[a] Calculated for thioketene-d_0.
[b] Calculated for thioketene-d_1.
[c] Calculated for thioketene-d_2.

and d_2. For thioketene-d_1, the C=C and C=S stretchings are found at 1760 and 770 cm^{-1}, respectively. The small but unusual shift to higher wave numbers of the ν(C=C) upon monodeuteration must lie in the fact that monodeuteration lowers the symmetry of the molecule to a C_s and consequently changes the nature of the coupling, as will be seen later in the potential energy distribution.

A band at 1840 cm^{-1} (m) is always observed in the spectrum of **1**-d_0. This band tends to diminish in intensity on warming the sample and no assignment is possible at this time.

C—H deformations

Two bands are observed at 1413 and 1323 cm^{-1} which fall in the CH_2 symmetric deformation region. For thioformaldehyde the symmetric deformation has been assigned to a band at 1447 cm^{-1} (17, 23, 24). In thioketene, however, this band should be at a much lower wavelength if one follows the parallelism between formaldehyde (1500 cm^{-1}) (25) and ketene (1115 cm^{-1}) (21), and therefore the stronger 1323 cm^{-1} band in thioketene-d_0, with counterparts at 1030 and 1210 cm^{-1} for **1**-d_2 and **1**-d_1 respectively, is assigned to the CH_2 symmetric deformation of thioketene. The other band of thioketene at 1413 cm^{-1} with counterparts at 1130 and 1268 cm^{-1} for thioketene-d_2 and d_1, respectively, is assigned to a $2\nu_5$ overtone (*vide infra*). Of the in-plane and out-of-plane asymmetric deformations, the out-of-plane is expected to be the more intense, and therefore the strong absorptions at 692, 555, and 625 cm^{-1} are assigned to the CH_2 out-of-plane deformations of thioketene-d_0, d_2, and d_1, respectively. As is common in the case of allenes (ref. 2, p. 70), this absorption frequently presents a detectable overtone to which the bands at 1413, 1130, and 1268 cm^{-1} (for **1**-d_0, **1**-d_2, and **1**-d_1) are assigned. Support for this comes from the fact that changing the host from argon to nitrogen causes the broad bands at 1413 and 692 cm^{-1} to split in well-defined doublets at 1430 and 1440 and 705 and 710 cm^{-1}, respectively. Similar effects are observed in the case of **1**-d_2 and **1**-d_1.

Skeletal vibrations

The two remaining vibrations are assigned to the in-plane and out-of-plane skeletal linear bending vibrations. In comparison to ketene, the presence of sulfur, a heavier atom than oxygen, should lower these two fundamentals and therefore they should be the two lowest vibrations. Therefore, the bands at 404 and 365 cm^{-1} for **1**-d_0 and at 375 and 308 cm^{-1} for **1**-d_2 are assigned to the b_1 and b_2 skeletal vibrations and bands at 325 and 382 cm^{-1} for **1**-d_1 to the a' and a'' skeletal vibrations.

Product rule

The theoretical Teller–Redlich rule (26) was applied for thioketene, based on the moments of inertia obtained with the geometrical parameters R(C=S) = 1.554 Å, R(C=C) = 1.314 Å, R(C—H) = 1.090 Å and the α(HCH) = 120.3° determined by Georgiou *et al.* from the microwave spectra (14). The values obtained are in good agreement with the observed values for each symmetry species, Table 4, thus supporting the assignment.

	C—C—S bend, in plane	356	393	10.4

$^a\Delta = \frac{\nu_{calcd} - \nu_{obs}}{\nu_{obs}} \times 100$

Normal coordinate analysis

The internal coordinates used in the normal coordinate analysis were the changes in the C=C, C=S, and C—H bond length (ΔR_C, ΔR_S, and Δr), changes in the HCH and HCC angles ($\Delta\alpha$,$\Delta\beta$), change in the angle between the C=C bond and the HCH plane ($\Delta\theta$), and the two perpendicular bendings of the linear C=C=S skeleton ($\Delta\gamma_x$, $\Delta\gamma_y$). The following symmetry coordinates were constructed with these internal coordinates:

$$a_1 : S_1 = (\Delta r_1 + \Delta r_2)/\sqrt{2}$$
$$S_2 = \Delta R_C$$
$$S_3 = \Delta\alpha$$
$$S_4 = \Delta R_S$$
$$b_1 : S_5 = \Delta\gamma_x$$
$$S_6 = \Delta\theta$$
$$b_2 : S_7 = (\Delta r_1 - \Delta r_2)/\sqrt{2}$$
$$S_8 = (\Delta\beta_1 - \Delta\beta_2)/\sqrt{2}$$
$$S_9 = \Delta\gamma_y$$

An initial force field was made up from force constants available in the literature on the basis of structural similarities in analogous molecules (i.e., ketene (27), thioformaldehyde (17)). This force field was then adjusted to fit the observed frequencies for thioketene-d_0, thioketene-d_2, and thioketene-d_1. The vibrational frequencies were calculated using a computer program (VSEC) written by Schachschneider (28).

The calculated normal frequencies together with the observed values are listed in Table 3. As seen, the agreement is quite satisfactory.

The derived force field in terms of the symmetry coordinates given above is listed in Table 5, together with the analogous force field reported for ketene (27) for comparison.

Table 6 shows the potential energy distribution for the calculated vibrational frequencies. The forms of the normal modes agree well with the assignments of the associated frequencies. Beside the strong interaction between the C=C and C=S stretchings, there is a considerable mixing in the normal modes of the thioketene-d_1 molecule.

MO calculation of vibrational frequencies

In a different approach, vibrational frequencies for the ground state ($^1A_1$) thioketene were calculated by the *ab initio* MO method using a 6-31G + polarization functions on the sulfur, 6-31G*, basis set. The calculations were based on an optimized geometry of thioketene obtained as reported (29) by a similar type of calculation. The harmonic vibrational frequencies were then computed at this optimized geometry using the HONDO 76 (IBM version) (30) program and the calculated and experimental values are presented in Table 7. As is common in this type of calculation (31), all the frequencies are predicted at higher wave numbers than the observed experimental values; however, the pattern per each symmetry group is in good agreement with the experimental. In our case, all the frequencies are predicted at 10 to 18% higher values except for the b_1 C—H out-of-plane deformation which is predicted at 43% higher. The deviations between computed and experimental frequencies found here are of similar magnitude to those found before in the case of thiirene (29, 32).

Synthesis and complexation of a tridentate organogallate ligand containing pyrazolyl and pyridylmethoxy donor groups

STEVEN J. RETTIG, ALAN STORR, JAMES TROTTER, AND KALEN UHRICH

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received March 26, 1984

STEVEN J. RETTIG, ALAN STORR, JAMES TROTTER, and KALEN UHRICH. Can. J. Chem. **62**, 2783 (1984).

The synthesis and complexation of the novel tridentate anionic organogallate ligands $[Me_2Ga(N_2C_3HR_2)\{OCH_2(C_5H_4N)\}]^-$ (where R = H or Me) have been investigated. The ligands, containing both pyrazolyl and pyridyl donor groups, have been incorporated into a variety of octahedral transition metal carbonyl compounds in a *fac* coordination mode. A tetrahedral nickel nitrosyl complex is also described and X-ray crystal structures of bis(pyridine-2-methanolatodimethylgallium) and [dimethyl(3,5-dimethyl-1-pyrazolyl) (2-pyridylmethoxy)gallato-N^2,O,N^3]tricarbonylrhenium(I) are reported. Crystals of bis(pyridine-2-methanolatodimethylgallium) are monoclinic, a = 16.716(2), b = 7.6513(6), c = 7.7591(8) Å, β = 108.349(5)°, Z = 2, space group $C2/m$. The structure was solved by conventional heavy-atom methods and was refined by full-matrix least-squares procedures to R = 0.029 and R_w = 0.032 for 809 reflections with $I \geq 3\sigma(I)$. The dimeric molecule has crystallographically imposed C_{2h} symmetry, the Ga atom having an irregular trigonal bipyramidal coordination geometry. Bond distances (corrected for libration) are Ga—O(eq) = 1.939(3), Ga—O(ax) = 2.086(3), Ga—N(ax) = 2.276(3), and Ga—C(eq) = 1.981(4) Å. Crystals of [dimethyl(3,5-dimethyl-1-pyrazolyl) (2-pyridylmethoxy)gallato-N^2,O,N^3]tricarbonylrhenium(I) are monoclinic, space group $P2_1/n$, a = 9.7457(7), b = 36.991(3), c = 10.8821(8) Å, β = 92.944(3)°, Z = 8. The structure was solved by heavy-atom methods and was refined to 0.042 and R_w = 0.047 for 5321 reflections. Each of the two crystallographically independent molecules displays the expected *fac* octahedral coordination geometry with Re—O = 2.142(6) and 2.143(8), Re—N = 2.166(10)–2.194(8), and Re—CO = 1.89(2)–1.919(11) Å.

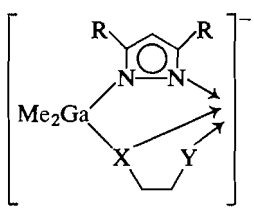
STEVEN J. RETTIG, ALAN STORR, JAMES TROTTER et KALEN UHRICH. Can. J. Chem. **62**, 2783 (1984).

On a étudié la synthèse et la complexation des nouveaux ligands organogallates tridentates anioniques $[Me_2Ga(N_2C_3HR_2)\{OCH_2(C_5H_4N)\}]^-$ dans lesquels R = H ou Me. On a incorporé les ligands contenant à la fois les groupes donneurs pyrazolyle et pyridyle dans une variété de composés carbonylés octaédriques du métal de transition qui sont caractérisés par un mode de coordination *fac*. On décrit aussi un complexe tétraédrique du nitrozyle de nickel et, utilisant la diffraction des rayons-X, on a déterminé les structures cristallines du bis(pyridineméthanolato-2 diméthylgallium) et du [diméthyl(diméthyl-3,5 pyrazolyl-1)(méthoxy-2 pyridinyl) gallato-N^2,O,N^3]tricarbonylrhénium(I). Les cristaux du bis(pyridineméthanolato-2 diméthylgallium) sont monocliniques, a = 16,716(2), b = 7,6513(6), c = 7,7591(8) Å, β = 108,349(5)°, Z = 2, groupe d'espace $C2/m$. La structure a été résolue par les méthodes conventionnelles aux atomes lourds et elle a été affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R = 0,029 et R_w = 0.032 pour 809 réflexions avec $I \geq 3\sigma(I)$. La molécule dimère possède une symétrie cristallographique C_{2h} imposée et la géométrie de coordination de l'atome de Ga est bipyramidale trigonale irrégulière. Les longueurs des liaisons (corrigées pour la libration) sont: Ga—O(éq) = 1,939(3), Ga—O(ax) = 2,086(3), Ga—N(ax) = 2,276(3) et Ga—C(éq) = 1,981(4) Å. Les cristaux du [diméthyl(diméthyl-3,5 pyrazolyl-1)(méthoxy-2 pyridyl) gallato-N^2,O,N^3]tricarbonylrhénium(I) sont monocliniques, groupe d'espace $P2_1/n$, a = 9,7457(7), b = 36,991(3), c = 10,8821(8) Å, β = 92,944(3)°, Z = 8. La structure a été résolue par la méthode des atomes lourds et elle a été affinée jusqu'à des valeurs de R = 0,042 et R_w pour 5321 réflexions. Chacune des deux molécules, qui sont cristallographiquement indépendantes, possède la géométrie de coordination attendue, *fac* octaédrique, avec Re—O = 2,142(6) et 2,143(8), Re—N = 2,166(10)–2,194(8) et Re—CO = 1,89(2)–1,919(11) Å.

[Traduit par le journal]

Introduction

Unsymmetrical uninegative tridentate chelating organogallate ligands, **1**, have been the subject of a number of recent publications (ref. 1 and references therein).

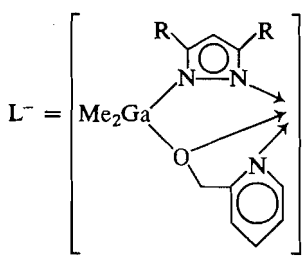


1

X = O; Y = NH_2, NMe_2, SEt, or SPh
X = S; Y = NH_2 or NMe_2

R = H or Me

These ligands all contain a monofunctional donor pyrazolyl moiety in conjunction with a bifunctional donor system, both being attached to a dimethyl gallium grouping. The many novel aspects displayed by compounds containing these ligands prompted us to extend our investigations in this area to include a pyridyl "aromatic" ring in the ligand system to give **2**.



2

R = H or Me

The new ligands have yielded a variety of transition metal complexes and one of these, $LRe(CO)_3$, has been characterized by X-ray crystallographic analysis.

Experimental

Air-sensitive materials were handled in a glove box under an atmosphere of oxygen-free dry nitrogen, in a nitrogen-blanketed apparatus or on a high-vacuum line. Tetrahydrofuran (THF) was dried by refluxing over Na/benzophenone and was used immediately following distillation. Benzene was dried by refluxing over molten potassium followed by distillation. Sodium pyrazolide and sodium 3,5-dimethyl-

* Measured in cyclohexane.

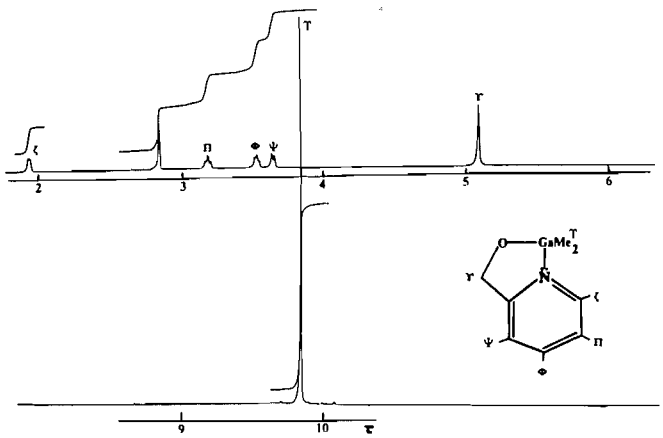

FIG. 1. 400 MHz ^{1}H nmr spectrum of $[Me_2GaOCH_2(C_5H_4N)]$ in C_6D_6.

pyrazolide were prepared by reacting sodium hydride (Alfa) with the appropriate pyrazole (K and K Laboratories) in THF. Trimethyl gallium (2), Ni(NO)I (3), $Mn(CO)_5Br$ (4), and $[Re(CO)_4Cl]_2$ (5) were prepared as previously described. Allyl bromide and 2-methylallyl chloride were distilled before use. $(MeCN)_3Mo(CO)_3$ was prepared from $Mo(CO)_6$ (Strem) by a standard route (6). Pyridyl-2-methanol (Aldrich) was used as supplied.

Preparation of $[Me_2GaOCH_2(C_5H_4N)]_2$

$$Me_3Ga + HOCH_2(C_5H_4N) \rightarrow (1/2)[Me_2GaOCH_2(C_5H_4N)]_2 + MeH$$

To a solution of trimethylgallium (2.42 g, 21.1 mmol) in THF was added pyridine-2-methanol (2.30 g, 21.1 mmol) in the same solvent. The reaction mixture was refluxed for 24 h and the solvent removed under vacuum. The solid obtained was extracted with benzene. The resulting solution afforded white needles of the desired product upon slow evaporation of the solvent. Yield ~85%. *Anal.* calcd. for $[Me_2GaOCH_2(C_5H_4N)]_2$: C 46.22, H 5.82, N 6.74; found: C 45.87, H 6.00, N 6.56. The ^{1}H nmr spectrum of the product is shown in Fig. 1.

Preparation of the ligand L^-

$$Na^+(N_2C_3HR_2)^- + Me_3Ga \rightarrow Na^+[Me_3Ga(N_2C_3HR_2)]^-$$

$$Na^+[Me_3Ga(N_2C_3HR_2)]^- + HOCH_2(C_5H_4N) \rightarrow Na^+L^- + CH_4$$

Typically, trimethylgallium (2.26 g, 19.7 mmol) in 50 mL THF was added to sodium 3,5-dimethylpyrazolide (R = Me) (2.33 g, 19.7 mmol) in 50 mL of the same solvent. After stirring the solution at room temperature for approximately 1 h a 50 mL THF solution of pyridine-2-methanol (2.15 g, 19.7 mmol) was added and the reaction mixture refluxed overnight. The solution was cooled and diluted to 250 mL in a standard flask. Aliquots of this standard solution were used in subsequent reactions.

Preparation of $LMn(CO)_3$

To a stirred solution of $Mn(CO)_5Br$ in THF (0.53 g, 1.97 mmol) was added 25 mL THF solution of the ligand Na^+L^- (R = Me) (1.97 mmol). The reaction mixture was stirred overnight at room temperature and the solvent was then removed under vacuum. The orange residue was extracted with benzene and the solution filtered. The filtrate, on slow evaporation of the solvent, gave dark orange–brown crystals of the product in approximately 70% yield. Analytical, ir, and nmr data for this complex and those described below, are collected in Tables 1 and 2. The $LRe(CO)_3$ complex was prepared similarly using the $[Re(CO)_4Cl]_2$ dimer as starting material. The product was collected in ~70% yield.

Preparation of $LNi(NO)$

To a stirred solution of Ni(NO)I (0.83 g, 3.84 mmol) in 50 mL THF was added 50 mL THF solution of Na^+L^- (R = Me) (3.94 mmol). The reaction mixture was stirred overnight at room temperature and the solvent was then removed under vacuum. The blue residue was extracted with benzene and recrystallization from this solvent afforded a deep blue microcrystalline product in ~65% yield.

Preparation of $Na^+LMo(CO)_3^-$ solution

To a stirred 50 mL THF solution of $(MeCN)_3Mo(CO)_3$ (2.703 g, 8.92 mmol) was added 100 mL THF solution of Na^+L^- (R = H) (8.92 mmol). The resulting mixture was stirred overnight and the resultant orange–brown solution of $Na^+LMo(CO)_3^-$ made up to 250 mL in a standard flask.

Preparation of $LMo(CO)_2(\eta^3\text{-}C_3H_5)$

To a 50 mL solution of $Na^+LMo(CO)_3^-$ (R = H) (1.78 mmol) was added an excess of allyl bromide. The mixture was stirred for 24 h and the solvent removed under vacuum. Recrystallization of the brown residue from benzene yielded waxy orange crystals of the product in ~65% yield.

The $LMo(CO)_2(\eta^3\text{-}C_4H_7)$ complex was prepared similarly, substituting 2-methylallyl chloride as one of the reactants. The product was obtained as orange crystals in ~70% yield.

X-ray crystallographic analyses

$[Me_2GaOCH_2(C_5H_4N)]_2$

A crystal bounded by the six faces (followed by their distances in mm from a common origin): ±(0 0 1), 0.188, ± (1 1 0), 0.094, ±(−1 1 0), 0.094 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 35–44°) measured on a diffractometer with Mo-$K\alpha$

* τ values refer to ($\tau_{C_6H_6}$ = 2.84 ppm), s = singlet, d = doublet, t = triplet, tt = triplet of triplets.
† Measured in acetone-d^6; τ values refer to ($\tau_{acetone}$ = 7.89 ppm).

Radiation ($\lambda(K\alpha_1)$ = 0.70930, $\lambda(K\alpha_2)$ = 0.71359 Å). Crystal data at 22°C are:

$C_{16}H_{24}Ga_2N_2O_2$ fw = 207.91

Monoclinic, a = 16.716(2), b = 7.6513(6), c = 7.7591(8) Å, β = 108.349(5)°, V = 941.9(2) Å^3, Z = 2, ρ_C = 1.466 g cm^{-3}, $F(0\,0\,0)$ = 424, μ(Mo-$K\alpha$) = 28.57 cm^{-1}. Absent reflections: hkl, $h + k$ odd, space group $C2/m$ (C_{2h}^3, No. 12) from structure analysis.

Intensities were measured with graphite-monochromated Mo-$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An ω-2θ scan at 1.26–10.06° min^{-1} over a range of (0.60 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 60°. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 2%. After data reduction,[1] an absorption correction was applied using the Gaussian integration method (7, 8). Transmission factors ranged from 0.439 to 0.652 for 96 integration points. Of the 1460 independent reflections measured, 809 (55.4%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The centrosymmetric space group $C2/m$ was indicated by the E-statistics. The coordinates of the Ga atom were determined from the Patterson function and those of the remaining atoms from subsequent difference syntheses. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms with isotropic thermal parameters. The scattering factors of ref. 9 were used for non-hydrogen atoms and those of ref. 10 for hydrogen atoms. Anomalous scattering factors from ref. 11 were used for the Ga atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of refinement. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.029 and R_w = 0.032 for 809 reflections with $I \geq 3\sigma(I)$. For all 1460 reflections R = 0.078. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.04 and 0.27σ, respectively. The mean error in an observation of unit weight was 1.402. A final difference map showed maximum fluctuations of −0.81 to +0.67 e Å^{-3} near Ga and ±0.17 e Å^{-3} elsewhere. The final positional and thermal parameters appear in Tables 3 and 7,[2] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 5. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (12). The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0027 Å^2. Analysis of the entire molecule (rms ΔU_{ij} = 0.0071 Å^2) showed significant independent motion of the Me_2Ga units. Fragment consisting of the pyridine ring plus C(6) and the Ga coordination group were separately analysed (rms ΔU_{ij} = 0.0026 and 0.0020 Å^2). The appropriate bond distances have been corrected for libration (12, 13), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 4 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 5. Intra-annular torsion angles defining the conformations of chelate rings are listed in Table 6 for $[Me_2Ga(N_2C_5H_7)OCH_2(C_5H_4N)]Re(CO)_3$. Bond lengths and angles involving hydrogen and a complete listing of torsion angles (Tables 8–10) are included as supplementary material.

$[Me_2Ga(N_2C_5H_7)OCH_2(C_5H_4N)]Re(CO)_3$

Experimental details are as above except where noted. The bounding planes of the crystal used for data collection were: ±(0 1 0),

0.113, ±(0 0 1), 0.250, ±(1 0 0), 0.263 mm. Reflections employed in the refinement of the unit-cell parameters had 2θ = 35–46°. Crystal data are as follows:

$C_{14}H_{15}GaN_3O_4Re$ fw = 545.21

Monoclinic, a = 9.7457(7), b = 36.991(3), c = 10.8821(8) Å, β = 92.944(3)°, V = 3917.8(5) Å^3, Z = 8, ρ_C = 1.849 g cm^{-3}, F(0 0 0) = 2064, μ(Mo-$K\alpha$) = 76.47 cm^{-1}. Absent reflections: 0k0, k odd, and h0l, $h + l$ odd, uniquely indicate the space group $P2_1/n$ (non-standard setting of $P2_1/c$, C_{2h}^5, No. 14, equivalent positions: ±(x, y, z; 1/2 − x, 1/2 + y, 1/2 − z)).

An ω scan at 1.44–10.06° min^{-1} over a range of (0.65 + 0.35 tan θ)° in ω was employed. Of 8952 independent reflections measured (to 2θ = 55°), 5321 (59.4%) had intensities greater than 3σ(I) above background. The intensities of the three check reflections remained constant to within 2.5%. Data were corrected for absorption using the analytical method (7, 14), transmission factors ranging from 0.057 to 0.199.

The structure was solved by conventional heavy-atom methods, the coordinates of the Re and Ga atoms being determined from the Patterson function and those of the remaining non-hydrogen atoms from subsequent difference maps. All non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were included as fixed atoms in idealized positions (C(sp^2)—H = 0.97 and C(sp^3)—H = 0.98 Å). An isotropic Type I extinction correction (Thornley–Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (15–17). The final value of g was 4.5(3) × 10^4. The structure was refined to 0.042 and R_w = 0.047 for 5321 reflections. The mean and maximum parameter shifts on the final cycle of refinement corresponded to 0.06 and 0.40 σ, respectively. The mean error in an observation of unit weight was 1.918. A final difference map showed maximum fluctuations of ±2.6 e Å^{-3} near Re. Calculated coordinates and thermal parameters for hydrogen atoms (Table 11) are included as deposited material. The two independent molecules are shown in Fig. 6.

Results and discussion

Several recent publications have discussed a variety of metal complexes with multidentate ligand systems containing both pyridyl and pyrazolyl donor functions (18, 19). It has been concluded that pyrazolyl has weaker π-acceptor capabilities (20) but stronger σ-donor properties than pyridine (18). The present study extends our work in the area of unsymmetrical uninegative tridentate organogallate ligands to include ligand systems incorporating both a pyrazolyl and a pyridyl donor function. A variety of transition metal complexes bearing these ligands has been characterized by the usual sporting physical

methods, and one of them has been further probed by X-ray crystallographic techniques.

The reactivity of pyridyl-2-methanol towards trimethylgallium was first investigated to confirm the expected methane elimination reaction. The product from this reaction, "$[Me_2GaOCH_2(C_5H_4N)]$", was shown to be monomeric in the gas phase, its mass spectrum displaying a weak monomer parent ion (P^+) signal and a very strong $P - Me^+$ signal. Similar dimethylgallium systems have been shown to be associated in the solid state (21, 22) and an X-ray crystal structure of the present pyridyl complex again demonstrated the dimerization of the monomer units via a four-membered [—Ga—O—]$_2$ ring, each gallium having a distorted trigonal bipyramidal arrangement. It is interesting to compare the Ga—N bond lengths in the three complexes $[Me_2GaOCH_2(C_5H_4N)]_2$, $[Me_2NCH_2CH_2OGaMe_2]_2$ (22), and $[Me_2NCH_2CH_2OGaH_2]_2$ (22). The pyridyl complex is comparable with the dihydride (Ga—N = 2.276(3) and 2.279(3) Å respectively), both bonds being considerably shorter than in the $[Me_2NCH_2CH_2OGaMe_2]_2$ dimer (Ga—N = 2.471(4) Å) where severe steric interactions between the "NMe_2" and "$GaMe_2$" moieties lead to bond lengthening.

The ^{1}H nmr of the pyridyl complex in C_6D_6 solution (Fig. 1) shows sharp singlets for both the "$GaMe_2$" protons and the —OCH_2— methylene protons. The spectrum is consistent with an overall planar structure for the monomer in dilute solution with the two GaMe groups and the two methylene protons lying above and below this plane.

The synthesis of the ligands Na^+L^-, **2**, proceeded smoothly as did the subsequent reactions to yield the transition metal complexes listed in Tables 1 and 2. Analysis of mass spectral, ir, and ^{1}H nmr data points to monomeric structures for the whole range of complexes studied. An octahedral structure is proposed for the manganese, rhenium, and molybdenum compounds with the tridentate gallate ligand occupying three facial positions. This arrangement has been proven conclusively for the $LRe(CO)_3$ complex by a crystal structure determination (see below). The LNi(NO) complex is believed to possess a tetrahedral transition metal centre although fluxional behaviour in solution at room temperature must be operative to explain the ^{1}H nmr results for this compound.

Infrared spectra

The ir spectral data reported in Table 1 for the octahedral

complexes are consistent with a *fac* tridentate gallate ligand in these molecules. Thus, the tricarbonyl complexes give three strong bands in the ν_{CO} region of the spectrum indicative of a facial arrangement of these ligands (23). The molybdenum dicarbonyl "allyl" complexes both show two strong ν_{CO} bands, indicative of a *cis* arrangement of the CO ligands. These data, together with our studies on related complexes (24–26) and the ^{1}H nmr data reported below, confirm a facial tridentate gallate ligand in these compounds. Comparison of the ir data of the pyridyl complexes (Table 1) with that of the corresponding complexes incorporating aminoalcohol moieties (**1**, R = H and Me, X = O, Y = NH_2 or NMe_2) (24) reflects the π-acidity of the pyridyl ring. Thus the frequencies for the pyridyl complexes are consistently ~10 cm^{-1} higher than those for the complexes in ref. 24, suggestive of weaker back-bonding to the ancillary ligands in the present complexes due to competitive back-bonding to the π-system of the pyridyl ring.

^{1}H nmr spectra

Selected ^{1}H nmr data for the transition metal complexes are compiled in Table 2 and representative spectra are shown in Figs. 2–4. The ^{1}H nmr spectra for the tricarbonyl species are consistent with the proposed facial arrangement of the gallate ligand. Thus the Ga—Me groups appear as two singlets and the —OCH_2— methylene protons as an AB quartet (Fig. 2). A

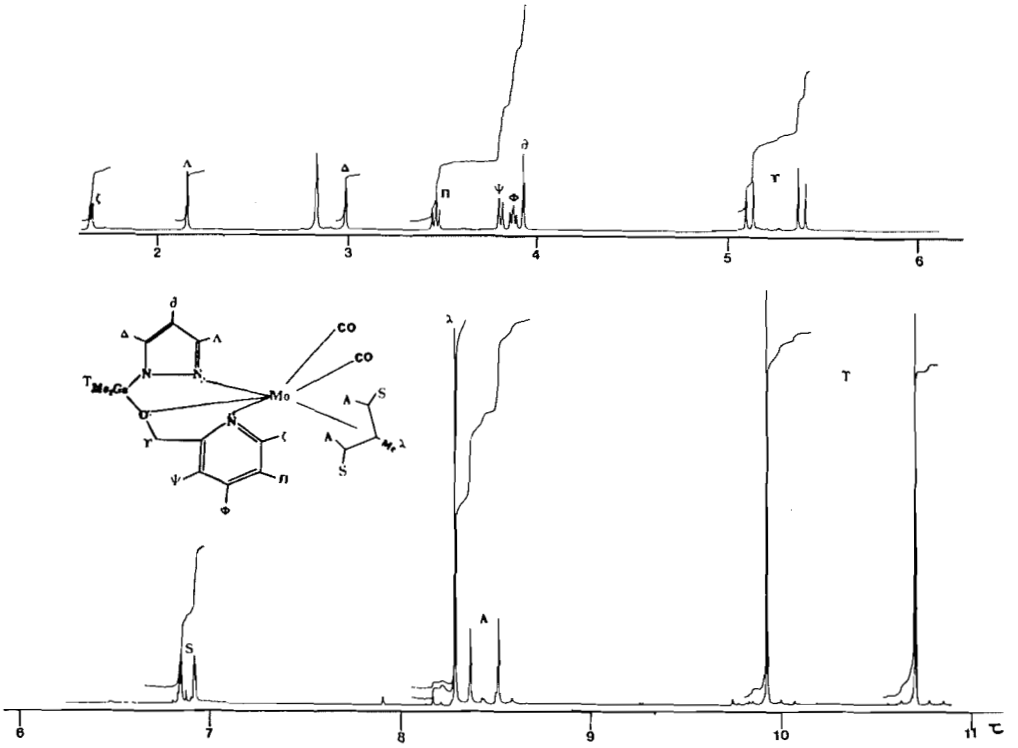

FIG. 4. 400 MHz ^{1}H nmr spectrum of $[Me_2Ga(N_2C_5H_7)\{OCH_2(C_5H_4N)\}]Mo(CO)_2(\eta^3\text{-}C_4H_7)$ in C_6D_6.

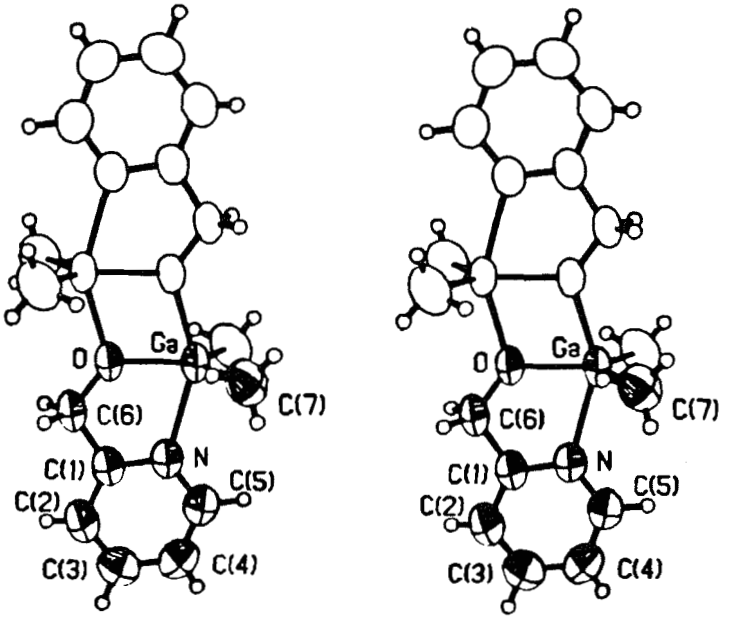

FIG. 5. Stereoscopic view of $[Me_2GaOCH_2(C_5H_4N)]_2$; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been assigned artificially small thermal parameters for the sake of clarity.

meridional arrangement of the gallate ligand, on the other hand, would most probably lead to equivalent Ga—Me groups and equivalent methylene protons and hence singlets in these regions of the spectra. Interestingly the room temperature ^{1}H nmr spectrum of the LNi(NO) complex displays singlets for both of these groupings (see Fig. 3). This result would suggest a square planar arrangement around the Ni centre with a pseudo-meridional gallate ligand. However, the unlikelihood of a square planar arrangement for this complex in light of previous studies which have shown that square planar {MNO}[10] complexes should have an M—N—O bond angle of 120° (27, 28) (contrary to the linear M—N—O grouping suggested by the observed ir results) led us to suspect that a fluxional process was responsible for the observed room temperature spectrum. The closely related $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]Ni(NO)$ complex has been shown to be fluxional in solution and to have a tetrahedral Ni centre in the solid state (29). On cooling a solution of the above LNi(NO) pyridyl complex to −85°C a marked broadening of both the —$GaMe_2$ and —OCH_2— singlets was observed, indicative of a slowing down of the flux-

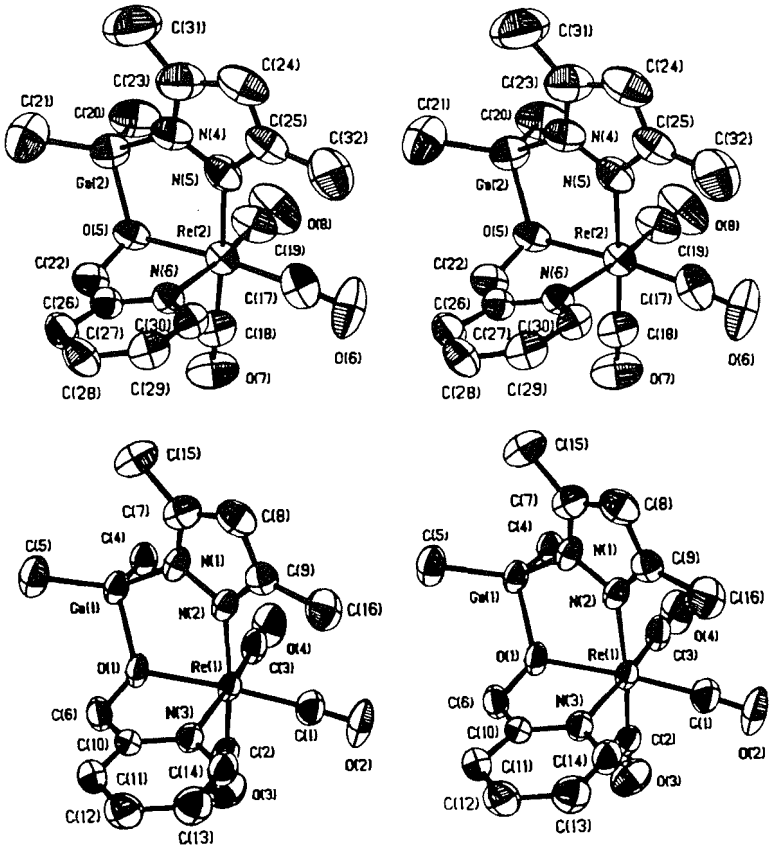

FIG. 6. Stereoscopic views of the two independent $[Me_2Ga(N_2C_5H_7)\{OCH_2(C_5H_4N)\}]Re(CO)_3$ molecules; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been omitted.

ional process. Unfortunately, instrumental limitations precluded the attainment of temperatures low enough to see a clear splitting of these signals.

Both molybdenum dicarbonyl "allyl" complexes in their solution ^1H nmr spectra again showed clearly the presence of inequivalent Ga—Me groups and —OCH_2— methylene protons, supportive of a facial tridentate gallate ligand. With these two complexes, positional isomerism is possible in that substitution of the allyl group for CO in the $LMo(CO)_3^-$ precursor could occur at any one of three positions. It is evident that the allyl group substitutes exclusively at one position only since there is only one set of Ga—Me signals in the spectra (Fig. 4). Molecular models indicate that, sterically, the most favored position is opposite the "pyrazolyl" moiety of the ligand, a position of substitution confirmed crystallographically for the related molecule $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NH_2)]Mo(CO)_2(\eta^3\text{-}C_4H_7)$ (25). It is interesting, however, that in the similar $\eta^3\text{-}C_7H_7$ dicarbonyl complexes $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NH_2)]Mo(CO)_2(\eta^3\text{-}C_7H_7)$ (30) and $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SEt)]Mo(CO)_2(\eta^3\text{-}C_7H_7)$ (1), the $\eta^3\text{-}C_7H_7$ ligand is found opposite the amino nitrogen and the alkyl sulphur donor atoms, respectively.

Crystal structures

$[Me_2GaOCH_2(C_5H_4N)]_2$

The structure of $[Me_2GaOCH_2(C_5H_4N)]_2$ consists of well-separated binuclear molecules having crystallographically imposed C_{2h} symmetry, the system of five fused rings being necessarily planar. The coordination about gallium is distorted trigonal bipyramidal, the angle between axial substituents (N—Ga—O′) being 148.81(12)°. The Ga—N distances have been discussed (see above). The Ga—O distances in the central four-membered ring (1.939(3) and 2.086(3) Å) are similar to the corresponding values of 1.911(3)–1.960(8) and 2.018(2)—2.078(3) Å observed for the bridging alkoxide oxygen atoms in $(Me_2NCH_2CH_2OGaR_2)_2$ (22) and $[MeN(CH_2CH_2O)_2GaH]_2$ (21). These values may also be compared with the distances of 1.933(3) and 2.469(3) Å for the bridging phenoxide oxygen in bis(salicylaldehydatodimethylgallium) (31) and 1.972(2) and 2.551(2) Å for the bridging tropolonato oxygen in bis(tropolonatodimethylgallium) (32). All other geometrical features of the molecule are as expected.

$[Me_2Ga(N_2C_5H_7)OCH_2(C_5H_4N)]Re(CO)_3$

The structure of $[Me_2Ga(N_2C_5H_7)\{OCH_2(C_5H_4N)\}]Re(CO)_3$ consists of discrete molecules separated by normal van der Waals distances. The two crystallographically independent molecules are essentially equivalent, each having the predicted *fac*-octahedral coordination geometry about the central metal atom. The Re—O distances are 2.142(6) and 2.143(8) Å. The equivalence of the Re—N(*pz*) (2.166(10) and 2.192(9) Å) and Re—N(*py*) (2.194(8), 2.177(8) Å) distances as well as the geometry of the Re—CO moieties *trans* to these bonds suggests a balancing of the σ and π effects for the pyrazolyl and pyridyl nitrogen donors (18, 20). Although there are no statistically significant differences between the Re—C or C—O distances, those CO ligands *trans* to oxygen are associated with the shortest Re—C and longest C—O distances.

All aromatic rings in the structure are planar to within experimental error. The conformations of the five-membered chelate rings differ significantly between the two molecules (see Table 6), presumably a result of packing forces. The Ga-containing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

ring in the molecule containing Re(1) deviates more from planarity than does the second chelate ring, this situation being reversed in the second molecule. Other structural parameters are normal.

Coordination compounds of indium. Part 41. The reaction between InX and InX_3 (X = Cl, Br, I) and the stability of the In—In bond

CLOVIS PEPPE AND DENNIS G. TUCK
Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received March 27, 1984

CLOVIS PEPPE and DENNIS G. TUCK. Can. J. Chem. **62**, 2793 (1984).

The reaction between InX (X = Cl, Br, I) and InY_3 (Y = Br, I) in toluene/CH_2Cl_2/tmen solution (tmen = *N,N,N',N'*-tetramethylethanediamine) at low temperature (<−20°C) yields the In—In bonded species X(Y)InInY$_2$ as the bis-tmen adduct. Infrared and nmr (^{1}H, ^{13}C) spectra of these indium(II) compounds are reported. No analogous products were obtained from InX + $InCl_3$. The pathway of the InX/InY_3 reaction, and the related problem of the stability of In_2X_4 species, are discussed in terms of a common process involving intramolecular halide transfer.

CLOVIS PEPPE et DENNIS G. TUCK. Can. J. Chem. **62**, 2793 (1984).

La réaction du InX (X = Cl, Br, I) et de l'InY_3 (Y = Br, I), dans une solution de toluène/CH_2Cl_2/tmen (tmen = *N,N,N',N'*-tétraméthyléthanediamine) et à basse température (<−20°C), conduit aux espèces X(Y)InInY$_2$, contenant une liaison In—In, comme adduits bis-tmen. On rapporte les spectres infrarouge et rmn (^{1}H et ^{13}C) de ces composés de l'indium(II). Il ne se forme pas de produits semblables lors de la réaction de InX + $InCl_3$. On discute des mécanismes possibles pour la réaction InX/InY_3 ainsi que le problème relié de la stabilité des espèces In_2X_4 en fonction d'un processus commun impliquant un transfert intramoléculaire d'halogénure.

Introduction

Compounds in which Group IIIA elements are formally in the +2 oxidation state have been the subject of speculation for many years. For gallium dichloride, dibromide, and diiodide, the solid state structure (1) is that of the ionic dimer $Ga^+GaX_4^-$, whereas in contrast the neutral adduct Ga_2Cl_4.2dioxan involves a metal−metal bond (2), as do the anionic derivatives $Ga_2X_6^{2-}$ (X = Cl, Br, I) (3, 4). The general features of the chemistry of the indium dihalides are similar. Spectroscopic studies have shown that both In_2Br_4 and In_2I_4 are ionic dimers in the solid and liquid states (5) and recent X-ray crystallographic work has confirmed this conclusion in the case of In_2I_4 (6). There is some doubt about the structure of solid indium dichloride, but ionic mixed valence species are involved, and the liquid state has been shown to contain $InCl_4^-$ anions (5). The $In_2X_6^{2-}$ anions are metal−metal bonded in the solid (7), and recent work has shown that for this element, as with gallium, neutral adducts of X_2In—InX_2 can be prepared, with the structural assignment being based on both spectroscopic and X-ray crystallographic evidence (8−10). It is important to note immediately that the number of adducts which are stable at room temperature is somewhat limited and apparently dependent on the nature of both halide and neutral donor ligands.

In a recent paper from this laboratory (11), the preparation and synthetic applications of non-aqueous solutions of indium(I) halides (InX; X = Cl, Br, I) were described. The solutions are stable at low temperatures, but decompose at ca. 0°C, generally depositing indium metal and forming neutral adducts of either InX_3 or In_2X_4, depending on halide and neutral ligand. The first step in the reaction was shown to involve the disproportionation

$$[1] \quad 3InX \rightarrow 2In^0 + InX_3$$

and the formation of InX_2 can then be seen as a reaction between InX_3 and excess InX

$$[2] \quad InX + InX_3 \rightarrow In_2X_4$$

We have now investigated reaction [2] as a preparative route to In_2X_4 adducts. The results lead to a discussion of reaction [2] as a reversible process, markedly affected by phase and by ligand, and related to the decomposition reactions of In_2X_4.

Experimental

General

Indium(I) halides were prepared by heating stoichiometric quantities of indium metal and indium trihalide in a sealed tube. Indium trichloride and tribromide were obtained by passing the halogen vapour over molten indium (12). Indium triiodide was prepared by the reaction of indium foil and iodine in refluxing xylene (13).

Methylene dichloride was distilled from phosphorus pentoxide; toluene, diethyl ether, and petroleum ether were dried over sodium; *N,N,N'N'*-tetramethylethanediamine (tmen) was used as supplied.

Infrared spectra were run as Nujol mulls on a Beckman IR-180 instrument; Raman spectra were recorded at McMaster University on a Spectrophysics instrument (264 exciter); ^{1}H nmr spectra were obtained on a Varian EM-360 instrument, and ^{13}C spectra on a Bruker CXP-100 spectrometer.

Analysis was by methods described previously (11). All experimental work was carried out in an atmosphere of dry nitrogen.

Preparative

Equimolar quantities (~3−6 mmol) of InX (X = Cl, Br, I) and InY_3 (Y = Cl, Br, I) were suspended in 50 mL of a toluene/methylene dichloride mixture (1 : 1, v/v), except that 50 mL of toluene alone was used for InI/InI_3. The suspension was cooled (to −20°C for X = Br, I, and to −78°C for X = Cl), and tmen (2−4 mL) syringed into the reaction mixture, at which point the characteristic red colour of solutions of InX in such mixtures was observed (cf. ref. 11). The solution was then allowed to warm up to room temperature over 3−4 h, and the resultant clear solution stirred for a further 30 min period. The subsequent isolation procedures are summarised in Table 1, which also gives the analytical results for the compounds isolated. Yields were close to quantitative.

Results and discussion

Preparative

The method described yields the bis-tmen adducts of a series of In_2X_4 and In_2XY_3 compounds. No such compounds could be obtained from $InCl_3$ with any indium monohalide, but we did isolate the methylene-bridged compounds Cl_2InCH_2-$InCl_2$.2tmen from $InCl_3$ + InCl, and the isostructural

$Cl_2InCH_2InClBr.2tmen$ from $InCl_3$ + InBr. The synthesis and structure of these compounds will be discussed elsewhere (14).

Spectroscopic results

The vibrational spectra of $In_2Br_4.2tmen$ and $In_2I_4.2tmen$ have been discussed previously (8). In addition to vibrations due to the tmen ligand, the ν(In—X) and ν(In—N) modes were identified, as was a strong Raman emission, at 141 cm^{-1} in the bromide and 110 cm^{-1} in the iodide, corresponding to ν(In—In). Table 2 shows that the far infrared spectra of the compounds prepared in this work are readily assigned on the same basis. Complete Raman spectra were not available, but for each compound we were able to identify a strong emission in the 100–150 cm^{-1} region, assigned as ν(In—In) (Table 3).

The ^1H and ^{13}C nmr spectra are presented in Table 4, for both the mixed halide compounds prepared in this work and the symmetrical $In_2X_4.2tmen$ compounds, prepared either from In_2X_4 (8), or by the solution phase reaction described in the Experimental Section. The ^1H spectra of the In_2Br_4 and In_2I_4 adducts show only one set of resonances from tmen, indicating the presence of two equivalent bidentate ligands. For the In_2ClI_3 adduct, we find two sets of sharp singlets, separated by ~2 Hz for the C_2H_4 resonances, and by ~5 Hz for those of $N(CH_3)_2$, corresponding to two non-equivalent non-exchanging tmen ligands whose differing chemical shifts reflect coordination at either ClInI or InI_2 centres. In the other In_2XY_3 systems, the ^1H spectra could not be resolved in this way,

TABLE 3. Raman emissions assigned as ν(In—In) in tmen adducts of In_2XY_3 (in cm^{-1})

Compound	ν(In—In)
In_2ClBr_3	143
In_2ClI_3	105
In_2Br_4	141
In_2Br_3I	131
In_2I_4	110
In_2I_3Br	118

but decoupled ^{13}C spectra show the appropriate set of four singlets from two non-equivalent ligands. The exception was $In_2ClBr_3.2tmen$; this may be due to an accidental coincidence in the chemical shifts, but could equally be due to fast ligand exchange and/or fast halide exchange between the ClInBr and $InBr_2$ sites.

The ^{13}C assignments are based on those for tmen itself (C_2H_4 57.24, NCH_3 46.08 ppm from Me_4Si), and for protonated tmen (shifts of −0.22 and −2.35 ppm) (15). The results in Table 4 suggest that the changes caused by complexation are similar to those due to protonation.

corresponds formally to the insertion of In^I into an In^{III}—Y bond

[3] $InX + InY_3 \xrightarrow{xs.tmen} X\text{—}In\text{—}In(Y)_2.2tmen$

Analogous insertion reactions with InX have been reported for a wide variety of substrates, including alkyl halides (11, 16, 17), S—S (18), Se—Se and O—O bonded species, and M—M bonded transition metal carbonyls (19, 20). The reaction of InCl and $PtCl(SiPh_3)(PMe_2Ph)_2$ to give $Cl_2InPt(SiPh_3)(PMe_2Ph)_2$ also corresponds to the insertion of indium into an M—X bond (21). There are at least two possible pathways for the overall reaction [3]. The first of these involves the base-catalysed dissociation of InY_3, followed by halide ion transfer to InX, followed by recombination:

[4] $InY_3 + nL \rightarrow InY_3L_n \rightleftharpoons InY_2L_n^+ + Y^-$

[5] $InX + Y^- \rightarrow InXY^-$

[6] $InY_2L_n^+ + InXY^- \xrightarrow{L} LY_2InInX(Y)L$

The chemical evidence for reaction [4] is that non-aqueous solutions of adducts of indium trihalides do show a significant conductivity, which has been explained in terms of ionisation of the type shown (12), while reaction [5], which implies that InX molecules are Lewis acids, is supported by the known existence of InX_2^- anions (X = Cl, Br, I, NCS) (22).

The second pathway depends on the ability of In^I species to function as both electron pair donors and acceptors. The importance of a lone pair in the structure of cyclopentadienylindium(I) has been demonstrated (23), and there is good reason to assume a similar feature in indium(I) halides. The alternative description of reaction [3] is then via a concerted process in which donation from InX into the In—Y bond of InY_3 is accompanied by donation from a halide ligand of InY_3 to InX.

[7] $XIn: + In(Y)_3 \rightleftharpoons X\text{—}In\rightarrow In(Y)_2 \xrightarrow{L} L.X(Y)InInX_2.L$

A similar reaction pathway has been proposed to account for the insertion of InX into various symmetric M—M bonded molecules (19). The essential difference between reaction [7] and the scheme represented by reactions [4]–[6] lies in the existence or otherwise of separate ionic species as part of the halide transfer process. We favour reaction [7] because of its compatibility with the apparent mechanism of other InX insertion reactions (19). For the InX/InY_3 system, the failure to form an In—In bonded product when Y = Cl is a reflection of the poor leaving group properties of this ligand, since in the absence of intramolecular halide transfer, the intermediate will revert to InX and InY_3. For InX itself, the polarisability of the indium, and hence the availability of the lone pair, will go in the order I > Br > Cl, again in keeping with the observed order of reactivity. Finally, the presence of neutral solvating ligands such as tmen may also enhance the availability of the lone pair of InX (see below).

The stability of the In—In bond

The above discussion refers to the solution phase formation of tmen adducts of In_2X_4 (X ≠ Cl) or In_2XY_3 (Y ≠ Cl). In fact, these adducts and those of triethylphosphine (8) are the only such compounds which we have been able to prepare by our methods. Sinclair and Worrall (9) have reported a number of other compounds of $InCl_2$, $InBr_2$, and InI_2 with monodentate donors. The essential difference between their preparations and ours lies in their use of solvent-free conditions, as opposed to the aromatic solvent (or solvent mixtures) used in this and earlier work. Even so, Sinclair and Worrall report that for a number of In_2X_4/ligand combinations, "decomposition to metal always occurred". We have now confirmed our earlier findings (8) that the pyridine adduct of In_2Br_4 cannot be prepared by the reaction of InBr + $InBr_3$ + pyridine in toluene or toluene/CH_2Cl_2. This mixture is stable at or below −20°C, but deposits indium metal when the temperature reaches ~0°C. Equally, no tmen adduct of In_2Cl_4 can be obtained from the reaction of InCl + $InCl_3$ + tmen in toluene; the clear yellow solution which is formed initially precipitates metal when the temperature rises.

These results reflect the differing factors which influence the stability of the In—In bond in such In_2X_4 systems. The discussion is best approached by regarding reaction [2] as a reversible process

[8] $InX + InX_3 \overset{L}{\rightleftharpoons} In_2X_4L_n$

whose equilibrium position depends on temperature, solvent, the properties of X, and the nature of any neutral ligand present.

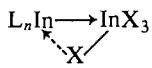
For personal use only.

In structural terms, it is clear that the solid state of In_2X_4 is best represented as $In^+InX_4^-$ (see Introduction), which can be regarded in the present context as the limiting case of halide transfer from InX to InX_3; in other words, the potential isomerisation

[9] $X_2InInX_2 \rightleftharpoons In^+InX_4$

which requires intramolecular halide transfer, lies completely to the right in the solid state. The treatment of $In^+InX_4^-$ with base does not usually lead to the formation of stable derivatives of In^I cationic complexes, but with crown ether, and with the tetradentate nitrogen base cyclam, $[InL]^+InX_4^-$ species were identified (X = Cl, Br, I) (24). The products of the reaction of InX_2 with aniline and morpholine have also been formulated in this way, although no structural information is available on these materials (25). The general reaction of $In^+InX_4^-$ with base is to yield either neutral In—In bonded adducts, or decomposition products. We propose that in all these cases, the first reaction between solid $In^+InX_4^-$ and neutral ligand is the formation of a salt of a cationic indium(I) complex $[InL_n][InX_4]$ by donation of ligand(s) to In^+. When L = crown ether or cyclam, this salt is the stable final product, either because In^+ is coordinatively saturated, or because steric hindrance prevents close association of the ion pair, thus preventing donor/acceptor interactions (see below). For the more general case, we suggest that the reduction of positive charge density of In^+ due to complexation makes the lone pair more available than it is in the bare ion, or in uncomplexed (or unsolvated) InX, thus giving a species in which insertion of the lone pair into an In—X bond is favoured. The intermediate for this insertion is then



1

If this intermediate is sufficiently stable in the reaction mixture for intramolecular halide transfer to occur, the product will be $L_n(X)In—InX_3$, which with a further halide transfer and rearrangement of the neutral ligand L gives LX_2InInX_2L. The proposed intermediate is therefore similar to that in reaction [7].

An alternative fate of **1** is that it may react with excess L to give a solvated complex **2** which can dissociate to L_nInX and L_mInX_3

[10]  $\rightleftharpoons L_nInX + L_mInX_3$

2

If L_mInX_3 is insoluble, or nearly so, in the reaction mixture, the dissociation of **2** will be driven to the right, leaving essentially a solution of L_nInX, which as we have shown is only stable for special cases of L and X. The most probable reaction observed with L_nInX is the disproportionation (11)

[11] $3L_nInX \rightarrow 2In^0 + L_mInX_3$

so that the solution phase decomposition of In_2X_4 in the presence of base, and the reaction of InX and InX_3 under similar conditions, may give either adducts of In_2X_4, or a mixture of indium metal and an adduct of InX_3. These processes, summarised in the reversible nature of reactions [8] and [10], are fundamentally related by the intermediates **1** and **2**. The stable products $LX(Y)InInY_2L$ (L = tmen) obtained in the present work thus apparently owe their stability in solution to the absence of ligand (halide or tmen) transfer, as shown by the ^1H and ^{13}C nmr spectra which establish the presence of two different tmen ligands in these complexes. The exception is In_2ClBr_3 where the ligand exchange may be rapid on the nmr time scale, although we note that the nmr method can give no information on this aspect of the behaviour of the symmetrical complexes LX_2InInX_2L. Halide transfer yields LInX and $LInX_3$, and this process sets up the conditions for the precipitation of InX_3L and the disproportionation of LInX. We conclude that kinetic rather than thermodynamic stability, specifically in terms of intramolecular halide transfer, is an important factor for In_2X_4 and related adducts. The favourable influence of low temperature in this and earlier preparative work is thus readily explained.

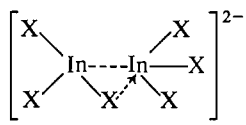
The role of neutral ligand in stabilising In_2X_4 or In_2XY_3 molecules is then understood qualitatively in terms of promoting maximum coordinative saturation at the indium atom. Since intramolecular halide transfer is a destabilising process, a saturated site will favour kinetic stability. Unfortunately, we have no way of quantifying this argument at present, given the lack of information on the coordination chemistry of indium(II).

We noted earlier that Sinclair and Worrall (9) prepared a number of In_2X_4 adducts not accessible via our solution phase reactions by condensing ligand onto solid In_2X_4 at low temperatures, obtaining either a suspension of a solution. Since the colour changes in the solution systems correspond to the formation of InX, these observations are compatible with the mechanism proposed above. Removal of the excess neutral ligand at these low temperatures yields the solid adduct, and halide transfer to InX + InX_3 adducts is prevented, since the solid is not in contact with a solution phase at temperatures at which decomposition is significant. In general, the results reported by these authors appear to be in keeping with the mechanism proposed in the present paper.

Finally, we review earlier work (26) on the equilibrium

[12] $In_2X_6^{2-} \rightleftharpoons InX_2^- + InX_4^-$

which is the analogue of reactions [8] and [10], with the presumed intermediate similar to that proposed in reaction



[10]. Our ^{115}In nmr measurements gave approximate values for K_{eq} for reaction [12], with I ⩾ Cl. We now suspect that although equilibrium [12] is correctly stated for X = I, there may be other anionic indium(III) species in the acetonitrile solutions studied. For X = Cl (and possibly X = Br), $[InX_4(CH_3CN)_2]^-$ anions would be stabilised in this medium (cf. $[InCl_4(bpy)]^-$, $[InCl_4(urea)_2]^-$ reported earlier (27, 28) bpy = 2,2′-bipyridine), and such species would not have been identified by the ^{115}In nmr method, which detects only highly symmetrical species. The order of the equilibrium constants may therefore be wrong, although there can be no doubt that a rapid equilibrium between the anionic complexes of indium(II), (I) and (III) is indeed established in solution, and that the qualitative results are in agreement with those for neutral indium(II) complexes.

Coordination compounds of indium. Part 42. The insertion of indium(I) halides into homonuclear bonds in non-aqueous media

CLOVIS PEPPE AND DENNIS G. TUCK
Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received March 27, 1984

CLOVIS PEPPE and DENNIS G. TUCK. Can. J. Chem. **62**, 2798 (1984).

Solutions of indium(I) halides (InX; X = Cl, Br, I) in toluene/pyridine or dichloromethane/pyridine are useful reaction media for studying the insertion of InX into various homonuclear R_nM-MR_n systems (M = O, S, Se, Co); the products are generally of the type $(R_nM)_2InX$, obtained as the bis-pyridine adducts. Reaction does not occur under these conditions for M = Sn, Pb, N, P, Te, Mn, Fe. The mechanism of such insertion processes is discussed; the donor and acceptor properties of both In^I and M are important. The InX/benzoyl peroxide system gives rise to a series of products which suggest re-arrangement reactions in solution following insertion of indium into the O—O bond.

CLOVIS PEPPE et DENNIS G. TUCK. Can. J. Chem. **62**, 2798 (1984).

Les solutions d'halogénures d'indium(I) (InX; X = Cl, Br, I) dans des mélanges de toluène/pyridine ou de dichlorométhane/pyridine s'avèrent des milieux réactionnels très utiles pour étudier l'insertion de InX dans divers systèmes homonucléaires R_nM-MR_n (M = O, S, Se, Co); les produits sont généralement du type $(R_nM)_2InX$ et ils sont obtenus sous forme d'adduits bis-pyridine. Dans ces conditions, il ne se produit pas de réaction si M = Sn, Pb, N, P, Te, Mn, Fe. On discute du mécanisme de tels processus d'insertion; les propriétés de donneur et d'accepteur tant du In(I) que du M sont importantes. Le système InX/peroxyde de benzoyle conduit à une série de produits qui suggère qu'en solution il se produit des réactions de transposition après l'insertion de l'indium dans la liaison O—O.

Introduction

The reaction between indium(I) halides (InX, X, = Cl, Br, I) and alkyl halides (RX) has been the subject of a number of reports (1, 2). The products correspond formally to the insertion of InX into a C—X bond

[1] $InX + RX \rightarrow RInX_2$

although the available evidence on these and related processes (1*d*, 2) points to a mechanism more complicated than is implied by reaction [1]. In related studies, we have shown that InX reacts at the S—S bond of 1,2-bis(trifluoromethyl)dithiete (3), as does cyclopentadienylindium(I) (4), and here again the formal stoichiometry implies oxidative insertion. The analogous oxidation of CpIn with iodine (5) and the reactions of InX_2^- and $In_2X_6^{2-}$ with X_2 (X = Cl, Br, I) (6) have also been reported, and possible mechanisms discussed.

A recent paper (7) from this laboratory reported the significant solubility of the indium(I) halides in mixtures of toluene and neutral nitrogen, phosphorus, or oxygen bases. The synthetic applications of such solutions were briefly explored in terms of the InX/RX reaction, and we have now extended these studies to include the reaction of InX (X = Cl, Br, I) with a variety of compounds with homonuclear M—M bonds, where M is a Group IV, V, or VI element, or a transition metal. An analysis of the preparative results leads to a tentative mechanism which is compatible with that proposed for the insertion of InX into In^{III}—X bonds (8).

Experimental

General

The preparative, spectroscopic, and analytical methods were those used in previous work (7, 8). Microanalysis was by Guelph Chemical Laboratories. All experimental procedures were carried out under dry nitrogen.

Preparative: general

In a standard experiment, 5 mmol of InX (X = Cl, Br, I) and an equimolar quantity of substrate were stirred together in a solvent phase of 2–5 mL of pyridine and 50 mL of toluene (or dichloromethane). The temperature was initially −80°C for InCl and −20°C for InBr or InI in toluene solution, and −80°C for InCl or InBr, and −20°C for InI when dichloromethane was used. The cooling bath was gradually removed and the temperature of the reaction mixture allowed to reach ambient over ca. 3 h after which the mixture was filtered to remove any solid material. The details of the isolation procedures are, in summary:

InX/R_2S_2 (X = Cl, Br; R = Ph). At the end of the reaction in CH_2Cl_2/pyridine, the volume of the solution was reduced by approximately 50%, and petroleum ether added to yield a solid which was collected and dried.

InI/Ph_2S_2. The oil obtained by pumping off the solvent toluene was redissolved in CH_2Cl_2 containing a molar equivalent of $^nPr_4NI$. Solvent was removed, and the product recrystallised from methanol, washed with diethyl ether, and dried.

InI/Me_2S_2. Reaction in toluene/pyridine was followed by an isolation procedure similar to that described above for InX/R_2S_2.

InX/Ph_2Se_2. For $InCl/Ph_2Se_2$, the reaction mixture (toluene/pyridine) was pumped to dryness and the resultant solid recrystallised from a CH_2Cl_2/petroleum ether mixture. For InBr and InI, the procedure was similar to that described for InX/R_2S_2.

$InX/Co_2(CO)_8$. Removal of the solvent (CH_2Cl_2/pyridine) by pumping *in vacuo* gave an oil which solidified on stirring with petroleum ether.

The characterisation of the products depended on indium and halogen analysis (Table 1), and on spectroscopic confirmation of the presence of organic ligands and/or cation. Table 2 summarises the ^1H nmr results. The identification of the pyridine and other aromatic resonances was based on the clear downfield separation of the resonance of the *ortho*-hydrogen atoms of pyridine from the rest of the aromatic region.

In a number of cases noted below, no evidence was obtained for any reaction between InX and the M—M species.

Reaction of InCl or InBr with benzoyl peroxide

(*a*) Equimolar quantities (2.6–4.8 mmol) of InX (X = Cl, Br) and dibenzoyl peroxide were mixed together in 50 mL of dichloromethane at −80°C (InCl) or −20°C (InBr). Pyridine (2 mL) was then syringed into the mixture, which was mechanically stirred as the cooling bath was removed. At 0°C, the indium(I) halide had obviously dissolved. The solvents were removed *in vacuo*, leaving a white solid which was collected, washed with diethyl ether, and dried *in vacuo*. The com-

position of the solids corresponded to the formula $In_2X_3(O_2CC_6H_5)_3py_3$: X = Cl: *Anal.* calcd. for $In_2Cl_3C_{36}H_{30}N_3O_6$: In 24.5, Cl 11.4, C 46.16, H 3.23, N 4.49; found: In 24.2, Cl 11.2, C 46.09, H 3.34, N 4.40. Yield 0.80 g (0.85 mmol), from 2.65 mmol InCl (32%).

X = Br: *Anal.* calcd. for $In_2Br_3C_{36}H_{30}N_3O_6$: In 21.5, Br 22.4; found: In 21.8, Br 23.0. Yield 1.33 g (1.24 mmol) from 4.77 mmol InBr (26%).

(*b*) In a subsequent experiment, the clear colourless solution obtained from 7.7 mmol InCl and 11 mmol Bz_2O_2 in 50 mL dichloromethane and 4 mL pyridine was stirred at room temperature for 5 days. Towards the end of this period, the reaction mixture consisted of a deep red solution and a suspension of a brown solid **A** (0.4 g. *Anal.* calcd. for $InCl_3(C_5H_5N)_3[(C_6H_5CO_2)_2]$: In 16.4, Cl 15.2; found: In 16.1, Cl 14.6. ^1H nmr spectrum 8.66–8.50 (m) (1H), 8.13–7.23, (m) (3H); 3py:2($C_6H_5CO_2$) requires 6H:19H). Addition of diethyl ether yielded 0.55 g of a second brown solid **B** (In 18.7%). Further solid (0.55 g) continued to deposit, and was removed from time to time. The final crop of colourless acicular crystals C (0.60 g) was shown to be $Cl_2In(O_2CC_6H_5)(C_5H_5N)_2$ by X-ray crystallography (9) (*Anal.* calcd. for $Cl_2In(O_2CC_6H_5)(C_5H_5N)_2$: In 24.7, Cl 15.3; found: In 24.5, Cl 15.0). When the final solution was pumped to dryness, the resultant solid **D** had the composition In 14.9, Cl 9.0. Total indium recovered approximately 5.2 mmol (67%).

Reaction of InI with benzoyl peroxide

Equimolar quantities of InI and benzoyl peroxide (5.6 mmol) were mixed in 50 mL dichloromethane and 2 mL pyridine at −20°C. The cooling bath was gradually removed from the stirred mixture, and the temperature allowed to reach ambient. Addition of petroleum ether to the solution precipitated 0.9 g of a yellow solid of unidentified structure (*Anal.* found: In 23.0, I 9.0). The filtrate was allowed to stand overnight, after which 1.2 g of yellow crystalline $IIn(O_2CC_6H_5)_2(C_5H_5N)_2$ deposited (*Anal.* calcd.: In 17. 9, I 19.8; found: In 17.5, I 19.6). Prolonged cooling yielded further solid which analyzed as $In_2I_3(O_2CC_6H_5)_3(C_5H_5N)_3$ (*Anal.* calcd: In 19.0, I 31.5; found: In 19.3, I 32.3). The solid obtained on removing the solvent (0.21 g) had In 20.1, I 28.6. Total indium recovered 83%.

Results and discussion

Group IV and V elements

The addition of 2,4-dinitrophenylhydrazine, tetraphenyl diphosphane, hexaphenyldistannane, or hexaphenyldiplumbane to a solution of InX in toluene/pyridine under the conditions described in the Experimental Section resulted in the deposition of indium metal in quantities corresponding to the process

[2] $3InX \rightarrow 2In^0 + InX_3$

and in the case of InI/Sn_2Ph_6, the tin compound was subsequently recovered unchanged from the reaction mixture. In view of these and other results described below, no further reactions of this type were performed with compounds of Group IV or V elements.

Group VI elements

We have successfully cleaved O—O, S—S, and Se—Se bonds, but Te—Te compounds did not react in this way under the conditions used. In summary, the results obtained were:

(*i*) The reaction of InX (X = Cl, Br, I) with benzoyl peroxide in dichloromethane/pyridine solution gave rise to products containing indium, halogen, and benzoate, with the metal in the +III oxidation state. The nature of the products suggests that the primary process is indeed the insertion

[3] $InX + (C_6H_5COO)_2 \rightarrow XIn(O_2CC_6H_5)_2$

which is followed by the rearrangement reactions

[4] $3XIn(O_2CC_6H_5)_2 \rightarrow In_2X_3(O_2CC_6H_5)_3 + In(O_2CC_6H_5)_3$

[5] $2XIn(O_2CC_6H_5)_2 \rightarrow X_2In(O_2CC_6H_5) + In(O_2CC_6H_5)_3$

The experimental evidence for these processes is summarised in the Experimental Section. No evidence has been found for the presence of $In(O_2CC_6H_5)_3$ in any of the solution phases, however, and the detailed validity of the above equations must therefore remain in question. This not unimportant point aside, there seems to be no doubt that the oxidative insertion process (reaction [3]) does indeed occur.

(*ii*) With a substrate of either Ph_2S_2 or Ph_2Se_2, the products of the reaction, isolated in high yield, correspond to the process

[6] $InX + Ph_2M_2 \xrightarrow[CH_2Cl_2]{py} XIn(MPh)_2py_2$ (M = S, Se)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

In the iodide case the anionic derivative $[I_2In(SPh)_2]^-$ was obtained as the tetra-*n*-propylammonium salt. A similar insertion was observed with InI and Me_2S_2, but the reaction of InI with either $Bu_2''S_2$ or $Bu_2'S_2$ under the conditions described lead to the deposition of indium metal.

(*iii*) When the substrate was Ph_2Te_2, the reaction again followed that in reaction [2], namely, the disproportionation of InX to indium metal and InX_3.

Binuclear metal carbonyls

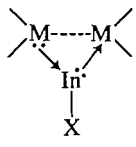
The synthesis of compounds in which indium is bonded to transition metal carbonyl groups has been achieved by the thermal reaction of InX with a variety of binuclear metal carbonyls. The conditions needed for these reactions depend quite critically on the carbonyl in question (see below).

In the present experiments, we find a smooth and rapid reaction between InX and $Co_2(CO)_8$, leading to the isolation of $XIn[Co(CO)_4]_2py_2$ (X = Cl, Br, I). With indium(I) halides and either $Mn_2(CO)_{10}$ or $[CpFe(CO)_2]_2$, the reaction mixture deposited indium metal, and no evidence could be obtained for the insertion of indium into the metal–metal bond. This behaviour corresponds to that previously reported for the analogous thermal reactions; indium(I) bromide reacts quickly at room temperature with $Co_2(CO)_8$ in tetrahydrofuran (10, 11) but the reaction with either $Mn_2(CO)_{10}$ or $[CpFe(CO)_2]_2$ requires temperatures above 100°C (12, 13), and insertion does not occur under milder conditions.

Reaction mechanism

Solutions of indium(I) halide in the non-aqueous media used in these experiments decompose slowly at room temperature, giving rise to indium metal and adducts of either InX_3 or In_2X_4, depending on the nature of X and the neutral ligand (7, 8). The significance of such processes in the present work is that formation of indium metal is evidence that decomposition is occurring via reaction [2], so that in such cases the substrate resists attack by indium(I) halide. In keeping with this, the products of insertion reactions are isolated in good yield only in those systems in which the precipitation of indium is not observed.

In the previous discussion (8), the properties of indium(I) species were shown to involve both electron pair donor and acceptor properties. Thus the formation of the intermediate in the insertion reaction may involve InX acting as either nucleophile, or electrophile, or both. As in the case of the insertion of InX into an In^{III}—X bond, the proposed mechanism is based on this duality in the chemistry of InX. The reaction of InX at a homonuclear (M—M) bond is unlikely to be a concerted process, since the insertion of a lone pair on InX, presumed to be in the HOMO orbital, into the LUMO of an M—M bond with u-symmetry would be energetically unfavourable. Following the previous discussion (8), we propose that the reaction involves electron pair donation from InX to one M atom, accompanied or followed by donation from the other M to InX. The proposed intermediate



1

then undergoes M—M fission to give the $XInM_2$ kernel. The insertion of InX therefore requires that the M atoms be both acceptor and donor sites, and it remains to show that the pattern of observed reactions, or absence of reaction, supports this mechanism.

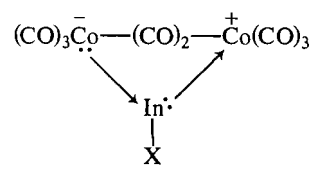
For dinuclear transition metal carbonyls, neither $Mn_2(CO)_{10}$ nor $[CpFe(CO)_2]_2$ react under the low temperature/solution phase conditions investigated in the present work, or under the mild condition used by Patmore and Graham (10, 11). The metal atoms in these carbonyls have an 18-electron configuration, and show neither acceptor nor donor functionality, so that an intermediate such as **1** cannot be easily formed. It seems likely that the more extreme conditions under which reaction does occur (12, 13) bring about thermal cleavage of the M—M bond, and that a subsequent free radical reaction with InX leads to the final products. Dicobalt octacarbonyl can exist in two tautomeric forms in solution (14), one with two μ-CO groups and the other the metal–metal-bonded $(CO)_4CoCo(CO)_4$. The latter, like $Mn_2(CO)_{10}$ and $[CpFe(CO)_2]_2$, cannot readily react with InX, but the carbonyl-bridged form, with a bent metal–metal bond, has the correct orientation for attack by InX. This is most easily seen by the interaction of InX with the dipolar canonical form of $Co_2(CO)_8$ to give the intermediate



which goes to $XIn[Co(CO_4]_2$ by rupture of the carbonyl bridges.

For the molecules Sn_2Ph_6 and Pb_2Ph_6, the absence of any insertion reaction is easily understood in terms of the lack of donor electrons on the metal. For 2,4-dinitrophenylhydrazine, the nitrogen atoms are potential donors, but cannot act as acceptors, and for tetraphenylphosphane there is little evidence of acceptor properties, even though the phosphorus atoms are known to be potential donors.

The Group VI compounds require more detailed comment. Compounds with S—S, Se—Se, and Te—Te bonds fulfill the required conditions, in that these atoms have potential donor

and acceptor properties. No reaction was observed with Ph_2Te_2, and this can be understood in terms of the poor donor ability, given that there is little evidence of such compounds acting as strong ligands. For Ph_2Se_2, the reaction is straightforward, yielding the pyridine adducts of $XIn(SePh)_2$ (X = Cl, Br, I). With disulphides, the easy reaction of Ph_2S_2 and Me_2S_2 contrasts with the absence of any detectable reaction with $Bu_2^nS_2$ or $Bu_2^tS_2$. These results show that the strongest bases undergo reaction, and the order of reactivity is very similar to that reported by Ichimura, Nosco, and Deutsch (15) who studied the electrophile–assisted cleavage of S—S bonds by nucleophiles, reactions which are similar in mechanism to the attack of InX on such bonds via the intermediate **1**.

In general then the reactivities observed in the various InX/M—M systems are readily explained by the proposed mechanism. The previously reported examples of InX insertion processes agree with, but do not confirm, the reaction scheme. Reaction with I_2 (CpIn, InX_2^-) (5, 6) to give In^{III} products are readily accommodated into the scheme, as are reactions with the S—S bond of 1,2-bis(trifluoromethyl)dithiete (3, 4). Similarly, the reaction of InX with RX′ can be viewed as the nucleophilic attack of InX on RX′, with donation from X′ to indium as required by the reaction pathway proposed here.

One final caveat concerns the undetermined effect of the solvation of InX in aromatic/donor solvent solutions used. We have written all the above reactions as though unsolvated InX molecules are involved, but our earlier work (7) demonstrated that solvation by the donor solvent is critically important. We have argued elsewhere (8) that such solvation could increase the availability of the lone pair on InX, but there may well be other effects on these and other features of the reaction.

The InX/benzoyl peroxide system

The complex series of products which are obtained from the InX/benzoyl peroxide reaction systems require some comment. The rapid formation of a clear solution phase implies that reaction [3] occurs readily under the reaction conditions. The reaction is no doubt aided by the presence of carbonyl groups adjacent to the O—O bond, which otherwise lacks the required donor and acceptor properties to form the intermediate **1**. This explains the sharp difference between the N—N and O—O bonded molecules studied.

The simplest system is for X = I, where the major compound isolated is the insertion product $IIn(O_2CC_6H_5)_2py_2$. For X = Cl or Br, the products which are eventually obtained on removing solvent, namely $In_2X_3(O_2CC_6H_5)_3py_2$, correspond to an equimolar mixture of InX_3 and $In(O_2CC_6H_5)_3$. In an earlier paper (16), the nature of a series of some unusual indium(III) acetate compounds was discussed in terms of a polymeric $In(OAc)_3$ lattice which can accommodate various neutral or charged species, and it seems reasonable that a similar structure should apply in the case of $In_2X_3(O_2CC_6H_5)_3py_2$, and this may explain why $In(O_2CC_6H_5)_3$ is not isolated from the reaction mixture (cf. reactions [4] and [5]).

With $InCl/Bz_2O_2$, the complex series of products **A**–**D** isolated from a lengthy reaction include **C**, which is the product of insertion (reaction [3]) followed by rearrangement (reactions [4] and [5]). The structures of substances **A** and **B** are not clear; product **D** corresponds analytically to an $InCl_2$ derivative, and again can be rationalized in terms of reaction [5]. In general, the materials confirm that solution rearrangement reactions which follow the initial insertion reaction play an important role here, as in other indium(III) systems.

Vibrational spectra of $XIn(MC_6H_5)py_2$ complexes (X = Cl, Br, I; M = S, Se)

Table 3 shows the previously unreported far infrared spectra of the neutral phenylthiolate complexes, and the infrared and Raman spectra of the $[I_2In(SPh)_2]^-$ anion. The latter is expected to have C_{2v} symmetry in the InI_2S_2 kernel, with two ν(In—S) and two ν(In—I), all active in both infrared and Raman modes. The ν(In—I) vibrations are readily assigned at 176 and 155 cm^{-1}. The identification of ν(M—S) modes has been the subject of debate (17), with frequencies between 400 cm^{-1} and 160 cm^{-1} being proposed. The ν(In—S) absorptions in indium–dithiolate anionic complexes were assigned in the 300–370 cm^{-1} range (18), and the only reasonable candidates in the spectrum of $[I_2In(SPh)_2]^-$ are the two vibrations at 332 and 344 cm^{-1}, frequencies which are also observed in the spectra of the neutral chloride and bromide compounds. None of the bending modes can be assigned at this stage.

The adducts $XIn(SPh)_2py_2$ (X = Cl, Br) each show one ν(In—X) infrared band, and absorption in the presumed ν(In—S) region, in agreement with the above discussion. The corresponding results for $XIn(SePh)_2py_2$ compounds (X = Cl, Br, I) are given in Table 4, and lend themselves to a similar

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

analysis with ν(In—Se) tentatively assigned in the 200–260 cm^{-1} region. The ν(In—N) modes are not identified in this analysis, and may well lie in the spectral region obscured by S—C_6H_5 or Se—C_6H_5 vibrations, since frequencies above 400 cm^{-1} have been reported for ν(In—N) in earlier work (19). The analysis of the spectra does not allow a choice to be made between the various stereochemistries possible for an In-$X(S)_2(N)_2$ kernel, but does confirm that the compounds concerned are mononuclear species.

Nitration of 2,6-di-*tert*-butylphenol in acetic anhydride or chloroform gives 2,6-di-*tert*-butyl-4-nitrophenol and 2-*tert*-butyl-4,6-dinitrophenol. The intermediates 2,6-di-*tert*-butyl-4-nitrocyclohexa-2,5-dienone and 2,6-di-*tert*-butyl-4,6-dinitrocyclohexa-2,4-dienone, have been observed by ^1H and ^{13}C nmr. Nitration of 2,4-di-*tert*-butylphenol gives successively 2,4-di-*tert*-butyl-6-nitrocyclohexa-2,4-dienone, 2,4-di-*tert*-butyl-6-nitrophenol, 2,4-di-*tert*-butyl-4,6-dinitrocyclohexa-2,5-dienone, and 2-*tert*-butyl-4,6-dinitrophenol. Nitration of 3,5-di-*tert*-butylphenol gives successively 3,5-di-*tert*-butyl-6-nitrocyclohexa-2,4-dienone, 3,5-di-*tert*-butyl-2-nitrophenol, 3,5-di-*tert*-butyl-2,4-dinitrocyclohexa-2,5-dienone, and 3,5-di-*tert*-butyl-2,6-dinitrophenol. 3,5-Di-*tert*-butyl-4-nitrocyclohexa-2,5-dienone and 3,5-di-*tert*-butyl-2,6-dinitrocyclohexa-2,4-dienone are also formed as intermediates. Nitration of 3,5-di-*tert*-butylphenoxyacetic and isobutyric acids gives in each case the 2-nitro derivative. Further nitration of 3,5-di-*tert*-butyl-2-nitrophenoxyacetic and isobutyric acids gives a mixture of the adducts 7,9-di-*tert*-butyl-6,10-dinitro-1,4-dioxaspiro[4,5]deca-6,8-dien-2-one and its 6,8-dinitro-6,9-diene isomer from the former and their 3,3-dimethyl derivatives from the latter. No dinitro acids are formed.

GORDON G. CROSS, ALFRED FISCHER et GEORGE N. HENDERSON. Can. J. Chem. **62**, 2803 (1984).

La nitration du di-*tert*-butyl-2,6 phénol, dans l'anhydride acétique ou le chloroforme, conduit au di-*tert*-butyl-2,6 nitro-4 phénol ainsi qu'au *tert*-butyl-2 dinitro-4,6 phénol. Faisant appel à la rmn du ^1H et du ^{13}C, on a pu observé la di-*tert*-butyl-2,6 nitro-4 cyclohexadiène-2,5 one ainsi que la di-*tert*-butyl-2,6 dinitro-4,6 cyclohexadiène-2,4 one qui se forment comme intermédiaires. La nitration du di--*tert*-butyl-2,4 phénol conduit successivement à la di-*tert*-butyl-2,4 nitro-6 cyclohexadiène-2,4 one, au di-*tert*-butyl-2,4 nitro-6 phénol, à la di-*tert*-butyl-2,4 dinitro-4,6 cyclohexadiène-2,5 one et finalement au *tert*-butyl-2 dinitro-4,6 phénol. La nitration du di-*tert*-butyl-3,5 phénol fournit successivement la di-*tert*-butyl-3,5 nitro-6 cyclohexadiène-2,4 one, le di-*tert*-butyl-3,5 nitro-2 phénol, la di-*tert*-butyl-3,5- dinitro-2,4 cyclohexadiène-2,5 one et finalement le di-*tert*-butyl-3,5 dinitro-2,6 phénol. La di-*tert*-butyl-3,5 nitro-4 cyclohexadiène-2,5 one et la di-*tert*-3,5 dinitro-2,6 cyclohexadiène-2,4 one se forment aussi comme intermédiaires. La nitration des acides di-*tert*-butyl-3,5 phénoxyacétique ainsi que phénoxyisobutyrique conduit, dans chaque cas, à la formation du dérivé nitro-2. Des nitrations plus poussées des acides di-*tert*-butyl-3,5 nitro-2 phénoxyacétique ou phénoxyisobutyrique conduisent, dans le cas du dérivé phénoxyacétique, à des mélanges d'adduits de la di-*tert*-7,9 dinitro-6,10 dioxa-1,4 spiro[4,5] décadiène-6,8 one-2 et de son isomère dinitro-6,8 diène-6,9 et aux dérivés diméthyl-3,3, dans le cas de la nitration des dérivés phénoxyisobutiryque. Aucun dérivé dinitré des acides ne se forme.

It is well established that nitration of an aromatic compound generally involves the formation of a cyclohexadienyl cation intermediate by the addition of nitronium ion to the aromatic substrate. The cation is deprotonated to the nitroaromatic in a subsequent step and the overall mechanism is classified as S_E2 (1). There have been a number of reports of the direct observation of the nitrocyclohexadienyl cation intermediate (2–4). However, it appears that most such reports are in error (5*a*) and that the only cyclohexadienyl cation that has a secondary nitro group which is likely to have been observed is that obtained in the nitration of anthracene (2). More extensive observations that point to the existence of the nitrocyclohexadienyl cation have been made for *ipso*-cations, i.e. cations formed by the addition of the nitronium ion at a substituted carbon. Olah *et al.* have observed by nmr the cations obtained by the addition of nitronium ion to hexamethylbenzene and to trifluoromesitylene (6). These nitrobenzenium cations are derived from fully substituted benzenes. In an *ipso* cation derived from a less substituted benzene it is likely that the nitro group would rapidly migrate by a sequence of 1,2-shifts to a proton-bearing carbon, deprotonation would ensue, and the nitrobenzene derivative would be formed (7), precluding direct observation of the cation. However, the methylnitrocyclohexadienyl cation with nitro *ipso* to methyl can be trapped by an appropriate nucleophile to form a pair of diastereoisomeric adducts (8). Such adducts can undergo reactions which are most readily explained in terms of the re-formation of the intermediate methylnitrocyclohexadienyl cation.

The failure either to observe, or to trap as adducts, nitrocyclohexadienyl cations with nitro attached to a proton-bearing carbon reflects the extremely facile deprotonation of such cations. Kinetic isotope effects are not normally observed in nitration, consistent with the deprotonation step being much faster than the reversion of the nitrocyclohexadienyl cation to the nitronium ion and the aromatic substrate. The cyclohexadienyl cation itself is strongly acidic. Introduction of the nitro group at the site of the acidic proton should greatly enhance the acidity. In the exceptional cases in which an isotope effect is observed in nitration and thus the deprotonation step is rate-determining, either the nitrocyclohexadienyl cation is unusually stable and (or) the transition state for the deprotonation reaction is subject to steric strain. Thus for nitration of anthracene an isotope effect is observed (2). The nitrocyclohexadienyl cation from anthracene is unusually stabilized with respect to reactant and product, as there is a relatively small loss of delocalization energy on forming the intermediate. Furthermore, the transition state for deprotonation is subject to steric strain as a result of interactions between the nitro group and the adjacent 1 and 8 hydrogens. An isotope effect is also observed in the nitration of 2-nitro-1,3,5-tri-*tert*-butylbenzene, a case in

[1] For Part XXIV, see ref. 14.

For personal use only.

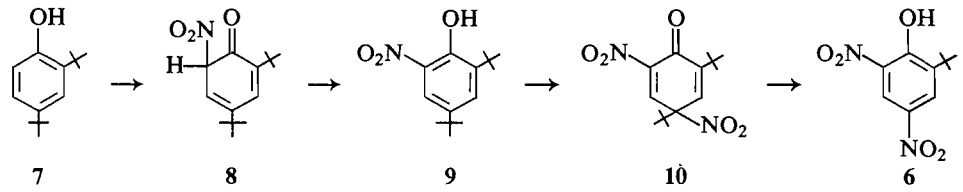
which there is steric strain in the deprotonation step (9). In this case the lifetime of the nitrocyclohexadienyl cation is such that another reaction of the cation also occurs: rearrangement to give (ultimately) 2,4-dinitro-3,5-di-*tert*-butyltoluene (10).

Nitration of phenols which are fully substituted in the reactive 2, 4, and 6 positions to 2,4,6-trisubstituted 4-nitrocyclohexa-2,5-dienones has long been known (11). More recently 4-alkyl-4-nitrocyclohexa-2,5-dienones (12) and 6-alkyl-6-nitrocyclohexa-2,4-dienones (13, 14) have been obtained from the nitration of less substituted phenols or phenyl acetates. The formation of nitrodienones can be viewed as a special case of *ipso* nitration and capture of the *ipso*-methylnitrocyclohexadienyl cation by a nucleophile. In this case the nucleophile is the substituent already present, i.e. hydroxyl. The discrete step of nucleophilic addition has been eliminated. Correspondingly the nitrodienone can be viewed, in one canonical form, as an oxide-substituted nitrocyclohexadienyl cation (Scheme 1). In this communication we report the first detailed observations of nitrodienones containing a secondary nitro group, i.e. oxide-substituted nitrocyclohexadienyl cations with nitro "*ipso*" to hydrogen. We also report the first isolation from a nitration reaction of a nitrocyclohexadiene containing a secondary nitro group. In a recent paper we reported the observation of similar dienones in the nitration of 2,3,6-trimethyl- and 2,3,5,6-tetramethylphenol (14). In those cases, the 2,5-dienone with nitro "*ipso*" to hydrogen was a minor component in a mixture in which the 6-methyl-6-nitrocyclohexa-2,6-dienone predominated and the structural information which could be obtained was limited to ^{1}H nmr observations.

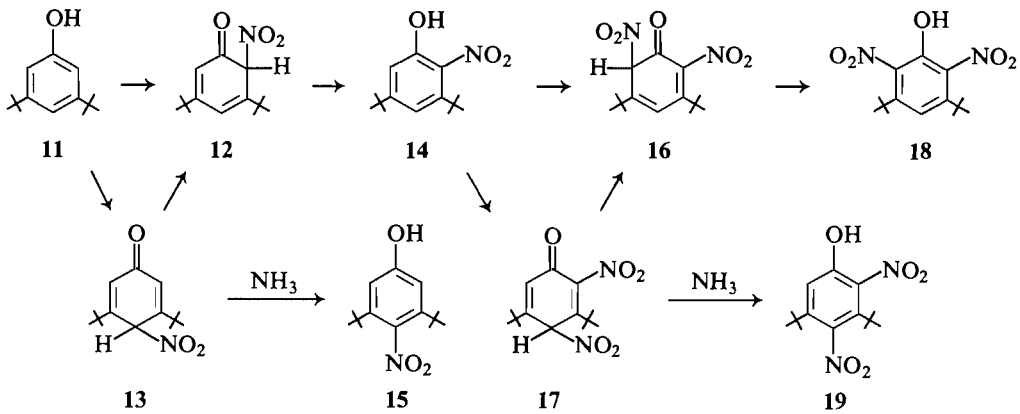
Results and discussion

Nitration of 2,6-di-*tert*-butylphenol (**1**) in both acetic anhydride and chloroform gave, successively, the species **2**, **4**, **5**, and **6** (Scheme 2). The nitrophenols **4** and **6** were isolated and characterized. The nitrodienone **2** was identified in reaction mixtures by ^{1}H and ^{13}C nmr spectra. The symmetry of the spectra, the doublet–triplet splitting in the ^{1}H nmr, and the characteristic dienone peaks at δ_C 80 (saturated carbon) and 184 ppm (carbonyl carbon) in the ^{13}C nmr are all consistent with this assignment. The isomeric 2,4-dienone **3** would exhibit more complex spectra. In some preliminary experiments another intermediate, presumably **3**, was formed but we were unable to find conditions under which this intermediate could be formed reproducibly in substantial amount. In the experiments in which the 2,4-dienone **3** was formed, **4** was the only aromatic product observed when the 2,4-dienone disappeared. It seems likely that the isomerization of **3** to **4** involves the initial rearrangement of **3** to **2** by a dissociation–recombination pathway (*vide infra*) followed by tautomerization of **2** to **4**. The dinitrodienone **5** was identified in reaction mixtures by ^{1}H and ^{13}C nmr. The absence of a plane of symmetry is evident from the spectra and this rules out a 2,5-dienone structure containing a *gem*-dinitro group. Nitration of **4** to **6** has been observed previously (15) and is an example of nitro-de-*tert*-butylation. Formation of the intermediate dienone **5** was not observed by Zlobina and Ershov (15). Loss of the *tert*-butyl group from the dinitrodienone is acid catalysed and presumably involves initial protonation at the carbonyl oxygen followed by loss of the *tert*-butyl cation (16). Note that in the case of the dienone **3** this pathway, which would lead to 2-*tert*-butyl-6-nitrophenol, under the reaction conditions is of higher energy than the **3** → **2** → **4** path and no 2-*tert*-butyl-6-nitrophenol is formed.

On nitration of 2,4-di-*tert*-butylphenol (**7**) in acetic anhydride, successive formation of the species **9**, **10**, and **6** could be observed (Scheme 3). We were not able to observe the nitrodienone **8** even when the reaction was carried out at −70°C. However, we were able to observe the transient formation of **8** in the reaction in chloroform, at −60°C. The 2,4-dienone **8** had three broad singlets in the vinyl-allylic region of the ^{1}H nmr. Its 2,5-dienone isomer would exhibit a 10-Hz vinyl proton coupling and no such coupling was observed. It is not possible to make a similar clear-cut distinction between **10** and its isomer 4,6-di-*tert*-butyl-2,6-dinitrocyclohexa-2,4-dienone. It is possible that the 2,6-dinitro isomer is formed and it, rather than **10**, could even be the observed dinitrodienone. What is clear is that **10** must be the immediate precursor to **6** and that it must be either the observed species, or formed as a transient intermediate from the observed species. Conversion of **10** to **6** is another example of nitro-de-*tert*-butylation and it is observed only when the process of nitro migration and tautomerization to



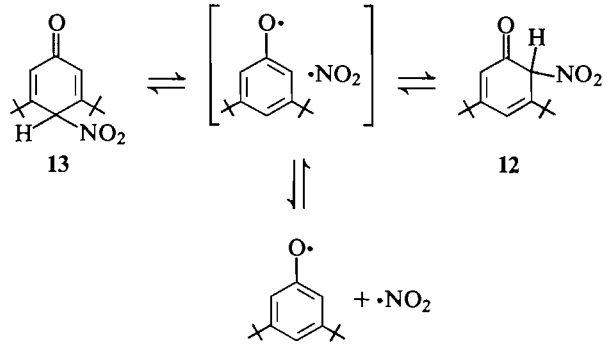
SCHEME 3



SCHEME 4

a nitrophenol is blocked. The dinitrodienone **10** which, like **5**, readily lost the *tert*-butyl group in the nitration mixture decomposed only slowly at 0°C in chloroform solution when the acid was removed, and even survived for a short period at +35°C, also like **5**. It is likely that these dienones could be isolated free from the dinitrophenol cleavage products although they do appear rather less stable than analogous dienones obtained by nitration of 2,4,6-tri-*tert*-butylphenol (17) and 2,6-di-*tert*-butyl-4-chlorophenol (18). It seems likely that, in accord with its electron-withdrawing effects, the additional nuclear nitro substituent facilitates the cleavage of the dinitrophenol moiety from the incipient *tert*-butyl cation.

Nitration of 3,5-di-*tert*-butylphenol (**11**) in acetic anhydride gave successively the dienone **12** and the nitrophenol **14** (Scheme 4). Precipitation occurred at this stage and the further reactions of **14** were obscured. It is likely that a dinitrodienone and finally the dinitrophenol **18** were formed (*vide infra*). The dienone **12** was identified by ^{1}H and ^{13}C nmr spectra. In the ^{1}H spectrum the three singlets of the ring protons were clearly resolved. In the ^{13}C spectrum peaks for all of the six-ring carbons were observed and in the gated spectrum the C-6 signal at 86 ppm was split into a doublet. The absence of symmetry in the dienone is evident from the spectra and thus the 2,5-dienone **13** is ruled out. Nitration in chloroform gave both nitrodienones **12** and **13**. These rearranged to give the nitrophenol **14**, which was further nitrated to dinitrodienone **17**, which rearranged to the 2,6-dinitrophenol **18**, the final product. The ^{1}H and ^{13}C nmr spectra of **13** are in accord with its symmetry. Further confirmation of the presence of **13** was provided by work-up after quenching with ammonia at low temperature: 3,5-di-*tert*-butyl-4-nitrophenol (**15**) was obtained by the ammonia-catalysed tautomerization of **13**, in addition to the 2-nitro isomer **14**. The assignment of the structure **17** to the dinitrodienone rather than the isomeric structure **16** is based on the experiment in which the reaction mixture from nitration of **14** was quenched with ammonia in methanol at low temperature: the 2,4-dinitrophenol **19** was obtained, as well as the



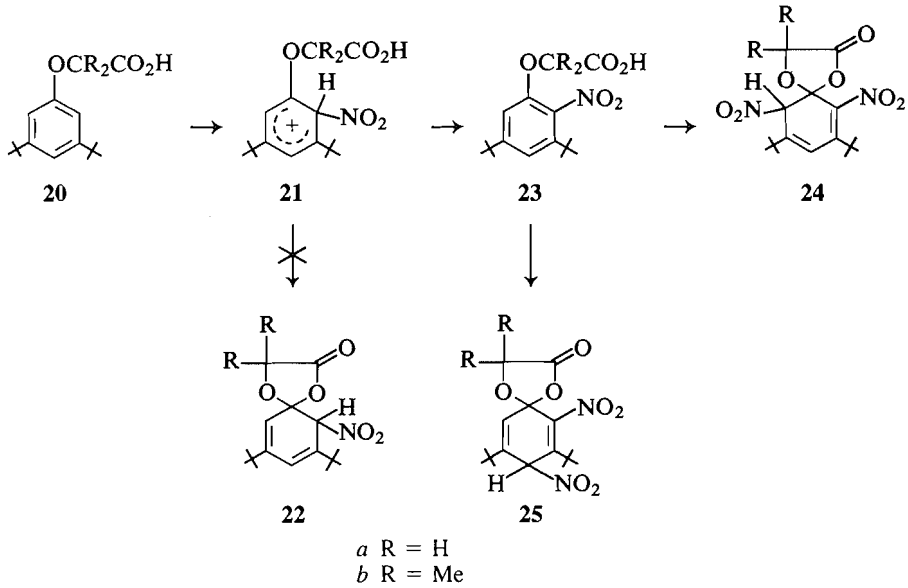
SCHEME 5

2,6-dinitrophenol **18** present in the reaction mixture before quenching.

Nitration of **11** should occur, in principle, at both of the unsubstituted 2 (6) and 4 positions to give, after deprotonation at oxygen, **12** and **13**, respectively. Steric hindrance to nitration would be expected to be greater at the 4 position than at the 2 position, but both products were observed in chloroform. The nitrophenol **15** was not observed under nitration conditions. Conversion of the 4-nitrodienone **13** to the 2-nitrophenol **14** undoubtedly involves the 2-nitrodienone **12** as an intermediate. Barnes and Myhre have shown that 4-methyl-4-nitrocyclohexa-2,5-dienone rearranges to 4-methyl-2-nitrophenol in organic and weakly acidic solvents by a radical dissociation–recombination process involving phenoxy and nitrogen dioxide radicals (19). Barnes and Myhre's mechanism as it applies to **13** is depicted in Scheme 5. Evidently tautomerization of **13** to **15** does not compete with this process unless a base (ammonia) is added, which would greatly enhance the rate of deprotonation. Tautomerization of **12** is much faster than tautomerization of **13**. Use was made of this for the selective aromatization of **12** so that the ^{13}C nmr of **13** could be observed.

Nitration of **14** would be expected to occur at each of the unsubstituted 4 and 6 positions to give **17** and **16**, respectively.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.



SCHEME 6

Evidently tautomerization of **16** to **18** is rapid since, while **17** was observed, **16** was not, although it must be an intermediate in the formation of **18**. As in the case of the mononitrodienones **12** and **13**, tautomerization of the 2,6-dinitro-2,4-dienone **16** is much faster than tautomerization of the 2,4-dinitro-2,5-dienone **17**, and the isomerization of **17** to **16** followed by tautomerization of the latter to **18** (cf. Scheme 5) is faster than the direct tautomerization of **17** to **19** – unless a base is added to accelerate the deprotonation step.

The nitrodienones **2**, **8**, **12**, **13**, and **17** have nitro attached to the same carbon as hydrogen. We have recently reported the formation of 4-nitro-2,5-dienones containing a secondary nitro group in the nitration of 2,3,6-trimethyl- and 2,3,5,6-tetramethylphenol (14). Together these constitute the first direct observations of monocyclic nitrodienones formed by addition of a nitronium ion to an unsubstituted position of a phenol. We attribute the (relative) stability of the dienones, i.e. the relative slowness of tautomerization, to a combination of steric strain in the transition state for deprotonation at the tetragonal nuclear position and steric hindrance to solvation, and hence protonation, at the carbonyl oxygen. The first factor should be the more important in, e.g., **13**, and the second the more important in, e.g., **2**. Both factors might be important in, e.g., 4-nitro-2,3,5,6-tetramethylcyclohexa-2,5-dienone. An interesting feature of the reactivity of the dienones from **11** is that **13** appears to be more stable than **12**, surviving to a considerably higher temperature than the latter, and **17** more stable than **16**. Yet **13** is proposed to rearrange to **12**, and **17** to **16**. The apparent relative stabilities of **13** and **12** and of **17** and **16** are not necessarily indicative of the relative thermodynamic stabilities. Rather, these reflect the relative stabilities toward deprotonation, i.e. the relative height of the transition state barriers to deprotonation. In the transition state the nitro group has to have moved in the direction of becoming coplanar with the two substituents *ortho* to it. These are the two *tert*-butyl groups in the cases of **13** and **17** (and hence a high barrier), but only one *tert*-butyl group and a smaller hydroxyl group in the cases of **12** and **16** (a lower barrier). We might expect **12** and **16** to be thermodynamically more stable than **13** and **17** since the former, being 2,4-dienones, should have greater resonance stabilization than the latter cross-conjugated 2,5-dienones.

Ershov and Volod'kin (20) isolated 4-bromo-2,6-dialkylcyclohexa-2,5-dienones from bromination of 2,6-dialkylphenols. Ershov *et al.* were not able to isolate or detect the analogous nitrodienones in the nitration of the same phenols (21). The nitrodienones would be expected to be less stable to tautomerization than the bromodienones. From a study of the kinetics of nitration of the 2,6-dialkylphenols, Ershov and coworkers inferred that a transient intermediate was formed during the reaction and they attributed the nitrodienone structure to this intermediate (22). The correctness of this attribution is in some doubt since (*i*) there is no evidence that the 4-nitro-2,6-dialkylphenol is the final reaction product under the reaction conditions employed for the kinetics studies, and (*ii*) in the region in which the formation of the dienone is allegedly rate determining, different 2,6-dialkylphenols exhibit different rates of reaction although, at the sulfuric acid concentration used (82.5% by wt.), these phenols should be nitrated at the encounter rate (5*b*).

Nitration of 3,5-di-*tert*-butylphenoxyacetic acid (**20***a*) in a mixture of acetic anhydride and chloroform at −60°C gave 3,5-di-*tert*-butyl-2-nitrophenoxyacetic acid (**23***a*, Scheme 6). None of the isomeric 4-nitro acid was observed and this presumably reflects the greater steric hindrance at the 4 position of **20***a*, flanked by two *tert*-butyl groups, as compared with the 2 position, flanked by one *tert*-butyl and a smaller ether function. There was no evidence for the formation of the diene **22***a*, which suggests that deprotonation of **21***a* is faster than ring closure. At +20°C the acid **23***a* was converted into a mixed anhydride (probably the phenoxyacetic anhydride), as evidenced by the appearance of an additional methylene peak in the ^{1}H nmr spectrum and the fact that, on reaction with ammonia, 3,5-di-*tert*-butylphenoxyacetamide was obtained. Further nitration of **23***a*, in a mixture of acetic anhydride, trifluoroacetic anhydride, and chloroform, occurred by addition of nitronium ion at both the 6 and 4 positions and was followed in each case by ring closure to give the dinitrodienes, **24***a* and **25***a* respectively, in a 2:1 ratio. These dienes exhibited the characteristic peaks high field to the aromatic region in both the ^{1}H nmr (**24***a*: δ 5.14, 6.47 ppm; **25***a*: δ 6.02, 6.08 ppm) and

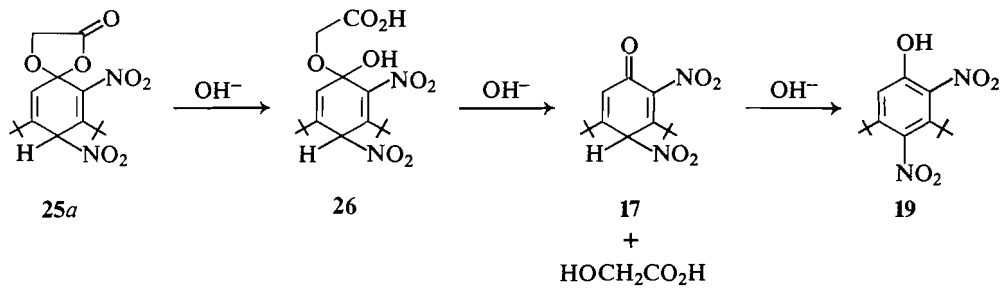

SCHEME 7

^{13}C nmr spectra (**24***a*: δ_C 85.2, 104.8 ppm; **25***a*: δ_C 82.3, 102.6 ppm). Their structures were assigned from the longer wavelength absorption (275 nm) of the extended conjugated system of **24***a*, as compared with the absorption of **25***a* at 223 nm, and from the fact that on treatment with sodium hydroxide **24***a* gave 3,5-di-*tert*-butyl-2,6-dinitrophenoxyacetic acid whereas **25***a* gave 3,5-di-*tert*-butyl-2,4-dinitrophenol. The presence of the nitro group in the 2 position of **23***a* effectively increases the size of the substituted ether group, since it restricts the conformations that the acetic acid moiety could otherwise adopt to reduce hindrance at the 6 position. As a result, addition of the nitronium ion at the 4 position of **23***a* becomes competitive with addition at the 6 position. Ring closure totally dominates deprotonation in the dinitrocyclohexadienyl cation intermediates between **23***a* and **24***a* and **23***a* and **25***a*. Most likely this can be attributed to the increase in steric strain attendant upon aromatization, with all five substituent groups forced into coplanarity with the aromatic ring. It is striking that, whereas **21***a* only deprotonates and does not undergo ring closure at all, its 6-nitro derivative and its regio isomer do not deprotonate at all and only undergo ring closure.

Nitration of 3,5-di-*tert*-butylphenoxyisobutyric acid (**20***b*) with nitric acid in acetic anhydride at −60°C gave the 2-nitro acid **23***b*, which was subsequently converted into the mixed anhydride as evidenced by reaction with ammonia to yield the amide of **23***b*. Nitration of **20***b* was also carried out under conditions designed to avoid the possible prior formation of the mixed anhydride of **20***b* with acetic anhydride (addition of solid **20***b* to the nitrating solution and, also, addition of a solution of **20***b* in [^{2}H]chloroform to the nitrating solution), but only the nitro acid **23***b* was obtained. In particular, no nitrodiene **22***b*, which would arise by ring closure of **21***b*, was observed. Under more vigorous conditions (nitration in trifluoroacetic anhydride/[^{2}H]chloroform) further nitration to the dinitrodiene, **24***b* (85%) and **25***b* (15%) occurred. As in the case of **20***a*, no ring closure occurs in the first nitration step and complete ring closure occurs in the second nitration step.

Each of the dienes **24***a*, **24***b*, **25***a*, and **25***b* can take stereoisomeric forms. The diastereoisomers of *ipso*-nitrocyclohexa-2,4-diene derivatives, in general,[2] and of 10-methyl-10-nitro-1,4-dioxaspiro[4,5]deca-6,8-dien-2-one and 3,3,10-trimethyl-10-nitro-1,4-dioxaspiro[4,5]deca-6,8-dien-2-one, in particular (23*a*), have readily distinguishable nmr spectra and thus it is clear that the compounds **24***a* and **24***b* were isolated as single diastereoisomers. As to the stereochemistry of the diastereoisomers obtained, we rely on the analogy to the *ipso*-nitration of 2-methylphenoxyacetic and 2-methylphenoxyisobutyric acids in which the *E*-diastereoisomer is formed preferentially (23*a*). The addition of nitronium ion to one face of the substrate is expected to shield that face and direct the ring closure, at the adjacent *ortho* position, to the opposite face. It is possible that a small amount of the *Z*-diastereoisomer of each compound could be formed in the nitration reactions, but remain undetected in solution. We estimate that this could not be as much as 5% of the amount of the predominant diastereoisomer and is probably substantially less. The diastereoisomers of 3,3,8-trimethyl-8-nitro-1,4-dioxaspiro[4,5]deca-6,9-dien-2-one, in which the spiro ring is attached *para* to the site of *ipso* addition, have identical nmr spectra. Compound **25***a*, with an identical pattern of nitro group, double bonds, and spiro ring, had a sharp melting point and must therefore have been isolated as a single diastereoisomer. We are unable to assign the stereochemistry of the diastereoisomer. Moreover, it is certainly possible that both diastereoisomers of **25***a* and **25***b* were formed in the nitration reactions since nitration of 4-methylphenoxyisobutyric acid gives both diastereoisomers of the *ipso*-nitrospirodienone (23*a*). However, we did not find any evidence of the presence of the second diastereoisomer when the mother liquor after crystallization of **24***a* was subjected to hplc.

The dienes **24***a*, **24***b*, and **25***a* are quite stable. They are unaffected on washing with aqueous sodium bicarbonate and do not aromatize on warming in organic solvents. The action of strong base (ammonia, sodium hydroxide) on **24***a* and **24***b* results in aromatization through deprotonation and ring opening to form the corresponding 3,5-di-*tert*-butyl-2,6-dinitrophenoxyacetic or isobutyric acid, respectively. Diene **25***a* reacts with aqueous sodium hydroxide to form 3,5-di-*tert*-butyl-2,4-dinitrophenol (**19**). A likely pathway (Scheme 7) involves $B_{AC}2$ cleavage of the lactone function to form hemiketal **26**, which undergoes base-catalysed regression to the dienone **17**, which in turn, under catalysis by the strong base, tautomerizes to **19**. A possible explanation for the proposition that lactone cleavage of **25***a* is preferred to deprotonation and ring opening (to give 3,5-di-*tert*-butyl-2,4-dinitrophenoxyacetic acid) is that deprotonation of **25***a* is sterically hindered and the product and the transition state leading to it would exhibit considerable steric strain as the nitro group moves into the plane of the flanking *tert*-butyl groups, one of which is buttressed. In the case of **24***a* the steric strain in the transition state and product of deprotonation and ring opening would be less and thus the lactone cleavage does not compete. An alternative (or contributing) explanation[3] of the difference in the behavior of **24***a* and **24***b* towards base is that lactone hydrolysis of **24***a* would be sterically hindered by the adjacent nitro group. This factor would be expected to be less significant for the *E*-diastereoisomer, the one obtained, than for the *Z*-diastereoisomer.

The dienes **24***a*, **25***a*, **24***b*, and **25***b* contain a secondary nitro

group. Dienes of similar structure have previously been obtained by rearrangement of *ipso*-nitro dienes (23). However, dienes containing a secondary nitro group have not been obtained before from nitration reactions. Normally the precursor secondary nitrocyclohexadienyl cation is too rapidly deprotonated for addition to compete. We may note that the nitrations of **23***a* and **23***b* represent cases in which, because of steric inhibition of deprotonation in the nitrocyclohexadienyl cation, addition of a nucleophile (ring closure) becomes a competitive pathway. The trapping reaction is further assisted by having the nucleophile already attached to the carbonium ion through the ether side chain. An unfavourable entropy factor that would reduce the rate of the trapping reaction is thereby removed.

Experimental

The ^{1}H nmr spectra at 90 MHz were determined on a Perkin–Elmer R32 spectrometer and ^{13}C nmr at 62.9 MHz on a Bruker WM250 instrument. Mass spectra were obtained on a Hitachi Perkin–Elmer RMU 7 spectrometer or a Finnigan 3300 system. Nitric acid was purified by distilling the fuming acid (600 cm^3) at 100 Pa from urea (20 g) and sulfuric acid (1 dm^3). 2,6- 2,4-, and 3,5-di-*tert*-butylphenol were obtained from Aldrich.

*3,5-Di-*tert*-butylphenoxyacetic acid (**20**a)*

A solution of 3,5-di-*tert*-butylphenol (4.0 g, 19 mmol) and sodium methoxide (1.05 g, 19 mmol) in methanol (120 cm^3) was heated under reflux for 2 h. The solution was evaporated to dryness, dry tetrahydrofuran was added, and the solution was again evaporated to dryness. Addition of tetrahydrofuran and evaporation to dryness were repeated. The sodium salt and 18-crown-6 (1.1 g) were dissolved in dry tetrahydrofuran (100 cm^3) and methyl bromoacetate (1.62 cm^3, 19 mmol) was added dropwise. A white solid formed almost immediately. Ether (100 cm^3) and water (100 cm^3) were added. The aqueous layer was separated, mixed with saturated brine (100 cm^3), and this solution was extracted with ether. The combined ether solution was dried and evaporated to yield white crystals (4.95 g) which contained 85% (by ^{1}H nmr) of the desired ester (80% yield). Methyl 3,5-di-*tert*-butylphenoxyacetate had ^{1}H nmr ($CDCl_3$) δ: 1.27 (s, 18, 3- and 5-C(CH_3)$_3$), 3.75 (s, 3, OCH_3), 4.60 (s, 2, CH_2), 6.75 (d, 2, J = 2 Hz, 2- and 6-*H*), and 7.06 (t, 1, J = 2 Hz, 4-*H*) ppm.

A mixture of the methyl ester (4 g) and aqueous KOH (0.5 mol in 250 cm^3) was stirred and heated under reflux for 1 h. The ester dissolved and, when the solution was cooled to ambient temperature, the sodium salt precipitated. This salt was soluble in ether. Acidification with concentrated hydrochloric acid, and extraction with ether (3 × 100 cm^3), followed by washing of the ether extract with brine (100 cm^3), drying ($MgSO_4$), and evaporation of the ether gave colourless crystals of **20***a* (3.45 g, 91%). On recrystallization from ether–pentane **20***a* had mp 141–142°C; ^{1}H nmr ($CDCl_3$) δ: 1.30 (s, 18, 3- and 5-C(CH_3)$_3$), 4.66 (s, 2, CH_2), 6.77 (d, 2, J = 2 Hz, 2- and 6-*H*), 7.08 (t, 1, J = 2 Hz, 4-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_C: 31.41 (C(CH_3)$_3$), 35.03 (C(CH_3)$_3$), 65.13 (CH_2), 109.21 (*C*-2 and *C*-6), 116.42 (*C*-4), 152.63 (*C*-3 and *C*-5), 157.18 (*C*-1), 174.85 (CO_2H) ppm; ms (70 eV) *m/e* (relative intensity): 265 (5), 264.176 (22, M_r $^{12}C_{16}{}^1H_{24}{}^{16}O_3$ = 264.173), 250 (17), 249 (100), 191 (12), 105 (13) 97 (10), 91 (11), 85 (13), 83 (10), 77 (11), 71 (16), 69 (14). *Anal.* calcd. for $C_{16}H_{24}O_3$: C 72.69, H 9.15; found: C 72.72, H 9.22.

*2-Methyl-2-(3,5-di-*tert*-butylphenoxy)propanoic acid (**20**b)*

3,5-Di-*tert*-butylphenol (8.24 g, 40 mmol) and sodium methoxide (2.16 g, 40 mmol) were dissolved in methanol (250 cm^3). The solution was stirred for 1.5 h and then evaporated to dryness. The sodium salt was dissolved in acetone, chloretone (1,1,1-trichloro-2-methyl-propan-2-ol) dihydrate (17.04 g, 80 mmol) was added, and the solution was stirred at 0°C while powdered sodium hydroxide (4.26 g, 106 mmol) was added. The stirred mixture was warmed to ambient temperature over several hours. The mixture was cooled to 0°C and the addition of sodium hydroxide was repeated twice. The mixture was stirred overnight at ambient temperature and then evaporated to dryness. The residue was dissolved in water (400 cm^3) and acidified (pH < 2) with hydrochloric acid. The suspension was extracted with ether, dried, and evaporated. The residue was heated to 75°C under reduced pressure (<100 Pa) to remove methacrylic acid. Crystallization from ether–pentane gave colourless crystals of **20***b* (7.3 g, 63%), mp 115–116°C; ^{1}H nmr ($CDCl_3$) δ: 1.28 (s, 18, C(CH_3)$_3$), 1.59 (s, 6, CH_3), 6.77 (d, 2, J = 2 Hz, 2- and 6-*H*), 7.09 (t, 1, J = 2 Hz, 4-*H*), 10.38 (br s, 1, CO_2H) ppm; ms (70 eV) *m/e* (relative intensity): 292.209 (22, M_r $^{12}C_{18}{}^1H_{28}{}^{16}O_3$ = 292.204), 206 (60), 191 (100); ms (chemical ionization, methane): 293 (M + 1).

*Nitration of 2,6-di-*tert*-butylphenol (**1**) in acetic anhydride*

A solution of nitric acid (0.95 g, 15 mmol) in acetic anhydride (4.25 cm^3) was prepared at −40°C, warmed to 0°C, and then cooled to −60°C and added, with stirring, to a solution of the phenol **1** (1.03 g, 5 mmol) in acetic anhydride (9.9 cm^3). A sample of the resulting solution was transferred immediately to an nmr tube at −60°C. The transfer pipette had been cooled previously in a cold finger filled with argon and immersed in solid carbon dioxide. The ^{1}H nmr spectrum was monitored at −60°C. The first spectrum showed 2,6-di-*tert*-butyl-4-nitrocyclohexa-2,5-dienone (**2**) (δ 5.93 (t, 1, J = 3 Hz, 4-*H*) and 6.95 (d, 2, J = 3 Hz, 3- and 5-*H*) ppm) and 2,6-di-*tert*-butyl-4-nitrophenol (**4**) (δ 6.97 (s, 1, O*H*) and 8.10 (s, 2, 3- and 5-*H*) ppm). After 60 min at −60°C, **4** was the only species present and the temperature of the nmr sample was then raised slowly. A yellow precipitate formed after 10 min at −40°C, but it dissolved on warming to −20°C. Doublets (J = 2.5 Hz) seen at δ 7.50 and 7.80 ppm were assigned to the 5- and 3- protons, respectively, of 2,6-di-*tert*-butyl-4,6-dinitrocyclohexa-2,4-dienone (**5**). At 0°C doublets (J = 2.5 Hz) appeared at δ 8.43 and 8.88 ppm, which were assigned to the 3- and 5-protons, respectively, of 2-*tert*-butyl-4,6-dinitrophenol (**6**). After 60 min at ambient temperature **6** was the only species present.

After stirring for 2 h at −60°C the bulk reaction mixture was poured into a stirred mixture of 30% aqueous ammonia (30 cm^3) and ether (50 cm^3), at −60°C. The resulting mixture was warmed to ambient temperature and the aqueous layer extracted with ether (3 × 50 cm^3). The ether solutions were combined, dried ($MgSO_4$), and the ether evaporated. Crystallization of the yellow-brown residue from methylene chloride gave **4** as yellow crystals (520 mg, 42%), mp 157–158°C (lit. (21) mp 153–154°C); ^{1}H nmr ($CDCl_3$) δ: 1.46 (s, 18, 2- and 6-C(CH_3)$_3$), 5.92 (s, 1, O*H*), 8.12 (s, 2, 3- and 5-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_C: 29.9 (C(CH_3)$_3$), 34.5 (C(CH_3)$_3$), 121.3 (*C*-3 and *C*-5), 136.7 (*C*-2 and *C*-6), 140.8 (*C*-4), 159.5 (*C*-1) ppm; ms (70 eV) *m/e* (relative intensity): 251.143 (24, M_r $^{12}C_{14}{}^1H_{21}{}^{14}N^{16}O_3$ = 251.152), 236 (100, M-CH_3), 208 (18).

In the preliminary experiments in which there was less efficient mixing of the nitrating and phenol solutions, and in which there was some warming of the reaction mixture during transfer to the nmr tube, an intermediate was formed which had a broad signal in the ^{1}H nmr spectrum from δ 6.6 to 6.8 ppm as well as a broad singlet at δ 1.29 ppm (recorded in [$^2H_6$]acetic anhydride as described below). This species was more stable than the dienone **2** but after 20 min at −40°C it gave **4**, then **5** and **6**. This intermediate was assigned as 2,6-di-*tert*-butyl-6-nitrocyclohexa-2,4-dienone (**3**). Experiments designed to generate this species in a reproducible significant amount were unsuccessful.

*Nitration of **1** in [$^2H_6$]acetic anhydride*

All solutions were prepared under an argon atmosphere. A stock nitrating mixture was prepared by adding [$^2H_6$]acetic anhydride (340 mm^3, 3.6 mmol) at 0°C to nitric acid (80 mg, 1.2 mmol), also at 0°C. A solution of **1** (21 mg, 0.10 mmol) in [$^2H_6$]acetic anhydride (200 mm^3) at −60°C was added, with stirring, to a portion (105 mm^3) of the nitric acid solution to which tetramethylsilane had been added and which was also at −60°C. The resulting solution was stirred at −60°C for 10 min, then transferred to an nmr tube. The reaction was monitored, initially at −60°C. A singlet at δ 1.24 ppm, which decreased in size with time, was assigned to the *tert*-butyl protons of **2** and a

singlet at δ 1.45 ppm, which increased in size with time, was assigned to the *tert*-butyl protons of **4**. On warming, peaks of the ring protons of **5** appeared in conjunction with singlets at δ 1.20 and 1.28 ppm. On further warming the ring proton peaks of **6** appeared in conjunction with a singlet at δ 1.47 ppm.

^{13}C nuclear magnetic resonance spectra of 2 and 5

The reaction mixture was prepared in acetic anhydride, as described above, except that CD_2Cl_2 (1.5 cm^3) was added to the nitrating mixture for a deuterium lock. The mixture was stirred at −60°C for 10 min and then a sample (3 cm^3) was transferred to the nmr sample tube at −60°C, as described. The ^{13}C nmr spectrum of **2** was recorded at −70°C, δ_C: 28.0 (CH_3), 34.8 ($C(CH_3)_3$), 80.0 (*C*-4), 130.1 (*C*-3 and *C*-5), 149.2 (*C*-2 and *C*-6), 184.4 (*C*-1) ppm.

In a separate experiment the reaction mixture was prepared at −60°C and then allowed to warm to −20°C. The yellow nitrophenol **4** crystallized but redissolved after 30 min. The ^1H nmr of the solution at this stage showed that **5** was the only species present in significant amount. The mixture was cooled to −40°C and the ^{13}C nmr spectrum recorded ($CDCl_3$ lock), δ_C: 24.13 ($C(CH_3)_3$), 27.53 ($C(CH_3)_3$), 34.57 (2-$C(CH_3)_3$), 41.72 (6-$C(CH_3)_3$), 99.95 (*C*-6), 127.29 (*C*-5), 131.97 (*C*-3), 145.73 and 146.09 (*C*-2 and *C*-4), 189.44 (*C*-1) ppm.

Nitration of 1 in [^2H]chloroform

A solution of **1** (1.03 g, 5 mmol) in [^2H]chloroform (3 cm^3) at −60°C was added, with stirring, to a mixture of nitric acid (473 mg, 7.5 mmol) and [^2H]chloroform (1 cm^3) at −60°C. After a few minutes a sample was transferred to a cold nmr tube and the reaction was monitored at −60°C. The first spectrum showed two species. The 2,5-dienone **2** (δ 5.62 (t, 1, J = 4 Hz, 4-*H*) and 6.79 (d, 2, J = 4 Hz, 3-*H* and 5-*H*) ppm) disappeared at −40°C. The 2,4-dienone **3** (δ 6.47 (br) ppm) disappeared slowly at ambient temperature. Both intermediates gave 4 (δ 8.05 (s) ppm). In the first experiment **3** was the major species formed initially (75%) but in subsequent experiments **2** was the major species.

Additional nitric acid (473 mg, 7.5 mmol) at −60°C was added, with stirring, to the bulk reaction mixture at −60°C. The solution was allowed to warm to ambient temperature and the solvent evaporated. On crystallization from ether–pentane yellow crystals of **6** were obtained, mp 128–131°C (lit. (24) mp 124–125°C); ^1H nmr ($CDCl_3$) δ: 1.48 (s, 9, $C(CH_3)_3$), 8.41 (d, 1, J = 3.5 Hz, 3-*H*), 8.87 (d, 1, J = 3.5 Hz, 5-*H*) ppm; ms (methane CI) *m/e* (relative intensity): 281 (5, M + 41), 269 (14, M + 29), 242 (12), 241 (100, M + 1).

Nitration of 4 in [^2H]chloroform

Nitric acid (630 mg, 10 mmol) at −40°C was added to trifluoroacetic anhydride (0.88 cm^3, 10 mmol), also at −40°C. The mixture was cautiously warmed to 0°C, [^2H]chloroform was added, and the solution cooled to −40°C to form a white slush. A solution of **4** (1.03 g, 4 mmol) in [^2H]chloroform (4 cm^3) at −40°C was added, with stirring, and a dark red solution was formed. The ^1H nmr spectrum showed **5** (δ 7.55 (d) and 7.82 (d) ppm, J = 3 Hz) and **6** (δ 8.49 (d) and 9.04 (d) ppm, J = 3 Hz), in an 82:18 ratio. At −30°C **5** cleaved to **6**. The bulk reaction mixture was washed twice in a cold (−20°C) separatory funnel with saturated brine, previously cooled at −20°C until it began to freeze. The resulting chloroform solution contained **5** (61%) and **6** (39%). In this washed solution the dienone **5** was more stable, decomposing to **6** slowly at +10°C and surviving for a few minutes at +35°C.

*Nitration of 2,4-di-*tert*-butylphenol (7)*

On nitration of **7** in acetic anhydride the initial ^1H nmr spectrum at −60°C showed **7** and 2,4-di-*tert*-butyl-6-nitrophenol (**9**) (δ 7.75 (d, 1, J = 3 Hz, 3-H) and 7.96 (d, 1, J = 3 Hz, 5-H) ppm). After 15 min at −60°C formation of **9** was complete. No intermediate species was seen and repetition of the reaction at −70°C gave the same result. On warming to −40°C **9** disappeared and equal sized doublets (J = 3 Hz) appeared at δ 7.31 and 8.06 ppm, assigned to 2,4-di-*tert*-butyl-4,6-dinitrocyclohexa-2,5-dienone (**10**). At 0°C **10** disappeared and the doublets (J = 3 Hz) at δ 8.44 and 8.89 ppm of 2-*tert*-butyl-4,6-dinitrophenol **6** appeared. The nitrophenol **9** was isolated after quenching the bulk reaction mixture at −60°C. On crystallization from ethanol–water it had mp 59–61°C (lit. (25) mp 62.5–63°C); ^1H nmr ($CDCl_3$) δ: 1.31 (s, 9, $C(CH_3)_3$), 1.44 (s, 9, $C(CH_3)_3$), 7.65 (d, 1, J = 2.5 Hz, 3-*H*), 7.96 (d, 1, J = 2.5 Hz, 5-*H*); ms (methane CI) *m/e* (relative intensity): 292 (5, M + 41), 281 (3), 280 (14, M + 29), 254 (2), 253 (17), 252 (100, M + 1); ms (70 eV) *m/e* (relative intensity): 251 (11, M), 236 (69), 162 (24), 145 (11), 132 (19), 131 (19), 129 (13), 128 (15), 117 (12), 116 (13), 115 (30), 105 (21), 103 (14), 91 (44), 79 (22), 78 (13), 77 (46).

On nitration of **7** with nitric acid in [^2H]chloroform at −60°C the initial ^1H nmr spectrum showed that all of **7** had reacted and **9** was the major species present. The minor species survived only 10 min at −60°C before conversion into **9** and was assigned as 2,4-di-*tert*-butyl-6-nitrocyclohexa-2,4-dienone (**8**), δ 5.88 (br s, 1,6-*H*), 6.15 (br s, 1,5-*H*), 7.01 (br s, 1,3-*H*) ppm.

Nitration of **9** with nitric acid and trifluoroacetic anhydride in [^2H]chloroform at −40°C gave a mixture of the dienone **10** (65%) (δ 1.20 (s, 9, $C(CH_3)_3$), 1.32 (s, 9, $C(CH_3)_3$), 7.36 (d, 1, J = 3 Hz, 3-*H*), and 8.06 (d, 1, J = 3 Hz, 5-*H*) ppm) and the dinitrophenol **6** (δ 1.57 (s, 9, $C(CH_3)_3$), 8.49 (d, 1, J = 3 Hz, 3-*H*) and 9.03 (d, 1, J = 3 Hz, 5-*H*) ppm). The dienone **10** slowly cleaved to **6** at −40°C and rapidly at −30°C. After washing the bulk nitration solution with cold brine the resulting solution contained **10** and **6** in a 45:55 ratio and in the solution **10** was converted into **6** very slowly at 0°C and even survived for a few minutes at +35°C.

*Nitration of 3,5-di-*tert*-butylphenol (11) in acetic anhydride*

The initial ^1H nmr spectrum at −60°C of the nitration of **11** in acetic anhydride showed a species (40%) assigned as 3,5-di-*tert*-butyl-6-nitrocyclohexa-2,4-dienone (**12**) (δ 5.85 (s, 1, 6-*H*), 5.93 (s, 1, 2-*H*), and 6.70 (s, 1, 4-*H*) ppm), which disappeared with time, and 3,5-di-*tert*-butyl-2-nitrophenol (**14**) (60%) (δ 7.00 (s, 1, 6-*H*), 7.09 (s, 1, 4-*H*), 8.20 (br s, 1, O*H*) ppm), which increased with time and which was the only species present after 45 min at −60°C. On warming to −20°C no additional species was seen and the nmr tube filled with precipitate so that no more spectra could be recorded. The nitrophenol **14** was isolated on quenching the bulk reaction mixture at −60°C and was crystallized from chloroform, mp 122–124°C (lit. (26) mp 127–128°C); ^1H nmr ($CDCl_3$) δ: 1.26 (s, 9, 5-$C(CH_3)_3$), 1.37 (s, 9, 3-$C(CH_3)_3$, 6.86 (br s, 1, O*H*), 6.92 (d, 1, J = 2 Hz, 6-*H*), 7.08 (d, 1, J = 2 Hz, 4-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_C: 30.95 ($C(CH_3)_3$), 31.04 ($C(CH_3)_3$), 35.24 ($C(CH_3)_3$), 36.39 ($C(CH_3)_3$), 113.02 (*C*-6), 117.87 (*C*-4), 137.66 (*C*-2), 143.72 (*C*-3), 149.13 (*C*-1), 155.57 (*C*-5) ppm; ms (70 eV) *m/e* (relative intensity): 251.141 (47, M_r $^{12}C_{14}{}^1H_{21}{}^{14}N^{16}O_3$ = 251.152), 236 (M − CH_3, 100). No 3,5-di-*tert*-butyl-4-nitrophenol (**15**) was detected. Nitration of **11** in [$^2H_6$]acetic anhydride at −60°C allowed the observation of the *tert*-butyl signals of **12** at δ 1.17 ppm (br s, 18) and of **14** at δ 1.26 (s, 9) and 1.32 (s, 9) ppm, as well as the signals of the nuclear hydrogens. The ^{13}C spectrum of **12** was obtained at −70°C; δ_C: 26.0 ($C(CH_3)_3$), 27.3 ($C(CH_3)_3$), 35.1 ($C(CH_3)_3$), 36.2 ($C(CH_3)_3$), 85.6 (*C*-6), 114.5 (*C*-2), 121.8 (*C*-4), 148.0 (*C*-5), 154.4 (*C*-3), 188.5 (*C*-1) ppm. The gated ^{13}C nmr spectrum was obtained in a separate experiment and the *C*-6 signal was split into a doublet (J_{HC} = 148 Hz).

Nitration of 11 in [^2H]chloroform

Nitration of **11** with nitric acid in [^2H]chloroform at −60°C showed only unreacted starting material in the initial spectrum, but after 10 min at −50°C there were three major species present: **12** (δ 5.68 (br s, 1, 6-*H*), 5.98 (br s, 1, 2-*H*), and 6.60 (br s, 1, 4-*H*) ppm), **14** (δ 6.96 (d, 1, J = 1.5 Hz, 6-*H*) and 7.04 (d, 1, J = 1.5 Hz, 4-*H*) ppm), and 3,5-di-*tert*-butyl-4-nitrocyclohexa-2,5-dienone (**13**) (δ 6.30 (s, 1, 4-*H*), 6.43 (s, 2, 2-*H* and 6-*H*) ppm). Dienone **12** tautomerized to **14** at −30°C. Dienone **13** survived for a few minutes at ambient temperature and also isomerized to **14**. The ^{13}C nmr of **13** was obtained by repeating the nitration using a smaller excess of nitric acid. The reaction mixture was then warmed to −20°C, at which temperature all of the dienone **12** had tautomerized to the nitrophenol **14**. The solution then contained (by ^1H nmr) dienone **13** (28%), nitrophenol **14** (56%), 3,5-di-*tert*-butyl-2,4-dinitrocyclohexa-2,5-dienone (**17**) (6%) (δ 6.49

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

(s, 1) and 6.53 (s, 1) ppm), and 3,5-di-*tert*-butyl-2,6-dinitrophenol (**18**) (11%). The solution (~6 cm^3) was concentrated to 1 cm^3 by evaporation at −20°C and the ^{13}C nmr of this solution was recorded at −20°C. Subtraction of the peaks due to phenols **14** and **18** gave the spectrum of **13**: δ_C 28.54 ($C(CH_3)_3$), 37.18 ($C(CH_3)_3$), 82.62 (*C*-4), 127.67 (*C*-2 and *C*-6), 160.31 (*C*-3 and *C*-5), and 189.59 (*C*-1) ppm. Peaks assigned to the dinitrodienone **17** appeared at δ_C 28.30 ($C(CH_3)_3$), 37.45 ($C(CH_3)_3$), 37.74 ($C(CH_3)_3$), 84.06 (*C*-4), and 126.93 (*C*-6).

When the nitration was repeated using equal amounts (5 mmol) of nitric acid and **11** at −60°C, and the reaction quenched with ammonia after warming to −50°C, only unreacted **11** was isolated after work-up. However, when the reaction mixture was warmed to −40°C the dienones **12** (31%) and **13** (31%) and the nitrophenol **14** (38%) were formed. The reaction mixture was then warmed to −20°C, to tautomerize **12** to **14**, and then cooled to −50°C and poured into an excess of ammonia in methanol at −50°C. The solution was warmed to ambient temperature and evaporated to a gum which contained the nitrophenols **14** (77% by ^1H nmr) and **15** (23%). Recrystallization of the residue from pentane gave **14**. Chromatography on silica with pentane and ether–pentane mixtures gave **14** in the initial fractions and **15** in the later fractions. After recrystallization from pentane **15** had mp 129–131°C; ^1H nmr ($CDCl_3$) δ: 1.30 (s, 18, 3- and 5-C(CH_3)$_3$), 6.90 (s, 2, 2-*H* and 6-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_C: 31.00 ($C(CH_3)_3$), 36.12 ($C(CH_3)_3$), 113.10 (*C*-2 and *C*-6), 143.34 (*C*-3 and *C*-5), 143.69 (*C*-4), 155.04 (*C*-1) ppm; ms (70 eV) *m/e* (relative intensity): 251.160 (24, M_r $^{12}C_{14}{}^1H_{21}{}^{14}N^{16}O_3$ = 251.152), 236 (100); ms (methane CI) *m/e* (relative intensity): 292 (3, *M* + 41), 281 (3), 280 (13, *M* + 29), 253 (17), 252 (100, *M* + 1), 251 (14).

Nitration of ***14*** *in [^2H]chloroform: 3,5-di-*tert*-butyl-2,6-dinitrophenol (**18**) and 3,5-di-*tert*-butyl-2,4-dinitrophenol (**19**)*

A solution of **14** (1.0 g, 4 mmol) in [^2H]chloroform (4 cm^3) at −40°C was added to nitric acid (252 mg, 4 mmol) at −40°C. After stirring for a few min at −40°C and 20 min at −30°C the solution was shown (^1H nmr) to contain both the dinitrodienone **17** (δ 1.26 (s, 9), 1.31 (s, 9), 6.46 (s, 1), and 6.50 (s, 1) ppm) and the dinitrophenol **18** (δ 1.37 (s, 18) and 7.30 (s, 1) ppm). On warming this nmr sample to ambient temperature and dissolving all of the material which precipitated by addition of acetone, the only compound present was **18**. The bulk reaction mixture, which had been maintained at −30°C, was poured into a solution of excess ammonia in methanol (30 cm^3) at −50°C. Hydrogen chloride was passed into the resulting solution, stirred at 0°C, until the solution was strongly acidic. Ammonium chloride was removed by filtration. The filtrate contained (^1H nmr, after evaporation) **18** and its 2,4-dinitro isomer **19** (δ 1.34 (s, 9), 1.42 (s, 9), 7.35 (s, 1) ppm) in a 60:40 ratio. This mixture was absorbed onto silica (3 g), then chromatographed on silica (20 g), eluting with ether–pentane (1:19). The first fraction (200 cm^3) contained only **18**, the second contained both **18** and **19**, and the third contained pure **19**. The dinitrophenol **18** was recrystallized from ether–pentane and had mp 196–197°C; ^1H nmr ($CDCl_3$) δ: 1.37 (s, 18, 3- and 5-C(CH_3)$_3$), 7.28 (s, 1, 4-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_C: 30.56 ($C(CH_3)_3$), 36.73 ($C(CH_3)_3$), 120.02 (*C*-4), 138.86 (*C*-2 and *C*-6), 142.72 (*C*-1), 145.11 (*C*-3 and *C*-5) ppm; ms (methane CI) *m/e* (relative intensity): 337 (5, *M* + 41), 326 (3), 325 (14, *M* + 29), 299 (2), 297 (100, *M* + 1), 296 (8). Dinitrophenol **19** had mp 175°C (dec.); ^1H nmr ($CDCl_3$/[$^2H_6$]acetone) δ: 1.33 (s, 9), 1.40 (s, 9), 7.36 (s, 1) ppm; ms (70 eV) *m/e* (relative intensity): 297 (16), 296.128 (100, M_r $^{12}C_{14}{}^1H_{20}{}^{14}N_2{}^{16}O_5$ = 296.137), 282 (15), 281 (98), 279 (18).

*Nitration of 3,5-di-*tert*-butylphenoxyacetic acid (**20**a) in acetic anhydride/[^2H]chloroform*

A solution of the acid **20***a* (1 mmol) in [^2H]chloroform (1 cm^3) was added dropwise over 5 min, with stirring, to a mixture of nitric acid (3 mmol) and acetic anhydride (1 cm^3) at −60°C. After a further 10 min at −60°C, a sample was transferred to an nmr tube at −78°C using a precooled pipette. The bulk of the reaction mixture was cooled to −78°C. The ^1H nmr spectra taken at −70°C and at −20°C showed only 3,5-di-*tert*-butyl-2-nitrophenoxyacetic acid (**23***a*); δ: 4.78 (s, CH_2), 6.92 (d, *J* = 2 Hz, 6-*H*), 7.18 (d, *J* = 2 Hz, 4-*H*) ppm. At +20°C an additional CH_2 group, attributed to the mixed anhydride of acetic acid and nitrophenoxyacetic acid, appeared at δ 4.98 ppm. There was no significant change in the aromatic region. After 5 min at +20°C there was 90% acid and 10% mixed anhydride. After 40 min at +40°C, 40% of the mixture was the mixed anhydride and the sample was poured into ether at −78°C. Ammonia gas was blown into the stirred solution until it was strongly alkaline. Water was added and the mixture was warmed to ambient temperature. The organic layer was separated and the aqueous layer was extracted with methylene chloride (2 × 25 cm^3). Drying and removal of the solvent from the combined organic extract gave reddish brown crystals of 3,5-di-*tert*-butyl-2-nitrophenoxyacetamide, ^1H nmr ($CDCl_3$) δ: 1.31 (s, 9, C(CH_3)$_3$), 1.37 (s, 9, C(CH_3)$_3$), 4.55 (s, 2, CH_2), 6.43 (br s, 2, NH_2), 6.88 (d, 1, *J* = 1.5 Hz, 6-*H*), 7.18 (d, 1, *J* = 1.5 Hz, 4-*H*) ppm. The aqueous layer was acidified (pH 1) with concentrated hydrochloric acid and extracted with ether (3 × 25 cm^3). Evaporation of the solvent from the dried ether solution gave the acid **23***a* as pale yellow crystals. Aqueous $NaHCO_3$ was added to the bulk of the reaction mixture at −78°C. It was allowed to warm to ambient temperature and enough solid $NaHCO_3$ to neutralize all the acid was added. After stirring for 3 h at ambient temperature, it was acidified (pH 1), extracted with ether (3 × 35 cm^3), and the ether solution was dried ($MgSO_4$). Removal of solvent gave the acid **23***a*.

Repetition of the nitration on a 2.2-mmol scale, at −60°C for 10 min followed by work-up, gave **23***a* (96%). After recrystallization from ether–pentane, **23***a* was obtained as pale yellow crystals, mp 187–188°C; ^1H nmr in $CDCl_3$ δ: 1.27 (s, 9, C(CH_3)$_3$), 1.35 (s, 9, C(CH_3)$_3$), 4.66 (s, 2, CH_2), 6.80 (d, 1, *J* = 2 Hz, 6-*H*), 7.17 (d, 1, *J* = 2 Hz), and 8.12 (br s, 1, CO_2H) ppm; ^{13}C nmr ($CDCl_3$) δ_C: 30.79 and 31.14 (3- and 5-C(CH_3)$_3$), 35.39 and 36.06 (3- and 5-$C(CH_3)_3$), 66.37 (CH_2), 109.16 (*C*-6), 118.49 (*C*-4), 139.97 (*C*-2), 141.59 (*C*-3), 149.03 (*C*-5), 153.62 (*C*-1), and 172.97 (CO_2H).

Nitration of ***23***a *in [^2H]chloroform*

A mixture of nitric acid (3 mmol) and acetic anhydride (1 cm^3) was cooled to −40°C and trifluoroacetic anhydride (423 mm^3, 3 mmol) was added with stirring. A solution of **23***a* (1 mmol) in [^2H]chloroform (1 cm^3) was added dropwise to the resulting mixture. Some precipitate was formed. After 10 min at −40°C, an nmr sample was removed using a precooled pipette and the bulk of the reaction mixture was cooled to −78°C. The reaction of the nmr sample at −40°C was followed by ^1H nmr. The results are qualitative because the sample was withdrawn from a heterogeneous mixture. After 20 min at −40°C, 48% of the starting material had reacted to give two new compounds, namely, 7,9-di-*tert*-butyl-6,10-dinitro-1,4-dioxaspiro[4,5]deca-6,8-dien-2-one (**24***a*, 31%) and 7,9-di-*tert*-butyl-6,8-dinitro-1,4-dioxaspiro[4,5]deca-6,9-dien-2-one (**25***a*, 17%). The sample was warmed to −30°C and, after 10 min, the reaction mixture had the composition 14% **23***a*, 56% **24***a*, and 30% **25***a*. After 20 min at −30°C, the reaction mixture was homogeneous and all the starting material had disappeared to give **24***a* (65%) and **25***a* (35%). No noticeable change took place on standing at −20°C for 15 min.

The above nmr sample was added to the bulk of the reaction mixture at −78°C and the mixture was sitrred at −30°C for 15 min and then at −20°C for 10 min. The mixture became homogenous after 3 min at −20°C. The ^1H nmr taken at −30°C, of a sample withdrawn from the reaction mixture after stirring for 10 min at −20°C, showed that all of the starting material had reacted to give **24***a* (67%) and **25***a* (33%). The mixture was poured with stirring into a mixture of excess $NaHCO_3$ solution and ice, in an ice bath, and stirred for 1 h. Extraction with ice-cold ether (3 × 20 cm^3), drying, and removal of the solvent at −20°C gave a pale yellow solid (320 mg). The ^1H nmr spectrum of the solid in $CDCl_3$ at 0°C showed only **24***a* (67%) and **25***a* (33%).

Nitration of ***20***a *in [^2H]chloroform – acetic anhydride – trifluoroacetic anhydride. Preparation of dienes* ***24***a *and* ***25***a

A preliminary small scale (1 mmol) nitration of **20***a* showed that the acid **23***a*, formed at −60°C, can be made to react further to give dienes **24***a* and **25***a*, thus eliminating the need for the preparation of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

mononitrophenoxyacetic acid.

Acid **20***a* (5 mmol) in $CDCl_3$ (5 cm^3) was added, dropwise with stirring (5 min), to a nitrating mixture, prepared from HNO_3 (20 mmol) and Ac_2O (5 cm^3), at −60°C. The mixture was stirred for a further 10 min at −60°C. The ^1H nmr (at −70°C) showed only the mononitrophenoxyacetic acid (**23***a*). The temperature of the reaction mixture was raised to −40°C and trifluoracetic anhydride (20 mmol, 2.8 cm^3) was added over 2 min and the mixture was stirred for 5 min at −40°C, 15 min at −30°C, and 10 min at −20°C. At −40°C a precipitate was formed that completely dissolved after 5 min at −20°C to give a clear yellow solution. The ^1H nmr of a sample at this stage showed only **24***a* (67%) and **25***a* (33%).

The reaction mixture was poured with stirring into excess saturated $NaHCO_3$–ice mixture at 0°C, cooled in an ice bath, and stirred for 1 h. The mixture was extracted with cold (0°C) ether (3 × 150 cm^3) and the extract was dried over $MgSO_4$. Removal of the solvent at −20°C gave a pale yellow solid (1.69 g) composed of **24***a* (68%) and **25***a* (32%). When the nmr sample was heated to 35°C for 10 min no change in the spectrum was noted.

Two recrystallizations of the crude product from ether–pentane gave pure **24***a* (474 mg), mp 149–150°C (dec.); uv (hexane): 274.8 (185) and 208.9 nm (274 m^2 mol^{-1}); ir (KBr): 1213 (C—O), 1360, 1522 (vinylic NO_2), 1558 (alkyl NO_2), and 1809 (C=O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.16 (s, 9, $C(CH_3)_3$), 1.21 (s, 9, $C(CH_3)_3$), 4.43 (d, 1, J = 14 Hz, 3-*H*), 4.51 (d, 1, J = 14 Hz, 3-*H*), 5.14 (s, 1, 10-*H*), 6.47 (s, 1, 8-*H*); ^{13}C nmr ($CDCl_3$, 0°C) δ_C: 27.88 and 28.09 (7- and 9-$C(CH_3)_3$), 36.41 and 36.67 (7- and 9-$C(CH_3)_3$), 64.51 (*C*-3), 85.22 (*C*-10), 104.81 (*C*-5), 124.04 (*C*-8), 136.94 (*C*-6), 142.17 (*C*-9), 143.08 (*C*-7), and 167.97 (*C*-2); ms *m/e*: 354.149 (M_r $^{12}C_{16}{}^1H_{22}{}^{14}N_2{}^{16}O_7$ = 354.143). *Anal.* calcd. for $C_{16}H_{22}N_2O_7$: C 54.23, H 6.25, N 7.90; found: C 54.26, H 6.20, N 7.80.

Part of the mother liquor containing **24***a* and **25***a* was subjected to preparative hplc on a semipreparative silica column using CH_2Cl_2 and hexane as eluents, and **25***a* (46 mg) was separated. Crystallization from ether–pentane gave colourless crystals of **25***a* (24 mg), mp 102–104°C (dec.); uv (hexane): 223 nm (312 m^2 mol^{-1}); ir (KBr): 1215 (C—O), 1370, 1532 (vinylic NO_2), 1568 (alkyl NO_2), 1820 (C=O) cm^{-1}; ^1H nmr ($CDCl_3$, 250 MHz) δ: 1.24 (s, 9, $C(CH_3)_3$), 1.27 (s, 9, $C(CH_3)_3$), 4.35 (d, 1, J = 15.1 Hz, 3-*H*), 4.45 (d, 1, J = 15.1 Hz, 3-*H*), 6.02 (s, 1, 8-*H* or 10-*H*), and 6.08 (s, 1, 10-*H* or 8-*H*) ppm; ^{13}C nmr ($CDCl_3$, 0°C) δ_C: 28.20 (9-$C(CH_3)_3$), 29.11 (7-$C(CH_3)_3$), 36.69 (9-$C(CH_3)_3$), 37.87 (7-$C(CH_3)_3$), 64.02 (*C*-3), 82.34 (*C*-8), 102.63 (*C*-5), 124.03 (*C*-6), 126.70 (*C*-10), 139.97 (*C*-9), 148.21 (*C*-7), 168.94 (*C*-2). *Anal.* calcd. for $C_{16}H_{22}N_2O_7$: C 54.23, H 6.25, N 7.90; found: C 53.68, H 6.21, N 7.78.

*Reaction of **24**a with aqueous sodium hydroxide in tetrahydrofuran*

Aqueous NaOH solution (2 cm^3, 0.2 mmol) was added dropwise (2 min) to a well-stirred solution of spirodiene **24***a* (35.4 mg, 0.1 mmol) in THF (1 cm^3), and stirring was continued for a further 30 min. As soon as the NaOH was added, the solution turned yellow. After the reaction, excess solid NH_4Cl was added to neutralize the excess NaOH. THF was removed on a rotavapor, saturated NaCl (5 cm^3) was added, and the mixture was extracted with ether (3 × 15 cm^3). The extract was dried ($MgSO_4$). Removal of the solvent gave 3,5-di-*tert*-butyl-2,6-dinitrophenoxyacetic acid as a light yellow solid (32 mg); ^1H nmr ($(CD_3)_2CO$) δ: 1.41 (s, 18, 3- and 5-$C(CH_3)_2$), 4.57 (s, 2, CH_2), 7.72 (s, 1, 4-*H*) ppm.

*Reaction of **25**a with aqueous sodium hydroxide in tetrahydrofuran*

Aqueous NaOH solution (1 cm^3, 0.1 mmol) was added (1 min) with stirring to a solution of diene **25***a* (17.7 mg, 0.05 mmol) in THF (0.5 cm^3). The solution turned yellow. The solution was stirred a further 30 min and worked up as described in the previous reaction to give 3,5-di-*tert*-butyl-2,4-dinitrophenol (**19**) (12 mg); ^1H nmr ($CDCl_3$) δ: 1.35 (s, 9, 5-$C(CH_3)_3$), 1.44 (s, 9, 3-$C(CH_3)_3$), 7.15 (s, 1, 6-*H*) ppm. The dinitrophenol **19** obtained from **25***a* is identical to the one obtained earlier in the nitration of **14**, after the nitration mixture had been reacted with ammonia in methanol.

*Nitration of α-(3,5-di-*tert*-butylphenoxy)isobutyric acid (**20**b) in acetic anhydride*

A solution of **20***b* (1.46 g, 5 mmol) in acetic anhydride (3 cm^3) at −60°C was added to a nitrating mixture prepared from nitric acid (0.95 g, 15 mmol) and acetic anhydride (1.72 cm^3), also at −60°C. The ^1H nmr spectrum taken a few minutes after mixing, 6.97 (br s, 1) and 7.29 (br s, 1) ppm, showed no change on warming the sample to ambient temperature. The reaction mixture was poured into a mixture of 30% aqueous ammonia (15 cm^3) and ether (50 cm^3) at 0°C. The ether layer was separated and dried and the ether evaporated to an oil which on crystallization from ether–pentane gave colourless crystals of α-(3,5-di-*tert*-butyl-2-nitrophenoxy)isobutyramide (325 mg), mp 146–148°C; ^1H nmr ($CDCl_3$) δ: 1.28 (s, 9, $C(CH_3)_3$), 1.36 (s, 9, $C(CH_3)_3$), 1.54 (s, 6, $(CH_3)_2$), 6.00 (br s, 1, NH_2), 6.54 (br s, 1, NH_2), 6.98 (d, 1, J = 2 Hz, 6-*H*), 7.21 (d, 1, J = 2 Hz, 4-*H*) ppm; ms (methane CI) *m/e* (relative intensity): 377 (8, M + 41), 365 (24, M + 29), 337 (100, M + 1).

*Nitration of **20**b in trifluoroacetic anhydride/[^2H]chloroform*

A solution of **20***b* (1.46 g, 5 mmol) in [^2H]chloroform (4 cm^3) at −60°C was added to a mixture of nitric acid (473 mg, 7.5 mmol) in trifluoroacetic anhydride at −60°C. The ^1H nmr spectrum indicated the formation of α-(3,5-di-*tert*-butyl-2-nitrophenoxy)isobutyric acid (**23***b*, δ 6.87 (s, 1) and 7.25 (s, 1) ppm) and 7,9-di-*tert*-butyl-3,3-dimethyl6,10-dinitro-1,4-dioxaspiro[4,5]deca-6,8-dien-2-one (**24***b*, δ 5.17 (s, 1) and 6.50 (s, 1) ppm). The ratio of **24***b* to **23***b* increased with time. Evaporation of the solvent from the reaction mixture gave an oil which was dissolved in ether and washed with aqueous sodium bicarbonate. The ether layer was separated, dried, and evaporated and the residue recrystallized from chloroform–pentane to give **24***b*, mp 154–158°C (dec.); uv (MeOH) λ_{max} (ε): 215 (645), 274 (524 m^2 mol^{-1}) nm; ^1H nmr ($CDCl_3$) δ: 1.15 (s, 9, $C(CH_3)_3$), 1.27 (s, 9, $C(CH_3)_3$), 1.44 (s, 3, 3-CH_3), 1.64 (s, 3, 3-CH_3), 5.16 (s, 1, 10-*H*), 6.44 (s, 1, 8-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_C: 24.63 (3-CH_3), 25.78 (3-CH_3), 27.95 (7- and 9-$C(CH_3)_3$), 36.31 ($C(CH_3)_3$), 36.44 ($C(CH_3)_3$), 79.32 (*C*-3), 86.56 (*C*-10), 102.03 (*C*-5), 123.88 (*C*-8), 137.70 (*C*-6), 141.58 and 141.64 (*C*-7 and *C*-9), 172.55 (*C*-2) ppm; ms (methane CI) *m/e* (relative intensity): 411 (5, M + 29), 383 (3, M + 1), 377 (5), 366 (3), 365 (9), 337 (85), 319 (4), 318 (3), 306 (3), 291 (5), 290 (5), 280 (17), 252 (100). The ^1H nmr of the crude nitration product showed that a second diene, presumably **25***b*, was formed in the ratio **24***b*/**25***b* = 85:15. This diene was not isolated but, from the mixture, it had ^1H nmr ($CDCl_3$) δ: 1.23 (s, 9, $C(CH_3)_3$), 1.27 (s, 9, $C(CH_3)_3$), 1.43 (s, 3, CH_3), 1.60 (s, 3, CH_3), 6.10 (s, 1, 4-*H* or 6-*H*), 6.18 (s, 1, 6-*H* or 4-*H*) ppm. The structural assignment is supported by the close similarity of the ^1H nmr spectra for corresponding hydrogen atoms of **25***a* and **25***b*. The interfacial layer from the sodium bicarbonate extraction was partitioned between ether and aqueous acid. The resulting ethereal solution was dried and the ether evaporated to give a mixture of crystals and oil from which the oil was removed by washing with pentane to give the acid **23***b*, mp 130–145°C (dec.); ^1H nmr ($CDCl_3$) δ: 1.27 (s, 9, $C(CH_3)_3$), 1.36 (s, 9, $C(CH_3)_3$), 1.58 (s, 6, $C(CH_3)_2$), 6.95 (d, 1, J = 2 Hz, 6-*H*), 7.19 (d, 1, J = 2 Hz, 4-*H*), 10.70 (br s, 1, COO*H*) ppm; ^{13}C nmr (CD_3OD) δ_C: 25.22 ($C(CH_3)_2$), 31.20 and 31.43 ($C(CH_3)_3$), 36.09 and 36.81 ($C(CH_3)_3$), 81.83 ($C(CH_3)_2$), 115.38 (*C*-6), 119.14 (*C*-4), 142.01 (*C*-3), 143.44 (*C*-2), 148.41 (*C*-5), 153.97 (*C*-1), 177.17 (*C*OOH) ppm; ms (methane CI) *m/e* (relative intensity): 378 (2, M + 41), 367 (4), 366 (16, M + 29), 339 (5), 338 (26, M + 1), 337 (8), 336 (4), 332 (3), 322 (6), 294 (3), 293 (22), 292 (100), 290 (7).

*Reaction of **24**b with base*

The dinitrodiene **24***b* did not rearomatize on heating under reflux in chloroform for 24 h. It also did not react to any significant extent when treated with aqueous sodium bicarbonate.

Excess ammonia was condensed into a solution of **24***b* (1.65 g) in ether (150 cm^3) at −60°C. The mixture was warmed to ambient temperature, water (100 cm^3) was added, and the mixture was then acidified by the dropwise addition of concentrated HCl. The ether layer was separated, dried, and the ether evaporated. Recrystallization

of the residue (1.31 g, 80%) from acetone–pentane gave α-(3,5-di-*tert*-butyl-2,6-dinitrophenoxy)isobutyric acid, mp 196°C (dec.); ^{1}H nmr ($(CD_3)_2CO$) δ: 1.38 (s, 18, 3- and 5-C(CH_3)$_3$), 1.48 (s, 6, (CH_3)$_2$), 7.69 (s, 1, 4-*H*) ppm; ^{13}C nmr ($(CD_3)_2CO$)/CD_3OD) δ_C: 24.94 (C(CH_3)$_2$), 30.91 (C(CH_3)$_3$), 37.41 (C(CH_3)$_3$), 87.43 (C(CH_3)$_2$), 125.58 (*C*-4), 141.92 (*C*-2 and *C*-6), 143.58 (*C*-3 and *C*-5), 146.28 (*C*-1), 175.42 (*C*OOH) ppm; ms (methane CI) *m/e* (relative intensity): 411 (11, M + 29), 383 (15, M + 1); ms (70 eV) *m/e* (relative intensity): 382.181 (1, M_r $^{12}C_{18}{}^1H_{26}{}^{14}N_2{}^{16}O_7$ = 382.174), 364.171 (1, M_r $^{12}C_{18}{}^1H_{24}{}^{14}N_2{}^{16}O_6$ = 364.163) 337 (3), 297 (5), 296 (20), 282 (4), 281 (27), 280 (3), 279 (4), 220 (3). Titration of this solid with aqueous NaOH indicated that 97.4 ± 2% of the material was the acid.

The chemistry of thujone. XI.[1] Thujone as a chiral synthon for the preparation of sesquiterpene lactones. Synthesis of (*l*)-α-santonin

JAMES P. KUTNEY AND ASHOK K. SINGH

Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6

Received April 17, 1984

JAMES P. KUTNEY and ASHOK K. SINGH. Can. J. Chem. **62**, 2813 (1984).

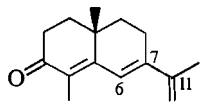
An efficient synthesis of (*l*)-α-santonin is described. The thujone-derived trienone **1**, bearing only one chiral center, is transformed, via a controlled hydroboration process, to the isomeric triols **7** and **9** in which four new chiral centers (C-3, C-6, C-7, and C-11) are established in one step and with the correct absolute configuration. An oxidative cyclization process converts **7** and **9** into 1,2-dihydro-6α-santonin (**3**), with the latter being transformed directly to the natural product employing DDQ as a dehydrogenating agent. The overall strategy reveals an attractive synthetic entry into the family of natural sesquiterpene lactones.

JAMES P. KUTNEY et ASHOK K. SINGH. Can. J. Chem. **62**, 2813 (1984).

On décrit une synthèse efficace de la (*l*)-α-santonine. Faisant appel à une réaction d'hydroboration contrôlée, la triénone **1**, qui est dérivée de la thujone et qui ne porte qu'un centre chiral, a été transformée en triols isomères **7** et **9** dans lesquels quatre nouveaux centres chiraux (C-3, C-6, C-7 et C-11) ont été établis en une seule étape et avec la bonne configuration absolue. Une cyclisation oxydante transforme les triols **7** et **9** en dihydro-1,2 6α-santonine (**3**) qui conduit directement au produit naturel si on fait appel à la DDQ comme agent de déshydrogénation. Il appert que cette stratégie globale représente une voie d'accès attrayante à la famille des lactones sesquiterpéniques naturelles.

[Traduit par le journal]

Our previous publications in this series (1–4) have indicated that thujone[2] can serve as an effective chiral synthon for the syntheses of various sesquiterpenes. We wish now to present our results relating to the synthesis of chiral sesquiterpene lactones from the thujone-derived trienone (**1**). In this study it is to be noted that three new chiral centers are readily introduced at C-6, C-7, and C-11 in **1** through a hydroboration–oxidative cyclization process.



1

In developing the synthetic strategy for a versatile and efficient route to chiral sesquiterpene lactones, we considered electrophilic addition to the 6,7-double bond in **1**, a reaction which was expected to proceed from the α-face of the molecule in accord with previous findings (2). Success in this direction would therefore afford the desired absolute stereochemistry at C-6 and C-7 as known in the family of naturally occurring sesquiterpene lactones. For this purpose hydroboration of **1** seemed like an attractive alternative and we initiated our experiments with diborane under varying conditions.

Reaction of diborane with **1** can obviously occur at the three olefinic centres and the carbonyl group under varying reaction rates. In order to ascertain the course of this process and, in turn, develop the optimum reaction conditions for the required intermediates, for example, **6** (Scheme 1), we have first developed the chemistry of santonin (Scheme 1) so as to derive standard comparison samples for the hydroboration study.

The natural product, α-santonin **2**, upon hydrogenation in ethanol–benzene over Wilkinson's catalyst (5) afforded the 1,2-dihydro-6α-santonin **3** (92%). Of particular relevance to the subsequent discussion, and relating to diborane addition to **1**, are the nmr data representing the three important chiral centers (C-6, C-7, and C-11). Thus the C-6 proton (δ 4.68, dd, J = 2 and 12 Hz) is coupled to C-7 and, through long range coupling, with the vinyl methyl group at C-4 (δ 2.01, d, J = 2 Hz). The C-6 – C-7 coupling constant of 12 Hz clearly reveals the expected *trans* relationship of these two protons and this analysis was confirmed when irradiation at the C-14 methyl group resonance caused the C-6 signal to collapse into a doublet (J = 12 Hz). The C-11 proton appears as a sextet (δ 2.35, J = 6 and 12 Hz), thus indicating coupling with the proton at C-7 and the C-13 methyl group (δ 1.28, d, J = 6 Hz). Irradiation at the latter group frequency causes the sextet to collapse into a doublet (J = 12 Hz), thereby confirming the *trans* relationship of the C-7 and C-11 protons. Irradiation at the C-11 proton frequency causes the C-13 methyl signal to collapse into a singlet. This detailed nmr evaluation allows subsequent unambiguous assignments to the chiral centers in the intermediates **4**–**9** (Scheme 1) and **10** (Scheme 2).

Compound **3** reacted smoothly with ethanedithiol, *p*-toluenesulphonic acid in benzene, giving **4** in 89% yield.

Treatment of **4** with lithium aluminum hydride (LAH) in boiling ether afforded the desired hydroxy thioketal **5** in 91% yield. The β-axial configuration of the C-6 proton in **5** was deduced from the 400-MHz nmr spectrum which showed a signal at δ 4.38 (1H, dd, J = 12, 2 Hz).

Hydrolysis of **5** with $HgCl_2$ and $CdCO_3$ in aqueous acetone gave hydroxyketone **6** in 16% yield. It should be noted that optimum conditions for this reaction were not pursued since **6**, as derived from natural santonin, was merely a standard comparison sample for future studies with **1**.

Dihydrosantonin **3**, when refluxed with a suspension of LAH in ether, afforded, as a major product, the triol **7** in 75% yield and a minor product, the triol **9** in 15% yield. The α-axial configuration of the C-3 hydroxyl group in **7** was confirmed from the 400-MHz nmr spectrum which showed the C-3 proton signal at δ 3.93 (1H, t, J = 6 Hz).

With the above compounds in hand, it was now appropriate

[1]For Part X, see ref. 4.

[2]Thujone is the major component (ca. 80%) of the steam distillate from the slash (waste) of Western red cedar.

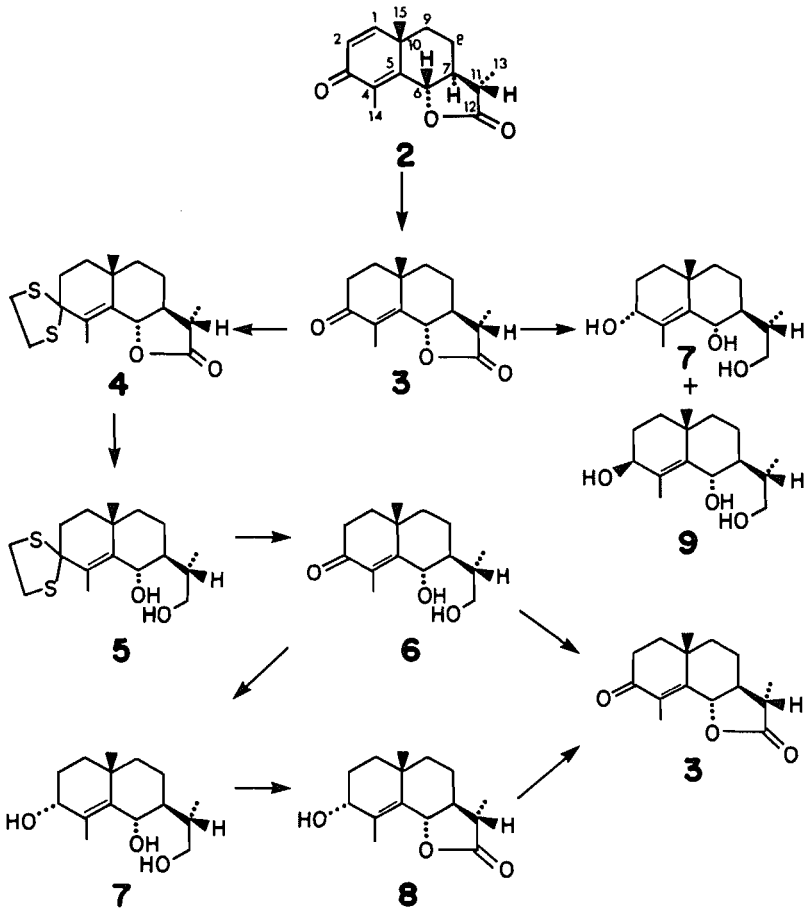

SCHEME 1

to study the elaboration of the thujone-derived intermediate **1** to sesquiterpene lactones. Hydroboration of **1** proceeded stepwise, the carbonyl being the first group attacked. Interruption of the reaction after short periods yielded mostly the hydroxy triene **10**. After a longer reaction time (5 h), two products **10** (36%) and **11** (50%) were obtained. Upon increase of reaction time (20 h), three products **10** (27%), **11** (39%), and **7** (10%) were obtained. Thus, it appears that there is a large increase in reactivity of the terminal double bond (C11—C12) and little effect on the internal double bond (C6—C7) following the hydroboration of the carbonyl group. A substantial increase in the initial amount of borane added revealed that highly reproducible results were obtained. Thus with 40 equivalents of diborane, a 62% yield of isomeric triols **7** and **9** was realized without the complicating presence of **10** and **11**. A general summary of these results is provided in Table 1.

Although the hydroxy compounds **10** and **11** are relatively unstable it was possible, nevertheless, to obtain data for complete structural assignments. The nmr spectra of **10** and **11** showed a triplet (J = 6 Hz) at δ 4.10 and 4.12 respectively. This is indicative of an equatorial proton at C-3. The nmr spectra of the products **7** and **9**, obtained from the borane reaction, were identical with those obtained from santonin.

Oxidation of a mixture of triols **7** and **9** with silver carbonate on Celite yielded a mixture of hydroxy-lactone and keto lactone **3**. The latter, without further separation, was subjected to CrO_3/pyridine oxidation to afford 1,2-dihydro-6α-santonin **3**. The physical properties were identical with **3** obtained from santonin. In summary, the overall yield in the sequence, **7**, **9**→**3** is 68% when isolation of intermediates is omitted.

TABLE 1. Summary of results obtained from hydroboration of trienone **1**

Amount of trienone (mg)	Time (h)	Amount of BH_3–THF (equivalents)	Products (%)		
			10	**11**	**7** and **9**
100	5	5	36	50	—
100	20	5	27	39	10
100	20	15	20	36	11
100	48	25	—	40	34
100	20	25	—	—	42
100	18	30	—	—	56
100	12	40	—	—	62

Oxidation of **3** with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) in benzene, under reflux for 64 h, afforded (*l*)-α-santonin in 84% yield, based on recovered starting material. The synthetic (*l*)-α-santonin was identical with natural (*l*)-α-santonin in all respects.

In order to substantiate the arguments made earlier from nmr studies of **3**, as they relate particularly to the stereochemistry at C-7, a detailed nmr study on santonin (**2**) was also made. In this instance the spectrum is better resolved in the region of relevance. Thus the C-7 proton appears as an octet (δ 1.82, dddd, J = 4 and 12 Hz), thereby indicating a coupling with the protons at C-6, C-11, and C-8. Irradiation at the C-7 proton resonance caused the C-6 signal to collapse into a singlet, the C-11 signal into a quartet (J = 6 Hz), the C-8 axial proton

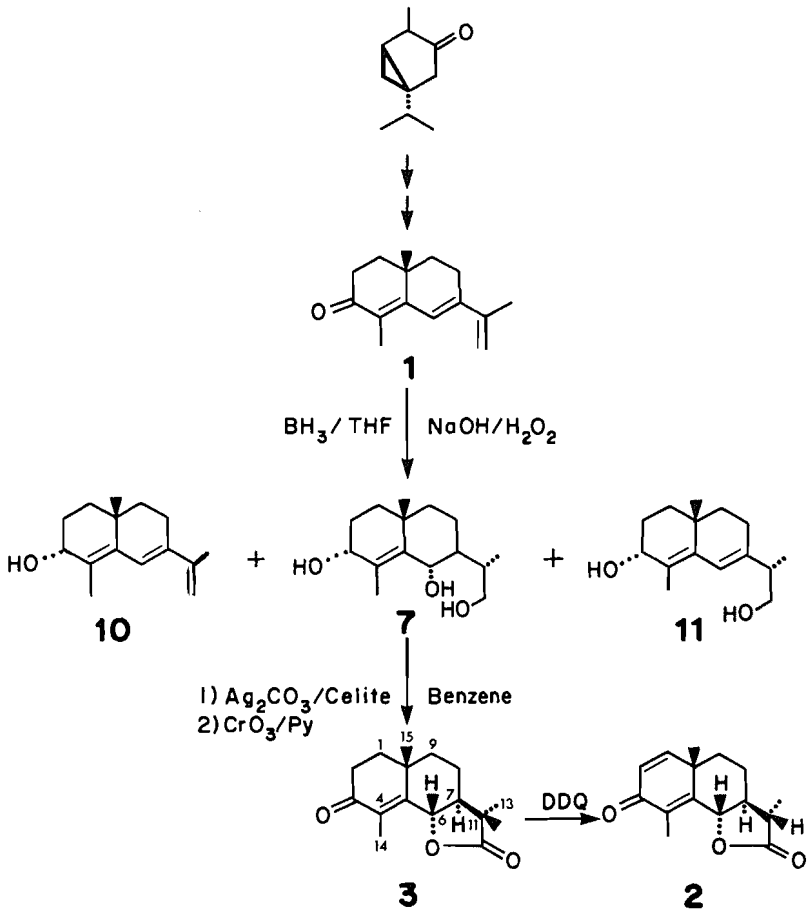

SCHEME 2

signal into a sextet (J = 4 and 12 Hz), and the C-8 equatorial proton signal into a sextet (J = 4 and 12 Hz). Hence it is clear that the C-7 proton is *trans* to protons at C-6 and C-11. The data for C-6 and C-11 are identical with those discussed earlier for **3**.

In conclusion, trienone **1**, with only one chiral center, is transformed efficiently via the hydroboration approach into the triols **7** and **9**, bearing four chiral centers of correct absolute stereochemistry, for efficient syntheses of optically active sesquiterpene lactones. This procedure affords the best overall approach to the synthesis of these natural products. Further studies with such intermediates are underway.

Experimental

Melting points were determined on a Büchi melting point apparatus and are uncorrected. Ultraviolet spectra were recorded on a Cary 15 spectrophotometer in methanol solution. Infrared spectra were measured on a Perkin–Elmer-710 spectrophotometer using chloroform as solvent. The ^{1}Hmr spectra were recorded on Bruker WH-400, Bruker WP-80, Varian XL-100, or Nicolet–Oxford H-270 instruments. Deuteriochloroform was used as the solvent with TMS as internal standard. Low resolution mass spectra were determined on either an AEI-MS-902 or an Atlas-CH-4B spectrometer. High resolution mass measurements were made on an AEI-MS-50 spectrometer. Optical rotations were recorded on a Perkin–Elmer 141 polarimeter using a cell with a path length of 10 cm. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia. Column chromatography utilized Merck silica gel 60 (70–230 mesh). Preparative and thin layer chromatography utilized Merck silica gel GF_{254}. Petroleum ether refers to the fraction with boiling range 30–60°C.

1,2-Dihydro-6α-santonin 3

A modified procedure of Sims *et al.* (6) was used for the preparation of **3**. To a solution of (*l*)-α-santonin **2** (1 g) in benzene–ethanol (220 mL, 1:1 v/v) was added tris(triphenylphosphine)rhodium(I)chloride (1.0157 g). The mixture was flushed with hydrogen and stirred under hydrogen for 24 h. The solvents were evaporated and the residue chromatographed on silica gel (70 g), eluted with ethyl acetate – petroleum ether (1:4, v/v) to give 1,2-dihyro-6α-santonin **3** (0.930 g, 92%). The latter was recrystallized from petroleum ether – carbon tetrachloride, mp 98–99°C (lit. (7) mp 101–102°C); $[\alpha]_D$ +71.29° (*c* 0.519, EtOH) (lit. (7) $[\alpha]_D$ +79° (*c* 1.42, $CHCl_3$)); ir ν_{max}: 1780, 1670, 1625 cm^{-1}; uv λ_{max}: 244 (ε 15 113) nm (lit. (7) λ_{max}: 244 (ε 14 700) nm); ^{1}Hmr δ: 1.28 (3H, d, J = 6 Hz), 1.34 (3H, s), 1.50–2.00 (7H, m), 2.01 (3H, d, J = 2 Hz), 2.35 (1H, sextet, J = 12, 6 Hz), 2.44 (1H, dt, J = 16, 4 Hz), 2.53 (1H, ddd, J = 16, 4 Hz), 4.68 (1H, dd, J = 12, 2 Hz), ms *m/e*: 248 (M^+), 233, 220, 205, 192. High resolution molecular weight determination, calcd. for $C_{15}H_{20}O_3$: 248.1412; found: 248.1413. *Anal.* calcd. for $C_{15}H_{20}O_3$: C 72.58, H 8.06; found: 72.10, H 8.01.

Thioketal lactone 4

The Ourisson (8) modified procedure was used in the preparation of **4**. A solution of 1,2-dihydro-6α-santonin **3** (500 mg) in anhydrous benzene (45 mL), ethanedithiol (1.5 mL), and *p*-toluenesulphonic acid (40 mg) was heated at reflux under nitrogen for 3 h. The cooled solution was diluted with water (50 mL) and extracted with chloroform (50 mL). The organic layer was washed with a saturated solution of sodium bicarbonate (50 mL), water (50 mL), saturated brine (50 mL), and dried ($MgSO_4$). Evaporation of the solvent left crystalline thioketal lactone **4** (579 mg, 89%). The analytical sample was obtained by recrystallization from ether – petroleum ether, mp 167–168°C (lit. (8) mp 166–168°C); $[\alpha]_D$ +41° (*c* 0.4098, $CHCl_3$); ir ν_{max}: 1766 cm^{-1}; ^{1}Hmr δ: 1.17 (3H, s), 1.23 (3H, d, J = 6 Hz), 1.35–1.93 (7H,

m), 2.11 (3H, d, J = 2 Hz), 2.18–2.31 (3H, m), 3.24 (1H, m), 3.31–3.42 (3H, m), 4.56 (1H, dd, J = 12, 2 Hz); ms m/e: 324 (M^+), 309, 296, 264. High resolution molecular weight determination, calcd. for $C_{17}H_{24}O_2S_2$: 324.1218; found: 324.1218. *Anal.* calcd. for $C_{17}H_{24}O_2S_2$: C 62.96, H 7.41, O 9.88; found: C 62.84, H 7.36, O 9.70.

Hydroxy thioketal **5**

To a suspension of lithium aluminum hydride (300 mg) in anhydrous ether (50 mL) was added a solution of thioketal lactone **4** (500 mg) in ether (25 mL). The mixture was refluxed for 1 h under nitrogen, then excess hydride was destroyed by the careful addition of cold water and extracted with ethyl acetate (2 × 75 mL). The organic extracts were dried ($MgSO_4$) and evaporated to afford hydroxy thioketal **5** (458 mg, 91%), which was recrystallized with ether – petroleum ether, mp 159–160°C; $[\alpha]_D$ +65.49° (c 0.284, $CHCl_3$); ir ν_{max}: 3250 cm^{-1}; ^{1}Hmr δ: 0.95 (3H, d, J = 6 Hz), 1.12 (3H, s), 1.25 (1H, m), 1.40–1.59 (5H, m), 1.69 (1H, m), 1.78–1.93 (3H, m, including 1.88 (2H, bs, D_2O exchangeable)), 2.08 (1H, m), 2.18–2.24 (4H, m, including 2.19 (3H, d, J = 2 Hz)), 3.25 (1H, m), 3.33–3.43 (3H, m), 3.54 (1H, dd, J = 12, 6 Hz), 3.65 (1H, dd, J = 12, 6 Hz), 4.38 (1H, dd, J = 12, 2 Hz); ms m/e: 328 (M^+), 310, 295, 268, 251, 236. High resolution molecular weight determination, calcd. for $C_{17}H_{28}O_2S_2$: 328.1531; found: 328.1535. *Anal.* calcd. for $C_{17}H_{28}O_2S_2$: C 62.19, H 8.54, O 9.76; found: C 62.00, H 8.27, O 9.56.

Hydroxyketone **6**

A solution of the hydroxy thioketal **5** (208.6 mg) in aqueous 95% acetone (20 mL) was added to an efficiently stirring solution of mercuric chloride (250 mg) and cadmium carbonate (250 mg) in the same solvent mixture (10 mL). The mixture was stirred for 26 h at ambient temperature and filtered through a sintered funnel. The filter cake was washed with CH_2Cl_2 – petroleum ether (50 mL, 1:1 v/v) and the organic solution evaporated to dryness. The residue was diluted with CH_2Cl_2 (75 mL) and washed successively with 5 M aqueous ammonium acetate (20 mL), water (25 mL), brine (25 mL), and dried ($MgSO_4$). The crude residue, after evaporation of the solvent *in vacuo*, was chromatographed on silica gel (4 g). Elution with ethyl acetate – petroleum ether (1:1, v/v) afforded hydroxyketone **6** (25 mg, 16%), which was recrystallized from ethyl acetate – petroleum ether, mp 142–143°C; $[\alpha]_D$ +92.11° (c 0.5103, $CHCl_3$); ir ν_{max}: 3400, 1600 cm^{-1}; uv λ_{max}: 252 (ε 12 618) nm; ^{1}Hmr δ: 1.02 (3H, d, J = 6 Hz), 1.26 (3H, s), 1.36–1.78 (6H, m), 1.70–2.02 (4H, m, including 1.94 (2H, bs, D_2O exchangeable)), 2.10 (3H, d, J = 2 Hz), 2.39–2.64 (2H, m), 3.60 (1H, dd, J = 12, 6 Hz), 3.75 (1H, dd, J = 12, 6 Hz), 4.54 (1H, dd, J = 10, 2 Hz); ms m/e: 252 (M^+), 234, 221, 219, 193. High resolution molecular weight determination, calcd. for $C_{15}H_{24}O_3$: 252.1725; found: 252.1724. *Anal.* calcd. for $C_{15}H_{24}O_3$: C 71.43, H 9.52, O 19.05; found: C 71.41, H 9.60, O 19.10.

Triols **7** *and* **9**

A solution of 1,2-dihydro-6α-santonin **3** (291 mg) in anhydrous ether (25 mL) was added to a suspension of lithium aluminum hydride (291 mg) in ether (50 mL) and the mixture refluxed for 2 h under nitrogen. It was cooled, excess LAH decomposed with cold water, extracted with ethyl acetate (150 mL), dried ($MgSO_4$), and concentrated *in vacuo*. The crude material was chromatographed on silica gel (20 g), and eluted with methanol – ethyl acetate (0.1:9.9, v/v) to give the less polar product **7** (0.229 g, 77%), mp 125–126°C; $[\alpha]_D$ −14.11° (c 0.5245, EtOH); ir ν_{max}: 3425 cm^{-1}; ^{1}Hmr δ: 0.93 (3H, d, J = 6 Hz), 1.10 (3H, s), 1.19–1.59 (7H, m), 1.63–1.78 (2H, m), 1.81–1.96 (2H, m), 2.02 (3H, s), 2.22–2.55 (2H, bs, D_2O exchangeable), 3.51 (1H, dd, J = 12, 6 Hz), 3.63 (1H, dd, J = 12, 6 Hz), 3.93 (1H, t, J = 6 Hz), 4.37 (1H, d, J = 10 Hz); ms m/e: 254 (M^+), 239, 236, 177. High resolution molecular weight determination, calcd. for $C_{15}H_{26}O_3$: 254.1882; found: 254.1886. *Anal.* calcd. for $C_{15}H_{26}O_3$: C 70.87, H 10.24; found: C 71.05, H 10.23. The more polar product was **9** (0.0458 g, 15%), mp 165–166°C; $[a]_D$ +61.83° (c 0.4205, EtOH); ir ν_{max} (Nujol): 3375 cm^{-1}; ^{1}Hmr (DMSO) δ: 0.85 (3H, d, J = 6 Hz), 0.97 (3H, s), 1.08–1.20 (2H, m), 1.28–1.36 (2H, m), 1.38–1.63 (5H, m), 1.97 (3H, s), 2.17 (1H, m), 3.23–3.30 (2H, m), 3.57 (1H, m, $\frac{1}{2}w$ = 12 Hz), 4.13 (1H, dd, J = 12, 4 Hz), 4.27 (1H, m, D_2O exchangeable), 4.36 (1H, m, D_2O exchangeable), 4.44 (1H, m, D_2O exchangeable); ms m/e: 254 (M^+), 236, 221, 218, 205. High resolution molecular weight determination, calcd. for $C_{15}H_{26}O_3-H_2O$: 236.1776; found: 236.1785. *Anal.* calcd. for $C_{15}H_{26}O_3$: C 70.87, H 10.24; found: C 70.58, H 10.28.

Hydroxy triene ***10*** *and hydroxy diene* ***11***

An aliquot of diborane (9.3 mL) (1 M BH_3 in tetrahydrofuran solution), was added to a stirring, ice-cold solution of triene **1** (400 mg) in THF (2 mL) kept under argon. The cooling bath was removed and the solution stirred at room temperature for 5 h. The reaction flask was cooled in an ice bath and excess diborane was destroyed by a careful addition of water (0.3 mL), followed immediately by 3 N NaOH solution (9.3 mL) and 30% aqueous hydrogen peroxide (9.3 mL). After stirring for 1 h at room temperature the mixture was saturated with NaCl and extracted with ethyl acetate (100 mL). The organic layer was washed with saturated brine (50 mL), dried ($MgSO_4$), and evaporated. The residual viscous oil was chromatographed over silica gel (30 g) and eluted with a mixture of ether and petroleum ether (4:6, v/v) to provide pure hydroxy triene **10** (144.9 mg, 36%) and hydroxy diene **11** (218.2 mg, 50%) as viscous oils. The physical properties are as follows: **10**: ir ν_{max}: 3338, 1646, 1616, 1590 cm^{-1}; ^{1}Hmr δ: 1.02 (3H, s), 1.10–1.70 (7H, m), 1.80 (3H, s), 1.97 (3H, s), 2.05–2.40 (2H, m), 4.10 (1H, t, J = 6 Hz), 4.90 (1H, s), 5.05 (1H, s), 6.42 (1H, s); ms m/e: 218 (M^+), 203; **11**: ir ν_{max}: 3288, 1640, 1616 cm^{-1}; ^{1}Hmr δ: 1.00 (3H, s), 1.02 (3H, d, J = 6 Hz), 1.22–1.62 (8H, m), 1.80 (3H, s), 1.94–2.52 (3H, m), 3.42–3.62 (2H, m), 4.12 (1H, t, J = 6 Hz), 6.20 (1H, s); ms m/e: 236 (M^+), 221, 218, 205, 187, 177. High resolution molecular weight determination, calcd. for $C_{15}H_{24}O_2$: 236.1776; found: 236.1783.

(l)-α-*Santonin* **2**

A solution of **1** (100 mg) in THF (2 mL) was hydroborated with an aliquot of diborane (18.5 mL) (1 M diborane in THF) at 0°C by dropwise addition of the diborane solution. The reaction mixture was stirred for 12 h at room temperature, cooled, and then treated with water (0.6 mL), 3 N NaOH solution (18.5 mL), and 30% H_2O_2 (18.5 mL). Work-up as above provided the crude product, which was then chromatographed over silica gel (20 g). Elution with methanol – ethyl acetate (0.1:9.9, v/v) gave an analytical sample of triol **7** (58 mg, 49%) and triol **9** (15 mg, 13%). The ir, ms, and ^{1}Hmr spectra of these products were identical with those obtained from naturally occurring santonin **2** as shown in Scheme 1.

To a round bottomed flask equipped with a magnetic stirring bar, a Dean–Stark trap, and a condenser, was added a mixture of triols **7** and **9** (100 mg), silver carbonate on Celite (3.4 g), and benzene (30 mL). The resulting mixture was refluxed for 3 h, cooled to ambient temperature, and filtered. The solvent was removed to provide a mixture of hydroxy-lactone and keto lactone (100 mg) as a viscous material. The latter was used for the subsequent reaction without further separation.

Chromic anhydride (225 mg) was added into pyridine (3 mL) and stirred for 10 min. The above crude mixture dissolved in pyridine (2 mL) was added, and the mixture was stirred at room temperature for 1 h. The reaction mixture was diluted with water (15 mL), extracted with ether (3 × 50 mL), dried ($MgSO_4$), and evaporated. The residue was chromatographed on silica gel (20 g) with ethyl acetate – petroleum ether (1:4, v/v) as eluting solvent to afford 1,2-dihydro-6α-santonin **3** (66 mg, 68%) as a crystalline solid. An analytical sample was obtained by recrystallization from CCl_4 – petroleum ether, mp 98–99°C. This material was identical by ^{1}Hmr, ir, and optical rotation with **3** prepared from (*l*)-α-santonin **2** (Scheme 1).

To a solution of **3** (32 mg) in dry benzene (10 mL), was added DDQ (87.8 mg) and the mixture was refluxed for 64 h under argon. The reaction mixture was cooled, filtered, and the solvent was removed under reduced pressure. Column chromatography of the residue on silica gel (10 g) with ethyl acetate – petroleum ether (1:4, v/v) as eluting solvent afforded (*l*)-α-santonin **2** (14.1 mg, 44%) and starting

material **3** (15 mg, 47%). Recrystallization from ethyl acetate – petroleum ether yielded material of analytical purity, mp 172–173°C (lit. (9) mp 170–173°C; $[\alpha]_D$ −172.8° (*c* 0.5535, EtOH) (lit. (9) $[\alpha]_D$ −172° (EtOH)); ir ν_{max}: 1886, 1666, 1641, 1616 cm^{-1}; uv λ_{max}: 240 (ε 13 000), 260 (8700) nm (lit. (10) λ_{max}: 240 (ε 13 182), 260 (8511) nm); ^{1}Hmr δ: 1.28 (3H, d, J = 6 Hz), 1.34 (3H, s), 1.52 (1H, dddd, J = 12, 4 Hz), 1.70 (1H, ddd, J = 12, 4 Hz), 1.82 (1H, dddd, J = 12, 4 Hz), 1.91 (1H, dddd, J = 12, 4 Hz), 2.03 (1H, ddd, J = 12, 4 Hz), 2.14 (3H, d, J = 2 Hz), 2.42 (1H, sextet, J = 12, 6 Hz), 4.80 (1H, dd, J = 12, 2 Hz), 6.25 (1H, d, J = 10 Hz), 6.70 (1H, d, J = 10 Hz); ms *m/e*: 246 (M^+), 231, 218, 203. High resolution molecular weight determination, calcd. for $C_{15}H_{18}O_3$: 246.1256; found: 246.1262. *Anal.* calcd. for $C_{15}H_{18}O_3$: C 73.17, H 7.32; found: C 73.06, H 7.42.

Novel benzo[*a*]naphthacene quinones from an actinomycete, *Frankia* G-2 (ORS 020604)

NANCY N. GERBER AND MARY P. LECHEVALIER

Waksman Institute of Microbiology, P.O. Box 759, Rutgers, The State University of New Jersey, Piscataway, NJ 08854, U.S.A.

Received November 7, 1983[1]

NANCY N. GERBER and MARY P. LECHEVALIER. Can. J. Chem. **62**, 2818 (1984).

Frankia sp. G2 (ORS 020604), grown for one month without shaking, produced a mixture of 2 quinonoid pigments. The structure of one, G-2N, was shown by chemical and physical methods to be 2-methyl-4,7,9,12-tetrahydroxy-5,6-dihydro benzo[*a*]naphthacene-8,13-dione. The other, G-2A, has the same structure with the addition of a carboxyl group at position 10 or 11. Natural quinones with this ring system have not been reported previously.

NANCY N. GERBER et MARY P. LECHEVALIER. Can. J. Chem. **62**, 2818 (1984).

Si l'on fait croître du *Frankia* sp. G2 (ORS 020604) pendant un mois sans agitation, il se forme un mélange de deux pigments de nature quinonoïde. Faisant appel à des méthodes chimiques et physiques, on a démontré que l'un de ces produits, le G-2N, est la méthyl-2 tétrahydroxy-4,7,9,12 dihydro-5,6 benzo[*a*]naphthacènedione-8,13. L'autre composé, le G-2A, possède la même structure de base, mais il porte en plus un groupement carboxyle dans les positions 10 ou 11. Aucune quinone naturelle comportant ce système cyclique n'avait été signalée antérieurement.

Actinomycetes of the genus *Frankia* fix nitrogen in symbiosis with angiospermous higher plants. Although the existence of these microorganisms had been known for more than one hundred years, they have been isolated and maintained in pure culture only recently (1–3). Several of the Frankiae under investigation in these laboratories produce pigments (4). *Frankia* sp. G2 (ORS 020604) isolated by Gautier *et al.* (5) from the nodules of a *Casuarina equisetifolia* plant in Guadeloupe was chosen for study because of its relatively rapid growth and simple pigment mixture.

As described in the experimental section, two red-orange crystalline quinonoid pigments G-2N and G-2A were obtained. The absorption spectrum of G-2N showed maxima at 265, 311, and 470 nm; the ir spectrum had bands at 3380(OH), 1620, and 1595 cm^{-1}. The pigment did not melt below 350°C, gave a positive ferric chloride test for phenolic hydroxyls, was decolorized by sodium borohydride, and reoxidized in air to the original compound. In the mass spectrum the molecular ion at 388 was the base peak and, except for $M + 1$, $M - 1$, and $M - 18$, all other peaks were less than 20% of the base peak. This indicated a very stable, cyclic structure.

G-2N has the molecular formula $C_{23}H_{16}O_6$; the four oxygens are accounted for by a quinone function and four hydroxyls, as the pigment forms a tetraacetate. Zinc dust distillation furnished a small amount of hydrocarbon which, after column chromatographic purification, had a uv spectrum virtually identical with that of 1,2-benzo[*a*]naphthacene (6) but whose molecular ion at 292, 14 more than that of benzonapthacene, suggested a methylbenzonaphthacene. The aromatic methyl subsitutent was seen at 2.25 ppm in the nmr of G-2N and at 2.35 ppm in the spectrum of the acetate derivative.

A fully aromatic methylbenzo[*a*]naphthacene with 7 substituents (4 hydroxy, 1 methyl, and 2 quinone carbonyls) could have only 14 hydrogens ($C_{23}H_{14}O_6$; mol. wt. = 386) and 7 of these would be in the aromatic region of the nmr spectrum. However, G-2N had 5 aromatic hydrogens and a slightly broadened singlet at 2.8 ppm equivalent to 4 hydrogens. This suggested that one of the unsubstituted double bonds in the benzo[*a*]naphthacene framework had been replaced by a single bond. The placement of the single bond in ring D as shown in Fig. 1 is the only location consistent with the magnetic equivalence of the four hydrogens shown by the 4H singlet band. Furthermore, the uv–visible absorption spectrum resembles the combined spectra of a hydroxy anthraquinone (267 and 470 nm) and an alkylated phenol (311 nm).

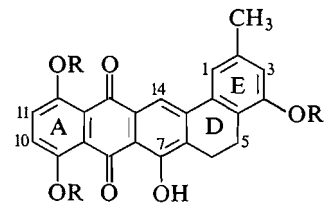

FIG. 1. The structures of G-2N, G-2N trimethylether, and G-2A. G-2N: R = H; G-2N trimethylether: R = methyl; G-2A: R = H, COOH at 10 or 11.

The arrangement of substituents on rings A through D follows in part from the nmr chemical shift (in DMSO-d_6) of H-14 at 8.8 ppm. Hydrogens *peri* to carbonyls are always deshielded (7); the range of values for this kind of H in some naturally occurring anthraquinones is 7.3 to 8.3 ppm (8) and in some anthracyclinones is 7.7 to 8.2 ppm (9). Thus H-14 is somewhat more deshielded than these examples; it may also be influenced by *peri* interactions with H-1. The nmr spectrum also shows two slightly broadened singlets at 6.70 and 6.68 ppm, each equivalent to one hydrogen, which are attributed to H-10 and 11. This is the normal appearance for an AB quartet where the difference between the chemical shifts is the same order of magnitude as the coupling constant (7). In addition, the shift of the visible absorption maximum from 470 nm in neutral solution to 553 nm in basic solution suggests an anthraquinone with three α hydroxyl substituents (8).

The problem of the location of the substituents on ring E is partially solved by the obviously *meta*-coupled aromatic protons at 6.61 and 7.16 ppm in the nmr of G-2N and at 7.2 and 7.9 ppm in the tetraacetate derivative. Since the hydrogens at positions 5 and 6 are magnetically equivalent in both spectra, they must be in an identical environment in both molecules. This leads to the arrangement of substituents on ring E shown

[1] Revision received June 20, 1984.

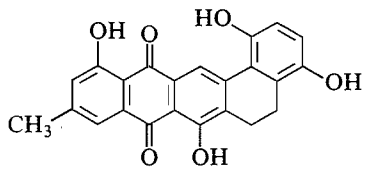

FIG. 2. A possible alternate structure for G-2N ruled out by nmr solvent shifts.

in Fig. 1 rather than alternative structures with substituents at positions 1 and 3 or one with the hydroxy at 2 and the methyl at 4. The possible alternate structure shown in Fig. 2, which retains the magnetic equivalence of H-5 and 6, is excluded by the chemical shift values of the *meta* coupled aromatic protons. In 3-methyl-1,6,8-trihydroxyanthraquinone the protons analogous to H-9 and 11 are observed at 7.10 and 7.64 ppm (8).

Although G-2N readily formed a tetraacetate derivative, it was difficult to methylate with dimethyl sulfate. A poor yield was obtained of a mixture of two monomethyl ethers, one di, one tri, and the tetramethyl ether. After preparative tlc separation the triether was used for nmr studies since the markedly different electronic absorption spectrum of the tetramethyl ether suggested molecular distortion due to steric strain.

The possible alternate structure shown in Fig. 2 is also excluded by the solvent shifts shown by G-2N trimethyl ether when the nmr solvent is changed from deuterochloroform to deuterobenzene. The upfield shift for the methyl band is small (0.26 ppm), not large (0.52–0.60 ppm) as would be expected for a C-2 or C-3 methyl substituent of an anthraquinone (10). The other solvent shifts, 0.6–0.7 ppm upfield for the three methoxyl methyls and 0.3 ppm downfield for H-14, are in accordance with published values (10).

The location of the methoxyl groups at positions 4, 9, and 12 in the trimethyl ether was shown by the appearance of the methylene band. No longer in a magnetically equivalent environment, the hydrogens at positions 5 and 6 are seen as a multiplet (2.75–2.89 ppm) with 2 small peaks at 2.82 and 2.86 ppm. In deuterobenzene the signals are completely separated and the two multiplets (2.40–2.59 and 2.84–3.03 ppm) resemble the A_2B_2 system pictured on p. 136 of ref. 7.

The electronic absorption spectrum of G-2A showed maxima at 300, and 460 nm; the ir spectrum had bands at 3360, 3110, 3030, 1720, 1620, and 1595 cm^{-1}; both spectra were very similar to those of G-2N. The pigment was sufficiently soluble in 5% aqueous sodium bicarbonate to impart a strong red coloration; the mass spectrum was virtually identical with that of G-2N except for a strong (100%) peak at $m/e = 44$ amu. This suggested that the structure of G-2A was identical to that of G-2N with the addition of a carboxyl group. However, when the room temperature acetylation procedure which furnished the tetraacetate derivative of G-2N was used for G-2A, a triacetate was obtained. This implied that the carboxyl group was adjacent and strongly hydrogen bonded to one of the four hydroxyl groups.

The G-2A tetraacetate was prepared by acetylation at 70°C. Although it was not sufficiently volatile for a satisfactory mass spectrum, the nmr spectrum clearly showed the four acetate groups and the other features associated with the G-2N structure: the aromatic methyl at 2.35 ppm, H-14 at 8.9 ppm, the 4H methylene singlet at 2.84 ppm, and the *meta* coupled hydrogens of ring E. Only the AB quartet was missing and replaced by a one-H singlet at 7.3 ppm. Thus the carboxyl group of G-2A was placed at C-10 or 11.

It is reasonable to assume that G-2N and G-2A are products of polyketide biosynthesis as are most other hydroxyquinones (8). There is circumstantial evidence that G-2A is transformed to G-2N, since production flasks incubated for 5 months yielded G-2N only. The location of the methyl and carboxyl groups (irrespective of whether the carboxyl is at 10 or 11) suggests that two polyketide chains are involved. Considering the methyl and carboxyl as chain terminals and using obvious and straightforward ways to visualize the assembly of G-2A from two polyketide chains, position 10 is favored over 11 as the location of the carboxyl group.

In a search of Chemical Abstracts we found no previous natural products from plants or microorganisms with the benzo[*a*]naphthacene ring system. Surprisingly, benzo[*a*]naphthacene has not been found carcinogenic although benzo[*a*]anthracene has (11). Free and glycosylated hydroxybenzo[*a*]anthraquinones are known as microbial products (12). They are biosynthesized from a single polyketide chain. We have also found one or both of these benzo[*a*]naphthacene compounds in other *Frankia* held in our collection, including D11 (ORS 020602), DBB-Eu11b, ULQ-EuN1$_f$, ULQ-EAN1$_{pcc}$, DBB-53001, and ULF-Hipp.

Experimental

Melting points were taken on a Kofler hot stage apparatus and are uncorrected. For column chromatography, neutral silica was HI-FLOSIL, 60/200 mesh, Applied Science Laboratories, State College, Pennsylvania; acidic silica was silicAR CC-4 from Mallinkrodt. The pH 8 silica was prepared from HI-FLOSIL by shaking it on a shaking machine with excess distilled water and adjusting, with NaOH, the pH to 8 initially and then intermittently until there was no change. The aqueous layer was decanted and the silica air-dried in a shallow pan. Polygram sil G/UV$_{254}$ 0.25-mm layer precoated plastic sheets, 5 × 10 cm, from Macherey–Nagel, were used for all analytical tlc. For preparative tlc, glass plates covered with Macherey–Nagel Kieselgel G were used. Ultraviolet–visible absorption spectra were recorded on a Beckman UV 5270 spectrophotometer; ir spectra were obtained using the Perkin–Elmer Model 283 spectrophotometer. Low resolution mass spectra were obtained with the Hewlett–Packard 5983 using the direct inlet, electron-impact mode with 70 eV; the high resolution instrument was the AEI-Kratos MS 50. The nmr spectra were taken on a Varian XL 100-15 or Varian FT-80 with tetramethyl silane as internal standard.

Production, isolation, and purification of G-2N and G-2A

Frankia sp. G2 was obtained through the kindness of Dr. Y. Dommergues of Dakar, Senegal. It is now referred to as ORS 020604 (Y. Dommergues, personal communication). It was maintained as a still culture in yeast-Czapeks (YCz) broth (13) at 27°C, transferring every 3 months. For pigment production, 3–4 week old cells, still-grown at 27°C in a medium containing 0.5% NZ Amine A (Sheffield Products, Memphis, Tennessee) and 0.1% potato starch in tap water, pH 7.0 before autoclaving, were used to inoculate fresh flasks of the same medium (5% inoculum). After 3–4 weeks of incubation, cells and the pigment, which had crystallized out of solution during growth, were harvested by centrifugation and extracted with 95% ethanol using overnight shaking. Three extractions were usually necessary to remove all of the color. Typical yields were 115 mg of red, partially crystalline, residue extracted from 4.3 g of moist cells which had been obtained from 75 Erlenmeyer flasks, each of which originally contained 50 mL of growth medium. The residue from the ethanol extracts was dissolved in methanol/concentrated ammonia 98:2 and added to 7 g of neutral silica. When dry, this was layered onto the top of a 100-g column of neutral silica which had been made up in chloroform/ethanol/concentrated ammonia 25:25:2. Elution with the same solvent mixture brought down the main red band, G-2N. With the solvent mixture in the ratio 25:50:3, the second major red

For personal use only.

band, G-2A, was eluted. Combined fractions of each component were allowed to evaporate to dryness. Typical yields were 25 and 35 mg respectively from 120 mg of residue. The two pigments were well separated by tlc using chloroform/ethanol/concentrated ammonia 10:10:1 (R_f 0.6 and 0.2) or chloroform/ethyl acetate 1:1 (R_f 0.8 and 0.1).

Crude G-2N (30 mg) was dissolved in about 50 mL of refluxing acetone containing 0.15 mL concentrated HCl. After hot filtration, the solution was concentrated to 20 mL and 20 mL of benzene added. The concentration and addition of benzene were repeated twice; toward the end a gel appeared. After standing overnight, the gel had changed to dark red crystals which were filtered by suction, yield 10 mg. G-2N could also be purified using a column of acidic silica and eluting with a chloroform/acetone gradient; uv (EtOH) λ_{max} nm(ϵ): 265 (8200), 311 (15 000), 470 (6900); (EtOH/NH_3) λ_{max} nm: 292, 328, 515; (EtOH/aq. NaOH) λ_{max} nm: 255, 293–306 (shoulder), 318, 348, 550; ir (KBr) ν_{max}: 3380 (O—H), 2920 (C—H), 1620 (C=O), 1595 (aryl), 1490, 1445, 1400, 1335, 1265, 1185, 1165, 1100, 760, 745, 600; ^{1}H nmr (DMSO-d_6) δ_{TMS}: 2.25 (s, 3H, Me), 2.76 (s, 4H, H-5 and 6), 6.61 (d, 1H, J = 2.5, H-3), 7.16 (d, 1H, J = 2.5, H-1), 6.70 (br s, 1H, H-10 or 11), 6.68 (br s, 1H, H-10 or 11), 8.81 (s, 1H, H-14); ms m/e: 389 (25.4%), 388 (100%), 387 (35%), 373 (12%), 371 (20%), 370 (28%), 69, 57, and 55 (all 20%); high resolution M^+ calcd.: 388.0945; found: 388.0951.

G-2A was not sufficiently soluble in any neutral organic solvent for recrystallization or column chromatography. It was obtained from the residue of the combined eluate fractions by trituration with 1% HCl in ethanol; it could be precipitated from solution in dry dimethylformamide by the addition of methanol; uv (EtOH) λ_{max} nm: 301, 463; (EtOH/ammonia), λ_{max} nm: 332, 400 (small), 515; (EtOH/NaOH) λ_{max} nm: 297, 345, 540; ir (KBr) ν_{max}: 3360, 3110, 3030, 2920, 2840, 1720, 1620, 1595, 1400, 1335, 1285, 1250, 1190, 1165, 1105, 760, 745 cm^{-1}; ms m/e: 389 (17.9%), 388 (70.7%), 387 (25.2%), 373 (12.1%), 371 (18.5%), 370 (25.3%), 194 (14.4%) 69 (13.6%), 57 (9.3%), 55 (11.0%), 44 (100%); high resolution M^+ − 44 calcd.: 388.0945; found: 388.0948.

G-2N tetraacetate

The acetyl derivative of G-2N (20 mg) was prepared using acetic anhydride (10 mL) and 3 drops of concentrated sulfuric acid at room temperature for 3–5 days. It was purified by column chromatography on neutral silica eluting with chloroform and recrystallized from chloroform/heptane; R_f 0.7 in chloroform/ethyl acetate 18:2, mp 248–253°C; uv (EtOH) λ_{max} nm (ϵ): 300 (21 700), 382 (1500); ir (KBr) ν_{max}: 2930, 1770 (aryl acetate), 1670 (C=O), 1590 (aryl), 1365, 1320, 1250, 1185, 1137, 1113, 1085, 1028 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ_{TMS}: 8.86 (s, 1H, H-14), 7.95 (d, 1H, J = 2.5, H-1 or H-3), 7.23 (d, 1H, J = 2.5, H-1 or H-3), 7.0 (br s, 1H, H-10 or H-11), 6.92 (br s, 1H, H-10 or H-11), 2.18 (s, 4H, H-5 and 6), 2.49 (s, 3H, OAc), 2.44 (s, 3H, OAc), 2.36 (s, 6H, OAc × 2), 2.35 (s, 3H, Me); ms m/e: 556 (M^+), 514 (M − 42), 472 (M − 42 × 2), 430 (M − 42 × 3), 388 (M − 42 × 4), 373 (388 − 15), 371 (388 − 17), 370 (388 − 18).

Zinc dust distillation of G-2N

This was carried out in the usual way in a 5-mm id Pyrex glass tube using a mixture of 10 mg G-2N and 200 mg Zn dust over which was layered an additional 1 g of Zn dust. When the tube and contents were heated with a small flame to dull red heat, yellow sublimate appeared in the upper portion of the tube. This was washed out with heptane and purified on a small silica column eluting with heptane. The absorption maxima of the purified material were: 448, 421, 397, 375, 316, 303, 291, 258 nm in heptane, 454, 426, 401, 379, 321, 307 nm in benzene, and the relative intensities of the various bands matched those of benzo[*a*]naphthacene. The literature values (6) for benzo[*a*]-naphthacene in benzene are, λ_{max} (log ϵ): 453 (4.0), 425 (3.97), 402 (3.8), 385 (3.5), 361 (3.16), 320 (4.98), 306 (5.01). The mass spectrum showed peaks at 278 (23%, $C_{22}H_{14}$), 292 (39%, $C_{23}H_{16}$), and 306 (12%, $C_{24}H_{18}$).

Methylation of G-2N

A mixture of G-2N, 26 mg, 3 g anhydrous potassium carbonate, 3 mL dimethyl sulfate, 10 mL dry acetone, and 5 mL dry dimethylformamide was refluxed 24 h. The mixture was poured into water, acidified with glacial HOAc, extracted twice with chloroform, and then extracted with EtOAc, which removed unreacted G-2N, 3 mg. Column chromatography of the chloroform extracts on acidic silica using a benzene/acetone gradient gave components A and B well separated, C, D, and E not well resolved, and 10 mg of recovered G-2N. From further chromatography of mixed fractions it could be seen that C and D cochromatographed on acidic silica but were well separated from E. On pH 8 silica, D and E cochromatographed but were well separated from C, which was the major product, 6.1 mg.

The properties of the 5 components are given in this order: R_f in benzene/acetone 19:1, color on tlc plate, fluorescence on tlc plate, λ_{max} nm (EtOH), λ_{max} nm (EtOH/aq. NaOH), mp (if obtained), ms m/e. A: 0.87, orange, red, 305 and 463, 280 and 515, 416 (M^+ 100%), 401 (M − 15), 398 (M − 18), a dimethylether, very minor amounts. B: 0.78, pale yellow, faint yellow, 304 and 445, 275 and 493, least amount, mass spectrum not obtained. C: 0.47, orange, dark red, 302 and 453, in base maxima flatten but do not shift, mp 261–263°C with sublimation and no dec., 430 (M^+ 100%), 415 (M − 15), 412 (M −18), a trimethyl ether, the major product; High resolution M^+ calcd.: 430.1417; found: 430.1404. D: 0.33, red-orange, none, 311 and 467, 515–535, crystal change at 305°C, sublimed away by 340°C with no melting, 402 (M^+ 100%), 387 (M − 15), 384 (M − 18), 385 (M − 17), a monomethyl ether. E: 0.22, yellow, orange, 302, and 415 (small), no shift in base, mp 245–249°C with sublimation and no dec., 444 (M^+ 52%), 429 (M − 15, 100%), 427 (M − 17), 426 (M − 18), 425 (M − 19), the tetramethyl ether.

The second methylation reaction used 27 mg of G-2N, methyl ethyl ketone instead of acetone; additional potassium carbonate (3 g) and dimethylsulfate (3 mL) were added after 4 h of refluxing. Nevertheless, half of the G-2N was recovered unchanged. Thin-layer chromatography disclosed components A, C, D, and E described above plus an additional component, F. All were obtained by preparative tlc on laboratory-made silica gel G plates run in benzene/acetone 95:5. Yields were (in mg): A, 0.6; D, 0.8; C, 1.5; E, 1.2; F, 0.6. Component F had uv (EtOH) λ_{max} nm: 308, 465; (EtOH/aq. NaOH) λ_{max} nm: 538 (broad); ms m/e: 402 (M^+ 100%), 387 (M − 15), 386 (M − 16), 315 (M − 87), a monomethyl ether which was clearly distinguished from monomethyl ether D by tlc on normal or NaOAc buffered plates, R_f for D, 0.6 and 0.6 respectively; for F, 0.4 and 0.5.

The λ_{max} and the ratio of optical density at 302–311 to the optical density at the visible maxima are given below in order to show the discontinuity between the values for the tetramethyl ether E and the others. G-2N: 311, 470, ratio 2.2; monomethyl ether D: 311, 467, ratio 2.0; monomethyl ether F: 309, 465, ratio 2.1; dimethyl ether A: 305, 463, ratio 2.7; trimethyl ether C: 302, 453, ratio 2.7; tetramethyl ether E, 302, 415, ratio 4.7.

Trimethyl ether C, ^{1}H nmr ($CDCl_3$) δ_{TMS}: 2.37 (s, 3H, Me), 2.75–2.89 (m, 4H, H-5 and 6), 4.03, 3.98, 3.94 (each s, 3H, 3 OMe) 7.50 (d, 1H, J = 2.5, H-1), 6.78 (d, 1H, J = 2.5, H-3), 6.73 (br s, 2H, H-10 and 11), 8.72 (s, 1H, H-14), 13.52 (s, 1H, O—H at C-7); (C_6D_6) δ_{TMS}: 2.11 (s, 3H Me), 2.45–2.59 (m, 2H, H-5 or 6) 2.84–2.99 (m, 2H, H-5 or 6), 3.24, 3.32, 3.40 (each s, 3H, 3 OMe), 6.36 (d, 1H, J = 3, H-3), 7.54 (d, 1H, J = 3, H-1), 6.40 (br s, 1H, H-10 or 11), 6.46 (br s, 1H, H-10 or 11), 9.2 (s, 1H, H-14).

G-2A tetraacetate

A mixture of 10 mg G-2A, 10 mL acetic anhydride, and 2 drops of sulfuric acid was heated for 1 h at 70°C. The reaction mixture was poured into 200 mL water and, after standing overnight, the crude product was obtained by centrifugation and washed. Dried crude product was dissolved in acetone and purified by preparative tlc on 20 laboratory-made silica gel G plates run in benzene/acetone/acetic acid 80:20:1. The desired tetraacetate shows a weak fluroescence on the plate, the R_f in analytical tlc is 0.3 in benzene/acetone/acetic acid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

18:2:0.2. Incompletely acetylated (or deacetylated) material appeared as slower moving spots with strong yellow fluorescence. Faster moving, red fluorescent spots, presumably impurities, were also present. The separation could not be accomplished using columns of neutral silica; with acidic silica deacetylation occurred. To minimize deacetylation during tlc, plates should be run right after material has been applied; solvent and eluant acetone should be stored over anhydrous potassium carbonate; the band of tetraacetate should be eluted within 1/2 h of removal from the tlc tank.

The yield of G-2A tetraacetate was 5.9 mg after precipitation from benzene with heptane; uv ($CHCl_3$) λ_{max} nm: 295, 370; (EtOH, difficultly soluble) λ_{max} nm: 300, 387; ir (KBr) ν_{max}: 3350, 3240, 2960, 1775 (OAc), 1750, 1720 (COOH), 1660 (C=O), 1585 (aryl), 1500, 1145, 920, 740; ^1H nmr ($CDCl_3$) δ_{TMS}: 2.35 (s, 6H, aryl Me and OAc), 2.84 (s, 4H, H-5 and 6), 7.96 (d, 1H, J = 2.5, H-1), 8.90 (s, 1H, H-14), 2.45 (s, 3H, OAc), 2.49 (s, 6H, 2 × OAc), bands for H-3 and H-10 or 11 obscured by solvent; (DMSO-d_6) δ_{TMS}: 2.23 (s, 3H, Me), 2.79 (br s, 4H, H-5 and 6), 7.90 (d, 1H, J = 2.5, H-1), 7.50 (d, 1H, J = 2.5, H-3), 7.3 (s, 1H, H-10 or 11), 8.67 (s, 1H, H-14), 2.34, 2.37, 2.40 (m, 4 × OAc, too close to solvent for accurate integration).

Methylation of G-2A

This was carried out as for the second methylation of G-2N using 36 mg of G-2A. Thin-layer chromatography of the combined chloroform extracts disclosed four components which were separated by suitable combinations of preparative tlc and column chromatography on neutral silica, as for the methyl ethers of G-2N. It was noted that component E runs ahead of F in tlc but behind F on columns. The recovered G-2A from ethyl acetate extracts was 27 mg. The properties of the 4 components are given in this order: R_f in benzene/acetone 18:2, color on tlc plate, fluorescence on tlc plate, λ_{max} nm (EtOH), λ_{max} nm (EtOH/ aq.NaOH), mp, yield, ms m/e. A: 0.87, yellow, yellow, 298 and 460, 283 and 515, 330–345°C dec., 0.8 mg, 474 (M^+ 72%), 473 (24%), 472 (39%), 442 (5.2%), 44 (100%), a dimethylether monomethyl ester or a trimethylether acid. B: 0.7, yellow, very bright yellow, 228, 298 and 458, 292 and 460, 240–245°C, 0.6 mg, 488 (M^+ 100%), 44 (100%), a trimethylether monomethylester or a tetramethylether acid. C: 0.6, orange, orange, 233, 298 and 475, 525, no melting under 350°C, 0.5 mg, not sufficiently volatile for ms, insoluble in benzene when pure. The structures of the nellionols. Synthesis of model abieta-8,11,13-trien-7-ones. Synthesis of 5-dehydronellionol trimethyl ether

ROBERT H. BURNELL, MICHEL JEAN, DONALD POIRIER, AND SYLVAIN SAVARD
Département de chimie, Université Laval, Québec (Qué.), Canada G1K 7P4

Received May 7, 1984

ROBERT H. BURNELL, MICHEL JEAN, DONALD POIRIER and SYLVAIN SAVARD. Can. J. Chem. **62**, 2822 (1984).

The synthesis of model ketones derived from podocarpic and dehydroabietic acids prompted us to question the published structures for the nellionols to accommodate more adequately their reported spectral characteristics. Both the originally proposed structure for 5-dehydronellionol and our suggested modification have been synthesized (as the methyl ethers). The nellionols must have the 11,12-dioxy structures rather than the isomeric 11,14-dioxy substitution pattern.

ROBERT H. BURNELL, MICHEL JEAN, DONALD POIRIER et SYLVAIN SAVARD. Can. J. Chem. **62**, 2822 (1984).

Les données spectrales recueillies lors de la synthèse de cétones dérivées des acides podocarpique et déshydroabietique nous ont amené à douter des structures proposées pour les nellionols. Deux synthèses de dérivés méthylés du déshydro-5-nellionol ont été effectuées: celle de la structure qui avait été proposée et celle de la structure que nous avons modifiée. Les structures des nellionols correspondent donc à celles de produits oxygénés aux positions 11 et 12 plutôt qu'aux positions 11 et 14.

Among the diterpenoid constituents isolated from *Premna latifolia* and described in structural detail by Rao *et al.* (1) were three "nellionols" for which the structures **1**, **2**, and **3** were advanced. Obviously the general features of these compounds could not be in doubt but we found the position of the nmr signals for the aromatic protons in all three cases reminiscent of a C.14 proton in close proximity to a C.7 carbonyl rather than of the C.12 type proposed. Many examples could be quoted to underline our suspicion, for instance ketones **8** and **15** which we have prepared in unambiguous fashion in unpublished model studies concerning the syntheses of coleon U (2) and taxodione (3).

8

The 11,14-dimethoxy compound **8** was prepared from sugiol methyl ether **4** (prepared from podocarpic acid (4)) via the quinone **5***a*. The latter was catalytically reduced and methylated *in situ* to give mostly the ester **6***a*, much smaller quantities of the incompletely methylated compounds **6***b* and **6***c*, and acidification of the aqueous phase afforded varying amounts of the dimethoxy acid **6***d*. All of these products could be used since both **6***b* and **6***c* gave the dimethoxy ester on further methylation. Ester **6***a* was also prepared from **4** by Baeyer–Villiger oxidation, which gave mostly the lactone **7**, and this on methanolysis afforded the previously mentioned phenol ester **6***c* and lesser amounts of the quinone ester **5***b*. Even though both of these products could be integrated into the synthesis (the former by methylation and the latter by reduction and methylation), the yields remained poor. Hydrolysis of the ester **6***a* was affected in aqueous base and the resulting acid **6***d* cyclized readily ($(CF_3CO)_2O$, room temperature) to the ketone **8**. The nmr spectrum of the latter shows a single aromatic proton at δ 6.97.

The abietatrien-7-one **9** was prepared from commercial dehydroabietic acid by known methods (5). Baeyer–Villiger oxidation of this aromatic ketone afforded the seven-membered lactone **10** which was (not isolated but rather) converted directly to the phenol ester **11** by methanolysis. Further oxidation of the phenol with benzene seleninic anhydride following Barton's procedure (6) gave two quinones of which the minor product was the previously described *para*-quinone ester **5***b* and the major product was the *ortho*-quinone **12**. The latter was catalytically reduced and the intermediate catechol was imme-

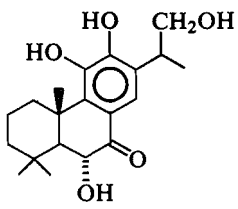
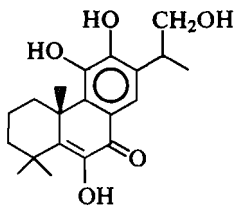
12

diately methylated, while still under hydrogen, to give the dimethoxy ester **14***a*. Hydrolysis to the acid **14***c* and trifluoroacetic anhydride-promoted cyclization gave the ketone **15**. The aromatic proton in the nmr spectrum of this isomer was at δ 7.70.

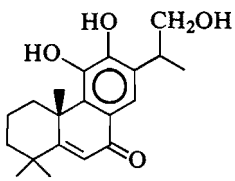
The published nmr figures for the nellionols and their derivatives show aromatic protons in the range δ 7.34 to 8.17 depending on the substituents, and the closest analogy to our two models (5-dehydronellionol dimethyl ether) shows the aromatic proton at δ 7.61. This compares favorably with our second model and can only mean that the structures proposed by Rao *et al.* (1) must be modified to **16**, **17**, and **18** respectively. It must be noted that the introduction of the enolic ketone at C.6 has virtually no effect on the chemical shift of the aromatic protons. Re-examining the evidence for the original structures suggests that undue importance was credited to the Gibbs test for free *para* positions in phenols, but this useful colour reaction is well known to be misleading (7). The "*para*-quinone" obtained by oxidation during the structure elucidation must have been an *ortho*-quinone and, while no uv/vis spectrum was quoted, the colour of the crystals is quite suggestive.



16

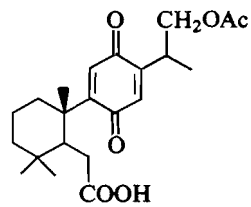


17



18

Having on hand a small quantity of the quinone **19** (from our synthesis of coleon C (8)) we saw that a rapid synthesis of Rao's 5-dehydronellionol was possible. As originally intended (9), the following sequence was carried through without formally isolating the intermediates and, while our reason was more the fear of insufficient material in this case, the reliability of the scheme has been well demonstrated (see refs. 2, 8, and 9). The product of each reaction was purified by dry column chromatography, the necessary spectral evidence was secured to identify both the nature and the homogeneity of the material, and this "clean" product was subjected to the next reaction in the scheme. Catalytic reduction of the quinone **19** and methylation *in situ* (under hydrogen) afforded the ester **20***a* which was readily hydrolysed to the acid **20***b*, some of which we had previously isolated from the methylation step (above). In trifluoroacetic anhydride the acid **20***b* cyclized in modest yield to the aromatic ketone **21** in which, due to the imposed rotation of the aromatic ring, the methoxyl residues are necessarily at C.11 and C.14. The C.6 position was oxidized by oxygen in *tert*-butanol containing potassium *tert*-butoxide to give the enolic α-diketone **22***a*, which could be O-methylated to the tri-O-methyl derivative **22***b*. As predicted, the synthetic compound, unambiguously corresponding to structure **22***b*, was not identical with the 5-dehydronellionol trimethyl ether described by Rao. The real structures for the nellionols must therefore contain the 11,12-dioxy substitution pattern.



19

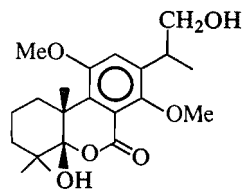
22*b* R = Me



23

In searching for a relatively simple but convincing synthesis of a nellionol, the ester **14***a*, which we had already prepared in earlier model studies, attracted our interest because the introduction of the sidechain hydroxyl would be straightforward in the absence of a competing benzylic position found in compounds containing the normal B ring. At first, attempted functionalization in the isopropyl group using *N*-bromosuccinimide gave discouraging results in that several compounds were formed. After some experimentation we returned to the normal reaction conditions which led to three major products: the isopropenyl derivative **25** (ca. 25%), the tertiary alcohol **24** (31%), and the bromohydrin **26** (41%), and all three could be transformed to the primary alcohol **28***a*. Obviously the alcohol

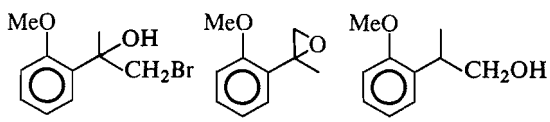
2-hydroxyisopropyl **28***a* was superior to 65%. Hydrolysis of the ester function in **28***a* gave the acid **28***b* which cyclized readily to the ketone **29**. The final oxidation was achieved in the normal manner with oxygen and strong base, and the enolic α-diketone was O-methylated for comparison with this same derivative (**30***b*) in the literature. The identity of the spectral results shows that this is indeed 5-dehydronellionol trimethyl ether. Our synthesis is not decisive as to the configuration at C.15; the original authors are not specific on this point either, and for this reason direct comparison would be of limited value since in the present synthesis (other than the selectivity induced by the asymmetry already present) no effort was made to direct the configuration at C.15. The diastereomers were in fact not readily separable.

After our preliminary reports (10*a*, *b*), Matsumoto's group also published convincing evidence (11) to correct the Rao structures. Their syntheses are quite different from those described here but the conclusions are the same. More recently (12), they have synthesized structure **18** (as the triacetate) only to find that their sample was not identical with the 5-anhydronellionol triacetate described in the literature. In fact the latter turned out to be the acetate of 5-dehydronellionol **17**.

The ^{13}Cmr spectra of many of the compounds described in these syntheses are listed in Table 1. The assignments are based on values given by Enzell and co-workers (13*a*), Wehrli and Nishida (13*b*) and Wenkert *et al.* (13*c*) and by comparing with many spectra of similar molecules which our recent syntheses



26*M* **27***M* **28***aM*

have engendered. The spectra of three very simple model compounds **26***M*, **27***M*, and **28***aM* are also included in the table in partial support for attributions of particular resonances where we had no previous experience.

Experimental

Unless otherwise stated, the conditions and instruments used to characterize the products were: melting points, Electrothermal, uncorrected; ultraviolet spectra, ethanol solutions (ε in parentheses), Hewlett Packard 8450A; infrared spectra, solids as KBr pellets and others as carbon tetrachloride solutions, Beckman 4250 and Perkin Elmer 457; proton magnetic resonance spectra, deuteriochloroform solutions, TMS internal standard, (multiplicity, integrated peak areas, coupling constants, and assignments in parentheses), Bruker HX 90; carbon-13 magnetic resonance spectra, deuteriochloroform solutions, TMS internal standard, Bruker WP 80; mass spectra, Hewlett Packard 5992. Elemental analyses were by Galbraith Laboratories, Knoxville, Tenn. The high resolution mass spectra were recorded on an AEI MS30.

Dry column chromatography (abbreviated dry col chrom) implies the use of Merck Kieselgel 60F (70–230 mesh) in nylon foil tubing and development with either hexane – ethyl acetate or carbon tetra-

chloride – ethyl acetate (proportions determined by prior thin layer chromatography using Machery–Nagel precoated plastic sheets).

Baeyer–Villiger oxidation of sugiol methyl ether **4** *and methanolysis of lactone* **7**

Sugiol methyl ether **4** (8.8 g) in $CHCl_3$ (100 mL) was added drop by drop to a stirred solution of *m*-chloroperbenzoic acid (9.8 g) in $CHCl_3$ (150 mL). Stirring was continued at room temperature for 4 days when another equivalent of *m*-CPBA was added and the reaction continued for 4 more days. The solution was well washed, dried, and evaporated, and a small portion of the product was purified by dry col chrom. With difficulty a small quantity of the pure lactone **7** was obtained, mp 145°C (needles from hexane); uv: 238(6300) and 279(4200) nm; ir: 1745 cm^{-1}; H nmr δ: 0.91, 1.16, and 1.51 (3s, Me at C.4 and C.10), 1.20 (d, 6H, J = 7 Hz, iPr Me), 2.60 (d, J = 5.5 Hz, C.6-H), 2.61 (d, J = 6.5 Hz, C.6-H), 1.83 (m, C.5-H), 3.27 (m, iPr CH), 3.86 (s, Ar-OMe), 6.82 and 6.96 (2s, arom H); ^{13}Cmr, see table; ms *m/e*: 330 (M^+, $C_{21}H_{30}O_3$) and 315.

The crude lactone (8.9 g) was dissolved in MeOH (160 mL) and, after adding concentrated H_2SO_4 (2.0 mL), the mixture was refluxed for 2 h. Ether extraction (after removing much of the MeOH under vacuum) gave a yellow oil (5.1 g) which was purified by column chromatography (SiO_2, hexane – ethyl acetate) to afford the phenol ester **6***c* (2.62 g; 27%; *methyl 2-(5-methoxy-2-hydroxy-4-isopropylphenyl)-2,6,6-trimethylcyclohexylethanoate)*, mp 171–172°C (needles, hexane); uv: 228(7000) and 290(6800) nm; ir: 3390 and 1710 cm^{-1}; H nmr δ: 0.97, 1.00, and 1.39 (3s, three Me-C), 1.12 (d, J = 7 Hz, iPr Me), 2.20 (d, J = 6.5 Hz, C.6-H), 2.21 (d, J = 4.5 Hz, C.6-H), 3.27 (s, COOMe – falls on m, C.5-H and iPr CH), 3.77 (s, Ar-OMe), 6.63 (s, C.11-H), and 6.76 (s, 2H, C.14-H and OH (D_2O)); ^{13}Cmr, see table; ms *m/e*: 362 (M^+) and 330. *Anal.* calcd. for $C_{22}H_{34}O_4$: C 72.89, H 9.45; found: C 72.69, H 9.56.

A second product from the chromatogram was the *p*-benzoquinone ester **5***b* (1.05 g; 11%; yellow oil); ir: 1735 and 1655 cm^{-1}; H nmr δ: 0.93 (s, 6H, *gem* diMe), 1.13 (d, J = 7 Hz, iPr Me), 1.18 (s, C.10-Me), 3.42 (s, COOMe), 6.45 and 6.53 (2s, olefinic H); ^{13}Cmr, see table; ms *m/e*: 346 (M^+).

Methylation of the phenol ester **6**c

The phenol (1.7 g), K_2CO_3 (24 g), and excess dimethyl sulfate were taken up in dry acetone (250 mL). After 24 h at reflux, the cooled mixture was diluted with water, most of the acetone was removed in vacuum, and the product was obtained by ether extraction. The yellow oil (1.7 g) was chromatographed to give unctuous yellow crystals of the ester **6***a*, *methyl 2-(2,5-dimethoxy-4-isopropylphenyl)-2,6,6,-trimethylcyclohexylethanoate*, mp 51–54°C (from CCl_4, 610 mg; 33%); ir: 1730 cm^{-1}; H nmr δ: 0.94 and 0.99 (2s, *gem* diMe), 1.22 (d, J = 7 Hz, iPr Me), 1.43 (s, C.10-Me), 2.13 (d, J = 5 Hz, C.6-H), 2.20 (d, J = 4.5 Hz, C.6-H), 3.25 (m, iPr CH), 3.28 (s, COOMe), 3.82 and 3.89 (2s, Ar-OMe), 6.76 and 6.84 (2s, arom H); ^{13}Cmr, see table; ms *m/e*: 376 (M^+). *Anal.* calcd. for $C_{23}H_{36}O_4$: C 73.36, H 9.64; found: C 73.13, H 9.90.

Reduction and methylation of the p-*quinone* **5**a

The *p*-quinone **5***a* (0.5 g) in MeOH (70 mL) was introduced into a hydrogenation flask containing prehydrogenated Adams' catalyst (40 mg) and MeOH (15 mL). The mixture was stirred under hydrogen until the yellow colour had disappeared (ca. 45 min) and then every hour, for 12 h, aqueous NaOH (2.0 mL of 30%) and dimethyl sulfate (1.5 mL) were added while the mixture was stirred under hydrogen. The catalyst was removed by filtration, most of the MeOH was removed at the pump, and the crude product (yellow oil, 0.46 g) obtained by ether extraction was purified by dry col chrom to give three products: dimethoxy ester **6***a* (362 mg; 64%), identical with that described above; phenol ester **6***c* (27 mg; 5%), also described above; the isomeric phenol ester **6***b* (16 mg; 3%), *methyl 2-(2-methoxy-5-hydroxy-4-isopropylphenyl)-2,6,6-trimethylcyclohexylethanoate*,white needles, mp 161–162°C (from hexane); ir: 3595, 3400 and 1715 cm^{-1}; H nmr δ: 0.96 (s, 6H, *gem* diMe), 1.12 (d, J = 7 Hz, iPr Me), 1.37 (s, C.10-Me), 2.12 (d, J = 3.5 Hz, C.6-H), 2.20 (d, J = 2.5 Hz, C.6-H), 3.18 (m, iPr CH), 3.24 (s, COOMe), 3.74 (s, Ar-OMe), 6.00 (s, OH (D_2O)), 6.53 and 6.70 (2s, arom H); ms *m/e*: 362 (M^+), 347 and 331. *Anal.* calcd. for $C_{22}H_{34}O_4$: C 72.89, H 9.45; found: C 72.81, H 9.49.

Further methylation of the phenol esters **6***b* and **6***c* (Me_2SO_4, NaOH) afforded the dimethoxy compound **6***a*.

Hydrolysis of ester **6**a

To the dimethoxy ester (0.5 g) in MeOH (25 mL) was added aqueous KOH (25 mL of 10%) and the mixture was refluxed for 4 h. After evaporation of most of the MeOH, the aqueous phase was washed with ether and then acidified to permit the extraction of the acid **6***d* with ether. The product, *2-(2,5-dimethoxy-4-isopropylphenyl)-2,6,6,-trimethylcyclohexylethanoic acid*, recrystallized from hexane, mp 148°C (white needles); ir: 1705 cm^{-1}; H nmr δ: 0.87 and 0.95 (2s, *gem* diMe), 1.13 and 1.15 (2d, J = 7 Hz, iPr Me), 1.30 (s, C.10-Me), 3.03 (m, iPr CH), 3.70 and 3.76 (2s, Ar-OMe at C.11 and C.14 resp), 6.66 and 6.76 (2s, arom H); ^{13}Cmr, see table; ms *m/e*: 362 (M^+) and 347. *Anal.* calcd. for $C_{22}H_{34}O_4$: C 72.89, H 9.45; found: C 73.00, H 9.48.

Cyclization to ketone **8**

A solution of the dimethoxy acid **6***d* (70 mg) in trifluoroacetic anhydride (1.0 mL) was stirred at room temperature for 24 h. The reaction mixture was poured into ice-water and the crude cyclized product (the enol trifluoroacetate) was taken up in MeOH (25 mL) and hydrolysed immediately by adding aqueous KOH (4 mL of 10%). After 1 h, the MeOH was evaporated and the product obtained by ether extraction. Dry col chrom afforded the ketone **8** (25 mg; 39%; *7-oxo-11,14-dimethoxyabieta-8,11,13-triene*), mp 98–99°C (from hexane) uv: 228(7800), 261(3200), and 331(7800) nm; ir: 1680 cm^{-1}; H nmr δ: 0.95 and 0.98 (2s, *gem* diMe), 1.22 (2d, J = 7 Hz, iPr Me), 1.34 (s, C.10-Me), 1.81 (dd, J = 10.5 and 7.5 Hz, C.5-H), 2.62 (d, J = 10.5 Hz, C.6-H), 2.64 (d, J = 7.5 Hz, C.6-H), 3.41 (sept, iPr CH), 3.78 and 3.82 (2s, Ar-OMe at C.11 and C.14 resp), and 6.97 (s, arom H); ^{13}Cmr, see table; ms *m/e*: 344 (M^+) and 328. *Anal.* calcd. for $C_{22}H_{32}O_3$: C 76.70, H 9.36; found: C 76.83, H 9.66.

7-Oxo-abieta-8,11,13-triene **9**

To a solution of abietatriene (prepared from dehydroabietic acid, 10 g) in glacial HOAc (75 mL) was added chromium trioxide (15.0 g) in 80% HOAc (115 mL). After 4 h at room temperature, the reaction mixture was poured into ice-water and the crude ketone (9.1 g; 86%), which was obtained by ether extraction, could be used as such for the next step. A small sample was purified by dry col chrom to give the pure ketone **9**, mp 89–90°C (from hexane); uv: 254(12 000) and 302(2300) nm; ir: 1690 cm^{-1}; H nmr δ: 0.94 and 1.01 (2s, *gem* diMe), 1.25 (d, J = 7 Hz, iPr Me), 1.24 (s, C.10-Me), 2.80 (sept, J = 7 Hz, iPr CH), 7.40 (m, 2H, arom H at C.11 and C.12), and 7.90 (d, J = 2 Hz, arom H at C.14); ms *m/e*: 284 (M^+), 269, 227, and 201. *Anal.* calcd. for $C_{20}H_{28}O$: C 84.45, H 9.92; found: C 84.47, H 10.02.

Baeyer–Villiger oxidation of ketone **9** *and methanolysis of lactone* **10**

A solution of *m*-chloroperbenzoic acid (13.0 g, 2 equiv.) in $CHCl_3$ (180 mL) was added dropwise to the ketone **9** (9.1 g) dissolved in $CHCl_3$ (55 mL). Stirring was continued at room temperature for 8 days but further equivalents of *m*-CPBA (6.5 g) in $CHCl_3$ (90 mL) were added after the second, fourth, and fifth days. After rigorous washing, the solution was filtered through a short column of silica gel and evaporated to give the lactone **10** as an oil (7.4 g); ir: 1760 cm^{-1} and ms *m/e*: 300 (M^+).

Without purification the lactone (7.2 g) was taken up in MeOH (75 mL) to which concentrated H_2SO_4 (3.0 mL) was added and the solution refluxed for 45 min. After evaporating most of the MeOH, the product was obtained by ether extraction. Crystallization from hexane gave the phenol ester **11** (1.5 g) and further quantities (2.07 g) were obtained by chromatography of the mother liquors. The yield of **11** was only 34% (from the ketone **9**, some of which (0.36 g) was recovered from the reaction). The ester **11** (*methyl 2-(2-hydroxy-4-isopropylphenyl)-2,6,6-trimethylcyclohexylethanoate*) showed mp

For personal use only.

141–143°C (from hexane–ether); ir: 3500–3200 (br, OH), 1710, and 1620 cm^{-1}; H nmr δ: 0.98, 1.01, and 1.39 (3s, Me-C), 1.18 (d, J = 7 Hz, iPr Me), 2.77 (sept, J = 7 Hz, iPr CH), 3.29 (s, COOMe), 3.40 (dd, J = 7 and 5 Hz, C.5-H), 6.60 (m, arom H at C.12 and C.14), 7.00 (s, OH (D_2O)), and 7.10 (d, J = 8 Hz, C.11-H); ^{13}Cmr, see table; ms m/e: 332 (M^+), 300, and 257. *Anal.* calcd. for $C_{21}H_{32}O_3$: C 75.86, H 9.70; found: C 76.08, H 9.84.

*Oxidation of the phenol ester **11** (to give quinones **12** and **5**b)*

The phenol ester **11** (0.48 g) was dissolved in THF (18 mL) and added dropwise to a stirred suspension of benzene seleninic anhydride (1.05 g; 2.5 equiv.) in THF (50 mL) heated to 50–55°C. The reaction was followed by tlc and was complete in ca. 3 h. After pouring the reaction mixture into ice-water, the organic layer was well washed and then evaporated to afford an orange oil (890 mg). Dry col chrom gave diphenyl diselenide (160 mg), the *p*-quinone **5***b* (160 mg; 32%), and the *o*-quinone **12** (296 mg; 59%; *methyl 2-(4-isopropylbenzoquinone-2,3)yl-2,6,6-trimethylcyclohexylethanoate*), mp 100–101°C (from hexane); uv: 274(700), 418(1600), and 586 (weak !) nm; ir: 1725, 1680, 1660, and 1650(sh) cm^{-1}; H nmr δ: 0.92 (s, 6H, *gem* diMe), 1.10 (d, J = 7 Hz, iPr Me), 1.19 (s, C.10-Me), 2.93 (sept, J = 7 Hz, iPr CH), 3.47 (s, COOMe), and 6.70 (ABq, J = 7 Hz, arom H at C.8 and C.14); ^{13}Cmr, see table; ms m/e: 348.2290 (M^+ + 2), 346.2119 (M^+, $C_{21}H_{30}O_4$ requires 346.2144), 318 and 316. *Anal.* calcd. for $C_{21}H_{30}O_4$: C 72.80, H 8.73; found: C 73.12, H 8.70.

*Reduction and methylation of quinone **12***

A solution of the *o*-quinone **12** (296 mg) in MeOH (10 mL) was added to prehydrogenated Adams' catalyst (20 mg) in MeOH (5 mL) in an atmospheric pressure hydrogenation apparatus. When the red color had disappeared, NaOH solution (total of 8 mL of 30%) and dimethyl sulfate (total 5 mL) were added over a period of 10 h with continuous stirring. After filtering, most of the MeOH was removed under vacuum and the product (270 mg) was obtained by ether extraction. Dry col chrom gave a small quantity of the starting quinone (30 mg; 10%), the 11-hydroxy-12-methoxy compound **14***b* (50 mg; 16%), and **14***a* (*methyl 2-(2,3-dimethoxy-4-isopropylphenyl)-2,6,6-trimethylcyclohexylethanoate*), 160 mg; 50%; yellow oil); ir: 1730 cm^{-1}; H nmr δ: 0.91, 0.97, and 1.31 (3s, Me-C), 1.19 (2d, J = 7 Hz, iPr Me), 3.24 (s, COOMe), 3.74 and 3.96 (2s, Ar-OMe), and 6.90 (ABq, J = 8 Hz, arom H); ^{13}Cmr, see table; ms m/e: 376 (M^+) and 345. *Anal.* calcd. for $C_{23}H_{36}O_4$: C 73.36, H 9.64; found: C 73.46, H 9.80.

*Hydrolysis to acid **14**c*

To the ester **14***a* (160 mg) in MeOH (20 mL) was added NaOH solution (10 mL of 10% aqueous) and the mixture was refluxed for 5 h. Most of the MeOH was removed at the pump and the aqueous residue was extracted with ether to remove unchanged starting material (40 mg). After acidification, the acid **14***c* (114 mg; 74%; *2-(2,3-dimethoxy-4-isopropylphenyl)-2,6,6-trimethylcyclohexylethanoic acid*) was obtained by ether extraction; ir: 1700 cm^{-1}; H nmr δ: 0.84, 0.94, and 1.24 (3s, Me-C), 1.13 (2d, J = 7 Hz, iPr Me), 3.18 (sept, J = 7 Hz, iPr CH), 3.66 and 3.87 (2s, Ar-OMe), 6.87 (ABq, J = 8 Hz, arom H), and 10.07 (s, COOH (D_2O)); ^{13}Cmr, see table; ms m/e: 362 (M^+), 347, and 332. *Anal.* calcd. for $C_{22}H_{34}O_4$: C 72.89, H 9.45; found: C 72.71, H 9.65.

*Cyclization to the ketone **15***

The acid **14***c* (94 mg) was dissolved in trifluoroacetic anhydride (3.0 mL) and the solution stirred for 6 h at room temperature. The mixture was decomposed by pouring onto ice and the crude enol trifluoroacetate, secured by ether extraction, was hydrolysed by taking up in MeOH containing aqueous KOH (5 mL of 10%). After 1 h, the neutral product was once more obtained by extraction. Dry col chrom gave the oily ketone **15** (70 mg; 78%; *7-oxo-11,12-dimethoxyabieta-8,11,13-triene*); $[\alpha]_D^{25}$ +52° (*c* 1.23, $CHCl_3$); uv: 273 (23 600) nm; ir: 1670 cm^{-1}; H nmr δ: 0.94, 0.99, and 1.39 (3s, Me-C), 1.21 and 1.24 (2d, J = 7 Hz, iPr Me), 3.20 (sept, J = 7 Hz, iPr CH), 3.85 (s, 6H, Ar-OMe), and 7.70 (s, arom H at C.14); ^{13}Cmr, see table; ms m/e: 344 (M^+) and 329. *Anal.* calcd. for $C_{22}H_{32}O_3$: C 76.70, H 9.36; found: C 76.91, H 9.49.

*Reduction and methylation of quinone **19***

The quinone **19** (300 mg: prepared from podocarpic acid by previously described methods (9)) in MeOH (10 mL) was added to prehydrogenated Adams' catalyst (50 mg) in MeOH (10 mL) in an atmospheric pressure hydrogenation apparatus. After the yellow solution had lost all color (ca. 1 h), portions of aqueous NaOH (2.0 mL of 30%) and dimethyl sulfate (1.0 mL) were added every 2 h (total, 12 mL NaOH and 6 mL Me_2SO_4) and the mixture stirred for a total of 72 h. The usual work-up gave a crude oil (300 mg) which was purified by dry col chrom to give the dimethoxy ester **20***a*, which was used as such for the next step (180 mg; 60%; *methyl 2-(4-(2-hydroxyisopropyl)-2,5-dimethoxyphenyl)-2,6,6-trimethylcyclohexylethanoate*); uv: 227(5600) and 290(3200) nm; ir: 3440 and 1730 cm^{-1}; H nmr δ: 0.92, 0.97 and 1.37 (3s, Me-C), 1.26 (d, J = 7 Hz, iPr Me), 2.01 (dd, J = 16 and 6 Hz, C.6-H), 3.08 (dd, J = 7 and 6 Hz, C.5-H), 3.28 (s, COOMe), 3.41 (m, C.15-H), 3.70 (d, 2H, J = 6 Hz, CH_2OH), 3.82 and 3.88 (2s, Ar-OMe), 6.73, and 6.87 (2s, arom H at C.8 and C.12 resp); ^{13}Cmr, see table; ms m/e: 392 (M^+).

A smaller quantity of the more polar acid **20***b* (80 mg; 28%) was also obtained from the column; for properties see later.

*Hydrolysis to acid **20**b*

The ester **20***a* (170 mg) was hydrolysed by refluxing in MeOH (20 mL) containing 10% aqueous NaOH (20 mL). The crude extract (161 mg) was chromatographed (dry col) to give the glassy acid **20***b* (150 mg; 92%; *2-(4-(2-hydroxyisopropyl)-2,5-dimethoxyphenyl)-2,6,6-trimethylcyclohexylethanoic acid*); uv: 232(sh, 4600) and 289(2700) nm; ir: 3600–2500 (br, COOH) and 1700 cm^{-1}; H nmr δ: 0.95 (s, 6H, *gem* diMe), 1.37 (s, C.10-H), 1.18 and 1.21 (3d, J = 7 Hz, iPr Me – two isomers), 1.97 (dd, J = 16 and 7 Hz, C.6-H), 3.05 (dd, J = 7 and 5 Hz, C.5-H), 3.73 and 3.80 (2s, Ar-OMe), 6.31 (br, 2H, COO*H* and OH (D_2O)), 6.63 and 6.65 (2s, total 1H, C.8-H – two isomers), and 6.84 (s, C.14-H); ^{13}Cmr, see table; ms m/e: 378 (M^+).

*Formation of ketone **21***

The acid **20***b* (160 mg) was stirred in trifluoroacetic anhydride (6 mL) for 12 h at room temperature. After isolation by ether extraction, the crude enol trifluoroacetate was hydrolysed by stirring for 1 h at room temperature in MeOH (20 mL) containing 10% aqueous NaOH (15 mL). Dry col chrom of the yellowish oil gave the cyclized ketone **21** (75 mg; 48%; *7-oxo-11,14-dimethoxy-16-hydroxyabieta-8,11,13-triene*), mp 92–95°C; uv: 231(10 200), 261(4200), and 330(2500) nm; ir: 3440 and 1680 cm^{-1}; H nmr δ: 0.96, 0.99, and 1.36 (3s, Me-C), 1.28 (d, J = 7 Hz, Me-CH), 1.82 (dd, J = 10 and 7 Hz, C.5-H), 1.99 (m, OH (D_2O)), 2.52 (dd, J = 10 and 17 Hz, C.6-H), 2.72 (dd, J = 17 and 7 Hz, C.6-H), 3.40 (sex, J = 7 Hz, Me-C*H*), 3.72 (d, 2H, J = 7 Hz, CH_2OH), 3.78 and 3.81 (2s, Ar-OMe), and 6.95 (s, arom H); ^{13}Cmr, see table; ms m/e: 360 (M^+).

*Oxidation to the enolic α-diketone **22**a*

The ketone **21** (72 mg) in *t*-BuOH (10 mL) was added to a solution prepared by dissolving potassium (1.6 g) in *t*-BuOH (40 mL). The mixture was vigorously stirred under oxygen for 1 h and then the crude product, obtained by extraction, was purified by dry col chrom to give the enol **22***a* (45 mg; 60%; *7-oxo-11,14-dimethoxy-6,16-dihydroxyabieta-5,8,11,13-tetraene*); uv: 245(10 200), 273(5900), and 340(6800) nm; ir: 3430, 3340, and 1620 cm^{-1}; H nmr δ: 1.28 and 1.31 (2d, 3H total, J = 7 Hz, Me-CH), 1.46 (s, 6H, *gem* diMe), 1.64 (s, C.10-Me), 3.36 and 3.83 (m, 3H, CH_2OH and C.15-H), 3.76 and 3.86, (2s, Ar-OMe), 7.04 (s, arom H), and 7.40 (s, OH (D_2O)); *Exact Mass* (m/e) calcd. for $C_{22}H_{30}O_5$: 374.2093; found: 374.2109.

A second, much more polar product was also obtained from the dry col. From the following characteristics and analogy with similar products, this minor component must be the lactol **23** (21 mg; 26%); uv: 212(7200), 233(3900), 264(1700), and 326(1100) nm; ir: 3400 and 1685 cm^{-1}; H nmr δ: 1.11, 1.21, and 1.46 (3s, Me-C), 1.29 (d, J = 6.5 Hz, Me-CH), 3.26–3.89 (m, 3H, CH_2OH and C.15-H), 3.80 and 3.83 (2s, Ar-OMe), and 6.99 (s, arom H).

Methylation to the trimethyl ether ***22b***

To the enolic α-diketone ***22a*** (40 mg) in MeOH (7 mL) was added 30% aqueous NaOH (5 mL). After stirring for 20 min, dimethyl sulfate (3 mL) was added and the mixture stirred at room temperature for 36 h. The extracted material was purified by dry col chrom affording the trimethyl ether ***22b*** (35 mg; 84%; *7-oxo-6,11,14-trimethoxy-16-hydroxyabieta-5,8,11,13-tetraene*), mp 99−100°C (from ether−hexane); uv: 226(sh, 17 400), 249(11 000), 271(sh, 8900), 296(7200), and 338(6300) nm; ir: 3420 and 1650 cm^{-1}; H nmr δ: 1.29 (d, J = 7 Hz, Me-CH), 1.43 (s, 6H, *gem* diMe), 1.63 (s, C.10-Me), 3.27−3.84 (m, CH_2OH and C.15-H), 3.72 (s, 6H, MeO at C.14 and C.6), 3.85 (s, MeO at C.11), and 6.78 (s, arom H); *Exact Mass* (*m/e*) calcd. for $C_{23}H_{32}O_5$: 388.2250; found: 388.2268.

Reaction of the dimethoxy ester ***14a*** *with* N-*bromosuccinimide*

N-Bromosuccinimide (92 mg) was introduced to a solution of dimethoxy ester ***14a*** in CCl_4 (10 mL). The mixture was heated to reflux and then illuminated (Photoflood DXC) for 50 min, the lamp acting as a source of both light and heat. The cooled solution was filtered and then evaporated in the presence of silica gel (1 g) and then chromatographed (dry col, hexane−EtOAc 9:1). Three products were obtained (in order of increasing polarity).

(*i*) *Olefin* ***25*** (32 mg; 25%; oil; *methyl 2-(4-isopropenyl-2,3-dimethoxyphenyl)-2,6,6-trimethylcyclohexylethanoate*); ir(film): 1738 cm^{-1}; H nmr δ: 0.93, 1.00, and 1.35 (3s, Me-C), 2.13 (m, J = 1 Hz, CH_3—C=CH_2), 2.92 (t, J = 6 Hz, C.5-H), 3.32 (s, COOMe), 3.76 and 4.04 (2s, Ar-OMe), 5.10 (m, H_2C=C), and 6.90 (ABq, J = 8 Hz, 2 arom H); ^{13}Cmr, see table.

(*ii*) *Bromohydrin* ***26*** (66 mg; 41%; oil; *methyl 2-(4-(2-bromo-1-hydroxyisopropyl)-2,3-dimethoxyphenyl)-2,6,6-trimethylcyclohexylethanoate*); ir(film): 3500 and 1740 cm^{-1}; H nmr δ: 0.92, 0.99, 1.34, and 1.69 (4s, Me-C), 3.33 (s, COOMe), 3.85 (m, CH_2Br), 3.91 and 3.96 (2s, Ar-OMe), and 7.02 (s, 2H, arom H); ^{13}Cmr, see table.

(*iii*) *Alcohol* ***24*** (42 mg; 31%; oil; *methyl 2-(4-(1-hydroxyisopropyl)-2,3-dimethoxyphenyl)-2,6,6-trimethylcyclohexylethanoate*); ir(film): 3520, 3440, and 1735 cm^{-1}; H nmr δ: 0.91, 1.00, 1.45, and 1.70 (6H, 4s, Me-C), 3.96 and 3.97 (2s, Ar-OMe), 4.40 (br s, OH (D_2O)), and 6.94 (ABq, J = 8 Hz, arom H).

Alcohol ***28a*** *from bromohydrin* ***26***

To the bromohydrin ***26*** (118 mg) in MeOH (25 mL) was added K_2CO_3 (55 mg) and the mixture was stirred at room temperature for 90 min. The MeOH was evaporated and the residue triturated with CCl_4 which was filtered and evaporated to give the epoxide(s) as a yellow oil (106 mg; ir: 1734 cm^{-1}; H nmr δ: 0.91, 0.99, 1.33, and 1.64 (4s, Me-C), 3.28 and 3.30 (2s, 3H, COOMe − two isomers), 4.01 (s, Ar-OMe), and 6.93 (s, 2H, arom H)).

Without further purification the epoxide(s) ***27*** (90 mg) in THF was added to a solution of diborane (0.23 mL of 1.0 *M* in THF) and BF_3·etherate (0.25 mL) in THF (2 mL), and cooled to 0°C. After stirring for 30 min, water was added to stop the reaction, the solution was saturated with K_2CO_3, and the product obtained by ether extraction. The crude oily material was purified by dry col chrom, affording the alcohol ***28a*** as a pale yellow oil (74 mg; 75% from the bromohydrin; *methyl 2-(4-(2-hydroxyisopropyl)-2,3-dimethoxyphenyl)-2,6,6-trimethylcyclohexylethanoate*); ir: 3440 and 1730 cm^{-1}; H nmr δ: 0.91, 0.98, and 1.33 (3s, Me-C), 1.22 and 1.23 (2d, J = 7 Hz, iPr Me), 3.28 (s, COOMe), 3.40 (m, iPr CH), 3.66 and 3.67 (2d, J = 7 Hz, CH_2OH), 3.79 (s, Ar-OMe), 3.98 and 3.99 (2s, 3H, Ar-OMe − two isomers), and 6.92 (ABq, J = 8 Hz, arom H); ^{13}Cmr, see table; *Exact Mass* (*m/e*) calcd. for $C_{23}H_{36}O_5$: 392.2563; found: 392.2562.

Alcohol ***28a*** *from olefin* ***25*** *and from alcohol* ***24***

The tertiary alcohol ***24*** (40 mg) was refluxed in glacial HOAc (10 mL) for 2.5 h and the solution then evaporated under vacuum. The residue was taken up in hexane−EtOAc (9:1) and filtered through a short column of silica gel. Two products were obtained, the more polar starting material (6 mg) and a pale yellow oil (21 mg; 65%), identical with the olefin ***25*** described above.

The olefin ***25*** (60 mg) in THF (4 mL), cooled in an ice bath, was treated with borane − methyl sulfide (0.05 mL of 10.2 *M*). After stirring for 10 h, aqueous NaOH (0.3 mL of 10%) was added, followed by H_2O_2 (30 wt.%, 0.12 mL). The mixture was heated to reflux for 1 h and then the crude product (57 mg) was obtained by ether extraction. Dry col chrom afforded the alcohol ***28a*** (49 mg; 78%; identical with that obtained earlier).

Hydrolysis of ester ***28a*** *and cyclization to the ketone* ***29***

To the ester ***28a*** (120 mg) in MeOH (10 mL) was added aqueous KOH (10 mL of 10%) and the mixture was refluxed for 4 h. Most of the MeOH was removed at the pump and the aqueous residue was washed with ether, acidified with concentrated HCl, and then extracted with ether to give the acid ***28b*** (110 mg; *2-(4-(2-hydroxyisopropyl)-2,3-dimethoxyphenyl)-2,6,6,-trimethylcyclohexylethanoic acid*); ir: 1700 cm^{-1}; H nmr δ: 0.89, 0.96, and 0.94, 0.97 (two × 2s, 2 Me-C, two isomers), 1.19 (d, J = 7 Hz, iPr Me), 1.32 (br s, Me-C), 3.30 (sex, C.15-H), 3.65 (d, J = 7 Hz, CH_2OH), 3.73 (s, Ar-OMe), 3.94 and 3.95 (2s, Ar-OMe − two isomers), 6.10 (br s, COOH and OH), and 6.90, 6.91 (2 × ABq, J = 8 Hz, 2 arom H − two isomers); ^{13}Cmr, see table; ms *m/e*: 378 (M^+).

The acid ***28b*** (100 mg − without further purification) was stirred in trifluoroacetic anhydride (4 mL) for 6 h at room temperature. The reaction mixture was poured onto ice and the product obtained by ether extraction (the enol trifluoroacetate) was hydrolysed by standing in aqueous KOH (5 mL of 10%). Ether extraction gave a yellowish neutral oil which was chromatographed (dry col) to afford the ketone ***29*** (oil, 73 mg; 72%; *7-oxo-11,12-dimethoxy-16-hydroxyabieta-8,11,13-triene*); ir: 3430 and 1680 cm^{-1}; H nmr δ: 0.96, 1.00, and 1.40 (3s, Me-C), 1.24 and 1.29 (2d, J = 7 Hz, iPr Me), 3.38 (sex, J = 7 Hz, iPr CH), 3.70 and 3.73 (2d, J = 7 Hz, CH_2OH), 3.86 (s, 6H, Ar-OMe), and 7.76 (s, arom H); ^{13}Cmr, see table; *Exact Mass* (*m/e*) calcd. for $C_{22}H_{32}O_4$: 360.2301; found: 360.2291.

Enolic α-diketone ***30a***

The ketone ***29*** (70 mg) in *t*-BuOH (10 mL) was added to the solution prepared by dissolving potassium (0.5 g) in *t*-BuOH (12 mL). A stream of oxygen was passed through the solution which became increasingly yellow. After 75 min the mixture was poured into ice-water, acidified with concentrated HCl, and extracted with ether. Evaporation gave a yellow oil which on dry col chrom gave the diosphenol ***30a***, mp 129−130°C (colorless needles from hexane/EtOAc; 46 mg; 65%; *7-oxo-11,12-dimethoxy-6,16-dihydroxyabieta-5,8,11,13-tetraene*); uv: 243(15 000), 279(16 000), and 321(17 000) nm; ir: 3580, 3480, 3360, 1625 and 1590 cm^{-1}; H nmr δ: 1.28 and 1.31 (2d, J = 7 Hz, iPr Me), 1.48 (6H) and 1.66 (2s, 3 Me-C), 3.40 (m, iPr CH), 3.72 and 3.80 (2d, J = 7 Hz, CH_2OH), 3.86 and 3.93 (2s, 2 Ar-OMe), 7.09 (s, OH (D_2O)), and 7.87 (s, arom H); ^{13}Cmr, see table; ms *m/e*: 374 (M^+) and 289. *Anal.* calcd. for $C_{22}H_{30}O_5$: C 70.56, H 8.08; found: C 70.30, H 8.21.

O-*Methylation of the enolic α-diketone* ***30a***

The enol ***30a*** (36 mg) in 50% aqueous EtOH (6 mL) was treated first with aqueous NaOH (2 mL of 30%) and then (slowly) with dimethyl sulfate (1.0 mL). After stirring for 24 h at room temperature, more water was added, the solution was acidified with dilute HCl, and the product was then obtained by ether extraction. Dry col chrom of the yellowish oil afforded first a tetra-O-methyl ether ***30c*** (8 mg; 21%) and then the tri-O-methyl ether ***30b*** (17.2 mg; 46%; *7-oxo-6,11,12-trimethoxy-16-hydroxyabieta-5,8,11,13-tetraene*), mp 159−160°C (from hexane−EtOAc; lit. (1) mp 153−154°C); uv: 240(7000), 275(9000), and 302(9500) nm; ir: 3500, 1638, and 1590 cm^{-1}; H nmr δ: 1.26 and 1.29 (2d, J = 7 Hz, iPr Me; lit. 1.29), 1.42 and 1.65 (2s, Me-C; lit. 1.44 and 1.64), 3.45 (m, C.15-H; lit. 3.43), 3.70 (m, CH_2OH; lit. 3.73), 3.80, 3.83, and 3.90 (3s, Ar-OMe), and 7.81 (s, arom H; lit. 7.80); ^{13}Cmr, see table; ms *m/e*: 402 (M^+), 387, 359, and 333 (base). *Anal.* calcd. for $C_{23}H_{32}O_5$: C 71.10, H 8.30; found: C 70.81, H 8.08.

Conformational consequence of stereoelectronic effects in seven-membered cyclic acetals: nuclear magnetic resonance investigation of 1,3-benzodioxepin and its 2-substituted derivatives

ROBERT ST-AMOUR, M. T. PHAN VIET, AND MAURICE ST-JACQUES

Département de Chimie, Université de Montréal, C.P. 6210, Succ. A, Montreal (Qué.), Canada H3C 3V1

Received March 28, 1984

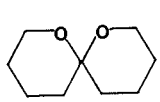
ROBERT ST-AMOUR, M. T. PHAN VIET, and MAURICE ST-JACQUES. Can. J. Chem. **62**, 2830 (1984).

The conformational and dynamic properties of 1,3-dioxa-4,5-benzocycloheptene (**8**) and several 2-substituted derivatives were investigated by ^1H and ^{13}C low temperature nmr methods. The results are strikingly different from those reported for the analogous symmetrical dioxepin isomers derived from **2**. The unexpectedly large preference of the 2-methoxy derivative (**8***c*) for the C_e conformation is explained in terms of deformed torsional angles in the seven-membered ring relative to those in the analogous six-membered one. These results therefore help delineate the limitations to the conformational biasing normally associated with the anomeric effect.

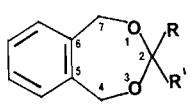
ROBERT ST-AMOUR, M. T. PHAN VIET et MAURICE ST-JACQUES. Can. J. Chem. **62**, 2830 (1984).

Les propriétés conformationnelles et dynamiques du dioxa-1,3 benzo-4,5 cycloheptene (**8**) et de quelques dérivés en position 2 ont été étudiées par les techniques de rmn ^1H et ^{13}C à basse température. Les résultats obtenus sont très différents de ceux précédemment rapportés pour les isomères analogues de la benzodioxépine symmétrique dérivés de **2**. La grande préférence du dérivé méthoxy-2 (**8***c*) pour la forme C_e est expliquée par une déformation des angles de torsion du cycle à sept chaînons comparativement aux dérivés analogues cycliques à six chaînons. Ces résultats permettent de mieux circonscrire les conséquences conformationnelles associées à l'effet anomère.

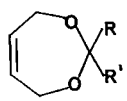
Stereoelectronic effects (1) in acetals and related functions have recently brought into focus the important relationship between conformation and reactivity for several classes of molecules. Studies on the simplest acetal, dimethoxymethane (2), indicate that the g^+g^+ arrangement is most stable in conformity with observations made on carbohydrates (3) and 2-substituted tetrahydropyrans (4). This preference constitutes the basis of the anomeric and the *exo*-anomeric effects extensively investigated for these molecules (5). The relative stabilities of the various arrangements possible for a $—CH_2—O—CH_2—O—CH_2—$ fragment have been difficult to assess (1) and the need for a quantitative evaluation based on experimental measurements led to the recent investigation (6) of a broader range of stereochemical arrangements as exist in bicyclic acetals such as **1**. By comparison, studies of the cyclic acetal 1,3-dioxane are limited because of the relatively high conformational energy of the twist-boat (*TB*) conformation (7) and the fact that only highly substituted derivatives have been found to exist in this form.



1

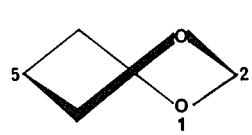


2

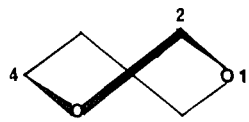


3

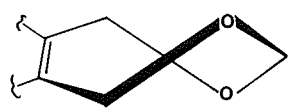
The two possible *TB* forms of 1,3-dioxane (**4** and **5**) are characterized by $—CH_2—O—CH_2—O—CH_2—$ fragments in the g^+g^+ disposition and slightly deformed g^+g^- disposition respectively. Previous studies (7) could not clearly distinguish experimentally between these forms because they interconvert easily as a result of the low energy barrier for the pseudorotation motion involved, although calculations suggest that **5** is more stable than **4** (7). In contrast, the dioxepins **2** and **3** provided an opportunity (8, 9) to investigate experimentally the stabilizing effect associated with the g^+g^+ acetal arrangement in a ring system because the only *TB* form possible for these molecules has the appropriate bond disposition as shown by **6**. On the other hand, the features of **5** can be found in a benzocycloheptene derivative only if a change in the position of the



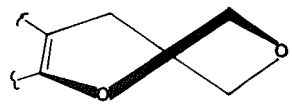
4



5



6



7

oxygen atoms takes place as in **7**, which represents the *TB* form of 1,3-benzodioxepin (**8**).

In addition, previous nmr observations on the 2-methoxy derivative of **2** (R = H, R' = OCH_3) have provided unique insight into the conformational change caused by the polar substituent. Whereas, for the analogous six-membered orthoformate 2-methoxy-1,3-dioxane, both axial and equatorial chair conformations (i.e. C_a and C_e respectively) are observed (10), the 2-methoxy derivative of **2** was found to exist only in the *TB* form (8). Presumably, repulsive steric interactions destabilize the C_a form while electronic factors destabilize the C_e form and stabilize the *TB* form.

Consequently, we sought to identify and quantify the various factors governing the conformational properties of seven-membered rings containing the acetal and related functions through a dynamic ^1H and ^{13}C nmr investigation of compounds **8** to **8***e*. The results show a behavior strikingly different from that of the symmetrical series **2** and provide a better appreciation of factors affecting the generalized anomeric effect.

Results

Variable temperature ^1H and ^{13}C nmr studies of compounds **8** to **8***e* revealed spectral modifications for all compounds except **8***a*. Table 1 contains a summary of the ^1H nmr parameters

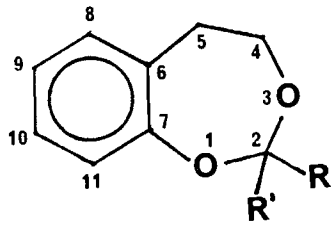
[a] Determined from spectra at 400.1 MHz.
[b] Because of the extensive averaging existing for these compounds, averaged coupling constants were not determined.
[c] This coupling constant is small and was not determined under the conditions used.
[d] The various coupling constants were determined by spectral simulation using the PANIC program included with the Bruker Aspect 2000 software package.



8 R = R' = H
8*a* R = H, R' = CH_3
8*b* R = H, R' = t-Bu
8*c* R = H, R' = OCH_3
8*d* R = CH_3, R' = CH_3
8*e* R = CH_3, R' = OCH_3

obtained at high and low temperatures for all six compounds, while Table 2 contains corresponding ^{13}C chemical shifts. The characteristic spectral changes observed are described next.

For compound **8** in CHF_2Cl only the ^{1}H nmr spectrum, recorded at 400.1 MHz, was found to undergo a change, as illustrated in Fig. 1. The singlet of the methylene protons at position 2 (H-2) splits into an AX pattern, whereas the signals of the H-4 and H-5 methylene protons also broaden and split, so that a 4-spin first-order pattern is observed at −137°C. Spectral analysis gave the parameters reported in Table 1, except for $^3J_{5e4e}$, which is too small to be observed in the low temperature spectrum. The various signals at −137°C are labelled in accordance with conformational assignments made in the next section. Finally, a free energy of activation of 8.4 kcal/mol is calculated at −77°C (the coalescence temperature T_c) from the splitting of the H-2 signal using the two-site approximation and a transmission coefficient of one-half (8).

Only the *tert*-butyl methyl signal of **8***b* showed a change at low temperature. At 20.15 MHz, the methyl ^{13}C nmr singlet was observed to split into a doublet with component intensity 2:1 at 157°C. A free energy of activation of 6.1 kcal/mol was estimated at −149°C (T_c) using the two-site approximation and a transmission coefficient of one.

Compound **8***c* (R = H, R^1 = OCH_3) showed a more complex behavior. Whereas both high field ^{1}H and ^{13}C nmr spectra for CHF_2Cl solutions were found not to change at low temperature, a change of solvent to dimethyl ether enabled a spectral change to be observed. Figure 2 illustrates the 100.6 MHz ^{13}C nmr spectral modification detected for the sp^3 carbon atoms. It is seen that C-2 and C-4 have broadened appreciably at −92°C and then split into doublets whose unequally intense components are identified by C_e and C_a in accordance with conformational arguments presented in the next section. Whereas the C_a lines of the C-2 signal and C-5 are readily observed, that of C-4 is most probably under the large solvent signal. The slight broadening of C-5 at −92°C is compatible with the closely spaced lines at −132°C. The OCH_3 signal is also very narrow at −92°C; if it does split, the minor component would be at lower field under the solvent peaks. Integration of the C-2 signals at −132°C yields 88% for the C_e line and 12% for the C_a line. Furthermore, an estimate of 7.8 kcal/mol is obtained for the free energy of activation at −88°C using the two-site approximation and a transmission coefficient of one. The free energy difference (ΔG^0) at −132°C is 0.56 kcal/mol.

The 400.1 MHz ^{1}H spectrum of **8***c* was recorded in CHF_2Cl and two other solvents. First-order analysis at high temperature provided the parameters in Table 1. The low temperature ^{1}H spectrum of **8***c* in CHF_2Cl is found much less useful than the ^{13}C spectra to identify the small signals arising from the minor conformation and was not studied in this work.

Both ^{1}H and ^{13}C high field nmr spectra of compound **8***d* (R = R^1 = CH_3), exhibited spectral changes at low temperatures. Figure 3 shows the effect of temperature on the ^{13}C spectra at 100.6 MHz in CHF_2Cl. It is seen that both the C-4 and C-5 signals split into doublets of unequal intensities labelled *C* and *TB* in accordance with conformational conclusions drawn in the next section. The methyl signal, on the other hand, shows a more complex behavior whereby it broadens and splits ($T_c \approx$ −73°C) into a broad doublet (−103°C in Fig. 3) which eventually becomes a four-line signal at −123°C; two lines are equally tall (88%), and the two other equally small (12%). Furthermore, the ^{13}C spectra of **8***d* in dimethyl ether showed a similar pattern with signals at −128°C in a ratio of 95:5; chemical shifts are very similar to those determined in CHF_2Cl and reported in Table 2. The free energy differences between

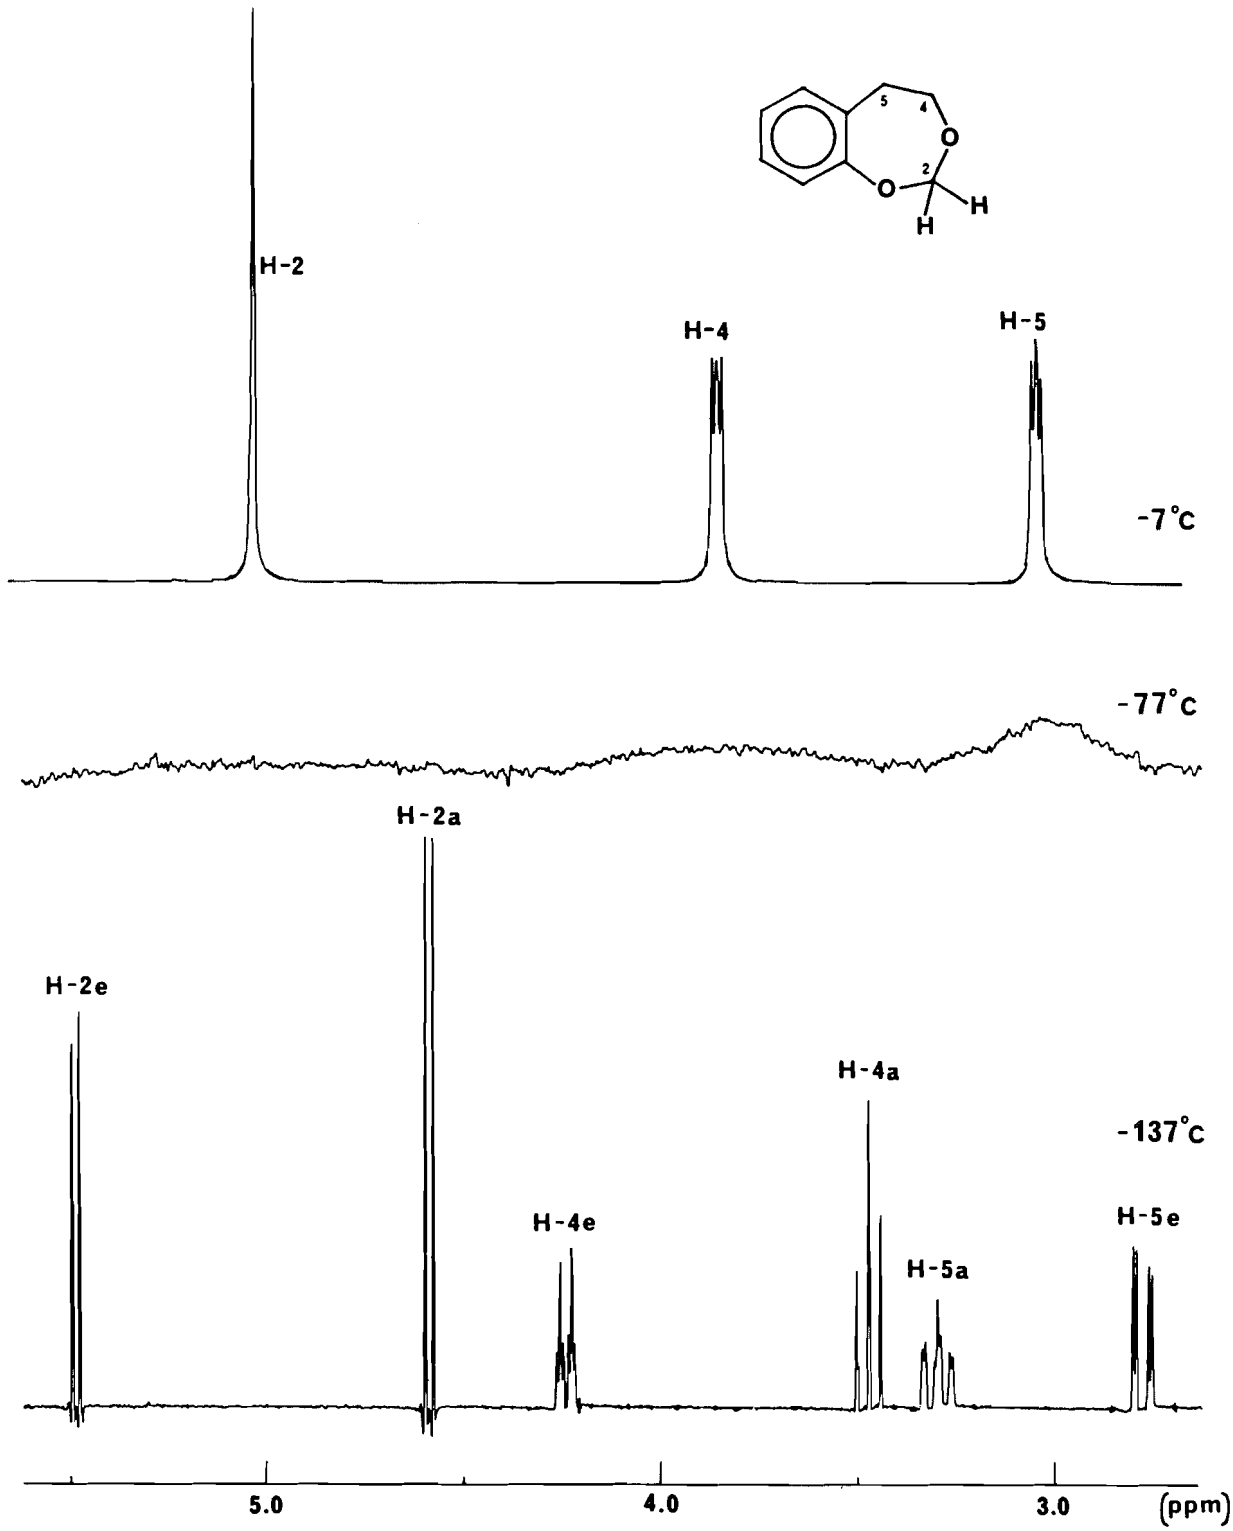

FIG. 1. Partial 400.1 MHz ^{1}H nmr spectra of the methylene protons of **8** in CHF_2Cl at several temperatures.

C and *TB* are 0.60 kcal/mol for CHF_2Cl at −123°C and 0.85 kcal/mol for CH_3OCH_3 at −128°C.

The two-site approximation yields a free energy of activation of about 7.8 kcal/mol at −93°C (T_c) from the splitting of the C-4 line in CHF_2Cl using a transmission coefficient of one. In addition, a complete lineshape analysis of the methyl signal changes (described in the next section) using the DNMR-2 program (ref. 11; a copy of the program was obtained from QCPE) gave two free energy values: 8.3 kcal/mol at −68°C and 7.5 kcal/mol at −101°C.

The 400.1 MHz ^{1}H nmr spectrum of **8***d* shows important changes for the H-4, H-5 and CH_3 signals. Firstly, the methyl singlet at room temperature splits at −90°C into an intense doublet and a weak one, centered at 1.47 ppm (separation = 148 Hz) and 1.53 ppm (separation = 112 Hz), respectively, at −130°C. Secondly, the room temperature triplet of the H-5

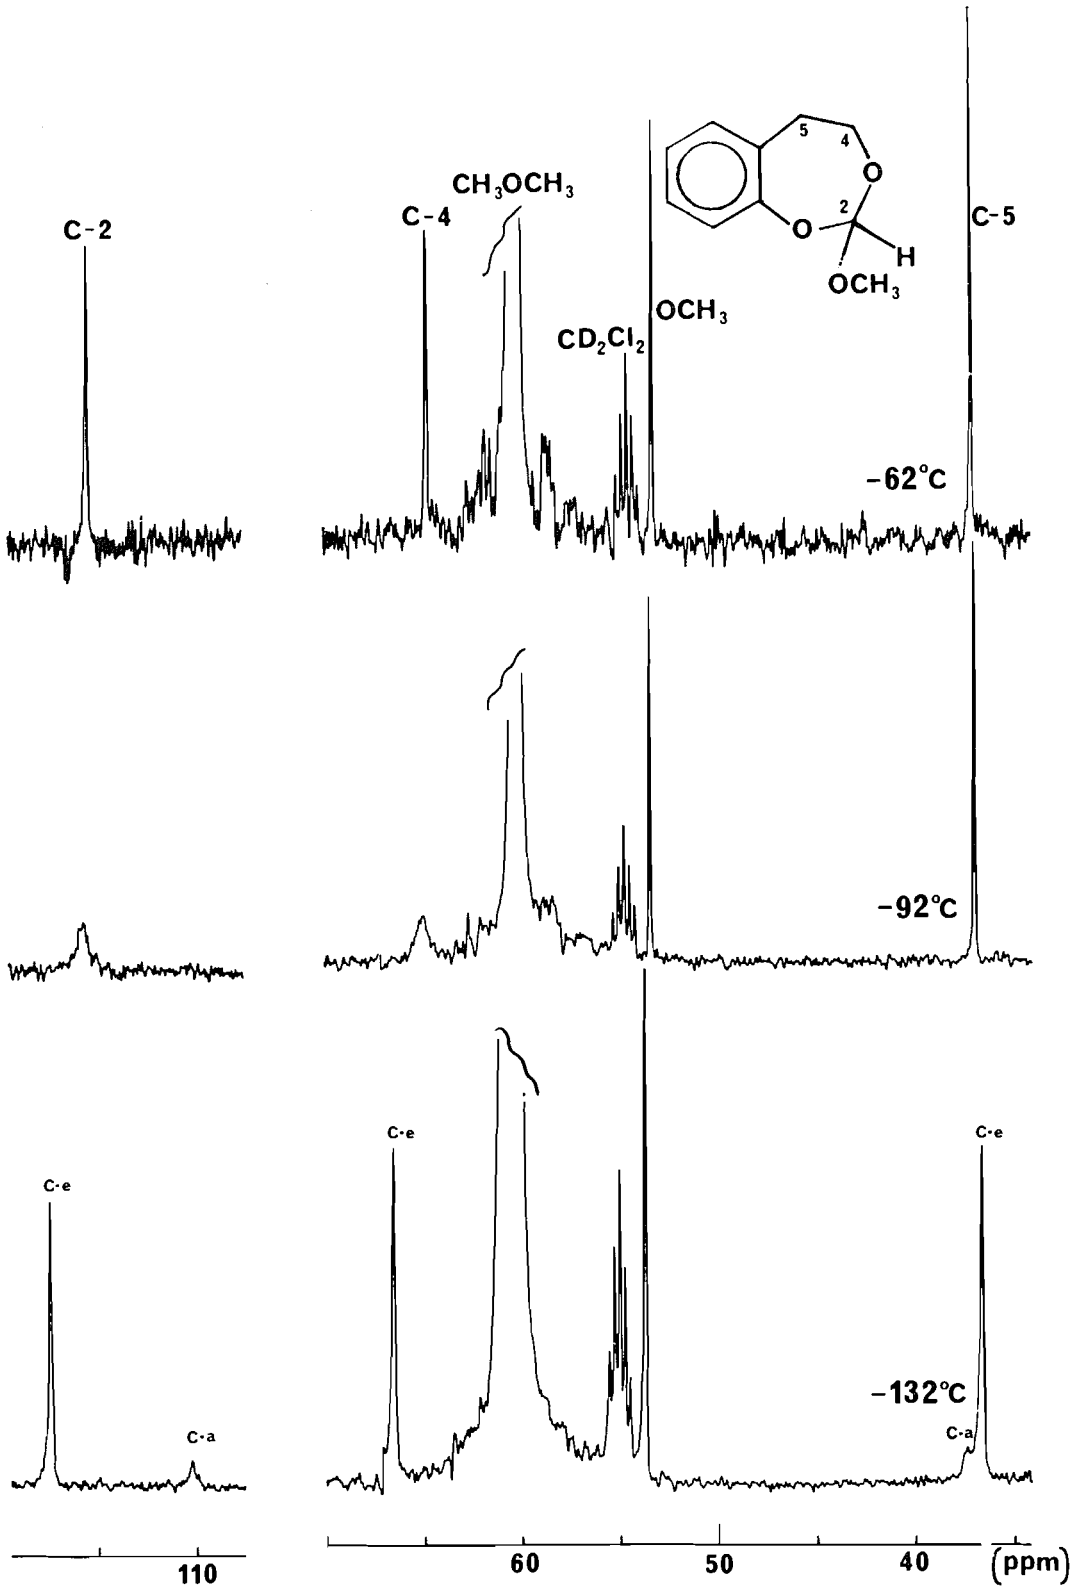

FIG. 2. Partial 100.6 MHz ^{13}C nmr spectra of the aliphatic carbons of **8***c* in CH_3OCH_3 at several temperatures.

methylene group changes below −90°C into a doublet and a quintet, in the ratio 1:1 for the major species and two broad unresolved signals for the minor one (~3.4 and ~2.9 ppm). Finally, the triplet of the H-4 methylene group becomes a doublet for the major conformer and two unresolved signals for the minor one (~4.2 and ~3.7 ppm). The spectrum of the major conformer of **8***d* at −130°C shows a pattern containing elements of deceptively simple spectra arising from the accidental equivalence of the H-4a and H-4e chemical shifts. The ^1H parameters were determined by a simulation using the

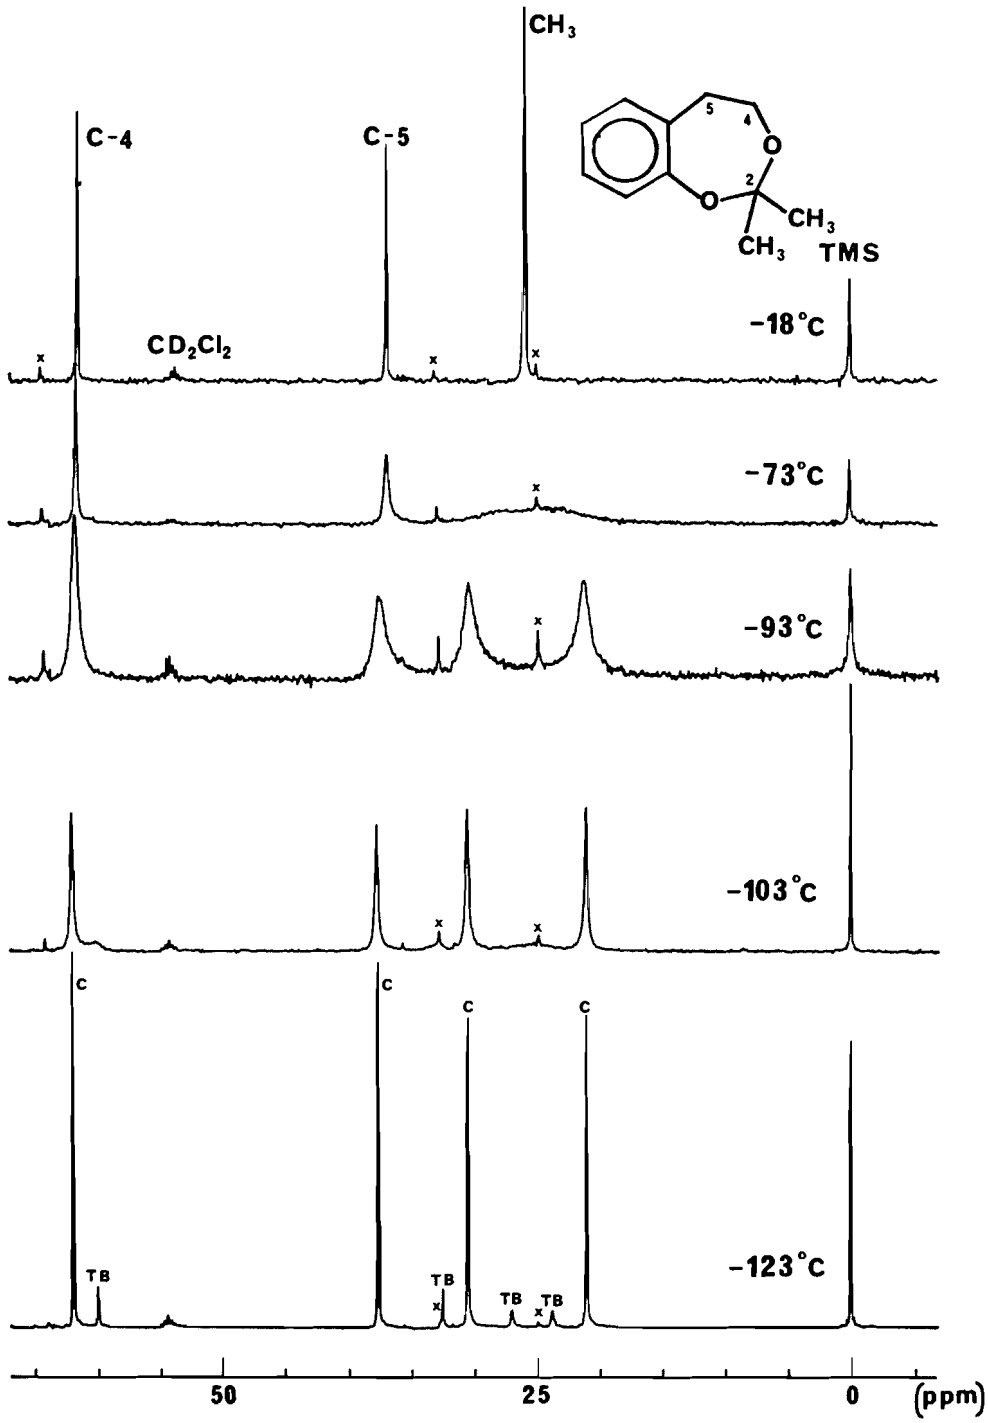

FIG. 3. Partial 100.6 MHz ^{13}C nmr spectra of the methylene and methyl carbons of **8***d* in CHF_2Cl at several temperatures (× denotes impurities).

PANIC program and are reported in Table 1.

Although the ^1H nmr spectrum of **8***e* (R = CH_3, R^1 = OCH_3) does not show a spectral modification of conformational dynamic origin, it shows, on lowering the temperature, large changes in chemical shifts which lead eventually to the merging of the signals of H-4e and H-4a, so that at −125°C only one signal is observed for the two H-4 protons. All other signals remain unchanged and the ^1H parameters at −90°C are reported in Table 1. The ^{13}C nmr spectra do not change on lowering the temperature and the ^{13}C parameters are reported in Table 2.

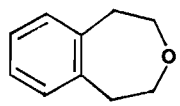
Discussion

Identification of the stable conformations

The absence of change in the ^{13}C nmr spectra of **8** down to −135°C indicates that it exists in only one conformation capable of an inversion process detected by the ^1H spectral modification shown in Fig. 1. The geometry of the stable conformation of **8** can be deduced from the following evidence, which points to a chair form.

One argument is based on the fact that the $^2J_{HH}$ coupling between the benzylic methylene protons is dependent on the

proton orientations with respect to the benzene ring (12). Assuming that the second oxygen at position 1 in **8** should not affect $^2J_{5a,5c}$ significantly, the value of −15.4 Hz (Table 1), being similar to the corresponding (13) value of −15.3 Hz for the chair form of 5-oxabenzocycloheptene (**9**), suggests that **8** and **9** should have a similar angular relationship about the C(5)—C(6) bond. This constraint is respected only if **8** also exists in the chair form. Confirming evidence is provided by a comparison of the vicinal coupling constants characterizing the C(4)—C(5) bond of **8** (given in Table 1), which are found to be similar to those reported earlier for the chair form of **9** ($^3J_{aa}$ = 11.2, $^3J_{ee}$ = 5.0, $^3J_{ae}$ = 2.0, and $^3J_{ea}$ = 0.6 Hz).

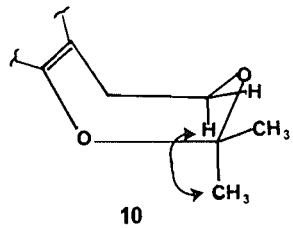


9

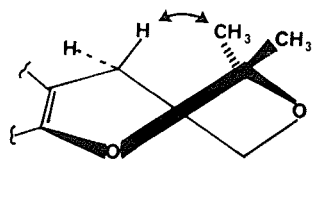
The interpretation of the data obtained for the methyl derivative (**8***a*) clearly shows that it exists exclusively in the C_e conformation. Firstly, Table 1 shows that ^{1}H chemical shifts and coupling constants of H-4 and H-5 are very similar to those characterizing the chair form of **8**. Secondly, the equatorial orientation of the methyl group is indicated by the comparison of the ^{13}C α, γ, and δ parameters characterizing C-2, C-4, and C-5 (namely 6.8, −0.7, and −0.6 ppm), with corresponding values (14) reported for the equatorial form of 2-methyl-1,3-dioxane (5.0, −0.1, and −0.8 ppm). Furthermore, analogous values for the C_e form of the 2-methyl derivative of **2** (i.e. **2***b*) are 6.22, −1.54, and −0.21 ppm (8). Thus the methyl group in **8***a* is equatorial and the larger γ parameter for **2***a* (−1.54 vs. −0.7 ppm) suggests that the dihedral angles about the C(2)—O(3) bond differ slightly in each seven-membered chair (15). Similarly, both ^{1}H and ^{13}C nmr data indicate that the *tert*-butyl derivative **8***b* also exists solely in the C_e form.

Before proceeding to the conformational analysis of compound **8***c* substituted with a polar methoxy group, it is useful to characterize the dimethyl derivative **8***d*. In contrast to the previous three compounds, the ^{13}C nmr spectra of **8***d* (Fig. 3) reveal the existence of two ring conformations in the ratio of 88:12 in CHF_2Cl. The assignment of the signals to the respective conformers is possible through a consideration of the ^{13}C parameters α, γ and δ relative to the chemical shifts of **8**. These values are 4.6, −8.0, and −0.8 ppm for the more intense signals and 5.8, −9.9, and −6.0 ppm for the weaker lines. The parameters determined for the intense signals are similar to those reported (14) for the chair form of 2,2-dimethyl-1,3dioxane (3.6, −7.0, and −0.9 ppm). It is therefore clear that the *C* conformation is dominant for **8***d*.

Possible conformations for the minor form of **8***d* are the boat (*B*) and twist-boat (*TB*) forms. Examination of structures **10** (*B*) and **11** (*TB*) shows that **10** contains a repulsive 1,3-*syn*-methyl-hydrogen interaction, whereas only a 1,4-methyl-hydrogen interaction is possible for **11**. The carbon-13 chemical shifts in Table 2 show that $\delta_{C\text{-}5}$ of the minor form is 5.17 ppm upfield from the signal of the major *C* form, whereas $\delta_{C\text{-}4}$ is only 1.97 ppm upfield. The upfield displacement for $\delta_{C\text{-}4}$ (γ effect) appears too small for *B* and the difference in chemical shifts observed for $\delta_{C\text{-}5}$ is similar to the difference observed (8) between the chemical shifts of the benzylic methylene carbons of the *C* and *TB* forms of **2**. These arguments therefore strongly indicate that the minor conformation of **8***d* has the *TB* geometry.



10



11

Additional support for the identity of the major conformation comes from the ^{1}H nmr parameters given in Table 1 for the most intense signals in the spectrum at −125°C, as determined by calculations using the PANIC program. The similar coupling constants for **8***d* and those for **8**, **8***a*, and **8***b* confirm that *C* is the predominant form for **8***d*.

It is interesting to draw attention to the near equivalence of the chemical shifts of H-4a and H-4e (~1 Hz difference) for the *C* form of **8***d*, while a difference of about 200–250 Hz characterizes the *C* form of the monosubstituted derivatives **8** to **8***b*. Anisotropic effects of the axial methyl group, whereby H-4a is deshielded by ~0.35 ppm and H-4e is shielded by ~0.3 ppm, are undoubtedly responsible in large part, as suggested by the report that, in 1,3-dioxanes, a 2-axial methyl group shifts H-4e upfield by about 0.16 ppm and H-4a downfield by about 0.2 ppm (16).

The presence of a single polar substituent in methoxy derivative **8***c* raises the interesting question of assessing the relative importance of stereoelectronic interactions involving the methoxy substituent on the relative stability of the possible conformations. The ^{13}C spectra in Fig. 2 show the existence of two conformations easily detected at −132°C in CH_3OCH_3 (88:12). Information on the geometry of the major form is derived in part from the proton–proton coupling constants reported in Table 1, where it is seen that all couplings are similar to those for the chair forms of **8**, **8***a*, **8***b*, and **8***d*. In addition, the ^{13}C parameters offer an equally valuable conformational probe because of the sensitivity of $\delta_{C\text{-}5}$ to ring conformation as was shown earlier (8, 15) for **2** and **3**, and in this work for **8***d*. Considering that a *TB* form should be characterized by a $\delta_{C\text{-}5}$ value about 5–6 ppm upfield from that observed for **8**, the observation that the C-5 chemical shifts of both lines of **8***c* are within 2 ppm of that of **8** suggests strongly that both conformations of **8***c* have a chair geometry.

The orientation of the OCH_3 substituent on the *C* form can now be determined from the analysis of α and γ substituent effects, which are known to be stereodependent. The corresponding substituent effects reported for 2-methoxy-1,3-dioxane are used as reference parameters (10); in CHF_2Cl at −144°C, the values are 19.1 and −1.3 ppm for C_e compared to 14.0 and −8.6 for C_a. As a consequence, the major conformer of **8***c*, being characterized by values of 19.2 and −2.6 ppm, is clearly the C_e form. Because the C-4 signal of the minor form was not located, only the α parameter can be used; its value of ~11.4 ppm (obtained using the data in CH_3OCH_3) is in reasonable agreement with the C_a form.

Furthermore, additional information on the relative populations of the C_e and C_a forms of **8***c* can be obtained at room temperature through the analysis of the weighted averaging of vicinal coupling constants for the $C(4)H_2$—$C(5)H_2$ fragment. Reference values for $^3J_{aa}$ and $^3J_{ee}$ are taken as those observed for **8***a* and **8***b* in $CDCl_3$, namely 11.8 and 3.7 Hz respectively. Thus the room temperature C_e/C_a ratio is found to be approximately 75:25 in $CDCl_3$ and 55:45 in CCl_4.

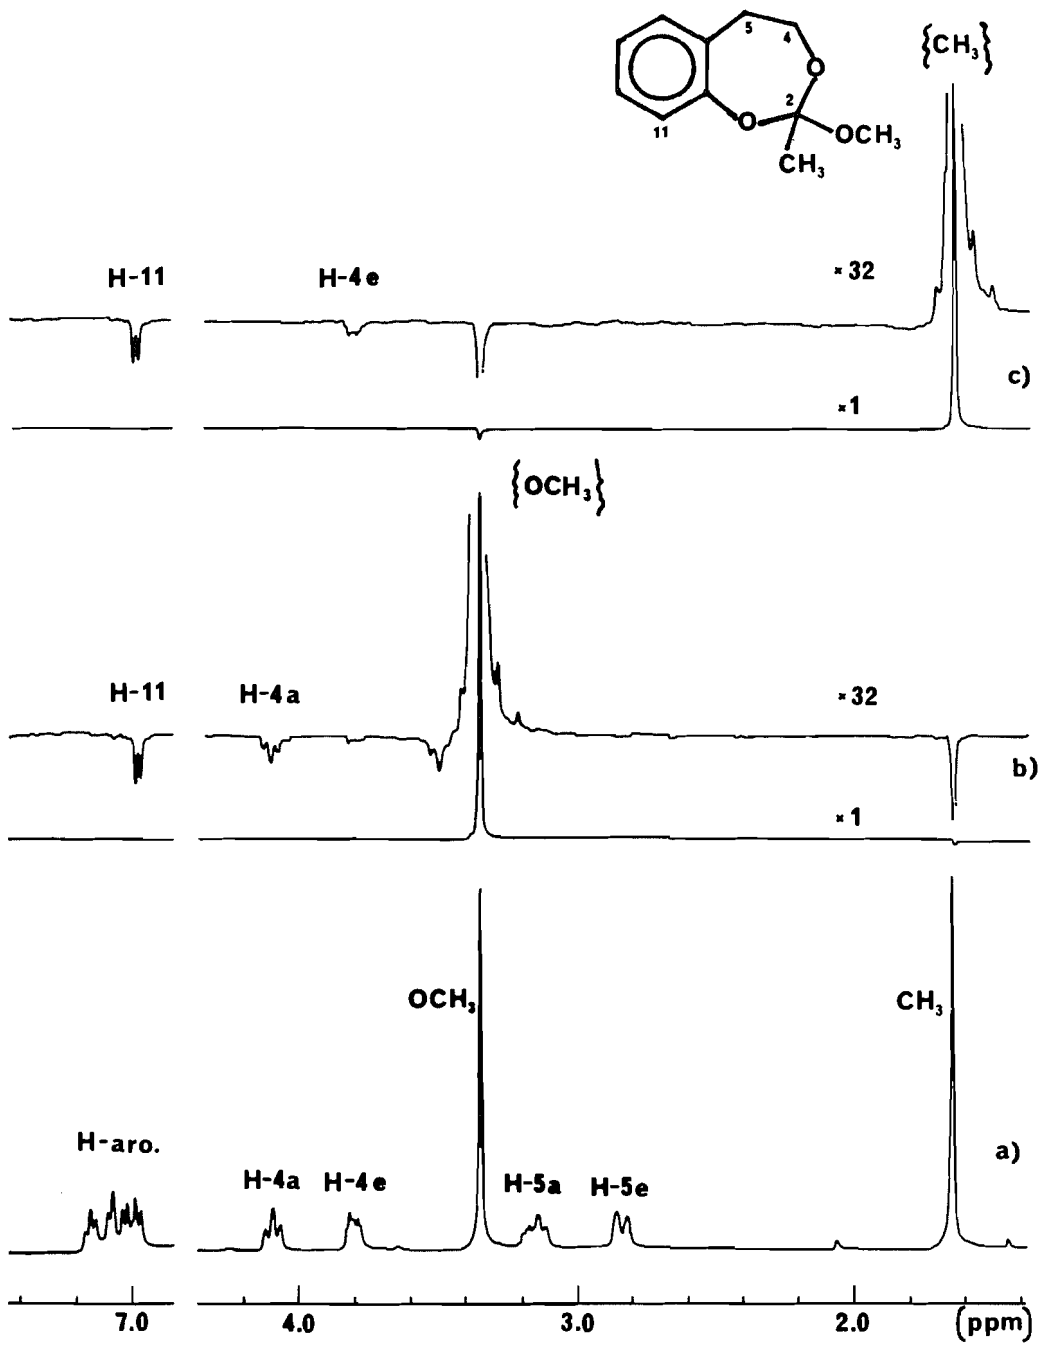

FIG. 4. The 400.1 MHz ^1H nmr spectra of **8***e* at room temperature. (a) Normal spectrum; (b) differential nOe spectrum produced by irradiation of the methoxy signal; and (c) effect produced by irradiation of the methyl signal. The effects of double irradiation are visible in the amplified (×32) spectra in (b) and (c).

Finally, compound **8***e* (OCH_3, CH_3) adopts only one stable conformation, as indicated by the absence of conformationally significant spectral change at low temperature. Coupling constants given in Table 1 indicate a chair form. Because the use of ^1H and ^{13}C nmr parameters does not lead to a clear-cut decision on the orientation of the methyl and methoxy groups, an nOe difference experiment on **8***e* was carried out at +20°C for a solution in $CDCl_3$ (see experimental section for details).

Figure 4 shows that irradiation of the methoxy protons produces a significant effect on the signal at δ_H 4.11, whereas irradiation of the methyl singlet produces an effect on the signal at δ_H 3.82. It is therefore possible to conclude that the signal at 4.11 ppm is *syn* to OCH_3 while the signal at 3.82 ppm is *syn* to the methyl group. The information that H-4a absorbs at 4.11 ppm, gained from the spectral analysis of the CH_2CH_2 pattern, indicates clearly that **8***e* exists in the chair form with the methoxy group in the axial position.

Features of the conformational equilibria

Table 3 shows that the families of compounds derived from **2** and **8** have different conformational properties, the most striking differences being manifested by **8***c*, **8***d*, and **8***e*.

At the outset it is useful to recall that the *TB* form of **2** is stabilized by the generalized anomeric effect (8). Consequently the conformational difference between **2** and **8** suggests significantly less stabilization of the acetal function in the *TB* form of

TABLE 3. Conformational equilibria[a] and activation energies[b] for the analogous series of compounds derived from **8** and **2**

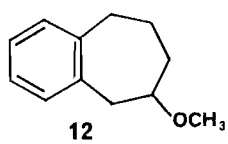
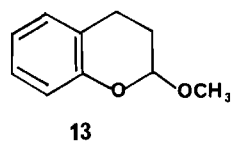
8. Indeed the C—O—C—O—C moiety has the most favorable g^+g^+ disposition in the *TB* conformation of **2** relative to the g^+g^- arrangement in *C*, while both the *TB* and *C* forms of **8** have the g^+g^- arrangement. It should be noted, however, that the g^+g^- bond arrangements are characterized by slightly different dihedral angles in the various forms.

In contrast to **2***c* for which only the *TB* form has been detected, the equilibrium $C_e \leftrightharpoons C_a$ has been identified for **8***c* in CH_3OCH_3. Surprisingly, the C_e form is found to be highly predominant at low temperature (88% at −132°C in CH_3OCH_3), contrary to straightforward expectation from the anomeric effect and steric interactions involving the axial OCH_3 group. In fact, previous studies (17) of 4-methoxybenzocycloheptene (**12**) have revealed that the C_a population at −100°C in CHF_2Cl is 37%, suggesting the absence of severe steric interactions.



12



13

The effect of successive incorporation of oxygen atoms in six-membered rings is revealed by low temperature nmr results (10), which have shown that the C_a amount in CHF_2Cl is 6% for methoxycyclohexane (at −128°C), 60% for 2-methoxytetrahydropyran (−130°C), and 30% for 2-methoxy-1,3-dioxane (−148°C), while the change of solvent to dimethyl ether increases these quantities to 13%, 84%, and 65% respectively. Finally, the oxygen atom at the benzylic position of **8***c* might also favor the C_a form, as a previous study of 2-methoxychromane (**13**) suggests (18). Why then is the axial form so weakly favored for **8***c* at low temperature? Obviously several factors must be examined in an attempt to rationalize this observation. The large equatorial preference for **8***c* may result from geometrical factors such as torsional angles specific to the seven-membered ring and (or) entropy effects, recently suggested as important for 2-methoxytetrahydropyran (19).

The fact that the $C_a \leftrightharpoons C_e$ equilibrium constant varies with temperature in comparably nonpolar solvents (from 1.2 in CCl_4 at +25°C to 7.3 in CH_3OCH_3 at −132°C) suggests that entropic factors are not as prevalent for **8***c* as may be the case for 2-methoxytetrahydropyran (19). Furthermore, the data summarized above suggest that the axial form should not be disfavored unduly by repulsive non-bonding interactions, so that it appears that torsional angles in **8***c* may play an important role as suggested by Pople and co-workers (2*a*) and Gorenstein and Kar (2*b*) from studies on dimethoxymethane.

Methods of calculation (2) to evaluate the relative stabilization from the anomeric effect have been developed for acetals; it is doubtful that they can be applied to orthoformates such as **8***c* without adaptation. In addition, the presence of a benzylic oxygen is specific to **8** and its derivatives. Nevertheless, the accepted models (2) reveal the nature of the relationship with the CH_3O—C(2)—O—C torsional angles and suggest that changes ought to modify the relative stability of the C_e and C_a forms.

Torsional angles involving the OCH_3 substituent about the C(2)—O(3) and C(2)—O(1) bonds are estimated from Dreiding models to be in the range 25–40° for the C_a form of **8***c* compared to 55–60° for the C_a form of 2-methoxy-1,3-dioxane. On the other hand, values in the range of 145–160° are observed for the C_e form of **8***c* compared to about 175–180° for the analogous 2-methoxy-1,3-dioxane. Such changes in angles are expected to modify the stabilization associated with factors contributing to the anomeric effect. This is particularly clear from the data reported by Jeffrey *et al.* (2*a*) for the C_a form, from which a decrease from 60° is predicted to lead to strong destabilization. Similarly, for the C_e form, a reduction in the C(2)—O torsional angles from 180° should lead to some destabilization, but the calculations suggest that the effect is stronger for the C_a form. The effect of the angular differences present in the seven-membered ring coupled with accompanying changes in dipolar interactions (20) could well account for the large equatorial preference of the methoxy group of **8***c*.

Table 3 shows that compound **8***d* (2,2-dimethyl) presents another interesting equilibrating conformational mixture. Whereas **2***d* exists only in the *TB* form, **8***d* is found to exist as a $C \leftrightharpoons TB$ equilibrium for which *C* is the predominant form.

The *TB* preference of **2***d* has been explained (8) in terms of stabilizing stereoelectronic and electrostatic interactions involving the ring oxygen atoms and favoring the *TB* form, together with a destabilization of the *C* form by significant repulsive non-bonded interactions between the axial methyl group and the two axial benzylic protons. In contrast, only one

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

such 1,3-axial interaction exists in the *C* form of **8***d*, suggesting less destabilization, whereas the *TB* form is not appreciably stabilized by the generalized anomeric effect. As a consequence, the *C* form predominates in the equilibrium mixture detected.

Finally, Table 3 shows that compound **8***e* also exhibits important conformational specificity, strikingly different from observations made for **2***e*. The greater stability of the *C* form for **8***e* follows from the arguments given above for **8***d* and the position of the substituents can be rationalized in terms of a greater equatorial preference by the methyl group for steric reasons.

In conclusion, the results for compounds **8** to **8***e* illustrate the consequence of lesser stabilization of the acetal function in the *TB* form **7** compared to **6**, contrary to extrapolations from studies on 1,3-dioxane where the opposite has been suggested (7). This result also suggests that more complete calculations for all possible conformations of 1,3-dioxane ought to be carried out using an approach which includes explicitly the stabilizing effect resulting from the anomeric effect (21).

Dynamic properties

Table 3 indicates that compounds **8**, **8***c*, and **8***d* undergo conformational averaging processes which can be characterized by the analysis of the ^1H and (or) ^{13}C nmr spectral changes observed at low temperatures.

As reference value, it is useful to recall that the inversion of the chair form of benzocycloheptene is characterized by a free energy value of 10.9 kcal/mol (22), which is associated with the flipping motion of the saturated end of the molecule involved in the $C \rightarrow B$ step of the inversion itinerary (23). The substitution of C-5 by an oxygen atom in 5-oxabenzocycloheptene (**9**) lowers the energy barrier to 9.5 kcal/mol (13). Furthermore, the presence of two oxygen atoms in the ring reduces the value to 7.9 kcal/mol for **2** and to 6.5 kcal/mol for 1,5-dioxa-6,7-benzocycloheptene (**14**) (8, 24). The free energy barrier determined for **8** (8.4 kcal/mol) is therefore higher than that of both **2** and **14**, whereas an intermediate value might have been expected if the effect of each oxygen atom were independent and additive.

The $\Delta G^{\neq}$ value for the $C_e \rightarrow C_a$ transformation of **8***c* is 7.6 kcal/mol, about 1 kcal/mol lower than the value noted for **8**. A similarly lowered energy barrier, by about 2 kcal/mol (from ~9.5 to 7.5 kcal/mol), has also been observed for the 2-methoxy derivative of 1,3-dioxane (10).

Finally, compound **8***d* exhibits spectral changes arising from the slowing down on the nmr time scale of two independent processes: the $C \leftrightharpoons TB$ interconversion (8.3 kcal/mol) and the *TB* inversion (7.5 kcal/mol). By comparison, the $\Delta G^{\neq}$ value for the pseudorotation motion of the *TB* inversion of **2***d* is about 2.5 kcal/mol higher (8), probably resulting in significant part from greater stereoelectronic stabilization in the *TB* form of **2***d* than of **8***d*, together with reduced steric interaction in the transition state of the *TB* inversion of **8***d*.

Experimental

The vpc analysis and separations were carried out on a Varian–Aerograph Model 920 instrument using helium as carrier gas. High resolution mass spectra at 70 eV were recorded using an Associated Electrical Industries Model MS-902 spectrometer.

The variable temperature ^1H nmr spectra were recorded at 400.13 MHz on a Bruker WH-400 spectrometer, located at the "Laboratoire régional de RMN à haut champ" in Montreal. Temperatures were determined directly using the B-VT-100 unit. Verification using a calibrated copper–constantan thermocouple inside a solvent-containing nmr tube indicates that the low temperatures reported are known within ±3°. The samples were studied as solutions in chlorodifluoromethane (5–25 mg in 0.55 mL of solution) containing ~15% of CD_2Cl_2 (for locking purpose) and a small quantity of TMS in 5-mm tubes which had been degassed and sealed. The ^1H nmr spectra at room temperature were recorded in $CDCl_3$ and CCl_4 (10–20 mg in 0.55 mL). The following instrumental parameters were used: flip angle = 25°; SW = 4500 Hz; data size = 16 K data points and zero filled to 32 K; acquisition time = 0.9 s. Gaussian multiplication was applied with LB values of −2 and −5 and GB = 0.4 to 0.9. The number of scans varied from 200 to 500.

The variable temperature ^{13}C nmr spectra were recorded at 100.6 MHz on the same Bruker WH-400. The samples were studied as solutions in chlorodifluoromethane and in dimethyl ether (80–150 mg in 2.2 mL of solution) containing ~15% of CD_2Cl_2 (for locking purpose) and a small quantity of TMS in 10-mm tubes which had been degassed and sealed. The following instrumental parameters were used: flip angle = 75°; SW = 1700–20 000 Hz; data size = 16 K or 8 K data points and zero filled to 16 K; acquisition time = 0.2–0.4 s; number of scans = 500–2000. The nmr data were treated by an exponential multiplication with LB varying from 1 to 6. A delay of 0.1 to 0.2 s was added between pulses for the spectra used for integration; this magnitude was found to be sufficient, as indicated by results published previously (25).

The complete ^{13}C nmr variable temperature study of **8***c* was done at 20.15 MHz on a Bruker WP-80 equipped with the Bruker variable temperature accessory. The parameters used were: flip angle = 75°; SW = 6000 Hz; data size = 8 K data points; acquisition time = 0.7 s; number of scans = 1000; RD = 0.1 s. The FID obtained was treated by exponential multiplication (LB = 4).

The rate constants were determined at the coalescence temperature using the equation $k = \pi \Delta\nu/\sqrt{2}$ for singlet to doublet splitting in ^{13}C nmr spectra; this equation is known to give acceptable approximation even in the case of lines of unequal intensities (26). The equation $k = \pi (\Delta\nu^2 + 6J^2)^{1/2}/\sqrt{2}$ was used for singlet to AB ^1H nmr spectral change. The free-energy barriers ($\Delta G^{\neq}$) were calculated from standard equations (27) using a transmission coefficient of one-half or one (*vide infra*).

Determinations of activation parameters of **8***d* ($\Delta G^{\neq}_{C \rightarrow TB}$ and $\Delta G^{\neq}_{TB \rightarrow TB'}$) were done by calculation of spectra at low temperature using a slightly modified version of the DNMR-2 program on a CDC Cyber 173 computer (24). The simulations were done by a visual comparison of the calculated and experimental spectra. Free energies of activation were calculated from a ln k/T vs. $1/T$ plot using the Eyring equation (28). Calculations of $\Delta S^{\neq}$ and $\Delta H^{\neq}$ were not expected to be sufficiently reliable because of the uncertainty in temperature (±3°), uncertainties in T_2 arising from possible small long-range coupling, as well as the fact that the conformational populations and chemical shifts were kept constant through the whole temperature interval. The complete treatment was done as reported previously (24).

The steady state nOe difference (29) measurements on **8***e* were done in a $CDCl_3$ solution which had been degassed and the nmr tube sealed. The FID were accumulated with 16 K data points. The difference spectra were obtained by subtraction of the transformed spectra; transients were collected after preirradiation (10–12 s) at selective frequencies and recycled to average the drift effect.

The ^1H nmr chemical shifts and coupling constants of **8***d* reported in Table 1 were determined from simulated spectra using the PANIC program, a Bruker version of the LAOCOON program.

1,3-Dioxa-4,5-benzocycloheptene (8) and its methyl (8a) and tert-butyl (8b) derivatives

These three compounds were prepared according to a published general procedure (30) from *o*-hydroxyphenethyl alcohol (Aldrich 99%, distilled before used), the corresponding aldehyde (formaldehyde, acetaldehyde, and trimethyl acetaldehyde), and *p*-toluenesulfonic acid (catalylic quality) in benzene. The benzene solvent was removed by flash evaporator and each compound was obtained pure

by reduced pressure distillation. Compound **8** was obtained in a 50% yield, **8***a* in a yield of 74% (bp 44°C at 0.1 Torr; 1 Torr = 133.3 Pa), and **8***b* in a yield of 76% (bp 60–62°C at 0.09 Torr). Their ^1H and ^{13}C nmr spectra (Tables 1 and 2) and the high resolution mass spectra are characteristic of the compounds. Compound **8**, *Mol. Wt.* calcd. for $C_9H_{10}O_2$: 150.0681; found (mass spectrum at 70 eV): 150.0691. Compound **8***a*, *Mol. Wt.* calcd. for $C_{10}H_{12}O_2$: 164.0838; found (mass spectrum at 70 eV): 164.0890. Compound **8***b*, *Mol. Wt.* calcd. for $C_{13}H_{18}O_2$: 206.1307; found (mass spectrum at 70 eV): 206.1305.

*2,2-Dimethyl-1,3-dioxa-4,5-benzocycloheptene (8*d)

Compound **8***d* was prepared by a procedure already published (8) from *o*-hydroxyphenethyl alcohol, dimethoxypropane, acetone, and *p*-toluene sulfonic acid (catalytic quantity) in benzene. The product was distilled under vacuum to give a colourless liquid (bp 38–40°C at 1.15 Torr) in a 50% yield. Its ^1H and ^{13}C nmr spectra (Tables 1 and 2) and its high resolution mass spectrum confirmed its identity as **8***d*. *Mol. Wt.* calcd. for $C_{11}H_{13}O_2$: 178.0894; found (mass spectrum at 70 eV): 178.0999.

*2-Methoxy-1,3-dioxa-4,5-benzocycloheptene (8*c*) and 2-methoxy-2-methyl-1,3-dioxa-4,5-benzocycloheptene (8*e*)*

A mixture of *o*-hydroxyphenethyl alcohol (1 equiv.) and trimethyl orthoformate (1.2 equiv.) with a catalytic amount of *p*-toluenesulfonic acid in benzene was stirred and refluxed to allow benzene and methanol to distill off. Dry benzene was added periodically to the reaction flask. The evolution of the reaction was followed by vpc (OV 101 at 1.5%, 4 ft at 80°C with a flow of 1 mL/s). After 8 h, most of the starting material had disappeared (less ~30%); compounds **8***c* and **8***e* were then isolated and purified from the crude mixture by vpc under the conditions given above. Each product was characterized by ^1H and ^{13}C spectra (Tables 1 and 2) and its high resolution mass spectra. Compound **8***c*, *Mol. Wt.* calcd. for $C_{10}H_{12}O_3$: 180.0787; found (mass spectrum at 70 eV): 180.0845. Compound **8***e*, *Mol. Wt.* calcd. for $C_{11}H_{14}O_3$: 194.2314; found (mass spectrum at 70 eV): 194.0782.

Synthesis, electronic spectra, and solvatochromic behaviour of 4-arylidene-1-(2,4-dinitrophenyl)-3-methyl-2-pyrazolin-5-ones

SAID A. IBRAHIM AND M. S. K. YOUSSEF

Department of Chemistry, Faculty of Science, Assiut University, Assuit, Egypt

Received July 19, 1983[1]

SAID A. IBRAHIM and M. S. K. YOUSSEF. Can. J. Chem. **62**, 2841 (1984).

The uv–visible electronic spectra of 4-arylidene-1-(2,4-dinitrophenyl)-3-methyl-2-pyrazolin-5-ones have been studied. The different bands observed have been assigned to the proper electronic transition. Solvatochromic behaviour of these compounds is investigated by studying their visible spectra in organic solvents of different polarities. The longer wavelength band displayed by *para*-hydroxy derivative is assigned to an intermolecular CT transition. The solvated H-bond complexes formed between ethanol or DMF and the *para*-hydroxy derivative are investigated. Transition moment (μ_{CTL}), ΔG, and K_f values of these complexes have been determined.

SAID A. IBRAHIM et M. S. K. YOUSSEF. Can. J. Chem. **62**, 2841 (1984).

On a étudié les spectres électroniques uv-visible des arylidène-4 (dinitro-2,4 phényl)-1 méthyl-3 pyrazoline-2 ones-5. On a attribué les diverses bandes observées aux transitions électroniques appropriées. On a étudié le comportement solvatochromique de ces composés en déterminant leurs spectres visibles dans des solvants organiques de polarités diverses. On a attribué la bande apparaissant à la plus grande longueur d'onde du spectre du dérivé *para*-hydroxy à une transition CT intermoléculaire. On a étudié les complexes dus aux liaisons hydrogènes solvatées qui se forment entre l'éthanol ou la DMF et le dérivé *para*-hydroxy. On a déterminé les valeurs des moments de transition (μ_{CT}) des ΔG et des K_f de ces complexes.

Introduction

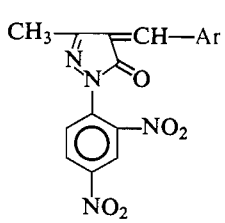
It is of interest to note that 2-pyrazolin-5-ones have wide applications in industry as purple and blue–green photographic colour couplers (1). This class of compounds is also known as filter dyes and electron acceptors (2). As these compounds are used in the preparation of cyanine dyes, they may be used as photosensitizers (3, 4). Some literature concerning the synthesis (5, 6) and electronic spectra (7) of pyrazolines is reported. However, data on the synthesis and electronic spectra of the title compounds are yet scarce in the literature. In view of these findings, 4-arylidene-1-(2,4-dinitrophenyl)3-methyl-2-pyrazolin-5-ones are prepared by reaction of 1-(2,4-dinitrophenyl)-3-methyl-2-pyrazolin-5-ones with aromatic aldehydes. Their electronic spectra and solvatochromic behaviour are studied. The solvated H-bond complexes formed in solution have been investigated.

Experimental

Preparation of the 4-arylidene-5-pyrazolones

A mixture of 1-(2,4-dinitrophenyl)-3-methyl-2-pyrazolin-5-ones (0.01 mol) and the appropriate aldehyde (0.015 mol) in absolute ethanol was refluxed on a water bath for 6 h. The solid that separated was filtered off and recrystallized from the proper solvent (cf. Table 1). The structure and purity of these compounds were checked by elemental analysis and ir spectra. The results are listed in Table 1.

The following compounds were prepared:



I, Ar = C_6H_5; **II**, Ar = $C_6H_4OH(o)$; **III**, Ar = $C_6H_4OH(p)$; **IV**, Ar = $C_6H_4NO_2(p)$; **V**, Ar = $C_6H_4Cl(p)$; **VI**, Ar = C_4H_3S(thienyl)

[1]Revision May 24, 1984.

Solutions

The organic solvents used (ethanol, ether, cyclohexane, DMF, DMSO) were all spectrograde BDH or Merck products.

Stock solutions (10^{-3} *M*) of the pyrazolone derivatives were prepared by dissolving the accurate amount of the recrystallized product in the required solvent. Solutions of lower molarities, used in spectral measurements, were obtained by accurate dilution.

Apparatus

The absorption spectra at 25°C were recorded on a Cary 219 spectrophotometer in the wavelength range 200–600 nm using 1-cm matched silica cells. Infrared spectra of the solids were recorded on a Perkin-Elmer 599 B spectrophotometer as KBr discs.

Results and discussion

Effect of molecular structure on the eletronic spectra

The electronic absorption spectral features (λ_{max} and ϵ_{max} values) of the arylidene pyrazolones under investigation in ethanolic solutions are cited in Table 2. The data given in this table reveal that spectra of these compounds comprise mainly three absorption bands. The one of shortest wavelength appearing in the range 212–224 nm can be assigned to a $\pi-\pi^*$ transition of the benzenoid system of the compounds. This assignment is substantiated from the observation that the λ_{max} of this band is slightly altered by the change of the substituent (Ar). The second uv band observed in the spectra of compounds **III**, **IV**, and **VI** within the wavelength range 275–320 nm may be attributed to the $n-\pi^*$ transition involving the non-bonding electrons of the pyrazolone carbonyl oxygen. The disappearance of this band in case of compound **II** (*o*-OH derivative) confirms its $n-\pi^*$ nature since the carbonyl oxygen is involved in an intramolecular H-bonding. The involvement of the OH group in H-bonding in compound **II** is substantiated by the lower frequency of the carbonyl stretching relative to that of compound **III**, that has its OH group in *para* position (Table 1). A further support for this $n-\pi^*$ assignment is achieved by the disappearance of this band in acidic solutions in which the n-electrons are expected to be blocked by H^+ ions.

The longer wavelength band observed in the spectra of these compounds in the wavelength range 338–385 nm can be as-

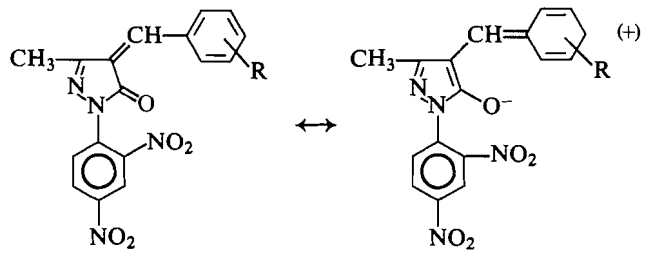
signed to a $\pi-\pi^*$ transition with considerable charge transfer character. The charge transfer character of this band is substantiated by the effect of the substituent (Ar) on its location and intensity. In general, this band exhibits a marked red shift, when the substituent is an electron-releasing one, relative to the unsubstituted or electron-withdrawing substituted derivatives. Also, the broadness of this band can be considered as an evidence for its CT nature (8). Such a charge transfer may take place from the aryl moiety as the donor to the pyrazolone carbonyl group as the acceptor center, and it can be represented schematically as follows:



The charge transfer character of this band is further confirmed by the solvatochromic behaviour observed on studying the effect of solvent, in the visible region, on the electronic spectra of these compounds as explained hereafter. Moreover, good evidence for the CT nature of this band is attained from ir spectra where the carbonyl stretching appears at lower frequencies characteristic for polarized C=O groups (cf. Table 1).

An extra new band with lower intensity is observed in the electronic spectra of compound **III** (Ar = $C_6H_4OH(p)$) at 490 nm. This band may be assigned to an intermolecular charge transfer transition (7, 9, 10–12). Such an assignment is supported by the non-linear relationship obtained on plotting the absorbance of this band against the molar concentration of the compound.

Effect of solvent

The electronic absorption spectra of the title pyrazolone derivatives, in the wavelength range 300–600 nm, are studied in different organic solvents, viz. cyclohexane, ether, DMF, and DMSO. This is made with the intention to investigate the solvatochromic behaviour of these compounds. λ_{max} and ϵ_{max} values of the intramolecular and intermolecular CT bands are given in Table 3. It is clear from these data that λ_{max} of the intramolecular CT band exhibits a marked red shift on transfer from nonpolar to polar solvent (Fig. 2). The observed shifts run according to the following order.

cyclohexane < ether < ethanol < DMF < DMSO

This order is in harmony with the increase in solvent polarity

in the same direction. This behaviour indicates that the polar excited states of these compounds are stabilized as the polarizability of the solvent is increased, i.e., lower excitation energy is required.

It is noteworthy that the intramolecular CT band appears at a longer wavelength in the case of compound **III** (*p*-OH) than that of compound **II** (*o*-OH) in all the solvents used (cf. Table 3). This behaviour reflects the role played by the intramolecular hydrogen bond established in molecules of compound **II** which hinders the charge transfer process. Such an intramolecular H-bond can be represented as follows

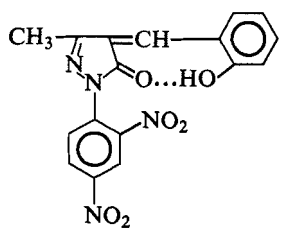

TABLE 3. Intramolecular charge transfer bands of compounds **I**–**VI** in various organic solvents

[b]λ in nm, ϵ in mol^{-1} cm^2.

Furthermore, a longer wavelength band having λ_{max} similar to that observed in ethanol (~490 nm) is observed in DMF and DMSO solutions of compound **III** (Fig. 2).

Spectra in mixed organic solvents

The visible spectra of compound **III** (*p*-OH) are investigated in cyclohexane–ETOH, ETOH–DMF, and cyclohexane–DMF mixtures. This is performed in order to study the solvated H-bond complexes liable to be formed between the solute molecules and H-bond acceptor solvents. The visible spectrum of this compound in pure cyclohexane displays only one band with λ_{max} = 384 nm (cf. Fig. 2). On adding ethanol or DMF, a new band at ~490 nm appears where its absorbance increases as the molarity of ethanol or DMF is increased; meanwhile the absorbance of the 384 nm band decreases. A fine isosbestic point is obtained in each case indicating the existence of an equilibrium between the solvated complex and the free solute molecules (Fig. 3). In the case of ethanol–DMF mixed solvent, the absorbance of the longer wavelength band (492 nm) increases, with a slight red shift, as the molarity of DMF is increased. At the same time, the absorbance of the shorter wavelength band decreases and a fine isosbestic point is obtained. This behaviour indicates that DMF molecules have greater tendency to form solvated complexes with the solute molecules relative to ethanol. This is due to the low ionization potential of DMF as well as its high H-bond accepting character.

A plot of absorbance of the longer wavelength band against the molarity of DMF or EtOH, gave a sigmoidal curve typical for an association process (Fig. 4). This can be considered as convincing evidence for the formation of solvated H-bond complexes.

A support for H-bond formation between solute and DMF molecules can be obtained from the value of the free energy of formation (ΔG) of the solvated complexes obtained from the relation

$$-\Delta G = RT \ln K_f$$

K_f values are calculated utilizing the reported relation for behaviour in mixed organic solvents (13). Values of K_f and ΔG are reported in Table 4.

The transition moment μ_{CT} of the solvated complexes formed are calculated using the folllowing equation (14):

$$\mu_{CT} = 0.0958 \left\{ \epsilon_{max} \frac{\Delta \bar{\nu}^{1/2}}{\bar{\nu}_{max}} \right\}^{1/2}$$

where ϵ_{max} is the molar extinction coefficient; $\Delta \bar{\nu}^{1/2}$ is the band

half-width in cm^{-1}. The obtained μ_{CT} values for the investigated solvated H-bond complexes together with ϵ_{max} values are assembled in Table 4. These values are quite high, indicating a strong CT interaction since it is reported that the stronger the CT interaction is, the longer the intensity of the CT absorption band (15).

The redox behavior of daunorubicin and its analogues has been studied by differential pulse polarography (DPP) in phosphate-buffered (pH 7.1) solutions at 37.5°C. The reductive deglycosidation reaction has been found to be under stereoelectronic control as the conformation of the alicyclic ring strongly affects the kinetics of the sugar moiety detachment. The substitution pattern of the anthraquinone system and/or the cyclohexene ring may determine the shape of the latter and in turn the stability of the glycosidic bond. We observe that while daunorubicin, 4-demethoxy-11-deoxydaunorubicin, and 10(*R*)-methoxydaunorubicin easily eliminate L-daunosamine upon polarographic reduction yielding the corresponding 7-deoxyaglycones, 4-demethoxy-6-deoxydaunorubicin and 10(*S*)-methoxydaunorubicin are stable towards deglycosidation. There is a pronounced stereoelectronic effect which results in a faster cleavage of those glycosidic bonds which have a relatively small dihedral angle with respect to the π-type orbital(s) of the anthraquinone system. Among the aglycones, the 10(*S*)-acetoxy and 10(*R*)-azidodaunomycinones are reductively converted to daunomycinone whereas the 10(*R*)- and 10(*S*)-methoxydaunomycinones do not undergo splitting of either the benzylic C10—OCH_3 or the C7—OH bond.

VINCENZO MALATESTA, SERGIO PENCO, NEREO SACCHI, LUIGI VALENTINI, ARISTIDE VIGEVANI, et FEDERICO ARCAMONE. Can. J. Chem. **62**, 2845 (1984).

Faisant appel à la polarographie pulsée différentielle (PPD) et opérant à 37,5°C, dans des solutions tampons de phosphate (pH 7,1), on a étudié le comportement redox de la daunorubicine et de ses analogues. On a trouvé que la réaction de déglycosidation réductrice se produit sous contrôle stéréoélectronique puisque la conformation du cycle alicyclique influence fortement la cinétique de la dissociation du sucre. Les divers types de substitution sur le système anthraquinone et/ou sur le cyclohexène peuvent éventuellement déterminer la forme de ce dernier et, par voie de conséquence, la stabilité du lien glycosidique. Alors que la réduction polarographique de la daunorubicine, de la déméthoxy-4 déoxy-11 daunorubicine et de la méthoxy-10(*R*) daunorubicine provoque une élimination facile de la L-daunosamine conduisant aux déoxy-7 aglycones correspondantes, la déméthoxy-4 déoxy-6 daunorubicine et la méthoxy-10(*S*) daunorubicine sont stables vis à vis de la déglycosidation. Il existe un effet stéréoélectronique prononcé qui provoque un clivage plus rapide des liaisons glycosidiques qui ont un angle dièdre relativement petit par rapport à (aux) l'orbitale(s) du système anthraquinone. Parmi les aglycones, les acétoxy-10(*S*) et azido-10(*R*) daunomycinones sont réduites en daunomycinones tandis que les méthoxy-10(*R*) et -10(*S*) daunomycinones ne subissent aucune rupture soit du lien benzylique C10—OCH_3 ou de la liaison C7—OH.

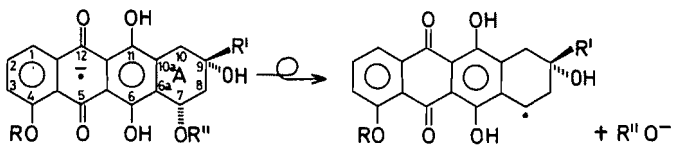
The investigation of the electrochemical behaviour of anthracyclines, a class of widely used antitumor antibiotics (1–3) has attracted a great deal of interest. It is anticipated that because of the quinone–hydroquinone character of the chromophore the redox states properties should relate to the expression of the biological anti-neoplastic activity of the anthracyclines.

Although the intercalation of anthracyclines within the base pairs of the DNA (3–8) has been proposed as a prerequisite in the mechanism of biological action of this class of antibiotics, the real possibility exists for covalent binding to other parts of the cell besides the intercalative region of stacked base-pairs. The same electronic features that render the anthracyclines molecules particularly suited for intercalation with DNA bases allow them to act as very efficient electron acceptors. Thus the anthracyclines can be activated in biochemical systems via enzyme mediated redox processes to free radical state (9–11). Their ability to generate active oxygen in the form of high energy oxygen centered radicals ($O_2^{\cdot-}$, OH·) that are claimed to be linked to the cardiotoxicity of these drugs (7, 12–14) is a result of this reductive activation.

There is a growing body of evidence suggesting that the single electron reduction product of the anthracyclines, the semiquinone, besides functioning as electron shuttle between the enzyme(s) and the molecular oxygen can undergo an intramolecular electron transfer and rearrange to give a sugar residue anion and a carbon centered radical (8, 12, 15–17) which could subsequently engage in the alkylation of biomolecules (bioalkylation).



R" = sugar residue

Furthermore, the involvement of a free radical intermediate in the metabolism by mammalian microsomes of the anthracyclines has been substantiated (13, 18–20), but its chemistry has not as yet been defined. It is within this perspective that an integrated understanding of the factors affecting the reductive splitting is of importance.

The work of Rao *et al.* (21) has shown that both daunorubicin and doxorubicin undergo, upon polarographic reduction, a loss of the amino sugar (*reductive deglycosidation*) to give the corresponding 7-deoxyaglycone through a consecutive two-steps electrochemical–chemical–electrochemical (E.C.E.) process (Scheme 1).

The differential pulse polarography (DPP) is a technique particularly suited for the study of systems characterized by two or more consecutive electron transfer steps, e.g., E.C.E. processes, especially when the half-wave potentials of the individual steps are so closely similar that the conventional direct current polarography (DCP) would not allow a clear-cut resolution. During the course of our DPP investigation of the electrochemical properties of new synthetic anthracycline analogues

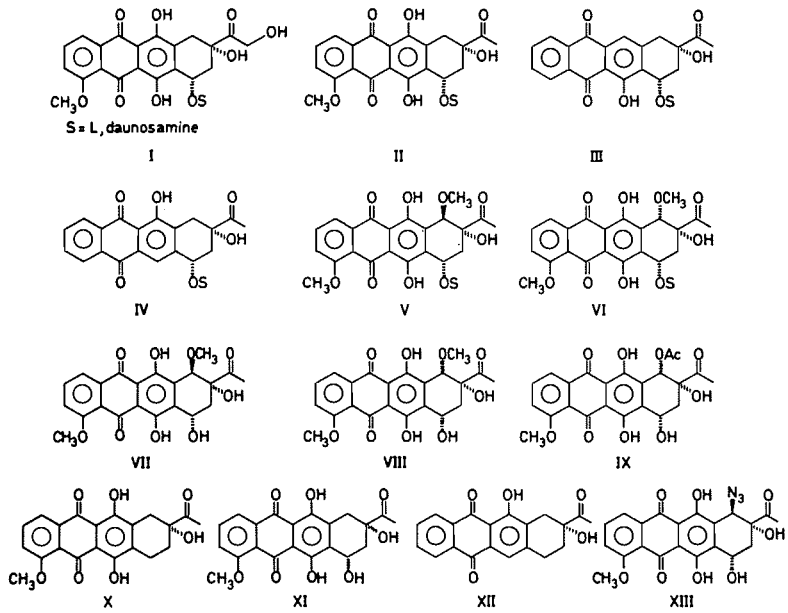


CHART 1

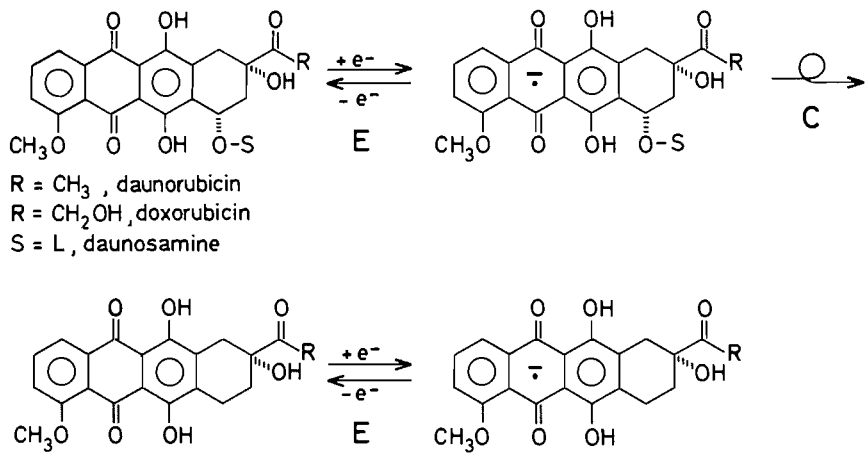

SCHEME 1

we were surprised to find out that the stability of the glycosidic bond was markedly different in two anthracycline derivatives differing by only the stereochemistry at C10. We found that while the 10(*R*)-methoxydaunorubicin (**V**, Chart 1) underwent a reductive deglycosidation to the corresponding 10(*R*)-methoxy-7-deoxydaunomycinone, the glycosidic bond of the enantiomeric 10(*S*)-methoxydaunorubicin (**VI**) was stable.

Previous nmr studies (22) on the 10(*R*)-and 10(*S*)-methoxydaunomycinone in $CDCl_3$ had shown that the two enantiomers differ by the conformation of the A ring with the 10(*S*) enantiomer preferring the distorted boat conformation to the more common half-chair form. The same two compounds adopt two different half-chair conformations in more polar solvents like DMSO-d_6 and D_2O (see infra). We have then sought other examples of anthracycline derivatives (Chart 1) characterized by such a conformational bias with the aim of ascertaining the generality of our observation. We found that the results of our polarographic studies require, in order to be rationalized, a conformation-dependent reactivity of the glycosidic linkage.

Results

Single peak differential pulse polarograms were obtained for the aglycones: 10(*R*)- and 10(*S*)-methoxydaunomycinones (**VII, VIII**), 7-deoxydaunomycinone (**X**), daunomycinone (**XI**), 4-demethoxy-6,7-bisdeoxydaunomycinone (**XII**), and the two glycosides 4-demethoxy-6-deoxydaunorubicin (**IV**) and 10(*S*)-methoxydaunorubicin (**VI**). The remaining glycosides of Chart 1 (**1, II, III, V**) and the two aglycones 10(*S*)-acetoxydaunomycinone (**IX**) and 10(*R*)-azidodaunonomycinone (**XIII**) all underwent an E.C.E. process, giving rise to two peaks polarograms.

E.C.E. and E. processes exemplified

*10(*R*)-Methoxydaunorubicin (V)*

The differential pulse polarography (0.0−1.0 V vs. Ag/AgCl electrode) of a 3.2×10^{-5} *M* solution of (**V**) gave two cathodic peaks (−0.536 and −0.596 V), Table 1, whose relative intensities depended on the drop time (Fig. 1*a*). At a drop time of 6 s the two peaks are clearly defined and at shorter

[a]Peak potentials (V) vs. Ag/AgCl at 37.5°C in phosphate buffer, pH 7.1.

drop times, e.g., 1.4 s, the second peak becomes less prominent. The HPLC analysis (see Materials and methods) of the coulometric reduction at fixed potential (−0.500 V) allowed us to identify the product of the first reduction step as the 10(*R*)-methoxy-7-deoxydaunomycinone.

10(S)-Methoxydaunorubicin (VI)

Only one peak (−0.532 V) was detectable at each of the drop times used in the present study (Fig. 1*b*). The fact that the shoulder noticeable at 1.4 s drop time does not show a (drop) time dependence does indicate that this is a peak due to some impurity. Cyclic voltammetry experiments confirmed the reversibility of the process and the absence of a chemical reaction following the electrochemical reduction. The ^{1}H-nmr spectrum (DMSO-d_6) of **VI** is similar to that of **V** ($J_{H10c-H8c}$ = 1.5 and 1.1 Hz, respectively) although one would expect that because of the opposite configuration at the C10 chiral center if the same ring A α-conformation (23) were retained, the 1,3-diequatorial coupling, i.e., $J_{H10c-H8c}$ should be observed only in the case of **V**. For **VI** the A ring boat conformation is also ruled out on the same grounds. The nmr data seem to be in keeping with a half-chair conformation having the C10—OCH_3 bond pseudoaxial and the glycosidic bond pseudoequatorial.[1] This assignment is supported also by the rather different values of the H7 J_{vic} which are 4.4 and 8 Hz for the 10(*R*)- and the 10(*S*)-methoxydaunorubicin, respectively.

4-Demethoxy-11-deoxydaunorubicin (III)

The alicyclic ring has the more common α half-chair form and the electrochemical behaviour of **III** stands in sharp contrast with that of **IV** in that the former compound undergoes an E.C.E process (first peak, −0.468 V; second peak, −0.540 V), whereas the latter is engaged in a simple, reversible, electrochemical process without concomitant splitting.

10(S)-Acetoxydaunomycinone (IX)

The differential pulse polarogram reveals two peaks attributable, the first (−0.468 V) to the reduction of the starting material and the second (−0.592 V) to the reversible reduction of the deacetylation product, daunomycinone. The most relevant resonances in the ^{1}H-nmr spectrum (DMSO-d_6) are: H10, 6.32 ppm (s, W_H = 3.0 Hz); H7, 4.90 ppm (dt, J_{vic} = 8.2, 6.2 Hz; J_{lr} = 1.6 Hz); H8eq, 2.31 ppm (ddd, J_{gem} = 14.0 Hz; J_{vic} = 6.2 Hz; $J_{H8e-H10e}$ = 1.6 Hz); H8ax, 2.08 ppm (dd, J_{gem} = 14.0 Hz; J_{vic} = 8.2 Hz). The presence of the long range coupling between H10 and H8 and the *S* configuration require a β half-chair conformation for the A ring.

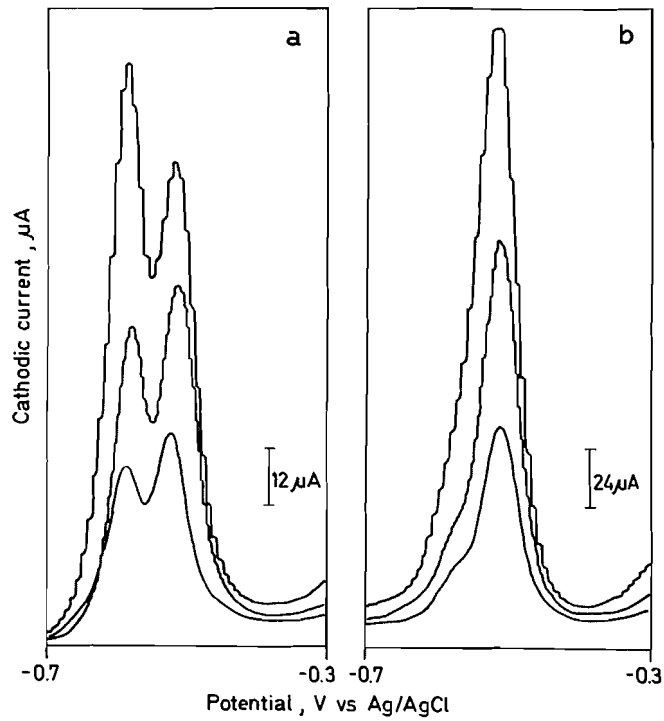

FIG. 1. Differential pulse polarograms of (*a*) 10(*R*)-methoxydaunorubicin (**V**) (3.3 × 10^{-5}*M*) and (*b*) 10(*S*)-methoxydaunorubicin (**VI**) (3.2 × 10^{-5} *M*), pH 7.1 in phosphate buffer at 37.5°C, ν = 1.33 mV/s. The drop time values are 1.4, 3, and 6 s for the lower, middle, and top curve, respectively.

10(R)-Azidodaunomycinone (XIII)

The loss of the azido group upon reductive activation of **XIII** is fast and even at the fastest drop time, 1.4 s, used in the present study the first peak of the polarogram is small. The prominent second peak is attributed to the reversible reduction of the reaction product, the daunomycinone.

Discussion

The reactivity towards reductive cleavage of a glycosidic bond and a benzylic bond in general on ring A of the anthracyclines could in principle depend, when all other electronic factors are the same, upon the configuration of neighbouring chiral centers and/or the conformation of the ring itself. We

[1]The nmr data are in agreement with those obtained in ref. 24, from University of Milan.

For personal use only.

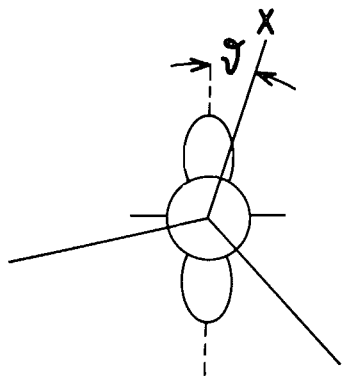
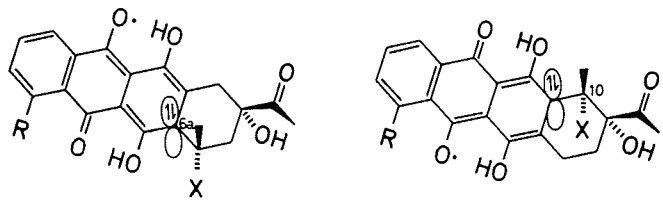
must note that the most stable conformation could also be determined by existing configurational features. We know for instance that the enantiomeric 10(*R*)- and 10(*S*)-methoxydaunorubicins adopt two different half-chair conformations for the A ring and that the reductive splitting of the glycosidic bond is observed only in the case of the 10(*R*) enantiomer. Thus the conformational features of the alicyclic ring must be determining the fate of the intermediate free radical or ion formed upon reduction of the antibiotics, assuming that the same conformation is retained in the reduced intermediate. It is well documented (25–29) that the heterolytic and/or homolytic fission is favoured when the bond undergoing cleavage can assume near *coplanarity* with the *adjacent semioccupied* p *orbital*, an *unoccupied non-bonding orbital* or *an occupied* π *orbital*. We have shown (30) that the theoretical rationalization of such an effect, the *stereoelectronic effect*, is based on the concept of conjugative delocalization. The extent of the delocalization is a function of the dihedral angle θ between the C—X bond being broken or formed and the orbital of π symmetry on the atom adjacent to the reaction center.



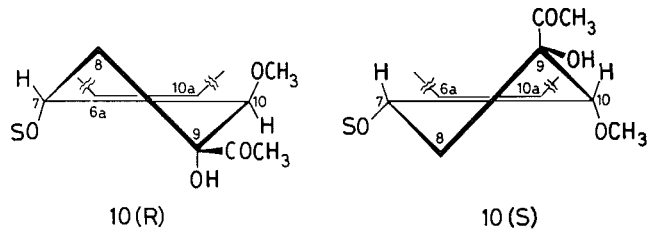
The interaction deemed to be important in determining the reactivity of the glycosidic linkage(s) (benzylic in general) in the anthracyclines radical anion is a conjugative delocalization between the doubly-occupied *p* orbital on C6a or C10a and the antibonding orbital of the C—X bond (p-σ^*_{C-X}) of the reaction center(s) C7 and/or C10. Resonance forms of the semiquinone for the C7 and C10 reaction centers can be represented as



As we have anticipated the p-σ^*_{C-X} interaction will be dihedral angle dependent with the value of θ being determined by the conformation of the alicyclic cyclohexenic A ring. In most of the anthracyclines so far reported the A ring has a half-chair form. It should, however, be emphasized that in the cyclohexene derivatives the conformational energy difference between the half-chair and the (skew) boat form is relatively small (ca. 2–4 kcal/mol) (31) and that small structural changes can easily alter the ring shape. Furthermore a β half-chair conformation is possible as seen in the case of the 10(*S*)-methoxydaunorubicin.

The different conformations adopted by the enantiomeric 10(*R*) (**V**) and 10(*S*)-methoxydaunorubicin (**VI**) serve to illustrate this point.

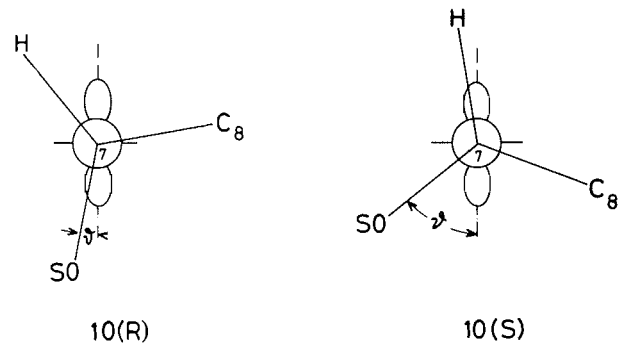
The Newman projections along the C7—C6a bond help to visualize the extent of the interaction responsible for the different reactivity.



In 10(*R*) because of the small dihedral angle ($\theta \leq 15°$) the conjugative delocalization (partial developing overlap) is expected to be effective and substantially contribute to the driving force of the reaction. On the other hand, because of the larger value of θ ($\geq 45°$) in 10(*S*), it is anticipated that the interaction is much less effective and the glycosidic bond more stable.

It is worth pointing out that the same rationale would apply whether the reductive deglycosidation mechanism is ionic (two-electron reduction) or free radical (one electron) in nature.[2]

Admittedly the extent of the interaction is expected to be energetically different for the free radical and the ionic intermediate but the magnitude of the interaction in 10(*R*) would still be sufficiently different from that in 10(*S*) to cause the observed reactivity pattern.



Another point deserves further comments. The C10—OMe bond in 10(*R*) is *trans*-diaxial with respect to the labile glycosidic bond and forms the same dihedral angle ($\theta \leq 15°$) with the π-type orbital(s) of the B ring. However, the stability of the CH_3O—C bond is not completely surprising in view of the fact that the methoxyl is not a good leaving group when compared to the sugar moiety. This is also confirmed by the stability towards reductive elimination of the OH and CH_3O groups in the aglycones. Indeed the differential pulse polarograms (see results) of the 10(*R*)-methoxydaunomycinone (**VII**) and daunomycinone (**XI**) show only one peak, corresponding to a reversible electrochemical reduction of the chromophore not followed by elimination of CH_3O^- or OH^-.

[2]It is a matter of current debate whether the electrochemical reduction intermediate is a radical ion, i.e., semiquinone or the dianion dihydroquinone. While the pH dependence of the half-wave potentials seems to indicate that two electrons – two protons are involved in each step of the E.C.E. process (21), the fact that the semiquinone is reported to form easily in multiple enzymatic and esr experiments (32) suggests that the first peak in the cyclic voltammograms of Rao *et al.* (21) is actually the one electron reduction to semiquinone (33).

*4-Demethoxy-6-deoxydaunorubicin (**IV**) and 4-demethoxy-11-deoxydaunorubicin (**III**)*

The stability of the glycosidic linkage in the 6-deoxy derivative **IV** further illustrates the reactivity dependence on the conformation. As we have noted the removal of the OH on C6 profoundly affects the conformation of the A ring which changes from the more common α half-chair to the β form. The 11-deoxy analogue **III**, on the other hand, maintains the α half-chair form and easily undergoes reductive splitting of the glycosidic bond. The same arguments we have used before nicely rationalize the observed results.

*10(S)-Acetoxydaunomycinone (**VIII**) vs. 10(S)-methoxydaunomycinone (**IX**)*

Although these two compounds are characterized by the same chirality at C10 their reactivity towards reductive elimination is strikingly different as the former compound, in contrast with the 10(*S*)-methoxydaunomycinone, easily eliminates the acetoxy group yielding the daunomycinone. In both compounds the A ring has a β half-chair conformation and therefore the dihedral angle θ has the same value. However, as the elimination occurs only in the case of the 10-acetoxydaunomycinone and as the resonance stabilized acetoxy is a better leaving group than the methoxy, we must conclude that the leaving group properties are also important in the deglycosidation reaction.

*10(R)-Azidodaunomycinone (**XIII**) vs. 10(R)-methoxydaunomycinone (**VII**)*

This is a particularly nice example of how the nature of the leaving group and *not* necessarily the configuration determines the reactivity of the bond on the benzylic position(s). Indeed, although both the conformation and configuration are the same in the two compounds, only the azido group is easily eliminated because of its better leaving group properties.

Kinetic considerations

Accurate values for the rate constants of the irreversible chemical reaction of deglycosidation in the E.C.E. process are difficult to obtain because of the heterogeneous nature of the reaction and the complicating absorption phenomena at the electrode. A qualitative comparison can, however, be made based on the values of the relative ratio of the first to the second peak at the same drop time. As the drop time increases the time available for the chemical reaction increases and the two peaks are more easily distinguishable (Fig. 1*a*). Then if we take the longest drop time, i.e. 6 s, we note that the ratio increases (0.84; 1.2; 2.2) along the series 10(*R*)-methoxydaunorubicin (**V**), daunorubicin (**I**), 4-demethoxy-11-deoxydaunorubicin (**III**) and that must correspond to an increase in the stability of the glycosidic bond. We can not invoke conformational effects to rationalize the trend as the three above compounds adopt the same half-chair conformation for the A ring. Rather, electronic effects must be determining the stability of the intermediate glycoside semiquinone. The removal of electron-donating groups such as OCH_3 and OH results in an increased stability of the radical anion and this in turn translates into a lower reactivity of the glycosidic bond. For this series the results seem to indicate that the deglycosidation reaction is under thermodynamic control. An extension of this rationalization would require that the reactivity of the 4-demethoxy-6-deoxydaunorubicin should be comparable with that of the 11-deoxy analogue. We have already seen that the two daunorubicins differ by the conformation of ring A and that unfavourable stereoelectronic effects reduce even further the reactivity of **IV**.

Conclusion

The compounds reported in Chart 1 can be divided into two classes. For **I**, **II**, **III**, **V**, **IX**, and **XIII**, a combination of small dihedral angle (**I**, **II**, **III**, **V**) and good leaving group properties (**IX**, **XIII**) contribute to the lability of the benzylic bond(s). On the other hand, **IV**, **VI**, **VII**, **VIII**, and **XI**, because of either a large dihedral angle (**IV**, **VI**) or the nature of the leaving group (CH_3O; HO), are stable towards reductive splitting. The evidence presented so far seems to establish that the reactivity of the groups on the benzylic C7 and C10 centers of the anthracyclines is under stereoelectronic control. It is therefore not possible to predict the reactivities of such centers by referring only to their configuration as the conformational requirements are clearly a key factor. As the bond-making and bond-breaking processes in enzyme catalyzed reactions are generally fast, we may expect that even small energy barriers of conformational origin can become significant and often rate determining and the stereoelectronic effects would also play an important role for the anthracyclines *in vivo* enzyme mediated reactions.

Finally, we would like to emphasize that although the understanding of the electrochemical behavior of the anthracyclines is *per se* important, their redox properties should not be dissociated from conformational considerations when trying to predict the reactivities of their intermediates.

Experimental

Materials and methods

All the compounds used in the present study were synthesised in our laboratories. They were purified by crystallization and/or semi-preparative HPLC on reverse phase Micro Pack MCH-10 column (250 × 8 mm) eluted (8 mL/min) with a H_2O–ACN mixture (69:21) buffered at pH 2.

The differential pulse polarograms were recorded on a Metrohom E 506 polarograph equipped with a dropping mercury electrode (DME). A three electrode system was used with the reference electrode being an Ag/AgCl electrode and the auxiliary electrode a platinum wire. The measurements were carried out in a 20 ml thermostated cell (37.5°C) flushed with prepurified N_2 (10 min) and kept during the experiments under a positive pressure of nitrogen. The concentrations of the solutions were in the range $3-5 \times 10^{-5}$ *M* depending on the solubility of the individual compounds. The solutions were buffered at pH 7.1 with 0.01 *M* phosphate buffer, 0.1 *M* KCl, and 0.004% triton X-100. In the case of the aglycones, because of their lower solubility it was necessary to add up to 33% of acetonitrile. The identification of the reduction products was made on the basis of the peak potential (E_p) and HPLC retention time values which were compared to those of authentic samples. For the E.C.E. processes the product identification was performed in two steps. For the product corresponding to the first E.C.E. stage a small scale reduction was carried out at a fixed potential ca. 50 mV less cathodic than the peak maximum in order to avoid a further reduction to hydroquinone. The solutions were then extracted with methylene chloride, the organic layer separated, and after drying (Na_2SO_4) the solvent was removed under vacuum. The residue was taken up in the proper solvent and an aliquot was analyzed by HPLC on a Brownlee RP8C column (250 × 4 mm) using the same above mentioned eluent. The remainder of the solution was evaporated to dryness and used for the second step of the reduction at a fixed potential corresponding to the second peak maximum. When the current dropped to ca. 5% of the starting value the hydroquinone formed was reoxidized to the quinone by sweeping the potential back to 0 V. The solution was extracted and analyzed as described above. The structure assignments were also confirmed by mass spectrometry and ^{1}H-nmr spectroscopy. The cyclic voltammetry was performed on a BAS CV-1B apparatus. The ^{1}H-nmr spectra were recorded on a Varian XL-200 spectrometer in the appropriate solvent (D_2O, $CDCl_3$,

DMSO-d_6) having TMS as internal standard. A Varian MAT 311A mass spectrometer operating on F.D. mode was used to obtain the mass spectra.

Viscosity data of binary mixtures: ethyl acetate + cyclohexane, + benzene, + toluene, + ethylbenzene + carbon tetrachloride, and + chloroform at 303.15 K

SHANTILAL OSWAL[1] AND MANAPRAGADA V. RATHNAM
Department of Chemistry, South Gujarat University, Surat-395007, India

Received November 11, 1982[2]

SHANTILAL OSWAL and MANAPRAGADA V. RATHNAM. Can. J. Chem. **62**, 2851 (1984).

Viscosities have been determined for six binary mixtures of ethyl acetate with cyclohexane, benzene, toluene, ethylbenzene, carbon tetrachloride, and chloroform at 303.15 K. Excess viscosities, η^E, and excess free energies of activation of flow, ΔG^{*E}, were calculated from these experimental data. Excess free energies of activation of flow, ΔG^{*E}, are large negative values for the mixture ethyl acetate + cyclohexane. The negative values of ΔG^{*E} are reduced when benzene, toluene, ethylbenzene, and carbon tetrachloride is used instead of cyclohexane in the binary mixture. High positive values of ΔG^{*E} are found for the mixture ethyl acetate + chloroform.

SHANTILAL OSWAL et MANAPRAGADA V. RATHNAM. Can. J. Chem. **62**, 2851 (1984).

On a mesuré les viscosités de six mélanges binaires de l'acétate d'éthyle avec le cyclohexane, le benzène, le toluène, l'éthylbenzène, le tétrachlorure de carbone et le chloroforme, à 303,15 K. A partir de ces données, on a calculé les viscosités en excès, η^E, et les énergies libres d'activation d'écoulement en excès, ΔG^{*E}. Les valeurs de ΔG^{*E} sont élevés et négatives pour le mélange acétate d'éthyle + cyclohexane. Si on remplace le cyclohexane par du benzène, du toluène, de l'éthylbenzène ou du tétrachlorure de carbone, les valeurs négatives du ΔG^{*E} sont réduites. Dans le cas du mélange d'acétate d'éthyle avec le chloroforme, les valeurs du ΔG^{*E} sont positives et élevées.

[Traduit par le journal]

Introduction

Excess thermodynamic functions have been used as a qualitative and quantitative guide to predict the extent of complex formation in binary liquid mixtures of nonelectrolytes (1–4). If the viscosity data for the mixtures could be obtained as a function of composition the existence or nonexistence of the specific interactions in them could be indicated by estimating the strength of interactions (5–7). A number of workers (8–11) have utilised the direct approach developed by Grunberg and Nissan (6) and Katti and Chaudri (7) to estimate the strength of interactions in binary mixtures of nonelectrolytes from viscosity data. In continuation of our work (12–15) on solution properties we report in this paper the viscosity measurements for the study of molecular interactions of six binary mixtures of cyclohexane, benzene, toluene, ethylbenzene, carbon tetrachloride, and chloroform in ethyl acetate at 303.15 K.

Experimental

Viscosity was measured with a modified Ubbelohde viscometer (16). The time of efflux of a constant volume of liquid through the capillary was measured with the help of a precalibrated RACER stopwatch correct to ±0.1 s. The viscometer was always kept in a vertical position in a water thermostat at 303.15 ± 0.02 K. The efflux time for water at 303.15 K was about 215 s. Viscosity was calculated from the measured efflux time (t) using the relation [1].

$$[1] \quad \eta = \rho(At - B/t)$$

where ρ is the density and A and B are characteristic constants of the viscometer, which were determined by taking water and benzene as the calibrating liquids. The correctness of these constants was checked by comparing the experimentally determined viscosities for cyclohexane, ethyl acetate, toluene, carbon tetrachloride, ethylbenzene, chloroform with corresponding literature values (17, 18) (Table 1). The agreement was within ±0.2%. Densities of mixtures needed to calculate viscosities of mixtures were taken from earlier reported data (15, 19).

Materials and solutions

Ethyl acetate (BDH Analar), cyclohexane (BDH Analar), benzene (BDH Analar), toluene (Analar), ethylbenzene (Fluka AG), carbon tetrachloride (BDH Spectroscopic), and chloroform (BDH Spectroscopic) were purified by standard procedure given by Riddick and Bunger (18). Ethyl acetate was fractionally distilled, stored over potassium carbonate for 15 days, and redistilled over phosphorous pentoxide before use. Cyclohexane was vigorously shaken with a mixture of concentrated nitric and sulphuric acids for 8 h at temperatures below 10°C, then washed repeatedly with distilled water, dried over calcium chloride, and fractionally distilled over sodium. Benzene and toluene were freed from thiophene by shaking with sulphuric acid, the samples so obtained were washed with water, followed by subsequent washings with sodium hydroxide and distilled water, dried thoroughly over anhydrous calcium chloride, and fractionally distilled thrice. Carbon tetrachloride was refluxed over alcoholic potassium hydroxide, washed with distilled water several times, dried over anhydrous calcium chloride, and fractionally distilled twice. Chloroform was shaken with concentrated sulphuric acid, then washed with dilute sodium hydroxide and with ice water, dried over potassium carbonate, and fractionally distilled twice. Ethylbenzene (Fluka AG) of purity greater than 99% was used as received. Purity of all these liquids was checked by measuring their densities and refractive indices at 303.15 K, which compared well with the literature data (17, 18) (Table 1).

Results and discussion

Viscosity (η) data at 303.15 K over the entire range of composition from 0.0 to 1.0 mole fractions were measured for binary mixtures ethyl acetate + cyclohexane, + benzene, + toluene, + ethylbenzene, + carbon tetrachloride, and + chloroform.[3] The excess viscosities η^E calculated from the relation [2]

$$[2] \quad \eta^E = \eta_{12} - [X_1\eta_1 + X_2\eta_2]$$

over the entire range of composition were fitted to the following empirical equation [3]

TABLE 2. Parameters for least-squares fit of results by eq. [3] and standard deviation σ for excess viscosity data

System	A_0	A_1	A_2	$\sigma\times10^3$
Ethyl acetate + cyclohexane	−0.5757	0.3605	−0.2178	4.16
Ethyl acetate + benzene	−0.1214	0.0443	−0.0080	2.16
Ethyl acetate + toluene	−0.0211	0.0154	0.0233	1.57
Ethyl acetate + ethylbenzene	−0.0193	−0.0199	0.0238	1.77
Ethyl acetate + carbon tetrachloride	−0.2400	0.1188	−0.0631	3.40
Ethyl acetate + chloroform	0.2405	−0.1386	−0.0929	2.47

$$[3]\quad \eta^E = X_1X_2[A_0 + A_1(X_1 - X_2) + A_2(X_1 - X_2)^2]$$

where 1, 2 represent the pure components, 12 their mixture, and A_0, A_1, and A_2 are constants. The method of least-squares was used to determine the values of the constants. The values of these constants along with the standard deviation σ defined by

$$\sigma^2 = \Sigma\{\eta^E_{exp} - \eta^E_{cal}\}/(n - 3)$$

are given in Table 2, where n is the total number of measurements. Excess free energies of activation of flow, ΔG^{*E}, are used to estimate the strength of interactions in the present study, using the relation [4]:

$$[4]\quad \Delta G^{*E} = RT[\ln \eta_{12}V_{12} - (X_1 \ln \eta_1V_1 + X_2 \ln \eta_2V_2)]$$

where V_{12}, V_1, and V_2 are the molar volumes of the mixture and of the pure components, R is the gas constant, and T is the absolute temperature. The results of ΔG^{*E} are represented graphically in Fig. 1. Memmi and Piekarski (11) have measured viscosity for ethyl acetate + cyclohexane mixtures at 298 K. Their value of Grunberg and Nissan (6) parameter $d = -0.82$ at $X = 0.5$ estimated from graph is in quite good agreement with ours (−0.83). It is observed that there is a large negative deviation from rectilinear dependence of viscosity on mole fraction for the mixture ethyl acetate + cyclohexane. The negative deviation is sufficiently reduced when cyclohexane is replaced either by benzene, toluene, ethylbenzene, or carbon tetrachloride. The large positive deviation is observed for the ethyl acetate + chloroform mixture.

It is instructive to compare the present ΔG^{*E} data with the few selected binary mixtures already reported in literature.

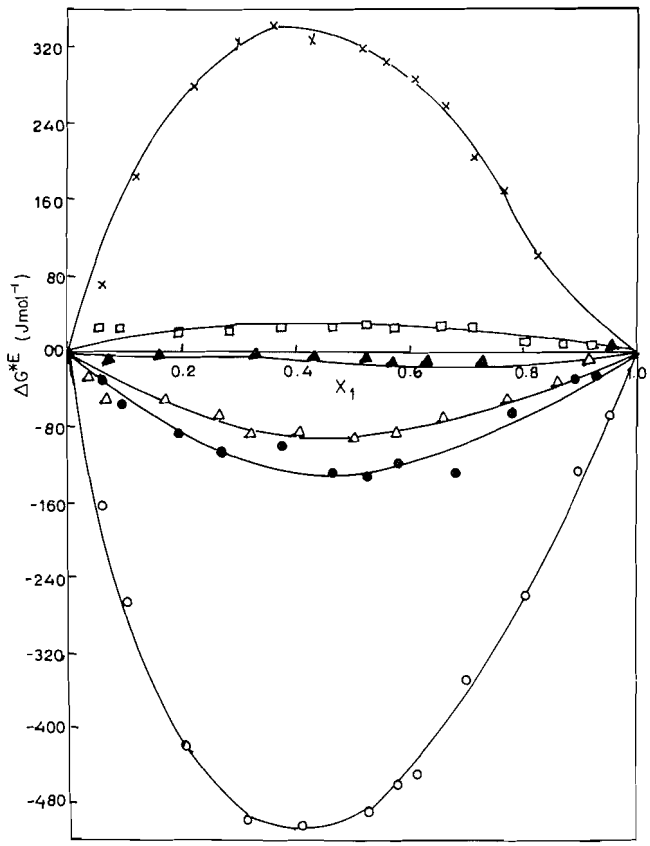

FIG. 1. Excess free energy of activation of flow ΔG^{*E} for ethyl acetate + cyclohexane ○; + benzene ●; + toluene △; + ethylbenzene △; + carbon tetrachloride □; + chloroform ×.

These are summarised in Table 3. Ethyl acetate + cyclohexane mixture has large negative ΔG^{*E} values. This behaviour is characteristic of mixtures in which dispersion forces are dominant, e.g., benzene + cyclohexane (20), cyclohexane + *n*-pentane (8), benzene + *n*-hexane (8), acetone + cyclohexane (9), methylethylketone + cyclohexane (9) and benzene + ethylene dichloride (5).

For mixtures ethyl acetate + benzene + toluene, + ethyl benzene, we observe less negative ΔG^{*E} values than that of ethyl acetate + cyclohexane. This behaviour is similar to that observed for the mixtures acetone + benzene (9), methylethylketone + benzene (9), methylethylketone + *p*-xylene (9), and acetone + *p*-xylene (9).

We observe large positive ΔG^{*E} values for the ethyl acetate + chloroform mixture, similar to those of chloroform + acetone (5), chloroform + dioxane (5, 8), and chloroform +

YOSHINORI ADACHI, BENJAMIN C.-Y. LU, and HIDEZUMI SUGIE. Can. J. Chem. **62**, 2854 (1984).

The umbrella sampling technique advanced by Torrie and Valleau for estimating free energies was followed in this work for calculating the excess Helmholtz free energy for the Lennard–Jones (6:12) fluid at 48 points. These values were combined with data available in the literature for the establishment of tables of excess Helmholtz and Gibbs free energies over wide ranges of T^* (0.50 to 2.75) and ρ^* (0.05 to 0.80). The values of excess Helmholtz free energy were used to develop a correction function for modifying the second-order perturbation term of the Barker–Henderson perturbation treatment with its subsequent application to the calculation of compressibility factor, vapor–liquid coexistence curve of the Lennard–Jones (6:12) fluid, and Henry's constants for 26 systems.

YOSHINORI ADACHI, BENJAMIN C.-Y. LU et HIDEZUMI SUGIE. Can. J. Chem. **62**, 2854 (1984).

Dans le présent travail, on a fait appel à la technique de l'échantillonnage en ombrelle proposée par Torrie et Valleau pour évaluer les énergies libres en excès de Helmholtz pour le fluide de Lennard–Jones (6:12) à 48 points. On a combiné ces valeurs avec les données disponibles dans la littérature pour établir des tables d'énergie libre en excès de Helmholtz et de Gibbs pour des valeurs de T^* allant de 0,50 à 2,75 et pour des valeurs de ρ^* s'étalant de 0,05 à 0,80. On a utilisé les valeurs d'énergie libres en excès de Helmholtz pour développer une fonction de correction en vue de modifier le terme de perturbation de second ordre du calcul de perturbation de Barker–Henderson; on a éventuellement appliqué cette expression modifiée au calcul du facteur de compressibilité, à la courbe de coexistence vapeur–liquide du fluide de Lennard–Jones (6:12) et aux constantes d'Henry de 26 systèmes.

Introduction

Torrie and Valleau (1, 2) have proposed the umbrella sampling method for estimating free energy of a fluid. This Monte Carlo technique involves the use of arbitrary sampling distribution chosen to facilitate the estimate instead of using the Boltzmann-weighted sampling distribution. It has been successfully applied by these authors to the Lennard–Jones (6:12) fluid in a wide range of temperature including part of the vapor–liquid coexistence region, using a small number of particles. Nevertheless, the free energy values reported by these authors as well as those from other Monte Carlo methods are still very fragmentary for the fluid. Extrapolation to the regions of low temperature and high density presents a serious problem due to the sensitivity of the numerical values to the variation of the density.

In this work, the excess Helmholtz free energy (ΔF^E) values for the Lennard–Jones (LJ) fluid were selectively calculated by means of the umbrella sampling method at six reduced temperature T^* ($= kT/\epsilon$) conditions and eight reduced density ρ^* ($N\sigma^3/v$) conditions for a total of 48 points. In our calculation, a slight modification was made in the umbrella sampling method on the weighting function. These values together with the values reported in the literature were correlated by the Lagrange interpolation method, resulting in a comprehensive table of 416 values of $\Delta F^E/NkT$. The LJ fluid was selected because it resembles the properties of the real fluid argon. Furthermore, the calculated results are useful to the extension of the calculation using the Kihara potential. In addition, the excess Gibbs free energy (ΔG^E) values were calculated over the same ranges of T^* and ρ^*.

The Barker–Henderson perturbation theory has been frequently used in chemical engineering calculations. In the calculation of vapor–liquid equilibrium values, Rogers and Prausnitz in 1971 (3) applied the theory to binary mixtures of spherical-type molecules at pressures up to the critical; Uno *et al.* (4) in 1976 applied the theory to normal fluid mixtures; and Masuoka *et al.* (5, 6) in 1977 applied the theory to systems containing a non-polar substance and a polar substance including ammonia. Other applications include the calculation of Henry's constant for normal fluids (7) and the calculation of *PVT* relations for non-polar and polar substances (8). All these applications involved the second-order term in the perturbation expansion. As an application of the excess Helmholtz free energy table, an effort was made to improve the second-order perturbation term of the Barker–Henderson treatment (9, 10) obtained from the macroscopic compressibility approximation (9). This modification was made by multiplying the term with a correction function in terms of ρ^*. The values of $\Delta F^E/NkT$ and compressibility factor Z calculated by means of the modified expression were compared with those obtained from other methods to verify the modification. An attempt was made to establish the limitations of the applicability of the LJ fluid by comparing the calculated Z values with those correlated by Lee and Kesler (11). The modified expression was also used to calculate the coexisting vapor–liquid curve for the LJ fluid and Henry's constants for 26 systems.

Calculation of excess free energies

According to the umbrella sampling method advanced by Torrie and Valleau (1, 2), the Helmholtz free-energy difference between the system of interest with internal energy of $U(q_N)$ at temperature T and a reference system with internal energy $U_0(q_N)$ at temperature T_0 is given by:

$$[1] \quad \frac{F}{kT} - \frac{F_0}{kT_0} = -\ln \int_{-\infty}^{\infty} f_0(\Delta U^*) \exp(-\Delta U^*)\, d\Delta U^*$$

[1] Revision received May 1, 1984.

where U^* is the reduced energy U/kT, $\Delta U^* = (U/kT - U_0/kT_0)$, and $f_0(\Delta U^*)$ is the probability density of ΔU^* in the reference fluid. Because of the difficulty encountered in estimating $f_0(\Delta U^*)$ exp $(-\Delta U^*)$ by means of the conventional Boltzmann sampling, a suitable weighting function $w(q_N) = W(\Delta U^*)$ is chosen by Torrie and Valleau to favor those configurations with values of ΔU^* important to the integral in eq. [1]. The Boltzmann distribution exp $(-\beta U)$ is therefore replaced by a new distribution, $W(\Delta U^*)$ exp $(-\beta U)$. The probability density $f_0(\Delta U^*)$ can be recovered from the probability density of ΔU^* in the biased Monte Carlo experiment, $f_w(\Delta U^*)$, by reweighting:

$$[2] \quad f_0(\Delta U^*) = \frac{f_w(\Delta U^*)/W(\Delta U^*)}{\langle 1/W \rangle_w}$$

The expression $\langle\rangle_w$ denotes an ensemble average over the weighted chain of configuration. Torrie and Valleau (2) adjusted $W(\Delta U^*)$ by trial and error until $f_w(\Delta U^*)$ is as wide and uniform as possible, and named their technique "umbrella sampling" because of the requirement that the sampling distribution specified by W should cover the regions of configuration space relevant to two or more physical systems simultaneously.

In this work, a simpler method was found to obtain the weighting function. An exponential expression, C_1 exp $\{C_2(\Delta U^* - C_3)C_4\}$, was used to fit the quantity $f_0(\Delta U^*)$ and the weighting function was expressed by eq. [3].

$$[3] \quad W(\Delta U^*) = \exp\{-C_2(\Delta U^* - C_3)^{C_4}\}$$

Other than the selection of the weighting function, the umbrella sampling technique was followed for the determination of the difference of Helmholtz free energy of eq. [1] for the LJ fluid.

The calculation procedure for determining the parameters of the weighting function may be briefly outlined as follows:

(*1*) Obtain the unweighted distribution of ΔU^* by means of the Monte Carlo sampling method of Metropolis *et al.* (12) for 100 000 steps.

(*2*) Determine the four parameters by fitting the distribution obtained from step 1 using the expression of C_1 exp $\{C_2(\Delta U^* - C_3)^{C_4}\}$. The initial values of $C_1 = 0.2$, $C_2 = 0.2$ were used in the fitting procedure. The value of $C_4 = 2$ was fixed at this stage. The value of C_3 depends on the location of the peak of the distribution.

(*3*) Choose a value of ΔU_1^* to "cover" the exp $(-\Delta U^*)$ distribution which is estimated in step 2 by calculating C_1 exp $\{C_2(\Delta U^* - C_3)^{C_4}\}$ exp $(-\Delta U^*)$, and let $\Delta U_2^* = C_3$. The weighting function $W(\Delta U^*)$ is obtained as follows:

$$W(\Delta U^*) = \begin{cases} \exp\{-C_2(\Delta U^* - C_3)^{C_4}\} & \text{if } \Delta U_1^* < \Delta U^* < \Delta U_2^* \\ \exp\{-C_2(\Delta U_1^* - C_3)^{C_4}\} & \text{if } \Delta U^* < \Delta U_1^* \\ \exp\{-C_2(\Delta U_2^* - C_3)^{C_4}\} & \text{if } \Delta U_2^* < \Delta U^* \end{cases}$$

(*4*) Do 500 000 steps of umbrella sampling (Run I), and check the shape of the weighted distribution. If the shape of the weighted distribution is not sufficiently flat and not adequate to cover the range of the exp $(-\Delta U^*)$ distribution, modify the value of C_4 empirically. The value of C_4 is usually around 1.7 to 2.0.

(*5*) Repeat step 4 and do Run II etc.

Typical distribution functions for (U_6/kT) are depicted in Fig. 1 (top) in which $\rho^* = 0.85$, $T^* = 2.74$, and $N = 32$. These values are identical to those used in the illustration of Torrie and Valleau (ref. 2, Fig. 1). They were selected in this work to facilitate comparison. The values of the parameters C_2, C_3, and C_4 of the weighting function (eq [4]) are 0.1518, −147, and 1.7, respectively. In the calculation (Run I), $\Delta U_1^* = -161$ and

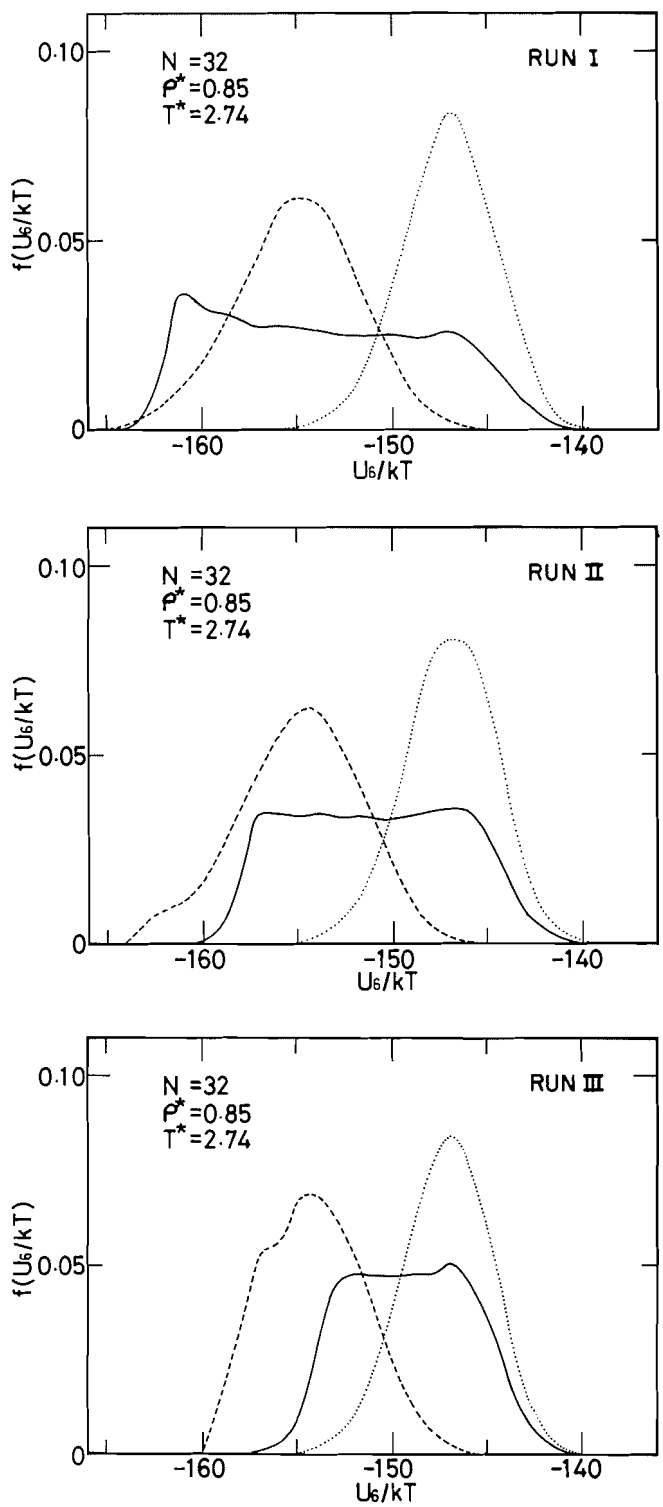

FIG. 1. Probability density distributions. Solid line (f_w): the biased probability density. Dotted line (f_0): the unbiased probability density obtained by reweighting f_w. Broken line: relative values of $f_0(U_6/kT)$ exp $(-U_6/kT)$ normalized to unity.

TABLE 1. Excess Helmholtz free energy, $\Delta F^E/NkT$, obtained from the umbrella sampling method for the Lennard–Jones fluid

	$\Delta F^E/NkT$ for $\rho^* =$							
T^*	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8
0.501	−1.38	−2.37	−3.46	−4.50	−5.59	−6.65	−7.40	−7.86
0.7	−0.88	−1.56	−2.25	−2.92	−3.56	−4.14	−4.66	−4.82
0.885	−0.62	−1.09	−1.58	−2.02	−2.46	−2.85	−3.14	−3.18
1.002	−0.48	−0.88	−1.25	−1.67	−1.96	−2.24	−2.47	−2.46
1.261	−0.32	−0.61	−0.93	−1.12	−1.32	−1.48	−1.52	−1.46
1.511	−0.22	−0.43	−0.61	−0.76	−0.90	−0.95	−0.92	−0.76

$\Delta U_2^* = -147$ ($=C_3$).

In order to illustrate the effect of the proposed weighting function on the determination of $\Delta F/N\epsilon$ values, we have used the above system ($\rho^* = 0.85$, $T^* = 2.74$, and $N = 32$) and altered the value of ΔU_1^* from −161 to −157 and −153 for two additional runs (Run II and Run III of step 5) without changing the parameter values of the weighting function. The resulting weighted distributions are depicted in Fig. 1 (middle and lower boxes). The values of $\Delta F/N\epsilon$ obtained from these three runs are as follows:

Run	$\Delta F/N\epsilon$
I	−12.855
II	−12.848
III	−12.835

All three values are in good agreement with the value reported by Torrie and Valleau ($\Delta F/N\epsilon = -12.85 \pm 0.015$, ref. 2, Table II). In other words, the equilibrium value of $\Delta F/N\epsilon$ has not been significantly affected by the significant variation in the weighted distribution. This may come as a result of sufficient number of configurations, i.e., 500 000. It was observed that the $\Delta F/N\epsilon$ values obtained from Run I and Run II are usually very close to each other, and the weighted distributions of Run II appear to be adequate. In this work, the average values of the first two runs are reported.

The $\Delta F/NkT$ values were determined in this work at six T^* conditions in the range of 0.5 to 1.5 and eight ρ^* conditions in the range of 0.1 to 0.8 for a total of 48 points. For the Lennard–Jones fluid, the reference system used in the calculation is the "soft sphere" fluid with internal energy $U_0 = U_{12}$ at the same density and temperature. This reference system was used by Hoover *et al.* (13) and was also adopted by Torrie and Valleau (1) in their calculations. Complete thermodynamic information on the reference system is available in the work of Hoover *et al.* (13), and was used in the calculation of excess Helmoltz free energy at the 48 conditions. The results are reported in Table 1. It should be mentioned that all runs were for 32-particle samples. Some 64- and 108-particle samples were carried out for checking purpose in this work, but the calculated equilibrium values are not significantly dependent on the number of particles of the samples.

The values of Table 1 were correlated together with other values reported in the literature (ref. 14, column 5 of Table 1; ref. 15, columns 3 and 5 of Table 1; ref. 16, column 7 of Table 4 for $T^* = 2.74$; and ref. 17, column 6 of Table 1) by means of the Lagrange interpolation method for establishing a set of ΔF^E values for the LJ fluid over wide ranges of temperature and density at specified intervals of T^* and ρ^*. These values in the form of $\Delta F^E/NkT$ are presented in Table 2, in which the ranges of T^* and ρ^* covered are 0.50 to 2.75 and 0.05 to 0.80, respectively. In terms of the properties of argon, the temperature range of the table extends from the temperature lower than the triple point to that twice above the critical temperature, and the density range extends from about twice the critical density to that of a large volume gas.

It should be mentioned that the Lagrange interpolation method was used twice in this work, one in the direction of ρ^* and the other, T^*. For each interpolated point, only four properly selected data points were used for its determination.

In addition, these excess Helmholtz free energy values were combined with *PVT* data (18, 19) for establishing a set of excess Gibbs free energy values for the LJ fluid over the same ranges of temperature and density with the same intervals of T^* and ρ^* as those listed in Table 2. The calculated $\Delta G^E/NkT$ values are presented in Table 3.

Modification of the second order perturbation term of the Barker–Henderson treatment

Perturbation theory is a very successful integral-equation extension of hard-sphere theory to real fluids. One of the approaches was developed by Barker and Henderson (BH). The BH expression for the Helmholtz free energy of a pure fluid is:

$$[4] \quad F = F_{hs} + 2N\pi\rho \int_\sigma^\infty u(r) g_{hs}(r) r^2 \, dr - N\pi\rho \left(\frac{\partial\rho}{\partial p}\right)_{hs} \int_\sigma^\infty u^2(r) g_{hs}(r) r^2 \, dr = F_{hs} + F_1 - F_2$$

when the so-called "macroscopic compressibility" approximation (9) is used in the derivation. In eq. [4], F_{hs}, g_{hs}, and $(\partial\rho/\partial p)_{hs}$ are the Helmholtz free energy, radial distribution function, and compressibility, respectively, of a reference hard-sphere system of effective diameter d; the quantities F_1 and F_2 are the first-order and the second-order perturbation terms, respectively. The quantity d is defined by:

$$[5] \quad d = \int_0^\sigma \left\{1 - \exp\left[-\frac{u(r)}{kT}\right]\right\} dr$$

It is dependent on the potential function $u(r)$ and temperature. The quantity σ is the value of molecular separation at $u(r) = 0$. The reason for using the macroscopic compressibility, instead of the local compressibility approximation, is because the former one is simpler to use computationally. Both of these approximations were suggested by Barker and Henderson (9) yielding similar results.

Correction function for F_2

The evaluation of Helmholtz free energy by means of eq. [4] is not exact. Because the exact second-order perturbation term cannot be easily calculated, the macroscopic compressibility approximation was used. In addition to this approximation, the truncation of higher-order perturbation terms and the solution of the Percus–Yevick (PY) approximation used for the hard-sphere radial-distribution function also caused errors in the evaluation. An attempt was made in this work to reduce these errors by introducing a correction function to F_2 of eq. [4]. The

correction function was obtained by: (*i*) calculating the differences of Helmholtz free energies between the values of Table 2 and the corresponding values calculated from eq. [4] but limited to the first-order perturbation term, (*ii*) obtaining correction factors by dividing these differences with the F_2 values obtained from eq. [4] at the corresponding conditions, and (*iii*) correlating these ratios in terms of T^* and ρ^*. In the calculation, the hard-sphere model of Carnahan and Starling (20) was used as the reference. The correlation results as shown in Fig. 2 indicate that the correction factors are not strongly de-

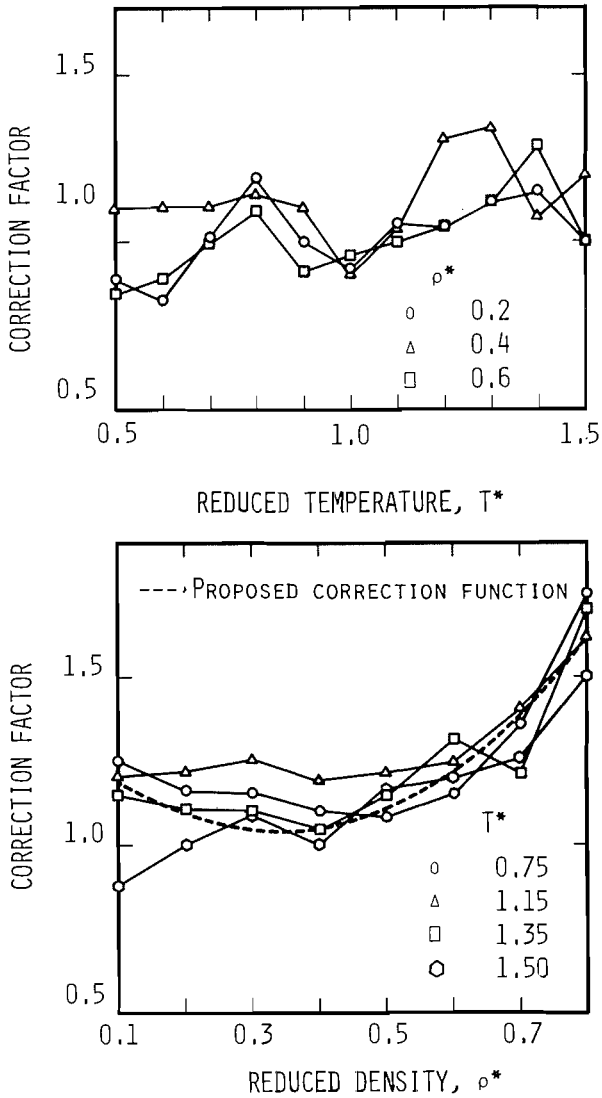

FIG. 2. The effect of T^* and ρ^* on correction factors.

pendent on temperature but more dependent on density. The need of a density correction function in the high density region can also be shown from the study of the radial distribution function of the hard-sphere fluid. The calculated radial distribution functions at three $\eta\,(=(\pi/6)\,\rho d^3)$ values, using the PY approximation and the Monte Carlo method, are depicted in Fig. 3. The deviations between the two methods increase with the increase of η. In this work, the correction function was simply expressed in terms of ρ^* by means of a quadratic equation,

$$[6] \quad C(\rho^*) = 1.6736 - 3.5710\rho^* + 5.3665\rho^{*2}$$

The approximate representation of the correction factors by means of eq. [6] is depicted in Fig. 2, and eq. [4] was modified to

$$[7] \quad F = F_{hs} + F_1 - C(\rho^*)F_2$$

Applicability of the proposed modification

The applicability of eq. [7] was first tested by calculating the excess Helmholtz free energy and the compressibility factor,

$$[8] \quad \left(\frac{P}{\rho kT}\right) = \left(\frac{P}{\rho kT}\right)_{hs} + \rho\frac{\partial}{\partial\rho}\left(\frac{F - F_{hs}}{NkT}\right)$$

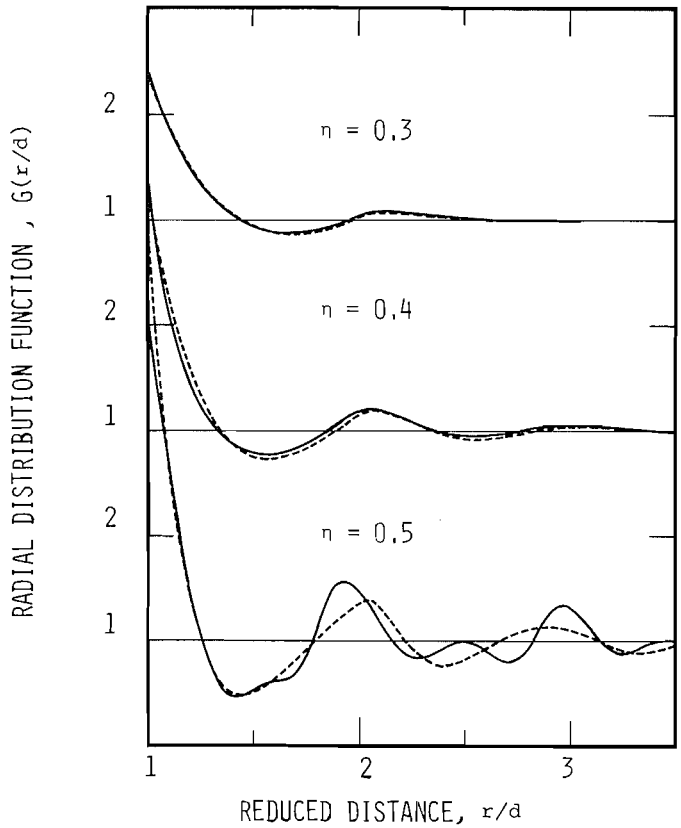

FIG. 3. Radial distribution function of the hard-sphere fluid ($\eta = (\pi/6)\,\rho d^3$): — Monte Carlo method, --- PY approximation.

for the LJ fluid at 20 selected conditions. In eq. [8], the subscript hs refers to the hard sphere. The calculated results were then compared in Table 4 with the values obtained from the Monte Carlo (MC) method, the perturbation theory advanced by Weeks, Chandler, and Andersen (WCA) (21) as well as those obtained from eq. [4]. The comparison indicates that the calculated values are as accurate as those obtained from the WCA method, which yields results closer to those obtained from the MC method than does the original second-order perturbation expression of Barker and Henderson. The proposed modification is, however, much simpler to use computationally than is the WCA method.

For the purpose of determining the limitations of the applicability of the LJ fluid, Z values were calculated at four values of acentric factor ω, in the ranges of reduced temperature $T_r(=T/T_c)$ from 0.8 to 2.0 and reduced pressure $P_r(=P/P_c)$ from 0 to 10. These values are compared with those correlated by Lee and Kesler (11) in Fig. 4.

At lower values of ω and at moderate pressures, the Z values obtained from eq. [7] are acceptable. However, at $\omega \geq 0.2$, the deviations become very noticeable even when the temperature is high. At $\omega = 0$, the calculated Z values are acceptable at $T_r \geq 1.0$, but the agreement is poor at $T_r < 1.0$, indicating the need of higher-order perturbation terms for the prediction of Z values at low temperatures.

The densities and pressures of the coexisting vapor and liquid phases for the LJ fluid were also calculated. The calculated reduced densities ρ^* are compared in Fig. 5 with the MC results of Adams (22) and the values obtained from the equation of state of Nicolas *et al.* (23) for the LJ fluid, and those from eq. [4], the original second-order perturbation expression of Barker

and Henderson. The data for argon reported by Gosman *et al.* (24) were converted into the reduced form by using $\sigma = 3.405$ Å and $\epsilon/k = 119.76$ K and are included in Fig. 5 for comparison. These parameter values were determined from the second virial coefficient of argon (18). Also included in the comparison is the locus of the mid-points (rectilinear diameters). The large cross included in the figure indicates the estimated location of the critical point of the LJ fluid (15).

TABLE 5. Comparison of calculated Henry's constants using parameters derived from different properties for the binary nitrogen–methane system

	Average absolute percentage deviations			
Temperature range (K)	Second virial coefficient	Viscosity	Saturation property	*PVT* data
120–160	26.1	24.9	15.5	10.6

The comparison indicates that much improved density prediction in the liquid phase was obtained with the proposed modification (eq. [7]) than the original BH expression. The calculated results agree well with the MC results of Adams and, with the exception of the critical region, the data of argon and the results from the analytical equation of Nicolas *et al.* The equation of Nicolas *et al.* is of the Strobridge type with its coefficient obtained from fitting the data of the LJ fluid.

The modified equation was further applied to the calculation of Henry's constants for 26 binary systems containing nitrogen, carbon dioxide, hydrogen sulfide, and normal alkanes up to heptane. In the calculation, a binary characteristic constant k_{12} was introduced in the mixing rule for the cross energy parameter ϵ_{12} as follows:

$$[9] \quad \epsilon_{12} = (\epsilon_{11}\epsilon_{22})^{1/2}\,(1 - k_{12})$$

with its value determined by minimizing the differences between the calculated values and those reported by Prausnitz and Chueh (25). The effect of the parameter values on the calculated results was evaluated. In addition to those values obtained from viscosity data and from second virial coefficients as reported by Hirschfelder *et al.* (26) for the LJ potential, the parameter values determined in this work from saturation properties and from *PVT* data were also used. The values obtained

* AAD = average absolute deviation.

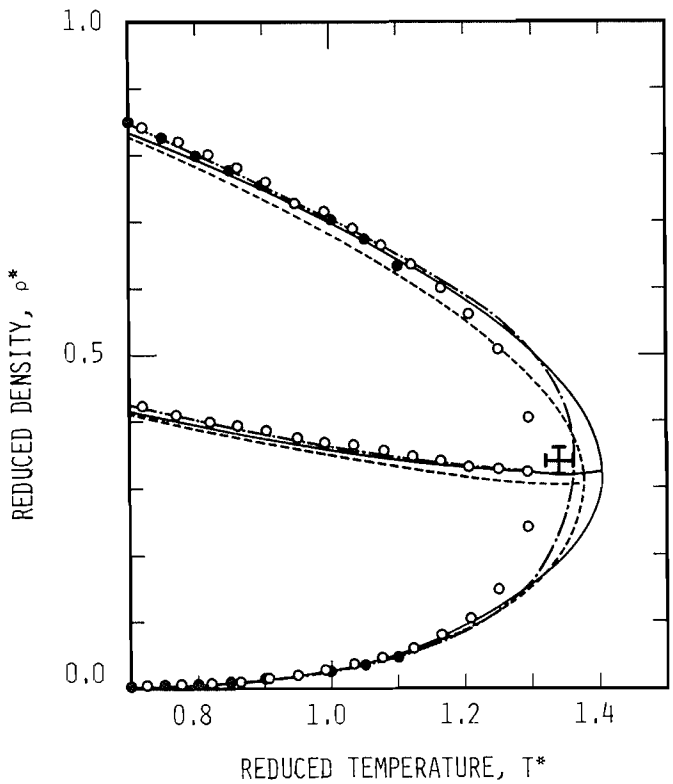

FIG. 5. Comparison of calculated saturation curves for the LJ fluid: ○, date of argon (24); ●, MC results of Adams (22); -·-·-; equation of Nicholas *et al.* (23); ---, eq. [4]; —, this work; +, estimated critical point (15).

in this work were generalized in terms of ω and critical properties. Hence from saturation properties (27–29),

$$[10]\quad \epsilon/kT_c = 0.7687$$

$$[11]\quad \sigma(NZ_c/V_c)^{1/3} = 0.4524 - 0.0766\omega$$

and from *PVT* data (11)

$$[12]\quad \epsilon/kT_c = 0.7700 - 0.1400\omega \quad (0 \le \omega \le 0.3)$$

$$[13]\quad = 0.7510 - 0.0745\omega \quad (0.3 \le \omega \le 0.5)$$

$$[14]\quad \sigma(NZ_c/V_c)^{1/3} = 0.4482 - 0.0723\omega$$

Henry's constants of nitrogen in methane were determined using these parameter values and compared with the values of Prausnitz and Chueh (25). As the values of Prausnitz and Chueh were reported at zero pressure, their values were adjusted to the saturation pressure by the Ponting correction. A comparison of the calculated results is shown in Fig. 6. The deviations between the calculated values and the adjusted Henry's constants are summarized in Table 5. It appears that the potential parameters determined from *PVT* data yielded the best results. Consequently, Henry's constants for all the binary systems tested were determined using the parameter values given by eqs. [12]–[14]. The values obtained from nitrogen in ethane and methane in heptane are depicted in Fig. 7. A summary of the calculated results is presented in Table 6. It is generally accepted that at high pressure (e.g. $P_r > 3$), the second-order BH perturbation expression cannot yield satisfactory Henry's constants. Nevertheless, with the introduction of the proposed correction function, the average absolute deviations obtained for most systems are less than 8%.

Structure, spectra, and stability of solid bismuth carbonates[1]

PETER TAYLOR, S. SUNDER, AND VINCENT J. LOPATA

Research Chemistry Branch, Whiteshell Nuclear Research Establishment, Atomic Energy of Canada Limited, Pinawa, Man., Canada R0E 1L0

Received April 16, 1984

PETER TAYLOR, S. SUNDER, and VINCENT J. LOPATA. Can. J. Chem. **62**, 2863 (1984).

A previously unreported basic bismuth carbonate, $(BiO)_4(OH)_2CO_3$, has been identified as an intermediate product in the interconversion of α-Bi_2O_3 and synthetic bismutite, $(BiO)_2CO_3$, in aqueous carbonate solutions. It has a narrow stability field, between CO_2 partial pressures of $10^{-5.5\pm1.0}$ Pa and $10^{-4.4\pm1.0}$ Pa, in the presence of dilute aqueous solution at 25°C. Gibbs energies of formation, calculated from these partial pressures, are $\Delta_fG^0((BiO)_4(OH)_2CO_3, s, 298.15\ K) = -1678 \pm 9$ kJ mol^{-1} and $\Delta_fG^0((BiO)_2CO_3, s, 298.15\ K) = -945 \pm 7$ kJ mol^{-1}. The two carbonates have been compared by thermogravimetric analysis, X-ray powder diffractometry, and infrared and Raman spectroscopy. The unit cell of $(BiO)_4(OH)_2CO_3$ is dimensionally orthorhombic, with $a = 10.772(1)$, $b = 5.4898(5)$, $c = 14.757(1)$ Å, $Z = 4$, but its true symmetry is probably triclinic. A structural model for $(BiO)_4(OH)_2CO_3$, and two modified models for $(BiO)_2CO_3$, are proposed. The possible natural occurrence of $(BiO)_4(OH)_2CO_3$ is discussed.

PETER TAYLOR, S. SUNDER, et VINCENT J. LOPATA. Can. J. Chem. **62**, 2863 (1984).

Un carbonate basique du bismuth qui n'avait pas été rapporté antérieurement, le $(BiO)_4(OH)_2CO_3$, a été identifié comme intermédiaire dans l'interconversion, en solutions aqueuses de carbonate, du α-Bi_2O_3 et de la bismutite synthétique $(BiO)_2CO_3$. Son domaine de stabilité est étroit; à 25°C et en solutions aqueuses diluées, il est défini par des pressions partielles minimales et maximales de CO_2 de $10^{-5.5\pm1.0}$ Pa et $10^{-4.4\pm1.0}$ Pa. Les énergies de formation de Gibbs, calculées à partir de ces pressions partielles, sont: $\Delta_fG^0((BiO)_4(OH)_2CO_3, s, 298{,}15\ K) = -1678 \pm 9$ kJ mol^{-1} et $\Delta_fG^0((BiO)_2CO_3, s, 298{,}15\ K) = -945 \pm 7$ kJ mol^{-1}. On a comparé les deux carbonates en faisant appel à l'analyse thermogravimétrique, à la diffraction des poudres par rayon-X et aux spectroscopies infrarouge et Raman. Du point de vue des dimensions, la maille élémentaire du $(BiO)_4(OH)_2CO_3$ est orthorhombique avec $a = 10{,}772(1)$, $b = 5{,}4898(5)$, $c = 14{,}757(1)$ Å, $Z = 4$; toutefois, sa symétrie réelle est probablement triclinique. On propose un modèle de structure pour le $(BiO)_4(OH)_2CO_3$ et deux modèles modifiés pour le $(BiO)_2CO_3$. On discute de l'existence possible du $(BiO)_4(OH)_2CO_3$ à l'état naturel.

[Traduit par le journal]

I. Introduction

Frondel (1), in his critical review of the mineralogy of bismuth oxides and carbonates in 1943, concluded that bismutite (Bi_2CO_5 or $(BiO)_2CO_3$) is the only well-established solid carbonate in the system $Bi_2O_3-CO_2-H_2O$. He determined that most prior reports of ill-defined natural and synthetic bismuth carbonates of other compositions are referable to bismutite, and that the water content of these materials is crystallographically non-essential. However, Sahama and Lehtinen (2) cautiously stated: "It seems that not all the water in bismutite can be considered entirely non-essential, but that the deficiency in CO_2 found in some bismutite samples is balanced by a certain water content."

Our interest in bismuth carbonates arose from possible applications to the immobilization of ^{14}C that is formed in nuclear power reactors (3). During an investigation of the interconversion of α-Bi_2O_3 and $(BiO)_2CO_3$ in aqueous carbonate solutions, we isolated and identified an additional solid, $(BiO)_4(OH)_2CO_3$; we report here its preparation and characterization.

II. Experimental

"Precipitated" bismutite (~5 g) was prepared by mixing solutions of $Bi(NO_3)_3 \cdot 5H_2O$ and excess Na_2CO_3 or K_2CO_3. "Autoclaved" bismutite was prepared by heating α-Bi_2O_3 (~5 g) with excess CO_2 in water for 3–5 days at 200°C in a Teflon-lined stainless-steel autoclave. The solid product was pulverized, then allowed to react further with aqueous CO_2, and the process was repeated until no Bi_2O_3 remained, as indicated by X-ray diffraction, and by the absence of yellow colour; usually three cycles sufficed.

A second basic bismuth carbonate, $(BiO)_4(OH)_2CO_3$, was first observed in overnight reactions between various proportions of M_2CO_3 (M = Na or K) and Bi_2O_3 (1 to 7 mmol of each, in 40 cm^3 of water), at room temperature. Bismutite was the major product at M_2CO_3:Bi_2O_3 ratios greater than one. The new phase occurred, admixed with bismutite and/or unreacted Bi_2O_3, at lower ratios. It was obtained as a pure phase when Bi_2O_3 (1 mmol) was allowed to react with a solution having MOH and M_2CO_3 concentrations both near 0.1 mol dm^{-3}. Products obtained with either Na_2CO_3 or K_2CO_3 were indistinguishable by X-ray diffraction, showing that the alkali ions are not essential components. Thermogravimetric experiments, described in section III.1, below, indicated the stoichiometry $2Bi_2O_3 \cdot CO_2 \cdot H_2O$ [$(BiO)_4(OH)_2CO_3$].

Experiments on solid interconversions were performed using suspensions of the solids in aqueous solutions of M_2CO_3 and MOH, contained in screw-topped plastic bottles and continuously agitated, at room temperature unless otherwise stated. These experiments followed a strategy similar to that previously used to determine stability limits between lead oxides and carbonates (4). Solids were isolated by filtration, washed with deionized water, air-dried, and identified by X-ray powder diffractometry (XRD), using a Philips PW-1150 diffractometer with CuKα radiation and a diffracted-beam monochromator. Further characterization was done on samples shown by XRD to be at least 95% phase-pure. Thermogravimetric analyses were obtained using a Perkin-Elmer TGS-1 thermobalance, with scanning rates of 5–20°C min^{-1}, in either a CO_2 or N_2 atmosphere.

Raman spectra were recorded using a SPEX-1403 double monochromator, equipped with an RCA C31034 photomultiplier tube and controlled by a SPEX-DATAMATE microprocessor. The spectra were excited using the 488.0 or 514.5 nm lines of a Spectra-Physics 165-09 Ar^+ laser, or the 647.1 nm line of a Coherent Radiation Innova 90-K Kr^+ laser. The incident laser beam was filtered using an interference filter. Samples were polycrystalline solids, contained in Pyrex melting-point capillaries. A 90° scattering geometry was used. Spectral resolution was ~1 cm^{-1}, unless otherwise stated. The spectrometer was calibrated using the emission lines of a mercury lamp, and the plasma lines of the Ar^+ laser.

Infrared spectra were obtained from polycrystalline samples dispersed in CsI and KBr discs, using a Nicolet MX-1 FT-IR spec-

trometer, and also a Perkin-Elmer PE-457 spectrophotometer. The spectrum of $(BiO)_2CO_3$ was also recorded on a PE-225 instrument at the Memorial University of St. John's, Newfoundland. Excellent agreement was observed between the spectra obtained using the different spectrometers. The FT-IR spectra were recorded using the standard settings of the MX-1 instrument, i.e. an effective resolution of ~2 cm^{-1} and an average of 27 scans.

III. Results and discussion

1. Thermogravimetry

Samples from three different preparations of both $(BiO)_4(OH)_2CO_3$ and $(BiO)_2CO_3$ were examined by thermogravimetric analysis (TGA), between 25°C and 550–700°C. One half of the experiments were run in an N_2 atmosphere, and the remainder in CO_2. Some additional runs were terminated before decomposition was complete.

All the TGA runs showed a slow, continuous weight loss of 0.1 to 0.4% below 200°C, which we attribute to sorbed water. The decomposition of $(BiO)_4(OH)_2CO_3$ then occurred in two principal stages. The first stage occurred on average between 230 and 325°C (extreme onset temperatures 200, 260°C; extreme termination temperatures 300, 350°C; there was no systematic variation with atmosphere). The weight loss, which we attribute to loss of water, ranged between 1.6 and 2.3%, with an average of 1.9%. Products removed at 350°C were shown by XRD to consist of Bi_2O_3 and $(BiO)_2CO_3$. Additional diffuse diffraction features may have arisen from an intermediate anhydrous phase, such as $Bi_4O_5CO_3$.

The second stage of decomposition was a prolonged weight loss in the temperature range 330–670°C, totalling 4.6 to 5.9% (average 5.0%) of the sample weight. The average onset temperature in a CO_2 atmosphere was about 50°C higher than in N_2, consistent with a process involving the evolution of CO_2. Some runs showed fine structure in the TGA trace, suggestive of intermediate compound formation, but only $(BiO)_2CO_3$ and α-Bi_2O_3 could be detected by XRD in products removed at 425 and 550°C. The final product of decomposition was phase-pure α-Bi_2O_3.

The TGA data yielded empirical formulae in the range $Bi_2O_3 \cdot 0.46-0.66H_2O \cdot 0.52-0.68CO_2$, with an average of $Bi_2O_3 \cdot 0.53H_2O \cdot 0.57CO_2$. On this basis, we assigned the stoichiometry $Bi_2O_3 \cdot 0.5H_2O \cdot 0.5CO_2$ ($\equiv (BiO)_4(OH)_2CO_3$). We recognize that a more complex formulation is possible, bearing in mind the unusual stoichiometries of many other basic bismuth salts, as exemplified by the nitrates (5–7). However, the assigned stoichiometry is completely compatible with the XRD data, discussed at length in section III.4, below. The thermal decomposition route is summarized in the following reaction sequence [1]:

$$[1a]\quad (BiO)_4(OH)_2CO_3 \xrightarrow{230-325°C} Bi_4O_5CO_3(?) + H_2O$$

$$[1b]\quad Bi_4O_5CO_3 \rightarrow (BiO)_2CO_3 + Bi_2O_3$$

$$[1c]\quad (BiO)_2CO_3 \xrightarrow{330-670°C} Bi_2O_3 + CO_2$$

Our TGA experiments on $(BiO)_2CO_3$ showed that it decomposed to Bi_2O_3 in a single prolonged process. In N_2 atmosphere, CO_2 evolution commenced at 350–390°C, and continued until 530–650°C. The onset temperature was consistently higher, 400–430°C, in a CO_2 atmosphere, as expected. These results are consistent with Beck's differential thermal analyses of three specimens of natural bismutite (8), which showed decomposition in air to occur between about 400 and 530°C. They also parallel the second stage in the decomposition of $(BiO)_4(OH)_2CO_3$, described above. There was no indication of any solid intermediate in the decomposition of $(BiO)_2CO_3$. The six TGA runs (two on each of three samples) yielded empirical compositions in the range $Bi_2O_3 \cdot 0.95-1.03CO_2$, with an average of $Bi_2O_3 \cdot 1.00CO_2$ $[(BiO)_2(CO_3)_{1.00}]$. The less reproducible data for $(BiO)_4(OH)_2CO_3$ than $(BiO)_2CO_3$ reflect the difficulty of preparing pure $(BiO)_4(OH)_2CO_3$.

2. Determination of stability limits

Interconversions between the bismuth compounds may be expressed in terms of anion exchange (reactions [2*a*], [3*a*], [4*a*] below), or of reactions involving CO_2 and water ([2*b*], [3*b*], [4*b*]):

$$[2a]\quad 2Bi_2O_3(s) + CO_3^{2-}(aq) + 2H_2O(l) \rightleftharpoons (BiO)_4(OH)_2CO_3(s) + 2OH^-(aq)$$

$$[2b]\quad 2Bi_2O_3(s) + CO_2(g) + H_2O(l) \rightleftharpoons (BiO)_4(OH)_2CO_3(s)$$

$$[3a]\quad (BiO)_4(OH)_2CO_3(s) + CO_3^{2-}(aq) \rightleftharpoons 2(BiO)_2CO_3(s) + 2OH^-(aq)$$

$$[3b]\quad (BiO)_4(OH)_2CO_3(s) + CO_2(g) \rightleftharpoons 2(BiO)_2CO_3(s) + H_2O(l)$$

$$[4a]\quad Bi_2O_3(s) + CO_3^{2-}(aq) + H_2O(l) \rightleftharpoons (BiO)_2CO_3(s) + 2OH^-(aq)$$

$$[4b]\quad Bi_2O_3(s) + CO_2(g) \rightleftharpoons (BiO)_2CO_3(s)$$

The anion-exchange equations give a more realistic description of the net reactions in alkaline solution, and equilibrium constants of the form $K_{eq} = \{OH^-\}^2/\{CO_3^{2-}\}$ define the boundaries of adjoining solid stability fields. The alternative equations involving $CO_2(g)$ are more convenient for general discussion of stability relationships, as described in ref. 4, and lead to an alternative expression of the equilibrium constants[2] as $1/p(CO_2)$. Hereafter, p_1 and p_2 refer to the equilibrium CO_2 partial pressures for reactions [2*b*] and [3*b*], respectively.

Reactions of bismuth oxide, α-Bi_2O_3

Bismuth oxide was converted to $(BiO)_4(OH)_2CO_3$ by reaction in solutions with $[K_2CO_3] = 0.25$ mol dm^{-3} and $[KOH] = 0.05$ to 0.4 mol dm^{-3}, or with $[K_2CO_3] = 0.1$ mol dm^{-3} and $[KOH] = 0.1$ to 0.3 mol dm^{-3}. When no KOH was added to the K_2CO_3 solutions, the reaction proceeded through to $(BiO)_2CO_3$. The final pH in such runs was only about 0.3 units less than in those with 0.1 mol dm^{-3} of KOH added, due to OH^- release according to reaction [4*a*]. No solid carbonates were formed when Bi_2O_3 was exposed to solutions with $[K_2CO_3] = 0.25$ mol dm^{-3} and $[KOH] \geq 0.5$ mol dm^{-3}.

Reactions of the basic bismuth carbonate, $(BiO)_4(OH)_2CO_3$

This solid was converted to $(BiO)_2CO_3$ by a 0.1 mol dm^{-3} solution of K_2CO_3. It was converted to Bi_2O_3 by solutions with $[K_2CO_3] \leq 0.1$ mol dm^{-3} and $[KOH] \geq 1.0$ mol dm^{-3}. It survived unchanged for 67 days when contacted with solutions having $[K_2CO_3] = 0.1$ mol dm^{-3} and $[KOH] = 0.1$ to 0.3 mol dm^{-3}.

Reactions of synthetic bismutite, $(BiO)_2CO_3$

"Precipitated" bismutite was converted to $(BiO)_4(OH)_2CO_3$

[2]The two equilibrium constants are interrelated by the carbonate ionization equilibrium: $CO_2(g) + 2OH^-(aq) \rightleftharpoons H_2O(l) + CO_3^{2-}(aq)$. For the forward reaction, $\Delta_r G^0 = -56.01$ kJ mol^{-1}, based on the Gibbs energy data of ref. 10, at 298.15 K and 1 bar. Hence, for any carbonate solution, the equilibrium CO_2 partial pressure, in pascals, is equal to $10^{-4.81} \times \{CO_3^{2-}\}/\{OH^-\}^2 = 10^{-4.81}/K_{eq}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

by solutions with $[K_2CO_3] = 0.25$ mol dm^{-3} and $[KOH] = 0.4$ to 1.0 mol dm^{-3}. Further decarbonation to α-Bi_2O_3 occurred with solutions having $[K_2CO_3] \leq 0.25$ mol dm^{-3} and $[KOH] \geq 1.0$ mol dm^{-3}. We did not observe $(BiO)_4(OH)_2CO_3$ in a similar series of reactions with "autoclaved" bismutite, probably because it was more crystalline, and hence less reactive, than the "precipitated" material.

Thermochemical deductions

We conclude from the above observations that $(BiO)_4(OH)_2CO_3$ has a narrow stability field in the system $Bi_2O_3-CO_2-H_2O-(KOH)$ at 25°C. The boundary for its conversion to $(BiO)_2CO_3$ lies within the range $0.05 < [KOH] < 0.3$ mol dm^{-3}, at $[K_2CO_3] = 0.1$ mol dm^{-3}. Using Davies' approximation (9) to estimate ionic activity coefficients — this approximation is at the very limit of its applicability at such high ionic strengths — these concentrations yield the following equilibrium relationship for reaction [3*a*]:

$$\log [\{OH^-\}^2/\{CO_3^{2-}\}] = -0.4 \pm 1.0$$

This corresponds to an equilibrium CO_2 partial pressure, $p_2 = 10^{-4.4\pm1.0}$ Pa (see footnote 2).

The boundary for the conversion of $(BiO)_4(OH)_2CO_3$ to α-Bi_2O_3 lies within the limits $0.3 < [KOH] < 1.0$ mol dm^{-3} at $[K_2CO_3] = 0.1$ mol dm^{-3}. These concentrations are too high for Davies' approximation to be applied. We could not measure the limits in more dilute carbonate solutions (10^{-2} and 10^{-3} mol dm^{-3}) due to slow kinetics and the difficulty of measuring small changes in carbonate concentration in strongly alkaline solutions. However, we can estimate p_1 by comparing our results for this system with those for the conversion of PbO to plumbonacrite, $Pb_{10}O(OH)_6(CO_3)_6$, reported in ref. 4. The limits for the PbO-plumbonacrite equilibrium (reaction [5])

$$[5] \quad \frac{5}{3}PbO(s) + CO_3^{2-}(aq) + \frac{3}{2}H_2O(l) \rightleftharpoons \frac{1}{6}Pb_{10}O(OH)_6(CO_3)_6(s) + 2OH^-(aq)$$

are $0.1 < [KOH] < 0.5$ mol dm^{-3} at $[K_2CO_3] = 0.1$ mol dm^{-3}. For reaction [5], measurements could be made at lower carbonate concentrations, and yielded a CO_2 partial pressure of $10^{-4.9\pm0.6}$ Pa for equilibrium [6] at 25°C:

$$[6] \quad \frac{5}{3}PbO(s) + CO_2(g) + \frac{1}{2}H_2O(l) \rightleftharpoons \frac{1}{6}Pb_{10}O(OH)_6(CO_3)_6(s)$$

Since the limiting solution conditions for the α-Bi_2O_3/$(BiO)_4(OH)_2CO_3$ interconversion at $[CO_3^{2-}] = 0.1$ mol dm^{-3} are slightly more alkaline than for the $PbO/Pb_{10}O(OH)_6(CO_3)_6$ case, we deduce that p_1 is slightly lower than $10^{-4.9\pm0.6}$ Pa, so we assign an estimated value of $10^{-5.5\pm1.0}$ Pa.

These estimated equilibrium partial pressures can be combined with literature values of the Gibbs energies of formation of the component oxides, to calculate the Gibbs energies of the solid carbonates. Reference 10 gives $\Delta_f G^0$(298.15 K, 1 bar) = -493.5 ± 1.5, -394.38 ± 0.17, and -237.14 ± 0.08 kJ mol^{-1}, for α-Bi_2O_3(s), CO_2(g), and H_2O(l), respectively. Applying these data to reaction [2*b*], with $p_1 = 10^{-5.5\pm1.0}$ Pa ($10^{-10.5\pm1.0}$ bar), we obtain:

$$\Delta_f G^0((BiO)_4(OH)_2CO_3, s, 298.15\ K) = 2\Delta_f G^0(\alpha\text{-}Bi_2O_3, s) + \Delta_f G^0(CO_2, g) + \Delta_f G^0(H_2O, l) + RT \ln (p_1/\text{bar}) = -1678 \pm 9\ \text{kJ mol}^{-1}$$

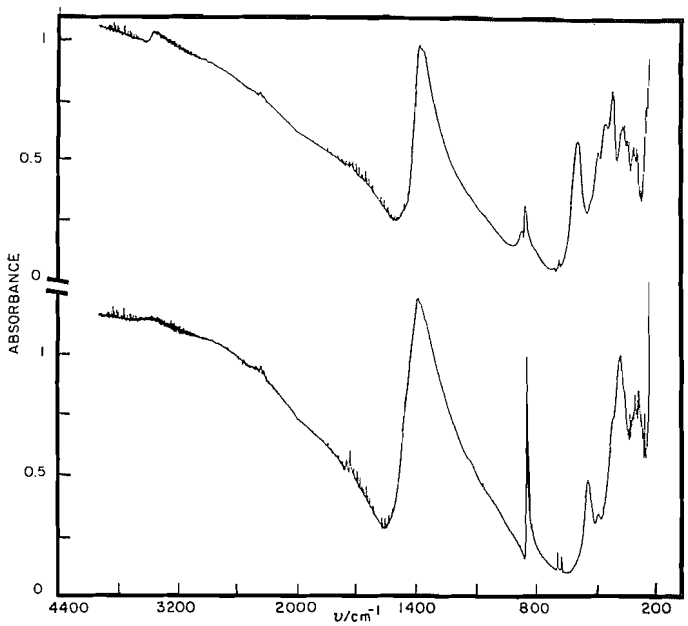

FIG. 1. Inrared spectra of $(BiO)_4(OH)_2CO_3$ (top spectrum) and $(BiO)_2CO_3$ (bottom spectrum), as polycrystalline solids dispersed in KBr pellets (about 1 mg in 200 mg of KBr).

Similarly, using reaction [3*b*], with $p_2 = 10^{-4.4\pm1.0}$ Pa ($10^{-9.4\pm1.0}$ bar), we obtain

$$\Delta_f G^0((BiO)_2CO_3, s, 298.15\ K) = \frac{1}{2}\{\Delta_f G^0((BiO)_4(OH)_2CO_3, s) + \Delta_f G^0(CO_2, g) - \Delta_f G^0(H_2O, l) + RT \ln(p_2/\text{bar})\} = -945 \pm 7\ \text{kJ mol}^{-1}$$

Note that the limits of stability of $(BiO)_4(OH)_2CO_3$, $10^{-5.5}$ Pa $\leq p(CO_2) \leq 10^{-4.4}$ Pa, apply in dilute aqueous solution. The stability field becomes narrower at lower water activities, and $(BiO)_4(OH)_2CO_3$ becomes unstable with respect to disproportionation, according to reaction [7], at relative humidities below $\simeq$ 10%:

$$[7] \quad (BiO)_4(OH)_2CO_3(s) \rightleftharpoons (BiO)_2CO_3(s) + Bi_2O_3(s) + H_2O(g)$$

This disproportionation is probably very slow at room temperature, but it is the first step in the dry thermal decomposition of $(BiO)_4(OH)_2CO_3$, as discussed in section III.1, above.

The narrowness of the stability field of $(BiO)_4(OH)_2CO_3$, and the low solubilities of all the solids ($<10^{-5}$ mol dm^{-3}), make it difficult to prepare pure $(BiO)_4(OH)_2CO_3$ in quantities greater than ~1 g. The stability field of $(BiO)_4(OH)_2CO_3$ is probably still narrower at higher temperatures, based on our previous observations on the lead carbonate system (4).

3. Vibrational spectroscopy

The infrared spectra of $(BiO)_4(OH)_2CO_3$ and $(BiO)_2CO_3$ are shown in Fig. 1, while Figs. 2, 3, and 4 show the 20–320, 200–1800, and 2800–3800 cm^{-1} regions, respectively, of the Raman spectra. These spectra confirm the distinct identities of the two solids. Frequencies (±1 cm^{-1} for sharp peaks), relative intensities (uncorrected for spectral response), and assignments of the observed spectral features are given in Table 1.

The infrared spectrum of $(BiO)_2CO_3$ in Fig. 1 is in general agreement with four earlier reports (11–14), except that ref. 13 shows an absorption near 723 cm^{-1}, which presumably arose

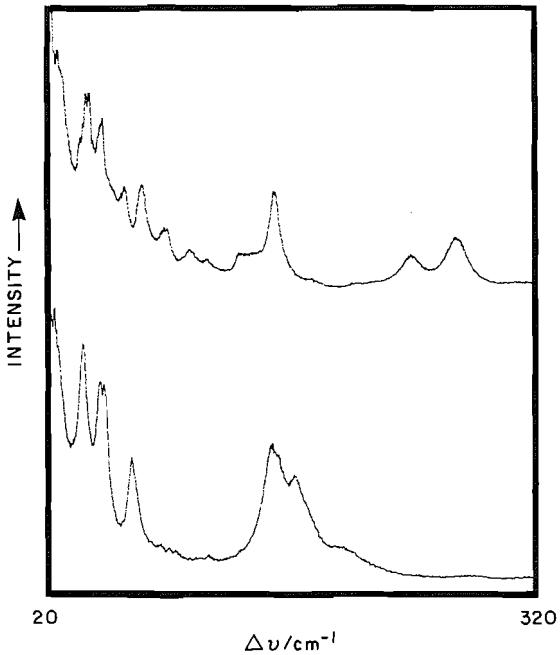

FIG. 2. Raman spectra of $(BiO)_4(OH)_2CO_3$ (top spectrum) and $(BiO)_2CO_3$ (bottom spectrum), as polycrystalline solids, for the 20–320 cm^{-1} region. Spectral band pass ~1 cm^{-1}, 647.1 nm excitation.

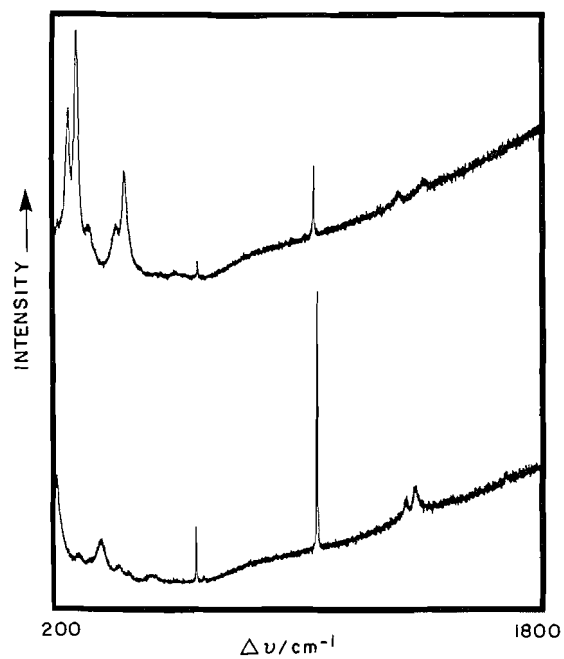

FIG. 3. Raman spectra of $(BiO)_4(OH)_2CO_3$ (top spectrum) and $(BiO)_2CO_3$ (bottom spectrum), as polycrystalline solids, for the 200–1800 cm^{-1} region. Spectral band pass ~1 cm^{-1}, 647.1 nm excitation.

from an impurity. We are also in essential agreement with Rulmont's report (14) of the Raman spectrum of $(BiO)_2CO_3$. However, we observed additional Raman bands closer to the exciting line, resolved some bands previously reported as single peaks into two or more features, and detected some additional low intensity features.

We have followed Herzberg's notation (15) in assigning the "internal vibrations" of hydroxyl and carbonate moieties in

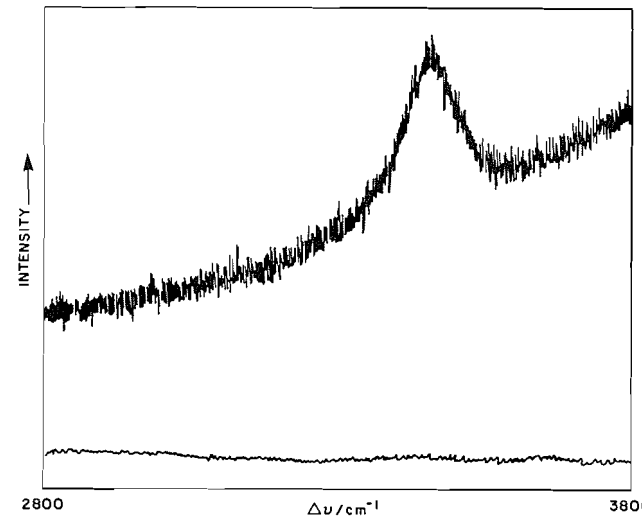

FIG. 4. Raman spectra $(BiO)_4(OH)_2CO_3$ (top spectrum) and $(BiO)_2CO_3$ (bottom spectrum), as polycrystalline solids, for the hydroxyl stretching region. Spectral band pass ~2 cm^{-1}, 514.5 nm excitation. These spectra are averages of four scans each.

Table 1. The fundamental vibrations of the carbonate ion are well established (15–19), and require no discussion. The assignment of some weak features to isotopically substituted species and overtone/combination bands is based on our earlier discussion in ref. 20.

The strong bands below 600 cm^{-1} are mainly due to "lattice vibrations". Those between 350 and 600 cm^{-1} probably arise from the motion of oxygen atoms in the polymeric $(BiO)_n^{n+}$ cation. This assignment is based on those suggested for the bismuth oxyhalides (BiOCl, BiOBr, BiOI, see refs. 14, and 21–25). These compounds have layered structures that are closely related to those of the carbonates, as discussed in the following section. There is an approximate correspondence between most of the lattice vibrations for $(BiO)_2CO_3$ and $(BiO)_4(OH)_2CO_3$, although the spectra of the latter compound are more complex, presumably reflecting its lower symmetry. Two strong bands at 244 and 272 cm^{-1} in the Raman spectrum of $(BiO)_4(OH)_2CO_3$ have no counterparts in the $(BiO)_2CO_3$ spectrum, so we tentatively assign them to concerted motions of the OH moieties.

The spectral features due to the internal vibrations of CO_3^{2-} are weaker for $(BiO)_4(OH)_2CO_3$ than for $(BiO)_2CO_3$, consistent with the former's lower carbonate content. The high symmetry structure (space group $I4/mmm$ (No. 139, D_{4h}^{17}), $z = 2$) suggested by Lagercrantz and Sillén (26) for $(BiO)_2CO_3$ requires carbonate ions to occupy sites with point symmetry D_{4h}. To reconcile this with the lower molecular symmetry, D_{3h}, of the ion, these authors postulated disorder or free rotation of the anions. Although a temperature-dependent study would be needed to rule out the possibility of freely rotating carbonate ions, the narrow profiles of the Raman bands assigned to carbonate vibrations do not seem consistent with a freely rotating anion, or a disordered structure (27–30). The sharp, narrow profiles of the bands assigned to the ν_1, ν_2, and ν_4 modes of CO_3^{2-} indicate orientational order in the carbonate sublattices of both solids. There is no observable splitting of the ν_1 mode of the carbonate ion in either compound, indicating that all the carbonate ions in each crystal structure occupy crystallographically equivalent sites. Turcotte *et al.* (12) made a similar observation for $(BiO)_2CO_3$, and for the "Type I" form of the

lanthanide oxycarbonates, $(LnO)_2CO_3$. This contrasts with the situation in the basic lead carbonates, hydrocerussite and plumbonacrite, and in the "Type IA" lanthanide oxycarbonates, all of which appear to contain more than one crystallographically distinct carbonate site (12, 20). The ν_2 mode is absent in our Raman spectra of the bismuth carbonates, and the ν_1 mode is a very weak feature of the infrared spectra, indicating that the carbonate ions are only slightly distorted from C_{3h} or D_3 symmetry. The reduction of molecular point symmetry from D_{3h} to either C_{3h} or D_3 does not change the selection rule for the ν_1 and ν_2 modes of the carbonate ion, as shown in the correlation table of the D_{3h} point group (31). Any further lowering of the carbonate site symmetry should make the ν_1 mode infrared-active and the ν_2 mode Raman-active.

The ν_1 mode frequency of CO_3^{2-} is about 10 cm^{-1} lower, and the splitting of the ν_3 mode is about 50 cm^{-1} greater, in $(BiO)_4(OH)_2CO_3$ than in $(BiO)_2CO_3$ (Table 1), suggesting weak hydrogen bonding between the OH^- and CO_3^{2-} ions. The OH stretching frequency is ~3455 cm^{-1}, confirming that hydrogen bonding is not strong. The sharp, well-defined shape of this band suggests that all hydrogen bonds are of approximately equal strength. Using the Lippincott–Schroeder curve, we estimate a hydrogen-bonded O(H) . . . . O distance of about 2.9Å (18, 32).

A calculation of lattice modes (33) for $(BiO)_2CO_3$, based on the primitive cell of the body-centred lattice reported by

Lagercrantz and Sillén (26), gives ten translational and two rotational modes ($A_{1g} + 3A_{2u} + B_{2g} + 2E_g + 3E_u$ and $A_2g + E_g$, respectively). Two of the translational lattice modes, one A_{2u} and one E_u, correspond to the acoustic branch, and will be optically inactive. The total numbers of infrared- and Raman-active lattice modes will thus be only four ($2A_{2u} + 2E_u$) and six ($A_{1g} + A_{2g} + B_{2g} + 3E_g$), respectively. The numbers of observed features in the lattice-vibration regions of the $(BiO)_2CO_3$ spectra are much greater (Table 1), indicating a larger unit cell and/or lower symmetry than in the reported structure (26). This is consistent with reports of a superlattice, in refs. 2 and 34. This combination of spectroscopic and crystallographic evidence prompted us to develop an alternative structural model for $(BiO)_2CO_3$, as described below.

4. *Crystallography*

The crystal structure of $(BiO)_2CO_3$

Lagercrantz and Sillén (26) showed that $(BiO)_2CO_3$ contains polymeric cations, $(BiO)_n^{n+}$, with a layer structure in which Bi atoms lie alternately above and below the interstices in a square lattice of O atoms, which is parallel to the (001) plane. These cations are stacked in a centred manner, such that the Bi atoms on the lower side of one layer lie directly above those on the upper side of the layer below. The stacking is body-centred with respect to the tetragonal sublattice, and face-centred with respect to the orthorhombic superlattice, as discussed below. The carbonate anions occupy two-dimensional tesselated arrays of tetragonal cavities, 3.87 Å × 3.87 Å × 4.38 Å, which are defined by the Bi atoms, as shown in Fig. 5. Many other oxysalts of Bi, Pb, and the lanthanides contain similar cations, with different stacking arrangements that are determined by their stoichiometries (14, 26, 35, 36). Bismutite is isostructural with the Type I lanthanide oxycarbonates, $(LnO)_2CO_3$ (12, 37).

Lagercrantz and Sillén (26) deduced that the tetragonal lattice of $(BiO)_2CO_3$, as indicated by X-ray diffraction (a = 3.867 Å, c = 13.686 Å), could only accommodate the carbonate ions in orientations parallel to the {110} planes, since other arrangements result in exceedingly close inter-anionic contacts. They favoured a disordered structure, but did not rule out an ordered arrangement. However, they reported Bi . . . . OCO_2 distances as low as 2.19 Å, which seems improbably short when compared with the Bi—O bond-length of 2.29 Å within the cation layers. Such a strong bond would cause much greater distortion of the carbonate anion than the spectroscopic data indicate (see section III.3).

Sahama and Lehtinen (2) and Nefedov (34) independently reported an orthorhombic, diagonal superlattice ($a' = b' = \sqrt{2}a$) for $(BiO)_2CO_3$. This superlattice removes the constraint for all carbonate ions to lie in identical orientations; indeed, it probably arises from an ordered alternation of anion orientations.[3] This is consistent with the conclusions in section III.3, that the structure is ordered, and has a larger unit cell and/or lower symmetry than is indicated by X-ray diffraction. (X-ray diffraction intensities are dominated by the Bi sublattice.)

Given the high symmetry of the anion cavity (Fig. 5), we expect one of the C_2 axes of the carbonate ion to coincide with one of the symmetry elements of the cavity. We considered two

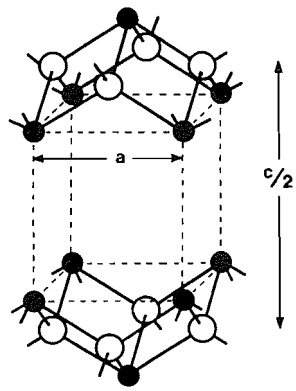

FIG. 5. Sections of two polymeric cations, $(BiO)_n^{n+}$, in the crystal structure of $(BiO)_2CO_3$. The broken lines outline an anion cavity. The dimensions a and c refer to the tetragonal unit cell of Lagercrantz and Sillén (26). Small filled circles and large open circles represent Bi and O atoms, respectively.

models, with a C_2 axis of the anion parallel and perpendicular to the crystallographic c-axis, respectively.[4] Each model could accommodate tolerable O . . . . O and Bi . . . . O contact distances (≥ 2.8 Å and 2.4 Å, respectively). Two possible arrangements, which are compatible with a $\sqrt{2}a$, $\sqrt{2}a$ superlattice, are shown in Fig. 6. In each case, the carbonate groups have been rotated from the diagonal of the pseudotetragonal cell, to optimize Bi . . . . O and O . . . . O contacts. There is no clear-cut choice between these models; both arrangements depart from tetragonal symmetry, the departure being greater in Fig. 6(*b*).

The crystal structure of $(BiO)_4(OH)_2CO_3$

The diffraction patterns of $(BiO)_4(OH)_2CO_3$ and $(BiO)_2CO_3$, which are compared in Table 2, are similar, but many $(BiO)_4(OH)_2CO_3$ peaks occur at d-values higher than the corresponding peaks for $(BiO)_2CO_3$. Also, some peaks are split into doublets, and many additional weak features are present. The two crystal structures thus appear related, but $(BiO)_4(OH)_2CO_3$ has a larger unit cell, and lower symmetry, than $(BiO)_2CO_3$.

We indexed all 23 strong diffraction peaks ($I/I_o > 5$) of $(BiO)_4(OH)_2CO_3$ on the basis of a monoclinic subcell, derived from the tetragonal pseudo-cell of $(BiO)_2CO_3$. The cell dimensions were refined, using the least-squares computer program of Appleman and Evans,[5] and constraining a and b to be equal by including *hkl* and *khl* reflections with equal d in the input data. This yielded the dimensions and standard deviations $a = b = 3.8451(3)$ Å, $c = 14.7574(11)$ Å, $\gamma = 91° 5.7(0.4)'$, with a maximum 2θ discrepancy of 0.020°. Systematic instrumental errors were not estimated, so the computed standard deviations reflect the precision, but not the accuracy, of the diffraction data. The excellent agreement between observed and calculated 2θ, with a and b held equal, indicates that the true symmetry is orthorhombic, with the monoclinic cell edges lying on diagonals of the orthorhombic lattice.

Most of the remaining weak diffraction peaks were indexed on the basis of a $2\sqrt{2}a$, $\sqrt{2}a$ orthorhombic superlattice derived from the monoclinic subcell, as shown in Table 2. The

[3]Sahama and Lehtinen (2) also observed electron diffraction features corresponding to a still larger superlattice, $a'' = 5a'$, for one sample of natural bismutite. We suspect that this arises from deviations from the ideal stoichiometry, $(BiO)_2CO_3$, rather than from purely structural/geometrical origins.

[4]In their discussion of $(LnO)_2CO_3$ structures, Turcotte *et al.* (12) only considered the perpendicular orientation, and only with the anion lying parallel to {100} or {110} planes.

[5]D. E. Appleman and H. T. Evans, Jr. U.S. Geological Survey, Geological Division, Washington, D.C. 20244.

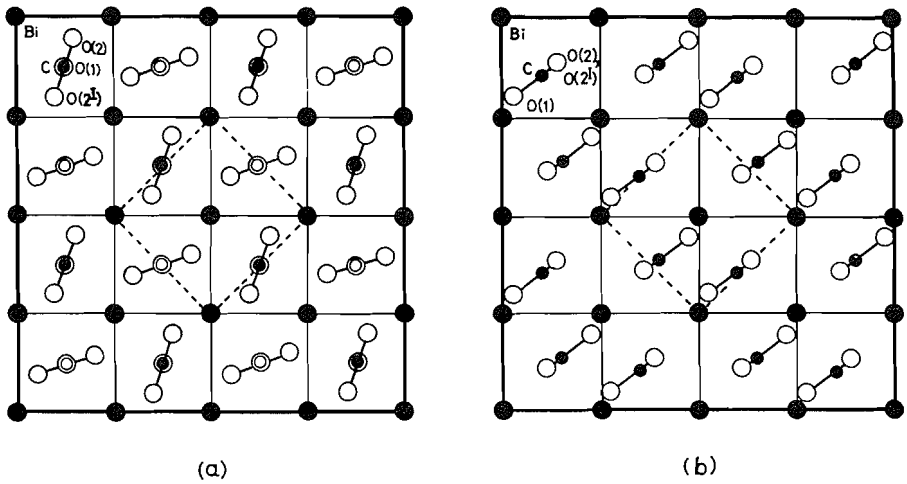

FIG. 6. Two possible arrangements of anion layers in $(BiO)_2CO_3$, viewed in projection down in the c-axis: (a) with a C_2 axis of the carbonate group, C—O(1), vertical, parallel to the crystallographic c-axis; (b) with C—O(1) horizontal. The arrangements are chosen to comply with the $\sqrt{2}a$, $\sqrt{2}a$ superlattice (broken lines), and to optimize Bi . . . . O and O . . . . O contact distances. Oxygen atoms in the polymeric cations have been omitted for clarity.

only unaccountable features with $d > 1.5$ Å were at 3.186, 2.777, 1.934, and 1.675 Å, all with $I/I_o \simeq 1$. Since these lie close to the major diffraction peaks of δ-Bi_2O_3 (3.187, 2.755, 1.953, 1.666 Å, ref. 38), we ascribe them to a δ-Bi_2O_3-like phase. The superlattice dimensions, calculated from the monoclinic subcell without further refinement, are a = 10.772(1), b = 5.4898(5), and c = 14.757(1) Å.

The related unit-cell dimensions of $(BiO)_2CO_3$ and $(BiO)_4(OH)_2CO_3$ indicate that the two structures contain similar cationic moieties. By analogy with other MOX salts (36), we assume that the longer c-axis in $(BiO)_4(OH)_2CO_3$ compared to $(BiO)_2CO_3$ reflects a greater inter-cation spacing. The inter-layer Bi . . . Bi distance in $(BiO)_2CO_3$, i.e., the depth of the anion cavity (Fig. 5), is $0.32c$ = 4.38 Å (2). The c-axis expansion, from 13.69 Å in $(BiO)_2CO_3$ to 14.76 Å in $(BiO)_4(OH)_2CO_3$, implies an inter-layer Bi . . . Bi spacing of 4.38 + 0.5(14.76 − 13.69) = 4.92 Å in the latter material (the factor of 0.5 arises because there are two layers per unit cell). It is noteworthy that $(BiO)_4(OH)_2CO_3$ has a higher volume per BiO^+ unit than $(BiO)_2CO_3$ (54.5 $Å^3$ vs. 51.3 $Å^3$). This contrasts, for example, with the relative crystallographic volumes per Pb atom for hydrocerussite and cerussite:

$\frac{1}{3}[Pb_3(OH)_2(CO_3)_2]$, 62.5 $Å^3$; $PbCO_3$, 67.5 $Å^3$ (39, 40).

Hydroxide ions might replace carbonate ions in $(BiO)_2CO_3$ to give $(BiO)_4(OH)_2CO_3$ in two ways: (i) complete substitution of alternate anion layers, or (ii) substitution of alternate anions within each layer. The first possibility can be ruled out, since alternation of $(BiO)_2CO_3$-type and BiOX-type (X = OH) layers would give a complex cation-stacking sequence, and hence a much longer c-axis than is observed (see Fig. 2 of ref. 2). Also, the anion layers would be too far apart, and too efficiently shielded by the cations, to permit the hydroxide-to-carbonate hydrogen-bonding, OH . . . . OCO_2, which was discussed in section III.3. The second possibility is compatible with both the spectroscopic and diffractometric data. The observed diagonal superlattice is consistent with the removal of alternate carbonate ions; the further doubling of a suggests a further alternation in the manner of their replacement by hydroxide ions.

Since there is only one type of cavity in the $(BiO)_2CO_3$ structure that can accommodate anions, each substituted cavity in $(BiO)_4(OH)_2CO_3$ must contain two hydroxide ions. These are expected to occupy diametrically opposed sites within the cavity. We believe that the observed c-axis expansion is caused by this "crowding" of anions; expansion in the ab plane is severely constrained by the rigidity of the cation (36).

We have developed a structural model for $(BiO)_4(OH)_2CO_3$ by placing pairs of hydroxide ions in alternate sites, and then adjusting anion positions to avoid unrealistically close contacts, and to achieve an efficient anion packing arrangement. This procedure was greatly assisted by assuming a rigid geometry for the $(BiO)_n^{n+}$ cations. (The departure from tetragonal dimensions necessitates a slight distortion of the cation.) The structural model was refined to meet six criteria: (i) No inter-anionic O . . . . O contacts should be less than 3.0 Å, except the slightly shorter hydrogen-bonded contacts. (ii) Weak bonding interactions between the anions and bismuth were accepted, with a minimum Bi . . . . O contact of 2.5 Å. (iii) The carbonate ion retains D_{3h} symmetry, with C—O = 1.29 Å (41). (iv) All CO_3^{2-} ions are crystallographically equivalent. (v) All OH^- ions have similar environments. (vi) There is no obvious "wasted space" in the anion packing.

The final structural model for the anion layer in $(BiO)_4(OH)_2CO_3$ is shown in Fig. 7. Atomic positional parameters and interatomic distances are listed in Tables 3 and 4, respectively. This model corresponds to the triclinic system, space group $P\bar{1}$ (No. 2, C_i^1). Higher dimensional symmetry is retained within experimental error, i.e., the triclinicity is very slight, because the anions are only slightly displaced from positions of higher symmetry. We emphasize that this is not a refined crystal structure in the usual sense, but is a realistic model based on limited structural data and reasonable crystal-chemical constraints.

This structure can accommodate several hydrogen-bonding arrangements, since the hydroxide ions are approximately equidistant from oxygen atoms on three different carbonate groups (e.g., O(1) has close contacts to O(4), O(5), $O(3^I)$ and $O(3^{II})$). We favour the arrangement shown in Fig. 7, because each hydroxide group is antiparallel to its three closest neighbour hydroxides. However, the atomic displacement required to achieve other hydrogen-bonding configurations are slight

[a]Data of Sahama and Lehtinen (2); indexed on pseudo-tetragonal cell, $a_0 = 3.870 \pm 0.002$ Å, $c_0 = 13.697 \pm 0.005$ Å, $Z = 2$, $\rho_{calcd} = 8.25$. Our results for synthetic $(BiO)_2CO_3$ are in good agreement with these data.

[b]Based on orthorhombic unit cell with $a_0 = 10.7716 \pm 0.0015$ Å, $b_0 = 5.4898 \pm 0.0008$ Å, $c_0 = 14.7574 \pm 0.0022$ Å (2σ), $Z = 4$, $\rho_{calcd} = 7.56$.

[c]Based on peak height measurements from diffractogram.

[d]These reflections are subject to slight preferred orientation effects.

[e]The 211 and 213 reflections for $(BiO)_2CO_3$ correspond to (231 + 611) and (233 + 613), respectively, for $(BiO)_4(OH)_2CO_3$.

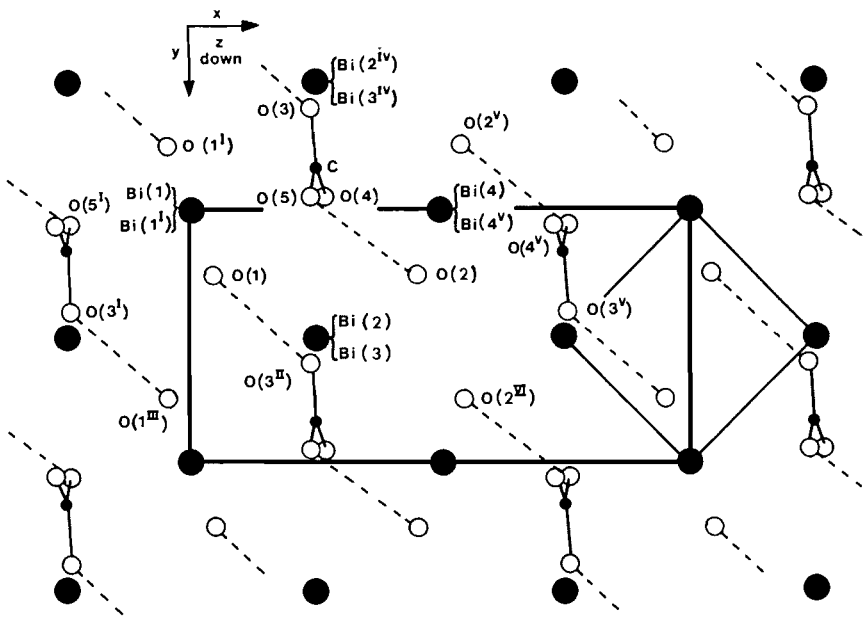

FIG. 7. Structural model for $(BiO)_4(OH)_2CO_3$, viewed in projection down the *c*-axis. The notation corresponds to that in Tables 3 and 4. The unit cell is outlined; the monoclinic (pseudo-tetragonal) sublattice is delineated by the Bi atoms. The oxygen atoms in the cation, and the second layer of Bi atoms, are omitted for clarity.

(<0.3 Å).

We can say little about the anion-layer stacking sequence in either $(BiO)_2CO_3$ or $(BiO)_4(OH)_2CO_3$, except that polytypic or disordered sequences seem likely, because of the high symmetry of the cations, and the effective shielding of the anion layers by the cations, in each structure. Any conclusions based on X-ray diffraction intensities would be tenuous, because of the dominance of Bi. However, the diffraction pattern of $(BiO)_4(OH)_2CO_3$ (Table 2) does include weak reflections that disobey both face-centring and body-centring conditions. A complete structural analysis of either compound would probably require high quality neutron-diffraction data.

5. Comments on natural occurrence

We have identified a previously undescribed basic bismuth carbonate, $(BiO)_4(OH)_2CO_3$, which is not identical with either of the unidentified solids observed by Lagercrantz and Sillén (26) in their hydrothermal synthesis of $(BiO)_2CO_3$ crystals, although they may well be structurally related. The narrow stability field of $(BiO)_4(OH)_2CO_3$ precludes its widespread occurrence in oxidized bismuth ore deposits. However, its presence could account for the water-rich, carbonate-deficient analyses reported by Sahama and Lehtinen for some natural bismutite specimens (2). Nearly all the analyses of natural bismutite, shown in Fig. 2 of ref. 2, lie within the composition triangle $(BiO)_2CO_3-(BiO)_4(OH)_2CO_3-H_2O$. This suggests that much of the water is indeed non-essential, as asserted by Frondel, but that some is chemically incorporated in $(BiO)_4(OH)_2CO_3$. It is interesting that this empirical formula corresponds to that of "Basobismutite", which was reported by Nenadkevitch (42), but was discredited by Frondel (1). We have observed minor quantities of both $(BiO)_4(OH)_2CO_3$ and $(BiO)_2CO_3$ on the surface of α-Bi_2O_3 powders that had been exposed to moist air. Therefore, it may well be worth exam-

O(4)	0.2690	−0.0510	0.0740
O(5)	0.2452	−0.0510	−0.0760

[a]Space group $P\bar{1}$ (C_i^1); cell dimensions are given in Table 2.
[b]Only those Bi atoms that delineate the anion cavities are listed. They do not occupy special positions, but they have not been displaced from sites (0,0,z), referred to the monoclinic sublattice. Additional Bi atoms are present at the positions (±1/4, 0, 1/3), (0,1/2, 1/3) and (1/2, 1/2, 1/3). The oxygen atoms in the $(BiO)_n^{n+}$ cations are situated at approximately (±1/8, ±1/4, 1/4) and (±3/8, ±1/4, 1/4). An additional anion layer is situated at $z/c \simeq 1/2$. The x and y coordinates of the atoms in this layer depend on the stacking sequence, as discussed in the text.
[c]The four-figure precision of the coordinates does not reflect the accuracy of the model, but was necessary to demonstrate that the model could meet the constraints on interatomic distances, within limits of ±0.01 Å.

[a]Roman numeral superscripts refer to the following symmetry operations on the parameters given in Table 3: I, ($\bar{x}$, $\bar{y}$, $\bar{z}$); II, (x, 1+y, z); III, ($\bar{x}$, 1−y, $\bar{z}$); IV, (x, y−1, z); V, (1−x, $\bar{y}$, $\bar{z}$); VI, (1−x, 1−y, $\bar{z}$). The numbering of atoms corresponds to that in Fig. 7.
[b]O(cat) refers to the closest contact of each oxygen to an oxygen atom in the cationic moiety.

ining samples of bismite (natural α-Bi_2O_3) and bismutite for possible minor natural occurrences of $(BiO)_4(OH)_2CO_3$.

NOTE ADDED IN PROOF: We have just learned that Levin and Roth (43) reported an unidentified compound, formed by aging Bi_2O_3 in air. They reported X-ray diffraction features at d = 3.71, 3.68, 3.02, 2.74, and 2.45 Å. These correspond to major peaks in the diffraction pattern of $(BiO)_4(OH)_2CO_3$ in Table 2.

Acknowledgements

R. LANZETTA, G. LAONIGRO, M. PARRILLI, and E. BREITMAIER. Can. J. Chem. **62**, 2874 (1984).

A combined use of homo- and heteronuclear nmr spectroscopy in the structure elucidation of a minor glycoside extracted from the bulbs of *Muscari comosum* is described. This glycoside **1**, termed muscaroside C, posseses a β-D-apio-D-furanosyl-(1→2)-β-D-glucopyranosyl(1→2)-α-L-arabinopyranosyl(1→6)-β-D-glucopyranosyl chain linked at the 3-position of (23*S*)-17,23-epoxy-3β,30,31,-trihydroxy-27-nor-5α-lanost-8-ene **2**.

R. LANZETTA, G. LAONIGRO, M. PARRILLI et E. BREITMAIER. Can. J. Chem. **62**, 2874 (1984).

On décrit une utilisation combinée des spectroscopies rmn homo- et hétéronucléaires permettant l'élucidation de la structure d'un glycoside mineur extrait des bulbes du *Muscari comosum*. Ce glycoside (**1**), que l'on a appelé muscaroside C, possède une chaîne β-D-apiofurannosyl (1→2) β-D-glucopyrannosyl (1→2) α-L-arabinopyrannosyl (1→6) β-D-glucopyrannosyle qui est reliée à la position 3 du (23*S*)-époxy-17,23 trihydroxy-3β,30,31 nor-27 5α-lanostène-8 (**2**).

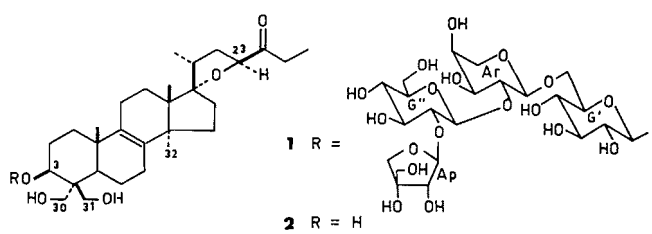
[Traduit par le journal]

In connection with our studies (1–5) on the glycoside fraction of *Muscari comosum* we recently reported the isolation and structure determination of muscarosides A (4) and B (5). In this paper we describe the structure elucidation of a minor glycoside, muscaroside C, **1**, which possesses a β-D-apio-D-furanosyl(1→2)-β-D-glucopyranosyl-(1→2)-α-L-arabinopyranosyl(1→6)-β-D-glucopyranosyl chain linked at the 3-position of (23*S*)-17,23-epoxy-3β,30,31-trihydroxy-27-nor-5α-lanost-8-ene **2** (2).

Muscaroside C was obtained by column chromatography and hplc purification (C-18 reverse phase column) of the crude glycoside extracted from bulbs as a homogeneous (tlc, ^{1}H and ^{13}C nmr spectroscopy) amorphous solid.

The FAB-ms spectrum of **1** showed a pseudomolecular ion peak at m/z 1085 ($M + Na^+$) which, together with ^{13}C data, suggested the molecular formula $C_{51}H_{82}O_{23}$.

Acid hydrolysis (7% H_2SO_4) of muscaroside C, which caused decomposition of the aglycone (3), afforded glucose, arabinose, and apiose as identified by tlc and hplc comparison with equilibrated authentic samples of the monosaccharides. A 2:1:1 molar ratio of glucose, arabinose, and apiose was established on integration of hplc peak areas and confirmed by fragmentation of **1** in the FAB-ms spectrum which showed the loss of two hexose units (see below).



Owing to the small amount of **1** available, structure determination was essentially based on nmr spectroscopy rather than chemical degradative methods. The results of the spectroscopic investigation are presented in Table 1.

The ^{1}H spectrum of **1** in Py-d_5 at 500 MHz shows, in the downfield part, four anomeric proton signals as doublets at δ 6.40 (2.0 Hz), 5.18 (4.1 Hz), 5.14 (7.8 Hz), and 5.07 (7.3 Hz); in the 4.8–3.6 ppm region, overlapping resonances of oligosaccharide rings; and, in the upfield part, signals of the aglycone moiety. In this zone the signals of five methyl groups are clearly recognized; three of them are tertiary (δ 0.92 s, 1.04 s, 1.47 s), one is secondary (δ 1.02 d), and one is primary (δ 1.04 t). In addition, a methylene signal appears at δ 2.52 as a quartet, correlated by scalar coupling with the primary methyl group. In combination with the general appearance of the ^{1}H nmr spectrum, these findings suggested **2** to be the aglycone moiety of **1**.

The ^{13}C nmr data were obtained from a proton noise-decoupled spectrum and from DEPT (6) experiments that allowed us to recognize the number of CH, CH_2, and CH_3 carbons unequivocally. The striking similarity between ^{13}C data of **1** in Py-d_5 and those of **2** in $CDCl_3$[3] (see Table 1) definitively confirmed the identification of the aglycone moiety. In this respect it is also important to emphasize that **2** had been isolated previously (2) on enzymatic hydrolysis of the entire *Muscari comosum* glycoside fraction.

The ^{13}C nmr permits identification of monosaccharide ring size by comparison with ^{13}C signal values of reference methyl-glycosides and, on the basis of the glycosylation shift (7–10), the positions of interglycosidic linkages. However, the identification of ^{13}C signals belonging to each single monosaccharide residue is often a serious problem when more units of the same

[1]Part 5: ref. 5.

[2]Author to whom correspondence should be addressed.

[3]The different solvents can be assumed not to affect the validity of this comparison as a closely related compound, eucosterol, displays very similar ^{13}C chemical shifts in both Py-d_5 and $CDCl_3$ (1, 4); see also ref. 7.

TABLE 1. (*concluded*)

Carbon	Reference substance[a]	DEPT[b]	Muscaroside C[b]	Proton	2D-COSY[b,c]	$J_{Z,Y}$[d] Hz	Z	Y
31	63.8	CH_2	62.7[i]	31a, 31b	4.58, 3.93	11.6	31a	31b
32	25.9	CH_3	26.3	32-H_3	1.47	—		

[a]Reference substances: A, methyl β-D-glucopyranoside (ref. 19); B, methyl α-L-arabinopyranosyl (ref. 19); C, methyl β-D-apio-D-furanoside (ref. 20); D, **2** (ref. 2).
[b]Measured in pyridine-d_5.
[c]Proton chemical shifts of the aglycone moiety were assigned mainly from two-dimensional carbon–proton shift correlation, except for some protons linked at carbons shifted by glycosylation (see text). Proton correlations clearly recognizable in the 2D-COSY are indicated by solid lines in the table.
[d]Absolute values of apparent coupling constants between protons Z and Y.
[e]Obscured by other resonances.
[f]Measured in $CDCl_3$.
[g]Value of $J_{AX} + J_{BX}$ of an X quartet of an ABX system.
[h]Interchangeable values.
[i]30-CH_2 and 31-CH_2 protons were assigned on the basis of nOe enhancements measured for the proton signals at δ 4.58 and at δ 4.35 upon irradiation of 19-H_3 and 3-H_α protons respectively.

monosaccharide are present in the sugar chain. This can now be facilitated by two-dimensional nmr experiments (11, 12) using nuclear proton shift correlation (COSY) (13) to establish the scalar connectivity of the proton resonances of each monosaccharide unit, starting from anomeric signals, and heteronuclear carbon–proton shift correlation (14) to trace out all one-bond carbon–proton connectivities. Substructures can be derived by combining the information of both shift correlation experiments.

Figure 1 displays the 2D-COSY spectrum of the 3.6–5.0 ppm and anomeric regions of **1** together with the corresponding segment of its one-dimensional spectrum. The analysis of 2D-COSY for one monosaccharide unit serves to illustrate the approach described above.

The anomeric proton at δ 5.14, indicated by G′-1 in Fig. 1, is coupled to the G′-2 signal at δ 4.00 and this to G′-3 at δ 4.07. Continuing this *J*-connectivity path (see figure, dotted lines), it was possible to identify G′-4 at δ 4.20, G′-5 at δ 3.82, G′-6a at δ 4.41, and G′-6b at δ 4.17. In this way the chemical shifts of all protons belonging to the G′ unit had been identified; they were subsequently assigned by two-dimensional carbon–proton shift correlation to the attached carbon chemical shifts at δ 105.5 (G′-1), 75.5 (G′-2), 78.3 (G′-3), 72.6 (G′-4), 75.5 (G′-5) and at δ 68.8 (G′-6) (see Table 1). When these ^{13}C data were compared with those of methyl β-D-glucopyranoside as reference, deshielding of G′-6 (+6.3) and shielding of G′-5 (−2.6) were observed, while the other chemical shifts were very similar. From these data a β-D-glucopyranosyl structure linked at its 6-position was inferred for the G′ residue.

Using a similar procedure, the ^{13}C data of other saccharide units of the sugar chain were assigned (see Table 1).

The downfield shifts observed for the Ar-2 (+7.2) and G″-2 (+5.0) signals, in addition to the upfield shifts of the Ar-1, Ar-3 and of the G″-1, G″-3 signals, compared with the ^{13}C data of methyl α-L-arabinopyranoside and methyl β-D-glucopyranoside, respectively, established that both of these units were linked at the 2-position. As for the apiose unit, a close similarity of its ^{13}C signals and those of methyl β-D-apio-D-furanoside indicated that this residue was the terminal one in the saccharide chain. This was confirmed by T_1 measurements: the apiose carbon atoms displayed the largest NT_1 values due to their segmental mobility at the end of the glycoside chain.

Analysis of the 2D-COSY spectrum also allowed assignment of those proton signals of the aglycone moiety which overlap saccharide resonances. Thus, the methine signals of 3-H_α and 23-H were identified at δ 4.49 and 4.61, respectively, while the protons of the AB systems of the 30- and 31-oxymethylene groups resonate at δ 4.92 and 4.35, and at δ 4.58 and 3.93, respectively. The carbons directly attached to these protons were identified by the heteronuclear-2D spectrum.

The glycosylation shift (+4.3) observed for C-3 of the aglycone moiety revealed (7–10) that the sugar chain is linked at this carbon. The upfield shifts of C-30 and C-5 signals were in agreement with this conclusion (9).

The proton assignments of **1** were also confirmed by the general appearance of the splitting patterns and, when it was possible, by $J_{H,H}$ values (see Table 1).

The sugar sequence was established by negative-ion FAB-ms on the basis of the following signals. The spectrum displayed a pseudomolecular ion at *m/z* 1061 $(M - H)^-$ and fragments at *m/z* 929 $((M - H) - 132)^-$, 767 $((M - H) - 132 - 162)^-$, 635 $((M - H) - 132 - 162 - 132)^-$, and 473 $((M - H) - 132 - 162 - 132 - 162)^-$, respectively, corresponding to the consecutive losses of the apiosyl, glucosyl, arabinosyl, and glucosyl units.

The significant Overhauser effect measured for the signal at δ 5.14 of the anomeric proton of the β-D-glucopyranosyl unit, linked at its 6-position upon irradiation of the 3-H_α proton, safely indicated that this glucose residue is directly attached to the aglycone moiety.

The relative configuration at the anomeric centres was inferred to be β for both glucopyranosyl units and for the apiosyl unit on the basis of the value of $^3J_{H\text{-}1,H\text{-}2}$ (7 Hz) (15) and the value of the anomeric carbon chemical shift (δ 111.2) (16), respectively.

No direct evidence for the α-configuration of the L-arabinopyranosyl unit was found, owing to its high conformational mobility (4, 5, 17). However, an α-configuration was inferred from the striking similarity between the ^{13}C data of the L-arabinopyranosyl unit of **1** and those found for the α-L-arabinopyranosyl residues identically located in muscarosides A and B (4, 5).

Experimental

Mass spectra were recorded with a VG ZAB HF instrument equipped with a FAB source. The hplc analysis was performed with a Varian 5020 instrument using a Waters R 401 differential refractometer as the detector. Thin-layer chromatography was carried out on precoated silica gel layers (0.25 mm, Merck F_{254}). Silica gel 0.05–0.20 (Merck) was used for column chromatography. Sugars were detected with aniline phthalate or *p*-anisaldehyde, glycosides with chromium oxide/sulphuric acid.

Isolation of muscaroside C

Fraction b (ref. 4) gave by hplc (Lichrosorb RP-18 (7 μm), 70:30 methanol–water, 5 mL min^{-1}), besides muscaroside B (5), a minor impure product (20 mg). This was subjected twice, successively, to analytical hplc (Lichrosorb RP-18 (5 μm), 80:20 methanol–water, 0.5 mL min^{-1}) to give pure muscaroside C (6 mg); FAB-ms: 1085 $(M + Na)^+$ m/z. The ^1H and ^{13}C data are given in Table 1.

Acidic hydrolysis of muscaroside C

Acidic hydrolysis of muscaroside C was performed as for muscaroside A (4). The water-soluble fraction of the hydrolysate was analyzed by tlc (silica gel layers, 14:6:1 chloroform–methanol–water) and by hplc (Lichrosorb NH_2 (10 μm), 4:1 acetonitrile–water, 0.5 mL min^{-1}); the presence of apiose, glucose, and arabinose was established by comparison with authentic samples. The hplc peak areas of the monosaccharides occurring in the hydrolysate were in the same ratio as a 2:1:1 mixture of equilibrated authentic glucose, arabinose, and apiose. The latter was obtained by hydrolysis of apiin, a flavanoid glycoside, purchased from ICN-K&K (New York).

Proton and carbon nuclear magnetic resonance spectra

Proton spectra were obtained on a Bruker WM-500 spectrometer equipped with an Aspect 2000 computer, operating in the Fourier transform mode with quadrature detection. One-dimensional spectra were typically obtained with 5000-Hz spectral width (0–10 ppm), using TMS as internal reference. For removal of exchangeable protons, the sample (6 mg) was solubilized three successive times in CH_3OD (0.5 mL) and the solvent evaporated at low pressure. The residue was dissolved in 0.4 mL of Py-d_5 and placed in a 20 cm × 5 mm diameter nmr tube.

Nuclear Overhauser enhancements were obtained in the difference mode as reported in ref. 2.

Two-dimensional correlated spectroscopy (COSY-45) (18) was executed with 90°–45° pulses separated by an incrementable evolution time t_1. Each spectrum required a total of 32 pulses in a 512 × 2048 data set, which took approximately 10 h to acquire. Quadrature detection was applied in both directions using a 16-step phase cycling for N-type peak selection. Data were multiplied with a sine-bell shaping function, zero filled, Fourier transformed, and symmetrized. Processing and plotting time for the spectrum was approximately 2h.

Carbon spectra were taken at 100.576 MHz on a Fourier transform Bruker instrument WM-400, equipped with dual probe, using the same sample (6 mg of **1** dissolved in 0.4 mL of Py-d_5 in a 5-mm diameter nmr tube) utilized for proton studies.

Two DEPT experiments were performed using polarization transfer pulses of 90° and 135°, respectively, obtaining in the first case only CH groups and in the other case positive signals for CH and CH_3 and negative ones for CH_2 groups. Polarization transfer delays were adjusted to an average CH coupling of 145 Hz. These delays were also applied for two-dimensional carbon–proton shift correlation in a 256 × 1024 data matrix. Each FID required a total of 600 scans. Total acquisition time was 36 h. An eight-step pulse cycle was used for P-type selection. Processing time (exponential multiplication in both dimensions, zero filling, Fourier transform) was 25 min.

Acknowledgments

We thank Professor H. Egge, Institut für Physiologische Chemie, Universität Bonn, for the FAB-ms spectrum, MPI (Ministero della Pubblica Istruzione, Roma) and CNR (Consiglio Nazionale delle Ricerche, Roma) for financial support, and DAAD (Deutscher Akademischer Austauschdienst, Bonn) for the award of a fellowship to R.L. The ^1H nmr spectra at 500 MHz were performed at IMIB-CNR, Arco Felice (Napoli).

Improved formulae for thermal unimolecular reaction rates with randomisation failure

S. R. VATSYA AND H. O. PRITCHARD
Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received January 19, 1984

S. R. VATSYA and H. O. PRITCHARD. Can. J. Chem. **62**, 2879 (1984).

Simpler and more general expressions are presented for the rate constants of thermal unimolecular reactions, for all randomisation rates $0 \leq \mu_r < \infty$, and for any number of reaction channels.

S. R. VATSYA et H. O. PRITCHARD. Can. J. Chem. **62**, 2879 (1984).

On a développé des expressions simples et plus générales pour les constantes de vitesse de réactions thermiques unimoléculaires, pour tous les taux de distribution au hasard $0 \leq \mu_r < \infty$ et quel que soit le nombre de canaux réactionnels.

Introduction

In an earlier paper, we provided a solution to the problem of the fall-off of a thermal unimolecular reaction in which the collisional excitation process is exponential, with rate μ, and the randomisation within grain r has rate μ_r, also exponential; numerical illustrations were provided for the case where μ_r was considered to be the same for all r (1).

This solution followed fairly closely the lines of a previous approximate treatment of the problem, in which it was assumed that the relaxations with rates μ and μ_r were separable, leading to the calculation of an effective rate constant $d_r\,[\equiv k(E)]$ with which the population of each grain would decay for the given randomisation rate μ_r (2). This approach to the coupled μ, μ_r problem led to formulae which were not always easy to use numerically because of cancellation; now, we develop a much more direct derivation of the rate constant (γ_0) for the coupled problem, resulting in a final expression which is relatively impervious to cancellation difficulties. It also avoids the necessity of calculating the eigenvalue spectrum for each grain, not a trivial problem when there are several decay channels to be taken into account.

Mathematical preliminaries

I. We begin with eq. [9] of ref. 1, i.e.

$$[1]\quad \gamma_0 = \mu(S_0, [\mu + \mathbf{V} + \mathbf{D} - \gamma_0]^{-1}\,[\mathbf{V} + \mathbf{D}]S_0)$$

where all the symbols are as defined before. Since $\mathbf{V}S_0 = 0$,

$$[2]\quad \gamma_0 = \mu(S_0, [\mu + \mathbf{V} + \mathbf{D} - \gamma_0]^{-1}\,\mathbf{D}S_0)$$

The first task is to derive a useful form for the matrix

$$[3]\quad [\mu + \mathbf{V} + \mathbf{D} - x]^{-1} = \left[\mu + \mathbf{D} - x + \sum_{r=1}^{M} \mu_r(I_r - \rho_{r0})\right]^{-1} = \sum_{r=1}^{M} [\mu + \mu_r - x + \mathbf{D}_r - \mu_r\rho_{r0}]^{-1}$$

Let $\mathbf{B} = \mathbf{A} - \nu\rho_0$ with $\rho_0 = \boldsymbol{u}_0(\boldsymbol{u}_0, \;)$ and $(\boldsymbol{u}_0, \boldsymbol{u}_0) = 1$: then

$$\mathbf{B}^{-1} = (\mathbf{A} - \nu\rho_0)^{-1} = \mathbf{A}^{-1} + \frac{\nu\mathbf{A}^{-1}\boldsymbol{u}_0(\mathbf{A}^{-1}\boldsymbol{u}_0, \;)}{1 - \nu(\boldsymbol{u}_0, \mathbf{A}^{-1}\boldsymbol{u}_0)}$$

whenever the right-hand side is defined (3); expression [3] now becomes

$$\sum_{r=1}^{M} \{[\mu + \mu_r - x + \mathbf{D}_r]^{-1} + \frac{\mu_r}{1 - \mu_r\lambda_r}[\mu + \mu_r - x + \mathbf{D}_r]^{-1}\,\rho_{r0}[\mu + \mu_r - x + \mathbf{D}_r]^{-1}\}I_r$$

where

$$[4]\quad \lambda_r = (I_rS_0, [\mu + \mu_r - x + \mathbf{D}_r]^{-1}I_rS_0)/(S_0, I_rS_0)$$

Also,

$$\rho_{r0} = I_rS_0(I_rS_0, \;)/(I_rS_0, I_rS_0)$$

and $(S_0, I_rS_0) = \beta_r$, the equilibrium population of grain r. Consequently,

$$[5]\quad [\mu + \mathbf{V} + \mathbf{D} - x]^{-1}f = \sum_{r=1}^{M} \left\{[\mu + \mu_r - x + \mathbf{D}_r]^{-1}\,I_rf + \frac{\mu_r}{\beta_r(1 - \mu_r\lambda_r)}[\mu + \mu_r - x + \mathbf{D}_r]^{-1} \times I_rS_0(I_rS_0, [\mu + \mu_r - x + \mathbf{D}_r]^{-1}I_rf)\right\}$$

where f is any arbitrary vector.

II. Let $\mathbf{A} = \mu(1 - p_0) + \mathbf{V} = \mu(1 - p_0) + \sum_{r=1}^{M} \mu_r(I_r - \rho_{r0})$; we have that $\mathbf{A}S_0 = 0$, i.e., the lowest eigenvalue $\sigma_0(\mathbf{A}) = 0$. For the next eigenvalue,

$$\sigma_1(\mathbf{A}) = \inf\,(\phi, \mathbf{A}\phi) \text{ where } \|\phi\| = 1 \text{ and } (S_0, \phi) = 0$$
$$= \inf\left(\phi, \left[\mu(1 - p_0) + \sum_{r=1}^{M} \mu_r(I_r - \rho_{r0})\right]\phi\right)$$
$$= \inf\left[\mu + \sum_{r=1}^{M} \mu_r(\phi, [I_r - \rho_{r0}]\phi)\right]$$

Since $\mu_r \geq 0$ and $(\phi, \rho_{r0}\phi) \leq (\phi, I_r\phi)$, $\sigma_1(\mathbf{A}) \geq \mu$.

III. We define two functions:

$$\bar{\phi}(x) = \alpha(S_0, [\mathbf{A} + \mathbf{D} + \alpha p_0 - x]^{-1}\,\mathbf{D}S_0)$$
$$\phi(x) = \alpha(S_0, [\mathbf{A} + \mathbf{D} + \alpha p_0 - x]^{-1}\,S_0)$$

As we have shown previously (4), for all $\alpha > 0$, $\bar{\phi}(\gamma_0) = \gamma_0$; moreover, if $\alpha \leq \sigma_1(\mathbf{A})$ and $x \leq \gamma_0$, then $\bar{\phi}(x) \leq \gamma_0$. Also $\chi(\gamma_0) = \gamma_0$ where $\chi(x) = \bar{\phi}(x)/\phi(x)$, and if $x \leq \gamma_0$, $\chi(x) \geq \gamma_0$. Thus, we have two independent procedures which can be used to form converging bounds to γ_0; however, it will not usually be necessary to resort to these successive approximation procedures. We have (4)

$$[6]\quad \chi(0) = \bar{\phi}(0)/\phi(0) \geq \gamma_0 \geq \bar{\phi}(0)$$

Also, since $\bar{\phi}(x) = \alpha - (\alpha - x)\phi(x)$, this inequality reads

$$\frac{\alpha\bar{\phi}(0)}{\alpha - \bar{\phi}(0)} \geq \gamma_0 \geq \bar{\phi}(0)$$

We may then choose $\alpha = \mu$ as a convenient and permissible value, giving

$$\chi(0) = \frac{\mu\bar{\phi}(0)}{\mu - \bar{\phi}(0)} \geq \gamma_0 \geq \bar{\phi}(0)$$

Now, if $\mu \gg \gamma_0$, as is often the case, then $\chi(0) \simeq \bar{\phi}(0)$, but since $\chi(0)$ and $\bar{\phi}(0)$ bracket γ_0, $\bar{\phi}(0)$ itself may be taken as the required solution.

IV. With $\alpha = \mu$, the inverse operator required in calculating both $\phi(x)$ and $\bar{\phi}(x)$ is

$$[\mathbf{A} + \mathbf{D} + \mu p_0 - x]^{-1} = [\mu + \mathbf{V} + \mathbf{D} - x]^{-1}$$

which was given above, eq. [5]. Consequently, after some straightforward manipulation

$$[7] \quad \bar{\phi}(x) = \mu \sum_{r=1}^{M} \frac{1}{1 - \mu_r\lambda_r} (I_r S_0, [\mu + \mu_r + \mathbf{D}_r - x]^{-1} \mathbf{D} S_0)$$

$$[8] \quad \phi(x) = \mu \sum_{r=1}^{M} \frac{1}{1 - \mu_r\lambda_r} (I_r S_0, [\mu + \mu_r + \mathbf{D}_r - x]^{-1} I_r S_0)$$

$$= \mu \sum_{r=1}^{M} \frac{\beta_r\lambda_r}{1 - \mu_r\lambda_r}.$$

Expressions for γ_0

Let each grain r be composed of $\dim(I_r)$ types of states, numbered $j = 0$ to $N = [\dim(I_r) - 1]$, with equilibrium populations as follows: β_{r0} states having zero decay rate; β_{r1} states having decay rate constant d_1; β_{r2} states having decay rate constant d_2, and so on, with

$$\beta_{rj} = (I_r S_0, I_{rj} I_r S_0) = (S_0, I_{rj} S_0)$$

$$\sum_{j=0}^{N} \beta_{rj} = \beta_r \text{ and } \sum_{j=0}^{N} d_j I_{rj} = \mathbf{D}_r$$

Then, from eq. [4]

$$\lambda_r(0) = \frac{1}{\beta_r} \sum_{j=0}^{N} \frac{\beta_{rj}}{\mu + \mu_r + d_j}$$

whence

$$[9] \quad \gamma_0 \simeq \bar{\phi}(0) = \mu \sum_{r=1}^{M} \frac{\sum_{j=0}^{N} \frac{\beta_{rj} d_j}{\mu + \mu_r + d_j}}{1 - \frac{\mu_r}{\beta_r} \sum_{j=0}^{N} \frac{\beta_{rj}}{\mu + \mu_r + d_j}}$$

Discussion

In both of our previous papers (1, 2), we provided *approximate* solutions for the rate constant when the randomisation process was not transparent; here, however, we present rigorous bounds to the exact eigenvalue γ_0. Inspection of eq. [6] shows that the quantity $\phi(0)$ defines the spread within which γ_0 must lie. Expanding eq. [8] in detail yields an expression almost identical to that for $\bar{\phi}(0)$ in eq. [9], but with two minor differences: (*i*) that we have just β_{rj} rather than $\beta_{rj} d_j$ in the numerator, and (*ii*) that the summation has to be taken, as well, over all the unreactive states below threshold, which simply adds a term $(1 - \Sigma'\beta_r)$ to the revised expression (Σ' is used here, as usual, to denote summation over states above threshold only). Thus, $\phi(0) \rightarrow (1 - \Sigma'\beta_r)$ as $\mu \rightarrow 0$, $\phi(0) \rightarrow 1$ as $\mu \rightarrow \infty$, and since the total equilibrium population above threshold is often miniscule, eq. [6] provides very tight bounds on γ_0 for all pressures. When compared with our earlier results, differences occurred in the fourth decimal place, or later, confirming the general quality of those earlier approximate solutions (and in which the computational effort was an order of magnitude greater). Thus, the use of eq. [9] should facilitate the examination of the problem of what values are required for the randomisation rate μ_r to reproduce the observed strong-collision behaviour in various thermal reactions, and of the effects of interference which can occur between competing reaction channels. Also, since we have defined weak-collision behaviour as the occurrence of departures from strong-collision properties (5), eq. [9] provides a vehicle for exploring such behaviour.

Notice that eq. [9] becomes inaccurate when $\mu_r \gg$ all d_j, but since the d_j are of the order of vibration frequencies, i.e. $\sim 10^{13}$ s^{-1}, this can be overcome very easily by performing the calculations in double-length arithmetic if exceedingly large values of μ_r are needed.

Determination of the limits of γ_0 with μ, μ_r is much simpler than before, by direct expansion of [8] and/or [9], but the results are the same as those given previously (1).

Molecular orbital treatment of substituent effects. II. Structures of some carboxylic acids and their conjugate bases

KENNETH E. EDGECOMBE AND RUSSELL J. BOYD[1]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received January 24, 1984

KENNETH E. EDGECOMBE and RUSSELL J. BOYD. Can. J. Chem. **62**, 2881 (1984).

Theoretical structures of the *cis* and *trans* conformations of acetic, fluoroacetic, difluoroacetic, trifluoroacetic, chloroacetic, dichloroacetic, and trichloroacetic acids and their carboxylate anions are compared with the available experimental structures. In every case the *cis* conformation, in which one of the atoms bonded to the α carbon lies in the carboxylate plane and is eclipsed with the carbonyl group, is predicted to have a lower energy than any other conformation of the acetic acids. The preferred conformation of the *trans* form of the haloacetic acids is characterized by a planar X—C—C—O—H ring which is interpreted in terms of an internal hydrogen bond. The long C—C bonds of the acetates at the minimal basis set level are corrected by partial geometry optimizations with split-valence basis sets. The partially optimized structures are very similar to the fully optimized structures and are sufficient for the elucidation of chemical trends. For more accurate acetate structures the 3-21 + G basis set introduced recently by von R. Schleyer and co-workers is recommended.

KENNET E. EDGECOMBE et RUSSEL J. BOYD. Can. J. Chem. **62**, 2881 (1984).

On compare les structures théoriques des conformations *cis* et *trans* des acides acétique, fluoroacétique, difluoroacétique, trifluoroacétique, chloroacétique, dichloroacétique et trichloroacétique ainsi que de leurs anions carboxylates avec les structures disponibles expérimentalement. Dans chaque cas, on prédit que l'énergie de la conformation *cis*, dans laquelle un des atomes liés au carbone α se trouve dans le plan du carboxylate et est éclipsé par le groupement carbonyle, sera plus faible que celle de n'importe quelle autre conformation des acides acétiques. La conformation privilégiée de la forme *trans* des acides haloacétiques est caractérisée par un cycle plan X—C—C—O—H que l'on interprète en rapport avec une liaison hydrogène interne. Les calculs effectués au niveau d'ensembles de base minimale prédisent que les liaisons C—C sont longues; on corrige ces prédictions en effectuant des optimisations partielles de la géométrie à l'aide d'ensembles de base du type valence dédoublée. Les structures partiellement optimisées sont très semblables aux structures complètement optimisées et elles sont appropriées pour l'élucidation des tendances chimiques. Si on veut obtenir des structures plus précises des acétates, il est recommandé d'utiliser l'ensemble de base 3-21+G introduit récemment par von R. Schleyer et ses collaborateurs.

Introduction

The first paper (1) in this series dealt with an *ab initio* molecular orbital (MO) study of multiple substituent effects in three series of carbon acids and their corresponding conjugate bases. The calculations were carried out to provide theoretical estimates of the proton affinities of some carbanions (CH_3^-, CH_2X^-, CHX_2^-, and CX_3^-, where X = F, CN, or NO_2) or equivalently the intrinsic acidities of the parent molecules. Within the series of methane acids, substitution takes place at the carbon atom to which the acidic proton is bonded. This may be contrasted with carboxylic acids in which substitution takes place at a carbon atom which is at least one bond removed from the oxygen to which the acidic proton is bonded. The observed dissociation constants in aqueous solution suggest that the acidity of acetic acid is much less enhanced by electronegative substituents than that of methane. Thus successive nitro substituents lower the pK_a of methane from 48[2] through 11 and 4 to 0 for trinitromethane (3). The corresponding values for the nitrile series are 31, 12, and 0, whereas the pK_a of acetic acid is only reduced from 4.75 to 2.85, 1.48, and 0.70 with one, two, and three chlorine substituents, respectively (4). In view of these marked differences and in order to complement our earlier study of multiple substituent effects in carbon acids, we have completed extensive *ab initio* MO calculations for the fluoro- and chloroacetic acids and their carboxylate anions.

Method

Standard single determinant *ab initio* MO theory, according to which closed-shell molecules and ions are treated by the spin-restricted Hartree–Fock (RHF) procedure (5), has been used throughout. The majority of the calculations were carried out using the GAUSSIAN 76 program (6*a*), or an expanded version (6*b*), on a CDC CYBER 170–720 computer. A few supplemental calculations were performed on a Perkin-Elmer 3230 computer using the GAUSSIAN 80 series of programs (7). Complete geometry optimizations, subject only to a planar carboxylate group, were performed at the STO-3G level (8). The assumption of a planar carboxylate group is supported by experiment and previous theoretical work (9, 10). In the case of the trichloroacetate anion the structure could not be optimized at the STO-3G level. Starting with a typical C—C bond length, the C—C bond lengthened and the OCO angle opened until a minimum corresponding to isolated CCl_3^- and CO_2 was obtained. The dissociative behaviour of $CCl_3CO_2^-$ was corrected by optimizing the C—C bond at the 4-31G level (11). The C—C bond was then fixed and the remainder of the molecule was optimized at the STO-3G level. The C—C bond was re-optimized at the 4-31G level and the cyclic procedure was repeated until the structure converged to an equilibrium geometry.

For each molecule, two conformations of the carboxylic acid group were optimized. In the *cis* (or *syn*) conformation, the acidic hydrogen forms a dihedral angle of 0° with the carbonyl oxygen, as shown in structure **I** of Fig. 1. In the *trans* (or *anti*) conformation the acidic hydrogen is at a dihedral angle of 180° with respect to the carbonyl oxygen. The *trans* conformation is

[1]To whom all correspondence should be addressed.

[2]Electrochemical measurements by Breslow and Grant (ref. 2) yield a pK_a for methane in the range 68 to 70.

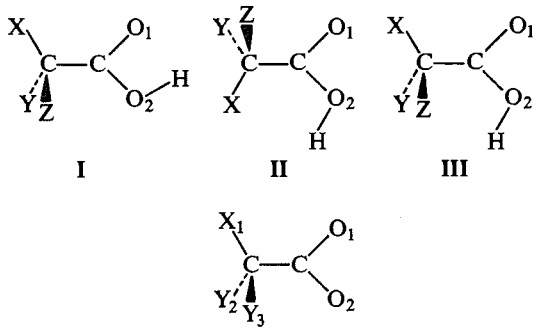

FIG. 1. The STO-3G equilibrium conformations of carboxylic acids and their conjugate bases. In the *trans* forms, structure **II** is favoured in all cases except acetic and trichloroacetic acids, for which structure **III** is favoured.

illustrated by structures **II** and **III** of Fig. 1. The STO-3G equilibrium geometries of the *cis* and *trans* conformations of some carboxylic acid molecules are compared with the available experimental data in Table 1. The corresponding results for the formates and acetates are listed in Table 2. For each species the point group of the equilibrium geometry is listed in the appropriate table, while the types of equilibrium conformations are illustrated in Fig. 1. The structures of *cis* and *trans* formic acid and *cis* acetic acid (10) are included for completeness.

Table 3 lists the STO-3G//STO-3G, K-LMG//STO-3G and K-LMG//"K-LMG" total energies, where "K-LMG" refers to the partial geometry optimizations described herein. The 4-31G basis set (11) has been used for molecules containing chlorine, while calculations with a split-valence basis set for the other species have been carried out at the 3-21G level (12). A few 4-31G single point calculations for some of the molecules are included for comparison with the STO-3G and 3-21G results.

Results and discussion

In this section we discuss the types of equilibrium conformations of the acetic acids and the extent to which the theoretical results are corroborated by experiment. Following a brief discussion of the barriers to interconversion of the conformations we compare the theoretical geometrical parameters with the experimental data. Particular attention is paid to the inadequate description of C—C bonds in acetates at the minimal basis set level and several methods for improving the results. We conclude by summarizing the experimental data which supports the interpretation of the preferred conformations of the haloacetic acids in terms of an internal hydrogen bond between a halogen and the carboxylic proton.

In the *cis* conformation of the carboxylic acid group, all acetic acid molecules are predicted to have equilibrium conformations corresponding to type I in Fig. 1, with the unique atom of the mono- and di-substituted species occupying position X. The *cis* conformation of the acetic acids is found to have a lower energy than any other conformation. These conclusions are consistent with the available gas-phase structures (9).

Optimization of the geometries of the *trans* acetic acids leads to two types of preferred conformations. In all but two cases, the lowest energy conformation is the type **II** structure shown in Fig. 1. The two exceptions occur for CH_3CO_2H and CCl_3CO_2H for which the type **III** structure is lower in energy. In molecules for which the type **II** structure is preferred, position X is occupied by a halogen. These observations are readily interpreted in terms of a competition between steric effects which favour **III** and intramolecular or internal hydrogen bonding which favours **II**. In *trans* acetic acid, where there is no hydrogen bonding, the lowest energy is obtained with conformer **III**. Among the substituted acetic acid molecules included in this work, steric effects would be at a maximum in the trichloro compound. Moreover, the long O—Cl distance, and the nonlinear arrangement, implies weak hydrogen bonding. The theoretical equilibrium conformation of *trans* trichloroacetic acid is, therefore, not surprising. Even in the preferred conformation **III**, there may be some hydrogen bonding. This suggestion is supported by recent microwave spectroscopic results (19) which indicate that the most stable conformation of glycine may be interpreted in terms of an internal bifurcated hydrogen bond between the carbonyl oxygen of the carboxylic group and two hydrogens of the amine group. Similarly, a weak bifurcated hydrogen bond between the hydroxyl group and two chlorine atoms of *trans* trichloroacetic acid may contribute to the stability of **III**.

With reference to the equilibrium conformations, it should be noted that the barriers to internal rotation about the C—C bond are much smaller than the barriers for the interconversion of the *cis* and *trans* acetic acids. The barriers for rigid rotation about the C—O bond at the STO-3G level are about 10 to 11 kcal/mol and are not strongly affected by the number of halogen substituents. This may be compared with the C—C barriers in the fluoroacetic acid series. For rigid rotation at the STO-3G level we obtain 5.5, 6.3, and 2.2 kcal/mol with one, two, and three fluorines, respectively, in the *trans* conformations and 1.0, 0.5, and 0.3 kcal/mol, respectively, in the *cis* conformations. The larger barriers for the *trans* conformations support the interpretation of the *trans* conformations in terms of internal hydrogen bonding. Furthermore, the lower value for trifluoroacetic acid suggests the presence of a bifurcated hydrogen bond in the type **III** conformation. Indeed, the rigid barriers of 0.5 and 1.7 kcal/mol at the STO-3G level in the *cis* and *trans* forms of trichloroacetic acid are consistent with the bifurcated hydrogen bond interpretation.

Lack of experimental data precludes a detailed analysis of the accuracy of the theoretical equilibrium structures. A few comparisons can be made, however, for the carboxylic acids. At the STO-3G level, the C=O bond length is insensitive to substituents, and where comparison with experiment is possible, the agreement is much better than average. Here we note that the STO-3G basis set usually gives bond lengths within 0.03 Å and bond angles within 4° of the experimental values for neutral molecules in their ground states (20). For the C=O bonds the agreement is about 0.01 Å or better. There is insufficient experimental data to confirm the STO-3G prediction that the C=O bond length is insensitive to the number of halogens on the carbon. In view of the underestimation of the effect of substituents on bond lengths in the carbon acids (1) at the minimal basis set level, the near constancy of the C=O bond lengths may be an anomaly of the STO-3G basis set. The STO-3G results for the C—OH bond show only slightly greater variation than the C=O values and are consistently too long relative to the experimental values. With the exception of the C—C bond lengths, the agreement between the STO-3G and experimental results for the other bond lengths and angles is quite typical (20).

The tendency of the C—C bond length to increase about 0.01 to 0.02 Å per fluoro and chloro substituent at the STO-3G level as the number of halogens on the α carbon increases is one

[i]Reference 9*d*.

of the most apparent features of Table 1. Furthermore, the C—C bond length of the acetate anion is of the order of 0.1 Å too long and each successive fluoro substituent stretches the C—C bond by about 0.02 Å, while the effect of chloro substituents is even greater. The effect is so great in the case of the trichloroacetate anion that dissociation to CCl_3^- and CO_2 is predicted. In the haloacetate anions the minimal basis set provides only a small number of basis functions for a relatively

large number of electrons. The number of basis functions varies stepwise from 23 in acetate to 47 in trichloroacetate. The corresponding number of electrons varies from 32 to 80, while the number of virtual orbitals remains constant at 7. Thus a large fraction (0.85) of the molecular orbitals are occupied in $CCl_3CO_2^-$ at the STO-3G level. The fraction is lower for the other ions (0.70 in the acetate ion), but still high relative to the range encountered in hydrocarbons (0.56 and 0.58 for ethane and benzene, respectively). After accounting for the many lone-pairs and inner pairs of electrons, the STO-3G basis is insufficiently flexible to provide a reasonable description of the C—C bond of the acetates. It is not surprising that the inadequacy of the STO-3G basis set is greater in the anions than in the parent acids, since it is well known that extended basis sets are necessary to obtain an accuracy comparable to the minimal basis set geometries of neutral molecules and cations (21–26). In the haloacetates the well-known difficulties associated with MO calculations on anions are compounded by the electron-rich character of the ions.

In order to improve upon the STO-3G results, split-valence basis sets were used. The size of the molecules and anions included in this work precludes complete geometry optimizations for all species and, therefore, we carried out partial geometry optimizations. A few full optimizations provide a check on the partial optimizations. With the remainder of the geometry constrained to the STO-3G structure, the C—C bond of each species was optimized at the 3-21G or 4-31G level. The latter was used for molecules containing chlorine since the 3-21G basis set for second-row atoms was not available at the time when these calculations were completed. For convenience we denote the partially optimized structures by "K-LMG" to distinguish them from the fully optimized K-LMG structures.

[a]All energies are in atomic units: 1 au = 27.2116 eV.

[b]Notation A//B indicates that the energy has been calculated at level A using a geometry which is optimum for level B.

[c]Values in parentheses were obtained by the cyclic method described in the text for trichloroacetate.

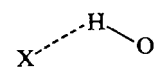
The "K-LMG" carbon—carbon bond lengths listed in parentheses in Tables 1 and 2 are closer to the observed range of C—C bond lengths. In the case of the parent acids there is a tendency for the partial optimizations to over-correct the minimal basis set values. This appears to be due to the choice of a split-valence basis set rather than to the optimization procedure since full 4-31G optimizations yield 1.533, 1.536, 1.494, and 1.506 Å for the C—C bonds of fluoroacetate, difluoroacetate, and *cis* and *trans* fluoroacetic acid, respectively. As a further test of the ability of the partial optimizations to yield good approximations to the full optimizations, we optimized the C—C bonds of formamide and *cis* acetic acid at the 3-21G level while constraining the remainder of the molecule to the STO-3G structure (10). This leads to 1.515 and 1.494 Å for the C—C bonds of CH_3CONH_2 and *c*-CH_3CO_2H, respectively, in excellent agreement with the fully optimized values (10) of 1.510 and 1.497 Å, respectively. The discrepancies between the partially and fully optimized values of the other geometrical parameters are small and well within the range of error associated with small basis set calculations (20).

We conclude that the partial optimizations yield C—C bond lengths within 0.01 Å of the true theoretical values and that the "K-LMG" structures form a useful set for the elucidation of chemical trends, such as the proton affinities discussed in the following paper (27). Here we would like to mention that von R. Schleyer and co-workers (23) have recently shown that diffuse function — augmented split-valence basis sets yield excellent geometries for anions. The 3-21+G value (23*c*) of 1.546 Å for the C—C bond length of acetate may be compared with the 3-21G value of 1.576 Å and the "3-21G" value of 1.566 Å listed in Table 2. The 3-21+G calculations make even greater demands on computer memory and time than the 3-21G calculations and are not practical for the large species considered in this paper. For example, a 3-21+G calculation on CCl_3CO_2H involves 105 basis functions. Since our objective is to study chemical trends, we treat all species at a uniform theoretical level. Furthermore, the errors associated with the "K-LMG" calculations appear to be largely systematic, as observed in K-LMG calculations on small anions (23), and, therefore, it is not unreasonable to expect chemically useful information from the present approach.

Some insight into the inadequacy of the STO-3G basis set for the prediction of the equilibrium structures of electron-rich species can be gained by use of mixed basis sets. With a 4-31G basis set on O, STO-3G on C and Cl, and the geometry constrained to the structure given in Table 2, optimization of the C—C bond of $CCl_3CO_2^-$ leads to 1.603 Å. Repeating the procedure with a 4-31G basis on C and STO-3G on the other centres leads to 1.638 Å for the C—C bond, while a 44-31G basis set on Cl and STO-3G elsewhere leads to a C—C bond length of 1.761 Å. This shows that the inadequacy of the STO-3G basis for the electron-rich acetates is primarily associated with the lone pairs on the oxygen atoms and not with the lone pairs on the halogen atoms. This is not surprising in view of the fact that the Mulliken atomic charges, as well as the formal charges associated with the Lewis structures, place the majority of the negative charge of the acetates on the oxygen atoms.

The total energies of the *cis* and *trans* conformations of the carboxylic acids and their conjugate bases are listed in Table 3. A detailed analysis will not be given in this paper but rather the energies will be used in the following paper (27) on the effect of multiple substituents on the proton affinities of the carboxylate anions. Analysis of the data in Table 3 reveals that the total energies are non-additive with respect to the number of substituents. Here we would like to emphasize that recent studies of multiple substitution at the same carbon by highly electronegative substituents exhibit similar nonadditive energetic and geometric effects (28−30).

To conclude our discussion we consider the extent to which experimental evidence corroborates the interpretation of the preferred conformations of the haloacetic acids in terms of internal hydrogen bonding of the type



where X may be either F or Cl. The most direct evidence is provided by a microwave spectroscopic and electron diffraction study of monofluoroacetic acid (9*b*). In the *cis* conformation the chain of atoms F—C—C—O—H is zig-zag, whereas the *trans* conformation is cyclic. Both conformations have a plane of symmetry. Thus the results summarized in Table 1 and

Fig. 1 are in complete agreement with the experimental studies on monofluoroacetic acid in the gas phase. Molecules in which the internal hydrogen bond involves five atoms in a ring include 2-fluoroethanol (31), 1,2-propanediol (32), β-hydroxyacrolein (33), and 2-fluoropropanol (34). Similarly there is much evidence for internal hydrogen bonding in rings involving six atoms in molecules such as malonaldehyde (33), triformylmethane (35), 2-nitrophenol (36), and the hydrogen maleate ion (37).

Molecular orbital treatment of substituent effects. III. Proton affinities of some methyl and carboxylate anions

KENNETH E. EDGECOMBE AND RUSSELL J. BOYD[1]

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received February 13, 1984

KENNETH E. EDGECOMBE and RUSSELL J. BOYD. Can. J. Chem. **62**, 2887 (1984).

Extensive *ab initio* molecular orbital calculations for the proton affinities of $CH_{n-1}X_{4-n}^-$, where n = 1, 2, 3, or 4 and X = F, CN or NO_2, formate, fluoroformate, and a number of acetates, $CH_{n-1}X_{4-n}CO_2^-$, where n = 1, 2, 3, or 4 and X = F or Cl are presented. Comparison of the theoretical and experimental gas-phase data indicates that the general chemical trends are well described by small basis sets of the split-valence type, but that better quantitative agreement is obtained by use of the diffuse function-augmented basis set (3-21+G) recommended by von R. Schleyer and co-workers (J. Comput. Chem. **4**, 294 (1983)) for anion calculations. Large basis sets and post Hartree–Fock calculations are included for CH_3^-, CH_2F^-, and CH_2CN^-.

KENNETH E. EDGECOMBE et RUSSELL J. BOYD. Can. J. Chem. **62**, 2887 (1984).

On rapporte des calculs poussés *ab initio* d'orbitales moléculaires relatifs à l'affinité pour les protons des anions $CH_{n-1}X_{4-n}^-$ où n = 1, 2, 3 ou 4 et X = F, CN, NO_2, formiate ou fluoroformiate et d'un certain nombre d'acétates, $CH_{n-1}X_{4-n}CO_2^-$, où n = 1, 2, 3 ou 4 et X = F ou Cl. Une comparaison des données théoriques et expérimentales indique que les tendances chimiques générales sont bien décrites par des ensembles de type valence-dédoublée tirées de bases restreintes; toutefois, on obtient un meilleur accord quantitatif si on utilise l'ensemble tiré d'une base rehaussée par une fonction diffuse (3-21+G) recommandé par von R. Schleyer et ses collaborateurs (J. Comput. Chem. **4**, 294 (1983)) pour des calculs relatifs aux anions. Dans le cas des anions CH_3^-, CH_2F^- et CH_2CN^-, on a aussi inclus des calculs obtenus à l'aide de bases élargies et de calculs post Hartree–Fock.

[Traduit par le journal]

Introduction

The proton affinity of an anion A^-, or equivalently the standard enthalpy change ΔH for the deprotonation reaction

[1] $AH \rightarrow A^- + H^+$

is determined experimentally by measurement of the equilibrium constant of the proton transfer reaction

[2] $A_1^- + A_2H \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} A_1H + A_2^-$

in the gas-phase (1). Recent measurements of the equilibrium constant for reaction [2] by high-pressure mass spectrometry (2), flowing afterglow (3), and ion cyclotron resonance spectrometry (4) have provided reliable gas-phase data on the acidities of a variety of carbon acids and a few carboxylic acids (1, 5). The gas-phase studies have yielded valuable information on the effect of substituents on the intrinsic properties of carbanions, whereas until recently our knowledge has been based on thermodynamic and kinetic studies in solution. The solution-phase results are often more a reflection of the effects of solvation than an accurate indication of the inherent properties of the anions. In fact, solvation energies, which are of the order of 50–90 kcal/mol (6) are often sufficient to obscure intrinsic acidity differences. For example, acetophenone is six orders of magnitude more acidic than fluorene in benzene (7), but in dimethyl sulfoxide, fluorene is 10^2 times stronger. In view of the complexity of the treatment of solute–solvent interactions (8), it is not practical to determine indirectly intrinsic acidity differences from solution-phase results.

An alternative method for obtaining data appropriate to molecules in the gas phase is provided by *ab initio* molecular orbital theory. Theoretical calculations have been shown to reproduce intrinsic acidity differences for a variety of systems, including those in which gas-phase and solution-phase results are in conflict. Several extensive studies on cations (9), anions (10, 11), and radicals (12) have been reported.

The purpose of this paper is to report an extensive *ab initio* MO study of the relative proton affinities of $CH_{n-1}X_{4-n}$, where n = 1, 2, 3, or 4 and X = F, CN or NO_2, formate, fluoroformate and a number of acetates, $CH_{n-1}X_{4-n}CO_2^-$, where n = 1, 2, 3, or 4 and X = F or Cl. Calculations with diffuse-function augmented basis sets and post Hartree–Fock calculations with extended basis sets are included for comparison with the results obtained with minimal and split-valence basis sets.

Method and results

The optimized structures and the total energies have been described elsewhere for the carbon acids and their conjugate bases (13) and the carboxylic acids and their conjugate bases (14). The proton affinities of the methyl anions are listed in Table 1 where the notation A//B indicates that the proton affinity has been calculated at the level of basis set A with the equilibrium geometry obtained at the level of basis set B. The available high-pressure mass spectroscopic values (5) are included for comparison. The corresponding data for some carboxylate anions are compiled in Table 2.

The theoretical proton affinities have been calculated as the difference between the total energies of the anion and its parent acid at their respective equilibrium geometries. Thus, for a chosen basis set the proton affinity of A^- is given by

[3] $PA(A^-) = E(A^-) - E(AH)$

In order to correct the relative proton affinities given by eq. [3] to absolute proton affinities several corrections must be made. These include a thermodynamic term, $(5/2)RT$, which arises from the change in the number of molecules and a change from absolute zero to the temperature of interest. In principle, a correction should also be made for the difference in the zero-

[a]In kcal/mol.

[b]The prefixes refer to the *cis* and *trans* forms of the corresponding carboxylic acids.

[c]All values were calculated by use of the 3-21G basis set, except in the chloro series for which the 4-31G basis set was used. The values in parentheses are the 4-31G//STO-3G results. The partial K-LMG optimizations, denoted by "K-LMG", are described in ref. 14.

[d]All data from ref. 5.

point energies of A^- and AH. The change in zero-point energy is readily calculated if all the vibrational frequencies of the normal modes are known. There is, however, insufficient data for the anions. A rough estimate of the magnitude of the zero-point correction and its dependence on the number and type of substituents can be obtained by noting that deprotonation of AH leads to a loss of three degrees of freedom, the most important of which is associated with a A—H stretching mode. If we assume that the structure of the anion is not significantly different from that of the parent acid, and that the fundamental frequencies are not appreciably affected, then the force constant of the A—H bond may be expected to yield a fairly good approximation to the change in the zero-point energy. For the methyl anions listed in Table 1 we obtain 5.31, 5.09, 4.93, 4.90, 5.15, 5.06, 4.97, 5.16, 5.02, and 5.01 kcal/mol, respectively, for the zero-point energy correction. These estimates are based on STO-3G force constants which are known to overestimate the force constants of most bonds (15). However, this overestimation is offset by neglecting two lower frequencies associated with bending modes. The STO-3G values for the O—H force constant yield 5.98, 6.02, 6.05, 6.03, 5.97, 5.97, 5.95, 5.95, 5.90, 5.95, 5.96, 5.93, 5.98, 5.98, 5.88, 6.21, 5.89, and 5.72 kcal/mol, respectively, for the zero-point correction of the anions listed in Table 2. The near constancy of the approximations to the zero-point energy correction is a reflection of the insensitivity of the C—H and O—H bonds to substituents (13, 14). In view of the larger changes in some of the other geometrical parameters associated with deprotonation of AH, it is quite likely that the simple force constant method may underestimate the zero-point energy correction. Even if the variation in the zero-point energy correction is an order of magnitude greater than the above estimate, differences of the order of 2 to 3 kcal/mol within a given series will not have a substantial effect on the general trends. Furthermore the thermodynamic correction term, which is about 1.5 kcal/mol for typical experimental conditions, and the zero-point energy correction contribute to the proton affinity with opposite signs (16). Neglecting the zero-point and thermodynamic correction terms leads to errors of about 5–8 kcal/mol. These errors are small, however, relative to the basis set error. The size of the larger members of the series of molecules dictates the use of small basis sets. In principle, we require a mathematically complete basis set for the calculation of the absolute acidities. The use of a finite basis set leads to a substantial error. Even with a complete basis we can do no better than attain the Hartree–Fock (HF) limit. The energies will still be in error due to neglect of electron correlation. To eliminate or even estimate the correlation error we must go beyond the Hartree–Fock limit by using configuration interaction (CI) or other techniques such as Møller–Plesset perturbation theory (17). Large basis sets and post Hartree–Fock calculations are impractical for all but the smallest members of the series included in this work. Consequently we have concentrated our study on basis sets and methods which can be applied to all members of the series. A few calculations with larger basis sets and post Hartree–Fock methods are included as a check on the small basis set calculations. The 3-21+G optimizations (11) and post Hartree–Fock calculations were carried out on a Perkin–Elmer 3230 computer using the GAUSSIAN 80 series of programs (18).

Discussion

Gas-phase proton affinities are available for only 5 of the 10

methyl anions included in this study. To make matters worse, a complete set of values is not available for any of the three series. Nevertheless, it is immediately apparent that the minimal basis set grossly overestimates the proton affinities, due to a larger basis set error for the energy of the anions than their corresponding conjugate acids. The 3-21G proton affinities are about 80 to 100 kcal/mol lower than the STO-3G values and are closer to the magnitude of the experimental values. Further improvement requires the addition of diffuse basis functions which provide a better description of the anion (19–21). Recent calculations by von R. Schleyer and co-workers (11, 21) have shown that diffuse function-augmented split-valence basis sets describe the proton affinities of anions better than minimal and standard split-valence basis sets. The mean deviation between theory and experiment for 21 anions is only 3.1 kcal/mol at the 3-21+G level (11), whereas the 3-21G and 4-31G mean deviations are 42 and 30.5 kcal/mol, respectively, for smaller subsets. From Table 1, it is apparent that the effect of adding a set of diffuse functions to the 3-21G basis set is to lower the proton affinities by amounts ranging from 14 to 35 kcal/mol, only a small fraction (0.6 kcal/mol in CH_3^-) of which is due to optimizing the structures at a higher level. Although the improvement is significant, the mean deviation of 12.7 kcal/mol between experiment and theory indicates that the 3-21+G basis set is much less successful for the present set of methyl anions than the ones studied by von R. Schleyer and co-workers (11). Furthermore, there is some indication that the 3-21+G basis set underestimates the proton affinities of the methyl anions containing two or three electronegative substituents, the largest of which are impractical to treat at the 3-21+G level. For example, a 3-21+G calculation on $CH(NO_2)_3$ involves 132 basis functions. For a discussion of general trends, we refer to the 3-21G values in Table 1 in order that all anions may be treated uniformly. Although the 3-21+G values are substantially lower than the 3-21G values, and on average closer to the experimental values, the two sets of data lead to the same chemical trends.

On the basis of the 3-21G results we may predict that within the fluoro series each successive fluorine substituent lowers the proton affinity more than the previous one, whereas in the cyano and nitro series there is an opposite effect associated with multiple substituents. Unfortunately, there is insufficient experimental data to corroborate the 3-21G predictions. We may note, however, that the data for the cyano series is consistent with this observation: the first cyano group lowers the PA by 44 kcal/mol and the second one by 36 kcal/mol in fair agreement with the 3-21G lowerings of 57 and 51 kcal/mol, respectively. The 3-21+G lowerings due to the first and second cyano groups are 48 and 43 kcal/mol, respectively. Also the 3-21G, the 3-21+G and experimental values show a larger decrease in PA for one nitro group than one cyano group. In general the tendency of the 3-21G calculations to underestimate the acidity of the C—H bond appears to diminish as the number of substituents increases.

From eq. [3] it is apparent that in order for small basis set calculations to yield proton affinities in good agreement with gas-phase data, there must be substantial cancellation of errors. Optimizing the structures with extended basis sets may be expected to lead to greater changes in the equilibrium geometries of the anions than the protonated species since larger basis sets are required to obtain the same accuracy for anions as obtained for neutral molecules and cations with smaller basis sets (10*b*, 11, 20–22). In order to provide an indication of the magnitude of the basis set and correlation energy errors we have carried out a few higher-level calculations for the proton affinities of CH_3^-, CH_2F^-, and CH_2CN^- (see Table 3). The data for CH_3^- illustrate a very large basis set dependence. Optimization of the CH_3^- and CH_4 structures at the 6-31G* level reduces the relative PA to 457.0 kcal/mol from the 3-21G//STO-3G value of 463.4 kcal/mol. Including the effects of electron correlation by means of Møller–Plesset perturbation theory (17) terminated at second (MP2) and third (MP3) order has little effect at the 6-31G* level, and actually leads to a small increase in the theoretical values. With a triple-split valence, polarized basis set, 6-311G** (23), substantial improvement is obtained at the HF, MP2, and MP3 levels, while maintaining the structures at their 6-31G* values. Repeating the calculations at the 6-311G** geometries leads to changes of about 0.1 kcal/mol. Configuration interaction (CI) with all single and double substitutions (CIDS) at the 6-311G** level leads to very similar results as the MP2 and MP3 methods. We note that inclusion of the size-consistency correction (SCC) and freezing the core electrons in the carbon 1*s* Hartree–Fock MO have little effect on the results. Optimizing the geometries at the MP2 level with the 6-311G** basis set lowers the energy of CH_3^- by only 7×10^{-5} au but has no effect on the computed proton affinity. None of the extended basis sets mentioned above is as effective, however, as the 3-21+G basis set recommended by von R. Schleyer. Even at the Hartree–Fock level the 3-21+G results are distinctly better. At the MP2/3-21+G//HF/3-21+G level the agreement with experiment is improved for CH_3^- by 7.0 kcal/mol (cf. Tables 1 and 3).

In view of the results presented in Table 3 for CH_3^-, the structures of CH_2F^- and CH_2CN^- were optimized at the HF/6-31G* level, and the proton affinities were calculated by the HF and MP2 methods at the 6-311G** level. The larger basis set lowers the proton affinities by 8 and 10 kcal/mol, respectively, relative to the 3-21G values. The correlation corrections for CH_2F^- and CH_2CN^- are smaller and larger, respectively, than in CH_3^- at the same level. The range of correlation corrections is, however, small. As in the case of CH_3^-, the addition of diffuse functions to the 3-21G basis set at the HF level has a much greater effect than any of the larger basis sets or post Hartree–Fock methods. Including electron correlation at the MP2/3-21+G//HF/3-21+G level further improves the result for CH_2CN^- by 2.0 kcal/mol.

As in the case of the methyl anions, the STO-3G basis set overestimates the relative proton affinities of the carboxylate anions. In fact the K-LMG values are of the order of 100 kcal/mol lower and closer to the range of experimental data. Both the minimal and split-valence basis set calculations are consistent with the observed trend: the proton affinity of the acetate ion decreases as the number of halogen substituents increases. This is also consistent with the increase in acidity in solution phase as the number of halogens increases. It is significant that despite the poor description of the C—C bonds at the STO-3G level (14) in the haloacetate anions, the K-LMG proton affinities at the partially optimized K-LMG geometries do not differ substantially from the K-LMG//STO-3G results. Furthermore full geometry optimizations at the 4-31G level on *c*-CH_2FCO_2H and $CH_2FCO_2^-$ raise the PA by only 0.6 kcal/mol. Comparing the 4-31G PA's in Table 2 with the seven experimental values indicates that the theoretical values are systematically too large by amounts ranging from 6.5 to 14 kcal/mol. The mean deviation of 11 kcal/mol and the fairly

TABLE 3. Post Hartree–Fock total energies and relative proton affinities of selected anions

[a]In atomic units. 1 au = 627.5095 kcal/mol.

[b]In kcal/mol.

[c]The equilibrium C—H bond lengths (Å) of CH_4 and CH_3^- and the HCH angle (deg) of CH_3^- are 1.084, 1.119, 101.7; 1.084, 1.117, 102.7; and 1.090, 1.122, 101.6 at the HF/6-31G*, HF/6-311G** and MP2/6-311G** levels, respectively. The 6-31G* equilibrium (C_s) structural parameters of CH_2F^- are r(CF) = 1.495, r(CH) = 1.117, ∠(HCF) = 100.2 and ∠(HCH) = 100.5°. The 6-31G* equilibrium (C_{2v}) structural parameters of CH_2CN^- are r(CN) = 1.165, r(CC) = 1.376, r(CH) = 1.075 and ∠(HCC) = 120.5. The 3-21+G equilibrium structures are given in footnote *c* of Table 1.

small range of mean deviations indicates that the PA's of the haloacetic acids are moderately well described at the 4-31G level. The 3-21G values for the fluoroacetic acids are about 13–14 kcal/mol higher than the 4-31G values. Adding diffuse basis functions would improve the agreement between theory and experiment. In fact, at the 3-21+G level the relative PA's of formate and acetate are calculated (11) to be 344.4 and 349.5 kcal/mol, respectively, in remarkable agreement with the experimental values of 345.2 and 348.5 kcal/mol.

Fluorosulfates of the noble metals. Part 6.[1] Synthesis and magnetic properties of fluorosulfato compounds of ruthenium

PATRICK C. LEUNG AND FRIEDHELM AUBKE

Department of Chemistry, The University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6

Received December 12, 1983[2]

PATRICK C. LEUNG and FRIEDHELM AUBKE. Can. J. Chem. **62**, 2892 (1984).

Oxidation of ruthenium by bis(fluorosulfuryl)peroxide in HSO_3F solution results in the formation of ruthenium(III) fluorosulfate, $Ru(SO_3F)_3$. Complexation reactions afford $ClO_2[Ru(SO_3F)_4]$ and $Cs[Ru(SO_3F)_4]$. The presence of alkali metal fluorosulfate allows oxidation of ruthenium to the 4+ oxidation state and the complexes $K_2[Ru(SO_3F)_6]$, $Cs_2[Ru(SO_3F)_6]$, and $Cs[Ru(SO_3F)_5]$ are obtained.

Vibrational spectra and the results of magnetic susceptibility measurements down to 80 K are reported and discussed.

PATRICK C. LEUNG et FRIEDHELM AUBKE. Can. J. Chem. **62**, 2892 (1984).

L'oxydation du ruthénium, par le peroxyde de bis(fluorosulfuryl) en solution dans le HSO_3F, conduit à la formation du fluorosulfate de ruthénium, $Ru(SO_3F)_3$. Des réactions de complexation fournissent le $ClO_2[Ru(SO_3F)_4]$ et le $Cs[Ru(SO_3F)_4]$. La présence d'un fluorosulfate d'un métal alcalin permet d'oxyder le ruthénium à son niveau d'oxydation 4+ et on a obtenu les complexes $K_2[Ru(SO_3F)_6]$, $Cs_2[Ru(SO_3F)_6]$ et $Cs[Ru(SO_3F)_5]$.

Opérant à des températures allant jusqu'à 80 K, on a déterminé les spectres vibrationnels et les susceptibilités magnétiques de ces composés et on discute des résultats obtenus.

[Traduit par le journal]

Introduction

Metal oxidation by bis(fluorosulfuryl)peroxide, $S_2O_6F_2$, in the presence of fluorosulfuric acid, HSO_3F, as a reaction medium, had proven in the past a simple and quantitative route to metal fluorosulfates, according to:

$$[1]\quad 2M + nS_2O_6F_2 \xrightarrow{HSO_3F} 2M(SO_3F)_n$$

as well as to metal fluorosulfato complexes as illustrated by a recent example (1):

$$[2]\quad 2CsCl + 2HSO_3F + Pd + 2S_2O_6F_2 \xrightarrow[120°C,\ 30\,h]{HSO_3F} Cs_2[Pd(SO_3F)_6] + 2HCl$$

While of general applicability, our interest had primarily focussed on reactions involving electron-rich 4*d*- and 5*d*-block elements, such as Pd(1), Ag(2), Au(3), Ir(4), and Pt(5) for the following reasons:

(*i*) The fluorosulfates obtained by reactions involving these elements were thermally stable up to 200°C and above, and decomposition to oxy- or fluorofluorosulfates did not occur.

(*ii*) All metals were found to be capable of forming a variety of anionic complexes, allowing more extensive studies.

(*iii*) Detailed studies had revealed unusual magnetic properties in some cases, such as Pd(II) with a $^3A_{2g}$ ground state (1) and Ag(II) in both a magnetically dilute and concentrated system (2). Interesting reactivity patterns were found in other instances, e.g. solutions of $Au(SO_3F)_3$ (3) and $Pt(SO_3F)_4$ (5) in fluorosulfuric acid had exhibited super acidity.

(*iv*) The metals studied had displayed a wide range of reactivity towards $S_2O_6F_2$, with the oxidation of gold complete within a few hours at 25°C (3) while the oxidation of iridium to the Ir^{4+} oxidation state required several days with a reaction temperature of 120°C (4).

We became interested in extending our study to ruthenium in search of similar features as had been discovered previously.

Experimental

Chemicals

Ruthenium metal powder, −80 mesh of 99.9% purity was obtained from the Ventron Corporation. Technical grade fluorosulfuric acid (Allied Chemicals) was double distilled at atmospheric pressure as described previously (6). Bis(fluorosulfuryl)peroxide (7) and chloryl fluorosulfate (8) were synthesized according to published methods. All other chemicals used in this study were obtained from commercial sources in the highest degree of purity available.

Instrumentation and analysis

Details on our instrumentation and the techniques employed in manipulating volatile and moisture-sensitive substances, the recording of infrared, Raman, epr, and electronic spectra and the calibration of magnetic susceptibility measurements have been published previously (2). The Gouy apparatus used in this study has been described earlier (9). Diamagnetic corrections were calculated from Pascals constants (10). Magnetic data on other ruthenium compounds were obtained from reference compilations (10).

All reactions were performed in Pyrex reaction vials of about 40 mL volume fitted with Kontes Teflon stem valves and Teflon coated magnetic stirring bars. The course of reaction was monitored by recording weight changes of the nonvolatile products. Microanalyses were performed by Analytische Laboratorien, Gummersbach, West Germany.

Synthetic reactions

(a) $Ru(SO_3F)_3$

In a typical reaction 0.253 g (2.503 mmol) of ruthenium powder were allowed to react at 60°C for 24 h with a mixture approximately 2.5 mL of $S_2O_6F_2$ and 5 mL of HSO_3F. Completion of the reaction was indicated by the consumption of all metal powder and the formation of a dark red–brown solution. After removal of all volatiles *in vacuo* at 60°C, 1.050 g of an almost black, dark red–brown solid remained, which analysed as $Ru(SO_3F)_3$. *Anal.* calcd.: Ru 25.38, S 24.15, F 14.31; found: Ru 25.15, S 24.02, F 14.46. $Ru(SO_3F)_3$ is hygroscopic, very soluble in HSO_3F, and thermally stable up to 140°C. Above this point decomposition is noted and a red–brown liquid is formed.

(b) $ClO_2[Ru(SO_3F)_4]$

Excess dark red ClO_2SO_3F (~5.6 g) was added to a one-piece Pyrex reactor containing 0.925 g (2.32 mmol) of $Ru(SO_3F)_3$ inside the drybox. After stirring the mixture at ~70°C for one day, complete dissolution of $Ru(SO_3F)_3$ was observed. Excess ClO_2SO_3F was then removed *in vacuo* with the reactor and content kept at 70°C. Due to the low volatility of ClO_2SO_3F, the residual amount was pumped off with the reactor kept at 100°C, leaving 1.334 g of black solid behind. The expected weight for $ClO_2Ru(SO_3F)_4$ was 1.312 g. Elemental analysis of the material suggests the composition $ClO_2Ru(SO_3F)_4$. *Anal.* calcd.: Ru 17.90, Cl 6.28, F 13.46; found: Ru 17.68, Cl 6.38, F 13.58. Infrared bands (cm^{-1}) are listed with estimated intensities in parentheses and bands attributed to ClO_2^+ denoted with an asterik: 1360 (s, b), 1295* (m), 1190 (vs), 1140 (s, sh), ~1040* (m, sh), 940 (s, vb), 810 (s, b), 630 (w), 575 (m), 545 (m), 515* (w), 475 (vw), 435 (vw).

(c) $Cs[Ru(SO_3F)_4]$

A 1:1 stoichiometric mixture of $Ru(SO_3F)_3$ (1.739 g, 4.366 mmol) and $CsSO_3F$ (1.013 g) was loaded into a one-part Pyrex reactor under an inert atmosphere. Excess HSO_3F (~10 mL) was directly distilled into the mixture. Subsequent stirring at ~60°C for one day resulted in complete dissolution. The HSO_3F was then removed *in vacuo* at ~60°C. The homogeneous, very dark brown–black solid obtained was identified by its elemental analysis to have the composition $Cs[Ru(SO_3F)_4]$. *Anal.* calcd.: Cs 21.09, Ru 16.04, F 12.06; found: Cs 20.97, Ru 15.90, F 11.96.

(d) $K_2[Ru(SO_3F)_6]$ and $Cs_2[Ru(SO_3F)_6]$

A 2:1 mole ratio mixture of KSO_3F (0.776 g) and ruthenium powder (0.284 g, 2.81 mmol) was loaded into a one-part Pyrex reactor inside the drybox. Approximately 5 mL of HSO_3F and an equal volume of $S_2O_6F_2$ were distilled successively onto the mixture. Subsequent stirring at ~60°C overnight resulted in a red solution. The excess $S_2O_6F_2$ and HSO_3F were removed *in vacuo* with the reactor and the content kept at ~50°C. Removal of all volatiles from the viscous red–orange solution yielded 2.188 g of a bright orange solid as compared to 2.174 g expected for $K_2[Ru(SO_3F)_6]$. An identical procedure was used to synthesize $Cs_2[Ru(SO_3F)_6]$. Elemental analyses gave the following.

(*i*) *Anal.* calcd. for $K_2[Ru(SO_3F)_6]$: K 10.11, Ru 13.06, F 14.73; found: K 9.99, Ru 13.06, F 14.77.

(*ii*) *Anal.* calcd. for $Cs_2[Ru(SO_3F)_6]$: Cs 27.65, Ru 10.51, F 11.86; found: Cs 27.78, Ru 10.57, F 11.97.

Electronic spectra (mull and diffuse reflectance) with λ_{max} in cm^{-1}, $K_2[Ru(SO_3F)_6]$: 22 200 cm^{-1}, $Cs_2[Ru(SO_3F)_6]$: 20 400 cm^{-1}.

(e) $Cs[Ru(SO_3F)_5]$

In a typical reaction, an approximately equimolar mixture of ruthenium powder, 0.232 g (2.296 mmol) and 0.534 g (2.302 mmol) of $CsSO_3F$ were allowed to react with ~10 mL of a 1:1 mixture (by volume) of HSO_3F and $S_2O_6F_2$ at about 60°C overnight. Removal of all impurities resulted in the formation of a slightly inhomogeneous looking mixture of a red–brown solid with dark brown impurities. An additional 3 mL of $S_2O_6F_2$ afforded 1.686 g (2.312 mmol) of a homogeneous looking red–brown powder that analysed as $Cs[Ru(SO_3F)_5]$. *Anal.* calcd.: Cs 18.22, Ru 13.86, S 21.98, F 13.03; found: Cs 18.38, Ru 13.68, S 22.12, F 13.17.

Results and discussion

Synthesis

Ruthenium is found to be moderately reactive in the oxidation reactions described above. Generally a reaction temperature of 60°C and reaction times of 24 h are sufficient for a complete conversion. If the metal alone is reacted, analytically pure $Ru(SO_3F)_3$ results, even though oxidation to the 4+ state is possible under very similar condition and illustrated by the isolation of $Cs_2[Ru(SO_3F)_6]$ and $Cs[Ru(SO_3F)_5]$. It may be argued that any $Ru(SO_3F)_4$ initially formed does subsequently decompose reversibly when the temperature is raised to 60°C, to allow complete removal of HSO_3F *in vacuo*. A number of unsuccessful attempts were made to achieve further oxidations of ruthenium: reaction of $Ru(SO_3F)_3$ with a large excess of $S_2O_6F_2$, was attempted initially at 60°C and later at 90°C. After 24 h the weight remains unchanged. Ruthenium metal, when reacted with bromine(I) fluorosulfate, $BrSO_3F$ at 85°C gives a red, viscous liquid. Complete reactant removal *in vacuo* requires a temperature of 100°C, before a dry product results. This product appears to be rather impure $Ru(SO_3F)_3$. Attempts to obtain either $Ru(SO_3F)_4$ or possibly an oxyfluorosulfate of ruthenium by the reaction of RuO_2 with either $S_2O_6F_2$, a $S_2O_6F_2/HSO_3F$ mixture or $BrSO_3F$ at elevated temperature result in only very minimal weight increases after reaction times of several days. It seems the noted lack of reactivity makes RuO_2 unsuitable as a starting material in oxidation reactions.

Complex formation of $Ru(SO_3F)_3$ is easily accomplished. Chloronium fluorosulfate, ClO_2SO_3F, is a viscous, very slightly volatile liquid (8), which offers some advantages in preliminary complexation reactions. No solvent is needed, the ClO_2^+ cation is well established (11) and many ClO_2^+ salts of noble metal fluorosulfates have been obtained by us (1, 3*a*, 4, 5). Furthermore, any excess of ClO_2SO_3F can be removed *in vacuo*. In our example the composition $ClO_2[Ru(SO_3F)_4]$ is confirmed by chemical analysis. Initial formation of $(ClO_2)_3[Ru(SO_3F)_6]$ can not be ruled out since temperatures of ~100°C are required before a dry material is obtained.

The corresponding salt $Cs[Ru(SO_3F)_4]$ forms again easily according to:

$$[3]\quad CsSO_3F + Ru(SO_3F)_3 \xrightarrow{HSO_3F} Cs[Ru(SO_3F)_4]$$

When a 3:1 molar ratio of $CsSO_3F$ and $Ru(SO_3F)_3$ is used instead, an inhomogeneous product results and the infrared spectrum reveals a mixture of $CsSO_3F$ (11) and $Cs[Ru(SO_3F)_4]$. While precedents like the ions $[RuCl_6]^{3-}$ (12) are found in solid complexes as well as in solutions, isolation attempts of analogous $[Ru(SO_3F)_6]^{3-}$ containing salts starting with $Ru(SO_3F)_3$ appear to be unsuccessful due to preferential $[Ru(SO_3F)_4]^-$ salt formation.

Where synthetic reactions, aimed at complex formation, involve ruthenium powder as starting material the metal oxidation leads to Ru(IV) complexes instead. The ease with which this oxidation occurs lends credence to the view, that the previously noted isolation of $Ru(SO_3F)_3$ may be due to the isolation method rather than to the limitations of the oxidizing agent. A close parallel is found in reactions of palladium (1). While all attempts to isolate $Pd(SO_3F)_4$ have failed and $Pd(SO_3F)_3$, formulated as $Pd^{(II)}Pd^{(IV)}(SO_3F)_6$, forms instead, salts like $K_2[Pd(SO_3F)_6]$ are very easily obtained (1).

The synthetic route to $Cs[Ru(SO_3F)_5]$, the first example of a pentakis(fluorosulfato)metallate (the tin (13) and platinum (5) analogues have been obtained since), is found by accident. A 1:1 molar ratio of $CsSO_3F$ and ruthenium was employed in an attempt to oxidize ruthenium to the 5+ oxidation state according to:

$$[4]\quad 2CsSO_3F + 2Ru + 5S_2O_6F_2 \xrightarrow{HSO_3F} 2Cs[Ru(SO_3F)_6]$$

however, $Cs[Ru(SO_3F)_5]$ forms instead. The solid is heated at 100°C in the presence of a large excess of $S_2O_6F_2$ for several days, however, no weight increase is noted and further oxidation of ruthenium does not seem to be possible under the

conditions stated. Our previously discussed failure to obtain $Ru(SO_3F)_4$ precludes the possibility of viewing $Cs[Ru(SO_3F)_5]$ as an equimolar mixture of $Cs_2[Ru(SO_3F)_6]$ and $Ru(SO_3F)_4$. It seems common to compounds of the general type $M'[M(SO_3F)_5]$ where M' = K or Cs and M = Ru, Pt, or Sn, that acid salts of the type $M'H[M(SO_3F)_6]$ are thermally not sufficiently stable to allow isolation.

Participation of HSO_3F in the formation of anionic fluorosulfato complexes is generally a definite possibility since the preparations are undertaken in HSO_3F as reaction medium. However, neither here nor in any previous study on similar complexes (refs. 1 to 5, 13) has there been any evidence for their presence as stable species. Microanalysis with a detection limit well below 0.1% and the absence of OH stretching vibrations, recognizing that H-bridge bonding may well cause shifts down to 2500 to 2000 cm^{-1}, are taken as criteria to probe into their presence. The absence of HSO_3F allows us to deduce the oxidation state of ruthenium from the chemical analysis data with additional support coming from magnetic susceptibility data (see below).

Vibrational spectra

The rather intense color of the ruthenium(III) compounds studied by us here prevents the use of Raman spectroscopy. This limits the use of vibrational spectroscopy severely, since the infrared bands are broad and only poorly resolved. This is particularly true for the spectra obtained for $Cs[Ru(SO_3F)_4]$ and $(ClO_2)[Ru(SO_3F)_4]$ listed in the experimental section. Only cautious comments in regard to these two compounds may be made. The three fundamentals attributed to ClO_2^+ are easily recognized and assigned by comparison (14). The remaining bands of $(ClO_2)[Ru(SO_3F)_4]$ agree well with those of $Cs[Ru(SO_3F)_4]$ in band position and intensity. The band positions in the SO_3 stretching region are not consistent with the sole presence of monodentate —OSO_2F or bidentate SO_3F groups. A tetrahedrally coordinated, mononuclear anion is also inconsistent with the magnetic data (*vide infra*), as is a regular octahedral environment. The broadness of many vibrational bands precludes any meaningful interpretation.

The infrared spectra obtained for $Ru(SO_3F)_3$ are of better quality. The data are listed in Table 1 and compared to published ir data of $Fe(SO_3F)_3$ (14) and $Sn(SO_3F)_4$ (15). For the latter compound infrared, Raman, and ^{119}Sn Mössbauer data are most consistent with a polymeric structure, with hexacoordination for tin and the presence of mono- and bidentate bridging SO_3F groups (15). Vibrational data and magnetic moments suggest a regular octahedral environment for Fe^{3+}, a $^6A_{1g}$ ground state for iron and hence bidentate bridging fluorosulfate groups, for $Fe(SO_3F)_3$ (14). For $Ru(SO_3F)_3$ the vibrational band pattern show a better agreement with those of $Sn(SO_3F)_4$ rather than with $Fe(SO_3F)_3$. The assignment presented in Table 1 is rather tentative without Raman data.

The value of Raman data becomes evident, when turning to a discussion of ruthenium(IV) fluorosulfato complexes. For $K_2[Ru(SO_3F)_6]$ and its cesium analogue, well-resolved Raman spectra are obtained, while the ir bands are again rather broad and poorly resolved, particularly in the stretching frequency range. The poor quality of the infrared spectra is due to the high reactivity of the complexes, which prohibits the use of mulling agents. The darker color of $Cs[Ru(SO_3F)_5]$ affects the quality of the Raman spectrum adversely, and only a limited number of bands in the stretching frequency range are observed. However, here a combination of ir and Raman data allows some structural conclusions. The vibrational frequencies for all three complexes are listed in Table 2 together with estimated intensities and a tentative assignment. The Raman spectrum of

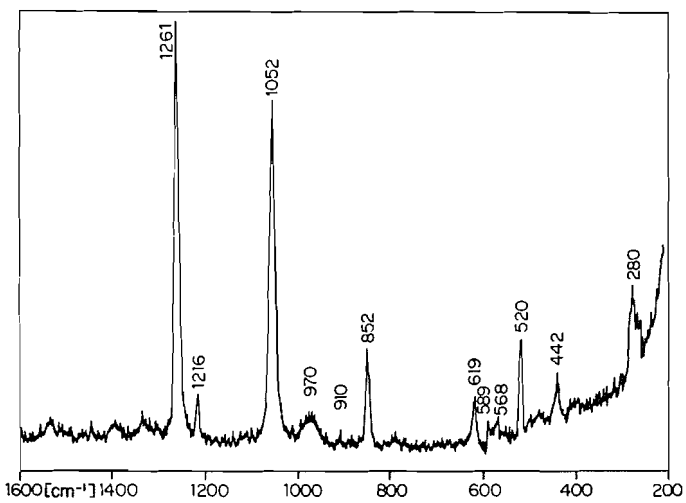

FIG. 1. The Raman spectrum of $K_2[Ru(SO_3F)_6]$.

$K_2[Ru(SO_3F)_6]$ is shown in Fig. 1.

The observed band pattern found for the two $[Ru(SO_3F)_6]^{2-}$ complexes with SO_3 stretching vibrations at ~1400, 1210, and 1050 to 970 cm^{-1} is characteristic for monodentate —OSO_2F groups in anionic complexes with vibrational interaction causing band proliferation. Very similar spectra have previously been obtained by us on other complexes containing the $[M(SO_3F)_6]^{2-}$ ion with M = Sn (16), Ge (13), Pd (1), Pt (1, 2, 5), and Ir (4), and identification by spectral comparison is readily accomplished. Bands at ~640, ~440, and 280 cm^{-1} are characteristic for hexakis(fluorosulfato)metallate(IV) complexes, and are seen to be, at least in part, due to M—O skeletal vibrations, mixed with —OSO_2F deformation modes. Not unexpectedly, these bands do show some dependency on the type of central atom present in the complex.

The more complex situation for $Cs[Ru(SO_3F)_5]$, which results in a greater number of bands, is best seen in the infrared spectrum. Two additional bands, not found for the two hexakis(fluorosulfato)ruthenate(IV) complexes, at 1140 and 1045 cm^{-1}, are indicative of SO_3 stretches in bidentate, possibly bridging fluorosulfate groups in anionic complexes. Bands in a very similar position are found for $Cs[Pt(SO_3F)_5]$ (6) as well as for $Cs[Sn(SO_3F)_5]$ (13) and a common structure involving an oligomeric, polynuclear anion is suggested. Additional evidence had come from the ^{119}Sn spectrum for $Cs[Sn(SO_3F)_5]$ (13). In our case, the electronic mull spectrum has two broad bands at 22 200 and 28 600 cm^{-1} rather than only one for $Cs_2[Ru(SO_3F)_6]$, suggesting a lower symmetry. The magnetic data, to be discussed below, suggest for $Cs[Ru(SO_3F)_5]$ weak antiferromagnetic interaction which is again consistent with the presence of a polynuclear anion.

Magnetic properties

In salts of the type $M_2[Ru(SO_3F)_6]$ with M = K or Cs and in $Cs[Ru(SO_3F)_5]$ a d^4 electron configuration is encountered. With spin pairing, a $^3T_{1g}$ ground term is anticipated in an octahedral ligand environment. As many precedents indicate (10), the magnetic moments should decrease with decreasing temperature from ~3.0 μ_B at room temperature to ~1.7 μ_B at 80 K. For example, K_2RuF_6 shows a magnetic moment of 2.86 μ_B at 300 K (16) with similar values found for other hexahalogeno complexes.

The hexakis(fluorosulfato)ruthenate(IV) complexes show a similar trend, as seen in Table 3. The gradual decrease is consistent with an octahedral environment, and differences in the magnitude may be due to a different packing mode in the crystal lattices of the two salts. Similar differences are encoun-

tered for hexahalogeno complexes of Ru(III) (10, 16). In any event the data suggest magnetically dilute complexes in both cases.

Noticeably lower magnetic moments are found for $Cs[Ru(SO_3F)_5]$ where the values range from 2.49 to 1.87 μ_B. It is likely that slight anti-ferromagnetic coupling is brought about by either bridging SO_3F groups in a superexchange process or weak direct metal–metal interaction. The data shown in Table 3 are consistent with the presence of a polynuclear complex anion, as suggested by the ir data.

A more complicated situation is found for the two ruthenium(III) compounds, where magnetic studies were undertaken, $Ru(SO_3F)_3$ and $Cs[Ru(SO_3F)_4]$. For Ru^{3+} a d^5 electron configuration is present and with spin pairing in an octahedral complex a $^2T_{2g}$ ground state should give rise to magnetic moments of about 2 μ_B at room temperature. Indeed all reported magnetic moments fall into this range with very few exceptions (10). The magnetic moments obtained for $Ru(SO_3F)_3$ shown in Table 4 are all below 1 μ_B. Furthermore, entirely inconsistent with the expected $^2T_{2g}$ ground state, the data follow the Curie–Weiss law with $C = 0.1291 \pm 0.0036$ and a Weiss constant $\theta = -43.4 \pm 6.7$ K. The resulting magnetic moments $\mu_{eff}^{C.W.}$ are 1.02 ± 0.02 μ_B invariant of temperature. However, this applied correction must be viewed with some caution because θ is fairly large here.

Electron paramagnetic resonance data obtained are tabulated in Table 5 and found to be consistent with the magnetic results. The variation in g_0 values between 295 and 80 K appears to be slight. The lack of fine structure, neither ^{99}Ru or ^{101}Ru hyperfine coupling, nor any resolution into parallel or perpendicular compounds of the g-tensor, suggests a low symmetry site for the paramagnetic species. A frozen solution of $Ru(SO_3F)_3$ in HSO_3F gives at 80 K an anisotropic spectrum with three distinct principle g-values; however, the solution process may have caused some structural changes.

While both a single, magnetically dilute environment for Ru^{3+} and a regular octahedral site for the cation are ruled out, three other structural proposals may also be dismissed: a mixed valency compound $Ru^{II}Ru^{IV}(SO_3F)_6$, reminiscent of the $Pd^{II}Pd^{IV}(SO_3F)_6$ structure (1, 17), with diamagnetic Ru^{II} and magnetically dilute Ru^{IV}, would have substantially higher magnetic susceptibilities and would not show Curie–Weiss law behavior. Likewise a binuclear structure, similar to the structure of $Ru_2(O_2CCH_3)_4Cl$ (18), with a $Ru_2(SO_3F)_4$ core and two terminally bonded —OSO_2F groups would either be more strongly paramagnetic, assuming a triplet ground state, or show

$Ru(SO_3F)_3$ powder	80	$g_0 = 1.777$
$Ru(SO_3F)_3$ in HSO_3F	80	$g_1 = 1.515 = g_\parallel$
		$g_2 = 1.831$
		$g_3 = 1.956$
		($g_0 = 1.777$)

a more pronounced temperature dependence of χ_M^{corr}, if a singlet–triplet equilibrium is encountered. For the very same reason, the lack of temperature dependence rules out a possible phase equilibrium between a diamagnetic and a paramagnetic form.

The existence of two, or perhaps even more structurally different phases for $Ru(SO_3F)_3$ remains a distinct possibility and ruthenium(III) chloride, $RuCl_3$, provides an example for such polymorphism. Depending on the method of preparation two structurally different forms are obtained (12). A black α-form has Ru^{3+} in a significantly distorted octahedron (19) resulting in paramagnetism with Curie–Weiss law behavior between 300 and 80 K (10) and a more complicated magnetic behavior at lower temperatures (19). The dark brown β-form is antiferromagnetic below 600 K on account of rather short Ru—Ru bonds (2.83 Å) (19); however, the presence of α-$RuCl_3$ as contaminant has obscurred the situation somewhat.

The $\beta-\alpha$ transition occurs at 450°C and is irreversible (20).

In summary the color, the magnetic behavior, the existence of mixed phases and the rather high transition temperature of $RuCl_3$ provide intriguing points of comparison and the previously mentioned unusual complexity in the vibrational spectrum of $Ru(SO_3F)_3$ is not inconsistent with the presence of a similar mixture. Furthermore, it is noteworthy that two different forms for $Os(SO_3F)_3$ have been detected and identified by differences in color and vibrational band positions (21).

Whether we are dealing with a mixture of two contrasting forms or an unusually complicated structure with both magnetically dilute paramagnetic and antiferromagnetic components remains an unanswered question. Interestingly magnetic measurement over the temperature range from 300 to 80 K on different preparations of $Ru(SO_3F)_3$ were virtually identical over the whole temperature range in spite of slight variations in the preparative procedure. This reproducibility might suggest a well defined albeit complicated structure. The experimental value of χ_M^{corr} at 298 K allows an approximate estimate of "paramagnetic Ru^{3+}" in the compound. Assuming the antiferromagnetic compound to be essentially diamagnetic at this temperature and a "normal" average μ_{eff} value of 2.0 to 2.1 μ_B would imply χ_M^{corr} between 1680 to 1850 $\times$ 10^{-6} cm^3 mol^{-1}, with approximately only 21 to 23% of Ru^{3+} in a magnetically dilute environment. This admittedly rough estimate does not readily suggest a simple, well-defined structure and further discussions do not appear to be warranted in the absence of a detailed structure.

For $Cs[Ru(SO_3F)_4]$ the situation appears to be even more complicated. The magnetic moments, measured between 300 and 77 K decrease from 0.54 to 0.31 μ_B. The χ_M^{corr} value at 300 K suggests magnetically dilute Ru^{3+} concentration of about 7%. The Curie–Weiss law does not appear to be followed. An epr signal at room temperature is barely detectable. At 80 K two overlapping lines with g_0 values of 1.979 and 1.846, respectively, suggest two slightly different sites for the paramagnetic centers. Again the bulk of the substance appears to be antiferromagnetic or diamagnetic, and it is significant that complexation of $Ru(SO_3F)_3$ with $CsSO_3F$ in HSO_3F solution has resulted in such a significant reduction in paramagnetic ruthenium(III).

One alternative interpretation still remaining is that ruthenium(IV), present as an impurity, may be the cause of the observed paramagnetism. However, the previously discussed reduction in χ_M^{corr} on complexation of $Ru(SO_3F)_3$, the Curie–Weiss law behavior found for this compound and the epr spectra, which are reportedly very rarely observable for d^4 ion, in particular for Ru^{4+} (22) and which compare well to previous reports for Ru^{3+} complexes (22), all argue strongly against the presence of significant amounts of ruthenium(IV), which would also affect the overall composition and the chemical analysis.

It appears then that $Ru(SO_3F)_3$ and $Ru(SO_3F)_4^-$ complexes are readily and cleanly obtainable, the occurrence of polymorphism appears to affect the vibrational spectra and even more noticeably the magnetic behavior, with ruthenium(III) chloride providing a reasonable precedent. Further oxidation to the 4+ state, only possible in the presence of SO_3F^- ions, results in more regular systems.

Solute–solute–solvent interactions in aqueous solutions of triethanolamine and dimethylsulfoxide. Microcalorimetric study

GIANNA BORGHESANI AND FERNANDO PULIDORI

Department of Chemistry, University of Ferrara, Via L. Borsari 46, 44100 Ferrara, Italy

Received October 19, 1983[1]

GIANNA BORGHESANI and FERNANDO PULIDORI. Can. J. Chem. **62**, 2898 (1984).

The heats of dilution of aqueous solutions of triethanolamine (TELA) and dimethylsulfoxide (DMSO) were determined up to ~3 mol kg^{-1}, at 25°C.

The various enthalpic pair and triplet interaction coefficients, h_{xx}, h_{xxx}, have been evaluated from the data.

The h_{xx} for both TELA and DMSO are positive and indicate a prevailing hydrophobic character of TELA and DMSO interactions in highly dilute aqueous solutions.

The triplet coefficients are small and negative for both compounds. Dipolar interactions and normal solvation through H-bonding seem to be more important than the size or the solvophobic effect in determining the triplet enthalpic coefficients.

GIANNA BORGHESANI et FERNANDO PULIDORI. Can. J. Chem. **62**, 2898 (1984).

Opérant à 25°C et à des concentrations allant jusqu'à environ 3 mol/kg, on a déterminé les chaleurs de dilution de solutions aqueuses de triéthanolamine (TELA) et de diméthylsulfoxyde (DMSO).

Utilisant ces données, on a évalué les divers coefficients, h_{xx} et h_{xxx}, d'interaction enthalpique.

Les valeurs de h_{xx} tant pour la TELA que pour le DMSO sont positives; ces résultats indiquent que, en solutions aqueuses très diluées, les interactions de la TELA et du DMSO ont un caractère prédominant qui est hydrophobe.

Pour chacun des composés, les coefficients triplets sont petits et négatifs. Les interactions dipolaires et la solvatation normale par le biais de liaisons hydrogènes semblent donc des facteurs plus importants que la taille ou l'effet solvophobe dans la détermination des coefficients enthalpiques triplets.

Triethanolamine (TELA) and dimethylsulfoxide (DMSO) belong to different classes of polar organic compounds which are miscible with water in any proportion. Whereas TELA, often defined as a highly hydrophilic substance, is polyfunctional in its interactions with water, DMSO is controversially defined (1, 2) and is only capable of acting as an H-acceptor in H-bonding with water.

The physicochemical properties, thermochemical ones in particular, of TELA and related compounds in aqueous solutions have not been extensively studied (3–7).

On the contrary, extensive studies have been performed on the thermochemical properties (1, 8–13) as well as other thermodynamic properties (14, 15) of DMSO-H_2O mixtures. Some of the works quoted, together with spectroscopic evidence of various nature (6, 8, 12, 16–19), underline the formation of H-bonded DMSO–H_2O complexes. Cautious and more in depth analysis (11, 19) points out the possibility of different kinds of interactions between DMSO and water in different concentration regions.

However, although some peculiarities of the above mentioned systems can be deduced from the analysis of the physicochemical properties over the whole composition range, the relationships between these properties, excess ones in particular, and composition are rather complicated, especially for sufficiently high organic concentrations. Thus from these relationships it is difficult to draw detailed information as to the nature and entity of solute–solute and solute–solvent pair and multiplet interactions.

This information is more easily obtained from direct measurements of excess thermodynamic properties of the system in the water-rich region, by considering the organic component as the solute.

Since, to our knowledge, no systematic work on this point has been done for either TELA or DMSO and since these substances are important in different biological and chemical application, the present work is devoted to the determination of the enthalpic properties of TELA and DMSO dilute aqueous solutions.

Particular attention is paid to the role hydrophobicity plays in defining the interactions of these "hydrophilic" compounds.

Experimental

Reagents and instrumentation

Pure TELA from Fluka Chemicals was further purified by fractional distillation under reduced pressure in a N_2 atmosphere. The fraction used had the following characteristics: bp (15 mm Hg) = 206°C; mp = 21.2°C; n_D^{25} = 1.4835; d^{25} = 1.1281 g mL^{-1}. Pure DMSO is hard to obtain, unless due care is taken (20). The pure reagent from Carlo Erba Chemicals was accordingly refluxed over CaH_2 in a N_2 atmosphere under reduced pressure, then fractionally distilled. The fraction boiling at 40–41°C (2–3 mm Hg) was collected and kept frozen in the dark until use. All solutions were prepared by weight with deionized and tridistilled water.

The integral heats of dilution were measured employing an LKB model 2701 flow microcalorimeter equipped with a pair of peristaltic pumps LKB-10200, each working at a preset flow rate. The flow rate of each pump was controlled after each dilution experiment by weighing the liquids pumped through the calorimeter over a defined time interval. The reproducibility of the heats of dilution was of about ±1%, i.e., consistent with this kind of measurement (21).

The flow calorimeter standardization was performed by titrating a 0.01 *N* HCl aqueous solution with NaOH and by comparing the water ionization enthalpy thus obtained with reference literature data (ΔH = 55.7 vs. 55.9 kJ mol^{-1} (22)). The agreement was always better than ±0.5%. The reliability of the calorimeter was also checked by measuring the dilution heats of urea (23) and sucrose (24) aqueous solutions for which good reference data are available and by calculating the related enthalpic pair coefficients, h_{xx}, of the excess enthalpy. The data obtained ($h_{xx,\,urea}$ = −345 ± 10 J mol^{-2} kg; $h_{xx,\,sucrose}$ = +580 ± 16 J mol^{-2} kg) were in good agreement with the values reported in the literature ($h_{xx,\,urea}$ = −350 ± 11 J mol^{-2} kg; $h_{xx,\,sucrose}$ = +577 J mol^{-2} kg (25, 26)).

All measurements were performed at 25 ± 0.02°C.

[1]Revision received March 16, 1984.

Results and discussion

The integral heats of dilution $\Delta H(m_i \rightarrow m_f)$ from the initial m_i to the final molality m_f are obtained by using the equation:

$$[1] \quad \Delta H(m_i \rightarrow m_f) = -(dQ/dt)/P_1$$

where dQ/dt is the stationary thermal flux and P_1 is the total mass flow rate of the solvent. The heats of dilution are expressed in J kg^{-1} of water in the final solution. The enthalpy change per kg of solvent, associated with the integral dilution process,also represents the corresponding excess enthalpy variation, ΔH^E.

The McMillan–Mayer theory of aqueous solutions (27) has long been considered particularly attractive and useful (28) in giving direct information on the interaction between solute molecules.

Accordingly, the excess enthalpy, H^E, of a solution containing 1 kg of solvent may be written as

$$[2] \quad H^E = h_{xx}m^2 + h_{xxx}m^3 + \ldots\ldots$$

where h_{xx}, h_{xxx}, ... are the pairwise, triplet, ... enthalpic interaction coefficients between solute molecules.

When working in suitably diluted solutions, the coefficients of eq. [2] can be obtained from the heats of dilution (21, 29) which can be fitted according to the following equation:

$$[3] \quad \frac{\Delta H(m_i \rightarrow m_f)}{m_f(m_f - m_i)} = h_{xx} + h_{xxx}(m_f + m_i)$$

The results of dilution experiments obtained with TELA and DMSO are collected in Tables 1 and 2, respectively.

Keeping in mind the suggestions of Monk and Wadsö (30) and in particular with the more viscous TELA solutions, separate runs were carried out by varying both the dilution ratios and the total flow rate between 40 and 4 mL h^{-1}. The results in terms of pair and triplet coefficients proved to be independent of the flow rate, thus demonstrating the completeness of the mixing process.

The h_{xx} and h_{xxx} values and their 95% confidence limits are reported in Table 3 together with those of some other aliphatic compounds for the sake of comparison and discussion.

As is well known, the theoretical expression of h_{xx} is

$$[4] \quad h_{xx} = \frac{1}{2}\int_0^\infty \frac{\partial(W(r)/kT)}{\partial(1/kT)}\, g(r)4\pi r^2 \cdot dr$$

where $W(r)$ is the potential of mean force and $g(r)$ the radial distribution function.

Since it is quite difficult to reproduce the experimental data through an adequate model representation of $W(r)$ and to attribute a reliable value to $g(r)$, it is worthwhile assigning a semiquantitative meaning to the h_{xx} coefficients in order to reasonably rationalize and foresee the behaviour of classes of solutes. This may be tried through the Savage and Wood additivity rule (26), which states that each functional group on molecule A interacts with every functional group on molecule B, independent of the mutual position of the interacting groups.

This is summarized by the equation:

$$[5] \quad h_{AB} = \sum_{i,j} n_i^A \cdot n_j^B \cdot H_{i,j}$$

where n_i^A, n_j^B are the number of i-type groups in the molecule A and of j-type groups in the molecule B respectively; $h_{i,j}$ is the characteristic contribution to the enthalpic coefficient from the i,j-th interaction. When A = B, $h_{AB} = h_{xx}$.

The limits of eq. [5] have been repeatedly discussed (29, 31–35). The group additivity principle seems to work correctly within classes of compounds which are of related structure. Instead its predictive ability appears strongly reduced or

fails when steric, inductive, or specific orientation-dependent solvation effects cannot be neglected.

The problem of the general applicability of $H_{i,j}$ values has been discussed particularly in connection with the contribution of polar groups in polyols and sugars (29, 31, 35). The peculiar behaviour of these classes of compounds has been explained in terms of their different conformational effects on the solute–water interactions (36, 37). In this context, the amount of useful h_{xx} data available on molecules containing —N< or SO groups are at present too limited (38, 39) to make an acceptably precise estimate of the corresponding $H_{i,j}$ contributions by means of eq. [5].

Nevertheless, h_{xx} of TELA, calculated as a first approximation by neglecting the group contributions bound to —N< and by using tabulated data for the interaction $CH_2 \ldots CH_2$, $OH \ldots OH$, $CH_2 \ldots OH$ (29, 35) and $CHOH \ldots CHOH$, $CH_2 \ldots CHOH$ (33, 34), varies between 1665 and 1899 J kg mol^{-2}. The low energy barrier of the nitrogen pyramidal inversion as well as the low TELA basicity ($pK_a^{25} = 7.76$ (40)), due both to inductive and steric factors (41), could justify some masking of the aminic nitrogen. However, only the sign and the order of magnitude of the calculated coefficient appear reasonable.

Neither value is in accordance with the experimental one (Table 3).

It may be noted that the calculated pair coefficient proved to be practically independent of the choice of characteristic polar groups. It seems rather to depend on the homogeneous (29, 33, 35) or non-homogeneous (34) character of the set of solutes from which the $H_{i,j}$ contributions were derived.

A further approach was tried by considering that h_{xx} is not only the resultant of hydrophobic and hydrophilic interactions but it also depends on the size of the solute itself. It was, therefore, assumed that it may be reasonable to consider one $N(CH_2CH_2OH)_3$ molecule equivalent in size and interaction to three (NCH_2CH_2OH) groups, even by analogy with the reported equivalence $NH_3 = 3NH$ (38). In this way, the enthalpic pair contribution associated with the moiety NCH_2CH_2OH, drawn from the expermental h_{xx} of TELA (Table 3) amounts to 384 J kg mol^{-2}.

This value is comparable to that reported for ethane-1,2-diol (Table 3) a molecule of size and hydrophilic/hydrophobic group ratio like those of the moiety considered. This allows one to assume that the various group contributions bound to tertiary nitrogen cannot be neglected. These should be not too different from those bound to OH groups.

Qualitatively, the h_{xx} value and sign point to a prevailing hydrophobic character of TELA interactions in highly dilute aqueous solutions. This agrees with the hydrophobic character

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

of dilute solutions of 2-aminoethanol, which steadily increases with the introduction of methyl groups into the molecule, as shown by the trend of partial molar volumes and enthalpies of these compounds (7).

Again in the case of DMSO, the group contribution principle cannot be correctly applied to calculate h_{xx}, due to the lack of experimental data. An evaluation of its reliability was made, as for TELA, by considering the h_{xx} value of a molecule of comparable size and hydrophilic/hydrophobic group ratio as, for example, acetone and with the aid of other h_{xx} experimental data, reported in Table 3.

When going from urea to acetone, the enthalpic pair coefficients of Table 3 vary from a very negative to a high positive value. Urea, a known "water structure breaker" participates in H-bond formation by interacting with the solvent and with itself in many ways. Acetone, a typical "hydrophobic solute" (32, 42), only acts as a weak acceptor for water hydrogens in H-bond formation. DMSO has a less pronounced hydrophobic character than acetone owing to the stronger $SO \ldots H_2O$ interactions, as indicated by ir and nmr measurements (8).

Furthermore, the data collected in Table 3 show that h_{xx} shifts towards more positive values when the hydrocarbon part of the molecule is increased. When identical hydrocarbon groups are present in different molecules, a decrease in the hydrophobic character is to be expected with an increase in the polar group hydrophilicity, as observed for DMSO in respect to acetone ($h_{xx,\mathrm{DMSO}} < h_{xx,\mathrm{acetone}}$, Table 3). The same trend is observed as the number of polar groups in the same aliphatic skeleton increases (e.g., butane-1-ol/butane-1,4-diol; propane-1-ol/glycerol, Table 3).

Regarding the triplet interaction coefficients of TELA and DMSO, h_{xxx}, the greater complexity of the related interactions is all the more reason why their evaluation is hardly possible by means of the additivity rule. From Table 3 it can be seen that, except in a few cases, the triplet interactions exert a negligible influence on the properties of the solutes, particularly for small and very soluble molecules at high dilutions. Triplet terms are generally one order of magnitude lower than the corresponding pair terms and can bear either positive or negative signs. Only when large hydrocarbon groups are present in a molecule may the triplet interaction coefficient become positive and higher than normal (e.g., alkylated ureas and alkanols, Table 3). This behaviour was ascribed to some cooperativity in the interactions of hydrocarbon groups and was defined as peculiar of the hydrophobic interaction (43).

Instead, for a great variety of molecules and, in particular, for simple highly polar solutes and most sugars, polyols and related compounds (32, 44), h_{xxx} coefficients are very small and often negative. It has been claimed (32, 44) that the scattering of dilution heats at high dilutions makes the triplet coefficients ambiguous or meaningless in these cases. However, the accuracy of TELA and DMSO experimental data is good enough for the following remarks. The negative sign of h_{xxx} observed for both TELA and DMSO (Table 3) should mean that dipolar interactions and normal solvation through H-bonding are more important than size or solvophobic effect in determining the triplet enthalpic coefficients. Therefore, what observed ($h_{xxx,\mathrm{DMSO}} < h_{xxx,\mathrm{acetone}}$) seems to be reasonable in view of the higher DMSO dipole moment ($\mu_{\mathrm{DMSO}} = 3.96$ D; μ_{acetone} 2.88 D).

Also the h_{xxx} coefficient found for TELA, nearly equal to $3h_{xxx}$ of ethane-1,2-diol (Table 3), may be qualitatively justified in terms of the greater polarity of TELA and the increased number of hydrophilic sites as well. This parallels the trend also observed for h_{xx} and h_{xxx} coefficients of more complex solutes, such as disaccharides, which are nearly equivalent to the sum of the corresponding coefficients of the monose subunits (44).

In conclusion, sign and entity of the enthalpic interaction coefficients of both TELA and DMSO point to the existence and prevalence of hydrophobic interactions in very dilute aqueous solutions. The measurement of other thermodynamic quantities as free energy and volumes (to be published) shows that the disturbances produced in water at high dilutions are limited, particularly for DMSO. With increasing concentration, other kinds of interactions, particularly H-bonding, will increasingly prevail, thus giving these compounds the typical "aqueous" or "hydrophilic" character.

Comments on the structure of alkylammonium hexachlorostannates

M. H. BEN GHOZLEN AND Y. MLIK

École Nationale D'ingenieurs SFAX, Ministère de l'Enseignement supérieur et de la recherche scientifique, Route de Soukra 3038 SFAX, Tunisia

Received January 22, 1984

M. H. BEN GHOZLEN and Y. MLIK. Can. J. Chem. **62**, 2903 (1984).

Both dimethyl and trimethylammonium hexachlorostannates crystallise in space groups which are subgroups of the antifluorite structure ($Fm3m$, $Z = 1$). These two symmetry changes are described on the basis of Landau theory for continuous phase transitions. The involved irreducible representation is E_g at the X high symmetry point of the cubic face centred Brillouin zone.

M. H. BEN GHOZLEN et Y. MLIK. Can. J. Chem. **62**, 2903 (1984).

Les hexachlorostannates de diméthyl- et de triméthylammonium cristallisent tous les deux dans des groupes d'espace qui sont des sous-groupes de la structure de l'antifluorine ($Fm3m$, $Z = 1$). On décrit ces deux changements de transition en faisant appel à la théorie de Landau pour des transitions de phase continues. La représentation irréductible impliquée est E_g au point de plus haute symétrie de X de la zone de Brillouin du cube à face centrée.

[Traduit par le journal]

Knop *et al.* (1) have recently reported an important experimental study on the alkylammonium hexachlorostannates (crystal structures and infrared spectroscopy). The solved cristalline structures at room temperature are compared to the antifluorite parent structure. Likewise, the authors try to relate all the obtained space groups to $Fm3m$ ($Z = 1$). In Table 15, they state that di- (2MHS) and trimethylammonium hexachlorostannate (3MHS) space group are not subgroups of $Fm3m$.

In fact, the analysis of the structures of these two compounds, which had been solved previously (2, 3), on the basis of a recent work on the $Fm3m$ subgroups (4) reveals that the symmetry changes from $Fm3m$ ($Z = 1$) to $Pnnm$ ($Z = 2$) and to $Pa3$ ($Z = 4$), the structures of 2MHS and 3MHS, respectively, are realized at the high symmetry point X of the cubic face centred Brillouin zone. The associated order parameters of these symmetry changes are, respectively (q, q, 0, 0, 0, 0) and (0, q, 0, q, 0, q); they transform as the irreducible representation E_g at the X point of $Fm3m$ (4).

For $Pnnm$ space group only one arm of the star is involved in the symmetry change (5). The corresponding order parameter is left invariant by the following $Fm3m$ symmetry operations (in the notation of Bradley and Cracknell (5)):

$$(C_{2c}|0),\ (C_{2y}|t_1),\ (C_{2e}|t_1),\ \text{and}\ (I|0)$$

The new Bravais battice can be described by

$$A = \frac{t_1 - t_2 + t_3}{2}$$

$$B = \frac{t_1 - t_3}{2}$$

$$C = t_2$$

The obtained primitive cell being pseudo-quadratic, agrees very well with the experimental values (7.220 (1) Å; 7.340 (2) Å; 14.446 (3) Å) of the crystal parameters.

For the distorted cubic structure of 3MHS all the arms of the star are involved in the symmetry change. The generator symmetry operations which lead to $Pa3$ space group are (again in the notation of Bradley and Cracknell):

$$(C_{2x}|t_3),\ (C_{2z}|t_2),\ (I|0),\ (C_{31}^{+}|0)$$

The translational part of the induced irreducible representation lead to the following cubic primitive cell:

$$A = -t_1 + t_2 - t_3$$

$$B = t_1 - t_2 + t_3$$

$$C = t_1 + t_2 - t_3$$

On the other hand, a study of the external vibrations for the two compounds shows that these symmetry changes are obtained from $Fm3m$ structure by slight distorsions which can be described as translations of the organic groups and rotations of the $SnCl_6^{2-}$ octahedra (6).

The polarographic reduction data of 4-arylazo-1-ethylmercapto-3-(4*H*)isoquinolone derivatives in 50% by volume ethanolic aqueous buffered media are reported and discussed. These compounds exist in several tautomeric forms so their structures have been investigated using ir and polarographic analyses. The data obtained indicated that these compounds in aqueous media and in solid state exist predominantly in the azo form. A mechanism interpreting the electrode process is proposed and confirmed via the identification of CPE products and Hammett's $\sigma-E$ relations.

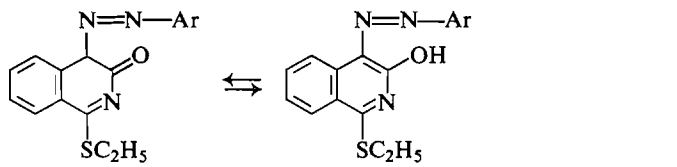
H. M. FAHMY, H. A. DABOUN, M. ABDEL-AZZEM, G. CAUQUIS, and G. PIERRE. Can. J. Chem. **62**, 2904 (1984).

On rapporte et on discute de données relatives aux réductions polarographiques, effectuées dans des milieux aqueux tamponnés contenant 50% par volume d'éthanol, d'arylazo-4 éthylmercapto-1 (4*H*)-isoquinolones-3. Ces composés existant sous plusieurs formes tautomères, on a étudié leurs structures en se basant sur des analyses des données ir et polarographiques. Les données obtenues indiquent que, en solution dans des milieux aqueux ainsi qu'à l'état solide, ces composés existent d'une façon prédominante sous la forme azo. On propose un mécanisme interprétant le processus au niveau de l'électrode et ce mécanisme est confirmé d'une part l'identification des produits CPE et d'autre part par les relations $\sigma-E$ de Hammett.

[Traduit par le journal]

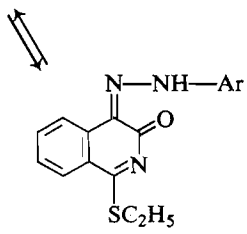
Introduction

We have been dealing for sometime with the electroreduction of five-membered heterocyclic systems of biological interest. These systems contain the sequence —S—C=N—CO—C—N=N— (1, 2) in their structure. It also seemed worthwhile to investigate this sequence in six-membered heterocyclic systems. 4-Arylazo-1-ethylmercapto-3-(4*H*)isoquinolones (**I***a*–*f*) attracted our attention since they met our requirement. These compounds may exist in one of the three potentially tautomeric structures **I**α–γ.



Iα

Iβ



Iγ

I*a* Ar = C_6H_5 — **I***d* Ar = p-OCH_3—C_6H_4
I*b* Ar = p-CH_3—C_6H_4 — **I***e* Ar = p-Cl—C_6H_4
I*c* Ar = m-CH_3—C_6H_4 — **I***f* Ar = p-NO_2—C_6H_4

[1]Revision received June 7, 1984.

Recently it has been shown that the polarographic data of azo–hydrazo tautomeric compounds can be used for their structural identification (3–6). In the present work the electrochemical reduction of **I***a*–*f* in 50% ethanolic aqueous buffers was studied to elucidate the mechanism of electroreduction and to determine the most predominant tautomeric structure of these molecules in aqueous media.

Experimental

1. Organic synthesis

To a cooled solution of 1-ethylmercapto-3-(4*H*)isonolone (7) (6.7 g) in 20 mL of ethanol containing 10 g of sodium acetate was added dropwise the diazonium chloride solution from 3.7 g of aniline. After addition was complete, the red product of **I***a* was collected by filtration, washed with water, and crystallized from ethanol. The above experiment was repeated using the appropriate diazotized amine to give arylazo derivatives **I***b*–*f*. Compounds **I***e* and **I***f* were recrystallized from acetic acid. Melting points (°C) of **I***a*–*f* are 155, 167, 161, 173, 198, and 283, respectively.

2. Polarographic investigations

(a) Apparatus

Voltammograms were obtained using a Tacussel instrumentation: PRT 40 as potentiostat, EPL 1 as recorder, and PRG 3 as pilot. The cell was a Tacussel RMO4 cell which can hold 20 mL of solution. The capillary was a Tacussel CMT 5/24, m = 0.33 mg s^{-1} for h = 50 cm and was controlled by a hammer with a frequency of 1 Hz. Infrared spectra were recorded in KBr pellets on a Perkin-Elmer 397.

(b) Measurements

All experiments were carried out at 20 ± 2°C. The half-wave potentials were measured graphically and expressed versus the saturated calomel electrode (SCE).

(c) Procedure

Ethanol and the appropriate Britton–Robinson modified universal

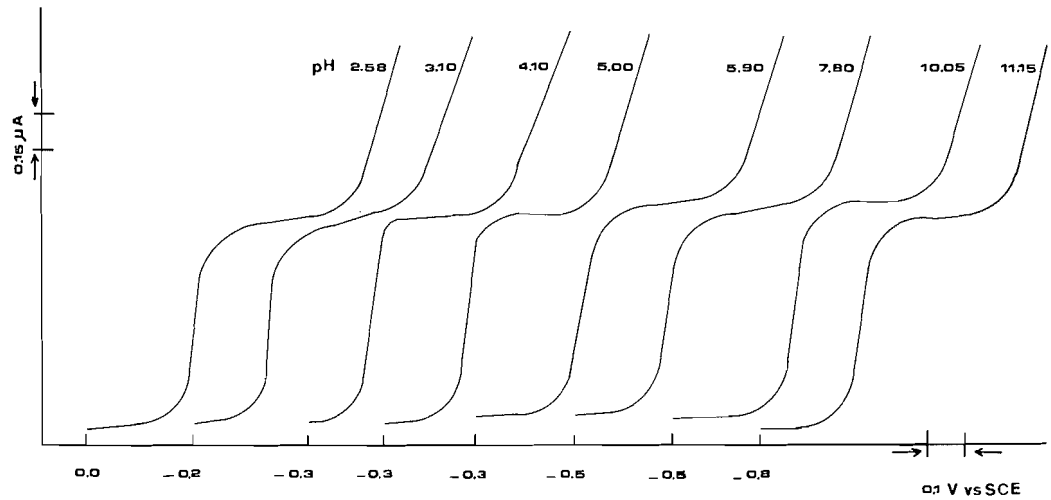

FIG. 1. Schematic representation of the polarograms of 10^{-4} *M* I*a* in 50% by volume ethanolic Britton–Robinson buffers.

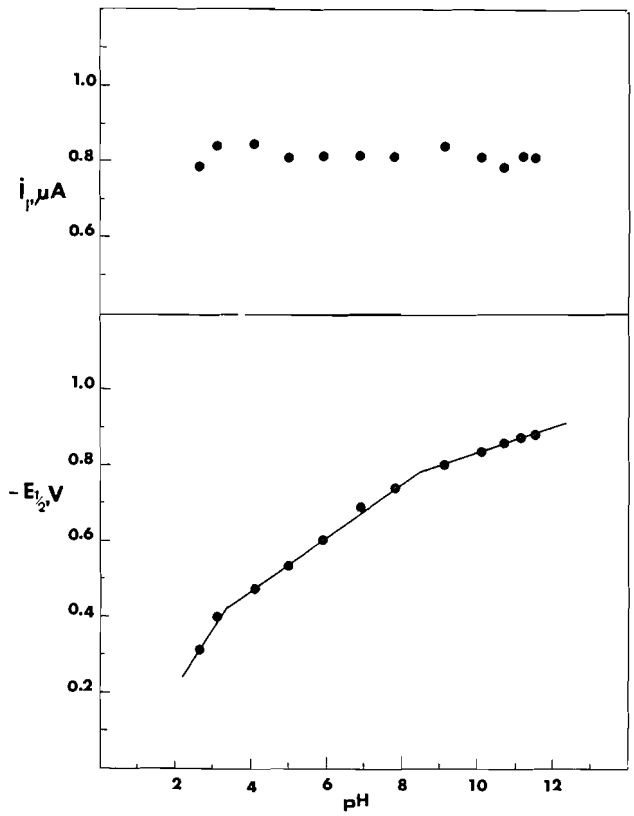

FIG. 2. $E_{1/2}$–pH and i_l–pH plots of the polarographic wave of 10^{-4} *M* I*a* in 50% by volume ethanolic Britton–Robinson buffers.

buffer (8) solutions were introduced into the polarographic cell. The solution was then deaerated by bubbling a stream of nitrogen for 10 min. The calculated amount of stock solution was then introduced into the cell so that the final concentration was 10^{-4} *M*.

3. Controlled potential electrolysis (CPE) and the identification of the resulting products

CPE was carried out on a mercury pool with 100 mg of I*a* taken as a typical example in 200 mL of 50% by volume ethanol – 10^{-2} *M* HCl solution, using the same apparatus as described in a former paper (9). The applied potential was −0.3 V, i.e., on the limiting current plateau of the wave. The number of electrons was found to be 4 mol of electrons per mol of product. After complete electrolysis, the solution was evaporated *in vacuo*. The obtained mixture was treated with water. The insoluble part was isolated by filtration and identified as 4-aminohomophthalimide hydrochloride (**V**) (by mp and mmp determination (10) and ir spectra). The soluble part was concentrated by evaporation to half its volume and the presence of aniline in the solution was revealed by a standard spot test (11).

Results and discussion

Polarographic behaviour of I*a–f*

Compounds I*a–e* exhibit one well-defined polarographic wave (cf. Fig. 1). The half-wave potential is pH-dependent, shifting to more negative values with the increase of pH as indicated by Fig. 2. The shift of $E_{1/2}$ with pH for compounds I*a–f* are compiled in Table 1 in the form of linear equations. On the other hand, the limiting current is practically independent of pH as shown in Fig. 2. The shift of $E_{1/2}$ with increase of pH by an average of 0.068 in the pH range 3–9 for the second segment together with the independency of i_l on pH is a direct indication that the rate-determining step is the preprotonation of the molecule. This is confirmed by applying the equation (12) $dE_{1/2}/dpH = (-2.3RT/\alpha n)\ p$ which gives a value of $1H^+$ per molecule. On the other hand, the abnormal increase in the value of $dE_{1/2}/dpH$ (0.153–0.204) for the first segment can be explained by the following: (*a*) that such basic molecules are most probably involved in other acid–base equilibria at their basic sites or with the buffer constituents of solution; (*b*) that a diprotonated species is the reduced form in pH values below 3.

At pH > 9 the $E_{1/2}$ values are practically pH-independent ($dE_{1/2}/dpH \sim 0.035$), this can be taken as an indication that at these pH values both the protonated (IH^+) and unprotonated (**I**) species are reduced at compatible potentials and that the unprotonated form is the predominant one. Cyclic voltammetry using a hanging mercury drop together with logarithmic analyses of the waves indicated that the process is irreversible in nature. Routine analyses of this wave through the effect of concentration and height of mercury column showed that this wave is diffusion controlled. In addition to the well-defined polarographic wave A exhibited by compounds I*a–e*, the polarograms of compound I*f* displayed another wave B at a more negative potential. Comparison of the polarograms of I*f* with those of I*a–e* indicates that this wave is due to the nitro group occupying the *para* position. Also, a wave-height ratio comparison with wave A indicates that B is a four-electron wave

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

and $E_{1/2}$–pH plot of B seemed to be compatible with the one reported for the reduction of aromatic nitro compounds into the hydroxylamine derivatives (13, 14), following the equation

$$E_{1/2} = -0.139 - 0.086\text{pH}$$

In the pH range 3–6 and pH > 10, another wave appeared with a limiting current equal to ~ 2 e with a pH-independent $E_{1/2}$. This wave can be suggested for the further reduction of the —NHOH group into the amino group as previously described in detail (15).

From the foregoing results it is not unreasonable to conclude that wave A is due to the reduction of an azo (—N=N—) moiety. This assignment is based on the following facts: (*1*) The comparison of $E_{1/2}$ position and shift is within good limits with those of similar heterocyclic azo and not hydrazono compounds (16–18). (*2*) The appearance of the reduction of nitro group after the wave A is a direct indication that the reduced species is an azo and not a hydrazono linkage (15, 19).

Thus one can assume that structures **I**α and **I**β are the most probable ones in 50% ethanolic aqueous media. Theoretically, the conjugation in system **I**β can be considered the most stable since the double single bond sequence is not interrupted. In addition, structure **I**β can be further stabilized through hydrogen bonding between OH group and the N attached to the aryl group. Furthermore, ir spectra indicate no sharp carbonyl CO band between 1700–1800 cm^{-1}.

Based on the above findings the following overall mechanism is suggested and is confirmed via the isolation and identification of both products of electrolysis: 4-aminohomophthalimide hydrochloride (**V**) and aniline.

Mechanism

That the polarograms displayed only one four-electron wave is rationalized by the fact that the values of E_1^a and E_2^a are too close and therefore merge to form a single well-defined wave. The fact that this wave predominates over the whole pH range indicates that these molecules are highly basic in nature. Furthermore, the ir spectra of compound **V** (cf. CPE) as main electrolysis product suggested that compound **IV** hydrolyses in highly acidic media (HCl) to give **V** (16).

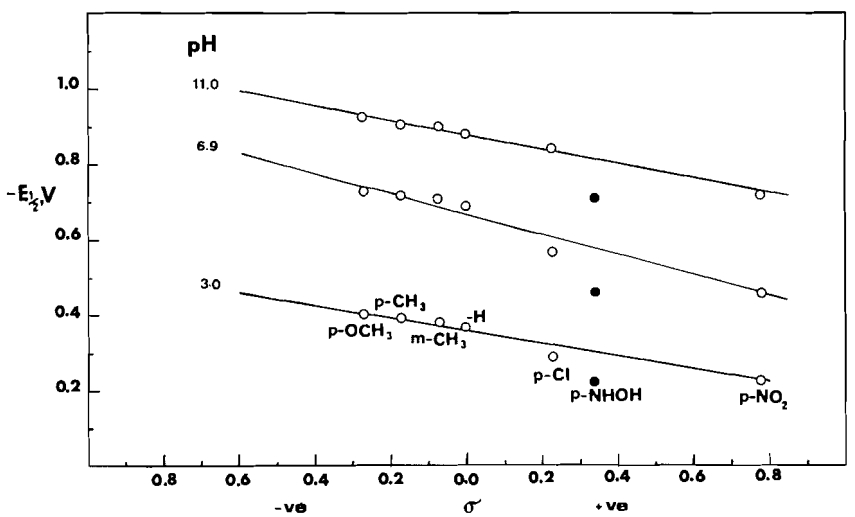

FIG. 3. $E_{1/2}$–σ relation for 4-arylazo-1-ethylmercapto3-(4*H*)isoquinolones derivatives at different pH values.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

TABLE 1. Linear representation of $E_{1/2}$–pH dependence of 4-arylazo-1-ethylmercapto-3-(4*H*)isoquinolones derivatives (**I***a–f*)

Compd No.	$E_{1/2}$–pH equation of the first segment	$E_{1/2}$–pH equation of the second segment
I*a*	$E_{1/2} = 0.137 - 0.173$pH	$E_{1/2} = -0.195 - 0.069$pH
I*b*	$E_{1/2} = 0.177 - 0.185$pH	$E_{1/2} = -0.192 - 0.073$pH
I*c*	$E_{1/2} = 0.231 - 0.204$pH	$E_{1/2} = -0.189 - 0.071$pH
I*d*	$E_{1/2} = 0.454 - 0.261$pH	$E_{1/2} = -0.183 - 0.074$pH
I*e*	$E_{1/2} = 0.489 - 0.256$pH	$E_{1/2} = -0.140 - 0.075$pH
I*f*	$E_{1/2} = 0.268 - 0.163$pH	$E_{1/2} = -0.176 - 0.048$pH

The most reliable $E_{1/2}$ values at selected pH have been correlated with different Hammett's constants (20). Statistical treatment of the data was carried using Jaffé calculations (21) (Table 2). Representative $E_{1/2}$–σ plots are illustrated in Fig. 3. As is clear the plots have reasonable linearity with $+\rho$ values varying between 0.186 and 0.298 for σ and σ^0 constants. These values are in good agreement with those reported for arylazo derivatives (22–24) and not hydrazones (25). That *r* and *s* values are better correlated with σ and σ^0 constants is an indication that substituents can affect the reaction center mainly by their inductive effects. The fact that the point for *p*-NO_2 derivative lies on the $E_{1/2}$–σ plots when using $\sigma_{p\text{-}NO_2}$ and deviates with $\sigma_{p\text{-}NHOH}$ or $\sigma_{p\text{-}NH_2}$ is another confirmation that the compound is in the azo and not in the hydrazono form; since it is well known that the N=N moiety is reduced prior to the NO_2 group. On the other hand, the NO_2 group will be reduced prior to C=N—NH in the case of hydrazones (15, 25).

TABLE 2. Results of statistical treatment of $E_{1/2}$–σ data for 4-arylazo-1-ethylmercapto-3-(4*H*)isoquinolones derivatives (**I***a–f*)

The X-ray crystal structure of Co(sacacen), sacacen = *N*,*N*′-ethylenebis(thioacetylacetoneiminato), has been determined to add a new member to the series of mononuclear complexes M(sacacen), M = Ni, Cu, Zn, whose structures were previously reported. The number of *d* electrons within the series is systematically varied from 7 to 10. The four structures are compared in detail to find the parameters that govern the deformation trends. An extended Hückel MO treatment has been applied to determine the relationships between the geometry and the number of *d* electrons at the metal. The results are compared with the esr and electrochemical experimental data that have been previously reported for these compounds.

RENZO CINI, ARNALDO CINQUANTINI, PIER LUIGI ORIOLI, CARLO MEALLI et MICHAL SABAT. Can. J. Chem. **62**, 2908 (1984).

Dans le but d'ajouter un nouveau terme à la série de complexes mononucléaires M(sacacen) dont les structures ont été publiées antérieurement (M = Ni, Cu, Zn) et faisant appel à la diffraction des rayons-X, on a déterminé la structure cristalline du complexe Co(sacacen) dans lequel sacacen = *N*,*N*′-éthylènebis(thioacétylacétoneiminato). Dans cette série, on a fait varier systématiquement de 7 à 10 le nombre d'électrons *d*. On a comparé en détail les quatre structures pour déterminer quels sont les paramètres qui gouvernent les tendances observées dans les déformations. On a appliqué un traitement élargie des OM de Hückel pour déterminer les relations existant entre la géométrie et le nombre d'électrons *d* du métal. On a comparé les résultats obtenus avec les valeurs expérimentales de la rpe et de l'électrochimie rapportées antérieurement pour ces composés.

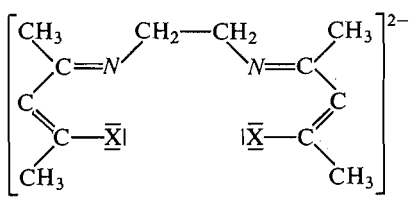
Introduction

The thio-iminato analog, sacacen, of *N*,*N*′-ethylenebis(acetylacetoneiminato), acacen (see **a**), represents an interesting alternative for the synthesis of new complexes that may be used as substrates for the activation of molecular oxygen or other small molecules (1).



a

X = S, sacacen
X = O, acacen

The bonding capabilities of sacacen toward transition metal atoms may be properly evaluated from a comparative examination of the crystal structures of a series of complexes where the number of *d* electrons is systematically varied. For this purpose we have now performed the crystal structure analysis of the compound Co(sacacen), **1**, which is the fourth member in the series of structures of M(sacacen) complexes. Structural details have been previously reported for the Ni, Cu, and Zn derivatives, **2**, **3**, and **4**, respectively (2). The *d* electrons at these bivalent metal centers span the numbers between seven and ten. It is obvious that the different electronic requirements of the metals may not be always compatible with the stericity of this particularly rigid ligand. In fact, the two lateral five-membered chelate fragments of the dianionic sacacen are normally forced to be planar on account of operative π-type conjugation and, at the same time, are held together by an ethylenic chain. The first goal of this study is that of individuating the geometrical parameters which govern both the coordination at the metal and the deformation inside the tetradentate ligand. The second step is that of gaining a deeper insight into the electronic structure of these compounds. With the aid of the extended Hückel method (3), the principal metal–ligand interactions are evaluated both in terms of the ligand's deformation parameters identified from the detailed analysis of the structures. Finally, the results will be checked against the findings of other experimental techniques already performed on these compounds. In particular esr data are available for some paramagnetic species of the series (1*d*–2*a*). These data contain precious information about the nature of the orbital having the unpaired electron and provide a good test for the reliability of the calculations. Electrochemistry of these compounds has been studied (4) with some interesting results that will be kept in mind during the discussion.

Comparison between the structures

Figure 1 shows views of the structures **1**–**4** down the bisector of the N—M—N angle. By examining Table 1, which reports some selected geometrical magnitudes of the compounds, a few conclusions can be drawn about the deformation trends within the series. Whereas the N_2M fragment is, in a first approximation, almost unchanged (the N—M—N angles vary

[a]The labelling of the atoms is not always consistent with that previously reported in refs. 2*a*–2*c*.

[b]N_2M/NC_3S is the dihedral angle between the planes defined by the N_2M fragment and the least-squares plane of the chelate fragment of the ligand (NC_3S).

in the narrow range 88.0(2)–83.2(1)°), the S—M—S angles change remarkably in going from cobalt to zinc (limiting values 80.5(1)° in **2** and 113.6(1)° in **4**). At the same time the M—N and M—S distances vary almost consistently with the sum of their covalent radii (5). Noteworthy, but not unexpected in view of the rigidity of the chelating bite, the N—M—S angles are practically equal in all cases (96.0 ± 1.0°). All these mean that the coordination geometry which is approximately square planar with C_{2v} symmetry in **1** and **2** becomes progressively distorted in **3** and **4**, where only C_2 symmetry is preserved. Since the two chelating arms of sacacen like to be as planar as possible to satisfy the π conjugation and since these arms are connected by an ethylenic chain, the whole ligand is highly constrained. Consequently it is hard for the metals richer in electrons to adopt the tetrahedral coordination which is the most favourable one for them.

A certain degree of flexibility is attained through torsions about the M—N bonds. Indeed the dihedral angles between the N_2M plane and the least-squares plane through the NC_3S atoms of the chelating fragments increase within the series up to a 30° value in **4**. The latter seems the largest torsion tolerated by the complexing ligand; on the other hand full coplanarity of the system seems also unobtainable: both in **1** and **2** one chelate ring is almost coplanar with the N_2M plane (dihedral angle <4°) whereas the other is biased of about 10°. Thus the ligand seems to have a minimum strain in **3**, as indirectly shown by the planarity of the NC_3S groupings (the largest deviation from the least-squares plane is ca. 0.004 Å); in all of the other complexes there is also some torsion about the C—C bonds of the chelating ring which in some cases can be as large as 15°. For this reason the deviation of the atoms from the NC_3S plane can be also an order of magnitude larger than in **3**. It is also noteworthy that in **1** and **2**, which are isostructural, one of the six-membered chelate rings is more distorted than the other.

In summary it seems evident that the different modes of coordination at the metal atoms are mainly obtained through

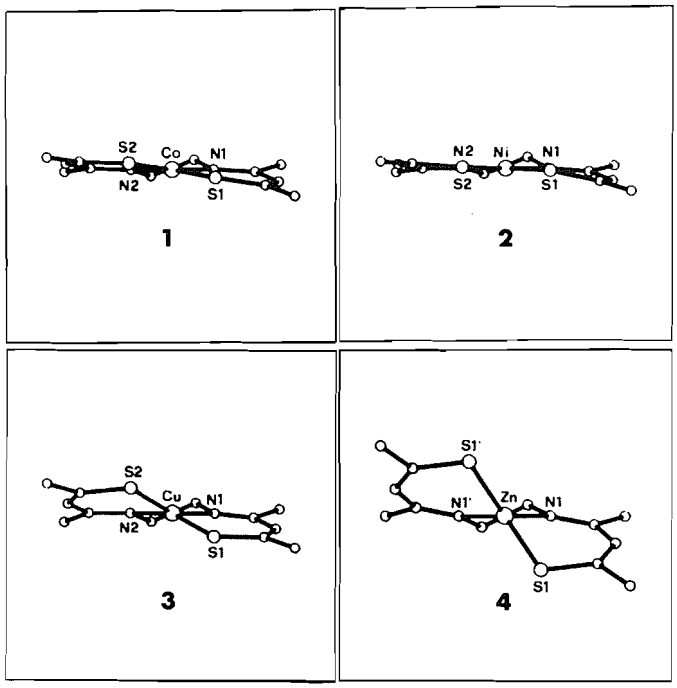

FIG. 1. Views of Co(sacacen) (**1**), Ni(sacacen) (**2**), Cu(sacacen) (**3**), and Zn(sacacen) (**4**) down the bisector of the N—M—N angle.

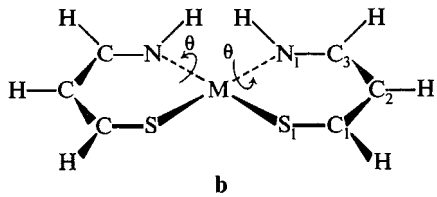
simultaneous clockwise (or anticlockwise) torsions at the M—N bonds. Since the two chelating fragments of the ligand are held together by the ethylenic chain and the nitrogen atoms maintain an sp^2 hybridization, the range of values for the torsion angles at the M—N bonds is restricted and not always suitable to fully cope with the stereochemical requirements of the different metals. Hence some other geometrical rearrangements are sought by the ligand to accommodate the different metal atoms. In effect, besides the mentioned distortions from planarity of the NC_3S groupings,some other minor variations in bond distances and angles are observed.

MO calculations

In order to simplify the MO analysis of these molecules, it is important to fix a model where the number of geometrical parameters that define the deformation pathway from d^7 to d^{10} species is as small as possible. Our starting model is the C_{2v} molecule shown in **b**. The ethylenic chain was purposely excluded. We fixed bond distances and angles to the values reported in the experimental section and we simulated the passage from one compound to another only through variations of the torsion angle θ and by artificially changing the number of d electrons at the metal.[2]



b

Unless specifically stated, the atomic parameters of nickel were invariably used for the calculations. The NC_3S groupings were kept planar and rigid; as a result the fit to the real structures becomes poorer in those cases where other magnitudes also change significantly: e.g., the metal–donor distances and degree of planarity of NC_3S. Whereas a simple torsion of 15° in θ reproduces the S—Cu—S angles of ca. 88° in **3**, a 30° torsion is insufficient to reproduce the S—Zn—S angle of 113.6(1)° in **4**. Nonetheless, we have found that significant pieces of information may be obtained by the evolution of the MO's in terms of the θ angle at least for structures **1**–**3** and these may be extrapolated to the zinc derivative. Figure 2 shows an interaction diagram of Ni(sacacen) having rigorous C_{2v} symmetry. The d_{xy} orbital is highly destablized on account of the antibonding interaction with the b_2 combination of lone pairs at nitrogen and sulfur atoms; the remaining four d orbitals are more closely compacted, a situation typical for square planar complexes. However, the relative order of these lower d orbitals is not the standard one for complexes having four exclusively σ donor ligands (6). The conjugation in the five-membered chelate arms places some ligand π* orbitals at comparable energies with those of the metal d orbitals. This new situation affects the yz orbital which is most destabilized and it is the HOMO in the cobalt and nickel complexes. The xz and $x^2 - y^2$ orbitals also suffer some destabilizing interaction with ligand orbitals mainly centered at the sulfur atoms, as seen in Fig. 2. The z^2 orbital remains at lower energy as an almost pure d orbital (85%). The different electron population of the HOMO in **1** and **2** should affect the distances between metal and donor atoms because of their π-type antibonding. However, it is hard to detect any such trend from the structural comparison. The fact that all the M—S distances are practically equal does not exclude that the Ni—S linkage is weaker than the Co—S linkage; bond lengths are not properly related to bond strengths when dealing with different pairs of atoms.

Very similar results have been obtained for the complex Co(acacen) by using different theoretical methods (1*b*, 1*d*, 7, 8). Remarkably only an *ab initio* calculation (9) assigned the HOMO as z^2, a result in clear disagreement with experimental epr data (1*d*). In our case the presence of sulfur in place of oxygen ensures a larger metal–ligand overlap and hence a larger splitting of yz with respect to the other d-orbitals (ca. 0.6 vs. 0.1 eV). The correct assignment of the HOMO also relies on recent epr results, reported for Co(sacacen) (1*d*, 2*a*). In fact, it has been ascertained that when Co(sacacen) is doped in a host Ni(sacacen) crystal, the unpaired electron unambiguously resides on the yz orbital. Conversely, the z^2 orbital becomes the HOMO of Co(sacacen) in a host crystal of Zn(sacacen). Also for this reason the evolution of the MO's as a function of θ, the parameter that macroscopically governs the deformation along the series, seems particularly interesting. A Walsh diagram is shown in Fig. 3. The most remarkable trend is the drop in energy of the xy (b_2) orbital (becomes 4*b* in C_2 symmetry) on account of the decreasing σ* character when the S atoms are displaced out of the main plane. The $2b_1$ and $2a_2$ levels are unaffected because of their π* ligand nature. The crossing between the latter and xy is unimportant when all the levels are empty as in **1** and **2**. The four low lying d orbitals are not shuffled; however, there are important changes in their composition. Notice that on account of the descent in symmetry three of them belong to the same species (**a**), and are allowed to mix with each other. In particular, whereas the $x^2 - y^2$ orbital is little engaged in mixing and remains substantially unchanged (2*a*), the orbitals 1*a* and 3*a* mix more and more with each other and eventually reverse their composition. This

[2] The torsion angle θ can be envisaged as the dihedral angle between the N_2M and NC_3S planes.

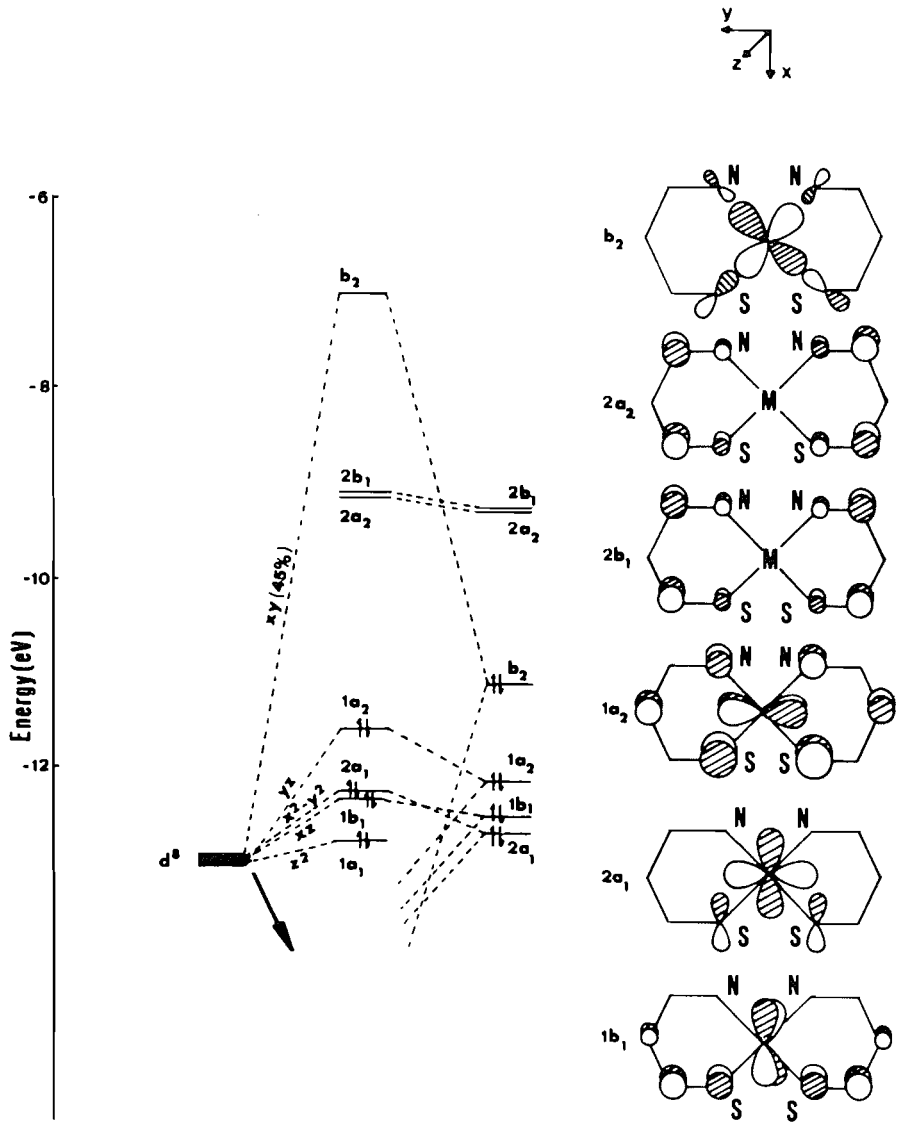

FIG. 2. Interaction diagram of Ni(sacacen) having rigorous C_{2v} symmetry.

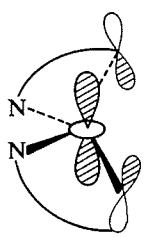
is intuitively understood since the reorientation of the NC_3S planes progressively reduces the overlap between *yz* and the combination of the sulfur p_π orbitals in the ligand's $1a_2$ level. At the same time these p_π orbitals become more involved in a π^* interaction with z^2, as shown in **c**. In order to avoid a crossing between orbitals of the same symmetry, the descending $3a$ and the ascending $1a$ levels mix into each other.



c

At $\theta \sim 40°$ the orbital $3a$, HOMO, has mainly z^2 character, having lost most of its initial *yz* character. The result is most interesting and fully matches the epr data for the cobalt doped zinc complex ($2a$). It is also worthwhile to point out that the deformation pathway is symmetry-allowed for **1** and **2** as no crossing of the HOMO with any other level is encountered.

In the copper complex, **3**, the unpaired electron lies almost certainly on the level $4b$, metallic *xy* in character and metal–ligand σ antibonding. The Walsh diagram of Fig. 3 was calculated by using the parameters of nickel. Were the copper parameters used, the general trends would not change dramatically: $4b$ crosses the ligand π orbitals at an earlier stage ($\theta \sim 15°$). The total energy continues to lower for larger θ values, but the experimental θ in **3** (ca. 15°) seems a good compromise between the energy gained on stabilizing the HOMO and that which would be lost on deforming excessively the tetradentate ligand.

In the zinc complex, **4**, there are two electrons which drop steeply in energy on increasing θ. More properly one can say that only at sufficiently large θ values the repulsion between the filled *xy* metal orbital and the σ lone pairs of the donor atoms is sufficiently relieved. The large torsion is hardly tolerated by sacacen and the complex undergoes other deformations as described in the previous paragraph.

The above qualitative MO picture is helpful in rationalizing some electrochemical results previously reported for com-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

pounds **2** and **3** (4). It has been ascertained that **2** undergoes a reversible oxidation with a maximum loss of four electrons. If the geometry is assumed to remain unchanged, the oxidized species must be guaranteed a formal 16-electron count that ensures stability to square planar complexes. The level which is first oxidized is $1a_2$ (see Fig. 2) which has ca. 60% ligand character; as a result the electron population at the metal is not excessively affected. From another point of view one can say that the interaction between *yz* and the ligand $1a_2$ orbital is 4-electron destabilizing and the depopulation of their antibonding combination triggers a stabilizing metal–ligand π bonding. In a sense $1a_2$ is equivalent to a fifth lone pair donated from the ligand to ensure a total 16-electron count anyway. Those illustrated above are two extreme points of view which frame the actual situation of the system, still stable upon oxidation. Similar arguments may be invoked for the second pair of electrons removed from the system. In this case, since the metal–ligand antibonding combinations involving *xz* and $x^2 - y^2$ orbitals are almost degenerate, it is difficult to predict which one is going to be depopulated. In a sense *xz* establishes with a ligand π^* orbital an interaction which is analogous to that involving *yz*: for this reason $1b_1$ seems a better candidate to oxidation than $2a_1$.

The nickel species may also be electrochemically reduced. However, the process is not easy as shown by the very negative value (−1.8 V vs. sce) of the peak potential. Some information on the location of the extra electron is provided by an esr spectrum in solution (4*a*). A *g* value of 2.13 in fact can occur only for an electron not localized over the ligand. This would be the case if either the $2a_2$ or $2b_1$ orbital of Figs. 2 and 3 were occupied. Since also for the d^8 case a θ torsion is a quite feasible process, it is likely that the electron is taken by the system after the *xy* orbital has crossed the two ligand orbitals. On the other hand, the copper(II) complex and the reduced nickel(I) species are not very dissimilar (4*a*).

In conclusion the present study has confirmed that the Schiff-base sacacen has π^* orbitals at comparable energies with metal *d* orbitals. When the stereochemistry is square planar, the ligand and metal orbitals interact well and the typical level ordering found in common square planar complexes is greatly altered. The π-type interactions are 4-electron destabilizing, thus an oxidation process, which transforms some of these into stabilizing bonding interactions, is not difficult. Distortion from planarity also lessens the destabilizing interactions, but the polydentate ligand, from a certain point on, is not easily deformed.

Experimental

Preparation of the crystals

Both ligand and metal complexes were prepared as previously described (10). Crystal of Co(sacacen) suitable for X-ray analysis were obtained by dissolving about 100 mg of the cobalt complex in 50 mL of toluene. The solution was filtered and then allowed to evaporate under a slow stream of nitrogen at room temperature. Well-shaped red crystals formed in about 24 h.

Crystallography

Crystal data are as follows:

$C_{12}H_{18}CoN_2S_2$ mw = 312.9

Orthorhombic, $P2_12_12_1$, a = 15.840(4), b = 12.010(4), c = 7.339(3) Å, U = 1396.2(8) Å^3, Z = 4, D_c = 1.49 Mg m^{-3}, $F(000)$ = 652, Mo-K$_\alpha$ radiation, λ = 0.7107 Å, μ(Mo-K$_\alpha$) = 3.13 cm^{-1}.

Intensity measurements

A total of 2614 reflections were collected on a Philips PW1100 diffractometer with θ–2θ scan techniques, in the range $5° < 2\theta < 40°$, on a crystal of dimension 0.10 × 0.17 × 0.60 mm. The scan width was 1.40°, and the scan speed was 0.03 (deg/s). Lattice constants were obtained by the least-squares method applied to the setting angles of 25 reflections. The crystal was confirmed to be isostructural with the compound Ni(sacacen). The intensity of three standard reflections ($\bar{7}\,\bar{1}\,1$, $7\,1\,1$, $7\,\bar{1}\,\bar{1}$) measured every 180 min showed no appreciable variation during data collection. A total of 1199 unique reflections with $I > 2.5\,\sigma(I)$ were observed and used for the crystallographic calculations. The intensities were corrected for Lorentz-polarization effects. No absorption correction was applied as a ψ scan on a few reflections showed a maximum deviation of 6%.

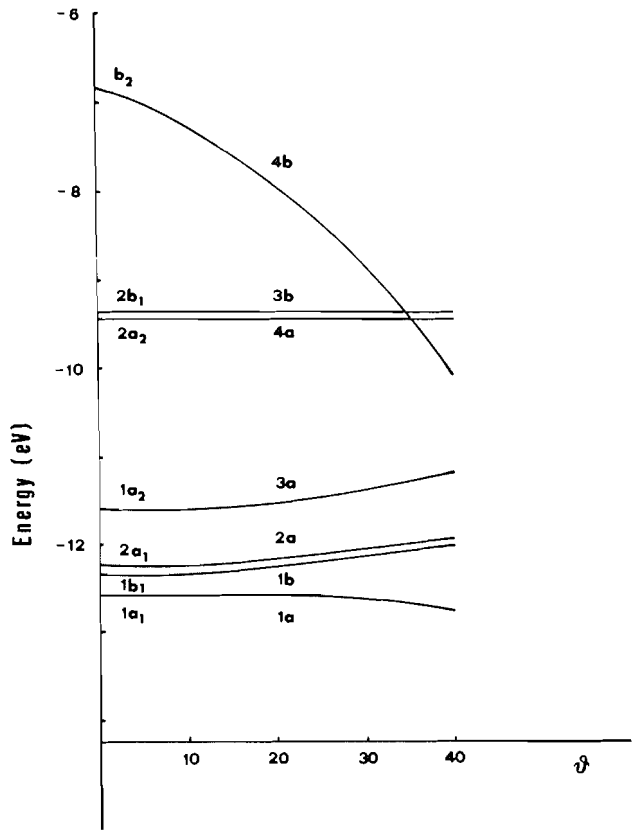


FIG. 3. A Walsh diagram.

Solution and refinement of the structure

The atomic parameters of the nickel derivative were used as starting values for the crystallographic refinement. A series of full-matrix least-squares cycles with anisotropic temperature factors for all the non-hydrogen atoms were performed. A total of 16 hydrogen atoms were included in the final refinement with fixed coordinates and fixed temperature factors U of 0.06 Å^2. The agreement index $R = \Sigma(|F_o| - |F_c|)$ reached the value of 0.0297. The index $R_w = \Sigma[w(|F_o| - |F_c|)^2/wF_o^2]^{1/2}$ was 0.0317. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$ with weights $w = 1/(\sigma^2(F) + 0.0005F^2)$. The atomic scattering factors of C, N, H, and S were taken from SHELX 76 (11) package; those of Co were taken from ref. 12. No unusual features were shown by a final ΔF map. The Hamilton test was applied to establish the absolute configuration of the molecule.

Table 2 lists the atomic coordinates for all the non-hydrogen atoms. The thermal parameters as well as the observed and calculated structure factors are available as supplementary material.[3]

[3] Complete set of data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Computational method

The program used to perform extended Hückel calculations was ICON8 (3) implemented on a SEL 32/70 computer. The parameters[4] used were those of Table 3 with the modified Wolfsberg–Helmholz approximation (14). In all the calculations, the M—N, N—C(3), C(3)—C(2), C(2)—C(1), and C(1)—S(1) distances were kept fixed at the values 1.92, 1.32, 1.46, 1.33, 1.70 Å, respectively. The angles N(1)—M—N(2), M—N(1)—C(3), N(1)—C(3)—C(2), C(3)—C(2)—C(1) were fixed at 87, 123, 128, 127, 133°, respectively. All the C—H or N—H distances were taken as 1.05 Å.

[4] The parameters for Cu were taken from ref. 13(*a*), those for Ni and other atoms (except S) were taken from ref. 13(*b*), and those for the sulphur atoms were taken from ref. 13(*c*).

Isomer enumeration of nonradical strictly *peri*-condensed polycyclic aromatic hydrocarbons

JERRY RAY DIAS

Department of Chemistry, University of Missouri, Kansas City, MO 64110, U.S.A.

Received January 16, 1984

JERRY RAY DIAS. Can. J. Chem. **62**, 2914 (1984).

A new concept for isomer enumeration of *peri*-condensed benzenoid hydrocarbons (PAH6) based on the enumeration of their excised internal structures is presented. Formulas corresponding only to strictly *peri*-condensed benzenoid hydrocarbons can be identified from a previously derived Formula Periodic Table for PAH6. The number of benzenoid PAH6 isomers having formulas $C_{38}H_{16}$, $C_{40}H_{16}$, $C_{42}H_{16}$, $C_{48}H_{18}$, $C_{50}H_{18}$, $C_{52}H_{18}$, $C_{60}H_{20}$, $C_{62}H_{20}$, and $C_{64}H_{20}$ are 10, 3, 1, 22, 7, 2, 20, 12, and 3, respectively (Fig. 1). A nomenclature for these PAH6s based on an already established nomenclature for their corresponding small-molecule, excised internal structures is proposed. The structure counts of these PAHs, being related to their resonance energy, have been determined, and this will permit researchers to estimate the most probable structures of the macromolecular benzenoid hydrocarbons of this class formed via pyrolytic processes.

JERRY RAY DIAS. Can. J. Chem. **62**, 2914 (1984).

On présente un nouveau concept qui permet de faire l'énumération des isomères d'hydrocarbures benzènoïdes *péri*-condensés (HAP6); ce nouveau concept est basé sur l'énumération des structures internes simplifiées de ces hydrocarbures. Faisant appel à un tableau périodique des formules de HAP6 qui a été dérivé antérieurement, on peut identifier des formules qui correspondent spécifiquement à des hydrocarbures benzènoïdes strictement *péri*-condensés. Parmi les produits benzènoïdes de formules $C_{38}H_{16}$, $C_{40}H_{16}$, $C_{42}H_{16}$, $C_{48}H_{18}$, $C_{50}H_{18}$, $C_{52}H_{18}$, $C_{60}H_{20}$, $C_{62}H_{20}$ et $C_{64}H_{20}$, les nombres d'isomères de HAP6 sont respectivement 10, 3, 1, 22, 7, 2, 20, 12 et 3 (Fig. 1). On propose un système de nomenclature de ces HAP6 isomères qui est basé sur un système de nomenclature des petites molécules correspondantes et de leurs structures internes simplifiées. On a déterminé que le compte de structure de ces HAP est relié à leur énergie de résonance et ceci permettra aux chercheurs d'évaluer les structures les plus probables des hydrocarbures benzènoïdes macromoléculaires de cette classe qui se forment par le biais de processus pyrolytiques.

Introduction

The enumeration of *cata*-condensed benzenoid hydrocarbons has been completely successful and was accomplished by use of a dualistic graph (1). Recent computer algorithms have been reported for enumerating geometrically planar hexagonal graphs having the same number of rings (2). However, options for inclusion of circulenes and nonplanar helicenes in the isomer enumeration need to be developed. For example, a nonplanar isomer of $C_{50}H_{28}$ and up to tetradecahelicene have been synthesized and would be excluded by restricting enumeration to planar hexagonal graphs (3, 4). Note that these computer results emphasized the *cata*-condensed benzenoids and have not yet been fully tested on totally *peri*-condensed benzenoids. Herein is reported a conceptually new approach for enumerating *peri*-condensed benzenoids without *cata*-condensed appendages. For a brief history of the related hexagonal animal and cell growth problems, the reader is referred to previous work and references therein (2).

Results and discussion

Enumeration of strictly peri*-condensed benzenoid hydrocarbons*

Our previous research resulted in the development of a Formula Periodic Table for PAH6 (benzenoid polycyclic aromatic hydrocarbons comprised of exclusively fused hexagonal rings, Table 1) which for the first time unified the formula–structure relationships of PAH6s into an overall systematic framework (5, 6). The basis for this formula periodic table is $d_s + N_{iC} = (1/2)(N_C - N_H) - 1 =$ constant for all isomeric PAH structures corresponding to a particular formula; a glossary of terms used in this paper appears at the end in an appendix (further details on these terms are to be found in ref. 6). Throughout this paper only the C—C σ-bonds are shown for all the structures. Since circulene or helicene structures are not possible for strictly *peri*-condensed PAH6s (7), the ambiguity associated with other benzenoid enumerations (2) is absent in this work.

Strictly *peri*-condensed benzenoid hydrocarbons have all their internal edges mutually connected. The formulas consisting of only isomers corresponding to strictly *peri*-condensed PAH6 without *cata*-condensed appendages appear in Table 1 along the extreme left-hand diagonal formula boundary, and the corresponding number of nonradical isomers are itemized by the number in parentheses adjacent to these formulas; the number of isomers for formulas ($C_{58}H_{20}$ and $C_{46}H_{18}$) adjacent to a boundary formula should be regarded as tentative since they possess isomers having a single *cata*-condensed benzo appendage (*vide infra*). The number of isomers given for the *cata*-condensed PAH6s in the $N_C = 2N_H - 6$ row series were obtained from previous work (1). Previously, it was shown that coronene-7 ($C_{24}H_{12}$) and coronene-19 (synonymous to circumcoronene and dodecabenzocoronene, $C_{54}H_{18}$) both have no other PAH6 isomers (7). Also, $C_{30}H_{14}$ was shown to have only 3 nonradical isomers (7). Ovalene ($C_{32}H_{14}$) is known to have no other PAH6 isomer. There are 10 nonradical PAH6 isomers (**1**–**10**) with the formula of $C_{38}H_{16}$, and circumanthracene ($C_{40}H_{16}$) is one of 3 possible isomers (**11**–**13**). Circumpyrene (**14**) ($C_{42}H_{16}$) has only one PAH6 isomeric form. There are 7 PAH6 isomers (**37**–**43**) of the formula $C_{50}H_{18}$, 2 PAH6 isomers (**44**, **45**) of the formula $C_{52}H_{18}$, 22 isomers (**15**–**36**) for $C_{48}H_{18}$, and 20 isomers for $C_{60}H_{20}$ (**46**–**65**). Figure 1 presents all these isomers (**1**–**65**).

All PAH6 formulas having the same number of hydrogens are found in a linear diagonal array of formulas (Table 1) and have the same perimeter length ($q_p = 2N_H - 6 =$ constant for $N_H =$ constant). The formulas in the $N_C = 2N_H - 6$ row series

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

have no internal third-degree carbon vertices ($N_{iC} = 0$ and $N_C = q_p$). Thus the two isomers of $C_{14}H_{10}$ both have a perimeter length of 14 carbon atoms, and pyrene ($C_{16}H_{10}$) has two internal third-degree carbon vertices ($N_{iC} = 2$) with a perimeter length of 14 carbon atoms, giving a total of 16 carbon atoms in its formula. Similarly, all five PAH6 isomers of $C_{18}H_{12}$ have a perimeter length of 18 carbon atoms, and the three isomers of $C_{20}H_{12}$ have $N_{iC} = 2$, the two nonradical PAH6 isomers of $C_{22}H_{12}$ have $N_{iC} = 4$, and coronene ($C_{24}H_{12}$) has $N_{iC} = 6$, all with a perimeter length of 18 carbon atoms. In hexagonal graphs the maximum number of internal third-degree carbon vertices that can be contained in a 10-carbon-atom peripheral cycle is zero (naphthalene), in a 14-carbon-atom peripheral cycle it is two (pyrene), and in an 18-carbon-atom peripheral cycle it is six (coronene). Polycircumnaphthalene, polycircumpyrene, and polycircumcoronene are three series of formulas appearing on the left-hand diagonal boundary of Table 1. Each formula of these series has only one corresponding PAH6 structure. These terminal formulas have PAH6 structures containing the maximum number of internal third-degree carbon vertices ($N_{iC(max)}$) that each corresponding peripheral $q_p = 4\tau + 2$ ($\tau = 2, 3, 4, \ldots$) carbon atom can contain. Table 2 summarizes the relevant information for these one-isomer series.

From the narration presented in the last paragraph, it is evident that PAH6s have an even number of perimeter carbon vertices, since $q_p = N_{pC} + N_H = 2N_H - 6$ must be an even number. From this it follows that N_{iC} is even for even PAH6 formulas and odd for odd radical PAH6 formulas (5). For *peri*-condensed PAH6s with N_{iC} internal third-degree vertices, the number of PAH6 isomers is equal to the number of nonradical isomeric excised internal structures having N_{iC} carbon atoms obtained by clipping N_{pC} internal edges (bonds) to perimeter carbons and attaching hydrogen to N_{pC} dangling bonds thus formed on the separated structures. It is important to note that all isomeric internal structures must have the same number of rings and carbon vertices (N_{iC} of parent), i.e., d_s = constant. This process is illustrated by the structures in Fig. 2. Ethene, having two carbons, is the excised internal structure of pyrene ($C_{16}H_{10}$), and $C_{16}H_{10}$ ($N_{iC} = 2$) can only have one possible PAH6 isomer. *s-trans*-1,3-Butadiene, having four carbons, is the excised internal structure of anthanthrene ($C_{22}H_{12}$, $N_{iC} = 4$), and *s-cis*-1,3-butadiene is the excised internal structure of benzo(*ghi*)perylene ($C_{22}H_{12}$, $N_{iC} = 4$); since triangulene and its excised structure, trimethylenemethane, (which are not shown) are diradicals, the formula of $C_{22}H_{12}$ can be represented only by the above two nonradical PAH6 isomeric structures. The excised internal structure of coronene ($C_{24}H_{12}$, $N_{iC} = 6$) is benzene, and $C_{24}H_{12}$ has only one PAH6 structure. The excised internal structure of circumcoronene ($C_{54}H_{18}$) is coronene ($C_{24}H_{12}$), and circumcoronene is the excised internal structure of dicircumcoronene ($C_{96}H_{24}$). Thus dicircumcoronene and circumcoronene have no other PAH6 isomers (7). Previously, it was shown that there were only three nonradical PAH6 isomers of the formula $C_{30}H_{14}$ (7). In Fig. 2, four PAH6 structures having the formula of $C_{30}H_{14}$ are shown, along with their corresponding excised internal structures. Styrene is the excised internal structure of naphtho(*abc*)coronene, 1,2-benzoquinodimethane of dibenzo(*bc*,*ef*)coronene, 1,3-benzoquinodimethane of the third $C_{30}H_{14}$ structure, and 1,4-benzoquinodimethane of dibenzo(*bc*,*kl*)coronene (dibenzoperopyrene). However, since 1,3-benzoquinodimethane is a diradical and the [22]annulene perimeter is an even alternant hydrocarbon, the third $C_{30}H_{14}$ structure shown in Fig. 2 must be a diradical

and is not counted. In general, if the excised internal structure is a diradical which can be formed by connecting a non-starred position of a monoradical with a starred position of a second monoradical, its parent PAH6 structure will also be a diradical. Note that a strictly *peri*-condensed polycyclic aromatic hydrocarbon cannot have a disconnected excised internal structure. Thus perylene is not a strictly *peri*-condensed PAH6, nor is dibenzo(*de*,*hi*)naphthacene diradical.

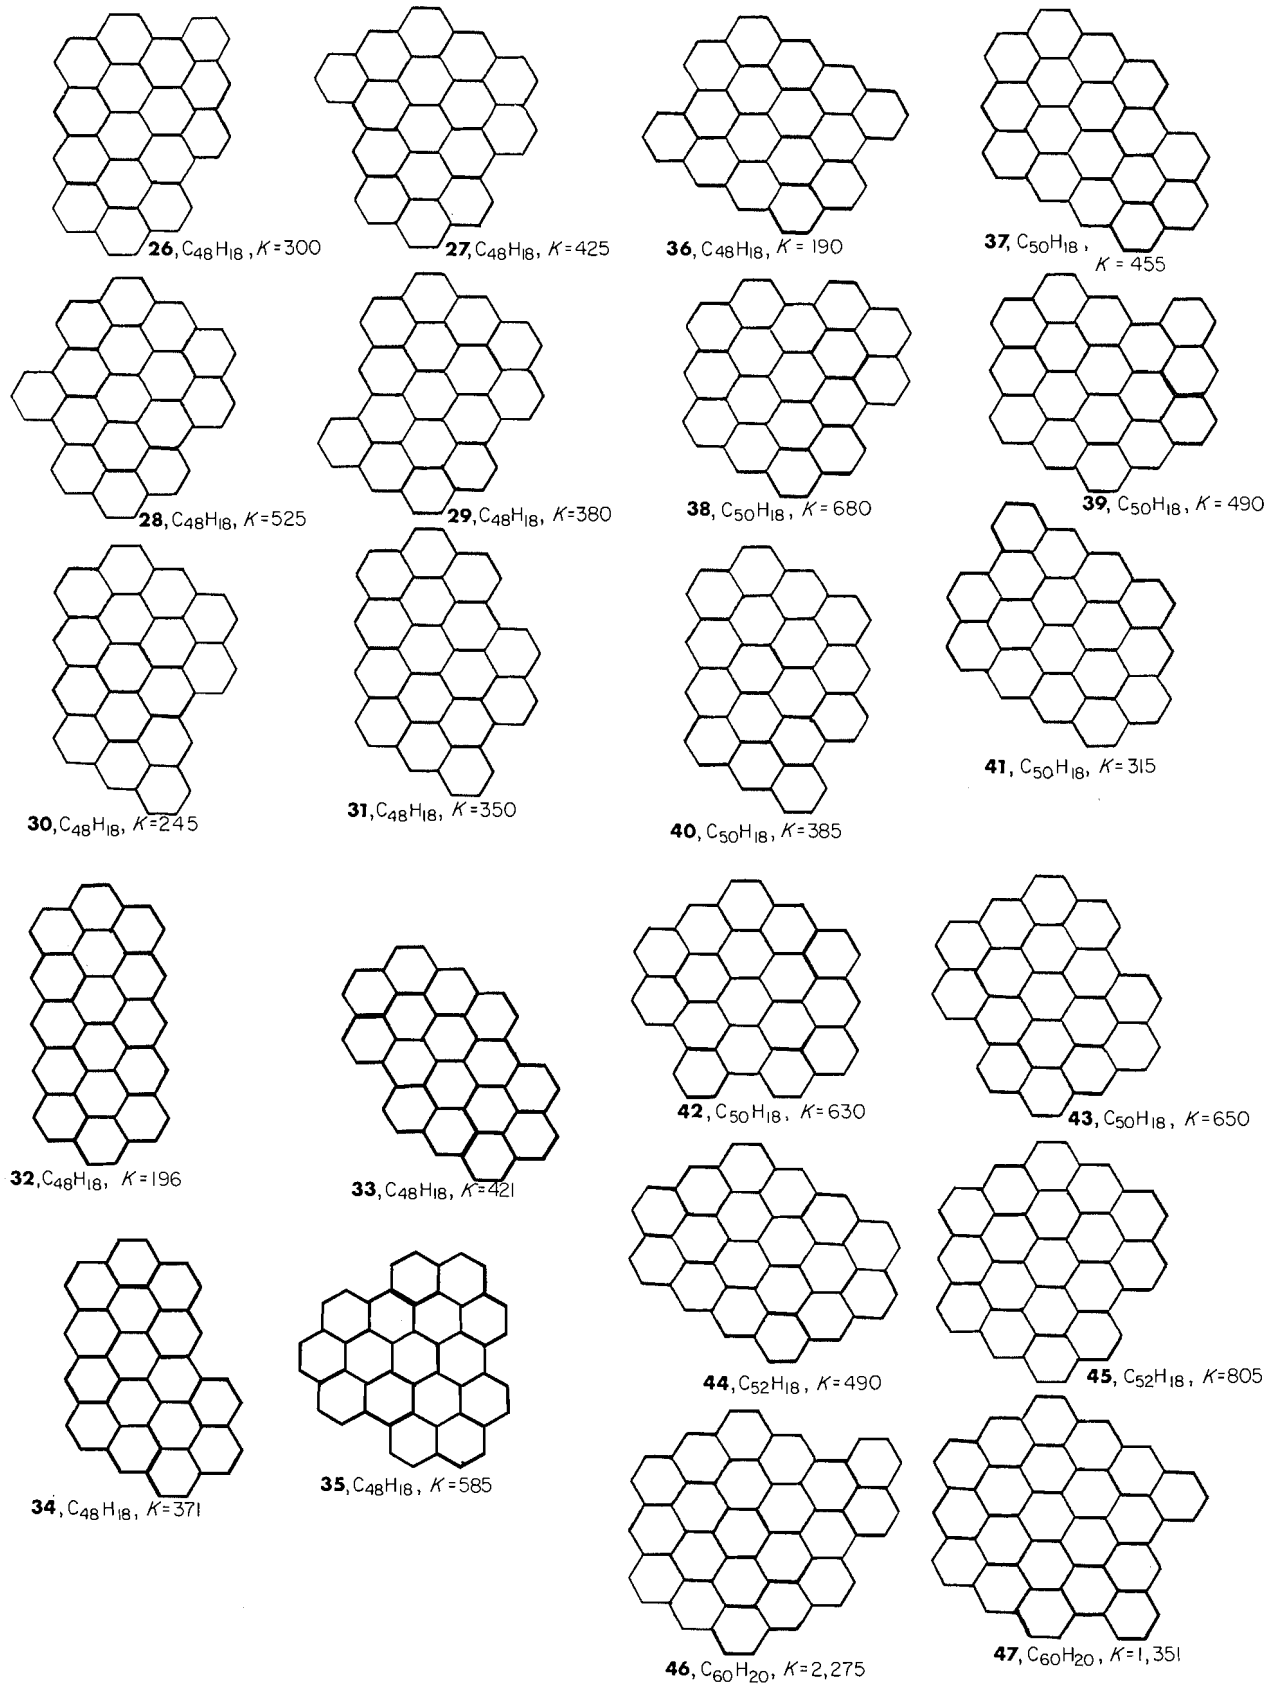

FIG. 1. (*continued*)

Enumeration of excised internal structures

Figure 3 presents all the corresponding (primed) excised internal structures of all the parent PAH6 isomers shown in Fig. 1. The first nine substituted naphthalene structures (**1′**−**9′**) and biphenyl (**10′**), all having twelve carbon atoms in Fig. 3, correspond in order and orientation to the ten $C_{38}H_{16}$ (N_{iC} = 12) isomers in Fig. 1. Only one of two possible conformers of 1-ethenylnaphthalene (**1′**) is presented, while both

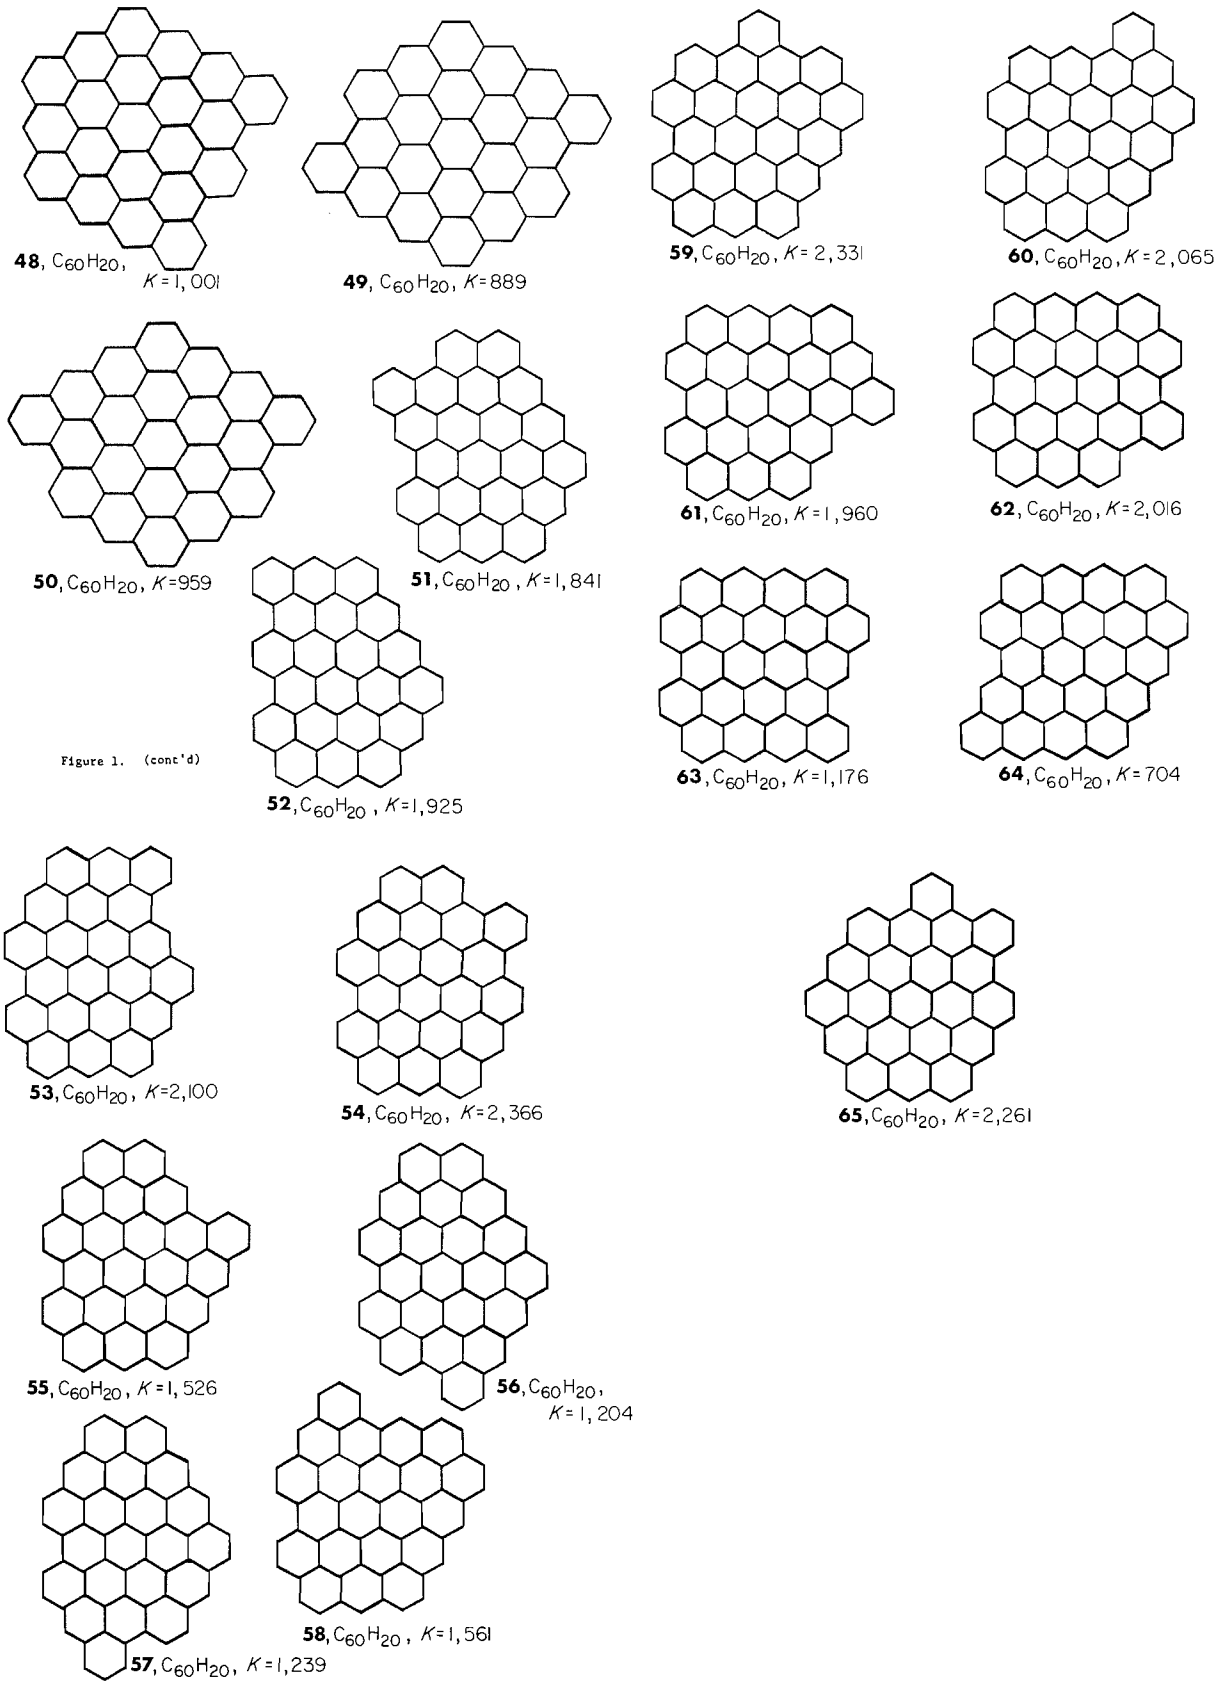

Figure 1. (cont'd)

FIG. 1. (*concluded*)

possible conformers (**2′**, **3′**) of 2-ethenylnaphthalene appear. This is because a two-carbon-atom gap needs to exist between the *s-cis*-1,3-butadiene system of any excised internal structure of a PAH6 parent. Thus the other conformer of 1-ethenylnaphthalene has a one-carbon-atom gap and is therefore excluded. Only six of ten possible naphthoquinodimethanes (**4′**−**9′**) are present in Fig. 3 because the other four are diradicals. There are only three nonradical isomeric conjugated

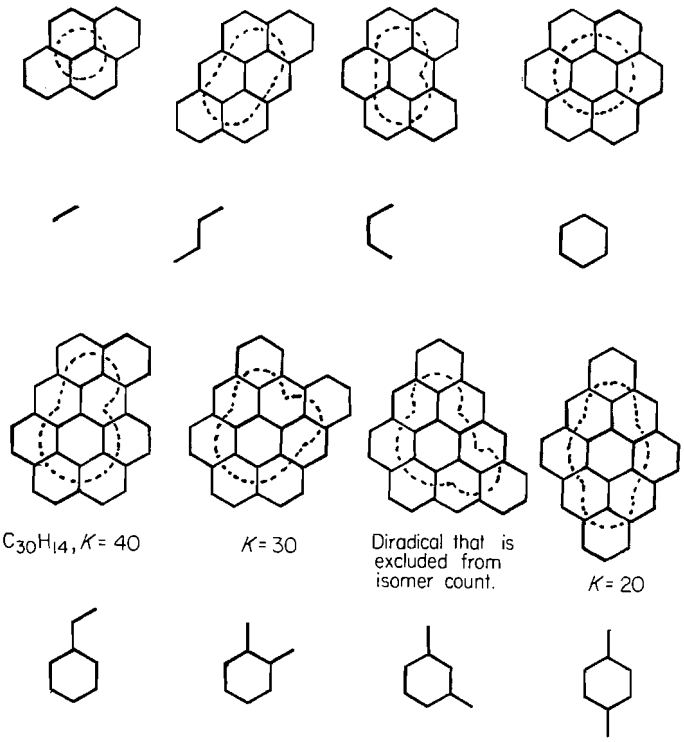

FIG. 2. Excised internal structures from strictly *peri*-condensed PAH6s.

three-ring structures of fourteen carbon vertices (**11′**−**13′**) and, therefore, only three corresponding benzenoid PAH6 structures of the formula $C_{40}H_{16}$ with N_{iC} = 14 exist. The Fig. 1 formula of $C_{42}H_{16}$ (N_{iC} = 16) has only one possible structure, circumpyrene, since the excised internal structure corresponds to pyrene (**14′**), which is the only arrangement possible for sixteen carbon vertices of four hexagonal rings.

All benzenoid PAH6 structures of the formula of $C_{48}H_{18}$ have N_{iC} = 18 and excision of their internal structures leads to three ethenylpyrene, (**15′**−**17′**), nine nonradical pyrenylquinodimethane (**18′**−**25′** and **36′**), six perianthracenylmethylene (**26′**−**31′**), naphthacene (**32′**), chrysene (**33′**), benzo(*a*)anthracene (**34′**), and triphenylene (**35′**) isomers of four rings and eighteen carbon vertices. The excised internal structures (Fig. 3) corresponding to PAH6s of the formula $C_{50}H_{18}$ (N_{iC} = 20) lead to benzo(*a*)pyrene, (**37′**), benzo(*e*)pyrene (**38′**), four methylene-substituted isomers of naphtho[2,1,8,7-*defg*]anthracene (**39′**−**42′**), and perylene (**43′**) ($C_{20}H_{12}$). The formula $C_{52}H_{18}$ (N_{iC} = 22) has only two excised internal isomeric structures, anthanthrene (**44′**) and benzo(*ghi*)perylene (**45′**) ($C_{22}H_{12}$), and therefore the benzenoid formula of $C_{52}H_{18}$ has only two corresponding PAH6 isomers. Finally, the formula of $C_{60}H_{20}$ (N_{iC} = 26) has 20 nonradical excised internal isomeric structures of twenty-six carbon vertices and seven rings (**46′**−**65′**) which correspond to 20 PAH6s.

Usually all isomers of *peri*-condensed benzenoid PAH6 isomers without *cata*-condensed appendages can be enumerated by finding all excised nonradical isomeric internal structures of N_{iC} (parent) carbon vertices. The limitations associated with this method can be illustrated by the enumeration of all eight non-radical isomers of $C_{28}H_{14}$. All the PAH6 isomers of $C_{28}H_{14}$ (N_{iC} = 6) and their corresponding excised internal structures are presented in Fig. 4. The first isomer, benzocoronene, has the same excised internal structure, benzene, as coronene and illustrates that *cata*-condensed appendages are not revealed by the excised internal structure method; this first $C_{28}H_{14}$ isomer has the only excised internal structure which is a ring, suggesting an implicit disconnection elsewhere. The next four isomers have excised internal structures corresponding to all possible conformations of 1,3,5-hexatriene that do not have less than two-carbon-atom gaps. Immediately following are the two isomers having the two conformations of 3-methylene-1,4-pentadiene as excised internal structures. Finally, the last two $C_{28}H_{14}$ benzenoid isomers have diradical excised internal structures. The first diradical can be constructed by the union of two allyl radicals through their nonstarred positions and the latter one by attaching the nonstarred position of one to the starred position of the other. Since the first diradical has two mutually exclusive $p\pi$-electron systems and the latter one does not, the corresponding PAH6 structure of the first diradical internal structure is nonradical (closed shell) and the corresponding PAH6 structure of the latter one is also a diradical (open shell) and is not included in the isomer count.

Above it was shown that the formula $C_{22}H_{12}$ had only two nonradical isomers, anthanthrene and benzo(*ghi*)perylene, with the corresponding internal excised structures of *s-trans*-1,3-butadiene and *s-cis*-1,3-butadiene (Fig. 2), respectively.

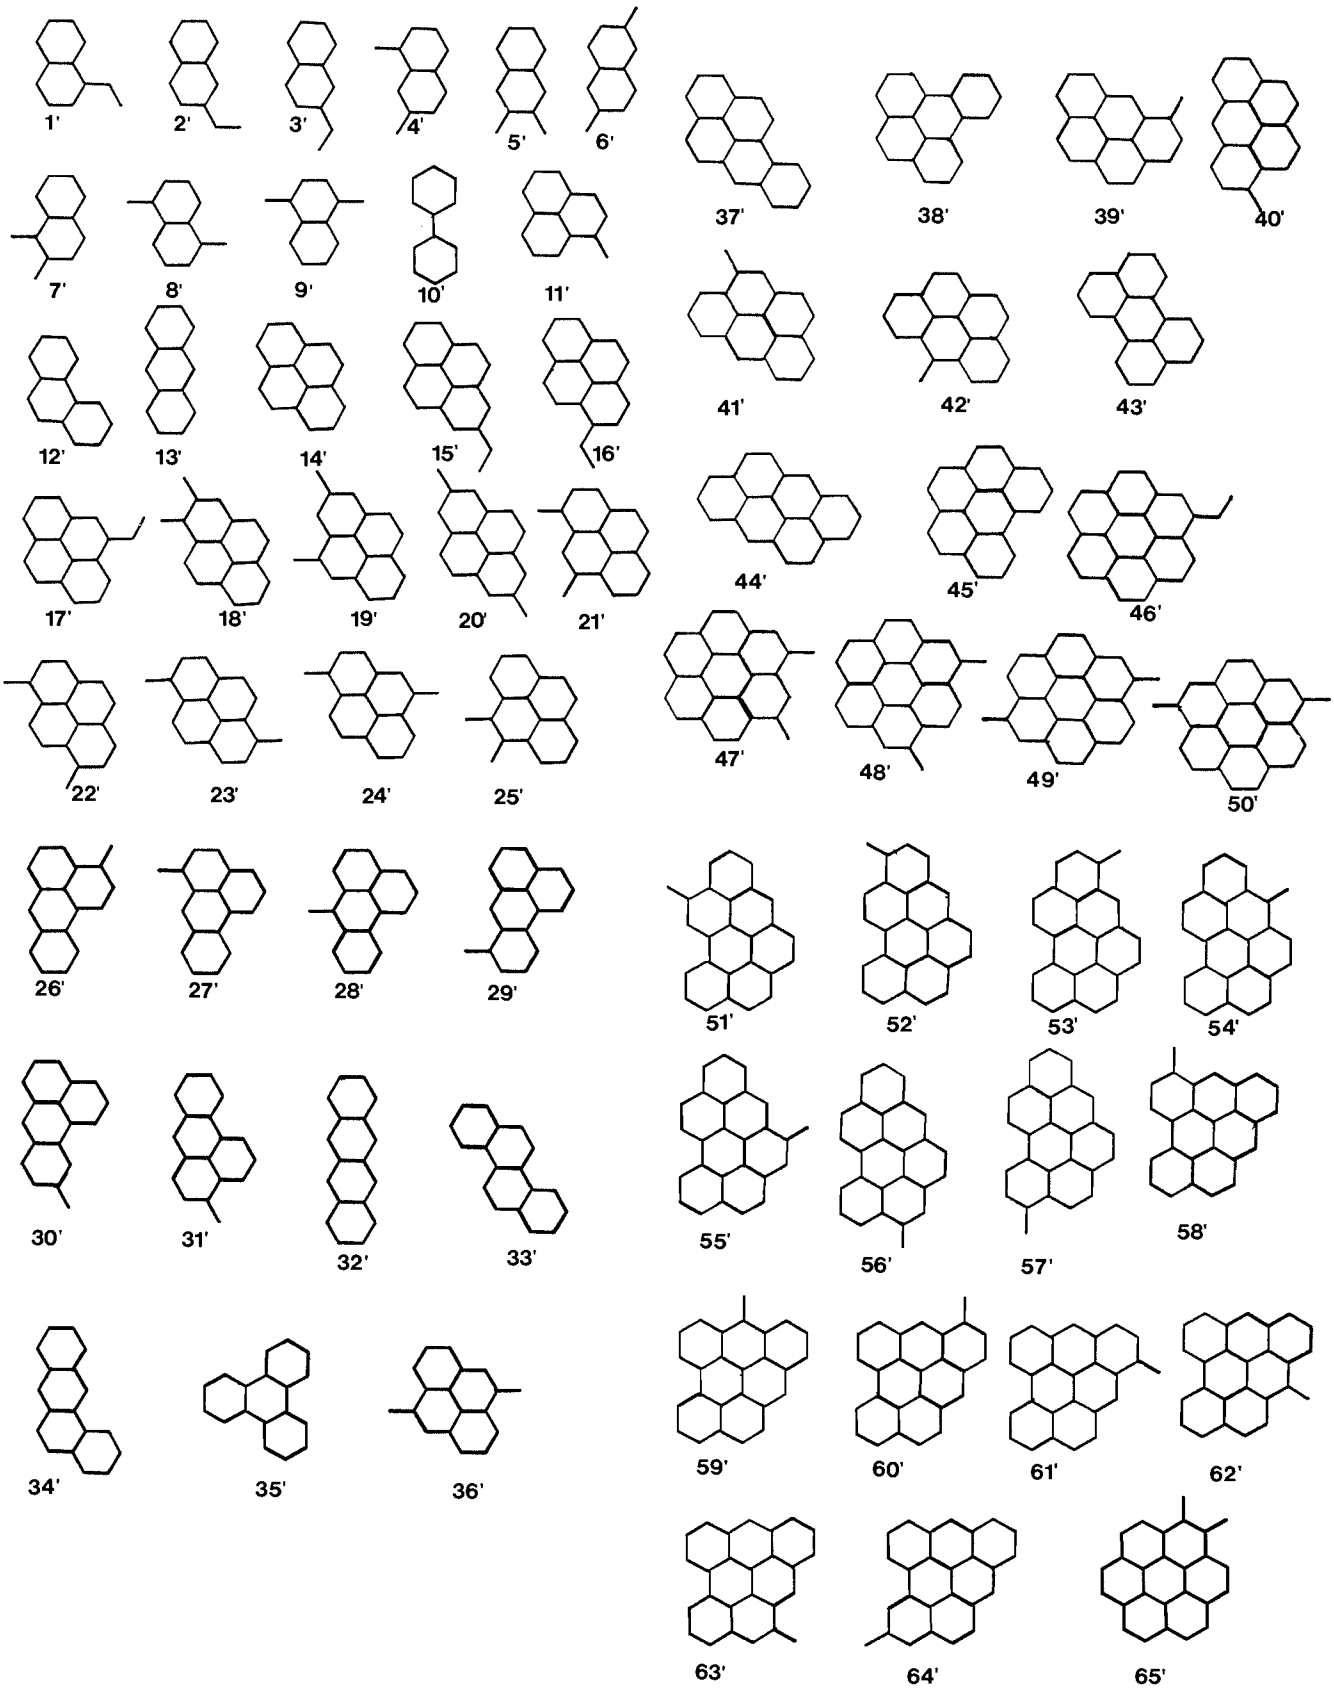

FIG. 3. Excised internal structures corresponding to the benzenoid PAH6 compounds in Fig. 2.

Anthanthrene and benzo(*ghi*)perylene are the excised internal structures of the two isomeric benzenoid hydrocarbons having the formula of $C_{52}H_{18}$ (Fig. 1); similarly, these isomeric $C_{52}H_{18}$ structures are the excised internal structures of the two benzenoid structures of the formula of $C_{94}H_{24}$, which in turn are the internal excised structures of the two benzenoid structures of the formula $C_{148}H_{30}$ (Fig. 5). There are three nonradical isomers of the formula $C_{30}H_{14}$, and these are the excised internal struc-

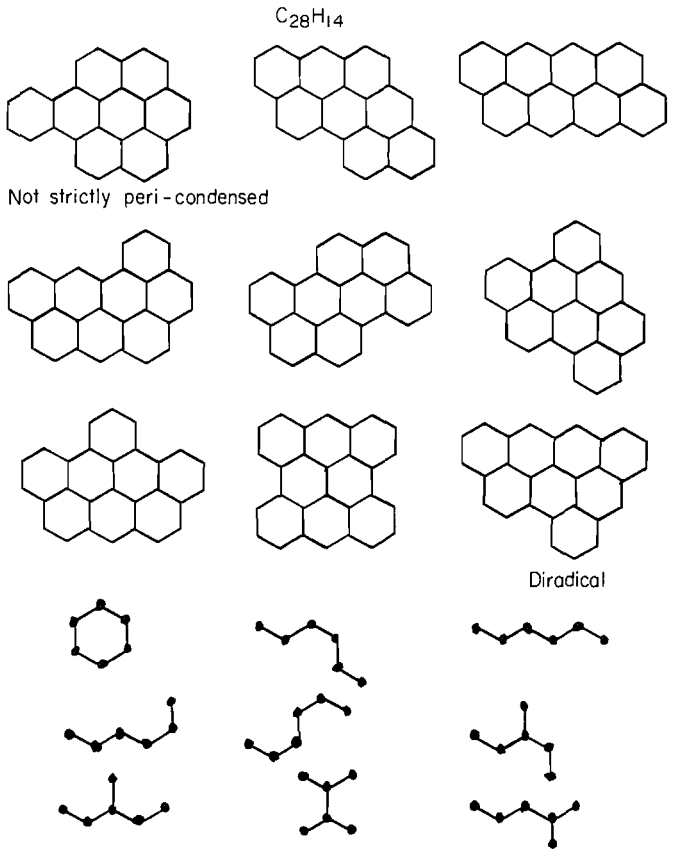

FIG. 4. All the benzenoid isomers of $C_{28}H_{14}$ and their corresponding excised internal structures.

tures of the benzenoid hydrocarbons having a formula of $C_{64}H_{20}$ (Fig. 6), which in turn are the excised internal structures associated with benzenoid hydrocarbons of the formula $C_{110}H_{26}$. Table 3 presents a summary of these polycircum two- and three-isomer series. Other polycircum isomeric series include $C_{40}H_{16}$, $C_{78}H_{22}$, $C_{128}H_{28}$ – where each of these formulas have 3 corresponding nonradical PAH6 isomers, and $C_{50}H_{18}$, $C_{92}H_{24}$, $C_{146}H_{30}$, – each having 7 corresponding nonradical PAH6 isomers.

Recognition of peri-*condensed diradical benzenoids*

Inspection of the diradical excised internal structures of triangulene, $C_{28}H_{14}$, and $C_{30}H_{14}$ reveals the following general principle for recognizing when even-carbon *peri*-condensed benzenoid hydrocarbons will be diradicals. If trimethylenemethane diradical is ultimately obtained upon successive excision and pruning of a specified benzenoid hydrocarbon having a formula below the $N_C = 2N_H - 4$ row series in Table 1, then that original benzenoid hydrocarbon is also a diradical. The trimethylenemethane diradical is the excised internal structure of triangulene and is also obtained by pruning off the even-carbon fragments of ethene from 2-methylenepentadienyl diradical (Fig. 4) and *s-trans*-butadiene from 1,3-benzoquinodimethane (Fig. 2). This recognition generalization is equivalent to taking the difference in opposing triangles generated by the corresponding dualist graph where a line is drawn from every point located at the center of all hexagons (8).

A simplified nomenclature for strictly peri-*condensed benzenoid hydrocarbons*

Successive excision of all strictly *peri*-condensed PAH6s

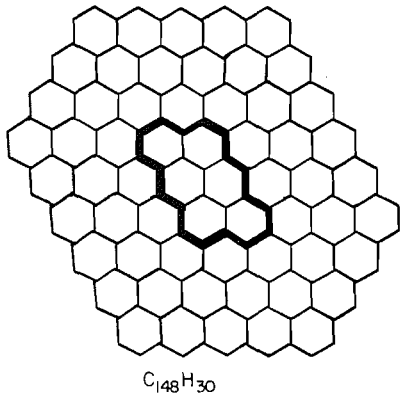

FIG. 5. Three successive excisions of $C_{148}H_{30}$ lead to isomers of anthanthrene.

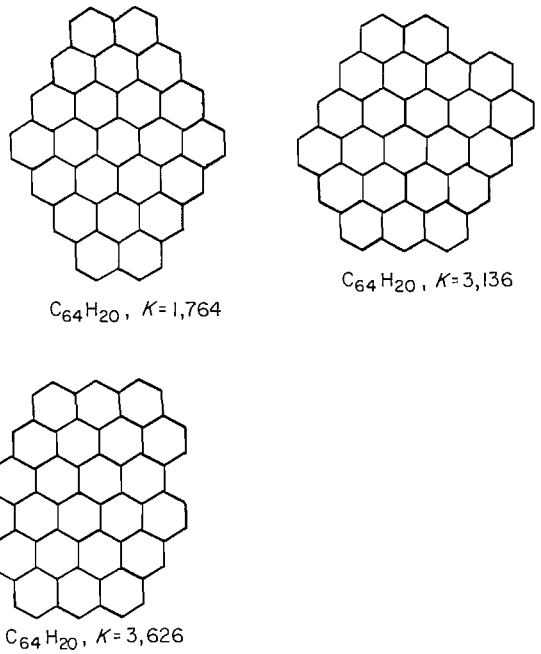

FIG. 6. The three nonradical isomers of $C_{64}H_{20}$.

usually leads to a simpler molecule which already has a standard nomenclature. Thus a straightforward nomenclature of complicated *peri*-condensed benzenoid hydrocarbons can be developed by using the corresponding excised internal structure for the parent name. Consider structure **60** in Fig. 1, which has structure **60′** in Fig. 3 as its corresponding excised internal structure. One name for this excised internal structure could be 9-methylenylbenzo(*fg*)anthanthrene, and the name of the corresponding $C_{60}H_{20}$ structure could be circum(34)[9-methylenylbenzo(*fg*)anthanthrene] where the number in parentheses after the "circum" prefix represents the number of peripheral carbon vertices circumscribed to the parent. This nomenclature would be deductively more obvious than the perifusene/dualist graph/three-digit coding nomenclature and its graphite lattice model variant previously proposed (9–11).

Computation of the number of Kekulé structures associated with strictly peri-*condensed benzenoids*

Since the logarithm of the structure count (number of Kekulé structures or 1-factor subgraphs) of benzenoid PAHs has been shown to be proportional to resonance energy, the structure count (SC = K) of the isomers shown in Fig. 1 was determined

[a]Reference 17.

(12). The computational procedure used consisted of the reduction of a given PAH6 into smaller PAH6 fragments of known structure count (13). A number of generalizations are made evident by comparison of the structure counts of the PAHs shown in Figs. 1, 2, and 6. The numerical order of the number of Kekulé structures associated with a set of isomers of strictly *peri*-condensed PAH6s parallels the numerical order of their corresponding excised internal PAH6 structures. For example, the two benzenoid isomers of $C_{52}H_{18}$ have K = 490 and 805 and their excised internal structures of anthanthrene and benzo(*ghi*)perylene have K = 10 and 14, respectively. Other things being equal, the more concave bay regions contained by a PAH6 structure, the larger the structure count. A strictly *peri*-condensed PAH6 has the same number of concave bay regions as its internal excised PAH6 structure; if its internal excised structure is not a PAH6, then its number of concave bay regions is determined by the number of distinct *s-cis*-1,3-butadiene substructures (subgraphs) present in its excised internal structure. For example, benzo(*ghi*)perylene has one bay region and its circumscribing $C_{52}H_{18}$ structure has one bay region, and anthanthrene has no bay region and its circumscribing $C_{52}H_{18}$ has no bay region (Fig. 5); the internal excised structure of benzo(*ghi*)perylene is *s-cis*-butadiene, and the excised internal structure of anthanthrene is *s-trans*-butadiene.

Conclusion

Isomer enumeration of strictly *peri*-condensed benzenoid hydrocarbons can be more easily achieved via enumeration of their excised internal structures. The formulas corresponding to strictly *peri*-condensed benzenoids can be easily identified as the left-hand diagonal boundary formulas found in the Formula Periodic Table for PAH6; these boundary formulas cannot have corresponding structures with benzo *cata*-condensed appendages, whereas the formulas immediately adjacent have some corresponding isomeric structures with benzo *cata*-condensed appendages not explicitly revealed by the excised internal structure. The (successive) excised internal structures of strictly *peri*-condensed PAH6 hydrocarbons result in simpler structures with existing standard nomenclature which can be utilized as parent names for the more complicated PAH6 derived by circumscribing them with peripheral carbon rings in a successive fashion. This need for research on very large benzenoid hydrocarbons has been pointed out by a definitive prior paper on this subject (14). Since the logarithm of the number of Kekulé structures is proportional to resonance energy and many PAH6 benzenoid compounds are produced via pyrolytic and combustion processes, the structures of the most probable macromolecular benzenoid isomers of this class formed via pyrolytic processes can be estimated from the listing of compounds in Fig. 1 (15). Strictly *peri*-condensed benzenoid hydrocarbons have totally connected internal edges and become more predominant as one moves from right to left in Table 1.

Appendix: Glossary of terms

d_s:	net tree disconnections of internal graph edges (positive values) or connections (negative values − called negative disconnection)
N_C:	total number of carbon atoms in a PAH
N_H:	total number of hydrogen atoms in a PAH
N_{iC}:	number of internal carbon atoms in a PAH having a degree of 3
N_{pC}:	number of peripheral carbon atoms in a PAH having a degree of 3
PAH6:	polycyclic aromatic hydrocarbon containing exclusively fused hexagonal rings
$\|P\|=p=N_C$:	total number of graph points
p_3:	number of graph points (vertices) having a degree of 3
$\|Q\|=q$:	number of graph edges (lines or C—C bonds)
q_i:	number of internal graph edges
q_p:	number of peripheral graph edges
r:	number of rings
τ:	number of rings obtained upon deletion of all internal third-degree vertices from a PAH6 σ-bond graph

Kinetics and mechanism of the reaction of iodine with isonicotinoylhydrazide

IRENE A. FUNAI AND MIGUEL A. BLESA[1]

Departamento Química de Reactores, Comisión Nacional de Energía Atómica, Avenida del Libertador 8250, 1429 Buenos Aires, Argentina

Received December 7, 1983[2]

IRENE A. FUNAI and MIGUEL A. BLESA. Can. J. Chem. **62**, 2923 (1984).

The title reaction proceeds through two parallel pathways involving attack by IOH (k_{14} = (5.69 ± 0.97) × 10^8 mol^{-1} dm^3 s^{-1}) and by I_2 (k_{13} = 0.31 ± 0.11) mol^{-1} dm^3 s^{-1}) on $^+HNC_5H_4C(O)NHNH_2$ (INAH). These results are similar to those of Hasty on the system N_2H_4 + I_2, but differ from the mechanisms proposed by Cooper and Bah and Yew for similar systems. Because k_{14} is close enough to (though significantly less than) the diffusion limit, our data permit us to estimate the first-order rate constant for I_2 hydrolysis, obtaining in reasonable agreement with previous data k_5 = 0.33 s^{-1} at pH = 1.66. The general kinetic law is shown to give rise to an [R-NH-NH_2] independent pathway of oxidation at sufficiently high pH. A mechanism is proposed to explain the much higher reactivity of IOH (as compared to I_2) towards R-NH-NH_2.

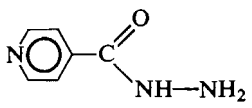
IRENE A. FUNAI et MIGUEL A. BLESA. Can. J. Chem. **62**, 2923 (1984).

La réaction mentionnée dans le titre peut se produire par le biais de deux voies parallèles impliquant des attaques soit du IOH (k_{14} = (5,69 ± 0.97) × 10^8 mol^{-1} dm^3 s^{-1}) ou du I_2 (k_{13} = 0.31 ± 0.11) mol^{-1} dm^3 s^{-1}) sur la $^+HNC_5H_4C(O)NHNH_2$ (INAH). Ces résultats sont semblables à ceux obtenus par Hasty sur le système N_2H_4 + I_2; ils diffèrent toutefois des mécanismes proposés par Cooper et Bah et Yew pour des systèmes similaires. La valeur de k_{14} étant proche (quoique plus basse d'une façon significative) de la limite de diffusion, nos données nous permettent d'évaluer la constante de vitesse du premier ordre pour l'hydrolyse du I_2 et d'obtenir une valeur en bon accord avec la constante k_5 = 0,33 s^{-1} (à un pH de 1,66) rapportée antérieurement. On montre que la loi cinétique générale donne lieu, à des pH suffisamment élevés, à des voies d'oxydation qui ne dépendent pas de la concentration en R-NH-NH_2. On propose un mécanisme pour expliquer la réactivité beaucoup plus grande du IOH (comparée à celle du I_2) vis-à-vis le R-NH-NH_2.

[Traduit par le journal]

Introduction

It is well known that iodine quantitatively oxidizes substances containing the —NH—NH_2 group. This reaction is the basis of one of the standard analytical procedures to titrate hydrazine and related substances, in particular isonicotinoylhydrazide (isoniazid, INAH),



which is widely used in the pharmaceutical industry because of its bacteriostatic properties against *Mycobacterium tuberculosis*. The rate of the oxidation reaction is very sensitive to all variables which affect the speciation of both reagents in solution, and thus the rate may vary widely according to the chemistry of the solution. In the present paper we report the results of a kinetic study of the oxidation of INAH by iodine, which is important per se and also helps to shed light on the general mechanisms of oxidation of the —NH—NH_2 function by iodine.

The mechanism of oxidation of hydrazine itself by iodine has been the subject of several studies, among which no complete agreement is found. Thus, Hasty (1) reports the rate law

$$[1] \quad R = k_a [N_2H_5^+][I_2] + k_b [N_2H_5^+][HIO]$$

the second term accounting for the largest fraction of reaction under experimental conditions (large excess of iodide and pH values in the range 1–2). The values for k_a and k_b are found to be ca. 1.0 dm^3 mol^{-1} s^{-1} and 2 × 10^9 dm^3 mol^{-1} s^{-1} which are interpreted as indicative of IOH being the most active among the various oxidized iodine species (HIO, I_2, I_3^-, I_5^-). According to this study, iodine itself also reacts with $N_2H_5^+$, and because $[I_2] \gg [IOH]$, the contribution to the overall rate of the first term in eq. [1] is not negligible.

On the other hand, Cooper and co-workers (2) propose a different mechanism, involving only I^+ and N_2H_4 in the activated state. This is reached from a pre-equilibrated $N_2H_4I^+$ species, the concentration of which is sensitive to I^-:

$$[2] \quad N_2H_4 + I_2 \rightleftarrows N_2H_4I^+ + I^-$$

$$[3] \quad N_2H_4I^+ \rightarrow \text{products}$$

$$[4] \quad R = \frac{k_3k_2 [N_2H_4] [I_2]}{k_{-2} [I^-] + k_3}$$

Because of the relationship between [IOH] and $[I_2]$ (eq. [5], $Q_5 = 4.83 \times 10^{-13}$) (ref. 3),

$$[5] \quad I_2 + H_2O \rightleftarrows IOH + I^- + H^+$$

and between $[N_2H_4]$ and $[N_2H_5^+]$ (eq. [6], $K_6 = 10^{-7.98}$) (ref. 4),

$$[6] \quad N_2H_5^+ \rightleftarrows N_2H_4 + H^+$$

both mechanisms are in fact compatible with the same set of experimental data; part of the difficulty is due to the similar pH dependency of [5] and [6] in the pH range of the kinetic studies, where $[IOH] \propto [H^+]^{-1}$ and $[N_2H_4] \propto [H^+]^{-1}$ (furthermore, the proportionality constants are not very different). Kinetic data indicate only a deprotonation equilibrium generating a reactive species at high pH values.

References 1 and 2 both agree in the existence of pathways which at high enough $[I^-]$ become proportional to $[I^-]^{-2}$, although the origin of this dependency is variously attributed to equilibrium [2] (2) or to equilibrium [5] (1), which together with

$$[7] \quad I_3^- \rightleftarrows I_2 + I^- \qquad Q_7 = (736)^{-1}$$

explains the observed partial order. Other authors (5) in turn

find a dependence on $[I^-]^{-1}$, giving rise to a third proposed rate law

[8] $R = k_8 [N_2H_4][I_2]$

attributed to the direct attack of I_2 on N_2H_4 as the rate-determining step. According to Hasty (1), the overall mechanism includes both the attack by IOH and by I_2 on hydrazine, although the $[H^+]$ dependency of this latter pathway is diversely reported to be of order −1 (5) or zero (1); the difference can be traced back to different assumptions as to the relative reactivities of $N_2H_5^+$ and N_2H_4.

Experimental

Analytical reagents were employed without further purification. INAH was a gift from G. Ramón Laboratories, Buenos Aires, and was recrystallized several times from doubly distilled ethanol in the presence of activated charcoal. All solutions were prepared with doubly distilled water. Iodine solutions were standardized with sodium thiosulfate.

Spectrophotometric measurements were carried out in a Hitachi–Perkin–Elmer 139 spectrophotometer fitted with thermostated cell compartments.

The kinetics of the reaction were followed by measuring the decrease in absorbance at 390 nm, 24.9°C, and I = 1 mol dm^{-3} (NaCl). The measurements were not made at 352 nm (λ_{max} of I_3^-) because, at this wavelength, background absorbance was inconveniently high.

A typical kinetic experiment was performed as follows: HCl and NaCl solution (Reagent A) and KI, I_2, and NaCl solution (Reagent B) were prepared. Solid INAH was dissolved in Reagent A and Reagent B was poured over it. The initial (analytical) concentration of iodine ($F^0_{I_2}$) was ca. 1.1×10^{-4} mol dm^{-3}. INAH and KI were in high excess over I_2. F_{INAH} and F_{I^-} were in the ranges $5 \times 10^{-3} - 5 \times 10^{-2}$ mol dm^{-3} and $1 \times 10^{-2} - 4 \times 10^{-2}$ mol dm^{-3} respectively, and were constant during each experiment. The pH was also constant during those runs without need of buffers because of the high acidities. In different experiments, pH varied in the range 1.3–2.0.

From the absorbance–time data, very good pseudo-first-order plots were obtained: $\log [(A_0 - A)/(A - A_\infty)]$ was a linear function of time for up to 5 half-lives. The reported k_{obsd} values were obtained from the slopes of the plots of duplicate experiments. No complications due to the formation of $^+HNC_5H_4C(O)HNNH(O)CC_5H_4NH^+$ were detected because, in the presence of a large excess of INAH, I_2 reacts quantitatively with the original reagent.

Results

The experimental rate constants k_{obsd} (eq. [9])

[9] $k_{obsd} = [I_3^-]^{-1} (-d[I_3^-]/dt) = F_{I_2}^{-1} (-d[I_3^-]/dt)$

are shown in Tables 1–3. Because of the large excess of I^-, the total analytical iodine concentration is identical to the actual I_3^- concentration in all the experiments.

The data in Table 1 show that the reaction is first order in INAH at pH = 1.66; similar results are found at other pH values, the rate increasing with increasing pH in the pH range 1.3–2.0 (see Table 2). The high sensitivity to pH is similar to that observed for N_2H_4. Table 3 gives the relationship between rate and F_{I^-}.

TABLE 1. Dependency of k_{obsd} on F_{INAH}; $F_{I^-} = 2 \times 10^{-2}$ mol dm^{-3}; pH = 1.66; t = 24.9°C; I = 1 mol dm^{-3} (NaCl). The data fit the equation $k_{obsd} = 4.52 \times 10^{-2}$ mol^{-1} dm^3 s^{-1} F_{INAH} with ρ = 0.9868

Discussion

In the presence of large excess of INAH, I_2 is quantitatively reduced according to eq. [10] (6).

[10] R—C(O)NH—NH$_2$ + $2I_3^-$ + H_2O → R—C(O)OH + N_2 + $6I^-$ + $4H^+$

Benzoic acid may further react with excess isoniazid, eq. [11] (6).

[11] R—C(O)NH—NH$_2$ + HO(O)C—R → R—C(O)NH—NH(O)C—R + H_2O

but this reaction is irrelevant for our study. The stoichiometry of the reaction is therefore similar to that of $I_2 + N_2H_4$.

In view of the proposed mechanisms for the $I_2 + N_2H_4$ reaction, our data will be analyzed in terms of a general set of elementary equations, involving attack by both I_2 and IOH. I_3^- and I_5^- can safely be disregarded because of the inhibitory effect of iodide (Table 3).

[5a] $I_2 + H_2O \xrightarrow{k_5} IOH + I^- + H^+$

[5b] $IOH + I^- + H^+ \xrightarrow{k_{-5}} I_2 + H_2O$

[7] $I_3^- \rightleftarrows I_2 + I^-$ $\quad Q_7 = (736)^{-1}$ (ref. 3)

[12] 
pK_a (INAH) = 1.85 (ref. 7)

[13] INAH + $I_2 \xrightarrow{k_{13}}$ products

[14] INAH + IOH $\xrightarrow{k_{14}}$ products

Thus,

[15] $-1/2 dF_{I_2}/dt = -1/2\ d\ [I_3^-]/dt = -d\ [INAH]/dt = \{k_{13}\ [I_2]\ [INAH] + k_{14}\ [IOH][INAH]\}$

The general expression for k_{obsd} under this mechanism is [16]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

$$[16]\quad k_{obsd} = 2\left\{k_{13} + \frac{k_{14}}{\left(\frac{F_{I^-}\,[H^+]}{Q_5} + \frac{k_{14}\,[INAH]}{k_5}\right)}\right\} \frac{[INAH]}{\left\{F_{I^-}Q_7^{-1} + 1 + \frac{1}{\left[\frac{F_{I^-}\,[H^+]}{Q_5} + \frac{k_{14}\,[INAH]}{k_5}\right)}\right\}}$$

where

$$[17]\quad [INAH] = F_{INAH}\,K_a\,(K_a + [H^+])^{-1}$$

Two limiting assumptions can be identified by inspection of the terms in eq. [16]:

$$[18]\quad k_{13} \ll k_{14}\,k_5\,(k_{-5}\,F_{I^-}\,[H^+] + k_{14}\,[INAH])^{-1}$$

$$[19]\quad k_{14}\,[INAH] \ll k_{-5}\,F_{I^-}\,[H^+]$$

Previous work on $I_2 + N_2H_4$ has accepted [19] as a general assumption, while the ratio of the I_2 to the IOH-pathway is a matter of controversy. It must be noted, however, that the second assumption is incorrect at high pH values, and even in the pH range 1–2 the error involved may be significant if k_{14} approaches diffusion control.

Our set of data was fitted to eq. [16] by a nonlinear least-squares fitting method. According to ref. 8, for the hydrolysis of I_2 the following scheme and rate constants apply:

$$[20]\quad I_2 + H_2O \underset{1.6 \times 10^{10}\ mol^{-1}\ dm^3\ s^{-1}}{\overset{2.1\ s^{-1}}{\rightleftharpoons}} I_2OH^- + H^+$$

$$[21]\quad I_2OH^- \underset{5 \times 10^{9}\ mol^{-1}\ dm^3\ s^{-1}}{\overset{3 \times 10^{7}\ s^{-1}}{\rightleftharpoons}} IOH + H^+$$

whence

$$[22]\quad k_5^{lit} = \frac{2.1 \times 3 \times 10^7}{(1.6 \times 10^{10}\,[H^+] + 3 \times 10^7)}\ s^{-1}$$

Rather than using this expression for k_5, taken from the work of Eigen and Kustin (8), k_5 was left as another adjustable parameter and the obtained values used as a check of the procedure by comparison with literature data. Our result agrees within a factor of 2 with the Eigen and Kustin data. These in fact refer to 20°C, and kinetic $Q_5 = k_5/k_{-5}$ does not agree with equilibrium measurements at 25°C. In terms containing (k_5/k_{-5}) we have used the equilibrium value; otherwise, kinetic k_5 values were used. These results are summarized in Table 4, which gives the values of k_{13} and k_{14} obtained for various $n = (k_5^{fitted}/k_5^{lit})$, together with the corresponding standard deviations. The best fit is achieved with large n values; improvement by increasing n beyond 2 is only marginal, and therefore we have selected from our data: $k_5 = 0.33\ s^{-1}$ at pH = 1.66 (cf. $k_5^{lit} = 0.17\ s^{-1}$ as calculated from eq. [22]); $k_{13} = (0.31 \pm 0.11)\ mol^{-1}\ dm^3\ s^{-1}$; $k_{14} = (5.69 \pm 0.97) \times 10^8\ mol^{-1}\ dm^3\ s^{-1}$. The calculated standard deviations for k_{13} and k_{14} demonstrate that the rate is not overly sensitive to k_{13}, so that this parameter is affected by rather large error brackets.

In order to demonstrate that deviations from the assumed dependency on a given variable (F_{INAH}, F_{I^-}, or pH) are not blurred by the fitting to the given reaction scheme, we have taken advantage of the approximate validity of assumption [18] to plot k_{obsd}^{-1} vs. F_{INAH}^{-1} (at constant F_{I^-} and pH), $k_{obsd}^{-1}\,(Q_7^{-1}F_{I^-} + 1)^{-1}$ vs. F_{I^-} (at constant F_{INAH} and pH), and k_{obsd}^{-1} vs. $[H^+]\,(K_a + [H^+])$ (at constant F_{INAH} and F_{I^-}) to show the validity of eq. [23]–[25] which are obtained from [16], [17], and [18] by appropriate rearrangements, see Figs. 1–3.

$$[23]\quad \frac{1}{k_{obsd}} = \frac{1}{F_{INAH}}\left\{\frac{[H^+]\,\{K_a + [H^+]\}F_{I^-}\,(Q_7^{-1}F_{I^-} + 1)}{2k_{14}\,K_a\,Q_5}\right\} + \frac{(Q_7^{-1}F_{I^-} + 1)}{2k_5}$$

$$[24]\quad \frac{1}{k_{obsd}(Q_7^{-1}F_{I^-} + 1)} = F_{I^-}\left\{\frac{[H^+]\,\{K_a + [H^+]\}}{2k_{14}\,K_a\,Q_5\,F_{INAH}}\right\} + \frac{1}{2k_5}$$

$$[25]\quad \frac{1}{k_{obsd}} = [H^+]\,\{K_a + [H^+]\}\left\{\frac{F_{I^-}\,(Q_7^{-1}F_{I^-} + 1)}{2k_{14}\,K_a\,Q_5\,F_{INAH}}\right\} + \frac{(Q_7^{-1}F_{I^-} + 1)}{2k_5}$$

Values of k_{14} and k_5 from the slopes and intercepts are given in Table 5 as a check for internal consistency. The differences are related to the use of approximation [18]. Note in [25] that k_5 should in fact be pH dependent; however, a good straight line is found for a limited range in $[H^+]$ (Fig. 3).

Conversely, accepting [19], eq. [16] leads to [26] and [27]. From the intercepts and slopes of the corresponding linear plots, values of k_{14} and k_{13} are obtained (Table 6), which illustrate the errors involved in [19].

$$[26]\quad k_{obsd}\,(Q_7^{-1}F_{I^-} + 1) = \frac{1}{F_{I^-}}\left\{\frac{2k_{14}\,K_a\,Q_5\,F_{INAH}}{[H^+]\{K_a + [H^+]\}}\right\} + \frac{2k_{13}\,K_a\,F_{INAH}}{\{K_a + [H^+]\}}$$

$$[27]\quad k_{obsd}\,\{K_a + [H^+]\} = \frac{1}{[H^+]}\left\{\frac{2k_{14}\,K_a\,Q_5\,F_{INAH}}{F_{I^-}\,(Q_7^{-1}F_{I^-} + 1)}\right\} + \frac{2k_{13}\,K_a\,F_{INAH}}{(Q_7^{-1}F_{I^-} + 1)}$$

Our data indicate that both IOH and I_2 are capable of oxidizing INAH. The relative importance of both reagents is essentially dominated by the low concentrations of IOH in the pH range studied, as k_{14} approaches the diffusion controlled limit. The ratio $[k_{13}/(k_{13} + k_{14}k_5\,(k_{-5}\,F_{I^-}\,[H^+] + k_{14}\,[INAH])^{-1})]$ gives the fractions of INAH which is oxidized by I_2; this value is in the range 0.22–0.67, the highest value corresponding to the highest $[H^+][I^-]$ value used in this study.

$k_{obsd} \times 10^4$ (s^{-1})	F_{I^-} (mol dm^{-3})
23.7	0.010
7.77	0.020
3.80	0.030
2.96	0.035
2.34	0.040

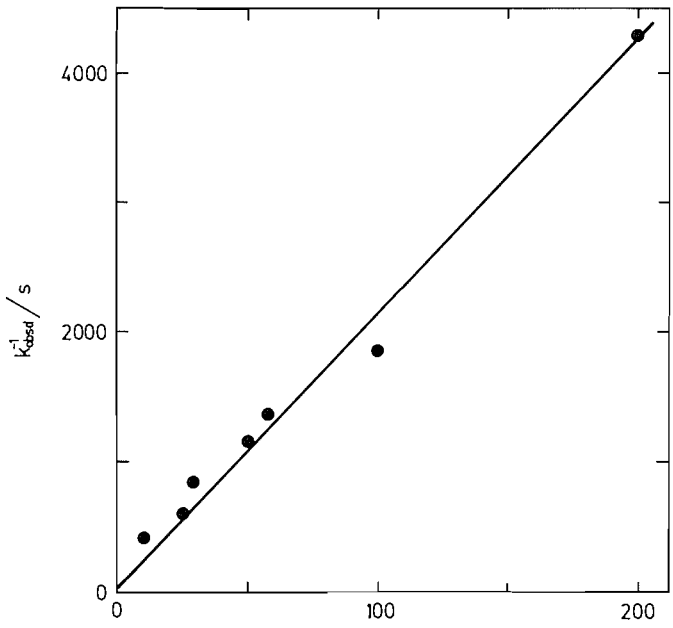

FIG. 1. k_{obsd}^{-1} as function of F_{INAH}^{-1}; $F_{I^-} = 2 \times 10^{-2}$ mol dm^{-3}; pH = 1.66; t = 24.9°C; I = 1 mol dm^{-3} (NaCl).

The value obtained for k_{14} is of the same order of magnitude as that calculated from Hasty's data (1) for:[3]

[28] $IOH + N_2H_4 \rightarrow$ products

This is reasonable in view of the high reactivity; it should be noted, however, that k_{14}, although close to the diffusion limit, is significantly below it. IOH discriminates between reacting with I^- ($+H^+$) and with R—NH—NH_2 in favour of the former for all our experimental conditions, where $[k_{-5} F_{I^-} [H^+]/k_{14} \times [INAH]] > 1$. On the other hand, it is interesting to note that under the conditions of the usual INAH titration procedure $k_{14}[INAH] > k_{-5} F_{I^-} [H^+]$, and thus the value of k_{obsd} (eq. [16]) would reduce to

$$[29] \quad k_{obsd} = 2[k_5 + k_{13} K_a F_{INAH} (K_a + [H^+])] (Q_7^{-1} F_{I^-} + 1)^{-1}$$

the IOH pathway being thus controlled by the hydrolysis of I_2 (eq. [5a]), and becoming zero order in INAH. It should also be noted that the values of the equilibrium quotients $Q_7 = (736)^{-1}$ and $Q_5 = 4.83 \times 10^{-13}$ are obtained from ref. 3, while $(k_7/k_{-7}) = (539)^{-1}$ and $(k_5/k_{-5}) = 6.82 \times 10^{-13}$ result from the

[3]From the data in Table 4 of ref. 1, the value $k_{28} = 2 \times 10^9$ mol dm^{-3} s^{-1} is obtained; this seems to be the correct value rather than that of 7×10^7 mol dm^{-3} s^{-1} later quoted in the same paper for $2k_{28}$.

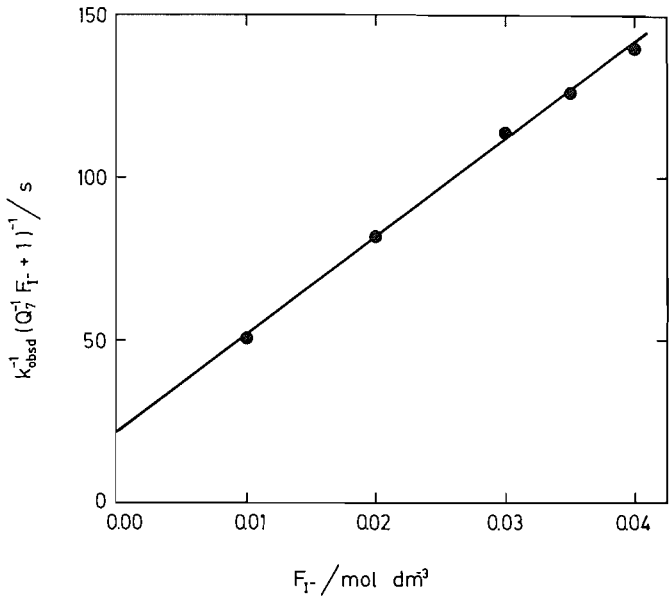

FIG. 2. $k_{obsd}^{-1} (Q_7^{-1} F_{I^-} + 1)^{-1}$ as function of F_{I^-}; $F_{INAH} = 2 \times 10^{-2}$ mol dm^{-3}; pH = 1.61; t = 24.9°C; I = 1 mol dm^{-3} (NaCl).

kinetic study of these reactions (8, 9). Furthermore, it has been suggested (3) that k_5 (and consequently k_5/k_{-5}) may be substantially larger. These errors are reflected directly in the value of k_{14}; we have chosen to use equilibrium data for Q_7 and Q_5 which are perhaps less uncertain, although sensitive to medium effects.

In part, the ambiguities in the interpretation of the data of the $I_2 + N_2H_4$ reaction arise from the pH dependency, which is consistent with either equilibrium [5] or [6].

In our system, replacement of one H by a nicotinoyl group allows us to avoid equilibrium [6] as a possible source of rate change with pH (protonation of the pyridine end is not likely to be of much influence); once the relevance of the R—NH—HN_3^+/R—NH—NH_2 equilibrium has been taken into account, it is still necessary to resort to a second pH-dependent equilibrium to explain our data, thus confirming the importance of IOH as oxidizer.

All the studies discussed thus far (including ours) yield information only on the composition of the activated state, in contrast with the information available for the oxidation of hydrazine with one-electron oxidants (known to take place via $N_2H_3^{\bullet}$ radicals or their organic analogs (10)). The nature of the species leading from R—NH—NH_2 to N_2 by reaction with I_2 is not known, but the very high ratios k_{14}/k_{13} (1.84×10^9 in our system, 2×10^9 in ref. 1) can be rationalized in terms of the following mechanism:

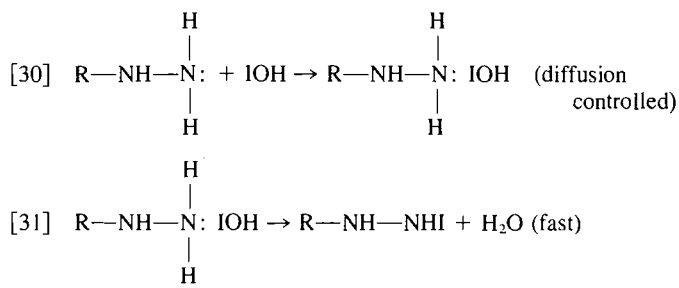

TABLE 4. Values of k_5, k_{13}, and k_{14} and their standard deviations from our experimental data

n*	$\sigma \times 10^4$ s^{-1}	k_{13} $mol^{-1}\ dm^3\ s^{-1}$	$\sigma_{k_{13}}$ $mol^{-1}\ dm^3\ s^{-1}$	$k_{14} \times 10^{-8}$ $mol^{-1}\ dm^3\ s^{-1}$	$\sigma_{k_{14}} \times 10^{-8}$ $mol^{-1}\ dm^3\ s^{-1}$

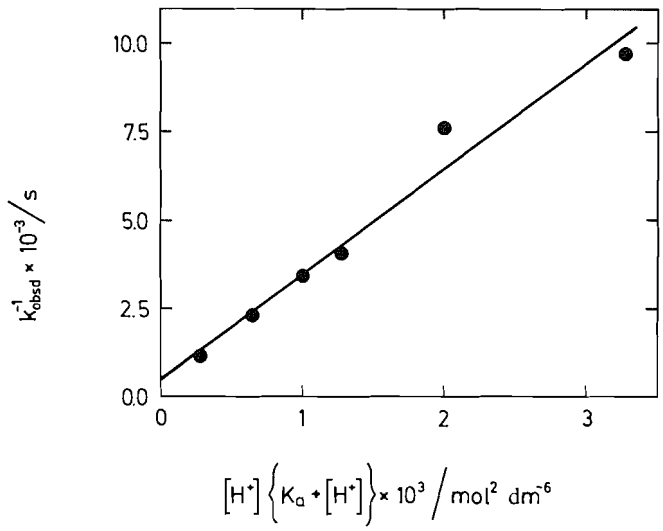

FIG. 3. k_{obsd}^{-1} as function of $[H^+]$ $(K_a + [H^+])$; $F_{INAH} = 2 \times 10^{-2}$ mol dm^3; $F_{I^-} = 3.5 \times 10^{-2}$ mol dm^3; $t = 24.9$°C; $I = 1$ mol dm^{-3} (NaCl).

TABLE 5. Estimations of k_{14} and k_5 from different sets of data, accepting approximation [18]

Equation	Variable	ρ	$k_{14} \times 10^{-8}$ $mol^{-1}\ dm^3\ s^{-1}$	k_5 s^{-1}
[23]	F_{INAH}	0.9954	8.75	0.25
[24]	F_{I^-}	0.9991	11.6	0.025
[25]	$[H^+]$	0.9835	11.5	0.025*

*See text. The nonlinear least-squares fitting method gives $k_{14} = (5.69 \pm 0.97) \times 10^8$ $mol^{-1}\ dm^3\ s^{-1}$.

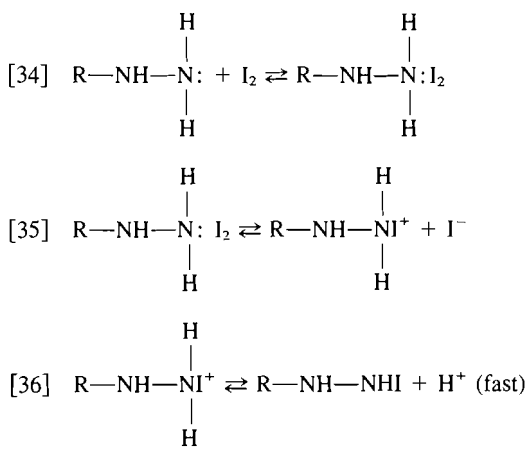

TABLE 6. Estimation of k_{14} and k_{13} from different sets of data, accepting approximation [19]*

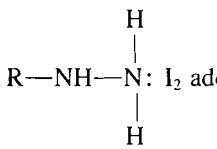
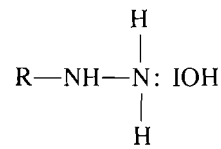
Equation	Variable	ρ	$k_{14} \times 10^{-8}$ $mol^{-1}\ dm^3\ s^{-1}$	k_{13} $mol^{-1}\ dm^3\ s^{-1}$
[26]	F_{I^-}	0.9977	5.85	0.22
[27]	$[H^+]$	0.9879	7.50	0.12

*The nonlinear least-squares fitting method gives $k_{14} = (5.69 \pm 0.97) \times 10^8$ $mol^{-1}\ dm^3\ s^{-1}$ and $k_{13} = (0.31 \pm 0.11)$ $mol^{-1}\ dm^3\ s^{-1}$.

The slower rate of I_2 could be due either to (*a*) the lower electrophilicity of I_2 as compared to IOH, which would make [34] reversible, as compared to irreversible [30]; or (*b*) the more difficult evolution of the possible



adduct (eq. [35]) as compared to



making more likely the reverse reaction [35].

In conditions of excess iodine, the stoichiometry of the initial reaction is described by eqs. [10] and [11]; thus, the analytical procedure for dosing INAH by I_2 according to ref. 6 prescribes a stoichiometry ratio $[I_2]/[INAH] = 1:1$ at 15-min reaction. By waiting longer, reaction [37] takes place:

[37] R-C(O)NH-NH(O)C-R + $2I_2$ + $2H_2O$ → 2R-C(O)OH + N_2 + $4I^-$ + $4H^+$

and therefore the ratio $[I_2]/[INAH] = 2:1$, as indicated for 90-min reaction in the U.S. Pharmacopaea (11). The kinetics of reaction [37] are currently being studied in our laboratories.

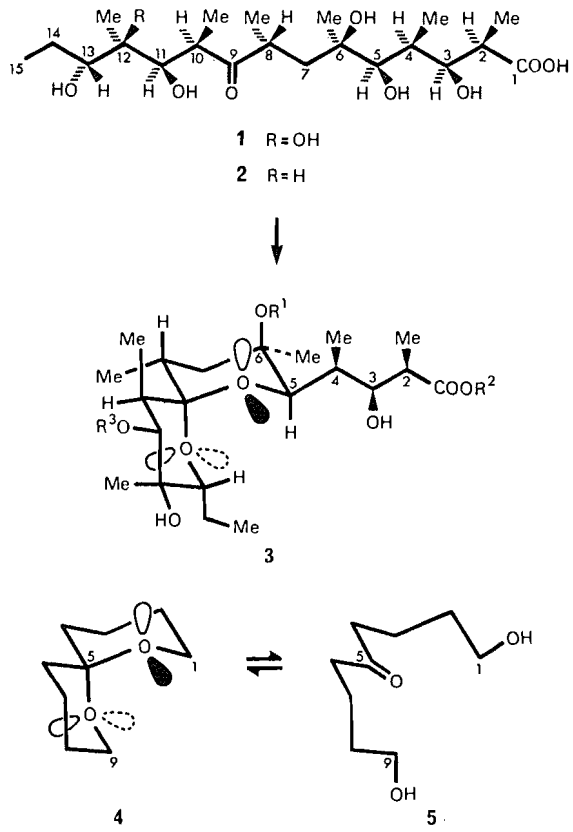
The macrolide antibiotics represent very appropriate target molecules to develop new strategies for the stereocontrolled synthesis of aliphatic chains containing several substituents and chiral centers. For instance, the total synthesis of erythromycin A has been reported by Woodward *et al.* (1) and several synthesis of the seco acid derivatives of erythronolide A (**1**) and B (**2**) have appeared in the literature (2) (Scheme 1).

A new strategy for the synthesis of erythromycin A and closely related macrolides has been developed in our laboratory.[2] This new approach to synthesis is based on the knowledge that the 1,7-dioxaspiro[5.5]undecane system is conformationally rigid, existing solely in conformation **4** (4, 5). In this conformation, steric effects are at their minimum and the acetal function has the maximum stabilizing stereoelectronic effects (3), i.e. two anomeric effects (6, 7). Consequently, the spiro system **4** can be viewed as an aliphatic chain (1,9-dihydroxyketone **5**) of nine carbon atoms that is locked rigidly in space by the acetal function; it can therefore be used as a template to introduce several chiral centers with a high degree of stereochemical control.

Erythromycin A was selected as a target molecule because its structure fits admirably well with the above strategy. Indeed, the seco acid **1** of erythronolide A can be viewed as an appropriately substituted "1,9-dihydroxyketone" which can be converted into the substituted 1,7-dioxaspiro[5.5]undecane **3** ($R^1 = R^2 = R^3 = H$) by internal acetalization. Compound **3** ($R^1 = R^2 = R^3 = H$) exists in the stereoelectronically preferred conformation **4** and most of the substituents are equatorially oriented. Thus, the spiro compound **3** ($R^1 = R^2 = R^3 = H$) has no undesirable strong steric interactions and it should be readily made from both erythromycin A and by total synthesis. The reconversion of **3** ($R^1 = R^2 = R^3 = H$) into erythromycin A would then complete the synthesis.[2]

The present work deals with the synthesis of the model compound **9** (Scheme 2), in which ring A is unsubstituted and ring B possesses the appropriate side chain at C-5 and the tertiary hydroxyl group at C-6 protected in the form of a benzyl ether.

The retrosynthetic analysis of compound **9** which contains five contiguous chiral centers is shown in Scheme 2; the main steps being (a) Claisen rearrangement of the allylic propionate (**6** → **7**), (b) hydration of the exomethylene double bond (iodolactonization followed by hydrogenolysis) (**7** → **8**), and (c) aldol condensation with methyl propionate (**8** → **9**). The preparation of spiro allylic propionate **6** and its successful conversion into compound **9** is reported in this article.



SCHEME 1

Results and discussion

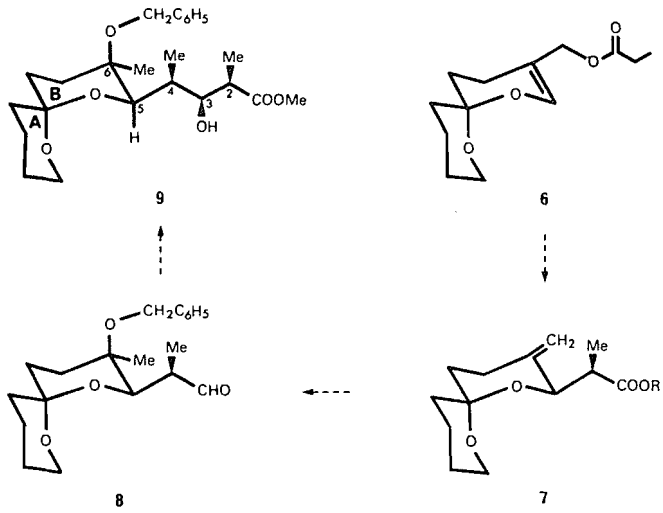
Syntheses of spiroketal ester 6

The allylic propionate spiroketal **6** was synthesized by two different methods.[3] The first synthesis is shown in Scheme 3.

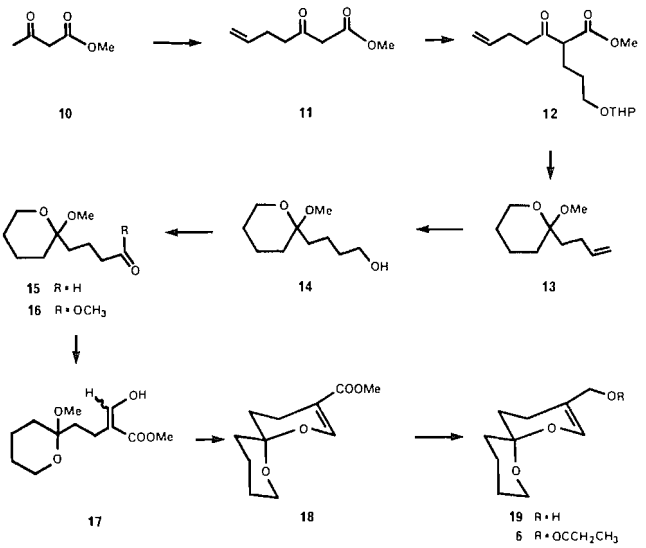
[1] Taken in part from the Ph.D. thesis of G. Sauvé, Université de Sherbrooke, 1981.

[2] For a previous discussion of this new synthetic approach, see pp. 330–333 in ref. 3.

[3] Several syntheses of spiro[5.5]undecane acetals have been reported in the literature; for examples, see ref. 8.

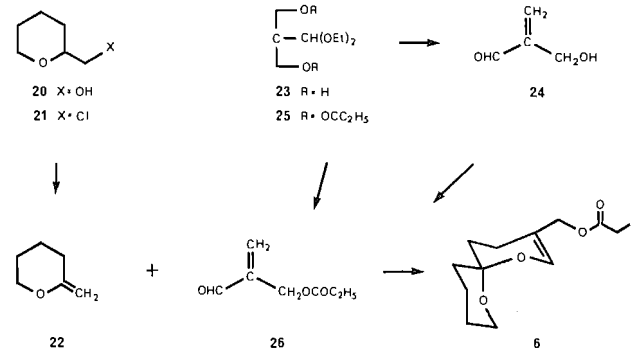


SCHEME 2



SCHEME 3

The disubstituted β-ketoester **12** was obtained by γ-alkylation of the dianion of methyl acetoacetate (**10**) with allyl bromide according to the method of Huckin and Weiler (9), followed by α-alkylation (10) of the monoanion of allyl-ketoester **11** with the tetrahydropyranyl derivative of 3-bromo-1-propanol. Decarboxylation of **12** in refluxing aqueous sodium hydroxide (11) and treatment of the crude ketone with *p*-toluenesulfonic acid in methanol containing methyl orthoformate gave the olefin cyclic acetal **13**. Hydroboration of **13** with borane – dimethyl sulfide complex (12) gave the hydroxy-acetal **14**, which was first converted into the aldehyde-acetal **15** by oxidation with Collins reagent (13) and then to the ester-acetal **16** by the reaction of ozone in basic methanolic solution (14). Hydroxymethylenation of ester-acetal **16** with methylformate (LDA) gave the crude hydroxymethylene ester **17**, which was cyclized with silica gel in methylene chloride to give the spiroketal unsaturated ester **18**. Finally, reduction of **18** with lithium aluminium hydride gave **19**, which was esterified with propionic anhydride ($(C_2H_5)_3N$ in CH_2Cl_2) to yield the allylic propionate spiroketal **6**. There are eleven steps in this synthesis and the overall yield is approximately 1%. A shorter route was therefore developed.



SCHEME 4

In the second synthesis, compound **6** was obtained via the Diels–Alder condensation of 2-methylenetetrahydropyran (**22**) with propenal-propionate **26** (Scheme 4). A similar cycloaddition has been previously reported between **22** and acrolein (15).

2-Methylenetetrahydropyran (**22**) was prepared by the method described by Taskinen (16): the readily available tetrahydropyranyl alcohol **20** was transformed ($SOCl_2$) into the chloride **21** (17), which was then treated with potassium hydroxide to give **22**. Propenal-propionate **26** was first produced by esterification with propionic anhydride of 2-hydroxymethyl-2-propenal (**24**), a known compound which is prepared from diol **23** (18). Diol **23** is readily available in three steps starting with dimethyl malonate (18). This sequence of operations was, however, not satisfactory due to the poor yield (~20%) in the conversion of **23** to **24**, the instability of the intermediate **24**, and the volatility of product **26**. The following modifications proved to be more satisfactory: (a) the diol **23** was acylated with propionic anhydride to give **25**, (b) the acetal function of **25** was then hydrolysed with formic acid (19) to give the corresponding aldehyde, which underwent an elimination of propionic acid on passing through a column of silica gel, yielding **26**.

The Diels–Alder reaction was carried out at room temperature by mixing 2-methylenetetrahydropyran (**22**) with the diene **26**, yielding the allylic propionate spiroketal **6** in 85% yield after distillation. This Diels–Alder route enabled us to prepare **6** in large scale and in only six steps from dimethyl malonate in 23% total yield.

Claisen rearrangement and lactonization

The allylic propionate spiroketal **6** was subjected to the Claisen rearrangement conditions developed by Ireland *et al.* (20) ((a) LDA, HMPA–THF, −78°C; (b) *t*-Bu$(CH_3)_2$SiCl, −78°C → 25°C; (c) NaOH–H_2O) to give a mixture of carboxylic acid **7** (R = H) and **27** (R = H) (Scheme 5) which on treatment with diazomethane yielded a 3:1 mixture of the two isomeric methyl esters **7** (R = CH_3) and **27** (R = CH_3). The mixture was used for the next operation. Saponification of **7** (R = CH_3) and **27** (R = CH_3) gave back the corresponding carboxylic acids which were transformed in high yield into a mixture of iodolactones **28** (X = I) and **29** (X = I) using standard experimental conditions (I_2, NaI, $NaHCO_3$, CH_3OH, H_2O, (21)). Hydrogenolysis of the iodolactone mixture with Raney nickel under a hydrogen atmosphere gave the two lactones **28** (X = H) and **29** (X = H) which were separated by chromatography on silica gel. The ^1H nmr spectrum of the major lactone **28** (X = H) shows a doublet (J = 1.0 Hz) at 3.79 ppm for the hydrogen at C-3. This small coupling is consistent with a dihedral angle close to 90° be-

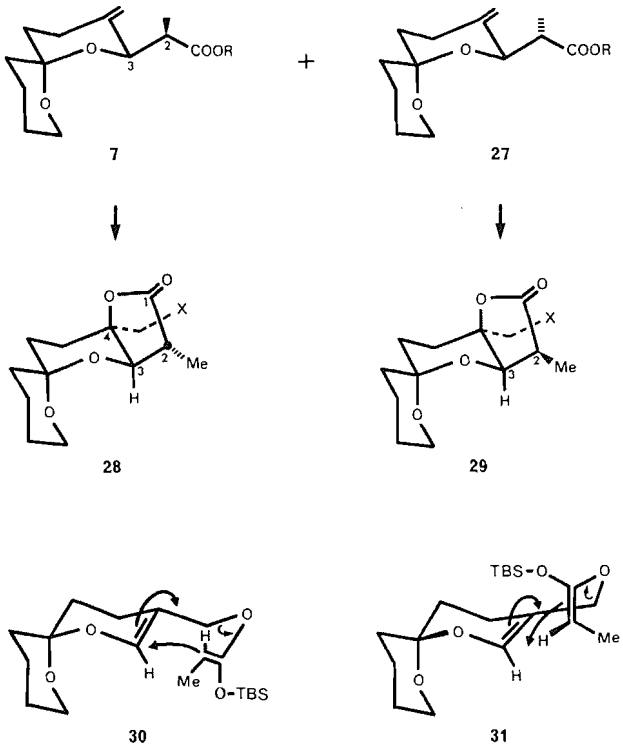
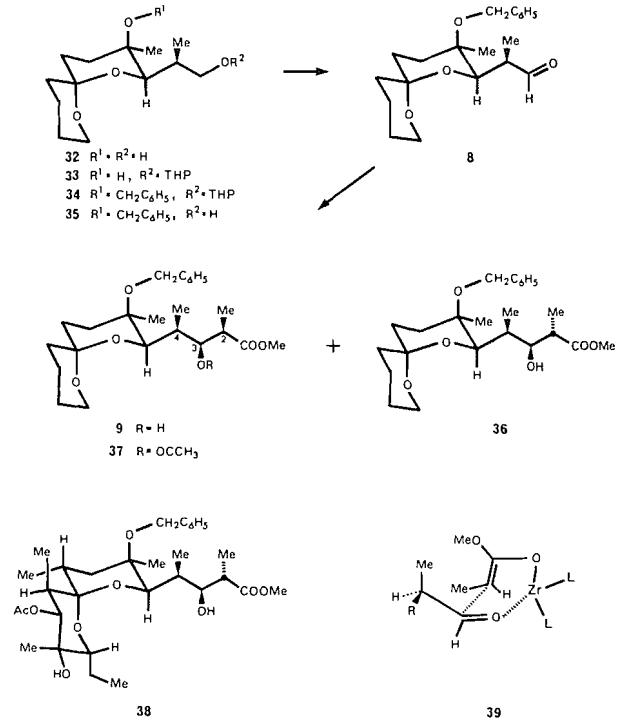


SCHEME 5



SCHEME 6

tween the hydrogens at C-3 and C-2. The ^{1}H nmr spectrum of the minor lactone **29** (X = H) shows a doublet (J = 4.4 Hz) at 3.93 ppm for the hydrogen at C-3. The magnitude of the coupling constant is in accord with the assigned stereochemistry.

The major lactone **28** (X = H) possesses the desired stereochemistry at the three contiguous chiral centers. The control of stereochemistry at C-4 is due to an internal process in which the formation of a *cis* five-membered lactone (**7** (R = H) → **28** (X = I)) is more favorable than that leading to a *trans* fused lactone. The internal Claisen rearrangement which must take place on the least hindered face of the cyclic enol ether double bond (**6** → **7**) controls the chiral center at C-3. Stereochemical control at C-2 is either due to the reaction of an *E*-enolate ion of the propionate ester via a chair-like transition state (cf. **30**) or by a *Z*-enolate reaction via a boat-like transition state (cf. **31**). Ireland *et al.* (22) have provided evidence that when a mixture of HMPA–THF is used, an *E*-enolate is preferentially formed. Consequently, the preferential formation of compound **7** (R = H) must have taken place through a transition state which has the stereochemistry illustrated by drawing **30**. In accord with this finding, when HMPA was omitted, a ~1:1 mixture of carboxylic acid **7** (R = H) and **27** (R = H) was observed.

Aldol condensation

The major lactone **28** (X = H) was first transformed into the required spiroaldehyde **8** (Scheme 6): reduction of lactone **28** (X = H) with lithium aluminium hydride gave the expected spirodiol **32** which on reaction with dihydropyran catalyzed by pyridinium *p*-toluenesulfonate (23) yielded the tetrahydropyranyl ether **33**. Treatment of **33** with sodium hydride and benzyl chloride in dimethylformamide gave the benzyl ether **34**, which was then hydrolysed to the corresponding spiroalcohol **35**. Finally, oxidation of **35** with pyridinium chlorochromate furnished the spiroaldehyde **8**.

The aldol condensation on spiroaldehyde **8** was carried out by utilizing the methodology originally developed by Evans and McGee (24). The zirconium enolate of methyl propionate was first prepared by the reaction of the lithium enolate of methyl propionate (LDA, THF) with bis(cyclopentadienyl) zirconium dichloride. The resulting solution was then added to the spiroaldehyde **8** to produce in a 8:1 ratio (62% yield) a mixture of the *erythro* and the *threo* products **9** and **36** respectively. Compounds **9** and **36** were separated by chromatography and the major *erythro* diastereoisomer **9** was converted into the corresponding acetate derivative **37**. The assignment of configuration at C-2 and C-3 in compounds **9** and **36** was made by high resolution ^{1}H nmr spectroscopic analysis, by comparison with compound **3** (R^1 = $CH_2C_6H_5$, R^2 = Me, R^3 = Ac) and its C-2 epimer **38** produced by degradation of erythromycin A.[2] Thus, following Evans' publication (24), the formation of the major *erythro* isomer **9** must be the result of a *pseudo*-boat transition state represented by drawing **39**.

The results obtained in this model study were then successfully applied for the total synthesis of erythromycin which is in progress in our laboratory.

Experimental

The ir spectra were taken on a Perkin–Elmer 257 spectrophotometer. The ultraviolet (uv) spectra were registered on a Varian Techtron 635 spectrophotometer. Proton nmr spectra were recorded on a Bruker WP-60 or Bruker WM-250 instrument. The following abbreviations have been used: s, singlet; d, doublet; d of d, doublet of doublet; t, triplet; m, multiplet; and br, broad. Chemical shifts are reported in δ values relative to tetramethylsilane as internal standard. The mass spectra (ms) were taken on a Hitachi–Perkin–Elmer RMU-6 and a Vg Micromass ZAB-2F mass spectrometer. Solutions were evaporated below 40°C under diminished pressure. Eastman chromagram plates of silica gel were used for thin-layer chromatography. Anhydrous sodium sulfate was used as the drying agent in working up reactions.

Disubstituted ketoester ***12***

A solution of sodium methoxide in methanol was prepared by adding sodium (900 mg, 39.1 mmol) to anhydrous methanol (50 mL). The allyl-ketoester **11** (5.0 g, 32 mmol), dissolved in dry methanol (15 mL), was added to the above solution. The solution was heated to gentle boiling during 10 min, then the tetrahydropyranyl 3-bromo-1-propanol derivative (prepared from 3-bromo-1-propanol and dihydropyran with acid catalyst) (8.24 g, 36.9 mmol) dissolved in dry methanol (15 mL) was added over a period of about 1 h and was refluxed for 18 h under an atmosphere of nitrogen. The mixture was cooled, filtered, and the filtrate was concentrated under reduced pressure to give an oil. This product was directly used for subsequent reactions. A small amount of the product was purified by preparative thin-layer chromatography on silica gel with hexane – ethyl acetate (9:1); ir ($CHCl_3$): 1740, 1710, and 1640 cm^{-1}; nmr ($CDCl_3$) δ: 5.60 (1H, m, olefinic proton), 4.90 (2H, m, olefinic protons), 4.55 (1H, br, OCHO), and 3.71 (3H, s, OCH_3); ms *m/e*: 198 ($M^+ - C_5H_8O_2$).

Olefin cyclic acetal ***13***

The crude disubstituted ketoester **12** was added to a solution of sodium hydroxide (1 *N*, 80 mL) and was refluxed for 20 h. After cooling, the reaction mixture was extracted with ether (5 × 40 mL). The organic phase was washed with saturated sodium chloride, dried, and evaporated. The residue, dissolved in anhydrous methanol (75 mL), was treated with *p*-toluenesulfonic acid (3 crystals) and methyl orthoformate (7.0 g, 66 mmol). The mixture was stirred at room temperature for 15 h under a nitrogen atmosphere. A saturated sodium bicarbonate solution (150 mL) was added and extracted with ether (5 × 75 mL). The organic extracts were dried over solid potassium carbonate and evaporated to an oil which was distilled under reduced pressure to yield pure olefin cyclic acetal **13** (1.5 g, 34% from **11**); bp 55°C, 0.5 Torr (1 Torr = 133.3 Pa); ir ($CHCl_3$): 1640 and 890 cm^{-1}; nmr ($CDCl_3$) δ: 5.90 (1H, m, olefinic proton), 4.90 (2H, m, olefinic protons), 3.15 (3H, s, OCH_3); ms *m/e*: 138 ($M^+ - HOCH_3$). *Mol. Wt.* (high resolution ms) calcd. for $C_{10}H_{18}O_2$: *m/e* 138.1044 ($M^+ - HOCH_3$); found: *m/e* 138.1042 ($M^+ - HOCH_3$).

Hydroxy-acetal ***14***

A solution of olefin cyclic acetal **13** (12.5 g, 73.5 mmol) in anhydrous tetrahydrofuran (300 mL) was cooled to 0°C and treated with borane – dimethylsulfide complex (5.60 g, 73.7 mmol) under a nitrogen atmosphere. The mixture was stirred for 1 h at 0°C and 1 h at room temperature. Then, after cooling to 0°C, sodium hydroxide solution (3 *N*, 100 mL) and hydrogen peroxide solution (30%, 100 mL) were added. The reaction mixture was stirred for 3 h at room temperature and extracted with ether (6 × 100 mL). The organic phase was dried with solid potassium carbonate, filtered, and evaporated to give crude hydroxy-acetal **14** (12.7 g), which was used without further purification; ir ($CHCl_3$): 3600 and 3450 cm^{-1}; nmr ($CDCl_3$) δ: 3.60 (4H, br, 2 × OCH_2), and 3.16 (3H, s, OCH_3).

Aldehyde-acetal ***15***

The hydroxy-acetal **14** (13.56 g, 72.0 mmol), dissolved in dichloromethane (10 mL), was added to a solution of chromium trioxide pyridine complex (13) (prepared from chromium trioxide (68.0 g, 0.68 mol) and pyridine (110 mL, 1.36 mol)) in the same solvent (700 mL) at 0°C. The reaction mixture was then stirred at room temperature for 30 min, decanted, and the salts were washed with ether (3 × 150 mL). The organic phase was washed with a sodium bicarbonate solution (5%, 150 mL) and saturated sodium chloride solution (400 mL). The organic extract was dried and evaporated. Distillation of the residue gave pure aldehyde-acetal **15** (6.90 g, 50% from olefin acetal **13**); bp 68°C, 0.15 Torr; ir ($CHCl_3$): 2820, 2720, and 1720 cm^{-1}; nmr ($CDCl_3$) δ: 9.60 (1H, t, J = 1.5 Hz, CHO), 3.10 (3H, s, OCH_3), and 2.40 (2H, br, CH_2CHO).

Ester-acetal ***16***

The aldehyde-acetal **15** (508 mg, 2.73 mmol) was dissolved in methanolic potassium hydroxide solution (0.5 *N*, 80 mL) and cooled to −78°C. Ozone was passed through the solution for 90 min and it was allowed to warm up to room temperature, then poured into water (75 mL), and extracted with ether (3 × 75 mL). The ether extract was washed with saturated sodium chloride solution (2 × 75 mL), dried over sodium carbonate, filtered, and evaporated to give ester-acetal **16** (325 mg, 55%) which was purified by distillation *in vacuo*; bp 75–78°C, 0.10 Torr; ir ($CHCl_3$): 1735 cm^{-1}; nmr ($CDCl_3$) δ: 3.67 (3H, s, CO_2CH_3), 3.18 (3H, s, OCH_3), and 2.40 (2H, m, $CH_2CO_2CH_3$); ms *m/e*: 184 ($M^+ - HOCH_3$).

Spiroketal unsaturated ester ***18***

n-Butyllithium (1.13 mL, 1.81 mmol, 1.6 *M* in hexane) was added dropwise to a solution of diisopropylamine (275 μL, 1.96 mmol) in tetrahydrofuran (10 mL) at 0°C under an atmosphere of nitrogen. After 15 min, the solution was cooled to −78°C and a solution of ester-acetal **16** (200 mg, 1.25 mmol) in tetrahydrofuran (10 mL) was added dropwise. After 30 min, methyl formate (225 mg, 3.73 mmol) was added and the reaction mixture was left at −78°C for 1 h, then at −20°C for 1 h, and finally at room temperature for 30 min. A saturated solution (20 mL) of ammonium chloride was added and the mixture was then extracted with ether (5 × 20 mL). The organic extract was washed with brine (25 mL), dried with sodium sulfate, filtered, and evaporated. The residue was added to a silica gel suspension in methylene chloride and stirred for 12 h. The silica gel was filtered, washed with ether, and the solvent was evaporated *in vacuo*. The residue was purified by preparative thin-layer chromatography on silica gel using ether–hexane (3.5:6.5) as eluant to yield pure spiroketal ester **18** (50 mg, 25%); uv (EtOH, 95%) λ_{max}: 237 nm (ε 11 500); ir ($CHCl_3$): 1700 and 1635 cm^{-1}; nmr (CD_2Cl_2) δ: 7.33 (1H, br s, olefinic proton), 3.54 (3H, s, OCH_3), and 2.15 (2H, m, allylic CH_2); ms *m/e*: 212 (M^+). *Mol. Wt.* (high resolution ms) calcd. for $C_{11}H_{16}O_4$: *m/e* 212.1048; found: *m/e* 212.1042.

Allylic alcohol ***19***

Lithium aluminium hydride (80.5 mg, 2.12 mmol) was added to a solution of spiroketal ester **18** (225 mg, 1.06 mmol) in anhydrous ether (10 mL) at 0°C. The mixture was stirred at 0°C for 2 h, then a saturated solution of sodium sulfate (10 mL) was added and extracted with ether (4 × 5 mL). Drying and evaporation of the organic phase gave crude allylic alcohol **19** (190 mg): ir ($CHCl_3$): 3600, 3420, and 1680 cm^{-1}; nmr ($CDCl_3$) δ: 6.36 (1H, s, olefinic proton), 3.99 (2H, s, CH_2OH), and 2.20 (2H, m, allylic CH_2).

Allylic propionate spiroketal ***6***

A solution of allylic alcohol **19** (194 mg, 1.05 mmol) in dry methylene chloride (25 mL) was treated at 0°C, under a nitrogen atmosphere, with propionic anhydride (1.60 mL, 12.6 mmol) and anhydrous triethylamine (4.5 mL, 32.3 mmol). The reaction mixture was stirred for 16 h and evaporated to give an oil (233 mg). An analytical sample of **6** was prepared by microdistillation *in vacuo*; ir ($CHCl_3$): 1740 and 1680 cm^{-1}; nmr ($CDCl_3$) δ: 6.39 (1H, s, olefinic proton), 4.46 (2H, s, CH_2OCOEt), 2.32 (2H, q, J = 7.5 Hz, $OCOCH_2CH_3$), 2.10 (2H, allylic CH_2), and 1.13 (3H, t, J = 7.3 Hz, $CO_2CH_2CH_3$); ms *m/e*: 240 (M^+).

2-Methylenetetrahydropyran (22)

The 2-chloromethyltetrahydropyran (**21**) (17) (60 g, 0.448 mol) was treated with potassium hydroxide powder (60 g, 1.07 mol) in a flask with Vigreux column and distillation head which was prewashed with potassium hydroxide solution and dried. The suspension was vigorously stirred and gradually heated to 190°C (the temperature of the distillation head must not exceed 110°C). The upper phase of the distillate containing the product **22** was redistilled under light vacuum and the distillate was collected at −78°C. Yield: 28.5 g (65%) of **21**; bp 62°C, 155 Torr; ir (neat): 3080 and 1655 cm^{-1}; nmr ($CDCl_3$) δ: 4.30 (1H, s, olefinic proton, *cis*), 4.03 (1H, s, olefinic proton, *trans*), 3.89 (2H, m, OCH_2), and 2.23 (2H, m, allylic CH_2).

Dipropionate ***25***

A solution of diol **23** (4.35 g, 24.4 mmol) in methylene chloride (25 mL) was treated with propionic anhydride (19 mL, 0.148 mol) and triethylamine (35 mL, 0.251 mol). The mixture was stirred for 15 h at room temperature under an atmosphere of nitrogen. It was then

diluted with ether (100 mL) and washed successively with sodium bicarbonate solution (5%, 2 × 50 mL) and with brine (2 × 50 mL). The organic phase was dried, filtered, and evaporated to an oil which was distilled under reduced pressure to yield pure dipropionate **25** (6.92 g, 98%); bp 126–128°C, 1 Torr; ir ($CHCl_3$): 1740 cm^{-1}; nmr ($CDCl_3$) δ: 4.52 (1H, d, J = 6.8 Hz, acetal CH), 4.38 and 4.15 (4H, AB part of ABX system, J_{AB} = 11 Hz, J_{AX} = 5.0 Hz, J_{BX} = 6.8 Hz, 2 × CH_2OCOEt), 3.64 and 3.55 (4H, 2q, J = 7.0 Hz, 2 × OCH_2CH_3), 2.33 (4H, q, J = 7.0 Hz, 2 × $O_2CCH_2CH_3$), 1.20 (6H, t, J = 7.0 Hz, 2 × OCH_2CH_3), and 1.13 (6H, t, J = 7.0 Hz, 2 × $O_2CCH_2CH_3$); ms m/e: 245 ($M^+ - OC_2H_5$).

Propenal-propionate ***26***

(a) *From 2-hydroxymethyl-2-propenal (**24**)*

A solution of 2-hydroxymethyl-2-propenal (**24**) (18) (75.0 mg, 0.872 mmol) in methylene chloride (4 mL) was treated, under a nitrogen atmosphere, at 0°C, with propionic anhydride (580 μL, 6.15 mmol) and dry triethylamine (1.22 mL, 8.75 mmol); the reaction mixture was stirred for 12 h at 0°C, and the solvent was evaporated. The residue was purified by thin-layer chromatography on silica gel with ether–hexane (4.5:5.5) to give pure propionate-propenal **26** (68.0 mg, 61%) as an oil; ir ($CHCl_3$): 3010, 2810, 2700, 1735, and 1695 cm^{-1}; nmr ($CDCl_3$) δ: 9.58 (1H, s, CHO), 6.44 (1H, s, olefinic proton, *cis*), 6.19 (1H, s, olefinic proton, *trans*), 4.82 (2H, s, allylic CH_2), 2.38 (2H, q, J = 7.2 Hz, $OCOCH_2CH_3$), and 1.14 (3H, t, J = 7.2 Hz, $CO_2CH_2CH_3$); ms m/e: 113 (M^+ − CHO).

(b) *From dipropionate **25***

Dipropionate **25** (2.95 g, 10.2 mmol) was dissolved in formic acid (30 mL) and stirred for 14 h at room temperature. Solvent was evaporated under reduced pressure and the product was purified by column chromatography on silica gel using hexane–ether (6:4) to give propionate-propenal **26** (1.20 g, 83%), identical with the material obtained from 2-hydroxymethyl-2-propenal (**24**).

Allylic propionate spiroketal ***6*** *from 2-methylenetetrahydropyran* ***22*** *and propenal-propionate* ***26***

A mixture of propenal-propionate **26** (2.30 g, 16.2 mmol) and 2-methylenetetrahydropyran (**22**) (6.5 g, 66.3 mmol) was heated for 5 h at 65°C. Evaporation of the excess **22** gave an oil which was distilled under reduced pressure to yield pure allylic propionate spiroketal **6** (3.30 g, 85%); bp 140°C, 0.2 Torr; identical with the material obtained from allylic alcohol **19**.

Claisen rearrangement of allylic propionate spiroketal ***6***

To a stirred solution of LDA (2.5 mmol) in hexamethylphosphoramide (1.0 mL) and tetrahydrofuran (2 mL) maintained at −70°C was added dropwise a solution of allylic propionate **6** (0.30 g, 1.25 mmol) in tetrahydrofuran (2 mL). The reaction mixture was stirred at −78°C for 0.5 h and a solution of *tert*-butyldimethylsilyl chloride (0.190 mg, 1.26 mmol) in tetrahydrofuran (1.5 mL) was added dropwise. Stirring was continued at −78°C for 3 h and at −30°C for 2 h. Water (20 mL) was added and the solution was extracted with ether (2 × 30 mL). The combined ethereal extracts were extracted back with sodium hydroxide solution (5%, 2 × 25 mL). The combined aqueous, basic extracts were acidified at 0°C with concentrated hydrochloric acid and extracted with ether (2 × 25 mL). The combined ethereal extracts were washed with dilute hydrochloric acid solution (0.5 N, 15 mL), dried over magnesium sulfate, filtered, and concentrated to yield 175 mg of a base-soluble product. The residue was dissolved in ether (20 mL) and treated with ethereal diazomethane. Evaporation of the ether gave an isomeric methyl ester mixture, **7** (R = CH_3) and **27** (R = CH_3) (159 mg, 50%; in a 3:1 ratio as determined from their 250-MHz ^1H nmr spectra), as a colourless oil after purification by chromatography on silica gel with hexane–ether (9:1) as the solvent; ir ($CHCl_3$): 3080, 1730 and 1655 cm^{-1}; nmr ($CDCl_3$) δ (2 isomers): 4.90, 4.75 and 4.83, 4.72 (2 × 2H, s, olefinic protons), 4.44 and 4.15 (2 × 1H, d, $J \simeq 7$ Hz, OCHR), 3.72 and 3.69 (2 × 3H, s, OCH_3), 3.65 (2 × 2H, m, OCH_2), 2.80 (2 × 1H, m, $CHCO_2R$), 2.20 (2 × 2H, m, allylic CH_2), and 1.31 and 1.25 (2 × 3H, d, $J \simeq 7$ Hz, $COOCH_3$); ms m/e: 254 (M^+). *Mol. Wt.* (high resolution ms) calcd. for $C_{14}H_{22}O_4$: m/e 254.1517; found: m/e 254.1514.

Hydrolysis of methyl esters ***7*** *(R = CH_3) and* ***27*** *(R = CH_3)*

The mixture of esters **7** (R = CH_3) and **27** (R = CH_3) (102 mg, 0.401 mmol) in dioxane (5 mL) was treated with a solution of sodium hydroxide (1 N, 2 mL) and stirred at room temperature for 12 h. Concentrated hydrochloric acid was added cautiously until a pH of 4 and then extracted with methylene chloride (6 × 15 mL). The organic phase was dried, filtered, and evaporated to give a mixture of acids, **7** (R = H) and **27** (R = H), as an oil (86 mg); ir ($CHCl_3$): 3300, 1715 and 1655 cm^{-1}; nmr ($CDCl_3$) δ (2 isomers): 10.5 (2 × 1H, br, CO_2H), 4.87 and 4.79 (2 × 2H, br s, olefinic protons), 2.91 (2 × 1H, q, J = 6.5 Hz, $CHCO_2$), 2.40 (2 × 2H, m, allylic CH_2), and 1.40 and 1.35 (2 × 3H, d, J = 7.0 Hz, $CH(CH_3)COOH$).

Iodolactonization of acids mixture ***7*** *(R = H) and* ***27*** *(R = H)*

To a solution of a mixture of acids **7** (R = H) and **27** (R = H) (95 mg, 0.396 mmol) and potassium bicarbonate (200 mg, 2.0 mmol) in methanol (7 mL) and water (3 mL) at 0°C were added potassium iodide (460 mg, 2.77 mmol) and iodine (240 mg, 0.945 mmol). The reaction mixture was stirred at 0°C for 2 h, then at room temperature for 12 h in darkness. Methylene chloride (50 mL) was added and the organic phase was washed successively with saturated sodium thiosulfate solution (20 mL) and brine (2 × 15 mL), then dried, filtered, and the solvent evaporated to give the crude iodolactones **28** (X = I) and **29** (X = I) as a mixture (135 mg); ir ($CHCl_3$): 1780 cm^{-1}; nmr ($CDCl_3$) δ (2 isomers): 4.25 and 4.04 (2 × 1H, d, J = 4.6 Hz and J = 2.7 Hz, OCH), 3.65 (2 × 2H, m, OCH_2), 3.45, 3.22, and 3.28 (2 × 2H, AB system, $J_{AB} \simeq 10$ Hz and s, CH_2I), and 1.45 and 1.27 (2 × 3H, d, J = 7.8 Hz and J = 7.0 Hz, CH_3).

Hydrogenolysis of iodolactones mixture ***28*** *(X = I) and* ***29*** *(X = I)*

To a solution of an epimeric mixture of iodolactones **28** (X = I) and **29** (X = I) (135 mg, 0.369 mmol) in ethanol (100 mL) was added Raney nickel (700 mg) and sodium bicarbonate (150 mg, 1.78 mmol). The reaction mixture was kept under an atmosphere of hydrogen (50 psi; 1 psi = 6.89 kPa) for 12 h with strong agitation. The suspension was filtered on silica gel and washed thoroughly with ethyl acetate, and the solvent was evaporated under reduced pressure to give a crude mixture of lactones **28** (X = H) and **29** (X = H) in a 3:1 ratio (determined from their 250-MHz ^1H nmr spectra). The crude product was purified by column chromatography with silica gel (hexane–ether, 9:1) to yield pure lactones **28** (X = H) (48.0 mg, 54%) and **29** (X = H) (16.0 mg, 18%).

Epimer ***28*** *(X = H)*: mp 52–54°C (ether–hexane); ir ($CHCl_3$): 1760 cm^{-1}; nmr ($CDCl_3$) δ: 3.79 (1H, d, J = 1.0 Hz, OCH), 3.66 (2H, m, OCH_2), 2.73 (1H, q, J = 8.0 Hz, $CHCO_2$), 1.43 (3H, d, J = 8.0 Hz, CH_3CHCO_2), and 1.41 (3H, s, CH_3); ms m/e: 240 (M^+). *Mol. Spirodiol ***32***

Lactone **28** (X = H) (215 mg, 0.90 mmol), dissolved in anhydrous ether (6 mL), was added to a suspension of lithium aluminium hydride (53 mg, 1.39 mmol) in ether (10 mL) at 0°C under an atmosphere of nitrogen. The reaction mixture was stirred for 30 min at 0°C and then added to a saturated sodium sulfate solution (20 mL) and extracted with methylene chloride (4 × 25 mL). The organic phase was dried, the solvent evaporated, and the residue was purified by chromatography on silica gel. Spirodiol **32** (160 mg, 73%) was obtained by elution with hexane – ethyl acetate (7:3); mp 73–75°C; ir ($CHCl_3$): 3580 and 3440 cm^{-1}; nmr ($CDCl_3$) δ: 3.75 (1H, d, J = 2.5 Hz, OCH), 3.68 (2H, d, J = 5.3 Hz, CH_2OH), 1.18 (3H, s, CH_3 tertiary), and 1.13 (3H, d, J = 6.3 Hz, $CHCH_3$); ms m/e: 245. *Mol. Wt.* (high

resolution ms) calcd. for $C_{13}H_{24}O_4$: *m/e* 245.1753; found: *m/e* 245.1753.

Tetrahydropyranyl ether 33

A solution of spirodiol **32** (35.0 mg, 0.134 mmol) in methylene chloride (5 mL) was treated under an atmosphere of nitrogen with dihydropyran (46 mg, 0.55 mmol) and pyridinium *p*-toluenesulfonate (5 mg). After 4 h, additional dihydropyran (46 mg, 0.55 mmol) and pyridinium *p*-toluenesulfonate (5 mg) were added. The reaction was left for 30 min. Saturated sodium bicarbonate solution (15 mL) was added and the mixture was extracted with methylene chloride (4 × 15 mL). The dried organic phase was evaporated and the crude product was purified by column chromatography on silica gel using ether–hexane (5:5) as eluant to give pure tetrahydropyranyl ether **33** (32 mg, 69%); ir ($CHCl_3$): 3580 and 3450 cm^{-1}; nmr ($CDCl_3$) δ: 4.57 (1H, br, acetal proton), 1.16 (3H, s, $C(OH)CH_3$), and 1.06 (3H, d, J = 6.8 Hz, $CHCH_3$); ms *m/e*: 311 ($M^+ - OH$).

Benzyl ether 34

A solution of tetrahydropyranyl ether **33** (22 mg, 0.067 mmol) in dry *N,N*-dimethylformamide (4 mL) was treated with benzyl bromide (144 mg, 0.841 mmol) and sodium hydride (50% in oil, 55 mg, 1.14 mmol). The reaction mixture was stirred at 55°C for 2 h under an atmosphere of nitrogen, then cooled to 0°C, poured into a saturated sodium bicarbonate solution (15 mL), and extracted with methylene chloride (4 × 20 mL). The organic extracts were dried and evaporated. The residue was purified by preparative thin-layer chromatography on silica gel using ether–hexane (3.5:6.5) as eluent to yield pure benzyl ether **34** (19 mg, 68%); ir ($CHCl_3$): 1600, 1490, 1450, and 710 cm^{-1}; nmr ($CDCl_3$) δ: 7.32 (5H, br, aromatic), 4.63 (1H, br, acetal proton), 4.43 (2H, s, $OCH_2C_6H_5$), 1.19 (3H, s, CH_3 tertiary), and 1.10 (3H, d, J = 6.8 Hz, $CHCH_3$); ms *m/e*: 333 ($M^+ - C_5H_9O$).

Spiroalcohol 35

To a solution of benzyl ether **34** (16 mg, 0.038 mmol) in 1,2-dimethoxy ethane (2.5 mL) was added water (5 drops) and hydrochloric acid (1 *N*, 10 drops). The reaction mixture was stirred at room temperature for 1 h and at 50°C for 45 min. After cooling, saturated sodium bicarbonate solution (15 mL) was added and extracted with methylene chloride (4 × 25 mL). The organic extracts were dried and evaporated to leave an oily residue which was purified by thin-layer chromatography on silica gel using ether–hexane (3.5:6.5) as an eluent; after 5 elutions the pure spiroalcohol **35** was obtained in 63% yield (8.0 mg); ir ($CHCl_3$): 3520, 3480, 1600 and 1450 cm^{-1}; nmr ($CDCl_3$) δ: 7.27 (5H, br, aromatic), 4.37 (2H, s, $OCH_2C_6H_5$), 1.16 (3H, s, CH_3 tertiary), and 1.10 (3H, d, J = 7.2 Hz, $CHCH_3$); ms *m/e*: 334 (M^+). *Mol. Wt.* (high resolution ms) calcd. for $C_{20}H_{30}O_4$: *m/e* 334.2144; found: *m/e* 334.2144.

Spiroaldehyde 8

Pyridinium chlorochromate (25 mg, 0.116 mmol) and pulverized molecular sieves 3 Å (~20 mg) were added to a solution of spiroalcohol **35** (8.0 mg, 0.024 mmol) in methylene chloride (5 mL). The reaction mixture was stirred at room temperature for 1 h, then the suspension was filtered through a column of silica gel and washed thoroughly with ether. Evaporation of the solvent gave pure spiroaldehyde **8** (7.5 mg, 94%); ir ($CHCl_3$): 2870, 2720, 1720, 1600, 1495, and 1450 cm^{-1}; nmr ($CDCl_3$) δ: 9.72 (1H, d, J = 1.5 Hz, CHO), 7.26 (5H, br, aromatic), 4.36 (2H, s, $OCH_2C_6H_5$), 3.94 (1H, d, J = 4.0 Hz, OCH), 2.70 (1H, m, *CH*CHO), 1.26 (3H, d, J = 7.2 Hz, $CHCH_3$), and 1.13 (3H, s, CH_3 tertiary); ms *m/e* 331 ($M^+ - H$).

Aldol condensation of spiroaldehyde 8

(a) *Preparation of zirconium enolate reagent solution*

n-Butyllithium (620 μL, 1.6 *M* in hexane, 0.992 mmol) was added dropwise to a solution of diisopropylamine (115 mg, 1.14 mmol) in tetrahydrofuran (10 mL) at 0°C under an atmosphere of nitrogen. After 15 min at 0°C, the solution was cooled to −78°C and methyl propionate (79 mg, 0.894 mmol) was added dropwise. After 30 min, a solution of bis(cyclopentadienyl) zirconium dichloride (290 mg, 0.992 mmol) in tetrahydrofuran (6 mL) was added and the reaction mixture was left at −78°C for 10 min, at −40°C for 10 min, and at room temperature for 30 min. This zirconied reagent (0.0558 *M*), used in the following aldol condensation, has a light yellow color.

(b) *Aldol condensation conditions*

A solution of spiroaldehyde **8** (18.0 mg, 0.054 mmol) in tetrahydrofuran (2 mL) at −78°C under an atmosphere of nitrogen was treated dropwise with a freshly prepared zirconied enolate solution (2.4 mL, 0.0558 *M* in tetrahydrofuran, 0.13 mmol; see above). The reaction mixture was stirred for 2 h at −78°C, then for 1 h at −50°C, and quenched with saturated ammonium chloride solution (10 mL). The mixture was extracted with methylene chloride (4 × 10 mL). The dried organic phase was evaporated and the crude product was purified by thin-layer chromatography on silica gel using hexane – ethyl acetate (7:3) to give *erythro* **9** (12.5 mg, 55%), *threo* **36** (1.5 mg, 7%), and starting material **8** (5 mg).

Erythro 9; ir ($CHCl_3$): 3500, 1735, 1500, and 1450 cm^{-1}; nmr ($CDCl_3$) δ: 7.32 (5H, m, aromatic), 4.43 and 4.37 (2H, AB system, J_{AB} = 11.5 Hz, $OCH_2C_6H_5$), 3.89 (1H, d of d, $J_{3,4}$ = 1.3 Hz, $J_{2,3}$ = 9.3 Hz, H-C3), 3.71 (1H, d, $J_{4,5}$ = 1.8 Hz, H-C5), 3.67 (3H, s, OCH_3), 2.69 (1H, d of q, J = 7.0 Hz, $J_{2,3}$ = 9.3 Hz, H-C2), 1.90 (1H, m, H-C4), 1.28 (3H, d, J = 7.0 Hz, CH_3-C2), 1.18 (3H, s, CH_3 tertiary), and 1.15 (3H, d, J = 7.0 Hz, CH_3-C4); ms *m/e*: 389 ($M^+ - OCH_3$). *Mol. Acetate 37

A solution of *erythro* **9** (13.0 mg, 0.039 mmol) in anhydrous triethylamine (2 mL) was treated with acetic anhydride (108 mg, 1.06 mmol) and 4-dimethylamino pyridine (1 crystal). The reaction mixture was stirred for 3 h at room temperature under an atmosphere of nitrogen, then the solvent was evaporated under reduced pressure. The residue was purified by thin-layer chromatography on silica gel using benzene–ether (8:2) to give acetate **37** (11 mg; 77%); ir ($CHCl_3$): 1740, 1600, 1500, and 1450 cm^{-1}; nmr ($CDCl_3$) δ: 7.31 (5H, m, aromatic), 5.38 (1H, d of d, $J_{3,4}$ = 6.9 Hz, $J_{2,3}$ = 5.4 Hz, H-C3), 4.44 and 4.39 (2H, AB system, J_{AB} = 11.7 Hz, $OCH_2C_6H_5$), 3.62 (3H, s, CO_2CH_3), 3.44 (1H, d, $J_{4,5}$ = 2.4 Hz, H-C5), 2.90 (1H, d of q, $J_{2,3}$ = 5.4 Hz, J = 7.0 Hz, H-C2), 2.34 (1H, m, H-C4), 2.06 (3H, s, CH_3CO_2), 1.20 (3H, s, CH_3 tertiary), 1.14 (3H, d, J = 7.0 Hz, CH_3-C2), and 1.09 (3H, d, J = 7.0 Hz, CH_3-C4); ms *m/e*: 431 ($M^+ - OCH_3$).

A simple method of preparing trimethylsilyl- and *tert*-butyldimethylsilyl-enol ethers of α-diazoacetoacetates and their use in the synthesis of a chiral precursor to thienamycin analogs

YASUTSUGU UEDA,[1] GUY ROBERGE,[2] AND VIVIANE VINET

Bristol Laboratories of Canada, 100 Industrial Boulevard, Candiac, P.Q., Canada J5R 1J1

Received June 1, 1984

YASUTSUGU UEDA, GUY ROBERGE, and VIVIANE VINET. Can. J. Chem. **62**, 2936 (1984).

A simple method of preparing trimethylsilyl- and *tert*-butyldimethylsilyl-enol ethers of various esters of α-diazoacetoacetic acid is described. Displacement reaction of 4-acetoxyazetidinone **8** with *tert*-butyldimethylsilylenol ethers **7***a*, followed by desilylation, afforded the key chiral precursor **2***a* for the synthesis of thienamycin analogs.

YASUTSUGU UEDA, GUY ROBERGE et VIVIANE VINET. Can. J. Chem. **62**, 2936 (1984).

On décrit une méthode simple de préparer des éthers énoliques triméthylsilylés et *tert*-diméthylsilylés de divers esters de l'acide α-diazoacétoacétique. La réaction de substitution de l'acétoxyazétidinone (**8**) par les éthers énoliques *tert*-butyldiméthylsilyles (**7***a*), suivie d'une réaction de désilylation, conduit au précurseur chiral **2***a* qui est un produit clé dans la synthèse d'analogues de la thiènamycine.

[Traduit par le journal]

Since the discovery of thienamycin **1** (R = $CH_2CH_2NH_2$), intense efforts have been directed toward the synthesis of thienamycin analogs **1** (1). While many methods are available for carbapenem synthesis, the most widely used process goes through a common intermediate, diazoazetidinone **2** (2, 3).

Recently two groups of scientists reported (3*a*, *b*) elegant ways of constructing this type of intermediate by direct introduction of the α-diazoacetoacetate moiety into the 4-position of 2-azetidinones. Karady *et al.* (3*a*) described the preparation of a chiral diazo intermediate **2** (R = CH_2Ph) by the displacement reaction of an optically active 4-chloroazetidinone **3** (R = Si*t*BuMe$_2$, X = Cl) with trimethylsilylenol ether of benzyl α-diazoacetoacetate (**4**) in the presence of silver tetrafluoroborate followed by desilylation. Similarly Reider and Grabowski (3*b*) employed a displacement reaction (4) of a chiral 4-acetoxyazetidinone **3** (R = H, X = OAc) with **4** in the presence of Lewis acid (zinc iodide) for their synthesis of an optically active diazoazetidinone **2** (R = CH_2Ph).

In both cases, the α-diazoacetoacetate unit they employed carried a benzyl group to protect the carboxylic acid. Although the benzyl ester is reported (3*a*) to be useful as a carboxyl protecting group, it has been recognized (2) and recently demonstrated (2*e*) that the *p*-nitrobenzyl ester is far superior to the benzyl ester in the synthesis of thienamycin analogs.

Karady *et al.* prepared trimethylsilylenol ether of benzyl α-diazoacetoacetate (**4**) from benzyl α-diazoacetoacetate (**5**, R = CH_2Ph) by generating the enolate with a strong base such as lithium hexamethyldisilazide, followed by trapping with trimethylsilyl chloride. While successful for the benzyl ester, unfortunately this method, which required a strong base, was not compatible with the *p*-nitrobenzyl ester, producing an intractable mixture with only a little of the desired material **6***a* (Scheme 1).

Here we wish to report (1) a facile preparation of trimethylsilylenol ether and *tert*-butyldimethylsilylenol ether of *p*-nitrobenzyl α-diazoacetoacetate (**6***a* and **7***a*) as well as some other corresponding esters (**6***b*−**6***d* and **7***b*−**7***d*), and (2) subsequent synthesis of a chiral carbapenem intermediate **2** (R = $-CH_2-C_6H_4-NO_2$) as shown in Scheme 1.

Thus, the trimethylsilylenol ether of *p*-nitrobenzyl α-diazoacetoacetate (**6***a*) was prepared in good yield from *p*-nitrobenzyl α-diazoacetoacetate (**5***a*)[3] by using trimethylsilyl trifluoromethanesulfonate as a silylating agent (5*a*) and triethylamine as a base. The reaction was complete within a few minutes in CH_2Cl_2 at 0−5°C. Although several other methods are available for the preparation of silylenol ethers (5*b*, *c*), we find this method simplest and most successful for the preparation of **6***a*. The structural assignment of this silylenol ether was made by means of its ^{1}Hmr spectrum, which showed disappearance of the acetyl group at 2.50 ppm (in compound **5***a*) and appearance of two sharp doublets at 4.23 and 4.93 ppm with a coupling constant of 2 Hz for the vinyl protons.

Although readily prepared, the trimethylsilylenol ether was somewhat labile and easily hydrolyzed to *p*-nitrobenzyl α-diazoacetoacetate (**5***a*) on contact with water or simply atmospheric moisture, thereby creating difficulty in handling. To overcome this problem, we prepared the corresponding *tert*-butyldimethylsilylenol ether **7***a* by the method described above using *tert*-butyldimethylsilyl trifluoromethanesulfonate (7) in place of trimethylsilyl trifluoromethanesulfonate (see Scheme 1). In contrast to the trimethylsilylenol ether **6***a*, the *tert*-butyldimethylsilylenol ether **7***a* was more stable towards neutral water, permitting aqueous work-up. The *tert*-butyldi-

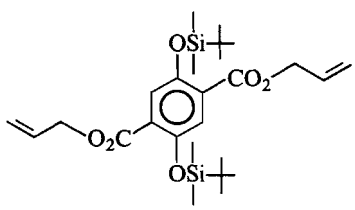
SCHEME 1.

methylsilylenol ether **7***a* (a yellow solid) has been stored in a capped bottle in a refrigerator (0–5°C) for more than 1 year without any hydrolysis to diazoacetoacetate **5***a*.

This method was found to be quite general. Thus, we prepared trimethylsilylenol ethers and *tert*-butyldimethylsilylenol ethers of allyl (**6***b* and **7***b*), trimethylsilylethyl (**6***c* and **7***c*), and ethyl (**6***d* and **7***d*) esters of α-diazoacetoacetic acid from α-diazoacetoacetates,[3] **5***b*–**5***d*. Some of these esters (e.g. allyl (8) and trimethylsilylethyl (9)) have been demonstrated to be useful carboxyl protecting groups in the synthesis of labile molecules such as penems and carbapenems.

The facile preparation of the *tert*-butyldimethylsilylenol ethers (**7***a*–**7***b*) is of particular interest, because generally the *tert*-butyldimethylsilylenol ether of α-diazoacetoacetates **7** could not be prepared, in our hands, by the method of Karady *et al.* (3*a*) which was successful for the preparation of the corresponding trimethylsilylenol ethers **6**. For example, the enolate generated from allyl α-diazoacetoacetate by lithium hexamethyldisilazide in the presence of tetramethylethylenediamine did not react with *tert*-butyldimethylsilyl chloride at −78°C. The reaction at 0°C produced diallyl terephthalate **10**[4], not silylenol ether **7***b*. The compound **10** was formed,[4] presumably by dimerization of the enolate of α-diazoacetoacetate followed by oxidation.

We investigated a direct introduction of the α-diazoacetoacetate moiety into the 4-position of 2-azetidinone by



10

displacement reaction of azetidinone **3** with these silylenol ethers under the conditions of Reider *et al.* (4). An optically active 4-acetoxyazetidinone **8** was chosen as an azetidinone counterpart, for it was available from 6-aminopenicillanic acid (11) and it had the correct stereoconfigurations at the 3- and 1′-positions, for the synthesis of thienamycin analogs **1**.

As expected, the trimethylsilylenol ether **6***a* gave, stereospecifically, *trans*-azetidinone **9***a* in 54% yield. Interestingly, the *tert*-butyldimethylsilylenol ether **7***a* also reacted smoothly with 4-acetoxyazetidinone **8** in the presence of zinc chloride to produce, stereospecifically, *trans*-diazoazetidinone **9***a* in 84% yield. The assignment of the *trans*-stereochemistry was readily achieved on the basis of a small coupling constant between H3 and H4 (J_{3-4} = 1.5 Hz).

This stereospecific formation of *trans*-azetidinone, combined with the fact that the starting 4-acetoxyazetidinone has the *tert*-butyldimethylsiloxyethyl group at the 3-position with the *S*-configuration, establishes the stereochemistry at the 4-position of the product as the one found in the natural series such as thienamycin.

Finally, desilylation of this diazoazetidinone **9***a* with 1 *N* aqueous HCl in MeOH afforded key thienamycin precursor **2***a* in 84% yield. The key intermediate, **2***a*, has spectroscopic properties (^{1}Hmr, ir) consistent with data reported by Christensen *et al.* (2*b*). This compound was previously converted to thienamycin **1** (R = $CH_2CH_2NH_2$) and its analogs (2).

This whole sequence, starting from *p*-nitrobenzyl α-diazoacetoacetate (**5***a*) via the *tert*-butyldimethylsilylenol ether **7***a* constitutes an improved and practical method for the synthesis of thienamycin analogs **1**.

In summary, the trimethylsilyl- and *tert*-butyldimethylsilylenol ethers of various esters (including *p*-nitrobenzyl ester) of α-diazoacetoacetic acid were prepared by use of trimethylsilyl trifluoromethanesulfonate and *tert*-butyldimethylsilyl trifluoromethanesulfonate respectively, and they were found to be useful synthons for the synthesis of key carbapenem precursors **2**.

Experimental

Melting points were determined on a Gallenkamp melting point

[4]The structure **10** was tentatively assigned, based on the mechanistic considerations and its spectroscopic data. Ethyl γ-chloroacetoacetate was also reported to produce diethyl 2,5-dihydroxyterephthalate by base treatment.

apparatus and are not corrected. The infrared spectra were recorded on a Perkin-Elmer 267 grating infrared spectrometer. The ^{1}H nuclear magnetic resonance spectra were taken with either the Varian EM-360 (60 MHz), unless specified, or a Varian CFT-20 (80 MHz) nmr spectrometer. Tetramethylsilane was used as an internal standard and chemical shifts are reported in parts per million (δ) relative to the internal standard. The ultraviolet spectra were recorded on a Unicam SP8-100 uv spectrometer. Optical rotations were measured with a Perkin–Elmer Model 141 polarimeter. Tetrahydrofuran was freshly distilled from lithium aluminum hydride. Anhydrous diethyl ether (Fisher) was used without further treatment. All other solvents were reagent grade and had been stored over molecular sieves before use. Triethylamine and tetramethylethylenediamine were distilled from CaH_2 and stored over NaOH. Anhydrous zinc chloride was fused under reduced pressure and pulverized prior to use. Allyl diazoacetoacetate (**5***b*) (12) and ethyl diazoacetate (**5***d*) (6*a*) were prepared by the general procedure of Regitz (6). Analytical thin layer chromatography (tlc) was conducted on precoated plates (Silica Gel 60F-254, E. Merck). Visualization was effected by uv light, and iodine or ammonium molybdate (VI). Preparative layer chromatography (plc) was performed on silica gel plates prepared from Silica Gel 60 GF-254 (E. Merck). For column chromatography, 70–230 mesh Silica Gel (E. Merck) was used. The analyses were performed by Micro-Tech Laboratories, Skokie, Illinois, U.S.A.

p-*Nitrobenzyl acetoacetate*

A mixture of ethyl acetoacetate (140 g, 1.08 mol; Aldrich) and *p*-nitrobenzyl alcohol (153 g, 1.00 mol; Aldrich) in toluene (1 L) was heated and slowly distilled, removing 900 mL of the distillate over a period of 15 h. After cooling, any insoluble material was removed by filtration over Celite, washed with toluene. The filtrate and washings were combined and evaporated *in vacuo* to obtain 280 g of a crude oil. This oil was crystallized at 5°C from diethyl ether (280 mL) to yield 181.55 g (0.766 mol, yield 76.6%) of the title compound as off-white crystals, mp 40–42°C; R_f 0.45 (Et_2O); ir (film) ν_{max}: 1740 (ester), 1715 (ketone), 1515 and 1345 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.98 (0.3H, s, *Me*(OH)═), 2.32 (2.7H, s, CH_3), 3.62 (1.8H, s, —CO*CH*$_2$CO$_2$—), 5.08 (0.1H, s, vinyl proton of the enol form), 5.28 (2H, s, —CO$_2$*CH*$_2$Ar), 7.53 (2H, 'd', *J* = 9 Hz, ArH's), and 8.23 (2H, 'd', *J* = 9 Hz, ArH's) ppm. An analytical sample was obtained by recrystallization from toluene–hexanes, mp 44–45°C; uv (CH_2Cl_2)λ_{max}: 267 nm (ε 10 800), *Anal.* calcd. for $C_{11}H_{11}NO_5$: C 55.70, H 4.67, N 5.91; found: C 55.59, H 4.62, N 5.85.

Trimethylsilylethyl acetoacetate

A solution of ethyl acetoacetate (2.60 g, 20 mmol; Aldrich) and trimethylsilylethanol (2.51 g, 21.1 mmol; Fluka) in toluene (100 mL) was heated and slowly distilled at 80–100°C with a Vigreux column (1.7 cm × 7 cm), removing most of the solvent over a period of 10 h. The residue was distilled under reduced pressure with a Vigreux column (1.7 cm × 7 cm) to obtain 3.34 g (16.5 mmol, yield 82.7%) of the title compound as a colourless oil; R_f 0.32 (20% EtOAc/hex); bp 85–88°C (0.3 Torr; 1 Torr = 133.3 Pa) (lit. (13) bp 77–80°C (1 Torr)); ir (neat) ν_{max}: 1740 (ketone) and 1720 (ester) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.07 (9H, s, $SiMe_3$), 1.00 (2H, 't' *J* = 8 Hz, $SiCH_2$), 1.93 (0.45H, s, *Me*C(OH)═), 2.28 (2.55H, s, MeCO), 3.12 (0.15H, s, OH of the enol form), 3.43 (1.7H, s, $COCH_2$), 4.2 (2H, 't', *J* = 8 Hz, CO_2CH_2), and 4.95 (0.15H, s, vinyl proton of the enol form) ppm; *Anal.* calcd. for $C_9H_{18}O_3Si$: C 53.43, H 8.97; found: C 53.19, H 8.82.

p-*Nitrobenzyl α-diazoacetoacetate* (*5*a)

To a solution of *p*-nitrobenzyl acetoacetate (134.6 g, 0.568 mol) and triethylamine (79.0 nL, 0.568 mol) in CH_3CN (340 mL) was added at 0–5°C under a nitrogen atmosphere *p*-toluenesulfonyl azide[5] (14) (130 g, 0.568 mol, estimated purity 86%) over a period of 15 min. During this period the title compound started precipitating. The cooling bath was removed and the mixture stirred at room temperature for 3 h. The mixture was cooled again in an ice bath for 30 min and the precipitate was filtered, washed with cold CH_3CN (75 mL), and then cold Et_2O (200 mL) to yield 135.06 g (0.514 mol, yield 90.4%) of the title compound as pale yellow powder; R_f 0.65 (EtOAc); ir (CH_2Cl_2) ν_{max}: 2130 (N_2), 1720 (ester), 1655 (ketone), 1520 and 1350 (NO_2) cm^{-1}; uv (CH_2Cl_2) λ_{max}: 260 nm (ε 17 400); ^{1}Hmr ($CDCl_3$) δ: 2.50 (3H, s, CH_3), 5.38 (2H, s, CO_2CH_2Ar), 7.53 (2H, 'd', *J* = 9 Hz, ArH's), and 8.27 (2H, 'd', *J* = 9 Hz, ArH's) ppm.

2-Trimethylsilylethyl α-diazoacetoacetate (*5*c)

To a solution of trimethylsilylethyl acetoacetate (10.6 g, 50.0 mmol) and triethylamine (7.10 mL, 51.5 mmol) in acetonitrile (85 mL) was added in an ice bath *p*-toluenesulfonyl azide[5] (14) (10.0 g, 50.7 mmol) and the reaction mixture stirred at room temperature for 20 h. After evaporation of the solvent *in vacuo*, the residue was extracted with Et_2O (90 mL) and this extract was washed with a solution of KOH (3.0 g) in H_2O (83 mL) and again a solution of KOH (0.9 g) in H_2O (30 mL), then brine, and dried (Na_2SO_4). Evaporation of the solvent *in vacuo* gave 11.6 g of a crude oil which was purified by column chromatography (SiO_2, 150 g) eluting with 20% EtOAc/hexanes, to obtain 9.65 g (42.3 mmol, yield 84.5%) of the title compound as yellowish oil; R_f 0.44 (20% EtOAc/hex); ir (neat) ν_{max}: 2130 (C═N_2), 1715 (ester), and 1660 (ketone) cm^{-1}; uv (CH_2Cl_2) λ_{max}: 257 nm (ε 7200); ^{1}Hmr ($CDCl_3$) δ: 0.07 (9H, s, $SiMe_3$), 1.03 (2H, 't' *J* = 8 Hz, CH_2Si), 2.47 (3H, s, $COCH_3$), and 4.30 (2H, 't' *J* = 8 Hz, CO_2CH_2) ppm.

2-Diazo-3-trimethylsilyloxy-3-butenoic acid esters (**6**a–**6**d) *(general procedure)*

To a stirred solution (or suspension for the *p*-nitrobenzyl ester) of α-diazoacetoacetic acid esters, **5***a*–**5***d*, (1 mmol) and triethylamine (0.20 mL, 1.4 mmol) in dry CH_2Cl_2 or CCl_4 (2 mL) was added at 0–5°C trimethylsilyl trifluoromethanesulfonate (0.22 mL, 1.1 mmol; Aldrich) under a dry nitrogen atmosphere and the mixture stirred (0–5°C, N_2) for 30 min. To this clear yellow solution was added anhydrous hexanes (30 mL for the *p*-nitrobenzyl ester or 5 mL for the other esters) and stirred for 10 min under a nitrogen atmosphere. After removing the oily deposit by gravity filtration, the hexanes solution was evaporated *in vacuo* and the residue was re-dissolved in anhydrous hexanes (50 mL for the *p*-nitrobenzyl ester or 10 mL for the other esters). The insoluble material was again removed by gravity filtration and the filtrate was evaporated *in vacuo* to obtain **6***a* as yellow crystals or **6***b*–**6***d* as orangish oil in 77–97% yield. The whole operation should be performed under an anhydrous atmosphere since the products are sensitive to moisture.

Compound **6**a: 90% yield: ir (film) ν_{max}: 2100 (C═N_2), 1705 (ester), 1520 and 1345 (NO_2) cm^{-1}; ^{1}Hmr (CCl_4) δ: 0.28 (9H, s, $SiMe_3$), 4.17 (1H, d, *J* = 2 Hz, vinyl proton), 4.93 (1H, d, *J* = 2 Hz, vinyl proton), 5.29 (2H, s, CO_2CH_2Ar), 7.50 (2H, 'd' *J* = 9 Hz, ArH's), and 8.20 (2H, 'd', *J* = 9 Hz, ArH's) ppm.

Compound **6**b: 77% yield: ir (neat) ν_{max}: 2100 (C═N_2), 1710 (ester), and 1605 (C═C) cm^{-1}; ^{1}Hmr (CCl_4) δ: 0.20 (9H, s, $SiMe_3$), 4.15 (1H, d, *J* = 2 Hz, vinyl proton), 4.63 (2H, d, *J* = 5 Hz, CO_2CH_2), 4.95 (1H, d, *J* = 2 Hz, vinyl proton), and 5–6.2 (3H, m, vinyl protons) ppm.

Compound **6**c: 97% yield; ir (neat) ν_{max}: 2090 (C═N_2), 1705 (ester), and 1605 (C═C) cm^{-1}; ^{1}Hmr (CCl_4) δ: 0.07 (9H, s, $SiMe_3$), 0.25 (9H, s, $OSiMe_3$), 1.00 (2H, 't', *J* = 8 Hz, CH_2Si), 4.15 (1H, d, *J* = 2 Hz, vinyl proton), 4.23 (2H, 't' *J* = 8 Hz, CO_2CH_2), and 4.98 (1H, d, *J* = 2 Hz, vinyl proton) ppm.

Compound **6**d: 78% yield; ir (neat) ν_{max}: 2090 (C═N_2), 1710 (ester), and 1605 (C═C) cm^{-1}; ^{1}Hmr (CCl_4) δ: 0.25 (9H, s, $SiMe_3$), 1.32 (3H, t, *J* = 7 Hz, CH_3), 4.17 (1H, d, *J* = 2 Hz, vinyl proton), 4.23 (2h, q, *J* = 7 Hz, CO_2CH_2), and 4.97 (1H, d, *J* = 2 Hz, vinyl proton) ppm.

[5]*p*-Toluenesulfonyl azide, when prepared from unpurified *p*-toluenesulfonyl chloride by warming (ca. 50°C) to dissolve in EtOH, was contaminated by ethyl *p*-toluenesulfonate (ca. 15%). *p*-Toluenesulfonyl azide, free from ethyl *p*-toluenesulfonate, can also be prepared in aqueous acetone.

p-*Nitrobenzyl 2-diazo-3-(*tert-*butyldimethylsiloxy)-3-butenoate (7a)*

To a stirred suspension of *p*-nitrobenzyl α-diazoacetoacetate (26.30 g, 0.100 mol) and triethylamine (20.0 mL, 0.140 mol) in CH_2Cl_2 (200 mL) was added at 2°C *tert*-butyldimethylsilyl trifluoromethanesulfonate (27.5 mL, 0.12 mol; Fluka), in 30 min, under a nitrogen atmosphere and the mixture stirred at 2°C for 1 h. The clear orange solution was diluted with CH_2Cl_2 (50 mL) and washed with water (3 × 200 mL) and then brine (100 mL), dried (Na_2SO_4), and evaporated, yielding 37.40 g (0.0991 mol, yield 99.1%) of the title compound as a yellow solid; R_f 0.44 (20% EtOAc/hex: partially decomposed to *p*-nitrobenzyl α-diazoacetoacetate on the plate); ir (film) ν_{max}: 2090 (br, C=N_2), 1694 (ester), 1600 (C=C), and 1344 (NO_2) cm^{-1}; uv (CH_2Cl_2) λ_{max}: 271 nm (ε 14 500); ^{1}Hmr ($CDCl_3$) δ: 0.26 (6H, s, $SiMe_2$), 0.96 (9H, s, Si-*t*Bu), 4.25 (1H, d, J = 2.5 Hz, vinyl proton), 4.97 (1H, d, J = 2.5 Hz, vinyl proton), 5.32 (2H, s, CO_2H_2), 7.48 (2H, 'd' J = 9 Hz, ArH's), and 8.22 (2H, 'd', J = 9 Hz, ArH's) ppm. This material was purified by crystallization from hexanes to obtain an analytical sample: uv (CH_2Cl_2) λ_{max} 270 nm (ε 15 500).

*2-Diazo-3-(*tert-*butyldimethylsiloxy)-3-butenoic acid esters (7b–7d) (general procedure)*

To a stirred solution of α-diazoacetoacetic acid esters, **5b–5d**, (1 mmol) and triethylamine (0.20 mL, 1.4 mmol) in dry CH_2Cl_2 (2 mL) was added, at 0–5°C, *tert*-butyldimethylsilyl trifluoromethanesulfonate (0.28 mL, 1.2 mmol; Fluka) under a nitrogen atmosphere and the yellow mixture stirred at 0–5°C for 15 min. This was diluted with hexanes (20 mL), washed with a diluted $NaHCO_3$ solution and then brine, dried (Na_2SO_4), and evaporated to obtain **7b–7d** as orangish oil in 93–99% yield.

Compound **7b**: 96% yield; R_f 0.6 (20% EtOAc/hex; partially decomposed to α-diazoacetoacetate on the plate); ir (film) ν_{max}: 2100 (C=N_2), 1715 (ester), and 1610 (C=C) cm^{-1}; uv (CH_2Cl_2) λ_{max}: 280 nm (ε 6000); ^{1}Hmr ($CDCl_3$) δ: 0.23 (6H, s, $SiMe_2$), 0.93 (9H, s, Si-*t*Bu), 4.20 (1H, d, J = 5 Hz, J = 2 Hz, vinyl proton), 4.63 (2H, br d, J = 5 Hz, CO_2CH_2), 4.95 (1H, d, J = 2 Hz, vinyl proton), and 5–6.3 (3H, m, vinyl protons) ppm.

Compound **7c**: 94% yield; R_f 0.7 (20% EtOAc/hex; partially decomposed to α-diazoacetoacetate on the plate); ir (film) ν_{max}: 2100 (C=N_2), 1710 (ester), and 1610 (C=C) cm^{-1}; uv (CH_2Cl_2) λ_{max}: 280 nm (ε 7600); ^{1}Hmr (acetone-d_6; CFT-20) δ: 0.06 (9H, s, $SiMe_3$), 0.25 (6H, s, $SiMe_2$), 0.94 (9H, s, Si-*t*Bu), 1.05 (2H, t, J = 8.3 Hz, $CO_2CH_2CH_2SiMe_3$), 4.31 (1H, d, J = 1.8 Hz, vinyl proton), 4.32 (2H, t, J = 8.3 Hz, $CO_2CH_2CH_2SiMe_3$), and 5.03 (1H, d, J = 1.8 Hz, vinyl proton) ppm.

Compound **7d**: 99% yield; R_f 0.66 (20% EtOAc/hex; partially decomposed to α-diazoacetoacetate on the plate); ir (film) ν_{max}: 2090 (C=N_2), 1710 (ester), and 1610 (C=C) cm^{-1}; uv (CH_2Cl_2) λ_{max}: 282 nm (ε 7950); ^{1}Hmr (acetone-d_6; CFT-20) δ: 0.25 (6H, s, $SiMe_2$), 0.94 (9H, s, Si-*t*Bu), 1.26 (3H, t, J = 7.1 Hz, $CO_2CH_2CH_3$), 4.25 (2H, q, J = 7.1 Hz, $CO_2CH_2CH_3$), 4.28 (1H, d, J = 2 Hz, vinyl proton), and 5.02 (1H, d, J = 1.9 Hz, vinyl proton) ppm.

*Attempted preparation of allyl 3-*tert-*butyldimethylsiloxy-2-diazo-3-butenoate 7b through the enolate (formation of diallyl terephthalate **10***

To a stirred solution of lithium hexamethyldisilazide in THF (1 *M* solution, 1.2 mL, 1.2 mmol; Aldrich) and tetramethylethylenediamine (0.16 mL, 1.1 mmol) in THF (4 mL) was added slowly at −78°C, under a nitrogen atmosphere, allyl α-diazoacetoacetate (**5b**) (12) (168 mg, 1.00 mmol) and the mixture stirred (−78°C, N_2) for 1 h. To this solution was added a solution of *tert*-butyldimethylsilyl chloride (237 mg, 1,57 mmol; Aldrich) in THF (0.8 mL) and this was stirred at −78°C for 20 min. The mixture (1.2 ml) was partitioned between H_2O and hexanes. The hexanes phase was dried (Na_2SO_4) and evaporated to obtain 52 mg of a crude oil, the ^{1}Hmr ($CDCl_3$) spectrum of which indicated this to be mainly the starting diazoacetoacetate **5b**. The rest of the reaction mixture was warmed gradually to 0°C by replacing the Dry Ice − acetone bath with an ice bath over a period of 2 h. This was diluted with hexanes, washed with H_2O, dried (Na_2SO_4), and evaporated, yielding 241 mg of an oily solid. Purification of this material by plc (SiO_2, Et_2O/hex 1:1) gave 101 mg of diallyl 2,5-bis (*tert*-butyldimethylsiloxy)terephthalate (**10**) as a white solid; R_f 0.19 (Et_2O/hex 1:1); ir (film) ν_{max}: 1720 (ester) cm^{-1}: ^{1}Hmr ($CDCl_3$) δ: 0.15 (6H, s, $SiMe_2$), 0.95 (9H, s, Si-*t*Bu), 4.75 (2H, br d, J = 6 Hz, CO_2CH_2), 5–6.4 (2H, m, vinyl protons), and 7.27 (1H, s, ArH) ppm.

This material in EtOH was treated with 1 *N* aqueous HCl at room temperature to obtain diallyl 2,5-dihydroxyterephthalate, mp 85–87°C; R_f 0.47 (EtOAc); ir (film) ν_{max}: 3400 (OH) and 1700 (ester) cm^{-1}; ^{1}Hmr ($CDCl_3$, CFT-20) δ: 4.89 (2H, 'd', J = 5.81 Hz, CO_2CH_2), 5–6.4 (2H, m, vinyl protons), 7.34 (1H, s, ArH), and 8.20 (br, OH) ppm. This compound gave intense purple colour when treated with an aqueous solution of ferric chloride, indicating the presence of a phenolic hydroxy group (10).

*(3S)-{(1R)-(*tert-*butyldimethylsiloxy)ethyl}-(4R)-{3-(*p-*nitrobenzyloxy) carbonyl-2-oxo-3-diazopropan-1-yl}azetidin-2-one (9a)*

To a stirred mixture of (3*R*)-{(1*R*)-(*tert*-butyldimethylsiloxy)-ethyl)-(4*R*)-acetoxy-2-azetidinone (**8**) (144 mg, 0.50 mmol, mp 101–103°C) (11) and anhydrous $ZnCl_2$ (34 mg, 0.25 mmol) in CH_2Cl_2 (3 mL) was added at room temperature, under a nitrogen atmosphere, a solution of *p*-nitrobenzyl 2-diazo-3-trimethylsiloxy-3-butenoate (**6a**) (308 mg, 1.00 mmol) or *p*-nitrobenzyl 3-(*tert*-butyldimethylsiloxy)-2-diazo-3-butenoate (**7a**) (226 mg, 0.60 mmol) over a period of 2–3 h. The mixture was stirred another 1–2 h under the same conditions. This was diluted with EtOAc (20 mL), washed with H_2O and then brine, dried (Na_2SO_4), and evaporated, yielding a crude oil. This was purified by column chromatography (SiO_2, 20 g) eluting with 20% EtOAc in CH_2Cl_2 to obtain 132 mg (0.269 mmol, yield 53.8%) from the reaction with **6a**, or 207 mg (0.422 mmol, yield 84.4%) from the reaction with **7a**, of the title compound as a colourless oil; R_f 0.39 (20% EtOAc/CH_2Cl_2); ir (neat) ν_{max}: 3000 (br, NH), 2140 (C=N_2), 1755 (β-lactam), 1720 (ester), 1655 (C=O), 1525 and 1350 (NO_2) cm^{-1}; $[\alpha]_D^{20}$ +44.3° (*c* 1.0, CH_2Cl_2); ^{1}Hmr ($CDCl_3$, CFT-20) δ: 0.06 (6H, s, $SiMe_2$), 0.86 (9H, s, Si-*t*Bu), 1.21 (3H, d, J = 6.3 Hz, 1′-Me), 2.85 (1H, dd, $J_{3-1'}$ = 5Hz, J_{3-4} = 2.5 Hz, 3-H), 2.96 (1H, dd, J_{gem} = 18 Hz, $J_{1''-4}$ = 9.5 Hz, 1″–Ha), 3.41 (1H, dd, J_{gem} = 18 Hz, $J_{1''-4}$ = 3.5 Hz, 1″–Hb), 3.8–4.3 (2H, m, 4–H and 1′–H), 5.35 (2H, s, CO_2CH_2Ar), 5.95 (br, s, NH), 7.53 (2H, 'd', J = 8.8 Hz, ArH's), and 8.26 (2H, 'd', J = 8.8 Hz, ArH's) ppm.

The reaction with **7a** was also carried out on a large scale (0.25 mol of **8**) without lowering the yield.

*(3S)-{(1R)-Hydroxyethyl}-(4R)-{3-(*p-*nitrobenzyloxy)carbonyl-2-oxo-3-diazopropan-1-yl}azetidin-2-one (2a)*

To a stirred solution of **9a** (39.25 g, 80.0 mmol) in MeOH (240 mL) was added 1 *N* aqueous HCl (80 mL) and the mixture stirred at room temperature for 6 h. During this period the title compound was precipitated. This was cooled, filtered, and washed with cold MeOH–H_2O (9:1) and then cold Et_2O to obtain 25.26 g (67.2 mmol, yield 84.0%) of the title compound as white solid, mp 151–152°C (CH_3CN); $[\alpha]_D^{22}$ +21.8° (*c* 0.23, CH_3CN); R_f 0.19 (EtOAc); ir (Nujol) ν_{max}: 3390 (OH), 2130 (C=N_2), 1730 (β-lactam), 1705 (ester), 1660 (ketone), 1605 (Ar), 1520 and 1350 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$, CFT-20) δ: 1.33 (3H, d, J = 6.3 Hz, 1′–Me), 1.91 (br, OH), 2.88 (1H, dd, $J_{3-1'}$ = 7.3 Hz, J_{3-4} = 2.2 Hz, 3–H), 3.25 (2H, m, 1′–H's), 3.8–4.2 (1H, m, 4–H), 4.17 (1H, 'q', J = 6.7 Hz, 1′–H), 5.36 (2H, s, CO_2CH_2), 5.96 (1H, br, NH), 7.54 (2H, 'd', J = 8.6 Hz, ArH's), and 8.27 (2H, 'd', J = 8.7 Hz, ArH's) ppm.

Reagents and synthetic methods 41: oxidations with chromium trioxide under the influence of crown ethers

M. JUARISTI, J. M. AIZPURUA, B. LECEA, AND C. PALOMO[1]

Kimika Organikako Departamentua, Kimika Fakultatea, Euskal Herriko Unibertsitatea, Altza, Donostia, Spain

Received May 16, 1984

M. JUARISTI, J. M. AIZPURUA, B. LECEA, and C. PALOMO. Can. J. Chem. **62**, 2941 (1984).

An unusual new application of crown ethers in organic synthesis is described. Chromium trioxide, in the presence of a crown ether as catalyst, in dichloromethane as solvent, was found an efficient oxidizing system for the chemoselective oxidation of mercaptans to disulfides. It is also highly efficient for the oxidation of hydroquinones to the corresponding benzoquinones in almost quantitative yield. A high conversion of polynuclear hydrocarbons into quinones in acetic acid media is also briefly described.

M. JUARISTI, J. M. AIZPURUA, B. LECEA et C. PALOMO. Can. J. Chem. **62**, 2941 (1984).

On décrit une utilisation nouvelle et exceptionnelle des éthers couronnes en synthèse organique. On a trouvé que le trioxyde de chrome dans le dichlorométhane, en présence d'un éther couronne comme catalyseur, permet d'oxyder les mercaptans en disulfures d'une manière efficace et chimiosélective. Ce système est également très efficace pour oxyder les hydroquinones en benzoquinones correspondantes avec un rendement presque quantitatif. On décrit brièvement une transformation, qui se fait avec des taux élevés de conversion, d'hydrocarbures polynucléaires en quinones en milieu acétique.

The use of crown ethers in organic synthesis has become significant during recent years. Concerning oxidation reactions, they have been used in phase transfer catalyzed permanganate, chromate, dichromate, and potassium superoxide promoted oxidation reactions (1); however, no report related to oxidation reactions achieved by means of chromium trioxide/crown ether systems has been described. We have recently reported the first application of crown ethers in the oxidation of alcohols to carbonyl compounds promoted by chromium trioxide (2). This communication describes a preparative application of this new oxidizing system.

Oxidation of mercaptans

Selective oxidation of mercaptans to disulfides without overoxidation is well investigated, and several reagents have been used for this purpose (3). However, selective oxidation between mercaptans is rare. We wish to report here the first evidence of the oxidation of mercaptans to disulfides promoted by powdered chromium trioxide under the influence of crown ethers. Moreover, our major finding is that arenethiols are chemoselectively oxidized to the corresponding arenedisulfides in the presence of alkanethiols by means of this oxidation system.

In order to find the optimum reaction conditions, we have tested this method for 4-chlorothiophenol using different molar ratios of thiol to chromium trioxide. The results are summarized in Table 1, and show that the molar ratio of thiol to chromium trioxide necessary for a total oxidation is 1:4. The role of the crown ether as phase transfer agent is not clear at present, but in its absence no oxidation takes place, and the starting thiol is recovered unchanged.

Figure 1 shows the chemoselective oxidation of an equimolecular mixture of benzenethiol and benzylmercaptan by means of this oxidizing system. Thus, equimolecular mixtures of the respective thiols were treated with chromium trioxide

and a catalytic amount of 18-crown-6 in dichloromethane for different reaction times. The reaction mixture was analyzed from its ^1H nmr spectrum, mainly by observing the change of the relative intensities of the corresponding mercapto groups. The chemoselectivity of this oxidation system is further demonstrated by the representative examples listed in Table 2. As shown in runs 4 and 5, benzylmercaptan alone is slowly oxidized to the corresponding disulfide, but this oxidation is minimized when an arenethiol is present. To our knowledge, this is an unusual oxidation reaction.

Preparation of quinones

Conversion of polynuclear aromatic hydrocarbons and hydroquinones into their corresponding quinones is of great preparative value in organic synthesis, because their structure is observed in some synthetic dyes and in many naturally occurring substances. Various oxidizing agents have been developed for the synthesis of quinones (4). Recently, Chaudhuri and co-workers (4*c*) have reported that pyridium fluorochromate oxidizes anthracene and phenanthrene to their corresponding quinones in good to excellent yields, but this method seems to be not very convenient for a large preparative scale. Pletcher *et al.* (4*d*) have described the oxidation of polynuclear hydrocarbons by dichromate anions in aqueous sulfuric acid under phase transfer conditions, even if low yields are obtained in the oxidation of naphthalenes.

In a first experiment, we have found that under the same conditions as those used in the oxidation of mercaptans, polynuclear aromatic hydrocarbons are oxidized into quinones in poor yields. However, when the reaction was carried out in glacial acetic acid, anthracenes were rapidly transformed into anthraquinones in nearly quantitative yield, and the reaction proceeded more smoothly than in the conventional procedure (4*c*). Although in the case of anthracenes the yields are comparable to those obtained from chromium trioxide/acetic acid alone (4*e*), the oxidation of naphthalenes into naphthoquinones in yields of the range 50–60% (Table 3) when crown ethers are used as catalysts is of special significance.

The wide utility of this oxidation system is further exemplified by the fast and mild oxidation of hydroquinones in almost quantitative yields. In a preliminary observation, we have found that 2-chlorohydroquinone was slowly oxidized to 2-chlorobenzoquinone by chromium trioxide in dichloromethane as solvent, but in the presence of a catalytic amount of 18-crown-6 the reaction takes place much more rapidly. When the hydroquinone was not soluble in dichloromethane, the reaction was carried out by adding a diethyl ether/dichloromethane (50% v) solution of the substrates to a suspension of powdered chromium trioxide in dichloromethane. In such cases, addition of crown ethers is not necessary and the reaction proceeds very quickly. We suppose that diethyl ether and crown ethers can act in a similar manner with chromium trioxide to form some active soluble species which are able to oxidize hydroquinones into benzoquinones under mild conditions and nearly quantitative yields. The results are summarized in Table 4. The synthetic utility of this procedure is shown by the conversion of trimethyl-*p*-hydroquinone to the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

corresponding *p*-benzoquinone, which is a key intermediate in the synthesis of tocopherol (Vitamin E) (5).

Conclusions

The results obtained show the versatility of the present method and the advantages of the use of readily accessible and inexpensive chromium trioxide instead of other reagents employed in oxidation reactions, especially when used on a molar preparative scale.

Experimental

Chemoselective oxidation of thiophenol

To a suspension of finely powdered chromium trioxide (4.0 g, 40 mmol) in dichloromethane (30 mL), 18-crown-6 (0.3 g, 1.1 mmol) was added and the suspension was stirred at room temperature for 10 min to form a red-brown heterogeneous mixture. Then, thiophenol (1.02 mL, 10 mmol) and benzyl mercaptan (1.18 mL, 10 mmol) were added consecutively and the mixture was stirred at room temperature until the arenethiol could no longer be detected by tlc analysis (silica gel plates; n-hexane/ethyl acetate 1:3). On completion (2.5 h), the reaction mixture was worked up by filtration through silica gel. Removal of the solvent left a mixture of products which was analyzed from its nmr spectrum and then purified by distillation and crystallization, to give phenyldisulfide (0.84 g, 77%), mp 60–61°C (lit. (*4c*) mp 61–62°C) and unchanged benzyl mercaptan (0.93 g, 75% recovered), bp 140–145°C/20 Torr (1 Torr = 133.3 Pa).

Naphthoquinone. Typical procedure

A solution of naphthalene (1.28 g, 10 mmol) in glacial acetic acid (10 mL) was added dropwise to a suspension of finely powdered chromium trioxide (4 g, 40 mmol) and a catalytic amount of 18-crown-6 (0.4 g) in the same solvent (30 mL), at room temperature. The reaction mixture was heated in a steam bath at 50–55°C during 30 min. Then the reaction was allowed to reach room temperature, filtered off through a pad of silica gel, and washed with dichloromethane (100 mL). The organic layer was washed with water (3 × 50 mL) and then with saturated sodium hydrogen carbonate solution (3 × 50 mL). The solvent was dried with sodium sulfate and evaporated under reduced pressure to give a crude product which was crystallized from hexane to afford naphthoquinone (0.79 g, 50%), mp 115–116°C (lit. (6) mp 117–118°C).

Oxidation of hydroquinones

2,3,5-Trimethylhydroquinone (1.52 g, 10 mmol) in dichloromethane (25 mL)/diethyl ether (30 mL) was added dropwise to a suspension of powdered chromium trioxide (5 g, 50 mmol) in dichloromethane (10 mL) at 0–5°C over 10–15 min, and the mixture was stirred at room temperature for 5 min. The resulting dark-brown suspension was filtered off through a pad of silica gel and washed with dichloromethane (100 mL). Removal of the solvent gave 1.43 g (97%) of pure 2,3,5-trimethylbenzoquinone, mp 32–35°C (lit. (6) mp 32°C).

Total regiospecific synthesis of the selagine tricyclic ring system[1]

D. GRAVEL,[2] L. BORDELEAU, G. LADOUCEUR, J. RANCOURT,[3] AND D. THORAVAL[4]

Département de Chimie, Université de Montréal, C.P. 6210, Succ. A, Montreal (Que.), Canada H3C 3V1

Received July 30, 1984

D. GRAVEL, L. BORDELEAU, G. LADOUCEUR, J. RANCOURT, and D. THORAVAL. Can. J. Chem. **62**, 2945 (1984).

Starting from 4-methylcyclohexanone, a total synthesis of the selagine tricyclic ring system is described in which complete control of regiospecificity is achieved in the elaboration of functionality.

D. GRAVEL, L. BORDELEAU, G. LADOUCEUR, J. RANCOURT et D. THORAVAL. Can. J. Chem. **62**, 2945 (1984).

A partir de la méthyl-4 cyclohexanone, une synthèse totale du squelette tricyclique de la sélagine est rapportée dans laquelle un contrôle complet de la régiospécificité a été atteint dans l'élaboration de toutes les fonctions.

The total synthesis of selagine (**1**), a Lycopodium alkaloid whose structure was determined over twenty years ago by Wiesner, Valenta, and co-workers (1), still remains an open challenge in the literature and recent publications which have appeared (2–5) attest to the interesting problems of regiochemistry posed by this molecule.

In the present communication we report the first total synthesis of the selagine tricyclic ring system **2** which is constructed in a regiospecific sequence starting from 4-methylcyclohexanone (**3**). In a first stage, rapid and efficient access is gained to the key bicyclic precursor **4** which has all of the necessary functionality properly positioned to complete the AB ring portion of the target compound **1**.

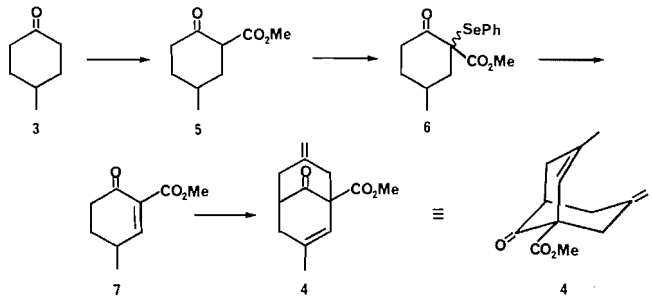
Carbomethoxylation of 4-methylcyclohexanone (**3**) by the Ruest–Blouin–Deslongchamps procedure (6) (NaH, KH cat., THF, Me_2CO_3, reflux) gave a 94% yield of the desired 2-carbomethoxy-4-methylcyclohexanone (**5**), bp 90–92°C/10 Torr (1 Torr = 133.3 Pa); ir ($CHCl_3$) ν_{max}: 1735, 1705, 1650, 1610 cm^{-1}; ^1H nmr[5] ($CDCl_3$) δ: 1.00 (d, J = 5.6 Hz, 3H), 1.0–2.5 (m, 7H), 3.75 (s, 3H), 12 (approx.) (s, 1H); ms, CI, *m/e*: 171 (MH^+), 140 ($MH^+ - OCH_3$). Introduction of unsaturation at the α,β-position also proceeded in essentially quantitative yield by the phenylselenenylation–oxidation method of Reich *et al.* (7). In a first step, phenylselenenylation of β-ketoester **5** (NaH, THF, PhSeCl, −78°C → rt) took place in a 96–100% yield to give **6** as a mixture of two isomers: orange oil; ir (film) ν_{max}: 1750–1705 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.93 and 0.99 (2d, J = 6.5 Hz and 7.0 Hz, 3H), 1.2–3.3 (m, 7H), 3.68 and 3.70 (2s, 3H), 7.2–7.8 (m, 5H); ms, CI, *m/e*: 324 (M^+), 326 ($M^+ + 2$). In a second step, oxidation of **6** (H_2O_2 30%, CH_2Cl_2, 0°C → rt) gave the expected α,β-unsaturated β-ketoester **7** in an 83–90% yield (crude): yellow oil, unstable, used as such for the next step; ir (film)



3 5 6 7 4 4

ν_{max}: 1735, 1685 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.24 (d, J = 7.0 Hz, 1H), 1.5–2.9 (m, 5H), 3.80 (s, 3H), 7.52 (m, 1H); ms, CI, *m/e*: 169 (MH^+). *Exact Mass* calcd. for $C_9H_{12}O_3$: 168.0787; found (ms): 168.0767. The crucial one-step annelation reaction (8) was then carried out on the α,β-unsaturated β-ketoester **7** using methallyl dichloride (NaH, DMF, $CH_2{=}C(CH_2Cl_2)$, 95°C) to yield the desired bicyclo[3.3.1] precursor **4** in a 35–42% yield: mp 102–103°C; ir (film) ν_{max}: 1740, 1718 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.74 (s, 3H), 2.1–3.3 (m, 7H), 3.79 (s, 3H), 4.8 (br s, 1H), 5.0 (br s, 1H), 5.3 (br s, 1H). *Anal.* calcd. for $C_{13}H_{16}O_3$: C 70.89, H 7.32; found: C 70.95, H 7.34.

Before coming to the second stage of the synthesis, i.e. the regiospecific introduction of a three-carbon side chain, precursor of the fused α-pyridone ring, some slight functional group adjustments were necessary. In the first instance, protection of the ketone in the usual manner was carried out prior to liberation of the latent carbonyl group by ozonolysis of the exocyclic methylene. Thus, ketalization of **4** (ethylene glycol, *p*-TsOH, C_6H_6, reflux) gave 70–80% of the corresponding ketal **8**: colorless oil; ir (film) ν_{max}: 1720 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.71 (s, 3H), 1.9–3.2 (m, 7H), 3.74 (s, 3H), 3.9 (m, 4H), 4.57 and 4.78 (2d, J = 2 Hz, 1H and J = 2 Hz, 1H), 5.28 (br s, 1H). *Exact Mass* calcd. for $C_{15}H_{20}O_4$: 264.1361; found (ms): 264.1360. Ozonolysis of the ketal **8** (O_3, CH_2Cl_2, −78°C, followed by Zn, AcOH, rt) yielded 70% of the desired ethylenedioxyketoester **9**: mp 77–78°C; ir ($CHCl_3$) ν_{max}: 1720 (br) cm^{-1}; ^1H nmr (400 MHz) ($CDCl_3$) δ: 1.72 (s, 3H), 1.94 (d, J = 17.8 Hz, 1H), 2.22 (ddd, J = 15.8, 2.7, and 1.8 Hz, 1H), 2.32 (m, 1H), 2.38 (dd, J = 14.9 and 2.8 Hz, 1H), 2.72 (dd broadened, $J \simeq 18$ and 6 Hz, 1H), 2.89 (dd, J = 15.7 and 6.6 Hz, 1H), 3.39 (d, J = 14.9 Hz, 1H), 3.76 (s, 3H), 3.93–4.14 (m, 4H), 5.45 (br s, 1H). *Exact Mass* calcd. for $C_{14}H_{18}O_5$: 266.1154; found (ms): 266.1154. This important intermediate in our synthetic plan was also synthesized by Kende *et al.* (5) using a totally different sequence and the reported spectroscopic data correspond to ours with minor discrepancies.

Having thus manipulated the functional groups to obtain

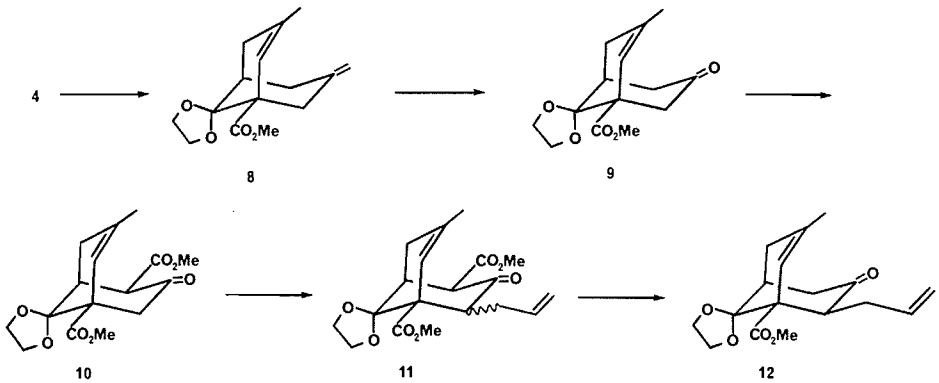
[5] The ^1H nmr spectra were recorded on a 90-MHz apparatus unless otherwise indicated.



intermediate **9** we were in a position, as stated above, to envisage the second stage of the synthesis, namely: the regiospecific introduction of a three-carbon side chain α to the ketone, precursor of the fused α-pyridone ring. This objective, it appeared, could possibly be attained in a number of ways, one of which readily achieved the desired regiospecific alkylation. Thus, a sequence of carbomethoxylation, alkylation, and decarbomethoxylation was employed. Application with slight modification of the procedure (6) used for compound **3** to the conversion of **9** (NaH, KH, MeONa, THF, Me_2CO_3, reflux), gave regiospecific α-carbomethoxylation at the methylene opposite to the angular carbomethoxy group to yield 65–70% of the bicyclic β-ketoester **10** (sole regioisomer found): mp 138–139°C; ir ($CHCl_3$) ν_{max}: 1730, 1660, 1620 cm^{-1}; ^1H nmr (400 MHz) ($CDCl_3$) δ: 1.72 (s, 3H), 1.95 (broadened d, J = 17.3 Hz, 1H), 2.37 (d, J = 18.1 Hz, 1H), 2.66 (broadened d, J = 17.4 Hz, 1H), 2.78 (dd, J = 5.1 and 1.4 Hz, 1H), 3.38 (d, J = 18 Hz, 1H), 3.76 (s, 3H), 3.77 (s, 3H), 3.89–4.08 (m, 4H), 5.47 (br s, 1H), 12.19 (br s, 1H). *Exact Mass* calcd. for $C_{16}H_{20}O_7$: 324.1209; found (ms): 324.1212. *Anal.* calcd. for $C_{16}H_{20}O_7$: C 59.25, H 6.22; found: C 59.42, H 6.46. Alkylation of **10** by the Weiler method (9) (LDA, THF, −78°C → 0°C, CH_2=CH—CH_2Br, HMPA, −78°C → rt) yielded 74–80% of the desired ketodiester **11** as a mixture of stereoisomers; more polar isomer (tlc, ethyl acetate – hexanes 2:3): yellowish oil; ir (film) ν_{max}: 1720, 1640, 1605 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.75 (br s, 3H), 1.7–2.9 (m, 5H), 3.69 (s, 3H), 3.77 (s, 3H), 4.0 (m, 4H), 4.9–6.1 (m, 4H), 5.59 (m, vinylic CH), 12 (approx.) (s, 1H). *Exact Mass* calcd. for $C_{19}H_{24}O_7$: 364.1522; found (ms): 364.1514; less polar isomer (tlc, ethyl acetate – hexanes 2:3): mp 104–105°C; ir (film) ν_{max}: 1740, 1650, 1610 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.66 (s, 3H), 1.7–2.9 (m, 6H), 3.66 (s, 3H), 3.77 (s, 3H), 4.1 (m, 4H), 4.7–6.1 (m, 4H), 5.67 (m, vinylic CH), 12 (approx.) (s, 1H). *Exact Mass* calcd. for $C_{19}H_{24}O_7$: 364.1522; found (ms): 364.1538. Finally, saponification and decarboxylation (10) of the β-ketoester moiety in **11** (10% aqueous KOH, dioxane, reflux) gave in a 54–74% yield the all-important precursor **12** regiospecifically alkylated in the desired position and ready for further elaboration to the selagine ring system **2**: colorless oil; ir ($CHCl_3$) ν_{max}: 1720, 1710 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.72 (s, 3H), 1.8–3.1 (m, 7H), 3.49 (dd, J = 7.6 and 4.1 Hz, 1H), 3.75 (s, 3H), 4.0 (m, 4H), 4.9–5.1 (m, 2H), 5.5–6.0 (m, 2H), 5.58 (m, vinylic CH). *Exact Mass* calcd. for $C_{17}H_{22}O_5$: 306.1467; found (ms): 306.1481.

Transformation of the allyl side chain to a methyl propionate chain took place smoothly by a hydroboration (Sia_2BH, THF, 0°C), oxidation (H_2O_2 30%, aqueous NaOH 5%, rt, followed by Jones), esterification (CH_2N_2, AcOEt) sequence to give the required ketodiester **13** in a 45% yield: colorless oil; ir ($CHCl_3$) ν_{max}: 1720 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.70 (s, 3H), 1.8–3.4 (m, 10H), 3.65 (s, 3H), 3.77 (s, 3H), 3.9–4.2 (m, 4H), 5.6 (s, 1H). *Exact Mass* calcd. for $C_{18}H_{24}O_7$: 352.1522; found (ms): 352.1542. Attempted formation of the corresponding dihydropyridone ($PhCH_2NH_2 \cdot AcOH$, n-butanol, reflux, 20 h) gave instead the piperidone **14** in a 48–58% yield: colorless gum; ir ($CHCl_3$) ν_{max}: 1720, 1660, 1630 cm^{-1}; ^1H nmr (400 MHz) ($CDCl_3$) δ: 1.59 (d, J = 17.2 Hz, 1H), 1.68 (s, 3H), 1.72 (dd, J = 12.7 and 4.7 Hz, 1H), 2.33 (dd, J = 5.4 and 5.4 Hz, 1H), 2.51 (m, 1H), 2.65 (dd, J = 13.0 and 5.8 Hz, 1H), 2.74 (ddd, J = 17.5, 4.7, and 2.3 Hz, 1H), 3.52 (d broadened, J = 12.6 Hz, 1H), 3.77 (s, 3H), 3.8–4.0 (m, 4H), 4.56 (d, J = 16.4 Hz, 1H), 4.80 (dd, J = 5.9 and 2.2 Hz, 1H), 5.38 (d, J = 16.4 Hz, 1H), 5.50 (s, 1H), 7.1–7.3 (m, 5H). *Exact Mass* calcd. for $C_{24}H_{27}NO_5$: 409.1889; found (ms): 409.1863.

Although the attempted isomerization of **14** in acid failed to

produce the corresponding dihydropyridone, treatment with bromine (Br_2, CH_2Cl_2, rt) gave bromopyridone **15** in a 58% yield: mp 203–204°C dec.; ir ($CHCl_3$) ν_{max}: 1720, 1650, 1580 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.52 (s, 3H), 2.3–2.9 (m, 2H), 3.89 (s, 3H), 4.0–4.2 (m, 4H), 4.83 (br s, 1H), 5.23 (d, J = 17.2 Hz, 1H), 5.85 (br s, 1H), 6.38 (d, J = 17.0 Hz, 1H), 6.74 (d, J = 9.8 Hz, 1H), 6.94 (d, J = 9.7 Hz, 1H), 6.8–7.4 (m, 5H). *Exact Mass* calcd. for $C_{24}H_{24}NO_5Br$: 485.0839; found (ms): 485.0833. Finally, reduction of bromopyridone **15** (Bu_3SnH, AIBN cat., C_6H_6, reflux) was achieved in an 80% yield to give the desired selagine tricyclic ring system **2**: mp 229°C; ir ($CHCl_3$) ν_{max}: 1720, 1650, 1580 cm^{-1}; ^1H nmr (400 MHz) ($CDCl_3$) δ: 1.64 (s, 3H), 1.72 (d, J = 18.6 Hz, 1H), 2.32 (dd, J = 7.1 and 7.1 Hz, 1H), 2.53 (d, J = 18.0 Hz, 1H), 2.58 (dd, J = 18.3 and 6.8 Hz, 1H), 3.28 (dd, J = 17.9 and 7.2 Hz, 1H), 3.85 (s, 3H), 3.9–4.0 (m, 4H), 5.06 (d, J = 16.4 Hz, 1H), 5.58 (d, J = 16.4 Hz, 1H), 5.87 (s, 1H), 6.52 (d, J = 9.4 Hz, 1H), 6.90 (d, J = 9.4 Hz, 1H), 7.1–7.3 (m, 5H). *Exact Mass* calcd. for $C_{24}H_{25}NO_5$: 407.1733; found (ms): 407.1760.

Further work is currently in progress in our laboratories to complete the total synthesis of selagine (**1**).
