Treatment of ethyl 2-pentynoate (**14**) with lithium (phenylthio)(tri-*n*-butylstannyl)cuprate (**12**) afforded, in 76% yield, ethyl (*Z*)-3-(tri-*n*-butylstannyl)-2-pentenoate (**15**). On the other hand, when compound **14** was allowed to react with the (tri-*n*-butylstannyl)copper reagent **13**, ethyl (*E*)-3-(tri-*n*-butylstannyl)-2-pentenoate (**21**) was produced in 83% yield. Reduction (diisobutylaluminum hydride, ether) of the esters **15** and **21** gave the alcohols **16** and **22**, respectively. Treatment of each of the latter substances with pyridine − sulfur trioxide complex, followed by further reduction of the resultant intermediates with lithium aluminum hydride, provided the geometrically isomeric alkenylstannanes **17** and **23**. Conjugate addition of (*E*)-3-lithio-2-pentene (**18**) (formed by transmetalation of **17**) to compound **19** produced the olefinic trimethylhydrazide **20**, which was converted (diisobutylaluminum hydride, ether; pyridinium dichromate, dimethylformamide) into the corresponding carboxylic acid **2**. Subjection of compound **23** to a sequence of reactions identical with that used for the conversion of **17** into **2** provided the isomeric acid **3**, which was identical (infrared, ^{1}H nmr) with the natural acid derived from triophamine (**1**). Conversion of **3** into the *p*-nitrophenyl ester **26**, followed by condensation of the latter substance with guanidine, afforded a chromatographically separable mixture of (±)-triophamine (**1**) and the corresponding diastereomer.

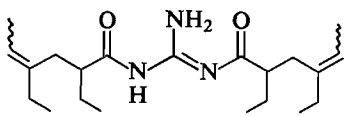
EDWARD PIERS, J. MICHAEL CHONG, KIRK GUSTAFSON et RAYMOND J. ANDERSEN. Can. J. Chem. **62**, 1 (1984).

Le pentyne-2 oate d'éthyl (**14**) réagit avec le (phénylthio)-(tri-*n*-butylstannyl)cuprate de lithium (**12**) pour donner, avec un rendement de 76%, le (*Z*)-(tri-*n*-butylstannyl)-3 pentène-2 oate d'éthyle (**15**). Par ailleurs, quand on fait réagir le composé **14** avec le réactif (tri-*n*-butylstannyl)cuivre (**13**), on obtient avec un rendement de 83%, le (*E*)-(tri-*n*-butylstannyl)-3 pentène-2 oate d'éthyle (**21**). Par réduction des esters **15** et **21** (par l'hydrure de diisobutylaluminium dans l'éther), on obtient respectivement les alcools **16** et **22**. Ces alcools, par une réaction avec le complexe de pyridine − trioxyde de soufre suivie de la réduction des intermédiaires résultants par l'alanate de lithium, conduisent aux alkénylstannates **17** et **23** qui sont des isomères géométriques. L'addition conjuguée du (*Z*)-lithio-3 pentène-2 (**18**) (formé par la transmétallation du composé **17**) sur le composé **19** conduit au triméthylhydrazide oléfinique **20** que l'on transforme (hydrure de diisobutylaluminium, éther; dichromate de pyridium, diméthylformamide) en l'acide carboxylique correspondant (**2**). Le composé **23**, soumis à la suite de réaction qui permet de transformer le composé **17** en composé **2**, donne l'acide isomère **3** que l'on a identifié (ir et rmn du ^{1}H) à l'acide naturel provenant de la triophamine (**1**). La transformation du composé **3** en ester *p*-nitrophényle (**26**), suivie de la condensation de l'ester sur la guanidine, donne un mélange de (±)-triophamine (**1**) et du diastéréoisomère correspondant que l'on peut séparer par chromatographie.

[Traduit par le journal]

Introduction

The skin extracts of many dorid nudibranchs contain novel metabolites, some of which are believed to function as chemical antifeedants (1). Recently, two of us reported the isolation of triophamine from the dorid *Triopha catalinae* and showed that this metabolite possesses the unique diacylguanidine structure shown in **1** (2). Although the stereochemistry of the



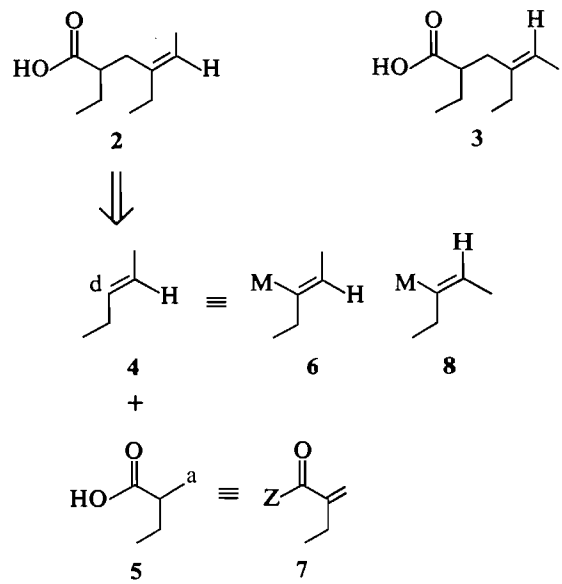
1

carbon−carbon double bonds present in triophamine was not defined by the structural elucidation work (2), it is pertinent to note that the structurally interesting carbon skeleton of the acyl residues of this substance has not been encountered previously in natural products and cannot be derived readily from "standard" biosynthetic pathways. We describe herein a total synthesis of (±)-triophamine which confirms the structural assignment and establishes the geometry about the alkene linkage in the acyl moieties.

Results and discussion

(a) *General considerations*

It seems clear that the final stages of a total synthesis of (±)-triophamine (**1**) would involve condensation of guanidine with a suitable functional derivative of one of the carboxylic acids **2** or **3** (see Scheme 1). Therefore, the first synthetic task was the stereoselective synthesis of one (or both) of the latter substances. Although many different routes for the preparation of **2** and **3** can be envisaged, our projected syntheses were



SCHEME 1

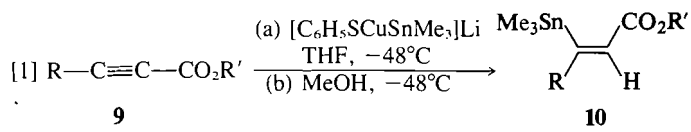
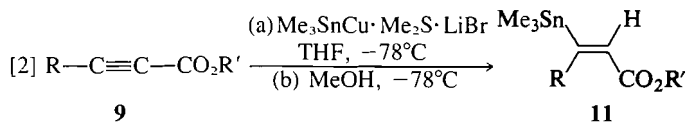
based on the retrosynthetic plan shown in Scheme 1. Thus, heterolytic disconnection of the C-3—C-4 bond in **2** provides, as one possibility, the donor synthon **4** and the acceptor synthon **5**. From a synthetic point of view, then, the acid **2** could be prepared by conjugate addition of a stereochemically homogeneous organometallic reagent **6** (M = Li, (CuY)Li, etc.) to a suitable derivative of 2-ethylpropenoic acid **7** (Z = OR, NR_2, etc.). Similarly, 1,4-addition of an organometallic reagent **8** to the substrate **7** would produce, after appropriate functional group manipulation, the olefinic acid **3**.

The synthetic plan outlined above was prejudiced by the results of some recent studies carried out in our laboratories. Explicitly, it had been shown (3, 4) that the reaction of α,β-acetylenic esters **9** with (trimethylstannyl)copper reagents can be controlled experimentally to produce, stereoselectively, either of the geometrically isomeric products **10** or **11**. For example, when **9** is allowed to react with lithium (phenylthio)(trimethylstannyl)cuprate under the conditions shown in eq. [1], the product consists very largely of the β-trimethylstannyl α,β-unsaturated ester **10**. On the other hand, reaction of **9** with (trimethylstannyl)copper at −78°C affords exclusively the geometrically isomeric olefinic ester **11**



9 **10**



9 **11**

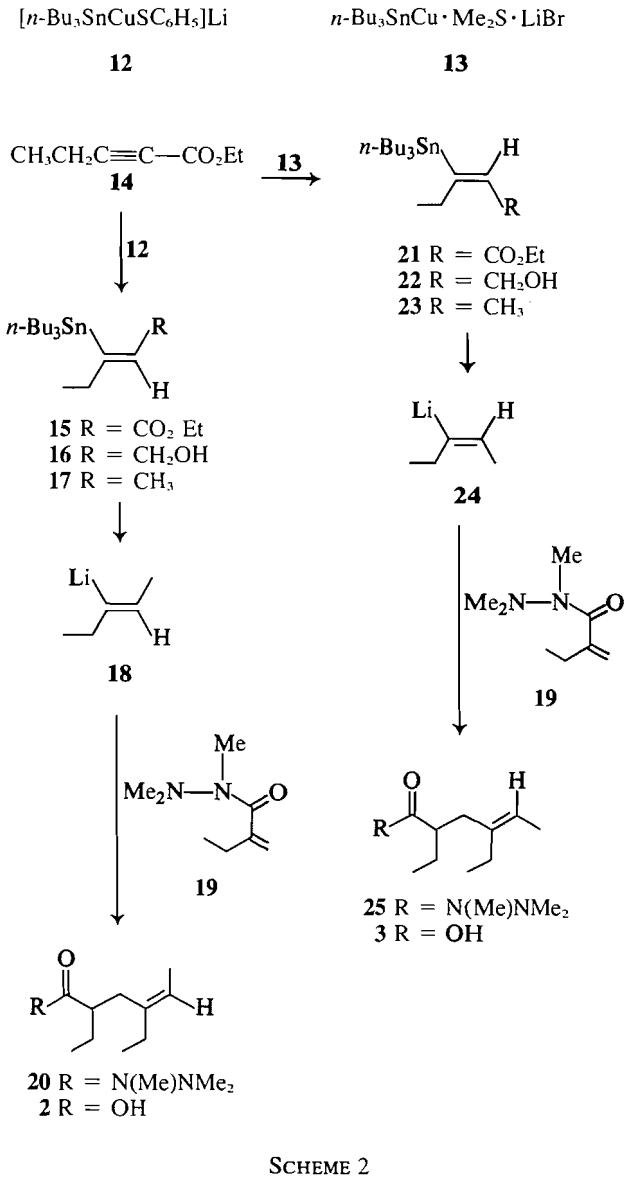
(eq. [2]). Since the transmetalation (RLi) of trialkylvinylstannanes to produce vinyllithium reagents is a well-known process, it appeared that compounds **10** and **11** (R = C_2H_5) would serve as convenient precursors of the required reagents **6** and **8** (M = Li, (CuY)Li, etc.), respectively.

(b) *Preparation of (Z)-(2) and (E)-2,4-diethyl-4-hexenoic acid (3)*

In our work involving the use of (trialkylstannyl)copper reagents, we have employed nearly exclusively trimethylstannyl compounds. However, since some of the projected trimethylstannyl intermediates necessary for the present work (for example, compounds **6** and **8**, M = $SnMe_3$) would probably be quite volatile, we chose to carry out this study with the corresponding tri-*n*-butylstannyl derivatives.

Treatment of a cold (−20°C) solution of (tri-*n*-butylstannyl)-lithium (5) in tetrahydrofuran (THF) with 1 equivalent of phenylthiocopper (6) provided a deep red solution of lithium (phenylthio)(tri-*n*-butylstannyl)cuprate (**12**)[2] (see Scheme 2). On the other hand, when (tri-*n*-butylstannyl)lithium (5) was allowed to react (THF, −78°C) with 1 equivalent of copper bromide − dimethyl sulfide complex (7), a solution (also dark red) of the (tri-*n*-butylstannyl)copper reagent **13**[2] (8) was

[2]The actual constitutions of reagents **12** and **13** are unknown. However, the formulations shown in **12** and **13** are used for the sake of convenience and on the basis of analogy with the usual representations of corresponding alkylcopper reagents.



SCHEME 2

produced.

Reaction of ethyl 2-pentynoate (**14**) with each of the reagents **12** (THF, −48°C) and **13** (THF, −78°C), followed in each case by appropriate work-up and chromatographic purification of the crude product, afforded, respectively, ethyl (*Z*)-3-(tri-*n*-butylstannyl)-2-pentenoate (**15**) (76%) and the corresponding geometric isomer **21** (83%). The proton nuclear magnetic resonance (^{1}H nmr) spectra of the latter substances fully corroborated the stereochemical assignments. Thus, the C-4 methylene protons of compound **15** give rise to a doublet of quartets (J = 7.5, 1.5 Hz) at δ 2.42 while the analogous signal for the corresponding protons of **21** is found at δ 2.88. It seems clear, therefore, that the ethyl group of the pentenoate chain is *cis* to the ester function in the latter isomer. Furthermore, in compounds such as **15** and **21**, the magnitude of the coupling constants associated with the coupling of the alkene proton with the tin nuclei (^{117}Sn and ^{119}Sn isotopes) is stereochemically diagnostic. It is known (9) that when the trialkylstannyl group and the vicinal alkene proton are in a *trans* relationship, $|J_{Sn-H}|$ is much larger than when these groups are *cis* to one another. In compounds **15** and **21**, the values of $|J_{Sn-H}|$ are 109 and 65

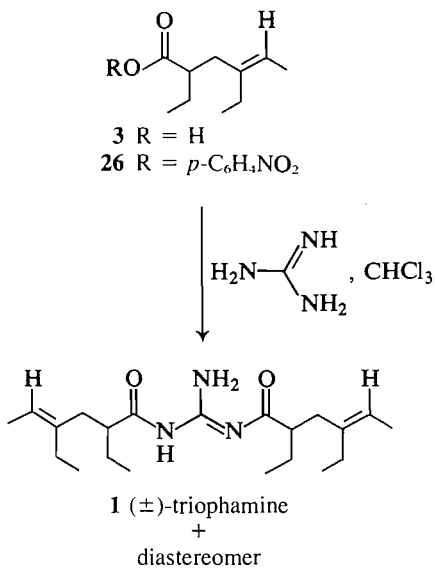

SCHEME 3

Hz,[3] respectively.

Reduction of the ester **15** with diisobutylaluminum hydride in ether afforded the alcohol **16**. When this material was allowed to react with pyridine − sulfur trioxide complex in THF, and the resultant intermediate was reduced directly with lithium aluminum hydride (10), (*Z*)-3-(tri-*n*-butylstannyl)-2-pentene (**17**) was produced in 87% yield. Transmetalation (*n*-butyllithium, THF, −20°C) of compound **17**, followed by conjugate addition (THF, −78°C) of the resultant vinyllithium species **18** to the *N*,*N*′,*N*′-trimethylhydrazide derivative of 2-ethylpropenoic acid (**19**)[4] (11), provided, in addition to small amounts of the starting materials **17** and **19**, the olefinic trimethylhydrazide **20** (42% yield).

Trimethylhydrazides are known to be very resistant to hydrolysis. It was, therefore, somewhat surprising to find that treatment of compound **20** with hot dilute hydrochloric acid for only 2 h totally converted this substrate into a single product (78% yield). However, spectral data showed that the product was 2,4,4-triethylbutyrolactone and it was thus clear that the carbon−carbon double bond had participated in the hydrolysis process.

It was found eventually that the desired conversion of the trimethylhydrazide **20** into the corresponding acid **2** could be effected by treatment of the former substance with 1.1 equivalents of diisobutylaluminum hydride (ether, 0°C), followed by direct oxidation of the resultant crude product with pyridinium dichromate in dimethylformamide (12). The purified product, (*Z*)-2,4-diethyl-4-hexenoic acid (**2**), was obtained in 50% yield based on unrecovered **20**, and provided spectra (infrared, ^{1}H nmr) which were very similar to, but clearly different from, those of the olefinic carboxylic acid obtained from natural triophamine. Presumably, therefore, the olefinic linkage of the acyl residues of triophamine possesses an (*E*) rather than a (*Z*) configuration.

[3]These coupling constants represent the average of the ^{117}Sn—H and ^{119}Sn—H values.

[4]This material was prepared from 2-ethylpropenoic acid via the corresponding acid chloride. See the experimental section for details.

The synthesis of the required carboxylic acid **3** was accomplished via a route which paralleled that described for the isomeric acid **2**. Thus, conversion of the ester **21**, via the intermediates **22** and **23**, into (*Z*)-3-lithio-2-pentene (**24**), followed by conjugate addition of the latter reagent to compound **19**, afforded the olefinic trimethylhydrazide **25**. The corresponding carboxylic acid **3**, obtained from **25** via a procedure identical with that used for the conversion of **20** into **2**, gave spectra (infrared, ^{1}H nmr) identical with those of the natural acid derived from triophamine.

(c) *Synthesis of triophamine (**1**) and its diastereomer (Scheme 3)*

Treatment of the carboxylic acid **3** with *p*-nitrophenol in the presence of N,N′-dicyclohexylcarbodiimide afforded in excellent yield the crystalline *p*-nitrophenyl ester **26**. Condensation of this material with guanidine under carefully monitored conditions provided a chromatographically separable mixture of (±)-triophamine (**1**) and the expected diastereomer. The former product gave spectra (infrared, ^{1}H nmr) identical with those of the natural product.

In summary, the synthetic work described herein corroborates the conclusions of structural work done on triophamine (2) and establishes the configuration of the olefinic double bonds present in this interesting natural product.

Experimental

General

Melting points and distillation temperatures are uncorrected. Infrared (ir) spectra were recorded on Perkin−Elmer model 710B spectrophotometers. Proton nuclear magnetic resonance (^{1}H nmr) spectra (deuterochloroform solution) were measured using Bruker spectrometers, models WP-80 and/or WH-400. Tetramethylsilane was employed as the internal standard for all compounds except those containing the tri-*n*-butylstannyl group. In these cases, the chemical shifts were measured relative to that of the chloroform proton (δ 7.25). High resolution mass spectrometric measurements were recorded on a Kratos MS-50 mass spectrometer. Gas−liquid chromatography (glc) was carried out with a Hewlett−Packard model 5832 A gas chromatograph.

*Ethyl (Z)-3-(tri-*n*-butylstannyl)-2-pentenoate (**15**)*

To a cold (−20°C) stirred solution of hexa-*n*-butylditin (6.96 g, 12.0 mmol) in 100 mL of dry THF under an atmosphere of argon was added a solution of *n*-butyllithium in hexane (7.14 mL, 1.68 *M*, 12.0 mmol). The resultant yellow solution was stirred at −20°C for 20 min. Phenylthiocopper (2.06 g, 12 mmol) was added and the deep red solution which formed within 1 min was stirred (−20°C) for an additional 20 min. After the reaction mixture had been cooled to −78°C, a solution of ethyl 2-pentynoate (**14**) (1.26 g, 10 mmol) in 5 mL of dry THF was added and the resulting solution was stirred at −78°C for 15 min and at −48°C for 4 h. Ethanol (1 mL) and ether (100 mL) were added and the mixture was allowed to warm to room temperature. During this time a flocculent yellow precipitate formed. The slurry was treated with anhydrous magnesium sulfate and then was filtered through a short column of Florisil. The column was washed with further volumes of ether. Removal of the solvent from the combined eluate gave a pale yellow oil which contained, on the basis of glc analysis, tetra-*n*-butyltin, hexa-*n*-butylditin, and a mixture of ethyl (*Z*)- (**15**) and (*E*)-3-(tri-*n*-butylstannyl)-2-pentenoate (**21**), in a ratio of 97:3, respectively. Subjection of this material to column chromatography on silica gel (150 g, elution with 1:100 ether − petroleum ether) provided a clear oil which upon distillation (air-bath temperature 128−135°C/0.3 Torr) gave 3.18 g (76%) of the unsaturated ester **15** as a colorless liquid; ir (film): 1700, 1595, 1200, 880 cm^{-1}; ^{1}H nmr δ: 0.7−1.8 (diffuse m, 33H), 2.42 (d of q, 2H, J = 7.5, 1.5

Hz, with satellite peaks indicating $J_{Sn-H} \approx 53$ Hz), 4.17 (q, 2H, J = 7 Hz), 6.38 (t, 1H, J = 1.5 Hz, with satellite peaks indicating J_{Sn-H} = 109 Hz). *Exact Mass* calcd. for $C_{15}H_{29}O_2{}^{120}Sn$ ($M^+ - C_4H_9$):[5] 361.1190; found: 361.1187.

Ethyl (E)-3-(tri-n-butylstannyl)-2-pentenoate (21)

To a cold (−20°C) stirred solution of hexa-*n*-butylditin (15.1 g, 26 mmol) in dry THF (200 mL) under an atmosphere of argon was added a solution of *n*-butyllithium in hexane (15.9 mL, 1.63 *M*, 26 mmol). The yellow solution was stirred at −20°C for 20 min and then was cooled to −78°C. Cuprous bromide − dimethyl sulfide complex (5.34 g, 26 mmol) was added and the mixture was stirred at −78°C for 30 min. To the resulting dark red solution was added a solution of ethyl 2-pentynoate (**14**) (2.52 g, 20 mmol) in 10 mL of dry THF and stirring was continued at −78°C for a further 3 h. Ethanol (1 mL), saturated aqueous ammonium chloride (pH 8, 20 mL), and ether (200 mL) were added successively and the mixture was allowed to warm to room temperature. The layers were separated and the aqueous phase was extracted thoroughly with ether. The combined extracts were washed with saturated aqueous ammonium chloride (pH 8) and dried over anhydrous magnesium sulfate. Removal of the solvent afforded a yellow oil which was subjected to column chromatography on silica gel (250 g, elution of the column with 1:50 ether − petroleum ether). Distillation (air-bath temperature 130°C/0.3 Torr) of the material obtained from the appropriate fractions gave 6.92 g (83%) of the unsaturated ester **21** as a colorless oil; ir (film): 1710, 1585, 1180, 870 cm^{-1}; ^1H nmr δ: 0.7−1.8 (diffuse m, 33H), 2.88 (d of q, 2H, J = 7.5, 1.2 Hz, with satellite peaks indicating $J_{Sn-H} \approx 56$ Hz), 4.16 (q, 2H, J = 7 Hz), 5.92 (t, 1H, J = 1.2 Hz, with satellite peaks indicating J_{Sn-H} = 65 Hz). *Exact Mass* calcd. for $C_{15}H_{29}O_2{}^{120}Sn$ ($M^+ - C_4H_9$): 361.1190; found: 361.1207.

(Z)-3-(Tri-n-butylstannyl)-2-penten-1-ol (16)

To a cold (−78°C) stirred solution of the ester **15** (418 mg, 1.0 mmol) in dry ether (12 mL) under an atmosphere of argon was added a solution of diisobutylaluminum hydride in hexane (2.5 mL, 1 *M*, 2.5 mmol). The colorless solution was stirred at −78°C for 1 h and at 0°C for 2 h. After 0.5 mL of saturated aqueous ammonium chloride had been added, the mixture was allowed to warm to room temperature. The resultant slurry was treated with anhydrous magnesium sulfate and then was filtered through a short column of Florisil. The column was washed with ether. Removal of the solvent from the combined eluate, followed by distillation (air-bath temperature 120−125°C/0.3 Torr) of the residual oil, furnished 339 mg (90%) of the alcohol **16** as a clear oil; ir (film): 3320, 1460, 1010 cm^{-1}; ^1H nmr δ: 0.8−1.7 (diffuse m, 31H), 2.22 (broad q, 2H, J = 7 Hz), 4.04 (d after addition of D_2O, 2H, J = 7 Hz), 6.22 (t of t, 1H, J = 6.5, 1.3 Hz, with satellite peaks indicating J_{Sn-H} = 128 Hz). *Exact Mass* calcd. for $C_{13}H_{27}O^{120}Sn$ ($M^+ - C_4H_9$): 319.1084; found: 319.1085.

(E)-3-(Tri-n-butylstannyl)-2-penten-1-ol (22)

This material was prepared by diisobutylaluminum hydride reduction of the unsaturated ester **21**, via a procedure identical with that described above. From 338 mg (0.81 mmol) of **21** there was obtained 286 mg (94%) of the alcohol **22** as a clear, colorless oil; ir (film): 3270, 1460, 1020 cm^{-1}; ^1H nmr δ: 0.7−1.1 (diffuse m, 31H), 2.31 (broad q, 2H, J = 7 Hz, with satellite peaks indicating $J_{Sn-H} \approx 56$ Hz), 4.25 (d after addition of D_2O, 2H, J = 6 Hz), 5.72 (broad t, 1H, J = 6 Hz, with satellite peaks indicating J_{Sn-H} = 70 Hz). *Exact Mass* calcd. for $C_{13}H_{27}O^{120}Sn$ ($M^+ - C_4H_9$): 319.1084; found: 319.1082.

(Z)-3-(Tri-n-butylstannyl)-3-pentene (17)

To a cold (0°C) stirred solution of the alcohol **16** (2.45 g, 6.52 mmol) in 20 mL of dry THF under an atmosphere of argon was added in one portion 1.56 g (9.77 mmol) of pyridine − sulfur trioxide complex. The resulting suspension was stirred at 0°C for 3 h. A solution-slurry of lithium aluminum hydride (1.1 g) in 20 mL of dry THF was added and the reaction mixture was stirred at 0°C for 1 h and at room temperature for 3 h. After the mixture had been recooled to 0°C, sodium sulfate decahydrate was added in portions until noticeable reaction ceased. The mixture was allowed to warm to room temperature, was treated with anhydrous magnesium sulfate, and then was filtered through a short column of Florisil. The inorganic salts were washed thoroughly with ether. Removal of the solvent from the combined filtrate, followed by distillation (air-bath temperature ~150°C/12 Torr) of the residual material afforded 2.04 g (87%) of the alkene **17** as a pale yellow oil; ir (film): 1620, 1460, 1080 cm^{-1}; ^1H nmr δ: 0.8−1.6 (diffuse m, 30H), 1.70 (broad d, 3H, J = 6.5 Hz), 2.17 (broad q, 2H, J = 7 Hz, with satellite peaks indicating $J_{Sn-H} \approx$ 48 Hz), 6.10 (q of t, 1H, J = 6.5, 1.3 Hz, with satellite peaks indicating J_{Sn-H} = 138 Hz). *Exact Mass* calcd. for $C_{13}H_{27}{}^{120}Sn$ ($M^+ - C_4H_9$): 303.1135; found: 303.1135.

(E)-3-(Tri-n-butylstannyl)-2-pentene (23)

Conversion of the unsaturated alcohol **22** into the alkene **23** was accomplished via a procedure identical with that described above. From 336 mg (0.93 mmol) of **22** there was obtained 278 mg (83%) of **23** as a pale yellow oil; ir (film): 1580, 1440, 1060 cm^{-1}; ^1H nmr δ: 0.7−1.6 (diffuse m, 30H), 1.70 (d, 3H, J = 6.6 Hz), 2.27 (broad q, 2H, J = 7.3 Hz, with satellite peaks indicating $J_{Sn-H} \approx 56$ Hz), 5.58 (broad q, 1H, J = 6.6 Hz, with satellite peaks indicating J_{Sn-H} = 71 Hz). *Exact Mass* calcd. for $C_{13}H_{27}{}^{120}Sn$ ($M^+ - C_4H_9$): 303.1135; found: 303.1132.

Preparation of the N,N',N'-trimethylhydrazide of 2-ethylpropenoic acid (19)

A solution of 2-ethylpropenoic acid (4.1 g, 41 mmol) and oxalyl chloride (11 mL, 3 equiv.) in 180 mL of hexanes was heated (reflux) for 1 h. The solvent and excess oxalyl chloride were removed by distillation (atmospheric pressure) and the residue was taken up in 10 mL of dry dichloromethane. This solution was added to a cold (−78°C) solution of trimethylhydrazine (6.1 g, 82 mmol) and triethylamine (17 mL, 123 mmol) in 150 mL of dichloromethane. The reaction mixture was stirred at −78°C for 1 h and then was allowed to warm to room temperature. Saturated aqueous ammonium chloride was added and the layers were separated. The organic layer was washed with 1 *N* hydrochloric acid and then was dried over anhydrous magnesium sulfate. Removal of the solvent (distillation at atmospheric pressure), followed by distillation (air-bath temperature 108−112°C/12 Torr) of the residual material, furnished 2.2 g (34%) of the trimethylhydrazide **19**; ir (film): 1650, 1450, 1380, 905 cm^{-1}; ^1H nmr δ: 1.05 (t, 3H, J = 7 Hz), 2.31 (broad q, 2H, J = 7 Hz), 2.47 (s, 6H), 2.88 (s, 3H), 4.95−5.10 (m, 2H). *Exact Mass* calcd. for $C_8H_{16}N_2O$: 156.1262; found: 156.1231.

Preparation of the N,N',N'-trimethylhydrazide of (Z)-2,4-diethyl-4-hexenoic acid (20)

To a cold (−20°C) stirred solution of the tri-*n*-butylstannane **17** (366 mg, 1.02 mmol) in 5 mL of dry THF was added a solution of *n*-butyllithium in hexane (0.6 mL, 1.62 *M*, 0.97 mmol). The solution was stirred at −20°C for 1 h and then was cooled to −78°C. A solution of the unsaturated trimethylhydrazide **19** (159 mg, 1.02 mmol) in 2 mL of dry THF was added dropwise and the reaction mixture was stirred at −78°C for 1 h. Saturated aqueous ammonium chloride and ether were added successively and the layers were separated. The aqueous layer was extracted with ether and the combined extracts were washed with saturated aqueous ammonium chloride and dried over anhydrous magnesium sulfate. Removal of the solvent provided an oil which, on the basis of the analysis by glc, consisted of a mixture of the desired product **20**, the two starting materials **17** and **19**, and tetra-*n*-butyltin. This material was subjected to column chromatography on silica gel (25 g, elution with 1:1 ether − petroleum ether). Evaporation of the solvent from the appropriate fractions gave 97 mg (42%) of the trimethylhydrazide **20**; ir (film): 1645, 1458,

[5]In accord with previous observations (13, 14) regarding mass spectrometry of trialkylstannyl compounds, the mass spectra of the tri-*n*-butylstannyl derivatives reported herein did not exhibit molecular ion peaks. Therefore, in each case, the high resolution measurement was carried out on the $m/e = M^+ - C_4H_9$ fragment.

1380, 1180, 1155 cm^{-1}; ^1H nmr δ: 0.82 (t, 3H, J = 7 Hz), 0.98 (t, 3H, J = 7 Hz), 1.17–2.33 (diffuse m, 9H), 2.48 (s, 6H), 2.88 (s, 3H), 3.25–3.73 (m, 1H), 5.25 (broad q, 1H, J = 7 Hz). *Exact Mass* calcd. for $C_{13}H_{26}ON_2$: 226.2045; found: 226.2046.

Preparation of the N,N′,N′*-trimethylhydrazide of* (E)*-2,4-diethyl-4-hexenoic acid (25)*

This substance was prepared from (*E*)-3-(tri-*n*-butylstannyl)-2-pentene (**23**) and the trimethylhydrazide **19** via a procedure essentially identical with that described above. Column chromatography (silica gel, 55 g; 1:1 ether – petroleum ether) of the crude material obtained from 900 mg (5.77 mmol) of the trimethylhydrazide **19** provided 534 mg (41%) of the desired product **25**; ir (film): 1640, 1450, 1380, 1180, 1150 cm^{-1}; ^1H nmr δ: 0.82 (t, 3H, J = 7 Hz), 0.98 (t, 3H, J = 7 Hz), 1.17–2.35 (diffuse m, 9H), 2.46, 2.50, 2.88 (s, s, s, 3H each), 3.25–3.75 (m, 1H), 5.20 (broad q, 1H, J = 7 Hz). *Exact Mass* calcd. for $C_{13}H_{26}ON_2$: 226.2045; found: 226.2046.

(Z)-2,4-Diethyl-4-hexenoic acid (2)

To a cold (−78°C) stirred solution of the trimethylhydrazide **20** (24 mg, 0.11 mmol) in 3 mL of dry ether was added a solution of diisobutylaluminum hydride in hexane (0.12 mL, 1 *M*, 0.12 mmol). The reaction mixture was stirred at −78°C for 30 min and at 0°C for 2 h. A few drops of saturated aqueous ammonium chloride were added and the mixture was allowed to warm to room temperature. After anhydrous magnesium sulfate had been added to the resultant slurry, it was filtered through a short column of Florisil. The column was washed with ether and the solvent was removed from the combined eluate. The residual mixture was taken up in dimethylformamide (2 mL), the resultant solution was treated with 200 mg of pyridinium dichromate, and the mixture was stirred overnight at room temperature. Water (10 mL) was added and the resultant mixture was extracted thoroughly with ether. The combined extract was washed successively with brine and 2 × 15 mL of 0.1 *N* aqueous sodium hydroxide (these extracts were retained, see below), and then dried over anhydrous magnesium sulfate. Removal of the solvent, followed by bulb-to-bulb distillation of the residual oil, provided 12 mg of the starting material **20**.

The above-mentioned basic extracts were acidified (1 mL of 3 *N* hydrochloric acid) and the resulting mixture was washed with dichloromethane (3 × 15 mL). The combined organic solution was dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature ~ 100°C/12 Torr) of the residual oil gave 4.5 mg (50% based on unrecovered **20**) of the acid **2**; ir (film): 3300–2550, 1700 cm^{-1}; ^1H nmr (400 MHz) δ: 0.99 (t, 3H, J = 7 Hz), 1.02 (t, 3H, J = 7 Hz), 1.55–1.79 and 1.66 (m, 2H and d, 3H, J = 6 Hz), 2.09 (q, 2H, J = 7 Hz), 2.28–2.40 (m, 1H), 2.49–2.63 (m, 2H), 5.05 (q, 1H, J = 6 Hz). *Exact Mass* calcd. for $C_{10}H_{18}O_2$: 170.1307; found: 170.1309.

(E)-2,4-Diethyl-4-hexenoic acid (3)

This compound was obtained from the trimethylhydrazide **25** via a procedure identical with that described above. From 516 mg of **25** there was obtained, in addition to 180 mg of the starting material **25**, 177 mg (70% based on unrecovered **25**) of the unsaturated acid **3**; ir (film): 3400–2400, 1700 cm^{-1}; ^1H nmr (400 MHz) δ: 0.95 (t, 3H, J = 7 Hz), 0.97 (t, 3H, J = 7 Hz), 1.51–1.65 and 1.58 (m, 2H and d, 3H, J = 6.5 Hz), 2.04 (q, 2H, J = 7 Hz), 2.15 (d of d, 1H, J = 14, 6 Hz), 2.35 (d of d, 1H, J = 14, 8 Hz), 2.42–2.52 (m, 1H), 5.24 (q, 1H, J = 6.5 Hz). *Exact Mass* calcd. for $C_{10}H_{18}O_2$: 170.1307; found: 170.1308.

p-*Nitrophenyl* (E)*-2,4-diethyl-4-hexenoate (26)*

To a stirred solution of the carboxylic acid **3** (120 mg, 0.71 mmol) and *p*-nitrophenol (150 mg, 1.08 mmol) in 3 mL of dry acetonitrile was added 300 mg (1.47 mmol) of *N,N′*-dicyclohexylcarbodiimide, and the resultant mixture was stirred at room temperature for 12 h. Removal of the solvent under reduced pressure provided a solid which was triturated with chloroform. Filtration of the mixture, followed by removal of the solvent from the filtrate, gave a solid which was purified by flash chromatography (15) on 28 g of silica gel. Elution of the column with 1:3 hexane–chloroform afforded 180 mg (87%) of the desired ester **26**. A small sample of this material, obtained from methanol, exhibited mp 45–46°C; ir ($CHCl_3$): 1755 cm^{-1}; ^1H nmr δ: 1.01 (t, 3H, J = 7 Hz), 1.04 (t, 3H, J = 7 Hz), 1.42–1.86 and 1.62 (m, 2H and d, 3H, J = 7 Hz), 2.13 (q, 2H, J = 7 Hz), 2.28–2.85 (m, 3H), 5.33 (q, 1H, J = 7 Hz), 7.23 (d, 2H, J = 9 Hz), 8.31 (d, 2H, J = 9 Hz). *Exact Mass* calcd. for $C_{16}H_{21}NO_4$: 291.1471; found: 291.1496.

(±)-Triophamine (1) and its diastereomer

Subjection of guanidine hydrochloride to ion-exchange chromatography on a column of Dowex 1-X8 (HO^- form) provided free guanidine. Small amounts of the latter material were added at 1 h intervals to a stirred solution of the *p*-nitrophenyl ester **26** (34 mg, 0.12 mmol) in 2mL of chloroform. The progress of the reaction was monitored by thin-layer chromatography (silica gel, 1:1 hexane–ether). It was found that if the reaction was allowed to proceed to completion (disappearance of **26**), appreciable quantities of side product(s) were formed and the yield of desired material was low. Therefore, after approximately 50–75% of the starting material **26** had reacted, the reaction mixture was filtered and the collected solid was washed with 4 × 5 mL of chloroform. Removal of the solvent from the combined filtrate gave a yellow oil which was subjected to preparative thin-layer chromatography. There was thus obtained 9.1 mg of the ester **26** and 7.4 mg (48% based on unrecovered **26**) of a mixture of (±)-triophamine (**1**) and its diastereomer. This mixture of diastereomers was separated by repeated preparative thin-layer chromatography on silica gel 60 PF-254 (19:1 hexane – isopropyl alcohol). (±)-Triophamine (4.0 mg) exhibited infrared and ^1H nmr spectra identical with those of the natural product (2), while the diastereomer exhibited ir ($CHCl_3$): 3323, 1700, 1630, 1160 cm^{-1}; ^1H nmr δ: 0.91 (t, 3H, J = 7 Hz), 0.95 (t, 3H, J = 7 Hz), 1.46–1.67 and 1.56 (m, 2H and d, 3H, J = 7 Hz), 2.03 (q, 2H, J = 7 Hz), 2.11 (d of d, 1H, J = 6, 13 Hz), 2.28–2.37 (m, 1H), 2.37–2.47 (m, 1H), 5.20 (q, 1H, J = 7 Hz). *Exact Mass* calcd. for $C_{21}H_{37}N_3O_2$: 363.2885; found: 363.2883.

Cellulose organic solvents: V. Conformational aspects of *N*,*N*-dimethyl ethanolamine *N*-oxide in its crystalline and diluted states

E. R. MAIA,[1] A. PÉGUY, AND S. PÉREZ[2]

Centre de Recherches sur les Macromolécules Végétales, C.N.R.S. B.P. 68, 38402 St Martin d'Hères Cédex, France[3]

Received January 18, 1983

E. R. MAIA, A. PÉGUY, and S. PÉREZ. Can. J. Chem. **62**, 6 (1984).

N,*N*-Dimethyl ethanolamine *N*-oxide (DMEAO) belongs to the class of tertiary amine oxide molecules that are good solvents for cellulose, although not being cyclic. Crystallographic investigation shows that anhydrous DMEAO is monoclinic, space group *Cc*, $a = 25.725(9)$, $b = 7.023(4)$, $c = 9.483(5)$ Å, $\beta = 101.16(10)°$, $Z = 12$. The crystal structure has been solved by direct methods and refined to a final *R* value of 0.063 for 575 observed reflexions. Three independent molecules are found within the asymmetric unit; one of these displays a pseudo-cyclic form dictated by the occurrence of a strong intramolecular hydrogen bond. Conformational investigation of DMEAO in solution, using ir and nmr spectroscopy shows that this pseudo-cyclic form is more likely to occur in diluted states. These findings are related to the ability of this tertiary amine oxide to act as a good solvent, up to a water content of one water molecule per DMEAO molecule.

E. R. MAIA, A. PÉGUY et S. PÉREZ. Can. J. Chem. **62**, 6 (1984).

Bien que ne possédant pas de structure cyclique, le *N*-oxyde de *N*,*N*-diméthyl ethanolamine (DMEAO) appartient à cette nouvelle classe de solvants organiques de la cellulose, que constituent les oxydes d'amines tertiaires. A l'état cristallin, la forme anhydre du DMEAO cristallise dans le groupe d'espace *Cc* du système monoclinique, caractérisé par les paramètres suivants: $a = 25.725(9)$, $b = 7.023(4)$, $c = 9.483(5)$ Å, $\beta = 101.16(10)°$, $Z = 12$. La structure cristalline a été résolue par méthodes directes et affinée jusqu'à un facteur de reliabilité final $R = 0.063$ calculé pour 575 réflexions indépendantes. La résolution de cette structure permet de mettre en évidence l'existence de 3 molécules cristallographiquement indépendantes, parmi lesquelles apparait une molécule dans une conformation pseudo-cyclique stabilisée par une forte liaison hydrogène intramoléculaire. Les études de spectroscopie ir et rmn en milieu dilué permettent de conclure que l'existence de cette conformation est aussi privilégiée en solution. Ces différents éléments permettent d'expliquer pourquoi cet oxyde d'amine tertiaire non cyclique agit comme un bon solvant de la cellulose et ce jusqu'à une valeur limite correspondant à un état monohydraté du DMEAO.

Introduction

In the search for new cellulose organic solvents, tertiary amine oxide molecules have particularly attracted attention (1–5). In the patents, a claim for tertiary amine oxide to be a solvent is to be cyclic, as for example *N*-methylmorpholine *N*-oxide (abbreviated MMNO). However, some examples have been found where a non cyclic molecule could exhibit good solvent properties; as in the case of *N*,*N*-dimethyl ethanolamine *N*-oxide (abbreviated DMEAO). For this particular molecule, the occurrence of a pseudo-cyclic form, stabilized by an intramolecular hydrogen bond, has been speculated (3). Such a conformation would meet the spatial requirements postulated (3, 4) for the ring dimension (5.15 Å) to fit into the hydrophobic portion of the cellulose macromolecule. Moreover, detailed crystallographic investigations on MMNO (6–8) coupled with computer simulation (9) have underlined that the solvent molecule should possess an hydrophobic end, in order to prevent any segmental recombination of the cellulose chains. Again this would tend to indicate a pseudo-ring shape for DMEAO. In order to ascertain the conformational behaviour of DMEAO, solid state and solution properties have been investigated using X-ray diffraction and infrared and nuclear magnetic resonance respectively. Among other parameters, cellulose dissolution in tertiary amine oxides is found to depend on the water content of the mixture. It was therefore of interest to investigate whether or not DMEAO was complexed with water molecules in the solid state.

Experimental

Material

N,*N*-Dimethyl ethanolamine *N*-oxide (DMEAO) was a gift from Dr. R. N. Armstrong, American Enka (U.S.A.). The starting material was dissolved in anhydrous acetone at 50°C. The solution was cooled to 35°C where nucleation occurred. A further lowering of the temperature of about 1°C a day, over a week, yielded single crystals. Crystals suitable for X-ray investigation ($0.2 \times 0.2 \times 0.15$ mm) were mounted in capillaries, all operations being performed in a drybox.

Infrared and nuclear magnetic resonance spectroscopy

Infrared spectra were recorded on a 598 Perkin Elmer spectrometer using KBr discs. A cell of about 2 cm path was used. CS_2 was used as a solvent, and checked into the cell in order to ascertain the lack of any absorption between 3000 and 4000 cm^{-1}.

The ^1H nmr spectra were run at 60, 100, and 250 MHz, respectively, on a Bruker WP60, on a Bruker WP100 and on a Cameca superconducting spectrometer. The spectra were recorded in dimethylsulfoxide D6 in 5 mm tubes at room temperature. Theoretical spectrum calculations were performed using the BNC12 ITRCAL computer program.

Crystal structure determination

The space group was determined from precession photographs. The unit-cell dimensions were obtained as part of the alignment process on an automatic diffractometer by a least-squares fit to the settings of 18 well-centered reflexions. The density was measured by flotation in a mixture of anhydrous CCl_4 and cyclohexane. The crystal data are as follows

$C_4O_2NH_{11}$ mw = 105.2

Monoclinic, space group *Cc* ($h\,k\,l$): $h + k \neq 2n$; ($h\,0\,l$): $l \neq 2n$, $h \neq 2n$; ($0\,k\,0$): $k \neq 2n$; $a = 25.725(9)$ Å, $b = 7.023(4)$ Å, $c = 9.483(5)$ Å, $\beta = 101.16(10)°$, $V = 1680.9$ Å^3, $Z = 12$, $d_c = 1.247$ Mg m^{-3}, $d_{obs} = 1.21$ Mg m^{-3}, μ(CuKα) = 0.66 mm^{-1}, λ(CuKα) = 1.54178 Å, F (000) = 696 e.

Intensity data were collected on a Philips PW1100 diffractometer using Ni-filtered Cu radiation and the 0–2θ scan mode, up to $\theta = 55°$.

The intensities of two reference reflexions, measured every 2 h, decrease by about 8% of their initial values over the duration of the data collection. This decrease was taken into account during the data reduction which was performed using the usual manner. Of the 841 independent reflexions measured, only 575 ($I > 2.5\sigma(I)$) were employed for the structure determination and refinement. Because of the small size of the crystals and the low value of the absorption coefficient ($\mu = 0.66$ mm^{-1}), no absorption correction was applied. The atomic scattering factors used for the hydrogen and non-hydrogen atoms were taken from Stewart *et al.* (10) and Cromer and Waber (11), respectively.

The systematic absences are compatible with both *Cc* and *C*2/*c* space groups. It was decided to solve the structure in the non-centrosymmetric space group *Cc*. From the observed density 1.21 Mg m^{-3}, it can be deduced that the asymmetric unit may contain up to three independent DMEAO molecules.

A set of normalized structure factors $|E|$ was obtained after isotropic temperature factor correction. Analysis of the $|E|$ statistics indicated a non-centrosymmetric space group. The structure was solved by a straightforward application of the MULTAN (12). The *E*-map computed with the best set of phases revealed first seven non-hydrogen atoms defining one DMEAO molecule. A second DMEAO molecule was revealed after two least-squares refinement cycles. Two more cycles of full-matrix least-squares refinement ($R = 0.16$) followed by a difference Fourier map, indicated the location of non-hydrogen atoms revealing the presence of a third DMEAO molecule. Therefore three crystallographically independent molecules were found; such an asymmetric unit content yields a calculated density of 1.25 Mg m^{-3} that compares well with the observed value. Several cycles of full-matrix least-squares refinement led to a conventional *R* value of 0.10. Thirty H atoms were located on successive Fourier difference synthesis and included in the refinement with isotropic temperature factors. Six H atoms (H(O1), H(O1″), H(C2″,1), H(C2″,2), H(C3″,1), and H(C3″,1)) could not been located. The final *R* values for the observed reflexions only and for all the measured reflexions were 0.063 and 0.079 respectively. The quantity minimized was $\Sigma w(F_o - F_c)^2$, each reflexion being assigned a unit weight. A final electron density map showed no significant residual peaks, the extreme fluctuations being -0.30 and 0.35 e$^-$ Å^3.

Results and discussion

The positional parameters are presented in Table 1.[4] A schematic diagram of the molecule along with the numbering of the atoms is shown in Fig. 1. In the following discussion, the atoms belonging to the three independent entities in DMEAO are labelled as unprimed, primed, and double primed.

Solid state

The interatomic distances, bond angles, and torsion angles are given in Tables 2, 3, and 4. For bond distances and bond angles, the estimated standard deviations are about 0.02 Å and 0.03°, respectively. For the unprimed and primed molecules the estimated standard deviations on torsion angles are about 1.7° and amount to 6.4° for the double primed residue. Thus the reliability of geometrical information is greatly reduced. This low accuracy is attributed to the paucity of the number of observed reflexions compared with the number of parameters being refined. Another puzzling structural feature is the intolerable C(2″)—C(3″) distance which is accompanied by a strong anisotropy of the associated thermal parameters that could re-

[4] The structure factor table is available upon request, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

sult from disorder. However, since the primary goal of this study was an investigation of the conformational behaviour of DMEAO, no other refinement approaches were tried to solve this anomaly. Within these restrictions, bond distances and angles conform to values tabulated for already solved *N*-oxide containing structures (9).

Without any doubt the more interesting aspect is the occurrence of three crystallographic independent molecules among which two different stable conformers are found. The overall conformation of DMEAO can be described by two torsional angles: τ1 (O(1)—C(2)—C(3)—N(4)) and τ2 C(2)—C(3)—N(4)—O(7)). With respect to these angles, two molecules occur in a *trans–gauche* form (Fig. 2), whereas a *cis–cis* arrangement is found for the third one (Fig. 2). This arrangement that results in a short non-bonded C(2″) . . . . O(7″) distance is stabilized by the strong intramolecular hydrogen bond between O(1″) and O(7″), the distance being 2.56 Å. When the H(O1″) hydrogen atom is considered, the resulting scheme is a planar system, made up of the six following atoms: H(1″), O(1″), C(2″), C(3″), N(4″), O(7″).

C(2)—C(3)—N(4)—C(6)	−179(2)	176(2)	−124(6)
C(2)—C(3)—N(4)—O(7)	−59(2)	55(2)	0(7)

FIG. 2. Stereoscopic views (PITMOS) of the molecule of DMEAO as occurring in the *trans–gauche* and *cis–cis* conformation.

A projection of the structure (13) onto the plane (0 1 0) is shown in Fig. 3, whereas Table 5 lists the hydrogen bond characteristics. Both primed and unprimed molecules that occur in a *trans–gauche* conformation are linked through hydrogen bonding in which the N—O site acts as the receptor, the donor being the alcohol group. The resulting feature is a propagation of molecules along the *c* axis in a polymer-like fashion. In contrast, the *cis–cis* conformer does not exhibit any strong intermolecular bonding, its surrounding being only weak van der Waals forces. Hence the overall packing feature is a layer type structure.

Conformation in solution

Typical infrared spectra obtained for a 0.005 *M* and 0.001 *M* concentration of DMEAO in CS_2 are shown in Fig. 4*a* and 4*b*, respectively; the occurrence of a peak at 3410 cm^{-1} can be clearly shown. This occurrence is independent of the concentration and can be assigned to the OH stretching frequency involved in an intramolecular hydrogen bonding, since it occurs at lower level than a free hydroxyl which absorbs at about 3625 cm^{-1}. At very low concentration (Fig. 4*b*) there is no peak at 3625 cm^{-1} thereby indicating that no free hydroxyl group is present. Moreover, the frequency of the absorption band remains concentration independent; this being a crucial test for intrabonding.

Further evidence for the occurrence of intramolecular hydrogen bonding can be inferred from nmr spectroscopy. ^1H spectra of DMEAO and dimethyl ethanolamine (abbreviated as DMEA) have been obtained. The coupling constants and $\Delta\nu_{AB}$ values corresponding to DMEAO and DMEA, along with those of *N*-methylmorpholine (abbreviated as NMM) are listed in Table 6. A four spin system involving protons of the two following types, either A_2X_2 or AA′BB′, yields spectrum symmetrical about its midpoint. In the case of A_2X_2 pattern, a further symmetry about the midpoint of each half of the pattern is disclosed. This is the case for dimethylethanolamine which exhibits a double triplet. This is an A_2X_2 type giving a first-order spectrum because A and X are equally coupled (un-

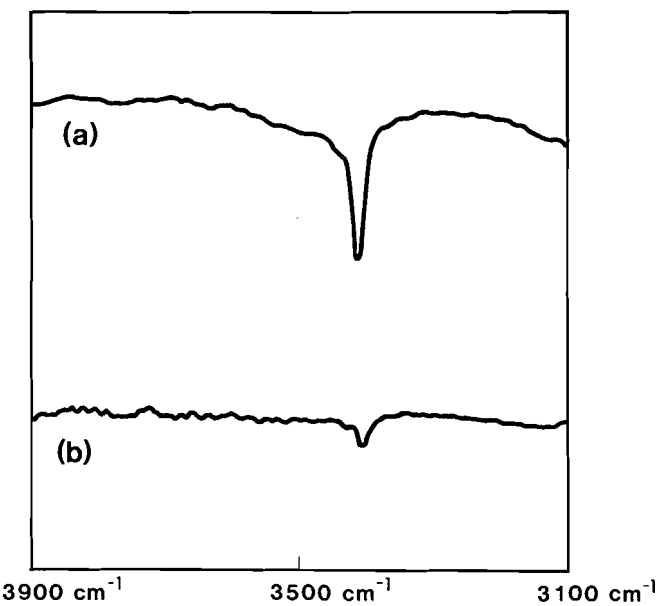

FIG. 4. Infrared spectrum of DMEAO in CS_2: (*a*) 0.005 *M* concentration, (*b*) 0.001 *M* concentration.

primed) ($J_{A,X}$ = 5.7 Hz and $\Delta\nu_{AX}$ = 1.18 ppm) and obey the simple multiplicity rules. Conversely, the ^{1}H DMEAO spectrum can be analyzed as a AA′BB′ system. Such a conclusion also arises from the coupling constant values (Table 6) which compare well with those derived from another AA′BB′ system displayed by *N*-methymorpholine (14). Dimethyl ethanolamine does not have any N—O bond and cannot exhibit any intramolecular hydrogen bond and its resulting "pseudo-cyclic" form. On the other hand, DMEAO in its diluted state, exhibits such an intramolecular cyclization. Indeed a *trans* conformation of the molecule should have yielded a double triplet due to the equally coupled hydrogen atoms. An intramolecular hydrogen bond involving N(4) instead of O(1) cannot be possible due to the magnitude of $J_{2e,3a}$ of about 6.8.

TABLE 6. Coupling constants (Hz) for the methylene protons of DMEAO and *N*-methylmorpholine (NMM)

Molecule	$J_{2e,2a}$	$J_{2e,3e}$	$J_{2e,3a}$	$J_{3e,3a}$	$\Delta\nu_{AB}$
DMEAO	−13.2	3.2	6.8	−13.0	0.57
NMM(14)	−13.2	3.05	6.65	−13.4	0.30

Conclusion

The present work shows that DMEAO can exhibit several stable conformers, among which a pseudo-cyclic structure may be expected to occur in diluted states. The overall geometrical shape of the pseudo-cyclic molecule is a ring, having dimension less than 5.15 Å, which seems to be the upper limit that tertiary amine oxide molecules can have in order to penetrate the cellulose structure and act as a good solvent. Moreover this cyclic structure results in a strong disparity between its polar N—O bond and the apolar end; this was shown to be an essential feature for the solvent molecules in order to prevent any segmental recombination of the cellulose chains (9). Therefore, it appears that the search for new solvents for cellulose should not be restricted to the consideration of molecules exhibiting cyclic moieties, as long as pseudo-cyclic forms can occur.

In a way similar to MMNO, the dissolving power of DMEAO depends on the temperature of the solution, the water content of the mixture, the concentration and the degree of polymerization of the cellulose. As the water content increases, the ability of DMEAO to dissolve cellulose decreases. No cellulose can be dissolved when the molecular ratio of water to DMEAO reaches 1, unless the water content is reduced by application of vacuum (15). In the case of MMNO, this nonsolvent character is reached for a water content equal to or greater than 2. Such a behaviour can be rationalized by the fact that in MMNO the oxygen atom of the N—O bond can interact through its two available lone-pairs, with either water molecules or hydroxylic oxygen atoms of cellulose. In contrast, the oxygen atom of the N—O bond in the pseudo-cyclic conformation of DMEAO has only one lone-pair available, through which strong intermolecular hydrogen bonding is possible. Therefore only one water molecule per DMEAO molecule is sufficient to saturate the hydrogen bond possibility of the N—O linkage to cellulose, and would hamper any solvent character.

Yields of *cis*-1,2-cyclohexanediol formed by the reaction of methanol–water solutions of potassium permanganate with cyclohexene varied from nearly zero to a high of 84% as a function of stirring efficiency and dilution. This unusual effect is attributed to the formation of an intermediate hypomanganate ester ion which after formation may undergo reaction [1] with water to form the glycol or [2] with excess MnO_4^- to form higher oxidation products. The factor of increased stirring and dilution reduced localized excess of MnO_4^- and, thereby, minimized the contribution of reaction [2]. Addition of modest concentrations of methanol increased the yield, and this is attributed to enhanced solubilization and dispersion of the insoluble cyclohexene. Sodium hydroxide was beneficial to the reaction but only in low concentrations.

JAY E. TAYLOR, DAVID WILLIAMS, KENNETH EDWARDS, DONALD OTONNAA et DAVID SAMANICH. Can. J. Chem. **62**, 11 (1984).

Les rendements en cyclohexanediol-1,2-*cis* formé lors de la réaction du cyclohexène avec du permanganate de potassium dans des solutions aqueuses de méthanol varient de 0 à près de 84% en fonction de l'efficacité de l'agitation et de la dilution. On attribue cet effect inhabituel à la formation d'un intermédiaire, un ion hypomanganique, qui après sa formation, peut subir soit la réaction [1] avec l'eau conduisant au glycol, soit la réaction [2] avec un excès de MnO_4^- pour former des produits plus oxydés. L'effet combiné d'une meilleure agitation et d'une plus grande dilution réduit la présence localisée d'excès de MnO_4^- et diminuent ainsi la contribution de la réaction [2]. L'addition de faibles quantités de méthanol augmente le rendement; on attribue ce résultat à une meilleure solubilisation et une plus grande dispersion du cyclohexène qui est insoluble. L'addition d'hydroxyde de sodium est bénéfique à la réaction mais uniquement à de faibles concentrations.

The conversion of cyclic alkenes to stereospecific glycols has been the subject of a number of investigations. Whereas performic acid quite generally gives good yields (60–90%) of *trans*-glycols (1) and is both easy to use and applicable to a wide variety of alkenes, the various reagents which have been used for the preparation of *cis*-glycols are each beset with serious disadvantages. Osmium tetroxide (2) and thallium acetate (3) are costly and poisonous and the procedures are quite involved. The iodine – silver acetate procedure (4) has been reported not to be dependably stereospecific (5) and is expensive for larger preparations as is the iodine – potassium iodate technique (6).

Potassium permanganate solutions (7, 8) have been used alone and with a variety of additives including sodium hydroxide, magnesium sulfate, acetone, various alcohols, and phase transfer reagents. Potassium permanganate solubilized in anhydrous dichloromethane has been reported to give good yields with several more complex alkenes (9), but other permanganate procedures have generally been characterized by yields often under 50% and commonly in the range of 10–30% for simple alkenes. Significantly higher yields have been obtained from only a very limited number of alkenes (8, 10, 11) which are generally substituted by negative and/or solubilizing groups. For certain glycols, the necessity of recovery of a highly soluble product from dilute aqueous solution has provided a further difficulty.

In view of the several advantages of permanganate peroxidations, a search for procedures to overcome the indicated disadvantages was initiated. This paper reports excellent success for *cis*-1,2-cyclohexanediol, both with respect to improvement of yields and ease of recovery of the glycol. In addition, some further insights concerning the mechanism of the reaction have evolved.

Experimental

cis-*1,2-Cyclohexanediol*

The apparatus used and a typical preparation are described for each of two reactor volumes. Variations on each of these procedures are defined in Table 1.

Procedure A (5-L reactor)

A solution containing 1 g NaOH (1.7 mL 50% solution) in 450 mL water was placed in a 5-L flanged reaction flask (Ace Glass Co.) with a 10-cm id neck. A fabricated 1/2-in. thick Plexiglas cover sheet, clamped to the flask, accommodated a thermometer, inlet tube, and stirrer whose shaft rotated inside a copper tube acting also as a condenser. The necessity of a sealed stirring unit was thereby eliminated.

The thermometer and addition tube were inserted through holes in the cover using rubber tubing to make gas tight seals. The addition tube consisted of a short length of 0.5-mm capillary tubing connected to a 2-L addition funnel, or equivalent, by 1.5–2.5-mm id capillary glass tubing. The lengths of capillary tubing and overall height of flow were selected to insure an addition time of 2–3 hours at a very consistent flow rate. The tip of the addition tube extended into the top of the reaction flask so that the $KMnO_4$ solution dripped with small droplets into the area of *maximum* turbulence. Both rapidity of dispersion and consistency of addition were highly essential for optimum yields.

The flask and stirrer were tipped at an angle of 45° to effect increased turbulence. The 3-prong, 5-cm diameter stirrer with 45° angle blades was activated by a 1/30 hp motor turning at ~1750 rpm. The 5/16-in. stirring shaft extended 40 cm below the motor and rotated inside the 1.3-cm id, 10.5-cm long copper tube. This tube is threaded through the Plexiglas cover and is located parallel to and as near as feasible to the lower edge of the neck of the flask. Since the flask and tube were at a 45° angle, a trough of Dry Ice supported outside the Cu tube provided cooling to make the Cu tube a condenser. (Note: an ice water condenser was later shown to be preferable.) The stirrer was extended sufficiently near the bottom of the flask so as to be immersed in the initial volume of liquid. The thrust of the stirrer was parallel to the shaft and angled off the bottom of the flask. Minimum circular

[a]This yield has been repeated.
[b]$MgSO_4 \cdot 7H_2O$ (25.5 g, 0.103 *m*) was added to the $KMnO_4$ solution to maintain neutrality.
[c]An additional 0.6 g of high melting nonacidic product was also isolated.
[d]Addition of $KMnO_4$ from dropping funnel.
[e]Initial charge.
[f]Alkene recovered.
[g]Yield based on initial charge less alkene recovered.
[h]Melting point was in the same range as in the preceding diols.
[i]Submerged jet addition.
[j]Disodium maleate (0.054 *m*) was added.
[k]This represents the approximate concentration of $KMnO_4$ remaining after reaction with the sodium maleate.
[l]Somewhat irregular addition of $KMnO_4$.
[m]Early experiment in which the SO_2 treated solution was not neutralized with $NaHCO_3$. The mp was low (85–90°C) due to adipic acid. Crystalline appearance was excellent. The yield was based on $KMnO_4$, assuming 1 $KMnO_4 \equiv 1$ alkene.
[n]A small reactor (~500 mL) was used with less efficient stirring than is described under procedures A or B.

motion of the liquid was necessary to provide maximum turbulence.

Freshly distilled cyclohexene, 24.9 g, 0.303 *m*, was added, followed by 100 mL methanol. The mixture was cooled to ~0°C using a Dry Ice – methanol bath or a methanol–ice bath maintained at −10 to −5°C. A filtered solution containing 48 g (0.3 *m*) $KMnO_4$ in 1.55 L solution was added over a period of 2–3 hours through the previously described addition tube. After completion of the addition, stirring was continued for 10–15 min, and then SO_2 gas was bubbled into the reactor to *just* dissolve the MnO_2. The cover and stirrer were then removed and solid $NaHCO_3$ was added with partial precipitation of $MnCO_3$ and $MnSO_3$ and neutralization of adipic acid. After a period of settling, at pH 7.5–8, the solution was filtered. The clear or slightly turbid solution was then extracted with CH_2Cl_2 continuously with a Wehrli type (12) extractor until no more product was obtained. The reflux time required was 5 days using a 2-hole rubber stoppered 2-L bottle extractor or two days with three 700-mL (48 mm × 40 cm) vertical tube extractors. The time depends on the rapidity of reflux and minimization of CH_2Cl_2 globule size. The globule size may be minimized by allowing the CH_2Cl_2 to pass through a perforated test tube underneath the water surface. Completion was indicated by extending the extraction period for one or two days.

The resulting CH_2Cl_2 solution was distilled to a volume of roughly 6 times the product weight and then was allowed to crystallize first at room temperature and finally at 4–7°C. The crystals were filtered and washed twice with CH_2Cl_2 previously cooled to −15°C. The filtrate was then concentrated to about 1/10 its volume and the above procedure repeated. Additional recoveries from the filtrates were continued if needed. Yield, 23.84 g; mp 95.5–97°C, plus 2.46 g, mp 91.5–94°C; total, 26.30 g, 75% yield.

The general procedure was also used with a 12-L flask.

Procedure B (One-liter reactor)

The reactor, a rectangular bottle, 8 × 12 cm base, top ground flat, was covered with a flat Plexiglas sheet, 1/4 in. thick, having entry ports for the identical stirrer and same accommodations as in Procedure A.

A solution containing 10 mL 1 *M* NaOH and 160 mL water was added to the covered reactor flask. The solution was cooled to ~0°C

in a methanol – Dry Ice bath, and 10 mL (8.09 g, 0.0895 *m*) freshly distilled cyclohexene was added followed by 30 mL methanol. The stirring was started and, with the temperature maintained between 0 and 3°C, a filtered solution of 15.57 g (0.0985 *m*) $KMnO_4$ in 500 mL water (0.097 *M*) was added in 1.7 hours using a calibrated capillary tube to control the rate of addition. The $KMnO_4$ was added in the form of a stream of small droplets impinging upon the area of maximum turbulence near the stirring shaft.

The product recovery procedure corresponds with that described under A, yield 8.40 g, 73%, mp 97–98°C.

The data

Since oxidation of an alkene by an aqueous solution of permanganate ion produces a variety of products, it may be assumed that each of the products is formed in separate subreactions as part of the overall oxidation. Accordingly, if the peroxidation step can be maximized and the other oxidations minimized, then greatly improved yields of glycols can be obtained. This appears to have been accomplished for cyclohexene via the simple expedients of turbulent mixing and dilution.

The yields of *cis*-1,2-cyclohexanediol formed by permanganate peroxidation of cyclohexene may vary from nearly zero to as high as 84% depending solely upon the nature of the imposed conditions of stirring and dilution. In expt. 6, Table 1, the entire amount of $KMnO_4$ was rapidly mixed with the cyclohexene, and the mixture was hand-stirred erratically over a period of about 30 min. After work-up of the product as in Procedure A, roughly 0.3 g of solid product, which included only a few scattered characteristic crystals of *cis*-1,2-cyclohexanediol, was obtained.

In complete contrast, the slow addition of dilute $KMnO_4$ to a slurry of cyclohexene under conditions of highly turbulent stirring gave a yield of 84%. See expt. 1, Table 1. Also, yields in the range of 71–75% were routinely obtained with less dilution under otherwise optimum conditions.

Minor alterations in procedure significantly affected the reaction. Yields could be markedly decreased if the $KMnO_4$ solution was not added in the area of maximum turbulence. Erratic addition of the $KMnO_4$ solution reduced yields as demonstrated in comparing expts. 16 and 17. In the latter experiments, occasional spurts of $KMnO_4$ altered the smoothness of flow, and the yield was lowered by about 6%. When the $KMnO_4$ solution was injected underneath the surface, there resulted an ~18% reduction in yields. Compare expt. 4 with expt. 10. Presumably there was a localized excess of $KMnO_4$ which was not as rapidly dispersed as in topside addition. The effect was not as pronounced, however, in the presence of excess alkene, as seen in comparing expts. 5 and 11. The addition of the $KMnO_4$ solution in the form of more numerous smaller droplets (expt. 9) as compared to fewer larger droplets (expts. 7 or 4) did not significantly affect yields.

Due to the difficulty in reproducing stirring efficiency in different experiments, it must be emphasized that there can be considerable variation in observed yields. Thus, the data are best interpreted qualitatively.

Similar yields were obtained upon employing Procedures A and B, i.e., 75 versus 73% yield. Compare expt. 4 with expt. 16.

A slower rate of addition of $KMnO_4$ did appear to decrease yields. Compare expts. 4 and 5 with 7 and 8. Possibly, this could have been due to loss of cyclohexene vapor during the elongated time of addition.

Under conditions of less than adequate stirring and low product yields, addition of excess alkene promoted a marked increase in yield. In expts. 18, 19, and 20 to crude yields increased from 15 to 40%, based on $KMnO_4$, as the $KMnO_4$–alkene ratio was varied from 1:2.45 to 1:7.35. With initial higher yields there was, in contrast, a lowering of the yield (based on cyclohexene used) upon increasing the alkene–$KMnO_4$ ratio from 1:1 to 3:2. Compare expt. 4 with 5, 7, with 8, and 10 with 11. Note, however, that in each of these cases, the gross product recovery was greater with excess alkene. Thus, the lowered overall yield was most probably due to solubility and vapor losses of alkene during the recovery process.

A variety of additives was tested for effectiveness on the peroxidation reaction. Very low concentrations of sodium hydroxide appeared to enhance yields and were used routinely on nearly all peroxidations. Mildly acidic conditions were particularly disastrous. The substitution of mangesium sulfate for sodium hydroxide reduce the glycol yield to ~7%. Compare expts. 1 and 3. In turn, higher basicity also reduced yields. The addition of 20 g NaOH instead of 4 g effected a decrease from 72 to 38%. See expts. 12 and 13.

Methanol appeared to be beneficial in lower concentrations. Compare expts. 15 and 17, where a 17% increase in yield occurred upon adding methanol in 15% initial concentration.

The additions of 0.1 *M* $CuSO_4$, 0.1 *M* NH_4OH, and saturated $NaHCO_3$ were all deleterious to the peroxidation reaction whereas adding 0.1–0.2 *M* Na_3PO_4 had no significant effect. The $NaHCO_3$ gave particularly poor results. The specific data are not included herein.

Due to the inconvenience of recovery of larger amounts of *cis*-1,2-cyclohexanediol from very dilute solutions, the more concentrated solutions as in expt. 4 are recommended for a preparative procedure.

The possibility of a synergistic affect by a second alkene on cyclohexene was considered. In expt. 14, a solution of 0.31 mol of $KMnO_4$ (0.19 *M*) was added to a slurry of 0.26 mol cyclohexene with 0.054 *m* sodium maleate. The maleate was oxidized rapidly forming tartrates, etc.; these products were retained in solution upon neutralization with $NaHCO_3$. The yield was lowered slightly but not to a significant extent.

A simple procedure for quantitative recovery of the glycols from dilute aqueous solutions has also been developed. The solution of the glycol is first made basic with $NaHCO_3$ and then extracted continuously for 2–7 days with CH_2Cl_2. The purpose of the $NaHCO_3$ is to prevent extraction of any organic acids.

Discussion

The data of the paper clearly indicate that the yields of *cis*-1,2-cyclohexanediol are extraordinarily sensitive to turbulent mixing and presumably to dilution. Thus, it appears that minimization of localized excesses of permanganate ion enhances glycol yields. The changes in yields due to variations on the basic procedures, e.g., injection under the surface, etc., also support this general concept. Obviously, permanganate ion is essential for the initial reaction, but secondary oxidations by that same ion lead to other undesirable (for this work) oxidation products.

The marked increase in yields with decreased localized excesses of MnO_4^- suggests further implications in the presently described mechanism (13). There is the possibility of reaction of excess permanganate ion with the product glycol, but this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

reaction appears to be quite slow and, therefore, of minor importance. Excellent evidence has been presented for the existence of an unstable intermediate hypomanganate ester ion (13–16) which forms rapidly and decomposes to various products.

The following mechanism, proposed to explain the data of this paper, is an adaptation of the hypomanganate ester concept specifically for glycol formation. The complex forms rapidly as follows:

[1] $MnO_4^- + -\overset{|}{C}=\overset{|}{C}- \rightarrow$  or Q^-

Once formed, Q^- may then undergo either of two alternative decompositions, one with excess MnO_4^- and the other with solvent water

[2] Q^- to $MnO_4^- \rightarrow$ diacid and other oxidation products

[3] $Q^- + H_2O \rightarrow MnO_3^- +$ 
[3*a*] $2MnO_3^- \rightarrow MnO_4^{2-} \rightarrow MnO_2$

[3*b*] $2H_2O + 3MnO_4^{2-} \rightarrow 2MnO_4^- + MnO_2 + 4OH^-$

Any conditions which reduces excess permanganate ion also reduces the probability of continued oxidation by reaction [2].

Reaction [1] depends on the efficiency of dispersion of the insoluble cyclohexene, which is greatly enhanced by turbulent stirring. Under the most ideal conditions of stirring, the cyclohexene globules are minimized in size, and surface contact with the MnO_4^- is maximized. The interaction between MnO_4^- and the double bond of cyclohexene, reaction [1], then becomes extremely rapid. Once the intermediate hypomanganate ester is formed, it may react with water, reaction [3]. Or, if a significant excess concentration of MnO_4^- is present, the more rapid reaction [2] occurs, forming products more highly oxidized than the glycol. Any condition which decreases the excess permanganate ion also reduces the probability of further oxidation by reaction [2]. Thus with efficient stirring the undesired oxidation products are minimized.

References in the literature concerning the obvious mechanical effects of stirring on the rates of reactions are extensive (17). In this paper an unusual mechanistic effect due to stirring is presented. More recently Bourne and co-workers (18) have made extensive studies of mixing upon a system of competitive consecutive reactions involving a diazo coupling of the type

[4] $A + B \rightarrow R$

[5] $R + B \rightarrow S$

The impact of the effect of stirring appears to be much greater in the permanganate reaction since there is a third reaction

[6] $R + H_2O \rightarrow T$

which provides an additional alternative and reaction [5] is highly sensitive to MnO_4^- (B) concentrations. The heterogeneity of the cyclohexene–water system precludes a more rigorous treatment of this reaction.

Methanol was selected as a cosolvent with water since it does not form oxidation or condensation products which interfere with the purification of the *cis*-1,2-cyclohexanediol. The beneficial effect of methanol at lower concentrations may be attributed to increased solubility of the alkene, permitting more efficient contact between MnO_4^- and alkene. Also the methanol may act as a mild dispersant to decrease size and increase stability of the cyclohexene globules. However, due to activity effects which may enhance reaction [2] and inhibit reaction [3], much larger amounts of methanol could have an adverse effect.

Since ionic strength also has a marked effect on ionic activity, added salts should significantly increase the rate of reaction [2] at the expense of reaction [3]. Accordingly, it is possible that the adverse effects of added NaOH (expt. 12), added $MgSO_4$ (expt. 3), or an excess of $NaHCO_3$ may be, at least in part, due to an ionic strength or activity effect.

In expts. 18–20, glycol yields increased as the alkene-to-$KMnO_4$ ratio was increased. This suggests the possibility that eq. [1] is reversible and Q^- increases with increasing alkene. This effect would be evident only at lower yield conditions as seen in expts. 4 and 5, etc. Obviously, further work is needed to affirm or deny the above suggestion.

Studies of permanganate peroxidations of various alkenes under high efficiency stirring conditions are being continued. Glycol yields in the range 50–60% have been obtained for cyclopentene, 1-methylcyclohexene, cycloheptene, and cyclooctene with minor adaptations in the procedure. These and certain other alkenes are under further investigation to determine if additional improvements in yields are possible.

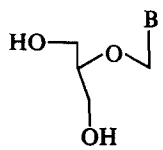
Introduction

Nucleoside analogues have gained increasing importance through their biological activity, particularly as antiviral and anticancer compounds (1). While many such analogues have an intact but modified furanose ring, others can be considered as ring-open nucleoside analogues (2–4). We have introduced a novel ring-open nucleoside structure **1** (5–7) which possesses all of the chemical functionality of deoxyribonucleosides but which lacks the rigid furanose ring structure. The purine derivatives of structure **1** have shown remarkable activity against herpesviruses (8–10). In this report we wish to describe the synthesis of a series of pyrimidine analogues of structure **1**.



1

A number of pyrimidine bases have conferred activity to nucleoside analogues. Halogens present at the 5-position of uracil (e.g. 5-fluorouracil and 5-iodouracil) have induced antitumor and antiviral activity to nucleoside analogues (11–15). 5-Methyluracil arabinonucleosides have been reported to selectively inhibit HSV-1 and HSV-2 (16). 5-Propyluracil nucleosides have been reported to possess antiviral activity (17, 18). The (*E*)-5-(2-bromovinyl)uracil nucleosides have significant inhibitory activity against HSV-1. 3-Deazauracil nucleosides inhibit replication in bacteria and RNA viruses (1). 5-Nitrouracil nucleosides show potent cytotoxic activity (21). We have prepared derivatives of our general structure **1** containing these and other modifications of the uracil ring and tested them for activity against herpesviruses.

Results and discussion

Compounds **4***a*–*e* were prepared (Scheme 1) by condensing the persilylated base (**2***a*–*e*) with the chloromethyl ether **3** (6). Both mercuric cyanide and tetra-*n*-butylammonium iodide (TBAI) were used as catalysts in the coupling reaction. While both are effective catalysts, TBAI has the advantage of lower toxicity, is required in smaller quantities, and the reactions are generally easier to manipulate during work-up. The 6-azauracil and 3-deazauracil derivatives **6***a* and **7***a* were also prepared by TBAI catalyzed coupling reactions.

The removal of the benzyl groups from **4** to give the unprotected compounds **5** generally proceeded smoothly in both direct or phase transfer catalytic hydrogenation. However, for the 5-bromo derivative **4***d* and the 5-nitro derivative **4***e* alternate routes were required. PdO catalyzed hydrogenation led to the removal of the 5-bromine atom from **4***d* and conversion of the 5-nitro to the 5-amino derivative **5***f*. Fortunately, the boron-trichloride cleavage (22) of the benzyl groups proceeded smoothly without effect on either the 5-bromo or 5-nitro substituents.

The synthesis of the 5-allyl and 5-*n*-propyl derivatives **8** and **9** (Scheme 2) was modelled after that of Ruth and Bergstrom (23) using organopalladium intermediates. The uracil derivative **5***a* was treated first with mercuric acetate followed by condensation with allyl chloride in the presence of Li_2PdCl_4. The 5-allyl derivative **8** was obtained in 62% yield and was hydrogenated to the 5-*n*-propyl derivative **9** in 97% yield.

The 5-iodouracil derivative **5***g* was of interest in its own right and as an intermediate to the bromovinyl derivative **13**. The method of Robins *et al.* (24) was used to introduce the iodine into position C-5 of the uracil ring. The treatment of **5***a* with iodine monochloride led to numerous unidentified products. However, the diacetyl derivative (**10**, Scheme 3) was smoothly converted into the 5-iodo derivative **11** using this procedure. Compound **11** was deacylated to **5***g* using potassium carbonate in methanol.

Compound **11** also served as the starting point for the introduction of the bromovinyl side chain at C-5. The general procedure of Dieck and Heck (25) as applied to nucleosides (26)

was used. This procedure involves the conversion of the 5-iodo to the 5-methyl propenoate (**12**). The *trans* assignment arises from the 16 Hz coupling constant between the vinylic hydrogens (23). The ester groups on **12** were hydrolyzed and the bromine was introduced using *N*-bromosuccinimide (27), giving **13** in 55% yield.

The properties of these compounds are collected in Tables 1 to 4. These compounds were tested for activity against HSV-1. None of the compounds tested showed significant activity, all having ED_{50} values equal to, or greater than, 32 μg/mL.

Experimental

General methods

Thin-layer chromatographic data (R_f values) are recorded from Merck Kieselgel 60F254 analytical sheets. Column chromatography was performed using Merck silica gel 60 (230–400 mesh) packed in glass columns (1.5 cm diameter up to 1 g of material, 5 cm diameter for over 1 g of material) using 15 g of silica per gram of crude material.

Uracil bases were purchased from Sigma Chemical Co. Compound **3** was prepared as previously described (6).

Ultraviolet spectra were recorded on a Cary 17 spectrometer. Nuclear magnetic resonance spectra were recorded using a Bruker WH-90, a Varian XL-200, and a Varian T60A spectrometer.

SCHEME 3

Preparation of 1,3-dibenzyloxy-2-chloromomethoxypropane (3)

1,3-Dibenzyloxy-2-propanol (95.9 g, 0.35 mol) and trioxymethylene (paraformaldehyde, 11.2 g) were added to 1,2-dichloroethane (250 mL, distilled from P_2O_5). The mixture was cooled in an ice-water bath and dry HCl was bubbled through the stirred mixture for 8 h (care is taken to exclude moisture). Anhydrous calcium chloride was added and after a few minutes the solution was collected by filtration. The solution was concentrated at reduced pressure (bath temperature 40°C) to a syrup. An ^{1}Hmr spectrum of this material indicated that it contained 87% of **3** and 13% unreacted 1,3-dibenzyloxy-2-propanol which does not interfere in subsequent condensations. 1,3-Dichloroethane was added to bring the weight of material to 306 g (which contains 306 mmol of **3**). This stock solution can be stored under refrigeration without deterioration for several months. The ^{1}Hmr spectrum of **3** shows signals at δ (ppm vs. TMS in $CDCl_3$): 3.70 (d, —CH_2—), 4.13 (m, —CH—), 4.58 (s, —CH_2—ϕ), 5.70 (s, —CH_2—Cl), and 7.38 (m, aromatic).

General procedure for the preparation of 1-[[2-hydroxy-1-(hydroxymethyl)ethoxy]methyl] derivatives 4, 6, and 7

5-Fluorouracil (4.0 g, 20 mmol) and ammonium sulfate (1 g) were added to hexamethyldisilazane (70 mL). The mixture was heated at reflux under the exclusion of moisture until the solution became clear (1 h in this example). The solvent was removed at reduced pressure and the residue was dried under vacuum. The residue was dissolved in benzene (50 mL) and mercuric cyanide (10.1 g, 40 mmol) was added. The mixture was heated below reflux temperature and chloromethyl ether **3** (9.6 g, 30 mmol) was added. The mixture was heated at reflux under a nitrogen atmosphere for 2.5 h. The solution was collected by filtration and concentrated to a gum at reduced pressure. Dichloromethane (150 mL) was added and the solution was extracted first with 30% potassium iodide solution (aqueous) followed by saturated sodium chloride solution. The solution was dried over sodium sulfate, collected by filtration, and concentrated to leave 13 g of material. This material was purified by chromatography on silica gel using ethyl acetate – hexane (6:4). Compound **4***c* was obtained (19.5 mmol) in 65% yield. Properties of **4***c* are collected, together with all compounds **4** as well as **6***a* and **7***a*, in Tables 1 to 4.

This procedure was used for the preparation of **4***b*–**4***d*. The solvent used for silica gel purification was ethyl acetate – hexane (6:4) in each case. Yields were **4***b*, 57%; **4***c*, 65%; and **4***d*, 60%.

Compounds **4***a*, **4***e*, **6***a*, and **7***a* were prepared in a similar fashion except that 0.16 mmol of tetra-*n*-butylammonium iodide was used in place of mercuric cyanide (30 mmol) as catalyst. The coupling reaction was carried out in dichloromethane instead of benzene. After heating at reflux for 1.5 h, the solution was cooled to room tem-

*Assignments are based, where possible, by analogy to base assignments in ref. 28, by heteronuclear correlated 2D spectra, or from the off-resonance decoupled spectra. (a) δ 5-CH_3 at 11.9 ppm (b) C-3 at 99.2 ppm (c) $CH_3C(=O)$— at 20.7 and 170.5 ppm (d) $CH_3OC(=O)$—CH=CH— assigned as 51.7, 167.8, 120.0, and 135.7 ppm respectively; $CH_3C(=O)$— at 20.7 and 170.6 ppm (e) C-3 at 98.4 ppm (f) CH_2=CH—CH_2 assigned as 116.5, 135.6, and 30.1 ppm respectively (g) $CH_3CH_2CH_2$— assigned as 13.5, 21.3, and 21.8 ppm respectively (h) BrCH=CH— assigned at 129.5 and 106.6 respectively.

†Spectra for compounds **4***b*–**4***e*, **7***a*, **11**, and **12** were obtained in $CDCl_3$. All others were obtained in DMSO-d_6. Normal spectra were recorded on a Bruker WH90 spectrometer. The heteronuclear correlated spectra were obtained on a Varian XL200 spectrometer.

perature and diluted with water (10 mL) and methanol (40 mL). After stirring for 2 min the solvents were removed at reduced pressure and the residue was dissolved in dichloromethane (75 mL). The solution was washed with saturated sodium chloride solution and water and then dried over sodium sulfate. The solvent was removed at reduced pressure and the product obtained by chromatography over silica gel. Compounds **4***a* and **4***e* were obtained using ethyl acetate – hexane (6:4) while ethyl acetate – hexane (1:1) was used for **6***a*. Compound **7***a* was obtained pure by direct crystallization from diethyl ether. Yields were **4***a*, 60%; **4***e*, 60%; **6***a*, 63%; and **7***a*, 94%. Properties are collected in Tables 1 to 4.

Procedures for the removal of benzyl groups

A. *Palladium oxide – ethanol – cyclohexene*

To 1 g of the dibenzyl derivative in a 25 mL flask was added ethanol (10 mL), cyclohexene (3 mL), and freshly prepared palladium oxide (200 mg). The reaction mixture was stirred until tlc showed only product material (usually 15–20 h). The solution was collected by filtration and evaporated to dryness at reduced pressure. Products were obtained pure after crystallization from ethanol. Products obtained in this manner and the observed yields are as follows: **5***a* (100%); **5***b* (77%); **5***c* (100%); **6***b* (100%); and **7***b* (96%). Compound **4***e* was converted into the 5-aminouracil derivative **5***f* (40%) by this procedure. Properties of the products are collected in Tables 1 to 4.

B. *Boron trichloride in dichloromethane*

To 2 g of the dibenzyl compound in dry dichloromethane (25 mL) was added boron trichloride in dichloromethane (5 mL, 1 *M* solution). The mixture was stirred under nitrogen at −78°C for 2 h. An additional 5 mL of the boron trichloride solution was added and stirring was continued for 1 h. At this point a solution (50 mL) of methanol and dichloromethane (1:1) was added and the solution was allowed to warm to room temperature. The solution was collected by filtration and the solvents were removed at reduced pressure. The dry residue was generally crystallized from ethanol to give the pure product. Products and yields obtained by this route were: **5***d* (87%) and **5***e* (85%). Properties are collected in Tables 1 to 4.

Preparation of the 5-allyluracil derivative 8

To a solution of **5***a* (760 mg, 2.5 mmol) in water (6 mL) was added a solution of mercuric acetate (1.27 g, 3.9 mmol) in water (7 mL). The mixture was stirred at 60°C for 21 h, whereupon the precipitate was collected by filtration and washed successively with 0.1 *N* sodium chloride in water (60 mL), ethanol (20 mL), and diethyl ether (30 mL). After drying, 1.15 g of white powder was obtained. Of this

≠Numbering system is as described in Table 2.

material, 760 mg was stirred with methanol (10 mL) for 10 min. Allyl chloride (1.28 g, 16.8 mmol), followed by a 0.1 *N* methanolic solution (3.6 mL, 0.37 mmol) of dilithium palladium tetrachloride (Li_2PdCl_4), was added to the milky white solution. The solution turned black and was stirred at room temperature for 16 h. Hydrogen sulfide was bubbled through the mixture for 45 s. The solution (yellow) was collected by filtration. The desired product **8** was obtained pure after silica gel chromatography (methanol–dichloromethane; 1:9). The yield was 62%. Properties are collected in Tables 1 to 4.

(a) *Conversion of **8** to the 5-propyluracil derivative **9***

Compond **8** (211 mg, 0.82 mmol) was dissolved in dry methanol (10 mL) and subjected to hydrogenation at 1 atm in the presence of 10% palladium on carbon. After 1.5 h the solution was collected by filtration through Celite. Compound **9** was obtained as a white crystalline compound, mp 105–106°C, in 97% yield. Properties are collected in Tables 1 to 4.

(b) *Preparation of the diacetyluracil derivative **10***

Compound **5***a* (600 mg, 2.7 mmol) was dissolved in pyridine (2 mL). Acetic anhydride (2 mL) was added and the solution was stirred at room temperature for 3 h. Solvents were removed at reduced pressure and the product was obtained after chromatography on silica gel (ethyl acetate – hexane; 7:3). Compound **10** was obtained as a crystalline compound in 96% yield. Properties are collected in Tables 1 to 4.

*Preparation of the 5-iodo derivatives **11** and **5**g*

To a solution of **10** (710 mg, 2.3 mmol) in dry dichloromethane (30 mL) was added a solution of iodine-monochloride, (780 mg, 4.8 mmol) in dichloromethane (10 mL). The mixture was heated at reflux for 2 h, cooled to room temperature, and washed successively with a 2% sodium bisulfite solution (aqueous, 7 mL), water, and finally, saturated sodium chloride solution. The solution was dried over sodium sulfate. The solvents were removed at reduced pressure and the product **11** was obtained in 87% after chromatography on silica gel using ethyl acetate – hexane (7:3).

The acetyl groups were removed from **11** to give **5***g* in 100% yield using anhydrous potassium carbonate in methanol (2.5 mg K_2CO_3/mL methanol/100 mg of **11**) for 65 h, followed by neutralization with Dowex 50XW-XH (H^+ form) resin.

Properties of **5***g* and **11** are collected in Tables 1 to 4.

*Analyses performed by Canadian Microanalytical Service, Vancouver, B.C.

(a) *Conversion of **11** into the propenoate derivative **12***

Dry *N,N*-dimethylformamide (10 mL) was added to a 25 mL round-bottom flask containing compound **11** (467 mg, 1.1 mmol), palladium acetate (11.2 mg, 0.05 mmol), methyl acrylate (172 mg, 2 mmol), and triethyl amine (121 mg, 1.2 mmol). The resulting solution was heated at 70°C for 5 h. The solvent was removed at reduced pressure and the product **12** was obtained in 68% yield after chromatography on silica gel using ethyl acetate – hexane (7:3). Properties of **12** are collected in Tables 1 to 4.

(b) *Conversion of **12** into the bromovinyluracil derivative **13***

Compound **12** (286 mg, 0.75 mmol) was dissolved in a 0.5 *N* sodium hydroxide solution (20 mL, aqueous) and the solution was stirred at room temperature for 2 h. The solution was neutralized with Dowex 50 W-XH (H^+ form) and the solvent was then removed at reduced pressure. The solid residue was redissolved in water (15 mL). Potassium acetate (134 mg) was added and the solution was heated to 70°C. *N*-Bromosuccinimide (121 mg, 0.68 mmol) was added to the hot solution which was then stirred for 2 h without external heating. The solvent was removed at reduced pressure and the residue was applied to a silica gel column which was eluted with dichloromethane–methanol (9:1). The product collected and crystallized from methanol (with ether) to give pure **13** in 55% yield. Properties are collected in Tables 1 to 4.

Laboratoire de Photochimie, Université Claude Bernard, Lyon I, 43 Boulevard du 11 novembre 1918, 69622 Villeurbanne Cedex, France

Reçu le 1 novembre 1982[2]

M. M. PETIT-RAMEL, G. THOMAS-DAVID, G. PERICHET et P. POUYET. Can. J. Chem. **62**, 22 (1984).

Les constantes d'association relatives aux complexes des ions Hg^{2+} avec les formes monomère (TM) et dimère (TD) de la thymine sont calculées à partir de mesures protométriques effectuées dans un large domaine de pH: $2 < pH < 11$. Le traitement des données de chacun des systèmes est conduit par une méthode de pit-mapping et l'on peut donner la répartition des diverses espèces complexes en fonction du pH.

En ce qui concerne le monomère, les ions Hg^{2+} ayant une coordinence de degré deux, traduite par la configuration linéaire d'espèces non chélatées, on peut mettre en évidence les complexes $[Hg(TM)]^+$ (log $\beta_{101} = 10{,}65$) et $[Hg(TM)_2]$ (log $\beta_{102} = 20{,}70$). Les photodimères (TD) obtenus par irradiation de la thymine monomère (TM) à 260 nm, en solution dans l'eau gelée à −10°C sont du type (*méso*) *cis*, *syn*. Il donnent des complexes avec Hg^{2+} de type $[Hg(TD)]$ (log $\beta_{101} = 13{,}55$), $[HgH_{-1}(TD)]^-$ (log $\beta_{1-11} = 6{,}73$) et $[HgH_{-2}(TD)]^{2-}$ (log $\beta_{1-21} = -1{,}69$). Le complexe $[Hg(TD)]$ a un spectre d'absorption nettement déplacé vers les grandes longueurs d'onde ($\lambda = 280$ nm), alors que le dimère (TD) n'absorbe qu'en dessous de 240 nm. Une irradiation à 280 nm provoque l'apparition du complexe $[Hg(TM)_2]$, donc la rupture du cycle cyclobutane au niveau du dimère.

M. M. PETIT-RAMEL, G. THOMAS-DAVID, G. PERICHET, and P. POUYET. Can. J. Chem. **62**, 22 (1984).

The association constants for Hg^{2+}-complexes involving monomeric (TM) and dimeric (TD) forms of thymine are determined by pH-titration measurements made over a wide pH range $2 < pH < 11$. In both systems, the experimental data have been analyzed by a pit-mapping method and the concentration distribution of the various complex species is plotted versus a pH gradient.

Because of the tendency of Hg^{2+} to form two bonds in a linear configuration, non-chelate complexes $[Hg(TM)^+]$ (log $\beta_{101} = 10.65$) and $[Hg(TM)_2]$ (log $\beta_{102} = 20.70$) are formed with the monomer thymine.

Photodimers, obtained after irradiation of monomer thymine at 260 nm in frozen water (−10°C), are the (*meso*)-*cis*, *syn* forms and can be complexed by the Hg^{2+} ions in $[Hg(TD)]$ (log $\beta_{101} = 13.55$), $[HgH_{-1}(TD)]^-$ (log $\beta_{1-11} = 6.73$), and $[HgH_{-2}(TD)]^{2-}$ (log $\beta_{1-21} = 1.69$) species. $[Hg(TD)]$ complex shows an absorption spectrum shifting towards 280 nm, whereas the free dimer ligand absorbs lower than 240 nm only. An irradiation at 280 nm provides the formation of the $[Hg(TM)_2]$ complex and consequently the breaking of the cyclobutane cycle in the dimer molecule.

Introduction

Beukers et Berends (1) ont montré que la thymine se dimérisait réversiblement en solution aqueuse par irradiation à 280 nm et pour une température voisine de 0°C. Le dimère obtenu, isolé sous forme cristalline présentait une absorption uv très différente de celle du monomère. En outre, L. Wulff et coll. (2, 3) ont précisé que la photosensibilisation de l'ADN "in vivo", à 280 nm, se produisait entre deux molécules adjacentes situées sur le même brin de l'hélice, les molécules de thymine passant ainsi d'un "état monomère" à un "état dimère".

Dans la mesure où il semble directement lié au blocage des virus et des bactéries et à l'activation des microorganismes, l'importance de l'interprétation biologique de ce phénomène de dimérisation a été soulignée par de nombreux auteurs (4−7). En ce qui concerne la réversibilité de la réaction photochimique, l'équilibre de conversion thymine-dimère en thymine-monomère peut être envisagé sous deux aspects complémentaires: (*i*) par irradiation, à une longueur d'onde voisine de 250 nm, de la molécule de thymine-dimère isolée (8); et (*ii*) par utilisation d'enzymes (E) de photoréactivation agissant selon le schéma:

[1] ADN bloqué (abs. <300 nm) + E (abs. <300 nm) → ADNE complexe (abs. >400 nm)

$$\xrightarrow[\text{visible}]{\text{irradiation}} \text{ADN} + \text{E}$$

Nous avons essayé de "modéliser" cette réaction au niveau de la thymine en utilisant les ions Hg^{2+}. Schématiquement, les réactions peuvent s'écrire de la façon suivante dans la mesure où une seule espèce complexe se formerait respectivement avec les thymines monomère et dimère:

[2] $H(TM) + H(TM) + h\nu \rightarrow H_2(TD)$

[3] $H_2(TD) + Hg^{2+} \rightarrow [Hg(TD)] + 2H^+$

[4] $[Hg(TD)] + h\nu' \rightarrow [Hg(TM)_2]$

La première irradiation $h\nu$, dimérisant normalement la thymine ligand monomère H(TM), le ligand dimère $H_2(TD)$ peut se complexer éventuellement en $[Hg(TD)]$. Une seconde irradiation $h\nu'$, favorise la décomposition du complexe dimérisé en complexe monomère $[Hg(TM)_2]$.

Notre contribution porte donc sur l'identification et le calcul des stabilités thermodynamiques de toutes les espèces complexes formées avec les oligomères de rang 1 et 2 de la thymine

[1]Avec la collaboration technique de C. Perret.

et nous tenterons de dégager une interprétation analytique des réactions précédentes.

Nous définirons par β_{pqr} la constante de stabilité globale d'une espèce complexe de formule générale $M_pH_qA_r$ où M représente l'atome métallique central, H l'atome d'hydrogène et A le ligand, dont la formation est régie par l'équilibre:

$$[5] \quad pM + qH + rA \rightleftarrows M_pH_qA_r$$

où

$$[6] \quad \beta_{pqr} = \frac{[M_pH_qA_r]}{[M]^p[H]^q[A]^r}$$

avec p et $r > 0$, $q > 0$ pour les espèces protonées, et $q < 0$ pour les espèces hydroxydées avec $[OH^-] = [H_{-1}]K_w$.

Lors de la neutralisation, nous pouvons définir un nombre moyen de protons neutralisables par mole de ligand:

$$[7] \quad \bar{q} = \frac{C_H - [H] + [OH]}{C_A}$$

où C_A est la concentration totale en ligand; [H] et [OH] sont respectivement les concentrations en H^+ et OH^- à l'équilibre; C_H est la concentration en protons telle que:

$$[8] \quad C_H = qC_A - B$$

B est la concentration de l'hydroxyde ajouté.

Les systèmes, dans lesquels interviennent les formes protonnées des coordinats et les espèces mono ou polynucléaires des complexes métalliques ont été résolus à l'aide d'un programme-type issu du Letagrop (9), modifié et testé dans notre laboratoire sur de multiples équilibres (10–12). Ce programme permet l'affinement des paramètres par la méthode du pit-mapping dont nous rappelons brièvement le principe.

Les transformées des courbes de titration $\bar{q} = f(\text{pH})$ sont rendues linéaires par un développement en série de Fourier et les équations issues de cette nouvelle expression sont dérivées jusqu'à une minimisation convenable de la somme $\gamma = \Sigma(\bar{q}_{exp} - \bar{q}_{calc})^2$. Cette dernière fonction dépend d'un nombre n de paramètres et est représentée dans un espace à $(n + 1)$ dimensions par une "nappe". Cette technique permet d'extrapoler les valeurs des paramètres β_{pqr} vers des valeurs voisines de celles rendant minimum l'expression γ. Cette méthode se justifie théoriquement dans la mesure où les écarts $(\bar{q}_{exp} - \bar{q}_{calc})$ sont des variables aléatoires de même écart-type, σ, et il est alors possible, compte tenu de l'erreur systématique expérimentale sur $\bar{q}_{exp}$, de calculer les déviations standards afférentes à chaque constante β_{pqr}.

Resultats

1. *Interactions Hg^{2+}—thymine monomère*

Les bases puriques et pyrimidiques, composantes des acides nucléiques, sont généralement faibles et bien qu'elles puissent complexer de nombreux cations tels Cu^{2+}, Ni^{2+}, Zn^{2+}, Co^{2+}, Mg^{2+} et Ca^{2+} (13–16), il existe des interactions métal-coordinat privilégiées avec les ions Hg^{2+} dont l'influence a été notée au niveau de la molécule de thymine, soit isolée (17), soit replacée dans une séquence d'ADN (18–20).

En ce qui concerne particulièrement la thymine monomère isolée, les travaux de Davidson et coll. (17) font état d'une liaison stable avec les ions Hg^{2+} par formation d'un seul complexe de type $[Hg(TM)_2]$.

Pour assurer un maximum d'homogénéité à notre étude, nous avons recalculé dans un premier temps, la constante de stabilité protonique β_{011}, de la thymine monomère H(TM), dont la valeur concorde parfaitement avec les références ci-dessus (tableau 1). Bien qu'il y ait, dans chaque molécule de monomère, deux possibilités d'échange relatives à chaque hydrogène porté par les fonctions amines en N_1 et N_3 (fig. 3), une seule déprotonation est observée dans le domaine de pH envisagé (fig. 1*a*). Les mesures protométriques se révélant inopérantes pour une telle différenciation, nous pouvons cependant supposer que le fort effet inductif des groupements C=O, portés par les C_2 et C_4 encadrant la fonction amine, activent préférentiellement la déprotonation en N_3, la seconde déprotonation de l'hydrogène porté par N_1 se situant vers pH 12 (13).

En présence des ions mercuriques, le choix des rapports ligand/métal > 4 dépend de deux phénomènes: (*i*) une hydrolyse importante, dès les faibles pH, par formation des espèces $[HgH_{-1}]$ soluble et $[HgH_{-2}]$ peu soluble; et (*ii*) une dismutation des ions Hg^{2+} (21), en présence d'un excès de métal:

TABLEAU 1. Constantes de formation des complexes Hg^{2+}—thymine monomère $\mu = 0{,}1$ ($NaClO_4$); $t^0 = 25°C$

[9] $Hg^{2+} + Hg \rightleftarrows Hg_2^{2+}$

En ce qui concerne la mise en évidence des espèces complexes et le calcul de leurs constantes de stabilité, la démarche que nous suivrons découle directement de l'examen des courbes de formation $\bar{n} = f(p(TM))$ — où $\bar{n}$ représente le nombre moyen de ligand libre déprotoné — qui permettent d'identifier deux espèces complexes successives répondant aux équilibres:

[10] $H(TM) + Hg^{2+} \rightleftarrows [Hg(TM)]^+ + H^+$

[11] $2H(TM) + Hg^{2+} \rightleftarrows [Hg(TM)_2] + 2H^+$

A partir de solutions 2×10^{-3} *M* en thymine-monomère et avec quatre rapports ligand/métal sensiblement égaux à 1, 2, 4 et 10, totalisant 240 points expérimentaux, la méthode d'affinement par pit-mapping sur le nombre moyen $\bar{q}$ de protons neutralisables (fig. 1*a*) de la molécule conduit aux valeurs rassemblées dans le tableau 1. L'introduction, dans le cycle d'affinement, de la constante $\beta_{1\text{-}10}$, relative à la formation de l'espèce hydroxydée soluble $[HgH_{-1}]$ n'améliore pas sensiblement la convergence bien que la valeur obtenue soit en bon accord avec nos références bibliographiques (22–24). Le tracé des courbes de distribution (fig. 1*b*) qui permet de suivre l'évolution des espèces formées en fonction du pH, montre en effet que dans nos conditions expérimentales (ligand/métal > 4) la quantité d'espèces hydroxydées reste négligeable.

Quant au complexe $[Hg(TM)]^+$, non signalé dans la littérature, il faut souligner que son domaine d'existence se situe vers les faibles pH, sa disparition étant presque totale à pH 4.

2. Interactions Hg^{2+}—thymine dimère

Le dimère étant beaucoup moins soluble que le monomère en solution aqueuse, la concentration utilisée ne peut excèder 10^{-4} *M*. Nous ne disposions d'aucune donnée bibliographique chiffrant les stabilités protoniques et a fortiori les stabilités des complexes et nous avons suivi le même protocole d'étude que pour le monomère.

La transformée des courbes de neutralisation $\bar{q} = f(pH)$ (fig. 2*a*) correspond bien à la présence de deux protons neutralisables $H_2(TD)$ relatifs aux constantes β_{021} et β_{011} du tableau 2.

La faible solubilité du dimère, impliquant de faibles concentrations en ions mercuriques a pour conséquence directe d'augmenter l'hydrolyse et de restreindre le rapport ligand/métal au voisinage de 1 et les calculs d'affinement ont porté sur deux valeurs de rapport $H(TD)/Hg^{2+} = 0{,}90$ et 1 soit environ 120 points expérimentaux. Selon le domaine de pH considéré, le traitement des données potentiométriques fait apparaître la formation simultanée du complexe simple [Hg(TD)] et d'espèces hydroxydées.

$3 < pH < 9$

[12] $H_2(TD) + Hg^{2+} \rightleftarrows [Hg(TD)] + 2H^+$

$3 < pH < 6$

[13] $Hg^{2+} + HH_{-1} \rightleftarrows [HgH_{-1}]^+ + H^+$

$6 < pH < 9$

[14] $\begin{cases} TD^{2-} + Hg^{2+} + HH_{-1} \rightleftarrows [HgH_{-1}(TD)]^- + H^+ \\ TD^{2-} + Hg^{2+} + 2HH_{-1} \rightleftarrows [HgH_{-2}(TD)]^{2-} + 2H^+ \end{cases}$

L'ensemble des constantes β_{101}, $\beta_{1\text{-}11}$ et $\beta_{1\text{-}21}$ correspondant respectivement aux équilibres de formation des espèces [Hg(TD)], $[HgH_{-1}]^+$, $[HgH_{-1}(TD)]^-$ et $[HgH_{-2}(TD)]^{2-}$ (tableau 2) conduit à une convergence rapide du processus d'affinement, la valeur recalculée de l'espèce $[HgH_{-1}]^+$ déjà prise en compte dans l'étude de la thymine monomère restant parfaitement concordante. La courbe de distribution des espèces en fonction du pH (fig. 2*b*) permet de situer précisément leurs domaines de formation, dans nos conditions expérimentales.

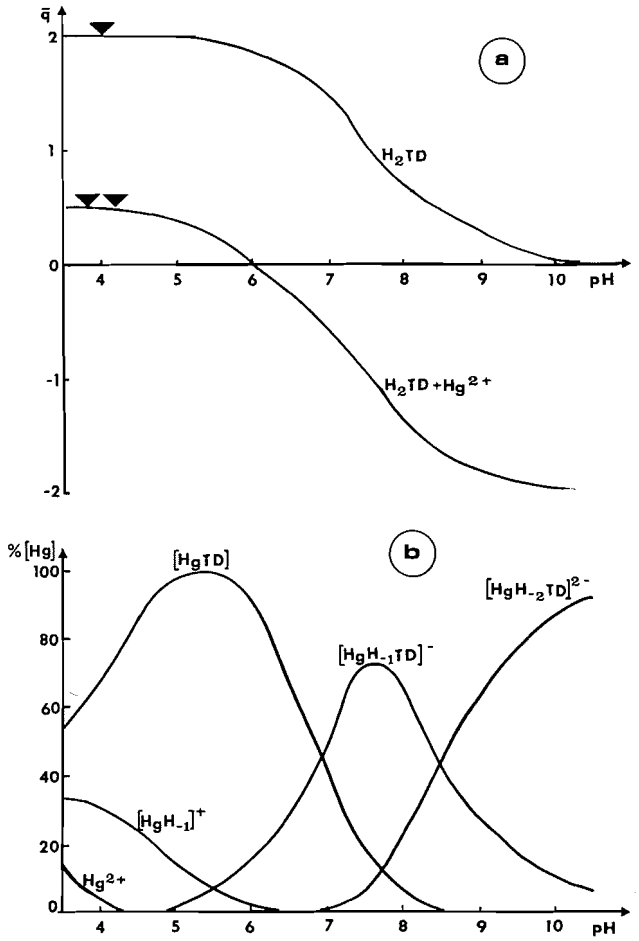

FIG. 2. Système Hg^{2+}—thymine dimère. (*a*) $\bar{q} = f(pH)$; ▼$[H_2TD] = 9{,}96 \times 10^{-5}$ *M*; ▼▼$[H_2TD] = 9{,}96 \times 10^{-5}$ *M*; $[Hg^{2+}] = 9{,}5 \times 10^{-5}$ *M*. (*b*) Répartition des espèces: $[H_2TD] = 9{,}96 \times 10^{-5}$ *M*; $[Hg^{2+}] = 9{,}5 \times 10^{-5}$ *M*.

Discussion

L'examen comparé des complexes mercuriques obtenus avec la thymine monomère et la thymine dimère appelle plusieurs remarques.

1. Ions mercuriques

Les interactions Hg^{2+}-coordinat sont généralement accom-

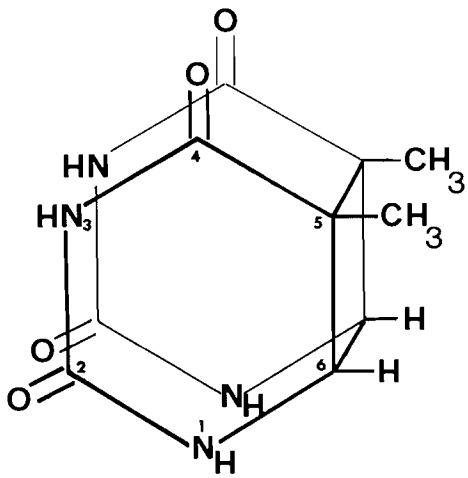

FIG. 3. Thymine dimère (isomère *cis-syn*).

pagnées de phénomènes secondaires: (*i*) Réaction d'hydrolyse simple sur les ions métalliques et formation, dès pH 2, de l'espèce soluble $[HgH_{-1}]^+$, qui, si elle reste négligeable pour le système monomère, atteint une valeur relative de 30% de la concentration totale en métal dans le cas du système dimère, les espèces supérieures $[HgH_{-n}]^{2-n}$ avec $n > 1$, n'étant pas retenues dans nos conditions expérimentales. (*ii*) Formation d'espèces complexes hydroxydées $[HgH_{-1}(TD)]^-$ et $[HgH_{-2}(TD)]^{2-}$, la dilution importante des solutions du système dimère favorisant la permanence des ions hydroxydes. (*iii*) Equilibre de dismutation des ions $[Hg_2^{2+}]$ dont nous nous sommes affranchis en travaillant à des concentrations $[Hg^{2+}] < 10^{-3}$ *M*.

2. Coordinats et complexes

Le monomère H(TM) et le dimère $H_2(TD)$ se comportent respectivement comme un mono et un diacide très faibles et les valeurs des tableaux 1 et 2 recoupent la règle générale de stabilité protonique plus élevée dans un cycle comportant une double liaison (monomère) que lorsque cette dernière est rompu (dimère).

Une étude systématique, à de faibles valeurs de pH, a permis de mettre en évidence un nouveau complexe: la première espèce du monomère $[Hg(TM)]^+$, la seconde $[Hg(TM_2]$, plus stable, ayant déjà été signalée (17).

Parmi les quatre formes isomériques de la thymine dimère décrites par Wulff et Fraenkel (2), le dimère (*meso*) *cis-syn* apparait comme la configuration la plus probable, que ce soit après irradiation d'une solution de thymine monomère gelée ou après photodimérisation des molécules adjacentes de thymine, situées sur chaque hélice d'ADN (fig. 3).

En présence d'ions Hg^{2+}, la formation de complexes du type [Hg(TD)], comme les espèces hydroxydées correspondantes, accrédite encore la configuration "*meso*" par liaison systématique du métal sur les atomes d'azote N_3.

En outre, l'absence d'espèces condensées en thymine dimère telles que $[Hg_2(TD)_2]$ et $[Hg_2(TD)_4]$ dont l'introduction dans l'affinement ne modifie en aucune manière la variance, trouve une justification normale au vu de nos conditions expérimentales. L'intervalle de variation des rapports ligand/métal, impérativement voisin de 1 pour raison d'hydrolyse, ne permet pas d'accréditer ces espèces polynucléaires de rang 2, dans la mesure où nous n'observons pas sur les courbes de formation $\bar{n} = f(p(TD))$, le déplacement caractéristique $\Delta p(TD)$ consécutif à une variation, Δm, de la concentration en métal (25), et que nous avons souvent mis en évidence dans d'autres systèmes (26, 27).

Partie expérimentale

Deux chaînes de mesure, convenablement étalonnées permettent de mesurer conjointement le pH et le pM dans un large domaine de pH: $2 < pH < 11$.

pH: électrode en verre / solution à 25 ± 0,1°C / NaCl saturé / électrode au calomel

pM: électrode de mercure en J / solution à 25 ± 0,1°C / Na_2SO_4 saturé / électrode au sulfate mercureux Hg_2SO_4/Hg

Chaque jeu d'électrodes est relié à un potentiomètre ISIS 20 000 TACUSSEL et les mesures sont effectuées sur des solutions aqueuses, thermostatées à 25 ± 0,1°C, dont la force ionique est maintenue constante à l'aide d'une solution de $NaClO_4$ 0,1 *M*.

Les solutions d'acide perchlorique Prolabo R.P. et de soude Merck sont dosées par des solutions étalons de biphtalate de potassium Merck. L'ajustement de la force ionique est effectuée par une solution de titre connu en perchlorate de sodium Merck. Le perchlorate de mercure est préparé par attaque à chaud d'hydroxyde mercurique par l'acide perchlorique jusqu'à neutralisation, puis dosé par l'EDTA à l'aide d'une électrode de mercure en J.

La thymine monomère utilisée provient des laboratoires Merck.

La thymine dimère est préparée par irradiation de solutions de thymine monomère dans l'eau (10^{-3} *M*) gelée à −10°C. L'irradiation a lieu à l'aide d'une lampe à vapeur de mercure haute pression. Les solutions sont évaporées à sec. Le résidu est ensuite dissous dans l'eau bouillante et filtré. Le filtrat est concentré et les cristaux de thymine dimère cristallisent avant ceux de monomère et Wang (28) a montré que seule la forme "*meso*" isomère *cis-syn* est obtenue.

Ab initio studies of complexes between SiF_4 and ammonia

J. M. CHEHAYBER, S. T. NAGY,[1] AND C. S. LIN[2]

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received June 6, 1983

J. M. CHEHAYBER, S. T. NAGY, and C. S. LIN. Can. J. Chem. **62**, 27 (1984).

Ab initio minimal basis set STO-6G calculations show axial-$SiF_4 . NH_3$ and *trans*-$SiF_4 . 2NH_3$ to be energetically more stable with respect to SiF_4 and ammonia. All other geometrical isomers are 1.0–2.0 eV higher.

Our calculation results rule out the steric hindrance between ligands as the reason $SiF_4 . 2NH_3$ is, according to experimental evidences, *cis* while complexes of bulkier ligands are *trans*.

Since the *cis*-$SiF_4 . 2NH_3$ has a large electric dipole moment and a suitable charge arrangement it is conceivably the favoured form in the solid phase. The *cis* → *trans* rearrangement may take place under conditions where the advantages of the *cis* are not operative.

Although there is some degree of covalency in the Si—N bond it remains largely electrostatic, with the lone pair of ammonia attracted to the positively charged Si atom. The lone pair does not appear to be extensively altered by the complex formation.

J. M. CHEHAYBER, S. T. NAGY et C. S. LIN. Can. J. Chem. **62**, 27 (1984).

Les calculs *ab initio* utilisant l'ensemble minimal de base STO-6G montrent que le $SiF_4 . NH_3$ axial et le $SiF_4 . 2NH_3$ *trans* sont, du point de vue énergétique, plus stables que le SiF_4 et l'ammoniac. Tous les autres isomères géométriques sont plus élevés de 1,0 à 2,0 eV.

Les résultats de nos calculs suggèrent que l'encombrement stérique entre les ligands n'explique pas pourquoi le $SiF_4 . 2NH_3$ est expérimentalement en position *cis* alors que des complexes impliquant des ligands plus encombrants sont en position *trans*.

Puisque le $SiF_4 . 2NH_3$ *cis* a un grand moment dipolaire électrique et un arrangement de charge convenable, on concoit que cette forme soit favorisée à l'état solide. La transposition *cis* → *trans* peut se produire dans des conditions où les avantages du composé *cis* n'interviennent pas.

Bien que la liaison Si—N soit covalente dans une certaine mesure, elle demeure principalement électrostatique avec le doublet libre de l'ammoniac attiré par l'atome de Si chargé positivement. Le doublet libre ne semble pas être fortement altéré par la formation du complexe.

[Traduit par le journal]

Introduction

Complexes of the type $MX_4 . nL$, with n = 1,2, M standing for Group IV metals (Si, Ge, Sn, Pb), X for halogen and L being uni- or bidentate ligands, e.g. Me_3N, Me_3P, NH_3, BiPy etc. have been known for a long time. Synthesis of the complex $SiF_4 . 2NH_3$ was first reported by Davy in 1812 (1) and various chemical and physical properties of the complex were subjects of several early studies (2–5).

For the 1:1 adducts, $MX_4 . L$, there are two plausible geometrical isomers, with the ligand L in the axial or equatorial positions. (Henceforth a complex will be labelled according to the position of the ligand; a for axial and e for equatorial.) Likewise, the octahedral 1:2 adducts, $MX_4 . 2L$, have two geometrical isomers, *trans* and *cis*.

The few studies on the complex $SiF_4 . L$ where L is NH_3 (6) or a strong base $(CH_3)_3N$ (7, 8) agreed on the axial configuration as the favoured isomer. As for the 1:2 adduct, $MX_4 . 2L$, the results are more contentious.

In 1960 Muetterties (9) reported ^{19}F nmr spectra of some soluble octahedral $SiF_4 . 2L$ complexes. A single resonance line was observed in each case, strongly indicative of the *trans* arrangement. Furthermore, several Group IV complexes are also shown by X-ray diffraction to favour the *trans* form in the solid state. These include $SiF_4 . 2Py$ (10), $GeCl_4 . 2Py$ (11), $SnCl_4 . 2HMPT$ and $SnBr_4 . 2HMPT$ (12). $SiF_4 . 2N(CH_3)_3$ was also known (7, 8) to be *trans*.

On the contrary, in their study of the ir spectra of $SiF_4 . 2NH_3$, Aggarwal and Onyszchuk (13) assigned the doublet, at 905 and 935 cm^{-1}, to the Si—N stretching and a broad peak centred on 725 cm^{-1} as the result of coupling among four bands attributable to the Si—F stretching modes. They thus concluded that the *cis* form was favoured.

These apparently conflicting experimental results suggest intriguing situations. For example, the geometrical preference of the complexes may depend very sensitively on their natures, e.g., electronegativities and/or bulkiness of the ligands. The energies of the complexes can be such that equilibria between the two geometrical isomers may shift from one form to the other under suitable conditions. It is also possible that the reaction pathways to 1:2 adducts lead to one form which subsequently transforms into the other as conditions change.

These studies are an attempt to clarify these questions. In the first part, we calculated the electronic structures of five complexes: *trans* and *cis* isomers of $SiF_4 . 2NH_3$ and a-, e-, and square pyramidal, sp-$SiF_4 . NH_3$. The results are described in this report.

Calculation and results

Since one of our purposes is to look into the pathways to $SiF_4 . 2NH_3$ calculations on the sp-$SiF_4 . NH_3$ is done as well.

A QCPE program based on the minimal basis set *ab initio* MO theory, GAUSSIAN 70 (14) was used in this work. In all cases optimal geometries were first determined by using a simpler basis set, STO-3G.

Molecular parameters of primary importance in these complexes are $r_{Si—N}$, ∠F—Si—N, and ∠F—Si—F′, followed by $r_{Si—F}$, and least crucial are the orientation of ammonia molecules and $r_{N—H}$. For *cis*-$SiF_4 . 2NH_3$ the angle ∠N—Si—N′ also belongs to the first group.

We first varied ∠F—Si—N and ∠F—Si—F′ for several values of $r_{Si—N}$ with the geometry of NH_3 frozen at its isolated state and $r_{Si—F}$ about 5–10% longer than in SiF_4. After the

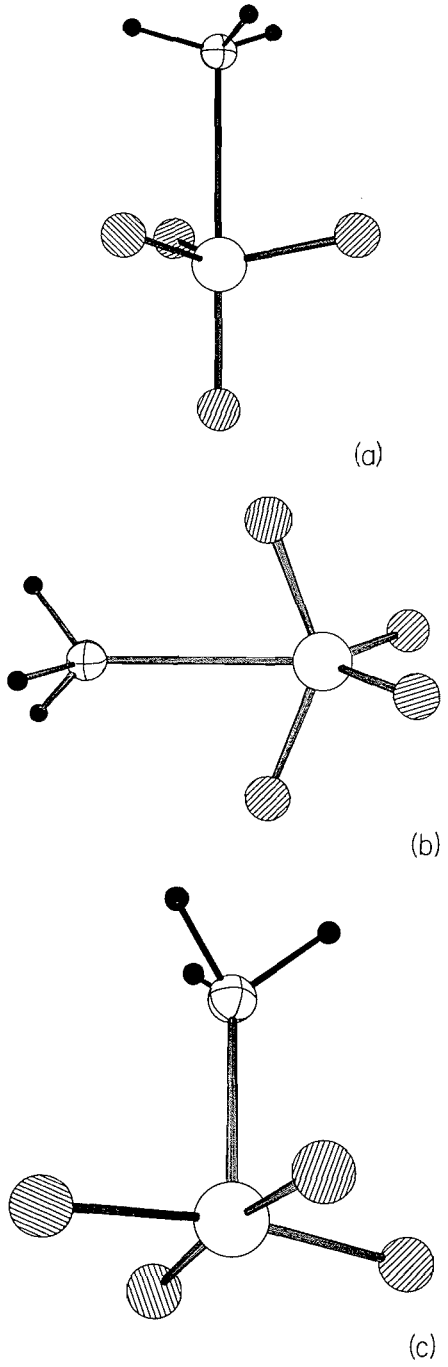

FIG. 1. (*a*) Axial $SiF_4.NH_3$. Bond lengths (Å): Si—N, 2.392; N—H, 1.007; Si—F_e, 1.573; Si—F_a, 1.621. Bond angles (deg): N—Si—F_e, 78.5; F_a—Si—F_e, 101.5; F_e—Si—F_e, 116.1. (*b*) Equatorial $SiF_4.NH_3$. Bond lengths (Å): Si—N, 2.439; Si—F_e, 1.609; Si—F_a, 1.604; N—H, 1.008. Bond angles (deg): N—Si—F_e, 109.9; N—Si—F_a, 69.4; F_a—Si—F_a, 101.6. (*c*) Square pyramidal $SiF_4.NH_3$. Bond lengths (Å): Si—N, 2.012; Si—F, 1.619; N—H, 1.007. Bond angles (deg): N—Si—F, 95.3; F—Si—F, 89.5. ○, Si; ⊕, N; ▨, F; ●, H.

primary group was optimized, r_{Si-F} was optimized and the same procedure was repeated once. Afterwards, the same was applied to the third and last group. These geometries were then used as the input for the optimization with the STO-6G. Since the total energies of these complexes are in the high hundreds of atomic units optimization was terminated when the total energy has converged to the fourth decimal place, 0.0001.

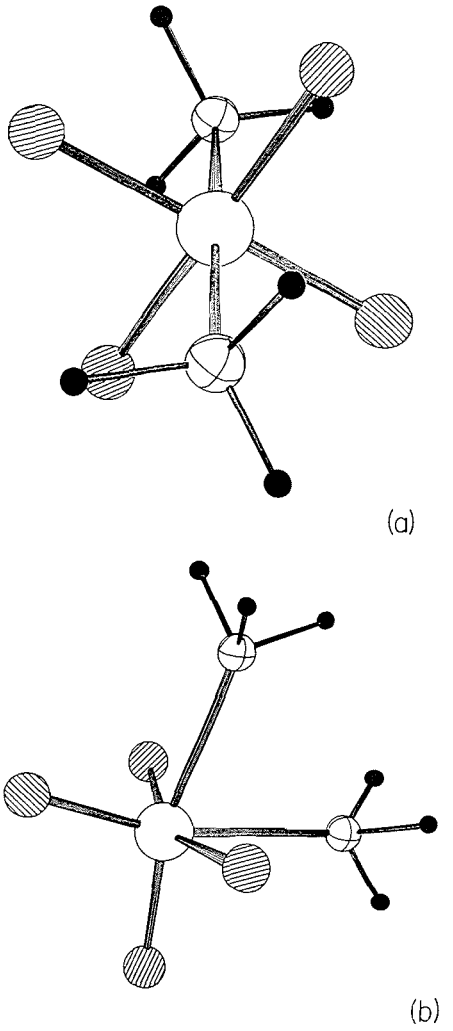

FIG. 2. (*a*) *trans*-$SiF_4.2NH_3$. Bond lengths (Å): Si—N, 2.041; N—H, 1.008; Si—F, 1.632. (*b*) *cis*-$SiF_4.2NH_3$. Bond lengths (Å) Si—N, 2.112; N—H, 1.007; Si—F_e, 1.638; Si—F_a, 1.640. Bond angles (deg): F_e—Si—F_a, 98.1; N_e—Si—F_e, 79.6; N—Si—F_e, 89.3; N—Si—N, 76.5.

Optimal geometries determined by the STO-6G are generally not significantly different from those from the STO-3G. Figures 1 and 2 give sketches of these molecules and their primary bond lengths and angles.

Energies and charge distributions are given in Table 1. For ease of comparison SiF_4 and NH_3 are also included.

Discussion

(A) Energy and molecular geometry

From Table 1 it is obvious that relative to the dissociation limit $SiF_4 + NH_3$ the most stable of the 1:1 adducts is the axial. This is in agreement with the consensus shown by experimental observations (6–8).

The equatorial form is 1.343 eV above the axial. Although this energy difference is not large considering all the internal degrees of freedom of a complex of this size, the 1:1 adduct is stable only at low temperature and it is not likely that the complex would exist in an equilibrium between the axial and equatorial forms. There has been no report of the experimental observation of e-$SiF_4.NH_3$.

Various bond lengths in the two isomers are very close and

[a]ΔE is the difference between E_T and the energies of appropriate component molecules.
[b]F_a and F_e refer, respectively to F atoms on the axial and equatorial positions.
[c]CT stands for charge transfer per NH_3.

the charge distributions are also within a few percent of each other. It is shown below that the net electrostatic interactions in these two isomers are the same and their Si—N bond orders are also very similar. Hence, to explain why the axial is more stable one must look at other factors.

Repulsion between two covalent bonds is a concept well accepted at all levels of chemistry. From Fig. 1(*a*) and 1(*b*) one can see that Si—F bonds fall into two categories. One has its axis perpendicular to, and the other parallel with, that of the lone pair of ammonia. Obviously they exert different repulsion against the lone pair. The axial has three Si—F bonds roughly perpendicular (79°) to the axis of the lone pair and one Si—F bond supplementary to the Si—N bond. In the equatorial, two Si—F bonds are at 70° to the lone pair and two are in the equatorial plane. The difference may explain the relative stabilities of these two isomers.

It is interesting to look at the molecular geometries of these isomers from the viewpoint of perturbation to the tetrahedral structure of SiF_4 due to the complex formation with NH_3.

With respect to the N atom, the four F atoms can be divided into two groups. Those F atoms on the same side of the Si atom as the N are the primary neighbours, F_p, of the N atom while those on the opposite side are the secondary neighbours, F_s. For example, all three F atoms on the equatorial position of the axial, Fig. 1(*a*) are three F_p's and the only axial F atom is the sole F_s.

One then observes in Fig. 1 that the angle $\angle F_s—Si—F_s$ is hardly perturbed from the tetrahedral angle of 109° 28′. On the other hand, $\angle F_p—Si—F_s$ of both axial and equatorial and $\angle F_p—Si—F_p$ of the axial show deviations of approximately −8° and +7°, respectively.

Thus, formation of a complex with NH_3 does not cause very large changes to the geometry of SiF_4 except in the sp-isomer. A more severe deviation from the tetrahedral structure is accompanied by a higher energy.

In these complexes the bond Si—N between NH_3 and SiF_4 is a coordinate covalent bond which essentially is a lone pair of N pointed to the positively charged Si because of the electrostatic effect. Optimal geometries of the axial and equatorial show the angle between a coordinate covalent bond and an ordinary covalent bond, $\angle F_p—Si—N$, to be smaller than the angle between two covalent bonds, $\angle F_p—Si—F_s$. Since repulsion between two bonds is an important factor in determining the bond angle, this can be construed as an indication of a weaker repulsion exerted by a lone pair. This observation agrees with the notion that a coordinate covalent bond is not a full-fledged covalent bond.

Of the two isomers of $SiF_4 . 2NH_3$ the *trans* form is found to be energetically lower than the *cis* by 1.54 eV. That those complexes which are experimentally observed to be *trans* (7−12) all have ligands much bulkier than NH_3 may prompt one to speculate that the steric effect is the dominating factor in the *cis*−*trans* question. Our calculation results clearly show this not to be the case.

Table 1 shows that while the total energy of *trans*-$SiF_4 . 2NH_3$ is 0.359 eV lower than the total dissociation products, $SiF_4 + 2NH_3$, the following equations are also true:

$$\text{a-}SiF_4 . NH_3 + NH_3 \rightarrow \textit{trans}\text{-}SiF_4 . 2NH_3 - 0.074 \text{ eV}$$

$$\text{e-}SiF_4 . NH_3 + NH_3 \rightarrow \textit{cis}\text{-}SiF_4 . 2NH_3 - 0.274 \text{ eV}$$

In both cases the total energy of the 1:2 adduct is higher by a small amount than that of the reactants.

Most certainly inclusion of CI and probably of 3*d* atomic orbitals on Si are likely to lower the calculated energy of the 1:2 adducts more than that of the 1:1, making the former energetically more stable since the differences are so small. In any event, the possibility of the 1:1 adduct, upon formation, to proceed to its 1:2 counterpart can not be ruled out. Thus, 1:1 and 1:2 adducts may establish an equilibrium unless other factors intervene.

Complexes $SiF_4 . L$ with a highly electronegative ligand are known (7, 8) to exist in equilibrium with the 1:2 adducts but for those of other ligands, e.g. NH_3, 1:1 adducts are chemically stable only at low temperatures and under specific conditions (13). Our calculation results generally agree with these observations.

In the course of calculations it was noticed that while the use of the STO-6G basis set lowered the total energy of these complexes by a sizable amount from those of STO-3G calculations the relative stabilities of the five complexes remained the same, although small changes in the detail were inevitable.

(B) Charge distributions

Going over Table 1 from the left to the right one finds that the very substantial positive charge on the Si atom of these complexes changes very little from the value of 1.434 in SiF_4. It is interesting to notice, however, that in all cases but the equatorial, the Si atom becomes even more positive, albeit only slightly, upon formation of complexes with the electron donor, NH_3.

The negative charge on N varies more widely in terms of % change. That the charge in the *cis* is significantly smaller than that in all other complexes and than that in ammonia is perhaps due to the proximity of two ammonia molecules in the *cis* arrangement.

Charges on the F atoms clearly fall into two groups. Those of axial and equatorial 1:1 adducts are around 0.385, or about 10% higher than in SiF_4. F atoms of the sp-$SiF_4.NH_3$ have a considerably larger negative charge and belong to the second group with 1:2 adducts where the charges range up to 30% greater than in SiF_4.

The large negative charges on the N and F atoms are reflected in the positive charge on the H atoms. Although the 1:2 adduct has twice as many H atoms per SiF_4 compared to the 1:1 complexes, the positive charge of the H atoms in the *trans* is nonetheless the largest of all, 0.243, or more than 40% larger than that of NH_3! Charge distributions in e-$SiF_4.NH_3$ come closest to those of component molecules. One also notices that the charges on all atoms of ammonia are always smaller in the *cis* than in the *trans*.

More interesting is the charge transfer from NH_3 to SiF_4. Table 1 shows the charge transfer (CT) in the axial and equatorial to be quite small. Thus, although these two complexes are all strongly polar, as the charges on each atom indicate, they are hardly ionic and the polarity is strictly an internal property of the component molecules SiF_4 and NH_3.

In contrast, sp-$SiF_4.NH_3$ and both 1:2 adducts are considerably more ionic. It must be noted that the charge transfer of 0.196 and 0.124 for the *trans*- and *cis*-$SiF_4.2NH_3$, respectively, are values per NH_3 molecule. Undoubtedly the drastic distortions from the tetrahedral structure of SiF_4 in these complexes led to this more extensive rearrangement of the electron density.

Net electrostatic interactions between SiF_4 and the ligand clearly reflect the degree of the charge transfer. The values are -0.25 eV for each of a- and e-$SiF_4.NH_3$, -0.56 for sp-$SiF_4.NH_3$, -1.13 eV and -0.80 eV, respectively, for *trans*- and *cis*-$SiF_4.2NH_3$.

Albeit with some variations, the exterior of these complexes is basically an ellipsoid where the major axis is not much longer than the minor axes. Referring to Figs. 1 and 2 and Table 1 it becomes evident that in all complexes, except *trans*-$SiF_4.2NH_3$, one end of the ellipsoid is spanned by the positively charged H atoms while the opposite half of the ellipsoid is defined by the four negatively charged F atoms. Enveloped inside this shell are the Si and N atoms.

This overall exterior polarity enables these four complexes to form an ionic solid with a head-to-tail arrangement, providing a further stabilization. This facility is most pronounced in the *cis* 1:2 adduct due to the larger charges on the atoms and the higher number of H atoms compared to the 1:1 adducts. Thus, although the total energy of the isolated *cis* isomer is 1.543 eV higher than that of the *trans*, when all factors are considered, it is highly possible that the *cis* arrangement becomes sufficiently stable in the solid phase to co-exist with the *trans* isomer or even become the favoured form. This is essentially the point Aggarwal and Onyszchuk (13) made in explaining their ir spectra.

The *trans* form of the 1:2 adduct is different. Because of its axial symmetry both ends of the ellipsoid are positively charged and only at the mid-section is a ring of negative charges composed of four F atoms. Despite its large charge transfer, 0.196 per NH_3, and high internal polarity, its overall exterior charge arrangements are not conducive with the additional stabilization mentioned above.

Is $SiF_4.2NH_3$ *trans* or *cis*? The answer seems to depend on the physical state of the complex. In the solid phase it is conceivably in the *cis* form. On the contrary, the *trans* arrangement should be favoured whenever the added stabilization from condensation is not in effect. This includes the gaseous and solution phases and when the complex is dispersed into solid matrices. This may explain the conflicting experimental observations on the 1:2 adducts. Since all bonds around the Si atom are single bonds, transformation between *cis* and *trans* isomers may not involve a very high barrier.

We rule out the size of the ligands as the deciding factor but its electronegativity may play a crucial part. We are presently looking into these questions.

(C) Si—N bonding

Being molecular complexes, the mode whereby the component molecules are linked together is of utmost interest. Bond angles are used above as a circumstantial evidence to assert that the Si—N bond is not a full-fledged covalent bond. It is also shown that the net electrostatic interaction is to hold the complexes together. In general, the more severe the distortion from the tetrahedral shape of SiF_4, the larger the magnitude of the net attraction is. While the ionicity of the complexes increases from 1:1 adducts to 1:2 adducts, the Si—N bond still has some covalent character. For example, a-$SiF_4.NH_3$ has a bond energy of 0.433 eV but its net electrostatic effect is only -0.25 eV. Obviously there must be covalency in the Si—N bond to account for the bond energy.[3]

The bond order is an approximate gauge of the covalency of a bond. It ranges from the value of ± 1.0 for purely covalent bond to 0.0 for a purely ionic bond. In the 1:1 complexes the Si—N bond has the highest bond order of 0.22 in the axial, followed by 0.15 in the equatorial, and -0.03 in the square pyramidal. The small charge transfer in the axial and the equatorial and their moderately low bond orders can be taken to indicate that the bonding between the ammonia and SiF_4 molecules is mainly electrostatic, involving the lone pair of ammonia. While some measure of covalency is established in the bond its bond order is low, even in comparison with a highly polar bond such as CO. Hence it seems safe to say that no fundamental change has been inflicted onto the lone pair of the ammonia molecule, despite the complex formation. For the square pyramidal the lone pair is even less affected and the bonding is exclusively electrostatic.

The *trans* isomer of the 1:2 adduct has a bond order of 0.12 and the *cis* is moderately antibonding at -0.15. Other than one being bonding and the other being antibonding, the nature of the Si—N bond in these two complexes should be quite similar to that of a- and e-$SiF_4.NH_3$.

[3]In fact the bond Si—N accounts for more than just the difference 0.183 eV (+0.433 − 0.25) since the value 0.433 eV is in reference to the neutral $SiF_4 + NH_3$ while -0.25 eV is in reference to $(SiF_4)^{-q} + (NH_3)^{+q}$, with $q = 0.084$.

Crystal structure of diethylammonium tetrachloro(*p*-phenoxyphenyl)tellurate

RAJ K. CHADHA, JOHN E. DRAKE, and MASOOD A. KHAN
Chemistry Department, University of Windsor, Windsor, Ont. Canada N9B 3P4

Received May 18, 1983

RAJ K. CHADHA, JOHN E. DRAKE, and MASOOD A. KHAN. Can. J. Chem. **62**, 32 (1984).

The crystal structure of diethylammonium tetrachloro(*p*-phenoxyphenyl)tellurate has been determined by the heavy atom method. The crystals are monoclinic, space group $C2/c$, with unit cell dimensions $a = 19.675(5)$, $b = 7.634(3)$, $c = 28.716(6)$ Å, $\beta = 105.58(2)°$, and $Z = 8$. For 2636 "observed" reflections ($I > 3\ \sigma(I)$), $R = 0.030$. The primary geometry about tellurium is based on a square pyramid with a secondary interaction on the vacant side of the tellurium coordination octahedron. The ions are apparently linked by weak interionic hydrogen bonding along the crystallographic *b* axis.

RAJ K. CHADHA, JOHN E. DRAKE et MASOOD A. KHAN. Can. J. Chem. **62**, 32 (1984).

On a déterminé la structure du cristal de tétrachloro(*p*-phénoxyphényl)tellurate de diéthylammonium par la méthode de l'atome lourd. Les cristaux appartiennent au groupe d'espace monoclinique $C2/c$ avec $a = 19,675(5)$, $b = 7,634(3)$, $c = 28,716(6)$ Å, $\beta = 105,58(2)°$ et $Z = 8$ pour 2636 réflexions observées avec ($I > 3\sigma(I)$) et $R = 0,030$. La géométrie primaire autour du tellure est une pyramide carrée avec une interaction secondaire du côté libre de la coordination octaédrique du tellure. Les ions sont apparemment liés par une faible liaison hydrogène interconique le long de l'axe cristallographique *b*.

[Traduit par le journal]

Introduction

The preparation and spectroscopic properties of a series of dialkylammonium tetrachloroaryltellurates have been reported by Miller and Chadha (1). It was suggested on the basis of vibrational spectroscopy and on ^1H nmr data recorded at various temperatures and dilutions that weak hydrogen bonding existed between the hydrogen atoms of the cations and chlorine atoms of the anions. To establish the nature of interionic interactions in the solid state, we present the crystal structure of diethylammonium tetrachloro(*p*-phenoxyphenyl)tellurate. A further reason for this study is the general lack of detailed structural investigations of penta-coordinated ionic salts of tellurium. Studies of these are of particular interest in terms of the question of the importance of a stereochemically active lone pair and of secondary tellurium–halogen interactions.

Experimental section

The compound was prepared by the method already described (1). Two recrystallisations of the crude product from CH_2Cl_2 afforded plate like colourless crystals of the title compound. The density was measured by the flotation method in CCl_4/CH_3I.

A crystal with approximate dimensions (0.06 × 0.1 × 0.2 mm) was mounted along the largest dimension, subsequently shown to be the *b* axis, and data were collected on a Syntex $P2_1$ diffractometer following the procedure described previously (2). The intensities of three monitor reflections did not change significantly during data collection. The systematic absences (hkl, $h + k = 2n + 1$; $h0l$, $l = 2n + 1$), are consistent with $C2/c$ and Cc space groups. The former was used and later assumed correct because of successful refinement of the structure. The data were corrected for Lorentz and polarisation effects and the analytical absorption correction was applied. Details of the X-ray data are given in Table 1.

The position of the tellurium atom was obtained from a sharpened Patterson synthesis and the positions of the remaining non-hydrogen atoms were determined from a difference Fourier map. The structure was refined anisotropically by the full-matrix least-squares methods. The refinement converged to $R = (\Sigma||F_o| - |F_c||/\Sigma|F_o|) = 0.040$. A difference map at this stage showed peaks at plausible hydrogen positions. Hydrogen atoms were included in subsequent refinement in ideal positions (C—H = N—H = 0.95 Å, ∠CCH = 120.0°, and ∠CNH = 109.5°) with isotropic values assigned 0.01 greater than the atoms they are attached to. Hydrogen atoms attached to the carbon atoms of the cation, $Et_2NH_2^+$, were not included in calculations because the cation was disordered, as reflected by high thermal parameters for the carbon atoms. Fixing the C—C bond length did not yield better refinement. Finally, it was decided to refine all the atoms anisotropically in order to allow the model which is closest to the real structure. Fortunately, the nitrogen atom is not disordered; therefore, this problem has little or no effect on the anion, which is the main theme of this work. Refinement gave final values of $R = 0.030$ and $R_{WF} = [\Sigma\omega\Delta^2/\Sigma\omega F_o^2]^{1/2} = 0.033$. In the final two cycles of refinement the largest shift/error ratio was 0.05, and the final difference map had no feature of chemical significance with the largest peak 0.5 e Å^{-3}. The function $(|F_o| - |F_c|)^2$ was minimized during least-squares refinement. Unit weights were used in the initial stages and in the final cycles, a weighting scheme of the form $\omega = 1/[\sigma^2(F) + \rho F^2]$ was employed with a final ρ value of 0.002. A few low-angle reflections were found to be affected by secondary extinction. An empirical

*U_{eq} for the non-hydrogen atoms is calculated from the refined anisotropic thermal parameters (deposited) ($U_{eq} = (1/3)\sum_{i=1}^{3}(\text{RMSD})_i^2$, RMSD values are taken from ORTEP output).

isotropic extinction parameter, x, was used employing the equation $F_c = F[1 - 0.0001x(F^2/\sin\theta)]$ and refined to a value of 0.00040.

Scattering factors for all non-hydrogen atoms, including the anomalous dispersion correction for Te and Cl were obtained from Ibers and Hamilton (3) and for hydrogen atoms from Stewart *et al.* (4). Programs used include SHELX, XANADU, ORTEP, and ABSORB (5).

The final atomic coordinates for non-hydrogen atoms are given in Table 2 and important distances and angles in Table 3.[1]

Results and discussion

The tellurium atom in the $[p\text{-PhOPhTeCl}_4]^-$ anion has an approximate square pyramidal coordination with the organic group in the apical position (Fig. 1). The square plane is slightly distorted with the chlorine atoms alternatively above and below their mean plane by 0.030(2) Å and with the tellurium atom positioned above the plane by 0.040(1) Å. The structure of the anion is similar to the $[MeTeI_4]^-$ anion in the compound β-Me_2TeI_2 (6) and the structural unit, $CTeCl_4$, of organotellurium trichlorides (7–9). It is generally assumed that these arrangements reflect a tendency for the tellurium atom to adopt octahedral geometry with the non-bonding electron-pair occupying the sixth position.

However, this sixth position also provides the site for a secondary-bonding interaction between the tellurium atom and a chlorine atom, Cl(3′), $(1/2 - x, 1/2 - y, -z)$ on an adjacent molecule at a distance of 3.619 Å. Such a distance is typical of Cl---Te secondary bonds and is significantly shorter than the sum of the van der Waals radii (4.0 Å)(5). The bond angle C(11)—Te---Cl(3′) is 162.2(2)° rather than the 180° that might be expected if in fact the tellurium lone-pair was stereochemically totally inactive. The two anions joined together by these secondary interactions constitute centrosymmetric dimers in which the $RTeCl_4$ units are associated base to base (Fig. 2).

Other examples in which secondary interactions have been noted on the vacant site of the coordination octahedron are $SeOCl_2.2Py$ (10), $C_9H_8NO^+SeOCl_3^-$ (11) and most notably in β-Me_2TeI_2 (6). In the latter case, which has been shown to be correctly formulated as $[Me_3Te]^+[MeTeI_4]^-$, the $[MeTeI_4]^-$ anions can also be described as made up of centrosymmetric dimers and the C—Te---I angle of 166° is very close to the value of the C—Te---Cl angle in $[p\text{-PhOPhTeCl}_4]^-$. For $[MeTeI_4]^-$ it was argued that the secondary interaction probably involved donation from the lone-pair on tellurium into vacant *d*-orbitals on iodine. However, such bonding seems improbable for chlorine atoms and the similarity in the structures suggests that in both cases the donation is more probably from halogen lone-pairs towards the more electro-positive tel-

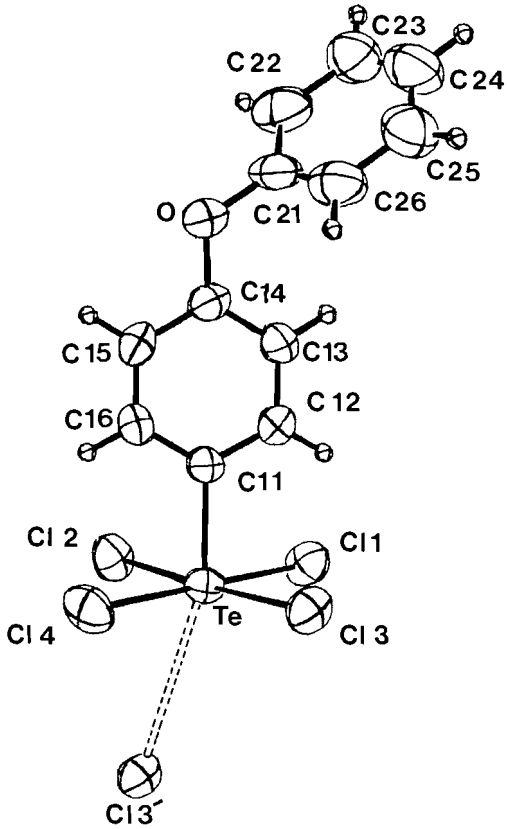

FIG. 1. ORTEP plot of the anion $[p\text{-}C_6H_5OC_6H_4TeCl_4]^-$. The non-hydrogen atoms are drawn with 50% probability ellipsoids. Hydrogen atoms are drawn arbitrarily small.

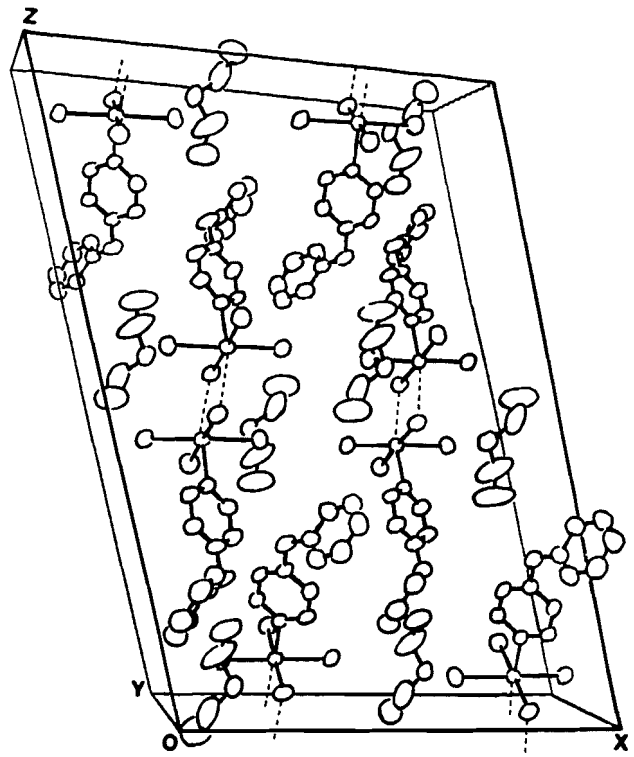

FIG. 2. Unit cell packing of $[(C_2H_5)_2NH_2]^+[p\text{-}C_6H_5OC_6H_4TeCl_4]^-$. Hydrogen atoms are omitted for clarity.

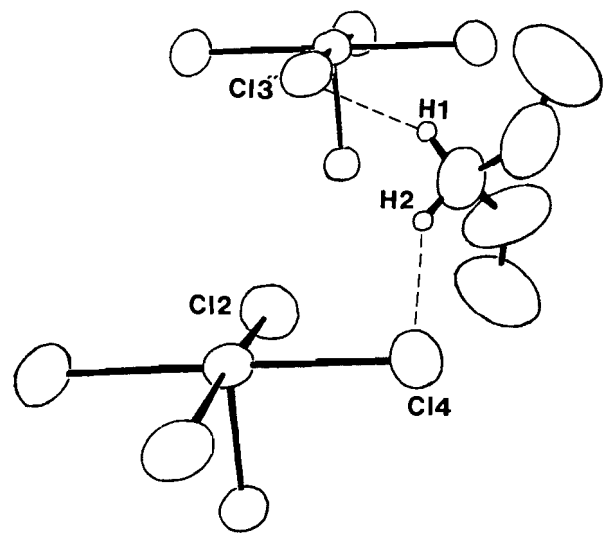

FIG. 3. Interionic hydrogen bonding parallel to the *y* axis.

lurium atom. With the chlorine atom essentially occupying the sixth coordination site, the stereochemical activity of the tellurium lone-pair, which is inactive in $[TeCl_6]^{2-}$ (12), is called into question. In both $[MeTeI_4]^-$ and $[p\text{-}PhOPhTeCl_4]^-$, there is a similar deviation from 180° so it is hard to believe the distortion arises from packing effects of the bulky *p*-PhOPh group or the counter-ion. The Te—Cl---Te′ angle is 78.5(3)°, rather than 90°, which results in the Cl(3) and Cl(3′) atoms in the bridge being moved further apart and the tellurium atoms closer together. On a model assuming stereochemically active lone-pairs on tellurium, any distortion would surely be expected to place the Te atoms further apart rather than closer together. The Te---Te′ distance of 4.007 Å is similar to that found in $TeCl_4$ which also has a distorted octahedral environment in the solid state (13).

In addition to the Te---Cl secondary interactions, the packing suggests that there are also some weak interionic hydrogen-bond interactions as had been suggested in studies on solutions (1). The closest H---Cl (2.368 Å) contact (Fig. 3) occurs between the H(1) atom of the cation $Et_2NH_2^+$ and Cl(3″) (x, $1 + y$, z) of the anion. Crystal growth is apparently most rapid along the crystallographic *y* axis as the longest dimension of the crystal is parallel to the *b* axis.

The Te—Cl primary bond lengths have significant differences and can be related to the involvement of the chlorine atoms in the interionic interactions. The longest bond (2.589 (1) Å) is formed by Cl(3), the chlorine atom involved in the secondary interaction with the tellurium atom of the adjacent molecule as well as in a weak hydrogen bond. The bond Te—Cl(4) is 2.558(1) Å. The atoms Cl(1) and Cl(2) are not involved in any significant secondary interactions, and the bond lengths Te—Cl(1) (2.482(1) Å) and Te—Cl(2) (2.451(1) Å) are shorter. The average Te—Cl bond of 2.52(1) Å is comparable to the Te—Cl bond length of 2.54 Å in $TeCl_6^{2-}$ (12), which adopts regular octahedral geometry.

L'électrodissolution du cuivre dans les solutions bromurées

ROBERT-LOUIS BROSSARD
Institut de recherche d'Hydro-Québec, C.P. 1000, 1800 Montée Ste-Julie, Varennes (Qué.), Canada J0L 2P0

Reçu le 24 mai 1983

ROBERT-LOUIS BROSSARD. Can. J. Chem. **62**, 36 (1984).

La dissolution de l'anode de cuivre a été étudiée en solution aqueuse de pH égal à 4 dont la concentration en NaBr dissous varie de 0,1 *M* à 1,2 *M*. Dans la zone où l'accumulation du produit de corrosion sur le cuivre est inexistante ou marginale, le courant de dissolution est décomposable en un phénomène de surface, d'une part, et en un phénomène de diffusion des ions dans la solution, d'autre part. Le courant associé à chacune de ces étapes lentes a été déterminé à partir des relations linéraire i^{-1} vs. $\omega^{-1/2}$.

Par ailleurs, les principales caractéristiques du comportement de l'anode de cuivre sont en termes de dérivées partielles: $(\partial E/\partial \log_{10} i)_{25°C,\ Br^-} \simeq 60$ mV/décade, $(\partial i_d/\partial\omega^{1/2})_{E,\ Br^-}$ = constante, $(\partial E/\partial \log_{10} (i_d\cdot\omega^{-1/2}))_{25°C,\ Br^-} \simeq 59$ mV/décade alors que l'ordre de la réaction par rapport aux ions bromures est égal à 2. De plus, la relation E vs. $\log_{10} i_\infty$ est assimilable à une droite, ce qui est la conséquence d'un phénomène de surface limité par un transfert électronique. Un modèle de dissolution est présenté à partir duquel on retrouve les principales caractéristiques de la dissolution du cuivre. Selon ce modèle, le terme i_d est entièrement attribuable à la diffusion d'un bromocomplexe de cuivre, le $CuBr_2^-$, depuis la surface de l'électrode jusqu'au sein de la solution. Pour sa part, le calcul de l'énergie d'activation apparente en considérant le modèle proposé est de 7 kcal/mol alors que la valeur expérimentale est de 6,5 kcal/mol.

Enfin, la vague d'oxydation observée lorsque la tension d'électrode devient suffisamment anodique par rapport à la tension réversible de la réaction Cu + Br^- = CuBr + e, est associée à la passivation du cuivre par le CuBr γ.

ROBERT-LOUIS BROSSARD. Can. J. Chem. **62**, 36 (1984).

The dissolution of a copper anode has been studied in aqueous solutions, at pH 4, for a range of concentrations varying from 0.1 *M* to 1.2 *M* in NaBr. Where the accumulation of the corrosion product on the copper was nonexistent or negligible, two phenomena account for the dissolution current: a surface phenomenon and a phenomenon of diffusion of the ions into the solution. The current associated with each of these slow steps has been determined from the linear relationship i^{-1} vs. $\omega^{-1/2}$.

The main characteristics of the copper anode behavior are expressed as partial derivatives: $(\partial E/\partial \log_{10} i)_{25°C,\ Br^-} \simeq 60$ mV/decade, $(\partial i_d/\partial\omega^{1/2})_{E,\ Br^-}$ = constant, $(\partial E/\partial \log_{10} (i_d\cdot\omega^{-1/2}))_{25°C,\ Br^-} \simeq 59$ mV/decade, while the reaction order for the bromide ions is equal to 2. Furthermore, the linearity of the relationship E vs. $\log_{10} i$ arises as a direct consequence of a surface phenomenon limited by an electron transfer. A dissolution model that describes the main characteristics of the copper dissolution is presented. According to this model, the term i_d is entirely ascribable to the diffusion of a copper bromide complex, $CuBr_2^-$, from the surface of the electrode into the solution. The apparent activation energy calculation is 7 kcal/mol according to the model, while the experimental value is 6.5 kcal/mol.

Finally, the observed oxidation wave when the electrode potential becomes sufficiently anodic compared to the reversible potential of the reaction Cu + Br^- = CuBr + e, is associated with the passivation of the copper by γ-CuBr.

[Journal translation]

Introduction

Un nombre relativement restreint de chercheurs se sont penchés sur l'étude de la dissolution du cuivre en présence des ions Br^- (1 à 6). Il a été établi que la valence de dissolution du cuivre est de +1 dans le domaine de dissolution active (1) alors que le cuivre a tendance à se recouvrir de CuBr lorsque la tension devient suffisamment anodique (2 à 4).

Le présent travail se propose d'élucider le procédé d'électrode durant la dissolution active du cuivre en solution aqueuse légèrement acide dont la concentration en Br^- est comprise entre 0,1 et 1,2 *M*.

Partie expérimentale

2.1 *La cellule et ses accessoires*

Les détails relatifs à la cellule et ses accessoires ainsi qu'aux électrodes de travail sont donnés dans un article précédent (7). L'électrode de cuive se présente sous la forme d'un fil de 0,64 cm de diamètre, d'une plaque de 1 cm × 2 cm ou d'un disque de 0,5 cm de diamètre, les surfaces de l'échantillon sont respectivement de 0,4 cm^2, 2 cm^2 et 0,196 cm^2.

2.2 *La préparation des essais*

Un barbottage d'azote de 6 h précède l'immersion de l'électrode de cuivre dans la solution. Les solutions contiennent entre 0,1 et 1,2 *M* de NaBr dissous. Un tampon à base de phtalate de potassium est utilisé pour stabiliser le pH à 4.

La méthode employée par Shoesmith et Lee (8, 9) a été retenue pour le polissage du cuivre: l'échantillon est d'abord poli mécaniquement par abrasion avec du papier au carbure de silicium, le polissage se termine avec de l'alumine de 1 μ. L'échantillon est alors rinçé à l'alcool, à l'acétone puis à l'eau distillée avant son immersion.

2.3 *Les techniques expérimentales utilisées*

Les courbes tension−courant ont été obtenues en balayage linéaire de la tension. L'électrode à disque tournant a été utilisée en imposant une tension d'électrode constante alors que la vitesse de rotation (ω) varie de 25,12 rad s^{-1} jusqu'à 628,3 rad s^{-1}. On obtient ainsi le courant en fonction ω. Le disque de cuivre est poli à chaque changement de tension. Un bain thermostatique a servi au contrôle de la température qui est comprise entre 22°C et 80°C.

Enfin, les valeurs de la tension sont données par rapport à l'électrode au calomel saturée.

Résultats expérimentaux

3.1 *Apparition du produit de corrosion*

L'enregistrement obtenu en balayage linéaire de la tension, reproduit à la fig. 1, et qui correspond à une vitesse de balayage en tension de 5 mV s^{-1}, est représentatif du comportement de l'anode de cuivre. La courbe montre une vague d'oxydation bien définie dont le maximum a comme coordonnées 20 mA cm^{-2} (i_{pl}) et −92 ± 4 mV_{ecs} (E_{pl}). D'après les travaux réalisés dans les solutions bromurées acides (1), la valence de dissolution du cuivre est égale à 1.

Par ailleurs, la relation E vs. $\log_{10} i$ est linéaire dans la partie

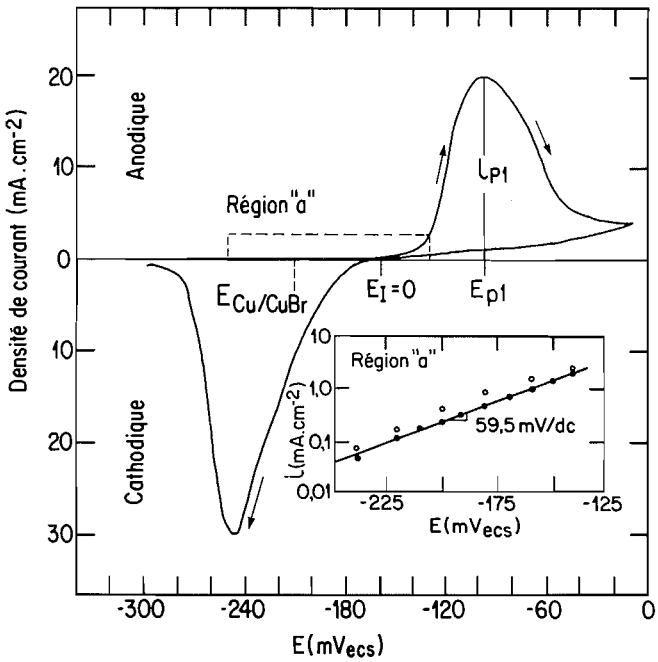

FIG. 1. Courbe de polarisation en balayage linéaire de la tension sur un fil de cuivre. Balayage à 5 mV s^{-1}. NaBr: 0,5 *M*. $E_{i=0}$: tension à courant nul. L'électrode est en position stationnaire. La région "a" en médaillon correspond à la première portion de la partie ascendante de la vague d'oxydation; ● sans agitation; ○ avec un barbottage d'azote de 87 mL min^{-1}.

ascendante de la vague d'oxydation, appelée région "a", sur la fig. 1. L'examen de la surface de l'anode par le microscope à balayage a permis d'observer que le cuivre reste à nu dans cette région. L'accumulation du produit de corrosion sur l'électrode est perceptible dès que la tension imposée dépasse de 70 mV environ (Figs. 1, 2) la tension réversible ($E_{Cu/CuBr}$) de la réaction:

[1] $Cu + Br^- = CuBr + e$

qui est donnée par (10, 11)

[2] $E_{Cu/CuBr} = -0{,}239 - 0{,}059 \log_{10} (Br^-)$

où $E_{Cu/CuBr}$ est en volt par rapport à l'électrode au calomel saturé. Pour sa part, E_{pl} dépasse de 115 mV environ $E_{Cu/CuBr}$.

Dans le cas illustré à la fig. 2, le produit de corrosion est présent d'une façon très discrète sur la surface pour des tensions de −170 mV et −140 mV; l'échantillon est alors dans la région "a" (Fig. 1). La présence du produit de corrosion est de plus en plus importante en dehors de la région "a" quand la tension augmente (−110 mV, −80 mV et 0 mV). On remarque que la surface n'est pas uniformément recouverte par le produit de corrosion alors que la vague d'oxydation est compatible avec la passivation de la surface par le produit de corrosion i.e. −80 mV et 0 mV. Pour sa part, la relation *E* vs. $\log_{10} i$ cesse d'être linéaire lorsque le produit de corrosion est présent sur le cuivre. Ce changement au niveau de la relation *E* vs. $\log_{10} i$ laisse croire à un changement au niveau du mécanisme de dissolution.

La diffraction aux rayons X a permis l'identification du produit de corrosion. Il est constitué d'un seul composé qui est le bromure cuivreux gamma (CuBr γ).

Enfin, la vague cathodique (Fig. 1) correspond à la réduction du CuBr γ.

3.2 *Comportement du cuivre dans la zone de dissolution active (région "a" (Fig. 1))*

L'anode de cuivre, polarisée à des tensions pour lesquelles le produit de corrosion est totalement absent ou présent d'une façon très discrète sur la surface de l'électrode, a les particularités suivantes:

(a) la relation *E* vs. $\log_{10} i$ est linéaire avec une pente voisine de 60 mV/décade (Fig. 3)

$$\left(\frac{\partial E}{\partial \log_{10} i}\right)_{25°C,\ Br^-} = 60 \text{ mV/décade};$$

(b) il y a élévation du courant de dissolution lorsque la vitesse de rotation de l'électrode (ω) augmente (Fig. 4); cependant que la pente ($\partial i/\partial \omega^{1/2}$) diminue avec ω croissant;

(c) l'ordre de la réaction par rapport aux ions Br^- est voisin de 2 (Fig. 5);

(d) la valence de dissolution est égale à 1;

(e) une augmentation de la température se traduit par une élévation significative du courant de dissolution (Fig. 6).

Discussion

4.1 *Analyse des courbes* i *vs.* $\omega^{1/2}$

L'allure des courbes *i* vs. $\omega^{1/2}$ est caractéristique d'un procédé d'électrode mixte (12), c'est-à-dire que le courant mesuré résulte de ce procédé d'électrode qui a deux étapes lentes. Ces étapes lentes sont la diffusion des ions dans la solution, d'une part, et un phénomène de surface comme le transfert électronique, d'autre part. Dans le cas où ces deux étapes lentes sont en série, le courant global est décomposable en deux courants selon (10):

[3] $i^{-1} = i_\infty^{-1} + i_d^{-1}$

où *i* est le courant global, i_∞ est le courant de dissolution indépendant de la vitesse de rotation de l'électrode alors que i_d est le courant attribué à la diffusion. D'après Levich (13), l'expression qui lie le courant de diffusion à la vitesse de rotation de l'électrode est

[4] $i_d = B\omega^{1/2}$

où *B* est une constante et ω est la vitesse de rotation de l'électrode en rad s^{-1}. Les relations [3] et [4] donnent:

[5] $i^{-1} = i_\infty^{-1} + B^{-1}\,\omega^{-1/2}$

Ainsi, i^{-1} exprimé en fonction de $\omega^{-1/2}$ doit donner une droite dont les valeurs de i_∞^{-1} et de B^{-1} sont déterminables à partir de la pente et de l'ordonnée à l'origine (Fig. 7) (9, 12). L'inverse de la pente $\partial(i^{-1})/\partial(\omega^{-1/2})$ correspond à *B*, c'est-à-dire au produit $i_d \cdot \omega^{-1/2}$ alors que i_∞^{-1} est obtenu par extrapolation de la droite jusqu'à $\omega^{-1/2}$ égal à zéro. Dans l'exemple reproduit à la figure 7, *B* est égal à 0,14 mA cm^{-2} $rad^{-1/2}$ $s^{1/2}$ alors que i_∞ est de 1,7 mA cm^{-2}. Les valeurs de *B*, i.e. de $i_d \cdot \omega^{-1/2}$, ont été déterminées pour différentes valeurs de la tension imposée dans 0,5 *M* NaBr (Fig. 8). La relation *E* vs. $\log_{10} (i_d \cdot \omega^{-1/2})$ est linéaire avec une pente de 60 mV/décade approximativement.

Par ailleurs, les valeurs calculées pour i_∞ sont données en fonction de la tension d'électrode à la figure 9 pour 0,5 *M* en NaBr. La relation *E* vs. $\log_{10} i_\infty$, assimilable à une droite dont la pente est de 100 ± 10 mV/décade, suggère que le phénomène de surface est contrôlé par un transfert électronique.

4.2 *Mécanisme de dissolution*

L'augmentation du courant de dissolution avec la vitesse de

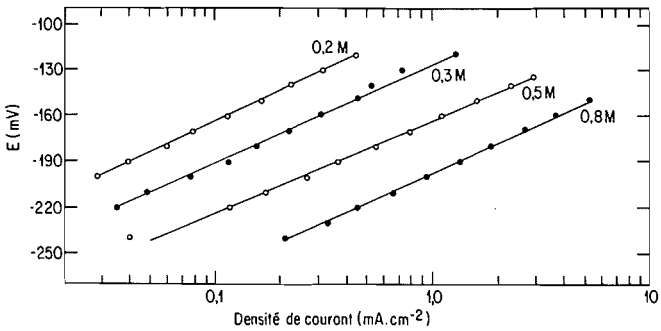

FIG. 3. Tension d'électrode en fonction du courant de dissolution anodique pour différentes concentrations en Br^-. Balayage à 5 mV s^{-1} sur un fil de cuivre en position stationnaire et en solution non agitée.

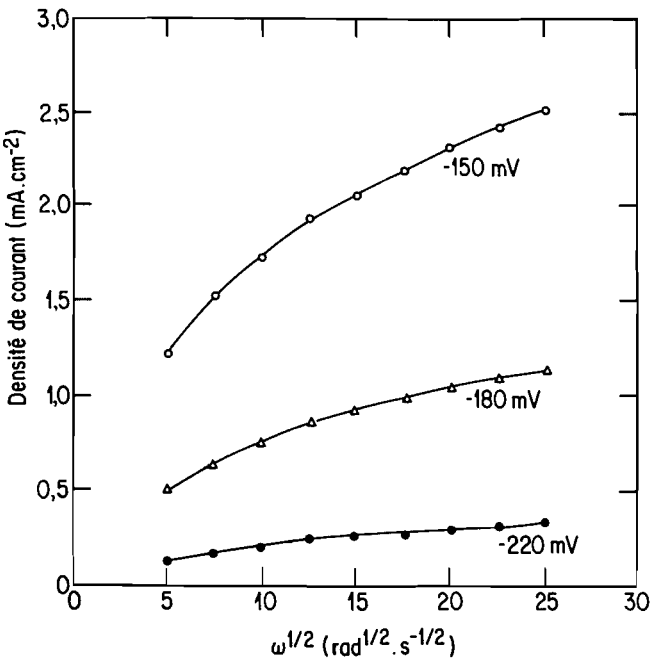

FIG. 4. Courant de dissolution anodique en fonction de $\omega^{1/2}$ à différentes valeurs de la tension imposée. NaBr: 0,5 *M*. La dissolution du cuivre est active.

rotation de l'électrode (Fig. 4), la linéarité de la relation i^{-1} vs. $\omega^{-1/2}$ (Fig. 7) et, enfin, le fait que la relation E vs. $\log_{10} i_\infty$ soit assimilable à une droite (Fig. 8) suggère que la réaction est contrôlée par deux étapes en série. La première est attribuable au transfert électronique à l'interface électrode–électrolyte, l'autre à la diffusion d'une espèce ionique en solution. Par ailleurs, l'espèce la plus stable pour le cuivre dissous est le $CuBr_2^-$ (14) dans la gamme de concentration en Br^- considérée. Ainsi, lorsque la dissolution du cuivre sous forme de $CuBr_2^-$ est envisagée, les étapes les plus probables sont:

[6] $\quad Cu + 2Br^- \rightarrow (CuBr_2^-)_i + e$

qui est suivie de

[7] $\quad (CuBr_2^-)_i \rightarrow (CuBr_2^-)_s$

où les indices i et s représentent la concentration à la surface de l'électrode et au sein de la solution. La première réaction, qui est une étape globale, correspond à l'oxydation du cuivre en $CuBr_2^-$; elle peut être décomposée en deux étapes dont l'une

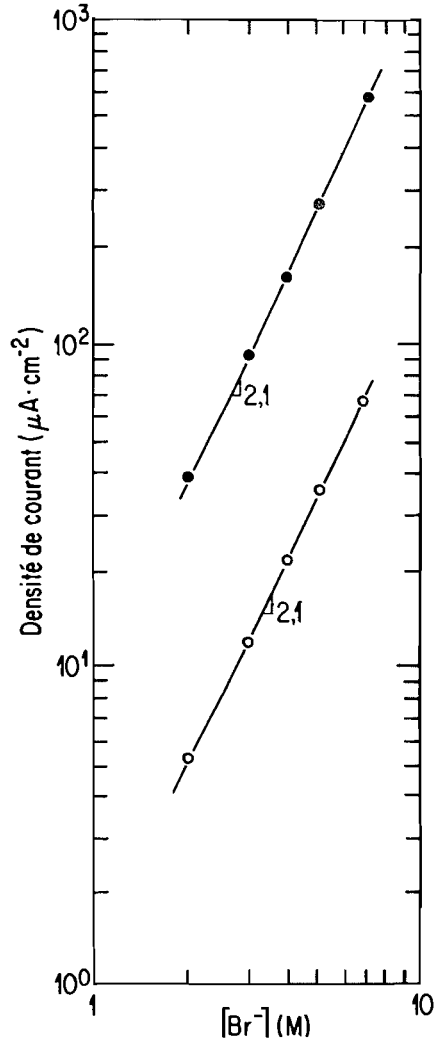

FIG. 5. Influence de la concentration en ions Br^- sur le courant de dissolution anodique. Balayage à 5 mV s^{-1} sur un fil de cuivre en position stationnaire et en solution non agitée; ● pour $E = -150$ mV; ○ pour $E = -200$ mV.

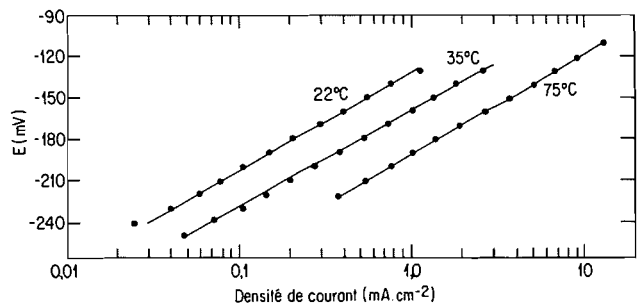

FIG. 6. Influence de la température sur le courant de dissolution. Balayage à 5 mV s^{-1}. NaBr = 0,4 *M*. L'échantillon est un fil de cuivre en position stationnaire et en solution non agitée.

d'entre elles correspond au transfert électronique. La deuxième étape coincide avec la diffusion du $CuBr_2^-$ depuis la surface de l'anode jusqu'au coeur de la solution.

4.2.1 *Cas des vitesses de rotation lente*

Pour sa part, la relation entre le courant qui traverse l'électrode et la vitesse de rotation de l'électrode (relation [5])

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

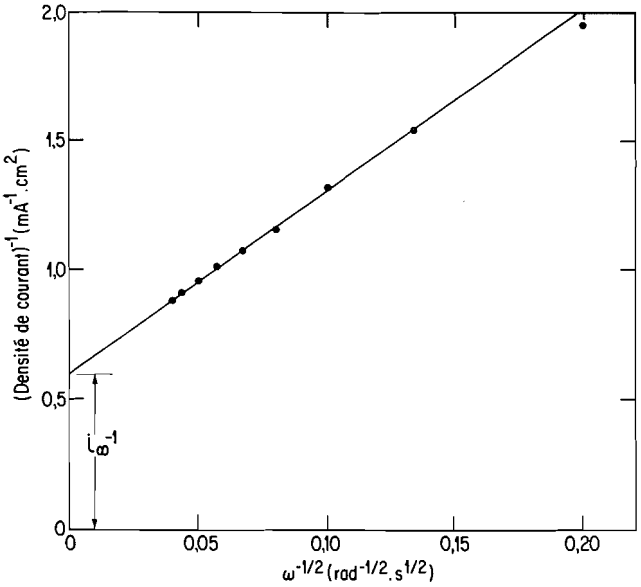

FIG. 7. Inverse du courant de dissolution anodique en fonction de $\omega^{-1/2}$ avec $E = -180$ mV et NaBr 0,5 M. i_∞ est le courant à vitesse de rotation infinie.

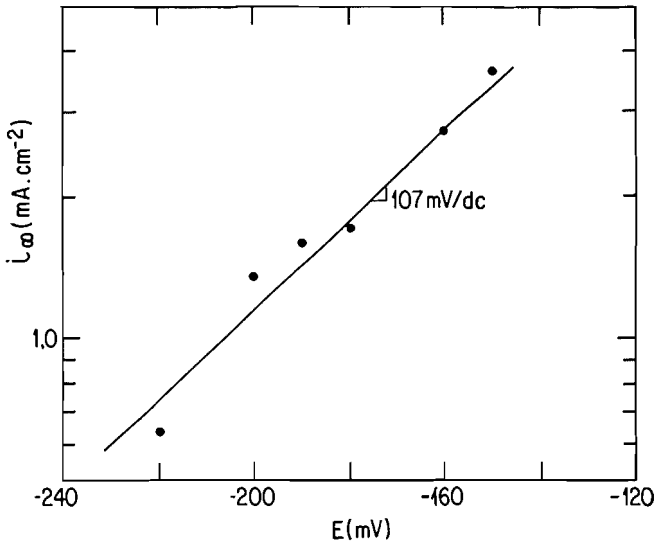

FIG. 9. Courant à vitesse de rotation infinie en fonction de la tension imposée pour NaBr égal à 0,5 M.

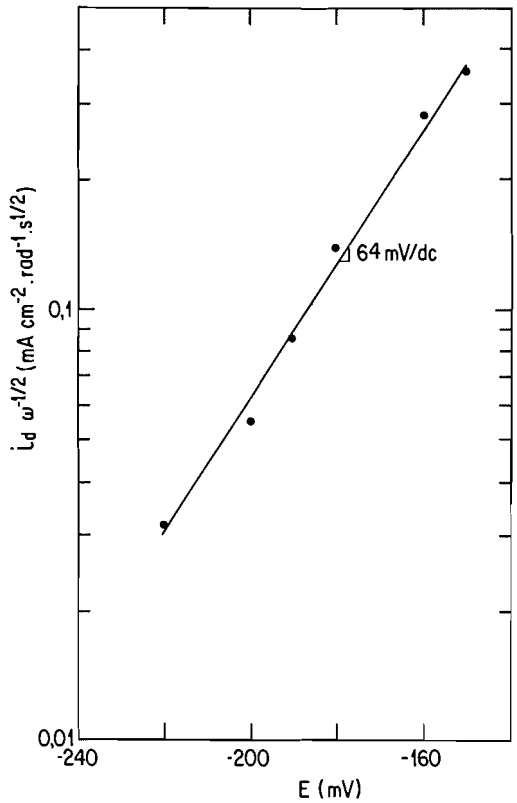

FIG. 8. $i_d \cdot \omega^{-1/2}$ en fonction de la tension imposée pour NaBr égal à 0,5 M.

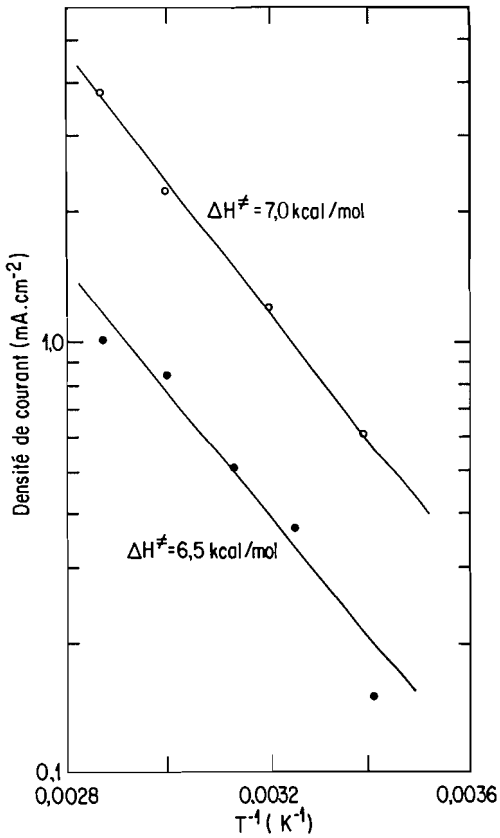

FIG. 10. Densité de courant anodique en fonction de l'inverse de la température; ● valeurs expérimentales du courant déduites des courbes E vs. $\log_{10} i$, représentées à la fig. 6, et qui correspondent à $E = -190$ mV; ○ valeurs relatives du courant calculées à partir de la relation [20].

indique que le terme $B^{-1}\omega^{-1/2}$ tend à devenir le terme dominant en présence d'une agitation peu intense, donc, le courant est contrôlé par la diffusion, c'est-à-dire que $i \sim i_d$ lorsque ω est petit. Dans ces conditions, il est raisonnable de considérer la réaction [6] comme l'étape rapide, et la réaction [7] comme l'étape déterminante. L'étape [6] est alors dans un état voisin de l'équilibre; ce qui autorise à utiliser l'équation de Nernst:

$$[8] \quad E = E^0_{Cu/CuBr_2^-} + \frac{RT}{F} \ln \frac{[CuBr_2^-]_i}{[Br^-]^2}$$

Le réarrangement des termes donne:

$$[9] \quad [CuBr_2^-]_i = [Br^-]^2 \exp \frac{F}{RT}(E - E^0_{Cu/CuBr_2^-})$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

Rappelons que l'étape lente est une étape de diffusion. Par conséquent, la vitesse de la réaction est donnée par la première loi de Fick:

$$[10] \quad i_d = \frac{ZFD}{\delta}[CuBr_2^-]_i$$

La combinaison des relations [8], [9] et [10] donne:

$$[11] \quad i_d = \frac{ZFD}{\delta}[Br^-]^2 \exp\frac{F}{RT}(E - E^0_{Cu/CuBr_2^-})$$

Pour un fil de cuivre en l'absence d'agitation imposée, l'écriture de la relation [11] se simplifie:

$$[12] \quad i_d = k_l[Br^-]^2 \exp\left(\frac{F}{RT}\right)(E - E^0_{Cu/CuBr_2^-})$$

où k_l est une constante de proportionnalité. L'utilisation de l'électrode à disque tournant permet d'écrire (13) selon Levich:

$$[13] \quad \delta = 1{,}63\, D^{1/3}_{CuBr_2^-}\, \nu^{1/6}\, \omega^{-1/2}$$

La substitution de δ dans la relation [11] donne:

$$[14] \quad i_d = 0{,}62\, ZF\, \nu^{-1/6}\, D^{2/3}_{CuBr_2^-}\, \omega^{1/2}\, [Br^-]^2 \exp\frac{F}{RT} \times (E - E^0_{Cu/CuBr_2^-})$$

où Z, la charge de l'espèce qui diffuse, est égale à 1; ν, la viscosité cinématique, est voisine de $0{,}96 \times 10^{-2}$ cm^2 s^{-1} (15); $D_{CuBr_2^-}$ est le coefficient de diffusion de l'espèce $CuBr_2^-$; ω est la vitesse de rotation de l'électrode en radians par seconde; E est la tension d'électrode alors que $E^0_{Cu/CuBr_2^-}$ est la tension d'équilibre standard pour la réaction [1].

Les dérivées partielles de la relation [12] sont:

$$[15] \quad \left(\frac{\partial E}{\partial \log_{10} i_d}\right)_{295\text{ K},\ Br^-} \simeq 59 \text{ mV/décade}$$

$$[16] \quad \frac{\partial i_d}{\partial [Br^-]_E} = 2$$

alors que les dérivées partielles de la relation [14] sont:

$$[17] \quad \left(\frac{\partial i_d}{\partial \omega^{1/2}}\right)_{E,\ Br^-} = \text{constante}$$

$$[18] \quad \left(\frac{\partial E}{\partial \log_{10}(i_d \cdot \omega^{-1/2})}\right)_{295\text{ K},\ Br^-} \simeq 59 \text{ mV/décade}$$

Les équations [15] et [16] sont semblables aux caractéristiques (a) et (c) trouvées pour la dissolution active du cuivre (Figs. 3, 5). De plus, la relation [17] est conforme à la relation [4], qui est la relation de Levich alors que la relation [18] correspond à la caractéristique observée à la fig. 8. Ainsi, le mécanisme de dissolution formé par les étapes [6] et [7] est en harmonie avec les caractéristiques du comportement de l'anode de cuivre. La formation du $CuBr_2^-$, proposée dans ce mécanisme, tend à confirmer le fait que le cuivre dissous a une tendance marquée à être associé aux ions Br^- pour former des complexes (14).

Pour sa part, le coefficient de diffusion est calculable à partir de l'équation [19] obtenue par transformation de la relation [14]:

$$[19] \quad D^{2/3}_{CuBr_2^-} = \frac{7{,}702 \times 10^{-6} \times (i_d \cdot \omega^{-1/2})}{[Br^-]^2 \exp[(38{,}92)(E - E^0_{Cu/CuBr_2^-})]}$$

Les termes Z, F, ν et F/RT ont été remplacés par leur valeur respective. $E^0_{Cu/CuBr_2^-}$ égal à -54 mV$_{ecs}$ a été calculée à partir des valeurs des enthalpies libres de formation standard pour les ions Br^- (11) alors que $-44{,}750$ cal mol^{-1} a été utilisé dans le cas du $CuBr_2^-$.[1] Il est donc suffisant de connaître $i_d \cdot \omega^{-1/2}$, pour des valeurs de Br^- et de E données (Fig. 5), pour que le coefficient de diffusion soit calculable à partir de la relation [19]. C'est ainsi que les valeurs du coefficient de diffusion, données au Tableau 1 pour 0,5 M Br^-, ont été déterminées; ces valeurs voisines de $1{,}4 \times 10^{-5}$ cm^2 s^{-1} sont indépendantes de la tension imposée. Elles sont tout à fait en accord avec celles de la littérature (réf. 15, p. 80 et réf. 16).

TABLEAU 1. Valeurs expérimentales du coefficient de diffusion pour 0,5 M NaBr

E (mV$_{ecs}$)	D (10^{-5} cm^2/s)[a]
−220	1,55
−200	1,11
−190	1,71
−180	1,40
−160	1,74
−150	1,39

[a]Déterminée à partir de la relation [19] et des valeurs données à la fig. 8.

Par ailleurs, l'appauvrissement de la solution en ions Br^- à la surface de l'électrode, $[Br^-]_i$, est envisageable d'après la réaction [6] lorsque le courant de dissolution est suffisamment élevé. Lorsque $[Br^-]_i$ est voisin de zéro, il est prévisible qu'un courant limite (i_l) soit atteint qui dépend de la diffusion des ions Br^- depuis le coeur de la solution jusqu'à la surface de l'électrode et en conséquence, i_l doit être directement proportionnel à la concentration en ions $[Br^-]$ dans la solution. Comme le montre l'enregistrement reproduit à la figure 1, un courant limite (i_{pl}) est effectivement observé, mais en dehors de la zone de dissolution active, i.e. de la région "a", alors que le courant dans la région "a" ne dépasse pas 0,14 i_{pl} environ. De plus, toujours dans la région "a", l'ordre de la réaction par rapport aux ions Br^- est voisin de 2 (Fig. 5).

Il est donc raisonnable de considérer que la concentration en ions Br^- est la même à la surface de l'électrode et au coeur de la solution dans la zone de dissolution active.

C'est ainsi que le courant de diffusion est entièrement explicable à partir de la diffusion de l'espèce $CuBr_2^-$ dans la solution.

L'énergie d'activation apparente, $\Delta H^{\ddagger}$, a été déterminée à partir de la pente de la droite donnée par le courant de dissolution en fonction de T^{-1} (Fig. 10). L'électrode était en position stationnaire et la solution n'était pas agitée. Le courant a été obtenu à partir des courbes E vs. $\log_{10} i$ (Fig. 6) dans une gamme de températures comprises entre 22°C et 75°C. Les densités de courant correspondent à une tension de -190 mV. La valeur expérimentale de $\Delta H^{\ddagger}$ est de 6,5 kcal/mol.

Pour leur part, les valeurs relatives du courant de dissolution (i_r) ont été calculées en fonction de la température pour une tension de -190 mV. La relation [20], dérivée de la relation [14], a été utilisée:

$$[20] \quad \log_{10} i \propto \frac{2}{3}\log_{10} D + \frac{F}{2{,}303\, RT}(E - E^0_{Cu/CuBr_2^-}) - \frac{1}{6}\log \nu$$

[1]L. Brossard et G. Larochelle. Résultats expérimentaux non publiés.

Rappelons que $i \sim i_d$ pour une électrode en présence d'une agitation peu intense. La variation de D (17) et de ν (18) avec la température a été pris en considération pour le calcul de i_r. D a été choisi égal à $1{,}4 \times 10^{-5}$ cm^2/s à 22°C (Tableau 1). Ainsi, la valeur de $\Delta H^{\ddagger}$, déduite de la droite $\log_{10} i_r$ vs. T^{-1}, est de 7,0 kcal/mol. Cette valeur est en harmonie avec 6,5 kcal/mol déterminée expérimentalement.

4.2.2. *Cas des vitesses de rotation rapide*

Enfin, la relation [5] suggère que le phénomène de surface devient prédominant lorsque ω est grand alors que le phénomène de diffusion est marginal. Selon le modèle de dissolution envisagé, la réaction [6] devient l'étape déterminante alors que la réaction [7] devient l'étape rapide. Dans ce cas, le phénomène de surface doit être caractéristique d'un transfert électronique; ce qui est confirmé expérimentalement (Fig. 8). En s'inspirant des travaux de Moreau (19) relatifs à la dissolution du cuivre dans les solutions concentrées en HCl, la réaction [6] est capable d'être décomposée en deux nouvelles étapes qui sont:

$$[21] \quad Cu + Br^- = (CuBr^-)_{ads}$$

$$[22] \quad (CuBr^-)_{ads} + Br^- \rightarrow (CuBr_2^-) + e$$

C'est l'étape [22], le transfert électronique, qui serait l'étape déterminante en présence d'une agitation intense. Néanmoins, l'utilisation de techniques transitoires combinées à l'utilisation de l'électrode à disque tournant avec anneau (réf. 12, chap. 8) devrait permettre de préciser davantage la nature de la réaction [6]. Des travaux de laboratoire sont actuellement en cours.

Conclusions

1. Les courbes du courant de dissolution en fonction de la racine carrée de la vitesse de rotation de l'électrode ont une allure qui est caractéristique d'un procédé d'électrode qui est mixte. Le procédé d'électrode est dominé par la diffusion des ions dans la solution lorsque ω est petit ou par un phénomène de surface lorsque ω est grand.

2. Le courant associé à chacune de ces étapes lentes est déterminable à partir des relations i^{-1} vs. $\omega^{-1/2}$. La linéarité entre la tension d'électrode et le logarithme de i_∞ suggère que le phénomène de surface est limité par un transfert électronique. Pour sa part, le terme i_d est entièrement imputable, selon le modèle considéré, à la diffusion d'un bromo-complexe de cuivre, le $CuBr_2^-$, depuis la surface de l'électrode jusqu'au coeur de la solution. Le modèle est valide dans le domaine de dissolution pour lequel l'accumulation du produit de corrosion sur la surface de l'électrode est inexistante ou marginale.

3. L'énergie d'activation apparente, $\Delta H^{\ddagger}$, est de 6,5 kcal/mol. Cette valeur est en accord avec la valeur de 7 kcal/mol déduite de l'expression générale du courant en fonction des différents paramètres expérimentaux.

4. Une vague d'oxydation est observée lorsque la tension d'électrode devient suffisamment anodique par rapport à la tension réversible $E_{Cu/CuBr}$. Cette vague est associée à la passivation de la surface du cuivre par le CuBr γ.

Remerciements

L'auteur tient à remercier Monsieur G. Larochelle qui a effectué une partie du travail expérimental ainsi que Messieurs A. Joly et R. Dubuc pour l'examen des surfaces.

Reçu le 27 janvier 1983[1]

CHRISTIAN MALAVAUD, THÉOPHILE N'GANDO M'PONDO, LUCIEN LOPEZ, JEAN BARRANS et JEAN-PIERRE LEGROS. Can. J. Chem. **62**, 43 (1984).

Les cyclotétraphosphazanes **2** et **5**, obtenus à partir de diamines-1,2 sont des oligomères de diazaphospholes-1,3,2 susceptibles de se dépolymériser par voie thermique, ou par complexation avec le trifluorure de bore. La présence du cycle orthophénylène stabilise la forme dicoordonnée et permet d'expliquer la réactivité des benzo-4,5 diazaphosphole-1,3,2 **3** vis-à-vis des composés à hydrogène mobile; ces réactions se font par une addition de type 1.2 tandis qu'avec les diazaphospholes complexés **4** et **8**, le butanol conduit à une addition du type 1.1.

CHRISTIAN MALAVAUD, THÉOPHILE N'GANDO M'PONDO, LUCIEN LOPEZ, JEAN BARRANS, and JEAN-PIERRE LEGROS. Can. J. Chem. **62**, 43 (1984).

Cyclotetraphosphazanes **2** and **5** obtained from 1,2-diamines are 1,3,2-diazaphosphole oligomers leading to the monomeric form by either thermal equilibrium or by complexing with boron trifluoride. The dicoordinated form stabilized by an orthophenylene ring could explain the reactivity of 4,5-benzo 1,3,2-diazaphosphole **3** with compounds having a mobile hydrogen; these reactions were a 1.2 type addition while butanol led to a 1.1 type addition with complexed 1,3,2-diazaphospholes **4** and **8**.

La chimie des composés du phosphore dicoordonné s'est beaucoup développée ces dernières années. Cependant, si de nombreux composés à liaison —P=C< ont été signalés (1), peu de composés à liaison —P=N— ont été isolés (2–5). Cette difficulté provient sans doute de la facilité de polymérisation des phosphazènes —P=N— en cyclophosphazanes: $(—\underset{|}{P}—\underset{|}{N}—)_n$ (n = 2, 3, 4) (6).

Néanmoins un équilibre thermique, monomère $P^{II} \rightleftarrows$ oligomère P^{III} a été observé pour la première fois dans le cas des diazadiphosphétidines par Scherer et Glässel (2*c*) et dans notre laboratoire dans le cas de tétramères (7); nous avons également montré que cette dépolymérisation était possible en complexant les benzocyclophosphazanes par des acides de Lewis (BF_3, $AlCl_3$, $ZnCl_2$. . .), réaction [1]:

[1] 
1 2 3 4

Dans le présent travail nous avons préparé des cyclophosphazanes **5** dérivant de *N*-alkyléthylènediamines et comparé leur stabilité à celle des cyclotétraphosphazanes **2** dérivant des *N*-alkylorthophénylènediamines, afin de dégager l'influence du reste phénylène-1,2 et celui des substituants de l'atome d'azote sur l'équilibre monomère $P^{II} \rightleftarrows$ oligomère P^{III}.

Pour mettre en évidence la présence du monomère, nous avons étudié l'addition de composés à hydrogène mobile, à la température ordinaire, sur ces dérivés (8) et sur leurs complexes **4** et **8** avec le trifluorure de bore.

Résultats et discussion

I. Réaction générale de synthèse

La tris(diméthylamino)phosphine, par réaction avec les

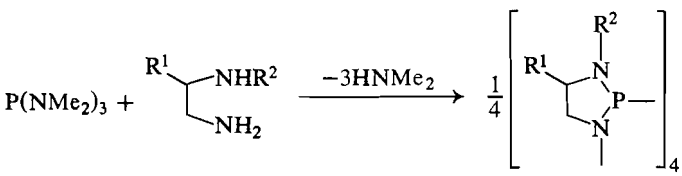
diamines-1,2, conduit à des oligomères tant pour les dérivés de l'orthophénylènediamine (tableau 1, composés **2***a*–*h*) que pour les dérivés de l'éthylènediamine (tableau 2, composés **5***a*–*f*).



5

Par spectrométrie de masse par désorption de champ nous avons montré (7) que $n = 4$ pour tous les dérivés **2** de l'orthophénylènediamine; il en est de même pour les dérivés **5** de l'éthylènediamine.

Une étude structurale par diffraction des rayons X du composé **5***d* confirme ces résultats: la structure cristalline est en effet constituée d'entités tétramères indépendantes. La molécule (Fig. 1) possède un centre de symétrie cristallographique; il en résulte que, contrairement à l'octaméthylcyclotétraphosphazane (6*b*), le cycle central à huit chainons ne présente pas la forme couronne; sa conformation (Fig. 2) s'apparente à la

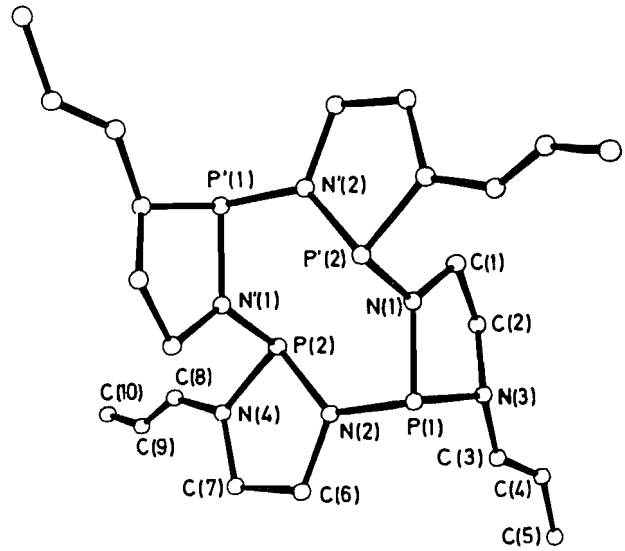


FIG. 1. Représentation perspective de la molécule tétramère **5***d*. L'opération d'inversion par rapport au centre de symétrie est indiquée par ' (apostrophe). Les atomes d'hydrogène sont omis. Distances et angles dans le cycle à huit chaînons: P(1)—N(1) = 1,711(4), P(1)—N(2) = 1,703(5), P(2)—N(2) = 1,714(5), P(2)—N'(1) = 1,694(5) Å; N(1)—P(1)—N(2) = 100,7(2), N'(1)—P(2)—N(2) = 103,6(2), P(1)—N(1)—P'(2) = 119,9(3), P(1)—N(2)—P(2) = 127,8(3)°.

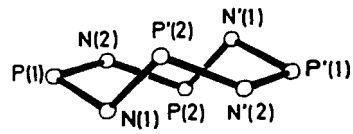

FIG. 2. Conformation du cycle à huit chaînons du tétramère **5***d*.

forme canonique "twisted chair" du cyclooctane (9).

Dans le tableau 3 sont consignés les distances et angles interatomiques. Les liaisons P—N du cycle central sont très voisines avec une longueur moyenne de 1,705(5) Å. Dans les cycles à cinq chaînons les liaisons P(1)—N(3) et P(2)—N(4) sont significativement plus longues que dans des molécules monomères analogues telles que les triazaphospholes (10). Les angles sur le phosphore N(1)—P(1)—N(3) et N(2)—P(2)—N(4) sont aussi plus fermés. La somme des angles ayant pour sommet un même atome de phosphore est en moyenne égale à 299(1)°. L'environnement des atomes d'azote N(1) et N(2) est rigoureusement plan, tandis que pour les atomes N(3) et N(4) il ne s'écarte que peu de la planéité (somme des angles = 353(2)° en moyenne). Cette dernière remarque doit d'ailleurs être tempérée à cause de l'existence d'un phénomène de désordre qui affecte les atomes de carbone; ce désordre, non résolu, est aussi responsable des valeurs anormales des distances C—C et des angles (N, C)—C—C (cf. partie expérimentale).

Les caractéristiques géométriques du tétramère **5***d* sont finalement très proches de celles observées pour un tétramère de triazaphosphole-1,2,4,3 complexé par $Cr(CO)_5$ (11).

Les spectres de masse par impact électronique du composé **5***d* montrent, outre les pics correspondants aux masses $\frac{M^+}{4}$ (130), $\frac{M^+}{2}$ (260), $\frac{3M^+}{4}$ (390) et M^+ (520), les ions $\left(\frac{M^+}{4} - 85\right)$, $\left(\frac{M^+}{2} - 85\right)$ et $(M^+ - 85)$, résultant du départ d'un groupe-

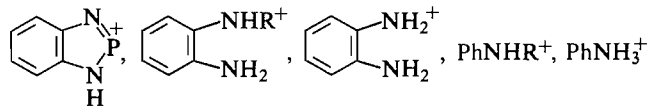
ment CH_2—CH_2—N—Pr; on observe aussi un pic correspondant au fragment $\left[\begin{matrix}\diagup\text{NHPr}\\ \diagdown\text{NH}_2^+\end{matrix}\right.$. Dans le cas des benzocylophosphazanes **2**, on observe seulement la présence du monomère $\left(\frac{M^+}{4}\right)$ ainsi que les fragments de cet ion dont les pics principaux correspondent à:

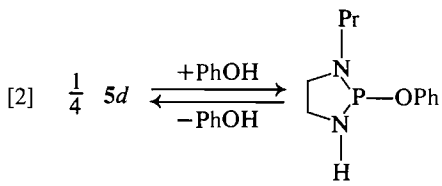


II. Réactivité des phosphazanes 2 et 5

1. *Réaction des composés à hydrogène mobile*

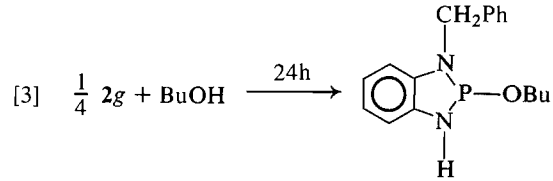
Parmi les réactifs à hydrogène mobile testés (alcool, phénol, amine), seuls les composés hydroxylés réagissent de façon notable à la température ordinaire.

Le phénol rompt les liaisons P—N des cycles phosphazanes **2** et **5**, pour donner des phénoxy-2 diazaphospholanes-1,3,2 qui, par élimination d'une molécule de phénol sous vide, redonnent les cyclophosphazanes selon la réaction [2]:



6*a* $\delta^{31}P = 124$

Le n-butanol par une réaction comparable, mais plus lente, donne avec les composés **2**, des butoxy-2 diazaphospholane-1,3,2 (réaction [3]):



7*a*

On n'observe aucune réaction du butanol avec les composés **5**.

2. *Stabilité thermique*

Par rmn de ^{31}P à température variable (60 à 150°C), nous avons pu mettre en évidence un équilibre [1] entre une forme dicoordonnée **3** et les cyclotétraphosphazanes **2** (7) (à l'exception du composé **2***a*, R = H, qui se décompose lorsqu'on le chauffe).

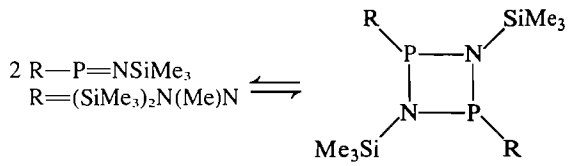
L'emploi de solvant polaire permet de déplacer cet équilibre. C'est ainsi que le pourcentage de **3***e* qui est de 30% dans le xylène à 130°C passe à 57% dans le nitrobenzène à cette même température. La pyridine qui est un bon solvant des cyclophosphazanes permet aussi d'obtenir l'équilibre précedent à sa température d'ébullition.

Variation de l'équilibre **2***e* ⇆ **3***e* dans le nitrobenzène

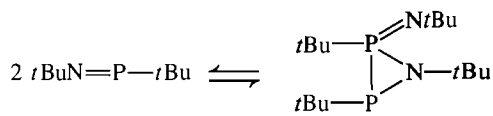
T(°C)	60	90	110	130	150
% **3***e*	0	0	2	57	100
% **2***e*	100	100	98	43	0

Il faut toutefois noter que lorsqu'on revient à la température ordinaire, le retour vers la forme cyclophosphazane **2** n'est pas instantané. On peut observer pendant plusieurs dizaines de minutes en rmn de ^{31}P, le signal correspondant à la forme dicoordonnée **3**.

Des équilibres thermiques monomère ⇌ dimère ont déjà été observés pour des composés du phosphore dicoordonné acycliques. La dimérisation se produit par une cyclo addition (2 + 2) (2*c*, 12) ou (2 + 1) (5):

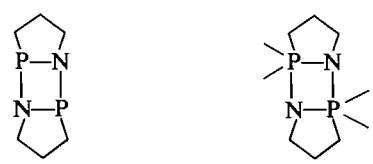


(réf. 2*c*)



(réf. 5)

La dimérisation (2 + 2) thermodynamiquement favorisée n'a pas lieu pour nos dérivés, probablement pour des raisons de contraintes de cycle. En effet à notre connaissance il n'a pas été signalé de diazadiphosphétidines du phosphore tricoordonné dont les atomes de phosphore et d'azote font partie d'un cycle à cinq chainons tel que A, alors que des diazadiphosphétidines B du phosphore pentacoordonné ont été isolées (13, 14).



(A) (B)

TABLEAU 4. Déplacement chimique et point de fusion des diazaphospholes

		3	4		8		
No	R	$\delta^{31}P$	$\delta^{31}P$	F(°C)	R	$\delta^{31}P$	F(°C)
a	H	238	222				
b	Et	232					
c	nPr	236	226	145			
d	iPr	228	225,6	132	nPr	285	78
e	sBu	225,8	226,7	104	iPr	284	
f	iPent	232	226		Ph	280	
g	$PhCH_2$	228	224,8	122			
h	Ph		205,9				

Les déplacements chimiques $\delta^{31}P$ des benzodiazaphospholes-1,3,2 **3** (tableau 4) sont comparables à ceux observés pour d'autres diazaphospholes (15*a*) (**4***c*).

Avec les cyclo(λ^3-phosphazanes) **5**, nous n'avons jamais pu observer, par rmn de ^{31}P, un équilibre thermique comparable à [1], quel que soit le solvant utilisé.

La possibilité de conjugaison de la liaison P=N— avec le reste phénylène semble donc être un facteur de stabilisation de la forme dicoordonnée, rendant possible son observation par rmn de ^{31}P. Notons que la présence d'une double liaison dans le cycle augmente la possibilité de conjugaison, et c'est ainsi que des triazaphospholes-1,2,4,3 et des diazaphospholes-1,3,2 stables ont pu être isolés (3, 4*c*).

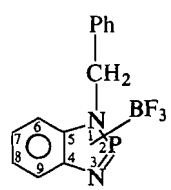
3. Complexation dépolymérisante

L'addition de trifluorure de bore sur les composés **2** donne instantanément les dérivés du phosphore dicoordonné **4***a*–*h* (tableau 4). Avec les phosphazanes **5**, la réaction plus lente (24 h) conduit également à des composés du phosphore dicoordonné **8***a*–*f* (tableau 4).

Le trifluorure de bore (acide dur) présentera une plus grande affinité pour les atomes d'azote (base dure) que pour l'atome de phosphore (base molle) (16, 17).

L'examen des spectres de rmn de ^{31}P montre que la complexation ne se fait pas sur l'atome de phosphore; en effet, si l'on compare le déplacement chimique de ^{31}P du diazaphosphole monomère obtenu par dépolymérisation thermique avec celui du diazaphosphole obtenu par complexation avec BF_3 (tableau 4) on remarque qu'ils sont très voisins; si la complexation avait lieu sur l'atome de phosphore on aurait d'une part des valeurs de $\delta^{31}P$ très différentes (blindage de l'ordre de 50 à 100), d'autre part un couplage bore–phosphore facilement observable (150 à 200 Hz) (18).

Pour déterminer sur quel atome d'azote se fait la complexation nous avons examiné plus particulièrement le complexe du trifluorure de bore et du benzyl-1 benzo-4,5 diazaphosphole-1,3,2 par rmn de ^{31}P, ^1H, ^{13}C et relevé les caractéristiques suivantes pour le groupement CH_2:



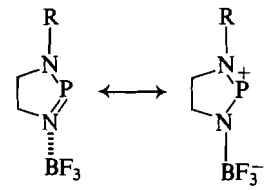
4*g*

rmn de ^{13}C δ = 50,54 $^2J_{P^{13}C}$ = 13,7 Hz
rmn de ^{31}P $^3J_{PH}$ = 8 Hz
rmn de ^1H δ = 4,4

Le groupement méthylénique du phosphazane initial **2***g* a pratiquement le même déplacement chimique δ^1H = 4,32. On peut remarquer aussi que ce signal est large ($\Delta\nu_{1/2}$ = 12 Hz) alors que dans le spectre de rmp du complexe la structure fine apparait bien puisque l'on peut mesurer la constante de couplage $^3J_{HP}$, ce ne serait pas le cas si BF_3 était fixé sur l'azote 1: on aurait d'une part un déblindage du signal CH_2 et apparition d'un couplage $^3J_{HF}$ (10 à 20 Hz) ou au moins élargissement du signal.

On peut donc raisonnablement penser que la complexation s'effectue sur l'azote 3; on note également le déblindage élevé ($\Delta\delta^1H$ = 1,5 ppm) du signal d'un noyau hydrogène du cycle benzénique (probablement le proton 9) dû à la proximité de BF_3 fixé sur l'azote en position 3.

La complexation d'un triazaphosphole par le trifluorure de bore amène un blindage du signal du déplacement chimique de ^{31}P de quelques ppm (3*b*) comme nous l'observons entre les composés **3** et **4**. La grande stabilité des composés **8**, le déplacement chimique de ^{31}P et l'absence d'observation de la forme dicoordonnée libre correspondante ne nous permettent pas d'exclure la contribution d'une forme chargée (B) isoélectronique des cations diazaphosphenium (15*b*–*e*) dont on a montré la grande stabilité (15*f*).

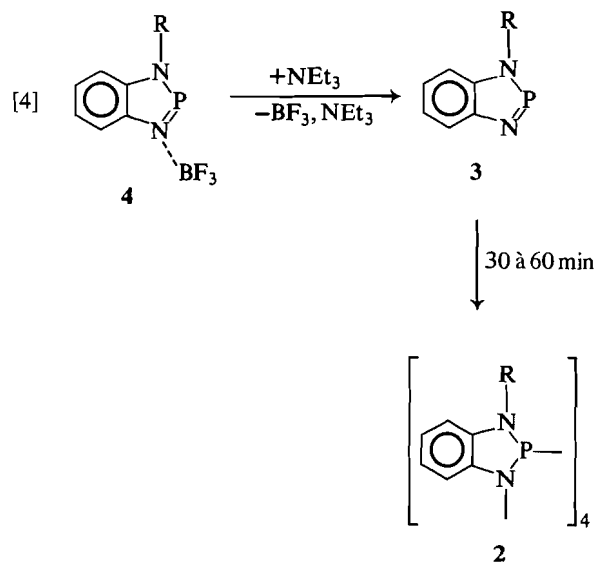


(A) (B)

III. Réactivité des complexes du phosphore dicoordonné ***4*** *et* ***8***

1. Action de la triéthylamine NEt_3

L'addition de triéthylamine sur **4** et **8** permet de revenir aux cyclotétraphosphazanes **2** et **5**. On doit remarquer que cette oligomérisation n'est pas instantantée, dans le cas des benzo-4,5 diazaphospholes-1,3,2 on voit persister pendant quelques dizaines de minutes le signal de rmn de ^{31}P du monomère libre (identique à celui observé dans la dépolymérisation thermique, tableau 4).

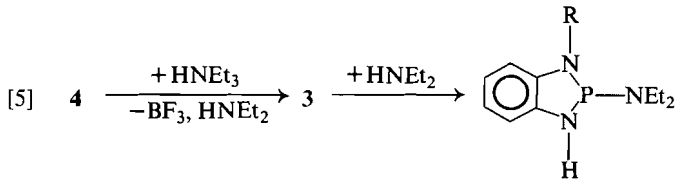


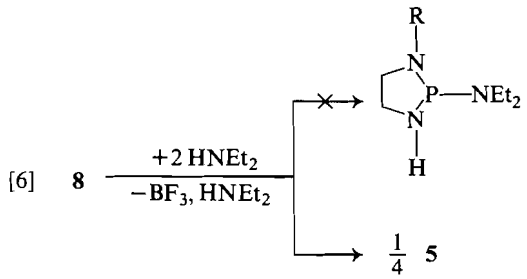
Dans le cas des diazaphospholes **8**, l'oligomérisation est instantanée et nous n'avons pas détecté de composé du phosphore dicoordonné intermédiaire analogue à **3**.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

2. *Action de la diéthylamine $NHEt_2$*

L'addition d'une amine secondaire (proportion 2:1) souligne la différence de réactivité des composés **4** et **8**. Alors que les composés **4** conduisent aux diéthylamino-2 diazaphospholane-1,3,2 par l'intermédiaire du composé du phosphore dicoordonné libre **3** (réaction [5]), les composés **8** ne donnent que les cyclotétraphosphazanes **5** (réaction [6]).

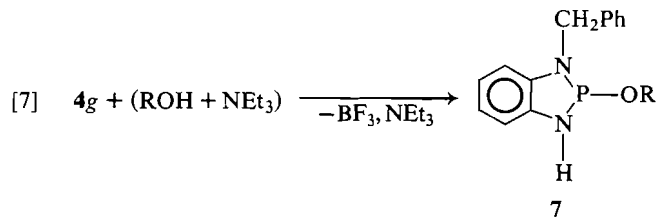




La réaction [6] s'explique si l'on admet que la vitesse d'oligomérisation du composé du phosphore dicoordonné libre est plus grande que la vitesse d'addition de la diéthylamine sur ce dérivé.

3. *Réaction des alcools en présence de base*

En présence d'une base tertiaire les composés **4** réagissent avec les alcools pour donner des alkoxy-2 diazaphospholane-1,3,2 résultant d'une addition 1.2 sur le composé du phosphore dicoordonné libre **3**.



7

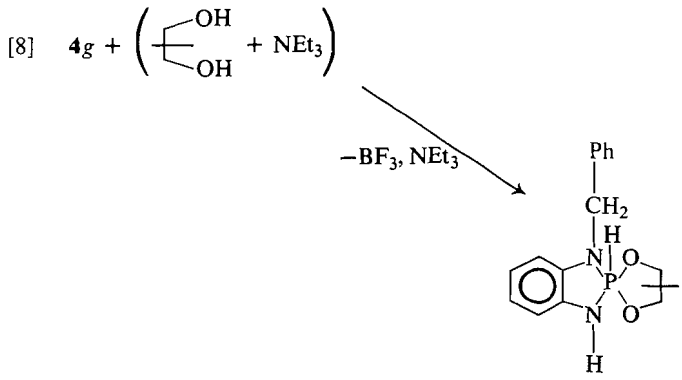
	R	$\delta^{31}P$ (ppm)	J_{PH} (Hz)
7*a*	nBu	101	30
7*b*	Me	101	25
7*c*	Et	101	30
7*d*	$PhCH_2$	104	

Les produits obtenus ont été identifiés par rmn de ^{31}P, par comparaison avec ceux que l'on obtient par action directe de Cl_2POR sur la diamine correspondante **1**.

Les diols en présence de base réagissent comme les alcools avec les composés **4**, mais conduisent, cette fois, à des spirophosphoranes à liaison PH **9** (réaction [8]).

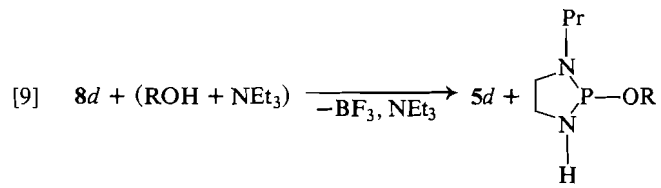
Ces produits ont été identifiés par comparaison de leurs spectres avec ceux de produits authentiques obtenus par action de diméthylamino-2 dioxaphospholane-1,3,2 sur les diamines correspondantes **1** (19).

En présence de base tertiaire, les composés **8** réagissent avec les alcools pour donner deux composés: le cyclotétraphosphazane **5** et l'alcoxy-2 diazaphospholane-1,3,2 (réaction [9]).



9

		$\delta^{31}P$ (ppm)	$^2J_{PH}$ (Hz)
9*a*	$(CH_2)_2$	−45,5	744
9*b*	$(CMe_2)_2$	−53	748
9*c*		−41	800

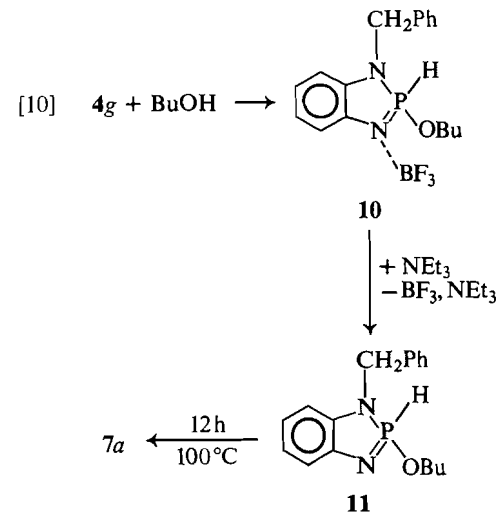


6

	R	$\delta^{31}P$
6*b*	Me	117,4
6*c*	nBu	118
6*d*	*t*Bu	117,8

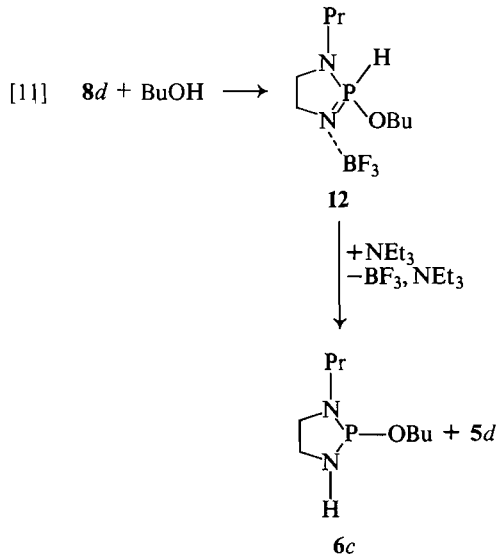
4. *Réaction des alcools suivie de la neutralisation des complexes*

En l'absence de base tertiaire les alcools réagissent différemment sur les complexes **4** et **8**. C'est ainsi que l'addition de butanol sur le composé **4***g* conduit par une réaction lente (4 jours) à la formation d'un dérivé du phosphore tétracoordonné **10** (δ ^{31}P = 9 ppm; J_{PH} = 725 Hz). L'addition ultérieure de triéthylamine modifie peu le spectre de rmn de ^{31}P (**11**: δ



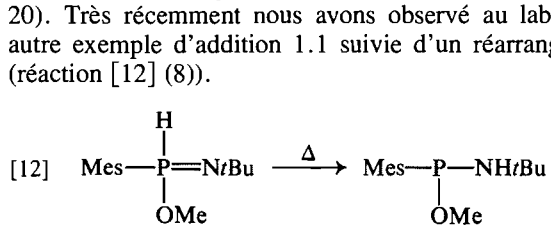
^{31}P = 9,5 ppm, J_{PH} = 687 Hz). Quand on chauffe 12 h à 100°C, on obtient un composé du phosphore tricoordonné **7***a* (δ ^{31}P = 101, J_{PNH} = 30 Hz) identique à celui de la réaction [3].

On observe également un composé du phosphore tétracoordonné **12** (δ ^{31}P = 39, J_{PH} = 698 Hz) par addition de n-butanol sur **8***d*; mais dans ce cas la réaction est immédiate, l'addition de triéthylamine fait disparaitre instantanément le dérivé tétracoordonné au profit de l'alcoxyphospholane **6***c* (118 ppm) et du tétracyclophosphazane **5***d*.



Le comportement de **4***g* et **8***d* vis-à-vis des alcools peut s'expliquer par une addition 1.1 des alcools, suivie d'un réarrangement (réactions [10] et [11]). Ici encore la stabilité du composé **11** serait dûe aux possibilités de conjugaison de la double liaison P=N avec le cycle benzo. Dans la réaction [11], on obtient les mêmes produits finals que dans la réaction [9], ce qui pourrait s'expliquer en admettant la libération de diazaphosphole libre et de butanol, puis leur réaction, lors de l'addition de triéthylamine sur **12**.

Des réactions d'addition 1.1 sur des composés du phosphore dicoordonné ont déjà été mentionnées dans la littérature (2*a*, 20). Très récemment nous avons observé au laboratoire un autre exemple d'addition 1.1 suivie d'un réarrangement 1.2 (réaction [12] (8)).



Conclusion

Ce travail montre que les cyclophosphazanes **2** et **5** dérivant des diamines-1,2 sont des tétramères, composés du phosphore tricoordonné qui, par chauffage ou par complexation dépolymérisante avec le trifluorure de bore, donnent des composés du phosphore dicoordonné possédant une liaison —P=N. On peut en outre faire les remarques suivantes.

1. La présence d'un cycle orthophénylène est un facteur de stabilisation des diazaphospholes **3**, et permet leur observation en rmn de ^{31}P; soit à partir de l'équilibre thermique [1] monomère $P^{II} \rightleftarrows$ tétramère P^{III} (excepté R = H), soit lors de la neutralisation des diazaphospholes complexés **4** (réaction [4]).

2. L'addition de réactifs à hydrogène mobile HX sur les diazaphospholes **3** se fait suivant une réaction de type 1.2 (réactions [2] [5] [7] [8]).

3. La complexation de l'atome d'azote de la double liaison P=N (diazaphospholes **4** et **8**) nous a permis, dans le cas des alcools, d'obtenir des additions 1.1, suivies d'un réarrangement (réactions [10] et [11]).

Partie expérimentale

Les analyses (C, H, N, P, B, F) ont été effectuées par le service central de microanalyse du C.N.R.S.

Les spectres de rmn de ^{1}H, ^{31}P et ^{13}C ont été respectivement enregistrés sur les spectromètres suivants: ^{1}H, Varian HA 100 (100 MHz) référence interne TMS; ^{31}P, Perkin–Elmer R32 (36,43 MHz) référence externe H_3PO_4, solution aqueuse à 85%; ^{13}C, Cameca (62,86 MHz) référence interne TMS.

Les spectres de masse par desorption de champ ont été réalisés avec un appareil Varian mat 311 A.

Les modes opératoires suivants sont typiques de la préparation de ces composés.

Cyclotétraphosphazanes **2**a–h *et* **5**a–f

Un mélange de tris(diméthylamino)phosphine 6,24 g (0,04 mol) et de 5,5 g (0,04 mol) de N-iPr(*o*)phénylènediamine dans 20 cm^3 de xylène est chauffé au reflux; la diméthylamine formée, entrainée par un courant d'azote sec, est titrée par une solution normale d'acide sulfurique. On neutralise 85% de la quantité théorique d'amine en une heure; le cyclophosphazane **2***d* cristallise au refroidissement, le précipité est lavé à l'hexane et séché sous vide sur anhydride phosphorique.

Diazaphospholes-1,3,2 complexés **4**a–h *et* **8**d–f

Trifluoro(butyl-1 benzo-4,5 diazaphosphole-1,3,2-N^3) bore **4**e

On ajoute en refroidissant 0,44 cm^3 d'éthérate de trifluorure de bore (0,0036 mol) à 0,69 g (0,009 mol) de *N*-butylcyclotétraphosphazane en suspension dans 4 cm^3 de benzène anhydre. Après une heure à la température ambiante, on concentre sous vide la solution jaune clair obtenue, et on isole les cristaux formés. On recristallise dans le benzène anhydre, Rdt, 96%, *F* = 104°C. *Poids Moléc.*: 260. *Anal.* calc.: C 46,19, H 5,04, N 10,91, P 11,92, F 21,92; tr.: C 45,58, H 5,13, N 10,54, P 11,70, F 20,89.

Trifluoro(n-propyl-1 dihydro-4,5 diazaphosphole-1,3,2-N^3) bore **8**d

A 3 g de *N*-propylcyclotétraphosphazane **5***d* dissous dans 10 cm^3 de CH_2Cl_2 anhydre, refroidi à 0°C, on ajoute sous atmosphère inerte 2,85 cm^3 de $BF_3 \cdot Et_2O$. Après 24 h, on concentre la solution et isole des cristaux blancs qui sont lavés deux fois à l'hexane anhydre, et séchés sur P_2O_5 sous vide, Rdt, 80%, *F* = 76–78°C. *Poids Moléc.* 198. *Anal.* calc.: C 30,30, H 5,56, N 14,14, P 15,66, B 5,56, F 28,79; tr.: C 30,3, H 5,30, N 13,56, P 15,47, B 5,21, F 26,98.

Spirophosphoranes à liaison PH **9**a–c

On chauffe au bain d'huile, un mélange équimoléculaire de diméthylamino-2 dioxaphospholane-1,3,2 et de *N*-benzylorthophénylènediamine (3×10^{-2} mol) dans 20 cm^3 d'acétonitrile; après réaction, on ajoute 10 cm^3 de toluène et évapore l'acétonitrile sous vide. La solution est abandonnée jusqu'à cristallisation (24 h). Les cristaux, filtrés sous vide, sont lavés avec Et_2O anhydre et séchés sur P_2O_5.

[a]Les écarts standards sont indiqués entre parenthèses.

Réactivité du trifluoro(benzyl-1 benzo-4,5 diazaphosphole-1,3,2-N^3) bore **4**g

Addition de $HNEt_2$ (réaction [5])

Dans un tube de rmn on introduit 0,175 g ($5,8 \times 10^{-4}$ mol) de **4***g* dissous dans 0,5 cm^3 de toluène, on enregistre le spectre de rmn ($\delta^{31}P = 226$), on ajoute alors, à 0°C, 0,086 g ($11,7 \times 10^{-4}$ mol) de diéthylamine fraichement distillée sur potasse; après quelques minutes d'agitation on enregistre à nouveau le spectre ($\delta^{31}P = 99$).

Addition des alcools en présence de triéthylamine (réactions [7] et [8])

Le mode opératoire est analogue à celui décrit précédemment mais on replace la diéthylamine par un mélange équimoléculaire d'alcool et de triéthylamine.

Addition de n-butanol (réaction [10])

A une solution de 0,0659 g de **4***g* dans 0,5 cm^3 de CH_2Cl_2, maintenue à 0°C ($\delta^{31}P = 226$), on ajoute 0,0255 g de n-BuOH. L'avancement de la réaction est suivi, à la température ordinaire, en enregistrant les spectres de rmn de ^{31}P: on observe une diminution du signal de **4***g* (226) au profit du signal de **10** ($\delta^{31}P = 9$, $J_{PH} = 725$ Hz); la réaction est terminée en quatre jours. On ajoute à 0°C un équivalent de triéthylamine en solution dans un cm^3 de toluène. Le chlorure de méthylène est évaporé sous vide; la solution toluénique, filtrée et concentrée sous vide, est spectrographiée (**11**: $\delta^{31}P = 101$, $J_{PNH} = 30$ Hz).

Réactivité du trifluoro(propyl-1 dihydro-4,5 diazaphosphole-1,3,2-N^3) bore **8**d

Les additions d'amine (réaction [6]), d'alcool en présence d'amine (réaction [9]) et d'alcool (réaction [11]) ont été effectuées d'une façon analogues aux réactions [5], [7], [8], [10] avec pour solvant le chlorure de méthylène.

Détermination de la structure cristalline de **5**d

$P_4N_8C_{20}H_{44}$ $M = 520,5$

Monoclinique, $a = 10,332(2)$, $b = 12,288(2)$, $c = 11,258(3)$ Å, $\beta = 92,34(2)°$, $V = 1428,1$ Å^3, $\rho_o = 1,19(3)$, $\rho_c = 1,21$ g cm^3 pour $Z = 2$, groupe spatial: $P2_1/C$, $F(000) = 560$, $\mu = 2,4$ cm^{-1} (MoKα, $\lambda = 0,71069$ Å).

Le groupe spatial a été déterminé photographiquement par la méthode de précession. Un diffractomètre automatique CAD4 Enraf−Nonius a été utilisé pour l'affinement des paramètres cristallins (sur 25 réflexions) et pour les mesures d'intensité. Les intensités des réflexions *hkl* et $\bar{h}kl$ ont été collectées pour $2° < \theta < 25°$ dans le mode de balayage $\theta/2\theta$. Sur les 2508 réflexions indépendantes mesurées, 1537 satisfaisant au critère $I > 2\sigma(I)$ ont été considérées comme observées et utilisées pour la détermination et l'affinement de la structure. La correction de Lorentz polarisation a été apportée mais aucune correction d'absorption n'a été appliquée en raison de la faible valeur de μ et de la forme parallélépipédique du cristal (0,6 × 0,4 × 0,4 mm).

La structure a été déterminée par les méthodes directes (21) et affinée avec inversion de la matrice complète en utilisant le système SHELX (22). Tous les atomes autres que l'hydrogène ont été affinés anisotropiquement tandis que les atomes d'hydrogène ont été placés en position calculée (C—H = 0.97 Å) et affectés d'un facteur de température isotrope fixe $U = 0,1$ Å^2. Après convergence les facteurs d'accord sont $R = \Sigma(k|F_o| - |F_c|)/\Sigma\, k|F_o| = 0,069$ et $R' = [\Sigma(k|F_o| - |F_c|)^2/\Sigma\, k^2|F_o|^2]^{1/2} = 0,065$.

La synthèse de Fourier différence finale ne présente aucun pic significatif. Cependant les valeurs anormalement élevées des facteurs de température des atomes de carbone, les liaisons C—C trop courtes, ainsi que les angles (N, C)—C—C trop grands (cf. tableau 3) révèlent un phénomène de désordre affectant principalement les groupes propyles. Ce désordre n'a pu être résolu. Les coordonnées finales des atomes autres que l'hydrogène figurent au tableau 5; leurs facteurs de température anisotropes (tableau 6) ainsi que la liste des amplitudes des facteurs de structure observés et calculés ont été confiés au dépôt des données non publiées.[2]

Received December 16, 1982[1]

KAMAL SHAKIR, KAMAL BENYAMIN, and MOURAD AZIZ. Can. J. Chem. **62**, 51 (1984).

Foam separation investigations over the 2.5–10.5 pH range show that U(VI) can be successfully separated from aqueous solutions by precipitation with oxine and subsequent flotation of the precipitate, either in absence or in presence of surfactant collectors. Collectors tested were: cetyl trimethyl ammonium bromide (CTAB) and sodium lauryl sulphate (NaLS). The extent of removal depends on many factors and removals as high as 98% could be achieved when uranyl oxinate precipitate was floated, under certain controlled conditions, in the presence of CTAB. Factors affecting the percentage removal were investigated and the best conditions were selected. The results obtained are discussed in terms of the hydrolytic behaviour of U(VI).

KAMAL SHAKIR, KAMAL BENYAMIN et MOURAD AZIZ. Can. J. Chem. **62**, 51 (1984).

Des études sur la séparation des mousses dans l'intervalle de pH allant de 2,5 à 10,5 révèlent que le U(VI) peut être séparé avec succès des solutions aqueuses par précipitation avec l'oxine et une flottation subséquente du précipité en présence ou non de collecteurs surfactants. Les collecteurs étudiés sont: le bromure de cétyltriméthylammonium (BCTA) et le sel de sodium du sulfate de lauryle (NaLS). Le taux de séparation dépend de plusieurs facteurs et on peut réaliser une séparation à 98% lorsqu'on fait flotter le précipité d'oxinate d'uranyle dans certaines conditions contrôlées en présence de BCTA. On a étudié les facteurs qui influencent le pourcentage de séparation et on a choisi les meilleurs conditions. On discute des résultats obtenus en fonction du comportement hydrolytique de l'U(VI).

Introduction

The increasing use of nuclear energy has stimulated the search for new simple processes to separate uranium from dilute solutions for either the metal recovery or solution decontamination. For these purposes, precipitate flotation seems to offer many advantages.

Two kinds of precipitate flotation are known (1). (*i*) In the first kind, the ion to be separated is precipitated, usually as hydroxide. A surface-active collector is then added to the dispersion and well stirred, whereby the collector is adsorbed on the surfaces of the precipitate particulates rendering them hydrophobic (2). (*ii*) In the second kind (3), precipitates with hydrophobic surfaces are obtained by allowing the metal ion to react with a suitable organic reagent (not a surfactant) to form an insoluble product with hydrophobic surface.

The separation of hexavalent uranium by precipitate flotation has received little attention. Few publications (4–7) which deal with separation of uranium by precipitate flotation processes of the first kind, and only one (8) which deals with its removal by a process of the second kind, have appeared in the literature. The aim of the present work was, therefore, to investigate the separation of U(VI) from aqueous media by precipitate flotation of the first and second kinds as well as by a process which combines both techniques. The surfactants sodium lauryl sulphate (NaLS) and cetyl trimethyl ammonium bromide (CTAB) were used as collectors for flotation of the first kind, while 8-hydroxyquinoline (oxine) was used as a precipitant in precipitate flotation of the second kind. Oxine was chosen because it has been sucessfully used in extraction of metal ions and in separation of uranium for analytical, recovery, and decontamination purposes (9–14).

[1] Revision received July 15, 1983.

Experimental

Apparatus and reagents

The flotation system and cell used were exactly similar to those previously described (15, 16).

A stock solution of 0.01 *M* uranyl chloride in 0.01 *M* HCl was prepared. The exact concentration of U(VI) in this stock solution was determined gravimetrically by the 8-hydroxyquinoline method (17).

Solutions of reagent grade sodium chloride, hydrochloric acid, and CO_2-free sodium hydroxide were used to adjust the ionic strength and/or the pH.

The collector solutions were freshly prepared daily. Absolute ethanol was used as a solvent as well as a frother, at a dose of two mL of alcohol per 450 mL of UO_2Cl_2 solution.

The solution of oxine was prepared weekly by dissolution in absolute ethanol and was preserved in dark bottles.

General procedure of flotation

Uranyl chloride solutions (1×10^{-4} *M*) were prepared in 500 mL volumetric flasks and were adjusted to 0.02 ionic strength and the desired pH. The solutions were then left to age for 10 minutes, shaken well, and 450 mL were transferred to the flotation cell. The pH of the solution in the cell was measured and recorded.

Flotation was started by passing pure N_2 gas at a rate of 55 cm^3/min. At the end of each experiment samples of the bulk solution were withdrawn, while the gas was still bubbling, for uranium analysis. Oxine was found to shift the pH of uranyl solutions to higher values. Therefore, unless otherwise specified, in experiments where oxine was used, 1 mL of oxine solution of the proper concentration was added dropwise to the uranyl solution in the volumetric flask prior to the pH adjustment. Collectors, when used, were injected into the bulk solution in the flotation cell.

In experiments with oxine alone, the removal was fast and reached its limit within a few minutes, whereas in the presence of collectors the ultimate removal was reached within one hour. Therefore, in the accompanying figures a time interval of 20 minutes was chosen for presenting the flotation results obtained with oxine. For results with

surfactants or with oxine plus surfactant, a time interval of 60 minutes was selected.

Analysis

For uranium analysis the samples were acidified with nitric acid to dissolve the precipitate, if any, then evaporated and heated on a bare flame to destroy the organic matter. Depending on the uranyl ion concentration, uranium was determined spectrophotometrically with either Thoron (18) or Aresenazo III (19) as the colorimetric reagent.

Results and calculations

1. Effect of pH

(a) Flotation of the first kind

Figure 1 shows the effect of pH on the percentage removal of U(VI) using different concentrations of either the anionic collector, NaLS, or the cationic collector, CTAB. For comparison, the figure also shows the theoretical precipitate flotation curve, that is, the precipitate formation curve as calculated from the data published for U(VI) hydrolysis.

In calculating the precipitate flotation curve it was assumed that insoluble hydrolysis products of U(VI) are completely removed by flotation and hence the percentage removal (% M) of the metal ion would be (20):

$$[1] \quad \% \text{ M} = 100\,(1 - C_s/C_a)$$

where C_a is the analytical U(VI) concentration, and C_s is the maximum concentration of soluble U(VI) species and can be related to the hydrogen ion activity by the equation:

$$[2] \quad C_s = H^*K_{so}[H + {}^*\beta_{1,1} + 2H^*\beta_{2,2}\,{}^*K_{so} + 3^*\beta_{5,3}\,{}^*K_{so}^2 + 3H^*\beta_{4,3}\,{}^*K_{so}^2]$$

where $^*K_{so}$ is the solubility or dissociation constant $[UO_2^{2+}]/[H]^2$ and $^*\beta_{1,1}$, $^*\beta_{2,2}$, . . . etc. are the overall formation constants of the hydrolysis products: $UO_2(OH)^+$, $(UO_2)_2(OH)_2^{2+}$; . . . etc.

The values of the various constants used to calculate the precipitate flotation curve were taken from ref. 21 and were corrected to our experimental ionic strength by eq. [3] (21):

$$[3] \quad \log {}^*\beta' = \log {}^*\beta + a\mu^{1/2}/(1 + \mu^{1/2}) + bm_x$$

where μ is the ionic strength and m_x is the molality of the chloride ion. The coefficients a and b were obtained from ref. 21.

The theoretical precipitate flotation curve (Fig. 1) shows that U(VI) starts precipitation at pH 5.7. The fraction of each of the hydrolysis species found in solution at the lower pH values could be calculated from the formation constants. The results obtained are presented in Fig. 2.

As shown from Fig. 1, the experimental flotation curves obtained with CTAB agree with the calculated precipitate flotation curve, indicating that the cationic collector, CTAB, can readily float uranyl precipitates but cannot remove the UO_2^{2+} ion or its polynuclear hydrolysis products. The anionic collector NaLS, on the other hand, cannot float uranyl precipitates though it can partially remove soluble uranyl species. Under our experimental conditions, optimum removals of about 46% and 95% were obtained with NaLS and CTAB respectively.

(b) Flotation of the second kind

Results of experiments on the UO_2^{2+}–HOx flotation systems investigated are summarized in Fig. 3. Removals are seen to increase and the effective pH range is extended towards both sides with increased HOx concentration; apparently the flotation process is very sensitive to this parameter. With the highest HOx concentration tested (2×10^{-3} *M*), removals greater than 92% could be achieved. The effective pH range of U(VI) removal lies in the range 4.2 to 8.2, but the curve shows a significant drop in the pH region 4.5–5.2 with a minimum at about pH 4.7.

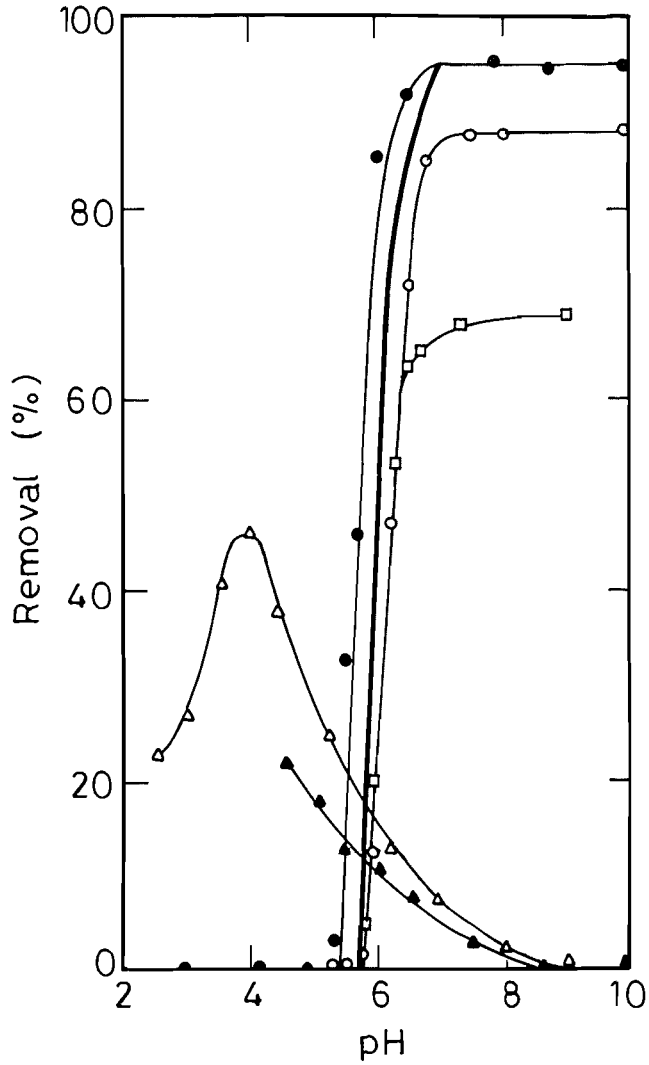

FIG. 1. Theoretical precipitate flotation curve and percentage removals obtained for 1×10^{-4} *M* UO_2Cl_2 solutions of various pH values using different concentrations of either NaLS or CTAB. (—) Theoretical precipitate flotation curve; NaLS: (△) 8×10^{-4} *M*; (▲) 3×10^{-4} *M*; CTAB: (●) 8×10^{-4} *M*; (○) 2×10^{-4} *M*, (□) 5×10^{-5} *M*.

(c) Combined flotation of the first and second kinds

Flotation experiments using HOx as precipitant and either NaLS or CTAB as collector were performed. The results are plotted in Fig. 4. When these are compared with those plotted in Fig. 3, it becomes obvious that CTAB significantly improves the flotation results though it does not affect the removal pattern. At the optimum pH, removals greater than 98% could be achieved. NaLS, on the other hand, slightly increases the percentage removal in the pH range ~5–6.5 but affects it adversely at higher pH values.

In the flotation experiments described in this work the uranyl solutions used to prepare the flotation systems had pH 3.9. When HOx was added to these solutions, the pH values of the resulting systems were found to increase to about 4.3, 4.6, and 5.35 for HOx concentrations of 3×10^{-4} *M*, 8×10^{-4} *M*, and

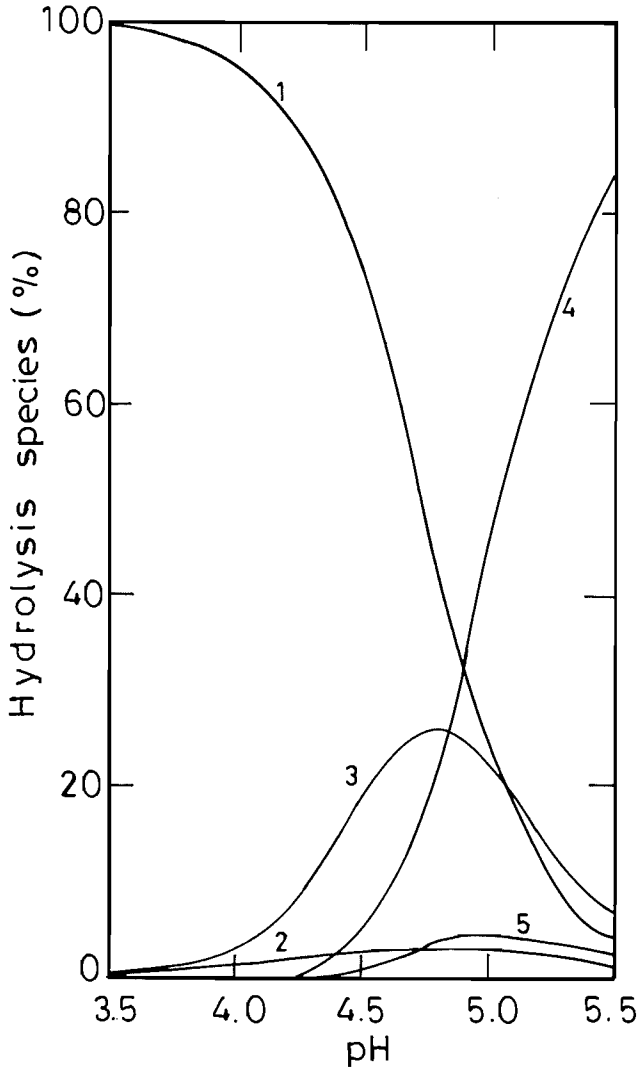

FIG. 2. Distribution of hydrolysis species in 1×10^{-4} *M* UO_2Cl_2 at $\mu = 0.02$ *M* (Cl^-) and 25°C. 1. UO_2^{2+}; 2. $UO_2(OH)^+$; 3. $(UO_2)_2(OH)_2^{2+}$; 4. $(UO_2)_3(OH)_5^+$, 5. $(UO_2)_3(OH)_4^{2+}$.

2×10^{-3} *M* respectively. These (original) pH's of the systems were then brought to the required values by adding either an acid or an alkali. However, when such systems were subjected to flotation, sharp drops in the percentage removals were observed at about pH 4.7 (Fig. 3 and Fig. 4, curves 2, 3, and 4). This defect could be amended by adding the oxine solution to uranyl solutions of pH values so low as not to allow the pH's of the resulting systems to exceed 3.5, the pH at which polynuclear hydrolysis species start formation (Fig. 2).

2. *Effects of HOx, CTAB, and HOx–CTAB concentrations on the percentage removal of U(VI)*

Figure 5 shows the percentage removals of U(VI) using: (*i*) varying concentrations of HOx, (*ii*) different CTAB concentrations, (*iii*) initial constant CTAB concentration (8×10^{-4} *M*) and different HOx concentrations, and (*iv*) initial constant HOx concentration (8×10^{-4} *M*) and varying CTAB concentrations.

As shown from the figure (curve No. 1), the percentage removal obtained with HOx sharply increases with increasing initial HOx concentration until an oxine – metal ion molar ratio of 7.0 is reached where the curve tends to level off. The addition of CTAB to the UO_2–HOx system significantly increases the percentage removal, especially when the proper

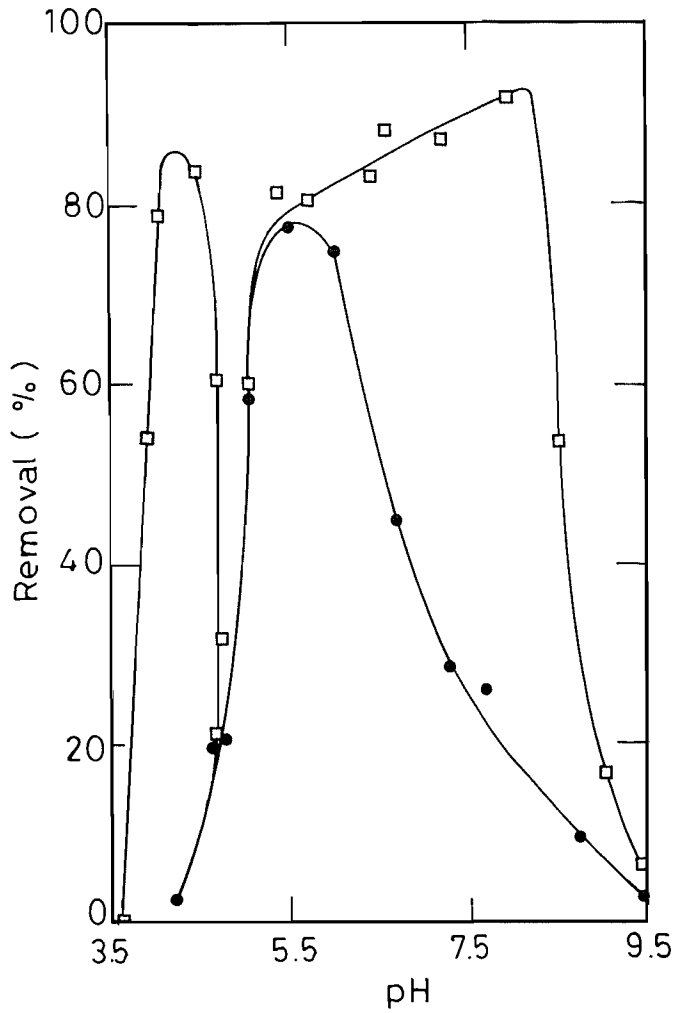

FIG. 3. Removals obtained for 1×10^{-4} *M* UO_2Cl_2 solutions of various pH values using different concentrations of oxine. HOx: (●) 8×10^{-4} *M*, (□) 2×10^{-3} *M*.

amounts of HOx and CTAB are used (curves No. 3 and 4). With improper ratios of the reagents, the percentage removal decreases from the maximum.

Discussion

Results obtained for the U(VI) flotation systems under investigation can be best interpreted in terms of the hydrolytic behaviour of the element and the complexing properties of oxine.

As shown from Fig. 1, with the strong anionic collector NaLS, maximum removal was obtained at pH 3.8 where the soluble UO_2^{2+} species predominates (Fig. 2) and decreased upon either decreasing or increasing the pH; that is, removal took place by only an ion flotation mechanism. In all our experiments, the initial ionic strength was kept constant, i.e., the sum of the initial concentrations of the sodium ions plus hydrogen ions was fixed and hence the sodium ion concentration decreased as the acidity was increased. Removals decreased from the maximum with decreasing pH (Fig. 1), apparently because the metal ion species could not compete against hydrogen ions for the collector anions as successfully as against sodium ions. This is readily explainable since H^+ has a higher charge density than Na^+ and is therefore harder to displace from the laurylsulphate anion.

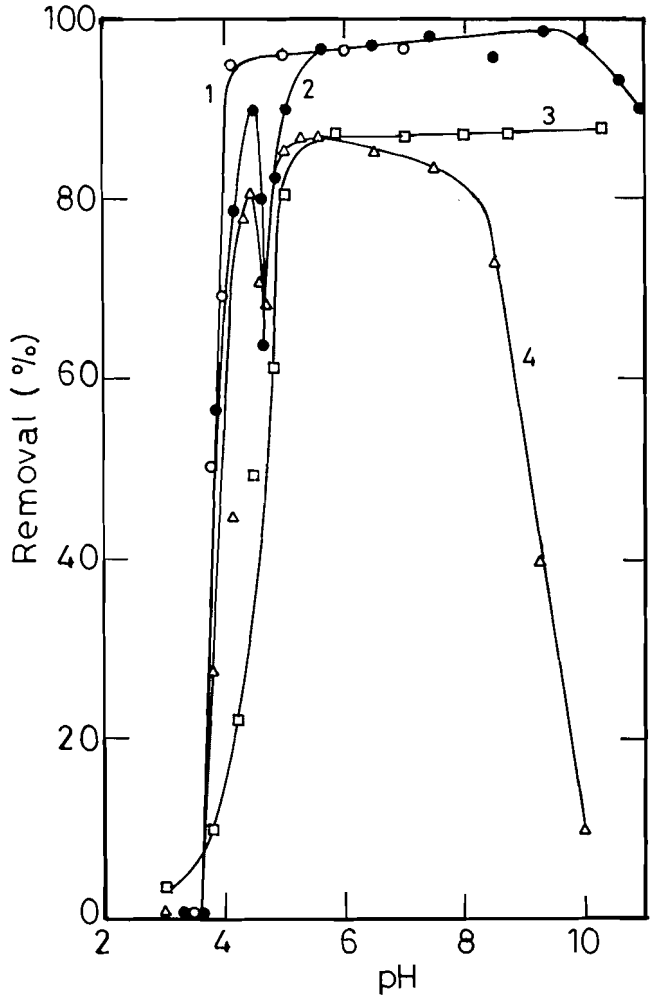

FIG. 4. Percentage removals obtained with either NaLS or CTAB for UO_2Cl_2–HOx systems adjusted to various pH values.

Curve No.	Collector (M)	HOx (M)	Original pH of the UO_2–HOx system
1	5×10^{-4} CTAB	2×10^{-3}	3.2
2	5×10^{-4} CTAB	2×10^{-3}	5.35
3	5×10^{-4} CTAB	3×10^{-4}	4.3
4	5×10^{-4} NaLS	2×10^{-3}	5.35

The decrease of removal with increasing pH can be attributed to the formation of polynuclear uranyl species. As the pH is increased towards the precipitation point, the concentration of the polynuclear hydrolysis species also increases (Fig. 2). Apparently, soluble polynuclear species do not compete as well for the collector anions as does UO_2^{2+} which has a higher charge density.

With CTAB, the soluble uranyl species could not be removed but insoluble species could be successfully floated. The soluble uranyl species are all positively charged and hence, from electrostatic considerations, these species would not be expected to be floated by the cationic collector, CTAB. The removal of the insoluble uranyl species with cationic collectors indicates that these species are negatively charged. However, the removal is not a simple function of the collector concentration since removals of about 70%, 88%, and 95% are obtained with collector – metal ion molar ratios of 0.5, 2, and 8 respectively (Fig. 1). This suggests that the precipitate is not

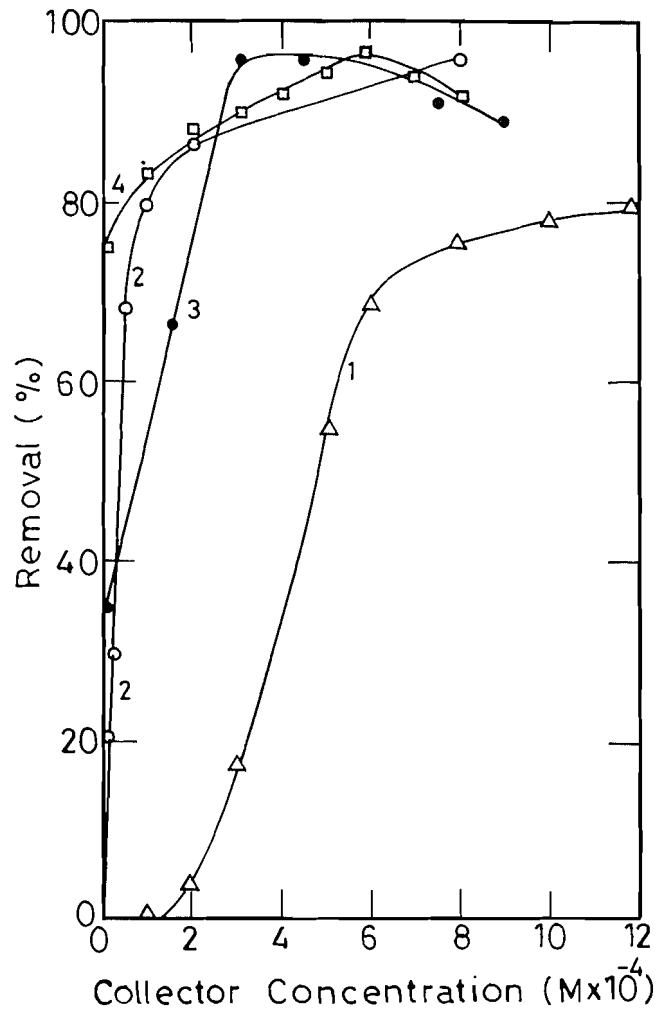

FIG. 5. Percentage removals obtained for 1×10^{-4} M UO_2Cl_2 solutions using different concentrations of oxine, CTAB, or mixtures of both. 1. HOx, pH 5.5; 2. CTAB, pH 8.5; 3. [CTAB] 8×10^{-4} M + [HOx] variable, pH 5.5; 4. [HOx] 8×10^{-4} M + [CTAB] variable, pH 5.5.

homogeneous in structure, i.e., species of various structures and charge densities and, consequently, of different flotation tendencies are present. This seems to be consistent with the literature (21–23) according to which uranyl hydroxide, owing to its pronounced amphoteric properties, can readily form uranates in neutral and basic media. Since uranates are solid solutions of various polyuranates (21, 22), they would be expected to have different flotation tendencies.

Precipitate flotation of the second kind was investigated using oxine. Under basic or weakly acidic conditions, oxine precipitates U(VI) quantitatively as a dark red adduct, $UO_2 \cdot Ox_2 \cdot HOx$ (24, 25). The theoretical precipitate flotation curve of this adduct could not be calculated owing to the lack of data on its equilibrium constants, but the effect of HOx and hydrogen ion concentrations on the formation and, consequently, removal of the adduct can be qualitatively shown by the equation:

$$[4] \quad UO_2^{2+} + 3HOx \rightleftharpoons UO_2Ox_2 \cdot HOx + 2H^+$$

for which the equilibrium constant would be:

$$[5] \quad K = \frac{[H^+]^2}{[UO_2^{2+}][HOx]^3}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

In agreement with the above equilibrium, it is found experimentally that the percentage removal of uranium highly depends on the HOx concentration and increases as the quantity of oxine added is increased (Fig. 3). At the lowest HOx concentration tested, 8×10^{-4} *M*, the optimum removal is attained at pH 5.7. The sharp decrease from the optimum removal with decreasing pH is attributed to the increased tendency of the precipitant (HOx) to be protonated, whereas the decrease of the removal from the maximum with increasing pH is caused by the increased competition of OH^- for U(VI) and the consequent formation of hydrolytic uranyl precipitates. As shown from Fig. 3, increasing the oxine concentration results not only in a higher percentage removal but also in a wider effective pH range of U(VI) flotation. With the highest oxine concentration tested, 2×10^{-3} *M*, the optimum pH for uranium removal lies in the range 4.2–8.2. This range agrees with that, 4.1–8.8, reported (26) for uranyl oxinate precipitation.

U(VI) separation by combined precipitate flotation of the first and second kinds was also investigated. On comparing the results (Fig. 4) with those obtained with oxine alone (Fig. 3), it is noticed that NaLS does not significantly affect the percentage removal whereas CTAB markedly improves it at pH values greater than 5. These results are readily explainable since, except around pH 3.8, NaLS cannot significantly remove U(VI) but CTAB can successfully remove uranyl hydroxide and uranates from neutral and alkaline media (Fig. 1). Therefore the increased removal which is observed when CTAB is added to the UO_2^{2+}–HOx system can be attributed to the simultaneous removal of hydrolytic uranyl precipitates by CTAB and the self-flotation of uranyl oxinate. CTAB cannot remove soluble uranyl species (Fig. 1) and it therefore does not affect the removal results obtained by oxine at pH values below that of U(VI) precipitation. At relatively high hydroxyl ion concentrations (pH >10) the removal decreases due to the high competitive effect of OH^-, against both oxine and CTAB, for U(VI).

The effects of reagent (CTAB and HOx) concentration on the percentage removal is summarized in Fig. 5 which suggests that uranium removal depends, among other factors, on the molar ratio of oxine/CTAB. With the initial concentration of one of these reagents held constant, the percentage of uranium removal increases with increasing concentration of the other reagent until an optimum is attained; then it tends to decrease. It was experimentally found that HOx can be removed with CTAB but hydrolytic uranyl products and the insoluble $UO_2 \cdot Ox_2 \cdot HOx$ appear to be removed in preference to HOx. Therefore, at the region of maximum uranium removal there should be a judicious balance between the ratios of free oxine, uranyl adduct, hydrolytic uranyl precipitates, and CTAB. Increasing the oxine concentration to values above that required for the balance results in increased competition of the excess oxine against the hydrolytic uranyl precipitates for CTAB. On the other hand, increasing the CTAB concentration to values higher than that of the balance results in removal of free oxine from the system by flotation, and consequently the adduct tends to dissociate. Besides, high CTAB concentrations can decrease the gas surface area available for the attachment of the uranyl adduct by reason of the increased competitive effect of CTAB for the surfaces of gas bubbles.

For recovery purposes, oxine and CTAB can be removed from the foam phase by the method suggested elsewhere (10).

Nuclear magnetic resonance studies of microemulsions and related systems: 2-butoxyethanol in water

O. DESROSIERS, T. VAN DINTER,[1] AND J. K. SAUNDERS
Department of Chemistry, Université de Sherbrooke, Sherbrooke, P.Q., Canada J1K 2R1

Received November 4, 1982[2]

O. DESROSIERS, T. VAN DINTER, and J. K. SAUNDERS. Can. J. Chem. **62**, 56 (1984).

The ^{13}C chemical shift, T_1, and ^2H T_1 data for 2-butoxyethanol (BE) in D_2O as a function of concentration are presented. The nmr parameters are consistent with thermodynamic data for the same system in that it appears that 2-butoxyethanol in water undergoes a pseudo phase transition at about 1.2 *M*. The chemical shift for each carbon is different in the microphase relative to either aqueous solution or pure BE. The shift differences are due to a combination of factors, conformer population changes, changes in the polarity of the oxygen, and a solvent effect on chemical shift. The more organic the medium, the higher the population of *trans* relative to *gauche* conformers. The motion of BE is more restricted in the microphase than in either dilute aqueous solution or in the pure liquid. The number of adsorbed D_2O molecules per molecule of BE is less in the microphase than in aqueous solution.

O. DESROSIERS, T. VAN DINTER et J. K. SAUNDERS. Can. J. Chem. **62**, 56 (1984).

On rapporte des déplacements chimiques du ^{13}C et des données de T_1 et ^2H T_1 relatives au butoxy-2 éthanol (BE) dans le D_2O en fonction de la concentration. Les paramètres de la rmn s'accordent avec les données thermodynamiques de ce système dans lequel il semble que le butoxy-2 éthanol dans l'eau subit une pseudotransition de phase à environ 1,2 *M*. Le déplacement chimique de chaque carbone est différent dans la microphase par rapport à la solution aqueuse de BE ou par rapport au BE pur. Les différences de déplacement chimique sont provoquées par une combinaison de facteurs: variation de la population du conformère, variation de la polarité de l'oxygène et l'effet du solvant sur le déplacement chimique. Plus le milieu est organique plus la population de conformère *trans* sera élevée par rapport à celle du conformère *gauche*. Le mouvement du BE est plus restreint dans la microphase que dans la solution aqueuse diluée ou dans le liquide pur. Le nombre de molécules de D_2O absorbées par molécule de BE est plus faible dans la microphase que dans la solution aqueuse.

The high solubilizing capacity of microemulsions (1), in particular in their application in tertiary oil recovery processes (2), has prompted extensive studies of their physicochemical properties (3, 4). Of particular interest is the role of the cosurfactant (5) and detection of microphase transitions if they occur. Nuclear magnetic resonance (nmr) can be of considerable value in these studies as the local environment of the various components can be ascertained from chemical shift data and the molecular dynamics can be determined from relaxation times (4) and pulsed gradient spin echo measurements (6).

As part of an nmr study of microemulsions we have examined the chemical shift (δ) and relaxation time (T_1) data of the system 2-butoxyethanol (BE) in D_2O. The study is restricted to the water-rich region. This system was chosen because BE has interesting properties as a cosurfactant (7) in microemulsions and thermodynamic data (8) have shown that it undergoes a microphase transition in the region of 0.02 to 0.04 mole fraction. Since this concentration corresponds to approximately 1.5 *M*, it was felt that it would be an excellent system to study the effect of pseudo phase transitions on nmr parameters. Also, a study of a relatively simple system should aid in the interpretation of the more complex microemulsion results. The most common microphase transition in binary aqueous systems is the formation of micelles. Chemical shift data (9–12) have been employed to detect the cmc, the concentration at which micellization occurs. From a ^{13}C relaxation time standpoint, this transition occurs at such low concentration that it is extremely difficult to detect (13). It is also difficult to detect the cmc by studying the relaxation data of the solvent, water, since the mole fraction of water at the cmc is virtually that of water itself and thus any changes in solvation are masked by the large proportion of nonsolvating water molecules.

Results and discussion

The ^{13}C chemical shifts at 32°C for C(2) (see Table 1) are plotted as a function of concentration in Fig. 1. The chemical shift dependence on concentration is not linear and an inflection occurs at 1.2 *M*, the concentration at which the microphase transition was detected by thermodynamic data (8). If follows therefore that the chemical shift in this system is sensitive to some form of phase transition and that the new microphase might be something resembling an ill-defined micelle or patches of relatively unsolvated BE molecules, as suggested by Iwasaki and Fujiyama (14). In the case of micelle formation, the number of monomers which associate to form the micelle has been determined (9, 10) by assuming the simple model $n\mathrm{M} \rightleftarrows \mathrm{M}_n$. The average aggregate number n can then be estimated using eq. [1]

$$[1] \quad \ln (C_t\, \delta_{obs}) = n \ln [C_t(\delta_{ag} - \delta_{obs})] + \ln K + \ln n - (n - 1) \ln \delta_{ag}$$

where C_t is the total concentration of solute, δ_{ag} the chemical shift in the micelle relative to aqueous solution, δ_{obs} the observed chemical shift relative to aqueous solution, and K is the equilibrium constant given by $K = [\mathrm{M}_n]/[\mathrm{M}]^n$. The value of δ_{ag} may be estimated from extrapolation of plots of δ_{obs} versus $1/C_t$ (9). Application of this model to the results for BE is given in Fig. 2 where a plot of $\ln (C_t\, \delta_{obs})$ versus $\ln [C_t\, (\delta_{ag} - \delta_{obs})]$ for C(3) at 32°C is given. The average value of n is found to be 8 ± 4, which corresponds to the value of 9 ± 3 obtained from thermodynamic data (15).

BE has the advantage relative to surfactants in that the chemical shift of pure BE can be determined directly. Table 4 con-

[a] In ppm relative to TMS; measured relative to dioxane and corrected using $\delta_{TMS} = \delta_{dioxane} + 67.4$; estimated error ±0.02 ppm.
[b] In seconds; estimated error ±5% for ^{13}C (22.6 MHz) and ±5% for ^2H (13.8 MHz).
[c] Measured at 100 MHz.
[d] Measured for OD deuterium of liquid 2-butoxyethanol at 46 MHz.

tains a comparison of pure BE chemical shifts with those obtained by extrapolation from a plot of δ_{obs} versus $[\text{concentration}]^{-1}$. For each carbon, the measured value is significantly undeshielded from that obtained by extrapolation. The most striking difference is that observed for C-3, which appears to be heading for higher field with increasing BE concentration but which is in fact deshielded in the neat liquid relative to that observed at infinite dilution in aqueous solution. Obviously then, from a chemical shift point of view, the environment for each carbon in the microphase differs from that in liquid BE.

The factors which influence ^{13}C chemical shift variations can be classified as (1) changes in conformer populations, (2) polarity changes, and (3) solvent effects. To illustrate the effect of conformer population changes, Table 3 contains the various conformations and the chemical shift increments (17) due to the *gauche* interactions in these conformations for butanol. The effect of changes in polarity and solvent effects are difficult to ascertain (18). One example where a polar effect is documented is the deprotonation of a protonated amine which deshields the β carbon by 5 ppm and the α, γ, and δ carbons by about 1 ppm (19).

The carbons of surfactants are all more deshielded when in a micelle than in aqueous solution. This has been interpreted in terms of an increase in the population of *trans* relative to the *gauche* conformations in the micelle (16). Similar results are obtained for alcohols solubilized in micelles (16) in the water-rich region. For BE, all carbons are more deshielded in the neat liquid than in the microphase. All carbons, with the exception of C-3, are more deshielded in the microphase than in aqueous solution. It appears, therefore, that more than one factor causes the chemical shift variations in BE. In order to reduce the number of factors, the chemical shifts of both 4-methylcyclohexanols, cyclohexanol, and butanol have been studied. Cyclohexanol was measured as a neat liquid and then at a relatively low concentration in water. The latter contained

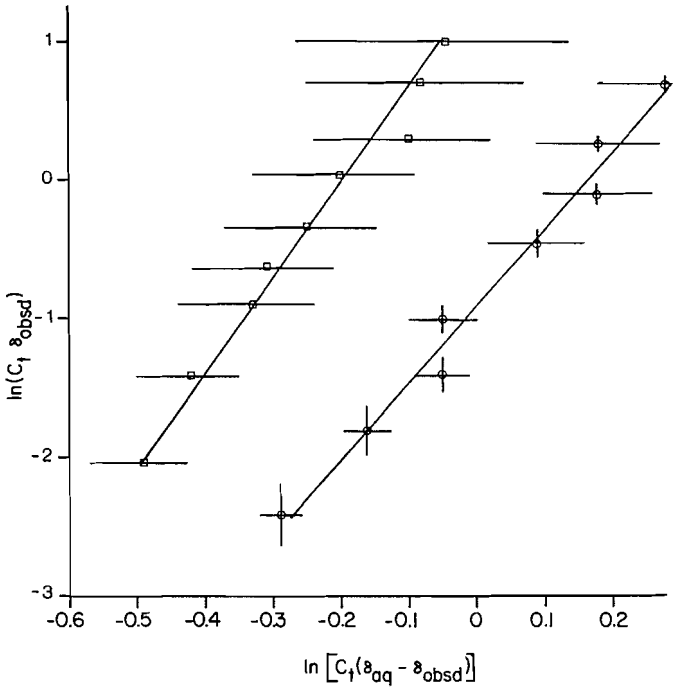

FIG. 2. Plot of ln (C_t δ_{obsd}) versus ln $C_t(\delta_{ag} - \delta_{obsd})$ for C(3) of BE at 32°C (□) and 8°C (○). The error bars for the results at 32°C represent an error of ±0.04 ppm in the estimation of δ_{ag}. The error bars for the plot at 8°C represent an error of ±0.02 ppm in δ_{obs}.

cyclohexanol present. Further dilution (factor of 5) resulted in an identical spectrum being recorded. The 4-methylcyclohexanols were measured under the same conditions. The δ values for n-butanol as a very dilute aqueous solution and as a neat liquid were also determined. The results from this study are given in Table 4.

The cyclohexanol derivatives can exist in two conformations. The preferred conformation of *trans*-4-methylcyclohexanol is estimated to be more stable by 2.6 kcal/mol (20). The energy difference for *cis*-4-methylcyclohexanol is 1 kcal/mol and for cyclohexanol it is 0.8 kcal/mol (20). Thus, for the *trans* compound, any chemical shift differences should be due to factors other than conformational population changes. The carbon carrying the hydrophilic group is more shielded in the organic than in the aqueous phase, whereas the reverse is observed for the other carbons. In light of the uniformity of the effect on the β, γ, and δ carbons, it appears unlikely that these differences represent differences in the polarity of the polar group. The differences will therefore be assigned to a direct solvent effect on chemical shift. The *cis* compound shows the same trends although the numerical values are different. The trend for the difference in Δδ values between *cis* and *trans* is consistent with an increase in the high energy conformer in aqueous solution. This corresponds to an increase in the *gauche* conformation for the methyl group. For cyclohexanol, the Δδ values are similar to those obtained for the *trans* compound. The small differences probably are a result of a conformational population change. All carbons are more deshielded in the neat liquid than when in the organic phase in water. The most significant effect is at C(2).

All carbons in butanol are deshielded in the organic relative to the aqueous phase. Inspection of Table 3 shows that a conformational population change affects all carbons in the same direction or has zero effect. The most logical interpretation of

TABLE 3. Conformations[a] and predicted chemical shift increments[b] for butanol

	Predicted shift increments			
Conformation	C-1	C-2	C-3	C-4
I	10	20	10	10
II	5	17	7	5
III	5	17	7	5
IV	7	17	5	10
VI	2	14	2	5
VII	7	17	5	10
VIII	2	14	2	5

[a] Conformations V and IX are neglected as they contain the high energy δ *syn* axial interaction.

[b] See ref. 25 for discussion of the various interactions. Since trends are required, each *gauche* interaction involving a C—H bond is incremented by 5 ppm and each C—C—C—C or O—C—C—C *gauche* interaction is incremented by 2 ppm.

the Δδ values is an increase in the *trans* conformations in the organic phase and a smaller direct solvent effect on chemical shift than that observed in *trans*-4-methylcyclohexanol.

Comparison of Δδ values for the appropriate carbons of BE with butanol suggest that the factors influencing the hydrophobic portion of BE are those which cause the Δδ values in butanol. The difference in Δδ values obtained by extrapolation relative to those recorded for a neat liquid are all in the same direction and of similar magnitude. This suggests that these differences are due mainly to changes in conformer populations, with *trans* conformations being more populated in the neat liquid. In view of the relative shielding of C(3) in the microphase relative to aqueous solution, one must conclude that these Δδ values must be due mainly to solvent effects on chemical shift. From inspection of Table 3,[3] it is obvious that conformer population changes cannot result in the relative shielding of one carbon and deshielding of all others.

Inspection of the data in Table 4 shows that the largest shift difference between pure liquid and aqueous solution occurs at the carbon β to the oxygen. From Table 3 it is evident that this cannot be ascribed to changes in conformer populations. As mentioned earlier, one factor which has a more pronounced

[3] The predicted effect on chemical shift for BE will be similar to those for butanol except that the numerical values for carbons 2–4 will show a larger variation.

[b] Organic (1) phase represents organic phase in D_2O either by extrapolation or direct measurement (see text). Organic (2) phase is as a pure liquid.
[c] For the methylcyclohexanols, C-5 refers to the methyl group carbon.

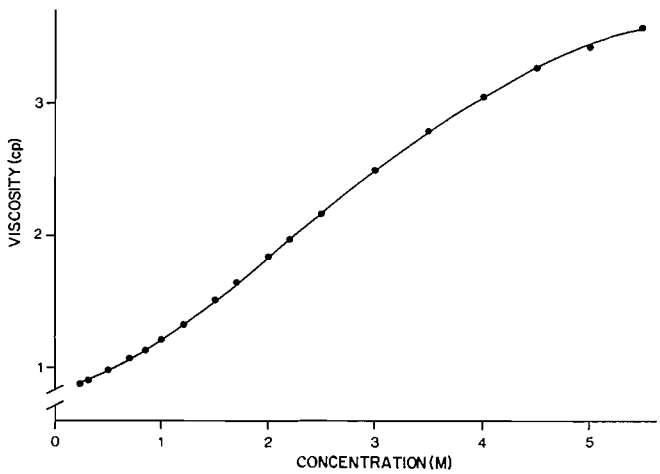

FIG. 3. Plot of viscosity as a function of concentration.

effect on the β carbon than any other carbon is a change in charge on the polar group. Thus by analogy with amines, the increased shielding at β carbons when dissolving the alcohol in water is the result of a decrease of effective negative charge on the oxygen in water. Using the amine results (19), one would expect C(2) of cyclohexanol to be shielded by about 5 ppm in the neutral species relative to the anion.

The chemical shift data at 8°C (see Table 2) show a similar dependence on concentration to that obtained at 32°C. Figure 1 contains a plot of δ as a function of concentration for C(2) at 8°C and Fig. 2 a plot of ln C_t δ_{obs} versus ln $C_t(\delta_{ag} - \delta_{obs})$ for C(3) at this temperature. The microphase transition as detected by this technique occurs at about 1.6 *M*, a higher concentration than at 32°C consistent with the thermodynamic data (8).

The relaxation rate, T_1^{-1}, is given by $T_1^{-1} = \bar{H}^2 \tau_c$ where τ_c is the correlation time and $\bar{H}$ represents the interaction responsible for the relaxation, in the present case either dipolar or quadrupolar. The correlation time according to the Stokes–Einstein equation is given by $\tau_c = 4\pi a^3\eta/3kT$, where a is the effective molecular radius and η the viscosity. Thus, in principle, the relaxation rate should depend on viscosity although in many cases this is not so. The viscosity of BE as a function of concentration is given in Fig. 3. There are 3 main points from this curve. First of all, there is an inflection at about 1.2 *M* which corresponds to the pseudo phase transition. Secondly, the viscosity at concentrations above 3.5 *M* is higher than that of liquid BE. Finally, there is no correlation between viscosity and relaxation rates.

The microphase transition is detected to be about 1.0 *M* at 32°C and 1.2 *M* at 8°C from T_1 data. Figure 4 illustrates the effect of concentration on the relaxation rate for C(1) at both temperatures. The curves for the other carbons are similar although the effect of concentration on carbons towards the end of the chain is less pronounced. Unlike surfactants in micelles (13) and microemulsions and alcohols in microemulsions (4), the relaxation rate is independent of spectrometer frequency. The nOe at 100 MHz for each carbon is 3 ± 0.1. The relaxation is therefore controlled by the dipolar interaction and the rotation can be characterized by one correlation time, τ_{eff}. The value of τ_{eff} can, however, have more than one component.

The observed relaxation rate $(1/T_1)_{obs}$ is given by eq. [2]

$$[2] \quad \left(\frac{1}{T_1}\right)_{obs} = \left[C_{ag}\left(\frac{1}{T_1}\right)_{ag} + C_m\left(\frac{1}{T_1}\right)_m\right][C_t]^{-1}$$

where the subscripts ag and m refer to BE in the microphase and as a monomer in aqueous solution respectively. This equation presumes that the T_1 values in the two phases remain constant with concentration. In view of the effect of concentration on δ values and on T_1 values in micelles (13), it would be expected that $(T_1)_{obs}$ would decrease with increasing concentration since the curve in Fig. 3 implies that $(T_1)_{ag}$ is greater than $(T_1)_m$. The fact that $(T_1)_{obs}$ remains constant after 1.7 *M* is

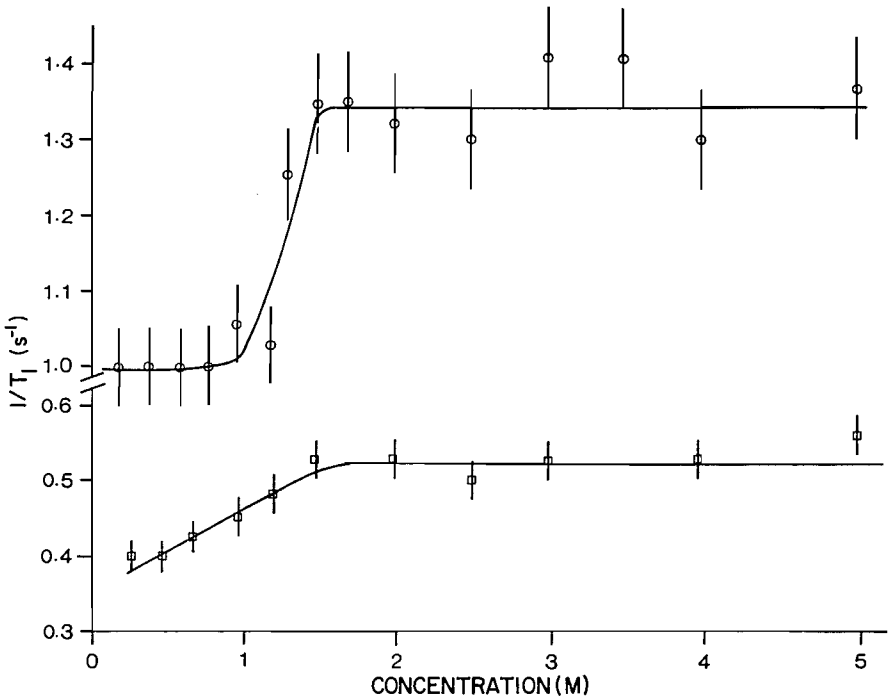

FIG. 4. Plot of $(1/T_1)_{obs}$ as a function of concentration for C(3) of BE at 32°C (□) and 8°C (○). Error bars correspond to an error of ±5%.

a consequence of either $(T_1)_m$ decreasing or $(T_1)_{ag}$ increasing as concentration increases or a combination of both.

The ^2H relaxation rates as a function of concentration are shown in Fig. 5 for the data obtained at 32°C and at 8°C. The curves have the same profile[4] at both temperatures but, again, the effect of concentration is more pronounced at the lower temperature. Since only one deuterium resonance is observed, there must be rapid exchange process between D_2O and the OD group of BE. The overall rate is then given by eq. [3]

$$[3]\quad \left(\frac{1}{T_1}\right)_{obs} = \left[2C_{D_2O}\left(\frac{1}{T_1}\right)_{D_2O} + C_{BE}\left(\frac{1}{T_1}\right)_{BE}\right][2\,C_{D_2O} + C_{BE}]^{-1}$$

where C_{D_2O} and C_{BE} are the concentrations of D_2O and BE respectively and $(T_1)_{BE}$ is the relaxation time of the deuterium of BE. The relaxation rate of the deuterium of the OD group of BE should be proportional to C(1) of BE provided the rotation rate about the C(1)—O bond remains constant and provided the quadrupolar coupling constant is independent of concentration. It has been shown (21) that the quadrupolar coupling constant of deuterium is proportional to the stretching frequency of the O—D (or O—H) bond. A study of overtones of this vibration as a function of concentration showed that ν_{O-D} was invariant within the concentrations of interest. Since the C(1) and C(2) T_1 values vary virtually identically with concentration, we have assumed that the OD does also, and have thus calculated $(T_1)_{D_2O}$ as a function of concentration using eq. [3], the C(1) T_1 values as a function of concentration, and the observed T_1 value of the OD group in BE. A plot of $(T_1^{-1})_{D_2O}$ versus concentration at 32°C is given in Fig. 6.

The relaxation rate of D_2O involved in solvation in which the D_2O is in rapid exchange between bulk liquid and being adsorbed is given by eq. [4] (22)

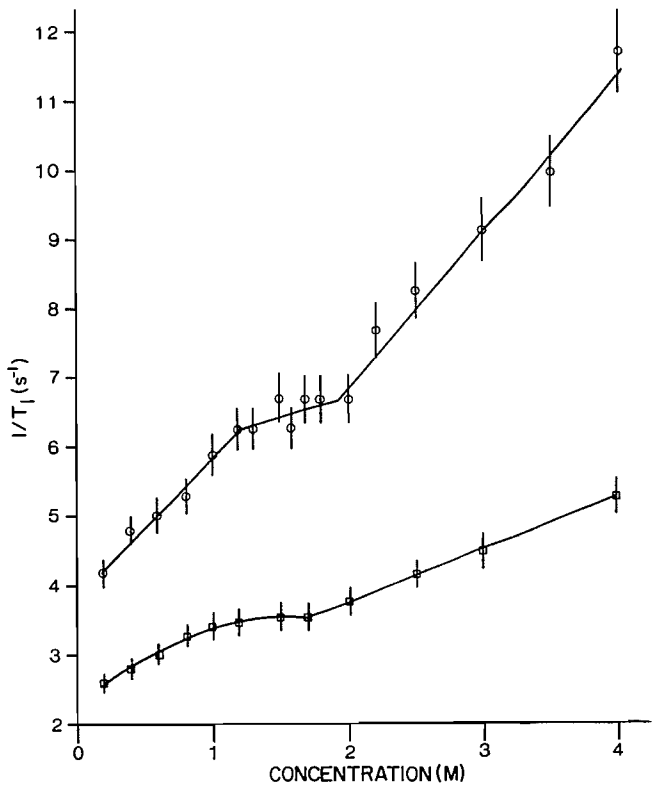

FIG. 5. Plot of ^2H $(1/T_1)_{obs}$ as a function of concentration at 32°C (□) and 8°C (○). Error bars correspond to an error of ±5%.

$$[4]\quad \left(\frac{1}{T_1}\right)_{obs} = \left(\frac{1}{T_1}\right)_{bulk}\left(1 - \frac{n_D C}{50}\right) + K^2\frac{n_D C}{50}\tau_c$$

where n_D is the number of adsorbed molecules, C the concentration of solute, $K = e^2qQ/h$ with the symbols having their usual significance, and τ_c is the correlation time of adsorbed D_2O. The relaxation rate thus increases with concentration

[4] At first glance it may appear that this curve could be represented by a straight line. We believe, however, that the curve drawn is a true representation of the effect of concentration on the deuterium relaxation rates (see experimental section for details).

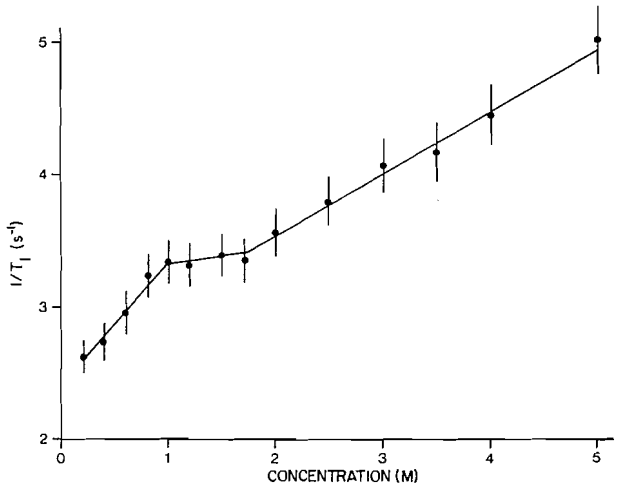

FIG. 6. Plot of $(1/T_1)_{D_2O}$ as a function of concentration at 32°C. Error bars correspond to an error of ±5%.

(23). The pseudo phase transition, then, from Fig. 6 is at about 1.25 *M*. From eq. [5] $d(1/T_1)dC$ is equal to $K^2 n_D \tau_c/50$ when $n_D c < 50$ (22). The initial slope of Fig. 5 gives, basically, $d(1/T_1)dC$ for the monomer. After the microphase transition, eq. [4] is no longer valid, since the solute is present both as a monomer and in the microphase. The second term of eq. [4] must be replaced by $K^2/50\ (n_{D_{ag}} \tau_{c_{ag}} C_{ag} + n_{D_m} \tau_{c_m} C_m)$. Extrapolation to zero concentration of the straight line in Fig. 6 obtained as a function of concentration above 1.7 *M* gives the same value of $(T_1^{-1})_{bulk}$ as the first part of the curve. The slope is less than that obtained for the first straight line. This implies that $n_{D_{ag}} \tau_{c_{AG}} < n_{D_m} \tau_{c_m}$ (n_D corresponds to the number of D_2O molecules per molecule of BE). The increase in τ_c for adsorbed D_2O relative to bulk D_2O is assumed to be due to the decreased motion of the solute causing decreased motion of the solvent rather than an increase in the structure of the water (23). In fact, $d(1/T_1)/dC$ is roughly proportional to molecular size (23) and it would therefore be expected that $\tau_{c_{ag}} > \tau_{c_m}$. We may then conclude that $n_{D_m} > n_{D_{ag}}$, which intuitively appears logical.

Conclusion

The intepretation of the effect of BE concentration on the nmr parameters employed herein is consistent with a microphase transition occuring at about 1.2 *M*, as had been detected by thermodynamic measurements. The nmr chemical shifts and thermodynamic data can satisfactorily be interpreted in terms of the simple model $n\text{BE} \rightleftarrows \text{BE}_n$. However, unlike the thermodynamic data which showed essentially BE properties after the transition, the nmr data of BE in the microphase differ from pure BE. The BE carbon relaxation rates suggest more restricted motion in the microphase than in the pure liquid. In micelles, the relaxation rates can also be interpreted in terms of the simple model $n\text{M} \rightleftarrows \text{M}_n$ which is not the case here. This may be due to failure of the model or, more likely, concentration-dependent relaxation rates of BE in the microphase, in the aqueous phase, or both. The chemical shifts for BE in the microphase differ from those observed in pure liquid. It is proposed that this difference is mainly due to conformer population changes.

The structure of the microphase from the nmr results can be rationalized better in terms of the model proposed by Iwasaki and Fujiyama (14) than in terms of some micelle-like structure. The behaviour of carbons 3–6 of BE with respect to chemical shift parallel those of cyclohexanol. For the latter, chemical shifts corresponding to cyclohexanol, both aqueous and organic phases, could be observed. For BE solutions, there is obviously rapid exchange between the aqueous and microphases such that on the nmr time scale only the average is observed. The D_2O relaxation rates are also in agreement with the model since it appears that the number of adsorbed D_2O molecules per molecule of BE is less in the microphase.

Experimental

2-Butoxyethanol, obtained from Baker Chemicals, was distilled and kept over 4 Å molecular sieves. Densities were measured with a commercial version (SODEV, Sherbrooke, Quebec) of a flow densimeter. Viscosities were measured using a standard Ostwald viscometer. Most of the nmr measurements were made on a Bruker HX-90 spectrometer. Chemical shifts were measured relative to dioxane in a central capillary and corrected to TMS. Generally such widths of 2000 Hz were employed using 8 K of data points. Shifts are estimated to be accurate to ±0.02 ppm. No corrections for bulk magnetic susceptibility were made. The T_1 measurements were obtained by use of the standard inversion recovery technique as described previously (24). Results were treated using both an exponential three-parameter fit and a logarithmic plot. The T_1 values are assumed accurate to ±5%.

These errors refer to absolute errors. The relative errors, particularly for ^2H, are significantly less. The signal-to-noise ratios for the ^2H spectra were very high and therefore many measurements could be recorded in a short time. The ^2H relaxation times at each concentration were measured several times (at least 6) and the results were reproducible to within ±2%. To verify that the curves given in Fig. 5 represent the true effect of concentration on the relaxation rates, measurements were performed at other temperatures. In each case the profile was the same, i.e. with increasing concentration T_1 decreased, then remained essentially constant, and then decreased again. Temperatures were measured by use of a thermocouple placed in an nmr tube in the magnet and are presumed accurate to ±2°C. The 100 MHz spectra were recorded at the NMR Regional Centre in Montreal.

Received April 20, 1983

TOYOAKI KIMURA, KAZUNOBU HIRAO, NAOTO OKABE, and KENJI FUEKI. Can. J. Chem. **62**, 64 (1984).

Optical absorption and photoconductivity spectra of trapped electrons in γ-irradiated 2,2,4-trimethylpentane (TMP)/2,2-dimethylbutane (DMB)/2-methyltetrahydrofuran (MTHF) mixture glasses at 77 K have been measured. It is found that the magnitude of the photocurrent increases with decreasing MTHF concentration, which is ascribed to the increase in electron mobility with decreasing MTHF concentration in TMP/DMB/MTHF systems. It is also found that the photoconductivity spectra shift to the lower energy side with decreasing MTHF concentration. Although the photoconductivity spectrum in the neat MTHF system is separated from the corresponding optical absorption spectrum, the spectrum becomes closer to the latter with decreasing MTHF concentration in TMP/DMB/MTHF systems. This result indicates that the extent of bound–free transitions increases relative to bound–bound transitions with decreasing MTHF concentration for the photon absorption process of trapped electrons in TMP/DMB/MTHF systems.

TOYOAKI KIMURA, KAZUNOBU HIRAO, NAOTO OKABE et KENJI FUEKI. Can. J. Chem. **62**, 64 (1984).

On a mesuré à 77 K les spectres d'absorption optique et de photoconductivité des électrons piégés dans un mélange vitreux de triméthyl-2,2,4 pentane (TMP)/diméthyl-2,2 butane (DMB)/méthyl-2 tétrahydrofuranne (MTHF) irradié aux rayons γ. On a trouvé que l'intensité du photocourant augmente lorsque la concentration du MTHF diminue, ce qui l'on attribue à une augmentation de la mobilité de l'électron lorsque diminue la concentration du MTHF dans le système TMP/DMB/MTHF. On a également trouvé que les spectres de photoconductivité glissent du côté de faible énergie lorsque la concentration de MTHF diminue. Bien que le spectre de photoconductivité du système MTHF pur soit séparé du spectre correspondant d'absorption optique, ces deux spectres se rapprochent beaucoup lorsque la concentration de MTHF du système TMP/DMB/MTHF diminue. Ce résultat indique que le taux de transitions liaison–libre augmente par rapport aux transitions liaison–liaison lorsque la concentration de MTHF diminue dans le processus d'absorption du photon pour les électrons piégés dans le système TMP/DMB/MTHF.

[Traduit par le journal]

Introduction

It is well known that ionizing radiations produce trapped electrons in organic glasses. Trapped electrons in γ-irradiated organic glasses at low temperatures, usually 77 or 4 K, have been widely investigated by various methods. Organic glasses used so far are such that excess electrons can be localized in them. Recently, we have found that a mixture of 2,2,4-trimethylpentane (TMP) and 2,2-dimethylbutane (DMB) makes a clear and crack-free glass at 77 K and that electrons are not stably trapped in this mixture glass (1). Previously we have used this TMP–DMB glassy matrix to investigate the mechanism of electron trapping and obtained some interesting results on trapped electrons in γ-irradiated TMP–DMB–3-methylhexane (3MHx) systems (1) and TMP–DMB–alcohol systems (2) at 77 K. Since TMP, DMB, and 3MHx are nonpolar substances, it is expected that the TMP–DMB–3MHx systems form homogeneous mixtures. On the other hand, it has been recognized that alcohol molecules aggregate and make clusters in hydrocarbon matrices (3). This implies that alcohol–hydrocarbon systems form inhomogeneous mixtures consisting of polar regions, namely, alcohol clusters and nonpolar regions surrounding the alcohol clusters. This is supported by the fact that trapped electrons in γ-irradiated alcohol–hydrocarbon systems show two separated optical absorption bands, each of which is nearly the same as that in γ-irradiated hydrocarbons or that in γ-irradiated alcohols (4). Because of such inhomogeneity, the nature of electrons trapped in alcohol clusters and in a hydrocarbon matrix is not basically affected by the concentration of added alcohol except at very low concentrations of alcohol (4). However, it has been suggested from an optical absorption study on trapped electrons in 2-methyltetrahydrofuran (MTHF)/3-methylpentane (3MP) mixture glasses that the MTHF/3MP systems are nearly homogeneous at 77 K (5). By analogy we may expect that MTHF and TMP/DMB make nearly homogeneous mixtures at 77 K. Then we could also expect that the nature of electrons trapped by polar MTHF molecules would be affected by the addition of TMP/DMB, in which electrons are not stably trapped.

In order to investigate the nature of trapped electrons in TMP/DMB/MTHF systems at 77 K, we have measured both optical absorption and photoconductivity spectra over the MTHF concentration range of 5 to 100 mol%. A number of studies have been made on the optical absorption spectra of trapped electrons in a neat MTHF glass (6), but there have been only a few photoconductivity studies of trapped electrons in this matrix (7, 8).

Experimental

Tokyo Kasei 2-methyltetrahydrofuran (guaranteed reagent) was passed through an activated alumina column under argon atmosphere and the middle portion was used for the next step of purification. This process was repeated twice. MTHF was degassed on a vacuum line and vacuum-distilled into a glass bulb with molecular sieve (13X) which had been activated at 550 K *in vacuo* for 12 h before use. After purification by the molecular sieve three times, MTHF was stored over a Na–K alloy. Nakarai Chemicals 2,2-dimethylbutane (guaranteed reagent) and Kishida Chemical 2,2,4-trimethylpentane (spectrograde) were purified using molecular sieve 13X by the same procedure as above. A mixture of TMP and DMB was made in 1:1 volume ratio at room temperature. The desired amount of sample was taken by a volumetric flask under vacuum and transferred into a conductivity cell (described below) and sealed off the vacuum line. The schematic view of the conductivity cell is shown in Fig. 1. Electrodes were made of Supracil quartz coated with In–Sn so that both conductivity and

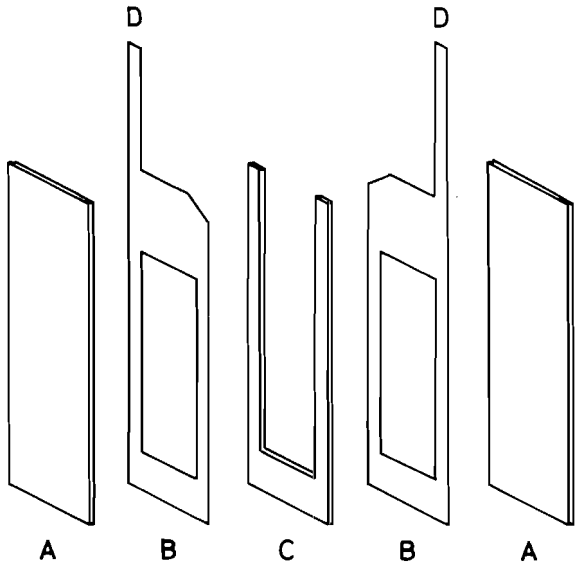

FIG. 1. Schematic view of photoconductivity cell. *A*, spracil quartz electrode coated with In−Sn; *B*, copper foil; *C*, Teflon spacer; and *D*, connection to tungsten wire (see text).

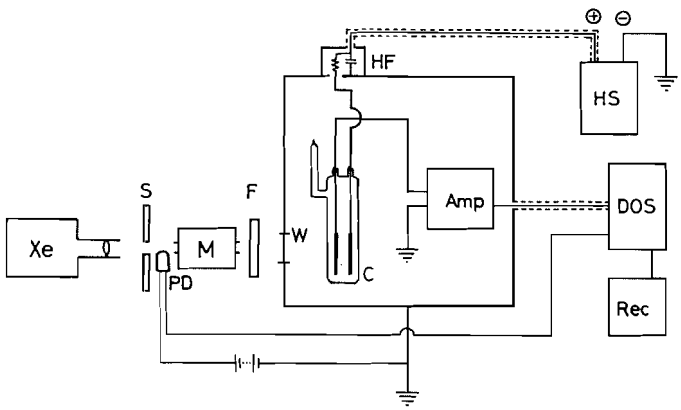

FIG. 2. Block diagram of photoconductivity measurement. Xe, xenon lamp; S, mechanical shutter; PD, photodiode; M, monochromator; F, optical filter; W, spracil quartz window coated with In−Sn; C, photoconductivity cell; HF, highvoltage filter; Amp, current amplifier; HS, high voltage supply; DOS, digital oscilloscope; Rec, recorder.

optical measurements can be made. The distance between the electrode (50 mm × 9 mm) was 0.6 mm. The block diagram of the photoconductivity measurement is shown in Fig. 2. γ-Irradiated samples in a liquid nitrogen Dewar were photoexcited by monochromatic light from a 1 kW xenon lamp (Xebex UXL 1000D-0) through a mechanical shutter, a monochromator (Ritsu MC-10N), and a glass filter. A dc voltage (500 V) from a power supply (Watanabe PH-8A) was applied to electrodes through an electrical filter. Photocurrents were amplified by a current amplifier (Keithley 427) and recorded on a digital oscilloscope (Nicolet 2090-204) which was triggered by a photodiode set behind the mechanical shutter. The photoconductivity cell unit and amplifier were shielded by a copper box which was connected to ground. Cable from the output connector of the amplifier to the oscilloscope, that from the high voltage supply to the filter, and the AC power line for the amplifier were shielded. Beside electrical noises, mechanical vibrations cause serious noises even when they are small. In order to minimize such noises from the vibrations, the copper box was mounted on a polystyrene foam and helium gas was introduced into liquid nitrogen in the Dewar before measurement. This can eliminate the noises arising from bubbling of liquid nitrogen during the measurement.

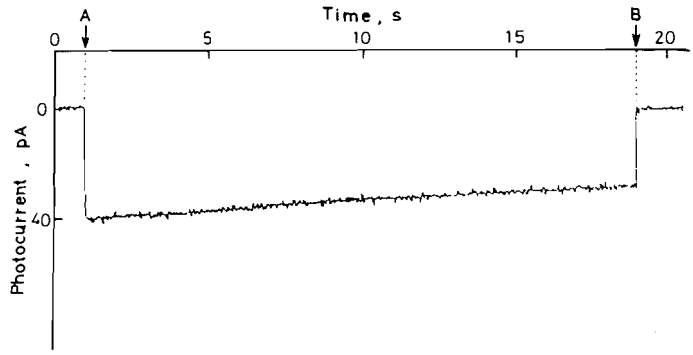

FIG. 3. Time profile of photocurrent in TMP − DMB − 5 mol% MTHF system. A, shutter opened; B, shutter closed.

For the photoconductivity measurement in the visible region, the monochromator with a bandwidth of <30 nm combined with a Toshiba UV-39 glass filter, which cuts off light shorter than 390 nm, was used. For the ir region the monochromator with a bandwidth of ~60 nm combined with either a Toshiba IR-D1A glass filter or a silicone filter, which cuts off light shorter than 900 nm or 1100 nm, respectively, was used. Light intensities were measured by a radiometer (YSI model 65A). We have made a device by which light intensities at the same position as that for the conductivity cell can be measured.

γ-Irradiation was made by γ-rays from a ^{60}Co source. The irradiation dose was 2.8×10^5 rad for photoconductivity measurements and 0.93×10^5 rad for optical absorption measurements. The optical absorption measurements were carried out with a Hitachi 323 spectrophotometer.

Results and discussion

1. Photocurrents in TMP/DMB/MTHF glasses

We have observed that photocurrents in a γ-irradiated neat MTHF glass are quite low compared with those in nonpolar hydrocarbons such as 3MP or 3MHx. The photocurrent per incident photon per unit time[1] in a neat MTHF glass was at most $\sim 10^{-31}$ C/photon, whereas those in 3MP and 3MHx are $\sim 10^{-27}$ (9) and $\sim 10^{-26}$ C/photon,[2] respectively. It is noted that the photocurrent in the neat MTHF glass is lower by five orders of magnitude than that in 3MHx. This contrasts with the published data (10) which report that the photocurrent in 3MHx is much smaller than that in MTHF, although the photocurrents are not measured with monochromatic light but by the differential filter method (8). This discrepancy might arise partly from the difference in the ways of purification. Purification in ref. 8 uses no activated alumina column with inert gas atmosphere. In a γ-irradiated MTHF glass, previously purified by an alumina column as described above, photobleaching of trapped electrons causes an esr radical signal to decrease in intensity, but a MTHF sample without such purification[3] does not show a decrease.

The time profiles of photocurrents in γ-irradiated TMP−DMB−MTHF glasses exhibit generally a flat shape. Figure 3 illustrates the time profile of the photocurrent in TMP − DMB − 5 mol% MTHF glass. It is seen that the photocurrent rises instantaneously when the shutter is opened and falls to zero

[1]The photocurrent per incident photon per unit time is expressed in units of A/(photons/s) or (C/s)/(photon/s) ≡ C/photon. Hereafter we simply call this quantity as the photocurent per incident photon.

[2]N. Okabe, T. Kimura and K. Fueki, unpublished results.

[3]The esr measurement was done at the Department of Chemistry, University of Wisconsin, in 1975.

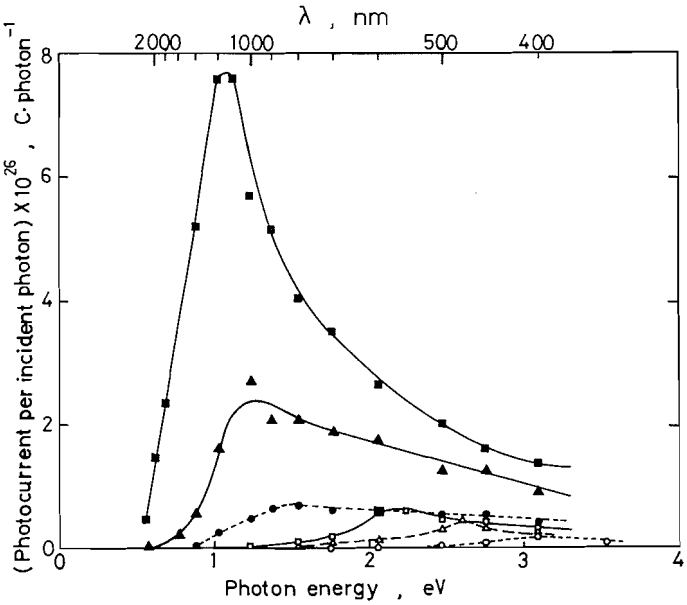

FIG. 4. Photocurrent per incident photon vs. photon energy in TMP–DMB–MTHF systems. ○, neat MTHF; △, TMP – DMB – 90 mol% MTHF; □, TMP – DMB – 75 mol% MTHF; ●, TMP – DMB – 50 mol% MTHF; ▲, TMP – DMB – 25 mol% MTHF; ■, TMP – DMB – 5 mol% MTHF.

when it is closed. In every case throughout this work neither a large decrease nor a slow rise of photocurrents such as those reported in the literature (7, 8) is observed.The flat profile of photocurrents seems reasonable because our monochromatic light cannot be expected to bleach out a significant fraction of trapped electrons within a second. It is also hard to understand the slow rise of photocurrents on a time scale of seconds unless the incident light causes a MTHF glass to increase in temperature leading to the thermal release of trapped electrons.

Since we confirm that the time profile is flat with a time constant (10 ms) of the amplifier, we use a time constant of 300 ms for the photoconductivity measurement in order to increase the S/N ratio when the photocurrent is low.

2. Photoconductivity spectra in TMP/DMB/MTHF glasses

Photocurrents per incident photon, observed at the start of light irradiation, in the TMP/DMB/MTHF systems are shown in Fig. 4. The photoconductivity spectrum for the neat MTHF glass in Fig. 4 shows that the photocurrent is maximum at a photon energy of 3.1 eV (λ_{max}^{ph} = 400 nm). This is somewhat higher than those reported in refs. 7 and 8. The photoconductivity threshold in the neat MTHF glass is obtained to be 1.5 eV (λ_{th}^{ph} = 800 nm) from the photoconductivity spectrum displayed on an enlarged scale (which is not shown here). The following facts can be seen from Fig. 4: (*1*) the maximum photocurrent in a specified TMP/DMB/MTHF system increases with decreasing MTHF concentration; and (2) the energy of the incident photons at which the photocurrent in a specified TMP/DMB/MTHF system is a maximum shifts to the lower energy side with decreasing MTHF concentration.

The photocurrent is proportional to the product of $\mu_e \cdot \tau \cdot \phi$, where μ_e is the electron mobility, τ is the lifetime of electrons in the conduction band, and ϕ is the probability of transition of the ground-state trapped electron to the conduction band induced by the incident photon (11). The values of electron mobilities in TMP and DMB at 77 K are not available at present. Tezuka *et al.* have reported the Arrhenius plot of μ_e in solid TMP in the temperature range down to 125 K (12). Extrapolating these data to 77 K leads to a value of 0.01 $cm^2\ V^{-1}\ s^{-1}$ for μ_e in TMP at 77 K, which is slightly lower than that in 3MP (13) and MTHF (14) at 77 K.[4] On the other hand, it is known that μ_e in DMB increases with decreasing temperature in the temperature range from 189 to 170 K (15). The reported value of μ_e in DMB at 170 K is ~20 $cm^2\ V^{-1}\ s^{-1}$. Thus it is expected that μ_e in DMB at 77 K would be higher than 20 $cm^2\ V^{-1}\ s^{-1}$ by simple extrapolation. The value of μ_e in MTHF is reported to be 0.055 $cm^2\ V^{-1}\ s^{-1}$ (14). However, Rice and Kevan have criticized this value later (16) and supported Ogasawara and Kevan's results, in which the lower limit of μ_e in MTHF is given to be 0.005 $cm^2\ V^{-1}\ s^{-1}$ (17). Clearly, μ_e in a 1:1 mixture of TMP and DMB would be considerably higher than that in MTHF at 77 K. Thus, the value of μ_e in TMP/DMB/MTHF systems at 77 K is expected to increase with decreasing MTHF concentration. As is shown in Fig. 4, the maximum photocurrent in TMP/DMB/5 mol% MTHF system is higher by two orders of magnitude than that in the neat MTHF system. The increase in the maximum photocurrent in the TMP/DMB/MTHF system with decreasing MTHF concentration may be explained in terms of the increase in μ_e. Another factor responsible for the increase in the maximum photocurrent would be an increase in τ with decreasing MTHF concentration, because electrons cannot be trapped in the TMP/DMB system at 77 K (1). Comparing the photocurrent in the TMP/DMB/5 mol% MTHF system with that in the neat MTHF system, the former is higher than the latter by more than one order of magnitude over the entire range of incident photon energies studied. Therefore it is unlikely that a large increase in the photocurrent in the TMP/DMB/5 mol% MTHF system is ascribed mainly to an increase in ϕ.

The V_0 values in MTHF, TMP, and DMB at 77 K are reported to be 1.15, 0.57, and 0.59 eV, respectively (18). The addition of TMP and DMB to MTHF therefore leads to lower V_0 values in the TMP/DMB/MTHF systems than that in the neat MTHF system at 77 K. The shift of the photoconductivity threshold and photocurrent maximum to the lower energy side with decreasing MTHF concentration in the TMP/DMB/MTHF systems can then be explained in terms of the decrease in the V_0 value.

3. Optical absorption spectra of trapped electrons in TMP–DMB–MTHF systems

Optical absorption spectra of trapped electrons in γ-irradiated TMP/DMB/MTHF systems at 77 K are shown in Fig. 5. Optical absorption maxima are observed around 1300 nm, indicating that electrons are trapped in MTHF aggregates. As is shown in Fig. 5, the optical absorption spectrum of trapped electrons decreases in the intensity with decreasing MTHF concentration. Two separated absorption peaks are observed over the MTHF concentration range from 50 to 100 mol%. The intensity of the peak at the shorter wavelength is higher than that at the longer wavelength in the neat MTHF system. The former is almost equal to the latter at the MTHF concentrations of 90 and 75 mol%, and the former is lower than the latter when the MTHF concentration is 50 mol%. Only one peak is observed at the MTHF concentrations of 25 and 5 mol%. Such a change in the absorption band structure perhaps indicates a change in the structure of the electron's

[4]Recent work (16) has shown that these electron mobility values (13, 14) were due to experimental artifacts.

solvation layer with MTHF concentration.

The tails of the optical absorption spectra on the shorter and longer wavelength sides converge to common curves within experimental errors over the MTHF concentration range from 25 to 100 mol% (Fig. 5). However, the curve of the spectrum for the TMP/DMB/5 mol% MTHF system lies above those for other systems at wavelengths longer than 1700 nm (0.72 eV). It should also be noted that the absorption maximum for the TMP/DMB/5 mol% MTHF system is shifted slightly to a longer wavelength compared with the remainder. The shift of the absorption maximum and the change in the relative intensities at wavelengths longer than the absorption maximum has also been reported for TMP/DMB/3MHx systems at 77 K (1).

In order to see the effect of MTHF concentration on the yield of trapped electrons in the TMP/DMB/MTHF systems, we have integrated the optical absorption spectra as displayed by OD vs. ν over the energy range from 3.65 eV (340 nm) to the thresholds of the spectra, which are obtained by extrapolating the absorption curves to zero OD. Let the number of trapped electrons per unit volume and the molar extinction coefficient of trapped electrons at ν be n_t and $\epsilon(\nu)$, respectively. The values of $n_t \int \epsilon(\nu)d\nu$ in an arbitrary unit thus obtained are shown as a function of electron fraction of added MTHF in Fig. 6. Unfortunately, no data are available for $\epsilon(\nu)$ of trapped electrons in the TMP/DMB/MTHF systems. Thus, we assume here that $\int \epsilon(\nu)d\nu$ is constant over the MTHF concentration range studied. If this assumption holds, the trapped electron yields in the TMP/DMB/MTHF systems will be higher than those expected from the contribution of direct radiolysis of MTHF added, because the experimental points lie above the dotted line in Fig. 6. Results similar to that in Fig. 6 have been previously obtained for alcohol–hydrocarbon systems in the liquid (19) and glassy states (4), but not in TMP/DMB/3MHx (1) and TMP/DMB/alcohol systems (2) at 77 K, where trapped electron yields are not higher than those expected from the contribution of direct radiolysis of 3MHx or alcohols added. Therefore it should be pointed out that the mechanism for electron trapping is different in TMP/DMB/MTHF systems and in TMP/DMB/3MHx or TMP/DMB/alcohol systems. Such difference in the electron trapping mechanism can be explained as follows: in TMP–DMB–3MHx systems, 3MHx is expected to mix homogeneously with TMP and DMB. High concentrations of TMP and DMB hinder the formation of 3MHx layers, which comprise several 3MHx molecules and are capable of trapping electrons, thus leading to a decrease in trapped electron yield. When one or two 3MHx molecules in a layer are replaced by one or two DMB molecules, the layer could lose its ability to trap an electron. On the other hand, in TMP/DMB/alcohol systems, the addition of alcohol does not appear to change substantially the property of the region outside the alcohol aggregate. Electrons generated in the TMP/DMB region outside the alcohol aggregate may preferentially react with geminate positive ions in the TMP/DMB region but not with the alcohol aggregate. Recently, we have found that some electron scavengers have considerably less efficiency for electron scavenging in the TMP/DMB systems than in other hydrocarbon systems at 77 K in which electrons can be localized.[5] The fact that the trapped electron yields lie above the dotted line in Fig. 6 can be explained if we assume that the property of TMP/DMB/MTHF systems is in between that of TMP/DMB/3MHx systems and that of TMP/DMB/alcohol systems. When MTHF is mixed with TMP and DMB, the recombination between electrons and positive ions mentioned above may be moderated by the MTHF molecules dispersing in the TMP/DMB region. In other words, since the MTHF molecule has a stronger affinity for electrons than the 3MHx molecule, it is capable of trapping electrons even when the MTHF concentration is relatively low. An alternative explanation for the difference in trapped electron yields between TMP/DMB/MTHF and TMP/DMB/alcohol systems may be the difference in the extent of aggregation of the polar component between these two systems.

It should also be noted that, as is seen from Fig. 6, the yield of trapped electrons varies by less than a factor of three over the MTHF concentration from 5 mol% to 100 mol%, but it is in the opposite direction to the change in magnitude of photocurrent.

4. Comparison between optical and photoconductivity spectra in the TMP/DMB/MTHF systems

As is already described, the photoconductivity spectra in the

25	1.4	0.7	0.89
5	1.1	0.5	0.84

TMP/DMB/MTHF systems shift towards the lower energy side with decreasing MTHF concentration, although the optical absorption spectra in these systems do not shift as significantly as the photoconductivity spectra. In order to demonstrate this clearly we have shown optical absorption and photoconductivity spectra in the TMP/DMB/MTHF system at the specified MTHF concentration in Fig. 7. The optical absorption and photoconductivity spectra in Fig. 7 are normalized to give the same value on the ordinate at each maximum. As is shown in Fig. 7, the optical absorption maximum, λ^{ab}_{max}, and photoconductivity maximum, λ^{ph}_{max}, in the neat MTHF system are separated by ~2 eV. However, λ^{ph}_{max} comes closer to λ^{ab}_{max} with decreasing MTHF concentration. In the TMP/DMB/5 mol% MTHF system the difference between λ^{ph}_{max} and λ^{ab}_{max} is ~0.2 eV. It is easy to visualize that the photoconductivity spectrum will be even closer to the optical absorption spectrum when the MTHF concentration is less than 5 mol%. The values of transition energies corresponding to λ^{ph}_{max}, λ^{ab}_{max}, and the photoconductivity threshold, λ^{ph}_{th}, for trapped electrons in the TMP/DMB/MTHF systems are listed in Table 1.

The optical absorption of trapped electrons is interpreted in terms of bound–bound and bound–free transitions (7–11, 20–22), although some workers have ascribed the entire spectrum to bound–free transitions (23). The present results also support the existence of bound–bound transitions. As is shown in Fig. 7*a*, bound–bound transitions dominate at the photon energy of ~1 eV and bound–free transitions at ~3 eV. When only bound–free transitions are allowed, photoconductivity and optical absorption spectra should be superimposable (11). Therefore, the fact that the photoconductivity spectrum in the TMP/DMB/MTHF system becomes closer to the corresponding optical absorption spectrum with decreasing MTHF concentration indicates that the extent of bound–free transitions increases with decreasing MTHF concentration. The V_0 value is expected to be lowered with decreasing MTHF concentration. The mean depth of electron traps in the TMP/DMB/MTHF system is also expected to be shallower with decreasing MTHF concentration. Thus, it seems plausible that the extent of bound–free transitions increases with decreasing MTHF concentration.

O-Methylation of a sulfone with methyl fluoride – antimony pentafluoride – sulfur dioxide. Preparation and properties of tetrahydro-1-methoxythiophenium 1-oxide hexafluoroantimonate[1]

MAGDY MALAK ABDEL-MALIK, PHILIP ARTHUR WOODWORTH DEAN, AND JAMES FREDERICK KING
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received July 5, 1983

MAGDY MALAK ABDEL-MALIK, PHILIP ARTHUR WOODWORTH DEAN, and JAMES FREDERICK KING. Can. J. Chem. **62**, 69 (1984).

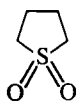
Reaction of sulfolane (tetrahydrothiophene 1,1-dioxide) (**1**) with methyl fluoride – antimony pentafluoride in liquid sulfur dioxide gives crystalline tetrahydro-1-methoxythiophenium 1-oxide hexafluoroantimonate (**2**), thereby providing the first characterized example of an alkoxysulfoxonium salt. This salt (**2**) is also formed, but more slowly, by reaction of methyl fluoride with the crystalline 1:1 complex of sulfolane and antimony pentafluoride. Reaction of **2** with nucleophiles leads to transfer of the methyl group, a facile process even with such weak nucleophiles as nitrobenzene and phenyl *N*,*N*-dimethylsulfamate. Spectroscopic evidence has been obtained for *O*-methylation of other sulfones, either by reaction with $MeF \cdot SbF_5 \cdot SO_2$, or via the sulfone $\cdot SbF_5$ complex and methyl fluoride, or by transmethylation with **2**.

MAGDY MALAK ABDEL-MALIK, PHILIP ARTHUR WOODWORTH DEAN et JAMES FREDERICK KING. Can. J. Chem. **62**, 69 (1984).

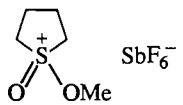
La réaction du sulfolane (tétrahydrothiophènedioxyde-1,1) (**1**) avec le fluorure de méthyle/pentafluorure d'antimoine dans du bioxyde de soufre liquide donne l'antimoine hexafluoro de tétrahydrométhoxy-1 thiophéniumoxyde-1 (**2**) cristallin fournissant ainsi le premier exemple caractérisé d'un sel d'alkoxysulfoxonium. Ce sel (**2**) se forme également, mais plus lentement, par la réaction du fluorure de méthyle avec le complexe cristallin 1:1 de sulfolane et de pentafluorure d'antimoine. Le composé **2** réagit avec les nucléophiles et conduit à un transfert de méthyle ce qui se produit très facilement même avec des nucléophiles faibles, tels le nitrobenzène et le *N*,*N*-diméthylphénylsulfamate. On a obtenu des preuves spectroscopiques pour la *O*-méthylation d'autres sulfones, soit par réaction avec le $MeF \cdot SbF_5 \cdot SO_2$ ou par l'intermédiaire du complexe sulfone $\cdot SbF_5$ et du fluorure de méthyle, soit par une trans-méthylation impliquant le composé **2**.

[Traduit par le journal]

Sulfones are notoriously weak nucleophiles, being protonated only by very strong acids and forming stable complexes only with powerful Lewis acids (1, 2, and refs. cited). The low reactivity of sulfolane[2] (**1**) has, in fact, led to its use as a solvent



1



2

for such powerful alkylating agents as methyl trifluoromethanesulfonate and trimethyloxonium tetrafluoroborate (4, 5). Whiting and co-workers (6) have shown that *O*-arylation of sulfones to form aryloxysulfoxonium salts can be effected with aryldiazonium salts, a reaction which apparently proceeds by way of the exceedingly reactive aryl cation. Alkoxysulfoxonium species, formed both by *O*-alkylation of sulfones (5, 7) and by other pathways (8–11), have been postulated as intermediates on a number of occasions. The only report known to us in which any property of an alkoxysulfoxonium salt has been described, however, is that of Jackman and co-workers (4) who mention briefly in a footnote that "treating anhydrous solutions of silver tetrafluoroborate or silver hexafluoroantimonate in sulfolane with methyl iodide" gives solutions showing a singlet at 4.45 ppm in the ^{1}Hmr spectrum; the solutions were described as "unstable at room temperature", decomposing in respectively 1 h and 24 h.

In connection with a collaborative study of the genotoxic effects of powerful alkylating agents, it has been found that sulfolane is an unreactive, water-miscible solvent suitable for the examination of the mutagenic activity of alkylating agents by the Ames test.[3] A particular focus of this study has been the use of very powerful alkylating agents not requiring any kind of potentiation *in situ* but which are added to the biological system in the form that actually delivers the alkyl group to the biological receptor. It is evident that in any such investigation the product of the alkylation of the solvent holds a unique position, since it is likely to be the most powerful alkylating agent that can reliably be added using the solvent as diluent. Any more potent alkylating agent than this will probably alkylate the solvent in the time taken to make up a solution and introduce it to the biological testing medium.[4] Accordingly, we set out to obtain a very simple *O*-alkylated derivative of sulfolane, viz. tetrahydro-1-methoxythiophenium 1-oxide hexafluoroantimonate (**2**). Its preparation and characterization, along with a preliminary study of its reactions with nucleophiles, form the basis of this paper; its behaviour in biological systems will be described elsewhere.

Results and discussion

Methyl fluoride – antimony pentafluoride in sulfur dioxide is an extremely powerful methylating agent which has been

[1]Part 25 in the series Organic Sulfur Mechanisms; for part 24, see ref. 23.

[2]In this paper we use the trivial name "sulfolane" in preference to the clumsier alternatives "tetramethylene sulfone" and "tetrahydrothiophene 1,1-dioxide"; the last is preferred by Chemical Abstracts, but the first – in its overseas form, "sulpholane" – is the entry name in the most recent edition of the Dictionary of Organic Compounds (3).

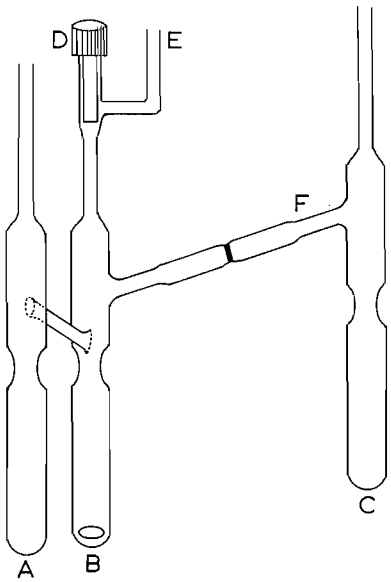

FIG. 1. Apparatus for preparation of **2**.

shown to contain $MeOSO^+$ $Sb_nF^-_{5n+1}$ (13–15). The reaction of sulfolane (**1**) with this methylating agent appeared, from preliminary experiments in conventional round-bottomed flasks, to lead to the *O*-methylated product (**2**). The ^{1}Hmr spectrum showed a sharp peak around 4.5 ppm along with complex signals centred around 3.9 and 2.6 ppm. This procedure generally gave the product as a yellowish syrup, though on one occasion white crystals were obtained; in all cases, however, the nmr spectrum of the product showed unreacted sulfolane. Use of dry box – vacuum line techniques with the apparatus shown in Fig. 1, as described in detail in the experimental section, led to a procedure in which premixed $MeF \cdot SbF_5 \cdot SO_2$ was added to a slight excess of **1** in SO_2, and which consistently gave **2** as a white crystalline solid. The identity of this material was established by elemental analysis, nmr spectroscopy, and its chemical reactions. The ^{13}Cmr spectrum of **2** (in liquid sulfur dioxide) showed resonances at δ 61.4, 50.4, and 22.7; sulfolane (**1**) itself under these conditions shows signals at 51.5 and 22.8 ppm. Comparison of the ^{13}Cmr spectrum of **2** with that of **1** and with those of other methylated sulfones (see below) allows the assignment of the signal at 61.4 ppm in the spectrum of **2** to the $\diagdown\overset{+}{\mathrm{S}}\mathrm{O}\text{—}\mathrm{O}Me\diagup$ group. The ^{1}Hmr spectrum of **2** (in CD_2Cl_2) consisted of a sharp singlet at 4.49 ppm and a pair of multiplets in the ranges 3.6 to 4.2 and 2.5 to 2.7 ppm; on decoupling (by irradiating at 2.6 and 3.9 ppm, respectively) the latter signals were in turn transformed into an AB quartet (δ 4.04 and 3.81, J_{AB} 15 Hz) and an apparent singlet (δ 2.58 ppm).

The ^{1}Hmr spectrum of a mixture of **1** and **2**, in CD_2Cl_2 or in neat **1**, is simply a superimposition of the spectra of **1** and **2**. When **2** is dissolved in sulfolane-d_8 (about 10 equiv.) and the spectrum run as soon as possible (<10 min), the multiplets around 3.9 and 2.6 ppm almost disappear, the strong signals at 3.0 and 2.2 ppm characteristic of sulfolane (**1**) appear, while the singlet at 4.49 ppm is unaltered; the spectrum remains unchanged on standing for at least one week. These observations clearly indicate that under our conditions the transfer of the methyl group from **2** to **1** is fast on the chemical time-scale ($t_{1/2}$ < 2 min), but slow on the nmr time-scale ($t_{1/2}$ > 0.025 s, as shown by the absence of coalescence of the methylene signals of **1** and **2** in CD_2Cl_2 or neat **1**).

In a sealed tube the alkoxysulfonium salt (**2**) keeps indefinitely as the crystalline solid or a solution in liquid sulfur dioxide; solutions of **2** in sulfolane showed no significant decomposition in one week but gradually turned brown over longer periods. As noted above, however, Jackman and coworkers (4) reported that **2** in sulfolane decomposes to methyl fluoride and SbF_5 in 24 h. It seems likely from the absorption they observed at 4.45 ppm in the ^{1}Hmr spectrum that they indeed had **2** in the solution, and in the absence of further information we ascribe the relatively rapid decomposition of their sample to the action of impurities.

We have also looked into the possibility of making **2** by reacting a preformed sulfolane·SbF_5 complex with methyl fluoride in the hope that, once formed, handling an easily prepared, stable isolable complex might avoid some of the experimental difficulties attendant upon frequent quantitative transfer of antimony pentafluoride. Sulfolane and SbF_5 gave a solid product which gave correct elemental analyses for a 1:1 complex and which showed ^{1}Hmr multiplets centered at 2.1 and 3.3 ppm and ^{13}Cmr lines at 53.3 and 22.6 ppm. Reaction of this complex with excess MeF in liquid SO_2 in an nmr tube showed a clean conversion to **2** which required, however, a number of hours at room temperature to go to completion.

Methylene chloride-d_2 solutions of **2**, though sufficiently stable for the determination of nmr spectra, gradually decompose ($t_{1/2}$ ~ 5 h) with formation of sulfolane and a peak at 3.0 ppm ascribed to methyl chloride; the same peak appears, but more slowly, with chloroform-*d*. These observations point to the following scheme involving initial formation of a dialkylchloronium ion (16) which then cleaves to methyl chloride and the unstable halocarbenium species (17).

$$\mathbf{2} + \mathrm{ClCD}_n\mathrm{Cl}_{(3-n)} \rightarrow \mathbf{1} + [\mathrm{CH_3}\text{—}\overset{+}{\mathrm{Cl}}\text{—}\mathrm{CD}_n\mathrm{Cl}_{(3-n)}] \rightarrow \mathrm{CH_3Cl} + [\overset{+}{\mathrm{C}}\mathrm{D}_n\mathrm{Cl}_{(3-n)}]$$

These observations, of course, imply that **2** is a very powerful methylating agent, and we have carried out some preliminary experiments using nmr to make a brief survey of its methylating capabilities. As expected, **2** reacts instantly with water, the ^{1}Hmr spectrum (in D_2O) showing a methanol resonance at 3.35 ppm and the two multiplets of sulfolane at 2.2 and 3.1 ppm. Table 1 summarizes a number of nmr experiments, which show that **2** rapidly methylates sulfoxides, diphenyl sulfide, and sulfones, and reacts rather more slowly with nitrobenzene and phenyl *N*,*N*-dimethylsulfamate. This last reaction allows a very rough comparison of **2** with methyl fluorosulfate. Whereas the reaction with **2** in CD_2Cl_2 solution (~0.1 *M* in substrate and ~0.05 *M* in **2**) was about two-thirds complete after about 40 min at room temperature, even neat methyl fluorosulfate was unreacted after 12 h at room temperature and required heating at 50°C for several hours to achieve the same extent of methylation (18); one may thus conservatively estimate that **2** is at least three orders of magnitude more reactive than methyl fluorosulfate. The reactions of **2** with dimethyl and diethyl sulfones were, like that with sulfolane-d_8, complete in less than the time required to observe the nmr spectrum. The spectra showed peaks appropriate to equilibrium mixtures (in CD_2Cl_2) with equilibrium constants, *K*, of roughly 0.3 and 0.6, respectively.

$$R_2SO_2 + \mathbf{2} \overset{K}{\rightleftharpoons} R_2\overset{+}{\mathrm{S}}(=\mathrm{O})\mathrm{OMe}\ \ SbF_6^- + \mathbf{1}$$

TABLE 1. Methylations[a] with tetrahydro-1-methoxythiophenium 1-oxide hexafluoroantimonate (**2**)

Substrate	^{1}Hmr peaks[b]	Assignment	Reaction extent and time
$PhNO_2$	4.84(s), 7.8–8.8.0(m), 8.6–8.7("d")		>60% in 40 min

[a]In CD_2Cl_2 at room temperature.
[b]XL-100 spectra.
[c]Reported: 4.65 and 7.6–8.2 ppm in liquid SO_2 (16).
[d]J. D. Lock (unpublished observations in this laboratory) found 3.23 and 4.02 ppm (in CD_3CN).
[e]Reported: 3.70 and 7.56 ppm (in CD_3CN) (18).
[f]Reported: 4.86, 3.18, 2.24 ppm in liquid SO_2 (16).

We have also explored the preparation of other *O*-methylated sulfones by reaction of the sulfone with $SbF_6 \cdot MeF \cdot SO_2$. The ^{13}Cmr spectrum of the product from dimethyl sulfone showed peaks at 60.9 and 39.9 ppm along with a signal for the unreacted sulfone (at 42.8 ppm). Upon washing with Freon 21 we obtained a solid material which appeared to be a 60:40 mixture of $Me_2\overset{+}{S}O$—OMe SbF_6^- and Me_2SO_2, but we were unable to remove the remaining sulfone. The peaks at 60.9 and 39.9 ppm also appeared when dimethyl sulfone was mixed with **2** in liquid SO_2, with the signal amplitudes corresponding to $K \sim 0.4$. Reaction of the solid $Me_2SO_2 \cdot SbF_5$ complex with methyl fluoride in liquid SO_2, overnight at room temperature, gave a material which showed strong ^{13}Cmr resonances at 60.7 and 39.8 ppm (from $Me_2\overset{+}{S}O_2Me$ and $Me_2\overset{+}{S}O_2$Me respectively) with only a weak signal (at 42.6 ppm) due to unreacted Me_2SO_2, thereby evidently providing the cleanest specimen of $Me_2\overset{+}{S}O$—OMe SbF_6^- that we have observed to date.

Attempts to methylate diethyl sulfone with $MeF \cdot SbF_5 \cdot SO_2$ gave only intractable oily products, while transmethylation with **2** in liquid SO_2 gave a mixture showing ^{13}Cmr lines due to unreacted diethyl sulfone (δ_C = 46.6 and 5.4 ppm), unreacted **2**, and the expected $Et_2\overset{+}{S}O_2$Me (δ_C = 61.0, 46.6, and 5.4 ppm); we estimate $K \sim 0.8$ in liquid SO_2. Similar reactions of diphenyl sulfone showed largely unreacted starting materials with small peaks at 62.3, 129.2, 132.0, and 139.3 ppm, reasonably attributable to $Ph_2\overset{+}{S}O$—OMe SbF_6^- ($K < 0.1$).

This study shows that alkoxysulfoxonium salts are stable, isolable materials with interesting potential as alkylating agents. We hope to exploit this potential in future work.

Experimental

Sulfolane (tetramethylene sulfone; Aldrich Chemical Co.) was purified as described in the literature (19) and stored over 3 Å molecular sieves at 40°C. Antimony pentafluoride (PCR Research Chemicals, Inc.) was distilled twice in a dry nitrogen atmosphere before use, then stored in a sealed container in a dry box. Sulfur dioxide (Canadian Liquid Air Ltd; anhydrous grade) and dichlorofluoromethane (Freon 21; Matheson of Canada Ltd.) were allowed to stand over 3 Å molecular sieves, in the gas and liquid phases, respectively, for at least 12 h before use. Neither methyl fluoride (Pfaltz and Bauer, Inc.) nor dimethyl sulfone (Aldrich Chemical Co.) showed any significant impurity by ^{1}Hmr spectroscopy; they were used as received, as were diphenyl sulfone (Aldrich), which showed no impurity by ^{13}C nmr, and sulfolane-d_8 (Merck Sharp and Dohme Canada Ltd.). Diethyl sulfone was prepared by oxidation of diethyl sulfide with hydrogen peroxide – acetic acid; mp 73°C (lit. (20) mp 70°C).

The reaction vessel for the reactions with methyl fluoride – antimony pentafluoride (Fig. 1) consisted of three 18-mm od glass tubes, A, B, and C, each with constriction, as shown, and of roughly 20-mL capacity. The upper part of tubes A and C was made of 9-mm od (ca. 6-mm id) special-wall glass tubing (which is particularly easy to flame seal) while tube B was topped by a 6-mm Rotaflo Teflon stopcock, D. The A–B connection was of 9-mm od special-wall tubing and sloped upwards at ca. 30° above horizontal from B to A while the C–B connection similarly sloped from B to C but had in it a 10-mm medium sinter; the A–B and B–C connections were mutually at right angles. Tube B, the principal reaction vessel, contained a Teflon-covered magnetic stirrer bar. The dimensions of the apparatus were determined in large part by the necessity of having it pass through the 30-cm diameter port of the glove box (see below).

The apparatus was baked out at 140°C (50°C for the Teflon stopcock) and then transferred to an N_2-filled dry box in which the dry atmosphere was maintained by circulation through liquid nitrogen cooled copper coils.

Reaction of sulfolane with methyl fluoride – antimony pentafluoride

In the glove box, antimony pentafluoride (4.2 g; 19 mmol) was added to tube B from an all-glass syringe. The stopcock D was closed and the openings on A and C were sealed with serum caps before the apparatus was removed from the dry box. Using standard N_2-vacuum techniques, warm liquid sulfolane (2.5 mL, 26 mmol) was injected into the tube A under nitrogen. The apparatus was then attached to a glass and Teflon vacuum line at E using a 3/8-in. Ultratorr fitting, evacuated, and, with A and B cooled in liquid nitrogen, the 9-mm tubes attached to A and C were flame sealed. On the calibrated

For personal use only.

vacuum line, SO_2 (ca. 75 mmol) was metered into tube B by gaseous volume and a similar amount was condensed onto the sulfolane. Methyl fluoride (25 mmol) was similarly condensed into tube B, before closing D. The apparatus was moved from the vacuum line and allowed to warm to room temperature (**with care!** the vessel being under ca. 3 atm pressure).

The mixture of SbF_5 and CH_3F in SO_2 was stirred for 15 min at room temperature, then poured into the sulfolane solution in tube A; the addition was noticeably exothermic and was accompanied by the appearance of a slight yellow colour. The total reaction mixture was returned to tube B and stirred for a further 15 min. Excess CH_3F and SO_2 were removed by slow cooling of tube A over a few hours. Finally A was frozen in liquid N_2 before flame sealing the arm between A and B. After reattachment to the vacuum line, dichlorofluoromethane (ca. 10 mmol) was condensed through D onto the oily, yellow viscous residue in tube B using liquid nitrogen cooling. The apparatus was once more removed from the vacuum line and allowed to warm to room temperature. The Freon–product mixture was stirred for 5–10 min before decanting the upper (Freon) layer (which contains unreacted sulfolane) from B into C. The Freon was returned to tube B by cooling and this washing process repreated twice. Finally, the Freon was returned to B and the heterogeneous mixture of the product with Freon kept in an ice bath for about 30 min. During this time, white crystals of the product formed. The mother liquor was decanted into C and the product washed twice with Freon before cooling C in liquid N_2 and flame sealing at F.

The rest of the apparatus (tube B) containing the pure product was reattached to the vacuum line and pumped for several hours to remove any residual Freon. In the dry box, the apparatus was broken at the constriction. The product (5.8 g, 82% yield) was transferred to a sealable glass container and stored in the dry box at room temperature. Under these conditions little deterioration was noticed over a period of several months. *Anal.* calcd. for $C_5H_{11}O_2SSbF_6$: C 16.19, H 2.99, S 8.64, Sb 32.82; found: C 16.05, H 3.09, S 8.66, Sb 33.13.

Preparation of antimony pentafluoride – sulfolane 1:1 adduct

A two-armed H-shaped glass reaction/filtration vessel of a type described earlier (21) was used for this synthesis. In the glove box, antimony pentafluoride (4.0 g, 18 mmol) was added from an all-glass syringe to the arm with no stirrer. The 9-mm od outlet of each tube was capped with a serum cap for removal of the apparatus from the dry box. Outside the glove box, liquid sulfolane (1.9 mL, 20 mmol) was added to the arm with the stirrer under a flow of dry nitrogen. The apparatus was attached to the vacuum line at the sulfolane side, evacuated, and flame sealed at the unattached outlet. Sulfur dioxide (ca. 75 mmol) was introduced with liquid nitrogen cooling prior to separation from the vacuum line by flame sealing at the 9-mm outlet. With care (see above), the apparatus was allowed to warm to room temperature, some SO_2 was condensed onto the SbF_5 by gentle cooling, and the SbF_5 solution was slowly added to the well-stirred sulfolane solution. Slow reduction of the solution volume by cooling the opposite arm, with the concomitant cooling effect on the product solution, resulted in crystallization of the product which was filtered off, washed with small portions of SO_2, and isolated in the general manner reported previously (21). *Anal.* calcd. for $C_4H_8O_2SSbF_5$: C 14.26, H 2.39; found: C 14.03, H 2.56.

Nuclear magnetic resonance samples and spectra

Samples for proton nmr spectroscopy, except those involving liquid SO_2 as solvent, were prepared in standard 5-mm od capped nmr tubes. The experiments in Table 1 were carried out by transferring **2** (~20 mg, ~0.05 mmol) to the nmr tube in the dry box and adding the substrate (~0.1 mmol), CD_2Cl_2 (1 mL), and TMS. The spectra (XL-100) were run within 5 min, with subsequent spectra to follow the course of slow reactions run on the T-60 at appropriate intervals.

For samples in liquid SO_2 the procedure was as follows: a 5-mm od medium-walled nmr tube sealed onto ca. 8-cm lengths of 9-mm od special-walled glass tubing was baked out at 140°C; under an atmosphere of dry nitrogen (in the dry box for solid materials or a flow of H_2SO_4-dried N_2 for liquids) an appropriate mass of each solid reactant or volume of liquid sulfolane was added to the tube; the tube was attached to the calibrated vacuum line via the 9-mm tubing and 3/8-in. Ultratorr union and evacuated; with liquid N_2 cooling, appropriate amounts of SO_2 and MeF, when needed, were metered into the tube before flame sealing at the top of the 5-mm od section. Samples for ^{13}C nmr spectroscopy of SO_2 solutions were made up in an analogous manner in flame-sealed handmade tubes of 10-mm od standard-wall glass tubing.

Samples contained in capped tubes were used immediately. Similarly the solutions in flame-sealed tubes were used fresh or stored in liquid nitrogen until used.

Proton nmr spectra were measured using a Varian T-60, Varian EM-360, or Varian XL-100-12 spectrometer. All the ^{13}C nmr spectra were obtained at 308 K using the XL-100-12 spectrometer system operating at 25.2 MHz in the FT mode; the 10-mm sample tubes were held coaxially in a 12-mm od standard nmr tube and a 10% (v/v) solution of dioxane in D_2O in the outer annulus was used as an external ^2D lock and ^{13}C reference, as described earlier (22). For this reference, δ_C (TMS in SO_2, int) = δ_C (dioxane in D_2O, ext) + 67.8 ppm (22). Typically, satisfactory ^{13}C nmr spectra of ca. 0.15 *m* solutions were obtained in several thousand transients with a 5 kHz spectra window, 3.3 s acquisition time, 3.5 s cycle time, and 35° (8.5 μs) tip angle (pulse width) (28° (7 μs) for samples containing Ph_2SO_2).

Vinyl ether hydrolysis. XVII. Oxacyclonon-2,8-diene and the question of the unorthodox reaction mechanism for 9-methoxyoxacyclonon-2-ene[1]

R. A. BURT, Y. CHIANG, A. J. KRESGE,[2] AND S. SZILAGYI

Department of Chemistry and Scarborough College, University of Toronto, Scarborough, Ont., Canada M1C 1A4

Received June 1, 1983

R. A. BURT, Y. CHIANG, A. J. KRESGE, and S. SZILAGYI. Can. J. Chem. **62**, 74 (1984).

The acid-catalyzed hydrolysis of the nine-membered ring cyclic vinyl ether, oxacyclonon-2,8-diene, occurs with a normal isotope effect, $k_{H^+}/k_{D^+} = 1.94$, which indicates that this reaction proceeds by the conventional vinyl ether hydrolysis mechanism involving rate-determining proton transfer to carbon. The specific rate of this reaction, $k_{H^+} = 3.9 \times 10^{-3} M^{-1} s^{-1}$, may then be used to show that there is no significant ring-size effect on the rate of hydrolysis of a vinyl ether group in a nine-membered ring. The previously noted unusually great reactivity of the vinyl ether group in 9-methoxyoxacyclonon-2-ene, for which an unorthodox reaction mechanism has been claimed, must therefore be due to some other cause.

R. A. BURT, Y. CHIANG, A. J. KRESGE et S. SZILAGYI. Can. J. Chem. **62**, 74 (1984).

L'hydrolyse de l'éther vinylique cyclique à 9 chaînons, oxacyclononedième-2,8, catalysée par un acide, se produit avec un effet isotopique normal $k_{H^+}/k_{D^+} = 1,94$ qui indique que cette réaction se fait selon le mécanisme conventionnel d'hydrolyse d'un éther vinylique qui implique comme étape déterminante le transfert du proton au carbone. On peut utiliser la vitesse spécifique de cette réaction $k_{H^+} = 3,9 \times 10^{-3} M^{-1} s^{-1}$ pour montrer alors que la dimension du cycle n'a pas un effet significatif sur la vitesse d'hydrolyse d'un éther vinylique dans un cycle à 9 chaînons. La grande réactivité d'un groupe éther vinylique dans le méthoxy-9 cyclononène-2 rapportée antérieurement, et pour laquelle on a proposé un mécanisme peu orthodoxe doit donc être dû à d'autres causes.

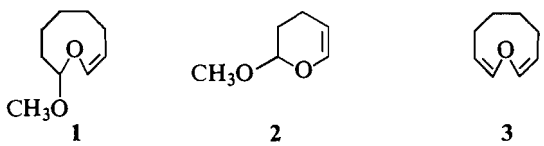
[Traduit par le journal]

The acid-catalyzed hydrolysis of simple vinyl ethers is known to occur by rate-determining protonation of the β-carbon atom of the double bond system [1], followed by rapid steps which convert the ensuing alkoxycation to a

$$[1]\quad CH_2{=}CHOR \xrightarrow[slow]{HA} CH_3\overset{+}{C}HOR$$

$$[2]\quad CH_3\overset{+}{C}HOR \xrightarrow[fast]{H_2O} CH_3\underset{OH}{C}HOR \xrightarrow[fast]{} CH_3\underset{O}{C}H + HOR$$

hemiacetal intermediate and then transform the latter into saturated alcohol plus aldehyde or ketone products [2] (1). The sole exception to this reaction mechanism appears to be the hydrolysis of the vinyl ether functional group in 9-methoxyoxacyclonon-2-ene, **1** (2).[3] Evidence obtained for this substrate



1 **2** **3**

suggests that, in dilute hydrochloric acid solution, it reacts by slow proton transfer to carbon, but that in acetic acid buffers some subsequent step becomes rate determining and carbon protonation therefore is reversible.[4]

We have tried, so far with no success, to induce a similar change in rate-determining step in the hydrolysis of other vinyl ethers (7). In the course of this work, however, we learned that **1** appears to be unusually reactive, even under conditions where its hydrolysis mechanism seems to be normal: the six-membered ring homolog of **1**, 2-methoxy-2,3-dihydropyran, **2**, is 500 times less reactive (7*b*). In order to detemine whether this unexpected reactivity is a consequence of the difference in ring size between **1** and **2**, or is caused by some further peculiarity in the mechanism of hydrolysis of **1**, we have now examined the reaction of oxacyclonon-2,8-diene, **3**, a cyclic vinyl ether whose ring contains the same number of atoms as **1**.

Experimental

Materials

Oxacyclonon-2,8-diene was prepared from 1,3-cyclooctadiene (Chemical Samples Co.) via the monoepoxide (8) by a modification of the thermolysis method of Crandall and Watkins (9), using a higher temperature and shorter reaction time plus diphenyl ether as a diluent to suppress polymerization. Maximum yields of the divinyl ether (48%) were obtained by heating the epoxide plus an equal amount of diphenyl ether at 255°C for 60 min in a Pyrex vessel, which had been washed with aqueous sodium hydroxide, water, and then carefully dried. The product was separated from diluent and unconverted starting material by hplc; its nmr spectrum was consistent with its structure.

All other materials were best available commercial grades. Solutions in H_2O were prepared using deionized water which was purified further by distillation from alkaline permanganate, and those in D_2O using heavy water (Merck, Sharpe, and Dohme) as received.

Kinetics

Rates of reaction were determined spectroscopically by monitoring the strong end absorption of oxacyclonon-2,8-diene at 200 nm. Measurements were made using a Cary Model 118C spectrometer with cell compartment thermostatted at 25.1 ± 0.05°C. Absorbance readings were generally taken to about 90% reaction and endpoints were measured after 10 half-lives. The latter were stable, and the data conformed to the first-order rate law precisely.

Results

First-order rate constants for the hydrolysis of oxacyclonon-2,8-diene catalyzed by dilute hydrochloric acid were deter-

[a]Ionic strength = acid concentration.

mined in H_2O and in D_2O solution; the data are summarized in Table 1. In both solvents the reaction rate proved to be exactly proportional to acid concentration with no detectable uncatalyzed component. Linear least-squares analysis gave the following second-order rate constants: $k_{H^+} = (3.90 \pm 0.02) \times 10^{-3}\ M^{-1}\ s^{-1}$ and $k_{D^+} = (2.01 \pm 0.03) \times 10^{-3})\ M^{-1}\ s^{-1}$; these provide the isotope effect $k_{H^+}/k_{D^+} = 1.94 \pm 0.03$.

Rates of reaction were also measured in concentrated perchloric acid in H_2O only, in the range 5–20 wt.% acid; these data are summarized in Table 2. In this medium, first-order rate constants increased with acidity more rapidly than in direct proportionality to the first power of acid concentration, and an acidity function had to be used to correlate the data. The X_0 function (10), which appears to be the best currently available measure of acidity in aqueous perchloric acid (11), gave a good linear relation (Fig. 1), but the second-order rate constant obtained from the intercept of this plot, $k_{H^+} = (4.71 \pm 0.11) \times 10^{-3}\ M^{-1}\ s^{-1}$, is some 20% higher than that measured directly in dilute hydrochloric acid solutions; this exemplifies the difficulty of making accurate extrapolations from concentrated to dilute aqueous acids.

Discussion

The isotope effect determined here for the hydrolysis of oxacyclonon-2,8-diene catalyzed by the hydronium ion is in the normal direction and of appreciable magnitude: $k_{H^+}/k_{D^+} = 1.94$. This indicates that proton transfer from this acid to the substrate occurs in the rate-determining step of this reaction, and that the hydrolysis of this vinyl ether takes place by the normal slow proton transfer mechanism of eqs. [1] and [2].

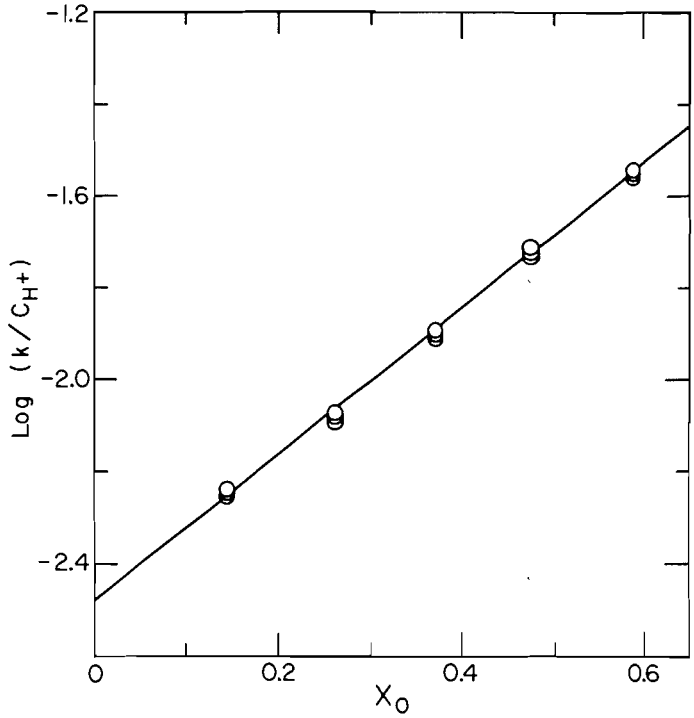

FIG. 1. Rates of hydrolysis of oxacyclonon-2-8-diene measured in concentrated aqueous perchloric acid correlated by the Cox–Yates X_0 function.

This mechanistic conclusion is reinforced by the very close correspondence of this isotope effect to the value predicted, $k_{H^+}/k_{D^+} = 1.97$, from a correlation of isotope effects with free energies of activation for a group of some 30 vinyl ethers known to react by this mechanism (1*c*).

With this mechanistic assignment in hand, an estimate of the effect of ring size upon the reactivity of the vinyl ether functional group in 9-methoxyoxacyclonon-2-ene, **1**, and 2-methoxy-2,3-dihydropyran, **2**, may be made. The fact that the presently studied substrate has two vinyl ether groups sharing the same oxygen atom, and will consequently be less reactive than a simple single vinyl ether, must be taken into account. This may be done by introducing the factor 210, which is the ratio of specific rate constants for the hydrolysis of ethyl vinyl ether, $k_{H^+} = 1.75\ M^{-1}\ s^{-1}$ (1*b*) and divinyl ether, $k_{H^+} = 8.3 \times 10^{-3}\ M^{-1}\ s^{-1}$ (12). This treatment gives $k_{H^+} = (3.9 \times 10^{-3})\ (210) = 0.82\ M^{-1}\ s^{-1}$ as the predicted specific rate of hydrolysis of the nine-membered cyclic vinyl ether oxacyclonon-2-ene, **4**, which is only a factor of three greater

4 **5**

than the observed specific rate of hydrolysis of the corresponding six-membered ring substrate, 2,3-dihydropyran, **5** (13).

This comparison shows that there is no significant ring-size effect on the rate of hydrolysis of a vinyl ether functional group when this group is incorporated into a six- or a nine-membered ring. The unusually great reactivity of the vinyl ether group in 9-methoxyoxacyclonon-2-ene, **1**, i.e. the factor of 500 by which the rate of hydrolysis of this substance exceeds that of its six-membered ring model, 2-methoxy-2,3-dihydropyran, **2**, must then be due to some other cause.

Enzymes in organic synthesis. 30.[1] Reaction conditions – control of enantiomeric purities. Horse liver alcohol dehydrogenase-catalyzed reductions of 2-alkylcyclohexanones and their thiopyran analogs

J. BRYAN JONES AND TETSUO TAKEMURA[2]
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received May 6, 1983

J. BRYAN JONES and TETSUO TAKEMURA. Can. J. Chem. **62**, 77 (1984).

The effects of buffer, pH, reaction time, and [enzyme]/[substrate] ratio on the enantiomeric purities of the alcohol products of horse liver alcohol dehydrogenase-catalyzed reductions of (±)-α-alkylcyclohexanones and -tetrahydrothiopyranones have been studied. For poor substrates of this type, formation of enantiomerically pure products is assured when pH 8 and $<0.5 \times 10^{-4}$ [E]/[S] ratio conditions are used.

J. BRYAN JONES et TETSUO TAKEMURA. Can. J. Chem. **62**, 77 (1984).

On a étudié les effets de tampon, de pH, de temps de réaction et du rapport [enzyme]/[substrat] sur la pureté énantiomorphe des alcools obtenus par la réduction des (±)α-alkylcyclohexanones et des tétrahydrothiopyranones catalysées par la déshydrogénase de l'alcool du foie de cheval. Dans le cas des substrats pauvres de ce type, on s'assure de la formation de produits énantiomorphes purs lorsque le pH est de 8 et le rapport [E]/[S] $< 0,5 \times 10^{-4}$.

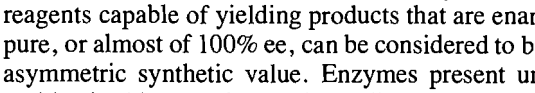
In recent years the requirements of synthetic organic chemists for reagents capable of effecting asymmetric tranformations have increased dramatically. Nowadays, only reagents capable of yielding products that are enantiomerically pure, or almost of 100% ee, can be considered to be of practical asymmetric synthetic value. Enzymes present unique opportunities in this regard, with horse liver alcohol dehydrogenase (HLADH)[3] being one of the best documented enzymes of synthetic value. HLADH is a commercially available enzyme that catalyzes oxidoreductions of the type depicted in eq. [1].



[1] $\text{>C=O} + \text{NADH} + \text{H}^+ \rightleftharpoons \text{>CHOH} + \text{NAD}$

Many HLADH-catalyzed reactions lead to enantiomerically pure products, particularly when the substrates are rapidly transformed (2, 3). However, for poor racemic substrates such as 2-alkylcyclohexanones (±)-**1** and 3-alkyltetrahydrothiopyranones (±)-**2**, for which both enantiomers can fit productively at the active site, products of <100% ee can result (4). We have now investigated the influence of reaction conditions on product ee. In this paper, limiting conditions are identified that guarantee enantiomerically pure products in HLADH-catalyzed reductions of poor substrates.

Results

2-Ethylcyclohexanone ((±)-**1***b*) and 3-ethyltetrahydrothiopyran-4-one ((±)-**3***b*) were selected as being representative of poor ketone substrates. Their HLADH-catalyzed reductions (Scheme 1) were studied under preparative-scale conditions on up to 2 g of the ketones, employing ethanol to effect coupled-substrate (3) recycling of the catalytic amount of nicotinamide coenzyme employed. The course of the reductions was monitored by glc and the *trans*-alcohol products **2***b* and **4***b* of primary interest were separated from the unchanged ketones by mplc.

Minor (<2%) amounts of the *cis*-alcohol isomers were isolated in a number of reactions (4). These by-products were discarded. The ees of the *trans*-alcohol products **2**,**4***b* were measured directly by ^{1}H nmr examination of the methoxyl peaks of their MTPA esters in the presence of Eu(fod)$_3$ (5). The ees of the recovered thiopyran ketones (−)-**3***b*, and of the cyclohexyl ketones (−)-**1***a*,*b* of Scheme 2 were established by ^{13}C nmr determinations on their (2*R*,3*R*)-2,3-butanediol ketals (6). The optical purities of the recovered 2-ethylcyclohexanones (−)-**1***b* of the Scheme 1 reactions were assigned from their optical rotations. The absolute configurations of the ketones (−)-**1**,**3***b* and alcohols (+)-**2**,**4***b* were verified by comparison with previously authenticated (4) samples.

The survey of reaction condition effects was begun by examining the influence of pH on the yield and rate of formation of the *trans*-alcohols **2***b* from (±)-**1***b*. The results are summarized in Table 1. The practical rates of reduction are slowest at the lowest pH's and reach a maximum at pH 8. Accordingly, the subsequent delineation of reaction conditions that maximize both yield and ee of the *trans*-alcohol products was largely performed at pH 8, using Tris-HCl buffer for convenience. The effects of varying the [E]/[S] ratio, the extent of reduction, and the reaction time are recorded in Table 2. The best yields and highest ees of both **2***b* and **4***b* are obtained with the shortest reaction times and employing the lowest [E]/[S] ratios.

HLADH-catalyzed oxidations of the racemic *trans*-alcohols **2***a*,*b* were carried out in order to confirm that the (1*S*,2*S*)-2-alkylcyclohexanol stereoisomers that formed preferentially in the Scheme 1 reductions were also the enantiomers most readily oxidized. This was found to be so, with the (1*R*,2*R*)-stereoisomers of **2***a*,*b* being recovered as shown in Scheme 2. FMN was used to effect recycling (7) of the NAD coenzyme in these experiments.

Discussion

All reactions were assayed under preparative-scale conditions since a practical, rather than kinetic, evaluation of the effects of reaction conditions on product ee was desired. The

thiopyranone (±)-**3***b* was a better substrate than its cyclohexane analog (±)-**1***b* (Table 2), but the responses of both substrates to the reaction conditions were very similar in stereospecificity terms, as expected (4). In keeping with the asymmetric synthetic thrust of the investigation, the products were isolated prior to their characterization and analysis. The ees of the *trans*-alcohols (+)-**2**,**4***b* of primary interest were determined directly by nmr and are considered accurate to ±3%. The optical purities of the recovered ketones (−)-**1***a*,*b* and (−)-**3***b* of Schemes 1 and 2 were too far below asymmetric synthetically valuable levels to warrant the precision of direct ee determinations, and optical rotation values, previously correlated with nmr-based ees (4), were used to calculate all but a few of their optical purities.

Each of the Table 1 and 2 assays was terminated at ≤50% reduction since the substrates were racemates. However, the reductions will proceed beyond the 50% point if longer reaction times are employed (Table 1), due to slow reductions of the less reactive ketone enantiomers. The latter also epimerize slowly under the reaction conditions, thereby gradually regenerating the more rapidly reduced enantiomers of **1**,**3***b*.

Of the two buffers used, Tris-HCl was the more suitable. Reactions in phosphate proceeded somewhat more slowly. More significantly, the latter also gave *trans*-alcohol products of somewhat lower ee. At the buffer concentrations used in this study phosphate is known (8) to bind to the active site of HLADH. Although this could presumably affect the stereospecificity, many different buffers have been used successfully in HLADH-catalyzed oxidoreductions (2) and, with one or two exceptions (9), the nature of the buffer used is usually unimportant. Of much greater significance is the pH of the medium. The rate of reduction is greatly influenced by pH, with the rate

reaching a maximum at pH ≥ 8 (Table 1).

The reduction rates are greatest at the highest enzyme concentrations, as expected from the Michaelis–Menten equation (10). However, the maximum ees are obtained when the [E]/[S] ratio is lowest, or when the reduction is <~30% complete. This is in accord with expectation for a kinetically controlled process involving preferential reduction of one enantiomer (2*a*, *b*). The lowerings in %ee of the (+)-*trans*-alcohol products as the reaction times increase are due to the slow accumulation of the opposite enantiomers via the unfavoured pathway for reduction of the much less reactive (−)-enantiomers of **1**,**3***b*.

A low [E]/[S] ratio is essential if *trans*-alcohol products of 100% ee are required. This conclusion is supported by the results of the Zurich (2*a*) and Antwerp (2*d*) groups for HLADH-mediated 2-alkylcyclohexanone reductions, in which enantiomerically pure alcohols were obtained using [E]/[S] ratios ~5–10-fold lower than the lowest values of Table 2. The practical lower limit of [E]/[S] will vary for different substrates. For poor substrates such as **1***a*,*b*, reductions become very slow at [E]/[S] ratios $<10^{-6}$.

Another factor contributing to lower ees of the *trans*-alcohol products (+)-**2**,**4***a*,*b* of long reductions at high [E] is that the reverse oxidation reaction can become significant. The more facile oxidation of (+)- than (−)-**2***a*,*b* was confirmed by the Scheme 2 reactions, during which the less reactive (1*R*,2*R*)-substrate enantiomers accumulated. The 2-methyl alcohol (−)-**2***a* isolated was of 100% ee while the lower optical purity of (−)-**2***b* indicates that manipulation of the [E]/[S] ratio could be beneficial in the oxidation mode also.

These results are believed to be generally valid for all HLADH-catalyzed reduction of poor substrates. In such cases the highest product ees will be attained at pH 8 by maximizing the rate of reduction with as high an enzyme concentration as feasible, while keeping the [E]/[S] ratio as low as possible and less than 0.5×10^{-4}.[4]

[4]A general formulation of the experimental conditions favouring formation of enantiomerically pure products from enzyme-catalyzed reactions has been published recently (11).

Experimental

The instrumentation and general purification and analytical procedures used were as described previously (4*b*). HLADH (EC 1.1.1.1) was 1× crystallized material from Sigma. The activity of each batch of enzyme was determined (12) prior to use; amounts of HLADH quoted refer to mg of active enzyme. NAD was obtained from Kyowa Hakko Kogyo, New York and FMN from Sigma. The physical and spectral properties of all racemic and optically active ketones **1**,**3***a*,*b* and alcohols **2**,**4***a*,*b*, and of their respective ketals with (−)-(2*R*,3*R*)-2,3-butanediol and MTPA esters, were identical with those reported previously for the fully characterized compounds (4).

*HLADH-catalyzed reductions of (±)-**1**,**3**b*

The following general procedure was employed. The ketone substrate and some ethanol were dissolved in buffer solution at 20°C. NAD was then added and the reduction was initiated by the addition of HLADH. The reaction mixture was kept at 20°C and the extent of reduction monitored by glc on Superpac 20 or 3% OV-101 on Chromasorb GHP columns. When sufficient (25–50%) reduction had occurred, the mixture was brought to pH 7 with 1 *N* HCl if buffer pH >7 was used, then saturated with NaCl and continuously extracted with chloroform for 2 days. The dried ($MgSO_4$) chloroform extract was analyzed by glc for the Table 1 runs, and, for the Table 2 experiments, evaporated and the residue purified by mplc on silica (ICN 0.032–0.063 mm) with ethyl acetate/hexane (1:8 for cyclohexane derivatives, 1:5 for thiopyrans). The individual compounds were then Kugelrohr-distilled.

*Effect of pH on reduction of (±)-**1**b*

2-Ethylcyclohexanone ((±)-**1***b*, 40 mg, 0.4 m*M*), EtOH (0.1 mL), NAD^+ (79 mg, 0.12 mmol), and HLADH (10 mg, 0.125×10^{-6} *M*) were reacted by the above procedure in 10 mL of 0.4 *M* potassium phosphate (pH 6, 8) or Tris-HCl (pH 6, 7, 8) buffer for 17–65 h. The results are summarized in Table 1.

*Influence of [E] and reaction time on reduction of (±)-**1**,**3**b*

The reductions were studied using the general procedure (4) on (±)-**1***b* (500 mg – 1.0 g, 3.96–7.92 mmol), EtOH (0.3–1.92 mL), NAD (150 mg – 1.48 g, 0.23–2.23 mmol), and HLADH (11–214 mg, 0.1382.68 × 10^{-6} mol) in 0.4 *M* Tris-HCl buffer (pH 8, 70–190 mL). For long reactions, the enzyme and NAD were added portion-wise every 2 days. The concentration ranges used were [S] 4.1–5.6 × 10^{-2} mol, [E] 1.94–20.8 × 10^{-6} *M*. The reactions were terminated after 26–49% reduction. The recovered ketones **1***b* (17–57% yields), typical bp 80°C (14 Torr) (lit. (4) bp 82–85°C

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12

(22 Torr)), had rotations $[\alpha]_D^{25}$ −2.9 to −12.9° (*c* 1−2, EtOH) which were used to calculate the %ee (lit. (2*a*) (−)-(2*R*)-**1***b*, $[\alpha]_D$ −18° (*c* 1.8, EtOH)). The *trans*-alcohols **2***b* (18−37% yields), typical bp 70°C (13 Torr) (lit. (4) bp 80°C (18 Torr)), had rotations $[\alpha]_D^{25}$ +17.0 −63.0° (*c* 0.6−1, EtOH) (lit. (2*a*) (+)-(1*S*,2*S*)-**2***b*, $[\alpha]_D$ +59.2° (*c* 1.5, EtOH)). The ees of the (+)-**2***b* samples were measured by nmr examinations of the methoxyl protons of their MTPA esters (5), prepared and characterized as described previously (4). The thiopyranone reductions were carried out similarly on (±)-**3***b* (4) (590 mg − 2.0 g, 4.09−48.2 mmol), EtOH (1.1−3.6 mL), NAD (0.9−3.2 g, 1.36−4.82 mmol), and HLADH (35.6−203 mg, 0.45−2.54 × 10^{-6} mol) in 0.4 *M* Tris-HCl buffer (pH 8, 200−700 mL). The concentration ranges used were [S] 2.0 × 10^{-2} *M*, [E] 0.67−3.63 × 10^{-6} *M*. The reductions were terminated after 34−49% reaction. The recovered ketones **3***b* (49−57% yields), typical bp 100°C (8 Torr), (lit. (4) bp 92°C (7 Torr)) had rotations $[\alpha]_D^{25}$ −16.5 to 27.5° (*c* 1−2, $CHCl_3$) (lit. (4) (−)-(3*S*)-**3***b* (58% ee), $[\alpha]_D^{25}$ −36.0° (*c* 1, $CHCl_3$)). The *trans*-alcohols **4***b* (21−43% yields), typical bp 100°C (1.3 Torr) (lit. (4) bp 90°C (2.5 Torr)), had rotations $[\alpha]_D^{25}$ +47.0−51.4° (*c* 0.6−2, $CHCl_3$) (lit. (4) (+)-(3*R*,4*S*)-**4***b* (78% ee), $[\alpha]_D^{25}$ +39.5° (*c* 1.1, $CHCl_3$)). The ees of the ketones (−)-**3***b* were determined by ^{13}C nmr measurements on their ketals with (−)-(2*R*,3*R*)-2,3-butanediol (6), and of the alcohols (+)-**4***b* via ^1H nmr determinations of their MTPA esters as before (4). The results are summarized in Table 2.

*HLADH-catalyzed oxidations of (±)-2*a,b

Both substrates were oxidized under the same general conditions. The *trans*-alcohol (±)-**2***a* or *b* (5.05 mmol) was dissolved in 0.05 *M* glycine−NaOH buffer (pH 9, 500 mL) at 20°C. NAD (880 mg, 1.3 mmol) and FMN (9.65 g, 20.2 mmol) were added and the pH readjusted to 9 with 2 *N* aqueous NaOH. HLADH (56 mg) was then added and the mixture kept at 20°C. The reaction mixture turned black within 2 h and the progress of the oxidation was monitored by glc analysis (3% OV 101 columns) of small aliquots. This analysis is accurate to ±5−10%.

When the reaction was ~50% complete (3 days), the solution was saturated with NaCl and continuously extracted with chloroform for 2 days. The chloroform extract was filtered through a short column of Hyflo Super Cel (4 cm) containing Norite (1 cm) and then dried ($MgSO_4$), filtered, and evaporated. The components were separated by medium pressure liquid chromatography on silica gel (ICN 0.032−0.063 mm) with ethyl acetate/hexane (1:8) elution and the products Kugelrohr-distilled.[5] The ees of the recovered alcohols were determined by the MTPA ester method and of the product ketones using the ^{13}C nmr-ketal approach (4). The individual reactions gave the following results.

*Oxidation of (±)-2*a (578 mg) for 3 days (~46% oxidation) yielded (+)-(2*S*)-**1***a* (102 mg, 18% yield, 21% ee), bp 45°C (7 Torr) (lit. (13) bp 89−90°C (20 Torr)); $[\alpha]_D^{20}$ +9.8° (*c* 1.57, EtOH) (lit. (13) $[\alpha]_D$ +12.1° (neat), (2*a*) $[\alpha]_D$ +14.4° (*c* 1.03, EtOH)), and (−)-(1*R*,2*R*)-**2***a* (200 mg, 35%yield, 100% ee), bp 75°C (7 Torr) (lit. Salting-out of triethylphosphate by inorganic electrolytes[1]

NORMAN H. SAGERT and DANNY W. P. LAU

Research Chemistry Branch, Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Man., Canada R0E 1L0

Received May 24, 1983

NORMAN H. SAGERT and DANNY W. P. LAU. Can. J. Chem. **62**, 81 (1984).

The salting-out of triethylphosphate (TEP) from water was measured at 25°C for twelve inorganic electrolytes. If salting out is taken as an additive property of ions, then the effectiveness for salting TEP out of water is $I^- < Br^- < Cl^- < \frac{1}{2}SO_4^{2-} < \frac{1}{2}CO_3^{2-}$ for anions and $\frac{1}{3}La^{3+} < Na^+ \approx NH_4^+ < Cs^+ < \frac{1}{2}Ca^{2+} \approx \frac{1}{2}Mg^{2+} < K^+ < \frac{1}{2}Ba^{2+}$ for cations. The results were fitted to three theories. The distribution theory of Conway, Desnoyers, and Smith predicts the order of magnitude of the experimental results, but does not discriminate well between salts of the same valence type. The electrostriction theory of McDevit and Long discriminates well between ions but gives results three or five times larger than those observed. Scaled particle theory predicts the results reasonably well, but the predictions depend critically on the choice of ionic and molecular parameters. Thus, none of these theories is entirely satisfactory.

NORMAN H. SAGERT et DANNY W. P. LAU. Can. J. Chem. **62**, 81 (1984).

On a mesuré le relargage du phosphate de triéthyle (PTE) à partir de l'eau à 25°C pour 12 électrolytes inorganiques. Si on considère le relargage comme une propriété additive des ions, l'efficacité du relargage du PTE à partir de l'eau est alors: $I^- < Br^- < Cl^- < \frac{1}{2}SO_4^{2-} < \frac{1}{2}CO_3^{2-}$ pour les anions et de $\frac{1}{3}La^{3+} < Na^+ \approx NH_4^+ < Cs^+ < \frac{1}{2}Ca^{2+} \approx \frac{1}{2}Mg^{2+} < K^+ < \frac{1}{2}Ba^{2+}$ pour les cations. Les résultats sont analysés à l'aide de trois théories. La théorie de distribution de Conway, Desnoyers et Smith prédit l'ordre de grandeur des résultats expérimentaux mais elle ne fait pas de distinction nette entre les sels de même type de valence. La théorie d'électrostriction de McDevit et Long prédit la différence entre les ions mais donne des résultats 3 à 5 fois supérieurs à ceux observés. La théorie des sphères rigides prédit les résultats raisonnablement bien mais les prédictions dépendent d'une façon critique du choix des paramètres ionique et moléculaire. Ainsi aucune de ces théories n'est entièrement satisfaisante.

[Traduit par le journal]

Introduction

Neutral organic phosphates are the active extractants in many industrial processes, including those used for reprocessing nuclear fuel (1). We are studying interfacial properties relevant to these extraction systems (2, 3), and need to know distribution coefficients for organic phosphates between hydrocarbons and various aqueous media (4), including aqueous media with added salt. Measuring such distribution coefficients is equivalent to measuring the salting coefficients (5).

The salting-out of non-electrolytes from aqueous solutions has been of interest for many years (6, 7). Many non-electrolytes, both polar and non-polar, have been used, but few data are available for organic phosphates. Some results have been reported for tri-*n*-butylphosphate (TBP) (1, 8), but results for smaller phosphates do not appear to be available. These phosphates are of some interest as solutes since they have a higher dipole moment (9) than most polar non-electrolytes previously studied, but have a considerable hydrophobic character (10). Recently, Treiner and Fromon (11) measured the salting-out of acetonitrile, which also has a high dipole moment but little hydrophobic character. The availability of data on the salting-out of organic phosphates should help to test the limits of the currently available theories. Therefore, in the work reported here we have measured salting coefficients of triethylphosphate (TEP) using several salts and have compared our results to three conventional theories.

Experimental

Vials containing 5.0 cm^3 of dodecane, 5.0 cm^3 of aqueous salt solution and, appropriate amounts of TEP were prepared as previously described (4) and shaken for at least 40 h in a water bath, controlled by a thermostat to ±0.1 K. Samples were withdrawn for analysis while keeping the vials in the water bath. Analyses for TEP were done by gas chromatography, as previously described (4). Since most of the TEP goes into the water phase (4), it was possible to determine distribution coefficients by analyzing the organic phase before and after equilibration, and using a mass balance. Thus, the necessity of analyzing aqueous solutions with high salt concentrations was avoided. The salt solutions were prepared by volume and were converted to molalities using known densities (12).

The sources and purification of dodecane, water, and TEP have been described (2, 4). The inorganic salts were of ACS reagent-grade purity, or better, and were used without further purification. All salts were dried above 140°C for at least 40 h and were stored in a desiccator.

Results

Distribution ratios, D, defined as the concentration of TEP in the organic phase divided by that in the aqueous phase, are shown in Fig. 1 for 2.15 mol kg^{-1} KCl at 25°C, as a function of TEP concentration in the aqueous phase. Also shown in the figure are the distribution ratios in the absence of salt, D_0, obtained previously (4). From Fig. 1 it is apparent that the distribution ratios do not change materially with TEP concentration in the concentration range investigated here and that ratios obtained with about 0.1 mol dm^{-3} TEP in the aqueous phase are essentially equivalent to those determined at infinite dilution.

Following Friedman (13, 14), we define a salting coefficient, k_s, by eq. [1]:

$$[1] \quad k_s = -\left(\frac{\partial \ln m_{TEP}}{\partial m_E}\right)_{\mu_{TEP}}$$

where m denotes molality, μ is chemical potential, and E refers to the electrolyte. Since our distribution ratios do not vary with m_{TEP}, then, to a good approximation, eq. [2] holds:

$$[2] \quad k_s = \frac{\partial \ln (D/D_0)}{\partial m_E}$$

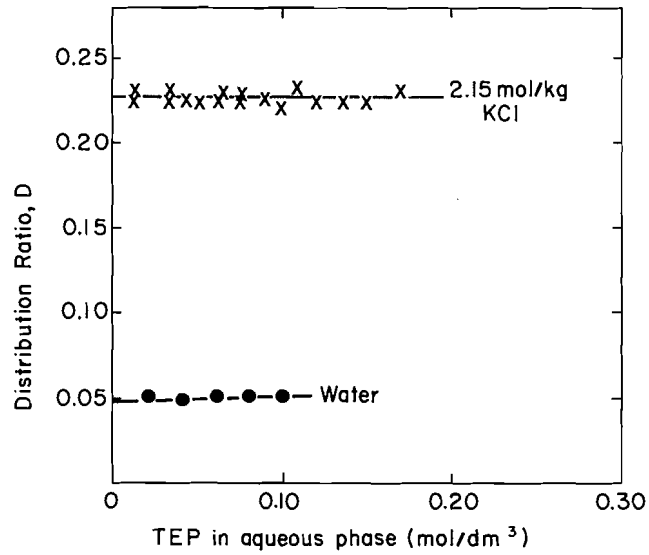

FIG. 1. Distribution ratios at 25°C as a function of TEP concentration, with 2.15 mol kg^{-1} KCl in the aqueous phase (×), and with pure water as the aqueous phase (●) (ref. 4).

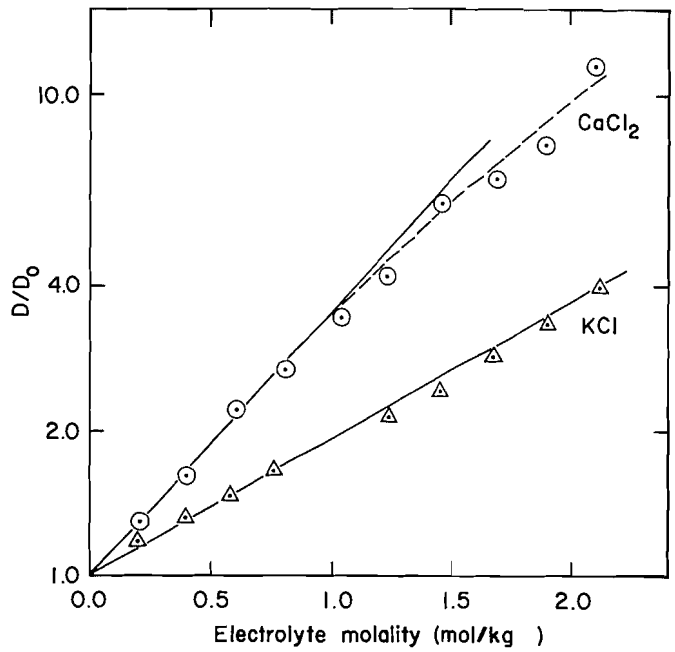

FIG. 2. The distribution ratio in the presence of salt divided by that in its absence, as a function of electrolyte molality at 25°C, for KCl (△) and $CaCl_2$ (○).

Figure 2 shows plots of the logarithm of (D/D_0) against electrolyte molality for both KCl and $CaCl_2$ solutions. The TEP concentration is close to 0.1 mol dm^{-3}. Reasonably good straight lines resulted, and from the slopes of these lines salting coefficients were obtained. Where some curvature was noted, the initial slopes were used. Table 1 lists experimental salting coefficients for the twelve electrolytes studied, along with theoretical values calculated by methods described below. Consideration of various sources of error led us previously (4) to ascribe an error of ±5% to the individual distribution ratios. Thus, the salting coefficients are likely reliable to within ±5%.

The definition of k_s in eq. [1] is such that, when multiplied by RT, k_s gives the standard Gibbs energy change accompanying the transfer of 1 mol of TEP at constant and low concentration from water to a 1-molal solution of salt (5). To obtain the standard Gibbs energy of transfer using the unit mole fraction standard states frequently (15), but not universally (16), employed, it is necessary to add to k_s the quantity $(0.0181\ \nu - \phi_0/1000)$, where ν is the number of moles of ions produced by the dissolution of 1 mol of electrolyte, and ϕ_0 is the apparent molal volume of the electrolyte (5). This quantity is quite small, usually within experimental error. For example, for KCl, the k_s for TEP transfer corresponds to a standard Gibbs energy of transfer of 1.593 kJ/mol for the concentration-based standard state and 1.616 kJ/mol for the mole fraction one.

Discussion

If salting-out results from additive contributions from the various ions in solution (6), then the effectiveness for salting-out of TEP is in the order

$$\tfrac{1}{3}La^{3+} < Na^+ \approx NH_4^+ < Cs^+ < \tfrac{1}{2}Ca^{2+} \approx \tfrac{1}{2}Mg^{2+} < K^+ < \tfrac{1}{2}Ba^{2+}$$

and

$$I^- < Br^- < Cl^- < \tfrac{1}{2}SO_4^{2-} < \tfrac{1}{2}CO_3^{2-}$$

For anions, the sequence is similar to that observed by others (5, 17) for salting-out of butanols. However, for cations, larger ones such as Cs^+ are somewhat more effective for salting-out TEP than for salting-out butanol. This is shown more clearly in Fig. 3, where k_s is plotted against cation ionic diameter for the alkali-metal chlorides and against anion ionic diameter for the potassium halides. The salting coefficient for KBr was calculated from those of KCl, NH_4Cl, and NH_4Br, assuming additivity. Also shown are results of Perron *et al.* (17) for *t*-butanol solutions at 25°C. For *t*-butanol, salting-out is less efficient for the larger cations, but for TEP, salting-out by these larger cations remains higher than for sodium ions. The salting coefficient for salting TEP from NaCl solution is close to that predicted by Treiner (18) for a polar solute, using a hard-sphere diameter for TEP calculated from the liquid density. Thus, it is the larger cations that give anomalously high results.

The TEP molecule is bifunctional. Its hydrocarbon chains are hydrophobic and should be strongly salted out. On the other hand, the phosphate group is highly polar and should be salted-in. Wilcox and Schrier (19) recognized that a similar, if less marked, situation would exist for alcohols. They studied the salting-out of a number of alcohols and devised an additivity scheme for the groups in the molecules. Using their numbers for CH_2 and CH_3, then, for NaCl, the hydrocarbon chains of TEP should be salted-out with a k_s of 1.02, and since the experimental value is 0.57, the phosphate is salted-in with a k_s of 0.45, or 1.12 kJ/mol. Thus the salting-out of TEP is clearly a balance between the strong salting-out tendency of the hydrocarbon chains and the weaker salting-in tendency of the phosphate group.

Three types of theories have frequently been used to account for salting coefficients (7). These are the distribution theories associated with many authors (7, 20), the electrostriction theory of McDevit and Long (21), and the scaled particle theory orginated by Reiss, Frisch, and Lebowitz (22). We will examine our data with these three theories and will not attempt to use the statistical-mechanical theory of Krishnan and Friedman (14). All three theories are deficient in that they do not take into account explicitly the bifunctional nature of the TEP molecule. However, since they have been applied to alcohols in the past, it is instructive to use them here to see how well they predict the behavior of TEP.

[a]Calculated from "effective pressures".

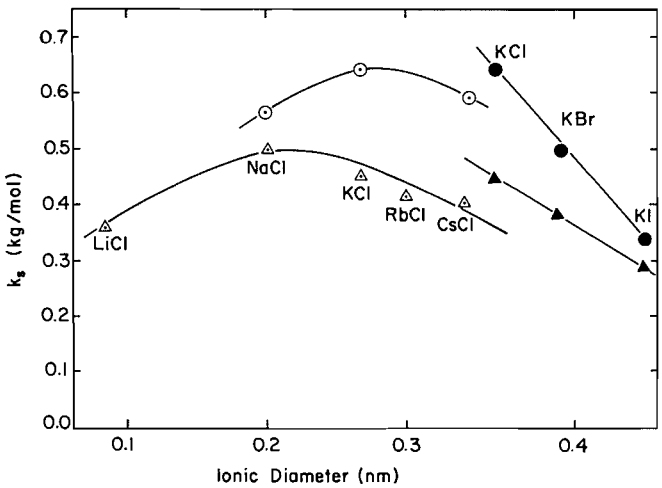

FIG. 3. Salting coefficients at 25°C as a function of ionic diameter. The open symbols refer to the cations of alkali-metal chlorides, the closed symbols the anions of potassium halides. Our results for TEP are shown as circles, and the results of Perron *et al.* (17) for *t*-butanol are shown as triangles.

Distribution theories

These theories treat salting-out by considering the behavior of polarizable solvent and solute molecules in the field of the ion. If, as is usually the case, the solvent, H_2O, is more polarizable than the solute, the ion − induced dipole interaction will preferentially attract solvent and result in a lower solubility for the solute. Such factors as proper handling of the potential function, dielectric saturation, and the use of realistic polarization functions have to be considered (7). A good approach is that of Conway *et al.* (20), who derived eq. [3]:

$$[3]\quad k_s = \frac{\pi N_A}{6000}(\sigma_h^3 - \sigma^3) + \frac{Z^2e^2}{2000\,kT\epsilon_0^2}\left(V_{TEP}\epsilon_0 - \frac{9}{2}P_{TEP}\right) \times \left[\frac{2}{\sigma_h} - \frac{1}{R}\right]$$

where N_A is the Avogadro's number, σ_h is the diameter of the hydrated ion, σ is the ionic diameter, Z is the charge on the ion, ϵ_0 is the dielectric constant, V_{TEP} is the molar volume of TEP, R is the co-sphere radius, and P_{TEP} is the total molar polarization of TEP. Equation [3] gives the salting coefficient for each ion, and it is necessary to sum the ionic contributions to get the salting coefficient for a given electrolyte. Calculated values (CDS) for each electrolyte are shown in Table 1. The hard-sphere ionic diameters used are those given in Table 2. The hydrated ionic diameters were taken from Nightingale (29). P_{TEP} was calculated from the refractive index and dipole moment of TEP (9). In general, this theory gives salting coefficients of the right order; however, it does not discriminate well between different salts of the same valence type.

Electrostriction theory

This theory is almost entirely due to McDevit and Long (21). The compression of solvent by the ions is used to derive an expression for the salting coefficient. This is done by considering the excess work that must be done to create a volume and noting that this work is proportional to the volume change on mixing the salt with water. The result is eq. [4]:

$$[4]\quad k_s = \frac{V_{TEP}(V_E - \phi_0)}{kT\beta}$$

where β is the compressibility of water and V_E is the hypothetical molar volume of the liquid salt at temperature T. Where "effective pressures" of the electrolyte in water are known, V_E can be calculated from them (21). Otherwise V_E can be taken as the molar volume of the crystalline state. Table 1 shows theoretical values (McDL) of k_s, the noted values being calculated from "effective pressures". The calculated values are several times larger than the experimental values, although they do discriminate well between different salts of the same valence type. This variation is not totally unexpected because the theory really takes into account differences between experimental densities. These density differences incorporate some of the specific interactions that other theories try to explain.

Scaled particle theory

Scaled particle theory purports to calculate the energy expended to form a cavity in the solvent large enough for a solute molecule, and then to calculate the energy regained by solute−solvent interaction when a solute molecule is placed in this cavity. It was originally developed for spherical non-polar molecules (22), but in recent years has been applied to systems involving polar molecules, with varying degrees of success (5, 11, 18). Masterton and Lee (30) developed equations specifically for calculating salting coefficients and, although these are given for 1:1 electrolytes, they are readily adapted for use with all electrolytes. The equations of Masterton and Lee (30) use the Mavroyannis−Stephen equation (31), eq. [5], to calculate

the energy parameter ϵ/k for the ions:

$$[5]\quad \frac{\epsilon_i}{k} = 721\,\frac{\alpha_i^{3/2} Z_i^{1/2}}{\sigma_i^6}$$

where α_i is the polarizability of the ion in nm^3, σ_i is its molecular diameter in nm, and Z_i is the total number of electrons in the ion. Thus, for the salt, it is necessary to know the apparent molar volume, ϕ_0, at infinite dilution and the diameters and polarizabilities of the ions. For TEP, the molecular diameter, the energy parameter and the polarizability must be known. For water, ϵ/k is usually taken as 85.3 K and the diameter as 0.275 nm (30). The values of the parameters used here are given in Table 2.

For TEP, values of ϵ/k and σ are not readily available, although the polarizability can be calculated from the refractive index to be 16.24×10^{-3} nm^3. Two approaches were used to obtain the values of ϵ/k and σ. One approach, suggested by Aveyard and Heselden (5), was to use empirical equations produced by Stiel and Thodos (32) for organic molecules. These equations predict the values of ϵ/k and σ from the critical properties. Since the critical properties of TEP are also unavailable, they were estimated from vapor-pressure data at lower temperatures (ref. 12, p. C429), using the procedures of Curl and Pitzer (33). These gave a critical pressure of 2.11 MPa, a critical temperature of 684 K, and a critical volume of 0.696 dm^3. The correlation of Stiel and Thodos (32) then gave a value of 340.3 K for ϵ/k and 0.84 nm for σ. Another procedure for calculating ϵ/k and σ, which has been used with some success (30, 34), is to calculate ϵ/k using the Mavroyannis–Stephen equation, eq. [5]. In this case, ϵ/k was found to be 190.9 K and σ was taken as 0.69_5 nm, as obtained from a correlation suggested by Stiel and Thodos (35) for polar molecules, which is closer to the value of 0.66 nm derived from the liquid density.

Our calculated salting coefficients are shown in the last two columns of Table 1. The second last column (SPT) shows results obtained using ϵ/k = 340.3 K and σ = 0.84 nm, while the last column (SPTMS) uses ϵ/k = 190.9 K (from the Mavroyannis–Stephen equation) and $\sigma = 0.69_5$ nm. In general, reasonable fits are obtained in both cases, with exceptions. The calculated salting coefficients of KI and NH_4Br are too high, by about a factor of two. For some salts, such as KCl, CsCl, Na_2SO_4, and $BaCl_2$, the parameters obtained from the Mavroyannis–Stephen equation give a better fit, but for other salts, such as $LaCl_3$ and possibly $MgCl_2$, the parameters derived from the Stiel–Thodos equations give a better fit. Thus, scaled particle theory can give good fits, but the choice of parameters is critical.

If the polar solute correlation of Stiel and Thodos (35) is used with the critical constants determined previously, then ϵ/k is predicted to be 613.5 K and σ, as before, is 0.69_5 nm. These parameters give very low calculated salting coefficients, e.g., 0.038 for KCl and 0.297 for NaCl, as is frequently observed for polar solutes (11, 30). Treiner and Fromon (11) observed that, with many polar molecules, very low values are obtained, but the fit is improved immensely if the anion interaction term is deleted. When this was done, very large calculated salting coefficients were obtained, e.g., 1.264 for KCl and 1.523 for NaCl. Thus, it is clearly not appropriate, for TEP, to say that the anions are solvated entirely by water; some form of preferential solvation cannot be ruled out.

In summary, none of the three theories described gives a really satisfactory fit to our experimental results. Scaled particle theory can give good fits under certain circumstances, but the choice of parameters is critical and, when a key parameter is not well known, as is the case with the ϵ/k value for TEP, the validity of any fit is questionable. Furthermore, scaled particle theory is not really expected to work well for polar molecules with a high dipole moment in a complex solvent like water. New theoretical approaches, ones recognizing explicitly the bifunctional nature of these solutes, are clearly required.

Kinetics of the reaction $H + C_2H_6 \rightarrow H_2 + C_2H_5$ in the temperature region of 1000 K

J.-R. CAO[1] AND M. H. BACK

The Ottawa–Carleton Institute for Research and Graduate Studies in Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received May 10, 1983

J.-R. CAO and M. H. BACK. Can. J. Chem. **62**, 86 (1984).

A system for the measurement of rate constants for elementary reactions of hydrogen atoms in the temperature region of 1000 K is described. The concentration of hydrogen atoms is controlled by the equilibrium constant for dissociation of hydrogen molecules. The kinetics of the rate of conversion of ethane to ethylene in this system has been studied over the temperature range 876–1016 K. The results show that the rate-controlling step is

$$H + C_2H_6 \rightarrow H_2 + C_2H_5$$

and the value obtained for the rate constant is

$$\log k \text{ (L mol}^{-1} \text{ s}^{-1}) = 11.72 \pm 0.05 - \frac{12\,800 \pm 200}{2.3RT}$$

(R = 1.987 cal mol^{-1} deg^{-1}). This value is compared with values obtained from other methods over the temperature range 300–1400 K. Combination with a recent measurement of the rate constant for the reverse reaction yields an experimental value for the equilibrium constant for the reaction.

J.-R. CAO et M. H. BACK. Can. J. Chem. **62**, 86 (1984).

On décrit un système qui permet de mesurer les constantes de vitesse des réactions élémentaires des atomes d'hydrogène aux environs de 1000 K. La constante d'équilibre de la dissociation des molécules d'hydrogène contrôle la concentration des atomes d'hydrogène. On a étudié la cinétique de la vitesse de transformation de l'éthane en éthylène dans ce système dans l'intervalle de température allant de 876 à 1016 K. Les résultats révèlent que l'étape déterminante est la réaction suivante:

$$H + C_2H_6 \rightarrow H_2 + C_2H_5$$

pour laquelle la constante de vitesse est de:

$$\log k \text{ (L mol}^{-1} \text{ s}^{-1}) = 11{,}72 \pm 0{,}05 - \frac{12\,800 \pm 200}{2{,}3RT}$$

(R = 1,987 cal mol^{-1} deg^{-1}). On a comparé cette valeur à celles obtenues par les autres méthodes dans l'intervalle de température de 300–1400 K. Lorsqu'on combine cette valeur avec les mesures récentes de la constante de vitesse de la réaction inverse, on obtient une valeur expérimentale de la constante d'équilibre de la réaction.

[Traduit par le journal]

Introduction

Measurements of rate constants for reactions of hydrogen atoms with hydrocarbons and other molecules have been attempted through a variety of techniques for many years. Published data have been recently summarized (1). Accurate values for such rate constants are essential for a proper understanding of the mechanisms of the wide variety of reactions in which hydrogen atoms play an important role. The main problem encountered in these measurements is the determination of the concentration of hydrogen atoms. A direct measure of the instantaneous concentration of atoms is undoubtedly the most desirable. During the past few years the technique of atomic resonance absorption has been successfully applied to measurements of the concentration of hydrogen atoms in several systems (2) and rate constants for reactions both producing (3) and consuming (4) hydrogen atoms have been obtained. Because of the high temperatures involved in these shock-heated reactants, however, rate constants involving only the most stable reactants have been reported. Measurements of rate constants for reaction of hydrogen atoms with ethane and higher hydrocarbons at lower temperatures have, except for studies using esr detection (5), relied on a relative measure of the hydrogen atom concentration.

In most systems the concentration of hydrogen atoms, unlike that of radicals, is not controlled by their rate of mutual combination, either homogeneously or heterogeneously, and other reactions consuming hydrogen atoms must be used as a reference. In the range of temperature 800–1100 K studies on the addition of hydrocarbons to reacting mixtures of hydrogen and oxygen (6) have used the reference reaction

$$H + O_2 \rightarrow OH + O$$

At slightly lower temperatures, 500–750 K, Marshall, Purnell, and co-workers have shown that in a flow system at low pressures with reactants ethylene (7) and ethane (8) the combination reaction

$$H + C_2H_5 \rightarrow 2CH_3$$

is the main competing process for removal of hydrogen atoms. At lower temperatures Yang (9) measured rate constants for abstraction reactions relative to $H + C_3H_6$, and other relative rate constants involving various abstraction and addition reactions have been reported. There is fairly good agreement among these various methods but there is no doubt that better accuracy is needed to give confidence to modelling studies and to assess the extent of curvature in the Arrhenius expression over the temperature range covered by the measurements.

A new method for the measurement of rates of hydrogen-atom reactions applicable in the temperature region of 1000 K

has been developed in this laboratory. The method is based on the fact that at moderate pressures of hydrogen in this temperature region the equilibrium concentration of hydrogen atoms provides a sufficient source for measurable reaction and on the assumption, which may be tested, that the dissociation equilibrium is rapidly attained in the system used. To this system is added a small quantity of reactant, a few ppm, and its rate of consumption measured. If the reaction is not too fast, the equilibrium concentration of hydrogen atoms should not be disturbed. The system was tested using the reactant ethylene (10) and from the results a value for the rate constant for reaction of ethyl radicals with hydrogen molecules was obtained. The present paper describes the results obtained with the reactant ethane and the values measured for the rate constant for the abstraction of hydrogen atoms from ethane.

$$H + C_2H_6 \rightarrow H_2 + C_2H_5$$

Experimental

The reaction was studied in a static system using a cylindrical quartz reaction vessel of 182 cm^3 volume. A second vessel packed with quartz tubes to give a S/V ratio of 7.5 cm^{-1} was used to test for the importance of surface reactions. Mixtures were prepared for introduction into the reaction vessel and tested for homogeneity. Research grade hydrocarbons were obtained from Matheson of Canada, Whitby, Ont. Hydrogen was purified by passage through a molecular seive 5A column at liquid nitrogen temperature with a residence time of about 2 s. The reactant and products were analyzed on a 1.2 m column of Durapak (Phenylisocyanate on Porasil) maintained at 30°C, using a Hewlett Packard Model 5750 Gas Chromatograph. Other details are described in earlier publications (10, 11).

Concentrations of ethane in hydrogen ranged from 16 to 56 ppm with total pressures from 50 to 125 Torr. Experiments covered the temperature range 876–1016 K. Reaction times ranged from 1 to 40 min.

Results and discussion

At temperatures below about 975 K ethylene was the principal product. Methane was a minor product, which became undetectable below about 900 K. Figure 1 shows a set of yield–time curves for formation of ethylene at various concentrations of ethane with a fixed total pressure. From such curves initial rates of formation of ethylene were obtained over the range of pressure and temperature indicated, and the data are summarized in Table 1.

The rate of formation of ethylene may be expressed as follows:

$$R_{C_2H_4} = k[H_2]^m[C_2H_6]^n$$

where k is an overall rate constant and m and n represent the order of the rate with respect to hydrogen and ethane, respectively. The measurements of the rate for a particular mixture of ethane and hydrogen at various total pressures provides data for the estimation of the total order, $m + n$. These results are shown in Fig. 2, as log of the initial rate of formation of ethylene as a function of log of the total pressure. From the slope of these plots, $m + n = 1.70 \pm 0.05$. To determine n the rate was measured at a constant total pressure for various mixtures of ethane in hydrogen (as illustrated in Fig. 1). Figure 3 shows some examples of these measurements, as a plot of log of the initial rate of formation of ethylene as a function of log of the concentration of ethane, giving a value of n of 1.25 ± 0.05. The value of m is therefore 0.45 ± 0.1. The order of the rate with respect to hydrogen may therefore be considered to be

0.5 while the order with respect to ethane is somewhat greater than 1.

The rate of the reaction was measured in the packed vessel at four temperatures and for a range of pressures and concentration of ethane. The results are given in Table 2. At temperatures where the rate of formation of methane was measurable no change in its rate was observed in the packed vessel. The rate of formation of ethylene, however, was increased by a factor between two and three. Furthermore, the order of the rate of formation of ethylene with respect to the concentration of ethane was close to two, a stronger dependence than was observed in the unpacked vessel. In both vessels the order was essentially constant over the temperature range of the experiments. Using the values for the order observed in the packed vessel (S/V = 7 cm^{-1}) and the unpacked vessel (S/V = 1 cm^{-1}) a linear extrapolation to S/V = 0 gives an order of 1.1. It seems reasonable to conclude, therefore, that the homogeneous reaction producing ethylene is first order

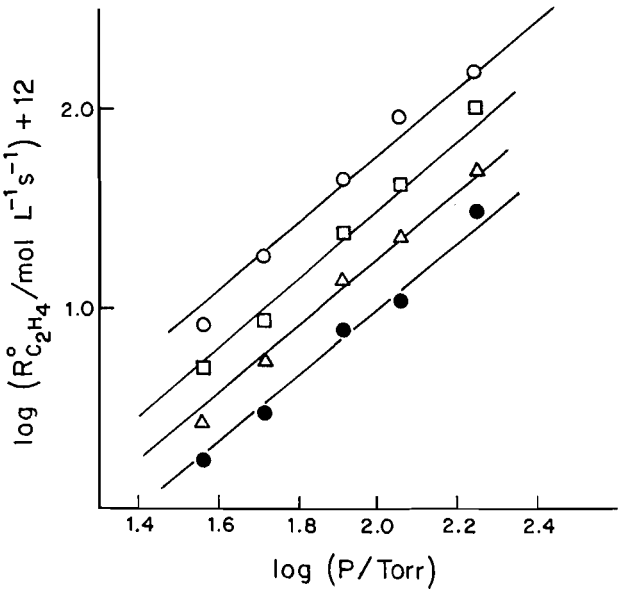

FIG. 2. log–log plot of the initial rate of formation of ethylene as a function of the total pressure at 922 K. $X_{C_2H_6}$ (ppm): ●, 16.4; △, 24.8; ○, 37.8; □, 56.

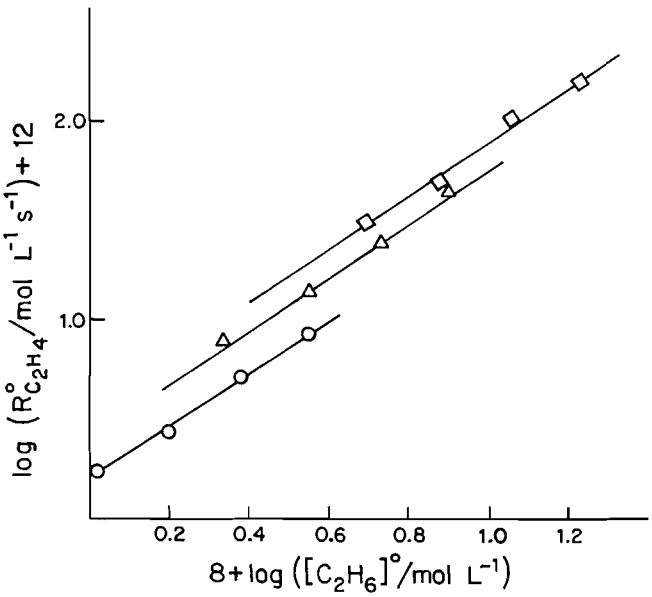

FIG. 3. log–log plot of the initial rate of formation of ethylene as a function of the concentration of ethane at 922 K. Total pressure (Torr): ○, 36.5; △, 82.5; ◇, 175.

with respect to the concentration of ethane and 0.5 order with respect to the concentration of hydrogen. The rate measured in the unpacked vessel has nevertheless a significant contribution from the heterogeneous reaction and a correction is required in order to obtain a rate constant relating to the homogeneous reaction [2]. The estimation of the correction as well as possible reasons for the strong dependence of the rate on the concentration of ethane in the packed vessel will be discussed later.

These results suggest that the formation of ethylene from reaction of ethane may occur through the following set of reactions:

[1] $H_2 \rightleftarrows 2H$

[2] $H + C_2H_6 \rightarrow C_2H_5 + H_2$

TABLE 2. Initial rate of formation of C_2H_4, S/V = 7.0 cm^{-1}

T (K)	P (Torr)	$X_{C_2H_6}$ (ppm)	[C_2H_6] × 10^7 (mol L^{-1})	$R^0_{C_2H_4}$ × 10^{11} (mol L^{-1} s^{-1})
894	185	7.96	0.264	0.896
		17.5	0.581	6.64
		35.7	1.190	16.6

		20.7	0.416	24.1
		39.8	0.800	64.3

[3] $C_2H_5 \rightarrow C_2H_4 + H$

In this simple mechanism the hydrogen atom concentration is controlled by the equilibrium with hydrogen molecules and every ethyl radical produced in reaction [2] yields ethylene by reaction [3]. Evidence was presented from the results obtained in a similar study (10) to show that an equilibrium concentration of hydrogen atoms was maintained under these conditions. Other reactions of the ethyl radical which may be important are,

[4] $H + C_2H_5 \rightarrow C_2H_6$

[−2] $C_2H_5 + H_2 \rightarrow C_2H_6 + H$

Taking into account reactions [1] to [4] the steady-state concentration of ethyl radicals may be expressed as follows:

$$[C_2H_5] = \frac{k_2(K_1[H_2])^{1/2}[C_2H_6]}{k_3 + k_{-2}[H_2] + k_4(K_1[H_2])^{1/2}}$$

and the rate of formation of ethylene is therefore

$$R_{C_2H_4} = k_3\left[\frac{k_2(K_1[H_2])^{1/2}[C_2H_6]}{k_3 + k_{-2}[H_2] + k_4(K_1[H_2])^{1/2}}\right]$$

The observed dependence of the rate on the concentration of hydrogen is a strong indication that neither reaction [−2] nor [4] is important. The rate definitely increased as the pressure of hydrogen increased whereas if reaction [−2] were important the rate should decrease as the pressure of hydrogen increased, or if reaction [4] were important, should remain independent of pressure of hydrogen. The relative magnitudes of the terms in the denominator may be estimated using a value for k_3 interpolated from the data of Lin and Back (12), whose measurements were made under similar conditions of temperature and pressure. Their data at 913 K indicate that at 120 Torr the ratio k_3/k_3^{∞} is about 0.3. Using their value for k_3, $10^{13.6-38\,000/RT}$, k_3 at 922 K and 120 Torr is about 1×10^4 s^{-1}. In the presence of hydrogen instead of ethane as a third body, this value may be further reduced by about a factor of four (13) to 0.25×10^4 s^{-1}. Taking an average value for k_{-2} of 5×10^5 L mol^{-1} s^{-1} (10) the product $k_{-2}[H_2]$ is about 1.1×10^3 s^{-1}, and therefore about half the value for k_3. At the lowest temperature, 876 K, the two rates become approximately the same. Although these estimates are only approximate, it might be expected that reaction [−2] could be important, particularly at the lower temperatures. Contribution from this reaction would reduce the rate of removal of ethylene and lead to too low a value for k_2. Although we believe from the measurements of the order of the rate with respect to hydrogen that this error is not serious, it might lead to a slight over-estimate of the activation energy for k_2. Using a collision rate constant for k_4 of 5×10^{10} L mol^{-1} s^{-1} the product $k_4(K_1[H_2])^{1/2}$ is about 10^4 times less than k_3 and this termination may be neglected.

TABLE 3. log k_2 (L mol^{-1} s^{-1})

T (K)	Packed vessel S/V = 7.0 cm^{-1}	Unpacked vessel S/V = 1.0 cm^{-1}	S/V = 0
956.0	9.194	8.822	8.759
915.5	9.094	8.696	8.656
894.0	9.005	8.625	8.569

Further evidence in support of this mechanism is provided by the value for the measured activation energy of the rate of formation of ethylene, E_r, of 70 kcal/mol. With the simple mechanism,

$$E_r = E_2 + \tfrac{1}{2}\Delta H_1$$

and E_r may be estimated as 64 kcal/mol, using the present value for E_2. If reaction [−2] is important in controlling the concentration of ethyl radicals then $E_r = E_3 + \Delta H_2 + \tfrac{1}{2}\Delta H_1$ and E_r would have a value of about 92 kcal/mol. If reaction [4] is important the value of E_r would be higher still. It appears, therefore, that the simple sequence of reactions [1] to [3] can account for the formation of ethylene in the initial stages of the reaction.

The rate of formation of ethylene may therefore be expressed as

$$[5] \quad R_{C_2H_4} = k_2 K_1^{1/2}[H_2]^{1/2}[C_2H_6]$$

Values for k_2 were calculated using eq. [5] and the rates obtained for concentrations of ethane in the neighbourhood of 20 ppm where the contribution from heterogeneous processes was a minimum. To estimate the correction for the heterogeneous reaction the rate constant k_2 was calculated in the same way for the measurements made in the packed vessel. Using both values for k_2 an extrapolation was made to S/V = 0. The values obtained were about 15% lower than the values obtained in the unpacked vessel. Examples are given in Table 3. The data for the determination of the temperature dependence of k_2 are given in Table 4, which includes the corrected values for k_2. The Arrhenius plot is shown in Fig. 4. The value of k_2 may be expressed as follows:

$$\log k_2 \text{ (L mol}^{-1}\text{ s}^{-1}\text{)} = 11.72 \pm 0.05 - \frac{12\,800 \pm 200}{2.3RT}$$

(R = 1.987 cal mol^{-1} deg^{-1}).

The values for the Arrhenius parameters of k_2 measured over the small temperature range of this study are not themselves as significant as the values obtained for the rate constant and their relation to other values measured with other techniques. This relation is shown in Fig. 5 where previous measurements covering the range 300−1400 K are shown. We have not included values of k_2 which, although quoted in the recent compilation (1), were not directly measured in the work described, for example, by Skinner and Ringrose (14), Bradley (15), and Clark, Izod, and Kistiakowsky (16). We have also omitted the early measurements by Darwent and Roberts (17) because it has been shown that the photolysis of H_2S, which was used as a source of hydrogen atoms, produced "hot" hydrogen atoms with consequent possibility for over-estimation of the rate of reaction (18).

Rate constants measured by addition of hydrocarbon to reacting mixtures of hydrogen and oxygen are determined relative to the branching reaction of hydrogen atoms with oxygen,

$$[6] \quad H + O_2 \rightarrow OH + O$$

Although there is essential agreement on the rate parameters for this reaction the actual values used by different laboratories may differ by as much as a factor of three. For comparison we have normalized the results of Tikhomirova and Voevodsky (19), Parsamyan *et al.* (20), and Gorban and Nalbandyan (21) to the value of k_6 used by Baldwin and Melvin (22).

$$\log k_6 \text{ (L mol}^{-1}\text{ s}^{-1}\text{)} = 11.33 - \frac{16\,500}{2.3RT}$$

This procedure has the effect of increasing the values of k_2 reported in these references and giving better consistency among values reported by this method.

The agreement between the results obtained by our method and those obtained from the H_2/O_2/hydrocarbon systems is useful confirmation for both techniques, particularly because all measurements reported above 750 K were obtained by the latter technique, except the unpublished data of Dove and Wagner, quoted in ref. 23, which are not included in Fig. 5.

The question of non-linearity in the Arrhenius relation has been much discussed for abstraction reactions of small radicals (23, 24) and has undoubtedly been observed in some cases. In Fig. 5 we have included as a dotted line the value of k_2 calculated by Clark and Dove (23). This calculation included such non-Arrhenius effects as temperature variation of quantum effects on vibrations and quantum mechanical tunnelling corrections. Camilleri *et al.* (8) concluded after an examination of the data that the variation of k_2 with temperature was best described by an Arrhenius relation over the range of temperature covered by the measurements shown in Fig. 5. This relation was expressed as follows:

$$[7] \quad \log k_2 \text{ (L mol}^{-1}\text{ s}^{-1}\text{)} = 11.0 \pm 0.1 - \frac{9600 \pm 200}{2.3RT}$$

R = 1.987 cal mol^{-1} deg^{-1}.

For our collection of data we did not make corrections to the results obtained below 770 K, but reasonable corrections based on stoichiometry discussed by Camilleri *et al.* (8) bring the data of Berlie and LeRoy (25) and Azatyan *et al.* (5) closer to an average value. It also appears that the value reported by Yang (9) measured relative to the addition of hydrogen atoms to propylene will be increased by using a more recent value for the reference reaction (1). Nevertheless, an examination of Fig. 5 shows that the correlation of the data with the calculated curve is almost as satisfactory as with a simple Arrhenius relation. The present measurements of k_2 are in agreement with either relation, but the measured value of the activation energy, 12.8 kcal mol^{-1}, is in good agreement with the value obtained from the calculated curve and suggests a small increase in activation energy with increasing temperature. Measurements of activation energies are, of course, subject to systematic errors and are less reliable than the rate constants themselves. The measured value of the frequency factor for k_2, $10^{11.7}$ L mol^{-1} s^{-1}, is between the values of $10^{11.1}$ and $10^{11.8}$ L mol^{-1} s^{-1} estimated by Benson (26) at 800 K for a transition state linear or non-linear, respectively. Taking our value for k_2 at 1000 K together with the lowest value calculated for the frequency factor, $10^{11.1}$ L mol^{-1} s^{-1}, a value for E_2 of 10.0 kcal mol^{-1} is obtained, which is reasonably close to the average value obtained from the Arrhenius relation. The present results, therefore, do not allow a clear choice between an Arrhenius or

*Corrected for heterogeneous reaction.

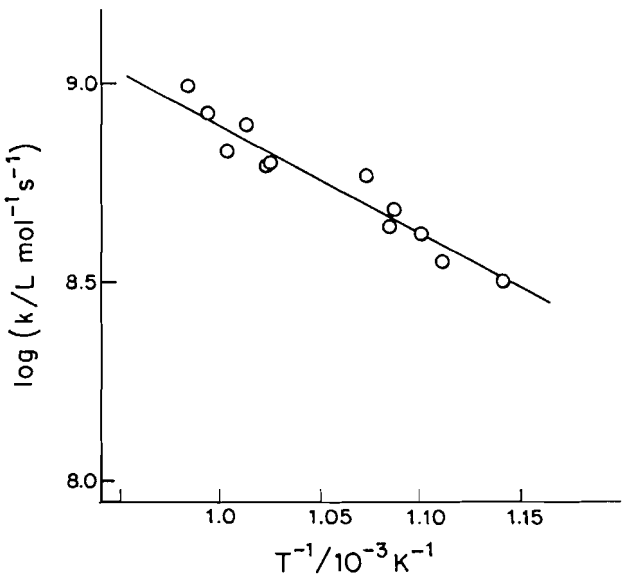

FIG. 4. Arrhenius plot of the corrected values of k_2.

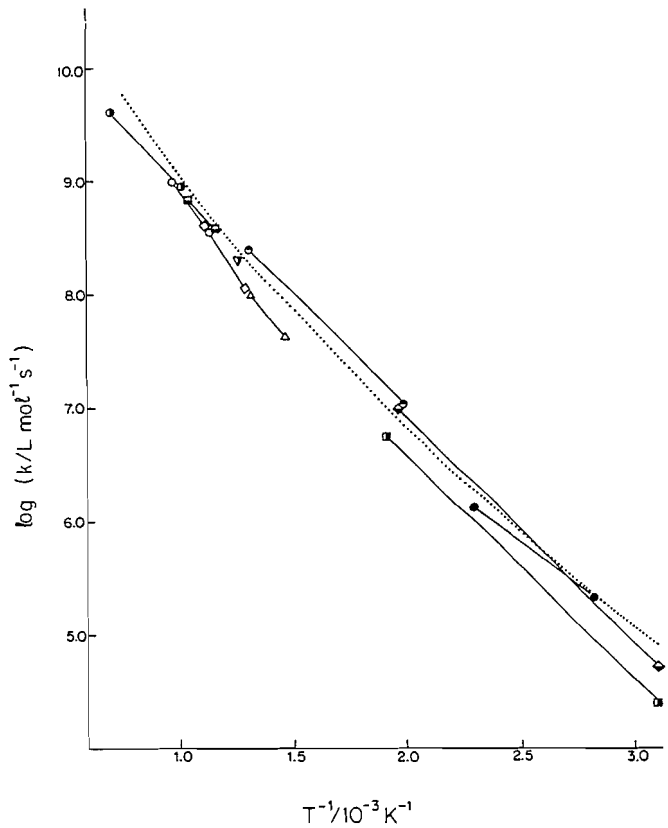

FIG. 5. Arrhenius plot of measurements of k_2 covering the temperature range 300–1400 K. ◑, ref. 28; ⬓, ref. 19; ◇, ref. 18; ▽, ref. 29; △, ref. 21; ◓, ref. 8; ⬙, ref. 5; ●, ref. 24; ◨, ref. 9; ○, present work. Dotted line: calculated curve, ref. 23.

non-Arrhenius relation for the dependence of k_2 on temperature. The equation suggested by Camilleri *et al.* (8) is probably the best average value of all the measurements.

The present values of k_2 may be compared to the values obtained for k_{-2} from the same method (10) through the equilibrium constant. This comparison, not only of our own results but of other published data on this system, provides evidence in support of a value for $\Delta H_f(C_2H_5)$ of 28 kcal mol^{-1} and will be presented and discussed in a forthcoming publication.

Finally we wish to comment on the results obtained in the packed reaction vessel. In the previous study of the kinetics of the hydrogenation of ethylene in a similar system the rates were not affected by a change in S/V ratio. It was concluded that the concentration of hydrogen atoms in the system was not altered in the packed vessel and that the equilibrium concentration was attained in both cases. This conclusion should also be valid in the present experiments and the heterogeneous reactions must involve the ethane molecule or its products. The rate of formation of methane, although only measurable at the highest temperature, was not altered in the packed vessel. Similar observations have been reported in studies of the thermal decomposition of ethane and it has been concluded that the dissociation reaction of ethane into two methyl radicals is a homogeneous process. In a recent study of heterogeneous processes in the pyrolysis of ethane, Pacey and Wimalasena (27) have concluded that the most important process occurring on the surface is a termination reaction of the ethyl radical. Such a reaction may occur in our system but would not affect the measured rate of formation of ethylene, since the rate-controlling step is reaction [2]. It seems more likely that a new decomposition process of the ethane molecule may be induced on the quartz surface, to give either an ethyl radical or ethylene directly. This type of reaction was not suggested in the pyrolysis of ethane itself because the ethylene formed by such a reaction would be negligible in comparison to the product

formed by the chain decomposition and would not, therefore, be observable. The actual rate of the surface process in the present system, where a chain decomposition does not occur, is only slightly larger than the homogenous initiation rate in the decomposition of ethane. Without more details of the surface process an empirical correction to the rate constant, such as that mentioned above, seems a reasonable method to obtain a rate constant which describes the homogeneous reaction.

In summary, the results presented here and previously demonstrate the validity of the technique for the utilisation of the equilibrium concentration of hydrogen atoms, obtained through the thermal dissociation of the hydrogen molecule for the measurement of rate constants for reactions of hydrogen atoms, and other small radicals. It should be noted that the principal assumption in the measurements is maintenance of an equilibrium concentration of hydrogen atoms and that under these circumstances absolute rather than relative values of the rate constants are obtained.

Carbon-13 and nitrogen-15 nmr chemical shifts of benzenediazonium salt and its *para*-substituted derivatives have been measured in sulfolane solutions. The chemcial shifts of $^{13}C1$ correlate linearly with the polarographic half-wave potentials. This relation indicates the linear increase of electron densities at C1 with the increase of electron-donating power of the substituents. Non-linear relationships between ^{15}N shifts of both nitrogen nuclei and the half-wave potentials were partly attributed to the second-order paramagnetic contributions to the ^{15}N shifts. This contribution is approximately proportional to the inverse of the uv absorption frequencies. Overall results suggest that in the ground state resonance structures of the benzenediazonium salts, the rehybridization of the C1—N1 bond is very unlikely and this bond remains as a single bond.

R. M. ELOFSON, N. CYR, J. K. LAIDLER, K. F. SCHULTZ et F. F. GADALLAH. Can. J. Chem. **62**, 92 (1984).

Faisant appel à la rmn du ^{13}C et du ^{15}N, on a mesuré les déplacements chimiques des sels de benzènediazonium et de ses dérivés substitués en position *para* en solution dans le sulfolane. Il y a une corrélation linéaire entre les déplacements chimiques du $^{13}C1$ et les potentiels de demi-onde polarographique. Cette relation indique une augmentation linéaire de la densité électronique en C1 avec l'augmentation du pouvoir électronneur des substituants. On attribue partiellement les relations non linéaires entre les déplacements chimiques du ^{15}N des deux noyaux de nitrogène et les potentiels de demi-onde, à des contributions paramagnétiques de second ordre aux déplacements du ^{15}N. Cette contribution est approximativement proportionnelle à l'inverse des préférences d'absorptions en uv. Les résultats généraux suggèrent que dans l'état fondamental de la structure de résonance des sels de benzènediazonium, la rehybridation de la liaison C1—N1 est inhabituelle et cette liaison demeure une liaison simple.

Introduction

Some time ago, Elofson and Gadallah obtained a good correlation of polarographic half-wave potentials of substituted benzenediazonium salts with Hammett substituent constants, $\sigma(1)$. We have had occasion to measure the ^{13}C nmr shifts of a number of substituted benzenediazonium salts in sulfolane, the solvent in which the polarographic correlation was obtained. We also obtained the natural abundance ^{15}N chemical shifts of some of the compounds.

Other workers (2–6) have noted various unusual aspects of the ^{13}C and ^{15}N chemical shifts, in particular, the very highfield shift of the C1 carbons and lowfield shift of diazo nitrogens in benzenediazonium salts, especially with electron-donating substituents. We have now extended the series and compared the nmr results with polarographic half-wave potentials which are a direct measure of the electrophilicity of these compounds. It was not surprising to find a good linear correlation between the polarographic half-wave potentials and $^{13}C1$ shifts. Nitrogen-15 nmr shieldings are found to be affected in opposite directions from those of $^{13}C1$ and they do not correlate linearly with the half-wave potential or the Hammet σ constants.

Sulfolane was chosen as a solvent for the nmr measurements in order to avoid the complications of specific solvation effects. Recently the effects of some other solvents on ^{15}N chemical shifts have been noted to be significant (7, 8). Also, the polarographic measurements in sulfolane have produced a good correlation and, with the most positive values for half-wave potentials, an indication of minimum solvation effects. It has been noted also in this laboratory that the chloride ion causes large displacement of $E_{1/2}$ to more negative potentials. This has been attributed to complex formation.[3] Therefore, chloride or other halide ions were carefully excluded from the diazotization procedures and tetrafluoroborate salts were used, except for sulfanilic acid diazonium zwitterion, in order to avoid specific interactions. Inclusion of chloride ions in diazotization procedures was largely responsible for the failure of early workers to obtain a correlation between $E_{1/2}$ and σ or σ^+.

Various resonance structures have been suggested for the ground state of aryldiazonium compounds (see Chart 1), including those with rehybridized C1—N1 and N1—N2 bonds (**3***a* and **3***b*). Significance of these resonance structures is discussed and, from the evidence of ^{13}C and ^{15}N chemical shifts, it is concluded that C1—N1 remains as a single bond.

Experimental

Carbon-13 and nitrogen-15 nmr spectra of benzenediazonium tetrafluoroborates were measured in approximately 15 mL of 1.5% sulfolane solutions on a Bruker WH-200 nmr spectrometer operating at 50.323 MHz for ^{13}C and 20.279 MHz for ^{15}N. Nitrogen chemical shifts were calculated from ammonia using the spectral reference numbers. Internal TMS was used as a carbon reference. Five percent of the solvent was perdeuterated sulfolane to provide a deuterium source for the field-frequency lock. All the measurements were made at 5°C and tetrabutylammonium fluoroborate (~0.1 *M*) was added to the solutions to prevent them from freezing.

Ultraviolet absorptions of the fluoroborate salts were measured in sulfolane/CH_3CN (9:1) in approximately 10^{-4} molar solutions using a Beckman Acta C-111 spectrophotometer.

Assignment ^{13}C signals

For *p*-CN benzenediazonium salt, the asssignments for C1, C4, and the cyano carbon were not straightforward. There are three peaks at 123.4, 119.3, and 116.1 ppm. First, a proton coupled ^{13}C spectrum showed that the signals at 123.4 ppm and 116.1 ppm were simple triplets and that at 119.3 ppm was a triplet of triplets. This indicates that the peak at 119.3 ppm was coupled to two sets of two equivalent protons. Therefore, this peak is not due to the cyano carbon, since there are only two protons which could couple to the carbon, and they

are separated from it by three bonds. Secondly, benzenediazonium fluoroborate wth the terminal nitrogen enriched with 95% ^{15}N was prepared, and its proton decoupled ^{13}C nmr spectrum, showed that the peak at 119.3 ppm was a doublet of ~5.5 Hz, indicating that this peak is due to the nearest carbon, C1. The other two peaks remained as singlets. From the above two experiments and the expected chemical shift of cyano carbons, the assignments were confirmed.

Results and discussion

The high stability of *p*-substituted benzenediazonium salts with electron-releasing substituents has been explained by Zollinger (9) as the result of strong contributions to the ground state structure from mesomeric forms **3***a* and **3***b* where the C1—N1 bond is a double bond. Although X-ray studies (10–15) have since shown the C1—N1 bond length in these compounds to be that of an ordinary single bond, and the N1—N2 distance to be the length of a normal triple bond, contributions to the structure from forms **3***a* and **3***b* have been invoked to explain the decrease in calculated bond order by Sukigara and Kikuchi (16), the lengthing of the N1—N2 bond in *p*-dimethylamino benzenediazonium salt by Polynova *et al.* (13), and the linear relationship between half-wave potentials and Hammett constants by this laboratory (1). Recently, studies of ^{13}C nmr chemical shifts of C4 (2, 6) and ^{15}N shifts of N1 and N2 (3, 7) again suggested significant contribution by structures **3***a* and **3***b* to the ground state of *p*-substituted benzenediazonium salts with electron-donating groups.

Carbon-13 and nitrogen-15 chemical shifts are listed in Table 1 together with the polarographic half-wave potential measured in the previous study (1). The equation for the linear correlation between ^{13}C1 shifts, δ, and half-wave potentials, $E_{1/2}$ in Fig. 1, is:

$$[1] \quad E_{1/2} = 0.016\,\delta - 1.51 \quad \text{corr. coeff.} = 0.979$$

where δ is in ppm from TMS. These results indicate a nearly linear increase in shielding of C1 as the electron-donating power of the substituents increases or the $E_{1/2}$ (electrophilicity) decreases. Since a linear relationship between the Hammett constants and $E_{1/2}$ has already been found (1), the ^{13}C chemical shifts also relate linearly with the Hammett constants according to the equation:

$$[2] \quad \delta = 13.216\,(\sigma \text{ or } \sigma^+) + 113.1 \quad \text{corr. coeff.} = 0.979$$

These results agree closely with those of Olah and Grant (2) and Ustynyk *et al.* (6).

The large upfield shifts of ^{13}C1 in various substituted benzenediazonium salts (refs. 2, 3, 5, 6 and footnote 2) indicate

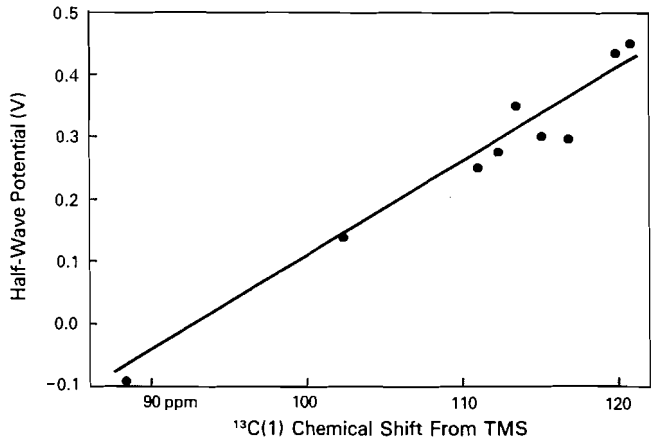

FIG. 1. Linear correlation between ^{13}C1 chemical shifts and polarographic half-wave potentials, $E_{1/2}$, of some aryl diazonium salts.

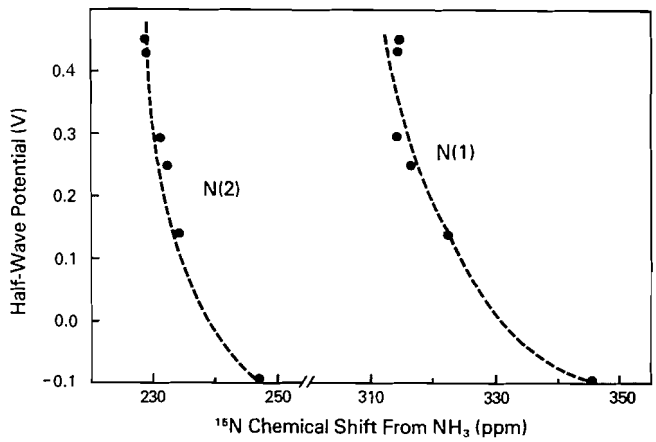

FIG. 2. Plots of ^{15}N chemical shifts with polarographic half-wave potentials, $E_{1/2}$, of some aryl diazonium salts.

the unusual effect of the diazonium group. These high shieldings are partly associated with the small second-order paramagnetic shift due to the N1≡N2 triple bond. The much higher shieldings of C1 found in phenylacetylene, 121.5 ppm (17), and in benzonitrile, 109.7 ppm(18), than found in styrene, 138.2 ppm (18), are analogous to the present observation.

The accumulation of electron charge on C1 is partly due to contributions from some of the accepted resonance structures of *para*-substituted benzenediazonium salts (Chart 1). Contributions from structures **1***b* and **1***c* reasonably explain the unusually high shielding of C1, and are particularly important when the substituent is capable of mesomeric donation of electrons to the ring.

In contrast to the ^{13}C chemical shifts, ^{15}N resonance absorptions shift downfield as the substituents become more electron donating. As shown in Fig. 2, the ^{15}N resonance shift generally to highfield as the half-wave potential, $E_{1/2}$, increases. The correlation is not linear.

The effect of rehybridization involving the phenyl ring and the *para* substituent (**1***b* and **1***c*) can be also seen from the ^{15}N chemical shifts. The large downfield shift in the amino ^{15}N resonance is the result of the loss of some electrons from this nitrogen to the ring. The ^{15}N chemical shift of the amino nitrogen of *p*-dimethylamino benzenediazonium salt is 128 ppm compared with a much more shielded value of 44.6 ppm dimethyl aniline (17), where such resonance structures as **1***b* and **1***c* make less contribution.

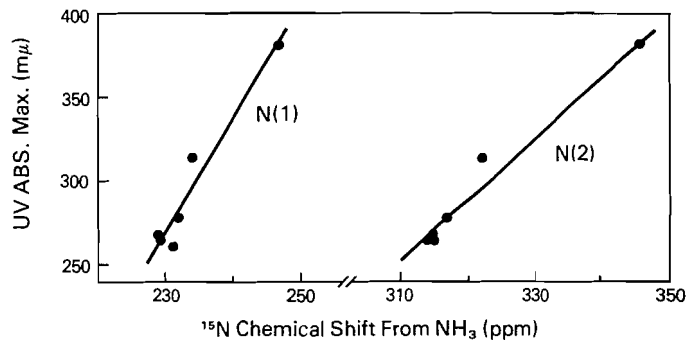

FIG. 3. Correlations between ^{15}N chemical shifts and the uv absorption maxima of some aryl diazonium salts.

The observed downfield shift of N1 and N2 with electron donating substituents may be further explained by including the resonance structues, **2***a*, **2***b*, or **2***c*. N1 shifts downfield by gaining a lone pair and N2 by gaining a positive charge (**1***a* → **2***a*, **2***b* or **2***c*). If we consider those resonance structures for compounds with electron-donating substituents, the correlation of ^{15}N chemical shifts, in the opposite direction from ^{13}C1 chemical shifts, with the half-wave potentials may be understood. The lack of a linear relationship between ^{15}N shifts and $E_{1/2}$ seems to indicate that differt mechanisms from those in the ^{13}C shifts dominate in ^{15}N chemical shifts.

The lengthening of the C1—N1 bond distance from 1.415 Å in benzenediazonium cations (11) to 1.48 Å in *o*-OCH_3 or *p*-$N(CH_3)_2$ derivatives (13, 14) predicts only about 5 ppm shift in ^{15}N resonance to the downfield if we consider only the decrease of diamagnetic contribution.[4] Second-order paramagnetic contributions due to the mixing of some excited states to the ground state may become important in this case. In Fig. 3, ultraviolet absorption maxima of the compounds studied here are plotted against ^{15}N chemical shifts. Figure 3 indicates that as the electron-donating property of the substituent increases, the absorption maxima shift toward the longer wavelength (lower excitation energy). The absorption of the dimethylamino compound is at a particularly long wavelength. If we assume that the mean excitation energy in the expression of the second-order paramagnetic shifts (19):

$$[3]\quad \sigma_p = -\frac{e^2h^2}{2m^2C^2\Delta E}\left\langle\frac{1}{r^3}\right\rangle_{2p}\left[Q_{NN} + \sum_{B\neq N} Q_{NB}\right]$$

can be approximated by the observed uv excitation energy (20), the non-linearity of the plot of the ^{15}N chemical shifts (see Fig. 2) with $E_{1/2}$ may be due mainly to the dominance of this term.

Resonance structures **2***a*, **2***b*, and **2***c* are also compatible with the slight lengthening of the N—N bond (14) and the calculated lower bond order (16) for the electron-donating dimethylamino derivative. These structures also agree with the single bond length found for C1—N1 bonds by X-ray studies (11–15). The downfield shift of ^{13}C4 (2) may also be due to the accumulation of positive charge on C4 (**1***b* and **2***b*). Moreover, the overall findings from the X-ray studies which eliminate structures **3***a* and **3***b* are fully supported here. Gadallah and Elofson (1) have shown that electrochemical reduction of aryldiazonium salts at controlled potentials in aprotic solvents produces phenyl radicals and N_2 gas as the only products, indicating an intact N≡N triple bond.

The increased shielding of C1 correlates well not only with $E_{1/2}$ as illustrated in Fig. 1 but also with coupling rates (21). The coupling rates of p-NO_2, unsubstituted, and p-OCH_3 benzenediazonium cations with 1-naphtholate are in the order of $NO_2 \gg H \gg OCH_3$. Again, no simple relationship exists between the $^{15}N1$ and $^{15}N2$ shifts and coupling rates. Perhaps the slightly decreased shielding of $^{15}N2$ observed by Casewit *et al.* (7) and in this study for p-NO_2, p-COOH, and p-CN compounds are significant. These shifts, although less than 1 ppm, are in the same direction (downfield) as the $^{13}C1$ resonances, compared to the unsubstituted compound. The maximum in the plot of $^{15}N2$ shifts against σ^+ (Fig. 2 in ref. 7) may be related to the well-known and still unexplained fact that both the p-NO_2 and p-OCH_3 derivatives decompose more slowly (22) in acid than the unsubstituted salt ($H > p$-$NO_2 \gg p$-OCH_3).

Received July 12, 1983

WESLEY G. TAYLOR and TOM T. NAKASHIMA. Can. J. Chem. **62**, 96 (1984).

Preparative-scale high pressure liquid chromatography on 3-acetyl-2-(2′,6′-dimethyl-5′-heptenyl)oxazolidine (**1**), a complex acetamide derivative of citronellal, resulted in isolation of the diastereomeric forms of this insect repellent. The two diastereomers were designated as **1***a* and **1***b* on the basis of their order of elution from silica gel and from a variety of capillary gas chromatography columns. Interpretation of the ^{13}C nuclear magnetic resonance spectra of **1***a* and **1***b* was accomplished by comparison with model compounds and by off-resonance proton-decoupling experiments. Absolute stereochemical assignments were not made. Because of the amide group, the diastereomers existed in solution at ambient temperature as *cis* and *trans* rotational isomers, which caused nonequivalence of most of the carbon atoms, including the olefinic carbons at C-5′ and C-6′. *trans* Isomer (**5**) was concluded to be the major contributor to the rotational equilibrium. The spectrum of 3-acetyl-2-(4′-methyl-3′-pentenyl)oxazolidine (**7**) was also recorded for comparison.

WESLEY G. TAYLOR et TOM T. NAKASHIMA. Can. J. Chem. **62**, 96 (1984).

La chromatographie liquide à haute pression à l'échelle préparative de l'acétyl-3 (diméthyl-2′,6′ heptène-5′ yl)-2 oxazolidine (**1**), un dérivé acétamide complexe du citronellal, a permis d'isoler deux formes diastéréoisomères de ce produit qui repousse les insectes. On désigne ces deux diastéréoisomères **1***a* et **1***b* en fonction de leur temps d'élution sur du gel de silice et en fonction d'analyses chromatographiques en phase gazeuse sur des colonnes capillaires. On a interprété les spectres de rmn du ^{13}C des composés **1***a* et **1***b* par comparaison avec des composés modèles et par des expériences de découplage hors résonance du proton. On n'a pas déterminé la stéréochimie absolue à cause du groupe amide; en solution les diastéréoisomères existent, à la température ambiante, sous forme d'isomères rotationnels *cis* et *trans*, ce qui provoque la non équivalence de ce plupart des atomes de carbone, y compris les carbones oléfiniques en C-5′ et C-6′. On conclut que l'isomère *trans* (**5**) est celui qui contribue d'avantage a l'équilibre rotationnel. On a également enregistré le spectre de l'acétyl-3 (méthyl-4′ pentène-3′-yl)-2 oxazolidine (**7**) en vue d'établir des comparaisons.

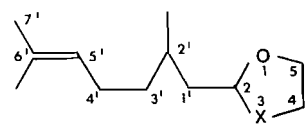
Introduction

A number of 2-substituted N-acetyloxazolidines, for example (±)-3-acetyl-2-(2′,6′-dimethyl-5′-heptenyl)oxazolidine (**1**), have insect repellent properties (1, 2) and **1** has been registered in some countries as a biting fly repellent.[1] Despite these initial claims on the identity of **1**, which was synthesized from (±)-citronellal (**2**), its structure and stereochemistry have not been investigated in detail. This is due, in large part, to the presence of four optical isomers, arising from the asymmetric centers at C-2 and C-2′. To our knowledge, the diastereomers of **1** and their enantiomeric counterparts have never been isolated in quantity. Recently, however, one pair of diastereomers (**1***a* and **1***b*) were separated by high resolution capillary gas chromatography (capillary gc) with achiral liquid phases and their mass spectra were compared (3). The ratio of **1***a* to **1***b*, calculated from integrated capillary gc peak areas, was 45:55 in various samples of **1**. As part of continuing efforts to understand the complexities of this unusual insect repellent, we now describe the isolation of **1***a* and **1***b* by preparative high pressure liquid chromatography (hplc) and the confirmation of structure of these diastereomeric components by ^{13}C nuclear magnetic resonance spectroscopy (^{13}C nmr).

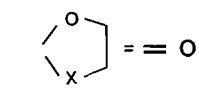
Results and discussion

Synthesis, chromatography, and purity assessments

Starting from **2** enriched in the (*R*) (+) enantiomer, **1** was obtained by the condensation of this aldehyde with ethanolamine followed by acetylation with acetic anhydride. Capillary gc with a variety of columns and conditions showed 45% of the first eluting diastereomer (**1***a*) and 55% of the second eluting diastereomer (**1***b*) as the two major products. As previously described (3), attempts were made to separate **1***a* and **1***b* by thin layer and column chromatography but without success.



1 X = $NCOCH_3$



2

3 X = O

The separation of **1***a* and **1***b* was, however, accomplished by hplc with commercial silica gel cartridges. With a solvent mixture of ethyl acetate – methylene chloride and using the shave–recycle technique (4), **1***a* and **1***b* were partially separated after one recycling of the mixture. Compound **1***a* was collected by shaving the upslope of the first peak whereas **1***b*

[a]The experimental conditions are given in Table 1.
[b]The peak height ratio of **5**:**6** was 72:28 ± 2%.
[c]The expected quartet was difficult to find in the off-resonance decoupled spectrum.

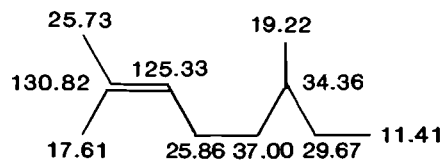
was isolated by shaving the backslope of the second peak. After redistillation of each sample, reasonable yields of **1***a* (20–25%) and **1***b* (40–60%) were isolated in at least 99% purity as shown by capillary gc with splitless injections. Each diastereomer also gave correct combustion analyses for its elements.

Samples of **1***a* and **1***b* (>98% diastereomeric purity by capillary gc) were checked for impurities by chemical ionization mass spectrometry using a direct insertion probe. Only the quasimolecular ion for **1***a* and **1***b* was detected, thus confirming the high purity of these samples.

The possibility existed that some chemical changes, such as rearrangement of the olefinic bond to give positional isomers, may have occurred during contact of the samples with silica gel, which would not have been detected by all of the above techniques. This did not occur because samples of **1** before hplc gave ^1H (3) and ^{13}C nmr spectra that were the same as the sum of the resonances in the purified diastereomers. Thirty resonances were detected in the ^{13}C nmr spectrum of **1**, which possessed 14 carbon atoms. Unfortunately, the ^1H nmr spectra (60 MHz) of **1***a* and **1***b* were virtually superimposable and the ^{13}C nmr spectra (22.6 MHz), although noticeably different, were still very complicated because two signals with unequal peak heights were observed for most of the carbon atoms, including the sp^2 carbons of the trisubstituted double bond. In attempts to characterize **1***a* and **1***b*, chemical shifts were first assigned, then reasons for the doubling of carbon signals in this system were investigated.

Assignments

Before commencing spectral analyses of **1***a* and **1***b*, the ^{13}C nmr spectra of **2** and citronellal ethylene acetal (**3**, ref. 5) were examined to aid in the interpretation. Chemical shift assignments (Table 1) were based on single-frequency off-resonance decoupling information and on available chemical shift data for related olefinic and isoprene compounds with analogous carbon structures (6–8). Couperus *et al.* (6) have reported the ^{13}C chemical shifts for a number of olefins and this work was of particular interest. The closest model for our system was 2,6-dimethyl-2-octene (**4**), shown below with the reported chemical shifts. From these values, the assignments for **2** and **3** followed directly.



4

The spectra of **2** and **3** were very similar for C-3′ to C-7′ and for the methyl groups at C-2′ and C-6′. In **2**, C-1′ was deshielded by 10 ppm and C-2′ was shielded by 1.2 ppm compared to the same carbons in **3**. The dioxolane ring carbons were readily identified (Table 1) and the assignments agreed with reported values for related aliphatic acetals (9). C-4 and C-5 displayed a small difference in chemical shift (0.1 ppm).

The highly purified samples of **1***a* and **1***b* in deuterochloroform solution gave ^{13}C nmr chemical shifts as shown in Table 2. Where doubling of carbon signals occurred, the paired signal of larger intensity was considered first. Assignments of carbon shifts to the 5′-heptenyl side chain, with the exception of C-1′, were based on comparisons to **2**–**4** and the assignments were supported by off-resonance decoupling experiments. Chemical shift assignments for C-1′ at 39.8 ppm (**1***a*) and 39.4 ppm (**1***b*) were based on C-1′ being the only remaining methylene carbon that would be expected to resonate

near 40 ppm.

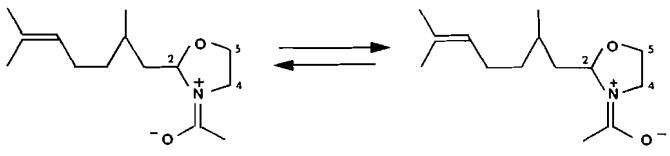
Assignment to C-2 of the oxazolidine ring (88.6 ppm for **1***a*; 88.2 ppm for **1***b*) was straightforward because of the expected large downfield shift from the other sp^3 hybridized tertiary carbon (C-2′). C-5 was deshielded relative to C-4, as noted in related N-nitrosooxazolidines (10). The only remaining carbons to assign were those of the N-acetyl group. As expected, the amide carbonyl carbon resonated near 168 ppm, whereas the main signal for the methyl group occurred at 23.2 ppm for both diastereomers. The latter carbon could be distinguished from C-2′ CH_3 by considering the similar chemical shifts for C-2′ CH_3 in **2** and **3** and by comparison to reported chemical shifts for related acetamides (11).

Compounds **1***a* and **1***b* gave very similar ^{13}C nmr spectra (Table 2). The largest differences in chemical shifts were found for C-2′ CH_3 (1.2 ppm), followed by C-3′ (1.1 ppm), C-2 (0.4 ppm) and C-1′ (0.4 ppm). These differences were not considered sufficiently large to attempt *R* or *S* stereochemical assignments at C-2.

cis–trans *Isomerism*

The ^{13}C nmr spectra of **1***a* and **1***b* showed that each diastereomer possessed nine nonequivalent carbons when recorded at ambient temperature in deuterochloroform solution. Four sites of nonequivalence were in the 5′-heptenyl side chain and the remainder were associated with the five carbon atoms of the N-acetyloxazolidine group (Table 2). With the exception of C-1′ and C-4, the chemical shifts of the paired signals differed by less than 1 ppm. The appearance of paired signals in **1***a* and **1***b* was different in one respect. In **1***a*, C-2′ gave one signal (29.2 ppm) and C-3′ gave two (36.6/36.3 ppm), whereas **1***b* gave two signals for C-2′ (29.0/28.8 ppm) and one for C-3′ (37.7 ppm).

Although N-acetyloxazolidines had not previously been examined by ^{13}C nmr, the carbon chemical shifts of N-acyl piperidines (12), N-acyl morpholines (13), N-acyl prolines (14), pyrrolidine-containing peptides (15), and other model amides (16) were influenced by the effects of restricted rotation about the amide bond, giving rise to sites of equivalence because of the existence of an equilibrium mixture of *cis* and *trans* rotational isomers. Thus, two well separated ^{13}C resonances have been observed at temperatures corresponding to a slow rate of amide bond rotation on the nmr time-scale. If **1***a* and **1***b* behaved similarly, the *trans* (**5**) and *cis* (**6**) isomers[2] must be present, and in unequal amounts, to account for the doubling of carbon signals when the spectra were recorded at ambient temperature.



5 6

To demonstrate the involvement of **5** and **6**, a variable-temperature ^{13}C nmr experiment was performed on **1***b*, the diastereomer isolated in larger quantity. It was predicted that **5** and **6** would interconvert rapidly as the temperature rose and at a temperature corresponding to a fast rate of interconversion of these isomers on the nmr time-scale, nonequivalence would disappear, leading to a simplified ^{13}C nmr spectrum. The ^{13}C nmr spectra were recorded from 250–330 K at 20 K intervals. The spectra were virtually identical up to 310 K but at 330 K, the upper practical limit with deuterochloroform as solvent, the paired signals began to coalesce.

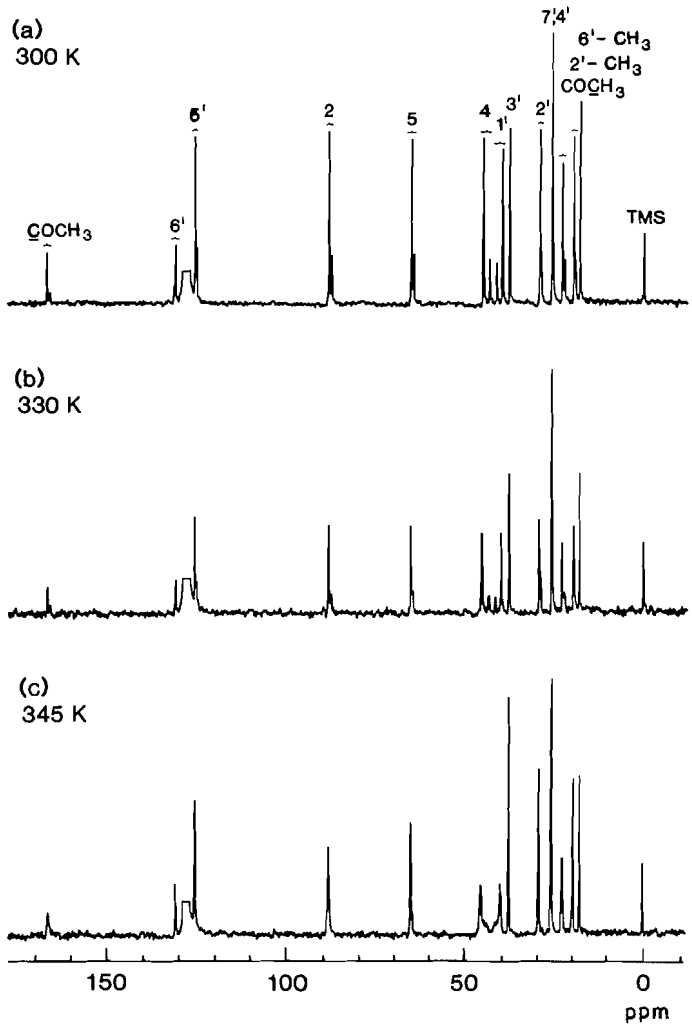


FIG. 1. The ^{13}C nmr spectra of 3-acetyl-2-(2′,6′-dimethyl-5′-heptenyl)oxazolidine (isomer **1***b*) at (a) 300 K, (b) 330 K, and (c) 345 K. The spectra were recorded with inverse gated decoupling with operating parameters as follows: decoupler delay, 2.2 s; decoupler switching delay 0.002 s; pulse width, 9 μs; acquisition time, 0.3 s; number of scans, 500. Peaks for the solvent (deuterobenzene) near 128 ppm have been truncated.

In order to extend the upper temperature limit the spectrum was recorded in deuterobenzene solution (Fig. 1). At 345 K, it can be seen that the paired signals had collapsed to singlets. This provided evidence for the existence of **5** and **6** and for the remarkable influence of these isomers on the doubling of signals for carbon atoms close to, and remote from, the amide group.

Comparison of the spectra run in deuterobenzene and in deuterochloroform solution at 300 K, representing the slow rate of interconversion on the nmr time-scale, was informative. The intensity of the nonequivalent carbon signals was unequal in both solvents but there was a higher population of one rotational isomer in deuterobenzene (~75:25 ratio) than in deuterochloroform (~70:30 ratio).

[2]This geometry (14, 15) designates orientation of the substituent at C-2 relative to the methyl group of the N-acetyl moiety.

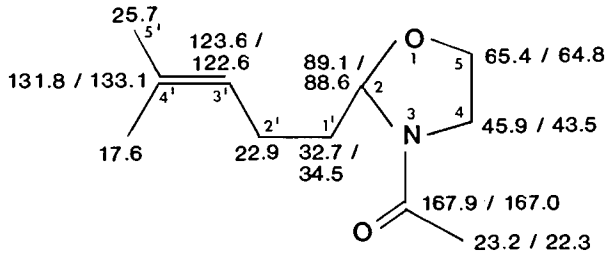

FIG. 2. Structure and ^{13}C nmr chemical shifts for 3-acetyl-2-(4′-methyl-3′-pentenyl)oxazolidine (**7**) in deuterochloroform at 303 K. Where doubling of carbon resonances occurred, the paired signal of larger intensity is given first.

Comparisons with other amides

With five- and six-membered N-acylated heterocycles, ^{13}C nmr studies have shown that a methylene carbon atom located *anti* to the carbonyl oxygen of the amide group is deshielded relative to the corresponding carbon in the *cis* isomer (12–15). This "α-to-nitrogen effect", when applied to C-4 of **1***a* and **1***b*, led to the conclusion that the major isomer in deuterobenzene and deuterochloroform had the *trans* geometry (**5**). In fact, under conditions of slow interconversion (Table 2), the main signal for C-4 in **1***a* and **1***b* occurred downfield by 2.3 ppm compared to the signal for C-4 in the minor isomer. This deshielding effect, although smaller, was also evident at the β-position (C-5).

The previous studies with amides also showed that an α-carbon *syn* to the carbonyl oxygen (in the *trans* isomer) was shielded relative to the same carbon atom in the *cis* isomer. This effect has been observed in aqueous solution with α-substituted pyrrolidines (15), the closest model we found to the oxazolidine system. With **1***a* and **1***b*, however, the main signal for C-2 resonated downfield by 0.4–0.5 ppm (Table 2). In fact, the main signals for C-1′ and C-6′ were the only paired signals that were shielded relative to the minor signal (Fig. 1). The evidence therefore suggested that 2-substituted N-acetyloxazolidines were exceptions to the "α-to-nitrogen effect" because not one but both of the α-carbons in the *trans* isomer (**5**) were deshielded compared to the α-carbons in the *cis* isomer (**6**). This anomaly is not entirely surprising because all of the factors influencing the carbon shifts of rotational isomers have not been elucidated. It was interesting to find that both the endocyclic (C-5) and exocyclic (C-1′) β-carbons behaved as the *syn–anti* argument had predicted.

3-Acetyl-2-(4′-methyl-3′-pentenyl)oxazolidine (**7**) was synthesized to compare its ^{13}C nmr spectrum with that of **1***a* and **1***b*. All carbons of the oxazolidine ring again gave two signals (~70:30 peak height ratio) and the main signal resonated downfield relative to the minor signal of the pair (Fig. 2). C-3′ of the 3′-pentenyl group behaved similarly. The other two nonequivalent carbons (C-1′ and C-4′) gave the main signal upfield relative to the minor signal as found with the comparable carbons in **1***a* and **1***b*. The presence of *cis* and *trans* isomers of **7** was again established by variable-temperature ^{13}C nmr, with slow, intermediate, and fast rates of interconversion in deuterobenzene solution corresponding to temperatures of 300, 330, and 345 K. As with **1***b*, the population of *trans* isomer was slightly higher in deuterobenzene than in deuterochloroform solution when the spectra were recorded at 300 K.

The techniques described here allow the exploration of **1** as an interesting stereochemical probe for investigating the metabolism (21) and mode of action of insect repellents. Differences in the repellent activity of both optical and *cis–trans* isomers may exist and further studies to examine these possibilities are in progress.

Experimental

High pressure liquid chromatography was performed with a Waters Prep LC/System 500 A instrument equipped with Prep PAK Silica cartridges (Waters Associates, Inc.) and a refractive index detector. Capillary gas chromatography was performed with a Hewlett–Packard 5838A chromatograph equipped with a flame ionization detector and a model 18835B capillary inlet system. The carrier gas was helium (30 cm/s flow velocity) and the makeup gas was nitrogen (30 mL/min). Injector and detector temperatures were 225°C and 250°C, respectively. Capillary columns, prepared by the method of Grob and Grob (17) or available commercially, were wall-coated with FFAP (fused silica, 25 m × 0.31 mm id, Quadrex Corporation, Woodbridge, CT), Carbowax 20M-TPA (Pyrex, 22 m × 0.33 mm), Carbowax 20M-TPA (Pyrex, 60 m × 0.29 mm), OV-105 (Pyrex, 30 m × 0.3 mm), SP2300 (Pyrex, 20 m × 0.29 mm), and OV-275 (Pyrex, 22 m × 0.33 mm). Samples were normally injected by the split technique. For mass spectrometry, a Hewlett–Packard 5985B instrument was used, with sample introduction by a capillary gc column of Carbowax 20M-TPA (15 m × 0.32 mm, splitless injections) or by a temperature-programmed direct insertion probe. Electron-impact mass spectra were recorded at 70 eV, whereas positive chemical ionization mass spectra were recorded using isobutane as the reagent gas at a source pressure of 0.5 Torr. Citronellal from commercial samples enriched in the (+)-enantiomer was obtained from Eastman Kodak Co., Rochester, NY or from Tridom/Fluka Chemical Corp., Hauppauge, NY. Mallinckrodt CC-7 silica gel was used for column chromatography. Elemental analyses were obtained from Dr. C. Daessle, Montreal, Quebec. Boiling points were recorded during vacuum distillations and are uncorrected. Evaporations were performed with a Buchi rotary evaporator at water aspirator vacuum below 50°C.

Fourier-transform ^{13}C nmr spectra (^{1}H broadband decoupled) were obtained at ambient temperature in deuterochloroform solution on a Bruker HFX-90 instrument at a frequency of 22.6 MHz. Single-frequency off-resonance ^{1}H decoupled spectra were also obtained with this spectrometer. Variable-temperature spectra were measured with a Bruker WM-250 instrument operating at 62.9 MHz and equipped with a BVT-1000 temperature control unit. Samples (0.75–1.5 mmol) were dissolved in 1.5 mL of solvent (10-mm nmr tubes) containing tetramethylsilane (TMS) as the internal standard. The ^{13}C chemical shifts are expressed downfield from TMS = 0.

*3-Acetyl-2-(2′,6′-dimethyl-5′-heptenyl)oxazolidine (**1**)*

A mixture of (+)-**2** (30.85 g, 0.2 mol), ethanolamine (26.9 g, 0.44 mol), and benzene (300 mL) was heated under reflux for 4 h (Dean–Stark trap) and acetic anhydride (45 g, 0.44 mol) was added at 5°C. After stirring at room temperature overnight, the product was isolated as described previously (method B in ref. 3) Distillation at 116–128°C (0.1 Torr) gave 39.27 g (82% yield) of a nearly colorless oil, which was a mixture of 44–46% **1***a* and 54–56% **1***b* by capillary gc with the columns indicated below. This sample was identical (capillary gc, ^{13}C nmr) to an analytical standard of **1** prepared from (±)–**2** (kindly supplied by S.C. Johnson and Son, Racine, WI); capillary gc retention times (in min), FFAP: 14.8 for **1***a*; 15.1 for **1***b*; 130–200°C at 3°C/min; 22 m Carbowax 20M-TPA: 18.8 for **1***a*; 19.5 for **1***b*; 180°C isothermally; 60 m Carbowax 20M-TPA: 36.9 for **1***a*; 38.0 for **1***b*; 180°C isothermally; OV-105: 8.9 for **1***a*; 9.0 for **1***b*; 160–220°C at 3°C/min; SP2300: 8.0 for **1***a*; 8.3 for **1***b*; 200°C isothermally; OV-275:9.7 for **1***a*; 9.9 for **1***b*; 200°C isothermally; ^{13}C nmr (WM-250, $CDCl_3$, 297 K) δ: 167.8, 167.0, 131.4, 131.0, 124.8, 124.3, 88.6, 88.1, 87.7, 65.2, 64.6, 45.6, 43.3, 41.5, 41.2, 39.8, 39.4, 37.7, 36.6, 36.3, 29.2, 28.9, 28.8, 25.7, 25.4, 23.2, 22.3, 20.3, 19.0, 17.6.

Isolation of **1**a *and* **1**b

The hplc was operated isocratically with a solvent system of ethyl acetate – methylene chloride (1:1 v/v, Caldeon ACS grade) and a flow rate of 250 or 300 mL/min. Samples of the mixture were diluted with the above solvent to give an injection volume of 5–7 mL. Before elution of the main peak, at 2.9–3.7 column volumes, the instrument was switched to the recycle mode. After one recycle, two partially resolved components were detected (~1:1 peak height ratio) and collections were initiated by shaving the leading and trailing peaks. Between collections, the mixture was recycled and collections were continued for 4–6 recycles.

In a typical experiment, 1 g of mixture (45% **1***a* and 55% **1***b* by capillary gc) was separated on a single silica cartridge and with 5 recycles (4 collections per isomer) over 60 min. The fractions were combined and concentrated by rotary evaporation of the solvents. Capillary gc (22 m Carbowax 20M-TPA) showed that the first fractions contained primarily **1***a* (7.7% of **1***b*), whereas the last fractions were enriched in **1***b* (5.7% of **1***a*). Samples of **1***a* from three runs were combined and one gram was repurified by hplc by recycling and collecting **1***a*. Fractions of **1***b* were discarded. This was repeated for combined (1 g) samples of **1***b*. Vacuum distillation gave 275 mg of **1***a* and 397 mg of **1***b*, with diastereomeric purities by capillary gc of 98–99%. The overall isolated yields, based on distilled samples and on the 45:55 mixture, were 25% for **1***a* and 36% for **1***b*. Capillary gc (FFAP, 20 m Carbowax 20M-TPA, SP2300, OV-275, 30-s splitless injection, 35°C for 1 min, 35–160°C at 25°C/min, 160–220°C at 1°C/min) indicated chemical purities of 99–99.5% for the samples of **1***a* and **1***b*.

Additional separations were performed with 2 g of the mixture and with two silica cartridges connected in series. The yields, based on the weight of products isolated after the two hplc separations and a final distillation, were 19–24% for **1***a* and 38–61% for **1***b*. The diastereomeric purities, determined by capillary gc with FFAP, Carbowax 20M-TPA, SP2300, or OV-275, ranged from 95–99%.

If traces of solvent impurities were suspected of being present, as evidenced by a slight coloration in the concentrated fractions from hplc, the samples were passed through a small column of silica gel (silicAR CC-7), by eluting first with hexane and then with mixtures of methylene chloride and hexane (both Caledon glass distilled grade). The fractions containing **1***a* or **1***b* were dried ($MgSO_4$), evaporated, and distilled *in vacuo*. No impurities were detected by tlc under conditions previously reported (3). *Anal.* calcd. for $C_{14}H_{25}NO_2$: C 70.25, H 10.53, N 5.85; found (**1***a*): C 70.21, H 10.68, N 5.98; found (**1***b*): C 69.90; H 10.15, H 5.77.

Purified samples of **1***a* and **1***b* were analyzed by chemical ionization mass spectrometry, using a direct insertion probe (temperature programmed from 30°C to 250°C at 15°C/min, then maintained at 250°C for 20 min) and with scanning from *m/z* 130–800. Under these conditions, one intense ion (at *m/z* 240) was found which corresponded to MH^+ for **1***a* and **1***b*.

Citronellal ethylene acetal (**3**)

This compound was prepared and purified as previously described (5).

3-Acetyl-2-(4'-methyl-3'-pentenyl)oxazolidine (**7**)

5-Methyl-4-hexenal was prepared from 2-methyl-3-buten-2-ol as described in the literature (18–20). This aldehyde (2.2 g, 0.02 mol) was reacted with ethanolamine (2.69 g, 0.044 mol) and acetic anhydride (4.5 g, 0.044 mol) as described for the preparation of **1**. A portion (1.4 g) of the crude product was purified by column chromatography with hexane and ether to give 0.86 g (45.2%) of **7** as a colorless oil: bp 91–114°C (0.05 Torr); ^{13}C nmr (see Fig. 2); ei–ms *m/z*: (% relative abundance): 197 ($M^{+\bullet}$, 1.5), 154 (23), 140 (17), 114 (18), 99 (11), 98 (22), 86 (14), 72 (100), 44 (13), 43 (18), 41 (11); ci–ms: 198 (MH^+, 100); ci–ms (direct insertion probe, as described for **1***a* and **1***b*) gave only one prominent ion, at *m/z* 198. Purified samples of **7** were homogeneous by capillary gc (FFAP) and tlc (3). *Anal.* calcd. for $C_{11}H_{19}NO_2$: C 66.97, H 9.71, N 7.21; found: C 66.86, H 9.98, N 7.21.

The structure of cubane mono and 1,4-dicarboxylic acids in lyotropic liquid crystalline solution

ALAN S. TRACEY
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received July 26, 1983

ALAN S. TRACEY. Can. J. Chem. **62**, 101 (1984).

Proton nmr studies of cubane mono and 1,4-dicarboxylic acids in lyotropic liquid crystalline solution show that these molecules are distorted from the cubane structure. The protons of cubane dicarboxylate which are vicinal to their respective carboxylate group are displaced towards those groups along the C_3 axis resulting in an elongation relative to a cube. In cubane monocarboxylate there is also a displacement of vicinal protons toward the carboxyl group, but this is accompanied by a displacement of the protons one carbon further removed, away from the carboxyl groups. The shape of this latter compound is comparable to that of a section of a cone with the narrow end of the cone defining the proton positions adjacent to the carboxyl group while the wide end of the cone defines the positions of the adjacent set of protons. The remaining proton of course sits on the C_3 axis which determines the centre of symmetry of the cone.

ALAN S. TRACEY. Can. J. Chem. **62**, 101 (1984).

Les études en rmn du proton des acides mono et dicarboxyliques-1,4 du cubane dans un cristal liquide lyotrope révèlent que ces molécules sont déformées par rapport à la structure du cubane. Les protons du dicarboxylate de cubane qui sont vicinaux avec leur groupe carboxylate respectif se déplacent vers les groupes le long de l'axe C_3 provoquant une élongation par rapport au cubane. Dans le monocarboxylate de cubane, il y a également un déplacement des protons vicinaux vers le groupe carboxyle; mais ce déplacement des protons vicinaux s'accompagne aussi d'un déplacement des protons qui sont sur la position suivante par rapport aux groupes carboxyles. La forme de ce dernier composé est comparable à celle d'une section d'un cône avec l'extrémité étroite du cône définissant la position du proton adjacent au groupe carboxyle tandis que l'extrémité plus large du cône définit les positions des ensembles de protons adjacents. Le proton restant se situe naturellement sur l'axe C_3 qui détermine le centre de symétrie du cône.

Introduction

The structures of pentacyclo[4.2.$0^{2,5}$.$0^{3,8}$.$0^{4,7}$]octane (cubane) derivatives are of considerable importance from a theoretical point of view since these are symmetric rigid molecules with a cagelike structure. Distortions from cubic symmetry are of interest. Although various theoretical studies of the cubane geometry have been reported (1–4), no structure determinations of cubane derivatives other than that of cubane itself (5) are available.

Lyotropic liquid crystalline materials are known to be good solvents for use in the structure determination of ionic solutes (6) and have been found to be free from the anomalous effects which are frequently encountered when thermotropic liquid crystals are employed (7–9).

In this study, the structures of the mono- and 1,4-dicarboxylates of cubane have been investigated by nuclear magnetic resonance (nmr) spectroscopy. The proton spectra give information about the relative proton positions via the interproton dipolar couplings (10, 11). These cubane derivatives have C_3 symmetry and consequently each requires one order parameter to describe its preferred alignment in the magnetic field of the nmr spectrometer.

The nmr spectrum of pentacyclo[4.2.$0^{2,5}$.$0^{3,8}$.$0^{4,7}$]octane-1,4-dicarboxylic acid (cubane dicarboxylate) is characterized by one chemical shift, three direct couplings, and three indirect coupling constants. The relative proton positions are determined by one ratio of internuclear distances and the alignment by one internuclear distance. Two dipolar couplings are therefore sufficient to determine both the proton positions and the molecular alignment. The structure is overdetermined by one coupling.

Pentacyclo[4.2.$0^{2,5}$.$0^{3,8}$.$0^{4,7}$]cubane-1-carboxylic acid (cubane monocarboxylate) provides an nmr spectrum characterized by six direct couplings, six indirect couplings, and three chemical shifts. Of the six direct couplings, four are required to specify internuclear distance ratios and the alignment. The structure of cubane monocarboxylate is therefore overdetermined by two couplings.

Experimental

The lyotropic mesophases used in this study were prepared according to standard procedures (6, 11) and had the following composition: decylammonium chloride, 385 mg; decanol, 8 mg; sodium chloride, 16 mg; deuteriated water, 607 mg. To separate preparations of this material, 10 mg of either cubane 1,4-dicarboxylic acid or cubane monocarboxylic acid was added. The preparation of these cubane derivatives is reported elsewhere and the compounds used here were received as a gift from those authors (12).

The nmr spectra were obtained from the lyotropic solution using a Bruker WM-400 nmr spectrometer operating at ambient temperature. The liquid crystalline solutions were allowed to equilibrate for 30 minutes in the spectrometer before nmr spectra were obtained.

Results and discussion

The nmr spectra of the two compounds investigated were well resolved and the spectra sufficiently overdetermined for good spectrum analysis. The six coupling constants (direct and indirect) and one chemical shift of cubane dicarboxylate were determined by 22 assigned transitions in the nmr spectrum. The three chemical shifts and 12 coupling constants of cubane monocarboxylate were determined from 90 assigned transitions. Table 1 gives the values obtained and their probable errors. The indirect couplings agree well with those previously reported (12). All spectra were analysed using the nmr program DIPUEA (13).

Figure 1 shows the coordinate system and position labelling adopted for this analysis. The structural and orientational parameters were obtained using the computer program SHAPE (14). For the structure analysis, the dipolar couplings were weighted according to the inverse of the probable error so that the best determined couplings had the most influence on struc-

tural parameters. A vicinal H—H distance of about 2.810 Å can be calculated from the X-ray structure for cubane. Using this value, the structural parameters of Tables 2, 3, and 4 were obtained. Any error in the reference distance will result in the appropriate scaling factor being applied to the tables. An important question raised by the analysis in Table 2 is why the RMS error of the fit is so large. The dipolar couplings are matched to an agreement generally no better than about 10 times their probable errors. The explanation in this case is quite straightforward. For an unperturbed cubane structure, the vicinal coupling constants D_{12} and D_{27} (see Table 1) are equal to zero since their corresponding internuclear vector lies at the zero transition (magic) angle and these dipolar couplings vanish. When bending motions occur, this vector deviates from the magic angle and a dipolar coupling arises. Even when the equilibrium angle is slightly removed from the magic angle, these bending contributions can be proportionately very important. An estimate of these contributions can easily be obtained by simply ignoring those couplings when performing the structure analysis. In this case, both structures are just determined. The results are shown in Table 3. It is clear that the contributions introduced to the dipolar couplings by the bending motions are of the same magnitude as the unperturbed coupling would be. On further consideration of Table 3, it can be seen that the major bending motion which contributes to the dipolar coupling is along the C_3 axis between geminal carbons. Thus H1, H4, and H6 preferentially bend toward position 7, while H2, H3, and H5 bend away from position 7. As a result of this bending, the contribution to D_{12} is negative, while that to D_{27} is positive, in agreement with Table 3. The remaining couplings are much less sensitive to the vibrational motions because the internuclear vectors do not lie near the magic angle. They consequently provide a much more accurate structure, though of course it is preferable to have an overdetermined structure.

A cube is defined by two distance ratios as 1:1.4142:1.7321. The values which correspond in the cubane dicarboxylate are 1:1.4035:1.7233, while two such sets of ratios can be obtained for the monocarboxylate. They are 1:1.4031:1.7254 and 1:1.4222:1.7417, where the second set of ratios is derived from distances to H7. These results show that there is an elongation of the cubane structure along the C_3 axis in the direction of the carboxyl groups. Considering for the moment the monocarboxylate, this result could mean that hydrogens 2, 4, and 6 are displaced towards the carboxyl group, leading to the r_{12} length of 2.837 Å compared to 2.810 Å for

the r_{27} distance. Similarly the distance r_{14} is 0.009 Å shorter than the corresponding distance, r_{17}, of 3.989 Å. It is known from deuterium nmr studies that C—D bonds bend toward polar substituents in aromatic systems (15, 16) and the same could be occurring here.

Concurrent with the displacement of hydrogens 2, 4, and 6, there is a corresponding movement of nuclei 1, 3, and 5 in the opposite direction. In this case, the latter set of nuclei become relatively further apart as is shown by the two distances r_{14} = 3.980 Å compared to 3.996 Å for r_{23}. These conclusions are perhaps made clearer by Table 4 where the experimental nuclear coordinates are compared to those for an undistorted cube.

Conclusions

Pentacyclo[4.2.$0^{2,5}$.$0^{3,8}$.$0^{4,7}$]octane 1-mono and 1,4-dicarboxylic acids (cubane mono and dicarboxylates) have been studied in lyotropic liquid crystalline solution by proton nmr spectroscopy. The results showed that rather large distortions from the cubane structure occur. The distortion is apparent as an elongation of the proton skeleton of the molecule along the C_3 axis of symmetry. This distortion results from a displacement of hydrogen atoms toward the adjacent carboxyl groups. No information concerning carbon positions was obtained.

The structure of the monocarboxylate can best be related to a section of a cone with the C_3 axis defining the rotation axis of the cone. The protons adjacent to the carboxyl sit on the narrow end of the conic section while those protons one carbon removed are located on the wide end of the cone. The remaining proton is located on the symmetry axis.

It was found that large vibrational contributions to vicinal hydrogen dipolar coupling constants occurred. This resulted from the fact that the H—H internuclear vectors are close to the zero splitting (magic) angle which leads to the large con-

For personal use only.

tributions. The major contribution to the vicinal dipolar couplings apparently arises from a bending of the C—H bond along the C_3 axis between the geminal carbon atoms.

The photochemical addition of *N*-haloamides to olefins: a comparison of cyclic and acyclic *N*-halo-*N*-alkylamides and *N*-halo-*N*-acylamides (*N*-haloimides)[1,2]

JEAN LESSARD,[3] YVON COUTURE, MARTINE MONDON,[4] AND DANIEL TOUCHARD[5]
Département de chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received April 15, 1983

JEAN LESSARD, YVON COUTURE, MARTINE MONDON, and DANIEL TOUCHARD. Can. J. Chem. **62**, 105 (1984).

Upon photochemical decomposition in the presence of cyclohexene and 1-octene, an *N*-halo-*N*-acylamide (*N*-haloimide) leads to better yields of addition than its *N*-halo-*N*-alkyl analogue, and cyclic *N*-halo-*N*-alkyl- and *N*-halo-*N*-acylamides add more efficiently than their acyclic analogues. The yields of addition were higher with *N*-chlorosuccinimide which has been added also to 1-methylcyclohexene than with *N*-bromosuccinimide which did not add to 1-methylcyclohexene.

JEAN LESSARD, YVON COUTURE, MARTINE MONDON et DANIEL TOUCHARD. Can. J. Chem. **62**, 105 (1984).

L'addition-1,2, par voie photochimique, d'un *N*-halo-*N*-acylamide (*N*-haloimide) aux cyclohexène et 1-octène est plus efficace que celle d'un analogue *N*-alkyle et celle d'un *N*-halo-*N*-acyl- ou d'un *N*-halo-*N*-alkylamide cyclique, plus efficace que celle d'un analogue acyclique. Le *N*-chlorosuccinimide, qui a été additionné également au 1-méthylcyclohexène, donne de meilleurs rendements en addition que le *N*-bromosuccinimide qui ne s'additionne pas au méthyl-1 cyclohexène.

Introduction

Recently, we have identified a number of factors having an influence on the yield of 1,2-addition in the photochemical reactions of *N*-haloamides (ZCONRX) with olefins (1): replacing the *N*-hydrogen (R = H) by an *N*-methyl group (R = CH_3) does cause a dramatic decrease in the yield of 1,2-addition; the 1,2-addition is favored when replacing X = Br for X = Cl, when lowering the temperature, and when increasing the electron-withdrawing power of Z.

This paper delineates further the scope and limitations of the radical addition of *N*-haloamides to olefins for the synthesis of *N*-(2-haloalkyl) amides by identifying two other factors having an effect on the yield of 1,2-addition: (*i*) an *N*-halo-*N*-acylamide (R = acyl) leads to better yields of addition than its *N*-halo-*N*-alkyl (R = alkyl) analogue and (*ii*) cyclic *N*-halo-*N*-alkyl and *N*-halo-*N*-acylamides add more efficiently than their acyclic analogues.[6]

The photochemical addition of *N*-chlorosuccinimide (NCS) and *N*-bromosuccinimide (NBS) to olefins has been described in ref. 2. Since then, reports on the successful radical addition of NCS (3), NBS (3, 4),[7] and *N*-bromo-3,3-dimethylglutarimide (3) to olefins, initiated by light, have been published. We had reported earlier the radical addition of NCS to cyclohexene promoted by chromous chloride (5).[8]

Results and discussion

The results are recorded in Table 1 and Table 2 for the photochemical additions to cyclohexene and to 1-octene respectively and in Scheme 2 for the addition of NCS (**9**) to 1-methylcyclohexene. The reaction conditions were the same as those used in ref. 1 and are specified in footnote *a* of the tables. No dark reaction was observed in the case of the *N*-chloro derivatives even after three days. With NBS (**10**), there was essentially no dark reaction during the time required for the photochemical reaction to be completed. After three days in the dark at room temperature the following results were obtained: in the presence of cyclohexene, 95% of NBS was consumed (iodometric titration) and 7% of *trans* 1,2-adduct **20** was isolated;[9] in the presence of 1-octene, 20% of NBS was consumed and no addition product was detected.

The orientation of the photochemical additions to 1-octene (Table 2) and to 1-methylcyclohexene (Scheme 2) – the amide moiety being added on the least substituted carbon atom – and the failure of the dark reactions strongly suggest that 1,2-addition occurs through a radical chain mechanism (eqs. [1] to [3]) as previously shown for the photochemical addition to olefins of a variety of *N*-haloamides (1), of NCS (3), NBS (3, 4), and *N*-bromo-dimethylglutarimide (3, 7).

[5]France–Quebec Predoctorate Fellow, 1970–72. Present address: Institut Universitaire de Technologie, Université de Nantes, 44606 Saint-Nazaire, France.

[6]The influence of these factors on the halogenation of cyclohexene will be reported in a forthcoming paper.

[7]The few reports on the addition of NBS to olefins, some of them being ionic, have been reviewed in ref. 4. *N*-Bromophthalimide has also been added to olefins (6), many of the additions involving most probably an ionic mechanism.

[8]The chromous chloride promoted addition of NBS to cyclohexene was reported also in ref. 5. However, attempts to repeat this addition were unsuccessful. The sole products isolated were succinimide (35%, not fully recovered because of its high solubility in water), *trans*-2-bromo-methoxycyclohexane (32%), and *trans*-2-bromocyclohexanol (25%). Thus electrophilic bromination appears to be faster than radical 1,2-addition.

[9]When the reaction mixture was saturated with oxygen, 15% only of NBS was consumed after three days in the dark: no 1,2-adduct was detected.

TABLE 1. Photochemical additions of *N*-haloamides and *N*-haloimides to cyclohexene[a]

Entry	*N*-Haloamide	Lamps[b] (λ, nm)	Reaction time[c] (h)	1,2-Adduct(s) Structure	Yield[d] (*cis*/*trans*) (%)	Yield[d] of parent amide (%)	Material balance[e] (%)

[a]Reaction conditions: 15–20°C, CH_2Cl_2 (distilled over P_2O_5) as solvent, solutions 0.2 to 0.5 *M* in *N*-haloamide, 2 mol of cyclohexene per mol of *N*-haloamide, inert atmosphere (nitrogen or argon).

[b]Pyrex cell with the 300 nm lamps, Vycor cell with the 254 nm lamps.

[c]The reported reaction times represent a rough estimate. The reaction was normally stopped when the starch–iodide paper test was negative. However, if a *trace* amount of *N*-haloamide was still present, a faint coloration was appearing after 15 to 30 s. Depending on the experimentalist, the reaction was stopped either when the *N*-haloamide was entirely consumed or when a trace amount was still present, which could make a noticeable difference in the reaction time.

[d]Yield of chromatographically (preparative layer chromatography, plc) pure products based on the *N*-haloamide.

[e]Addition product(s), parent amide, plus any product containing the amide moiety or derived from the amide moiety.

[f]Taken from ref. 1.

[g]Many successive separations by plc led to a sample still contaminated with another product.

[h]Besides the parent amide, $C_2H_5OCON(CH_3)CH_2COOC_2H_5$ was isolated in a 31% yield (see ref. 1).

[i]By vpc.

One of the main features of Tables 1 and 2 is the increase in the yield of 1,2-addition when going from an *N*-chloro-*N*-alkylamide to its *N*-acyl analogue (*N*-chloroimide): compare entries 1 and 3, 4 and 5, 7 and 9 of Table 1; compare entries 1 and 2, 3 and 4, 6 and 8 of Table 2. This feature could be readily explained if both the rate of step [2] and that of step [3] of the addition chain are faster with an *N*-halo-*N*-acylamide than with its *N*-alkyl analogue, because the 1,2-addition process would then compete more effectively with the other chain processes such as halogenation (hydrogen abstraction processes). Indeed, an *N*-acylamidyl radical should react more rapidly with a carbon–carbon double bond than an *N*-

Y = C=O	**33**, 10%	**34**, ≤ 1% (not isolated)
Y = CH_2	**27**, ≤ 1% (not isolated)	**28**, 3%

SCHEME 1

alkylamidyl radical (step [2]) since the former, having two electron-withdrawing acyl groups linked to the nitrogen, should be more electrophilic (the SOMO should be lower in energy).[10] Furthermore, by analogy with the fact that the reactivity of ZCONHX as a halogen-atom transfer agent towards a carbon radical increases with the electron-withdrawing power of ZCO (10), an *N*-halo-*N*-acylamide should be a better halogen-atom donor (step [3]) than its *N*-halo-*N*-alkyl analogue.

Some evidence for the fact that an *N*-halo-*N*-acylamide is a better halogen-atom donor than its *N*-halo-*N*-alkyl analogue comes from a comparison of the addition of NCS (**9**) and of *N*-chlorobutyrolactam (**7**) to 1-octene (Table 2, entries 8 and 6 respectively). The adducts **33**, **34**, **27**, and **28** are derived from the addition of the amidyl radical on the most substituted carbon atom of the double bond (see Scheme 1). The 1,2-adducts **33** and **27** (see A) result from chlorine-atom transfer onto the intermediate radical adduct and the adducts **34** and **28** (see B) from hydrogen-atom abstraction. In the case of NCS (Y = C=O), A (**33**) (chlorine-atom transfer) was the major adduct, whereas in the case of *N*-chlorobutyrolactam (Y = CH_2), B (**28**) (hydrogen abstraction) was the major adduct. Therefore NCS (**9**) appears to be a better chlorine-atom donor than *N*-chlorobutyrolactam (**7**).

From entry 2 of Table 1, it can be seen that an *N*-cyanomethyl group is not electron-attracting enough to allow the observation of the 1,2-addition process with cyclohexene.

The other main feature of Tables 1 and 2 is the better yields of addition obtained with cyclic *N*-chloroamides as compared with their acyclic analogues: compare entries 1 and 7, 3 and 9, 4 and 8 of Table 1; and entries 1 and 6, 2 and 8, 3 and 7 of Table 2. To account for this second feature we propose that cyclic amidyls are more reactive in the addition step [2] than their acyclic analogues for steric and electronic reasons. In acyclic amidyls, Z and R (R = alkyl or acyl) must prefer the *trans* arrangement by analogy with carboxamides (11) and carboxylic esters (12), whereas in cyclic amidyls, Z and R are necessarily *cis* to each other:

acyclic amidyl (*trans*) cyclic amidyl (*cis*)

There are more steric interactions between the alkene and the attacking amidyl in the *trans* arrangement (acyclic amidyl) than in the *cis* arrangement (cyclic amidyl) according to the inspection of models. The activation entropy term ($-T\Delta S^{\ddagger}$) might also be larger in the case of acyclic amidyls. As for the electronic reasons, it is conceivable that the more reactive Σ_N electronic state could be more accessible in the case of cyclic amidyls than in the case of acyclic amidyls.[11]

As seen from Table 2, the additions of cyclic *N*-haloamides to 1-octene are less regioselective than those of their acyclic analogues. Indeed, cyclic *N*-haloamides gave addition products resulting from the attack of the amidyl radical on the most substituted atom of the double bond (entries 6 to 9) whereas in the case of acyclic *N*-haloamides, no such adducts were detected (entries 2 to 5).[12] Thus cyclic amidyls would be less regioselective. This lends support to the greater reactivity of cyclic amidyls in step [2].

The 1,2-adducts **33** and **36** (Table 2, entries 8 and 9) could have been formed via electrophilic halogenation of 1-octene but they most likely result from a radical process for the following reasons: (*i*) adduct **36** was not formed in the dark reaction of NBS with 1-octene; (*ii*) a similar ratio of regioisomer was obtained with NCS (**33**/**32** = 0.22) and NBS (**35**/**36** = 0.19) although NBS is a better electrophilic halogenating agent; (*iii*) the chromous chloride promoted addition of NCS to 1-octene gave also a mixture of regioisomers **32** and **33** in a 15% yield (**33**/**32** = 0.15) and electrophilic halogenation under these conditions leads to halohydrins and halomethoxy derivatives but not to 1,2-adducts (5).

In contrast to the addition to 1-octene, the radical addition of NCS (**9**) to 1-methylcyclohexene either photochemically initiated or promoted by chromous chloride (Scheme 2), appears to be regiospecific. This can be attributed to the larger steric hindrance of a trisubstituted carbon atom. Interestingly, the *cis* adduct **37** was formed whereas, with cyclohexene, only the *trans* adduct **19** (Table 1, entry 9) was isolated. This observation agrees with the general observation (1, 5) that, in radical 1,2-additions of *N*-haloamides, 1-methylcyclohexene gives a larger proportion of *cis* isomer than cyclohexene. NBS does not

[10]For an interpretation of the electrophilic character of radicals and their reactivity towards alkenes in terms of frontier orbital interactions, see ref. 8. An application to the reactivity of alkoxy radicals towards olefins has been reported in ref. 9.

[11]The electronic ground state of acyclic *N*-alkylcarboxamidyls (13–15) and of one cyclic carboxamidyl (14*b*) has been shown to be π_N. The ground state of succinimidyl is probably π_N also, according to MNDO (16) and INDO (17) calculations. However, Skell and co-workers (18*a*) have shown that two varieties of succinimidyl radicals, the π_N and the Σ_N states, can be produced from NBS and NCS according to the reaction conditions. In the radical addition to alkenes such as cyclohexene and tertiobutylethylene, the more energetic Σ_N state appears to be involved (18*b*) and this is supported by MNDO reaction path calculations for the attack of $CH_3^{\cdot}$ on NCS (17). By analogy, the Σ_N state of *N*-alkylcarboxamidyls could be involved in chemical reactions, as was suggested for some intramolecular additions to double bonds (19) and to an aromatic ring (20).

[12]Chow and co-workers (4) have studied the photochemical addition of NBS (**10**) to 1-hexene in acetonitrile and in the presence of ethylene oxide and reported that the addition is completely regiospecific, giving only the isomer with the succinimide moiety attached to the least substituted carbon atom.

SCHEME 2

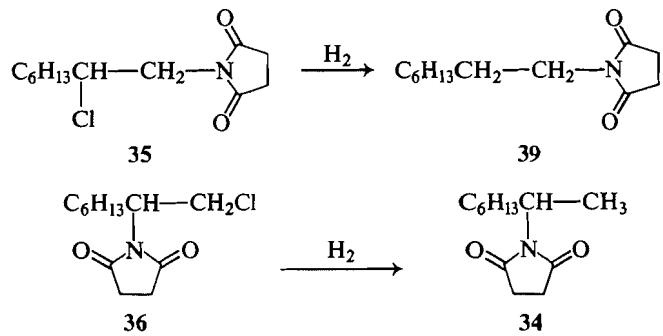
add to 1-methylcyclohexene either photochemically or with chromous chloride.

Since we found that, with *N*-bromocarboxamides, lowering the temperature to −78°C caused a dramatic increase in the yield of 1,2-addition to cyclohexene (e.g. from 25% at 15−20°C to 95% in the case of *N*-bromoacetamide) (1, 21), the addition of NBS (**10**) was carried out at −78°C but without any improvement of the yield of 1,2-adduct **20**: 19% as compared to 22% at 15−20°C (Table 1, entry 10). However, NBS being practically insoluble in methylene chloride at −78°C, we used a 1:1 mixture of acetonitrile and methylene chloride as solvent and, in order to obtain a reasonable reaction time (7 h), the 254 nm lamps were used instead of the 300 nm lamps (see the Experimental). With 1-octene, the yield of addition was 20% at −78°C and 11% at 15−20°C (Table 2, entry 9).

Structure and stereochemistry of the addition products

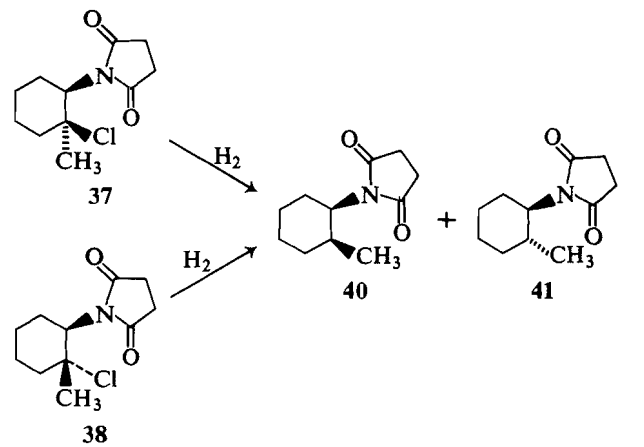
All the addition products had ir and ^{1}H nmr spectra, an elemental analysis, and/or a mass spectrum consistent with their structure. For the 1,2-adducts derived from cyclohexene, the *cis* isomer was easily identified by ^{1}H nmr spectroscopy from the chemical shift of the equatorial proton at C-2 (carbon bearing the halogen), which is more deshielded than the axial proton of the *trans* isomer (1, 5).

The 1,2-adducts derived from 1-octene were compared (^{1}H nmr and, in a few cases, ^{13}C nmr spectrum) to adducts **35** and **36** whose structure was proven by hydrogenolysis of the C—Br bond.[13] The major adduct **35** gave *N*-(1-octyl)succinimide (**39**) whereas the minor adduct **36** gave *N*-(2-octyl)succinimide (**34**) (Scheme 3).



SCHEME 3

Hydrogenolysis of the 1,2-adducts **37**[14] and **38** obtained from 1-methylcyclohexene gave the stereoisomeric *N*-(2-methylcyclohexyl)succinimides **40** and **41** (Scheme 4), thus showing that the succinimido group was attached to the least substituted carbon atom and that the hydrogenolysis was not stereospecific. In the ^{1}H nmr spectrum of **40**, the axial proton at C-1 appears as a doublet of triplets (J = 13 and 4 Hz, ΣJ = 21 Hz) whereas in the case of **41**, it appears as a triplet of doublets (J = 11 and 4 Hz, ΣJ = 26 Hz). Therefore **40** must be the *cis* isomer (H2 equatorial) and **41**, the *trans* isomer (H2 axial). The *trans* stereochemistry was assigned to the major 1,2-adduct **38** on the basis that the addition of NCS (**9**) to cyclohexene gave exclusively the *trans* 1,2-adduct **19** (1, 5). We found that the proportion of *cis* addition is larger with 1-methylcyclohexene than with cyclohexene in all the radical additions of *N*-haloamides studied so far (1, 5).



SCHEME 4

Experimental[15]

Most of the pertinent general information is the same as that given in refs. 1 and 5. The amides were obtained commercially.

N-Haloamides

NCS (**9**) and NBS (**10**) are commercially available and were recrystallized from water and methylene chloride (100% active halogen). The preparation of *N*-chloro-*N*-methylacetamide (**1**) and of ethyl *N*-chloro-*N*-methylcarbamate (**4**) has been reported (1). The following *N*-chloroamides were prepared by the chlorine method (1): *N*-chloro-

[13]The chloro analogue **33** was inert towards hydrogen under the same conditions.

[14]Since **37** could not be separated from **38**, the hydrogenolysis was carried out on a 40:60 mixture of **37** and **38**.

[15]For the new products not described in the experimental section, the microanalytical and/or mass spectral data, together with the ir and ^{1}H nmr characteristic absorptions, are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, K1A 0R6.

N-cyanomethylacetamide (**2**) (55% yield, 83% active chlorine); ethyl *N*-chloro-*N*-acetylcarbamate (**5**) (60% yield, 90% active chlorine); diethyl *N*-chloro-imidomalonate (**6**) (65% yield, 80% active chlorine); *N*-chloro-2-pyrrolidone (**7**), mp 46–47°C (100% yield, 100% active chlorine); *N*-chloro-2-oxazolidone (**8**), mp 61–62°C (95% yield, 99.5% active chlorine). *N*-Chloro-*N*-acetylacetamide (**3**) was prepared by treating, in the dark, *N*-acetylacetamide with tertiobutylhypochlorite (1.1 equiv.) in carbon tetrachloride at room temperature: 60% yield, 75% active chlorine.

The ^{1}H nmr spectra of the crude *N*-chloroamides prepared by the chlorine method showed that they consisted of the pure *N*-chloroamide plus the extracting solvent (CH_2Cl_2). That explains why the active chlorine content was lower than 100%. Since the photochemical reactions were carried out in methylene chloride, no attempt was made to remove it completely. The ^{1}H nmr spectrum of crude **3** also showed that it consisted of pure **3** which then did contain some carbon tetrachloride.

Photochemical reactions

The general procedure was the same as that given in ref. 1. A typical procedure is described below.

Addition of N-*bromosuccinimide (**10**) to 1-octene at −78°C*

NBS (0.80 g, 4.49 mmol) in CH_2Cl_2 (40 mL) and CH_3CN (40 mL), both freshly distilled from P_2O_5, were placed in a Vycor cell. Nitrogen was bubbled through the solution for 10 min and the cell was cooled with acetone − Dry Ice (~−78°C)

1-Octene (1.0 g, ~9 mmol) was added. After degassing for a further 10 min and while maintaining a low stream of nitrogen, the solution was irradiated (254 nm lamps) until the starch−iodide paper test was negative (7 h). The reaction mixture was evaporated to dryness (rotating evaporator), then dissolved in methylene chloride (50 mL). The resulting solution was washed with water (3 × 10 mL), dried over Na_2SO_4, then evaporated to dryness (664 mg). The residue was separated by plc (ether−hexane 4:1) to give two main fractions. The less polar fraction consisted of N-*(1-chloro-2-octyl)succinimide* (**36**) (38 mg, 3%). Microdistillation at 90°C (0.005 Torr) afforded the analytical sample; ν_{max} ($CHCl_3$): 1780 (w) and 1710 (s) (C=O), 1390, 1370, 1135 cm^{-1}; δ ($CDCl_3$): 0.88 (CH_3), 2.73 (s, 4H), 3.4–4.6 ppm (complex pattern, 2H1 + H2); *m/e*: 289, 291 (1:1, M^+), 288, 290 (1:1, $M^+ - 1$), 210 ($M^+ - Br$), 100 (base peak, $C_4H_6NO_2^+$) (22). *Anal.* calcd. for $C_{12}H_{20}BrNO_2$: C 49.66, H 6.94; found: C 49.54, H 6.93.

The more polar fraction consisted of N-*(2-chloro-1-octyl)-succinimide* (**35**) (208 mg, 16%). Microdistillation at 100°C (0.004 Torr) gave the analytical sample; ν_{max} ($CHCl_3$): 1785 (w) and 1710 (s) (C=O), 1390, 1140 cm^{-1}; δ ($CDCl_3$): 0.89 (CH_3), 2.73 (s, 4H), 3.4–4.6 ppm (complex pattern, 2H1 + H2); *m/e*: 289, 291 (1:1, M^+), 288, 290 (1:1, $M^+ - 1$), 210 ($M^+ - Br$), 100 ($C_4H_6NO_2^+$) (22). *Anal.* calcd. for $C_{12}H_{20}BrNO_2$: C 49.66, H 6.94; found: C 49.54, H 6.79.

The aqueous phases were combined and continuously extracted with CH_2Cl_2 for 2 days to afford, after evaporating the solvent, succinimide, mp 116–119°C (31 mg, 70%).

Hydrogenolysis of 35

The procedure is based on that reported in ref. 23. Palladium (10%) on charcoal (15 mg) was prehydrogenated at room temperature in 95% ethanol (10 mL) at 40 lbs/in^2 for 30 min. The bromo derivative **35** (38 mg, 0.13 mmol) and potassium acetate (50 mg, 0.51 mmol) were added. After 42 h at room temperature under hydrogen (40 lbs/in^2), the catalyst was filtered, washed with 95% ethanol, and the filtrate evaporated to dryness. Water (15 mL) and ether (15 mL) were added. The mixture was shaken and the two phases were separated. The aqueous phase was extracted with ether. The organic phases were combined, dried over Na_2SO_4, and the solvent was evaporated to afford crude N-*(1-octyl)succinimide* (**39**) (15 mg, 55%). The analytical sample was prepared by microdistillation at 85°C (4 Torr); ν_{max} ($CHCl_3$): 1780 (w) and 1705 (s) (C=O), 1395, 1150, 1120 cm^{-1}; δ ($CDCl_3$): 0.85 (CH_3), 263 (s, 4H), and 3.45 ppm (t, J = 7 Hz, 2 H1); *m/e*: 211 (M^+), 100 (base peak, $C_4H_6NO_2^+$) (22). *Anal.* calcd. for $C_{12}H_{21}NO_2$: C 68.21, H 10.02; found: 68.06, H 9.99.

Hydrogenolysis of 36

It was carried out as above to afford N-*(2-octyl)succinimide* (**34**) (21 mg, 90%). The analytical sample was obtained by microdistillation at 90°C (4 Torr); ν_{max} ($CHCl_3$): 1780 (w) and 1705 (s) (C=O), 1390, 1370, 1360, 1160, 1110 cm^{-1}; δ ($CDCl_3$): 0.87 (CH_3), 1.36 (d, J = 7 Hz, CH_3), 2.65 (s, 4H), and 4.18 ppm (sextuplet, J = 7 Hz, H2); *m/e*: 211 (M^+), 100 (base peak, $C_4H_6NO_2^+$) (22). *Anal.* calcd. for $C_{12}H_{21}NO_2$: C 68.21, H 10.02; found: C 68.28, H 9.83.

Under the same conditions the chloro analogue **32** showed no sign of hydrogenolysis even after 9 days.

Hydrogenolysis of 38

It was carried out as above using 150 mg of Pd/C, 134 mg of **38** (0.45 mmol), 150 mg of potassium acetate (1.5 mmol), and a hydrogen pressure of 44 lbs/in^2. The hydrogenation was stopped after 6 days and the ^{1}H nmr spectrum of the crude product (139 mg) showed that it consisted of 41% (w/w) of starting material and 59% of a 64:36 mixture of *cis* and *trans* N-*(2-methylcyclohexyl)succinimides* (**40** and **41** respectively). Separation by plc on silica gel (ether−hexane 2:3) followed by microdistillation at 75°C (2 Torr) gave an analytical sample of a mixture of **40** and **41**; ν_{max} ($CHCl_3$): 1780 (w) and 1700 (s) (C=O), 1360, 1165, 1125 cm^{-1}; *m/e*: 196 ($M^+ + 1$), 195 (M^+), 100 ($C_4H_6NO_2^+$) (22). *Anal.* calcd. for $C_{11}H_{17}NO_2$: C 67.66, H 8.78; found: C 67.47, H 8.90. Homogeneous samples of **40** and **41** were obtained after several successive plc separations; **40**: δ ($CHCl_3$): 0.94 (d, J = 7 Hz, CH_3), 2.65 (s, 4H), and 4.08 ppm (d of t, J = 13 and 4 Hz); **41**: δ ($CHCl_3$): 0.73 (d, J = 7 Hz, CH_3), 2.64 (s, 4H), and 3.63 ppm (t of d, J = 11 and 4 Hz).

Hydrogenolysis of a mixture of 38 and 39

The conditions used above (50 mg of Pd/C, 40 mg of a 45:55 mixture of **38** and **39**, 50 mg of potassium acetate, 44 lbs/in^2 of hydrogen, 6 days) gave a mixture of starting material, **40**, and **41** in a 30:40:30 molar ratio.

The intramolecular equilibrium in 2-*tert*-butylphenol and some derivatives. An anomalous $^5J_m^{H,OH}$ indicating steric distortion

TED SCHAEFER, RUDY SEBASTIAN, and SALMAN R. SALMAN[1]
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received June 28, 1983

TED SCHAEFER, RUDY SEBASTIAN, and SALMAN R. SALMAN. Can. J. Chem. **62**, 113 (1984).

The ^{1}H nmr spectral parameters in dilute carbon tetrachloride solution are reported for 2-*tert*-butylphenol, as obtained by decoupling of the sidechain protons. Long-range couplings between hydroxyl and ring protons are also reported for five derivatives of 2-*tert*-butylphenol. In the *cis* conformer of 2-*tert*-butylphenol an anomalous $^5J_m^{OH,H-5}$ occurs, most likely as a consequence of a significant distortion of the COH geometry. Such an anomaly, which leads to an incorrect estimate of the *cis*–*trans* equilibrium constant, does not occur in other alkyl phenols, for example, in 2-*tert*-butyl-6-methylphenol. The coupling constant data provide no evidence for out-of-plane conformational preferences of the hydroxyl group in these compounds.

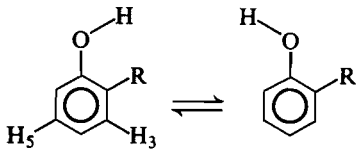
TED SCHAEFER, RUDY SEBASTIAN et SALMAN R. SALMAN. Can. J. Chem. **62**, 113 (1984).

On rapporte les paramètres spectraux en rmn du ^{1}H obtenus en découplant les protons de la chaîne latérale du *tert*-butyl-2 phénol en solution dans le tétrachlorure de carbone. On rapporte également les couplages à longue distance entre le groupe hydroxyle et les protons du cycle de cinq dérivés du *tert*-butyl-2 phénol. Dans le conformère *cis* du *tert*-butyl-2 phénol, il se produit un $^5J_m^{OH,H-5}$ anomal qui serait une conséquence d'une déformation importante de la géométrie du groupe COH. Une telle anomalie, qui conduit à une évaluation incorrecte de la constante d'équilibre *cis*–*trans*, ne se produit pas dans les autres phénols alkylés: comme par exemple avec le *tert*-butyl-2 méthyl-6 phénol. Les données de constante de couplage n'apportent pas la preuve d'une préférence conformationnelle hors du plan du groupe hydroxyle de ces composés.

[Traduit par le journal]

Introduction

The first direct measurement (1) of the *cis*–*trans* equilibrium in solution for 2-methylphenol was based on the stereospecific spin–spin coupling between the hydroxyl proton and



1*a* (*cis*) **1***b* (*trans*)

the ring protons in the *meta* position, $^5J_m^{H,OH}$. It was assumed, in line with data from a variety of phenol derivativs (2–6), that in **1***a* (R = CH_3) $^5J_m^{OH,H-3}$ is negligibly small as is $^5J_m^{OH,H-5}$ in **1***b*. Measurement of $^5J_m^{H,OH}$ then yields the free energy difference between **1***a* and **1***b* as $-RT \ln K = -RT \ln {}^5J_m^{OH,H-3}/{}^5J_m^{OH,H-5}$. In CCl_4 solution, this difference is -1590 ± 170 J/mol at 305 K (**1***b* more stable), in excellent agreement with an indirect measurement based on infrared band intensities in 2-*tert*-butylphenol and 2-*tert*-5,6-dimethylphenol (7).

As for 2-methylphenol, the hydroxyl stretching band in 2-isopropylphenol is also unresolvable into *cis* and *trans* components (7). It is shifted only 2 cm^{-1} from the phenol value. The $^5J_m^{H,OH}$ numbers give a free energy difference of -2510 ± 290 J/mol in CCl_4 solution at 305 K, **1***b* more stable for R = $CH(CH_3)_2$ (8). For 2-isopropyl-6-methylphenol the same procedure yields 1170 ± 330 J/mol as the free energy favoring the conformation in which the hydroxyl group lies *trans* to $CH(CH_3)_2$. Within experimental error this number agrees with the additive preference derived from the monosubstituted phenols.

Furthermore, the long-range couplings over five bonds involving the methine proton of the isopropyl group are also stereospecific and suggest the free energy difference between **1***a* and **1***b* in 2-isopropylphenol as -2340 ± 420 J/mol, to the advantage of **1***b*, in agreement with $^5J_m^{H,OH}$ as an indicator. This agreement implies that the methine C—H bond lies *cis* to the hydroxyl group in **1***b* and *trans* to it in **1***a*.

Now, in 2-*tert*-butylphenol the hydroxyl stretching band is resolvable into two components, one shifted to higher frequency by 32 cm^{-1} from the phenol band and the other, less intense, to lower frequency by 8 cm^{-1} (7). The free energy difference favoring **1***b* (R = *tert*-butyl) is 6570 J/mol and was derived from corrected band intensity ratios (7). A study of the temperature dependence of the band intensities in CCl_4 solution and in the vapour phase (9, 10) showed that the entropy difference between the two conformers was less than 1 J/mol K, indicating that the free energy differences are effectively enthalpy differences.

In this paper, $^5J_m^{H,OH}$ is reported for 2-*tert*-butylphenol and some of its derivatives. An apparently anomalous value of $^5J_m^{OH,H-5}$ is interpreted in terms of a pronounced distortion of the hydroxyl group geometry in **1***a*. The free energy difference derived from $^5J_m^{H,OH}$ in the 6-methyl derivative agrees with that based on infrared band intensities. Conclusions are also drawn about the possible presence of noncoplanar conformations of the hydroxyl group in these compounds.

Experimental

The 2-*tert*-butylphenol was a gift from Pitt–Consol Chemical Co., as were the 6-methyl- and the 6-*tert*-butyl derivatives from The Ethyl Corporation. The other compounds were acquired from Aldrich.

Solutions as dilute as 0.2 mol%, but never larger than 5 mol%, in CCl_4, containing ca. 4 vol.% of tetramethylsilane, were transferred to 5-mm od nmr sample tubes. The solutions were degassed by a number of freeze–pump–thaw cycles and were then flame-sealed under vacuum. Intermolecular proton exchange was retarded as described previously (5).

The ^{1}H nmr spectra were recorded in the frequency-sweep mode on a HA100 nmr spectrometer at a probe temperatur of 305 K. Careful calibrations of peak positions were made as described before in detail (11). Because the methyl protons of the *tert*-butyl groups caused

broadening of peaks from other protons, calibrations were usually combined with strong irradiation of the *tert*-butyl ^{1}H nmr peak or peaks. Because these δ values are relatively small, the decoupling fields were adjusted in amplitude so as not to perturb the TMS internal lock signal unduly.

The sign of $^4J_o^{H,OH}$ was determined by weak irradiation experiments (12) on 2-*tert*-butyl phenol, as was that of $^5J_m^{OH,H-5}$. The sign of $^5J_o^{OH,CH3}$ in the 6-methyl derivative was also determined.

Results and discussion

Spectral analyses

Full spectral analyses were carried out with the computer program LAME (13, 14). The ^{1}H nmr spectral parameters for 2-*tert*-butylphenol are given in Table 1. Figure 1 indicates the spectral quality and illustrates the necessity of decoupling the *tert*-butyl protons for a precise analysis. The signs of the coupling constants for the hydroxyl proton in Table 1 are relative to $^5J_m^{OH,H-3}$, which is positive (15).

The analysis of a 0.87 mol% solution of 2,6-di-*tert*-butylphenol in CCl_4 solution gave ν_{OH} as 497.292(6) Hz, $\nu_{3,5}$ as 702.403(7) Hz, and ν_4 as 666.477(7) Hz. $^3J^{H,H}$ is 7.852(8) Hz and decoupling of the hydroxyl proton narrowed line 3, the single transition between antisymmetric spin states in an AB_2 spin system, by ca. 0.03 Hz. Therefore $^6J_p^{H,OH} \leq 0.03$ Hz. $^5J_m^{H,OH}$ is 0.310(8) Hz, indicating $^5J_{trans}^{OH,H}$ as 0.62(2) Hz. Substitution by chlorine at the para position gave $^5J_m^{H,OH}$ as 0.314(6) Hz, suggesting $^5J_{trans}^{OH,H}$ as 0.63(2) Hz, for a 3 mol% solution in CCl_4, whereas the presence of a 4-methyl group gave $^5J_m^{H,OH}$ as 0.32(1) Hz. The average of the sum of the $^5J_m^{H,OH}$ values for the last four compounds in Table 2 is 0.62 Hz, whereas if there is only one *tert*-butyl substituent in the *ortho* position in these phenols, the sum is nearer 0.80 Hz.

The 1a ⇌ 1b *equilibrium in* 2-tert-*butylphenol*

$^5J_m^{OH,H-3}$ and $^5J_m^{OH,H-5}$ are 0.613(5) and 0.196(5) Hz, respectively. Writing $-RT \ln K = -RT \ln 0.613/0.196 = -RT \ln 3.13$, yields −2890 J/mol as the free energy difference favoring **1***b*. The infrared band intensities (7) yielded K as 13.3 and therefore a free energy difference of 6560 J/mol. The striking disagreement is unexpected in view of the discussion above. Agreement between the two equilibrium constants would demand a much smaller $^5J_m^{OH,H-5}$, roughly 0.05 instead of 0.196 Hz.

Furthermore, in 2-*tert*-butyl-6-methylphenol, the $^5J_m^{OH,H}$ numbers give a free energy difference of 4350 ± 570 J/mol to the advantage of the conformer in which the hydroxyl group lies *trans* to the larger alkyl substituent (the error is estimated on the basis of the errors in $^5J_m^{OH,H}$). The infrared band intensities gave 4400 J/mol for both the enthalpy and for the free energy differences (9, 10). Combined with the $^5J_m^{OH,H}$ data from previous work (1, 8, 16), in which a comparison of the free energy differences between *cis* and *trans* conformers of the 2-X-phenols allowed the prediction of those differences for the 2-X-6-Y phenols on an additive basis (X = CH_3, allyl, isopropyl, and the X−Y pairs being any two of these), this agreement, in conjunction with the apparently anomalous $^5J_m^{OH,H-5}$ in 2-*tert*-butylphenol, suggests a distortion of the hydroxyl group geometry in the *cis* conformer, **1***a*. Note also that the stretching band for this conformer is shifted to *high* frequency by a repulsive interaction.

INDO MO FPT (17) calculations of $^5J_m^{OH,H-5}$

If, as seems likely, the predominant distortion of the geometry of **1***a* involves bond angles, then it is of interest whether

TABLE 1. The ^{1}H nmr spectral parameters for a 2.0 mol% solution of 2-*tert*-butylphenol in CCl_4 at 305 K

Parameter	Value	Parameter	Value
ν_{CH_3}[a]	138.8	$^4J_{46}$	1.293(5)
ν_{OH}	440.395(3)[b,c]	$^5J_{36}$	0.310(5)

[b]Numbers in parentheses are the standard deviations in the last significant figure.
[c]A 0.2 mol% solution has ν_{OH} equal to 436.99 Hz.
[d]Above a relative intensity of 0.05.

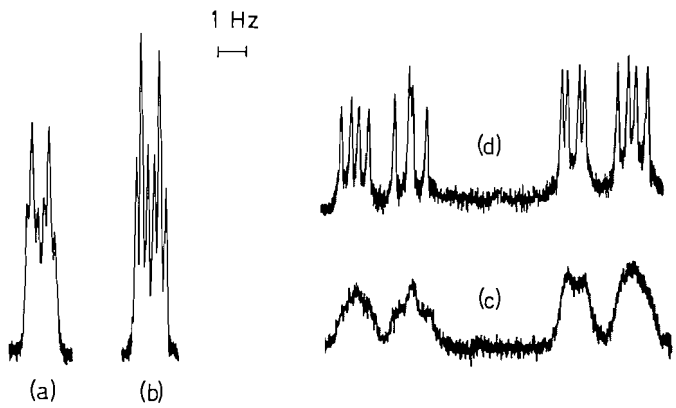

FIG. 1. In (a) is shown the ^{1}H nmr spectrum of the hydroxyl group of a 2.0 mol% solution of 2-*tert*-butylphenol at 100.001 MHz and 305 K. In (b) the hydroxyl proton peaks are displayed while the *tert*-butyl protons are being decoupled. The hydroxyl proton is coupled to H-3, H-5, and H-6. In (c) the ^{1}H nmr spectrum of H-3 is displayed and in (d) the same spectrum is shown while the *tert*-butyl protons are decoupled. Various weak irradiation experiments showed that the $^5J_m^{H,OH}$ numbers are positive, whereas $^4J_o^{H,OH}$ is negative.

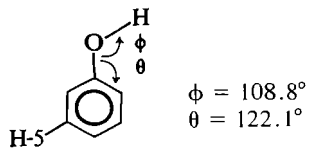
INDO open shell calculations of $^5J_m^{OH,H}$ reflect such a distortion. It is known that INDO MO FPT computations give a *qualitatively* correct representation of a variety of five-bond coupling constants (18−20). The geometry of phenol is precisely known (21) and is given in **2** for the angles θ and ϕ. The INDO calculations assumed a standard geometry for the



2

benzene ring, quite close to the actual geometry (21), and were done for a series of θ and ϕ values. It seemed likely that steric repulsion from a 2-*tert*-butyl group would increase both angles in **1***a*.

Angles θ and ϕ were varied between 120° and 126° and between 108.8° and 114°, respectively, yielding 20 combinations in all. In all cases, an increase in either angle increased

2,6-Di-*tert*-butyl-4-Me (2)	0.32(1)	0.32(1)[d]	477.2[f]

[a]Concentration in mol% is given in parentheses.
[b]436.99 Hz to low field of internal TMS for a 0.2 mol% solution.
[c]$^4J_o^{OH,H}$ is −0.21(1) Hz.
[d]The presence of this interaction was first noted by Freeman (ref. 34).
[e]$^5J_o^{OH,CH_3}$ is −0.22 ± 0.02 Hz.
[f]A full spectral analysis was not performed, leading to larger errors. The upfield shift of the hydroxyl proton peak is expected on the basis of electron release by the 4-methyl substituent (31).

$^5J_m^{OH,H-5}$ in **2**. For a given angle θ, increasing φ from 108.8° to 114° led to an increase of 0.12 to 0.13 Hz in this coupling. An increase of 2° in θ for a given φ increased the calculated ^5J by 0.04 Hz. In other words, the INDO MO FPT trends are in qualitative agreement with a model in which a repulsive interaction with a 2-*tert*-butyl substituent distorts the COH geometry in the *cis* form and entails an anomalously large $^5J_m^{H,OH}$ in that conformation. The present calculations did not allow for changes in C—O and O—H bond lengths and therefore for charge redistributions connected with such changes. Nevertheless, we suggest that the anomalous $^5J_m^{H,OH}$ data for 2-*tert*-butyl- and 2,4-di-*tert*-butylphenol can be accounted for in this manner.

CNDO MO FPT calculations gave results similar to the INDO trends, the calculated $^5J_m^{OH,H-5}$ values increasing by 0.16 Hz as θ and φ increased to 126° and 114°, respectively, that is, to 0.70 Hz. A precise X-ray or, better, a neutron diffraction study would be of interest.

It would follow that in the presence of another *ortho* substituent, the repulsive interaction is not large enough to cause significant angle changes of the COH moiety, as judged by the $^5J_m^{H,OH}$ values in Table 2. There is no evidence for significant out-of-plane conformations of the hydroxyl group in any of the compounds, as discussed further on in this paper.

Concerning the coplanarity of the hydroxyl group

The internal barrier to rotation about the C—O bond in phenol in the gas phase is 14.6 kJ/mol (22−24), apparently the same as when oriented in a nematic phase (25). For a 2,6-di-*tert*-butyl arrangement, dielectric relaxation (26), hydroxyl stretching frequencies (27), ultraviolet absorption (28), ^1H spin-lattice relaxation rates (27, 29), X-ray diffraction results (30, 31), and hyperfine splittings in a cation radical (32) are all consistent with a substantial coplanar preference of the hydroxyl group.

The present proton coupling data agree with such a preference, $^6J_p^{H,OH}$ and/or $^7J_p^{OH,CH_3}$ being ≤0.03 Hz for all the compounds in Table 2. These couplings should follow $\sin^2\theta$, where θ is the out-of-plane twist of the hydroxyl group, and might be as large as 1 Hz for θ = 90°(33). Accordingly, the discussion above in terms of **1***a* ⇌ **1***b* appears reasonable.

Conclusions

An anomalous $^5J_m^{OH,H-5}$ *in 2-tert*-butylphenol is very likely a consequence of a substantial distortion of the COH geometry in the *cis* conformer. The use of $^5J_m^{OH,H}$ values as indicators of *cis-trans* equilibria in phenol derivatives is reliable for other *ortho* alkyl phenols (methyl, isopropyl, allyl) and also for *ortho tert*-butylphenols which contain a second *ortho* alkyl group. All available evidence is compatible with an effectively coplanar conformation of the hydroxyl group, even in the presence of two *ortho tert*-butyl substituents.

An esr and CIDEP study of the photoreduction of chromone and chromanone and their organometallic radical adducts

BABATUNDE B. ADELEKE,[1] DOUGLAS WEIR, M. CATHERINE DEPEW, and JEFFREY K. S. WAN[2]
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received February 28, 1983

BABATUNDE B. ADELEKE, DOUGLAS WEIR, M. CATHERINE DEPEW, and JEFFREY K. S. WAN. Can. J. Chem. **62**, 117 (1984).

The esr and CIDEP results show that the photoreduction of chromones and chromanones by phenol and by triethylamine proceeds via a spin polarized $T(n,\pi^*)$ triplet state which abstracts a hydrogen atom from the donor. Both chromone and chromanone are found to be reactive to the addition of organometallic radicals to form some radical adducts, including organotin, organosilicon, and organogermane.

BABATUNDE B. ADELEKE, DOUGLAS WEIR, M. CATHERINE DEPEW et JEFFREY K. S. WAN. Can. J. Chem. **62**, 117 (1984).

Les résultats de la rpe et du PEIDC montrent que la photoréduction des chromones et des chromanones par le phénol et la triéthylamine se produit par l'intermédiare d'un état triplet à spin polarisé $T(n, \pi^*)$ qui enlève un atome d'hydrogène du donneur. On a trouvé que la chromone et la chromanone réagissent lors de l'addition de radicaux organométalliques en donnant quelques adduits radicalaires comprenant l'organoétain, un organosilicium et un organogermane.

Introduction

In nature benzopyran analogs are widespread and many of them have interesting biological and physical properties (1, 2). As a class of compounds, chromones and chromanones have been attracting much attention among chemists in different fields. In photochemistry, the early studies of substituted γ-pyrones have established a number of photochemical paths, including photodimerization (3), photorearrangement (4, 5), and photoaddition to olefins (6). In cycloalkane solvents, evidence of the primary photochemical processes involving the carbonyl chromophore has been documented (6). But the exact nature of the chemically active excited states of chromones and chromanones has remained controversial. Gallivan (7) and co-workers (8) have shown that chromones have two low-lying triplet states of $n\pi^*$ and $\pi\pi^*$ in character which are nearly isoenergetic and can thus be readily re-ordered by changing solvents. On the other hand, Wolfbeis and Knierzinger (9) have demonstrated the sensitivity of chromones towards acidic solvents, leading to protonation of the ground state molecule and consequent strong fluorescence. A more recent picosecond spectroscopic study by Hamanoue and co-workers (10) further concluded that in the primary photophysical processes involving chromone, chromanone, and flavone, the direct intersystem crossing from $S_1(n\pi^*)$ to the lowest triplet $T(\pi\pi^*)$ occurs efficiently in *polar* solvents while the corresponding transition to $T(n\pi^*)$ is observed in *non-polar* solvents. In general, it is recognized for carbonyl compounds triplet states of mixed orbital character such as the $T(\pi\pi^*)$ is much less chemically active than the $T(n\pi^*)$. However, for some biphenyl ketones the structure of their $T(\pi\pi^*)$ allows for substantial unpaired spin density on the carbonyl oxygen atom, thus making them fairly reactive (11). The carbonyl chromophore has been notoriously suited for initial electron polarization studies and many ketones and quinones have been used in our laboratory as model systems for CIDEP studies. We have, therefore, examined this interesting series of compounds the chromones and chromanones, by esr and CIDEP techniques. Our results will further shed some light on their triplet properties and their chemical behaviours towards photoreduction as well as in organometallic radical reactions.

Experimental

All of the benzopyran analogs used were supplied by Aldrich. Organic solvents and triethylamine were purified by the appropriate methods (12) before use. Sample solutions were all deoxygenated by bubbling with nitrogen gas immediately before photolysis. In cw experiments, samples were irradiated with a 200 W super pressure mercury lamp with Pyrex optics directly within the cavity of a X-band esr spectrometer with a 100 kHz field modulation. Magnetic fields were measured with a Bruker nmr oscillator and calibrated against DPPH. Microwave frequency was monitored by a Hewlett-Packard 5432 frequency counter. The transient spin-polarized radicals were generated by laser photolysis using a Molectron 1 MW nitrogen laser. The CIDEP apparatus and the method of estimating T_1 from the experimental data were described previously in detail (13).

Results and discussion

1. Chromone and chromone-2-carboxylic acid

The photolysis of chromone in either THF or ethanol at room temperature did not produce any significant esr observation. When a more reactive hydrogen donor, 2,6-di-*tert*-butylphenol, was added to the solution and irradiated, two radicals were clearly observed. The 2,6-di-*tert*-butylphenoxy radical was readily recognized and the other radical is assigned to the chromone ketyl radical (**I**) with the esr parameters listed in Table 1. The assignments of the two primary radicals formed in a primary photochemical act (see below) are further confirmed by the CIDEP observation of totally emissive polarization for both radicals. The photoreduction of chromone by phenol is therefore consistent with the following mechanism:

TABLE 1. Electron spin resonance parameters of radicals produced by photoreduction of chromone, cromone-2-carboxylic acid, and thiachroman-4-one

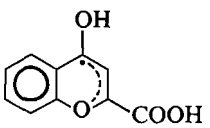
Radical	Solvent	g	Proton hyperfine coupling constants* (G)
I	THF	2.0035±0.0002	$a_1 = 9.96$; $a_2 = a_3 = 2.92$ $a_4 = a_5 = 0.58$; $a_{OH} = 1.08$
I	THF	2.0034	$a_2 = a_3 = 2.15$ $a_{OH} = 0.3$
II	THF	—	$a_{1\alpha} = 30.4 \pm 0.4$

*Refer to diagrams in text for proton positions.

The symbol ** represents electron spin polarization. The initial polarization of the chromone triplet via the differential intersystem crossing processes to the T_{+1} sublevel is typical of many of the aromatic carbonyl compounds (14, 15). In order to preserve the spin polarization in the primary chemical processes [2], the reaction with phenol must proceed at a rate comparable to or greater than the relaxation process which can destroy the triplet spin polarization. Although phenol is a good hydrogen donor, the abstraction reaction [2] will only proceed efficiently if the triplet state is of $T(n\pi^*)$ character (11). Since very strong polarization of both radical **I** and the phenoxy radical is observed, we concluded that in THF or ethanol solution, the reactive triplet state of chromone in reaction [2] is indeed $T(n\pi^*)$. Gallivan and Brinen (8) have suggested that at low temperature the lowest triplet state of chromone is $T(\pi\pi^*)$ in ethanol and $T(n\pi^*)$ in 2-methyl tetrahydrofuran. They have also recognized that the two triplet states are almost isoenergetic. The present CIDEP experiments of chromone in ethanol and in THF confirmed the isoenergetic aspect of the two triplet states and at room temperature, regardless of the polarity of the solvent the chemically reactive triplet of chromone is $T(n\pi^*)$.

The photolysis of a THF solution containing chromone and triethylamine produced the same radical **I** which is also strongly polarized in the total emissive mode. This observation suggests that the primary photochemical reaction between the triplet chromone and the amine is not an electron transfer process but an abstraction of a hydrogen atom from the ethyl group of the amine. A similar reaction has been reported in the CIDEP study of benzophenone with triethylamine (16). Apparently, in THF solvent the chromone radical **I** does not undergo ionization to yield a radical anion.

Identical experiments were performed with a substituted chromone, the chromone-2-carboxylic acid. The corresponding chromone-2-carboxylic radical (**II**) was observed in all cases. The esr parameters of **II** is given in Table 1. The much



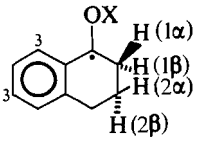
II

smaller hyperfine coupling constant of the hydroxylic proton in **II** as compared to **I** is typically due to the dynamic exchange between the hydroxylic proton and the carboxylic proton of the parent molecule and/or the radical. Similar CIDEP results were obtained also for the radical **II**.

T_1's of radicals **I** and **II** were measured at −15°C in THF solvent. The estimated values are 5.0 ± 0.3 and 6.3 ± 0.6 μs, respectively for radicals **I** and **II**. The larger T_1 of the radical **II**, the chromone-2-carboxylic acid radical, reflects the probable hydrogen-bonding character of the carboxylic proton. Both values, however, are comparable to the T_1 of the naphthosemiquinone (17) and consistent with the theoretical analysis of the T_1 data (18).

2. Chromanone and thiachroman-4-one

Many natural products, including vitamin E, contain the *chroman* ring as a common structural unit. The chroman unit can further be used to synthezise the corresponding chromones and chromenes. It is, therefore, most interesting to compare directly the photochemical properties of chromanones with chromones. Photolysis of 4-chromanone in toluene at room temperature did not produce any significant esr observation. The addition of triethylamine in room temperature photolysis of 4-chromanone did not improve the esr observation. When the temperature was lowered to −40°C, a poorly resolved esr spectrum became observable. There is no doubt that the esr spectrum is associated with the 4-chromanone radical but the poor intensity could be attributed to either the low reactivity of the triplet chromanone or the fast decay of the radicals themselves. In THF at −40°C, CIDEP showed that the chromanone radical is in emissive mode. The simple fact that CIDEP is observed in the photolysis of 4-chromanone with triethylamine indicates that the triplet reactivity is reasonable and therefore the $T(n\pi^*)$ of 4-chromanone is involved in the primary reaction. The low steady state concentration of the chromanone radical is due to the faster decay of the chromanone radical, as compared to radical **I**. This is reasonable, since in chromanone the ring is a smaller π-system:



4-Chromanone radical

While it is disappointing that a good esr assignment of the above chromanone radical could not be made, very good esr results are obtained for the chromanone organometal radical adducts in which the hydroxylic proton is replaced by a variety of bulky organometallic group (see below). Thus, esr parameters for the basic chromanone ring still can be deduced and their interesting features will be discussed later.

Experiments with thiachroman-4-one and triethylamine in THF at −70°C produced a slightly better esr spectrum and a much better CIDEP observation of the emissive radical. The improved resolution allows us to report the largest proton hyperfine coupling in the 1α position (see the 4-chromanone radical formula above) of the thiachromanone radical in Table 1. A good estimate of the T_1 of the thiachromanone radical at −70°C gives a value of 9.5 μs. Thiachromanone also produces good concentrations of organometallic radical adducts for esr study which are given next.

3. Organometallic radical adducts of chromones, chromanone, and thiachromanones

Photolysis of a number of organometals in benzene in the presence of di-*t*-butyl peroxide usually generated the corresponding metal-centered radicals which can be trapped by carbonyl compounds such as quinones, aromatic ketones, and

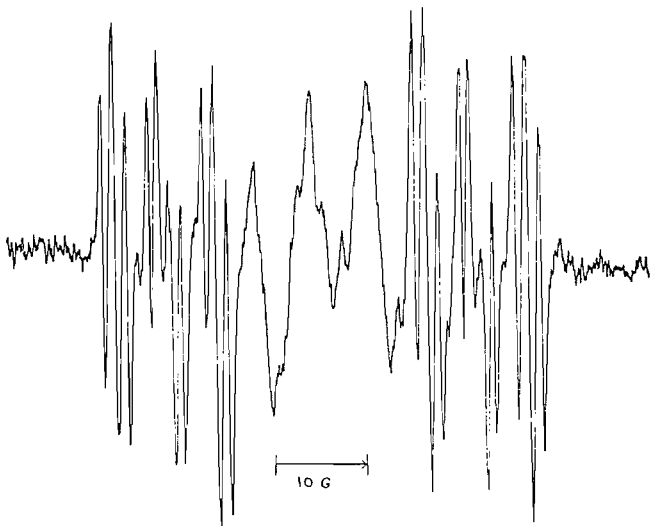

FIG. 1. The observed esr spectrum during the photolysis of thiachroman-4-one in THF at −60°C and in the presence of hexamethylditin.

thiobenzophenones (19). Thus, tin-, silicon-, and germanium-centered radicals are systematically added to chromones, chromanone, and thiachromanones and the resulting radical adducts are reported in Table 2. For the chromones, the addition of an organometallic group to the carbonyl oxygen does not alter significantly the spin densities of the chromone ring as compared to the radicals **I** and **II**. g-Factors of the organometallic adducts decrease from silyl to stannyl adducts which is consistent with other reports in literature (20). Similar observations and conclusions can be made for the chromanone and thiachromanone series of adducts. It is worth noting that in all the radical adducts reported in Table 2, hyperfine coupling constants due to the metallic nuclei had not been experimentally resolved, despite the fact that the radical adducts are rather persistent, giving excellent, intense spectra. For example, Fig. 1 shows the esr spectrum of the Me_3Sn−chromanone radical adduct and the chromanone radical is shown in the background for comparison. In the esr investigation of organometalloxy and organometalthio-pyryl radicals from the photolyses of heterocyclic pyrones and analogs, Alberti and co-workers (21) have found that the primary "ketyl" radicals of these compounds are too short-lived for esr observation, but the radical adducts can be readily detected. In their series, they observed a large Sn splitting order in the order of hundred gauss which they correctly assigned to a tin nuclei being non co-planar with the ring. A similar structure for the chromone and chromanone adducts would have produced also a large tin splitting. It is not immediately apparent to us why the chromone and chromanone radical adducts do not exhibit resolvable metal splittings and we intend to examine this fact further in an on-going CIDEP study of metal adducts to chromanones, as the T_1 values of these radical adducts should shed some light on the structure of the radicals. The results of the interaction of metals with chromones and chromanones should be of great interest to the biological properties of these compounds.

The synthesis of trisubstituted cyclopentadienes and their reactivity in the intramolecular Diels–Alder reaction

SANDRA J. ALWARD AND ALEX G. FALLIS

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received May 6, 1983

SANDRA J. ALWARD and ALEX G. FALLIS. Can. J. Chem. **62**, 121 (1984).

The intramolecular Diels–Alder reactivity of several trisubstituted cyclopentadienes is described and a general method for their preparation reported. In general, sidechain keto-ester functionality has an adverse effect on these internal cycloadditions.

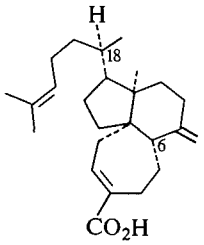
SANDRA J. ALWARD et ALEX G. FALLIS. Can. J. Chem. **62**, 121 (1984).

On a examiné la réactivité de plusieurs cyclopentadiènes trisubstitués vis-à-vis des réactions de Diels–Alder intramoléculaires et on rapporte une méthode générale de synthèse de ces composés. En général, la fonction céto-ester de la chaîne latérale a un effet négatif sur ces cycloadditions internes.

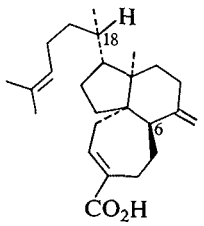
[Traduit par le journal]

Introduction

The novel tricylic sesterterpene gascardic acid was isolated by Brochere and Polonsky in 1960 (1) from *Gascardia madagascariensis* and extensive work by Arigoni and Scartazzini (2)[1] led to the assignment of the tentative structure **1**. However, the complete structure was not determined until 1979 when Boeckman *et al.* (3) synthesized gascardic acid and established its structure as **2** by X-ray diffraction studies. These studies



1



2

clarified the sidechain stereochemistry at C18 and necessitated a revision of the ring fusion at C6, which was previously felt to be *cis* (2) on the basis of chemical correlations.

In recent years the intramolecular Diels–Alder reaction has gained widespread popularity in synthetic studies (4). Although a great deal is known about this reaction, there is still much that remains a mystery, particularly the subtle effects of sidechain substituents (5). In order to use these cycloadditions synthetically one must be able to predict the feasibility of the cyclization with various substitution patterns in both the reacting units themselves and the connecting chain. In spite of these uncertainties, the synthesis of gascardic acid via an intramolecular Diels–Alder reaction was undertaken with the double aim of completing the synthesis and learning more about the Diels–Alder reaction.

The route under development is a general one for the construction of quarternary, spiro-fused tricyclic skeletons of varying ring size and relies on an intramolecular Diels–Alder/oxy-Cope rearrangement sequence, as outlined in Scheme 1. It provides stereochemical control and, depending upon the final target, gascardic acid, retigeranic acid, senoxydene, laurenene, etc., the length of the sidechain may be varied and the resulting cyclohexanone contracted or expanded as required.

Results and discussion

In order to prepare gascardic acid, the original plans called for intermediates such as keto-esters **3** and **4** which, after Diels–Alder cycloaddition, should afford **5** and **6** respectively. These tricyclic products possess the seven-membered ring required for gascardic acid **2** as well as a keto-ester moiety properly situated for development into the α,β-unsaturated car-

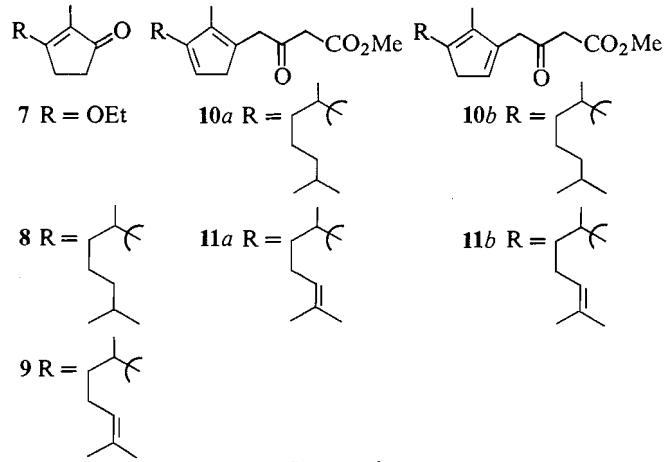


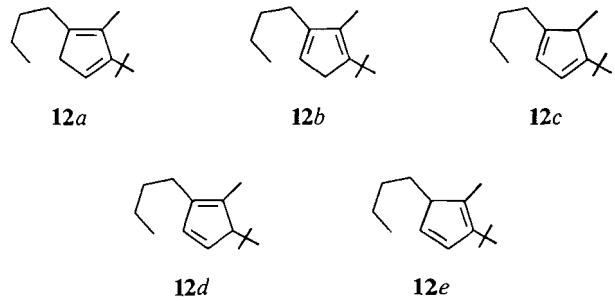
SCHEME 2

boxylic acid. Unfortunately, attempts to cyclize keto-esters **3** and **4** met with no success, yielding either starting materials or decomposition products. In light of these results it was decided to pursue some model studies to ascertain why the intramolecular Diels–Alder reaction was unsuccessful with compounds such as **3** and **4**.

Initially it appeared two factors might be contributing to the failure of the intramolecular Diels–Alder reaction. First it was possible that the entropy involved in forming a seven-membered ring might be too large to overcome, under the reaction conditions employed. There are no carbocyclic examples of substituted cyclopentadienes leading directly to cycloheptanes in the literature, although closely related heterocyclic cases have been reported (4). Secondly the keto-ester will likely be in equilibrium with its enol and, if it adopts the *E* geometry, then the dienophile is held in a position in which close approach to the cyclopentadiene is not feasible, thus inhibiting cyclization. In order to study these variables a number of suitable cyclopentadienes were synthesized.

The literature on trisubstituted cyclopentadienes is sparse but the route developed in Scheme 2 proved most versatile. Thus enone **7**, prepared in a manner analogous to 3-ethoxy-2-cyclohexen-1-one (6), was dissolved in ether and reacted with either 2-bromo-6-methylheptane or 2-bromo-6-methyl-5-heptene in the presence of lithium to yield the α,β-unsaturated ketones **8** and **9** respectively. Both products displayed evidence of the α,β-unsaturated ketone moiety in their ir spectra, which contained peaks at 1700 and 1640 cm^{-1}. Treatment of **8** or **9** with the dianion of methyl acetoacetate, generated by the method of Huckin and Weiler (7), gave a mixture of the cyclopentadienes **10***a* and **10***b* or **11***a* and **11***b* respectively. While five isomers of each of the cyclopentadienes are possible, the ^{1}Hmr spectra of the products show evidence of only the two isomers illustrated and there is no sign of the three possible C5-substituted isomers. Supporting this conclusion, the ^{1}Hmr spectrum of the mixture of **10***a* and **10***b* displayed a multiplet at δ 5.92 (1H, vinylic proton of cyclopentadiene) and a multiplet at δ 2.93 (2H, methylene of cyclopentadiene). A similar pattern was displayed in the ^{1}Hmr spectrum of **11***a* and **11***b*. These results were not unexpected since our studies on the trisubstituted cyclopentadiene **12**[2] showed evidence of isomers **12***a* and **12***b* only, in the ^{1}Hmr spectrum. Furthermore it was observed the ratio of these isomers of **12** showed no apparent change over the temperature range −50°C to 50°C.

[2]C. Mullaly, P. Moore, and S. J. Alward, unpublished results.



The incorporation of the dienophile into the molecule required reacting the keto-esters **10** and **11** with the appropriate alkylating agents. In view of the different acidic sites these keto-esters are prone to dialkylation but this could be controlled using potassium hydride to generate the keto-ester anion in dimethoxyethane followed by addition of the alkylating agent. The progress of the alkylations was followed by monitoring the disappearance of the characteristic methylene protons at approximately δ 3.3 (singlet, 2H, $COCH_2COOMe$) and the appearance of the methine proton at approximately δ 3.4 (triplet, J = 6.5 Hz, 1H, COCHRCOOMe) in their ^{1}Hmr spectra.

In this manner, cyclopentadienes **13** to **17** (see Table 1) were prepared from keto-esters **10** and **11**. (Only one of the cyclopentadiene isomers is depicted but both are present in all cases.) None of these compounds yielded intramolecular Diels–Alder products when heated in toluene at 180°C and under these reaction conditions only starting materials or extensive decomposition resulted. Since cyclization of **14**, **15**, and **17** would have led to six-membered ring products and since there are ample examples in the literature (4) of this type of reaction, it suggests that the failure to cyclize is a consequence of the sidechain functionality. Unfavourable entropy may inhibit the formation of a seven-membered ring (*vide infra*) but it should not retard cyclohexane generation.

The second complication involving the formation of an unfavourable geometry in the enol form of the keto-ester was automatically negated by the failure of the dialkylated compound **15** to undergo cyclization since no enol form is possible. Consequently there must be a third factor inhibiting cyclization.

In view of the influence sidechain substituents can have on the intramolecular Diels–Alder reaction (5), the ester functionality was removed to see if its absence would affect the reactivity. Thus the keto-ester **14** was heated in wet dimethyl sulfoxide with lithium chloride to give the ketone **18**. The absence of the methyl ester signal in the ^{1}Hmr and the evolution of gas during the reaction attested to the success of the decarboxylation. When ketone **18** was heated in toluene at 180°C for 3 days it gave the desired Diels–Alder product **22** in 77% yield. The ^{1}Hmr spectrum of **22** showed the absence of vinylic protons and the ir spectrum displayed a carbonyl peak at 1720 cm^{-1}, consistent with a ketone in a cyclohexanone. Clearly the β-ester functionality has a deleterious effect on the internal cycloaddition.

Encouraged by the results with ketone **18**, keto-ester **13** was decarboxylated to give ketone **19**. But when ketone **19** was heated in toluene at 180°C for 3 days no Diels–Alder product was formed and starting material was recovered with some sign of decomposition products. Thus it appears that the formation of a seven-membered ring in these systems is indeed disfavored. This result is in accord with the results of Bennett on bis-cyclopentadiene systems (4, 8).

24

Cyclization to a cyclopentane was examined next. Keto-ester **11** was decarboxylated to give ketone **20** which on heating in toluene at 180°C for 7 days gave the cyclized product **24** in 53% yield. The reaction proceeds via ketone **23**, with the double bond then migrating into conjugation with the ketone to give **24**. The ir spectrum of **24** is consistent with the assigned structure, showing peaks at 1685 and 1620 cm^{-1} (α,β-unsaturated ketone), while the ^{1}Hmr spectrum shows no cyclopentadiene or vinylic methyl signals but does display signals at δ 0.87 and 1.05 (6H, s, tertiary methyls) and 6.00 (1H, m, vinylic proton).

Since these experimental results imply that the formation of a seven-membered ring intramolecular Diels–Alder product is improbable, a synthesis of gascardic acid will require a six-membered ring with subsequent ring expansion. In one contemplated route the two olefins may compete as dienophiles and a further model was examined to test the results of this competition. Hence, keto-ester **17** was decarboxylated in the usual manner to give ketone **21** which on heating in toluene at 180°C for 4 days gave the Diels–Alder product **25** in 76% yield. The structure of **25** was compatible with the ^{1}Hmr spectrum which lacked signals characteristic of the cyclopentadiene or $CH{=}CH_2$ systems, while a signal attributed to the side chain vinylic proton is present at δ 4.97 (1H, br t, $J \simeq 6.0$ Hz). The ir spectrum of **25** contains a peak at 1720 cm^{-1} consistent with a six-membered ring ketone. Thus, provided the dienophile is trisubstituted, cyclohexane ring formation takes precedence.

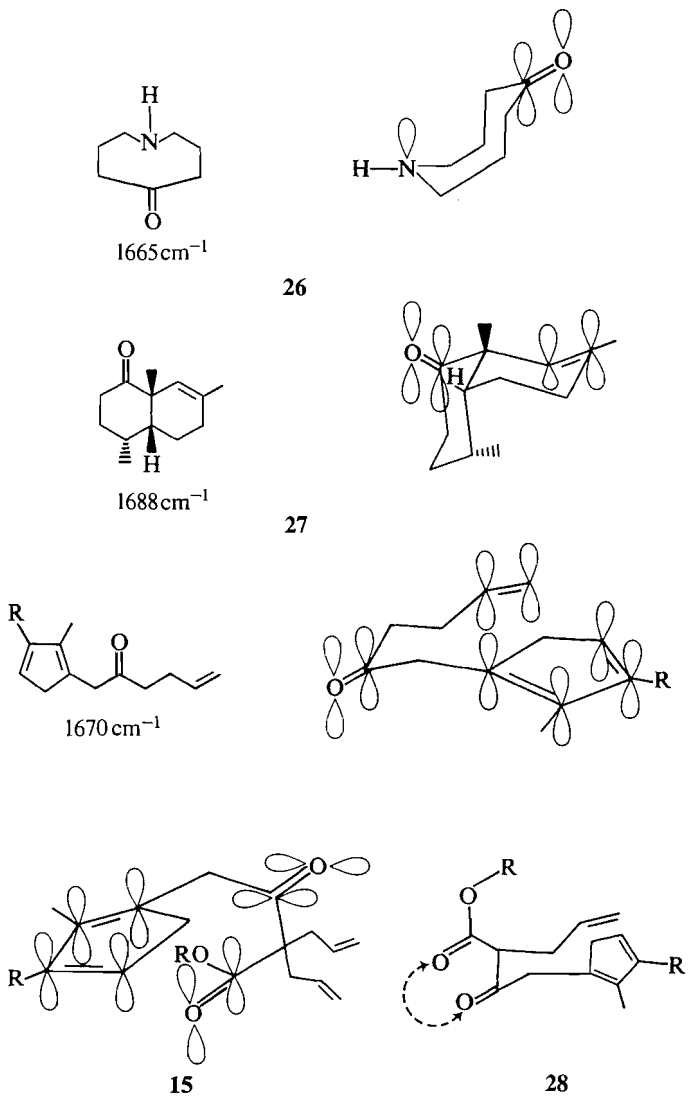

SCHEME 3

The ketones **18**–**21** display unusual infrared carbonyl absorptions and it seems likely that the success or failure of these intramolecular Diels–Alder reactions is largely a result of the stereochemical consequences induced by the alignment of the π systems which are responsible for these absorptions. The infrared spectra, of which **18** is typical, display a weak absorption at 1710, a strong signal at 1670, an intermediate peak at 1640, with the most intense band in the spectrum falling at 1575 cm^{-1}. The carbonyl band at 1670 cm^{-1} is certainly atypical for a non-conjugated ketone but is explicable for a pseudo conjugated carbonyl in which the π system of the diene has a direct influence. This band (1670 cm^{-1}) is not a double bond signal since the trisubstituted cyclopentadiene **12** displays only a very weak absorption at 1625 cm^{-1}. The ultraviolet spectrum of **12** contains a broad band at 250 nm (ϵ = 6 000) while the ketone **18** displays an intense absorption at 307 nm (ϵ = 27 000), unexpected for a saturated ketone but consistent with a through-space interaction between the π systems of the carbonyl and the cyclopentadiene, as illustrated in Scheme 3. This same influence is responsible for the 1670 cm^{-1} carbonyl absorption and finds analogy in the spectra of **26** (9) and **27** (10) in which the carbonyl bands are also shifted to lower frequency due to through-space overlap. The practical consequences of this overlap in the cyclopentadiene examples are that the dienophile can readily assume the orientation required for the Diels–Alder transition state. However, in the case of **19**, in spite of favourable spectral features, even this is insufficient to overcome the unfavourable entropy effect.

In contrast, when the ester is present it appears to interact preferentially with the cyclopentadiene, although this cannot be definitely ascertained from its infrared spectrum which is normal, placing the dienophile in a conformation remote from the diene as illustrated for **15**. If this analysis is correct, it should be possible to hold the keto-ester in the correct geometry for cycloaddition, either by coordination with a complexing agent or using an additional ring (cf. **28**). This is currently being explored.[3]

In other trienes the dominating influence of a carbonyl function on the course and stereochemistry of the adducts has been noted due to the desire of the carbonyl function to retain maximum overlap with the neighbouring π systems ("carbonyl coplanarity effect") (4, 11). These results add to our understanding of this phenomenon and will facilitate the application of these concepts in total synthesis.

Our work on the total synthesis of gascardic acid is continuing and, in view of the above, the route has been modified to proceed via a tricyclo[6.2.1.$0^{1,6}$]undecene which is suitably functionalized for subsequent ring expansion.

Experimental

General

The ir spectra were recorded as thin films with a Perkin–Elmer model 237B spectrophotometer. Proton magnetic resonance spectra were measured using a Varian Model EM-360 spectrometer in carbon tetrachloride solutions containing tetramethylsilane as an internal standard. Band positions are reported in parts per million downfield from tetramethylsilane (δ scale). High resolution mass spectrometric measurements were determined on a Kratos MS-50 spectrometer.

All reactions were carried out under a nitrogen atmosphere and, unless otherwise indicated, reaction products were isolated by the following procedure. The product was extracted into the specified solvent and the extract was washed two or three times with appropriate aqueous solutions as indicated. The original aqueous layer (if any) and the aqueous washings were extracted three times with the solvent and the combined extracts were dried over anhydrous magnesium sulfate, filtered, and evaporated on a Büchi rotary evaporator. Petroleum ether refers to the fraction with boiling range 30–60°C. Brine refers to a saturated aqueous solution of sodium chloride. Merck silica (230–400 mesh ASTM) was used for purification of products by flash chromatography (12).

3-Ethoxy-2-methyl-2-cyclopenten-1-one, 7

A solution of 2-methyl-1,3-cyclopentanedione (25 g, 0.22 mol, Aldrich) and *p*-toluenesulfonic acid (1.5 g, 7.9 mmol) in benzene (500 mL) and ethanol (300 mL) was refluxed through molecular sieves (4 Å) for 48 h. The solvent was evaporated and the residue was distilled to give enone **7** (28 g, 90%); bp 93–100°C (0.5 Torr); mp 36–38°C; ^{1}Hmr δ: 1.32 (3H, d, J = 6.5 Hz, OCH_2CH_3), 1.50 (3H, br s, $C{=}CRCH_3$) and 4.22 (2H, q, J = 6.5 Hz, OCH_2). The compound is air sensitive and gradually reverts to starting materials if not stored in a well-sealed container.

6-Methyl-2-heptanol

A mixture of 6-methyl-5-hepten-2-ol (25.0 g, 0.195 mol, Aldrich), 10% palladium on charcoal (2.0 g), and ethanol (150 mL) was hydrogenated (3 atm) for 7 h. The mixture was filtered to remove the

[3]Since submitting this manuscript, cyclization of a keto-ester has been accomplished with the lower homologue of **3** at 120°C in the presence of tetramethylethylenediamine as a complexing agent. This reaction failed in the absence of tetramethylethylenediamine.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

catalyst and the catalyst was washed with ethanol. The solvent was evaporated and the residue distilled to give 6-methyl-2-heptanol (18.8 g, 74%); bp 78–80°C (12 Torr); ir: 3320 cm^{-1} (hydroxyl); ^{1}Hmr δ: 0.87 (6H, d, J = 6.5 Hz, $RCH(CH_3)_2$), 1.10 (3H, d, J = 6.5 Hz, $C(OH)CH_3$) and 3.63 (1H, m, H—COH). *Exact mass* calcd. for C_8H_{16} (mass − H_2O): 112.1252; found: 112.1258.

2-Bromo-6-methylheptane

To triphenylphosphine (32.52 g, 0.124 mol, Chemalog), suspended in cold (ice bath) dry acetonitrile (500 mL), a solution of bromine (19.8 g, 0.124 mol) in acetonitrile (100 mL) was added dropwise followed by pyridine (10.0 mL, 0.123 mol). The reaction mixture, after stirring for 0.25 h in the ice bath, was warmed to room temperature and a solution of 6-methyl-2-heptanol (see above) (16.5 g, 0.124 mol) was added dropwise. The resulting clear solution was left at 0°C overnight, the solvent was evaporated, and the residue was triturated with petroleum ether. The petroleum ether was evaporated and the crude product distilled to give 2-bromo-6-methylheptane (10.72 g, 45%); bp 75–76°C (12 Torr); ^{1}Hmr δ: 0.88 (6H, d, J = 6.5 Hz, $RCH(CH_3)_2$), 1.67 (3H, d, J = 6.5 Hz, $CBrCH_3$) and 4.00 (1H, sextet, J = 6.5 Hz, CHBr). *Exact Mass* calcd. for C_8H_{17} (mass − Br): 113.1330; found: 113.1324.

3-(1,5-Dimethylhexyl)-2-methyl-2-cyclopenten-1-one, 8

A mixture of enol ether **7** (10.0 g, 71.4 mmol) and 2% Na in Li alloy in ether (300 mL) was treated dropwise with 2-bromo-6-methylheptane (see above) (10.1 g, 52.3 mmol) while being irradiated in an ultrasonic bath (14) for 3.5 h. The mixture was then filtered to remove unreacted lithium and treated with 3 M aqueous hydrochloric acid (300 mL). The reaction mixture was worked up in the usual manner with ether and brine. The product was purified by flash chromatography (12) (30% ether/petroleum ether) to give enone **8** (4.86 g, 45%) as an oil; ir: 1700 and 1640 cm^{-1} (α,β-unsaturated ketone); ^{1}Hmr δ: 0.85 (6H, d, J = 6.5 Hz, $RCH(CH_3)_2$), 1.07 (3H, d, J = 6.5 Hz, R_2CHCH_3), 1.60 (3H, m, $C{=}CRCH_3$) and 2.83 (1H, sextet, J = 6.5 Hz, R_2CHMe). *Exact Mass* calcd. for $C_{14}H_{24}O$: 208.1827; found: 208.1829.

3-(1,5-Dimethyl-4-hexenyl)-2-methyl-2-cyclopenten-1-one, 9

The treatment of enol ether **7** (20.3 g, 0.145 mol) with 2-bromo-6-methyl-5-heptene (13) (27.6 g, 0.145 mol) in a manner analogous to the preparation of compound **8** gave the α,β-unsaturated ketone **9** (13.6 g, 46%) as an oil; ir: 1700 and 1640 cm^{-1} (α,β-unsaturated ketone); ^{1}Hmr δ: 1.15 (3H, d, J = 6.5 Hz, R_2CHCH_3), 1.60 (3H, br s, $C{=}CRCH_3$), 1.65 and 1.68 (6H, d, J = 2 Hz, $C{=}C(CH_3)_2$), 2.93 (1H, sextet, J = 6.5 Hz, R_2CHMe) and 5.07 (1H, br t, $J \simeq 6$ Hz, $CH{=}CMe_2$). *Exact Mass* calcd. for $C_{14}H_{22}O$: 206.1671; found: 206.1673.

Methyl 3-oxo-4-[2-methyl-3-(1,5-dimethylhexyl)cyclopentadienyl]-butyrate, 10

A mixture of sodium hydride, as a 60% oil dispersion (1.00 g, 25 mmol, Aldrich), in anhydrous tetrahydrofuran (70 mL) was cooled in an ice-water bath and treated dropwise with methyl acetoacetate (2.90 g, 25 mmol, Eastman). The solution was stirred for 10 min, then treated dropwise with a solution of 2.4 M butyllithium in hexane (10.5 mL, 25 mmol, Alfa) and stirred for another 10 min. The enone **8** (4.53 g, 22 mmol) was added in one portion and the resulting solution stirred for 20 min before adding to 3 M hydrochloric acid (100 mL). The mixture was stirred vigorously for 45 min and worked up in the usual manner with ether and brine. The product was flash chromatographed (30% ether/petroleum ether) to give cyclopentadiene **10** (4.53 g, 68%) as an oil; ir: 1745, 1670, 1635, 1605 and 1570 cm^{-1} (keto-ester and cyclopentadiene); ^{1}Hmr δ: 0.83 (6H, d, J = 6.5 Hz, $RCH(CH_3)_2$), 1.03 (3H, d, J = 6.5 Hz, R_2CHCH_3), 2.93 (2H, br m, $C{=}CCH_2C{=}C$), 3.32 (2H, s, $COCH_2COOR$), 3.63 (3H, s, OCH_3) and 5.92 (1H, br s, $C{=}CHCH_2C{=}C$). *Exact mass* calcd. for $C_{19}H_{30}O_3$: 306.2195; found: 306.2196.

Methyl 3-oxo-4-[2-methyl-3-(1,5-dimethyl-4-hexenyl)cyclopenta-dienyl]butyrate, 11

Following the method outlined for the preparation of compound **10**, enone **9** (3.99 g, 19 mmol) was converted to keto-ester **11** (5.08 g, 86%) after flash chromatography (30% ether/petroleum ether); ir: 1745, 1635, 1600 and 1570 cm^{-1} (keto-ester and cyclopentadiene); ^{1}Hmr δ: 1.07 (3H, d, J = 6.5 Hz, R_2CHCH_3), 1.53 to 1.73 (9H, $C{=}C(CH_3)_2$ and $C{=}CCH_3$), 2.95 (2H, br m, $C{=}CCH_2C{=}C$), 3.35 (2H, s, $COCH_2COOR$), 3.68 (3H, s, OCH_3), 5.03 (1H, br t, $J \simeq 6$ Hz, $HC{=}C(Me)_2$) and 6.00 (1H, t, $J \simeq 1$ Hz, $C{=}CHCH_2C{=}C$). *Exact Mass* calcd. for $C_{19}H_{28}O_3$: 304.2038; found: 304.2051.

Methyl 2-(3-butenyl)-3-oxo-4-[2-methyl-3-(1,5-dimethylhexyl)cyclo-pentadienyl]butyrate, 13

A mixture of potassim hydride, as a 35% oil dispersion (0.670 g, 5.86 mmol, Aldrich), in anhydrous dimethoxyethane (8 mL) was cooled in an ice-water bath and treated dropwise with a solution of keto-ester **10** (1.783 g, 5.83 mmol) in dimethoxyethane (10 mL). The ice bath was removed and 1-bromo-3-butene (2.8 g, 20.7 mmol, Aldrich) was added in one portion. The reaction mixture was stirred at 75°C for 2 h, then worked up in the usual manner with ether and brine. The residue was flash chromatographed (10% ether/petroleum ether) to give the alkylation product **13** (1.786 g, 85%) as an oil; ir: 1740, 1670, 1640 and 1560 cm^{-1} (keto-ester and cyclopentadiene); ^{1}Hmr δ: 0.87 (6H, d, J = 6.5 Hz, $RCH(CH_3)_2$), 1.07 (3H, d, J = 6.5 Hz, R_2CHCH_3), 0.97 (2H, br m, $C{=}CCH_2C{=}C$), 3.42 (1H, t, J = 6.5 Hz, COCHRCOOR), 3.67 (3H, s, OCH_3), 4.85 to 6.03 (3H, m, $CH{=}CH_2$) and 6.03 (1H, br s, $C{=}CHCH_2C{=}C$). *Exact Mass* calcd. for $C_{23}H_{36}O_3$: 360.2664; found: 360.2657.

Methyl 2-allyl-3-oxo-4-[2-methyl-3-(1,5-dimethylhexyl)cyclopenta-dienyl]butyrate, 14

A mixture of potassium hydride, as a 35% oil dispersion (0.414 g, 3.62 mmol, Aldrich), in anhydrous dimethoxyethane (3 mL) was cooled in an ice-water bath and treated dropwise with a solution of keto-ester **10** (1.05 g, 3.43 mmol) in dimethoxyethane (10 mL). The ice-bath was removed and allyl bromide (0.480 g, 3.97 mmol, Aldrich) was added in one portion. The reaction mixture was stirred at room temperature for 4.5 h, then worked up in the usual manner with ether and brine. The crude product was flash chromatographed (20% ether/petroleum ether) to give the desired product **14** (0.863 g, 73%) as an oil; ir: 1745, 1675, 1640 and 1570 cm^{-1} (keto-ester and cyclopentadiene); ^{1}Hmr δ: 0.85 (6H, d, J = 6.5 Hz, $RCH(CH_3)_2$), 1.05 (3H, d, J = 6.5 Hz, R_2CHCH_3), 2.97 (2H, br m, $C{=}CCH_2C{=}C$), 3.40 (1 H, t, J = 6.5 Hz, COCHRCOOR), 3.62 (3H, s, OCH_3), 4.77 to 5.93 (3H, m, $CH{=}CH_2$) and 5.93 (1H, br s, $C{=}CHCH_2C{=}C$). *Exact Mass* calcd. for $C_{22}H_{34}O_3$: 346.2508; found: 346.2506.

Methyl 2,2-diallyl-3-oxo-4-[2-methyl-3-(1,5-dimethylhexyl)cyclo-pentadienyl]butyrate, 15

A mixture of sodium hydride, as a 60% oil dispersion (0.220 g, 5.50 mmol, Aldrich), in anhydrous dimethoxyethane (3 mL) was cooled in an ice-water bath and treated dropwise with a solution of keto-ester **10** (1.53 g, 5.00 mmol) in dimethoxyethane (2 mL). The solution was warmed to room temperature for 10 min, then cooled in a Dry Ice/acetone bath and treated with allyl bromide (0.600 g, 5.04 mmol, Aldrich). The reaction mixture was stirred at room temperature for 1 h, then worked up in the usual manner with ether and brine. The crude reaction mixture was purified by flash chromatography (30% ether/petroleum ether) to give monoalkylated product **14** (0.727 g, 42%) as well as the desired dialkylation product **15** (0.617 g, 32%) as an oil; ir: 1730, 1665, 1640 and 1570 cm^{-1} (keto-ester and cyclopentadiene); ^{1}Hmr δ: 0.83 (6H, d, J = 6.5 Hz, $R_2CH(CH_3)_2$), 2.94 (2H, br m, $C{=}CCH_2C{=}C$), 3.59 (3H, s, OCH_3), 4.70 to 5.77 (6H, m, $CH{=}CH_2$) and 5.77 (1H, br s, $C{=}CHCH_2C{=}C$). *Exact Mass* calcd. for $C_{25}H_{38}O_3$: 386.2821; found: 386.2820.

Methyl 2-(3-butenyl)-3-oxo-4-[2-methyl-3-(1,5-dimethyl-4-hexenyl)-cyclopentadienyl]butyrate, 16

Alkylation of keto-ester **11** (1.256 g, 4.13 mmol) with 1-bromo-3-butene as outlined above in the preparation of **13** gave,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

after flash chromatography (10% ether/petroleum ether), the desired product **16** (0.961 g, 65%) as an oil; ir: 1740, 1670, 1640 and 1570 cm^{-1} (keto-ester and cyclopentadiene); ^{1}Hmr δ: 1.07 (3H, d, J = 6.5 Hz, R_2CHCH_3), 1.54 to 1.75 (9H, m, $C{=}C(CH_3)_2$ and $C{=}CRCH_3$), 2.95 (2H, br m, $C{=}CCH_2C{=}C$), 3.40 (1H, br t, J = 6.5 Hz, COCHRCOOR), 3.67 (3H, s, OCH_3), 4.85 to 6.03 (4H, m, $CH{=}CH_2$ and $CH{=}C(Me)_2$) and 6.03 (1H, br s, $C{=}CHCH_2C{=}C$). *Exact Mass* calcd. for $C_{23}H_{34}O_3$: 358.2507; found: 358.2532.

Methyl 2-allyl-3-oxo-4-[2-methyl-3-(1,5-dimethyl-4-hexenyl)-cyclopentadienyl]butyrate, 17

Alkylation of keto-ester **11** (2.10 g, 6.91 mmol) with allyl bromide as outlined above in the preparation of **14** gave, along with some dialkylated compound, the desired keto-ester **17** (1.151 g, 48%) as an oil; ir: 1740, 1670, 1640 and 1575 cm^{-1} (keto-ester and cyclopentadiene); ^{1}Hmr δ: 1.05 (3H, d, J = 6.5 Hz, R_2CHCH_3), 1.55 to 1.73 (9H, m, $C{=}C(CH_3)_2$ and $C{=}CRCH_3$), 2.97 (2H, br m, $C{=}CCH_2C{=}C$), 3.42 (1H, t, J = 6.5 Hz, COCHRCOOR), 3.65 (3H, s, OCH_3), 4.83 to 5.97 (4H, m, $CH{=}CH_2$ and $CH{=}C(Me)_2$) and 5.97 (1H, t, $J \simeq 1$ Hz, $C{=}CHCH_2C{=}C$). *Exact Mass* calcd. for $C_{22}H_{32}O_3$: 344.2351; found: 344.2364.

2-Oxo-1-[2-methyl-3-(1,5-dimethylhexyl)cyclopentadienyl]-5-hexene, 18

A stock solution of wet dimethyl sulfoxide was prepared by adding water (0.31 mL) to anhydrous dimethyl sulfoxide (29 mL). A solution of keto-ester **14** (0.863 g, 2.49 mmol) in wet dimethyl sulfoxide (4.3 mL) was treated with lithium chloride (0.212 g, 5.00 mmol) and heated at 175°C for 0.5 h. The resulting mixture was worked up in the usual manner with ether and water and flash chromatographed (20% ether/petroleum ether) to give ketone **18** (0.478 g, 67%) as an oil; ir: 1710, 1670, 1640 and 1575 cm^{-1} (ketone and cyclopentadiene); uv (EtOH) λ_{max}: 307 nm (ε = 27 000); ^{1}Hmr δ: 0.83 (6H, d, J = 6.5 Hz, $RCH(CH_3)_2$), 1.02 (3H, d, J = 6.5 Hz, R_2CHCH_3), 1.68 (3H, $C{=}CRCH_3$), 2.93 (2H, br m, $C{=}CCH_2C{=}C$), 4.72 to 5.80 (3H, m, $CH{=}CH_2$) and 5.80 (1H, br s, $C{=}CHCH_2C{=}C$). *Exact Mass* calcd. for $C_{20}H_{32}O$: 288.2453; found: 288.2458.

2-Oxo-1-[2-methyl-3-(1,5-dimethylhexyl)cyclopentadienyl]-6-heptene, 19

Decarboxylation of keto-ester **13** (1.22 g, 3.39 mmol) as outlined above in the preparation of **18** yielded ketone **19** (0.720 g, 70%); ir: 1710, 1670, 1640 and 1575 cm^{-1} (ketone and cyclopentadiene); ^{1}Hmr δ: 0.85 (6H, d, J = 6.5 Hz, $RCH(CH_3)_2$), 1.05 (3H, d, J = 6.5 Hz, R_2CHCH_3), 1.70 (3H, br s, $C{=}CRCH_3$), 2.93 (2H, br m, $C{=}CCH_2C{=}C$), 4.80 to 5.90 (3H, m, $CH{=}CH_2$) and 5.90 (1H, t, J = 1 Hz, $C{=}CHCH_2C{=}C$). *Exact Mass* calcd. for $C_{21}H_{34}O$: 302.2609; found: 302.2563.

2-Oxo-1-[2-methyl-3-(1,5-dimethyl-4-hexenyl)cyclopentadienyl]-propane, 20

Decarboxylation of keto-ester **11** (3.288 g, 10.8 mmol) as outlined above in the preparation of **18** yielded ketone **20** (2.149 g, 81%); ir: 1700, 1670, 1645 and 1570 cm^{-1} (ketone and cyclopentadiene); ^{1}Hmr δ: 1.03 (3H, d, J = 6.5 Hz, R_2CHCH_3), 1.50 to 1.73 (9H, $C{=}C(CH_3)_2$ and $C{=}CRCH_3$), 2.08 (3H, s, $COCH_3$), 2.90 (2H, br m, $C{=}CCH_2C{=}C$), 4.97 (1H, br t, $J \simeq 6$ Hz, $CH{=}CMe_2$) and 5.83 (1H, br s, $C{=}CHCH_2C{=}C$). *Exact Mass* calcd. $C_{17}H_{26}O$: 246.1984; found: 246.1993.

2-Oxo-1-[2-methyl-3-(1,5-dimethyl-4-hexenyl)cyclopentadienyl]-5-hexene, 21

Decarboxylation of keto-ester **17** (1.165 g, 3.39 mmol) as outlined above in the preparation of **18** yielded ketone **21** (0.631 g, 65%) as an oil; ir: 1710, 1670, 1640 and 1575 cm^{-1} (ketone and cyclopentadiene); ^{1}Hmr δ: 1.03 (3H, d, J = 6.5 Hz, R_2CHCH_3), 1.55 to 1.75 (9H, $C{=}C(CH_3)_2$ and $C{=}CRCH_3$), 2.97 (2H, br m, $C{=}CCH_2C{=}C$), 4.80 to 6.17 (4H, m, $CH{=}CH_2$ and $CH{=}CMe_2$) and 5.90 (1H, br s, $C{=}CHCH_2C{=}C$). *Exact Mass* calcd. for $C_{20}H_{30}O$: 286.2297; found: 286.2297.

10-Methyl-9-(1,5-dimethylhexyl)tricyclo[6.2.1.0^{1,6}]-9-undecen-3-one, 22

A solution of ketone **18** (0.470 g, 1.63 mmol) in toluene (15 mL) was heated in a sealed tube at 180°C for 3 days. The solvent was evaporated and the residue was flash chromatographed (20% ether/petroleum ether) to give Diels–Alder adduct **22** (0.364 g, 77%) as an oil; ir: 1720 cm^{-1} (ketone); ^{1}Hmr δ: 0.80 to 1.10 (9H, m, $RCH(CH_3)_2$ and R_2CHCH_3), 1.61 (3H, br s, $C{=}CRCH_3$). *Exact Mass* calcd. for $C_{20}H_{32}O$: 288.2453; found: 288.2509.

2,6,6,9-Tetramethyl-8-(2-oxo-propylidenyl)tricyclo[5.2.1.0^{1,5}]-decane, 24

A solution of ketone **20** (1.00 g, 4.07 mmol) in toluene (15 mL) was heated in a sealed tube at 170°C for 7 days. The solvent was evaporated and the residue was flash chromatographed (20% ether/petroleum ether) to give ketone **24** (0.527 g, 53%) as an oil; ir: 1710, 1680 and 1620 cm^{-1} (α,β-unsaturated ketone); ^{1}Hmr δ: 0.87 and 1.05 (6H, s, *exo*- and *endo*-CH_3), 2.07 (3H, s, $COCH_3$), 3.00 to 3.53 (2H, overlapping m, C7 and C9 methines) and 6.00 (1H, br s, C=CH). *Exact Mass* calcd. for $C_{17}H_{26}O$: 246.1984; found: 246.2031.

10-Methyl-9-(1,5-dimethyl-4-hexenyl)tricyclo[6.2.1.0^{1,6}]-9-undecen-3-one, 25

A solution of ketone **21** (0.470 g, 1.64 mmol) in toluene (15 mL) was heated in a sealed tube at 180°C for 4 days. The solvent was evaporated and the residue flash chromatographed (20% ether/petroleum ether) to give cyclization product **25** (0.357 g, 76%) as an oil; ir: 1720 cm^{-1} (ketone); ^{1}Hmr δ: 0.93 and 1.02 (3H, d, J = 6.5 Hz, R_2CHCH_3), 1.55 and 1.64 (9H, $C{=}C(CH_3)_2$ and $C{=}CRCH_3$) and 4.97 (1H, br t, $J \simeq 6$ Hz, $CH{=}CMe_2$). *Exact Mass* calcd. for $C_{20}H_{30}O$: 286.2297; found: 286.2300.

Received June 28, 1983

V. B. KARTHA, L. C. LEITCH, and H. H. MANTSCH. Can. J. Chem. **62**, 128 (1984).

Lithium, sodium, potassium, cesium, and ammonium palmityl sulfates were prepared by sulfonation of *n*-hexadecanol, followed by treatment with the corresponding alkali carbonates; selectively deuterated palmityl sulfates were also synthesized to aid the assignment of certain vibrational modes. The infrared and Raman spectra of the polycrystalline solids were interpreted and discussed in terms of acyl chain and head group vibrations. Spectral evidence is presented for the existence of different solid polymorphic forms.

V. B. KARTHA, L. C. LEITCH et H. H. MANTSCH. Can. J. Chem. **62**, 128 (1984).

On a préparé les sels de lithium, de sodium, de potassium, de césium et d'ammonium du sulfate de palmityle par une sulfonation du *n*-hexadécanol suivie de la réaction du sulfate acide avec les carbonates basiques correspondants. On a également synthétisé des sulfates de palmityle deutérés de façon sélective dans le but de faciliter l'identification de certains modes de vibration. On interprète les spectres infrarouge et Raman des solides polycristallins et on en discute en fonction des vibrations des chaines acylées et des groupes directeurs. On présente des preuves spectrales de l'existence de différentes formes de solides polymorphiques.

Introduction

A considerable amount of work has been done on the amphiphilic properties and phase transitions of alkali salts of alkyl sulfates (for a review, see ref. 1), yet except for a few nmr studies (2, 3), mostly non-spectroscopic techniques were used. Recently, the technique of Fourier-transform infrared spectroscopy has been used by us extensively in the study of biological membranes and related amphiphilic systems to gain information about micellar aggregation (4–6) and thermotropic phase behavior (7–10). These studies have now been extended to alkali salts of alkyl sulfates which are common micelle forming surfactants and may be used as models for the thermotropic phase behavior of sulfolipids found in natural sources (11, 12).

In the present study we assign and discuss the vibrational bands of the alkali salts of palmityl sulfate in terms of crystal structure differences, and establish correlations between individual group frequencies and the nature of the counter-ions. We have chosen to study the palmityl rather than the better known dodecyl salts, as C_{16} is the most abundant chain length found in biological systems.

Experimental

Materials

As the alkali palmityl sulfates are not commercially available, the Li, NH_4, Na, K, Rb, and Cs palmityl sulfates were all prepared in our laboratory starting from *n*-hexadecanol. A solution of 13.5 g (0.05 mol) of *n*-hexadecanol (Chemical Sample Co., Columbus, OH) and 5 g (0.05 mol) of 98% sulfuric acid in 100 mL of petroleum ether (bp 30–60°C) was heated under reflux for 1/2 h. The pale reddish solution was subdivided into 10 mL aliquots for the preparation of individual alkali salts.

In a typical preparation the 10 mL aliquot of *n*-hexadecyl hydrogen sulfate was added to a mixture of 50 mL of *n*-butanol and 10 mL of water in a 100 mL round-bottomed flask and the reaction mixture was neutralized by adding small portions of the alkali carbonate or bicarbonate, with stirring until the pH was 7.5 on indicator paper. The solution was then evaporated to dryness under reduced pressure. The residue was extracted with 50 mL of hot chloroform–methanol (9:1 v/v) and filtered hot from a small excess of the carbonate. On cooling, the product crystallized in pearly white plates, which were filtered off with suction, washed with ether, and dried (yield 1.5 g). Elemental analyses were carried out for all the samples. A typical result for the cesium salt was: *Anal.* calcd. for $C_{16}H_{33}O_4SCs$: C 42.29, H 7.32, S 7.06; found: C 41.95, H 7.48, S 6.93.

The 1,1-d_2-palmityl sulfates were prepared starting with ethyl palmitate. A solution of 2.0 g of ethyl palmitate (Sigma Chemical Co., St. Louis, MO) in 50 mL ether was added to 0.5 g $LiAlD_4$ in 50 mL ether. The mixture was heated under reflux for 1 h and then decomposed by dropwise addition of dilute HCl. The ether layer was separated and dried over $MgSO_4$. Evaporation of the ether gave the 1,1-d_2-hexadecyl alcohol which crystallized at room temperature (yield ~2 g). From this alcohol, the 1,1-d_2-palmityl hydrogen sulfate and the corresponding alkali salts were obtained by the same procedure as described above for the preparation of the non-deuterated alkali palmityl sulfates.

Methods

Infrared spectra were obtained with KBr and CsI pellets. For the Li, Na, and K salts spectra were also recorded with Nujol and Fluorolube mulls; these spectra showed practically no differences from the pellet spectra. All infrared spectra were recorded on a BOMEM DA3-02 Fourier transform infrared spectrometer, equipped with a high-speed vector processor, and a PDP 11-03 computer for data processing. A germanium coated KBr beamsplitter and a high sensitivity, liquid nitrogen cooled mercury cadmium telluride detector were used for the 4000–500 cm^{-1} region, while a mylar beam splitter and a pyroelectric DTGS detector were used to cover the 700–200 cm^{-1} region. Typically, 250 scans were coadded at an apodized resolution of 1 cm^{-1}. Frequencies of absorption peaks were determined by computing centers of gravity of the bands by using programs developed in our laboratories (13). Shoulder peaks and very weak bands were measured visually on an expanded display by using the cursor position. For more accurate frequency measurements on overlapping bands the spectra were Fourier deconvoluted to produce sharper bands (14).

Raman spectra were recorded on a Spex 0.75 m double monochromator, equipped with a DATAMATE data collection system. Spectral slit-widths of 1.5–2 cm^{-1} were used. The DATAMATE was used in Burst Mode 1, where the spectrometer slews to the starting frequency, collects and integrates the photon counts for a specified integration time, then slews through an increment in frequency and repeats the collection and integration process. Frequency increments of 1 cm^{-1} with integration times of 3 s gave good spectra with 200–250 mW of laser power from the 514.5 nm line of a Coherent Radiation CRL Model 12 argon ion laser.

Results and discussion

Each of the alkali palmityl sulfates was purified by separate recrystallizations from *n*-butanol and from a chloroform–methanol mixture (9:1 v/v); for the sodium and potassium salts we found two different solid forms, whereas all other salts had identical infrared and Raman spectra regardless of whether they were obtained by recrystallization from *n*-butanol or from chloroform–methanol. The mid-infrared spectra of the lithium, ammonium, rubidium, and cesium salts of palmityl sulfate are shown in Fig. 1, along with the spectrum of the parent compound, *n*-hexadecanol; each of these solid salts was found to occur only in one polymorphic form. Figure 2 shows the infrared spectra of sodium palmityl sulfate and of the 1,1-d_2-palmityl salt, each obtained by recrystallization from *n*-butanol or chloroform–methanol (9:1 v/v); in this case two different polymorphs were obtained from both sodium salts. The Raman spectra of the alkali palmityl sulfates and that of *n*-hexadecanol are shown in Fig. 3 for the region of interest.

The vibrational spectra of these compounds are best discussed in terms of crystal structure differences, which are seen most clearly in the acyl chain modes, and in terms of the cation effect, which is most evident on the head group frequencies.

Acyl chain modes

As no crystal structure information is available on any of the alkali palmityl sulfates, one has to make use of correlations which have been established between certain infrared and Raman spectral features and known crystal structures of related compounds, such as *n*-alkanes or fatty acids. Thus, it can be seen that the infrared spectra of the lithium, ammonium, and rubidium salts in Fig. 1, like that of *n*-hexadecanol, show clear splitting of the CH_2 scissoring (1470 cm^{-1}) and the CH_2 rocking modes (720 cm^{-1}); these spectra resemble those of *n*-alkanes with a known orthorhombic subcell (15–18). The methylene scissoring and rocking modes are split in two components in the spectra of *n*-alkanes and polyethylene when the subcell is orthorhombic (19); this factor group or crystal field splitting arises from intermolecular interactions between the two chains in the orthorhombic subcell. Evidence for a two band system is also obtained from the corresponding Raman spectra. Thus, the two components of the CH_2 scissoring mode are clearly evident at 1420 and 1440 cm^{-1} in the Raman spectra of the lithium, ammonium, and rubidium salts as well as in that of *n*-hexadecanol (Fig. 3); the 1420 cm^{-1} component is absent in all the other salts. Furthermore, the Raman spectra of the CH_2 stretching modes, Fig. 4*A*, shows the 2848 cm^{-1} (symmetric CH_2 stretch) and 2880 cm^{-1} (antisymmetric CH_2 stretch) bands with intensities and widths observed in *n*-alkanes and fatty acids with the orthorhombic packing (17). These spectral features, which are compatible with an orthorhombic or monoclinic (which have a common orthorhombic subcell) packing pattern, we have designated as type I spectra.

As seen from Fig. 2 the spectrum of the sodium salt of palmityl sulfate depends on the method of crystallization. Samples crystallized from *n*-butanol show rather broad bands with practically no splitting, while samples crystallized from chloroform–methanol show very sharp bands. We designate these as type II and type III respectively since they possess spectral features similar to those observed in *n*-alkanes and fatty acids with known hexagonal and triclinic chain packing, respectively (15–18). The infrared spectrum of the cesium salt in Fig. 1 is quite different from that of the lithium, ammonium, and rubidium salts; like Na(III) it shows a larger number of

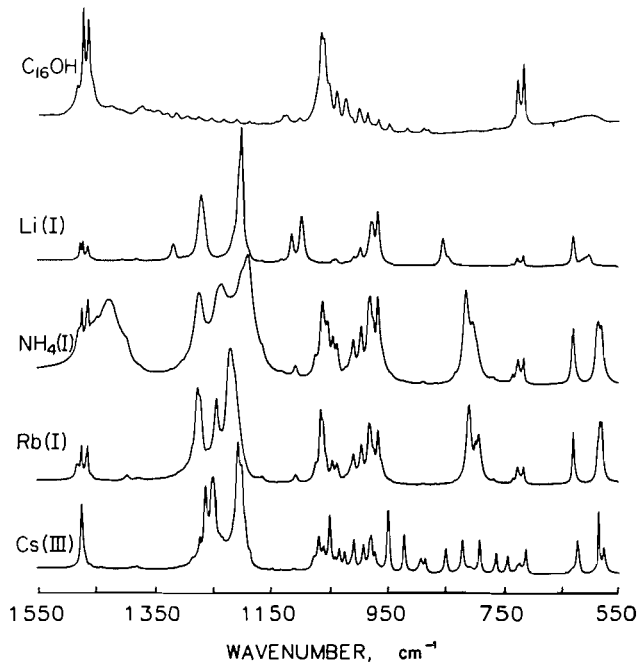

FIG. 1. FT-ir spectra of KBr pellets (1 mg sample/200 mg KBr) of polycrystalline *n*-hexadecanol and of lithium, ammonium, rubidium, and cesium palmityl sulfate in the 550–1550 cm^{-1} region.

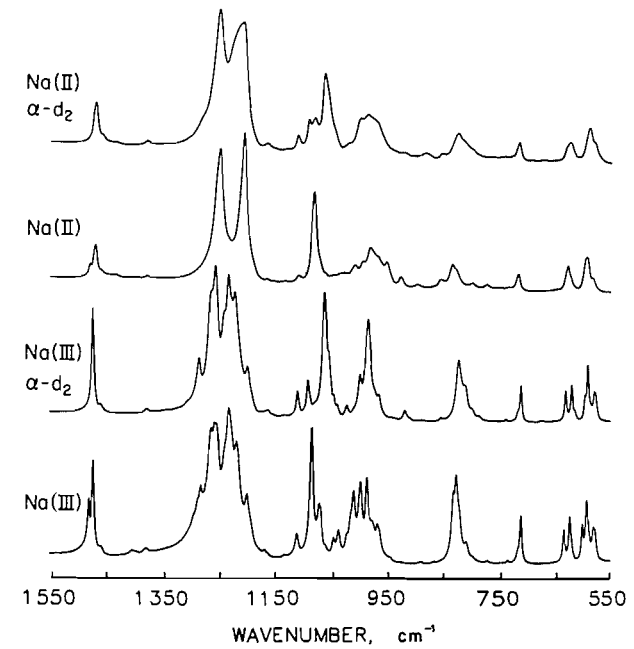

FIG. 2. Infrared spectra of type II and type III sodium palmityl and sodium 1,1-d_2-palmityl sulfate in the 550–1550 cm^{-1} region.

sharp bands. Neither type II nor type III spectra show splitting for the CH_2 rocking mode around 720 cm^{-1}; however, type III sodium palmitate shows an apparent splitting of the CH_2 scissoring mode with two bands at 1472 and 1479 cm^{-1} (Fig. 2). The absence of splitting of the CH_2 rocking mode makes it unlikely that the two bands in the CH_2 scissoring region belong to the same mode and deuteration of the α-CH_2 group in sodium and lithium palmitate have led to an unambigous assignment of the 1479 cm^{-1} band to the α-CH_2 scissoring mode. In fact, a band at 1479 ± 1 cm^{-1} is observed in practically all alkali

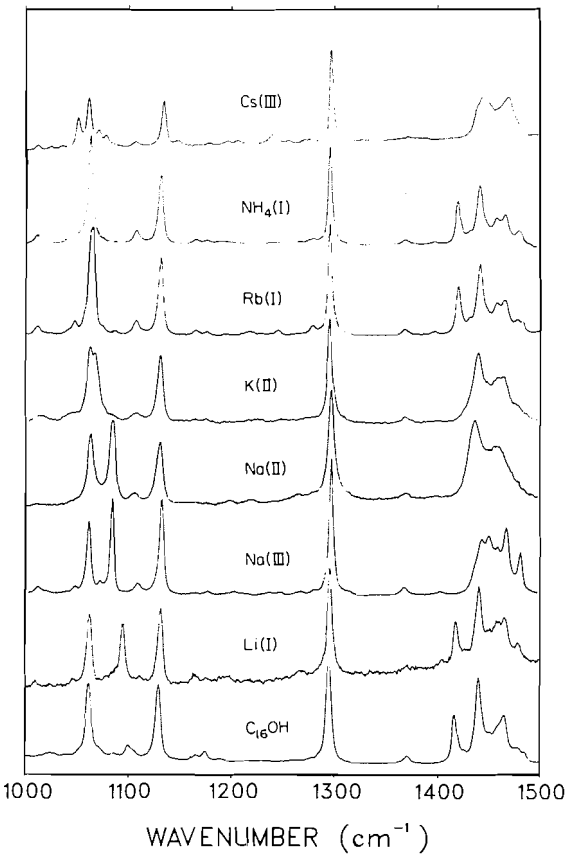

FIG. 3. Raman spectra of polycrystalline *n*-hexadecanol and of lithium, sodium (type II and type III), potassium, rubidium, ammonium, and cesium palmityl sulfate in the 1000–1500 cm^{-1} region.

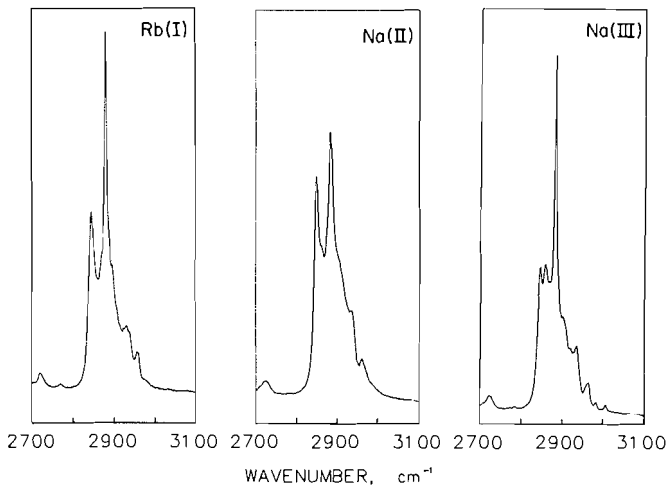

FIG. 4. Typical Raman spectra of type I, type II, and type III palmityl sulfates in the 2700–3100 cm^{-1} region.

palmityl sulfates, but as shown in the infrared spectra of 1,1-d_2-sodium palmityl sulfate in Fig. 2, this band disappears upon deuteration of the α-methylene group and is replaced by a new band at 1092 cm^{-1} which is also observed in the corresponding Raman spectra and can be assigned to the α-CD_2 scissoring vibration.

A detailed list of the infrared and Raman bands of all alkali palmityl sulfates, along with their assignment, is given in Table 1. The infrared frequencies of the CH_2 rocking modes are 721 cm^{-1} in type II and 716 cm^{-1} in type III samples. The values of the CH_2 scissoring and CH_2 rocking modes and the absence of any splitting, taken in conjunction with infrared spectra of *n*-alkanes and fatty acids of known crystal structure (15–18), strongly suggest a hexagonal packing for the acyl chains in type II and a triclinic packing in type III samples. Nevertheless, these conclusions eventually have to be confirmed by diffraction studies; therefore we prefer to use the nomenclature, type I, II, and III, instead of orthorhombic, hexagonal, and triclinic, respectively.

The assignments based on ir data are fully supported by the corresponding Raman data. As shown in Fig. 4, type II samples show the symmetric and antisymmetric CH_2 stretching modes with similar intensities (Fig. 4*B*), while type III samples possess two bands in the region of the symmetric CH_2 stretching mode (Fig. 4*C*, see also Table 1). These spectral features concur with those observed in the Raman spectra of crystalline hydrocarbons with hexagonal or triclinic packing, respectively (17). Furthermore, the 1420 cm^{-1} component of the CH_2 scissoring mode, characteristic of the orthorhombic subcell, is absent in both type II and type III spectra (Fig. 3).

Head group modes

Figures 1–3 show a number of strong infrared and Raman bands due to localized head group vibrations. It should be mentioned, however, that the concept of type I, type II, and type III packing applied to the acyl chain modes will not be applicable to the head groups modes. As has been shown by Sundell in the case of sodium dodecyl sulfate (20), the molecular arrangement in the system is too highly irregular to allow any formal subcell description for the whole molecule. The infrared and Raman spectra of the alkali hexadecyl sulfates reflect this aspect of the structure as shown by the complex splitting pattern observed for some of the head group bands.

The head group vibrations in these alkali palmityl sulfates involve four sulfur–oxygen stretching and five S—O angle bending modes of the SO_4 group; some of the vibrations could, in principle, be degenerate. The strongest bands in the infrared spectra of the alkali palmityl sulfates appear in the 1200–1300 cm^{-1} region and are due to the asymmetric SO_3 stretching modes (Figs. 1 and 2). These bands are absent or very weak in the corresponding Raman spectra (Fig. 3), where this region is dominated by an acyl chain mode, namely the strong CH_2 twisting band around 1300 cm^{-1}. The type II palmityl salts, as well as sodium dodecyl sulfate, show only two infrared bands around 1200 and 1270 cm^{-1}, while the type I and type III palmityl salts show at least three bands in the region of the asymmetric SO_3 stretching vibrations. In a planar arrangement, such as in a hexagonal subcell, all sulfate groups are equivalent and only two asymmetric SO_3 stretching modes are expected. This is indeed the case with type II salts. However, from the crystal structure of sodium dodecyl sulfate it is evident that the sulfate groups of adjacent molecules are alternately displaced by about 2 Å (20). The similarity of the infrared spectra of sodium dodecyl and sodium palmityl sulfate makes it not unrealistic to expect that this staggered structure also occurs in the palmityl sulfates; thus, different sulfate groups will have different environments, i.e. different sets of sites are occupied, producing an effect analogous to factor group splitting. In the more crystalline type I and type II palmityl salts, some of the sharp shoulder bands could also arise from the CH_2 wagging band progression (17). The spectra of the alkali palmityl salts in micellar solutions are identical with only two broad bands around 1210 and 1240 cm^{-1} (21).

[a]The frequencies (in cm^{-1}) are rounded off to the nearest integer.
[b]Too weak or masked by stronger bands.

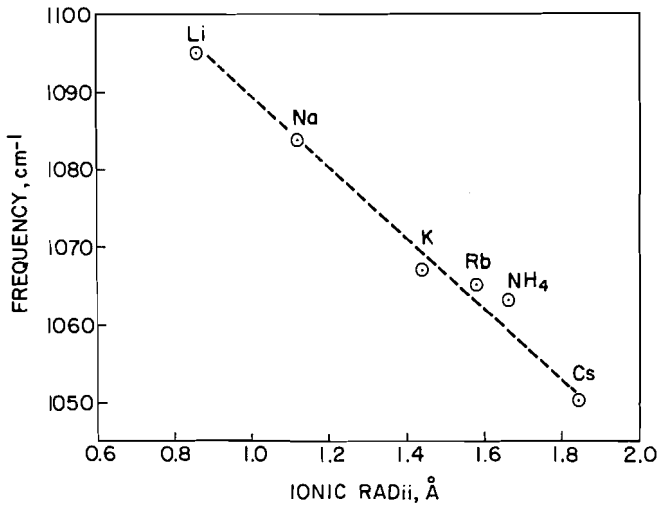

FIG. 5. Correlation between the position of the symmetric SO_3 stretching mode and the ionic radii of the alkali ions. The Ladd radii were used here (22), although the corresponding Pauling radii give a similar relationship with the same slope, but displaced by about 0.2 Å.

While we found no obvious correlation between the asymmetric SO_3 stretching bands and the nature of the alkali cations, the symmetric SO_3 stretching modes could be correlated with the ionic radius of the individual alkali cations. This umbrella-type vibration involves the concerted expansion and contraction of the three S—O bonds. The band is easily identified by its behavior on cation substitution, particularly in the Raman spectra. Figure 3 shows that the symmetric SO_3 stretching band occurs about midway between the two strong skeletal C—C bands at 1130 and 1062 cm^{-1} in the lithium salt, but with increasing cation size it moves towards the 1062 cm^{-1} band and even overtakes the latter in the cesium salt. As expected, the band is absent in the Raman spectrum of *n*-hexadecanol. Although the symmetric SO_3 stretching mode is quite strong in the infrared, it largely overlaps with the strong CCO stretching modes. The latter, however, show a considerable shift to lower frequencies upon deuteration of the α-methylene group, which allows a better assignment of the infrared modes in this region (Table 1).

As shown in Fig. 5 the frequency of the symmetric SO_3 stretching mode in the alkali palmityl sulfates decreases linearly with increasing ionic radius of the alkali ions (22). Furthermore, the symmetric S—O(C) stretching mode also shows a similar relationship between its frequency and the crystal radii of the alkali ions. This vibration yields a strong band at 855 cm^{-1} in the infrared and Raman spectra of the lithium salt which decreases also linearly with increasing cationic size; in the cesium salt this band was found at 796 cm^{-1} (Table 1).

The S—O angle bending modes of the SO_4 group can be identified in the 400–650 cm^{-1} region as a group of five medium strong bands around 430, 480, 520, 590, and 630 cm^{-1} (Table 1). Like in the case of the asymmetric SO_3 stretching mode no obvious correlation could be established between the frequency of these bands and the nature of the alkali cations.

In conclusion, the present study shows that while the vibrational modes of the palmityl moiety are invariant in the solid alkali palmityl sulfates, except for differences arising from packing of the methylene chains, some vibrational modes of the sulfate moiety show a linear relationship between their frequency and the crystal radii of the ions. The latter correlation becomes particularly important when studying the critical micellization temperature of these polycrystalline alkali palmityl sulfates (21).

Résonance magnétique nucléaire ^{13}C des dérivés allyliques de la colonne IV-A,[1] de type $(C_6H_5)_3ECH_2CH{=}CH{-}CH_3$. Effets électroniques du substituant du noyau aromatique

E. MATARASSO-TCHIROUKHINE

Laboratoire de Recherches de Chimie Organique de l'E.N.S.C.P., 11, Rue Pierre et Marie Curie, 75231 Paris Cedex 05, France

Reçu le 24 janvier 1983[2]

E. MATARASSO-TCHIROUKHINE. Can. J. Chem. **62**, 133 (1984).

L'étude par rmn ^{13}C de la série $(C_6H_5)_3ECH_2CH{=}CH{-}CH_3$ **1***E* pour tous les éléments de la colonne IV-A a mis au jour les effets électroniques du substituant du noyau aromatique en fonction de l'élément E-IV-A; à savoir (a) un effet électro-accepteur par hyperconjugaison pour E = Si, Ge, Sn, (b) un effet inverse, électrodonneur par hyperconjugaison pour E = Pb, impliquant une électronégativité plus élevée pour cet élément et (c) un effet donneur par induction (I) pour E = C. L'énergie moyenne d'excitation de la molécule gouverne les déplacements chimiques des carbones *ipso* et *ortho*. Il semble qu'elle soit également déterminante quant au couplage $^1J(^{13}C{-}^{207}Pb)$.

E. MATARASSO-TCHIROUKHINE. Can. J. Chem. **62**, 133 (1984).

The ^{13}C nmr study of the series $(C_6H_5)_3ECH_2CH{=}CH{-}CH_3$ **1***E* shows, for the aromatic nucleus, a polarization consistent with a mesomeric electron withdrawing effect of the substituent in the case of E = Si, Ge, Sn; inversely, a mesomeric donating effect, in the case E = Pb, involving a higher electronegativity for Pb; and a donating π inductive effect, in the case E = C. The mean electronic excitation energy seems to dominate the chemical shifts of the aromatic carbons C_{ipso} and C_{ortho}, as well as the coupling $^1J(^{13}C{-}^{207}Pb)$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

L'étude comparative des déplacements chimiques et des couplages le long de la colonne IV-A pour une même série $R_3ECH_2CH{=}CH{-}CH_3$ **1***E*, *Z* ou $R_3ECH(CH_3)CH{=}CH_2$ **2** avait permis d'interpréter les résultats obtenus en termes d'hyperconjugaison $\sigma{-}\pi$ (1).

Dans le but d'apporter des renseignements quant aux comportement respectif des hétéroéléments Si, Ge, Sn et Pb vis à vis du noyau aromatique, il nous a paru souhaitable de compléter ces travaux par l'étude comparative du fragment aromatique de la série $(C_6H_5)_3ECH_2CH{=}CH{-}CH_3$, **1***E*.

En ce qui concerne *la partie expérimentale*, se rapporter à la *première partie* de ce travail (1).

Résultats et discussion

Paramètres $\delta^{13}C_{Ar}$

Les résultats numériques expérimentaux concernant les déplacements chimiques $\delta^{13}C_{Ar}$ se trouvent consignés dans le tableau 1.

Il convient de rappeler, d'une part, que l'introduction d'un substituant sur le noyau benzènique conduit à une polarisation des électrons π du noyau phényle. Cette polarisation est gouvernée à la fois par le facteur de polarité σ_I, et le facteur de résonance σ_R, du substituant; et, d'autre part, que (a) les déplacements chimiques $\delta^{13}C_p$ et $\delta^{13}C_m$ sont proportionnels à la charge totale, $q_t = q_\sigma + q_\pi$, portée respectivement par les carbones *para* et *meta*; ils sont liés aux paramètres d'induction σ_I et de résonance σ_R du substituant par une relation linéaire (2). Pour les carbones *ipso* C_i, et *ortho*, C_o, il faut ajouter l'effet stérique ainsi que toute contribution ayant pour origine l'effet d'anisotropie du substituant (3); et que (b) le paramètre $\Delta\delta^{13}C_p$ par rapport au benzène est fonction linéaire de $\Delta q_\pi{}^{C_p}$, lui-même proportionnel à $\Delta q_t{}^{C_p}$.

Il en résulte que le caractère donneur ou accepteur d'un substituant peut être déduit directement du déplacement chimique du carbone en *para*.

Il convient de distinguer $\Delta q_\pi{}^{C_p}$ et $\epsilon\Delta q_\pi$ (transfert de charge total) entre le substituant et le noyau aromatique, lequel dépend presque exclusivement de la constante σ_R, tandis que $\Delta q_\pi{}^{C_p}$ dépend de façon relativement importante de la polarité du substituant (2).

TABLEAU 1. Déplacements chimiques des carbones aromatiques, $\delta^{13}C_{Ar}$; composés **1***E*[a]

E	$\delta^{13}C_{Ar}$ ppm			
	C_i	C_o	C_m	C_p
Pb	151,19 [+22,69]	137,48 [+8,98]	129,16 [+0,66]	128,18 [−0,32]
Sn	138,64 [+10,14]	136,99 [+8,49]	128,37 [−0,13]	128,82 [+0,32]
Ge	136,66 [+8,16]	134,82 [+6,32]	127,88 [−0.62]	128,62 [+0,17]
Si	135,16 [+6,6]	135,92 [+7,42]	127,62 [−0,88]	129,26 [+0,76]
C	147,4 [+18,9]	129,42 [+0,92]	127,58 [−0,92]	125,79 [−2,71]

[a]Solutions saturées dans $CDCl_3$; référence interne TMS; précision: ±0,05 ppm. Entre parenthèses: déplacements chimiques rapportés au benzène, $\delta^{13}C_{C_6H_6}$ = 128,50 ppm. (12).

Effets électromères des substituants
—E(C₆C₅)₂(CH₂CH=CH—CH₃)

Les effets électromères observés sont faibles (Tableau 1).

(a) *E = C*

La polarisation du noyau benzènique ($\delta^{13}C_p < \delta^{13}C_m$) est congruente avec un *effet donneur pour le substituant*. Sur la base de résultats acquis antérieurement pour le méthylbenzène (4), admis pour le *tert*-butylbenzène (5) et sachant qu'une hyperconjugaison $\sigma{-}\pi$ nécessite des énergies comparables pour les orbitales σ et π, ce qui est réalisé dans le cas des composés organométalliques (6), tandis que dans le cas du composé **1***E* (E=C) cette hyperconjugaison se trouve très vraisemblablement minimisée du fait de la différence d'énergie entre les orbitales σ et π, nous concluons à une polarisation du noyau phényle par effets π inductifs du substituant.

(b) *E = Si, Ge, Sn*

La polarisation du noyau benzènique ($\delta^{13}C_p > \delta^{13}C_m$) indique un effet *électroaccepteur pour le substituant*. Cet effet ne peut être attribué à des effets inductifs, car d'après l'échelle d'électronégativité établie pour les éléments E (1), un effet π inductif conduirait à un résultat inverse de celui observé. On peut conclure à un *effet électroaccepteur par résonance*.

(c) *E = Pb*

La polarisation du noyau phényle ($\delta^{13}C_p < \delta^{13}C_m$) est congruente avec un effet donneur pour le substituant. Pour des raisons exposées dans le cas précédent, on peut conclure à un *effet électrodonneur par résonance*. L'effet donneur par hyperconjugaison de la liaison C—E, favorisé par des énergies similaires pour les orbitales σ et π concernées, croît avec la densité électronique des orbitales *p* des atomes reliant les systèmes π et σ (6); il est favorisé par une électronégativité accrue de l'élément E (5). Le caractère électrodonneur par résonance distingue le dérivé du plomb des autres groupements $—E(C_6H_5)_2(CH_2CH{=}CH—CH_3)$ de la série E-IV-A; des résultats similaires ont été obtenus pour les groupements $E(C_6H_5)_3$ (E = Sn, Pb) (5, 10) rapprochant, de ce fait, les dérivés du plomb des dérivés arylmercuriques plûtot que des dérivés de l'étain (10).

La différence $\Delta = \delta^{13}C_p - \delta^{13}C_m$ est fonction linéaire du facteur de résonance σ_R^0 (9); les données de la littérature (9) ont été mises à profit pour déterminer des ordres de grandeur pour les effets de résonance σ_R^0 des substituants, étudiés en fonction de l'hétéroélément (Tableau 4).

La comparaison des paramètres $\delta^{13}C_{Ar}$ (Tableau 1) pour la série **1***E* avec les paramètres correspondants d'alkylbenzènes (7, 8) d'une part, et ceux des phényllithium et bromure de phénylmagnésium (11) de l'autre montre que: (a) le profil du spectre du dérivé ***1E*** du carbone (E = C) est similaire à ceux du toluène et du n-butylbenzène; (b) le profil des spectres des composés hétéroatomiques E = Si, Ge, Sn, Pb, présente une analogie (surtout marquée pour les dérivés du plomb) avec celui des spectres du phenyllithium et du bromure et de phenylmagnésium, à savoir, un déblindage des carbones *ipso* (C_i) (5−25 ppm/benzène) et *ortho* (C_o) (7 ppm/benzène).

Les déplacements chimiques paramagnétiques $\delta^{13}C_i$ et $\delta^{13}C_o$ pour le phényllithium et le bromure de phenylmagnesium avaient été interprétés (11) en suggérant que l'anisotropie de la liaison C_i—M était à l'origine des déplacements paramagnétiques $\delta^{13}C_i$ et $\delta^{13}C_o$ et que ceux-ci étaient gouvernés par l'énergie moyenne d'excitation de la molécule, ΔE ($\sigma_{C_i—M} \rightarrow \pi^*$); on sait que les déplacements chimiques du carbone sont essentiellement déterminés par le terme paramagnétique de la constante d'écran, δ_p^{AA}, qui peut être exprimé (2) en termes d'énergie moyenne d'excitation de la molécule, ΔE, à laquelle il est inversement proportionnel.

Pour les composés hétéroatomiques étudiés **1***E*, il paraît raisonnable d'interpréter les déplacements chimiques paramagnétiques des carbones C_i et C_o de la même manière; ΔE décroît de Si à Pb (6) ce qui est en accord avec le déplacement paramagnétique de C_i lorsque E varie de Si à Pb.

On remarque (Tableau 1) que pour le dérivé du silicium (à l'encontre des autres dérivés hétéroatomiques), le profil du spectre rmn ^{13}C correspond pour tous les carbones à une polarisation du noyau phényle induite par un substituant électroaccepteur. $\delta^{13}C_p > \delta^{13}C_m$ et $\delta^{13}C_{ortho} > \delta^{13}C_{ipso}$; le résultat s'accorde avec un effet électroaccepteur par résonance du groupement $(C_6H_5)_2(CH_3CH{=}CH—CH_2)E—$ qui serait relativement plus important pour le dérivé du silicium par rapport aux dérivés du germanium et de l'étain et qui serait déterminant; quant aux positions relatives des déplacements chimiques des carbones aromatiques. Ce résultat est en accord avec les travaux théoriques antérieurs (6).

TABLEAU 2. Couplages $^1J(^{13}C_{Ar}—E)$; composés **1***E*, *Z*; **2**

E		$J(^{13}C_{Ar}—E)$ (Hz) C_i	C_o	C_m	C_p
Sn	**1***E*	495,2; 472,8	34,8	48,3	11,1

$\Delta = \delta C_p - \delta C_m$	+1,64	+0,79	+0,45	−0,98
σ_R^0	+0,085	+0,05	+0,035	−0,03

Couplages

Les résultats expérimentaux sont rassemblés dans les tableaux 2 et 3.

(a) *Couplage hétéroélément−carbone* $^1J(^{13}C—E)$

On remarque (Tableau 2), pour le dérivé de l'étain (E = Sn), un couplage $^1J(^{13}C—^{119,117}Sn)$ = 495,2; 472,8 Hz, donc très voisin d'un couplage "typique" d'une liaison étain tétrahédrique sp^3 − carbone sp^2 (13); en revanche pour le dérivé du plomb, E = Pb, on observe un couplage bien inférieur aux valeurs admises comme valeurs caractéristiques de la liaison plomb tetrahedrique sp^3 − carbone sp^2 (14), à savoir, pour $(C_6H_5)_4Pb$, $^1J(^{13}C—^{207}Pb)$ = 480,9 Hz et pour $(CH_2{=}CH)_4Pb$, $^1J(^{13}C—^{207}Pb)$ = 454,1 Hz. Il convient également de noter que pour $(C_6H_5)_3PbCH_3$, $^1J(^{13}C—^{207}Pb)$ = 439 Hz (15); comme il a été montré par de Vos, ^1J est fonction du nombre de phényles liés au plomb et décroît à 348 Hz, pour $(C_6H_5)Pb(CH_3)_3$; l'auteur interpréte ce phénomène en termes de charge effective portée par le plomb et du caractère *s* de la liaison C—Pb.

Rappelons que le terme de contact de Fermi gouverne le couplage $^1J(E—X)$ qui est (a) inversement proportionnel à l'énergie moyenne d'excitation de la molécule, ΔE, et (b) proportionnel à la charge effective du noyau et au caractère *s* de l'orbital hybride formant la liaison E—X.

Dans le cas du composé **1***E* (E = Pb) la faible valeur du couplage ^1J observée peut être rationalisée en termes

d'hyperconjugaison $\sigma-\pi$ de la liaison C—E et de la double liaison allylique; en effet, l'existence d'une hyperconjugaison conduit à un accroissement de la charge positive sur le plomb, ayant pour conséquence, un accroissement de ΔE, ce qui est congruent avec une diminution de $J(^{13}C—^{207}Pb)$.

(b) *Couplage carbone–proton* $J(^{13}C—H)$

Le tableau 3 montre pour les couplages $J(^{13}C—H)$ les résultats suivants: $^1J(^{13}C_m—H) < {}^1J(^{13}C_p—H)$ pour E = Si, Sn et $^1J(^{13}C_p—H) > {}^1J(^{13}C_m—H)$ pour E = Pb.

Ces résultats laissent entendre que ces couplages sont gouvernés par la charge effective des carbones C_m et C_p. Dans ce cas les inégalités observées correspondraient à une polarisation du noyau phényle induite par un substituant électro-accepteur, pour E = Si, Sn et par un substituant électrodonneur pour E = Pb; ce qui confirme les résultats déduits de l'étude des paramètres $\delta^{13}C_{Ar}$.

Received April 20, 1983

JULIO CASADO, FRANCISCO MANUEL LORENZO, MANUEL MOSQUERA, and MARÍA FLOR RODRÍGUEZ PRIETO. Can. J. Chem. **62**, 136 (1984).

The effect of the aliphatic alcohols methanol, ethanol, propanol, isopropanol, 2-butanol, isobutanol, and *tert*-butanol on the rate of nitrosation of morpholine at pH 3 and 25°C has been studied. The inhibition observed is attributed to the formation of alkyl nitrites, which are poor nitrosating agents in acid media. The equilibrium constants for the formation of alkyl nitrites from nitrous acid and alcohols have been calculated both spectrophotometrically and from kinetic data for the inhibitory effect, and there is agreement between the two sets of results. The molar absorptivities at 265 nm of the alkyl nitrites have also been determined. When the concentration of alkyl nitrite is very low, a slight catalytic effect considered to be an effect of the medium has been observed.

JULIO CASADO, FRANCISCO MANUEL LORENZO, MANUEL MOSQUERA et MARÍA FLOR RODRÍGUEZ PRIETO. Can. J. Chem. **62**, 136 (1984).

Nous avons étudié l'effet des alcools aliphatiques: méthanol, éthanol, propanol, isopropanol, 2-butanol, isobutanol et *tert*-butanol sur la vitesse de nitrosation de la morpholine. On y trouve une inhibition attachée à la formation de nitrites d'alkyle qui sont faibles agents nitrosants dans milieu acide. On a utilisé l'étude cinétique de cet effet inhibiteur pour calculer les constants de formation des nitrites d'alkyle, dont les valeurs ont été aussi calculées par une méthode spectrophotométrique en obtenant par les deux voies résultats équivalents. On a mesuré aussi les absorptivités molaires des nitrites d'alkyle à 265 nm. Le faible effet catalytique observé a été interpreté comme un effet du milieu.

Introduction

Nitrosamines, which in weakly acid conditions are formed from nitrites and secondary or tertiary amines, constitute a risk to human health as carcinogenic substances present in the environment (1, 2). Their formation is affected by a number of chemical factors present in a normal everyday diet. The ions Cl^-, Br^-, I^-, and SCN^- all promote the formation of nitrosamines, whereas it is inhibited by ascorbic acid, hydroxylamine, sodium azide, and, under certain conditions, phenols.

In recent years a number of articles have been published reporting studies of the effect of alcohols on nitrosation reactions. Williams and Aldred (3) found the nitrosation of amines to be inhibited by alcohols, thiols, and carbohydrates in the presence of 0.08 *M* sulphuric acid or 0.04 *M* perchloric acid. However, Kurechi *et al.* (4) found inhibition at pH 3 but catalysis at pH 5. The present article reports a kinetic study which, given the importance of alcohols and other hydroxylated compounds such as carbohydrates and alkanolamines, has been undertaken with the intention of clarifying these findings. The effects of seven aliphatic alcohols upon the formation of *N*-nitrosomorpholine in acid media were studied.

Experimental

All reagents used were Merck p.a. except the Merck p.s. morpholine, whose perchlorate was used after recrystallization in ethanol.

For the measurements of reaction rate, a spectrophotometric technique has been used (5). The absorbance of *N*-nitrosomorpholine was determined at 265 nm, an isosbestic point for nitrite at which its molar absorptivity ($7.41 \pm 0.04\ M^{-1}\ cm^{-1}$) is much smaller than that of the nitrosamine ($1870 \pm 4\ M^{-1}\ cm^{-1}$). In the kinetic study, the initial rate method was used in view of the slowness of the reaction being studied and to avoid competition from the decomposition of nitrous acid. The percentage reaction followed never exceeded 2%. The initial reaction rates are given by the slope of the absorbance–time curves, which were all perfectly linear. All kinetic measurements were carried out at 25°C, pH 3, and an ionic strength of 0.5 *M* controlled using $NaClO_4$. No buffer was added to the medium because, for the short period of the reaction followed, the nitrite – nitrous acid system present sufficed for maintaining constant acidity.

The equilibrium constants of the reactions of formation of the alkyl nitrites were studied spectrophotometrically by measuring the absorbance of the reaction mixture at 265 nm. Equilibrium is rapidly established, and at 265 nm the difference between absorption by alkyl nitrites and nitrous acid is much greater than at longer wavelengths (6). These experiments were carried out at 25°C, an ionic strength of 0.5 *M*, and a concentration of perchloric acid of 0.1 *M*.

To measure absorbances a Perkin–Elmer–Coleman 55 spectrophotometer was used. Acidity was measured with a Radiometer PHM 82 pH-meter. The data were processed on a TI 59 programmable calculator.

Results and discussion

Mechanism and rate equation

Working conditions were chosen in which the only effective nitrosating agent in the absence of alcohol is N_2O_3. The mechanism in these conditions is (7):

1. $2HNO_2 \rightleftharpoons N_2O_3$ fast

2. $N_2O_3 + \text{O(CH}_2\text{)}_4\text{NH} \longrightarrow \text{O(CH}_2\text{)}_4\text{NNO} + HNO_2$ slow

so that the rate equation is:

$$[1] \quad v_0 = \frac{\alpha[\text{nit}]_0^2[\text{MOR}]_0}{[H^+](1 + K_a/[H^+])^2}$$

where $[\text{nit}]_0$ and $[\text{MOR}]_0$ are the initial stoichiometric concentrations of nitrite and morpholine, K_a is the acidity constant of the nitrous acid, and α the product of the equilibrium and rate constants. The order of the reaction with respect to nitrite and morpholine was found to remain unchanged when an alcohol (EtOH) was added to the medium.

The fact that no first order term in nitrite was observed shows that the alkyl nitrites, or more probably their protonated forms, are weak nitrosating agents, and agrees with the results ob-

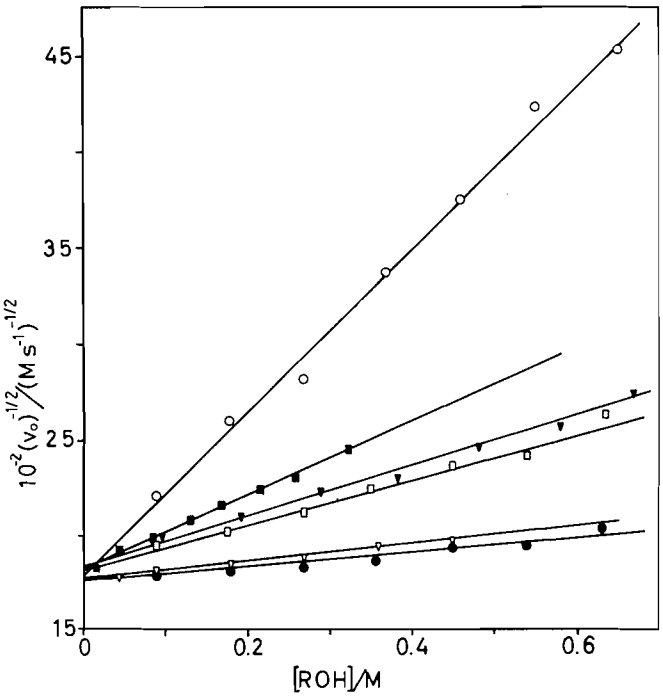

FIG. 1. Dependence of the initial rate of nitrosation of morpholine on the concentration of alcohol at 25°C, ionic strength 0.5 *M*, pH 3, $[nit]_0 = 1.09 \times 10^{-2}$ *M* and $[MOR]_0 = 7.2 \times 10^{-3}$ *M*. MeOH (○), isoBuOH (■), EtOH (▼), PrOH (□), 2-BuOH (▽), and isoPrOH (●).

tained by Aldred and Williams (8) in a kinetic study of nitrosation by propyl nitrite in 1-propanol.

The influence of the concentration of each alcohol on the reaction rate was determined in a series of experiments in which its concentration was varied. The reaction rate was in all cases found to decrease as the concentration of alcohol increased, in accordance with an equation of the form (Fig. 1):

$$[2] \quad (v_0)^{-1/2} = a + b[ROH]$$

The alcohols' inhibition of the formation of *N*-nitrosomorpholine may be explained (ref. 3) by supposing them to remove nitrous acid from the reaction medium to form alkyl nitrites, as a result of which the concentration of N_2O_3 falls. In the presence of alcohols, the mechanism for the nitrosation of morpholine shown above must therefore be supplemented by a third step, the fast equilibrium for the formation of alkyl nitrites:

$$3. \quad HNO_2 + ROH \overset{K}{\rightleftarrows} RONO + H_2O$$

If the concentration of alcohol is assumed to greatly exceed that of nitrite, the rate equation now becomes:

$$[3] \quad v_0 = \frac{\alpha[nit]_0^2[MOR]_0}{[H^+](1 + K_a/[H^+] + K[ROH])^2}$$

which in the working conditions of the present study may be expressed as:

$$[4] \quad (v_0)^{-1/2} = \frac{1 + K_a/[H^+]}{\beta} + \frac{K}{\beta}[ROH]$$

where β is a constant.

Equation [4] is of the same form as the experimental equation [2]. *K* may be calculated by simply dividing the slope of the experimental curves by the ordinate at the origin and multiplying by $(1 + K_a/[H^+])$. The value of pK_a used was 2.945, as found by Lumme and Tummavuori at 25°C and an ionic strength of 0.5 *M* (9). The resulting values of *K* are shown in Table 1, together with values obtained, likewise by kinetic methods, by Schmid and Riedl in a study of the influence of alcohols on the nitrosation of phenol (10) and by Aldred and Williams when studying the kinetics of the formation of alkyl nitrites from nitrous acid and alcohols (11).

The spectrophotometric determination of K

No direct spectrophotometric determination of *K* has so far been reported, and its purpose in the present study is not only to permit comparison of the results with the indirectly obtained values shown in Table 1, but also to confirm the proposed reaction mechanism. Since the measurements were carried out at constant ionic strength, an equilibrium constant for the formation of alkyl nitrites may be defined by:

$$[5] \quad K = \frac{[RONO]}{[HNO_2][ROH]}$$

In the conditions of acidity at which the experiments were carried out:

$$[6] \quad [nit] = [HNO_2] + [RONO]$$

so that:

$$[7] \quad A(1 + K[ROH]) = \epsilon_{HNO_2}[nit] + \epsilon_{RONO}[nit]K[ROH]$$

where *A* is the absorbance at 265 nm and ϵ_{HNO_2} and ϵ_{RONO} are the molar absorptivities of the nitrite and the alkyl nitrites at this wavelength.

To see whether the experimental results fit eq. [7], the parameter *K* was optimized using the unidimensional algorithm of Davies, Swann, and Campey implemented on a Texas TI 59 programmable calculator (12, 13). As can be seen in Fig. 2, there is a good fit between eq. [7] and the absorbance – concentration of alcohols curves, and the values of *K* and molar absorptivities of the alkyl nitrites calculated accordingly are shown in Table 1 beside the values of *K* obtained indirectly, which are in good agreement with the direct values.

The influence of the medium

Since Dix and Williams (14) found alcohols to cause an effect of the medium on their own nitrosation, we sought for a similar effect on the nitrosation of morpholine. Experiments were carried out under constant working conditions in tetrahydrofuran (THF), a solvent that does not react with nitrous acid. A catalysis of less than 30% was observed in 1 *M* THF, a higher concentration than that used in our kinetic experiments with alcohols. The same effect of the medium has been observed in the presence of acetic acid and other solvents such as DMSO and dioxane (15), and is comparable to that found by Schelly (16) in the diazotization of aniline in methanol–CCl_4 mixtures by NOCl which, like N_2O_3, is a neutral nitrosating agent. Schelly found that the reaction rate fell as the polarity of the medium increased. In the present case, since the effect of the medium is catalytic rather than inhibitory, it supports the assumption that the inhibition caused by alcohols at pH 3 is not due to such an effect.

When working with *tert*-butanol we have observed it to cause a slight catalytic effect. This we attribute to the effect of the medium in this case outweighing the inhibitory effect due to the reduction of the concentration of N_2O_3. In these conditions it has therefore been impossible to calculate *K*, though its value must clearly be small. That calculated by Schmid may perhaps have been influenced by an effect of the medium,

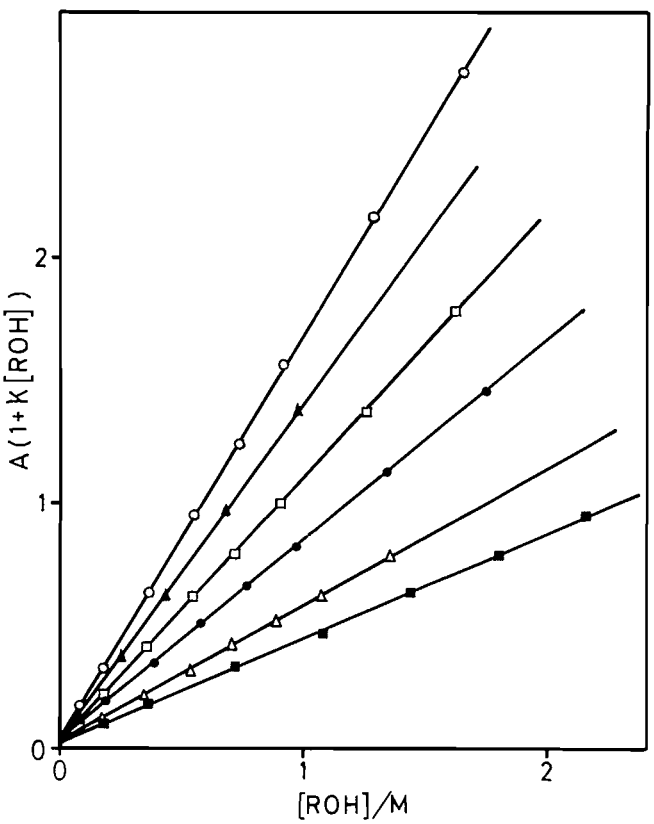

FIG. 2. Determination of the formation constants of the alkyl nitrites and their molar absorptivities. Verification of eq. [7] at 25°C, ionic strength 0.5 M, $[HClO_4] = 0.1\ M$ and $[nit] = 2.17 \times 10^{-3}\ M$. MeOH (○), isoBuOH (▲), PrOH (□), EtOH (●), 2-BuOH (△), and isoPrOH (■).

which is apparently inhibitory when, as in the nitrosation of phenols, the nitrosating agent is NO^+ (15, 17).

The effect of the medium may also explain the catalysis observed by Kurechi *et al.* (cf. ref. 4) in the nitrosation of dimethylamine and diethylamine at pH 5. At this pH the quantity of alkyl nitrites formed is very small and, since the concentrations of alcohol used were quite high (up to 42% by volume of ethanol), the effect of the medium may be expected to have prevailed over the inhibition caused by the formation of inefficient alkyl nitrites.

Temperature dependence of the NH–proton hyperfine splitting in Bu^{t}NHO·[1]

ROBERTO HENRIQUEZ AND M. JOHN PERKINS[2]
Department of Chemistry, Chelsea College, Manresa Road, London, SW3 6LX England
AND
DAVID GRILLER
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received December 21, 1982[3]

ROBERTO HENRIQUEZ, M. JOHN PERKINS, and DAVID GRILLER. Can. J. Chem. **62**, 139 (1984).

Hyperfine splitting by the NH proton in Bu^{t}NHO· decreases markedly with increasing temperature, whilst the nitrogen hyperfine interaction shows a small increase. These observations are consistent with an increase in the out-of-plane bending as the temperature is raised.

ROBERTO HENRIQUEZ, M. JOHN PERKINS et DAVID GRILLER. Can. J. Chem. **62**, 139 (1984).

Le découplage hyperfin du proton du NH dans le Bu^{t}NHO· diminue fortement lorsque la température augmente tandis que l'interaction hyperfine de l'azote augmente légèrement. Ces observations sont en accord avec une augmentation de la déformation hors du plan lorsque la température augmente.

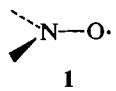
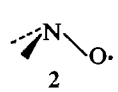
The geometry of the nitroxide group has for years been a somewhat controversial subject (1). Molecular orbital calculations of varying degrees of sophistication have failed to agree in predicting whether the minimum energy geometry is planar (**1**) or pyramidal (**2**), although the majority favour a pyramidal structure in which the barrier for inversion is tiny (2). Indeed, for H_2NO·, all calculations agree in concluding that there is little energy difference between the planar structure and one pyramidalized as far as "sp^3" geometry. It seems reasonable, therefore, to expect an out-of-plane bending vibration, in unconjugated nitroxides, which has a large amplitude and low force constant, but no experimental probe has yet yielded unambigous evidence for this.

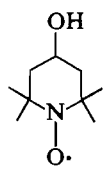
Recent infrared and Raman studies on bistrifluoromethyl nitroxide (3) led to the conclusion that this molecule probably has a planar energy minimum with a "soft" out-of-plane bending vibration,[4] and that simple dialkyl nitroxides would be expected to be more rigidly planar. Nevertheless, crystallographic studies have identified both bent (e.g. **3**), and planar (e.g. **4**) types among relatively strain-free di-*tert*-alkyl nitroxides (1), so that conformational and/or lattice forces are more than sufficient to overcome any inherent preference for a particular geometry at the nitrogen centre. The implied lack of well-defined intrinsic geometry for the nitroxide function has, in fact, been recognised for many years (1, 2*c*), but the obvious application of electron spin resonance to investigate changing vibration amplitude with variation in temperature has been relatively unproductive. For example, the tiny temperature dependence in a^N described recently for di-*tert*-butyl nitroxide (5) is within the range which might be expected solely on the basis of a *volume* change (6). In view of this, any attempt to interpret the observed reduction in $d(a^N)/dT$ as T increases in terms of an incipient turning point in the curve, as was suggested by Bullock and Howard (5), must remain open to question until the curvature has been established in a solvent which is not approaching its boiling point at the onset of curvature.



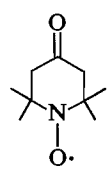
1



2



3



4

For simple dialkyl nitroxides, the insensitivity of a^N to out-of-plane vibrational amplitude may possibly be attributed to compensation of two effects. These are (*i*) the change in hybridization at nitrogen which causes a^N to increase as the molecule is bent, and (*ii*) change in spin distribution between oxygen and nitrogen which does the reverse (cf. ref. 2*c*). The two nitroxides **3** and **4**, which are respectively pyramidal and planar at nitrogen in the crystal, actually have almost identical isotropic a^N-values in solution (7).

Whilst the most sophisticated calculations of a^N for H_2NO· do suggest a change in value as the molecule is bent, the absolute values are markedly dependent on the level of refinement, and geometry optimization has not always been complete for bent structures. It is apparent, however, from published calculations, that *a larger dependence* of a^H upon nitroxide geometry might be expected (2*a*). We were unaware of any experimental test of this result, and have therefore examined the temperature dependence of a^H(NH) in the relatively accessible *tert*-butyl nitroxide, Bu^{t}NHO·.

Electron spin resonance spectra of Bu^{t}NHO· have been recorded on many occasions (7), but we found it difficult to adapt existing procedures in such a way as to obtain satisfactory spectra over a wide temperature range. However, we have observed that intense spectra of Bu^{t}NHO· may be obtained from solutions of *tert*-butylhydroxylamine and piperidine in toluene which have been shaken with PbO_2, filtered, and degassed. With these solutions, measurements were possible over the range −60° to +100°C. A regular dependence of a^H equal to ca. 8.4×10^{-3} gauss/degree (Fig. 1) was found over this range. The change in a^N, $d(a^N)/dT$, was much smaller (ca. 2.3

[1]Issued as NRCC No. 22646.
[2]Author to whom correspondence should be addressed.
[3]Revision received August 3, 1983.
[4]The uncertainty in this area is illustrated by an earlier assertion from the same laboratory (4) that "there can be no doubt that $(CF_3)_2NO$· is non-planar"!

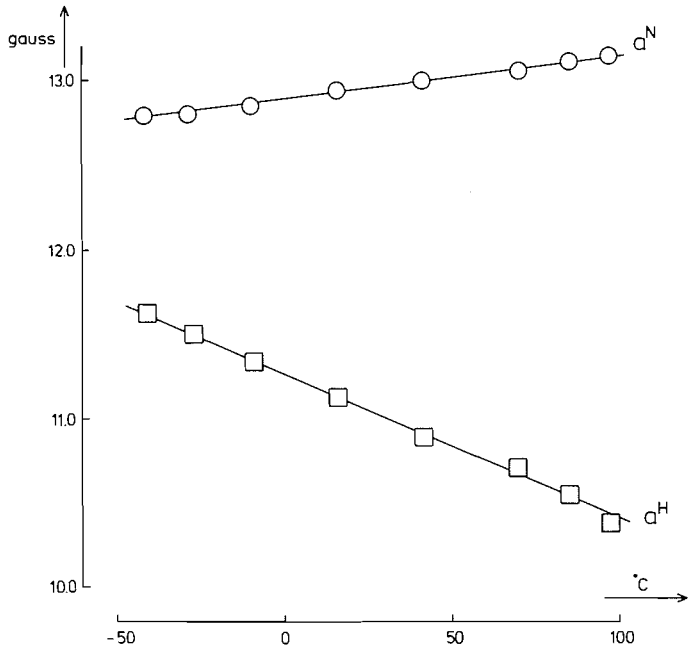


FIG. 1. Variation of a^N and a^H (NH) with temperature for Bu'NHO·.

$\times 10^{-3}$ gauss/degree), but, in contrast to the results with di-*tert*-butyl nitroxide (5, 6), was positive.

To eliminate the possibility that the piperidine exerted a significant solvent effect by complexing with the nitroxide, we repeated the experiments using ca. 0.01 *M* *tert*-butylhydroxylamine in toluene alone as solvent. Although the signals obtained were much weaker, the temperature dependencies of the hyperfine splittings were found to be the same, within experimental error. In addition, it should be noted that values of the hyperfine splittings measured in polar solvents (8) are substantially different to those reported herein which are typical of those measured in non-polar environments (8).

Salotto and Burnelle (2*a*) calculated splitting constants for planar and "best" bent structures of H_2NO·; the figures were 7.67 and 11.19 respectively for a^N, and −16.27 and −8.77 respectively for a^H (the out-of-plane angle for the bent structure being 26°). Clearly, the variations of a^N and a^H and their relative magnitudes now reported for Bu'NHO· are consistent with an interpretation in terms of increasing amplitude of the out-of-plane bending as the temperature is raised, although any attempt to give a quantitative analysis of the results in terms of an energy profile would be premature.

Experimental

Solutions of *tert*-butylhydroxylamine (10 mg) in a 1:1 mixture of toluene and piperidine (0.3 mL) were shaken with lead dioxide for 2 min, filtered, and thoroughly deoxygenated by passing purified nitrogen gas for a few minutes. Initial electron spin resonance spectra were recorded on a Varian E4 spectrometer, but measurements were made using a Varian E109 instrument equipped with field-frequency lock.

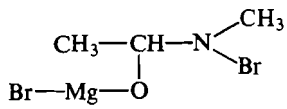
L'action des ions Mg^{2+} sur les protéines ou les peptides est un sujet de recherche de grande importance en biologie animale ou végétale. La spectrométrie infrarouge nous a permis de suivre dans le temps la transformation du *N*-méthylacétamide (NMA) en solution dans CCl_4 en présence de $MgBr_2$ anhydre. Nous avons pu à l'aide du spectre infarouge du composé final montrer la formation d'un organomagnésien de formule:



Conditions expérimentales

Le bromure de magnésium anhydre est préparé par action du magnésium sur le dibromoéthane en solution dans l'éther éthylique anhydre. Le NMA est un produit Merck, redistillé sous azote; le CCl_4 est un produit Merck, les dernières traces d'eau sont éliminées à l'aide de P_2O_5 pulvérulent; toutes les solutions sont faites en boite à gants à balayage d'azote. Les spectres infrarouge sont enregistrés sur un Perkin–Elmer 180.

Résultats

Le spectre infrarouge du NMA a été abondamment étudié et les attributions ont été faites par de nombreux auteurs; nous n'en citerons que deux (1) auxquelles nous nous référons. Le spectre infrarouge du produit final de l'action de $MgBr_2$ sur le NMA en solution dans CCl_4, subit une importante transformation (Fig. 1): (*i*) toutes les bandes caractéristiques du groupe peptidique, bande amide I, II et III, ont disparu; (*ii*) il n'existe plus de vibrateur NH (lié ou non) ni de vibrateur C=O (amidique, cétonique ou acide).

Discussion

La profonde modification au cours de la réaction des zônes spectrales, 3000 cm^{-1} – 2700 cm^{-1} et 1500 cm^{-1} – 1300 cm^{-1} des vibrations de valence et de déformation du CH_3, est représentée sur les figures 2 et 3. De nombreuses études, relatives aux fréquences de vibrations νCH et δCH des méthyles dans différents composés, ont mis en évidence l'influence de la nature de l'atome porteur et l'état d'hydridation du carbone porteur (2). Pour préciser et classer ces effets, nous avons entreprise l'étude méthodique des fréquences et des intensités des bandes d'absorption des CH_3, fixés sur le carbone, l'azote, l'oxygène ou le soufre, en solution dans CCl_4 (3). Les principales conclusions sont les suivantes.

Si l'atome porteur est un carbone d'hydbridation sp^2, la double liaison se faisant avec l'oxygène, le méthyle présente trois bandes νCH, d'intensité équivalente mais assez faible (coefficient d'extinction de l'ordre de 20 L mol^{-1} cm^{-1}) situées entre 3010 cm^{-1} et 2920 cm^{-1}. Par contre la vibration δ_s est très intense (coefficient de l'ordre de 50 L mol^{-1} cm^{-1}) et située vers 1360 cm^{-1}; les deux autres bandes δ_a et δ'_s faibles se trouvent entre 1440 et 1400 cm^{-1}.

Si le carbone porteur présente l'hybridation sp^3 et une substitution alcool, la vibration νCH se décompose en trois bandes d'intensité très inégale, dont l'une due à ν_{as} à 2972 cm^{-1} très intense (coefficient d'extinction égal à 45) et deux faibles à 2926 cm^{-1} et 2890 cm^{-1} comme le montre la figure 4 pour le propanol-2 dans CCl_4. Par contre la vibration δ_s est plus faible (coefficient d'extinction de l'ordre de 20) et toujours située à 1380 cm^{-1}; les deux autres δ_a et δ'_s faibles se trouvent au-dessus de 1450 cm^{-1}.

Si l'atome porteur est un azote d'hybridation sp^3, les bandes de vibration de valence sont très intenses et situées à des fréquences basses: entre 2900 et 2800 cm^{-1}, les bandes de vibration de déformation ont des intensités plus faibles et se trouvent toujours au-dessus de 1440 cm^{-1}. Dans le cas d'un azote d'hybridation sp^2, avec un groupe C=O en α comme dans le cas du groupe peptidique, les vibrations de valence des CH_3 sont très semblables, en intensité et position, à celles des CH_3 fixés sur un groupe C=O, la vibration de déformation δ_s est également très intense (coefficient d'extinction de l'ordre de 50) et la fréquence est voisine de 1400 cm^{-1}.

Quant aux vibrateurs OH et NH, leur coefficient d'extinction molaire est du même ordre de grandeur, soit environ 50, que celui des CH_3 fixé sur un carbone sp^3, s'ils existent ils sont donc aussi facilement détectables que les CH_3; le coefficient du vibrateur de la fonction alcool est environ une fois et demi celui de νCH_3 sur un carbone sp^3, quant au vibrateur C=O son intensité est au moins cinq fois celle d'un CH_3.

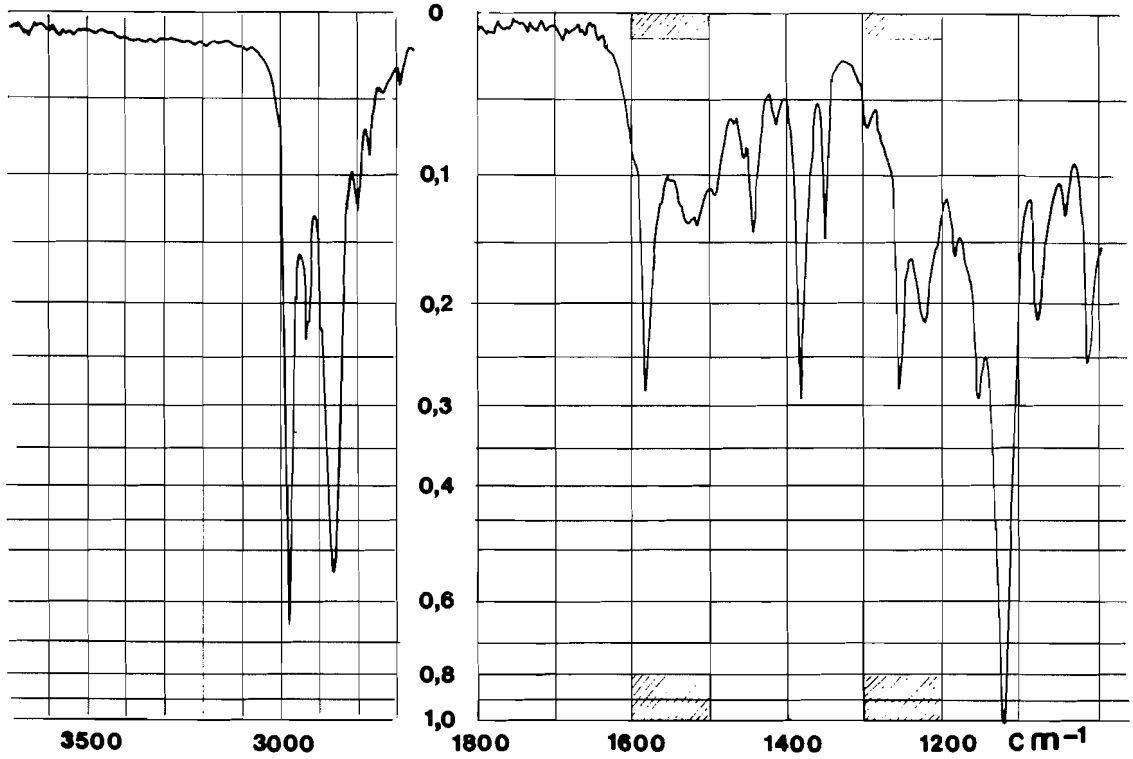


FIG. 1. Spectre infrarouge entre 4000 cm^{-1} et 1000 cm^{-1} de la solution de NMA laissée 24 h sur $MgBr_2$ anhydre. Les zônes hachurées correspondent aux zônes de forte absorption du CCl_4, les bandes y apparaissant ne sont donc pas significatives.

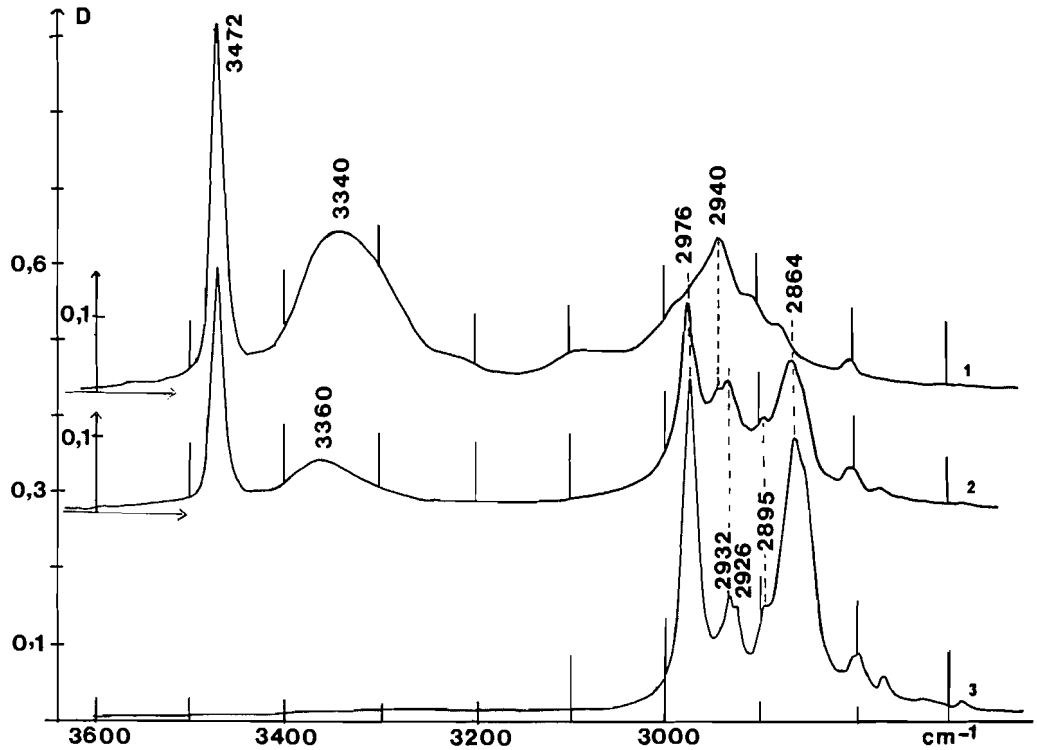

FIG. 2. Spectre infrarouge de la solution de NMA de 3600 à 2700 cm^{-1}; 1, solution NMA/CCl_4; c = 0,035 mol L^{-1}; 2, même solution laissée 4 h sur $MgBr_2$ anhydre; 3, même solution après après 24 h.

En conséquence le spectre infrarouge du produit final (Fig. 2 et 3) de la réaction $CH_3CONHCH_3$ + $MgBr_2$, montre qu'il n'y a plus qu'un CH_3 fixés sur un carbone sp^3, caractérisé par les bandes ν_a 2976 cm^{-1}, ν_s' 2926 cm^{-1} et ν_s 2895 cm^{-1}, la bande δ_s à 1380 cm^{-1} (provenant de la bande du NMA à 1365 cm^{-1} due à δ_s à C—CH_3, et environ deux fois et demi plus faible) et un CH_3 fixé sur un azote sp^3, caractérisé par la forte bande ν_s de 2864 cm^{-1} et une bande plus faible à 2932 cm^{-1}. La bande due à la vibration δ_s CH_3 du méthyl fixé sur l'azote du NMA à 1412 cm^{-1} disparaît progressivement également et est rempla-

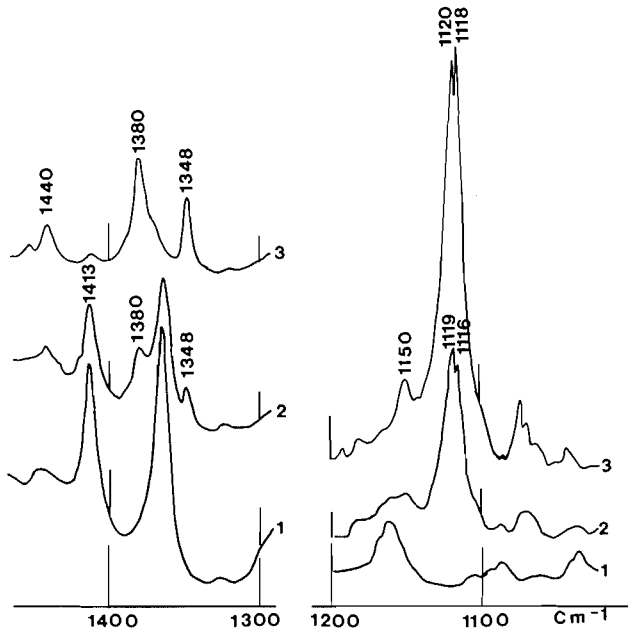

FIG. 3. Spectre infrarouge des mêmes solutions entre 1450 cm^{-1} et 1300 cm^{-1}.

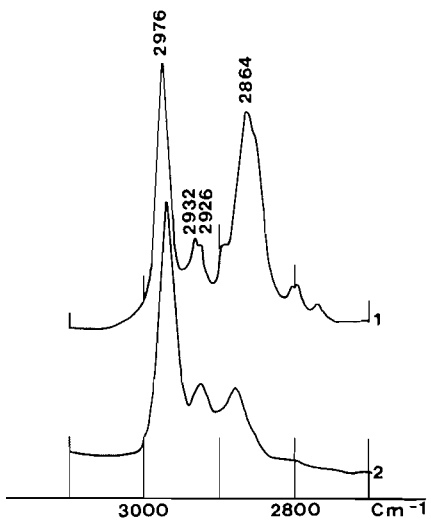

FIG. 4. Spectre infrarouge comparé de la solution 3 et de la solution propanol-2/CCl_4; c = 0,0228 mol L^{-1}.

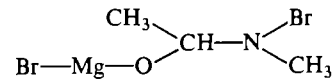
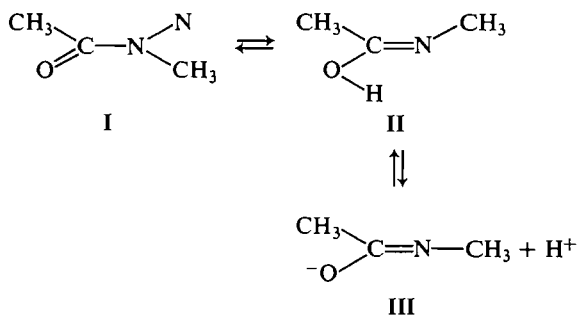
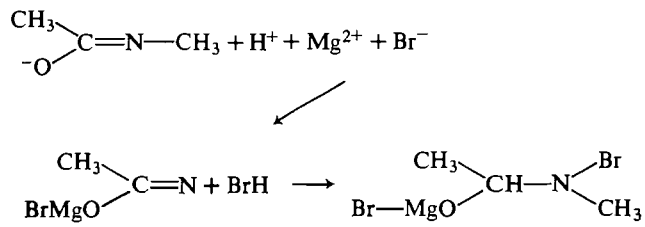
cée par une bande faible à 1440 cm^{-1}, qui correspond bien à une vibration de déformation d'un méthyle fixé sur un azote sp^3. L'apparition d'une bande, intense, une fois et demie celle des δCH_3, à 1120 cm^{-1}, correspond bien à une bande de vibration de valence d'un C—O. Cette bande prend la forme d'un doublet, qui doit sans doute correspondre à la présence de deux isomères. La bande à 1348 cm^{-1} peut être attribuée à la vibration de déformation dans le plan du vibrateur CH qui s'est formé ou à la vibration de valence νC—N (4) des deux atomes C et N d'hybridation sp^3, ou aux deux à la fois. Pour confirmer ces deux hypothèses, il serait intéressant d'étudier la même réaction avec le NMA, N deutérié et substitué avec ^{15}N. De ces observations, il s'en suit que la formule du produit final peut s'écrire:



Il est possible d'intepréter la réaction de la façon suivante: en solution diluée le NMA est en équilibre sous trois formes I, II, III



En présence de $MgBr_2$, l'équilibre est déplacé par disparition de la forme "énolique"



La forme II n'a jamais pu être mise en évidence, soit parce qu'elle est en infime proportion, soit parce qu'elle disparaît au fur et à mesure de sa formation.

Conclusion

Grâce à la spectrométrie infrarouge, nous avons pu mettre en évidence l'action des ions Mg^{2+} sur le NMA et la formation d'un organomagnésien, par addition du $MgBr_2$ sur le groupe peptidique CONH.

Cette réaction très importante doit sans doute représenter l'un des premiers maillons dans la chaîne de transmission de l'energie en biologie animale ou végétale.

Received June 21, 1983

JOHN T. EDWARD, SIN CHEONG WONG, and ROBERT A. MCCLELLAND. Can. J. Chem. **62**, 144 (1984).

The rate of lactamization of benzylstrychnine in aqueous solution at 25°C increases with acid concentration up to 5–10% sulfuric acid, and thereafter decreases. The maximum can be explained by taking account of the extent of protonation of the aromatic amino group with increasing acid concentration. This amino group is unusually weakly basic (pK_{BH^+} 0.3), perhaps because it is locked in an extremely rigid cage structure which opposes the rehybridization of N which must take place when it is protonated.

JOHN T. EDWARD, SIN CHEONG WONG et ROBERT A. MCCLELLAND. Can. J. Chem. **62**, 144 (1984).

La vitesse de lactamisation de la benzylstrychnine en solution aqueuse à 25°C augmente avec la concentration de l'acide sulfurique allant jusqu'à 5–10%, plus diminue. On peut expliquer le maximum en tenant compte du taux de protonation du groupe amino aromatique avec l'augmentation de la concentration de l'acide. Ce groupe amino est de façon inhabituelle faiblement basique (pK_{BH^+} 0,3) peut être à cause du fait qu'il est bloqué dans une structure en cage entièrement rigide qui s'oppose à la réhybridation de l'azote qui devrait se produire lorsqu'il est protoné.

[Traduit par le journal]

The lactam ring of benzylstrychninium ion (B in Scheme 1) is rapidly hydrolysed in warm sodium hydroxide, and the zwitterionic benzylstrychnine (A^-) crystallizes from the solution (1). In acid solution the amino acid HA recyclizes to the lactam (1). We wished to study the electrostatic effects of charged and dipolar substituents on the rates of lactamization of this and related amino acids, but first it was necessary to study the effects of acid concentration and temperature on the rate of lactamization of the parent compound, benzylstrychnine, in order to discover satisfactory conditions for kinetic studies. For convenience, it is desirable to have reasonably (but not excessively) rapid reactions; on the other hand, for interpreting the results in terms of electrostatic theory it is desirable that the ionic strength (acid concentration) be as low as possible; these two requirements are often in conflict.

The rate of the reaction at 25°C was studied in solutions ranging in aciditiy from very dilute acid (pH 3.5) to 71.6% sulfuric acid. The results[1] are shown in Fig. 1. The rate increases with acid strength to a flat maximum in 5–10% acid, and thereafter decreases.

In order to understand this result, it is necessary to know the protonation constants pK_1 and pK_2 of Scheme 1. The constant pK_1 for the equilibrium: $H_2A^+ \rightleftarrows H^+ + HA$ was determined by following the protonation of HA by the decrease in ultraviolet absorbance of the solution (cf. ref. 2). This occurred in the acid range pH 2 to $H_0 = -2$, exactly the region in which cyclization is occurring most rapidly. However, the ultraviolet absorbance could be obtained by stopped-flow methods before appreciable cyclization had occurred. Protonation followed H_0, and $pK_1 = 0.30$.

This is a pK without precedent in the literature of alkylated anilines. The pK of 5.43 for 8-methoxytetrahydrocarbazole is reduced to 2.66–2.70 for the aromatic amino centre of de-

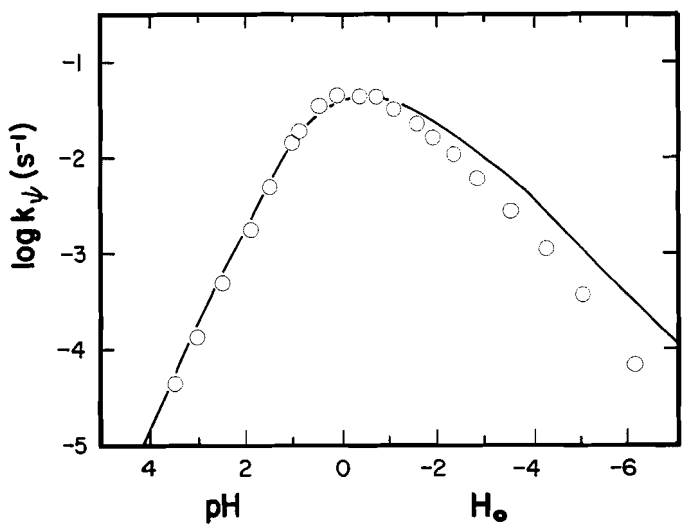

FIG. 1. Change in pseudo-first-order rate constant k_ψ for the lactamization of benzylstrychnine with change in acid concentration. Curve: theoretical, from eq. [1]. Points: experimental.

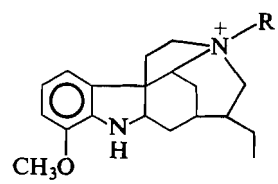
acetylaspidospermine (**1***a*) and its $N_{(b)}$-methyl derivative (**1***b*) (3), chiefly (it is to be presumed) because of the electrostatic



1*a* (R = H)
b (R = Me)

effect of the positive charge on $N_{(b)}$ transmitted across the low-dielectric molecular cavity. Another effect must be operating in the closely-similar HA to reduce the basicity by about another two pK units. We suggest this may be steric. The

[1]Rate constants k_ψ in different concentrations of acid and at different temperatures are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ontario, Canada K1A 0R6.

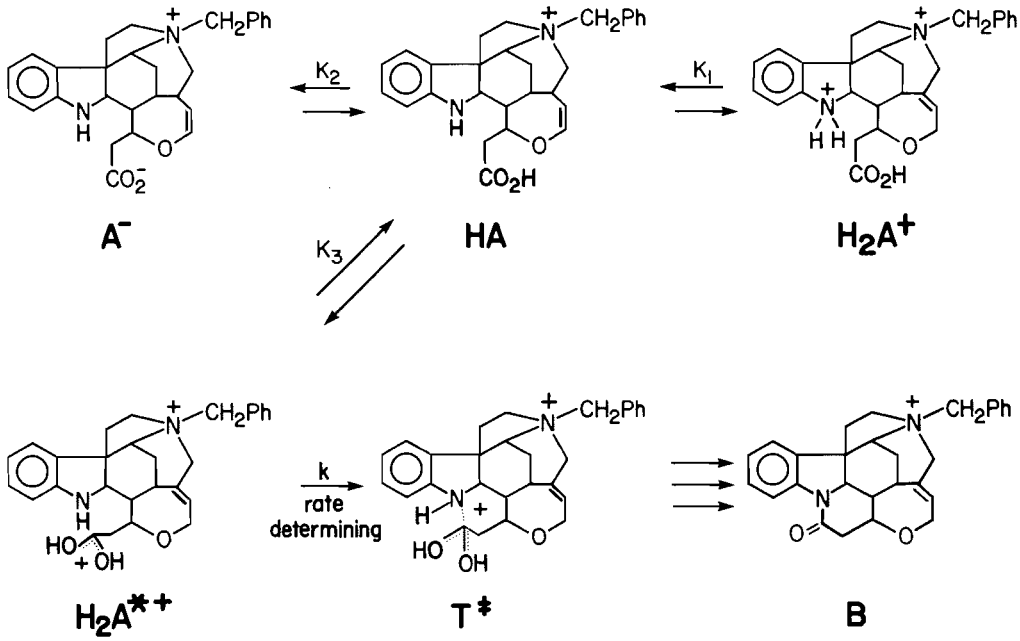

SCHEME 1

nitrogen of aniline is probably a flattened pyramid, whose angles are reduced towards tetrahedral values on protonation (4). CPK models show that the fusion of the benzo ring to the cage structure of HA is very strained with trigonal nitrogen, and even more strained with tetrahedral nitrogen.

The zwitterion A^- has extremely low solubility in water. Advantage was taken of this property to determine pK_2 by following the change in absorbance (due to a constant amount of A^- and increasing amounts of HA in solution) as the pH of the solution was lowered (5). The pK_2 of 4.20 ± 0.04 is about the value expected from the acid-strengthening effect of the distant quaternary nitrogen atom.

It is possible that formation of the lactam ring of B proceeds by way of the carboxyl-protonated intermediate H_2A^{*+} going through the transition state $T^{\ddagger}$.[2] The protonation of most carboxyl groups (7) is governed by the H_A acidity function (8). Accordingly, application of the Bronsted–Bjerrum treatment to the mechanism of Scheme 1 yields the following equation:

$$[1] \quad k_\psi = k[HA]h_A f_{H_2A^{*+}}/K_3([A^-] + [HA] + [H_2A^+])f_{T^{\ddagger}}$$

$$[1a] \quad = \frac{k}{K_3}\left(\frac{h_a}{1 + \frac{K_2}{[H^+]} + \frac{h_0}{K_1}}\right)\left(\frac{f_{H_2A^{*+}}}{f_{T^{\ddagger}}}\right)$$

where k_ψ is the pseudo-first-order rate constant for the lactamization of benzylstrychnine in the large excess of acid used, and the f's are activity coefficients. The curve shown in Fig. 1 was calculated using this equation, assuming log $k/K_3 = -0.69$ and log $(f_{H_2A^{*+}}/f_{T^{\ddagger}}) = 0$. The latter assumption is unlikely to be exactly true (9), particularly in the higher acid concentrations, and protonation of the carboxyl of HA may follow an acidity function differing slightly from H_A (8),[3] so the deviations of the experimental points from the theoretical curve at the higher acid concentrations are not serious.

We can now understand why the rate goes through a maximum with increasing concentration of acid. Going from low acidities to pH 1, A^- is being converted to HA, and thence to H_2A^{*+} (trace) and H_2A^+ (preponderance) in a ratio determined by K_3/K_1: hence the increase in rate. However, by the time the acidity has risen to $H_0 = -1.4$, protonation of HA to H_2A^+ is effectively complete, and $[A^-] \approx [HA] \approx 0$. Consequently, [1] can be simplified to

$$[2] \quad k_\psi = \frac{k\,K_1}{K_3}\left(\frac{h_A}{h_0}\right)\left(\frac{f_{H_2A^{*+}}}{f_{T^{\ddagger}}}\right)$$

With increasing acid concentration h_A increases much more slowly than h_0 (8), and hence k_ψ must decrease.

The position of the maximum is determined by pK_1, a value greater than 0.30 shifting the peak of the calculated curve to the left of the position shown in Fig. 1, and a smaller value shifting the peak to the right. Consequently, the curve offers support for the pK_1 of 0.3.

The activation parameters for the lactamization reaction[1] are

[2] The experimental results are equally compatible with a transition state involving acid-catalysed breakdown rather than formation of the neutral tetrahedral intermediate. A referee has pointed out that "the reaction is the reverse of acid-catalysed amide hydrolysis, and differs from that reaction only because the equilibrium position is over towards the amide in this case. A similar transition state to that supposed to obtain in acid-catalysed amide hydrolysis would therefore be expected . . . . . McClelland . . . . . has shown that very little oxygen exchange accompanies acid-catalysed amide hydrolysis (6), and this and other evidence has by several workers been taken to indicate a transition state which in the hydrolysis direction comes before the tetrahedral intermediate and involves attack of water on the O-protonated amide. In reverse, therefore, hydronium ion catalysed breakdown of a neutral tetrahedral intermediate (the immediate product of which is the O-protonated amide which then loses a proton) seems more likely and is equally consistent with all the other observations . . . . " We agree with this comment.

[3] A better fit in the higher acidities would almost certainly be obtained using an acidity function h_0^m with m as a variable. In light of the uncertainties in the activity coefficient and acidity function terms, the significance of this would, however, be questionable.

TABLE 1. Activation parameters for the acid-catalysed lactamization of benzylstrychnine

Acidity	ΔH (kcal/mol)	ΔS (eu)
0.003 *M* HCl	11	−36
0.01	11	−33
0.03	11	−33
0.1	10	−32
1.0% H_2SO_4	10	−33
2.1	10	−30
5.3	11	−26
9.7	11	−26
15.3	13	−20
20.7	14	−20
31.6	14	−18
43.6	15	−18
57.8	17	−14
71.6	19	−14

given in Table 1. Over the region 0.003 *M* − 0.1 *M* hydrochloric acid, benzylstrychnine exists essentially completely as HA, and the activation parameters for this region refer to the overall change: HA → $T^{\pm}$. On the other hand, in concentrations of sulfuric acid greater than 20.7% in Table 1, benzylstrychnine exists essentially completely as H_2A^+, and activation parameters refer to the overall change: $H_2A^+ \rightarrow T^{\ddagger}$. Since H_2A^+ will almost certainly be more hydrated (and more stabilized) than HA, one can understand the higher $\Delta H^{\pm}$ and the higher $\Delta S^{\pm}$ values required to reach the common $T^{\pm}$ state. Furthermore, the decreasing activity of water as the sulfuric acid concentration is increased to 71.6% will result in a progressive loss of stabilizing hydration from both H_2A^+ and $T^{\pm}$. In spite of its more diffuse charge, $T^{\pm}$ is likely to receive greater stabilization from hydration than H_2A^+, because oxonium ions are more hydrated than ammonium ions (9). Consequently, the progressive dehydration should lead to an increase in $\Delta H^{\ddagger}$ and in $\Delta S^{\ddagger}$ with increased acid concentration over the range 31.6−71.6%, as is observed.

Experimental

Determination of pK_1

A 10^{-4} molar solution of A^- in 0.002 *M* NaOH was placed in one syringe of a Durrum−Gibson stopped-flow apparatus, and mixed with acids ranging from pH 2.5 to $H_0 = -2$. The absorbance at 293 nm was recorded immediately after mixing (stopped-flow dead-time − 2 ms). The sigmoidal curve of absorbance vs. pH (H_0) so obtained was treated in the normal fashion to give pK_1.

Determination of pK_2

pK_2 was determined by noting the increase in absorbance at 293 nm of saturated solutions (containing fixed amounts of A^- and variable amounts of HA) obtained by shaking an excess of A^- with buffer solutions of decreasing pH. Theory and practical details are given in ref. 5.

Rate measurements

The lactamization of benzylstrychnine (λ_{max} 293 nm) is accompanied by a large increase in absorbance at 254 nm as the benzylstrychninium ion (λ_{max} 254 nm) is formed. Rate measurements were carried out by monitoring the increase in absorbance at 254 nm. For activation parameters, rates were obtained at three temperatures, chosen from 5°, 15°, 25°, 35° 45°, and 65°C, according to the concentration of acid.[1]

The crystal structure of 5-(propyn-1-yl)-1-(β-D-arabinofuranosyl)uracil, an analog of the active antiherpes nucleoside 1-(β-D-arabinofuranosyl)thymine, was determined by X-ray diffraction. The compound crystallizes in the space group $P2_12_12_1$ with $a = 4.925(1)$, $b = 14.326(2)$, $c = 17.454$ Å. Reflections were measured on a diffractometer and the structure was solved by direct methods. Least-squares refinement converged at $R = 0.032$ for 1159 observed reflections. The sugar ring exhibits an ^3E or a C(3′)*endo* conformation with a pseudorotation angle $P = 28.3°$ and puckering amplitude $\tau_m = 31.7°$. The orientation of the —CH_2OH side chain is g^+. The base is in an *anti* conformation with respect to the sugar ring, with a glycosidic torsion angle $\chi = 33.7°$. Changes in the C(5)—C(6) and C(6)—N(1) bond lengths suggest some interaction of the propynyl group with the pyrimidine ring. The C≡C bond length of 1.121 Å is very short. Its shortening could result from intermolecular interactions with the neighboring pyrimidine ring and nearby oxygen atoms.

MIROSLAW CYGLER, WAYNE F. ANDERSON, JERZY GIZIEWICZ et MORRIS J. ROBINS. Can. J. Chem. **62**, 147 (1984).

On a déterminé, par diffraction des rayons-X, la structure cristalline du (propyne-1 yl)-5 (β-D-arabinofurannosyl)-1 uracyle, un analogue du nucléoside actif contre l'herpes, la (β-D-arabinofurannosyl)-1 thymine. Le composé cristallise dans le groupe d'espace $P2_12_12_1$ avec $a = 4{,}925(1)$, $b = 14{,}326(2)$, $c = 17{,}454$ Å. On a mesuré les réflexions à l'aide d'un diffractomètre et on a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés jusqu'à une valeur de $R = 0{,}032$ pour 1159 réflexions observées. Le cycle du sucre a une conformation ^3E ou C(3′)*endo* avec un angle de pseudorotation $P = 28{,}3°$ et une amplitude de gauchissement $\tau_m = 31{,}7°$. L'orientation de la chaine latérale —CH_2OH est g^+. La base a une conformation "anti" par rapport au cycle du sucre avec un angle de torsion glycosidique de $\chi = 33{,}7°$. Les variations des longueurs de liaison C(5)—C(6) et C(6)—N(1) suggèrent l'existence d'une interaction entre le groupe propynyle et le cycle pyrimidine. La longueur de la liaison C≡C, 1,121 Å, est très courte. Son racourcissement peut être dû à des interactions intermoléculaires avec le cycle pyrimidine voisin et avec les atomes d'oxygène situés à proximité.

[Traduit par le journal]

Introduction

A number of 5-substituted pyrimidine 2′-deoxyribo- and arabino-nucleosides have been shown to exhibit selective biological activity (1). Beside the clinically effective 5-iodo (2), 5-trifluoromethyl (3), and 5-ethyl derivatives (4), several other 5-substituted 2′-deoxyuridines have been found to be potent antiviral agents (1). Among these analogues, (*E*)-5-(2-halovinyl)-2′-deoxyuridines (bromo and iodo derivatives) are the most potent and selective known inhibitors of Herpes simplex type I virus replication in cell cultures and experimental animals (5, 6). It has also been shown that some 5-alkyl and alkenyl derivatives of 1-(β-D-arabinofuranosyl)uracil (araU) effectively inhibit HSV replication without significant effect on host cell growth (7, 8). A number of derivatives of araU containing a two carbon unit at the 5-position, including the (*E*)-(2-halovinyl) group, have recently been synthesized and tested. Some have shown highly selective inhibition of HSV multiplication (9, 10).

The 5-(alkyn-1-yl)pyrimidine nucleosides represent a new group of analogues with antiviral and antitumor activities. Only 5-ethynyluracil and 5-ethynylcytosine and their nucleosides had been synthesized (11, 12) and biologically evaluated (5, 13, 14). A convenient and high-yield method for the preparation of 5-(alkyn-1-yl)uracil nucleosides has recently been developed (15, 16) and utilized for the synthesis and biological investigation of selected 2′-deoxy- and arabinofuranosides (17).

In comparison to ribo- and deoxyribonucleosides our understanding of solid state conformations of arabino-, xylo-, and lyxonucleosides is much more limited. There is only one structure of a β-D-lyxonucleoside (18) and one of a β-D-xylonucleoside (19) reported in the literature. Arabinonucleosides are better represented with 15 solid state structures reported.[3] Such a number allows some generalizations on their conformational trends to be drawn. One of the first observed conformations of the arabinofuranosyl ring was O(4′)*endo*—C(1′)*exo* (20), which is rarely observed in ribonucleosides. When more structures were determined it became clear that this conformation also is not common for arabinonucleosides. However, such a conformation might be of some importance in solution. Ekiel *et al.* (21) concluded from a compilation of nmr spectra of arabinonucleosides that the *S*-type state in solution may either be a mixture of C(2′)*endo*—C(3′)*exo* and O(4′)*endo*—C(1′)*exo* conformations or is shifted from C(2′)*endo*—C(3′)*exo* toward the C(2′)*endo*—C(1′)*exo* conformation.

[3] Structures of 2′-anhydro-β-D-arabinofuranosylnucleosides are not included here as the conformations of their sugar rings are highly influenced by the additional ring fusion. For discussion see ref. 49.

We now report the molecular structure of 5-(propyn-1-yl)-1-(β-D-arabinofuranosyl)uracil (17) (araU-5-propyne). This compound is an acetylenic analog of the antiherpes active 1-(β-D-arabinofuranosyl)thymine (araT (22)) and also the biologically active 5-vinyl, 5-halovinyl, and other 5-alkenyl and 5-ethynyl-2′-deoxyuridines (13).

Experimental

Colorless, needle-shaped crystals of araU-5-propyne (17) were obtained from ethanol–water solution by slow cooling to 0°C. Systematic absences on precession photographs indicated the orthorhombic space group $P2_12_12_1$. The cell dimensions, determined on a Syntex $P2_1$ diffractometer using 15 high angle reflections, are: $a = 4.925(1)$, $b = 14.326(2)$, $c = 17.454(2)$ Å, $V = 1231.5$ Å^3, $Z = 4$. A crystal chosen for data collection had the dimensions $0.09 \times 0.10 \times 0.32$ mm (see Discussion). There were 1200 independent reflections measured up to 2θ of 126° with Ni-filtered CuKα radiation, of which 1159 had $I > 2.5\sigma(I)$. The $\theta/2\theta$ scan mode was used with the scan width $\Delta(2\theta) = 1.5° + \alpha_1 - \alpha_2$ splitting. The background was measured at each end of the scan for the total time equal to half that of the scan through the peak. Scan speed was in the range 1.4–15°/min (2θ motor). Every 400 reflections the orientation matrix of the crystal was redetermined. Three reflections were used as the intensity controls. Their intensities fluctuated by ±1.5% during data collection from their average values. They were used for appropriate scaling. The intensities of measured reflections were reduced to F values in the usual way. No absorption correction was applied.

The structure was solved by direct methods using SHELX 76 (23). All non-hydrogen atoms were located on the best E-map. After a few cycles of the full-matrix least-squares refinement, first with isotropic, and later with anisotropic temperature factors, a difference map was calculated and it revealed positions of all hydrogen atoms. Peaks corresponding to the H atoms of the methyl group, C(9), were relatively weak and these atoms, when included in the refinement, drifted away from C(9) (up to 1.3 Å). These atoms were refined with restraints put on their geometry. A weighting scheme $w^{-1} = \sigma^2(F_o) + 0.0033\,|F_o|$, where the $\sigma(F_o)$ are from counting statistics, was used at the end of the refinement. The largest shift/esd in the final cycle of the refinement was 0.05 for 237 refined parameters. There were no peaks above 0.15 e/Å^3 on the final difference map. Three low angle reflections probably affected by extinction were given zero weight in the refinement. At convergence the agreement indices were $R = 0.032$, $R_w = 0.038$ for 1155 observed reflections and $R = 0.034$, $R_w = 0.040$ for all measured reflections.

Final atomic parameters are given in Table 1.[4]

TABLE 1. 5-(Propyn-1-yl)-1-(β-D-arabinofuranosyl)uracil: final fractional coordinates with esd's in parentheses and isotropic temperature factors ($\times 10^4$, $\times 10^3$ for H atoms)

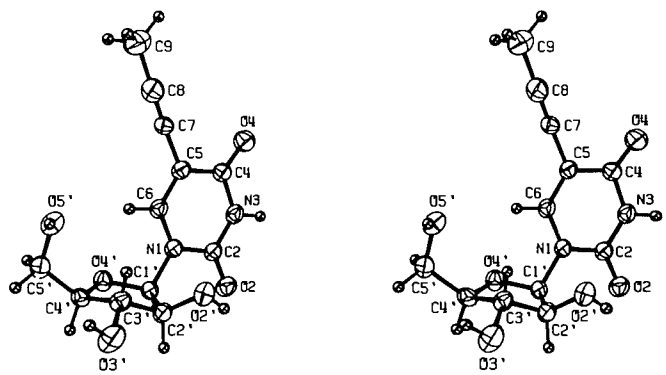

FIG. 1. Stereoscopic view of 5-(propyn-1-yl)-1-(β-D-arabinofuranosyl)uracil with the numbering scheme. Thermal ellipsoids correspond to a 50% probability level.

Discussion

The conformation of araU-5-propyne is shown in a stereoview in Fig. 1. Bond distances and valence angles are shown in Fig. 2 and selected torsion angles are given in Table 2.

The length of C(7)≡C(8) triple bond obtained in this study is unusually short. To check that this is not an artifact, we collected a new data set from a slightly larger crystal and used longer counting times and a more intense X-ray beam. Experimental details given in the previous section correspond to this more precise data set. Positional parameters of non-hydrogen atoms refined independently with both data sets do not differ by more than three standard deviations and 88% of them are within two esd's. Virtually identical values for the length of the C≡C bond were obtained from the two data sets. Atomic parameters (Table 1) and geometrical details given below are based on the second, more precise data set, which gave lower estimated standard deviations.

Arabinofuranose ring

The sugar ring exhibits an ^3E or a C(3′)*endo* conformation (N

[4] Tables of anisotropic temperature factors of the non-hydrogen atoms, observed and calculated structure amplitudes, and the table of C≡C bond lengths and compound codes obtained through a search of the Cambridge Database are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

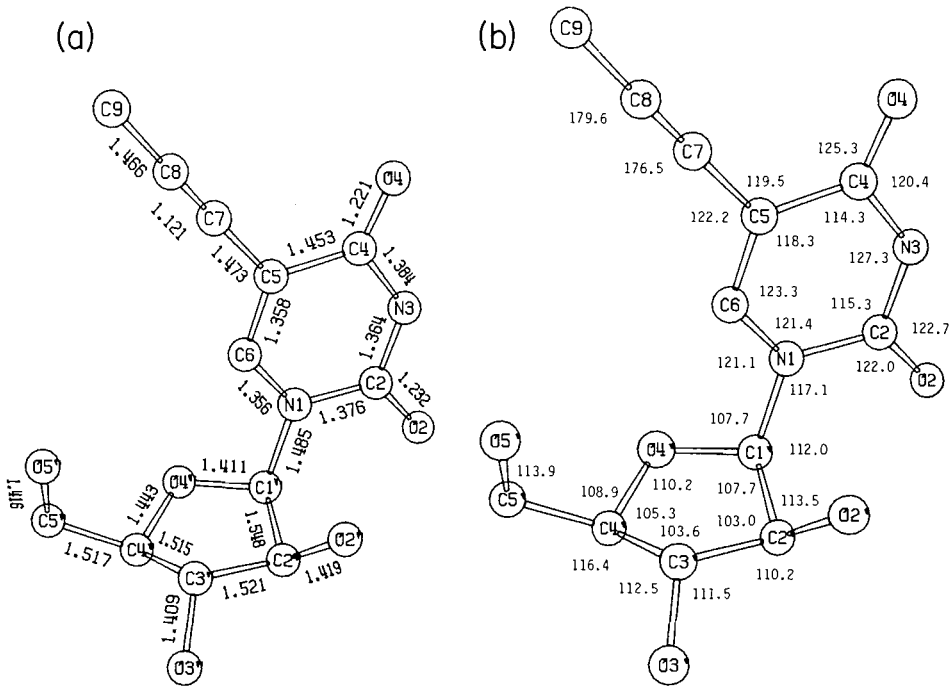

FIG. 2. (*a*) Bond distances (Å) and (*b*) valence angles (deg) in 5-(propyn-1-yl)-1-(β-D-arabinofuranosyl)uracil. Estimated standard deviations are in the range 0.003–0.004 Å for bonds and 0.01–0.03° for angles.

TABLE 2. Selected torsion angles for araU-5-propyne

Atoms	Angle* (deg)
O(4′)—C(1′)—C(2′)—C(3′)	−14.7
C(1′)—C(2′)—C(3′)—C(4′)	27.9

C(3′)—C(4′)—O(4′)—C(1′)	23.6
C(4′)—O(4′)—C(1′)—C(2′)	−5.4
C(3′)—C(4′)—C(5′)—O(5′)	41.3
C(6)—N(1)—C(1′)—O(4′)	33.7

*Estimated standard deviations are in the range 0.3–0.5°.

type according to the nomenclature of Altona and Sundaralingam (24)). The pseudorotation parameter is $P = 28.3°$ and the puckering amplitude is $\tau_m = 31.7°$.

The amplitude of puckering is rather low, ~7° lower than the average pucker of a ribose ring, but is not unusual. Similar or even lower puckering was found in some 9-(β-D-furanosyl)purine 5′-phosphates (see Table 2 in ref. 25) and, for example, in N^6-(*N*-threonylcarbonyl)adenosine (26) and 8-bromo-9-(β-D-xylofuranosyl)adenine (19). Such a flattened conformation has not been observed in arabinonucleosides. The lowest pucker, with $\tau_m = 35.9°$, was found in arabinofuranosylcytosine hydrochloride (27).

Similar to other nucleosides the C(4′)—O(4′) bond is longer than O(4′)—C(1′) (by 0.03 Å). The C(1′)—C(2′) bond (1.548 Å) is long and C(2′)—C(3′) is short (1.521 Å). This pattern is typical for arabinonucleosides but opposite to that observed in ribonucleosides. It reflects different steric interactions of the 2′-hydroxyl group with neighboring atoms.

Endocyclic angles are typical for the C(3′)*endo* conformation of the sugar ring. From an analysis of sugar conformations observed in the solid state, Westhof and Sundaralingam (28) derived the relationship between τ_m and the average endocyclic angle $\langle\theta\rangle$:

$$\langle\theta\rangle = 108° - 0.00202\ \tau_m^2$$

The value of $\langle\theta\rangle$ calculated from this relationship for the present molecule (105.97°) is in excellent agreement with the experimental value of 105.96°.

The exocyclic angles show a usual pattern, with smaller values inside the O(2′)—C(2′)—C(3′)—O(3′) fragment and larger values outside, and with an opening of the C(3′)—C(4′)—C(5′) angle to 116.7°. The O(2′) atom, which is on the same side of the furanose ring as the pyrimidine base, is in close contact with the N(1) atom; the O(2′)...N(1) distance of 2.696(3) Å is shorter than the sum of the van der Waals radii of these two atoms.

The CH_2OH side chain is found in a g^+ conformation with a C(3′)—C(4′)—C(5′)—O(5′) torsion angle of 41.3°. There is no intramolecular hydrogen bond between O(2′) and O(5′) because of the unfavorable sugar ring conformation. Such a hydrogen bond is possible with a C(2′)*endo* conformation of the ring and a g^+ orientation of the side chain, and was observed in arabinofuranosylcytosine (29) and arabinofuranosyluracil (30, 31). In arabinofuranosylcytosine hydrochloride (27) the sugar ring also exhibits a C(2′)*endo* conformation but the CH_2OH side chain is in the *t* orientation and no intramolecular hydrogen bond is formed.

The distribution of pseudorotation angles, *P*, in arabinofuranose rings is shown in Fig. 3*a*.[3] For seven observed *N*-type states, *P* spans a very narrow range from 9.3 to 28.3°, clustering around 11° and 25°. More structures, however, have to be determined to evaluate the significance of this clustering. The *S*-type states fall into two categories: an O(4′)*endo*—C(1′)*exo* conformation with $P \cong 106°$ (two structures) and a C(2′)*endo* conformation with *P* in the range 156.3 to 171.3° (six structures).

Base moiety

The pyrimidine ring is planar. The average deviation of an

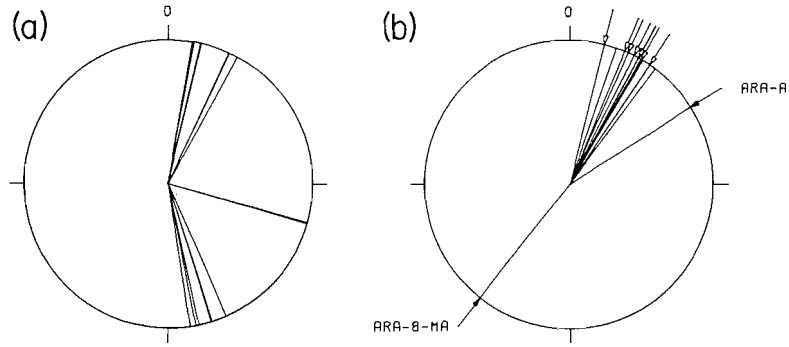

FIG. 3. Distribution of (*a*) pseudorotation angles ***P*** and (*b*) glycosidic torsion angles χ in arabinonucleosides (the torsion angle is measured positive if the far bond is rotated clockwise). The following structures are represented in the diagrams (***P***, χ in parentheses): 9-(β-D-arabinofuranosyl)adenine hydrochloride (43) (9.3°, 29.7°), 5-iodo-1-(2-deoxy-2-fluoro-β-D-arabinofuranosyl)cytosine (44) (10.0°, 19.0°), 1-(β-D-arabinofuranosyl)cytosine-5′-monophosphate (45) (12.6°, 30.7°), 4-thio-1-(β-D-arabinofuranosyl)uracil (37) (12.9°, 36.6°), 8-*N*-morpholino-1-(β-D-arabinofuranosyl)adenine (38) (ara-8-Ma; 24.5°, −142.1°), 9-(β-D-arabinofuranosyl)adenine (39) (araA; 24.8°, 57.8°), 5-(propyn-1-yl)-1-(β-D-arabinofuranosyl)uracil (this paper; 28.3°, 33.7°), 1-(β-D-arabinofuranosyl)thymine (33) (105.5°, 24.1°), 5-bromo-1-(β-D-arabinofuranosyl)uracil (20) (106°, 30°), 1-(β-D-arabinofuranosyl)uracil (30, 31) (156.3°, 34.0°), 1-(β-D-arabinofuranosyl)cytosine (29) (162.3°, 28.8°), 1-(β-D-arabinofuranosyl)-5-methylcytosine (46) (162.7°, 22.6°), 1-(3-methoxy-β-D-arabinofuranosyl)cytosine (47) (167.8°, 28.7°), 1-(β-D-arabinofuranosyl)cytosine hydrochloride (27) (169.0°, 26.7°), 1-(β-D-arabinofuranosyl)cytosine Pt(II) complex (48) (171.3°, 14.0°). Open arrows in (*b*) indicate *S*-type states.

atom from the mean plane of the ring is 0.0115 Å with the largest being 0.0174 Å. The O(2) atom lies in the plane of the ring, while O(4) and C(1′) deviate slightly from it in opposite directions by 0.0525 and 0.0981 Å, respectively. The C(5)—C(6) and N(1)—C(6) bond lengths differ slightly from those in thymidine (32) and araU (30, 31).[5] The former bond in araU-5-propyne is ~0.015 Å longer and the latter is ~0.020 Å shorter than in the two reference structures, which might suggest some conjugation with the propyn-1-yl group. Comparably small changes were also observed in 5-ethynyl-2′-deoxyuridine (34) (dUrd-5-ethyne) and 5-acetyl-α-2′-deoxyuridine (35). Those authors suggested a degree of conjugation of the C(5)=C(6) double bond with the 5-substituent.

The C(2)—O(2) bond of 1.232(3) Å in araU-5-propyne is ~0.01 Å longer than in all of the above mentioned compounds, and this is accompanied by a shortening of the C(2)—N(3) bond also by ~0.01 Å. In the present compound the O(2) atom forms a strong intermolecular O . . . H—N hydrogen bond and makes another short contact with the 5′-hydroxyl group (Table 3). Similar lengthening of C(2)—O(2) and simultaneous shortening of the C(2)—N(3) bond was observed in thymine monohydrate crystals (36). In that compound the O(2) atom also forms two hydrogen bonds. In most of the other compounds mentioned above the O(2) atom is not involved in hydrogen bonding. In araU (30, 31) and arabinofuranosyl-4-thiouracil (37), O(2) forms a strong O . . . H—O bond. However, the C(2)—O(2) and C(2)—N(3) bonds are of normal length in the two latter structures.

The pyrimidine moiety of araU-5-propyne is in an *anti* orientation with respect to the sugar ring. The distances from the C(6) atom to O(4′) and O(2′) are 2.718(3) and 3.307(3) Å, respectively. The glycosidic torsion angle, C(6)—N(1)—C(1′)—O(4′) (χ), is 33.7°. It falls in the upper range of the values observed in arabinonucleosides.

The distribution of the glycosidic torsion angles observed in the solid state is shown in Fig. 3*b*. The *syn* conformation was observed only in 8-morpholino-1-(β-D-arabinofuranosyl)-adenine (38), in which a very bulky group was attached at C(8). This conformation was additionally stabilized by an intramolecular O(5′)—H . . . N(3) hydrogen bond. When *n*-butylamine was substituted at C(8) the usual *anti* conformation was found. The reported angles span a narrow range from 14 to 37° (except for arabinofuranosyladenine (39)), with very little dependence on the sugar conformation. The average value for five molecules with the *N*-type conformation is 30.0°, and for eight molecules with the *S*-type conformation is 25.5°. This χ angle distribution differs markedly from that for ribo- and deoxyribonucleosides in the *anti* conformation. The average values in the N type state are $\langle\chi\rangle$ = 19° for ribo- and 20° for deoxyribonucleosides (with very limited data for the 2′-deoxy series); for the *S*-type state $\langle\chi\rangle$ = 52° for ribo- and 39° for deoxyribonucleosides (25). Similar conclusions regarding the narrowing of the range of the χ angle in arabinonucleosides and

[5] The structure of arabinofuranosylthymine has also been determined (33); however, the somewhat lower precision of this study does not warrant a meaningful comparison for such small effects.

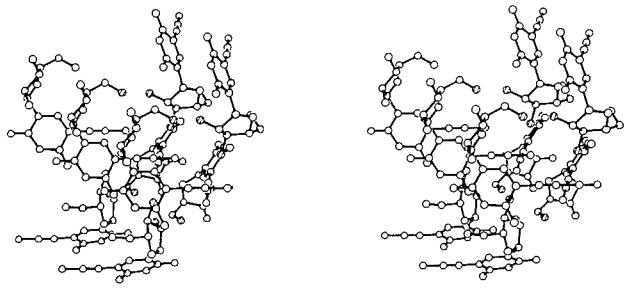

FIG. 4. Stereoscopic view of the environment of the propynyl group (shown in the center of the diagram). Surrounding oxygen atoms are dashed.

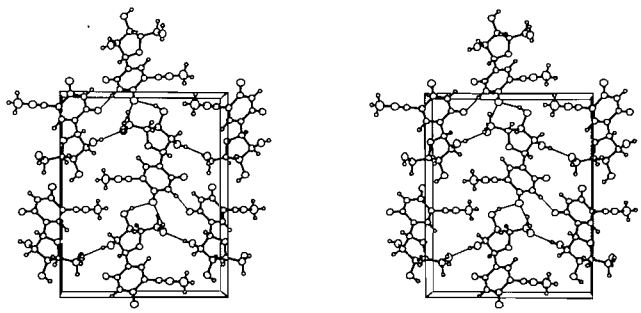

FIG. 5. Stereoscopic view of the unit cell with hydrogen bonds marked.

different dependence on the sugar conformation than found in ribonucleotides were put forward by Yathindra and Sundaralingam (40) on the basis of semi-empirical energy calculations.

Propynyl group

This group is nearly linear and is inclined by 3.7° to the pyrimidine ring plane. The C(7)≡C(8) triple bond, at 1.121(3) Å, is very short. The average C≡C bond in the propynyl group obtained from a search of the Cambridge Database (41) is 1.189 Å (for 34 compounds). In a related compound, dUrd-5-ethyne, the C≡C bond length of 1.182 Å is in the usual range. The pyrimidine C(5) to C≡C single bond is 0.03 Å shorter in dUrd-5-ethyne than in araU-5-propyne. The shortest reported triple bond in a propynyl group was observed in *N,N*-dimethyl-(*O*-ethyl)phenylpropiolamidium tetrafluoroborate (42) and was 1.149 Å. The authors suggested that this shortening could result from an intermolecular interaction of the C≡C bond with a neighboring aromatic six-membered ring. They also observed the shortening of a bond in the ring closest and parallel to the C≡C bond. The distance between the centers of these bonds was 3.47 Å. A similar arrangement is also present in araU-5-propyne. The environment of the propynyl group is shown in Fig. 4. The C(7)≡C(8) bond is parallel to the N(1)—C(6) bond and the corresponding distances are C(7)...N(1) = 3.542(3) Å and C(8)...C(6) = 3.445(3) Å. In addition, each C atom of the propynyl group is in close contact with an oxygen atom: C(7)...O(4′) = 3.212(3) Å, C(8)...O(3′) = 3.165(3) Å, and C(9)...O(3′) = 3.179(3) Å.

The atoms of the propynyl group vibrate with increasing amplitude the further they are from the center of the ring (see Fig. 1). The equivalent isotropic temperature factor, U_{iso}, increases by 0.011 from C(7) to C(8) and by 0.015 from C(8) to C(9). Due to the large vibrational movements of the terminal methyl group the positions of the C(9) H atoms are poorly determined.

Crystal packing and hydrogen bonding

As was mentioned above there are no intramolecular hydrogen bonds. Instead, all H-bonding groups take part in an extensive network of intermolecular interactions. A stereoview of the unit cell is shown in Fig. 5 and the hydrogen bond geometry is presented in Table 3. The O(4) atom accepts two hydrogen bonds from the O(3′) and O(5′) hydroxyl groups in the molecule related by the $^{-}2_1$ screw axis. These bonds join molecules into chains parallel to the *z*-axis. These chains are joined through O(2′)—H...O(5′) bonds into layers parallel to the *yz* plane, and these in turn are joined through O(2)...H—N(3) bonds into a three dimensional network. As a result the crystals exhibit a high melting point, mp = 242°C.

The hydration parameter and the excess acidity functions in $H_2SO_4-H_2O$ and $HClO_4-H_2O$ media

PIETRO GIUSEPPE TRAVERSO
Istituto di Chimica Industriale, Università, calle Larga S. Marta 2137, 30123 Venezia, Italy

Received June 20, 1983

PIETRO GIUSEPPE TRAVERSO. Can. J. Chem. **62**, 153 (1984).

Excess acidities, X, for aqueous H_2SO_4 and $HClO_4$ are derived under conditions of fixed pK_{BH^+} and m^* in both media, and of fixed m^* only, and compared among themselves and with newly derived and previous scales obtained without constraint, or with fixed pK_{BH^+} values. Analysis shows few or no real differences among these scales, which means that the equation $\log I + \log C_{H^+} = pK_{BH^+} + m^*X$ applies without the necessity of involving a "second-order" $m^{**}X^2$ term, at least for these media.

PIETRO GIUSEPPE TRAVERSO. Can. J. Chem. **62**, 153 (1984).

On a dérivé les acidités en excès, X, des milieux aqueux de H_2SO_4 et de $HClO_4$ pour des conditions où le pK_{BH^+} et le m^* sont fixés dans les deux milieux ainsi que lorsqu'uniquement m^* est fixé; on compare ces valeurs entre elles, avec les nouvelles échelles ainsi qu'avec les anciennes échelles obtenues sans contrainte ou avec des valeurs fixés de pK_{BH^+}. L'analyse ne révèle que peu ou pas de différence réelle parmi ces échelles, ce qui signifie que l'équation $\log I + \log C_{H^+} = pK_{BH^+} + m^*X$ s'applique sans la nécessité de faire intervenir un terme du "second degré" $m^{**}X^2$, au moins pour ces milieux.

[Traduit par le journal]

Introduction

In the last ten years the original Bunnett–Olsen (1) method of defining the basicity of organic bases has begun to be replaced by the excess acidity method, at least in aqueous H_2SO_4 and $HClO_4$. The latter method is a logical development of the first. Two parameters, pK_{BH^+} and the "solvation parameter", ϕ_e (1), n (2, 3), or m^* (4), are judged to be necessary (and sufficient) to describe the protonation equilibria of weak bases. Solvation parameters are becoming more important, mainly due to the results obtained by measuring the protonation of some representative compounds in the gas phase (5), for estimating the hydration behaviour of different classes of base (5, 6).

$$[1] \quad \log I - \log C_{H^+} = pK_{BH^+} + m^*X$$

The excess acidity functions X arise from a "first-order" approximation (7), defined by eq. [1] according to Cox and Yates' symbolism (4, 7).[1] The parameter m^* in eq. [1] is invariant with acid concentration.

$$[2] \quad \log I - \log C_{H^+} = pK_{BH^+} + m^*X + m^{**}X^2$$

A "second-order" approximation (7) has recently been proposed. Edward *et al.* (9) analyzed some data obtained in aqueous DMSO mixtures, and showed that the first-order approximation was insufficiently accurate in that case. Accordingly the new relation [2] was suggested (7, 9). It states that the m^* term in eq. [1] would *not* be invariant with acid concentration. The second-order approximation is undoubtedly superior to the first one, in principle. Hence one is forced to suspect that the results which have been obtained to date by the first-order approximation (e.g. equilibrium constants, hydration parameters, also the interpretations of them and of some reaction mechanisms), might suffer from error, possibly larger than that expected from experimental uncertainties only.

The aim of this paper is to show that this seems not to be the case, at present, in the most studied aqueous acid solutions, H_2SO_4 and $HClO_4$.

Experimental

All the computations used the mathematical procedure previously described (2, 3), partially modified to allow two parameters, m^* and pK_{BH^+}, to be fixed. In order to constrain both parameters, a slight change was adopted in step (*ii*) of the mathematical procedure in ref. 3. For each indicator, a 2×2 system was required, having the above parameters as unknowns. The same system had to be a 3×3 one in the case of pairs of corresponding indicators for the two acid media, since three unknowns were required for two connected indicators. When both parameters were fixed for the pair, as happens in the present case, a 2×2 system again results, now involving data for two indicators. Only a few experimental $\log I$ values were discarded, mainly those measured in the lowest acidity ranges (up to 0.2 M). This is because very small errors in C_{H^+} may cause large errors in the $\log I - \log C_{H^+}$ values.

The solutions obtained by the mathematical treatments are a mass of m^* and pK_{BH^+} values, and a generatrix (3) excess acidity function which is analytically expressed in polynomial form. The algorithm converges starting from the option *zero*,[2] that is by choosing the starting set $a_0 = a_1 = \ldots = a_i = 0$ (a_i are the polynomial coefficients).

The excess acidity functions which are compared in Fig. 1 are the generatrix functions obtained. The ones on the y axis of plots (e) and (f) in Fig. 1. were obtained as follows. The tabulated generatrix functions were multiplied by $m_f/m_{f'}$, where m_f is the hydration parameter of ferrocene, and $m_{f'}$ is the value related to the excess acidity function on the x axis. It is gratifying to observe that the slopes of plots (e) and (f) are very close to the expected value of unity.

Results and discussion

Three main arguments induce us to believe that the m^{**} term in eq. [2] is probably unnecessary, at least at present, in aqueous H_2SO_4 and $HClO_4$: (a) the discussions of Scorrano and co-workers (5, 6) showing how the parameter m^* in eq. [1] (in terms of ϕ_e) can be used to compare the solvation requirements of weak bases; (b) the latest results of Marziano *et al.* (3),

[1] Cox and Yates' symbolism is adopted in this paper because it has gained much more diffusion in the literature than the one previously proposed in ref. 2. The term m^*X represents the "excess acidity" of the weak base B, according to Perrin's definition (8). X itself represents the excess acidity of a defined hypothetical indicator.

[2] This option is chosen, as usual, in order to avoid misleading interpolations (14). A starting set of parameters must necessarily be chosen in order for the program to operate.

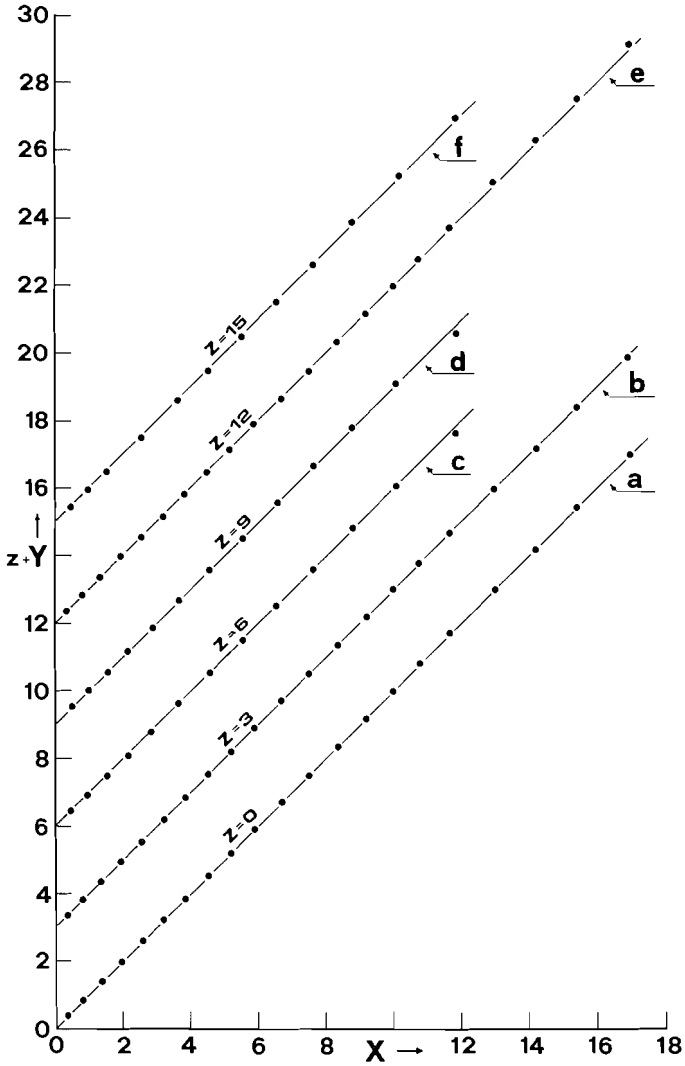

FIG. 1. Comparisons between the differently obtained excess acidity functions in this paper. x axis, excess acidities with: m^* and pK_{BH^+} fixed in $H_2SO_4-H_2O$ and in $HClO_4-H_2O$. y axis, excess acidities with: line a (H_2SO_4), m^* fixed; line b (H_2SO_4), pK_{BH^+} fixed; line c ($HClO_4$), m^* fixed; line d ($HClO_4$), pK_{BH^+} fixed; line e (H_2SO_4) and line f ($HClO_4$), no term fixed.

which have shown that the first-order approximation is compatible with the possibility of obtaining the same pK_{BH^+} values for the same indicators regardless of medium ($H_2SO_4-H_2O$ or $HClO_4-H_2O$); and (c) the observation that the ($-H_{GF}$ − log C_{H^+}) functions (10) are linearly related to the X (or M_C) functions (3, 5) and give equal m^* values in both acid media.[3]

If the first approximation can be accepted, and *if* the m^* terms are solvation parameters, one may expect the m^* values to be the same for the same bases regardless of the aqueous medium. They should be invariant because water is the common reference state. If the m^{**} terms were not very small in both aqueous solutions, the results in ref. 3 could hardly have been obtained.

We will examine this question (1) by calculating excess acidity functions for H_2SO_4 and $HClO_4$ simultaneously, forcing the weak bases to have the same m^* values regardless of medium; (2) by recalculating previous functions simultaneously, forcing the indicators to have the same pK_{BH^+} and m^* values regardless of medium; and (3) by comparing these results to each other and to the results which can be obtained without any constraint, or with the constraint in ref. 3.

TABLE 1. Multiple correlation coefficients (r), standard errors (S.E.), and slopes of the plots in Fig. 1

Line	r	S.E.	Slope
a	0.99999	1.03×10^{-3}	1.00±0.02
b	0.99999	0.81×10^{-3}	1.00±0.02
c	0.99986	5.1×10^{-3}	1.00±0.02
d	0.99981	5.9×10^{-3}	1.01±0.03
e	0.99995	2.04×10^{-3}	1.06±0.05
f	0.99990	4.2×10^{-3}	0.95±0.04

Lines a, b, c, d: 95% confidence interval from a simple regression analysis; lines e, f: the standard errors of estimate of each m^*_{lcc} values are also accounted for.

TABLE 2. Mean-square errors of the excess acidity functions obtained

Fixed term	Acid	σ^2
None	H_2SO_4	1.87×10^{-3}
None	$HClO_4$	1.49×10^{-3}
m^*	Both	1.92×10^{-3}
pK_{BH^+}	Both	1.93×10^{-3}
m^*, pK_{BH^+}	Both	2.78×10^{-3}

Some new carefully-measured log I values (11) were added to the set of data previously used in defining the M_C scale (2, 3). In addition ($-H_{GF}$ − log C_{H^+}) values derived from ref. 10 were processed. Inorganic anion values, and some kinetic data for benzene and halobenzenes used in (3), were discarded.[4] Seventy-one weak bases in $HClO_4-H_2O$ (782 experimental values), and 138 in $H_2SO_4-H_2O$ (1235 experimental values) were processed; results for 31 "key" indicators (3) were available in both media.

The plots in Fig. 1 show the comparisons among the excess acidity functions obtained in the acidity ranges 0−18.4 M H_2SO_4 and 0−13 M $HClO_4$. No essential difference among the derived functions can be deduced from the plots. The depicted points have excellent straight-line correlations; quantitative data are given in Table 1. The standard errors and r-values show that almost exactly the same excess acidity functions are obtained if pK_{BH^+}, or m^*, or m^* and pK_{BH^+}, are fixed, or when no term is fixed. This observation is reinforced by the analysis and comparison of the mean-square errors (σ^2 values) in Table 2. These are affected very little whether no, one, or two parameters are fixed; a variation of 0.95×10^{-3} units in σ^2 is too small to interpret, unless by accepting that it is due entirely to experimental uncertainty.

In Figs. 2 and 3 two very expressive comparisons are shown. The plots in Fig. 2. show the comparisons among the pK_{BH^+} values which have been obtained by processing the experimental data in $H_2SO_4-H_2O$ and $HClO_4-H_2O$ simultaneously, ensuring that indicators have the same pK_{BH^+} values, or the

[3]This fact can easily be observed by comparing the interpolated X and M_C functions, related to the same reference base, and the ($-H_{GF}$ − log C_{H^+}) functions (which are also excess acidity functions) in the cited media.

[4]Satisfactory straight lines for the discarded data were found by plotting the cited values against the M_C functions (2, 3), but the interpretations of such observations are still an open problem (12).

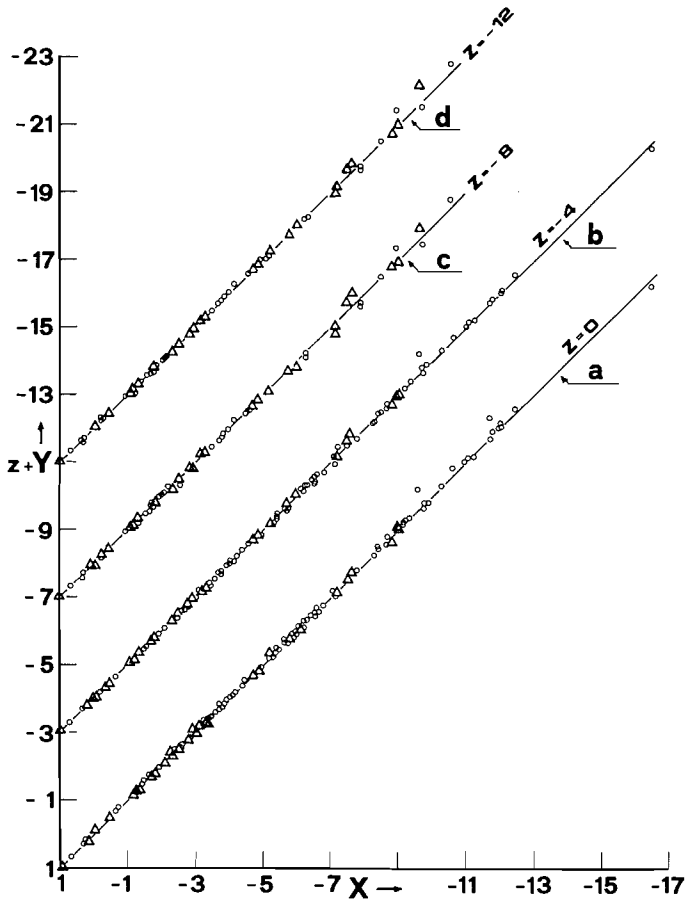

FIG. 2. Comparisons between the differently obtained pK_{BH^+} values in this paper. x axis: m^* and pK_{BH^+} are fixed in $H_2SO_4-H_2O$ and in $HClO_4-H_2O$. y axis: lines a and b (H_2SO_4), m^* or pK_{BH^+} fixed, respectively; lines c and d ($HClO_4$), m^* or pK_{BH^+} fixed, respectively. (△ = key compounds).

same m^* values, or the same pK_{BH^+} and m^* values, regardless of medium. The depicted points show that the imposed constraints do not essentially modify the pK_{BH^+} values.

The plots in Fig. 3 lead to the same conclusions one derives from Fig. 2, now referring to the hydration parameters m^*. Only four points are outside the expected ranges around the diagonals in Fig. 3. These are analyzed in Table 3. The σ values show that the experimental log I data are well correlated by all of the excess acidity functions. Hence these "exceptions" are only apparent ones, easily justified by the experimental uncertainties.

The data comparison in Figs. 2 and 3 is also shown in Table 4, where the results obtained by regression analysis are given. Only the data referring to the "key" indicators have been processed, because they have (and are expected to have) a wider spread around the diagonals. These results show no reason to deny the strong suggestion that the same indicators have the same pK_{BH^+} and m^* values regardless of medium.

Conclusions

All the results of the previous analysis are in accord with the opinion that the second-order approximation (7) is unnecessary in $H_2SO_4-H_2O$ and in $HClO_4-H_2O$, at least at present. The results must mean that the term m^{**} in eq. [2] is very small. Hence the chemical information which has been obtained to date by means of the excess acidity functions can still be reasonably accepted. Nothing has been found which suggests that the uncertainties are larger than the ranges suggested by the random experimental errors.

The differences between the excess acidity functions derived in this paper and previous ones (2–4) are small enough to dissuade us from suggesting new scales and from tabulating new pK_{BH^+} and m^* (or n) values.[5]

When the excess acidity scales of different authors have to be compared, a common "reference" must be found. This is still an open problem. Some interesting proposals have been advanced (13, 14), but some complications remain. During the work presented in this paper it was observed that the ($-H_{GF}$ − log C_{H^+}) functions show large m^* values (more than twice as

[5]The new acidity scales and/or m^* and pK_{BH^+} values, and the computer program used, can be obtained from the author on request.

[c]S.E.I. = standard error of intercept.

large as the nitroanilines). Moreover the experimental H_{GF} values are spread over wide acidity ranges. These facts might suggest a choice of the excess acidity function of ferrocene as the reference, notwithstanding some approximations (15). We have followed this suggestion in order to obtain plots (e) and (f) in Fig. 1. It is apparent that both slopes are strictly unity, as expected when a good reference is chosen.

As a corollary it can be underlined that the results in this paper suggest that Wojcik's theoretical objection (16) is not likely to be of serious consequence in $H_2SO_4-H_2O$ and in $HClO_4-H_2O$ media. Nevertheless we advise against the opinion that the second-order approximation might be unnecessary in general. Many acid solutions probably exist where the first-order approximation is not sufficient. This will form the thesis of a future paper.

Fall-off shape and incubation times in weak-collision thermal unimolecular reactions

H. O. PRITCHARD

Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received March 30, 1983

H. O. PRITCHARD. Can. J. Chem. **62**, 157 (1984).

A new formula for the weak-collision unimolecular rate constant is readily interpretable in terms of bottleneck concepts. This formula is used to explore the correlation between variations in relaxation structure and fall-off shape in weak-collision thermal unimolecular reactions; some information is also presented relating to collision efficiency factors β_c, and to incubation times.

It is conjectured that randomisation failure is an important feature which causes near-Lindemann behaviour to occur in practical weak-collision thermal reactions.

H. O. PRITCHARD. Can. J. Chem. **62**, 157 (1984).

Une nouvelle formule pour la constante de vitesse unimoléculaire pour les collisions faibles peut être interprétée facilement en fonction de concepts "d'emboutaillage". On utilise cette formule pour étudier la corrélation existant entre les variations dans la structure de relaxation et la forme de chute des réactions thermiques unimoléculaires à faibles collisions. On présente également quelques informations relatives au facteur d'efficacité de collision β_c et aux temps d'incubation. Il est possible que le fait que la distribution au hasard ne s'établisse pas soit une caractéristique importante qui provoque un comportement pratiquement égal à celui prevu par Lindemann lors de réactions thermiques à faibles collisions.

Introduction

It was shown recently that the placing of a bottleneck in the activation process for a thermal unimolecular reaction could lead to the occurrence of strict Lindemann behaviour in the fall-off (1); it has also been found that if the randomisation processes become rate-limiting, strict Lindemann behaviour likewise ensues (2). Since several weak-collision thermal systems exhibit fall-off behaviour which is very close indeed to strict Lindemann (3), it is important to decide whether such behaviour may result from a bottleneck in the activation ladder or from a bottleneck in the randomisation process (or, perhaps, a combination of both). Unfortunately, our original model of a bottleneck in the activation ladder (1) was an extremely artificial one, for which the same fall-off shape results no matter at what point below threshold the bottleneck is placed. In the present note, therefore, we investigate numerically an extremely simple stepladder model of a weak-collision thermal reaction, in order to find out what kinds of patterns of activation parameters might lead to the occurrence of strict Lindemann behaviour; also, since it may be possible to make a classification into weak- or strong-collision behaviour on the basis of the observed ratio of the incubation time (τ_{inc}) to the relaxation time (τ_{rel}) (4–6), a cursory inspection of these ratios is also undertaken.

The use of tridiagonal matrices to describe weak-collision unimolecular reactions

The rate constant for a thermal unimolecular reaction is calculated as the smallest eigenvalue γ_0 of a reaction matrix $[\mathbf{A} + \mathbf{D}]$ where $\mathbf{A}$ is (the negative of) the symmetrised form of the matrix $\mathbf{Q}$ describing relaxation processes among the states of the reactant molecule, and $\mathbf{D}$ is a diagonal matrix of decay rate constants for states above reaction threshold (6). Given the enormous number of states in any polyatomic molecule of practical interest, the individual elements of $\mathbf{Q}$ and $\mathbf{D}$ must represent suitably averaged rate constants which may be applied to groups of states (grains), in any feasible calculation.

Now, provided that the matrix $\mathbf{Q}$ does not have degenerate eigenvalues, it may be reduced by a similarity transformation to a tridiagonal matrix having non-zero entries on the codiagonal (7); the same is true of $\mathbf{A}$ or $[\mathbf{A} + \mathbf{D}]$. Also, in view of the complexity of the molecule, there can be no special relationships between the elements of $\mathbf{Q}$ so that, in general, it must be a non-degenerate matrix; in the unlikely event that a chance degeneracy could occur, it can always be removed by making an alternative choice for the graining. Thus, except for the strong-collision case, where the matrix $\mathbf{A}$ is totally degenerate (6, 8), any (weak-collision) unimolecular reaction process can be described by a tridiagonal reaction matrix, and the use of a tridiagonal matrix to represent the process does not imply a restriction to step-ladder or nearest-neighbour processes. As a consequence, those properties of a unimolecular reaction system which depend only upon the eigenvalues can be explored by the use of a tridiagonal matrix $[\mathbf{B} + \mathbf{D}]$. On the other hand, those unimolecular reaction properties which require the knowledge of the eigenvector(s) of $[\mathbf{A} + \mathbf{D}]$ will be defective unless the similarity transformation required to reduce the original, true, relaxation matrix $\mathbf{A}$ to the tridiagonal form $\mathbf{B}$ is known.

The rate constant for a tridiagonal reaction matrix

The rate constant for a tridiagonal reaction matrix was first derived in Theorem 4 of ref. 8, but the result was given in a rather forbidding recursive form which, although easy to compute, did not lend itself to intuitive analysis. More recently, Vatsya (9) has found a much more direct result, which may be written as

$$[1] \quad \gamma_0^{-1} = -\sum_{j=0}^{N-1} \frac{1}{J_{j+1}} \left[\sum_{i=0}^{j} \beta_i^{1/2} \prod_{l=1}^{j-1} \{B_{l,l+1}/J_{l+1}\} \right]^2$$

where N is the order of the matrix, β_i is the Boltzmann population in grain i, B_{ij} are the elements of the (symmetric) tridiagonal matrix, and

$$J_1 = -(B_{00} + D_{00})$$

$$J_{i+1} = -(B_{ii} + D_{ii} + B_{i-1,i}^2/J_i)$$

Equation [1] is valid provided only that γ_0 is small compared with the non-zero eigenvalues of $\mathbf{B}$, i.e. the relaxation rates; notice that unlike previous analytic solutions to the weak-collision problem, this solution is valid for all pressures, any pattern of transition probabilities, and any distribution of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

energy levels. Furthermore, eq. [1] simplifies enormously at the low-pressure limit to a form which is amenable to intuitive analysis. Recalling our earlier discussion of bottleneck effects in diatomic dissociation (10), we may write an effective impedance associated with a transition between states j and $j + 1$ as

$$[2] \quad t_j = \left(\sum_{k=0}^{j} \beta_k\right)^2 / \beta_j q_{j,j+1}$$

which is obtained from eq. [17] of ref. 10 by neglecting some small quantities, and in which $q_{j,j+1}$ is the rate constant for the transition from state j to state $j + 1$, i.e. the codiagonal element of the unsymmetrised form of **B**. Let j_+ be the index of the first grain above the thermal threshold, and j_- be the index of the last grain below it. Then, providing that the total equilibrium population of the reactive states

$$\sum{}' \beta_j = \sum_{j=j_+}^{N-1} \beta_j$$

is negligible in comparison with the total population

$$\sum_{j=0}^{N-1} \beta_j = 1$$

the limiting low-pressure rate constant is given by

$$[3] \quad k_0 = \left[\sum_{j=0}^{j=j_-} t_j\right]^{-1}$$

Previous steady-state treatments of this problem have yielded [3], but with a slightly different form for the t_j (11–13); a proof of this result will be provided in a separate communication.

Thus, we have the potential for the occurrence of bottleneck effects in weak-collision unimolecular reactions similar to those which have been supposed to occur in diatomic dissociation (10) or inert-gas ionisation (14) processes; eq. [3] provides a straightforward vehicle for the examination of such effects.

A simple reaction model for exploring bottleneck properties

In order to make an initial exploration of possible bottleneck effects, it is useful to have a very simple reaction model, and the one used here is chosen to follow, in a rough and ready manner, the thermal dissociation of carbon dioxide. An energy span of 160 kcal mol^{-1} was divided into 40 equally spaced grains labelled 0 to 39: of these, 30 were below reaction threshold, and 10 above.

The tridiagonal relaxation matrix **Q** (unsymmetrised) was chosen in the form

$$[4a] \quad q_{i,i-1} = i^p q_{10}$$

where p is variable; the value q_{10}, the deactivation rate constant for the first excited grain, was taken to be fixed throughout the whole series of calculations, as 2.5×10^3 Torr^{-1} s^{-1}. The symmetrisation operation (6, 8, 10) requires a knowledge of the grain populations β_i, and two different models were explored, one labelled F where the state density was taken to be constant for all energies, and another labelled V in which the actual state densities for carbon dioxide were used; these two models give rise to markedly different population distribution functions β_i.

Likewise, the elements of the **D** matrix were chosen to have a very simple form, viz.

$$[4b] \quad d_i = \left(\frac{i - 29}{i}\right)^2 \times 10^{11} \text{ s}^{-1}$$

in other words, of RRK form with $s = 3$. The temperature was considered to be 4000 K throughout.

The major features examined in this series of numerical experiments were the fall-off shape, the apparent collision efficiency β_c, and the incubation time τ_{inc}, and their dependence, if any, on bottleneck features introduced into the system by variations in eqs. [4a] and [4b].

We introduce at this stage a very simple device for making comparison between the shapes of fall-off curves; the inappropriateness of the traditional measure, the Kassel s parameter, has been discussed extensively elsewhere (6, 8). Because the Lindemann form is a limiting shape (15, 16), we simply make a comparison between the observed shape and the strict Lindemann curve having the same high-pressure and low-pressure limits; this is most easily done by defining the area enclosed between the two curves, plotted in the usual log k vs. log p fashion, as a quantity Δ. We will consider two such quantities, Δ_S, the area between the strong-collision curve and Lindemann, and Δ_W, the area between the fall-off curve for the tridiagonal system and Lindemann.

The apparent collision efficiency β_c is defined in the usual way. The hard-sphere collision number for carbon dioxide at 4000 K is $\omega = 2.07 \times 10^6$ Torr^{-1} s^{-1}, given a collision diameter of 3.73 Å (17); thus, since the limiting low-pressure strong-collision rate constant is $k_{0,S} = \omega \Sigma' \beta_i$ (8), the apparent collision efficiency $\beta_c = k_0/k_{0,S} = k_0/\omega\Sigma'\beta_i$.

Calculation of the incubation time requires a knowledge of the eigenvector Ψ_0 of $[\mathbf{A} + \mathbf{D}]$ corresponding to γ_0, whence (4)

$$[5] \quad \tau_{inc} = \gamma_0^{-1} \ln [\mathbf{E}^{1/2}\boldsymbol{\beta}(0), \Psi_0)/(\Psi_0, \Psi_0)]$$

where $\mathbf{E}^{-1/2}$ is a matrix arising in the transformation symmetrising **Q** to **A** (6, 8, 10), and $\boldsymbol{\beta}(0)$ is the initial distribution, taken to be $\beta_0 = 1$, $\beta_i = 0$, $i \neq 0$. The notation (,) in [5] denotes the scalar product of two vectors, Ψ_0 is normalised so that $(S_0, \Psi_0) = 1$, and S_0 is the eigenvector of **A** corresponding to its zero eigenvalue. Unfortunately, the zeroth eigenvector ϕ_0 of $[\mathbf{B} + \mathbf{D}]$ is not equal to the zeroth eigenvector Ψ_0 of $[\mathbf{XBX}^T + \mathbf{D}]$, where $\mathbf{X}, \mathbf{X}^T$ denote the similarity transformation matrices required to reduce the original full symmetric relaxation matrix **A** to the tridiagonal form **B**; hence, the substitution of ϕ_0 for Ψ_0 in [5] restricts the conclusions concerning incubation times to a truly tridiagonal (i.e. step-ladder) model. However, it seems likely that the differences between step-ladder systems and general systems will only be in matters of detail, so that we can infer qualitative conclusions about incubation times from these calculations. It is usual to make a comparison of τ_{inc}/τ_{rel} and the relaxation time τ_{rel} is taken to be λ_1^{-1}, where λ_1 is the first non-zero eigenvalue of **B**. This is not strictly the relaxation time (4, 6), but the exact connection between τ_{rel} and λ_1^{-1} cannot be known unless the structure of the relaxation is known at a molecular level *within* grains; nevertheless, in practice, the disparity between τ_{rel} and λ_1^{-1} is not likely to be very severe when the uptake of vibrational energy is large (6), as it is in a reacting system.

Numerical results

Except for the high-pressure limit where the rate constant is $k_\infty = \Sigma \beta_i d_i$, and at the low-pressure limit where eq. [3] can be used, eq. [1] provides the most efficient method for calculating the rate constant as a function of pressure; standard matrix numerical methods are considerably slower.

Table 1 summarises two sets of calculations in which the value of p in eq. [4a] is varied, with designations F_p, V_p, for

TABLE 1. Variation of unimolecular reaction properties as a function of the parameter p in eq. [4a]

Standard values: E_∞ = 106.2 kcal mol^{-1}; k_∞ = 4.68 × 10^5 s^{-1}; Δ_S = 0.28						

*The case designation F means fixed state-density model, V means variable state-density model; the digit following is the (integer) value of p. Δ_S is the area contained between the strong-collision fall-off curve and the strict Lindemann form.

fixed, variable, state densities, respectively. Apart from some necessary differences, the two sets of calculations are remarkably similar: the rates are much higher in the variable density case because of the greater populations at higher energies, and the activation energies E_∞, E_0, are lower because the larger populations change more slowly with temperature.

In both sets, the low-pressure limiting rate constant increases strongly with increasing p in eq. [4a], despite the fact that q_{01}, q_{10}, remain unchanged throughout each set; along with this, β_c increases strongly too, and soon exceeds the value of unity! The increase in relaxation rate, λ_1 with p is much weaker.

In both sets too, the ratio of the incubation time to the relaxation time exceeds unity, as expected (4), by amounts typical of earlier numerical experiments (18, 19); notice that increasing p corresponds to an increasingly strong acceleration of the relaxation among the higher states of the molecule, causing τ_{inc} to decrease more quickly with p than does τ_{rel}. Also, although not detailed in Table 1, the ratio τ_{inc}/τ_{rel} appears to be rather insensitive to the degree of fall-off: for example, the values listed are for conditions close to the high-pressure limit, whereas at $p_{1/2}$, the ratio is 3.1 for case F1 and 3.0 for case V1.

The most startling feature of both calculations is that the computed fall-off curves are uniformly *much* broader than the strong-collision shape; the case F1 is shown in Fig. 1. This is in strong conflict with the experimental observation that many weak-collision thermal systems exhibit almost pure Lindemann behaviour (3) i.e. $\Delta_W \approx 0$, and conversely, that fall-off shapes broader than the strong-collision one are not seen. Thus, a major concern is how to choose a set of grained transition rates in such a way that we can achieve Lindemann behaviour, a problem which is examined in the next series of numerical experiments.

Certain conditions for the existence of strict Lindemann behaviour have been established recently as follows: (*i*) if there is only one (grained) reactive state above threshold, regardless of the form of the transition matrix **A** (8); (*ii*) if **A** is the strong-collision relaxation matrix, and all reactive grains have the same decay rate constant (8); (*iii*) if the relaxation above threshold is *very* much faster than that below threshold (1) — this was only proved for the case when both relaxations are of strong-collision form, but it may be true more generally; (*iv*) a fourth condition, proposed in ref. 3, has been shown to be unattainable (8).

Table 2 shows the results of a series of experiments to test

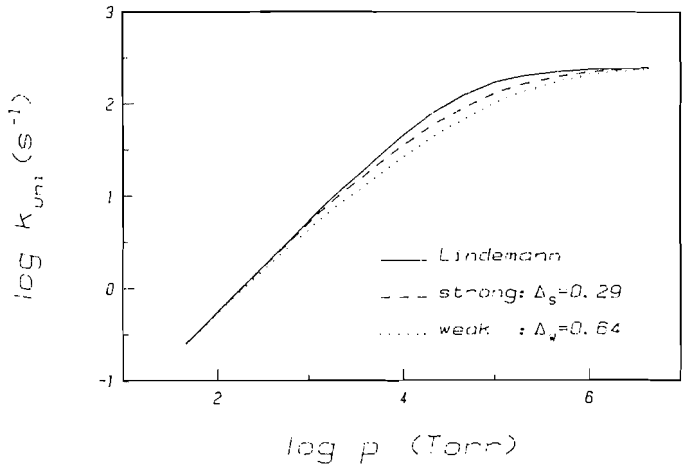

FIG. 1. Illustration of the method for characterising the shape of a unimolecular fall-off curve; the curves shown here are for the calculation labelled F1 in Table 1.

these points, with the results for cases F1 and V1 transcribed from Table 1 for comparison. Cases F1(1) and V1(1) are for p = 1 in eq. [4a], but with [4b] altered to read $d_i = 10^{11}$ s^{-1} for all $i \geq j_+$; these results are consistent with point (*ii*) above. Cases F1(0) and V1(0) are similar, but with $d_i = 10^{11}$ s^{-1} for $i = j_+$ only, and all other $d_i = 0$; this illustrates point (*i*). Point (*iii*) is partly illustrated in Table 1 because the larger the value of p in eq. [4a], the faster are the transitions between the reactive states. A further test of this point is made in cases V1(*a*), V1(*b*), and V1(*c*) in Table 2; notice that the differences between the F series and the V series of experiments are always small, and from here on, only the (more realistic) variable state-density results will be reported. These three cases all have the same relaxation matrix as case V1, except that the transition rates between grains *above threshold only* are all multiplied by a constant factor of 30, 100, or 1000 respectively; a significant progression towards strict Lindemann behaviour is found.

Since the transition probability distributions [4a] are smooth functions of the degree of excitation, none of the numerical experiments, except the last three, exhibits significant bottleneck effects in the sense described in ref. 10 and 14, i.e. that one of the t_j of eq. [2] is significantly *larger* than its neighbours — c.f. Fig. 1 of ref. 10. However, the arbitrary multiplication of all probabilities above threshold by these large factors auto-

V1(*c*)	4.23	4.69×10^{5}	0.28	0.004

*Cases F1 and V1 are the standard cases transcribed for Table 1. The designation 1(1) means that *all* states above threshold have the same decay rate constant; the designation 1(0) means that *only one* state above threshold has a non-zero decay rate. The designations (*a*), (*b*), (*c*) mean that all transitions *above* threshold are artificially accelerated by constant factors of 30, 100, 1000, respectively. For all cases listed in this table τ_{inc}/τ_{rel} lies between 3.0 and 3.2 near the high pressure limit, or between 2.9 and 3.1 at $p_{1/2}$.

TABLE 3. Changes in shape of the fall-off curve as the result of single-transition perturbations

Case*	k_0 (Torr^{-1} s^{-1})	Δ_W
V1	4.23	0.61
V1(+1→+2)×30	4.23	0.52
V1(−→+1)×30	4.23	0.44
V1(−→+)×30	5.75	0.71
V1(−1→−)×30	5.22	0.67
V1(−6→−5)×30	4.46	0.63
V1(−→+)/30	0.47	0.16
V1(−6→−5)/30	1.65	0.36
V1(−11→−10)/30	3.10	0.52
V1(−11→−10)/100	1.88	0.39
V1(−11→−10)/1000	0.31	0.12

*The designation (+→+1) means that the transition rate for $j = j_+$ to $j = j_+ + 1$ was perturbed by the operator following the bracket; likewise (−6 → −5) refers to the transition between $j = j_- - 6$ and $j = j_- - 5$.

matically creates a bottleneck between grains j_- and j_+, and the stronger this bottleneck effect, the closer to Lindemann behaviour we find. This clearly establishes a link between Lindemann behaviour and activation bottlenecks.

The question now arises as to whether bottlenecks placed in other positions in the activation ladder can affect the shape of the fall-off curve, and the results of these experiments are summarised in Table 3. The first five entries show what happens when the rate of a specific transition (and its reverse), either just above or just below threshold, are multiplied by an arbitrary factor of 30; the unimolecular reaction properties of the system are insensitive to variations of this kind further away from the threshold level. Above threshold, k_0 is independent of the variations in q_{ij} as required by eq. [3], although the fall-off shape changes somewhat; otherwise, the rate is most sensitive to the rate of transport *across* the threshold, and the further below the threshold one arbitrarily lowers the impedance, the smaller is the effect on k_0 and Δ_W. Lowering the impedance anywhere above threshold narrows the fall-off curve — the same effect as in case V1(*a*) above, but not as marked — whereas lowering the impedance elsewhere broadens the fall-off, with the largest effect at the cross-threshold transition.

This multiplication of a specific rate by an arbitrary factor does not create a bottleneck in the accepted sense — it only creates an implied bottleneck at the preceding step. Consequently, the second set of five entries in Table 3 shows the effect of making arbitrary reductions in a specific transition rate, giving rise to a strong increase in impedance for that step. The first three experiments in this class show that as this extra impedance is moved down the activation ladder, we approach the normal behaviour of case V1; however, extra impedance for the transition *across* threshold does lead to a marked sharpening of the fall-off curve, $\Delta_W = 0.16$, which is actually a sharper curve than the strong-collision fall-off shape, $\Delta_S = 0.28$ for the variable state-density case. The same effect can be generated by placing the artificial bottleneck further below threshold, but the severity of the bottleneck has to be made much greater in order to achieve the same result, as is shown in the final three entries of this group.

Concluding remarks

The numerical experiments described in this paper have been used to explore three facets of the weak-collision unimolecular reaction problem, incubation times, collision efficiencies, and fall-off shapes; this development is based upon a new expression for the weak-collision rate, valid for all pressures.

The results obtained for the incubation times are the least satisfactory in that they do not throw a great deal of light on the cause of the inequality $\tau_{inc} > \tau_{rel}$ in weak-collision systems (4). Moreover, these results are strictly valid only for step-ladder probabilities because of the difference between ϕ_0 and Ψ_0, but it has often been found in the past that step-ladder calculations are of qualitative value. Only three points of substance stand out, a confirmation that $\tau_{inc} > \tau_{rel}$, that the ratio τ_{inc}/τ_{rel} is not very sensitive to the extent of the fall-off, but that τ_{inc} is sensitive to variations in the transition rates among some of the higher states.

The result that the apparent collision efficiency, β_c, can exceed unity may seem odd at first; it only means that the weak-collision rate is greater than the strong-collision rate at the low-pressure limit. It is quite easy to see how this can happen with the help of eq. [3]. At the low-pressure limit, the strong-collision rate is $k_{0,S} = \omega\Sigma'\beta_i$, where as we have noted, $\omega \simeq 2 \times 10^6$ Torr^{-1} s^{-1}, and $\Sigma'\beta_i$ is of the order of 3×10^{-7} (4×10^{-4}) for the F (V) series respectively; thus, the values of $k_{0,S}$ are 6×10^{-1} (8×10^2) Torr^{-1} s^{-1}. On the other hand, q_{10} is fixed at 2.5×10^3 Torr^{-1} s^{-1} in both cases, and since the temperature is 4000 K, q_{01} is of a similar magnitude too; the actual values of t_0 calculated by eq. [2] are 2.5×10^{-4} (1×10^{-6}) Torr s respectively. Now imagine an extremely artificial set of transition rates, such that all $t_j \approx 0$, $j \geq 1$: in other words, at the low-pressure limit, virtually any molecule which succeeds in being excited out of the bottom state will dissociate. Then $k_0 \approx t_0^{-1} \approx 4 \times 10^3$ (1×10^6) Torr^{-1} s^{-1}, whence $\beta_c \approx 10^4$ (10^3); this is what happens in the thermal ionisation of atoms (14). In the present case, the appearance of values of $\beta_c > 1$ is associated with values of $q_{j+1,j} > \omega$ near threshold; since there is no strong evidence that transition rates for high vibrational states grossly exceed those for lower states, β_c will not be expected to exceed unity in practice.

However, the major conclusion from this set of numerical experiments is that it is not easy to choose a set of transition rates which will lead to Lindemann or near-Lindemann behav-

iour, as appears to be the case for most so-called weak-collision thermal reactions (3). The only way, in fact, in which it can be done is to construct the transition rates in such a manner that the rate of relaxation among the reactive states *far exceeds* the rate constants for activation to those states. This was shown by the last three cases in Table 2 and, in fact, the last three entries in Table 3 are examples of the same effect, constructed in a slightly different manner. In the absence of this bottleneck effect, the fall-off curves are *much* too broad, broader in fact than the strong-collision shape.

It is not clear that the requirement of a collisional relaxation among the reactive states greatly exceeding (by a factor of at least an order of magnitude) the rate of collisional excitation across threshold, is a reasonable one, and yet, within the framework of the usual model of unimolecular reaction, it would have to be so if we are to account for the common observation of near-Lindemann behaviour in weak-collision systems. Rather than attempt to force agreement by postulating a new effect in collisional relaxation processes associated with only the reactive states, it is preferable to look for other possible causes for the common occurrence of this near-Lindemann behaviour; it is known already that a restriction in the randomisation rates among the reactive states can lead to strict Lindemann behaviour if it is sufficiently severe (2), and since the reactive states are relatively far apart in energy in these simple molecules (6), this seems to be the logical cause to pursue in this case, at least for the time being.

Oxidation of sulfur compounds. I. The photolysis of CH_3SH and $(CH_3S)_2$ in the presence of NO[1]

R. JEFFREY BALLA AND JULIAN HEICKLEN

Department of Chemistry and Center for Air Environment Studies, The Pennsylvania State University, University Park, PA 16802, U.S.A.

Received May 10, 1983

This article is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

R. JEFFREY BALLA and JULIAN HEICKLEN. Can. J. Chem. **62**, 162 (1984).

Both CH_3SH and $(CH_3S)_2$, as well as their mixtures, were photolyzed in the presence of NO at 23 ± 1°C. The photolyses were carried out in a 631 mL quartz vessel with a pinhole bleed to a quadrupole mass spectrometer for continual analysis of products. After the termination of exposure, further product analysis was made by gas chromatography.

The identified products of the reaction were CH_3SNO, $(CH_3S)_2$, H_2, and N_2. Hydrogen atoms, formed from the photolysis of CH_3SH, reacted with both NO and CH_3SH:

[4] $H + NO + M \rightarrow HNO + M$

[5] $H + CH_3SH \rightarrow H_2 + CH_3S$

with $k_5/k_4 = 626 \pm 42$ Torr for NO as a chaperone. The CH_3S radical adds to NO

[2*a*] $CH_3S + NO \rightleftarrows CH_3SNO\dagger$

[2*b*] $CH_3SNO\dagger + M \rightarrow CH_3SNO + M$

with $k_{-2a}/k_{2b} = 83 \pm 52$ Torr. As the CH_3SNO accumulates, CH_3S also reacts with CH_3SNO

[6] $CH_3S + CH_3SNO \rightarrow (CH_3S)_2 + NO$

with $k_6/k_{2a} \simeq 0.84 \pm 0.27$. At high NO pressures a chain process occurs which is attributed to:

[7] $H + NO \rightarrow \text{adduct} \xrightarrow{CH_3SH} H + \xi CH_3S$

where ξ is probably 4.0. Termination is most easily represented by

[8] $HNO \rightarrow$ termination

with $k_8/k_7 = 85.0 \pm 7.8$ Torr.

R. JEFFREY BALLA et JULIAN HEICKLEN. Can. J. Chem. **62**, 162 (1984).

On a photolysé le CH_3SH et le $(CH_3S)_2$ ainsi que leurs mélanges en présence du NO à 23 ± 1°C. On a réalisé les photolyses dans un récipient en quartz de 631 mL muni d'un très petit orifice relié à un spectromètre de masse quadrupolaire en vue d'une analyse continuelle des produits. A la fin de la photolyse, on analyse les produits par chromatographie en phase gazeuse.

On a identifié les produits suivants: CH_3SNO, $(CH_3S)_2$, H_2 et N_2. Les atomes d'hydrogène formés au cours de la photolyse du CH_3SH réagissent avec le NO et le CH_3SH.

[4] $H + NO + M \rightarrow HNO + M$

[5] $H + CH_3SH \rightarrow H_2 + CH_3S$

avec $k_5/k_4 = 626 \pm 42$ Torr pour le NO comme chaperon. Le radical CH_3S s'additionne au NO.

[2*a*] $CH_3S + NO \rightleftarrows CH_3SNO\dagger$

[2*b*] $CH_3SNO\dagger + M \rightarrow CH_3SNO + M$

avec $k_{-2a}/k_{2b} = 83 \pm 52$ Torr. Au fur et à mesure que le CH_3SNO s'accumule, le CH_3S réagit également avec lui

[6] $CH_3S + CH_3SNO \rightarrow (CH_3S)_2 + NO$

avec $k_6/k_{2a} \simeq 0{,}84 \pm 0{,}27$. Pour de fortes pressions de NO, il se produit une réaction en chaine que l'on attribue à

[7] $H + NO \rightarrow \text{adduit} \xrightarrow{CH_3SH} H + \xi CH_3S$

ou ξ est probablement égal à 4. On représente plus facilement la fin de la réaction par

[8] $HNO \rightarrow$ Fin de réaction

avec $k_8/k_7 = 85{,}0 \pm 7{,}8$ Torr.

Introduction

The photolysis of CH_3SH in the presence of NO has been studied by Steer and Knight (1). They studied the reaction in steady-state photolysis and analyzed the products after termination of irradiation. They found that the H_2 formed in the absence of NO decreased in yield as the NO pressure was increased. The major product of the reaction was CH_3SNO. The sum of its yield plus twice the $(CH_3S)_2$ yield was constant for NO pressures <20 Torr, but at higher NO pressures, the yields of both compounds increased indicating a chain reaction. N_2 was also a major product at high NO pressures and it must also be formed in the chain process. They also found that both CH_3SNO and N_2 were produced in post-irradiation dark reactions, though the H_2 concentration was not affected. There was no dark reaction between NO and CH_3SH. The investigators were unable to provide a mechanism for their observations.

Recently the photolysis of CH_3SNO has been examined by Niki *et al.* (2) who also measured its uv and ir absorption cross sections. They found $(CH_3S)_2$ and NO to be produced in stoichiometric amounts. From this they concluded the mechanism to be

$$[1] \quad CH_3SNO + h\nu \rightarrow CH_3S + NO$$

$$[2] \quad CH_3S + NO \rightarrow CH_3SNO$$

$$[3] \quad 2CH_3S \rightarrow (CH_3S)_2$$

We have studied the reaction of CH_3S radicals with NO and report the results here. Most of our studies were done using the photolysis of CH_3SH as the source of CH_3S. However, we also have results using $(CH_3S)_2$ photolysis as the source of CH_3S.

Experimental

Photolysis was performed in a 631-mL spherical quartz cell equipped with Pyrex-quartz graded seals which contributed no more than 4% to the dead volume. Radiation was from one, two, or three unfiltered low-pressure Hanovia mercury lamps, No. Z1400-013, which emit essentially only 254 and 185 nm radiation (3). The 185 nm line is absorbed by air between the lamps and reaction vessel. All experiments were performed at 23 ± 1°C.

Gases were admitted to the reaction cell by using a conventional grease- and mercury-free vacuum line equipped with Teflon stopcocks. Gas pressures were measured by a Whittaker Model CD25 pressure transducer, oil manometer, or 0–800 Torr Wallace and Tiernan gauge. The transducer and manometer were calibrated with respect to a McLeod gauge which was kept carefully isolated from the vacuum system.

Continuous product analysis was performed by allowing the contents of the cell to bleed through a small pinhole into an Extranuclear type II quadrupole mass spectrometer. In the course of these experiments the total pressure in the cell ranged from 20 to 300 Torr pressure. In order to maintain the operating pressure of the mass spectrometer below 4×10^{-6} Torr, a series of three glass pinholes of different area were used. The glass pinholes were used over the following total pressure ranges: 20–60 Torr, 60–150 Torr, and 150–300 Torr. Under all experimental conditions, sample depletion never exceeded 5%. Mass spectrometric determinations were performed with 40 eV electrons by measuring the product ion current peaks relative to the $m/e = 40$ peak from a known amount of argon which was added to the mixture prior to irradiation. This reduces errors from instrumental and other periodic fluctuations. Methylthionitrite (CH_3SNO) and dimethyldisulfide $(CH_3S)_2$ were quantitatively determined by measuring their relative signals at $m/e = 77$ and $m/e = 94$, respectively, to that of argon at $m/e = 40$.

The H_2 produced was expanded into a sample loop after irradiation for analysis by gas chromatography. Separation was performed on a 12 ft.-long × 1/4 in.-diameter stainless steel column containing molecular sieve 5A maintained at room temperature. Nitrogen was used as the carrier gas with a flow rate of 40 mL/min. All gases which would not pass through the column were retained in the sample loop using an isopentane slush bath maintained at −160°C. Analysis for N_2 was performed using a 4 ft.-long × 1/4 in.-diameter stainless steel column packed with molecular sieve 5A at 23°C with a helium flow rate of 40 mL/min. An isopentane slush bath was used to retain the larger molecules, such as CH_3SH, in the sample loop in order to prevent column contamination. N_2O was analyzed with a 6 ft.-long × 1/4 in.-diameter stainless steel column packed with Porapak QS at 23°C with a helium flow rate of 55 mL/min.

TABLE 1. Mass spectrum of CH_3SNO[a]

m/e	Fragment	% relative height

[a]Taken on an Extranuclear Type II mass spectrometer at 40 eV electron energy.

Methylmercaptan, obtained from Matheson at 99.5% minimum purity, was distilled trap-to-trap from −94 to −160°C. Matheson C.P. grade nitric oxide was distilled from −186 to −196°C and thoroughly degassed prior to experimental use. Matheson prepurified argon was used without further purification. Gold label dimethyldisulfide, obtained from Aldrich, was distilled from 0 to −63°C prior to use. Methylthionitrite was prepared by photolyzing $(CH_3S)_2$ at 254 nm in the presence of a threefold excess of NO. Its mass spectrum is given in Table 1. Purification was accomplished by trap-to-trap distillation from −84 to −160°C. The purified material was stored in a darkened bulb at −196°C to prevent thermal as well as photolytic decomposition (4).

NO_2 (Matheson) was purified as follows. One hundred Torr of NO was mixed with 600 Torr O_2. This mixture was frozen at −196°C, then allowed to warm to room temperature. The freeze–thaw procedure was repeated until the blue color of N_2O_3 disappeared and the frozen mixture became pure white. The NO_2 was then distilled from −63 to −130°C. The pure NO_2 was kept in a dark storage bulb and degassed prior to each experiment.

Mass spectra of all gases were obtained and compared with the EPA-NIH mass spectral data base. In all cases, no extraneous peaks were obtained.

Actinometry was performed by photolysis of methylmercaptan at 254 nm. The products obtained, dimethyldisulfide and hydrogen, have quantum yields of 0.99 ± 0.1 (5) and 1.00 ± 0.05 (1), respectively. In all cases, the absorbed intensity, I_a, obtained from $(CH_3S)_2$ by mass spectrometry and from H_2 by gas chromatography, agreed within a few percent. For the photolysis of $(CH_3S)_2$ at 254 nm, CH_3SH was used as an actinometer at matched absorbances. We found the extinction coefficients to be 8.27×10^{-3} (to base 10) $Torr^{-1}\ cm^{-1}$ for $(CH_3S)_2$ and 2.36×10^{-3} (to base 10) $Torr^{-1}\ cm^{-1}$ for CH_3SH. Our extinction coefficient for CH_3SH agrees exactly with that of $2.4 \times 10^{-3}\ Torr^{-1}\ cm^{-1}$ reported by Bridges and White (5).

Some runs were done in which $(CH_3S)_2$ was photolyzed in the presence of CH_3SH. This could be done because $(CH_3S)_2$ absorbs light

slightly beyond 300 nm, while the extinction coefficient for CH_3SH is negligible above 275 nm. In these experiments three Hanovia medium-pressure Hg lamps were used with two Corning 0-53 filters to remove radiation <280 nm. To be certain that CH_3SH was not absorbing any radiation, an experiment was performed in which pure CH_3SH was irradiated, and no $(CH_3S)_2$ was found.

Results

When mixtures of CH_3SH and NO were photolyzed with 254 nm radiation, the products found were CH_3SNO, $(CH_3S)_2$, H_2, and N_2. Possibly NO_2 is also formed, but we were unable to analyze for it. The CH_3SNO and $(CH_3S)_2$ were monitored continuously throughout the run by mass spectrometry. The H_2, and in some cases N_2, was measured by gas chromatography after the termination of the irradiation. These results are in accord with the findings of Steer and Knight (1).

Curves of growth for CH_3SNO and $(CH_3S)_2$ are shown for two different runs in Figs. 1 and 2. In both cases, $[CH_3SNO]$ is proportional to irradiation time initially, but then rises less rapidly as the CH_3SH is consumed and $(CH_3S)_2$ is produced. The $(CH_3S)_2$ is formed with an induction period in both cases. The run at lower intensity shows a much more pronounced induction period. The major difference between the two runs is that there is no further growth of products after the termination of radiation for the run with 6.0 Torr NO (Fig. 1), whereas there is a post-irradiation dark reaction for the run with 50.0 Torr NO (Fig. 2).

To see if the post-irradiation dark reaction could be caused by the presence of CH_3SNO, mixtures of ≃200 Torr NO, ≃10 Torr CH_3SNO, ≃15 Torr of Ar, and either 0 or ≃16 Torr CH_3SH were allowed to stand for 775–1050 s in the dark. In none of these experiments did any reaction take place.

Figure 3 shows log–log plots of $[(CH_3S)_2]$ vs. reaction time for the irradiation of three different CH_3SH–NO mixtures. During most of the run, the plots can be fitted by lines of slope 2.0, indicating that $[(CH_3S)_2]$ is proportional to the square of the irradiation time.

The data for all of our runs in the CH_3SH–NO system are tabulated in Table 2, where the values listed for $\Phi\{CH_3SNO\}$ are initial values. The initial quantum yields of CH_3SNO formation rise from about 2 at low NO pressure to about 8 at 200 Torr NO, thus confirming the chain reaction demonstrated by Steer and Knight (1). In agreement with their findings $\Phi\{H_2\}$ decreases as the NO pressure is raised, reaching values as low as 0.21 with 200 Torr NO and 6 Torr CH_3SH. The quantity $[(CH_3S)_2]/t^2$ varies widely with changes in reaction conditions. In general it increases with I_a and decreases with increasing NO pressure.

The N_2 is produced in the dark reaction (1), so that measuring its quantum yield by gas chromatography is not very meaningful. We did confirm that N_2 is a product of the reaction, but report no quantum yields.

We had expected that N_2O might be a product, since it is formed from the interaction of two HNO molecules which are produced in the H + NO reaction. We looked for, but did not find, N_2O. For an experiment with 20.5 Torr NO, 21.5 Torr CH_3SH, 16.0 Torr Ar, and $I_a = 3.7 \times 10^{-4}$ Torr/s, $\Phi\{N_2O\} < 0.011$. Likewise for an experiment with 173 Torr NO, 21.0 Torr CH_3SH, 17.0 Torr Ar, and $I_a = 3.6 \times 10^{-4}$ Torr/s, $\Phi\{N_2O\} < 0.005$.

Another probable product of the reaction is NO_2. Possibly this molecule could be responsible for the post-irradiation dark reaction. We could not analyze for this molecule because the CH_3SH mass spectral cracking peaks interfered with m/e 46. However, we mixed NO_2 with CH_3SH and did find a dark reaction. A sample run is shown in Fig. 4, where the reaction was monitored continuously by mass spectrometry. The CH_3SH is rapidly removed by NO_2, and $(CH_3S)_2$ is formed as a stable product. CH_3SNO is also produced, as reported previously by Fierce *et al.* (6). However, its concentration rises to a maximum in <50 s, and then decreases as the CH_3SH is consumed.

We examined the photolysis of $(CH_3S)_2$ in the presence of NO. The sole reaction product is CH_3SNO, and it is formed linearly with time. There is no dark reaction either prior to or after irradiation. The quantum yields of CH_3SNO are given in Table 3. They are independent of pressure and have an average value of 2.04 ± 0.06.

Three experiments were also done in which $(CH_3S)_2$–NO mixtures were photolyzed at 280–300 nm in the presence of CH_3SH. The reaction conditions were $[CH_3SH] \simeq 8$ Torr, $[(CH_3S)_2] \simeq 10$ Torr, $[NO] \simeq 201$ Torr, $[Ar] \simeq 14$ Torr, and $I_a \simeq 0.49$ mTorr/s. One of these runs is shown in Fig. 5. There is no dark reaction, either prior to or following irradiation. During irradiation CH_3SNO is formed at a constant rate, its average quantum yield for the 3 experiments being 2.16 ± 0.14, based on the assumption that $\Phi\{CH_3SNO\} = 2.0$ in the absence of CH_3SH.

Discussion

The photolysis of CH_3SH at 254 nm is a clean source of CH_3S radicals. Inaba and Darwent (7) photolyzed CH_3SH with a medium pressure Hg arc and found the only important noncondensable gas to be H_2, with some CH_4 being formed in secondary processes. From this they concluded that the sole primary process was

$$CH_3SH + h\nu \rightarrow CH_3S + H \qquad \text{Rate} = I_a$$

Steer and Knight (1) came to the same conclusion. They found the quantum yield of H_2 with 254 nm radiation to be 1.00 ± 0.05 at low pressure and concluded that the above reaction proceeded with unit quantum yield. However, Bridges and White (5) obtained $\Phi\{H_2\} = 0.83 \pm 0.03$, $\Phi\{CH_4\} = 0.16 \pm 0.03$, and $\Phi\{(CH_3S)_2\} = 0.99 \pm 0.1$ with 254 nm radiation. From this they concluded that the quantum yield for the above reaction was only 0.93 and that CH_3 + SH was produced with a quantum yield of 0.07.

We have used the yield of $(CH_3S)_2$ as an actinometer, since a quantum yield of 1.0 for this compound is consistent with all three earlier studies. At low NO pressures, $\Phi\{H_2\}$ is close to 1.0, which supports the conclusion of Steer and Knight (1) and Inaba and Darwent (7) that the formation of CH_3S + H is the only primary process. However, if small amounts of CH_3 and SH are produced, our conclusions should not be affected significantly.

The H atoms produced can react with either NO or CH_3SH in well-known reactions:

[4] $\quad H + NO + M \rightarrow HNO + M$

[5] $\quad H + CH_3SH \rightarrow H_2 + CH_3S$

CH_3SNO is formed as a primary product. The indicated reaction is an addition of CH_3S to NO, which may be in the pressure fall-off region. Thus

[2*a*] $\quad CH_3S + NO \rightleftarrows CH_3SNO\dagger$

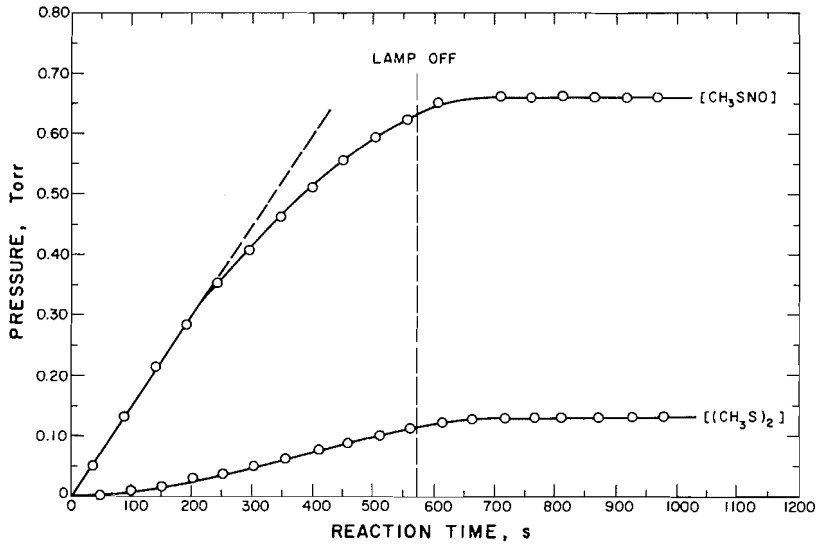

FIG. 1. Plot of product concentrations vs. reaction time for a mixture of 6.18 Torr CH_3SH, 6.00 Torr NO, and 15.4 Torr Ar at 23°C with I_a = 0.83 mTorr/s.

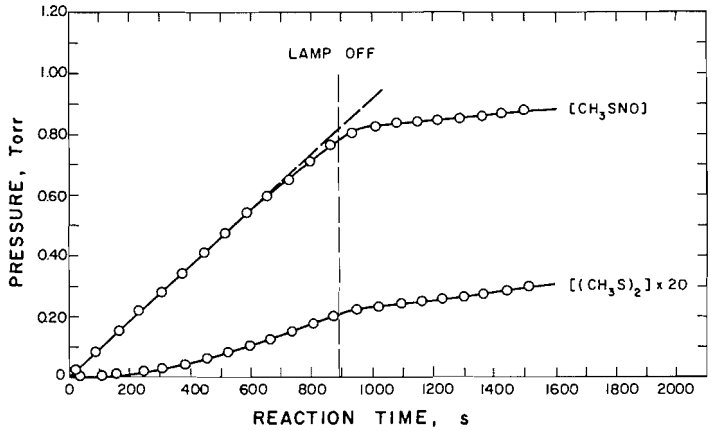

FIG. 2. Plot of product concentrations vs. reaction time for a mixture of 21.8 Torr CH_3SH, 50.0 Torr NO, and 16.3 Torr Ar at 23°C with I_a = 0.38 mTorr/s.

[2b] $CH_3SNO\dagger + M \rightarrow CH_3SNO + M$

The $(CH_3S)_2$ is formed with an induction period and thus is not a primary product. It cannot be formed by direct combination of two CH_3S radicals via reaction [3]. It must be formed by the reaction of CH_3S with a primary product. The indicated reaction is

[6] $CH_3S + CH_3SNO \rightarrow (CH_3S)_2 + NO$

The above reactions account for the formation of the measured products: CH_3SNO, H_2, and $(CH_3S)_2$. They do not account for the long chains or the post-radiation dark reaction observed under some conditions. Our results on the photolysis of $(CH_3S)_2$–NO mixtures in the absence or presence of CH_3SH show no chain or post-irradiation dark reaction. Thus these phenomena must be associated with the HNO species. In order to fit the data we need two reactions such as the following:

[7] $HNO + NO \rightarrow \text{adduct} \xrightarrow{CH_3SH} H + \xi CH_3S$

[8] $HNO \rightarrow \text{termination}$

where ξ is for the moment an unspecified stoichiometric factor. For the time being we shall leave reactions [7] and [8] in this form, and show that they lead to a mechanism that fits the data. These reactions will be discussed in more detail later. The reaction of two HNO species to give $H_2O + N_2O$ is omitted since we looked for, but could not find N_2O.

The mechanism leads to the following rate law for H_2 production:

$$[I] \qquad (\Phi\{H_2\}^{-1} - 1)^{-1} \frac{[NO][M]}{[CH_3SH]} = \frac{k_5}{k_4}\left(1 + \frac{k_7[NO]}{k_8}\right)$$

If [M] can be evaluated, then the left-hand side of eq. [I] can be computed and plotted vs. [NO]. We have evaluated [M] by using various efficiencies for NO, Ar, and CH_3SH as chaperone gases. The results are quite insensitive to the values chosen, and the expression

$$[M] \equiv [NO] + [Ar] + 3[CH_3SH]$$

fits the data as well as anything else. Figure 6 shows the appropriate plot for eq. [I]. The plot can be fitted by a straight line which gives least-square parameters for the intercept and slope of 626 ± 42 Torr and 7.64 ± 0.20 (uncertainties are one standard deviation). Thus k_5/k_4 = 626 ± 42 Torr and k_8/k_7 = 85.0 ± 7.8 Torr.

Equation [I] can be rearranged to:

$$[II] \quad \alpha(\Phi\{H_2\}^{-1} - 1)^{-1} = k_5[CH_3SH]/k_4[NO][M]$$

where

$$\alpha \equiv (1 + k_7[NO]/k_8)^{-1}$$

The left-hand side of eq. [II] can be computed using the value of k_8/k_7 obtained from eq. [I] and Fig. 6. This is plotted vs. $[CH_3SH]/[NO][M]$ on a log–log plot in Fig. 7. This plot extends the range of variables over that in Fig. 6. The data are force-fitted to a line of slope 1.0. The least-squares intercept of this plot gives log $(k_5/k_4) = 2.803 \pm 0.37$ or $k_5/k_4 = 636 \times/ 2.4$. While the uncertainty for k_5/k_4 is much greater from this plot than from Fig. 6, the value is essentially the same in the two plots. The reason for the larger uncertainty in Fig. 7 than in Fig. 6 is that, at large values of the ordinate, $\Phi\{H_2\} \simeq 1$, so that their difference has a large error.

Another way to estimate k_5/k_4 is to incorporate the data on CH_3SNO. In the initial phase of each run, all the CH_3S produced forms CH_3SNO. This fact leads to the rate law

$$[III] \quad \frac{(1-\alpha)\Phi\{H_2\}}{\Phi\{CH_3SNO\} - \Phi\{H_2\} - 1} = \frac{k_5[CH_3SH]}{\xi k_4[NO][M]}$$

The left-hand side of eq. [III] is computed using the value for k_8/k_7 obtained from eq. [I] and Fig. 6. It is plotted vs. $[CH_3SH]/[NO][M]$ in a log–log plot in Fig. 8. Again the data can be fitted by a line of slope 1.0. The intercept gives log $(k_5/\xi k_4) = 2.185 \pm 0.141$ or $k_5/\xi k_4 = 154 \times/ 1.38$ Torr. To make this value consistent with the value of $k_5/k_4 = 626 \pm 42$ Torr found from Fig. 1, ξ should be 4.1 ± 1.3 (1σ). A later discussion of the detailed mechanism for reaction [7] will suggest that ξ is likely to be 4.0. If so then Fig. 8 gives $k_5/k_4 = 616 \times/ 1.38$ Torr. The absolute value for k_4 with Ar as a chaperone has been reported to be 1.99×10^{-32} cm^6/s at 296 K (8). If we accept the value for k_5/k_4 to be 626 Torr, then $k_5 = 4.1 \times 10^{-13}$ cm^3/s.

Later in the reaction, $(CH_3S)_2$ is formed by reaction [6] giving rise to the rate law:

$$d[(CH_3S)_2]/dt = k_6[CH_3SNO][CH_3S]$$

Over most of the reaction, the rate of CH_3SNO formation is constant. Thus

$$[CH_3SNO] \simeq \Phi\{CH_3SNO\} I_a t$$

$$[CH_3S] = \Phi\{CH_3SNO\} I_a/\beta k_3[NO]$$

where $\beta \equiv (1 + k_{-2a}/k_{2b}[M])^{-1}$. Substitution of these expressions into the rate equation and integration gives

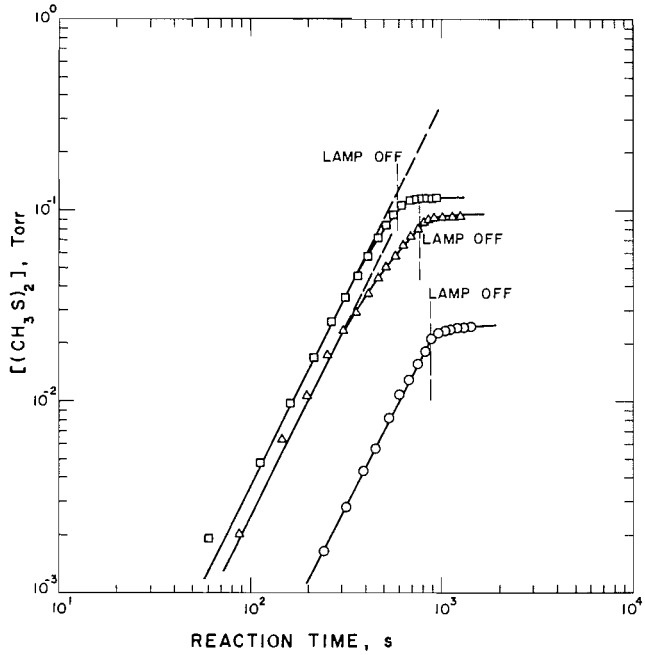

FIG. 3. log–log plot of the $(CH_3S)_2$ concentration as a function of reaction time: ○, $[CH_3SH]$ = 20.0 Torr, [NO] = 10.0 Torr, [Ar] = 16.9 Torr, I_a = 0.35 mTorr/s; △, $[CH_3SH]$ = 21.0 Torr, [NO] = 21.0 Torr, [Ar] = 15.7 Torr; I_a = 1.29 mTorr/s; □, $[CH_3SH]$ = 60.0 Torr, [NO] = 60.0 Torr, [Ar] = 15.0 Torr, I_a = 2.40 mTorr/s.

TABLE 3. Photolysis of $(CH_3S)_2$–NO mixtures at 253.7 nm

[NO] (Torr)	$[(CH_3S)_2]$ (Torr)	[Ar] (Torr)	I_a (mTorr/s)	$\Phi\{CH_3SNO\}$
5.4	9.62	14.2	1.72	2.02
11.9	9.22	16.5	1.65	2.08
30.0	2.46	14.9	0.44	2.06
30.0	5.30	14.2	0.95	1.96
30.1	9.08	15.0	1.62	2.14
49.6	10.05	20.3	0.62	2.14
50.0	9.76	15.4	1.74	2.03
100.0	14.0	19.5	0.85	1.93
198.2	9.00	14.8	1.61	2.01

$$[IV] \quad \frac{2[NO]\{[(CH_3S)_2]/t^2\}}{(\Phi\{CH_3SNO\}I_a)^2} = \frac{k_6}{k_{2a}}\left(1 + \frac{k_{-2a}}{k_{2b}[M]}\right)$$

If all the data are used to plot the left-hand side of eq. [IV] vs. $[M]^{-1}$, the data are very badly scattered. A somewhat better, but still badly scattered plot, is obtained if only the 12 data points involving the most accurate measurements of $[(CH_3S)_2]/t^2$, i.e. the runs giving the best straight line plots of $[(CH_3S)_2]$ vs. t^2, are used. This plot is shown in Fig. 9. The data are fitted by a least-squares line of intercept 0.84 ± 0.27 and slope = 0.069 ± 0.023 Torr. Thus k_6/k_{2a} = 0.84 ± 0.27 and k_{-2a}/k_{2b} = 83 ± 52 Torr.

Equation [IV] can be rearranged to

$$[V] \quad 2\beta\{[(CH_3S)_2]/t^2\} = k_6(\Phi\{CH_3SNO\}I_a)^2/k_{2a}[NO]$$

The left-hand side of this equation is plotted vs. $(\Phi\{CH_3SNO\}I_a)^2/[NO]$ for all of the data on a log–log plot in Fig. 10. This plot extends the range of variables over that in Fig. 9. The data are fitted to a line of slope 1.0 and the least-squares intercept gives log k_6/k_{2a} = −0.005 ± 0.30 or

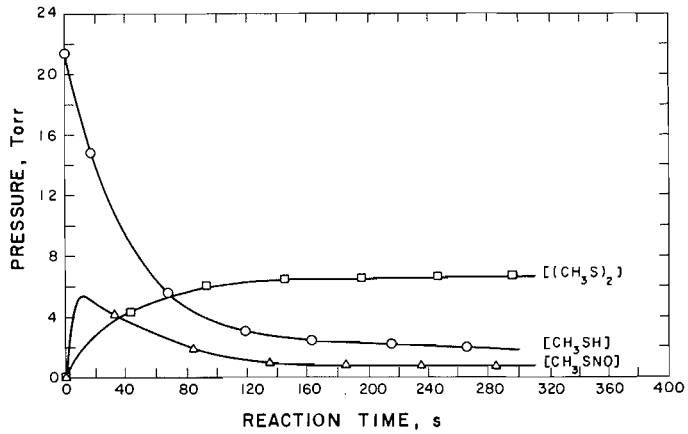

FIG. 4. Concentration profile vs. reaction time in the dark reaction of a mixture initially containing 21.4 Torr CH_3SH, 16.0 Torr NO_2, and 16.8 Torr Ar.

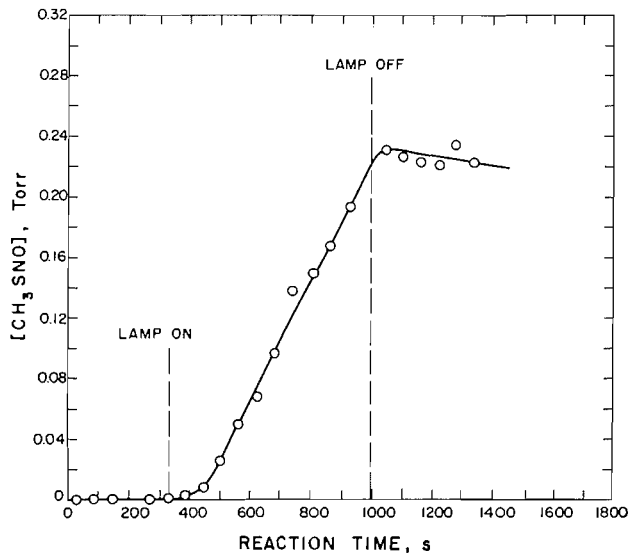

FIG. 5. Plot of $[CH_3SNO]$ vs. reaction time for the photolysis of 10.06 Torr $(CH_3S)_2$ at 280–300 nm in the presence of 7.54 Torr CH_3SH, 13.6 Torr Ar, and 200.8 Torr NO. I_a = 0.50 mTorr/s.

k_6/k_{2a} = 0.99 ×/ 2.0. This value is in good agreement with the value of 0.84 ± 0.27 obtained from Fig. 9. (If only the data from Fig. 9 are used in plotting Fig. 10, the intercept is −0.098 ± 0.148 or k_6/k_{2a} = 0.80 ×/ 1.4.)

A summary of the rate coefficient ratios obtained in our work is given in Table 4.

We now turn to a discussion of the reactions of HNO. In the presence of excess NO at room temperature, the known reactions are (9):

$$[9] \quad 2HNO \rightarrow N_2O + H_2O$$

$$[10a] \quad HNO + 2NO \rightarrow HNO_3 + N_2$$

$$[10b] \quad \rightarrow H + N_2 + NO_3 \xrightarrow{NO} 2NO_2$$

Reaction [9] is reported to be bimolecular with a rate coefficient ≃2.4 × 10^6 M^{-1} s^{-1} (10). However, we believe reaction [9] is too slow to be occurring in our system for two reasons: (*1*) our results are adequately fitted if the termination step is first-order in HNO, and (*2*) we looked for, but did not find N_2O as a product.

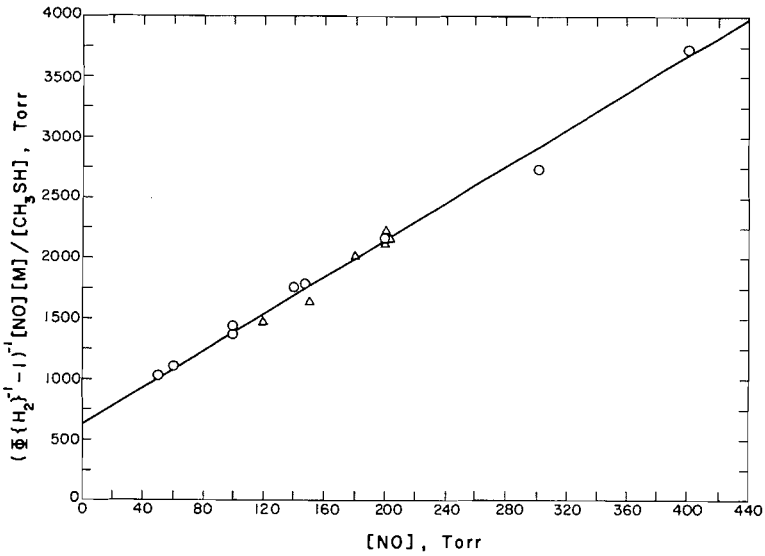

FIG. 6. Plot of $(\Phi\{H_2\}^{-1} - 1)^{-1}[NO][M]/[CH_3SH]$ vs. [NO]: △, 6.3 Torr CH_3SH; ○, 21 Torr CH_3SH.

Likewise we do not believe that reaction [10] is important in our system because the data are fitted by a termination step zero order in NO and not by one second order in NO. Reaction [10] proceeds in detail via:

[11] $HNO + NO \rightleftarrows H(NO)_2$

[12] $H(NO)_2 + NO \rightarrow HNO_3 + N_2$ or $H + N_2 + NO_3$

with reaction [12] being so slow that reaction [11] is always in equilibrium. We speculate that in the presence of CH_3SH, the $H(NO)_2$ intermediate is always intercepted by CH_3SH in a rapid reaction such as the following:

[13] $H(NO)_2 + 4CH_3SH \rightarrow$ 
$H + N_2 + 2H_2O + 4CH_3S$

The pair of reactions [11] followed by [13] leads to a reaction which is first-order in both HNO and NO (i.e. reaction [7]) and has the overall stoichiometry

[14] $HNO + NO + 4CH_3SH \rightarrow H + N_2 + 2H_2O + 4CH_3S$

This reaction also provides the rational for $\xi = 4$ in reaction [7].

The bond dissociation energy for the S—H bond of CH_3SH would have to be $\leq$79.3 kcal/mol for reaction [14] to be thermal neutral or exothermic based on the enthalpies of formation listed in Table 5. This is very much smaller than the value of $\geq$87.0 ± 2 kcal/mol obtained from the most recent measurement of ΔH_{298} for CH_3S (11).

It is possible for reaction [13] to be rapid and yet be $\simeq$32 kcal/mol endothermic. Reaction [13] involves the scission of seven bonds. These could proceed by seven successive steps, each of which is $\simeq$5 kcal/mol endothermic, and this could proceed readily at room temperature. However, another possibility is that the bond dissociation enthalpy for the S—H bond of CH_3SH is much weaker than 87 kcal/mol, since this value is in part computed, and is not obtained entirely from experimental measurements.

Further evidence that the bond dissociation energy for the S—H bond of CH_3SH may be <87 kcal/mol comes from our work on the thermal reaction of NO_2 with CH_3SH. Presumably this reaction is initiated by either:

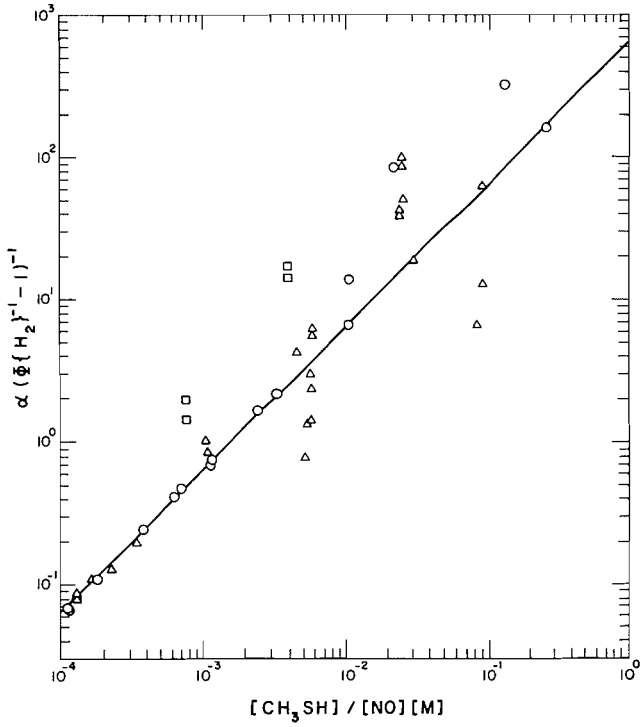

FIG. 7. log–log plot of $\alpha(\Phi\{H_2\}^{-1} - 1)^{-1}$ vs. $[CH_3SH]/[NO][M]$: △, 6.3 Torr CH_3SH; ○, 21 Torr CH_3SH; □, 60 Torr CH_3SH.

[15*a*] $CH_3SH + NO_2 \rightarrow CH_3S + HNO_2$

[15*b*] $\rightarrow CH_3SNO + HO$

Since the CH_3S—NO bond presumably is weaker than the HO—NO bond, reaction [15*b*] is energetically less favorable than reaction [15*a*]. For reaction [15*a*] to be thermal neutral or exothermic, the bond dissociation energy for S—H bond in CH_3SH would have to be $\leq$78.35 kcal/mol.

The details of the termination step, reaction [8], are not clear. One possibility is that HNO is removed by the wall in a

first-order process and then reacts with NO on the wall according to reaction [10]. In any event the removal reaction is one that does not produce N_2O as a product.

The reason for the post-irradiation dark reaction with high NO pressures has not been explained yet. We suspect that it comes from reaction of CH_3SH with NO_2, the NO_2 being

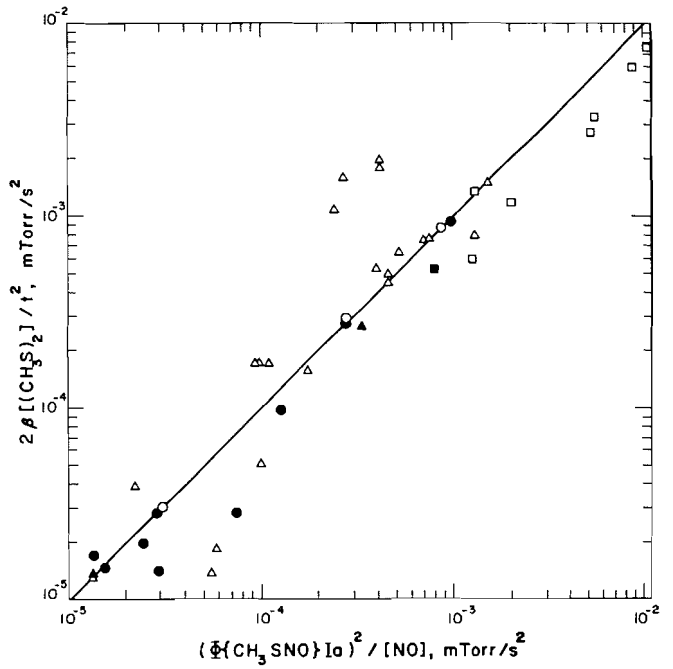

FIG. 10. log–log plot of $2\beta[(CH_3S)_2]/t^2$ vs. $(\Phi\{CH_3SNO\}I_a)^2/[NO]$. △, 6.3 Torr CH_3SH; ○, 21 Torr CH_3SH; □, 60 Torr CH_3SH. Filled symbols are for the 12 most reliable data points for $[(CH_3S)_2]/t^2$.

TABLE 5. Enthalpies of formation

Species	$\Delta H_f\{298\}$	Reference
H	52.103	12

The effect of pH and complexation on redox reactions between RS· radicals and flavins

RIZWAN AHMAD AND DAVID A. ARMSTRONG
Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received April 14, 1983

RIZWAN AHMAD and DAVID A. ARMSTRONG. Can. J. Chem. **62**, 171 (1984).

Elementary considerations indicate that thiol radicals, RS·, should have a high redox potential ($E_2^0 \sim 1.0$ V):

[2] $RS\cdot + e^- = RS^-$

However, the equilibrium [4],

[4] $RS^- + RS\cdot = RS\dot{S}R^-$

which is established in the presence of excess RS^-, would convert RS· to $RS\dot{S}R^-$, which is a reducing species. Experimentally it was demonstrated that thiol radicals made by γ radiolysis of β-mercaptoethanol solutions effected two-electron oxidation of dihydroflavin FlH_2 at pH 6.3 and of FlH^- at pH 8. On the other hand, $RS\dot{S}R^-$ readily reduced Fl to FlH_2 or FlH^- as expected. At pH 9, photostationary states were established after a few minutes radiolysis and the ratios $[FlH^-]_{ss}/[Fl]_{ss}$ were a function of $[RS\dot{S}R^-]/[RS\cdot]$. The main reactions occurring were:

[19] $Fl + RS\dot{S}R^- \rightarrow \cdot Fl^- + RSSR$

[−23] $2\cdot Fl^- + H^+ \rightarrow FlH^- + Fl$

[22] $FlH^- + RS\cdot \rightarrow \cdot Fl^- + RSH$

The values of k_{19} and k_{22} were both large. The ratio k_{19}/k_{22} was ~0.8 for lumiflavin and ~0.3 for flavin adenine dinucleotide.

The cyclic disulphide anions of lipoamide and dithiothreitol ($L\dot{S}_2^-$ and $D\dot{S}_2^-$) also effected two-electron reductions of flavins. However, the protonated form of $L\dot{S}_2^-$ (i.e. $L\dot{S}_2H$) oxidized FlH_2, and the photostationary ratio $[FlH^-]_{ss}/[Fl]_{ss}$ was an approximate linear function of $[L\dot{S}_2^-]/[L\dot{S}_2H]$. The implications of the observed changes in redox properties of sulphur radicals on complexation with RS^- and protonation were briefly considered.

RIZWAN AHMAD et DAVID A. ARMSTRONG. Can. J. Chem. **62**, 171 (1984).

Des considérations élémentaires indiquent que les radicaux thiyles, RS·, doivent avoir un potentiel rédox élevé ($E_2^0 \sim 1{,}0$ V):

[2] $RS\cdot + e^- = RS^-$

Cependant, l'équilibre [4]

[4] $RS^- + RS\cdot = RS\dot{S}R^-$

qui s'établit en présence d'un excès de RS^-, transforme RS· en $RS\dot{S}R^-$ qui est une espèce réductrice. On démontre expérimentalement que les radicaux thiyles produits par radiolyse aux rayons γ de solutions de β-mercaptoéthanol provoquent une oxydation à deux électrons de la dihydroflavine (FlH_2) à un pH de 6,3 et de la FlH^- à un pH de 8. Par ailleurs, le composé $RS\dot{S}R^-$ réduit facilement la Fl en FlH_2 ou en FlH^- tel qu'attendu. A un pH de 9 il s'établit des états photostationnaires après quelques minutes de radiolyse et les rapports $[FlH^-]_{ss}/[Fl]_{ss}$ dépendent du rapport $[RS\dot{S}R^-]$ [RS·]. Les principales réactions qui se produisent sont les suivantes:

[19] $Fl + RS\dot{S}R^- \rightarrow \cdot Fl^- + RSSR$

[−23] $2\cdot Fl^- + H^+ \rightarrow FlH^- + Fl$

[22] $FlH^- + RS\cdot \rightarrow \cdot Fl^- + RSH$

Les valeurs de k_{19} et de k_{22} sont élevées. Le rapport k_{19}/k_{22} est de ~0,8 pour la lumiflavine et de ~0,3 pour le dinucléotide flavine adénine. Les anions disulfures cycliques du lipoamide et du dithiothréitol ($L\dot{S}_2^-$ et $D\dot{S}_2^-$) provoquent également des réductions à deux électrons des flavines. Cependant la forme protonée de $L\dot{S}_2^-$ ($L\dot{S}_2H$) oxyde la FlH_2 et le rapport photostationnaire $[FlH^-]_{ss}/[Fl]_{ss}$ est une fonction approximativement linéaire de $[L\dot{S}_2^-]/[L\dot{S}_2H]$. On considère brièvement les effets des changements observés dans les propriétés redox des radicaux sulfurés sur la complexation avec RS^- et sur la protonation.

[Traduit par le journal]

Introduction

Sulphur structures play important roles in the chemistry of redox proteins. In metal-containing enzymes, such as xanthine oxidase (1) and copper proteins (2), thiol groups frequently serve as binding ligands, while in other systems they may be involved as separate entities in the electron transport pathway. For example, in glutathione reductase, lipoamide dehydrogenase and thioredoxin reductase, for which the substrates themselves are sulphur-containing species, the electron transfer pathway in the direction of substrate oxidation is considered to be (3–5):

[1] $\text{Substrate} \xrightarrow{1} S{-}S \xrightarrow{2} Fl \xrightarrow{3} NAD^+$

Here the disulphide (S—S) is covalently bound to the protein, while the flavin (Fl) is strongly but non-covalently bound.

An understanding of the mechanisms of electron transport in such highly intricate systems clearly requires a knowledge of the relative redox potentials of the various sulphur species, and

of the effects on these of complexation and protonation. This publication is concerned with redox reactions of the thiol radical – thiolate ion couple:

[2] $RS\cdot + e^- = RS^-$

and the disulphide–disulphide anion:

[3] $RSSR + e^- = R\dot{S}SR^-$

The species RS· and $R\dot{S}SR^-$ are linked through the reversible reaction:

[4]/[−4] $RS\cdot + RS^- = R\dot{S}SR^-$

and, given time, equilibrium is readily established between them (6–8). As examples, values of K_4 are $1.8 \times 10^3\ M^{-1}$ for β-mercaptoethanol (6, 9) and $1.3 \times 10^3\ M^{-1}$ (8) for β-mercaptopropionic acid.

The standard reduction potential E^0 for reaction [5] with typical biological thiols

[5] $RSSR + 2H^+ + 2e^- = 2RSH$

like cysteine and glutathione is about 0.074 V (10). From this and the thiol pK, which is typically 8.3 (e.g. for cysteine (11)), it can be shown that $E^0_{5a} = -0.42$ V. If one takes D as the free energy of dissociation of the disulphide bond in reaction [6]

[5a] $RSSR + 2e^- = 2RS^-$

[6] $RSSR = 2RS\cdot$

in solution in J mol^{-1}, elementary thermodynamics then leads to $E^0_2 = -0.41 + d$, $E^0_3 = -0.24 - d$ and $E^0_7 = -0.19 + d$, where $d = D\ (2 \times 96487\ c\ mol^{-1})^{-1}$ and reaction [7] is:

[7] $R\dot{S}SR^- + e^- \rightarrow 2RS^-$

Unfortunately D is not a readily measurable quantity. However, as a first approximation one may neglect the entropy change in reaction [6] and set D equal to the S—S bond dissociation energy. That quantity has been reported (12) to be 280 ± 25 kJ mol^{-1}, and d is therefore about +1.5 V. Thus, despite the present approximation, it is evident that: E^0_2 (~+1.1 V) and E^0_7 (~+1.3 V) are positive, while E^0_3 (~−1.7 V) is strongly negative.

The large magnitudes of E^0_3 and E^0_7 would suggest that $R\dot{S}SR^-$ might serve as both a powerful oxidant and reductant. While this is true in a thermodynamic sense, $R\dot{S}SR^-$ is not expected to be capable of rapid reactions as an electron acceptor. This is because the additional electron must enter an antibonding orbital, and the energy of the —S—S— system would be prohibitively high until dissociation occurred. No such restriction applies to electron loss, and from a *dynamic point of view* $R\dot{S}SR^-$ should therefore be primarily a reductant. This is borne out in its reaction with oxygen and several other substances (11). On the other hand, the large positive value of E^0_2 indicates the role of a general oxidant. In this study we shall demonstrate the transition between these characteristics for RS· and $R\dot{S}SR^-$, using as references the flavin half reactions:

[8] $Fl + H^+ + e^- = \cdot FlH;\quad E^0_8 = 0.17$ (13)

and

[9] $\cdot FlH + H^+ + e^- = FlH_2;\quad E^0_9 = 0.22$ (13)

Two reports of one electron transfer from $R\dot{S}SR^-$ species to Fl have already been made (14, 15).

One other point deserves further attention here. While $R\dot{S}SR^-$ anions formed by reaction [4] are highly unstable with respect to reaction [−4] (8), those made by electron attachment to protein-bound S—S groups are stabilised by the tertiary protein structures and have been seen to have lifetimes extending into the 1 s range (16). This stabilisation can be simulated with small molecules, if the disulphide group is present in a ring having three or four aliphatic carbon atoms. In the case of lipoic acid or lipoamide:

which we shall abbreviate to LS_2, both the anion $L\dot{S}_2^-$ and its conjugate acid $L\dot{S}_2H$ are believed to be cyclic in structure (8, 14, 17, 18). This is also true of the anion of dithiothreitol DS_2 (19). The pK's for protonation of both $L\dot{S}_2^-$ and $D\dot{S}_2^-$ are in the region of 5.4–5.6 (14, 17–19). Also either anion can be produced by H atom abstraction from the disulphydryls $L(SH)_2$ and $D(SH)_2$ (14, 18, 19), for example:

[10] $L(SH)_2 + \cdot OH(\text{or } H\cdot) \rightarrow L\dot{S}_2H + H_2O\ (\text{or } H_2)$

[11] $L\dot{S}_2H = H^+ + L\dot{S}_2^-$

In the present study the directions and stoichiometry of electron transfer between flavins and $D\dot{S}_2^-$, $L\dot{S}_2^-$, and $L\dot{S}_2H$ were also investigated. These and the other sulphur radicals RS· and $R\dot{S}SR^-$ were produced by ^{60}Co γ radiolysis through the sequence of reactions

[12] $4.2\ H_2O \xrightarrow{^{60}CO\,\gamma} 2.7\ e^-_{aq} + 0.5\ H\cdot + 2.8\ \dot{O}H + 2.7\ H^+_{aq} + 0.5\ H_2 + 0.7\ H_2O_2$

[13] $e^-_{aq} + N_2O + H_2O \rightarrow N_2 + OH^- + \cdot OH$

[14] $\cdot OH\ (\text{or } H\cdot) + RSH \rightarrow H_2O\ (\text{or } H_2) + RS\cdot$

[12]–[13]–[14] or [12]–[13]–[10]–[11]. As in earlier studies (14, 17–21) solute concentrations were adjusted so that ·OH, H·, and e^-_{aq} did not react directly with the flavin. The two flavins used were lumiflavin (LFl) and flavin adenine dinucleotide (FAD). A preliminary report of a small part of this work was presented in 1982 (15). The inspiration for it came partly from ref. 14.

Experimental

Materials

Lumiflavin, flavin adenine dinucleotide, lipoamide, β-mercaptoethanol, and β-mercaptopropionic acid were obtained from Sigma Chemical Company. Reduced dithiothreitol was from Kodak Chemical Company. Dihydrolipoamide was made by the method of Reed *et al.* (22). The water for preparing solutions was redistilled, first from alkaline permanganate and then from acid dichromate.

Apparatus and procedure

All experiments were conducted at room temperature (24 ± 1°C) with solutions containing 5 mM phosphate buffer. Irradiations were performed in an A.E.C.L. ^{60}Co γ cell with a steady dose rate of ~15 grays per min. This was checked periodically as described earlier (20). Oxidation and reduction of flavins was followed by recording the spectra of the solutions on a Cary 219 UV-Visible spectrophotometer. Extinction coefficients used were 12320 at 440 nm and 11300 at 450 nm for LF and FAD, respectively (21).

Precautions were taken to prevent air oxidation in the preparation of sulphydryl solutions. The buffer solution and other solutions were placed in the volumetric flask and then the RSH or $D(SH)_2$ was added. Immediately after that the solution was deaerated with N_2O, which had been passed through a "ridox" column supplied by the Fisher Scientific Company. In the case of $L(SH)_2$ the solution was deaerated

For personal use only.

before adding the sulphydryl. Finally the pH was adjusted by adding NaOH or $HClO_4$.

Calculation of moles of sulphur radicals produced

As explained in ref. 15*b*, the number of mol per L of radicals produced, e, was calculated with the equation:

$$[15] \qquad e = 1.04 \times 10^{-7}\, Qt\,(g_r + aG^{M}_{H_2O_2})$$

Here Q was the dose rate in grays per min; t, the radiation time; g_r, the number of radicals formed per 100 eV of radiation energy; and $G^{M}_{H_2O_2}$, the yield of hydrogen peroxide in molecules per 100 eV. The inclusion of this term was necessary because H_2O_2 oxidised FlH_2 in a 1:1 stoichiometry (15*b*). The coefficient a has values of +2 and −2 for oxidising the reducing radicals, respectively, for pH ≤ 8. From data in ref. 23 it can be shown that above pH 8 reaction with RS^- would remove H_2O_2, and therefore a can be set equal to zero. The magnitudes of g_r and $G^{M}_{H_2O_2}$ were taken from the data of Draganić and Draganić (24) or from published yields of $G(LS_2)$ in lipoate (14) or lipoamide (18) solutions. Typical values were 6.0 and 0.6 for 2 m*M* formate and 6.3 and 0.6 for 2 m*M* lipoamide, respectively.

Results

Thermal reactions

A number of experiments were carried out to check the rate of the thermal reduction of the flavins by lipoamide and mercaptans. In agreement with the earlier data of Gascoigne and Radda (25) and others (26)[1] the rates were found to be negligible below the p*K* of RSH. Even at pH 10, where the thiol groups were ionised, with typical conditions of 2 m*M* $L(SH)_2$ and 20 μ*M* Fl the half life of reaction [16] was still several hours. Since our radiolysis experiments were complete in ~20

$$[16] \qquad L(SH)_2 + Fl \rightarrow LS_2 + FlH^- + H^+$$

min, the thermal reactions could be neglected. One may note that p*K* of FlH_2 is ~6.7 (13), so that at pH 7 it would be present mainly as FlH^-.

Reduction with $L\dot{S}_2^-$ and $D\dot{S}_2^-$ at pH 7

The changes in absorbance which occurred in the wavelength region 250 to 520 nm on treatment of 14.6 μ*M* lumiflavin with $L\dot{S}_2^-$ radicals are shown in Fig. 1*a*. As in our earlier study with $\cdot CO_2^-$, the initial flavin spectrum with peaks at ~365 and ~440 nm was bleached during each successive exposure to $L\dot{S}_2^-$ until finally the spectral changes ceased. This has been illustrated in Fig. 2*a*, where the decrease in absorbance, ΔA, at 440 nm has been plotted against the ratio of the number of equivalents of $L\dot{S}_2^-$ produced per L of solution to the initial molar concentration of flavin. A similar titration plot for a more concentrated LFl solution has also been presented.

As will be demonstrated below, the spectrum after irradiation (dashed line, Fig. 1*a*) was indicative of FlH^- formation. This was consistent with the fact that the initial spectrum of Fl was restored on admission of air (dotted line). The small increase in absorbance in the 290 to 370 nm region can be attributed to the LS_2 produced in the overall reaction:

$$[17] \qquad 2L\dot{S}_2^- + Fl + H^+ \rightarrow 2LS_2 + FlH^-$$

This compound has negligible absorption above 400 nm and a maximum at 330 nm with $\epsilon = 127\ M^{-1}\ cm^{-1}$ (Fig. 1*b*). Hence by taking into account excess absorbance at 330 nm after oxidation with air, one can calculate the LS_2 concentration and thence obtain a corrected spectrum of the reduced flavin product per se. This has been presented in Fig. 1*b*, where it has been

[1] Loechler and Hollocher cite other studies in ref. 26.

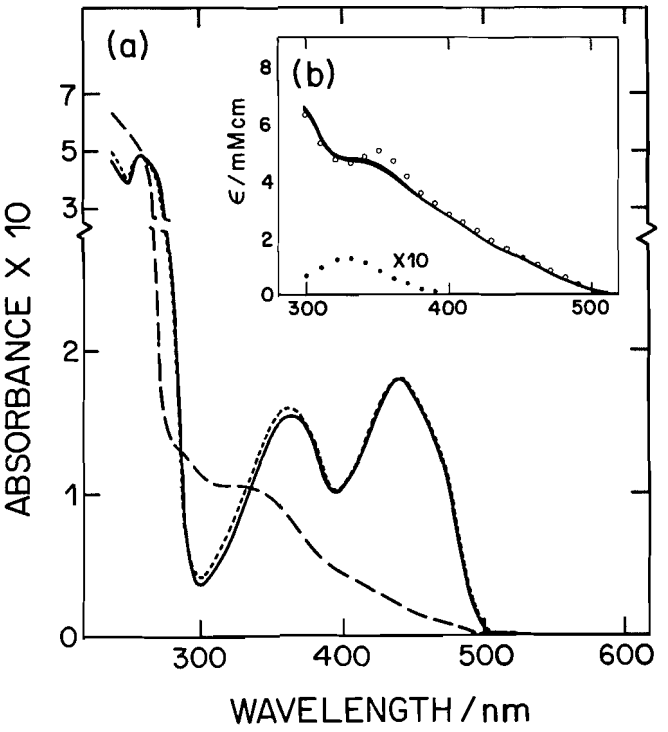

FIG. 1. (*a*) Spectra obtained from N_2O saturated solution of 14.61 μ*M* LF in 2 m*M* $L(SH)_2$ at pH 6.9 before irradiation (—), when the spectral changes ceased (– – –) and after addition of air to the irradiated solution (- - -). (*b*) Spectrum of fully reduced flavin ($LFlH^-$) obtained by: $\cdot CO_2^-$ reduction (thick line), $L\dot{S}_2^-$ reduction (open circles). The dots are the spectrum of LS_2.

compared with the spectrum of FlH^- prepared by $\cdot CO_2^-$ reduction under otherwise similar conditions. Both are the mean of replicate determinations, with extremes of the deviations for $\cdot CO_2^-$ shown by the thickness of the line.

Although it could be argued that the peak at 350 nm was due to insufficient correction for absorbance by LS_2 in some instances, it was observed repeatedly with $L\dot{S}_2^-$, being of the same magnitude over the pH range studied (see below). A similar peak was seen with FAD and $L\dot{S}_2^-$ and with both flavins and $D\dot{S}_2^-$ as reductant. This suggests that some addition compounds, e.g. H—Fl—SLSH, were formed, since thiol C-4a adducts of flavins have absorption maxima in that region with ϵ_{max} ~8000 M^{-1} cm^{-1} (27). The weakness of the present absorption peak demonstrates that the product was largely (≳85%) FlH^-. Also, unlike the addition products observed with aliphatic carbon radicals (15*b*), the flavin derivatives formed here were all readily converted to Fl by air oxidation.

Similar absorption changes were seen following reaction of LFl with $D\dot{S}_2^-$, and FAD with $L\dot{S}_2^-$ and $D\dot{S}_2^-$. Using the absorbance coefficients of the products at 440 nm from Fig. 1*b* and at 450 nm from an analogous plot for FAD and the known absorbance coefficients of the flavins, one can calculate the percentage of flavin reacted when spectral changes ceased. These percentages have been summarised in Table 1. For each case where there was 98+% conversion, η, the number of radicals reacting per flavin, was calculated from the break in the titration plot (see arrows, Fig. 2*a* and *c*). For lower conversions it was found from the initial slope of a plot of Δ[Fl] versus e (Cf. Fig. 2*b*). Values of η have also been listed in Table 1. For $L\dot{S}_2^-$ the percentage reduction and η were independent of LFl or $L(SH)_2$ concentration.

TABLE 1. Flavin reduction at pH 7

$[Fl]_0/\mu M$	Radical	Radical source (Conc./mM)	η, radicals reacted per Fl molecule	Percent Fl reacted at steady state
LFl				
15–20	$\cdot CO_2^-$	HCO_2^- (2.0)	2.1*	99+
15	$L\dot{S}_2^-$	$L(SH)_2$ (2.0)	1.8	99
28	$L\dot{S}_2^-$	$L(SH)_2$ (2.0)	1.9	98
21	$D\dot{S}_2^-$	$D(SH)_2$ (2.0)	4.2	~60
FAD				
4.8	$L\dot{S}_2^-$	$L(SH)_2$ (0.4)	2.1	99
4.5	$L\dot{S}_2^-$	$L(SH)_2$ (0.8)	2.1	98
5.2	$L\dot{S}_2^-$	$L(SH)_2$ (1.5)	1.9	98
19	$D\dot{S}_2^-$	$D(SH)_2$ (1.0)	2.8	~84

*From ref. 21.

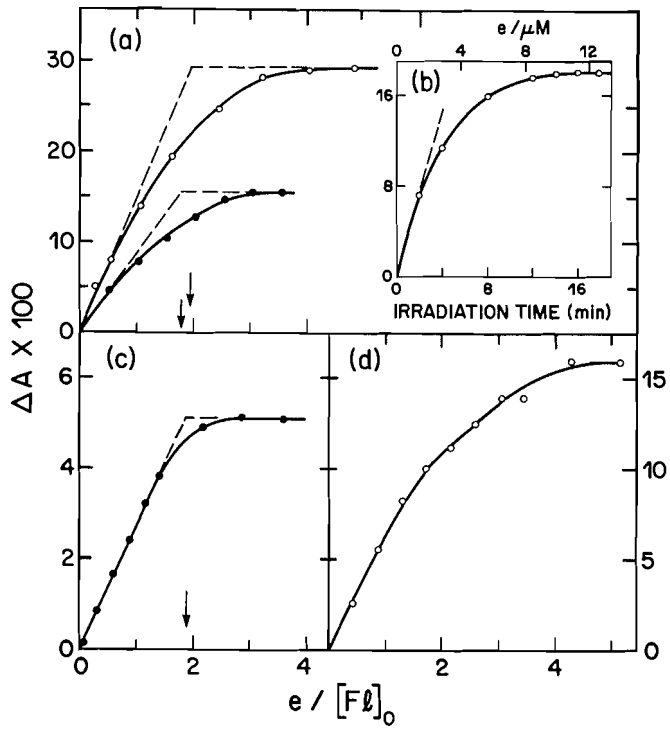

FIG. 2. Change in absorbance of flavin versus equivalents of reducing species produced by γ radiation in N_2O saturated solutions of 1–2 mM $L(SH)_2$ or $D(SH)_2$ and 13.5 mM RSH. (*a*) $L\dot{S}_2^-$ + LFl 27.5 μM (○) and 14.6 μM (●); (*b*) $RSSR^-$ + LFl 24.2 μM; (*c*) $L\dot{S}_2^-$ + FAD 5.2 μM; (*d*) $D\dot{S}_2^-$ + FAD 18.7 μM; pH = 9 in (*b*) and 7 for all others; dose rate = 1.4 gray min^{-1} in (*c*) and 12–16 gray min^{-1} otherwise.

Plots of absorbance changes for FAD titrated with $L\dot{S}_2^-$ and $D\dot{S}_2^-$ are presented in Fig. 2*c* and *d*.

The pH dependence of reactions with $R\dot{S}SR^-$ and RS·

Similar spectral changes and complete return to Fl on subsequent addition of air were also observed in RSH solutions at pH 9 and 10. However, as illustrated in Fig. 2*b* for 24.2 μM LFl in 13.5 mM β-mercaptoethanol at pH 9, the extent of reduction when steady state was reached at RSH concentrations in the range 2–15 mM was never complete.

The concentrations of flavin and reduction product at steady state were calculated from the changes in absorption as described above. The ratios $[FlH^-]/[Fl]$ at steady state have been plotted in Fig. 3 against the ratio $y = [R\dot{S}SR^-]/[RS\cdot]$. This was calculated from expression [18].

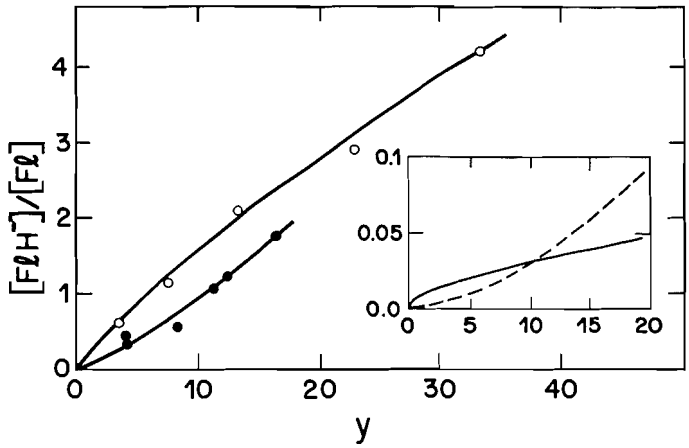

FIG. 3. The ratio of $[FlH^-]$ to [Fl] at stationary state obtained on γ radiolysis plotted as a function of y, the ratio of $[R\dot{S}SR^-]/[RS\cdot]$, for: 20 μM LFl (closed symbols; abscissa scale × 0.1) and FAD (open symbols). Inset: plots of $[\cdot Fl^-]_{ss}/[Fl]_{ss}$ (—) and $y[\cdot Fl^-]_{ss}/[Fl]_{ss}$ (– – –) versus y.

$$[18] \qquad [R\dot{S}SR^-]/[RS\cdot] = [\text{Total RSH}] \times K_4 \times \{1 + [H^+]/K_i\}^{-1}$$

The required assumption that reactions [4] and [−4] were sufficiently rapid to maintain equilibrium [4] can be justified from rate constants in refs. 6 and 8. The term K_i is the thiol ionisation constant. The results of similar experiments with 20 μM FAD at pH 9 have also been given. The steady-state ratios $[FlH^-]_{ss}/[Fl]_{ss}$ in all cases increased with y. The form of that increase will be discussed later. For all of the reductions reported in Fig. 3 the values of η from initial slopes of plots like that in Fig. 2*b* were 2.0–2.5.

In earlier work with β-mercaptoethanol and FAD at pH 7, where $[R\dot{S}SR^-]/[RS\cdot]$ is several hundredfold less than at pH 10 (K_i of β-mercaptoethanol $\simeq 10^{10}$ (6, 9)), we actually observed *oxidation* of FAD dihydroflavin by RS· (15*b*). Using the same procedure of reduction with $\cdot CO_2^-$ followed by addition of RSH, in the present series of experiments we demonstrated that the RS· radicals from a second thiol — β-mercaptopropionic acid — also oxidised the dihydroflavin of FAD. Oxidation with $\eta = 2.0–2.4$ was observed at pH 6.3, 6.9, and 8.1 in solutions containing 20 μM FlH_2 and 0.28 M RSH. However, at pH 9, where the ratio $[R\dot{S}SR^-]/[RS\cdot]$ would have become significant, oxidation did not occur.

Effect of pH on steady-state reduction with $L\dot{S}_2^-$ and $L\dot{S}_2H$ radicals

The pH dependence of the fraction of flavin reduced at steady state was examined in N_2O saturated solutions, which contained 16 to 24 μM LFl, 2 mM $L(SH)_2$, and 5 mM phosphate buffer. Concentrations of Fl and FlH_2 were calculated from absorbances at 440 nm as above. The values of η from initial slopes were in the region 1.8 to 2.2. The results have been shown as triangles in Fig. 4. The solid line is a pK curve with a pK value of 5.5.

Discussion

Reactions of RS· and $R\dot{S}SR^-$

The increase in the extent of reduction of flavin with the rise

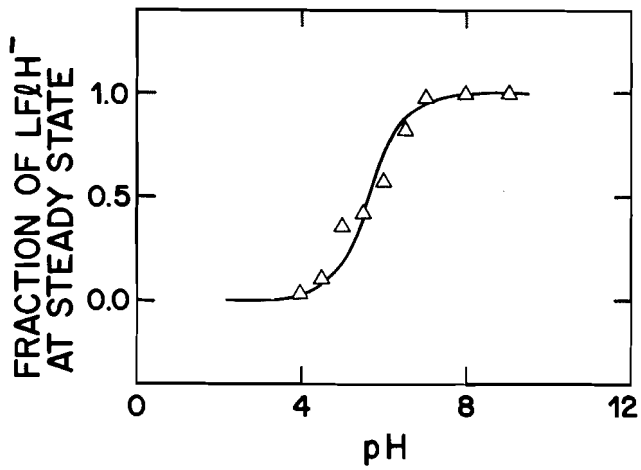

FIG. 4. Fraction of flavin present in reduced form, when stationary state was reached in the γ radiolysis of N_2O saturated 16–24 μ*M* LFl solutions containing 2 m*M* $L(SH)_2$ and 5 m*M* phosphate buffer, plotted as a function of pH.

in $[R\dot{S}SR^-]/[RS\cdot]$ in Fig. 3 demonstrates that $R\dot{S}SR^-$ reduces Fl. The first step in that process must be

[19] $\quad R\dot{S}SR^- + Fl \rightarrow RSSR + \cdot Fl^-$

(The $\cdot Fl^-$ form of the radical predominates at pH 9, because the p*K* is ~8.4 (13).) Independent evidence for reaction [19] has recently been obtained from a pulse radiolysis study at pH 9 and 10, which gave k_{19} values of 4×10^8 for FAD at pH 9 and 7×10^8 and $\sim 2 \times 10^8\ M^{-1}\ s^{-1}$ for LFl and FAD respectively at pH 10 (28). Thus the original observation of a reaction between lipoate $L\dot{S}_2^-$ and FAD by Chan, Chan, and Bielski (14) has now been extended to include $R\dot{S}SR^-$ ions and $D\dot{S}_2^-$ (15), and can be considered a general reaction of —S—$\dot{S}^-$-anions and flavins. Likewise the oxidation of FlH_2—FlH^-, which was reported earlier for $HOCH_2CH_2S\cdot$ radicals at pH 7 (15*b*) and confirmed here for $\cdot SCH_2CH_2CO_2^-$ radicals at pH 6.3, 7, and 8.0, now appears to be a general characteristic of thiyl radicals.

In addition to the primary reactions of $R\dot{S}SR^-$ with Fl and of $RS\cdot$ with FlH^-, one must examine the possibility that the overall two-electron reductions at pH 9 involve reactions between these sulphur radicals and flavin radicals. The reactions which must be considered are therefore [4], [19], and [20] to [23]:

[20] $\quad R\dot{S}SR^- + \cdot Fl^- + H^+ \rightarrow RSSR + FlH^-$

[21] $\quad RS\cdot + \cdot Fl^- \rightarrow RS^- + Fl$

[22] $\quad RS\cdot + FlH^- \rightarrow RS^- + \cdot Fl^- + H^+$

[23]/[−23] $\quad Fl + FlH^- = 2 \cdot Fl^- + H^+$

The fact that the initial values of η were never significantly less than 2 rules out the possibility of reaction [−22], which would have caused a chain reduction of Fl and low values of η. The absence of evidence for this process is consistent with the large

[−22] $\quad RS^- + \cdot Fl^- + H^+ \rightarrow RS\cdot + FlH^-$

positive value estimated for E_2^0 in the Introduction. Likewise there is no evidence for $RS\cdot$ addition to Fl or of $\cdot Fl^-$ + RSSR reactions.

A consideration of the kinetic equation for the above reactions when steady $[FlH^-]_{ss}$ and $[Fl]_{ss}$ have been reached, yields eq. [24]:

$$[24] \qquad \frac{[FlH^-]_{ss}}{[Fl]_{ss}} = \frac{k_{19}y}{k_{22}} + \frac{k_{20}}{k_{22}} \times y\frac{[\cdot Fl^-]_{ss}}{[Fl]_{ss}} - \frac{k_{21}}{k_{22}} \times \frac{[\cdot Fl^-]_{ss}}{[Fl]_{ss}}$$

The second and third terms on the right hand side are concerned with the radical + radical reactions, and for the following reasons are expected to be small relative to the first at any $[FlH^-]_{ss}/[Fl]_{ss}$ in Fig. 3. From the known magnitude of $k_{-23} = 3 \times 10^8\ M^{-1}\ s^{-1}$ (28) and the dose rate used one can show that the value of $[\cdot Fl^-]_{ss}$ would be 0.02 μ*M*, if reactions [23], [20], and [21] were neglected. The highest possible $[\cdot Fl^-]_{ss}$ would be realised if the equilibrium [23]/[−23] were maintained, giving

$$[\cdot Fl^-]_{ss} = \sqrt{K_{23}[Fl]_{ss}[FlH^-]_{ss}}$$

Taking $K_{23} = 10^{-3}$ at pH 9 (calculated from eq. [2] and the parameters for lumiflavin —3-CH_2COO^- in ref. 29) one can show that $[\cdot Fl^-]$ would not exceed 0.4 μ*M* when the total flavin concentration is 20 μ*M*. The calculated values of $y \times [\cdot Fl^-]_{ss}/[Fl]_{ss}$ and $[\cdot Fl^-]_{ss}/[Fl]_{ss}$ which apply to the reduction of LFl in Fig. 3 have been plotted as a function of *y* in the insert. The first of these is seen to rise more slowly, but eventually it crosses the second and increases very rapidly. Both are less than 0.03 over the range of *y* from zero to ten.

A detailed analysis of the plots in Fig. 3 is not possible, because specific values of K_{23} are lacking and too many rate constants are unknown. However, the curvature exhibited by the points for FAD suggests that the third term in eq. [24] is more important than the second (i.e. k_{21}/k_{22} is probably larger than k_{20}/k_{22}), while the opposite appears true for LFl. Approximate values of k_{19}/k_{22} obtained from the initial slopes of the experimental points in Fig. 3 where $[\cdot Fl^-]_{ss}/[Fl]_{ss}$ is small are 0.8 for LFl and 0.3 for FAD, respectively. From the magnitudes of k_{19} noted above it follows that k_{22} is in the region of 0.5 to $2 \times 10^9\ M^{-1}\ s^{-1}$ for these flavins. It is hoped that some of the other rate constants may be determined by independent techniques.

Reactions of $L\dot{S}_2^-$ and $L\dot{S}_2H$

The magnitudes of η in Table 1 and the spectral changes described in the second section of Results have demonstrated that, like $\cdot CO_2^-$, $L\dot{S}_2^-$ radicals effect a two-electron reduction of FAD and LFl in accord with reaction [17] at pH 7. The reactions responsible must be [19*l*], [23], and possibly also [20*l*].

[19*l*] $\quad L\dot{S}_2^- + Fl + H^+ \rightarrow LS_2 + \cdot FlH$

[20*l*] $\quad L\dot{S}_2^- + \cdot FlH \rightarrow LS_2 + FlH^-$

The role of [20*l*] cannot at present be assessed, since its rate constant has not been determined. However, the spectral evidence for a small amount of C4-a HSLS—FlH adduct (Fig. 1*b*) suggested that some radical + radical reactions had occurred as follows:

[20′*l*] $\quad L\dot{S}_2^- + \cdot FlH \rightarrow {}^-SLS—FlH$

Recent investigations (25, 26) of reaction [16] imply that such adducts decompose to $FlH^- + LS_2$, which would give the same stoichiometry as reaction [20*l*].

Although the rate constant for reaction of $D\dot{S}_2^-$ with FAD ($=9 \times 10^8\ M^{-1}\ s^{-1}$ (15)) is similar to k_{19l} ($=2.4 \times 10^8\ M^{-1}\ s^{-1}$ (14)), the percentage reduction observed at steady state was much less for the former (see Table 1). The same pattern was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

observed with LFl. It is apparent therefore that reactions other than [19*l*], [20*l*], and [23] can occur, and that their relative importance varies from one disulphide anion to the next. This is also seen from a comparison of the titration plots in Fig. 2*a*, *c*, and *d*. From those the titration of FAD by $L\dot{S}_2^-$ (Fig. 2*c*) was most efficient, as judged by the linearity of the ΔA versus $e/[Fl]_0$ plot.

As shown in Fig. 4 the fraction of flavin reduced to FlH_2 at steady state falls with decreasing pH. We attribute this to the fall off in the fraction of lipoamide radicals present in the deprotonated $L\dot{S}_2^-$ form. Also reaction [22*l*] and possibly also [21*l*] must occur, otherwise the yield of FlH_2 would have

[22*l*] $\quad L\dot{S}_2H + FlH_2 \rightarrow L(SH)_2 + \cdot FlH$

[21*l*] $\quad L\dot{S}_2H + \cdot FlH \rightarrow L(SH)_2 + Fl$

been maintained through the sequence [11]–[19*l*]–[23].

It is apparent that reactions [19*l*] to [22*l*] are analogous to [19] to [22] and that an equation similar to [24] should also apply here. Neglecting [20*l*] and [21*l*] because of the low value of $[\cdot FlH]_{ss}/[Fl]_{ss}$ as justified above, one has in first approximation: $[FlH_2]_{ss}/[Fl]_{ss} = yk_{19l}/k_{22l}$. When k_{19l}/k_{22l} is unity, this equation is equivalent to:

(Fraction of flavin as $FlH_2)_{ss}$ = (Fraction of radicals as $L\dot{S}_2^-$)

The pK of lipoamide $L\dot{S}_2^-$ has recently been found by us (18) to be 5.5, in good agreement with the published values for lipoic acid $L\dot{S}_2^-$ (14, 17). The solid line in Fig. 4 shows the fraction of radicals present as $L\dot{S}_2^-$, calculated from that pK. The fit to the observed values of (fraction of flavin as $FlH_2)_{ss}$ is excellent, indicating that k_{19l}/k_{22l} must be near unity. Since k_{19l} is $= 2.4 \times 10^8\ M^{-1}\ s^{-1}$ (14) it follows that k_{22l} is of a similar magnitude.

From pK_5 = 5.5 one can show that $E^0_{3'l}$ is 0.33 V larger than

[3′*l*] $\quad LS_2 + H^+ + e^- = L\dot{S}_2H$

[3*l*] $\quad LS_2 + e^- = L\dot{S}_2^-$

E^0_{3l}. Thus the failure of $L\dot{S}_2H$ to act as a reductant of Fl can be rationalised. However, its ability to oxidise FlH_2 deserves further comment. Reaction [22*l*] may proceed as written, or as an electron transfer,

[22′*l*] $\quad L\dot{S}_2H + FlH_2 \rightarrow LSH.S^- + FlH_2^+$

followed by proton exchange. However, both [22*l*] and [22′*l*] assume simultaneous breakdown of the cyclic $L\dot{S}_2H$ (see comment on $R\dot{S}SR^-$ as an oxidant in Introduction). This inhibitory requirement does not apply to ·H and e^- transfers of the non-cyclic LSH.S· radical, and its reactions should therefore be faster. Thus we cannot eliminate the possibility that a small proportion of that species is always in equilibrium with $L\dot{S}_2H$ and is in fact the oxidant. In the related case of $D\dot{S}_2H$ the relatively small absorbance near 390 nm (19) suggests that the open radical structure DSH.S· may actually dominate over the cyclic radical. If the oxidation of FlH_2 by DSH.S· is fast (i.e. $k \gtrsim 10^9\ M^{-1}\ s^{-1}$) the residual proportion of DSH.S· at pH 7 may be sufficient to cause the large values of η and low percentages of reductant seen in Table 1.

Summary

This study has confirmed the strong oxidising nature of the RS· radical and its conversion to a reducing species on complexation with RS^- to form $R\dot{S}SR^-$. In the cyclic stable disulphides protonation is seen to increase E^0. These findings are clearly of importance in considering the role of sulphur species in electron transfer mechanisms and structures of redox proteins. For example, in the specific case of the flavoproteins mentioned in the Introduction flavin and sulphur radical pair species have been considered (30) as possibly existing in the doubly reduced form of lipoamide dehydrogenase. From this study the

S· ·FlH

structure is seen to be unstable. Actually radical pair structures have been discarded in favour of forms with either doubly reduced disulphide or flavin. Careful spectrophotometric studies demonstrate that charge transfer and base interactions play very important stabilising roles (4, 5). The enzymatic reactions require fast transfer of e^-/H^+ pairs between the sulphur and flavin entities in these stable structures. The rapidity of the reactions observed between the flavin and sulphur species studied here (all reactions were close to the diffusion control limit) implies that $S\dot{S}^-$ anions coupled with ·FlH or $\cdot Fl^-$ radicals could be transitory intermediates. However, before the feasibility of sequential one electron transfers involving such species can be properly assessed, one must also examine interactions between thiolate ions and ·FlH or $\cdot Fl^-$, since these could markedly effect E^0_8 and/or E^0_9 and the rates of electron transfer. One thiol group in lipoamide dehydrogenase and glutathione reductase is known to be in close proximity to the flavin, and a charge transfer interaction between its ionised form and the flavin has already been postulated (3–5).

Influence of temperature and concentration on the densities and viscosities of solutions of $CsNO_3$ in a low-melting nitrate melt

MAURICE ABRAHAM AND MARIE-CHRISTINE ABRAHAM

Département de Chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal (Qué.), Canada H3C 3V1

Received May 12, 1983

MAURICE ABRAHAM and MARIE-CHRISTINE ABRAHAM. Can. J. Chem. **62**, 178 (1984).

The densities and viscosities of solutions of $CsNO_3$ in a low melting nitrate melt ($AgNO_3$ + $TlNO_3$) have been measured in the temperature range 371−403 K. The mole fraction X_{Cs} of $CsNO_3$ in the solution was varied between 0 and 0.1. The viscosities follow an Arrhenius relation:

$$\eta = A \exp (E^*/RT)$$

in which both ln A and E^* were found to be linear functions of X_{Cs}:

$$E^* \text{ (kJ mol}^{-1}) = 19.06X_{Cs} + 27.18$$

$$\ln A \text{ (cP)} = -4.273X_{Cs} - 5.687$$

These results are explained considering the preservation of ionic species in the mixtures when the mole fraction X_{Cs} is varied, and the assumption of the predominance of short range interactions.

MAURICE ABRAHAM et MARIE-CHRISTINE ABRAHAM. Can. J. Chem. **62**, 178 (1984).

On a mesuré les densités et les viscosités de solutions de $CsNO_3$ dans un mélange de nitrates à bas point de fusion ($AgNO_3$ + $TlNO_3$) dans l'intervalle de température 371−403 K. On a fait varier la fraction molaire X_{Cs} de $CsNO_3$ dans les solutions entre 0 et 0,1. Les viscosités obéissent à une relation d'Arrhénius:

$$\eta = A \exp (E^*/RT)$$

où ln A et E^* apparaissent tous deux comme des fonctions linéaires de X_{Cs}:

$$E^* \text{ (kJ mol}^{-1}) = 19{,}06X_{Cs} + 27{,}18$$

$$\ln A \text{ (cP)} = -4{,}273X_{Cs} - 5{,}687$$

Ces résultats s'expliquent par la conservation des espèces ioniques dans les mélanges quand on fait varier X_{Cs} et par la prédominance d'interactions à courte distance.

Introduction

Several studies have been recently performed on solutions where a molten ($AgNO_3$ + $TlNO_3$) eutectic mixture is the solvent (1, 2). The mole composition of this mixture is (3):

$AgNO_3$: 0.515, $TlNO_3$: 0.485

and its freezing point is 83°C.

Our understanding of the properties of molten salts mixtures is often restricted by a lack of precision in the measurements due to the high temperatures required to obtain the liquid states and associated technological difficulties. The above solvent gives solutions with other nitrates at low concentrations which lend themselves to investigations by experimental methods similar to those used at ordinary temperature.

In a study of solutions of $Cd(NO_3)_2$, simple empirical equations were found, giving the molar volume and viscosity as functions of the temperature and solute mole fraction (2).

The viscosity of a liquid is often expected to decrease with increasing temperature, following an Arrhenius type equation:

[1] $$\eta = A \exp (E^*/RT)$$

and this was again true with these solutions of $Cd(NO_3)_2$. But, for the first time, we believe, both the activation energy E^* and the logarithm of the preexponential factor A were found to be linear functions of the solute mole fraction X_{Cd}:

[2] $$E^* = \alpha X_{Cd} + \beta$$

[3] $$\ln A = \gamma X_{Cd} + \delta$$

in the solute mole fraction range $0 < X_{Cd} < 0.1$ and the temperature range $98 < \theta < 130$°C.

The sign of the parameters α, β, γ, and δ are equally noticeable:

$$\alpha, \beta > 0 \text{ and } \gamma, \delta < 0$$

When $Cd(NO_3)_2$ mole fraction increases, E increases whereas A decreases.

Before an answer can be brought to any question arising from these results, more experimental investigation is needed. In the present work, attention is focused on Cs^+ which is a cation with large ionic radius and polarizability (4). A study of the influence of temperature and solute mole fraction on the molar volume and viscosity of solutions containing this particular ion is made.

Experimental

The densities were measured by a picnometric method and the viscosities with an Ostwald−Ubbelhode viscometer. Most of the technological details, measurements procedures, origins of reagents, preparation and storage of solutions, purifications when necessary are given elsewhere (5). $CsNO_3$ from K and K Laboratories (99.9%) and from Aldrich Chemical Co. (99.99%) were used as received. Emphasis has been laid on improving the device to ensure perpendicularity of the capillary tube of the viscometer. The essential feature is the alignment of the capillary tube with respect to a metallic rod fixed up in a vertical position, with a plumb-line as a reference. For this reason the viscosities of the solvent itself have been measured again.

Results and discussion

Experimental values of the density ρ, molar volume V, and viscosity η are given elsewhere.[1]

The density and molar volume are related by

[4] $$V = (X_{Ag}M_{Ag} + X_{Tl}M_{Tl} + X_{Cs}M_{Cs})/\rho$$

Figure 1 shows that, at a given composition, the molar volume is a linear function of the temperature, in the range studied (100−130°C):

[5] $$V = aT + b$$

Values of the empirical parameters a and b are given for each composition in Table 1.

The viscosity conforms quite closely to eq. [1]. Figure 2 shows, for two compositions, an Arrhenius type plot of the viscosity:

[6] $$\ln \eta = f(1/T) = \ln A + E^*/RT$$

The preexponential factor A and activation energy E^* vary with the composition of the solution. Values of A and E^* are given for each composition in Table 2, together with those of the coefficient of correlation r for the fitting of ln η to eq. [6]. The effect of the solute mole fraction X_{Cs} on E^* and A, shown in Figs. 3 and 4, may be expressed by the equations:

[7] $$E^* \text{ (kJ mol}^{-1}) = 19.06X_{Cs} + 27.18$$

[8] $$\ln A \text{ (cP)} = -4.273X_{Cs} - 5.687$$

and the simultaneous effect of T and X_{Cs}, by the equation:

[9] $$\ln \eta \text{ (cP)} = -5.687 - 4.273\,X_{Cs} + 3269T^{-1} + 2292X_{Cs}T^{-1}$$

Cs^+ gives empirical linear relations as does Cd^{2+} previously studied (2). To explain this simple result, reference will be made to a closely related work (8). In the study of very concentrated aqueous solutions of nitrates simple additivity properties of the BET constants (6, 7) for the dissolution of water, were analysed (8). These properties were found to be compatible with several characteristics which are often met with in molten salts, and likely to appear when there is no chemical reaction or complex formation on mixing of the salts. It was put forward that the additivity properties of the BET constants may be the result of complete ionic dissociation in both single and mixed salts, the preservation of ionic species when the salts are mixed and the predominance of short range interactions in the phenomenon of adsorption of water. When water molecules come between a cation and its nearest neighbours, which are anions, the BET constants r_{BET} and E_{BET} depend particularly upon the nature of the cations and nearest anions neighbours. Surrounding cations which are further distant would influence r_{BET} and E_{BET} relatively little. Configurational characteristics reflected by r_{BET} and energetic characteristics reflected by E_{BET} would essentially be determined by the local environment. When one substitutes a cation M_1 for a cation M_0, one changes the local $r_{0,BET}$ to $r_{1,BET}$ and the local $E_{0,BET}$ to $E_{1,BET}$. The preservation of ionic species in mixtures means that the values of local $r_{0,BET}$, $r_{1,BET}$, $E_{0,BET}$, and $E_{1,BET}$ in mixtures are close to their values in single salt melts. Thus in a mixture one measures a mean of $r_{0,BET}$ and $r_{1,BET}$ and a mean of the products $(r_{0,BET}) \times (E_{0,BET})$ and $(r_{1,BET}) \times (E_{1,BET})$. Deviations from these additivity properties can be expected when the mixing takes place with chemical reactions.

In the above explanation one assumption should be underscored because it is likely to appear more and more important in the study of all kinds of highly ionic liquids, whether containing water or not: the predominance of short range interactions. Thus the same sort of explanation would hold good for some aspects of the present work on anhydrous molten nitrates. Although the electrostatic forces have long range effect, the net field action on an ion in a highly ionic liquid may be the result of the predominance of short range effects not purely ionic. The high density of packing ions and the lack of long range order in conjunction with the presence of holes (9−12) may produce compensation phenomena of long distance effects. We will consider that in a binary mixture of strongly ionic melts containing a common anion, the cations may be thought of as moving in a matrix of anions which continuously adjust their positions so that anions and cations move simultaneously to maintain electroneutrality. The Gibbs free energy of activation, ΔG^*, most of which is required to form the cationic holes for the particles to jump into, depends particularly upon the nature of the cations and nearest neighbours. Surrounding cations and anions which are further distant would influence ΔG^* relatively little, thus being essentially determined by the local

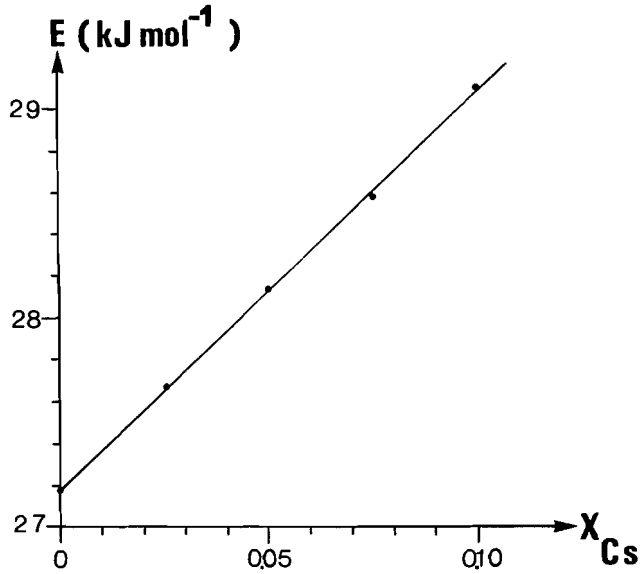

FIG. 3. The effect of the solute mole fraction on the activation energy.

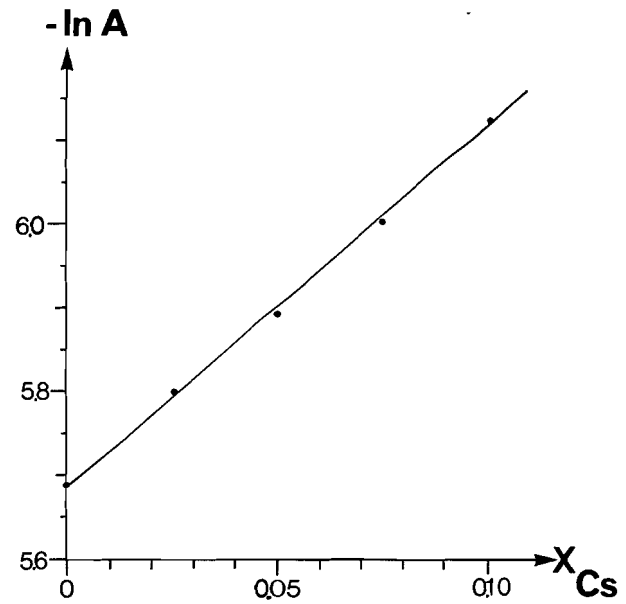

FIG. 4. The effect of the solute mole fraction on the preexponential factor.

environment. When one substitutes a cation M_1 for a cation M_0, one changes the local ΔG_0^* to ΔG_1^*. The preservation of ionic species in mixed melts, if there are no chemical reactions or complex formations, means that the local values of ΔG_0^* and ΔG_1^* in mixtures are close to their values in single salt melts. Thus, one measures a mean of ΔG_0^* and ΔG_1^*:

$$[10] \quad \Delta G^* = X_0 \Delta G_0^* + X_1 \Delta G_1^*$$

This equation can be interpreted in terms of entropy and enthalpy contributions, the latter being close to the energy ΔE^* in eq. [1]

$$[11] \quad \Delta G^* = X_0 \Delta E_0^* + X_1 \Delta E_1^* - T(X_0 \Delta S_0^* + X_1 \Delta S_1^*)$$

The complete and explicit expression of A in eq. [1] is unknown for the liquids under study in the present work. But it may be assumed that it is proportional to $\exp(-\Delta S^*/R)$ by analogy with classical theories (8), thus giving

$$[12] \quad \eta = \kappa \exp - \frac{X_0 \Delta S_0^* + X_1 \Delta S_1^*}{R} \exp \frac{X_0 \Delta E_0^* + X_1 \Delta E_1^*}{RT}$$

Provided κ is much less dependent on the composition of the solution than the exponential factors, the linear relation [7] and [8] are clear consequences of eq. [12] in the concentration and temperature ranges experimentally covered.

Moreover, the numerical coefficients in eq. [12] satisfactorily express the difference in behaviour between Cs^+ and Cd^{2+}. The extrapolated values of E^* and $-\ln A$ for the pure salts are much greater for Cd^{2+} than for Cs^+.

REVIEW/SYNTHÈSE

The intramolecular Diels–Alder reaction: recent advances and synthetic applications

ALEX G. FALLIS

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received March 7, 1983

ALEX G. FALLIS. Can. J. Chem. **62**, 183 (1984).

Recent advances and examples of the intramolecular Diels–Alder reaction are summarized and applications to the total synthesis of natural products, both completed and in progress, noted. A detailed discussion of trienes leading to bicyclo[4.3.0]nonene skeletons is followed by examples of bicyclo[4.4.0]decenes and adducts arising from *ortho*-quinodimethane precursors. Cycloadditions affording bicyclo[*n*.4.0] systems and bridged-ring adducts from cyclic dienes conclude this survey which is followed by a discussion of unreactive trienes and a brief analysis of synthetic strategy to complete the review.

ALEX G. FALLIS. Can. J. Chem. **62**, 183 (1984).

On résume les récents développements et des exemples de réaction de Diels–Alder intramoléculaire et on note leur utilisation dans la synthèse des produits naturels déjà effectués de même que dans celles qui sont en cours. Une discussion détaillée des triènes conduisant aux squelettes bicyclo[4.3.0]nonène est suivie d'exemples de bicyclo[4.4.0]décenes et d'adduits provenant de précurseurs *ortho*-quinodiméthane. Les cycloadditions conduisant aux systèmes bicyclo[*n*.4.0] et à des adduits cycliques pontés à partir de dièns servent de conclusion à cette étude qui est suivie d'une discussion sur les triènes non réactifs et d'une brève analyse de stratégie en vue de compléter cette étude.

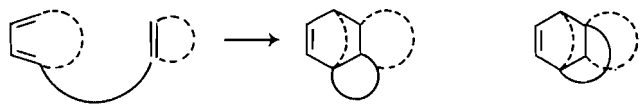
[Traduit par le journal]

Introduction

In the arsenal of the synthetic organic chemist the Diels–Alder reaction occupies a position of particular prominence. A partial survey of carbon–carbon bond forming reactions reveals that this [4π + 2π] cycloaddition is one of the most widely used synthetic procedures, rivaling alkylation methods for ring formation (1). This utility is enhanced by the formation of two bonds "simultaneously" with the introduction of up to four new asymmetric centres and its widespread application is a consequence of its good yields, mild reaction conditions, high stereoselectivity, and predictability.

In the past decade, interest in the intramolecular Diels–Alder reaction, where the diene and dienophile are constrained in the same molecule, has increased exponentially. Obviously, when the reacting components are themselves cyclic and/or have ring substituents, complex multicyclic arrays, such as those contained in drugs and natural products, can be constructed in a single step (Scheme 1). Often the syntheses of molecules of this complexity are more difficult and lengthy by other routes. The additional intramolecular advantages gained due to entropy, reactivity, regio-, stereo-, and diastereoselectivity account for the explosive growth in the study and application of this internal cycloaddition for the synthesis of natural products.

Indicative of this worldwide activity is the frequency with which reviews of this rapidly expanding field have appeared during the recent past: 1974 (2), 1976 (3), 1977 (4), and 1980 (5). While this manuscript was in its infancy, I learned of three other accounts of the intramolecular Diels–Alder reaction that were in preparation: a chapter in Organic Reactions (6) which includes comprehensive tables, a monograph (7) which includes a chapter on triene preparations, and a section of a chapter on asymmetric cycloadditions for a book (8). This knowledge, plus space limitations, influences the orientation and scope of this review. Emphasis is placed on recent developments in our understanding of the intramolecular Diels–Alder reaction and its application to total synthesis. The literature since 1979 has been carefully scrutinized and the majority of these publications are summarized. In addition, a broad cross-section of earlier examples is included to represent the major structural types, particularly those cyclizations which have culminated in total syntheses. As organic chemists we read "by structures"; to facilitate comparison, a standard format for representing the trienes is adopted and adducts are listed in tabular form according to structural class. Of necessity this results in "unnatural" orientations and occasionally the opposite optical series for some molecules in order to emphasize the Diels–Alder component. Although prone to transcription error, this is frequently a useful exercise when contemplating a total synthesis. Synthetic targets are identified by name and if they have been totally synthesized by an internal [4 + 2] cycloaddition sequence the name is underlined. It is hoped that this account will stimulate further study of the Diels–Alder reaction itself, of improved procedures for triene preparation, etc., and that, as our knowledge increases, this reaction will be even more widely used in order to occupy a central place in synthetic design and methodology.



SCHEME 1

Background

The first example of an intramolecular Diels–Alder reaction appears to have been reported by Alder and Schumaker in 1953 (9), although it was not until the early sixties that isolated examples were published (10–13). Particularly relevant were the synthesis of γ-apopicropodophyllin (14), an attempted synthesis of longifolene (15), a systematic study of methyl

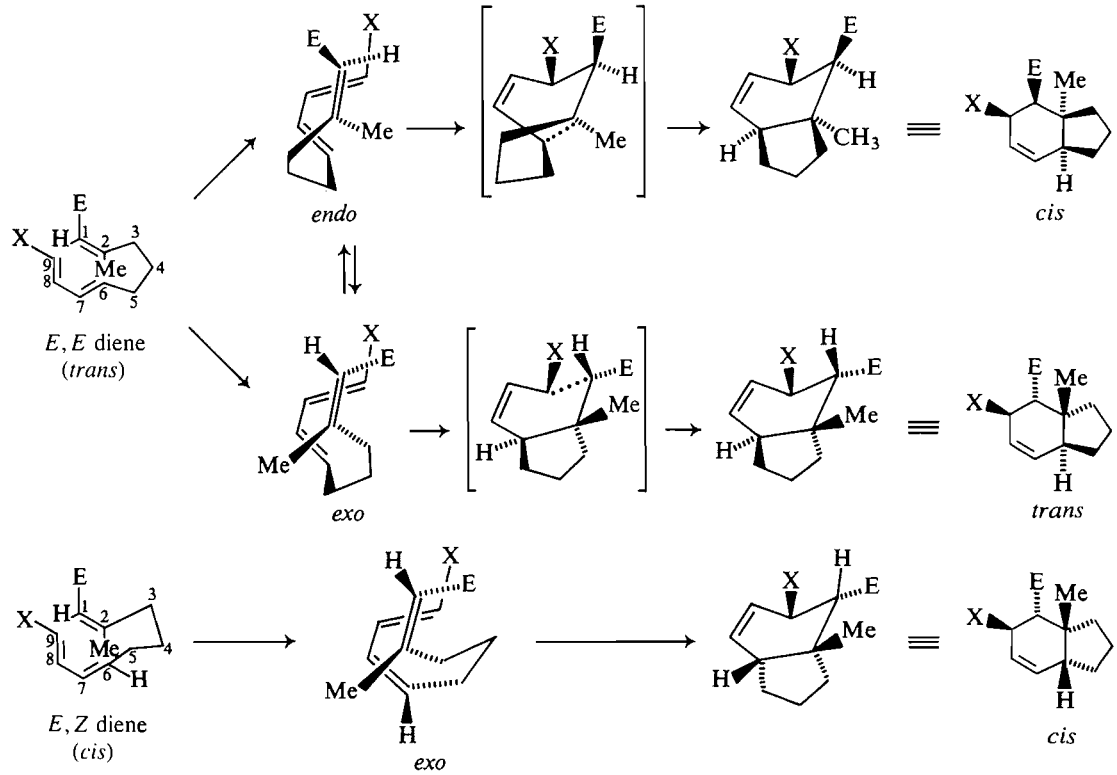

SCHEME 2

2,7,9-decatrienoates (16), an investigation of the intramolecular reactivity of diverse cyclohexadienes (17), the exploration of the *in situ* generation and internal cyclization of *ortho*-quinodimethanes (18), and the application of this strategy to the total synthesis of chelidonine (19). These studies set the stage for the more recent developments of the past decade.

Bicyclo[4.3.0]nonenes (tetrahydroindans, perhydroindenes, hydrindenes

The first detailed studies in this area are those of House and Cronin (16), who showed that the preparation of a bicyclo-[4.2.0]octene is not feasible by an intramolecular Diels–Alder reaction and thus the chain linking the diene and dienophile must contain three or more atoms for the reaction to succeed, although in certain specialized cyclic and bridged cases this generalization is not valid. The reactions are regiospecific and give annulated (fused) rather than bridged-ring products. The products result from a kinetically-controlled reaction and this regiochemical pattern, to fused adducts, is encountered in most cases as a consequence of geometric constraints present in competing orientations, irrespective of dienophile substitution. It is only with longer connecting chains (Table 5) and with cyclic dienes (Table 6(*a*)) that this influence can be overridden by other factors. Thus the resulting perhydroindenes are "*meta*-substituted" in contrast to the "*ortho*-substitution" pattern encountered in related intermolecular cases.

Several recent studies of related triene systems, carrying a variety of substituents, are summarized in Table 1(*a*). The tables follow a general sequence used throughout, listing carbocycles first, followed by heterocycles in which the heteroatom is in the connecting (side) chain, and then heterocycles with heteroatom dienophiles or dienes. Temperatures, times, and yields are included to provide a relative measure of reactivity and utility.[1]

In all cases, the stereochemistry of the cyclization is established by the spatial orientation of the dienophile as it approaches the diene, so that cyclization may proceed in a suprafacial–suprafacial manner. The ring fusion is determined by a complex interplay of conformational, steric, and electronic effects which may vary independently. Scheme 2 outlines the case for a model triene and illustrates the subtleties involved. The influence of sidechain substituents (at C3, C4, C5) should be noted. A C7 substituent experiences a nonbonded interaction with groups at C3, while C7 and C4 experience partial eclipsing in the *endo* transition state. These features are alleviated in the *exo* conformation and thus increased selectivity for *trans*-fused adducts should result, as has been found.

In general, steric effects are more important than electronic ones because the bicyclic products are predominantly *trans*-fused, yet this selectivity, especially in the case of terminally activated dienophiles, is independent of dienophile (*E* or *Z*) stereochemistry (20). Thus in these intramolecular reactions the Alder *endo* rule fails, emphasizing that secondary orbital interactions are not of prime importance in most instances. However, when Lewis acid catalysts are employed, the rates increase and selectivity improves in certain cases. This is a consequence of the increased dienophile polarization which results in a lowering of the LUMO energy at C2 for terminally activated systems and, in the case of *trans*-dienophiles, produces a marked increase in stereoselectivity so that *trans*-adducts are produced exclusively. In these cases (**3**–**6**) the

[1]E = CO_2CH_3 throughout unless otherwise indicated; ⌐ = compounds generated *in situ*. Many reactions are run in sealed tubes and are improved by additives, silanized glassware, etc.; however, except for Lewis acids, which are indicated, space precludes their inclusion. Reference numbers are in parentheses on the right-hand side.

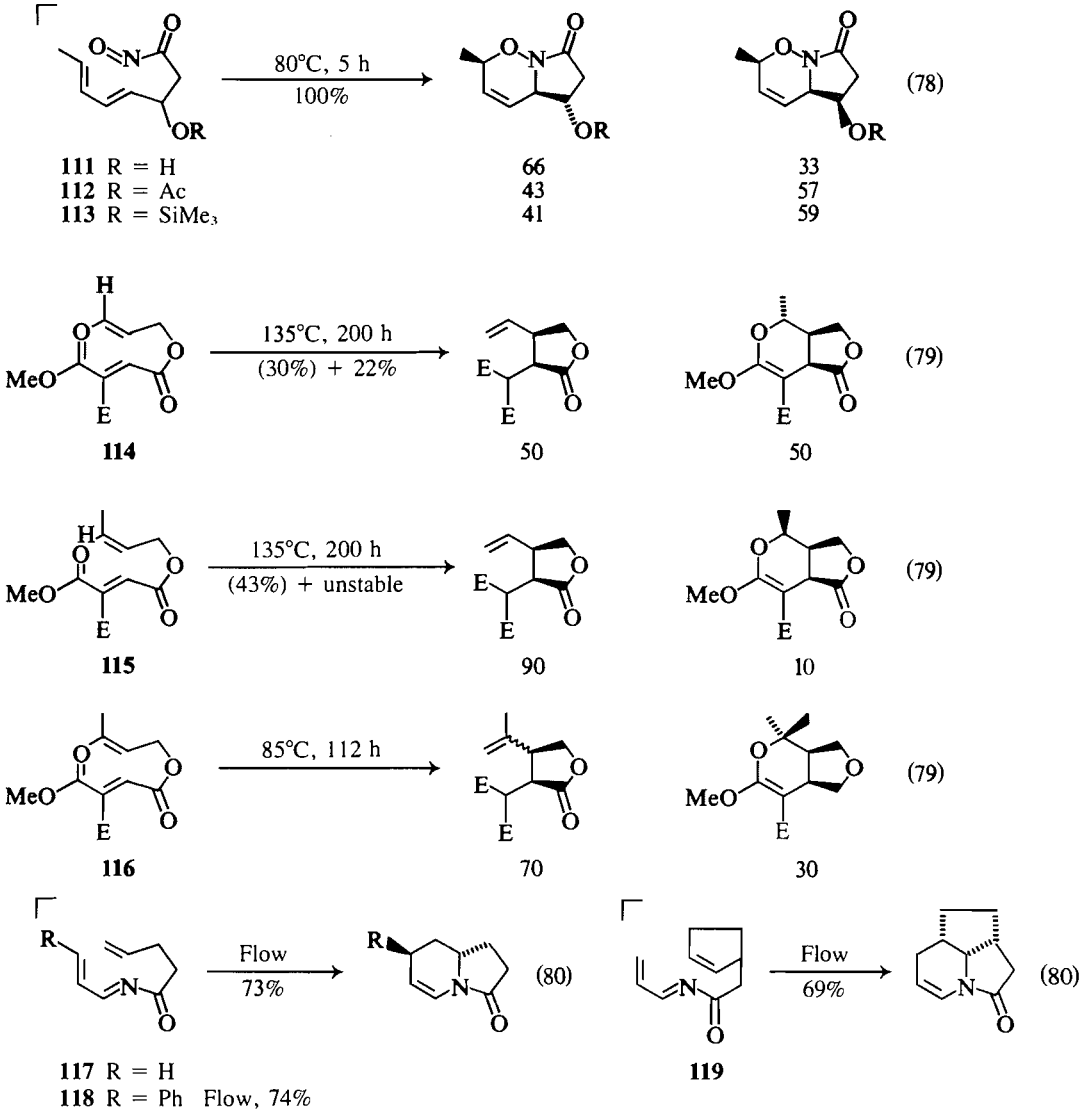
TABLE 1(*a*). (*Concluded*)



combined influence of the preferred transition state geometry (*endo*) and secondary orbital interactions are additive. In contrast, for *cis*-dienophiles, these factors are opposed and poor yields of mixtures are obtained. Catalysts also fail when ether oxygen substituents are present and chiral Lewis acids give negligible induction even for **3** and **4**. It is necessary to use the catalysts stoichiometrically, the best being ethylaluminum dichloride, diethylaluminum chloride, and methoxyaluminum dichloride. The combination of Lewis acid catalysts and a chiral dienophile affords diastereomeric excesses (de) of 30 to 75% (**5** and **6**).

In spite of the general failure of the *endo* rule, secondary orbital interactions do have an influence and several authors (31, 34, 40, 47) have pointed out that the rationalization of product distributions is facilitated if one postulates a nonsynchronous bond formation. The reaction is still concerted, in the sense that both bonds are initiated simultaneously, but an unsymmetric transition state is achieved by minimizing nonbonded interactions and bonding occurs preferentially between the termini with the largest LUMO coefficients. Thus with terminally activated dienophiles the C2 coefficient will be larger than C1 (as in Lewis acid cases above), facilitating formation of the C2—C6 bond so a "cyclopentane"-like species is formed early in the transition state leading preferentially to *trans*-adducts. In systems such as **20**–**22**, which lack dienophile activation, this influence is reduced and selectivity declines unless other steric demands are introduced as in **29**–**31**. In contrast, when the activating group is attached to C2 (e.g., carbonyl replaces methyl and E = H in Scheme 2), the LUMO coefficients are reversed and the outer termini (C1 and C9) may bond preferentially, leading to a *cis*-like transition state via a "cyclononene"-like species in which nonbonded interactions are minimized so that *cis*-fused adducts tend to dominate (cf., **23**, **24**, **26**, **50**). However, this influence may often be counteracted sterically by the choice of suitable substituents as in **25**, because entropy effects frequently override frontier orbital influences in intramolecular Diels–Alder reactions. If angularly methylated *trans*-perhydroindans are desired, maximum selectivity is achieved with terminally activated dienophiles such as **18** and **19**. In examples **33**–**35**, a four-fold rate increase is generated by the sidechain geminal methyl substituents at C4. An additional rate enhancement

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

is encountered with **35** as a consequence of the linearity (decreased bulk) of the nitrile functions and the lowering of the LUMO energy. Activated acetylenes are particularly useful dienophiles and generally cyclize under relatively mild conditions, as found for **41** and **45**.

The difference in transition state energies for the *endo* and *exo* conformations is not large, ~0.5−1 kcal/mol, but with careful choice of substituents and activating groups it is possible to significantly influence the product distribution. Thus, with the selective introduction of suitable nonbonded interactions, the *trans*-selectivity may be increased and is further enhanced by lower cyclization temperatures, consistent with kinetic products.

These studies have culminated in the total synthesis of several diverse natural products which incorporate a bicyclo[4.3.0]-nonane component (Table 1(*b*)). The *E,Z* triene corresponding to **15** (i.e., **492**) experiences severe steric congestion (cf. Scheme 2) in the conformation required for bonding and thermally isomerizes to **15** whose adduct was used for the total synthesis of 8-epi-dendrobine (28). More recently, the propylene glycol acetal corresponding to **16** ($n = 2$) has been employed in an improved synthesis of dendrobine by Roush and Gillis (29) which previously proceeded via **8** ($R = SiMe_3$) (23). Three groups, Nicolaou (24), Ley (25), and Roush (26) and their collaborators have approached the right-hand portion of antibiotic X-14547A using the trienes **10** to **14** and the total synthesis has been completed by Nicolaou *et al.* (50). Consistent with the suggestion that the natural product may be formed biosynthetically via an intramolecular Diels−Alder sequence is recent evidence (27) that **14** cyclizes spontaneously to give predominantly the *trans*-fused adduct. Two syntheses of coronafacic acid, derived from coronatine, have employed **25** (35) and **26** (36) respectively. The interesting terpene marasmic acid has been prepared by Boeckman and Ko (39) from **32** in which both adducts were utilized. They are also developing a related approach to the fused ring tricyclic system in ikarugamycin (81).

The furan system **55** is a key component in an approach to secofuranoeremephilane (49). Several different groups (32, 33, 38, 43) intend to use systems such as **21**, **30**, **31**, and **38** to generate the C-D rings of steroids such as vitamin D, 11-oxy-estrones, and cortisone, and **39** is destined for use in an approach to the total synthesis of retigeranic acid (44).

As the model system in Scheme 2 illustrates, *E,Z* dienes are restricted to a single transition state geometry which should afford the *cis*-fused adduct exclusively. Although, in principle, *Z* dienes can isomerize via a 1,5-sigmatropic rearrangement, as appears to happen for **15** (28), **61** (51, 116), and possibly **89** (65), sterically less demanding cases, even though highly substituted, do not present a practical difficulty and **36** selectively affords the *cis*-product. Not surprisingly, due to the congested transition state, the reaction is slower (~42×) than for the *E* diene **32** (41).

For unsymmetrically substituted chiral dienes, asymmetric induction should be feasible if the reaction occurs from a single diastereotopic face of the dienophile. This has been achieved by placing a chiral centre in the sidechain (at C5), which directs the cycloaddition so as to minimize nonbonded interactions and gives only one *cis*-fused adduct as illustrated in examples **90−93**. Fuchs and co-workers (66, 67) have developed this concept into a practical procedure for the introduction of five new asymmetric relationships simultaneously. The resulting adducts are being utilized in a total synthesis of cytochalasin C.

Kuehne *et al.* (68−70) have generated *in situ* several dehydrosecodines **94−100** which are *Z* dienes. These have been employed for a variety of biomimetic aspidospermine alkaloid syntheses which include tabersonine, vincadifformine, minovine, and ervinceine, etc. In these syntheses the natural products arise from a formal [4 + 2] cycloaddition as was postulated earlier (71), although in some cases an alternative stepwise ionic mechanism cannot be ruled out.

A number of heterocyclic systems have been prepared in which the heteroatom is in the sidechain. The lactone examples afford a product distribution similar to the carbocyclic cases in which the *trans*-adduct is dominant. Example **52**, which gives the thermodynamically favoured *cis*-fused lactone, is an exception, perhaps due to a reversible reaction (47). The esters **57** and **58** afford the tricyclic lactones with the correct stereochemistry for further elaboration into cytochalasin A and proxiphomine respectively (52, 53). These cases provide excellent examples of the stereo and regio control available in the intramolecular Diels−Alder reaction.

Sidechain hetero-atoms and/or carbonyl substituents influence the product distribution, but the trends are not clear. A carbonyl prefers to retain π overlap in the transition state (carbonyl coplanarity effect, *vide infra*); however, carbonyl−diene coplanarity results in a rather strained transition state for reactions leading to bicyclo[4.3.0]nonenes, so mixtures are generally encountered. It should be noted that the predominance of *trans*-adducts in the lactams **74** to **81** is governed by internal chelation with magnesium salts (61). In contrast, lactam products with the nitrogen adjacent to the dienophile are usually *cis* and advantage of this has been taken by Martin *et al.* to develop routes to the aspidospermine nucleus from **87** (64) and lycorine from **84** (63). Benz-[f]isoindoline derivatives are formed stereoselectively from various styrenes (120).

Imino dienophiles have been used by Weinreb *et al.* to prepare indolizidine alkaloids, including γ-coniceine, from **103** (73), elaeokanine A and B from **109** (72), slaframine from **107** (75), and tylophorine from **106** (77). Nitroso groups generated *in situ* will also function as dienophiles as exemplified by **111−113**, and related systems form the key construction for total syntheses of heliotridine and retronecine (78). A few cases of heteroatom dienes have been reported (**114−119**) and, although the ene reaction competes, in the case of **114** it is being employed in a synthesis of elenolic acid (79).

Bicyclo[4.4.0]decenes (decalins, octalins)

The addition of an extra methylene unit to the sidechain connecting the unsaturated centres in decatrienes permits the adoption of both *endo* and *exo* transition states with greater facility (cf. Scheme 2), leading to mixtures of *cis*- and *trans*-fused adducts, although in the absence of bulky substituents there is a slight preference for *cis*-products (Table 2(*a*)). This statement oversimplifies the situation, however, since substituents, sidechain heteratoms, adjacent rings, and carbonyl functions can markedly alter the ratio. The well established preference of six-membered rings to adopt a chair conformation and the tendency of substituents to adopt an equatorial rather than axial orientation frequently manifests itself in the highly ordered Diels−Alder transition state so that the dominant conformation is the one with the least bond-angle strain and fewest nonbonded interactions. This equatorial substituent effect is apparent in case **122** compared to **127**; however, the danger of oversimplification and the subtleties involved are illustrated by

the different product ratios from **127** and **128**. A γ-diene substituent promotes the formation of *trans*-fused products due to nonbonded interactions with sidechain functionality including hydrogen (cf. **120**, **121**, **125**, **126**, **132**). Although secondary orbital effects play a role, especially if sidechain ketones are present, these effects are generally of lesser importance. The stereochemical controlling influence of a carbonyl group, alluded to in the previous section, due to overlap between the adjacent π systems, was first noted by Oppolzer and Fröstl (54) with amides **173** and **175**. The major products result from adoption of the conformation in which overlap is most easily retained in the transition state. Thus judicious placement of a carbonyl group often permits the preparation of the desired adduct stereoselectively as a consequence of "carbonyl coplanarity control". In the carbocyclic series, *trans*-products often predominate when the sidechain carbonyl is in conjugation with the diene, as is evident by comparing **133** with **141**–**144** in which this coplanar effect is absent and the stereoselectivity is reversed. An additional contribution to *trans*-product domination can arise from facile enolization after cycloaddition. In similar fashion, replacing the sp^2 hybridized carbon by a cyclic acetal (**149**–**151**) affords mostly *cis*-fused products. These *cis*-adducts also usually dominate in cases where the sidechain carbonyl is adjacent to the dienophile (**156**–**164**), thus encouraging an *endo* transition state. This has been used to advantage in the cyclization of **170**, a key intermediate in the total synthesis of gibberellic acid by Corey *et al.* (85).

As in the perhydroindene series, secondary orbital interactions derived from C1 ester substituents are of minor importance and product selectivity is independent of dienophile stereochemistry. However, Lewis acid catalysis of simple esters can promote selective adduct formation (**146** and **148**) (21). Example **135**, in which internal coordination is assumed, provides a dramatic contrast with the closely related case **136**. Further studies with metal assisted systems (21) such as $MeTiCl_3$ and $MeNbCl_4$ hold promise to exercise stereocontrol but at present polymerization is a practical problem. An interesting construction of 11-keto steroids, developed by Stork *et al.*, employs **163** which gives mostly the desired *cis*-adduct upon catalysis with trifluoroacetic acid (86). This selectivity was further improved when **164** was cyclized in the presence of rhodium chloride (87).

In view of the widespread occurrence of decalin systems in nature, a number of natural products, in addition to those above, have been synthesized by internal Diels–Alder reactions (Table 2(*b*)). These include α-eudesmol, stereoselectively from **122** (88), epizonarene from **125** (89), selina-3,7(11)-diene from **132** (90), and eremoligenol and valerianol from **140** (91). Compound **162** cyclizes spontaneously to the required stereoisomer for the synthesis of torreyol (92) and **160** is utilized for γ-cadinene (93) by analogy with the route followed from **161** for khusitene (104). The alleged chiloscyphone has been synthesized from **158** (94) and cyclostachine B was prepared from **137** using a presumed biomimetic approach (95). The required *trans-anti-trans* perhydrophenanthrene skeleton is formed by cyclization of **123** for conversion to fichtelite (96). Compactin has recently been synthesized in enantioselective fashion from **156** (97). Two other approaches being developed to compactin employ the allene **153** (98) and the Lewis acid catalyzed cyclization of **155** (99). A route to chlorotricolide, based on the cyclization of the acetylenes **165** and **166**, is being developed (100).

A number of amide systems have been studied and many form the basis for total syntheses. Pumiliotoxin C has been prepared in both racemic and chiral form from **172** (114). Cyclization of **199** provides a building block for the yohimbane skeleton (116) while a different sequence is planned using **188** (51). Andranginine results from heating **171** via a presumed biomimetic cycloaddition (113). The lycorane skeleton of the amaryllidaceane alkaloids is generated stereospecifically from **182** (117) and a closely related cyclization of **183** is employed in the preparation of *cis*-dihydrolycoricidine (119). The same lycorane ring system has been synthesized by construction of a

different cyclohexane unit using **184** (118). The imino ether **193** is utilized in the synthesis of lysergic acid (123). Heteroatom dienes are used to prepare the hexahydrocannabinol skeleton enantioselectively from **195** (125), in which cyclization is directed by the chiral methyl centre. An intermediate for an approach to eupolauramine is generated from the oxazole **199** (128) and a recently completed total synthesis of deoxynuphanidine employs **201** (129).

ortho-Quinodimethane adducts

The *in situ* generation of *ortho*-quinodimethanes which are trapped intramolecularly by a dienophile to give fused ring systems was developed by Oppolzer and Keller (4, 18, 19) and has been studied extensively, particularly for the total synthesis of steroids. Several reviews have appeared (134–138) and thus recent applications to natural product synthesis are highlighted. The success of this methodology has stimulated the development of a number of procedures, in addition to benzocyclobutene fragmentation, for the preparation of the *ortho*-quinodimethane unit. One of the more versatile utilizes the thermal cheletropic elimination of sulphur dioxide (139, 140), while the mildest employs fluoride anion-induced silyl elimination (141–143) permitting diene generation and cycloaddition below 100°C. Generally *E*-quinodimethanes are formed preferentially and cyclize regioselectively to the fused ring product. They may be regarded as special examples of the preceding sections in which the selectivity (generally *trans* ring fusion) is enhanced due to the increased planarity of the reactive components. It is possible in many instances to direct the intramolecular cycloaddition towards the dominant formation of either the *endo*- or *exo*-adduct by modifications of the sidechain functionality and application of "carbonyl coplanarity control" as exemplified in examples such as **256–257** and **262–263** (145). In addition, several asymmetric syntheses have been conducted, particularly of steroids, by using a chiral ring D unit.

Steroid approaches have utilized a C,D ring construction as in **202–204** for the preparation of intermediates directed towards estradiol, cortisone, and progesterone (147, 148), while cyclization of **205** forms the basis for an approach to grayanotoxin-I (148).

Many groups have synthesized estradiol and its relatives based on a B,C ring assembly and typical examples **210–217** are tabulated (Table 3(*a*)). Kametani and co-workers are developing different Diels–Alder approaches to the quassinoid klaineanone; one route employs **223** (159), another the tetracyclic intermediate derived from **243** (160).

Chiral cyclohexane derivatives have proved useful for asymmetric synthesis of chenodeoxycholic acid from **227** (161) and as an entry to the pregnanes from **224** (162, 163). The ring fusion stereochemistry is changed to *cis* by the presence of a nitrile, as in **228** and **229**, providing intermediates from which the crustacean molting hormone 20-hydroxyecdysone was synthesized (164) (cf. **231** and **232**). Similar ring contraction of the adduct from **230** provides an alternative route to estrone (165).

Key intermediates for the total synthesis of the triterpenes alnusenol and friedelin have been prepared from **231** and **232**, respectively (166). The formal total synthesis of the diterpene alkaloids atisine, veatchine, garryine, and also gibberellin A_{15} was accomplished from **236**, in which the nitrile substituent again promotes the *cis*-product (167).

An alternative route to *o*-xylylenes has been developed by Funk and Vollhardt (137, 169), using cobalt-mediated co-oligomerization of bis(trimethylsilyl)acetylene and 1,5-hexadiyne so that the steroid nucleus can be generated in a single chemical operation. Cases **237–242** are representative and include the synthesis of estrone from **240** and **241** (169).

Kametani and co-workers have utilized exocyclic dienophiles to generate the tetracyclic nuclei of diverse terpenes. These studies have resulted in the total synthesis of hibaol from **246** (170) and approaches to isoatisirene and grayanotoxin I are being pursued from **244** and **245**, respectively (171, 172).

Magnus and co-workers have generated indole-2,3-quinodimethanes such as **254** which was employed in a synthesis of aspidosperimidine (177). Two syntheses of chelidonine have been completed by Oppolzer and Keller (19, 178), the most recent of which employs **259** in a highly stereoselective cycloaddition via an *exo* (with respect to nitro group) transition state.

The basic skeleon of aphidicolin has been constructed using the five-carbon sidechain contained in **271** (182), while the lignan carpanone was prepared by a biosynthetic-type cyclization of **270** (181) and, in related fashion, **273** afforded deoxybruceol (122).

Bicyclo[5.4.0]undecenes

Only two preparations of this ring system appear to have been reported (130, 131), each of which was used to synthesize himachalene (Table 4). As expected, the extra freedom in the sidechain and the carbonyl coplanar effect combine to give exclusively *cis*-fused products from **274** and **275**, although epimerization is possible in the latter case.

Bicyclo[*n*.4.0] skeletons

Only a few examples with sidechains containing more than five atoms have been studied (see Table 5). In general, with increased chain length both stereo- and regioselectivity diminish, as is evident for cases **276** and **277** (132) which resemble related intermolecular examples. However, the more sterically demanding dienophile in **278** cyclizes with greater regioselectivity and forms the basis for an approach to cytochalasin B (133). Part of the loss of selectivity in these examples is a consequence of entropy and free energy of activation changes, since the 5–7 kcal/mol reduction in activation barriers found for intramolecular cycloadditions (59) is largely forfeit with lengthy connecting chains.

Bridged ring adducts (cyclic dienes)

Cyclic dienes (Table 6(*a*)) have received a considerable amount of attention, initially as a consequence of the total synthesis of diverse bridged sesquiterpenes (Table 6(*b*)) by various Swiss chemists. The structural format used to this point has been altered to better reflect the actual transition states involved and to facilitate comparison with the synthetic targets.

5-Alkylcyclopentadienes undergo rapid 1,5-sigmatropic rearrangement to the C1 isomer from which intramolecular cyclization usually occurs. This has been used to advantage by Breitholle and Fallis in the cyclization of **283** for the total synthesis of cedrene and cedrol (186). Although this sigmatropic rearrangement leading to **280** foiled an early approach to longifolene (15), a similar ring system from **284** is currently being investigated as a route to the sesterterpene gascardic acid (187).

As a consequence of the strain inherent in the competing pathways, it was found that systems such as **291** afford a single

α and β-Himachalene

adduct from the C5 isomer. The regiochemistry varies with the cyclopentadiene and dienophile substituents. In the case of **293** it is regioselective, in accord with frontier molecular orbital correlations, and Snowden has utilized this in a total synthesis of sativene (190). A related cyclization is being studied in an approach to sinularene (191) from **295** and a fused cyclopentadiene **296** plays a key role in a route being developed to capnellene (195). An early stage of the recently completed total synthesis of dodecahedrane (193) depends upon the cyclization of **297** (192).

An alternative solution to the pestiferous cyclopentadiene rearrangement problem is to use a suitable blocking group, although chlorine was found to be unsatisfactory (198). This has been accomplished with a cyclopropane unit and **302** is employed in a recently completed total synthesis of the marine sesquiterpene sinularene (196). In similar fashion, an asymmetric total synthesis of longifolene is being developed from **303**, in which the chiral cyclopropane centre directs the cyclization (197).

Cyclohexadienes are more civilized in their behaviour and cyclization of **304** forms the basis for a total synthesis of khusimone by Büchi *et al.* (199), while the related higher homologue **306** provides an entry to a pleasant smelling, acid catalyzed rearrangement product of thujopsene (201). The aromatic triene system **307** is being developed into a synthesis of the diterpene alkaloid atisine (202). Of the five total syntheses of 9-isocyanopupukeanane or the ketone derived from it, four employ an intramolecular Diels–Alder cycloaddition as a key step from **308**, **318**, **319**, and **320** respectively (203–206). The regiochemistry of these cyclizations usually disfavours the "twistane" type product; however, the planarity of the sidechain, the presence of a carbonyl group, and nonbonded interactions can tip this balance, as in **309** and **310** compared to **308**. In these three examples the "twistane" (bridged) product is anticipated on the basis of molecular orbital considerations, although in the cases of **308** and **309** they may be converted (250°C, 5 min, for **308**) to the thermodynamically more stable isomers. The adducts from **310** and **312** have been utilized in a total synthesis of seychellene (208) and norseychellanone (209). A chiral synthesis of patchouli alcohol by Näf *et al.* (215) employs **314** in which the sidechain methyl function directs the reaction, since only one diastereomer cyclizes, and a related triene **317** is used for norpatchoulenol (216). Examples **280**, **283**, **304–307**, **370–375**, **382–383**, **413–420** illustrate the difficulty of predicting whether the new ring will be *exo* or *endo* in view of subtle substituent effects, but there is a preference for cyclopentanes (three connecting atoms) to be *exo*.

Obviously, when the sidechain contains rings (cf. Scheme 1), multicyclic systems can be constructed using cyclohexadienes, anthracenes, cycloheptadienes, etc., and representative examples are tabulated. Recently Nicolaou *et al.* have completed the total synthesis of endiandric acids A, B, and C from **335** and **336**, respectively (274, 275). (A and B actually possess a bicyclo[4.3.0]nonene nucleus but are included here for convenient comparison.) These studies lend support to the suggestions of Black and co-workers (270) that these compounds arise in nature, where they are found in racemic form, from a series of electrocyclizations culminating in an internal Diels–Alder reaction. *In situ* generation of the appropriate polyunsaturated, acyclic ester precursors **337** and **338** affords, after brief heating, the natural products A or B and C in which 4 new rings and 8 asymmetric centres are formed (276). They arise via a fascinating sequence involving an 8π electron conrotatory ring closure to a cyclooctatriene, rearrangement via 6π electron disrotatory cyclobutene formation (shown), followed by an intramolecular $\pi 4s + \pi 2s$ cycloaddition.

A large number of heterocyclic dienes have been studied but relatively few have been employed in total syntheses in spite of their potential for the introduction of diverse groups and selective functionalization of more than one position. Furans of type **381–383** are being utilized by De Clercq and co-workers in interesting approaches to gibberellic acid (232) and functionalized steroids (233). In the latter case formation of the kinetic product is facilitated by using water as a solvent (234). Cyclization of the furanobenzyne **374** provides an intermediate employed in the preparation of mansone E (231), and Keay and Rodrigo (273) have recently completed a total synthesis of resistomycin from the isobenzofuran **384**. Karahana ether has been synthesized by Mukaiyama *et al.* using the magnesium complexed triene **394** (237), which fails to cyclize as the free alcohol **393** possibly due to a diminished population of the required *s-cis* amide conformer and the absence of the Lewis acid contribution of the complex. They have utilized the same procedure for the asymmetric preparation of farnesiferol C from **414**, in which the chiral substituent on nitrogen directs the cyclization (239).

Facile bridge loss after cycloaddition is characteristic of many *bis*-heteroatom dienes and advantage is taken of this in a total synthesis of actinidine from **461** by Sammes and co-workers (254). Oxazoles also behave in this fashion (cf. **200**) and cyclization of **436** affords evodone (243) while the related systems **434** and **435** were used by Jacobi and Walker (244) to synthesize ligularone and petasalbine, respectively.

A different approach to bicyclic skeletons involves the use of butadienes with the connecting chain attached to the β position. Shea and his co-workers have studied a number of trienes which afford bridgehead olefins and intend to use this approach for taxane skeletons (144), such as taxusin.

Troublesome trienes

A risk involved in the application of the intramolecular Diels–Alder reaction to total synthesis is the failure of the carefully synthesized triene to cyclize! This can occur even when there are closely related literature precedents of successful cyclizations, as is evident by comparing these trienes with those in earlier sections. As a guide to future work several examples which failed to cyclize under the conditions examined are tabulated (Table 7). In cases designated with an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

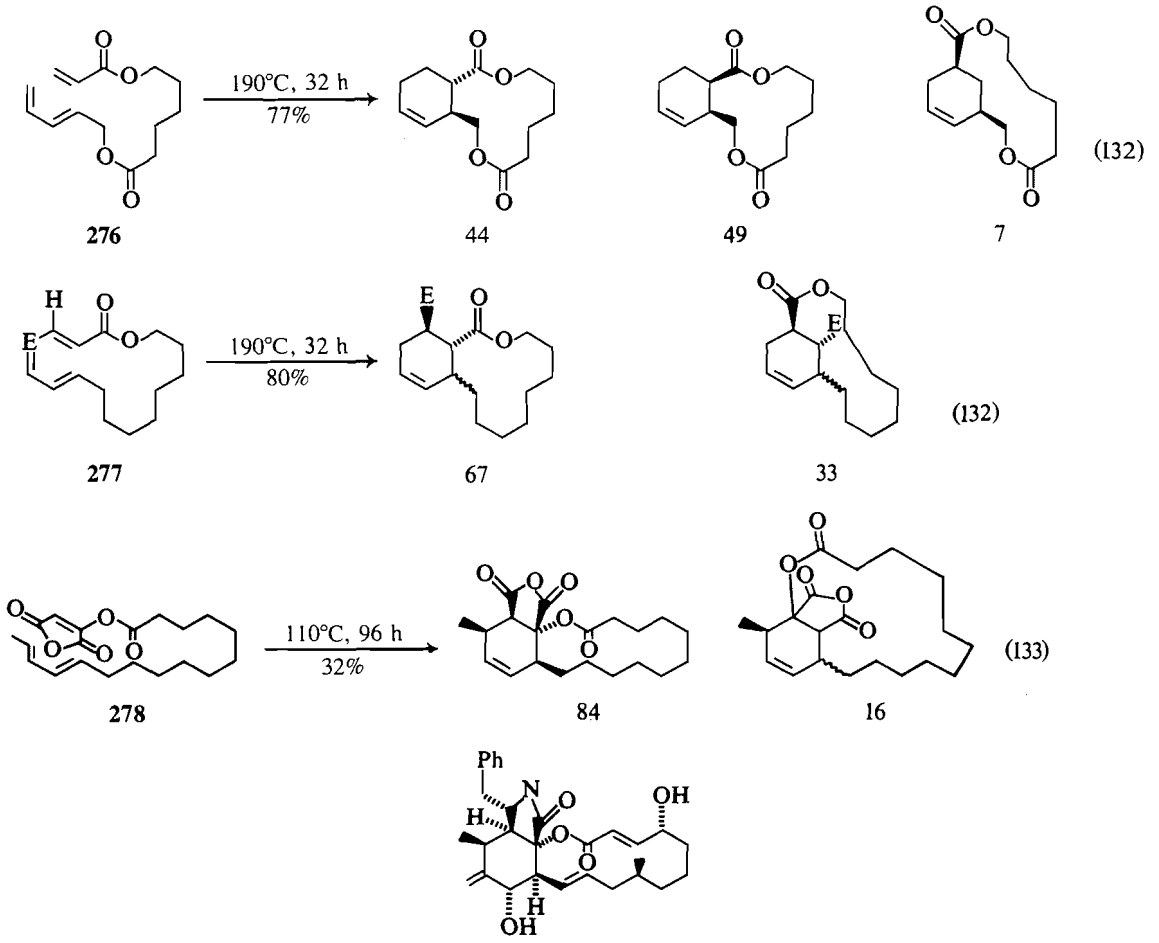
TABLE 5. Bicyclo[n.4.0] skeletons



asterisk, other Diels–Alder adducts were formed as a result of isomerization of the original compound. Example **548** is a special case in which a [2 + 2] sequence, involving a vinylcyclobutane intermediate, takes precedence and the formal bridged [4 + 2] adduct **549** arises from further thermolysis via a diradical reaction (265).

The beneficial effects of a sidechain carbonyl group in altering product stereochemistry were discussed above; however, it can also be a liability due to its preference for coplanarity. This "carbonyl coplanarity effect" is often sufficient to inhibit cyclization. In cases **503** and **504**, part of an approach to vernolepin, no cyclization was observed below 220°C and at higher temperatures diene isomerization into conjugation precedes cycloaddition. In spite of the strain, overlap may be more readily maintained, in the transition state leading to the perhydroindene skeleton (cf. **50**, **51**) (46). It is likely, given the large number of compounds with connecting chain carbonyls in the table, that some of these suffer from a similar effect. In principle, it should be possible to circumvent this difficulty by alteration of the carbonyl functionality (reduction, protection, etc.) but even this may fail, as in **522** (233), and the examples in **519** only cyclize when a homoallylic oxygen substituent is present (196).

Deleterious steric effects are probably the prime culprit preventing cyclization in many instances and examples **488–490**, **492**, **493**, **508**, and **509** are representative. Although **508** and **509** could not be used in an approach to quassin (264), a different disconnection holds promise for realizing this goal (108). A related phenomenon is the restricted geometry imposed by the sidechain so that efficient diene–dienophile overlap cannot be achieved (**484**, **485**, **510**, etc.). At the other extreme, when the connecting chain is lengthened to 5 bridging atoms, the preferred conformations are not the folded ones required for cyclization, and the barrier to achieve them is increased. For example, **521** reacts preferentially with the trisubstituted olefin to form a five- rather than a seven-membered ring. This reluctance to form cycloheptanes is also exemplified by **538–540** and **547**. In intermolecular cases, the tendency of furan adducts to dissociate is well established and the large number of reluctant furan systems may reflect, in part, some situations where the equilibrium with the adduct is unfavourable, rather than the inability of the cyclization to actually occur. A recent study (266) of a furan intramolecular Diels–Alder cycloaddition confirmed the existence of a negative volume contribution from the approach of the reacting centres which, although smaller than intermolecular examples, suggests that high pressure should facilitate cyclization in difficult cases.

In view of the well defined geometric and electronic requirements of the Diels–Alder transition state, it is likely that detailed conformational analysis coupled with molecular orbital calculations might provide some insight into these sys-

tems. If closely related successful and unsuccessful cases were calculated and compared, it might improve our understanding and provide a better predictive basis for future work. A partial step in this direction has been taken by Wilson and Huffman (101) using the data base available in the Cambridge Crystallographic Data File.

Synthetic strategy

To date, most applications of the intramolecular Diels–Alder reaction to total synthesis have involved construction of a bi- or tricyclic ring system which may be readily discerned by retro-synthetic inspection of the natural product. Many examples are apparent upon comparison of the tables and related synthetic targets depicted above. In some cases, as mentioned, these follow a possible biomimetic route, for although an internal cycloaddition has been suggested for the biosynthesis of a variety of natural products, in most cases rigorous proof is lacking. Nevertheless, increasing circumstantial evidence is provided by a number of laboratory cyclizations under mild conditions to give the natural ring systems. An example of the caution required is provided by a recent synthesis of a stabilized dehydrosecodine which failed to undergo the anticipated intramolecular cycloaddition(s) to the alkaloid skeleton(s) (267) even though other evidence suggests some Aspidosperma and Iboga skeletons may be formed in this way (68–70, 113, 269). Additional natural products for which an internal [4 + 2] cyclization has been implicated include ikarugamycin (82), X-14547A (26), iricinianin (268), cyclostachines, cyclopiperstachine (95), carpanone (181), lachananthocarpone (269), endiandric acid (270), morellin (271), gambogic acid (272), some other lignans (277), and possibly also the Aspergillus metabolite andibenin B (278).

In the hierarchy of synthesis, schemes which are short (efficient), chiral, stereocontrolled, and proceed under mild (neutral) conditions are particularly desirable. Frequently the intramolecular Diels–Alder approach fulfills these requirements for cyclohexenes, as noted, but its application need not be limited to six membered rings since ring expansion, contraction, and cleavage sequences facilitate the construction of many different skeletons. Indeed, the wide range of complex functionality that is compatible with this cycloaddition suggests that this strategy can often be used to best advantage when the adduct constructed is not part of the final target. Several examples illustrate these features. Rearrangement of suitable intermediates was used for seychellene (208) and khusimone (199), while ring expansion of the Diels–Alder adducts afforded the required skeletons for cedrene, cedrol (186), and sativene (190). Cleavage of the cyclized intermediate for subsequent elaboraion is important in the preparation of sinularene (196), mansone E (231), resistomycin (273), farnesiferol C (239), karahana ether (237), and in approaches to gibberellic acid (232), longifolene (197), and capnellene (195). Useful variations on this cyclization–cleavage approach are those schemes in which extra rings are attached to the modified (cleaved) adduct, frequently by annulation, base catalyzed condensation, addition, or rearrangement reactions. Total syntheses of gibberellic acid (85), oxygenated steroids (86, 87), dodecahedrane (193), and approaches to gascardic acid (187), klaineanone (160), and grayanotoxin I (172) fall in this general category. Given the current level of chemical ingenuity, the array of reagents available, and the range of complex targets that warrant attention, it is likely that many more sophisticated schemes whose net result is a synthetic simplification will continue to be reported. Indeed, if a molecule is worth synthesizing, an intramolecular Diels–Alder approach is worth considering.

NOTE: The following refer to intramolecular Diels–Alder papers which arrived after November 1, 1982. Allenecarboxanilides (279); see example **14** (280); see cases **145–148** (281); heterodienophiles review (282); intra-

Acknowledgements

I thank Mrs. K. Stewart and Ms. T. Barker for their typing and Mrs. C. Chen for transforming my hieroglyphics into lucid structures. I am particularly indebted to chemists around the world who generously supplied information on their Diels–Alder research, including their "troublesome trienes". Fruitful discussions with my colleagues and frequent collaborators Professors S. J. Alward and J. F. Kingston facilitated the preparation of this manuscript and we are grateful to Memorial University of Newfoundland and the Natural Sciences and Engineering Research Council of Canada for financial support of our research. It is also a pleasure to acknowledge the assistance of our co-workers W. L. Brown, R. R. Bukownik, J. Hellou, R. S. Smith, Drs. K. Antczak, and S. K. Attah-Poku whose skill and dedication are bringing our ideas to fruition.

The importance of the $\sigma^*-\pi^*$ orbital mixing for the nucleophilic displacement on the unsaturated carbon

SHINICHI YAMABE,[1] TSUTOMU MINATO, AND YUMI KAWABATA
Department of Chemistry, Nara University of Education, Takabatake-cho, Nara 630, Japan

Received January 31, 1983

SHINICHI YAMABE, TSUTOMU MINATO, and YUMI KAWABATA. Can. J. Chem. **62**, 235 (1984).

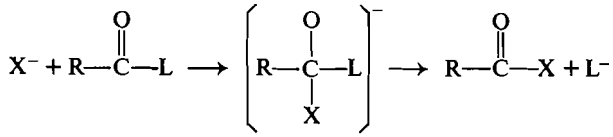
The reactivity of carbonyl and aromatic compounds for the nucleophilic displacement is investigated theoretically. LUMO (lowest unoccupied MO) obtained by the mixing of the π^* MO with the σ^* MO is a uniform criterion of the relative reactivity of substrates. The presence or absence of the tetrahedral intermediate is found to depend on the energy difference between the π^* and σ^* MO's.

SHINICHI YAMABE, TSUTOMU MINATO et YUMI KAWABATA. Can. J. Chem. **62**, 235 (1984).

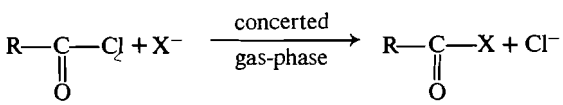
On a étudié sur une base théorique la réactivité des composés carbonylés et aromatiques lors d'un déplacement nucléophile. Le critère uniforme de la réactivité de ces substrats est le LUMO obtenu en mélangeant une OM π^* avec une OM σ^*. On a trouvé que la présence ou l'absence d'un intermédiaire tétraédrique dépend de la différence d'énergie entre les OM π^* et σ^*.
[Traduit par le journal]

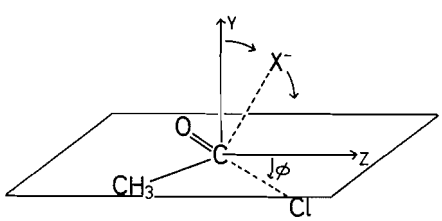
I. Introduction

A nucleophilic substitution on the unsaturated carbon (e.g., the acyl carbon) is known to proceed via a tetrahedral intermediate.

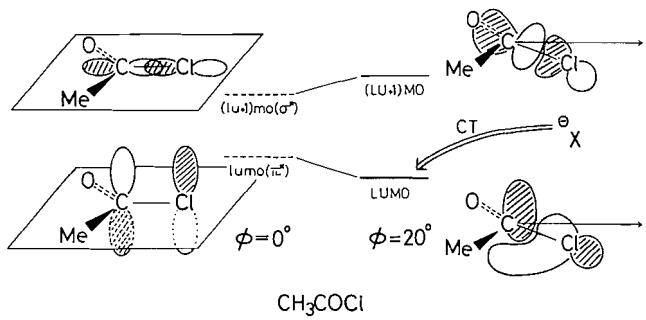


The mechanistic details of the reactions like ester hydrolysis have been extensively investigated, because of the relevance to the enzymatic catalysis in reactions of carboxylic acids (see, for example, ref. 1). Using the ion cyclotron resonance spectroscopy, Brauman and co-workers studied the kinetics of the gas-phase nucleophilic displacement (2). Such solvent-free data provide important information on the difference of the potential-energy surfaces between reactions in the gas phase and in the liquid phase. In our previous work (3), we sought the minimum-energy path of the gas-phase nucleophilic displacement on the acyl chloride. The reaction is initiated by the formation of the π $X^- \cdots CH_3CO—Cl$ complex and takes place in a concerted manner. No tetrahedral intermediate is found. The bent-out motion of the C—Cl bond from the *XZ* plane lowers the lowest unoccupied MO (LUMO) to enhance the charge-transfer (CT) interaction (LUMO−CT relation).





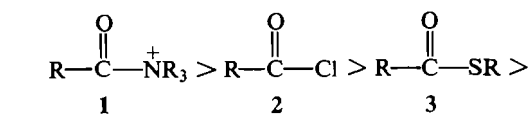
[1]To whom correspondence should be addressed.

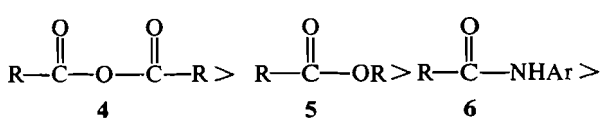


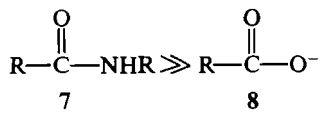
In this work, we would like to compare the reactivity of various carbonyl compounds theoretically, extending the concept of the LUMO−CT relation. An aromatic nucleophilic substitution is also studied to examine whether the tetrahedral intermediate is formed. Finally, the possibility of the intermediate is evaluated in terms of the extent of the $\pi^*-\sigma^*$ MO mixing. The solvent effect on the potential energy surface is discussed.

II. The reactivity of carbonyl compounds in the nucleophilic displacement

The order of the reactivity toward a nucleophile is established experimentally (see, for example, ref. 4).







The order is explained in terms of both the activity of the leaving group (L) and the extent of the conjugation to the carbonyl group. More systematic and uniform comparison may

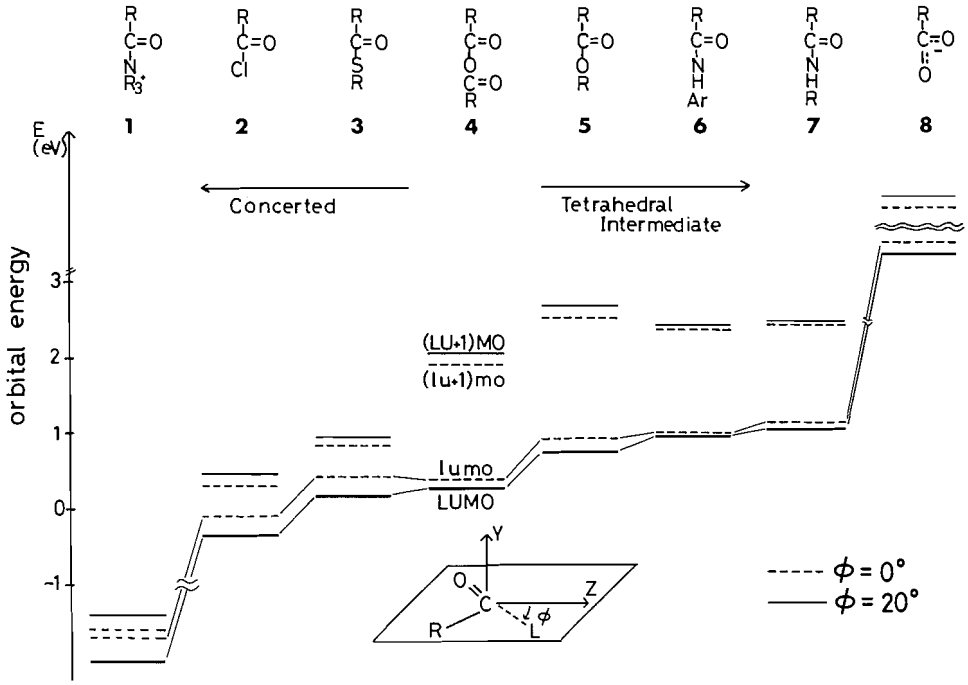

FIG. 1. The unoccupied-orbital energies of carbonyl compounds computed with the MNDO MO method. The broken levels, lumo and (lu + 1)mo, are for the equilibrium geometry. The full-line levels, LUMO and (LU + 1)MO, are for the bent-out geometry. lumo means the lowest unoccupied MO, and (lu + 1)mo the second lowest unoccupied MO. Substituent R is the methyl group and Ar is the phenyl ring in the MO calculation.

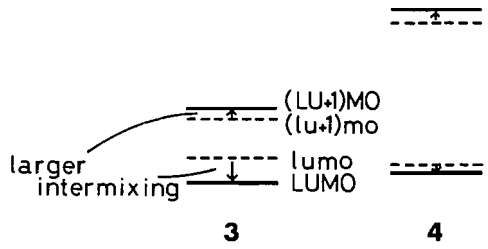
be made by applying the frontier orbital theory (5). In Fig. 1, lumo and (lu + 1)mo are displayed by broken lines. The lowest unoccupied MO, lumo, of the equilibrium geometry ($\theta = 0°$) is the π^* orbital, and (lu + 1)mo is σ^*_{C-L}. Although lumo's are almost in the correct order, we find a discrepancy between **3** and **4**. That is, lumo of **3** is higher than that of **4**, which is in disagreement with the experimental order. Here, we calculate LUMO and (LU + 1)MO which are obtained by bending the C—L bond ($\theta = 20°$). Since the angle θ may be taken arbitrarily as a non-zero value, 20° is used throughout this study. The deformation causes the destabilization of the substrates by 2.7 ~ 5.4 kcal/mol. This energy loss is, however, so small that the electronic stabilization is expected to overcome it readily. The distortion intermixes the π^* MO with the σ^* MO, resulting in the enlargement of the energy separation. These two energy levels denoted by full lines are also shown in the diagram below. When the levels of LUMO's (bold lines) are compared, they are found to be just in the right order. The discrepancy appearing in **3** and **4** is removed by the larger intermixing of π^* and σ^* in **3**.



lumo(**3**) is higher than lumo(**4**)
but LUMO(**3**) is lower than LUMO(**4**)

This result indicates that the relative reactivity of the carbonyl compounds *should not* be evaluated by lumo alone. LUMO which is given by the small distortion along the reaction coordinate predicts the proper reactivity. The energy lowering by lumo → LUMO (i.e., $\phi = 0 \rightarrow 20°$) is larger, when the energy difference between lumo and (lu + 1)mo is smaller. π^* MO calls for the nucleophile X^-, and σ^* MO causes the C—L bond scission after the electronic charge of X^- is accepted. LUMO is a uniform criterion involving these two operations.

The σ^* level reflects the C—L bond strength. For **2** with the weak C—L bond, no tetrahedral intermediate is found (3). The intermediacy seems, however, to be a matter of degree of the σ^* level. To examine this, we seek the structure of $F^- \cdots HCOOCH_3$ (as **5**) and $H^- \cdots H_2C{=}O$ (as model) with the *ab initio* MO of the 4-31G basis set. Although the latter is not realistic,[2] its C—L (C—H) bond is the strongest and formaldehyde is a good model to check the intermediacy. As a result of calculation, those two are found to be intermediates. In Fig. 2, these geometries are exhibited together with that of the transition state of $Cl^- \cdots CH_3CO{-}Cl$ reported previously (3). By the MNDO calculation, the orbital energies of π^* and σ^*_{C-Cl} of **2** are −0.09 and 0.30 eV, respectively (shown in Fig. 1). Those of **5** are 1.20 and 2.75 eV, and those of the model are 0.93 and 3.86 eV. The $\pi^* - \sigma^*$ energy gap is in the order, **2** > **5** > model. Thus, the intermediacy depends on the energy difference between π^* and σ^* MO's. It is surprising in Fig. 2 that the C—O bond length in **2** is the same as that in the transition state (1.18 Å). This is in contrast to the result for the latter systems. This apparent maintenance arises from the back-donation of the $\bar{\pi}$ charge of the carbonyl oxygen to the carbon, schematically illustrated below. For $F^- \cdots HCOOCH_3$, such back-donation (although smaller) makes the C—O bond shorter (1.30 Å) than the standard value (~1.43 Å).

[2]The potential energy of the model reaction was computed in ref. 6.

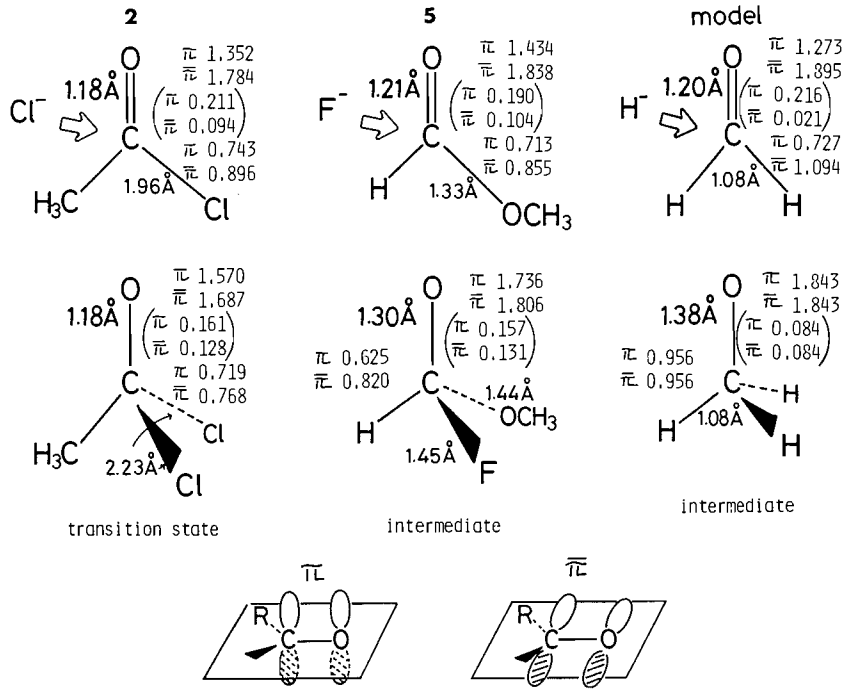

FIG. 2. The optimized structures of substrates, acyl chloride (as **2**), methyl formate (as **5**), and formaldehyde (as model). Those of the transition state and two intermediates are also shown. The numbers of π and $\bar{\pi}$ are orbital electron densities, and those in parentheses are π-type bonding electron densities between carbon and oxygen atoms. Densities are calculated with a fixed C—O bond length (of the substrate) for comparison. All calculations are made with the 4-31G basis set.

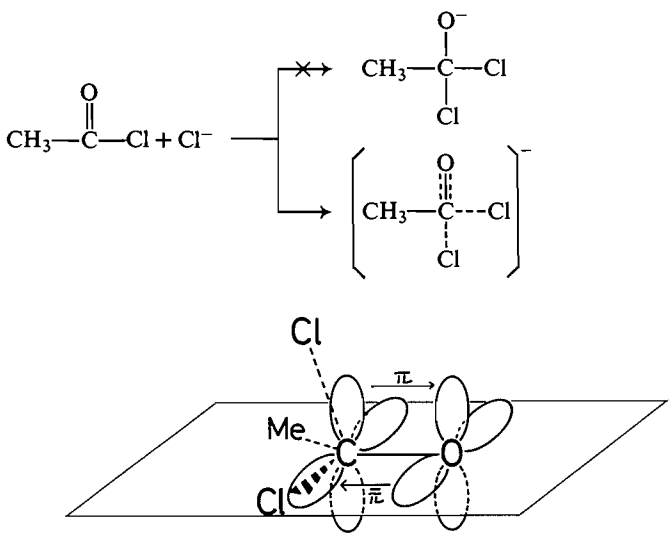
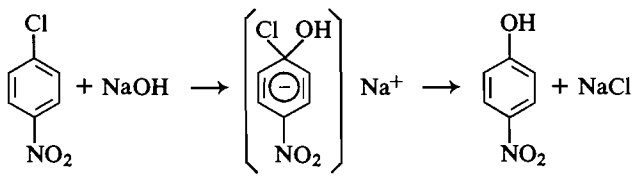
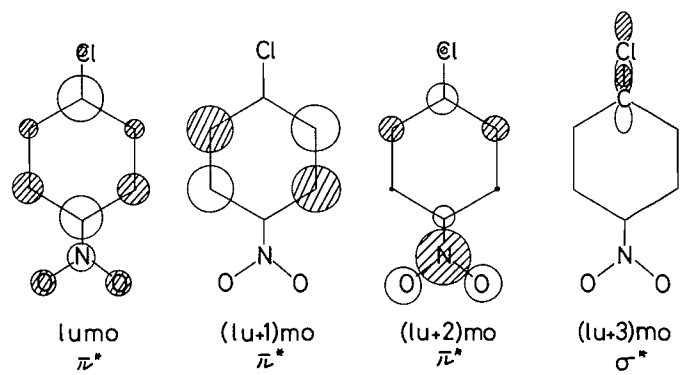


III. The aromatic nucleophilic displacement

In contrast to the S_N2 reaction of the alkyl halide, the aromatic nucleophilic substitution is thought to proceed via the benzenium-ion intermediate. This ion is stabilized by the nitro substituent on the phenyl ring (7).



To examine the intermediacy, the minimum-energy path of the alkaline hydrolysis of *para*-nitrochlorobenzene is traced theoretically. In Fig. 3, the potential-energy profile is exhibited together with the optimized parameters. In Fig. 4, the snapshot of the minimum-energy path is given. The curve in Fig. 3 shows that there is no energy maximum corresponding to the transition state. Since this theoretical datum does not include the solvent effect at all, the energy variation is for the gas-phase reaction. In Fig. 5, the change of the orbital energies and spatial extensions along the bending is illustrated. There are three π^* MO's in the substrate of the planar structure. Through bending, lumo and (lu + 1)mo intermix with (lu + 3)mo, respectively, resulting in the larger energy splitting.



As a substrate, *para*-nitrochlorobenzene has the enough low σ^* level to mix effectively with π^* orbitals. This leads to the concerted nucleophilic displacement. In contrast to this type, the substrate with the high-lying σ^* orbital may generate the tetrahedral intermediate. 1-Methoxy-2,4,6-trinitrobenzene (A) is readily converted to 1-ethoxy-2,4,6-trinitrobenzene (C) via a stable intermediate (B) of the red crystal (8).

θ(°)		90	65	45	27	0	
R(Å)	∞	3.11	1.42	1.39	1.37	1.35	1.35
r(Å)	1.75	1.75	1.88	1.98	2.22	3.44	∞
l(Å)	1.41	1.42	1.48	1.47	1.45	1.43	1.41
l′(Å)	1.41	1.42	1.43	1.43	1.43	1.42	1.41

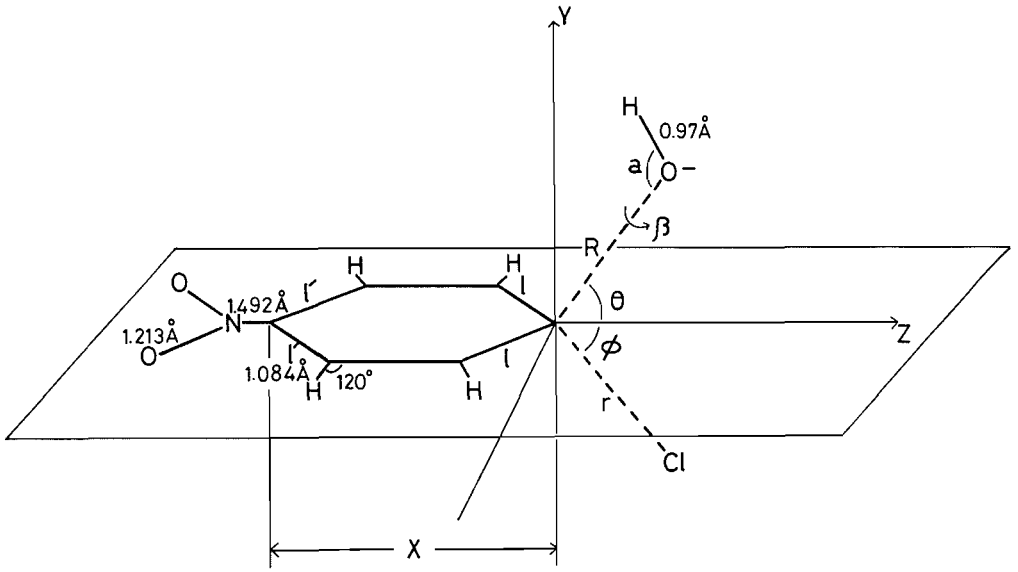

FIG. 3. The potential-energy profiles of the gas-phase reaction between *para*-nitrochlorobenzene and hydroxide ion. At a given angle θ, eight parameters, R, φ, r, l, l', X, α, and β, are optimized with the MNDO MO method. The total energy (E_T) given by the full line is calculated with the 4-31G + p (on Cl atom) + p' (on O atom) basis set. E_T is uniformed to zero at $R = \infty$. The C—N bond fixed here to 1.492 Å is found to be almost constant (at most 0.02 Å shortened) during the substitution.

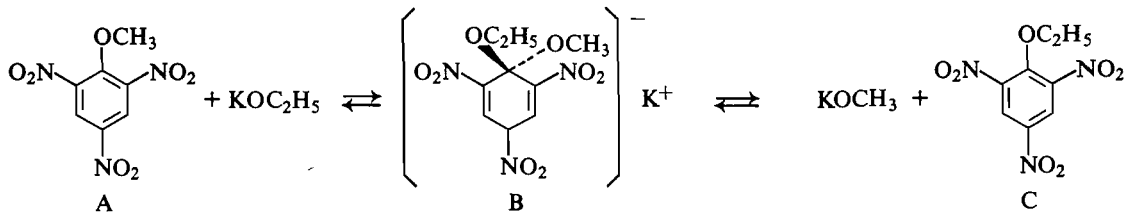

In Fig. 6, the MO energy levels of 4-nitromethoxybenzene (A′) and its intermediate (B′) are displayed. Omitting two *ortho* nitro groups, we adopt A′ for comparison with the reaction of *p*-nitrochlorobenzene in Fig. 3. The substantial difference of σ* levels as well as π lumo levels gives the different mechanism. Thus, similar to the nucleophilic displacement on the carbonyl carbon, the energy of the σ* level may be the criterion for the intermediacy.

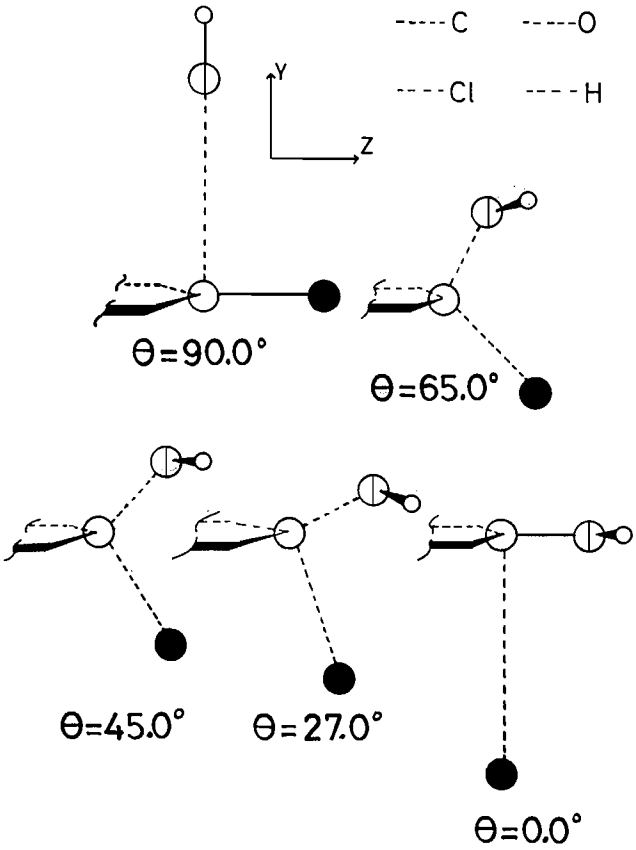

FIG. 4. The calculated path of the nucleophilic displacement on the phenyl α carbon.

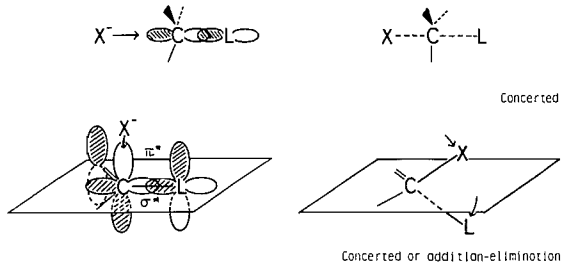
IV. Concluding remarks

Different from the S_N2 reaction of the alkyl substrate, the nucleophilic displacement on the unsaturated carbon needs the $\pi^*-\sigma^*$ orbital mixing during the reaction.



In the latter case, the σ^* level determines the mechanism (concerted or stepwise). In other words, if the C—L bond is weak, the concerted process is likely, and vice versa. The discussion made so far is based purely on the electronic structure of the substrate in the gas phase. To rationalize the application of the frontier-orbital theory to the liquid-phase reaction, comparison of the potential energies in the gas phase and in the liquid phase is necessary. Brauman *et al.* showed such comparison for the S_N2 reaction of the alkyl substrate (9). In Fig. 7, three types of the potential energies are suggested. Protic solvents such as water and alcohols are considered for the liquid phase. In Type I, the intermediate appears in both phases. The activation barrier is brought about by solvation or desolvation. The rate-determining step depends on the extent of the solvation ability. In the aromatic S_N2 reaction, however, the first energy barrier is known to control the kinetics (7). When X and L are first-row

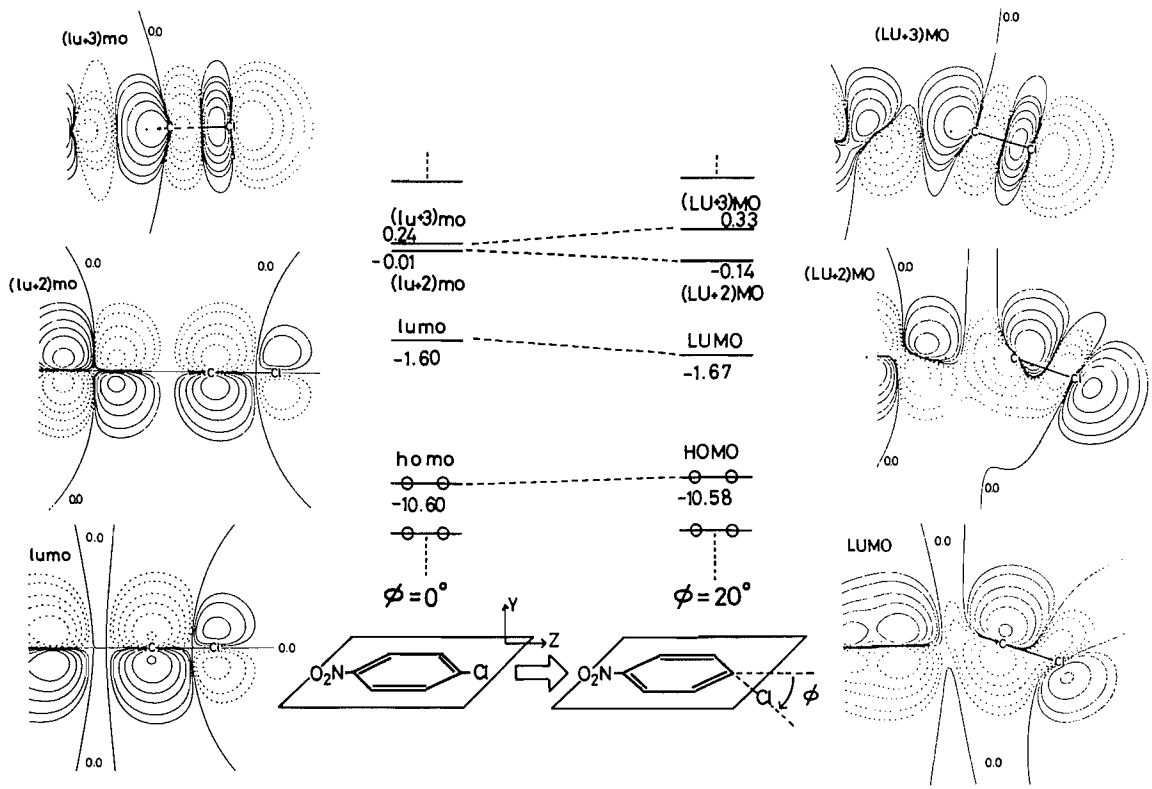


FIG. 5. The change of the orbital energies (in eV) and the shapes through bending the C—Cl bond out of the phenyl plane. The values attached to the contour lines in the *YZ* plane are ±0.5, ±0.2, ±0.1, ±0.05, ±0.02, ±0.01, and 0.0 $(e/Å^3)^{1/2}$ from inside to outer side.

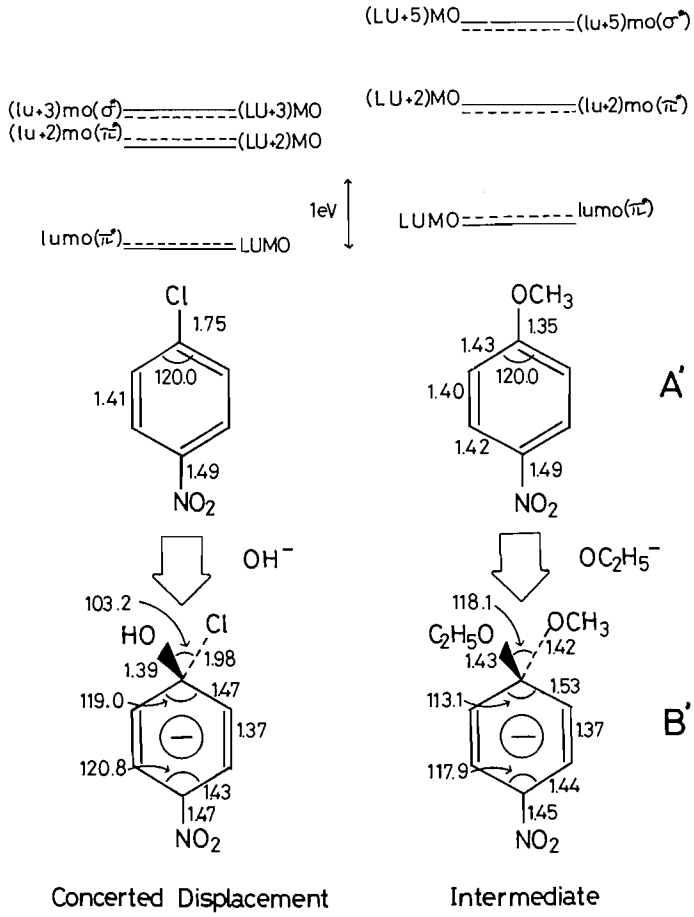

FIG. 6. The low-lying unoccupied levels (ϕ = 0 and 20°) of 4-nitrochlorobenzene and 4-nitromethoxybenzene (A'). For the former substrate, the geometry of the reacting system of θ = 45° (see Fig. 3) is shown. For the latter, the geometry of the intermediate (B') is exhibited. The optimization of geometries is carried out with the MNDO MO method. The bond length is in Å and angle in deg.

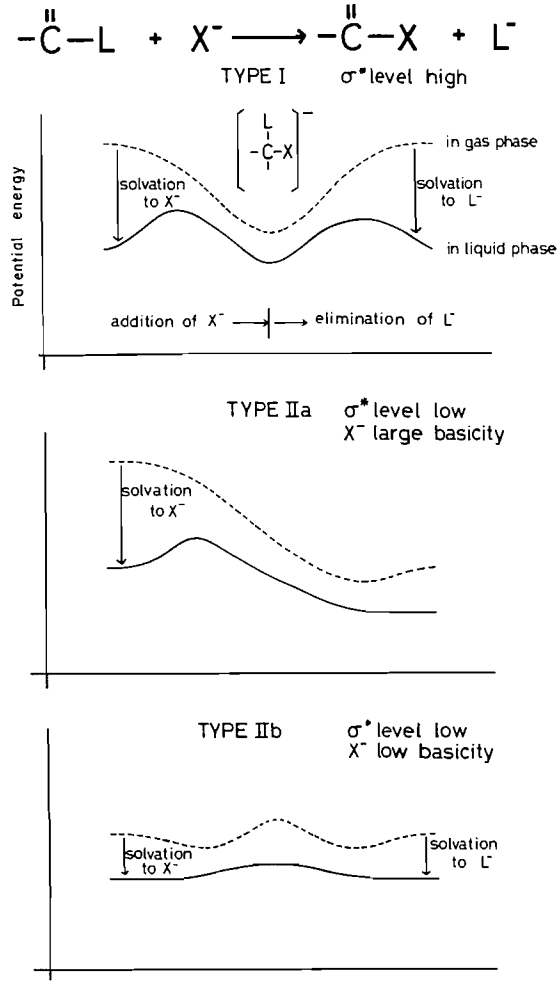

FIG. 7. Schematic sketch of three kinds of the potential energy diagram of the nucleophilic displacement on the unsaturated carbon. Full curves denote the liquid-phase reactions, and the broken curves the gas-phase reactions.

atoms or groups such as F and OCH_3, this type of the energy curves is likely. In Type IIa, the activation barrier is again due to the solvation to X^-. F^- + CH_3—CO—Cl and OH^- + O_2N—ϕ—Cl are the examples. In Type IIb, the energy barrier is given by bond interchange. Cl^- + CH_3—CO—Cl is the case. In Type II, no tetrahedral intermediate is formed. In all types, the rate-determining step is related to the energy change at the initial stage of the reaction. The energy lowering by the solvation is almost entirely for the nucleophile, X^-, and the energy of the substrate is hardly affected by solvation. Therefore, the frontier-orbital theory dealing with LUMO of the substrate may predict the proper relative reactivity, regardless of the type of the potential energy.

Acknowledgments

All *ab initio* calculations are performed with the GAUSSIAN 70 and its extended version GAUSSIAN 127 (10).[3] The authors thank the Institute for Molecular Science (IMS) for allotment of the CPU time of the HITAC M-200H computer. Permission to use the FACOM M-382 computer at the Data Processing Center, Kyoto University, is also acknowledged. They are grateful to Dr. Satoshi Inagaki for his valuable advice on the change of the C—O bond length in Fig. 2. The program of MNDO MO calculation is taken from the QCPE library (11).

The synthesis of a series of purine analogues of the acyclonucleoside compound A* (A-Star, **1**) is described. Compounds in this series have been shown to have pronounced activity against herpesviruses. These compounds have been designated "the glycerosides". The glyceropurines are described in this report. Nucleotides have been constructed containing glyceroadenine (A*, compound **1**). These nucleotides are resistant to degradation by phosphodiesterases. The compound A* is both a poor substrate and a poor inhibitor of adenosine deaminase.

KELVIN K. OGILVIE, NGHE NGUYEN-BA, MICHAEL F. GILLEN, BRUNO K. RADATUS, UKKEN O. CHERIYAN, H. RIZK HANNA, KENDALL O. SMITH et KAREN S. GALLOWAY. Can. J. Chem. **62**, 241 (1984).

On décrit la synthèse d'une série de purines qui sont des analogues du composé acyclonucléoside A* (A étoilé-**1**). Les composés de cette série ont une activité assez marquée contre les virus de l'herpès. On les appelle "les glycérosides". Dans ce travail, on décrit les glycéropurines. On a construit des nucléotides contenant la glycéroadénine (A*, composé **1**). Ces nucléotides résistent à la dégradation par les phospodiestérases. Le composé A* est à la fois un substrat pauvre et un pauvre inhibiteur de la désaminase adénosine.

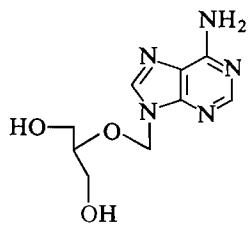
[Traduit par le journal]

Introduction

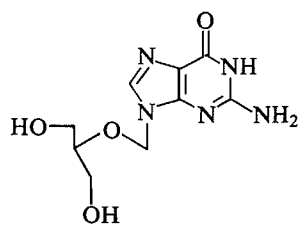
During our studies on cyclonucleosides we observed that 8,2′-thioanhydroadenosine was a good substrate for adenosine deaminase (1). This was surprising since 8-methylthioadenosine was a very poor substrate of adenosine deaminase. We reasoned (1) that 8-methylthioadenosine must prefer the "*syn*" conformation about the *N*−glycoside bond. Since 8,2′-thioanhydroadenosine is locked in the "*anti*" conformation, the implication drawn was that adenosine deaminase would recognize as substrates only those adenosine derivatives capable of existing in the "*anti*" conformation (1).

It was also known at the time that many adenosine derivatives are biologically active in vitro but are inactive in vivo because of deamination by adenosine deaminase to inactive inosine derivatives. We then made the assumption that a molecule (such as **1**) which has all of the chemical features of deoxyadenosine, but which lacks a rigid carbohydrate ring structure, would be a poor substrate of adenosine deaminase. We further reasoned that if compound **1** were also a poor inhibitor (i.e. had low binding to the enzyme) of adenosine deaminase, then it might serve as an excellent antiviral agent. This reasoning was purely intuitive and was based on the assumption that key viral enzymes would have a less rigorous structural requirement in their substrates than would the equivalent mammalian enzymes. Thus a molecule such as **1** might be exempt from degradation by adenosine deaminase and other mammalian enzymes but might be accepted as a substrate by replicative enzymes in viral systems.

We therefore began a program to synthesize a series of molecules based on the general structure **1**. One such molecule,



1



2

the guanine analogue **2** known as BIOLF-62, has shown remarkable activity against herpesviruses (2−5). The pyrimidine derivatives generally have lower activity toward the herpesviruses HSV-1 and HSV-2 (2*b*, 2*c*). In this report we wish to describe the synthesis of compound **1**, nucleotides derived from **1**, and a series of modified purine analogues of **1**. A preliminary account of some of these results has appeared (6).

Discussion and results

The general procedure for the synthesis of compound **1** and its analogues is outlined in Scheme 1. The chloromethyl ether **3** is prepared from 1,3-dichloro-2-hydroxypropane as shown. Compound **3** can be coupled directly to purines. For example, 6-chloropurine reacts with **3** in DMF to produce the 9-alkylated product **4** and the N-7 isomer **5**. Heating the mixture of products **4** and **5** results in the complete conversion of **5** into **4** resulting in a good overall yield of the desired product. Treatment of **4** or **5** with methanolic ammonia results in the adenine compounds **6** or **7**. The benzyl groups can easily be removed from **6** by catalytic hydrogenation to give **1**. Compound **1** is 9-[[2-hydroxy-1-(hydroxymethyl)ethoxy]methyl]adenine. For simplicity we have referred to this molecule as A* or A-Star.

An alternate route to compound **1** involved the direct (Scheme 2) condensation of adenine with **3**. In DMF with triethylamine only 17% of the desired product **6** was obtained.

[1]Part V in a series on antiviral and ring-open nucleoside analogues. Parts III and IV are refs. 2*b* and 2*c* respectively.

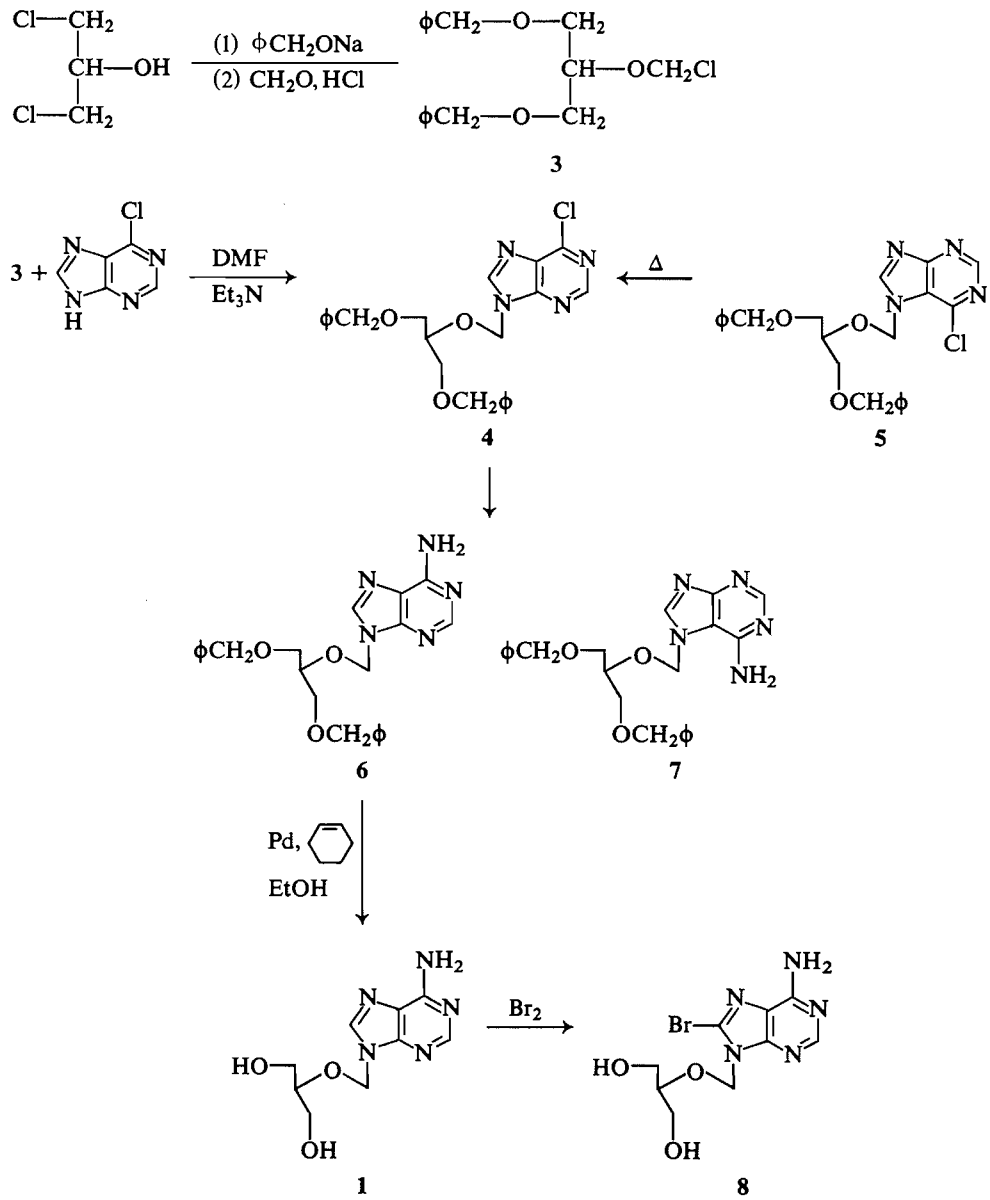


SCHEME 1

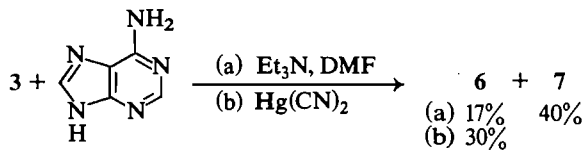
The major product (40%) was the N-7 isomer (**7**). The mercuric cyanide catalyzed coupling of adenine to **3** gave the desired product **6** in 30% yield.

Adenosine deaminase studies on 1

Initial velocities for the deamination of A* and adenosine in buffered solutions of varying substrate concentrations were determined and the data plotted according to the method of Lineweaver and Burk (7). The results are shown below.

Substrate	$K_m(M\times10^5)$	Rel. V_{max}
Adenosine	4.83	1.00
A*	187	2.55×10^{-2}

Clearly A* is weakly bound to the enzyme relative to adenosine. It appears that while A* had the structural features that should enable it to bind to the enzyme (8, 9), its conformational flexibility prevents efficient binding. In order to obtain an initial idea of the effect of base substituents on deaminase activity, 8-bromoA* (**8**) was prepared by standard procedures



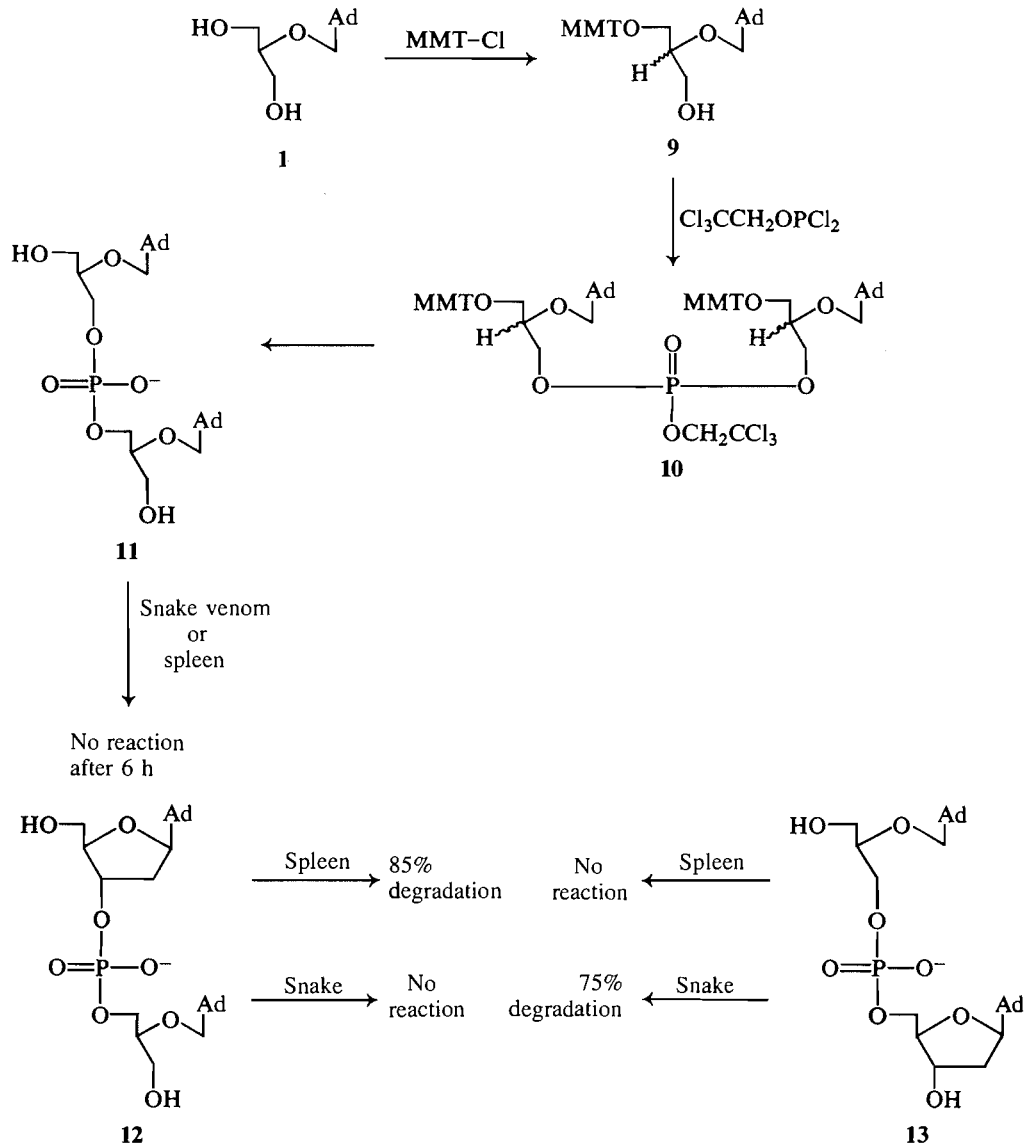
SCHEME 2

(10). A* and 8-bromoA* were treated with high concentrations of adenosine deaminase and 8-bromoA* was found to be 140 times less reactive than A*. A* is a weak competitive inhibitor of adenosine deaminase with a K_i value of 2.04×10^{-4} *M*.

*Dinucleotides from A**

It was of interest to synthesize dinucleoside monophosphate analogues from A*. This was readily accomplished (Scheme 3) by preparing the monomethoxytrityl derivative **9** (MMT-A*). The isomers of **9** were not resolved and the nucleotide **10** was prepared by coupling two equivalents of **9** with 1 equivalent of 2,2,2-trichloroethylphosphorodichloridite. The isolated yield of **10** was 56% and after complete deprotection the nucleotide analogue **11** was obtained.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.



SCHEME 3

Compound **11** was completely resistant to both snake venom and spleen phosphodiesterases for 6 h under standard conditions. On the other hand, the mixed nucleotides **12** and **13**, each containing a unit of deoxyadenosine and A*, showed some degradation. For example, after 6 h, **12** was 85% degraded by spleen but was unaffected by snake venom. The reverse was true for **13**. These results indicate that the ring-open structure of A* is not recognized as a normal substrate by phosphodiesterases.

*Changes in the acyclic portion of A**

In order to determine the effect of replacement of the hydroxyl groups of A* with regard to biological activity, the azido and amino derivatives **18**, **22**, **23**, and **24** were prepared. The synthesis of these compounds is outlined in Scheme 4.

The mono and bis tosylated derivatives **16** and **20** were prepared by standard procedures. Sodium azide in DMF gave clean displacement of the tosyl groups in both cases and after deprotection the azido derivatives **18** and **22** were obtained. Compound **18** and **22** could be obtained directly from A* as an easily separable mixture using the procedure of Hata and co-workers (11). Direct reduction of the azido derivatives gave the monoamino derivative **23** and the diamino derivative **24**.

Changes in the purine base

Numerous purines have conferred biological activity to nucleoside structures. Among those of most interest, other than the guanine analogue, were purine, 2-aminopurine, 2,6-diaminopurine, 2-fluoro-6-aminopurine, isoguanine, 6-chloropurine, and 6-chloroguanine. 2,6-Diaminopurine nucleosides have shown activity against herpesviruses (12) while the purine, nebularine, is a nucleoside antibiotic (13). The 2-halopurine nucleosides have shown activity against malignant lymphoblasts (14) while isoguanine derivatives have shown a range of biological activities including uses as muscle relaxants and anti-inflammatory agents (15, 16).

Direct coupling of 2,6-diaminopurine to **3** was not successful under the usual conditions. However N^2,N^6-diacetyl-2,6-diaminopurine coupled to **3** to give **25** in 55% yield (Scheme 5). Removal of acetyl and benzyl groups produced the desired compound (**27**).

The 2-amino group in 2,6-diaminopurine derivatives can be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

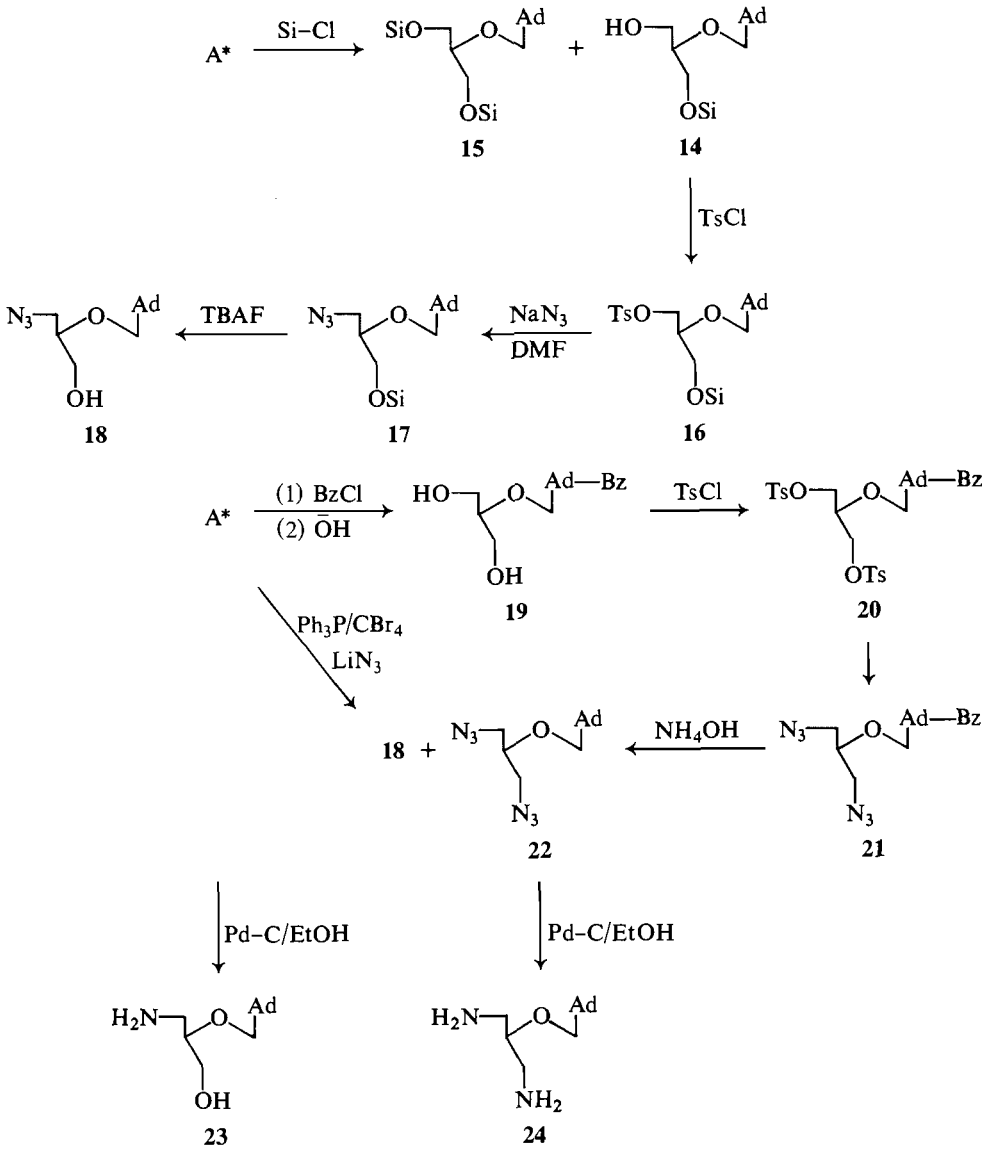

SCHEME 4

selectively replaced by halogens using procedures described by Robins and Uznanski (17). Treatment of **26** with *tert*-butylnitrite in 60% HF/pyridine gave the desired 2-fluoro derivative **28** in 35% yield. These reaction conditions also resulted in the partial loss of benzyl groups and compound **29** was obtained in 15% yield. Complete removal of benzyl groups from **28** produced **30** in 88% yield.

The 2-amino group in **26** could also be selectively diazatized to an oxygen function giving rise to the isoguanine structure **31** in 55% yield. Removal of the benzyl groups from **31** gave the isoguanine derivative **32** which is isomeric to BIOLF-62 (**2**).

While compounds A* (**1**) and **27** are not good substrates for adenosine deaminase they do undergo deamination when a large excess of enzyme is used. This process can be used on a preparative scale. In this work the 2,6-diaminopurine derivative **27** was treated with an excess of adenosine deaminase and was quantitatively converted into BIOLF-62 (**2**). Similar treatment of A* led to a 90% isolated yield of the inosine derivative **33**.

The chlorine atom in position 6 of the 6-chloropurine and 6-chloroguanine derivatives **4** and **34** could be hydrogenolyzed without any significant loss of benzyl protecting groups (18). The benzyl groups in **35** were quite resistant to hydrogenolysis under standard conditions. However, the boron trichloride method (19) worked well. In fact, this method led to cleavage of the benzyl groups from **4** and **34** without affecting the chlorine atom at position 6, producing the 6-chloropurine and 6-chloroguanine compounds **37***a* and **37***b* (Scheme 6).

Biological activity

The compounds described in this report were all tested for activity against HSV-1. The two most active compounds were the guanine derivative, **2**, and the 6-chloroguanine derivative, **37***b*. The ED-50 values vs. HSV-1 were 0.13 μg/mL and 6.6 μg/mL respectively. Neither compound showed any detectable toxicity towards cells at concentrations up to 1000 μg/mL. All other compounds had ED-50 values ≥ 100 μg/mL. Compounds **30** and **37***a* showed significant cellular toxicity at concentrations of 32 μg/mL.

Compound **2** is also active against HSV-2 with an ED-50 value of 0.25 μg/mL. It has previously and erroneously been reported (2, 3) that compound **2** is inactive against cytomegalovirus (CMV). In fact, compound **2** is very active against CMV with an ED-50 value of 20 μg/mL. Compounds **1**, **37***a*,

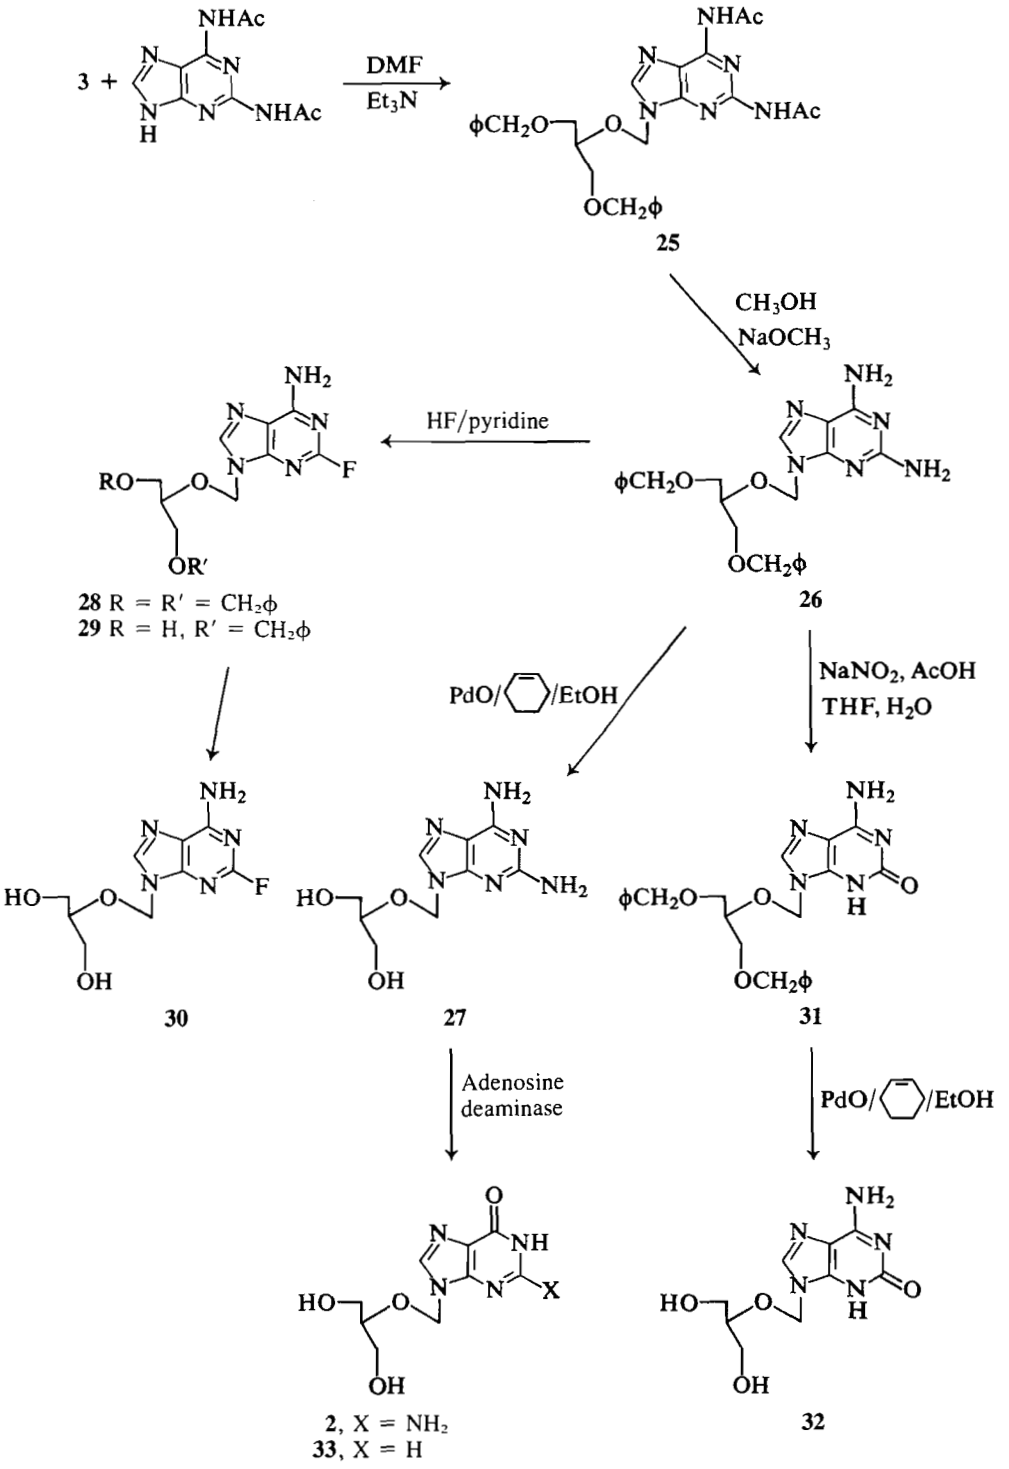

SCHEME 5

and **37***b* are also active against cytomegalovirus with viral ED-50 values of 20, 60, and 32 μg/mL repsectively. The results of complete biological testing will be reported elsewhere.

Experimental

General methods

Products from preparative scale reactions were isolated by column chromatography using Merck silica gel 60 (230–400 mesh) packed in glass columns (15 g of silica per gram of crude material). Thin-layer chromatographic data (R_f values) are recorded from Merck Kieselgel 60F254 analytical sheets. Purine bases were purchased from Sigma Chemical Co. Ultraviolet spectra were recorded on a Cary 17 spectrometer. Nuclear magnetic resonance spectra were recorded using a Bruker WH-90, a Varian XL-200, and a Varian T60A spectrometer.

Elemental analyses

C, H, and N analyses were performed by Canadian Microanalytical Service. Analyses of new compounds were ±0.4% of the calculated values.

1,3-Dibenzyloxy-2-propanol

Benzyl alcohol (500 mL) was placed in a three-neck round-bottom flask (2 L) through which dry nitrogen was passed continuously.

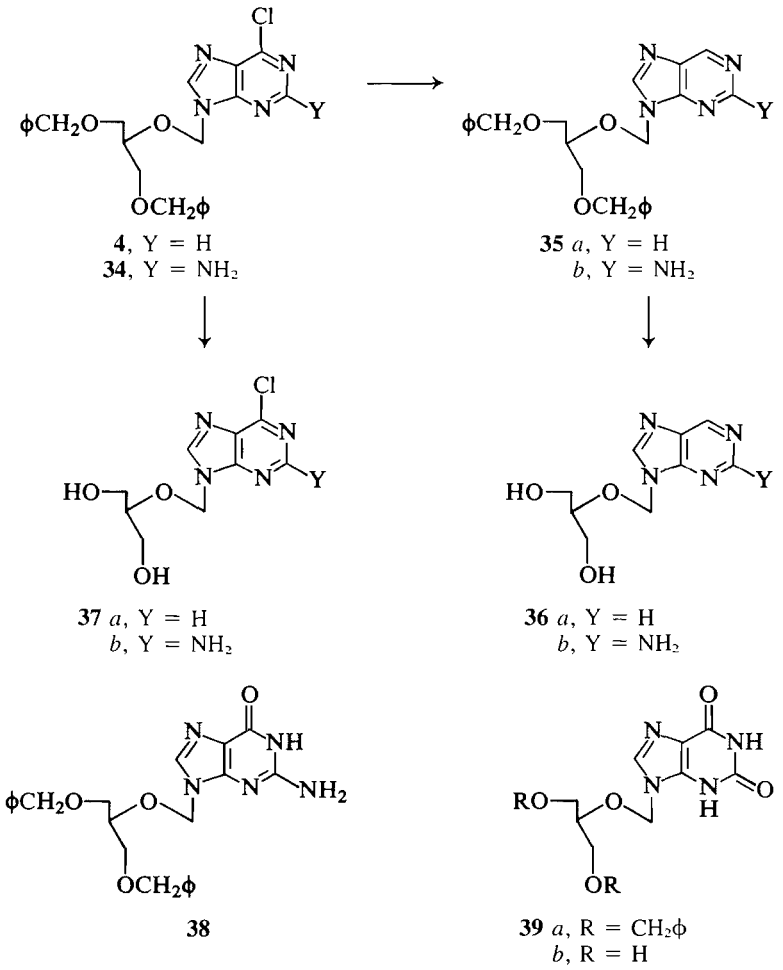

SCHEME 6

Sodium hydride (40 g of 50% NaH in oil, 0.834 mol of NaH) was washed with hexanes and added in portions to the benzyl alcohol with stirring. The addition required 15 min and stirring was continued for an additional hour. 1,3-Dichloropropan-2-ol was added and the system was heated at 100°C overnight. The reaction mixture was extracted with ether which was then washed sequentially with water, 20% aqueous HCl, and water (2×). The ether solution was dried over sodium sulfate and the ether was removed at reduced pressure. The excess benzyl alcohol was removed on a horizontal evaporator at reduced pressure. The remaining oil distilled under high vacuum to give 53 g (96%) of 1,3-dibenzyloxy-2-propanol (bp 195–210°C at 3 Torr). The product had R_f 0.35 in ether–hexane (1:1) and showed peaks in the ^{1}Hmr (60 MHz, $CDCl_3$) at δ: 2.92 (1H, OH), 3.58 (d, 4H, —$CH_2CHOHCH_2$—), 4.03 (m, 1H, —$CH_2CHOHCH_2$—), 4.58 (s, 4H, 2 × $PhCH_2$—), and 7.45 (m, 10H, 2 × Ph). The mass spectrum showed a molecular ion at *m/e* 272.

1,3-Dibenzyloxy-2-chloromethoxypropane (3)

1,3-Dibenzyloxy-2-propanol (50 g, 0.18 mol) was added to 1,2-dichloroethane (350 mL, distilled from P_2O_5) followed by paraformaldehyde (8 g). The reaction mixture was cooled in an ice bath and dry HCl gas was bubbled through the stirred solution for 6 h. Anhydrous calcium chloride was then added and after stirring for a few minutes the solution was collected by filtration. The filtrate was evaporated at reduced pressure to yield 53.5 g (91%) of compound **3** as a sirup. The product, which showed the following peaks in the ^{1}Hmr (60 MHz, $CDCl_3$), δ: 3.70 (d, 4H, —CH_2CHCH_2—), 4.13 (m, 1H, —CH_2CHCH_2—), 4.58 (s, 4H, 2 × $PhCH_2$—), 5.70 (s, 2H, OCH_2—Cl), and 7.38 (m, 10H, 2 × Ph), was used directly in coupling experiments.

9-[[2-Benzyloxy-1-(benzyloxymethyl)ethoxy]methyl]-6-chloropurine (4) and 7-[[2-benzyloxy-1-(benzyloxymethyl)ethoxy]methyl]-6-chloropurine (5)

6-Chloropurine (9 g, 58.5 mmol) was dissolved in DMF (50 mL) and triethylamine (7 g) was added. The solution was cooled in an ice–salt bath and compound **3** (58.5 mmol in 50 mL of DMF) was added. Triethylamine hydrochloride precipitated immediately. After 1 h the mixture was removed from the ice bath and was allowed to stand at room temperature for 12 h. The solution was collected by filtration and the solvents were removed at reduced pressure on a horizontal evaporator to yield 26.6 g of sirup. The residue was dissolved in a minimum of chloroform and applied to a silica gel column (24 × 6.3 cm) eluted with 1% methanol in chloroform. The yield of compound **4** was 14.8 g (60%) and that of compound **5** was 6.1 g (23%).

Compound **4** showed λ_{max}: 264 nm (pH 1), 264 nm (H_2O), and 264 nm (pH 13). The nmr spectrum in $CDCl_3$ showed signals at δ (ppm) of 3.53 (d, 4H, J = 5.5 Hz, —CH_2CHCH_2—), 4.03 (m, 1H, —CH—), 4.45 (s, 4H, 2 × $PhCH_2$—), 5.88 (s, 2H, —OCH_2N—), 7.33 (m, 10H, 2 × Ph—), 8.23 (s, 1H, H-2), and 8.78 (s, 1H, H-8).

Compound **5** had λ_{max} 268 nm at pH 1, 7, and 13. The nmr spectrum ($CDCl_3$) gave signals at δ (ppm) of 3.53 (d, 4H, J = 5.0 Hz, —CH_2CHCH_2—), 3.82 (m, 1H, —CH—), 4.47 (s, 4H, $PhCH_2$—), 5.98 (s, 2H, —OCH_2N—), 7.27 (m, 10H, 2 × Ph—), 8.33 (s, 1H, H-2), and 8.82 (s, 1H, H-8).

Compound 4. Direct route

6-Chloropurine (15.6 g) was dissolved in DMF (75 mL) and triethylamine (11.1 g) was added. The solution was cooled in an ice–salt bath and 32.3 g of **3** in DMF (50 mL) was added. After 2 h

*Solvents for tlc: dichloromethane–methanol (a) 7:3; (b) 9:1; (c) 8:2. Solvent for paper chromatography: A (*i*PrOH–NH_4OH–H_2O; 7:1:2, v/v/v).

the mixture was removed from the ice bath and allowed to stand at room temperature for 18 h. The work-up was the same as in the above experiment except that the sirup obtained (48 g) was not applied directly to silica gel but was heated at 90°C for 24 h. Nuclear magnetic resonance showed that all of **5** had disappeared and the only product present was **4**. The product was further purified by chromatography on silica gel using $CHCl_3$–EtOAc (7:3) as eluant. Compound **4** was obtained as a sirup in 69% yield.

9[[2-Benzyloxy-1-(benzyloxymethyl)ethoxy)]methyl]adenine (6)

Compound **4** (22.3 g, 0.05 mol) was dissolved in methanol (15 mL) and 60 mL of saturated methanolic ammonia was added. The solution was sealed in a steel bomb which was then placed in an oil bath maintained at 110°C for 36 h. On cooling, the mixture was removed from the bomb, concentrated to about half its original volume, and then shaken with a mixture of water and chloroform. The organic phase was separated, washed with water, and dried over sodium sulfate. On evaporation of the solvent, 20 g of crude product was obtained. After recrystallization from ethanol, a total of 18.8 g (88%) of compound **6** was obtained as a white solid, mp 129–131°C. Compound **6** had a λ_{max} at 258 nm (pH 1), 260 nm (pH 7), and 260 nm (pH 13). The nmr spectrum ($CDCl_3$) showed signals at δ (ppm) of 3.55 (d, 4H, —CH_2—CH—CH_2—), 4.03 (m, 1H, —CH—), 4.47 (s, 4H, 2 × $PhCH_2$—), 5.77 (s, 2H, —OCH_2N—), 6.47 (bs, 2H, —NH_2), 7.28 (m, 10H, 2 × Ph—), 7.93 (s, 1H, H-2), and 8.38 (s, 1H, H-8).

7[[2-Benzyloxy-1-(benzyloxymethyl)ethoxy]methyl]adenine (7)

Compound **5** (2 g, 4.6 mmol) was treated as above for **4**. The product was purified from tlc using MeOH—$CHCl_3$ (5:95). The product crystallized from ethanol to give 1.03 g (54%) of **7** (mp 91–93°C). Compound **7** had a λ_{max} at 273 nm (pH 1) and 268 nm at pH 7 and 13. The nmr spectrum ($CDCl_3$) showed signals at δ (ppm) of 3.53 (d, 4H, —CH_2CHCH_2—), 3.93 (m, 1H, —CH—), 4.43 (s, 4H, 2 × $PhCH_2$—), 5.72 (s, 2H, —OCH_2N—), 7.82 (s, 1H, H-2), and 8.42 (s, 1H, H-8).

9-[[2-Benzyloxy-1-(benzyloxymethyl)ethoxy]methyl]adenine (6)

Adenine (500 mg) was suspended in HMDS (30 mL) and ammonium sulfate (200 mg) was added. The mixture was heated at reflux until a clear solution was obtained. The excess HMDS was removed at reduced pressure and the residue was dissolved in benzene (30 mL) to which mercuric cyanide (1.12 g) was added. After heating this mixture at reflux for 10 min, compound **3** (2.52 g dissolved in 10 mL of benzene) was added and refluxing was continued for 2 h. After cooling to room temperature, the solution was filtered from some insoluble material and was then extracted with methylene chloride (3 × 100 mL). The methylene chloride solution was washed successively with 30% aqueous potassium chloride (2 × 100 mL) and water (100 mL) and then dried over magnesium sulfate. The solvent was removed at reduced pressure to leave a residue that was dissolved in methanol (50 mL) and the resulting solution was heated at reflux for 1 h. The solution was concentrated to a small volume and subjected to silica gel chromatography using methylene chloride – methanol (9:1). Compound **6** was obtained in 30% yield (465 mg).

9-[[2-Hydroxy-1-(hydroxymethyl)ethoxy]methyl]adenine (1)

Compound **6** (20.5 g) was dissolved in hot ethanol (500 mL) and fresh palladium oxide (10 g) and cyclohexene (200 mL) were added. The reaction mixture was stirred overnight (18 h) at room temperature followed by heating at reflux for 2-1/2 h. The mixture was cooled and filtered. The residue was washed with 800 mL of hot ethanol. The filtrate and washings were combined and evaporated to yield 10.7 g of crude product. The crude product was treated with decolorizing carbon in hot water. Crystals were obtained by diluting a solution of the product in 10 mL of hot water with 400 mL of ethanol. A total of 9 g of compound **1** (77%, mp 193–195°C) was obtained. Signals in the nmr spectrum (DMSO-d_6) occurred at δ (ppm): 3.40 (m, 4H), 3.98 (m, 1H), 4.58 (t, 2H), 5.61 (s, 2H), 7.2 (s, 2H, —NH_2), 8.06 (s, 1H), and 8.13 (s, 1H). Other properties are collected in Tables 1 and 2.

8-BromoA (8)*

8-BromoA* was prepared according to a standard procedure (10). A* (72 mg, 0.3 mmol) was dissolved in 0.5 mL of 0.5 *M* Na^+OAc^- buffer (adjusted to pH 4.3 with AcOH). A saturated solution of bromine–water (0.25 mL) was then added and the reaction mixture was allowed to stir at 22°C for several hours. Thin-layer chromatography was used to monitor the reaction and after ~3 h most of A* had been converted to a faster moving material. A few milligrams of sodium bisulfite were then added to the reaction mixture until the red color had disappeared. The solution was then evaporated to dryness, dissolved in ~1 mL of 95% EtOH, and applied to two thick-layer silica gel plates. The plates were developed in $CHCl_3$–EtOH

*Spectra were obtained in DMSO-d_6 on a Bruker WH90 spectrometer.

(8:2) and a band at R_f 0.24 was eluted with methanol. The methanol was then evaporated to leave 78 mg (82%) of 8-bromoA* as a white solid (mp 172–174°C); R_f: 0.24 ($CHCl_3$–EtOH (8:2)), 0.09 ($CHCl_3$–EtOH (6:1)); uv (95% EtOH), λ_{max}: 264 nm; λ_{min}: 233 nm; ^{1}Hmr (DMSO-d_6), δ: 8.17 (1H, s, C2—H), 7.37 (2H, s, NH_2), 5.6 (2H, s, O—CH_2—N), 4.67 (2H, t, OH), 4.0 (1H, m, H—C—O), 3.43 (4H, d, (HO—CH_2)$_2$—CHO).

Monomethoxytrityl A (9)*

Compound **1** (598 mg, 2.5 mmol) was dissolved with gentle heating in "dry" pyridine (40 mL) and the solution was cooled to room temperature. Monomethoxytrityl chloride (781 mg, 2.53 mmol) was then added and the reaction mixture was stirred at 22°C for 24 h. Pyridine was then removed under reduced pressure by co-distilling with toluene to leave a gummy foam which was dissolved in $CHCl_3$ (6 mL) and applied to 12 thick-layer silica gel plates. The plates were developed in $CHCl_3$–EtOH (8:2) and a uv absorbing band at R_f 0.63 was eluted with methanol. The methanol was then evaporated to leave a gum which was dissolved in $CHCl_3$ (5 mL). Addition of hexanes (25 mL) resulted in the precipitation of a fluffy white material which after drying under vacuum afforded 767 mg (60%) of the desired product (mp 94–97°C); R_f: 0.16 (EtOAc), 0.63 ($CHCl_3$–EtOH; 4:1), 0.35 (THF–EtOAc; 1:1); uv (95% EtOH) λ_{max}: 259, 231 nm; λ_{min}: 246, 227 nm; ^{1}Hmr ($CDCl_3$), δ: 8.3 (1H, s, C8—H), 7.83 (1H, s, C2—H), 6.7–7.43 (14H, m, trityl), 6.1 (2H, s, NH_2), 5.73 (2H, s, O—CH_2—N), 4.83 (1H, s, OH), 3.77 (4H, m, OCH_3, H—C—O), 3.25 (4H, d, (HO—CH_2)$_2$—CHO).

General procedure for the preparation of nucleotides

$$\overset{O}{\overset{\|}{}}$$

A. *Preparation of (MMT-A*)$_2$ $POCH_2CCl_3$ (10)*

Collidine (4.2 equiv.) was added to THF (0.5 mL) in a vial fitted with a rubber septum and a magnetic stirrer. The vial was then cooled to −78°C in a Dry Ice − acetone bath. 2,2,2-Trichloroethylphosphorodichloridite (0.55 equiv.) was then added. A solution containing MMT-A* (0.5 mmol) in THF (0.5 mL) was added dropwise over a 5-min period. The reaction mixture was vigorously stirred throughout the addition. Stirring was continued for an additional 30 min at −78°C followed by 30 min at 22°C.

Iodine (1.1 equiv.) and pyridine (2 drops) in THF–H_2O (2:1, v/v, 1.5 mL) was then added and the septum was removed. After 20 min the solvents were removed at reduced pressure. The residue was dissolved in chloroform which was washed successively with 5% $NaHSO_3$ (20 mL) solution and water (20 mL). The chloroform solution was concentrated to a small volume and applied to six thick-layer plates developed in $CHCl_3$–EtOH (6:1). The product band was eluted with ethyl acetate and the product was obtained by precipitation with hexane. The yield of **10** was 56% (mp 103–104°C). The product had an R_f of 0.42 in $CHCl_3$–EtOH (6:1) and showd λ_{max} at 258 nm (95% EtOH).

The product **10** was deprotected in the sequence (1) removal of methoxytrityl, (2) removal of the trichloroethyl group by Zn–Cu couple in DMF to give the nucleotide **11** (A*pA*). Compound **11** had λ_{max} at 258 nm (95% EtOH) and had $R_f^{\wedge}$ of 0.32 (paper chromatography) and E_m^{Tp} of 0.22 (pH 7.5).

B. *Mixed nucleotides d-ApA* (12) and A*pdA (13)*

This procedure was similar to that above except that 0.2 mmol of MMT-dA and 0.22 mmol of $TCEOPCl_2$ were used and stirring was continued for only 10 min at −78°C. At this point MMT-A* (0.18 mmol) in THF (0.5 mL) containing collidine (0.75 mmol) was added rapidly with stirring. The solution was stirred at −78°C for 20 min followed by 20 min at 22°C. Iodine was added as described in A above and the rest of the procedure is also as described in A. The yield of

$$\overset{O}{\overset{\|}{}}$$

MMT-dA P(OTCE) A*MMT was 65% (mp 112–116°C); R_f 0.62 ($CHCl_3$–EtOH; 6:1); λ_{max}: 258 (95% EtOH).

This material was deprotected as in A above to give dApA*, λ_{max} 258 nm (95% EtOH), $R_f^{\wedge}$ of 0.36, and E_m^{Tp} of 0.20.

The nucleotide of A*pdA (**13**) was prepared in a similar manner and had λ_{max} 258 nm (95% EtOH), $R_f^{\wedge}$ of 0.33, and E_m^{Tp} of 0.20.

Enzyme assays

A. *Adenosine deaminase*

(a) *Substrate studies*

A stock solution of adenosine was prepared by dissolving the nucleoside (10.22 μmol, 2.730 mg) in 100 mL of a stock solution of potassium phosphate (KH_2PO_4) buffer (pH 7.5, 0.055 *M*). Aliquots of the adenosine stock solution were then taken to prepare solutions with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

adenosine concentrations of 81.72 μ*M*, 61.29 μ*M*, 51.08 μ*M*, 40.86 μ*M*, and 20.43 μ*M*. Each solution was prepared by placing the appropriate stock solution aliquot in a 10-mL volumetric flask and adjusting to volume with KH_2PO_4 buffer solution.

A stock solution of adenosine deaminase was prepared by weighing the enzyme (1 mg) into a 10-mL volumetric flask and adjusting to volume with the stock solution of KH_2PO_4 buffer solution.

The following procedure was then carried out to measure deaminase activity.

(*i*) An aliquot (2 mL) of each adenosine solution was placed in a 1 cm × 1 cm quartz cuvette (sample cell). KH_2PO_4 buffer solution (0.5 mL) was then added and the solution shaken to enhance mixing. KH_2PO_4 buffer solution (2.5 mL) was then placed in a second cuvette (reference cell) and the absorbance of each adenosine solution measured at 259 nm at 22°C on a Cary 17 spectrophotometer. The reading for each solution was recorded as absorbance at time of mixing, i.e. at $T = 0$.

(*ii*) Procedure (*i*) above was then repeated for each adenosine solution. However, instead of 0.5 mL of buffer being added to the sample cell, 0.5 mL of the adenosine deaminase stock solution was added. The reference cell contained 2 mL of KH_2PO_4 buffer and 0.5 mL of the adenosine deaminase stock solution. For each sample, when the deaminase solution was added, a timer was started and absorbance readings at 259 nm were taken every 10 s for 1.5 min. For all sample solutions, the absorbance was found to decrease linearly with time over the first 60 s.

(*iii*) The change in absorbance for each adenosine solution (for the first minute of reaction) was converted to change in concentration (for the conversion of adenosine to inosine at 259 nm, $\Delta A = 7400 \cdot b \cdot \Delta C$, (where b = cell path length)), the reaction velocity, V, in μmol/min/mg of enzyme was determined, and a plot of $1/S$ (S = substrate concentration) vs. $1/V$ made. Thus, by the method of Lineweaver and Burk, the Michaelis and maximum velocity constants, K_m and V_{max} respectively, were determined.

The above procedure was then repeated for the adenosine analogue A*. The initial stock solution of A* was 50 μ*M* (1.185 mg/100 mL of KH_2PO_4 buffer solution) and the enzyme stock solution contained 20 mg of enzyme/mL of buffer. Ultraviolet readings were taken over a period of 1.5 min. As with adenosine itself, K_m and V_{max} for A* were determined according to the methods of Lineweaver and Burk. The results are summarized in the discussion section.

(b) *Inhibition studies*

The general procedure described above for the determination of deaminase activity with adenosine as substrate was followed. However, substrate solutions in this assay contained A* in addition to the natural nucleoside.

Stock solutions of adenosine in KH_2PO_4 buffer (2.73 mg/50 mL buffer) and A* in KH_2PO_4 buffer (2.39 mg A*/50 mL buffer) were first prepared. A series of substrate solutions to be used in the assay were then prepared as follows. Aliquots (5 mL, 4 mL, 3 mL, 2.5 mL, 2 mL, and 1 mL) of the adenosine stock solution were placed in 10-mL volumetric flasks. To each flask, 5 mL of the A* stock solution was added. Each volumetric was then brought to volume with KH_2PO_4 buffer solution. Deaminase activity was then measured as described above. The apparent Michaelis constant, K_1, was determined according to the methods of Lineweaver and Burk.

B. *Snake venom phosphodiesterase (Russel's viper venom)*

Two hundred units of lyophilized enzyme obtained from Calbiochem were dissolved in 1 mL of tris-(hydroxymethyl)amino methane buffer (adjusted to pH 9.2 with 0.1 *N* HCl). The enzyme solution (0.1 mL) was then added to the nucleotide (0.2 to 0.5 mg) in a small vial and the reaction mixture was incubated at 37°C for 6 h. The solution was then applied to Whatman 3 MM paper as a 3-cm wide band. Papers were developed in solvent A or solvent F and nucleoside and nucleotide bands were cut out, eluted with water, and diluted to a known volume. The ultraviolet absorbance of each band was recorded against the absorbance of appropriate blanks. Blanks were prepared by cutting bands from the paper directly opposite the nucleotide bands and of the same size and shape as the nucleotide bands. The blanks were eluted with water and brought to the same volume as the corresponding nucleotide bands. Absorbances were measured for each solution in 1-cm path length quartz cells.

C. *Spleen phosphodiesterase (bovine, type 1)*

Ten to fifteen units of lyophiized enzyme obtained from Nutritional Biochemicals Corp. were dissolved in 1 mL of 0.01 *M* sodium pyrophosphate buffer (adjusted to pH 6.5 with phosphoric acid). The enzyme solution (0.1 mL) was added to the nucleotide (0.2–0.5 mg) previously dissolved in 0.2 mL of 0.05 *M* ammonium acetate buffer (adjusted to pH 6.5 with acetic acid). The mixture was then incubated at 37°C for 6 h. Degradation products were separated and ratios determined spectrophotometrically as described in B above.

Silylation of A (production of **14** and **15**)*

Compound **1** (1.0 g, 4.17 mmol) and imidazole (0.34 g, 1.2 equiv.) were suspended in DMF (30 mL). TBDMS-Cl (0.63 g) was added in portions over a 20-min period and the mixture was stirred for an additional 10 min. Solvents were removed at reduced pressure and the residue was chromatographed on silica gel (column) using methylene chloride – methanol (9:1) as eluant. The bis-silylated A* (**15**) was obtained in 25% yield (0.45 g, mp 160–161°C, R_f 0.59 (CH_2Cl_2–MeOH; 9:1). Compound **15** showed signals in the nmr (DMSO-d_6) at δ (ppm): 0.90 (s, 18H), 3.65 (m, 5H), 3.73 (s, 2H), 6.60 (bs, 2H, NH_2), 7.93 (s, 1H), and 8.33 (s, 1H).

In addition to compound **15**, starting material (360 mg, 36% recovery) and monosilyl derivative **14** (550 mg, 38%) were also recovered. Compound **14** had mp 153–155°C, R_f 0.29 (CH_2Cl_2–MeOH; 9:1) and showed signals in the nmr (DMSO-d_6) at δ: 0.00 (s, 6H, $(CH_3)_2Si$), 0.86 (s, 9H, $(CH_3)_3C$), 3.38–3.68 (m, 4H, —CH_2CH—CH_2—), 4.72 (t, 1H, —CH), 5.72 (s, 2H, —CH_2N), 7.18 (b, 2H, NH_2), 8.25 (s, 1H, H-2), and 8.3 (s, 1H, H-8).

*Tosylation of compound **14***

Compound **14** (725 mg) was dissolved in pyridine (15 mL) and the solution cooled to 0°C in an ice bath. *p*-Toluenesulfonyl chloride (470 mg, recrystallized) was added and the solution was stirred at 0°C for 2 h followed by 18 h at −10°C. Solvents were removed at reduced pressure and by coevaporation of benzene to remove the last traces of pyridine. The residue was purified by silica gel chromatography using CH_2Cl_2–MeOH (9:1). In addition to 100 mg of starting material, 810 mg (90%) of compound **16** was obtained, mp 115–118°C, R_f of 0.49 (CH_2Cl_2–MeOH; 9:1), and showing signals in the nmr ($CDCl_3$) at δ (ppm): 0.0 (s, 6H, $(CH_3)_2Si$), 0.8 (s, 9H, $(CH_3)_3C$), 2.45 (s, 3H, CH_3—), 3.5 (d, 2H, —CH_2—OSi), 3.8–4.2 (m, 3H, —CH—CH_2OTs), 5.65 (s, 2H, —CH_2—N), 6.24 (b, 2H, NH_2), 7.2–7.4, 7.63–7.78 (9H aromatic), 8.0 (s, 1H, H-2), and 8.4 (s, 1H, H-8).

Preparation of N*-benzoylA* (**19**)*

Compound **1** (2.7 g, 11.3 mmol) was suspended in pyridine (60 mL) and benzoyl chloride (12 equiv.) was slowly added. The mixture was stirred at room temperature for 20 h and then diluted with methanol (20 mL). Solvents were removed at reduced pressure to leave a sirup which was dissolved in methylene chloride. The solution was washed with water (2×), dried over sodium sulfate, and concentrated to a viscous residue at reduced pressure. The residue was washed with ethanol (5 mL) which was separated by filtration and discarded. The white solid remaining was dissolved in pyridine (80 mL) to which 2 *N* NaOH (100 mL) was added. After stirring for 1 h the solution was neutralized with Dowex 50 WX8 (H^+ form). The solvent was collected by filtration and concentrated to a small volume at reduced pressure. The product was isolated by silica gel column chromatography using methylene chloride – methanol (9:1, 500 mL) followed by the same solvents in a 7:3 ratio. The product **19** was obtained as a white solid, mp 188–190°C (52%). The nmr spectrum (DMSO-d_6) showed signals at δ (ppm): 3.67 (bm, 5H), 5.86 (s, 2H), 7.66 (m, 3H, aromatic), 8.12 (m, 2H, aromatic), 8.63 (s, 1H), and 8.80 (s, 1H). Other properties are collected in Tables 1 and 2.

Tosylation of N*-benzoylA**

Compound **19** (2.4 g) was dissolved in pyridine (50 mL) and the solution was cooled in an ice bath. *p*-Toluenesulfonyl chloride (6 g,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

~5 equiv.) was added and, after stirring for 1 h, the solution was kept in a cold chest (−10°C) for two days. The solvent was removed at reduced pressure and the residue was dissolved in methylene chloride which was washed with water and dried over sodium sulfate. The solvent was removed at reduced pressure to leave a viscous gum. This material did not solidify after numerous attempts at crystallization. The material appeared homogeneous on tlc and nmr and was used directly in subsequent steps; R_f 0.5 (CH_2Cl_2−CH_3OH; 9:1); signals appeared in the nmr ($CDCl_3$) with δ (ppm) of 2.43 (s, 3H, CH_3—), 3.83−4.13 (m, 4H, —CH(CH_2O—)$_2$), 5.63 (s, 2H, —CH_2—N), 7.2−8.06 (m, 13H, aromatic), 8.1 (s, 1H, H-2), 8.76 (s, 1H, H-8), and 9.16 (b, 1H, —NHC(=O)—).

9[[2-Azido-1-(azidomethyl)ethoxy]methyl]-N-*benzoyladenine* (**21**)

Compound **20** (4 g) was dissolved in DMF (50 mL) and sodium azide (2 g) was added. The mixture was heated at 90−95°C for 3 h. The solvent was removed at reduced pressure and the residue was dissolved in methylene choride which was washed with water and dried over sodium sulfate. The solvent was removed at reduced pressure and the residue crystallized from ethanol to yield 1.86 g (77%) of compound **21** (mp 130−133°C). Compound **21** (R_f 0.65; CH_2Cl_2−CH_3OH (9:1)) had λ_{max} at 292 nm (pH 1), 282 nm (pH 7), and 302 nm (pH 14). The infrared spectrum (KBr) had a signal at 2100 cm^{-1} (—N_3). The nmr spectrum ($CDCl_3$) showed signals at δ (ppm) of 3.36 (d, 4H, —CH_2N_3, J = 6 Hz), 4.03 (t, 1H, —CH—), 5.83 (s, 2H, —OCH_2N—), 7.76 (m, 5H, Ph—), 8.20 (s, 1H, H-2), 8.80 (s, 1H, H-8), and 8.99 (b, 1H, —NHC(=O)—).

9-[[2-Azido-1-(azidomethyl)ethoxy]methyl]adenine (22)

Compound **21** (1.21 g) was dissolved in pyridine (15 mL) and 29% aqueous NH_4OH solution (60 mL) was added. The mixture was heated at 55°C for 3 h with stirring. The solvent was then removed at reduced pressure to leave a solid which crystallized from ethanol to give compound **22** (787 mg, 89%, mp 168−170°C). The nmr spectrum (DMSO-d_6) showed signals at δ (ppm): 3.20 (d, 4H), 4.10 (t, 1H), 5.70 (s, 2H), 7.23 (b, 2H, —NH_2), 8.13 (s, 1H), and 8.23 (s, 1H). Other properties are collected in Tables 1 and 2.

Direct conversion of A to 8 and 22*

Compound **1** (A*, 1 mmol), triphenylphosphine (2 mmol), and lithium azide (10 mmol) were dissolved in DMF (20 mL). Carbon tetrabromide (2 mmol) was added and the mixture was stirred at room temperature for 24 h. The solvents were removed at reduced pressure and the residue was dissolved in a minimum amount of pyridine and subjected to flash chromatography on silica gel using methylene chloride − methanol (9:1) as eluant. The minor product was compound **22** obtained in 14% yield. The major product was 9[[2-azido-1-(hydroxymethyl)ethoxy]methyl]adenine (**18**) obtained in 53% yield (mp 200−204°C, ir (KBr): 2080 cm^{-1} (—N_3)). The nmr spectrum (DMSO-d_6) showed signals at δ (ppm): 3.50 (d, 2H), 3.78 (d, 1H), 4.0 (m, 1H), 5.80 (s, 2H), 8.25 (s, 1H), and 8.35 (s, 1H). Other properties are collected in Tables 1 and 2.

Conversion of 17 into 18

Compound **17** (200 mg in THF (10 mL)) was treated with tetrabutylammonium fluoride (0.68 *M* in THF (3 mL)) for 2 h. After removal of solvents and chromatography of the residue on silica gel using methylene chloride − methanol (4:1), 110 mg of compound **18** was obtained (80% yield). The product was identical to the material obtained above.

9-[[2-Amino-1-(aminomethyl)ethoxy]methyl]adenine (24)

Compound **22** (300 mg) was dissolved in ethanol (50 mL) and subjected to hydrogenation at room temperature and one atmosphere of hydrogen over 5% palladium on charcoal (100 mg) for 18 h. The solvent was collected by filtration and the residue was washed with ethanol (200 mL). The combined filtrate and washings were concentrated at reduced pressure. The residue crystallized from ether to yield compound **24** (220 mg, 90%, mp 106−109°C). The nmr spectrum (DMSO-d_6) showed signals at δ (ppm): 2.56 (d, 4H), 3.43 (t, 1H), 5.63 (s, 2H), 8.16 (s, 1H), and 8.27 (s, 1H). Other properties are collected in Tables 1 and 2.

Conversion of 18 to 9-[[2-Amino-1-(hydroxymethyl)ethoxy]methyl]-adenine (23)

Compound **18** (400 mg) was dissolved in 70% aqueous ethanol and 5% Pd on charcoal (150 mg) was added. The mixture was subjected to room temperature hydrogenation under 30 psi of hydrogen for 2 h. The solution was collected by filtration and the residue washed with 95% ethanol (200 mL). The combined filtrate and washings were evaporated to dryness. The residue crystallized from ethanol−ether to give compound **23** (210 mg, 52%). The nmr spectrum (DMSO-d_6) showed signals at δ (ppm): 3.45 (bm, 5H), 5.73 (s, 2H), 8.28 (s, 1H), and 8.37 (s, 1H). Other properties are collected in Tables 1 and 2.

9-[[2-Hydroxy-1-(hydroxymethyl)ethoxy]methyl]-2,6-diamino-purine (27)

N^2,N^6-Diacetyl-2,6-diaminopurine (4.45 g) was suspended in DMF (350 mL). Triethylamine (2.3 g) and compound **3** (7.3 g in DMF (20 mL)) were added and the resulting solution was stirred for 60 h at room temperature, followed by heating at 40°C for 1 h. The clear solution was concentrated at reduced pressure and the residue was dissolved in chloroform (50 mL). The chloroform solution was washed with a saturated solution of sodium chloride, followed by water, and then dried over magnesium sulfate. The solvent was removed to give a viscous residue which crystallized from ethanol to give 5.4 g of white, crystalline **25** (mp 188−192°C); the nmr spectrum in $CDCl_3$ showed signals with δ (ppm) of 2.5 (s, 3H, CH_3CO—), 2.6 (s, 3H, CH_3CO—), 3.54 (d, 4H, 2 × —CH_2—O), 4.1 (q, 1H, —CH), 4.43 (s, 4H, 2 × —CH_2C), 5.75 (s, 2H, —CH_2—N),7.3 (s, 10H, 2 × —C_6H_5—), 8.3 (s, 1H, H-8), 9.7 (s, 1H, —NH—CO), 9.8 (s, 1H, —NH—CO).

Compound **25** (5.15 g) was dissolved in 400 mL of methanol containing 460 mg of sodium. The mixture was heated at reflux for 2 h and then stirred at room temperature for 12 h. The solution was neutralized with acetic acid and the solvent was removed at reduced pressure. The residue was dissolved in chloroform (500 mL) which was washed with water and then dried over magnesium sulfate. The solvent was removed at reduced pressure to leave a white solid (4.2 g) which crystallized from methylene chloride − ether to give compound **26** (3.7 g, 85%, mp 85−87°C). The nmr spectrum of **26** in $CDCl_3$ showed signals at δ (ppm) of 3.50 (d, 4H, 2 × CH_2O), 4.0 (q, 1H, —CH), 4.43 (s, 4H, 2 × —$CH_2\phi$), 5.18 (bs, 2H, —NH_2), 5.6 (s, 2H, —CH_2N—), 6.0 (bs, 2H, —NH_2), 7.15 (s, 10H, 2 × C_6H_5—), and 7.6 (s, 1H, H-8).

Compound **26** (800 mg) was dissolved in ethanol (100 mL) to which palladium oxide (400 mg) and cyclohexene (60 mL) were added. The mixture was heated at reflux for 3 h, cooled, filtered, and the residue washed with 70% aqueous ethanol (200 mL). The combined filtrates and washings were evaporated to dryness. The residue crystallized from ethanol to yield compound **27** (370 mg, 80%). The nmr spectrum (DMSO-d_6) showed signals at δ (ppm): 3.60 (bm, 5H), 5.53 (s, 2H), 6.93 (b, —NH_2), and 7.93 (s, 1H). Other properties are collected in Tables 1 and 2.

Enzymatic conversion of compound 27 to BIOLF-62

Compound **27** was subjected to adenosine deaminase (0.4 mg/mg **27**) at pH 7.5 (0.05 *m* phosphate buffer, 0.2 mL/mg **27**). The solution was allowed to stand at 25°C for 18 h. At this point tlc showed that compound **27** had been completely converted into BIOLF-62 (compound **2**). The yield of **33** was virtually quantitative and properties were identical to those previously reported (2).

Enzymatic conversion of A to 33*

The above procedure was repeated using 30 mg of adenosine deaminase and 500 mg of A* in 25 mL of buffer solution at 20°C for 24 h. The solvent was concentrated at reduced pressure to 2 mL and poured into hot ethanol (100 mL). The precipitate was removed by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

filtration. The filtrate was concentrated to a dry residue which crystallized from water to yield 455 mg (90%) of compound **33**. The nmr spectrum (DMSO-d_6) showed signals at δ (ppm): 3.51 (m, 5H), 5.70 (s, 2H),6.73 (b, —NH), 8.10 (s, 1H), and 8.23 (s, 1H). Other properties are collected in Tables 1 and 2.

*9-[[2-Hydroxy-1-(hydroxymethyl)ethoxy]methyl]-2-fluoroadenine (**30**)*

Compound **26** (2 g) was dissolved in 60% HF in pyridine (16 mL) at −70°C (Dry Ice − acetone). The temperature of the mixture was allowed to rise to −40°C, at which point *tert*-butylnitrite (750 μL) was added. The mixture was stirred at −30 to −40°C for 15 min and then poured into ice-water (100 g). The aqueous mixture was extracted with chloroform (5 × 100 mL) and the combined chloroform extracts were washed successively with 5% sodium bicarbonate solution and water. After drying over magnesium sulfate, the solvent was removed at reduced pressure and the residue chromatographed on silica gel using methylene chloride − methanol (92:8) as eluant. In addition to recovery of starting material (300 mg), 200 mg of the monobenzyl product **29** and 200 mg of the dibenzyl product **28** were obtained. Compound **29** (mp 190−193°C) had signals in the nmr spectrum (DMSO-d_6) at δ (ppm) of 3.4 (bd, 4H, —CH_2O—), 3.8 (m, 1H, —CH), 4.4 (s, 2H, —$CH_2\phi$), 5.6 (s, 2H, —CH_2N—), 7.27 (s, 5H, C_6H_5), 7.77 (bs, 2H, —NH_2), and 8.2 (s, 1H, H-8). Compound **28** (mp 142−145°C) had signals in the nmr spectrum ($CDCl_3$) with δ (ppm) of 3.45 (d, 4H, 2 × —CH_2O—), 4.0 (g, 1H, —CH), 4.5 (s, 4H, 2 × —CH_2O), 5.70 (s, 2H, —CH_2N—), 6.37 (bs, 2H, —NH_2), 7.3 (s, 10H, 2 × C_6H_5—), and 7.90 (s, 2H, H-8).

Compound **28** (600 mg) was dissolved in ethanol (100 mL) to which was added palladium oxide (300 mg) and cyclohexene (60 mL). The mixture was heated at reflux for 3 h and worked up in the usual manner to yield, after crystallization from ethanol, compound **30** in 88% yield (313 mg). The nmr spectrum (DMSO-d_6) showed signals at δ (ppm): 3.6 (bm, 5H), 5.57 (s, 2H), 7.70 (bs, 2H, —NH_2), and 8.20 (s, 1H). Other properties are collected in Tables 1 and 2.

*9-[[2-Hydroxy-1-(hydroxymethyl)ethoxy]methyl]isoguanine (**32**)*

Compound **26** (660 mg) was dissolved in a mixed solvent containing tetrahydrofuran (15 mL) and water (10 mL). Sodium nitrite (600 mg) was added to the solution, followed by glacial acetic acid (8 mL). The solution was stirred at 50°C for 90 min, at which point additional sodium nitrite (600 mg), acetic acid (3 mL), and water (5 mL) were added and stirring at 50°C was continued for an additional 60 min. The mixture was cooled to room temperature, neutralized with 28% aqueous ammonium hydroxide, and extracted with methylene chloride (3 × 100 mL). The extracts were washed with water, dried over magnesium sulfate, and evaporated. The residue was chromatographed on silica gel using methylene chloride − methanol (4:1). Compound **31** was obtained in 55% yield and, on crystallization from methylene chloride − ether, had mp 183−185°C. In the nmr ($CDCl_3$), compound **26** showed signals at δ (ppm) of 3.50 (bd, 4H, 2 × —CH_2O—), 4.0 (m, 1H, —CH), 4.43 (s, 4H, 2 × —$CH_2\phi$), 5.53 (bs, 2H, —CH_2N—), 7.2 (s, 10H, 2 × C_6H_5—), and 7.50 (s, 1H, H-8).

Compound **31** (980 mg) was dissolved in ethanol (200 mL) and palladium oxide (500 mg) and cyclohexene (100 mL) were added. The mixture was heated at reflux for 12 h and filtered while hot. The residue was washed with hot 70% aqueous ethanol (300 mL). The combined filtrate and washings were evaporated and the residue was dissolved in hot water (20 mL). Ethanol (70 mL) was added and the solution was allowed to stand at room temperature. After 24 h the precipitate was collected by filtration to yield compound **32** (460 mg, 80%). The nmr spectrum (D_2O) showed signals at δ (ppm): 3.40 (bm, 5H), 5.33 (s, 2H), and 7.73 (s, 1H). Other properties are collected in Tables 1 and 2.

*9-[[2-Hydroxy-1-(hydroxymethyl)ethoxy]methyl]purine (**36**a)*

Compound **4** (1.7 g) was dissolved in absolute ethanol (100 mL) and 5% palladium on carbon (400 mg) and anhydrous sodium acetate (500 mg) were added. Hydrogenation was conducted at room temperature under 40 psi of hydrogen for 18 h. The residue was collected by filtration and washed with CH_2Cl_2−CH_3OH (1:1, 200 mL). The combined filtrate and washings were concentrated at reduced pressure to a dry residue. After chromatography on silica gel using CH_2Cl_2−CH_3OH (95:5), compound **35**a (1.37 g, 87%) was obtained as a viscous sirup; nmr, δ (ppm): 3.50 (d, 4H, —CH_2CHCH_2—), 4.0 (m, 1H, —CH—), 4.40 (s, 4H, 2 × $PhCH_2$—), 5.77 (s, 2H, —OCH_2N—), 7.20 (s, 10H, 2 × Ph—), 8.13 (s, 1H, H-2), 8.90 (s, 1H, H-8), and 9.90 (s, 1H, H-6).

Compound **35**a (767 mg) was dissolved in CH_2Cl_2 (50 mL) and the solution was cooled to −78°C. 1 *N* BCl_3 in CH_2Cl_2 (15 mL) was added to the solution under a nitrogen atmosphere. After 3 h at −78°C, the solution was diluted with CH_2Cl_2−CH_3OH (1:1, 100 mL) and allowed to stand at room temperature for 1 h. Upon addition of excess aqueous ammonia (28%), a precipitate formed. The solution was collected by filtration, concentrated to dryness, and the residue was extracted with methanol (50 mL). Silica gel (10 g) was added to the methanol solution and the excess solvent was removed at reduce pressure. The silica gel was added to a prepared silica gel column and the whole solumn was eluted with CH_2Cl_2−CH_3OH (8:2). Compound **36**a was obtained pure in 87% yield (370 mg). General properties of **36**a are collected in Tables 1 and 2. The nmr spectrum (DMSO-d_6) showed signals at δ (ppm): 3.40 (m, 5H), 4.60 (t, 2H), 5.80 (s, 2H), 8.70 (s, 1H), 8.96 (s, 1H), and 9.13 (s, 1H).

*9-[[2-Hydroxy-1-(hydroxymethyl)ethoxy]methyl]-2-aminopurine (**36***b*)*

Compound **34** (1.54 g) was treated as above for compound **4**. Compound **35***b* was obtained as a viscous sirup in 98% yield (R_f 0.42 (CH_2Cl_2−CH_3OH; 9:1); nmr, δ (ppm): 3.50 (d, 4H, —CH_2CH—CH_2—), 4.0 (m, 1H, —CH—), 4.37 (s, 4H, $PhCH_2$—), 5.60 (s, 2H, —OCH_2N—), 6.03 (b, 2H, —NH_2), 7.20 (s, 10H, 2 × Ph), 7.93 (s, 1H, H-8), and 8.56 (s, 1H, H-6). Compound **35***b* was treated with BCl_3 as described above for **35***a*. Compound **36***b* was obtained in 70% yield and general properties are collected in Tables 1 and 2. The nmr spectrum (D_2O) showed signals at δ (ppm): 3.33 (bm, 5H), 5.53 (s, 2H), 8.03 (s, 1H), and 8.37 (s, 1H).

*9-[[2-Hydroxy-1-(hydroxymethyl)ethoxy]methyl]-6-chloropurine (**37**a)*

Compound **4** (2.8 g) was treated with the 1N BCl_3 in CH_2Cl_2 solution as described above for compounds **35**. The product **37***a* was obtained pure from silica gel chromatography in 70% yield (1.16 g). General properties of **37***a* are collected in Tables 1 and 2. The nmr spectrum (DMSO-d_6) showed signals at δ (ppm): 3.56 (bm, 5H), 4.6 (t, 2H), 5.83 (s, 2H), and 8.82 (s, 2H).

*9-[[2-Hydroxy-1-(hydroxymethyl)ethoxy]methyl]-6-chloro-2-aminopurine (**37**b)*

Compound **34** (600 mg) was treated as above for compound **4**. The product, compound **37***b*, was obtained pure in 95% yield (345 mg). General properties are collected in Tables 1 and 2. The nmr spectrum (DMSO-d_6) showed signals at δ (ppm): 3.40 (bm, 5H), 5.52 (s, 2H), 6.35 (bs, 2H, —NH_2), and 8.15 (s, 1H).

*9-[[2-Hydroxy-1-(hydroxymethyl)ethoxy]methyl]xanthine (**39**b)*

Compound **38** (1 g) was dissolved in glacial acetic acid (100 mL) and water (50 mL). A solution containing 1 g of sodium nitrite in water (10 mL) was added dropwise over a period of 75 min at room temperature. The mixture was stirred for a further 3 h at room temperature. The solvents were removed at reduced pressure and the residue was extracted with dichloromethane. The extracts were washed with 5% aqueous sodium bicarbonate followed by saturated sodium chloride. The solution was dried over sodium sulfate and concentrated to a small volumne. The product **39***a* (mp 176−178°C, 60%) was obtained from silica gel chromatography using CH_2Cl_2−CH_3OH (92:8). The nmr spectrum in DMSO-d_6 showed signals at δ (ppm) of 3.50 (d, 4H, —CH_2CH—CH_2—), 4.0 (m, 1H, —CH—), 4.66 (s, 4H, 2 × $PhCH_2$—), 5.66 (s, 2H, —OCH_2N—), 7.30 (s, 10H, 2 × Ph), 7.80 (s, 1H, H-8), and 10.76 (b, 1H, NH).

Compound **39***a* was treated with BCl_3 as previously described. The

product, **39***b*, crystallized from ethanol–water and was obtained in 85% yield. The nmr spectrum (DMSO-d_6) showed signals at δ (ppm): 3.55 (bm, 5H), 5.53 (s, 2H), 7.20 (b, 1H, —NH), 7.80 (s, 1H), and 10.76 (b, —NH). Properties are collected in Tables 1 and 2.

On the structure and energies of protonated cations of H_2CS, HFCS, and F_2CS

FRIEDRICH GREIN

Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 6E2

Received May 20, 1983

FRIEDRICH GREIN. Can. J. Chem. **62**, 253 (1984).

Using 4-31G basis sets, the geometries of H_2CS, HFCS, and F_2CS as well as their protonated cations were optimized. In each case, three protonation sites, S, C, and H (for H_2CS) or F (for HFCS and F_2CS) were considered. The H or F protonation leads to molecular complexes of the form $HX \ldots YCS^+$. For H_2CS and F_2CS, the S-protonation site is favored, whereas for HFCS the linear complex $HF \ldots HCS^+$ is the most stable protonated form. Predicted proton affinities are 177.4 for H_2CS (180.9 experimental), 172.0 for HFCS, and 149.1 kcal/mol for F_2CS.

FRIEDRICH GREIN. Can. J. Chem. **62**, 253 (1984).

Faisant appel aux ensembles de base 4-31G, on a optimisé les géométries du H_2CS, du HFCS et du F_2CS et de leurs cations protonés. On a considéré dans chaque cas trois sites de protonation, S, C et H pour (H_2CS) ou F (pour HFCS et F_2CS). La protonation de H ou de P conduit à des complexes moléculaires de la forme: $HX \ldots YCS^+$. Dans le cas de H_2CS et de F_2CS, le site de protonation S est favorisé tandis que pour HFCS le complexe linéaire $HF \ldots HCS^+$ est la forme protonée la plus stable. Les prédictions d'affinités pour le proton sont de: 177,4 pour H_2CS (valeur expérimentale 180,9), de 172,0 pour HFCS et de 149,1 kcal/mol pour F_2CS.

Introduction

Experimental studies of reactions yielding the thiomethoxy cation H_3CS^+ and the thiolmethyl carbonium ion H_2CSH^+ have been reported in the literature (1–4). Experimental work is presently in progress to find and characterize protonated species of HFCS and F_2CS (5).

Theoretical investigations of cation structure and related proton affinities have been shown to be very useful. In the following, *ab initio* calculations at the 4-31G level will be reported for geometries and energies of cations resulting from the protonation of H_2CS, HFCS, and F_2CS. Besides the two obvious protonation sites — sulfur and carbon — molecular complexes of the form $HX \ldots YCS^+$, where X and Y are H or F, formally corresponding to protonation at the H or F site, were also considered, leading to some interesting and unexpected results.

Method

All geometry optimizations were performed using the 4-31G basis set (6), and the HONDO 5 (7), the GAUSSIAN 70 (8), and an IBM version (9*a*) of the GAUSSIAN 80 (9*b*) computer program. Unless stated otherwise, restricted Hartree–Fock (RHF) energies are given for singlet states. Several triplet states were calculated with the unrestricted Hartree–Fock (UHF) method. In general, gradient optimization techniques were employed. For each compound, three different protonation sites were investigated.

Results

H_2CS and protonated forms

The results for H_2CS, H_2CSH^+, H_3CS^+ (singlet), and $H_2 \ldots HCS^+$ are given in Table 1. Here, and in the following text, the various protonated isomers are distinguished by the placement of the additional H in the molecular formula. H_2CSH^+ refers to protonation at the sulfur site, H_3CS^+ to protonation at carbon, whereas $H_2 \ldots HCS^+$ indicates a molecular complex with weak interaction between the components H_2 and HCS^+. Thioformaldehyde, H_2CS, has been the topic of several *ab initio* studies (10–15). The 4-31G geometry and energy obtained by Bernardi *et al.* (12) agrees with ours. Experimental geometry parameters (16) are included in Table 1. The best geometry optimization was performed by Jaquet *et al.* (15), using a good double ζ plus polarization (DZP) basis set, and the CEPA-PNO method. Their CS and CH bond distances agree with the experimental values within 0.002 Å. The S-protonated structure H_2CSH^+, which is overall the most stable (singlet) isomer, was also studied by Bernardi *et al.* (12). Their optimized geometry parameters and energy are very similar to ours. These authors also investigated nonplanar conformations of H_2CSH^+ and a linear C—S—H^+ arrangement, but found them to be less stable. The optimized geometry obtained for H_2CSH^+ is very similar to that of protonated H_2CO, which for obvious reasons prefers oxygen as protonation site (17).

In C_{3v} symmetry, H_3CS^+ has the electron configuration $\ldots 2e^4 1a_1^2 3e^2$, which normally leads to a lowest-energy singlet state of A_1 symmetry. For this state, the single-determinant SCF method is unable to form the required linear combination, and the SCF wavefunction corresponds to a mixture of symmetry species. A two-determinant wavefunction of the form $e_x^2 + e_y^2$ would be required for the correct linear combination. On the other hand, an SCF geometry optimization in C_s symmetry overcomes the problem of the symmetry impurity, and the results are expected to be very close to the C_{3v} results for $^1A_1$. Therefore, a C_s SCF optimization was carried out. The results are given in Table 1. Dill and McLafferty (3) gave for the STO-3G optimized C_s geometry of H_3CS^+ (R_{CS} = 1.790 Å, R_{CH} = 1.103/1.091 Å) the 4-31G energy of −436.21806 hartree, only marginally higher than our energy. In each case, the CS distance increases by more than 0.2 Å relative to H_2CS.

Yamabe *et al.* (18) reported results for the triplet e^2 state of H_3CS^+, which according to Hund's rule is expected to be of lower energy than the singlet. Their UHF optimized geometry is R_{CS} = 1.94 Å, R_{CH} = 1.08 Å, and ∠HCS = 105.8°. The UHF energy is −436.30362 hartree, much lower than the RHF singlet energy. Since the UHF method is not subject to the symmetry restriction, a comparison of UHF with RHF energies is not meaningful. The triplet state resulting from the e^2 orbital occupation would have A_2 symmetry. Dill and McLafferty (3) obtained a similarly low energy for the triplet state of H_3CS^+ (−436.30145 hartree). By estimating the difference in correlation energies for triplet and singlet states, they came to the conclusion that the singlet C_{2v} structure (H_2CSH^+) is more

[e]Calculated proton affinity.

stable than triplet C_{3v} by about 10 kcal/mol. This agrees qualitatively with their experimental findings. Roy and McMahon (4), in an experimental study designed to observe the different proton transfer reactions resulting from the two isomers H_3CS^+ and H_2CSH^+, failed to discover any evidence of H_3CS^+. From a theoretical point of view, configuration-interaction calculations on both triplet H_3CS^+ and singlet H_2CSH^+ are required, using in each case RHF molecular orbitals. Attempts to confirm the UHF-triplet H_3CS^+ results mentioned above (3, 18) failed. For the geometry reported by Yamabe *et al.*, a higher energy (−436.20176 hartree) was obtained. For other geometries, either a higher energy or convergence difficulties were encountered.

In the last column of Table 1, results are given for the $H_2\ldots HCS^+$ molecular complex, formally corresponding to protonation at one of the H-sites. The optimal geometry is of C_{2v} symmetry, corresponding to a weak bond between H_2 and HCS^+, with a stabilization energy relative to $H_2 + HCS^+$ of 0.70 kcal/mol. In the same basis (4-31G), the geometry of isolated HCS^+ is R_{CS} = 1.488 Å, R_{CH} = 1.068 Å, with an energy of −435.08206 hartree, and the H—H distance of isolated H_2 is 0.730 Å, with an energy of −1.12682 hartree. Only extremely small distortions are encountered in the formation of the complex. The distance of the center of mass (CM) of H_2 to H of HCS^+ was optimized to be 2.342 Å. However, due to the weak interaction between the two components, a complete distance optimization is beyond the accuracy of the employed methods. Yamabe *et al.* (18) reported the same stabilization energy of 0.7 kcal/mol, but an H_2 (CM)..H distance of 3.5 Å. For protonated H_2CO, a similar complex, $H_2\ldots HCO^+$, was proposed by Schleyer *et al.* (19).

Of the three isomers of protonated H_2CS studied here, the S-protonated H_2CSH^+ is the most stable, corresponding to a proton affinity of 177.4 kcal/mol. Lossing (1) obtained 181.6 kcal/mol, and Roy and McMahon reported a very similar experimental value of 180.9±1 kcal/mol. The agreement with the *ab initio* result is excellent.

HFCS and protonated forms

Thioformyl fluoride, HFCS, is not known. $HFCSH^+$ occurs in mixtures of H_2S and CHF_3 which are currently under experimental study (5). So far, there is no knowledge about the likely structure of the $HFCSH^+$ ion.

Results of the 4-31G geometry optimizations are given in Table 2. HFCS has CS and CH distances similar to H_2CS, and a normal CF single bond distance. The geometry of HFCS, as well as F_2CS, was optimized by Kapur *et al.* (13) using an STO-3G basis set.

Protonation of HFCS at the sulfur site gives a proton affinity of 162.5 kcal/mol. Note that the proton is *cis* with F. In the *trans* form, the energy is only insignificantly higher (1×10^{-5} hartree). Nonplanar configurations of $HFCSH^+$ were also considered, but were found to be less stable than the planar ones.

The C-protonated singlet isomer H_2FCS^+ is again characterized by a long CS distance, about 0.3 Å over the normal CS double bond distance. Due to the proximity of F, the CH distances also increase significantly. The proton affinity of this singlet isomer is quite small. Not given are the results of a UHF geometry optimization for triplet H_2FCS^+. The CS distance is 2.105 Å, CF 1.345 Å, CH 1.072 Å, the FCS angle is 103.1°, HCS 102.9°, and the dihedral angle of H with respect to the FCS plane, for rotation about CS, is 118.2°. The UHF energy, corresponding to this geometry, is −534.99760 hartree. This energy should not be compared with the RHF values for singlet states. But since it is higher than the RHF energy of $HFCSH^+$ one may conclude that triplet H_2FCS^+ is no competitor for the most stable protonated form of HFCS. The situation with respect to triplet states is quite different from the previous case of H_3CS^+. There, the C_{3v} symmetry allowed for degenerate orbitals, and the two highest-energy electrons resided in an *e*-orbital. For such cases, qualitative predictions place the triplet state lower than the singlet. The C_s symmetry of H_2FCS^+, on the other hand, does not lead to any symmetry-caused degeneracies, and only doubly occupied orbitals are expected. The same situation will apply to HF_2CS^+.

The geometry optimization of the F-protonated species was started with a proton attached sideways to the fluorine of HFCS. The gradient optimization eventually lead to the linear arrangement $HF\ldots HCS^+$, data of which are contained in Table 2. It is seen that the HCS^+ part of the complex has a

[b] Calculated proton affinity.

structure very similar to isolated HCS^+, and the HF bond length in the complex (0.928 Å) is similar to the optimized bond distance of 0.922 Å for HF (the 4-31G energy of HF is −99.88728 hartree). Relative to HF + HCS^+, the complex is stabilized by 17.2 kcal/mol. If one considers HF . . . HCS^+ as a proton-bound dimer of HF with CS, then the stabilization energy is 209.0 kcal/mol. (Isolated CS is calculated to have an optimal CS bond distance of 1.555 Å and an energy of −434.77617 hartree). For a proton-bound dimer, such as $H_2O \ldots H^+ \ldots OH_2$, or $H_2O \ldots H^+ \ldots OCH_2$, one expects the protons to be more evenly spaced between the two monomers (see refs. 20, 21), and not closely attached to one of them with a regular AH single bond distance.

The HF . . . HCS^+ molecular complex has a lower energy than $HFCSH^+$, and corresponds therefore to the most stable protonated form of HFCS. Experimental investigations on this ion would be of great interest. According to our results, the S-protonated $HFCSH^+$ is still more stable than isolated HF + HCS^+ (by about 8 kcal/mol), and should therefore not decompose.

F_2CS and protonated forms

Optimized geometries and energies of thiocarbonyl fluoride F_2CS and its various protonated forms are given in Table 3. The CS and CF bond distances of F_2CS are larger than the experimental values (22) by about 0.02 Å. With polarization functions on S, the CS bond shortens to 1.581 Å, while the CF bond length remains similar (14). The STO-3G optimized CS distance is 1.588 Å (13), slightly shorter than the experimental distance.

The sulfur protonated form, F_2CSH^+, shows regular bond distances and bond angles. The proton affinity of F_2CS relative to this isomer is 149.1 kcal/mol. The carbon protonated ion HF_2CS^+ shows an even longer CS bond than the corresponding ions of H_2CS and HFCS, but has regular CF and CH distances. The corresponding proton affinity is only 105.1 kcal/mol. UHF geometry optimizations on triplet HF_2CS^+ resulted in very weak CS bonds, with bond distances moving between 2.5 and 3 Å without much change in total energy. Due to this, the gradient optimization did not converge.

The optimized geometry of the HF . . . FCS^+ complex is shown in the diagram of Table 3. FCS^+ is almost linear, whereas HF is attached to one side, with a long CF distance of 2.373 Å. Geometry optimization of linear FCS^+ gave a CS distance of 1.499 Å, a CF distance of 1.239 Å, and an energy of −533.76976 hartree. The CF distance of the complex is exactly the same, and the CS distance differs by 0.001 Å only. The HF distance of the complex is identical to that of the HF . . . HCS^+ complex. So again, the complex is composed of FCS^+, very weakly interacting with HF. The stabilization with respect to HF + FCS^+ is 14.9 kcal/mol. A proton bound dimer explanation is not possible.

A linear complex with an HF . . . F atomic arrangement is not expected to be stable. Geometry optimizations on a linear complex with an FH . . . F arrangement were done, but the complex was found to dissociate. For F_2CS, the most stable protonated form is calculated to be F_2CSH^+, with a proton affinity of 149.1 kcal/mol. The HF . . . FCS^+ molecular complex is only 6 kcal/mol less stable, and formation in gas-phase ion experiments should be possible.

Discussion

In Table 4, the calculated proton affinities are summarized for the three possible protonation sites. The S-protonation energy decreases from H_2CS to F_2CS. Similarly, the C-protonation energy decreases quite regularly with increasing fluorine substitution, and the C-site proton affinities are always well below the S-site values. A very irregular behavior, however, is seen for the H or F protonation, which leads to molecular complexes. The HF . . . HCS^+ complex is exceptionally stable, about 30 kcal/mol more stable than HF . . . FCS^+, relative to the parent molecules.

The high stability of HF . . . HCS^+ causes an irregularity in the "best" proton affinity (last column of Table 4), which switches from the S-site for H_2CS to the F-site for HFCS and back to the S-site for F_2CS. The structure and stability of the complexes of H_2 or HF with HCS^+ or FCS^+ are of interest in their own right. In Table 5, shapes, distances, and stabilization energies are summarized. Again, HF . . . HCS^+ shows to be an exception in terms of stabilization energy and distortion. Whereas for $H_2 \ldots HCS^+$ and HF . . . FCS^+ distortions relative to the isolated species are in general only 0.002 Å or less (0.006 Å for the HF distance of HF . . . FCS^+), the HF distance

F_2CS		2.373	1.500 (1.499)	1.239 (1.239)	0.928 (0.922)	14.9

[a]Distances in Å, energies in kcal/mol. Values in parentheses were optimized for the isolated monomers H_2/HF and HCS^+/FCS^+.

of $HF\ldots HCS^+$ is elongated by (the same) 0.006 Å, but the CH distance by 0.015 Å. Such distortions are representative of the interactions taking place between the two components of the complex. One may say that $HF\ldots HCS^+$ shows a very small amount of proton-bound-dimer character, which becomes noticeable in its larger stabilization energy.

Summary

Proton affinities of H_2CS, HFCS, and F_2CS were calculated, considering in each case three different protonation sites. In general, protonation at sulfur leads to the greatest stabilization, and therefore to the most likely to be encountered protonated species. However, for HFCS the linear molecular complex of the form $HF\ldots HCS^+$ is calculated to be more stable than the S-protonated form $HFCSH^+$. The elongation of the CH distance relative to isolated HCS^+ shows that a small amount of charge transfer in the direction $F^{(-)}\ldots H^{(+)}$ takes place, which cannot be so easily accomplished for the other two complexes, $H_2\ldots HCS^+$ and $HF\ldots FCS^+$. In the case of $HF\ldots FCS^+$, HF is attached to C, the most electropositive element of FCS^+. Here, only a small energy difference of 6 kcal/mol between the S-protonated form and the molecular complex is predicted.

The question of a possible triplet H_3CS^+ ion, which, from qualitative arguments, should have lower energy than (singlet) H_2CSH^+, has not been addressed. A comparison of UHF energies for triplet H_3CS^+ with RHF energies of singlet H_2CSH^+ is not valid. RHF calculations on triplet H_3CS^+ can, in principle, be performed, and the calculated energies be compared with those of H_2CSH^+. However, due to symmetry problems and the different amounts of correlation energy expected for triplet and singlet states, it appears that the only acceptable method of treating this problem is by configuration interaction calculations on both triplet H_3CS^+ and singlet H_2CSH^+. Such work is being planned.

Inclusion of d-orbitals as well as diffuse functions in the basis set would undoubtedly lead to more accurate results. This, however, would require a much higher amount of computer time. Since the calculated proton affinity of H_2CS agrees well with the experimental one, and the inclusion of polarization and diffuse functions usually changes optimized geometries and energies very little, no compelling reason can be seen at this time for carrying out more expensive calculations with larger basis sets.

Acknowledgements

Dr. T. B. McMahon suggested this investigation. His continuous help and interest is gratefully acknowledged. Neilan Mehta, Chris Grein, and Uday Sishta performed many of the calculations. The financial support by NSERC and the generous allocation of computer time by the University of New Brunswick were essential to the success of this study.

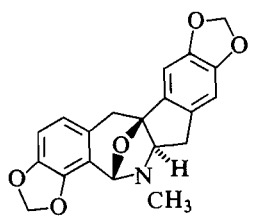
Recent reports (1, 2) of the isolation of an alkaloid with the structure **1** prompt us to describe our own characterization of this compound.[2]



1

In 1969, during a study of the alkaloids of *Argemone grandiflora* Sweet subsp. *grandiflora*, we isolated small amounts of a base which we first designated alkaloid F, and subsequently called grandiflorine. High-resolution mass spectrometry indicated that grandiflorine had the molecular composition $C_{20}H_{17}NO_5$, and this was substantiated by X-ray crystallography of the hydrobromide salt (q.v.). Infrared spectroscopy revealed that grandiflorine did not contain hydroxyl or carbonyl groups, while ^{1}H nmr indicated the presence of two disubstituted methylenedioxybenzene units, a benzylic CH_2, an N—CH_3, and what appeared to be a carbinolamine ether (cf. Table 1). The uv spectrum showed that the two benzenoid chromophores were nonconjugated.

The genus *Argemone* is a rich source of tetrahydrobenzylisoquinoline derivatives (4), and indeed the major and all minor alkaloids which we isolated (5) from *A. grandiflora* subsp. *grandiflora* proved to belong to this group; so we anticipated that grandiflorine would, too. However, the spectroscopic data seemed to be accommodated by several structures and, as a paucity of material prevented extensive chemical investigations, we decided to solve the problem by X-ray crystallography of grandiflorine hydrobromide.

The crystals of this salt were orthorhombic, space-group $P_{2_1}P_{2_1}P_{2_1}$, $a = 11.10_4$, $b = 18.80_5$, $c = 9.21_0$ Å, with 4 molecules to the unit cell, $d_{obs} = 1.490$ (mol. wt. ≡ 431.4; calcd. for $C_{20}H_{18}BrNO_5$: 432.3). Intensity data were estimated visually from multiple-film Weissenberg photographs taken with CuK_α radiation, and the structure was solved by normal heavy atom methods. By present-day standards, these methods were primitive and the *R*-factor, for 1045 independent reflexions and 153 parameters, was large (17.5%). The standard deviation of an observation of unit weight was 0.787. No correction was made for absorption or anomalous dispersion. Nevertheless, the results revealed that grandiflorine had the *relative stereochemistry* shown in **1**, a structure in full accord with the other spectroscopic data.

Having exhausted our stock of grandiflorine and pending another, still unmade, collection of more plant material, we set aside the problem of determing the absolute stereochemistry of grandiflorine. There matters rested until Castedo and coworkers announced (1) that X-ray crystallography of an alkaloid which his group had isolated from *Sarcocapnos crassifolia*, and *Corydalis claviculata*, and named ribasine, had the structure *including absolute stereochemistry* shown in **1**. The physical constants reported for ribasine (1) left little doubt that it was the same as our alkaloid, and a comparison of the ir spectra of the two compounds clinched this identification.

Although limogine, isolated from *C. claviculata* by another group, was reported to be amorphous, the phsysical data given (2) leave no doubt that it is **1**; i.e. grandiflorine, ribasine, and limogine are identical.

Experimental

Instrumental methods were as described previously (6).

Grandiflorine was isolated from the minor bases of *A. grandiflora* subsp. *grandiflora* by preparative tlc on silica gel, using the solvent system MeOH–$CHCl_3$ 2:98 (v/v); or column chromatography on alumina using anhydrous Et_2O as eluant. It amounted to ca. 0.6% of the total alkaloid content, and had the following properties: mp 202.5–203.5°C; $[\alpha]_D$ +125° (*c* 1, $CHCl_3$); uv (EtOH) λ_{max} (log ε): 238 sh (3.79 and 297 nm (3.78), λ_{min} 260 nm; ir (KBr) ν_{max}: 3030 (w), 2960 (w), 2950 (m), 2890 (m), 2880 (m), 2860 (m), 2840 (m), 2770 (m), 1600 (w), 1480 (m), 1460 (s), 1435 (s), 1355 (m), 1310 (s), 1280 (w), 1265 (m), 1230 (br s), 1205 (m), 1185 (m), 1165 (m), 1150 (m), 1115 (m), 1090 (w), 1070 (m), 1055 (w), 1030 (br s), 1010 (s), 995 (s), 955 (s), 935 (s), 905 (m), 860 (m), 815 (m), 790 (m), 785 (m), 755 (w), 730 (w), 710 (w), 685 (w), 660 (w), 640 (w), 630 (w), 605 (w), 525 (w), 545 (w), 510 (w), 485 (w), 455 (m) cm^{-1}, superimposable upon that of ribasine; ^{1}H nmr, see Table 1; ms (70 eV EI) *m/z*: 351.1106 (87) (calcd. for $C_{20}H_{17}NO_5$: 351.1107), 350 (100), 322 (15), 287 (12), 189 (13), 188 (72), 165 (12), 147 (14), 135 (11), 89 (12), 77 (14), 63 (10), 51 (10) and 42 (22). Hydrobromide salt, mp 220–240°C (dec.) (lit. (1) mp for ribasine 194–195°C), $[\alpha]_D$ +126 (*c* 0.13, $CHCl_3$); uv (EtOH) λ_{max} (log ε): 213 (4.37), 240 sh (4.01), and 292 (4.07) nm.

Received June 22, 1983

MANSSUR YALPANI, LAURANCE D. HALL, JACQUES DEFAYE, and ANDRÉE GADELLE. Can. J. Chem. **62**, 260 (1984).

Diamagnetic and paramagnetic amine derivatives of cellulose have been prepared from selectively oxidized cellulose precursors via the reductive amination method using sodium cyanoborohydride. 4-Amino-2,2,6,6-tetramethylpiperidine-1-oxyl was employed in the syntheses of nitroxide spin labelled cellulose derivatives **4** and **5** from 3-oxy-cellulose (**1**) and 6-*O*-triphenylmethyl-2-oxy-cellulose (**2**). Conversion of the linear polymer **1** into a highly branched, water soluble 3-deoxy-cellulose derivative **6** was accomplished by attachment of glucosamine side chains. 3-Amino-3-deoxy-cellulose **7** was obtained using ammonium acetate. A novel type of organometallic cellulose conjugate **8** was prepared by condensation of **2** and *p*-toluidine chromium tricarbonyl. Similarly, 1,10-diazo-18-crown-6 was added to **2** to form the crown ether derivative **9**. The synthetic strategies involving either 6-*O* protected or unprotected oxy-cellulose intermediates are compared in terms of reaction yields and product properties.

MANSSUR YALPANI, LAURANCE D. HALL, JACQUES DEFAYE et ANDRÉE GADELLE. Can. J. Chem. **62**, 260 (1984).

Faisant appel à la méthode d'amination réductrice utilisant le cyanoborohydrure de sodium, on a préparé des dérivés aminés diamagnétiques et paramagnétiques de la cellulose à partir de celluloses oxydées de façon sélective. L'amino-4 tétraméthyl-2,2,6,6 pipéridineoxyle-1 réagit avec de l'oxy-3 cellulose (**1**) et la *O*-triphénylméthyl-6- oxy-2- cellulose (**2**) pour conduire aux dérivés **4** et **5** de la cellulose contenant le nitroxyde comme marqueur de spin. On a transformé le polymère linéaire **1** en un dérivé de la déoxy-3 cellulose fortement ramifié et soluble dans l'eau en y attachant des chaines latérales de glucosamine. En utilisant l'acétate d'ammonium, on a obtenu l'amino-3 déoxy-3 cellulose **7**. On a préparé un nouveau type de conjugué organométallique de la cellulose **8** en condensant le composé **2** sur la *p*-toluidine chrome tricarbonyle. De la même façon, on a additionné le diazo-1,10 18-couronne-6 sur le composé **2** pour obtenir l'éther couronne **9**. Les méthodes de synthèse font intervenir soit des intermédiaires oxycellulose protégés ou non en position *O*-6 et on les compare du point de vue du rendement et des propriétés des produits.

[Traduit par le journal]

Introduction

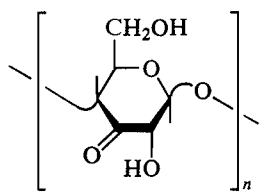
Products derived from cellulose and other natural polysaccharides play prominent roles in various industrial and biomedical applications (1). The requirement for constant improvement of the properties of such products for specific, and often narrowly-defined end-uses, as well as the growing interest in the fundamental relationship between polysaccharide structure and properties (2), have prompted the development of new chemical approaches for the selective modification of the native biopolymers.

Substantial advances have recently been achieved in this regard for amylose and cellulose by the selective oxidation of secondary hydroxyl functions and their subsequent characterization (3). Using the mild acetic anhydride – dimethylsulfoxide reagent system, the 6-*O*-(triphenylmethyl) derivatives of amylose (4) and cellulose (5) or the corresponding 6-*O*-acetyl derivative of cellulose (3) can be selectively oxidized at the C-2 position, while for the C-6 unprotected polymers, the same oxidative reagent, in conjunction with the dimethylsulfoxide–paraformaldehyde solvent system leads to oxidation at C-3 (3). We report here on the utility of 2-oxy- and 3-oxy-cellulose derivatives, in combination with the reductive amination procedure.

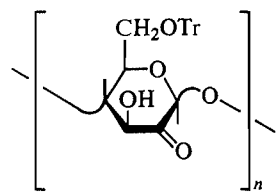
[1]Present address: B.C. Research, Chemical Technology Division, 3650 Wesbrook Mall, Vancouver, British Columbia, Canada, V6S 2L2.

Results and discussion

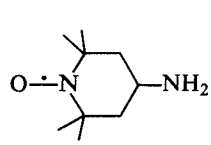
The preparation and characterization of 3-oxy-cellulose, **1**, and the 6-*O*-triphenylmethylated 2-oxy analogue, **2**, have previously been reported (3,5). Both derivatives **1** and **2** had a carbonyl content (degree of oxidation) of about 0.8 and a degree of polymerization of approximately 150.



1



2



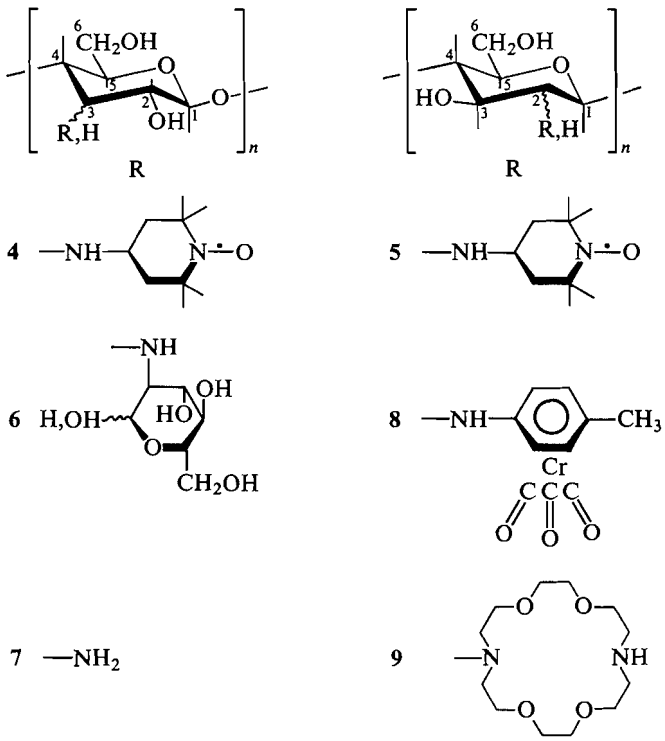
3

Derivatizations of the oxy-cellulose intermediates were performed using both the protected and unprotected species in order to evaluate the effects of the 6-*O*-triphenylmethyl substituent on parameters such as reaction yield and product solubility. Thus reductive amination of the oxy-celluloses **1** and **2**, using 4-amino-2,2,6,6-tetramethylpiperidine-1-oxyl, **3**, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

sodium cyanoborohydride in methanolic medium at ambient temperature afforded the corresponding spin-labelled derivatives **4** and **5** with degrees of substitution (d.s.) of 0.28 and 0.09, respectively. The relatively low d.s. value of derivative **5** appears to be principally attributable to steric hindrance by the bulky C6-trityl group.

The trityl group also contributes to the expected solubility differences observed for the two spin-labelled products. Derivative **4** is water soluble but insoluble in organic solvents, whereas derivative **5** is water insoluble but soluble in chloroform and other organic solvents. These solubility characteristics



are also reflected in the esr spectra of the materials (Fig. 1): the ambient temperature spectrum of derivative **4** in water reveals typical triplet features of a nitroxide moiety tumbling in solution (Fig. 1a), whereas derivative **5** produces an immobilized, "polycrystalline" spectrum (Fig. 1b) in the same medium. Conversely, the latter derivative in chloroform solution produces a three-line spectrum indicative of a highly mobile nitroxide moiety (Fig. 1d), whereas derivative **4** exhibits a powder spectrum (Fig. 1c). Two further features of the esr spectra of these materials should be noted. First, the residual signals which are superimposd on the spectral envelope of the covalently-linked nitroxide moiety of derivative **5** (Fig. 1b) arise from trace quantities of unreacted amine spin label **3** that could not be removed despite exhaustive washing (6). Second, pronounced exchange narrowing is observed in Figs. 1c and e as a result of dipolar nitroxide interactions in the relatively highly substituted derivative **4**; these dipolar interactions are absent in the powder spectrum of the less substituted derivative **5** (Fig. 1f).

We subsequently prepared a series of diamagnetic cellulose derivatives employing the reductive amination procedure. Using, for example, the primary amine function of glucosamine, we converted the linear 3-oxy-cellulose derivative **1** into a highly-branched (d.s. 0.7), water soluble derivative **6**. Derivative **6** was prepared in analogy to a series of branched chitosan derivatives whose preparation (7) and rheological properties (8) we have described elsewhere.

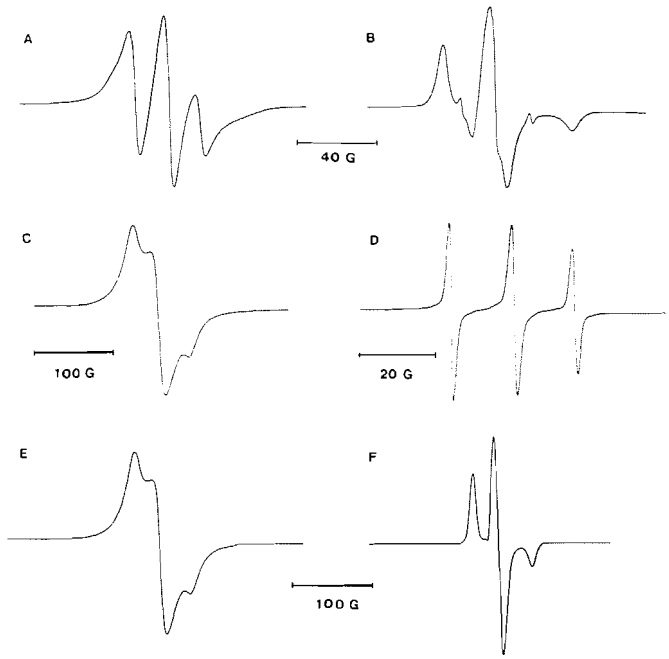


FIG. 1. Ambient temperature esr spectra of derivatives (a) **4** and (b) **5** in water, and derivatives (c) **4** and (d) **5** in chloroform. Powder spectra (at 77°K) of derivatives (e) **4** and (f) **5**.

The ketone derivatives **1** and **2** also constitute useful precursors for the synthesis of aminocellulose derivatives, as exemplified here by the reductive amination of derivative **2** using ammonium acetate, which afforded the 3-amino-3-deoxycellulose derivative **7** (d.s. 0.3). It may be noted that for the preparation of aminocellulose derivatives the reductive amination procedure is more facile than the procedure involving oximation and subsequent lithium aluminium hydride reduction as described by, for example, Teshirogi *et al.* (9). The method described here appears to offer the additional advantage of leading to substantially lower extents of polymer degradation (10).

The preparation of two other types of novel cellulose derivatives is illustrated here by the reductive amination of derivatives **1** and **2**, using *p*-toluidine chromium tricarbonyl and 1,10-diazo-18-crown-6, which afforded derivatives **8** (d.s. 0.25) and **9** (d.s. 0.06), respectively. The crown ether derivative **9** was soluble in organic solvents and is of potential interest as macromolecular complexing agent or phase transfer catalyst (11). The cellulose chromium derivative **8** constitutes, to our knowledge, the first covalent organometallic polysaccharide conjugate, and may find applications in catalysis.

Conclusions

We have demonstrated here the versatility of the combined selective oxidation–reductive amination method for obtaining a range of new cellulose products. It is worthwhile to briefly compare the relative merits of synthesizing selectively modified cellulose derivatives via either *O*-6-protected or unprotected oxy-intermediates. The major advantage of retaining the protective function on the primary hydroxyl groups of 2-oxy-cellulose intermediates derives from the fact that it assists in achieving homogeneous conditions in reactions involving hydrophobic reagents. The bulky size of the trityl group imposes, however, limitations on reaction yields. Conversely, removal of the triphenylmethyl group prior to deriva-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

tization leads to improved yields and avoids exposure to hydrolytic conditions of any acid-labile amine moieties, such as nitroxide labels, attached to the cellulose matrix. One can, of course, alternatively use *O*-6 unsubstituted cellulose as substrate using the dimethylsulfoxide–paraformaldehyde route (3), which is more facile and avoids the polymer degradation (10) and side reactions (12) generally associated with tritylation reactions, but gives access only to 3-deoxy-cellulose products.

Experimental

General methods and materials

Sodium cyanoborohydride and 4-amino-2,2,6,6-tetramethylpiperidine-1-oxyl were purchased from Aldrich Chemical Co. Ammonium acetate was from Malinckrodt, glucosamine hydrochloride from Sigma Chemical Co., *p*-toluidine chromium tricarbonyl from Strem Chemicals, and 1,10-diazo-18-crown-6 from Chemical Dynamics Corp. 3-Oxy-cellulose and 6-*O*-triphenylmethyl-2-oxy-cellulose were prepared as described previously (3, 5). *Anal.* calcd. for **1**, d.s. 0.8, $[(C_6H_8O_5)_{0.8}(C_6H_{10}O_5)_{0.2}]\cdot 0.18\ H_2O$: C 44.00, H 5.39; found: C 43.78, H 5.20. *Anal.* calcd. for **2**, d.s. 0.85 $[(C_{25}H_{23}O_5)_{0.85}(C_6H_{10}O_5)_{0.15}]\cdot 0.2\ H_2O$: C 71.71, H 5.83; found: C 71.94, H 5.63.

Microanalyses were performed by the Microanalytical Laboratory, Department of Chemistry, University of B.C. and Canadian Microanalytical Services, Vancouver. The esr spectra were recorded at X-band using a Varian E-3 instrument and methods described elsewhere (6).

*Preparation of nitroxide-labelled cellulose derivatives **4** and **5***

A dispersion of 3-oxy-cellulose (378 mg, 2.36 mmol) in methanol (7 mL) was treated with amine spin label **3** (412 mg, 2.41 mmol) and sodium cyanoborohydride, $NaBH_3CN$ (400 mg, 6.4 mmol). A few drops of water were added and the mixture was shaken for 33 h at ambient temperature. The product was isolated by filtration, successive washing with water (100 mL), ethanol (150 mL), acetone (50 mL), and diethyl ether (50 mL), and subsequent drying *in vacuo* (50°C). Derivative **4** had a d.s. value of 0.28. *Anal.* calcd. for $[(C_{15}H_{27}N_2O_5)_{0.28}(C_6H_8O_5)_{0.52}(C_6H_{10}O_5)_{0.2}]\cdot 1.55\ H_2O$: C 44.11, H 7.31, N 3.38, (C/N 13.04); found: C 43.73, H 5.97, N 3.37 (C/N 12.98). 2-Oxy-6-*O*-trityl cellulose **2** was labelled under the same conditions yielding a product **5** with d.s. ~0.09. *Anal.* calcd. for $[(C_{34}H_{41}N_2O_5)_{0.086}(C_{25}H_{22}O_5)_{0.764}\ (C_6H_{10}O_5)_{0.15}]\cdot 0.31\ H_2O$: C 71.61, H 5.94, N 0.62; found: C 71.22, H 5.54, N 0.61.

*Preparation of 3-N-(2-amino-2-deoxy-D-glucose)-3-deoxycellulose derivative, **6***

An aqueous sodium bicarbonate solution (10 mL) of glucosamine hydrochloride (600 mg, 2.8 mmol) containing $NaBH_3CN$ (800 mg, 12 mmol) was added under stirring to a methanolic solution of derivative **1** (259 mg, 1.6 mmol, 20 mL). After stirring the reaction mixture for 30 h at ambient temperature, the product was precipitated with chloroform (200 mL), filtered, washed with 100 mL each of chloroform and methanol, and dried. The resulting white material had a d.s. of 0.7. *Anal.* calcd. for $[(C_{12}H_{21}NO_9)_{0.7}(C_6H_8O_5)_{0.15}(C_6H_{10}O_5)_{0.15}]\cdot 1.41\ H_2O$: C 40.81, H 6.80, N 3.27; found: C 40.48, H 6.24, N 3.11.

*Preparation of 3-amino-3-deoxycellulose **7***

A dispersion of derivative **1** (204 mg, 1.28 mmol) in aqueous methanol (15 mL) was treated with an aqueous solution of ammonium acetate (500 mg, 8 mmol) and $NaBH_3CN$ (800 mg, 12 mmol, 10 mL). After stirring the reaction mixture for 30 h, the product was filtered, exhaustively washed with water and chloroform, and dried, yielding derivative **7** with d.s. 0.3. *Anal.* calcd. for $[(C_6H_{11}NO_4)_{0.3}(C_6H_8O_5)_{0.5}(C_6H_{10}O_5)_{0.2}]\cdot 0.36\ H_2O$: C 43.07, H 6.04, N 2.51; found: C 42.85, H 6.31, N 2.27.

Preparation of p*-toluidine chromium tricarbonyl cellulose derivative **8***

A chloroform dispersion of derivative **1** (322 mg, 1.99 mmol, 20 mL) was purged with nitrogen and treated with a solution of *p*-toluidine chromium tricarbonyl (623 mg, 2.56 mmol) and $NaBH_3CN$ (800 mg, 12 mmol) in chloroform (10 mL) in the dark and under a nitrogen atmosphere for 30 h. The resulting green solution was precipitated by the addition of aqueous methanol (100 mL). The product was filtered, exhaustively washed and dried, yielding a fine turquoise powder (193 mg, 56%), d.s. 0.25. *Anal.* calcd. for $[(C_{16}H_{17}CrNO_7)_{0.25}(C_6H_8O_5)_{0.6}(C_6H_{10}O_5)_{0.15}]\cdot 0.1\ H_2O$: C 46.60, H 4.95, N 1.60, Cr 5.94; found: C 46.61, H 4.95. N 1.28, Cr 6.18.

*Preparation of 1,10-diazo-18-crown-6-cellulose derivative **9***

To a solution of derivative **2** (300 mg, 0.77 mmol) in methylene chloride (50 mL) was added 1,10-diazo-18-crown-6 (326 mg, 2.3 mmol) and $NaBH_3CN$ (400 mg, 6 mmol); the reaction mixture was stirred for 48 h at room temperature, then diluted with methanol to 100 mL, and the product precipitated with diethyl ether (1 L), yielding derivative **9**, d.s. 0.06, after filtration, washing (diethyl ether), and drying. *Anal.* calcd. for $[(C_{37}H_{48}N_2O_8)_{0.06}\ (C_{25}H_{23}O_5)_{0.79}(C_6H_{10}O_5)_{0.15}]\cdot 0.05\ H_2O$: C 71.73, H 5.97, N 0.44; found: C 71.25, H 5.57, N 0.36.

Introduction

A large number of H-bond assisted reactions involving fluoride have now been reported, and a wide variety of types of fluorides and reaction solvents have been suggested for such reactions (1, 2). As part of our studies on the use of fluorides in organic synthesis (3, 4), we have carried out some investigations on the effects of varying the fluoride, and of varying the solvent, on the course and efficiency of the alkylation of phenols with benzyl halides.

Results and discussion

In the reaction of a phenol with a benzyl halide in the presence of a fluoride, the reaction may follow up to four pathways giving O-alkylated and C-alkylated phenols. Benzyl fluoride and benzyl alcohol are possible products, as shown below (Scheme 1). Further products may result from participation of the solvent in the reaction. We have compared the results from the reactions of phenols with benzyl bromide in a typical non-polar aprotic solvent (toluene) and in a typical polar aprotic solvent (DMF) using the most popular sources of fluoride, KF (oven dried) and tetra-n-butylammonium fluoride (as a solid hydrate). The results are summarized in Table 1.

It is interesting to note that only in one case is any C-alkylated phenol observed, and this occurs when the reaction may be considered to be totally heterogeneous (KF/toluene) as opposed to partially homogeneous (KF/DMF) or totally homogeneous (TBAF reactions). Presumably, in solution we are dealing with an H-bonded, F···HOAr complex where the negative charge is highly localized on the electron donor (fluoride) and electron acceptor (HO—) species. The concept of

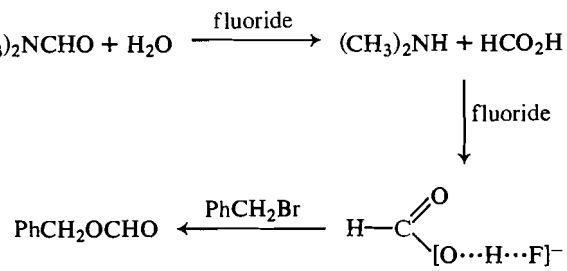
TABLE 1. Products from the reactions of phenols with benzyl bromide in the presence of KF (oven dried) or TBAF (solid hydrate)[a]

Phenol	Fluoride	Solvent	Conditions (time(h)/temp(°C))	O-alkylated fluoride	Fluoride
Phenol	KF	Toluene	27/60	—	—[b]
Phenol	KF	DMF	24/60	67	10
Phenol	TBAF	Toluene	24/82	20[c]	76[c,d]
Phenol	TBAF	DMF	78/23	54[c]	40[c,e]
Phenol	TBAF	Benzene +10% DMF	24/70	15[c]	80[c,e]
p-Nitrophenol	KF	Toluene	72/80	—	—
p-Nitrophenol	KF	DMF	19/60	76	—
p-Nitrophenol	TBAF	DMF	24/23	76	—
p-Nitrophenol	TBAF	Benzene +25% DMF	1/23	75	—
2,6-Di-*t*-butyl-4-methylphenol[f]	TBAF	Toluene	24/82	—	80
2,6-Di-*t*-butyl-4-methylphenol	TBAF	DMF	24/23	—	48[g]

[a] Isolated yield unless stated otherwise.
[b] 20% C-alkylated phenol.
[c] Yield based on ^{1}H nmr.
[d] Along with 4% benzyl alcohol.
[e] Along with 5–6% benzyl formate.
[f] No reaction using KF in toluene or DMF.
[g] Along with 8% benzyl formate and 44% unidentified products.

H-bond charge localization is consistent with the current theory on hydrogen bonds involving fluoride based on the theoretical calculations (see, for example, ref. 5), on ion cyclotron resonance studies (6), and on other experimental observations (2). The reverse selectivity observed in the heterogeneous system is interesting and of potential importance to fluoride chemistry. Heterogeneous reactions showing unusual reaction selectivity is a subject of considerable current interest (see, for example, ref. 7).

In some of our reactions, we detected significant amounts of benzyl formate. DMF is known to be susceptible to hydrolysis, and under basic conditions should produce methanoic acid. The acid should compete for the fluoride and through the resulting H-bond activation be capable of attacking the alkylating agent as shown below.



In reactions where KF was employed and the water content could be assumed to be very small, no hydrolysis products (benzyl formate or benzyl alcohol) could be detected. Introduction of water into KF–DMF reactions resulted in the production of benzyl formate as a side product.

Recently, it has been reported that the method of drying the KF may affect the course or efficiency of KF promoted reactions (8). We have compared oven dried KF and freeze dried KF in assisting the reaction of phenol with benzyl bromide in DMF. Whereas the oven dried KF produces both O-alkylated and fluorinated products (Table 1), freeze dried KF produced the O-alkylated product only (73% recovered yield after 24 h at 60°C). It is possible that freeze drying produces a material of higher surface area and hence either of higher solubility in DMF, or of greater reactivity if the reactions occur in part on the surface of the KF.

TABLE 2. The course of fluoride promoted alkylations of phenols using benzyl halides

Fluoride	Reaction
KF/toluene	Slow C-alkylation
KF(oven dried)/DMF	O-alkylation + fluoride (for unactivated phenols)
KF(freeze dried)/DMF	O-alkylation
KF/Bu^n_4NBr(catalytic)/DMF	O-alkylation (more rapid than KF alone)
TBAF/toluene	Mixture
TBAF/DMF	Mixture (unless phenol is activated)

Finally, we carried out some phenol alkylations under solid–liquid phase transfer conditions (KF/R_4NBr). When carried out under anhydrous conditions, these reactions gave good results using benzyl chloride or benzyl bromide as the alkylating agent. In all cases, only O-alkylation resulted, and isolated yields of 60% after 4–10 hours at 60°C were obtained easily. It is important to note that the role of the "onium" salt in these reactions is truly catalytic. The use of as little as 1 mol% (with respect to the KF) reduced the reaction time for complete conversion of the phenol to one-half of that required when KF was used alone. Furthermore, the phase transfer reactions gave only the one product. Tordeux and Wakselman (9) have recently reported simple fluorinations using similar KF/R_4NF systems to produce acylfluorides and fluoroformates.

In conclusion, it is apparent from our work that the nature of both the fluoride and the reaction medium can affect the course and rate of fluoride assisted reactions. Not surprisingly, TBAF reactions occur more rapidly than those employing KF, although this is at the cost of selectivity, halogen exchange with

the alkylating agent and solvent participation being the most common competing reactions where TBAF is used. O-alkylation is the major reaction at the phenol, especially when the phenol is activated or the solvent is polar aprotic. C-alkylation occurs only under totally heterogeneous conditions. Our results are summarized in Table 2.

A Fourier transform infrared study of the electrophilic attack at the N_7-site of guanosine-5′-monophosphate

H. A. TAJMIR-RIAHI AND T. THEOPHANIDES
Département de Chimie, Université de Montréal, Montréal (Qué), Canada H3C 3V1

Received June 2, 1983

H. A. TAJMIR-RIAHI and T. THEOPHANIDES. Can. J. Chem. **62**, 266 (1984).

Fourier transform infrared spectra of several N_7-bound cations of guanosine-5′monophosphate disodium salt (5′-$GMPNa_2$), such as N_7-H^+GMP, N_7-MeGMP, and N_7-MGMP, where Me = CH_3^+ and M = divalent metal ions, Cd, Mn, Co, Ni, Cu, Pt, and Mg, have been recorded and a correlation between the spectral changes and the nature of the electrophile (H^+, CH_3^+, and M^{2+}) bound has been established. Spectroscopic evidence shows that methylation of the N_7-position of 5′-$GMPNa_2$ causes larger perturbation on the guanine ring system than protonation or metalation, in the order $Me^+ > H^+ > M^{2+}$. The effect of an N_7-electrophilic attack on the vibrational frequencies of the purine, the sugar, and the phosphate group is discussed.

H. A. TAJMIR-RIAHI et T. THEOPHANIDES. Can. J. Chem. **62**, 266 (1984).

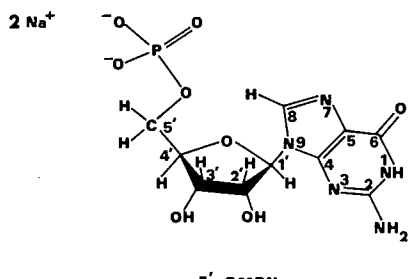
On a enregistré les spectres infrarouges en transformation de Fourier de plusieurs cations du sel de sodium de la guanosine-5′ monophosphate, ($GMPNa_2$-5′) liés par l'azote en position 7, tels le N_7-H^+GMP, le N_7-MeGMP et le N_7-MGMP où Me = CH_3^+, et M = ions métalliques bivalents: Cd, Mn, Co, Ni, Cu, Pt et Mg et on a établi une corrélation entre les variations du spectre et la nature de l'électrophile de la liaison (H^+, CH_3^+ et M^{2+}). Les preuves spectroscopiques montrent que la méthylation de l'azote en position 7 du $GMPNa_2$-5′ provoque une plus grande perturbation sur le cycle de la guanine que la protonation ou la métallation, dans l'ordre suivant: $Me^+ > H^+ > M^{2+}$. On discute de l'effet d'une attaque électrophile en N_7 sur les fréquences de vibration de la purine, du sucre et du groupe phosphate.

[Traduit par le journal]

Introduction

The interaction of the electrophilic agents, H^+, R^+, and M^{2+} with the nucleic acids and their components has been the subject of recent studies (1–3). The interest in this area of research lies in the anti-tumor activity of the alkylating agents (1) (nitrogen mustards), the *cis*-platinum (*cis*-$Pt(NH_3)_2Cl_2$) and other related platinum compounds (4) which are assumed to interact with the DNA molecule *in vivo*. Raman and nmr spectroscopy has often been used (1, 2, 5–8) to characterize the nature of such electrophilic interaction with mono- and polynucleotides, whereas ir is the least used technique for this purpose, so far (9–11).

In the present work, we wish to describe and analyse the FT-IR spectra of a number of structurally known N_7-bonded metal–GMP complexes (12–16) and the corresponding protonated (17) and methylated analogs. Having at our disposal unambiguous structural information (12–17) on some N_7-bonded compounds, we have recorded and analyzed their FT-IR spectra in order to establish a correlation between the spectral changes and the nature of the N_7-electrophile bound (H^+, CH_3^+, and M^{2+}) on the guanine base. We have also studied the ribose–phosphate vibrational frequencies of these systems for a possible phosphate interaction. The structure and atomic numbering of 5′-$GMPNa_2$ is illustrated below.



Experimental

The 5′-GMP acid, the N_7-MeGMP, and the Na salt of the mononucleotide were purchased from Sigma Chemical Company. The K_2PtCl_4 was purchased from Johnson Matthey Ltd., and was converted to *cis*- and *trans*-$Pt(NH_3)_2Cl_2$ by published methods (18, 19). All the other chemicals were BDH reagent grade and were used without further purification.

Preparation of the N_7-species

The metal–GMP complexes were synthesized and recrystallized following published methods (12–16). The preparation of Pt^{2+} and Mg^{2+} complexes was described earlier (20). The free 5′-GMP acid was used as N_7-protonated and was recrystallized by the reported method (17).

Elemental analysis

C, H, and N were analyzed by Schwarzkopf microanalysis (U.S.A.). The metal ions and the halide were determined as previously reported (20).

Physical measurements

The FT-IR spectra have been recorded on a DIGILAB FTS-15/C Fourier Transform Michelson Interferometer, equipped with a high-sensitivity HgCdTe detector and a KBr beam splitter with a spectral resolution of 2–4 cm^{-1}, and KBr pellets. The bands are accurate to ± 1 cm^{-1}.

Results and discussion

Structural data show (12–15) that [$(H_2O)_5M$(5′-GMP)].$3H_2O$, where M = Cd^{2+}, Mn^{2+}, Co^{2+}, and Ni^{2+}, contains a six-coordinated metal cation bonded to the N_7-site of guanine and five water molecules (three of the remaining water molecules are waters of crystallization). The Cu^{2+} ion is five coordinated, binding to the phosphate group and to the N_7 atom of guanine, as well as to three water molecules in Cu_3(5′-GMP)$_3$.$8H_2O$ (16). The free 5′-GMP acid exists in a zwitterionic form (17) with protonation at the N_7-position of the guanine and at an ionic phosphate oxygen. The N_7-$MeGMPNa_2$ is known (21) to contain a CH_3^+ group at the N_7-site of the purine ring (the crystal structure of this compound is not known). In this work the FT-IR spectra of these N_7-bonded species have been recorded in the region of 4000–400 cm^{-1} and a comparison with the spectrum of 5′-$GMPNa_2$ (which is free of N_7-bonding) has been made.

4000–2700 cm^{-1}

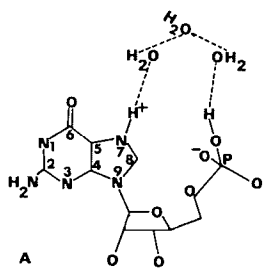
In this region, the asymmetric and symmetric stretching vibrations of the NH_2, NH, H_2O, OH, CH_2, and CH of the sugar moiety and the base residue of the free 5′-$GMPNa_2$ have been studied (22, 23) and show no considerable changes in the spectra of all these N_7-bonded species. The small shifts observed in this region of the spectra are due to a rearrangement of the hydrogen-bonding network of the free ligand upon N_7-complexation. Due to the presence of a strong hydrogen-bonding system in the free mononucleotides and their N_7-adducts, one cannot draw a conclusion on the nature of the electrophilic attack at the N_7-site of the ring system from this region.

1800–400 cm^{-1}

Drastic spectral changes occurred in this region upon formation of the N_7-electrophile compounds, these are dealt with separately.

N_7-protonation

Sundaralingam *et al.* (24) have demonstrated the zwitterionic character of the free acid form of the mononucleotide, 5′-$GMPNa_2$ in the solid state. The crystal structure of 5′-GMP acid protonated at N_7 exists in a zwitterionic form with an ionized phosphate group (17). The proton at the N_7-site is linked to the phosphate group via three hydrogen-bonded water molecules (A). The C_6=O group is shielded from hydrogen



A

bonding, whereas the NH_2 group and the nitrogen atoms of the pyrimidinic ring as well as the sugar moiety are involved in a strong hydrogen-bonding network (17). The FT-IR spectra of this acid exhibits (Fig. 1*c*) a strong absorption band at 1705 cm^{-1} related to the free C_6=O stretching frequency (25), whereas in the 5′-$GMPNa_2$ salt the corresponding absorption band appears at 1692 cm^{-1} (Fig. 1*a* and Table 1). The small shift of the C_6=O stretching vibration to a lower frequency in the sodium salt is mainly due to the hydrogen bonding of the C_6=O group through the oxygen atom. The crystal structure of 5′-$GMPNa_2$ (26) shows an indirect Na–carbonyl interaction through a coordinated water molecule. The scissoring motion of the NH_2 group appeared (25) as a shoulder absorption band at 1600 cm^{-1} in the spectrum of the 5′-$GMPNa_2$ and shifted to a lower frequency at 1641 cm^{-1} in the spectrum of the free 5′-GMP acid. The shift of the scissoring vibration of the NH_2 group to a lower frequency and that of the NH_2 stretching vibration at 3400 cm^{-1} to a higher frequency is indicative of a rearrangement of the strong hydrogen-bonding system of the NH_2 group in 5′-$GMPNa_2$ upon N_7-protonation. The weaker hydrogen-bonding network of the NH_2 group causes an increase of the NH_2 stretching and a lowering of the NH_2 scissoring frequency. The N_7-protonation also produces small intensity changes and shifting of the absorption bands at 1600, 1580, and 1535 cm^{-1}, which are mainly assigned (25) to the C_4—N_3, C_5—C_4, and C_4—N_9 skeletal frequencies, respectively. Since protonation of the N_7-position of the guanine ring has been found (24) to have a considerable effect on the purine ring geometry, therefore, it should also perturb the electron distribution within the ring system and produce changes in the skeletal vibrational frequencies. An absorption band with a medium intensity at 1478 cm^{-1}, in the spectra of 5′-$GMPNa_2$ was assigned to a purine ring vibrational frequency (1). This frequency involves mainly stretching of C_8=N_7 and C_8—H bending motions and is shifted to a higher frequency (1480 cm^{-1}) in the N_7-protonated compound. The shift of the C_8=N_7 stretching to a higher frequency upon protonation is consistent

with the C=N$^+$ frequencies, which were experimentally found (27, 28) to be higher than the parent C=N groups. A strong absorption band at 1359 cm^{-1} in the spectrum of the free base related to a pyrimidinic ring vibration (29) lost intensity and shifted to a higher frequency (1369 cm^{-1}) upon protonation. The shift observed for that absorption frequency is most likely due to the different hydrogen binding system of the pyrimidinic ring upon N_7-protonation than to any inductive effects caused by N_7-binding, since the effect of electrophilic attack at the N_7-site hardly goes beyond the purine ring system (24). The other absorption bands at 1330 (sh), 1255 (m), 1234 (m), and 1175 cm^{-1} (m) in the spectra of 5′-GMPNa$_2$ are attributed mainly to C_8—N_9, C_5—N_7, C_8—N_7, stretchings and to the bending mode of C_8—H (25, 30). The bands showed considerable changes in the spectra upon N_7-protonation. The first absorption band disappeared and the rest shifted to lower frequencies (Table 1). These absorption bands are mainly related to the purine ring vibrational frequencies. Structural studies show (24) that protonation of N_7- in purines causes a large alteration on the bond distances of N_7—C_5, N_7—C_8, C_8—N_9, and the angles of N_7—C_8—N_9, C_5—N_7—C_8, C_4—C_5—N_7 distorting the molecular structure (Table 2). Therefore, it seems that an electrophilic attack at the N_7-position does perturb mainly the electron distribution of the imidazol ring system, where the vibrations are mostly localized and imposes a predominant distortion to the whole purine ring system. The band of medium intensity at 682 cm^{-1} in the spectrum of the 5′-GMPNa$_2$ related to the guanine ring breathing mode (25) shifted slightly to about 680 cm^{-1} in the spectrum of the N_7-protonated compound.

The effect of N_7-protonation on the phosphate and sugar vibrations

The ir spectra of the mononucleotide phosphate group has been reported earlier (20). The phosphate group of $ROPO_3^{2-}$ moiety in 5′-GMPNa$_2$ shows five vibrational frequencies in the region 1100−350 cm^{-1} (20, 23). The strong and broad absorption at 1075 cm^{-1} is assigned to the PO_3^{2-} degenerate stretching, the sharp band at 975 cm^{-1} is assigned to the PO_3^{2-} symmetric stretching, the absorption band with the medium intensity at about 800 cm^{-1} is assigned to the P—O stretching frequency, and the two other weaker absorption bands at about 450 and 400 cm^{-1} are assigned to the PO_3^{2-} symmetric and degenerate deformations, respectively (23). The three absorption bands at 1075, 975, and 800 cm^{-1} in the spectrum of 5′-GMPNa$_2$ show considerable changes upon direct or indirect phosphate−electrophile interaction. Deprotonation of the phosphate group and protonation of the N_7-position of the gua-

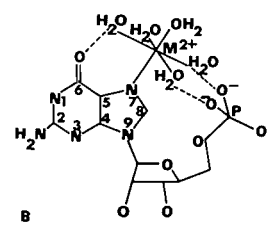
nine ring, as well as indirect interaction of the proton-phosphate group through hydrogen bonded water molecules (A), brings considerable changes to the phosphate vibrational frequencies. Splitting of the bands at 1075 and 975 cm^{-1} in the spectrum of 5′-GMP acid upon N$_7$-protonation is indicative of the strong proton−phosphate interaction via the hydrogen-bonded water molecules. In the corresponding spectrum of the free ligand where the Na−OPO$_3$ interaction is largely electrostatic (26), such splitting and shifting of the phosphate absorption bands does not occur (Fig. 1*a* and Table 1). It is worth noting that the indirect interaction between the N$_7$-proton and the phosphate oxygens allows the phosphate group to approach the purine ring system (31) with a torsion angle ϕ (C5′—O5—P) of about −164° (17). These conformational changes around the phosphate−sugar bond (32) induce intensity changes and shifting of the ribose−phosphate vibrational frequencies centered at 900−700 cm^{-1} (33) in the spectrum of the N$_7$-protonated 5′-GMP molecule.

N$_7$-metalation

The polymeric copper complex, Cu$_3$(5′-GMP)$_3$.8H$_2$O, shows (16) that each Cu^{2+} ion is five-coordinated. The crystal structure analysis shows that binding takes place through the N$_7$-atom of the guanine ring and the oxygen atoms of the phosphate group, as well as through three water molecules, whereas the corresponding Cd, Mn, Co, and Ni complexes are only N$_7$-bonded and coordinated to five water molecules (12−15). Two of these water molecules are strongly hydrogen-bonded to a phosphate group, and the carbonyl group is also indirectly bound to the central metal cation via a coordinated water molecule (B).



B

The FT-IR spectrum of the free 5′-GMPNa$_2$ shows a strong and broad absorption band at 1692 cm^{-1}, which is assigned to the C$_6$=O and the C$_6$—C$_5$ stretching frequencies (25). This absorption band lost intensity and appeared almost in the same position in the spectra of structurally known N$_7$-bonded metal complexes (Fig. 1*d* and Table 1). The small changes of the C$_6$=O stretching frequency are mainly due to the indirect metal−carbonyl interaction via a coordinated water molecule

upon N_7-metalation. The bending mode of the NH_2 group of the free ligand absorbs (25) at 1660 cm^{-1}. This vibration appears as a strong absorption band at a slightly lower frequency in the spectra of the N_7-metalated complexes (Fig. 1 and Table 1). The shifting and splitting of the NH_2 bending motion to a lower frequency, together with the shift of the NH_2 stretching frequency at 3400 cm^{-1} to a higher frequency, is indicative of weaker hydrogen-bonding network of the NH_2 group in the N_7-metalated complexes. The absorption bands at about 1600, 1580, and 1535 cm^{-1}, in the spectra of the free base were mainly assigned to the skeletal vibrations (25) of the ring system and showed intensity changes and shifting in the spectra of the N_7-metalated compounds similar to those of the N_7-protonated compound (see N_7-protonated section). The absorption band at 1478 cm^{-1} in the spectrum of the free 5′-GMPNa$_2$ shifted to a higher frequency ($\Delta\nu$ = 10–20 cm^{-1}) in the spectra of the N_7-bonded platinum metal complexes (Fig. 1*f* and Table 1). Since this absorption band contains the C_8—N_7 stretching and the C_8—H bending vibrational frequencies (1), it seems to follow that metalation of the N_7-site induces an increase of the C_8—N_7 stretching frequency. Similar behaviour was observed (34) in the spectra of the structurally known metalated C=N group for some lanthanide Schiff base complexes. The pyrimidine ring vibration (29) at 1359 cm^{-1} in the spectra of the free ligand splits into two weak absorption bands at higher and lower frequencies in the spectra of the N_7-metal derivatives (Fig. 1 and Table 1). The changes observed for that absorption frequency are mainly due to the alteration of the hydrogen-bonding network of the pyrimidine ring system (base pairing) upon N_7-metalation (20). The absorption bands at 1330, 1255, 1234, and 1175 cm^{-1} with medium intensities in the spectrum of the free base show considerable changes (shifting and splitting), in the spectra of the N_7-metal complexes. These absorption bands have been primarily assigned (25, 30) to the purine ring vibrational frequencies, involving C_8—N_7, C_5—N_7 stretching and N_7—C_8—N_9 and C_8—H bending vibrations. It seems, therefore, that the distortion of the molecular geometry (12–16) of the ring system caused by N_7-metalation (Table 2) brings a large perturbation to the purine ring electronic distribution and alters the imidazol ring vibrational frequencies the most. The guanine ring breathing mode (25) of the free ligands at 682 cm^{-1} shifted towards higher frequencies (~700 cm^{-1}) in the spectra of the N_7-bonded metal cations and this is a characteristic feature of the N_7-metal bonding in DNA and its components (8, 20).

The effect of N_7-metalation on the phosphate and sugar vibrations

The phosphate absorption bands at 1075, 975, and 800 cm^{-1} in the spectrum of the free base show considerable changes upon direct or indirect metal–phosphate interaction. The effect of direct and indirect metal–phosphate binding on the vibrational frequencies of the $ROPO_3^{2-}$ of the mononucleotides has been described earlier (20). The ir spectra of the N_7-bonded copper complex Cu$_3$(5′-GMP)$_3$.8H$_2$O (20) shows splitting and shifting of the bands at 1075, 975, and 800 cm^{-1} (Fig. 1 and Table 1). These absorption bands have been assigned (20, 23) to the PO_3^{2-} degenerate and symmetric stretching vibrations, as well as to the P—O stretching frequency. The indirect metal–phosphate interaction through the hydrogen-bonded water molecules in the N_7-bonded metal complexes (Cd, Mn, Co, and Ni) caused shifting of the phosphate vibrational frequencies at 1075, 975, and 800 cm^{-1} (Table 1). The direct metal–phosphate interaction observed in the N_7-bonded Mg(5′-GMP).6H$_2$O synthesized in acidic solution (20) shows shifting and splitting of the phosphate vibrational frequencies (Table 1). The spectra of Mg^{2+} and Pt^{2+}—GMP complexes, on the other hand, obtained at neutral pH values with indirect metal–phosphate bonding and direct N_7-bonding (20) exhibit small shifting of the phosphate vibrational frequencies (Table 1). A shoulder absorption band at 1124 cm^{-1} in the spectrum of the free 5′-GMPNa$_2$ assigned to the C—O stretching of the sugar moiety (23) as well as the absorption bands near 900–700 cm^{-1} assigned mainly to the phosphate–ribose stretching vibrations (33) show intensity changes and shifting in the spectra of the N_7-bonded metal-complexes. The small changes occurred are mainly due to the conformational changes around the phosphate–ribose bond (32) and to the rearrangement of the hydrogen-bonding system of the sugar residue, upon direct or indirect metal–phosphate bonding. The torsional angle (ϕ) found (16) for Cu$_3$(5′-GMP)$_3$.8H$_2$O is about 122–151° (direct metal–phosphate bonding) and 153° for Cd(5′-GMP).8H$_2$O (indirect Cd–phosphate interaction) (12), which is indicative of the closer approach of the phosphate moiety towards the purine ring system upon direct metal OPO_3^{2-} interaction.

N_7-methylation

It has been suggested (1, 21) that the N_7-methylguanosine-monophosphate (N_7-MeGMP) molecule exists in equilibrium between a zwitterionic form (D) and a keto form (C), in aqueous solution. The crystal structure of this compound is not yet known. The CH_3^+ group is bound to the N_7-position of the ring system and shows the zwitterionic character (D) in basic solution (pH = 9), whereas in acidic media (pH = 4) the keto form

(C) is more predominant (1). The FT-IR spectrum of the N_7-MeGMP shows a strong absorption band at 1703 cm^{-1}, assignable to the C_6=O stretching frequency (25). The position of this band is similar to the corresponding band in the N_7-protonated species (Fig. 1*b*), which is also indicative of a free carbonyl group (shielded by the methyl group from hydrogen-bonding) in the N_7-MeGMP molecule. The bending motion of the NH_2 group appears as a strong absorption band at 1620 cm^{-1}, similar to the NH_2 bending mode in the N_7-protonated compound (Fig. 1*b*), which is consistent with the presence of the NH_2 group in a similar hydrogen-bonding network found (17) for the N_7-protonated species. It has been demonstrated (1) that the N_7-MeGMP shows a strong Raman line at 1620 cm^{-1} (pH = 9) with no carbonyl line at 1692 cm^{-1}, which indicates the presence of the N_7-MeGMP in the zwitterionic form (D) and therefore the line at 1620 cm^{-1} was tentatively assigned (1) to the C—O^- stretching frequency. Solution studies of the O_6-methylated inosine molecule (10) show that the absence of the band at 1690 cm^{-1} (C_6=O stretching) is accompanied by the appearance of a new absorption band at 1300 cm^{-1} in basic media which was related to the presence of the C—O^- stretching frequency. Therefore, the latter assignment of the C—O^- stretching vibration at 1300 cm^{-1} is more realistic, unless the double bond character of the C_6=O is still predominant in the former case (1). The presence of the strong absorption band at 1703 cm^{-1} and the absence of any new absorption band at 1300 cm^{-1} here indicates that the N_7-MeGMP molecule exists in a keto form (C). The other absorption bands at 1590, 1566 and 1533 cm^{-1}, in the spectra of the N_7-MeGMP show marked similarities with that of the corresponding N_7-protonated species. Since, these absorption bands have been mainly assigned to skeletal vibrations of the ring system (23), it seems that protonation and methylation of the N_7-position of the guanine ring perturbs in a similar fashion as the ring vibrational frequencies. The absorption band at 1478 cm^{-1} in the spectrum of the free 5′-$GMPNa_2$ has been shifted to a lower frequency at 1467 cm^{-1} in the spectrum of the N_7-methylated compound (Fig. 1*c*). The shift of this absorption band to a lower frequency on methylation is not consistent with that of protonation or metalation of the N_7-site in 5′-GMP, which on the contrary induces an increase to that absorption frequency. Since this absorption band has been mainly assigned (1) to the C_8—N_7 stretching and C_8—H bending frequencies, it appears that methylation of the N_7-site induces different electronic perturbation within the ring system, which could be explained by the more covalent character of the N_7—CH_3^+ bond compared to the corresponding protonated and metalated compounds. It has been shown (1) that the Raman line at 1480 cm^{-1} in the spectra of 5′-GMP disappears upon N_7-methylation (1, 35) and it shifts upon deuteration of H_8 (33), whereas heavy metalation, particularly platination (4, 35), affects that Raman line to a lesser extend. The pyrimidinic ring vibration (29) at 1359 cm^{-1} in the spectra of the free base loses intensity and disappears or remains as a weak band at 1378 cm^{-1} in the spectra of the N_7-methylated compound (Fig. 1*b*). The changes observed for this absorption frequency are mainly related to the rearrangement of the hydrogen-bonding network of the pyrimidinic ring nitrogen atoms. The absorption bands at 1330, 1255, 1234, and 1175 cm^{-1} in the spectrum of the free ligand, attributed mainly to the C_8—N_7, C_5—N_7, C_8—N_9 stretchings, and C_8—H bending frequency (25, 30) lose intensity and shift to higher frequencies in the spectra of the N_7-MeGMP compound (Table 1). Similar trends are observed in the spectra of the N_7-metalated species and since these absorption bands have been assigned to the purine ring vibrations, it seems that the addition of CH_3^+ to the N_7-position of the ring system produces large electronic perturbations within the purine ring and distorts the imidazol ring system. The absorption band at 682 cm^{-1} in the spectrum of free 5′-$GMPNa_2$ assigned to the guanine ring breathing mode (25) decreases in intensity and appears in the same position in the spectrum of the N_7-MeGMP compound (Table 1).

The effect of N_7-methylation on the phosphate and sugar vibrations

The phosphate vibrational frequencies of the free 5′-$GMPNa_2$ at 1075, 975, and 800 cm^{-1} (described in the protonation and metalation sections) shift moderately in the spectra of the N_7-MeGMP (shift of the above bands to 1100, 975, and 789 cm^{-1}, respectively). The changes occurred are mainly due to the hydrogen bonding of the phosphate via water molecules. Similar changes were also observed in the ir spectra of the structurally known N_7-bonded Cd^{2+}, Mn^{2+}, Co^{2+}, and Ni^{2+}—GMP complexes (20), that contain hydrogen-bonded phosphate groups through water molecules. The other absorption bands at 1125 cm^{-1} (assigned to the C—O stretching of the sugar moiety) and at 900−800 cm^{-1}, assigned to the phosphate−ribose stretching frequencies (23, 33), exhibit slight shifting and intensity decreases. The alteration of these absorption bands is mainly related to the hydrogen-bonding system of the sugar and the conformational changes around the phosphate−ribose bond upon N_7-methylation of the 5′-GMP molecule (32).

Conclusion

The vibrational modes of the guanine ring system are strongly coupled and it is difficult to observe characteristic vibrations localized between two atoms. The vibrations are spread over the entire molecule. The N_7-site coordination, however, may be a useful probe for studying and understanding the vibrational problem in these molecules. Comparing the FT-IR spectra of each type of N_7-electrophile bound with existing X-ray crystal structural data, systematic spectral changes have been observed depending on the strength of the N_7-electrophilic attack. The FT-IR results in this work support the following statements:

(*1*) Methylation and protonation at the N_7-site of the guanine ring shield the C_6=O group from hydrogen-bonding and shifts this band towards higher frequencies near 1703 cm^{-1}. The N_7-metalation, on the other hand, seems to involve indirectly the carbonyl group, via a coordinated hydrogen-bonded H_2O molecule. Intensity changes and/or slight shifting of the C_6=O stretching frequency ($\Delta\nu$ = ±5 cm^{-1}) have been observed.

(*2*) The scissoring motion of the NH_2 group at 1660 cm^{-1} (sh), in the spectrum of the free 5′-$GMPNa_2$, appears as a strong absorption band at 1650 cm^{-1} in the metal complexes, at 1641 cm^{-1} in the protonated species, and at 1620 cm^{-1} in the methylated species. The shift of the NH_2 bending mode to a lower frequency is indicative of a rearrangement and the weakening of the hydrogen-bonding network of the NH_2 group. The order of the perturbation is as follows: $CH_3^+ > H^+ > M^{2+}$.

(*3*) The effect of the N_7-bonding on the skeletal vibrations of the ring system at about 1600 cm^{-1}, 1580 and 1535 cm^{-1}, in the free ligand spectra is related to the nature of the N_7-electrophilic addition. The maximum perturbation has been observed for methylation and protonation rather than for metalation (CH_3^+

$> H^+ > M^{2+}$).

(*4*) The medium absorption band at 1478 cm^{-1} in the free base spectrum related to the C_8—N_7 and C_8—H of the purine ring vibrational frequencies is shifted to a higher frequency, upon metalation and protonation ($\Delta\nu$ = 2−20 cm^{-1}). The N_7-methylation, on the contrary, induced a decrease to this absorption frequency ($\Delta\nu$ = −10 cm^{-1}). The largest perturbation has been observed for N_7-methylation and metalation rather than for protonation ($CH_3^+ > M^{2+} > H^+$). The increase of this absorption band upon metalation or protonation may be due to the formation of the —C=N^+—, which has in general higher frequencies than the parent C=N group.

(*5*) The pyrimidinic ring vibration at 1359 cm^{-1} in the spectra of the free base was perturbed largely by metalation (splitting and shifting) rather than by protonation or methylation of the N_7-site of the guanine ring system ($M^{2+} > CH_3^+ > H^+$).

(*6*) The purine ring vibrational frequencies at about 1330, 1255, 1234, and 1175 cm^{-1} in the free base spectrum were strongly affected by the electrophilic attack at the N_7-site of the ring system. The larger perturbation has been observed for the N_7-metalation and protonation rather than for methylation. The structural studies of the N_7-metalated and protonated compounds show large alteration of the bond distances and the angles (Table 2). It seems that the distortion of the molecular dimensions of the purine ring system is accompanied by a perturbation of the electronic distribution of the ring system (due to the charge transfer from the ring nitrogen atom to the H^+, M^{2+}, and CH_3^+), which affects the vibrations associated with the local attack at N_7. Such perturbation of the electronic distribution of the purine ring system upon N_7-protonation was indicated from theoretical calculations on protonated DNA components in a recent study (36).

(*7*) A large perturbation of the phosphate vibrational frequencies at 1075, 975, and 800 cm^{-1} is observed for direct metal−phosphate interactions and to a lesser extent for an indirect metal or proton−phosphate interaction through hydrogen-bonded water molecules. Methylation at the N_7-site affects little the phosphate vibrational frequencies. The order of perturbation upon N_7-coordination on the phosphate vibrational frequencies is: direct metal−phosphate bonding > indirect metal−phosphate > proton−phosphate > CH_3^+.

(*8*) The sugar and sugar−phosphate vibrational frequencies at 1125 cm^{-1} and near 900−700 cm^{-1} are also mostly affected by the direct and indirect N_7−metal and proton−phosphate interaction, which induces conformational changes around the sugar−phosphate bond. The N_7-methylation shows little effect on these vibrational frequencies. This is most probably due to the absence of any strong hydrogen-bonding of the methyl group with the phosphate oxygen atoms.

(*9*) Finally, the guanine ring breathing mode at 682 cm^{-1} in the free 5′-GMPNa_2 is perturbed more by metalation at the N_7-site than by protonation or methylation, in the order $M^{2+} > H^+ > CH_3^+$.

Substituent effects in the hydrogenation of $\Delta^{1,9}$-octalins

CIRILL SCHMIDT AND TIBOR BREINING[1]

Department of Chemistry, University of Prince Edward Island, Charlottetown, P.E.I., Canada C1A 4P3

Received May 30, 1983

CIRILL SCHMIDT and TIBOR BREINING. Can. J. Chem. **62**, 273 (1984).

The presence of the 4α-methyl group in olefin **4** or in conjugated ketone **10** prevents catalytic hydrogenation from the α side, leading exclusively to *cis*-fused decalins.

CIRILL SCHMIDT et TIBOR BREINING. Can. J. Chem. **62**, 273 (1984).

On rapporte que l'hydrogénation catalytique de l'oléfine **4** ou de la cétone conjuguée **10** conduit exclusivement a la *cis*-décaline correspondante étant donné la présence du groupement méthyle-4α qui empêche la réaction de s'effectuer du côté α de la molécule.

[Traduit par le journal]

For personal use only.

We wish to report an example which might improve the predictability of ring junctures in decalins resulting from the catalytic hydrogenation of substituted $\Delta^{1,9}$-octalins **1**. The known cases are collected in Table 1. They show that any particular combination of methyl groups near the double bond profoundly influences the *cis*/*trans* isomer ratio of the decalins formed. However, these influences are not entirely understood.

Admittedly, the predominant and exclusive formation of *trans*-fused decalins from octalins **1***a* (1), **1***c* (3), and their derivatives (4) can readily be explained as the result of preferential adsorption of the less hindered side of the substrate on the surface of the catalyst. On the other hand, the predominance of the *cis* isomer in the hydrogenation of octalin **1***b*, containing an angular methyl group, is contrary to this explanation (2).

Octalin **1***d* should also be examined in this context, but to our knowledge this compound and its hydrogenation have not been reported. We have therefore prepared hydroxyketone **4** for this purpose.

The sterically hindered keto group in the recently reported dioxolane **2** (5) was reduced to the equatorial alcohol **3** with $LiAlH_4$ in refluxing THF as evidenced by a coupling constant of 11 Hz. After deketalization, hydroxyketone **4** was hydrogenated in acetic acid, in the presence of Adam's catalyst, to a single hydroxy ketone **5***a*, which will be shown to possess a *cis*-fused system.

We recently reported the preparation of the *trans*-fused ketone **11** from dimethylether **10** (5). The latter compound was hydrogenated to ketone **9** which, after elimination, led to ketone **8**, isomeric with the authentic *trans*-fused ketone **11**.[2]

Since the only possible stereochemical difference is due to the ring juncture, ketone **8** must be *cis*-fused. The same ketone was also obtained by elimination of mesylate **5***b* to olefin **6**, followed by reduction to alcohol **7***a* (8), methylation to **7***b* (9), and allylic oxidation to ketone **8** (10). It is to be mentioned that the only reagent which produced the pure equatorial alcohol **7***a* was Na in liquid ammonia (8). With complex hydrides, the undesired axial alcohol was also present.

The catalytic hydrogenations **4** → **5***a* and **10** → **9** led exclusively to *cis*-fused systems, even under the most *trans*-producing conditions (11). This indicated that the 4α-equatorial methyl group seriously inhibited the absorption of the substrate by the α side. This stereochemical result seems similar to that found in the selective reduction of diketone **12** to keto-alcohol **13** by $NaBH_4$, in which the hydride ion attacks from the β side (5), in spite of the usual α-attack encountered in the case of 6-ketosteroids (12). Clearly the 4α-methyl group seriously decreases the accessibility of the α side in both reactions.

It could be suggested that some secondary force of attraction may exist between the catalyst and the angular methyl group in octalin **1***b*, promoting the formation of a *cis*-fused system (55%), and, since hydrogenation leading to the *trans* product is prevented by the 4α-methyl group in compound **4**, the *cis*-decalin **5***a* is the only product formed. However, this attractive force between an angular methyl group and the catalyst in octalin **1***c* cannot operate, due to the presence of the second axial group.

Experimental

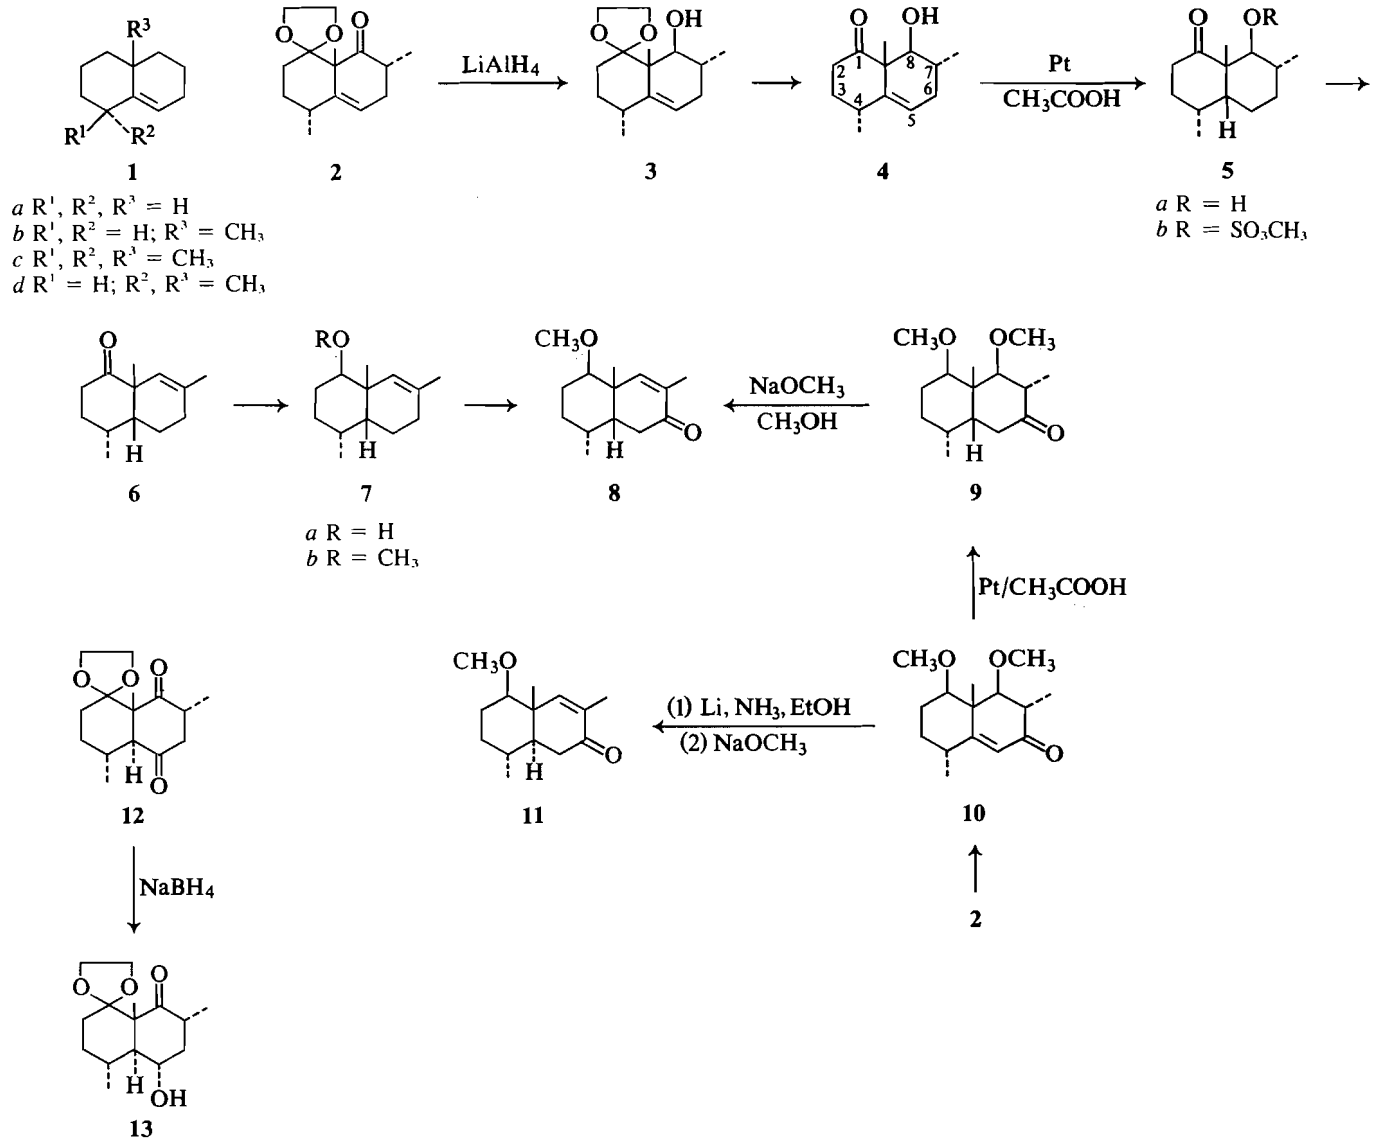
All melting points were taken on a Fisher–Johns melting point apparatus and are uncorrected. The elemental analyses were carried out by Pascher Mikroanalytical Laboratorium, Bonn, West Germany, and Schwarzkopf Mikroanalytical Laboratory, Woodside, N.Y. The ir spectra were recorded on a Perkin–Elmer Model 137B infracord spectrophotometer. The uv spectrograms were taken on a Coleman–Hitachi Model 124 double-beam grating spectrophotometer. The nmr spectra were recorded on a Varian Associates T60 spectrophotometer. The mass spectra were obtained with a Hitachi Perkin–Elmer Model RMS-4 spectrometer.

*8β-Hydroxy-4α,7α,8aβ-trimethyl-3,4,6,7,8,8a-hexahydronaphthalen-1(2*H*)-one ethylene ketal* **3**

A solution of 2α,5α,8aβ-trimethyl-3,6,7,8a-tetrahydronaphthalen-1,8 (2*H*,5*H*)-dione-8-ethylene ketal **2** (30.00 g, 0.119 mol) dissolved in dry THF (150 mL) was dropped into a magnetically stirred suspension of $LiAlH_4$ (4.55 g, 0.119 mol) in dry THF (150 mL). The reaction mixture was stirred while refluxing for 4 h, then the stirring was continued at room temperature for 14 h. Water (50 mL) was dropped carefully into the chilled suspension. The resulting suspension was filtered through Celite and the filter cake was washed with ether (100 mL). After separation of the ether layer, the aqueous phase was extracted with ether (4 × 50 mL). The combined organic phase was washed with water (50 mL), dried ($MgSO_4$), and concentrated *in vacuo* leading to crystalline, tlc (silica gel, benzene/ether 4:1) homogeneous product (28.4 g, 93.9%). An analytical sample was prepared by recrystallizing from pentane, mp 78–79°C; ir: 3460, 2850, 2820, 1450, 1095, 1050 cm^{-1}; nmr ($CDCl_3$, 60 MHz), δ: 1.02 (d, 6, J = 6 Hz, 4-CH_3 and 7-CH_3), 1.50 (s, 3, 8a-CH_3), 3.28 (dd, 1, J = 11 Hz, 4 Hz, 8-proton), 4.07 (m, 4, O—CH_2—CH_2—O), 4.33 (d, 1, J = 4 Hz, OH), 5.47 (m, 1, olefinic proton); mass spectrum (70 eV) m/e (relative intensity): 252 (9, M^+), 100 (32), 99

[1]On leave from Chinoin Pharmaceutical and Chemical Works Ltd., Budapest, Hungary.

[2]Ketone **11** was also prepared by P. Grieco *et al.* by an entirely different route (6, 7).



(100). *Anal.* calcd. for $C_{15}H_{24}O_3$: C 71.39, H 9.59; found: C 71.31, H 9.63.

8β-Hydroxy-4α,7α,8aβ-trimethyl-3,4,6,7,8,8a-hexahydronaphthalen-1(2H)-one **4**

A solution of 8β-hydroxy-4α,7α,8aβ-trimethyl-3,4,6,7,8,8a-hexahydronaphthalen-1(2*H*)-one-ethylene ketal **3** (15.00 g, 0.059 mol) dissolved in diethyl ether (150 mL) was magnetically stirred for 14 h at room temperature with a solution of *p*-toluenesulfonic acid (1.5 g) in water (75 mL). After separating the two phases, the water layer was extracted with ether (2 × 50 mL). The combined ether extracts were washed with 10% $NaHCO_3$ solution (20 mL), dried ($MgSO_4$), and concentrated *in vacuo* furnishing a tlc (silica gel, benzene/ether 4:1) homogeneous oil (12.0 g, 96%), which was converted to **5***a* without further purification; ir ($CHCl_3$): 3500, 2960, 2930, 2880, 1678, 1655, 1460, 1045 cm^{-1}; nmr ($CDCl_3$, 60 MHz), δ: 1.07 (d, 3, J = 5 Hz, CH_3), 1.08 (d, 3, J = 6 Hz, CH_3), 1.62 (s, 3, 8a-CH_3), 2.98 (after the addition of D_2O, d, 1, J = 11 Hz, 8-proton), 3.85 (d, 1, J = 11 Hz, OH), 5.50 (m, 1, olefinic proton); mass spectrum (70 eV) *m/e* (relative intensity): 208 (82, M^+), 151 (100), 138 (60), 135 (69), 123 (78).

8β-Hydroxy-4α,7α,8aβ-trimethyl-3,4,4aβ,5,6,7,8,8a-octahydronaphthalen-1(2H)-one **5**a

A solution of 8β-hydroxy-4α,7α,8aβ-trimethyl-3,4,6,7,8,8a-hexahydronaphthalen-1(2*H*)-one **4** (10.00 g, 0.048 mol) in acetic acid (100 mL) was hydrogenated at room temperature until the consumption of one equivalent hydrogen (1152 mL) at atmospheric pressure in the presence of prehydrogenated Pt (obtained from 50 mg of Adam's catalyst). After filtration, most of the acetic acid was distilled off at reduced pressure (5 Torr). Traces of CH_3COOH were removed by codistillation with ethyl acetate. The resulting colorless oil, homogeneous in tlc (silica gel, benzene/ether 4:1) was used without further purification for the preparation of mesylate **5***b*; ir ($CHCl_3$): 3510, 2995, 2950, 2930, 2870, 1680, 1450, 1050, 1036 cm^{-1}; nmr ($CDCl_3$, 60 MHz), δ: 1.00 (d, 3, J = 7 Hz, CH_3), 1.05 (d, 3, J = 6 Hz, CH_3), 1.57 (s, 3, 8a-CH_3), 2.62 (with D_2O, d, 1, J = 10 Hz, 8-proton), 3.37 (d, 1, J = 11 Hz, OH); mass spectrum (70 eV) *m/e* (relative intensity): 210 (67, M^+), 193 (55), 192 (90), 159 (100), 149 (98), 133 (73).

8β-Methanesulfonyloxy-4α,7α,8aβ-trimethyl-3,4,4aβ,5,6,7,8,8a-octahydronaphthalen-1(2H)-one **5**b

Methanesulfonyl chloride (5 mL) was dropped into a chilled solution of 8β-hydroxy-4α,7α,8aβ-trimethyl-3,4,4aβ,5,6,7,8,8a-octahydronaphthalen-1(2*H*)-one **5***a* (5.00 g, 0.024 mol) in dry pyridine (25 mL), over a 15-min period, while stirring magnetically. The reaction mixture was stirred at room temperature for 3 h, then it was poured into a mixture of crushed ice (25 g) and 10% H_2SO_4 (25 mL). After extraction with chloroform (4 × 20 mL), the combined extracts were washed in succession with 10% H_2SO_4 (2 × 30 mL), 10%

TABLE 1. The influence of substituents on the catalytic hydrogenation of $\Delta^{1,9}$-octalins

Substrate	Percentage of isomers *trans*	*cis*	Conditions	Reference
1*a*, R^1, R^2, R^3 = H	77	23	Pd/CH_3COOH	1
1*b*, R^1, R^2 = H; R^3 = CH_3	45	55	Pd/C_2H_5OH or CH_3COOH	2
1*c*, R^1, R^2, R^3 = CH_3	100	0	Pt/CH_3COOH	3,4
4, R^1 = H; R^2, R^3 = CH_3	0	100	Pt/CH_3COOH	This article
10, R^1 = H; R^2, R^3 = CH_3	0	100	Pt/CH_3COOH	This article

$NaHCO_3$ (20 mL), and water (20 mL). After drying ($MgSO_4$) and concentration *in vacuo*, diethyl ether (10 mL) was added to the residue. The product crystallized on scratching with a glass rod, after 15 min (5.35 g, 78%, mp 140–142°C). It was used without purification for the preparation of olefin **6**; ir ($CHCl_3$); 3010, 2960, 2930, 2865, 1695, 1320, 1158, 1145, 910, 890, 876 cm^{-1}; nmr ($CDCl_3$, 60 MHz), δ: 1.07 (d, 3, J = 7 Hz, CH_3), 1.05 (d, 3, J = 6 Hz, CH_3), 1.57 (s, 3, 8a-CH_3), 3.10 (s, 3, CH_3—SO_2), 4.08 (d, 1, J = 11 Hz, 8-proton).

4α,7,8aβ-Trimethyl-3,4,4aβ5,6,8a-hexahydronaphthalen-1(2H)-one **6**

Into a stirred suspension of Li_2CO_3 (1.50 g) and LiBr (1.50 g) in dry DMF (10 mL), a solution of 8β-methanesulfonyloxy-4α,7α,-8aβ-trimethyl-3,4,4aβ,5,6,7,8,8a-octahydronaphthalen-1(2*H*)-one **5***b* (3.00 g, 0.0104 mol) dissolved in DMF (30 mL) was dropped at 160°C under an atmosphere of dry nitrogen. The reaction mixture was then stirred at 170°C for 30 min. After cooling to room temperature, the solution was diluted with water (50 mL) and extracted with benzene (3 × 15 mL). The combined extracts were washed with water (2 × 30 mL), dried ($MgSO_4$), and concentrated *in vacuo* giving a yellow tlc (silica gel, benzene) homogeneous oil (1.97 g, 98.5%) which was used without purification for the preparation of unsaturated alcohol **7***a*; ir ($CHCl_3$); 2955, 2930, 2870, 1688, 1442, 1120 cm^{-1}; nmr ($CDCl_3$, 60 MHz), δ: 1.03 (d, 3, J = 7 Hz, 4-CH_3), 1.32 (s, 8a-CH_3), 1.72 (d, 3, J = 1 Hz, 7-CH_3), 5.38 (m, 1, olefinic proton); mass spectrum (70 eV) *m/e* (relative intensity): 192 (62, M^+), 159 (27), 149 (100), 135 (70).

4α,7,8aβ-Trimethyl-1,2,3,4,4aβ,5,6,8a-octahydronaphthalen-1β-ol **7**a

To a stirred solution of 4α,7,8aβ-trimethyl-3,4,4aβ,5,6,8a-hexahydronaphthalen-1(2*H*)-one **6** (3.00 g, 0.0156 mol) in ether (15 mL), ethanol (15 mL), and liquid ammonia (100 mL), freshly cut pieces of sodium (3 g) were added. The 500-mL three-neck flask was cooled with Dry Ice/acetone and was equipped with a Dry Ice condenser attached to a drying tube containing soda lime. The reduction was allowed to proceed for 30 min after the appearance of the blue color. After the evaporation of ammonia (1 h), water (30 mL) was added and the product was extracted with ether (4 × 10 mL). The combined extracts were washed with water (10 mL), dried ($MgSO_4$), and concentrated *in vacuo* giving a tlc (silica gel, benzene/ether 4:1) homogeneous oil (2.80 g, 92.4%) which was used without further purification for the preparation of methyl ether **7***b*; ir ($CHCl_3$): 3450, 2900, 1450, 1370, 1040, 1010 cm^{-1}; nmr ($CDCl_3$, 60 MHz), δ: 0.87 (d, 3, J = 6 Hz, 4-CH_3), 1.00 (s, 3, 8a-CH_3), 1.63 (d, 3, J = 1 Hz, 7-CH_3), 2.50 (broad s, 1, OH), 3.65 (dd, 1, J = 10 Hz, 6 Hz, 1-proton), 5.38 (m, 1, olefinic proton); mass spectrum (70 eV) *m/e* (relative intensity): 194 (94, M^+), 192 (68), 176 (94), 136 (86), 135 (100).

4α,7,8aβ-Trimethyl-1,2,3,4,4aβ,5,6,8a-octahydronaphthalen-1β-ol methyl ether **7**b

In a dry 100-mL three-neck flask equipped with reflux condenser, drying tube ($CaCl_2$), dropping funnel, and magnetic stirrer, sodium hydride (as 50% oil suspension, 2.00 g, 41.66 mmol, Alfa Inorganics) was placed under an atmosphere of dry nitrogen. After washing it by decantation with dry pentane (3 × 5 mL), the last traces of pentane were removed with a stream of dry nitrogen. Then tetrabutylammonium iodide (1 g) and dry THF (20 mL) were added.

A solution of 4α,7,8aβ-trimethyl-1,2,3,4,4aβ,5,6,8a-octahydronaphthalen-1β-ol **7***a* (2.00 g, 10.29 mmol) dissolved in dry THF (20 mL) was dropped into the stirred suspension. The suspension was stirred at room temperature, then methyl iodide (2.0 mL) was added over a 15-min period. The reaction mixture was stirred for 14 h at room temperature. After the addition of water (10 mL), most of the THF was removed by distillation at atmospheric pressure, using a short fractionating column. The residue was taken up in diethyl ether and the mixture of water and ether was filtered through Celite. After separation, the water phase was extracted with ether (2 × 10 mL). The combined ether extracts were washed with water (2 × 10 mL), dried ($MgSO_4$), and concentrated *in vacuo* giving a tlc (silica gel, benzene) homogeneous, slightly yellow oil (1.86 g, 86.8%) which was converted to the unsaturated ketone **8** without further purification; ir ($CHCl_3$): 2900, 1450, 1370, 1090 cm^{-1}; nmr ($CDCl_3$, 60 Hz), δ: 0.88 (d, 3, J = 7 Hz, 4-CH_3), 1.00 (s, 3, 8a-CH_3), 1.67 (d, 3, J = 1 Hz, 7-CH_3), 3.33 (s, 3, CH_3O), 5.47 (m,1 , olefinic proton); mass spectrum (70 eV) *m/e* (relative intensity): 208 (46, parent peak), 176 (31), 135 (100), 108 (59), 107 (96).

5β-Methoxy-3,4aβ,8α-trimethyl-4a,5,6,7,8,8aβ-hexahydronaphthalen-2(1H)-one **8**

(a). *By the allylic oxidation of methyl ether* **7**b

3,5-Dimethylpyrazole (1.66 g, 17.28 mmol) was added all at once to a magnetically stirred suspension of chromium trioxide (dried over P_2O_5 for 24 h, 1.73 g, 17.28 mmol) in dry methylene chloride (15 mL), at −20°C. The mixture was stirred for 15 min at −20°C, then a solution of 4α,7,8aβ-trimethyl-1,2,3,4,4aβ,5,6,8a-octahydronaphthalen-1β-ol methyl ether **7***b* (300 mg, 1.44 mmol) dissolved in dry CH_2Cl_2 (5 mL) was dripped in 5 min. The reaction mixture was stirred for 4 h at −10 to −20°C, then 5 *N* NaOH (10 mL) was added and the solution was stirred at 0°C for 1 h. After extracting with ether (3 × 30 mL), the combined organic extracts were washed in succession with 10% H_2SO_4 (2 × 10 mL) and 10% $NaHCO_3$ (10 mL). After drying ($MgSO_4$) and concentration (to 10 mL) the solution was passed through a short column of Fluorosil (10 g). The eluted colorless solution was concentrated to an oil (240 mg, 75%), whose spectroscopic properties were identical with those prepared from dimethoxy ketone **9** (see next paragraph).

(b). *By the base-catalyzed elimination of dimethoxy ketone* **9**

To a solution of 4β,5β-dimethoxy-3α,4aβ,8α-trimethyl-3,4,4a,-5,6,7,8aβ-octahydronaphthalen-2(1*H*)-one **9** (300 mg, 1.17 mmol) in methanol (5 mL), a solution of sodium methylate (20 mg) in methanol (2 mL) was added. The reaction mixture was allowed to stand at room temperature for 14 h, then it was diluted with water (15 mL) and extracted with ether (4 × 5 mL). The combined ether extracts were washed with water (2 × 5 mL), dried ($MgSO_4$), and concentrated *in vacuo* furnishing a slightly yellow oil (240 mg, 92%). The tlc (silica gel, benzene/ether 9:1) homogeneous oil was microdistilled, 115°C/0.1 Torr. Infrared ($CHCl_3$): 2950, 2930, 2870, 1660, 1455, 1362, 1092 cm^{-1}; $uv_{\lambda max}$: 238 nm (ε = 10 110); nmr ($CDCl_3$, 60 MHz), δ: 0.85 (d, 3, J = 6 Hz, 8-CH_3), 1.17 (s, 3, 4a-CH_3), 1.78 (d,

3, J = 1 Hz, olefinic 3-CH_3), 3.30 (s, 3, CH_3O), 6.73 (d, 1, J = 1 Hz, olefinic proton); mass spectrum (70 eV) *m/e* (relative intensity): 222 (30, parent peak), 190 (12), 175 (11), 140, (52), 123 (100), 122 (41). *Anal.* calcd. for $C_{14}H_{22}O_2$: C 75.63, H 9.97; found: C 75.70, H 10.01.

4β,5β-Dimethoxy-3α,4aβ,8α-trimethyl-3,4,4a,5,6,7,8,8aβ-octahydronaphthalen-2(1H)-one **9**

A solution of 4β-5β-dimethoxy-3α,4aβ,8α-trimethyl-4,4a,5,6,7,8-hexahydronaphthalen-2(3*H*)-one **10** (250 mg, 0.99 mmol) in acetic acid (2 mL) was hydrogenated at room temperature, while stirring magnetically, in the presence of prehydrogenated Pt (prepared from 50 mg of Adam's catalyst) until the consumption of one equivalent hydrogen (24 mL). After filtering the catalyst, the filtrate was dropped to a saturated solution of $NaHCO_3$ (30 mL), while stirring, and extracted with chloroform (4 × 10 mL). The combined organic extracts were washed with 10% $NaHCO_3$ (10 mL), dried ($MgSO_4$), and concentrated *in vacuo*, furnishing a colorless tlc (silica gel, benzene/ether 4:1) homogeneous oil (0.25 g, 99%) which was eliminated to the unsaturated ketone **8** without further purification. Infrared ($CHCl_3$): 2990, 2930, 1703, 1452, 1092 cm^{-1}; nmr ($CDCl_3$, 60 MHz), δ: 0.82 (d, 3, J = 7 Hz, CH_3), 1.18 (d, 3, J = 6 Hz, CH_3), 1.25 (s, 3, 4a-CH_3), 3.40 (s, 3, CH_3O), 3.50 (s, 3, CH_3O); mass spectrum (70 eV) *m/e* (relative intensity): 254 (8, parent peak), 222 (78), 190 (24), 175 (19), 149 (100), 139 (49), 125 (30), 123 (94).

O—O stretching frequencies of cyclic peroxides. Stabilization of peroxides by alkoxy substituents[1]

KARL R. KOPECKY and RODRIGO RICO GOMEZ[2]
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received June 9, 1983

KARL R. KOPECKY and RODRIGO RICO GOMEZ. Can. J. Chem. **62**, 277 (1984).

The O—O stretching frequencies of some alkyl substituted 1,2-dioxacyclohexanes are near 730 cm^{-1} and those of some alkyl substituted 1,2-dioxetanes are in the range 670 ± 20 cm^{-1}. Alkoxy substituents cause the frequency to increase; that for tetramethoxy-1,2-dioxetane is 752 cm^{-1}. Alkoxy substituents appear to stabilize peroxides.

KARL R. KOPECKY et RODRIGO RICO GOMEZ. Can. J. Chem. **62**, 277 (1984).

Les fréquences d'élongation de la liaison O—O de certains dioxa-1,2 cyclohexanes ayant un substituant alkyle sont à environ 730 cm^{-1} et celles des dioxétanes-1,2 ayant des substituants alkyles sont à 670 ± 20 cm^{-1}. Les substituants alkoxy provoquent une augmentation de la fréquence; cette fréquence est de 752 cm^{-1} pour le tétraméthoxy dioxétane-1,2. Les substituants alkoxy semblent stabiliser les peroxydes.

Introduction

The luminescent thermolysis of 1,2-dioxetanes has been proposed (1) to proceed by a two-step process with initial cleavage of the O—O bond to a diradical intermediate as the rate determining step, eq. [1]. While values of the activation

[1] 
parameters for the thermolysis of a variety of alkyl and aryl substituted 1,2-dioxetanes, as estimated by thermochemical calculations (1) based on this mechanism, are in good agreement with the values determined experimentally, there are also 1,2-dioxetanes for which a significant difference has been found between calculated and observed parameters (2). Steric effects must be involved in alkyl substituted 1,2-dioxetanes and both steric and electronic effects may be present in 1,2-dioxetanes with other substituents. The factors which influence the stability of 1,2-dioxetanes are still being studied (1–3).

In the present report it is suggested that the inductive effect of alkoxy subsituents may strengthen the O—O bond of a 1,2-dioxetane and an attempt is made to detect the difference in the O—O bond strengths of alkyl and alkoxy substituted 1,2-dioxetanes by measuring the O—O stretching frequencies of these compounds.

Results and discussion

There is a marked effect of substituents on the O—O bond strengths and stretching frequencies of peroxides, Table 1. A molecular orbital explanation of this effect proposes (4)[3] that electronegative substituents bonded to oxygen donate little electron density into the antibonding orbitals of the peroxide and the O—O bond order is accordingly decreased by a small amount from that in the oxygen molecule. Substituents which can donate more electron density into the antibonding orbitals cause a greater reduction of the O—O bond order. According to this reasoning, alkoxy substituted 1,2-dioxetanes should have stronger O—O bonds and higher O—O stretching frequencies than the alkyl substituted analogues.

TABLE 1. Stretching frequencies and dissociation energies of some O—O bonds

Compound	ν_{O-O} (cm^{-1})	Ref.	D_{O-O} (kcal/mol)	Ref.

$(CH_3)_3COOC(CH_3)_3$	771	14	38.0	2*b*, 16

In an early report it was suggested that peroxides absorb in the range 890–830 cm^{-1} in the infrared (17). A number of 1,2-dioxetanes have been found to absorb in this region and this was taken as evidence for the 1,2-dioxetane ring system. However, it has been pointed out that the O—O stretch of peroxides should give rise to very weak infrared absorption and be Raman active, and this was shown to be so (14). The present study confirms these observations for a variety of cyclic peroxides (Table 2), and extends the structural diversity of peroxides for which O—O stretching frequencies have been determined.

The O—O stretching frequencies were identified in the following way. All the bands listed in Table 2 are either absent or very weak in the infrared spectra of these molecules. Only one intense band is present between 1400 and 500 cm^{-1} in the Raman spectra of several of these compounds. One additional strong band is present in this region in the spectra of the other molecules. The Raman spectra of the diperoxides of acetone and cyclohexanone each contain a second strong band at 895 and 860 cm^{-1}, respectively, but these are also infrared active. A strong band at 778 cm^{-1} is present in the Raman spectrum of the dioxetane of adamantylideneadamantane, but this appears to be associated with the adamantyl skeleton as the spectra of adamantane and 1-adamantanol exhibit strong bands at 762 and 778 cm^{-1}, respectively. A medium intensity band at 832 cm^{-1}

in the Raman spectrum of tetramethoxy-1,2-dioxetane is infrared active. Thus, it seems fairly secure that the frequencies listed in Table 2 are associated with the O—O stretch.

The O—O stretching frequencies of the cyclic peroxides do depend upon structure and all those listed in Table 2, except that of the tetramethyldioxacyclopentane, are significantly lower than those of the acyclic dialkyl peroxides dimethyl and di-*tert*-butyl peroxide. With the limited data available here it appears as if each class of cyclic peroxide containing only alkyl substituents has a characteristic range of O—O stretching frequencies: near 730 cm^{-1} for the dioxacyclohexanes, whether mono- or bicyclic, and near 670 ± 20 cm^{-1} for dioxetanes. Oxygen substitution does result in an increased frequency of the O—O stretch and an increase in the energy of activation for thermolysis, and the former effect is especially marked for tetramethoxy-1,2-dioxetane. It is tempting to use this as evidence in support of the suggestion made above that alkoxy substituents stabilize dioxetanes by withdrawing electron density from the antibonding orbitals of the peroxy group relative to alkyl substituted dioxetanes. However, it should be pointed out that the O—O stretch of peroxides is strongly coupled with other vibrations in these molecules (26) and an unambiguous assessment of the various factors will be difficult. Nevertheless, it appears to be possible to determine whether a peroxy group is part of a four, five, or six membered ring on the basis of the O—O stretching frequency.

Experimental

Raman spectra were recorded on a Beckman Model 700 Laser Raman spectrometer using the 514.5 nm exciting line from a Coherent Radiation Model 52 argon laser. The spectra of the five and six membered cyclic peroxides and of the dioxetane of adamantylideneadamantane were obtained from the neat liquids or crystals in capillary tubes at ambient temperatures. Those of the other dioxetanes were obtained from solid films in a flat bottomed cylindrical rotating cell at −20 to −50°C with the incident light focused on the bottom edge of the cell. Infrared spectra were recorded on a Perkin–Elmer Model 457 spectrometer.

The dioxetane of adamantylideneadamantane was a gift from Prof. A. P. Schaap, acetone (27) and cyclohexanone (28) diperoxides were prepared as described, tetramethoxyethylene was oxygenated (3) to prepare the dioxetane, the other dioxetanes were available from previous studies (23, 25) and the other peroxides were prepared by Prof. R. S. Brown (29).

Micellar properties of sodium alkyl sulfoacetates and sodium dialkyl sulfosuccinates in water

DAVID J. JOBE and VINCENT C. REINSBOROUGH
Chemistry Department, Mount Allison University, Sackville, N.B., Canada E0A 3C0

Received July 8, 1983

DAVID J. JOBE and VINCENT C. REINSBOROUGH. Can. J. Chem. **62**, 280 (1984).

Viscosity, conductivity, density, and fluorescence quenching studies were conducted in aqueous micellar solutions at 25.0°C of sodium alkyl sulfoacetates and sodium dialkyl sulfosuccinates in a comparison of one-tailed and two-tailed surfactant systems. The hexyl, octyl, and decyl members of the former group and the dihexyl and dioctyl members of the latter group were investigated. The results indicated that the sulfoacetates most likely form spherical micelles with aggregation numbers 20 for hexyl, 42 for octyl, and 70 for decyl with three methods for size determination giving concordant results. For the sulfosuccinates, the aggregation numbers from fluorescence quenching were 38 for the dihexyl and 56 for the dioctyl in agreement with the results from the conductance technique which means that spherical micelles are likely formed also. Volume changes on micellization were obtained for the sulfoacetates.

DAVID J. JOBE et VINCENT C. REINSBOROUGH. Can. J. Chem. **62**, 280 (1984).

On a étudié la viscosité, la conductivité, la densité et l'extinction de fluorescence de solutions micellaires aqueuses d'alkylsulfoacétates de sodium et de dialkylsulfosuccinates de sodium à 25°C en comparant les surfactants à une tête et à deux têtes. On a étudié les dérivés hexyle, octyle et décyle sulfoacétates et les dihexyl et dioctylsulfosuccinates. Les résultats indiquent que les sulfoacétates forment plus communément des micelles sphériques avec des nombres d'aggrégation de 20 pour l'hexyle, de 42 pour l'octyle et de 70 pour le décycle. Les trois méthodes de détermination de la grosseur utilisées donnent des résultats concordants. Pour les sulfosuccinates, les nombres d'aggrégation obtenus par extinction de fluorescence sont de 38 et de 56 pour le dihexyle et le dioctyle respectivement en accord avec les résultats obtenus à partir de la technique de conductance ce qui indique qu'il se forme également des micelles sphériques. On a obtenu des changements de volumes lors de la formation des micelles dans le cas des sulfoacétates.

Introduction

Two-tailed surfactants are generally thought to form bilayer vesicles in water while single-tailed surfactants form micelles (1–3). If the carbon chains are long enough, for example with dioctadecyldimethylammonium chloride (DODAC) and dihexadecylphosphate (DHP), there seems to be little doubt that vesicles do form with two-tailed surfactants and these can be useful in membrane mimetic studies (4). The phospholipids of natural membranes may be two-tailed for this very reason. On the other hand, short-chained phospholipids can form micelles (5) and vesicles can be made in some instances from single-chain amphiphiles (6). Chain length appears critical in determining whether two-tailed surfactants will form vesicles or micelles.

This study examines the solution properties of two closely allied families of ionic surfactants of short to medium carbon chain length that differ essentially only by having either one tail or two tails of equal length. The aim was to provide insight into the size and shape of the surfactant aggregates in these solutions and to see whether the extra appendage changed the basic nature of this aggregate. The families selected for this study were the sodium alkyl sulfoacetates and the sodium dialkyl sulfosuccinates which, despite their different names, have the same sulfonate head group and differ essentially only in the number of their tails. In the former family, the hexyl (SHSA), octyl (SOSA), and decyl (SDSA) homologs were studied while in the latter, the dihexyl (SDHSS) and dioctyl (SDOSS) members received attention. Sodium didecyl sulfosuccinate was synthesized but its solubility range in water proved too limited. The hexyl homologs were chosen as the other extreme since amphiphiles seem to require at least a six carbon chain before micellization is possible below one molal in aqueous solution. It should be noted here that the well-known surfactant, Aerosol OT or AOT, is a sodium dialkyl sulfosuccinate where the alkyl group is 2-ethylhexyl. Athough well characterized in non-aqueous solvents as a bilayer vesicle (7, 8), its aqueous solution structure beyond the critical micelle concentration (cmc) is still a matter of conjecture, mainly because it has rarely been studied in water.

The results from a variety of experimental techniques are reported here because no one technique can unambiguously characterize micellar size and form. Measurements were made on the viscosities, conductivities, densities, and fluorescence quenching abilities of the five surfactant systems.

Experimental

Viscosities of the surfactant solutions were obtained with a Hoeppler precision viscometer (precision ±0.1%) which was wrapped in glass wool to avoid heat loss.

Conductivities were measured with a Beckman RC-18A conductivity bridge with the solutions in a Jones-Bollinger cell calibrated with KCl solutions of known concentration. Temperature control to ±0.1°C ensured a precision of ±0.1% in the conductivity data.

A Sodev OD2 digital flow densimeter was used to measure the solution densities in conjunction with a Fluke 1952A frequency meter. Temperature control to ±0.005°C enabled the densities to be measured with a relative error of 3 ppm (9).

Fluorescence quenching data were obtained by the single photon counting technique at the University of Kent at Canterbury (U.K.) with apparatus described by Bridge and Solomon (10). The fluorescent probe was acridinium (1.18×10^{-3} mol dm^{-3}) and the quencher was Co^{2+} (4.5×10^{-4} to 1.0×10^{-3} mol dm^{-3}). Decay profiles (log intensity against channel number) were recorded for the background and for the surfactant solutions with and without quencher. The surfactant concentrations were approximately twice the cmc for the sulfoacetates and SDHSS and twenty times the cmc for SDOSS.

The sulfoacetates were synthesized using a modified Hikota and Meguro approach (11). Equimolar quantities (usually 0.1 mol of each) of chloroacetyl chloride and the appropriate alcohol were mixed to

form the chlorester. Then, 100 cm^3 of 2 mol dm^{-3} aqueous sodium sulfite was added and the solution refluxed overnight. Vacuum drying at 50°C removed most of the water leaving a residue that was further dried in a dessicator overnight. This residue was extracted several times with hot ethanol. Crystallization of the surfactant occurred from the cooled extracts. Recrystallization was effected from hot ethanol also.

Caryl's procedure (12) formed the basis for obtaining the sodium dialkyl sulfosuccinates. To 0.1 mol of maleic anhydride was added 0.22 mol of the appropriate alcohol. After heating for 2 h, 100 cm^3 of 2 mol dm^{-3} aqueous sodium bisulfite was added and the mixture refluxed overnight. As with the alkyl sulfoacetates, several extractions with hot ethanol followed with the surfactants crystallizing in the cooled extracts. Recrystallization was carried out as outlined by Williams *et al.* (13) which ensured that the product was the monohydrate. The yields of both procedures were in the 60–65% range.

The structures of the surfactants were confirmed by nmr and their purities determined gravimetrically by precipitation as barium salts (purity >98%). All other reagents were the best obtainable commercially and were not further purified. All measurements were conducted at 25.0°C except for the SDOSS solutions which were done at 30.0°C because of solubility problems at the lower temperature (SDOSS appears to have a Krafft point around 27°C).

Results

The density, viscosity, and conductivity data for the five surfactant systems have been deposited.[1] In each system for each property usually about 15 determinations at different concentrations were required above and below the cmc. The cmc was determined by the break in the conductivity and viscosity curves and these values, which agreed with literature values where available, are listed in Table 1 (11, 14). For SDOSS, this break point was too uncertain from the viscosity and conductivity data (this is probably why such a wide range of cmc values is found in the literature for this compound (14)) so the cmc in this system was detected by the dye solubility method using pyridine-2-azo-*p*-dimethylaniline (PADA). The solubility of PADA is low in water (2.8×10^{-4} mol dm^{-3} at 30.0°C) and does not change until micelles are present when a several fold uptake of PADA occurs as the surfactant concentration is increased. This is a markedly sensitive method of detecting the cmc especially with long chained surfactants. The cmc for SDOSS at 30.0°C was thus determined to be 6.8×10^{-4} mol dm^{-3}.

The cmc values of the sulfoacetates correspond approximately to those for the sulfonates having two more carbon atoms in the chain reflecting the effective lengthening of the chain with the insertion of the acetyl group. The cmc values of the sulfosuccinates fall in line with the usual observation with double-tailed surfactants that they are intermediate between the cmc for the longest chain, single-tailed counterpart and the cmc for the single-tailed counterpart where the chains are laid end on end (15) (Fig. 1). Thus the cmc for SDHSS is roughly the cmc for SDSA.

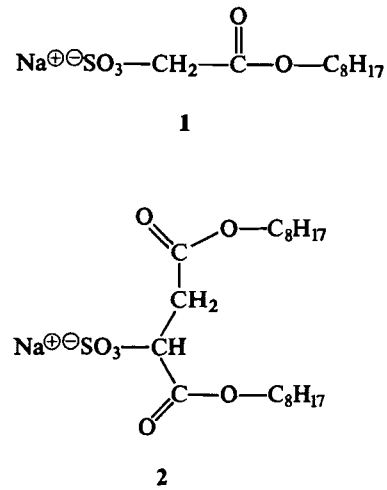

FIG. 1. Structural representations for sodium octyl sulfoacetate (*1*) and sodium dioctyl sulfosuccinate (*2*).

Aggregation numbers were calculated from the fluorescence quenching, viscosity, and conductivity data. Of these three methods, the first is probably the most reliable being less dependent on the model being assumed for micelle structure. The chief assumptions entail the rates of quenching and fluorescent decay, the distribution of probe and quencher, and the strength of the association of both to the micelle (16, 17). From the total intensities of the quenched (I) and unquenched (I_0) curves, the aggregation number can be determined from

$$I = I_0 \exp(-C_Q/C_{MIC})$$

where C_Q is the concentration of the quencher and C_{MIC} that of the micelles. C_{MIC} is given by $(C - \text{cmc})/\bar{n}$ where C is the total surfactant concentration and $\bar{n}$ is the mean aggregation number. A detailed analysis of the technique is given by Almgren and Löfroth (17).

Figure 2 depicts the unquenched and quenched decay profiles for 0.463 mol dm^{-3} SDSA. The aggregation number obtained from the slope of the computer linearizing of ln I against the inverse of the micellar concentration was 71 ± 2. With the smaller size of the SOSA micelle the difference between the

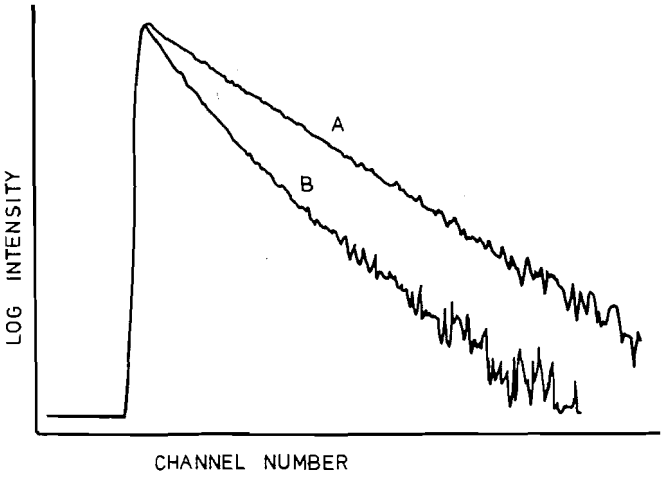

FIG. 2. Fluorescence decay profiles for 4.63×10^{-2} mol dm^{-3} sodium decyl sulfoacetate with no quencher (A) and with 9.45×10^{-4} mol dm^{-3} $CoSO_4$ as quencher (B).

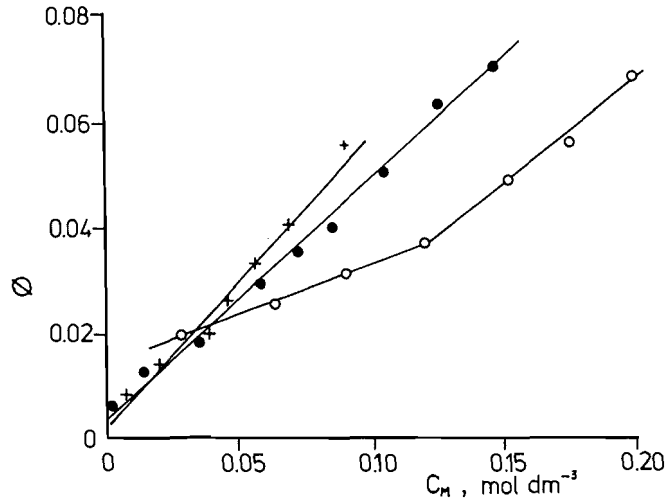

FIG. 3. Volume fraction (ϕ) dependence upon surfactant micellar concentration(C_M): ○, SHSA; ●, SOSA; +, SDSA.

two curves for the intensities was less pronounced with a value of $\bar{n} = 42 \pm 3$ being the result. For SHSA, the two curves differed so slightly at the quencher concentrations employed that meaningful estimates of the aggregation number were not possible. The decay profiles for the two-tailed SDHSS and SODSS surfactants were similar to the sulfoacetates with values of 38 ± 3 and 56 ± 2, respectively, being obtained for the mean aggregation numbers.

For short-chained (C_6—C_{10}) ionic surfactants, viscosity measurements provide micellar size parameters (18). The chief assumptions relate to the sphericity of the micelles and the neglecting of the electroviscous effect.

The volume fraction of the micelles (ϕ) is first calculated through the Guth and Simha equation (19, 20):

$$\eta = \eta_0(1 + 5\phi/2 + 109\phi^2/14)$$

where η is the solution shear viscosity and η_0 is its value at the cmc. With spherical micelles

$$\phi = 4\pi l^3 N_{ave} C_M/3000\bar{n}$$

where l is the radius of the hydrated micelle in cm and N_{ave}, Avogadro's number. C_M is the concentration of the surfactant in the micellar phase.

In Fig. 3 is shown the volume fraction dependence on micellar surfactant concentration for the three alkylsulfoacetate systems. From the best straight lines drawn through the points, the ratios of $l^3/\bar{n}$ were obtained. For SHSA, the curve consisted of two straight lines intersecting at roughly twice the cmc. The shortest chained sodium alkylsulfates showed a similar behaviour (18). This is interpreted as indicating that only beyond twice the cmc do SHSA micelles achieve a relatively constant size.

It was found previously that, by putting l equal to the "dry" extended length of the surfactant monomeric ion, statisfactory aggregation numbers were obtained for short-chained, ionic surfactants. This was attempted here also by estimating l as equal to the extended length of the hydrocarbon chain as reckoned by Tanford's formula (21) with 6 Å added to account for the $CO_2CH_2SO_3$ portion of the alkylsulfoacetate monomeric ion. The 6 Å extra extended length was estimated from crystallographic radii and geometry. These values of l were used to calculate $\bar{n}$ from the least error slopes. Both l and $\bar{n}$ values thus obtained are listed in Table 1.

This treatment was also extended to the viscosity data for the two-tailed surfactant SDHSS but two problems developed. First, the cmc was too low to neglect the electroviscous effect in all but concentrated micellar solutions. Second, estimates of the extended, "dry" length of the two-tailed monomeric ion are dependent upon the amount of spreading of the two tails. An unrealistic value of $\bar{n} = 10$ resulted for $l = 15$ Å, the estimated length of the SDHSS monomer with the two chains packed in closely side-by-side.

Evans (22) has developed a procedure by which conductivity data can yield micellar aggregation numbers.The equivalent conductance of the micellar solution is assumed to be the sum of the contributions of the conductances of the ionic species in solution, i.e. Λ_{Na}, Λ_S, and Λ_M, where the subscripts S and M refer to the surfactant monomer and the micelle:

$$1000\,K = \text{cmc}\,(\Lambda_{Na} + \Lambda_S) + C_M\Lambda_M/\bar{n} + C_M(n - g)\,\Lambda_{Na}/\bar{n}$$

where K is the specific conductance and g is the number of counter-ions associated with each micelle. From Stokes' theorem and noting that at the cmc $\Lambda_{Na} + \Lambda_S = 1000K_0/\text{cmc}$ (K_0 is the specific conductance at the cmc), this equation reduces to

$$1000S_1 = f^2\bar{n}^{2/3}(1000\,S_2 - \Lambda_{Na}) + f\Lambda_{Na}$$

where S_1 is the slope of the specific conductance plot below the cmc, S_2 is the corresponding slope above the cmc, and f is the fraction of free counter-ion, i.e. $(\bar{n} - g)/\bar{n}$. Values of $\bar{n}$ and f can be found by computer-fitting the observed slopes of the conductance curves to the above equation to give least error. These best-fit values of $\bar{n}$ and f are listed in Table 1.

The aggregation numbers obtained through conductances are in agreement with the fluorescence quenching $\bar{n}$ values for both the single-tailed and double-tailed surfactants. The viscometrically derived $\bar{n}$ values agree with those from the other two methods for the single-tailed surfactants. The apparent underestimate of $\bar{n}$ for SDSA was found also with sodium decylsulfate (18) and signifies that the electroviscous assumption of the viscometric technique is beginning to break down when the alkyl chain is ten carbons in length. The calculated fractions of unbound counter-ion in each system are in the expected range when compared to other surfactant systems and decrease

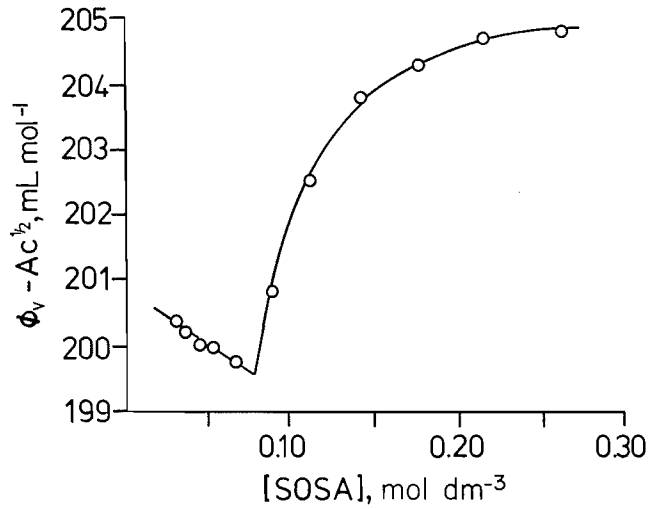

FIG. 4. Concentration dependence of apparent molal volume at 25.0°C for sodium octyl sulfoacetate solutions.

in the usual fashion with increasing aggregation in a particular series of surfactants.

Apparent molal volumes (ϕ_v) were calculated from the density data (9, 23) for each of the surfactant systems. Plots of $\phi_v - 1.868c^{1/2}$ against molarity for both the sulfoacetates and sulfosuccinates gave curves typical of micelle formers (Fig. 4). The curves consisted essentially of two plateaus with a sharp increase in $\phi_v - 1.868c^{1/2}$ in the cmc region. Volume changes upon micellization (ΔV_m) can be obtained from noting the height of the step in these plots (24, 25) or from partial molal volumes which entailes plotting $\Delta(m\phi_v)/\Delta m$ against the mean molarity (26). The latter method is more thermodynamically correct but leads to greater scatter in the experimental points.

Both methods were used to obtain ΔV_m and the mean value was listed for each surfactant in Table 1. The two determinations of ΔV_m agreed to within at least 1 mL mol^{-1} for the single-tailed surfactants. The low cmc values for both SDHSS and SDOSS prevented accurate estimates of ΔV_m for both these surfactants by this technique. The best estimate of ΔV_m for SDHSS was 16 ± 5 mL mol^{-1} which appears high in view of Lang's recent ultrasonic ΔV_m determinations for dialkylmethylammonium chloride micelles which were in the 8–10 mL mol^{-1} range (27).

The ΔV_m values for the sulfoacetates are reasonable when compared to literature values of one-tail surfactants of comparable chain length (23, 25). The positive value of ΔV_m for surfactants is generally observed and is attributed to the loss of hydrocarbon–water contact with the transfer of the surfactant molecule from bulk water to the micelle.

Discussion

The aggregation numbers of the single-tailed sulfoacetates are in accord among the three methods of determination which suggests that the basic premises of each method are correct. Even the short-fall of the $\bar{n}$ value determined by viscometry for SDSA is exactly what happens with sodium decylsulfate which forms spherical micelles. Thus, the sulfoacetates from the hexyl to the decyl member likely form spherical micelles beyond the cmc with micellar radii approximating the length of the extended monomeric hydrocarbon chain and with unbound counter-ion fractions in the 0.5 to 0.3 range. This probably means that there is considerable chain folding in the micelle but that hydration of the head group and counter-ion binding nullifies this loss in length in making the hydrated micellar radius roughly equivalent to the extended, "dry" monomeric length. The magnitudes of the volume changes upon micellization and the constant effective surface area per head group of about 100 Å^2 support this view since these are what are found with similar surfactants that form micelles.

The shorter the chain the less stable is the micelle (28), so that the SHSA micelles are relatively unstable. This is reflected in the small ΔV_m value of 2.0 mL mol^{-1} suggesting a loose association of monomers for SHSA micelles in which water has significant penetration. Otherwise, a value of ΔV_m larger than 7 mL mol^{-1} would be expected from assuming that half the ΔV_m value for SDSA would be the micellar volume contribution of an unwetted pentyl chain.

If all other factors were equal, the ΔV_m values for the sulfosuccinates should be roughly twice the values for the sulfoacetates with the hydrocarbon surface area being doubled. However, both SHSA and SOSA form relatively unstable micelles compared to SDHSS and SDOSS (micellar stability can be estimated from ultrasonic characteristic frequencies which vary generally as the cmc values (27, 28)) so that the ΔV_m values for the latter should exceed twice the ΔV_m values for the former. This appears to be the case with SDHSS with its ΔV_m of 16 reflecting a 10% in volume in the transition from bulk water to the micellar environment. The corresponding increase in ΔV_m for SOSA is 3% (see Fig. 4).

With the dialkyl sulfosuccinates SDHSS and SDOSS, agreement in aggregation numbers between the conductance and fluorescence quenching methods argues for near sphericity for these micelles. The fluorescence quenching technique is the more reliable because it is less model-dependent and, in particular, does not require that the micelles be spherical. This assumption is implicit in the conductance derivation since Stokesian flow of the aggregates and monomers is assumed. The apparent failure of the viscosity technique to obtain reasonable values of $\bar{n}$ for SDHSS may be due to several reasons as explained previously and non-sphericity in the micelles could be added to these. A referee has suggested that SDHSS micelles could be discs with thickness of 15 Å consisting of 30–36 monomers, i.e. about 70 chains, as obtained by the other two methods. This possibility cannot be ruled out but, in light of the agreement in $\bar{n}$ values obtained in fluorescence quenching and conductimetrically, spherical micelles are more likely present in these two micellar dialkyl sulfosuccinate systems.

The crystal and molecular structure of bis(2,3-butanedione dioximato)chloro-(hydroxodiphenylarsine)cobalt(III): assignment of the nature of the arsenic-based ligand

MONICA PIZZEY, LYNN MIHICHUK,[1] RICHARD J. BARTON, AND BEVERLY E. ROBERTSON
Faculty of Science, University of Regina, Regina, Sask., Canada S4S 0A2

Received July 21, 1983

MONICA PIZZEY, LYNN MIHICHUK, RICHARD J. BARTON, and BEVERLY E. ROBERTSON. Can. J. Chem. **62**, 285 (1984).

The Co(II) cobaloximes, (B)Co(dmgH)$_2$ (where B = phosphine or phosphite; dmgH = dimethylglyoximato monoanion) react with $(C_6H_5)_2AsCl$ to form ClCo(dmgH)$_2$B and a compound of formula $C_{20}H_{25}AsClCoN_4O_5$. A crystal structure analysis of the arsenic compound indicated it to be bis(2,3-butanedione dioximato)chloro(diphenylhydroxoarsine)cobalt(III), $[(C_6H_5)_2As(OH)Co(dmgH)_2Cl]$. The crystals are orthorhombic, space group $Pna2_1$, a = 15.334(2), b = 11.173(2), c = 13.745(4) Å at 19(2)°C with Z = 4. The structure has been refined by the least-squares method to a weighted residual of 0.071 using 2345 independent reflections. The Co atom is bonded equatorially to two dmgH ligands (average [Co—N] = 1.89(1) Å) with a Cl atom above this plane ([Co—Cl] = 2.252(2) Å) and the As atom of the $(C_6H_5)_2As(OH)$ group below it ([Co—As] = 2.322(1) Å). The [As—O] bond length is 1.781(7) Å, corresponding to a single bond and is consistent with the observed H atom on the oxygen atom.

MONICA PIZZEY, LYNN MIHICHUK, RICHARD J. BARTON et BEVERLY E. ROBERTSON. Can. J. Chem. **62**, 285 (1984).

Les cobaloximes de type Co(II), (B)Co(dmgH)$_2$ (où B = phosphine ou phosphite; dmgH = le monoanion diméthylglyoximato) réagissent avec le $(C_6H_5)_2AsCl$ pour donner le ClCo(dmgH)$_2$B et un composé de formule $C_{20}H_{25}AsClCoN_4O_5$. L'analyse de la structure cristalline du composé de l'arsenic indique qu'il s'agit du bis(butanedione-2,3 dioximato)chloro-(diphénylhydroxoarsine)cobalt(III) $[(C_6H_5)_2As(OH)Co(dmgH)_2Cl]$. Les cristaux sont orthorhombiques et appartiennent au groupe d'espace $Pna2_1$, a = 15,334(2), b = 11,173(2), c = 13,745(4) Å à 19(2)°C avec Z = 4. On a résolu la structure et on l'a affinée par la méthode des moindres carrés jusqu'à une valeur de R = 0,071 pour 2345 réflexions indépendantes. L'atome du Co est lié équatorialement aux deux ligands dmgH (moyenne [Co—N] = 1,89(1) Å) avec l'atome de Cl au dessus de ce plan ([Co—Cl] = 2,252(2) Å) et l'atome de As du groupe $(C_6H_5)_2As(OH)$ en dessous de ([Co—As] = 2,322(1) Å). La longueur de la liaison [As—O] = 1,781(7) Å correspond à une liaison simple et est en accord avec l'atome d'hydrogène observé sur l'atome d'oxygène.

[Traduit par le journal]

Introduction

Compounds containing arsenic σ-bonded to transition metals have not been well documented (1–3). The Co—$\ddot{A}sR_2$ moiety is of particular interest because very little information is available concerning this system. As well, it has been suggested that the cobaloxime compounds containing σ-bonded —$\ddot{A}sR_2$ may have some relevance to models for the biological methylation of arsenic (4). We have studied the structure of **A**, $(C_6H_5)_2As(OH)Co(dmgH)_2Cl$, which is closely related to **B**, $(CH_3)(C_6H_5)As(O)Co(dmgH)_2Cl.H_2O$, recently reported by Mihichuk *et al.* (5). In the structure of the latter compound the authors concluded, based on their refinement in an ordered non-centrosymmetric space group and a disordered centrosymmetric space group, that the disordered model was to be preferred. Hence, they were unable to determine the order of the [As—O] bond.

The molecule in this investigation has two equivalent groups on the arsenic atom. If it adopts the same molecular packing as **B**, the molecule may be able to utilize the mirror plane in the space group *Pnam* and thereby avoid the disorder problem.

Experimental

$C_{20}H_{25}AsClCoN_4O_5$ mw = 569.74
Orthorhombic, space group $Pna2_1$, a = 15.334(3), b = 11.173(2), c = 13.745(4) Å, T = 19(2)°C, V = 2354.94 Å^3, Z = 4, D_x = 1.607 g cm^{-3}, D_m = 1.61 g cm^{-3}, μ(MoKα) = 22.69 cm^{-1}.

The compound **A** was prepared according to the method previously reported by Mihichuk *et al.* (5). Crystals of **A** were obtained by slow evaporation of a dichloromethane/hexane solution at 20°C.

Anal. calcd. for **A**: C 42.12, H 4.43, N 9.84; found: C 42.39, H 4.62, N 9.32.

A crystal in the form of an amber-coloured plate of dimensions 0.55 × 0.35 × 0.10 mm was chosen for study. Laue symmetry and systematic absences ($k + l = 2n + 1$ for $h = 0$, $h = 2n + 1$ for $k = 0$) indicated the orthorhombic space groups *Pnam* (standard notation, *Pnma*) or $Pna2_1$. The density was determined by flotation in a chloroform/bromoform mixture.

Intensity data were measured on a modified Picker diffractometer with graphite-monochromated MoKα radiation (λ = 0.71069 Å), using the NRCC diffractometer control system (6). Accurate cell dimensions were calculated from the centred settings of 65 reflections with 11° < 2θ < 60°. Diffraction intensities in the range 3° ≤ 2θ ≤ 60° were measured using a scan speed of 2 deg min^{-1} and a scan width of (1.6 + 0.692 tan θ) degs. Three standard reflections which were measured after every 47 reflections showed no systematic changes. The intensities of 3558 reflections were measured, of which 2345 were considered as observed with $I > 2.0\sigma(I)$. ($\sigma(I)$ is the standard deviation of the intensity derived both from the counting statistics of the individual reflection, and the extent to which the scatter in the intensities of the standard reflections exceeded that predicted from the counting statistics.) Absorption corrections were applied using μ = 22.69 cm^{-1} in the XRAY76 set of programs (7). Scattering factors for all atoms were taken from the XRAY76 system (7). Dispersion corrections which were taken from International tables for X-ray crystallography (8) were applied to the scattering factors of the Co, As, and Cl atoms.

The structure was solved by the heavy-atom method.The values of $\langle|E|\rangle$ and $\langle E^2 - 1\rangle$ were 0.802 and 0.949, respectively, which are intermediate between those expected for a centrosymmetric and a non-centrosymmetric space group but close to those expected for the centrosymmetric space group *Pnam*. We might expect that a centrosymmetric space group containing structural elements with local centers of symmetry, such as contained in **A**, would give parameters further removed from the theoretical non-centrosymmetric values.

[a]Thermal parameters are of the form $\exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{12}hka^*b^* + 2U_{13}hla^*c^* + 2U_{23}klb^*c^*)]$ and U(equiv) = $(1/3)\sum_{i=1}^{3}\sum_{j=1}^{3}[U_{ij}a_i^*a_j^*(\mathbf{a}_i\cdot\mathbf{a}_j)]$.

[b]All H atoms except H(11) and H(22) were constrained during refinement.

Nevertheless, a structure solution was first attempted in the centrosymmetric space group.

The coordinates of the three heavy atoms, Co, Cl, and As were determined from a Patterson map, and the remaining non-hydrogen atoms were located in successive electron-density difference maps. The solution showed the molecule located on the mirror plane, but it was either disordered in the centrosymmetric space group or it was ordered in the non-centrosymmetric space group $Pna2_1$ and the apparent disorder was an artifact of an incorrect choice of space group. A disordered model for the structure would lead to severe steric problems involving overlap of phenyl rings of neighbouring molecules. This

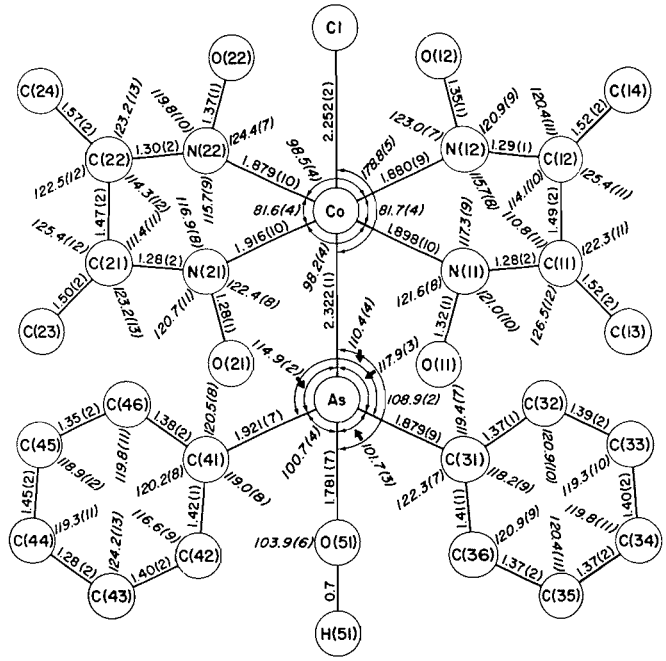

FIG. 1. Schematic diagram showing atom labelling, bond lengths, and angles for **A** with estimated standard deviations.

observation and the indefinite statistical results of the analysis of normalized structure factors suggested that the correct space group was $Pna2_1$.

Refinement was continued based on an ordered model in the non-centrosymmetric space group. The temperature factors of the non-hydrogen atoms were refined initially using isotropic temperature factors and then anisotropically. The positions of the hydrogen atoms on the phenyl rings were calculated and constrained to their corresponding carbon atoms during refinement. The three other H atoms bound to oxygen atoms in the structure were found from an electron density difference map. These three peaks in the difference map corresponded very nearly to an electron density of 1 electron $Å^{-3}$. The two hydrogen atoms on the equatorial oxime rings were refined with isotropic temperature factors. H(51), the hydrogen atom bonded to the oxygen atom O(51) was fixed at the position of maximum electron density as determined from the difference Fourier map. Least-squares refinement gave a position too close to the atom O(51). Because of computer core limitations it was necessary to refine the structure in five blocks of atoms. The blocks were chosen so as to retain any expected significant correlations between least-squares parameters. The agreement factors converged to:

$$R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o| = 0.056$$

$$R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.071$$

The weighting scheme, which was chosen to remove bias with respect to $|F_o|$ from the distribution of $w(|F_o| - |F_c|)^2$, was $w = 1.0/(\sigma(|F_o|)^2 + 3 \times 10^{-5}(|F_o|)^3)$. The average shift/error and the maximum shift/error for a structural parameter were 0.022 and 0.14, respectively, at the termination of refinement.

The enantiomorphically alternative structure was refined to convergence and gave values of R and R_w which were 0.057 and 0.073, respectively, greater than for the molecular arrangement reported here. Using Hamilton's significance test (9) and assuming no systematic errors, the choice of enantiomer is correct with a significant level better than (1/2)%.

The atomic coordinates and equivalent isotropic thermal parameters for all atoms are listed in Table 1. Figure 1 shows the atomic labelling, the configuration of the molecule, and important bond lengths and angles. A stereoscopic view of the molecule drawn using ORTEP (10) is shown in Fig. 2. Orientation of the arsine moiety with respect to the

two equatorial oxime ligands is shown in a schematic diagram of the molecule in Fig. 3.[2]

Discussion

The coordination about the cobalt atom, is octahedral. The Co atom is coordinated to two bidentate dmgH ligands, related to each other by a pseudo-mirror plane passing through the cobalt atom. This plane is located equidistant between the two equatorial oxime ligands, and contains the Co—Cl vector. The dihedral angle formed by the planes of the two ligands is 4.2°. The cobalt atom is also coordinated to the Cl atom and the As atom of a $(C_6H_5)_2As(OH)$ group on opposite sides of the plane of the oxime ligands. The slight fold of the oxime ligands is away from the arsenic atom. The average [Co—N] distance is 1.90(2) Å and the [Co—Cl] and [Co—As] distances are 2.252(2) Å and 2.322(1) Å, respectively. The [N—Co—N] *bite* angles are approximately 81.6(4)°. These values are similar to those found for other $Co^{III}(dmgH)_2XY$ compounds (11). Bond lengths and bond angles within the dmgH ligands are in agreement with those for previously reported dmgH complexes.

The arsenic atom is bonded to the oxygen atom O(51), to the two phenyl rings, and to the cobalt atom. The average [C—C] distance in the phenyl rings is 1.38(2) Å. The observed molecular geometry associated with the carbon atom, C(44), is not reasonable. Furthermore, this atom is strongly influenced by the apparent libration of the phenyl ring and has unusually large temperature factors. The estimated standard deviations in its positional parameters are probably unrealistically low. There are no unusually short intermolecular contacts.

The arsenic-based ligand is strongly indicated to be $(C_6H_5)_2As^{III}$—OH and not $[(C_6H_5)_2As^{V}{=}O]^+$. The [As—O] bond length of 1.781(7) Å is longer than previously reported first-order [As—O] bonds; $(C_6H_5)_3As(OH)X$ (X = Cl, Br) (1.70(1) Å) (12) and $[(C_6H_5)_3As$—OH . . . Cl . . . HO—As-$(C_6H_5)_3]^+(ICl_2)^-$ (1.72 Å) (13). Also the hydrogen atoms located from electron-density difference maps show that each oxime ligand is mono-protonated. The atoms O(11) and O(22) are hydrogen-bond donors to O(21) and O(12), respectively, ([O(11)—H(11)] = 0.9(1) Å and [O(22)—H(22)] = 0.7(1) Å), making a pseudo two-fold axis along the [Cl—Co] vector relating the oxime ligands. The other hydrogen atom, H(51), is formally bonded to O(51), necessitating an [As—O(51)] single bond.

The oxime [O . . . O] intramolecular distances are slightly asymmetric ([O(12)—O(22)] = 2.54(1) Å and [O(21)—O(11)] = 2.49(1) Å). The greater value for [O(12)—O(22)] is consistent with the observation that the hydrogen atom of the OH group on the arsenic atom is hydrogen-bonded to O(12). ([O(51) . . . O(12)] = 2.871 Å, [O(51)—H(51)] = 0.7 Å, [Co—As—O(51) . . . O(12)] = 0.3°, [O(12) . . . H(51)—O(51)] = 116°, and [H(51) . . . O(12) = 2.5 Å).

The rotation angles between the pseudo-mirror plane of the cobaloxime moiety and the two [As—C] bonds and the [As—O] bond (Fig. 3) show that this plane does not apply to the arsine moiety. Looking along the Co—As vector, the angles define the degree of rotation from the pseudo-mirror relating the two equatorial oxime ligands. The angle with respect to O(51) is 25.8°, to C(31) is 140.9°, and to C(41) is 273.8°. These angles are set primarily by the hydrogen bond to O(12) from O(51). Therefore, the rotation angles between the atom O(51) and the atoms C(31) and C(41) of the phenyl rings are 115.1° and 112.0°, respectively. The rotation angle between the phenyl rings is 132.9°.

The orientation of the phenyl rings is further defined by the torsional angles about the As—C bonds which are 73.3° for [C(36)—C(31)—As—Co] and 77.6° for [C(46)—C(41)—As—Co]. The [As—C] distances are also significantly different at 1.879(9) and 1.922(9) Å but the reason for this is not readily apparent. The two phenyl rings are bent at the bridge-

[2]The structure amplitude table, a table of general anisotropic temperature factors, and a table of mean plane data are avaiable, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

head carbon atoms so that the As atom is 0.142 and 0.071 Å out of their respective average planes. These parameters and the afore-mentioned upward tilt of the oxime ligands are related to the steric interactions between the oxime ligands and the arsenic ligands. Short contacts to the plane of the oxime ligand [N(11), C(11), C(12), N(12)] are: C(31), 3.30 Å; O(51), 2.79Å. The shortest contact to the plane of the ligand [N(21), C(21), C(22), N(22)] is: C(41), 3.14 Å.

JOHAN K. TERLOUW, WIGGER HEERMA, PETER C. BURGERS, and JOHN L. HOLMES. Can. J. Chem. **62**, 289 (1984).

The title ions are generated by the loss of C_2H_4 from ionised 4-methoxybutan-1-ol and butan-1,4-diol, respectively, and are best described as complexes between $[CH_2{=}CHOH]^{+\cdot}$ and CH_3OH (dissociation energy 21 kcal mol^{-1}) and between ionised vinyl alcohol and H_2O (dissociation energy $\geq$ 13 kcal mol^{-1}). ΔH_f^0 of the ions $[CH_2{=}CHOH/H_2O]^{+\cdot}$ and $[CH_2{=}CHOH/CH_3OH]^{+\cdot}$ were measured as $\leq$110 and 112 kcal mol^{-1}, respectively.

JOHAN K. TERLOUW, WIGGER HEERMA, PETER C. BURGERS et JOHN L. HOLMES. Can. J. Chem. **62**, 289 (1984).

On obtient les ions mentionnés dans le titre respectivement à partir du méthoxy-4 butanol-1 et du butanediol-1,4 ionisés qui perdent du C_2H_4. On peut décrire très bien ces ions comme étant des complexes entre le $[CH_2{=}CHOH]^{+\cdot}$ et le CH_3OH (énergie de dissociation 21 kcal mol^{-1}) et entre l'alcool vinylique ionisé et le H_2O (énergie de dissociation $\geq$ 13 kcal mol^{-1}). On a mesuré le ΔH_f^0 des ions $[CH_2{=}CHOH/H_2O]^{+\cdot}$ et $[CH_2{=}CHOH/CH_3OH]^{+\cdot}$ et on a trouvé que les ΔH_f^0 sont de $\leq$110 et 112 kcal mol^{-1}, respectivement.

[Traduit par le journal]

Introduction

Examination of collisionally induced unimolecular fragmentations of ions in the gas phase has proved to be an important method for investigating the structures of ions having internal energies below their first dissociation threshold. This technique has been particularly valuable for distinguishing between isomeric ions which are able to interconvert below the threshold for their common unimolecular fragmentation of lowest energy requirement, because such ions cannot be distinguished by means of their metastable peak characteristics.

Recently, collisional activation (CA) mass spectra have successfully been used unequivocally to identify both odd and even electron ions having unusual structures. Examples include the series of methylene-onium ions $[CH_2XH]^{+\cdot}$, where X = OH, SH, NH_2, F, Cl, Br, I (1) and the oxycarbenes $[C(OH)_2]^{+\cdot}$, $[HCOH]^{+\cdot}$ (2), and $[COH]^+$ (3, 4). The $[CH_2XH]^{+\cdot}$ ions are the lowest members of a potential homologous series of ions $[C_nH_{2n}XH]^{+\cdot}$, some higher members of which have been reported for n = 2, X = OH (5), OCH_3 (1*a*), NH_2 (1*b*). These species have been referred to as radical – ion dipole complexes by virtue of their major dissociations leading to $[C_2H_4]^{+\cdot}$ + XH, behaviour quite unlike that of their isomers of conventional structure. In general, these new ions have heats of formation close to, or in some cases below, those of their conventional isomers.

In this short paper we present evidence for the existence of complexes between ionised vinyl alcohol and the polar methanol and water molecules.

Results and discussion

Structure assignment and heat of formation of $[CH_2{=}CHOH/CH_3OH]^{+\cdot}$

Ionised 4-methoxy-butan-1-ol generates an ion at m/z 76, $[C_3H_8O_2]^{+\cdot}$, of abundance ca. 10% of base peak (m/z 45).

The collisional activation (CA) mass spectrum of this ion displays only two peaks of significant abundance, m/z 44, $[C_2H_4O]^{+\cdot}$ (80%), and m/z 33, $[CH_3\dot{O}H_2]$ (20%). Both daughter ions are also prominently observed in the metastable ion mass spectrum of m/z 76. The m/z 44 daughter ions, generated in the ion source and in the m/z 76 → m/z 44 metastable

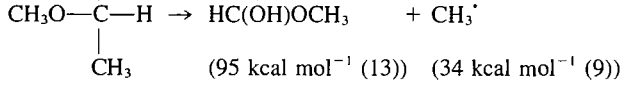
fragmentation, were shown by their CA mass spectrum (6) to consist solely of ionised vinyl alcohol, $[CH_2{=}CHOH]^{+\cdot}$. Furthermore, the appearance energy (AE) of the very narrow ($T_{0.5}$ = 3.9 meV) metastable peak (7) m/z 76 → 44, 10.7 ± 0.1 eV is close to that calculated for $[CH_2{=}CHOH]^{+\cdot}$, 10.6 eV. ($\Delta H_f^0[CH_3OCH_2CH_2CH_2CH_2OH]$ = −98.0 kcal mol^{-1} (by additivity (8), $\Delta H_f^0[C_2H_4]$ = 12.5 kcal mol^{-1} (9), $\Delta H_f^0[CH_3OH]$ = −48.1 kcal mol^{-1} (9), $\Delta H_f^0[CH_2{=}CHOH]^{+\cdot}$ = 181 kcal mol^{-1} (10).) Such a major loss of CH_3OH is not observed in either the normal or CA mass spectra of the $C_3H_8O_2$ isomers $HOCH_2CH_2CH_2OH$, $HOCH_2CH(OH)CH_3$, $CH_3OCH_2CH_2OH$, and $(CH_3O)_2CH_2$, all of which are dominated by m/z 45 or m/z 31.

Isomers of $[C_3H_8O_2]^{+\cdot}$, which could be expected prominently to lose CH_3OH, are the unconventional ions related to an ionised vinyl alcohol–methanol complex **I***a*, *b*, and *c* or possibly the ionised hemi-acetal $CH_3OCH(OH)CH_3$, **II** which are shown in Scheme 1, together with a possible mechanism for their formation. Ions **I***a*, *b*, and *c*, although formally structurally distinct symmetrical complex or σ-bonded ions, are unlikely to be distinguishable via their fragmentation characteristics. (Compare the similar systems $[C_2H_4 \cdot H_2O]^{+\cdot}$ (5) and $[CH_2CO \cdot H_2O]^{+\cdot}$ (11).) In the absence of further information concerning the relative stabilities of these ions (such as high-level *ab initio* calculations (12)), we will simply represent them by the formula $[CH_2{=}CHOH/CH_3OH]^{+\cdot}$.

This assignment is in keeping with observations on labelled compounds. $^{13}CH_3OCH_2CH_2CH_2CH_2OH$ cleanly produced m/z 77 which in turn only yielded m/z 44 and m/z 34 $[^{13}CH_3OH_2]^+$, i.e., no label retention in the $[CH_2{=}CHOH]^{+\cdot}$ ion; similarly, the CD_3 analogue produced only m/z 36 $[CD_3OH_2]^+$, m/z 44 with some (ca. 13%) m/z 45. The latter probably arises from exchange between the CH_3OH moiety and the vinyl alcohol hydroxyl group: m/z 77 from the OD precursor molecule again shows a clean displacement to m/z 34 $[CH_3ODH]^+$ whereas m/z 44 and m/z 45 are now of comparable abundance.

Ion **II** could also be generated via a more complex route than that shown in Scheme 1. Although they may play a role among reacting configurations (see below) ions of structure **II** cannot be the *stable* $[C_3H_8O_2]^{+\cdot}$ ions derived from 4-methoxybutan-1-ol.

First, ion **II** has as its *direct* bond cleavage of lowest energy requirement the reaction



ΔH_f^0 products = 129 kcal mol^{-1}, an energy 4 kcal mol^{-1} *lower* than that for the rearrangement leading to ionised vinyl alcohol, ΔH_f^0 = 181 kcal mol^{-1}, plus methanol, ΔH_f^0 = −48 kcal mol^{-1}. Thus the CA mass spectrum of **II** would be dominated by m/z 61 rather than m/z 44. For ions **I**, the production of ionised vinyl alcohol plus CH_3OH is *their* direct bond cleavage of lowest energy requirement.

Secondly, the heat of formation, ΔH_f^0, of the $[C_3H_8O_2]^{+\cdot}$ ion was measured to be 112 ± 1 kcal mol^{-1} (AE m/z 76 = 9.64 ± 0.05 eV, energy selected electrons (14); AE metastable peak (7) = 9.7 ± 0.1 eV (Gaussian type peak, $T_{0.5}$ = 20 meV). The ΔH_f^0 for $[CH_3OCH(OH)CH_3]^{+\cdot}$ is unknown but can be estimated as follows: ΔH_f^0 for the neutral molecule = −98.4 kcal mol^{-1} (by additivity (8)) and its ionisation energy will be similar to that for $CH_3CH(OCH_3)_2$, 9.5 eV (15), leading to ΔH_f^0 for ionised **II** of ~ 121 kcal mol^{-1}. Alternatively, ΔH_f^0[**II**] may be estimated by considering OH substitution in $[CH_3CH_2OCH_3]^{+\cdot}$ or OCH_3 substitution in $[CH_3CH_2OH]^{+\cdot}$ and the enthalpy-structure correlations described elsewhere (16); these yield 118 and 117 kcal mol^{-1}, respectively. All three estimated values lie significantly above the observed ΔH_f^0 and are deemed unlikely to be in error by so large an amount.

We therefore conclude that the new m/z 76 ion is best described as $[CH_2{=}CHOH/CH_3OH]^{+\cdot}$.

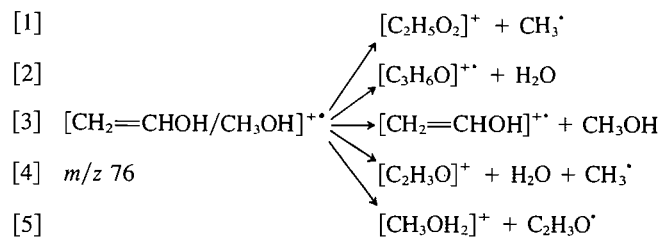
From the above thermochemical results it is clear than an appreciable binding energy (21 ± 2 kcal mol^{-1}) exists between ionised vinyl alcohol and methanol, i.e. the ion–molecule reaction

$$[CH_2{=}CHOH]^{+\cdot} + CH_3OH \rightarrow \mathbf{I}$$

is exothermic by this amount.

Dissociation characteristics of $[CH_2{=}CHOH/CH_3OH]^{+\cdot}$

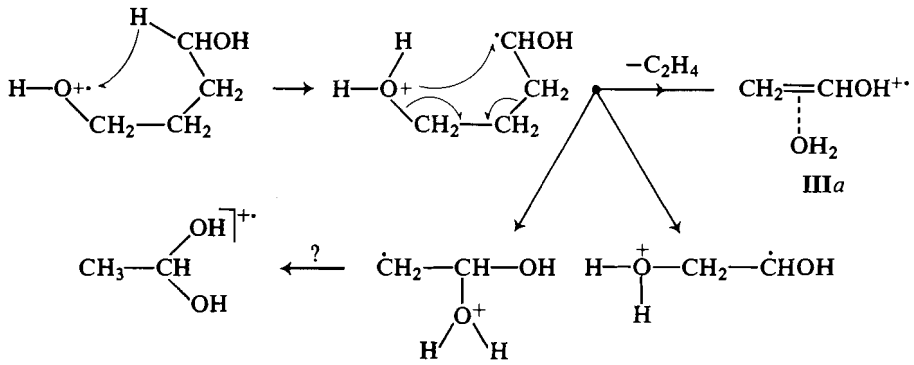
As described above the CA mass spectrum of the new ion contains only two intense peaks, m/z 44 and m/z 33; in marked contrast, the metastable $[C_3H_8O_2]^{+\cdot}$ ions undergo five competing fragmentations:



Only reaction [3] would be a direct bond cleavage for our proposed ion structure. This reaction becomes increasingly important among metastable ions of higher internal energy content, i.e. shorter lifetime. This can be seen from comparison of metastable peak abundances measured in the first field free region of a Kratos-AEI MS902S mass spectrometer (average ion lifetime ca. 1.8 μs (17)) 14:12:*100*:11:24, respectively, with those observed in the second field-free region of a VG Micromass ZAB-2F instrument (average ion lifetime ca. 13 μs (17)), relative abundances 100:75:*100*:54:44, respectively. These observations show that reaction [3] has a more steeply rising rate constant vs. internal energy curve than reactions [1], [2], [4], and [5]. The latter four would all require some rearrangement before fragmentation. The identifications of the daughter ions and mechanisms for reactions [1], [2], [4], and [5], which will provide insight as to the isomerisation of the complex ion, are being pursued.

Structure assignment and heat of formation of $[CH_2{=}CHOH/H_2O]^{+\cdot}$

Ionised butan-1,4-diol also loses C_2H_4 to produce an ion at m/z 62, $[C_2H_6O_2]^{+\cdot}$, of abundance ca. 3% of base peak (m/z 31). We propose that the ion m/z 62 has the structure $[CH_2{=}CHOH/H_2O]^{+\cdot}$, an analogue of the m/z 76 ion described above both in regard to its structure and mechanism of formation:

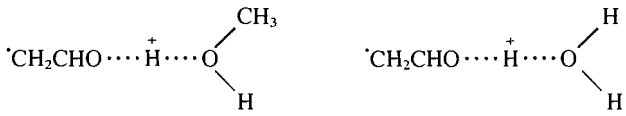


IV III*c* III*b*

Both MI and CA mass spectra are dominated by one peak, m/z 44, similarly shown to be ionised vinyl alcohol. Again the AE of the very narrow Gaussian type metastable peak, 10.5 ± 0.2 eV, showed that $[CH_2{=}CHOH]^{+\cdot}$ is generated ($\Delta H_f^0[HOCH_2CH_2CH_2CH_2OH] = -102.7$ kcal mol^{-1} (by additivity (8)), $\Delta H_f^0[H_2O] = -57.8$ kcal mol^{-1} (9) calculated AE for $[CH_2{=}CHOH]^{+\cdot} = 10.3$ eV). In addition the m/z 64 ion derived from the $(OD)_2$ derivative specifically loses HDO in the metastable dissociation and predominantly (82%) in the CA mass spectrum.

The ΔH_f^0 value for m/z 62 was measured as $\leq 110 \pm 1$ kcal mol^{-1} from AE = 9.78 ± 0.05 eV. Note that the apparent binding energy between $[CH_2{=}CHOH$ and $H_2O]^{+\cdot}$ in this ion is ca. 13 kcal mol^{-1}, less than that for the CH_3OH complex. However, it should be noted that the AE for m/z 62 is within experimental error, the same as the IE for butan-1,4-diol, 9.75 eV. Thus, the heat of formation of the ion may well represent an upper limit. The only isomeric $[C_2H_6O_2]^{+\cdot}$ ion which might be expected to yield $[CH_2{=}CHOH]^{+\cdot} + H_2O$ without major rearrangement is ion **IV**. (Note that $[HOCH_2CH_2OH]^{+\cdot}$ and $[CH_3OOCH_3]^{+\cdot}$ have no m/z 44 ion in their mass spectra.) However, an estimate of the heat of formation of **IV**, 132 ± 5 kcal mol^{-1} (by consideration of the effect of OH substitution on $[CH_3CH_2OH]^{+\cdot}$ (16)), indicates that such an ion would be "hot" with respect to fragmentation to $[CH_2{=}CHOH]^{+\cdot}$ and in any case lies well above the observed ΔH_f^0, 110 kcal mol^{-1}.

Finally, it must be re-emphasised that the experiments described above do not permit clear distinctions to be drawn between the proposed structures of these novel ions. Moreover, as cogently pointed out by a referee, another type of structure, to wit a proton-bound radical–molecule pair e.g.



I*d* III*d*

may also be stable, by analogy with closed shell systems (18–20). Indeed the major fragmentations in the CA mass spectra of **I** and **III** can be rationalised by considering the relative proton affinities of the radical and molecules involved in **I***d* and **III***d*. High level *ab initio* quantum mechanical calculations are required to solve this dilemma.

Experimental

Collisional activation mass spectra and metastable peak shapes were measured with the VG ZAB-2F mass spectrometer as described elsewhere (21). Metastable peak abundances and appearance energies were measured using an AEI-Kratos MS902S mass spectrometer (7) and daughter ion AE values were obtained with an apparatus comprising an electrostatic electron monochromator with a quadrupole mass analyser and minicomputer data system (14).

Butan-1,4-diol was obtained from Aldrich Co. and 4-methoxybutan-1-ol was prepared by reacting the former with CH_3I (22); the labelled analogues required CD_3I and $^{13}CH_3I$, obtained from Merck, Sharp and Dohme.

Relative rates of radical–radical processes in the pyrolysis of ethane

PHILIP D. PACEY AND JAYANTHA H. WIMALASENA[1]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received May 6, 1983

PHILIP D. PACEY and JAYANTHA H. WIMALASENA. Can. J. Chem. **62**, 293 (1984).

Ethane has been pyrolysed in a flow system at 900 to 963 K, at residence times from 0.5 to 50 s and with $[C_2H_6]$ from 1×10^{-4} to 4×10^{-3} mol L^{-1}. From measurements of yields of minor products at 902 K, it is concluded that the combination reaction, [5*a*], and disproportionation reaction, [5*b*], of C_2H_5 radicals have the rate constant ratio, $k_{5b}/k_{5a} = 0.44 \pm 0.07$. It is suggested that this ratio has a curved Arrhenius plot, which is interpreted in terms of activated complex theory. The cross-combination of CH_3 and C_2H_5 radicals becomes significant at low pressures, reaching 1.5% of the sum of the rates of [5*a*] and [5*b*] when $[C_2H_6] = 10^{-3}$ mol L^{-1} at 902 K. With $[C_2H_6] = 10^{-4}$ mol L^{-1} at 963 K, the yield of CH_4 was greater in the presence of an SiO_2 surface than in the presence of a PbO surface, consistent with the occurrence of the atom-cracking reaction,

[7*a*] $H + C_2H_5 \rightarrow 2CH_3$

at 15% of the combined rates of [5*a*] and [5*b*]. Rate parameters are also reported for the C—C scission in C_2H_6, for the abstraction of H from C_2H_6 by CH_3, for the decomposition of C_2H_5, and for the reaction of C_2H_5 at PbO surfaces.

PHILIP D. PACEY et JAYANTHA H. WIMALASENA. Can. J. Chem. **62**, 293 (1984).

On a étudié la pyrolyse de l'éthane à faible avancement en réacteur dynamique entre 900 et 963 K avec $[C_2H_6]$ entre 1×10^{-4} et 4×10^{-3} mol L^{-1}. Le rapport $[C_3H_8]/[CH_4]$ avait une valeur moins de 0.8% et était en accord avec un mécanisme de formation de C_3H_8 par la combinaison de radicaux CH_3 et C_2H_5. En présence des parois de PbO, il y avait une légère diminution de la vitesse de formation de CH_4, expliquée par l'extinction de la réaction,

[7*a*] $H + C_2H_5 \rightarrow 2CH_3$

qui arrive 15% aussi souvent que les terminaisons des chaines à 963 K, avec $[C_2H_6]$ égale à 1×10^{-4} mol L^{-1}. Extrapolé à l'avancement nul et aux hautes pressions, le rapport $[CH_4]/[C_4H_{10}]$ correspond à la valeur de 0.44 ± 0.07 pour le rapport des constantes de vitesse de dismutation et de combinaison de radicaux C_2H_5. Pour la réaction de dismutation, avec l'aide de la théorie du complexe activé, on suggère que les paramètres d'Arrhénius varient avec la température. On trouve également des constantes de vitesse pour l'amorçage, pour l'arrachement de H de C_2H_6 par CH_3 et pour la disparition unimoléculaire homogène et hétérogène de C_2H_5.

Introduction

According to the simple mechanism for the pyrolysis of ethane, the ratio of the yield of CH_4 to that of n-C_4H_{10} is predicted to be close to two. Instead, it is found experimentally (1–3) that the ratio is often three or more. It has been suggested that minor heterogeneous and homogeneous processes are responsible for this difference. The heterogeneous processes have been examined recently in this laboratory (4). The purpose of this article will be to examine the minor, homogeneous, radical–radical processes.

The simple mechanism is as follows:

[1] $C_2H_6 \rightarrow 2CH_3$

[2] $CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$

[3] $C_2H_5 \rightarrow C_2H_4 + H$

[4] $H + C_2H_6 \rightarrow H_2 + C_2H_5$

[5*a*] $2C_2H_5 \rightarrow C_4H_{10}$

[5*b*] $2C_2H_5 \rightarrow C_2H_6 + C_2H_4$

Making the steady-state assumption for this mechanism, it is found that $[CH_4]/[C_4H_{10}]$ is equal to $2k_5/k_{5a}$, where k_5 is the sum of the rate constants for reactions [5*a*] and [5*b*]. If k_{5b}/k_{5a} is assumed to have the value of 0.13 ± 0.02, as at room temperature (5), then $[CH_4]/[C_4H_{10}]$ should be 2.26 ± 0.04.

Additional reactions which could affect this ratio are as follows (2–4, 6):

[6] $C_2H_5 \xrightarrow{w}$ products

[7*a*] $H + C_2H_5 \rightarrow 2CH_3$

[7*b*] $H + C_2H_5 \rightarrow C_2H_6$

[7*c*] $H + C_2H_5 \rightarrow H_2 + C_2H_4$

[8*a*] $CH_3 + C_2H_5 \rightarrow C_3H_8$

[8*b*] $CH_3 + C_2H_5 \rightarrow CH_4 + C_2H_4$

Making the steady-state approximation and the long chain approximation, neglecting reactions of products and eliminating sums in the denominator or within square roots using the binomial expansion, retaining leading terms only, expressions for relative rates of product formation have been obtained.[2]

When termination is strongly dominated by reaction set [5], initial yield ratios are predicted to be as follows:

$$[9] \quad \left(\frac{[CH_4]}{[C_4H_{10}]}\right)_0 = \frac{2k_5}{k_{5a}}\left(1 + \frac{k_6}{2(k_1k_5[C_2H_6])^{1/2}} + \frac{k_3k_7}{k_4k_5[C_2H_6]} + \frac{k_1^{1/2}(k_{8a} + 2k_{8b})}{k_2k_5^{1/2}[C_2H_6]^{1/2}} - \cdots\right)$$

[1] Present address: Department of Chemistry, University of Sri Jayewardenepura, Nugegoda, Sri Lanka.

$$[10]\quad \left(\frac{[C_3H_8]}{[CH_4]}\right)_0 = \frac{k_1^{1/2}k_{8a}}{k_2k_5^{1/2}[C_2H_6]^{1/2}}\left(1 - \frac{k_6}{4(k_1k_5[C_2H_6])^{1/2}} - \frac{k_3(k_{7b} + k_{7c})}{2k_4k_5[C_2H_6]} - \frac{k_1^{1/2}(k_{8a} + 2k_{8b})}{k_2k_5^{1/2}[C_2H_6]^{1/2}} + \ldots\right)$$

These series converge; all terms but the first are less than unity.

Comparing rates of formation of CH_4 when reaction set [5] dominates termination, $R_{CH_4,5}$, and when reaction [6] dominates, $R_{CH_4,6}$, but when temperature and $[C_2H_6]$ are the same, one obtains

$$[11]\quad \frac{R_{CH_4,5}}{R_{CH_4,6}} = 1 + \frac{k_3k_{7a}}{k_4k_5[C_2H_6]}\left(1 - \frac{4k_1k_5[C_2H_6]}{k_6^2} - \ldots\right) - \frac{k_1^{1/2}k_{8a}}{k_2k_5^{1/2}[C_2H_6]^{1/2}}\left(1 - \frac{(4k_1k_5[C_2H_6])^{1/2}}{k_6}\ldots\right) - \ldots\ldots$$

In eq. [11], k_6 has its value when reaction [6] dominates termination, and the series converge.

Examining eq. [9], it is seen that $[CH_4]/[C_4H_{10}]$ should be greater than $2k_5/k_{5a}$ when the terms in k_6, k_7, and $(k_{8a} + 2k_{8b})$ are not zero. It should be possible to obtain information about the terms in k_7 and $(k_{8a} + 2k_{8b})$ by experimental studies applying eqs. [11] and [10], respectively, in which similar quotients appear. Based on the orders of k_1 and k_3 at 894 K (1), the orders of the terms in eq. [9] in k_6, k_7, and $(k_{8a} + 2k_{8b})$ are predicted to be -0.56 ± 0.01, -0.46 ± 0.04, and -0.44 ± 0.01, respectively. These are all close to -0.5, so a plot of $([CH_4]/[C_4H_{10}])_0$ as a function of $[C_2H_6]^{-1/2}$ should give a straight line of intercept $2k_5/k_{5a}$.

Experimental

Most of the apparatus and experimental techniques have been described in refs. 4 and 8. An additional, dual reactor system was constructed with two 3 mm inside diameter cylindrical quartz tubes placed side by side in an 11 mm inside diameter quartz tube, which was surrounded by an 18 mm outside diameter brass tube and an electrically heated furnace. Both inner tubes were washed with concentrated HNO_3 and distilled water. One was rinsed with a 1 *M* solution of $Pb(NO_3)_2$ and heated slowly to obtain a PbO deposit. Reagent flow was directed alternatively to these two reactor chambers.

Products were analyzed by gas chromatography (4).

Results

Propane formation

Experiments[2] to determine the yields of C_3H_8 have been performed in 8 and 17 mm inside diameter quartz reactors at temperatures from 900 to 905 K, at six C_2H_6 concentrations from 1.07×10^{-3} to 4.4×10^{-3} mol L^{-1} and at residence times from 1.4 to 50 s.

Values of the ratio $[C_3H_8]/[CH_4]$ have been extrapolated to initial time to eliminate interference by reactions of the products. The initial values, approximately equal to $k_1^{1/2}k_{8a}/(k_2k_5^{1/2}[C_2H_6]^{1/2})$ by eq. [10], had an order with respect to $[C_2H_6]$ of -0.33 ± 0.20, in agreement within experimental uncertainty with the value -0.44 ± 0.01, predicted by eq. [10]. (Here and elsewhere quoted uncertainties are standard deviations.) The largest value (at the lowest $[C_2H_6]$) was 7.7×10^{-3}, indicating that this is a very minor termination process.

The concentrations of products and reactant were also used to calculate $k_2/k_{-1,\infty}^{1/2}$, as in ref. 3. (The factor of $(1.15)^{1/2}$, included in ref. 3, was omitted. See footnote 2.) The order of the quotient, $k_2/k_{-1,\infty}^{1/2}$, was found to be 0.08 ± 0.12, or zero within experimental uncertainty. The average of the six values was 26 ± 4 $L^{1/2}$ $mol^{-1/2}$ $s^{-1/2}$. Taking $k_{-1,\infty}$ from ref. 8, it is found that $k_2 = 3.9 \times 10^6$ L mol^{-1} s^{-1}.

From CH_4 yields k_1 is calculated (1–3) to have values from 1.1×10^{-5} to 1.8×10^{-5} s^{-1}.

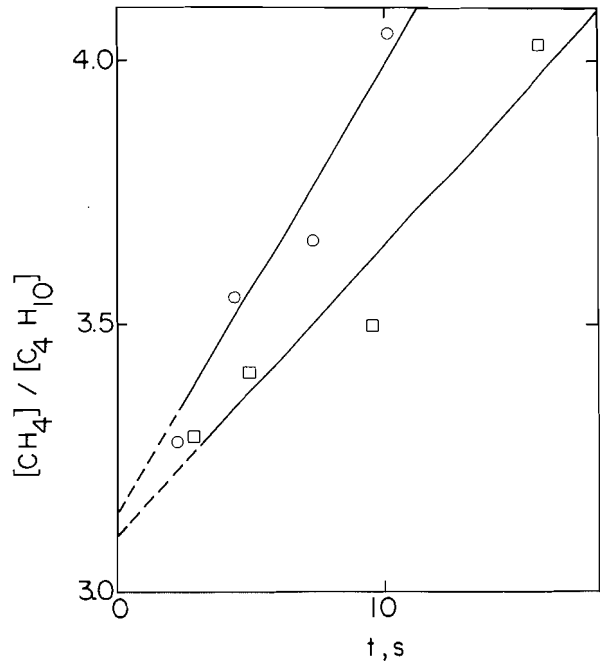

FIG. 1. Dependence of $[CH_4]/[n\text{-}C_4H_{10}]$ on residence time in the 8 mm diameter reactor at 902 K; □, 3.5×10^{-3} mol C_2H_6 L^{-1}; ○, 1.7×10^{-3} mol C_2H_6 L^{-1}; —, least-squares straight lines.

Dual reactor experiments

Pure C_2H_6 at a concentration of 1.05×10^{-4} mol L^{-1} was pyrolyzed in the dual reactor system at 963 K. Rates of formation of CH_4 and C_2H_4 in the presence of the SiO_2 and PbO surfaces are summarized[2] in Table 1. It can be seen that the PbO surface reduced the rate of formation of C_2H_4 by an order of magnitude and reduced the rate of formation of CH_4 by 10%. The difference in the CH_4 rates was small but by the test of analysis of variance it was significant at the 99% confidence level (9).

CH_4-to-C_4H_{10} ratio

The ratio of CH_4 to C_4H_{10} yields has been measured in experiments[2] at 900 to 902 K in clean quartz reactors of 8 mm diameter at $[C_2H_6]$ from 2.5×10^{-4} to 3.5×10^{-3} mol L^{-1}.

The dependence of this ratio on reactor residence time is shown in Fig. 1 for experiments at 3.5×10^{-3} and 1.7×10^{-3} mol L^{-1} at 902 K. It can be seen that the ratio increases sharply with increasing residence time, mainly because of secondary processes which reduce the later yields of C_4H_{10}. The data in Fig. 1 may be reliably extrapolated to determine the initial ratio, $([CH_4]/[C_4H_{10}])_0$. However, it was necessary that the shortest residence times be less than about 4 s in order to confidently predict this intercept.

Initial values of the ratios are shown in Fig. 2, plotted as a function of $[C_2H_6]^{-1/2}$, as suggested by eq. [9]. The solid, straight line is a least-squares fit. The intercept, which by eq. [9] should be equal to $2k_5/k_{5a}$, was found to be 2.88 ± 0.13. The disproportionation to combination ratio, k_{5b}/k_{5a}, is then calculated to be 0.44 ± 0.07. The ratio of slope to intercept,

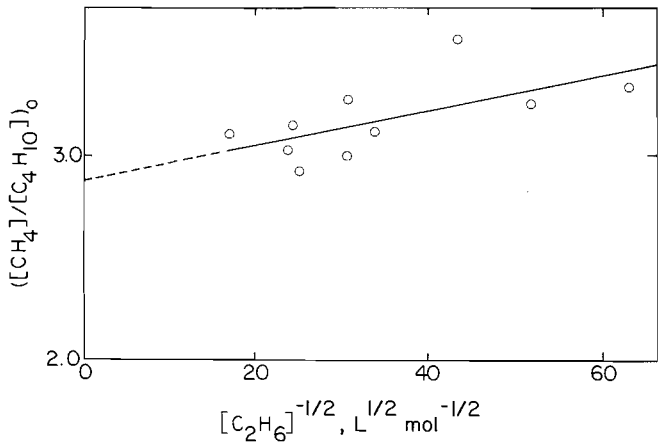

FIG. 2. Dependence of initial values of $[CH_4]/[n\text{-}C_4H_{10}]$ on $[C_2H_6]^{-1/2}$ at 900–902 K in the 8 mm diameter reactor; ○, intercepts of analogues of Fig. 1; —, least-squares straight line.

which is related to the terms in k_6, k_7, and $(k_{8a} + 2k_{8b})$ in eq. [9], is 3.0 (±1.3) × 10^{-3} $mol^{1/2}$ $L^{-1/2}$.

Discussion

Reactions [2] and [8a]

Possible sources of systematic error in the determination of $k_2/k_{-1,\infty}^{1/2}$ were thoroughly discussed in ref. 3. The value determined in this work, 26 ± 4 $L^{1/2}$ $mol^{-1/2}$ $s^{-1/2}$ may be compared with values calculated from Arrhenius parameters determined in the following temperature ranges: 21 $L^{1/2}$ $mol^{-1/2}$ $s^{-1/2}$, 931–1038 K (3); 24 $L^{1/2}$ $mol^{-1/2}$ $s^{-1/2}$, 880–1068 K (10); 5.9 $L^{1/2}$ $mol^{-1/2}$ $s^{-1/2}$, 303–797 K (11). The value from the present work is four times larger than that extrapolated from measurements at lower temperatures (11). There is growing evidence that the Arrhenius plot for reaction [−1] is straight (8, 12). The value of $k_2/k_{-1,\infty}^{1/2}$ determined in this work agrees well with the other data obtained at high temperatures and further confirms the suggested Arrhenius plot curvature (3, 10) for reaction [2].

It was seen in the Results section that $k_1^{1/2}k_{8a}/(k_2k_5^{1/2} \times [C_2H_6]^{1/2})$ is small under these conditions. It must make only a minor contribution in eqs. [9] and [11]. Applying the literature value of k_{8b}/k_{8a} (13), reactions [8*a*] and [8*b*] explain only 10% of the ratio of slope to intercept in Fig. 2.

Reactions [5a] and [5b]

Values of the disproportionation to combination ratio, k_{5b}/k_{5a}, calculated from the intercepts of graphs like Fig. 2, are shown as the solid points in Fig. 3. The results are based on the data of refs. 1, 2, and 3 as well as the present work. Results of experiments of ref. 1 at 873 and 894 K are not shown, as conversions were much greater than those in Fig. 1. The average of the values from C_2H_6 pyrolysis in Fig. 3 is 0.44 ± 0.12. These values could be fitted to an Arrhenius expression as follows

$$\log_{10}(k_{5b}/k_{5a}) = 0.5 \pm 0.4 - (15 \pm 6)\ \text{kJ mol}^{-1}/(2.3\ RT)$$

If one assumed a dependence on $[C_2H_6]^{-1}$ or an independence of $[C_2H_6]$ in Fig. 2, one would obtain k_{5b}/k_{5a} equals 0.52 ± 0.04 or 0.59 ± 0.10, respectively. Thus the conclusion, that k_{5b}/k_{5a} is about 0.5, does not depend on the interpretation of the small pressure dependence of $[CH_4]/[C_4H_{10}]$ in Fig. 2. For the conditions of the earliest points in Fig. 1, yields of C_3H_6 were only 2% of the yields of CH_4; the reaction,

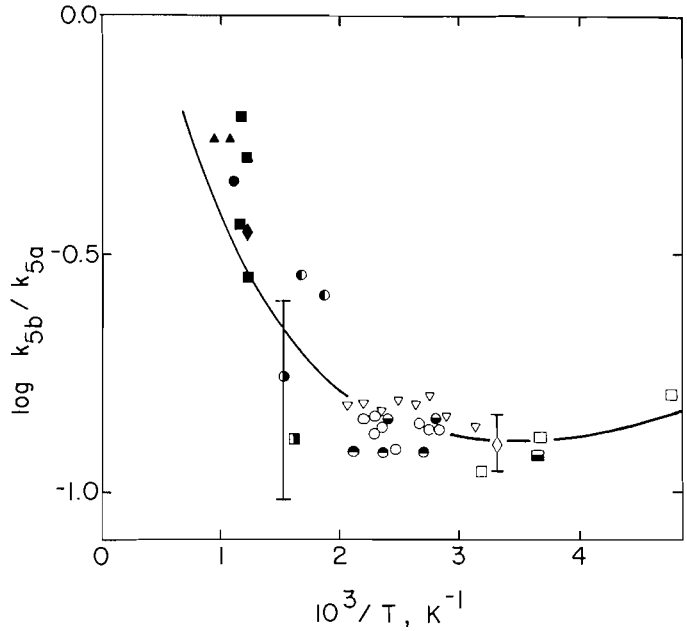

FIG. 3. Arrhenius plot for k_{5b}/k_{5a}: ■, extrapolated from the data of ref. 1; ◆, from ref. 2; ▲, from ref. 3; ◇, room temperature data from ref. 5; ◒, ref. 7; ◨, ref. 14; ◓, ref. 15; □, ref. 16; ▽, ref. 17; ○, ref. 18; ⬓, ref. 19; ◐, ref. 20; ◑, ref. 21; ●, this work; —, activated complex theory results.

$$C_2H_5 + C_2H_4 \rightarrow CH_3 + C_3H_6$$

is not a significant initial source of CH_4.

In the low pressure pyrolysis of azoethane at 860 K (22) the value of k_{5b}/k_{5a} was found to be 1.5, which would be reduced to about 0.7 when k_{5a} is adjusted to its limiting high pressure value. This value is similar to those from C_2H_6 pyrolysis.

The present authors consider that the most reasonable interpretation of the data is that the Arrhenius plot for reaction [5*b*] is a curve. In this way, it would join several other atom transfer reactions, for example, reaction [2], and the disproportionation of OH radicals (23). For these reactions, activation energies increase by 20 to 40 kJ mol^{-1} at high temperatures and pre-exponential factors approach collision numbers.

Also shown in Fig. 3 is a curved line calculated by activated complex theory. In this calculation, k_{5b} was favoured by a statistical factor of 6. Four free internal rotational degrees of freedom of ethyl radicals in the complex for combination were replaced by four vibrational modes (ω = 85 cm^{-1}) in the complex for disproportionation. The zero point energy for the disproportionation complex was 3 kJ mol^{-1} less than that for combination. Other parameters were identical for k_{5a} and k_{5b}. Replacement of the rotational modes by vibrational modes leads to the upward curvature at high temperatures. The small difference in zero point energies leads to the slight increase in the ratio at low temperatures. This increase is not clearly established experimentally (24). The illustrated model is not intended to be exact, but to indicate that most of the data were compatible with a single, reasonable explanation.

Reaction [7a]

The most straightforward interpretation of the reduction in the CH_4 yields observed in Table 1 is to suppose, following eq. [11], that this reduction is a measure of the reduction in the rate of formation of CH_3 by reaction [7*a*]. However, there are at least two other possible interpretations.

TABLE 1. Summary of experiments in dual 3 mm diameter reactors at 963 K with $[C_2H_6] = 1.05 \times 10^{-4}$ mol L^{-1}

Surface	$10^8 \times [CH_4]/t$ (mol L^{-1} s^{-1})	$10^6 \times [C_2H_4]/t$ (mol L^{-1} s^{-1})
SiO_2	2.75 ± 0.12	1.30 ± 0.08
PbO	2.48 ± 0.13	0.135 ± 0.007

One possibility is that CH_3 was removed at the PbO surface, without forming CH_4. This reaction could not be reaction [−1], as this reaction is not favoured by thermodynamics. However, such a reaction could have formed C_2H_4 and H_2, for example.

It is also possible that the greater rate of formation of CH_4 in the clean reactor was the result of the reaction,

$$[12] \quad H + C_2H_6 \rightarrow CH_4 + CH_3$$

In hot atom experiments (25) this reaction was found to be much slower than the process in which hydrogen atoms are simply exchanged. Even the latter process has a much higher threshold energy than reaction [4] and is unable to compete in thermal systems.

Neither of these possibilities can be completely eliminated, so Table 1 does not constitute a proof that reaction [7*a*] occurs in C_2H_6 pyrolysis. Nevertheless, we shall interpret Table 1 assuming that the change in CH_4 yields is a measure of the influence of reaction [7*a*] in order to compare our conclusions with those in the literature.

In eq. [11], the left hand side was calculated assuming that reaction set [5] dominates termination in the clean reactor and that reaction [6] dominates in the PbO reactor. From the relative C_2H_4 yields, by the methods of ref. 4, the quotient $(4k_1k_5[C_2H_6])^{1/2}/k_6$ (PbO) is found to be 0.10. Finding k_1 from CH_4 yields (1–3), adjusting our earlier value of $k_2/k_{-1,\infty}^{1/2}$ for temperature (3) and taking the cross-combination ratio (7), the quotient $k_1^{1/2}k_{8a}/(k_2k_5^{1/2}[C_2H_6]^{1/2})$ is calculated to be 0.039. The quotient, $k_3k_{7a}/(k_4k_5[C_2H_6])$, is then found from eq. [11] to be 0.15. Taking k_5 from ref. 26 and finding k_3 from C_2H_4 yields (4), $k_{7a}/(k_4k_5^{1/2})$ becomes 1.3 (±0.8) × 10^{-3} $mol^{1/2}$ $s^{1/2}$ $L^{-1/2}$. The latter quotient is important in flow discharge systems containing H atoms and C_2H_6 or C_2H_4. Taking the Arrhenius parameters of ref. 6 for k_4 and those of refs. 6, 27, or 28 for k_{7a} and k_5, the value of $k_{7a}/(k_4k_5^{1/2})$ at 963 K is calculated to be 1.6×10^{-3}, 0.9×10^{-3} or 0.4×10^{-3} $mol^{1/2}$ $s^{1/2}$ $L^{-1/2}$, respectively. Considering the extrapolation of 200 K or more, this is satisfactory agreement, supporting the present interpretation of the data in Table 1.

From the data of Table 1 the following kinetic parameters may also be calculated (1–4, 26): $k_1 = 1.2 \times 10^{-4}$ s^{-1}, $k_3 = 1300$ s^{-1}, k_6 (PbO) = 240 s^{-1}, $k_7/k_4 = 110$, γ (probability of termination per collision of C_2H_5 with PbO) = 8×10^{-4}. Residence times were an order of magnitude greater than those needed for the use of the steady-state assumption (26).

Reaction [7*a*] does not play a major role in C_2H_6 pyrolysis. This role becomes smaller at lower temperatures and higher pressures, where it would be hard to detect (2). The reaction would become more important at lower pressures or higher temperatures, but would be difficult to study because of reduced analytical sensitivity or increased competition from secondary reactions, respectively. Camilleri *et al.* (6) reported that the rate of reaction [7*c*] is about 5% of that of reaction [7*a*], independent of temperature. The ratio of dissociation, [7*a*], to stabilization, [7*b*], has been calculated using the method of ref. 29 and RRKM model of ref. 30. The integration was performed with energies of the complex starting at 410 kJ mol^{-1}. At 901 K, the ratio, k_{7b}/k_{7a}, was calculated to have values from 0.08 at 1.8×10^{-4} mol L^{-1} to 1.1 at 4.4×10^{-3} mol C_2H_6/L.

Taking $k_{7a}/(k_4k_5^{1/2})$ as above, increasing by 13% to allow for reactions [7*b*] and [7*c*], adjusting for the temperature dependence of k_4 (6), and taking k_3 and k_5 from ref. 26, it is predicted that the quantity, $k_3k_7/(k_4k_5[C_2H_6]^{1/2})$ would have the value 1.5×10^{-3} $mol^{1/2}$ $L^{-1/2}$ at 902 K. This is half the ratio of slope to intercept in Fig. 2.

Reaction [6]

According to the preceeding sections, 10% of the slope in Fig. 2 can be attributed to reaction set [8] and about 50% to reaction set [7]. The remainder could be attributed to reaction [6]. From eq. [9], then, $k_6(SiO_2)/(2k_1^{1/2}k_5^{1/2}) = 1.2$ (±1.6) × 10^{-3} $mol^{1/2}$ $L^{-1/2}$, small enough to ensure that reaction set [5] dominates termination in clean quartz reactors. This value may be shown (4) to correspond to a probability, $\gamma(SiO_2)$, of reaction per wall collision of 5 (±7) × 10^{-6}. The following values of γ have been calculated by the same method from the data of ref. 1: 823 K, unpacked, 40 (±30) × 10^{-6}, packed, 20 (±5) × 10^{-6}; 844 K, 11 (±16) × 10^{-6}; 858 K, 70 (±20) × 10^{-6}.

The above values of γ are imprecise. This reflects the uncertainty in the slopes and perhaps also a difference in the history of the surfaces. We have previously reported (4) a value of γ = 11 (±3) × 10^{-6} at 823 K based on the data of ref. 1 but calculated from the changes in C_4H_{10} yields on changing surface-to-volume ratio. The previous method is more direct and more reliable, as it avoids the need to measure small slopes and avoids assumptions regarding k_7 and k_8. The above values of γ are quoted only to show that their orders of magnitude are similar and that the present interpretation of the variation of CH_4 to C_4H_{10} ratios is reasonable.

It has been assumed by other workers (2, 31) that the heterogeneous reaction in pyrolysis is

$$[13] \quad H \xrightarrow{w} (1/2)H_2$$

It has been shown (4) that reaction [6] is more consistent with the data for C_2H_6 pyrolysis. However, if reaction [6] is replaced by reaction [13], the term in k_6 in eq. [9] would be replaced by $k_3k_{13}/(2k_4(k_1k_5)^{1/2}[C_2H_6]^{3/2})$, which has an order of −1.02 ± 0.04. The rate constants calculated herein for heterogeneous processes would lose their meaning, but those for homogeneous processes would not change significantly.

In summary the rate of reaction [8*a*] has been measured directly. Less direct and less reliable estimates have been obtained for the rates of reactions [6] and [7*a*]. The disproportionation to combination ratio, k_{5b}/k_{5a}, has been calculated from high pressure ratios of $[CH_4]/[C_4H_{10}]$. Arrhenius plot curvature has been confirmed for reaction [2] and is suggested for reaction [5*b*]. At high pressures reactions [5*a*] and [5*b*] are the dominant radical–radical processes, accounting for 70 and 30%, respectively, of the total. At lower pressures, especially at high temperatures, reactions [7*a*] and [8*a*] also contribute. Further studies of disproportionation reactions at high temperatures are recommended.

Received May 12, 1983

WILLIAM A. AYER, LESLIE F. BALL, LOIS M. BROWNE, MOTOO TORI, LOUIS T. J. DELBAERE, and ALEXIS SILVERBERG. Can. J. Chem. **62**, 298 (1984).

The structure of spirolucidine, a new type of *Lycopodium* alkaloid related to the lucidines, has been determined. Chemical and spectroscopic data, together with biogenetic considerations, led to the correct constitution of spirolucidine. An X-ray crystallographic study of tetrahydrodeoxyspirolucidine, the lithium aluminum hydride reduction product of spirolucidine, confirmed the constitution and established the relative stereochemistry of the alkaloid.

WILLIAM A. AYER, LESLIE F. BALL, LOIS M. BROWNE, MOTOO TORI, LOUIS T. J. DELBAERE et ALEXIS SILVERBERG. Can. J. Chem. **62**, 298 (1984).

On a déterminé la structure de la spirolucidine, un nouvel alcaloïde du type *Lycopodium*. Les données chimiques et spectroscopiques ainsi que des considérations portant sur la biogénèse conduisent à la structure exacte de la spirolucidine. Une étude par cristallographie aux rayons-X de la tétrahydrodéoxyspirolucidine, le produit de réduction de la spirolucidine par l'alanate de lithium, confirme la structure et établit la stéréochimie relative de l'alcaloïde.

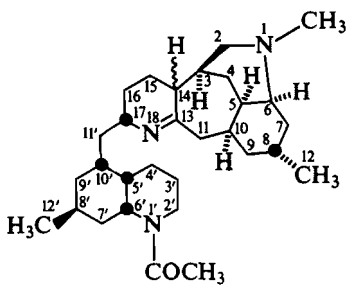
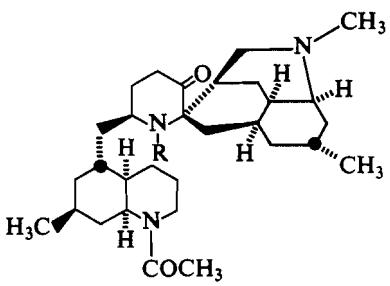
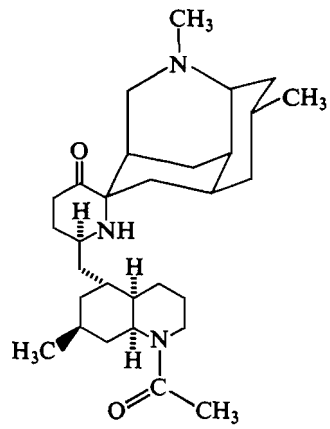
We have recently reported the structure of three $C_{30}N_3$ alkaloids isolated from *Lycopodium lucidulum* (1). These alkaloids represent a new structural type among the Lycopodium alkaloids, represented here by lucidine B (**1**).[1] We now wish to report the structure of a related weakly basic alkaloid, which we have named spirolucidine, isolated from the same source. Spirolucidine is shown to possess structure **2**, and is a possible biogenetic precursor of the lucidines. The conformational drawing of spirolucidine (**2***a*) shows the close relationship between the top portion of the molecule and the tricyclic alkaloid luciduline (**3**) (2).



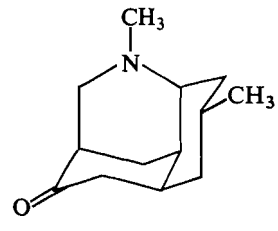
1



2 R = H
4 R = CHO



2*a*



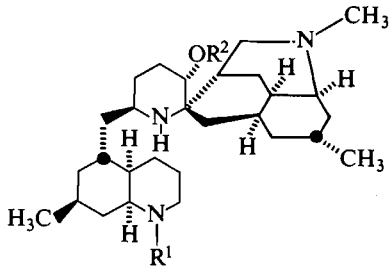
3

The weak bases of *L. lucidulum* were separated by 100-funnel countercurrent distribution as previously described (2). The weakest base fraction (tubes 1–12) was further separated by chromatography over neutral alumina to give luciduline (**3**) (least polar), dihydrolycolucine (1), and then spirolucidine (**2**) (most polar), obtained as a viscous gum which showed a single spot on tlc using several solvent systems.[2] High resolution mass spectrometry reveals that spirolucidine has the molecular formula $C_{30}H_{49}N_3O_2$. The infrared spectrum shows ketonic absorption at 1710 cm^{-1} and amide absorption at 1630 cm^{-1}. The ^1H nmr spectrum shows the presence of two secondary *C*-methyl groups (doublets at δ 0.82 and 0.89), an *N*-methyl group (s, δ 2.03), and an *N*-acetyl methyl (δ 2.08 and 2.09 (rotamers)).

The base peak in the mass spectrum of spirolucidine appears

[1]In ref. 1 the stereochemistry of lucidine B (**1**) and related compounds, at C-17, is incorrectly shown. The hydrogen should be above the plane, and the substituent below the plane, in accord with the X-ray structure shown as Fig. 1 in ref. 1.

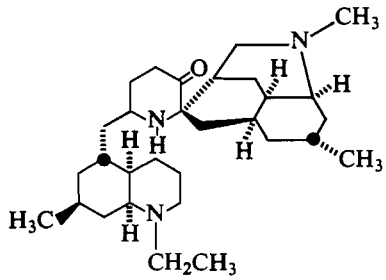
[2]Full details of the separation may be found in ref. 3. In ref. 3 spirolucidine is referred to as "the 483-ketone".



5 R' = $COCH_3$, R^2 = H
6 R' = R^2 = $COCH_3$
7 R' = CH_2CH_3, R^2 = H

at *m/z* 455, corresponding (hrms) to the loss of CO from the molecular ion, and was the first indication that we were dealing with an α-aminoketone (4). The infrared spectrum of spirolucidine does not show a clear N—H stretching vibration and attempted acetylation (Ac_2O-py) gave only starting material. However, treatment of spirolucidine with acetic formic anhydride gave *N*-formylspirolucidine (**4**) (δ 8.68, s, N—C*H*O; ν_{max}: 1710, 1650, 1630 cm^{-1}), confirming the presence of the secondary amino function and yet indicating its hindered nature.

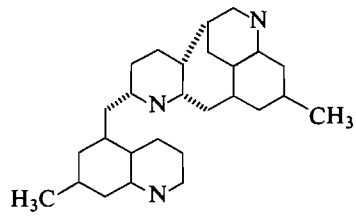
Sodium borohydride reduction afforded dihydrospirolucidine (**5**) (ν_{max}: 3400, 1620 cm^{-1}) which on acetylation gave the *O*-acetyl derivative **6**. Reduction of spirolucidine (**2**) with lithium aluminum hydride provided tetrahydrodeoxyspirolucidine (**7**). Oxidation of **7** with Jones' reagent gave dihydrodeoxyspirolucidine (**8**) (ν_{max}: 1700 cm^{-1}). Treatment of **8** with sodium deuteroxide in D_2O—CH_3OD led to the incorporation of two C-bound deuterium atoms (mass spectrometry).



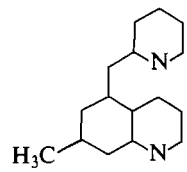
8

This finding, along with the fact that spirolucidine shows a *singlet* in the ^{13}C nmr at δ 65.9, in the region for carbons bonded to nitrogen, demonstrates that *spirolucidine does not have the same skeleton* as the lucidines (skeleton 1).

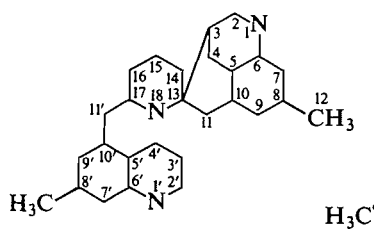
As has been pointed out (1, 5), the lucidine skeleton **1** may be biogenetically derived by the fusion of two $C_{11}N$ units such as that found in luciduline (**3**), with a piperidine ring as illustrated in **9**. The phlegmarines (skeleton 10) are a group of Lycopodium alkaloids in which one $C_{11}N$ unit is joined to a piperidine ring (6). The unusual biogenetic feature of the lucidine structure is that the C-3 to C-14 bond represents the fusion of a β (to nitrogen) carbon (C-3) of one ring system with the β (to nitrogen) carbon (C-14) of the piperidine ring. Normally this type of bond is from the β-carbon of one ring system (enamine) to the α-carbon of the other (immonium ion). It was this consideration, along with the finding that one carbon α to nitrogen was fully substituted, which led us to consider the spiro structure **11** for the new alkaloid. Location of the ketonic carbon at C-14 follows from the finding that there are two hydrogens α to the carbonyl. Location of the carbonyl oxygen at C-11′ is ruled out since this structure would not explain the facile loss of carbon monoxide from the molecular ion in the mass spectrum of spirolucidine (**2**).



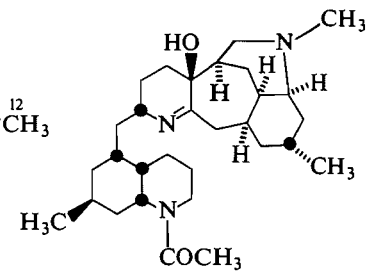
9



10



11



12

Attempts to bring about acid-catalyzed rearrangement of oxolucidine B (**12**) to the spiro ring system of spirolucidine were unsuccessful. The conditions investigated included treatment with aqueous sulfuric acid, aqueous hydrochloric acid, trifluoroacetic acid in tetrahydrofuran, and *p*-toluenesulfonic acid in refluxing benzene. Similarly, attempts to rearrange the spiro system of dihydrospirolucidine (**5**) by treatment with phosphorous oxychloride or by mesylation and solvolysis, led to the formation of many products, none of which appeared to have the lucidine skeleton.

Although spirolucidine and many of its derivatives could not be induced to crystallize, tetrahydrodesoxyspirolucidine (**7**), obtained by lithium aluminum hydride reduction, crystallizes nicely from ether–pentane to give colorless rhombic crystals, mp 149–152°C. In order to verify the structural hypothesis and to determine the stereochemistry of the alkaloid, an X-ray crystallographic study was carried out on tetrahydrodesoxyspirolucidine (**7**). A perspective drawing of the molecule is shown in Fig. 1. All of the six-membered rings are in a chair conformation. The major intermolecular contact (2.89 Å) is a hydrogen bond between the hydroxyl group of the molecule and the N-1′ of an adjacent molecule. The crystal packing of the molecule is illustrated in Fig. 2 which is a projection of the molecule down the $-a$-axis of the unit cell.

An unusual feature revealed by the X-ray crystal structure is the stereochemistry of the decahydroquinoline portion of the molecule. In lucidine B (**1**) and those compounds correlated with it (1), the *cis*-ring junction hydrogens (at C-5′ and C-6′) are *syn* to the methyl group located at C-8′, whereas in spirolucidine they are *anti* to the methyl. Another unexpected result is that the configuration at C-17 of spirolucidine is opposite to that in lucidine B.

Experimental

High resolution mass spectra were recorded on an A.E.I. MS-50 mass spectrometer coupled to a DS 50 computer. Unless diagnostically significant, only peaks greater than 20% of the base peak are

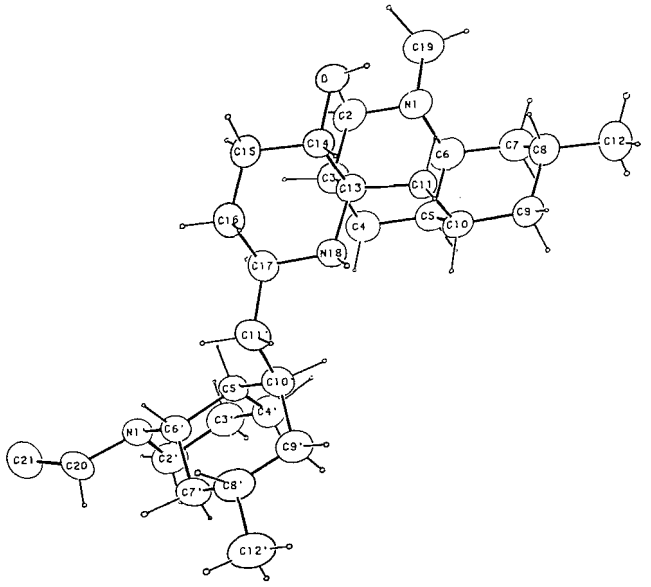

FIG. 1. Perspective drawing of tetrahydrodeoxyspirolucidine (11). For clarity, only one of the three partially-occupied positions of C-21 is illustrated.

reported. Infrared spectra were recorded on a Unicam SP 1000 or a Nicolet 7199 FT spectrometer. The nmr spectra were determined on a Varian HA-100 spectrometer (^{1}H nmr) interfaced to a Digilab FTS/NMR-3 data system and on a Bruker HFX-90 spectrometer (^{13}C nmr), with TMS as internal standard. Thin layer chromatography (tlc) was carried out on aluminum oxide GF_{254} (Type 60-E, E. Merck), aluminum oxide G (Type 60-E), or Woelm basic alumina for tlc, and the compounds were visualized using Dragendorff's reagent. Woelm neutral aluminum oxide (grade IV) or Woelm basic alumina (B-Super I, activity III) was used for column chromatography. Skellysolve B refers to Skelly Oil Company light petroleum, bp 62–70°C.

Isolation of spirolucidine

The "weak bases" of *L. lucidulum* (5.1 g) (2) were subjected to one-hundred funnel countercurrent distribution using chloroform (40 mL per tube) as the stationary phase and a saturated solution of potassium hydrogen tartrate (pH 3, 40 mL per tube) as the moving phase. Tubes 1–12 contained mainly three components (by tlc) and were combined (1.5 g). These very weak bases were chromatographed over alumina (150 g, activity IV). Elution with benzene gave luciduline (**3**, 0.06 g), benzene–ether (9:1) gave dihydrolycolucine (3.1 mg after further purification by preparative tlc), and benzene–ether (7:1) gave crude spirolucidine (0.28 g). This was further purified by column chromatography over basic alumina (activity I) and then preparative tlc to provide 88 mg of spirolucidine (**2**) as a viscous oil. Infrared ($CHCl_3$): 2790 (N—CH_3), 1710 (ketone), 1630 (amide) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.82 (3H, d, J = 7 Hz), 0.89 (3H, d, J = 7 Hz), 2.03 (3H, s), 2.08 and 2.09 (3H, *N*-acetyl CH_3, two rotamers); ms *m/z*: 483 (M^+, 11%), 455 (100), 205 (99), 192 (69). *Mol. Wt.* calcd. for $C_{30}H_{49}N_3O_2$: 483.3825; found (hrms): 483.3828.

N-*Formylspirolucidine (4)*

Spirolucidine (**2**, 5.3 mg) was treated with acetic formic anhydride (1 mL) in CH_2Cl_2 (2 mL) at 0°C for 15 min, then at room temperature overnight. Methanol was added to decompose excess acetic formic anhydride and the reaction mixture was concentrated. The residue was dissolved in $CHCl_3$. The $CHCl_3$ extract was washed successively with 10% Na_2CO_3 solution, H_2O, and brine, then dried over anhydrous Na_2SO_4. The $CHCl_3$ extract was filtered and concentrated to give *N*-formylspirolucidine (**4**) (5.4 mg); ir ($CHCl_3$ cast): 2770, 1720, 1650 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.82 (d, CH_3), 0.94 (d, CH_3), 2.03, 2.06 (s, NCH_3 and $NCOCH_3$), 8.68 (s, 1, N—CHO); ms *m/z*: 511 (M^+, 34), 483 (37), 192 (100).

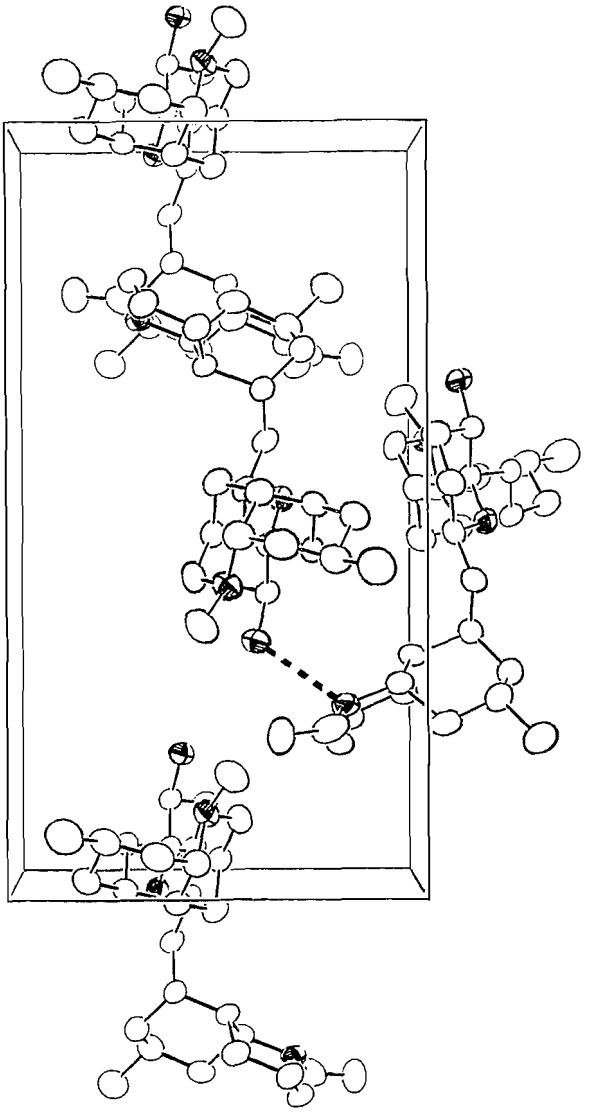

FIG. 2. Crystal packing diagram for tetrahydrodeoxyspirolucidine projected down the $-a$-axis of the unit cell. For clarity, only one of the three partially-occupied positions of C-21 is illustrated.

Dihydrospirolucidine (5)

Sodium borohydride (38 mg) was added to a stirred solution of spirolucidine (**2**, 28 mg) in methanol. The mixture was allowed to stir under a N_2 atmosphere overnight. The mixture was diluted with water and extracted with $CHCl_3$. The $CHCl_3$ extract was dried (anhydrous Na_2SO_4), filtered, and concentrated to give dihydrospirolucidine (**5**, 26 mg); ir ($CHCl_3$ cast): 3400 (br), 2780, 1620 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.81 (d, J = 6 Hz, CH_3), 0.86 (d, J = 6 Hz, CH_3), 2.06, 2.08, 2.12 (s, N—CH_3 and N—$COCH_3$ rotamers); ms *m/z*: 485 (M^+, 23), 467 (6), 207 (100), 205 (47).

O-*Acetyldihydrospirolucidine (6)*

Dihydrospirolucidine (**5**, 3.3 mg) was treated with acetic anhydride (0.5 mL) in pyridine (1 mL) under a N_2 atmosphere at room temperature overnight. The reaction mixture was concentrated *in vacuo* by azeotropic distillation with toluene to give *O*-acetyldihydrospirolucidine (**6**, 3.5 mg); ir ($CHCl_3$ cast): 1720, 1620, 1250 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.81 (d, J = 6 Hz, CH_3), 0.86 (d, J = 6 Hz, CH_3). 2.03, 2.04, 2.06, 2.07 (s, $OCOCH_3$, N—CH_3 and $NCOCH_3$ rotamers); ms *m/z*: 527 (M^+, 76), 467 (97), 333 (18), 319 (38), 273 (67), 259 (70), 205 (100).

Tetrahydrodeoxyspirolucidine (7)

Spirolucidine (**2**, 4.8 mg) in dry tetrahydrofuran was added to a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

stirred solution of lithium aluminum hydride (48 mg) in dry tetrahydrofuran (8 mL) under a N_2 atmosphere. The reaction mixture was heated under reflux for 3 hours, cooled, and excess lithium aluminum hydride destroyed by cautious addition of dry ethyl acetate, then water. The reaction mixture was filtered and extracted with $CHCl_3$. The $CHCl_3$ extract was dried (anhydrous Na_2SO_4) and concentrated to give tetrahydrodeoxyspirolucidine (**7**, 4.6 mg) which was crystallized from ether–pentane, mp 149–152°C; ir ($CHCl_3$ cast): 3370 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.85 (d, J = 6 Hz, CH_3), 0.89 (d, J = 6 Hz, CH_3), 1.10 (t, J = 7 Hz, NCH_2CH_3), 2.08 (s, NCH_3); ms m/z: 513 (M^+, 36), 453 (23), 178 (100).

Dihydrodeoxyspirolucidine (8)

Tetrahydrodeoxyspirolucidine (**7**, 3.2 mg) in acetone (3 mL) was treated with Jones' reagent (0.5 mL) under a N_2 atmosphere at room temperature for 30 min. Isopropyl alcohol was added to decompose unreacted oxidizer. The reaction mixture was filtered and concentrated. Purification by preparative tlc over alumina (ether–methanol, 98:2) gave dihydrodeoxyspirolucidine (**8**, 3.1 mg); ir ($CHCl_3$ cast): 1700 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.82 (d, J = 6 Hz, CH_3), 0.91 (d, J = 6 Hz, CH_3), 1.14 (t, J = 7 Hz, NCH_2CH_3), 2.03 (s, NCH_3); ^{13}C nmr ($CDCl_3$) δ: 213.6 (s, C=O); ms m/z: 469 (M^+, 18), 441 (77), 205 (86), 192 (86), 180 (55), 178 (100).

Deuterium exchange on 8

To a stirred solution of sodium deuteriomethoxide (prepared from Na (80 mg) and CH_3OD (0.5 mL)) was added a solution of dihydrodeoxyspirolucidine (**8**, 6.5 mg) in CH_3OD (0.5 mL) at room temperature under a N_2 atmosphere. D_2O (0.25 mL) was added and the reaction mixture was allowed to stir for 2 h. Further D_2O was added and the reaction mixture was extracted with $CDCl_3$ (total 15 mL). The organic extract was washed with D_2O (5 mL), H_2O (5 mL), dried (anhydrous Na_2SO_4), and concentrated to give a residue which was analyzed (ms) directly without further purification.

Single crystal X-ray diffraction analysis of tetrahydrodeoxyspirolucidine

Tetrahydrodeoxyspirolucidine crystallized as {110} rhombic prisms and the crystal data were the following.

$C_{30}H_{53}N_3O$ mw = 471.8

$P2_12_12_1$, a = 14.482(1) Å, b = 19.434(1) Å, c = 10.507(1) Å, V = 2957.1 Å^3, Z = 4, ρ_c = 1.06 gm cm^{-3}, $F(000)$ = 1048e, radiation Ni-filtered Cu K_α λ = 1.5418 Å, $2\theta_{max}$ = 140°, crystal dimensions (mm) 0.24 × 0.40 × 0.38, max. decay correction 1.05, temp. = 14°C.

A single crystal was mounted about the c-axis on an Enraf–Nonius CAD4F diffractometer and data were collected with an $\omega/2\theta$ scan. A total of 2177 reflections (of 3075 total) had net $I > 3\sigma(I)$ and these reflections were used in the analysis. The data were corrected for Lorentz and polarization effects. Observational weights (7) for the reflections were derived from the formula:

$$W = (2I)^2/|F_o|^2(T + (0.02I)^2 + r^2B)$$

where I is the net intensity, F_o is the observed structure amplitude, T is the total peak count, B is the sum of the background counts, and r is the ratio of the peak-scan time to the total background-counting time (r = 2 for these data).

An initial model of the structure was chosen from the E map of the MULTAN 80 (8) trial solution which had the lowest R_{Karle} (9) value, 0.182, but this model resisted least-squares refinement. Subsequently, the trial solution which had the second lowest R_{Karle} value, 0.195, was shown to be correct. The E map of this latter solution contained a fused tricyclic fragment of fourteen atoms which refined by least-squares methods. Subsequent difference maps and least-squares refinement led to the location of all of the nonhydrogen atoms of the molecule. The terminal carbon atom (C-21) of the ethyl group bonded to N-1′ is disordered in the crystal structure, and three statistically occupied positions were assigned to this atom with occupancies of 0.4, 0.4, and 0.2 based on peak heights from difference maps. All of the hydrogen atoms of the molecule were found except for those on C-21 and also for one hydrogen on C-20. Block diagonal least-squares refinement of the atomic parameters (anisotropic temperature factors for the nonhydrogens and isotropic for the hydrogens) converged to a final R index ($R = (\sum_{hkl} |F_o| - |F_c|)/\sum_{hkl} |F_o|$) of 0.047 and R_w = 0.049 ($R_w = (\Sigma W\Delta^2/\Sigma W|F_o|^2)^{1/2}$). Crystallographic computations were carried out using the XRAY 76 System (10) on the DEC 2060 computer at the University of Saskatchewan. The nonhydrogen atom coordinates are given in Table 1.[3]

Transference numbers and solvation studies in *n*-butanol

J. S. BANAIT, K. S. SIDHU, and J. S. WALIA
Department of Chemistry, Punjabi University, Patiala-147002, India

Received March 11, 1983

J. S. BANAIT, K. S. SIDHU, and J. S. WALIA. Can. J. Chem. **62**, 303 (1984).

Transference numbers of tetrabutylammonium bromide have been measured in *n*-butanol at 25°C in the concentration range 5.79−12.86 × 10^{-2} mol dm^{-3}. The variation of transference number with concentration is negligible. The limiting transference number of tetrabutylammonium ion has been determined by the Longsworth method. Combining the limiting transference number and limiting equivalent conductance of this salt, limiting ionic conductances of tetrabutylammonium and bromide ions have been found to be 8.05 and 8.02 ohm^{-1} cm^2 mol^{-1}, respectively. From these values limiting ionic conductances of other univalent ions, effective ionic radii and solvation numbers have been computed. The solvation numbers of anions have been found to be more than those of cations which shows the protic nature of this solvent.

J. S. BANAIT, K. S. SIDHU et J. S. WALIA. Can. J. Chem. **62**, 303 (1984).

On a mesuré les facteurs de transport de bromure de tétrabutylammonium dans le *n*-butanol à 25°C dans l'intervalle de concentration allant de 5,79 à 12,86 × 10^{-2} mol dm^{-3}. La variation du facteur de transfert en fonction de la concentration est négligeable. On a déterminé le facteur de transfert limite de l'ion tétrabutylammonium selon la méthode de Longsworth. En combinant le facteur de transfert limite et la conductivité équivalente limite de ce sel, on a trouvé que les conductances limites des ions tétrabutylammonium et bromures sont respectivement de 8,05 et de 8,02 ohm^{-1} cm^2 mol^{-1}. On a calculé, a partir de ces valeurs les conductances ioniques limites des autres ions univalents, les rayons ioniques effectifs et les facteurs de solvation. On a trouvé que le facteur de solvation des anions est plus élevé que ceux des cations; ceci montre la nature protique de ce solvant.

Introduction

Conductances of some alkyl substituted ammonium and alkali metal salts (1−3) in *n*-butanol have been reported. Due to the lack of transference number data, approximate limiting equivalent ionic conductances of various ions in this solvent have been computed on the basis of the Walden product of large ions and Kohlrausch's law of independent ion migration. However, this approximation has not been found satisfactory in many solvents (4−6). In order to evaluate limiting equivalent ionic conductances accurately, transference numbers of tetrabutylammonium bromide have been measured in *n*-butanol at 25°C using a modified Hittorf method. Effective ionic radii in solution and solvation numbers of ions have been calculated to throw light on ion−solvent interactions in this solvent.

Experimental

n-Butanol (BDH, Analar) was purified as described by Evans and Gardam (1). Freshly distilled solvent was used for each experiment and the physical constants (density, 0.80576 g mL^{-1}; viscosity, 2.589 cP; and specific conductance, $<2 \times 10^{-7}$ ohm^{-1} cm^{-1}) were checked before use.

Tetrabutylammonium bromide (Riedal pure) was crystallized from conductivity water and dried at 100°C in vacuum.

Transference numbers have been determined by Hittorf method. The apparatus and procedure were essentially the same as those reported by Paul *et al.* (7). The instruments have been calibrated and the precision of the results has been checked by determining the transference number of potassium chloride in water. A current of 0.5 to 2.0 mA was employed in various experiments. Transference numbers of anion have been determined by direct measurements and those of cation were put equal to $1 - t_-$.

In order to determine the concentration of the solutions after electrolysis, the solutions were analysed for bromide ions using Volhard's method (8).

Results and discussion

In view of the high resistance offered by the cell and the analytical difficulties, the measurements of transference numbers in *n*-butanol at 25°C have been carried out in a moderately high concentration range (5.79 −12.86 × 10^{-2} mol dm^{-3}). The results are given in Table 1. The cation transference numbers increase with an increase in concentration. However, the variation is very small. Variation of transference numbers with concentration can be written as (9):

TABLE 1. Transference numbers of tetrabutylammonium bromide in *n*-butanol at 25°C

Concentration (mol dm^{-3})	t_+	t_-
0.0000	0.5010	0.4990
0.0579	0.5015	0.4985
0.0866	0.5016	0.4984
0.1188	0.5018	0.4982
0.1286	0.5022	0.4978

$$[1] \quad \left(\frac{dt_\pm}{d\sqrt{C}}\right)_{C\to 0} = \frac{(t_\pm^0 - 0.5)\beta}{\Lambda_0}$$

where β is the electrophoretic parameter and all other symbols have their usual meanings.

It is clear from eq. [1] that the transference numbers of the ions increase with increasing concentration if they are more than 0.5 and decrease with increasing concentration if they are less than 0.5. It further shows that the closer the transference number of the ions are to 0.5, the less will be their variations with concentration. These conclusions have been verified by transference number measurements in various solvents (10−12). In the present study, the transference numbers of the ions are quite close to 0.5 and the variations with concentration are also negligible.

The limiting transference number ($t_\pm^0$) of tetrabutylammonium ion has been determined by using the Longsworth equation (13).

$$[2] \quad t_+^{0\prime} = \frac{t_+\Lambda' + (1/2)\beta C^{1/2}}{\Lambda' + \beta C^{1/2}} = t_+^0 + \beta' C$$

All the symbols have their usual meanings (13). While calcu-

For personal use only.

lating Λ' and $t_+^{0\prime}$ at different concentrations, C has been replaced by αC (α being the degree of dissociation) because of ion-association of tetrabutylammonium bromide. The value of α has been computed with the help of association constant of this salt ($K_A = 860$) in *n*-butanol. The plot of $t_+^{0\prime}$ versus C is linear and its extrapolation given a value of 0.5007.

Limiting ionic conductances ($\lambda_\pm^0$) of tetrabutylammonium and bromide ions have been determined by combining (14) the limiting transference numbers ($t_\pm^0$) of these ions with the limiting equivalent conductance (Λ_0) of tetrabutylammonium bromide (1). The limiting ionic conductances of tetrabutylammonium and bromide ions have been found to be 8.05 and 8.02 ohm^{-1} cm^2 mol^{-1} respectively. Evans and Gardam (1) have reported conductance studies of various uni-univalent electrolytes in *n*-butanol at 25°C. They have computed the limiting ionic conductances on the basis of the Walden product of tetraalkylammonium salts. The present values of limiting ionic conductances differ by 0.21 ohm^{-1} cm^2 mol^{-1} from those reported by Evans and Gardam. Limiting ionic conductances obtained by transference number methods and the approximate methods such as Walden product method, equal division of the limiting equivalent conductances of the reference electrolyte etc., have been found to differ by up to 0.5 ohm^{-1} cm^2 mol^{-1} in other solvents also (4, 5, 15). However, the values obtained by transference number method are considered more accurate. This is because the molecules of different solvents have different modes of interactions with the ions. Thus a single approximation cannot be generalised for all the solvents.

The limiting ionic conductance of various ions has been computed from the conductance data (1–3, 16) and the limiting ionic conductance of tetrabutylammonium and bromide ions (present work) using Kohlrausch's law of independent ion migration. A few ions are arranged in the order of decreasing ionic conductances in *n*-butanol.

$$Et_4N^+ > Me_4N^+ > Pr_4N^+ > Li^+ > Bu_4N^+ > (i\text{-}Am)_3BuN^+\ ClO_4^- > I^- > Br^- > Cl^-$$

The limiting ionic conductances of tetraalkylammonium ions (except that of tetramethylammonium ion) decrease with the increase in the size of the ions. This is in accordance with the findings in other solvents. These ions remain unsolvated because of their large size. However, tetramethylammonium ion, being smallest in the series, seems to be slightly solvated as its conductance does not fit into the pattern. In some other solvents also, this ion has been found to be solvated (4, 17).

Solvated radii, corrected solvated radii in solution, and the solvation numbers of various ions have been determined by the method reported by Paul *et al.* (18). All the relevant data are given in Table 2.

Perusal of Table 2 reveals that the solvation number of anions decreases with an increasing anion size, this is in accord with the findings in various solvents (4, 14, 18, 19). Chloride and bromide ions are more solvated in this solvent than lithium ion though the crystallographic radii of these ions are more than three times that of lithium ion, which shows that the anions are heavily solvated in this solvent. This is due to the superimposition of hydrogen bonding on anion–dipole interactions whereas cations are solvated due to the cation–dipole interaction only.

According to Parker's (20) classification of solvents, protic solvents solvate the anions more whereas in aprotic solvents, solvation of anions is very small. Comparison of solvation numbers of anions in *n*-butanol with those in other protic solvents shows that except in lower alcohols, the solvation numbers of anions in *n*-butanol are higher than those in most of the solvents (21).

TABLE 2. Limiting ionic conductance ($\lambda_\pm^0$), crystallographic (r_c)*, solvated (r_s), and corrected (r_{corr}) radii, and solvation numbers (N) of various univalent ions in *n*-butanol at 25°C

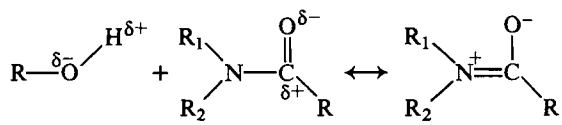
*Reference 22.

Higher solvation numbers of anions in alcohols than in other protic solvents like formamide, *N*-methylformamide, and *N*-methylacetamide can be explained on the basis of the structure of these solvent molecules:



The approach of the anions to the positive end of the solvent molecules is easier in alcohols and seems to be sterically hindered in other solvents.

Solvation numbers of alkali metal, ammonium, and silver ions decrease with the increase in the size of these ions in most of the solvents. However, in *n*-butanol lithium ions are less solvated than ammonium ions (Table 2). In tetramethyl urea (4) and *N*,*N*-dimethyl acetamide (15), sodium ions have been found to be less solvated than potassium ions. Barker and Caruse (17) have attributed this to the fact that smaller ions are comparatively less solvated in these solvents because of the large size of the solvent molecules. In *n*-butanol less solvation of lithium ions can also be explained on the basis of similar steric factors.

Synthesis of phthalideisoquinolines by direct coupling of phthalide anions with 3,4-dihydroisoquinolinium salts

RICHARD MARSDEN and DAVID B. MACLEAN[1]

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received July 19, 1983

RICHARD MARSDEN and DAVID B. MACLEAN. Can. J. Chem. **62**, 306 (1984).

The condensation of phthalide anions, derived from phthalide itself and from its 6,7- and 5,6-dimethoxy derivatives, with 6,7-dimethoxy-2-methyl-3,4-dihydroisoquinoline is described. The reaction products obtained in ca. 40% yield are easily separable mixtures of substituted (±)-*erythro* and (±)-*threo*-phthalidetetrahydroisoquinolines. The reaction is potentially useful for synthesis of naturally occurring akaloids of this family.

RICHARD MARSDEN et DAVID B. MACLEAN. Can. J. Chem. **62**, 306 (1984).

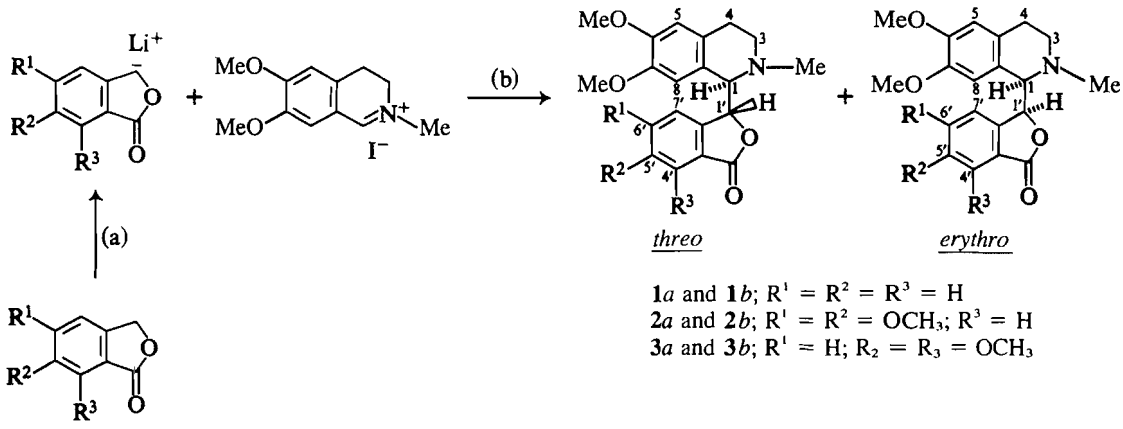
On décrit la condensation des anions phtalides, provenant du phtalide lui-même et de ses dérivés diméthoxy-6,7 et diméthoxy-5,6 sur la diméthoxy-6,7 méthyl-2 dihydro-3,4 isoquinoléine. Les produits de la réaction obtenus avec un rendement d'environ de 40% sont des mélanges facilement séparables de (±) *érythro* et de (±) *thréo* phtalidetétrahydroisoquinoléines substituées. La réaction est potentiellement utile pour la synthèse des alcaloïdes naturels de cette famille.

[Traduit par le journal]

Perkin and Robinson (1) reported in 1911 the first successful synthesis of a phthalideisoquinoline alkaloid, although in low yield, by treating cotarnine with meconin in boiling alcohol. Many synthetic approaches to these alkaloids have appeared in the intervening years, which are summarized in several reviews (2–6) and in a recent paper (7). Several reports describing new and efficient syntheses of these alkaloids based on the Perkin–Robinson approach have recently appeared. In 1979 a preliminary account appeared of the reaction between 3-halophthalides and 2-methyl-3,4-dihydroisoquinolinium salts in the presence of Zn metal or Zn–Cu couple (8) and a full account of this reaction was published in 1981 (7). The validity of this approach to phthalideisoquinoline alkaloid synthesis has recently been confirmed by Shono *et al.* (9) who carried out the same reaction in a different solvent system. The electrochemical coupling of bromophthalides and 3,4-dihydroisoquinolinium salts has also been reported (10). In another approach Prager *et al.* (11) have shown that 2-methylisoquinolinium salts condense with phthalides in the presence of sodium methoxide yielding adducts that may be reduced catalytically with hydrogen or with sodium cyanoborohydride to the 2-methylphthalidetetrahydroisoquinoline system present in the naturally occurring alkaloids. Prager *et al.* (11) noted that they were unable to carry out a similar addition to 3,4-dihydroisoquinolinium salts. In this laboratory we had encountered similar difficulties in the past. Now, however, by preparation of the phthalide anions at low temperature using LDA, we are able to report the direct coupling of phthalide anions with 3,4-dihydroisoquinolinium salts.

Phthalide anions have been prepared and used successfully by Broom and Sammes (12) as Michael donors. Sammes' group has also shown that they add to acyclic imines forming isoquinolones (13) and we have shown that they add to 3,4-dihydroisoquinolines (cyclic imines), forming in one step the berberine ring system (14). Their addition to iminium salts, derived from 3,4-dihydroisoquinolines, is described here.

The overall reaction is outlined in Scheme 1. The anion, prepared by treatment of the phthalide with LDA, was added to a slurry of the iminium salt in THF, both operations being conducted at low temperature. The reaction mixture was al-



(a) LDA, THF, −70°C
(b) THF, −70°C, then at room temperature

lowed to warm to room temperature and was worked up in the conventional manner, yielding the expected mixture of racemates in approximately equal amount and in an overall yield of approximately 40%. Attempts to improve the yield by variation of the reaction conditions were unsuccessful. Exchange of Li for Zn by treating the solution of Li phthalide with anhydrous $ZnCl_2$ before addition to the iminium salt did not improve the yield. Apparently deprotonation of the iminium salt competes with addition across the carbon–nitrogen double bond.

The racemic compounds prepared in this study have all been reported previously. Compounds **1***a* and **1***b* have recently been described by de Silva *et al.* (15), while the isocordrastines **2***a* and **2***b* (7, 16) and the cordrastines **3***a* (cordrastine I) and **3***b* (cordrastine II) (17–19) have been synthesized and examined by several groups. The structures of compounds **1**–**3** have been established by comparison of their properties with published data in the case of **1***a* and **1***b* or by direct comparison with samples previously prepared in this laboratory in the case of **2***a*, **2***b*, **3***a*, and **3***b*.

Through appropriate choice of substituted phthalide (now readily prepared by recently developed aromatic lithiation reactions (20–22)) and substituted 3,4-dihydroisoquinoline, this method should be applicable to the preparation of many of the naturally occurring alkaloids of this group (23).

Experimental

Apparatus, materials, and methods

The continuous wave ^{1}H nmr spectra were run on a Varian EM 390 spectrometer. Unless otherwise specified, the samples were dissolved in $CDCl_3$ using tetramethylsilane (TMS) as the internal standard. Chemical shifts, quoted as δ values, were measured in relation to TMS. The symbols s, singlet, d, doublet, q, quartet, and m, multiplet are used in reporting spectra.

Infrared spectra were recorded on a Perkin–Elmer 283 spectrometer in chloroform solution. Melting points were determined using a Gallenkamp apparatus and are uncorrected.

Thin layer chromatography (tlc) was performed using Polygram Sil G/UV_{254} plates. Preparative layer chromatography (plc) was performed using Silica Gel PF-254. Flash column chromatography was employed as described in the literature (24).

Diisopropylamine was refluxed over calcium hydride and distilled onto molecular sieves (4 Å). THF was dried by distillation from Na/benzophenone under a nitrogen atmosphere just prior to use. All the reactions described were carried out under a blanket of argon, using syringes and septa for transfer of reagents.

The following compounds were prepared by standard methods and gave satisfactory physical data: meconin (22), *m*-meconin (25), 6,7-dimethoxy-2-methyl-3,4-dihydroisoquinolinium iodide (26).

*6,7-Dimethoxy-2-methyl-1-phthalidyl-1,2,3,4-tetrahydroisoquinolines, 1*a *and 1*b

To a stirred solution of diisopropylamine (0.42 mL, 3 mmol) in dry THF (5 mL) at −10°C was added n-BuLi (2 mL of a 1.65 *M* solution in hexane, 3.3 mmol). After 5 min the LDA solution was cooled to −70°C (Dry Ice/acetone bath) and treated dropwise with a solution of phthalide (0.402 g, 3 mmol) in dry THF, producing initially an orange solution. Towards the end of the addition a suspension was observed; homogeneity was restored by adjusting the temperature to −35°C. After stirring at −35°C for 20 min the solution was added to a suspension of 6,7-dimethoxy-2-methyl-3,4-dihydroisoquinolinium iodide (1 g, 3 mmol) in dry THF at −35°C. Treatment and work up as for **2***a* and **2***b* below yielded a yellow oil which was subjected to flash chromatography (silica gel, applying the oil to the column in EtOAc/CH_2Cl_2, 1:1, then eluting with EtOAc) to give the following two components.

(a) *threo* Isomer **1***a*, 195 mg (19.2%), R_f 0.73 (silica gel, EtOAc), mp 165–167°C (from EtOH) (lit. (9) mp 163–164°C, (15) mp 168–170°C); ir ($CHCl_3$) ν_{max}: 1760 cm^{-1} (γ-lactone); ^{1}H nmr δ: 2.1–3.4 (4H, m, C-3 and C-4 H's), 2.66 (3H, s, —NCH_3), 3.69 (3H, s, —OCH_3), 3.78 (3H, s, —OCH_3), 4.14 (1H, d, J = 4 Hz, C-1 H), 5.72 (1H, d, J = 4 Hz, C-1′ H), 6.33 (1H, s, C-8H), 6.69 (1H, s, C-5H), 7.2–7.9 (4H, m, C-4′, 5′, 6′ and 7′ H's).

(b) *erythro* Isomer **1***b*, 215 mg (21.1%), R_f 0.34 (silica gel, EtOAc), oil; ir ($CHCl_3$) ν_{max}: 1760 cm^{-1} (γ-lactone); ^{1}H nmr δ: 2.2–2.3 (4H, m, C-3 and C-4 H's), 2.58 (3H, s, —NCH_3), 3.60 (3H, s, —OCH_3), 3.85 (3H, s, —OCH_3), 4.11 (1H, d, J = 4 Hz, C-1 H), 5.72 (1H, d, J = 4 Hz, C-1′ H), 6.25 (1H, s, C-8 H), 6.62 (1H, s, C-5 H), 6.95–7.1 and 7.4–7.9 (4H, m, C-4′, 5′, 6 and 7′ H's). The picrate of **1***b* was obtained as a yellow crystalline powder, mp 209–211°C (from MeOH) (lit. (9, 15) mp 208–210°C).

Isocordrastines **2**a *and* **2**b

An LDA (3 mmol) solution, prepared as described above, was treated dropwise with a solution of *m*-meconin (0.582 g, 3 mmol) in dry THF. The resulting clear orange solution was stirred for 20 min at −70°C and added dropwise to a suspension of 6,7-dimethoxy-2-methyl-3,4-dihydroisoquinolinium iodide (1 g, 3 mmol) in dry THF at −70°C. The mixture was kept at this temperature for 20 min, then allowed to warm to room temperature and stirred overnight. The THF was evaporated, 10% HCl (40 mL) added, and the aqueous phase extracted with CH_2Cl_2. The organic extracts were discarded and the acidic aqueous layer neutralized (to pH 7–9) with aqueous NaOH. Extraction with CH_2Cl_2, drying (Na_2SO_4), and evaporation of the solvent gave a yellow oil which was subjected to flash chromatography (silica gel, initial eluant EtOAc to obtain the faster running isomer, then EtOAc + 10% MeOH to recover the slower running isomer), yielding the following two components.

(a) *threo*-Isocordrastine **2***a*, 290 mg (24.2%), R_f 0.4 (silica gel, EtOAc), mp 146–148°C (from EtOH) (lit. (16, 27), mp 115–117°C, (7) mp 144–146°C; ir ($CHCl_3$) ν_{max}: 1755 cm^{-1} (γ-lactone); ^{1}H nmr δ: 2.3–3.3 (4H, m, C-3 and C-4 H's) 2.70 (3H, s, —NCH_3), 3.72 (3H, s, —OCH_3), 3.79 (3H, s, —OCH_3), 3.83 (3H, s, —OCH_3), 3.94 (3H, s, —OCH_3), 4.11 (1H, d, J = 4 Hz, C-1 H), 5.62 (1H, d, J = 4 Hz, C-1′H), 6.33 (1H, s, C-5 H), 6.69 (1H, s, C-8 H), 7.03 (1H, s, C-4′ H), 7.15 (1H, s, C-7′ H).

(b) *erythro*-Isocordrastine **2***b*, 240 mg (20.1%), R_f 0.08 (silica gel, EtOAc), mp 170–171°C (from EtOH) (lit (7, 9) mp 169–171°C); ir ($CHCl_3$) ν_{max}: 1750 cm^{-1} (γ-lactone); ^{1}H nmr δ: 2.1–3.2 (4H, m, C-3 and C-4 H's), 2.58 (3H, s, —NCH_3), 3.70 (3H, s, —OCH_3), 3.80 (3H, s, —OCH_3), 3.85 (3H, s, —OCH_3), 3.92 (3H, s, —OCH_3), 4.12 (1H, d, J = 4 Hz, C-1 H), 5.58 (1H, d, J = 4 Hz, C-1′ H), 6.29 (1H, s, C-7′ H), 6.38 (1H, s, C-8 H), 6.63 (1H, s, C-5 H), 7.26 (1H, s, C-4′ H).

Cordrastines **3**a *and* **3**b

An LDA solution (3 mmol), prepared as described above, was treated dropwise with a solution of meconin (0.582 g, 3 mmol) in dry THF. Treatment of the clear orange solution as in the preparation of the isocordrastines gave, after work-up, an orange oil. Flash chromatography (silica gel, initial eluant $CHCl_3$ + 1.5% MeOH to obtain the faster running isomer, then $CHCl_3$ + 2% MeOH to recover the slower running isomer) gave the following two components.

(a) *threo*-Cordrastine **3***a*, 270 mg (26.2%), R_f 0.41 (silica gel, EtOAc), mp 158–159°C (from EtOH) (lit. (17), mp 156–157°C); ir ($CHCl_3$) ν_{max}: 1760 cm^{-1} (γ-lactone); ^{1}H nmr δ: 2.3–3.2 (4H, m, C-3 and C-4 H's) 2.65 (3H, s, —NCH_3), 3.74 (3H, s, —OCH_3), 3.81 (6H, s, 2 × —OCH_3), 3.90 (3H, s, —OCH_3), 4.06 (1H, d, J = 4 Hz, C-1 H), 5.69 (1H, d, J = 4 Hz, C-1′H), 6.36 (1H, s, C-5 H), 6.71 (1H, s, C-8 H), 7.02 and 7.33 (2H, ABq, J = 8.5 Hz, C-6′ and C-7′ H's, respectively).

(b) *erythro*-Cordrastine (cordrastine II), **3b**, 225 mg (18.8%), R_f 0.09 (silica gel, EtOAc), oil; ir ($CHCl_3$) ν_{max}: 1765 cm^{-1} (λ-lactone); ^{1}H nmr δ: 2.3–3.2 (4H, m, C-3 and C-4 H's), 2.60 (3H, s, —NCH_3), 3.67 (3H, s, —OCH_3), 3.87 (3H, s, —OCH_3), 3.91 (3H, s, —OCH_3), 4.03 (3H, s, —OCH_3), 5.57 (1H, d, J = 4 Hz, C-1′ H), 6.29 (1H, s, C-8 H), 6.63 (1H, s, C-5 H), 6.59 and 7.14 (2H, ABq,

J = 8.5 Hz, C-7′ and C-6′ H's, respectively). The doublet at ca. 4.05 ppm is partially obscured by the singlet appearing at 4.03 ppm.

The picrate of **3***b* was obtained as a yellow crystalline powder, mp 204–205°C (lit. (9) mp 205°C, (17) mp 208°C).

When an ethanol/ether solution of the oil was seeded with an authentic sample of cordrastine II, crystals were deposited, mp 119–120°C (lit. (17, 18) mp 117–119°C.

Synthetic cardenolides and related products. IV.[1] *D*-homo derivatives

J. M. FERLAND and Y. LEFEBVRE

Ayerst Research Laboratories, Montréal, P.Q., Canada H3C 3J1

Received June 1, 1983

J. M. FERLAND and Y. LEFEBVRE. Can. J. Chem. **62**, 309 (1984).

The synthesis of novel structures related to naturally occurring cardiotonic agents such as resibufogenin is described. These products retain the essential features of aglycones needed for biological activity. They are, however, thermodynamically stable and easily available from smilagenin. The methods of preparation, together with the proof of structures and configuration, are reported.

J. M. FERLAND et Y. LEFEBVRE. Can. J. Chem. **62**, 309 (1984).

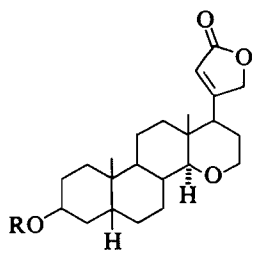
On a synthétisé de nouveaux agents isomères de cardénolides naturels tels la résibufogénine. Ces produits retiennent les caractéristiques essentielles à l'activité biologique des aglycones. Ils sont cependant thermodynamiquement stables et ont été préparés à partir de la smilagénine, un produit naturel abondant. Les méthodes de synthèses ainsi que les preuves de structure et de configuration sont décrites.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

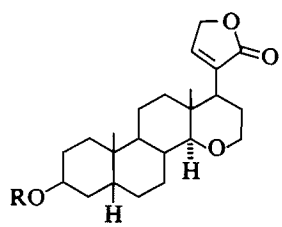
Naturally occurring cardenolides exist in a thermodynamically unfavoured configuration (2): 17β-side chain, 14β-orientation, A/B and C/D *cis*-fused rings, and 3β-oriented substituents.

The preparation of such compounds is relatively difficult as emphasized by Sondheimer (2) in his review on "Synthesis in the Cardiac Active Steroid Field". However, these stereochemical features are important and often slight modifications will result in a net loss of biological activity (3, 4). It is also known that the synthetic cardenolides (1*a*), with a lactone isomeric to the natural one, retain biological activity (5).

It appeared interesting to synthesize compounds of types **A** and **B** which would retain the essential features of natural and synthetic aglycones, but would be thermodynamically more stable and easily available from the abundant smilagenin.

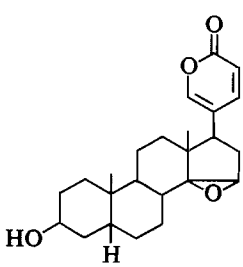


A

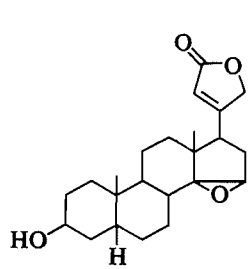


B

These products are analogous to the naturally occurring 14β,15β-oxido-steroids, such as resibufogenin **C**, or to 14β,15β-oxido-anhydrodigitoxigenin **D**, which are known to exhibit cardiotonic activity (6) insofar as the 15-oxygen of the *D*-homo-15-oxa ring of compounds **A** and **B** has the same configuration as the oxygen of the epoxide functions of compounds **C** and **D**.



C



D

[1]For parts I–III, see ref. 1.

The key intermediate for such a synthesis was the 5β-androstan-15-one derivative **7**. This product was obtained from smilagenin which was degraded to the 17-ketone **1**. The latter was then transformed into ketone **7** by a route described by Kelly and Sykes (8). In order to differentiate between the 3- and the 17-hydroxyls in **7**, appropriate protecting groups had to be selected. These reactions are summarized in Scheme 1.

The stereochemistry of ketone **7** was confirmed by circular dichroism and optical rotary dispersion curves which showed a positive Cotton effect (9).

As shown in Scheme 2, the Baeyer–Villiger oxidation of ketone **7** to lactone **8** gave the expected rearrangement (10) with retention of configuration in C14 (11). Indeed, the coupling constant of the 14α-proton with the 8β-hydrogen (dihedral angle of 180°) is equal to $J = 10$ Hz. This is in agreement with reported values (12*b*) for lactones in ring A of steroids.

The lactone **8** was then hydrogenolysed to the cyclic ether **9** (13). The removal of the 3-chloroacetate (**9** → **10**) was not as selective as expected, and the amount of sodium bicarbonate used had to be carefully controlled in view of the ease of hydrolysis of the 17-acetate. This facile hydrolysis is most probably due to an anchimeric assistance from the 14β-oxygen, which is only possible with the proposed stereochemistry. The diol **11**, always present in the hydrolysis reaction, was oxidized to the dione **14**. Protection of the 3-OH in **10** as the THP ether, followed by hydrolysis of the 17-acetate and subsequent oxidation with the $Et_3N—SO_3$ complex afforded the 17-ketone **13**. Those reactions are described in Scheme 2.

The ketone **13** was then treated with 3-furyllithium to give two isomeric furyl derivatives **15** and **16** in a proportion of 2:1. These products were isolated and identified as the 3-acetyl derivatives **15***b* and **16***b*.

As expected (14), the 17α-furyl derivative **15** was the major isomer isolated. The nmr data (Table 1) are indicative of the proposed stereochemistry for products described in Scheme 3. The 18-CH_3 of products **15***b* and **17** with a 17α-furyl substituent is strongly deshielded in comparison with the 18-CH_3 of products **16***b* and **18** where the furyl moiety has the 17β-configuration. In the furyl derivatives **16**, it is interesting to note the deshielding of the 14α-proton *cis* to the 17β-hydroxyl group. This phenomenon is analogous to the one observed (15) with 17β-H, 14β-OH that exists in some naturally occurring cardenolides.

The unsaturated furyl derivative **17** was obtained on treat-

TABLE 1. Characteristic nuclear magnetic resonance of 17-substituted ethers (δ)

Products	14-H	18-CH_3	19-CH_3
15 (R = Ac)	2.86 (d, J = 8.5 Hz)	1.16	0.97
16 (R = Ac)	3.48 (d, J = 8.0 Hz)	0.86	0.95
17 (R = Ac)	3.05 (d, J = 9.0 Hz)	1.16	1.00
18 (R = Ac)	2.80 (d, J = 8.0 Hz)	0.84	0.96

ment of the 17-alcohols **15***b* and **16** with phosphorus oxychloride or from **15***b* when stirred in presence of 4 *N* HCl. Under the latter conditions the *trans*-diaxial alcohol **16***b* remained unchanged. These results can only be explained by a steric decompression resulting from the removal of the furyl moiety from the concave face of the molecule.

Hydrogenation of the unsaturated furyl derivative **17** yielded product **18**. The lactones **19** and **20** were obtained by oxidation (1*a*, 1*c*) of the furyl derivative **18** with *N*-bromosuccinimide for **20** and with peracetic acid followed by sodium borohydride reduction for **19**.

These lactones were found to be devoid of cardiotonic activity.

Experimental

Melting points are uncorrected. The ir spectra were taken on a Perkin–Elmer 225 ir spectrophotometer and nmr were recorded on a Varian A-60A spectrometer operating at 60 MHz; TMS was used as internal standard. Merck silica gel 60 (60–230 mesh) was used. The $[\alpha]_D$ were taken at 20–23°C in 1% chloroform solutions. Otherwise, the solvent is mentioned.

3β-Hydroxy-15-benzyloxy-5β-androstan-17-one (**4**a)

This product was prepared from **1** (**7**) following the methods described by Kelly and Sykes (8) in the androst 5-ene series. It was purified by chromatography (silica gel; EtOAc/hexane, 1:1), yield 62% as an oil; nmr ($CDCl_3$): 1.03 (C18—CH_3), 1.17 (C19—CH_3), 4.11 (C3 and C15—H), 4.33, 4.50, and 4.60 (unresolved peaks for —$OCH_2\phi$) and 7.30 (5 aromatic H) ppm.

In Table 2 are found some analytical data of the intermediates leading to product **4***a*.

15-Benzyloxy-3β-tetrahydropyranyloxy-5β-androstran-17-one (**4**b)

To a solution of the 3-OH derivative **4***a* (125 g) in $CHCl_3$ (5 L) and dihydropyran (600 mL) was added a solution of phosphorous oxychloride (2 drops) in EtOAc (10 mL). The reaction mixture was stirred at 50°C for 4 hours. The mixture was washed with water, 5% $NaHCO_3$, water, dried, and evaporated. The crude product was chromatographed on silica gel (hexane/EtOAC, 17:3) to give the title product (125 g) as an oil, yield 83%; nmr ($CDCl_3$): 1.01 (C19—CH_3), 1.17 (C18—CH_3), 3.67 (CH_2O—THP), 4.0 (C3 and C15—H), 4.33 and 4.57 (ϕCH_2O—), 4.65 (OCHO—THP), and 7.33 (5 aromatic H) ppm.

17β-Acetyloxy-15-benzyloxy-3β-tetrahydropyranyloxy-5β-androstane (**4**c)

To a solution at 0°C of the 17-ketone **4***b* (125 g) in methanol (6.25 L) was slowly added sodium borohydride (125 g) in water (1.25 L). The mixture was then stirred at room temperature for one hour and poured into ice-cold water. The solid obtained was filter dried and acetylated (pyridine/acetic anhydride). The product obtained was chromatographed on silica gel (hexane/EtOAc, 3:1) to give the title product (105 g) as an oil, yield 77%, nmr ($CDCl_3$): 0.80 (C18—CH_3), 0.97 (C19—CH_3), 2.03 (OAc), 3.55 (CH_2O—THP), 3.9 and 4.38 (ϕCH_2O—), 4.62 (OCHO—THP), and 7.28 (5 aromatic H) ppm.

17β-Acetyloxy-3β-chloroacetyloxy-15-benzyloxy-5β-androstane (**4**d)

A solution of the THP–ether (**4***c*) (105 g) in ethanol (2.6 L) and 0.1 *N* HCl (1.1 L) was stirred at 45°C for 4 hours. The ethanol was evaporated to half of its initial volume and the remaining solution poured into ice cold water. The crude alcohol obtained was filtered and dried (85 g). A sample was crystallized from CH_2Cl_2/hexane, yield 65%, mp 177–179°C; ir ($CHCl_3$): 3620, 3480, 1728, 1250, and 1027 cm^{-1}; nmr ($CDCl_3$): 1.0 (C18–CH_3), 1.05 (C19—CH_3), 1.72 (OH), 2.03 (OAc), 4.1 (C3 and C15—H), and 4.52 (C17—H, J = 8.5 Hz) ppm. *Anal.* calcd. for $C_{21}H_{34}O_4$: C 71.96, H 9.78; found: C 71.48, H 9.44. To this alcohol in dioxane (680 mL) and pyridine (170 mL) at 10°C was added, over a period of 15 minutes, a solution of chloroacetylchloride (51 mL) in dioxane (150 mL). The reaction mixture was stirred at 10°C for 10 min. It was then diluted with ether. The organic solution was washed once with water, then with brine, dried, and evaporated. The crude product obtained was chromatographed on silica gel (hexane/EtOAc, 3:1) to give **4***d* (83 g).

A solution of this derivative (65 g) in glacial acetic acid was hydrogenated at room temperature and atmospheric pressure over 10% Pd/C (16 g). The catalyst was removed by filtration and the acetic acid evaporated under reduced pressure. The residue was dissolved in EtOAc and the organic solution washed with $NaHCO_3$, brine, dried,

2*c*	MeOH/H_2O	210–212	95			
3*a*[a,b]	Ether/hexane	150–152	78	0.91	1.00	3620, 3480, 1665, and 1030
3*b*[b]	Acetone/H_2O	160–165	95			

[a]This product analyzed for $C_{21}H_{32}O_3$; C 75.86, H 9.70; found: C 75.51, H 9.73.
[b]The 3-phenylmethyloxy-(**16***a*, *b*) or the *tert*-butylsilyloxy-derivative (**16***c*) of these products has already been described.

and evaporated. The crude 17β-acetyloxy-3β-chloracetyloxy-15-hydroxy-5β-androstane (**5**) obtained (51 g) was used as such for the following reaction. The nmr ($CDCl_3$): 1.02 (C18—CH_3), 1.05 (C19—CH_3), 2.03 (OAc), 4.05 ($ClCH_2CO$), 4.53 (C17—H), and 5.20 (C3—H) ppm.

*17β-Acetyloxy-5β-androstane-3,16-dione (**6**)*

A mixture of 3-chloroacetyloxy-15-hydroxy derivative (**5**) (4.6 g) and $KHCO_3$ (1.3 g) in methanol (330 mL) and water (70 mL) was heated at reflux for 3 hours. Most of the methanol was evaporated under reduced pressure and the residue was taken into EtOAc. The organic solution was washed with brine, dried, and evaporated. The crude product obtained (4.8 g) was chromatographed on silica gel (toluene/EtOAc, 1:1).

The 3,15-diol obtained (3.3 g) was dissolved in acetone (150 mL) and oxidized at 0°C with 8 *N* Jones' reagent (4 mL). After 10 min the excess reagent was destroyed and the mixture concentrated under reduced pressure. It was then taken into EtOAc and the organic solution washed with brine, dried, and evaporated. The crude product obtained (2.3 g) was crystallized 3 times from acetone/hexane to give the pure title product (1.6 g), mp 170–172°C, $[\alpha]_D$ +60.2°; ir ($CHCl_3$): 1732 and 1704 cm^{-1}; nmr ($CDCl_3$): 0.90 (C18—CH_3), 1.05 (C19—C_3), 2.09 (OAc), and 5.00 (C17—H, t, J = 8.5 Hz) ppm. *Anal.* calcd. for $C_{21}H_{30}O_4$: C 72.80, H 8.73, found: C 72.86, H 8.82.

*17β-Acetoxy-3β-chloroacetoxy-5β-androstane-15-one (**7**)*

Jones' reagent was added dropwise (40 mL) to a stirred solution in acetone, at 0°C of the 15-OH derivative **5** (51 g) (obtained from the 17-ketone **1**). The mixture was stirred for 10 more minutes after the addition and the excess reagent destroyed with isopropanol. Most of the acetone was evaporated under reduced pressure and the residue was partitioned between ethyl acetate and water. The organic layer was washed with salt-saturated water, dried, and evaporated. The product obtained was chromatographed on silica gel (hexane/EtOAc, 3:1) to give the title compound (37 g). An analytical sample was crystallized twice from EtOAc/hexane, yield 62%, mp 148–150°C, $[\alpha]_D$ +35.4°; ord (*c* 8.5 mg/mL; dioxan) 20°C $[\phi]_{350}$ +2100°; $[\phi]_{322}$ +7000°; $[\phi]_{298}$ 0°; cd mμ (ΔE): 320 (+0.501), 301 (+2.90), 274 (+0.50); ir ($CHCl_3$): 1735 cm^{-1}; nmr ($CDCl_3$): 0.87 (C18—CH_3), 1.00 (C19—CH_3), 2.07 (OAc), 2.05 and 2.80 (H16 and H16′, 2d, $J_{16,16'}$ = 18 Hz, $J_{16,17}$ = $J_{16',17}$ = 8.5 Hz), 4.06 (CH_2Cl), 4.97 (H17, m), and 5.20 (H3, m) ppm. *Anal.* calcd. for $C_{23}H_{33}ClO_5$: C 65.01, H 7.84, Cl 8.35; found: C, 64.92, H 7.90, Cl 8.13.

*17β-Acetoxy-3β-chloroacetoxy-5β-D-homo-15-oxaandrostan-15-one (**8**)*

To a solution in CH_2Cl (720 mL) at 0°C of the 15-ketone **7** (36 g) was added bicarbonate (27 g) and *m*-chloroperbenzoic acid (36 g). The mixture was stirred at room temperature for 16 h, then heated under reflux for 2 h. The organic solution was washed in succession with ice-cold water, sodium sulfite, sodium bicarbonate, water, dried, and evaporated. The crude product obtained was chromatographed on silica gel (hexane/EtOAc, 2:1) to give the title compound (31 g).

The analytical sample was crystallized twice from acetone, yield 85% mp 220–222°C, $[\alpha]_D$ −34.8°; ir ($CHCl_3$): 1735 cm^{-1}; nmr ($CDCl_3$): 1.00 (C18 and C19—CH_3), 2.08 (17–OAc), 2.46, 3.18 (H16,16′, 2d for each proton, $J_{16,16'}$ = 18.5 Hz, $J_{16,17}$ = 9 Hz, $J_{16',17}$ = 8.5 Hz), 4.06 (CH_2Cl), and 3.68 (C14—H, d, J = 10 Hz) ppm. *Anal.* calcd. for $C_{23}H_{33}O_6Cl$: C 62.66, H 7.49; found: C 62.50, H 7.60.

*17-aβ-Acetoxy-3β-hydroxy-5β-D-homo-15-oxaandrostane (**10**)*

A solution of lactone **8** (31 g) in glacial acetic acid (750 mL) was hydrogenated over platinum oxide 85% (10.0 g) at atmospheric pressure and room temperature until no more hydrogen was absorbed (72 h). The catalyst was removed by filtration and the filtrate evaporated under reduced pressure to one-third of its initial volume. It was then diluted with ethyl acetate and the organic solution washed carefully with bicarbonate solution, salt-saturated water, dried, and evaporated. The crude product obtained was chromatographed on silica gel (pet. ether 60–80°C/ether, 2:1) to give the 17β-acetoxy-3β-chloroacetoxy-5β-D-homo-15-oxaandrostane (**9**) (25 g).

To a solution of this product (25 g) in methanol (2.4 L) was added a solution of potassium bicarbonate (6.0 g) in water (600 mL) over a period of 5 minutes. The mixture was heated under reflux for 2 hours. It was then poured into ice-cold water and the solid obtained filtered. It was chromatographed on silica gel (benzene/EtOAc, 3:1). The faster moving compound was the title product **10** (15 g).

The analytical sample was crystallized twice from methanol–water, yield 87%, mp 186–188°C, $[\alpha]_D$ −26.9°; ir ($CHCl_3$): 3620, 3480, 1715, 1240, 1110, and 1025 cm^{-1}; nmr ($CDCl_3$): 0.97 (C18 and C19—CH_3), 1.62 (OH), 2.03 (OAc), 2.69 (C14—H, d, J = 8 Hz), and 3.50 – 4.00 (C15—CH_2O,m) ppm. *Anal.* calcd. for $C_{21}H_{34}O_4$: C 71,96, H 9.78; found: C 71.99, H 9.92.

The slower moving compound (2.5 g) was assumed to be the 3,17-diol **11** and was oxidized with Jones' reagent as in **7**. The crude product obtained (1.6 g) was crystallized twice from acetone–hexane to give the pure 5β-D-*homo-15-oxaandrostane-3-17a-dione* (**14**), mp 158.160°, $[\alpha]_D$ −52.5°; ir ($CHCl_3$): 1700 and 1104 cm^{-1}; nmr ($CDCl_3$): 1.04 (C18—CH_3), 1.20 (C19—CH_3), 2.91 (C14—H, d, J = 9.0 Hz), and 3.33, 4.53 (C15—H, m) ppm. *Anal.* calcd. for $C_{19}H_{28}O_3$: C 74.96, H 9.27; found: C 74.79, H 9.34.

*3β-Acetoxy-17aβ-hydroxy-17α-[3-furyl]-5β-D-homo-androstane (**15**b) and 3β-acetoxy-17aα-hydroxy-17β-[3-furyl]-5β-D-homo-androstane (**16**b)*

A solution of phosphorous oxychloride (4 drops) in ethyl acetate (10 mL) was added to a solution at 50°C of the 3-OH, 17-aβ-acetate (**10**) (11.5 g) in chloroform (480 mL) and dihydropyran (50 mL). The mixture was stirred at this temperature for 1-1/2 hours, cooled, and washed carefully with 10% sodium bicarbonate solution and water. The organic layer was then dried, evaporated, and chromatographed on silica gel (hexane/ether, 1:1) to give the 3-tetrahydropyranyl ether derivative (*12a*) (15.5 g) as an oil which was used as such for the subsequent reaction.

To a solution of the 17-acetate (**12***a*) (15.5 g) in methanol (800 mL) was added a solution of potassium bicarbonate (5.0 g) in water (200 mL). The mixture was then heated under reflux for 1 hour. Most of the methanol was evaporated and the remaining oil was extracted with ethyl acetate. The organic solution was washed with water, dried,

For personal use only.

and evaporated to give the *17-alcohol* (**12***b*) (14.5 g) which was used as such for the following reaction.

To a solution at room temperature of **12***b* (14.5 g) in DMSO (40 mL) and triethyl amine (42 mL) was added dropwise, over a period of 10 min, a solution of NEt_3—SO_3 complex (17.3 g) in DMSO (70 mL). The mixture was stirred for 1 hour, poured into water, and the solution neutralized to pH 3–4 with 1 *N* HCl. The solid obtained was filtered, washed with water, and dried. The crude 17-ketone (**13**) (14 g) was used as such for the following reaction.

A solution of this ketone (3.2 g) in anhydrous ether (100 mL) was added slowly to a solution of 3-furyl lithium (prepared at −70°C from 3-bromofuran (1.54 g) in anhydrous ether (60 mL) and 20% butyl lithium (2.94 mL)) maintained at −70°C. The mixture was then stirred at room temperature for 1 hour. Salt-saturated water was carefully added to the mixture. The organic layer was then washed with brine, dried, and evaporated. The crude product obtained was chromatographed on silica gel (Et_2O/pet. ether 60–110°C) to get a mixture of **15***a* and **16***a* (1.72 g); ir ($CHCl_3$): 3600, 3450, 1495, 1100, 1018, and 870 cm^{-1}; nmr ($CDCl_3$): 0.87 and 0.95 (C18—CH_3), 1.17 (C19—CH_3), 2.91 (C14—H, d, J = 9 Hz), 4.70 (OCHO, THP), 6.67 (C4′—H), 7.50 (C3′—H, m), and 7.64 (C2′—H, m) ppm.

A solution of these ethers (1.6 g) in ethanol (40 mL) and 0.1 *N* sulfuric acid (15 mL) was heated at 40°C for 4 hours. The crude alcohols isolated (1.3 g) were acetylated (pyridine/acetic anhydride) and the crude 3-acetate derivatives isolated were chromatographed on silica gel (ether/pet. ether 30–60°C, 3:1). The faster moving product (0.95 g) was crystallized twice from methanol–ether to give the pure *3β-acetoxy-17aβ-hydroxy-17α-[3-furyl], 5β-D-homo-15-oxaandrostane (15*b) mp 205–208°C $[\alpha]_D$ −7.1°; ir ($CHCl_3$): 3410, 1720, 1495, 1230, 1018, and 865 cm^{-1}; nmr ($CDCl_3$): 0.97 (C19—CH_3), 1.16 (C18—CH_3), 1.83 (17–OH), 2.03 (3-$OCOCH_3$), 2.86 (C14—H, d, J = 8.5 Hz), 6.56 (C4′—H,m), 7.40 (C5′—H, t, J = 1,5 Hz), and 7.53 (C2′—H, m) ppm. *Anal.* calcd. for $C_{25}H_{36}O_5$: C 72.08, H 8.71; found: C 72.21, H 8.81.

The fractions containing only the slower moving product were evaporated and the product obtained (0.090 g) was crystallized twice from CH_2Cl_2/EtOH/hexane to give *the pure 17β-[3-furyl]-derivative* (**16**b), mp 251–253°C, $[\alpha]_D$ −10.5°; ir ($CHCl_3$): 3600, 3460, 1720, 1577, 1495, and 868 cm^{-1}; nmr ($CDCl_3$): 0.86 (C18—CH_3), 0.95 (C19—CH_3), 1.74 (C17—OH), 2.05 (3-$OCOCH_3$), 3.48 (C14—H, d, J = 10 Hz, and 7.40 (C2′and C5′—H, m) ppm. *Anal.* calcd. for $C_{25}H_{36}O_5$: C 72.08, H 8.71; found: C 71.76, H 8.63.

*3β-Acetoxy-17a-[3-furyl]-5β-*D*-homo-15-oxaandrost-16-ene (**17**)*

Method A

A solution of the mixture of 17α- and 17β-[3-furyl]-3-THP ethers (**15***a* and **16***a*) (1.73 g) in ether (200 mL) and CH_2Cl_2 (70 mL) was stirred at room temperature for 1 hour in presence of 4 *N* HCl in water. After dilution with more ether, the organic phase was washed with brine until neutral, dried, and evaporated. The crude product obtained (1.25 g) was acetylated (pyridine/acetic anhydride). The crude 3-acetates obtained (1.3 g) were chromatographed on silica gel (ether/pet. ether 30–60°C, 2:1). The faster moving product (0.570 g) was crystallized from ether–methanol to give the pure title product **17** (0.475 g), mp 147–149°C, $[\alpha]_D$ +63.7; ir ($CHCl_3$): 1720, 1650, 1560, 1490, and 870 cm^{-1}; uv (MeOH): λ_{max} 224, ϵ 5500; nmr ($CDCl_3$): 1.00 (C18—CH_3), 1.16 (C19—CH_3), 2.05 (3-$OCOCH_3$), 3.05 (C14—H, d, J = 9 Hz), 4.34 (C15—H, d, J = 3 Hz), 5.64 (C16—H, t, J = 3 Hz), 6.40 (C4′—H, m), and 7.38 (C2′—H and C5′—H, m) ppm. *Anal.* calcd. for $C_{25}H_{34}O_4$: C 75.34, H 8.60; found: C 75.25, H 8.38.

The slower moving product (0.320 g) was isolated and proved to be identical (mp, ir and nmr spectroscopy, and $[\alpha]_D$) with the 17β-derivative **16***b* described above (0.19 g after crystallization).

Method B

A solution of the 17β-[3-furyl]-3 acetate derivative **16***b* (0.2 g) in pyridine (5 mL) and phosphorous oxychloride (0.62 mL) was heated at 100°C for 16 h. The cold solution was then poured onto ice-cold water and the solid obtained filtered and taken into ethyl acetate. The organic solution was washed with water, 10% sulfuric acid solution, brine, dried, and evaporated. The crude product obtained was chromatographed on silica gel (pet. ether 30–60°C/ether, 4:1). The product obtained was crystallized (0.120 g) and proved to be identical (mp, ir and nmr spectroscopy, and $[\alpha]_D$) with the unsaturated product **17**.

Under similar conditions **15***b* also yielded **17**.

*3β-Acetoxy-17aβ-[3-furyl]-*D*-homo-5β-androstane (**18**)*

A solution of the unsaturated furyl derivative **17** (8.1 g) in EtOAc (400 mL) was hydrogenated over 5% $Pd/CaCO_3$ (8.1 g) at room temperature and atmospheric pressure. The reaction was stopped after one equivalent of hydrogen was absorbed. The catalyst was filtered and the filtrate evaporated. The product obtained was chromatographed on silica gel (pet. ether 30–60°C/ether, 4:1) to give the title product (5.6 g) which was crystallized twice from methanol–hexane (5.0 g), mp 137–138°C, $[\alpha]_D$ 0°; nmr ($CDCl_3$): 0.84 (C18—CH_3), 0.96 (C19—CH_3), 2.06 ($OCCH_3$), 2.80 (C14—H, d, J = 8 Hz), 3.90 (C15—H, m), 6.34 (C4′—H, m), 7.28 (C5′—H, m), and 7.44 (C2′—H, m) ppm. *Anal.* calcd. for $C_{25}H_{36}O_4$: C 74.96, H 9.06; found: C 75.05, H 9.11.

*3β-Acetoxy-23-hydroxy-*D*-homo-24-nor-15-oxa-5β, 14α, 17a-chol-20(22)-en-21-oic acid γ lactone (21 → 23) (**20**)*

To a well-stirred solution of the 17β-furyl derivative (**18**) (2.5 g) in dioxane (125 mL) and water (10 mL) was added NBS (2.3 g) over a period of 10 min. The mixture was then diluted with salt-saturated and extracted with EtOAc. The organic solution was washed with 10% $NaHCO_3$, brine, dried, and evaporated. The product obtained was treated with zinc (25 g) in acetic acid (100 mL) for 1/2 hour. The zinc was filtered and the filtrate evaporated (bath temperature <40°C). The remaining oil was taken into chloroform and the organic solution washed with water, dried, and evaporated. The crude product was chromatographed on silica gel (pet. ether 30–60°C/ether, 2:1) to give the title product **20** (2.27 g). It was crystallized twice from methanol–hexane (1.33 g), mp 220–222°C $[\alpha]_D$ −9.1°; ir ($CHCl_3$): 1748, 1720, 1255, and 1100 cm^{-1}; nmr ($CDCl_3$): 0.88 (C_{18}—CH_3), O ‖ 0.95 (C19—CH_3), 2.05 ($OCCH_3$), 2.86 (C14—H, d, J = 8 Hz), 3.90 (C15—H), 4.86 (CH_2-lactone), and 7.25 (C=CH-lactone ring) ppm. *Anal.* calcd. for $C_{35}H_{36}O_5$: C 72.08, H 8.71; found: C 72.13, H 8.92.

*3β-Acetoxy-*D*-homo-15-oxa-5β,14α,17a-card-20(22)-enolide (**19**)*

A mixture of the 17-furyl derivative (**18**) (2.5 g), 40% peracetic acid (2.6 mL), and sodium acetate (2.6 g) in chloroform (75 mL) was stirred at room temperature for 3 hours. It was then diluted with more chloroform and the organic solution washed with water, 10% $NaHCO_3$, water, dried, and evaporated. The crude product obtained (2.8 g), in methanol (125 mL), was treated with sodium borohydride (2.34 g) in water (25 mL). The solution was poured onto a 5% ice-cold sulfuric acid solution. The solid obtained was filtered, taken into EtOAc, and the organic solution washed with brine, dried, and evaporated. The crude product obtained was chromatographed on silica gel (pet. ether 30–60°C/EtOAc, 2:1) to give the title product (2.214 g). This was crystallized twice from ethyl acetate (1.7 g), mp 212–215°C, $[\alpha]_D$ +13.6°; ir ($CHCl_3$): 1782 (weak), 1745, 1724, 1625 and 1250 cm^{-1}; nmr ($CDCl_3$): 0.94 and 0.96 (C18 and C19—CH_3), 2.06 ($OCCH_3$), 2.76 (C14—H, d, J = 8 Hz), 3.60 and 4.50 (C15—H, m), 4.83 (CH_2-lactone), and 5.92 (=CH, lactone) ppm. *Anal.* calcd. for $C_{25}H_{36}O_5$: C 72.08, H 8.71; found: C 72.16, H 8.81.

15-Oxa-*D*-homosteroids

J. M. FERLAND and Y. LEFEBVRE
Ayerst Research Laboratories, Montreal, P.Q., Canada H3C 3J1

Received June 1, 1983

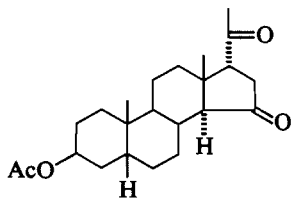
J. M. FERLAND and Y. LEFEBVRE. Can. J. Chem. **62**, 315 (1984).
Novel 15-oxa-*D*-homosteroids related to pregnane and estrane derivatives have been prepared.

J. M. FERLAND et Y. LEFEBVRE. Can. J. Chem. **62**, 315 (1984).
On a préparé des stéroides 15-oxa-*D*-homo dont les structures sont reliées à celles des pregnanes et des estranes.

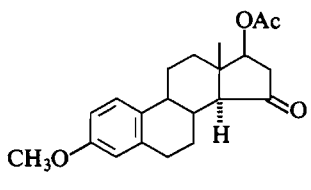
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

In a previous paper (1) we described the preparation of novel 15-oxa-*D*-homocardenolides which retain some of the essential stereochemical features of natural cardiotonic agents. It appeared interesting to prepare similar types of products related to pregnane and estrane derivatives.

The key intermediates to achieve the preparation of such products were the 15-oxa-14α-steroids of type **A** and **B**.



A

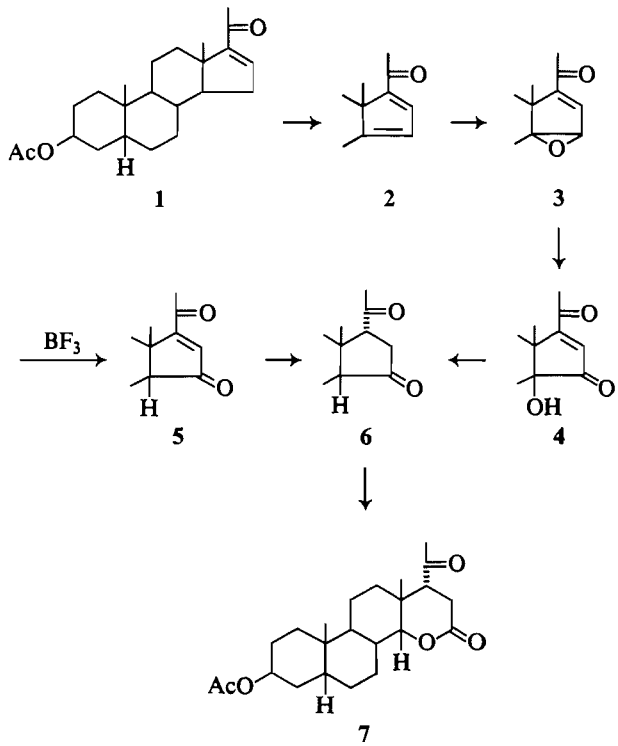


B

An attractive route to the preparation of such compounds has been described by Tschesche and Müller-Albrecht (2) in their partial synthesis of dehydrodiginigenon. However, the treatment with BF_3 of the epoxide **3** obtained from the known derivatives **1** and **2** (3) yielded the 14β-unsaturated ketone **5** which, on hydrogenation or treatment with zinc in acetic acid, gave the diketone **6**. This latter product was again obtained when the oxido derivative (**3**) was oxidized (CrO_3/AcOH) to the hydroxyketone **4** which was transformed to diketone **6** on treatment with zinc in acetic acid. In the 5α-series (4, 5), the more stable 14β,17α-pregnane-15,20-dione was obtained when the epoxide was treated under similar conditions. This discrepancy between Tschesche's results and ours is most certainly due to the lack of the proper substitution in ring C of our derivatives.

The 14β-configuration of the 15-ketones **4**, **5**, and **6** was further confirmed in the transformation of the last derivative **6** to the lactone **7** through a Baeyer–Villiger oxidation. This reaction is known to proceed with retention of configuration. The nmr spectrum of lactone **7** shows a band at 3.9 ppm with a $W/2$ equal to 3.5 Hz, a value in agreement with a dihedral angle of 0° to 10° and indicative (7) of a 14β-stereochemistry. The results are presented in Scheme 1 and Table 1.

In order to overcome this difficulty, the oxido derivative (**3**) was reduced with sodium borohydride. The 17α-derivative **8** obtained was then transformed into the esters **8***a* or **8***b*. On treatment with BF_3, the epoxide **8***a* rearranged to the 14α,15-oxo derivative **9***a* as evidenced by positive ord and cd curves (2, 6, 8). The epimeric ketone **10** (ord and cd curves are negative (2, 6, 8)) was obtained when **9***a* was treated under basic conditions followed by reacetylation. The nmr signal of the $18CH_3$ of **10** is strongly deshielded in comparison with the $18\text{-}CH_3$ of **9***a* (Table 1), thus further confirming the proposed



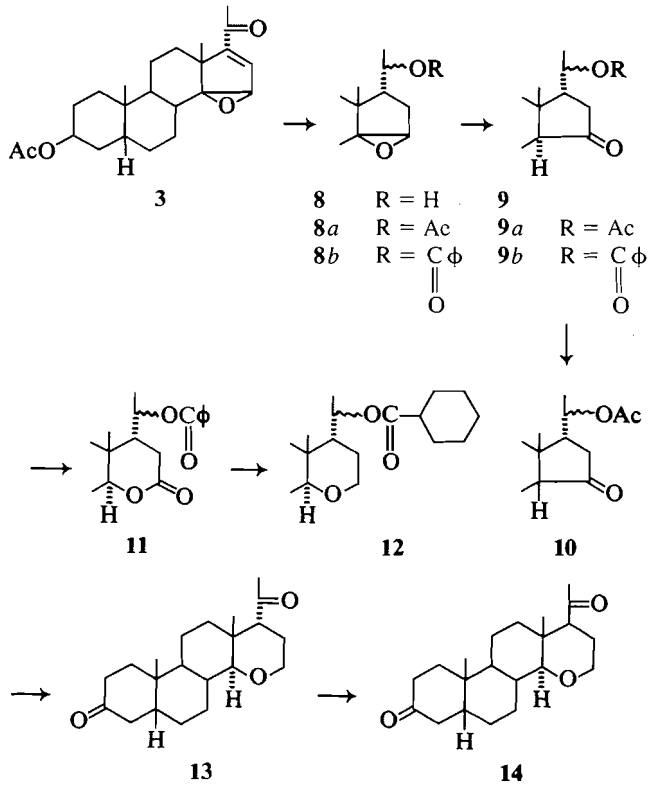
SCHEME 1

TABLE 1. Nuclear magnetic resonance data of some ketones, lactones, and ethers

Products	$18CH_3$ (δ)	14-H (δ)
6	1.32	
9*a*	0.98 (0.97 for **9***b*)	
10	1.25	
15	0.91	
7	1.17	3.90 ($W/2$ = 3.5 Hz)
11	1.09	3.77 (d, J = 8.5 Hz)
16	1.03	3.78 (d, J = 10 Hz)
13	1.12	3.40 (m)
14	1.01	
18	1.03	
21	0.96	
22	0.94	

stereochemistry.

When treated with BF_3, the epoxide **8***b* rearranged to the 14α,15-oxo derivative **9***b* which yielded the lactone **11** through a Baeyer–Villiger oxidation. This latter reaction proceeds with retention of configuration in the 14-position as evidenced by the coupling constant of the doublet for the 14-proton coupled



SCHEME 2

with the 8β-hydrogen which is equal to 8.5 Hz. This value is consistent with an angle of 180° (7), characteristic of a C/D ring junction.

Hydrogenolysis (9) of lactone **11** yielded the ether **12** which was then transformed by hydrolysis and oxidation (Jones' reagent) into diketone **13**. The latter yielded a novel diketone **14** when treated with KOH in MeOH. As demonstrated in Table 1, the position of the 18-CH_3 in **14** as compared with the one of **13** is indicative of the epimerization of the 17α-side chain. This is only possible with the proposed 14α-stereochemistry and constitutes an unequivocal proof. These results are shown in Scheme 2.

In a similar fashion, but starting this time from 15-oxo-estradiol (**15**) (8), the *D*-homo-oxaestradiol **19** and the 19-nor-*D*-homo-oxatestosterone derivatives **20**, **21**, and **22** were prepared. It is worthwhile to note that the ether **19** could not be obtained easily through the usual hydrogenolysis procedure. The aromatic ring of estrone was partially reduced in the presence of platinum. However, this difficulty was circumvented when the lactone **16** was reduced to lactol **17***a* using diisobutyl aluminum hydride. It was then acetylated (**17***b*) and hydrogenolysed to ether **18** using Pd/C. The methyl ether derivative **19** was then prepared (K_2CO_3; $(CH_3)_2SO_4$; KOH) and transformed into the derivatives **20**, **21**, and **22** using the classical Birch reduction method. These reactions are described in Scheme 3.

It is worthwhile to note in Table 1 that the 14β-H of the *cis*-lactone **7** is found at a lower field than the 14α-proton of lactones **11** and **16**. This deshielding effect is due to the anisotropy of the carbon–carbon bond and agrees (7*b*) with values described for ring A *cis* or *trans* lactones.

Experimental

Melting points are uncorrected. The ir spectra were taken on a Perkin–Elmer 225 ir spectrophotometer and nmr were recorded on a Varian A-60A spectrometer operating at 60 MHz; TMS was used as internal standard. Merck silica gel 60 (60–230 mesh) was used. The $[\alpha]_D$ were taken at 20–23°C in 1% chloroform solutions. Otherwise, the solvent is mentioned.

3β-Acetoxy-14,15β-epoxy-5β-pregn-16-en-20-one (3)

This product was prepared from 3β-acetoxy-5β-pregna-14,16-diene-20-one (**2**) (3) (520 g) using 85% *m*-chloroperbenzoic acid (200 g) according to the methods described by Nambara *et al.* (4) or by Tschesche and Müller-Albrecht (2).

The crude product obtained (520 g) was chromatographed on silica gel (ether–hexane, 1:1) to give the title product (220 g). The analytical sample was obtained after two crystallizations from methanol, mp 105–108°C $[\alpha]_D$ +60.2°; ir ($CHCl_3$): 3630, 3480, 1720, 1663, 1590, and 1250 cm^{-1}; nmr ($CDCl_3$): 1.00 (C19—CH_3), 1.32 (C18—CH_3), 2.05 (OAc), 2.26 (C21—CH_3), 3.84 (C15—H), 5.20 (C3—H), and 6.94 (C16—H) ppm. *Anal.* calcd. for $C_{23}H_{32}O_4$: C 74.16, H, 8.66; found: C 74.00, H 8.68

3β-Acetoxy-5β,14β,17α-pregnane-15,20-dione (6). Tschesche's method (2)

Method A

A freshly distilled solution of BF_3–ether complex (2.5 mL) in anhydrous ether (25 mL) was added, dropwise, to a stirred solution of the epoxide **3** (5.0 g) in dry benzene (1.25 L). The mixture was then stirred at room temperature for 64 h. It was washed with water, dried, and evaporated.The crude product obtained was chromatographed on silica gel (hexane–ether, 1:1) to give **5** (3.5 g).

A solution of the crude 16-ene derivative **5** (3.0 g) in absolute ethanol (75 mL) was hydrogenated at room temperature and atmospheric pressure over 10% Pd on barium sulfate (1.5 g) until no more hydrogen was absorbed (0.5 hour). The catalyst was removed by filtration and the filtrate evaporated. The crude product obtained was chromatographed on silica gel (ether–hexane, 1:1). The fractions containing the pure title product were mixed together and evaporated (1.3 g). The analytical sample was crystallized from CH_2Cl_2–ether, mp 188–190°C, $[\alpha]_D$ −40.1°; ir ($CHCl_3$): 1725, 1718, 1698, 1252, and 1018 cm^{-1}; nmr ($CDCl_3$): 0.92 (C19—CH_3), 1.43 (C18—CH_3), 2.04 (OAc), and 2.25 (C21—CH_3) ppm. *Anal.* calcd. for $C_{23}H_{34}O_4$: C 73.76, H 9.15; found: C 73.84, H 9.21.

Method B

On a treatment of the 16-ene derivative **5** (3.0 g) with zinc powder (12 g) in glacial acetic acid, the pure title product was again obtained after one crystallization from CH_2Cl_2–ether, yield 50%, mp 188–190°C.

Method C

3β-Acetoxy-14β-hydroxy-5β-pregn-16-ene-15,20-dione (4) (Method described by Mitsuhashi and Fukuoka (5))

A mixture of the epoxide (**3**) (44 g) in AcOH (1320 mL) was treated with CrO_3 (15.4 g) in AcOH (660 mL) and stirred at room temperature for 24 h. The acetic acid was removed under reduced pressure and the solid obtained taken into CH_2Cl_2. The organic layer was washed with 5% $NaHCO_3$, water dried, and evaporated. The residue was chromatographed on silica gel (benzene–EtOAc, 4:1) and the title product obtained crystallized from CH_2Cl_2–hexane to give the analytical sample, 19 g, mp 163–165°C, $[\alpha]_D$ +19.1°; nmr ($CDCl_3$): 0.93 (C19—CH_3), 1.26 (C18—CH_3), 2.46 (C21—CH_3), and 6.64 (=CH) ppm. *Anal.* calcd. for $C_{23}H_{32}O_5$: C 71.10, H 8.30; found: C 71.01, H 8.44.

3β-Acetoxy-5β,17α-pregnane-3,20-dione (6)

Zinc granules (70 g) were added to a solution of the dione (**4**) (7.0 g) and the mixture was heated under reflux for 1.5 hours. The solvent was removed under reduced pressure and the residue obtained was chromatographed on silica gel (benzene–EtOAc, 4:1). The title product obtained (5.6 g) was crystallized twice from CH_2Cl_2–ether (3.0 g), mp 186–189°C $[\alpha]_D$ −37.1°; nmr ($CDCl_3$): 0.92 (C19—CH_3), 1.43 (C18—CH_3), and 2.25 (C21—CH_3) ppm. *Anal.* calcd. for $C_{23}H_{34}O_4$: C 73.76, H 9.15; found: C 73.78, H 9.16.

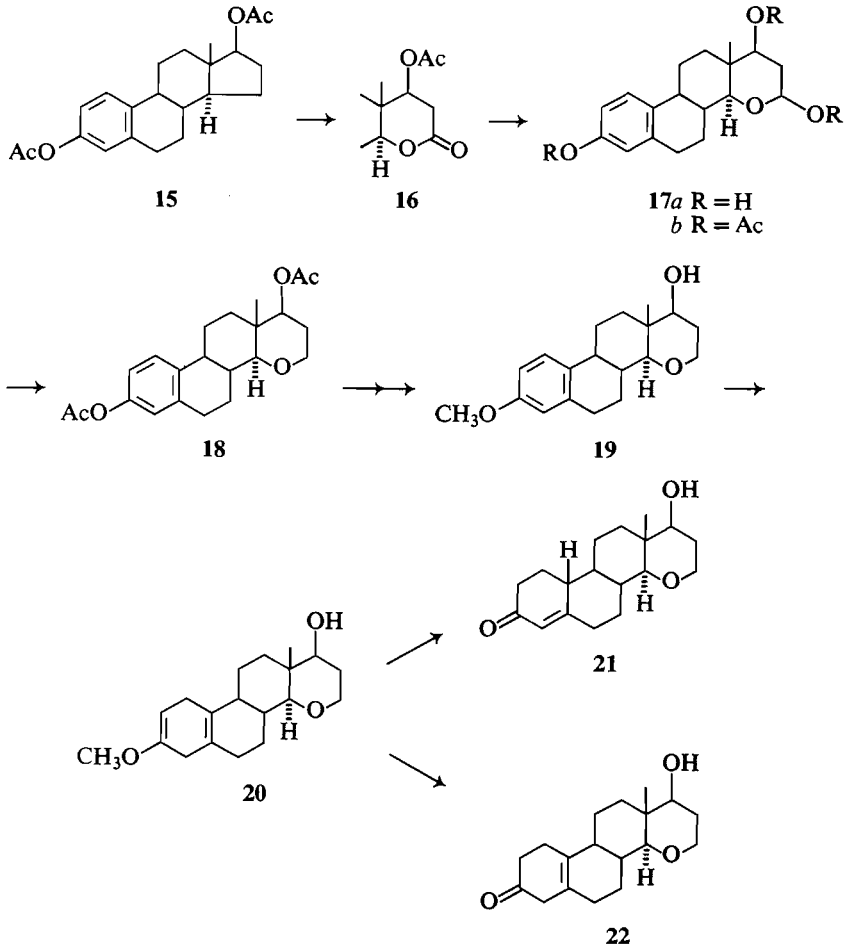

SCHEME 3

3β-Acetoxy-hydroxy-15-oxa-pregnan-16,20-dione (7)

A mixture of the dione (**6**) (1.0 g), $NaHCO_3$ (1.5 g), and *m*-chloroperbenzoic acid (2.0 g) was stirred in CH_2Cl_2 for 20 h. It was then heated under reflux for 3 hours. The mixture was diluted with more chloroform and washed in succession with $NaHCO_3$, water, 5% $Na_2S_2O_3$, water, dried, and evaporated. The crude product obtained was chromatographed on silica gel (benzene–EtOAc, 7:3) to give the title product (0.56 g). It was crystallized twice from ethane–hexane, mp 138–140°C, $[\alpha]_D$ +30.5°; ir ($CHCl_3$): broad C=O at 1715 cm^{-1}; nmr ($CDCl_3$): 0.96 (C19—CH_3), 1.17 (C18—CH_3), and 3.90 (C14—H, $W/2$ = 3.5 Hz) ppm. *Anal.* calcd. for $C_{23}H_{34}O_5$: C 70.74, H 8.78; found: C 70.91, H 8.81.

*3β-Acetoxy-20-benzoyloxy-14,15β-epoxy-5β,17α-pregnane (8*b)

A solution of $NaBH_4$ (50 g) in water (300 mL) was added to a solution at 0°C of the unsaturated ketone **3** (50 g) in methanol (3 L). The mixture was stirred at room for 2 hours and poured into water. The solid obtained was filtered, washed with water, dried, and crystallized from CH_2Cl_2–hexane to give the 20-alcohols (**8**) (25 g).

To a solution at 0°C of these alcohols (10 g) in pyridine (60 mL) was added benzoyl chloride (6 mL). The solution was let at room temperature overnight. It was then poured into water and the solid obtained filtered and dried. It was crystallized twice from EtOAc–hexane to give the pure title product (8.5 g), mp 204–206°C $[\alpha]_D$ +89.4°; ir ($CHCl_3$): 0.95 (C18—CH_3), 1.19 (C19—CH_3), 1.28 (C21—CH_3, d, J = 7 Hz), and 7.5 and 8.0 (5 aromatic H) ppm. *Anal.* calcd. for $C_{30}H_{40}O_5$: C 74.97, H 8.39; found: C 75.15, H 8.45.

*3β,20-Diacetoxy-14,15β-epoxy-5β,17α-pregnane (8*a)

The 20-alcohols **8** (1.0 g) were acetylated in the usual fashion and the product isolated used as such.

*3β,20-Diacetoxy-5β,14α-17α-pregnan-15-one (9*a)

A freshly distilled solution of ethereal BF_3 (0.55 mL) in dry ether (15 mL) was added dropwise over a period of 10 min to a solution of the diacetate **8***a* (1.0 g) in dry benzene (100 mL). The mixture was stirred overnight, washed with water, dried, and evaporated.

The crude product obtained (1.0 g) was chromatographed on silica gel (EtOAc/C_6H_6, 5:1) and the product obtained crystallized twice from ether–hexane to give the pure title product (315 mg), mp 136–138°C; ir: ($CHCl_3$): 1718, 1245, and 1014 cm^{-1}; ord (*C* 10.4 mg/mL; CH_3OH) 20°C: $[\phi]_{350}$ + 960°; $[\phi]_{316}$ + 3460°; $[\phi]_{298}$ O°; $[\phi]_{274}$ −5600; $[\phi]_{249}$ −3900; $[\phi]_{227}$ −5100; cd Mμ (ΔE); 320 (+0.4), 296 (+1.6), 267 (+0.4); nmr ($CDCl_3$): 0.88 (C19—CH_3), 0.98 (C18—CH_3), 1.25 (C21—CH_3, d, J = 6 Hz), and 2.04 (OAc) ppm. *Anal.* calcd. for $C_{25}H_{38}O_5$: C 71.74, H 9.15; found: C 71.71, H 9.13.

*3β-Acetoxy-20-benzoyloxy-5β,17α-pregnan-15-one (9*b)

This compound was prepared as for **9***a*, starting from **8***b* (8.6 g). The crude product isolated was chromatographed on silica gel to give the title product (6.2 g) which was used as such for the following reaction. The nmr spectrum ($CDCl_3$): 0.92 (C19—CH_3), 0.97 (C18—CH_3), 1.78 (C21—CH_3, d, J = 7 Hz), and 2.04 (OAc) and 7.56 and 8.0 (5 ar H) ppm.

3β,20-Diacetoxy-5β,14α,17α-pregnan-15-one (10)

A solution of the diacetate **9***a* (200 mg) in methanol (40 mL) containing KOH (2.0 g) was stirred at 60°C for 2 hours. Most of the methanol was evaporated under reduced pressure, water was added, and the solid obtained filtered. It was taken into CH_2Cl_2, the organic solution was washed with water, dried, and evaporated.

The crude product obtained (0.165 g) was acetylated (pyridine–Ac_2O) and the product isolated chromatographed on silica gel

(EtOAc–hexane, 1:5). The material obtained was crystallized twice from ether–hexane to give the pure title product (127 mg), yield 63%, mp 170–172°C; ir ($CHCl_3$): 1720, 1240, and 1017 cm^{-1}; ord (c 10.8 mg/mL; CH_3OH), 20°C: $[\phi]_{350}$ −670°; $[\phi]_{326}$ −2350°, $[\phi]_{308}$ 0°; $[\phi]_{285}$ +3400; $[\phi]_{233}$ +1800°; cd Mμ (ΔE) = 320 (−0.8), 305 (−1.48), 287 (−0.8); nmr ($CDCl_3$): 0.91 (C19—CH_3), 1.18 (C21—CH_3, d, J = 6 Hz), 1.25 (C18—CH_3), and 2.04 (OAc) ppm. *Anal.* calcd. for $C_{25}H_{38}O_5$: C 71.74, H 9.15; found: C 71.60, H 9.15.

*3β-Acetoxy-20-benzoyloxy-*D*-homo-15-oxa-17a-pregnan-16-one (**11**)*

An ice-cold solution made of trifluoroacetic anhydride (18.6 mL) and 90% hydrogen peroxide (3.7 mL) in CH_2Cl_2 (125 mL) was added dropwise to a stirred suspension of the 15-ketone **9***b* (6.2 g) and disodium hydrogen phosphate (12.4 g) in CH_2Cl_2 (150 mL). The mixture was then stirred at room temperature for 48 h, diluted with more CH_2Cl_2, washed with saturated solutions of $NaHCO_3$, NaI, $Na_2S_2O_3$, water, dried, and evaporated.

The product was chromatographed on silica gel (EtOAc–benzene, 1:1) to give the title product (3.8 g) as an oil. It was used as such for the following reaction. The nmr ($CDCl_3$): 0.96 (C19—CH_3), 1.09 (C18—CH_3), 1.38 (C21—CH_3, d, J = 5 Hz), 3.77 (C14—H, d, J = 8.5 Hz), and 7.54 and 8.03 (5 aromatic H) ppm.

*3β-Acetoxy-20-cyclohexylcarbonyloxy-*D*-homo-15-oxa-5β,17α-pregnane (**12**)*

A solution of lactone (**11**) (3.8 g) in acetic acid (50 mL) was added to a mixture of prehydrogenated 83% PtO_2 (1.8 g) in acetic acid (20 mL) containing perchloric acid (0.18 mL). The whole was stirred at room temperature and atmospheric pressure until no more hydrogen was absorbed.

The catalyst was removed by filtration and the filtrate diluted with CH_2Cl_2. The organic solution was washed with water, dried, and evaporated. The crude product obtained (3.5 g) was chromatographed on silica gel (ether/hexane, 1:1) to give the title product (1.2 g).

The analytical sample was crystallized three times from cold petroleum ether (30–60°C), mp 133–134°C, $[\alpha]_D$ −3.4°; nmr ($CDCl_3$): 0.96 (C19—CH_3), 1.10 (C18—CH_3), 1.25 (C21—CH_3, d, J = 7 Hz), and 5.25 (C20—H, quartet, J = 6.5 Hz) ppm. *Anal.* calcd. for $C_{30}H_{48}O_5$: C 73.73, H 9.90; found: C 73.67, H 10.00.

*D-Homo-15-oxa-5β,17aα-pregnan-3,20-dione (**13**)*

A solution of the diester (**12**) (1.0 g) in ethanol (50 mL) and water (10 mL) was heated under reflux in presence of KOH (1.0 g). Most of the ethanol was evaporated under reduced pressure, water was added, and the solid obtained filtered and dried.

A solution of the crude diol isolated (0.8 g) in acetone (30 mL) was oxidized with Jones' reagent in the usual fashion. The product obtained was chromatographed on silica gel (EtOAc/benzene, 1:3) to give the title product (0.5 g). The analytical sample was crystallized twice from acetone–hexane, mp 159–161°C, $[\alpha]_D$ −61.9°; ir ($CHCl_3$): 1698 and 1080 cm^{-1}; nmr ($CDCl_3$): 1.01 (C19—CH_3), 1.12 (C18—CH_3), 2.20 (C21—CH_3), and 3.40 (C14—H) ppm. *Anal.* calcd. for $C_{21}H_{32}O_3$: C 75.85, H 9.70 found: C 75.50, H 9.69.

*D-Homo-15-oxa,5β,17aβ-pregnane-3,2-dione (**14**)*

A solution of the dione (**13**) (6.0 g) in 5% KOH in methanol (1.2 L) was heated at 60°C for 2 hours. Most of the methanol was evaporated and the remaining diluted with water and extracted with EtOAc. The organic solution was washed until neutral, dried, and evaporated. The crude product isolated was chromatographed on silica gel (ether–hexane, 2:1) to give the title product (4.2 g). The analytical sample was crystallized twice from acetone–hexane (3.2 g), mp 133–135°C, $[\alpha]_D$ +42.1°; ir ($CHCl_3$): 1698 and 1100 cm^{-1}; nmr ($CDCl_3$): 1.01 (C19—CH_3 and C18—CH_3) and 2.16 (C21—CH_3) ppm. *Anal.* calcd. for $C_{21}H_{32}O_3$: C 75.86, H 9.70; found: 76.00, H 9.85.

*3β,17β-Diacetoxy-estra-1,3,5 (10)-trien-15-one (**15**)*

This compound was prepared from estrone as described by Pettit and Brown (8); mp 174–176°C, $[\alpha]_D$ 71.3°; (lit. mp 173–174°C, $[\alpha]_{589}$ + 90°, $[\alpha]_{350}$ +54°); nmr ($CDCl_3$): 0.91 (C18—CH_3) and 5.03 (C17—H, t, J = 8.5 Hz) ppm. *Anal.* calcd. for $C_{22}H_{26}O_5$: C 71.33, H 7.07; found: C 71.14, H 6.91.

*3,17aβ-Dihydroxy-*D*-homo-15-oxaestra-1,3,5(10)-trien-16-one (**16**)*

m-Chloroperbenzoic acid (13 g) was added to a cooled suspension of the 15-ketone (20 g) and sodium bicarbonate (10 g) in CH_2Cl_2 (400 mL). The mixture was stirred at room temperature for 24 h. More peracid (13 g) and bicarbonate (10 g) were added and stirring continued for two more hours. The material in suspension was removed by filtration and the filtrate washed with a 5% solution of sodium bisulfite, water, dried, and evaporated. The crude product obtained was chromatographed on silica gel (C_6H_6/EtOAc, 9:1). Some starting ketone (4.7 g) was recuperated, followed by the title product (16 g).

The latter was crystallized from CH_2Cl_2/ether, mp 156–158°C, $[\alpha]_D$ +12.9°; ir ($CHCl_3$): 1740, 1610, 1580, and 1495 cm^{-1}; uv (EtOH): λ_{max} 267, 274; ε, 695 and 665; nmr ($CDCl_3$): 1.03 (C18—CH_3), 3.78 (C14—H, d, J = 10.7 Hz), and 6.65 and 7.50 (3 ar H) ppm. *Anal.* calcd. for $C_{22}H_{20}O_6$: C 68.38, H 6.78; found: C 68.64, H 6.78.

*3,16,17aα-Triacetoxy-*D*-homo-15-oxaestra-1,3,5,(10)-triene (**17**b)*

A solution of 3.2 equiv. of diisobutyl aluminum hydride in hexane was added dropwise to a solution at −20°C of lactone **16** (2.0 g) in dry THF (60 mL). The mixture was stirred at −20°C for 30 min and the reaction quenched with a saturated solution of sodium potassium tartrate. The organic layer was separated and diluted with EtOAc. It was washed with water, dried, and evaporated. The crude product obtained was filtered on silca gel (acetone/benzene, 1:2) to give the triol **17***a* (1.3 g) which was acetylated in the usual fashion. The crude triacetate isolated was crystallized twice from i-propyl ether to give the pure title product, mp 184–185°C, $[\alpha]_D$ +43.9°; ir ($CHCl_3$): 1747, 1725 inflexion, and 1060 cm^{-1}; nmr ($CDCl_3$): 1.05 (C18—CH_3), and 6.67 and 7.50 (3 ar H) ppm. *Anal.* calcd. for $C_{24}H_{30}O_7$: C 66.96, H 7.06; found: C 66.77, H 7.05.

*3,17aα-Diacetate-*D*-homo-15-oxaestra-1,3,5(10)-triene (**18**)*

A solution of the triacetate **17***b* (6.0 g) in acetic acid (250 mL) was hydrogenated at room temperature and atmospheric pressure over 10% Pd/C (3.0 g) until no more hydrogen was absorbed (~48 h). The catalyst was removed by filtration and the filtrate evaporated. The crude product obtained was chromatographed on silica gel (hexane/EtOAc, 5:1) to give the title product (3.6 g). It was crystallized from hexane, mp 148–150°C, $[\alpha]_D$ +10.6°; ir ($CHCl_3$): 1748, 1723, 1608, 1580, and 1493 cm^{-1}; nmr ($CDCl_3$): 1.03 (C18—CH_3), and 6.67 and 7.50 (3 ar H) ppm. *Anal.* calcd. for $C_{22}H_{28}O_5$: C 70.94, H 7.58; found: C 70.94, H 7.39.

*The 15-oxa-*D*-homoestren-3-one derivatives **21** and **22***

A mixture of the diacetate **18** (3.2 g) and sodium carbonate (2.4 g) in methanol (380 mL) containing water (120 mL) was heated under reflux for 4 hours. Most of the methanol was evaporated and the remaining mixture extracted with CH_2Cl_2. The organic solution was dried and evaporated. The crude oil obtained (2.3 g) was treated with dimethylsulfate (18.5 mL) and 50% KOH (18.5 mL) in the usual manner to give the *3,17aβ-dihydroxy-*D*-homo-15-oxaestra-1,3,5(10)-triene-3-methylether (2.2 g) (**19**)*; uv (MeOH): λ_{max} 286, 275; ε = 2056, 2142. This product was used as such for the following reaction.

Lithium wire (2.25 g) was added in portions over a period of 10 min to a stirred solution at reflux of the 3-methyl ether **19** (2.1 g) in dry ether (120 mL) and distilled ammonia (~200 mL). Absolute ethanol (45 mL) was then added dropwise over a period of 1 hour. Ammonia was evaporated and the mixture diluted with water. The ether layer was recuperated and the water layer extracted once more with ether. The ethereal solution was washed with a solution made of KOH (35 g) in water (25 mL) and MeOH (100 mL) then with water, dried, and evaporated. The crude crystalline *17aβ-hydroxy-3-methoxy-15-oxa-*D*-homo-ester,2,5(10)-diene (**20**) isolated* (2.1 g) was used for the following reactions without further purification. Infrared ($CHCl_3$): 1695 and 1665 cm^{-1}.

A suspension of the methoxy-diene (**20**) (1.05 g) in methanol (20 mL) containing concentrated HCl (2.1 mL) was stirred at room temperature for 1 hour. It was then diluted with water and most of

the methanol evaporated under reduced pressure. The mixture was extracted with CH_2Cl_2. The organic solution was washed with water, dried, and evaporated. The crude product obtained was chromatographed on silica gel (EtOA/C_6H_6, 1:5) and the *17aβ-hydroxy-15-oxa*-D-*homoestr-4-en-3-one* obtained was crystallized from CH_2Cl_2/hexane to give the analytical sample, mp 162–164°C, $[\alpha]_D$ +13.7°; ir ($CHCl_3$): 3600, 3460, 1658, 1610, and 1095 cm^{-1}; nmr ($CDCl_3$): 0.96 (C18—CH_3), 2.03 (OH), 3.45 (C15—H, m), 4.04 (C17—H, m), and 5.86 (C4—H, s) ppm. *Anal.* calcd. for $C_{18}H_{26}O_3$: C 74.45, H 9.02; found: C 74.28, H 9.06.

A suspension of the methoxydiene (**20**) (1.05 g), methanol (21 mL), and acetic acid (2.1 mL) was heated under reflux for 15 min. It was cooled and poured into ice-cold water. The solid obtained was filtered, washed, and dried.

The crude product obtained was crystallized from CH_2Cl_2–hexane to give the *17αβ-hydroxy-15-oxa*-D-*homoestr-5(10-ene-3-one (22)* (0.5 g), yield 50%, mp 178–180°C; ir ($CHCl_3$): 3600, 3470, 1704, and 1090 cm^{-1}; nmr ($CDCl_3$): 0.94 (C18—CH_3), 1.85 (OH), 2.44 (C18—2H, m), 2.75 (C4–2H, m), 3.45 (C15—H, m) and 4.05 (C17—H, m) ppm. *Anal.* calcd. for $C_{18}H_{20}O_3$: C 74.45, H 9.02; found: 74.01, H 9.17.

JAMES P. KUTNEY, JEFFREY D. LEMAN, PHILLIP J. SALISBURY, TREVOR YEE, and IGNACIO H. SÁNCHEZ. Can. J. Chem. **62**, 320 (1984).

The microbial degradation of the lichen antibiotic (+)-usnic acid (**1**) by means of the fungal isolate *Mucor globosus* has been studied. It is shown that this organism provides the metabolite (+)-2-desacetylusnic acid (**2**) as a major component via a novel deacylation reaction.

JAMES P. KUTNEY, JEFFREY D. LEMAN, PHILLIP J. SALISBURY, TREVOR YEE et IGNACIO H. SÁNCHEZ. Can. J. Chem. **62**, 320 (1984).

On a étudié la dégradation microbienne de l'acide (+) usnique (**1**) un antibiotique de lichen, par le *Mucor globosus*, un produit isolé de champignons. On montre que le métabolite principal fournit par cet organisme est l'acide (+) désacétyl-2 usnique (**2**) formé par l'intermédiaire d'une nouvelle réaction de désacylation.

[Traduit par le journal]

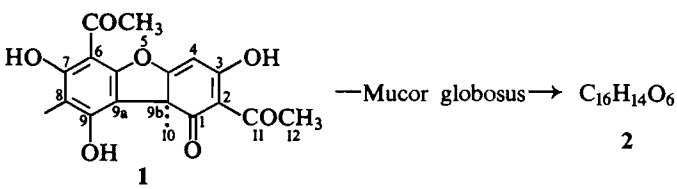
As a continuation of our studies (1, 2) on the microbial degradation of the lichen antibiotic (+)-usnic acid (**1**) (3, 4), the fungal isolate *Mucor globosus* (Fischer, 1892) (5), isolated from surface soil samples collected in the Whistler Mountain area of British Columbia, was chosen as a promising candidate for further investigation. This organism is rather unique in the sense that it is capable of converting **1** quite efficiently via a novel and selective deacylation reaction predominantly to the metabolite (+)-2-desacetylusnic acid (**2**). In comparison, our preliminary studies of the biodegradation of **1** by the fungus *Mortierella isabellina* (1, 2) had yielded complex mixtures of metabolites. The new metabolite (**2**) was isolated from the fermentation broth of *Mucor globosus* essentially as a single major component. We wish to record our detailed investigations concerning the structure elucidation of **2** and its chemical reactions which are of general interest within the usnic acid area.

By following fermentation conditions similar to those developed during our other biodegradation studies (1, 2) (see Experimental), a *Mucor globosus* isolate, strain MU-1, was shown to degrade samples of (+)-usnic acid (**1**) to a single component, isolated in up to 32% yield as yellow crystals, mp 221–222°C, in addition to some recovered substrate (11%).



1 **2**

This material had the molecular formula $C_{16}H_{14}O_6$ as shown by high resolution mass spectrometry and elemental analysis, and was optically active, $[\alpha]_D^{27}$ +635° (CH_3CN). Its ultraviolet spectrum (λ_{max} (MeOH): 330, 287, 218 nm) resembled quite closely that of the starting material (6) and suggested that the aromatic chromophore was unaltered. However, important structural differences were indicated by its infrared spectrum, which lacked the band characteristic of the chelated non-aromatic ring C acetyl grouping, usually occurring in the 1560–1540 cm^{-1} region,[2] suggesting that a novel deacylation of the alicyclic β-triketone system had taken place.

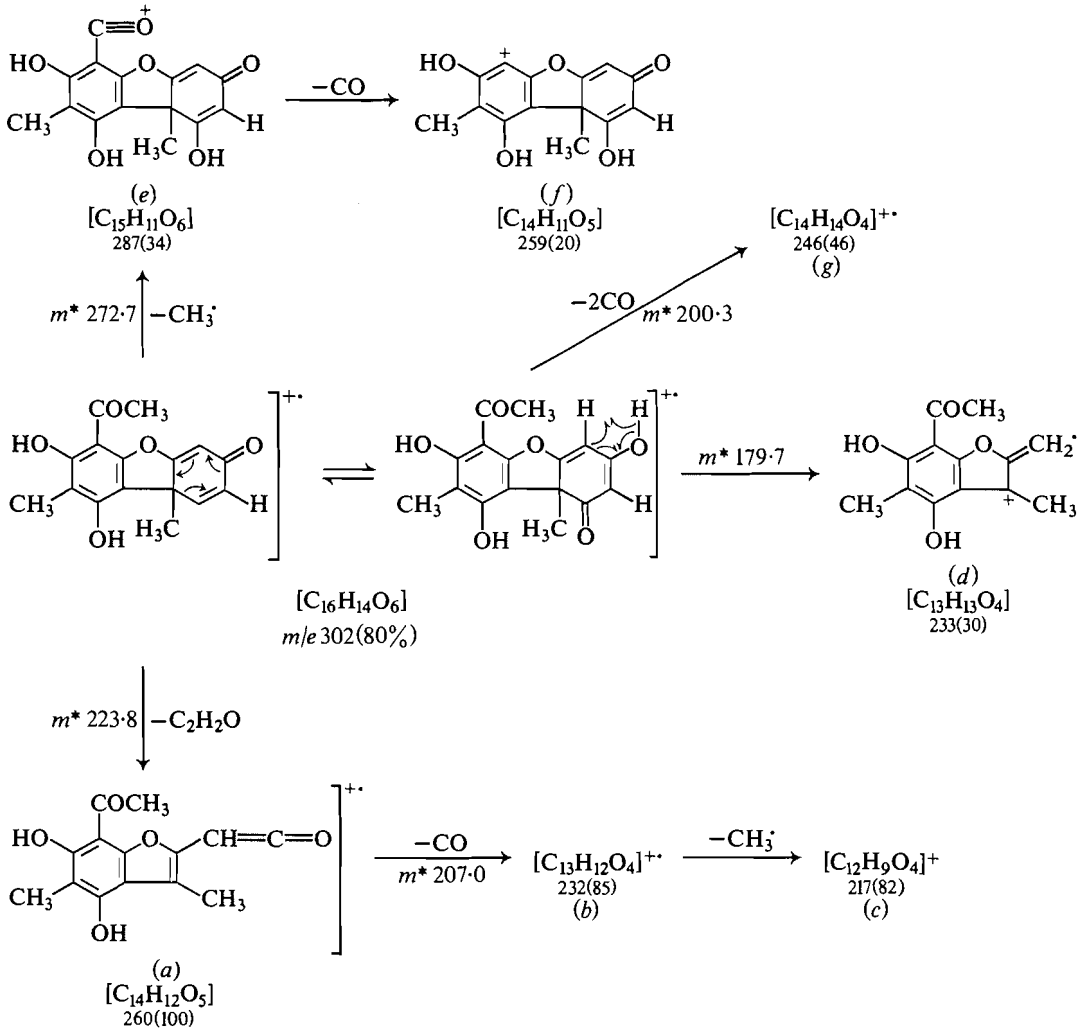
The same conclusion was obtained upon analysis of its ^1H nmr spectrum, which showed the two three-proton singlets corresponding to the angular and aromatic methyl groups (δ: 1.70 and 2.05 ppm, respectively). Whereas in usnic acid (**1**) the absorption characteristics of the C2- and C6-acetyl groupings coalesce into a six-proton singlet at δ: 2.70, compound **2** shows only one singlet (3H) at δ: 2.65 assigned to the ring A acetyl since the corresponding chelated phenolic hydroxyl at the C-7 position appears at its normal position (δ: 13.31). Furthermore, the C-4 olefinic proton is now observed as a doublet (J = 2 Hz) centred at δ: 5.85 showing long range coupling (8) with a new one-proton doublet at δ: 5.38 that can now be attributed to the C-2 hydrogen atom.

As expected, its mass spectral fragmentation pattern (Scheme 1) completely agreed with the proposed structure **2**. Specifically, the retro Diels–Alder fragmentation pathway, arising from cleavage of the C-ring, produces a fragment with 42 mass units less than that resulting from the equivalent process in usnic acid (**1**) itself (9) and further pinpoints the place where the fungal deacylation had taken place.

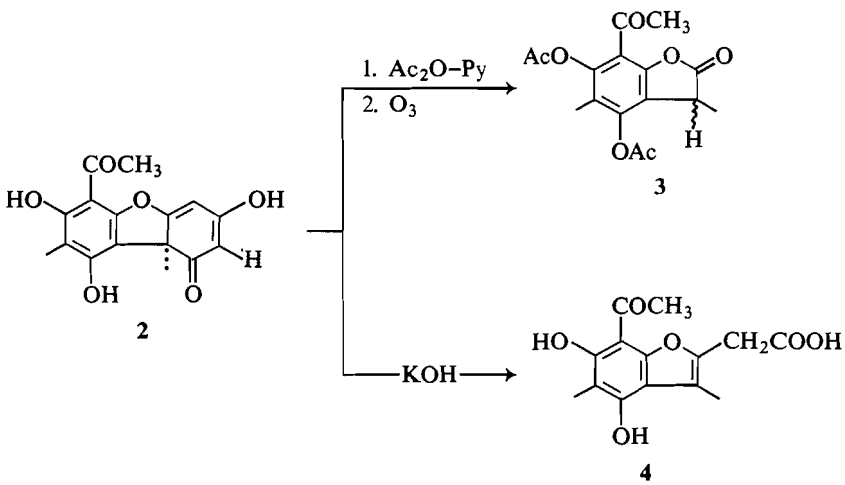
Further evidence for structure **2** was obtained through the appropriate chemical degradation reactions or preparation of derivatives. On the one hand, acetylation and subsequent ozonolysis furnished the known (10) α-coumaranone diacetate **3**, whereas treatment with 75% aqueous potassium hydroxide afforded usnetic acid (**4**), identical to that obtained directly from **1** (11).

[1] For Part VIII, see ref. 1.

[2] For a discussion of the infrared spectrum of (+)-usnic acid (**1**), see ref. 7.



SCHEME 1. Postulated fragmentation pattern for (+)-2-desacetylusnic acid (**2**)

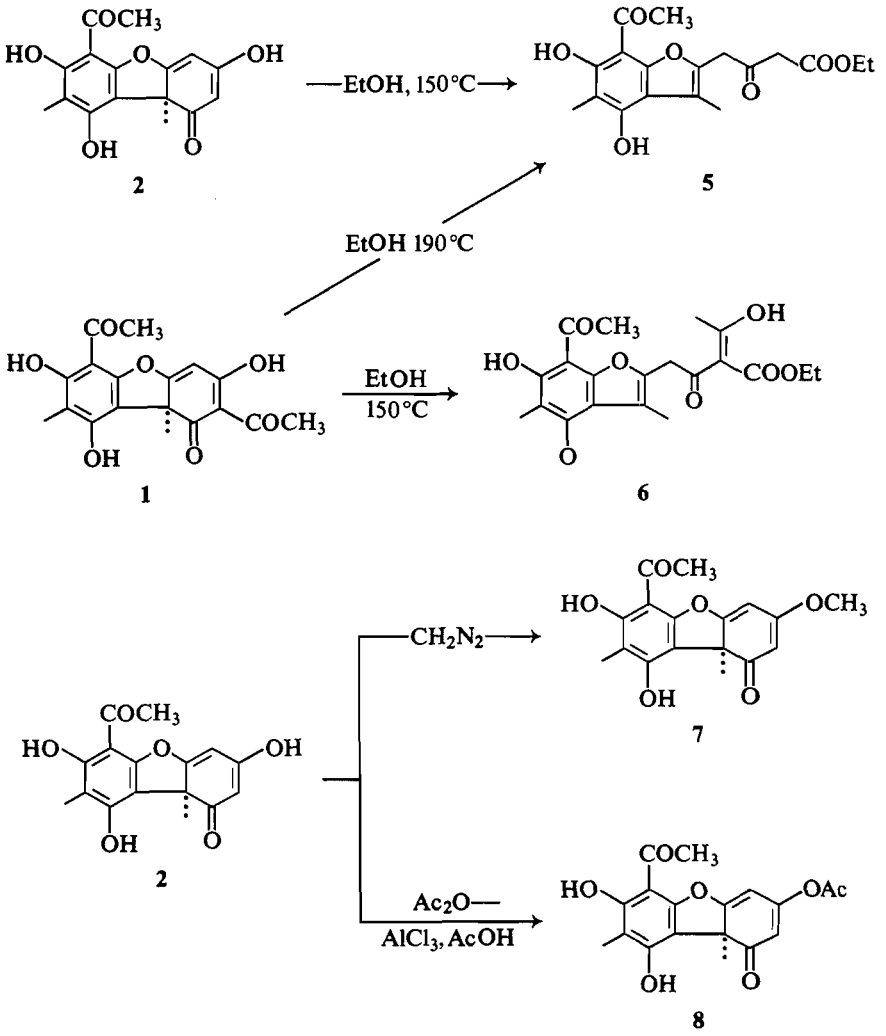


On the other hand, **2** was converted into ethyl acetusnetate (**5**) by conditions (4) (ethyl alcohol in a sealed tube at 150°C) under which usnic acid (1) gives rise to the C-acetyl analog, usnic acid ethoxide (**6**). However, under more vigorous treatment (12) (e.g., heating at 190°C in a sealed tube) cleavage of the C-ring in **1** occurs with concomitant deacylation to furnish again the β-ketoester **5**.

Further proof of the ring C enolic β-diketone system was obtained through the formation of its methyl enol ether **7** and the corresponding enol acetate **8** derivatives by treatment with excess ethereal diazomethane in methanolic solution,[3] or by a mild aluminium trichloride-catalyzed enol acetylation, respectively.

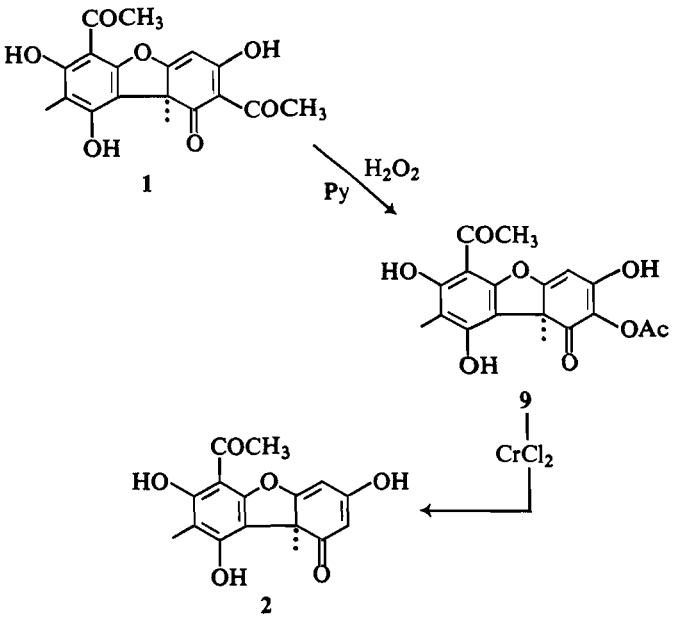
[3] For the formation of ether derivatives of (+)-usnic acid (**1**), see ref. 13.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.



Finally, since the direct C-acylation of **2** was not possible, a direct chemical correlation with **1** was attempted by means of its laboratory preparation. The key step of our degradative scheme consisted of the generation of a C-ring α-acetoxy-β-diketone derivative by a chemoselective process whereby reaction would occur preferentially with an (alicyclic) enolic α-acetyl-β-diketone system rather than with a chelated aromatic methyl ketone. The type of transformation required here (i.e., a Baeyer–Villiger oxidation), has been successfully carried out in other alicyclic β-triketone systems using either alkaline peroxide (14) or peracids (15), although no information regarding the aromatic vs. alicyclic chemoselectivity was available. To our delight, when (+)-usnic acid (**1**) was reacted with 30% hydrogen peroxide in dry pyridine at room temperature, an 83% yield of the desired oily α-acetoxy derivative **9** was realized. This compound proved identical as well to another of the metabolites characterized during our studies with the fungal isolate *Mortierella isabellina* (1). Moreover, during this work we were also able to show that chromium(II) chloride reaction[4] of (natural or synthetic) **9** afforded a 72% yield of (+)-2-desacetyl usnic acid (**2**), identical in all respects to the isolated metabolite.

Finally, it should be noted that prior to the development and completion of the above chemistry, it was possible to obtain an X-ray analysis of **2**[5] and the latter eliminated any doubt about the structure as proposed herein. Also the isolation of **2** as a



[4] For a recent review of the reduction of various functional groups with chromium(II) salts, see ref. 16.

[5] An X-ray diffraction study of (+)-2-desacetylusnic acid (**2**) has already been performed; see ref. 17.

minor component from our studies with *Mortierella isabellina* has been achieved (1).

Experimental

Melting points were determined on a Kofler block and are uncorrected. Ultraviolet (uv) spectra were recorded on a Cary 15 spectrophotometer in methanol solution (unless otherwise noted). The wavelength of the absorption maxima are reported in nanometres (nm). Infrared (ir) spectra were measured routinely on a Perkin–Elmer model 710 spectrophotometer. Analytical or comparison spectra were recorded on a Perkin–Elmer model 457 spectrophotometer using matched cells with a cell path of 0.2 mm in chloroform solution. Calibration was achieved using the 1601 cm^{-1} absorption band of polystyrene. The absorption maxima are quoted in wave numbers (cm^{-1}). Proton magnetic resonance (^{1}Hmr) spectra were measured at 60 or 100 MHz in deuterochloroform ($CDCl_3$) solution (unless otherwise indicated) at room temperature. Line positions are given in the δ (ppm) scale using tetramethylsilane (TMS) as internal standard. The integrated peak areas, multiplicity, and proton assignments are indicated in parentheses. Low resolution mass (ms) spectra were determined on either an AEI-902 or an Atlas CH-4B mass spectrometer, with high resolution mass spectra being recorded exclusively on an AEI-MS-902 mass spectrometer. Optical rotations ($[\alpha]_D$) were measured on a Perkin–Elmer model 141 polarimeter at the sodium D line in chloroform solution (unless otherwise noted) using cells with a 0.1-dm path. Circular dichroism (cd) spectra were obtained on a Jasco model J-20 spectropolarimeter in methanol solution. Microanalyses were performed by Mr. P. Borda of the Microanalytical Laboratory, University of British Columbia. Merck silica gel G (acc. to Stahl) impregnated with oxalic acid (2%) and with 2% fluorescent indicator added, was used as adsorbent for thin layer chromatography (tlc), unless otherwise noted. The tlc plates were activated in an oven at 90°C for 4 h before use. For qualitative chromatography, layers of 0.3-mm thickness were used and the spots were visualized by viewing under ultraviolet (uv) light or spraying with a 1% ethanolic ferric chloride solution. For preparative (plc) chromatography, large (20 × 20 and 20 × 60 cm) plates with a thicker layer (0.7 mm) were used. The developing systems were A, petroleum ether (30–60°C) – acetone (4:1), and B, chloroform – ethyl acetate (3:2), unless otherwise indicated. Column chromatography was performed on either Mackerey–Nagel (0.2–0.5 mm grain size) or Merck 60 (0.063–0.2 mm grain size) silica gel. (+)-Usnic acid was obtained from Koch-Light Laboratories, England.

Maintenance and growth conditions

A sample of the isolated used, identified as *Mucor globosus*, strain MU-1, was maintained on modified malt agar plates (2) by transfer every two weeks from a two-week old agar plate growth into a fresh sterile plate.

A "stock culture" of the purified fungal isolate was stored on modified malt agar in culture tubes placed in the refrigerator.

Aseptic techniques were used throughout in handling the cultures. To ensure proper aeration, the volume of the nutrient solution (2) should never exceed about two-fifths of the total volume of the flask.

Media and stock solutions have been fully described (2).

Fermentation conditions and extraction procedures

Surface soil samples obtained by Dr. J. D. Leman in the Whistler Mountain area produced, by serial dilution of soil and plating on modified malt agar, a fungal isolate able to degrade (+)-usnic acid (**1**). The culture has since been purified and was characterized as *Mucor globosus* by Dr. John J. Ellis of the United States Department of Agriculture, Agricultural Research Service, Northern Utilization Research and Development Division, Fermentation Laboratory, Peoria, Illinois 61604, U.S.A.

Inoculation of shake culture flasks was carried out by transferring a small segment (about 1/4-in. square) of active growth (not older than 2 weeks) and agar to a sterile Erlenmeyer flask containing an appropriate volume of nutrient medium.

The biodegradation of (+)-usnic acid (1). Isolation of (+)-2-desacetyl-usnic acid (2) (6-acetyl-1,9b-dihydro-8,9bα-dimethyl-3,7,9-trihydroxy-1-oxodibenzofuran)

The (+)-usnic acid (**1**) (190 mg, 0.552 mmol) was added as an acetone solution to a 3–4 days old liquid culture of *Mucor globosus* (strain MU-1, 300 mL) and the flask agitated on a rotary shaker at room temperature for 14 days. The cells were then filtered off, suspended in benzene (50 mL), and stirred at room temperature for one hour. The organic extract was dried over anhydrous sodium sulfate and evaporated under reduced pressure to produce (+)-usnic acid (**1**) (22.1 mg, 0.0642 mmol; 11.6%), yellow crystals from chloroform – ethyl alcohol, mp 201–202°C; mixture mp with authentic (+)-usnic acid, 201–203°C.

The clear filtrate (300 mL, pH 8) was extracted with ethyl acetate (2 × 100 mL), and the combined extracts washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure. The residue (46.2 mg) was shown by thin layer chromatography (silica gel – oxalic acid plates, solvent A, run twice) to consist mainly of dark brown polar and base line materials and was not investigated further.

The yellow mother liquors were then acidified with tartaric acid to pH 4 and extracted with ethyl acetate (2 × 100 mL). The combined extracts were washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure to afford a yellow residue (68.3 mg). Purification by preparative layer chromatography (silica gel – oxalic acid plates, solvent A) produced (+)-2-desacetylusnic acid (**2**) (54.2 mg, 0.179 mmol; 32.4%), bright yellow prisms from ethyl acetate – petroleum ether, mp 221–222°C; $[\alpha]_D^{26}$ (CH_3CN) +635° (*c*, 0.063); uv λ_{max} (log ε): 330 (3.49), 287 (4.03), 218 (4.28); ir (Nujol) ν_{max}: 3300–2500 (OH, chelated), 1670 (C=O, dienone system), 1625 (C=O, chelated aromatic acetyl), 1620, 1600 (C=C); ^{1}Hmr (100 MHz, $CDCl_3$ – DMSO-d_6) δ: 1.70 (3H, singlet, C9b—CH_3), 2.05 (3H, singlet, C8—CH_3), 2.65 (3H, singlet, C6—COCH_3), 5.38 (1H, doublet, *J* = 2 Hz, C2—*H*), 5.85 (1H, doublet, *J* = 2 Hz, C4—*H*), 11.85 (1H, broad, C9—O*H*), 13.31 (1H, singlet, C7—O*H*) ppm; ms (70 eV) *m/e*: 302 (M^+), 287 (*M* − 15), 260 (base peak), 246, 233, 232, 217. *Anal.* calcd. for $C_{16}H_{14}O_6$: C 63.57, H 4.67%; found: C 63.47, H 4.66%. High resolution molecular weight determination calcd.: 302.0789; found: 302.0749; cd λ_{max} (Δε): 375 (+0.94), 333 (+6.08), 298 (−4.32), 273 (+5.27), 238 (−5.67).

Ozonolysis of (+)-2-desacetylusnic acid (2). Isolation of (±)-7-acetyl-3,5-dimethyl-4,6-dihydroxy-coumaran-2-one diacetate (3)

A solution of (+)-2-desacetylusnic acid (**2**) (100 mg, 0.231 mmol) in a 1:1 mixture of acetic anhydride – pyridine (6 mL) was allowed to stand at room temperature overnight. The reaction mixture was then poured onto ice (20 g), extracted with ethyl acetate (3 × 10 mL), and the combined extracts washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure. The crude residue (135 mg) was dissolved in dry carbon tetrachloride (10 mL) and cooled to 0°C in an ice bath. Ozonized oxygen (26 mg O_3/minute) was then bubbled through until the yellow color was discharged and the crystalline ozonide began to precipitate. The resulting suspension was then diluted with distilled water (10 mL) and heated to reflux in a steam bath for 15 min. The organic fraction was then evaporated, washed with 2% sodium bicarbonate solution, water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure to produce (+)-7-acetyl-3,5-dimethyl-4,6-dihydroxycoumaran-2-one diacetate (**3**) (32.1 mg, 0.100 mmol; 30%), colorless crystals from ethyl alcohol, mp 131–132°C (lit. (4) mp 130–132°C); $[\alpha]_D$ (CH_3CN) 0° (*c*, 0.17075); uv λ_{max} (log ε): 297 (3.19), 245 (3.65), 213 (4.14); ir ν_{max}: 1815 (C=O, lactone), 1765 (C=O, acetates), 1690 (C=O, aromatic acetyl), 1605 (C=C); ^{1}Hmr (100 MHz) δ: 1.50 (3H, doublet, *J* = 7.5 Hz, C3—CH_3), 1.98 (3H, singlet, C5—CH_3), 2.33 (3H, singlet, C4—OCOCH_3), 2.39 (3H, singlet, C6—OCOCH_3), 2.61 (3H, singlet, C7—COCH_3), 3.73 (1H, quartet, *J* = 7.5 Hz, C3—*H*) ppm; ms (70 eV) *m/e*: 320 (M^+), 278, 236 (base peak), 211, 208.

Anal. calcd. for $C_{16}H_{16}O_7 \cdot \frac{1}{4}H_2O$: C 59.16, H 5.12%; found: C 59.52, H 5.08%. High resolution molecular weight determination calcd. for $C_{16}H_{16}O_7$: 320.0895; found: 320.0877.

Base cleavage of (+)-2-desacetylusnic acid (2). Isolation of usnetic acid (4)

(+)-2-Desacetylusnic acid (**2**) (48 mg, 0.1589 mmol) in 75% potassium hydroxide (2 mL) was heated at 90–95°C (oil bath temperature) under nitrogen atmosphere for 25 min. The reaction mixture was cooled to 0°C (ice bath) and carefully acidified with 1 *N* hydrochloric acid. The resultant brown precipitate was filtered, washed with water, dried, and recrystallized from methanol to produce usnetic acid (27 mg, 0.0971 mmol; 61%), mp 208–210°C (lit. (4) mp 209–210°C); mixture mp with authentic usnetic acid, 209–210°C. Both samples displayed identical chromatographic and spectroscopic properties.

Conversion of (+)-2-desacetylusnic acid (2) to ethyl acetusnetate (5)

A suspension of (+)-2-desacetylusnic acid (**2**) (40 mg, 0.132 mmol) in absolute ethyl alcohol (8 mL) was heated in a sealed tube at 150°C for 5 hours. The tube was then cooled, opened, and stored at 0°C overnight. The pale yellow precipitate was filtered and recrystallized from ethyl alcohol to produce ethyl acetusnetate (5) (30 mg, 0.0862 mmol; 65%), pale yellow needles, mp 147–149°C (lit. (4) mp 150°C); mixture mp with authentic ethyl acetusnetate, 147–149°C; $[\alpha]_D$ (CH_3CN) 0° (*c*, 0.1775); uv λ_{max} (log ϵ): 346 (3.40), 301 (3.86), 243 (3.98); ir (Nujol) ν_{max}: 3600–3100, 2800–2400 (OH, chelated), 1725 (C=O, ester grouping of the β-ketoester side chain), 1700 (C=O, ketone of the β-ketoester side chain), 1620 (C=O, chelated aromatic acetyl; C=C), 1600 (C=C); ^{1}Hmr (100 MHz) δ: 1.22 (3H, triplet, J = 7 Hz, O—CH_2—CH_3), 2.10 (3H, singlet, C5—CH_3), 2.30 (3H, singlet, C3—CH_3), 2.70 (3H, singlet, C7—$COCH_3$), 3.49 (2H, singlet, CO—CH_2—CO), 4.16 (2H, quartet, J = 7 Hz, O—CH_2—CH_3), 4.18 (2H, singlet, C2—CH_2—CO), 5.86 (1H, singlet, C4—OH), 13.71 (1H, singlet, C6—OH) ppm; ms (70 eV) *m/e*: 348 (M^+), 260, 234, 223 (base peak), 219, 215, 69. *Anal.* calcd. for $C_{18}H_{20}O_7$: C 62.06, H, 5.78%; found: C 61.97, H 5.82%. High resolution molecular weight determination calcd: 348.1208; found: 348.1229.

Preparation of usnic acid ethoxide (6)

A suspension of (+)-usnic acid (**1**) (1 g, 2.9069 mmol) in absolute ethyl alcohol (25 mL) was heated in a sealed tube at 150°C for 4.5 hours. The tube was then cooled, opened, and stored at 0°C overnight. The pale yellow precipitate was filtered, dried, and recrystallized from ethyl alcohol to give usnic acid ethoxide (**6**) (680 mg, 1.743 mmol; 60%), yellow crystals, mp 103–105°C; $[\alpha]_D$ (CH_3CN) 0° (*c*, 0.0435); uv λ_{max} (log ϵ): 347 (3.41), 296 (3.91), 241 (4.01); ir ν_{max}: 3600–3100, 2800–2400 (OH, chelated), 1705, 1665 (C=O, β-ketoester side chain), 1620 (C=O, chelated aromatic acetyl; C=C), 1600 (C=C); ^{1}Hmr (100 MHz) δ: 1.33 (3H, triplet, J = 6 Hz, O—CH_2—CH_3), 2.05 (3H, singlet, C5—CH_3), 2.28 (3H, singlet, C3—CH_3), 2.38 (3H, singlet, C=C (OH) CH_3), 2.70 (3H, singlet, C2—$COCH_3$), 4.18 (2H, singlet, C2—CH_2—CO), 4.30 (2H, quartet, J = 6 Hz, O—CH_2—CH_3), 6.56 (1H, singlet, C4—OH), 13.66 (1H, singlet, C6—OH), 17.50 (1H, broad singlet, C=C (CH_3) OH) ppm; ms (70 eV) *m/e*: 390 (M^+), 344, 260, 234, 233 (base peak), 219, 217, 215, 191, 76. *Anal.* calcd. for $C_{20}H_{22}O_8$: C 61.54, H 5.64%; found: C 61.47, H 5.67%. High resolution molecular weight determination calcd.: 390.1314; found: 390.1322.

Treatment of (+)-2-desacetylusnic acid (2) with diazomethane. Isolation of (+)-2-desacetyl-3-methoxyusnic acid (7) (6-acetyl-1,9b-dihydro-7,9-dihydroxy-8,9bα-dimethyl-3-methoxy-1-oxodibenzofuran)

A solution of (+)-2-desacetylusnic acid (**2**) (50 mg, 0.165 mmol) in dry methanol (10 mL) was treated at 0°C with excess ethereal diazomethane and the reaction mixture allowed to stand in an ice bath for 30 min. The solvent was then evaporated under reduced pressure and the residue (55 mg) purified by preparative layer chromatography (silica gel – oxalic acid plates, solvent A) to produce (+)-2-desacetyl-3-methoxyusnic acid (**7**) (20 mg, 0.06329 mmol; 38%), yellow prisms from chloroform – petroleum ether, mp 163–165°C; $[\alpha]_D^{26}$ (CH_3CN) +622° (*c*, 0.07075); uv λ_{max} (log ϵ): 370 (2.60), 330 (3.25), 282 (4.00), 218 (4.23); ir ν_{max}: 3400–3200 (OH, chelated), 1692 (C=O, enone system), 1634 (C=O, chelated aromatic acetyl; C=C); ^{1}Hmr (100 MHz) δ: 1.71 (3H, singlet, C9b—CH_3), 2.04 (3H, singlet, C8—CH_3), 2.60 (3H, singlet, C6—$COCH_3$), 3.85 (3H, singlet, C3—OCH_3), 5.30 (1H, doublet, J = 1.8 Hz, C2—*H*), 5.74 (1H, doublet, J = 1.8 Hz, C4—*H*), 11.19 (1H, singlet, C9—O*H*), 13.26 (1H, singlet, C7—O*H*) ppm; ms (70 eV) *m/e*: 316 (M^+, base peak), 301, 273, 260, 232, 217, 69, 43. *Anal.* calcd. for $C_{17}H_{16}O_6$: C 64.55, H 5.10%; found: C 64.63, H 5.30%. High resolution molecular weight determination calcd.: 316.0946; found: 316.0971; cd λ_{max} ($\Delta\epsilon$): 375 (+4.62), 338 (+7.96), 300 (−7.49), 270 (−4.94), 253 (+0.95), 245 (−1.91), 231 (+9.88).

Preparation of (+)-2-desacetylusnic acid enol acetate (8) (3-acetoxy-6-acetyl-1,9b-dihydro-7,9-dihydroxy-8,9bα-dimethyl-1-oxodibenzofuran)

A suspension of (+)-2-desacetylusnic acid (**2**) (56 mg, 0.185 mmol) in acetic anhydride (5.6 mL) and glacial acetic acid (0.4 mL) was treated with anhydrous aluminum trichloride (25 mg, 0.1879 mmol), heated at 40°C (oil bath temperature) under nitrogen atmosphere for one hour and then stirred at room temperature overnight. The resulting bright yellow solution was poured onto crushed ice (15 g), extracted with ethyl acetate (3 × 5 mL), and the combined extracts washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure. The residue (62 mg) was recrystallized from methanol to produce (+)-2-desacetylusnic acid enol acetate (**8**) (54 mg, 0.156 mmol; 84%), yellow prisms, mp 159–160°C; $[\alpha]_D^{26}$ (CH_3CN) +564° (*c*, 0.078); uv λ_{max} (log ϵ): 386 (3.23), 338 (3.58), 282 (4.26), 214 (4.41); ir ν_{max}: 3600–3200 (OH, chelated), 1769 (C=O, enol acetate), 1681 (C=O, enone system), 1623 (C=O, chelated aromatic acetyl; C=C), 1215 (C—O, enol acetate); ^{1}Hmr (100 MHz) δ: 1.75 (3H, singlet, C9b—CH_3), 2.09 (3H, singlet, C8—CH_3), 2.31 (3H, singlet, C3—$OCOCH_3$), 2.65 (3H, singlet, C6—$COCH_3$), 5.89 (2H, singlet, C2—*H* and C4—*H*), 10.59 (1H, singlet, C9—O*H*), 13.29 (1H, singlet, C7—O*H*) ppm; ms (70 eV) *m/e*: 344 (M^+), 302, 287, 260 (base peak), 232, 217, 43. *Anal.* calcd. for $C_{18}H_{16}O_7$: C 62.78, H 4.69%; found: C 62.70, H 4.74%. High resolution molecular weight determination calcd.: 344.0895; found: 344.0881.

Preparation of (+)-2-acetoxyusnic acid (9) (2-acetoxy-6-acetyl-1,9b-dihydro-8,9bα-dimethyl-3,7,9-trihydroxy-1-oxodibenzofuran)

(+)-Usnic acid (**1**) (150 mg, 0.436 mmol) was dissolved in warm pyridine (2.5 mL), treated at room temperature with 30% hydrogen peroxide (0.1 mL, 0.885 mmol), and the reaction allowed to proceed with stirring for one hour. The resulting orange solution was cooled to 0°C (ice bath), acidified with 1 *N* hydrochloric acid, and extracted with ethyl acetate (3 × 5 mL). The combined extracts were washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure to produce a bright yellow foam (159 mg). Purification by preparative layer chromatography (silica gel – oxalic acid plates, solvent A), produced (+)-2-acetoxyusnic acid (**9**) (130 mg, 0.361 mmol; 83%), unstable bright yellow glassy material that could not be induced to crystallize; $[\alpha]_D^{26}$ (CH_3OH) +389° (*c*, 0.05525); uv λ_{max} (log ϵ): 334 (3.39), 289 (3.93), 223 (4.17); ir ν_{max}: 3400–2600 (OH, chelated), 1768 (C=O, acetate), 1715, 1695 (C=O, β-diketone), 1625 (C=O, chelated aromatic acetyl; C=C); ^{1}Hmr (100 MHz, $CDCl_3$ – DMSO-d_6) δ: 1.77 (3H, singlet, C9b—CH_3), 2.20 (3H, singlet, C8—CH_3), 2.24 (3H, singlet, C2—$OCOCH_3$), 2.61 (3H, singlet, C6—$COCH_3$), 5.86 (1H, singlet, C4—H), 9.30 (2H, broad, C3—O*H*, and C9—O*H*), 13.28 (1H, singlet, C7—O*H*) ppm; ms (70 eV) *m/e*: 360 (M^+), 318, 302, 300, 272, 262, 260, 232, 217, 202, 199, 97 (base peak), 84, 83. High resolution molecular weight determination calcd. for $C_{18}H_{16}O_8$: 360.0844; found: 360.0801.

Preparation of synthetic (+)-2-desacetylusnic acid (2)

(+)-2-Acetoxyusnic acid (**9**) (85 mg, 0.236 mmol) was dissolved in

dry acetone (10 mL) and at 0°C (ice bath) saturated with carbon dioxide (CO_2). Under a stream of carbon dioxide a freshly prepared solution of chromium(II) chloride (10 mL, 10.130 mmol $Cr^{II}Cl_2$) was added, the flask stoppered, sealed with Parafilm, and allowed to stand at room temperature in the dark for 3 days. The resulting green solution was concentrated under reduced pressure to one-third its original volume, diluted with cold distilled water (10 mL), and extracted with ethyl acetate (3 × 10 mL). The combined extracts were washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure. Purification by preparative layer chromatography (silica gel – oxalic acid plates, petroleum ether – acetone (3:2)) and recrystallization from ethyl acetate produced (+)-2-desacetylusnic acid (**2**) (51 mg, 0.168 mmol; 72%), bright yellow plates, mp 220–221°C; mixture mp with authentic (+)-2-desacetylusnic acid, 220–222°C; $[\alpha]_D^{26}$ (CH_3CN) +625° (*c*, 0.08); uv λ_{max} (log ϵ): 328 (3.52), 289 (4.04), 216 (4.32); ir (Nujol) ν_{max}: 3300–2300 (OH, chelated), 1670 (C=O, enone system), 1630, chelated aromatic acetyl; C=C), 1600 (C=C); ^{1}Hmr (100 MHz, $CDCl_3$ – DMSO-d_6) δ: 1.73 (3H, singlet, C9b—CH_3), 2.06 (3H, singlet, C8—CH_3), 2.65 (3H, singlet, C6—COCH_3), 5.41 (1H, doublet, J = 2 Hz, C2—H), 5.85 (1H, doublet, J = 2 Hz, C4—H), 11.96 (1H, broad, C9—OH), 13.43 (1H, singlet, C7—OH) ppm; ms (70 eV) *m/e*: 302 (M^+), 287, 260 (base peak), 233, 232, 217. *Anal.* calcd. for $C_{16}H_{14}O_6$: C 63.57, H 4.67%; found: C 63.42, H 4.62%. High resolution molecular weight determination calcd.: 302.0789; found: 302.0784; cd λ_{max} ($\Delta\epsilon$): 374 (+0.95), 333 (+6.10), 298 (−4.29), 272 (+5.23), 238 (−5.63).

Spin–spin coupling between hydroxyl and aldehydic protons in some salicylaldehyde derivatives. Correlation with the hydroxyl proton chemical shift

TED SCHAEFER, RUDY SEBASTIAN, REINO LAATIKAINEN,[1] AND SALMAN R. SALMAN[2]
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received June 27, 1983

TED SCHAEFER, RUDY SEBASTIAN, REINO LAATIKAINEN, and SALMAN R. SALMAN. Can. J. Chem. **62**, 326 (1984).

^{1}H nmr spectral parameters are reported for salicylaldehyde and 15 of its derivatives in dilute CCl_4 solutions. In those compounds in which sufficiently large substituents are placed *ortho* to either of the functional groups or in which substituents enhance the charge density in the carbonyl group, a positive spin–spin coupling is observed between the two sidechain protons. This coupling, formally over five bonds, correlates with the chemical shift of the hydroxyl proton. The coupling mechanism is discussed from various viewpoints. STO 3G MO calculations give an optimized planar structure for salicylaldehyde. Nonplanar structures are less stable than the planar form. The energy of the hydrogen bond in salicylaldehyde lies near 30 kJ/mol and increases to 36 kJ/mol in the 4,6-dimethoxy derivative. Other small long-range spin–spin coupling constants in these compounds are also discussed.

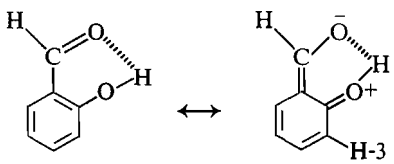
TED SCHAEFER, RUDY SEBASTIAN, REINO LAATIKAINEN et SALMAN R. SALMAN. Can. J. Chem. **62**, 326 (1984).

On rapporte les paramètres spectraux du salicylaldéhyde et de 15 de ses dérivés en solution diluée dans le CCl_4. On observe un couplage spin–spin positif entre les protons des chaînes latérales des composés dans lesquels des substituants assez volumineux sont en position *ortho* par rapport aux groupes fonctionnels ou dans lesquels les substituants augmentent la densité de charge du groupe carbonyle. Ce couplage, formellement établi à travers plus de 5 liaisons, est en accord avec les déplacements chimiques du proton hydroxylique. On discute du mécanisme du couplage à partir de diverses considérations. Les calculs STO 3G OM donnent une structure plane optimisée pour le salicylaldéhyde. Les structures non planes sont moins stables que la forme plane. L'énergie de la liaison hydrogène du salicylaldéhyde est d'environ 30 kJ/mol et augmente jusqu'à 36 kJ/mol dans le dérivé diméthoxy-4,6. On discute également d'autres faibles constantes de couplage spin–spin à longue distance observés dans ces composés.

[Traduit par le journal]

Introduction

At 308 K the chemical shift of the hydroxyl proton in phenol, δ_{OH}/(ppm), at infinite dilution in CCl_4 is 4.26 (1). In salicylaldehyde δ_{OH} is near 11 (2), reflecting the presence of a normal[3] intramolecular hydrogen bond in **1**, whose energy has been variously estimated as lying between 3.3 and 35.2 kJ/mol (3–8).



1 **1*a***

It is likely that the quinoid resonance structure (canonical form), **1*a***, is important. Indeed, it has been recommended that all phenols with strong hydrogen bonds be regarded as quinoids (9). This attitude is certainly valid for the keto–enol tautomerization observed in the Schiff bases derived from salicylaldehyde (9). However, it is unlikely that tautomerization or an (asymmetric) double minimum potential with a low barrier exists in **1** (10). Substitution of the hydroxyl proton by deuterium and tritium nuclei, together with the measurement of their chemical shifts (primary isotope effects), demonstrates this situation for **1**. As the proton moves nearer towards a point midway between the heavy atoms it becomes less shielded (11, 12) and a low-barrier double minimum potential is not indicated for δ_{OH} less than 12.7 ppm (10).

Nevertheless, it is of interest whether δ_{OH} in salicylaldehyde derivatives is sensitive to electronic and/or steric perturbations by the ring substituents. It turns out that, for a number of such compounds, there is a good correlation between δ_{OH} and $^5J_o^{OH,CHO}$, the spin–spin coupling constant over five formal bonds between the hydroxyl and the aldehydic protons. As far as we know, this coupling has not been previously observed.

Experimental

Of commercial origin, salicylaldehyde derivatives were prepared as dilute (<5 mol%) solutions in CCl_4, tetramethylsilane was added as an internal reference, transfer to 5-mm od nmr sample tubes was followed by degassing via freeze–pump–thaw cycles, and the tubes were flame-sealed after the last pump cycle. Calibration of the ^{1}H nmr spectra on an HA100 nmr spectrometer at a probe temperature of 305 K involved the procedure described in detail recently (13). STO 3G MO (14) and INDO MO FPT (15) calculations were performed on an Amdahl 470/V7 system.

Results and discussion

Spectral analyses

The computer program LAME (16, 17) was employed in spectral analytical procedures. Table 1 gives the spectral parameters obtained for salicylaldehyde as a 4.0 mol% solution in CCl_4. Although the linewidths at half-height were typically $\leq$0.1 Hz, no coupling between hydroxyl and aldehydic protons was evident in single or double resonance spectra. The presence of certain ring substituents gives rise to such a coupling. Thus, in 3,5-diiodosalicylaldehyde, this coupling is +0.125(3) Hz. Its sign was determined in a series of nine double resonance experiments, under conditions of weak irradiation (18), which showed that $^5J_m^{OH,H\text{-}4}/^5J_m^{OH,H\text{-}6} > 0$, $^5J_m^{OH,H\text{-}6}/^5J_o^{OH,CHO} > 0$, and $^5J_m^{OH,H\text{-}6}/^4J_o^{CHO,H\text{-}6} < 0$. Because $^5J_m^{OH,H\text{-}4}$ is certainly positive (19), $^5J_o^{OH,CHO}$ follows as positive. The signs of the ratios above

TABLE 1. The ^{1}H nmr spectral parameters for a 4.0 mol% solution of salicylaldehyde in CCl_4 at 305 K and 100.001 MHz

Parameter	Value	Parameter	Value
ν_{CHO}[a]	985.102(2)[b]	$^4J_o^{H,HO}$	−0.011(3)[c]
ν_{OH}	1089.635(2)	$^5J_m^{CHO,H-3}$	0.623(4)
ν_3	691.793(2)	$^5J_m^{CHO,H-5}$	−0.015(3)[c]
ν_4	744.615(2)	$^5J_m^{OH,H-4}$	0.480(3)
ν_5	693.986(2)	$^5J_m^{OH,H-6}$	0.043(3)
ν_6	747.039(2)	$^5J_o^{OH,CHO}$	<0.02[d]
$^3J_{34}$	8.435(4)	$^6J_p^{OH,H}$	−0.001(3)
$^3J_{45}$	7.258(3)	$^6J_p^{CHO,H}$	0.003(3)
$^3J_{56}$	7.709(3)	Transitions calcd.	224[e]
$^4J_{35}$	1.040(3)	Transitions assigned	170
$^4J_{46}$	1.747(3)	Peaks observed	70
$^5J_{36}$	0.461(4)	Largest difference	0.022
$^4J_o^{H,CHO}$	−0.111(3)	Deviation r.m.s.	0.010

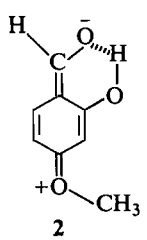
[a] In Hz to low field of internal TMS; ν_3 corresponds to the proton *ortho* to the hydroxyl group.
[b] Numbers in parentheses are the standard deviations in the last significant figure.
[c] No evidence for a finite value.
[d] From decoupling.
[e] Above 0.05 intensity.

are in agreement with previous sign determinations of $^5J_m^{OH,H-6}$ in 3-methoxysalicylaldehyde (19) and of $^4J_o^{OH,H-6}$ in 4-*N*,*N*-dimethylaminobenzaldehyde (20).

Figure 1 displays various multiplets, indicating the spectral quality obtainable with many of these molecules. Table 2 presents the spectral parameters of immediate interest for 15 compounds.

The correlation between δ_{OH} and $^5J_o^{OH,CHO}$

$^5J_o^{OH,CHO}$ is not observed for those compounds having only a fluorine or methoxy substituent *ortho* to the hydroxyl groups.[4] A larger substituent at this position *or* at the position *ortho* to the aldehyde function induces an observable $^5J_o^{OH,CHO}$; for example, 3-*tert*-butyl, 3-Br, or 6-Cl. Furthermore, a 4-methoxy group entails a $^5J_o^{OH,CHO}$ whose magnitude is enhanced by the further addition of a 6-methoxy substituent. By way of contrast, a 3- or a 5-methoxy group is associated with no observable $^5J_o^{OH,CHO}$. These observations (see Table 2) suggest, first, that large substituents placed *ortho* to the functional groups in salicylaldehyde exert steric or compressive forces which enhance the transfer of nuclear spin state information within the hydrogen bonded moieties; second, that a π-electron donor *para* to the aldehydic group provides, via resonance structures like **2**, additional electron density in the hydrogen bond region, again to the advantage of the coupling mechanism.



2

[4] In 3-methoxysalicylaldehyde, $^5J_o^{H,CH_3}$ is (−)0.27(1) Hz, see also ref. 21, showing that the methoxy group is oriented towards H-4, and therefore presenting only the oxygen atom to the hydroxyl group (22).

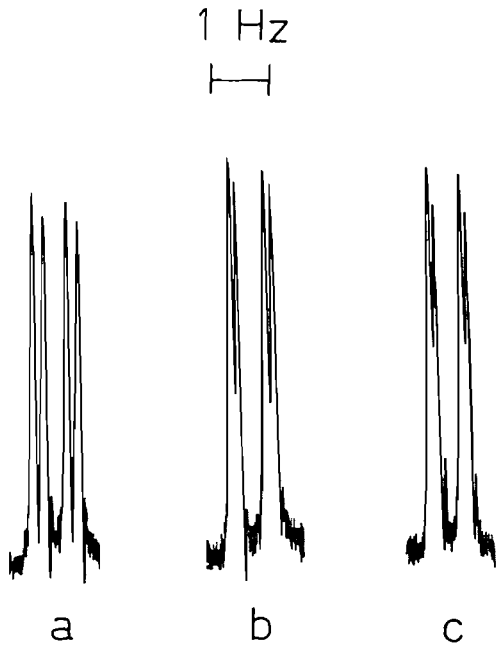


FIG. 1. In (a) the aldehydic proton resonance is displayed for a 2.0 mol% solution of 4,6-dichlorosalicylaldehyde in CCl_4 at 100 MHz and a probe temperature of 305 K. The smaller splitting of 0.195(3) Hz arises from coupling to the hydroxyl proton. In (b) the aldehydic proton peaks are shown for a 2.0 mol% solution of 4-methoxysalicylaldehyde in CCl_4 under conditions in which the hydroxyl proton is decoupled. The smaller splitting of 0.093(3) Hz represents the coupling to H-6. In (c) the hydroxyl proton peaks are given for a 2.0 mol% solution of 3,5-diiodosalicylaldehyde in CCl_4 while the aldehydic proton is being irradiated strongly. The smallest splitting of 0.098(6) Hz involves an interaction with H-6.

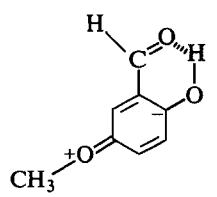
The latter structure might well increase the strength of the intramolecular hydrogen, increasing δ_{OH} (6), and because electron density is increased in the aldehydic region, the aldehydic proton resonance should shift to high field. Both phenomena are observed (Table 2). Steric compression usually causes deshielding, as noted for the aldehyde proton in these compounds in Table 2 with 6-substituents.

In Fig. 2, $^5J_o^{OH,CHO}$ is plotted versus the shift in Hz to low field of the hydroxyl proton relative to salicylaldehyde for the nine derivatives in which the coupling is observed. Equation [1] describes a linear relationship between the two quantities (r = 0.991), in which ν_S is the shift in salicylaldehyde. This

$$[1]\quad {}^5J_o^{OH,CHO}(\text{Hz}) = -0.002 + 1.807 \times 10^{-3}(\nu_{OH} - \nu_S)/(\text{Hz})$$

equation predicts a negligible coupling in salicylaldehyde itself. Note that the equation is not meant to hold for $\nu_{OH} < \nu_S$ and no coupling is actually observed for 5-methoxysalicylaldehyde in which $\nu_{OH} - \nu_S$ is −41 Hz; this number would imply $^5J_m^{OH,CHO}$ as -0.07_5, easily detectable. Very probably, structure **3** is a contributor, placing negative charge near the hydroxyl group, reducing its electron donation to the ring,



3

[a]Concentrations in mol%.

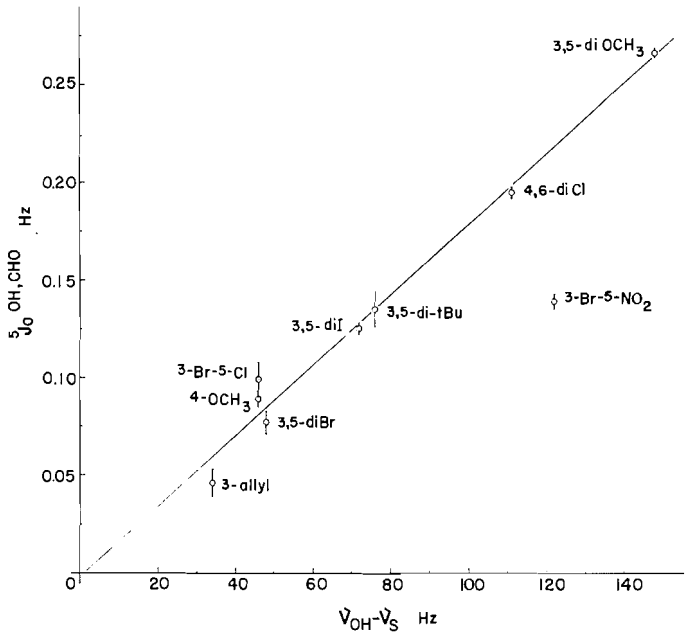

FIG. 2. $^5J_o^{OH,CHO}$ in Hz is plotted versus $\nu_{OH} - \nu_S$ in Hz at 100 MHz for a number of salicylaldehyde derivatives. ν_S is the shift of the hydroxyl proton in salicylaldehyde. The data are found in Table 2. Excluding the point for 3-bromo-5-nitrosalicylaldehyde yields the equation $^5J = -0.002 + 1.807 \times 10^{-3}(\nu_{OH} - \nu_S)$ with a correlation coefficient of 0.991 for 8 points. See text for further discussion.

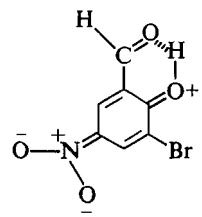
and therefore leading to a somewhat weakened hydrogen bond and an increased shielding of the hydroxyl proton.

Further, note that 3-bromo-5-nitrosalicylaldehyde is excluded from the correlation in eq. [1]. Comparison with δ_{OH} and $^5J_o^{OH,CHO}$ in the 5-bromo (no coupling) and the 3,5-dibromo derivatives suggests that resonance structure **4** contributes to the excess low-field shift of the hydroxyl proton. Relative to the 3,5-dibromo compound, the low-field shift is 74 Hz and, allowing for the upfield shift of 6 Hz in the 5-bromo derivative relative to the parent compound, one arrives at 68 Hz for the deshielding by the 5-nitro group. In 4-nitro-2,6-di-*tert*-butylphenol, in which no intermolecular hydrogen bonding apparently occurs, the 4-nitro substituent causes a low-field



4

shift of 88 Hz in CCl_4 solution (23). Of course, a certain attenuation of the shift due a *para* nitro group would be expected in the salicylaldehyde, the hydroxyl proton region have already lost a significant amount of electron density (24). Although the 5-nitro substituent does lead to an increase in $^5J_o^{OH,CHO}$, its magnitude is less than that expected on the basis of δ_{OH} (see Fig. 2). One may argue as follows.

Examination of the substituent effects on $^5J_o^{OH,CHO}$ (Fig. 2 displays them most clearly) reinforces the suggestions at the beginning of this section. Steric compression (3-allyl; 3,5-diBr; 3-Br-5-Cl; 3,5-diI; 3,5-di-*t*-butyl; 4,6-diCl) by sufficiently large substituents placed *ortho* to either of the functional groups forces the hydroxyl proton closer to the carbonyl group. The hydrogen bond strengthens, leading to a larger δ_{OH}, and spin state information is transferred more efficiently via the $=\overset{+}{O}—H\cdots\bar{O}—C—H$ pathway. Via structure **2**, a 4-OCH_3 substituent strengthens the hydrogen bond by placing more negative charge density on the carbonyl oxygen and again enhances $^5J_o^{OH,CHO}$ by the pathway above. In the 4,6-dimethoxy derivative both steric compression and charge redistribution are active, leading to the largest observed $^5J_o^{OH,CHO}$. On this basis, the $^5J_o^{OH,CHO}$ in the 3-bromo-5-nitro compound falls off the correlation line in Fig. 2 because structure **4** interferes with **1***a*, as does a 5-methoxy substituent because of structure **3**.

Evidence for structures **1**a, **2**, **3**, *and* **4**

Some evidence for the contributions from resonance structures **1***a* to **4** can be adduced from $^3J^{H,H}$ values in these compounds. It is known that $^3J^{H,H}$ in di- and trisubstituted benzene derivatives depends in an additive way on the presence of substituents (25–28). For 14 trisubstituted benzenes in which no strong resonance interaction is expected between the substituents (27), the mean deviation between observed and calcu-

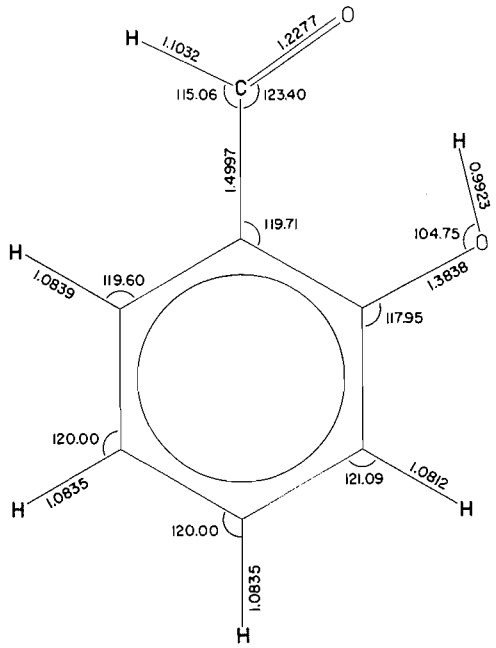

FIG. 3. The STO-3G geometry for salicylaldehyde in which the sidechain chain geometries have been optimized. The total energy is −412.96918 au. The dipole moment is 2.34 D, μ_x is 1.51 D, and μ_z is 1.79 D; the z axis lies along the C1—C2 bond. The geometry of the sidechains is remarkably similar to those found in phenol and benzaldehyde. See text for a discussion of nonplanar geometries.

lated values is ca. 0.05 Hz and for only two of these is the observed value significantly larger (0.05 and 0.13 Hz) than the one based on additivity. It was suggested very early (25) that appreciable deviations from additivity would indicate substituent interactions. This suggestion was later substantiated (29).[5] With reference to structure **1***a*, these studies imply that $^3J_{34}$ and $^3J_{56}$ should be larger than those predicted on an additivity basis and that $^3J_{45}$ should be smaller, reflecting partial double bond fixation (30). Indeed, they are +0.33, +0.11, and −0.07 Hz larger, respectively, than predicted on an additive basis (Table 1 and ref. 25). Furthermore, in 3-methoxysalicylaldehyde, $^3J^{H,H}$ is 0.29 Hz larger, in line with **2**, and is 0.27 Hz larger in the 5-methoxy compound, as expected if **3** is an important resonance structure.

Evidence from $^4J_o^{H,CHO}$

In *para* substituted benzaldehydes $^4J_o^{H,CHO}$ is an average of the *cis* and *trans* arrangements of the aldehydic and ring C—H bonds. This negative coupling increases in magnitude if the *para* substituent is a π electron donor and decreases if it is a π electron acceptor (20). It has been argued that this increase is a consequence of a shorter C—C bond for the aldehydic group (31); see structure **2**. Structure **4** should therefore have a smaller magnitude for $^4J_o^{H,CHO}$ than **1***a*. In salicylaldehyde, this coupling is −0.11 Hz and could not be detected in the 3-bromo-5-nitro derivative (careful decoupling experiments). However, in the 3-methoxy and 5-methoxy compounds $^4J_o^{H,CHO}$ is not significantly different from its value in salicylaldehyde. Therefore the evidence from this source for the importance of **1***a* to **4** is mixed.

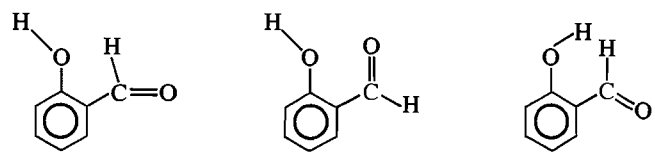
STO 3G MO calculations of geometry and energy

The STO 3G optimization of the sidechain geometries gave the structure in Fig. 3. The exocyclic geometries are remarkably similar to the optimized geometries reported for phenol and benzaldehyde with the same minimal basis set (32). The only significant differences are that the COH angle has decreased by 0.7° and the C1—C7 (HO) bond length has decreased by 0.02 Å in salicylaldehyde. At this level of theory there is no evidence for an O—H bond as long as 1.15 Å, apparently found in the 3-methoxy derivative (33, 34) or as long as 1.16 Å, suggested for salicylaldehyde itself (35, 36). In a correlation of O—H and O···O bond lengths (37), an O···O distance of 2.63 Å as in Fig. 3 corresponds to an O—H distance of ca. 0.99 Å.

In a paper on quadrupole coupling constants (38) the O···O distance is quoted as 2.68 Å, whereas a microwave study suggests 2.62 Å (39). The latter also quotes an O—H bond length of 1.04 and an O—H···O separation of 1.76 ± 0.01 Å. According to a relationship (39*b*) between the deuterium quadrupole coupling constant and the H···O distance, together with the known value of 196 kHz in salicylaldehyde (39*c*), this distance is 1.70 Å. The STO 3G structure in Fig. 3 gives 1.72 Å.

In any event, it seems unlikely that the O—H bond length in salicylaldehyde is significantly longer than 1.00 Å. An interesting correlation (40) exists between δ_{OH} in solids and the O···O distance and is roughly compatible with the δ_{OH} for salicylaldehyde in Table 1 and a theoretical calculation (11).

A correlation of δ_{OH} and the energy of the intramolecular hydrogen bond in phenol derivatives (6) gives the energy of that bond in salicylaldehyde as 29.7 kJ/mol. Because an STO 3G calculation can give hydrogen bond energies in rough agreement with experiment,[6] the energies of **5**, **6**, and **7** were computed. These are, respectively, 23.6, 32.2, and 41.8 kJ/mol less stable than **1**. In another STO 3G MO computation



5 **6** **7**

(8), the energy difference between **1** and **6** was 31.1 kJ/mol and was taken as the hydrogen bond strength. In our opinion, **5** is the stable form of salicylaldehyde in the absence of a hydrogen bond (as found for 2-fluorobenzaldehyde, for example (41)). In any case, it appears that the energy of the hydrogen bond in **1** lies at the high end of the available estimates.

Parenthetically, the calculated dipole moment of 2.34 D for **1** is 0.52 D less than the observed 2.86 D (42). The STO 3G MO dipole moment of phenol agrees with experiment to within 0.01 D (32), but is too low by 1.4 D for benzaldehyde (43). The INDO MO value for **1** is 3.77 D, suggesting too large a charge separation.

INDO MO FPT calculations of $^5J_o^{OH,CHO}$

The INDO MO FPT value of $^5J^{OH,CHO}$ for the STO 3G geometry is −0.51 Hz[7] and the CNDO MO FPT number is −0.11 Hz. An STO 3G optimization of the enol structure yielded an energy 122 kJ/mol higher in energy than **1**. $^5J_o^{OH,CHO}$ now becomes $^3J^{HOCH}$ and is calculated as −2.49 Hz by INDO and as −1.03 Hz by CNDO!

[5] Also R. E. Wasylishen, private communication to T. Schaefer.

[6] See ref. 24, p. 115.

[7] The INDO values are exponentially dependent on the O—H bond length, $-7.8057 \times 10^{-6} \exp(11.17r)$ (r = 0.9994).

For personal use only.

In an attempt at tracing the coupling path in **1**, Barfield's method (44), involving the deletion of certain off-diagonal elements in the Fock matrix, was employed. This approach prevents the development of spin polarization via the overlap of selected orbitals and can give useful information about coupling pathways. For $^5J_o^{OH,CHO}$ this technique gave somewhat ambiguous results. For example, if all elements involving the hydroxyl hydrogen 1*s* orbital and the 2*s* and 2*p* orbitals of C-2 are set to zero, the coupling becomes 0.11 Hz. This might be taken as an indication that elimination of a pathway via the ring orbitals gives rise to reasonable agreement with experiment. However, deletion of all elements containing the hydroxyl hydrogen orbital and the valence orbitals of C-1 and the aldehydic carbon and oxygen atoms, yields $^5J_o^{OH,CHO}$ as 0.05 Hz, whereas doing the same for the 1*s* orbitals of the two sidechain hydrogen atoms gave 0.19 Hz. Elimination of the carbonyl oxygen atom valence orbital elements gave 0.62 Hz. In other words, support for the pathway indicated by the experiments above could not be established.

The simplest explanation consistent with observation is that increased charge on the carbonyl oxygen atom, together with steric forces favouring a close approach of this atom to the hydroxyl proton, enhances $^5J_o^{OH,CHO}$.

Concerning a possible nonplanarity of salicylaldehyde

The microwave spectra of salicylaldehyde and two if its isotopomers yield a planar molecule (39), a COH angle of 109° (the INDO results above did not change appreciably for an angle of 108° as contrasted to the STO 3G angle), and allowed out-of-plane torsions of the sidechains. In a nematic phase, the observed dipolar couplings (45) were consistent with a nonplanar structure as well as with an average of nonplanar structures with energies greater than a planar minimum. The present STO 3G computations gave the following results, where θ_1 is

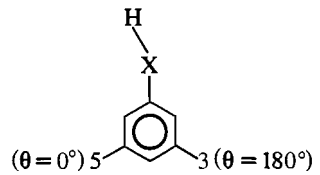
θ_1 (deg)	Energy (kJ)	θ_2 (deg)	Energy (kJ)
5	1.9	5	0.7
10	7.0	10	2.7
15	13.8	15	5.9
20	20.7	20	10.1

the angle by which both groups twist out of the ring plane so that the protons remain on the same side of the plane; θ_2 is the twist angle if the protons of the sidechains move to opposite sides of that plane. The second alternative is favoured and a twist of 10° is equal to *kT* at 305 K, in disagreement with the nmr results for a nematic solution, which favor the protons on the same side of the ring (45).

For none of the appropriate compounds in Table 2 were there observable $^6J_p^{H,CHO}$ or $^6J_p^{OH,H}$ numbers. Substantial nonplanarity, say 20° of torsion, should lead to easily observable couplings. For example, in 2,6-dichlorobenzaldehyde $^6J_p^{H,CHO}$ is −0.15 Hz (46) and is not observable in benzaldehyde (47). Our observations are consistent with a planar minimum for the energy of salicylaldehyde and the other compounds in Table 2. Apparently, steric compression is relieved by formation of a stronger hydrogen bond, stronger by as much as 6 kJ/mol on the basis of δ_{OH} and the empirical relationship mentioned above. Out-of-plane movement of the aldehyde group, for example in the 4,6-dichloro derivative, would furthermore lead to a high-field shift (ring anisotropy), but a low-field shift is observed.

Concerning $^5J_m^{OH,H-6}$

Spin–spin coupling over five bonds between sidechain protons and *meta* ring protons is stereospecific. For example, for benzaldehyde derivatives there is no evidence that $^5J_m^{CHO,H-5}$ in **8** is nonzero. In none of the compounds in Table 2 was there an observable $^5J_m^{CHO,H-5}$ (not tabulated), except of course for 3-nitrobenzaldehyde in which the internal hydrogen bond involves the nitro group. Again, $^5J_m^{H,SH}$ in thiophenol derivatives can be written as $^5J = A \sin^2\theta + B \sin^2(\theta/2)$, where θ is the angle by which the S—H bond twists out of the ring plane (48). *B* is the value of the coupling for θ = 180° (see **8**). A similar equation has been derived for toluene derivatives (49).



8

In a variety of phenol derivatives, no evidence for a $^5J^{OH,H}$ with θ = 0° exists (50–52), *except* for salicylaldehyde and its derivatives. A previous value of +0.13 ± 0.05 Hz in 3-methoxysalicylaldehyde (19) is substantiated in Table 2, where it is given as 0.093(5) Hz. The nitro group forms a stronger hydrogen bond to the hydroxyl group than does the carbonyl bond (see the 3-nitro derivative in Table 2). Yet the coupling analogous to that observed in salicylaldehyde is not present, nor does it appear in 2-fluoro-6-nitro- or 3-fluoro-6-nitrophenol (50). Its largest value is 0.11 Hz in 3-bromo-5-nitrosalicylaldehyde, in which the largest $^5J_o^{OH,CHO}$ and δ_{OH} also occur for those compounds where $^5J_o^{OH,CHO}$ is observable in Table 2. One possible explanation therefore involves a coupling pathway through the carbonyl group orbitals, an alternate five-bond interaction if the hydrogen bond is counted as a bond. However, no $^5J_m^{OH,H-6}$ is observed in the 4-methoxy or 3,4-dimethoxy derivatives, so that this coupling pathway must be considered tentative at best.

Conclusions

Salicylaldehyde and many of its derivatives most likely prefer a planar conformation. The intramolecular hydrogen bond has an energy near 30 kJ/mol and increases by as much as 6 kJ/mol in the presence of substituents which cause steric compression, increase the electron density in the carbonyl group, or decrease the electron density near the hydroxyl proton. As the hydrogen bond energy increases, a coupling between the hydroxyl and aldehydic protons appears, apparently transmitted via the hydrogen bond.

Complexes with macrocyclic ligands. II. The crystal structures of $HgCl_2 \cdot$ 18-crown-6 and $CdCl_2 \cdot$ 18-crown-6, and the FAB mass spectrum of $HgCl_2 \cdot$ 18-crown-6

CHRISTOPHER ROBIN PAIGE AND MARY FRANCES RICHARDSON
Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received January 19, 1983[1]

CHRISTOPHER ROBIN PAIGE and MARY FRANCES RICHARDSON. Can. J. Chem. **62**, 332 (1984).

$HgCl_2$ and $CdCl_2$ form 1:1 complexes with 1,4,7,10,13,16-hexaoxacyclooctadecane (18-crown-6). The complexes are isostructural. The metal coordination is hexagonal bipyramidal, with chlorine atoms strongly coordinated in the axial positions and the 18-crown-6 in the equatorial place. The symmetry of the complex is crystallographically required to be $\bar{3}$ (C_{3i}), but is very nearly $\bar{3}m$ (D_{3d}). The Hg—Cl, Hg—O, Cd—Cl, and Cd—O distances are 2.314(1), 2.825(4), 2.3645(5), and 2.752(1) Å, respectively. Crystals of $HgCl_2 \cdot$ 18-crown-6 are rhombohedral, space group $R\bar{3}$, a = 7.746(2) Å, α = 95.26(3)°, Z = 1 unit of $HgCl_2C_{12}H_{24}O_6$, R = 0.026 for 543 independent reflections with $\theta < 25°$, $I > 3\sigma(I)$. Crystals of $CdCl_2 \cdot$ 18-crown-6 are also rhombohedral, space group $R\bar{3}$, a = 7.712(3) Å, α = 95.57(2)°, Z = 1 unit of $CdCl_2C_{12}H_{24}O_6$, R = 0.022 for 534 independent reflections with $\theta < 25°$, $I > 3\sigma(I)$.

CHRISTOPHER ROBIN PAIGE et MARY FRANCES RICHARDSON. Can. J. Chem. **62**, 332 (1984).

Les sels $HgCl_2$ et $CdCl_2$ forment des complexes 1:1 avec l'hexaoxa-1,4,7,10,13,16 cyclooctadécane (18-couronne-6). Les complexes sont isostructuraux. Le métal a une coordination hexagonale bipyramidale avec les atomes de chlore fortement coordonnés en position axiale et le 18-couronne-6 en position équatoriale. Du point de vue cristallographique le complexe devrait avoir une symétrie $\bar{3}$ (C_{3i}) mais elle est très proche de $\bar{3}m$ (D_{3d}). Les distances Hg—Cl, Hg—O, Cd—Cl et Cd—O sont respectivement de 2,314(1), 2,825(4), 2,3645(5) et 2,752(1) Å. Les cristaux du $HgCl_2 \cdot$ 18-couronne-6 sont rhomboédriques et appartiennent au groupe d'espace $R\bar{3}$ avec a = 7,746(2) Å, α = 95,26(3)°, Z = 1 unité de $HgCl_2C_{12}H_{24}O_6$, R = 0,026 pour 543 réflexions indépendantes avec $\theta < 25°$, $I > 3\sigma(I)$. Les cristaux de $CdCl_2 \cdot$ 18-couronne-6 sont également rhomboédriques et appartiennent au groupe d'espace $R\bar{3}$ avec a = 7,712(3) Å, α = 95,57(2)°, Z = 1 unité de $CdCl_2C_{12}H_{24}O_6$, R = 0,022 pour 534 réflexions indépendantes avec $\theta < 25°$, $I > 3\sigma(I)$.

Introduction

Macrocyclic ligands are of great interest both because they are able to impose unusual coordination numbers and geometries on metal ions (1) and because they serve as models for metal ion transport across membranes (2). We have been investigating cadmium and mercury complexes of macrocyclic ligands (3). Mercury(II) has a strong tendency to linear two-coordination (4, 5), but this is not a special feature of cadmium(II) stereochemistry (4). In complexes of 18-crown-6, the ligand frequently adopts a true "crown" configuration with six oxygen donor atoms in a nearly planar arrangement about the enclosed metal ion (6). However, folded conformations are known to occur both in metal complexes and in uncomplexed 18-crown-6 (7–10). We thus decided that the complexes of $HgCl_2$ and $CdCl_2$ with 18-crown-6 provided a fascinating opportunity to observe unusual metal coordination or unusual crown configurations, and their structures are reported in this paper.

Experimental

Syntheses

$HgCl_2 \cdot$ 18-crown-6 was prepared as follows. Solutions containing 0.27 g $HgCl_2$ (1.0 mmol) in 20 mL 1-BuOH and 0.26 g 18-crown-6 (1.0 mmol) in 20 mL 1-BuOH were heated almost to boiling, and then mixed. Slow cooling yielded small transparent crystals. $CdCl_2 \cdot$ 18-crown-6 was synthesized in a similar manner, except $CdCl_2$ was dissolved in water. Crystals of the complex grew at the water–BuOH interface. Analyses of both compounds were satisfactory.

Structure determination and refinement for $HgCl_2 \cdot$ 18-crown-6

A crystal 0.05 × 0.16 × 0.70 mm was mounted with epoxy glue on a thin glass fiber. Preliminary oscillation and Weissenberg photographs initially suggested monoclinic symmetry. However, there were small differences between reflections which should have been equivalent in monoclinic symmetry. The crystal system was thus taken as triclinic (pseudomonoclinic) with the long axis of the crystal parallel to the pseudomonoclinic c-direction.

The crystal was transferred to a CAD-4 diffractometer, and cell dimensions were determined from 25 reflections having $9.5° < \theta < 22°$ (graphite-monochromatized MoKα radiation, λ = 0.7107 Å). The cell found by the INDEX routine of the CAD-4 had rhombohedral dimensions, but we chose to retain the triclinic (pseudomonoclinic) cell for data collection. For a C-centered triclinic cell having Z = 2, a = 10.444(2), b = 11.458(1), c = 7.745(1) Å, α = 90.04(1), β = 82.21(2), γ = 90.01(1)°. The full sphere of data was collected by the ω–2θ scan technique. The ω scan angle was 0.70 + 0.35 tan θ, the maximum ω scan speed was 2° min^{-1}, and the maximum scan time was 300 s. The orientation was checked every 100 reflections, and a standard was measured every hour. The standard decreased to about 85% of the starting value by the end of the data collection. Backgrounds were counted for one-quarter of the scan time at each end of the scan. A total of 4370 reflections was measured with $2° < \theta < 25°$. The reflections were corrected for variations in the standard intensity and for Lorentz and polarization effects. No absorption correction was applied. All reflections were observed.

The structure was solved in space group $C\bar{1}$ by the heavy-atom method. The Hg atoms were placed on centers of symmetry. Non-hydrogen atoms were given anisotropic thermal parameters; hydrogen atom positions were calculated, and hydrogen atoms assigned an isotropic U of 0.070 Å^2. Refinement was carried out by full-matrix least-squares on $\Sigma w(F_o - F_c)^2$ to R = 0.045. Scattering factors were from the International tables for X-ray crystallography (11). At this point the $\bar{3}$ symmetry of the complex strongly indicated that the rhombohedral cell was correct. Refinement was completed in $R\bar{3}$, with the mercury atom in the (1a) position ($\bar{3}$ symmetry required). Reflections equivalent in $R\bar{3}$ were averaged, yielding R = 0.058. Two cycles of least-squares refinement resulted in convergence at R = 0.026, R_w = 0.024, for 543 independent reflections. The weights used were $w = (\sigma^2(F) + 0.006F^2)^{-1}$. The final difference map had no features greater than 0.6 e Å^{-3} high.

$C_{12}H_{24}Cl_2HgO_6$ fw = 535.5
Rhombohedral, $R\bar{3}$, a = 7.746(2) Å, α = 95.26(3)°, V = 458.5 Å^3,

H(4)	−0.3103	−0.2709	0.2203	0.070

[a] $U_{eq} = (1/3)\ \Sigma_i\Sigma_j U_{ij} a_i^* a_j^* \boldsymbol{a}_i \cdot \boldsymbol{a}_j$.

$\rho_o = 1.87$, $Z = 1$, $\rho_c = 1.93\ cm^{-3}$ (room temperature), $F(000) = 258$, $\mu(MoK\alpha) = 85.6\ cm^{-1}$.

Structure determination and refinement for $CdCl_2 \cdot$ 18-crown-6

A crystal 0.04 × 0.28 × 0.8 mm was used for the data collection. The determination of cell dimensions, collection of a full sphere of data, and data reduction were the same as described for $HgCl_2 \cdot$ 18-crown-6. There was no decrease in the standard during data collection.

$C_{12}H_{24}CdCl_2O_6$ fw = 447.3

Rhombohedral, $R\bar{3}$, $a = 7.712(3)$ Å, $\alpha = 95.57(2)°$, $V = 451.7$ Å^3, $\rho_o = 1.61$, $Z = 1$, $\rho_c = 1.64\ g\ cm^{-3}$ (room temperature), $F(000) = 226$, $\mu(MoK\alpha) = 14.6\ cm^{-1}$.

The structure was solved with the coordinates for $HgCl_2 \cdot$ 18-crown-6 as a starting point. Hydrogen atom positions were refined, together with an isotropic thermal parameter for the four hydrogen atoms. The final R and R_w were 0.022 and 0.027 for the 534 observed reflections, obtained by averaging the six equivalent *hkl* reflections for rhombohedral symmetry. The weights taken were $w = (\sigma^2(F) + 0.003F^2)^{-1}$. The final difference map had no features higher than 0.2 e Å^{-3}.

Computer programs used included SHELX (12) and ORTEP (13). The Cambridge Crystallographic Data Base (14), implemented as CRYSTOR by the Canadian Institute for Scientific and Technical Information, was searched for complexes of cadmium and mercury. The master file was used, complete with updates through September 1982 (34 246 entries).

Mass spectra

Conventional mass spectra were obtained with an AEI MS-30 double beam mass spectrometer operating at 4 kV acceleration potential and 70 eV ionization potential. The samples were vaporized by heating the probe. FAB (fast atom bombardment) mass spectra were obtained on the same instrument operating at a 2 kV acceleration potential. The samples were vaporized from a di-*t*-amylphenol matrix by xenon atom bombardment at 6 kV.

Results and discussion

Tables 1 and 2 present the fractional atomic coordinates of $HgCl_2 \cdot$ 18-crown-6 and $CdCl_2 \cdot$ 18-crown-6, and Table 3 lists important bond distances and angles. Table 4 reports deviations from least-squares planes. The numbering scheme and thermal ellipsoids of the mercury complex are shown in Fig. 1; numbering for the cadmium compound is analogous. Tables of the anisotropic thermal parameters and structure factors have been deposited.[2]

[2] This material is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

The metal coordination

$HgCl_2 \cdot$ 18-crown-6 and $CdCl_2 \cdot$ 18-crown-6 are isostructural. The metal ions lie on crystallographic $\bar{3}$ axes. Each has a linear Cl—M—Cl^i group surrounded by the 18-crown-6 ligand (Fig. 1). The Hg—Cl and Hg—O distances are 2.314(1) and 2.825(4) Å, respectively. Corresponding distances for the cadmium complex are 2.3645(5) and 2.752(1) Å, respectively.

The problem arises of assigning a coordination number to the metal ions. They can either be regarded as two-coordinate or as eight-coordinate; the latter is rare for both cadmium and mercury (Table 5), and the former is not frequent for cadmium. The pattern of two short contacts and six long ones is a feature of the present complexes, $Ca(NCS)_2 \cdot$ 18-crown-6 (15), $[(CH_3)_2Tl \cdot$ dicyclohexano-18-crown-6$]^+$ (16), $[(CH_3)_2Tl \cdot$ dibenzo-18-crown-6$]^+$ (17), the CdI_2 and HgI_2 complexes of 7,16-diaza-18-crown-6 (18), and others, including UO_2^{2+} complexes (4). Most of these compounds have been taken as examples of the relatively rare hexagonal bipyramidal geometry, but $(CH_3)_2Tl^+$ was regarded as being "threaded" through the dibenzo-18-crown-6 cavity (17).

A van der Waals radius of 1.73 Å for mercury(II) has been recommended (19). This, coupled with the normal van der Waals radius for oxygen of 1.40 Å, suggests that the Hg—O distance of 2.825 Å in the 18-crown-6 complex should be treated as a bonding interaction, albeit a weak one. This gives

TABLE 4. Least-squares planes and deviations (in Å), asterisks designate atoms used in calculating the plane, symmetry superscripts are listed in Fig. 1

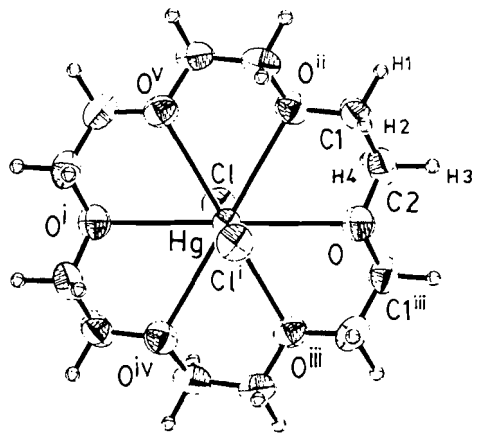

FIG. 1. A molecule of $HgCl_2 \cdot$ 18-crown-6, showing the numbering scheme and thermal ellipsoids. Symmetry superscripts: *i* $(-x, -y, -z)$; *ii* $(-y, -z, -x)$; *iii* $(-z, -x, -y)$; *iv* (y, z, x): *v* (z, x, y).

mercury a coordination number of eight and a hexagonal bipyramidal geometry. The Hg—Cl distance of 2.314(1) Å is somewhat longer than the value of 2.25 Å observed for $HgCl_2$ itself (5). This again supports the idea of bonding between $HgCl_2$ and 18-crown-6, as there is a steady lengthening of the Hg—Cl bonds as other ligands become progressively more strongly coordinated (5).

Also to be noted are the HgX_2 complexes of open-chain polyethers such as tetraethyleneglycol dimethyl ether (20) and 1,15-bis(2-bromophenyl)-2,5,8,11,14-pentaoxapentadecane (21). In both of these complexes, the Hg(II) atom organizes the five oxygen donor atoms around itself in a pentagonal arrangement, with the halides completing a pentagonal bipyramidal coordination. The Hg—O bond distances are 2.78–2.96 Å in the former complex and 2.718–3.059 Å in the latter.

The $CdCl_2$ complex of tetraethyleneglycol dimethyl ether (22) is quite different from the corresponding $HgCl_2$ complex. The two independent cadmium ions in this structure are both six-coordinate, with Cd—Cl and Cd—O distances of 2.425–2.682 and 2.409–2.735 Å, respectively. The upper limits of these values are not greatly different from the Cd—Cl and Cd—O bond distances in $CdCl_2 \cdot$ 18-crown-6. Thus cadmium, too, exhibits hexagonal bipyramidal coordination in its 18-crown-6 complex.

The shorter Cd—O and longer Cd—Cl distances, by comparison to these quantities for the mercury complex (Table 3), are in line with simple hard–soft acid–base predictions.

TABLE 5. Results of searching the Cambridge Crystallographic Data Base for complexes of cadmium and mercury (does not include purely inorganic compounds)

	No. of complexes with coordination number							
Metal	2	3	4	5	6	7	8	9+
Cd	16	7	51	22	94	20	6	0
Hg	185	59	145	23	20	3	2	0

The ligand structure

The 18-crown-6 ligand has nearly perfect D_{3d} symmetry, as shown in Fig. 1. The oxygen atoms lie alternately above and below the plane defined by the six oxygens (Table 4), which is typical for 18-crown-6 in this conformation (6). The chelate rings are all *gauche*. The bond distances and angles in the ligand are typical (6, 10).

Molecular packing

Figure 2 shows a view of the packing projected down the pseudomonoclinic *c*-axis, and Fig. 3 shows a projection down the rhombohedral $\bar{3}$ axis. The $HgCl_2$ and $CdCl_2$ units do indeed define a monoclinic unit cell with $C2/m$ symmetry, which accounts for the fact that the Weissenberg photographs initially looked as though they came from a monoclinic crystal. The monoclinic symmetry is destroyed by the crown ligands. The pseudomonoclinic to rhombohedral transformation is given by:

$$\begin{pmatrix} a \\ b \\ c \end{pmatrix}_{\text{rhombohedral}} = \begin{pmatrix} 0 & 0 & -1 \\ 0.5 & 0.5 & 0 \\ 0.5 & -0.5 & 0 \end{pmatrix} \begin{pmatrix} a \\ b \\ c \end{pmatrix}_{\text{pseudomonoclinic}}$$

There are no intermolecular contacts significantly shorter than the van der Waals distances.

Mass spectra

The normal mass spectrum of $HgCl_2 \cdot$ 18-crown-6 contained peaks due to Hg^+ and fragments from the 18-crown-6 ligand; with the exception of peaks due to the Hg^+ cluster, it was essentially identical to the mass spectrum of 18-crown-6 alone (23). However, the FAB-source mass spectrum clearly showed a cluster of peaks centered at m/z 501, attributable to the $[HgCl(18\text{-crown-6})]^+$ ion ($^{202}Hg^{35}Cl^{12}C_{12}{}^{1}H_{24}{}^{16}O_6$ has a mass of

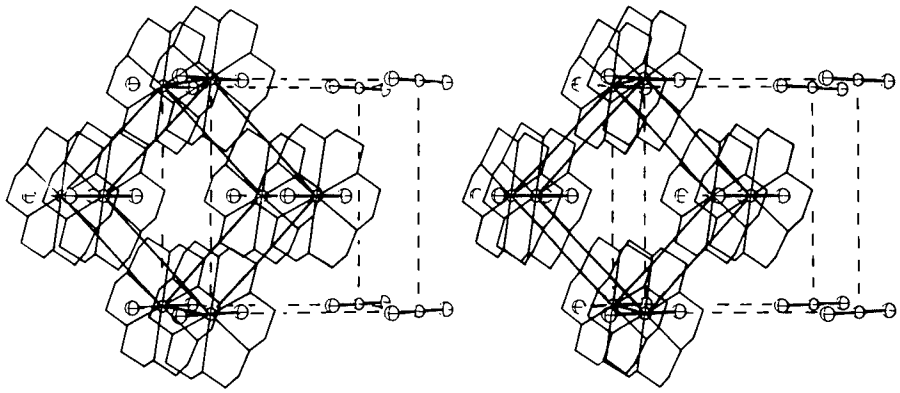

FIG. 2. Packing of $HgCl_2 \cdot$ 18-crown-6 as viewed down the pseudomonoclinic c-axis. The pseudomonoclinic a and b axes are horizontal and vertical, respectively. Dotted lines show the pseudomonoclinic cell; solid lines outline the true rhombohedral cell.

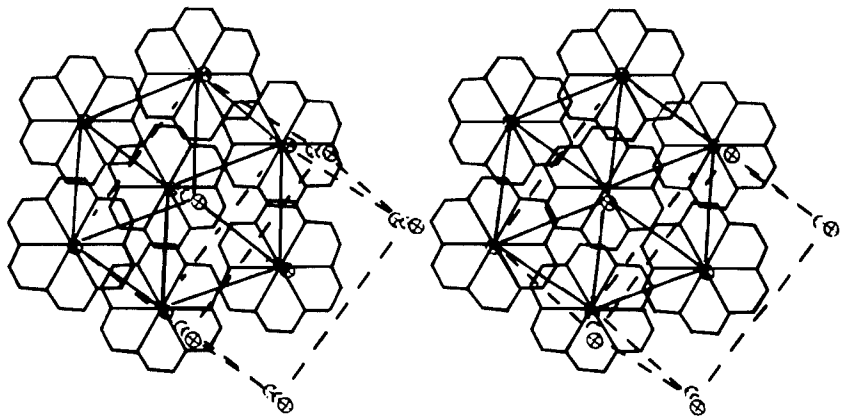

FIG. 3. Packing of $HgCl_2 \cdot$ 18-crown-6 as viewed down the rhombohedral $\bar{3}$ axis.

501 au). The appearance of this ion as the highest-mass peak is normal for chlorinated compounds, which usually exhibit much stronger $[M—Cl]^+$ peaks than $[M]^+$ peaks. The significance of the FAB-source spectrum is that it shows that the mercury ion remains associated with the 18-crown-6 ligand, in spite of the long, presumably weak, mercury–oxygen bonds. Thus, FAB mass spectroscopy may prove to be a useful tool in characterizing metal complexes, especially when they pyrolyze or dissociate upon heating in a conventional mass spectrometer probe.

Received July 11, 1983

JESÚS M. AIZPURUA, CLAUDIO PALOMO, and ANTONIO L. PALOMO. Can. J. Chem. **62**, 336 (1984).

Silylation of ketones, alcohols, mercaptans, and carboxylic acids with *N*-trimethylsilyl-2-oxazolidinone (TMSO) and triflic acid as catalyst has been described from synthetic and mechanistic points of view.

JESÚS M. AIZPURUA, CLAUDIO PALOMO et ANTONIO L. PALOMO. Can. J. Chem. **62**, 336 (1984).

On décrit l'emploi de la *N*-triméthylsilyl-oxazolidinone-2 (TMSO) avec l'acide triflique comme catalyseur pour la silylation de cétones, d'alcools, de mercaptans et d'acides carboxyliques d'un point de vue mécanistique et de son application en synthèse.

[Traduit par le journal]

The utility of the silylation reaction in organic synthesis is well recognized (1, 2), and the introduction of new reagents and the modification of existing ones is a continuous challenge. Although there are numerous reports on different silylation methods, most of them require energetic conditions. Recently, silylations with trimethylsilyl triflate generated *in situ* from allyltrimethylsilane and triflic acid have been reported (3). However, in this method, the silylation of mercaptans needs high temperatures and long reaction times. In connection with our first reports (4, 5) on silylation of organic compounds by means of *N*-trimethylsilyl-2-oxazolidinone (TMSO), recent publications from our laboratory have revealed that this reagent is a powerful silylating agent for (a) carboxylic acids (6), (b) 1,3-dicarbonyl compounds (7), (c) alcohols (8), and (d) amino acids (4, 9).

We now wish to report that TMSO, together with triflic acid as catalyst, may be efficiently used for the silylation of carboxylic acids, alcohols, mercaptans, and carbonyl compounds.

Although we have recently described the use of this reagent for the synthesis of trimethylsilyl carboxylates and trimethylsilyl ethers under basic, neutral, or acidic catalysis, we have now found that trimethylsilylation of carboxylic acids and alcohols takes place almost instantaneously when 2–3 drops of triflic acid are added to a mixture of the substrate and *N*-trimethylsilyl-2-oxazolidone **1**, with the immediate precipitation of 2-oxazolidinone **4**. In order to provide fundamental

2*a*: RCOOH, 2*b*: ROH, 2*c*: R—SH

SCHEME 2

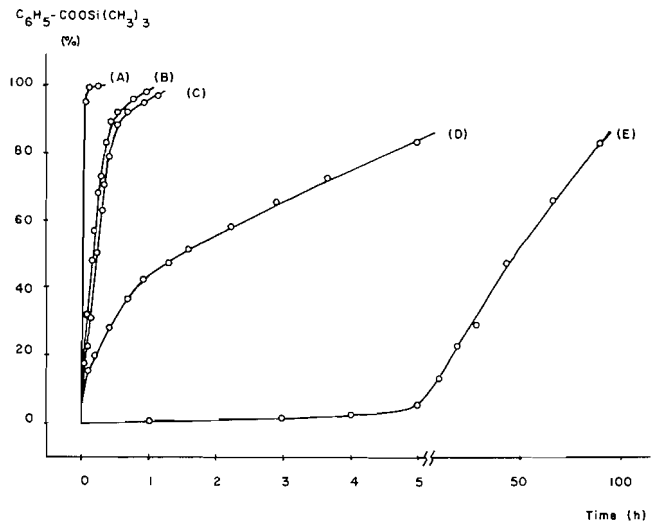

FIG. 1. Silylation of benzoic acid with TMSO at 25°C. Solvent: CH_2Cl_2. Reagent concentration: 0.5 *M*. Catalyst concentration: 2 mol%. Catalysts: (A) F_3CSO_3H, (B) DBU, (C) $N(C_2H_5)_3$, (D), $ClSi(CH_3)_3$, (E) none.

information regarding these factors, we have studied the effect of some catalysts on the outcome of the silylation of benzoic acid by means of this reagent **1**. Thus, an equimolecular mixture of *N*-trimethylsilyl-2-oxazolidinone **1** and the substrate in dichloromethane was treated at 25°C with different catalysts in an nmr sample tube, and the reaction was monitored mainly by observing the change of the relative intensities of the trimethylsilyl groups; the trimethylsilyl group of TMSO appeared consistently at a slightly higher field than that of the product. Measurements were done in the presence of a catalytic amount of triethylamine, 1,8-diazabicyclo[5.4.0]undec-7-ene, trimethylchlorosilane, triflic acid, and in their absence, and the results are shown in Fig. 1. While, in the absence of any catalyst, the transformation proceeds very smoothly, the catalytic assistance of triflic acid increases the silylation rate. Moreover, the reaction proceeds much faster than with basic catalysis.

The generalization of these results is shown in Table 1. The utility of this method can be observed in the silylation of phenylmalonic acid, which easily undergoes decarboxylation under basic or thermal conditions.[2]

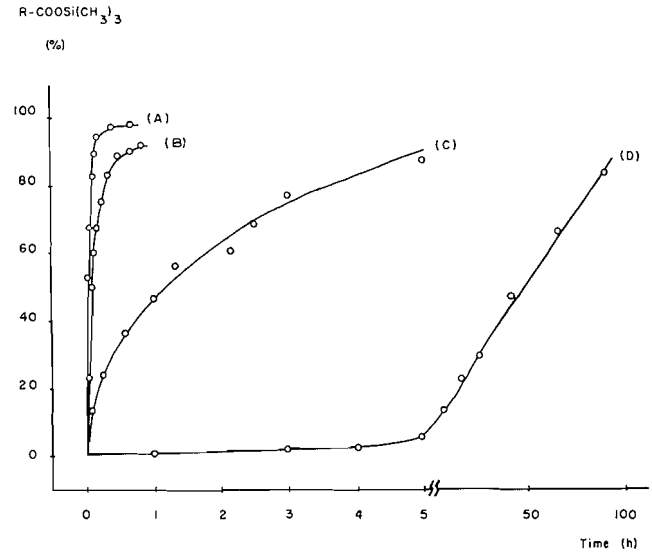

FIG. 2. Silylation of carboxylic acids with TMSO in the absence of catalyst at 25°C. Reagent concentration: 0.5 *M*. Solvent: CH_2Cl_2. Carboxylic acids: (A) Cl_3C—COOH (pK_a = 0.70), (B) Cl_2CH—COOH (pK_a = 1.48), (C) $NCCH_2$—COOH (a mixture of CH_2Cl_2/CH_3CN (9:1) was used as solvent) (pK_a = 2.45), (D) C_6H_5—COOH (pK_a = 4.19).

This aroused our interest in examining, in the same way, the silylation of some carboxylic acids with different pK_a values (Fig. 2). The rapid conversion of strong carboxylic acids into the corresponding silyl esters seems to indicate that the autocatalytic acid effect is important in the silylation rate. When triflic acid is present in the reaction mixture the transformation takes place almost instantaneously.

From a preparative point of view, the reaction of carboxylic acids or alcohols with the trimethylsilyl triflate generated *in situ* from *N*-trimethylsilyl-2-oxazolidinone **1** is carried out at room temperature and the by-product, 2-oxazolidinone **4**, can be separated by filtration or the silylated product **3** can be distilled directly from the reaction mixture.

The silylation of thiols under similar catalytic reaction conditions is shown in Table 2. In this case the acid catalysis is also more efficient than the basic catalysis and the trimethylsilyl thio derivatives were obtained in high yields and in a short time.[3]

This fast transformation may be rationalized by assuming that the equilibrium **1** + **2** $\rightleftharpoons$ **3** + **4** is shifted to the side of **3** by the precipitation of 2-oxazolidinone **4**.

It should be noted that the separation of the side product **4** from the reaction mixture is necessary, because the direct distillation of the mixture gives the starting products, as we have observed in the case of n-propylmercaptan.

Furthermore, the utility and general superiority of the present silylating system have been demonstrated by the silylation of carbonyl compounds. In these cases an equimolecular amount of triflic acid was needed to perform the silylation reaction. In this way we have found that trimethylsilyl triflate can be obtained from reagent **1** and not from other commercial silylating agents such as monotrimethylsilylacetamide (MSA), bistrimethylsilylacetamide (BSA), or

[2] Under neutral conditions the yield of the isolated product is also high, but the reaction proceeds more smoothly than in the method described here (6).

[3] In comparison, in the allyltrimethylsilane – triflic acid method, the trimethylsilyl thio derivatives are obtained upon reflux in carbon tetrachloride for 8–10 h (3).

[c] Tetrachloromethane was used as solvent.
[d] All compounds were identified by physical properties (bp, ir and ^1H nmr spectral characteristics).

TABLE 2. Trimethylsilyl thio derivatives prepared[a]

Compound	Catalyzer (2%)	Time (min)	Yield (%)	Boiling point (°C/Torr) Found	Lit. (ref.)
$CH_3CH_2—SH$	DBU[b]	30	82	128–130/760	130/760(1)
$CH_3CH_2—SH$	F_3CSO_3H	10	86		
$CH_3CH_2CH_2—SH$	DBU	30	78	152/760	151/760(1)
$CH_3CH_2CH_2—SH$	F_3CSO_3H	10	83		
$C_6H_5—SH$	DBU	60	89	40–42/0.3	72/8(12)
$C_6H_5—SH$	F_3CSO_3H	10	93		
$HOOCCH_2CH_2—SH$[c]	F_3CSO_3H	10	92	70–72/17[d]	

[a] All reactions were carried out at room temperature, without solvent.
[b] DBU: 1,8-diazabicyclo[5.4.0]undec-7-ene.
[c] From two equivalents of TMSO, the product obtained is $Me_3SiS—CH_2CH_2COOSiMe_3$, (see Experimental).
[d] O-silylated.

trimethylsilyl imidazole (TMSI), as is shown in Table 3. Thus, equimolecular amounts of TMSO **1** and triflic acid are mixed at room temperature and the trimethylsilyl triflate is directly distilled under vacuum from the mixture into a solution of the appropriate ketone and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU). The reaction takes place rapidly, 15–30 min, at room temperature and the desired silyl enol ethers are obtained in high yield.

It should be noted that the thermodynamic-to-kinetic isomer ratio for methylcyclohexanone, 89:11, was different from the ratio 78:22, reported by House *et al.*, with triethylamine in refluxing dimethylformamide (10). This seems to be due to the difference in reaction conditions.

The above-mentioned results clearly demonstrate that *N*-trimethylsilyl-2-oxazolidinone (TMSO) is indeed a highly effective reagent for the transformations studied, and may prove to be a useful alternative to other reagents in silylation reactions.

Experimental

General procedure for silylation of carboxylic acids **2**a *and alcohols* 2b

A mixture of *N*-trimethylsilyl-2-oxazolidinone **1** (3.1 mL, 20 mmol), triflic acid (0.05 mL, cat.), and the corresponding carboxylic acid **2***a* (20 mmol) or alcohol **2***b* (20 mmol) was stirred at 0°C for 3 min. Distillation of the reaction mixture afford the trimethylsilyl carboxylates **3***a* or trimethylsilyl ethers **3***b*, respectively.

General procedure for the preparation of trimethylsilyl thio ethers

A mixture of *N*-trimethylsilyl-2-oxazolidinone **1** (3.1 mL, 20 mmol), triflic acid (0.05 mL, cat.), and the corresponding thiol **2***c* (20 mmol) was stirred at room temperature for 10 min. n-Hexane (10 mL) was added and the reaction mixture stirred for 2 min again, after which 2-oxazolidinone **4** was filtered off. Evaporation of the solvent gave the crude trimethylsilyl thioether **3***c* which was purified by distillation.

S,O-*bis(trimethylsilyl)thio propionate: typical procedure*

A mixture of TMSO **1** (6.4 mL, 40 mmol), 3-mercaptopropionic acid (1.74 mL, 20 mmol), and triflic acid (0.05 mL, cat.) was stirred

[b] Isomer ratio calculated from ^1H nmr in CCl_4.

at room temperature for 10 min, after which n-hexane (25 mL) was added and the mixture stirred for 5 min again. The 2-oxazolidinone was filtered off and the solvent evaporated at reduced pressure to give crude *S,O*-bis(trimethylsilyl)thio propionate which was purified by distillation (2.30 g, 92%), bp 114–118°C/17 Torr (lit. (1) bp 120–121°C/16 Torr); ^1H nmr (CCl_4–TMS), 0.19 (s, 9H, CH_3), 0.21 (s, 9H, CH_3), 2.51 (m, 4H, CH_2), δ ppm.

Trimethylsilyl triflate

Triflic acid (1.76 mL, 20 mmol) was slowly added to TMSO **1** (3.2 mL, 20 mmol) and the resulting solution was stirred for 2 min and distilled at reduced pressure, affording trimethylsilyl triflate (3.55 g, 80%), bp: 40°C/18 Torr (lit. (11) bp 36°C/12 Torr); ^1H nmr (CCl_4–TMS), 0.50 (s, 9H, CH_3), δ ppm.

General procedure for the preparation of trimethylsilyl enol ethers

Triflic acid (1.32 mL, 15 mmol) was slowly added to cooled (0°C) and stirred *N*-trimethylsilyl-2-oxazolidinone **1** (2.40 mL, 15 mmol). The reaction mixture was then heated to reflux under reduced pressure (15–20 Torr) and simultaneously distilled into a solution of the corresponding carbonyl compound (10 mmol) and DBU (3.0 mL, 20 mmol). The resulting mixture was stirred at 0°C for 30 min and then distilled at reduced pressure to afford the corresponding enol silyl ether.

N-trimethylsilylimidazolium triflate

Triflic acid (0.44 mL, 5 mmol) was slowly added to cooled (0°C) and stirred trimethylsilylimidazole (MSI) (0.74 mL, 5 mmol). The resulting white solid was dried under reduced pressure (0.1 Torr) to give *N*-trimethylsilylimidazolium triflate (1.30 g, 96%), mp 72–75°C; ^1H nmr ($CDCl_3$–TMS), 0.53 (s, 9H, CH_3), 7.24 (bs, 2H, CH), 8.48 (s, 1H, N=CH), 13.35 (s, 1H, NH), δ ppm.

MNDO calculations for some allotropes, hydrides, and oxides of phosphorus

N. COLIN BAIRD
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received May 18, 1983

N. COLIN BAIRD. Can. J. Chem. **62**, 341 (1984).

Molecular orbital calculations by the MNDO method are reported for some allotropes, hydrides, and oxides of phosphorus. The aim of the study is to test further the ability of MNDO to reproduce the energetics of PP, PH, and PO bonds, and to apply MNDO to interesting problems in the chemistry of such systems. Different isomers of P_4, P_6, and P_8 are considered, as well as ions of P_3, P_5, and P_7. The method is found to overestimate strain energy in three-membered rings, and to underestimate the strength of three-electron PP bonds. The strength of PO π bonds apparently also is overestimated. Possible isomers of P_2O_2 and P_2O_3 are discussed.

N. COLIN BAIRD. Can. J. Chem. **62**, 341 (1984).

On rapporte des calculs d'orbitale moléculaire, selon la méthode MNDO, relatifs à quelques formes allotropes d'hydrures et d'oxyde de phosphore. Le but de l'étude est de vérifier d'avantage la capacité du MNDO à reproduire les liaisons énergétiques du PP, PH et PO et d'appliquer le MNDO à des problèmes intéressants dans la chimie de tels systèmes. On a considéré les différents isomères de P_4, de P_6 et de P_8 aussi bien que les ions de P_3, de P_5 et de P_7. On trouve que la méthode surestime l'énergie de contrainte des cycles à trois chainons et sous estime la force des liaisons PP à trois électrons. La force des liaisons π PO est apparamment surestimée également. On discute des isomères possibles de P_2O_2 et de P_2O_3.

Introduction

Although sophisticated *ab initio* molecular orbital calculations are becoming feasible for larger and larger systems, semiempirical MO computations still are useful in many contexts — including reaction mechanisms and the study of molecules which contain many electrons. Two methods which are claimed to be sufficiently accurate and general for most purposes are the MINDO and MNDO schemes developed by Dewar and co-workers (1). Recently we have initiated a study of the use of the MNDO method in the field of covalent inorganic chemistry and have reported on applications to the various forms of elemental sulfur (2). In the present report we extend our analysis to the catenation behavior of phosphorus, and to some phosphorus oxides.

Method of calculation

All calculations reported herein were obtained by the MNDO method without CI unless otherwise indicated. Thiel's program (3) was used on the CDC cyber 170–835 computer at the University of Western Ontario.

Results and discussion

Phosphorus allotropes and hydrides

In analogy with nitrogen, phosphorus atoms could conceivably form triple, double, and single PP bonds in the various allotropes P_n and in the phosphorus hydrides P_nH_m. The simplest molecule, P_2, contains a P≡P bond. Since its predicted heat of formation (ΔH_f) in Table 1 exactly equals the experimental value, presumably this species was included in the MNDO parameterization procedure for this element.

To determine whether MNDO accounts quantitatively for the strength of unstrained phosphorus–phosphorus single bonds, a calculation for the infinitely polymeric "black" phosphorus would be desirable. Since this computation is not feasible with the current MNDO program, an indirect approach based upon the group additivity value for —P<, derived from predicted ΔH_f's for P_nH_m chains, has been used instead. From the MNDO ΔH_f's for the unbranched chains PH_3, P_2H_4, P_3H_6, and *n*-P_4H_8 listed in Table 2, we can derive a group value of −6.9 kcal for >PH (from the limiting $\Delta\Delta H_f$ along this series), −1.8 kcal for —PH_2 and +3.9 kcal for PH_3. Extrapolation of these values yields a group value for >P— of about −11 or −12 kcal. A more direct evaluation is obtained from an MNDO calculation for $P(PH_2)_3$; from its ΔH_f and the group value for PH_2, we obtain −14.4 kcal for —P<. Thus we conclude that the MNDO value for —P<, and thus the predicted ΔH_f per atom in black phosphorus, is about −14 kcal mol^{-1}. Since experimentally the heat of formation for the black allotrope is −9.4 kcal (4), we conclude that MNDO slightly overestimates, by about 3 kcal (i.e. 2/3 of the ΔH_f error for >P—) the energy of each unstrained PP single σ bond. A similar group value analysis for alkane chains does lead to the correct value for diamond if experimental ΔH_f's are used, but not if MNDO predictions are employed, because MNDO substantially underestimates the stability of highly-branched hydrocarbon chains. Our conclusion regarding P—P bond energy is also supported by the calculated ΔE for the reaction

$$2PH_2 \rightarrow P_2H_4$$

for which MNDO predicts −65.7 kcal compared to −61 ± 4 experimental (5). Thus the strength of the P—P single bond in P_2H_4 seems to be overestimated by 5 ± 4 kcal, which is not inconsistent with the value of 2 ± 3 obtained above.

Given that the total energy for the one σ and two π bonds in P_2 is correctly predicted, we can conclude that MNDO must underestimate the energy of each phosphorus–phosphorus π bond by about 1.5 kcal.

Since the MNDO ΔH_f's for P_nH_m chains are accurately duplicated using the group values derived above, strain energies in various conceivable cyclic structures formed by phosphorus atoms can be derived from their MNDO-predicted heats of formation (listed in Tables 1 and 2). Before proceeding with such an analysis, however, it is useful to note that a strong preference is evident in all MNDO calculations for PP single-bonded molecules for an *anti* conformation of the lone pair positions on adjacent phosphorus atoms. According to MNDO, it requires an input of 4.2 kcal to eclipse the lone pairs (and hydrogens) in P_2H_4, and 2.6 kcal to achieve *gauche* lone pairs relative to the *anti* conformations. The optimum conformations for all the P_nH_{n+2} chains studied is *anti* for adjacent lone pairs.

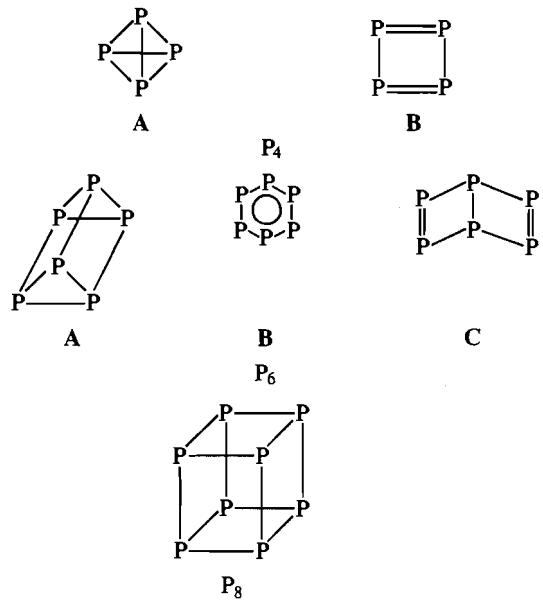

FIG. 1. Lewis structures for P_4, P_6, and P_8 molecules.

In all cases, disproportionation of the chains to elemental hydrogen and phosphorus (black) is predicted to be energy-releasing, which may account for the fact that such species have never been prepared:

$$P_nH_{n+2} \rightarrow nP + \left(\frac{n}{2} + 1\right)H_2 \qquad \Delta E < 0$$

MNDO predicts rather different stabilities for the two isomers of the three-membered $(PH)_3$ ring system; that with one hydrogen located on the side of the P_3 plane opposite to the other two is favoured by 6.0 kcal, presumably because it involves two less eclipsing lone pair − lone pair (and H−H) interactions, compared to the isomer with all three hydrogens on the same side of the P_3 plane. The strain energy of 24.9 kcal calculated for the stabler isomer of $(PH)_3$ presumably includes a contribution of 3 or 4 kcal from the one eclipsing lone pair − lone pair interaction and 21−22 kcal from bending to 60° the PPP angles from their preferred 101°−102° (predicted for unbranched chains) or 104.5° (predicted for $P(PH_2)_3$). These strainless angles are slightly larger than the values of 96.3° and 102.1° found experimentally in black phosphorus (6).

From the heat of formation calculated for gaseous white phosphorus, P_4 (isomer *A* in Fig. 1) which contains a tetrahedron of P atoms and therefore has four P_3 faces, an MNDO strain value of about 92 kcal is derived, i.e. the strain per PPP face is almost identical to that for $(PH)_3$. Experimentally, the ΔH_f for $P_4(g)$ is +14.1 kcal (4) which, when combined with the presumably strain-free value for —P< of −9.4 kcal yields a total strain energy of 51.7 kcal, i.e. 13 kcal per face. Thus MNDO apparently overestimates strain energy in three-membered rings of phosphorus, as it also does for hydrocarbons and rings of sulfur atoms (1*e*, 2).

For the four-membered ring $(PH)_4$, MNDO predicts that the isomer with hydrogen atoms alternating positions relative to the local P_3 planes is more stable by 16.3 kcal than that with all hydrogens on the same side; thus each of the four eclipsing lone pair − lone pair (or H−H) interactions in the latter destabilizes the molecule by 4.1 kcal. A strain energy of 8.5 kcal is derived from the calculated ΔH_f of the isomer which is free of lone pair − lone pair eclipsing interactions. This rather small value is not unexpected given that the average PPP angle in the ring of ~86° is not very different from the strain-free value (see above). The cross-ring[1,3] destabilizing interactions which contribute substantially to the net strain energy in other four-membered rings also operate here since the planar form of the ring (where such interactions are magnified) lies 5.3 kcal above the equilibrium geometry — in which the PPPP dihedral angle is 29°. Thus the total strain for a planar four-membered ring is 14 kcal.

We have performed MNDO calculations for the "cubane"-like isomer of P_8, i.e. with a geometry in which each phosphorus atom lies at the corner of a cube. The predicted ΔH_f of +4.1 kcal corresponds to 0.5 kcal per mol of P atoms, the lowest value we obtained for any of the finite P_n systems (n = 2, 4, 6, 8) studied herein. Nevertheless the total strain energy 116 kcal is large, and corresponds to 19 kcal per face, i.e. slightly more than that found for the planar $(PH)_4$ ring.

The strain energy computed for the stablest P_6 isomer we found, i.e. the phosphorus equivalent of prismane (P_6-**A**), is 110 kcal, i.e. 22 kcal per each of the five faces (two of which are three-membered rings and three four-membered rings). Since MNDO overestimates the strain energy of three-membered phosphorus rings, the prismane strain probably also is an upper limit. Unfortunately, there is no experimental data for any four-membered phosphorus ring from which we can decide the sign or magnitude of the MNDO error for such systems. If the MNDO results for sulfur rings are a guide here, the overestimate of strain in P_4 is approximately transferrable as a percentage, i.e. 60%, to four-membered rings.

For P_4 and P_6, we have performed calculations for isomers which contain phosphorus−phosphorus double bonds. For HP=PH itself, MNDO predicts the existence of two stable isomers, both planar, with the *trans* geometry more stable than the *cis* by 2.1 kcal. The PPH angle of 107.2° in the *cis* is larger than the 100.2° for the *trans*, due presumably to steric effects. The double bond in HP=PH is predicted to be less stable than the average of PP triple and single bonds, since for the disproportionation reaction

$$2\ P_2H_2 \rightarrow P_2 + P_2H_4$$

the ΔE predicted by MNDO is +17.0 kcal.

Since PP σ bonds are substantially more stable than the π bonds, it is not surprising that P_4 and P_6 isomers containing P=P are predicted to be less stable than isomers with P—P bonds only, notwithstanding the (overestimated) strain in the small rings found for the exclusively singly-bonded structures. Thus the P_4 analog of cyclobutadiene, (P_4-**B**), is calculated to be 25.4 kcal less stable than predicted for **A**, the analog of tetrahedrane (P_4-**A**).

In contrast to the cyclobutadiene analog (P_4-**B**) which is predicted to have bond lengths which alternate strongly (see Table 1), the phosphorus analog of benzene, P_6-**B**, is stabilized by resonance since even when the MNDO calculation is initiated with PP distances appropriate to an alternating Kekule-like structure, a planar structure with all bond lengths equal is obtained. The resonance effect in these molecules can be estimated by comparing their calculated ΔH_f to that expected from the group value for *cis* —P= of +8.9 kcal which was derived by combining the heats of formation of *cis* HP=PH and HP=P—P=PH (planar, all-*cis* conformation) listed in Table 2. (A comparable analysis of experimental values for hydrocarbons leads to 21.6 kcal for the resonance energy in benzene, i.e. the "Dewar Resonance Energy" value (7).) By this mea-

For personal use only.

sure, the benzene analog is stabilized by 22.5 kcal, and the cyclobutadiene analog is destabilized by 26.0 kcal — due presumably to a combination of antiaromaticity and angle strain effects. (The destabilizations due to eclipsing lone pairs are automatically included by using group values appropriate to *cis* units.)

The prismane analog of P_6 is predicted to be 5 kcal more stable than the benzene analog (although the stability of the former probably is underestimated), and about 10 kcal more stable than the analog of Dewar benzene, i.e. P_6-**C** in Fig. 1. MNDO calculations for the $(PH)_6$ ring confirm that this molecule is strainless, at least in the chair conformation, since it adopts bond angles (averaging 101.7°) which are virtually identical to those in free chains and since its calculated ΔH_f actually is 2 kcal more negative than that expected from the group values.

It is somewhat disconcerting that MNDO calculations for various P_6 and P_8 systems predict heats of formation for P atoms which are comparable to that observed for P_4, and yet only the tetramer apparently is observed in the vapour phase of the element. The possibility of splitting P_6 rings from black phosphorus as it decomposes seems most feasible, given that the atoms occur in fused six-membered rings in this infinite polymer.

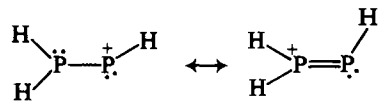
An MNDO calculation was performed for the P_7H_5 structure shown below. The P_7 framework here is of interest since red–violet phosphorus is known to contain such units, with each of the hydrogen atoms in P_7H_5 replaced by bonding to other P_7 units. The calculation we have done has all hydrogen atoms, except that of the bridgehead, pointing up toward the bridge, since this is the conformation in red–violet phosphorus (8). The calculated strain energy of 15.9 kcal amounts to 2.3 kcal per mol of phosphorus atoms. The actual strain energy in red–violet phosphorus should be larger than this, since the bond joining the bridgehead atoms is abnormally long (and therefore weak) and since additional strain may be associated with fusion of the rings.

Ions and radicals

In our calculations for elemental sulfur and the sulfur hydrides, it was established that whereas MNDO deals fairly successfully with the homonuclear π bonds in S_2, the strength of three-electron π bonding between nonequivalent sulfurs in free radicals is underestimated substantially (2). We suspect that an even more serious underestimation occurs for phosphorus molecules. In particular, MNDO calculations for the energy of hydrogen abstraction predict that the process for P_2H_4, whose resultant radical P_2H_3 can be stabilized by three-electron π bonding between the two P atoms, requires only 1.3 kcal less than that (27.5 kcal) for PH_3. Unfortunately no experimental information appears to be available regarding this process. In P_2H_3, the calculated PP distance of 1.985 Å is much closer to the values computed for single bonds (2.01–2.08 Å) than for double (1.83–1.86 Å). In addition, the geometry at the tricoordinate atom is distinctly pyramidal (see Table 2), and the unpaired electron is almost completely localized on the dicoordinate phosphorus.

Similarly, in the triplet state of the open-chain P_3H_3 the optimum geometry is so nonplanar at all three P atoms as to eliminate the possibility of any substantial three-electron π bonds. The calculated energy to remove two hydrogens from the P_3H_5 chain, one from each terminal atom, is only 5.2 kcal less than twice the energy to remove an H from PH_3.

π-Bonding is, however, predicted by MNDO calculations to be an important factor in stabilizing closed-shell cations of phosphorus rings and hydrides. The PH_2PH^+ system is predicted planar, with a PP distance of 1.846 Å and a stabilization energy of 25.5 kcal (as judged by the difference between the energies required to abstract a hydride ion from PH_3 and from P_2H_4) much of which can be attributed to π bonding:



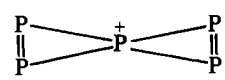
Encouraged by this result, we decided to investigate P_3^+ and P_7^+, the phosphorus analogs of the hydrocarbon analogs $C_3H_3^+$ and $C_7H_7^+$ both of which are known to be aromatic since they contain two and six π electrons respectively.

The optimum geometry for P_3^+ has equal bond lengths of 1.952 Å and an electron configuration corresponding to two π electrons. Its energy of formation via hydride abstraction from P_3H is virtually identical to that of PH_2PH^+ from P_2H_4.

The optimum geometry for P_7^+ has one phosphorus slightly out of the plane of the other six and some slight variation of bond lengths around the ring, but has an average PP distance (1.90 Å) almost as short as that (1.89 Å) predicted for the benzene-like analog of P_6.

The anion P_5^- in the geometry of a monocyclic ring is analogous to cyclopentadienyl anion and has six π electrons if planar. Although we began the MNDO calculations with a half-envelope geometry, in the geometry optimization the anion became planar with all bond lengths equal at 1.894 Å. Thus there appears to be some aromatic character associated with this system.

Calculations for planar, monocyclic P_5^+ were not performed due to the need for configuration interaction on this network. However, we did consider an interesting isomer (shown below) which is the analog of spiropentadiene. The length for the "double" bond here is 0.05 Å longer than for PH=PH (though shorter than for the P_3^+ system), whereas the "single" bonds are 0.03 Å shorter. These bond length variations are not



unexpected given that the filled π MO of one P=P pair is of the correct symmetry to donate electron density into the empty π^* MO of the other unit and vice-versa. As a result of such interactions, the bond orders for the formal double bonds are reduced but some bonding between the two P=P pairs is created, thus reducing the lengths of the "single" bonds (see also the analysis for spiro systems by Goldstein and Hoffmann (9)).

Phosphorus–oxygen molecules

The heats of formation and structures calculated by MNDO for several P_nO_m molecules of interest are summarized in Table 3. Since MNDO cannot handle quantitatively phosphorus in the pentavalent state, most of the interesting oxides and oxyacids were not considered.

TABLE 3. MNDO calculations for phosphorus oxides

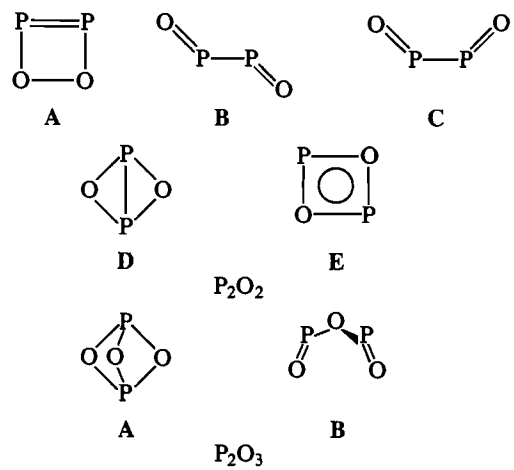

FIG. 2. Lewis structures for oxides of phosphorus.

Since MNDO overestimates, by 14.3 kcal, the stability of the ·P═O free radical in its π state (experimental ΔH_f = −6.8 kcal (4)), we suspect that this trend may appear as well in all structures containing the —P═O unit.

For ·PO_2, MNDO predicts that the unpaired electron occupies a σ orbital (as is found in the analogous ·NO_2 system) which is rather evenly delocalized over all three atoms. The phosphorus−nitrogen analogy breaks down somewhat for P_2O since although we obtained a PPO rather than a POP structure (no convergence obtained when the calculation was initiated with a POP geometry), the PPO angle is only 164° rather than 180°.

Five isomers, covering a range of stability of 105 kcal, were obtained in MNDO calculations for P_2O_2; see Fig. 2 for their Lewis structures. Least stable is **A** which contains P═P and O—O linkages. The chains **B** and **C** are next in stability, being each about 20 kcal more favourable than two separated ·P═O units. Although the (initially) *trans* isomer is almost planar, the (initially) *cis* geometry reverted to a twisted molecule similar to hydrogen peroxide. Although conjugation of the π bonds with each other is destroyed by twisting to this conformation, the geometry does allow donation of electron density from the lone pair of one phosphorus into the π* MO at the other end of the molecule. By this mechanism the PP bond is strengthened, as is manifested by its contraction of 0.021 Å relative to that in the *trans* and by the energetic preference for the twisted form of 2.2 kcal.

Even with the exaggerated stability for π bonds in MNDO and the strain associated with small rings, the inherent superiority of phosphorus−oxygen σ bonds to π bonds leads to the greater stability of the P_2O_2 isomers **D** and **E** compared to **B** and **C**. The "bicyclobutane" analog, **D**, possesses PO and PP σ bonds of usual length; the angle between the two POP planes is 76°. The "cyclobutadiene" analog **E** is much the stabler of the pair since it contains only a four-membered ring and since the π network contains six electrons and therefore is "aromatic" to some degree:

For personal use only.

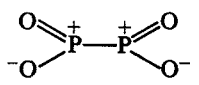
The PO bond lengths are all equal at 1.592 Å, which is the single bond length minus one quarter of the contraction associated with a double bond.

Given the experience above, the only isomers we considered for P_2O_3 are those having only phosphorus–oxygen bonds. Structure **A** contains only σ bonds whereas **B** has both σ, and π, the latter potentially conjugated via the central oxygen.

Energetically **A** is preferred to **B** by 9.1 kcal according to MNDO; this value probably is a lower limit given the method's underestimation of the preference for σ over π bonds in PO links. The phosphorus–oxygen bond lengths predicted for **A** are identical with those for other single bonds between these atoms; as a result the phosphorus–phosphorus distance is only 2.22 Å, i.e. only 10% greater than the P—P value. In **B**, the terminal bond lengths are those expected for P=O whereas the middle pair show significant contraction from the usual P—O length. Starting from both the all-*cis* and the all-*trans* planar forms for **B**, the same nonplanar structure is obtained (see Table 3 for details). The helix shape adopted by **B**, with a wide POP angle, allows for substantial overlap of the lone pairs on the central oxygen each with one of the π networks on the terminal atom pairs. The electron density associated with the p_π orbitals in each P=O is 2.11 electrons, indicating substantial donation from the central oxygen into each $\pi^*_{P=O}$ molecular orbital.

To our knowledge, none of the above-mentioned P_2O_2 or P_2O_3 molecules have been observed. Experimentally, the burning of phosphorus in (limited) oxygen produces P_4O_6, which contains only P—O bonds in a geometry which is rather strain-free, namely a tetrahedron on phosphorus atoms with one oxygen atom associated with (but pushed away from) each of the six edges of the P_4 tetrahedron. We performed an MNDO calculation for P_4O_6, starting with this symmetrical structure but allowing all bond lengths and angles to vary independently. After many iterations, a structure of rather low symmetry was obtained. The P—O bond lengths vary from 1.54 to 1.71 Å, compared to 1.64 Å experimentally (10), and the PP (nonbonded) distances vary from 2.75 to 3.02 Å. The POP angles, 126.4 ± 0.7° experimentally, vary in our structure from 119° to 137°, and the OPO angles vary from 70° to 80° compared to 99.8 experimentally (10). The calculated ΔH_f of −466.4 kcal is much more stable than that computed for $2P_2O_3$ units (by 102.6 kcal) and than that of −381.9 kcal obtained experimentally (5*b*). Frenking *et al.* report an MNDO calculation for P_4O_{10} with a calculated ΔH_f of −521.2 kcal, and a single PO length (11). The experimental ΔH_f they quote is −529.2 kcal, based presumably on the older determination (12).

Finally, we performed a calculation for P_2O_4, starting with a structure similar to that known for N_2O_4:



Although a nonplanar geometry was initially assumed, the MNDO calculations converged to an exactly planar structure, with PO lengths virtually identical to those in PO_2 and with a ΔH_f which is 19.9 kcal *less* stable than that for two PO_2 molecules. Analogous calculations for N_2O_4 yield a molecule which is 39.1 kcal less stable than $2NO_2$ and which is 90° twisted about the NN bond.

Conclusions

MNDO does quite well in predicting the strengths of both σ and π two-electron bonds between phosphorus atoms. The strain energy in three-membered rings, however, is overestimated, and the strength of three-electron π bonds apparently is underestimated. These trends are very similar to those obtained with sulfur, although there MNDO overestimated strain in other small rings as well, whereas this may not be true for phosphorus. The MNDO predictions for P_6 and P_8, and for the ions P_3^+, P_5^-, and P_7^+ indicate that these systems are relatively stable energetically, and should be capable of detection under appropriate experimental conditions. However, on the basis of *ab initio* and bond energy calculations Trinquier and co-workers predict that cubic P_8 will be substantially less stable than two tetrahedral P_4 due mainly to unfavourable bond–bond interactions in the former (13).

The experience with MNDO calculations for the oxides of trivalent phosphorus indicate that the method handles PO σ bonds very well but overestimates the strength of π bonds.

Received March 10, 1983

MAHADEO A. NABAR and BHARAT N. JUKAR. Can. J. Chem. **62**, 348 (1984).

A new series of double malonates of some of the lanthanides and yttrium with sodium having the formula $Na_5Ln(C_3H_2O_4)_4.7.5\ H_2O$ was synthesised. The compounds were characterised using X-ray powder diffractometry and infrared absorption spectroscopy.

MAHADEO A. NABAR et BHARAT N. JUKAR. Can. J. Chem. **62**, 348 (1984).

On a synthétisé une nouvelle série de malonates doubles de quelques lanthanides et de l'yttrium avec le sodium de formule: $Na_5Ln(C_3H_4O_4)_4.7.5H_2O$. On a caractérisé les composés en faisant appel à la diffraction des poudres par rayons-X et à la spectroscopie d'absorption dans l'infrarouge.

Introduction

Davitashvili *et al.* have studied the reaction of different rare earth nitrates with alkali metal oxalates and ammonium oxalate in water (1–5). Formation of double oxalates, $M^ILn(C_2O_4)_2.xH_2O$ (M^I = alkali metal or ammonium, Ln = lanthanide) was observed in most cases. In a few cases, however, these compounds started dissolving at higher $C_2O_4^{2-}:Ln^{3+}$ ratio, with the formation of more stable soluble complexes, which did not precipitate even after a long duration. However, no further attempts were made to isolate them.

Research is in progress in this laboratory on the double salts of malonic acid, the next higher homologue of oxalic acid, to examine the systematics of these systems. The lighter lanthanide ions, in the presence of concentrated aqueous alkali metal (Na, K) malonates, precipitated the double salts of the type $M^ILn(C_3H_2O_4)_2{\cdot}xH_2O$. However, here again the soluble complexes at higher ionic ratios of $C_3H_2O_4^{2-}:Ln^{3+}$ could not be isolated. On the other hand, for heavier rare earth elements (Gd, Tb, Dy, Ho) and yttrium, the soluble complexes formed could be obtained in solid form by crystallization.

The present article describes the synthesis and study of some of the physicochemical properties of the isolated rare earth double malonates, $Na_5Ln(C_3H_2O_4)_4.7.5H_2O$, where Ln = Gd–Ho, or Y.

Experimental

Synthesis

An aqueous solution of sodium malonate (324 mg of $(C_3H_2O_4)^{2-}$ cm^{-3}) was mixed with the rare earth malonate in the ionic ratio $Ln^{3+}:C_3H_2O_4^{2-}$ as 1:4. The mixture was warmed on the water bath to get a clear solution, which on evaporation at ambient temperature gave the desired double malonate. The crystallised compound, after transferring to a filter, was washed with 50 cm^3 of 90% methanol and dried over silica gel under vacuum.

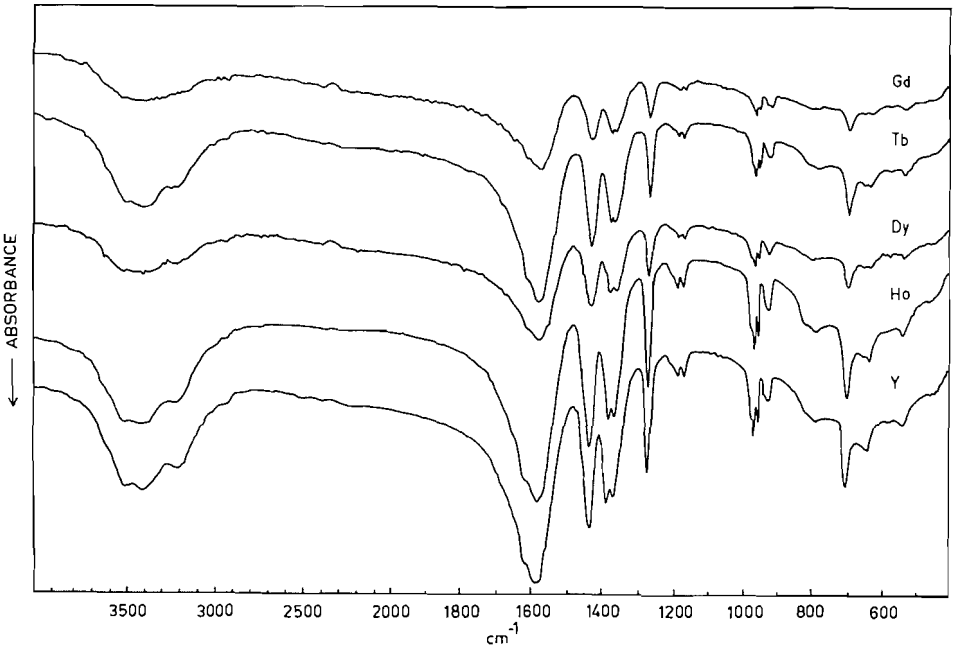

FIG. 1. Infrared spectra of $Na_5Ln(C_3H_2O_4)_4.7.5H_2O$.

Analyses

The sodium and rare earth contents in the double malonates were determined flame photometrically and complexometrically, respectively. Malonate ion percentage was estimated using ion exchange method. The water of crystallization was determined by isothermal dehydration at suitable temperature. Analytical results are given in Table 1.

Ni filtered CuK_α radiation was used for the X-ray powder diffraction study. The densities of the compounds were determined by the flotation method, using bromoform – *n*-hexane mixture as a working medium. Infrared absorption spectra of the double malonates were scanned in the frequency range 4000–400 cm^{-1} with a Perkin-Elmer Model 377 by CsBr disc method.

Results and discussion

X-ray diffraction

The double malonates are isomorphous and are indexed on a monoclinic cell using Ito's (6) method. The unit cell comprised four formula units and the probable space group assigned is $P2_1/m$, (systematic extinctions: $0k0:k = 2n + 1$). There is a linear decrease in lattice dimensions a, b, and c and hence in the volume (Table 2) from gadolinium to holmium, in accordance with the lanthanide contraction.

The indexed powder data of dysprosium double malonate are reported in Table 3, as a representative example.

Infrared absorption spectroscopy

The infrared spectra of the double malonates are similar to each other (Fig. 1). The spectral data of the compounds are reported in Table 4. The attributions of various vibrations are done by comparison with the published data (7–9). In particular, it may be pointed out that the $\nu(OCO)_{asym}$ (~1590 cm^{-1}) and $\nu(OCO)_{sym}$ (~1380 and 1370 cm^{-1}) frequencies for the double malonates appear at higher and lower frequencies, respectively, than the corresponding frequencies in potassium malonate (7), indicative of an increase in the covalent nature of Ln—O bond.

Pseudobase formation from 9-substituted 10-methylacridinium cations in aqueous solution

JOHN W. BUNTING, VIVIAN S. F. CHEW, SUDHIR B. ABHYANKAR, AND YUKIKO GODA
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received July 18, 1983

JOHN W. BUNTING, VIVIAN S. F. CHEW, SUDHIR B. ABHYANKAR, and YUKIKO GODA. Can. J. Chem. **62**, 351 (1984).

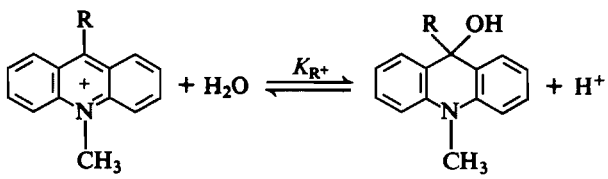
Rates of cation–pseudobase equilibration have been measured for a series of C-9 substituted (CH_3, CH_3CH_2, $C_6H_5CH_2$, $(CH_3)_2CH$, C_6H_5, 4-$(CH_3)_2NC_6H_4$) 10-methylacridinium cations in aqueous solution at 25°C over the pH range of approximately 9–13. Separation of the rate constants for formation (k_{OH}) and decomposition (k_2) of each of these pseudobases allowed the calculation of the pK_{R^+} value for each cation. The presence of a C-9 isopropyl substituent enhances the stability of the pseudobase relative to the cation, whereas all other C-9 substituted cations have pK_{R^+} values greater than the 10-methylacridinium cation. There is no simple quantitative relationship between pK_{R^+} and the size of the C-9 substituent. Rate constants (k_{OH}) for hydroxide ion attack on these C-9 substituted cations are in the order: H > primary alkyl > secondary alkyl > aryl, while rate constants (k_2) for pseudobase decomposition are less predictable but generally follow the order: H > primary alkyl > aryl > secondary alkyl. These phenomena are shown to be consistent with a competition between destabilization of the cation by *peri* interactions between the C-9 substituent and H(1) and H(8) and reduced pseudobase solvation for large C-9 substituents. Resonance interactions of 9-aryl substituents with the acridine moiety of these cations are shown to be quite small. 9-Aryl-10-methylacridinium cations are approximately 30-fold more reactive towards hydroxide ion attack than are their triphenylmethyl carbocation analogues.

JOHN W. BUNTING, VIVIAN S. F. CHEW, SUDHIR B. ABHYANKAR et YUKIKO GODA. Can. J. Chem. **62**, 351 (1984).

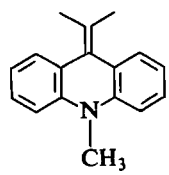
On a déterminé les vitesses d'équilibre de la pseudobase cationique d'une série de cations méthyl-10 acridinium ayant un substituant en position 9 (CH_3, CH_3CH_2, $C_6H_5CH_2$, $(CH_3)_2CH$, C_6H_5, $CH_3)_2NC_6H_4$-4), en solution aqueuse à 25°C, dans un intervalle de pH allant de 9 à 13. La séparation des constantes de vitesse de formation (k_{OH}) et de la décomposition (k_2) de chacune de ces pseudobases permet de calculer la valeur du pK_{R^+} de chaque cation. La présence d'un substituant isopropyle en C-9 augmente la stabilité de la pseudobase par rapport au cation tandis que tous les autres cations substitués en C-9 ont des valeurs de pK_{R^+} plus élevées que celle du cation méthylacridinium-10 lui-même. Il n'y a pas de relation quantitative simple entre le pK_{R^+} et la taille du substituant en C-9. Les constantes de vitesse (k_{OH}) de l'attaque de l'ion hydroxyde sur ces cations substitués sont dans l'ordre suivant: H > alkyle primaire > alkyle secondaire > aryle, tandis que les constantes de vitesse (k_2) de décomposition de la pseudobase sont plus difficiles à prédire mais suivent en général l'ordre: H > alkyle primaire > aryle > alkyle secondaire. On montre que ces phénomènes sont en accord avec une compétition entre la déstabilisation du cation par des interactions *péri* entre le substituant à C-9 et les hydrogènes H(1) et H(8) et la solvatation réduite de la pseudobase pour des substituants grands en C-9. On montre que les interactions de résonance, des substituants aryles avec l'unité acridine de ces cations, sont très faibles. Les cations aryl-9 méthyl-10 acridinium réagissent environ 30 fois plus rapidement avec les ions hydroxydes que les carbocations triphénylméthyles analogues.

[Traduit par le journal]

Previous attempts (1) to measure the pK_{R^+} values for pseudobase formation from 9-alkyl-10-methylacridinium cations (**1**) were hampered by the limited solubilities of these pseudobases (**2**) in strictly aqueous media. A further complication arises for those 9-alkyl substituents having hydrogen atoms on the carbon atom that is directly bonded to C-9 of the acridine moiety. In such cases, the formation of an anhydrobase (**3**) in a deprotonation reaction competes with the hydroxide ion addition reaction to form **2**. Based upon a limited number of observations (1), it seems that the pseudobase (**2**) is the kinetically-controlled product from **1** in basic solutions, whereas the anhydrobase (**3**) is the thermodynamically more stable product. Thus, attempts to measure equilibrium constants for pseudobase formation from the electronic absorption spectra of equilibrated basic aqueous solutions of **1** are frustrated by both limited solubility and a competing reaction.



1 **2**



3

We have now overcome these complications by measuring pseudo-first-order rate constants for the approach to the cation–pseudobase equilibrium over the first few half-times of the reaction. Separation of the rate constants for the forward and reverse reactions then allows the calculation of pK_{R^+}.

Experimental

9-Alkylacridines and 9-phenylacridine were synthesized by the high temperature reaction of diphenylamine with the appropriate carboxylic acid (2). These bases were then methylated with dimethyl sulfate and the crude 9-alkyl-10-methylacridinium methylsulfates were converted to the corresponding chloride salts by Albert's general method (ref. 2, p. 343). These chloride salts were recrystallized several times from ethanol and characterized by ^{1}Hmr spectroscopy in trifluoroacetic acid solution.

9-(4-Dimethylaminophenyl)-10-methylacridinium chloride was prepared by refluxing 10-methylacridinium chloride with *N*,*N*-dimethylaniline in ethanol as described by Ballard *et al.* (3).

Rates of cation–pseudobase equilibration were followed spec-

trophotometrically in aqueous solution (ionic strength 0.1 (KCl + buffer)) at 25°C, by mixing a solution of the acridinium cation (within the range 0.01–0.02 m*M*) in water with appropriate buffer solutions on either a Varian Cary 210 spectrophotometer or a Durrum–Gibson stopped-flow spectrophotometer. Each cation was studied in 10–15 solutions of different pH over a range of at least 3 pH units spanning the pK_{R^+} value.

All reactions proved to be kinetically first-order in total acridine concentration for at least three half-lives, although deviations from strictly first-order behaviour were observable at longer reaction times, especially in the slower reactions. These deviations were readily attributable to either precipitation or anhydrobase formation. In general, rate constants were obtained by digitizing absorbance vs. time curves at approximately 40 points over the first three reaction half-times, and then fitting the data by the Guggenheim technique.

Results

Acridinium cations (**1**) display an intense electronic absorption maximum in the vicinity of 360 nm and a series of less intense maxima in the region 390–420 nm. The corresponding pseudobases (**2**) show an intense maximum only in the vicinity of 280 nm (where **1** only weakly absorbs), and are essentially transparent at all wavelengths longer than about 320 nm. Thus the rate of equilibration of **1** with **2** can be readily measured either from the increase in absorbance with time at 280 nm, or alternatively from the decrease in absorbance with time at essentially any wavelength between 320 and 450 nm. All rate constants reported in this work were independent of the wavelength of observation. Decreases in absorption in the region of 400 nm are consistent only with pseudobase formation since the anhydrobases show absorption maxima in the vicinity of 400 nm. The most basic solutions of **1**: R = CH_3, C_2H_5, and $C_6H_5CH_2$, the rates of cation–pseudobase equilibration were sufficiently rapid that stopped-flow spectrophotometry was required. In less basic solutions of the above cations, and also for **1**: R = $(CH_3)_2CH$ and 4-$(CH_3)_2NC_6H_4$ over the entire pH region, rates of equilibration were readily accessible on a recording spectrophotometer after manual mixing of solutions.

The pH dependences of the experimentally determined pseudo-first-order rate constants for cation–pseudobase equilibration are displayed in Fig. 1 for **1**: R = CH_3, CH_3CH_2 $(CH_3)_2CH$, $C_6H_5CH_2$, and 4-$(CH_3)_2NC_6H_4$. In each case k_{obs} is linear in $[HO^-]$ in the more basic solutions, but approaches pH independence in the less basic solutions. The data of Fig. 1 were fitted to eq. [1] by regression analysis, and the parameters k_{OH} and k_2 that were evaluated in this way are listed in Table 1.

$$[1] \quad k_{obs} = k_{OH}[HO^-] + k_2$$

In an earlier detailed kinetic study (4) of cation–pseudobase equilibration for **1**: R = H and C_6H_5, the rates of equilibration in the region pH > 9 (as used in the current work) were shown to be controlled by a kinetically second-order reaction between HO^- and **1** for pseudobase formation, and a pH-independent decomposition of pseudobase to cation by expulsion of hydroxide ion from **2**. Thus the empirically derived parameters of eq. [1] can be associated with the kinetic processes of eq. [2].

$$[2] \quad \mathbf{1} + HO^- \underset{k_2}{\overset{k_{OH}}{\rightleftharpoons}} \mathbf{2}$$

Thus pK_{R^+} for the equilibration of **1** and **2** can be calculated from

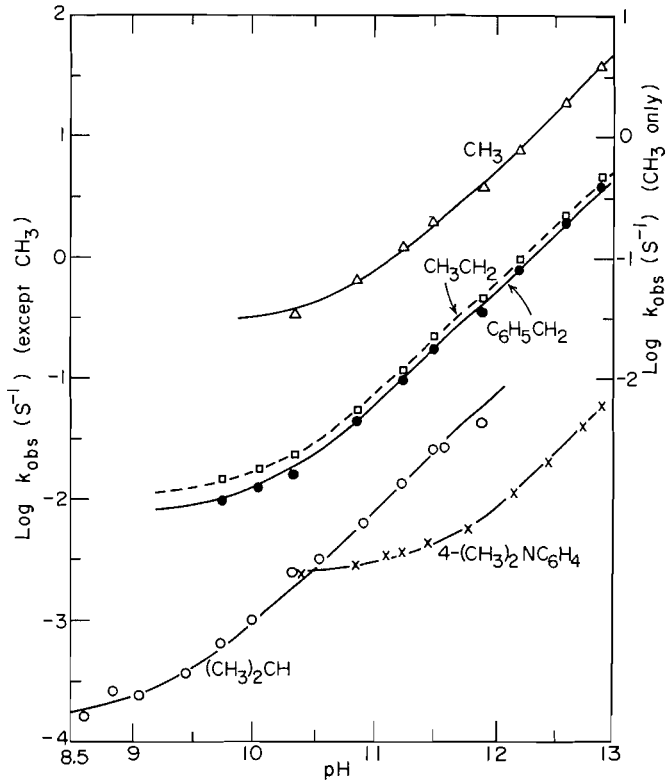

FIG. 1. pH dependence of k_{obs} for equilibration of **1** and **2** for various C-9 substituents as indicated. Curves are calculated from eq. [1] using the parameters in Table 1.

TABLE 1. Rate and equilibrium constants for equilibration of **1** and **2**[a]

R	pK_{R^+}	k_{OH} (M^{-1} s^{-1})	k_2 (s^{-1})
H[b]	10.01	550	0.058
CH_3	10.8	49±2	0.033±0.008
CH_3CH_2	10.3	59±3	0.011±0.001
$C_6H_5CH_2$	10.2	50±2	0.008±0.002

C_6H_5[b]	11.03	1.3	0.0014
4-$(CH_3)_2NC_6H_4$	11.54[c]	0.69±0.05	0.0024±0.0002

[a]In aqueous solution, ionic strength 0.1, 25°C.
[b]Data from ref. 4.
[c]pK_{R^+} = 11.51 from absorbance vs. pH of equilibrated basic solutions.

$$K_{R^+} = \frac{[H^+][\mathbf{2}]}{[\mathbf{1}]} = \frac{K_w \cdot [\mathbf{2}]}{[\mathbf{1}][HO^-]} = K_w \cdot k_{OH}/k_2$$

Values of pK_{R^+} evaluated in this way are included in Table 1. For **1**: R = 4-$(CH_3)_2NC_6H_4$, pK_{R^+} was also accessible from the pH dependence of the electronic absorption spectrum of the equilibrated mixture of cation and pseudobase. The pK_{R^+} value evaluated in this way is 11.51 and is in excellent agreement with the value obtained from the kinetic data.

Discussion

The pK_{R^+} values in Table 1 indicate that, whereas a C-9 methyl, ethyl, or benzyl group slightly stabilizes the 10-methylacridinium cation towards pseudobase formation, the presence of the more sterically hindered isopropyl substituent at C-9 actually somewhat enhances the thermodynamic stability of the pseudobase relative to the cation. This relative enhancement of pseudobase stability in the 9-isopropyl deriva-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

tive is not reflected, however, in the rate of hydroxide ion attack to form the pseudobase. Thus, whereas the equilibrium constant for pseudobase formation is 5-fold larger for **1**: R = $(CH_3)_2CH$ than for **1**: R = H, the second-order rate constant for hydroxide ion attack at C-9 is 70-fold larger in the latter case. Although the 9-isopropyl pseudobase is the most thermodynamically stable of all the cases in Table 1, its rate of formation is slower than for all other 9-alkyl derivatives.

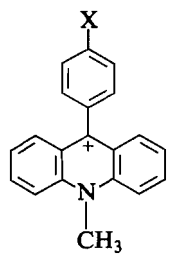
In general, the values of k_{OH} in Table 1 decrease with increasing size of the C-9 substituent (H > primary alkyl > secondary alkyl > aryl), and are presumably a simple reflection of steric hindrance to the rate of hydroxide ion attack at C-9. Values of k_2 show much less order than do those of k_{OH}, and it seems clear that it is the k_2 values that are primarily responsible for the unpredictable variation that is found for the dependence of pK_{R^+} upon the C-9 substituent.

Variation of the C-9 substituent will most directly influence the stability of **1** via increasingly unfavourable *peri* interactions between R and the C-1 and C-8 hydrogen atoms as R increases in size. Such steric interactions are relieved in the pseudobases relative to the cation, and also somewhat relieved in the transition state for cation–pseudobase interconversion. This phenomenon is quite obvious in the case of the 9-isopropyl derivative, both in the enhanced stability of the pseudobase relative to the cation (lowest pK_{R^+}), and also in the dramatic reduction in k_2 which reflects the enhanced steric congestion in the transition state relative to the pseudobase.

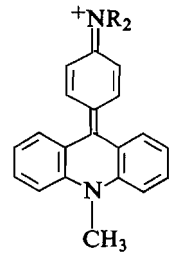
For the primary alkyl C-9 substituents (CH_3, CH_3CH_2, $C_6H_5CH_2$), the *peri* interactions are apparently not sufficiently great to produce a net increase in pseudobase stability relative to the cation when compared with the C-9 unsubstituted species. This suggests that there may be another factor which offsets to some extent the influence of the *peri* interactions in these species. We suggest that such a factor is probably to be found in the solvation requirements of the C-9 hydroxyl group in the pseudobases. The presence of a C-9 alkyl substituent will disrupt the solvation pattern of the hydroxyl group relative to the C-9 unsubstituted pseudobase species, and in so doing will result in a reduced pseudobase stability. Thus the 9-isopropyl derivative is the only case in Table 1 in which the unfavourable *peri* interactions in the cation are sufficiently great to completely offset this solvation effect, and therefore produce a net increase in pseudobase stability.

Within the series of methyl, ethyl, and benzyl C-9 substituents, the variations in pK_{R^+} and k_2 are probably mainly attributable to differences in the *peri* interactions of these substituents with H(1) and H(8). The essentially constant value for k_{OH} for these primary alkyl groups is presumably a reflection of the fact that hydroxide ion attack can occur from either face of the acridine ring system. The sp^3 hybridization of the α-methylene group of a primary alkyl group (RCH_2) will require the R group to lie on one side of the plane of the acridine ring system. Hydroxide attack from the other face of the acridine plane would then encounter a common steric interaction with the methylene group irrespective of the nature of R. The 9-isopropyl substituent can take up a conformation in which both methyl groups are on the same side of the acridine plane. The relatively small reduction in k_{OH} for the 9-isopropyl substituent relative to these primary alkyl groups can then be readily accounted for by hydroxide ion attack on the side away from these methyl groups. The smallest values for k_{OH} are observed for the 9-aryl substituents. These substituents are expected (5) to take up a conformation at a significant angle to the acridine plane, and therefore to inhibit attack at C-9 from both faces of the tricyclic system.

The 9-phenyl and 9-(4-dimethylaminophenyl) substituents both lead to enhanced cation stability towards pseudobase formation relative to the 9-unsubstituted cation. In these cases, possible contributions from resonance interactions for the stabilization of the cations must also be considered, in addition to the steric interactions and solvation effects considered above for 9-alkyl substituents. Resonance effects are most readily discussed by reference to the canonical structure **4**.



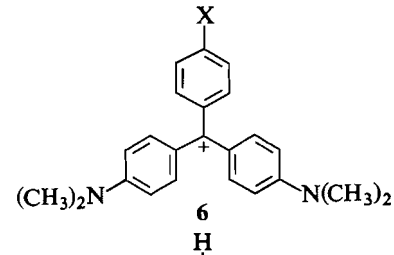
4



5

In view of the *peri* interactions of the 9-aryl substituents with the hydrogen atoms on C-1 and C-8, it is clear that the 9-phenyl ring cannot achieve coplanarity with the tricyclic acridine ring system. The dipole moment of 9-phenylacridine has been interpreted (5) as requiring an angle of greater than 40° between the planes of the phenyl and acridine rings. Such an angle should allow little overlap between the π-orbitals of the phenyl and acridine systems, and would suggest that there will be little resonance stabilization from the 9-phenyl substituent in **4**. On the other hand, the electronic absorption spectra of 9-(4-aminophenyl)acridinium cations show pronounced bathochromic shifts relative to 9-phenylacridinium cations, and these shifts have been interpreted in terms of resonance stabilization via **5** (ref. 2, p. 186).

The pK_{R^+} values for **4**: X = H and $(CH_3)_2N$ in Table 1 allow a quantitative evaluation of the importance of resonance stabilization in these systems. The 4-dimethylamino substituent does show an enhanced stability of the cation relative to the 9-phenyl substituent. However, based upon the observed $\Delta pK_{R^+} = 0.5$, this stabilization is only 0.7 kcal/mol. This is clearly much smaller than the stabilization of 3.3 kcal/mol ($\Delta pK_{R^+} = 2.45$) which is found upon comparison of the relative susceptibilities of the malachite green (**6**: X = H) and crystal violet (**6**: X = $(CH_3)_2N$) cations to carbinol formation (6). These comparisons, which should be free of solvation and steric influences, indicate that resonance interactions of the 9-aryl groups with the acridine π-system must be quite small. In fact, ΔpK_{R^+} for **4**: X = H and $(CH_3)_2N$ is even smaller than the electronic effect of a *para*-dimethylamino substituent upon the pK_a of benzoic acid ($\Delta pK_a = 0.83$ (7)).



6

TABLE 2. Rate and equilibrium constants for hydroxide ion addition to **4** and **6**

Cation	X	pK_{R^+}	k_{OH} (M^{-1} s^{-1})	k_2 (s^{-1})
4	H	11.0	1.3	1.4×10^{-3}
4	$(CH_3)_2N$	11.54	0.69	2.4×10^{-3}
6	H[a]	6.94	2.18	1.5×10^{-7}
6	$(CH_3)_2N$[a]	9.39	0.205	4.7×10^{-6}
6	X[b]	11.0	0.04	4.0×10^{-5}

[a]Data from ref. 6.
[b]Rate constants calculated as described in text for a hypothetical cation **6** having $pK_{R^+} = 11.0$.

It is of interest that $\Delta pK_{R^+} = 1.0$ for **1**: R = C_6H_5 and H is of similar magnitude to $\Delta pK_{R^+} = 1.33$ for **6**: X = H and **7** (9). While this comparison might be used to argue for similar resonance interactions of the phenyl substituents with the electron-deficient benzylic carbon atom in these two cases, we feel that steric and solvation effects are unlikely to be negligible in such a comparison, and the similarity in pK_{R^+} values in this case is probably fortuitous.

It is of particular interest to compare rate and equilibrium effects upon pseudobase formation from **4**: X = H and $(CH_3)_2N$ with analogous data for the well studied carbinol formation from the malachite green and crystal violet cations. Rate and equilibrium data for these two series of cations are collected in Table 2.

Despite their unfavourable *peri* interactions which destabilize the cations relative to the pseudobases, the 9-aryl-10-methylacridinium cations are considerably less susceptible towards pseudobase formation than their triphenylmethyl carbocation analogs. This enhanced cation stability in the acridinium system can be attributed to the resonance stabilization that is available in the tricyclic acridine ring system. Consideration of the rate constants for cation–pseudobase equilibrium indicates that, whereas k_{OH} is similar for the 9-arylacridinium and triphenylmethyl cations, k_2 for loss of hydroxide ion from the pseudobase is quite different in these two systems. This comparison can also be extended to the activation parameters for the k_{OH} and k_2 reactions. Thus whereas the entropies and enthalpies of activation are similar for hydroxide attack on the 9-phenyl-10-methylacridinium ($\Delta H^{\ddagger} = 13.8$ kcal/mol, $\Delta S^{\ddagger} = -12$ eu (4)) and the crystal violet cation ($\Delta H^{\ddagger} = 15.3$ kcal/mol, $\Delta S^{\ddagger} = -10$ eu (6)), these parameters are quite different for the k_2 step in these two cases ($\Delta H^{\ddagger} = 14$ kcal/mol and $\Delta S^{\ddagger} = -24$ eu for **2**: R = C_6H_5 (4); $\Delta H^{\ddagger} = 21.9$ kcal/mol and $\Delta S^{\ddagger} = -10$ eu for the carbinol of **6**: X = 4-$(CH_3)_2N$ (6)).

The most direct comparison of rate constants for acridinium and triphenylmethyl cations would employ cations of similar pK_{R^+} values in the two series (8). Ritchie *et al.* (6) have reported rate and equilibrium data for carbinol formation from a variety of substituted triphenylmethyl cations. Their data can be analyzed to give the rate–equilibrium correlation of eq. [3]. The relatively low correlation coefficient is indicative of some scatter in the data; however, the greatest variation of any experimental k_{OH} value from this correlation equation is by less than a factor of 3.

$$[3] \quad \log k_{OH} = -0.40(\pm 0.05)\ pK_{R^+} + 3.0(\pm 0.3) \qquad (r = 0.965)$$

Equation [3] may be used to estimate that a triphenylmethyl cation of $pK_{R^+} = 11$ would have $k_{OH} = 0.04\ M^{-1}\ s^{-1}$. Comparison of this value with $k_{OH} = 1.3\ M^{-1}\ s^{-1}$ for **1**: R = C_6H_5 indicates that 9-arylacridinium cations are 30-fold more reactive towards attack by hydroxide ion than are triphenylmethyl carbocations. The simplest interpretation of this result is probably an indication that, whereas resonance delocalization of charge occurs over all three rings of the triphenylmethyl cations, geometric considerations allow delocalization only within the tricyclic acridine ring system and not to any significant extent into the pendant phenyl ring of the 9-arylacridinium cations.

Mechanistic aspects of the methoxide-catalyzed transformation of 4-acyloxy-1,3,4-oxadiazines to N-amino-oxazolidonylhydrazones

DONALD MACKAY AND DEANE DOUGLAS MCINTYRE

The Guelph–Waterloo Center for Graduate Work in Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received January 3, 1983[1]

DONALD MACKAY and DEANE DOUGLAS MCINTYRE. Can. J. Chem. **62**, 355 (1984).

When the 1,3,4-oxadiazine **2**, one of three known isomers formed by cycloaddition of 2,5-dimethyl-3,4-diphenylcyclopentadienone and dimethyl azodicarboxylate, is isomerized by MeO^-–MeOH to the hydrazone **4**, the MeO of the ester group of **2** is lost and MeO is incorporated into **4** from the solvent. In acid, e.g. trifluoroacetic acid, demethylation of **2** gives **14** in which the ester Me is lost. The hydrazone **4** also gives **14** with acid, but by a different pathway.

These results were established using the structurally isomeric oxadiazines **10** and **11** as mechanistic probes; an X-ray analysis of **10** established the individual identities of these.

DONALD MACKAY et DEANE DOUGLAS MCINTYRE. Can. J. Chem. **62**, 355 (1984).

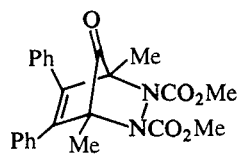
La oxadiazine-1,3,4 (**2**), l'un des trois isomères obtenus dans la cycloaddition de la diméthyl-2,5 diphényl-3,4 cyclopentadiénone et de l'azodicarboxylate de diméthyle, s'isomérise en présence de MeO^-–MeOH en hydrazone **4**; le composé **2** perd un groupe MeO^- et ce dernier s'incorpore dans le composé **4** à partir du solvant. En milieu acide, par exemple l'acide trifluoroacétique, le composé **2** subit une déméthylation et conduit au composé **14** dans lequel de groupe Me de l'ester est perdu. L'hydrazone **4** conduit également au composé **14** en présence d'un acide mais selon un mécanisme différent.

On a établi ces résultats en utilisant les isomères de structure des oxadiazines **10** et **11** comme références; l'analyse par rayons-X du composé **10** permet d'identifier individuellement les isomères.

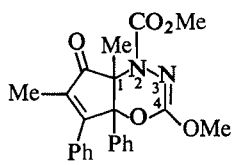
[Traduit par le journal]

Introduction

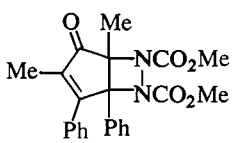
We have previously shown that heating of 2,5-dimethyl-3,4-diphenylcyclopentadienone with dimethyl azodicarboxylate rapidly gave the bridged adduct **1** which isomerized reversibly to the oxadiazine **2**, and more slowly, but irreversibly, to the diazetidine **3** (1). Recently we have described the conversion of **2** into another isomer, the dimethyl carbonate hydrazone **4** (2). The four isomers thus show a wide variety of bicyclic structural arrangments: [2.2.1], [3.4.0], [3.2.0], and [3.3.0].



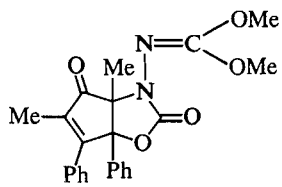
1



2



3

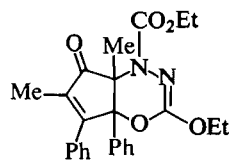


4

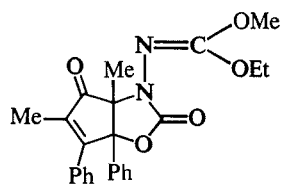
The formation of **4** required the use of a dilute solution of KOH or NaOMe in MeOH; KOH in EtOH or H_2O completely degraded **2**. This suggested that external MeOH was incorporated into **4**, confirmation of which came from the conversion of the oxadiazine **5** by KOH in MeOH into a mixture of the diastereomeric hydrazones **6** and **7**. Though **4** is an isomer of **1**–**3**, it is not an isomerization product.

We briefly describe here experiments which help to clarify the nature of the transformation of **2** into **4**. We also wish to comment further on the acid-catalyzed demethylation of the isomers **1**–**4**.

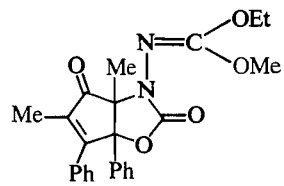
[1]Revision received July 28, 1983.



5



6



7

Base-catalyzed formation of the carbonate hydrazones

Reactions **2** → **4** and **5** → **6** + **7** leave us with the following questions. (*i*) Which MeO group in **2** is lost? One MeO (and only one) is lost since **5** gives **6** and **7**, but gives neither **4** nor the analogous di-ethoxy compound. (*ii*) Why does **5** gives *both* diastereomeric hydrazones? Restated for the transformation **2** → **4**, why are the MeO groups in **4** scrambled with respect to their origin from **2** and the solvent? (*iii*) Which N in **2** becomes the exocyclic N in **4**? (*iv*) Why is MeOH apparently so specific? The analogous transformation is not observed in other alcohols, e.g. ethanol.

(i) and (ii)

Further evidence for the inclusion of external MeOH came from repetition of the reaction of **2** with 0.1 *M* KOD in methanol-d_4 at 65°C. Disappearance of the MeO peaks of **2**, coincident at 3.67 (δ values in CD_3OD), was accompanied by the growth of new MeO peaks at 3.30 (**4** and MeOH) and 3.70 (**4**). Their ratios throughout indicated that the two peaks for **4** were growing at about the same rate. After work-up these MeO peaks were of equal intensity and each was half that of the C-Me peaks.

This result is consistent either with the intermediacy of a

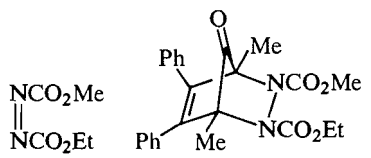
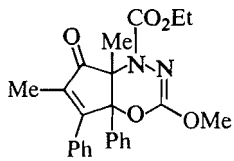
symmetric precursor to **4**, containing one CH_3O and one CD_3O group, or, more likely, with the formation of a single diastereomeric hydrazone, which is rapidly *E,Z* equilibrated. This equilibration is certainly not catalyzed by addition of MeO^- to the imino carbon (thus allowing C—N rotation), since the CH_3O^- is not all lost in the labelled experiment. Thermal *E,Z* inerconversion is most likely. Though the MeO peaks of **4** in CD_3SOCD_3 ($\Delta\nu$ = 16.2 Hz at 80 MHz[2]) did not coalesce at 150°C (2), the lower limit associated with this barrier ($\Delta G^{\ddagger}$ = ca. 22 kcal/mol; the associated rotation frequency is 36 s^{-1}) does not allow us to rule out thermal rotation on the time scale of the experiment.[3]

An answer to the question of which MeO group in **2** is lost requires a distinction between these groups to be created, either isotopically or though the replacement of one of them by a constitutionally different variation. Perforce we chose the latter. Conditions necessary for removal of the ester group (acid or base) in **2**, and thence replacing it with an isotopically different methoxycarbonyl group, lead to rapid transformation of the heterocyclic ring.

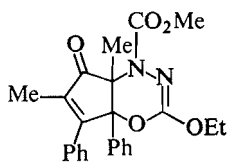


8

9



10



11

Our starting point was the unsymmetrical azo compound **8**. Its synthesis and that of its cyclone adduct **9** were unexceptional. Refluxing of **9** in MeCN for 40 h gave the equilibrium mixture of oxadiazines (cf. ref. 1), as well as traces of the diazetidines (cf. **3**). Separation of the individual oxadiazines from this five-component mixture was tedious, requiring column chromatography and repeated crystallizations. Small amounts were obtained pure with melting points 124.5−125.5°C and 133−135°C. The former was subjected to X-ray analysis and found to be the carboethoxy-containing isomer. Its crystal structure is shown in Fig. 1, which also confirms the *cis* ring junction stereochemistry which we have hitherto assumed (5). The two isomers were characterized for diagnostic purposes in subsequent experiments by their OMe

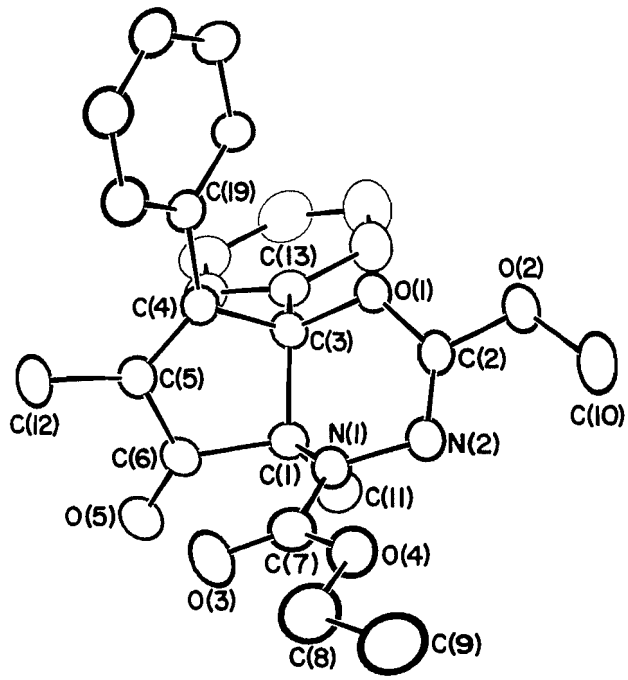


FIG. 1. ORTEP plot for compound **10**.

and OCH_2 ^1H nmr absorptions (δ, $CDCl_3$) at 3.80 and 4.22 for **10** and 3.77 and 4.16 for **11**.

A sample of **10** subjected to the conditions used for the conversion of **2** → **4** gave **4** as *the sole product*. By contrast, similar treatment of **11** gave the *same mixture* of **6** and **7** obtained from **5**. The alkoxy group of the ester is thus exclusively solvolyzed.

(iii)

The exocyclic N in **4** must surely be N_3 in **2**: for numbering see formula **2**. Given the demonstrated loss of the exocyclic MeO group in **2**, and the inclusion of one from the solvent, it is clear that the transformation which makes N_3 exocyclic requires at a minimum only the formal migration of O_5 from C_4 to C(=O). By contrast, to make N_2 exocyclic requires at a minimum the migration of C_1 from N_2 to N_3 and of OMe from C_4 to C(=O), as well as the loss of the exocyclic carbonyl O and the gain of an external O.[4]

(iv)

An appealing enough mechanism can be visualized for the transformation of **2** (Scheme 1), which accounts for the proven origin of the MeO groups in **4**, one from C4 and one from the solvent, and for the presumed migration of N_3 out of the ring.[5] If such a mechanism is valid it follows that k_{-1} is small compared with k_2 since otherwise more than one equivalent of CD_3O would have been incorporated into **4** in the labelled experiment, and in the reactions of **5** and **11** with MeO^- (from OH^-) a bias towards hydrazones with more MeO than EtO would have been observed.

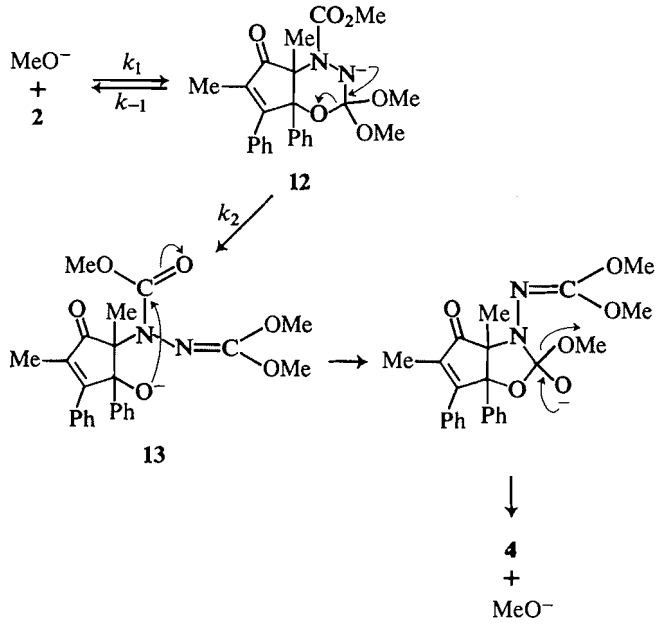
Scheme 1 does not, however, explain why EtO^-−EtOH

[2]Diastereotopic shifts, though much smaller ones, were also observed by us in the MeO peaks in acyclic dimethyl carbonate hydrazones (2), and in the methyl (but not the methylene)absorptions of some acyclic diethyl carbonate hydrazones reported in the literature (3).

[3]The result at 150°C can be extrapolated to 65°C (the temperature of the deuteration experiment) by treating $\Delta G^{\ddagger}$ as temperature independent, a reasonable assumption since in most conformational rotation processes $\Delta S^{\ddagger}$ is usually very small (4). The rotation frequency drops from an upper limit of 36 s^{-1} to one of about 3 min^{-1}, still very fast on the experimental time scale.

[4]We are of course applying Occam's Razor here. We have no *proof* whatsoever of the origin of any of the atoms or groups in the oxazolidone ring of **4** or its side chain, except that one of its MeO groups was originally that on C_4 in **2**.

[5]Anions like **12** or **13** may not of course be involved, since two or more of the steps shown may be concerted.



SCHEME 1

decomposes **2**,[6] as it also does **5** (2). Whether conversion of these first into hydrazones does occur cannot be determined, since in a control experiment the hydrazone **4** was rapidly and completely degraded by this reagent.

The decreasing efficiency in MOH of CN^- and CO_3^{2-} (as compared with MeO^- or OH^-) (2) is presumably related to their decreasing basicities. The equilibrium concentration of MeO^- generated by these anions would be extremely low.

A final comment about the hydrazone formation is in order. An alkoxy 1,3,4-oxadiazine like **2** is itself a cyclic hydrazone of an unsymmetrical carbonate, derived in this case from MeOH and a benzylic alcohol. Thus the reaction **2** → **4** represents the conversion of a cyclic hydrazone and an exocyclic urethane into an exocyclic hydrazone and a cyclic urethane.

Acid-catalyzed demethylation reactions

The acid hydrolysis product formed from each of **1**–**4** has been shown by X-ray analysis to be the oxazolidone **14** (footnote 5, ref. 2), the crystal structure of which is given in Fig. 2. We had concluded in earlier work on the hydrolysis of **1**–**3** that it had the structure **16** (5). The reaction of these three isomers in the presence of trifluoroacetic acid (TFA), as followed by nmr spectroscopy, was complex in dilute TFA in $CDCl_3$, isomerization between **1**, **2**, and **3** preceding solvolysis. In concentrated TFA (8% or greater) only solvolysis was observed, through a rapidly formed common intermediate which decayed to product with first-order kinetics. The rate constant of the solvolysis decreased with TFA concentration (e.g. 8% TFA, $t_{1/2}$ = 1.2 min; 100% TFA, $t_{1/2}$ = 30 min). We speculated that the intermediate, which had one very low-field MeO absorption (at δ 4.7 in neat TFA), was a mono- or multiprotonated form of **2**, but this view was biased by our belief that the final demethylation product had the 6-membered heterocyclic ring.

[6]A referee has pointed out that this experiment, done at reflux, represents more severe reaction conditions than those used in the transformation of **2** → **4** in refluxing MeOH. We have repeated the EtO^- (0.5 *M*) catalyzed reaction in scrupulously dried EtOH in a refluxing MeOH bath. Again, complete degradation of **2** was observed.

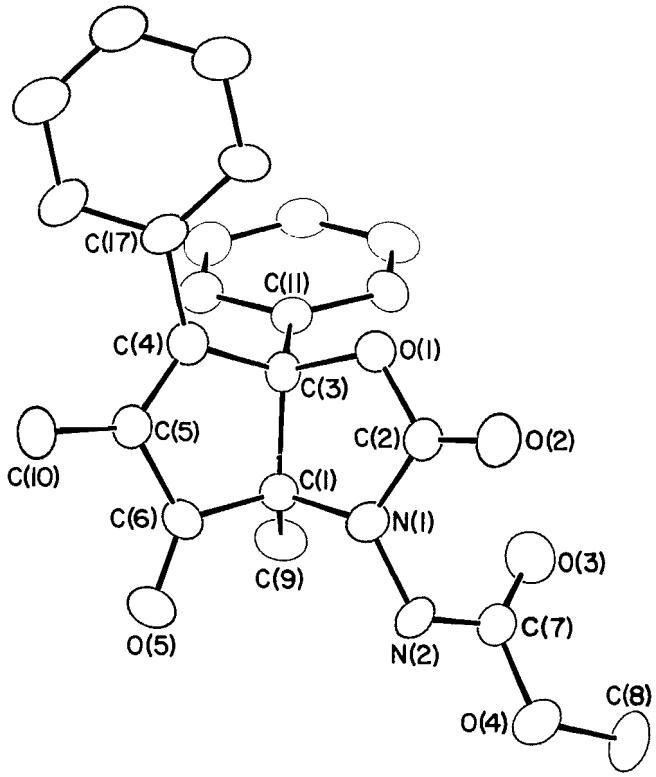


FIG. 2. ORTEP plot for compound **14**.

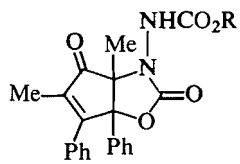
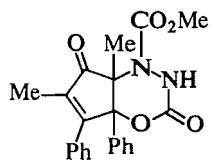


14, R = Me
15, R = Et



16

We are no clearer about the structure of the immediate precursor to **14**, but we have now shown that in the solvolysis of the oxadiazines it is the exocyclic (ester) site which is dealkylated, just as it is the exocyclic alkoxy group which is lost in the base-catalyzed hydrazone formation. This was determined using a 1:5 mixture of the oxadiazines **10**/**11**. In TFA the mixture of complexes obtained had the MeO peak at δ 4.7 as the major low-field alkoxy absorption. Work-up at the end of the reaction gave a 1:5 mixture of **14**/**15**. Protonation thus occurs on or near the ester group and it is its alkyl group that is solvolyzed.

The solvolysis of **4** → **14** in TFA goes through a different intermediate, characterized by *two* low-field MeO absorptions at δ 4.4 and 4.7. These decay together to **14**, faster ($t_{1/2}$ = 8 min) than the intermediate from **1**–**3** decays to **14**. This solvolysis thus goes by a different mechanism than the one common to the solvolysis of **1**, **2**, and **3**.

Experimental

The following spectrometers were used: infrared, Beckman IR-10; nuclear magnetic resonance, Perkin–Elmer R12-B or Bruker WP-80. Melting points are uncorrected. MeOH was dried by distillation from magnesium methoxide and ethanol by distillation from sodium ethoxide.

Triclinic; a = 8.736(2), b = 8.816(3), c = 15.093(3) Å; α = 96.80(2), β = 94.81(2), λ = 107.92(2)°, V = 1089.5(5) Å^3, space group $P\bar{1}$, Z = 2, ρ_c = 1.282 g cm^{-3}, $F(000)$ = 444, λ = 0.71069 Å, μ(MoKα) = 0.98 cm^{-1}.

From a total of 3061 diffractometer measured reflections ($2\theta \leq 46°$), 2467 were considered observed ($I \geq 3\sigma(I)$). The structure was solved by direct methods (MULTAN 80) and refined with anisotropic thermal parameters to an R of 0.077.

Compound **14**: $C_{22}N_{20}N_2O_5$ Mol. Wt. 392.42
Orthorhombic; a = 14.263(3), b = 16.229(4), c = 16.585(4) Å, V = 3839(1) Å^3, space group $Pbca$, Z = 8, ρ_c = 1.358 g cm^{-3}, $F(000)$ = 1648, λ = 0.71069 Å, μ(MoKα) = 1.05 cm^{-1}.

From a total of 2529 independent diffractometer measured reflections ($2\theta \leq 45°$), 1527 were considered observed $I \geq 3\sigma(I)$). The structure was solved by direct methods (MULTAN 80) and refined with anisotropic thermal parameters to an R of 0.076 (cf. refinement of solution in footnote 5, ref. 2). Tables 1 and 4 give bond lengths and angles for compounds **10** and **14**.

Reaction of oxadiazine 2 with KOD − methanol-d_4

To a 0.1 *M* solution of KOD (made by repeated exchange of KOH in D_2O) in CD_3OD (0.5 mL) was added the oxadiazine (50 mg, 0.12 mmol) and the solution was heated in an nmr tube in refluxing MeOH (65°C). The ^{1}H nmr spectrum was monitored at intervals. The coincident MeO peaks of **2** at δ 3.67 decreased and new peaks for **4** at 3.30 and 3.37 grew, the latter being coincident with that of the MeOH displaced from **2**. The peaks for **4** were judged to be of equal intensity at all times. Work-up of the solution in the usual way (2) gave the deuterated hydrazone whose ^{1}H nmr spectrum in $CDCl_3$ showed the

MeO peaks to be equal in intensity and half the intensity of the C-Me peaks.

Methyl ethyl azodicarboxylate

This compound has been described in the patent literature (6).

A solution of ethyl carbazate (52 g, 0.50 mol) in methylene chloride (600 mL) was kept chilled in CO_2–acetone as necessary while methyl chloroformate (57 g, 0.60 mol) was carefully added, followed by sodium carbonate (56 g, 0.50 mol). The whole was stirred for 24 h (a check showed about 70% reaction in 5 h), evaporated to dryness, and extracted with hot ethyl acetate (600 mL, refluxed 1h). The hot solution was filtered and evaporated to give the crude methyl ethyl hydrazinedicarboxylate (98%). It could be recrystallized from ethyl acetate – isooctane in an overall yield of 75%; mp 84.5–86°C; δ ($CDCl_3$): 7.15 (broad, NHNH), 4.19 (q, J = 7.0 Hz, OCH_2), 3.75 s, OMe), 1.27 (t, Me).

The hydrazine (7 g, 74 mmol) was added all at once to a solution of *N*-bromosuccinimide (12 g, 67 mmol) and pyridine (5.3 mL, 67 mmol) in methylene chloride (250 mL) in a separatory funnel. There was an immediate orange coloration. After 30 min, during which the funnel was occasionally shaken to ensure dissolution of all the hydrazine, the whole was extracted with 4 × 250 mL water, dried, and evaporated. The residual orange oil (8.0 g, 66%) had δ($CDCl_3$): 4.45 (q, J = 7.0 Hz, OCH_2), 4.00 (s, OMe), 1.41 (t, Me).

*2-Ethoxycarbonyl-3-methoxycarbonyl-1,4-dimethyl-5,6-diphenyl-7-oxo-2,3-diazabicyclo[2.2.1]hept-5-ene (**9**)*

A solution of the azo ester (5.0 g, 31.2 mmol) and 2,5-dimethyl-3,4-diphenylcyclopentadienone (8.0 g, 30.8 mmol) in benzene (100 mL) was refluxed for 2 h. Evaporation and trituration of the residue with ether–hexane gave a colorless crystalline product (11 g, 85%). Recrystallization from ether–hexane gave prisms, mp 109–111°C; ν (Nujol): 1800 (bridging CO), 1748 (ester CO) cm^{-1}; δ ($CDCl_3$): 7.4–6.8 (m, 10H, Ph), 3.96 (A of ABX_3, J_{AB} = 9.3, J_{AX} = 7.1 Hz, 1H, OCH_2), 4.12 (B of ABX_3, J_{BX} = 7.1 Hz, 1H, OCH_2), 3.65 (s, OMe), 1.84 (s, Me), 1.80 (s, Me), 1.01 (t, Me). *Anal.* calcd. for $C_{24}H_{24}N_2O_5$: C 68.56, H 5.75, N 6.66; found: C 68.66, H 5.69, N 6.69.

*Isomerization of **9** to **10** and **11***

A sample of **9** (10 g) was refluxed in acetonitrile (250 mL) for 40 h. Evaporation gave a sticky residue whose ^1H nmr spectrum showed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

unreacted **9** and the two expected oxadiazines, as well as small amounts of the isomeric diazetidines (cf. ref. 1). Chromatography was carried out on silica gel from 1:2 ether–hexane. Both diazetidines and the first runnings of the oxadiazines appeared in the first few fractions. The central fractions consisted only of the oxadiazines, with a bias towards **10** (as was later demonstrated by the X-ray analysis result) in the early, and towards **11** in the late, fractions. The last fractions contained **9**, **10**, and **11**.

The fractions richest in **10**, but also contaminated by the diazetidines, were crystallized from acetone–isooctane, and after removal of a first crop the filtrate slowly deposited crystals of pure oxadiazines in the ratio **10**/**11** = 5:1. This was recrystallized from ethyl acetate – isooctane and finally from MeOH to give pure **10**, mp 124.5–125.5°C; ν (Nujol): 1736 (ester CO), 1700 (ketone CO), 1662 (C=N) cm^{-1}; δ ($CDCl_3$): 7.6–7.0 (m, 10H, Ph), 4.22 (q, J = 7.1 Hz, OCH_2), 3.80 (s, OMe), 2.21 (s, vinylic Me), 1.31 (t, ester Me), 1.04 (s, *tert*-Me).

The fractions richest in **11** were crystallized, first from acetone–isooctane and then thrice from MeOH to give **11**, mp 133–135°C; ν (Nujol): 1735 (ester CO), 1701 (ketone CO), 1652 (C=N) cm^{-1}; δ ($CDCl_3$): 7.6–7.0 (m, 10H, Ph), 4.16 (q, J = 7.0 Hz, OCH_2), 3.77 (s, OMe), 2.21 (s, vinylic Me), 1.24 (t, alkoxy Me), 1.05 (s, *tert*-Me).

A representative sample of a mixture of pure **10** and **11** was analyzed. *Anal.* calcd. for $C_{24}H_{24}N_2O_5$: C 68.56, H 5.75, N 6.66; found: C 68.52, H 5.63, N 6.63.

A single crystal of **10** was subjected to X-ray analysis and found to have the assigned structure.

*Base-catalyzed conversion of **10** into **4***

A solution of **10** (35 mg, 0.083 mmol) in 0.2 *M* KOH–MeOH (5 mL) was refluxed for 3 h and worked up exactly as described for the isomerization of **2** to **4**. The glassy residue (33 mg, 98%) had a ^1H nmr spectrum ($CDCl_3$) identical with that of **4**, alone or in admixture with authentic **4**.

*Base-catalyzed conversion of **11** into **6** and **7***

A solution of **11** (contaminated with a trace of **10**) (44 mg, 0.10 mmol) was similarly solvolyzed. Work-up as before gave a glassy residue (41 mg, 94%) whose ^1H nmr spectrum was identical with that of the similarly prepared solvolysis product of **5**, viz. compounds **6** and **7**. Mixing of the two solutions in $CDCl_3$ gave a spectrum in which no new peaks could be observed. Peak separations and peak positions could be determined with great precision using the Bruker WP-80 spectrometer.

*Reaction of **4** with $EtO^- - EtOH$*

A solution of the hydrazone **4** (100 mg, 0.25 mmol) in 0.2 *M* NaOEt in EtOH (50 mL) became red-brown when refluxed for 30 min. It was worked up in the usual manner (2) and gave a residue with an extremely complex ^1H nmr spectrum.

*Solvolysis of the oxadiazines **10** and **11** with TFA*

A 1:5 mixture of **10**/**11** (50 mg) was dissolved in TFA (0.50 mL) in an nmr tube and the spectrum run repeatedly until reaction was complete (about 3 h). The most strongly downfield-shifted major peak, at a maximum when the spectrum was first run, was the MeO peak, at δ 4.7. The final mixture of **14** and **15** was worked up by blowing off the acid in a stream of N_2, and treating the residue with methylene chloride and aqueous sodium hydrogen carbonate. The dried organic layer was evaporated. Its ^1H nmr spectrum was that of a 1:5 mixture of **14**/**15**. Crystallization from ethyl acetate – isooctane gave **15**, identified by comparative ^1H nmr spectroscopy and mixture mp (5).

*Solvolysis of **4** with TFA*

A solution of **4** (50 mg, 0.12 mmol) in TFA (0.5 mL) was similarly kept and periodically monitored in an nmr tube. Both MeO peaks derived from **4** were observed at low field, δ 4.7 and 4.4, in the immediately formed protonated intermediate. The decay of the latter was much more rapid ($t_{1/2}$ = 8 min) than that of the corresponding intermediate from **2** ($t_{1/2}$ = 30 min (5)). Work-up as described earlier (2) gave compound **14**.

Reçu le 8 juillet 1983

JEAN-CLAUDE BOLLINGER, GERMAINE YVERNAULT, THÉOPHILE YVERNAULT et RAYMOND HOURIET. Can. J. Chem. **62**, 361 (1984).

On a déterminé les constantes physiques du 3,3′-oxydipropionitrile (ODPN) à 25°C (densité, indice de réfraction, viscosité, constante diélectrique, moment dipolaire, paramètre de solubilité), ainsi que certains critères de basicité (nombre donneur, déplacement chimique du proton de $CHCl_3$, basicité en phase gazeuse). Ces résultats sont comparés à ceux de quelques autres solvants usuels; ils permettent d'expliquer les propriétés de l'ODPN comme solvant pour des dosages acide–base, ainsi que l'existence de l'homoliaison-hydrogène dans ce milieu.

JEAN-CLAUDE BOLLINGER, GERMAINE YVERNAULT, THÉOPHILE YVERNAULT, and RAYMOND HOURIET.. Can. J. Chem. **62**, 361 (1984).

Physical constants (density, refractive index, viscosity, dielectric constant, dipole moment, solubility parameter) and some basicity parameters (donor number, proton chemical shift variation for $CHCl_3$, gas phase basicity) have been determined for 3,3′-oxydipropionitrile (ODPN) at 25°C. These results are compared with those for other usual solvents; they permit an explanation of its properties as a solvent for acid–base titrations, and the appearance of homohydrogen bonding in this medium.

Introduction

Plusieurs travaux récents ont montré l'intérêt du 3,3′-oxydipropionitrile $O(CH_2CH_2CN)_2$ ou ODPN, en tant que solvant pour des études électrochimiques (1–5) et d'extraction liquide–liquide (6, 7). Toutefois, on ne dispose pas actuellement d'un ensemble de valeurs précises de ses constantes physiques, mis à part certains résultats préliminaires indiqués dans la réf. 7; d'autre part, son emploi comme solvant pour des dosages acide–base, pur (5) ou en mélange avec l'eau (8), rend intéressantes les mesures que nous avons effectuées pour certains critères de basicité concernant ce produit.

Partie expérimentale

L'ODPN Fluka "purum" est déshydraté et conservé sur tamis 3 Å. Contrairement au solvant synthétisé par Persin et Gal (5), nos échantillons ne contenaient pas d'impuretés acido-basiques; leur teneur en eau, mesurée par le Karl–Fischer coulométrique, était de 50 à 80 mg L^{-1}.

Les indices de réfraction sont mesurés pour la raie D du sodium avec un réfractomètre d'Abbe, thermostaté à 25 ± 0,05°C et étalonné avec un verre d'indice n_D = 1,5166. Les mesures diélectriques sont réalisées, à la fréquence de 1 MHz, à l'aide d'un pont de capacité automatique Hewlett–Packard 4270 A, équipé d'une cellule type CS 601 Férisol thermostatée à 25 ± 0,05°C; la cellule est étalonnée à la même température avec des liquides organiques (9). Le moment dipolaire de l'ODPN, à dilution infinie dans le benzène Merck "pour spectroscopie", a été calculé selon la méthode de Guggenheim et Smith (10), à partir des résultats rassemblés dans le Tableau 1.

Pour les autres constantes physiques, on a utilisé: un densimètre SODEV 02D (11), couplé à un compteur/timer Hewlett–Packard 5308 A et à un système de mesures Hewlett–Packard 5300 B, thermostaté à 25 ± 0,01°C et étalonné par de l'azote et de l'eau; ainsi qu'un viscosimètre à capillaire (k = 15,05 × 10^{-9} m^2 s^{-2}) thermostaté à 25 ± 0,05°C.

La mesure du déplacement chimique du proton de $CHCl_3$ (spectromètre Varian EM 360) est réalisée à 60 MHz, sur une solution de 10 μL de chloroforme Merck "pour spectroscopie" dans 0,4 mL d'ODPN. Le nombre donneur selon Gutmann a été déterminé avec un ensemble microcalorimétrique LKB 8700, dans les conditions décrites par ailleurs (12); on obtient les valeurs suivantes: enthalpie de dissolution ΔH_d = (0,45 ± 0,06) × 10^3 J mol^{-1} et enthalpie de réaction ΔH_r = −(80,2 ± 0,2) × 10^3 J mol^{-1}, d'où DN = 79,75 kJ mol^{-1} ou 19,0 kcal mol^{-1}.

TABLEAU 1. Détermination du moment dipolaire de l'ODPN, à dilution infinie dans le benzène (T = 25°C)

Fraction en poids ODPN w_2	n_D	ϵ
0,00000	1,4978	2,274
0,01694	1,4971	$2,59_7$
0,03175	1,4968	$2,88_9$
0,07226	1,4948	$3,78_4$

$d\epsilon/dw_2 = 21,01_5$; $dn_D^2/dw_2 = -0,127_2$.

La basicité en phase gazeuse (GB) de l'ODPN a été déterminée par résonance cyclotronique des ions, à l'aide d'un dispositif expérimental dont les caractéristiques sont indiquées par ailleurs (13); afin de favoriser la formation d'ions ODPN.H^+, du méthane a été ajouté comme gaz réactant. Une série de mesures avec diverses bases B a été réalisée, dans les conditions suivantes: P_{CH_4} = 5 × 10^{-6} Torr, P_{ODPN} = 4 × 10^{-6} Torr, P_B = 4 × 10^{-6} Torr (env.), temps de piégeage = 100 ms. On aboutit à la séquence ci-dessous, pour laquelle on a fait réagir les divers partenaires B cités avec l'ODPN:

$$GB(Me_2O) < GB(Me_2CO) < \underline{GB(ODPN)} < GB(MeCOOMe) < GB(THF) < GB(Et_2O)$$

ce qui donne comme résultat final GB(ODPN) = 797 ± 2 kJ mol^{-1} (référence $GB(NH_3)$ = 821,7₄ kJ mol^{-1} (14)).

Le paramètre de solubilité de l'ODPN a été calculé à l'aide de son enthalpie de vaporisation, ΔH_v = 67,3 kJ mol^{-1}, calculée par nous à partir des valeurs rapportées dans la réf. 15, en utilisant la relation de Van't Hoff.

Résultats et discussion

Le Tableau 2 rassemble les résultats de nos mesures sur l'ODPN. On constate aisément que l'ODPN entre bien dans la

[1]Auteur à qui la correspondance doit être adressée.

TABLEAU 2. Propriétés physiques et basicités de l'ODPN à 25°C

Paramètre	Valeur	Paramètre	Valeur
Indice de réfraction	1,4390	Paramètre de solubilité ($MPa^{1/2}$)	23,4
Masse volumique ($g\ mL^{-1}$)	$1,04471_9$	Nombre donneur ($kJ\ mol^{-1}$)	79,75
Viscosité (10^{-3} Pa s)	$9,35_0$	Déplacement chimique du proton de $CHCl_3$ (ppm)	0,25
Constante diélectrique	66,66	Basicité en phase gazeuse ($kJ\ mol^{-1}$)	797
Moment dipolaire (D; dans C_6H_6)	4,91		

catégorie des solvants dipolaires à forte constante diélectrique; toutefois, on sait (5) que dans ce solvant les phénomènes d'association par homoliaison-hydrogène entre acide et base conjugués sont fréquents:

$$AH + A^- \rightleftarrows AHA^-; \qquad BH^+ + B \rightleftarrows BHB^+$$

ce qui le rapproche de l'acétonitrile (AN), du sulfolane (S) et du carbonate de propylène (CP) de constante diélectrique voisine; ce ne sont donc pas les seuls paramètres diélectriques qui interviennent dans cette propriété (16). Sa densité est voisine de l'unité, cependant sa viscosité élevée peut limiter son emploi.

L'enthalpie de vaporisation de l'ODPN peut être estimée à l'aide des paramètres empiriques de groupes ou de liaisons établis par Ducros et coll. (17), soit $\Delta H_v \simeq 74,9\ kJ\ mol^{-1}$ ou à partir des paramètres de Guthrie et Taylor (18), soit $72,0 \pm 1,7\ kJ\ mol^{-1}$ ou $74,9 \pm 1,7\ kJ\ mol^{-1}$. L'écart avec la valeur calculée par nous, $\Delta H_v = 67,3\ kJ\ mol^{-1}$, à partir de données de la littérature (15), est important, mais ceci peut être expliqué par la forte polarité de l'ODPN. Le paramètre de solubilité obtenu, $\delta = 23,4\ MPa^{1/2}$, est tout à fait comparable à ceux de l'acétonitrile, $\delta = 24,3\ MPa^{1/2}$, ou du propionitrile, $\delta = 22,1\ MPa^{1/2}$ (19).

Afin de caractériser ses propriétés basiques, nous avons déterminé ici trois paramètres différents: (a) le nombre donneur DN selon Gutmann (20), qui correspond à l'enthalpie de complexation avec $SbCl_5$, en solution infiniment diluée dans le dichloro-1,2 éthane:

$$ODPN_{soln} + SbCl_{5\,soln} \rightarrow ODPN.SbCl_{5\,soln} \qquad DN = -\Delta H$$

(b) la variation de déplacement chimique du proton du chloroforme, $\Delta\delta$, entre l'état libre et l'état lié par liaison-hydrogène (21):

$$ODPN + HCCl_3 \rightarrow ODPN \ldots . HCCl_3$$

$$\Delta\delta\ (ppm) = \delta_{CHCl_3\,libre} - \delta_{CHCl_3\,lié}$$

(c) la basicité en phase gazeuse GB, qui est la variation d'enthalpie libre pour la réaction de déprotonation en phase gazeuse (14):

$$ODPN.H^+_g \rightarrow ODPN_g + H^+_g \qquad GB = \Delta G°$$

Ces trois critères de basicité correspondent à des phénomènes fort différents, puisqu'ils caractérisent respectivement: (a) la molécule isolée, dispersée dans un solvant inerte; (b) le solvant en masse; (c) la molécule isolée en phase gazeuse. Ils donnent toutefois la même indication, à savoir que l'ODPN est un solvant très faiblement basique, comparable à l'éther diéthylique Et_2O; ceci permet de penser que le site basique de l'ODPN est probablement l'atome d'oxygène.

D'autre part, on observe les classements suivants, pour des solvants courants, avec les trois critères considérés ici:

$$AN < S \simeq CP < ODPN \simeq Et_2O < H_2O < HMPT \quad \text{pour DN}$$

$$ODPN < AN < Et_2O = S < HMPT \quad \text{pour } \Delta\delta$$

$$H_2O < AN < ODPN < Et_2O < HMPT \quad \text{pour GB}$$

De plus, l'ODPN se comporte également comme une base de Bronsted extrêmement faible, puisque nous n'avons pas pu le doser par $HClO_4$ dans le mélange sulfolane/benzène 98/2 p/p, qui permet pourtant des dosages de bases très faibles (22), y compris l'eau. On comprend ainsi mieux les propriétés de l'ODPN, qui permet lui-même des dosages acide/base non réalisables dans d'autres solvants, comme de différencier les acides qui sont forts dans l'eau, ou de doser des bases très faibles (urée, DMSO, HMPT) (5).

Remerciements

Additivity methods for estimating heat capacities of vaporization for organic compounds

J. PETER GUTHRIE[1] AND KATHLEEN F. TAYLOR
Department of Chemistry, University of Western Ontario, London., Ont., Canada N6A 5B7

Received July 14, 1983

J. PETER GUTHRIE and KATHLEEN F. TAYLOR. Can. J. Chem. **62**, 363 (1984).

Additivity methods permitting the estimation of heat capacities of vaporization for organic liquids have been developed, using atom, bond, and group additivity parameters. Previously it had been common to use an average value for all organic liquids, which can lead to considerable errors. For the atom level scheme, 193 compounds could be fitted using 20 parameters, with a standard deviation of 1.50 cal/deg/mol, and only 29 deviations greater than 2 cal/deg/mol. For the bond level scheme, 197 compounds could be fitted using 23 parameters, with a standard deviation of 1.47 cal/deg/mol, and only 37 deviations greater than 2 cal/deg/mol. For the group level scheme, 177 compounds could be fitted using 39 parameters, with a standard deviation of 1.05 cal/deg/mol, and only 13 deviations greater than 2 cal/deg/mol. The significant terms in the correlation matrix are given for each set of parameters.

J. PETER GUTHRIE et KATHLEEN F. TAYLOR. Can. J. Chem. **62**, 363 (1984).

On a développé des méthodes d'additivité permettant d'évaluer les capacités calorifiques de vaporisation de liquides organiques qui font appel à des paramètres d'additivité d'atomes, de liaisons et de groupes. Antérieurement, il était courant d'utiliser une valeur moyenne pour tous les liquides organiques et ceci pouvait entraîner des erreurs considérables. A l'aide du schéma au niveau des atomes, il est possible d'établir une corrélation pour 193 composés en utilisant 20 paramètres; la déviation standard est de 1,50 cal/deg/mol et il n'y avait que 29 déviations qui soient plus grandes que 2 cal/deg/mol. Au niveau des liaisons, il est possible d'établir une corrélation pour 197 composés en utilisant 23 paramètres; la déviation standard est de 1,47 cal/deg/mol et il n'y a que 37 déviations qui soient plus grandes que 2 cal/deg/mol. Au niveau des groupes, il est possible d'établir une corrélation pour 177 composés en utilisant 39 paramètres; la déviation standard est de 1,05 cal/deg/mol et il n'y a que 13 déviations qui soient plus grandes que 2 cal/deg/mol. On donne les termes importants de la matrice de corrélation pour chaque ensemble de paramètres.

Introduction

In investigations of organic reaction mechanisms we have made use of free energies of formation calculated from heats of formation and various thermodynamic parameters obtained from the literature or estimated following accepted procedures. As part of this process it is frequently necessary to estimate the vapor pressure of an organic liquid at 25°C from meager vapor pressure data. In such estimations it is often not permissible to assume a constant heat of vaporization, because the heat of vaporization is well known to be a function of temperature (1). The next level of approximation is to assume a temperature independent heat capacity of vaporization. It has been suggested that the heat capacity of vaporization for any organic liquid may be taken as -12 ± 4 cal/deg/mol (2, 3). In the course of gathering data for a recent paper on estimation methods for heats of vaporization (4) we became aware that there were enough data for heat capacities of vaporization in the literature to allow an examination of this assumption. In fact it is clear that the heat capacity of vaporization does depend on structure, and can be estimated with useful precision by additivity methods at the atom, bond, or group (5) level of approximation.

It must be borne in mind that any such estimation procedure is only an interpolation technique and will decline rapidly in reliability as it is extrapolated to types of compound not used in the parameterization. This is particularly the case for polyfunctional compounds where there may well be interactions which need to be explicitly allowed for, and for which there are no parameters in the present set. Due caution is urged on anyone using the estimation procedures reported here. Despite these caveats, we feel that having estimation procedures will be of practical use in the application of thermodynamic calculations to real problems in organic chemistry. Since it is unlikely that measurements of thermodynamic properties will ever catch up to synthesis of new organic compounds, there will always be a need for estimation procedures.

Results and discussion

Table 1 gives the compounds which we used, the experimental heat capacities of vaporization, and the values calculated at the atom, bond, and group levels of approximation. Data were gathered from the literature, from sources cited in Table 1, frequently in the form of heats of vaporization as a function of temperature. Such heats of vaporization were fitted by least squares (6, 7) to a straight line dependence on temperature, and the slope was taken as the heat capacity of vaporization. For a few compounds we used data for the heat capacity of the liquid, and calculated the heat capacity of vaporization by difference from the heat capacity of the gas. For the set of data in Table 1 used for the least squares fitting of parameters, the average value of ΔC_{vap} was -12.9 ± 5.7. Parameters were fitted by least squares (6, 7) using a computer program written for the purpose (8); in general, only parameters based on more than two independent compounds were determined by least squares. A number of additional parameters were calculated on the basis of 1 or 2 compounds. These values must be regarded as provisional only. In the least squares fitting, weights were calculated on the assumption of 20% errors in ΔC_{vap}, i.e. assuming constant relative error. This will be overly conservative for some data, but it is in many cases difficult or impossible to make a better estimate of the uncertainty, and the scatter in values from different laboratories is such as to inspire a certain caution.

In one case, that of ethyl bromide, the value of ΔC_{vap} calcu-

[a] C_{vap} is evaluated at 25°C; with adequately precise data we expect that C_{vap} will itself be a function of temperature.

[b] A synthetic value for ethylene had to be used to obtain convergence; the value used was taken as twice the value for $[C_dH_2]$ generated by the least squares program in a run which showed severe problems attributed to covariance among the parameters involving olefinic carbon. The synthetic value was assigned a large error to ensure it had low statistical weight.

[c] This value was obtained by using a heat capacity of the liquid calculated from data in ref. 31 and $C_p(g)$ from ref. 11.

[d] These values were obtained using heat capacity data for the liquids at various temperatures (30) fitted to linear equations by least squares to allow extrapolation to 25°C, and $C_p(g)$ from ref. 11.

[e] This value was obtained using a heat capacity for the liquid from ref. 10 and $C_p(g)$ from ref. 11.

[f] Not included in the least squares fit.

[g] Unique parameter.

lated from the temperature dependence of ΔH_{vap} (9) was seriously out of line with the trend for similar compounds; the value obtained for ethyl bromide was −18.1 cal/deg/mol (data from ref. 9) while the value for n-propyl bromide was −14.6 cal/deg/mol (data from ref. 9). A value based on $C_p(l)$ (10) and $C_p(g)$ (11) was in better agreement with expectation; this value was −8.8 cal/deg/mol.

The atom level parameters were the first to be determined; this was done using batch mode computations, where a deck of data cards was submitted for each run. This procedure was

[34]	4-Ring[b]	−1.6		

[a]C means tetrahedral carbon; C_d means doubly bonded (olefinic) carbon; C_B means aromatic carbon; C_t means triply bonded (acetylenic) carbon; CO is treated as a divalent atom; CN and NO_2 are treated as univalent atoms.

[b]Correction for flexible ring.

tedious, and altering the data set was a time consuming operation. For the bond and group schemes we entered the data using the SIR database management system on the Cyber 170/835 at the University of Western Ontario Computing Center, and used this system to handle corrections to the database and in preparation of a data file for the least squares program. Actual data entry was done using a Xitan microcomputer, and the data file was then transmitted to the Cyber for processing. The last few compounds for which values were found were not included in the atomic parameter calculations because it seemed unlikely that any significant change would result; manual calculation showed that the deviations were in the usual range.

Table 2 gives the atom level parameters which were evaluated by least squares fitting; Table 3 gives the bond level parameters and Table 4 gives the group level parameters. For the bond and group parameters we have followed Hine's notation (12) rather than Benson's (13). In all three tables we have included the significant (absolute value greater than 0.5) elements of the correlation matrix (4). This matrix is diagonal, so that only half the terms need be listed, and is sparse, with most terms being negligibly small.

For the compounds used in the atom parameterization we were able to fit 193 compounds using 20 parameters with a standard deviation of 1.50. Only 29 compounds gave deviations of more than 2 cal/deg/mol, and only 12 gave deviations of more than 3 cal/deg/mol. With the bond parameterization, we were able to fit 197 compounds using 23 parameters with a standard deviation of 1.47. Only 37 compounds gave deviations of more than 2 cal/deg/mol, and only 17 gave deviations of more than 3 cal/deg/mol. In this case the bond level scheme uses only slightly more parameters than the atom level scheme and is, if anything, poorer at representing the data. With a richer data set we would expect to see more bond level parameters required, and an improvement in estimation power relative to the atom level scheme. With the group parameterization scheme, we were able to fit 177 compounds using 39 parameters and a standard deviation of 1.05. Only 13 compounds gave deviations of more than 2 cal/deg/mol, and only 4 gave deviations of more than 3 cal/deg/mol. As is usually

[a]C means tetrahedral carbon; C_d means doubly bonded (olefinic) carbon; C_B means aromatic carbon; C_t means triply bonded (acetylenic) carbon; CO is treated as a divalent atom; CN and NO_2 are treated as univalent atoms; N_B means aromatic nitrogen of a heterocycle; S_B means aromatic sulfur of a heterocycle.
[b]Correction for flexible ring.
[c]Calculated assuming $[NH_2(C_B)] = [NH_2(C)]$.
[d]Calculated assuming $[SH(C_B)] = [SH(C)]$.

found (5), the group level scheme gives much better estimates at the price of a much larger parameter set.

A possibly fairer comparison of the three schemes is to take 177 compounds which can be handled by all three, and calculate the rms error for estimation by each scheme. The results were: atom, 1.42; bond, 1.45; group, 1.05. The numbers of serious deviations were: atom, 25 greater than 2, 12 greater than 3; bond, 28 greater than 2, 13 greater than 3; group, 13 greater than 2, 4 greater than 3.

In the atomic parameterization scheme we used C_{tr} and N_{tr} to represent both simple doubly bonded atoms and members of aromatic rings; it was not necessary to make any further correction for the rigid aromatic ring, although corrections were necessary for the presence of flexible rings. In the bond parameterization scheme, we were not able to include pyridines and thiophenes because this would require redefining the scheme to include C⋯C, C⋯N, and C⋯S bonds explicitly. The scheme which we used incorporated the aromatic C⋯C bonds in the C_B atoms so that one endocyclic bond was implicitly included in each explicitly defined exocyclic bond. Our experience with the parameterization of ΔH_{vap} (4) led to the expectation that there would be severe covariance problems if one used the more elaborate scheme, and there seemed little hope of including a realistic value for naphthalene, which was the key to obtaining convergence in the case of ΔH_{vap} (4). In the group parameterization scheme, we were able to include parameters for $N_B(C_B)_2$ and $S_B(C_B)_2$, representing the aromatic N and S atoms bonded to two aromatic C atoms, with these parameters incorporating all of the effects of the heteroatoms, so that the remaining C atoms in the rings were all represented by $C_B(X)$ with no distinction being made as to what atoms of the ring a C in the ring was bonded to. This is clearly not the proper way to set up the parameters, but the data set is too small at present to allow anything more realistic.

The clear conclusion is that at present there is no advantage to using a bond level scheme, and the group level scheme is better but not dramatically so. In a practical sense this is very convenient, because it means that a useful estimate of ΔC_{vap} can be made using a small set of atomic level parameters.

We also feel that the evidence is now conclusive that ΔC_{vap} is *not* a constant for all organic liquids, but should be measured or estimated for the particular compound of interest.

That ΔC_{vap} can be estimated from structural parameters has been implicit in the literature for some years. By definition, $\Delta C_{vap} = C_p(g) - C_p(l)$. Benson has shown (5, 13) that $C_p(g)$ can be estimated at various temperatures by his additivity procedures. Shaw (3) reported a scheme for $C_p(l)$ of organic liquids at 25°C and Benson and Luria (32) have reported an

additivity scheme for liquid hydrocarbons permitting the calculation of $C_p(l)$ as a function of temperature. Obviously ΔC_{vap} should also be a function of temperature, but at present the data permitting such a parameterization for a wide range of organic compounds simply do not exist.

The quality of the overall fit and the range of the available data are shown by Figs. 1, 2, and 3. Although it is clear that the data for heat capacity of vaporization values do not span as wide a range as would be desired for testing an estimation procedure, it is also clear that we can do much better by such procedures than by assuming a structure independent average value.

Dipole oscillator strength distributions (DOSDs) have been constructed for ground state methanol, ethanol, and *n*-propanol and used to evaluate integrated ("band") oscillator strengths and the dipole oscillator strength sums S_k and L_k (for a variety of k values) for these molecules. Each DOSD is constructed by using available experimental and theoretical photoabsorption cross sections and by constraining the resulting dipole oscillator strength data to satisfy the Thomas–Reiche–Kuhn sum rule and molar refractivity constraints. The discussion includes an analysis of the reliability of the results.

B. L. JHANWAR et WILLIAM J. MEATH. Can. J. Chem. **62**, 373 (1984).

On a évalué les distributions de force d'un oscillateur dipolaire (DFOD) pour l'état fondamental du méthanol, de l'éthanol et du *n*-propanol et on les a utilisées pour évaluer les forces d'un oscillateur intégré ("bande") et les sommes S_k et L_k, des forces d'un oscillateur dipolaire S_k et L_k (pour diverses valeurs k), de ces molécules. On a construit chaque DFOD en utilisant les sections droites de photoabsorption expérimentales et théoriques disponibles et en restreignant les données relatives à la force de l'oscillateur dipolaire de façon à satisfaire à la règle d'additivité de Thomas–Reiche–Kuhn et les contraintes de réfractivité molaire. La discussion comporte une analyse de la fiabilité des résultats.

[Traduit par le journal]

1. Introduction

The purpose of this paper is to present reliable results for many of the dipole properties of the methanol, ethanol, and *n*-propanol molecules. The results are obtained through the construction of globally reliable dipole oscillator strength distributions (DOSDs) for the molecules. The properties considered explicitly are the dipole oscillator strength sums S_k, $k = -10(1)2$, the logarithmic oscillator strength sums L_k, $k = -2(1)2$, and the molar refractivities R_λ for wavelengths λ associated with the visible and ultraviolet region of the spectrum.

The approach (Section 2) used to evaluate the properties is based on the relationship (1–11) between the dipole properties and the DOSDs and upon the construction of the DOSDs by using a quantum mechanical constraint procedure (9) and a given dipole oscillator strength (DOS) input data base. The initial DOSDs, and properties, obtained from the original experimental and theoretical DOS input are unreliable due to errors inherent in the original DOS data. In order to provide reliable results, the initial DOSDs are modified to satisfy the Thomas–Reiche–Kuhn sum rule (1, 12) and two other constraints provided by values of the molar refractivity of the relevant dilute gas. A variety of refractivity and experimental and/or mixture rule DOS sources are used for the evaluation of the dipole properties of the alcohols and results are also presented for various integrated ("band") oscillator strengths evaluated from the constructed DOSDs (Section 3). Experimental refractive index data are used to provide constraints for methanol whereas, because of a lack of experimental data, those for ethanol and *n*-propanol are generated by additivity relations. The discussion (Sections 3 and 4) contains an assessment of the reliability of the results for the dipole properties, with particular emphasis on errors arising from the lack of accurate experimental refractivity constraints, and a summary of the relevance of the results and the method by which they are obtained.

2. Construction of the dipole oscillator strength distributions (DOSDs)

Many important dipole properties (1–5) of molecules can be determined from DOSDs by evaluating dipole oscillator strength sums S_k and L_k defined by

$$[1] \quad S_k = \int_{E_0}^{\infty} \left(\frac{E}{2R}\right)^k \left(\frac{df}{dE}\right) dE$$

and

$$[2] \quad L_k = \int_{E_0}^{\infty} \left(\frac{E}{2R}\right)^k \left(\frac{df}{dE}\right) \ln E \, dE$$

where E_0 is taken to be the electronic absorption threshold for the molecule, R is the Rydberg constant of energy, and (df/dE) is the differential dipole oscillator strength of the molecule at excitation energy E. Related properties include the number of electrons N in the molecule, $S_0 = N$, the static dipole polarizability $\alpha_d = S_{-2}$, mean excitation energies (for various processes) $I_k = 2R \exp[L_k/S_k]$, and the molar refractivity of the dilute molecular gas, R_λ, which is related to the refractive index, $n(\lambda)$, of the gas at wavelength λ;

$$[3] \quad R_\lambda = \rho^{-1}[n^2(\lambda) - 1]/(n^2(\lambda) + 2]$$

$$= \frac{4\pi}{3} N_A (2R)^2 a_0^3 \int_{E_0}^{\infty} \frac{(df/dE)}{E^2 - (hc/\lambda)^2} dE$$

where ρ is the molar density of the gas, N_A is Avogadro's number, a_0 is the Bohr radius, h is Planck's constant, and c is the speed of light.

The choice of E_0 as the electronic (uv) absorption threshold is in a sense arbitrary, although this is the usual choice. For example, it is not difficult to include the effects of the ir part of the spectrum although for many (but not all) properties and/or molecules this has little effect on the calculated properties (6–8).

The evaluation of the molecular properties via results like eqs. [1]–[3] is straightforward if accurate values of molecular dipole oscillator strengths are available over a wide range of

excitation energies E. Generally, however, the direct use of such data is not a trivial matter since there are often large errors (typically 2−20%, e.g. ref. 9 and some of the references therein) associated with even good oscillator strength data and there is often a severe lack of molecular data over wide energy regions.

In order to obtain a recommended DOSD, from an initial data base of (df/dE) versus E values, we follow Zeiss *et al.* (9) (see also refs. 7, 8, 10) and divide the excitation energies for a given molecule into N regions from E_0 to very large values of E. The original differential oscillator strength data for the jth region is then modified according to

$$[4] \quad (df/dE)^j_{\text{mod}} = (1 + a_j)(df/dE)^j_{\text{initial}}, \quad j = 1, 2, \ldots, N$$

so that the total modified DOSD satisfies constraints through the choice of the parameters a_j. Particularly good constraints (4, 5, 7−11) are provided by the Thomas−Reiche−Kuhn sum rule (1, 12), $S_0 = N$, and values of R_λ for two well separated values of λ and these are used in the work reported in Section 3. The lack of reliable experimental values for R_λ is a limiting factor in this procedure (see refs. 10, 13 and the sequel).

The constraints S_0 and the R_λ are written as the sum of N integrals, one each for every value of j in [4]. If N_i sources of oscillator strength data are used for the ith spectral region, the total number of initial DOSDs is given by $\prod_{i=1}^{N} N_i$. The parameters a_j are determined for each initial DOSD by using the constrained least-squares procedure outlined in ref. 9 where the initial DOSD data are allowed to vary within their expected uncertainty while satisfying the imposed constraints. The final "recommended" DOSD for each molecule is that which requires the least overall adjustment in the original input DOSD data. Often DOSDs that differ considerably locally (e.g. pointwise as a function of E) agree well globally in the sense of yielding very similar results for a variety of dipole properties, see refs. 8, 14 and what follows. Thus while the constraint procedure can often be used to discriminate between various sources of DOSD input data, considerable care should be used in this application of the method.

Each DOSD is represented by a set of data points, E_l and $(df/dE)_l$, for $l = 1, 2, \ldots, N_p \gg N$, and a set of $(N_p - 1)$ interpolating functions. For very high energies $\gtrsim 10^9$ eV, (df/dE) is represented by the Born dipole formula (12) $AE^{-3.5}$. The "recommended" DOSDs for the molecules treated in this paper have been placed in the Depository for Unpublished Data.[4] The dipole properties [1]−[3] can be readily evaluated (9) using this representation of the DOSDs.

3. DOSDs and related properties for methanol, ethanol, and *n*-propanol

The following experimental photoabsorption cross sections σ were used in constructing the DOSDs for the primary alcohols: *Methanol (CH_3OH)*: 6.2−7.4 eV (Harrison *et al.* (15)); 6.2−10.0 eV (Salahub and Sandorfy (16)); 7.4−16 eV (Heubner and Cellota (17)); 7.4−21 eV and 10.0−11.8 eV (Person and Nicole, refs. 18 and 19, respectively); 30−100 eV (de Reilhac and Damany (20)). *Ethanol (C_2H_5OH)*: 6.1−7.4 eV (15); 6.1−10.3 eV (16); 7.4−16 eV (17); 7.4−21 eV (18); 10.3−11.8 eV (19); 27−100 eV (20). *N-Propanol (C_3H_7OH)*: 6.1−10 eV (16); 9.3−24 eV (Ogawa and Cook (21)); 25−100 eV (20). The data of Ogawa and Cook (21) are widely spaced in energy and are used explicitly to construct the DOSD for *n*-propanol only. The cross sections due to Heubner and Cellota (17) are obtained from electron energy loss spectra.

Apparently experimental refractive index data for the gaseous normal alcohols are available only for methanol (22).

Due to the limited direct experimental DOS and refractive index data available for these molecules, it is augmented by photoabsorption cross sections and molar refractivities generated by additivity rules. Many possible additivity rules can be developed using available literature DOSD data and those used here for σ and R_λ are meant to be representative examples. In general, additivity rules based on elementary substances that most closely reflect the environment of the atoms making up the molecule of interest yield the most reliable results. Additivity rules for the various molecular dipole properties, including the molar refractivity, the closely related static dipole polarizability, and the DOSD itself, have been discussed in detail in previous papers (10, 23, 24) and some of the references therein. These papers contain dicussions of how the usefulness of the additivity rules depends both on the index k occurring in [1] or [2] and on the choice of elemental substances used in the rules.

Very often when molecules are used as elemental substances in applications of the mixture or additivity rule for DOSDs, and in particular for the lower members of a homologous series of molecules, there is little to choose between various additivity schemes in that the differences between the DOS data produced are less than the expected experimental error in reliable DOS data. In general, the mixture rule is not useful if the photon energy E is too low. For example, in what follows the mixture rules involving O_2 and H_2O are considered only for $E > 20$ eV since the DOSDs for these substances have structure for lower photon energies. Mixture rules employing atomic DOS data become reasonable only for larger photon energies where the effects of intramolecular forces, which are responsible for the breakdown of atomic additivity, become less important.

In general, the additivity rules for molecular properties are less reliable as the index k decreases below zero. For this reason the molar refractivity additivity rules for ethanol and *n*-propanol used here are group additivity rules based on experimental methanol and CH_2 group refractivity data, the latter being generated by normal alkane results.

3.A. Methanol

No direct experimental cross section data are available between 21 and 30 eV. In the first instance cross sections for this region were obtained, following de Reilhac and Damany (20), by using a plot of ln σ versus ln E to extrapolate their data for $E < 30$ eV; the extrapolated data merge satisfactorily with those of Ogawa and Cook (21) for $E > 20$ eV.

The experimental data for methanol are augmented by using the following mixture rules:

$$[5] \quad (M.1)\ \sigma(CH_3OH) = \sigma(C) + 2\sigma(H_2) + \tfrac{1}{2}\sigma(O_2)$$

$$[6] \quad (M.2)\ \sigma(CH_3OH) = \sigma(CH_4) + \sigma(H_2O) - \sigma(H_2)$$

$$[7] \quad (M.3)\ \sigma(CH_3OH) = \sigma(CH_4) + \tfrac{1}{2}\sigma(O_2)$$

$$[8] \quad (M.4)\ \sigma(CH_3OH) = \tfrac{1}{2}\sigma(C_2H_6) + \sigma(H_2O) - \tfrac{1}{2}\sigma(H_2)$$

$$[9] \quad (M.5)\ \sigma(CH_3OH) = \tfrac{1}{2}[\sigma(C_2H_6) + \sigma(O_2) + \sigma(H_2)]$$

[4]The appendix is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

For personal use only.

The input for these mixture rules are our recommended (9, 10, 7) DOSDs for H_2, O_2, H_2O, CH_4, and C_2H_6 while the $\sigma(C)$ data are those used in our treatment (10) of the normal alkanes.

The molar refractivity constraints, at $\lambda = 6400$ and 4359 Å, are obtained from the refractive index data of Ramaswamy (22).

The energy spectrum for methanol is divided into thirty energy regions as indicated in Table 1 which includes our "recommended" integrated dipole oscillator strengths together with the original experimental and/or mixture rule values for each region. Four "recommended" DOSDs have been constructed.

First we considered the available experimental data for $E \leq 50$ eV, together with all the mixture rule data considered individually from 50−100 eV and (M.1) data used for $E > 100$ eV. DOSD-I is obtained by subjecting these data to the constraint procedures reviewed in Section 2. DOSD-II is constructed by using the experimental data only for $E \leq 21$ eV, mixture rules (M.2) to (M.5) considered individually for 21−100 eV, and (M.1) for $E > 100$ eV. DOSD-III is obtained analogously to DOSD-II except that only mixture rule (M.3) is used in the 21−100 eV energy range. DOSD-I was constructed under the assumption that de Reilhac and Damany's data are too low for $E > 50$ eV; see also refs. 8, 9. To help verify this DOSD-IV was constructed, analogously to DOSD-I, except that de Reilhac and Damany's data were included in the constraint procedure for $50 \leq E \leq 100$ eV.

It is clear from Table 1 that the mixture rule data are in good agreement with each other and with the recommended, and most of the available experimental, values for $E \gtrsim 20$ eV. All the DOSDs are very similar for all energy regions except between 21 and 24 eV where DOSD-III and/or DOSD-IV can be as much as 20% lower than DOSD-I or DOSD-II. It seems clear that the original DOS data from (20) are too small for $E > 50$ eV, and in particular for $50 \leq E \leq 70$ eV.

Table 2 compares our calculated values of R_λ with Ramaswamy's (22) experimental results as a function of λ and Table 3 contains our calculated values for S_k, $-10 \leq k \leq 2$, and L_k, $-2 \leq k \leq 2$, for the four DOSDs. The DOSD results for R_λ are in excellent agreement with the available experimental values and each other. The differences between the values of the dipole properties evaluated from the four DOSDs, see Table 3, are much less, for all k, than the expected errors inherent in the DOSD constraint method (9, 5), namely ~2−3% for $k = 1$ and 2 and ~1% for $-6 \leq k \leq 0$ assuming the refractivity constraints are accurate to within a few tenths of a percent. These results also strongly suggest that reliable values for the dipole properties of the molecule can be obtained by using mixture rule DOSD data for $E \gtrsim 21$ eV. Our result for $S_{-2} = 21.94$ is in reasonable agreement with the results 21.69 and 21.74 obtained by Kubo (25) and Cartright (26).

3.B. Ethanol

As in the case of methanol, de Reilhac and Damany's data are extrapolated to fill the gap in the cross section data between 21 and 27 eV and the following mixture rules are employed:

[10] (M.1) $\sigma(C_2H_5OH) = 2\sigma(C) + 3\sigma(H_2) + \frac{1}{2}\sigma(O_2)$

[11] (M.2) $\sigma(C_2H_5OH) = 2\sigma(CH_4) + \sigma(H_2O) - 2\sigma(H_2)$

[12] (M.4) $\sigma(C_2H_5OH) = \sigma(C_2H_6) + \sigma(H_2O) - \sigma(H_2)$

[13] (M.6) $\sigma(C_2H_5OH) = \frac{1}{2}\sigma(C_4H_{10}) + \sigma(H_2O) - \frac{1}{2}\sigma(H_2)$

[14] (M.7) $\sigma(C_2H_5OH) = \sigma(CH_3OH) + \sigma(CH_4) - \sigma(H_2)$

[15] (M.8) $\sigma(C_2H_5OH) = \sigma(CH_3OH) + \sigma(C_2H_6) - \sigma(CH_4)$

[16] (M.9) $\sigma(C_2H_5OH) = \sigma(CH_3OH) + \frac{1}{2}[\sigma(C_4H_{10}) - \sigma(C_2H_6)]$

The additional input for these mixture rules relative to those for methanol are the butane recommended DOSD of ref. 10 and DOSD-I for methanol. The group mixture rules (M.8) and (M.9) are used for $E \gtrsim 15$ eV while the other mixture rules are used explicitly to construct the ethanol DOSD only for $E \gtrsim 21$ eV.

Apparently there are no experimental refractive index data for gaseous C_2H_5OH. The initial molar refractivity contraints, at $\lambda = 6440$ and 2302 Å, are generated by the additivity rule

[17] $R_\lambda(C_2H_5OH) = R_\lambda(CH_3OH) + R_\lambda(C_2H_6) - R_\lambda(CH_4)$

and, as input, the experimental data of Watson and Ramaswamy (27) and Friberg (28, 29), as normalyzed to (27) at $\lambda = 5462$ Å, for C_2H_6 and CH_4 at $\lambda = 6440$ and 2302 Å respectively, the experimental data of Ramaswamy (22) for CH_3OH at $\lambda = 6440$ Å, and the result obtained from DOSD-I for CH_3OH at $\lambda = 2302$ Å (see Table 2). The constraints are $R(\lambda = 6440) = 13.0546$ and $R(\lambda = 2302) = 15.2096$ cm^3 mol^{-1}.

The molar refractivity constraints and the various dipole oscillator strength data are used to construct three ethanol DOSDs. DOSD-I and DOSD-II are obtained analogously to the corresponding DOSDs for methanol by using the mixture rules [10]−[16] for $E \gtrsim 50$ eV and $E \gtrsim 21$ eV, respectively. DOSD-III is constructed by constraining all the experimental data for $E \leq 15$ eV, the mixture rule (M.8) and (M.9) data for $15 \leq E \leq 100$ eV, and (M.1) data for $E \gtrsim 100$ eV. Table 4 contains the "recommended" integrated oscillator strengths, together with the initial experimental and/or mixture rule results used in the construction of the "recommended" DOSDs, for various spectral regions.

It is evident from Table 4 that the mixture rule data are in satisfactory agreement with one another and with the recommended DOSDs for $E \gtrsim 15$ eV. Mixture rule (M.9) data require the least overall adjustment of all the mixture rules for $15 \leq E \leq 100$ eV. As for methanol the DOS data from ref. 20 are considerably too small for larger energy values, in particular for $50 \leq E \leq 70$ eV.

The results for the dipole properties S_k and L_k for the three DOSDs are all very similar (the spread in the results are analogous to those for CH_3OH, see Table 3) and only those corresponding to DOSD-I are given in Table 5. Since experimental data for the refractivity results are not available, the reliability of our values for these dipole properties is open to question. To investigate this we generated other values for R_λ at 6440 and 2302 Å by using the additivity rules

[18] $R_\lambda(C_2H_5OH) = R_\lambda(CH_3OH) + R_\lambda(C_3H_8) - R_\lambda(C_2H_6)$

and

[19] $R_\lambda(C_2H_5OH) = R_\lambda(CH_3OH) + \frac{1}{2}[R_\lambda(C_4H_{10}) - R_\lambda(C_2H_6)]$

The additional input for [18] and [19], relative to [17], is the experimental data for C_3H_8 due to Watson and Ramaswamy (27) and Friberg (28), as normalyzed to ref. 27 at 5462 Å, the experimental data of ref. 27 at 6440 Å for *n*-butane, and the result obtained from our recommended C_4H_{10} DOSD (10) at 2302 Å. The resulting molar refractivity constraints are $R(\lambda = 6440) = 13.1134$, 13.0175 and $R(\lambda = 2302) = 15.3399$,

*The table contains the recommended oscillator strengths, obtained by applying the constraint procedures discussed in the text, and the oscillator strengths obtained by using the unmodified experimental or mixture rule dipole oscillator strength data considered in constructing the recommended DOSDs. The reference given with each recommended value indicates the source of the original DOS data for each specified spectral region.

†Between 21 and 30 eV extrapolated results based on ref. 20 are employed.

L_{-2}	−10.71	−10.71	−10.73	−10.70

*The dipole properties evaluated from the four DOSDs are essentially identical. By the method of construction DOSD-I is marginally recommended. The results for S_{-5}, S_{-7}, and S_{-9} for this DOSD are 17.82(1), 11.74(2), and 10.04(3), respectively. Estimated errors for the properties are discussed in the main text.

15.2409 $cm^3\ mol^{-1}$, respectively, corresponding to [18] and [19]. These values were used to construct DOSD-I′ and I″ which are analogous to DOSD-I but with the molar refractivity constraints generated by [17] replaced by those obtained from [18] and [19], respectively. The corresponding values of the dipole properties S_k and L_k are included in Table 5.

There is little to choose between the results for the dipole properties evaluated using the three DOSDs until reliable experimental data for the molar refractivity of ethanol are available. On chemical grounds the molar refractivity rule [18] appears preferable to [19], and particularly [17], and we nominally choose our recommended values of the dipole properties to be those evaluated using DOSD-I′. An estimate of the error in these results is given by the magnitude of the maximum discrepancies between the values of the dipole properties evaluated using the three DOSDs. It appears the errors in the S_k and L_k, for $-2 \leq k < -4$, obtained from DOSD-I′ are of about the same size as those inherent in the DOSD method itself. Our result for S_{-2} = 34.29 is in good agreement with, and probably more reliable than, the literature values (30, 31) of 33.20 and 35.61. The errors in our calculated results for the dipole properties for $k \leq -4$ probably become progressively worse as k decreases; this is in agreement with the point that the S_k, increasingly so for increasing negative values of k, emphasize the low energy part of the photoabsorption spectra which is largely constrained by the values of R_λ (10, 23). Values of R_λ evaluated using DOSD-I′, for λ = 5462, 5087, 4801, and 4359 Å, are R_λ = 13.1513, 13.2049, 13.2552, and 13.3549 $cm^3\ mol^{-1}$, respectively.

It is clear from the above discussion that mixture rules based on group additivity schemes can be used with confidence for $E > 15$ eV for the purposes of calculating reliable dipole properties for the higher alcohols.

3.C. n-Propanol

The following mixture rules are used to augment the experimental photoabsorption cross section data for this molecule:

[20] (M.1) $\sigma(C_3H_7OH) = 3\sigma(C) + 4\sigma(H_2) + \frac{1}{2}\sigma(O_2)$

[21] (M.10) $\sigma(C_3H_7OH) = \sigma(C_3H_8) + \sigma(H_2O) - \sigma(H_2)$

[22] (M.7) $\sigma(C_3H_7OH) = \sigma(CH_3OH) + 2[\sigma(CH_4) - \sigma(H_2)]$

[23] (M.8) $\sigma(C_3H_7OH) = \sigma(CH_3OH) + 2[\sigma(C_2H_6) - \sigma(CH_4)]$

[24] (M.9) $\sigma(C_3H_7OH) = \sigma(CH_3OH) + \sigma(C_4H_{10}) - \sigma(C_2H_6)$

[25] (M.11) $\sigma(C_3H_7OH) = \sigma(C_2H_5OH) + \frac{1}{2}[\sigma(C_4H_{10}) - \sigma(C_2H_6)]$

[26] (M.12) $\sigma(C_3H_7OH) = 2\sigma(C_2H_5OH) - \sigma(CH_3OH)$

The additional input for these mixture rules relative to those for ethanol is the recommended DOSD of ref. 10 for propane and DOSD-I for ethanol. Mixture rules (M.7)–(M.11) are used explicitly to construct the propanol DOSD only for $E \geq 15$ eV while (M.12) is used for $E \geq 10$ eV; the mixture rules, in particular (M.12), provide an alternative to the widely spaced DOS data of Ogawa and Cook (21) between 9.3 and 24 eV.

The initial molar refractivity constraints for propanol are obtained from the group additivity rule

[27] $R_\lambda(C_3H_7OH) = R_\lambda(CH_3OH) + R_\lambda(C_3H_8) - R_\lambda(CH_4)$

The input data have been discussed previously in the context of additivity rules [17] and [18] and the constraints correspond to the R_λ values for λ = 6440 and 2302 Å (see Table 6).

In the constraint procedure the experimental data of Salahub and Sandorfy (16) was used for $E \leq 10$ eV, the mixture rule (M.12) was employed for $10 \leq E \leq 15$ eV, all the mixture rules were used individually between 15 and 100 eV, and (M.1) was used for $E > 100$ eV. The corresponding integrated oscillator strengths for the twenty-one spectral regions considered in constructing the DOSD for *n*-propanol are given in Table 7. For comparative purposes the integrated oscillator strengths for 10–23 eV, obtained from the relatively widely spaced DOS data of Ogawa and Cook (21), are also listed in this table; the agreement with the mixture rule data is generally satisfactory. As typical examples, DOSD-I and DOSD-II integrated oscillator strengths, which correspond to using (M.12) and (M.9) in the constraint procedure between 15 and 100 eV, are given in Table 7. It is evident from this table that mixture rules (M.7)–(M.12) are in satisfactory agreement with each other

L_0	19.79	19.93	20.14
L_{-1}	−5.79	−5.84	−5.73
L_{-2}	−17.30	−17.64	−17.51

*The properties evaluated using DOSD-I′ are nominally recommended. The results for S_{-5}, S_{-7}, and S_{-9} for this DOSD are 28.77(1), 18.87(2), and 15.94(3), respectively. Estimated errors for the properties are discussed in the main text.

TABLE 6. Comparison of the values of R_λ evaluated using the *n*-propanol DOSDs-I, I′, I″, I‴ as a function of λ for 2302 ≤ λ ≤ 6440 Å

	R_λ			
λ (Å)	DOSD-I	DOSD-I′	DOSD-I″	DOSD-I‴
6440*	17.8164	17.7575	17.8751	17.6832
5462	17.9517	17.8901	18.0130	17.8205
5087	18.0266	17.9636	18.0895	17.8966
4801	18.0969	18.0324	18.1612	17.9680
4359	18.2363	18.1690	18.3035	18.1097
2302*	20.8130	20.6828	20.9434	20.7453

*These values are used as constraints for the construction of the relevant DOSDs and are evaluated by using the molar refractivity additivity rules [27] through [30] respectively.

and with the recommended DOSDs for $15 < E < 100$ eV and that (M.1) merges nicely from below (9, 10) with the other mixture rules for $70 \leq E \leq 100$ eV. The results of de Reilhac and Damany (20) appear to be consistently too low.

The dipole properties for *n*-propanol, including R_λ for $6440 \geq \lambda \geq 2302$ Å, have been evaluated using the various DOSDs constructed from the input data discussed above. The results are all very similar (the differences being analogous to those for methanol, see Tables 2 and 3) and only those corresponding to DOSD-I are given in Tables 6 and 8.

To investigate possible errors in the calculated values of the properties arising from the use of [27], three other refractivity additivity rules were employed to generate R_λ constraint values at 6440 Å and 2302 Å;

$$[28]\quad R_\lambda(C_3H_7OH) = R_\lambda(CH_3OH) + 2[R_\lambda(C_2H_6) - R_\lambda(CH_4)]$$

$$[29]\quad R_\lambda(C_3H_7OH) = R_\lambda(CH_3OH) + 2[R_\lambda(C_3H_8) - R_\lambda(C_2H_6)]$$

$$[30]\quad R_\lambda(C_3H_7OH) = R_\lambda(CH_3OH) + R_\lambda(C_4H_{10}) - R_\lambda(C_2H_6)$$

The input used to generate the three sets of refractivity constraints corresponding to [28]−[30], see Table 6, is discussed in the context of [17]−[19]. These results are used to construct DOSD-I′ through DOSD-I‴, which are analogous to DOSD-I but with the molar refractivity constraints obtained from [27] replaced with those generated by [28]−[30], respectively. The dipole properties R_λ, S_k, and L_k evaluated using these DOSDs are included in Tables 6 and 8 and the integrated oscillator strengths for the first two DOSDs are given in Table 7 as illustrative examples.

Keeping the input DOS data the same and varying the refractivity constraints affects the final DOSDs only for relatively low values of the photon energy E; compare the integrated oscillator strengths of Table 7 corresponding to DOSDs-I, I′, and I″. This is in agreement with the fact that the molar refractivity constraints, like S_{-2}, are dominated by the low energy ($E \lesssim 30$ eV) portion of the DOSD (10, 23). Thus, as is clear from Table 8, the dipole properties determined from DOSD-I through DOSD-I‴ vary substantially only for $k < -2$ since the constraints do not vary drastically; for example, the discrepancies in Table 8 for S_{-2}, S_{-3}, and S_{-4} are 1.1, 2.1, and 3.8% respectively and the discrepancy for S_{-2} is, of course, essentially the same as that in Table 6 for the higher wavelength values of R_λ ($R_\infty \sim S_{-2}$). For recommended values of the dipole properties we nominally choose those corresponding to DOSD-I″ which are very similar to those obtained from DOSD-I‴ for all k. Our result for $S_{-2} = 46.9$ is probably more reliable than the literature value (30) of 45.5. It appears that the uncertainty in our results for S_k and L_k, $-2 \leq k \leq 0$, is ~1% while that for $k = 1$ and 2, which is related to the uncertainties in the high energy portion of the DOSD, is probably ~2% (9). The limiting factor in our treatment of *n*-propanol is the lack of accurate experimental refractivity data and because this molecule is further removed from methanol than is ethanol, it is probably prudent to increase the estimated errors for $-2 \leq k \leq 0$ to ~2%.

4. Discussion

For fixed R_λ constraints different DOS input data can yield DOSDs that differ from one another locally (for given photon energies E) while agreeing globally in the sense that they yield essentially identical results for a variety of dipole properties. Examples are furnished in Section 3 for the three molecules studied here and earlier work (14) using 1-butene as a model, see also ref. 9, indicates that DOSDs with considerably more local disagreement than those of Section 3 yield markedly similar results for the dipole properties.

A limiting factor in the constraint procedure for determining the dipole properties is the lack of reliable experimental values for the molar refractivity constraints for a variety of molecules. The effect on the calculated properties S_k and L_k of varying the R_λ constraints for fixed DOSD input data is also illustrated by some of the calculations of the properties of ethanol and *n*-propanol. As expected (10, 23) from the structure of the integrals [1] and [2] defining the properties, the effect is largest for $k \leq -2$, increases as k decreases from −2, and is the same as the discrepancy in the higher wave length R_λ constraint for S_{-2}. For the typical variations in the constraints investigated in Section 3 the changes induced in the calculated properties are small ($\lesssim$1%) for $k \geq -3$.

The results obtained for the properties of methanol have the errors normally associated with the constraint procedure assuming the molar refractivity constraints are reliable (~1−2%

TABLE 7. Integrated dipole oscillator strengths for *n*-propyl alcohol*

Energy values (eV)	Recommended values				Original experimental and/or mixture rule values
	I	II	I′	I″

for $2 \geq k \geq -6$). For the other alcohols this estimate of the reliability of the properties applies only for $k \geq -3$. The properties of most interest for a variety of applications correspond to these latter values of k.

The accurate *ab initio* or non-empirical quantum mechanical evaluation of the dipole properties of even relatively simple molecules is a difficult problem. Similarly the accurate *direct* experimental determination of many of these properties is often very difficult (for example see ref. 4). The quantum mechanical constraint procedure used here for determining the dipole properties of the alcohols offers a method for the reliable determination of many molecular properties if suitable input data are available or can be constructed using additivity relations. The usefulness of results of this type for testing the *ab initio* and non-empirical approaches is clear (32). An important application of reliable results for the dipole properties lies in the construction of group or bond properties which can be used in additivity formalisms to evaluate the properties of large species from those of smaller molecules and/or atoms (23, 24). A preliminary report on some of the group properties associated with the alcohols studied here can be found in ref. 24 and a full study will be published in due course. One of the drawbacks of the approach used in this paper is that it is, at present, only generally applicable to the evaluation of the rotationally averaged (isotropic) dipole properties of molecules primarily because of the lack of symmetry adapted dipole oscillator strength data.

In this paper, we have taken the lower limit for the integrals over photon energy defining the dipole properties, see [1] and [2], to be the electronic (uv) absorption threshold, see Section 2. The effect of including the ir part of the spectrum on the values of S_{-2} has been considered for H_2O, CH_4, and CO_2 in refs. 7, 8, and 33 and for these and many other molecules in ref. 34. The influence of the ir oscillator strengths on the values

L_{-2}	−24.30	−23.94	−24.66	−24.40

*The properties evaluated using DOSD-I″ are nominally recommended. The results for S_{-5}, S_{-7}, and S_{-9} for this DOSD are 40.01(1), 25.86(2), and 20.97(3) respectively. Estimated errors for the properties are discussed in the main text.

of the S_k, as a function of k, has been discussed in ref. 8 for CO_2 and in general the ir contribution can increase markedly as k decreases.

We have considered here only dipole properties involving one integral over the DOSD for the molecule of interest. Many other important properties, for example, the dipole−dipole and the triple-dipole interaction dispersion energies between molecules, depend on two or more such integrals. These properties are much more readily evaluated by constructing pseudo-DOSDs (35) and these and the dispersion energies involving the alcohols considered in this paper will be presented elsewhere.

Synthetic and Raman spectroscopic study of the fluorosulfates of zinc, cadmium, and mercury

S. P. MALLELA AND F. AUBKE

Department of Chemistry, The University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received April 5, 1983

S. P. MALLELA and F. AUBKE. Can. J. Chem. **62**, 382 (1984).

The group IIB metal fluorosulfates of the type $M(SO_3F)_2$, with M = Zn, Cd, or Hg, are conveniently obtained in a simple one-step procedure: the metal oxidation in a mixture of bis(fluorosulfuryl)peroxide and fluorosulfuric acid. The resulting white polymeric solids are all excellent Raman scatterers and provide the first consistent set of Raman data for this structural type. Above 400 cm^{-1} six sharp Raman lines indicate retention of C_{3v} symmetry for the tridentate fluorosulfate groups, with coordination through oxygen evidenced by frequency shifts, in particular in the stretching range and the rigid polymeric structure causing a different band intensity pattern than the one found for ionic fluorosulfates. Bands below 300 cm^{-1} are observed as well and some are tentatively assigned to skeletal metal–oxygen vibrations.

S. P. MALLELA et F. AUBKE. Can. J. Chem. **62**, 382 (1984).

Utilisant un procédé simple en une étape, ou a pu obtenir facilement des fluorosulfates des métaux du groupe IIb du type $M(SO_3F)_2$, où M = Zn, Cd ou Hg: le procédé implique une oxydation du métal dans un mélange de peroxyde de bis-(fluorosulfuryl) et d'acide fluorosulfurique. Les solides polymériques blancs qui en résultent diffractent bien le Raman et permettent d'obtenir pour la première fois des données cohérentes en Raman pour ce type de structure. Au-dessus de 400 cm^{-1}, la présence de six lignes Raman bien définies indique que la symétrie C_{3v} est retenue pour les groupes fluorosulfates tridentates, avec une coordination par le biais de l'oxygène démontrée par des déplacements de fréquences, en particulier dans la région de l'élongation, et la structure polymérique rigide provoquant un changement dans l'arrangement des intensités des bandes par rapport à celui trouvé pour les fluorosulfates ioniques. On observe aussi la présence de bandes en-dessous de 300 cm^{-1} et on en attribue quelques-unes à des vibrations du squelette métal–oxygène.

[Traduit par le journal]

Introduction

The fluorosulfates of the metals zinc, cadmium, and mercury of the type $M(SO_3F)_2$ have been known for some time. Zinc fluorosulfate was first obtained by Goubeau and Milne (1) in the reaction of anhydrous $ZnCl_2$ with fluorosulfuric acid in the presence of potassium fluorosulfate. The same authors have reported the infrared spectrum down to ~100 cm^{-1}. Both $Cd(SO_3F)_2$ and $Zn(SO_3F)_2$ are also prepared by the solvolysis of the corresponding metal benzoates in an excess of HSO_3F (2), while $Hg(SO_3F)_2$ was obtained by the oxidation of mercury with an excess of bis(fluorosulfuryl)peroxide, $S_2O_6F_2$, in a rather slow reaction (3).

Structural proposals for all three and a number of other fluorosulfates of divalent metals (2) have involved a 3-dimensional polymer with the tridentate fluorosulfate group retaining C_{3v} symmetry and the metal achieving regular octahedral coordination (Fig. 1). Since all attempts so far have failed to obtain single crystals suitable for an X-ray diffraction study, and since the compounds are all high melting, do not sublime, and are completely insoluble in HSO_3F and other inert solvents, evidence has come from infrared spectra (2), and in case of some transition metal fluorosulfates like $Pd(SO_3F)_2$ (4), from their magnetic properties and the electronic spectra. Again a regular octahedral environment for Pd(II) is indicated (4).

Our interest in these compounds centered around three points. (*i*) Metal oxidation in a mixture of HSO_3F and $S_2O_6F_2$ had proven a very simple and efficient method to prepare metal fluorosulfates. This method should be extendable to the group IIB fluorosulfates as well. (*ii*) Controlled metal oxidation may even provide evidence for low valency, metal–metal bonded species, in particular in case of mercury. (*iii*) All compounds are colorless and should be excellent Raman scatterers. We hoped to settle some of the discrepancies found in the published infrared data (2, 3) and provide for the first time a detailed and consistent set of Raman data for compounds with a tridentate bridging fluorosulfate group. In addition, we hoped to find some spectral features in the low frequency region, characteristic of the suggested polymeric structure. Only for $Zn(SO_3F)_2$ are vibrational modes below 400 cm^{-1} reported (1). This region should be more easily accessible by Raman spectroscopy but so far no Raman data on these compounds have been reported.

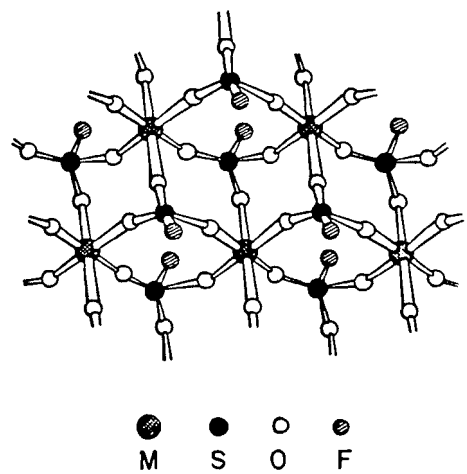

FIG. 1. Proposed structure of $M(SO_3F)_2$.

Experimental

Both zinc and cadmium were of analytical grade; mercury was doubly distilled. Bis(fluorosulfuryl)peroxide was prepared by catalytic (AgF_2) direct fluorination of sulfur trioxide according to Cady and Shreeve (5). Technical grade fluorosulfuric acid (Allied Chemical Corp.) was doubly distilled at atmospheric pressure in a counter stream of dry nitrogen.

Raman spectra were obtained with a Spex Ramalog 5, equipped with a Spectra Physics 164 argon ion laser. The line at 514.5 nm was

used for excitation and solid samples were contained in melting point tubes. A Perkin-Elmer 457 grating infrared spectrophotometer was used with samples pressed between AgCl windows.

All reactions were performed in Pyrex reaction vials of about 40 mL capacity, filled with Kontes Teflon stem valves. Volatile materials were manipulated using standard vacuum line techniques. Solids were handled in a Vacuum Atmosphere Corporation "Dri Lab", model No. HE-43-2 filled with purified dry nitrogen and equipped with a "Dri Train" model HE-93-2. All reactions were followed by weight.

Synthetic reactions

A mixture of fluorosulfuric acid and bis(fluorosulfuryl)peroxide ~1:1 by volume was used. About 200−300 mg of metal were allowed to react with approximately 5 to 8 mL of the mixture of HSO_3F and $S_2O_6F_2$. The reaction with mercury proceeded vigorously, and went to immediate completion with the reaction mixture initially at room temperature. The reactions of zinc and cadmium took 3−4 weeks with the temperature gradually raised to 90°C. Completion was judged by the disappearance of the grey colour due to unreacted metal. In all instances white powders precipitated out of solution. After completion of the reaction all volatiles were removed *in vacuo*.

Attempts to obtain lower valent compounds involving primarily mercury were performed in a similar way using small proportions of oxidizer.

Results and discussion

Metal oxidation by bis(fluorosulfuryl)peroxide is a simple, one-step route, resulting in the preparation of the group IIB metal fluorosulfates. The role of HSO_3F is crucial in all three instances. The preparation of $Hg(SO_3F)_2$ is speeded up and is essentially complete within minutes. The other two metals are both unreactive towards $S_2O_6F_2$ alone, but in the presence of fluorosulfuric acid quantitative conversion is achieved even though rather long reaction times are required. The advantage over solvolysis reactions of either anydrous chlorides or benzoates is threefold: (*a*) the starting materials are available at a very high degree of purity, (*b*) no preparation or drying of starting materials is needed, and (*c*) isolation of the final products by removal of all volatiles *in vacuo* is, in case of moisture-sensitive material, more advantageous than filtration and results in theoretical yields. While this procedure can be used for a wide range of metals, there are limitations to its use. Attempts by us to extend this study to the preparation of fluorosulfates of aluminum, boron, or indium were totally unsuccessful. Even at temperatures up to 110°C no reaction occurred.

In the case of the IIB metals the observed reactivity of mercury is somewhat surprising, since it is generally attested to be the least reactive of the three with the highest first and second ionization energies. We feel that the lack of reactivity for Zn and Cd may be caused by the initial formation of an unreactive coating on the metal surface preventing further reaction. The bis(fluorosulfates) of all three metals are indeed completely insoluble in HSO_3F, not inconsistent with their polymeric structure. Similar arguments apply to the observed lack of reactivity for the IIIA metals. Also unsuccessful were attempts to obtain lower valent fluorosulfates. Our attempts had centered primarily on mercury, because Hg_2^{2+} is by far the most stable of the three M_2^{2+} ions, and other chainlike ions such as Hg_3^{2+} and Hg_4^{2+} are known (6). In all instances where small amounts of $S_2O_6F_2$ are used, only $Hg(SO_3F)_2$ forms and unreacted mercury is noted as well.

All solid metal bis(fluorosulfates) are indeed excellent Raman scatterers and high quality spectra with a very good signal-to-noise ratio, reasonably straight baselines, and sharp Raman lines down to below 100 cm^{-1} are obtained. The spectrum of $Hg(SO_3F)_2$ is shown in Fig. 2. The Raman shifts observed are listed in Table 1 together with measured relative intensities in the region of the internal vibration of the SO_3F group. The noted base line shift in the region below 250 cm^{-1} allows only a rough estimation of intensities. Also listed are the corresponding infrared data. Our own infrared data agree reasonably well with the published data (1; 2); however, there are some minor exceptions. Two weak bands reported for $Hg(SO_3F)_2$ (2) at 581 and 574 cm^{-1} are not observed, nor is a weak band at 1067 cm^{-1} for $Zn(SO_3F)_2$ (1). None of these bands have Raman counterparts and may be due to combination bands or solid state effects. There is also, particularly in the SO— and SF stretching region, a discrepancy in the reported band position, up to about 20−25 cm^{-1} in some cases. This discrepancy is in our view caused by the rather broad bands found in the infrared spectra for these compounds in the stretching region. It should also be kept in mind that all materials are polymers with different synthetic routes at different reaction conditions, possibly resulting in a different degree of polymerisation. In addition, the reported infrared spectra were obtained on mulls with Nujol, hexachlorobutadiene, and fluorocarbon oils used as mulling agents (1,2), while our ir spectra were obtained on solid samples pressed between AgCl plates. In the deformation region the ir bands sharpen up and agreement is very good. The Raman spectrum of KSO_3F (7) is listed for reference purposes. Also listed are reported infrared data for $Pd(SO_3F)_2$ (4), where the electronic spectrum and the magnetic behavior indicate an undistorted environment and provide convincing evidence for the proposed structural type, so frequently encountered for metal bisfluorosulfates (1, 2, 4). Here the SO_3F^- ion has C_{3v} symmetry as well. Discussion of the spectra will first focus on the internal SO_3F vibrations.

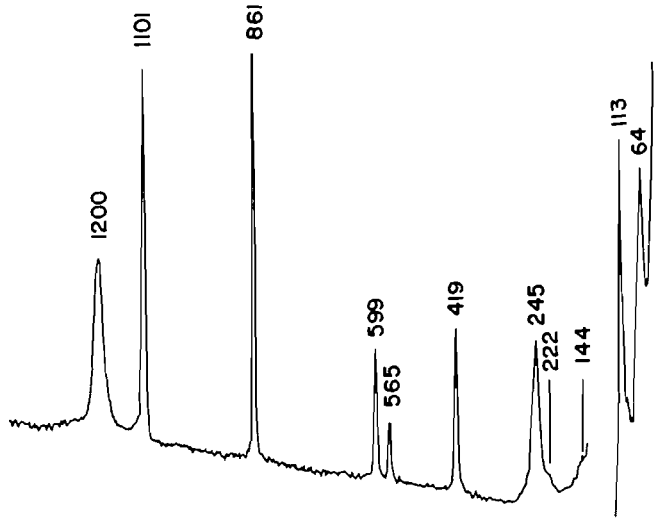

FIG. 2. Raman spectrum of $Hg(SO_3F)_2$.

Agreement with ir data in this region is generally good. The reported value of 832 cm^{-1} for νSF in $Zn(SO_3F)_2$ (1) may be abnormally low. Both in ref. 2 and in our own study, values of 854 and 859 cm^{-1} respectively are suggested in better agreement with the Raman shift of 871 cm^{-1}. Other discrepancies in the stretching region may be due to the various factors discussed above.

The proposed (2) retention of C_{3v} symmetry for the tridentate bridging fluorosulfate group is well confirmed by the Raman spectra for all three compounds. Only six fundamentals are

observed and in no instance is there any band splitting or shoulder noted, which might imply a removal of degeneracy for any of the three E modes. The intensities of the fundamentals show a rather interesting departure from the pattern usually observed for ionic fluorosulfate groups (1, 7). In two instances, the spectra for $Zn(SO_3F)_2$ and $Hg(SO_3F)_2$, the S—F stretching frequency is even more intense than ν_1, the symmetric SO_3 stretch, while for $Cd(SO_3F)_2$ ν_1 is only slightly more intense than νSF. In ionic fluorosulfates, ν_2 is commonly broad and of rather low intensity. This intensity reversal and the shift in band position discussed below becomes a diagnostic feature for the tridentate fluorosulfate group.

A reversal of intensities is noted for the two SO_3 bending modes ν_3 and ν_5 in all three spectra. The higher frequency band had been assigned as ν_5, in ionic compounds the asymmetric SO_3 bend (1, 7), and this assignment had been aided by an observable but small band splitting (7) and the relative intensities. For the group IIB metal fluorosulfates a rather intense band at ~600 cm^{-1} is followed in the Raman spectra by a weaker band at ~570 cm^{-1}.

It seems reasonable to reverse the assignment in this case with $\nu_3(A')$ now at ~600 cm^{-1} and $\nu_5(E)$ at 570 cm^{-1} for the tridentate bridging group.

The basic difference between ionic SO_3F^- and the tridentate bridging form encountered here is due to the rather rigid polymeric frame work, which eliminates disorder problems as they are encountered in KSO_3F (8) and produces a more even intensity pattern with sharp Raman lines.

The shift in band position can now also be seen more clearly and affects predominantly the stretching modes ν_1, ν_2, and ν_4. The band separation between ν_4 and ν_1, the SO_3 stretches, has decreased to about 110 ± 10 cm^{-1} from 206 cm^{-1} in KSO_3F (7) while ν_2, the SF stretch, has moved up by about 115 cm^{-1} compared to its position in KSO_3F. This reflects a change in $p_\pi - d_\pi$ back bonding on coordination through the three oxygen as has been noted before (2). The weighted average of the SO_3 stretching bands in $M(SO_3F)_2$ decreases from 1203 for Zn over 1198 to 1167 cm^{-1} for Hg and may reflect the increase in the mass of the metal tightly held in the polymeric structure.

The deformation modes show only rather small shifts and are obviously not as useful in recognizing the bonding mode of the SO_3F group.

Both intensity pattern and band positions in the range of internal vibrations of the fluorosulfate group are very indicative of a common structural type. The stated complete retention of C_{3v} symmetry suggests a regular octahedral environment for the MO_6— skeleton and indeed a common pattern emerges in the low frequency range as well with two minor exceptions. A strong increase in intensity at ~120 cm^{-1} has made it impossible to locate a weak Raman band, expected at ~150 cm^{-1} in the spectrum of $Cd(SO_3F)_2$, and a rather intense band at 245 cm^{-1} for $Hg(SO_3F)_2$ has weaker counterparts in the spectra of both $Zn(SO_3F)_2$ and $Cd(SO_3F)_2$. Agreement with infrared bands observed by Goubeau and Milne (1) is fair and assignment of bands at ~250 and 220 cm^{-1} as MO stretching modes is based on their original proposal for the related system. This assignment must remain tentative. Previous work on IIB metal compounds with coordinated oxyanions has rarely been extended down below 400 cm^{-1}. Infrared bands for $Zn(NO_3)_2$ at 317 and 287 cm^{-1} and for $Cd(NO_3)_2$ at 199 cm^{-1} have been attributed to M—O skeletal vibrations (9) and frequency trends for these and similar metal nitrates and carbonates have been rationalized with trends in the polarizing power of the various M^{2+} ions. In CH_3HgNO_3 a band at 292 cm^{-1} has been assigned to νHg—O (10), but in all these cases the coordination geometry around the metal is different from the octahedral environment suggested for the fluorosulfates.

Any further assignment would be hazardous in the absence of a detailed structure, but it is fair to say that the Raman spectra provide an additional recognition pattern for the polymeric structure in these metal fluorosulfates. The group IIB fluorosulfates have proven very useful indeed since neither interference from color nor from a distortion of the MO_6 skeleton causes problems.

The photodecomposition of several alkyl benzoylformates has been examined using quantum yield and laser flash photolysis techniques. The Norrish Type II reaction is a major triplet deactivation path in all substrates having γ-hydrogen atoms. Representative triplet lifetimes are 670, 500, and 310 ns, for the methyl, ethyl, and isopropyl esters, respectively, in 1:4 chlorobenzene:*n*-heptane at 298 K. Product studies suggest that several competing reactions are involved in the decay of the 1,4-biradical; some of these lead to highly absorbing (and presumably quenching) products, that make it essential to extrapolate quantum yields to "zero conversion" conditions.

M. V. ENCINAS, E. A. LISSI, A. ZANOCCO, L. C. STEWART et J. C. SCAIANO. Can. J. Chem. **62**, 386 (1984).

On a étudié la photodécomposition de plusieurs benzoformates alkylées en utilisant les techniques du rendement quantique et de la photolyse flash au laser. La réaction de type Norrish II consiste principalement en une désactivation du triplet de tous les substrats ayant des atomes d'hydrogène en position γ. Les principaux temps de vie du triplet sont respectivement de 670, 500 et 310 ns pour les esters méthylique, éthylique et isopropylique à 298 K dans un mélange 1:4 de chlorobenzène–*n*-heptane. L'étude des produits suggère que plusieurs réactions compétitives sont impliquées dans la désintégration du biradical 1,4; certaines d'entres-elles conduisent à des produits qui absorbent fortement (et qui probablement s'inhibent) ce qui oblige d'extrapoler les rendements quantiques aux conditions "où il n'y a pas eu de transformation".

[Traduit par le journal]

The photochemistry of α-keto esters has been the subject of a limited number of studies (1–3). In particular, there are few reported data on the rate of photoprocesses taking place from excited aromatic keto esters. The only reported rate constant has been given by Zanocco *et al.* in a communication on the photolysis of methyl benzoylformate (4). The product distribution and product quantum yield in the photolysis of aliphatic esters of benzoylformic acid are extremely dependent both upon the solvent (1) and temperature (5). In solvents bearing labile hydrogen atoms the main products have been rationalized by a mechanism involving keto ester photoreduction (1). In the photolysis of ethyl benzoylformate in benzene, Leermakers *et al.* found carbon monoxide, benzaldehyde, and acetaldehyde as main products. These were explained in terms of a Type II intramolecular abstraction (6). Due to the large conversions involved, these products could alternatively arise from secondary photolysis of unstable primary photoproducts. Further, the reactive state has not been characterized and its lifetime has not been measured.

In this paper we report the results obtained in a study of the photochemistry of several esters of benzoylformic acid, **I–VIII**.

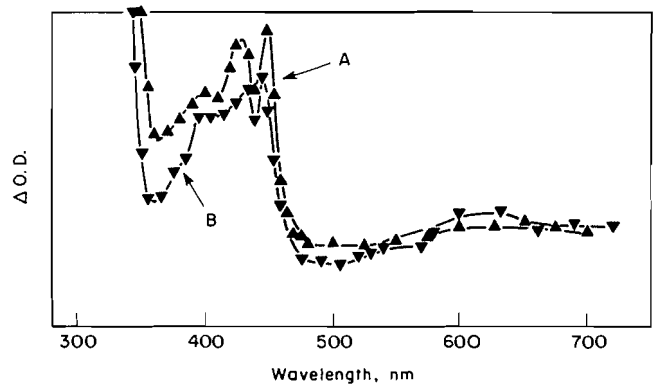

FIG. 1. Absorption spectra of the transients produced in the photolysis of **IV** (*A*) and **I** (*B*) in benzene at 298 K.

This study comprises both direct measurements of transient lifetimes and product analysis under a variety of experimental conditions.

Results

The absorption spectra of the transients produced in the photolysis of **I** and **IV** in benzene are shown in Fig. 1. The shape of the spectra was nearly independent of the delay following laser excitation and was similar for all compounds considered. In particular, it is relevant to the following discussion that the transient spectrum obtained employing compound **VII** was essentially the same as those obtained for the other compounds. These spectra can then be attributed to T–T transitions (4). The decay of the absorption followed first order kinetics and was independent of the monitoring wavelength. The lifetimes were measured at 440 nm; at this wavelength a small residual absorption was observed in some solvents (e.g. hexane

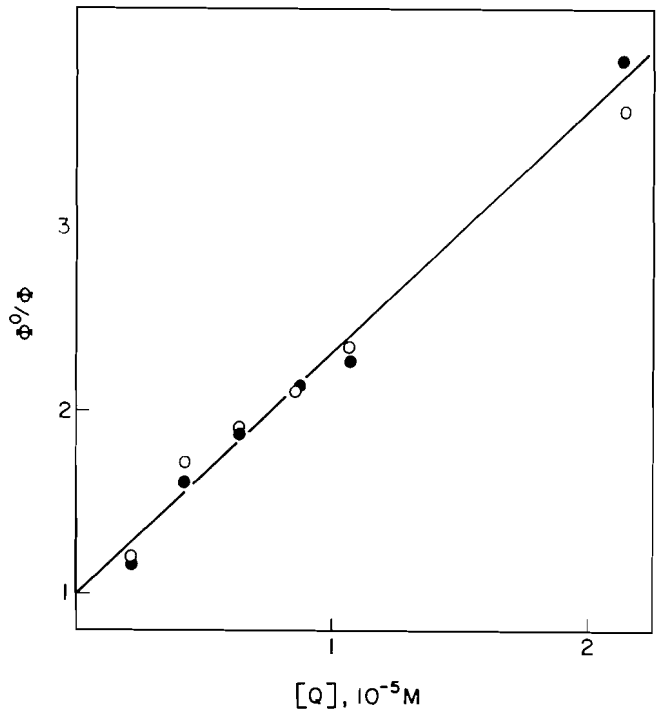

FIG. 2. Effect of the diene concentration upon benzaldehyde (○) and aliphatic carbonyl (●) yields in the photolysis of **VI**. Solvent: *n*-heptane containing 20% chlorobenzene.

or benzene). The lifetimes obtained were independent of the light intensity and of the ester concentration but decreased in the presence of triplet quenchers (e.g. amines and dienes). Quenching rates by 2,5-dimethyl-2,4-hexadiene were determined directly by following the change in triplet lifetimes as a function of added diene. The values obtained in *n*-heptane, benzene, and heptane containing 20% chlorobenzene were (4 ± 1) × 10^9 M^{-1} s^{-1} at 300 K, and, within the error limits given, were independent of the solvent used.

The τ_T values in benzene and *n*-heptane containing 20% chlorobenzene are given in Table 1. This table gives τ_T values measured directly by monitoring the triplet decay and values obtained from product quenching experiments. The latter were obtained from Stern–Volmer plots assuming a quenching rate constant of ~4 × 10^9 M^{-1} s^{-1} for 2,5-dimethyl-2,4-hexadiene.

Stern–Volmer plots were linear and similar results were obtained by measuring the effect of the diene upon benz-

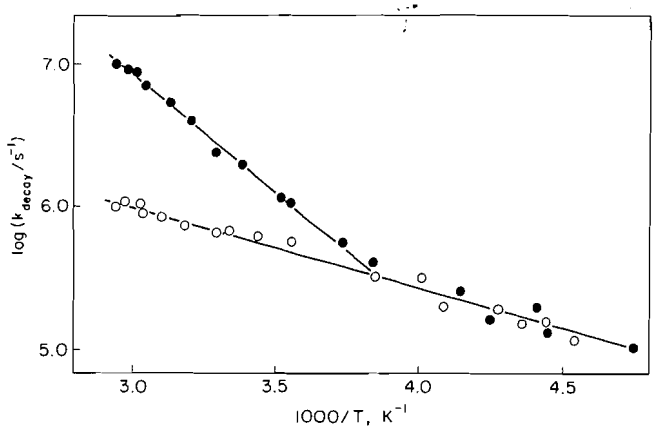

FIG. 3. Decay rate as a temperature function for **VI** (●) and **VII** (○). Solvent: *n*-heptane containing 20% chlorobenzene.

aldehyde or the aliphatic carbonyl compound (see Fig. 2 for a typical set of results).

Triplet lifetimes as a function of temperature were measured for **I**, **IV**, **VI**, and **VII**. The data obtained for **VI** and **VII** are given in Fig. 3. The data of **VI** show two distinct slopes, with a more pronounced temperature dependence at the higher temperatures. The same behaviour was observed for **IV** and **I**.

No measurable photoproducts ($\Phi < 0.01$) were observed in the photolysis of **VII**. In the photolysis of the other compounds (general formula PhCOC(O)OCHR'R), the only products detected by gas chromatography were benzaldehyde and the corresponding aliphatic carbonyl [RC(O)R']. Benzene, the alcohol RR'CHOH, the saturated hydrocarbon RR'CH_2, the olefins R(—H)CHR' and R'(—H)CHR were below our detection limit ($\Phi < 0.01$).

The product quantum yields were very dependent on the solvent and photolysis time. In several solvents (e.g. benzene, ethyl acetate, carbon tetrachloride, or dichloromethane) the reaction mixture develops, upon irradiation, a strong absorption at $\lambda \leq 430$ nm that makes the measurements of quantum yields relatively unreliable. The strongest absorption was observed in ethyl acetate. The change in uv spectra during the irradiation is shown in Fig. 4. When 1% of water was added to the solvent prior to the photolysis, the formation of the coloured compound was markedly diminished. Furthermore, this absorption is bleached when air is admitted to the reaction tube after photolysis.

The ir spectra of samples of methyl benzoylformate photolyzed in carbon tetrachloride show bands at 3390 and 2130 cm^{-1} that increase with irradiation time. The band at 2130 cm^{-1} disappears when the photolyzed sample is exposed to air. The bands at 2130 cm^{-1} and 3390 cm^{-1} could be attributed to the presence of >C=C=O and —OH linkages, respectively (7).

In hydrocarbon solvents (e.g. dodecane) a white precipitate was observed after prolonged photolysis. In methanol as solvent, the photolysis of methyl benzoylformate at long irradiation times gives a white crystalline solid (mp 156–158°C), nmr ($CDCl_3$, TMS): 3.85 (s, 3H), 4.9 (s, 1H), 7.15 (s, 5H). This spectrum agrees with that expected for dimethyl-2,3-dihydroxy-2,3-diphenyl succinate.

The product quantum yields were determined for all the compounds in *n*-heptane–chlorobenzene (4:1). This mixture was selected since no precipitate was observed and the absorption developed in the visible – near uv region is weak enough that it can be neglected at short irradiation times. The product

Discussion

The data in Table 1 show that lifetimes measured by direct transient detection or by product quenching with a typical triplet quencher (e.g. 2,5-dimethyl-2,4-hexadiene) show a similar pattern. The differences observed between both sets of results are within the experimental error. This fact, together with the linearity of the Stern–Volmer plots, would indicate that all observed products originate from a single excited triplet. This conclusion is similar to that reached for other aromatic carbonyls (8). Furthermore, the fact that the triplet lifetime is related to the type of hydrogen in the γ-position to the carbonyl group and to the type of products obtained are compatible with a significant contribution of an intramolecular hydrogen abstraction to the triplet lifetime. The photochemistry of compounds **I** to **VIII** can be interpreted then in terms of the following reaction scheme

[1] $K \xrightarrow{h\nu} {}^1K$

[2] ${}^1K \rightarrow K$

[3] ${}^1K \rightarrow {}^3K$

[4] ${}^3K \rightarrow K$

[5] ${}^3K \rightarrow$ products

In this scheme, reaction [4] involves all processes that deactivate the triplet, other than intramolecular hydrogen abstraction. The most important process is likely to involve impurity quenching. This is supported by the triplet lifetime dependence on solvent for **VII** (see Table 1), and the Arrhenius parameters obtained for its triplet lifetime in *n*-heptane – chlorobenzene (see Fig. 3 and Table 3).

The product distribution, the dependence of the lifetime upon the type of γ-hydrogen and the lack of photoproducts in the

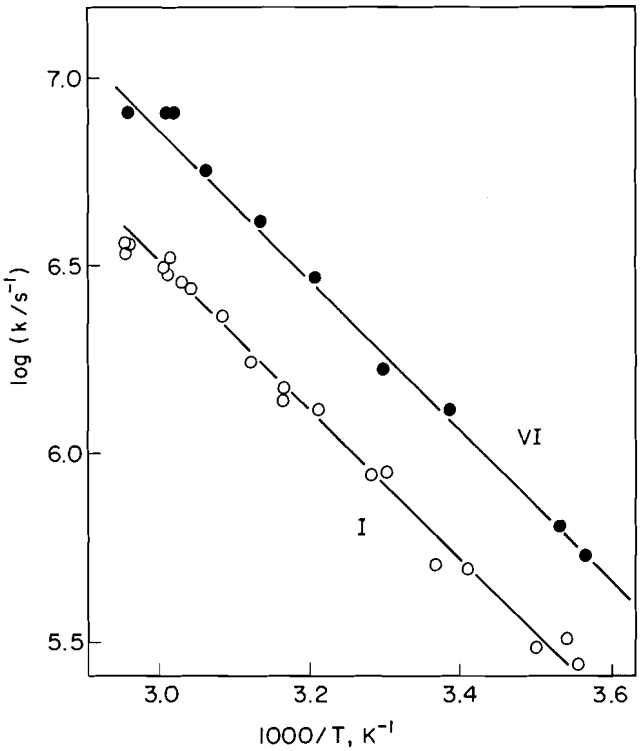

FIG. 6. Arrhenius plot for the intramolecular hydrogen abstraction for **I** (○) and **VI** (●).

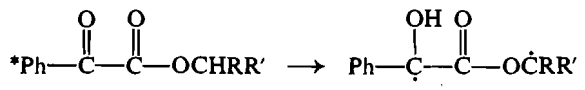
irradiation of **VII** imply that Type I cleavage and intramolecular β-hydrogen abstraction are negligible. From the known behaviour of other $n\pi^*$ carbonyl compounds (9), the most likely pathway of reaction [5] is the Norrish Type II process, i.e.



followed by reactions of the 1,4-biradicals.

The values of k_5 and their Arrhenius parameters can be obtained by subtracting from the high temperature lifetimes the values obtained by extrapolation of the low temperature data using the method described in an earlier report (10). The values of k_5 so obtained, plotted according to the Arrhenius equation, are shown in Fig. 6 for **I** and **VI**. The Arrhenius parameters obtained are collected in Table 3. This table also includes values of $(k_5\tau_T)$ estimated at 298 K. These values measure, according to the above reaction scheme, the 1,4-biradical quantum yield.

The *A*-factors obtained for the intramolecular hydrogen abstraction are, for three compounds considered, $\sim 5 \times 10^{12}$ s^{-1}. These values are nearly an order of magnitude higher than those reported for other Type II photoprocesses involving γ-hydrogen abstraction (10–12) and explained in terms of an adiabatic reaction. Nevertheless, this difference could be partly related to the restricted character of the internal rotation along the carbon bond between both carbonyl groups.

The activation energies given in Table 3 are higher than those measured for monocarbonyl ketones (10–12). This fact can be related to the lower triplet energy of the α-keto esters which implies a smaller exothermicity for the hydrogen abstraction process. In fact, for the carbonyl compounds in-

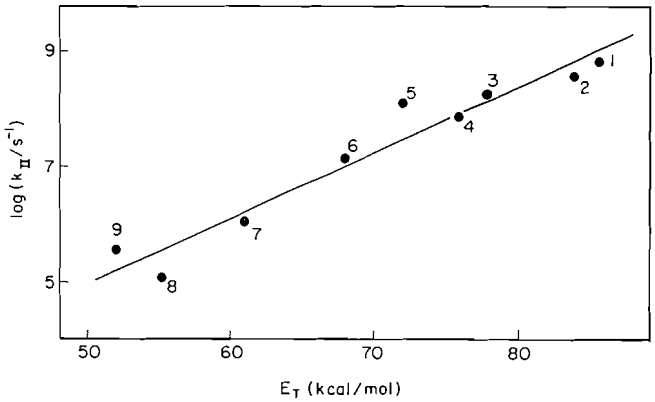


FIG. 7. Relationship between intramolecular secondary γ-hydrogen abstraction and excitation energy of the carbonyl group: (*1*) 2-heptanone singlet (ref. 21); (*2*) *n*-pentanal singlet (ref. 22); (*3*) 2-heptanone triplet (ref. 12); (*4*) *n*-pentanal triplet (ref. 22); (*5*) valerophenone triplet (ref. 20); (*6*) ethylpyruvate triplet (ref. 15); (*7*) *n*-butyl benzoylformate triplet (this work); (*8*) 2,3-heptanedione triplet (ref. 13); (*9*) 1-phenyl-1,2-pentanedione triplet (ref. 14).

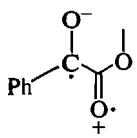
vestigated to date there is a fair correlation between excited state energy and intramolecular hydrogen abstraction rate (Fig. 7).

The values of k_5 given in Table 3 show that the relative values of primary, secondary, and tertiary sites are 1:3.2:7.5, respectively, per reactive hydrogen. This small selectivity (manifested also in the similarity of the activation energies) contrasts with those observed in Type II processes of other carbonyl (10, 12) and α-dicarbonyl (13, 14) compounds, and appears to be a peculiarity of α-keto esters (2, 15). This indicates that in these systems there is no direct relationship between reactivity and selectivity. Wagner *et al.* (14) have suggested that a zwitterionic structure like



could contribute significantly to the electronic configuration in the excited triplet. In this case, the reactive oxygen should be highly nucleophilic. Substitution at the γ-carbon, while decreasing the strength of the C—H bond, will increase the charge density. The effect of substitution upon the rate of hydrogen abstraction could then be less than that expected from the C—H bond weakening. Another factor to be taken into account is the rather peculiar effect of oxygen atoms bound to the γ-carbon in the photolysis of aromatic ketones (16). Wagner and Kemppainen found that in the photolysis of ketones of general formula Ph—CO—CH_2—CH_2—CHR_1R_2, when $R_1 = CH_3$, the ketone with $R_2 = CH_3$ reacts four times faster than that with R_2 = H. However, when $R_1 = OCH_3$, the ketone with $R_2 = CH_3$ reacts 1.3 times slower than that with R_2 = H.

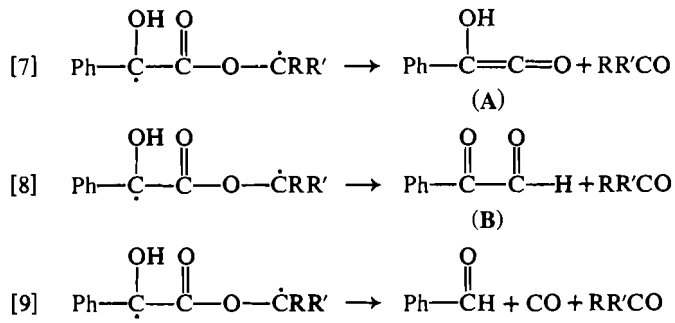
The product distribution depends strongly both upon the solvent and conversion. Nevertheless, the yields obtained at very low conversion in "inert" solvents (e.g. benzene, chlorobenzene, butyronitrile, *n*-heptane) are very similar to those given in Table 3.

Comparison of $\Phi_{carbonyl}$ (Table 2) with Φ_5 (Table 3) shows that for compounds **IV** and **VI**, both values are similar. This

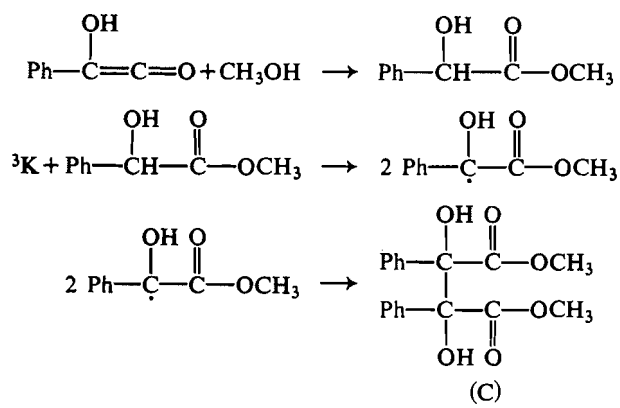
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

indicates that the biradical cleaves almost quantitatively to produce carbonyl compound even in non-polar solvents. This behaviour contrasts with that observed in other 1,4-biradicals (9). Further, these results support the simplified reaction Scheme assumed, that disregards singlet photoprocesses other than intersystem crossing.

The data in Table 2 show that, for all compounds, the yield of aliphatic carbonyls extrapolated to zero time is larger than the benzaldehyde yield. This result can be explained in terms of the following competing 1,4-biradical reactions:



While the three processes give RR'CO, only reaction [9] gives benzaldehyde. The formation of **B** and **A** could explain the yellow colour developed during the photolysis in non-polar solvents. Nevertheless, the characteristics of the developed spectra are different from those shown by a solution of phenylglioxal in the same media. The lack of phenylglioxal formation (or accumulation) is also in agreement with previous results (1). On the other hand, the production of an hydroxy ketene as intermediate has been proposed both in the photolysis of alkyl benzoylformates (5), alkyl pyruvates, and oxoamides (17). The results obtained in the present work would support this suggestion. In particular, the response of the yellow absorption to the sample treatment and the ir spectra observed in carbon-tetrachloride would point to the formation of the ketene. The lack of yellow absorption in protic solvents and the product obtained in methanol can be also explained in terms of the fast solvolysis of the ketene. In methanol, the sequence could explain the production of **C**, although **C** may also result from photoreduction by the solvent followed by self-reaction of the ketyl radicals.



Experimental

Benzoylformic (phenylglyoxylic) acid (Fluka) was employed without further purification. The acid chloride was prepared as previously described (18). All benzoyl formic esters were prepared by reaction of the chloride of the benzoylformic acid with the aliphatic alcohol in basic media. A representative procedure is described below for **VI**.

Isopropyl benzoylformate (VI)

A solution of isopropanol (1.47 g) and pyridine (2.42 g) in 90 mL of dry benzene, cooled to 0°C, was added dropwise over 20 min to benzoylformic chloride (4.4 g) dissolved in 40 mL of dry benzene. The final mixture was stirred for 30 min. The white solid formed was filtered and to the filtrate were added 100 mL of ethyl ether. The organic phase was washed with 10% sodium bicarbonate, distilled water, and dried over Na_2SO_4. After solvent evaporation, the residue was distilled under reduced pressure yielding 4.6 g (92% yield) of the final product, bp 94–95°C, (1 Torr); nmr (CCl_4, TMS): 1.37 (d, 6H); 5.28 (m, 1H); 7.57 (m, 3H), 7.95 (m, 2H) ppm.

Methyl benzoylformate

Yield 94%, bp 75–76°C (1 Torr); nmr (CCl_4, TMS): 3.90 (s, 3H); 7.54 (m, 3H); 7.95 (m, 2H) ppm.

Ethyl benzoylformate

Yield 88%, bp 83–84°C (1 Torr); nmr (CCl_4, TMS): 1.40 (t, 3H); 4.43 (q, 2H), 7.54 (m, 3H); 7.98 (m, 2H) ppm.

n-*Propyl benzoylformate*

Yield 92%, bp 84–85°C (0.8 Torr); nmr (CCl_4, TMS): 0.97 (t, 3H); 1.73 (m, 2H); 4.33 (t, 2H); 7.54 (m, 3H); 7.95 (m, 2H) ppm.

n-*Butyl benzoylformate*

Yield 90%, bp 103–104°C (0.9 Torr); nmr (CCl_4, TMS): 0.94 (t, 3H); 1.55 (m, 4H); 4.37 (t, 2H); 7.54 (m, 3H); 7.95 (m, 2H) ppm.

Isobutyl benzoylformate

Yield 91%, bp 91–92°C (0.7 Torr); nmr (CCl_4, TMS): 0.95 (d, 6H); 1.80 (m, 1H); 4.12 (d, 2H); 7.54 (m, 3H); 7.95 (m, 2H) ppm.

t-*Butyl benzoylformate*

Yield 69%, bp 90–91°C (0.9 Torr); nmr (CCl_4, TMS): 1.62 (s, 9H); 7.54 (m, 3H), 7.95 (m, 2H) ppm.

Isoamyl benzoylformate

Yield 90%, bp 107–109°C (0.8 Torr); nmr (CCl_4, TMS): 0.95 (d, 6H); 1.67 (m, 3H); 4.37 (t, 2H); 7.54 (m, 3H); 7.97 (m, 2H) ppm.

Triplet spectra and triplet lifetimes were determined in nitrogen purged samples using for excitation the pulses from a Molectron UV-24 nitrogen laser (337.1 nm, ~8 ns, up to 10 mJ). The detection system makes use of a RCA-4840 photomultiplier tube whose signals were processed through an R-7912 Tektronix transient digitizer and analyzed using a PDP 11/23 computer. Further details can be found elsewhere (19).

Steady state photolyses at 20°C were carried out on deaerated samples. The light source was a medium pressure mercury lamp with a 366 nm glass filter. The reaction products were analyzed by gas chromatography using flame ionization detectors. The photofragmentation of valerophenone in *n*-hexane ($\phi_{acetophenone} = 0.33$ (20)) was used as an actinometer.

COMMUNICATION

Olefin hydrogenation catalysed by chrysotile asbestos fibres and supported titanocene

DANIEL COZAK[1] AND CHRISTIAN DEBLOIS
Chemistry Department, Laval University, Quebec, P.Q., Canada G1K 7P4

Received September 22, 1983

DANIEL COZAK and CHRISTIAN DEBLOIS. Can. J. Chem. **62**, 392 (1984).

The double bond hydrogenation at NTP catalysed by both natural short fibre chrysotile asbestos and $(\eta^5\text{-}C_5H_5)_2TiCl$ treated fibres is reported for some linear and cyclic olefins.

DANIEL COZAK et CHRISTIAN DEBLOIS. Can. J. Chem. **62**, 392 (1984).

Nous avons étudié les propriétés hydrogénantes à TPN de la fibre d'amiante chrysotile et de la fibre traitée au $(\eta^5\text{-}C_5H_5)_2TiCl$. Nous rapportons ici les propriétés catalytiques des fibres naturelles et traitées, pour l'hydrogénation de quelques oléfines linéaires et cycliques.

Chrysotile is a naturally occurring magnesia–silicate mineral best described by the ideal formula $[3MgO \cdot 2SiO_2 \cdot 2H_2O] \cdot nH_2O$, where n is the number of loose water molecules. Furthermore, the natural fibre contains varying amounts (total < ca. 4 wt.%) of transition metals such as iron, manganese, chromium, and nickel. Moreover, chrysotile has a unique and highly organized structure made up typically of 16–18 rolled up coaxial brucite–silicate bilayers. This gives chrysotile fibres an hollow-tube-like morphology (1). Also, several bis(cyclopentadienyl)titanium complexes are known to be catalytically active for both the homogeneous phase (2) and for the mineral oxide supported heterogeneous phase hydrogenation of olefins (3–5). Bearing this in mind, we have prepared a titanocene, $(\eta^5\text{-}C_5H_5)_2TiCl$, treated fibre and studied its hydrogenating properties. We have, in the course of this work, observed a remarkably high activity and selectivity, reported here, for the untreated natural chrysotile asbestos comparable to the treated chrysotile catalyst. Hence we wish to report in this communication the hydrogenation curves and initial hydrogenation rates observed in the alkene-to-alkane conversion reaction of some olefins using both the untreated chrysotile and chrysotile–titanocene treated fibres as catalyst.

The chrysotile asbestos used in our study was of the short fibre variety, obtained by sedimentation and flocculation of commercial 4T30 chrysotile asbestos (6). The scanning electron microscope (SEM) revealed that the fibres were mainly 1–10 μm in length, 200–400 Å in diameter and monofibrils.

The titanocene treated chrysotile was obtained by reacting $(\eta^5\text{-}C_5H_5)_2TiCl$ with short fibres in refluxing toluene under a positive argon pressure for 12 h. The air-sensitive green solid product was then rinsed and thoroughly washed in a soxhlet extractor with benzene for 24 h. Also, we observed that it is possible to introduce up to 3.2 wt.% titanium on the fibre, depending on the initial complex concentration and reaction times, without destroying its morphology. The following equation is proposed for the reaction, based on both spectroscopic data and the reactivity of titanium chlorides with chrysotile (6, 7),

$$\text{chrysotile} + (\eta^5\text{-}C_5H_5)_2TiCl \xrightarrow{\text{toluene}} \text{chrysotile-Ti}(\eta^5\text{-}C_5H_5)_2 + HCl$$

Hydrogenation of the olefins was carried out in the following manner for all the experiments. The fibres (ca. 1.0 g) were placed in a glass reactor containing toluene (10 mL, temperature controlled 27 ± 0.1°C) and equipped with a mercury gas burette to monitor the hydrogen uptake. The fibres were then reduced with *n*-butyllithium (1.80 mmol) and the argon atmosphere replaced by pure hydrogen at atmospheric pressure (755 Torr). Gas uptake was measured immediately after adding the olefin from a dropping funnel to the stirred fibre suspension.

When natural chrysotile asbestos short fibres were used as catalyst in the reactor, hydrogen consumption was observed for cyclohexene, cyclooctene, 1-hexene, 1-heptene, 1-octene, 1-decene, and 1,4-hexadiene, with concomitant conversion of the olefin to the corresponding saturated alkane. The hydrogenation products and conversion yields were measured by gc (12 foot Carbowax column, 70°C) and by gc – mass spectroscopy. Table 1 summarizes the reaction conditions used and hydrogenation data for the studied olefins. All reactions were carried out at normal temperature and pressure (27°C, 755 Torr) and the alkene–alkane conversion yields were all quantitative when the gas consumption ceased.

Figure 1 shows the hydrogen uptake curves as a function of time for some monoolefins studied, measured during hydrogenation using chrysotile asbestos fibres. The curves show that the initial hydrogen uptake varies almost linearly. Hence, the slope or the hydrogenation rate is estimated to be constant for this portion of the reaction. The initial hydrogen uptake rates given in Table 1 were calculated from such curves. We have also noticed that this rate is of zero order in olefin concentration. Another feature observed in the hydrogenation reactions is the bending of the curve, leading to a plateau towards the end of the reaction, when most of the olefin is consumed. The hydrogenation curve for 1-hexene (curve *3*) illustrates well this phenomenon. Hence, for this curve the initial hydrogen consumption is 0.58 mL H_2 min^{-1} g^{-1} of chrysotile till approximately 75% of the heptene is converted to heptane. After this concentration there is a sharp bend in the curve and the slope slowly tapers off till the remaining olefin is hydrogenated. Another visible feature in several reactions is a sharp absorption step from 0 to 6 mL (0.27 mmol) when the olefin is added to the fibre suspension. For example, this is visible in curves *2* and *4* and is not believed to be directly related to the catalytic hydrogenation absorption by the olefins.

In one experiment, the catalytic behavior of the chrysotile fibres was checked by performing two successive hydro-

	1.27		1.02	0.24
1-Decene (*5*)	1.06	1.03		0.67[e]
	1.06		1.01	0.13
1,4-Hexadiene	0.85	1.01		0.85
	0.85		1.09	0.068 (±0.006)

[a]The hydrogenation cell was temperature-controlled to within ±0.1°C and pressure variations did not exceed ±5 Torr during the reaction. The values reported in this table have been corrected for atmospheric variations between readings on the gas burette.
[b]Asbestos chrysotile short fibres treated with $(\eta^5\text{-}C_5H_5)_2TiCl$. The fibres used here are all from the same reaction (50 g batch) and contained 0.99 wt.% Ti.
[c]Unless otherwise indicated, error = ±0.03.
[d]The numbering corresponds to the curves given in Fig. 1.
[e]A second addition of 1.27 mmol olefine to the same reaction mixture gave the same initial hydrogen uptake rate, see text.

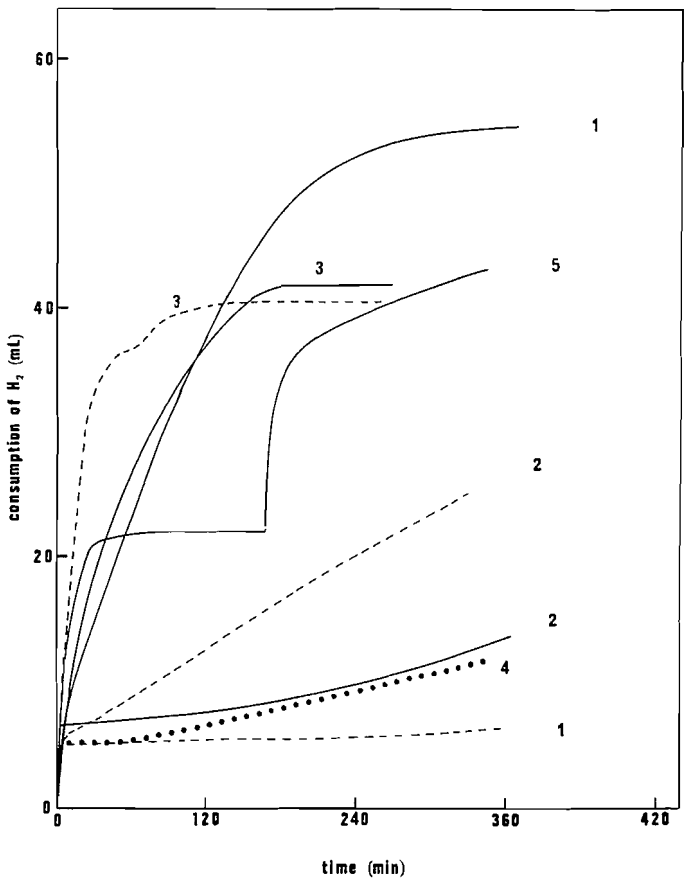

FIG. 1. Hydrogen consumption versus time curves for the hydrogenation of some monoolefins by chrysotile asbestos short fibres (—), chrysotile–titanocene short fibres (---), and commercial 4T30 Quebec chrysotile asbestos (···). The numbering corresponds to the alkenes in Table 1.

genation reactions using the same fibre. Curve *5* shows the hydrogen uptake for this experiment. The first part of the curve, segment A–B, corresponds to the gas uptake for the first 1.06 mmol 1-decene added to the reaction. Segment B–C shows the gas uptake after the second addition, 1.27 mmol 1-decene, to the same reaction mixture. These two segments are almost identical and the initial olefin reaction rates for both additions are the same (cf. Table 1).

In another experiment the hydrogenation of 1-heptene was carried out using commercial 4T30 chrysotile asbestos as received, curve *4* in Fig. 1. The hydrogenation rate of the commercial asbestos, 0.021 (±0.005) mL H_2 min^{-1} g^{-1} of chrysotile, is an order of magnitude slower than the rate for selected short fibres. We believe that this is due to the presence of amorphous mineral impurities usually associated with natural asbestos (8). Also chrysotile fibres containing non-bonded water were found to be less active for the hydrogenation of olefins.

Catalytic hydrogenation of the studied olefins was also observed for $(\eta^5\text{-}C_5H_5)_2TiCl$-treated fibres. The hydrogenation reaction conditions were identical to those used for the untreated chrysotile discussed above, and the experimental hydrogenation rates are given in Table 1. Figure 1 also shows the hydrogen consumption curves of some monoolefins for the chrysotile–titanocene catalyst. The fibres used in these experiments contained 0.99 wt.% titanium. The outstanding difference in the hydrogenation properties of untreated and titanocene treated fibres is the observed high selectivity of the latter for linear olefins over cyclohexene, as evidenced by the null hydrogenation rate observed for this olefin (cf. Table 1 and Fig. 1). Moreover, several hydrogenation experiments were carried out with different titanocene treated fibres[2] using equi-

[2]Both $(\eta^5\text{-}C_5H_5)_2TiCl$ and $(\eta^5\text{-}C_5H_5)_2TiCl_2$ reacted short fibre chrysotile containing up to 3.2 wt.% Ti were used in these experiments.

For personal use only.

molar mixtures of 1-octene and cyclohexene. The only hydrogenation product detected in these experiments was octane. Furthermore, in all cases the cyclohexene was totally recovered, even after 3 days of reaction. This is, to the best of our knowledge, the first time such a selectivity for a titanocene catalyst is reported.

In order to verify if the observed hydrogenation was due to a homogeneous catalytic reaction arising from dissolved titanocenes, a new olefin addition was made to the decanted filtrate taken from a previous hydrogenation run. Under these conditions no hydrogen consumption was observed when 1-octene was added to the filtrate. Moreover, the amount of titanium measured in the filtrate of several runs never exceeded 8 ppm and is believed to be due mainly to small suspended fibres in the filtrate.

The fibrous structure and chemical composition of the catalysts were checked both before and after hydrogenation by elemental microanalysis,[3] SEM micrography, ir, and SEM-ED X-ray[4] spectroscopy. These results indicate that initial composition of the fibres is not significantly affected by the hydrogenation process and the fibre morphology is preserved. From microanalysis, high carbon and hydrogen values were found for both the titanocene-treated fibres and the fibres recovered after hydrogenation. Furthermore, SEM micrographs (20 000×) of the brown–black solid after catalysis show that the fibres retained their fibrous morphology. Also the SEM-ED X-ray spectra of the fibres after catalysis remained unchanged as evidenced from the Si/Mg and Ti/Mg intensity ratios. Similarly, the ir spectra (KBr pellet) of reacted fibres in all cases showed the characteristic brucite vibrations at 3685 and 3640 cm^{-1} and silicate vibrations at 1075, 1015, and 950 cm^{-1}. However, the intensity of the water bands at ca. 3400 and 1625 cm^{-1} increased in the spectra of the titanium-treated fibres and after hydrogenation reactions. Moreover, two new bands of weak intensity at 1260 and 795 cm^{-1} and slight changes for the silicate intensities at 1015 and 950 cm^{-1} are indicative of some chemical or structural modification in the fibres (9).

We are presently investigating the chemical origin of the observed catalytic property of natural chrysotile asbestos. The reaction rates measured so far seem to indicate that the active species in the natural chrysotile asbestos and the chemically modified chrysotile–titanocene fibres are not the same.

[3]Elemental microanalyses. *Anal.* calcd. for $Mg_3Si_2O_9H_4$: Si 20.27, Mg 26.31, H 1.44; found for the untreated chrysotile before catalysis (after catalysis): Si 18.89 (19.31), Mg 24.71 (24.59), Ti <0.05, C 0.25 (2.09), H 1.67 (1.38); found for the titanocene treated chrysotile before catalysis (after catalysis): Si 18.44 (19.18), Mg 24.80 (23.65), Ti 0.99 (0.93), C 1.67 (2.14), H 1.68 (1.29) %.

[4]The intensities were calculated by averaging the X-ray counts (300 s) from three spectra of the same sample. Found for chrysotile before catalysis (after catalysis): Si/Mg = 1.2 (1.2); found for the titanocene treated chrysotile before catalysis (after catalysis): Si/Mg = 1.2 (1.3) ± 0.1 and Ti/Mg = 0.03 (0.02) ± 0.002. Literature value Si/Mg = 1.3, from ref. 10.

Stability and solubility relationships between some solids in the system $PbO-CO_2-H_2O$[1]

PETER TAYLOR AND VINCENT J. LOPATA

Research Chemistry Branch, Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Man., Canada R0E 1L0

Received May 9, 1983

PETER TAYLOR and VINCENT J. LOPATA. Can. J. Chem. **62**, 395 (1984).

We have determined equilibrium conditions for each reaction in the solid interconversion sequence $PbO \rightleftharpoons Pb_{10}O(OH)_6(CO_3)_6$ (plumbonacrite) $\rightleftharpoons Pb_3(OH)_2(CO_3)_2$ (hydrocerussite) $\rightleftharpoons PbCO_3$ (cerussite), in aqueous carbonate solutions near 25°C. Our data yield the following Gibbs energies of formation from the elements, $\Delta_f G°$(298.15 K): plumbonacrite, -5310 ± 31 kJ mol^{-1}; hydrocerussite, -1705 ± 11 kJ mol^{-1}; cerussite, -628.0 ± 3.9 kJ mol^{-1}. Corresponding estimated values of $\Delta_f G°$(373 K) are -5120 ± 50, -1643 ± 18, and -612 ± 9 kJ mol^{-1}, respectively. We have demonstrated the existence of a narrow stability field for plumbonacrite, and convenient small-scale preparations of hydrocerussite and plumbonacrite are described. Gibbs energy data for the solids have been combined with selected data for aqueous lead species in a detailed computation of solubility behaviour for this system at 25°C.

PETER TAYLOR et VINCENT J. LOPATA. Can. J. Chem. **62**, 395 (1984).

Nous avons déterminé les conditions d'équilibre de chaque réaction dans les interconversions suivantes à l'état solide: $PbO \rightleftharpoons Pb_{10}O(OH)_6(CO_3)_6$ (plumbonacrite) $\rightleftharpoons Pb_3(OH)_2(CO_3)_2$ (hydrocérussite) $\rightleftharpoons PbCO_3$ (cérussite), dans des solutions aqueuses de carbonate à environ 25°C. Nos données fournissent les énergies de Gibbs suivantes pour la formation à partir des éléments $\Delta_f G°$(298,15 K): plumbonacrite, -5310 ± 31 kJ mol^{-1}; hydrocérussite -1705 ± 11 kJ mol^{-1}; cérussite $-628,0 \pm 3,9$ kJ mol^{-1}. Les $\Delta_f G°$(373 K) sont respectivement évalués comme étant suivantes; -5120 ± 50, -1643 ± 18 et -612 ± 9 kJ mol^{-1}. Nous avons démontré l'existence d'un champ étroit de stabilité pour le plumbonacrite et nous décrivons une préparation convenable à faible échelle de l'hydrocérussite et du plumbonacrite. On a combiné les données d'énergie de Gibbs des solides avec des données choisies pour des composés du plomb en solution aqueuse dans un calcul détaillé du comportement de ce système en ce qui a trait à la solubilité à 25°C.

[Traduit par le journal]

Introduction

Many solids exist in the system $PbO-CO_2-H_2O$. Of these, two polymorphs of PbO (litharge and massicot) and three carbonates (cerussite, $PbCO_3$; hydrocerussite, $Pb_3(OH)_2(CO_3)_2$; plumbonacrite, $Pb_{10}O(OH)_6(CO_3)_6$) occur in aqueous systems near ambient temperature and pressure (1, 2). Garrels and Christ (3) have discussed the stability fields of PbO, cerussite, and hydrocerussite in the system $Pb-O_2-CO_2-H_2O$ at 25°C. Recently, plumbonacrite was reported (4) to be metastable with respect to decomposition according to reaction [1]:

[1] $$Pb_{10}O(OH)_6(CO_3)_6 \rightarrow PbO + 3Pb_3(OH)_2(CO_3)_2$$

Several phases of the type $aPbCO_3 \cdot bPbO$ occur during thermal decomposition of the named carbonates, but do not normally occur in aqueous systems (5–7). Grisafe and White (7) determined the stability fields of these phases in the system $PbO-CO_2$ at elevated temperatures and pressures. A hydrated lead(II) oxide, $3PbO \cdot H_2O$ or $Pb_6O_4(OH)_4$, is also known (8–11), and early solubility measurements indicate that it may be marginally stable with respect to reaction [2] at ambient temperature (11):

[2] $$6PbO(s) + 2H_2O(l) \rightarrow Pb_6O_4(OH)_4(s)$$

Our interest arose from the possible use of lead compounds to precipitate $^{14}CO_3$ species, which are radioactive contaminants produced in the heavy-water moderator systems of Canadian nuclear reactors (12). The formation of lead carbonates may also be important in high-level radioactive waste disposal, since lead has been proposed as an investment material for used nuclear fuel in a deep underground disposal vault (13). Lead carbonates are also of some importance in the environmental and mineralogical behaviour of lead (14–18). We have studied interconversions among the five named solids to determine equilibrium constants and hence to compute solubility and stability relationships.

Experimental

Starting materials were reagent-grade PbO, KOH, K_2CO_3 (Fisher), and CO_2 (Matheson). Carbonate-free KOH solutions (J. T. Baker) were used in key determinations. Potassium salts were used in preference to sodium salts to avoid precipitation of $NaOH \cdot 2PbCO_3$, which is less soluble than $KOH \cdot 2PbCO_3$ (19). The PbO reagent was a mixture of litharge and massicot; this was adequate for most purposes, since their Gibbs energies of formation differ by only about 1 kJ mol^{-1} (20, 21). Samples of litharge and massicot were collected whenever they were obtained as pure reaction products. Recrystallized litharge, prepared in an earlier study (22), was also used in a few experiments.

(a) Preparation of cerussite

Pure cerussite was readily made by bubbling CO_2 through a suspension of PbO (20 g) in dilute acetic acid (10^{-3} mol dm^{-3}, 200 cm^3) at room temperature for 6 h. Unlike Olby (2), we did not obtain plumbonacrite or hydrocerussite as pure intermediates, although they did occur sequentially as major phases. Our preparation was on a smaller scale than Olby's, with a more dilute suspension of PbO.

(b) Preparation of hydrocerussite

Pure hydrocerussite was prepared by shaking a suspension of cerussite (5 g) in a solution of K_2CO_3 (8 g in 200 cm^3) for 48 h at room temperature. Alternatively, cerussite (5 g) was added to aqueous KOH (10^{-3} mol dm^{-3}, 200 cm^3), and the pH of the stirred suspension was maintained at 11 for 24 h, using an automatic titrator charged with KOH solution (0.1 mol dm^{-3}).

(c) Preparation of plumbonacrite

Hydrocerussite (5 g) was suspended in a solution (200 cm^3) of K_2CO_3 (13 g) and KOH (2 g), which was then stirred for 48 h at 100°C. The filtered product comprised plumbonacrite (>80%) and

hydrocerussite. This was crushed using a pestle and mortar, and returned to the solution for a further 24 h at 100°C. Care was needed to maintain the pH near 13, to remain within the narrow stability field of plumbonacrite (see below). This procedure was repeated until hydrocerussite was reduced to <5% (usually two or three cycles); it was difficult to eliminate completely.

(d) Interconversion reactions

Over 200 experiments were run, in which the various solids were exposed to solutions of different pH and total carbonate concentration, $[C_t]$.[2] Most experiments were run in screw-topped plastic bottles; long equilibration runs were performed in flame-sealed Pyrex glass vials. Solid products were identified and their purity estimated by X-ray powder diffractometry (XRD), using CuK_α radiation and a Philips PW-1150 diffractometer equipped with a diffracted-beam monochromator. When necessary, solutions were analyzed for lead by atomic absorption spectrophotometry, and for carbonate by titration or using a CO_2-sensing electrode (Orion model 95-02). Measurements of pH were made with a glass electrode. When precise pH measurements were needed (see Table 1), the electrode was calibrated with a fresh sodium borate buffer solution having pH = 9.00 or 9.18.

Results and discussion

(a) Theoretical considerations

The solid interconversion reactions are conveniently expressed by reactions [3] to [5] below. In reaction [3], distinction should be drawn between reactions involving litharge and massicot.

$$[3] \quad \tfrac{5}{3}PbO(s) + CO_2(g) + \tfrac{1}{2}H_2O(l) \overset{p_1}{\rightleftharpoons} \tfrac{1}{6}Pb_{10}O(OH)_6(CO_3)_6(s)$$

$$[4] \quad \tfrac{3}{2}Pb_{10}O(OH)_6(CO_3)_6(s) + CO_2(g) + \tfrac{1}{2}H_2O(l) \overset{p_2}{\rightleftharpoons} 5Pb_3(OH)_2(CO_3)_2(s)$$

$$[5] \quad Pb_3(OH)_2(CO_3)_2(s) + CO_2(g) \overset{p_3}{\rightleftharpoons} 3PbCO_3(s) + H_2O(l)$$

Although these reactions involve many aqueous species, the equilibrium constant for each reaction can be expressed simply as the reciprocal of a carbon dioxide partial pressure,[3] $p(CO_2)$ (3, 23). The anionic activity quotient, $\{OH^-\}^2/\{CO_3^{2-}\}$, obtained from equilibria such as [6], is sometimes more convenient.

$$[6] \quad Pb_3(OH)_2(CO_3)_2(s) + CO_3^{2-}(aq) \rightleftharpoons 3PbCO_3(s) + 2OH^-(aq)$$

The $p(CO_2)$ value associated with a solution is conveniently manipulated between 10^{-6} and 10^2 Pa by adjusting pH and $[C_t]$. Total carbonate activity $\{C_t\}$, proton activity $\{H^+\}$, and $p(CO_2)$ are interrelated at 25°C by expression [7], which is derived from equations given by Stumm and Morgan (ref. 23, chapt. 4) and accepted Gibbs energy data for water and carbonate species (e.g. 21, 24):

$$[7] \quad \frac{\{C_t\}}{p(CO_2)} = \left[1 + \frac{4.34 \times 10^{-7}}{\{H^+\}} + \frac{2.04 \times 10^{-17}}{\{H^+\}^2}\right] \times 3.4 \times 10^{-7} \text{ mol } kg^{-1} \text{ Pa}^{-1} (\approx \text{mol } dm^{-3} \text{ Pa}^{-1})$$

We have not distinguished between molal and molar concentration units, since the resulting errors are much less than the experimental uncertainties. We have used expression [8] as proposed by Davies (ref. 23, pp. 134–136; ref. 25) to estimate the mean ionic activity coefficient, $f_\pm$, and hence bicarbonate and carbonate activities, from the ionic charge, z, and the ionic strength, I.

$$[8] \quad -\log f_\pm = 0.5z^2\left[\frac{I^{1/2}}{1 + I^{1/2}} - 0.3I\right]$$

Where necessary, I was calculated from measured pH and $[C_t]$ values by an iterative procedure.

(b) Reactions of cerussite with KOH

Reactions between cerussite (0.25 g) and KOH solutions (40 cm^3; various concentrations up to 5 mol dm^{-3}) were investigated at room temperature (22 ± 2°C). Cerussite alone was recovered from reactions with final pH below about 9.5. Hydrocerussite was the major product in the pH range 9.5–12. Plumbonacrite and hydrocerussite occurred together at pH ≈ 12–13.5. Lead(II) oxide was formed at pH ≈ 13.5–14; both litharge and massicot occurred, often one or the other as a pure phase, but with no obvious pattern of occurrence. Above pH ≈ 14, clear undersaturated lead solutions were formed. These observations are consistent with McIntyre's stability calculations reported by Garrels and Christ (3), except for the occurrence of plumbonacrite. Further experiments were designed to define the stability fields more exactly, with special attention to plumbonacrite.

[2] In this account, $[C_t]$ and $\{C_t\}$ represent the sums of the concentrations and activities, respectively, of non-complexed carbonate species, i.e. "H_2CO_3", HCO_3^-, and CO_3^{2-}, and do not include complexes such as $PbCO_3^0$ and $Pb(CO_3)_2^{2-}$.

[3] Strictly speaking, this term should be fugacity, rather than partial pressure, but the two are indistinguishable at the pressures of concern here.

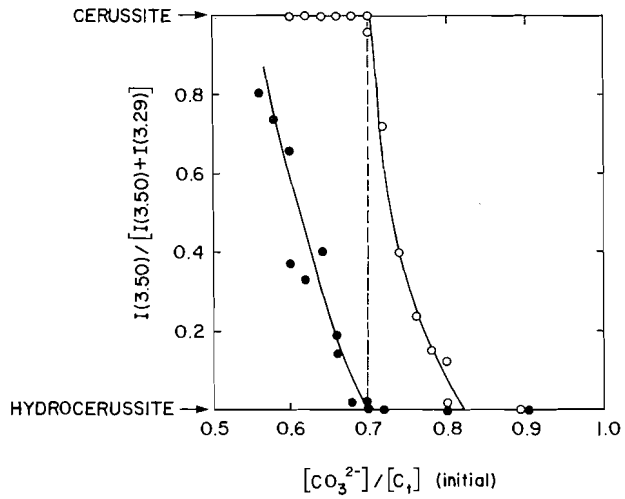

FIG. 1. Summary of X-ray diffraction data for products of reactions between cerussite (○) or hydrocerussite(o) with solutions having $[C_t] = [HCO_3^-] + [CO_3^{2-}] = 0.125$ mol dm^{-3}, for 48 h at 22°C. $I(3.50)$ and $I(3.29)$ are the peak heights of the most intense features in the cerussite and hydrocerussite diffraction patterns (3.50 Å and 3.29 Å, respectively). The ordinate function is thus an approximate measure of the extent of conversion.

(c) Cerussite–hydrocerussite interconversion

Experiments in which either cerussite or hydrocerussite was exposed to carbonate/bicarbonate solutions clearly showed that this interconversion is readily reversible at room temperature. XRD data, summarized in Fig. 1, indicated that hydrocerussite and cerussite were in equilibrium at $[CO_3^{2-}]/[C_t] = 0.70 \pm 0.02$ and $[C_t] = 0.125$ mol dm^{-3}. At lower $[CO_3^{2-}]/[C_t]$ ratios, hydrocerussite was converted to cerussite, and the reverse reaction occurred at higher ratios. Although equilibrium conditions are thus narrowly defined, ionic activities could not be estimated sufficiently well to calculate p_3 as precisely as we wished. Further experiments were therefore run at lower $[C_t]$, down to 10^{-3} mol dm^{-3}. At these lower concentrations, the quantity of hydrocerussite or cerussite consumed or formed in the reactions was too small to determine equilibrium conditions by XRD. We therefore deduced the direction of reaction, and judged whether equilibrium had been achieved, by careful measurement of pH and $[C_t]$.

Twenty-five experiments with $[C_t]$ between 10^{-3} and 10^{-2} mol dm^{-3} yielded values for p_3 between 8 and 16 Pa. In the final determination, duplicated experiments were run in sealed Pyrex glass vials, starting with a mixture of cerussite and hydrocerussite (0.5 g each) in solutions with various $[HCO_3^-]/[C_t]$ ratios and $[C_t] = 3 \times 10^{-3}$ mol dm^{-3}. This concentration provides the best compromise between the respective limitations of the carbonate analyses and the estimation of activity coefficients. One series of experiments ((*a*) in Table 1) was run for 5 days, and the second ((*b*) in Table 1) for 13 days. The pH was measured immediately after opening each vial. The solutions were then filtered and analyzed for carbonate and bicarbonate by titration; a pH value was then calculated from the titration data. Most measured and calculated pH values agreed within 0.04 units, the largest discrepancy being 0.08 units. We conclude that solution analyses were not substantially affected by exchange of CO_2 with the atmosphere. The results are summarized in Table 1. The values of p_3 at 25°C, determined from these runs, range from 12.8 to 14.1 Pa, with an average of 13.3 Pa. No correction was made for the actual experimental temperature of 22 ± 2°C, since the equilibrium quotient, $[CO_3^{2-}]/[C_t]$, changes only slightly between 22 and 100°C (see below).

Our determination of p_3 is in fair agreement with the value of 27 Pa obtained from the Gibbs energy data recommended by Sadiq and Lindsay (21). The discrepancy corresponds to a disagreement of about 1.8 kJ mol^{-1} in the Gibbs energy of reaction for reaction [5]. Our result is also consistent with Garrels' estimate of $p_3 \simeq 10$ Pa, which was based on deductions from the natural occurrence of cerussite and hydrocerussite (17).

(d) Interconversions involving plumbonacrite

Preliminary experiments indicated a narrow stability field for plumbonacrite, so subsequent work concentrated on confirming this observation and defining the boundaries of the field.

Plumbonacrite persisted unchanged for seven days in solutions with $[C_t] = 0.125$ mol dm^{-3} and [KOH] between 0.02 and 0.4 mol dm^{-3}. It was converted to massicot at [KOH] ≥ 0.6 mol dm^{-3}, with partial conversion occurring at 0.5 mol dm^{-3}. In similar experiments starting with PbO, plumbonacrite was formed at [KOH] = 0.1, but not at 0.5 mol dm^{-3}. Slow, partial conversion of plumbonacrite to hydrocerussite occurred at [KOH] ≤ 0.01 mol dm^{-3}, and the reverse reaction was observed in some runs with KOH concentrations between 0.05 and 0.08 mol dm^{-3}. The latter reaction, accelerated by heating to 100°C, provided the basis for our synthesis of plumbonacrite, described above. In triplicated experiments starting with mixtures of plumbonacrite and hydrocerussite at [KOH] = 0.01 and 0.1 mol dm^{-3}, the relative amount of plumbonacrite in the product was consistently higher at the higher KOH concentration. Although these interconversions are less clear-cut than the hydrocerussite–cerussite reaction, we could nevertheless observe reversible reactions in the sequence PbO ⇌ plumbonacrite ⇌ hydrocerussite, thus confirming that plumbonacrite has a narrow stability field. This narrowness can account for the scarcity of plumbonacrite in nature (4).

Further experiments in sealed glass vials were run for 7–14 days with mixtures of PbO and plumbonacrite (0.3 g each) in 20 cm^3 aliquots of solutions with various KOH concentrations at $[K_2CO_3] = 10^{-1}$, 10^{-2}, and 10^{-3} mol dm^{-3}. Most runs did not reach equilibrium, but the direction of reaction [9] (equivalent to reaction [3]) could be determined from solution analyses for carbonate and/or hydroxide.

$$[9] \quad \frac{5}{3}\,PbO + CO_3^{2-} + \frac{3}{2}\,H_2O \rightleftharpoons \frac{1}{6}\,Pb_{10}O(OH)_6(CO_3)_6 + 2OH^-$$

The results are presented in Fig. 2. From these we estimate the equilibrium constant $\{OH^-\}^2/\{CO_3^{2-}\} = 10^{0.1 \pm 0.6}$ mol dm^{-3}, which corresponds to $p_1 = 10^{-4.9 \pm 0.6}$ Pa. We did not discern reproducible differences between reactions involving PbO reagent and our synthetic litharge, except that the latter material reacted more lethargically. Based on the free energies of formation of massicot and litharge, p_1 values for the two forms of PbO should differ by a factor of about 1.5, whereas we estimate an error of a factor of four in p_1.

Interconversion between hydrocerussite and plumbonacrite was too slow at $[C_t] \leq 10^{-2}$ mol dm^{-3} to pin-point the equilibrium at low ionic strength. The close crystallographic similarity between these phases may promote epitaxial crystallization with consequent passivation of one phase by the other. Furthermore, their solubility behaviour is very similar (see Fig. 5), so the driving force for interconversion is slight.

For personal use only.

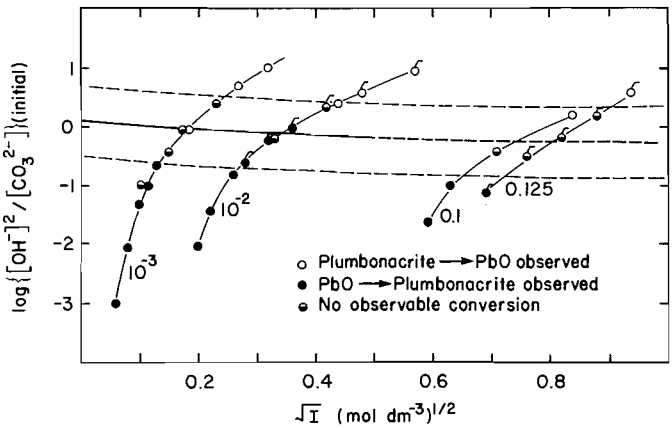

FIG. 2. Summary of conditions under which interconversion of PbO and plumbonacrite was observed. The numbering on the figure indicates carbonate concentration (mol dm^{-3}). The bold lines correspond to log $K = 0.1 \pm 0.6$ for eq. [9], using eq. [8] to estimate deviation from ideality. Flagged data points correspond to determinations by visual observation ($[CO_3^{2-}] = 0.01$ mol dm^{-3}) or X-ray diffraction ($[CO_3^{2-}] = 0.125$ mol dm^{-3}). The remaining observations are based on solution analyses.

Based on the results obtained at $[C_t] = 0.125$ mol dm^{-3} we estimate that p_2 exceeds p_1 by one to three orders of magnitude, so we assign the value $p_2 = 10^{-2.9 \pm 1.6}$ Pa. Since plumbonacrite and hydrocerussite differ only slightly in composition, calculated Gibbs energies and solubilities are much less sensitive to errors in p_2 than in p_1 or p_3, so precise measurement of p_2 is relatively unimportant in the overall description of the system, except in determining the plumbonacrite–hydrocerussite stability boundary (see expressions [12] and [13] below).

(e) Gibbs energies of formation of the carbonates

When expression [10] is applied successively to reactions [3] to [5], using Gibbs energy data from ref. 21, we obtain relationships [11] to [13]. These permit us to calculate the Gibbs energies of formation, $\Delta_f G°(298.15\ K)$, of the three lead carbonates from the $p(CO_2)$ data.[4]

[10] $\Delta_f G°(\text{products}) = \Delta_f G°(\text{reactants}) + RT \ln p(CO_2, \text{equilibrium, atmospheres})$

[11] $\Delta_f G°(\text{plumbonacrite, s, } 298.15\ K) = -(4970.8 - 34.25 \log p_1') = -5310 \pm 31\ \text{kJ mol}^{-1}$

[12] $\Delta_f G°(\text{hydrocerussite, s, } 298.15\ K) = -(1593.8 - 10.28 \log p_1' - 1.14 \log p_2') = -1705 \pm 11\ \text{kJ mol}^{-1}$

[13] $\Delta_f G°(\text{cerussite, s, } 298.15\ K) = -(583.7 - 3.43 \log p_1' - 0.38 \log p_2' - 1.90 \log p_3') = -628.0 \pm 3.9\ \text{kJ mol}^{-1}$

(Estimated errors include our own experimental uncertainties, plus those in Gibbs energies of formation of the parent oxides, as indicated in ref. 24, since the latter uncertainties are not stated in ref. 21. Data from ref. 21 were used for consistency with the solubility computations, shown below.)

[4] The data of ref. 21 refer to a standard state pressure of one atmosphere (1.013×10^5 Pa). In eqs. [11] to [13], p_1', p_2', p_3' are partial pressures in atm.

TABLE 2. Gibbs energy data used to determine equilibrium relationships

Species*	$\Delta G°_{f,298}$ (kJ mol^{-1})	Reference
$PbCO_3$(s)	−628.0	This work
$Pb_3(OH)_2(CO_3)_2$(s)	−1705	This work
$Pb_{10}O(OH)_6(CO_3)_6$(s)	−5310	This work
PbO(s) (litharge)	−189.3	21
CO_2(g)	−394.38	21
H_2O(l)	−237.18	21
"H_2CO_3(aq)"	−623.21	21
HCO_3^-(aq)	−586.89	21
CO_3^{2-}(aq)	−527.94	21
Pb^{2+}(aq)	−24.69	21
$PbOH^+$(aq)	−217.94	21
$Pb(OH)_2^0$(aq)	−397.73	21
$Pb(OH)_3^-$(aq)	−575.89	21

$Pb(CO_3)_2^{2-}$(aq)	−1141.17	44, 45

* Our grounds for omission of the following species are presented in the text: PbO(s) (massicot), $Pb(OH)_2$(s), $Pb_6O_4(OH)_4$(s), $Pb_3(OH)_3^{3+}$(aq), $Pb_3(OH)_5^+$(aq), $Pb_6(OH)_8^{4+}$(aq).

Our experimental Gibbs energy for cerussite, -628.0 ± 3.9 kJ mol^{-1}, lies within the range of reported values cited by Sadiq and Lindsay (21), −625.5 to − 629.0 kJ mol^{-1}, and is not significantly different from their recommended, recalculated value of −629.7 kJ mol^{-1}, originating from the calorimetric work of Adami and Conway (26). Our value of -1705 ± 11 kJ mol^{-1} for hydrocerussite agrees with their calculation of −1711.6 kJ mol^{-1}, derived from the pioneering solubility study by Randall and Spencer, the only source they cite (11, 21). Our estimate of -5310 ± 31 kJ mol^{-1} for plumbonacrite is much more negative than the value of −5121 kJ mol^{-1} reported by Haacke and Williams (4). The source of so large a discrepancy is not readily apparent, since few details are given in ref. 4. We emphasize that our value is consistent with extensive observations of interconversion reactions involving plumbonacrite.

(f) Calculation of solubility–stability relationships

Solubility calculations were performed using the computer program DIST, which was developed at these laboratories by Robert J. Lemire and Nava C. Garisto.[5] This program calculates species distributions, at given pH and ligand activities, from Gibbs energies of formation of the solid and solution species concerned. The results are expressed as activities, in molal units. We have used molar units throughout the discussion, since the resulting errors are negligible at the level of precision of our data. Our selected Gibbs energy data are shown in Table 2.

[5] Strictly speaking, this program calculates the activities of species in saturated solutions. It is reasonable to equate the total lead activity, $\{Pb_t\} = \Sigma x\{Pb_xL_y^{z+}\}$, to solubility at ionic strengths below about 0.01 mol dm^{-3}.

Although hydroxo- and carbonato-lead(II) complexes have received much experimental attention, some uncertainties about them persist. The most recent detailed assessment of thermochemical data for hydroxo-lead(II) complexes appears to be that reported by Sadiq and Lindsay (21), and most of our data are from this source. These data originate mainly from the work of Olin and Carell (27–30), as previously compiled by Baes and Mesmer (31) and by Smith and Martell (32). Sadiq and Lindsay have adjusted the Gibbs energy data tabulated by Smith and Martell for internal consistency with their recalculated values for PbO(s) and Pb^{2+}(aq).

We have omitted two species which were included in Sadiq and Lindsay's compilation: $Pb(OH)_4^{2-}$(aq) and $Pb(OH)_2$(s). The former had been included on the basis of a single report by Aksel'rud (33), cited by Karapet'yants and Karapet'yants (34). We found that its inclusion led to unrealistically high computed lead concentrations at high pH, exceeding 1 mol dm^{-3} above about pH = 13.5. The data selected by Sadiq and Lindsay imply that $Pb(OH)_2$(s) is stable relative to litharge and water by 26.0 kJ mol^{-1} at 25°C. This is based on two earlier thermochemical compilations, but the original source is obscure. However, there is considerable doubt about the very existence of solid $Pb(OH)_2$, many earlier reports being referable to basic lead nitrates (35–37). We noted above that the hydrated lead(II) oxide, $Pb_6O_4(OH)_4$, may be marginally stable with respect to PbO(s) and H_2O(l) (11). However, we have not observed it, except in some electrochemical experiments under conditions of high supersaturation.[6] We omitted massicot, since the consensus is that it is metastable with respect to litharge at 25°C (21, 24).

Two further species, $Pb_3(OH)_5^+$ and $Pb_3(OH)_3^{3+}$, have recently been reported (38–40). When we included $Pb_3(OH)_5^+$ in our data set, it led to unrealistically high computed solubilities for PbO around pH = 9 to 11, with a minimum solubility of about 5×10^{-4} mol dm^{-3}. The computed minimum solubility when $Pb_3(OH)_5^+$ was omitted was about 2.5×10^{-5} mol dm^{-3}, in better agreement with the experimental minimum solubility of litharge, 6.7×10^{-5} mol dm^{-3} (41). The species $Pb_3(OH)_5^+$ may thus be present, but its reported stability constant appears to be too high. We therefore omitted it from our final computations. We also omitted $Pb_3(OH)_3^{3+}$, since its formation constant has only been determined at high ionic strength (3.0 mol dm^{-3} $LiClO_4$) (39, 40). The quality of agreement between Olin's speciation model and experimental data indicates that the inclusion of further species will only have minor effects on computed solubility behaviour (27–30, 38–40). Ohtaki and co-workers (39, 40) present evidence that the species formerly identified as $Pb_6(OH)_8^{4+}$ is in fact $Pb_6O(OH)_6^{4+}$, which has also been observed in the solid state (10, 42, 43). We have incorporated this suggestion by subtracting the Gibbs energy of formation of H_2O(l) from that recommended for $Pb_6(OH)_8^{4+}$ in ref. 21, the two species being related by reaction [14]:

$$[14] \quad Pb_6(OH)_8^{4+} \rightleftharpoons Pb_6O(OH)_6^{4+} + H_2O$$

Several workers have measured formation constants, β, for the two lead carbonate complexes $PbCO_3^0$ and $Pb(CO_3)_2^{2-}$. Clever and Johnston (44) tentatively recommended the respective values $\beta = 2 \times 10^6$ and 6×10^9 at $I = 0.1$ mol dm^{-3}, as reported by Bilinski *et al.* (45). We have used these data, corrected to zero ionic strength using eq. [8]. We note that Bilinski and Schindler (14) recently reported somewhat lower formation constants (log β = 5.40 and 8.86, respectively, at $I = 0.3$ mol dm^{-3}).

It is convenient to discuss the solubility calculations in terms of pC_t and pPb_t, the negative logarithms of $\{C_t\}$ and $\{Pb_t\}$, respectively (cf. pH). We computed species distributions at pH intervals of 0.5 and pC_t intervals of 1.0. A finer grid was used to elucidate details of complex behaviour in some portions of the pH–pC_t matrix. Results are summarized in Figs. 3 to 5. Figure 3 is a composite solubility diagram, showing pPb_t and the stability fields of litharge and the three carbonates as functions of pH and pC_t. Figure 4 shows the computed fields of preponderance of the various aqueous lead species in saturated solutions, superimposed on solubility contours corresponding to Figure 3. Figure 5 shows the computed solubilities of the four solids, including conditions of their metastable occurrence, as a function of pH at $pC_t = 4$. Table 3 lists computed equilibrium pPb_t and pC_t values, as a function of pH, for the three stable solid assemblages (litharge + plumbonacrite; plumbonacrite + hydrocerussite; hydrocerussite + cerussite).

(g) Description of solubility–stability relationships

Figure 3 illustrates the development of the lead carbonate stability fields as total carbonate activity increases. At $pC_t > 9.5$ and $pPb_t > 0$, litharge is the sole stable solid, with a minimum computed solubility of $pPb_t \simeq 4.6$ at pH ≃ 10.3. (See top of Fig. 3; note that a portion of the PbO solubility curve at $pC_t = 10$ is obscured in this view of the solubility surface.) Most of the litharge solubility surface at pH < 9 is probably not accessible in practice without precipitation of basic lead salts. As pC_t decreases (i.e. total carbonate activity increases), solid lead carbonates progressively suppress lead solubility, and their stability fields encroach into that of litharge. Plumbonacrite initially appears at $pC_t \simeq 9.5$, hydrocerussite at $pC_t \simeq 9.0$, and cerussite at $pC_t \simeq 5.5$. The stability field boundaries (dashed lines in Fig. 3) progress to higher pH as pC_t decreases. Encroachment by the stability fields of the complex salts $MOH \cdot 2PbCO_3$ (not shown in Fig. 3) occurs at pH ≃ 10 and $pC_t < 1$ (M = Na) or $pC_t < 0$ (M = K), when Na and K are the counterions in the added carbonate salts.

The preponderance diagram (Fig. 4) shows that polymeric hydroxo-lead complexes are important only at about $pC_t > 8$ and pH < 10 for realistic lead concentrations. At lower pC_t values, polymerization is suppressed by precipitation of the solid carbonates. Lead solubility reaches a minimum, $pPb_t \simeq 6.6$, in slightly alkaline solution near $pC_t = 4$; at still lower pC_t values solubility is enhanced by carbonato-lead(II) complex formation. This behaviour is consistent with the solubility data of Bilinski and co-workers (14, 46). The field of predominance of $Pb(CO_3)_2^{2-}$ (Fig. 4) indicates that the best area for further experimental evaluation of the formation constant of this species would be near $pC_t = 1–2$ and pH = 9–11. The low and relatively constant computed lead solubility within the field of predominance of $PbCO_3^0$ indicates that solubility measurements are unlikely to shed further light on this complex.

There is some interest in whether cerussite or hydrocerussite is the stable form of lead carbonate in natural surface waters (14, 15). Our data indicate that cerussite should be the stable phase at the usual atmospheric $p(CO_2)$ of ≃ 30 Pa, but that only slight depletion of CO_2 would be necessary to enter the hydrocerussite stability field. However, Fig. 5 shows that the solubilities are similar, especially near neutral pH. This similarity also explains the substantial uncertainty in p_1, as determined

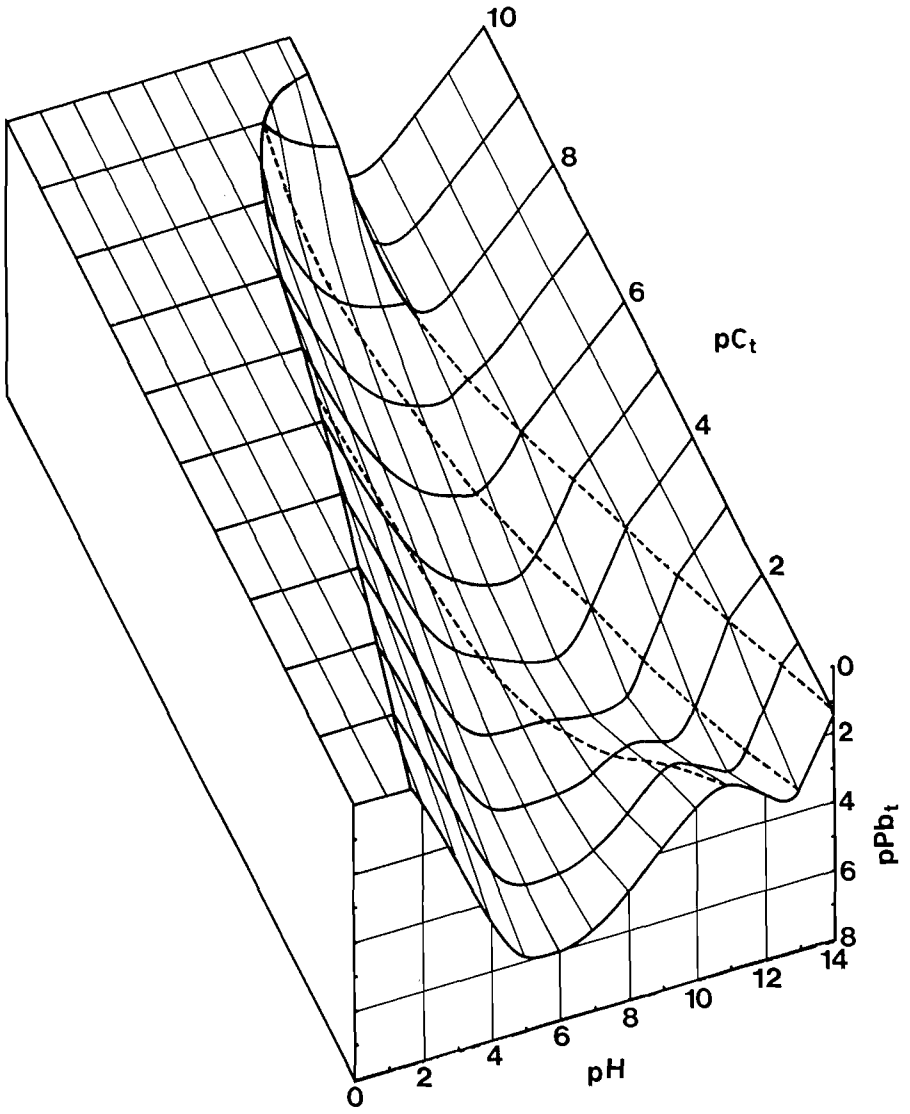

FIG. 3. Computed solid/solution equilibrium surface in the lead carbonate system at 25°C, expressed as negative logarithms of proton, total lead and total carbonate activities (pH, pPb_t, and pC_t, respectively). Dashed lines represent stability boundaries between solid phases in the sequence (left to right) cerussite, hydrocerussite, plumbonacrite, litharge.

from solubility measurements (14), compared with direct observation of phase transformations. Interestingly, the minimum computed lead solubility varies only within the narrow limits, $5.8 < pPb_t < 6.6$, as $p(CO_2)$ varies between 10^{-3} and 10^5 Pa, although the position of the minimum progresses from pH $\simeq$ 10 to 6.5.

Most of our lead solubility measurements were in the range pH > 10 and $pC_t < 3$, and thus lay within the predominance fields of $Pb(CO_3)_2^{2-}$ and $Pb(OH)_3^-$. These measurements were not sufficiently precise to permit any further critique of the computed solubilities, but the general trends paralleled the behaviour described in the appropriate portions of Figs. 3 and 4.

(h) Phase equilibria above 25°C

We briefly investigated the solid phase interconversions at 50, 75, and 100°C, in solutions with $[C_t]$ near 0.1 mol dm^{-3}. We found only a slight temperature dependence for all three equilibria, when expressed as concentrations of carbonate and bicarbonate or hydroxide. However, applying Helgeson's data for the dissociation equilibria of water and carbonic acid at

elevated temperatures (47) to the estimated equilibrium solution concentrations, we obtain substantial increases in all three equilibrium partial pressures, as expected. We estimate the following values at 100°C:

$$p_1 = 10^{-1.1 \pm 1.0}\ \text{Pa}$$

$$p_2 = 10^{+0.9 \pm 2.0}\ \text{Pa}$$

$$p_3 = 10^{+1.9 \pm 1.0}\ \text{Pa}$$

Combining these estimates with high-temperature Gibbs energy data for PbO, CO_2, and H_2O from ref. 23, we obtain the following estimates of Gibbs energies of formation:

$$\Delta_f G°(\text{plumbonacrite, s, 373 K}) = -5120 \pm 50\ \text{kJ mol}^{-1}$$

$$\Delta_f G°(\text{hydrocerussite, s, 373 K}) = -1643 \pm 18\ \text{kJ mol}^{-1}$$

$$\Delta_f G°(\text{cerussite, s, 373 K}) = -612 \pm 9\ \text{kJ mol}^{-1}$$

By analogy with the computed high-temperature Gibbs energy data reported (24) for aragonite, strontianite, and witherite, which are all isostructural with cerussite, and display similar $\Delta_f G°-T$ relationships, we would anticipate $\Delta_f G°$ (cerussite, s, 373 K) $\simeq -608$ kJ mol^{-1}, in reasonable agreement with our experimental estimate. The temperature dependence of p_3 appears to differ substantially from that of p_1 and p_2. Whereas p_3 increases by only about an order of magnitude between 25 and 100°C, p_1 and p_2 both increase by about four orders of magnitude. This is probably because H_2O is a reactant in the forward reaction of equilibria [3] and [4], but a product in reaction [5]. These $p(CO_2)-T$ relationships indicate that the stability field of cerussite encroaches on that of hydrocerussite with increasing temperature. The stability fields of hydrocerussite and plumbonacrite in the presence of H_2O(l) are likely to disappear at about 150 and 200°C, respectively. However, the phase diagram will probably be further complicated in this region by the emergence of stability fields for the anhydrous basic carbonates, $a\text{PbCO}_3 \cdot b\text{PbO}$ (8).

Surface photochemistry: generation of benzyl radical pairs on dry silica gel[1]

BRADLEY FREDERICK, LINDA J. JOHNSTON, PAUL DE MAYO, AND S. KING WONG
Photochemistry Unit, Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received July 6, 1983

BRADLEY FREDERICK, LINDA J. JOHNSTON, PAUL DE MAYO, and S. KING WONG. Can. J. Chem. **62**, 403 (1984).

Singlet and triplet benzyl radical pairs have been generated on silica gel by photolysis of a benzyl phenylacetate, a dibenzyl ketone, and a dibenzyl sulfone. The extent of geminate radical recombination has been measured and requires that translational motion of radicals occur on the silica gel surface. This motion was affected by the radical pair multiplicity and the photolysis temperature, but was relatively insensitive to the state of hydration of the silica gel and the presence of coadsorbates. The presence of certain rearranged starting materials, which are not formed in solution, amongst the products from photolysis of both dibenzyl ketone and dibenzyl sulfone on silica gel indicates the restrictions on radical movement on the surface on the shorter timescale of the benzyl–phenylacetyl and benzyl – benzyl sulfonyl radical pairs.

BRADLEY FREDERICK, LINDA J. JOHNSTON, PAUL DE MAYO et S. KING WONG. Can. J. Chem. **62**, 403 (1984).

On a généré des paires de radicaux benzyles singulet et triplet sur du gel de silice par photolyse d'un acétate de phényle, d'une dibenzylcétone et d'une dibenzylsulfone. On a mesuré la quantité de recombinaison radicalaire geminée et on a observé que cette valeur requière que le mouvement translationnel des radicaux se produise à la surface du gel de silice. Ce mouvement est influencé par la multiplicité de la paire de radicaux et par la température de photolyse; il n'est toutefois pas sensible à l'état d'hydratation du gel de silice et à la présence de substances coadsorbées. Certains produits de départ transposés, qui ne se forment pas en solution, se retrouvent parmi les produits de photolyse de la dibenzylcétone ainsi que de la dibenzylsulfone sur le gel de silice; leur présence indique qu'il existe des restrictions au mouvement des radicaux sur la surface à l'échelle de temps plus courte pour les paires de radicaux benzyle–phénylacétyle et benzyle–benzylsulfonyle.

Although radical pairs have been widely studied in solution (1) their behaviour, when adsorbed on solid surfaces, has not been extensively examined.[2] Modification of the normal solution behaviour is, however, to be expected for such adsorbed radicals. In a solution solvent-cage a spin correlated geminate radical pair, either singlet or triplet, may undergo a number of processes: (*A*) it may recombine to regenerate starting materials; (*B*) it may either recombine in a different manner, or it may disproportionate, to form new products; (*C*) it may be transformed into a new radical pair; or (*D*) it may diffuse apart to form free radicals. The rates of both processes (*A*) and (*B*) depend on the radical pair multiplicity since they can occur only with singlet radical pairs. Because intersystem crossing must precede reaction of a triplet radical pair, spin independent processes (*C*) and (*D*) compete more effectively with geminate recombination for triplet than for singlet pairs. Changing either the rate of intersystem crossing of the radical pair or its rate of diffusional separation will affect the relative contributions of processes (*A*–*D*) to the decay of a particular radical pair. For example, increasing the viscosity of the medium or generating the radical pair in an environment in which its movement is restricted, as, for example, in a micelle (9) or on a solid surface (3, 4, 7), will both affect the diffusional behaviour of the radical pair. Such effects may be readily evaluated by measuring the changes in the amount of geminate radical recombination under various conditions.

Until recently, few studies have examined the possibilities of movement of radicals adsorbed on inorganic solids such as silica gel, alumina, and porous Vycor (2–10). The examination of mobility of adsorbed closed-shell molecules has also been neglected although both the surface–adsorbate interaction and the nature of the surface have been investigated in detail (11).

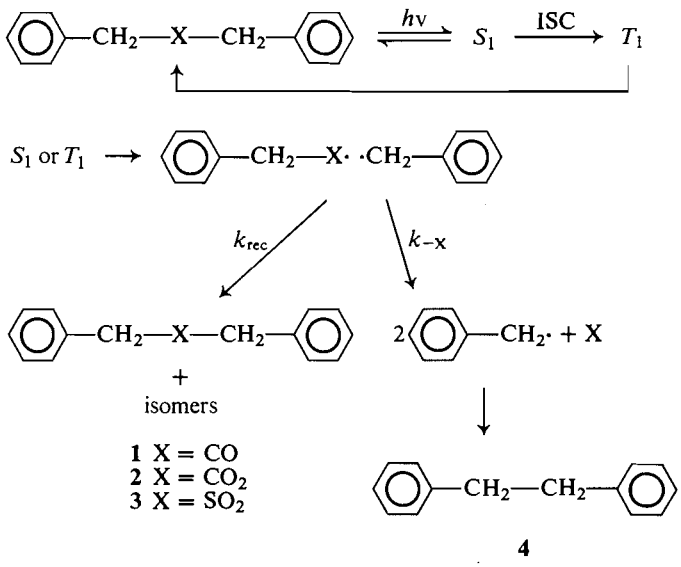
On silica gel surfaces there are two functional groups: the silanols and siloxanes; physisorbed water molecules are also important (11). The presence of ~5 silanols/nm^2 for water-equilibrated surfaces appears to be generally accepted. The recent application of ^{29}Si nmr to the study of silica surfaces (12, 13) will probably resolve the controversy concerning the relative contributions from isolated, vicinal and geminal silanols. London dispersion forces, electrostatic interactions, and hydrogen bonding provide the major adsorption interactions for organic molecules on silica and the type of surface–adsorbate binding, as well as its strength, depends on the adsorbate polarity and the activation treatment of the silica. The surface silanols are thought to be the principal adsorption sites, but siloxanes and hydrogen-bonded water molecules may also be involved.

One of the earlier investigations of adsorbed radical mobility involved the generation of cyanopropyl radical pairs in a silica gel slurry (2). It was claimed therein, from product analysis, that the adsorbed radicals were not free to rotate on the surface. However, a later reinvestigation of this system indicated that both rotational and, to a lesser extent, translational motion occur for cyanopropyl radicals adsorbed on silica gel, both dry and in a slurry (3). Rotational and translational radical movement has also been suggested on the basis of esr studies of adsorbed free, persistent, radicals, but the conclusions may be oversimplified since the effects of surface heterogeneity were not considered (10). More recently, limited translational motion on a silica gel surface has been shown to precede recombination of a singlet radical pair generated in the photo-Fries rearrangement (4). Similarly, substantial surface mobility has been observed for radical pairs generated by photolysis of azocumene (5) and diacyl peroxides (6) on silica gel, although decomposition of the latter is reportedly complicated by the intervention of ionic processes. Evidence for restriction of the mobility of adsorbed radicals has been provided by the observation, on silica gel, of previously undetected reaction pathways in the photolysis of benzoin methyl ether (7).

Dibenzyl ketones (14–16), benzyl phenylacetates (17–20), and dibenzyl sulfones (17, 21, 22) have all been shown to

[1] Publication No. 307 from the Photochemistry Unit, Department of Chemistry, University of Western Ontario.

[2] Most of the previous work is contained or cited in refs. 3–9.



SCHEME 1

undergo photoextrusion reactions in solution to produce benzyl radical pairs (Scheme 1). Studies of the Type I photolysis of dibenzyl ketone, **1**, have shown that excitation is followed by rapid intersystem crossing to a short-lived triplet which undergoes α cleavage to generate a phenylacetyl–benzyl radical pair (15). Both the photodecarbonylation quantum yields of less than unity ($\phi = 0.7 \pm 0.1$ in benzene (15)) and the observation of CIDNP emission for the methylene protons of **1** during its photolysis (16) indicated that geminate recombination of the original radical pair to regenerate **1** occurs. However, in solution, diffusional separation provides the main decay pathway for the initial radical pair. The free phenylacetyl radicals then lose carbon monoxide ($k_{-CO} = 5-9 \times 10^6\ s^{-1}$ (23), depending on the solvent) to give benzyl radicals which combine to give quantitative yields of dibenzyl. The statistical dibenzyl product ratios obtained upon photolysis of unsymmetrical dibenzyl ketones (15) and CIDNP studies (16) showed that cage recombination of benzyl radicals does not occur.

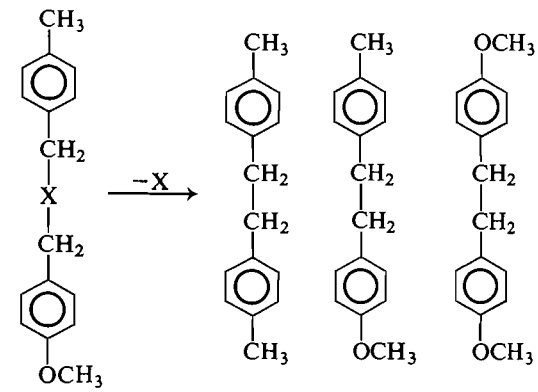
The efficiency of photodecarboxylation of benzyl phenylacetates (18–20) varies considerably with substituents and solvent, but is always lower than that for the decarbonylation of dibenzyl ketones; for example, ϕ_{-CO_2} for benzyl phenylacetate, **2**, is 0.31 in dioxane (19*a*) and 0.19 in methanol (18). Although it has been concluded that the photolysis proceeds by a radical pathway, the multiplicity of the excited state involved and the nature of the decarboxylation step are less certain. Early claims that the photolysis of several phenylacetates involved triplet precursors have been disproved for naphthylmethyl phenylacetates (19). It is likely that the photolysis of **2** and its derivatives also follows a singlet pathway (21). The decarboxylation is thought to proceed by initial cleavage of the carbon – ether oxygen bond followed by rapid loss of carbon dioxide (19*c*). Recombination of the initial benzyl–phenylacetoxy radical pair has not been demonstrated. In contrast to results obtained for dibenzyl ketones, unsymmetrically substituted benzyl phenylacetates show substantial cage effects, particularly in relatively viscous solvents (19*a*, 20).

The photoextrusion of sulfur dioxide from several arylmethyl sulfones has been previously examined (17, 21, 22). Dibenzyl sulfone, **3**, shows both singlet and triplet reactivity and its photodecomposition and that of similar sulfones proceeds by cleavage of one bond to produce a benzylsulfonyl–benzyl radical pair. This either recombines to produce racemized starting material (as shown by the loss of optical activity in *S*-α-methyldibenzylsulfone recovered after partial photolysis), or loses sulfur dioxide to produce a benzyl radical pair (21*b*). The dibenzyl products are derived from both geminate and random free radical combination; decreased amounts of geminate recombination are observed for triplet sensitized photolysis (21).

We report here an account of the generation, on a silica gel surface, of benzyl radical pairs by photolysis of a dibenzyl ketone (**5**), a benzyl phenylacetate (**6**), and a dibenzyl sulfone (**7**). A preliminary account of part of this work has been published (24).

Results and discussion

The same three dibenzyl products, **8**, **9**, and **10** were formed from each of the three precursors (**5**, **6**, and **7**). Since the symmetrical dibenzyls, **8** and **10**, could arise only by nongeminate combination, i.e., by union of radicals which had escaped from their original partners, the product ratios provided a useful probe for translational radical movement on the surface.



5 X = CO
6 X = CO_2
7 X = SO_2

8 **9** **10**

The solution photolysis of ester **6** had been previously examined by Givens (19*a*); the product dibenzyl distribution ranged from 1:2.5:1 in dioxane ($\eta = 1.087 \times 10^{-3}\ N\ s\ m^{-2}$) to 1:5.07:1 in 2-propanol ($\eta = 1.765 \times 10^{-3}\ N\ s\ m^{-2}$), a marked cage effect being noted in the more viscous solvents. In contrast, photolysis of ketone **5** in 2-propanol gave a statistical (1:2:1) product distribution; even at −78°C the product ratio of 1.0:2.2:1.0 indicated that most of the radicals escaped from the solvent cage before recombining. Photolysis of sulfone **7** yielded product distributions of 1.1:2.7:1.0 in dioxane and acetone and 1.1:2.9:1.0 in 2-propanol. These product ratios, since they were intermediate between those obtained for **5** (triplet) and **6** (singlet), suggested that both singlet and triplet excited states were involved in the photolysis of **7**.

Photolysis of 5, 6, and 7 on silica gel

Samples of **5**, **6**, and **7** were adsorbed on silica gel at various coverages; monolayer coverages were obtained either from Langmuir adsorption isotherms (Fig. 1) or by calculations based on the silica gel surface area and the molecular areas determined from space filling models. The agreement between the coverages obtained from isotherms or by calculation was acceptable given the errors involved in each method.

As in solution, dibenzyls **8**, **9**, and **10** were formed in good

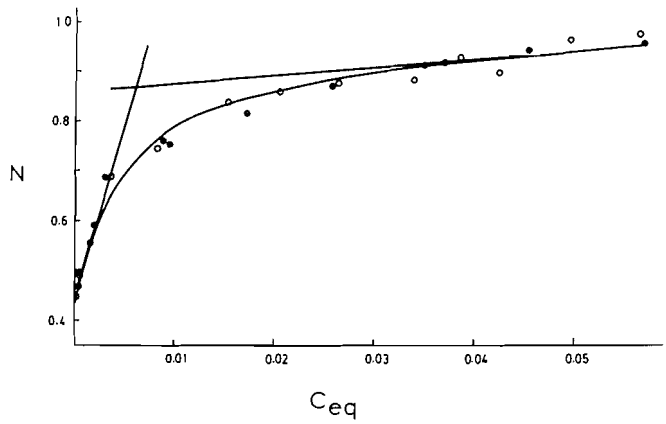

FIG. 1. Adsorption isotherms for ketone **5** (○) and ester **6** (●) on silica gel; N (mmol/g versus C_{eq} (M).

yield (75–100%) when **5**, **6**, and **7** were photolyzed on dry silica gel.

The dibenzyl product distribution (Table 1) was not far removed from statistical when ketone **5** was photolyzed on silica gel at room temperature. However, there was clear indication that some recombination of benzyl radicals with their original partners had occurred. Thus, for example, at 10% coverage the dibenzyl ratio indicated that 23% of the radicals recombined in the original geminate pair. The remaining radicals must have become "free" and found a radical from another pair with which to react. These results require that translational movement of the benzyl radicals occur even if the ketone molecules be unevenly distributed on the surface (e.g., small pools of ketone molecules and large areas of "bare" silica gel). The amount of movement, but not the necessity for its occurrence, will depend upon the adsorbate distribution. The probability of the generation of a second radical pair from a nearby substrate molecule is $\ll 1$, even if the radical pair has a lifetime of milliseconds (i.e., the chance of two photons being absorbed within the space occupied by 2 substrate molecules on this time-scale is negligibly low).

The fraction of geminate recombination did not increase at 50% coverage. Lowering the photolysis temperature to −55°C did, however, yield a larger amount of the unsymmetrical dibenzyl **9**, although the product distribution (1 : ~6 : 1, Table 1) still required some radical movement. Further lowering of the temperature to −165°C gave >95% of **9**. At this temperature on the time-scale of the experiment the ketone is presumably translationally immobile; the benzyl radicals may also be so, but on warming become mobile between this temperature and −55°C where the product ratios require movement. These results reflect the increased restrictions placed upon radical movement on the surface at low temperatures, and demonstrate that there is an activation energy for this radical motion.

Photolysis of ester **6** on dry silica gel at 10% coverage gave a dibenzyl distribution similar to that obtained in 2-propanol solution. As with ketone **5**, the product ratios did not change appreciably from 1 to 50% coverage. However, more geminate recombination to produce the unsymmetrical dibenzyl, **9**, was always observed for the ester than for the ketone under the same conditions. These differences were more pronounced at low temperature: at −50°C >96% of the unsymmetrical dibenzyl was obtained from **6** whereas much lower temperatures were required before similar results were obtained from **5**. It is apparent that less translational movement occurs before

recombination for radicals generated from **6** than for those from **5**.

The dibenzyl distribution (Table 1) obtained when sulfone **7** was photolyzed on silica gel at room temperature showed slightly more geminate recombination than did the ester. These results lead to the conclusion that translational motion on the surface of silica gel competes more effectively with radical recombination for **5** than for **6** or **7**. The benzyl radicals formed from all three are the same; only the distances between the radical centres and their multiplicities differ. The radical pair from **6** is formed with the greatest separation and should, therefore, be the most likely to diffuse apart and exhibit more nongeminate recombination. The opposite is observed so an explanation based on the multiplicity of the radical pair is favoured. The decomposition of **5** occurs from a triplet (15), whereas **6** is thought to decompose by a singlet pathway (19, 21). The singlet radical pair generated from **6** should recombine faster than the triplet pair from **5** and, thus, should show more geminate recombination, as the results indicate. Similarly, the increase in unsymmetrical dibenzyl formation for the ester as compared to the ketone in 2-propanol may also reflect this difference in spin multiplicity of the benzyl radical pair; additionally, it may also reflect the difference in the rate of formation of the benzyl radical pairs by decarboxylation as compared to decarbonylation.

The situation with sulfone **7** is less clear. The surface results, since they are similar to those obtained with the ester, suggest a singlet precursor. However, dibenzyl ratios for **7** in solution are intermediate between those of the ester and ketone and provide evidence for a mixture of singlet and triplet pathways. If a primarily singlet decomposition is occurring for the sulfone on the surface, the increase in geminate recombination for **7** as compared to **6** may reflect the slightly greater separation for the radical pair generated from the former.

The results for the adsorbed versus the solution phase sulfone could be interpreted as a reflection of changes in the relative amounts of singlet and triplet excited states. For example, changes in the rates of either intersystem crossing or radi-

ationless deactivation processes could decrease the amount of triplet reaction occurring for the adsorbed sulfone. Previously observed variations in excited state energy levels (25) and in excited state lifetimes (8), because of changes in radiationless deactivation rates, have been well documented for adsorbed molecules and provide support for the above hypothesis. More information concerning the multiplicity of excited state sulfones is obviously needed before any conclusions can be reached.

The results obtained for adsorbed **5**, **6**, and **7** thus demonstrate that translational motion occurs for benzyl radicals adsorbed on the silica gel surface and that this movement has a significant activation energy. This will vary for movement from different adsorption sites. Thus, when interaction of a molecule with two (or more) silanols is possible, translational motion need not require the simultaneous disruption of all bonding, as would motion which occurred by vaporization. Furthermore, if the molecule moves toward a silanol group, bonding to it may occur as the original silanol bonding is disrupted. According to this model, the most rapid translational motion is to be expected for surfaces with large numbers of silanols or for ones with very few silanols. An energy profile may then be as first suggested by Dacey (26). The deepest wells correspond to the preferred sites and the height of the barrier will vary with the amount of bonding retained in the transition state. The preferred sites must represent some favorable arrangement of surface and silanols, and, hence, will depend, in part, on the specific molecules, especially if large.

Although translational motion was shown to depend on the radical pair multiplicity (and, hence, on its lifetime), movement of the radicals was unaffected by increased coverages of starting material. An increased amount of adsorbate might be expected either to interfere with, or to increase, radical movement. The latter could, presumably, occur because the probability of a specific molecule being adsorbed at a stronger binding site would be lower at higher coverages. Neither effect was, however, observed for benzyl radicals over the 1–50% coverage range.

An estimate of the effective surface "viscosity" of the silica gel at room temperature may be obtained for singlet derived benzyl radicals for which the surface product ratios have been shown to resemble those in 2-propanol. It should be noted that this apparent "viscosity" changes when either the radical pair multiplicity or the photolysis temperature is varied. Consequently, a surface viscosity can only be expressed with reference to a particular adsorbate and specified conditions.

The absence of evidence for preferential adsorption sites, that is, the insensitivity of the amount of geminate recombination to changes in surface coverage, in light of recent results,[3] could have been caused by the presence of sufficient water to fill the active surface sites. Although the present experiments were carried out under "dry" conditions (silica gel dried at 200°C), some water would have been added in even the dry solvent. Typically, the methylene chloride after drying contained 10 ppm water; the use of 4 mL/g silica would, thus, result in the addition of 0.5 mg water/g. Recently, the addition of similar amounts of water to dry silica gel has been shown to produce dramatic changes in the emission spectra for pyrene adsorbed at low coverage on dry silica gel.[3] These results suggest that either the preferred sites are already modified or occupied, or, more probably, that the occupancy of a preferred site for ketone, ester, or sulfone does not require that the subsequently formed benzyl radical also find itself in a preferred site.

Turro and Weed (9) have recently reported results for the photolysis of the unsymmetrical ketone, 1,3-diphenylbutan-2-one, adsorbed on porous glass and on silica gel tlc plates. The observed product ratios indicated "cage" effects of 38% and 9%, respectively. The authors attributed their results to the constraints imposed upon the diffusional separation of geminate radical pairs by the "super-cage" environment. It should be noted that this usage of the word "cage" referring to a surface is somewhat misleading; since, on the surface, a radical pair is not surrounded by a solvent "wall" (or anything else) as it is in solution. If a functional analogy be required — which is dubious — then, rather than invoke the misleading "super-cage" concept, recourse may be had to the relationship of flies to flypaper as more adequately representing the relationship of an adsorbed molecule to the adsorbent surface . . . .

The behaviour of adsorbed benzyl radical pairs may also be compared to that in micelles. Extensive geminate recombination has been recorded for benzyl radical pairs generated in micellar environments from **6** (24) and from **5** (24) and from several other dibenzyl ketones (9, 27). For example, the dibenzyl product mixture was ≥88% **9** when ester **6** was photolyzed in 0.08 *M* potassium dodecanoate. The micellar environment is apparently more effective in preventing diffusional separation of benzyl radicals than is the silica gel surface at room temperature.

Photolysis of ***5*** *and* ***6*** *on modified surfaces*

Several experiments aimed at determining the effects of modification of the silica gel surface were undertaken. Firstly, the silica gel was heated at 750°C, at which temperature most of the surface silanols are thought to be removed (11). Because the major adsorption interaction is with the silanols, an extensively dehydrated silica might be expected to provide less restriction to movement of adsorbed radicals or molecules. Photolysis of ketone **5** on dehydrated silica gel at two coverages at room temperature gave dibenzyl products in the ratios shown in Table 2. The small decrease in the unsymmetrical product yield from that on the normal hydrated surface is consistent with an

increased radical mobility on the dehydrated silica but is unimpressive.

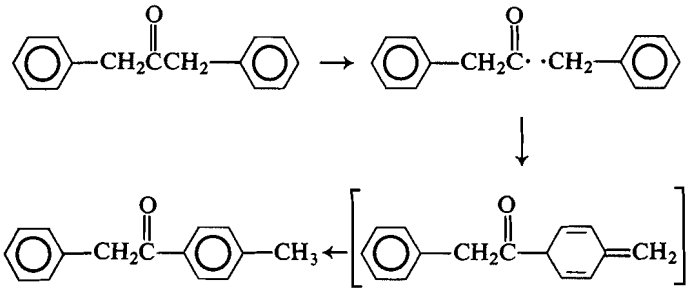
Irradiation of ester **6** on this silica gel also showed only a small variation in the dibenzyl distribution and it would appear that large changes in mobility are not to be expected on partial dehydration. This may not have been carried far enough, since, assuming that approximately one isolated silanol/nm^2 remains on the silica surface (11) and using the calculated area of ~0.98 nm^2 for ester **6**, each substrate molecule should still be able to interact with one or two silanols. The results for the partially dehydrated silica are, therefore, not surprising.

Secondly, the effect of coadsorbates on the translational mobility of benzyl radicals on the silica gel was examined. Coadsorbates might be predicted to influence radical mobility in several ways: they could interfere with and, thus, decrease translational motion; they could adsorb preferentially on stronger adsorption sites leaving the substrate the weaker sites from which the radicals could more easily escape; or they could change the substrate distribution on the surface.

Ketone **5** was photolyzed on silica in the presence of coadsorbed cyclohexane diol, **10**, at −55°C: only small variation from the product distribution obtained on silica gel was observed in the presence of the highest concentration of coadsorbed diol (Table 2). The increase in the amount of unsymmetrical product for the higher diol coverage (~20%) was consistent with some interference by the diol with movement of the benzyl radicals.

Photolysis of dibenzyl ketone

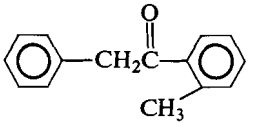
Photolysis of dibenzyl ketone, **1**, in micellar solution has been shown by Turro and co-workers (28) to produce small amounts of a rearranged ketone, 1-phenyl-4′-methylacetophenone, **11**. This product presumably arises via recombination of the original acylbenzyl radical pair with subsequent rearomatization. Although 5–10% yields of **11** have been reported for photolysis of **1** in hexadecyltrimethylammonium micelles, the isomer has not been observed in homogeneous solution photolyses (28).



11

Irradiation of **1** on silica gel at 20°C yielded small amounts of **11** along with the major product, dibenzyl. The isomer was isolated and its identity confirmed by comparison with an authentic sample. Typical yields were from 1–2% for irradiation of **1** on silica (irrespective of the manner of drying) at 20°C; photolysis at −55°C resulted in higher yields of 3–4%. At both temperatures the percentage of **11** decreased considerably at higher conversions (e.g., 0.1–0.4% for >97% reaction), presumably owing to its photodecomposition.

There appeared to be no obvious reason for the formation of **11** but not that of the analogous *ortho* compound, 1-phenyl-2′-methylacetophenone, **12**; however, its formation has not previously been reported (28).

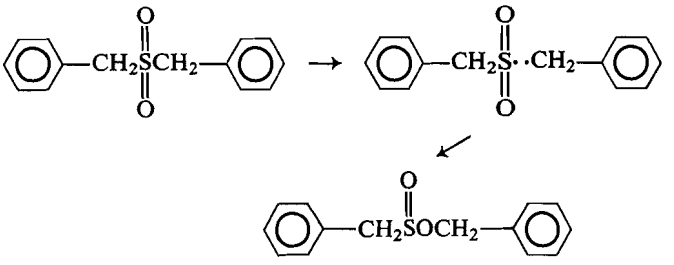


12

The gc retention times of **1** and **12** were identical on the SE 30 column normally used for analysis of reaction products, but the two were separable from each other, and from **11**, on a carbowax column. Analysis of the reaction products obtained in micelle solution showed the presence of isomer **12** (~2–4% yields) as well as **11**. Lesser amounts (<0.5%, estimated) of **12** were also detected in silica gel reaction mixtures at 20 and −55°C. The observation of both *ortho* and *para* rearranged starting material is consistent with the earlier observation of both *ortho* and *para* products in the photo-Fries rearrangement on dry silica gel (5) and with the suggestion that both *ortho* and *para* LATs are formed in the photoreduction of benzophenone (29).

Photolysis of dibenzyl sulfone

Solution photolyses of dibenzyl sulfone, **3** (in benzene (21, 22) and in ethanol (22)), have been reported to produce dibenzyl as the only isolated product, although in less than quantitative yields. No evidence for sulfur to oxygen migration has been found (21*a*). However, photolysis of **3** on silica gel at 20°C yielded small amounts of a rearranged starting material in addition to dibenzyl: the isomer was shown to be sulfinate **13** by comparison with an authentic sample. This ester is presumably formed by recombination of the benzyl — benzyl sulfonyl radical pair before its destruction either by desulfonylation or by diffusional separation. Sulfinates have been detected among the thermolysis and photolysis products from other sulfones (30).



13

Following photolysis of **3** on silica gel at 20°C dibenzyl **4** and sulfinate **13** accounted for ~40% and ≤5%, respectively, of the decomposed sulfone. Decreasing the photolysis temperature to −55°C gave an increased yield of the sulfinate (10%). In contrast, photolysis of **3** in methanol at either 20 or −77°C gave much lower yields of **13** (~0.5%). The low overall recoveries may result from formation of toluene-α-sulfinic acid or toluene-α-sulfonic acid (22). The isolation of acidic products was not attempted.

The decreased yield of sulfinate at higher conversions on silica gel suggested that **13** was not stable on the silica gel surface. To test for this possibility two samples of **13** adsorbed on silica gel were prepared; one sample was kept in the dark for 24 h and the other was irradiated using the same conditions as those used for sulfone photolyses. The "dark" sample showed ~80% sulfinate recovery. From the irradiated sample there was obtained 63% unreacted **13** in addition to dibenzyl and dibenzyl sulfone, **3** (13% and 8%, respectively, based on sulfinate con-

sumed). The presence of a number of other unidentified compounds was also evident. An irradiated methanol solution of **13** similarly indicated the presence of dibenzyl, dibenzyl sulfone, and a number of unidentified compounds.

The above results indicate that recombination of the initial radical pair formed by photolysis of dibenzyl sulfone does occur with benzyl migration from sulfur to oxygen when the sulfone is adsorbed on silica gel. The reported yields of sulfinate represent lower limits because of the instability of **13** on silica gel and its photolability. Recombination of the radical pair can compete more effectively with its diffusional separation on the silica gel surface than in solution.

Conclusions

Translational motion of benzyl radicals adsorbed on silica gel has been demonstrated. The radical mobility has been shown to depend on both the radical pair multiplicity and the photolysis temperature, but was not particularly sensitive to the dehydration of the silica or to the presence of coadsorbed cyclohexanediol. The formation of rearranged starting materials amongst the products from the photolysis of adsorbed dibenzyl ketone and dibenzyl sulfone provided additional evidence for restrictions to radical movement on the surface.

Experimental

Apparatus

Ultraviolet spectra were recorded on a Varian Cary 219 spectrophotometer. Proton nmr spectra were recorded on either a Varian T-60 (60 MHz) or an XL-100 (100 MHz) spectrometer using tetramethylsilane as the internal standard. Mass spectra were measured on a Varian MAT 311A mass spectrometer. Melting points were measured on a Reichert hot stage and are uncorrected. Gas chromatography was done on a Varian 2400 instrument equipped with a flame ionization detector, a temperature programmer, and a 5′ × 1/4″ glass column packed with 10% SE 30 on Chromosorb W (except for the identification of **12** for which a Carbowax column was used). The carrier gas was helium, flow rate 40 mL/min. Operating conditions for the analysis of products from the photolysis of various substrates were as follows: **1**, **5**, **6**, **7**: injector, 225°C; column, 170°C (**1**), 185°C (**5**, **6**), and 185°C for 15 min followed by 200°C for 25 min (**7**); detector, 250°C; **3**, **13**: injector, 190°C; column, 170°C for 20 min followed by 176°C for 25 min; detector, 250°C. Irradiations were carried out with a 150 W or 1000 W XBO high pressure xenon lamp in a Photochemical Research Associates lamp housing (with an infrared water filter) or in a Rayonet reactor equipped with either 254.7 or 300 nm lamps.

Materials

Silica gel (35–70 mesh, Merck) was used as received or dried as outlined below. Dehydrated silica gel was prepared by heating the above silica slowly over a 6 h period to 750°C and leaving it at that temperature for 48 h at atmospheric pressure in an open container. The sample was then evacuated for 2 h at ~0.1 Torr, cooled slowly to 20°C while still under vacuum and stored over P_2O_5 until used. All solvents for solution photolyses or for preparation of silica gel samples were Fisher spectrograde. Methylene chloride was refluxed over P_2O_5 and distilled directly before use for adsorption of compounds onto dry silica gel. Cyclohexane, acetone, and dioxane were dried over molecular sieves. 2-Propanol was dried by refluxing over magnesium/iodine and was then distilled. Anhydrous ether (Fisher) was used as received or distilled from $LiAlCl_4$ when particularly dry ether was required. All other solvents were reagent grade and were used as received.

Dibenzyl ketone (ICN Pharmaceutical) was recrystallized from ether (at −78°C) or petroleum ether (40–60°C) (mp 30.5–32°C) and was stored at 0°C in the dark in a desiccator. Cyclohexanediol (Aldrich, *cis* and *trans*) was recrystallized twice from acetone. Dibenzyl sulfone (Fairfield Chemical Company) as received contained ~50% dibenzyl sulfoxide. The mixture was oxidized with 3-chloroperbenzoic acid and the sulfone obtained recrystallized three times from 95% ethanol (mp 153–155°C). The literature procedure (19*b*) for the preparation of 4-methylbenzyl-4-methoxyphenyl acetate was used (mp 31.5–32°C). 1-Phenyl-4′-methylacetophenone (31) was prepared by Friedel Crafts acylation of toluene (mp 108–109°C). 1-Phenyl-2′-methylacetophenone (32) was prepared by the literature procedure (33) for the preparation of substituted dibenzyl ketones. Benzyl-α-toluenesulfinate (34) was prepared by condensation of α-toluenesulfinyl chloride and benzyl alcohol (mp 49.5–50°C).

1-(4-Methylphenyl)-3-(4-methoxyphenyl)-2-propanone, 6

A general literature procedure (33) for the synthesis of other unsymmetrically substituted dibenzyl ketones was employed. The product was obtained as a yellow oil which contained ~30% dibenzyl and was purified by crystallization from ether at −77°C to give white crystals: mp 48–49°C; ^{1}H nmr (δ, $CDCl_3$) 7.1–6.8 (m, 8H), 3.79 (s, 3H), 3.65 (s, 2H), 3.64 (s, 2H), 2.33 (s, 3H); uv (cyclohexane) λ_{max} 275 nm (ε 1580 M^{-1} cm^{-1}).

4,4′-Methoxymethyldibenzyl sulfone, 7

The sulfone was prepared by condensation of 4-methylbenzyl chloride and 4-methoxybenzyl thiol, followed by hydrogen peroxide oxidation. The product was recrystallized from ethanol to give white plates: mp 141–142°C; ^{1}H nmr (δ, $CDCl_3$) 7.33–6.86 (m, 8H), 4.07 (s, 2H), 4.05 (s, 2H), 3.81 (s, 3H), 2.36 (s, 3H); uv (ethanol) λ_{max} 274 nm (ε 1520 M^{-1} cm^{-1}); mass spectrum (70 eV) *m/e* (relative intensity) 290 (0.4), 226 (6), 121 (100).

Monolayer coverages

Adsorption isotherms (35) were measured for **5** and **6** on silica gel using cyclohexane as solvent and uv analysis. Values obtained for 100% coverage were the same within experimental error for both substrates: 0.9 mmol/g from plots of N versus C_{eq} (Fig. 1) and 1.0 mmol/g from plots of C_{eq}/N versus C_{eq}. Monolayer coverages were also calculated from the surface area of the silica gel (560 m^2/g) and the molecular area determined from space filling molecular models (**5**, 0.94 nm^2; **6**, 0.98 nm^2; **10**, 0.37 nm^2).

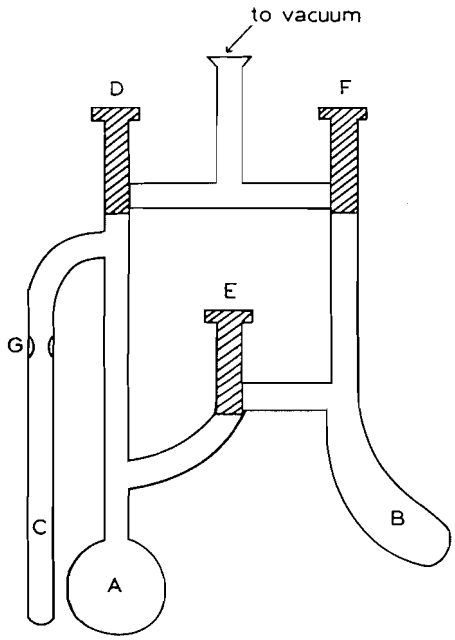

FIG. 2. Cell for preparation of dry silica gel samples.

Photolysis of 5, 6, and 7 on silica gel

Poor material balances and irreproducible product ratios resulted when **5** and **6** were photolyzed on silica gel which had not been dried in the following manner. A preweighed silica sample was heated at 200°C at ≤1 Torr for ≥5 h in compartment A of the cell shown in Fig. 2. The sample was cooled under vacuum and stopcocks D and E were closed. The substrate was then adsorbed without reexposing the silica gel to the atmosphere. A methylene chloride solution of the substrate was added through F to compartment B of the cell. After brief degassing of the solution, F was closed, E was opened, and the solution was poured onto the silica gel. Compartment B was rinsed with fresh solvent by closing E, adding ~2 mL solvent, degassing the solvent and adding it to the slurry in compartment A. The solvent was removed (E and F open, D closed) to give a free-flowing sample. All stopcocks were then closed and the cell was attached to a vacuum line and degassed to $\sim 10^{-5}$ Torr by three or more freeze–thaw cycles at liquid nitrogen temperatures. After degassing, the sample was transferred to irradiation tube C which was sealed at point G. For samples to be irradiated at low temperature, dry, deoxygenated nitrogen was added to the tube before it was sealed; this was necessary to ensure adequate sample cooling.

The rotated sample tubes were irradiated with the 150 W xenon lamp (**4**) or the Rayonet reactor (**5** and **6**) at room temperature with cold running water and air cooling, respectively. All low temperature irradiations were performed with the 1000 W xenon lamp. The light was focused on the end of a 16 mm quartz light pipe and the sample tube was rotated under the other end. Both the tube and the end of the light pipe were immersed in a cooling bath (methanol/dry ice or liquid nitrogen). All photolysis temperatures refer to internal sample temperatures.

The adsorbed products were removed from the silica gel by extraction with 100 mL of diethyl ether (**5** and **6**) or methylene chloride (**7**). The filtrate was concentrated and analyzed by gc after the addition of a known amount of tetracosane as internal standard. Calibration curves were constructed for all compounds analyzed quantitatively; the average of three or more injections was used for each determination.

Dibenzyls **8**, **9**, and **10** were isolated from preparative scale photolyses of each of **5**, **6**, and **7** on silica gel. They were separated by chromatography and recrystallized from methanol; the identity of each was established by comparison of its mp and spectra with those in the literature (19*b*).

Photolysis of 5 and 6 on modified silica

Samples of **5** and **6** on dehydrated silica gel were prepared, degassed, irradiated, and analyzed as outlined above. For silica samples containing coadsorbed cyclohexanediol, the diol was adsorbed first and then the ketone; all procedures were as outlined above.

Photolysis of 1, 3, and 13 on silica gel

Samples of **1**, **3**, and **13** were adsorbed on silica gel which had not been predried. A methylene chloride solution of the adsorbate was added to a preweighed silica sample in a round bottom flask. After solvent removal by evacuation, the sample was transferred to an irradiation cell. The sample was then evacuated at ~0.5 Torr for 15 min before being degassed. Dry, deoxygenated nitrogen was added before the tube was sealed. Samples of **1** were rotated and water cooled during irradiation with the 1000 W xenon lamp plus light pipe assembly. They were extracted with 100 mL ether and analyzed by gc with eicosane as the internal standard. Rotated samples of **3** and **13** were air cooled, irradiated in the Rayonet (254.7 nm), extracted with 100 mL methylene chloride, and analyzed by gc with docosane as the internal standard.

The isomeric ketones, **11** and **12** were isolated from a preparative scale photolysis of **1** on silica gel. Each was separated by chromatography and identified by comparison with an authentic sample. Sulfinate **13** was isolated from a preparative scale photolysis of **3** and also identified by comparison with an authentic sample. Products from the photolysis of **13** were identified tentatively by comparison of gc retention times but were not separated.

Solution photolyses

All solutions to be irradiated were deaerated by purging with nitrogen for 30 min. Ketone **5** was irradiated with the 150 W xenon lamp; all others were irradiated at 254 nm in the Rayonet with air cooling. Products were analyzed by gc, as already described.

JAGABANDHU DAS, MASATOSHI KAKUSHIMA, ZDENEK VALENTA, KRZYSZTOF JANKOWSKI, and RHÉAL LUCE. Can. J. Chem. **62**, 411 (1984).

A chemical correlation is described by which the two adducts resulting from a catalyzed addition of *trans*-piperylene to 2-methyl-2-cyclohexenone, **7** and **8**, are proven to be stereoisomers. Various reaction conditions for the addition of *trans*-piperylene to 2-cyclohexenone are also summarized.

JAGABANDHU DAS, MASATOSHI KAKUSHIMA, ZDENEK VALENTA, KRZYSZTOF JANKOWSKI et RHÉAL LUCE. Can. J. Chem. **62**, 411 (1984).

On décrit une corrélation chimique qui permet de prouver que les deux adduits (**7** et **8**) provenant de l'addition catalysée du pipérylène-*trans* sur la méthyl-2 cyclohexénone-2 sont des stéréoisomères. On résume également différentes conditions de réaction pour l'addition du pipérylène-*trans* sur la cyclohexénone-2.

It was assumed until recently that 2-cyclohexenone and its alkyl derivatives (as well as other 2-cycloalkenones) are not suitable for synthetically useful Diels–Alder reactions. Several reports during the last few years have shown, however, that catalyzed diene additions (1, 2) work efficiently, if somewhat slowly, to give good yields of the desired *cis*-octalones **1** or **2** (3–11) in which R^1 and R^2 can be an H-atom or an alkyl group and R^3 is an alkyl group. Concerning substitution of the dienophile olefinic bond, it is thus clear now that the 2-position can be unsubstituted (R^2 = H) or alkyl substituted (R^2 = alkyl). Also, the saturated C-atoms of the 2-cyclohexenone may bear alkyl groups.

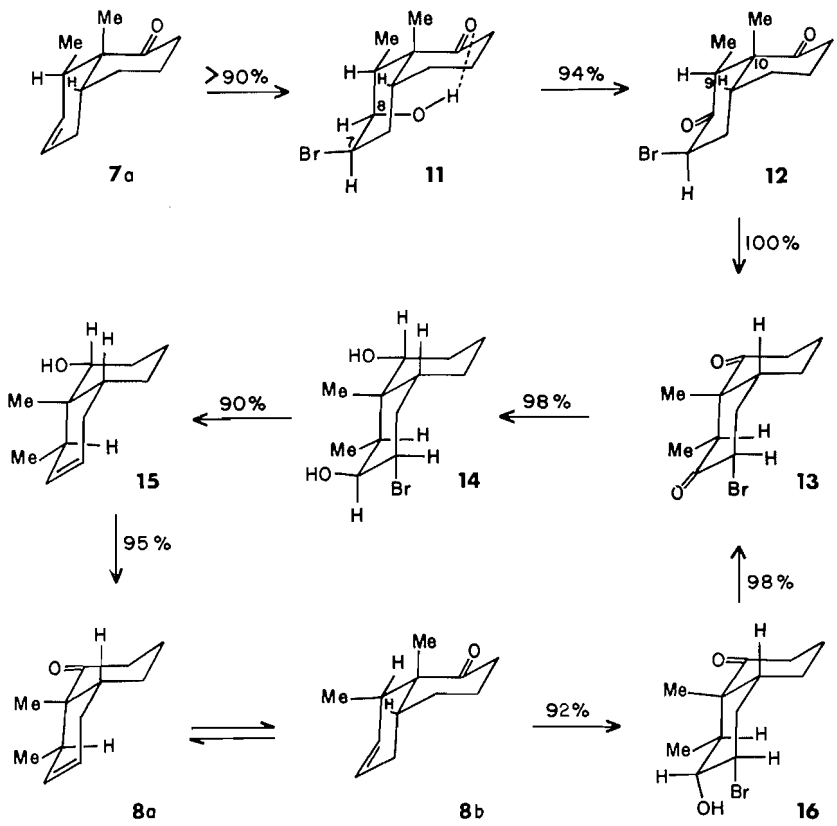
SCHEME 1

In contrast, no additions (thermal or catalyzed) have been reported to simple 2-cyclohexenones of type **3** in which the 3-position is alkyl substituted. As suggested by Liotta *et al.* (12), this lack of reactivity is likely due to a combination of electronic and steric factors. Exceptions to this "rule of unreactivity" are instructive. Complexes **4** (12) and **5** (13, 14) have been reported to add to dienes with facility and this is presumably due to a lower lying LUMO (15) as well as a sterically less hindered approach of the diene in these cases.

In an important contribution, Wenkert and co-workers (11) have recently reported their extensive work on the $AlCl_3$-catalyzed addition of 1,3-butadiene, isoprene, and *trans*-piperylene to 2-cyclopentenones, 2-cyclohexenones, and 2-cycloheptenones, and their analysis of product structures, done mainly by ^{13}Cmr spectroscopy, has shown that the *ortho*- and *para*-rules of addition (16) are followed in all cases.

We wish to report in more detail on one of the additions described by them, that of *trans*-piperylene to 2-methyl-2-cyclohexenone **6** (Scheme 1). Our study was undertaken in order to establish rigorously whether the *ortho*-rule of addition



SCHEME 2

TABLE 1. Condensation of *trans*-piperylene with 2-methyl-2-cyclohexenone **6**

Catalyst	Solvent	*t* (h)	*T* (°C)	Total yield[a] (%)	Products (% of total) 7	8
$BF_3 \cdot Et_2O$	C_6H_6	48	20	75	67	33
$AlCl_3$	C_6H_6	72	20	80	78	22

[a]Yield based on the dienophile; diene was used in large excess. Total yield is the sum of isolated pure adducts.

is followed quantitatively in this case; a previous report (5) indicated the formation of a substantial amount of the *meta*-adduct **9** and we deemed it essential to find out whether this addition constitutes an important exception to the *ortho*-rule (16). Two adducts are formed and we have been able to convert the major (*endo-ortho*) adduct **7** into the minor (*exo-ortho*) adduct **8** in a 6-step sequence and an overall yield of 70% (17). This proves rigorously that the two products are stereoisomers (i.e., that the *meta*-adduct **9** is absent) and thus strengthens the structural assignments based on spectroscopy (11). From the synthetic standpoint, it furthermore makes *cis*-octalones of type **8** available in good yield. Eremophilane sesquiterpenoids (skeleton **10**) (18) provide one example for which the geometry present in **8** is required.

In order to establish best experimental conditions and analytical procedures, we have also studied catalyzed additions of *trans*-piperylene to 2-cyclohexenone (10, 11) in detail.

Catalyzed additions of trans*-piperylene to 2-methyl-2-cyclohexenone*

As summarized in Table 1, good yields (based on dienophile) of the two adducts were obtained in reactions of *trans*-piperylene with **6** in the presence of BF_3-etherate or $AlCl_3$.[2] The reactions were found to be relatively slow and the diene was used in excess since it was found to polymerize slowly under the reaction conditions. The mixture of the two adducts was first separated from polymers by distillation and the pure adducts were then obtained by chromatography on a silver nitrate impregnated silica gel column. Gas chromatography of the distilled mixture showed the presence of only two products in both reactions.

The following findings prove rigorously that the major adduct has the expected structure **7** and the minor one structure **8**. Treatment of **7** with bromine and sodium hydroxide in methylene chloride at −20°C gave an excellent yield of crystalline bromohydrin **11**. A broad peak at 3380 cm^{-1} (—OH) and a peak at 1690 cm^{-1} (C=O) in the ir spectrum of **11** indicated that the two functions are H-bonded. The ^{1}Hmr spectrum of **11**, after exchange of the hydroxyl H-atom with D_2O, showed two deshielded equatorial protons (Table 2), one at δ 3.8 and one at δ 4.4. The position and multiplicity of these signals, together with the ir data, are only compatible with structure and conformation **11**. Clearly, the only bromohydrin formed is the one expected after an attack of the double bond in **7***a* from the less hindered convex side followed by a *trans* diaxial opening of the intermediate bromonium ion.

Oxidation of **11** with Jones' reagent gave bromoketone **12** in a 94% yield after chromatography. The appearance of a sharp quadruplet in the ^{1}Hmr spectrum of **12** (H_A, Table 2) establishes that the secondary methyl group is located at C-9.[3]

[2]Wenkert and co-workers (11) have reported a yield of 92% (based on chromatographic analysis) and a product ratio **7**/**8** = 2.2:1 in a reaction catalyzed by $AlCl_3$ in toluene.

[3]See formula **17** for carbon numbering and proton notation.

TABLE 2. Proton magnetic resonance data for selected protons in compounds **7** to **16** (δ, ppm)[a]

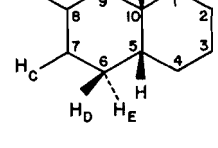
Compound	Angular CH_3	CH—CH_3 (J, Hz)	H_A (J, Hz)	H_B (J, Hz)	H_C (J, Hz)	C_1(OH)(H)
7	1.3 (s)	1.1 (d, 7)		5.4 (s)	5.4 (s)	
8	0.9 (s)	0.8 (d, 7)		5.4 (m)	5.4 (m)	
11[b]	1.5 (s)	1.2 (d, 7)		3.8 (t, 3.5)	4.4 (q, 3)	
12	1.6 (s)	1.15 (d, 6.5)	2.95 (q, 6.5)		4.4 (t, 3.5)	
13	1.0 (s)	0.9 (d, 6.5)	3.3 (q, 6.5)		5.0 (t, 10)	
14	1.3 (s)	1.2 (d, 6.5)		3.8 (t, 3)	4.6 (o, 13, 5, 3)	3.2 ($W/2$ = 22)
15	1.05 (s)	1.1 (d, 7)		5.4 (m)	5.4 (m)	3.6 (m)
16[b]	1.15 (s)	0.9 (d, 7)			3.6 (t, 10)	4.35 (o, 11.5, 10, 7)

[a]Spectra taken on a Varian T-60 instrument in $CDCl_3$; see formula **17** for proton notation; s = singlet, d = doublet, t = triplet, q = quadruplet, o = octet, m = multiplet.
[b]D_2O added.

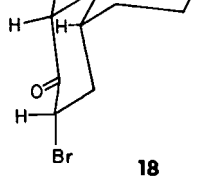
Irradiation of H_A changed the methyl doublet at δ 1.15 to a singlet as expected. A one-proton triplet (H_C) at δ 4.4 (J = 3.5 Hz) shows that the proton adjacent to the bromine atom is coupled to two protons and that the bromine is axially oriented.

On standing for three days at ambient temperature, either in crystalline state (!) or in chloroform solution, **12** was converted quantitatively into an isomer. The ^{1}Hmr signal corresponding to the proton adjacent to the bromine atom (δ 5.0; t, J = 10 Hz) in the spectrum of the new isomer showed that the compound contains an equatorial bromine. Clearly, there are two ways in which **12** can isomerize to give a product of greater stability. Epimerization at C-7 would lead to bromoketone **18**. Alternatively, a conformational flip and an epimerization at C-9 would give compound **13**. Both **13** and **18** contain the two epimerizable groups, bromine and secondary methyl, in an equatorial position. The quaternary methyl group at C-10 cannot be expected to have a decisive influence since it is axial to one ring and equatorial to the other ring in all the possible *cis*-decaline dione systems.

Structure **13** for the isomerization product was proven in the following simple way. Reduction of **13** with sodium borohydride gave diol **14** as the only product. Its ^{1}Hmr spectrum (Table 2) shows clearly that the hydroxyl group vicinal to bromine is axial (H_B; δ 3.8; t, J = 3 Hz), whereas the other OH-group is equatorial (C_1—H; δ 3.2; m, $W/2$ = 22 Hz). Interestingly, the screening of the bromoketone ring by the axial methyl group thus completely prevented the more commonly observed axial attack by the hydride ion.



17



18

Reduction of **14** with zinc in acetic acid gave a 90% yield of olefin **15**. On Jones' oxidation, **15** was converted to a ketone which was found to be identical in all respects with minor Diels–Alder adduct **8**.

This correlation completely clarifies the whole series. Obviously, both Diels–Alder adducts have a methyl group at C-9 and must thus be epimeric at that position.[4] Furthermore, the isomerization of bromoketone **12** discussed above must involve a change of configuration at C-9, since otherwise the subsequent three steps (**13** → **14** → **15** → **8**) would have converted the isomerized product back to **7**, rather than **8**. Finally, the spectroscopic data for all compounds in this series make sense only if the major adduct is assigned structure **7** (*endo*-adduct) and the minor adduct structure **8** (*exo*-adduct).

The fact that diketone **13** has a configuration at C-9 identical to that of minor adduct **8** was further confirmed by a treatment of **8** with bromine and aqueous sodium hydroxide at ambient temperature for 2 h to form bromohydrin **16** in a high yield. The configuration and conformation of **16** follows clearly from its ^{1}Hmr spectrum (Table 2). Finally, Jones' oxidation of **16** gave diketone **13** in high yield.

The above results can be summarized in the following way. (1) *trans*-Piperylene adds to 2-methyl-2-cyclohexenone **6** in the presence of BF_3-etherate or $AlCl_3$ to give exclusively the *ortho*-adducts **7** and **8**. (2) The *endo*-adduct **7** can be isolated in a yield of 62% from the $AlCl_3$-catalyzed addition. (3) The *exo*-adduct **8** can be obtained in a maximum yield of 60–62% by a combination of direct isolation (Table 1) and of conversion of **7** (Scheme 2) from additions catalyzed by either BF_3-etherate or $AlCl_3$. (4) Diketone **13** can presumably be obtained from a mixture of **7** and **8** without the necessity of chromatographic separation (Scheme 2). (5) Adduct **7** reacts in conformation **7***a* in agreement with the conformation proposed for **7** on the basis of a ^{13}Cmr study (11). Not surprisingly, the addition of the elements of HOBr to adduct **8** is much slower than that to **7** since both faces of the double bond are screened in either conformation of **8** (Scheme 2). Nevertheless, one bromohydrin is formed exclusively (**16**) and it clearly arises from a diaxial opening of a bromonium ion corresponding to conformer **8***b*, followed by a conformational inversion.

Based on available evidence, it can be predicted that the exclusive *ortho*-addition will take place in catalyzed reactions of similar dienes and dienophiles in which the methyl groups (Scheme 1) have been replaced by other alkyl groups. A similar prediction concerning the *endo* (**7**)/*exo* (**8**) ratio would, however, be unwise. The amount of the *exo*-adduct **8** formed (Table 1) (11) is unusually large. Wenkert and co-workers have, furthermore, shown that this *exo*-addition is specific to 2-methyl-2-cyclohexenone; catalyzed additions of *trans*-piperylene to 2-methyl substituted 2-cyclopentenones and 2-cycloheptenones gave only the expected *endo*-adducts (11). A subtle nonbonded interaction is probably involved (11) and this could well be affected drastically by replacing the methyl groups in *trans*-piperylene and in **6** by larger alkyl groups.

[4]An ^{1}Hmr induced shift study using $Eu(fod)_3$ (see Experimental) is in full agreement with this conclusion.

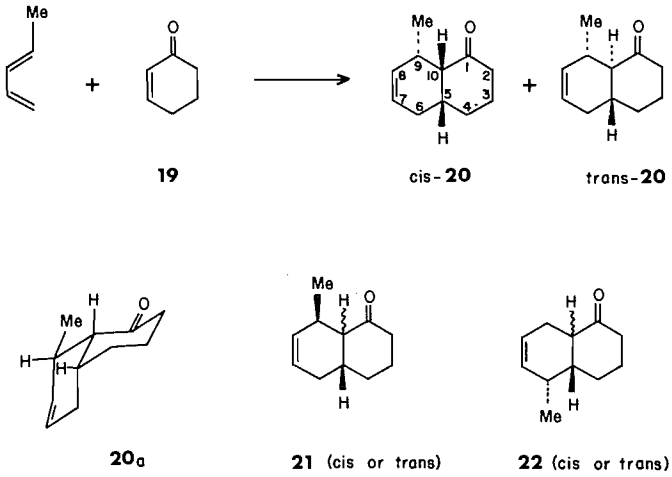

SCHEME 3

Catalyzed additions of trans*-piperylene to 2-cyclohexenone*

The results of all additions of *trans*-piperylene to **19** (Scheme 3) are summarized in Table 3. It should be noted that particularly good yields of the partially equilibrated *cis*–*trans* mixture of the expected *endo-ortho* adduct **20** are obtained using BF_3-etherate in benzene, while useful yields also result using $AlCl_3$ in benzene.[5] Tin tetrachloride proved to be an inferior catalyst in this case.

A high temperature thermal addition was performed (see Table 3) in order to acquire a comparison with the catalyzed additions and to obtain gas chromatographic data for the greatest possible number of adducts. Table 4 lists gc retention times and major ms peaks for the four products obtained in the thermal addition. Equilibrations with alumina clearly established that the two major products showing retention times of 9.5 and 10.8 min, respectively (see Table 4), are interconvertible *cis*-*trans* isomers and that the two minor products (retention times of 11.9 and 12.1 min, respectively) are similarly related.

Since the two minor products were formed in negligible quantities in the catalyzed additions (3% or less, Table 3), their structure elucidation was not pursued. This *cis*-*trans* pair must clearly result either from the *exo-ortho* adduct **21** or the *endo-meta* adduct 22.

Mixture of the two major products obtained in all additions gave up to 96% of *trans*-**20** on treatment with neutral alumina. The ^{1}Hmr data for the two compounds together with an induced shift study using $Eu(fod)_3$ (Table 5) clearly show that the CH_3 group is in the vicinity of the carbonyl group and that *cis*-**20** is thus the expected *ortho*-adduct. Furthermore, simulation of the ^{1}Hmr shift reagent experiments using the JULIE program (19)

[5]A yield of 81% was reported (11) for the addition using $AlCl_3$ in toluene.

confirms the predominance of conformation **20***a* for the *cis*-isomer.

In contrast to the thermal addition which requires high temperature and gives a 50% total yield of a mixture of at least four products, a catalyzed addition of *trans*-piperylene to 2-cyclohexenone can thus be accomplished at 20°C to give a very high yield of the *ortho-endo* adduct **20**.[6]

Experimental

General

The ^{1}Hmr spectra were determined on a Varian T-60 or HR-220 MHz spectrometer in $CDCl_3$ (≃10%, TMS). The ir spectra were recorded on Perkin–Elmer 457 or 700-A spectrometers. The gc–ms analyses were perfomed using a PE-990 chromatograph coupled to a Hitachi RM-50 mass spectrometer. The column OV-101 (15% on WHP 80/100, 6 ft × 6 mm) was used in the programmed temperature mode. The mass spectra were recorded at 70 eV (EI); source temperature was kept at 200°C. High resolution mass spectra were determined by Dr. A. M. Hogg, University of Alberta. Elemental analyses were performed by Dr. F. Pascher, Bonn, West Germany. Melting points were determined on a Kofler hot stage and are uncorrected. Thin-layer chromatography was performed on 0.25-mm silica gel G plates containing a fluorescent indicator; preparative tlc was done on 0.75-mm silica gel G plates (20 × 20 cm). Solutions were dried over anhydrous magnesium sulfate.

Catalyzed addition of trans*-piperylene to 2-methyl-2-cyclohexenone*

1. 2-Methyl-2-cyclohexenone **6** (1.10 g, 10 mmol) prepared according to Warnhoff *et al.* (20) and *trans*-piperylene (6.80 g, 100 mmol) were dissolved in dry benzene (30 mL); BF_3-etherate (1.42 g, 10 mmol) was added in one lot at 5°C and the reaction mixture was maintained at 20°C for 48 h. It was then diluted with ether (50 mL), washed twice with a saturated $NaHCO_3$ solution, twice with water and twice with brine, and dried. Removal of solvent under reduced pressure gave a viscous oil which was distilled (75°C/0.04 Torr) to give a mixture of adducts **7** and **8** (1.28 g, 80%). Gas chromatographic study revealed the presence of only two compounds. Elution with 5% ether in hexane on chromatography on a silver nitrate-impregnated silica gel column (10% silver nitrate by weight) gave (1). minor adduct **8** (0.40 g, 25% yield) as colorless oil; ir (film): 1700 (C=O) cm^{-1}; ms m^+ 178; ^{1}Hmr: see Table 2; relative shifts on addition of [Eu(fod)$_3$]: C-10 methyl 3.7 ppm; C-9 methyl 1.9 ppm; (2). major adduct **7** (0.80 g, 50% yield) as colorless oil; ir (film): 1700 (C=O) cm^{-1}; ms m^+ 178; ^{1}Hmr: see Table 2; relative shifts on addition of [Eu(fod)$_3$]: C-10 methyl 2.5 ppm, C-9 methyl 2.0 ppm.

2. In a similar way, ketone **6** (2.20 g, 20 mmol) and *trans*-piperylene (3.40 g, 50 mmol) were reacted in benzene (25 mL) in the presence of aluminum chloride (0.66 g, 5 mmol; freshly sublimed in a stream of HCl) at 20°C for 72 h. Work-up identical to the one above gave adduct **8** (0.64 g, 18% yield) and adduct **7** (2.20 g, 62% yield) as colorless oils, homogeneous by tlc, gc, and ^{1}Hmr.

Conversion of adduct 7 into bromohydrin 11

A solution of adduct **7** (524 mg, 2.95 mmol) in methylene chloride (25 mL) was treated at −20°C with 50% aqueous sodium hydroxide (5 mL) followed by bromine (1 mL, 15 mmol). The mixture was stirred at −20°C for 5 min and then poured into water. The organic layer was separated and the aqueous layer was extracted with three 20-mL portions of methylene chloride. The combined organic layer was washed twice with water, twice with brine, and dried. Evaporation of solvent under reduced pressure gave an oily residue which crystallized from ether, mp 76–80°C (770 mg, 95% yield); ir ($CHCl_3$): 3380 (OH) and 1690 (C=O) cm^{-1}; ^{1}Hmr: see Table 2; ms M^+ calcd. for $C_{12}H_{19}O_2{}^{79}Br$: 274.05684; found: 274.05683.

[6]We do not ascribe much significance to the exact ratio of *cis* and *trans* isomers of **20** as listed for all the additions in Table 3. It can be assumed that the equilibration can partially take place both during the additions and in the process of analysis.

Oxidation to bromoketone 12

A 0.07 molar Jones' oxidation reagent (CrO_3–H_2SO_4–H_2O) (21) was added dropwise at 20°C to a stirred solution of bromohydrin **11** (214 mg, 0.78 mmol) in acetone (20 mL). The addition was continued until the color of the reagent persisted. The reaction mixture was stirred at 20°C for an additional 30 min and the excess of Jones' reagent was then destroyed by the addition of a saturated sodium bisulfite solution. The reaction mixture was then extracted three times with ether and the ethereal extract was washed twice with saturated sodium bicarbonate solution, twice with water, and twice with saturated brine. Drying and evaporation of solvent gave an oily residue which was chromatographed on silica gel plates. Elution with 30% ether in hexane gave ketone **12** (202 mg, 94% yield) as colorless crystals, mp 96–100°C; ir ($CHCl_3$): 1725 and 1710 cm^{-1} (shoulder) (carbonyls); ^{1}Hmr: see Table 2; ms m^+ 272 and 274. *Anal.* calcd. for $C_{12}H_{17}O_2Br$: C 52.40, H 6.23, O 11.63; found: C 52.66, H 6.32, O 11.62.

Isomerization to ketone 13

Crystalline bromoketone **12** (150 mg) was allowed to stand in the air at 20°C for 72 h to give pure **13**. The same transformation was observed in chloroform solution, monitored by ^{1}Hmr spectroscopy. Ketone **13** was crystallized from ether, mp 135–137°C; ir ($CHCl_3$): 1730 and 1710 cm^{-1} (carbonyls); ^{1}Hmr: see Table 2; ms m^+ 272 and 274. *Anal.* calcd. for $C_{12}H_{17}O_2Br$: C 52.40, H 6.23, O 11.63; found: C 52.18, H 6.25, O 11.13.

Reduction to diol 14

Ketone **13** (550 mg, 2 mmol) was reacted with sodium borohydride (228 mg, 6 mmol) in absolute ethanol at 20°C for 30 min. The reaction mixture was then poured into ice-water and extracted three times with ether. The combined ether extracts were washed twice with brine and dried. Evaporation of solvent gave **14** as a colorless oil (545 mg, 98% yield) homogeneous on tlc; ir ($CHCl_3$): 3600 and 3460 (OH) cm^{-1}; ^{1}Hmr: see Table 2; ms m^+ 276 and 278; M^+ calcd. for $C_{12}H_{19}O_2{}^{79}Br - H_2O$: 258.01619; found: 258.0636.

Formation of olefin alcohol 15

Diol **14** (414 mg, 1.5 mmol) was heated under reflux with reagent grade zinc dust (250 mg. 3.75 mmol) in glacial acetic acid (15 mL) for 1 h). The cooled reaction mixture was diluted with ether, residual zinc was filtered and washed with ether. The combined organic layer was evaporated to near dryness, the residue dissolved in ether (30 mL) and washed three times with saturated $NaHCO_3$ solution and twice with brine. Drying and evaporation of solvent gave an oily residue which was chromatographed on silica gel plates. Development with hexane–ether (1:2) gave oily olefin **15** (240 mg, 90% yield); ir ($CHCl_3$): 3605 and 3460 (OH) cm^{-1}; ^{1}Hmr: see Table 2; ms M^+ calcd. for $C_{12}H_{20}O$: 180.1514; found: 180.1519.

Oxidation of olefin alcohol 15 to diketone 8

Alcohol **14** (180 mg, 1 mmol) was oxidized in acetone (20 mL) with Jones' reagent (21) under conditions comparable to those described above for the formation of bromoketone **12**. A similar work-up gave an oil which was chromatographed on silica gel plates. Development with hexane–ether (2:1) gave an oil (170 mg, 95% yield) which was found to be identical with minor adduct **8** in ir, ^{1}Hmr, ms, tlc, and gc.

Conversion of adduct 8 into bromohydrin 16

A solution of adduct **8** (336 mg, 1.9 mmol) in methylene chloride (20 mL) was treated with 50% aqueous sodium hydroxide (5 mL) followed by bromine (1 mL, 15 mmol). The reaction mixture was stirred at 20°C for 2 h, when tlc showed that **8** had been consumed. Water was then added, the methylene chloride layer separated, and the aqueous layer extracted with two 20-mL portions of methylene chloride. The combined organic layer was washed three times with water, three times with brine, and dried. Evaporation of solvent gave an oily residue which on crystallization from ether gave colorless crystals of **16** (478 mg, 92% yield), mp 128–141°C; ir ($CHCl_3$): 3590 (OH) and 1705 (C=O) cm^{-1}; ^{1}Hmr: see Table 2; ms m^+ 274 and 276; M^+ calcd. for $C_{12}H_{19}O_2{}^{79}Br$: 274.05684; found: 274.05683.

*Oxidation of bromohydrin **16** to ketone **13***

Bromohydrin **16** (413 mg, 1.5 mmol) was oxidized in acetone (15 mL) under conditions comparable to those described above for the formation of ketone **12**. A similar work-up gave an oil (415 mg) which was chromatographed on silica gel plates. Development with 30% ether in hexane gave crystalline ketone **13** (400 mg, 98% yield), mp 135–137°C, identical in all respects with the product of isomerization of ketone **12**.

Condensation of trans*-piperylene with 2-cyclohexenone*

The two starting materials were obtained from the Aldrich Chemical Company.

(a) *Thermal*

Equimolar quantities of the two compounds were heated in a sealed tube at 220°C for 48 h in the presence of a few milligrams of hydroquinone. Extraction with $CHCl_3$ was followed by washing with 5% aqueous $NaHCO_3$ and saturated brine. The solution was dried and subjected to distillation. The fraction boiling at 93–105°C/0.2 Torr was analyzed by gc as shown in Table 4.

(b) *Catalytic*
