Potassium *tert*-butoxide (50 g, 0.45 mol) was suspended in anhydrous tetrahydrofuran (THF) (400 mL) containing 18-crown-6 ether (1 g, Aldrich) and to this stirred, refluxing suspension 1-chloro-6-hydroxyhexane (20.4 g, 0.15 mol, Aldrich) in THF (50 mL) was added dropwise over 0.85 h. Reflux was continued for 1 h after addition was complete, the reaction mixture was concentrated, and hexane added. The mixture was washed with water, the aqueous layer extracted with hexane (3 × 50 mL), the combined organic layers dried and filtered, and the product distilled, bp 62–63°C/12 Torr (lit. (19) bp 57–58°C/15 Torr) to give 6-hexenol, 11 g (72%).

To a solution of triphenylphosphine (28.8 g, 0.11 mol) in dry benzene (90 mL), mechanically stirred and cooled in an ice bath, bromine (16.8 g, 0.105 mol) was added dropwise. The resulting suspension of Ph_3PBr_2 was stirred at 22°C (1 h), pyridine (8.7 g, 0.11 mol) added, the stirred mixture recooled to 0°C, and 6-hexenol (10 g, 0.10 mol) in benzene (20 mL) added dropwise. After addition was complete, the ice bath was removed and stirring was continued for a further 5 h at 22°C. Petroleum ether (300 mL) was added, the flask cooled in the freezer to precipitate triphenylphosphine oxide, the mixture filtered, concentrated, and the bromide purified by distillation, bp 73–74°C/58 Torr (lit. (18) bp 47–51°C/16 Torr) to give the bromide, 13.04 g (80%).

5-Bromopentene was prepared in 73% yield from 5-pentenol (Aldrich) by an analogous procedure, bp 74–76°C/160 Torr (lit. (19) bp 127–129°C/770 Torr).

Preparation of olefins ***15–17***

3-(3-Butenyl)-2-methyl-2-cyclopentenone ***(15)***

Enol ether **14** (19, 20) (7.0 g, 0.05 mol) was dissolved in anhydrous ether (200 mL) in a 500-mL three-necked flask containing 2% sodium in lithium alloy (0.8 g) and equipped with a nitrogen inlet tube, condenser, and pressure-equalizing dropping funnel. The flask was immersed in an ultrasonic bath (21) and 4-bromobutene (7.43 g, 0.055 mol, Aldrich), dissolved in anhydrous ether (70 mL), added dropwise to the exothermic reaction. After 3 h the residual alloy was removed by filtration, the ethereal solution washed with 3 *N* hydrochloric acid, saturated aqueous Na_2CO_3, and brine, then dried, filtered, concentrated, and chromatographed (petroleum ether/ether, 10:1) to give **15** (5.1 g, 68%); ir (film): 1685 (C=O), 1630 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 1.61 (3H, s, CH_3C=C), 1.8–2.6 (8H), 4.81 (1H, br s, CH=C), 5.02 (1H, br d, J = 4.5 Hz, CH=C), 5.3–6.0 (1H, m, CH=C). *Exact Mass* calcd. for $C_{10}H_{14}O$: 150.1044; found: 150.1041.

3-(4-Pentenyl)-2-methyl-2-cyclopentenone ***(16)*** was prepared from 5-bromopentene and **14** in similar fashion in 64% yield; ir (KBr): 1698 (C=O), 1645 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 1.61 (3H, s, CH_3C=C), 1.7–2.6 (10H), 4.78 (1H, br s, CH=C), 4.99 (1H, br d, J = 4 Hz, CH=C), 5.3–6.1 (1H, m, CH=C). *Exact Mass* calcd. for $C_{11}H_{16}O$: 164.1201; found: 164.1202.

3-(5-Hexenyl)-2-methyl-2-cyclopentenone ***(17)*** was prepared from 6-bromohexene and **14** as above in 65% yield; ir (film): 1690 (C=O), 1645 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 1.60 (1H, s, CH_3C=C), 1.8–2.7 (10H), 4.80 (1H, br s, CH=C), 5.00 (1H, m, CH=C), 5.35–6.1 (1H, m, CH=C); (400 MHz, $CDCl_3$) δ: 1.45 (2H, m, CH_2), 1.55 (2H, m, J = 6.5 Hz, CH_2), 1.70 (3H, t, J = 1.8 Hz, CH_3—C=C), 2.10 (2H, m, J = 6.5, ~1 Hz, CH_2), 2.39 (2H, m, J = 1.8 Hz, CH_2—C=C), 2.44 (2H, t, J = 6.5 Hz, CH_2—C=C), 2.51 (2H, br s, CH_2—C=O), 4.99 (1H, m, J = 10.5, 2.5, 1Hz, CH=C), 5.04 (1H, m, J = 17.5, 2.5, 1Hz, CH=C), 5.82 (1H, m, J = 17.5, 10.5, 6.5 Hz, CH=C).

3-(1,1-Dimethyl-4-pentenyl)-2-methyl-2-cyclopentenone ***(32)*** was prepared from the lithium derivative of 5-bromo-5-methylhexene (itself obtained by Grignard addition of MeMgCl to 5-hexen-2-one (Aldrich) and treatment with PBr_3) and **14** in 35% yield; ir (film): 1685 (C=O), 1645, 1620 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 1.28 (6H, s, $(CH_3)_2C$), 1.79 (3H, s, CH_3C=C), 4.79 (1H, br s, CH=C), 5.01 (1H, br d, J = 5 Hz, CH=C), 5.3–6.1 (1H, m, CH=C). *Exact Mass* calcd. for $C_{13}H_{20}O$: 192.1514; found: 192.1521.

Preparation of bromides ***18–20, 33***

The appropriate olefin (0.025 mol) was added to a 2.2 *M* solution (40 mL) of HBr in acetic acid to which $ZnBr_2$ (0.5 g) had been added and the reaction mixture stirred in the dark, at 22°C for 15 h. The mixture was poured into ice-water (150 mL), extracted with ether, the ethereal extracts washed with saturated aqueous Na_2CO_3 until basic, then with brine, dried, filtered, concentrated, and chromatographed (petroleum ether/ether, 2:1 → 1:1) to give the bromides **18–20** and **33** in 87%, 93%, 90%, and 88% yield, respectively.

3-(3-Bromobutyl)-2-methyl-2-cyclopentenone ***(18)***, ir (film): 1685 (C=O), 1640 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 1.65 (3H, d, J = 7 Hz, CH_3CH), 1.78 (3H, s, CH_3—C=C), 4.02 (1H, sextet, J = 7 Hz, CHBr). *Exact Mass* calcd. for $C_{10}H_{15}BrO$: 230.0307; found: 230.0299.

3-(5,6-Epoxyhexyl)-2-methyl-2-cyclopentenone (23), ir (film): 1708, 1685 (C=O), 1640 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 1.51 and 1.59 (9H, br s, CH_3C=C and CH_2's), 2–3 (9H, complex). *Exact Mass* calcd. for $C_{12}H_{18}O_2$: 194.1307; found: 194.1311.

Cyclization studies of bromides 18–20, 33

Potassium hydride (0.24 g, 2.1 mol, 35% oil suspension, Aldrich) was suspended in anhydrous dimethoxyethane (DME) under nitrogen, cooled in an ice bath, and stirred magnetically. The appropriate bromide (2 mmol) dissolved in DME (5 mL) was added dropwise and after ~10 min at 0°C the reaction was stirred at 22°C for 1–15 h, diluted with ether, and washed with saturated aqueous ammonium chloride. The aqueous layer was extracted with ether (2×) and the combined ether fractions dried, filtered, concentrated, and chromatographed (petroleum ether/ether 4:1 → 2:1) to give the conjoint ring systems **25** and **27** in yields of 95% and 81%, respectively. The preparation of **26** (60%) required 0.5 h at 0°C and 10 minutes reflux. Bromide **33** afforded **34** (70%) as a 10:1 isomeric mixture accompanied by ~10% elimination to olefins. Isomers were separated by hplc.

3-(2-Methylcyclopropyl)-2-methyl-2-cyclopentenone (25), ir (film): 1735, 1690 (C=O), 1650 (C=C) cm^{-1}; ^1H nmr (80 MHz, $CDCl_3$) δ: 0.80 (1H, m, cyclopropyl H), 1.0–1.35 (5H, br s, cyclopropyl H, CH_3CH), 1.68 (1H, m, cyclopropyl H), 1.75 (3H, t, J = 1.8 Hz, CH_3—C=C), 2.0–2.4 (4H, complex); (400 MHz (*cis*), $CDCl_3$) δ: 0.70 (1H, m, J = 7, 8 Hz, cyclopropyl H), 1.05 (3H, d, J = 7 Hz, CH_3—CH), 1.10 (1H, m, J = 8, 1.5 Hz, cyclopropyl H), 1.38 (1H, m, J = 7, 8 Hz, cyclopropyl $CHCH_3$), 1.81 (3H, t, J = 1.8 Hz, CH_3C=C), 1.85 (1H, m, J = 8 Hz, cyclopropyl CH—C=C), 2.39 (4H, m, O=C—CH_2CH_2—C=C); (400 MHz (*trans*), $CDCl_3$) δ: 0.82 (1H, m, J = 8, 5 Hz, cyclopropyl H), 1.10 (1H, m, J = 8, 5 Hz, cyclopropyl H), 1.22 (3H, d, J = 6 Hz, CH_3CH), 1.30 (1H, m, J = 8, 6, 5 Hz, cyclopropyl $CHCH_3$), 1.75 (1H, m, J = 8, 5 Hz, cyclopropyl CH—C=C), 1.80 (3H, t, J = 1.8 Hz, CH_3—C=C), 2.15 (2H, m, CH_2—C=O), 2.40 (2H, m, CH_2—C=C). *Exact Mass* calcd. for $C_{10}H_{14}O$: 150.1044; found: 150.1044.

3-(2-Ethylcyclobutyl)-2-methyl-2-cyclopentenone (26), ir (film): 1735, 1690 (C=O), 1640 (C=C) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.01 (3H, overlapping d, J = 6.5 Hz, CH_3CH), 1.59 (3H, br s, CH_3C=C), 2.91 (1H, m, J ~ 7 Hz, CH—C=C); (400 MHz, $CDCl_3$) δ: 1.02 (3H, d, J = 6.5 Hz, CH_3CH), 1.61 (3H, t, J = 1.8 Hz, CH_3—C=C), 1.96 (5H, complex, CH_2), 2.30 (2H, m, CH_2—C=C), 2.50 (2H, br s, O=C—CH_2), 3.00 (1H, m, J = 7.5 Hz, allylic CH). *Exact Mass* calcd. for $C_{11}H_{16}O$: 164.1201; found: 164.1204.

3-(2-Methylcyclopentyl)-2-methyl-2-cyclopentenone (27), ir (film): 1695 (C=O), 1640 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 0.80, 0.98 (3H, overlapping d, J = 6.5 Hz, CH_3CH), 1.61 (3H, br s, CH_3C=C), 3.14 (1H, m, J ~ 7, CH—C=C); (400 MHz (*cis*), $CDCl_3$) δ: 0.83 (3H, d, J = 7 Hz, CH_3CH), 1.69 (3H, t, J = 1.8 Hz, CH_3C=C), 2.38 (4H, complex, O=C—CH_2CH_2—C=C), 3.12 (1H, m, J ~ 8 Hz, allylic H); (400 MHz (*trans*), $CDCl_3$) δ: 0.96 (3H, d, J = 6.5 Hz, CH_3CH), 1.33 (1H, m, CH_2), 1.67 (1H, m, CH_2), 1.72 (3H, t, J = 1.8 Hz, CH_3—C=C), 1.74 (1H, m, CH_2), 1.87 (2H, m, CH_2), 1.96 (2H, m, CH_2), 2.40 (2H, m, J ~ 5 Hz, CH_2—C=C), 2.50 (2H, m, O=C—CH_2), 2.58 (1H, m, J = 8.5 Hz, allylic H). *Exact Mass* calcd. for $C_{12}H_{18}O$: 178.1358; found: 178.1362.

2,2,5,9-Tetramethylbicyclo[4.3.0]non-9-en-8-one (34), ir (film): 1700 (C=O), 1625 (C=C) cm^{-1}; ^1H nmr (400 MHz (major), $CDCl_3$) δ: 1.02 (3H, d, J = 6 Hz, CH_3CH), 1.16 (1H, m, CH_2), 1.20 (3H, s, CH_3), 1.41 (3H, s, CH_3), 1.88 (3H, d, J = 1.8 Hz, CH_3—C=C), 1.97 (1H, dd, J = 18.5, 2.5 Hz, O=C—CH_2C), 2.38 (1H, m, J = 11, 4, 2.5, 1.8 Hz, $W_{1/2}$ = 25 Hz, CH—C=), 2.54 (1H, dd, J = 18.5, 6.5 Hz, O=C—CH_2). *Exact Mass* calcd. for $C_{13}H_{20}O$: 192.1514; found: 192.1499; ir (film): 1700 (C=O), 1625 (C=C) cm^{-1}; ^1H nmr (400 MHz (minor)) δ: 0.70 (3H, d, J = 6 Hz, CH_3CH), 1.24 (3H, s, CH_3), 1.36 (1H, m, J = 14, 4 Hz, CH_2), 1.42 (3H, s, CH_3), 1.54 (1H, m, CH_2), 1.75 (1H, m, J = 14, 4 Hz, CH_2), 1.89 (3H, d, J = 1.8 Hz, CH_3—C=C), 1.97 (1H, m, CH_2), 2.14 (1H, m, J = 9.5, 1Hz, O=C—CH_2), 2.20 (1H, m, CH_2), 2.36 (1H, m, J = 19, 7 Hz, O=C—CH_2), 3.06 (1H, m, J = 7, 5, 2.5, 1.8 Hz, $W_{1/2}$ = 17 Hz, CH—C=C). *Exact Mass* calcd. for $C_{13}H_{20}O$: 192.1514; found: 192.1538.

Cyclization studies with lithium diisopropyl amide (LDA) were conducted as follows. LDA was generated at −78°C and the appropriate ketohalide added. The reaction mixture after 5 min at −78°C was allowed to warm to room temperature (22°C) and the progress of the reaction monitored by tlc.

Bromide 20

LDA (1.1 equiv.) in DME or THF gave recovered **20**.

LDA (1.1 equiv.) in DME/HMPA (5:2) afforded ketone **27** (85%).

LDA (2.2. equiv.) in DME caused some elimination (~10%) and gave recovered **20**.

LDA (2.2 equiv.) in DME/HMPA (5:2) gave only elimination products.

Bromide 33

LDA (1.1 equiv.) in DME gave recovered **33**.

LDA (2.2 equiv.) in DME after chromatography (petroleum ether/ether, 5:1) afforded **34** (66%), olefins (4%), and 1,2,5,5-tetramethylbicyclo[4.3.0]non-7-en-9-one (**35**) (30%); ir (film): 1705 (C=O) cm^{-1}; ^1H nmr (CCl_4) δ: 0.82 (6H, overlapping CH_3, CH_3C, CH_3CH), 1.04 (3H, s, CH_3—C), 1.08 (3H, s, CH_3—C), 6.18 (1H, m, C=CH—C=O), 7.38 (1H, m, CH=C—C=O).

Based on the conditions of Johnson and Vajs (6), cyclization of **20** was also examined. The bromide **20** (0.259 g, 1 mmol) in dimethyl sulfoxide (3.75 mL) and water (1.25 mL) containing NaOH (52 mg) was stirred at room temperature under N_2 for 2 h. The reaction mixture was diluted with petroleum ether, extracted, washed with water, dried, filtered, and concentrated to give the conjoint product **27**, 0.180 g (99%) as a 1:1 isomeric mixture.

Cyclization of epoxides 21–23

Potassium hydride (0.24 g, 2.1 mmol, 35% oil suspension, Aldrich) was suspended in anhydrous tetrahydrofuran (THF) under nitrogen, cooled in an ice bath, and stirred magnetically. The appropriate epoxide (2 mmol) dissolved in THF (5 mL) was added dropwise and after 20 min at 0°C the reaction was stirred at 22°C for 15 h, diluted with ether, and washed with saturated aqueous ammonium chloride solution. The aqueous layer was extracted with ether (3×), and the combined ether fractions were dried, filtered, concentrated, and chromatographed (ether/2-propanol, 1:0 → 95:5) to give the cyclized alcohol(s) in 60% yield. A single *trans* isomer was formed in the case of **28**, while **30** and **31** occurred in 1:11 and 19:7 *cis*/*trans* ratios, respectively. No conditions were found for effective cyclization of **22**.

3-[(2-Hydroxymethyl)cyclopropyl]-2-methyl-2-cyclopentenone (28), ir (film): 3300–3500 (br, OH), 1680 (C=O), 1630 (C=C) cm^{-1}; ^1H nmr (80 MHz) ($CDCl_3$) δ: 0.85–1.22 (m, CH_3 and cyclopropyl H), 1.80 (3H, t, J = 1.8 Hz, CH_3—C=C), 3.60 (2H, m, J ~ 6, 2 Hz, CH_2—O); (400 MHz, $CDCl_3$) δ: 1.00 (1H, m, J = 7, 4.5 Hz, cyclopropyl H), 1.14 (1H, m, cyclopropyl H), 1.55 (1H, m, cyclopropyl H), 1.78 (3H, t, J = 1.8 Hz, CH_3—C=C), 1.94 (1H, m, J = 4.5 Hz,

allylic cyclopropyl H), 2.18 (2H, br, O=C—CH_2), 2.33 (2H, m, J ~ 5, 2.5 Hz, CH_2C=C), 3.64 (2H, m, J ~ 6 Hz, CH_2—O). *Exact Mass* calcd. for $C_{10}H_{14}O_2$: 166.0994; found: 166.0991.

3-[(2-Hydroxymethyl)cyclopentyl]-2-methyl-2-cyclopentenone (30) (trans), ir (CCl_4): 3610 (sh, OH), 3410 (br, OH), 1685 (C=O), 1635 (C=C) cm^{-1}; ^1H nmr (80 MHz, $CDCl_3$) δ: 1.70 (3H, t, J = 1.8 Hz, CH_3C=C), 2.2–2.6 (4H, complex, CH_2—C=C), 2.88 (1H, m, CH—C=C), 3.53 (2H, m, J ~ 5.5 Hz, CH_2—O); (400 MHz, $CDCl_3$) δ: 1.62 (2H, m, CH_2), 1.73 (2H, m, CH_2), 1.75 (3H, t, J = 1.8 Hz, CH_3—C=C), 1.96 (2H, m, CH_2), 2.20 (1H, m, J = 8.5 Hz, CH—CH_2OH), 2.42 (2H, m, CH_2—C=C), 2.56 (2H, br, O=C—CH_2), 2.96 (1H, m, J = 8.5, CH—C=C), 3.58 (2H, m, J = 5.5 Hz, CH_2O). *Exact Mass* calcd. for $C_{12}H_{18}O_2$: 194.1307; found: 194.1305; (*cis*), ^1H nmr ($CDCl_3$ 80 MHz) δ: 1.73 (3H, t, J = 1.8 Hz, CH_3—C=C), 2.43 (4H, br m, O=C—CH_2CH_2—C=C), 2.88 (1H, m, CH—C=C), 3.46 (2H, m, J ~ 6 Hz, CH_2—O); (400 MHz, $CDCl_3$) δ: 1.72 (3H, t, J = 1.8 Hz, CH_3—C=C), 2.38 (2H, m, CH_2—C=C), 2.51 (2H, m, O=C—CH_2), 3.28 (1H, m, CH—C=C), 3.56 (2H, m, J = 5.5 Hz, CH_2—O).

3-(3-Hydroxycyclohexyl)-2-methyl-2-cyclopentenone (31) (cis), mp 59–62°C; ir (CCl_4): 3590 (OH), 3400 (br, OH), 1685 (C=O), 1640 (C=C) cm^{-1}; ^1H nmr (80 MHz, $CDCl_3$) δ: 1.69 (3H, t, J = 1.8 Hz, CH_3—C=C), 2.38 (4H, br m, O=C—CH_2CH_2—C=C), 2.75 (1H, m, CH—C=C), 3.69 (1H, m, CH—O); (400 MHz, $CDCl_3$) δ: 1.35 (4H, m, CH_2), 1.63 (1H, m, J = 12, 3 Hz, CH_2), 1.72 (3H, t, J = 1.8 Hz, CH_3—C=C), 1.94 (2H, m, J = 11, 3 Hz, CH_2), 2.08 (1H, d of m, J = 12 Hz, CH_2), 2.39 (2H, m, CH_2—C=C), 2.52 (2H, m, O=C—CH_2), 2.78 (1H, m, J = 12, 3 Hz, CH—C=C), 3.74 (1H, m, J = 11, 3 Hz, CH—O). *Exact Mass* calcd. for $C_{12}H_{18}O_2$: 194.1307; found: 194.1311; (*trans*), mp 87–89°C; ir (CCl_4): 3610 (OH), 3460 (br, OH), 1690 (C=O), 1640 (C=C) cm^{-1}; ^1H nmr (80 MHz) ($CDCl_3$) δ: 1.71 (3H, t, J = 1.8 Hz, CH_3C=C), 2.38 (4H, br m, O=C—CH_2CH_2—C=C), 3.21 (1H, m, CH—C=C), 4.22 (1H, m, CH—O); (400 MHz, $CDCl_3$) δ: 1.41 (2H, m, CH_2), 1.65 (4H, m, CH_2), 1.74 (3H, t, J = 1.8 Hz, CH_3—C=C), 1.85 (2H, m, CH_2), 2.38 (2H, m, J = 4 Hz, CH_2—C=C), 2.50 (2H, br m, O=C—CH_2), 3.24 (1H, m, J = 12, 3 Hz, CH—C=C), 4.28 (1H, m, J = 2.5 Hz, CH—O). *Exact Mass* calcd. for $C_{12}H_{18}O_2$: 194.1307; found: 194.1301.

Preparation of substituted cyclopentenones 27, 36, 37, 38

The procedure was identical to the one outlined above for the preparation of olefins **15–17** from enol ether **14**.

For the preparation of authentic **27**, the requisite bromide (2-methylbromocyclopentane) was synthesized from cyclopentanone by addition of methyl lithium, acid-catalyzed elimination to methylcyclopentene, followed by HBr addition. The sample of **27** prepared in this manner (35%) was a 1:20 *cis/trans* isomeric mixture.

Ketone **36**, bp 45–47°C/0.2 Torr was obtained in 82% using an excess (3 *M*) of bromoethane; ir (film): 1690 (C=O), 1640 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 1.52 (3H, t, J = 7 Hz, CH_3—CH_2), 1.62 (3H, s, CH_3C=C), 2.27 (2H, m, CH_2—C=C), 2.45 (2H, m, CH_2—C=O).

An authentic sample of 3-isopropyl-2-methyl-2-cyclopentenone (**37**) was prepared in 63% yield with an excess (3 *M*) of 2-bromopropane; ir (film): 1690 (C=O), 1640 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 1.15 (6H, d, J = 7 Hz, $(CH_3)_2CH$), 1.60 (3H, s, CH_3—C=C), 2.33 (2H, CH_2—C=C), 2.48 (2H, CH_2—C=O), 3.03 (1H, septet, J = 7 Hz, H—$C(CH_3)_2$).

An authentic sample of 3-*tert*-butyl-2-methyl-2-cyclopentenone **38**, bp 114–122°C/10 Torr was prepared in 53% yield from commercial *tert*-butyllithium; ir (film): 1700 (C=O), 1620 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 1.25 (9H, s, $(CH_3)_3C$), 1.77 (3H, t, J ~ 1.5 Hz, CH_3C=C), 2.20 (2H, m, CH_2—C=C), 2.52 (2H, m, CH_2—C=O). *Exact Mass* calcd. for $C_{10}H_{16}O$: 152.1201; found: 152.1204.

Quenching studies: preparation of silyl enol ethers 39–41

A. *LDA/DME method*

Ketone **36** (0.62 g, 0.5 mmol) in DME (5 mL) was added dropwise to LDA (6.5 mmol) in DME (5 mL) at −78°C followed by rapid addition of a DME (10 mL) solution containing triethylamine (0.7 mL, 5 mmol) and chlorotrimethylsilane (2 mL, 15 mmol). After 20 min at −78°C the reaction mixture was allowed to warm to room temperature (22°C), the solvents removed, and the residue distilled (bp 50–51°C/0.5 Torr) to give the endocyclic enol ethers, 0.78 g (83%), **39** and **40** (~5:1, glc); ir (film): 1645 (C=C), 1140 (C—O) cm^{-1}; ^1H nmr (CCl_4) δ: 0.30 (9H, s, $(CH_3)_3$—Si), 1.11 (3H, t, J = 7 Hz, CH_3—CH_2), 1.77 (3H, s, CH_3—C=C), 2.37 (2H, overlapping q, J = 7 Hz, CH_2—CH_3), 2.72 (2H, m, J ~ 2 Hz, =C—CH_2—C=), 4.98 (major), 5.33 (minor) (1H, m, J ~ 2 Hz, CH=C).

B. *$Me_3SiCl/NEt_3/ZnCl_2$ based on the method of Danishefsky and Kitahara (22)*

Zinc chloride (30 mg) and triethylamine (2.5 g) were dissolved in benzene, and chlorotrimethylsilane (4 mL) and ketone **36** (1.24 g, 10 mmol) added. The reaction was stirred under nitrogen for 15 h at 22°C, diluted with hexane, filtered, concentrated, and distilled to give 1.72 g (66%) of the endocyclic enol ethers **39** and **40** (~4:1, glc).

C. *KH/DME method*

Potassium hydride (0.350 g, 8 mmol, 35% oil dispersion, Aldrich) was washed with petroleum ether to remove the oil and DME (5 mL) added. The resulting stirred suspension was cooled in an ice bath and a DME solution (3 mL) of ketone **36** (0.62 g, 5 mmol) added dropwise, followed by a solution of chlorotrimethylsilane (2 mL, 15 mmol) and triethylamine (0.3 mL, 3 mmol) dissolved in DME (5 mL). After 5 min at 0°C and 0.5 h at 22°C the reaction was concentrated, hexane added, the resulting precipitates removed by filtration, and the product distilled, bp 48–50°C/0.5 Torr, to give **41**, 0.4 g (41%); ^1H nmr (CCl_4) δ: 0.19 (9H, s, $(CH_3)_3$—Si), 1.51 (3H, br s, CH_3—CH=C), 1.64 (3H, br s, CH_3—C=C), 2.32 (4H, m, O=C—CH_2CH_2—C=C), 4.88 (1H, br q, J = 6.5 Hz, CH=C).

D. *Intermolecular alkylation with methyl iodide*

Potassium hydride (0.38 g, 3.3 mmol, 35% oil dispersion, Aldrich) was washed with petroleum ether to remove the oil and DME (10 mL) added. The resulting stirred suspension was cooled to −78°C and a DME solution (3 mL) of ketone **36** (0.372 g, 3 mmol) added dropwise, followed by a solution of methyl iodide (0.43 g, 3 mmol) dissolved in DME (1 mL). The reaction was allowed to warm to 22°C, quenched with saturated aqueous ammonium chloride solution, extracted with ether, dried, concentrated, and chromatographed (petroleum ether/ether, 2:1) to give three fractions: 0.126 g (**36**); 0.072 g (mostly **37**); 0.036 g (**37**, **38**, and probably some 3-ethyl-2,5-dimethyl-2-cyclopentenone). The mixtures were not further resolved by glc but comparison of their ^1H nmr spectra with those of authentic samples established their identity.

Received February 23, 1983[2]

W. KLIEGEL, H.-W. MOTZKUS, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **62**, 838 (1984).

Details of the synthesis, physical properties, and molecular structures of 4,4-dimethyl-2,5,5-triphenyl-1,3-dioxa-4-azonia-2-bora-5-boratacyclopentane, **4**, and 4,4,5,5-tetramethyl-2,2-diphenyl-1,3-dioxa-4-azonia-2-boratacyclopentane, **5**, are reported. Crystals of **4** are triclinic, a = 9.841(2), b = 14.722(3), c = 6.6701(12) Å, α = 86.79(1), β = 102.95(1), γ = 93.89(1)°, Z = 2, space group $P\bar{1}$; and those of **5** are monoclinic, a = 14.9164(12), b = 6.4732(3), c = 18.2248(15) Å, β = 117.263(3)°, Z = 4, space group Cc. Both structures were solved by direct methods and were refined by full-matrix least-squares procedures to final R values of 0.032 and 0.035 for 1456 and 1649 observed reflections, respectively. Molecules of **4** contain non-planar BOBON rings with an unusually long N(sp^3)—B(sp^3) distance of 1.728(3) Å and in **5** there is a long N(sp^3)—C(sp^3) bond of 1.591(3) Å. These structural features are ascribed to steric hindrance.

W. KLIEGEL, H.-W. MOTZKUS, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **62**, 838 (1984).

On rapporte les détails relatifs à la synthèse, aux propriétés physiques et aux structures moléculaires du diméthyl-4,4 triphényl-2,5,5 dioxa-1,3 azonia-4 bora-2 borata-5 cyclopentane (**4**) et du tétraméthyl-4,4,5,5 diphényl-2,2 dioxa-1,3 azonia-4 borata-2 cyclopentane (**5**). Les cristaux de **4** sont tricliniques, a = 9,841(2), b = 14,722(3), c = 6,6701(12) Å, α = 86,79(1), β = 102,95(1), γ = 93,89(1)°, Z = 2, groupe d'espace $P\bar{1}$; ceux de **5** sont monocliniques, a = 14,9164(12), b = 6,4732(3), c = 18,2248(15) Å, β = 117,263(3)°, Z = 4, groupe d'espace Cc. On a résolu les deux structures par des méthodes directes et on les a affinées par la méthode des moindres carrés (matrices complètes) jusqu'à des valeurs finales respectives de R de 0,032 et 0,035 pour 1456 et 1649 réflexions observées. Les molécules de **4** comportent des cycles BOBON qui ne sont pas plans et qui contiennent des liaisons N(sp^3)—B(sp^3) qui sont anormalement longues (1,728(3) Å); dans **5**, il existe une liaison N(sp^3)—C(sp^3) qui est longue (1,591(3) Å). On attribue ces caractéristiques à l'empêchement stérique.

[Traduit par le journal]

Introduction

It is known (1) that *O*-acylation of *N,N*-dialkylhydroxylamines by organoboron compounds leads to *N,N*-dialkylaminoxyboranes. In solution these compounds exist both as monomeric "BON" compounds and as dimeric "BONBON" compounds, depending on steric requirements and the interaction between the N- and B-substituents. The product **2** of the acylation of *N-N*-dimethylhydroxylamine, **1**, with diphenylborinic acid derivatives Ph_2B—X (e.g. X = $OBPh_2$) was trapped by reaction with phenylboronic acid or with acetone. The resulting 1:1 adducts of the "monomeric" form of **2** with phenylboronoxide[3] and with acetone show elemental analyses consistent with the proposed structures **3**–**6**. ^{1}H nmr spectra and reactions with diphenylcarbazone (2) indicate the presence of intact Ph_2B moieties and hydrolysis followed by oxidation of the liberated *N,N*-dimethylhydroxylamine with triphenyltetrazolium chloride (3) indicates the presence of intact N—O bonds in both of the 1:1 adducts.

The phenylboronoxide adduct can be described by the structures **3** or **4**, both of which are consistent with the chemical and spectral data for the isolated material. Both forms contain diphenylborinic acid and phenylboronic acid residues in anhydridic linkage as well as a hydrolytically separable *N,N*-dimethylhydroxylamine moiety. The form **3**, favored on steric grounds, corresponds to the diphenylboron chelates of *N,N*-dimethylhydroxylamine–aldehyde adducts (4), the structure of this type of compound having been confirmed by the X-ray crystallographic analysis of the representative example **8** (5). The alternate form **4** resembles the diphenylborinates of amino-alcohols, for which intramolecular N→B coordination has been established by X-ray analyses of a number of examples (6–9), as well as comparable oxime derivatives such as **7** which also contain N→B coordinative bonds (10). The mass spectrum of the phenylboronoxide adduct, which shows a molecular ion of low intensity, does not unambiguously indicate either **3** or **4**. Prominent fragments such as $(M - Ph)^+$, $(M - PhBO)^+$, or $(M - Ph_2BO)^+$ are consistent with either form. An X-ray crystallographic study was undertaken in order to resolve this ambiguity.

A very similar problem arises with the acetone adduct, for which the two alternative structures **5** and **6** come into question. An identical compound was also isolated during an attempted recrystallization of **3**/**4** from acetone. Structure **5** is analogous to the well established (5) diphenylboron chelate type **8**. The form **6** can otherwise be regarded as a carba-analog of **4**, considering the exchange of the boronate ester group for the acetal group. However, the similarity of the components in the synthesis of **8** and in that of the acetone derivative supports the

[1]Previous paper in this series: ref. 9.

[2]Revision received November 4, 1983.

[3]The anhydride of phenylboronic acid ("phenylboronoxide") exists only as a trimeric triphenylboroxin, $(PhBO)_3$, under normal conditions.

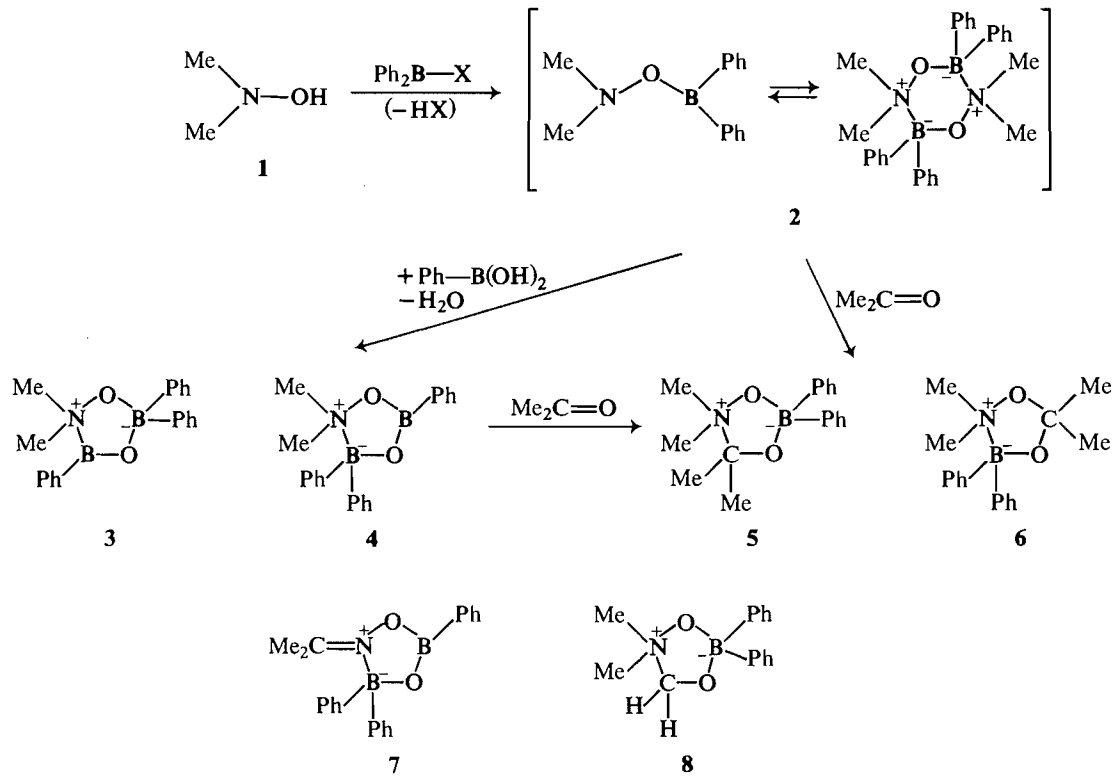
For personal use only.



chelate structure **5**.

For both ring systems, **5** and **6**, a considerable steric strain can be expected to influence the stability of the compound. The mass spectrum does not register a peak corresponding to the molecular ion. Typical fragments are $(M - Me_2CO)^+$, $(M - Me_2CO - O)^+$, $(Ph_2BO)^+$, and $(Ph_2B)^+$. An x-ray crystallographic analysis of this compound was undertaken in order to verify the structure **5** and to assess the structural differences between this compound and the more stable derivative **8**.

Experimental

4,4-Dimethyl-2,5,5-triphenyl-1,3-dioxa-4-azonia-2-bora-5-boratacyclopentane, 4

Method A

To a solution of *N,N*-dimethylhydroxylamine hydrochloride (0.49 g, 5 mmol) in 1 *M* NaOH (5 mL), oxybis(diphenylborane) (0.87 g, 2.5 mmol) was added. After shaking this mixture with chloroform (30 mL), the organic phase was separated and the chloroform removed *in vacuo*. The remaining oil was dissolved in ethanol (10 mL). After dissolving phenylboronic acid (0.61 g, 5 mmol) in this solution, crystallization of a white substance began at room temperature. The product was recrystallized from ethanol. Yield: 1.29 g (78%). Mp 103°C.

Method B

N,N-Dimethylhydroxylamine hydrochloride (0.49 g, 5 mmol), oxybis(diphenylborane) (0.87 g, 2.5 mmol), and phenylboronic acid (0.61 g, 5 mmol) were disolved in ethanol (10 mL). This solution was then carefully underlayed with 1 *M* NaOH (5 mL), avoiding mixture. At the interface between the two layers, white crystals began to grow at room temperature which were analytically pure after washing with ethanol. Yield: 1.09 g (65%). This substance is shown to be identical to that synthesized by method A by mp and ir spectrum.

Anal. calcd. for $C_{20}H_{21}B_2NO_2$ (fw = 329.0): C 73.01, H 6.43, B 6.57, N 4.26; found: C 72.62, H 6.43, B 6.24, N 4.60. ^{1}H nmr (90 MHz, $CDCl_3$/TMS): δ(ppm) = 2.76 (s, NMe_2), 7.1–8.1 (m, BPh_2, BPh). Mass spectrum (70 eV): *m/e* (% relative intensity) = 329(3, M^+), 312(3, $[PhBO]_3$), 284(4), 268(1), 252(100, M − Ph), 237(1), 225(3, M − PhBO), 209(7, M − $PhBO_2$), 181(12, Ph_2BO), 174(15), 165(68, Ph_2B), 154(54), 148(60, M − Ph_2BO), 132(34), 113(12), 105(51, PhBOH), 91(39), 77(49), 70(20), 58(22), 53(42), 44(49).

The substance gives a positive blue color reaction with diphenylcarbazone (2) in methanolic solution. An ethanolic solution of the substance and crystals of triphenyltetrazolium chloride gives a deep red color reaction upon addition of aqueous NaOH (3). Crystals suitable for X-ray analysis were obtained according to method B.

4,4,5,5-Tetramethyl-2,2-diphenyl-1,3-dioxa-4-azonia-2-boratacyclopentane, 5

Oxybis(diphenylborane) (0.87 g, 2.5 mmol) and *N,N*-dimethylhydroxylamine hydrochloride (0.49 g, 5 mmol) were suspended in acetone (15 mL). After the addition of 1 *M* NaOH (5 mL) white crystals began to precipitate at room temperature. The substance was recrystallized from acetone. Yield: 1.33 g (94%). Mp 142–143°C.

Anal. calcd. for $C_{17}H_{22}BNO_2$ (fw = 283.2): C 72.11, H 7.83, N 4.95; found: C 71.85, H 7.86, N 4.94. ^{1}H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 2.17 (s, CMe_2), 2.62 and 2.82 (s, 5H and s, 1H, NMe_2), 7.2–7.9 (m, BPh_2). Mass spectrum (70 eV): *m/e* (relative intensity) = 312(5, $[PhBO]_3$), 252(96, M − Me_2CO), 209(11, M − Me_2CO − O), 195(3), 185(45, Ph_2BO), 165(100, Ph_2B), 154(4), 148(56, M − Me_2CO − Ph), 137(34), 132(45, M − Me_2CO − O − Ph), 121(64), 113(33), 105(43, PhBOH), 91(39), 77(68), 58(32), 51(45), 43(52).

The substance gives a positive blue color reaction with diphenylcarbazone and a red color reaction with triphenyltetrazolium chloride similar to compound **4**. Compound **5** was also obtained by recrystallization of **4** from acetone. Crystals of **5** suitable for X-ray analysis were obtained by recrystallization from acetone.

X-ray crystallographic analyses

4,4-Dimethyl-2,5,5-triphenyl-1,3-dioxa-4-azonia-2-bora-5-boratacyclopentane, 4

A crystal bounded by the six faces (followed by their distances in mm from a common origin): ±(1 0 0), 0.050, ±(0 1 0), 0.131, ±(0 1 2), 0.213 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25

reflections ($2\theta = 30-40°$) measured on a diffractometer with Mo-Kα Radiation ($\lambda(K\alpha_1) = 0.70930$, $\lambda(K\alpha_2) = 0.71359$ Å). Crystal data at 22°C are:

$C_{20}H_{21}B_2NO_2$ fw = 329.0

Triclinic, $a = 9.841(2)$, $b = 14.722(3)$, $c = 6.6701(12)$ Å, $\alpha = 86.79(1)$, $\beta = 102.95(1)$, $\gamma = 93.89(1)°$, $V = 938.8(3)$ Å^3, $Z = 2$, $\rho_c = 1.164$ g cm^{-3}, $F(000) = 348$, μ(Mo-Kα) = 0.68 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ (C_i^1, No. 2) from structure analysis.

Intensities were measured with graphite-monochromated Mo-Kα radiation on an Enraf-Nonius CAD4-F diffractometer. An $\omega-2\theta$ scan at 1.06–10.06° min^{-1} over a range of $(0.65 + 0.35 \tan\theta)$ degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to $2\theta = 51°$. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 3%.

Of the 3474 independent reflections measured and processed,[4] 1456 (42%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count. The structure was solved by direct methods, the positions of all non-hydrogen atoms being determined from an E-map. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to $R = 0.084$, all 21 hydrogen atoms were positioned from a difference map and were subsequently included in the refinement with isotropic thermal parameters. The scattering factors of ref. 11 were used for non-hydrogen atoms and those of ref. 12 for hydrogen atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of refinement. Unobserved reflections were not included in the refinement. Convergence was reached at $R = 0.032$ and $R_w = 0.036$ for 1456 reflections with $I \geq 3\sigma(I)$. For all 3474 reflections $R = 0.130$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.07 and 0.51σ, respectively. The mean error in an observation of unit weight was 1.630. A final difference map showed no unusual features. The final positional and thermal parameters appear in Tables 1 and 2[5] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[5]

4,4,5,5-Tetramethyl-2,2-diphenyl-1,3-dioxa-4-azonia-2-boratacyclopentane, ***5***

Experimental details are as above except where noted. The crystal employed for data collection was bounded by the 10 faces (followed by their distances in mm from a common origin): ±(1 1 0), 0.213, ±(1 0 −1), 0.188, ±(1 −1 0), 0.250, ±(0 0 1), 0.325, (−1 0 0), 0.250, and (−1 −1 1), 0.238. Crystal data are as follows:

$C_{17}H_{22}BNO_2$ fw = 283.2

Monoclinic, $a = 14.9164(12)$, $b = 6.4732(3)$, $c = 18.2248(15)$ Å, $\beta = 117.263(3)°$, $V = 1564.2(2)$ Å^3, $Z = 4$, $\rho_c = 1.202$ g cm^{-3}, $F(000) = 608$, μ(Mo-Kα) = 0.74 cm^{-1}. Absent reflections: hkl, $h + k$ odd, and $h0l$, l odd, space group Cc (C_s^4, No. 9) assumed on the basis of the number of molecules in the unit cell.

An $\omega-2\theta$ scan at 1.68–10.06° min^{-1} over a range of $(0.85 + 0.35 \tan\theta)°$ in ω was employed. Of 2261 independent reflections measured (to $2\theta = 60°$), 1649 (73%) had intensities greater than $3\sigma(I)$ above background. The intensities of the check reflections remained constant to within 2%.

The structure was solved by direct methods, all non-hydrogen atoms being located from an E-map. After refinement of the non-hydrogen atoms with anisotropic thermal parameters to $R = 0.065$, all 22 hydrogen atoms were positioned from a difference map and were refined with isotropic thermal parameters in subsequent least-squares cycles. Convergence was reached at $R = 0.035$ and $R_w = 0.041$ for 1649 observed reflections, for all 2261 reflections $R = 0.053$. The mean and maximum parameter shifts on the final cycle of refinement corresponded to 0.08 and 0.70σ, respectively, the maximum shift being associated with the y coordinate of H(3c). The mean error in an observation of unit weight was 1.846.

Analysis of thermal motion

The thermal motion in both structures (Figs. 1 and 2) has been analysed in terms of the rigid-body modes of translation, libration, and screw-motion (13). The rms errors in the U_{ij} (derived from the least-squares analyses) are 0.0009 and 0.0012 Å^2 for **4** and **5** respectively. In each case analysis of the entire molecule indicated significant independent motion of various fragments which were separately analysed (rms $\Delta U_{ij} = 0.0007-0.0038$ Å^2). The appropriate bond distances have been corrected for libration (13, 14), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 4. Intra-annular torsion angles defining the conformations of chelate rings are listed in Table 5. Bond lengths and angles involving hydrogen and a complete listing of torsion angles (Tables 6–8) are included as supplementary material.

Results and discussion

The X-ray analyses show that the "phenylboronoxide" and acetone adducts of **2** have the structures **4** and **5**, respectively. The crystal structure of **4** consists of discrete molecules separated by normal van der Waals distances, and that of **5** consists of molecules each linked to two others (related by translations along b) by weak C—H···O interactions (C(16)—H(16b) ···O(1) (x, 1 + y, z), H···O = 2.46(4), C···O = 3.411(4) Å, C—H···O = 159(2)°).

The five-membered BOBON ring in **4**, unlike the essentially planar analogs in **7** (10) and **9** (15), is significantly non-planar and has a distorted B(2)–envelope conformation (see Table 5). The phenyl ring bonded to the trigonal planar boron atom is twisted out of the B(1) coordination plane by 7.1°, this value being similar to those observed for other derivatives of phenylboronic acid (10, and references therein). The non-planarity of the five-membered heterocycle results from steric interactions between the adjacent Ph_2B and Me_2N moieties, which would be in an eclipsed conformation with respect to the N—B bond if the ring were planar. The strain is also relieved by a considerable lengthening of the N—B bond to 1.728(3) Å,[6] compared with a mean[7] value of 1.654(1) Å for compounds **10** (R = H) (6–8), 1.630(3) Å in L-prolinatodiphenylboron **11** (16),

[4]The computer programs used include locally written programs for data processing and locally modified versions of the following: MULTAN 80, multisolution program by P. Main, S. J. Fiske, S. E. Hull, L. Lessinger, G. Germain, J. P. Declercq, and M. M. Woolfson; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin and H. A. Levy; FORDAP, Patterson and Fourier synthesis, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

[5]The structure factor table, Table 2 (anisotropic thermal parameters) and other material mentioned in the text are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[6]Libration-corrected bond lengths (esd's assumed equal to those of the uncorrected values) are employed throughout the discussion. All distances compared to those reported here have been similarly treated except those for compound **12**, the structure of which was determined at 87 K.

[7]Here and elsewhere in this report mean values refer to weighted means with rms deviations from the mean in parentheses.

TABLE 1. Final positional (fractional) and isotropic thermal parameters ($U \times 10^3$ Å^2) with estimated standard deviations in parentheses

1.635(3) in **12** (17), 1.676(4) Å in the closely related azomethene derivative **7** (10), 1.692(2) Å in the pyroboronate complex **9** (15), and 1.691(2) Å for the sterically hindered bond in **10** (Ar = Ph, R = Me) (9). It was noted previously (10) that despite significant differences between corresponding bond lengths, the sums of bond lengths in the planar BOBON rings of **7** and **9** are identical. In **4** those bonds in the stable —B—O—B(Ph)O— moiety are equal in length (within experimental error) to those in **7**, while both bonds involving nitrogen are significantly longer than those in **7** and **9**. As in **7** and **9**, there is the characteristic short anhydridic O—B(sp^2) bond (1.340(3) Å), indicative of a strong π-interaction. The mean B(sp^3)—C and B(sp^2)—C distances (1.605(11) and 1.553(4) Å) are normal and essentially equal to those in **7**

(1.603(1) and 1.548(5) Å).

The five-membered BOCNO ring in **5** has a distorted C(1)—envelope conformation in which both O(1) and B lie on the same side of the NCO(2) plane. In **8** the corresponding ring has a distorted O(1)—envelope conformation with C(1) and N on the same side of the OBO plane. The conformational change allows for partial staggering of the methyl groups about the C(1)—N bond, analogous to the situation in **4**. The C(1)—N bond is lengthened to 1.591(3) Å as a result of the steric hindrance, the corresponding distance in **8** being 1.505(10) Å. This increase in the C(1)—N distance is compensated by a shortening of the B—O(2) bond from 1.556(8) Å in **8** to 1.534(3) Å in **5**, the remaining bond lengths in the five-membered heterocyclic rings of **5** and **8** being equal within experimental error. The N(sp^3)—Me bond lengths in both **5** and **8** assume normal values of about 1.50 Å. The bond angles in the five-membered ring also show evidence of the steric strain; the angles at N, C(1), and O(1) being 102.12(15),

Received May 4, 1983[2]

W. KLIEGEL, D. NANNINGA, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **62**, 845 (1984).

The title compound was prepared by the reaction of 8-methyl-6,6-diphenyl-5,7-dioxa-8-azonia-6-borata-6,7-dihydro-5*H*-benzocycloheptene (**1**) with phenylboronic acid. Crystals of 3*a*-methyl-2,4,9*a*-triphenyl-1,2,3*a*,4,9,9*a*-hexahydro-1,3,9-trioxa-3*a*-azonia-2-bora-9*a*-boratacyclopenta[*b*]naphthalene are monoclinic, a = 11.8548(4), b = 22.7837(4), c = 8.5457(3) Å, β = 106.952(2)°, Z = 4, space group $P2_1/n$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to R = 0.040 and R_w = 0.047 for 2970 reflections with $I \geq 3\sigma(I)$. The molecule was found to be a formal addition product between **1** and PhBO which had undergone a 1,4-shift of a phenyl group from boron to carbon. The backbone of the molecule consists of a folded system of three fused rings. The structure contains the longest known B(sp^3)—N(sp^3) bond, 1.759(2) Å.

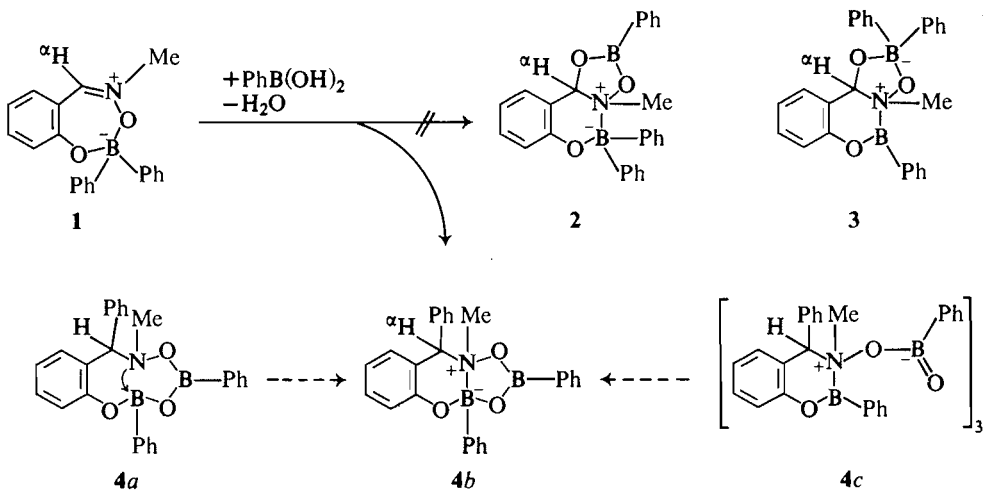
W. KLIEGEL, D. NANNINGA, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **62**, 845 (1984).

On a préparé le composé mentionné dans le titre en faisant réagir de l'acide phénylboronique avec le méthyl-8 diphényl-6,6 dioxa-5,7 azonia-8 borata-6 dihydro-6,7 5*H*-benzocycloheptène (**1**). Les cristaux du méthyl-3*a* triphényl-2,4,9*a* hexahydro-1,2,3*a*,4,9,9*a* trioxa-1,3,9 azonia-3*a* bora-2 borata-9*a* cyclopenta[*b*]naphtalène sont monocliniques, a = 11,8548(4), b = 22,7837(4), c = 8,5457(3) Å, β = 106,952(2)°, Z = 4, groupe d'espace $P2_1/n$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrices complètes) jusqu'à des valeurs de R = 0,040 et R_w = 0,047 pour 2970 réflexions avec $I \geq 3\sigma(I)$. On a trouvé que la molécule est le produit d'addition formelle entre **1** et PhBO qui a subi une transposition 1,4 du groupement phényle du bore au carbone. La base de la molécule comporte un système replié de trois cycles condensés. La structure comporte la liaison $B(sp^3)$—N(sp^3) la plus longue connue, 1,759(2) Å.

[Traduit par le journal]

Introduction

By heating the diphenylboron chelate **1** of *N*-methylsalicylaldonitrone (1) (which contains a seven-membered chelate ring) with $PhB(OH)_2$ in refluxing benzene with the continuous removal of water, a crystalline reaction product is formed. The elemental composition of this product corresponds to an addition compound of **1** + PhBO. Infrared and ^{1}H nmr data indicate the loss of the nitrone function of **1**. The characteristic C=N$^+$ absorption of **1** at 1650 cm^{-1} (1) disappears after the addition of PhBO, and the low-field resonance signal of the proton ($^\alpha$H) identifying the nitrone group (δ ~ 8 ppm) is shifted to higher field by more than 2 ppm. At first sight this indicates a 1:1 adduct of "phenylboronoxide" (Ph—B=O) to **1** which could have the structure **2** as a result of a 1,3-dipolar cycloaddition of "phenylboronoxide" to the nitrone group of **1**, or the isomeric structure **3**.[3] The five-membered BONCO ring structure of **3**



[1]Previous paper in this series: ref. 3.

[2]Revision received November 3, 1983.

[3]The anhydride of phenylboronic acid ('phenylboronoxide') exists only as a trimeric triphenylboroxine, $(PhBO)_3$, under normal conditions.

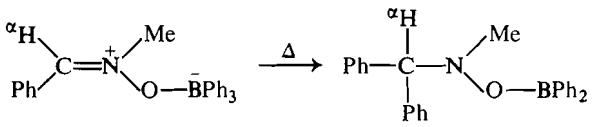
4d **4e** **4f**

resembles the well-known (2, 3) BONCO ring systems of similar cyclic B,N-betaines. However, after careful purification of the adduct by repeated recrystallizations, a negative color reaction with diphenylcarbazone (4) precluded the presence of an intact diphenylboron moiety in this new compound.

It is known (5, 6) that triphenylborane adducts of nitrones undergo thermal rearrangement during which one of the phenyl groups shifts from boron to the alkylidene carbon atom of the nitrone function. This 1,4-shift results in the formation of phenylalkylaminoxydiphenylboranes (cf. **5** → **6**). If this type



5 **6**

of rearrangement were to occur in the case of the diphenylboron chelate **1**, the alternate structures **4***a*–*f* could arise from thermal rearrangement during the insertion of a PhBO moiety. Comparison of the ^{1}H nmr data of **5** and **6** (5) with those of **1** (1) and the addition/rearrangement compound **4** shows parallels in the upfield shifts of the H and CH_3 proton resonance signals, demonstrating the transformation of the $^{\alpha}HC{=}NCH_3$ moiety into an $^{\alpha}HC{-}NCH_3$ grouping (see Table 1).

The bicyclic structures **4***a* and **4***d* can be excluded *a priori* on the basis of unfavorable ring sizes as well as the potential for transannular coordinative bonding. The adducts **4***c* and **4***f* should exist only in trimeric forms (as boroxine derivatives),[4] but could also undergo intramolecular coordination to produce **4***b* and **4***e*, respectively. Since chemical methods did not allow an unambiguous structure assignment, an X-ray crystallographic analysis has been undertaken in order to determine which of the isomeric structures, especially **4***b* or **4***e*, represents that of the adduct.

Experimental

3a-Methyl-2,4-9a-triphenyl-1,2,3a,4,9,9a-hexahydro-1,3,9-trioxa-3a-azonia-2-bora-9a-boratacyclopenta[b]naphthalene, **4***b*

8-Methyl-6,6-diphenyl-5,7-dioxa-8-azonia-6-borata-6,7-dihydro-5*H*-benzocycloheptene, **1**, prepared as described previously (1) (0.63 g, 2 mmol) and phenylboronic acid (0.25 g, 2 mmol) were heated in refluxing benzene, using a Dean-Stark trap for the continuous removal of water. The solution was refluxed for 14 h and then cooled. Upon the addition of petroleum ether, 0.82 g (92% yield) of colorless crystals precipitated and were subsequently recrystallized from dioxane/hexane or from cyclohexane, mp 192°C. *Anal.* calcd. for $C_{26}H_{23}B_2NO_3$ (fw 419.0): C 74.51, H 5.53, B 5.16, N 3.34; found: C 74.17, H 5.49, B 5.41, N 3.34. ^{1}H nmr ($CDCl_3$/TMS): δ (ppm) = 2.36 (s, CH_3), 6.63–8.0 (m, 3 C_6H_5, C_6H_4).

[4]An example of Lewis-base adducts to boroxines is the crystalline addition compound of three equivalents of *N*-methylbenzaldonitrone and one equivalent of triphenylboroxine which dissociates in solution upon warming (7).

X-ray crystallographic analysis

A crystal bounded by the six faces (followed by their distance in mm from a common origin): ±(1 1 0), 0.100, ±(1 −1 0), 0.096, ±(1 1 −1), 0.150 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 80–101°) measured on a diffractometer with Cu-Kα Radiation (λ(Kα$_1$) = 1.54056, λ(Kα$_2$) = 1.54439 Å). Crystal data at 22°C are:

$C_{26}H_{23}B_2NO_3$ fw = 419.10

Monoclinic, a = 11.8548(4), b = 22.7837(4), c = 8.5457(3) Å, β = 106.952(2)°, V = 2207.9(1) Å^3, Z = 4, ρ_c = 1.261 g cm^{-3}, F(000) = 880, μ(Cu-Kα) = 6.02 cm^{-1}. Absent reflections: $h0l$, $h + l$ odd, and $0k0$, k odd uniquely indicate the space group $P2_1/n$ [non-standard setting of $P2_1/c$, C_{2h}^5, No. 14, equivalent positions: ±(x, y, z; 1/2 − x, 1/2 + y, 1/2 − z)].

Intensities were measured with graphite-monochromated Cu −Kα radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 0.86–10.06° min^{-1} over a range of (0.80 + 0.15 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 150°. The intensities of three check reflections, measured every 3600 s throughout the data collection, showed only small random fluctuations. After data reduction,[5] an absorption correction was applied using the Gaussian integration method (8, 9). Transmission factors ranged from 0.820 to 0.920 for 96 integration points. Of the 4557 independent reflections measured, 2970 (65.2%) had intensities greater than 3σ(I) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The structure was initially solved and refined using a data set collected with Mo radiation (1681 observed data from 5043 independent reflections to 2θ = 55°). The structure was solved by direct methods, the coordinates of all non-hydrogen atoms being determined from an E-map. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to R = 0.076, all 23 hydrogen atoms were located from a difference map and were

[5]The computer programs used include locally written programs for data processing and locally modified versions of the following: MULTAN 80, multisolution program by P. Main, S. J. Fiske, S. E. Hull, L. Lessinger, G. Germain, J. P. Declercq, and M. M. Woolfson; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

refined with isotropic thermal parameters in subsequent least-squares cycles. The structure was refined to $R = 0.032$ and $R_w = 0.033$ for 1681 reflections. In order to improve the data/parameter ratio a second set of data was collected using a different crystal and Cu radiation (see above). The refinement was continued employing the more extensive data set. The scattering factors of ref. 10 were used for non-hydrogen atoms and those of ref. 11 for hydrogen atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of refinement. Unobserved reflections were not included in the refinement. Convergence was reached at $R = 0.040$ and $R_w = 0.047$ for 2970 reflections with $I \geq 3\sigma(I)$. For all 4557 reflections $R = 0.085$. The function minimized was $\sum w(|F_o| - |F_c|)^2$, $R = \sum||F_o| - |F_c||/\sum|F_o|$ and $R_w = (\sum w(|F_o| - |F_c|)^2/\sum w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.02 and 0.33σ, respectively. The mean error in an observation of unit weight was 2.073. A final difference map was essentially featureless, the largest fluctuations being -0.24 and $+0.14$ e Å^{-3}.

The esd's of the refined parameters for the Cu data were found to be generally about 1/3 less than those for the Mo data set. The results presented below are thus based on the refinement employing the data set collected with Cu radiation. A half-normal probability plot for the atomic coordinates of all atoms derived from the two refinements has been deposited.[6] This plot shows a unit slope and zero intercept, indicating correctly estimated standard deviations and an absence of systematic errors for both analyses. There are no statistically significant deviations between corresponding derived parameters (i.e. bond lengths, angles, etc.) for the two refinements of the structure. The final positional and thermal parameters appear in Tables 2 and 3 respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[6]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (12). The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0010 Å^2. Analysis of all 32 non-hydrogen atoms indicated significant independent motion of segments of the molecule. Five smaller groups were separately anaysed: C(7)Ph, B(1)Ph, B(2)Ph, O(1)C(1−7), and the 10-atom group consisting of the two heterocyclic rings plus C(8) (rms ΔU_{ij} = 0.0015, 0.0012, 0.0017, 0.0015, and 0.0029 Å^2, respectively). The appropriate bond distances have been corrected for libration (12, 13), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 4 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 5. Intra-annular torsion angles defining the conformations of five- and six-membered heterocyclic rings are listed in Table 6. Bond lengths and angles involving hydrogen and a complete listing of torsion angles (Tables 7−9) are included as supplementary material.

Results and discussion

The X-ray analysis shows that the addition product has the structure **4***b*. The 1,4-shift of the phenyl group from boron to carbon, similar to that noted for 1:1 triphenylborane−nitrone adducts (5, 6), is confirmed. The crystal structure of **4***b* consists of discrete molecules separated by normal van der Waals distances.

The backbone of the molecule consists of a system of three fused rings; the central six-membered C_3OBN ring has a distorted boat conformation (see Table 6). The five-membered heterocycle is *cis*-fused to the central ring at adjacent pseudo-equatorial positions, resulting in a marked folding of the fused-ring system, the angle between normals to the mean planes of the terminal rings being 71.9(2)°.

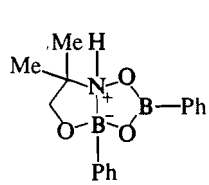
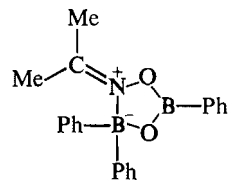
C(9)—C(14)	1.395(2)	1.402			

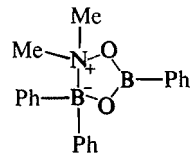
The five-membered BOBON ring in **4***b* is significantly non-planar, having a flattened B(1)-envelope conformation. In the less sterically demanding molecules **7** (14) and **8** (3), the analogous rings are essentially planar while that in the monocyclic compound **9** (15) is markedly non-planar. Steric interactions between the B-phenyl and N-methyl groups of **9** are minimized by a combination of torsional twisting about the B—N bond (O—B—N—O = 24.4(2)°) and lengthening of that bond to 1.728(3) Å, longer than any previously reported B(sp^3)—N(sp^3) distance (ref. 15, and references therein). Torsional freedom about the B—N bond in **4***b* is constrained by the occurrence of this bond at the junction of two rings (O—B—N—O = 9.0(2)°). The presence of the N-methyl group limits the possible orientations of the C(7)- and B(1)-phenyl rings, which interact sterically with O(2) and O(3) of the BOBON ring, respectively (O(2)···C(14) = 2.910(2) and O(3)···C(16) = 2.898(2) Å). The strain in **4***b* is thus relieved by an even greater lengthening of the B—N bond (to 1.759(2) Å) than that observed in **9**, as well as a significant increase in the N—C(7) distance (to 1.529(2) Å from the expected value of 1.48 Å). Other distances in the five-membered ring, including the characteristic short anhydridic B(sp^2)—O bond length of 1.334(2) Å, are similar to those in **7**, **8**, and **9**. The bond lengths involving the tetrahedrally coordinated boron atom, with the exception of the B—N distance discussed above, are essentially the same as the corresponding distances in **7** (14).



7



8



9

The trigonally coordinated boron atom B(2) is displaced 0.024(2) Å from the plane of its substituents. The phenyl ring bonded to B(2) is twisted out of the B(2) coordination plane by 19.1°, this value being in the range normally observed for derivatives of phenylboronic acid (refs. 3, 15, and references

therein). The C(1)—C(6), C(9)—C(14), and C(21)—C(26) rings are slightly, but significantly, non-planar (χ^2 = 158.0, 58.7, and 42.8; maximum deviations 0.012(2), 0.009(2), and 0.012(3) Å, respectively); C(15)—C(20) ring is planar within experimental error. The atom C(7) is considerably displaced (0.223(2) Å) from the C(1)—C(6) mean plane. The substituent induced geometrical distortions of the phenyl rings are as expected (16).

Received August 4, 1983

MASOOD A. KHAN, N. KUMAR, and DENNIS G. TUCK. Can. J. Chem. **62**, 850 (1984).

The title compound was prepared by the addition of 2,2′bipyridine (bpy) to an electrochemically prepared solution of thorium(IV) nitrate in tri-*n*-butyl phosphate. The structure has been established by a complete three-dimensional X-ray diffraction study. The compound crystallises in the space group $P\bar{1}$, with a = 9.300(2) Å, b = 14.161(3) Å, c = 17.037(4) Å, α = 108.79(2)°, β = 95.77(2)°, γ = 102.88(2)°, V = 2034(1) Å^3. Diffraction intensities were collected with a Syntex $P2_1$ automated diffractometer using MoKα radiation. The structure was solved by the heavy atom method and refined by block-matrix least-squares calculations to the final discrepancy indices R_F = 0.029 and R_{WF} = 0.031 for 5783 observed reflections ($2\theta_{max}$ = 50°). The structure of the $[Th(NO_3)_6]^{2-}$ anion is described as a nonsymmetric distorted icosahedron in which symmetric bidentate nitrato ligands occupy all the available sites. Three $bpyH^+$ cations are hydrogen-bonded to a nitrate ion to form the unusual $[(bpyH)_3NO_3]^{2+}$ cation.

MASOOD A. KHAN, N. KUMAR et DENNIS G. TUCK. Can. J. Chem. **62**, 850 (1984).

On a préparé le composé mentionné dans le titre en ajoutant de la bipyridine-2,2′ (bpy) à une solution de nitrate de thorium(IV) dans du phosphate de tri-*n*-butyle qui a été préparée électrochimiquement. On a établi la structure par une étude tridimensionnelle complète effectuée grâce à la diffraction des rayons-X. Le composé cristallise dans le groupe d'espace $P\bar{1}$ avec a = 9,300(2), b = 14,161(3), c = 17,037 Å, α = 108,79(2), β = 95,77(2), γ = 102,88(2)°, V = 2034(1) Å^3. On a mesuré les intensités à l'aide d'un diffractomètre automatique Syntex $P2_1$ en utilisant la radiation MoKα. On a résolu la structure par la méthode de l'atome lourd et on l'a affinée par la méthode des moindres carrés (matrices diagonales) jusqu'à des valeurs de R_F = 0,029 et R_{WF} = 0,031 pour 5783 réflexions observées ($2\theta_{max}$ = 50°). On peut décrire la structure de l'anion $[Th(NO_3)_6]^{2-}$ comme étant celle d'un eicosaèdre déformé et non symétrique dans lequel les ligands nitrato bidentates symétriques occupent tous les sites disponibles. Les trois cations $bpyH^+$ sont liés par des ponts hydrogènes avec une ion nitrate et ils forment un cation inhabituel de $[(bpyH)_3NO_3]^{2+}$.

[Traduit par le journal]

Introduction

Nitrato complexes of actinide elements play an important role in the separation chemistry of these elements, and the literature contains a number of reports of synthetic studies (1). There is less information on the detailed stereochemistry of these interesting compounds, in which the matter of unusually high coordination numbers is of importance. In the course of studies of the electrochemical synthesis of thorium complexes by the oxidation of the metal in non-aqueous media (2, 3), we obtained the unusual title compound, whose crystal structure has now been established by X-ray diffraction crystallography. The lattice consists of $[Th(NO_3)_6]^{2-}$ anions and monopositive 2,2′-bipyridinium cations, which are hydrogen bonded to an uncomplexed nitrate ion to give the unusual $[(bpyH)_3NO_3]^{2+}$ unit.

There have been three previous reports (4–6) of structural determinations involving the $[Th(NO_3)_6]^{2-}$ anion, and we discuss the details of these below. The analogous hexanitratocerate(IV) anion has also been studied (7), as has thorium(IV) nitrate pentahydrate, for which both X-ray (8) and neutron diffraction (9) results are available.

Experimental

Preparative

The electrochemical procedures were essentially those described in earlier papers from this laboratory (2, 3, 10). The solution phase consisted of 20 cm^3 of a 3.65 *M* solution of nitric acid in tri-*n*-butyl phosphate prepared by liquid–liquid equilibration (11). A disc of thorium metal (0.8 cm diameter, 0.2 cm thick) suspended on a platinum wire formed the anode and a platinum foil (1 × 1 cm^2) on a second platinum wire was the cathode. An applied voltage of 2 V from a Coutant LQ 50/50 dc power supply gave an initial current of 10 mA; electrolysis for a period of 8 h resulted in the dissolution of 0.154 g of thorium metal. The electrodes were then removed from the cell, and a solution of 0.42 g 2,2′-bipyridine (bpy) in ethanol (10 cm^3) added. The mixture was stirred for 2 h at room temperature, after which the volume was reduced by about 30% by pumping *in vacuo*. The white solid which was thrown out of solution was collected, washed with diethyl ether, and recrystallised from 1:1 (v/v) acetone/toluene. *Anal.* calcd. for $C_{30}H_{27}N_{13}O_{21}Th$: Th 20.3; found (EDTA titration): Th 20.8. Yield 80%, based on thorium dissolved.

A detailed discussion of this and other direct electrochemical syntheses of thorium nitrate complexes, including the choice of solvent, will be given elsewhere (12).

Crystallographic analysis

A colourless prismatic-shaped crystal of the title compound mounted directly on a thin-glass fiber with its axis parallel to the long dimension was used to obtain both the cell dimensions and the intensities. All data were obtained at room temperature on a Syntex $P2_1$ diffractometer following the procedure described elsewhere (13). The space group $P\bar{1}$ was assumed and confirmed by this analysis. The crystal was stable during data collection and the intensities of three monitor reflections did not change significantly. The data were corrected for Lorentz and polarization effects and an analytical absorption correction was also applied.

The structure was solved by sharpened Patterson and Fourier methods. The structure was refined by the block-matrix least-squares method in two blocks. The positional and anisotropic temperature coordinates for the thorium atom, and an overall scale factor, were refined in each block; the first matrix contained, in addition, the positional and anisotropic coordinates for all seven nitrate groups, while the second contained the positional and isotropic temperature coordinates for the $bpyH^+$ cations. Convergence was achieved in ten cycles to R = 0.032. A difference Fourier synthesis then showed electron density maxima in some of the plausible hydrogen atom locations. All C—H hydrogen atoms were included in the subsequent refinement in the idealized positions, with C—H = 0.95 Å, and were

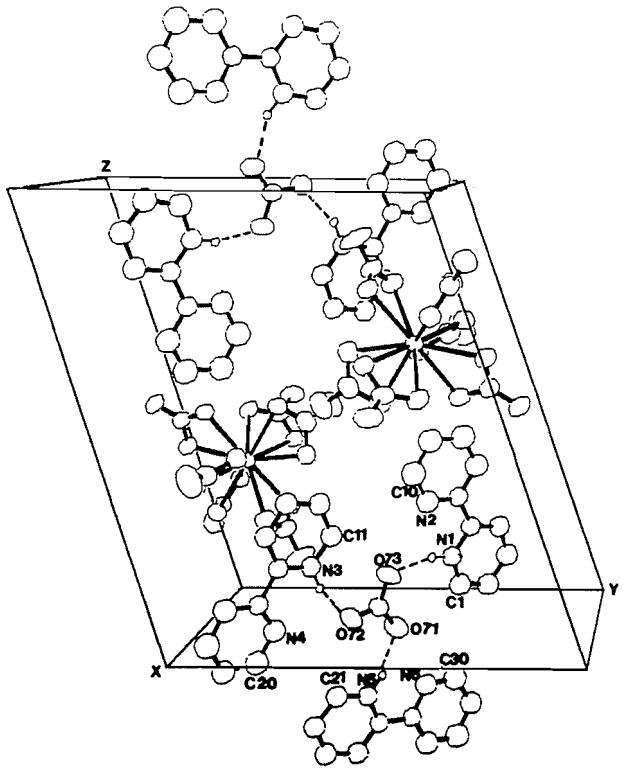

FIG. 1. Unit cell packing of $[(bpyH)_3NO_3][Th(NO_3)_6]$. Hydrogen bonds are shown by dotted lines. The symmetry-equivalent positions for bipyridinium cations with labels N1/N2 are $1-x, 1-y, 1-z$; with N3/N4 x, y, z; and with N5/N6 $x, y, z-1$.

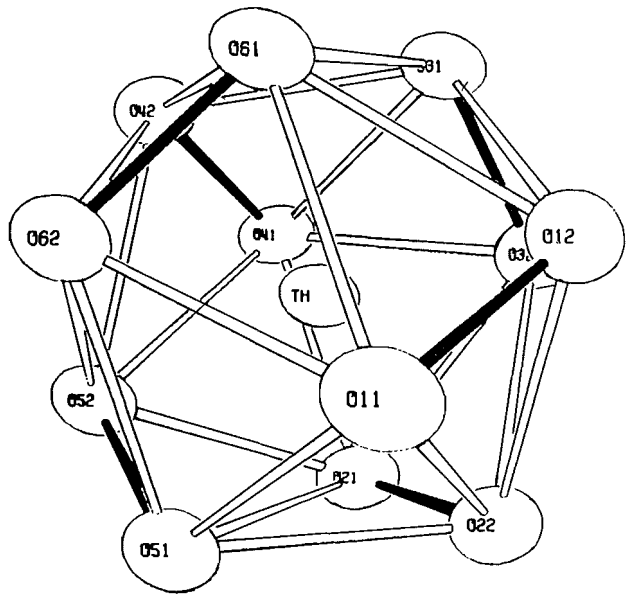

FIG. 2. ThO_{12} polyhedron, showing approximate C_2 symmetry.

constrained to ride on the appropriate carbon atoms with individual isotropic temperature factors which were refined for each hydrogen atom. Six cycles of refinement gave an R-value = 0.030, and the difference map showed peaks for H(N1) and H(N3) atoms (see Figs. 1 and 2 for nomenclature). The H(N5) atom was assumed to be on N(5), both because of its position, and because the distance from the O(71) atom seemed appropriate for the formation of a hydrogen bond (see below). These three hydrogen atoms were also included in the subsequent refinement in the idealized positions (N—H = 0.95 Å).

TABLE 1. Summary of crystal data, intensity collections, and structural refinement for $C_{30}H_{27}N_{13}O_{21}Th$, $[(bpyH)_3NO_3][Th(NO_3)_6]$

Cell constants	a = 9.300(2) Å, b = 14.161(3) Å, c = 17.037(4) Å, α = 108.79(2)°, β = 95.77(2)°, γ = 102.88(2)°
Cell volume	2034(1) Å^3
Space group	$P\bar{1}$ (No. 2)
Z	2
M_r	1137.65
ρ(calcd)	1.857 g cm^{-3}
Absorption coefficient	μ = 35.7 cm^{-1}
Crystal dimensions	0.30 × 0.23 × 0.19 mm
Radiation	MoK_α (λ = 0.71069 Å)
Min/max absorption correction	1.803/2.172
2θ angle	4–50°
Scan type	coupled θ (crystal)/2 θ (counter)
Scan width	$K_{\alpha 1}$ − 1° to $K_{\alpha 2}$ + 1°
Scan speed	2.02–4.88°/min
Background time/scan time	0.5
Total reflections measured	7197
Unique average data	5783[$F_o^2 > 3\sigma(F_o)^2$]
No. of parameters (NP)	262, 181, blocked, see text
$R = (\Sigma\Delta/\Sigma\lvert F_o\rvert)$	0.029
$R_w = [\Sigma w\Delta^2/\Sigma wF_o^2]^{1/2}$	0.031

The refinement converged to six more cycles, with the final R = 0.029 and the final R_w = 0.031. The weighting scheme employed was $w = 1/[\sigma^2(F) + 0.001F^2]$. In the final cycle of refinement all shifts were less than 0.1 esd, and a final difference synthesis had no significant features, the maximum peak being ~0.7 e Å^{-3} and close to the thorium atom.

Scattering factors for all non-hydrogen atoms, including the anomalous dispersion correction terms ($\Delta f'$) and ($\Delta f''$) for thorium, were taken from ref. 14, and for the hydrogen atoms from ref. 15. All calculations were carried out on the IBM 3031 computer with the programmes CHECK, PROC, ABSORB, SHELX 77, XANADU, and ORTEP (16).

The cell constants and other related crystal data are given in Table 1. The atomic coordinates are given in Table 2, and the interatomic distances and angles are listed in Tables 3 and 4. Tables of hydrogen coordinates, anisotropic thermal parameters, and observed and calculated structure factor amplitudes are available as supplementary data.[2]

Results and discussion

Previous studies of $[Th(NO_3)_6]^{2-}$

As noted in the Introduction, there have been three previous reports of structural determinations of the $[Th(NO_3)_6]^{2-}$ anion. The earliest of these (4), based on the photographic recording of 152 reflections, with R = 0.124, established that the thorium atom is surrounded by an irregular icosahedron in which oxygen atoms of bidentate nitrate ligands occupy all the available sites. The average Th—O distance was reported to be 2.63 Å, with the range 2.50–2.80 Å. The thorium atom was placed in a centrosymmetric position because of crystallographic requirements, so that the polyhedron is also centrosymmetric.

Alcock and co-workers (5) identified the $[Th(NO_3)_6]^{2-}$ anion in a complex lattice also containing the $[Th(NO_3)_3(Me_3PO)_4]^+$ cation. The geometry of the anion is again described as icosahedral, but with the thorium atom in a non-centric position (R = 0.090; Th—O (ave) = 2.61 Å). Studies of the related ionic complex $[Th(NO_3)_3(tdpo)_4]_2[Th(NO_3)_6]$ (tdpo = tris(dimethyl-

[a] U_{eq} for the first 29 atoms is calculated from the refined anisotropic thermal parameters (deposited) ($U_{eq} = (1/3)\sum_{i=1}^{3}(\text{rmsd})_i^2$, rmsd values are taken from ORTEP output, esd's are mean esd values of U_{11}, U_{22}, and U_{33}).

amido)phosphine oxide) by English *et al.* (6) lead to a description of two different anionic sites; in this analysis (R = 0.138; Th—O (ave) 2.60 Å), the thorium coordination was described as involving six octahedrally-sited bidentate nitrate groups, and the deviation of the N—Th—N angles from the required value of 90° was reportedly less than 3°.

Structure of $[Th(NO_3)_6]^{2-}$

The present work is fortunately based on more reliable methods than those available to Sćavnicar and Prodić (4), and the structural analysis is not affected by disorder problems, or by poor quality data as in the other studies noted (5, 6). The present work therefore allows the structural features of the $[Th(NO_3)_6]^{2-}$ anion to be identified with greater certainty than was previously possible.

The fundamental geometry of the coordination kernel of the anion is that of a distorted icosahedron, essentially as reported by Sćavnicar and Prodić (4), with twelve isosceles and eight equilateral triangles forming the surface of the polyhedron (Fig. 2). The approximate symmetry of the icosahedron is C_2, in contrast to the asymmetry reported earlier (4, 6). The structure is clearly not octahedral (c.f. ref. 6), as demonstrated by the N—Th—N angles in Table 4. Figure 2 shows the ThO_{12} polyhedron, with solid lines indicating short O---O contacts (2.154(2) Å) arising from chelating nitrato groups, and double lines showing the longer ones (2.86(2) Å).

The distortions within the ThO_{12} icosahedron are established not so much by the Th—O bond lengths, which lie randomly in the range 2.540(4)–2.602(3) Å (ave 2.567 Å), as by the O—Th—O angles. If one considers a regular ThO_{12} icosahedron, and identifies a specific oxygen atom, then the O—Th—O angles will be 63.5° (five such), 116.5° (five such), and 180° (one such). The results in Table 4 show that these values are not found. In discussing the experimental results, it is convenient (and accurate) to divide the oxygen atoms into two sets, labelled O(i1) and O(i2) (i = 1–6). The immediate environment of a specific oxygen atom in each of these two sets is such that the short O—O contacts are parallel to each other in the first set, but approximately perpendicular in the second.

The O—Th—O angles associated with each type of oxygen atom are set out in Table 4. For O(i1), the angles fall into values grouped around 49.6° (six), 67.5° (eighteen), 112.2° (eighteen), 131.5 (six), and 177.6° (three), where the numbers in parentheses are the total number of such angles within the icosahedron. For the O(i2) atoms, the associated O(i2)—Th—O angles are grouped around average values of

Nitrato ligand

Although there are significant differences in the Th—O bond distances to the nitrato ligands of the anion, and especially for nitrates 3–6, the average difference in bond length between the N(*i*)—O(*i*1) and N(*i*)—O(*i*2) bonds is 0.001 Å, in keeping with the limits quoted by Addison *et al.* (17) for symmetrical bidentate nitrate. The average lengths of the N(*i*)—O(*i*1), N(*i*)—O(*i*2) and N(*i*)—O(*i*3) bonds are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12

1.274(6), 1.275(5), and 1.202(9) Å, very close to those previously reported (4, 5) for $[Th(NO_3)_6]^{2-}$ and $Th(NO_3)_4(H_2O)_3 \cdot 2H_2O$ (6), and for the analogous cerium(IV) anion (7) $[Ce(NO_3)_6]^{2-}$. The average O—N—O angles are 115.3(4)°, 122.2(6)°, and 122.4(6)°, again similar to previously reported values. Following the arguments of Addison *et al.* (17), and Hester and Grossman (18), one concludes that the total valence bond order in the nitrato ligand is 3.9.

The 2,2′-bipyridinium cation and the $[bpyH)_3NO_3]^{2+}$ complex

Monoprotonated 2,2′-bipyridinium cations have been identified in three earlier crystal structure studies (19, 21). The present work, like that of earlier authors, shows that in the crystal lattice, the cation adopts a configuration in which two nitrogen atoms are *syn*, in contrast to the *anti* stereochemistry found in the neutral molecule (22), and in the diprotonated cation (23). The rings of the monopositive cation are both planar, but the *syn* conformation is apparently stablized by a slight twisting about the C—C axis, producing dihedral angles of 6.6, 4.3, and 7.8°.

The N—C and C—C bond lengths in the present structure are consistent with those reported for 2,2′-bipyridine (22), the 2,2′-bipyridinium cation (19), and coordinated 2,2′-bipyridine (19, 24, 25). There are some significant differences between the protonated and non-protonated rings, as noted previously by Figgis *et al.* (19). The most significant points are an increased C—N—C angle at the protonated nitrogen atoms N(1), N(3), and N(5), and a corresponding decrease in the angles at adjacent carbon atoms C(1), C(11), C(21). It is interesting that the geometry of the coordinated ligand is generally closer to that of the neutral compound, or to that of the non-protonated ring of the monopositive cation, than to the protonated C_5H_4N moiety of the cation.

The nitrate ion N(70), O(71,72,73) in the lattice is essentially trigonal (average angle 120.0(7)°, average N—O bond length 1.239(11) Å) and planar. The bond length is similar to other reported distances for ionic nitrate (e.g. ref. 26). Each oxygen atom is hydrogen-bonded to the N—H^+ function of a 2,2′-bipyridinium molecule, with an average O--H--N distances of 2.810 Å, typical of such bonds (27). The hydrogen atom can be identified at an average distance of 1.90 Å from oxygen in this bond.

The effect of this hydrogen bonding is to produce the unusual cationic complex $[(bpyH)NO_3]^{2+}$ in the lattice. This unit has approximate C_3 symmetry (see Fig. 1). Attempts to investigate the stability of this cation in solution have so far proved inconclusive, largely because of the lack of a suitable solvent. It is not unreasonable to conclude that the stability of the lattice of the title compound is maximised by the formation of a large dipositive cationic unit which acts as the counterion for $[Th(NO_3)_6]^{2-}$.

Received May 2, 1983

HENRYK PIEKARSKI, ALINA PIEKARSKA, and STEFANIA TANIEWSKA-OSIŃSKA. Can. J. Chem. **62**, 856 (1984).

The enthalpy of NaI solution was determined in water mixtures with methanol, ethanol, propanol, and isopropanol in the entire range of mixed-solvent concentration at 288.15 and 308.15 K, and in water mixtures with *s*-butanol and *tert*-butanol in the range of 0–5 mol% alcohol at 308.15 K. The dependence of $\bar{C}^0_{p_2}$ on solvent composition was studied. The enthalpic pair interaction coefficients h_{EN} for NaI–alcohol in water and NaI–water in alcohols were determined, and the effect of temperature on h_{EN} values in the systems under study was analyzed.

HENRYK PIEKARSKI, ALINA PIEKARSKA et STEFANIA TANIEWSKA-OSIŃSKA. Can. J. Chem. **62**, 856 (1984).

On a déterminé l'enthalpie de solutions de NaI dans des mélanges aqueux de méthanol, d'éthanol, de propanol et d'isopropanol dans l'intervalle complet de concentration des solvants mixtes à 288,15 et à 308,15 K et également dans des mélanges aqueux de *s*-butanol et de *tert*-butanol à des concentrations allant de 0 à 5 mol% d'alcool à 308,15 K. On a étudié l'effet de la composition du solvant sur la valeur de $\bar{C}^0_{p_2}$. On a déterminé les coefficients enthalpiques des paires d'interaction, h_{EN}, pour NaI–alcool dans l'eau et NaI–eau dans des alcools et on a analysé l'effet de la température sur les valeurs de h_{EN} dans les systèmes étudiés.

Introduction

While calorimetric investigations of electrolyte solutions in water – aliphatic alcohols have often been conducted at various laboratories, there is little data on the effect of temperature on the thermochemical properties of electrolyte–alcohol–water systems in the whole range of mixed-solvent composition (1). In view of this we decided to measure the enthalpy of NaI solution in methanol, ethanol, propanol, and isopropanol mixtures with water over the entire range of mixed-solvent concentration at 288.15 K and 308.15 K. We have also determined the enthalpy of NaI solution in *s*-butanol and *tert*-butanol mixtures with water at 308.15 K in the range of a few mol% of alcohol. Sodium iodide had been used previously as an electrolyte because of its good solubility in the systems under investigation and, consequently, we had at our disposal substantial material for comparison.

Experimental

Materials

Sodium iodide, analytically pure (JT Baker Chemicals B.V., Holland); solvents methanol, ethanol, propanol, isopropanol, all analytically pure (POCh Gliwice, Poland); and *s*-butanol and *tert*-butanol, A.R. (Reanal, Hungary), were purified and dried using the procedure described in an earlier paper (2).

Apparatus and method of measurement

The measurements of solution enthalpies were made using an "isoperibol" calorimeter. The calorimeter and the method of measurement have been described in an earlier report (3). Six to eight experimental runs were performed for each composition of mixed solvent. The range of electrolyte concentration was 0.003–0.015 mol/kg of solvent. The uncertainties in the measured enthalpies did not exceed ±0.5% of the measured value.

Results and discussion

Solution enthalpy

The measured enthalpies of solution were extrapolated to infinite dilution by the method of Criss and Cobble (4). The dielectric permittivity and the density of water–alcohol mixture were adopted from the literature (5, 6). The standard enthalpies of NaI solution in all mixtures under study are collected in Tables 1 and 2. As an example, Fig. 1 illustrates the effect of temperature on the shape of the $\Delta H^0 = f(x)$ NaI plot in water–ethanol mixtures. As can be seen from these data, the plot of ΔH^0 for NaI in water–alcohol mixture under investigation exhibits a maximum in the range of small alcohol content. A similar maximum of ΔH^0 has been observed in all electrolyte–water–alcohol systems studied thus far. It is assumed that this maximum is connected with the structure-making or -stabilizing effect of the added alcohol on water (7–10). Previous research (1–3) as well as the results of the present study suggest that the position of the maximum of ΔH^0 depends on the size of the alcohol molecule (Tables 1, 2). As the molecular size increases, the maximum shifts towards

smaller alcohol content in the mixture.

An analysis of the results obtained shows that in all mixtures under investigation, in the temperature range 288.15–308.15 K, the standard enthalpy of NaI solution becomes more exothermic as the temperature increases, with the shape of $\Delta H^0 = f(x)$ isotherms remaining essentially unchanged. The only effect that is observed is the lowering and flattening of the maximum of ΔH^0, but its position does not change. The standard enthalpies of NaI solution determined in this study made it possible to calculate the molar specific heat of NaI in infinitely dilute solution $\bar{C}^0_{p_2}$ in all mixtures under study (Fig. 2).

$$[1]\quad \frac{d\Delta H^0}{dT} = \Delta C^0_p = \bar{C}^0_{p_2} - C_{p_{cryst.}}$$

where $C_{p_{cryst.}}$ is molar heat of crystalline electrolyte. It follows from the data obtained that in all systems under investigation $\bar{C}^0_{p_2}$ NaI is negative in all mixed solvent composition over the entire temperature studied. The $\bar{C}^0_{p_2} = f(x)$ curves exhibit a minimum in the range of small alcohol content, and its position and depth depend on the kind of alcohol. As the size of the alcohol molecule increases, this minimum becomes deeper and shifts towards lower alcohol content. The position of the minimum of $\bar{C}^0_{p_2}$ approximately corresponds to the position of the ΔH^0 maximum. Further increase in alcohol content beyond the minimum produces a gradual increase in $\bar{C}^0_{p_2}$. In alcohol-rich mixtures, the $\bar{C}^0_{p_2} = f(x)$ curves for different water–alcohol mixture lie close to one another.

The presence of the $\bar{C}^0_{p_2}$ minimum seems to favour the view of the maximum ordering of the water–alcohol mixture, with composition corresponding to maximum standard enthalpy of

NaI solution in these mixtures. The increase in $\bar{C}^0_{p_2}$ NaI beyond the minimum is probably related to the breaking of the maximum ordered structure of the mixture with increasing alcohol content. Mixed water−alcohol associates may be present in the intermediate composition range of the mixture. In the temperature range studied, the structure of the pure alcohol may also be less sensitive to a change in temperature than the maximum-ordered structure which corresponds to the minimum $\bar{C}^0_{p_2}$. The calculated value[1] of $\bar{C}^0_{p_2}$. NaI in water, −54.2 J K^{-1} mol^{-1} is in fair agreement with that obtained in the same way by Mishchenko *et al.* (−59.5 J K^{-1} mol^{-1}) (12) but it differs considerably from the value −76.5 J K^{-1} mol^{-1} determined by the direct method of Desnoyers *et al.* (13). The discrepancy must be a result of an error in the solution enthalpy measurement and in the extrapolation to infinite dilution on the values of the coefficient $d\Delta H^0/dT$.

Enthalpic pair interaction coefficients

As is well known, quantitative determination of the interaction of solute molecules in three-component systems can be conveniently expressed in pair, triplet, etc., interaction coefficients, as proposed by McMillan-Mayer (14). For this reason we thought it advisable to calculate, on the basis of the data obtained, enthalpic pair interaction coefficients for NaI−nonelectrolyte in water and for NaI−water in the nonaqueous solutions studied.

The h_{EN} coefficients calculated by the method described in the previous paper (2) are collected in Tables 3 and 4. To permit comparison enthalpic pair interaction coefficients for other nonelectrolyte−NaI pairs calculated on the basis of literature data (15−18) are also included. It has to be pointed out that the h_{EN} coefficients listed in the table constitute, in each case, the "mean ionic" pair interaction coefficients, or, more precisely, in the case of 1−1 electrolyte (E), they correspond to half the sum of the enthalpic effect of the interaction between the molecule of the given nonelectrolyte (N) and the cation (K^+) and the anion (A^-):

$$[2] \quad h_{EN} = \frac{1}{2}[h(K^+A^-—N)] = \frac{1}{2}[h(K^+—N) + h(A^-—N)]$$

It follows from the data presented in Table 3 that the positive coefficients h_{EN} are for pairs in which the nonelectrolytes are aliphatic alcohols, known as water structure-making or -stabilizing substances. In the case of the remaining nonelectrolytes, with the exception of THF, the pair interaction coefficients for NaI−nonelectrolyte are negative for reasons not fully understood. It seems, however, that the observed difference in the sign of the h_{EN} coefficient is connected with the different effect of the molecule of the above-mentioned two nonelectrolyte groups on the structure of water.

In an earlier study (2), a linear correlation was obtained between h_{EN} for NaI−alcohol pairs in water and the polarizability of alcohol molecule. An analysis of the h_{EN} values for NaI−alcohol in water obtained in this study as well as those reported in the above-mentioned paper has further shown that there is also a linear dependence of h_{EN} and the reciprocal of the dielectric permittivity of the alcohol $1/\epsilon$ (Fig. 3). This is somewhat surprising, for in contradistinction to polarizability (α), which is a molecular quantity, dielectric permittivity (ϵ) is related to a number of molecules. There exists, to be sure, a nonlinear dependence between α and ϵ, but the "structure" of pure liquid substance plays a significant role in it.

The values of the coefficient h_{EN} for electrolyte−alcohol in water in the temperature range 288.15−308.15 K (Table 3) lead to the conclusion that the strongest interactions between ions and alcohol molecules in water take place in the system containing methanol, possibly because of the small size of the methanol molecules and their similarity to water molecules. In view of the fact that in water solutions, alcohol molecules with large alkyl radicals may undergo hydrophobic hydration, ion−

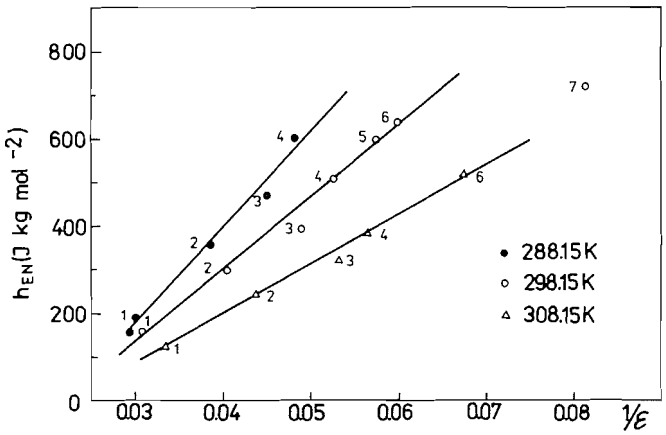

FIG. 3. Dependence of the enthalpic pair interaction coefficients of NaI−alcohol in water solutions on reciprocal of the alcohol dielectric permittivity (1-methanol, 2-ethanol, 3-propanol, 4-isopropanol, 5-isobutanol, 6-*s*-butanol, 7-*tert*-butanol).

[1] $C_{p\,\text{cryst. NaI}} = 54.31$ J K^{-1} mol^{-1}.

[a]From ref. 20.

alcohol interactions become weaker as the size of the alcohol molecule increases. As a result, the endothermicity of the coefficient h_{EN} also increases. The values of the pair interaction coefficient h_{EN} for NaI–water in alcohols (Table 4) suggest that the weakest ion–water interaction takes place in methanol solution. This may be related to the strong solvation of both ions and water molecules by methanol molecules.

Among the systems under investigation, the strongest electrolyte–water interaction takes place in butanol solutions, where the enthalpic pair interaction coefficients h_{EN} have high negative values.

The effect of temperature on the pair interaction coefficient h_{EN} for NaI–alcohol in water is presented in Fig. 4, which also includes h_{EN} data for other electrolyte–nonelectrolyte–water systems calculated on the basis of literature data (15) or adopted from other studies (19). As can be seen, with increasing temperature the h_{EN} values for all systems studied, both the positive and the negative ones, tend to zero. In quantitative terms, the effect of temperature on the values of h_{EN} can be presented by means of function C_{EN} defined by equation

$$[3] \quad h_{EN}(T_2) = h_{EN}(T_1) + C_{EN}(T_2 - T_1)$$

The calculated mean values of C_{EN} for NaI–alcohol and NaI–water in the temperature range 288.15 to 308.15 K are collected in Table 5. For the sake of comparison C_{EN} values for NaCl–alcohol pairs in water adopted from Perron *et al.* (20) are also included. As can be seen from the results above, the C_{EN} coefficients for the investigated electrolyte–alcohol pairs in water have negative values. The larger the alcohol molecule, the more negative the C_{EN} values. It seems that the above findings cannot be accounted for until more work is done on other electrolytes and/or on three-component systems containing, in addition to the electrolyte, two nonaqueous solvents. Appropriate studies are in progress.

The crystal structure of $Pt(CH_3CN)_2Cl_2$ has been determined twice independently. The compound is the *cis* isomer. It crystallizes in the monoclinic $P2_1/c$ space group, a = 6.660(3) [6.668(4)], b = 12.500(7) [12.519(8)], c = 10.277(6) [10.308(5)] Å, β = 105.42(4) [105.41(4)]°, V = 824.7(8) [829.6(9)] Å^3. The structure was refined by full-matrix least-squares analysis to a conventional R factor of 0.054 [0.058] and R_w = 0.053 [0.057] for 1578 [1226] observed reflections. The coordination is square planar with bond lengths (Pt—N = 1.98(1), 1.98(1) [1.95(2), 1.99(2)] Å and Pt—Cl = 2.264(4), 2.263(3) [2.270(6), 2.277(5)] Å) slightly shorter than normal. The N—C bonds are 1.10(2), 1.11(2) [1.11(3), 1.16(2)] Å. The C—CH_3 bonds are shorter than normal single bonds (1.48(2), 1.45(2) [1.49(3), 1.45(3)] Å and the N—C—C framework is almost linear. Infrared (4000–100 cm^{-1}) and Raman (4000–60 cm^{-1}) spectra of the crystalline solid have been measured and assigned; the vibrational spectra confirm the *cis* structure. A rough molecular force constant analysis based on a *cis*-planar C_{2v} skeleton (ignoring H atoms) was carried out and aided in the vibrational assignments. The ν(Pt—Cl) bands occur at 362 and 333 cm^{-1}; the ν(Pt—N) bands occur at 463 and 408 cm^{-1}, and show strong coupling with the PtNC deformations.

F. D. ROCHON, R. MELANSON, H. E. HOWARD-LOCK, C. J. L. LOCK et G. TURNER. Can. J. Chem. **62**, 860 (1984).

La structure cristalline de $[Pt(CH_3CN)_2Cl_2]$ a été déterminée indépendamment par deux groupes de chercheurs. Le composé est l'isomère *cis*. Le cristal appartient au système monoclinique et le groupe d'espace $P2_1/c$. Les paramètres de maille sont a = 6,600(3) [6,668(4)], b = 12,500(7) [12,519(8)], c = 10,277(6) [10,308(5)] Å, β = 105,42(4) [105,41(4)]° et V = 824,7(8) [829,6(9)] Å^3. La structure a été affinée par moindres carrés à matrice entière jusqu'à un facteur R = 0,054 [0,058] et R_w = 0,053 [0,057] pour 1578 [1226] réflections observées. La coordination autour de l'atome de platine est un plan carré, avec les liens Pt—N (1,98(1), 1,98(1) [1,95(2), 1,99(2)] Å) et Pt—Cl (2,264(4), 2,263(3) [2,270(6), 2,277(5)] Å) légèrement plus courts que des liens normaux. Les liens N—C sont 1,10(2), 1,11(2) [1,11(3), 1,16(2)] Å et les liens C—CH_3 sont plus courts (1,48(2), 1,45(2) [1,49(3), 1,45(3)] Å) que des liens simples normaux. Les ligands acétonitriles sont presque linéaires. Les spectres infrarouges (4000–100 cm^{-1}) et Raman (4000–60 cm^{-1}) du composé à l'état solide ont été mesurés et l'attribution en a été faite. Les spectres vibrationels ont confirmé la structure *cis*. Une analyse approximative des constantes de force basée sur le squelette *cis* plan carré C_{2v} (en négligeant les atomes H) a été faite et utilisée pour l'attribution des bandes. Les vibrations ν(Pt—Cl) absorbent à 362 et 333 cm^{-1}; celles ν(Pt—N) à 463 et 408 cm^{-1}, et montrent un couplage avec les déformations PtNC.

Introduction

Certain platinum complexes have been shown to be potent antitumor agents (1) and more recently it has been suggested that "platinum blues" might act as useful second generation platinum anti-tumor drugs (2). These "platinum blues" are obtained from the reaction of pyrimidines with *cis*-dichlorodiammineplatinum(II) (2) and also from the reaction of platinum(II) complexes with carbohydrates (3). Lippard *et al.* (4) have prepared a "platinum blue" with α-pyridone units bridging pairs of platinum atoms, which also each have two *cis*-ammine groups coordinated to them.

$Pt(CH_3CN)_2Cl_2$ was first prepared by Hoffmann and Bugge in 1907 (5) and platinum blue or "platinblau" was the name originally assigned to the intense blue colour obtained when $Pt(CH_3CN)_2Cl_2$ was treated with aqueous silver nitrate, and the resulting solution allowed to stand in air (6). It was postulated that "platinblau" was an acetamide complex of platinum, the acetamide being obtained by insertion of water into coordinated acetonitrile (7). Brown *et al.* (8) determined that the reaction product of $Pt(CH_3CN)_2Cl_2$ and molten trimethylacetamide had a *trans* stereochemistry. They implied that this product was a typical "platinblau" complex. The reaction of $Pt(CH_3CN)_2Cl_2$ with ammonia also gives a product with a *trans* stereochemistry (9). $Pt(CH_3CN)_2Cl_2$ prepared in the usual manner (5) has been postulated, however, to be the *cis* complex. Lebedenskii and Golovnya (10) assigned the *cis* configuration to the compound, based on its chemical reactions. In 1964, Gillard and Wilkinson (7) suggested that the infrared data of the compound were consistent with the *cis* structure. Walton (11*a*) measured the infrared spectra of the complexes $[M(RCN)_2Cl_2]$ (M = Pt, Pd and R = methyl and phenyl) and showed that $[Pd(RCN)_2Cl_2]$ were the *trans* isomers while $[Pt(RCN)_2Cl_2]$ were the *cis* isomers. In order to characterize all the compounds involved in these reactions we have used X-ray crystallographic methods. The crystal structure of $[Pt(CH_3CN)_2Cl_2]$ was determined, independently in Montreal and in Hamilton. We became aware of this when one of us (C.J.L.L.) was asked to referee the work of the other (F.D.R.). It seemed appropriate to present the work in a joint paper. Of the data reported here, the first values refer to the work in Montreal and the latter values [in square brackets] refer to the work in Hamilton.[2]

Experiments

Preparation of bis(acetonitrile)dichloroplatinum(II), cis-[Pt(CH$_3$CN)$_2$Cl$_2$]

The title compound was prepared by the standard method (5).

[1] Revision received November 18, 1983.

Crystals were grown from water at room temperature [by evaporation of the mother liquor at 5°C]. The ^{15}N-enriched derivative was prepared by reaction of 95.2 atom % ^{15}N-enriched CH_3CN (MSD Isotope) with K_2PtCl_4 in H_2O.

Vibrational spectra and other experiments

X-ray powder diffraction showed that the compound obtained consisted of a single product. The powder pattern could be indexed on the basis of the cell obtained from the single crystal sample.

Vibrational spectra were obtained for normal and ^{15}N-enriched ligand and complex. Infrared spectra were obtained on Perkin Elmer Model 521 and 283 spectrometers, from KBr discs in the range 4000–200 cm^{-1}, and on a Nicolet Model 7199 Ft-IR spectrometer from Nujol mulls in polyethylene plates in the range 500–100 cm^{-1}. Spectra were calibrated with indene and polystyrene. Raman spectra were obtained from crystalline samples on Coderg PHO and Spex 14018 spectrometers, the exciting radiation being the 6417 Å (and 5145 Å) line of a Spectra-Physics Model 164-02 Krypton (and Argon) ion laser. The spectrometer was calibrated with a neon lamp; the wavenumber readout was constant to ±1 cm^{-1}. The vibrational spectra could be assigned on the basis of a *cis* complex. These spectra are reported in Table 5. There was no difference in the spectra of samples obtained from several different preparations of the title compound. The samples obtained readily gave the deep blue "platinblau" colour on treatment with aqueous silver nitrate solution.

Collection of diffraction data

The crystal used for the X-ray study had nine faces and approximate dimensions 0.20 × 0.20 × 0.30 mm [irregular yellow parallelepiped, ground to a cylinder 0.40 mm long × 0.18 mm in diameter]. A set of precession photographs indicated the monoclinic $P2_1/c$ space group. The cell parameters were obtained by least-squares refinement from the setting angles of 15 automatically centred reflections on a Syntex P$\bar{1}$ diffractometer using graphite-monochromatized MoKα radiation. Crystal data are as follows:

$PtCl_2C_4H_6N_2$ mw = 348.10

Monoclinic $P2_1/c$, a = 6.660(3) [6.668(4)], b = 12.500(7) [12.519(8)], c = 10.277(6) [10.308(5)] Å, β = 105.42(4) [105.41(4)]°, V = 824.7(8) [829.6(9)] Å^3, Z = 4, D_x = 2.803 g cm^{-3}, D_m = 2.80(2) [2.79(1)] g cm^{-3} (flotation), λ(MoKα) = 0.71069 Å, μ(MoKα) = 184.5 cm^{-1}, and T = 295 [295] K.

A total of 2417 [1775] independent reflections were measured in the range $2\theta < 60°$ [55°] by the $2\theta/\theta$ scan technique using MoKα radiation. The scan rate was 1° [4°] (2θ) min^{-1} for most reflections, but rates as high as 24° [24°]/min^{-1} were selected for strong reflections by the autocollection program. A 2θ scan range of 1° below $K\alpha_1$ and 1° above $K\alpha_2$ was chosen. The background time to scan time ratio was 0.50. During the data collection three [one] standard reflections, measured after every 47 [49] reflections, showed intensity fluctuations within ±3% [±1.6%] of their mean values.

The 1578 [1226] reflections with $I > 2.5\sigma(I)$ [$3\sigma(I)$] were considered observed, where $\sigma(I)$ was calculated as already described (12, 13). An absorption correction based on the equations of the crystal faces was applied to all reflections. The transmission factors varied from 0.042 to 0.107 [0.050 to 0.075]. The data were then corrected for the Lorentz and polarization effects. The scattering factors of Cromer and Waber (14) were used. The anomalous dispersion terms (15) of Pt and Cl were included in the calculations.

Solution of the structure

The Pt atom was easily located from the three-dimensional Patterson map. The positions of all the other atoms were obtained by structure-factor and Fourier-map calculations. The refinement of the parameters was done by full-matrix least-squares methods. In the early stages of refinement, unit weight was assigned to all the reflections. Later individual weights $w = 1/\sigma^2(F)$ were applied. The refinement of the scale factor, the coordinates, and anisotropic temperature factors of all atoms converged to $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.054$ [0.058] and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma|F_o|^2]^{1/2} = 0.053$ [0.057]. The final residual electron density map showed a few peaks as high as 1.5 e Å^{-3} [0.58 e Å^{-3}] in the very close environment of the platinum atom.

The calculations were carried out with a Cyber 73 [Cyber 170/730] computer and the programs used have already been described (12, 13).[3]

Discussion

The refined atomic parameters are listed in Table 1. A list of the anisotropic temperature factors is available.[3] A labelled diagram of the molecule is shown in Fig. 1. The bond lengths and the bond angles are shown in Table 2.

The two structural determinations agree very well in all aspects. Most parameters agree to better than 2σ ($\sigma = (\sigma_1^2 + \sigma_2^2)^{1/2}$) and the only values which are significantly different are V (4σ), Cl(2)—Pt—N(2) (6σ), N(1)—Pt—N(2) (3.2σ), N(1) y coordinate (5σ), and C(3) y coordinate (4.7σ). Even the temperature factors agree well. The errors are slightly lower for the Montreal structure; this is probably caused by the greater number of observed reflections, partly from the larger cut-off value of 2θ and partly because of the lower value of significance used to define an observed reflection.

As expected, the coordination around the platinum atom is square planar. The angles around the Pt atom are close to the expected 90 and 180°. The weighted best plane was calculated through the five atoms. The deviations from this plane are: Pt, −0.0001(5); Cl(1), −0.004(4); Cl(2), 0.006(4); N(1), −0.037(12); and N(2), 0.063(10) Å. One acetonitrile ligand is slightly above the platinum plane while the second ligand is below the platinum plane. The deviations of the other atoms from the plane are: C(1), −0.14(1); C(2), −0.20(1); C(3), 0.21(1); and C(4), 0.41(1) Å.

The compound is the *cis*-isomer as predicted by infrared spectroscopy. The Pt—Cl bonds are 2.264 [2.270(6)] and 2.263(3) [2.277(5)] Å. They seem shorter than normal bonds (2.29–2.30 Å). The *trans* influence of CH_3CN seems therefore smaller than the one of amines, halides, and sulfoxides.

The *trans*-effect of acetonitrile is not well known but it should be fairly high because of the high multiplicity of the C—N bond. We have studied the reactions between $K[Pt(CH_3CN)Cl_3]$ and pyridine (py) and between $K[Pt(py)Cl_3]$ and acetonitrile. We have found the following reactions:

$$K[Pt(py)Cl_3] + CH_3CN \xrightarrow[3\ h]{H_2O} \textit{cis}\text{-}[Pt(CH_3CN)(py)Cl_2]$$

$$K[Pt(CH_3CN)Cl_3] + py \xrightarrow{H_2O} \textit{trans}\text{-}[Pt(CH_3CN)(py)Cl_2]$$

Because Cl^- has a higher *trans* effect than pyridine, only *cis*-$[Pt(CH_3CN)(py)Cl_2]$ is formed in the first reaction. The ir spectrum of this product showed two ν_{Pt-Cl} vibrations at 339 and 349 cm^{-1}. In the second reaction, the *trans* isomer is first formed. It has one ν_{Pt-Cl} vibration at 330 cm^{-1}. These results indicate that the *trans* effect of acetonitrile is greater than the *trans* effect of chlorine. It is generally believed than ligands containing multiple bonds have a high *trans* effect but their *trans* influence is not well known. In the compound *mer*-$[Os(CH_3CN)Cl_3(PPh_3)_2]$, the Os—Cl bond in *trans* position to CH_3CN is equal in length to the other two Os—Cl bonds *trans* to each other (16). But in octahedral complexes, the *trans*

[3] Lists of structure factors and anisotropic thermal parameters are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

effect is much less important than in square planar compounds. It might be similar for the *trans* influence.

The acetonitrile ligands are bonded to platinum through the lone-pair of electrons on the nitrogen atom. The Pt—N bonds are 1.977(12) [1.95(2)] and 1.981(11) [1.99(2)] Å. These distances are probably slightly shorter than the normal Pt—N(amine) bonds (17, 18). This is the first structure determination of a compound where acetonitrile is bonded to platinum. Acetonitrile is expected to accept electron density from the metal, much like CO and other unsaturated ligands which possess available empty π orbitals. Infrared spectroscopic studies of $[Pt(CH_3CN)_2Cl_2]$ (11*a*) have shown that the N≡C bond is strengthened upon coordination to platinum rather than weakened as in conventional metal carbonyl complexes. However, the results of crystallographic studies of compounds containing CH_3CN are not very conclusive. Table 3 summarizes several recent crystal structures containing CH_3CN, either free as a molecule of crystallization or bonded to a metal. The structure of acetonitrile has been determined in 1955 (19) by electron diffraction, but the standard deviations are high. A better geometry was calculated from rotational spectra by Costain (20). It is interesting to observe that CH_3CN seems to have almost the same structure, whether it is coordinated to a metal or free as a molecule of crystallization. In *cis*-$[Pt(CH_3CN)_2Cl_2]$, the C—N bonds are 1.102(19) [1.11(3)] and 1.113(16) [1.16(2)] Å while the C—C bonds are shorter (1.449(17) [1.45(3)] and 1.480(21) [1.49(3)] Å) than normal single bonds, as observed in other CH_3CN crystal structures. In structures where the CH_3CN is not bound to the metal (i.e. "lattice" CH_3CN), the average C—N and C—CH_3 bonds are 1.14 and 1.42 Å (Table 3). These values are not very precise since most of the published structures have high standard deviations. Many of them contain disordered CH_3CN molecules. In structures where the CH_3CN is bound to the metal, the thermal motion is reduced and more precise results are obtained. The average C—N and C—CH_3 bonds in the metal-bonded CH_3CN structures are 1.13 and 1.45 Å. These results are in the right direction, assuming a stronger C—N bond and a weaker C—CH_3 bond upon coordination as suggested by infrared spectroscopy. But at the moment, we are not sure if the observed differences are significant.

The Pt—N—C bond angles 175(1) [177(2)] and 174(1) [175(2)]° deviate slightly from 180° as do the analogous angles for most other M—$NCCH_3$ complexes listed in Table 3. The nonlinearity of the Pt—N—C moiety is probably due, as suggested previously (41), to the use of partial sp^2 character by the donor nitrogen atom. The acetonitrile ligands are linear 177(1) [179(1)] and 179(1) [177(2)]° as in most other published struc-

tures (Table 3).

The packing of the molecules within the cell is shown in Fig. 2. The molecules lie in layers roughly parallel to the 102 planes and thus the distance between layers is about 3.6 Å. The forces within the plane and between the planes are primarily van der Waals, although the molecules are oriented to give dipole–dipole interactions between translationally equivalent molecules in the *b* direction. There is one contact shorter than the sum of the van der Waals radii. The intermolecular distance C(2) . . . Cl(1) is 3.497 Å and the angle C(1)—C(2) . . . Cl(1) is 130.7(9) and may indicate very weak hydrogen bonding.

The vibrational spectra of $PtCl_2(CH_3CN)_2$ have been recorded previously (11) but only one or two bands have been reported. We have recorded complete (4000–60 cm^{-1}) infrared and Raman spectra. Many of the vibrations were assigned by comparison with spectra of similar compounds, but an aid to the assignments, particularly of the Pt—N stretches, was a rough force constant analysis.

For the purpose of carrying out the force constant analysis only the symmetry of the heavier skeleton of the complex was considered and the CH_3 groups were treated as discrete units. This skeleton was assumed to be planar with C_{2v} symmetry, with the C_2 axis parallel to the *z*-axis of the Cartesian coordinates. The skeleton contains nine atoms and has 21 normal modes of vibration. It was further assumed that the C—C≡N—Pt chains are rectilinear and that the adjacent angles around the Pt atom in the *yz* plane are all 90°. By standard group theoretical methods it can be shown that the number of normal modes of each symmetry species is $8a_1$, $3a_2$, $7b_1$, and $3b_2$. These modes are all Raman-allowed and all except the a_2 modes are infrared-allowed. The numberings, symmetry, and approximate description of the normal modes

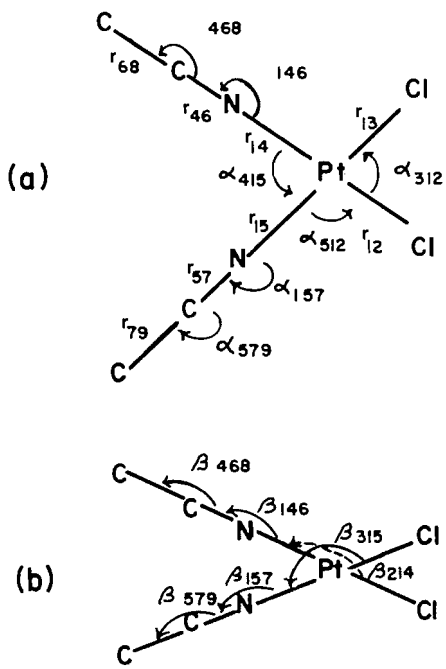

FIG. 3. Internal coordinates for the $Cl_2Pt(NCC)_2$ entity, (*a*) in-plane and (*b*) out-of-plane.

are shown in Table 4.

The numberings of the internal coordinates are indicated in Fig. 3. The *r*'s are bond-stretching deformations, the α's are in-plane angle deformations, and the β's are out-of-plane angle deformations. Even if the angles at Pt were not 90°, most likely α_{314} would be equal to α_{512}. (Table 2 shows that the angles α_{312}, α_{314}, α_{512}, α_{415} are close to 90°.) The redundancy condition $\alpha_{312} + 2\alpha_{314} + \alpha_{415} = 360°$ holds for the in-plane bends, and therefore α_{314} and α_{512} were not used as independent coordinates. The symmetry coordinates for the skeletal unit are also listed in Table 4.

Choice of interaction force constants

The limited number of observed frequencies limits the number of interaction constants which can be chosen. It seems reasonable to assume that the interactions between adjacent bonds, e.g. C—C and C≡N, will be greater than interactions between non-adjacent bonds, e.g., the two C≡N bonds. When one works through the symmetrization algebra, however, the force constant for the a_1 C≡N stretching vibration F_{a_1} is distinguished from that for the b_1 vibration F_{b_1} by the C≡N, C≡N interaction; that is (ignoring other terms),

[1] $F_{a_1}, \nu_{C\equiv N} = F_{C\equiv N} + F_{C\equiv N, C\equiv N} + F_{C\equiv N, C-C}$

[2] $F_{b_1}, \nu_{C\equiv N} = F_{C\equiv N} - F_{C\equiv N, C\equiv N} + F_{C\equiv N, C-C}$

$F_{C\equiv N, C-C}$ may be much larger than $F_{C\equiv N, C\equiv N}$, but it does not

differentiate between the two frequencies governed by the two different force constants described by eqs. [1] and [2]; hence $F_{C\equiv N.C\equiv N}$ cannot be ignored.

These two frequencies occur at 2333 and 2305 cm^{-1}, and so $F_{C\equiv N.C\equiv N}$ is about 1.0% of $F_{C\equiv N}$ (i.e. ~0.20). $F_{C\equiv N.C-C}$ will of course contribute to the mean position of both $\nu_{C\equiv N}$ and ν_{C-C}. Similarly, $F_{C\equiv N.Pt-N}$ will contribute to the position of ν_{Pt-N}, and $F_{Pt-N.Pt-Cl}$ to the position of ν_{Pt-Cl}.

TABLE 6. Force constants used in normal coordinate analysis of $Pt(NCC)_2Cl_2$*

Index	Force constant†	Original value (mdyn Å^{-1})	Refined value (mdyn Å^{-1})
1	F_{PtCl}	2.620	2.251
2	$F'_{PtCl,PtCl}$	0.100	0.196
3	F_{PtN}	3.050	4.050
4	$F'_{PtN,PtN}$	0.100	0.402
5	F_{CN}	18.580	18.400
6	$F'_{CN,CN}$	0.138	0.196
7	F_{CC}	4.970	4.830
8	$F'_{CC,CC}$	0.0760	0.004
9	F_{ClPtCl}	0.470	0.291
10	F_{NPtN}	0.630	0.318
11	F_{PtNC}	0.150	0.098
12	F_{NCC}	0.299	0.093
13	$F_{PtNC\perp}$	0.100	0.153
14	$F_{NCC\perp}$	0.100	0.041
15	$F_{NPtCl\perp}$	0.050	0.092

*F' denotes interaction force constants for coordinates at 90° (F_2, F_4, F_6, F_8).
† $\perp$ denotes force constants for out-of-plane coordinates (F_{13}, F_{14}, F_{15}).

There is no simple way of describing the bending motions around the N_2PtCl_2 core because each motion contains some change in the Cl—Pt—N angles: it seems reasonable, however, to expect that for some motions either the Cl—Pt—Cl or the N—Pt—N contribution will dominate. Two bending motions which move a common bond may be expected to show a greater interaction than others. For example, of the a_1 deformations, ν_4 and ν_5 will interact with each other as will ν_5 and ν_7. Of the a_2 twisting deformations ν_9 and ν_{10} will interact, as will ν_{10} and ν_{11}. Of the b_1 deformations, ν_{15} and ν_{16} will interact, as will ν_{16} and ν_{18}; and of the b_2 deformations, ν_{19} and ν_{20} will interact, as will ν_{19} and ν_{21}.

Without the use of more isotopically substituted species the number of observed frequencies is limited, and therefore certain arbitrary but reasonable assumptions in the selection of interaction and bending force constants were required and are summarized here: (*1*) Where an interaction exists between the stretching force constants for two adjacent bonds, such as $F_{C\equiv N}$, F_{C-C}, then this interaction was assigned a value of 5% of the lower of the two force constants. Thus if $F_{C\equiv N} = 18$ mdyn Å^{-1} and $F_{C-C} \approx 5$ mdyn Å^{-1}, then $F_{C\equiv N,C-C} \approx 0.25$ mdyn Å^{-1}. An exception was made for $F_{C\equiv N,Pt-N}$, (2.5% of F_{Pt-N}), since the C≡N and Pt—N stretching vibrations have a large frequency difference. It was found for $ReO_2(CN)_4^{3-}$ that the lower force constant for the adjacent bonds Re—C and C≡N was $F_{Re-C} = 2.4$ mdyn Å^{-1}, and that $F_{CN,Re-C}$ was 0.06 mdyn Å^{-1}; the latter constant seemed surprisingly small, but the frequency difference was large for the two stretching vibrations C≡N and Re—C (42). (*2*) For simplicity in treating the deformations around the N_2PtCl_2 core the number of bending force constants was restricted to two: F_{N-Pt-N} and $F_{Cl-Pt-Cl}$. The b_1 mode then has a force constant $\frac{1}{2}[F_{N-Pt-N} - F_{Cl-Pt-Cl}]$. The interaction force constants between different adjacent bending coordinates were set at zero for the a_1 and b_1 blocks, and 2.5–5% for the a_2 and b_2 blocks. The interaction force constant of a bending coordinate with itself was set equal to 2.5% that is, $F_{Pt-N-C,Pt-N-C} = 0.025\,F_{Pt-N-C}$.

The Raman spectrum of CH_3CN has been discussed by Herzberg (43). CH_3CN is transparent between 1124 and 918, 918 and 380, and below 380 cm^{-1}; many bands for the complex fall in these "windows"; also bands below 380 cm^{-1} result from various Pt—N and Pt—Cl deformations.

*Observed wavenumbers for $Pt(CH_3CN)_2Cl_2$ and calculated wavenumbers for the skeleton $Pt(NCC)_2Cl_2$.

Computations for the force constant analysis were carried out as described previously (42). The force constants of the $Pt(NCC)_2Cl_2$ entity were refined from 20 observed vibrational frequencies. The trial and refined force constants are listed in Table 6. A comparison of observed and calculated frequencies is shown in Table 7. There is excellent agreement, the largest single difference being ~4% (ν_6) and the average difference <2% for the a_1 and b_1 blocks. The agreement is slightly poorer for the a_2 and b_2 blocks. The potential energy distribution is shown in Table 8. The distribution for the ^{15}N species was the same within the error limits and is not listed here. The high degree of coupling is evident for the in-plane vibrations ν_3 and ν_4; ν_{11} and ν_{12} and ν_6 and ν_{14}. The out-of-plane angle deformations are also highly coupled, especially δNCC and δNPtCl. Figure 4 shows the spectra in the region 465–325 cm^{-1} with the inset showing the νC≡N region.

Coordination through the lone pair on nitrogen always increases the C≡N frequency because of kinematic coupling and the ionic character of the C—N bond (44, 45). The title complex shows the expected increase in ν(C≡N): 2249 cm^{-1} (ligand), 2332 cm^{-1} (complex).

The frequencies 1124 cm^{-1} and 380 cm^{-1} in CH_3CN belong to the two degenerate vibrations of the linear system (H_3)—C—C≡N, the former being mainly a CH_3 rocking vibration, and the latter a C—C≡N bending vibration. For the platinum complex, bands at 1123 and 384 cm^{-1} were observed by us in the Raman spectrum, and are assigned to similar vibrational motions.

The bands at 1034 and 1020 cm^{-1} are assigned to the in-phase and out-of-phase C—C stretching vibrations, $\nu_2(a_1)$ and $\nu_{13}(b_1)$. In free CH_3CN the C—C vibration is at 918 cm^{-1}, in

C_2H_6 it is at 993 cm^{-1}, and CH_3OH has the C—O vibration at 1034 cm^{-1}.

The frequencies of Pt—N and Pt—Cl stretching vibrations have been discussed by numerous authors. Studies of Pt(IV) and Pt(II) complexes containing a variety of ligands have been made (46–51). There is a considerable variation in bond lengths and bond strengths.

Hendra (46) studied the Raman spectrum of *trans*-$Pt(NH_3)_2Cl_2$ in the region 0–600 cm^{-1} and found that the symmetric metal–nitrogen mode had a higher frequency than the asymmetric mode, while the metal–halogen vibrations showed the more common asymmetric > symmetric frequency. He noted that the force constant equations do not allow for this characteristic, and therefore the Pt—N force constant was calculated on the basis of each mode separately; an average value was 2.4 mdyn $Å^{-1}$. Nolan and James (47, 48) found the highest observed ν(Pt—N) to be the symmetric one for several chloro ammine complexes of Pt(IV). Their range for ν(Pt—N) was 516–568 cm^{-1} with one low intensity band at 600 cm^{-1}.

Typical Pt—N force constants collected in Nakamoto's recent book (52) are in the range 2.0–3.8 mdyn $Å^{-1}$. A calculated ν(Pt—N) for a relatively low force constant of 2.0 would be 600 cm^{-1}, on the assumption of a relatively weak bond. Because the Pt—N distances of the title compound lie at the lower end of the range of Pt—N distances we infer that the Pt—N bond is stronger than most other Pt—N bonds and indeed the force constant analysis gives 4.05 mdyn $Å^{-1}$.

It seems reasonable, therefore, to assign a fairly high frequency to ν(Pt—N) and at first consideration one might expect it to fall in the higher portion of the 500–700 cm^{-1} region. The CCN group, however, has about the same mass as Cl, and there seems to be such strong coupling that ν(Pt—N) is lost as a pure vibration, and the mode observed is a motion of the whole CCN group against Pt. The force constant analysis shows these interactions and the bands at 463 and 408 cm^{-1} have the highest contribution of ν(Pt—N) but are coupled with δPtNC, δNPtN, and δCCN. These three deformations combine to produce a high frequency mode which is largely δPtNC and a very low frequency mode which has a contribution of all three (which may be pictured as an accordian-like deformation of the whole skeleton). In scanning the low frequency region at a higher laser power (~500 mW) we observed very weak broad bands at 618 and 583 cm^{-1} which coincide with infrared bands at 620 and 580 cm^{-1}. We assign these to combinations.

Although this complex is an unusual one for ν(Pt—N) assignments, it seems that most authors have assigned much too low a frequency to the ν(Pt—N) mode. Before the discovery of the chemotherapeutic uses of platinum complexes, the interest in *cis*- and *trans*-Pt(II) complexes was concentrated on metal–halogen vibrations, rather than the metal–nitrogen ones. Also the frequency ranges previously observed were restricted: Hendra's Raman frequency shifts covered the region 600 cm^{-1} and below (46); Adams *et al.* (50) infrared spectra covered 170–460 cm^{-1}. Walton (11*b*) reporting infrared spectra in the 500–200 cm^{-1} region observed no bands >350 cm^{-1} which could be assigned to ν(Pt—N) modes and suggested that these modes occur below 200 cm^{-1}. Meester (51) also made some very low ν(Pt—N) assignments. A low polarizability change in the Pt—N bond has made observations of Raman scattering difficult and it may well be that electronic spectra or resonance Raman spectra will provide more data in future work.

It has been found in *cis*-$[PtCl_2L_2]$ type complexes that the position of ν(Pt—Cl) is directly related to the *trans* effect of

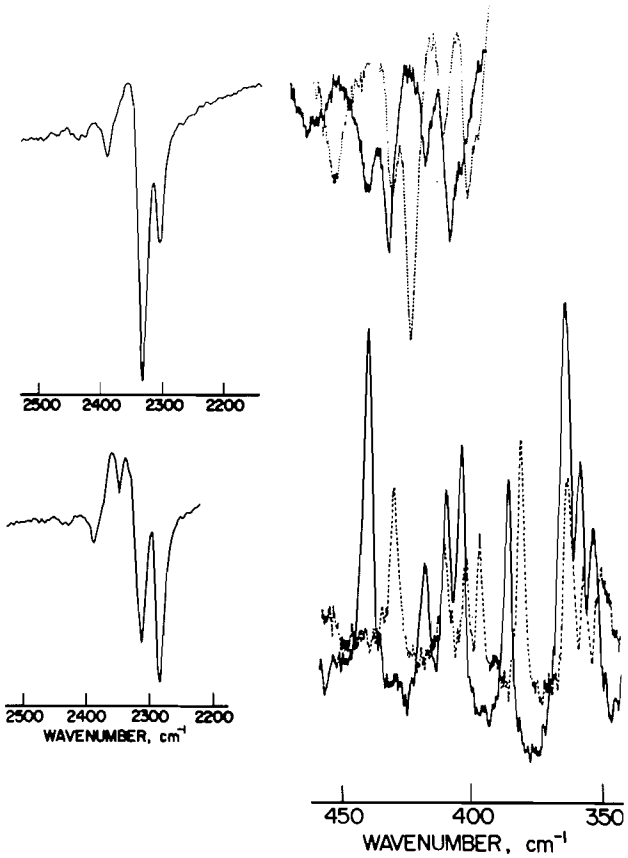

FIG. 4. The vibrational spectra of $Pt(CH_3CN)_2Cl_2$, 470–325 cm^{-1}. Upper, infrared of KBr pellet; lower, Raman of solid. Solid line, normal complex; dashed line, ^{15}N-enriched complex. Inset: infrared of KBr pellet, 2500–2200 cm^{-1}: upper, normal complex; lower, ^{15}N-enriched complex.

the ligand L. Assignments for ν_{Pt-Cl} wave number range 320–360 cm^{-1} are typical. The observation here of two ν(Pt—Cl) bands in both Raman and infrared is consistent with the *cis* configuration. In the *trans* compounds there is a single Pt—Cl mode observed in the 330–335 cm^{-1} region. The expected Cl isotope effect is a splitting into three components of relative intensity 9:6:1 which is most likely to be seen on the a_1 band. This effect was observed by us for the Raman band at 358 cm^{-1}.

Simple geometric considerations show that for a *cis* configuration the separation between symmetric and asymmetric frequencies is a function of angle. The asymmetric frequency is higher, and the maximum spread of symmetric and asymmetric frequencies is for angles of 180°, e.g. C—C≡N. The separation becomes smaller as the angle decreases until at 90° the two frequencies are the same. The symmetric frequency becomes higher than the asymmetric frequency for a bond angle of 60°. This is just a result of the geometry change, and does not depend on force constants (53). In the title compound the Cl—Pt—Cl bond angle is 90.7°, the large difference in frequencies (25 cm^{-1}) is likely caused by very strong Pt—Cl coupling with consequent strong interaction force constants. Indeed, the Pt—Cl interaction was found to be ~7% of the primary Pt—Cl force constant.

All *trans*-$PtCl_2XY$ complexes show two bands in the infrared and Raman at about 130 and 160 cm^{-1}. These are assigned to Pt—Cl deformation modes (46). In this work we observe bands at 125 and 175 cm^{-1} which are so assigned.

N—Pt—N deformations are generally close to 250 cm^{-1}. We assign the broad bands centred at 230 cm^{-1} in the infrared to some or all of these modes.

The remaining deformations are C—C≡N and C≡N—Pt which we assign to the observed frequencies 387, 407 cm^{-1} (C—C≡N) and 431, 440 cm^{-1} (C≡N—Pt). There is a reasonable comparison for the latter with the $ReO_2(CN)_4^{3-}$ complex (470, 434 cm^{-1} for δRe—C≡N) (42).

The assumption that the CH_3 groups can be treated as discrete units seems to be an adequate one, since there is no evidence for interaction of the CH_3 vibrations with other vibrations. It is still possible, however, to assign the vibrations of the CH_3 groups, since they fall into characteristic regions of the spectrum. Both stretches and deformations are motions which are well localized within the CH_3 groups. These are listed in Table 5 with descriptions, but without mode numberings.

Gas chromatography − mass spectrometry of osulose derivatives: *O*-trimethylsilyl, *O*-acetyl, *O*-isopropylidene, methyl glycosides, and 1,1-dimethyl acetals

PEDRO ANTONIO GARCÍA RUIZ, INMACULADA CARTAGENA TRAVESEDO, AND ANTONIO SOLER MARTINEZ
Department of Organic Chemistry, Faculty of Science, University of Murcia, Murcia, Spain

Received October 21, 1982[1]

PEDRO ANTONIO GARCÍA RUIZ, INMACULADA CARTAGENA TRAVESEDO, and ANTONIO SOLER MARTINEZ. Can. J. Chem. **62**, 870 (1984).

Structure determination of the *O*-trimethylsilyl, *O*-acetyl, and *O*-isopropylidene derivatives of some hexosuloses, pentosuloses, and one tetrosulose, as well as their methyl glycosides and 1,1-dimethyl acetals has been achieved by gas chromatography − mass spectrometry.

By study based on the qualitative and quantitative differences in the 36 derivatives obtained, and their analogues prepared from tetradeuterio methanol and/or hexadeuterio acetone, and comparison with results reported in the literature, criteria for the unambiguous determination of the structural grouping are proposed. The relative abundance of each compound when the osulose forms more than one isomeric derivative in the same reaction, as well as chromatographic data for the isolated products, are reported.

PEDRO ANTONIO GARCÍA RUIZ, INMACULADA CARTAGENA TRAVESEDO et ANTONIO SOLER MARTINEZ. Can. J. Chem. **62**, 870 (1984).

Faisant appel à la chromatographie en phase gazeuse couplée à la spectrométrie de masse, on a déterminé la structure des dérivés *O*-triméthylsilyl, *O*-acétyl et *O*-isopropylidène des quelques hexosuloses, pentosuloses et d'un tétrosulose ainsi que de leurs glucosides de méthyle et de leurs diméthyl-1,1 acétals.

En se basant, d'une part, sur les différences qualitatives et quantitatives observées dans les 36 dérivés obtenus et dans leurs analogues préparés à partir du tétradeutéro méthanol et/ou de l'hexadeutéro acétone et, d'autre part, sur une comparaison avec les résultats rapportés dans la littérature, on propose des critères pour la détermination non-ambigue des caractéristiques de structure. On rapporte aussi les données chromatographiques pour les produits isolés ainsi que les abondances relatives de chaque composé formé lorsque les osuloses forment plus d'un dérivé isomère dans la même réaction.

Introduction

Although, glc−ms is a powerful tool for the structural elucidation (1) of the sugars, and analyses of some of the volatile derivatives of aldoses (2) and ketoses (3) that have been reported, until now no efficient method for the determination of the volatile derivatives of the osuloses has been published.

The present paper describes studies by electron impact mass spectrometry of four types of volatile derivatives of eight osuloses. These were the isopropylidene acetals, trimethylsilyl ethers, and acetate esters of the free sugars, and the isopropylidene acetals of the methyl glycosides.

Results and discussion

The derivatives detected and identified by gas chromatography, their relative retention times, and the relative abundance of each compound when the osulose forms more than one derivative in the same reaction, have been summarized in Tables 1 and 2.

The assignment of structure was made on the basis of the presence or absence of certain fragments characteristic of the structures of the ring types (4). The hydrogen contribution of the substituents in the fragments was confirmed by the relation between their m/e elevation and the number of hydrogen atoms changed by preparation of deuterated analogues (5).

Because the spectra of diastereoisomeric sugars differ only in the intensity of particular peaks (4), only one of them is discussed in detail (i.e., of the compounds **3**, **7**, and **13**, only compound **3** is discussed). The corresponding data for all of the compounds listed in Table 1 are available in the Journal's Depository of Supplementary Material.[2] The characteristic peaks of the general types of structural groupings will be discussed in the following sections.

A. *The molecular weight determination*

O-*Isopropylidene derivatives*

No molecular ions can be observed with the acetonides, but an intense $M^{+\cdot} - 15$ species (formed by the loss of one methyl group in the isopropylidene moiety to give an oxonium ion (6)) makes possible an easy calculation of the molecular weight. Further decompositon of $M^{+\cdot} - 15$ occurs by the loss of 58 (acetone), 60 (acetic acid), and 58 + 60 mass units. These fragments are found in the spectra of all the di-*O*-isopropylidene derivatives (3). The tri-*O*-isopropylidene derivatives show, in addition, peaks at $M^{+\cdot} - 15 - 58 - 58$; $M^{+\cdot} - 15 - 58 - 58 - 60$; $M^{+\cdot} - 58$; $M^{+\cdot} - 58 - 58$; $M^{+\cdot} + 1 - 58 - 58 - 58$; and $M^{+\cdot} + 1$.

The presence of many other linkages leads to a noticeable $M^{+\cdot} + 1$ peak. This small peak is easily recognized on the original record (7), especially when easily fragmented groups such as —OH or —$CH(OMe)_2$, linked to the ring, are absent.

For the mono-*O*-isopropylidene derivatives, the loss of acetone from the $M^{+\cdot} - 15$ species is not possible, because it requires an intact second isopropylidene moiety; peaks corresponding to $M^{+\cdot} - 15 - 58$ and $M^{+\cdot} - 15 - 60$ are absent in the spectrum (7). Only occasionally is the $M^{+\cdot} - 15 - 60$ species formed by several derivatives.

All the isopropylidene derivatives show two abundant fragments of lower mass, at m/e 59 (m/e 65 for the compounds from hexadeuterio acetone), corresponding to the protonated acetone ion, and at m/e 43 (m/e 46 for the compounds from hexadeuterio acetone) due to Me—CO^+; this is often the base peak.

The molecular weight and the most characteristic ions are summarized in Table 3A. This table shows, moreover, the m/e of the fragments for the analogous compounds prepared from

TABLE 1. Identified osulose derivatives

Compound number	Substituents	Ring size
Parent osulose: D-*arabino* hexos-2-ulose		
1	2,3:4,5-Di-*O*-isopropylidene	2,6-Pyranose
2	2,3:4,5-Di-*O*-isopropylidene; 1,1-dimethyl acetal	2,6-Pyranose
3	1,2:2,3:5,6-Tri-*O*-isopropylidene	1,4-Furanose
4	2,3:5,6-Di-*O*-isopropylidene; methyl glycoside	1,4-Furanose
5	2,3,4,6-Tetra-*O*-trimethylsilyl	2,5-Furanose
6	2,3,4,6-Tetra-*O*-acetyl	2,5-Furanose
Parent osulose: D-*lyxo* hexos-2-ulose		
7	1,2:2,3:5,6-Tri-*O*-isopropylidene	1,4-Furanose
8	4,6-*O*-Isopropylidene; methyl glycoside	2,5-Furanose
9	4,6-*O*-Isopropylidene- methyl glycoside; 1,1-dimethyl acetal	2,5-Furanose
10	2,3,4,6-Tetra-*O*-trimethylsilyl	2,5-Furanose
11	1,3,5,6-Tetra-*O*-trimethylsilyl	1,4-Furanose
12	1,3,5,6-Tetra-*O*-acetyl	1,4-Furanose
Parent osulose: L-*xylo* hexos-2-ulose		
13	1,2:2,3:5,6-Tri-*O*-isopropylidene	1,4-Furanose
14	2,3,4,6-Tetra-*O*-trimethylsilyl	2,5-Furanose
Parent osulose: 6-deoxy-L-*arabino* hexos-2-ulose		
15	1,2:2,3-Di-*O*-isopropylidene	1,5-Pyranose
16	2,3-*O*-Isopropylidene	2,5-Furanose
17	2,3-*O*-Isopropylidene; 1,1-dimethyl acetal	2,5-Furanose
18	2,3,4-Tri-*O*-trimethylsilyl	2,5-Furanose
19–20	2,3,4-Tri-*O*-acetyl	2,5-Furanose
Parent osulose: D-*erythro* pentos-2-ulose		
21	1,2:3,4-Di-*O*-isopropylidene	1,5-Pyranose
22	3,4-*O*-Isopropylidene	2,5-Furanose
23	3,4-*O*-Isopropylidene; methyl glycoside	2,5-Furanose
Parent osulose: D-*erythro* hexos-2-ulose		
24	3,4-*O*-Isopropylidene; 1,1-dimethyl acetal	2,5-Furanose
25	3,4-*O*-Isopropylidene; methyl glycoside; 1,1-dimethyl acetal	2,5-Furanose
26	2,3,4-Tri-*O*-trimethylsilyl	2,5-Furanose
27	1,3,5-Tri-*O*-acetyl	1,4-Furanose
28	2,3,4-Tri-*O*-acetyl	2,5-Furanose
Parent osulose: L-*erythro* pentos-2-ulose		
29	3,4-*O*-Isopropylidene; 1,1-dimethyl acetal	2,5-Furanose
30	2,3,4-Tri-*O*-trimethylsilyl	2,5-Furanose
31–32	2,3,4-Tri-*O*-acetyl	2,5-Furanose
Parent osulose: D-*threo* pentos-2-ulose		
33	2,3-*O*-Isopropylidene	2,5-Furanose
34	1,3,5-Tri-*O*-trimethylsilyl	1,4-Furanose
Parent osulose: D-*glycero* tetros-2-ulose		
35	1,2:2,3-Di-*O*-isopropylidene	1,4-Furanose
Pentose: D-erythrose		
36	2,3-*O*-Isopropylidene	1,4-Furanose

hexadeuterio acetone and tetradeuterio methanol which are in agreement with the hydrogen contribution of the substituents in the fragments: e.g., for compound **1**, the $(M - 15)^+$ ion (corresponding to the loss of one Me group from the acetone) increases their m/e by nine mass units in the deuterated analogue, as should be expected for a di-*O*-isopropylidene derivative.

O-*Trimethylsilyl derivatives*

The mass spectra show very weak peaks for the molecular ions and more abundant peaks at $(M - 15)^+$, $(M - 15 - 90)^+$, $(M - 15 - 90 - 90)^+$, $(M - 73)^+$, and $(M - 89)^+$ as are characteristic of the TMS derivatives of the sugars (8) (see Table 3B) which occur through the loss of the Me (15), $SiMe_3$ (73), $OSiMe_3$ (89), and $HOSiMe_3$ (90) groups.

O-*Acetyl derivatives*

According to the literature data for discerning the molecular ions (6, 9, 10), the acetates show peaks at $M + 43$; $M + 1$; $M - 43$; $M - 59$; $M - 43 - 59$; and $M - 59 - 60$ through loss of the acetyl (43), acetic acid (59), and acetate anion (60) (see Table 3C).

The molecular weight is also confirmed on the basis of all the fragments obtained from $M^{+\cdot}$ by loss of characteristic groups such as CH_2OR or CHO.

B. *The ring type determination*

The different pyranoid or furanoid forms may be distinguished on the basis of low m/e cyclic fragments. Thus, the fragment at m/e 99 (3, 7, 9, 11) is relatively abundant in the 2,5-furanoses, the 1,5-pyranoses, and the 1,4-furanoses. The

$(M - 59 - 60)^{+\cdot}$	227(2.61)	169(—)	155(—)

The most marked characteristic differences, which provide a firm basis for distinguishing between ring types, are the positions and intensities of peaks corresponding to the fragments formed by fission of the side chains or groups connected to the carbon α to the ring oxygen (6−9). These fragmentations are discussed below for the most characteristic X groups, and all the investigated compounds show abundant peaks at $M^{+\cdot} - X$ and their corresponding series, as has been indicated (3, 9).

C. *The formyl group determination*

It has been shown for the aldehydo derivatives of sugars that the most intense peaks are formed by cleavage of the C_1—C_2 bond with the subsequent loss of the Me, ROH, R_2O, and other typical fragments (3, 9, 13). For example, in the aldehydo acetates the fragments of a series arise from the fission of the formyl group (—CHO) (20 mass units) and subsequent elimination of Ac_2O (102 mass units), AcOH (60 mass units), and ketene (42 mass units) (13, 18).

All the investigated compounds containing the CHO group (as revealed in Table 4) show the following fragments.

O-Isopropylidene derivatives: $M^{+\cdot} - 29$ ($M^{+\cdot}$ − CHO) and $M^{+\cdot} - 29 - 58$ ($M^{+\cdot}$ − CHO − Me_2CO) which show the expected *m/e* in the deuterio analogues.

O-Trimethylsilyl derivatives: $M^{+\cdot} - 29$; $M^{+\cdot} - 29 - 28 - 1$ ($M^{+\cdot}$ − CHO − CO − H^+); $M^{+\cdot} - 29 - 89 - 15$ ($M^{+\cdot}$ − CHO − $OSiMe_3$ − Me); and $M^{+\cdot} - 29 - 103$ ($M^{+\cdot}$ − CHO − CH_2 − $OSiMe_3$).

O-Acetyl derivatives: $M^{+\cdot} - 29$; $M^{+\cdot} - 29 - 59$ ($M^{+\cdot}$ − CHO − MeCOO·); $M^{+\cdot} - 29 - 42$ ($M^{+\cdot}$ − CHO − CH_2CO); $M^{+\cdot} - 29 - 42 - 60$($M^{+\cdot}$ − CHO − CH_2CO − MeCOOH); and *m/e* 100 (MeCOOCHCO).

Furthermore, fragments such as *m/e* 57 (CHO—CO^+), *m/e* 69 (protonated furan), and *m/e* 73 (MeO^+=CH—CHO), have been reported to be characteristic of the formyl group (2, 9, 14), but their presence does not establish the presence of the formyl group because each peak may be obtained by other routes.

D. *The formyl dimethyl acetal group determination*

In the spectra of compounds **2**, **9**, **17**, **24**, **25**, and **29**, the most intense peaks are formed by cleavage of the C_1—C_2 bond, as occurs with the aldehydo dithioacetals (19). This series is represented by the ions *m/e* 75 (MeOCH=OMe) (9, 20) (which usually is the base peak), $M^{+\cdot} - 58 - 75$, and $M^{+\cdot} - 75$.

Furthermore, the presence of this group produces two other series of fragments. The loss of one of the methoxyl groups as MeO· (*m/e* 31) (5) and the subsequent elimination of acetone gives the ions $M^{+\cdot} - 31$, $M^{+\cdot} - 31 - 58$ and $M^{+\cdot} - 31 - 58 - 58$. On the other hand, the loss of Me—OH—Me (*m/e* 47) and acetone produces the ions at $M^{+\cdot} - 47$, $M^{+\cdot} - 47 - 58$, and *m/e* 47.

As revealed in Tables 5A and 5B, the observed *m/e* values of the deuterio analogues are in agreement with the loss of these groups. For the peak at *m/e* 47, as revealed in Tables 5A and 5B, the major contribution to this fragment is provided by the two methyl groups of the $CH(OMe)_2$ unit; because the MeOH was replaced by CD_3—OD, their series shifted by six *m/e* units.

E. *The CH_2OR group determination*

Analogously, the loss of the substituent α to the ring oxygen (the CH_2OR group) with the formation of the $M^{+\cdot} - CH_2OR$ ions and the loss of the CHO—CH_2OR group, are indicative of this group (6, 8−11, 14). As shown in Table 6A, the trimethylsilyl derivatives give fragments at *m/e* 103, $M^{+\cdot} - 103$, *m/e* 133, and $M^{+\cdot} - 132$, and the acetates at *m/e* 73, $M^{+\cdot} - 60 - 73$ and $M^{+\cdot} - 102$, in accordance with the expected fragmentations for structures which contain the CH_2OR group.

F. *The CHOR—CH_2OR group determination*

The most characteristic fragmentation process for the com-

[a]A: *m/e*; B: *m/e* for the analogue prepared from hexadeuterio acetone; C: *m/e* for the analogue prepared from tetradeuterio methanol; D: *m/e* for the analogue prepared from hexadeuterio acetone and tetradeuterio methanol; E: % relative intensity.

pound with this group is the cleavage of the C_4—C_5 bond (7) resulting in the fragments at *m/e* 205 for the trimethylsilyl derivatives (8) or at *m/e* 145 for the acetates (9, 10) (Table 6B), and their fragment series.

Compound **11** shows fragments at *m/e* 205, $M^{+\cdot} - 205$, $M^{+\cdot} - 205 - 15$, and *m/e* 115 (*m/e* 205 − 90) whereas the acetylated compound **12** shows peaks at *m/e* 145, $M^{+\cdot} - 145$, $M^{+\cdot} - 145 - 42$, $M^{+\cdot} - 145 - 60 - 42$, *m/e* 103, and *m/e* 85, as expected.

G. *The methoxyl group on the methyl glycosides*

The degradation of methyl glycosides (20) proceeds through elimination of MeO· (fragment which is unstable and produces only a small peak at *m/e* 31) (ref. 9) and the subsequent elimination of acetone to give the $M^{+\cdot} - 31$ and $M^{+\cdot} - 31 - 58$ peaks. The loss of MeOHMe (*m/e* 47) produces small peaks at *m/e* 47, $M^{+\cdot} - 47 - 58$ because only one of the Me groups of the *m/e* 47 is derived from the glycoside, whereas the other is derived from the isopropylidene group.

In addition, other fragments which contain the OCH_3 group, such as the *m/e* 73 (MeO=CH—CHO) (21, 24) and *m/e* 113 ( —CH=$\overset{+}{O}$—Me), have been observed. Table 7 shows the *m/e*, relative abundances, and the *m/e* of the deuterio analogues (in accordance with the preceding losses).

H. *The free hydroxyl group determination*

The study of the *O*-isopropylidene derivatives bearing a free OH group showed, as expected, the fragmentation series $M^{+\cdot} - 1$, $M^{+\cdot} - 1 - 58$, $M^{+\cdot} - 17$, and $M^{+\cdot} - 17 - 58$ ($M^{+\cdot} - OH - Me_2CO$). Compounds **4**, **21**, **22**, **24**, **29**, and **36** have more intense $M^{+\cdot} - 1$ and $M^{+\cdot} - 17$ peaks due to the attachment of the OH to the C_1 or C_2 rather than to some other carbon atom (5). The fragments are listed in Table 7.

I. *The 5,6-O-isopropylidene structural unit*

The most characteristic fragmentation process for the com-

(CHOR—CH_2OR) − CH_2CO		103(9.17)
M − (CHOR—CH_2OR) − (CH_2CO)		159(3.71)

pounds with this structural unit is the cleavage of the C_4—C_5 bond (7) resulting in the fragments at *m/e* 101 (very intense peak shifted to *m/e* 107 in the acetone deuterated analogues (6)), $M^{+\cdot} - 101$, $M^{+\cdot} - 101 - 15$, and $M^{+\cdot} - 130 - 15$. These peaks are listed in Table 8A.

Other characteristic fragments of the compounds with this structural unit are the *m/e* 129 (shifted to *m/e* 136 in the deuterated analogues, and which seem to represent the cleavage of the C_3—C_4 and O—C_1 bonds (7)), *m/e* 117 (with shift to *m/e* 123 in the deuterated analogues (7)), *m/e* 115 (with shift to *m/e* 118 (3)), and *m/e* 72 ($\cdot CH_2$—O=CMe_2 with shift to *m/e* 78 (3, 7, 11)).

Furthermore, other fragments typical of *O*-isopropylidene derivatives are also present but in reduced relative intensity, because of the competitive cleavage of the C_4—C_5 bond (7).

J. *The 4,6-O-isopropylidene structural unit*

As in the compounds of the preceding structural unit, compounds **8** and **9** show fragments at *m/e* 101, 115, and 129 which must proceed from a rearrangement (9). Characteristic of this structural unit (7, 19, 22) are abundant peaks at *m/e* 72, *m/e* 113 (Me_2C—O—CH=CH—CHO shifted by 119 (7, 9) in deuterated analogues), *m/e* 85 (shifted by 88), *m/e* 71 (shifted by 74), and *m/e* 117, as shown in Table 8B.

K. *Other O-isopropylidene structural units*

For the *O*-isopropylidene derivatives that do not contain structural units equivalent to those discussed in sections I or J, the C_4—C_5 fragmentation to give such ions is impossible (3, 23).

These *O*-isopropylidene derivatives give a characteristic peak at *m/e* 85 (shifted by 88 in deuterated analogues).

L. *The Me group of the 6-deoxy-osulose derivatives*

For the acetates, the fragments at $M^{+\cdot} - 15$, $M^{+\cdot} - 15 - 29$, $M^{+\cdot} - 15 - 60$, $M^{+\cdot} - 15 - 60 - 60$, $M^{+\cdot} - 15 - 42$, and $M^{+\cdot} - 15 - 60 - 42$ make possible its assignment for the compounds **19** and **20** by criteria analogous to those employed in the preceding structural unit (see Table 8C).

M. *Fragmentation data and elimination of alternative structure*

In the preceding sections (A to L) the molecular weight and the presence of the characteristic groups and structural units were determined unambiguously in the compounds studied. This determination makes possible the assignment of structure, because alternative structures (for example, another ring type) should have (a) lower molecular weight (for compound **3** the 2,5-furanose or the 2,6-pyranose is not possible for a tri-*O*-isopropylidene derivative), or (b) other groups (for compound **5** the 1,4-furanose should give peaks corresponding to the CH_2OR—CHOR—group), or (c) the absence of the characteristic peaks of some groups (for compound **5** in the 1,4-furanose, the peaks for a CHO group should be absent), or (d) the absence of the characteristic peaks of the assigned structure (for compound **5**, the characteristic peaks of the furanose ring should be absent in the alternative pyranose rings).

With respect to the latter, although the mass spectra provide strong evidence for the assigned structures, these assignments have been verified for compounds **1** (24−26) and **3** (27) and all the bibliographic results were consistent with the assigned structures for the TMS and acetate derivatives (24, 28−31), and with the conclusion that the substrate was an osulose or other sugar *O*-isopropylidene derivative which contains formyl (24−26, 32, 33), formyl dimethyl acetal (30, 34, 35), and methoxyl groups (35), the 5,6-*O*-isopropylidene structural unit (27, 36, 37),or ring types (24 to 37) as assigned in the present paper.

Preparation of osulose derivatives

The *O*-isopropylidene derivatives were prepared by the acetone (and acetone-d_6) – sulphuric acid method (41, 42). The methyl glycosides and 1,1-dimethyl acetals were prepared from methanol (and methanol-d_4) (43). The acetates were prepared by the acetic anhydride – sodium acetate method (44). The literature method was modified only for the preparation of the trimethylsilyl derivatives (45), the solvent (pyridine) being replaced by *N,N*-dimethyl formamide (33, 46).

Analytical methods

Gas–liquid chromatography was performed on a Perkin–Elmer F-30 gas chromatograph equipped with a flame-ionization detector and coiled stainless columns (6 ft × 1/8 in.) packed with 3% SE-30 and SE-52 on Chromosorb W HP 80–100. Nitrogen was used as the carrier gas, at a flow rate of the 30 mL/min. The temperature of the oven was programmed from 100–275°C at 2°C/min.

The determination of the relative abundances of each compound when the osulose formed more than one derivative in the same reaction was made by glc (47).

For the glc–ms analyses, a Hewlett–Packard 5980 A gas chromatograph was used in combination with a Hewlett–Packard 5710 A mass spectrometer, operating at 70 eV under the same conditions as described above for glc, although the carrier gas was helium in this case.

Capacités calorifiques, volumes, expansibilités et compressibilités des solutions aqueuses concentrées de LiOH, NaOH et KOH

ALAIN H. ROUX,[1] GÉRALD PERRON ET JACQUES E. DESNOYERS[2]

Département de chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Reçu le 15 août 1983

ALAIN H. ROUX, GÉRALD PERRON et JACQUES E. DESNOYERS. Can. J. Chem. **62**, 878 (1984).

Les masses volumiques et capacités calorifiques de solutions aqueuses d'hydroxydes alcalins ont été mesurées entre 4 et 55°C à l'aide d'un densimètre à tube vibrant et d'un microcalorimètre dynamique. Le domaine de concentration étudié est respectivement de 0,04 à 3,8 mol kg^{-1} pour LiOH, 0,02 à 10,9 mol kg^{-1} pour NaOH et 0,02 à 15,5 mol kg^{-1} pour KOH. Les volumes et capacités calorifiques molaires partiels ($\bar{V}_2$, $\bar{C}_{p,2}$) ont été calculés par dérivation des équations analytiques obtenues à l'aide d'une méthode de moindres carrés appliquée aux grandeurs molaires apparentes (V_ϕ, $C_{p,\phi}$) en fonction de la molalité. De l'influence de la température sur les grandeurs molaires apparentes à une concentration donnée, nous avons déduit les expansibilités molaires apparentes E_ϕ et $(\partial C_{p,\phi}/\partial T)_P$. Les vitesses ultrasonores ont aussi été mesurées à 25°C pour NaOH dans le domaine des faibles concentrations et ont été utilisées pour calculer les compressibilités et les capacités calorifiques molaires partielles à volume constant dans l'état standard. Les données présentées ont été comparées avec les valeurs de la littérature. La dépendance avec la concentration des propriétés des solutions d'hydroxydes est semblable à celle des autres électrolytes 1:1 bien que les déviations à la loi limite de Debye–Hückel soient plus grandes.

ALAIN H. ROUX, GÉRALD PERRON, and JACQUES E. DESNOYERS. Can. J. Chem. **62**, 878 (1984).

The densities and heat capacities of various alkali hydroxides were measured in water with a vibrating tube densimeter and a flow microcalorimeter in the temperature range 4 to 55°C. The concentration ranges investigated were respectively: 0.04 to 3.8 mol kg^{-1} for LiOH, 0.02 to 10.9 mol kg^{-1} for NaOH, and 0.02 to 15.5 mol kg^{-1} for KOH. The partial molar volumes ($\bar{V}_2$) and heat capacities ($\bar{C}_{p,2}$) were calculated from the least-squares fit of the apparent molar quantities (V_ϕ and $C_{p,\phi}$) as a function of molalities. From the temperature dependence of these functions the apparent molar expansibilities (E_ϕ) and $(\partial C_{p,\phi}/\partial T)_P$ were derived. The ultrasonic velocities were also measured for the dilute solutions of NaOH at 25°C, and can be used to calculate the standard partial molar compressibilities and isochoric heat capacities. The present data were compared with literature values. The general trends as a function of concentration are similar to those of other 1:1 electrolytes even though the deviations from the Debye–Hückel theory are larger.

Introduction

L'étude des propriétés des solutions aqueuses d'hydroxydes alcalins aux fortes concentrations présente un intérêt certain lié en particulier au domaine de l'énergie électrochimique (1). Ces systèmes sont aussi importants au point de vue fondamental car il n'est pas encore clairement établi quel rôle l'interaction particulière entre l'ion OH^- et H_2O peut avoir sur les interactions soluté–soluté aux fortes concentrations (2). Ainsi, l'influence de la concentration des hydroxydes alcalins sur les réactions d'hydrolyse de diverses molécules organiques se traduit par un effet catalytique observé depuis longtemps (3–7). Finalement, les théories des solutions concentrées d'électrolytes ont été développées surtout pour les solutions d'électrolytes simples comme NaCl (8–10) où la solvatation joue un rôle beaucoup moins important que dans le cas des hydroxydes alcalins.

Lors de l'étude des solutions concentrées, une bonne connaissance des fonctions thermodynamiques est nécessaire pour améliorer notre compréhension des interactions ion–solvent et ion–ion et pour prédire l'influence de la température et de la pression sur ces systèmes. La plupart des études réalisées sur un grand domaine de température sont assez anciennes (11) et souvent les études plus récentes, sauf exception (12), ne concernent que le domaine dilué ou un domaine limité en température. Il nous a donc paru utile, avec l'avènement d'instrumentation moderne, d'effectuer une étude assez complète des volumes et capacités calorifiques des hydroxydes alcalins sur une gamme étendue de concentration et de température. Nous avons aussi déterminé les compressibilités isentropiques aux faibles concentrations de soude à 25°C de façon à obtenir les capacités calorifiques à volume constant dans l'état standard.

Méthode expérimentale

Les mesures de masse volumique ont été effectuées à l'aide d'un densimètre Picker à tube vibrant fonctionnant en écoulement continu (Sodev, modèle 01D) dont le principe et les performances sont bien connus (13). Les mesures de capacités calorifiques volumiques ont été réalisées à l'aide d'un microcalorimètre différentiel à écoulement Sodev déjà décrit dans la littérature (14, 15). La régulation thermique est stable à ±0,001°C et la température de mesure a été contrôlée à 0,01°C au moyen d'un thermomètre à quartz (Hewlett–Packard).

Les compressibilités ont été évaluées à partir de mesures de vitesses ultrasonores déterminées à l'aide de la technique "sing around" (Nusonic modèle 6105). La technique (16) et la cellule (17) ont déjà été décrites. L'étalonnage de l'appareil a été réalisé à partir des valeurs de référence pour l'eau obtenues par Delgrosso et Mader (18).

Les produits utilisés ont $LiOH \cdot H_2O$ solide (Baker certified), une solution 10 *N* NaOH (Fisher certified) et une solution 40% de KOH (Fisher Certified). Toutes les solutions one été préparées par pesée, soit directement soit à partir d'une solution mère elle-même préparée par pesée. Dans tous les cas on a utilisé de l'eau distillée et déionisée, dégazée sous vide pour éviter toute carbonation des solutions d'hydroxydes ainsi que toute formation de bulles. Les solutions ont été conservées sous atmosphère d'azote en récipient plastique étanche.

Les solutions mères ont été dosées par conductométrie à l'aide d'une solution étalon de HCl (Analar), elle-même dosée par conductométrie avec une solution de nitrate d'argent préparée par pesée à partir du sel anhydre pur.

Résultats

Les résultats de volumes et de capacités calorifiques sont exprimés en quantités molaires apparentes V_ϕ (cm^3 mol^{-1})

$$[1] \quad V_\phi = \frac{M}{d} - \frac{10^3(d - d_0)}{mdd_0}$$

et $C_{p,\phi}$ (J K^{-1} mol^{-1})

$$[2] \quad C_{p,\phi} = Mc_p + 10^3 (c_p - c_{p,0})/m$$

où M (g mol^{-1}) est la masse moléculaire, d et d_0 (g cm^{-3}) les masses volumiques de la solution et du solvant, c_p et $c_{p,0}$ (J K^{-1} g^{-1}) les capacités calorifiques massiques de la solution et du solvant et m est la molalité (mol kg^{-1}) de la solution. La différence des capacités calorifiques massiques $c_p - c_{p,0}$ a été calculée à partir des capacités calorifiques volumiques σ et σ_0 et des masses volumiques.

$$[3] \quad c_p - c_{p,0} = c_{p,0} \left\{ \frac{\sigma - \sigma_0}{\sigma} + 1 \right\} \frac{d}{d_0} - c_{p,0}$$

Les valeurs de référence pour l'eau pure sont celles de Kell pour d_0 (19) et Stimson pour $c_{p,0}$ (20), soit

T (K)	d_0 (g cm^{-3})	$c_{p,0}$ (J K^{-1} g^{-1})
277,15	0,999972	4,2045
283,15	0,999700	4,1919
298,15	0,997045	4,1793
313,15	0,992716	4,1783
328,15	0,985695	4,1821

Les compressibilités isentropiques β_S (bar^{-1}) sont obtenues à partir de la masse volumique (g/cm^3) et de la vitesse u (cm s^{-1}), par la relation usuelle

$$[4] \quad \beta_S = \frac{10^6}{d\,u^2}$$

et la grandeur molaire $K_{S,\phi} = -(\partial V_\phi/\partial P)_T$ (cm^3 bar^{-1} mol^{-1}) par

$$[5] \quad K_{S,\phi} = V_\phi\beta_S + 10^3 (\beta_S - \beta_{S,0})/md_0$$

Les résultats obtenus sont donnés aux Tableaux 1 et 2.

Traitement des données

Les grandeurs molaires apparentes Y_ϕ d'un électrolyte en fonction de la molalité sont généralement représentées sous forme d'un développement limité en $m^{1/2}$ de la forme

$$[6] \quad Y_\phi = \bar{Y}_2^\theta + A_Y m^{1/2} + B_Y m + C_Y m^{3/2} + \ldots$$

où $\bar{Y}_2^\theta$ est la grandeur molaire partielle standard (dilution infinie) du soluté. Des coefficients de la série, seul le premier, A_Y, peut être calculé à partir de la théorie de Debye–Hückel. Plusieurs auteurs ont développé d'autres expressions, pour les solutions concentrées, entre autres Guggenheim (21) et Pitzer (22), qui conviennent bien pour les solutions d'électrolytes simples et requièrent donc moins de paramètres ajustables. Dans le cas des hydroxydes alcalins, les déviations à la loi limite de Debye–Hückel sont grandes et le même nombre de paramètres ajustables est généralement nécessaire quelque soit la relation utilisée. Aussi, nous nous en sommes tenus à l'équation la plus simple, c'est-à-dire à la relation [6].

Au Tableau 3 on trouve les valeurs des paramètres de l'éq. [6] obtenues à l'aide d'une méthode de moindres carrés. Le paramètre A_Y a été fixé aux valeurs prédites par la théorie de Debye–Hückel, celles calculées auparavant (23) pour les volumes et les capacités calorifiques. Nous avons remarqué que si on considère plutôt A_Y comme une variable dans l'analyse par moindres carrés on utilise parfois moins de paramètres dans l'éq. [6] mais l'écart quadratique est souvent du même ordre de grandeur et les valeurs standard, extrapolées à dilution infinie, diffèrent rarement de plus de 0,2 cm^3 mol^{-1} pour les volumes et de 3 J K^{-1} mol^{-1} pour les capacités calorifiques. Il est toutefois préférable de toujours utiliser l'éq. [6] avec A_Y prédit car c'est dans ce cas que nous obtiendrons le paramètre $\bar{Y}_2^\theta$ le plus fiable (24).

A partir de l'équation de lissage et des paramètres figurant au Tableau 3, il est possible de calculer les grandeurs molaires partielles du soluté $\bar{Y}_2$;

$$[7] \quad \bar{Y}_2 = Y_\phi + m\partial Y_\phi/\partial m$$

Nous pouvons aussi calculer, à partir des volumes et des capacités calorifiques à diverses températures, les expansibilités molaires apparentes $E_\phi = (\partial V_\phi/\partial T)_P$ et les valeurs de $(\partial C_{p,\phi}/\partial T)_P$. Pour cela, les valeurs de V_ϕ et $C_{p,\phi}$ sont calculées à des molalités fixes et exprimées en fonction de la température par la relation polynomiale suivante:

$$[8] \quad Y_\phi(T) = Y_\phi(T_0) + A(T - T_0) + B(T^2 - T_0^2) + C(T^3 - T_0^3)$$

où T_0 est la température de référence, habituellement 298,15 K. Ensuite, par dérivation de cette relation on obtient les valeurs de E_ϕ et de $(\partial C_{p,\phi}/\partial T)_P$ aux températures choisies. On peut remarquer qu'il existe un écart sensible (de quelques pourcents) entre les valeurs issues de cette formulation et l'approximation habituelle $E_\phi \simeq \Delta V_\phi/\Delta T$. Ces grandeurs apparentes ont aussi été lissées au moyen de l'éq. [6] et les paramètres obtenus pour NaOH et KOH sont résumés au Tableau 4.

Les compressibilités isentropiques de NaOH ont aussi été exprimées au moyen de l'éq. [6] et la relation obtenue est 10^4 $K_{S,\phi} = -82{,}01\ (\pm 0{,}29) + 2{,}555\ m^{1/2} + 9{,}892\ (\pm 2{,}312)\ m$, l'écart quadratique étant de $0{,}24 \times 10^4$ cm^{-3} bar^{-1} mol^{-1}. En combinant $\bar{K}_{S,2}^\theta$ avec $\bar{C}_{P,2}^\theta$ et $\bar{E}_2^\theta$ on peut calculer les compressibilités isothermes $\bar{K}_2^\theta$ et les capacités calorifiques isochores à partir des relations suivantes:

$$[9] \quad \bar{K}_2^\theta = \bar{K}_{S,2}^\theta + \frac{2\alpha_0 T}{\sigma_0}\bar{E}_2^\theta - \frac{\alpha_0^2 T}{\sigma_0^2}\bar{C}_{P,2}^\theta$$

et

$$[10] \quad \bar{C}_{V,2}^\theta = \bar{C}_{P,2}^\theta - \frac{2\alpha_0 T}{\beta_{T,0}}\bar{E}_2^\theta + \frac{\alpha_0^2 T}{\beta_{T,0}^2}\bar{K}_2^\theta$$

où α_0 est le coefficient de dilatation thermique (K^{-1}), $\beta_{T,0}$ la compressibilite isotherme (bar^{-1}) et σ_0 la capacité calorifique volumique (J K^{-1} cm^{-3}) de l'eau à la température T_0. Les deux derniers termes des relations [9] et [10] doivent être multipliés par, 0,1 pour obtenir les bonnes unités. Les valeurs de $\bar{K}_2^\theta$ et $\bar{C}_{V,2}^\theta$ sont respectivement $-78{,}35 \times 10^{-4}$ cm^3 bar^{-1} mol^{-1}, $-137{,}6$ J K^{-1} mol^{-1}.

Comparaison des résultats

Comme règle générale l'accord entre nos résultats et les valeurs de la littérature est assez bon aux concentrations élevées. Les divergences sont plus grandes aux faibles concentrations où les incertitudes expérimentales sont généralement accentuées. Nos comparaisons se feront donc surtout pour les quantités standard où l'incertitude est maximum.

(a) *Volumes*

Peu de résultats permettent une comparaison avec LiOH. La valeur un peu ancienne de Gucker (25), $\bar{V}_2^0 = 6{,}0$ cm^3 mol^{-1} à 25°C, diffère notablement de la présente valeur, −5,06 cm^3 mol^{-1}.

Beaucoup plus de résultats sont disponibles pour NaOH. Sur un large domaine de concentration nous avons pu comparer nos données avec celles d'Akerloff et Kegeles (26). Aux concentrations élevées l'écart est faible, tandis qu'à 1 *m*, à 40°C l'écart est de 0,25 cm^3 mol^{-1}, et à 10°C de 0,62 cm^3 mol^{-1}. Par contre, pour les valeurs à dilution infinie à 40 et 10°C, ces auteurs obtiennent −4,94 et −8,16 alors que nous avons évalué −4,16 et −7,37 cm^3 mol^{-1} en bon accord avec Allred et Woolley (27) qui retiennent −4,30 et −7,54. A 25°C, notre valeur −5,26 cm^3 mol^{-1} se compare bien avec celles de Millero *et al.* (28), −5,20; Hepler *et al.* (29), −5,25; Swarin et Curran (30), −5,42; Allred et Woolley (27), −5,37; mais moins bien avec les résultats de Bodansky et Kauzmann (31), −4,60; de Lanman et Mair (32), −6,48; de Gucker (33), −6,7; de Owen et Brinkley (34), −6,8; de Hamann et Lin (35), −6,8; et d'Akerloff et Kegeles (26), −5,94.

Dans le cas de KOH nous pouvons constater un excellent accord, 0,1 cm^3 mol^{-1}, entre nos valeurs et celles d'Akerloff et Bender (36) sur toute la gamme de concentration et de température où les résultats peuvent être comparés. Seules les valeurs extrapolées à dilution infinie divergent. Respectivement à 40 et 10°C ces auteurs ont déterminé 5,05 et 1,86 alors que nous avons déterminé 5,72 et 2,98 cm^3 mol^{-1}. A 25°C, nous obtenons 4,83 en mauvais accord avec 3,4 de Owens et Brinkely (34), 3,6 de Fajans et Johnson (37) et 2,9 de Gucker (33).

En général, les différences les plus notables sont observées pour les valeurs à dilution infinie si on compare nos résultats avec ceux de travaux anciens. Ceci provient à la fois de la précision des techniques utilisées pour le domaine dilué et de la procédure d'extrapolation qui ne tenait pas compte de la pente limite de Debye−Hückel.

L'application de la règle d'additivité pour $\bar{V}_2^0$ permet d'effectuer un test de cohérence et aussi de juger de la précision (reproductibilité) des résultats. Par exemple la différence

$$\Delta V^0_{K^+-Na^+} = \bar{V}_2^0\,(KOH) - \bar{V}_2^0\,(NaOH)$$

à 25°C est 10,09 cm^3 mol^{-1}, en bon accord avec les valeurs suggérées par Millero (24), 10,2; et par Desnoyers *et al.* (38), 10,25; mais en moins bon accord avec la valeur moyenne 10,7 obtenue par Roux *et al.* (50). De la même manière $\Delta V^0_{Na^+-Li^+}$ est −0,20 pour les hydroxydes en bon accord avec les résultats de Redlich et Rosenfeld (39), −0,14; Vaslow (40), −0,36; Desnoyers *et al.* (38), −0,29, pour d'autres anions communs.

(b) *Expansibilités*

Il est assez difficile de comparer nos résultats pour E_ϕ obtenus à partir de l'éq. [8] avec les valeurs de la littérature car la plupart des auteurs ont calculé cette quantité à partir de $\Delta V_\phi/\Delta T$ pour des intervalles de température assez grands. Malgré ceci, l'accord est excellent pour NaOH et KOH entre nos résultats et ceux d'Akerloff (26, 36) dans le domaine concentré, l'écart s'accentuant aux faibles concentrations. A 25°C, notre valeur pour NaOH, $\bar{E}_2^0 = 0{,}096$ cm^3 mol^{-1} K^{-1} est en accord satisfaisant avec celle de Allred et Woolley (27), 0,108.

(c) *Capacités calorifiques*

Dans tous les cas, nos résultats sont en excellent accord avec les valeurs repertoriées par Parker (41) pour les concentrations supérieures à 1 *m*. Par contre, l'écart s'accroît lorsque la concentration diminue pour atteindre un maximum à dilution infinie. Ceci provient du manque de précision des techniques antérieurement à 1965 et de la méthode d'extrapolation. Il est donc préférable de comparer $\bar{C}^0_{p,2}$ seulement avec les valeurs récentes. Pour NaOH à 25°C, notre valeur, −97,4 J K^{-1} mol^{-1}, se compare avec celles de Singh *et al.* (42), −96,2; Allred et Woolley (27), −100,5 Desnoyers *et al.* (15), −94,6. A 10 et 40°C, Allred et Woolley (27) obtiennent −167,4 et −67,3 tandis que nous avons −164,8 et −65,8 J K^{-1} mol^{-1}.

Une meilleure idée de la précision peut être obtenue par le principe d'additivité. Notre valeur pour $\Delta C^0_{P,K^+-Na^+} = -33{,}1$ J K^{-1} mol^{-1} est en accord raisonable avec les valeurs suggérées par Desnoyers *et al.* (15), −30; par Singh *et al.* (42), −30,8, par Roux *et al.* (50), −26. Les valeurs obtenues pour $\Delta C^0_{P,Na^+-Li^+} = -19{,}5$ J K^{-1} mol^{-1}, sont en excellent accord avec les valeurs suggérées par Desnoyers *et al.* (15), −19.

(d) $(\partial C_{p,\phi}/\partial T)_P$

L'accord avec les valeurs déduites du répertoire de Parker (41) est bon aux concentrations élevées seulement. A dilution infinie, notre valeur pour NaOH, 3,0 J K^{-2} mol^{-1} est en bon accord avec celle d'Allred et Woolley (27), 3,3.

(e) *Compressibilité*

Seule la soude a été étudiée dans le domaine dilué. La valeur à dilution infinie, $\bar{K}^0_{S,2} = -82{,}0 \times 10^4$ cm^3 bar^{-1} mol^{-1}, est en excellent accord avec la valeur de Millero *et al.* (43), $-82{,}8 \times 10^{-4}$ et en moins bon accord avec celles de Mathieson et Conway (44), $-85{,}3 \times 10^{-4}$ et Allan et Lee (45), −86,8.

Par additivité on peut obtenir les valeurs pour LiOH et KOH. A partir des valeurs de Millero *et al.* (43) par $\Delta K^0_{S,Na^+-Li^+}$ et $\Delta K^0_{S,K^+-Na^+}$ on en déduit.

$$\bar{K}^0_{S,LiOH} = -68{,}9 \times 10^{-4}\ cm^3\ bar^{-1}\ mol^{-1}$$

$$\bar{K}^0_{S,KOH} = -76{,}4 \times 10^{-4}\ cm^3\ bar^{-1}\ mol^{-1}$$

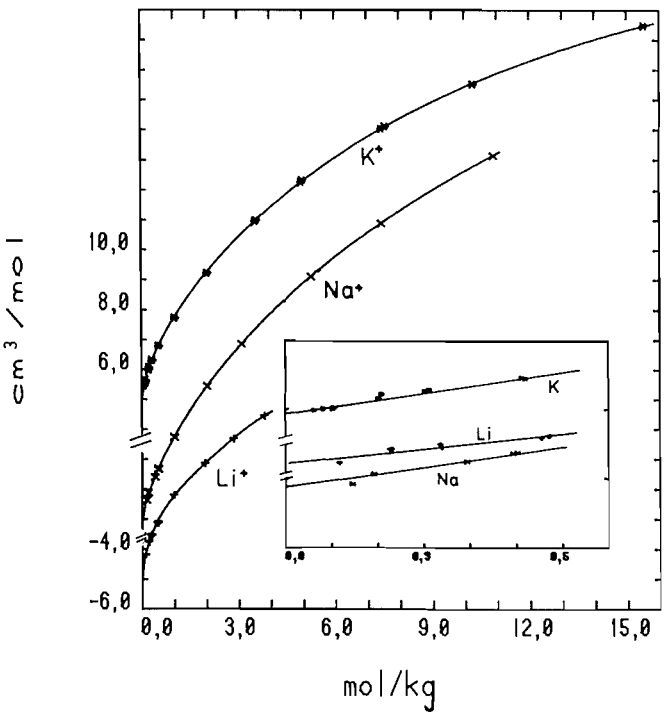

FIG. 1. Volumes molaires apparents en fonction de la concentration: LiOH(+), NaOH(×) et KOH(*) à 25°C. L'ordonnée dans l'insertion est $V_\phi - A_v m^{1/2}$.

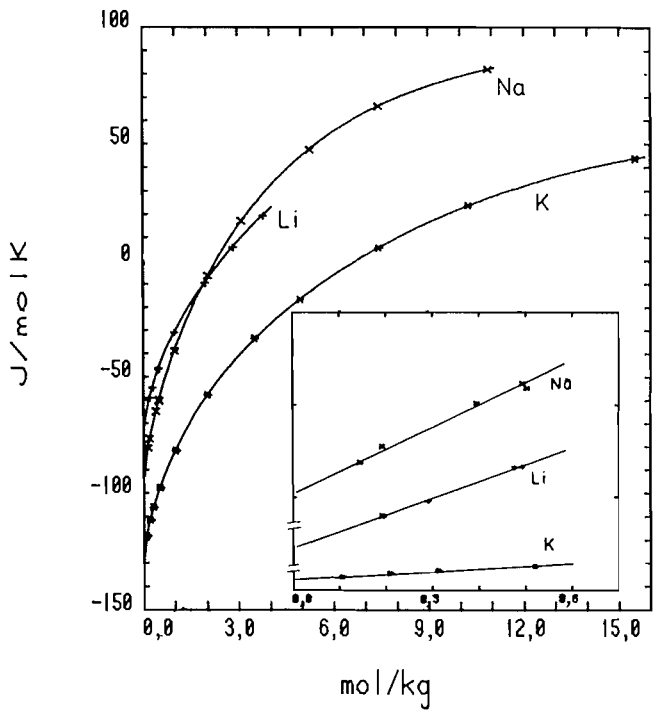

FIG. 2. Capacités calorifiques molaires apparentes en fonction de la concentration: LiOH(+), NaOH(×) et KOH(*) à 25°C. L'ordonnée dans l'insertion est $C_{p,\phi} - A_c m^{1/2}$.

Discussion

Les différentes quantités thermodynamiques Y_ϕ varient d'une façon assez régulière en fonction de la molalité tel qu'on peut le voir aux figures 1 et 2 pour les volumes et les capacités calorifiques à 25°C. Les écarts à la loi limite de la théorie de Debye–Hückel sont positifs aux faibles molalités et d'autant plus importants que la température est basse comme on le voit avec NaOH (Fig. 3). Aux fortes concentrations, les valeurs de $C_{p,\phi}$ varient assez peu avec la température.

Ces résultats suggèrent donc que NaOH est fortement briseur de structure aux basses concentrations et basses températures ($\bar{C}_{p,2}^\theta$ très négatif). Les interactions soluté–soluté vont dans la direction d'une diminution de cette solvatation. Aux concentrations plus élevées que 5 mol kg^{-1} la solution ressemble plutôt à un sel fondu hydraté où les effets structuraux ont complètement disparu. Les variations avec la température aux fortes concentrations viennent probablement de facteurs plus macroscopiques tels que la constante diélectrique du milieu. Cette explication des changements de capacité calorifique avec la température n'est pas en contradiction avec la forte hydratation qu'on reconnaît généralement aux ions OH^- tant dans la phase gazeuse (46) qu'en solution (47, 48). L'effet briseur de structure s'additionne à l'hydratation hydrophile. Contrairement aux propriétés telles que les enthalpies et entropies d'hydratation, ou les coefficients B de viscosité, $\bar{C}_{p,2}^\theta$ est peu sensible à la solvatation hydrophile mais dépend beaucoup des effets structuraux (49).

Les quantités molaires partielles, $\bar{V}_2$, $\bar{C}_{p,2}$ et $\bar{E}_2$, et apparentes, E_ϕ et $\partial C_{p,\phi}/\partial T$, sont représentées en fonction de la molalité en NaOH dans l'eau à 25°C à la figure 4. Alors que $\bar{V}_2$ augmente régulièrement, les autres fonctions ont plutôt tendance à plafonner aux concentrations élevées. Les légers

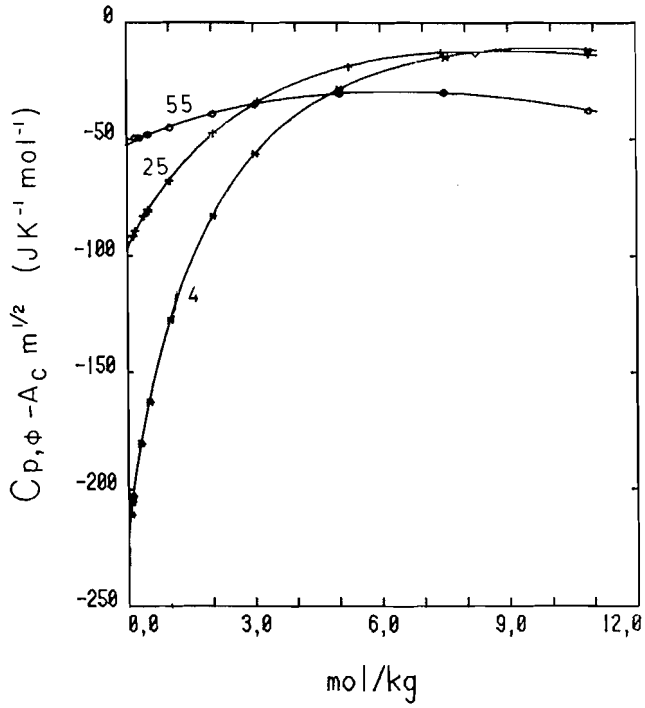

FIG. 3. Déviations à la loi limite de la théorie de Debye–Hückel pour les capacités calorifiques de NaOH à différentes températures: 4(*), 25(+) et 55(○)°C.

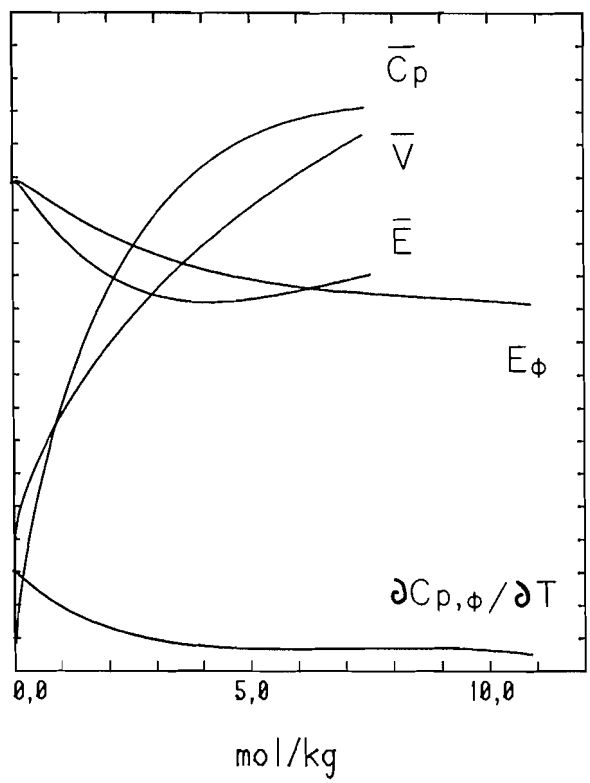

FIG. 4. Comparaison des quantités molaires partielles ou apparentes pour NaOH à 25°C: $\bar{V}$(cm^3 mol^{-1}), $\bar{C}_p$(J K^{-1} mol^{-1}), $\bar{E}$(cm^3 mol^{-1} K^{-1}), E_ϕ(cm^3 mol^{-1} K^{-1}), $\partial C_{p,\phi}/\partial T$ (J K^{-2} mol^{-1}).

changements de pentes pour E_ϕ et $\partial C_{p,\phi}/\partial T$ aux concentrations supérieures à 7,5 mol kg^{-1} ne sont pas significatives et proviennent fort probablement du lissage des données de V_ϕ et $C_{p,\phi}$ en fonction de la température. Ici encore l'allure de toutes ces quantités ressemble à celles des électrolytes 1:1 et ne montre aucune anomalie pour ces systèmes.

Remerciements

The formation of 3,4,6,tri-*O*-benzyl-2,5-anhydro-L-iditol from 2,3,4,6-tetra-*O*-benzyl-D-glucopyranose. Intramolecular displacement of a secondary mesyloxy group by a benzyloxy group, in the presence of cesium propionate

VANGA S. RAO AND ARTHUR S. PERLIN

Received May 31, 1983[1]

VANGA S. RAO and ARTHUR S. PERLIN. Can. J. Chem. **62**, 886 (1984).

The reaction between 2,3,4,6-tetra-*O*-benzyl-1,5-di-*O*-mesyl-D-glucitol and cesium propionate in dimethylformamide at 100°C leads to an almost quantitative conversion into 3,4,6-tri-*O*-benzyl-1-*O*-propionyl-2,5-anhydro-L-iditol. Closure of the anhydro ring appears to entail anchimeric assistance by the 2-*O*-benzyl substituent in an S_N2 displacement at C-5, leading to an inversion at the latter position. Probable contributors to the marked regio- and stereoselectivity observed for the reaction are a unique property of cesium propionate as compared with other carboxylate salts, large differences in rate between competing reactions, and a geometry highly favorable to an intramolecular displacement process. Conformational properties of 2,5-anhydro-L-iditol, as well as of isomeric 2,5-anhydro-D-mannitol, are described, based on nmr evidence.

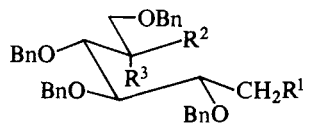
VANGA S. RAO et ARTHUR S. PERLIN. Can. J. Chem. **62**, 886 (1984).

La réaction du tétra-*O*-benzyl-2,3,4,6 di-*O*-mésyl-1,5 D-glucitol avec le propionate de césium dans le diméthylformamide à 100°C conduit à une conversion presque quantitative en tri-*O*-benzyl-3,4,6-*O*-propionyl-1 anhydro-2,5 L-iditol. La fermeture du cycle anhydro semble impliquer une assistance anchimérique du substituant *O*-benzyl-2 au cours d'une substitution S_N2 en C-5; ceci conduit à une inversion de configuration dans cette position. Les principales causes des régio- et stéréo-sélectivités remarquables notées au cours de cette réaction sont probablement (a) une propriété unique du propionate de césium comparée aux autres sels carboxyliques, (b) de grandes différences dans les vitesses des réactions qui sont en compétition et (c) une géométrie hautement favorable à une réaction de substitution intramoléculaire. Utilisant des données de rmn, on décrit les propriétés conformationnelles de l'anhydro-2,5 L-iditol et de l'anhydro-2,5 D-mannitol qui lui est isomère.

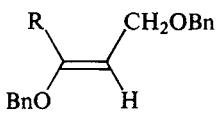
[Traduit par le journal]

Introduction

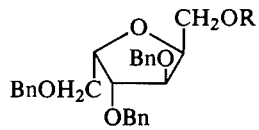
Earlier (1), in examining possibilities for a facile and convenient synthesis of L-idose, we attempted to use potassium superoxide as an oxygen nucleophile in a reaction with 2,3,4,6-tetra-*O*-benzyl-1,5-di-*O*-mesyl-D-glucitol (**1**). Rather



1, $R^1 = R^2 = OSO_2CH_3$; $R^3 = H$
2, $R^1 = R^3 = OH$; $R^2 = H$
4, $R^1 = OCOC_2H_5$; $R^2 = OSO_2CH_3$; $R^3 = H$



3, R = $(CHOBn)_2CH_2OH$(L-threo)



5, R = COC_2H_5
6, R = H

than the expected S_N2 displacement product, **2**, a novel regio- and stereoselectively formed olefin,[2] **3**, was obtained in an intramolecularly initiated elimination process. Our continuing search for a suitable oxygen nucleophile now encompasses the use of cesium carboxylates (2) in dimethylformamide as a possible means for the introduction of a hydroxy substituent by intermolecular S_N2 nucleophilic substitution.

Results and discussion

Cesium propionate, prepared from cesium carbonate and propionic acid in methanol, was selected. If this compound were to displace both of the mesyloxy substituents of **1**, then, after ester hydrolysis, the desired product (**2**) should be obtained. In fact, however, the reaction of **1** with cesium propionate in DMF at 50–60°C for 2 days in a nitrogen atmosphere gave about a 90% yield of a compound characterized as a monopropionate (**4**), admixed with ~10% of **5**, the identification of which will be described later. The ^1H nmr spectrum of **4** (Table 1) contained a quartet at δ 2.29 and a triplet at δ 1.12, attributable to the $—CH_2$ and $—CH_3$ groups, respectively, of a propionyloxy moiety at C-1, and a singlet at δ 2.93 characteristic of the CH_3 resonance of a mesyloxy substituent. The relative positions of the sulfonate and propionate ester groups were inferred indirectly from the following information, dealing with the formation and characterization of compound **5**.

At a reaction temperature of 90–100°C, product **5** was formed in almost quantitative yield. The ^{13}C nmr spectrum of the product (Table 2) showed resonances at δ 174.19 (—O—*C*=O), 138.48, 138.05, 137.78 (*ipso*, phenyl), 81.94, 81.46 (characteristic of the C-4 resonance (4) of a furanoid ring, substituted by an alkyl group), 68.22, 63.22 ($—CH_2—$O), 27.51, and 15.32 ($—CH_2$ and $—CH_3$ of an $—OCOCH_2CH_3$ group). These data suggested that a furanoid ring had been formed from **1** as the result of a concomitant loss of both a mesyloxy and a benzyloxy group, and substitution of the other mesyloxy group by a propionate moiety.

When the crude reaction mixture was subjected to methanolysis catalysed by sodium methoxide, the product (**6**) gave

[1] Revision received December 5, 1983.

[2] When the characterization of **3** was reported (1), the location of the double bond was clearly evident, whereas its geometric configuration was unknown. Nevertheless, based on the mechanism postulated for its formation, olefin **3** was expected to be the *E*-isomer. Additional support for this assignment has been found, since then, in ^{13}C chemical shift similarities between **3** and 1,5-di-*O*-acetyl-2,4,6-tri-*O*-benzyl-2-dehydro-3-deoxy-D-*erythro*-hex-2-(*E*)-enitol (for boron assisted departure of a benzyloxy group, see ref. 3), which is viewed as evidence that the substitution patterns on the carbon atoms of the latter and of **3** are analogous.

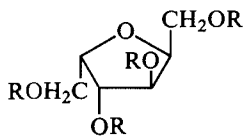
TABLE 2. Carbon-13 chemical shifts (δ) for compounds **5**, **7**, **8**, **9**, and **10**

Compound (solvent)	C-1	C-2	C-3	C-4	C-5	C-6	Others
5 ($CDCl_3$)	63.22	81.94[a]	79.25, 78.06 73.58, 72.56 72.40[b]		81.46[a]	68.22	15.32 (CH_3), 27.51 (CH_2), 174.19 (—C=O), $OCOCH_2CH_3$; 127.74, 128.39, 128.55 (phenyl), 137.78, 138.05, 138.48 (*ipso*-phenyl)
7 (D_2O)	60.91	81.25	77.47	77.47	81.25	60.91	—
9 ($CDCl_3$)	61.88	~78.44	75.85	75.85	~78.44	61.88	20.61, 20.82 (CH_3), 169.34, 170.58 (—C=O), $OCOCH_3$
(C_6D_6)	61.93	77.36	76.12	76.12	77.36	61.93	19.91, 20.28 (CH_3), 168.91, 169.82 (—C=O), $OCOCH_3$
8 (D_2O)	62.15	83.30	77.40	77.40	83.30	62.15	—
10 ($CDCl_3$)	63.23	81.24	78.33	78.33	81.24	63.23	20.77 (2 × CH_3), 169.93, 170.63 (—C=O), $OCOCH_3$

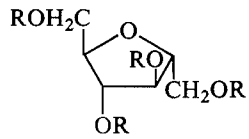
[a] Interchangeable.
[b] These include three resonances from 3 × OCH_2Ph groups.

a ^1H nmr spectrum (Table 1) that showed the presence of a hydroxymethyl group (δ 3.84, 3.76), two methylene protons at δ 3.73 and 3.69, and three AB quartets characteristic of the methylene groups of benzyloxy substituents. Reesterification of **6** with Ac_2O in pyridine shifted the resonances at δ 3.84 and 3.76 to δ ~4.4 and 4.2, respectively, confirming that the original propionyloxy group was present on a primary carbon atom. Catalytic transfer hydrogenation (5) of **6** with 10% Pd–C and formic acid in methanol removed the *O*-benzyl substituents, giving **7**. Identification of the latter was made by comparison of its nmr spectra (Tables 1 and 2) with those of appropriate, known, sugar derivatives.

The ^1H nmr spectrum of **7** contains signals at δ 3.58 (dd), 3.51 (dd), characteristic of the AB part of an ABX spin system, and a complex multiplet centered at δ 4.02. The latter signal was converted, by simultaneous irradiation of the signals at δ 3.58 and 3.51, into an AB quartet with chemical shifts of δ 4.04 and 4.01. The ^{13}C spectrum contains only three resonances, i.e., at δ 81.25, 77.47, and 60.91. These data indicate that there are four types of protons attached to three different types of carbon atoms, one of which is primary (δ 60.91), and



7, R = H
9, R = Ac



8, R = H
10, R = Ac

that the molecule possesses C_2 symmetry. Also, as mentioned, the nmr data for **5** indicated the presence of a furanoid ring structure. Hence, if the configuration at C-3 and C-4 of **1** had been preserved in the product, only two structures, namely 2,5-anhydro-L-iditol (**7**) and 2,5-anhydro-D-mannitol (**8**), can accommodate the spectral data. Acetylation of the anhydroalditol resulted in deshielding appropriate to the assignments given for its ^1H nmr spectrum (compare **7** and **9**, Table 1), and both the ^1H and ^{13}C (Table 2) data for **9** demonstrate once again the symmetrical nature of the compound. Confirmatory evidence for the structure of **7** comes from the fact that its ^{13}C nmr spectrum corresponds fully to published data (6) for 2,5-anhydroiditol, and that **7** exhibits a *positive* optical rotation.

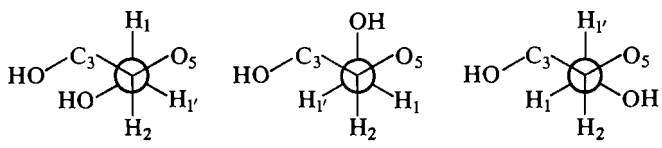
For personal use only.

The mass spectrum of the acetylated derivative (**9**) showed the occurrence of mass units at 375 and 333, whereas the calculated molecular weight of **9** is 332. Hence, the peak at 333 must have been due to $M + H^+$, indicating that the molecule undergoes self chemical ionization. Similarly, the peak at 375 must have arisen from self chemical ionization due to an acetyl cation (CH_3CO^+),[3] resulting in a ($M + CH_3CO^+$) ion, i.e., 375. Furthermore, the ratio 375:333 increased with an increase in temperature and the source pressure, results that are consistent with the notion overall that the molecule has a molecular ion ($M^{+\cdot}$) of 332 and hence a molecular weight of 332.

In order to add further to the structural elucidation of **7**, and also to gain some insight into its conformational behavior and that of furanoid ring compounds having a diastereomeric relationship with it, 2,5-anhydro-D-mannitol (**8**) was prepared by a known method (7) and its ^1H nmr and ^{13}C nmr data were compared with those of **7**. The ^{13}C nmr data for **8** (Table 2) agree well with those already published (6). This is taken as additional confirmatory evidence that, in the reaction between **1** and cesium propionate in DMF, at elevated temperatures, the product formed is 1-*O*-propionyl-3,4,6-tri-*O*-benzyl-2,5-anhydro-L-iditol (**5**), rather than the *manno* isomer.

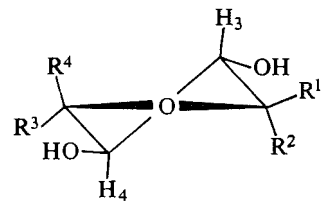
A comparison of the ^1H nmr chemical shifts of **7** and **8** indicates that when a *cis* relationship exists between the —CH_2OH and —OH groups at C-2 and C-3, as in **7**, as compared with their *trans* arrangement, as in **8**, then the protons (H-2, H-3) attached to the carbon atoms bearing these substituents appear at lower field, i.e., at δ 4.01 and 4.04 in **7** vs. δ 3.70 and 3.86 in **8**. The same trend is also observed for their acetylated derivatives. On the other hand, the opposite trend is found in their carbon chemical shifts (6), i.e., the C-2 resonance of **8** is at lower field (δ 83.3) than the corresponding shift in **7** (δ 81.25). The C-1 shifts also are in the same direction, although the shift difference is smaller, whereas the C-3 shifts are virtually unchanged.

The diastereotopic exocyclic methylene protons (H-1, 1′) of **8** show differential coupling with H-2, indicating a preferential rotamer population around the C-1—C-2 bond. The combination of couplings of 3.2 Hz and 5.4 Hz suggests a contribution of rotamers **B** and either **A** or **C**, not both **A** and **C**. Although a basis for choosing between **A** and **C** is not obvious, the

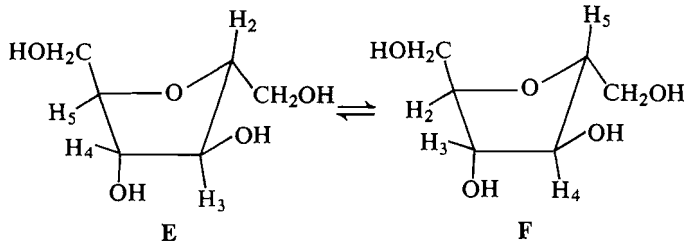


A **B** **C**

magnitude of the couplings observed suggests (8) an analogy with the rotamer population around the C_5—C_6 fragment in D-glucopyranose and its derivatives. The apparent[4] large coupling constant (7.3 Hz) between H-2 and H-3 requires these protons to be nearly *anti* to each other, and also suggests a



D, $R^1 = R^3 = CH_2OH$; $R^2 = R^4 = H$
G, $R^1 = R^3 = H$; $R^2 = R^4 = CH_2OH$



E **F**

conformational preference for the five-membered furanoid ring in its envelope-twist pseudorotational itinerary (for an excellent overview, see ref. 9). Such conformations may be realized either in a twist form **D** ($^3T_4$) or two rapidly interconverting envelope forms **E** and **F** (^2E and ^5E). These ring conformations also facilitate a high population of rotamer **B**, by flexing the carbon atom (C-2) bearing the —CH_2OH group so that this moiety is farther away from the ring atoms, and also of rotamer **C**. In these ring conformations, rotamer **A** may, indeed, be destabilized due to a *semi* 1,3-parallel interaction between the primary hydroxyl group and the OH-3 group. If this analysis is valid, then the downfield methylene signal with smaller coupling (3.2 Hz) may tentatively be assigned (8) to the proton having the pro-*R* configuration, and the upfield signal with larger coupling (5.4 Hz) to that having the opposite configuration (pro-*S*).

The methylene proton (H-1, 1′) couplings with H-2 in **7** are 4.6 and 6.8 Hz. Although their magnitude is larger than for **8**, the differential nature of these couplings requires an inhomogeneous mixture of rotamers **A**, **B**, and **C** to be present. Hence, this situation appears similar to that of the rotamer population around the C-5—C-6 fragment in D-galactopyranose (8). As to the ring conformation, the observed small coupling between H-2 and H-3 (3.3 Hz) is not as informative as for **8**, although it readily serves to distinguish **7** from **8**. Because of the *cis* disposition of the substituents on C-2 and C-3, a twist about the C-2—C-3 bond is anticipated, and hence the same two envelopes and the corresponding twist ring (**G**) conformation as deduced for **8** may well accommodate the steric requirements of **7**.

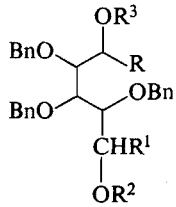
The formation of anhydride **5** from **1** and cesium propionate deserves comment.[5] As already noted, product **5** was not obtained earlier (1) in the reaction of **1** with potassium superoxide. Furthermore, it has not been detected in other experiments (unpublished) employing potassium acetate, sodium acetate, or sodium benzoate. Consequently, in yielding **5** as the *sole* product, cesium propionate shows remarkably distinctive behaviour which, we expect, is due to the highly polarizable cesium ion rather than the propionate moiety.

In the sickle conformation (10) of **1** (or of intermediate **4**),

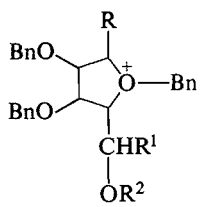
[3] Attributable to the formation of an acetyl cation and/or the elements of acetic acid as a normal step in the fragmentation pathway (O. Mamer, private communication).

[4] In the ^1H nmr spectrum of **8**, the H-3 signal, instead of giving a doublet, actually showed 6 lines characteristic of combination lines arising from *virtual* coupling. The $J_{3,4}$ value calculated was 8.9 Hz. The high rms error (0.35) obtained was due to imperfect matching between the experimental and calculated spectrum of the H-2 resonance, although the matching of the H-3 resonance was excellent.

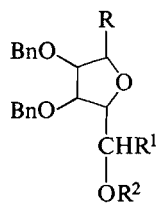
[5] We are indebted to the referees for a very helpful discussion of this matter.



1, R = $C(6)H_2OBn$; R^1 = H; R^2 = R^3 = mesyl



11



5, R = $C(6)H_2OBn$; R^1 = H; R^2 = propionate

12, R = R^1 = H; R^2 = R^3 = tosyl

13

14, R = R^1 = H; R^2 = tosyl

the 2-*O*-benzyl group appears to be suitably positioned[6] to displace the 5-*O*-mesyl group in an S_N2 fashion, causing an inversion of configuration at C-5, as depicted by the sequence **1** → **11** → **5**. This possibility is supported by observations (11) on anhydro-ring formation during the solvolysis of 1,5-di-*O*-tosyl-2,3,4-tri-*O*-benzyl-pentitols. For example, the D-*xylo* isomer (**12**), when heated under reflux in 95% ethanol, yielded 1,4-anhydro-2,3-di-*O*-benzyl-5-*O*-tosyl-DL-xylitol (**14**) and benzyl tosylate. As shown (11) by kinetic evidence, there was anchimeric assistance of the *O*-tosyl displacement step by the 4(or 2)-*O*-benzyl group, indicating that the transformation involved such an intermediate as **13**.

Aside from these apparent analogies, however, the reactions of **1** and **12** differ notably in that the ring-closure to give **14** occurred at a primary carbon atom, whereas a secondary position was involved in the formation of **5**. Presumably, because ethanol is a relatively poor nucleophile, the displacement of the 1-*O*-tosyl group of **12** favored participation by the 4-*O*-benzyl group (and the 5-*O*-tosyl by the 2-*O*-benzyl). By contrast, the 1-*O*-mesyl substituent of **1**, as seen by the initial, selective, formation of monoproprionate **4**, was far more amenable to displacement by the strongly nucleophilic cesium propionate than to an intramoleuclar attack by its 4-*O*-benzyl group. Consequently, there was a complete reversal in the comparative effectiveness of cesium propionate and the (2)-*O*-benzyl group in displacing the 5-*O*-mesyl substituent of **1**.

This combination of contrast and analogy may be explained in terms of relative rates. That is, the rate of displacement of the 1-*O*-mesyl group of **1** by cesium propionate is far higher than is the rate for participation of the 4-*O*-benzyl group, whereas the solvolysis of the 1-*O*-tosyl group of **12** does not compete effectively with participation by its 4-*O*-benzyl group. In the displacement of the 5-*O*-mesyl substituent of **1**, however, the propionate anion acts as a much less efficient nucleophile than the intramolecular 2-*O*-benzyl, towards secondary carbon-5. An analogous situation does not apply for **12**, which contains only primary *O*-sulfonyl groups. Consequently, the outcome of reactions such as these may vary not only with the experimental conditions, but from compound to compound and, possibly, with configuration as well, because the latter might determine the relative ease of achieving an intermediary orientation favorable for neighboring-group participation by an *O*-benzyl group.

Experimental

Solutions were evaporated below 40°C under diminished pressure. Solvents were dried by conventional procedures (methanol over magnesium methoxide, dimethyl formamide over barium oxide, and pyridine over sodium hydroxide), distilled, and stored over molecular sieves (Type 4A). Cesium carbonate and propionic acid were obtained from Aldrich Chemicals, and 2,3,4,6-tetra-*O*-benzyl-D-glucopyranose from Pfanstiehl Laboratories (Waukegan, IL). Eastman Chromagram sheets of silica gel with fluorescent indicators were used for thin-layer chromatography. Proton magnetic spectra were recorded with a Varian XL-200, or a Bruker WH-400, with the aid of homonuclear decoupling. Chemical shifts (δ) are reported with reference to tetramethylsilane with $CDCl_3$ as solvent, and HOD (δ 4.61) with D_2O as solvent. Carbon-13 nmr spectra were recorded with a Bruker WH-90 spectrometer. The theoretical proton nmr spectrum of compound **8** was calculated using ITRCAL program (Nicolet Instrument Corporation) on a B-NC 12 model minicomputer (Bruker Data System). Carbon-13 chemical shifts are reported with reference to tetramethylsilane, with $CDCl_3$ as the solvent, or to methanol (CH_3OH, δ 49.8) with D_2O as the solvent. Mass spectra were obtained with an LKB 9000 spectrometer at an ion source of 70 eV.

Cesium propionate

To a stirred solution of cesium carbonate (3.3 g, 10 mmol) in dry methanol (80 mL) was added, through a septum, a solution of propionic acid (2.2 g, 30 mmol) in the same solvent (20 mL). After stirring at room temperature for 3 h, the solution was evaporated and the residue (white powder) was washed three times with dry ether (3 × 100 mL). Due to the extremely hygroscopic nature of the cesium propionate, washing was carried out by serum capping the flask and removing the supernatant liquid with the aid of a double-tipped needle under nitrogen pressure.[7] The white solid residue was dried in vacuum at ~40°C for several hours.

*2,3,4,6-Tetra-*O*-benzyl-1,5-di-*O*-mesyl-D-glucitol (1)*

The title compound was prepared according to a procedure already described (1). That is, 1,3,4,5-tetra-*O*-benzyl-L-gulitol, obtained by reduction of 2,3,4,6-tetra-*O*-benzyl-D-glucopyranose with sodium borohydride in 7:3 tetrahydrofuran–water, was di-*O*-mesylated with methanesulfonyl chloride in pyridine to afford **1**. The ^1H nmr data are given in Table 1.

*2,3,4,6-Tetra-*O*-benzyl-1-*O*-propionyl-5-*O*-mesyl-D-glucitol (4)*

To a vigorously stirred solution of cesium propionate (0.68 g, weighed under dry nitrogen) in dry dimethylformamide (30 mL) under nitrogen was added a solution of **1** (0.25 g) in the same solvent (4 mL) through a serum cap. The mixture was heated to ~60°C, at which time a clear solution was obtained, and maintained at that temperature for ~48 h. Then it was poured into ice water (400 mL) saturated with sodium chloride, extracted with chloroform, and the extract was washed successively with cold 10% hydrochloric acid, sodium hydrogen carbonate, and water, dried (anhydrous sodium sulfate), and evaporated to a syrupy residue (0.24 g). The ^1H nmr data are given in Table 1.

[6] By contrast, in the zigzag conformation, the O-2 and O-4 benzyl groups, as well as the substituents on C-3 and C-5, should all involve destabilizing 1,3 parallel interactions.

[7] Extreme care must be taken that the needle is not blocked by fine solid particles during this procedure. Alternatively, the powder may be washed on a filter under a nitrogen atmosphere.

1-O-Propionyl-3,4,6-tri-O-benzyl-2,5-anhydro-L-iditol (5)

An analogous reaction was carried out with 0.66 g of cesium propionate in dry dimethylformamide (30 mL) and **1** (0.5 g) in the same solvent (8 mL) at ~100°C for ~48 h under dry nitrogen. Following the work-up procedure, as described for **4**, a syrupy product consisting of a single component (tlc and nmr evidence) was isolated (yield, 0.39 g). The ^{13}C nmr data are given in Table 2.

1-O-Acetyl-3,4,6-tri-O-benzyl-2,5-anhydro-L-iditol (6)

Product **5** was subjected to methanolysis with sodium methoxide in dry methanol, the solution was neutralized with IR 120 (H^+) ion-exchange resin, the suspension was filtered, and evaporation of the filtrate gave **6**. The ^1H nmr data are presented in Table 1.

Compound **6** was acetylated with 1:2 acetate anhydride – pyridine to afford the title compound. The ^1H nmr data ($CDCl_3$) δ: 4.60 and 4.51 (AB, 2H, OCH_2, J_{gem} 12.0 Hz), 4.53 and 4.48 (AB, 2H, OCH_2, J_{gem} 12.1 Hz), 4.60 and 4.51 (AB, 2H, OCH_2, J_{gem} 12.1 Hz), 4.39–4.31 (m, 3H, H-1, 2, 5), 4.20 (dd, H-1′, $J_{1',2}$ 8.65, $J_{1,1'}$ 12.5 Hz), 4.03 or 3.99 (dd, 2H, H-3, H-4, $J_{3,4}$ 1.3, $J_{4,5}$ 3.8 Hz), 3.73 (dd, H-6, $J_{5,6}$ 6.5, $J_{6,6'}$ 9.6 Hz), 3.69 (dd, H-6′, $J_{5,6'}$ 6.1 Hz), 2.04 (s, 3H, CH_3).

1,3,4,6-Tetra-O-acetyl-2,5-anhydro-L-iditol (9)

Removal of the *O*-benzyl groups from **6** by catalytic transfer hydrogenolysis with 10% Pd–C/formic acid/methanol (5) yielded 2,5-anhydro-L-iditol (**7**); $[\alpha]_D^{25}$ +6.4 (*c* 1.1, H_2O) (lit. (12) $[\alpha]_D$ +9.7). The ^1H nmr data are given in Table 1. Compound **7** was acetylated with 1:2 acetic anhydride – pyridine to afford **9**. The ^1H nmr data are given in Table 1. Mass spectrum, *m/z*: 333 (1.8, $M + 1$), 259 (5.6, $M - CH_2OAc$), 145 (25.7, $AcOCH_2 - \overset{+}{C}HOAc$ or triacetoxonium ion (13)), 119 (15.7, $CH_3—\overset{H}{\overset{|}{O}}—\overset{+}{O}=CH_2CH_2OAc$), 103 (17.2, AcO – $\overset{+}{C}H_2CHOH$ or diacetoxonium ion (13)), 85 (86.3, 145 – HOAc or), 83 (99.8, 84 – 1), 43 (83.4, $CH_3\overset{+}{C}O$).

1,3,4,6-Tetra-O-acetyl-2,5-anhydro-D-mannitol (10)

Following a literature procedure (7), 2-amino-2-deoxy-D-glucose hydrochloride was subjected to deamination and ring contraction with sodium nitrate in acetic acid to afford 2,5-anhydro-D-mannose, which was immediately reduced with sodium borohydride to give 2,5-anhydro-D-mannitol (**8**). Acetylation of **8** with acetic anhydride in pyridine gave the title compound (**10**). The ^1H and ^{13}C nmr data for **8** and **10** are given in Tables 1 and 2, respectively.

Acknowledgments

Generous support by the Natural Sciences and Engineering Research Council of Canada is acknowledged with thanks. We are especially grateful to Dr. O. Mamer for assistance in interpreting the mass spectra. The 400 MHz ^1H nmr spectra were recorded by P. V. M. Tan at Laboratoire Régional de RMN à Haut Champ, Université de Montréal.

Structure and magnetic exchange in poly-bis(μ-dialkylphosphinato)copper(II) compounds

JOHN S. HAYNES, KATHERINE W. OLIVER, STEVEN J. RETTIG, ROBERT C. THOMPSON, AND JAMES TROTTER
Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received October 12, 1983

JOHN S. HAYNES, KATHERINE W. OLIVER, STEVEN J. RETTIG, ROBERT C. THOMPSON, and JAMES TROTTER. Can. J. Chem. **62**, 891 (1984).

The preparation, magnetic and thermal properties, electronic and infrared spectra, and molecular structure of poly-bis(μ-di-*n*-hexylphosphinato)copper(II) are described. Crystals of the compound are triclinic, a = 9.800(3), b = 12.336(6), c = 13.352(8) Å, α = 88.53(3), β = 74.02(4), γ = 82.33(3)°, Z = 2, space group $P\bar{1}$. The structure was solved by Patterson and Fourier syntheses and was refined by full-matrix least-squares procedures to R = 0.045 and R_w = 0.056 for 3095 reflections with $I \geq 3\sigma(I)$. The crystal structure of $Cu[(n\text{-}C_6H_{13})_2PO_2]_2$ consists of well-separated infinite chains of centrosymmetric spiro-fused eight-membered rings propagating along the crystallographic a axis.

The magnetic susceptibility of $Cu[(n\text{-}C_6H_{13})_2PO_2]_2$ was studied over the temperature range 4.2 to 300 K. The compound shows ferromagnetic behaviour and the data have been successfully analyzed according to the isotropic Heisenberg model for linear chains with g = 2.16 and J = 2.58 cm^{-1}. For comparison, the magnetic susceptibilities of $Cu[(C_2H_5)_2PO_2]_2$ and $Cu[(n\text{-}C_4H_9)_2PO_2]_2$ have also been measured over the range 4.2 to 300 K. The butyl derivative shows ferromagnetic exchange with g = 2.16 and J = 2.22 cm^{-1} while the ethyl derivative is antiferromagnetic with g = 2.19 and $-J$ = 1.27 cm^{-1}. The structural details of all three compounds are examined in the light of the differing magnetic properties.

JOHN S. HAYNES, KATHERINE W. OLIVER, STEVEN J. RETTIG, ROBERT C. THOMPSON et JAMES TROTTER. Can. J. Chem. **62**, 891 (1984).

On décrit les propriétés magnétiques et thermales, les spectres électronique et infrarouge, et la structure moléculaire de poly-bis(μ-di-*n*-hexyle phosphinato) cuivre(II). Les cristaux sont tricliniques, a = 9,800(3), b = 12,336(6), c = 13,352(8) Å, α = 88,53(3), β = 74,02(4), γ = 82,33(3)°, Z = 2, groupe d'espace $P\bar{1}$. On a résolu la structure par les synthèses de Patterson et de Fourier et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R = 0,045 et R_w = 0,056 pour 3095 réflexions avec $I \geq 3\sigma(I)$. La structure du cristal de $Cu[(n\text{-}C_6H_{13})_2PO_2]_2$ consiste en chaînons, infinis et bien séparés, des cycles de huit membres, centrosymmetriques et spiro-fusées, qui sont propagés suivant l'axe c.

On a étudié la susceptibilité magnétique dans l'intervalle de température de 4.2 à 300 K. La composé présente les propriétés ferromagnétiques et on a analysé les données d'après la modèle isotropique de Heisenberg pour les chaînons linéaires, avec g = 2,16 et J = 2,58 cm^{-1}. Par comparaison, les susceptibilités magnétiques de $Cu[(C_2H_5)_2PO_2]_2$ et de $Cu[(n\text{-}C_4H_9)_2PO_2]_2$ ont été mesurés aussi dans l'intervalle 4,2 à 300 K. Le dérivatif butylique exhibe l'échange ferromagnétique, avec g = 2,16 et J = 2,22 cm^{-1}, tandis que le dérivatif éthylé est antiferromagnétique avec g = 2,19 et $-J$ = 1,27 cm^{-1}. On a examiné les particularités structurales de tous les trois composés en vue des propriétés magnétiques différentes.

Introduction

Single crystal X-ray diffraction studies on $Cu[(C_2H_5)_2PO_2]_2$ (1) and $Cu[(n\text{-}C_4H_9)_2PO_2]_2$ (2) have shown them to be polymeric with well-separated infinite chains of copper atoms (flattened tetrahedral coordination geometries) linked by double phosphinate bridges. Interest in the magnetic properties of these materials has been expressed because of the possibility of the propagation of magnetic exchange via the O—P—O bridges (1, 2); however, because of the lack of magnetic susceptibility studies to cryogenic temperatures no clear evidence concerning exchange was obtained prior to the present work. We report here magnetic susceptibility studies over the range from room temperature to 4.2 K. As alluded to earlier (3), it is not possible to predict at the present time the nature of the exchange in systems such as these. Indeed, it was interesting to note in the present work that, in spite of their structural similarities, the ethyl and *n*-butyl derivatives exhibit magnetic exchange coupling (albeit weak in both cases) of opposite sign.

In the course of our studies on the synthesis, structure, and properties of copper(II) phosphinates generally we obtained one other compound, the *n*-hexyl derivative, in crystalline form suitable for X-ray structure determination. The structure and magnetic properties of this material were also studied here in order to explore magneto-structural correlations in these systems more fully.

Experimental

Syntheses

Poly-bis(μ-di-*n*-butylphosphinato)copper(II), $Cu[(n\text{-}C_4H_9)_2PO_2]_2$, and poly-bis(μ-di-*n*-hexylphosphinato)copper(II), $Cu[(n\text{-}C_6H_{13})_2PO_2]_2$, were prepared by the reaction of copper(II) sulfate pentahydrate with the appropriate acid, neutralized with slightly less than a stoichiometric amount of sodium hydroxide. The preparation of poly-bis(μ-diethylphosphinato)copper(II), $Cu[(C_2H_5)_2PO_2]_2$, has been reported previously (1).

Di-*n*-hexylphosphinic acid was synthesized by the peroxide catalyzed addition of hypophosphorous acid to 1-hexene (4). A solution of the acid (5.7 mmol) in 3:1 ethanol:water was neutralized with aqueous sodium hydroxide (5.6 mmol) and an aqueous solution of copper(II) sulfate (2.8 mmol) was added dropwise with stirring. Precipitation began almost immediately and after the addition of the copper solution was complete, an equivalent volume (500 mL) of water was added to the reaction mixture (this prevents the formation of the blue–green sulfate co-polymer) and the resultant solution was stirred overnight. The blue precipitate was separated by filtration, washed with water, then ethanol, yielding pure $Cu[(n\text{-}C_6H_{13})_2PO_2]_2$ (77% yield). *Anal.* calcd. for $CuC_{24}H_{52}P_2O_4$: Cu 11.98, C 54.37, H 9.89; found: Cu 12.04, C 54.24, H 9.88. Crystals of $Cu[(n\text{-}C_6H_{13})_2PO_2]_2$ suitable for crystallographic studies were obtained by slow evaporation of a solution in 60–90° petroleum ether.

Di-*n*-butylphosphinic acid was prepared following the procedure of Kasolapoff and Watson (5), with the exception that the oxidation of the intermediate di-*n*-butylphosphite, $(n\text{-}C_4H_9)_2POH$, was accom-

plished with aqueous potassium permanganate rather than hydrogen peroxide and the final product was recrystallized from acetone rather than benzene. An aqueous solution of copper(II) sulfate (8.0 mmol) was added slowly, with stirring, to an aqueous solution of the partially neutralized acid (16.0 mmol acid; 15.9 mmol sodium hydroxide). After the addition of approximately one half of the copper solution, a blue solid began to precipitate. After the addition was complete the mixture was stirred for 1.5 h; the solid was then separated by filtration and washed with cold water. Additional product was obtained by concentrating the filtrate under vacuum. Total yield was 90%. *Anal.* calcd. for $CuC_{16}H_{36}P_2O_4$: Cu 15.20, C 45.98, H 8.68; found: Cu 15.23, C 45.80, H 8.60.

Carbon and hydrogen were determined by P. Borda of the Department of Chemistry, The University of British Columbia. Copper was determined by EDTA titration.

Solubilities

Qualitative solubility tests show $Cu[(n\text{-}C_4H_9)_2PO_2]_2$ to be soluble (in excess of 0.1 g in 100 mL) in water and chloroform, slightly soluble in methanol, ethanol, and dichloromethane, and insoluble in acetone, carbon tetrachloride, benzene, and petroleum ether. $Cu[(n\text{-}C_6H_{13})_2PO_2]_2$ is soluble in dichloromethane, chloroform, carbon tetrachloride, and petroleum ether, slightly soluble in benzene and ethanol, and insoluble in water, methanol, and acetone.

Differential scanning calorimetry (DSC)

$Cu[(C_2H_5)_2PO_2]_2$ exhibits a reversible endothermic phase transition (ΔH = 24 J g^{-1}) at 128.1°C, followed by reversible melting at 240.0°C (ΔH = 41 J g^{-1}); the compound oxidatively decomposes above 280°C. $Cu[(n\text{-}C_4H_9)_2PO_2]_2$ undergoes a reversible endothermic phase transition at 130.4°C (ΔH = 14 J g^{-1}), melts at 155.1°C (ΔH = 64 J g^{-1}) and oxidatively decomposes above 235°C. $Cu[(n\text{-}C_6H_{13})_2PO_2]_2$ melts at 108.8°C (ΔH = 75 J g^{-1}) and oxidatively decomposes above 250°C.

The DSC studies were made using a Mettler DSC 20 cell and a Mettler TC 10 TA Processor.

Infrared spectra

$Cu[(n\text{-}C_4H_9)_2PO_2]_2$. Data for the range 1400 to 300 cm^{-1}: 1304 m, 1276 w, 1223 m, 1204 w sh, 1162 vs, 1096 w sh, 1057 s, 1043 w sh, 1035 w sh, 904 m, 892 w sh, 806 s, 780 vw, 772 w, 745 w, 725 m, 545 s, 517 m, 428 vw, 420 vw, 362 m, 322 w. (w = weak, m = medium, s = strong, v,= very, br = broad, sh = shoulder.)

$Cu[(n\text{-}C_6H_{13})_2PO_2]_2$. Data for the range 1400 to 300 cm^{-1}: 1317 w, 1289 w, 1259 m, 1238 w, 1205 w, 1113 vs, 1061 s sh, 1039 s, 975 vw, 963 vw, 891 w, 880 vw, 865 w, 856 w sh, 803 s, 777 vw sh, 751 vw, 722 m, 709 w sh, 551 s, 514 m, 480 vw sh, 442 m, 401 m, 380 vw sh, 361 m, 339 m sh. (abbreviations as above.)

Infrared spectra were obtained on samples mulled in Nujol and pressed between KRS-5 plates (Harshaw Chemical Co). The infrared spectrophotometer was a Perkin-Elmer model 598.

Electronic spectra

Electronic spectra of Nujol mulls were obtained using a Cary 14 spectrophotometer (range 3 800 to 30 000 cm^{-1}). $Cu[(n\text{-}C_4H_9)_2PO_2]_2$ and $Cu[(n\text{-}C_6H_{13})_2PO_2]_2$ exhibit broad absorption bands centered at 11 500 cm^{-1} and 11 600 cm^{-1}, with shoulders at 13 200 and 13 300 cm^{-1}, respectively.

Magnetic susceptibilities

Variable temperature magnetic susceptibility measurements over the range 125 to 4.2 K were made using a Princeton Applied Research Model 155 Vibrating Sample Magnetometer, internally calibrated with ultrapure nickel metal. Temperature equilibration was obtained using a Janis Research Company Model 153 cryostat and a Princeton Applied Research Model 152 cryogenic temperature controller with a gallium arsenide diode temperature sensor.

Temperature measurement was achieved with a chromel vs. Au − 0.02% Fe thermocouple (6) located in the sample holder immediately above the sample. The thermocouple was calibrated using the known susceptibility versus temperature dependence of tetramethylethylenediammonium tetrachlorocuprate(II) and checked with mercury tetrathiocyanatocobaltate(II) (7). From the scatter in data points for four separate calibration runs the temperatures are estimated to be accurate to ±1% over the range studied.

The calibration was checked further by immersing the sample rod with thermocouple directly into liquid helium, oxygen, and nitrogen and the measured temperatures agreed with expected values to within the error of measurement. Thermocouple potentials were measured using a Fluke 8200 A digital voltmeter.

A Walker-Magnion model L75BF electromagnet and model HS 1050 power supply provided magnetic fields up to 10 000 G. Measurements were normally obtained with a field of 9625 G with checks for field dependence of magnetic susceptibilities using several or all of the following values: 1280, 2549, 3850, 5251, 6200, 7501, 8520, 9225, and 9625 G. None of the samples studied in the present work gave evidence of field dependence. Magnetic fields were set to an accuracy of 0.5% and measured using a F. W. Bell Inc. Model 620 Gaussmeter.

Samples weighing approximately 100 mg were placed in gelatin capsules attached to a Kel-F holder. The sample holder was attached to the drive rod which had been modified as recommended by Drake and Hatfield (8) so as to reduce the diamagnetic background and to allow for the passage of the thermocouple leads. Corrections were applied for the background diamagnetism of the sample holder. Magnetic susceptibilities were corrected for the diamagnetism of all atoms (155×10^{-6}, 215×10^{-6}, and 344×10^{-6} cm^3 mol^{-1} for the ethyl, *n*-butyl, and *n*-hexyl derivatives, respectively) and the temperature independent paramagnetism (60×10^{-6} cm^3 mol^{-1}) of copper(II).

Variable temperature magnetic susceptibility measurements over the range 300−80 K were made using Gouy equipment described elsewhere (9).

X-ray crystallographic analysis of $Cu[(n\text{-}C_6H_{13})_2PO_2]_2$

Selection of a crystal suitable for X-ray analysis proved to be a difficult task. The elongated, very thin plates could not be cleaved in any direction except parallel to the long axis of the crystal. The smaller specimens were found to be somewhat bowed, necessitating the use of a sufficiently thick crystal. Of the many crystals examined by X-ray photographs, only one was deemed suitable for data collection. This crystal (bounded by the six faces (followed by their distances in mm from a common origin): ±(100), 0.35, ±(010), 0.20, ±(001), 0.03) was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections measured on a diffractometer with MoKα radiation ($\lambda(K\alpha_1)$ = 0.70930, $\lambda(K\alpha_2)$ = 0.71359 Å). Crystal data at 22°C are:

$C_{24}H_{52}CuO_4P_2$ fw = 530.17

Triclinic, a = 9.800(3), b = 12.336(6), c = 13.352(8) Å, α = 88.53(3), β = 74.02(4), γ = 82.33(3)°, V = 1538(1) $Å^3$, Z = 2, ρ_c = 1.145 g cm^{-1}, $F(000)$ = 574, μ(MoKα) = 8.4 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ (C_i^1, No. 2, reduced cell) from structure analysis.

Intensities were measured with graphite-monochromatized MoKα radiation on an Enraf-Nonius CAD4-F diffractometer. An ω−2θ scan at 1.44−10.06° min^{-1} over a range of (0.75 + 0.35 tan θ)° in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of three check reflections, monitored every hour throughout the data collection, remained constant to within ±4%. After data reduction,[1] an absorption correction was applied using the Gaussian integration method (10, 11). Transmission factors ranged from 0.765 to 0.921 for 96 sampling points. Of the 7040 independent reflections measured,

*U_{eq} = (1/3) trace u_{diag}.

3095 had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The centrosymmetric space group $P\bar{1}$ was indicated both by the E-statistics and by the Patterson function. The coordinates of the Cu and P atoms were determined by conventional heavy-atom techniques, and those of the remaining non-hydrogen atoms from subsequent difference maps. Refinement of all non-hydrogen atoms with anisotropic thermal parameters resulted in $R = 0.058$. The last two or three atoms of each n-hexyl group display high degrees of thermal motion and are not particularly well-defined. Although the possibility of disorder was considered (in particular for the C(10)—C(12) fragment), no clearcut secondary positions for these atoms were in evidence. The refinement was continued with the assumption that these terminal n-hexyl fragments are not disordered but are subject to excessive thermal motion. Hydrogen atoms were included as fixed atoms in idealized positions (C—H = 0.98 Å, staggered methyl groups, B = 1.1 × value for bonded C atom) in subsequent cycles of refinement, the coordinates and thermal parameters for hydrogen atoms being recalculated after each least-squares cycle. The scattering factors and anomalous scattering terms for Cu and P were taken from ref. 12. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of refinement. Convergence was reached at $R = 0.045$ and $R_w = 0.056$ for 3095 reflections with $I \geq 3\sigma(I)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.04 and 0.38 σ, respectively. The mean error

*Here and elsewhere in this report primed and double-primed atoms have coordinates related to those in Table 1 by the symmetry operations $-x$, $1 - y$, $1 - z$, and $1 - x$, $1 - y$, $1 - z$, respectively.

in an observation of unit weight was 2.232. A final difference map was essentially featureless, the largest residual density (+0.45 e Å^{-3}) being located near P(2). The final positional and thermal parameters for the non-hydrogen atoms appear in Tables 1 and 6[2], respectively. Calculated hydrogen coordinates and thermal parameters are given in Table 5.[2] Bond distances, bond angles, and intra-annular torsion angles are given in Tables 2–4. A complete listing of torsion angles (Table 7) and the measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

Results and discussion

The crystal structure of Cu[(n-C_6H_{13})$_2$$PO_2$]$_2$

Atom labelling in the asymmetric unit is shown in Fig. 1. The crystal structure of Cu[(n-C_6H_{13})$_2$$PO_2$]$_2$ consists of well-separated infinite chains of centrosymmetric spiro-fused eight-membered rings propagating along the crystallographic a axis (see Fig. 2). The overall structure is very similar to those observed for the ethyl (1) and n-butyl (2) derivatives. There are a number of small but significant differences between the three structures which are discussed below in relation to the electronic spectra and magnetic properties of these compounds. The anomalous geometrical parameters for the n-hexyl groups (Tables 2 and 3) result from the large degree of thermal motion noted above.

Electronic spectra

The X-ray crystal structures of all three of the compounds considered here reveal the copper atoms to be in compressed tetrahedral environments of four oxygens with approximate D_{2d} symmetry. Earlier (1) we assigned the spectrum of Cu[(C_2H_5)$_2$$PO_2$]$_2$ to a crystal field model (13) involving the crystal field parameters Dq and Cp and a distortion parameter α (half the largest O—Cu—O bond angle). The CuO_4 chromophores in the n-butyl and n-hexyl derivatives are slightly less compressed than in the ethyl derivative (α = 74.3, 73.3, and 73.0° for the ethyl, n-butyl, and n-hexyl derivatives, respectively, from the X-ray data). Assuming the same Dq and Cp

[2]Complete set of data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

values as derived for the ethyl compound (1665 and 1800 cm^{-1}, respectively) and employing an α value of 73° yields predicted energies of 11 500, 11 800, and 13 900 cm^{-1} for the $^2B_2 \rightarrow {}^2A_1$, ^2E, and $^2B_1$ transitions. This is in excellent agreement with the observed spectra for the *n*-butyl and *n*-hexyl compounds, assuming as before (1) that the observed band at 11 500 and 11 600 cm^{-1} is assigned to the unresolved $^2B_2 \rightarrow {}^2A_1$, ^2E transition with the shoulder assigned to the $^2B_2 \rightarrow {}^2B_1$ transition. It is not too surprising that there is no detectable difference in the crystal field parameters for the different R_2PO_2 groups with differences in the electronic spectra arising primarily from small differences in the coordination geometries.

Infrared spectra

A complete listing of observed frequencies (1400 to 300 cm^{-1}) for both $Cu[(n\text{-}C_4H_9)_2PO_2]_2$ and $Cu[(n\text{-}C_6H_{13})_2PO_2]_2$ is given in the Experimental section. A partial assignment made as described previously (1) identifies the antisymmetric and symmetric PO_2 stretching frequencies at 1116 and 1057 cm^{-1},

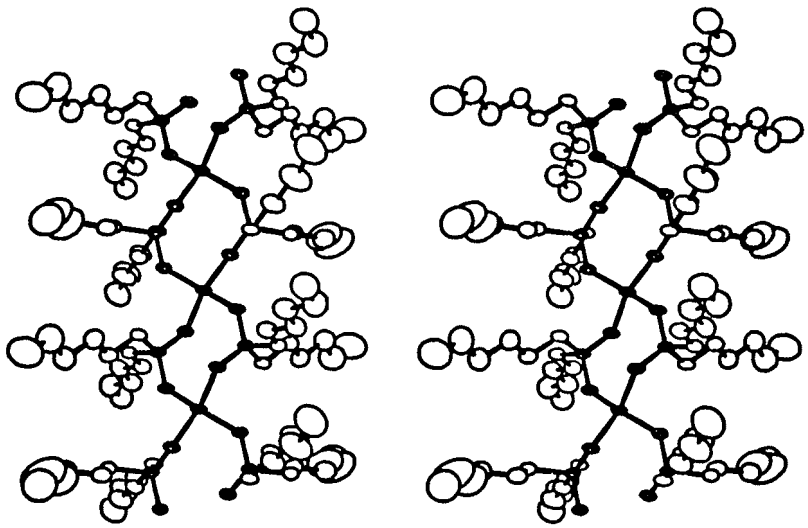

FIG. 2. Stereoview of the polymeric structure of $Cu[(n\text{-}C_6H_{13})_2PO_2]_2$.

respectively, for the butyl derivative and 1113 and 1039 cm^{-1}, respectively, for the hexyl derivative (14). Bands at 806 and 725 cm^{-1} in the butyl compound and 803 and 722 cm^{-1} in the hexylphosphinate are tentatively assigned to the antisymmetric and symmetric PC_2 vibrations (15), with bands in the 510–550 cm^{-1} range assigned to angle bending of both PC_2 and PO_2 groups (16). The medium intensity bands near 360 cm^{-1} in both compounds probably arise primarily from Cu—O stretching (1).

Magnetic properties

Magnetic susceptibilities, measured over the range 300 to 4.2 K, are given in Table 8 and the magnetic moments are plotted in Fig 3. While the data show virtually no temperature dependence from 300 to 100 K, significant dependencies are seen at lower temperatures, particularly below 10 K, for all three compounds.

The magnetic properties of $Cu[(C_2H_5)_2PO_2]_2$ suggest weak antiferromagnetic coupling. In view of the known structure of this material (1), the magnetic data were analyzed according to the isotropic Heinsberg model for linear chains. Employing the polynomial expression developed by Hall (17, 18) for the magnetic susceptibility, the best fit to the data was found with the parameters $J = -1.27$ cm^{-1} and $g = 2.19$ (rms deviation in the magnetic susceptibility is 12×10^{-6} cm^3 mol^{-1}). The data are plotted as magnetic moment against temperature in Fig. 3(*a*) where the solid line is calculated from theory using the best fit values of g and J. The criterion for best fit is that set of parameters which give the minimum value of the rms deviation. The accuracy to which the value of J is measured by this analysis is considered to be ±10% or better (agreement between theory and experiment for a 10% variation in J is illustrated in Fig. 4(*a*)) while g is considered accurate to about ±2% (see Fig. 4(*b*)).

Both $Cu[(n\text{-}C_4H_9)_2PO_2]_2$ and $Cu[(n\text{-}C_6H_{13})_2PO_2]_2$ exhibit increasing magnetic moments with decreasing temperature at low temperatures indicative of ferromagnetic coupling. Employing the polynomial expression of Baker *et al.* (18, 19) for the isotropic Heisenberg model for ferromagnetically coupled chains, the best fits to the magnetic susceptibility data gave g values of 2.16 for both compounds and J values of +2.22 and +2.58 for the butyl- and hexyl-derivatives, respectively (rms deviations were 18×10^{-6} and 13×10^{-6} cm^3 mol^{-1} for the butyl and hexyl derivatives, respectively). The data are plotted as magnetic moments in Fig 3(*b*) and 3(*c*); the lines are calculated from theory employing the best fit g and J values.

The excellent agreement between experiment and theory for the magnetic properties of chains of $S = 1/2$ ions supports the conclusion that in all three compounds studied here intrachain coupling dominates and there are no significant interchain magnetic interactions. This is not too surprising considering the large separations of the Cu—O—P—O—Cu backbones in neighbouring chains and the mutual insulation of the chains provided by the alkyl groups attached to phosphorus. The shortest intrachain copper–copper distances are of the order of 5 Å, too large, probably, for direct metal–metal interactions and requiring, therefore, a superexchange mechanism for the exchange. In view of the observation of antiferromagnetically coupled metal centres in the ethyl derivative and ferromagnetically coupled centres in the other two, we examined the structural details of the eight-membered $Cu(R_2PO_2)_2Cu$ rings closely for a possible explanation.

There are only relatively minor differences in the structural details of the inorganic backbones of the three compounds studied here. The ethyl derivative has slightly longer copper–copper distances (4.9555(8) and 5.0245(8)[3] Å (1) versus 4.938(2) for the butyl derivative (2) and 4.9277(8) and 4.9310(8) Å for the hexyl compound). The CuO_4 chromophore is slightly more planar in the ethyl compound than in the other two. The average values of the two large O—Cu—O angles are 148.6, 146.5, and 146.1° for the ethyl, butyl, and hexyl derivatives, respectively. Two crystallographically distinct eight-membered rings containing the copper atoms are seen for each compound. Very little difference in bond angles and lengths is seen from compound to compound. Total path lengths for superexchange, obtained by summing the appropriate bond lengths, are within experimental error, the same for all three compounds. All rings are distinctly puckered. The torsion angles have been given for the ethyl(1) and hexyl derivatives (Table 4) and a measure of the total deviation from planarity is the average of the absolute values of these angles. The average values of the torsion angles for the two rings in the ethyl derivative are 70.59 and 70.39°, and are slightly greater

[3]This distance was inadvertently omitted in ref. 1.

than the values of 67.10 and 69.85° calculated for the hexyl derivative (the corresponding mean deviations (Å) from the mean planes are 0.247, 0.242; 0.214, and 0.235 respectively). Finally we note interesting structural differences involving the alkyl groups, in particular structural conformation involving the α-carbons. In both the butyl and hexyl derivatives each phosporus has one α-carbon on which the hydrogens are staggered with respect to a P—O bond, and one on which the hydrogens are staggered with respect to a P—C bond. This has the effect of orienting both alkyl groups in an axial configuration with respect to the eight-membered ring. In the ethyl derivative, on the other hand, one of the rings has alkyl group orientations as seen for the other derivatives, while in the other ring both alkyl groups on each phosphorus have α-carbons with hydrogens staggered with respect to P—O bonds. The effect is to orient one of the alkyl groups axial to this ring and the other equatorial in the ethyl derivative. The orientations of the alkyl groups relative to the eight-membered rings affect the nature of the interchain packing and this in turn may cause some of the small differences seen in the bonding parameters of the inorganic backbone.

In summary, small but significant intrachain magnetic exchange coupling is observed in the diethyl, di-*n*-butyl, and di-*n*-hexylphosphinates of copper(II). It is possible that both antiferromagnetic and ferromagnetic routes for superexchange (20) are available in all three compounds with the observed behaviour dependent on which route dominates for a particular compound. The ethyl derivative has the flattest CuO_4 chromophore, the longest copper–copper distance (through space) and the most-puckered eight-membered rings. Any or all of these structural features may enhance the antiferromagnetic over the ferromagnetic route, thus accounting for the overall antiferromagnetic exchange observed for this compound. It is important to note that one of these structural features, namely the CuO_4 stereochemistry, has been correlated previously with the nature of magnetic exchange in copper compounds. It has long been noted that in binuclear copper(II) complexes distortion from a tetrahedral to a planar environment results in increased antiferromagnetic coupling (21, 22).

Primary kinetic isotope effect in the gas phase photochlorination of ethyl chloride-1-d_1

JAN NIEDZIELSKI,[1] T. YANO,[2] AND E. TSCHUIKOW-ROUX[3]
Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received October 12, 1983

JAN NIEDZIELSKI, T. YANO, and E. TSCHUIKOW-ROUX. Can. J. Chem. **62**, 899 (1984).

The abstraction of hydrogen/deuterium from CH_3CHDCl by ground state chlorine atoms produced photolytically from Cl_2 has been investigated at temperatures betwen 280 and 368 K. The relative rates for the internal competition

$$CH_3CHDCl + Cl \rightarrow CH_3CDCl + HCl \quad k_H$$
$$\rightarrow CH_3CHCl + DCl \quad k_D$$

are found to conform to an Arrhenius rate law:

$$k_D/k_H = (0.865 \pm 0.025) \exp[(-133 \pm 7)/T]$$

These data, taken together with the external competition results for the C_2H_5Cl/CH_3CHDCl system, in conjunction with the competitive results using CH_4 as a primary reference, have yielded the rate constants ($cm^3\ s^{-1}$):

$$k_H = (1.20 \pm 0.04) \times 10^{-11} \exp[-(480 \pm 20)/T]$$

$$k_D = (1.04 \pm 0.04) \times 10^{-11} \exp[-(613 \pm 20)/T]$$

The relatively weak primary kinetic isotope effect, k_H/k_D, decreases with increasing temperature from 1.85_5 at 280 K to 1.66 at 365 K. The results are compared with those obtained based on the BEBO method. While both the trend and the magnitude of the kinetic isotope effect are satisfactorily predicted, the activation energy is not.

JAN NIEDZIELSKI, T. YANO et E. TSCHUIKOW-ROUX. Can. J. Chem. **62**, 899 (1984).

Opérant entre 280 et 368 K, on a étudié l'enlèvement de hydrogène/deutérium du CH_3CHDCl par des atomes de chlore à l'état fondamental qui sont générés photochimiquement à partir du chlore. On a trouvé que les vitesses relatives pour la compétition interne

$$CH_3CHDCl + Cl \rightarrow CH_3CDCl + HCl \quad k_H$$
$$\rightarrow CH_3CHCl + DCl \quad k_D$$

sont en accord avec la loi de vitesse d'Arrhenius:

$$k_D/k_H = (0{,}865 \pm 0{,}025) \exp[(-133 \pm 7)/T]$$

Utilisant ces données de concert avec les résultats de compétition externe obtenus avec le système C_2H_5Cl/CH_3CHDCl et en conjonction avec les résultats compétitifs obtenus en utilisant le méthane comme référence primaire, on peut en déduire les constantes de vitesses ($cm^3\ s^{-1}$):

$$k_H = (1{,}20 \pm 0{,}04) \times 10^{-11} \exp[-(480 \pm 20)/T]$$

$$k_D = (1{,}04 \pm 0{,}04) \times 10^{-11} \exp[-(613 \pm 20)/T]$$

L'effet isotopique cinétique primaire, k_H/k_D, est relativement faible et il diminue avec une augmentation de la température; il passe de $1{,}85_5$ à 280 K à 1,66 à 365 K. On compare les résultats obtenus avec ceux obtenus en se basant sur la méthode BEBO. Même si on prédit correctement tant l'amplitude que l'évolution de l'effet isotopique cinétique, il n'est pas possible de prédire l'énergie d'activation.

[Traduit par le journal]

Introduction

In a recent paper from this laboratory (1) the photochlorination of gaseous ethyl chloride and ethyl chloride-d_5 was examined. Kinetic data on the hydrogen and deuterium atom abstraction by photochemically generated chlorine atoms were obtained, and the magnitude of the overall kinetic isotope effect was established. In the present work these studies are extended to the photochlorination of ethyl chloride-1-d_1. Our aim is twofold: firstly, to determine accurately the primary kinetic isotope effect and the absolute rate parameters by way of a suitable reference reaction, and, secondly, to compare these values with those predicted using semiempirical schemes applicable to metathetical atom transfer reactions. Of these, the most widely used is the bond energy – bond order (BEBO) method (2, 3) based on Johnston's concept of bond order conservation (4). The approach is purely empirical, and the necessary input data are drawn entirely from structural, non-kinetic information. Although the BEBO method is too crude to account for the fine points of the experiment, the general trends can usually be pointed out correctly. In the case of several classes of reactions to which abstractions by chlorine atoms belong, the BEBO method is known to fail (3, 5). Generally, activation energies can be calculated to within 1 or 2 kcal/mol compared with the experimental data, whereas abstractions of hydrogen by chlorine atoms are predicted to have activation energies much higher than those observed, frequently by 6–7 kcal/mol. If the reactant is a chlorinated hydrocarbon, as in the present

case, the reasons for the failure of the BEBO method may be sought in terms of non-bonding interactions between the attacking chlorine atom and the bound chlorine in the molecule, as suggested by Johnston and Goldfinger (6). While activation energies are known to be highly sensitive to non-bonding interactions the kinetic isotope effects are not. In the latter case, the potential energy field around the atom being transferred and the atomic masses involved are the crucial factors. An extensive study of kinetic isotope effects in the photochlorination of hydrogen, methane, methyl chloride, and ethane was reported by Chiltz *et al.* (7). The BEBO method was applied to calculate activation energies, kinetic isotope rate constant ratios, and their temperature coefficients, but met only with partial success. Although the calculations broadly fitted the experimental temperature dependence of the kinetic isotope effects, no unique set of adjustable BEBO parameters could be assigned which would quantitatively predict all the experimental data. Clyne and Walker (8), using improved experimental data for the pairs CH_4/CD_4 and $CHCl_3/CDCl_3$, obtained a better, albeit still not completely satisfactory, fit with the theory. Recently, the necessity to update the original BEBO parameters has been emphasized (9–11). New calculations should incorporate the refinements in potential parameters for rate gas clusters, the revision of the numerical factor in Pauling's bond length – bond order rule, and new assessments of the magnitude of triplet repulsions. In the present paper we reexamine whether or not the updated BEBO version will provide a reasonable description of the kinetic isotope effects in the chlorination of ethyl chlorides.

Experimental

The apparatus, light source, and experimental procedure have been described previously (1). Photolyses were carried out over the temperature range 7–95°C using filtered visible light centered at 424 nm. The only products observed were 1,1- and 1,2-dichloroethanes. Analyses were performed by gas chromatography in the first instance,and the determination of the contribution of the deuterated dichloroethanes to the total yield was accomplished by coupled gc/ms (computer-controlled Hewlett-Packard, Model HP-5992A) which featured a standard selected ion monitor program. The parent peaks were monitored at a source pressure of ca. 10^{-6} Torr to prevent the occurrence of ion–molecule reactions.

For each dichloroethane three different parent peaks were observed, reflecting the natural isotopic abundance of $^{35}Cl_2$, $^{35}Cl^{37}Cl$, and $^{37}Cl_2$ in the molecules. The abundance of peaks corresponding to the $^{37}Cl_2$ moiety, i.e., m/e = 102 for $C_2H_4Cl_2$ and m/e = 103 for C_2H_3DCl were small, hence a greater scatter in the experimental results occurred and these data were rejected. Only four peaks were therefore monitored: 98, 99, 100, and 101. Ideally, the peak ratios 98/99 and 100/101 should be identical, and both yield the contribution of the deuterated species to the total yield of either 1,1- or 1,2-dichloroethane. However, the parent ions were always found to be accompanied by some fragment ions. For example, to apply the appropriate corrections to each of the m/e = 98 and m/e = 100 ion abundances for the presence of the peaks 99 and 101, respectively, the cracking patterns of all four products involved (CH_3CHCl_2, CH_3CDCl_2, CH_2ClCH_2Cl, $CH_2ClCHDCl$) were determined (Table 1). In the case of normal dichloroethanes, the results obtained using both authentic samples, and the products of the photochlorination of pure ethyl chloride under our experimental conditions were in satisfactory agreement. Since commercial samples of the monodeuterated dichloroethanes were not available to us, the 1,2-dichloroethane-d_1 ($CH_2ClCHDCl$) was manufactured by the photochlorination of ethyl chloride-1-d_1 (CH_3CHDCl) and isolated by gas chromatography. Similarly, 1,1-dichloroethane-1-d_1 (CH_3CDCl_2) was obtained from the photolysis of ethyl chloride-1,1-d_2 (CH_3CD_2Cl).

TABLE 1. Mass spectral cracking patterns of normal and monodeuterated dichloroethanes[a]

	Intensity for m/e =			
Dichlorethane	98	99	100	101
CH_3CHCl_2	100	6.9±0.3	84.9±0.5	1.8±0.2
CH_2ClCH_2Cl	100	3.8±0.8	87.0±0.5	1.8±0.4
$CH_2ClCHDCl$	8.1±0.4	100	11.2±0.2	94.7±0.3
CH_3CDCl_2	5.4±0.6	100	7.8±0.2	90.0±0.3

[a]The error limits are ±1σ.

Parenthetically, it may be noted that all the cracking patterns determined here showed some dependence on the operating parameters of the mass spectrometer. Therefore, every series of experiments, including all the necessary calibrations, was completed under unchanged conditions. The reliability of these procedures was checked by introducing a known mixture of CH_3CH_2Cl and CH_3CHDCl into the ion source. The composition of the mixture was reproduced accurately to within 1%.

Ethyl chloride-1-d_1 (Merck, Sharp and Dohme) 99% D was thoroughly purified by bulb-to-bulb vacuum distillations until the level of impurities, mainly ethylene and methyl chloride, was approximately three orders of magnitude smaller than the amounts of products. The peak intensities for m/e = 64 ($C_2H_5{}^{35}Cl$) and m/e = 53 ($CD_2{}^{37}Cl$) were negligible; however, a detailed examination of the mass spectral cracking pattern revealed that the compound was contaminated with about 1% of CH_2DCH_2Cl. Ordinary ethyl chloride and chlorine (Matheson) were purified as described previously (1).

Results and discussion

Experimental results

The photochlorination of CH_3CHDCl has been investigated over the range of temperatures 7–95°C at total pressures of about 21 Torr. The reagent was used in about twenty-fold excess over chlorine which insures that the prevailing chain termination is by radical–radical combination (1). Light intensities and photolysis times were kept sufficiently low to prevent the formation of detectable amounts of secondary photochlorination products. The pertinent rate laws, as well as the verification of the long chain assumption, have been presented elsewhere (1).

Under these conditions the relevant processes are the three abstraction reactions

[1] $CH_3CHDCl + Cl \rightarrow CH_3CDCl + HCl$

[2] $\rightarrow CH_3CHCl + DCl$

[3] $\rightarrow CH_2CHDCl + HCl$

followed by

[4] $R + Cl_2 \rightarrow RCl + Cl$

where R denotes any of the chloroethyl radicals formed in reactions [1]–[3]. It should be noted that the radicals R are thermal and hence can neither decompose nor undergo any internal rearrangement prior to reaction with Cl_2. It can also be readily shown that, for low conversions, other side reactions, viz., hydrogen/deuterium and/or chlorine exchange, or the abstraction of H or D from the product hydrogen halides, are of no importance (1, 12). The sequence of reactions [1]–[4] leads to the formation of three final products: CH_3CDCl_2 (reaction [1]), CH_3CHCl_2 (reaction [2]), and $CH_2ClCHDCl$ (reaction [3]).

For internal competition and long chains, the product ratio

determines the rate constant ratio for the abstraction reaction directly (1)

$$\frac{k}{k'} = \frac{[RCl]}{[R'Cl]}$$

For reactions [1] and [2] the rate constant ratio k_1/k_2 yields the magnitude of the primary kinetic isotope effect, i.e., the effect associated with the C—H and C—D bonds being broken. Since the task of separating the CH_3CDCl_2 and CH_3CHCl_2 pair cannot be achieved by gas-chromatography alone, the photolysis products were subjected to gc/ms analysis. The results are shown in Fig. 1 and the plots are linear.

Although on theoretical grounds a strictly Arrhenius behaviour is not to be expected, as has been observed in the chlorination of methane in the temperature range 200−500 K (13, 14), over the narrower range of temperatures covered in this study no deviations from linearity are apparent. From the slopes and intercepts, using a least-squares treatment, we obtain the relative Arrhenius parameters presented in Table 2. The precision of the measurements is on the level of 2−4% but, unfortunately, the overall accuracy is worse, due to the occurrence of a significant systematic error which is evidenced by the inequality of the results obtained using m/e = 99/98 and 101/100 monitoring. The lack of agreement is especially striking in the case of the *A*-factors (Table 2). Apparently some experimental artefacts are operative because the errors involved in the determinations of the mass spectral cracking patterns are too small to account for this difference. On the other hand, the discrepancies in the differences in activation energies are within the stated error limits.

In order to obtain the absolute Arrhenius parameters for k_1 and k_2, reaction [3] can be used, in principle, as an internal standard. To this end the ratio $c_i/c_j = (CH_3CDCl_2 + CH_3CHCl_2)/CH_2ClCHDCl$ was measured by gas chromatography and its temperature dependence was established. As shown in Fig. 2 over the temperature range 7−95°C the plot is also linear, and satisfies the following expression:

$$[5] \quad \ln [(k_1 + k_2)/k_3] = -0.114 \pm 0.05 + (361 \pm 16)/T$$

where the stated uncertainty limits are one standard deviation and account for both, the experimental precision, and for the systematic errors due to uncertainties in the calibration coefficients for the gc detector sensitivity towards 1,1- and 1,2-dichloroethanes. This relative correction factor was determined previously (12) as: $[CH_3CHCl_2] = (1.057 \pm 0.013) \times [CH_2ClCH_2Cl]$. However, any small differences in the detector response towards monodeuterated dichloroethanes were not taken into account.

Although the Arrhenius-like parameters given by eq. [5] are devoid of simple physical meaning they provide a numerical means for arithmetical material balancing. Using the k_1/k_2 values determined by the gc/ms analysis in conjunction with eq. [5], the temperature dependence of k_1/k_3 and k_2/k_3 can be calculated, which, in turn, would yield absolute Arrhenius parameters for k_1 and k_2 based on those for k_3 established previously (12). However, the problem of choosing between the two values presented in Table 2 for A_2/A_1 would still not be solved. Therefore, supplementary external competition experi-

The concentration of CH_3CHCl_2 refers to the contribution from reaction [6].

ments were performed using C_2H_5Cl as a secondary standard, serving as a check for the internal self-consistency of the results. The presence of C_2H_5Cl as competitor introduces two additional reactions

[6] $CH_3CH_2Cl + Cl \rightarrow CH_3CHCl + HCl$

[7] $\rightarrow CH_2CH_2Cl + HCl$

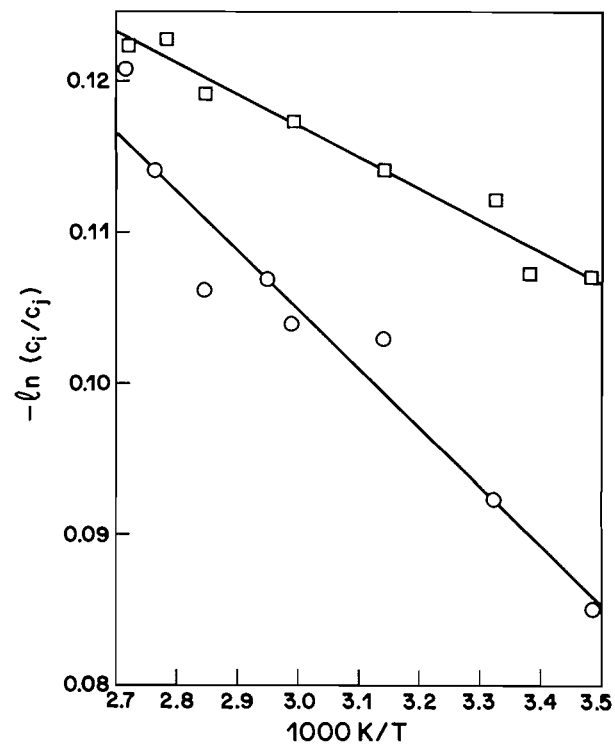

FIG. 4. Temperature dependence of the rate ratios for external competition in the system CH_3CHDCl/CH_3CH_2Cl; c_i/c_j = [$CH_2ClCHDCl$]/[CH_2ClCH_2Cl]; circles: 99/98 ions monitored; squares: 101/100 ions monitored.

which, coupled with reactions [1]–[3], yield altogether four different dichloroethane products. For competitive photochlorination of CH_3CHDCl (RH) with a reference compound CH_3CH_2Cl (R′H) the rate constant ratio, in terms of the product yields up to moderate conversions (~30%), is given by (15):

$$\frac{k}{k_r} = \frac{[RCl]\,[R'H]_m}{[R'Cl]\,[RH]_m}$$

where the subscript m refers to the mean reactant concentration. This equation holds also in the case of simultaneous internal competition against an external standard for each identifiable chlorination product. Under the experimental conditions used, the conversion with respect to both RH and R′H was so low that no noticeable loss in accuracy was introduced by using the initial rather than the mean concentrations.

Furthermore, it was hoped that the use of C_2H_5Cl as an external standard would yield data on the secondary kinetic isotope effects: an effect of the first kind resulting from the difference in the residual isotopic composition at the carbon atom undergoing C—H/C—D bond rupture (CH_3CH_2Cl/CH_3CHDCl), and an effect of the second kind due to isotopic substitution in the vicinal group (CH_3CH_2Cl/CH_3CHDCl).

The products of the photolysis of the (CH_3CH_2Cl/CH_3CHDCl) system were also analyzed by both the gc and gc/ms methods. The gc/ms results for the pairs CH_3CHCl_2/CH_3CDCl_2 and CH_2ClCH_2Cl/$CH_2ClCHDCl$ are shown in Figs. 3 and 4, respectively, and included in Table 2. As previously, the discrepancies between the values obtained using m/e = 99/98 and 101/00 monitoring are outside the limits of experimental precision. For purposes of cross-checking, the data based on the gc analysis are plotted in Fig. 5. The linear plot obeys the expression:

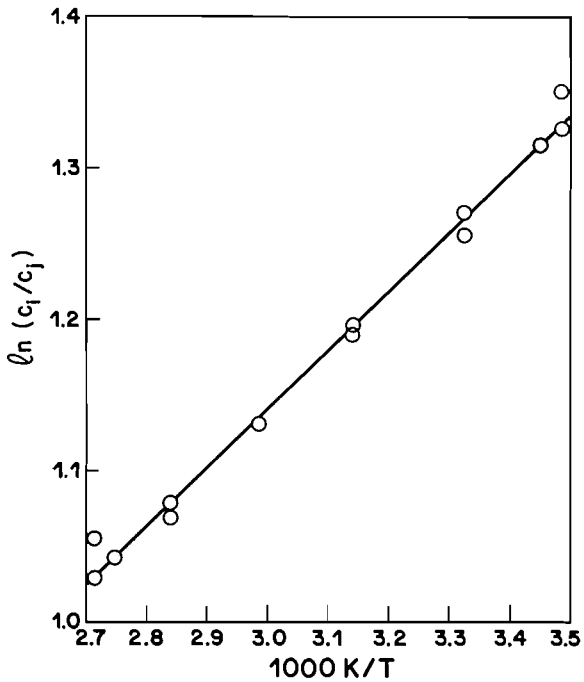

FIG. 5. Temperature dependence of the product ratios for external competition in the system CH_3CHDCl/CH_3CH_2Cl; c_i/c_j = $([CH_3CDCl_2] + [CH_3CHCl_2])/([CH_2ClCHDCl] + [CH_2ClCH_2Cl])$.

$$[8] \quad \ln [(k_1 + k_2 + k_6)/(k_3 + k_7)] = -0.027 \pm 0.04 + (389 \pm 13)/T$$

Three checks for the internal self-consistency of the results are now available, and can be of some assistance in the task of choosing the more reliable values. Using $A_2/A_1 = 0.865$ (Table 2) and eq. [5], $A_1/A_3 = 0.488$ may be obtained. This value, coupled with $A_6/A_1 = 1.806$ (Table 2) and $A_6/A_7 = 1.099$ (taken from ref. 12) leads to $A_7/A_3 = 0.802$ in good agreement with the values $A_7/A_3 = 0.799$ and 0.838 reported in Table 2. Similarly $E_3 - E_7 = 46.8/R$ K can be calculated, which is in reasonable agreement with the independent value of $39.6/R$ reported in Table 2. Another check for self-consistency involves the use of eq. [8]. For example, at a temperature of 300 K the gc data represented by this equation give ln $[(k_1 + k_2 + k_6)/(k_3 + k_7)] = 1.27 \pm 0.047$, in agreement with an independent value of 1.29 based on the evaluation of $(k_1 + k_2)/k_3$, k_6/k_7, k_6/k_1, and k_2/k_3 at 300 K. Another independent value, k_7/k_3, may be included for comparison; the value for ln $[(k_1 + k_2 + k_6)/(k_3 + k_7)]$ becomes 1.16 which is still satisfactory.

TABLE 4. Absolute Arrhenius parameters for[a] H/D-atom abstraction from ethyl chlorides by chlorine atoms

[a]The uncertainties in the Arrhenius parameters for the reference reaction [9] are not taken into account.
[b]Preferred values, see text.

Even though these tests are not very sensitive they do provide some useful clues, and, based on these, the preferred values for the relative Arrhenius parameters are assembled in Table 3. Also included in Table 3 are the Arrhenius parameters for the competitive photochlorination of C_2H_5Cl against methane (12), which make it possible to calculate the absolute Arrhenius parameters as shown in Table 4. The choice of CH_4 as a reference, as well as the choice of the absolute rate constant value ($cm^3\ s^{-1}$) for the chlorination of methane reported by Keyser (16).

$$[9] \quad k_{CH_4} = (1.64 \pm 0.32) \times 10^{-11} \exp [-(1530 \pm 68)/T]$$

have been discussed previously (1). The uncertainty limits of the reference reaction are of necessity not included in the data presented in Table 4.

Of the five sets of data reported in Table 3 that are concerned with CH_3CHDCl (II, III, V−VII), two,VI and VII, are interrelated. Using either one and the remaining four sets of data to assess the parameters shown in Table 4, we obtain two different sets of Arrhenius parameters for processes [1] and [2]. The differences are small, e.g., for reaction [1] the pre-exponential factors are 1.20 and 1.11×10^{-11} $cm^3\ s^{-1}$ while the activation energies are 954 and 1021 cal mol^{-1}, respectively. The former values are preferred because they pass the test for self-consistency better. Also the values of the secondary kinetic isotope effects calculated using the latter parameters are too large.

[a]Based on updated BEBO method (see text). Values in parentheses are based on original BEBO formulation (2). In both cases contribution from quantum mechanical tunnelling is ignored.
[b]Includes tunnelling correction based on Bell's truncated parabola (3, 30).
[c]Includes tunnelling correction based on unsymmetrical Eckart barrier (3).

Based on the data presented in Table 4 both primary and secondary kinetic isotope effects can be determined over the range of temperatures covered in these studies. Experimental values for the primary effect, k_H/k_D, at selected temperatures, are shown in Table 5. These determinations are based on internal competition experiments exclusively, and the overall accuracy is assessed to be about 4%. Both the magnitude of this effect and the decreasing trend with increasing temperature agree very well with our previous data on ethyl chloride-d_5 (1). However, the secondary kinetic isotope effects are based on external competition experiments, thus additional errors are involved and the overall accuracy deteriorates to an estimated ±10%. This accuracy is not adequate to establish the existence of an effect, much less its magnitude or temperature dependence. Therefore, numerical values are not reported. Still, the results for these effects are reasonable, and, within the limits of experimental error, are close to unity as expected. Hence our confidence in the reliability of the primary effects, determined more accurately, is much enhanced.

BEBO calculations

The bond energy – bond order (BEBO) method was used to calculate both the kinetic isotope effect (kie) and the activation energy for the abstraction of secondary hydrogen by Cl atoms from ethyl chloride. As has been noted earlier, although the BEBO method has been usually fairly successful for a large number of reactions in predicting activation energies and kie values (17–19), perhaps the worst disagreement between theory and experiment is encountered in the case of hydrogen abstraction by chlorine atoms. For instance, both the magnitude and the trend in activation energy with the heat of reaction for chlorine atom attack in chloromethanes and chloroethanes is predicted, contrary to experiments (6). Furthermore, the chlorination of C_2H_6/C_2D_6 is one of the few examples of the failure of the BEBO method for the calculation of kie (3, 7). In the case of ethyl chloride the situation might have been expected to be even worse based on the arguments of Johnston and Goldfinger (6) that the preferential attraction of the chlorine atom by the bound chlorine may result in collision complexes of the form C—Cl---Cl superseding those of the form C—H---Cl to the extent that in the case of a molecule such as $CHCl_3$ a hydrogen atom transfer complex may never be formed. Nevertheless, we thought it worthwhile to examine whether the failure of the BEBO method, when applied to this class of reactions, could be remedied by updating the input parameters as has been recently recommended (10, 11). However, no attempt was made to *adjust* parameters so as to achieve an exact fit of experiment with theory.

The derivation of the BEBO theory has been lucidly presented by Johnston (3). The main feature in the formulation is that the path of minimum potential energy for reaction lies along the line of constant bond-order ($n_1 + n_2 = 1$). Accordingly, for a hydrogen transfer process

$$AH + B \rightarrow A\text{---}H\text{---}B \rightarrow A + BH$$

the potential energy of the system is given by

$$[10] \quad V = D_{1s}(1 - n^{p_1}) - D_{2s}(1 - n)^{p_2} + D_{3s}B(n - n^2)^{\gamma}[1 + B(n - n^2)^{\gamma}]$$

where n is the progress variable ranging from 1 to 0; D_{1s}, D_{2s}, D_{3s} are single bond energies of AH, BH, and AB, respectively, and the constants p_1, p_2, B, and γ are non-adjustable parameters which can be calculated by combining empirical correlations and spectroscopic data for reactant and product molecules. Since the cited changes affect these input parameters their definitions are briefly reviewed:

$$[11] \quad B = f \exp(-\beta \Delta R_s)$$

$$[12] \quad \gamma = a\beta$$

where β is a function of the force constant and bond dissociation energy between end atoms ($\beta = (F/2D_0)^{1/2}$), and ΔR_s relates to single bond lengths ($\Delta R_s = R_{1s} + R_{2s} - R_{3s}$). The factor f in eq. [11], which can be traced to the modified Sato triplet function (3), was taken as 1/2 in the original formulation. More recently, Zavitsas (20) has shown that $f = 0.45$ gives a value for the triplet repulsive term which is more consistent with a value obtained based on variational calculations, and this value has been adopted by Gilliom (11) and here. In eq. [12] the factor a is the constant in Pauling's formula relating bond length to bond order

$$[13] \quad R_n = R_s - a \ln n$$

When the bond lengths are expressed in Ångstrom units the original Pauling value of a is 0.26. This numerical value is a subject of some controversy. Refinements in the values of bond lengths for C—C, C=C, and C≡C led Gilliom (10) to redetermine the constant as $a = 0.28$. A similar value of 0.277 was suggested by Marschoff and Jatem (21) and an even higher value of 0.30 by Burton *et al.* (22). According to a generalization of the Pauling equation developed by Agmon (23) the value of a ceases to be constant and depends on the equilibrium separation of atoms. In our calculations we have adopted Gilliom's value.

The partial bond index p which appears in the "bonding" terms in eq. [10] is evaluated by combining Pauling's rule, eq. [13], with Johnston's correlation for bond energy – bond order (2, 3)

$$[14] \quad D_n = D_s n^p$$

for a value of n corresponding to a noble-gas diatomic cluster ($n \rightarrow x$)

$$[15] \quad p = a[\ln (D_s/D_x)]/(R_x - R_s)$$

where D_x is the depth of the attractive potential, and R_x is the

internuclear distance for the rare gas "molecule" in the same row of the periodic table as the interacting atoms. In the original evaluation of the p parameters Lennard-Jones potentials were used (3). More recently, both Jordan and Kaufman in their criticism of BEBO (9), and Gilliom in his modification of the method (10), utilized the rare gas intermolecular potentials obtained from molecular beam differential elastic scattering measurements by Lee and co-workers (24, 25). However, Lee's values are no longer tenable; further measurements with improved techniques yielded significantly different results (26, 27). We have adopted the following values: for He—Ne a well depth of $D_x = 45.4$ cal mol^{-1} and $R_x = 2.97$ Å (26); for He—Ar, $D_x = 58.4$ cal mol^{-1} and $R_x = 3.47$ Å (27). Other input parameters are collected in Table 6.

Using these data, the potential function V, eq. [10], was evaluated point by point for values of n from 1 to 0 at increments of 0.01. The maximum value of V, which corresponds to the potential energy of activation, was found at $n^* = 0.53$, $V^* = 6.59$ kcal/mol. The potential energy of activation exceeds the experimental activation energy by about 5.5 kcal/mol. Corrections for zero point energies do not alter the situation significantly. The use of other values for Pauling's constant (22, 23) resulted in even higher values for V^*. The conclusion which must be drawn is that the updating of the input parameters did not result in any improvement in the BEBO prediction of the activation energy for this system. It has been pointed out (28) that the BEBO calculations are quite sensitive to the adopted values of the p parameters. However, for the C—H and H—Cl bonds these values are, respectively, slightly above and below unity, and no reasonable adjustments for the rare gas intermolecular potentials can significantly alter the calculated V^* value. The contribution of the partial bonds is relatively small and negative in the present case, and V^* is mainly determined by the end atom triplet repulsion, the evaluation of which is the most arbitrary part of the theory, as pointed out by Jordan and Kaufman (9). Finally, we note that Johnston's prescription (3) that the theory will fail if the zero-point energy of the bond being broken exceeds the potential energy of activation holds true in this case.

Kinetic isotope effect calculations were based on a linear three-atom activated complex model which is both simple and adequate (29). Once the value of n^* is determined, all the needed parameters for a vibrational analysis are available. Two sets of vibrational frequencies are listed in Table 7. The first set represents the values obtained using the updated BEBO parameters; the values in parentheses were calculated using the original parameters of Johnston and Parr (2). Since for H and D transfer the reactants are identical, the expression for kie has the simple form (3)

$$[16] \quad k_H/k_D = (\nu^*\Gamma^*\Pi\Gamma)_H\dagger/(\nu^*\Gamma^*\Pi\Gamma)_D\dagger$$

where ν^* denotes the imaginary frequency associated with the reaction coordinate, $\Gamma = x/\sinh x$ where $x = h\nu/2kT$ and Γ^*

[b]Values in parentheses are calculated according to original prescription of Johnston and Parr (2).

is a tunnelling correction. The calculated values of k_H/k_D, with and without the tunnelling correction, are listed in Table 5. A comparison with the experimental data shows that the uncorrected values of $(k_H/k_D)_{calcd}$, column 3, are lower than experimentally determined, and, moreover, show an inverse temperature dependence. Column 4 shows the corresponding ratio and would provide a measure of the tunnelling contribution, if the calculated maximum along the potential energy path were a good representation of the locus of the activated complex. The theoretical evaluation of the quantum tunnelling correction is not straightforward. However, simple model calculations can readily be made. For small degrees of tunnelling, the correction for an inverted parabolic barrier has been given by Bell (30).

$$[17] \quad \Gamma^* = |x^*|/\sin x^*$$

where $|x^*| = h|\nu^*|/2kT$. Equation [17] is applicable when the reaction coordinate is separable, $|x^*| < \pi$. For H-atom transfer at room temperature this condition is not met, and application of eq. [17] overestimates the tunnelling effect (column 5, Table 5). However, it does restore the observed decreasing trend in the values of k_H/k_D with temperature. A more appropriate correction for these exothermic processes is provided by considering an unsymmetrical Eckart potential for which the barrier penetration factors, Γ^*, have been evaluated and tabulated by Johnston (3) as a function of dimensionless parameters. The information needed to use this table can be obtained from the activation and zero point energies, the enthalpy of the reaction, and the imaginary frequencies of the activated complex. Corrected k_H/k_D values based on the Eckart potential are listed in column 6 of Table 5. The agreement with the experimental data is markedly improved, both with respect to the magnitude (within ~6%) and temperature dependence. However, this agreement may be fortuitous. The three atom model for the transition state alone is expected to cause deviations on the level of 10%. In a recent series of papers Garrett and Truhlar (31–33) have recommended a canonical variational theory rather than the conventional transition state theory for practical computations of gas-phase reaction rate constants. As far as kinetic isotope effects are concerned they suggest a more

For personal use only.

sophisticated treatment involving not only mass differences but also differences in force constants and bond distances, based on arguments that the location of the transition state may depend strongly on isotopic substitution. Therefore, no more is claimed for the BEBO method presented here other than it is simple and does corroborate the experimental data on the kinetic isotope effect if not the activation energy.

The proton activating factor and its application to acid and base catalysis of aldehyde hydration

ROSS STEWART
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received October 12, 1983

ROSS STEWART. Can. J. Chem. **62**, 907 (1984).

The data of McClelland and Coe for the general acid and general base catalyzed hydration of a series of substituted benzaldehydes has been analyzed in terms of the proton activating factor, *paf*, and concepts related thereto. Although the latter were derived for use with prototropic systems, the present work shows that they have application to nucleophilic addition as well. Three conclusions emerge from the analysis. 1. Alternative means of calculating *paf* from buffer catalytic data that were previously derived on theoretical grounds can be used in practice to give essentially the same results. 2. The mechanism of the general acid catalyzed pathway for aldehyde hydration is that favoured by McClelland and Coe and by Jencks, to wit the class (e) mechanism, rather than the class (n) mechanism. 3. Electron-withdrawing groups in the benzaldehyde ring cause the disparity between the contributions of alternative, kinetically equivalent, pathways for the uncatalyzed reaction to become greater.

ROSS STEWART. Can. J. Chem. **62**, 907 (1984).

Les données de McClelland et Coe concernant l'hydratation, soumise à une catalyse générale des acides et des bases, d'une série de benzaldéhydes substitués ont été analysées en termes du facteur activant des protons, *fap*, et de concepts qui lui sont reliés. Quoique ces derniers ont été développés pour utilisation avec des systèmes prototropiques, le présent travail démontre qu'ils ont aussi des applications dans le domaine des additions nucléophiles. Il ressort trois conclusions de notre analyse. 1. Les méthodes alternatives de calculer *fap* à partir de données catalytiques tamponnées, que l'on a antérieurement dérivées sur des bases théoriques, peuvent être utilisées en pratique pour donner essentiellement les mêmes résultats. 2. Le mécanisme impliquant le chemin de catalyse acide générale pour l'hydratation de l'aldéhyde est celui favorisé par McClelland et Coe et par Jencks, à savoir le mécanisme de classe (e) plutôt que le mécanisme de classe (n). 3. Les groupes électro-affinitaires attachés au benzaldéhyde favorisent les contributions des voies alternatives, mais cinétiquement équivalentes, pour la réaction qui n'est pas catalysée.

Introduction

There are two important classes of organic reactions that are subject to acid and base catalysis. One of these is the prototropic process in which a proton is removed from one location in a molecule and transferred to a second location (unless some other process intervenes). Enolization and the transformations for which it is the first step (many condensations, oxidations, and other processes) typify the prototropic reaction. One way of analyzing such reactions is in terms of the proton activating factor *paf*, a term introduced by Stewart and Srinivasan to indicate the degree of activation that results from protonation of the substrate molecule (1–3). Consider a molecule Z undergoing enolization (or enolate anion formation) as a result of attack by a base A^- on Z or on its conjugate acid ZH^+ (eq. [1]). The quotient of the rate constants, k'/k, the proton activating factor, can be obtained using eq. [2], where k_{HA} and k_{A^-} are the experimental catalytic coefficients, and K_{ZH^+} and K_{HA} are the acidity constants of the substrate and the catalyzing buffer acid HA, respectively.

[1] $$\begin{array}{ll} Z + A^- & \xrightarrow{\;k\;} \\ \downarrow\uparrow & \qquad \text{products or reactive intermediates} \\ ZH^+ + A^- & \xrightarrow{\;k'\;} \end{array}$$

[2] $$paf = \frac{k'}{k} = \frac{k_{HA} K_{ZH^+}}{k_A - K_{HA}}$$

In the absence of buffer acids the same process can be brought about by a water molecule or an hydroxide ion filling the role of the general base, in which case the *deprotonating factor, dpf*, becomes pertinent. It represents the degree of activation brought about by removal of a proton from the base.

It has been found that *paf* varies enormously in size, depending on various characteristics of the reaction and the substrate, but in all cases examined it is considerably less, often by a very large factor, than *dpf*. That is, removing a proton from the base is more effective than adding a proton to the substrate, which is to be expected since the proton removed from the base comes from the atom that is the basic centre, whereas the proton added to the substrate takes a position that is merely adjacent to the reaction centre (eq. [3]). In the case of acetone, *dpf/paf* is greater than 10^3 (2).

[3] 
The second major class of organic reactions that is subject to general acid and base catalysis involves reactions at carbonyl centres. A recent paper by McClelland and Coe (4) describes a detailed study of such a reaction, the hydration of aromatic aldehydes catalyzed by general acids and bases (eq. [4]). Their work provides sufficient kinetic data to enable the reaction and its component steps to be scrutinized in a way similar to that previously employed with prototropic processes.

[4] $ArCHO + H_2O \rightleftharpoons ArCH(OH)_2$

There are three points of interest that emerge from the present study. The first is a check of the equivalence of alternative means of determining *paf* that had been previously described. The second is an examination of the alternative routes, known as mechanisms (e) and (n) (4, 5), for the general acid catalyzed pathways in the light of the magnitude of the *paf* and *dpf* values that are calculated herein. The third is concerned with the width of the valley in the plot of log *k* against pH in the absence of buffers, and the significance of this quantity in terms of alternative reaction pathways.

TABLE 1. Basicity constants for benzaldehydes and the apparent *paf* values for their hydration in various buffers calculated using eq. [2] and the catalytic coefficients reported in ref. 4[a]

Substituted benzaldehyde	$-pK_{BH^+}$	$paf^{app} \times 10^9$ Buffer acids					
		Acetic	Formic	β-Chloropropionic	Methoxyacetic	Chloroacetic	Cyanoacetic
3,5-$(NO_2)_2$	6.65	23	11	32	13	9.1	7.0
3-NO_2,4-Cl	5.48	4.5	1.9	2.9	1.3	1.9	1.2
4-NO_2	5.35	3.8	1.7	3.7	2.1	2.1	1.8
3-NO_2	5.28	4.4	1.9	1.9	2.5	2.0	—
4-CF_3	4.89	2.4	1.2	2.4	2.5	—	—
3-Cl	4.59	2.0	1.3	1.9	1.8	—	—
4-Cl	4.11	1.1	0.9	1.2	—	—	—

[a]The catalytic coefficients for the buffer acids and anions reported in Table 1 of ref. 4 refer to the sum of the rate constants for hydration and dehydration; however, they can be used directly to calculate *paf* for hydration as can be seen by combining eq. [7] of ref. 4 with eq. [2] herein.

Alternative means of determining *paf*

In order to determine *paf* using eq. [2] the basicity constant of the aldehyde, pK_{ZH^+}, needs to be known (eq. [5]).

[5] $ArCHOH^+ \rightleftharpoons ArCHO + H^+$

The pK_{ZH^+} values of the aldehydes have been calculated as follows. Edward and Wong (6) have determined the pK values of a number of oxygen bases using characteristic vector analysis and the Bunnett–Olsen equation; their value for benzaldehyde is −3.91. (This value suggests that aromatic aldehydes are more basic than had hitherto been believed; use of earlier values would simply exacerbate the *paf/dpf* anomaly described in the next section and reinforce the mechanistic conclusions reached therein.) The pK_{ZH^+} values for substituted benzaldehydes were calculated using the Hammett equation (7), σ^+ values, and the ρ value of −1.85 determined earlier by Stewart and Yates (8). In view of what is now known about the behaviour of acidity functions, their reported ρ value may be too large (9–11). However, any errors introduced to the calculations by use of an incorrect ρ will only have a significant effect on the least basic aldehydes considered herein and will not seriously affect the conclusions to be drawn. Table 1 lists the pK_{ZH^+} values for the seven aldehydes and the apparent *paf* values calculated for each of them using eq. [2] and the catalytic data for the six neutral acids reported by McClelland and Coe.

It will be seen from the discussion in the next section that the principal general acid catalyzed route does not appear to involve protonation of the substrate, unlike the prototropy case. Hence, the *paf* calculated here is more correctly designated as an *apparent paf* (paf^{app}) and we have done so in Table 1. (The same equations can be used to calculate *paf* and paf^{app} since the alternative routes considered below are kinetically equivalent, with parallel lines on the left hand side of plots such as that shown in Fig. 1.)

The relative contributions that the components of an acid–base pair make to a general acid–base reaction of the type shown in eq. [1] depend on three factors: the pH, the basicity of the substrate, and the pK of the buffer acid. In general, for a series of buffer acids, a plot of log k_{HA} and log k_{A^-} against pK_{HA} will give two intersecting straight lines, whose slopes depend on the Bronsted α and β values. Such a plot is shown in Fig. 1 for 3,5-dinitrobenzaldehyde and the six buffer acids under consideration. We have shown previously that the dissociation constant of a hypothetical buffer whose pK

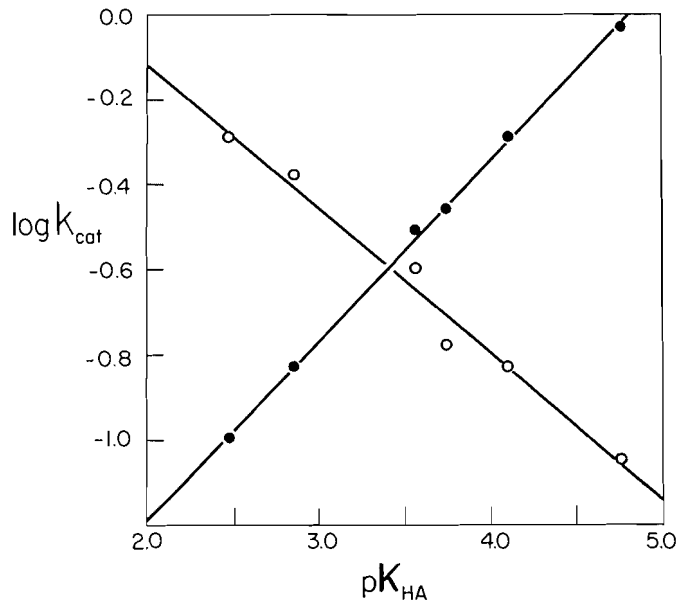

FIG. 1. A plot of the logarithm of the catalytic coefficients for the hydration of 3,5-dinitrobenzaldehyde against acidity constants of the buffer acids; buffer acid catalysis (open circles), buffer anion catalysis (filled circles). Data from ref. 4.

corresponds to the pH of intersection should be equal to K_{ZH^+}/paf (2). Thus, *paf* can be calculated by taking K at the point of intersection of plots such as that in Fig. 1 and multiplying by K_{ZH^+} of the substrate. This has been done for each of the six aldehydes, and the values are given in Table 2 together with the average of each set of values reported in Table 1. It can be seen that there is good correspondence between the numbers determined in these two ways. (As, indeed, there should be, since the two methods derive from the same assumptions regarding the mechanism of the acid and base catalyzed processes.)

The *paf* for any one compound will be independent of the identity of the buffer pair provided the sum of the Bronsted α and β coefficients is unity (2). The work of McClelland and Coe shows that this condition is not quite met in the present cases and is doubtless the cause of the drift to higher *paf* values that can be seen in Table 1 as the strength of the buffer acids declines.

Mechanism of the general acid catalyzed pathway

Simplified versions of the two routes considered by Jencks

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

and co-workers (5) and by McClelland and Coe (4) for the general acid catalyzed hydration of aldehydes are shown in eq. [6] for the class (e) and class (n) mechanisms. Both these groups favour the class (e) mechanism.

[6] 
either donation of a proton to the carbonyl group (class (e)) or removal of a proton from the water molecule (class (n)).

We have calculated *dpf* for the present compounds from the data of McClelland and Coe for the water and hydroxide catalyzed rates, and the values are listed in Table 2. It can be seen that without exception *dpf* is smaller than the *paf* that is calculated on the assumption that the class (n) route prevails, that is, that the aldehyde is protonated in a pre-equilibrium step in a way that is analogous to that found in enolization processes. The *dpf* has always been found to be much larger than *paf* in other systems, suggesting that the actual rate of the class (n) route is considerably less than the rate determined experimentally. Hence we conclude that the class (e) reaction must be providing a more favourable route to products than that provided by the class (n) reaction, in agreement with the conclusions of Jencks and McClelland.

It should be pointed out that the true *paf* might well be greater for a carbonyl reaction than for an enolization process since the site of protonation in the former case is closer to the atom being attacked by the nucleophile or base. However, it seems very unlikely that such activation would actually be greater than that produced by deprotonating the attacking nucleophile.

It is generally agreed that the general base catalyzed route for aldehyde hydration follows the course shown in eq. [7], making it similar to the general base catalyzed pathway for enolization (eq. [8]).

[7] 
[8] 
It might be expected that *dpf* would be similar in the two kinds of reactions and this is indeed the case. The *dpf* values found for the enolization of ketones are in the range of 10^8 to 10^{10} (2); the values found herein are of the order of 10^9.

Alternative pathways for the uncatalyzed reaction

There are two kinetically equivalent pathways for the uncatalyzed enolization of a compound Z; they are $Z + H_2O$ and $ZH^+ + HO^-$. For ideal systems we have shown that the ratio of their rates (though not which is greater) is a function of the

The (e)/(n) designation was introduced by Jencks (5*b*) to distinguish the sites of catalysis in additions of nucleophiles to carbonyl and like groups. In the case of general acid catalysis of aldehyde hydration, the rate-controlling step can involve

width of the flat valley[1] found at the bottom of the curve when buffer-free rates are plotted against pH (3)[2]. (An ideal system is one in which *paf* and *dpf* are independent of the ionic state of the base and the substrate.) As has been shown, the nucleophilic process examined herein is somewhat more complicated in that the acid catalyzed rate responsible for the left hand part of the pH–rate profile appears to involve a water molecule reacting with the complexed species $Z \cdot H_3O^+$ rather than with the fully protonated species ZH^+. Regardless of mechanism, the distance apart of the flat valley's extremities depends on the quantity $k^2_{H_2O}/k_{H^+}k_{HO^-}$ and the data of McClelland and Coe reveal that this quantity increases steadily as the electron-withdrawing character of the group in the benzaldehyde ring increases. For 3,5-dinitrobenzaldehyde it is some 440 times greater than for the 4-chloro compound, meaning that the valley is some 2.7 pH units (log 440 = 2.7) wider than that of the 4-chloro compound. If the water catalyzed reaction is analogous to that for buffer acids, then its mechanism is that shown in eq. [9], rather than those shown in eqs. [10*a*], or [10*b*], which both involve attack by hydroxide ion on the activated substrate.

TABLE 2. Comparison of *dpf* and paf^{app} for the hydration of substituted benzaldehydes

Substituted benzaldehyde	$dpf \times 10^9$	$paf^{app} \times 10^9$ Method 1[a]	$paf^{app} \times 10^9$ Method 2[b]
3,5-$(NO_2)_2$	0.79	10	15
3-NO_2, 4-Cl	0.70	4.3	2.3
4-NO_2	0.84	2.0	2.6
3-NO_2	0.72	2.4	2.1
4-CF_3	0.67	2.0	2.1
3-Cl	0.69	1.7	1.8
4-Cl	0.52	1.8	1.0

[a] Using the point of intersection of plots of log k_{HA} and log k_{A^-} against pK_{HA} of the buffer acids (see Fig. 1) and multiplying by K_{ZH^+}.
[b] Average values taken from Table 1.

[1] The term *plateau* has sometimes been used to describe this region of the curve, but *valley* would appear to have better geographical antecedents.
[2] A corrected statement regarding the valley's limits appears in ref. 12.

Reactions [10*a*] and [10*b*], which can be assumed to be minor pathways, will have similar responses to changes in aldehyde basicity and so one can use the effect of ring substituents on the quantity $k^2_{H_2O}/k_{H^+}k_{HO^-}$ (which strictly speaking applies only to systems that are ideal and that follow routes [9] and [10*a*]) as a measure of the relative importance of the major and minor routes. This treatment shows that an increase in the electron-withdrawing character of the aldehyde's substituents causes the contribution of the minor routes to diminish even further. Conversely, electron-donating groups, which increase the concentration of the aldehyde conjugate acid, can be expected to increase markedly the contribution of route [10*a*] (and presumably [10*b*]), and, indeed, the latter might be expected to make significant contributions to the uncatalyzed reaction in such cases. A plot of log $(k^2_{H_2O}/k_{H^+}k_{HO^-})$ against σ, the Hammett substituent parameter (7, 13), gives a straight line of slope 2.05, correlation coefficient 0.995 (Fig. 2). The substantial slope indicates how sensitive the rate ratio for the two uncatalyzed routes [9] and [10] is to the electronic effect of ring substituents.

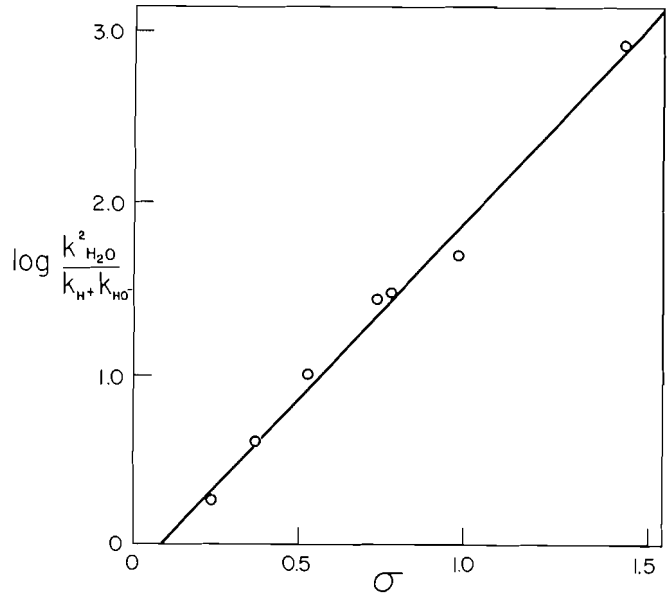

FIG. 2. A plot of log $k^2_{H_2O}/k_{H^+}k_{HO^-}$ (data from ref. 4) against the Hammett substituent constant ρ (values from ref. 13) for the hydration of substituted benzaldehydes.

GILBERT DANA, ESTERA TOUBOUL, MARTHA MORALES-RIOS, MICHÈLE PHILOCHE-LEVISALLES et CLAUDETTE BOIS. Can. J. Chem. **62**, 911 (1984).

Les trois éthers A, B et C formés aux cours de l'hydrolyse des dérivés dibromés tétrahydrofuranniques **1** ont une structure racémique. Dans les trois cas, la sélectivité de la réaction correspond donc à une association entre énantiomères de même configuration absolue. Dans les trois molécules étudiées, le cycle tétrahydrofurannique a une conformation caractérisée notamment par des groupes polaires en 2 (effet anomère) et en 3 diaxiaux et un groupe aromatique d'autant plus équatorial qu'il est volumineux.

GILBERT DANA, ESTERA TOUBOUL, MARTHA MORALES-RIOS, MICHÈLE PHILOCHE-LEVISALLES, and CLAUDETTE BOIS. Can. J. Chem. **62**, 911 (1984).

The three ethers A, B, and C formed during the hydrolysis of dibrominated tetrahydrofuran derivatives **1** are racemic. In all three cases, the reaction selectivity corresponds to an association between enantiomers of the same absolute configuration. In the three molecules studied, the tetrahydrofuran ring assumes a conformation characterized by polar groups in the 2-position (anomeric effect) and in the 3-position being diaxial and by the bulky aromatic group being equatorial.

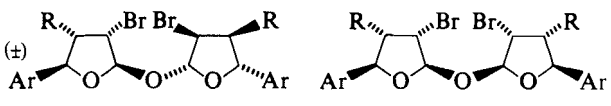
1 **2** **3**

La rmn du proton ou du ^{13}C ne nous a pas permis de déterminer s'il s'agit de l'isomère **3** *méso* ou **3** *dl*.



3 *dl* **3** *méso*

L'étude du mécanisme de la reconnaissance énantiomérique (1) au cours de cette réaction nécessitant la connaissance de la structure du produit formé, nous avons entrepris sa détermination par diffraction de rayons X, dans trois cas:

composé A: Ar = C_6H_5, R = H;

composé B: Ar = C_6H_5, R = CH_3;

composé C: Ar = $(CH_3)_3C_6H_2$, R = H.

Par ailleurs, ce travail conduit à la connaissance de la conformation des cycles tétrahydrofuranniques correspondants, utile pour une étude en cours des propriétés des bromhydrines **2** et de leurs dérivés.

Partie expérimentale

Les monocristaux ont été obtenus par évaporation lente de solutions dans l'éther de pétrole léger à température ambiante.

Les mesures ont été faites sur un diffractomètre automatique quatre cercles Philips PW 1100, à monochromateur de graphite, en utilisant la radiation MoKα (0,7107 Å). Les réflexions ont été enregistrées dans un intervalle $2° < \theta < 25°$, avec une vitesse de balayage en $\omega/2\theta$ de 0,05° s^{-1} et une amplitude de balayage de 1,2° + 0,3° tg θ. Le fond continu a été mesuré de part et d'autre de chaque tache. L'enregistrement d'une tache de référence toutes les 120 minutes a permis de vérifier que le cristal ne s'altérait pas. Les paramètres de la maille ont été obtenus par affinement à partir des angles de 25 réflexions.

L'enregistrement des composés B et C a été fait à température ambiante. Celui de B a été refait à 233 K pour tenter d'obtenir un plus grand nombre de données utilisables pour les affinements, mais les résultats furent similaires. L'enregistrement de A a été effectué directement à 233 K.

Les intensités ont été corrigées des facteurs de Lorentz et de polarisation. Pour les corrections d'absorption une tentative a été faite pour la première structure étudiée (B), sans apporter d'amélioration notable. A notre avis, la difficulté du problème réside plutôt dans le trop grand nombre de réflexions faibles (mesurées avec trop peu de précision). Cette correction d'absorption n'a donc pas été faite pour les deux structures suivantes. Les structures ont été résolues, par interprétation de la fonction de Patterson qui a permis la localisation du brome. Une série de Fourier "différence" a fait alors apparaître les autres atomes lourds. Les coordonnées de ces atomes ont été affinées (leur agitation thermique étant supposée anisotrope). Les atomes d'hydrogène ont tous pu être placés sur une série de Fourier différence; leurs coordonnées ont été affinées (pour A et B) et on leur a attribué

un facteur d'agitation thermique isotrope, égal au B équivalent de l'atome porteur. L'affinement a été poursuivi jusqu'à ce que les variations des paramètres soient toutes inférieures à 0,05 fois l'écart type. Les dernières séries-différences ne laissent alors apparaître que des résidus de 0,4 e Å^{-3}. En ce qui concerne C, le nombre insuffisant de réflexions conservées en fonction du critère $F > 2\sigma(F)$ n'a pas permis d'affiner leurs coordonnées; de plus les pics correspondant aux atomes d'hydrogène des groupes méthyle étaient diffus, en raison sans doute du grand nombre de ces groupes et de leur rotation quasi-libre.

Les affinements par la méthode des moindres carrés ont été réalisés à l'aide du programme AFFINE adapté de ORXFLS (2), utilisant une matrice complète. Les réflexions ont été pondérées par un facteur $\omega = 1/\sigma^2(F)$. On a tenu compte de la correction de dispersion anomale (partie réelle) pour le brome.

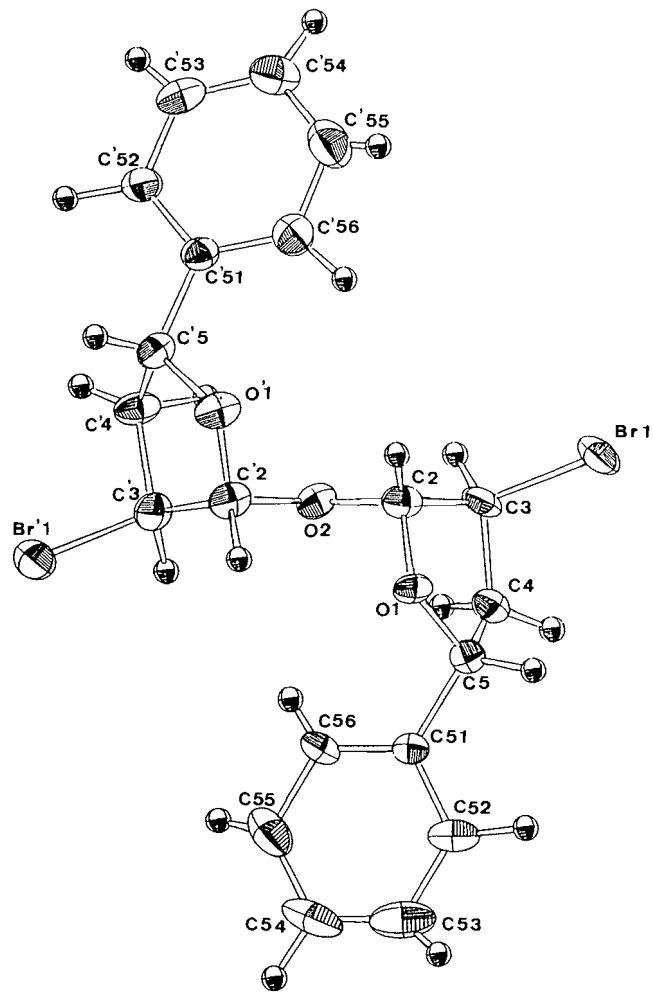

FIG. 1. Vue en perspective du composé A indiquant la numérotation des atomes.

Les tableaux 1, 2 et 3 donnent les coordonnées atomiques respectivement pour les composés A, B et C ainsi que leurs écarts types.

Notons que pour le composé B (groupe $P4_2/n$) nous avons choisi l'origine sur un centre d'inversion. Les tableaux des amplitudes des

facteurs de structure, des coordonnées des atomes d'hydrogène, et des facteurs d'agitation thermique anisotrope sont disponibles.[1]

Résultats et discussion

Les structures des 3 composés sont constituées de molécules discrètes, liées entre elles par des forces de van der Waals. Pour B et C, la molécule a une symétrie C_2, l'atome O(2) occupant une position spéciale ($\frac{1}{4}$, $\frac{3}{4}$, z) sur un axe binaire.

Pour A, les deux fragments de la molécule sont symétriquement indépendants, cependant on peut observer aussi une symétrie C_2 très approximative (fig. 1). Les figures 1, 2 et 3 tracées à l'aide du programme ORTEP (3) représentent les molécules et donnent la numérotation des atomes; les ellipsoïdes correspondent à une probabilité de présence de 40% et les tailles des atomes d'hydrogène sont arbitraires, la molécule du composé C est projetée sur un plan perpendiculaire à

son axe binaire, la molécule de A sur un plan perpendiculaire à O(2)M (M est le milieu de C(2)—C′(2)).

Le tableau 4 donne les principales distances et les angles de valence pour les trois composés. Bien que certaines liaisons équivalentes présentent des différences notables, celles-ci ne sont pas significatives, compte tenu des écarts types.

Le tableau 5 donne les dièdres entre les substituants comportant un atome lourd, aussi que les angles de ces substituants avec le plan moyen tétrahydrofurannique T. Les angles de torsion de ce cycle sont donnés dans la figure 4.

Il apparaît dans les trois cas examinés que l'isomère formé dans la réaction 1 est le produit **3** racémique et non pas *méso*, c'est à dire que la duplication deshydratante ne se produit qu'entre substrats de même configuration absolue. Une étude plus détaillée de cette énantiosélectivité est en cours.

L'étude conformationnelle des cycles pentagonaux connaît actuellement un grand développement utilisant le concept de pseudorotation (4–6).

En désignant par θ_1, θ_2 . . . les dièdres C3—C4, C2—C3, O1—C2 . . . , on évalue (6) la phase de pseudorotation P par:

$$\operatorname{tg} P = \frac{\theta_3 + \theta_5 - \theta_2 - \theta_4}{3{,}08\ \theta_1}$$

et le gauchissement du cycle θ_m par $\theta_m = \theta_1/\cos P$.

Nous pouvons alors comparer la conformation des cycles tétrahydrofuranniques dans les trois structures étudiées. Dans la fig. 4, nous avons représenté les 4 cycles obtenus pour A, A′, B et C en utilisant les dièdres des liaisons des cycles et le caractère axial des substituants (8) (pour les valeurs positives, le substituant axial est vers l'avant; le caractère axial est réputé faible pour une valeur absolue inférieure à 30 ou 40°).

1. *Gauchissement du cycle* θ_m

On peut remarquer que le puckering θ_m du cycle tétrahydrofurannique des molécules B, C et de la première partie du composé A est de l'ordre de 37° alors qu'il n'est que de 33,5° pour la deuxième partie de A (partie primée des tableaux).

Ce cycle est donc plus aplati que les trois autres. En recherchant les distances courtes entre atomes non liés, nous avons remarqué que la distance de deux bromes appartenant aux parties A′ de deux molécules voisines est de 3,75 Å, ce qui est légèrement inférieur à la somme (2 × 1,95 Å) des rayons de van der Waals de deux bromes. Une telle compression dans l'empilement moléculaire ne se retrouve pas pour les autres cycles. On peut penser que le faible puckering du cycle A′ résulte de l'écrasement de cette partie de la molécule et la valeur θ_m = 37° apparaît comme la valeur normale pour les molécules de cette étude. Cet écrasement se manifeste également par la rotation du cycle benzénique dont l'angle α avec T (tableau 5) se réduit à 50° alors qu'il est de 78 à 88° dans les

* Les dièdres du cycle sont donnés dans la figure 4.

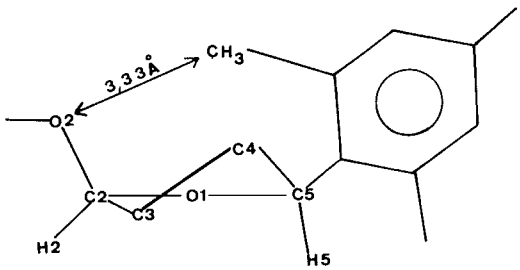
trois autres cas. De plus la densité de A est particulièrement élevée (1,63 g/cm^3) comparée à celles des deux autres composés et sa température de fusion (109°C) bien plus basse.

2. *Phase de pseudorotation* P

Notons la grande analogie des conformations entre le premier cycle A et le cycle B (même forme enveloppe avec $P = 198° \pm 1°$). (Le cycle A′ en raison de ses tensions particulières se rapproche plutôt d'une forme twist.)

Le groupe aromatique y occupe une position à peine équatoriale et ce n'est pas le groupe anomère (9) (—OR en 2) qui

occupe la position la plus axiale, mais le brome en 3 (cf. figures 1, 2, 3 et angles β et γ du tableau 5). Pour B, on note que le méthyle occupe la position d'un hydrogène équatorial de A et n'introduit pas de nouvelle tension dans le cycle (même valeur P et θ_m pour A et B). Tout au plus, peut-on noter que l'angle α du plan du benzène avec le plan moyen du tétrahydrofurannique (tableau 5) augmente en présence du méthyle et les deux plans deviennent presque perpendiculaires (α = 78°5 pour A devient 87°9 pour B).



Dans le cas du composé C, le groupe aromatique, plus volumineux, occupe une position plus nettement équatoriale. Mais ceci semble obtenu au détriment du caractère axial de l'oxygène anomère (voir également l'angle β, tableau 5). On peut en effet noter que les méthyles *ortho* du groupe mésitylène exercent une pression sur l'oxygène O(2) qui entraine à la fois le groupe aromatique dans une position plus équatoriale et le groupe anomère dans une position moins axiale; la distance O(2)—C(521) n'est en effet que de 3,33 Å, c'est-à-dire à peine égale à la somme des rayons de van der Waals de l'oxygène (1,40 Å) et du méthyle (2 Å).

Toutefois l'angle α entre les plans des deux cycles reste identique à celui trouvé pour A (78,6°).

A. ALBA, A. ARAMENDIA, V. BORAU, A. GARCIA-RASO, C. JIMENEZ, and J. M. MARINAS. Can. J. Chem. **62**, 917 (1984).

The hydrogen transfer reduction of benzylideneacetone derivatives *p*-X-C_6H_4—CH=CH—CO—R (X = —OCH_3, H; R = C_6H_5, alkyl, OR, OH) using cyclohexene as hydrogen donor has been studied. The selective reduction of the C=C bond is observed and the effects of the nature of X and R, solvent, catalyst, and reaction temperature on the initial reaction rate are analyzed. In all cases, and for any substrate or catalyst, the reaction is first-order with respect to the hydrogen donor and acceptor.

A. ALBA, A. ARAMENDIA, V. BORAU, A. GARCIA-RASO, C. JIMENEZ et J. M. MARINAS. Can. J. Chem. **62**, 917 (1984).

Utilisant le cyclohexène comme donneur d'hydrogène, on a étudié la réduction par transfert d'hydrogène des dérivés de la benzylidèneacétone *p*-X-C_6H_4—CH=CH—CO—R (X = —OCH_3, H; R = C_6H_5, alkyl, OR, OH). On a observé une réduction sélective de la liaison C=C et on analyse les effets de la nature de X et de R, du solvant, du catalyseur et de la température de la réaction sur la vitesse initiale de la réaction. Dans tous les cas et pour tous les substrats ou catalyseurs, la réaction est du premier ordre par rapport au donneur d'hydrogène et à l'accepteur.

[Traduit par le journal]

Introduction

Hydrogen transfer reduction of organic compounds is one of the most rapidly developing areas of organic synthesis (1). The process can be homogeneously (2, 3) or heterogeneously (4, 5) catalyzed. The process has some advantages with respect to classical hydrogenation, such as the simplicity of the method and apparatus necessary. Moreover, the reactions are carried out at atmospheric pressure and usually at low temperatures, avoiding the use of gaseous hydrogen. We have recently shown the usefulness of catalysts obtained by supporting palladium on $AlPO_4$, $AlPO_4-SiO_2$, and $AlPO_4-Al_2O_3$ in the hydrogen transfer reduction of organic functional groups using different hydrogen donors, e.g., reduction of aromatic nitro compounds using cyclohexene (6), or formic acid/triethylamine (7) as hydrogen donors, or the selective reduction of the C=C bond of α,β-unsaturated carbonyl compounds using $HCOOH/NEt_3$ (8).

In the present paper the reduction of different benzylidene derivatives by hydrogen transfer, using cyclohexene as a hydrogen source and different catalysts obtained by supporting Pd on commercial silica or $AlPO_4-SiO_2$ supports, is described.

Experimental

Fixed amounts of hydrogen acceptor (benzylidene derivative), hydrogen donor (cyclohexene), and catalyst (see below) are introduced in a three-necked flask equipped with a thermometer, a refluxing refrigerant, and a rubber subseal. The flask is immersed in a silicone oil bath electrically heated to maintain a vigorous reflux of the reaction mixture while magnetically stirred (720 rpm). Samples are periodically withdrawn through the rubber subseal with a syringe and analyzed during the reaction.

The benzylidene derivatives have been synthesized by methods published elsewhere (9, 10). Cyclohexene was from Merck, ref. 802824, and was distilled immediately before use. Solvents were from Merck or Fluka.

Catalysts

The catalysts have been synthesized in our laboratories. Table 1 collects some physicochemical properties of the catalysts. Support S was a commercial silica (Merck ref. 7734), while supports PM2, F72, 72P, EL, and E correspond to 80:20 by weight SiO_2-AlPO_4 mixtures gelled in different organic media. Their syntheses have been reported in ref. 11. Particles sizes between 70–230 mesh were used.

TABLE 1. Physicochemical characteristics[a] of the supports of the Pd catalysts

Support	Gelling medium	$S_{esp} \pm 15$ (m^2/g)	$V_p \pm 0.05$ (mL/g)	I.P.
E	Ethylene oxide	395	0.56	3.4
EL[b]	Ethylene oxide	420	0.58	3.8
PM2	Propylene oxide	465	0.56	4.3
72P[c]	Propylene oxide	410	0.56	4.0
F72	Ammoniacal	310	0.52	3.2
S	Commercial (Merck)	395	0.55	1.0[d]
F	Ammoniacal	156	0.49	3.2

[a] S_{esp}: specific surface area by the BET method; V_p: total pore volume; I.P.: zero point of charge, as measured following Brunelle (12).
[b] The gel is air-dried and then washed with isopropyl alcohol.
[c] The gel is ripened with isopropyl alcohol for 15 days.
[d] According to Brunelle (12).

Two different methods were used to support the palladium: ionic exchange for palladium content lower than 1% and impregnation for those catalysts with more than 1% palladium content.

Taking into account the zero point charge of the supports (Table 1), $[Pd(NH_3)_4]^{2+}$ was chosen as the metallic precursor, being incorporated following a method previously described (7). On the other hand, for those catalysts obtained by impregnation, $Na_2(PdCl_4)$ (precursor M) and $Pd(NH_3)_4Cl_2$ (precursor N) were used. When naming the catalysts, "C" and "NC" indicate if calcination has or has not been, respectively, carried out before reduction, following a thermal treatment (with air instead of hydrogen) similar to that used for reduction. The initial and final reduction temperatures (in °C) are indicated in brackets in the name of the catalyst. Reduction was carried out in a flow of hydrogen (60 mL min^{-1}) at a linear heating rate of 1°C min^{-1} up to the final reduction temperature, which was maintained for 5 min, and then cooling to room temperature.

The metallic content in the catalysts was measured by atomic absorption using a Perkin–Elmer model 370 spectrometer. The metallic dispersion was determined by CO adsorption in a conventional gravimetric system for the low-loaded catalysts, while X-ray diffraction was also used for those having a metal loading between 3–5%,

following a method previously described (13), with a Philips 1130/00/60 instrument. In the palladium-rich samples a good agreement between CO adsorption and X-ray diffraction results was observed, this last technique being faster.

Blank experiments

These were carried out to check that, under the experimental conditions here used, the reaction was not diffusion-controlled. Moreover, blank runs indicate a lack of activity in the absence of metallic phase, even in the presence of the pure support.

Analysis of the products

The analysis of the products was carried out by gas chromatography using a Hewlett–Packard model 5830 A instrument provided with a flame ionization detector, and a Perkin–Elmer model 2025/7 liquid chromatograph with a C-8 column using a 75:25 (by volume) CH_3OH/H_2O mixture as carrier when analyzing 4-nitrochalcone.

Mass and infrared spectra of the products were recorded with a Hewlett–Packard 5992 B ms–gc instrument and a Perkin–Elmer 599 B spectrophotometer coupled to a data station, respectively. The data for reaction rates (in mol/h $g_{Pd} \times 10^3$) shown in the tables correspond to the average value of three experiments. The upper limit of the error found was 2×10^{-4}, therefore all the data displayed are significant.

Results

Effect of the solvent

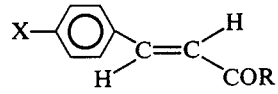
As shown in Table 2, when polar or high boiling point solvents are used, the reduction rate of the C=C bond of benzylideneacetone is increased.

Effect of the catalyst

The effect of several parameters of the catalyst on the reduction rate of benzylideneacetone has been studied, and the corresponding results have been summarized in Tables 3 to 6. Thus, the effect of the nature of the support (Table 3), the nature of the support and of the reduction process (Table 4), the nature of the starting palladium salt and the reduction process (Table 5), and the promoting effect of Ag and Pt on the catalytic activity of Pd (Table 6) have been studied; in this last case, the amounts of Ag or Pt correspond to 0.3% (w/w) of the total palladium content.

Effect of the nature of X and R on the reduction rate of the C=C bond

The substances to be reduced were of the type



In all cases, a 100% selectivity towards reduction of the C=C bond has been achieved.

Conversions after 3 hours reaction for 17 different substrates have been collected in Table 7, as well as the initial reduction rate given in mol h^{-1} g_{Pd}^{-1} (r_0) and mol h^{-1} m_{Pd}^{-2} (r_0'). As shown in this table, both X and R play an important role in the reduction rate. Because of its *para* position from the C=C

[a] See footnote *a*, Table 4.

moiety, it can be safely assumed that group X has no steric effect, but rather electronic, on the reduction rate. So, if X = OCH_3 (electron-donating substituent) the reduction rate is increased, while for X = NO_2 (electron acceptor) the reduction rate is sharply decreased. The opposite results have been reported by Beaupére *et al.* (14) when reducing similar substrates with alcohol and $RhH(PPh_3)_4$ as a catalyst, thus suggesting in our case a cationic polar intermediate. Regarding R, it seems to play an electronic and/or steric effect on the reduction of the C=C bond. So, for R = alkyl substituents, the reduction rate decreases in the order i-Bu > n-Bu > *t*-Bu. It should be noted that while the stretching O—H mode of free phenol is recorded at 3603 cm^{-1}, when associated with *p*-X—C_6H_4—CH=CH—CO—R substrates (R = i-Bu, n-Bu, *t*-Bu), the ν_{O-H} band is recorded at 3371, 3397, and 3404 cm^{-1}, respectively, this order being the same as that for the reduction rate, thus indicating the importance of steric effects on the reduction rate.

For linear alkyl substituents (methyl to butyl), the initial reduction rate increases with the length of the hydrocarbon chain, decreasing for n-pentyl; this fact can be due to an increase in the initial reduction rate with the +I electron donor ability of R, while for the pentyl-substituted substrate the steric hindrance predominates over the electronic effect.

When R is changed to phenyl, methyl or *tert*-butyl, the reduction rate increases in the order Ph < Me < *t*-Bu, while for the corresponding benzylidene derivatives the half-wave potentials (15) are −1.35, −1.58, and −1.63 V, respectively, i.e., the lower the half-wave potential, the slower the reduction rate, thus suggesting that the rate-determining step for reduction may be the transference of a proton from cyclohexene to the substrate.

It is worthy of note that, for homogeneous hydrogen transfer reduction of benzylidene derivatives similar to those here studied, Beaupére *et al.* (14) have reported that the reduction rate decreases when R is changed in the order Me > Ph > *t*-Bu, opposite to that here reported (related to the reduction half-wave potentials) and related to the shift of the ν_{O-H} band of phenol when associated with the carbonyl group of the benzylidene derivatives to be reduced; thus these authors conclude that R has a steric effect on the reduction rate.

[a]Moles of cyclohexene: 5.9×10^{-2}; moles of substrate: 1.76×10^{-3}; temperature: 100°C; catalyst: 1.5×10^{-3} g metal (Pd $EL_{0.75}$ (50–300)C); r_0: initial reduction rate of the C=C bond (mol h^{-1} g^{-1}_{Pd}); r'_0: initial reduction rate of the C=C bond (mol h^{-1} m^{-2}_{Pd}); X (% 3 h): conversion after 3 h reaction, in wt.%.

Kinetics of the reduction

The experimental results conform to a kinetic equation typical of a first-order process with respect to both the donor and the acceptor. An identical kinetic expression has been found for all α,β-unsaturated ketones studied, regardless of the catalyst used.

Discussion and conclusions

As the hydrogenation rate is enhanced when the dielectric constant of the solvent is increased, it can be concluded that the process takes place through polar intermediates. On the other hand, as the reduction rate of the C=C bond depends on the nature of both X and R, a 1,4 reduction mechanism can be claimed, the rate-determining step seeming to be the proton transfer from the donor (cyclohexene) to the substrate to be reduced.

The reduction takes place under mild conditions and with a yield close to 100% when operating under the following conditions: 2.5×10^{-3} moles of substrate, 5.9×10^{-2} moles of cyclohexene, and 0.30 g of catalyst with 5% Pd.

The full selectivity towards reduction of the C=C bond and the ease of separation by distillation of the non-oxidized reactive (cyclohexene) as well as its oxidized form (benzene) make this method very useful in obtaining saturated carbonyl compounds from the corresponding α,β-unsaturated compounds.

Finally, it should be noted that the catalyst can be repeatedly used, with no activity loss, after being washed and dried in vacuum.

The difference in activity of the catalysts may be attributed to the following.

1. Differences in the particle size of the catalyst.
2. Changes in the number of active sites of the catalyst or in the surface morphology (16, 17).
3. Alterations in metal–support interactions (18–21).

The influence of the last two factors is rather difficult to assess. With regard to the nature of the catalyst, the largest activity is obtained when the content of silica is increased in the ion-exchanged catalysts (Table 3), as a consequence of the enhanced metallic dispersion. However, the palladium particles are markedly sintered by treatments above 300°C (Table 4), as checked by X-ray diffraction, thus leading to a lower activity.

The most active catalysts are those prepared using $Na_2(PdCl_4)$ as the precursor salt, probably because of an enhanced dispersion of Pd in the presence of sodium. However, no promoting effect of Pt or Ag is observed, as these metals lead to a worse dispersion of Pd. Calcination of the catalyst before reduction yields better results, especially for catalysts obtained from $Na_2(PdCl_4)$.

Received July 26, 1983

MIN H. LIEN and ALAN C. HOPKINSON. Can. J. Chem. **62**, 922 (1984).

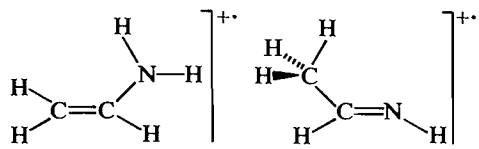
The structures and relative energies of seven possible $C_2NH_5^{+\cdot}$ isomers have been calculated using *ab initio* molecular orbital theory. Structure optimisations have been performed with a 4-31G basis set, using both the restricted (RHF) and unrestricted (UHF) Hartree–Fock methods. The optimum geometries were then used for single point calculations using the 6-31G* basis set. The relative energies are **1** < **7** < **5** < **3** ≈ **2** ≈ **6** < **4**. This order is the same, with the exception of **6**, as for isomers on the $C_2H_4O^{+\cdot}$ surface and the relative energies are very similar to those on the $C_2H_4O^{+\cdot}$ surface. The structures of the radical cations $C_2NH_5^{+\cdot}$ are compared with those of the neutral molecules C_2NH_5.

MIN H. LIEN et ALAN C. HOPKINSON. Can. J. Chem. **62**, 922 (1984).

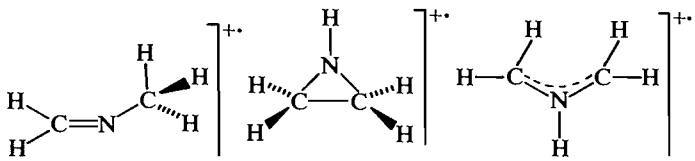
Faisant appel à la théorie *ab initio* des orbitales moléculaires, on a calculé les structures et les énergies relatives des sept isomères possibles pour le $C_2NH_5^{+\cdot}$. On a optimisé les structures à l'aide d'une base 4-31G et en utilisant les méthodes restraintes (RHF) et non-restraintes (UHF) de Hartree–Fock. On a ensuite utilisé les géométries optimales pour faire des calculs en un point unique à l'aide d'une base 6-31G*. Les énergies relatives sont dans l'ordre **1** < **7** < **5** < **3** ≈ **2** ≈ **6** < **4**. A l'exception de **6**, l'ordre est le même que pour les isomères sur la surface de $C_2H_4O^{+\cdot}$ et les énergies relatives sont très semblables à celles sur la surface de $C_2H_4O^{+\cdot}$. On compare les structures des radicaux cations $C_2NH_5^{+\cdot}$ avec celles des molécules neutres C_2NH_5.

[Traduit par le journal]

There has been considerable experimental (1–4) and theoretical (5, 6) work on the structures, stabilities, and relative energies of various isomers on the $C_2H_4O^{+\cdot}$ energy hypersurface. The isoelectronic $C_2NH_5^{+\cdot}$ species is one of the principal ions in the mass spectra of nitrogen-containing compounds and five different isomers (**1** – **5**) have been identified (7, 8). Deuterium labelling studies have established **5** to be the base peak for pyrrolidine and both **3** and **5** are produced from



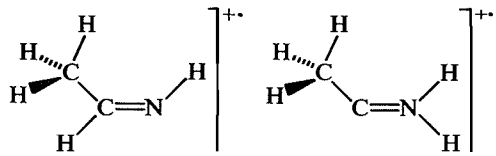
1 **2**



3 **4** **5**

piperidine (9). From metastable ion studies different ions, given structures **1**, **2**, **3**, and **4** and/or **5**, were shown to retain their structural identities prior to fragmentation by loss of hydrogen atom (7), and subsequent studies (8) using collision-induced dissociation have established that **5** is the dominant ion, with **4** being produced only from aziridine. Ion **2** (or its *cis*-isomer **6**) has also been reported as a minor product in the laser photolysis of methylamine (10), but no structural information was provided.

The transient nature of these ions precludes a detailed experimental study of their structures and even the relative energies of these ions are not known. We now report an *ab initio* molecular orbital study of the $C_2NH_5^{+\cdot}$ energy hypersurface in which we determine the relative energies of isomers **1** → **6** and we also report details of their structures. All structures were found to be at minima on the surface and an additional structure, **7**, not previously mentioned in the literature was found to be at the second lowest minimum. Initally all structures were subjected to geometry optimisation at the 4-31G (11) level of theory using the unrestricted Hartree–Fock method (UHF). However, spin contamination created a problem with structures **1** and **7** and we therefore decided to use the restricted Hartree–Fock method (RHF).



6 **7**

All calculations were performed with the MONSTERGAUSS program (12) using the optimally conditioned optimisation algorithm (13) for geometry optimisations. In all the molecular species the norm of the gradient vector was less than 5×10^{-4} mdyn at convergence, a condition which usually produces bond lengths and angles within 0.0001 Å and 0.01°, respectively, of the true optimum value (14). Single calculations were performed at the 6-31G* (15, 16) level of theory, using the 4-31G optimised geometry and we denote these results by the label 6-31G*//4-31G.

Results and discussion

After preliminary studies at the STO-3G level all radical cations were subjected to complete geometry optimisation in C_s symmetry using the 4-31G basis set. Two of the ions, **4** and **5**, were found to be planar and to belong to the C_{2v} point group. Geometries were also optimised for the neutral molecules

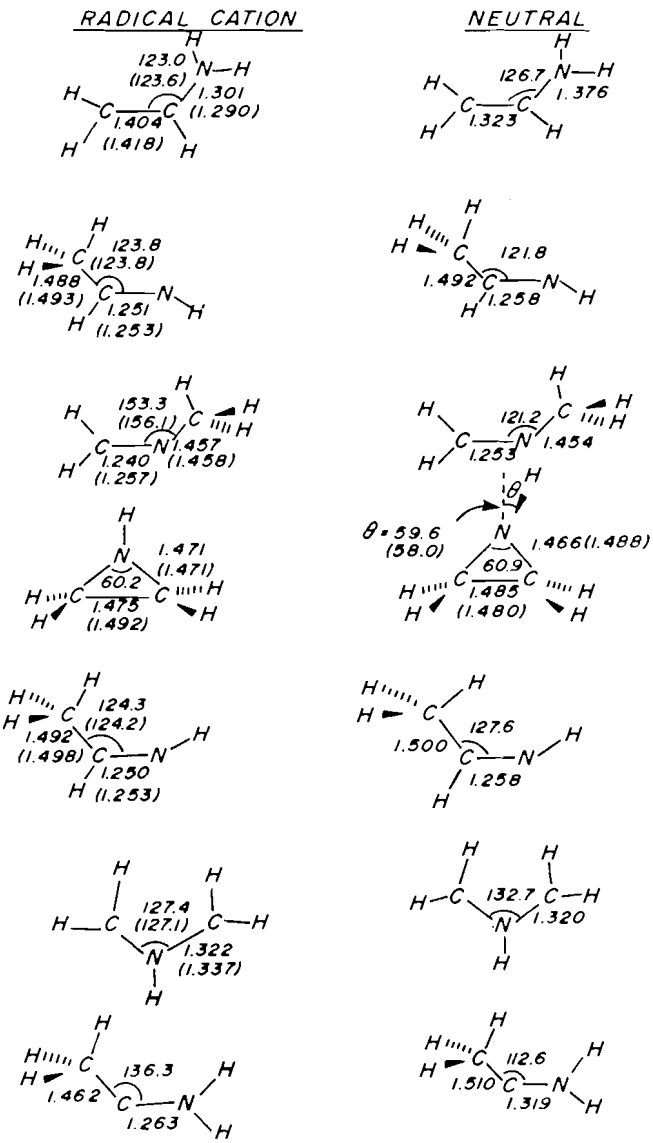

FIG. 1. Geometries for isomers of $C_2NH_5^{+\cdot}$ and C_2H_5N. All bond lengths are in Ångstroms and angles are in degrees. For the cations values in parentheses are from UHF calculations. For aziridine the numbers in parentheses are experimental values from ref. 22.

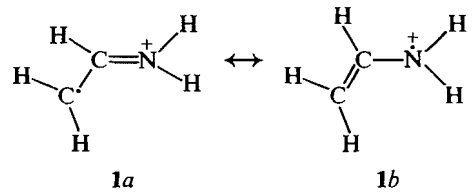
formed by addition of an electron to the radical cations. The optimum geometries for the radical cations and the corresponding neutrals are given in Fig. 1. For the sake of simplicity only the bond lengths and bond angles associated with bonding between "heavy atoms" are given. Geometry optimisations were performed with both the RHF and UHF methods for the radical cations and the latter are given in parentheses on the structures. There is satisfactory agreement between the structures provided by the two open shell methods.

Comparison of the geometries of cations with the corresponding neutral molecules shows most bond lengths to be slightly shorter in the cations. Major structural changes occur either in the bond from which an electron is removed or in the bond angles around nitrogen when an electron is removed from the lone pair on nitrogen. In **1** a π-electron is removed from aminoethylene resulting in an increase in the C—C bond length and a slight decrease in the C—N bond. Radical cation **1**, then, is best described in valence bond terminology by the canonical structures **1***a* and **1***b*.



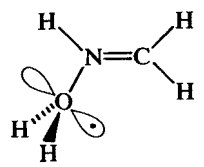
1*a* **1***b*

Ions **2**, **3**, **6** are formed by removal of an electron from the nitrogen lone pair. In these σ-radicals the bond lengths are only slightly changed but the bond angles at nitrogen are much larger than those in the corresponding neutral compounds (149.0° compared with 115.6° in **2**, 156.1° compared with 121.2° in **3**, and 149.5° compared with 115.7° in **6**).

The inversion barrier in the neutral aziridine molecule is 49 kJ mol^{-1} at the 4-31G//4-31G level and removal of an electron from the nitrogen lone pair is expected to decrease this barrier. In fact, radical cation **4** is found to be planar at nitrogen. Ring-opening of **4** to give **5** is an exothermic process but structure **4** was found to have no imaginary vibrational frequencies and this ion then is at a minimum on the $C_2NH_5^{+\cdot}$ energy hypersurface.

Methyl groups usually eclipse double bonds (17) and only eclipsing structures were examined for **2**, **3**, and **6**. Ions **6** and **2** are *cis* and *trans* isomers about C=N and the *trans* isomer is very slightly lower in energy (0.5 0.8 kJ mol^{-1}) at all three levels of calculation (Table 1).

In radical cation **5** the barrier to rotation of one methylene group is very low (8 kJ mol^{-1} at 4-31G//4-31G and 7 kJ mol^{-1} at 6-31G*//4-31G). The perpendicular ion has a short C—N bond (1.267 Å) for the in-plane methylene group and a long C—N bond (1.450 Å) for the out-of-plane methylene. This perpendicular radical cation then is best described by the canonical structure **5**a, where the unpaired electron is on the



5*a*

carbon of the rotating methylene group (the unpaired spin density on C is 0.98 at the 6-31G*//4-31G level).

The isoelectronic allyl radical also has a low barrier to rotation (18 kJ mol^{-1} from MINDO/3 (18) and 25.0 kJ mol^{-1} at the 4-31G//4-31G level (19)). As in **5***a* the allyl radical has one long bond (1.475 Å) and one short bond (1.319 Å) at the 4-31G//4-31G level.

The neutral compound corresponding to structure **5** is an imine ylide. Geometry optimisations on this molecule showed it to belong to the C_{2v} point group, with a structure very similar to that of the radical cation and not to be a zwitterion (i.e., *not* **5***a* with the unpaired electron replaced by a lone pair). No valence bond structure can be drawn for this symmetrical molecule and it is therefore not surprising that this molecule is by far the highest energy species on the C_2NH_5 energy hypersurface.

In radical cation **7**, the methyl group preferentially eclipses the carbon–nitrogen bond but the barrier to rotation is very low (2 kJ mol^{-1} at 4-31G//4-31G and 3 kJ mol^{-1} at 6-31G*//4-31G). In this σ-radical the C—N distance (1.263 Å) is approximately that found for a double bond and the C—C dis-

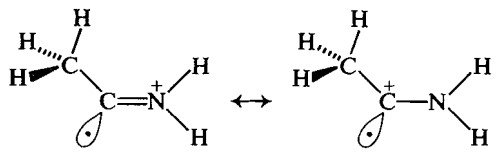
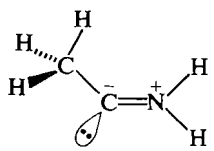
7	C_s	—	−132.60136	−132.78899	72

tance (1.462 Å) is intermediate between a single and a double bond. Most of the spin (0.92 at the 6-31G*//4-31G level) is located on the central carbon atom. The charges are +0.23 on CH_3, +0.55 on the carbene C, and +0.22 on NH_2 and the ion is best described in valence bond terminology by structures *7a* and *7b*.



7a *7b*



7c

The neutral molecule corresponding to **7** is an α-aminocarbene. In this structure the C—C (1.510 Å) and C—N (1.319 Å) bonds are both longer than in the radical cation, but the latter is much shorter than a single C—N bond (1.47 Å (20). Clearly then there is some π-donation from the nitrogen lone pair to the electron-deficient carbon and the α-aminocarbene has some zwitterionic character (structure *7c*). These conclusions are supported by the π-populations on N (1.72e) and on the carbene C (0.30e). However, the net-charge on the amino group is −0.17 and that on the carbene carbon +0.27, and the molecule is best represented by a carbene structure rather than by the zwitterionic structure *7c*.

On both the C_2NH_5 and the $C_2NH_5^{+\cdot}$ energy hypersurfaces the aminoethylene structure has the lowest energy (Tables 1 and 2). On the C_2NH_5 surface aziridine and molecules **5** and **7**, for which it is not possible to draw neutral structures, are all high in energy but the other molecules all have similar but lower energies. However, on the $C_2NH_5^{+\cdot}$ surface the energies of the radical cations are more widely separated with the cyclic ion again being the highest but **5** and **7** now being the two lowest above **1**.

The relative energies of the radical cations given in Table 1 are basis set dependent and all decrease on going from the 4-31G//4-31G to the 6-31G*//4-31G level. Polarisation functions are particularly important in cyclic structures and **4** is improved the most by the improvement in basis set. Inclusion of correlation energy is beyond the scope of the present investigation but this would also be expected to further decrease the energy differences and to be most significant for the cyclic

TABLE 2. Total energies (hartrees) for isomers on C_2NH_5 surface and energies (kJ mol^{-1}) relative to aminoethylene

6	C_s	−132.87060	12
7	C_s	−132.82640	128

[a]The amino group was assumed to be planar.

structures. For example, in a recent study (21) of carbocations the allyl cation was found to be more stable than the cyclopropyl cation by 37.8 kcal mol^{-1} at the 6-31G**//6-31G level but inclusion of correlation energy decreased the difference to 35.6 kcal mol^{-1} (at the MP4(DSQ)//6-31G* level).

Comparison of the relative energies of isomers for the isoelectronic $C_2NH_5^{+\cdot}$ and $C_2H_4O^{+\cdot}$ surfaces revealed that the corresponding isomers (NH replacing O) are, with one exception, in the same order (**1** < **7** < **5** < **3** ≈ **2** ≈ **6** < **4**) and the energy differences are also remarkably similar. The one exception is the radical cation derived from acetaldehyde, $CH_3CHO^{+\cdot}$, which is 52 kJ mol^{-1} less stable than the vinyl alcohol radical cation, whereas the analogous $CH_3CHNH^{+\cdot}$ is 121 kJ mol^{-1} less stable than the aminoethylene ion.

Summary

The structures of seven isomers on the $C_2NH_5^{+\cdot}$ energy hypersurface were determined with both the RHF and UHF methods and there is good agreement in the calculated structures. Similar good agreement was found between the two methods for the isoelectronic $C_2H_4O^{+\cdot}$ species.

Five isomeric cations, **1**, **2**, **3**, **4**, and **5** have been shown experimentally to retain their identity in the gas phase and, of these, molecular orbital calculations show **1** to have the lowest energy. One other structure, **7**, which is not known experimentally, is lower in energy than all other isomers except **1**. Radical cation **7** could form **1** by a 1,2-hydrogen shift but **7** was found to be at a minimum on the surface. Similarly, the aziridine radical cation **4** can ring open to give **5**, and **3** can also yield **5** via a 1,2-hydrogen shift. However, the calculations show both **3** and **4** to be at minima on the surface. No attempt was made here to investigate the barriers to intramolecular rearrangement but ring opening of the oxirane radical cation was previously shown to have a high barrier.

E. BUNCEL, H. S. SHIN, R. A. B. BANNARD, and J. G. PURDON. Can. J. Chem. **62**, 926 (1984).

The results of a comparative extraction study of potassium phenoxide, *p*-nitrophenoxide, and picrate, from aqueous medium into methylene chloride in the presence of crown ether and cryptand complexing agents, are reported. The efficiency of extraction varies extremely widely with the nature of the anion and the ligand. An analysis of the results in terms of constituent equilibrium constants, and the factors which influence these, is presented. The significance of the results to other areas including phase transfer catalysis is pointed out.

E. BUNCEL, H. S. SHIN, R. A. B. BANNARD et J. G. PURDON. Can. J. Chem. **62**, 926 (1984).

On rapporte les résultats obtenus lors d'une étude effectuée en vue de comparer les possibilités relatives d'extraire du phénolate, du *p*-nitrophénolate et du picrate de potassium contenus dans des phases aqueuses par du chlorure de méthylène en présence d'éthers couronnes et d'agents complexants cryptants. L'efficacité des extractions varie considérablement suivant la nature de l'anion et du ligand. On présente une analyse des résultats en termes de constantes d'équilibre des constituants et des facteurs qui les influencent. On met en relief l'importance de ces résultats pour d'autres domaines comme la catalyse par transfert de phase.

As part of a continuing study on the effect of complexing agents on reactivity (1), we have previously reported on the results of a detailed extraction study of potassium *p*-nitrophenoxide into a variety of organic solvents by crown ether and cryptand complexing agents (2). The results of that study, when compared with some literature data pertaining to picrate as the counterion, showed interesting and major differences for the two cases. A systematic study was hence undertaken which would allow us to compare the series potassium phenoxide, *p*-nitrophenoxide, and picrate in their extraction characteristics into common organic solvents by macrocyclic agents. As well, the results for potassium phenoxide could be of further interest since phenoxide ion is a commonly employed nucleophile in reactivity studies.

Ever since the discovery of the crown ethers by Pederson (3*a*) and his development of the picrate extraction method for measuring their complexation abilities (3*b*,*c*), extraction procedures have been frequently used to assess the complexing properties of newly synthesized macrocyclic ligands (4–10). This is because many of the synthetic macrocycles are very sparingly soluble in aqueous solution and studies of the complexing equilibria in a single organic phase are correspondingly difficult to carry out. Picrate anion has generally been used in such studies as the counterion, presumably because of its relative ease of transport into nonaqueous media and convenient spectral properties.

In this study we consider ligand–solvent systems for which the partitioning of both the ligands and complexed salts between the two phases can be determined, while information on the complexing properties in aqueous solution is already available. This permits a much more detailed analysis of the overall extraction process in terms of the constituent equilibria that are involved. The influence of the anion on the extraction process, from aqueous medium into methylene chloride, as a typical nonpolar organic solvent, has been studied by using the series phenoxide, *p*-nitrophenoxide, and picrate. The nature of the counterion is shown to have a dramatic effect on the ease of extraction of the potassium salts by the different complexing agents.

Results

The extraction studies with potassium phenoxide, *p*-nitrophenoxide, and picrate, from aqueous medium into methylene chloride, were performed using dicyclohexano-18-crown-6 ether (DC-18-C-6), dibenzo-18-crown-6 ether (DB-18-C-6), 18-crown-6-ether (18-C-6), and [2.2.2]cryptand (2,2,2) as the complexing agents. The stability constants (K_s) of K^+ with these ligands in water are known (Table 1). The distribution constants (K_{dc}) of the ligands between the aqueous and organic phase were determined using the method described by Frensdorff (4) and are included in Table 1.

The spectrophotometrically determined percent extraction values for the potassium aryloxide salts are given in Table 2. These results were obtained under optimized conditions of concentration of ArO^-, K^+ (introduced as ArOH and KOH, respectively), and complexing agent (see Experimental and

[b]Concentrations of ArO^-, KOH, and C pertaining to the percent extraction values in this table are given in Table 3.

TABLE 3. Initial concentrations of complexing agent, aryloxide, and potassium ions in extraction experiments

Complexing agent (C)	ArO^- (X^-)	% Extr.	[ArOH] (M)	[KOH] (M)	[C] (M)
DC-18-C-6	PhO^-	5.6	5.26×10^{-2}	1.00	0.140
	p-NO_2PhO^-	88.0	4.65×10^{-2}	0.25	0.263
	$PicO^-$	98.9	5.30×10^{-4}	0.01	5.67×10^{-3}
DB-18-C-6	PhO^-	1.8	5.37×10^{-2}	1.00	0.103
	p-NO_2PhO^-	9.0	4.82×10^{-2}	0.25	0.123
	$PicO^-$	87.0	5.30×10^{-4}	0.01	4.85×10^{-3}
18-C-6	PhO^-	5.2	5.26×10^{-2}	1.00	0.105
	p-NO_2PhO^-	34.8	4.65×10^{-2}	0.25	0.260
	$PicO^-$	96.0	5.21×10^{-4}	0.01	4.00×10^{-3}
(2,2,2)	PhO^-	58.8	5.26×10^{-2}	1.00	9.76×10^{-2}
	p-NO_2PhO^-	99.9	4.68×10^{-2}	0.13	9.77×10^{-2}
	$PicO^-$	>99.9	5.10×10^{-4}	0.01	3.90×10^{-3}

Table 3). Equilibrium constants, as defined in the following section, were calculated according to the method given in the Appendix. The results are presented in Table 2.

Discussion

1. *Extraction efficiencies*

The results in Table 2 clearly point to the relative extraction order for the three anions as picrate > *p*-nitrophenoxide > phenoxide, which holds for all four ligands studied. This relative order remains valid even though standard conditions in the three sets of experiments could not be maintained owing to the very large differences in ease of extraction of these anions (e.g. in the picrate systems very much smaller concentrations of both ligand and salt had to be used compared to the phenoxide systems).

2. *Analysis of equilibria*

A more quantitative analysis of the data requires detailed consideration of the various equilibria that are involved in these systems (15, 16). This in turn reveals certain fundamental relationships which tend to be obscured when viewing only percentages of extraction, as a result of the interplay of several constituent factors which contribute to this overall result.

A pictorial representation of the possible equilibria involved in this system is given in Scheme 1, which expands on the earlier treatment given by Frensdorff (4), while introducing also a more systematic nomenclature for the various equilibria involved.

Not included in this scheme is the possibility of dissociation of the ion pairs M^+X^- in the organic phase into the free ions $M^+ + X^-$, or the dissociation of the complexed ion pairs MC^+X^- in the organic phase into $MC^+ + X^-$. The assumption that $(M^+X^-)_{org}$ does not dissociate into the free ions is probably valid for nonpolar organic solvents. It is considered that this assumption, as well as that $(MC^+X^-)_{org}$ does not dissociate, will not affect the overall conclusions regarding the trends observed (see below).

The equilibrium constants in Scheme 1 are defined as: K_s: stability constant for complex formation in aqueous phase; K_{ds}: distribution constant of salt between aqueous and organic phases; K_{dc}: distribution constant of complexing agent between aqueous and organic phases; K_{dcs}: distribution constant of complexed salt between aqueous and organic phases; K_a: equilibrium constant for complexation of salt in organic phase.

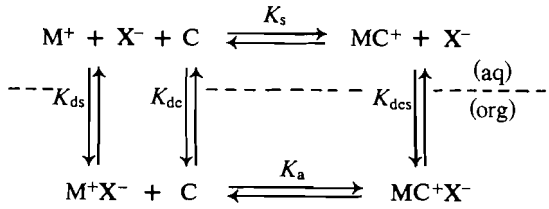

SCHEME 1

The algebraic expressions for the respective equilibrium constants are given in eqs. 1–5.[1]

$$[1] \quad K_s = \frac{[MC^+]_{aq}}{[M^+]_{aq}\,[C]_{aq}}$$

$$[2] \quad K_{ds} = \frac{[M^+X^-]_{org}}{[M^+]_{aq}\,[X^-]_{aq}}$$

$$[3] \quad K_{dc} = \frac{[C]_{org}}{[C]_{aq}}$$

$$[4] \quad K_{dcs} = \frac{[MC^+X^-]_{org}}{[MC^+]_{aq}\,[X^-]_{aq}}$$

$$[5] \quad K_a = \frac{[MC^+X^-]_{org}}{[M^+X^-]_{org}\,[C]_{org}}$$

Of the above equilibrium constants, only four are independent quantities. Also, K_s, K_{ds}, and K_{dc} can be measured independently of the ligand extraction experiments.

Previous studies of extraction equilibria have included discussion (3, 4, 15) of the extraction equilibrium constant, K_e, as defined by eq. [6]:

$$[6] \quad K_e = \frac{[MC^+X^-]_{org}}{[M^+]_{aq}\,[X^-]_{aq}\,[C]_{org}}$$

K_e provides a practical measure of the extraction efficiency of a given ligand for a particular salt from the aqueous to the organic phase. However, K_e values only relate directly to the extraction percentages in systems where the ligand is effectively confined to the organic phase. It will be seen that this is not the case for 18-C-6 and [2,2,2] in the present work.

Scheme 1 entails seven different species in equilibrium. The concentrations of the various species at equilibrium can be evaluated using the stoichiometric relationships [7]–[9],

$$[7] \quad [C]_{tot} = [C]_{aq} + [C]_{org} + [MC^+]_{aq} + [MC^+X^-]_{org}$$

$$[8] \quad [M^+]_{tot} = [M^+]_{aq} + [MC^+]_{aq} + [M^+X^-]_{org} + [MC^+X^-]_{org}$$

$$[9] \quad [X^-]_{tot} = [X^-]_{aq} + [M^+X^-]_{org} + [MC^+X^-]_{org}$$

together with the measured equilibrium concentration of $(X^-)_{aq}$ and the known equilibrium constants K_s, K_{ds}, and K_{dc} (eqs. [1]–[3]). In the present system, K_{ds} values were too small to be measurable; correspondingly, K_a values are too large in this system to be meaningfully discussed. An iterative procedure, as described in the Appendix, was used to derive the various calculable quantities.

It is useful to define a further equilibrium constant, K_e'. For many systems considered in the literature, the extent of partition of the ligand into the aqueous phase is small and has often been neglected. Hence these literature values strictly refer to an "equilibrium constant", K_e', defined by eq. [10]:

$$[10] \quad K_e' = \frac{[MC^+X^-]_{org}}{[M^+]'_{aq}\,[X^-]_{aq}\,[C]'_{org}}$$

where $[M^+]'_{aq}$ and $[C]'_{org}$ are the total concentrations of M^+ and C exclusive of $[MC^+X^-]_{org}$. Thus:

$$[M^+]'_{aq} = [M^+]_{total} - [MC^+X^-]_{org}$$

$$[C]'_{org} = [C]_{total} - [MC^+X^-]_{org}$$

This assumes that $[C]_{aq}$ and $[MC^+]_{aq}$ are negligibly small. K_e' values can then readily be calculated (Table 2).

3. *Evaluation of results*

(a) *Comparison of* K_e *and* K_e' *values*

The values of these two equilibrium constants are expected to agree under the conditions that (*i*) the partition of the ligand into the aqueous phase is small (K_{dc} large), and (*ii*) the stability constants (K_s) of the aqueous complexes are small.

The results in Table 1 show that these conditions are met for the DC-18-C-6 and DB-18-C-6 complexes of all three anions. On the other hand, large differences between K_e and K_e' are found for the 18-C-6 complexes and especially for the (2,2,2) complexes (note that K_e/K_e' ratios vary by up to 10^5). For the latter, this is the result of moderate partitioning of the free ligand into the aqueous solution in conjunction with very strong complex formation in aqueous solution (Table 1).

The effects are much smaller for picrate extraction by 18-C-6 because the total concentrations of K^+ and C used were sufficiently low that the concentrations of KC^+ and C in the aqueous phase were relatively low. On the other hand, for (2,2,2) where the stability constant is much larger, the overall effect is still important so that K_e and K_e' differ appreciably.

(b) *Absolute* K_e *values*

Inspection of the K_e values reveals the order DB-18-C-6 < DC-18-C-6 < 18-C-6 ≪ (2,2,2), which holds for all three anions. While this is in the same order as the percentage extracted values, the K_e values greatly exaggerate the apparent extraction efficiency of (2,2,2) relative to the other ligands. This is essentially because the concentration of (2,2,2) in the organic phase represents only a small fraction of the total (2,2,2) present in the system; thus (2,2,2) partitions efficiently into the aqueous phase and complexes avidly with K^+. (Note that in eq. [6], $[C]_{org}$ is extremely small for (2,2,2) because any (2,2,2) not in the form of $(MC^+X^-)_{org}$ is almost completely partitioned into the aqueous phase.)

(c) *The ligand effect on* K_{dcs} *values*

The overall order of K_e values suggests that (2,2,2) is by far the most effective ligand in terms of extracting the salt from the aqueous into the organic phase. However, if we focus on the transfer of the complexed salt MC^+X^- across the phase boundary, a different picture emerges. Thus the K_{dcs} results show in fact that DC-18-C-6, DB-18-C-6, and (2,2,2) are comparable in effectiveness, and significantly more effective than 18-C-6

[1] It is recognized that the expressions for the various equilibrium constants should strictly contain activity terms in place of concentrations as given in the present treatment. The practice of using concentration terms in extraction studies of this type, in common with other authors (e.g. refs. 5, 6, 8, 9), stems in part from the scarcity of data concerning activity coefficients for the majority of the systems investigated. However, in order to test the assumptions employed, we have carried out sample calculations for different concentrations of the aryloxide, potassium hydroxide, and complexing agent used. The resulting K_e values generally showed satisfactory agreement, indicating the overall validity of the methods employed.

in extraction ability.

Two factors should largely govern the ease of transfer of the complexed cation into the organic phase: (*i*) the "organic" nature or hydrophobicity of the ligand, and (*ii*) the extent to which the solvent molecules have been shed from the cation's solvation sphere on complexation. Compared with DC-18-C-6 and DB-18-C-6, (2,2,2) can be considered as less hydrophobic (cf. K_{dc} values, Table 2), but the 3-dimensional nature of the ligand cavity in (2,2,2) should be much more effective in excluding direct cation–solvent interactions. The net effect of these two factors appears to be a roughly equal degree of transfer of the complexed cation. On the other hand, 18-C-6 is less hydrophobic than DC-18-C-6 and DB-18-C-6, and it also allows cation–solvent interactions to persist, at least in part, in the complex. Hence the 18-C-6 complexed cation has a much greater tendency to remain in the aqueous phase, as judged by the K_{dcs} value.

(d) *The anion effect on* K_e *and* K_{dcs}

Increasing charge dispersal in the series phenoxide → *p*-nitrophenoxide → picrate has a dramatic effect on K_e and K_{dcs} values, as clearly shown in Table 2. This must predominantly reflect the relative free energies of transfer of the respective anions from aqueous to the nonpolar media employed. In the absence of ion-pair formation in the organic phase, relative K_{dcs} values for the different anions should be independent of the complexing agent involved. However, ion-pair formation in the organic phase will tend to reduce the differences in transfer of the anions. Thus the relative stabilization of the anions in the organic solvent through ion-pair formation should be in the order phenoxide > *p*-nitrophenoxide > picrate. This stabilization through ion-pair formation will also be expected to be greatest for 18-C-6 relative to the other ligands, as discussed above. Some evidence for this is seen through comparison of K_e and K_{dcs} values for DC-18-C-6 and 18-C-6. Thus for example, K_{dcs} (picrate)/K_{dcs} (phenoxide) = 1×10^7 for DC-18-C-6 and 1×10^5 for 18-C-6.

4. *Significance to other areas including phase transfer catalysis*

The present results show also that the effective range of reactivities of different anions that can be achieved through a phase transfer (17) type of experiment is much lower than might be expected from a consideration of the relative reactivities of the anions in a pure organic solvent. For example, comparing phenoxide with picrate, although the intrinsic reactivity of phenoxide ion as a nucleophile is very much greater, the concentrations that can be achieved in the organic phase are very much smaller than those of picrate. This results in a levelling effect on the overall capabilities of the two ions to react in a phase transfer system. Similar comments should also apply to other series of related anionic nucleophiles or bases.

Experimental

Materials

The macrocyclic ligands were purchased from BDH, Aldrich, Merck, or Parish Chemical Co. and used as received. The organic solvents were purified, dried, and distilled. Phenol and *p*-nitrophenol were reagent grade. Picric acid was recrystallized from ethanol.

Extraction procedure

A standard aqueous solution of the potassium aryloxide was prepared from the phenol and a standard KOH solution, the latter being in excess. A standard solution of the ligand in a particular organic solvent was also prepared. Equal volumes (1 mL) of the two solutions were placed in a small glass-stoppered test tube and after thorough mixing on a Vortex mixer for 1 min were allowed to stand for phase separation to occur; alternatively separation was effected by centrifugation. The equilibrium concentrations of aryloxide in both phases were determined after appropriate dilution using a Beckman DU-8 spectrophotometer. In the phenoxide experiments, following extraction the organic phase was diluted with 2 mL of 20% methanolic tetramethylammonium hydroxide solution in order to prevent a slow conversion of phenoxide ion to phenol on standing. This, however, was not required in the case of the *p*-nitrophenoxide and picrate ion extractions. The measured value of the aryloxide concentration in the organic phase, and the value obtained by difference before and after extraction of the aqueous solution, agreed satisfactorily. A "blank" extraction in the absence of ligand was also performed for evaluation of the distribution constant K_{ds}. There was no detectable dissolution of the potassium aryloxides in methylene chloride in the absence of the macrocyclic ligands, i.e. K_{ds} is negligibly small in these cases.

Details of the concentrations of reagents used, corresponding to the results in Table 2, are given in Table 3. The percent extraction values given are the mean of two determinations which usually agreed within ±2%.

K_{dc} values were determined spectrophotometrically using the procedure described by Frensdorff (4).

Appendix

In the present systems K^+ is in excess over the other species involved in the various equilibria represented in Scheme 1 (see Table 3). Also the amount of salt extracted in the absence of complexing agent is extremely small and can be neglected.

Therefore, as a starting point in the iteration, we take the following:

$$[K^+X^-]_{org} = 0$$

$$[A1] \quad [K^+]'_{aq} = [K^+]_{total} - [KC^+X^-]_{org}$$

It then follows that

$$[KC^+X^-]_{org} = [X^-]_{total} - [X^-]_{aq}$$

and hence

$$[A2] \quad [C]'_{org} = [C]_{total} - [KC^+X^-]_{org} = [C]_{org} + [C]_{aq} + [KC^+]_{aq}$$

From eq. [3],

$$[C]_{aq} = [C]_{org}/K_{dc}$$

and from eq. [1],

$$[KC^+]_{aq} = K_s[K^+]_{aq}[C]_{aq} = K_s[K^+]_{aq}[C]_{org}/K_{dc}$$

Substitution for $[C]_{aq}$ and $[KC^+]_{aq}$ in eq. [A2] gives

$$[A3] \quad [C]_{org} = \frac{[C]'_{org}}{1 + 1/K_{dc} + K_s[K^+]_{aq}/K_{dc}}$$

Substitution for $[K^+]'_{aq}$ from eq. [A1] gives $[C]_{org}$, and hence $[C]_{aq}$ (eq. [3]) and $[KC^+]_{aq}$ (eq. [A2]).

A second estimate of $[K^+]_{aq}$ is then made from the expression

$$[A4] \quad [K^+]_{aq} = [K^+]_{total} - [KC^+X^-]_{org} - [KC^+]_{aq}$$

This is substituted into eq. [A3] giving new estimates of $[C]_{org}$, $[C]_{aq}$, and $[KC^+]_{aq}$ and hence of $[K^+]_{aq}$ from eq. [A4] using the new value of $[KC^+]_{aq}$. The process is repeated until the values converge. At this stage, concentrations of all species required for calculation of K_c and K_{dcs} have been obtained. Convergence within reasonable limits (<2%) usually occurs after about 2–3 iterative cycles.

Transposition des cations radicaux aminés en spectrométrie de masse

HENRI EDOUARD AUDIER, JEAN PIERRE DENHEZ, ARIELLE MILLIET ET GEORGES SOZZI
Laboratoire de Synthèse Organique, Ecole Polytechnique, 91128 Palaiseau Cedex, France

Reçu le 11 juillet 1983

Ce travail est dédicacé au Professeur E. Lederer à l'occasion de son 75ème anniversaire

HENRI EDOUARD AUDIER, JEAN PIERRE DENHEZ, ARIELLE MILLIET et GEORGES SOZZI. Can. J. Chem. **62**, 931 (1984).

Il est montré en spectrométrie de masse, que les cations radicaux de faible énergie interne des alkylamines substituées en position 2, s'isomérisent au travers d'intermédiaires constitués par des cyclopropanes ionisés, liés à une molécule d'ammoniac. Ce processus est induit par le transfert sur l'azote d'un hydrogène de la chaîne situé en position 3. L'ouverture et la dissociation de ces complexes conduisent à des ions fragments m/z 44, 58 et 72 de structure $[CH_3(CH_2)_nCH\ NH_2]$. Le mécanisme de leur formation est démontré par les données des spectres MIKE de composés marqués, soit au ^{13}C, soit au deutérium. Les résultats expérimentaux sont en accord avec ceux précédemment obtenus par Gross et coll. qui ont étudié les produits de fragmentation du complexe résultant de la réaction entre une molécule d'ammoniac et des cyclopropanes substitués ionisés, en phase gazeuse.

HENRI EDOUARD AUDIER, JEAN PIERRE DENHEZ, ARIELLE MILLIET, and GEORGES SOZZI. Can. J. Chem. **62**, 931 (1984).

It is demonstrated in mass spectrometry that alkylamines substituted at C2 and containing weak internal energy isomerize in the gas phase into intermediary ions composed of ionized cyclopropanes complexed with an ammonia molecule. This process is induced by a C3 hydrogen shift on the nitrogen atom. After opening of the cyclopropane, the dissociation of these complexes leads to m/z 44, 58, and 72 ions having $[CH_3(CH_2)_nCH\ NH_2]$ structures. The mechanism of their formation is demonstrated by the MIKE spectra of ^{13}C and deuterium labelled compounds. The experimental results are in good agreement with those described by Gross *et al.*, who studied the fragmentation of the complexes formed during the reaction between substituted ionized cyclopropanes and ammonia in the gas phase.

Introduction

Dans un travail préliminaire, un mécanisme de transposition des chaînes alkylées a été proposé (1) pour expliquer la fragmentation en phase gazeuse de cations radicaux organiques de faible énergie interne.

Ce mode de réarrangement (schéma 1) a été mis en évidence lors de l'étude des éthers (1, 2), des benzoates d'alkyle (3) et de l'acide isopentaoïque (4).

Il est induit par le transfert d'un hydrogène de la chaîne sur la fonction présente dans la molécule, conduisant à un intermédiaire dans lequel un ion cyclopropanique substitué est lié à une molécule neutre.

Le même mode de transposition est observé pour les amines. Alors qu'à 70 eV, le spectre de masse des ions aminés $[R—CH_2—NH_2]^{+\cdot}$ ne présente qu'un seul pic très intense: m/z 30 (CH_2—NH_2), ce pic est le plus souvent absent du spectre MIKE dès lors que la longueur de la chaîne excède trois carbones (1, 5–7). Des pics intenses apparaissent à m/z 44, 58, 72, etc... Ils correspondent à des ions plus substitués et donc plus stables dont la formation implique une transposition préalable de la molécule.

Ainsi la décomposition métastable de l'isoamylamine (1) conduit à l'obtention d'un ion fragment abondant m/z 58 de structure $[(CH_3)_2—C^+—NH_2]$ (8) dont la formation a été expliquée par le mécanisme représenté schéma 2.

Afin de vérifier la validité et la généralité de ce mécanisme, les amines alkylées et substituées en position 2 ont été étudiées dans ce travail (**1** à **5**, schéma 3).

Résultats et interprétation

1. *Données expérimentales*

(a) Les spectres MIKE des ions **1** à **5** (tableau 1) présentent: des ions correspondant à l'élimination d'un radical (m/z 44, 58, 72 et m/z 30 dans le seul cas de **1**) qui sont généralement intenses; des ions découlant de la perte d'une molécule d'alcène dès lors que la chaîne principale contient cinq carbones au moins (ions m/z 59 et 73 dans les amines **3** et **5**); des ions m/z 32, $[CH_3—NH_3]^+$ de faible abondance; enfin des ions $[M - NH_3]^+$ dont l'étude est rendue difficile par la présence fréquente d'ions situés à une unité de masse inférieure et dont l'origine n'a pu être précisée.

(b) Les spectres ont été comparés à ceux d'amines isomères. Seuls ont été rapportés les résultats relatifs aux amines **6** à **10** à cinq atomes de carbone, isomères de **2**. Tous ces spectres diffèrent fondamentalement de celui de **2**, ce qui indique que cette amine ne s'isomérise pas en une forme moléculaire ionisée avant dissociation.

(c) Tous les pics correspondant à la perte d'un radical sont fins, les valeurs de $T_{0.5}$ étant faibles et inférieures à 0,020 eV (tableau 2).

(d) Les structures des ions m/z 44 et 58 ont déjà fait l'objet d'une étude particulière (8). Dans le cas des amines **1** à **4**, l'ion m/z 44 a toujours la structure $[CH_3—CH—NH_2]^+$ et l'ion m/z 58: $[CH_3—CH_2—CH—NH_2]^+$.

(e) Enfin de nombreux composés marqués ont été préparés (tableaux 3, 4 et 5).

2. *Les spectres MIKE des composés **1** à **5** et de leurs dérivés marqués sont en accord avec le mécanisme d'isomérisation proposé*

Ruptures simples et réarrangements

Le comportement de l'isobutylamine **1** se distingue nettement de celui des homologues supérieurs **2** à **5**: le pic m/z 30 est très intense dans le spectre MIKE de **1** (tableau 1); il est totalement déplacé à m/z 32 pour l'isobutylamine 1,1-d_2 et correspond donc à une rupture simple; et les pics m/z 44 et 58 sont de très faible intensité.

Par contre l'absence de pic m/z 30 dans les spectres MIKE des amines **2** à **5** (tableau 1), l'élimination totale des hydrogènes en position 1 lors de la formation des ions m/z 44 notamment (tableaux 3, 4 et 5) prouvent qu'il y a réarrangement des ions moléculaires avant leur dissociation.

En particulier, les spectres MIKE des amines isomères **3** et **4** présentent des pics intenses aux mêmes unités de masse avec des valeurs de $T_{0.5}$ très proches. Seules les intensités respectives

des pics et notamment l'existence d'un pic important à *m/z* 59 pour **3**, permettent de différencier les deux spectres. Ces observations suggèrent l'existence d'intermédiaires de fragmentation communs.

Mécanisme de réarrangement de la méthyl-2 pentylamine ***3***

La fragmentation de l'amine **3** est précédée d'un échange des hydrogènes du groupe NH_2 (tableau 3: **3***a*). Toutefois cet échange n'implique pas les hydrogènes en position 1 (**3***b*) ou 2 (**3***c*); la même observation a déjà été faite pour les amines linéaires (7). Les hydrogènes portés par le C3′ ne s'échangent que lentement; par contre, ceux portés par les groupes CH_2 sont nettement impliqués (**3***e*). C'est donc par la migration sur l'azote de l'un des hydrogènes échangeable que débute la fragmentation; cette première étape conduit aux ions *a*, *b* et *c* (schéma 4).

Les ions *a* et *b* conduisent aux formes *d* dans lesquelles un ion cyclopropane ionisé est lié à une molécule d'ammoniac. Ces entités s'isomérisent par fixation de NH_3 sur un carbone substitué du cyclopropane qui s'ouvre pour donner les ions intermédiaires de type *e* dont la dissociation conduit aux ions

fragments m/z 44, 58 et 72 (schéma 4).

Les mécanismes de formation de ces fragments sont confirmés par l'étude des spectres des composés spécifiquement marqués (tableau 3). (*i*) La formation de l'ion m/z 44, de structure $[CH_3—CH—NH_2]^+$ (8), se produit avec rétention des hydrogènes du C2 (**3***c*) et du groupe CH_3 en position 3′ (**3***d*, **3***f* et **3***g*) mais avec élimination des hydrogènes du C1 (**3***b*), ce qui est conforme au mécanisme proposé. (*ii*) Le pic m/z 72 est déplacé à m/z 74 pour le composé **3***b*, à m/z 73 pour **3***c* et **3***f*, à m/z 75 pour **3***d* et **3***g*, ce dont rend compte le schéma 4. (*iii*) Enfin, conformément à ce schéma, l'ion m/z 58, de structure $[CH_3—CH_2—CH—NH_2]^+$ (8), a deux origines. Pour 20% environ (tableau 3) cet ion se forme à partir de *a* avec élimination des hydrogènes portés par les carbones C1, C2 et C3′. La fraction dominante de l'ion m/z 58 découle de *b*: selon ce mécanisme, l'ion est déplacé à m/z 59 pour **3***c* et **3***f*, à 60 pour **3***b* et à 61 pour **3***d* et **3***g*.

Dans les dérivés marqués pour lesquels il y a échange d'hydrogène avant isomérisation, les résultats expérimentaux ont été comparés à ceux d'un calcul statistique en supposant l'échange rapide d'atomes d'hydrogène portés par le groupe NH_2 avec les quatre portés par les groupes CH_2 en positions 3 et 4. Un tel calcul revient à rechercher par exemple dans le dérivé **3***a*, les intensités respectives des pics m/z 44, 45 et 46 en considérant un système H_4D_2 (9) avec rétention de deux de ces atomes dans l'ion comme le prévoit le mécanisme proposé. Les bonnes corrélations obtenues pour les dérivés **3***a* (H_4D_2) et **3***e* (H_4D_2 avec rétention du groupe CD_3) confirment que l'échange des hydrogènes en 3 et 4 est facile et celui des hydrogènes en 3′ beaucoup plus lent (tableau 3).

Enfin l'ion *c* ne saurait être précurseur des ions fragments étudiés: en effet, la fixation de NH_3 sur le carbone 4 à partir de *c* conduirait à un ion m/z 44 contenant les carbones 4 et 5, ce qu'infirment les spectres des dérivés marqués. Par contre, par rupture simple, *c* donne l'ion m/z 59 (schéma 4).

*Intermédiaires de fragmentation communs à la méthyl-2 pentylamine **3** et à l'éthyl-2 butylamine **4***

Du fait de son caractère symétrique, la fragmentation de l'amine **4** est plus simple (schéma 5). Le transfert d'un hydrogène de la position 3 sur l'azote conduit au complexe d_1, puis après isomérisation à d_2 et d_3.

Les ions m/z 44, 58 et 72 découlent des ruptures de d_2 et d_3. Les intermédiaires d_1, d_2 et d_3 sont identiques à ceux formés à partir de l'amine **3** (schémas 4 et 5): l'identité des valeurs de $T_{0,5}$ pour les ions m/z 44 et 72 (tableau 2) dans les spectres de **3** et **4** témoigne de l'existence de ces intermédiaires communs.

Les composés marqués (tableau 4) corroborent le mécanisme: il y a élimination des H1 et H2 lors de la formation de l'ion m/z 44, rétention de ces hydrogènes lors de celle de l'ion m/z 72 et élimination des H1 lors de celle de l'ion m/z 58. Il y a par ailleurs échange rapide des H3 et H4 avec ceux du groupe NH_2 avant isomérisation.

Les comportements de **3** et **4** se distinguent toutefois sur deux points: (*i*) le pic m/z 58 est nettement plus intense dans le spectre de **3**: comme il a été montré, la fraction principale de ce pic provient dans ce composé de la fragmentation de l'ion *b* qui ne peut se former à partir de **4** (schéma 4); l'élimination d'alcène est une fragmentation importante pour l'amine **3** (m/z 59, $[M - C_3H_6]^+$) alors que le pic correspondant m/z 73 $[M - C_2H_4]^+$ est pratiquement inexistant dans le spectre de **4**. La plus grande stabilité de la molécule de propène par rapport à celle d'éthylène serait à l'origine de ce phénomène.

[a] Ce pic, beaucoup plus fin, correspond très probablement à une impureté qui n'a pu être éliminée.

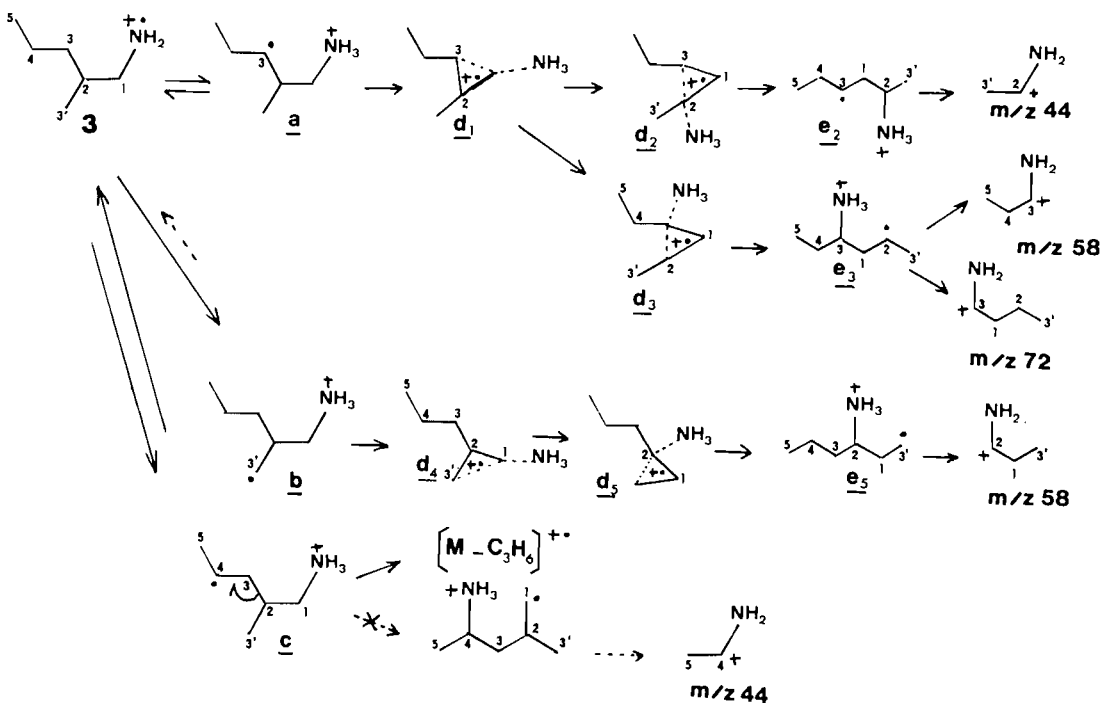

SCHÉMA 4

L'ensemble de ces données permet de conclure que **3** et **4** se fragmentent au travers des intermédiaires communs d_1, d_2 et d_3 et que les réactions **3** ou **4** → *d* ne sont pas réversibles.

La méthyl-2 butylamine **2** *conduit à un intermédiaire dans lequel les carbones en positions 3 et 4 jouent un rôle symétrique*

Les composés marqués (tableau 5) de la méthyl-2 butylamine **2** montrent tout d'abord que les modes d'échange des hydrogènes sont les mêmes que ceux déjà décrits: absence de participation des H1 et H2, échange lent des H3′ primaires, échange rapide des H3 secondaires (comparaison des spectres de **2***a* et **2***f*).

Le transfert d'un H3 ou d'un H3′ conduit aux ions *h* et *i* puis aux formes cyclopropaniques *j*.

Dans le mécanisme proposé, l'ion j_1 étant symétrique doit

SCHÉMA 5

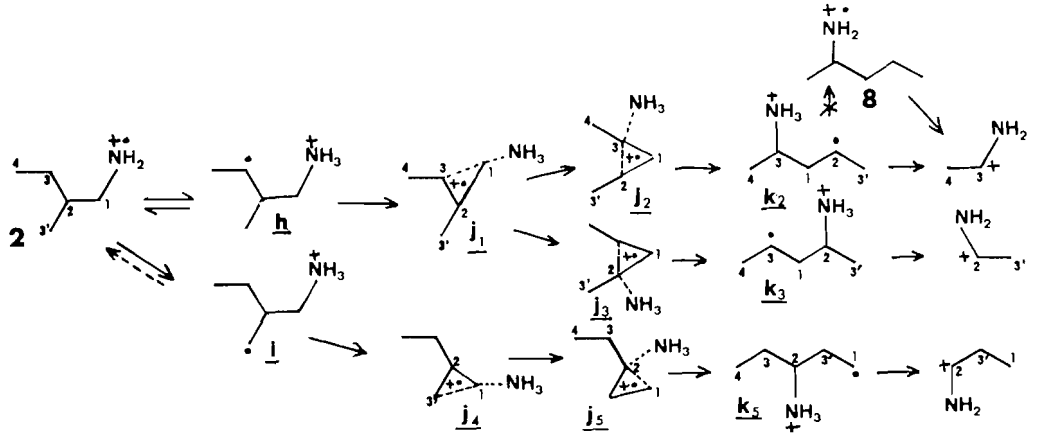

SCHÉMA 6

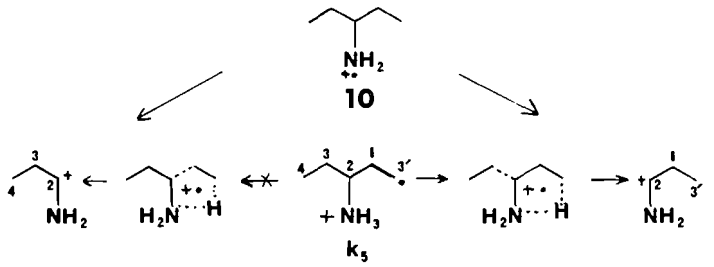

SCHÉMA 7

conduire après isomérisation à deux ions m/z 44 de structure $CH_3—\overset{+}{C}H—NH_2$ (8) contenant des carbones placés différemment dans l'ion moléculaire initial (schéma 6).

Conformément à ce schéma, le pic m/z 44 est déplacé environ pour moitié[1] à m/z 45 dans les spectres des dérivés **2***c* et **2***e* et m/z 47 pour **2***d* tandis que les H1 sont éliminés (**2***b*) (tableau 5).

La formation de l'ion m/z 58 $CH_3CH_2—\overset{+}{C}H—NH_2$ (8) est induite par le transfert sur l'azote d'un hydrogène en 3′ (schéma 6): il y a bien rétention des H1, H2 et H3′ (tableau 5).

Afin de préciser le mécanisme conduisant à la dissociation de **2**, le spectre de **2** a été comparé à ceux des isomères **8**, **9** et **10**. Le spectre de **8** comme celui de **9** présente un pic intense m/z 43 (tableau 1) lié à l'élimination d'une molécule de propane (10). Ce pic est totalement absent dans le spectre de **2**: il n'y a pas isomérisation $k_2 \rightarrow$ **8** ou **9**. La formation de l'ion m/z 44 à partir de k_2 résulte donc de la rupture d'une liaison C—C concertée avec le transfert sur le radical d'un hydrogène du groupe NH_3 (schéma 6).

De même le spectre de **10** (schéma 6) présente un pic m/z 57 lié à l'élimination d'éthane, phénomène qui n'est pas observé pour l'amine **2** (tableau 1). L'absence d'isomérisation $k_5 \rightarrow$ **10** est confirmée par les spectres des composés marqués: si un tel processus avait lieu avant formation de l'ion m/z 58, celui-ci ne conserverait que la moitié des H1 et des H3′, ce qui n'est pas le cas (schéma 7).

Deux types de facteur déterminent le mode de fragmentation des ions *k* (ou des ions *e* provenant de **3** et **4**): (*i*) la nature du radical élininé n'est pas sans incidence sur le processus. Ainsi un radical méthyle s'élimine difficilement: les pics $[M - CH_3]^+$ sont très généralement de faible intensité ou inexistants dans les dérivés **1** à **5**; (*ii*) quand un ion de type *k* est susceptible d'éliminer deux radicaux identiques mais suivant des états de transition différents ($[C_2H_5]^•$ à partir de k_5 par exemple: schéma

[1] La présence d'un pic de faible intensité m/z 45 dont l'origine n'a pu être précisée rend difficile une appréciation exacte du taux de déplacement de l'ion m/z 44.

SCHÉMA 8

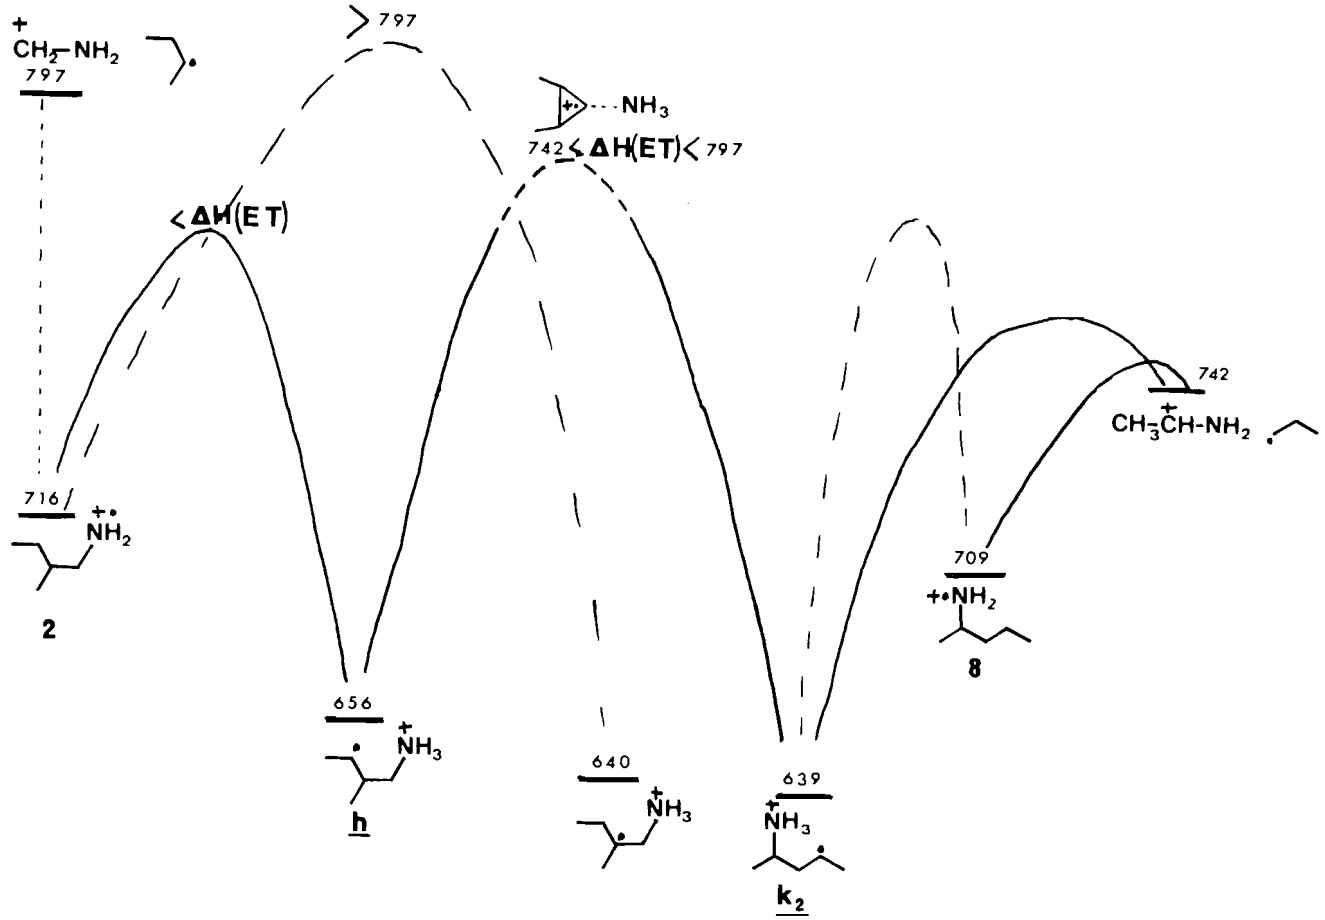

FIG. 1. Profil réactionnel de fragmentation de l'amine **2**. Les ΔH_f sont exprimés en kJ mol^{-1}.

7), il y a rétention dans l'ion de la chaîne portant initialement le radical.

Dans le but de vérifier le caractère général de la sélectivité de ce mode de rupture, l'amine **5** a été étudiée. Le spectre de ce composé présente un pic m/z 72 qui est déplacé pour 80% à 74 dans le spectre de sont dérivé bideutérié en position 1, **5***a*: schéma 8.

Discussion

(a) *Les ions* m/z *44, 58 ou 72 sont plus substitués donc plus stables que l'ion* m/z *30*, $\overset{+}{C}H_2$—NH_2 (fig. 1). Lossing *et al.* (11) ont en effet mis en évidence une différence de 88 kJ mol^{-1} entre le ΔH_f de $\overset{+}{C}H_2$—NH_2 (744 kJ mol^{-1}) et celui de l'ion CH_3—$\overset{+}{C}H$—NH_2 (656 kJ mol^{-1}).

Dans ces conditions, alors que la rupture simple **2** → $[30]^+$ nécessite 81 kJ (voir partie expérimentale), le ΔH_f correspondant à l'état final de l'ion m/z 44 est situé 26 kJ seulement au-dessus du ΔH_f de l'ion moléculaire **2**.

(b) *La première étape de la fragmentation – la protonation de l'azote par un hydrogène de la chaîne – est fortement exothermique*. Ainsi le ΔH_f de l'ion *h* (656 kJ mol^{-1}) est 60 kJ mol^{-1} plus faible que celui de l'ion **2** dont il provient.

Le ΔH_f de l'état de transition conduisant à l'ion m/z 30 étant au moins égal à 797 kJ mol^{-1}, les isomérisations de *h* conduisant à un ion stable et dont l'énergie critique est inférieure à 141 kJ seront observées (fig. 1).

Toutefois, même si ΔH_f (*h*) < ΔH_f (**2**), la réaction de protonation de l'azote présente une énergie critique qui dépend de la nature et de la position de l'hydrogène transféré. Il apparaît notamment que les migrations des hydrogènes en positions 1 et 2 ne s'effectuent pas (tableau 5).

L'étude de la formation du pic m/z 30 dans l'isobutylamine **1** explique cette constation. Ce pic est totalement déplacé à m/z 32 dans le dérivé bideutérié en position 1 et demeure à m/z 30 dans le composé 2-d_1. L'énergie critique nécessaire à des trans-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

For personal use only.

ferts et échanges de ces hydrogènes est donc supérieure à l'énergie de la rupture **1** → $[30]^+$, soit 85 kJ. Ces transferts ne peuvent donc être observés lors de la formation des ions m/z 44, 58, ou 72 dans les amines **2** à **5**.

(c) *Des formes intermédiaires ou des états de transition de type cyclopropanique ont été proposés pour expliquer la fragmentation de nombreux composés:* alcènes (12–14), alcanes (15), acides et esters (16, 17) dérivés phénoliques (18), etc. . .

Par ailleurs, l'existence de formes stables dans lesquelles un ion $[C_nH_{2n}]^+$ de structure éthylénique, carbénique ou cyclopropanique est lié à une molécule d'eau ou d'ammoniac a été montrée (19–24). Quand l'entité C_nH_{2n} a une structure éthylénique ou carbénique, ces formes stables ont des ΔH_f souvent inférieurs à ceux des alcools et amines isomères. Il n'existe par contre pas de données thermodynamiques quant aux complexes cyclopropaniques proposés dans ce travail.

Toutefois les données expérimentales indiquent que les réactions donnant ces intermédiaires constituent une barrière dans le processus d'isomérisation.

Tout d'abord ces réactions sont irréversibles. En effet, dans l'hypothèse d'une réversibilité de la réaction $h \rightleftarrows j$ (schéma 6), l'ion m/z 58 formé à partir de **2** contiendrait – fut-ce partiellement – le carbone en position quatre, ce qui est contraire aux données expérimentales (tableau 5, schéma 6). Les différences de comportement de **3** et **4** déjà évoquées vont dans le même sens.

Par ailleurs, alors que dans les amines **2**, **3** et **4**, les hydrogènes en position 3 s'échangent statistiquement avant formation de l'ion m/z 44, l'échange de ces mêmes hydrogènes est très lent avant formation du même ion m/z 44 dans la 3,3-d_2 heptylamine.

Ceci montre que l'énergie critique nécessaire à la formation de l'ion m/z 44 au travers d'une forme cyclopropanique est supérieure à celle nécessaire à sa formation à partir des amines linéaires pour lesquelles l'intermédiaire proposé est constitué par un ion alcène lié à une molécule de NH_3 (7).

Enfin la stabilité du complexe intermédiaire proposé dépend nécessairement du nombre et de la nature des substituants du cyclopropane. Il est connu en effet (25) que l'énergie d'ionisation du méthyl-cylopropane est supérieure à celle de l'éthyl-cyclopropane et plus encore à celle d'un diméthyl-cyclopropane.

Dans le cas de l'isobutylamine **1**, l'intermédiaire de transposition donnant l'ion m/z 44 est précisément le méthyl-cyclopropane ionisé lié à NH_3 moins stable que les complexes cyclopropaniques formés à partir des homologues supérieurs.

Cette observation peut expliquer la faible intensité de l'ion m/z 44 et corrélativement l'abondance de l'ion m/z 30 découlant de la rupture simple de **1**.

Conclusion

Un mode général d'isomérisation en phase gazeuse des cations aminés a été mis en évidence dans ce travail sur la base de nombreuses données expérimentales.

Le mécanisme proposé est en accord avec les résultats obtenus par Gross et Lin (26) qui ont étudié à 15 et 25 eV les fragmentations des complexes formés par action d'un ion cyclopropane substitué et d'une molécule de NH_3: un ion m/z 44 est observé quand un carbone du cyclopropane est substitué par un groupe méthyle, un ion m/z 58 est formé quand l'un des carbones porte, soit un groupe éthyle, soit deux groupes méthyles.

D'autres travaux sur la fragmentation des amines sont en cours afin de préciser si les "complexes" proposés dans ce travail constituent des formes métastables ayant une certaine durée de vie ou ne sont simplement que des états de transition.

Partie expérimentale

Les ΔH_f des radicaux propyle (86 kJ), isopropyle (73 kJ) et *sec*-butyle (53 kJ) figurent dans les tables (25).

Le ΔH_f (**2**) = 716 kJ mol^{-1} a été calculé à partir du ΔH_f de la molécule neutre (−120 kJ mol^{-1}) déterminée par la méthode de Benson (25) et de l'énergie d'ionisation de l'isobutylamine, soit 8,70 eV (25).

Le même calcul et les mêmes sources conduisent à ΔH_f (**1**) = 732 kJ mol^{-1} et à ΔH_f (**8**) = 709 kJ mol^{-1}.

Les ΔH_f [$\overset{+}{C}H_2$—NH_2] = 744 kJ mol^{-1} et ΔH_f [CH_3—$\overset{+}{C}H$—NH_2] = 656 kJ mol^{-1} ont été déterminés par Lossing *et al.* (11).

Le ΔH_f (*h*) = 653 kJ mol^{-1} est calculé à partir du ΔH_f de la méthyl-2 butylamine (−120 kJ mol^{-1}) de l'affinité protonique (27) de l'isobutylamine (932 kJ mol^{-1}) et de l'énergie de dissociation d'une liaison CH—H (28).

Les spectres MIKE ont éte réalisés sur un appareil VG.ZAB.2F. Les valeurs de $T_{0.5}$ ont été déterminées à partir de la largeur à mi-hauteur des pics après correction liée à la largeur du faisceau principal.

Les composés marqués ont été préparés suivant des procédés classiques: alkylation en α des nitriles, réduction par $AlLiD_4$, etc. . .

Reçu le 5 août 1983

JOËL VEBREL, DANIELLE GRÉE et ROBERT CARRIÉ. Can. J. Chem. **62**, 939 (1984).

Les ylures d'azométhine s'additionnent d'une manière stéréospécifique aux méthoxycarbonyl-3 dihydro-1,2 naphtalènes substitués en 1 ou 2. La diastéréospécificité de la réaction est discutée. Le comportement des méthoxycarbonyl-2 ou -3 indènes et du méthoxycarbonyl-4 dihydro-1,2 naphtalène est également étudié.

JOËL VEBREL, DANIELLE GRÉE, and ROBERT CARRIÉ. Can. J. Chem. **62**, 939 (1984).

Azomethine ylids add stereospecifically to 3-methoxycarbonyl-1-2-dihydronaphthalenes substituted in the 1 or 2 position. The diastereospecificity of the reaction is discussed. The behaviour of 2- or 3-methoxycarbonyl indenes and of 4-methoxycarbonyl-1,2-dihydronaphthalene is also studied.

Dans le cadre d'une étude de la diastéréosélectivité des réactions de cycloaddition dipolaire-1,3 l'addition d'ylures d'azométhine résultant de l'ouverture thermique d'aziridines aux méthoxycarbonyl-3 dihydro-1,2 naphtalènes monosubstitués en 1 ou 2 (composés **1**) a été étudiée.

L'objet essentiel de ce travail était de préciser si la diastéréospécificité observée lors de ces réactions avec les azides (2) (dipôles de la classe propargyl allénique (1) persistait avec les dipôles de la classe allylique tels que les ylures d'azométhine.

En outre, les recherches entreprises ont permis de préciser la réactivité dipolarophilique des oléfines bicycliques **1**, et des composés apparentés dihydro-1,2 naphtaléniques et indéniques **2**, **3** et **4** vis à vis des ylures d'azométhine et notamment d'établir l'orientation de l'addition.

I. Obtention d'ylures d'azométhine et addition aux composés ethyléniques

Depuis les travaux de Padwa et Hamilton (3), Heine *et al.* (4), Huisgen et collaborateurs (5, 6), il est connu que certaines aziridines sont susceptibles de s'ouvrir photochimiquement ou thermiquement entre les atomes de carbone cycliques. L'aziridine est en équilibre avec l'ylure d'azométhine ainsi formé.

Lors de nos recherches les ylures d'azométhine **5***a* et **5***b* proviennent de l'ouverture des aziridines **6***a* et **6***b* préparées à partir des oléfines **7***a* et **7***b* selon le schéma 1.

L'aziridine **6***a* est obtenue quantitativement par thermolyse de la triazoline **8***a* (15 à 20 min à 170°C) sous atmosphère d'azote sec (7*a*). L'aziridine **6***b* résulte de la décomposition thermique de la triazoline **8***b* (8) dans les mêmes conditions. L'équilibre entre l'aziridine **6***a* et l'ylure d'azométhine correspondant **5***a* intervient dès la température ambiante (7 à 10). L'aziridine **6***b* n'est en équilibre avec l'ylure correspondant **5***b* qu'à plus haute température. L'existence de **5***b* a été mise en évidence dans le xylène bouillant (8).

Etudiant l'addition de l'ylure d'azométhine **5***a* résultant de l'ouverture thermique de l'aziridine **6***a* à diverses oléfines monoactivées, Texier et Carrié (7) remarquent que l'orientation de l'addition dépend de la stéréochimie de l'oléfine. Le cinnamate de méthyle et le cinnamonitrile *cis* conduisent chacun à deux pyrrolidines résultant d'une addition dans les deux sens alors qu'un seul cycloadduit est obtenu avec les oléfines *trans*. Pour celles-ci l'orientation unique se fait de telle sorte que le carbone nucléophile du dipôle se lie au carbone électrophile du dipolarophile (11).

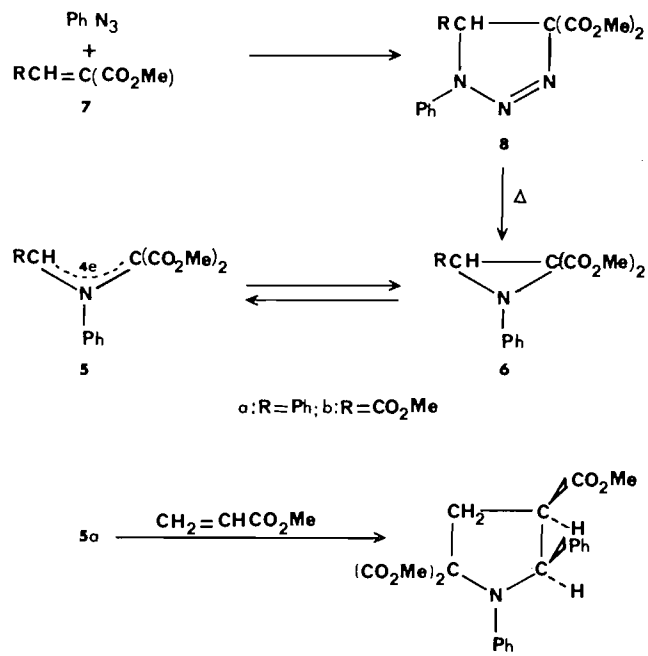

SCHÉMA 1

L'importance des facteurs stériques intervenant lors de l'approche du dipolarophile par le dipôle et déterminant la stéréochimie des cycloadduits a été soulignée (12). Cependant les travaux de Texier et Carrié (13) montrent qu'il convient de tenir compte des effets orbitalaires. Ainsi, lors de la réaction de **5***a* avec l'acrylate de méthyle l'approche des deux réactifs (supposés dans des plans pratiquement parallèles) est telle que le phényle lié au carbone du dipôle se place sous le groupement ester du dipolarophile (obtention d'un adduit *cis*, schéma 1).

TABLEAU 1. Obtention des pyrrolidines **9** à **13**. Conditions opératoires. Rendements

Pyrrolidines	n	R	X	R^1	R^2	Température de réaction (°C)	Durée de la réaction (h)	Rdt (%)[a]

[a]Rendement en produit pur.
[b]Environ 5% de l'oléfine de départ n'ont pas réagi (rmn).
[c]Environ 10% de l'oléfine de départ sont mis en évidence à l'aide de la chromatographie.
[d]8% d'oléfine n'ont pas réagi (chromatographie).
[e]Moins de 5% d'oléfine restante (chromatographie).

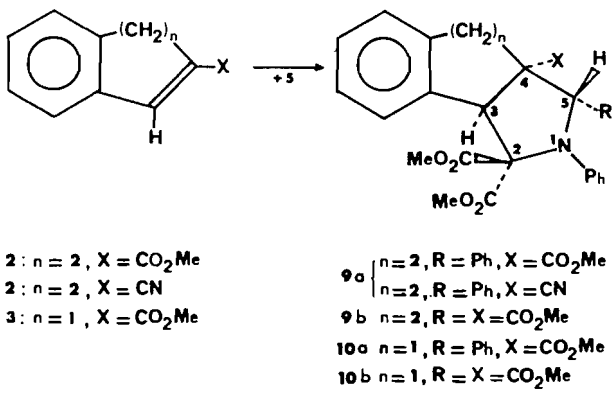

SCHÉMA 2

Les influences orbitalaires qui en résultent ont été discutées en détail avec d'autres dipôles comme les nitrones et les esters nitroniques (14); elles sont suffisamment importantes pour supplanter l'effet stérique attendu. Des comportement analogues ont été observés avec d'autres oléfines *Z* activées (8).

Lors de ce travail, les cycloadditions aux dipolarophiles **1** à **4** sont conduites en milieu anhydre sous atmosphère d'azote en solution dans le xylène ou le mésitylène bouillant, les réactifs étant en proportion équimoléculaires. Les conditions expérimentales et les rendements des pyrrolidines **9** à **13** obtenues sont précisés dans le tableau 1.

II. Addition des ylures d'azométhine 5 aux composés indéniques et dihydronaphtaléniques 2 et 3

Les différentes réactions (Schéma 2) s'effectuent avec des rendements pratiquement quantitatifs.

On constate (Tableau 1) que le dipolarophile indénique manifeste, avec le même ylure d'azométhine, une plus grande réactivité que son homologue dihydronaphtalénique.

Les principales caractéristiques spectroscopiques des pyrrolidines obtenues (ir, rmn ^1H) sont données dans le tableau 2.

L'examen du tableau 2 met en évidence les points importants suivants: l'addition est unidirectionnelle et son orientation est en accord avec celle que laissent prévoir les données de la littérature (7). Les signaux des protons H_3 et H_5 des pyrrolidines **9** et **10** sont en effet des singulets.

Il est connu qu'en série pyrrolidinique (13) les protons d'un groupement ester sont nettement blindés par un phényle en *cis* (blindage minimum de 0,3 à 0,4 ppm), lorsque ces deux groupements sont portés par des carbones vicinaux.

L'examen des données relatives aux composés **9***a* et **10***a* (R = Ph, X = CO_2Me) montre que les protons de deux groupements esters sont blindés, ce qui laisse penser que l'ester porté par le carbone 4 (X = CO_2Me) est en *cis* du phényle substituant le carbone 5 (R = Ph). Les données relatives au composé **9***a* (X = CN) dont les méthyles d'un seul groupement ester sont blindés, confirment l'attribution de la stéréochimie précédente.

La stéréochimie des composés **9***b* et **10***b* (R = CO_2Me) n'est pas établie. Elle est supposée être analogue à celle des composés **9***a* et **10***a*.

III. Addition de l'ylure d'azométhine 5 aux composés indénique et dihydronaphtalénique 4

Il nous a paru intéressant de comparer le comportement des composés **2** et **3** avec celui des dipolarophiles **4** isomères différant des précédents par la position du groupement ester. Les réactions suivantes (Schéma 3) ont été effectuées.

Les rendements sont excellents sauf pour **12***b* (Tableau 1). Dans ce cas le rendement n'est pas optimisé.

Les principales caractéristiques ir et rmn ^1H des pyrrolidines obtenues **11** et **12** sont données dans le tableau 3. L'analyse du spectre de rmn du composé **11***a* s'est révélée délicate et a nécessité des découplages de spin.

L'orientation de l'addition est parfaitement établie. Le proton H_5 est un doublet résultant du couplage ^3J avec H_4. Ces deux protons sont donc portés par deux carbones vicinaux. La littérature (7, 11) laissait prévoir l'orientation inverse. La compréhension des résultats nécessiterait une étude théorique délicate étant donné que les ylures d'azométhine ne sont pas isolables et par suite leurs géométries ne sont pas connues.

Si les données de rmn sont en accord avec les structures proposées, la configuration relative des carbones 4 et 5 ne peut être précisée avec certitude. Toutefois, la faible valeur obser-

SCHÉMA 3

vée pour le couplage ^3J entre H_4 et H_5 pour **12***b* (3,9 Hz) semble indiquer que ces deux hydrogènes sont en *trans*.

IV. Addition de l'ylure d'azométhine 5a à quelques composés dihydronaphtaléniques substitués 1

Le comportement des méthoxycarbonyl dihydro-1,2 naphtalènes **1** substitués en α ($R^1 \neq H$, $R^2 = H$) et en β ($R^1 = H$, $R^2 \neq H$) a été étudié. Comme nous l'avons indiqué le but essentiel poursuivi était de voir si la diastéréospécificité constatée lors de la cycloaddition des azides (2) aux dipolarophiles **1**, s'observait également avec les ylures d'azométhine.

Chaque dipolarophile étudié conduit à une seule pyrrolidine. La réaction est à la fois régio et diastéréospécifique. Les réactions effectuées figurent au schéma 4.

Les rendements (rmn du produit brut) sont excellents; cependant l'examen du tableau 1 montre que l'introduction d'un substituant R^1 ou $R^2 \neq H$ diminue considérablement la vitesse de cycloaddition. Remarque: Toutes ces cycloadditions conduisent à *une seule pyrrolidine* (isolable) contrairement à ce que nous avons publié (15) en discutant uniquement le spectre de rmn ^1H du produit brut de la réaction.

Les principales données spectroscopiques (ir et rmn ^1H) des pyrrolidines obtenues **13** figurent au tableau 4. (Les caractéristiques des protons aromatiques entre 6,40 et 7,90 ppm ne sont pas précisées.)

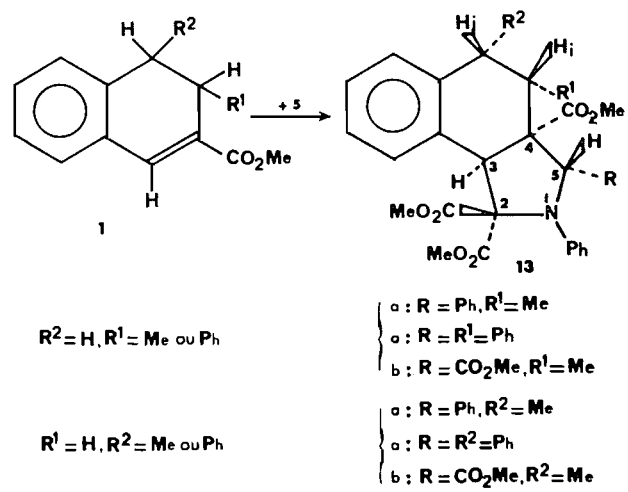

SCHÉMA 4

L'orientation de l'addition est déterminée sans ambiguité, les protons H_3 et H_5 n'étant pas couplés.

La rmn ^1H ne permet pas d'établir la stéréochimie des pyrrolidines. Cependant, un certain nombre de précisions intéressantes peuvent être apportées lorsque R = Ph.

(a) Les protons de deux des trois groupements esters sont fortement blindés ce qui donne la configuration relative des carbones 4 et 5 (ester et R = Ph en *cis*).

(b) L'enregistrement des spectres des composés **13** à haut champ (270 MHz) permet une analyse au premier ordre et l'examen des constantes de couplage des protons du carbocycle benzocondensé fournit des renseignements conformationnels intéressants: quelle que soit la nature de R^1 (Me ou Ph) des composés **13***a*, R = Ph, R^2 = H, le proton H_i n'est jamais fortement couplé avec H_j et R^2 ce qui exclut un couplage de type *trans* diaxial supérieur généralement à 10 Hz. Le substituant R^1 (Me ou Ph) occupe donc préférentiellement une position pseudo axiale. Lorsque R^2 = Me ou Ph, R = Ph, R^1 = H (composés **13***a*, le proton H_j est couplé sensiblement de la même façon avec R^1 et H_i ($5,0 < J < 7,5$) ce qui lui confère

une position pseudo équatoriale préférentielle et implique que le substituant R^2 soit pseudo axial.

V. Diastéréospécificité de la cycloaddition

(a) Détermination de la stéréochimie des cycloadduits

La discussion nécessite la connaissance de la stéréochimie des pyrrolidines. La structure des composés **13***a*, R = Ph, R^1 = H, R^2 = Me et **13***a*, R = Ph, R^1 = Me, R^2 = H, a été déterminée à l'aide de la diffraction des rayons-X par l'équipe du Professeur Meinnel que nous remercions (16). Les figures 1 et 2 permettent de discuter cette stéréochimie.

Les structures obtenues montrent sans ambiguité que le méthyle substituant le cycle à six chaînons est en *cis* du groupement ester lié au même cycle. On remarque comme l'analyse rmn le laissait supposer que ce méthyle R^1 ou R^2 est dans les deux cas en position pseudo axiale.

(b) Discussion de la diastéréosélectivité

Les résultats observés avec les azides sont confirmés (2) et les interprétations avancées restent valables.

Les dipolarophiles **1**, $R^1 \neq H$, R^2 = H et **1**, R^1 = H, $R^2 \neq H$ adoptent des conformations privilégiées pour lesquelles les substituants R^1 ou R^2 sont en position pseudo axiale (2). Lors d'une cycloaddition, les réactifs sont en général supposés s'approcher dans deux plans parallèles. Le dipôle attaque la face du dipolarophile *anti* par rapport aux substituants R^1 ou

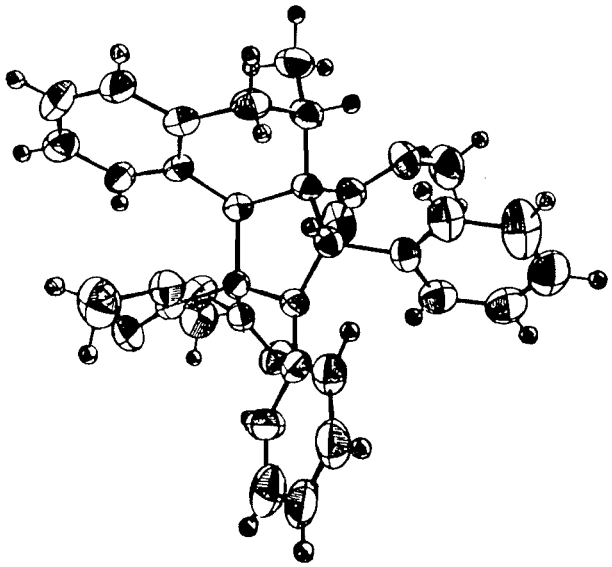

FIG. 1. Pyrrolidine **13***a* (R = Ph, R^1 = Me, R^2 = H).

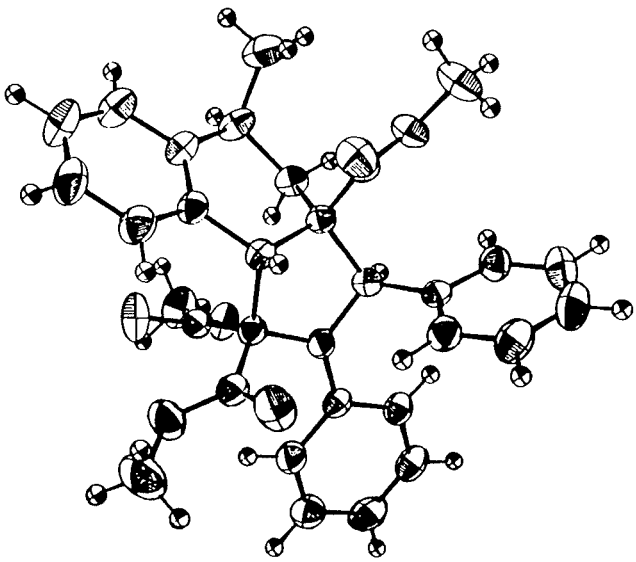

FIG. 2. Pyrrolidine **13***a* (R = Ph, R^1 = H, R^2 = Me).

R^2 qu'ils soient en α (Fig. 3) ou en β (Fig. 4) de l'insaturation.

Le dipôle approche la face la moins encombrée de l'oléfine conduisant aux adduits **13** (groupement ester du dipolarophile en *cis* des substituants R^1 ou R^2).

Les conclusions tirées des recherches conduites avec les azides semblent donc généralisables. La conformation du dipolarophile a une influence déterminante sur la diastéréochimie de la réaction. L'étude expérimentale et théorique de l'addition du diazométhane est actuellement en cours.

Partie expérimentale

Les spectres de rmn ont été enregistrés soit à l'aide d'un appareil à onde continue (JEOL MH, 100 MHz) soit avec un appareil à transformée de Fourier (Bruker WP 80 DS, 80MHz pour ^{1}H et 20,115 MHz pour ^{13}C et Bruker WH 270 (270 MHz pour ^{1}H)). Les caractéristiques infra-rouge sont obtenues à l'aide d'un spectrophotomètre Perkin–Elmer, modèle 325; les liquides sont examinés sous forme de films, les composés solides sont pastillés dans KBr. Les spectres de masse sont enregistrés en utilisant un appareil Varian mat 311 (Centre de Mesures Physiques de Rennes) avec une source à

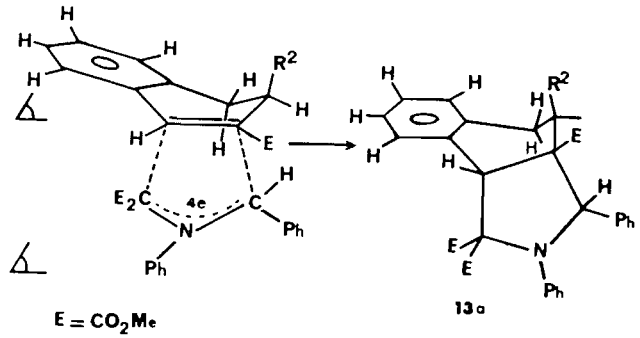

FIG. 3.

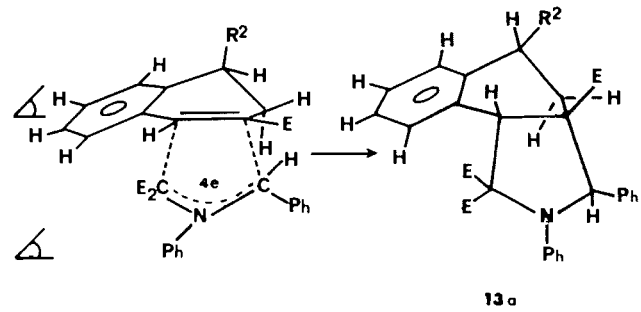

FIG. 4.

impact électronique; l'énergie du faisceau électronique est 70 eV, l'intensité du courant d'émission 300 μA et la tension d'accélération des ions 3 kV. Les points de fusion sont pris à l'aide d'un banc chauffant Kofler et les analyses élémentaires effectuées par le Service Central de Microanalyses du C.N.R.S.

I. Synthèses des dipolarophiles

A l'exception du cyano-3 dihydro-1,2 naphtalène obtenu selon la technique décrite par Julia (17), la synthèse des dipolarophiles a été décrite précédemment (18).

II. Synthèse des triazolines 8

(a) Oléfines RCH=C(CO$_2$Me)$_2$ 7

La méthode de Allen et Sprangler (19) est utilisée pour la préparation du benzylidène malonate de méthyle. Lorsque R = CO_2Me, à la méthode de House *et al.* (20) modifiée par Hall et Ykman (21), nous avons préféré la technique de Ouali *et al.* (22) qui donne d'excellents rendements (95%).

(b) Triazolines 8

Le phénylazide et le composé éthylénique sont mélangés en quantités équimoléculaires. Le mélange est maintenu sans solvant à 60°C pendant un mois pour **8***a* (7*b*) ou à 40°C pendant 15 jours pour **8***b* (8). Composé **8***a*, Rdt 70% F, 172°C (MeOH); rmn ($CDCl_3$) δ: 5,90 (s, 1H), 3,18 (s, 3H), 3,88 (s, 3H). Composé *8b*, Rdt 44%, F 118°C (MeOH); rmn ($CDCl_3$) δ: 5,45 (s, 1H), 4,00 (s, 3H), 3,94 (s, 3H), 3,79 (s, 3H).

III. Synthèse des pyrrolidines

(a) Modes opératoires généraux

Procédure A

Le mélange équimoléculaire de triazoline **8***a* et de dipolarophile dissous dans 20 cm^3 de mésitylène anhydre est porté progressivement à 160–165°C sous atmosphère d'azote. Une coloration caractéristique de l'ylure d'azométhine (rose d'abord, rouge violacé ensuite) se développe. La thermolyse s'accompagne d'un intense dégagement gazeux. Lorsque celui-ci a cessé (30 à 45 min), on porte alors à reflux du mésitylène (160–165°C). Les temps de réaction sont compris entre 24 et 72 h. Après refroidissement, le mésitylène est distillé sous pression réduite. Le résidu huileux est repris avec un peu d'éther qui provoque

la cristallisation de la pyrrolidine. Dans le cas contraire, le produit brut huileux est chromatographié.

Procédure B

Il consiste à remplacer le mésitylène par le xylène dont la température d'ébullition est suffisante pour assurer une thermolyse rapide de la triazoline **8***b* (la thermolyse commence dès 110–115°C). La solution d'aziridine **6***b* en équilibre avec l'ylure d'azométhine **5***b* a une coloration jaune très caractéristique. Après distillation du solvant et addition d'une petite quantité d'éther la pyrrolidine cristallise.

Composé **9***a*, $n = 2$, R = Ph, X = CO_2Me. Procédure A. Rdt 96%; F 162–163°C (méthanol). *Anal.* calc. pour $C_{30}H_{29}NO_6$: C 72,13, H 5,85, N 2,80; trouvée: C 72,3, H 5,9, N 2,8.

Composé **9***a*, $n = 2$, R = Ph, X = CN. Procédure A. Rdt 92%; F 186–187°C (méthanol). *Anal.* calc. pour $C_{29}H_{26}N_2O_4$: C 74,68, H 5,58, N 6,01; trouvée: C 74,4, H 5,5, N 6,1.

Composé **9***b*, $n = 2$, R = X = CO_2Me. Procédure B. Rdt 89%; F 89–90°C (éther–hexane). *Anal.* calc. pour $C_{26}H_{27}NO_8$: C 64,86, H 5,61, N 2,91; trouvée: C 64,6, H 5,7, N 2,9.

Composé **10***a*, $n = 1$, R = Ph, X = CO_2Me. Procédure A. Rdt 92%; F 188–189°C (méthanol). *Anal.* calc. pour $C_{29}H_{27}NO_6$: C 71,74, H 5,61, N 2,89; trouvée: C 71,7, H 5,4, N 3,1.

Composé **10***b*, $n = 1$, R = X = CO_2Me. Procédure B. Rdt 95%; F 161–162°C (méthanol). *Anal.* calc. pour $C_{25}H_{25}NO_8$: C 64,24, H 5,37, N 2,99; trouvée: C 64,4, H 5,4, N 2,9.

Composé **11***a*, $n = 1$, R = Ph. Procédure A. Le résidu (huile rougeâtre), après distillation du mésitylène, est chromatographié sur gel de silice (230–400 mesh; éluant: cyclohexane–éther, 50:50). Rdt 87%; F 201–202°C (méthanol). *Anal.* calc. pour $C_{29}H_{27}NO_6$: C 71,75, H 5,61, N 2,89; trouvée: C 71,8, H 5,7, N 2,8.

Composé **11***b*, $n = 1$, R = CO_2Me. Procédure A. Après élimination du mésitylène le résidu est chromatographié sur gel de silice (70–230 mesh; éluant: cyclohexane éther, 50:50). Rdt 89%; F 134–135°C (éthanol à 95°C). *Anal.* calc. pour $C_{25}H_{25}NO_8$: C 64,24, H 5,37, N 2,99; trouvée: C 64,0, H 5,4, N 3,0.

Composé **12***b*, $n = 2$, R = CO_2Me. Procédure A. Le solvant éliminé, l'huile rougeâtre résiduelle est chromatographiée sur gel de silice (230–400 mesh; éluant: cyclohexane–éther, 50:50). Rdt 78%; F 124–125°C (éthanol à 95°C). *Anal.* calc. pour $C_{26}H_{27}NO_8$: C 64,86, H 5,61, N 2,91; trouvée: C 64,6, H 5,7, N 2,9. Lors de la chromatographie on isole environ 5% d'aziridine **6***b* (huile) caractérisée à l'aide de la rmn (8) ^1H (TMS, C_6D_6) δ: 3,94 (H cyclique), 3,06, 3,39 et 3,60 (CO_2CH_3).

Composé **13***a*, R = Ph, R^1 = Me, R^2 = H. Procédure A. Purification par chromatographie sur gel de silice (230–400 mesh; éluant: hexane–éther, 60:40). Rdt 70%; F 158–159°C (méthanol). Spectrométrie de masse, masse moléculaire calc. pour $C_{31}H_{31}NO_6$: 513,215; trouvée: 513,213. Les cristaux étudiés à l'aide de la diffraction des rayons X (16) sont obtenus par cristallisation lente à 0°C d'une solution de pyrrolidine pure dans le mélange méthanol–acétone (95:5).

Composé **13***a*, R = Ph, R^1 = Ph, R^2 = H. Procédure A. On dissout dans le mélange acétone – éther éthylique (60:40) le résidu obtenu après distillation du mésitylène. La pyrrolidine cristallise lentement au réfrigérateur. Rdt 75%; F 232–233°C (mélange acétone – éther éthylique, 50:50). Spectrométrie de masse, masse moléculaire calc. pour $C_{36}H_{33}NO_6$: 575,231; trouvée: 575,227.

Composé **13***b*, R = CO_2Me, R^1 = Me, R^2 = H. Procédure A. Après élimination du mésitylène l'huile jaune orangée résiduelle est chromatographiée sur gel de silice (70–230 mesh; éluant: cyclohexane–éther, 50:50). Rdt. 70%; F 135–136°C (éthanol à 95°C). Spectrométrie de masse, masse moléculaire calc. pour $C_{27}H_{29}NO_8$: 495,189; trouvée: 495,188. La chromatographie permet d'isoler sous forme d'huile environ 10% d'aziridine **6***b* qui est caractérisée par son spectre de rmn ^1H.

Composé **13***a*, R = Ph, R^1 = H, R^2 = Me. Procédure A. On ajoute une petite quantité d'éther éthylique à l'huile jaune obtenue après distillation du mésitylène. Par refroidissement à 0°C, la pyrrolidine cristallise en partie. Les eaux mères de filtration sont chromatographiées sur gel de silice (230–400 mesh; éluant: hexane–éther, 60:40). Rdt 72%; F 158–159°C (méthanol). Spectrométrie de masse, masse moléculaire calc. pour $C_{31}H_{31}NO_6$: 513,215; trouvée: 513,213. Les cristaux étudiés à l'aide de la diffraction des rayons X (16) sont obtenus par cristallisation lente à 0°C d'une solution de pyrrolidine pure dans un mélange méthanol–acétone (95:5).

Composé **13***a*, R = Ph, R^1 = H, R^2 = Ph. Procédure A. L'huile rouge épaisse obtenue après élimination du mésitylène est chromatographiée sur gel de silice (230–400 mesh; éluant: hexane – éther éthylique, 60:40). Rdt 80%; F 186–187°C (mélange hexane – éther éthylique, 60:40). *Anal.* calc. pour $C_{36}N_{33}NO_6$: C 75,13, H 5,74, N 2,43; trouvée: C 74,9, H 5,8, N 2,4.

Composé **13***b*, R = CO_2Me, R^1 = H, R^2 = Me. Procédure A. Après élimination du mésitylène, il reste une huile rouge-orangée qui est chromatographiée sur gel de silice (70–230 mesh; éluant cyclohexane – éther éthylique, 50:50). Rdt 85%; F 180–181°C (éthanol à 95°C). *Anal.* calc. pour $C_{27}H_{29}NO_8$: C 65,45, H 5,86, N 2,83; trouvée: C 65,3, H 5,9, N 2,7. Lors de la chromatographie on isole environ 5% d'aziridine **6***b* caractérisée par son spectre de rmn ^1H.

Low-temperature infrared study of ammonium carbamate formation

I. C. HISATSUNE

Department of Chemistry, 152 Davey Laboratory, The Pennsylvania State University, University Park, PA 16802, U.S.A.

Received September 6, 1983

I. C. HISATSUNE. Can. J. Chem. **62**, 945 (1984).

Two types of infrared spectra observed during the formation of ammonium carbamate $NH_4^+NH_2CO_2^-$ from the reaction of NH_3 and CO_2 in the solid state at low temperatures have been re-examined. These spectra had been assigned previously to amorphous and crystalline ammonium carbamate but the present data suggest their origins to be $NH_4^+NH_2CO_2^-$ and its unstable precursor $(NH_3)_2CO_2$ in which CO_2 is bent. Spectra of amorphous and crystalline ammonium carbamate have been distinguished by comparing the systems NH_3/CO_2 and $NH_3/CO_2/H_2O$. Hydrogen ion transfer in the diammoniates occurred at about $-80°C$ for NH_3/CO_2 and about $-40°C$ for ND_3/CO_2.

I. C. HISATSUNE. Can. J. Chem. **62**, 945 (1984).

On a réétudié deux types de spectres infrarouges observés au cours de la formation du carbamate d'ammonium, $NH_4^+NH_2CO_2^-$, par réaction de l'ammoniac et de l'anhydride carbonique à l'état solide et à basse température. Au cours des travaux antérieurs, ces spectres avaient été attribués aux formes amorphes et cristallines du carbamate d'ammonium; toutefois, les nouvelles données suggèrent qu'ils sont dus au $NH_4^+NH_2CO_2^-$ et à son précurseur instable, $(NH_3)_2CO_2$, dans lesquels le CO_2 serait déformé. On a pu distinguer les formes amorphe et cristalline du carbamate d'ammonium en les comparant aux systèmes NH_3/CO_2 et $NH_3/CO_2/H_2O$. Il se produit un transfert d'ions hydrogènes dans les diammoniates à environ $-80°C$ pour NH_3/CO_2 et à environ $-40°C$ pour ND_3/CO_2.

[Traduit par le journal]

Introduction

It was reported earlier (1) that in acid–base reactions involving hydrogen-bonded solids, proton-transfer occurs at temperatures significantly above the boiling point of liquid nitrogen. Hence, such reactions can be studied conveniently in conventional, liquid-nitrogen cooled, low-temperature infrared cells. In the present investigation, the same experimental technique was used to examine the formation of ammonium carbamate from ammonia and carbon dioxide in the solid state at low temperatures. This interesting system had been studied previously by Frasco (2) who observed two kinds of infrared spectra. The origin of one type of spectrum was attributed to an amorphous solid ammonium carbamate since this species was the first to be formed at $-78°C$. Warming of this initial species to $-25°C$ gave rise to the second type of spectrum which was assigned to crystalline ammonium carbamate $NH_4^+NH_2CO_2^-$. Results from the present investigation indicate that this interpretation must be modified.

Experimental

Ammonia and carbon dioxide gases were from the Matheson Co., and they were distilled or sublimed, respectively, under reduced temperature and pressure into gas storage bulbs. Ammonia-d_3 from Merck, Sharp, and Dohme of Canada, Ltd., was degassed and then used directly.

A liquid-nitrogen cooled, low-temperature cell described before (3) was used to record the infrared spectra of the samples. Spectra were taken on Perkin-Elmer Model 521 or 621 grating spectrophotometers.

Results and discussion

According to the top spectra in Figs. 1 and 2 and in agreement with an earlier observation of Frasco (2), no products were formed when mixtures of ammonia and carbon dioxide gases were condensed on an infrared window cooled at $-190°C$. Broad peaks present in the $1400-1600\ cm^{-1}$ region in these initial scans are due to solid ammonia and not to any products. However, warming of these matrices to about $-160°C$ and above caused new absorption peaks to appear. Reactions giving rise to these new peaks were evidently over by about $-130°C$. The middle spectra in Figs. 1 and 2 illustrate the changes caused by these warming sequences, and their peak frequencies are summarized in Table 1 (columns 2 and 3). The present spectra are similar to those identified as Type I by Frasco (2) although he reported no frequency values.

Additional changes in the spectra of NH_3/CO_2 and ND_3/CO_2 matrices occurred when sample temperatures reached near $-80°C$ and $-40°C$, respectively. Most notably, the peak at 3370(2510) cm^{-1} disappeared and new peaks appeared at 3475(2600), 3310(2430), 1485(1072), 1265(915), 1040(~810), 728(~700), and 460(342) cm^{-1} where values in parentheses are for the ND_3/CO_2 system. These new spectra (Figs. 1 and 2) and their peak frequencies (Table 1) are essentially the same as those from the Type II species in the work of Frasco (2). No further changes in these spectra were observed until about 0°C when the samples began to sublime off the infrared window and absorption bands of gaseous ammonia became visible.

The source of Type II spectra had been proposed by Frasco (2) to be a crystalline ammonium carbamate $NH_4^+NH_2CO_2^-$. The present work provides additional support for this interpretation. During the formation of this product as evidenced by the changes described in the preceding paragraph, continued annealing of a sample caused single peaks in the spectrum to change into multiplets characteristic of amorphous to crystalline phase changes. Such multiplets were observed at 3120/3010, 2830/2750, 1485/1464/1447, 745/728, 580/567, and 512/460 cm^{-1}. Since water was expected to stabilize the amorphous phase through hydrogen-bond formation (1), several mixtures of $NH_3/H_2O/CO_2$ with NH_3/H_2O mole ratios ranging from one to two were also examined. These systems gave complex spectra due to the presence of ammonia hydrates and low yields of the carbamate since the reactivity of NH_3 was reduced and sufficient CO_2 could not be maintained in the matrix at the reaction temperatures. However, in such matrices, the multiplet bands all appeared as single peaks even at temperatures where the samples began to sublime off the infrared window. The spectra of these amorphous samples were also distinct from those of the initial reaction product (central spectra, Figs. 1 and 2). In particular, the spectra of amorphous ammonium carbamate always showed a pair of peaks at 3460

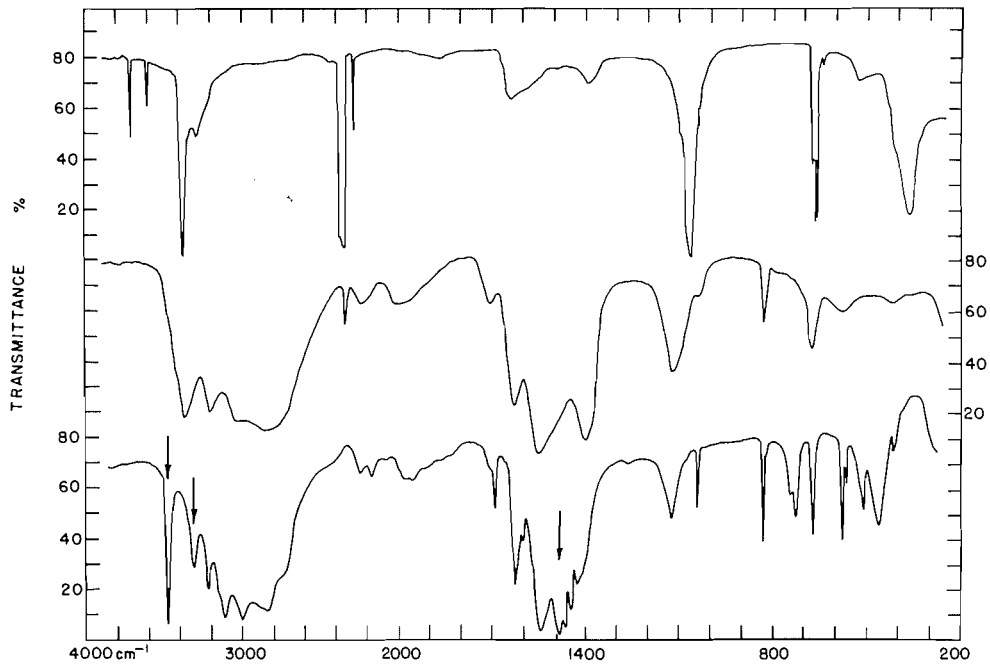

FIG. 1. Infrared spectra of NH_3/CO_2 = 3.0 system at −190°C. Top spectrum, initial; central spectrum, after warming to −100°C; lower spectrum, after warming to −25°C. Arrows indicate characteristic $\nu(NH_2)$ and $\delta(NH_4^+)$ absorption bands.

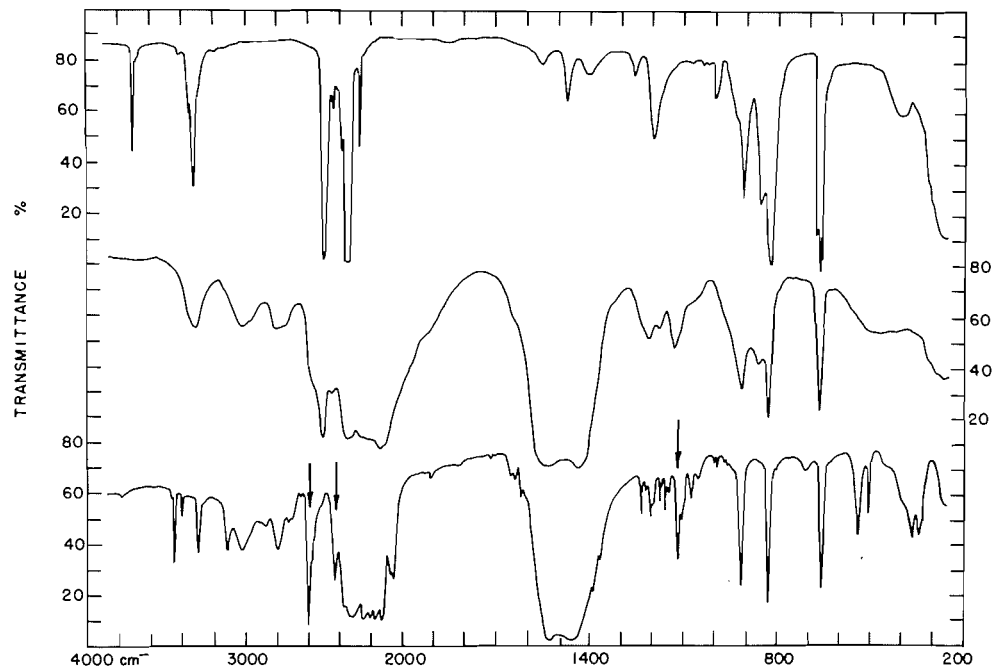

FIG. 2. Infrared spectra of ND_3/CO_2 = 2.0 system at −190°C. Top spectrum, initial; central spectrum, after warming to −75°C; lower spectrum, after warming to −40°C. Arrows indicate characteristic $\nu(ND_2)$ and $\delta(ND_4^+)$ absorption bands.

and 3300 cm^{-1} as well as a broad single peak at about 1470 cm^{-1}. Corresponding peaks in the crystalline sample are identified in Table 1 and in Figs. 1 and 2. Other peaks in the amorphous spectra were at ~3000, 1680, 1620, 1530, 1110, 826, ~730, 665, 570, and ~460 cm^{-1}.

If the Type I species is not an amorphous ammonium carbamate as was originally suggested (2), then it must be an unstable precursor of the final reaction product. Since several unstable ammoniates of water (4) and of sulfur dioxide (5) are known, it is reasonable to expect this precursor to be an ammoniate of CO_2. In view of the ease (−80°C for NH_3 and −40°C for ND_3) with which proton-transfer took place to change this precursor into the final product, this complex must be $(NH_3)_2CO_2$. Here, the two ammonia molecules may not be equivalent just as in the case of $(NH_3)_2H_2O$ (4, 6). One NH_3 may be forming an NC bond causing the carbon dioxide molecule to be bent and giving rise to intense $\nu(CO_2)$ bands at 1545 and 1400 cm^{-1}. The second NH_3 molecule, on the other hand, may be only hydrogen-bonded to an oxygen atom of CO_2. According to the temperature dependence study, both isotopic diammoniates are formed at about −160°C, but there is a significant isotope effect in the transformation of this complex

to the carbamate. Water (1, 4) and sulfur dioxide (5) also form mono-and di-ammoniate complexes.

Tentative assignments of the fundamental modes of carbon dioxide diammoniate and ammonium carbamate are summarized in Table 1. The assignments for the carbamate follow those of Frasco (2) with minor modifications. In ND_3 system, bands were observed at 810 and 915 cm^{-1} whereas Frasco reported bands at 748 and 968 cm^{-1}. A transient band was detected at 970 cm^{-1} as well as at 2440, 880, 870, 622, 538, 510, 470, and 410 cm^{-1} when an ND_3/CO_2 system was warmed to −50°C, but it disappeared at −40°C when the sample changed to the carbamate. In order to identify bands due to isotopic dilution, H_2O was condensed on top of several samples of ND_3/CO_2 and exchange reactions were followed as these samples were allowed to warm to 0°C several times. Exchange reactions did occur in these samples, but the bands listed in Table 1 under the deuterium species did not appear to change their relative intensities. Hence, peaks of deuterium species with no hydrogen counter-parts listed in Table 1 presumably have their corresponding hydrogen peaks hidden by other strong bands in the spectra. Finally, the ease with which an ionic $NH_4^+NH_2CO_2^-$ sublimes at room temperature into NH_3 and CO_2 is reminiscent of room temperature sublimations of ionic $(NH_4)_2SO_3$ into NH_3, H_2O, and SO_2 (5) and of ionic $NO_2^+NO_3^-$ into gaseous N_2O_5 (7). All of these ionic solids can be pumped off readily at room temperature. Their infrared spectra, so far, have not provided any clues as to why these salts sublime so readily.

JEAN-PIERRE E. GROLIER and GEORGE C. BENSON. Can. J. Chem. **62**, 949 (1984).

Excess molar volumes, V_m^E, and excess molar heat capacities at constant pressure, $C_{p,m}^E$, have been obtained for some *n*-alkanone + *n*-alkane mixtures at 298.15 K from density and volumetric heat capacity measurements using liquid-flow techniques. The $C_{p,m}^E$ data are much more accurate than those estimated from the temperature dependence of other thermodynamic properties (excess free energies and/or excess enthalpies). The rather *unusual* composition dependence of the excess heat capacities — two minima, or W-shape curves — is most likely due to cooperative induced conformational molecular "arrangements" in these mixtures.

JEAN-PIERRE E. GROLIER et GEORGE C. BENSON. Can. J. Chem. **62**, 949 (1984).

Les volumes d'excès, V_m^E, et les capacités calorifiques d'excès, $C_{p,m}^E$, ont été obtenus pour quelques mélanges *n*-alcanone + *n*-alcane à 298.15 K à partir de mesures des densités et des capacités calorifiques volumiques, à l'aide de techniques à écoulement de liquide. Les valeurs de $C_{p,m}^E$ ainsi obtenues sont beaucoup plus précises que celles estimées à partir de la variation, avec la température, d'autres propriétés thermodynamiques (enthalpies libres d'excès et/ou enthalpies d'excès). La variation avec la concentration des capacités calorifiques d'excès se manifeste par des formes de courbe tout à fait *inhabituelles* — deux minima ou forme en W —, ce qui traduit probablement des "arrangements" moléculaires par effets conformationnels coopératifs et induits, dans ces mélanges.

Binary *n*-alkanone + *n*-alkane mixtures have been investigated fairly extensively from a thermodynamic point of view. For our part, we have measured a number of heats of mixing, and recently we published two review papers (1, 2) analysing the information available in the literature about the thermodynamic properties of this class of mixtures in terms of a quasi-chemical group contribution model. Surprisingly, no data could be found for their heat capacities. This lack of information, and our interest in binary liquid mixtures having an *n*-alkane as one component and a simple organic compound as the other, prompted us to investigate the excess molar heat capacity at constant pressure, $C_{p,m}^E$, of *n*-alkanone + *n*-alkane mixtures. $C_{p,m}^E$ is of importance since it is related to the structures of the pure component liquids and their variation when the liquids are mixed.

The present paper reports $C_{p,m}^E$ and excess molar volumes, V_m^E, both at 298.15 K, for binary mixtures of methylethylketone (MEK, or 2-butanone) with *n*-heptane, *n*-dodecane, and *n*-tetradecane, and of diethylketone (DEK, or 3-pentanone) with *n*-heptane. In addition, V_m^E is reported for MEK + *n*-decane at 298.15 K.

Experimental

Component liquids

Sources of the primary materials were as follows: methylethylketone and diethylketone (Certified Grade reagents) from Fisher Scientific Co., *n*-heptane (stated purity ≥ 99.5 mol%), *n*-decane (stated purity ≥ 99 mol%), *n*-dodecane (stated purity ≥99 mol%), and *n*-tetradecane (stated purity ≥ 99.5 mol%) from Fluka. The two ketones were purified chromatographically using a column packed with Chromosorb P (60/80 mesh) containing 25 mass % Apiezon L. The alkanes were used without further purification. Prior to the experimental measurements, the component liquids were carefully dried with molecular sieve beads (Union Carbide Type 4A) from Fluka.

Density and heat capacity measurements

Binary mixtures were prepared by weighing. Densities, ρ, of the pure liquids and their mixtures were determined with a vibrating-tube densimeter (3) from Sodev (Model 02D). Before each series of measurements, the instrument was calibrated using a vacuum and degassed doubly distilled water: ρ(298.15 K) = 997.047 kg m^{-3} (4). Excess molar volumes

$$[1]\quad V_m^E = V_m - xV_1 - (1-x)V_2$$

were obtained from the density ρ of the mixture according to the relation

$$[2]\quad V_m^E = xM_1(\rho^{-1} - \rho_1^{-1}) + (1-x)M_2(\rho^{-1} - \rho_2^{-1})$$

where V_i, M_i, and ρ_i denote respectively the molar volume, molar mass, and density of pure component i (1 for *n*-alkanone, 2 for *n*-alkane), and x is the mole fraction of *n*-alkanone.

Heat capacities per unit volume, $C_{p,m}/V_m$, were determined with a Picker flow microcalorimeter (5, 6) from Setaram using the stepwise procedure (6, 7). Excess molar isobaric heat capacities were calculated from the molar heat capacities, $C_{p,m}$, for the mixture, and $C_{p,i}$ for the components using the equation

$$[3]\quad C_{p,m}^E = C_{p,m} - xC_{p,1} - (1-x)C_{p,2}$$

Details of the experimental techniques and of the accuracy attainable for non-electrolyte mixtures may be found in previous publications; see, for example, refs. 7 and 8.

Results and discussion

Experimental results for the pure substances are summarized in Table 1, where some literature values (9–17) are given for comparison. Although small discrepancies are evident between the results from different sources, the overall agreement is satisfactory and attests to the reliability of our experimental techniques.

V_m^E and $C_{p,m}^E$ for the mixtures are listed in Table 2. Graphical representations of these results are shown in Figs. 1–3. For each mixture, the excess quantities were fitted by the method of unweighted least-squares with a smoothing polynomial of the type

$$[4] \quad Q^E = x(1 - x) \sum_{i=0}^{n-1} A_i(1 - 2x)^i$$

where Q^E is either V_m^E/(cm^3 mol^{-1}) or $C_{p,m}^E$/(J K^{-1} mol^{-1}). The coefficients A_i and the corresponding standard deviations $s(Q^E)$ are given in Table 3. These coefficients were used to calculate the curves shown in Figs. 1–3.

As expected from the excess molar enthalpies (18), the excess molar volumes (Fig. 1) for MEK with *n*-alkanes are more positive than for DEK with the corresponding *n*-alkane. Also, for a given *n*-alkanone, the excess molar volumes become more positive as the length of the *n*-alkane increases.

The only V_m^E data at 298.15 K found in the literature are those

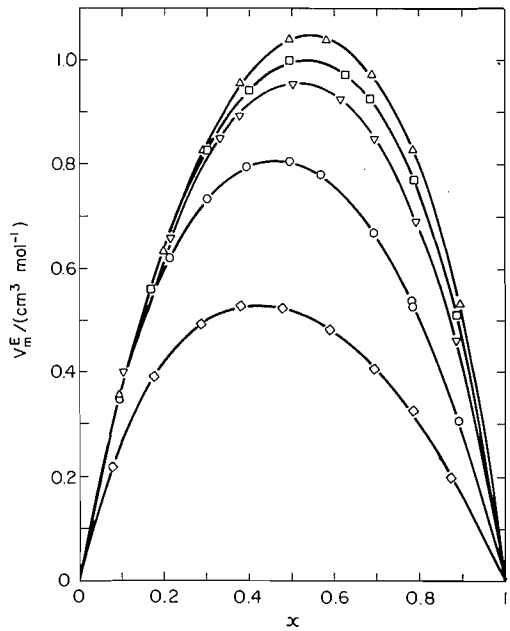

FIG. 1. Experimental excess molar volumes, V_m^E, at 298.15 K for $x CH_3COC_2H_5 + (1 - x)C_nH_{2n+2}$: ○, $n = 7$; ▽, $n = 10$; □, $n = 12$; △, $n = 14$; and for $xC_2H_5COC_2H_5 + (1 - x)C_7H_{16}$: ◇. The curves were calculated from eq. [4] with coefficients from Table 3.

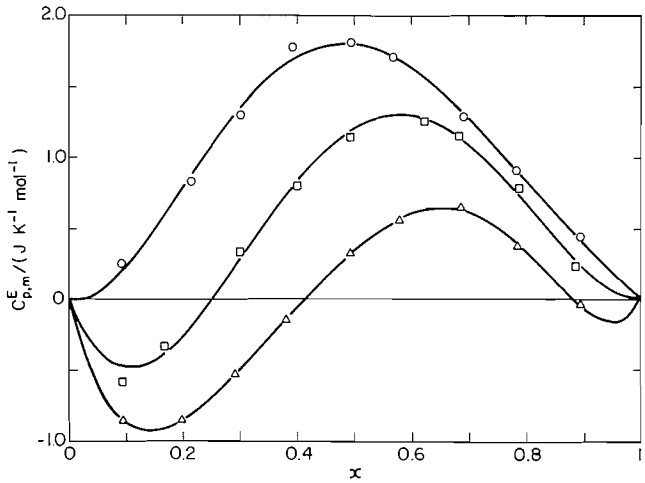

FIG. 2. Experimental excess molar isobaric heat capacities, $C_{p,m}^E$, at 298.15 K for $x CH_3COC_2H_5 + (1 - x)C_nH_{2n+2}$: ○, $n = 7$; □, $n = 12$; △, $n = 14$. The curves were calculated from eq. [4] with coefficients from Table 3.

of Rhim *et al.* (19) and Dusart *et al.* (20) for MEK + *n*-heptane, and those of Messow *et al.* (21) for MEK + *n*-dodecane. Rhim *et al.* obtained V_m^E from pyconometric measurements of densities; Dusart *et al.* used a vibrating-tube densimeter similar to ours. A comparison with these two sets of data is given in Fig. 4, where deviations from the representation of our results for MEK + *n*-heptane by eq. [4] are plotted. In general, the results of Rhim *et al.* are lower than ours with deviations of more than 5% occurring for $x > 0.7$. On the other hand, the V_m^E reported by Dusart *et al.* are higher than our results, particularly for $x < 0.5$. The V_m^E curve reported by Messow *et al.* (21) for MEK + *n*-dodecane (not shown here) falls below our curve and corresponds to relatively large deviations from our results over most of the concentration range.

No direct measurements of excess molar heat capacities

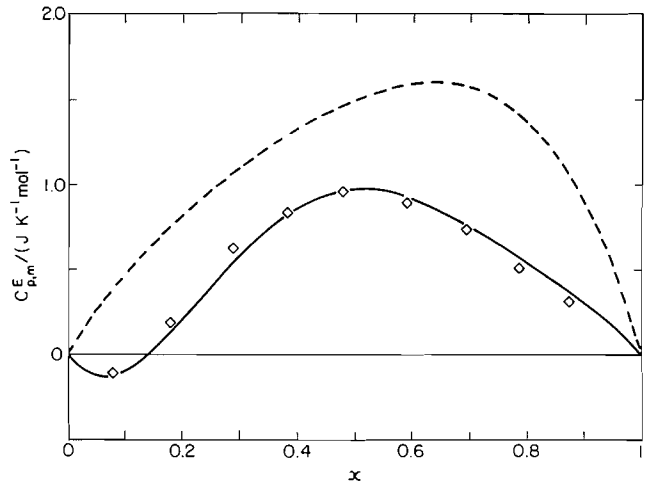

FIG. 3. Experimental excess molar isobaric heat capacities, $C_{p,m}^E$, at 298.15 K for $xC_2H_5COC_2H_5 + (1 - x)C_7H_{16}$: ◇. The full curve was calculated from eq. [4] with coefficients from Table 3. The broken curve represents $(\partial H_m^E/\partial T)_p = C_{p,m}^E$ at 298.15 K, estimated from the H_m^E data of Geiseler and Köhler (22).

could be found for any of the systems investigated here. However, Geiseler and Köhler (22) measured excess molar enthalpies, H_m^E, of DEK + *n*-heptane at 10 K intervals from 283.15 to 313.15 K. From their results we estimated values of $(\partial H_m^E/\partial T)_p = C_{p,m}^E$ at 298.15 K. These give no indication of a sigmoid variation with concentration (see Fig. 3) and are almost two times larger than our experimental results. This is not unexpected in view of the small number and scatter of the primary H_m^E data. It is well established that direct calorimetric measurements of $C_{p,m}^E$ generally yield much more accurate results than those estimated from the temperature variation of H_m^E. In the latter case, results of comparable accuracy are obtained only when using H_m^E data of the highest quality.

Estimation of $C_{p,m}^E$ from a combination of H_m^E data and excess molar free energies, G_m^E, was also investigated. Following the method outlined by Van Ness (23), we used two sets of G_m^E data and one set of H_m^E data, each at a different temperature, T_i. Assuming that $C_{p,m}^E$ is independent of temperature, it can be shown that

$$[5]\quad C_{p,m}^E = \frac{\dfrac{G_m^E(T_1)}{T_1} - \dfrac{G_m^E(T_2)}{T_2} + H_m^E(T_3)\left(\dfrac{1}{T_2} - \dfrac{1}{T_1}\right)}{\ln\left(\dfrac{T_2}{T_1}\right) + T_3\left(\dfrac{1}{T_2} - \dfrac{1}{T_1}\right)}$$

Data are available in the literature for the G_m^E of MEK + *n*-heptane (24, 25), of MEK + *n*-dodecane (21, 26) and of DEK + *n*-heptane (22). Unfortunately they are at temperatures from 20 to 55 K above 298.15 K. The data used for H_m^E at 298.15 K (21, 27, 28) are relatively more reliable, but estimates of $C_{p,m}^E$ obtained from eq. [5] are unrealistic; thus for an equimolar mixture $C_{p,m}^E$ $(x = 0.5)$/(J K^{-1} mol^{-1}) = −34.8, 3.0, and −3.2 for the three systems, respectively, as compared to 1.80, 1.20, and 0.97 calculated from eq. [4].

The most interesting and intriguing feature of the present results is the unusual composition dependence of $C_{p,m}^E$. A broad positive maximum is observed in the central range of concentration with a point of inflexion on each side of this range. These two inflexions eventually become two distinct minima when the chain length of the *n*-alkane is increased. This behav-

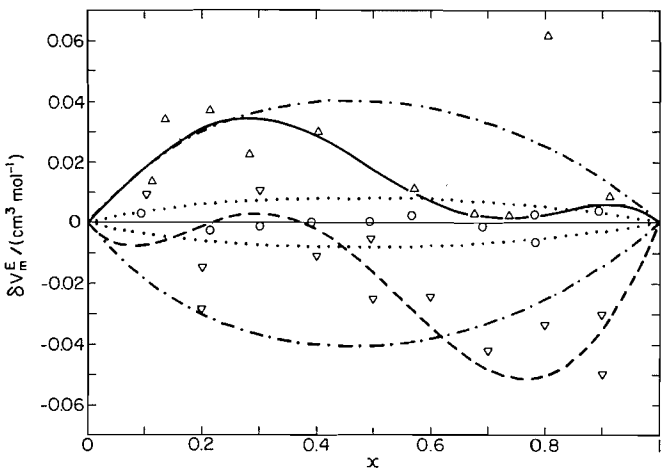

FIG. 4. Comparison of excess molar volumes, V^E_m, at 298.15 K for $x CH_3COC_2H_5 + (1-x) C_7H_{16}$. Plot shows $\delta V^E_m = V^E_m$(expt.) − V^E_m (eq. [4]): ○, present results; ▽ and - - -, Rhim *et al.* (19); △ and ——, Dusart *et al.* (20). The curves ··· and ·-·-· indicate deviations of ±1% and ±5%, respectively.

ior, more pronounced in the case of MEK (Fig. 2) than DEK (Fig. 3), is reported here for the first time for mixtures containing *n*-alkanones. The present results, as well as those reported recently for other mixtures showing a similar composition dependence of $C^E_{p,m}$, provide evidence of possible cooperative induced conformational "arrangements" in mixtures of certain types of molecules with aliphatic hydrocarbons. Previously $C^E_{p,m}$ curves with two minima were observed for 1,4-dioxane + *n*-alkane mixtures (14, 29); the two minima were more marked for longer *n*-alkanes (as for the present mixtures) and the more prominent minimum was situated at small mole fractions of the cyclic ether. A W-shaped $C^E_{p,m}$ curve was also observed for 2,5,8-trioxanonane + *n*-heptane mixtures (30), the more prominent minimum again being situated at small mole fractions of the ether. In addition, similar behavior was reported for 1,4-dioxane + cyclohexane mixtures (31) but was not observed for oxane + cyclohexane (31). In the former mixture, the more prominent minimum again occurs at small mole fractions of the cyclic ether.

A more detailed discussion will be possible when other different organic liquids have been studied in mixtures containing an *n*-alkane or cyclohexane. The present $C^E_{p,m}$ data will be useful for a reevaluation of the energy parameters used for calculating the main thermodynamic properties of *n*-alkanone containing mixtures in terms of the general quasi-chemical group contribution theory (1, 2, 32).

The carbon acid 1-(4-nitrophenyl)-1-nitroethane reacts with phenyltetramethylguanidine in the aprotic solvents acetonitrile, benzonitrile, and chlorobenzene in a bimolecular proton transfer reaction. The primary isotope effects, k_H/k_D, for these reactions at 25°C are 8.5 ± 0.4, 6.1 ± 0.4, and 16 in acetonitrile, benzonitrile, and chlorobenzene respectively. The magnitude of the isotope effects on the enthalpy of activation ($\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger}$) are 2.3 ± 0.2, 1.6 ± 0.7, and 4.2 ± 0.6 kcal mol^{-1}, which indicates a contribution from proton tunnelling to the reaction rate of the normal substrate.

ARNOLD JARCZEWSKI, PRZEMYSLAW PRUSZYNSKI, MOHAMMED KAZI et KENNETH T. LEFFEK. Can. J. Chem. **62**, 954 (1984).

La carbone acide du (nitro-4 phényl)-1 nitro-1 éthane réagit avec la phényltétraméthylguanidine dans les solvants aprotiques, acétonitrile, benzonitrile et chlorobenzène, par une réaction de transfert de proton bimoléculaire. Les effets isotopiques primaires, k_H/k_D, pour ces réactions effectuées à 25°C sont respectivement 8,5 ± 0,4, 6,1 ± 0,4 et 16 pour les réactions dans l'acétonitrile, le benzonitrile et le chlorobenzène. Les amplitudes des effets isotopiques sur l'enthalpie d'activation ($\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger}$) sont 2,3 ± 0,2, 1,6 ± 0,7 et 4,2 ± 0,6 kcal/mol; ceci indique qu'il y a une contribution de l'effet tunnel du proton à la vitesse de réaction du substrat normal.

[Traduit par le journal]

Introduction

Proton transfer reactions from carbon acids to bases of various strength and steric hindrance in polar aprotic solvents show considerably smaller values of the primary kinetic isotope effect, k_H/k_D, relative to those found in nonpolar solvents (1, 2). This was attributed (1, 2) to an increase in the effective mass of the transferred proton in the polar solvents, reflecting the motion of large solvent molecules in the reaction path from the initial to the transition state, particularly for ionogenic reactions with more ordered transition states than initial states. However, the value of k_H/k_D found for such systems frequently exceeded the standard value of 7 which is predicted by the assumption of the complete loss of the carbon–hydrogen stretching vibration during the activation process. This was interpreted as a significant contribution from tunnelling to the reaction rate (1–13).

In a case where the steric hindrance to proton abstraction was very great, the reaction between 1-(4-nitrophenyl)-1-nitroethane with the strong base, 2,7-dimethoxy-1,8-bis(dimethylamino)naphthalene, first-order kinetics were observed with no dependence on the base concentration (11). This was explained as a two-step proton transfer reaction to the highly hindered base where the first step, the ionization of the carbon acid, was rate determining.

For the reaction of 1-(4-nitrophenyl)-1-nitroethane and the base phenyltetramethylguanidine (PTMG), which involves appreciable but not excessive steric crowding in the base molecule, it was expected to show second-order kinetics and large isotopic rate ratios arising from a narrow potential energy barrier. Phenyltetramethylguanidine is a weaker base than tetramethylguanidine and there is no hydrogen atom present at the nitrogen of the imino group to allow the isotopic "scrambling effect" observed by Rogne (4), who asserted that the reversibility of the proton–deuteron transfer reaction in the case of the reaction of the deuterated carbon acid with normal TMG was the cause of the very high values of k_H/k_D found for several reactions with TMG base. Therefore, the present investigation attempts to provide a measure of the isotope effects free from this uncertainty, with an enhanced contribution from steric hindrance of the base to the isotope effect. The carbon acid 1-(4-nitrophenyl)-1-nitroethane is very similar to the 4-nitrophenylnitromethane used by Caldin and Mateo (1, 2) and by Rogne and co-workers (4–7), except that the additional methyl group adds to the steric hindrance to proton transfer, so this system serves as a general check of the extensive studies carried out with the methane acid.

Results and discussion

The reaction of 1-(4-nitrophenyl)-1-nitroethane with phenyltetramethylguanidine in chlorobenzene, acetonitrile, and benzonitrile solvent gives a product with a single absorption peak at λ_{max} 478 nm, 525 nm, and 520 nm respectively. These maxima show the same type of solvent dependence as observed by Caldin and Mateo (1) for the proton transfer from 4-nitrophenylnitromethane, and the position of the maximum in acetonitrile is very similar to our previous studies of proton transfers from the ethane to other nitrogen bases in the same solvent (11, 12). The equilibrium constants, K, and molar absorptivity, ϵ, were determined by fitting the change in optical density, O.D., with base concentration [B], to eq. [1]

$$[1] \quad [A]/O.D. = 1/K\epsilon[B] + 1/\epsilon$$

The acid concentration, [A] was maintained constant at a level very much smaller than the base [B]. Equation [1] is derived with the assumption that the product is an ion-pair. Good linear plots of [A]/O.D. vs. 1/[B] were obtained, indicating that the reaction is well represented by eq. [2].

[2] 
The intercept of the plots yielded a molar absorptivity, ϵ, of 10 000 $dm^3\ mol^{-1}\ cm^{-1}$ and the slopes gave equilibrium constants for the reaction at 20°C of 3 $dm^3\ mol^{-1}$ in chlorobenzene, 40 $dm^3\ mol^{-1}$ in benzonitrile, and 300 $dm^3\ mol^{-1}$ in acetonitrile. These equilibrium constants are smaller than those observed for the same acid reacting with 1,8-diazabicyclo-[5.4.0]undec-7-ene (DBU) which has a K about 50 times larger in acetonitrile solvent (12), reflecting the fact that PTMG is a weaker base than DBU.

The rate constants for the reaction of 1-(4-nitrophenyl)-nitroethane and its deuterated analogue with PTMG in the three solvents are shown in Table 1, together with the isotopic rate ratios. The second-order rate constants were the calculated slopes of plots of the pseudo first-order rate constant k_{obs}, versus base concentration. The second-order rate constants were obtained by a linear least-squares calculation and are quoted with their standard deviations. The observed rate constants were a function of base concentration according to eq. [3] except for the deuterated substrate in chlorobenzene

$$[3]\quad k_{obs} = k_f[B] + k_b$$

solvent, where the experimentally determined relationship was eq. [4].

$$[4]\quad k_{obs} = k_f[B]$$

Melander and Saunders (14) have shown that eq. [4] may be derived for the deuteron transfer when the concentration of exchangeable protons is large compared to the initial concentration of the carbon acid. Under these conditions the reverse reaction of the carbanion to produce the deuterated carbon acid may be neglected. This situation may apply in the present reactions when the equilibrium constant is small and when even a very small amount of adventitious moisture will be sufficient to bring about complete and rapid exchange of the deuterium in the carbanion ion-pair. Even with the greatest care to exclude adventitious moisture, it was not possible to observe in chlorobenzene the dependence shown in eq. [3]. Thus, the rate constant for the reverse reaction could not be determined, although the deuterium exchange does not affect the determination of the rate constant for the forward reaction.

The second-order rate constant for the normal substrate in chlorobenzene solvent is very difficult to determine with precision. Since the equilibrium constant in this solvent is only 3 $dm^3\ mol^{-1}$, the slope of the plot of k_{obsH} vs. base concentration is small and the intercept (k_b) is comparatively large. The values of k_{obsH} therefore change very slowly with base concentration, so that the ±2% precision (at best) of the stopped-flow spectrophotometer yields a scatter in k_{obsH} which is reflected in a very large standard deviation in k_{fH}. This problem does not exist for the deuterated substrate which follows eq. [4]. The rate ratios, k_K/k_D, in chlorobenzene solvent are believed to be reliable to about ±3.

Since the equilibrium constant in the other two solvents is larger, the effect of deuterium exchange is not so pronounced. However, a test of its importance may be made by comparing the equilibrium constants, determined by k_f/k_b for the normal and deuterated substrate. If these differ by more than a few percent, exchange is indicated.

If exchange is negligible, eq. [3] is obeyed and the ratio k_f/k_b gives the true equilibrium constant. If exchange is taking place, then k_{obs} will follow neither eq. [3] nor eq. [4] but some combination of the two. In this case the k_b value will be spuriously low for the deuterated compound. The results in Table 1 show that in acetonitrile k_f/k_b for the normal compound is 320 at 20°C, in good agreement with the value of 300 from the equilibrium measurements, whereas k_f/k_b for the deuterated substrate is 660. Thus it is concluded that the k_{bD} values contain a significant error due to deuterium exchange. The good agreement between the value of k_f/k_b for the normal substrate and the K determined from equilibrium measurements shows that eq. [2] is a good description of the reaction, i.e. decomposition of the ion-pair product other than to substrate and base is negligibly small.

In benzonitrile solvent, k_f/k_b for the protium substrate is 44 at 20°C, in good agreement with K determined from equilibrium measurements. However, k_f/k_b for the deuterated analogue is abnormally low.

The reaction in all three solvents is second-order, indicating that phenyltetramethylguanidine is not sufficiently sterically hindered to bring about the first-order kinetics observed with 2,7-dimethoxy-1,8-bis(dimethyl-amino)naphthalene (11).

The kinetic isotope effects confirm that the proton transfer is rate determining, although the rate ratios do not follow the expected order with respect to solvent polarity (1). Large isotope effects are expected in solvents of low polarity, but benzonitrile, while less polar than acetonitrile, shows a slightly smaller isotopic rate ratio. The reaction does show a large effect, k_H/k_D about 16 to 25°C, in chlorobenzene. However, this value is much smaller than the 50 ± 8 observed by Caldin and Mateo (1) for the reaction 4-nitrophenylnitromethane with tetramethylguanidine in chlorobenzene. The value of 16 at 25° is generally in agreement with the maximum values observed by Rogne and co-workers for various reactions (4–7, 15).

The activation parameters derived from the rate constants collected in Table 1 are shown in Table 2. The enthalpy of activation is largest in benzonitrile and smallest in chlorobenzene solvent, an effect which is overcompensated by the entropies of activation so that the second order rate constant is also largest in benzonitrile and smallest in chlorobenzene. It is not possible to account for this behaviour from these data above, but it is interesting to note that Caldin and Mateo found the same qualitative relation in these three solvents for $\Delta H^{\ddagger}$ and also observed a rate reversal between acetonitrile and benzonitrile, for the reaction 4-nitrophenylnitromethane and tetramethylguanidine (1). Their more extensive study of solvent dependence showed that the above observations were scatter within a general semiquantitative correlation of the rate constants (and $\Delta H^{\ddagger}$) with the dielectric constant of the solvent.

Although the isotopic rate ratios are smaller than those observed by Caldin and Mateo (1), the isotope effects on the enthalpy of activation are about the same, within experimental error. Thus it is concluded that tunnelling is important in the proton transfer from 1-(4-nitrophenyl)-1-nitroethane, as it is in proton transfer from 4-nitrophenylnitromethane.

Thus nearly all of the general observations of the kinetics of

the proton transfer from 4-nitrophenylnitromethane to TMG found by Caldin and Mateo (1) have closely parallel features in the present study. The major exception is the very large primary kinetic isotope effect, k_H/k_D up to 50, observed in chlorobenzene and other solvents of low polarity. Rogne and co-workers (7) have reported a k_H/k_D of 13.7 ± 0.4 at 25°C for 4-nitrophenylnitromethane and PTMG in toluene and Kresge and Powell found 14.2 ± 0.2 and 13.8 ± 0.2 at 25°C for the same acid reacting in toluene with TMG and PTMG respectively (9), calculated from a primary tritium isotope effect. If the later rate constant measurements of Caldin *et al.* (10) are interpreted according to eq. [4] derived by Melander and Saunders (14), a good fit is obtained which yields a significantly higher value of k_D and a lower k_H/k_D by about 30%. Such a reinterpretation, on the reasonable assumption that deuterium exchange cannot be avoided, would reduce the isotope effect reported by Caldin and Mateo from a k_H/k_D of 45 to about 30.

Notwithstanding this, the present study clearly confirms the reports of Rogne and co-workers (7) and Kresge and Powell (9) that primary deuterium isotope effects of these nitroalkanes reacting with guanidine bases in solvents of low polarity are only slightly larger than those in more polar solvents.

Experiments

Materials

1-(4-Nitrophenyl)-1-nitroethane and its α-deuterated analogue were prepared as previously described (11).

The solvents were prepared by standard methods (1), carefully dried, and distilled. They were always purified immediately before use in the kinetic runs.

Phenyltetramethylguanidine was prepared by the method of Bredereck and Bredereck (16) using tetramethylurea, $POCl_3$, and aniline. The reaction was carried out in benzene solvent.

Equilibrium constant measurements

The absorbance at equilibrium for a series of reaction mixtures with constant acid concentration and various base concentrations, always in large excess, was determined using uv−vis spectrophotometers fitted with thermostated cells. The results fitted eq. [1] and did not fit the analogous equation derived on the assumption that the product exists as free ions.

Kinetic measurements

The kinetic measurements were carried out under pseudo first-order conditions with the base concentration in large excess. The solutions of the carbon acid and the deuterated carbon acid were always freshly prepared using freshly distilled solvent and were kept under a nitrogen atmosphere. The reaction rates were measured with a stopped-flow spectrophotometer using the standard technique previously described (17) except for the reaction in chlorobenzene solvent for which a standard spectrophotometer was used with a slave pen recorder. A sample run is given in Table 3. The kinetic runs were analyzed by the Guggenheim method (18), except that the runs in chlorobenzene were also analyzed using the infinity readings. Generally, the rate constants obtained from the two methods differed by a few percent, although there was no systematic variation. The rate constants quoted are those obtained by the Guggenheim method.

We have studied the infrared spectra of Nafion membranes in twenty different cationic forms, in order to characterize the water–anion–cation interactions at low water contents. Spectra in the OH stretching region and in the H—O—H bending region allow the distinction between hydrogen-bonded and non-hydrogen-bonded water molecules, and yield information on the mode of attachment of water molecules to the anion–cation pairs. When there is a good match between the Lewis acid strength of the cation and the Lewis base strength of the anion, ion pairs are relatively stable and water molecules tend to attach on the outside. When the acid strength of the cation and the base strength of the anion are mismatched, as is the case for small cations of high charge or for large cations of low charge, water molecules tend to be inserted between the ion pairs even at the lowest water contents.

SYLVIO QUEZADO, JAN C. T. KWAK et MICHAEL FALK. Can. J. Chem. **62**, 958 (1984).

Nous avons étudié les spectres infrarouge de vingt formes cationiques différentes de membranes de Nafion, afin de caractériser les interactions eau–anion–cation à basses teneurs d'eau. Les spectres dans la région des vibrations de valence OH et aussi dans la région des vibrations de déformation H—O—H nous permettent de distinguer entre les molécules d'eau liées et non-liées par liaison hydrogène et de constater le mode d'attachement de H_2O aux paires d'ions. Quand il y a équilibre entre l'acidité Lewis du cation et la basicité Lewis de l'anion, les paires anion–cation sont relativement stables et les molécules d'eau tendent à s'attacher à l'extérieur. Quand il y a déséquilibre, comme dans le cas de petits cations de haute charge ou de gros cations de faible charge, les molécules d'eau tendent à s'introduire entre le cation et l'anion.

Introduction

Nafion is an ion-containing polymer whose physical properties are of considerable interest in connection with the use of Nafion membranes as electrochemical separators and ion-exchangers (1). Nafion consists of a perfluorinated polyethylene backbone with pendant ether-linked side-chains terminating with a sulfonate group, $—O—CF_2—CF_2—SO_3—M^+$, where M^+ represents an exchangeable cation. Water penetrates Nafion easily and resides within the ionic regions, the equilibrium water content being dependent on the nature of the cation, pre-treatment of the sample, and water activity of the surroundings (2).

The Nafion–water system offers an opportunity of examining water–ion interactions by infrared spectroscopy because (unlike in the spectra of other ion-containing polymers (3, 4)) in the Nafion spectrum the OH stretching fundamentals of the hydrogen-bonded and non-hydrogen-bonded protons of water are particularly clearly separated. This has been demonstrated in an earlier paper (5) in which the OH stretching absorption of water in Nafion has been shown to consist of distinct sub-bands corresponding to the bonded and non-bonded protons, the latter being well separated to high wavenumbers under the influence of the fluorocarbon medium. Those observations yielded information about the local environment of the water molecules and the geometry of the hydrated ion clusters (5, 6). Preliminary infrared studies of perfluorocarboxylate membranes have shown that, as in the Nafion spectrum, the bonded and non-bonded protons give rise to well-separated OH stretching bands (7).

We have now extended our infrared study to include Nafion membranes with a variety of counterions of charge one, two, and three. Our main concern has been to characterize the water–ion interactions at very low water contents. In the nearly dry membrane, when not more than one water molecule is associated with an ion pair, two principal modes of attachment may occur: the water molecules may be *inserted* between the cation and the anion (or between the cation and a pair of anions) as in Fig. 1*a*, or they may be *attached* to the cation–anion pair without disrupting the cation–anion bond as in Fig. 1*b* or 1*c*. At higher water contents the insertion mode must prevail, leading eventually to a complete dissociation of all ion pairs, in analogy with the dilute solutions of electrolytes. At low water contents, however, local situations may be present involving either *insertion* (*a*) or *attachment* without insertion (*b* or *c*), depending on the relative affinity of the cations, anions, and water molecules for one another. In the case of insertion both water protons would be hydrogen bonded, while in the case of attachment one or both protons might be exposed to the fluorocarbon medium. This situation may be expected to give rise to spectroscopically distinguishable doubly-bonded, singly-bonded, and non-bonded water molecules. With this expectation we have examined the trends that occur in the spectrum of water at low water content when the nature, size, and charge of the counterion in Nafion is varied.

Experimental

The Nafion membranes used were of type 142 E, which corresponds to a thickness of 51 μm and equivalent weight of 1400 g per mol of SO_3^-. The samples were supplied by the manufacturer (Du Pont de Nemours and Co.) in the acid form. In accordance with a standard procedure, the samples were boiled in distilled water for half an hour, neutralized by immersion in aqueous salt solution of the desired cation for another half an hour, rinsed in distilled water, wiped with filter

paper, and stored in stoppered glass containers. Completeness of cation exchange was verified by the disappearance of the infrared absorption bands of the acid form of Nafion (6).

Infrared spectra corresponding to Figs. 2, 3, and 10 and Tables 1 and 2 were measured on a Perkin-Elmer grating infrared spectrophotometer model 180. In these measurements the water content was controlled by placing the sample in a closed chamber through which moist air with a controlled H_2O/D_2O ratio was circulated. For D_2O measurements a matching undeuterated sample was placed in the reference beam to compensate the absorption at about 2360 cm^{-1} due to an overtone of the C—F stretching mode.

All other infrared spectra were measured in the range 4000–800 cm^{-1} on a Bomem DA3.02 Fourier transform infrared spectrophotometer. Usually 64 interferograms were coadded, which required about 1.5 min, and the Fourier transform was calculated at an apodized resolution of 2 cm^{-1}. Peak wavenumbers were measured visually on the video display by using the cursor position. The membranes were placed inside the sample compartment which was then evacuated. Different evacuation times were used to obtain different water contents. Examination of successive spectra confirmed that the water content of the samples remained very nearly constant during the coadding of interferograms.

Water content was calculated from the band area of the HOH bending fundamental (6). Low water contents for the salts of the divalent and trivalent cations could only be achieved by heating the samples in vacuum at 100°C to 160°C for periods of 24 h or longer.

Results and discussion

OH stretching of HDO at low water contents

Spectra of isotopically dilute HDO were studied for the five alkali metal salts and four alkaline earth metal salts of Nafion listed in Table 1. Figure 2 shows the region of the OH stretching fundamental for the five alkali metal salts at low water content. All five spectra can be seen to contain two bands, *A* at 3680 ± 10 cm^{-1} and *B* at 3522 ± 8 cm^{-1}. Their halfwidths are of the order of 200 cm^{-1} for band *B* and 25 cm^{-1} for band *A*, values typical for hydrogen-bonded and non-hydrogen-bonded OH protons in condensed phases, respectively.[3] Spectra of Mg, Ca, Sr, and Ba salts of Nafion (not shown) are very similar, with the relative intensity of band *A* greater than for the Li salt. The positions of bands *A* and *B* (Table 1) differ only slightly from Li to Cs and again from Mg to Ba. The intensity ratio of the two bands, on the other hand, varies considerably: relative intensity of band *A* increases in the series Cs to Li and increases still further for the alkaline earth salts.

TABLE 1. Observed peak positions (cm^{-1}) in the OH stretching region of the spectrum of isotopically diluted HDO (85% D, 15% H) in the alkali and alkaline earth metal salts of Nafion at low water content (about 1 water molecule per $—SO_3^-$)

Counterion	Band A	Band B

[e] Not observed due to overlap with ν_1(BB).
[f] Position uncertain due to overlap with ν_1(BB).

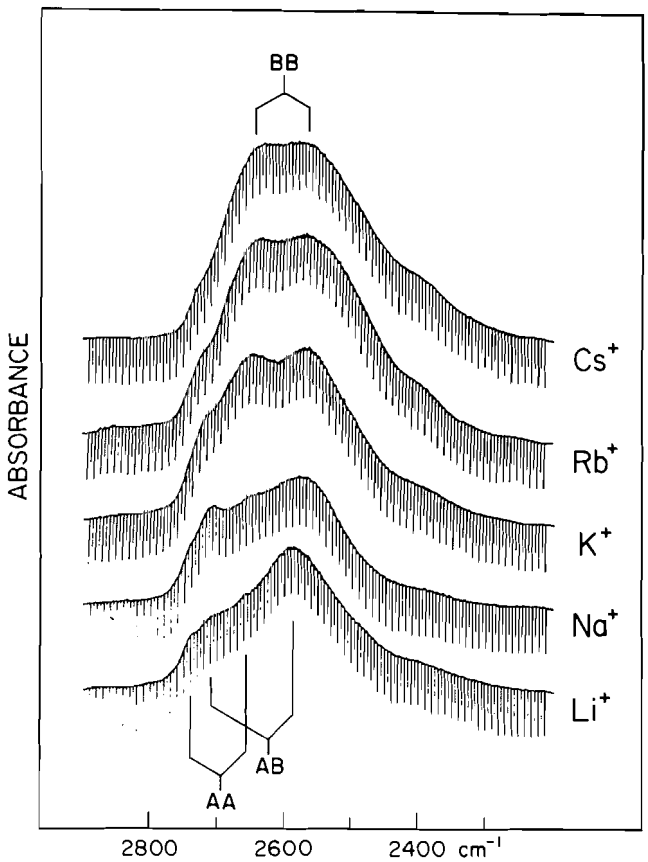

FIG. 3. The OD stretching region of D_2O in the spectra of alkali metal salts of Nafion. Water content and H/D ratio as in Fig. 2.

In the following, as in ref. 5, we shall associate band *A* with the protons exposed to the fluorocarbon medium, OH . . . CF_2, and band *B* with the protons participating in O—H . . . O hydrogen bonds. At low water contents the hydrogen-bond acceptors must be preponderantly the oxygen atoms of the sulfonate anions.

Assignment of H_2O and D_2O stretching fundamentals

As discussed in ref. 5, spectra of H_2O and D_2O in Nafion salts in the region of the stretching fundamentals are more complex than the corresponding spectra of HDO. Assuming the existence of two spectroscopically distinct proton environments, A and B, there should be three types of water molecules, labelled AA, BB, and AB, and these should give rise to six stretching fundamentals: ν_3(AA) and ν_1(AA); ν_3(BB) and ν_1(BB); ν_A(AB) and ν_B(AB).[4]

The wavenumbers of these six bands should be related to those of the corresponding A and B bands of HDO as indicated in Fig. 6 of ref. 5. Because of band overlap and low populations of some water species, the six stretching fundamentals are never resolved completely in any one spectrum. However, a consistent set of assignments of the observed H_2O stretching bands can be made with the use of (*i*) HDO, D_2O, and H_2O spectra of each Nafion salt, (*ii*) spectral trends upon increasing the water content, and (*iii*) low-temperature spectra.

The spectra of H_2O and D_2O in the stretching region contain a contribution from the overtone of the bending vibration, $2\nu_2$, present as a shoulder at about 2400 cm^{-1} for D_2O and 3250 cm^{-1} for H_2O.

The OD stretching fundamental of D_2O at low water content

The positions of the observed bands in the spectra of D_2O in the five alkali metal salts and four of the alkaline earth metal salts of Nafion, at low water content, and their assignments in terms of AA, AB, and BB species of water are recorded in Table 2. Relative intensities of the AA, AB, and BB bands vary considerably from Li to Cs (Fig. 3). The spectrum of the Cs salt is dominated by the BB bands. These bands diminish in intensity in the series Cs, Rb, K, Na, Li. In the spectra of the Na and Li salts the AA and AB bands have become appreciably intense.

Stretching bands in the spectra of Mg, Ca, Sr, and Ba salts of Nafion (not shown) resemble those of the Li salt, with an even higher relative intensity of the AB bands. The differences between the spectral profiles in the series Mg to Ba are minor.

[4] The two stretching fundamentals of AB molecules were designated ν_1(AB) and ν_3(AB) in refs. 5 and 6. The present designation, ν_A(AB) and ν_B(AB), seems more appropriate, since the two vibration modes lie close in wavenumber to the ν_A and ν_B modes of HDO and should correspond largely to motions of the A proton and B proton, respectively.

[g] Not resolved due to overlap with ν_A(AB).
[h] Not resolved due to overlap with ν_B(AB).
[i] Observed clearly only at very low water contents (0.05 $H_2O/—SO_3^-$).

The OH stretching of H_2O at low water content

Spectra of Nafion salts in the OH stretching region of H_2O resemble the corresponding spectra of D_2O, except that the $\nu_3 - \nu_1$ wavenumber splitting is smaller for H_2O.[5] Because of smaller splitting, the bands due to ν_1(AA) and ν_3(AA) are closer together and in most cases overlap with ν_A(AB) to yield a single unresolved absorption band. Similarly, ν_1(BB) and ν_3(BB), together with ν_B(AB), tend to yield one unresolved band. On the other hand, ν_1(AA), which in the D_2O stretching spectra of most Nafion salts tends to coincide with ν_3(BB), lies some 70 cm^{-1} above ν_3(BB) in the corresponding H_2O spectra. As a result, for H_2O the three A bands, i.e., ν_3(AA), ν_A(AB), and ν_1(AA), lie above 3650 cm^{-1}, while the three B bands, i.e., ν_3(BB), ν_B(AB), and ν_1(BB), tend to lie below 3650 cm^{-1}. In this way the A and B band systems overlap much less for H_2O than for D_2O. Consequently, the relative integrated intensity contributions of the three A bands may be roughly estimated from the ratio

[1] **A** = (band area above 3650 cm^{-1})/(total band area)

The positions of the observed bands in the spectrum of H_2O at low water contents for the different salts of Nafion are recorded in Table 3, with band assignments in terms of the AA/AB/BB model.

The spectra of alkali metal salts of Nafion in the OH stretching region of H_2O at low water contents are shown in Fig. 4 (top left). As also observed for HDO and D_2O spectra of this series, the intensity of the A region of the spectrum (above 3650 cm^{-1}) decreases gradually from Li to Cs, while the intensity of the B region (below 3650 cm^{-1}) increases substantially. In addition, the H_2O spectra, like the corresponding D_2O spectra, indicate a rather large variation in the relative contributions of AA, AB, and BB absorptions along the series. The spectrum of the Cs salt has an intense BB absorption (unresolved ν_1 and ν_3), with only a small admixture of AB and an even smaller contribution of AA. The relative intensity of AB bands increases from Cs to Li. AA bands first become clearly visible in the spectrum of the Na salt and become fairly intense in the Li salt. Only the high-wavenumber ν_3(AA) band is observed in the spectrum of the Na salt while the low-wavenumber ν_1(AA) band shows up more clearly in the spectrum of the Li salt.

Figure 4 (top right) shows the spectra of four alkaline earth metal salts of Nafion in the OH stretching region of H_2O. The overall intensity of the A region in these spectra is appreciably greater than in the Li salt and the major contributor to the spectrum appears to be the AB molecules. A small, relatively sharp band at about 3620 ± 10 cm^{-1}, assigned to ν_1(AA), indicates a small contribution of AA molecules, increasing somewhat along the series from Mg to Ba. A broader band at about 3550 ± 20 cm^{-1} assigned to ν_3(BB) decreases from Mg to Ca, then increases again from Ca to Ba, indicating that the population of BB molecules may pass through a minimum. The spectrum of the Be salt of Nafion differs considerably from that of the other salts of this group and will be described below.

Figure 4 (bottom left) shows the spectra of divalent transition metal salts (Mn, Co, Ni, Cu, and Zn) of Nafion in the OH stretching region of H_2O. The spectra of Mn, Co, and Ni salts resemble closely those of the Mg–Ba series. The two major bands are due to ν_A(AB) and ν_B(AB), with much smaller bands near 3610 cm^{-1} and 3510 cm^{-1} assigned to ν_1(AA) and ν_3(BB), respectively, indicating appreciable contribution of the AA and

[5] In the vapor state $\nu_3 - \nu_1$ = 2788.1 − 2671.5 = 116.6 cm^{-1} for D_2O and 3755.8 − 3656.7 = 99.1 cm^{-1} for H_2O (8).

For personal use only.

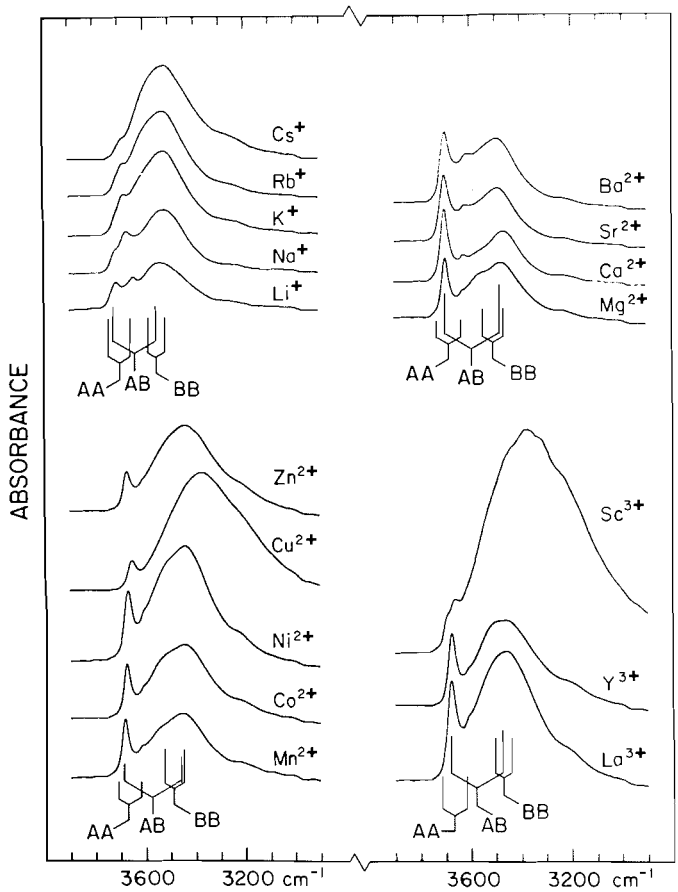

FIG. 4. The OH stretching region of H_2O in the spectra of different salts of Nafion. Water content mostly below 1 $H_2O/—SO_3^-$ (see Table 3).

BB molecules as well. The spectrum of the Zn salt shows a somewhat less intense A region and a much less intense ν_1(AA) band, while the spectrum of the Cu salt shows an even less intense ν_A(AB) band and no detectable ν_1(AA). Thus in the case of the Cu salt all the water molecules appear to be of type AB and BB. The ν_A(AB) band of the Cu salt is over 20 cm^{-1} below that in the spectra of other divalent metal salts. At the same time the center of the B absorption region, probably largely made up of ν_B(BB), centered at 3360 cm^{-1}, lies some 80 cm^{-1} below those in the spectra of the other divalent metal salts. This indicates substantially stronger hydrogen bonding, implying a stronger polarization of H_2O by the Cu^{2+} ion.

The spectra of trivalent Sc, Y, and La salts of Nafion in the OH stretching region of H_2O are shown in Fig. 4 (bottom right). The spectra of Y and La salts resemble those of the divalent salts such as Mg and Mn, the major contributor being AB molecules. That of the Sc salt, on the other hand, is distinctive in that the A region is of very low intensity and in that it contains two small bands of comparable low intensities at about 3700 cm^{-1} and 3670 cm^{-1}, assigned to ν_3(AA) and ν_A(AB). This is the only case in which AA and AB molecules appear to be present in nearly equal proportions.

The spectra of Be and Al salts of Nafion in the OH stretching region of H_2O are shown in Fig. 5. These spectra resemble each other and differ from those of the other salts in that the A region is of exceedingly low intensity, only about 2% of the total band area, and the B region is shifted to much lower wavenumbers, 3240 and 3230 cm^{-1}, respectively, for Be and Al. This attests

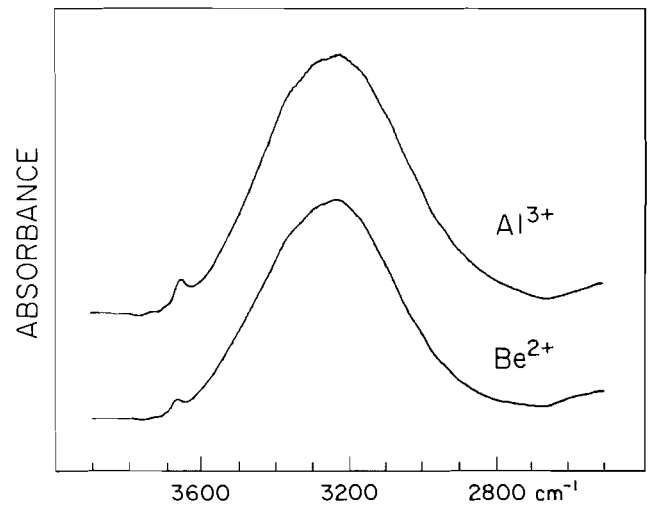

FIG. 5. The OH stretching region of H_2O in the spectra of Al and Be salts of Nafion.

to very strong hydrogen bonding brought about by a strong polarization of H_2O by these two cations.

Spectral changes with varying water content

The spectra described in the preceding sections are those corresponding to low water content, in most cases below 1 $H_2O/—SO_3^-$. Spectra obtained at still lower water contents, down to 0.1 $H_2O/—SO_3^-$ are not appreciably different. We therefore believe that our results correspond closely to the ultimate behaviour of isolated water molecules interacting with anion–cation pairs.

Changes which occur upon increasing the water content of the membranes are the same for all Nafion salts and involve increased intensity of the absorption in the hydrogen-bonded region of the spectrum, below 3650 cm^{-1}, relative to the absorption in the non-hydrogen-bonded region, above 3650 cm^{-1}. This is illustrated for the H_2O spectrum of the Li salt of Nafion in Fig. 6. It can be seen that the B region of the spectrum increases rapidly with respect to the A region. AA bands, detectable at lower water contents, become submerged at higher water contents and BB bands dominate the spectrum.

The HOH bending fundamental

An interesting finding of the present study is that for several salts of Nafion the bending fundamental of H_2O resolves into two components which clearly correspond to water molecules in structurally distinct environments. Such resolution is very rarely observed for systems containing several types of water molecules[6] and confirms that water in Nafion occurs in widely different bonding environments.

Spectra of the Li and La salts of Nafion, representative of those for which the bending fundamental resolves into a doublet, are shown for different water contents in Fig. 7. At low water contents the low-wavenumber component, *L* (at 1616 cm^{-1} for Li and 1606 cm^{-1} for La), accounts for most of the band intensity in the case of La and about one-third in the case of Li. In either case its intensity increases less rapidly with increasing water content than that of the high-wavenumber

[6] For example, in the spectra of aqueous solutions of electrolytes the bending fundamental is an unresolved singlet even in cases where the stretching fundamental is resolved into widely separated bands as with perchlorates and fluoroborates (10, 11).

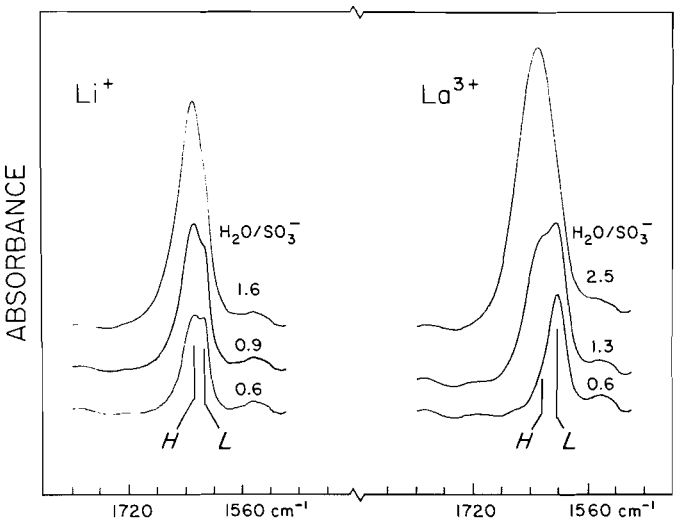

FIG. 7. The HOH bending fundamental region of H_2O in spectra of Li and La salts of Nafion at different water contents.

component, *H* (1629 cm^{-1} for Li and 1625 cm^{-1} for La), which becomes the dominant feature at high water contents. It is clear that *H* originates in more strongly hydrogen-bonded water molecules and *L* in less strongly hydrogen-bonded water molecules for the following reasons:

(*i*) Hydrogen bonding is known to raise the wavenumber of the bending fundamental of water just as it lowers the wavenumber of the stretching fundamental (9).

(*ii*) The bandwidth of component *H* is larger than that of component *L*, a characteristic of more strongly hydrogen-bonded systems.

(*iii*) Lowering the temperature (cf. Fig. 10) shifts *L* to lower wavenumbers and *H* to higher wavenumbers, as expected from the observation that strong hydrogen bonds (which tend to be

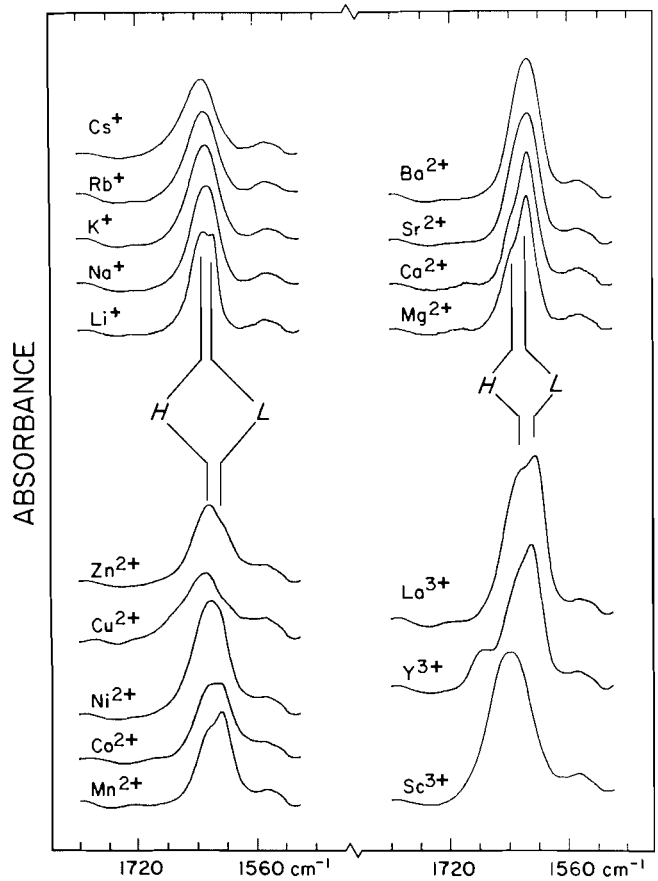

FIG. 8. The HOH bending fundamental region of H_2O in the spectra of different salts of Nafion (water content as in Table 4).

linear (12)) are strengthened at lower temperatures, while weak hydrogen bonds (which tend to be bent (12)) are weakened at lower temperatures (13).

(*iv*) At different water contents the relative areas of components *H* and *L* vary roughly in proportion to the relative band areas of water species BB and AB, respectively, in the region of the stretching fundamental.

We therefore provisionally assign component *H* to the fully hydrogen-bonded BB molecules and component *L* to the partially bonded AB molecules with a possible contribution of the non-hydrogen-bonded AA molecules. This leaves open the question why bands due to AA and AB molecules are not resolved. In the spectra of most Nafion salts studied by us the population of AA species is small, but at least in the case of the Li salt AA bands in the OH stretching region are fairly intense so that AA population must be significant. Possibly the bending fundamental of AA is not very far separated from that of AB.

In nine of the cases studied, the HOH bending fundamental did not resolve into a doublet at any water content. Lowering of temperature down to 10 K did not bring about band resolution.[7] In all cases the overall band center shifted to higher wavenumbers with increasing water content, the increase being largest for Cs and smallest for Na. This behaviour is consistent with the unresolved component *H*, corresponding to hydrogen-

[7] The bandwidths in the OH stretching and HOH bending region showed only a minor decrease from 300 K to 10 K, indicating that the factors responsible for the bandwidth are not dynamic in nature, but are probably due to a distribution of local environments of the H_2O molecule.

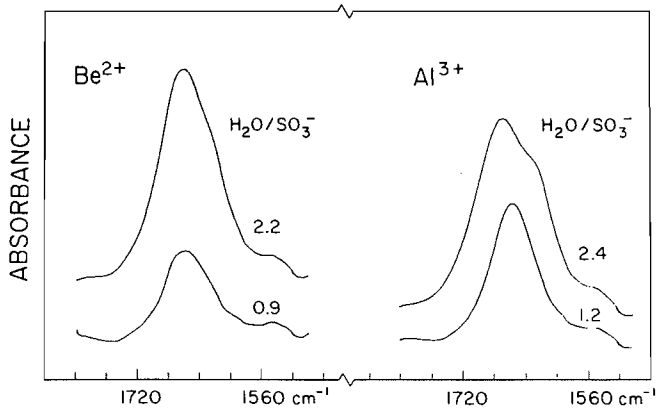

FIG. 9. The HOH bending fundamental region of H_2O in the spectra of Be (left) and Al (right) salts of Nafion at different water contents.

bonded water molecules, increasing with increasing water content in the same manner as for Li and La salts.

Spectra in the HOH bending region are shown in Fig. 8 (top left) for the five alkali metal salts of Nafion at low water content. Only the spectrum of the Li salt exhibits a resolved doublet; those of Na through Cs show broad bands, centered at 1625 cm^{-1} to 1632 cm^{-1}, which we interpret as unresolved doublets.

In the spectra of the alkaline earth salts of Nafion, shown in Fig. 8 (top right), the bending fundamental at low water content resolves into two components in the case of Mg and Ca salts, but remains unresolved for the Sr and Ba salts. For Mg and Ca, the low wavenumber component, at about 1614 cm^{-1}, is the major contributor to the band intensity at low water contents. This is consistent with the conclusion from the OH stretching spectral region that AB is the major species. Again, the relative intensity of the high-wavenumber component increases with increasing water content for Mg and Ca salts, while for Sr and Ba salts the unresolved band shifts gradually to higher wavenumbers, indicating a similar underlying increase in the proportion of the hydrogen-bonded water molecules.

The spectrum of the Be salt of Nafion is different from those of the other alkaline earth salts. Only one broad band is observed in the region of the HOH bending, centered at the unusually high wavenumber, 1660 cm^{-1} (Fig. 9, left). This clearly corresponds to strongly hydrogen bonded water molecules, and is consistent with the unusually low wavenumber of the H_2O stretching fundamental at about 3200 cm^{-1}, and the very low incidence of the incompletely hydrogen-bonded molecules — deduced from the spectrum in the OH stretching region. The center of the band at 1660 cm^{-1} is considerably above the wavenumber of the bending fundamental in pure liquid water at room temperature (about 1640 cm^{-1}). At higher water contents a new distinct band appears at about 1630 cm^{-1}. This band must be due to fully hydrogen-bonded water molecules in the outer hydration shell of the Be ion and no longer strongly polarized by the cation.

The spectra of the Nafion salts of the divalent transition metals Mn, Co, Ni, and Zn all show doublets in the HOH bending region at low water content, resolved to varying extent as shown in Fig. 8 (bottom left). In all of these the high-wavenumber component becomes more prominent at higher water contents. Relative intensity of the low-wavenumber component correlates with that of the ν_A(AB) band in the stretching region; it is dominant in the spectrum of the Mn salt and

[c] Observed only at higher water contents (see Fig. 9).

decreases in the series Mn/Co/Ni/Zn. The spectra of the Cu salt do not resemble the rest of this series; the bending fundamental is broader, the high-wavenumber component higher, and the low-wavenumber component lower than for Mn.

At low water contents the Sc salt, whose spectrum in the stretching region showed a dominant BB band, exhibits only the *H* band in the bending region (Fig. 8, bottom right). On the other hand, the Y and La salts which show large AB bands in the OH stretching region, exhibit doublets in the HOH bending region, with the *L* component dominant.

The spectra of the Al salt in the H—O—H bending region (Fig. 9, right) resemble closely those of the Be salt, again in agreement with their general resemblance in the OH stretching region.

Resolution enhancement by Fourier self-deconvolution

Because of severe band overlap it was difficult to estimate the band areas of *H* and *L* components directly even in the 11 cases where they were partly resolved in the original spectra. In order to calculate these areas we have enhanced the resolution by Fourier self-deconvolution (14). This procedure, known to preserve the band areas of individual components, diminished band overlap and thus minimized the experimental error in the area measurements. In order to diminish the error arising from the small residual band overlap, the area fraction **L** of the low-wavenumber component was obtained from the deconvolved spectra as follows:

$$[2] \quad \mathbf{L} = I_L/(I_L + I_H)$$

where I_L is the band area below the peak position of band *L* and I_H is the band area above the peak position of band *H*. **L** values are recorded in column 4 of Table 4.

For most of the nine salts with unresolved HOH bending fundamentals a clear-cut decomposition into components could

not be achieved by self-deconvolution. One exception was the spectrum of the Na salt, in which the original singlet at 1625 cm^{-1} upon self-deconvolution yielded a doublet at 1632 and 1614 cm^{-1}.

Band areas and populations of AA, AB, and BB species

The difficulties of calculating the populations of the molecular species of water in Nafion from the observed intensities of the infrared absorption bands in the OH stretching region are of three types:

(*i*) *Inadequacy of the model*. The three-species AA–AB–BB model oversimplifies the real situation in the Nafion–water system. The observed components may be themselves a mixture of further unresolved components, so that a continuum-type model might in fact be more appropriate for some purposes.

(*ii*) *Band overlap* makes it difficult to estimate the areas belonging to the individual bands. Attempts to enhance the resolution by means of Fourier self-deconvolution were not successful because of widely different widths of A and B component bands.

(*iii*) *Uncertain absorptivities*. Bands B, which originate in the hydrogen-bonded OH groups are probably at least four times as intense per oscillator as bands A (5). The exact absorptivities of the AA, AB, and BB bands are not known and could be to some extent variable: absorptivities tend to increase with decreasing wavenumbers of OH stretching, and there are considerable differences between the positions of the maxima of the B bands in the spectra of the different Nafion salts (cf. Table 3).

In view of (*ii*) and (*iii*) it is not possible to calculate very accurately the populations of AA, AB, and BB species from the intensities of the corresponding H_2O absorption bands, even within the framework of the three-species model. However, we have been able to derive rough estimates of the population fractions and these are tabulated in columns 4–6 of Table 5. These values were obtained from visually estimated relative band intensities, assuming that the integrated absorptivities of

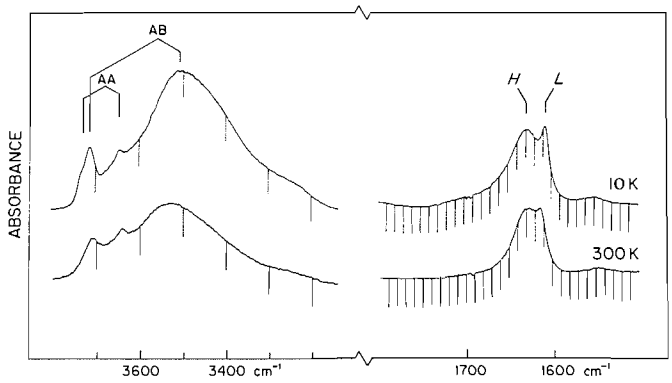

FIG. 10. The OH stretching region (left) and HOH bending fundamental region (right) of H_2O in the spectra of Li salt of Nafion. Temperatures: 10 K (top spectra) and 300 K (bottom spectra).

ν_3(AA), ν_1(AA), and ν_A(AB) are roughly equal. The necessary scaling was accomplished by assuming that AB population fractions are approximately equal to the area fraction **L** for those seven salts for which this quantity could be calculated (Table 4). This procedure was intended to ensure that the numbers within each column correctly reflect the trends for the increasing or decreasing populations of each species, even though the numbers along rows may be in error. The trends observed in this manner coincide with those set by the area fraction **A** defined by [1] and obtained directly from the spectra (column 3 in Table 5).

Mode of attachment of the water molecule to anion–cation pairs

Our results, tabulated in columns 3–6 of Table 5, show that at low water content different cationic forms of Nafion are characterized by widely different porportions of water molecules in configurations AA, AB, and BB. With the Al and Cs salts we see almost exclusively the BB configuration, while in the Ca salt the AB configuration dominates. This is interpreted to indicate that in the Al and Cs salts the water molecule is predominantly inserted between the cation and anion as depicted in Fig. 1*a*, while in the Ca salt the water molecule attaches to the ion pair largely without insertion, as in Fig. 1*b* and *c*. The results for the 20 cationic forms studied appear at first puzzling, as the trends do not simply follow the variation of ionic radius: for the monovalent cations the BB fraction *increases* with increasing ion size, but it *decreases* for the trivalent cations, while for divalent cations it varies irregularly. However, the trends we observe must reflect the tendency of an isolated water molecule to enter between an anion and a cation, and this must depend fairly specifically on anion–cation affinity. The property of anions and cations which is most intimately connected with such affinity is the *Lewis acid strength* of the cation and the *Lewis base strength* of the anion (15). The base strength of the sulfonate anion in Nafion can be approximated by that for the sulfonate anion in $CF_3SO_3^-$ salts, 0.27 ± 0.02 units (16). The best match and hence the greatest anion–cation affinity would be expected for those cations whose acid strength is also around 0.27.

The values of acid strength for the cations used in the present study are recorded in column 2 of Table 5. When the area fraction **A** (column 3) is plotted against the Lewis acid strength of the cation (Fig. 11), a clear pattern emerges: a maximum in the value of fraction **A**, indicating a minimum of water insertion between anion and cation, appears at acid strength of

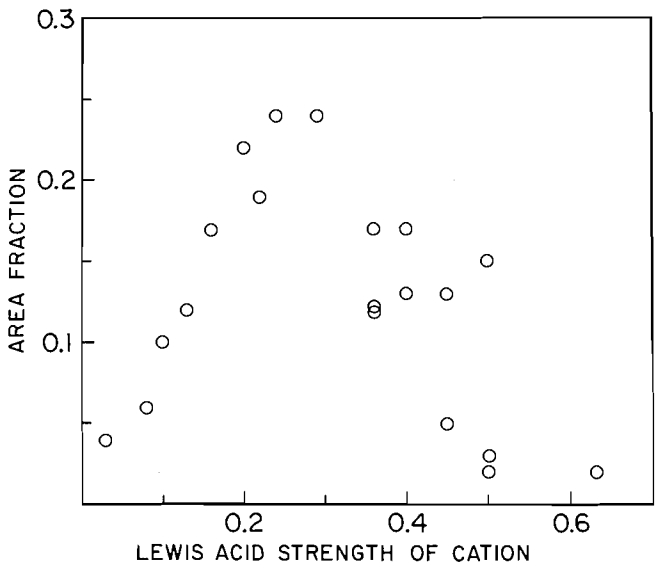

FIG. 11. Plot of the area fraction **A** against the Lewis acid strength of the cation.

about 0.26 ± 0.02 units, corresponding to the estimated base strength of the sulfonate anion in Nafion. On either side of this maximum, **A** fraction falls off rapidly, indicating increasing occurrence of insertion. Large deviations from a smooth plot are largely due to the transition-metal cations, for which highly variable acid strengths are encountered (15, 16). Very similar plots are obtained when the population fractions of columns 4–6 of Table 5 are plotted against the cation acid strength, with AA population showing a maximum at Li (acid strength ~0.22), AB population showing a maximum at Ca (acid strength ~0.30), and the BB population passing through a minimum at Sr (acid strength ~0.24).

The following picture emerges: when the anion–cation pair is relatively stable, which tends to happen when there is a good match between the acid strength of the cation and the base strength of the anion, water molecules are not inserted between the anion and the cation, but tend to be attached on the outside. When, on the other hand, the ion-pair is mismatched, there is a strong tendency for the water molecule to be inserted. Lewis acid and base strengths of cations and anions appear to be a good indicator of their affinity for each other and of the resistance of cation–anion pairs to disruption by water molecules.

Synthesis and properties of a series of linked porphyrin–quinone molecules designed as models of the reaction centre in photosynthesis[1]

TE-FU HO, ALAN R. MCINTOSH, AND ALAN C. WEEDON[2]

Photochemistry Unit, Department of Chemistry, The University of Western Ontario, London, Ont., Canada N6A 5B7

Received June 28, 1983[3]

TE-FU HO, ALAN R. MCINTOSH, and ALAN C. WEEDON. Can. J. Chem. **62**, 967 (1984).

The synthesis of the covalently linked porphyrin–quinone compounds **4***a*, **4***b*, and **4***c* is described. The structures of the linked compounds and their precursors in the synthetic route are established by ultraviolet/visible absorption spectroscopy, ^{1}H nmr, ir, and mass spectroseopy. Some of the photophysical properties of the compounds prepared are reported with reference to their use as models of the reaction centre in photosynthesis.

Introduction

The primary photochemical process in green plant photosynthesis is transfer of an electron from a photoexcited chlorophyll donor to an acceptor (ultimately a benzoquinone derivative in many cases), these two species being held together in close proximity in a reaction centre protein. Very little is known about the structural requirements for orientation of the components in the electron transfer reaction *in vivo* and there has recently been much interest in attempts to mimic the electron transfer process in model systems. These investigations include the preparation of covalently linked chlorophyll chromophores (1), of capped, bridged, and cofacially linked porphyrins (2–5), and of other molecules which are capable of light induced intramolecular electron transfer (6–10).

We wished to gain an understanding of the structural and electronic factors governing the efficiency of electron transfer between a photo-excited molecule and an adjacent acceptor molecule, and also of the factors affecting the rate of the subsequent back electron transfer in the radical ion pair generated. To this end, compounds have been prepared in this laboratory (11), using the method of Kong and Loach (6), which consist of a tetraarylporphyrin attached by a covalent linkage of variable length to a benzoquinone (compounds **4***d*, **4***e*, and **4***f*). The epr spectra produced when these compounds are irradiated with visible light suggest that the porphyrin transfers an electron to the benzoquinone to generate a radical ion pair. At low temperatures this charge separated species is stable, while at higher temperatures it reverts to the neutral, linked porphyrin–benzoquinone precursor, suggesting that an activation barrier for back electron transfer exists (11).

Studies of the photophysical properties of these compounds have been hindered by the hydrolytic instability of the diester linkage between the porphyrin and the benzoquinone. This problem is especially acute, as we wish to investigate light induced electron transfer in these molecules (which possess surfactant properties) in monolayer assemblies in aqueous systems where conformational mobility of the linkage between porphyrin and benzoquinone is minimized. To solve this problem, we embarked upon a program aimed at synthesizing a series of compounds analogous to **4***d*–**4***f* where the ester linkages are replaced by hydrolytically more stable amide functions. In addition, it was hoped that the linkage between the porphyrin and quinone would be made more rigid, with respect to conformational mobility, in consequence of the greater double bond character of the carbon to heteroatom bond in the amide functions as compared to the ester functions. We describe here the synthesis and some properties of the compounds **4***a*–**4***c* in which a porphyrin and a benzoquinone are linked together via two amide bonds and a methylene chain of variable length.

Results and discussion

The synthetic sequence leading to compounds **4***a* to **4***c* is shown in Scheme 1 and will be described below for the 1,3-diaminopropane linked molecule **4***b*. Commercially available 2,5-dimethoxyphenylacetic acid was converted to its methyl ester and treated with a large excess of 1,3-diaminopropane to yield the amide **1***b*. Preparation of **1***b* by direct acylation of the diamine with 2,5-dimethoxyphenylacetyl chloride was found to be unsatisfactory; under all conditions examined, including standard Schotten–Bauman conditions and addition of the acid chloride to excess diamine in organic solvents, the major product was the diacylated compound *N,N'*-di(2,5-dimethoxyphenylacetyl)-1,3-diaminopropane.

The structure of **1***b* was readily confirmed by the ^{1}H nmr spectrum which exhibited signals ascribable to the primary amine, secondary amide, and methylene protons. The compound was further characterized by conversion to its *N*-acetylated derivative.

The porphyrin 5-(*p*-carboxyphenyl)-10,15,20-tri(*p*-tolyl)-porphyrin ("PCO_2H") was prepared by the condensation of pyrrole with a mixture of *p*-tolualdehyde and 4-carboxybenzaldehyde in refluxing propionic acid, followed by chromatographic separation of the mono- and polycarboxyporphyrins obtained (12). The monocarboxyporphyrin was converted to its acid chloride ("PCOCl") with thionyl chloride and treated with the amine **1***b* in the presence of pyridine to give the porphyrin–dimethoxybenzene linked compound **2***b*, which was purified by chromatography.

The ^{1}H nmr spectrum of the linked compound **2***b* is shown in Fig. 1. Despite the fact that 54 hydrogen atoms are present

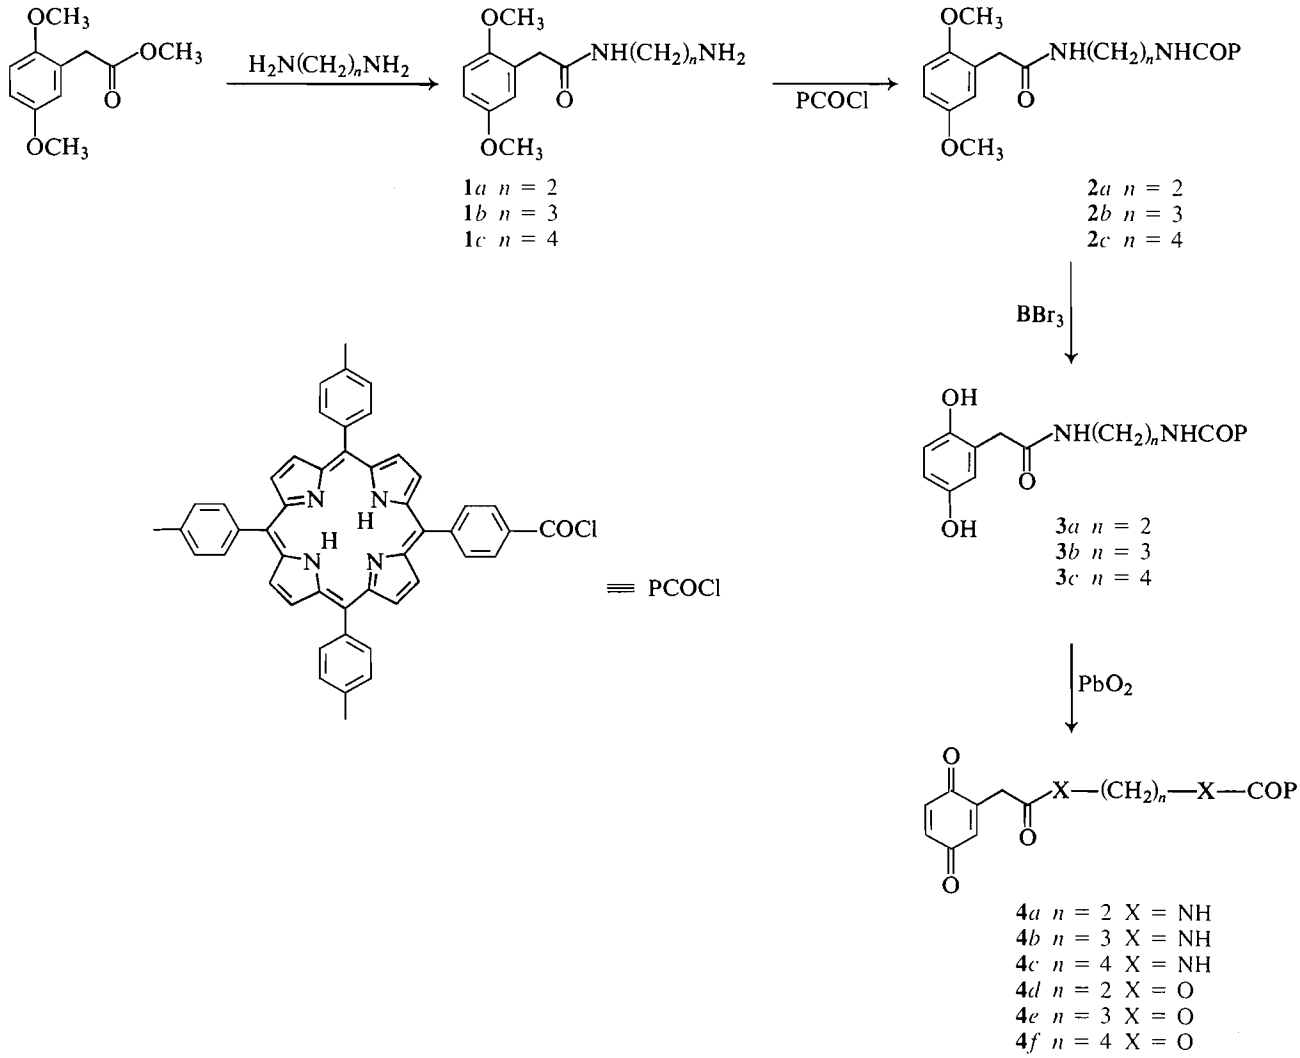

SCHEME 1

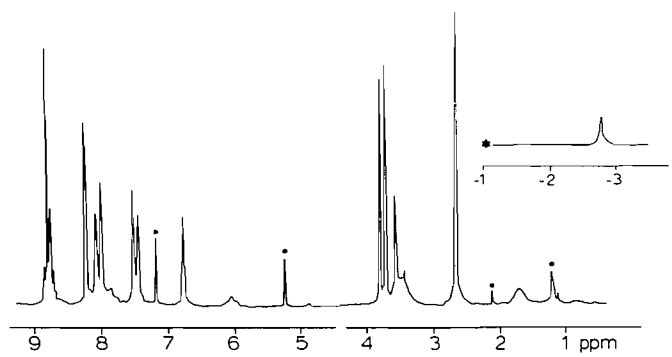

FIG. 1. The ^{1}H nmr spectrum (100 MHz) of **2***b* in $CDCl_3$. Peaks marked by asterisks are impurities in the solvent. The inset shows the porphyrin NH protons.

in the molecule, the environments of nonequivalent positions are sufficiently different and isolated that the protons appear over a chemical shift range of 12 ppm with minimal coupling and can all be easily distinguished. The highly shielded protons on the porphyrin nitrogen atoms appear at −2.8 ppm while those on the β-positions of the pyrrolic rings are highly deshielded and appear at ca. 8.8 ppm. The tolyl ring protons are visible as an AA′BB′ system at 7.4–8.2 ppm and the corresponding methyl groups are at 2.68 ppm. The aromatic protons on the linking phenyl of **2***b* resonate at 8.35 ppm and those on the dimethoxybenzene at 6.75 ppm. The secondary amide protons show as a broadened signal at 6.1 ppm and the methylenes of the propane linkage at 1.6–2.0 and 3.3–3.6 ppm. The methoxyl groups of the protected hydroquinone and the adjacent benzylic protons are also observed clearly at 3.75, 3.72, and 3.64 ppm, respectively.

The ultraviolet/visible spectrum of **2***b* exhibits the characteristic porphyrin Q-bands in the visible region and the more intense Soret band at 420 nm (Table 1). The absorption spectrum confirms that the porphyrin in **2***b* is metal-free and nonprotonated. Porphyrins are excellent metal scavengers and are also weak bases; unless pretreated with base, chlorinated organic solvents often contain sufficient hydrochloric acid to produce appreciable amounts of diprotonated porphyrin, and silica gel used for preparative thin layer chromatography contains sufficient metal ions (mainly zinc silicate, present as a fluorescor) to produce large quantities of metal centred porphyrins. Such contamination is readily detected chromatographically and by inspection of the absorption spectrum (see below, and Table 2.)

Conversion of the dimethoxybenzene portion of **2***b* to the corresponding hydroquinone was achieved by treatment with

boron tribromide at low temperature under standard conditions (13). This step proceeded much more cleanly than with the corresponding ester linked analogue where substantial ester cleavage occurred. The hydroquinone **3***b* obtained by this route was relatively unstable, as has previously been observed for these compounds (5), and was contaminated with the quinone **4***b* (see below); the compound could be purified by chromatography to give a homogeneous sample for rapid spectroscopic analysis, but attempts to obtain microanalytical data were unsuccessful. The ^{1}H nmr spectrum of **3***b* confirmed that the desired transformation had occurred. In particular, the methoxyl groups present in **2***b* were absent from the spectrum of **3***b* and the hydroquinone ring protons appeared as a multiplet with peaks at 6.76 and 6.72 ppm (Fig. 3a), which compares well with the spectrum obtained of methylhydroquinone in the same solvent where a multiplet with peaks at 6.70 and 6.64 ppm was observed.

Oxidation of the hydroquinone **3***b* to the corresponding quinone **4***b* could be achieved under mild conditions using high potential quinone oxidants such as dichlorodicyanobenzoquinone (DDQ). However, purification of product, particularly removal of the products of DDQ reduction by **3***b*, was difficult and it was found preferable to achieve the transformation of **3***b* to **4***b* by two-phase oxidation of **3***b* using a suspension of lead dioxide in methylene chloride (5, 14). In this way essentially quantitative conversion of **3***b* to **4***b* could be achieved and the excess oxidant and its reduction products removed by filtration, obviating the need for chromatographic purification of the quinone. The course of the oxidation was conveniently followed by uv/visible spectroscopy; as oxidation proceeded, the quinone absorption at 246 nm increased to a maximum while a weak band at 300 nm assigned to the hydroquinone chromophore decreased. The visible (porphyrin Q-bands) and near uv (porphyrin Soret band) regions of the absorption spectrum indicated that the porphyrin was unaffected during oxidation and, in particular, did not incorporate a metal atom. Figure 2 shows these transformations for the oxidation of **3***b* to **4***b*. The extinction coefficients at 246 and 300 nm were determined for **3***b* and **4***b* and, using the values obtained, it was determined that samples of **3***b* direct from the boron tribromide mediated cleavage of **2***b* contained approximately 25% of **4***b* and 75% of **3***b*.

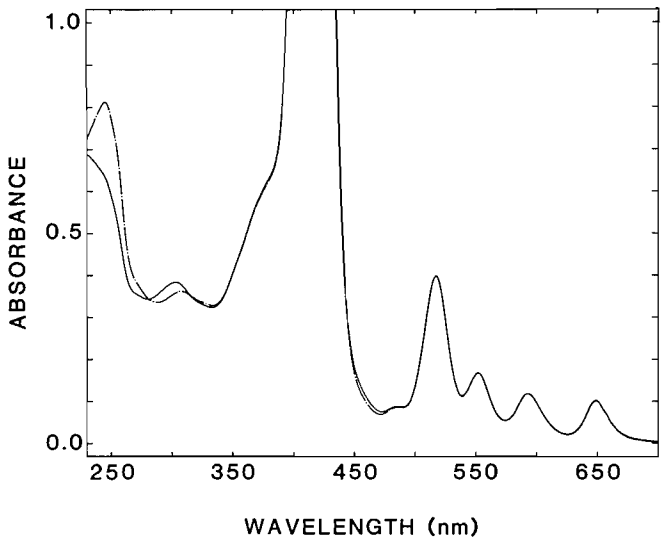

FIG. 2. Ultraviolet/visible absorption spectra showing the transformation **3***b* to **4***b*. Solid line, **3***b*; broken line, **4***b*.

The ^{1}H nmr spectrum of **4***b* was similar to that of its precursor **3***b*. The major difference is in the signals assigned to the aromatic ring protons and these are shown in Fig. 3. In Fig. 3(a) the hydroquinone ring protons of **3***b* are seen at 6.76 and 6.72 ppm; Fig. 3(b) shows the spectrum of the same sample after incomplete oxidation with lead dioxide, where the quinone ring protons are seen at 6.84 ppm superimposed upon the remaining hydroquinone signals. The linked porphyrin–quinone **4***b* was also found to be relatively unstable; on standing, it slowly reverted to the hydroquinone **3***b*. This transformation is shown in Fig. 3(c) and is in contrast to the observations of Ganesh and Sanders (5) who have reported finding that a quinone capped porphyrin was stable, but that the hydroquinone precursor was unstable with respect to formation of what was tentatively identified as a semiquinone species. An analogous semiquinone species has not been observed for either **3***b* or **4***b*; in particular, no epr signal was found which could be ascribed to the semiquinone form.

The linked porphyrin–quinone molecules **4***a*, **4***b*, and **4***c* were chosen as synthetic targets in order to study the effect of separation of the two chromophores upon the efficiency of light induced intramolecular charge transfer. Prior to such a study it is necessary to determine if there is any ground state interaction of the chromophores, either intramolecularly or intermolecularly. To this end the optical properties of the precursors **2***a*–**2***c*, **3***a*–**3***c*, and the quinones **4***a*–**4***c* were studied.

The visible and near uv spectra of these compounds are shown in Table 1. Spectra were recorded in dichloromethane with the addition of 4% methanol to achieve sufficient solubility over a range of 10^{-4} to 10^{-6} *M*. Under these conditions the Beer–Lambert Law was obeyed, suggesting that the compounds are monomeric and not subject to aggregation. The

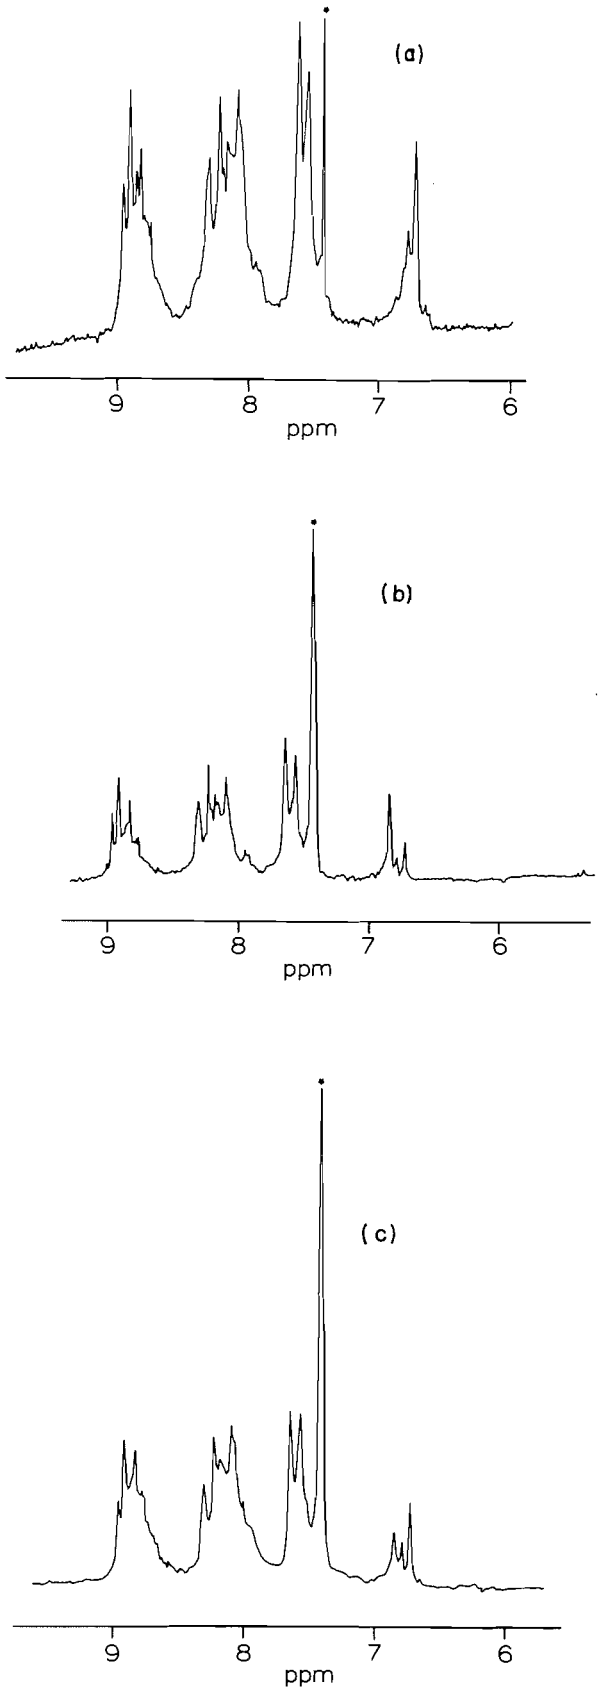

FIG. 3. Partial ^{1}H nmr spectra showing the transformation **3***b* to **4***b*. The asterisk marks residual protium in $CDCl_3$. (a) Aromatic region for hydroquinone **3***b*. (b) Aromatic region following ca. 70% oxidation to **4***b*. (c) Same as (b) after standing overnight.

spectra were also recorded in the presence of 1% trifluoroacetic acid; under these conditions the porphyrin exists as its dication and this results in a bathochromic shift of the Soret band and the Q-bands of the porphyrin with one of the latter increasing greatly in intensity. The spectra of the dications are given in Table 2.

The absorption spectra of the linked porphyrin–dimethoxybenzene compounds **2***a*, **2***b*, and **2***c* were essentially identical and all show the presence of a normal porphyrin chromophore, indicating that no strong interaction exists between the two halves of the molecule. This is illustrated in Fig. 4(a) where the absorption spectra of the porphyrin–dimethoxybenzene compound **2***b* in the Soret band region is shown superimposed upon the spectrum of 5-(*p*-carboxyphenyl)-10,15,20-tri(*p*-tolyl)porphyrin. The absorption spectrum of the porphyrin–hydroquinone molecule **3***c*, in which the two chromophores are linked by 1,4-diaminobutane, is also normal, indicating no intramolecular interaction. However, the spectra of **3***a* and **3***b* are perturbed, with the bands showing a slight bathochromic shift. In addition, the Soret band exhibits substantial broadening. This is illustrated in Fig. 4(b) where the absorption spectra of the linked porphyrin–hydroquinones **3***a*, **3***b*, and **3***c* are shown superimposed upon each other. These effects suggest that, with the shorter linkages present in **3***a* and **3***b*, there is an interaction between the porphyrin and the hydroquinone chromophores in the ground state which is not possible in **3***c*, presumably because the longer linkage prevents adoption of the required conformation. That the interaction does not occur for the porphyrin–dimethoxybenzene linked molecules **2***a*–**2***c* may be due to steric interference by the methyl groups present.

The absorption spectra of the linked porphyrin–benzoquinones **4***a*–**4***c* were essentially identical to those of their precursors **3***a*–**3***c* apart from changes in the bands assigned to benzoquinone at shorter wavelength, discussed above. Thus the postulated intramolecular interaction giving rise to a bathochromic shift of the Soret band in **3***a* and **3***b* is also present in **4***a* and **4***b* but not **4***c*.

The fluorescence spectra of 5-(*p*-carboxyphenyl)-10,15,20-tri(*p*-tolyl)porphyrin and of compounds **2** and **3**, and **4** were also recorded. The fluorescence data for compounds **2** and **3** are given in Table 3, and the fluorescence spectra for the unlinked porphyrin and for compounds **3***b* and **4***b* are shown in Fig. 5. From Fig. 5 it can be seen that excitation of the Soret band (420 nm) of the porphyrins **3***b* and **4***b* produces normal porphyrin fluorescence, while excitation at longer wavelength (440 nm) produces a fluorescence which is red shifted. This effect is not observed for the unlinked porphyrin. This may reflect excitation of different conformers of the linked porphyrins with irradiation at longer wavelength preferentially exciting the conformation in which the two ends of the molecule are interacting and which gives rise to the bathochromic shift observed in the absorption spectrum. Fluorescence quantum yields were also determined for compounds **2***b*, **3***b*, and **4***b* relative to tetraphenylporphyrin (Table 4). The values obtained suggest that some quenching of the singlet excited state is occurring, but since the quantum yield is reduced for **3***b* as well as for **4***b* this may arise from an interaction between the two chromophores in the molecule which is perturbing the rate of intersystem crossing rather than from electron transfer quenching.

The results of a more detailed study of the photophysical properties of these molecules which support the above conclusions and demonstrate light induced intramolecular electron transfer in compounds **4***a*–*c* will be reported elsewhere.

Experimental

The ^{1}H nmr spectra were recorded on a Varian T-60 or Varian XL-100 instrument with tetramethylsilane as internal standard. The uv/visible absorption spectra were recorded on a Cary 219 spectrometer and fluorescence spectra were recorded on a Perkin–Elmer MPF-4 fluorescence spectrometer in 1.00 cm cells using low optical density solutions of porphyrin in methylene chloride. Elemental analyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ontario.

TABLE 4. Quantum yields of fluorescence for air saturated solutions of linked porphyrin in methylene chloride*

Compound	ϕ_f
2*b*	0.11
3*b*	0.06
4*b*	0.03

* Measured using *meso*-tetraphenylporphyrin as a standard and assuming a quantum yield of 0.11 for this compound (15).

Analytical and preparative thin layer chromatography of porphyrin containing compounds was performed using Polygram Sil-N-HR silica gel from Macherey–Nagel to avoid incorporation of metal ions used as fluorescors in other brands. Porphyrins were handled in subdued light and stored in darkness to avoid self-sensitized photooxidation. Melting points of all linked porphyrin compounds were found to be greater than 300°C.

Methyl 2,5-dimethoxyphenylacetate

A solution of 2,5-dimethoxyphenylacetic acid (4 g, 0.02 mol), dimethylsulphate (3.8 g, 0.03 mol), and potassium carbonate (5.5 g, 0.04 mol) in anhydrous acetone (200 mL) was refluxed under nitrogen for 5 h. After cooling, filtration to remove inorganic salts, and evaporation, a residue was obtained which was purified by column chromatography on silica gel using methylene chloride as eluent. The material so obtained was recrystallized from chloroform – petroleum ether to give **2** (3.4 g, 80%) which had mp 40°C (lit. (16) mp 44°C).

N-*(2,5-Dimethoxyphenylacetyl)-1,2-diaminoethane*, **1***a*

Methyl 2,5-dimethoxyphenylacetate (0.5 g, 2.38 mmol) was stirred in ethylenediamine (2.5 mL) at room temperature for 2 days. Excess amine was removed under reduced pressure and the residue was chromatographed on silica gel using methanol containing concentrated aqueous ammonia (98:2) as eluent to yield **1***a* (70%), mp 91°C; ir (Nujol): 3330–3295, 1650, 1550, 1230 cm^{-1}; uv (MeOH): 296 (ϵ = 3 800), 227 (ϵ = 8 000) nm; ^{1}H nmr ($CDCl_3$): 1.61 (s, 2H, exch.), 2.6–3.0 (m, 2H), 3.0–3.4 (m, 2H), 3.47 (s, 2H), 3.72 (two singlets almost superimposed, 6H), 6.2 (bs, 1H, exch.), 6.77 (s, 3H) ppm; *m/e*: 238 (M^+), 178, 151. *Mol. Wt.* calcd. for $C_{12}H_{18}N_2O_3$: 238.1317; found: 238.1315.

N-*(2,5-Dimethoxyphenylacetyl)-1,3-diaminopropane*, **1***b*

Compound **1***b* was prepared in an analogous manner to **1***a* in 70% yield and had similar ir and uv spectra. For **1***b*, mp 68°C; ^{1}H nmr ($CDCl_3$): 1.4–1.78 (m, 4H), 2.65 (m, 2H), 3.13–3.43 (m, 2H), 3.47 (s, 2H), 3.73 (two singlets, almost superimposed, 6H), 6.2 (bs, 1H), 6.7 (s, 3H) ppm; *m/e*: 252 (M^+), 178, 151. *Mol. Wt.* calcd. for $C_{13}H_{20}N_2O_3$: 252.1471; found: 252.1466.

N-*(2,5-Dimethoxyphenylacetyl)-1,4-diaminopropane*, **1***c*

Compound **1***c* was prepared in an analogous manner to **1***a* in 65% yield and had similar ir and uv spectra. For **1***c*, mp 80°C; ^{1}H nmr ($CDCl_3$): 1.25–1.6 (m, 4H), 1.45 (s, 2H, exch.), 2.4–2.8 (m, 2H), 2.9–3.33 (m, 2H), 3.47 (s, 2H), 3.73 (two singlets, 6H), 6.1 (bs, 1H), 6.7 (s, 3H) ppm; *m/e*: 266 (M^+), 178, 151. *Mol. Wt.* calcd. for $C_{14}H_{22}N_2O_3$: 266.1630; found: 266.1634.

N,N′-*Di-(2,5-dimethoxyphenylacetyl)-1,2-diaminoethane*

2,5-Dimethoxyphenylacetic acid (0.5 g) was dissolved in a mixture of benzene (50 mL) and thionyl chloride (6 mL) and refluxed for 1 h. The solvents were evaporated and the residue was added to a solution of ethylene diamine (1 mL) in 10% aqueous sodium hydroxide (10 mL) and the mixture was shaken vigorously for 15 min. Dilution with water (30 mL), filtration, and purification of the product by chromatography (silica gel, methanol–chloroform, 5:95) gave 0.38 g (79%) of the diamide which had mp 138°C; ir (Nujol): 3295, 1650,

1550, 1230 cm^{-1}; ^1H nmr ($CDCl_3$): 3.2–3.3 (m, 4H), 3.46 (s, 4H), 3.68, 3.73 (two singlets, 12H), 6.1 (b, 2H), 6.76 (s, 6H) ppm; *m/e*: 416 (M^+).

N,N′-*Di-(2,5-dimethoxyphenylacetyl)-1,3-diaminopropane*

The diamide was prepared as above in 72% yield and had mp 118°C; ^1H nmr ($CDCl_3$): 1.2–1.7 (m, 2H), 3.0–3.3 (m, 4H), 3.47 (s, 4H), 3.7 (two singlets, 12H), 6.2 (b, 2H), 6.75 (s, 6H) ppm; *m/e*: 430 (M^+).

N,N′-*Di-(2,5-dimethoxyphenylacetyl)-1,4-diaminobutane*

The diamide was prepared as above in 63% yield and had mp 135°C; ^1H nmr ($CDCl_3$): 1.2–1.55 (m, 4H), 3.0–3.3 (m, 4H), 3.47 (s, 4H), 3.73 (two singlets, 12H), 6.0 (b, 2H), 6.77 (s, 6H) ppm; *m/e*: 444 (M^+).

N-*Acetyl*-N′-*(2,5-dimethoxyphenylacetyl)-1,3-diaminopropane*

The acetylation was performed using acetyl chloride as above to give the product in 85% yield and had ^1H nmr ($CDCl_3$): 1.4–1.78 (m, 2H), 1.95 (s, 3H), 3.0–3.4 (m, 4H), 3.47 (s, 2H), 3.7 (2 singlets, 6H), 6.2 (b, 2H), 6.77 (s, 3H) ppm.

N-*(2,5-Dimethoxyphenylacetyl)*-N′-*(5*-p-*benzoyl-10,15,20-tri*-p-*tolylporphyrin)-1,2-diaminoethane*, **2**a

The unsymmetrically substituted porphyrin 5-*p*-carboxyphenyl-10,15,20-tri-*p*-tolylporphyrin (12) (0.25 g, 0.36 mmol) was dissolved in thionyl chloride (25 mL) and the solution was refluxed under nitrogen for 1 h. The excess thionyl chloride was removed by evaporation under vacuum to yield the crude acid chloride, as its green hydrochloride salt. This material was dissolved in methylene chloride (20 mL) and the solution was added dropwise to an ice-cooled, stirred solution of the amine **3***a* (0.5 g, 2.1 mmol) in methylene chloride (30 mL) containing pyridine (1 mL). After the addition was complete the solution was stirred at room temperature overnight. The reaction mixture was diluted with chloroform (200 mL) and washed with water (3 × 50 mL), dried (Na_2SO_4), and evaporated to give a purple solid which was chromatographed on a column of silica gel using chloroform and then chloroform–methanol (98:2) as eluent. The major component was further purified by preparative thin layer chromatography on silica gel (chloroform–hexane–methanol, 70:26:4) to give the product **2***a* in 45% yield. This material had mp > 300°C; ir (Nujol): 3260–3340, 1665, 1545, 1225, 1038 cm^{-1}; ^1H nmr ($CDCl_3$): −2.8 (bs, 2H, exch.), 2.7 (s, 9H), 3.4–3.6 (m, 4H), 3.62 (s, 2H), 3.68 (s, 3H), 3.82 (s, 3H), 6.3 (bs, 2H, exch.), 6.76–6.88 (m, 3H), 7.58–7.48 (d, 6H), 8.0–8.12 (d, 6H), 8.22–8.34 (m, 4H), 8.75–8.91 (m, 8H) ppm; *m/e*: 920 (M^+). *Anal.* calcd. for $C_{60}H_{52}N_6O_4$: C 78.24, H 5.69, N 9.12%; found: C 78.36, H 5.74, N 9.20%.

N-*(2,5-Dimethoxyphenylacetyl)*-N′-*(5*-p-*benzoyl-10,15,20-tri*-p-*tolylporphyrin)-1,3-diaminopropane*, **2**b

This compound was prepared in an analogous manner to compound **2***a* in 40% yield and had mp > 300°C; ir (Nujol): 3260–3340, 1665, 1636, 1550, 1230 cm^{-1}; ^1H nmr ($CDCl_3$): 1.6–2.0 (m, 2H), 2.68 (s, 9H), 3.3–3.64 (m, 4H), 3.64 (s, 2H), 3.72 (s, 3H), 3.75 (s, 3H), 6.1 (bs, 2H, exch.), 6.76–6.73 (m, 3H), 7.45–7.55 (d, 6H), 8.02–8.12 (d, 6H), 8.34–8.39 (m, 4H), 8.75–8.91 (m, 8H) ppm. *Anal.* calcd. for $C_{61}H_{54}N_6O_4$: C 78.35, H. 5.82, N 8.99%; found: C 78.28, H 5.85, N 9.01%.

N-*(2,5-Dimethoxyphenylacetyl)*-N′-*(5*-p-*benzoyl-10,15,20-tri*-p-*tolylporphyrin)-1,4-diaminobutane*, **2**c

This compound was prepared in an analogous manner to compound **2***a* in 50% yield and had mp > 300°C; ir (Nujol): 3260–3330, 1665, 1640, 1550, 1230 cm^{-1}; ^1H nmr ($CDCl_3$): 1.6–2.0 (m, 4H), 2.68 (s, 9H), 3.3–3.7 (m, 4H), 3.64 (s, 2H), 3.72 (s, 3H), 3.75 (s, 3H), 6.1 (bs, 2H), 6.73–6.76 (m, 3H), 7.45–7.55 (d, 6H), 8.0–8.12 (d, 6H), 8.25 (m, 4H), 8.75–8.91 (m, 8H) ppm. *Anal.* calcd. for $C_{62}H_{56}N_6O_4$: C 78.46, H 5.95, N 8.85%; found: C 78.32, H 6.00, N 8.68%.

N-*(2,5-Dihydroxyphenylacetyl)*-N′-*(5*-p-*benzoyl-10,15,20-tri*-p-*tolylporphyrin)-1,2-diaminoethane*, **3**a

Compound **2***a* (0.202 g, 0.2 mmol) in methylene chloride (30 mL) was cooled in an acetone – Dry Ice bath and the solution was maintained under a blanket of dry nitrogen. Boron tribromide (2.9 g) in methylene chloride (8 mL) was added dropwise with stirring and, at completion of the addition, the mixture was stirred for a further 3 h at −70°C before being allowed to warm to 0°C. Water (15 mL) was added dropwise and the organic phase was washed with aqueous saturated sodium bicarbonate (2 × 100 mL) and water (2 × 100 mL), dried (sodium sulphate), and evaporated to give a residue which was purified by column chromatography on silica gel and then by preparative thin layer chromatography on silica gel using chloroform–methanol (97:3) to give **3***a* in 20% yield. This material had mp > 300°C and ^1H nmr ($CDCl_3$ + CD_3OD): 2.68 (s, 9H), 3.4–3.6 (m, 4H), 3.63 (s, 2H), 6.6–7.0 (m, 3H), 7.53 (d, 6H), 8.08 (d, 6H), 8.04–8.31 (m, 4H), 8.88 (m, 8H) ppm.

N-*(2,5-Dihydroxyphenylacetyl)*-N′-*(5*-p-*benzoyl-10,15,20-tri*-p-*tolylporphyrin)-1,3-diaminopropane*, **3**b

This compound was prepared from **2***b* in the same manner, and in similar yield as for **3***a*. For **3***b*, mp > 300°C; ^1H nmr ($CDCl_3$ + $(CD_3)_2SO$): −2.85 (bs, 2H), 2.7 (s, 9H), 3.3–3.63 (m, 4H), 3.63 (s, 2H), 6.58–6.78 (m, 3H), 7.51 (d, 6H), 8.05 (d, 6H), 8.30 (m, 4H), 8.7–8.92 (m, 8H), 9.12 (bs, 2H) ppm.

N-*(2,5-Dihydroxyphenylacetyl)*-N′-*(5*-p-*benzoyl-10,15,20-tri*-p-*tolylporphyrin)-1,4-diaminobutane*, **3**c

This compound was prepared from **2***c* in the same manner and in similar yield as for **3***a*. For **3***c*, mp > 300°C; ^1H nmr ($CDCl_3$ + CD_3OD): 1.53–1.66 (m, 4H), 2.68 (s, 9H), 3.1–3.5 (m, 4H), 3.45 (s, 2H), 6.5–7.0 (m, 3H), 7.44 (d, 6H), 8.10 (d, 6H), 8.05–8.22 (m, 4H), 8.83 (m, 8H) ppm.

Procedure for oxidation of hydroquinones **3**a–c *to quinones* **4**a–c

The hydroquinone **3** (1 mg) in chloroform (3 mL) was stirred with excess lead dioxide (150 mg) at room temperature for 10 min and then filtered. Removal of solvent from the filtrate gave the quinone **4**. In the case of **3***b*, the oxidation was judged to be quantitative, based upon uv and ^1H nmr spectroscopy. In the cases of **3***a* and **3***c* the product quinones were contaminated with ca. 25% of the hydroquinone precursors. Attempted further purification of the quinones led to reversal of the oxidation and increased hydroquinone contamination. The spectral data for **4** are given in Table 1 and Figs. 2 and 3.

Some chemical and analytical aspects of polysaccharide modifications. IV.[1] Electron spin resonance studies of nitroxide-labelled chitin and chitosan derivatives[2]

MANSSUR YALPANI[3] AND LAURANCE D. HALL

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received September 14, 1983

MANSSUR YALPANI and LAURANCE D. HALL. Can. J. Chem. **62**, 975 (1984).

Nitroxide spin labels have been attached to chitin, chitosan, and their derivatives in order to investigate the solution and gel characteristics of these polymers. Thus, chitin was nonselectively acylated using the chloroacetamide label **3** to afford the corresponding nitroxide derivative **4**. Selective and nonselective labelling of chitosan was accomplished either via reductive alkylation using the keto label **5** and sodium cyanoborohydride or via a chitosan sulfate intermediate using labels **3** or **5**. Two branched water soluble chitosan derivatives, carrying C-6 oxidized, terminal galactose side chains were selectively labelled by reductive amination using the amine label **13** to yield derivatives **14** and **15**. Motional correlation values of the covalently-linked nitroxide moieties were shown to reflect the nature of the linkage between spin label and polymer, as well as structural differences between the branch residues of derivatives **14** and **15**. The spin-probe – spin-label method was employed to demonstrate structural heterogeneities for the chitosan derivatives **7** and **15**.

MANSSUR YALPANI et LAURANCE D. HALL. Can. J. Chem. **62**, 975 (1984).

Dans le but d'étudier les caractéristiques de ces polymères en solution et sous forme de gel, on a attaché des marqueurs de spin de type nitroxyde à la chitine, au chitosane et à leurs dérivés. Ainsi, on a acylé la chitine d'une façon qui n'est pas sélective, en utilisant le marqueur chloroacétamide **3** pour obtenir le dérivé nitroxyde **4** correspondant. On a réalisé le marquage sélectif et non sélectif du chitosane soit par une alkylation réductrice en utilisant soit le cétomarqueur **5** et le cyanoborohydrure de sodium soit via l'intermédiaire du sulfate de chitosane en utilisant les marqueurs **3** ou **5**. Utilisant le marqueur aminé **13** qui conduit aux dérivés **14** et **15** par amination réductrice, on a marqué de façon sélective deux dérivés du chitosane qui sont solubles dans l'eau et qui portent comme chaînes latérales des unités terminales de galactose oxydé en C-6. On montre que les valeurs de corrélation de mouvement des unités nitroxydes liées par des liaisons covalentes réflètent la nature de la liaison entre le marqueur de spin et le polymère ainsi que les différences structurales entre les unités ramifiées des dérivés **14** et **15**. On a utilisé la méthode du marqueur de spin/sonde de spin pour démontrer les hétérogénéités structurales des dérivés **7** et **15** du chitosane.

Introduction

The current interest in the development of new chitin- and chitosan-derived products for a diverse range of applications (1) is reflected in increasing efforts to establish a better understanding of the fundamental physical characteristics of these vastly abundant and inexpensive biopolymers. Chitin and chitosan and their derivatives are distinguished from most other polysaccharides by several unique features such as, for example, their solution and gel behaviour. However, many of their properties are not yet thoroughly evaluated, mainly due to their intractability. Several studies have recently explored the shape and molecular properties of these aminopolysaccharides. Buffington and Stevens (2) have concluded from circular dichroism data that inter- rather than intra-molecular interactions between *N*-acetyl groups play an important factor in the gel formation of chitan and chitin. Hirano *et al.* (3) have observed pronounced changes in specific rotation of chitosan during Schiff's base formation and the attendant gelation process. More recently, Komai and co-workers (4) have studied the molecular motions of a spin-probe in films of various acylchitins, while Aleksandrova *et al.* (5) have examined the segmental mobility of chitosan using the spin-labelling technique. We have previously employed nitroxide labels to demonstrate the formation of inclusion complexes for a branched chitosan derivative (6).

As part of a general programme of nmr (7) and esr (8) studies of native and derivatized polysaccharides, and in continuation of our development of new, water soluble products derived from chitin and chitosan (6, 9), we were interested in establishing facile methods for the preparation of new types of chitin/chitosan derivatives which would exhibit a range of solubility and gelling characteristics. We report here on the synthesis and characterization of various nitroxide spin-labelled aminopolysaccharide derivatives.

Results and discussion

Syntheses

Spin labelling of chitin, **1**, was accomplished by pretreatment of the solid material with dimethyl sulfoxide and aqueous sodium hydroxide, followed by nonselective acylation using 4-chloroacetamido-2,2,6,6-tetramethylpiperidine-1-oxy-1, **3**, to produce the labelled derivative **4**. The degree of substitution (d.s.) was low (0.04), but suitable for our subsequent experiments. It was found that derivative **4** swelled to a limited extent in aqueous or alcohol suspensions.

Several unsuccessful attempts were made to selectively spin label chitin under homogeneous conditions by reductive alkylation of the residual free amine groups with 4-oxy-2,2,6,6-

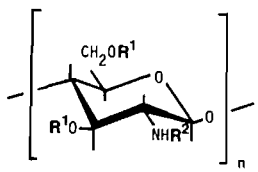
tetramethylpiperidine-1-oxyl, **5**, using sodium cyanoborohydride and the lithium chloride – dimethylacetamide solvent system (10).

Reductive alkylation of chitosan, on the other hand, proceeded smoothly using the keto label **5** and methanol – aqueous acetic acid as solvent to afford a product **7** (d.s. 0.1) which gelled considerably in methanol or aqueous media. Chitosan could alternatively be spin labelled via the *N*-sulfate derivative **8**, exploiting the fact that the latter is moderately soluble in water at elevated temperatures. Thus, labelling of derivative **8** using nitroxides **3** and **5** readily afforded the corresponding derivatives **9** (d.s. 0.5) and **10** (d.s. 0.45), respectively. Both of these derivatives formed gels in aqueous solution at low concentrations (ca. 3% w/v).



9 $R^1, R^2 = H$, 
7,10 $R^1 = H; R^2 =$ 
In an alternative approach to the synthesis of labelled, water soluble compounds, we employed the branched chitosan derivatives **11** and **12** which were available from another study (6, 9). The selective labelling of these derivatives at terminal positions of their side chains was readily accomplished by activation of the C-6 hydroxyl function of the pendant D-galactose residues via oxidation with Galactose Oxidase (E.C.1.1.3.9.) (6). The resultant C-6 aldehyde derivatives were reductively aminated, using 4-amino-2,2,6,6-tetramethylpiperidine-1-oxyl (**13**) to yield the corresponding labelled products **14** (d.s. 0.35) and **15** (d.s. 0.15), respectively. Derivatives **14** and **15** were both freely soluble in water, forming viscous solutions at low concentrations, which added further interest to studies of their esr spectra.

Electron spin resonance

Spin label experiments

The esr spectra of the spin-labelled chitin and chitosan derivatives revealed a number of interesting spectral characteristics, as illustrated in Figs. 1 and 2. The chitin derivative **4** (Fig. 1A), for example, was found to enjoy a greater freedom of rotational reorientation than the various chitosan derivatives, its motional correlation time, τ_c, (2 ns) being about an order of magnitude smaller. This presumably derives from the fact that the chitin derivative, in contrast to the latter, was labelled under essentially heterogeneous reaction conditions. The difference in treatment seems to have led not only to a lower overall level of substitution in derivative **4**, but also to a concentration of labels only at the more accessible surface of the solid particles. The tumbling rate of these labels would be determined only by their degree of rotational freedom about their acetamide linkage to the polymer, with the latter making no motional contribution on the esr time scale (i.e. $\tau_c > 100$ ns). It is reasonable that these readily solvated spin labels should also be more mobile than those attached to the chitosan derivatives, whose overall tumbling rate includes a motional component from the polymer chains within a gel matrix or solution aggregate. That the proposed relation between solvation and nitroxide tumbling

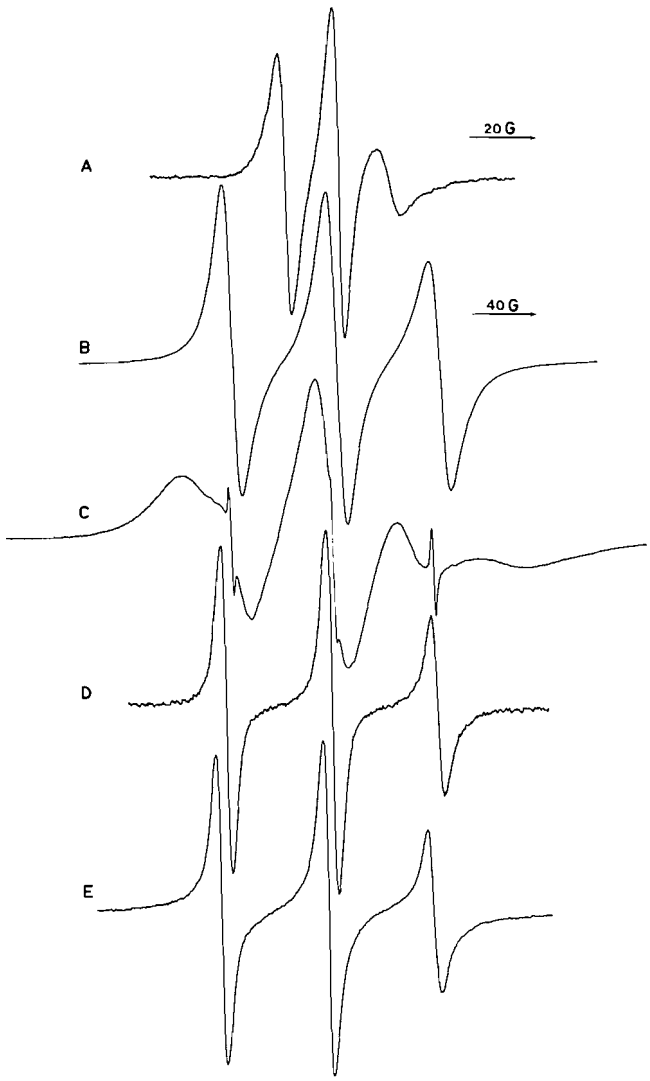

FIG. 1. Ambient temperature esr spectra of derivatives (A) **4**; (B) **9**; (C) **10**; (D) **14**; and (E) **15** in aqueous solution.

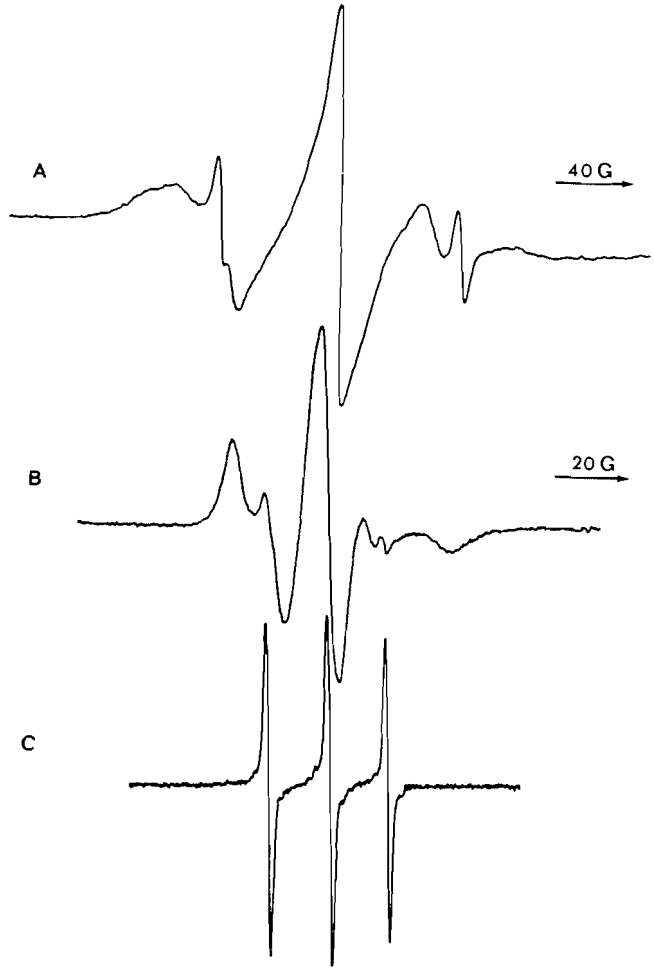

FIG. 2. Ambient temperature esr spectra of gels of derivative **7** in solvent cycle experiment: (A) in aqueous suspension; (B) in methanol suspension; (C) aqueous suspension; see text for discussion.

rate exists is also supported by the fact that the use of a somewhat less polar solvent (methanol) resulted in increases in the A_z component and in the width of the low-field line of derivative **4**.

Within the series of labelled chitosan products, the esr spectra of derivatives **9**, **14**, and **15** (Figs. 1B, D, E) displayed similar spectral lineshapes consisting of single component triplets which were indicative of moderately rapid rotational motions. The correlation time values of these derivatives ranged between 35 and 70 ns. Derivatives **7** (Fig. 2) and **10** (Fig. 1C) exhibited multicomponent esr spectra, as will be discussed below; their complex lineshape precluded τ_c determinations.

Interestingly, a comparison of Figs. 1B and 1C reveals that derivative **10** is much more immobilized than derivative **9**, with the former displaying solid-like characteristics, and the latter an almost isotropic spectrum, despite the fact that both products were obtained from the same chitosan sulfate precursor and that they were substituted to about the same extent. It would therefore be reasonable to assume that the spectral differences are attributable to structural distinctions. For derivative **10**, the keto spin label is attached to only one specific site, i.e. the amine function, whereas derivative **9** is also randomly labelled at both the primary and secondary alcohol functions. Thus, nitroxide moieties linked to the C-6 position of derivative **9** would enjoy a greater motional freedom than those attached to the 2-amine functions of derivative **10**. An additional contribution to the mobility of **9** derives from the four-bond acetamide linkage which constitutes a spacer group between the paramagnetic centre and the polymer.

Similar arguments appear to apply to the marked difference in the τ_c values of derivatives **14** (68 ns) and **15** (43 ns), which presumably arises from the different types of linkages involved. The melibiityl derivative **15** contains α-1,6-linked, six-carbon acyclic D-glucityl moieties, whereas the lactityl derivative **14** has β-1,4-linked, four-carbon D-glucityl moieties with additional two-carbon residues at C-4. The more extended side-chains of derivative **15** could give rise to a more ordered, sterically less restricted polymer solution structure, whereas the branched side-chains of derivative **14** would tend to lead to a more disordered conformation in which the nitroxide moieties enjoy relatively smaller motional freedom due to entanglement of the side chains. These conclusions were also supported by the results of previous SEM (scanning electron microscopy) studies of the diamagnetic, solid precursors (11).

Gels of derivative **7** in water exhibited a complex esr spectrum (Fig. 2A) consisting of an immobilized component with a split high-field signal and a superimposed mobile nitroxide signal. The presence of the latter signal, even after extensive

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

washing of the material, could be attributed to either an unbound, physically trapped, or to a bound, but very mobile nitroxide sub-population. The esr spectrum of derivative **7** appeared to consequently indicate the presence of at least two nitroxide populations residing in sites which were accessible to different degrees to solvent.

Further experiments were conducted to confirm the above implications and to exclude the possibility that the observed esr lineshape arose from a single isotropically tumbling nitroxide population.

First, gels of derivative **7**, dispersed in methanol instead of water, gave esr spectra with similarly complex lineshapes in which there was a proportionally smaller presence of the more mobile nitroxide component (see Fig. 2B). Second, when a sample of derivative **7** was subjected to an experiment in which the supernatant solvent was successively replaced (water–methanol–water) over periods of two weeks, a drastic redistribution of the spectral components was observed. The mobile nitroxide population was found to predominate over a less mobile, barely detectable one (Fig. 2C) on completion of the solvent cycle, indicating a gradual structural reorganization of the gel into an assembly in which the spin labels were more accessible to solvent. It should be noted that these spectral changes were not associated with an apparent softening or dissolution of the gel; while the gel seemed to retain its rigidity, we did notice an almost two-fold increase in its macroscopic volume in the last transition of the solvent cycle. This volume expansion could, at least partially, account for the observed enhancement of the nitroxide mobility.

Selective broadening experiments

Previous workers (12–17) have demonstrated the utility of paramagnetic "probe" ions, such as transition metal ions, which lead to exchange broadening of the esr lines of spin labels, both in solution and attached to macromolecules, and thereby provide valuable structural information. While, for instance, such probe ions cause line broadening of *free* nitroxides in solution beyond the detection limit, any residual spectra obtained for *polymer-bound* spin labels are indicative of some form of steric hindrance which interferes in the rapid exchange between at least a certain fraction of the bound nitroxides and the probe ions in solution. We therefore employed the spin-probe – spin-label method (13) in order to confirm our previous evidence for structural heterogeneities in the chitosan derivatives.

The line width of the nitroxide esr signal of the free hydroxyl label **6** in solution increased rapidly with increasing nickel sulphate concentration, with no signal being detectable above 3 m*M* $Ni(H_2O)_6^{2+}$ concentrations. In contrast, the branched chitosan derivative **15**, for example, produced a more complex pattern with a residual signal being observable even at tenfold higher nickel ion concentrations, although reduced in intensity by approximately two orders of magnitude in comparison with the signal obtained in the absence of metal ion.

Figure 3 illustrates the probe-induced line broadening of label **6** and of derivatives **7** and **15** in terms of the dependency of the increase in peak-to-peak width of the centre field line $[\Delta\omega_0(C) - \Delta\omega_0(O)]$ on paramagnetic ion concentration. At low nickel concentrations, a rapid, linear increase in the line broadening of derivatives **7** and **15** was observed, while the probe seemed to exert little or no influence at concentrations above 10 m*M*. The nonlinear features in Figs. 3B and 3C confirm (13) the presence of nitroxide sub-populations in derivatives **7**

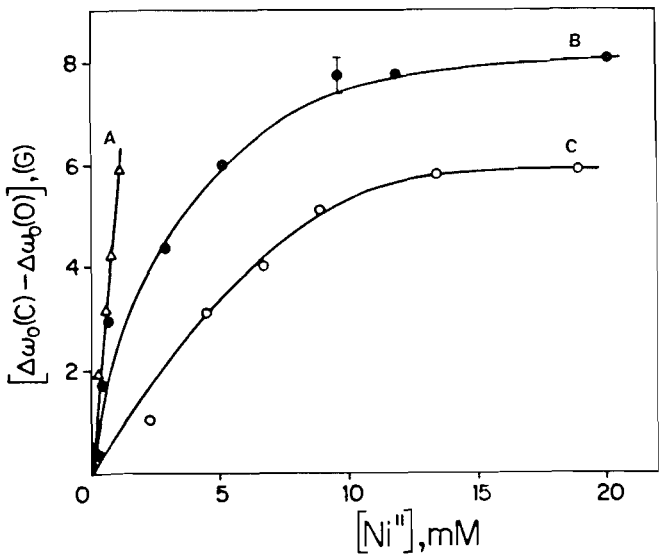

FIG. 3. Broadening of centre field line width as a function of added nickel sulfate for (A) hydroxyl spin label **6**; (B) derivative **15**; and (C) derivative **7** in aqueous solution.

and **15**, which seemed to be unaffected by the paramagnetic probe ions in solution.

It should be noted that similar phenomena were also found for derivative **10**, which showed a residual esr spectrum at nickel concentrations of up to 26 m*M*. However, its unresolved lineshape at higher probe ion concentrations precluded line broadening determination in this case. The observation of structural microenvironments for derivative **10** is not surprising in light of its close structural similarity to the chitosan derivative **7**. It is also not unexpected that the esr spectrum of derivative **9**, in contrast to that of **10**, was broadened beyond detection limits in the presence of only 4 m*M* nickel, since this finding is consistent with the previously discussed mobility differences between derivatives **9** and **10**. Similarly, derivative **14** lost its residual esr spectrum at six-fold lower (5 m*M*) probe ion concentrations than its analogue **15**, confirming previously indicated structural distinctions.[4,5] If our aforementioned arguments about the respective structures of derivatives **14** and **15** are valid, the selective broadening results could tentatively be interpreted as an indication that the proposed, more regular structure of derivative **15** gives rise, by way of intra- or intermolecular associations, to an organized type of solution structure, which is unattainable by derivative **14** on account of its structural irregularities. Clearly, a more detailed explanation of the nature of these solution structures, as well as the site variations for derivative **15**, requires complementary spectroscopic evidence.

Conclusions

The generally mild reaction conditions of the spin-labelling procedures described here and the, in some instances, some-

[4] Selective broadening experiments were not conducted for the chitin derivative **4** in view of its limited swelling capacity.

[5] Throughout these experiments, we found no evidence of interference from nickel chelation by the polymers. This is presumably a result of the relatively short experimental time scale involved (minutes) which would be insufficient for any substantial chelation to occur (23). The high nickel ion concentrations employed would additionally offset any effects from this source.

what laborious synthetic approach involving, for example, activated or intermediate polymer species, were imposed by considerations of both the acid lability of the nitroxide moieties and the requisite ultimate physical state (solution, gel, or solid) of the resulting chitin and chitosan derivatives. These methods complement our previously reported fluorescent labelling (18) and other selective derivatization (6, 9) procedures for chitin and chitosan, which together provide a versatile array of synthetic techniques for further evaluations of the physical properties of these biopolymers. These methods have facilitated, for the first time, spectroscopic studies of chitosan and its derivatives in both the solution and gel form in *aqueous* medium, whereas previous investigations involved either chitosan films suspended in organic solvents (4) or solutions in aqueous organic acids (3, 5).

It has been demonstrated that spin labelling provides a useful and sensitive analytical tool for studying molecular solution parameters of chitin and chitosan. Thus, the solvation and swelling of the polymer matrices were reflected in the variation in correlation times, similar to observations from previous studies with spin-labelled polystyrene (19) and agarose (16).

It is noteworthy that the τ_c values of our chitosan derivatives are of the same order of magnitude as that found by Aleksandrova *et al.* (5) for chitosan in acetic acid solution (14.5 ns). Perhaps the most interesting result of our esr study is the observation of structural heterogeneities for the chitosan derivatives which seem to arise from the nature of the respective solution and gel structures.

These features may be of significance for understanding certain chitosan solution and other properties, such as its metal chelation performance. Precedence for the presence of such structural microenvironments, with restricted solute and solvent accessibilities, exists for other polysaccharides, such as for cellulose (17) and agarose (16). It should be noted, however, that the selective labelling methods employed for derivatives **7** and **15** have the distinct advantage of eliminating a potential source of confusion in the interpretation of site variations, namely product mixtures arising from nonselective derivatization methods (16, 17).

Experimental

General methods and materials

The esr spectra were recorded at X-band with a Varian E-3 instrument. Correlation times for rotational reorientation were determined using the quadratic term of the ratio-of-heights method of McConnell and co-workers (20), assuming isotropic nitroxide tumbling. No computer simulation of spectra was performed, since only estimates for relative comparisons were required here. All esr spectra were obtained in aqueous solution or dispersion (ca. 5% w/v, pH 7), unless indicated otherwise. All other esr methods have been previously described (8).

Elemental microanalyses were performed by Mr. P. Borda of the Microanalytical Laboratory, Department of Chemistry, University of British Columbia.

Chitosan (from shrimp shells, ca. 15% *N*-acetylated) and chitin (from crab shells, ca. 10% *N*-deacetylated; both previously characterized (6)) were purchased from Sigma and used without further purification. The chemical derivation reactions of chitosan resulted in a slight reduction of the residual *N*-acetyl content (6). Sodium cyanoborohydride, 4-amino-2,2,6,6-tetramethylpiperidine-1-oxyl, and 4-oxo-2,2,6,6-tetramethylpiperidine-1-oxyl were purchased from Aldrich Chemical Co. The other spin labels, 4-hydroxy-2,2,6,6-tetramethylpiperidine-1-oxyl and 4-chloroacetamido-2,2,6,6-tetramethylpiperidine-1-oxyl, were synthesized using the method of McConnell (22).

*Preparation of [4-acetamido-2,2,6,6-tetramethylpiperidine-1-oxyl] chitin, **4***

Chitin (180 mg, 0.85 mmol) was soaked in methyl sulfoxide (15 mL) for 48 h, then filtered and suspended in aqueous (65%) NaOH solution (40 mL) for 1 h, after which the alkali chitin was filtered, pressed, and resuspended in isopropanol (25 mL). A solution of the label **3** (250 mg, 0.92 mmol) was added with stirring. After 2 h, the product was filtered, washed (water 100 mL, methanol 150 mL), and dried. The product had d.s. 0.04. *Anal.* calcd. for $[(C_8H_{13}NO_5)_{0.96}(C_{19}H_{32}N_3O_7)_{0.04}]\cdot 0.47\ H_2O$: C 45.77, H 6.70, N 6.83; found: C 45.58, H 6.45, N 6.78.

Attempted reductive amination: chitin (1 g, 4.72 mmol) was dissolved in a mixture containing 3.6% (w/v) LiCl and dimethylacetamide (DMAC) (40 mL) and the undissolved material was separated by filtration through glass wool. To the filtrate was added a solution of keto spin label **5** (3.6 g, 21 mmol) in DMAC (10 mL) and $NaCNBH_3$ (2 g, 33 mmol). The reaction mixture was warmed (50°C) for 24 h, after which aqueous methanol (70 mL) was added to separate the product out as a gel. The product was found to contain no bound label.

Preparation of [4-N-(2,2,6,6-tetramethylpiperidine-1-oxyl)] chitosan, 7

Chitosan (250 mg, 1.5 mmol) was dissolved in 10% aqueous acetic acid (50 mL) and precipitated by addition of an aqueous ammonium sulfate solution. The precipitated chitosan sulfate (21) was collected by centrifugation, and then suspended in phosphate buffer (20 mL, pH 6.5). The solution was heated to 50°C to dissolve the sulfate salt upon which keto spin label **5** (340 mg, 2.0 mmol) and $NaCNBH_3$ (0.44 g, 7.2 mmol) were added with stirring. The reaction mixture was kept at 50°C for 5 h, then aqueous sodium hydroxide solution was added to precipitate the product at slightly alkaline pH. The product, **7**, had a d.s. 0.45. *Anal.* calcd. for $[(C_8H_{13}NO_5)_{0.10}(C_6H_{12}NO_7S)_{0.45}(C_{15}H_{27}N_2O_5)_{0.45}]\cdot 0.6\ H_2O$: C 43.63, H 7.17, N 7.20; found: C 43.55, H 6.99, N 7.44.

The spin labelling was also attempted by reacting chitosan with spin label in 2 *M* aqueous pyridine and 1% aqueous acetic acid, resulting, however, in a much lower yield.

*Preparation of [4-acetamido-2,2,6,6-tetramethylpiperidine-1-oxyl] chitosan, **9***

The labelling was carried out via the chitosan sulfate intermediate (200 mg, 0.8 mmol) described above, which was dissolved in hot water (20 mL, adjusted to pH 6.5). A solution of 4-chloroacetamido-2,2,6,6-tetramethylpiperidine-1-oxyl, **3** (176 mg, 1 mmol), in 65% aqueous acetone (2 mL) was added with stirring and the reaction mixture was kept at 40–50°C for 6 h, at which time gelation occurred. The gel was separated, washed consecutively with water, ethanol, acetone, and ether, and then dried; the product had d.s. 0.25. *Anal.* calcd. for $[(C_8H_{13}NO_5)_{0.1}(C_6H_{12}NO_7S)_{0.65}(C_{17}H_{30}N_3O_6)_{0.25}]\cdot 1.2\ H_2O$: C 36.73, H 6.55, N 7.18; found: C 36.60, H 6.49, N 7.14.

The same reaction carried out in the presence of 4-dimethylaminopyridine catalyst (100 mg, 0.8 mmol) gave a product with greater d.s. (0.5). *Anal.* calcd. for $[(C_8H_{13}NO_5)_{0.1}(C_6H_{12}NO_7S)_{0.4}(C_{17}H_{30}N_3O_6)_{0.5}]\cdot 1.35\ H_2O$: C 42.87, H 7.32, N 8.55; found: C 42.64, H 7.28, N 8.88.

*Preparation of [4-N-(2,2,6,6-tetramethylpiperidine-1-oxyl)] chitosan, **10***

Chitosan (500 mg, 3 mmol) was dissolved in a mixture (1:1) of methanol and 0.4% aqueous acetic acid (50 mL) to which was added, with stirring, a solution of 4-oxy-2,2,6,6-tetramethylpiperidine-1-oxyl, **5**, (1.0 g, 5.8 mmol) and $NaCNBH_3$ (0.9 g, 15 mmol) in methanol (10 mL). The solution was stirred for 12 h, at which point a soft white gel had formed. The product had a d.s. 0.1. *Anal.* calcd. for $[(C_8H_{13}NO_5)_{0.02}(C_6H_{11}NO_4)_{0.88}(C_{15}H_{27}N_2O_7)_{0.10}]\cdot 0.49\ H_2O$: C 44.72, H 7.38, N 8.27; found: C 44.47, H 7.10, N 8.15.

*Preparation of spin-labelled, branched chitosan derivatives **14** and **15***

(a) The C-6′ aldehydo lactityl chitosan derivative (43 mg, 0.06

mequiv. galactose) obtained from derivative **11** (6), was suspended in aqueous methanol (15 mL) to which was added a solution of amine spin label **13** (150 mg, 0.9 mmol) and $NaCNBH_3$ (0.1 g, 2 mmol) in the same solvent (5 mL). The amination was carried out for 12 h and the product, **14**, was purified by dialysis (3 d); esr double integration gave a d.s. ~0.35 (the microanalytical results could not be exactly matched with a molecular formula; found: C 40.82, H 6.53, N 3.87).

(b) The C-6′ aldehydo melibiityl chitosan derivative (58 mg, 0.08 mequiv. galactose) obtained from derivative **12** (6), was treated as above, yielding a product (**15**) with d.s. ~0.15 (from esr); (found: C 41.47, H 6.77, N 9.32).

An approximate absolute ^{33}S nuclear magnetic shielding scale

RODERICK E. WASYLISHEN,[1] CHUCK CONNOR,[2] AND JAN O. FRIEDRICH[2]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received October 6, 1983

RODERICK E. WASYLISHEN, CHUCK CONNOR, and JAN O. FRIEDRICH. Can. J. Chem. **62**, 981 (1984).

Sulfur-33 chemical shifts have been measured for a number of simple compounds, e.g. SF_6, $HFSO_3$, X_2SO_2, SO_2, Cl_2SO, CH_3SH, H_2S, and OCS, which have not been previously reported. Our results indicate that the range of ^{33}S chemical shifts is approximately 1000 ppm, slightly less than that observed for ^{17}O and approximately one half the range reported for ^{77}Se. Using the ^{33}S nuclear spin-rotation constant of OCS measured by molecular-beam electric resonance and Flygare's procedure, an absolute ^{33}S shielding constant of 843 ± 12 ppm is calculated for OCS, permitting an approximate absolute shielding scale to be proposed for this nucleus.

RODERICK E. WASYLISHEN, CHUCK CONNOR et JAN O. FRIEDRICH. Can. J. Chem. **62**, 981 (1984).

On a mesuré les déplacements chimiques du soufre-33 d'un certain nombre de composés simples (comme le SF_6, le $HFSO_3$, le X_2SO_2, le SO_2, le Cl_2SO, le CH_3SH, le H_2S et le OCS) qui n'avaient pas été étudiés antérieurement. Nos résultats indiquent que les déplacements chimiques du ^{33}S s'étalent sur environ 1000 ppm; cette valeur n'est que légèrement inférieure aux valeurs observées pour le ^{17}O et n'est approximativement que la moitié de la valeur rapportée pour le ^{77}Se. En utilisant la constante de rotation de spin nucléaire du ^{33}S du OCS mesurée par résonance électrique de faisceau moléculaire et par la méthode de Flygare, on peut calculer que la constante de blindage du ^{33}S du OCS est égale à 843 ± 12 ppm; ceci permet de proposer une échelle absolue et approximative du blindage provoqué par ce noyau.

Introduction

In most nmr studies one measures a difference in Larmor resonance frequencies between some nucleus of interest, ν_i, and that of a reference compound containing the same isotopic species, ν_{ref}. It is then customary to define the chemical shift of i using eq. [1].

$$[1] \quad \delta = \frac{\nu_i - \nu_{ref}}{\nu_{ref}} \times 10^6$$

Since $\nu_i = \gamma/2\pi(1 - \sigma_i)B_0$, the chemical shift can be expressed in terms of shielding or screening constants, σ's (eq. [2]).

$$[2] \quad \delta = \frac{\sigma_{ref} - \sigma_i}{1 - \sigma_{ref}} \cong \sigma_{ref} - \sigma_i$$

Although it is generally possible to measure differences in shielding constants very accurately, often to better than 0.1 ppm, a knowledge of their absolute value is a much more difficult problem (1). If the absolute value of σ is known for any compound of a particular isotopic species, it is then possible, in principle, to establish an absolute nuclear shielding scale. The procedure of establishing an *approximate* absolute ^{33}S chemical shielding scale is outlined below (under theory) and the ^{33}S chemical shifts of several relatively simple compounds are reported.

Sulfur-33 has a natural abundance of 0.76%, a nuclear spin of 3/2, and relatively large quadrupole moment, -5.5×10^{-30} m^2 (2). In the absence of a symmetric electric field gradient at the nucleus, the large quadrupole moment generally leads to electric quadrupole coupling constants in the range of 20 to 50 MHz (3), hence very efficient nuclear spin relaxation with concomitant broad resonances. For ^{33}S, the line width at half maximum height is given by eq. [3], where all symbols have their usual meaning (4).

$$[3] \quad \nu_{1/2} = \frac{2}{5}\pi\,(1 + \eta^2/3)\,(e^2qQ/h)^2\,\tau_{eff}$$

This represents a lower limit on the line width. The potential of ^{33}S nmr in structural chemical studies was first explored by Retcofsky and Friedel (5). Subsequently Lutz and co-workers (6–9) have determined accurate ^{33}S chemical shifts for a few simple compounds and have suggested that the ^{33}S resonance of the sulfate anion serve as a ^{33}S nmr reference (6). More recently, ^{33}S nmr studies of some simple sulfones and sulfonic acids have been reported (10, 11).

Theory

The nuclear shielding tensor, σ_{ij}, is generally expressed as a sum of two terms of opposite sign, the so-called diamagnetic and paramagnetic terms (ref. 4, Chapt. 6). In isotropic solution nmr studies one measures a quantity related to the average value of σ_{ij}, hence

$$[4] \quad \sigma_{av} = \sigma^d_{av} + \sigma^p_{av}$$

Flygare and co-workers (12–15) have shown that for a nucleus S in a molecule the diamagnetic term can be approximated by eq. [5]

$$[5] \quad \sigma^d_{av}(S) \simeq \sigma^d_{av}\,(\text{free atom}) + \frac{e^2}{3mc^2}\sum_n \frac{Z_n}{r_n}$$

where σ^d_{av} (free atom), the diamagnetic shielding in the free atom obtained from atomic Hartree–Fock functions, is 1050.5 ppm for sulfur (16), Z_A is the atomic number of the n^{th} nucleus ($n \neq S$), and r_n is the distance between n and S. The paramagnetic term in eq. [4] is closely related to the nuclear spin-rotation constant, for a linear molecule,

$$[6] \quad \sigma^p_{av}(S) = \left(\frac{2\pi e}{3mhc}\right) R_\perp I_\perp - \frac{e^2}{3mc^2}\sum_n \frac{Z_n}{r_n}$$

where $R_\perp = M_\perp/g_S\mu_0$ and $M_\perp/h$ is the nuclear spin rotation constant in Hz, μ_0 is the nuclear magneton, $g_S(^{33}S) = 0.429$ (6), and $I_\perp$ is the moment of inertia. Note that the nuclear contribution to $\sigma^d_{av} + \sigma^p_{av}$ is zero. For ^{33}S, the only spin-rotation

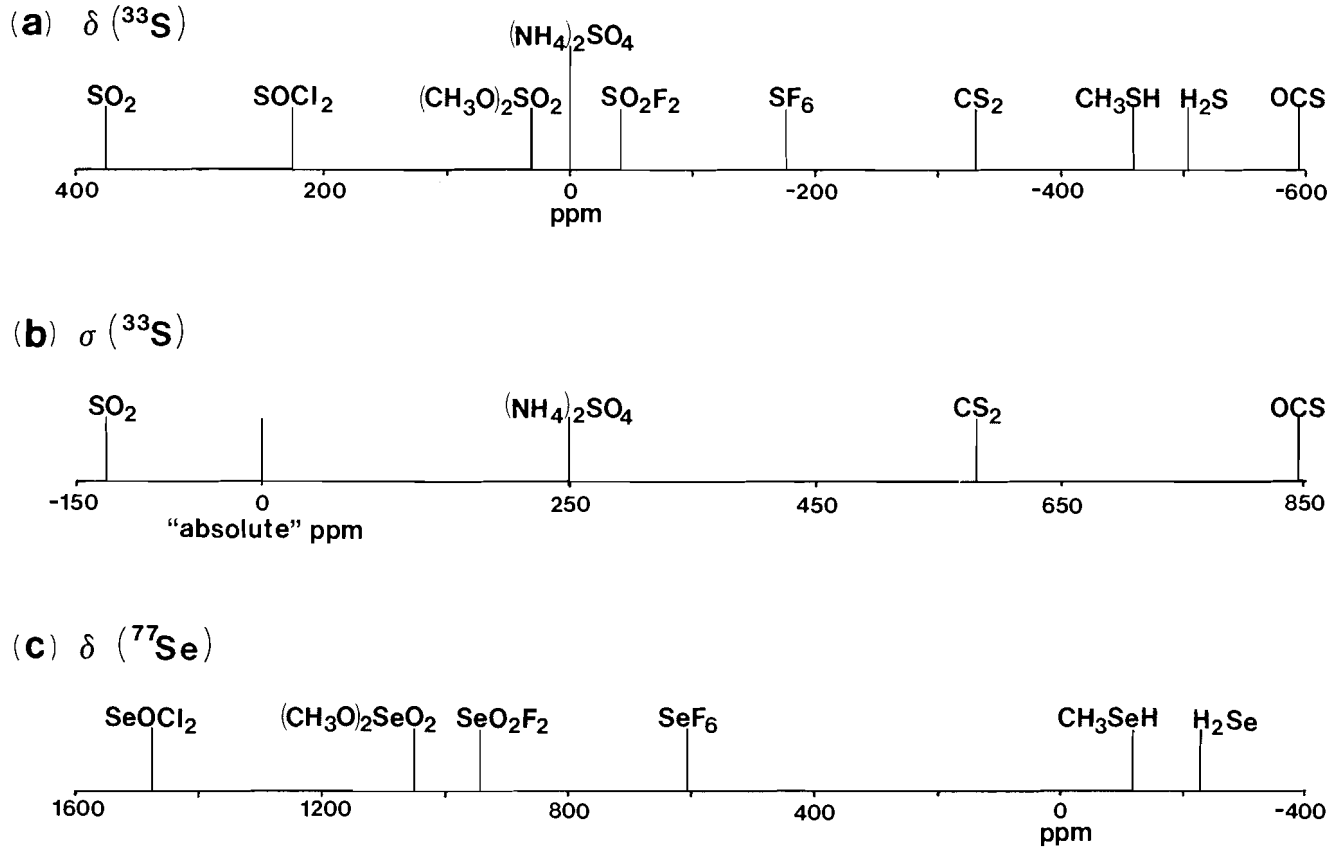

FIG. 1. (a) Sulfur-33 nmr chemical shifts with respect to 4 *m* $(NH_4)_2SO_4$; positive values are to high frequency of the reference; (b) an approximate absolute ^{33}S nmr chemical shielding scale, see text; (c) ^{77}Se nmr chemical shifts with respect to $(CH_3)_2Se$, ref. 21.

constant we are aware of is that of OCS. For the ground vibrational state $M_\perp/h$ = 870 ± 50 Hz (17). Substitution into eq. [5] and [6] gives σ_{av} = 843 ± 12 ppm. This of course is the average ^{33}S nuclear shielding constant of an isolated OCS molecule in the ground vibrational state.

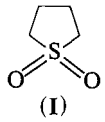
Experimental

All ^{33}S nmr measurements were carried out at 27.7 MHz on a Nicolet 360 (B_0 = 8.480 T) using a broad-band (16 to 56 MHz variable temperature 10-mm probe. The probe was tuned and matched for each sample. The $\pi/2$ pulse width was approximately 45 μs. Neat samples of H_2S, CH_3SH, OCS, SF_6, SO_2, and SO_2F_2 from Matheson were prepared on a gas rack by condensing each of the above gases in thick walled 10-mm od nmr tubes. The nmr samples of SO_2Cl_2, $SOCl_2$, and $HFSO_3$ were prepared in an inert atmosphere.

Results and discussion

(i). *General features of the ^{33}S nuclear magnetic resonance spectra*

The results of this study are summarized in Table 1 and Fig. 1(a). With the exception of SF_6, $(NH_4)_2SO_4$, and sulfolane (tetramethylene sulfone (**I**)), the ^{33}S nmr line widths at half-height were significantly greater than 100 Hz but less than 2



(**I**)

kHz. The sharpest lines ($\nu_{1/2}$ < 1 Hz) were observed for SF_6 at 295 K where the central line had an apparent T_1 of 10 ± 2 s! The

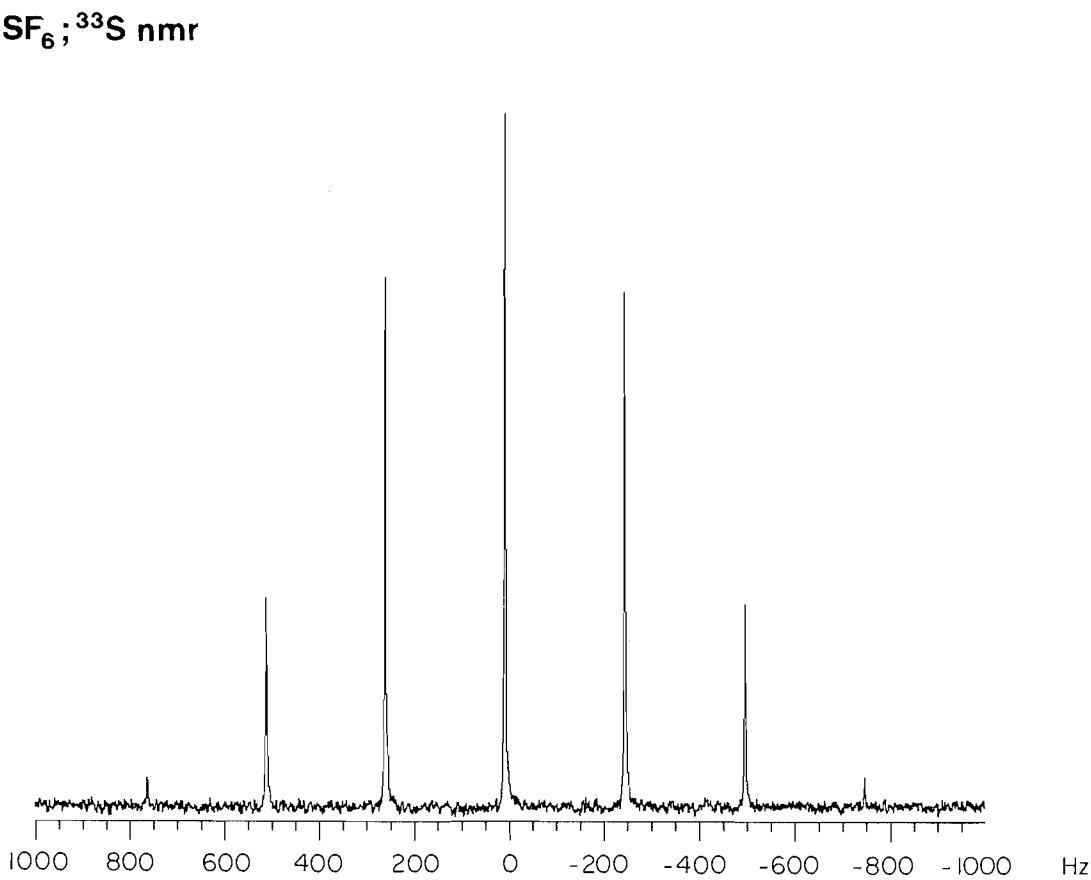

FIG. 2. The ^{33}S nmr spectrum of neat liquid SF_6 at 295 K.

cause the natural line widths are substantially greater than the spin–spin couplings. A ^{33}S nmr spectrum more typical of those obtained for the compounds listed in Table 1 is that of OCS, Fig. 3. Approximately 5.5 min were required to obtain this spectrum (3200 scans, acquisition time of 0.1024 s, and line broadening of 25 Hz). Substituting the ^{33}S nuclear quadrupole coupling constant, 29.12 MHz (17), and the observed line width, 440 ± 50 Hz, into eq. [3] implies a rotational correlation time of 0.41 ps for OCS. This is significantly shorter than the value, 1.3 ps, reported for liquid CS_2 at 288 K (19).

(ii). *Relative chemical shifts*

The ^{33}S chemical shift of SO_2 is 340 ppm to higher frequency than that of any other sulfur resonance previously investigated. The central ^{17}O of ozone which is structurally analogous to the ^{33}S of SO_2 is also highly deshielded relative to $^{17}OH_2$ (20), 1032 ppm. On the basis of the data in Fig. 1, the chemical shift range of ^{33}S is less than 1000 ppm, which is slightly less than the ^{17}O chemical shift range (20*b*). The ^{77}Se chemical shift range (21) is much larger than that of ^{33}S and ^{17}O. In Fig. 1(c) the ^{77}Se chemical shifts of several compounds with respect to $(CH_3)_2Se$ are given; note that the scale used to express the relative ^{77}Se chemical shifts is double that used for the ^{33}S shifts. The close correspondence between the relative ^{33}S and ^{77}Se chemical shifts in analogous compounds is quite striking. For example, the ^{33}S resonance of SF_6 is approximately 325 ppm to high frequency of H_2S and 400 ppm to low frequency of $SOCl_2$; similarly, the ^{77}Se resonance of SeF_6 is approximately 836 ppm to high frequency of H_2Se and 890 ppm to low frequency of $SeOCl_2$ (21).

The relative chemical shift ranges for ^{17}O, ^{33}S, and ^{77}Se are analogous to those reported for the group IV nuclides, ^{13}C, ^{29}Si, and ^{73}Ge. Silicon has a chemical shift range of approximately 400 ppm, smaller than carbon (22), but germanium has a chemical shift range of at least 1200 ppm, much greater than either carbon or silicon. Similarly, the chemical shift range of ^{31}P, ~600 ppm, is less than that of N, ~1000 ppm; unfortunately the large quadrupole moment of ^{75}As severely limits the range of As compounds which can be investigated (23). On moving across the second row elements there is a definite increase in the range of chemical shift; Si (400 ppm), P (600 ppm), and S (1000 ppm).

The replacement of a hydrogen in H_2S by a methyl group leads to a high frequency ^{33}S nmr shift of 44.7 ± 2 ppm; the corresponding ^{77}Se shift in H_2Se relative to CH_3SeH is 110 ppm (21*b*). Because of hydrogen bonding effects, these values are probably dependent on solvent (21*c*).

(iii) *An absolute ^{33}S shielding scale*

In order to establish an absolute ^{33}S nmr shielding scale, we must assume that the gas to liquid chemical shifts are similar for our primary reference (OCS) and any other sulfur compound, S. Typically, the nucleus becomes more shielded on going from the gas to liquid phase and the magnitude of the shift appears to be related to the chemical shift range of that particular isotope (24). Attempts to measure the ^{33}S nmr resonance frequency of OCS in the gas phase (8.8 atm) have been unsuccessful to date. For the ^{17}O nucleus of OCS, we have observed a gas to liquid shift of −4.9 ppm (greater shielding in the gas phase). The ^{17}O and ^{33}S chemical shift ranges are both similar (1000 ppm), thus gas to liquid ^{33}S chemical shifts are probably generally small and eq. [7] is a good approximation.

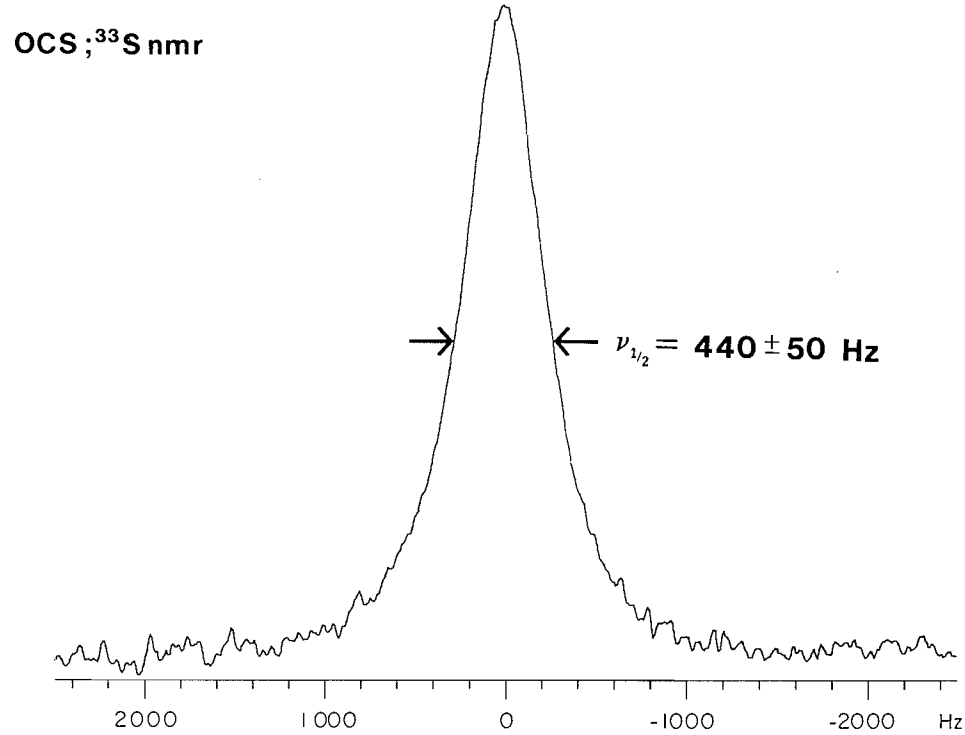

FIG. 3. The ^{33}S nmr spectrum of neat liquid OCS at 295 K.

[7] $\sigma_e^S \simeq \sigma_0^{OCS} + \sigma^S$ (liq. T) $- \sigma^{OCS}$ (liq. T)

Here σ_e^S is the average absolute shielding of nucleus S for the equilibrium configuration, and σ_0^{OCS} is the average absolute shielding of an isolated OCS molecule, +843 ppm. The absolute ^{33}S scale is sketched in Fig. 1(b); σ is 249 ppm and 581 ppm for 4 *m* ($(NH_4)_2SO_4$ and CS_2, respectively, two common ^{33}S nmr references.

Few theoretical calculations of ^{33}S shielding constants have been reported (25, 26). The most recent calculations by Ridard *et al.* (26) use a pseudo-potential technique. For the ^{33}S nucleus of H_2S they calculate the following average shielding constants: σ^d = 1062.4 ppm, σ^p = −327.8 ppm, and σ = 734.6 ppm;[3] using the data in Table 1 and eq. [7], σ = 752 ppm. Considering the error in σ_0^{OCS} and the assumptions in applying eq. [7], the agreement is excellent.

Further ^{33}S nuclear spin-rotation constants and nuclear shielding calculations will be necessary to test the reliability of the scale proposed here. Nevertheless the results in Table 1 expand our knowledge of ^{33}S chemical shielding and represent a first step in establishing a ^{33}S shielding scale. We believe that ^{33}S will become a more important nucleus for chemists as nmr pulse programmers and probe designs improve, particularly if studies are carried out at high applied magnetic fields.

Acknowledgements

All sulphur-33 nmr spectra were obtained at the Atlantic Regional NMR Center. We are grateful to NSERC for financial support in helping establish and maintain this center and for operating (R.E.W.) and summer assistantship (C.C. and J.F.) grants.

[3] NOTE ADDED IN PROOF: More recent calculations by Höller and Lischka (27) yield σ = 721 ppm for H_2S.

Vapour pressure and thermodynamic data for the binary liquid mixture of pyridine and sulphur dioxide

C. L. GARDNER and R. W. DAY

Defence Research Establishment Ottawa, Ottawa, Ont., Canada K1A 0Z4

Received September 8, 1983

C. L. GARDNER and R. W. DAY. Can. J. Chem. **62**, 986 (1984).

Solubility and nmr data are presented for the pyridine – sulphur dioxide system. The data have been analyzed to determine partial vapour pressures, activity coefficients, and thermodynamic functions. The results indicate that a 1:1 complex of pyridine and SO_2 is formed in these solutions.

C. L. GARDNER et R. W. DAY. Can. J. Chem. **62**, 986 (1984).

On rapporte des données relatives à la solubilité et à rmn du système pyridine – dioxyde de soufre. On a analysé les données pour déterminer les tensions de vapeur partielles, les coefficients d'activité et les fonctions thermodynamiques. Les résultats indiquent que, dans ces solutions, il y a formation d'un complexe 1:1 entre la pyridine et le SO_2.

1. Introduction

In recent years a number of high energy density battery systems using lithium as the anodic material have been introduced. Among these, the lithium – sulphur dioxide system has been one of the most successful. The electrolyte in this battery consists (1) of a mixture of sulphur dioxide, acetonitrile, and a lithium salt, usually lithium bromide. While this electrolyte offers exceptional performance, under certain conditions, reaction of excess lithium with the acetonitrile can lead to the formation of relatively large amounts of lithium cyanide (2). In addition, the solubility of sulphur dioxide in acetonitrile is not as high as in other solvents (3) and, as a result, the internal pressure in lithium – sulphur dioxide cells is relatively high.

In our laboratory, we have initiated studies of alternative electrolyte systems that offer improved safety. In this regard, a detailed study of the sulphur dioxide/*N*-methyl-2pyrrolidinone system has been published (4). In this paper we report solubility results for the pyridine – sulphur dioxide system while results of Raman spectroscopic studies will be reported in the near future (5).

The formation of relatively strong addition compounds between nitrogen bases and sulphur dioxide is well known (6). It was suggested as early as 1935 (7) that a compound of pyridine with sulphur dioxide existed at low temperatures. The phase equilibrium of pyridine and the picolines with sulphur dioxide was studied by Hoffman and Van der Werf (8). These results showed clearly that a 1:1 addition compound was formed between sulphur dioxide and pyridine. The system has also been examined by dielectric measurement (9) and more recently by Raman spectroscopy (5, 10, 11). These studies show clearly that the complex formed between pyridine and sulphur dioxide is charge transfer in nature.

Vapour pressure and calorimetric data for the solution of sulphur dioxide in pyridine given by Benoit and Milanova (3) show pyridine to be an excellent solvent for sulphur dioxide. The work reported in this paper extends the solubility work of Benoit and Milanova to higher pressures, enabling the range of complex formation in this solution to be examined in more detail and thermodynamic excess functions to be determined.

2. Experimental

The pyridine (Fisher centified ACS) was vacuum distilled (40 kPa at about 40°C) from a calcium hydride slurry. Samples of pyridine were tested for water content on a Perkin Elmer Sigma 3 gas chromatograph using a Poropack QS column on a thermal conductivity detector. The results indicated the water content to be about 14 ppm. The distilled solvent was stored in an argon atmosphere in a Vacuum Atmospheres glove box. All manipulations were carried out under anhydrous conditions. The purified liquid was loaded into the solubility flask in the glove box and degassed immediately before use on the vacuum line by several freeze–pump–thaw cycles. Matheson anhydrous SO_2 was used for the measurements without further purification.

Gas solubility measurements were made by introducing a known amount of SO_2 gas (measured using a gas burette) to a known amount of pyridine (typically of the order of 0.5 g) and noting the pressure above the solution after equilibration which normally took about 1 h. The solubility flask was thermostatted to better than ±0.5°C using a constant temperature bath. The solution was stirred constantly using a small magnetic stirrer. The pressure above the solution was measured using a mercury manometer. Corrections to the mass of SO_2 dissolved were made assuming the gas in the space above the solution to follow the ideal gas equation of state.

Nuclear magnetic resonance spectra were recorded on a Varian T-60 spectrometer at 308 K. The samples for the nmr were prepared gravimetrically in the glove box by bubbling SO_2 into a known weight of pyridine. A thermoelectric cooler was used to cool the pyridine as the SO_2 was added since a significant amount of heat was liberated during the dissolution process. The samples were sealed in nmr tubes with screw caps and Teflon sealers to prevent loss of SO_2. Spectra were recorded soon (usually the same day) after preparation. Loss of SO_2 through Teflon sealers was negligible during this period.

The samples were run with an external standard of *N*,*N*-dimethyl formamide (DMF), sealed in a capillary tube, which was inserted into each nmr tube. DMF was chosen since it offered a peak adjacent to the peak due to the *ortho* protons in the pyridine and provided a convenient reference.

3. Results and discussion

The total vapour pressures for mixtures of sulphur dioxide and pyridine at six temperatures are listed in Table 1 and illustrated in Fig. 1. From Fig. 1, it is seen that the system shows a large negative deviation from Raoult's law.

Partial vapour pressures, P_{SO_2} and P_{py}, of the sulphur dioxide and the pyridine were obtained using a method similar to that described in refs. 4, 12, and 13. In this method it is assumed that the excess free energy of mixing, ΔG^e_{mix}, can be expressed as the polynomial

$$\Delta G^e_{mix} = RTX_{SO_2}X_{py} \sum_{i=1}^{n} C_i(X_{SO_2} - X_{py})^{i-1}$$

From the relationship

* Mole fraction of SO_2.
† Gibbs excess free energy of mixing.

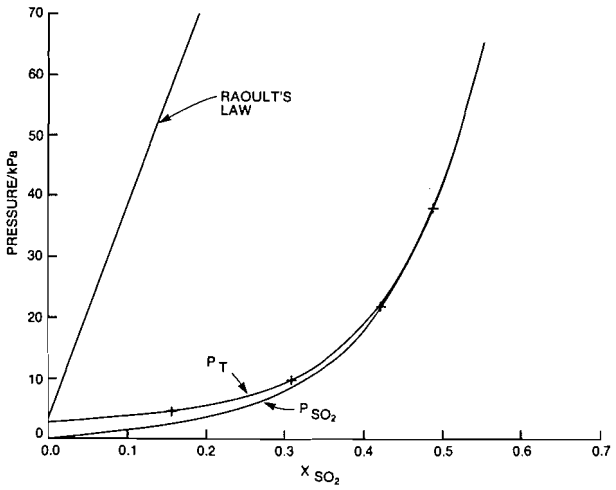

FIG. 1. Total pressure and partial vapour pressure of SO_2 above a pyridine–SO_2 solution at 25°C.

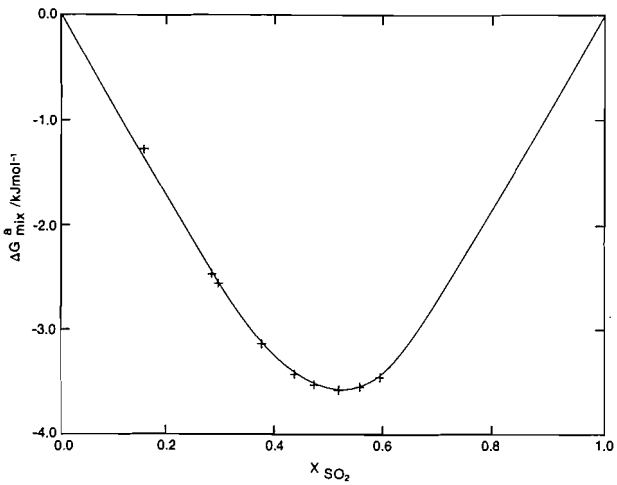

FIG. 2. Excess Gibb's free energy of mixing for a pyridine–SO_2 solution at 15°C.

$$\Delta G^e_{mix} = -RT\{X_{SO_2} \ln \gamma_{SO_2} + X_{py} \ln \gamma_{py}\}$$

and the Gibbs–Duhem equation

$$X_{SO_2} \, d \ln \gamma_{SO_2} + X_{py} \, d \ln \gamma_{py} = 0$$

the activity coefficients can be expressed as

$$\ln \gamma_{SO_2} = X^2_{py}\left\{C_1 + \sum_{i=2}^{n} C_i(2iX_{SO_2} - 1)(X_{SO_2} - X_{py})^{i-2}\right\}$$

and

$$\ln \gamma_{py} = X^2_{SO_2}\left\{C_1 + \sum_{i=2}^{n} C_i(1 - 2iX_{py})(X_{SO_2} - X_{py})^{i-2}\right\}$$

The number of parameters, n, used to fit the vapour pressure data using a non-linear least-squares method, at the six temperatures was chosen to be four. Trials were done using from two to six parameters. For the low number of data points, six parameters proved to be too high. The use of only two parameters did not produce a good fit. The use of four parameters was a compromise between a good fit and a forced fit since the number of parameters did not usually approach the number of data points. The partial vapour pressures, activity coefficients for each component, and excess free energies of mixing, ΔG^e_{mix}, obtained from these calculations are included in Table 1. The excess enthalpy and entropy of mixing, ΔH^e_{mix} and ΔS^e_{mix}, can be obtained from the data for ΔG^e_{mix} at different temperatures. The values obtained for ΔH^e_{mix} and ΔS^e_{mix} for a mole fraction of SO_2 of 0.5 are -19.9 ± 2.5 kJ mol^{-1} and -54.7 ± 9.3 J K^{-1} mol^{-1}, respectively.

Figure 2 shows ΔG^e_{mix} as a function of solution composition at 15°C. At all temperatures ΔG^e_{mix} is a minimum at a mole fraction of 0.5 ± 0.05. These results support previous Raman spectroscopic (10, 11) and phase equilibrium (8) studies that suggest the formation of a 1:1 addition compound in mixtures pyridine and sulphur dioxide.

When two components of a binary mixture form a complex, a simple equilibrium equation of the form

$$A + B \overset{K}{\rightleftharpoons} AB$$

can be used. As discussed by Prausnitz (14), it can be shown from a simple chemical theory of binary solutions that complex formation causes negative deviations from Raoult's law and results in a minimum in ΔG^e_{mix} at $X_A = 0.5$. The equilibrium constant K can be related to the activity coefficients of SO_2, using the relationship

$$\gamma_{SO_2} = \{kX_{SO_2} - 2 + 2(1 - kX_{SO_2}X_{py})^{1/2}\}/kX^2_{SO_2}$$

where

$$k = 4K/(K + 1)$$

By rearrangement, it can be shown that

$$k = (2A + B)/A^3$$

where

$$A = (X^2_{SO_2}\gamma_{SO_2} - X_{SO_2})/2$$

and

$$B = X_{SO_2}X_{py}$$

Values of K obtained by this procedure are tabulated in Table 1. These values are reasonably consistent up to a mole fraction of SO_2 of about 0.5. At higher mole fractions the procedure breaks down (in some cases K becomes negative).

The inconsistency in K values that is observed at high mole fractions may be the result of the formation of other complexes in solution. Laser Raman spectroscopic results of Adams and Dierker (5) have shown evidence for the formation of a 2:1 SO_2 to pyridine complex at mole fractions of 0.45 and above.

Nuclear magnetic resonance spectroscopy was also used to study the formation of complexes in the mixtures of SO_2 and pyridine. The addition of SO_2 to pyridine causes an upfield shift of the resonance due to the ortho protons. Using DMF as a reference, the successive chemical shifts of the *ortho* protons of the pyridine were recorded for a number of samples containing increasing amounts of SO_2. The upfield shift of the *ortho* protons can be attributed to the formation of the Py.SO_2 addition complex. Assuming rapid equilibrium, the field position will be a weighted average of the resonances for free and complexed pyridine. The data were treated using Job's method (15) and the Job's plot is illustrated in Fig. 3. The maximum observed in the Job's plot at 0.5 indicates that the 1:1 Py.SO_2 complex is the major species formed in this solution.

As described in the paper of Adams, Kruus, and Patraboy (4), the solubility data can also be used to obtain the free energy of solution from the relation

For personal use only.

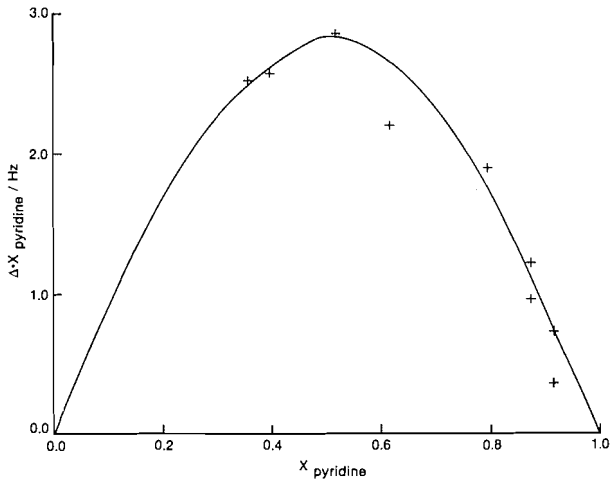

FIG. 3. Job plot for the pyridine–SO_2 system at 35°C. $\Delta = \partial_{\text{pyridine}} - \partial_{\text{obs}}$. Experimental values for *ortho* protons.

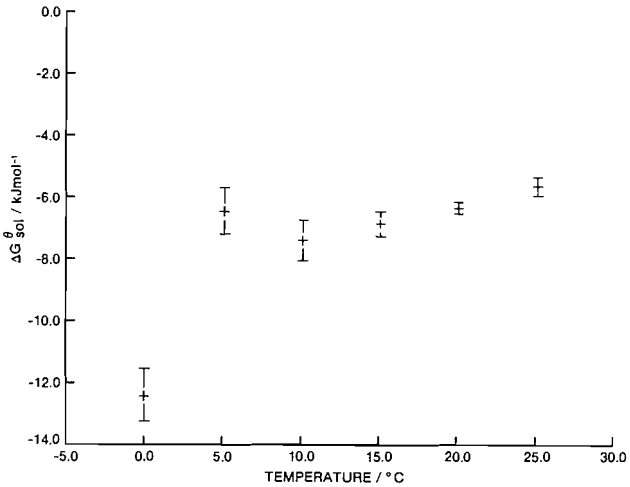

FIG. 4. $\Delta G^{\theta}_{\text{sol}}$ for SO_2 in pyridine as a function of temperature.

$$\Delta G_{\text{sol}} = -RT \ln K_c$$

where $K_c = X_{SO_2}/P_{SO_2}$. The free energy of solution at infinite dilution, $\Delta G^{\theta}_{\text{sol}}$, is obtained by extrapolating the data for ΔG_{sol} to $X_{SO_2} = 0$. The value of $\Delta G^{\theta}_{\text{sol}}$ was obtained by using a least-squares method to fit a quadratic curve to the experimental data. Because a relatively long extrapolation is required there is considerable uncertainty in the values obtained.

This uncertainty is especially high at low temperatures because the pressures being measured are very small at low mole fractions and could not be determined accurately with the apparatus used. Figure 4 shows $\Delta G^{\theta}_{\text{sol}}$ as a function of temperature.

The enthalpy and entropy of solutions can be obtained using the relationships

$$\Delta H^{\theta}_{\text{sol}} = \partial(\Delta G^{\theta}_{\text{sol}}/T)/\partial(1/T)$$

and

$$\Delta S^{\theta}_{\text{sol}} = -\partial(\Delta G^{\theta}_{\text{sol}})/\partial T$$

Because the error in $\Delta G^{\theta}_{\text{sol}}$ is considerably greater at the lower temperature than at the higher temperatures, a weighted least squares method (16) was used to fit the data. Using this method one obtains values of $\Delta H^{\theta}_{\text{sol}} = -54.6 \pm 6.6$ kJ mol^{-1} and $\Delta S^{\theta}_{\text{sol}} = -166 \pm 23$ J K^{-1} mol^{-1}. If only the four high temperature points are used, values of $\Delta H^{\theta}_{\text{sol}} = -51.6 \pm 5$ kJ mol^{-1} and $\Delta S^{\theta}_{\text{sol}} = -148 \pm 17$ J K^{-1} mol^{-1} are obtained using a simple least-squares fit. These values can be compared with the values of $\Delta H^{\theta}_{\text{sol}} = -48.5$ kJ mol^{-1} and $\Delta S^{\theta}_{\text{sol}} = -142.7$ J K^{-1} mol^{-1} obtained by Benoit and Milanova (3).

4. Conclusions

Solubility and nmr studies have shown clearly that a relatively strong 1:1 complex is formed when SO_2 is dissolved in pyridine. These results are in agreement with phase equilibrium (8) and Raman spectroscopic studies (11). The solubility data has been analyzed to determine partial vapour pressures, activity coefficients, and thermodynamic functions for binary mixtures of SO_2 in pyridine.

Effects of added cations on rate enhancements for the nickel(II)−PADA reaction in micellar solutions

JOANNE R. HICKS AND VINCENT C. REINSBOROUGH
Chemistry Department, Mount Allison University, Sackville, N.B., Canada E0A 3C0

Received October 17, 1983

JOANNE R. HICKS and VINCENT C. REINSBOROUGH. Can. J. Chem. **62**, 990 (1984).

Rate enhancements of the Ni^{2+}−PADA bidentate formation reaction have been obtained at 25.0°C in anionic micellar solutions with added electrolyte. Sodium dodecylsulfate, sodium octanesulfonate, and sodium octylsulfate were the surfactants employed and Na^+, Ca^{2+}, and Mg^{2+} were the added cations. Kinetic analyses revealed that the chief effect in leading to a decreased rate enhancement with salt present was a lowering of the surface potential manifested by an increase in the reaction volume. The binding of the Ni^{2+} ion to the micelles showed little change beyond an initial drop with the lowest Na^+ addition with sodium dodecylsulfate. The binding of the hydrophobic reagent PADA decreased more gradually but not sufficiently to account for the reduction in rate enhancements. In the presence of Ca^{2+} or Mg^{2+} ions, the rate enhancements and the kinetic parameters did not show unusual behaviour except that Mg^{2+} ion appeared to be slightly more effective in excluding Ni^{2+} ion from the micellar surface region. The sphere-to-rod micellar transformation that occurs at 0.4 mol dm^{-3} Na^+ does not have a pronounced effect on the micellar surface region.

JOANNE R. HICKS et VINCENT C. REINSBOROUGH. Can. J. Chem. **62**, 990 (1984).

Opérant à 25°C, dans une solution micellaire anionique contenant un électrolyte ajouté, on a déterminé les accroissements de vitesse de réaction pour la formation du bidentate Ni^{2+}−PADA. Les agents de surface utilisés sont les dodécylsulfate, octylsulfonate et octylsulfate de sodium et les cations ajoutés sont les ions Na^+, Ca^{2+} et Mg^{2+}. Les analyses cinétiques ont révélé que l'effet principal conduisant à une diminution de l'accroissement de vitesse avec le sel présent est un abaissement du potentiel de surface qui se manifeste par une augmentation du volume de la réaction. Avec le dodécylsulfate de sodium, la liaison de l'ion Ni^{2+} avec les micelles ne change pas beaucoup au delà d'une chute initiale avec la plus faible addition de Na^+. La liaison du réactif hydrophobe PADA décroit plus graduellement mais pas suffisamment pour intervenir dans la diminution des accroissements de vitesse. En présence des ions Ca^{2+} ou Mg^{2+}, les accroissements de vitesse et les paramètres cinétiques ne révèlent pas de comportement inhabituel à l'exception des ions Mg^{2+} qui semblent légèrement plus efficaces dans l'exclusion des ions Ni^{2+} de la région de la surface micellaire. La transformation micellaire de la forme sphère à la forme de bâtonnet qui se produit à une concentration en ion Na^+ de 0,4 mol dm^{-3} n'a pas d'effet marqué sur la région de la surface micellaire.

Introduction

Added salt generally decreases micellar rate enhancements (1−3). The extra counterions can effectively compete with ionic reagents for micellar sites, thus lowering the surface potential. This decrease in rate occurs despite the increase in aggregation number which accompanies salt addition and which by itself should favour greater solubilization of hydrophobic reagents to give larger rate enhancements. The bidentate formation reaction that occurs with $Ni^{2+}_{(aq)}$ and pyridine-2-azo-*p*-dimethylaniline (PADA) involves both an ionic and a hydrophobic reagent and the kinetic model developed by Robinson and co-workers (3, 4) from Berezin's original concept (5) allows the influence of each reagent on the pronounced rate enhancements to be evaluated separately and quantitatively. This reaction is then well suited for such a kinetic analysis whereby the effects of added salt on rate enhancements might be better understood in terms of each reagent's contribution. This reaction can also serve kinetically as a probe of the micellar surface region (6) and, in this context, should shed light on any changes occurring in the surface region as the micelles undergo structural changes on salt addition. Thus, the main purposes of this project were to discover why basically rate enhancements in micellar solutions decreased with salt additions when one reagent was ionic and the other hydrophobic and how the micellar surface region was affected by the sphere-to-rod transition that occurs in salt-doped surfactant solutions.

Experimental

The kinetic rate constants (k_{obs}) for the Ni^{2+}−PADA reaction were measured at pH 7.8−8.0 by the stopped-flow technique under pseudo-first order conditions (usually 1.0×10^{-3} mol dm^{-3} Ni^{2+} and 1×10^{-5} mol dm^{-3} PADA). Details of the method and apparatus are given elsewhere (4, 6, 7). Activation energies for the reaction were measured in $NaNO_3$-doped solutions to ensure that the rate-determining step was still the ejection of water from hydrated Ni^{2+} ion. The results were always confirmatory.

Salt additions were made with nitrates rather than chlorides since the latter complexed with $Ni^{2+}_{(aq)}$ in the time range of the stopped-flow determinations (dead-time was approximately 3 ms).

Chemicals were supplied by Sigma Chemicals (sodium octanesulfonate and PADA), Fisher Scientific (sodium octylsulfate and the inorganic salts) and BDH (specially pure sodium dodecylsulfate). They were used without further purification.

Results and discussion

In the presence of anionic micelles, the Ni^{2+}−PADA reaction takes place in two media, bulk water and the surface region of the micelles. In the latter, the two reagents are preferentially adsorbed, one electrostatically and the other chiefly by hydrophobic attraction. Any rate enhancement that is observed in micellar solution will depend on how strongly each reagent is bound to the micelle where sheer proximity of the two ensures a faster reaction rate. If one reagent is very weakly bound to the micelle, the rate enhancement will not be pronounced no matter how strongly the other reagent is partitioning into the micelle. The kinetic expression that embodies all of this quantitatively at constant pH is the following (8, 9):

$$[1] \quad k_{obs} = k_1^m[Ni^{2+}]/(CV_s\{1 + (CK_{Ni})^{-1}\}\{1 + (CK_{PADA})^{-1}\}) + k_{-1}^m$$

where k_{obs} is the observed first-order rate constant; k_1^m and k_{-1}^m,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

the forward and backward rate constants for the reaction on the micelle surface; C, the surfactant concentration in the micelles in mol dm^{-3}; K_{Ni} and K_{PADA}, the binding constants for each reagent to the micelles; and V_s, the reaction volume in dm^3 per mole of surfactant. The kinetics of the reaction occurring in the bulk water phase is given by a similar equation. However, since the observed kinetic trace was analyzed only for the faster pseudo-first order rate constant, eq. [1] need only be considered.

Approximating k_1^m and k_{-1}^m by the corresponding rate constants in water has been shown to be reasonable (3, 10) and has even been invoked in alcoholic micellar systems (11). This assumption is difficult to test directly since all the quantities in eq. [1] cannot be independently obtained experimentally. However, the continued adequacy of this equation to represent micellar rate enhancements quantitatively and, in particular, to yield reasonable V_s values (the only quantity that is as yet inaccessible to experimental verification) argues for the validity of the approximation. An additional re-assurance in the present case is that the activation energy for the probe reaction is unaltered from the water situation when salt is introduced to the micellar systems.

The partitioning or binding constant, K_{PADA}, is defined as $[PADA]_M/C[PADA]_W$ where the two PADA concentrations are those for the micellar and aqueous "phases". K_{Ni} is similarly expressed. These constants can be obtained independently of the kinetic data. For example, K_{PADA} can be determined through solubility measurements (4, 8, 9) and K_{Ni} by the murexide technique (12, 13). For short-chained surfactants especially, the murexide technique is open to much uncertainty because estimates of the activity coefficients are necessary. Consequently, it is more convenient and as accurate to obtain K_{Ni} by computer-fitting the k_{obs} data to eq. [1] using K_{PADA} values from solubility measurements with V_s as variable also.

The reaction volume cannot yet be independently measured. Berezin (5) approximated V_s by the molar volume of the surfactant. In the pseudo-phase ion exchange model for micellar catalysis, the reaction is assumed to occur only in the Stern layer of the micelle which for sodium dodecylsulfate is 0.14 dm^3 mol^{-1} or about half the molar volume (2). This strictly defined reaction volume, issuing from a model that precludes much flexibility and dynamism in micelle structure, cannot easily accommodate k_{obs} data for short-chained surfactants where V_s values are often two to three times the molar volume (8, 9). This may be at the heart of recently reported "failures" of the pseudo-phase model (14, 15). We prefer to allow V_s to seek its own value in accordance with eq. [1] where, with surfactants of medium chain length (about 12 carbons) or greater, the Berezin estimate of the molar volume is invariably found. Given the present dynamic view of micelles where monomers are continually partially popping out into the solution (16), a reaction volume for a micellar surface becomes difficult to define especially where a hydrophobic reagent may be deeply embedded in the core of the micelle.

The k_{obs} data are more conveniently plotted as k_1^{app}/k_1^w where k_1^{app} is the apparent rate constant (coefficient of $[Ni^{2+}]$ in eq. [1]). This ratio of rate constants (R) is a direct measure of the rate enhancement achieved in the presence of micelles. The value of k_1^w increases with increasing ionic strength from 1.20 $\pm$ 0.05 $\times$ 10^3 dm^3 mol^{-1} s^{-1} with no added salt to 1.78 $\pm$ 0.05 $\times$ 10^3 dm^3 mol^{-1} s^{-1} at 0.80 mol dm^{-3} $NaNO_3$.

In Fig. 1 are shown the R values for sodium dodecylsulfate (SLS) solutions for the probe reaction at 25.0°C for $NaNO_3$ additions in the range 0.10–0.80 mol dm^{-3}. The maximum in

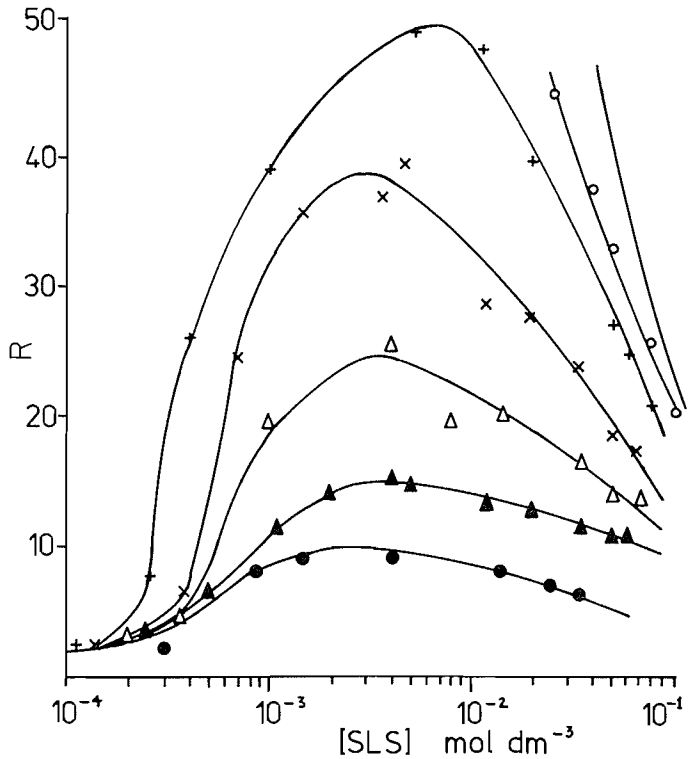

FIG. 1. Rate enhancements (R) in SLS solutions with added salt: ○, 0.10 mol dm^{-3} Na^+; +, 0.20 mol dm^{-3} Na^+; ×, 0.30 mol dm^{-3}; △, 0.40 mol dm^{-3} Na^+; ▲, 0.60 mol dm^{-3} Na^+; ●, 0.80 mol dm^{-3} Na^+. The top line to the right is the pure solution curve.

the R curve for 0.10 mol dm^{-3} $NaNO_3$ additions was inaccessible to the stopped-flow apparatus but could be sketched for the other salt additions. It is clear that added electrolyte strongly depresses the rate enhancements with the maximum in R in the presence of 0.80 mol dm^{-3} $NaNO_3$ being only 1% of the corresponding R for pure SLS. Salt additions also shifted the critical micelle concentrations (CMC) and the maximum value of R to progressively lower concentrations.

Complete kinetic analyses according to eq. [1] were conducted on each of the systems depicted in Fig. 1 and the resulting fitted values of K_{Ni} and V_s along with the K_{PADA} values obtained through solubility measurements were listed in Table 1.

The major change that apparently occurs in Na^+ ion addition in SLS solutions is an increase in the volume of reaction (see Fig. 2). Little change from the molar volume of SLS ($\approx$0.3 dm^3 mol^{-1}) occurs until 0.2–0.3 mol dm^{-3} Na^+ is present but then V_s increases quite markedly until at 0.8 mol dm^{-3}, V_s is 10 times the pure surfactant value. It is well known that salt addition causes an increase in aggregation number in SLS micellar solutions (17–20) and that, around 0.4 mol dm^{-3} in Na^+ ion, the spherical SLS micelles become rod-like in structure (17, 18, 21). A case can be made from Fig. 2 for a structural change of some sort in the 0.2–0.4 mol dm^{-3} Na^+ region. It is not clear, however, how V_s should be affected by changes in aggregation number and in structure. V_s values increase on descending a homologous series of surfactants until, with the most weakly forming ones, V_s values are several times the molar volumes of the surfactants themselves (8, 9). In this same direction, micellar surface potentials rapidly decrease. Zachariasse *et al.* (22) have noted that the surface polarity of SLS micelles changes only slightly to 0.25 mol dm^{-3} Na^+ ion

TABLE 1. Rate enhancement parameters for anionic surfactants with added salt

Surfactant	Added cation (mol dm^{-3})	K_{PADA} (dm^3 mol^{-1})	K_{Ni} (dm^3 mol^{-1})	V_s (dm^3 mol^{-1})
SLS	—	2800	650	0.29
	0.10 Na^+	800	40	0.35
	0.20 Na^+	600	41	0.48
	0.30 Na^+	530	50	0.74
	0.40 Na^+	440	53	1.07
	0.60 Na^+	370	55	1.78
	0.80 Na^+	310	60	2.84
SOSO	—	160	22	0.70
	0.10 Na^+	150	26	0.62
	0.50 Na^+	80	26	1.29
SOS	—	300	11	0.55
	0.50 Na^+	210	16	1.32
	0.05 Ca^{2+}	200	12	0.55
	0.10 Ca^{2+}	180	14	0.82
	0.10 Mg^{2+}	180	6	0.48

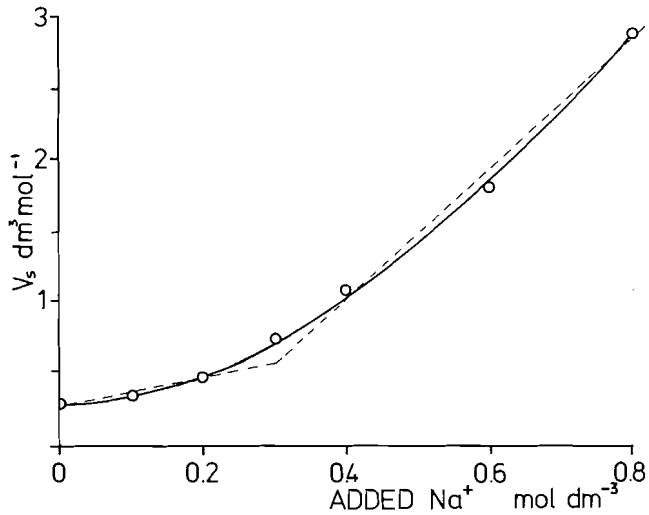

FIG. 2. Reaction volumes (V_s) in SLS solutions with varying amounts of added Na^+ ion.

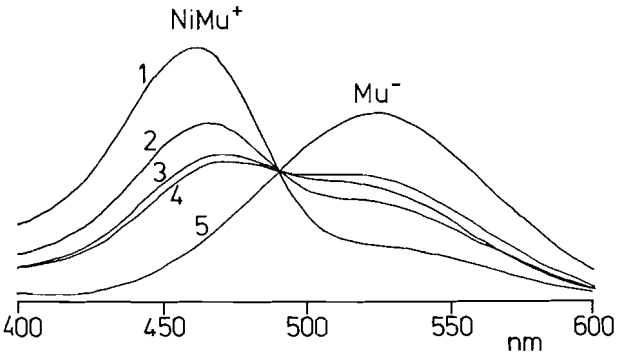

FIG. 3. Spectra of Ni^{2+} and murexide ion (Mu^-) in salt-doped SLS solutions at 25.0°C. $[Mu^-] = 2.10 \times 10^{-5}$ mol dm^{-3} and $[Ni^{2+}] = 2 \times 10^{-3}$ mol dm^{-3}. pH = 3.9 − 4.2. (*1*) No additives, (*2*) 0.20 mol dm^{-3} Na^+, (*3*) 0.05 mol dm^{-3} SLS and 0.40 mol dm^{-3} Na^+, (*4*) 0.05 mol dm^{-3} SLS and 0.02 mol dm^{-3} Na^+, and (*5*) 0.05 mol dm^{-3} SLS with no added salt.

followed by a rapid decrease with further salt additions. V_s is a measure of the volume per mole of surfactant accessible to reaction so that the product CV_s defines the volume fraction of the solution in which the probe reaction occurs. The lowered surface potential will result in the reactant species being less closely bound in the micellar surface region which will then extend further into the solution. The reactants on the surface will have been effectively diluted and the rate enhancements will not be as pronounced as with surfactant in water alone.

The increase in V_s is accompanied by changes in K_{Ni} and K_{PADA} which act in the same direction on the rate enhancements. These are undoubtedly inter-related and influenced by the decrease in micellar surface potential. K_{Ni} is most obviously affected with the Ni^{2+} ion being less attracted into the micellar surface region. The first Na^+ ion addition of 0.10 mol dm^{-3} reduces K_{Ni} to less than 10% of its value in pure SLS solutions (Table 1) but further Na^+ ion additions do not further change K_{Ni}. The two positively charged ions compete for surface sites and the presence of 0.10 mol dm^{-3} Na^+ ion with 10^{-3} mol dm^{-3} Ni^{2+} ion radically lowers the Ni^{2+} ion concentration in the surface region. Increasing the salt content further causes little further change in K_{Ni}, in part due to the compensating increase in V_S.

This was tested by examining Ni^{2+} − murexide spectra in various salt-doped SLS solutions. One such series of spectra is given in Fig. 3. With no SLS present, $NiMu^+$ is the predominant species in the visible spectrum (460 nm) but, in micellar SLS solutions, the Ni^{2+} ion is adsorbed into the micellar surface region, reversing the $NiMu^+$ equilibrium, and essentially only the Mu^- peak at 525 nm is found. Adding 0.02 mol dm^{-3} $NaNO_3$ to the latter system dramatically restores the equilibrium to an intermediate position. Of course, in 0.02 mol dm^{-3} Na^+ ion solution, the ratio of Na^+ ion to Ni^{2+} ion is at least 20 to 1 (augmented slightly by Na^+ ions from the surfactant) so that the Na^+ ion despite its lower charge competes successfully for surface sites. This sharp drop in K_{Ni} with low salt additions of only 0.10 mol dm^{-3} Na^+ ion is thus not unreasonable. The spectra for the two Na^+ ion solutions are almost the same confirming that K_{Ni} undergoes little further change with increasing salt additions.

The solubility data from PADA and hence K_{PADA} reveal that the hydrophobic reagent is bound less strongly to micelles with increasing Na^+ ion solution content. This decrease in K_{PADA}, which is much smoother and less dramatic than with K_{Ni}, may

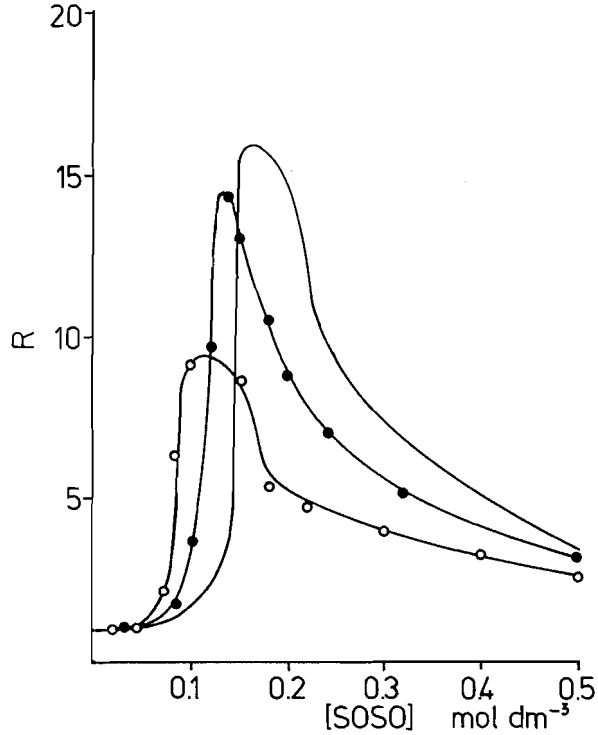

FIG. 4. Rate enhancements (R) for SOSO solutions with added Na^+: ●, 0.10 mol dm^{-3}; ○, 0.50 mol dm^{-3}. The top curve is the pure SOSO curve.

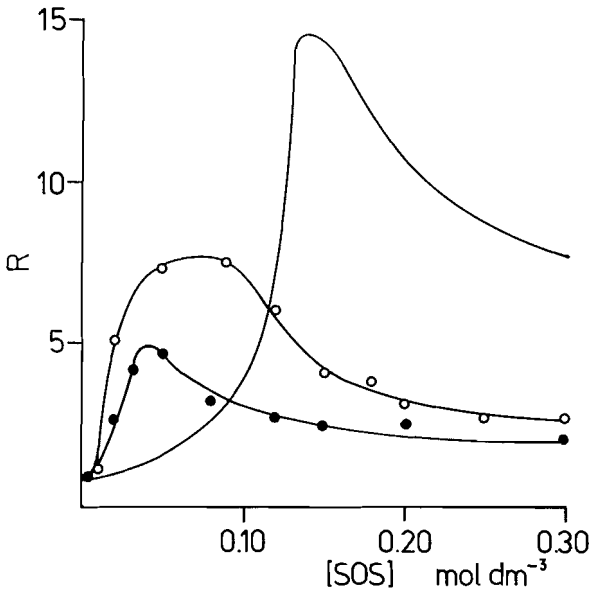

FIG. 5. Rate enhancements (R) for SOS solutions with added Na^+: ○, 0.20 mol dm^{-3}; ●, 0.50 mol dm^{-3}. The top curve is the pure SOS curve.

simply be an activity coefficient effect with some input from the decreased surface polarity since PADA is slightly polar.

Rate enhancements were also measured in salt-doped sodium octanesulfonate (SOSO) and sodium octylsulphate (SOS) micellar solutions. These short-chained surfactants have high CMC values and thus contribute substantial Na^+ ion amounts, often in excess of the added electrolyte, to the total Na^+ ion concentration. Thus, the near constant ionic strength situation that prevailed in salt-doped SLS micellar systems does not hold here. Nevertheless, the results are informative in a comparative sense since the rate enhancements in the pure and salt-doped short-chained surfactant systems were measured under the same conditions.

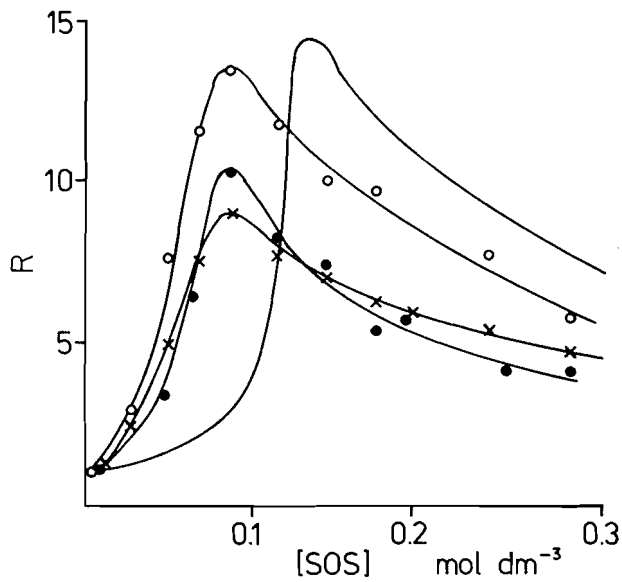

FIG. 6. Rate enhancements (R) for SOS solutions with added Ca^{2+} and Mg^{2+}: ○, 0.05 mol dm^{-3} Ca^{2+}; ●, 0.10 mol dm^{-3} Ca^{2+}; ×, 0.10 mol dm^{-3} Mg^{2+}. The top curve is the pure SOS curve.

Figures 4 and 5 show the rate enhancements for the Ni^{2+}–PADA reactions in SOSO and SOS solutions with added Na^+ ion. The R curves were similar in behavior to the salt-doped SLS system. The complete kinetic analysis was performed with representative salt systems for each surfactant and the values of the parameters displayed the same trends as with SLS solutions (Table 1). For example, with 0.50 mol dm^{-3} $NaNO_3$ in SOSO solutions, K_{PADA} declined a third from the pure solution value, K_{Ni} remained the same and V_s increased threefold. The binding of Ni^{2+} in pure SOS micellar solutions is already weak due to the 100-fold excess of Na^+ ion from the surfactant itself. In this respect there is a difference from the SLS system because further additions of Na^+ ion through $NaNO_3$ to SOS solutions will have little further effect on K_{Ni} while even small Na^+ ion additions of the order of 0.02 mol dm^{-3} causes K_{Ni} in SLS solutions to plunge from the pure solution value to a relatively constant value.

Calcium and magnesium additions were also made to micellar SOS solutions. Raman spectra studies had indicated that Ca^{2+} ion but not Mg^{2+} nor Na^+ ion binds to the sulfate head group of the micellar surfactant (23). If this complexing evidence in Raman time (ca. 10^{-10} s) were to persist in stopped-flow time (10^{-3} s), then negative charge centres in the micellar surface region would be eliminated to produce considerably lower rate enhancements with Ca^{2+} ion than with either of the other two ions. The R curves for two Ca^{2+} ion and one Mg^{2+} ion series of additions to SOS are shown in Fig. 6. Complete kinetic analyses were conducted on all three and the resulting parameters listed in Table 1. It is clear that Ca^{2+} ion has no more effect on R than Na^+ ion of double the concentration or Mg^{2+} ion. Either the complexation rates of Ca^{2+} with the sulfate head group are more rapid than can be seen in the stopped-flow technique or else the lowering of the surface potential induced by foreign cations is not determined by whether an actual bond forms with micellar charge centres.

Magnesium ion appears to influence the rate enhancements in slightly different fashion than either Ca^{2+} ion or Na^{+} ion. The kinetic analysis reveals that K_{Ni} is about half the pure solutions value with Mg^{2+} ion present and V_s is relatively unchanged. Apparently, the greater charge density of unhydrated Mg^{2+} ions over either Ca^{2+} and Ni^{2+} ions which are roughly the same size gives Mg^{2+} ion a competitive edge over Ni^{2+} ions for surface sites that Ca^{2+} ions do not enjoy.

Protonation de l'adénine, de la purine et de l'adénosine en milieu acide fort[1]

ROBERT L. BENOIT ET MONIQUE FRÉCHETTE
Département de chimie, Université de Montréal, C. P. 6210, Succ. A, Montréal (Qué.), Canada H3C 3V1

Reçu le 29 août 1983

ROBERT L. BENOIT et MONIQUE FRÉCHETTE. Can. J. Chem. **62**, 995 (1984).

Faisant suite à une valeur proposée pour l'enthalpie de seconde protonation de l'adénine, on a étudié par ealorimétrie et spectroscopie rmn la protonation des bases B biologiquement importantes: adénine, purine, adénosine, et incidemment, celle de l'imidazole et de l'amino-3 pyridine. Les chaleurs de dissolution des bases solides et les déplacements chimiques de leurs protons et carbones-13 ont été déterminés en fonction des concentrations des acides $HClO_4$ et H_2SO_4. Nos résultats démontrent que contrairement à une utilisation antérieure, un effet de milieu important rend impossible l'emploi des données calorimétriques pour calculer les fonctions thermodynamiques des réactions de protonation. D'un autre côté, les données de carbone-13 ont été interprétées avec succès en utilisant la méthode de Cox et Yates dite "excess acidity". Les valeurs obtenues pour $pK_{BH_2^{2+}}$ et $pK_{BH_3^{3+}}$ sont respectivement: adénine −0,43, −4,23, purine −1,66, < −6, adénosine −1,4 avec hydrolyse du glucoside. Les sites de protonation ont été confirmés comme étant essentiellement sur le cycle imidazole pour la seconde protonation et sur le cycle pyrimidine (N-3) pour la troisième.

ROBERT L. BENOIT and MONIQUE FRÉCHETTE. Can. J. Chem. **62**, 995 (1984).

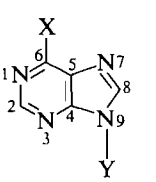
In view of a previously proposed enthalpy value for the second protonation of adenine, a calorimetric and nmr spectroscopic study has been made of the protonation of biologically important bases B: adenine, purine, adenosine and, incidentally, that of imidazole and 3-amino pyridine. Heats of solution of the solid bases, and their carbon-13 and proton chemical shifts were determined as a function of $HClO_4$ and H_2SO_4 concentration. Our results demonstrate that, contrary to previous usage, a strong medium effect precludes the use of the calorimetric results to calculate the thermodynamic functions for the protonation reactions. On the other hand, the carbon-13 nmr data are successfully interpreted on the basis of the Cox and Yates excess acidity method. The values obtained for $pK_{BH_2^{2+}}$ and $pK_{BH_3^{3+}}$ are, respectively: adenine −0.43, −4.23, purine −1.66, < −6, adenosine −1.4 with hydrolytic cleavage of the glycosidic bond. The protonation sites are confirmed as being essentially on the imidazole ring for the second protonation and on the pyrimidine ring (N-3) for the third one.

L'adénine, une base importante dans les systèmes biologiques, et particulièrement ses réactions avec le proton et les ions métalliques ont fait l'objet de nombreuses études. Le caractère basique des 3 azotes hétérocycliques, N-1, N-3 et N-7 a été mis en évidence ainsi que des relations complexes entre les basicités relatives de ces 3 azotes et la nature de l'acide de Lewis. Avec le proton en solution diluée, l'adénine (amino-6 purine) réagit en N-1 (1, 2) et les caractéristiques thermodynamiques associées à cette réaction de protonation sont connues: pK_1 = 4,19 et $\Delta H_1 = -21{,}2$ kJ mol^{-1} (3).

La molécule d'adénine avec ses trois sites basiques peut aussi réagir successivement avec plusieurs ions H^+. Ainsi, des sels d'adénine diprotonée (N-1 et N-7) (4) ont été caractérisés par cristallographie aux rayons-X. Dans les solvants non-aqueux acides HCF_3CO_2 et HSO_3F, Wagner et von Philipsborn (5) ont identifié par rmn du proton à différentes températures, les cations diprotonés (N-1 et N-7) et triprotonés (N-1, N-7 et N-3) respectivement. En solution aqueuse, Budo et Tomasz (6) ont utilisé les faibles différences spectrales dans l'uv pour calculer une valeur $pK = -0{,}35$ pour le cation diprotoné. La seule étude calorimétrique concernant les seconde et troisième protonations de l'adénine est, à notre connaissance, l'étude de Kilday (7) en milieu HCl concentré. Cet auteur propose pour l'enthalpie ΔH_2 une valeur de +7,9 kJ mol^{-1} et suggère la possibilité d'une troisième protonation pour des concentrations de HCl supérieures à 5 *M*.

Dans notre travail, nous avons cherché à caractériser plus précisément les deuxième et troisième étapes de protonation de l'adénine. Nous avons d'abord évalué les résultats calorimétriques et l'interprétation de Kilday en déterminant, comme cet auteur, la chaleur de dissolution de l'adénine solide dans des solutions concentrées d'acide mais en utilisant $HClO_4$ et H_2SO_4. Devant les difficultés d'interprétation de nos résultats et notre mise en question des conclusions de Kilday, nous avons alors procédé à une étude de la protonation de l'adénine dans $HClO_4$ et H_2SO_4 concentrés par spectroscopies rmn du proton et du carbone-13. Afin d'évaluer la validité des méthodes calorimétriques et spectroscopiques de détermination de pK en milieu acide fort, nous avons étudié par ces deux méthodes le comportement de l'imidazole, pK = 7,2 (8) et la seconde protonation de l'amino-3 pyridine dont le pK_2 (−1,4) a déjà été établi par spectroscopie uv (9).

Nous avons aussi étendu notre étude en examinant par les mêmes méthodes la protonation de deux autres composés voisins de l'adénine, l'adénosine et la purine. Aucune donnée thermodynamique ne semble disponible pour l'adénosine, mais pour la purine Schumacher et Günther (10) ont tout récemment évalué le pK du cation diprotoné (N-1 et N-7/N-9) à −1,5 à partir des faibles variations des constantes de couplage du ^{13}C et ^1H dans D_2SO_4.



Adénine (Ade): X = NH_2, Y = H
Adénosine (Ado): X = NH_2, Y = D-ribose
Purine (Pur): X = H, Y = H

Partie expérimentale

Réactifs

L'adénine et l'adénosine (Aldrich) et la purine (Sigma) ont été utilisées sans purification ultérieure. Le titrage acidimétrique des bases par une solution de $HClO_4$ dans l'acide acétique indique une pureté de 99,5 ± 0,5%. L'amino-3 pyridine et l'imidazole (Aldrich) ont été recristallisés et séchés, ils titrent 99,9 ± 0,3%.

Les solutions aqueuses de HCl, $HClO_4$ et H_2SO_4 ont été préparées par dilution de solutions de concentrations connues. Les solutions de $NaClO_4$ ont été obtenues par neutralisation de solutions de $HClO_4$

[1] Partiellement présenté au Minisymposium de Chimie Organique Physique, Montréal, 1–3 octobre 1982.

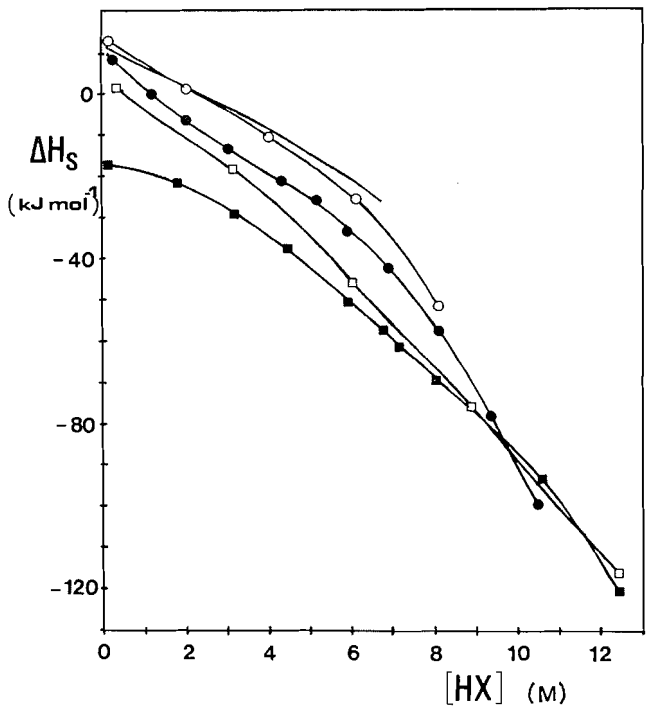

FIG. 1. Chaleurs de dissolution, ΔH_s, de l'Ade, l'Ado et l'Ampy en fonction de la concentration d'acide, [HX]. Ade–HCl (—), Ade–$HClO_4$ (●), Ade–H_2SO_4 (□), Ado–$HClO_4$ (○), Ampy–H_2SO_4 (■).

titrées par Na_2CO_3 (McArthur) jusque pH = 6, les solutions ont été filtrées puis diluées.

Mesures

Calorimétrie

Les chaleurs de dissolution de poids connus (0,035–0,125 g) des bases solides dans 100 mL de solutions d'acides de concentrations connues ont été mesurées à 25,00 ± 0,01°C avec un calorimètre isopéribolique LKB (modèle 8721-1). Le système calorimétrique précédemment décrit (11) a été légèrement modifié. La cellule utilisée est de 100 mL. La thermistance de 2000 Ω constitue l'une des branches du pont de Wheatstone. Le circuit électrique est alimenté par une source de courant constant (300 ou 500 μA). Le signal du détecteur de zéro (Keithley 155) après passage par un diviseur de potentiel, est enregistré sur un appareil Tacussel EPLI. La résistance chauffante de calibration (50 Ω) est alimentée par une source de tension stabilisée (Tacussel PRT 500 LC) et le temps de chauffage est mesuré avec un chronomètre (Precision Scientific) commandé par un interrupteur double. La tension aux bornes de la résistance est lue sur un multimètre digital (Keithley 179). Le calcul des quantités de chaleur est fait comme précédemment (11). Les performances du calorimètre ont été évaluées en mesurant la chaleur de neutralisation du THAM solide dans HCl aqueux 0,10 *M*. Les valeurs obtenues correspondent aux données de la littérature à mieux de 0,5% (12).

Résonance magnétique nucléaire

Les spectres rmn du carbone-13 ont été obtenus à 20,2 MHz sur un appareil Bruker WP-80. Les concentrations d'adénine, adénosine, purine, imidazole et amino-3 pyridine dans les solutions aqueuses de $HClO_4$ et H_2SO_4 et dans HCF_3CO_2 sont comprises entre 0,2 et 0,7 *M*. Les déplacements chimiques des carbones-13 sont mesurés par rapport au dioxanne en référence externe et rapportés au tétraméthylsilane en donnant aux carbones du dioxanne un déplacement de 67,40 ppm. Quelques mesures ont été effectuées à 100,6 MHz avec le spectromètre Bruker WH-400 sur des solutions 0,10 *M* d'adénine.

Les spectres rmn du proton ont été enregistrés à 90,0 MHz sur un appareil Bruker WH-90. Les déplacements chmiques ont été mesurés par rapport aux CH_3 du DSS ($(CH_3)_3Si(CH_2)_3SO_3^-Na^+$) en référence

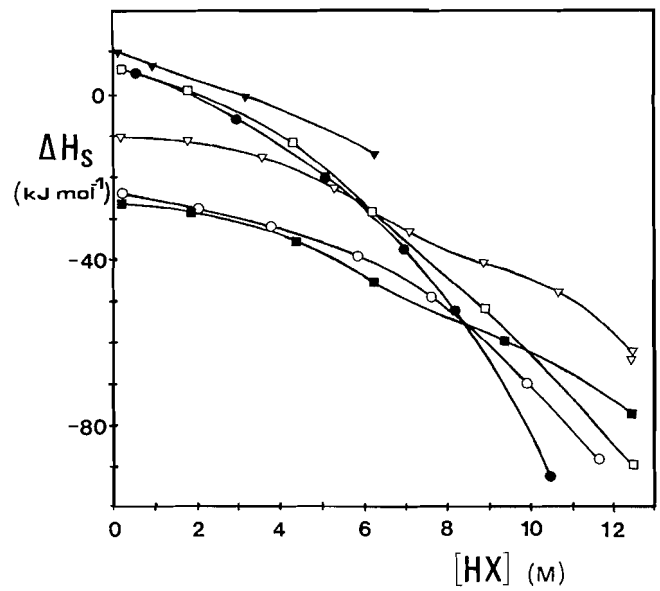

FIG. 2. Chaleurs de dissolution, ΔH_s, de la Pur, l'Imid et le Benzimid en fonction de la concentration d'acide, [HX]. Pur–HCl (▲), Pur–$HClO_4$ (●), Pur–H_2SO_4 (□), Imid–$HClO_4$ (○), Imid–H_2SO_4 (■), Benzimid–H_2SO_4 (△).

interne. Les valeurs des déplacements sont rapportées au TMS en prenant des valeurs identiques nulles pour les protons de CH_3 du DSS et ceux du TMS (13).

Résultats

Calorimétrie

Nous avons déterminé les chaleurs de dissolution de l'adénine (Ade) dans H_2SO_4 et $HClO_4$, celles de l'adénosine (Ado) dans $HClO_4$ et celles de l'amino-3 pyridine (Ampy) dans H_2SO_4. Les enthalpies molaires de dissolution ΔH_s sont portées en fonction des concentrations molaires des acides dans la figure 1. Les valeurs obtenues par Kilday pour l'Ade en milieu HCl sont aussi données à titre de comparaison. La figure 2 reflète les résultats relatifs à la purine (Pur) dans HCl, $HClO_4$ et H_2SO_4, à l'imidazole (Imid) dans $HClO_4$ et H_2SO_4 et au benzimidazole (Benzimid) dans H_2SO_4. L'effet de la concentration de l'adénine (6 valeurs entre $2,2 \times 10^{-3}$ et $1,7 \times 10^{-2}$ *M*) a été étudié à deux niveaux de concentration de $HClO_4$, 2,02 *M* et 0,20 *M*. On a obtenu respectivement pour les enthalpies molaires de dissolution des valeurs indépendantes de la concentration $-6,87 \pm 0,30$ kJ mol^{-1} ($r = 0,9998$) et $+8,55 \pm 0,20$ kJ mol^{-1} ($r = 0,9996$). Ces résultats nous ont fait conclure que compte tenu de la précision des mesures, les enthalpies calculées peuvent être assimilées aux valeurs à dilution infinie. Une série de mesures de ΔH_s de l'Ade a aussi été effectuée avec des solutions de concentration constante 1,113 *M* en $HClO_4$ mais variables en $NaClO_4$. En augmentant la concentration de $NaClO_4$ jusqu'à 6,38 *M*, les valeurs de ΔH_s passent graduellement de −0.6 à −18,0 kJ mol^{-1}. Ces variations font entrevoir un effet de milieu important sur la protonation de l'Ade.

Résonance magnétique nucléaire

Les spectres rmn du proton et du carbone-13 ont été pris pour l'Ade dans des solutions de $HClO_4$ aux acidités moyennes et de H_2SO_4 aux fortes acidités étant donné les solubilités limitées des sels, (bisulfates et perchlorates), dans certains domaines d'acidités. Les concentrations d'acides libres [HX] en solution

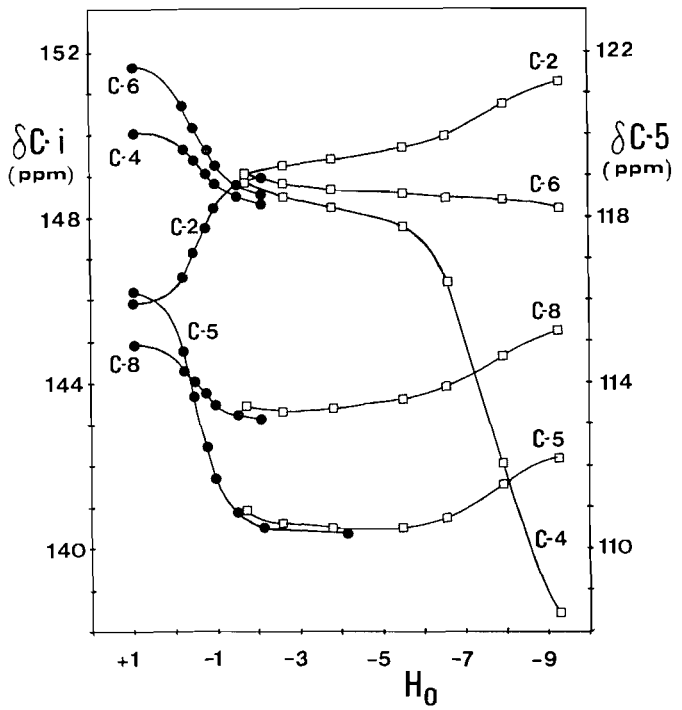

FIG. 3. Déplacements chimiques des carbones-13 de l'Ade, δC-*i*, en fonction de H_0 dans $HClO_4$ et H_2SO_4. Ade–$HClO_4$ (●), Ade–H_2SO_4 (□). [Ade] = 0,10 *M* à 0,71 *M*.

ont été calculées en retranchant des concentrations initiales *n* fois les concentrations des espèces BH_n^{n+} formées dans les réactions de protonation de l'Ade. Ces dernières concentrations ont été obtenues à partir des concentrations de la base et du rapport *I* déduit des déplacements chimiques δ observés et des δ limites pour les espèces BH_n^{n+} (éq. [2]). Les valeurs des fonctions d'acidité H_0, H_+ et H_A ont alors été déduites des valeurs de [HX] en utilisant les données dans la littérature (14–16, 17, 18–20). L'attribution des cinq carbones de l'adénine a été faite sur la base des données de la littérature (21) et de résultats en milieu DMSO[2] et vérifiée avec les spectres de découplage off-resonance. On a représenté Fig. 3 les courbes d'allure sigmoïde donnant les δ des 5 carbones de l'adénine en fonction de H_0. Les courbes correspondant aux solutions dans H_2SO_4 et $HClO_4$ sont déplacées d'environ 0,3 ppm, celles pour H_2SO_4 étant à des champs plus faibles.

Les résultats correspondants pour la purine en milieu H_2SO_4 sont donnés à la Fig. 4. Les spectres sont enregistrés rapidement pour éviter une certaine décomposition dans les milieux d'acidité intermédiaire (0,5–4 *M*). Les déplacements chimiques des carbones-13 de l'amino-3 pyridine et de l'imidazole dans H_2SO_4 sont donnés à la Fig. 5 en fonction des valeurs de H_0. Pour l'Ampy, l'attribution du carbone C-3 dont le signal apparaît à des champs nettement plus faibles, est faite avec le spectre découplé. Une étude plus poussée serait nécessaire pour identifier les autres carbones et n'entre pas dans le cadre des objectifs poursuivis ici. Les spectres de l'adénosine représentés Fig. 6 ont été pris en deça d'une heure afin de minimiser la réaction d'hydrolyse de ce nucléoside (22) et la dégradation du D-ribose, réactions de plus en plus notables lorsque l'acidité croît. Pour une concentration de $H_2SO_4 \geq 10{,}7$ *M*, le spectre de l'adénosine n'a pu être obtenu. Les produits de l'hydrolyse, adénine et D-ribose, ont été facilement identifiés par comparaison des spectres rmn dans les mêmes milieux acides. Les carbones sont attribués à partir des valeurs obtenues pour l'adénosine monoprotonée par l'acide picrique dans le Me_2SO[2], de données de la littérature (23) et des spectres découplés. Les courbes des déplacements chimiques des protons H-2 et H-8 de l'adénine en fonction de H_0 pour les acides $HClO_4$ et H_2SO_4, ont aussi une allure sigmoïde. On remarque toutefois un effet de milieu important, les valeurs de δ en milieu H_2SO_4 étant décalées d'environ 0,5 ppm vers les champs plus forts par rapport aux valeurs en milieu $HClO_4$ (Fig. 7).

[2] D. Boulet et M. Fréchette. Résultats non-publiés.

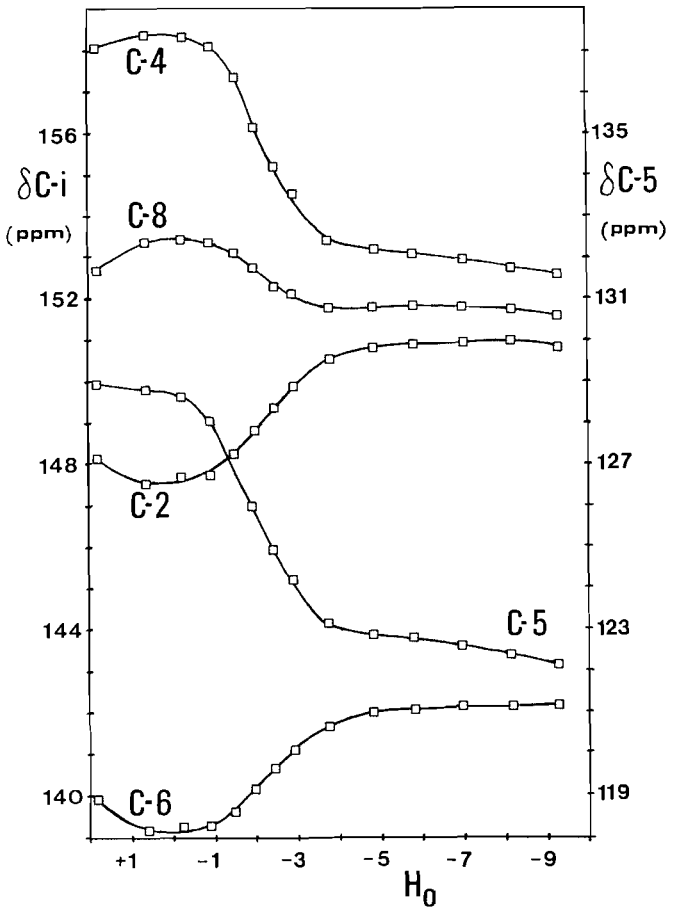

FIG. 4. Déplacements chimiques des carbones-13 de la Pur, δC-*i*, en fonction de H_0 dans H_2SO_4. [Pur] = 0,29 *M* à 0,51 *M*.

Dans le domaine de concentration des bases étudiées (0,1–0,7 *M*) (les intervalles étant précisés dans les légendes des Fig. 3 à 6), on n'a pas noté d'effet de concentration sur les valeurs des déplacements chimiques. Les points expérimentaux se placent bien sur les courbes sigmoïdes et leurs composantes horizontales. Read et Goldstein (24) ont aussi remarqué qu'avec la purine l'effet de concentration de la base sur les déplacements du proton disparaît lorsque la base est protonée.

Le calcul des $pK_{BH_n^{n+}}$ des espèces BH_n^{n+} ($n = 2,3$) à partir des résultats de rmn présente des difficultés, tout d'abord au niveau du choix de la fonction d'acidité H_i qui convient. Ce point est illustré au Tableau 1 où sont rassemblées les valeurs des pK_n et pentes m_n obtenues pour l'Ampy (pK_2) et l'Ade (pK_2 et pK_3) à partir des graphiques des différentes fonctions H_0, H_+, H_A en fonction de log *I*. Ces graphiques sont basés sur l'équation:

$$[1] \quad H_i = pK_n - m_n \log \frac{|BH_n^{n+}|}{|BH_{n-1}^{(n-1)+}|} = pK_n - m_n \log I$$

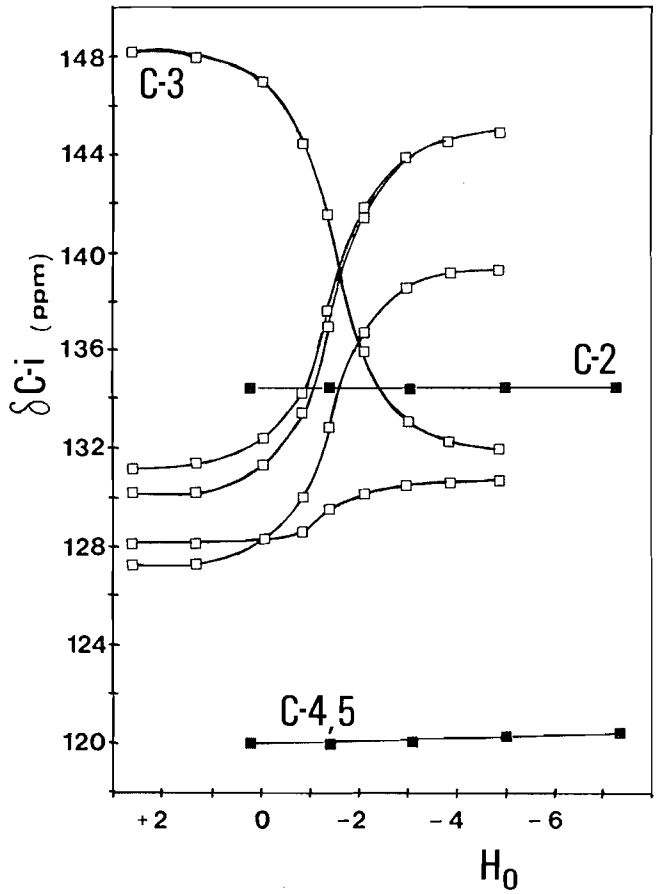

FIG. 5. Déplacements chimiques des carbones-13 de l'Ampy et l'Imid, δC-*i*, en fonction de H_0 dans H_2SO_4. Ampy (□), Imid (■). [Ampy] = 0,30 *M* à 0,45 *M* et [Imid] = 0,39 *M* à 0,73 *M*.

où les rapports *I* des concentrations des espèces BH_n^{n+} et $BH_{n-1}^{(n-1)+}$ sont obtenus à partir des valeurs de δ et celles des δ limites pour les deux espèces:

$$[2] \quad I = \frac{|BH_n^{n+}|}{|BH_{n-1}^{(n-1)+}|} = \frac{\delta - \delta_{BH_n^{(n-1)+}}}{\delta_{BH_n^{n+}} - \delta}$$

Dans une certaine mesure pour contourner le problème du choix des fonctions d'acidité H_i, d'autres méthodes générales de calcul des pK_n ont été proposées en particulier par Bunnett et Olsen (25) et récemment par Cox et Yates (26). Cette dernière méthode dite "excess acidity method" est basée sur la résolution de l'équation

$$[3] \quad \log I - \log C_{H^+} = m^* X + pK_n$$

Les valeurs de *X* et $\log C_{H^+}$ sont connues, indépendemment de la base utilisée pour un acide donné en concentration donnée (27). Log *I* est déduit de nos résultats de rmn tel qu'indiqué plus haut. Un programme permet alors d'ajuster les paramètres inconnus m^* et pK_n. Les résultats sont consignés dans le Tableau 2.

Discussion

La comparaison des résultats obtenus pour la protonation des bases Ade, Pur, Ado et Ampy en rmn et en calorimétrie met en évidence des différences essentielles. D'un côté les courbes donnant les déplacements, δ, des carbones-13 en fonction de

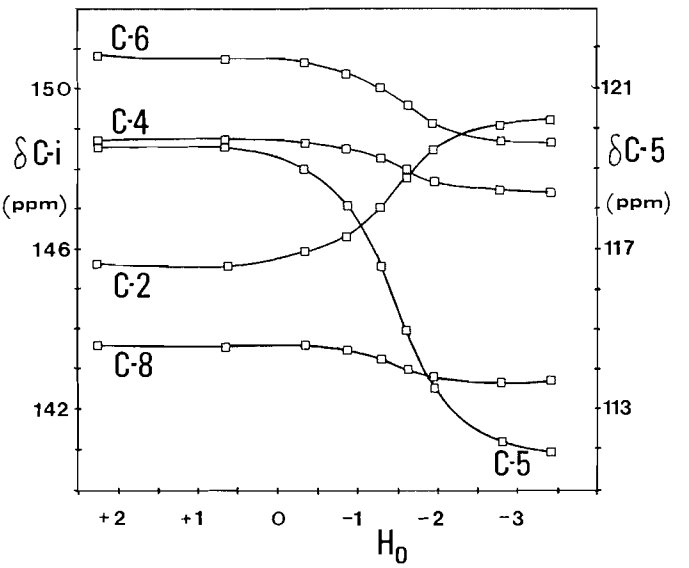

FIG. 6. Déplacements chimiques des carbones-13 de l'Ado, δC-*i*, en fonction de H_0 dans H_2SO_4. [Ado] = 0,38 *M* a 0,78 *M*.

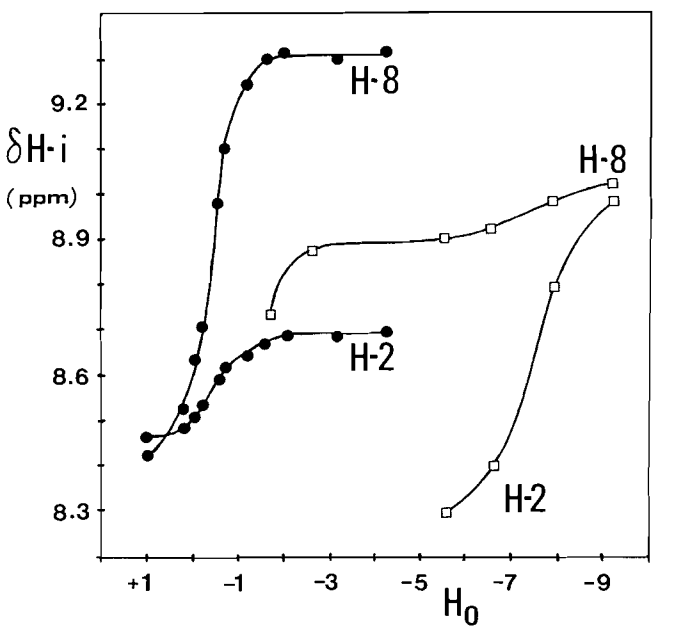

FIG. 7. Déplacements chimiques des protons de l'Ade, δH-*i*, en fonction de H_0 dans $HClO_4$ et H_2SO_4. Ade–$HClO_4$ (●), Ade–H_2SO_4 (□). [Ade] = 0,10 *M* à 0,71 *M*.

H_0 (Fig. 3–6) ont l'allure sigmoïde attendue des réactions de protonation. Par contre, les courbes de la chaleur de dissolution, ΔH_s, des bases en fonction de H_0 (ou de la concentration d'acide, Fig. 1, 2) ne réflètent qu'une exothermicité croissante alors que l'on devrait avoir aussi des courbes sigmoïdes analogues à celle obtenue en fonction du pH ($2 < pH < 6$) pour la première protonation de l'Ade (3). Les résultats inattendus de calorimétrie s'expliquent en considérant le cas plus simple de la base imidazole, B ($pK_{BH^+} = 7,2$ (8)). On note Fig. 5 que les variations des δ des carbones C-4, 5 de l'imidazole sont inférieures à 0,5 ppm entre $+0,2 > H_0 > -9,4$ (soit 0,5 *M* < H_2SO_4 < 17,2 *M*) et celles du C-2 sont négligeables. Ces résultats nous font conclure que dans le domaine d'acidité considéré, d'une part il n'y a pas de réaction de protonation additionnelle de l'ion imidazolium, BH^+, et d'au-

Ade	−0,43	−4,23
Ado	−1,48	Hydrolyse
Pur	−1,66	< −6

tre part que l'effet de milieu sur les δ des carbones-13 est très faible. Par contre, en dépit de cette absence de protonation additionnelle de BH^+, la chaleur de dissolution ΔH_s de l'imidazole change de façon continue et considérable avec la concentration de $HClO_4$ et H_2SO_4 (Fig. 2). Ainsi ΔH_s qui est de −24,3 kJ mol^{-1} dans $HClO_4$ 0,20 *M* (en excellent accord avec la valeur de −24,0 kJ mol^{-1} dans HCl 0,20 *M* (28)) passe à −88,7 kJ mol^{-1} dans $HClO_4$ 11,65 *M*. On doit donc conclure à un effet du milieu extrêmement important, −64,4 kJ mol^{-1}, sur le ΔH_s de la réaction de protonation de l'imidazole,

[4] $B(c) + H^+ClO_4^- = BH^+ClO_4^-$

Nous avons alors cherché à évaluer les contributions respectives des variations d'enthalpie de $H^+ClO_4^-$ et $BH^+ClO_4^-$ à l'effet du milieu sur la réaction [4]. On déduit de [4] que lorsque l'on passe par exemple d'un premier milieu dilué, tel que $HClO_4$ 0,20 *M*, à un second milieu concentré, tel que $HClO_4$ 11,65 *M*, la variation de ΔH_s est égale à la différence des enthalpies de transfert ΔH_t d'une mole de $BH^+ClO_4^-$ et de $H^+ClO_4^-$ du milieu concentré au milieu dilué.

[5] $\delta\Delta H_s = \Delta H_t(BH^+ClO_4^-) - \Delta H_t(H^+ClO_4^-)$

On calcule qu'avec ces deux milieux, d'après les données de la littérature (29), $\Delta H_t(H^+ClO_4^-) = -41{,}8$ kJ mol^{-1}, il reste donc pour $\Delta H_t(BH^+ClO_4^-)$ −64,4 + 41,8 soit −22,6 kJ mol^{-1}. En d'autres termes, le passage de ΔH_s de −24,3 kJ mol^{-1} dans $HClO_4$ 0,20 *M* (chaleur de solution de B, +12,8 kJ mol^{-1}, plus chaleur de protonation de B, −37,1 kJ mol^{-1}) à −88,7 kJ mol^{-1} dans $HClO_4$ 11,65 *M* est due pour 65% à la chaleur de transfert d'une mole de $H^+ClO_4^-$ d'un milieu à l'autre et pour 35% à celle d'une mole de $BH^+ClO_4^-$. On peut aussi réécrire [5]

[6] $\delta\Delta H_s = \Delta H_t(BH^+) - \Delta H_t(H^+)$

Cette équation relie cette fois le ΔH_s aux enthalpies de transfert ioniques de BH^+ et H^+ entre deux milieux, la contribution importante étant vraisemblablement celle de H^+. L'équation [6] montre aussi que des variations analogues de ΔH_s doivent se retrouver avec les autres acides concentrés utilisés HCl et H_2SO_4. Ainsi, et cette fois dans le cas de l'adénine, lorsque l'on passe de HCl 0,10 *M* à HCl 6,6 *M*, les concentrations limites utilisées par Kilday (7) pour obtenir ΔH_2, l'enthalpie de la seconde protonation de l'adénine, on calcule $\Delta H_t(H^+Cl^-) = -16{,}7$ kJ mol^{-1}. Ceci signifie que lorsque la chaleur de dissolution de l'adénine solide passe de +10,8 kJ mol^{-1} dans HCl 0,10 *M* à −25,3 kJ mol^{-1} dans HCl 6,6 *M* (7), la diminution de −36,1 kJ mol^{-1} inclut déjà une contribution majeure de −33,4 kJ mol^{-1} due au seul transfert de 2 moles de H^+Cl^-, l'Ade étant diprotonée à cette acidité. Nous avons d'ailleurs essayé de corriger les valeurs expérimentales de ΔH_s obtenues par Kilday entre HCl 0,10 et 6,6 *M* en retranchant les contributions dues au seul transfert de H^+Cl^-, le nombre de moles de HCl transféré étant calculé d'après $pK_2 = -0{,}43$. Les ΔH_s ainsi corrigés portés en fonction de H_0 ont donné une courbe d'allure sigmoïde. On a alors calculé à partir de ces valeurs $\Delta H_2 = -3{,}7$ kJ mol^{-1} pour la réaction

[7] $BH^+Cl^- + H^+Cl^- = BH_2^{2+}(Cl^-)_2$

Toutefois en répétant le même processus avec nos valeurs de ΔH_s en milieux $HClO_4$ et H_2SO_4, on a obtenu pour ΔH_2 des valeurs totalement différentes. Apparemment les contributions opposées de $\Delta H_t(BH^+X^-)$ et $\Delta H_t(BH_2^{2+}(X^-)_2)$ (où $X^- = Cl^-$, ClO_4^-, HSO_4^-) qui restent incluses dans les valeurs ainsi calculées de ΔH_2 ne se compensent pas. En conclusion, non seulement il n'est pas possible d'atteindre un ΔH_2 valable en corrigeant seulement pour le transfert de l'acide, mais aussi la valeur de +7,9 kJ mol^{-1} calculée par Kilday sans correction aucune, est à rejeter totalement.

Passons maintenant aux résultats de rmn. Les très faibles variations des valeurs des déplacements chimiques, δ, des carbones-13 de l'imidazole dans H_2SO_4 (Fig. 5) laissent prévoir un effet de milieu négligeable pour les autres bases étudiées. On n'a d'ailleurs décelé par la méthode Cox–Yates qu'un très faible effet de milieu pour la purine et aucun effet pour l'adénine et l'adénosine.[3] Le calcul des $pK_{BH_n^{n+}}$ est ainsi facilité. Comparons d'abord nos valeurs de pK_2 de l'amino-3 pyridine données au Tableau 1 avec la valeur de −1,43 obtenue par spectroscopie uv (9) mais sans tenir compte d'un effet de milieu possible. En considérant le choix de la fonction d'acidité, on aurait pu penser à priori que la fonction H_+ convenait mieux pour la deuxième protonation de l'Ampy mais la valeur correspondante de la pente, $m_2 = 1{,}30$, est élevée. De plus, Brignell *et al.* (9) dans leur étude uv ont utilisé la fonction H_0 et obtenu une pente de 1,08. Avec H_0 notre pente est $m_2 = 1{,}30$ mais par contre avec H_A dont le choix est moins justifiable nous obtenons une valeur $m_2 = 1{,}06$ plus satisfaisante. Pour éviter ce problème de sélection de fonction d'acidité, nous avons utilisé la méthode Cox–Yates pour calculer les p*K* retenus au Tableau 2. Notre valeur de $pK_{BH_2^{2+}} = -0{,}43$ pour l'adénine est en bon accord avec la valeur −0,35 trouvée par spectroscopie uv (6). Quant à la valeur correspondante pour la purine, −1,66, elle se compare favorablement à la récente valeur −1,5 estimée à partir de données sur $^1J(^{13}C,^1H)$ dans D_2SO_4 (10). On note que les différences des valeurs des p*K*, $pK_{BH_2^{2+}} - pK_{BH^+}$ sont d'environ −4,5 unités tandis que $pK_{BH_3^{3+}} - pK_{BH^+}$ est de −8,3 unités. Comme les p*K* correspondant aux deux protonations d'une pyrimidine voisine l'amino-4 diméthyl-2,6 pyrimidine (7,0 et −1,7)[2] diffèrent de −8,7, les p*K* obtenus suggèrent que la seconde protonation des bases B se fait sur le cycle imidazole et la troisième sur le cycle pyrimidine.

Examinons pour terminer l'incidence de nos résultats de rmn sur le choix des sites de protonation des bases Ade, Pur et Ado et les attributions faites antérieurement. La première protonation de l'Ado et de l'Ade en N-1 est bien établie (1, 2) et

[3] R. A. Cox. Communication personnelle.

For personal use only.

celle de la Pur sur le même azote a été confirmée par spectroscopie rmn du proton (24) puis du carbone-13 (30). Notre choix du site de la seconde protonation des bases est fait en comparant les variations des déplacements chimiques des carbones observés lors du passage de BH^+ à BH_2^{2+} aux données obtenues pour la protonation du benzimidazole (28). Les déplacements chimiques des carbones correspondants, pour l'Ade, Pur, Ado d'une part et le benzimidazole d'autre part sont tous dans le même sens, celui du C-6 de la purine mis à part. Cette comparaison nous fait mettre la seconde protonation de l'Ado, Ade et Pur sur le cycle imidazole, c'est-à-dire en N-7 (Ado) et N-7/N-9 (Ade, Pur) compte tenu de la présence de tautomères pour B (31). La protonation de N-7 est en accord avec l'effet α noté par Pugmire et Grant (30). Ces auteurs ont observé que les carbones situés en α des sites de protonation d'hétérocycles azotés se déplaçaient vers les champs forts lors de la protonation. Les variations des C-5 et C-8 adjacents à N-7 sont bien dans le sens prévu par cette règle et une protonation en N-3 conduirait à un déplacement du C-2 inverse de celui qui est observé. La seconde protonation de l'Ade et Pur sur le cycle imidazole est aussi en accord avec les conclusions atteintes par d'autres chercheurs en interprétant d'une part la variation des constantes de couplage spin–spin ^{13}C, ^1H dans des milieux D_2SO_4 (10) et d'autre part les spectres rmn du proton dans HCF_3CO_2 (TFA), HSO_3F et HSO_3F–SbF_5–SO_2 à 27, −20 et −55°C (5). Toutefois Wagner et von Philipsborn (5) supposent la présence exclusive dans le TFA des espèces $AdeH_2^{2+}$ et $PurH^+$ respectivement. En comparant nos valeurs des déplacements du ^{13}C dans le TFA et les solutions de $HClO_4$ et H_2SO_4, nous avons déduit que dans le TFA on avait $AdeH_2^{2+}/AdeH^+ = 4:1$ et $PurH_2^{2+}/PurH^+ = 1:2$; les valeurs de ces rapports sont confirmés pour l'Ade par nos données en rmn du proton sur Δ(H-8) − (H-2) et pour la Pur par les résultats de Schumacher et Günther (10).

Quant au site de la troisième protonation de l'Ade, nous l'avons placé en N-3 sur le cycle pyrimidine en comparant les variations des déplacements chimiques des carbones de l'Ade et du cycle pyrimidine de l'amino-4 diméthyl-2,6 pyrimidine (Adp) lors des protonations successives. Les carbones C-4 et C-5 de l'Ade se déplacent vers les champs forts et faibles respectivement comme les carbones correspondants de l'Adp (C-6 et C-5) lors de la première protonation en position N-1 (32) tandis que le carbone C-2 de l'Ade, entre deux azotes protonés, est déplacé vers les champs faibles comme le C-2 de l'Adp lors de sa deuxième protonation. Notre attribution du site de la troisième protonation à N-3 est aussi conforme à celle de Wagner et von Philipsborn (5).

Finalement, dans le cas de l'Ade les variations des déplacements des deux protons H-2 et H-8 (Fig. 7) sont en accord avec la deuxième protonation en N-7/N-9 et la troisième en N-3, les déplacements des protons en α des sites de protonation, respectivement H-8 et H-2, montrent les plus grandes variations. La figure 7 complémente aussi utilement le schéma donné par les auteurs précités (5) pour illustrer le double "croisement" des valeurs des déplacements de H-2 et H-8 lorsqu'en augmentant l'acidité du milieu, ils passent de l'Ade (H_2O) ($\delta_{H\text{-}2} > \delta_{H\text{-}8}$) à $AdeH_2^{2+}$ (TFA) ($\delta_{H\text{-}2} < \delta_{H\text{-}8}$) puis à $AdeH_3^{3+}$ (HSO_3F) ($\delta_{H\text{-}2} > \delta_{H\text{-}8}$). Les valeurs de H-2 (8,98 ppm) < H-8 (9,02 ppm) à la Fig. 7 pour notre milieu le plus acide (H_0 = −9,3, H_2SO_4 17,0 *M*) ne correspondant qu'à $AdeH_3^{3+}/AdeH_2^{2+} = 87:13$, on a calculé pour $AdeH_3^{3+}$ H-2 (9,08 ppm) > H-8 (9,04 ppm), c'est-à-dire une différence de 0,04 ppm en accord satisfaisant avec les 0,09 ppm observés dans HSO_3F ($H_0 \sim -15$). L'attribution à H-2 du proton apparaissant au champ le plus faible dans ce milieu est ainsi correcte (5).

Remerciements

Nous remercions le Conseil de recherches en sciences naturelles et en génie du Canada pour son aide financière. Nos remerciements vont aussi au Professeur K. Yates pour l'intérêt qu'il a porté à ce travail et au Dr. R. A. Cox qui a très aimablement calculé les constantes d'acidité avec son programme.

COMMUNICATION

Surface photochemistry: use of spiropyrans as indicators of surface polarity

PAUL DE MAYO, ALI SAFARZADEH-AMIRI, AND S. KING WONG

Photochemistry Unit, Department of Chemistry, The University of Western Ontario, London, Ont., Canada N6A 5B7

Received December 2, 1983

PAUL DE MAYO, ALI SAFARZADEH-AMIRI, and S. KING WONG. Can. J. Chem. **62**, 1001 (1984).

The position of the long wavelength absorption band in the spectrum of a spiropyran is sensitive to solvent polarity. This property has been used to determine the polarity of the silica gel surface.

PAUL DE MAYO, ALI SAFARZADEH-AMIRI et S. KING WONG. Can. J. Chem. **62**, 1001 (1984).

La position de la bande d'absorption à une longueur d'onde élevée, dans le spectre d'un spiropyranne, est sensible à la polarité du solvant. On a utilisé cette propriété pour déterminer la polarité de la surface du gel de silice.

Recently there has been a burst of activity in several laboratories as regards the investigation of the photochemistry (see ref. 1 for a recent review, ref. 2) and photophysics (3, 4) of organic molecules adsorbed on solid oxide supports. The purpose has been two-fold: to use these techniques to learn about the adsorbent surface, and to use the surface properties to induce new photochemistry. Amongst the surface properties of general importance is polarity, and we describe here a technique for its determination on dry and hydrated silica gel surfaces.

Solvatochromic dyes, such as 1-alkylpyridinium iodides and pyridinium-*N*-phenol betaines (for a review, see ref. 5) have been used successfully as indicators of solvent polarity by measuring the shift of the long wavelength absorption band as a function of solvent polarity. The oscillator strength of this transition is small and, in solvents of high polarity, appears as a shoulder on a much stronger absorption band and is ill-resolved; moreover, the substances are very unstable on dry silica gel and cannot be used. Pyrene (E_p), a recent candidate, when used fluorimetrically (6) suffers from insensitivity to hydrogen-bonding, evidently a critical weakness on a hydroxylated surface. Indolinobenzospiropyrans (e.g. **1**) in their open, coloured, forms (e.g. **2**) are sensitive to solvent polarity:[1] the intense, well-resolved long wavelength absorption band moves to higher energy with increasing solvent polarity. The transition energies (E_{sp}) of **2** in a variety of solvents are given in Table 1, and a plot of E_{sp} against the well-established E_T (5) is shown in Fig. 1. Evidently, the correlation between E_{sp} and E_T is very satisfactory.

To test the use of the spiropyran **1** on silica gel, the gel was first dehydrated (720°C/5 h) *in vacuo* which reduced the concentration of silanols from 5–6/nm^2 to ca. 2/nm^2 (7, 8), and the surface modified by the addition of various amounts of water (Table 2). The resultant hydrolysis of strained siloxane bonds and the regeneration of silanol functions plus the presence of physisorbed water should render the surface more polar.[2] That this is so is indicated in Table 2. The surface with isolated, unsolvated (8, 9) silanol functions had an E_{sp} close to that of MeOH/H_2O (40:60), whilst the most polar surface, that of silica gel equilibrated with the atmosphere was close to that of MeOH/H_2O (30:70) whether the silica gel was pre-heated or not.

TABLE 1. The position of λ_{max} and transition energies of spiropyran (E_{sp}) and the E_T[a] values for several solvents

Solvents		λ_{max} (nm)	E_{sp} (kcal/mol)	E_T (kcal/mol)[b]
CH_3OH/H_2O	30:70	498	57.4	58.4[c]
	40:60	517	55.3	58.9[c]
	50:50	525	54.5	57.6[c]
C_2H_5OH/H_2O	50:50	537	53.2	54.6[c]
	80:20	545	52.6	53.6
CH_3OH		545	52.6	55.5
C_2H_5OH		548	52.2	51.9
1-Propanol		557	51.3	50.7

Chlorobenzene		584 and 614	48.9 and 46.6	37.4
Benzene		585 and 622	48.9 and 46.0	34.5

[a] From ref. 5.
[b] Using 1-(4-hydroxy-3,5-diphenylphenyl)-2,4,6-triphenylpyridinium betaine.
[c] Obtained with the aid of E_T values of 1-(*p*-hydroxyphenyl)-2,4,6-triphenylpyridinium betaine and conversion to scale in *b*.
[d] Could not be measured.

[1] A detailed discussion of all aspects of the chemistry of these substances is contained in ref. 11.

[2] After modification of the surface, the dye (0.5 mg/g SiO_2) in benzene was transferred and the benzene removed *in vacuo*. The silica gel was then transferred to a 1 mm cuvette, the absorption being measured on the "dry" powder, and the entire operation being performed in a closed system. The sequence of the steps is critical. An application of Kosower's *Z* to a silica gel slurry has been reported (10).

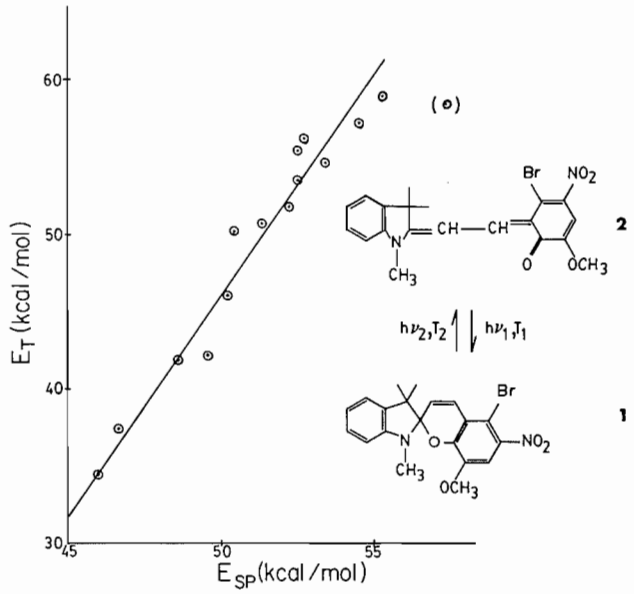

FIG. 1. Plot of E_T vs. E_{sp}. The solid line is the least-squares fit of the data points to a straight line excluding the point in the parenthesis ($r = 0.98$).

TABLE 2. Variation of E_{sp} of **2** on treated silica gel[a]

E_{sp} (kcal/mol)	λ_{max} (nm)	Treatment[b] (mol/g SiO_2)
54.5	525	4.2×10^{-4} 1-decanol
54.9	521	—
55.2	518	2.8×10^{-4}
55.4	516	5.6×10^{-4} H_2O
56.1	510	1.1×10^{-3} H_2O
56.5	506	2.2×10^{-3} H_2O
56.9	502	[c]
56.9	502	[d]

[a] The silica gel was 35–70 mesh (EM reagents).
[b] All specimens except *d* where heated 5 h in vacuum at 700°C.
[c] Equilibrated with atmosphere.
[d] Equilibrated with the atmosphere without heating.

The addition of alcohols should lead to alcoholysis and physisorption, both of which, because of the hydrophobic hydrocarbon "tails", should render the surface less polar. The observations were again in accord with expectation (Table 2). Addition of 1-decanol decreased the surface polarity in comparison to that of silica gel without any coadsorbent and its polarity was similar to that of MeOH/H_2O (50:50 mixture).

Synthesis, spectroscopic, and magnetic studies of new alkoxy and allied bimetallic derivatives of nickel(II) with aluminium

R. C. MEHROTRA[1] AND JAGVIR SINGH
Chemical Laboratories, University of Rajasthan, Jaipur-302004, India

Received June 24, 1983

R. C. MEHROTRA and JAGVIR SINGH. Can. J. Chem. **62**, 1003 (1984).

Nickel(II) tetraisopropoxyaluminate undergoes alcoholysis reactions with various alcohols and acetylacetone to yield products with the composition: $Ni[Al(OR)_4]_2$ (when ROH = methanol, ethanol, 2,2,2-trifluoroethanol, 2,2,2-trichloroethanol, *n*-butanol, and 1,3-dichloro-2-propanol); $Ni[Al(O\text{-}i\text{-}Pr)(O\text{-}t\text{-}Bu)_3]_2$ (with tertiary butyl alcohol); $Ni[Al(O\text{-}i\text{-}Pr)_2(O\text{-}t\text{-}Am)_2]_2$ (with tertiary amyl alcohol); and $Ni[Al(O\text{-}i\text{-}Pr)_2(acac)_2]$ (with acetylacetone). On the basis of their visible reflectance and infrared spectra along with molecular weights and magnetic susceptibilities, and octahedral geometry is tentatively suggested for these complexes in the solid state with indications of an equilibrium between tetrahedral and octahedral forms in solution. The alkoxy ligands have also been fitted into the spectrochemical and nephelauxetic series.

R. C. MEHROTRA et JAGVIR SINGH. Can. J. Chem. **62**, 1003 (1984).

Le tétraisopropylate d'aluminium et de nickel(II) subit des réactions d'alcoolyse avec divers alcools et avec l'acétylacétone qui conduisent, suivant les conditions, aux produits de compositions suivantes: $Ni[Al(OR)_4]_2$ (quand ROH = méthanol, éthanol, trifluoro-2,2,2 éthanol, trichloro-2,2,2 éthanol, *n*-butanol et dichloro-1,3 propanol-2); $Ni[Al(O\text{-}i\text{-}Pr)(O\text{-}t\text{-}Bu)_3]_2$ (avec l'alcool butylique tertiaire); $Ni[Al(O\text{-}i\text{-}Pr)_2(O\text{-}t\text{-}Am)_2]_2$ (avec l'alcool amylique tertiaire) et $Ni[Al(O\text{-}i\text{-}Pr)_2(acac)_2]_2$ (avec l'acétylacétone). En se basant sur leurs spectres de réflectance visible et sur leurs spectres infrarouges ainsi que sur leurs poids moléculaires et sur leurs susceptibilités magnétiques, on suggère qu'à l'état solide, ces complexes existent sous une géométrie octaédrique; il y a des indications à l'effet qu'en solution, il existerait un équilibre entre les formes tétraédriques et octaédriques. On a aussi ajusté les ligands alcoolates dans les séries spectrochimiques et néphélauxétiques.

Introduction

Although the simple alkoxides (1–4) of the later "3*d*" metals including nickel are insoluble, polymeric, and non-volatile in nature, a number of bimetallic isopropoxides of these metals have been reported (5, 6) in recent years as soluble monomeric volatile products with the general formula, $M[Al(O\text{-}i\text{-}Pr)_4]_n$ where $n = 3$, when M = Cr(III) or Fe(III) and $n = 2$, when M = Mn(II), Fe(II), Co(II), Ni(II), or Cu(II) by reacting their anhydrous chlorides (or their benzene soluble adducts) with potassium tetraisopropoxyaluminate in isopropanol–benzene medium in the required stoichiometric ratios. A few bimetallic alkoxides of nickel(II), $Ni[Al(OR)_4]_2$ (where R = CH_3, C_2H_5, $n\text{-}C_3H_7$, $n\text{-}C_4H_9$) have also been reported more recently by Stumpp and co-workers (7) employing a different technique.

Except for some steric factors (8) in cases of highly ramified alcohols, the alkoxides of non-transition and earlier transition metals undergo facile alcoholysis reactions (1). By contrast, recent studies on the alcoholysis reactions of simple alkoxides of later "3*d*" metals have shown interesting features including specificity in certain directions (6). For example, the primary alkoxides $Ni(OR)_2$ do not appear to undergo alcoholysis with secondary, tertiary, and higher primary alcohols even under favourable conditions. Nickel isopropoxide, on the other hand, undergoes facile interchange with primary alcohols, but does not react with tertiary or other secondary alcohols. These interesting differences have been correlated with changes in the stereochemistry of nickel(II) in combination with different types of alkoxy groups (9). In view of these differences a study of alcoholysis reactions of bimetallic alkoxides of nickel appeared to be of considerable interest.

Compared with simple alkoxides, the bimetallic nickel tetraisopropoxyaluminate appears to undergo facile alcoholysis reactions which are controlled under certain conditions by steric factors only. We, therefore, describe here our results on the synthesis of a variety of bimetallic alkoxides, $Ni[Al(OR)_4]_2$, by the alcoholysis of $Ni[Al(O\text{-}i\text{-}Pr)_4]_2$ and a study of their physicochemical properties with a view to elucidate their structural features.

Results and discussion

1. Synthetic studies

Alcoholysis reactions of $Ni[Al(O\text{-}i\text{-}Pr)_4]_2$ have been carried out with various alcohols and acetylacetone. In the cases of methanol, ethanol, and 2,2,2-trifluoroethanol, the bimetallic isopropoxide was refluxed with large excess of the alcohol for 2–3 h. In all other cases, the reaction mixture of $Ni[Al(O\text{-}i\text{-}Pr)_4]_2$ with the alcohol in benzene was refluxed under a fractionating column and the progress of the reaction was followed by estimation of isopropanol collected in the azeotrope (Table 1). Like methoxides (simple as well as bimetallic) in a number of other cases, $Ni[Al(OMe)_4]_2$ (a yellowish green solid) is insoluble in organic solvents and is non-volatile. $Ni[Al(OEt)_4]_2$ is a purple viscous liquid which can be distilled under reduced pressure; it is insoluble in benzene but dissolves in ethanol (monomeric). Other tetraalkoxyaluminates of nickel synthesised during the course of these investigations (Table 1) are volatile and dissolve in benzene also.

The reactions with excess of tertiary butyl and amyl alcohols result in only partial replacement of the isopropoxy groups of $Ni[Al(O\text{-}i\text{-}Pr)_4]_2$ with the formation of monomeric soluble volatile products, $Ni[Al(O\text{-}t\text{-}Bu)_3(O\text{-}i\text{-}Pr)]_2$ and $Ni[Al(O\text{-}t\text{-}Am)_2(O\text{-}i\text{-}Pr)_2]_2$, respectively:

$$Ni[Al(O\text{-}i\text{-}Pr)_4]_2 \xrightarrow{t\text{-BuOH}} Ni[Al(O\text{-}i\text{-}Pr)(O\text{-}t\text{-}Bu)_3]_2 + 6i\text{-PrOH}$$

$$\xrightarrow{t\text{-AmOH}} Ni[Al(O\text{-}i\text{-}Pr)_2(O\text{-}t\text{-}Am)_2]_2 + 4i\text{-PrOH}$$

Reactions of $Ni[Al(O\text{-}i\text{-}Pr)_4]_2$ with acetylacetone (Hacac) have been carried out in 1:4 and 1:8 molar ratios in benzene

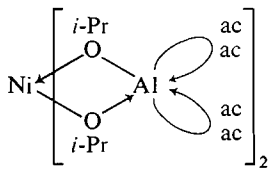
and can be represented as below:

$$Ni[Al(O\text{-}i\text{-}Pr)_4]_2 \xrightarrow{4Hacac} Ni[Al(O\text{-}i\text{-}Pr)_2(acac)]_2 + 4i\text{-}PrOH$$

$$\xrightarrow{8Hacac} Ni[(acac)_2 + 2Al(acac)_3 + 8i\text{-}PrOH$$

The product $Ni[Al(O\text{-}i\text{-}Pr)_2(acac)_2]_2$ could be sublimed and its molecular weight in benzene corresponded to the formula weight; it can, therefore, be represented by the structure:



Magnetic studies

Magnetic moments of these derivatives, $Ni[Al(OR)_4]_2$, have been measured at room temperature. Values of the magnetic moments for all these derivatives fall in the range 3.28 to 3.47 BM, which correspond to two unpaired spins anticipated for both tetrahedral and octahedral geometries (10). The low temperature magnetic susceptibility measurements in the range 80 to 300 K have been made for $Ni[Al(O\text{-}i\text{-}Pr)_4]_2$ and the moments are found to be practically independent of temperature. This behaviour is indicative of octahedral geometry (9) for the complex. The plot of $1/\chi_M$ (corr.) versus T gives a straight line with the value of θ as 0 K.

Spectroscopic studies

Infrared spectra

The infrared spectra (4000–400 cm^{-1}) of all the nickel(II) bimetallic alkoxides exhibit the characteristic frequencies for alkoxy groups, aluminium–oxygen, and nickel–oxygen bands.

Electronic spectra

The data for the electronic spectra of the products are summarised in Table 2. The observed bands in the regions of 12 790 – 14 860 and 23 255 – 25 455 cm^{-1} have been assigned to the transitions ν_2, $[^3A_{2g} \rightarrow {}^3T_{1g}(F)]$ and ν_3, $[^3A_{2g} \rightarrow {}^3T_{1g}(P)]$, respectively, for octahedral nickel(II) species. As ν_1, $[^3A_{2g} \rightarrow {}^3T_{2g}(F)]$ which represents $10Dq$, could not be observed under the experimental conditions employed. The values of ν_1 as well as that of Racah parameter β (column 8) were calculated by the equations given by Underhill and Billings (11):

$$340Dq^2 - 18(\nu_2 + \nu_3)Dq + \nu_2\nu_3 = 0$$

$$15B = \nu_2 + \nu_3 - 30Dq$$

In addition to the above, another band in the range 17 095 to 19 340 cm^{-1} has been observed in the spectra of a few derivatives and this has been ascribed to the transition ν_3, $[^3T_1 \rightarrow {}^3T_1(P)]$ of tetrahedral nickel(II).

In view of the observed (1, 5, 12) bidentate nature of the ligand $[Al(OR)_4]^-$, the monomeric bimetallic nickel aluminium alkoxides, $Ni[Al(OR)_4]_2$, could be expected to be tetrahedral compounds in which both aluminium as well as nickel atoms exhibit tetrahedral geometry. However, physicochemical characteristics of these monomeric nickel(II) bimetallic derivatives appear to show a tendency of nickel to acquire an octahedral geometry, indicating the possibility that in such situations, $[Al(OR)_4]^-$ may act as a tridentate ligand:

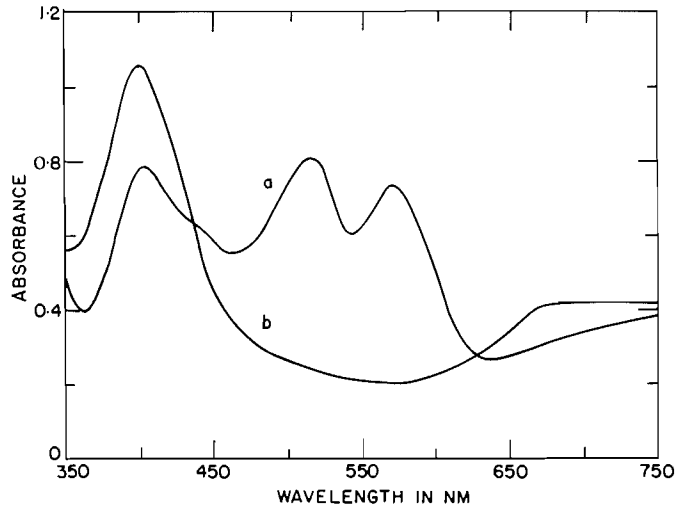


FIG. 1. Visible spectra of $Ni[Al(OEt)_4]_2$ in (*a*) Nujol and (*b*) ethanol.

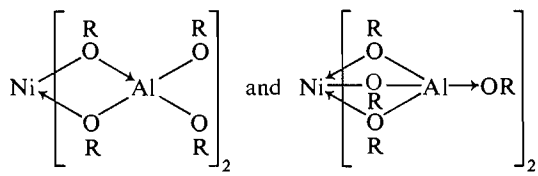
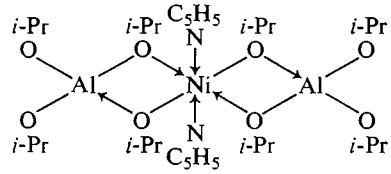


Tetrahedral Octahedral

The above tendency to attain octahedral geometry appears to increase as the alkoxy groups become smaller and less ramified. For example, $Ni[Al(OMe)_4]_2$ shows only two bands at 13 985 and 25 445 cm^{-1}, characteristic of Ni(II) in an octahedral geometry. The spectra of $Ni[Al(OEt)_4]_2$ and $Ni[Al(O\text{-}i\text{-}Pr)_4]_2$, on the other hand, show increasing proportions of tetrahedral nickel species in equilibrium with octahedral forms.

On dissolving purple–green $Ni[Al(OEt)_4]_2$ in ethanol, a pinkish solution is obtained and the bands due to tetrahedral molecules disappear (Fig. 1, Table 2). A plausible explanation for this could be that the coordination of solvent ethanol molecules converts the tetrahedral species into octahedral ones. The spectra of $Ni[Al(O\text{-}i\text{-}Pr)_4]_2$ in film and in benzene solution are almost identical, showing bands (Table 2) characteristic of both octahedral and tetrahedral forms. In isopropanol solution, the spectrum of $Ni[Al(O\text{-}i\text{-}Pr)_4]_2$ indicates a greater intensity of octahedral bands in comparison to the tetrahedral ones. This can again be tentatively explained by the coordination of isopropanol molecules which, however, appears to be partial due to steric factors. The spectrum of $Ni[Al(O\text{-}i\text{-}Pr)_4]_2$ was, therefore, recorded in a stronger donor ligand solvent pyridine, in which case, as expected, the conversion to octahedral form shown below:



appears to be complete as shown by disappearance of tetrahedral bands (Table 2) in the spectrum.

The spectra of mixed tertiary butoxy and tertiary amyloxy

derivatives (columns 5 and 6 in Table 2) show comparatively more predominant bands due to tetrahedral forms as could be expected from the steric factors of more ramified tertiary alkyl groups. The spectrum of $Ni[Al(O\text{-}i\text{-}Pr_2(acac)_2]_2$ again depicts bands characteristic of an octahedral as well as a tetrahedral form, which appears to be much more predominant. The spectrum of the product with the composition $Ni[Al(acac)_4]_2$ is almost identical with that of the pure octahedral $Ni(acac)_2$ (13), and shows it to be a mixture of $Ni(acac)_2$ and $Al(acac)_3$.

Ligand field parameters for nickel(II) derivatives

From the spectroscopic data, various spectroscopic parameters like ligand field energy (10 *Dq*), Racah interelectronic-repulsion parameter (*B*), and covalency factor (β_{35}) have been calculated (Table 2). It is observed that the values of ν_1 (10 *Dq*), ν_2, and ν_3 transitions change markedly from the methoxide to ethoxide derivative but those for ethoxide and butoxide are almost similar. These values, however, show a marked decrease from *n*-butoxide to isopropoxide derivatives. Similarly there is a marked decrease in the values of ν_1 (10 *Dq*) from the isopropoxide to the tertiary butoxide derivative which is almost of same order as that of the tertiary amyloxide derivative. The values of Racah interelectronic repulsion parameter (*B*) obtained in these bimetallic alkoxides of nickel(II) are below the free ion value (1041 cm^{-1}) which are indicative of considerable covalent nature of the metal–ligand bond.

Spectrochemical and nephelauxetic series

The values of ligand field parameters (10 *Dq*) and (β_{35}) for alkoxy ligands can be fitted into the following spectrochemical and nephelauxetic series (14), respectively:

$$\underset{(680)}{Br^-} < \underset{(720)}{Cl^-} < \underset{(725)}{F^-} < \underset{(830)}{C_2H_5O^-} < \underset{(840)}{CH_3O^-} < \underset{(850)}{H_2O} < \underset{(895)}{i\text{-}C_3H_7O^-} < \underset{(910)}{n\text{-}C_4H_9O^-} < \underset{(1080)}{NH_3}$$

$$\underset{(0.92)}{F^-} > \underset{(0.91)}{CH_3O^-} > \underset{(0.89)}{H_2O} \simeq \underset{(0.89)}{C_2H_5O^-} > \underset{(0.84)}{NH_3} > \underset{(0.83)}{n\text{-}C_4H_9O^-} > \underset{(0.79)}{Cl^-} > \underset{(0.74)}{i\text{-}C_3H_7O^-} > \underset{(0.73)}{Br^-}$$

Experimental section

To avoid hydrolysis of starting materials as well as products, stringent precautions were taken to exclude moisture throughout the experimental work.

Hydrated $NiCl_2$ (B.D.H.) was made anhydrous by heating it carefully in an atmosphere of dry hydrogen chloride gas. Aluminium isopropoxide, $Al(O\text{-}i\text{-}Pr)_3$, was prepared (15) from aluminium foil and distilled (95°/0.5 mm) before use. Benzene and alcohols were dried according to the standard literature procedures. 2,2,2-Trifluoroethanol (Aldrich), 2,2,2-trichloroethanol (Aldrich), and 1,3-dichloro-2-propanol (Aldrich) were used after distillation.

Aluminium in the bimetallic compounds of nickel and aluminium was estimated as oxinate after removing nickel as nickel dimethylglyoximate. Isopropanol in the azeotrope was determined by a chromate oxidimetric method (8).

A semi-micro ebulliometer (Gallenkamp) with thermistor sensing was used for molecular weight determinations. The magnetic susceptibility measurements were carried out by Gouy Method.

Reactions of nickel aluminium isopropoxide, $Ni[Al(O\text{-}i\text{-}Pr)_4]_2$ with methanol, ethanol, and 2,2,2-trifluoroethanol

The benzene solution of $Ni[Al(O\text{-}i\text{-}Pr)_4]_2$ is refluxed with alcohol (methanol, ethanol, or 2,2,2-trifluoroethanol in excess) for 2–3 h and benzene and unreacted alcohol were removed from the reaction mixture under reduced pressure. The products thus obtained were finally dried at 30°/1 mm and analyzed. Synthetic and analytical data of these reactions are given in Table 1.

Reactions of $Ni[Al(O\text{-}i\text{-}Pr)_4]_2$ with n-butyl, tertiary butyl, and amyl alcohols, 2,2,2-trichloroethanol, and 1,3-dibromo-2-propanol

The reactions of $Ni[Al(O\text{-}i\text{-}Pr)_4]_2$ with *n*-butyl, tertiary butyl, and amyl alcohols, 2,2,2-trichloroethanol, and 1,3-dibromo-2-propanol have been carried out by heating a mixture of $Ni[Al(O\text{-}i\text{-}Pr)_4]_2$ and alcohol in benzene followed by azeotropic removal of liberated isopropanol. The completion of the reactions could be known by estimating the isopropanol content of the azeotrope quantitatively. When temperature became constant at 80°C, excess of solvent was removed under reduced pressure and the products were purified by distillation. With tertiary butyl and amyl alcohols, the amounts of isopropanol liberated as well as the analysis of the end products isolated corresponded to $Ni[Al(O\text{-}i\text{-}Pr)(O\text{-}t\text{-}Bu)_3]_2$ and $Ni[Al(O\text{-}i\text{-}Pr)_2(O\text{-}t\text{-}Am)_2]_2$, respectively. No further replacements of isopropoxy group with tertiary butoxy and amyloxy groups were possible even after a prolonged reflux (~5 h). The details of these reactions are shown in Table 1.

Reactions of $Ni[Al(O\text{-}i\text{-}Pr)_4]_2$ with acetylacetone in 1:4 and 1:8 molar ratio

Reactions of $Ni[Al(O\text{-}i\text{-}Pr)_4]_2$ with acetylacetone were carried out in benzene in 1:4 and 1:8 molar ratios. Calculated amount of acetylacetone was added to the benzene solution of $Ni[Al(O\text{-}i\text{-}Pr)_4]_2$ and contents were refluxed for ~10 h with the fractionation of the liberated isopropanol between 72–80°C. Completion of the reaction was checked by estimation of the amount of isopropanol in the azeotrope. Excess solvent was stripped off under reduced pressure. The pure compound $Ni[Al(O\text{-}i\text{-}Pr)_2(acac)_2]_2$ was isolated by distillation under reduced pressure, whereas $Ni[Al(acac)_4]_2$ was disproportionated into $Ni(acac)_2$ and $Al(acac)_3$ on attempted distillation. Other details of the reactions are given in Table 1.

Excess heat capacities and excess volumes of tetraalkyltin compounds: $SnR_4 + SnR'_4$. Effect of correlations of molecular orientations and steric hindrance. Part 1

BERNARD RIEDL AND GENEVIÈVE DELMAS
Department of Chemistry, University of Quebec at Montreal, Montreal, P.Q., Canada H3C 3P8

Received July 4, 1983

BERNARD RIEDL and GENEVIÈVE DELMAS. Can. J. Chem. **62**, 1008 (1984).

A Picker flow calorimeter has been used to obtain molar excess capacities (c_p^E) through the concentration range at 25°C for the systems $SnR_4 + SnR'_4$ where R is the alkyl group C_nH_{2n+1} ($n = 1, 2, 3, 4, 8, 12$). Excess volumes have also been measured for the mixtures. Two contributions to c_p^E and v^E were investigated: those associated with disordering the long alkyl chains and with steric hindrance. The steric hindrance contribution has been found to occur for molecules having a highly substituted central atom. The sign of this contribution is negative in h^E and positive in c_p^E, indicative of an ordering or loss of mobility for the molecules going from pure liquid to solution. The c_p^E results confirm the more sterically hindered character of the ethyl and propyl derivatives already found with h^E. The separation of the disorder and steric contribution is possible in systems involving long-chain compounds. It is found that the orientational order contribution diminishes more slowly with temperature than the steric hindrance effect. The trend of v^E in the series is reasonably well predicted by the Prigogine–Patterson–Flory theory.

BERNARD RIEDL et GENEVIÈVE DELMAS. Can. J. Chem. **62**, 1008 (1984).

Opérant à 25°C, sur un large éventail de concentrations et utilisant un calorimètre à écoulement du type Picker, on a déterminé les capacités molaires en excès (c_p^E) des systèmes $SnR_4 + SnR'_4$ où R est un groupe alkyle du type C_nH_{2n+1} ($n = 1, 2, 3, 4, 8, 12$). On a également mesuré les volumes molaires en excès de ces mélanges. On a évalué deux contributions au c_p^E et au v^E soit celle associée au désordre apporté par les longues chaînes alkylées ainsi que celle due à l'encombrement stérique. On a trouvé que la contribution due à l'encombrement stérique se manifeste dans les molécules ayant un atome central très substitué. Cette contribution a un signe négatif pour h^E et un signe positif pour c_p^E; ceci indique la présence d'un agencement spécial ou une perte de mobilité pour les molécules passant du liquide pur à la solution. Les résultats pour c_p^E confirment les conclusions qui découlent de h^E à l'effet que les dérivés éthyliques et propyliques sont stériquement plus encombrés. Il est possible de séparer la contribution relative au désordre et de la contribution stérique dans les systèmes impliquant des composés à longue chaîne. On a trouvé que la contribution due à l'ordre orientationel diminue plus lentement avec la température que l'effet dû à l'encombrement stérique. La tendance de v^E dans la série peut être prévue de façon raisonnable par la théorie de Prigogine–Patterson–Flory.

Introduction

This work is part of an investigation of the effect of the molecular shape on the thermodynamic properties of mixtures. The SnR_4 ($R = C_nH_{2n+1}$) molecules are convenient for this purpose since the gradual lengthening of the R group will transform the molecular shape from globular to star-shape without significantly changing the chemical nature. Furthermore, the presence of a tetrasubstituted Sn central atom gives the molecule some special features similar to those in carbon compounds (for example, $C(C_2H_5)_4$ or 3,3-diethyl pentane (DEP)). Heats of mixing of the $SnR_4 + SnR'_4$ compounds (1) as well as those of SnR_4 with linear and branched alkanes (2, 3) have given a coherent picture of the orientational order in long chain alkane-like compounds. Orientational order occurring in the pure compounds (A) may be partially preserved if the second component (B) is also ordered (3). On the contrary, globular (B) molecules destroy the order in A and this disordering process is associated with a large endothermic heat. Excess volumes (4) and excess viscosities (5, 6) of mixtures involving SnR_4 compounds have been obtained and compared with theoretical predictions using recent data on equation of state parameters (7) of the SnR_4 liquids. The order of pure liquids diminishes rapidly with increasing temperature as does the corresponding contribution to h^E (8–10).

Since unexpected values of h^E have been found in many systems involving some molecules whose central atom is highly substituted (10–13), a new negative contribution to the heats of mixing, h^E (steric hindrance), has been suggested. This contribution has also been called "condensation" contribution by Patterson (13–15) and "coupling of torsional oscillations" contribution by de Ligny (16). The term condensation is in line with the negative sign of the heat, interpreted as a reduction of the mobility of the flexible —CH_2—CH_2— segments (and possibly of the other component) after mixing. In the series of differently substituted hexanes, heptanes, octanes, the extent of steric hindrance of the pure compounds has been related (16) to the mean number of *gauche* configurations, Z_g (17). The steric hindrance contribution is smaller in trialkylamine series (8, 12, 18) but large in polymeric solutions (19).

In previous work, the heats of mixing were written as the sum of four different contributions:

$$[1]\quad h^E(\text{exp}) = h^E(\text{chem}) + h^E(\text{f.v.}) + h^E(\text{dis.}) + h^E(\text{ster. hindr.})$$

where f.v. stands for free volume, dis. stands for disorder, and ster. hindr. for steric hindrance.

This equation was found to be a convenient way to describe the heats even if there is no proof that these contributions are independent and additive.

Similarly, c_p^E may be written in the same format:

$$[2]\quad c_p^E(\text{exp}) = c_p^E(\text{chem}) + c_p^E(\text{f.v.}) + c_p^E(\text{dis.}) + c_p^E(\text{ster. hindr.})$$

where c_p^E(chem) and c_p^E(f.v.) refer, respectively, to the contributions coming from force field and free volume difference and c_p^E(dis.) and c_p^E(ster. hindr.) from the disordering and steric hindrance contributions that we are focussing on in the present work.

TABLE 1. Expected signs of h^E, v^E, and c_p^E for the different contributions

Parameter	Force field difference	Free volume difference	Disordering	Sterical hindrance
h^E	$+^a$	$-^{b,d}$	+	−
Change of h^E when T increases	Little change	More −	Less +	Less −
c_p^E	About 0	$-^{b,d}$	−	+
v^E	+	$-^{b,c,d}$	+	−

[a] In non-polar systems.
[b] Depends mostly on the difference in expansion coefficients.
[c] Depends also on the relative cohesive energy of the two components.
[d] Values have been calculated in ref. 1 for h^E, in Tables 3 and 4 for c_p^E and v^E.

Signs of h^E *and* c_p^E

The excess heat capacity $c_p^E = dh^E/dT$ may be used to separate the different contributions to the heats or at least to detect the dominant one. For non-polar systems, the normal sign of h^E is positive and that of c_p^E is usually negative but small. However, when h^E is due to the destruction of order, c_p^E is expected to be large and negative since the orientational order diminishes rapidly when T increases. The facts that the steric hindrance contribution is linked with the mobility of the molecule, and that it is found to increase with a low free volume second component (8) and the direct determination of h^E(ster. hindr.) with temperature (13) all indicate that this contribution, like h^E(dis.), diminishes with temperature. Fortunately, since h^E(ster. hindr.) is exothermic, c_p^E(ster. hindr.) is expected to be positive, a feature which will assist the separation of the contributions to c_p^E. Table 1 gives a summary of the above considerations.

In the present work, excess volumes and heat capacities have been measured at 25°C for the fourteen $SnR_4 + SnR_4'$ systems listed in Table 2. The aim was mainly to confirm the steric hindrance character of the propyl and ethyl derivatives and support the validity of the separation of the contributions as proposed for the h^E. A comparison will be made between the stability with temperature of the correlations of molecular orientations in the SnR_4 molecules and the alkanes (14). In the following text, the names of the SnR_4 will be shortened to $SnMe_4$, $SnEt_4$, etc. as listed in Table 3.

Experimental section

Materials

The tetraalkyltin derivatives were prepared by the Organisch Chemical Instituut (Utrecht) except for $SnDodec_4$ which has been obtained from Inorganic Chem. Corp. (Sun Valley, Calif.). Density and gas chromatography were used to test their purity. The latter, as given by a Hewlett Packard 5730A gas chromatograph was 99.8% or more for five compounds and 98.6 and 97.4% for $SnPr_4$ and br-C_{16}, respectively (Table 3). For non-volatile compounds such as $SnOct_4$ and $SnDodec_4$, the largest difference in density with those previously measured (1, 8) was 7×10^{-4} g cm^{-3}.

Apparatus

Excess heat capacities were obtained at 25°C throughout the concentration range using the Picker flow calorimeter (Techneurop, Montreal, and Setaram, Lyon) as described previously (20). For more viscous solutions, the cross section of the tubing was increased from 0.5 to 1.0 mm^2. Densities have been measured with an Anton-Paar precision densitometer (Fisher Co.) described elsewhere (5). *Precision and accuracy*: for the reference system c-C_6 + n-C_{16}, the present c_p^E values are within 0.02 J K^{-1} mol^{-1} of the published data. For a given system, the reproducibility of the measurements which include solution density and heat capacity data is about the same. For the $SnDodec_4$ systems, the reproducibility is poorer (0.1 to 0.2 J K^{-1} mol^{-1}) due to the high viscosity of the solutions. For each system, the number of points made and the mean square standard deviation have been added in the table.

Physicochemical constants and calculated parameters

Table 3 gives the densities, thermal expansion coefficients, and thermal pressure coefficients (γ) of the SnR_4 compounds. The parameters necessary to calculate the equation of state terms in h^E, v^E, and c_p^E such as P^*, V^*, are also listed. V^* is the core volume or volume at 0 K. The details of the calculations and, in particular, the equations for the free volume contribution to h^E, c_p^E, and v^E and the interaction energy parameters X_{12} are given in the Appendix.

Molecular shape

The molecular surface-to-volume ratios used in the Prigogine–Patterson–Flory theory can be obtained from models. A cylindrical model for the linear alkanes (n-C_7 to n-C_{16}) gives s values between 1.0 and 0.9 Å^{-1}. For $SnMe_4$ a spherical model gives $s = 0.96$. A combination of the two models gives s values between 0.82 and 0.86 for the SnR_4 compounds ($2 \leq n \leq 12$).

Results and discussion

The c_p^E and v^E values are represented by the Redlich–Kister equations:

$$c_p^E = x_1 x_2 \sum_{i=0}^{2} C_i (x_1 - x_2)^i$$

$$v^E = x_1 x_2 \sum_{i=0}^{2} B_i (x_1 - x_2)^i \quad [3]$$

The concentrations, the values at the maximum, and the values of the constants B_i, C_i are listed in Tables 2 and 4. The B_i, C_i parameters have been omitted for systems involving the dodecyl component due to the lack of precision caused by the high viscosity of $SnDodecyl_4$.

In Table 2, the systems are divided into two groups: six systems made of globular SnR_4 are listed in the type-A group for which h^E(dis.) $\simeq c_p^E$(dis.) = 0 and eight systems are in the type-B group for which the disordering of $SnOct_4$ and $SnDodec_4$ brings a large disordering contribution in h^E and c_p^E.

The X_{12} interchange energy parameter calculated from the experimental heats from which the free volume contribution has been subtracted, corresponds to the sum of the three other contributions. A negative value of X_{12} is an indication of the importance of the steric hindrance contribution since it is the only contribution which gives negative heats apart from the free volume one. For the mixture of globular molecules (A systems), X_{12} is found negative for only one system, $SnEt_4 + SnPr_4$

[e] Using a Hewlet-Packard 5730A gas chromatograph, with a polydimethyl siloxane column (OV-101), set at $T = T_E - 20$ K where T_E is the boiling point of the solvent.

(tenth column of Table 4). This is not surprising since a small positive h^E(chem) must occur in the mixtures of lighter SnR_4. The advantage of the c_p^E is indeed to allow a finer separation of the contributions as will be seen later. On the type-B systems, the large irregularities in the series of h^E or X_{12} were interpreted as an indication of sizeable steric hindrance contributions.

Two of the contributions to c_p^E in eq. [2] will not come into the discussion. On the one hand, the c_p^E(chem) are negligible for two reasons: the similarity in force field of these molecules and the lack of variation with temperature of h^E(chem) and, on the other hand, the c_p^E(f.v.) which can be calculated. By assuming c_p^E(chem) = 0, eq. [3] becomes, for the type-B systems:

$$[4]\quad c_p^E(\text{exp}) - c_p^E(\text{f.v.}) = c_p^E(\text{dis.}) + c_p^E(\text{ster. hindr.})$$

while, for the type-A group mixtures, it reduces to:

$$[5]\quad c_p^E(\text{exp}) - c_p^E(\text{f.v.}) = c_p^E(\text{ster. hindr.})$$

The free volume contribution to c_p^E has been listed in the eighth column of Table 2. (See Appendix for the expression.) The last column is $c_p^E - c_p^E$(f.v.). For six systems out of the fourteen, the c_p^E(f.v.) is less than 5% of the experimental value.

The signs of the c_p^E(exp) listed in Table 2 are all negative except for the system $SnEt_4 + SnPr_4$. This means that for all the other systems, the free volume and disordering contributions combine to mask the steric hindrance term, if there is one, as was the case with h^E.

Mixtures of globular SnR_4: (type-A systems)

For the $SnEt_4 + SnPr_4$ system, the positive c_p^E gives the same information as h^E, i.e., dominance of a steric hindrance contribution. For four other systems, the subtraction of c_p^E(f.v.) gives values of the difference inferior to 0.2 J K^{-1} mol^{-1} so that no special comment is necessary on such small values which must be the combination of several small effects as were the small (<60 J mol^{-1}) h^E. The c_p^E measurements may have revealed a steric hindrance contribution on the $SnMe_4 + SnBut_4$ system since c_p^E(exp) − c_p^E(f.v.) is +0.57. However, one must be careful in this conclusion for the following reason. Many indications have been gathered (1–3, 21) on a large variety of systems, showing that the free volume term calculated is too large for important free volume differences between the components with the consequence of an increased X_{12} for these systems. Similar errors in the calculated c_p^E(f.v.) would generate positive values of c_p^E(exp) − c_p^E(f.v.) which would not have a physical meaning in terms of steric hindrance. Although it is not unlikely that the calculated c_p^E(f.v.) are not as much overestimated as the h^E(f.v.), it is only possible to say that the steric hindrance may indeed occur for this system but that it is not very large. Fortunately, on the type-B group containing the $SnOct_4$ and $SnDodec_4$ molecules made of long —CH_2—CH_2— sequences which can be disordered, the steric hindrance contribution will be seen without ambiguity.

Mixtures of globular + linear SnR_4: (type-B systems)

In order to compare the experimental values for the different systems, c_p^E(exp) per cm^3 at the maximum of the concentration range for the different systems have been plotted in the bottom part of Fig. 1 versus the core volume of the second component. A line is drawn through the points for the $SnOct_4$ and another for the $SnDodec_4$ results.

$$[6]\quad (c_p^E)_v = c_p^E \text{ per cm}^3 = c_p^E \text{ per mole}/(x_1 V_1^* + x_2 V_2^*)$$

The same plot is given in the top part of Fig. 1, using h_v^E, the experimental heat of mixing per cm^3 defined in the same way as $(c_p^E)_v$.

The characteristic features of these SnR_4 mixtures given by this figure are the following: (*1*) The $(c_p^E)_v$ are large and negative and increase between $SnOct_4$ and $SnDodec_4$. (*2*) The irregularities observed in h_v^E with $SnEt_4$ and $SnPr_4$ and interpreted as due to an extra exothermic steric hindrance contribution for these two components, are seen on the $(c_p^E)_v$ and correspond to a positive term as expected. (*3*) The $(c_p^E)_v$ curves are mirror images of the h_v^E indicating probably that, in each case, one contribution, that of disordering the long chains, is dominant.

Variation of the steric hindrance contribution with the size of the alkyl group SnR_4

When the length of the alkyl group becomes greater the influence of the central crowded atom along the chain and towards the second component in solution is likely to diminish so that the steric hindrance contribution decreases also. However, since the steric hindrance effect has been shown (19,21) to increase for low free volume of the sterically hindered component, one can expect the size of the steric hindrance contribution to be lower for the volatile SnR_4. Consequently, the apparently maximum effect with $SnPr_4$ is then not unreasonable. Furthermore, $SnMe_4$ may fail to give a steric hindrance contribution on mixing (or give a lower one than $SnEt_4$ and $SnPr_4$) not only for its large free volume but also because of the shielding effect of the four bulky methyl groups which prevent the second component to come near enough to the central atom.

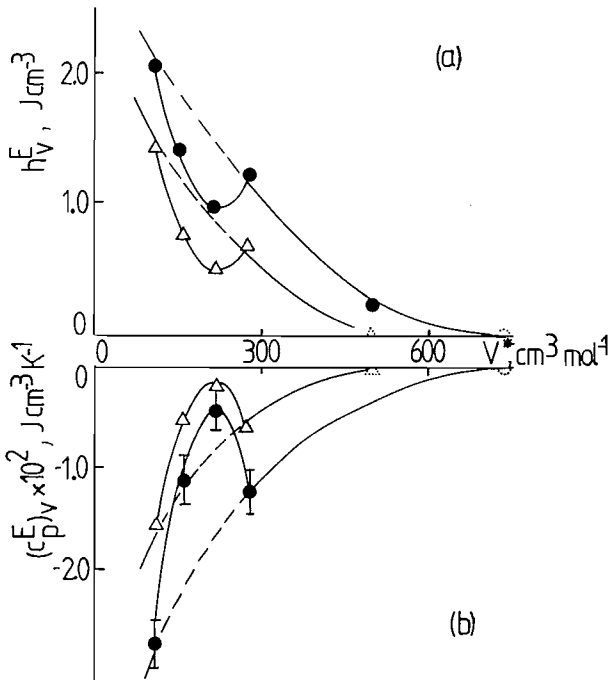

FIG. 1. Excess heats in J cm^{-3} (curve *a*) and excess heat capacities in J cm^{-3} K^{-1} (curve *b*) for $SnOct_4$ (△) and $SnDodec_4$ (●) mixed with $SnMe_4$, $SnEt_4$, $SnPr_4$, $SnBut_4$ plotted against the core volume V^* of the smaller SnR_4. The main contribution comes from the disordering of the long chain giving positive h^E and negative c_p^E. The difference between the curves and the dotted lines corresponds to the extra steric hindrance contribution with $SnEt_4$, and $SnPr_4$ ($h^E < 0$ and $c_p^E > 0$) plotted in Fig. 2 (curve *a*).

1. Quantitative evaluation of the disordering contribution c_p^E(dis.)

Because of the more negative values of c_p^E for the four systems $SnMe_4$ and $SnBut_4$ mixed with the dodecyl and octyl derivatives, the assumption will be made for these four systems that:

$$c_p^E(\text{exp}) - c_p^E(\text{f.v.}) = c_p^E(\text{dis.})$$
$$h_p^E(\text{exp}) - h^E(\text{f.v.}) = h^E(\text{dis.}) \quad [7]$$

2. Temperature variation of the order in long chain liquids

If the order is assumed to diminish exponentially with temperature, the disordering contribution of h^E and c_p^E can be written (14):

$$h^E(\text{dis.}) = h_0 \exp(-T/\tau)$$
$$c_p^E(\text{dis.}) = \frac{h_0}{\tau} \exp(-T/\tau) \quad [8]$$
$$h^E(\text{dis.})/c_p^E(\text{dis.}) = -\tau$$

One would then expect a linear relationship between h^E(dis.) and c_p^E(dis.). Such a relationship has indeed been found for the four systems cited above with a characteristic temperature τ of 120 K as shown in Fig. 2.

However, instead of plotting the disordering contribution as defined in eq. [7], the h^E(exp) and c_p^E(exp) have been used directly. We make this choice because of the likely dominance of one contribution; the four points lie reasonably well on a straight line and it extrapolates to 0. Due to the large calculated free volume contributions to h^E (−100 J mol^{-1}) and c_p^E (1.0 J K^{-1} mol^{-1}) in the $SnMe_4$ systems, there may be as much error subtracting the free volume terms as ignoring them. The difference between the characteristic temperatures 50 K for n-C_{16} and 120 K for $SnOct_4$ and $SnDodec_4$ is quite reasonable. At equal free volume, one would expect the order of a chain of the SnR_4 to be stabilized by the order of the three others and by the large mass of the compounds. Consequently, when the temperature increases the order would disappear more slowly than that of the worm-like alkane chains. The method to find h^E(dis.) which could appear arbitrary seems to be justified by the results which compare well with h^E(dis.) found for linear alkanes (8, 12, 14).

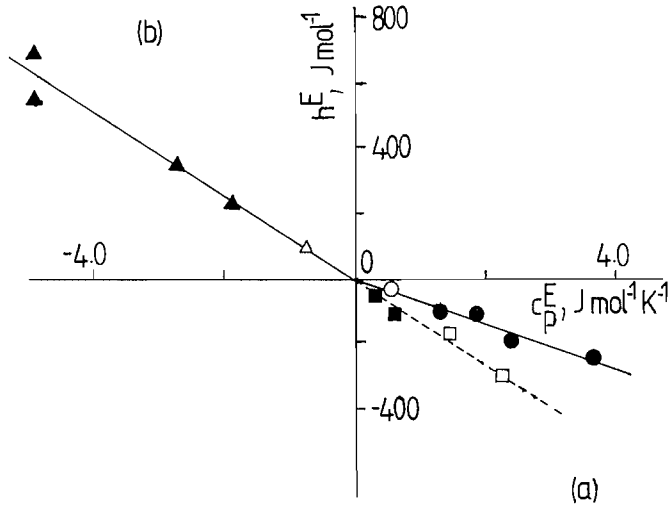

FIG. 2. Correlation between the h^E and c_p^E for the steric hindrance contribution (curve *a*) and the disordering contribution (curve *b*), of $SnOct_4$ and $SnDodec_4$ mixed with $SnMe_4$ and $SnBut_4$ (▲) and with $SnEt_4$ and $SnPr_4$ (●). From eq. [8] the characteristic temperatures are found to be 120 K and 70–80 K for the disordering and steric hindrance effects, respectively. In the disorder quadrant, the point corresponding unexpectedly to the $SnEt_4$ + br-C_{16} system (△) has been added (Part 2, to be published). In the steric hindrance part, two values in the literature on the systems 3,3-DEP + n-C_9 and n-C_{16} (□), have been plotted for comparison as well as two systems presented in part 2, $SnPr_4$ and $SnBut_4$ + br-C_{16}. (■). Direct experimental data for the $SnEt_4$ + $SnPr_4$ system (○).

Analysis of the steric hindrance contribution

The systems involving long-chain components will again be used to evaluate the magnitude of the steric hindrance contribution. In Fig. 1, the two points on the peak of the dodecyl curve (●) and the two points on that of the octyl curve (△) corresponding to the c_p^E values in mixtures with the ethyl and propyl derivatives will be considered. The difference between the experimental value and the expected value on the dotted line will be assumed to represent the steric hindrance contribution for these four systems. The values per mole obtained after multiplying by the molar volume at the concentration of the maximum are, respectively, in J K^{-1} mol^{-1}, 1.3 and 1.8 for $SnEt_4$ and $SnPr_4$ mixed with $SnOct_4$ and 2.4 and 3.6 for the same mixed with $SnDodec_4$. Other ways of obtaining the expected value without steric hindrance such as interpolating a plot of c_p^E versus α rather than c_p^E versus V^* or using the molar c_p^E would give c_p^E(ster. hindr.) within 0.1 to 0.2 J K^{-1} mol^{-1} of the ones listed above. On the lower part of Fig. 2, the points c_p^E(ster. hindr.) have been plotted versus h^E(ster. hindr.) which was obtained in ref. 1 using a procedure similar to that described above for c_p^E(ster. hindr.). The alignment of the four

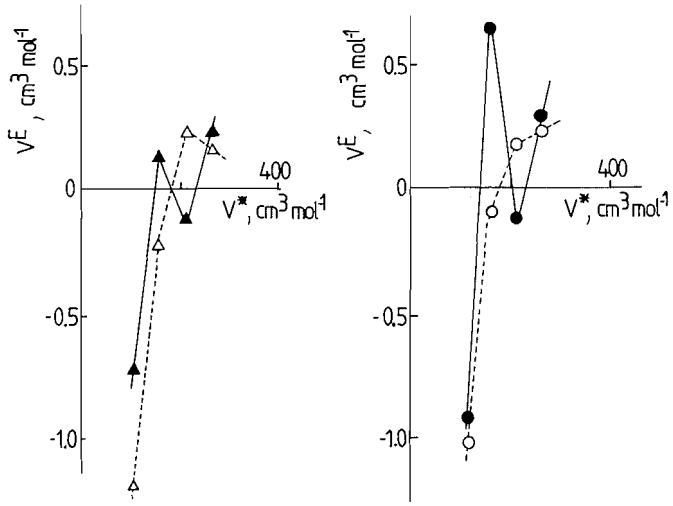

FIG. 3. v^E(exp) for the systems $SnOct_4$ (▲) and $SnDodec_4$ (●) + $SnMe_4$, $SnEt_4$, $SnPr_4$, and $SnBut_4$ plotted against the core volume V^* of the smaller SnR_4 compounds. The dotted lines correspond to the calculated values. With these two compounds, as with others (18), the v^E values in the $SnEt_4$ mixtures are unexpectedly high.

points with the origin and with the point obtained directly (○, $SnEt_4$ + $SnPr_4$ system) gives some confidence in the validity of the method of evaluation of a specific contribution. The c_p^E(ster. hindr.) are positive as expected from an exothermic contribution to the heats which becomes less important when the temperature is raised. With the same assumption as that made for the temperature dependence of order (eq. [8]), the characteristic temperature is found to be between 70 and 80 K for the steric hindrance effect compared to 120 K for the disorder one.

The corresponding steric hindrance contributions for two other systems whose components are rather similar in shape with the present ones have been plotted on Fig. 1*b*. They are 3,3-DEP (or CEt_4) mixed with *n*-C_9 and *n*-C_{16} (9, 10). There, the separation of the steric contribution has been done by subtracting the values obtained with 3,3-DEP from those obtained with an isomer 2,2,5-trimethylhexane which is considered much less or not at all sterically hindered. This effect is found to be of similar magnitude in the two series, their differences in slope and characteristic temperatures may have several origins. It may be due to the difference in shape of the ordered molecules, i.e. *n*-C_{16} and $SnDodec_4$ or a difference in steric hindrance due to the central atoms, C for DEP and Sn for $SnEt_4$ and $SnPr_4$ respectively. Probably, the procedures of separation used in the two series, which cannot be identical since non-sterically hindered isomers of the SnR_4 do not exist, may introduce some difference in the characteristic temperature.

Excess volumes

As verified over a large number of systems (4, 15, 18) the Prigogine–Patterson–Flory theory with the van der Waals model can successfully predict v^E for non-polar or polar mixtures due in part to the fact that the experimental h^E is included in the calculation. Table 2 gives the overall v^E results and Fig. 3 the comparison between v^E(exp) and v^E(calcd) for the type-B systems.

Type-A systems

v^E(exp) − v^E(calcd) is less than 0.1 cm^3 mol^{-1} for four of the six systems in this group. Columns 6 to 9 give the details of the three contributions to v^E(calcd). The negative v^E are due mainly to the contraction on mixing of the lighter SnR_4 when mixed with a less volatile compound. For the second and third systems, v^E is found to be too large because of the $v^E(P^*)$ term whose negative contribution adds to $v^E(\tilde{v})$. On similar systems (18), $v^E(P^*) = (\tilde{v}_1 - \tilde{v}_2)\,(P_1^* - P_2^*)$ also appeared overestimated for relatively large differences in $\tilde{v}$ or in P^* of the two components.

Type-B systems

The dotted lines in Fig. 3 give the calculated v^E, at the maximum, for eight systems. For the two larger order-breakers, $SnPr_4$ and $SnBut_4$, the disordering of the octyl and dodecyl chains is at the origin of the dominant positive contribution while the difference of free volumes contributes to the negative v^E for the more volatile SnR_4. The general trend of the experimental results is well predicted. However, the two systems involving $SnPr_4$ and the two with $SnEt_4$ present interesting large difference between v^E(calcd) and v^E(exp). The more negative v^E(exp) when a sterically hindered compound is mixed with a long chain has been found previously (4) with two highly branched alkanes, probably reflecting the diminution of mobility due to steric hindrance. The result obtained for the system $SnEt_4$ + $SnDodec_4$ is completely anomalous since it is found to be 0.66 cm^3 mol^{-1} while the predicted value is 0.12 cm^3 mol^{-1}. A similar high positive value is seen in the $SnEt_4$ + $SnOct_4$ system although the anomaly is less pronounced. The result seems less eccentric when other v^E measurements on mixtures involving $SnEt_4$ (Part 2, to be published, and ref. 18*b*) also show unexpected positive v^E. But for the other systems, h^E is also positive or more positive than expected. The present system constitutes then an interesting and rare case where the v^E shows an anomaly not yet seen on the heats.

In the SnR_4 + SnR_4' mixtures, the experimental results on c_p^E confirm the interpretation of the h^E in terms of free volume, disordering and steric hindrance contributions and, in particular, of the greater importance of the latter in the $SnEt_4$ and $SnPr_4$ systems when the second component is a long flexible —CH_2—CH_2— chain.

Appendix

Calculation of the free volume terms

$h^E(f.v.)$ *and* $X_{12}s_1^{-1}$

The free volume term depends only on the difference between the reduced volume of the pure components. We apply a developed (22) form of the Prigogine–Flory theory which separates the interactional and free volume contributions. The free volume contribution h^E(f.v.) is defined as:

$$[A1]\quad h^E(\text{f.v.})/(x_1U_1^* + x_2U_2^*) = \tilde{c}_p(\tilde{T}_u)\,(\psi_1\tilde{T}_1 + \psi_2\tilde{T}_2 - \tilde{T}_u)$$

Here $\tilde{T}_u$ is the average reduced temperature for the solution appropriate to the energy $\tilde{U}$ and is defined by:

$$\tilde{U}(\tilde{T}_u) = \psi_1\tilde{U}(\tilde{T}_1) + \psi_2\tilde{U}(\tilde{T}_2)$$

With the van der Waals model, $\tilde{U}(\tilde{T}_u) = -1/\tilde{v}$, so that the volume corresponding to $\tilde{T}_u$ is $1/\tilde{v}_u = \psi_1/\tilde{v}_1 + \psi_2/\tilde{v}_2$, where $\psi_1 = x_1U_1^*/(x_1U_1^* + x_2/U_2^*)$. In this model, the reduced volume of the pure components is obtained from their expansion coefficients α and $\tilde{v}^{1/3} = [(4/3)\alpha T + 1]/(\alpha T + 1)$. The reduced temperature is calculated from the reduced volume and $\tilde{T} = \tilde{v}^{-1}(1 - \tilde{v}^{-1/3})$. Also $\tilde{c}_p(\tilde{T}_u) = [(4/3)\tilde{v}_u^{-1/3} - 1]^{-1}$ and $U^* = P^*V^*$ and $P^* = \gamma\tilde{v}^2T$ where γ is the thermal pressure coefficient. Equation [A1] does not depend on the surface-to-volume ratio. In the Flory terminology, the interactional contribution, which is the difference between the experimental value of the heat and the free volume contribution, is expressed through the X_{12} parameter. In the present form, X_{12} is obtained by eq. [A2]

$$[A2]\quad h^E(\text{exp}) - h^E(\text{f.v.})/(x_1U_1^* + x_2U_2^*) = (X_{12}/P_1^*)\,\theta_2\psi_1 f(\tilde{v})$$

The term $f(\tilde{v})$ $(= (\tilde{v}^{-1} + T\tilde{c}_p))$ is not very different from 1. ψ_1 and θ_2 ($\theta_2 = x_2V^*s_2/(x_1V_1^*s_1 + x_2V_2^*s_2)$) are used rather than the mole fractions. The units of X_{12} are in energy per cm^3. The parameter $X_{12}s_1^{-1}$ is independent of the choice of 1 or 2 as a second component, i.e. $X_{12}s_1^{-1} = X_{21}s_2^{-1}$. The left side of eq. [A2] does not depend on the surface-to-volume ratio s_1 and s_2 while X_{12} and θ_2 do to some extent. $X_{12}s_1^{-1}$ also relies very little on s_1 and s_2. The core volume, V^*, is obtained from the molar volume V and $\tilde{V} = V/V^*$.

c_p^E(*f.v.*)

It is given by the equation:

$$[A3]\quad c_p^E = \tilde{c}_{p,s}[x_1(U_1^*/T_1^*) + x_2(U_2^*/T_2^*)] - x_1\tilde{c}_{p1}(U_1^*/T_1^*) - x_2\tilde{c}_{p2}(U_2^*/T_2^*)$$

The reduced volume of the solution $\tilde{v}_s$ used to calculate $\tilde{c}_{p,s}$ is obtained from the solution reduced temperature $\tilde{T}_s$ defined as an energy average.

$$\tilde{T}_s = (\psi_1\tilde{T}_1 + \psi_2\tilde{T}_2)\,(1 - X_{12}\psi_1\theta_2/P_1^*)$$

The X_{12} term has not a large effect on $\tilde{T}_s$ in the present systems.

v^E

The excess volume can be written using the van der Waals model:

$$[A4]\quad \frac{v^E}{x_1V_1^* + x_2V_2^*} = \tilde{T}_v\frac{\partial\tilde{v}}{\partial\tilde{T}_v}\psi_1\theta_2(X_{12}/P_1^*) + (\tilde{v}_1 - \tilde{v}_2)\,(\psi_1 - \phi_1) - \frac{1}{2}\left(\frac{\tilde{v}_1 - \tilde{v}_2}{\partial\tilde{v}/\partial\tilde{T}_v}\right)^2\frac{\partial^2\tilde{v}}{\partial\tilde{T}_v^2}\{\psi_1\psi_2 + (\psi_1 - \theta_1)^2\}$$

here $\tilde{v}_v = \phi_1\tilde{v}_1 + \phi_2\tilde{v}_2$ and $\tilde{T}_v$ corresponds to $\tilde{v}_v$. By developing the second term in eq. [A4] we can show that $\psi_1 - \phi_1$ varies as $P_1^* - P_2^*$. The first term of eq. [A4] is $v^E(h^E)$, the second $v^E(P^*)$, and the last v^E(f.v.) as listed in Table 4.

Reactions between Ni(II) and $NaBH_3CN$ in the presence of bidentate phosphines

DAVID G. HOLAH, ALAN N. HUGHES, AND NAZRUL I. KHAN
Department of Chemistry, Lakehead University, Thunder Bay, Ont., Canada P7B 5E1

Received September 6, 1983

DAVID G. HOLAH, ALAN N. HUGHES, and NAZRUL I. KHAN. Can. J. Chem. **62**, 1016 (1984).

Reactions between Ni(II) and $NaBH_3CN$ in the presence of $Ph_2P(CH_2)_nPPh_2$ (n = 1, Dppm; n = 2, Diphos) have been studied. With Dppm, the main products are Ni(I)–CN–Dppm complexes and the nature of the actual product formed depends critically upon the reaction conditions. With Diphos, the products mainly involve coordinated BH_3CN^- in Ni(II)–Diphos complexes. Evidence from ^{31}P nmr and ir spectra are used to support proposed structural assignments.

DAVID G. HOLAH, ALAN N. HUGHES et NAZRUL I. KHAN. Can. J. Chem. **62**, 1016 (1984).

On a étudié les réactions entre le Ni(II) et le $NaBH_3CN$ en présence de $Ph_2P(CH_2)_nPPh_2$ (n = 1, Dppm; n = 2, Diphos). Avec le Dppm, les produits principaux sont des complexes de Ni(I)–CN–Dppm et la nature exacte des produits formés dépend d'une façon critique des conditions de la réaction. Avec le Diphos, les produits impliquent principalement des anions BH_3CN^- coordonnés à des complexes de Ni(II)–Diphos. On a utilisé des données des spectres de rmn du ^{31}P et des spectres ir pour proposer des attributions de structure.

Introduction

Reactions between transition metal ions and $NaBH_4$ in the presence of tertiary phosphines are rapid, making it difficult to isolate intermediate products (1). $NaBH_3CN$ is a milder reducing agent (2) and, therefore, similar reactions (and reductions) should proceed more slowly, making it easier to isolate products of both a terminal and intermediate type. This paper presents the results of studies on reactions between Ni(II) and $NaBH_3CN$ in the presence of the bis(diphenylphosphino)alkanes $Ph_2P(CH_2)_nPPh_2$ (n = 1, Dppm; n = 2, Diphos). These bidentate phosphines were chosen because an earlier study (1) showed that in reactions of Ni(II) with $NaBH_4$ in the presence of similar bidentate phosphines, minor variations in phosphine ligand structure cause major variations in final product type. Further examples of both known modes of coordination of $NaBH_3CN$ (metal–$NCBH_3$ and metal–$NCB(H_2)H$–metal) will be reported.

Experimental

Materials

The phosphines were obtained from Strem Chemicals Inc. and used without further purification. $NaBH_3CN$ and $NaBD_3CN$ (98% isotopic purity) were obtained from the Aldrich Chemical Company and the Alfa Division of the Ventron Corporation respectively, and were stored over $CaCl_2$. $NaBH_3C^{15}N$ was synthesized from $NaC^{15}N$ (purchased from Stohler Isotope Chemicals) and a borane–tetrahydrofuran solution (Aldrich) in a manner similar to that reported (3) for the preparation of $NaBH_3CN$: $\nu_{C^{15}N}$2152 ($\nu_{C^{14}N}$2179 cm^{-1}). *Anal.* calcd. for $NaBH_3C^{15}N$: C 18.2, H 4.6, N 21.3; found: C 18.3, H 4.6, N 20.6.

All solvents were reagent grade and were purified by distillation and degassed with oxygen-free dry nitrogen before being stored over type 4A molecular sieves in a glove box.

Analyses and measurements

All air-sensitive samples were properly protected from atmospheric oxidation or hydrolysis during weighing or data collection. Microanalytical data for nitrogen, carbon, and hydrogen were acquired on a Perkin Elmer model 240 Analyser, using, where necessary, V_2O_5 as a combustion aid. Chloride analyses were determined by the Mohr titration method. The ir spectra of the samples were recorded on Beckman IR-12 and IR-4250 spectrophotometers (calibrated periodically with a polystyrene reference film) as Nujol mulls pressed between NaCl plates (600–4000 cm^{-1}) or between polyethylene plates (200–600 cm^{-1}). A Bruker WP-80 Fourier transform instrument equipped with an automatic temperature control device (B-VT 1000) was used to record ^1H and proton-decoupled ^{31}P nmr spectra at 80 MHz and 32.3 MHz, respectively. The chemical shifts were measured relative to internal tetramethylsilane (TMS) and external H_3PO_4 for ^1H and ^{31}P respectively and are positive if downfield from the reference signal.

X-ray powder diffraction measurements, electronic reflectance spectra, mass spectra, magnetic moments, and electrical conductivities were recorded as previously described (1).

Molecular weights were determined in $CHCl_3$ solution at 45°C using a Knauer Vapour Pressure Osmometer calibrated with Benzil in benzene at 45°C and the accuracy was checked periodically by measurement of the molecular weight of pentaerythrityl tetrastearate.

Syntheses

Unless otherwise specified, all synthetic work was carried out under a flow of pure nitrogen in a glove box. In general, an ethanolic solution of $NaBH_3CN$ was added to a mixture of Ni(II) chloride or perchlorate (dissolved in ethanol) and the phosphine (dissolved in toluene or benzene). Yields were generally in the 25–35% range. As the formation of some products depends rather critically on reaction conditions, complete details will be given for each synthesis. Some ir data are recorded in this section, and some later in the "Results and discussion" section.

(Cyanotrihydroborato)bis[bis(diphenylphosphino)methane]-nickel(II) perchlorate, $[Ni(BH_3CN)(Dppm)_2]ClO_4$

An ethanolic solution (20 mL) of $NaBH_3CN$ (0.10 g, 1.59 mmol) was added dropwise over a period of 2 min to a stirred mixture of $Ni(ClO_4)_2 \cdot 6H_2O$ (0.3 g, 0.82 mmol) and Dppm (0.63 g, 1.63 mmol) in benzene/ethanol (1:1, 20 mL). One drop of $NaBH_3CN$ solution turned the reaction mixture instantly from yellow to brown and upon complete addition of the $NaBH_3CN$, the solution was filtered, yielding a brown solid. This was washed with benzene (~10 mL), ethanol (~10 mL), and n-hexane (~5 mL) before drying under reduced pressure. It is soluble in CH_2Cl_2, THF, DMF, and acetone but it decomposes in all solvents within 30 min. The complex was therefore purified by precipitation from CH_2Cl_2 by very rapid addition of n-hexane and dried under reduced pressure for 12 h. This complex is air stable in the solid state. The analogous reaction has also been carried out with $NaBD_3CN$. *Anal.* calcd. for $[Ni(BH_3CN)(Dppm)_2]ClO_4$: C 63.3, H 4.9, N 1.4; found: C 62.9, H 5.2, N 1.4; ^{31}P nmr (CH_2Cl_2) δ −62.75.

(Cyanotrihydroborato)(cyano)bis[bis(diphenylphosphino)-methane]dinickel(I), $Ni_2(BH_3CN)(CN)(Dppm)_2 \cdot 0.5EtOH$

$Ni(ClO_4)_2 \cdot 6H_2O$ (0.3 g, 0.82 mmol) and Dppm (0.63 g, 1.63 mmol) were mixed in ethanol (40 mL) and this immediately precipitated a yellow solid. An ethanolic solution (20 mL) of $NaBH_3CN$ (0.4

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

g, 6.30 mmol) was added dropwise to the stirred yellow suspension over a period of 10 min during which the mixture changed first to brown, then to light green, and finally to deep green. The mixture was stirred for a further 3 h and the greenish brown solid which precipitated was filtered off, washed with ethanol (~10 mL) and *n*-hexane (~10 mL), and dried under reduced pressure for several hours. The complex dissolves to give green solutions in EtOH, CH_3OH, CH_2Cl_2, THF, benzene, and CH_3CN, but it decomposes to give light brown solutions within a few minutes. This colour changes to violet after a few hours. Purification by recrystallization was therefore not possible but was effected by washing the crude product with small amounts of cold ethanol followed by benzene. Similar reactions using $NaBD_3CN$ and $NaBH_3C^{15}N$ produced the appropriately labelled complex. The complex is air stable and the synthesis is reproducible. *Anal.* calcd. for $Ni_2(BH_3CN)(CN)(Dppm)_2 \cdot 0.5EtOH$: C 65.3, H 5.1, N 2.9; found: C 65.4, H 5.2, N 2.8; ^1H nmr ($CDCl_3$) EtOH at δ 1.25(t), 3.75(q); integration EtOH:Dppm = 1:4; ^{31}P nmr (EtOH) δ +29.30, +28.42. The ethanol could not be removed even by pumping at 10^{-6} Torr for several hours.

The same complex was also synthesized from $NiCl_2 \cdot 6H_2O$ as follows. A solution of $NaBH_3CN$ (0.079 g, 1.25 mmol) in ethanol (20 mL) was added over a period of 2 min to a stirred mixture containing $NiCl_2 \cdot 6H_2O$ (0.15 g, 0.63 mmol) and Dppm (0.52 g, 1.35 mmol) in ethanol (40 mL). The pink solution immediately turned green upon addition of the $NaBH_3CN$ and the mixture was allowed to stir for 3 h. The resulting solid was separated and purified as discussed above.

Bis(cyano)tris[bis(diphenylphosphino)methane]dinickel(I), $Ni_2(CN)_2(Dppm)_3 \cdot 4EtOH$

This deep green crystalline solid was obtained in low yield from the filtrates of the two reactions described above after they were allowed to stand at room temperature for 48 h. The crystals were filtered off, washed with ethanol (~10 mL), and dried under reduced pressure for 24 h. The product is soluble in EtOH, CH_2Cl_2, benzene, THF, MeOH, and DMF to give, initially, a deep green solution, which, after 24 h, turned to a deep violet, although the EtOH and MeOH solutions seemed the most stable. This compound is air stable in the solid state. Labelled complexes were also prepared using $NaBD_3CN$ and $NaBH_3C^{15}N$. *Anal.* calcd. for $Ni_2(CN)_2(Dppm)_3 \cdot 4EtOH$: C 67.8, H 6.0, N 1.9; found: C 67.5, H 5.1, N 1.9. ^1H nmr ($CDCl_3$) EtOH at δ 1.25(t), 3.75(q); integration EtOH:Dppm = 4:3. This ethanol was retained after drying under reduced pressure (10^{-6} Torr) for 24 h. ^{31}P nmr (EtOH) δ +15.98(s).

In addition, when the time that the above reaction mixtures were allowed to stir at room temperature was increased from 3 to 17 h, $Ni_2(CN)_2(Dppm)_3 \cdot 4EtOH$ was separated directly from the reaction mixture as the major product.

Bis(cyano)bis[bis(diphenylphosphino)methane]dinickel(I), $Ni_2(CN)_2(Dppm)_2 \cdot EtOH$ and $Ni_2(CN)_2(Dppm)_2 \cdot C_6H_6$

(a) From $Ni(ClO_4)_2 \cdot 6H_2O$. To a stirred suspension containing $Ni(ClO_4)_2 \cdot 6H_2O$ (0.3 g, 0.8 mmol) and Dppm (0.63 g, 1.63 mmol) in ethanol (20 mL), a solution of $NaBH_3CN$ (0.05 g, 0.79 mmol) in ethanol (10 mL) was added dropwise over a period of 2 min. The mixture was stirred at room temperature for a further 22 h during which time a pinkish yellow solid precipitated. This was filtered off and the deep violet filtrate concentrated under reduced pressure to yield violet crystals. It was necessary to recrystallize several times from ethanol, methanol, or benzene to obtain a pure product, as the ethanol or benzene solvate. The same product was prepared using $NaBD_3CN$ and the ^{15}N-labelled complexes were prepared in a similar manner using $NaBH_3C^{15}N$.

The complex has some air stability and is soluble in all common solvents, with slow decomposition over about 48 h. Thereafter the solutions turn brown. *Anal.* calcd. for $Ni_2(CN)_2(Dppm)_2 \cdot EtOH$: C 65.9, H 5.1, N 2.8; found: C 65.9, H 4.9, N 2.7. ^1H nmr ($CDCl_3$) EtOH at δ 1.25(t), 3.75(q); integration EtOH:Dppm = 1:2; ^{31}P nmr (EtOH) δ 1.4(s). *Anal.* calcd. for $Ni_2(CN)_2(Dppm)_2 \cdot C_6H_6$: C 68.5, H 4.9, N 2.8; found: C 68.5, H 5.0, N 2.7. The presence of benzene was confirmed by mass spectrometry. The solvent molecules were retained after pumping (10^{-6} Torr) for 24 h.

(b) From $NiCl_2 \cdot 6H_2O$. An ethanolic solution (20 mL) of $NaBH_3CN$ (0.316 g, 5.02 mmol) was added over a period of 5 min to a stirred mixture of $NiCl_2 \cdot 6H_2O$ (0.15 g, 0.63 mmol) and Dppm (0.519 g, 1.35 mmol) in ethanol (40 mL) and the mixture stirred for 1 h at 77°C. The solution was then stirred at room temperature for a further 4 h, during which time a small amount of purple solid was formed. This was filtered off, washed with a little ethanol and *n*-hexane, and purified as above.

Hydridobis[bis(1,2-diphenylphosphino)ethane]nickel(II) perchlorate or cyanotrihydroborate, $[NiH(Diphos)_2]X$, $X = ClO_4^-$, BH_3CN^-

(a) $X = ClO_4^-$. $NaBH_3CN$ (0.26 g, 4.07 mmol) in ethanol (20 mL) was added dropwise over a period of 15 min to a stirred mixture of $Ni(ClO_4)_2 \cdot 6H_2O$ (0.75 g, 2.05 mmol) in toluene/ethanol (10 mL, 1:1) and Diphos (2.45 g, 6.15 mmol) in toluene (20 mL). The mixture was stirred for 21 h at room temperature and the orange–red precipitate was filtered off, washed with toluene (~5 mL), ethanol (~5 mL), and *n*-hexane (~5 mL), and then dried under reduced pressure for several hours. More product was obtained from the red filtrate after several days at room temperature. The complex is air stable and soluble in CH_2Cl_2, $CHCl_3$, THF, DMF, and acetone to give solutions which are stable for up to 12 h. The complex was identified as the known (1) species, $[NiH(Diphos)_2]ClO_4$; ^1H nmr ($CDCl_3$) δ −13.1(quintet), J_{PH} = 5.6 Hz; ^{31}P nmr ($CHCl_3$), δ 44.95; ir, ν_{Ni-H}, 1950 cm^{-1}.

(b) $X = BH_3CN^-$. From the wine-red filtrate of the reaction mixture described in (*a*) below, a wine-red crystalline solid was separated by filtration after 24 h at room temperature, washed with ethanol (~5 mL) and *n*-hexane, and then dried under reduced pressure for several hours. The product was precipitated from CH_2Cl_2 with addition of *n*-hexane (1:1). Solutions in CH_2Cl_2, THF, $CHCl_3$, DMF, and acetone are stable for 24 h. The solid is air stable. $[NiD(Diphos)_2]BD_3CN$ was synthesized using $NaBD_3CN$. *Anal.* calcd. for $[NiH(Diphos)_2](BH_3CN)$: C 71.1, H 5.8, N 1.6; found: C 71.1, H 5.8, N 1.6; ^1H nmr ($CDCl_3$) δ −13.1(quintet), J_{PH} 5.6 Hz; ^{31}P nmr ($CHCl_3$) δ 44.95(s); ir ν_{CN} 2179, ν_{BH} 2330(s), 2290(w, sh), ν_{NiH} 1950 cm^{-1}.

Tris(cyanotrihydroborato)bis[bis(1,2-diphenylphosphino)-ethane]dinickel(II)chloride or perchlorate, $[Ni_2(BH_3CN)_3(Diphos)_2]X$ where $X = Cl^-$ or ClO_4^-

(a) $X = ClO_4^-$. To a stirred yellow mixture of $Ni(ClO_4)_2 \cdot 6H_2O$ (0.98 g, 2.68 mmol) in ethanol (20 mL) and Diphos (1.96 g, 4.92 mmol) in ethanol (20 mL) was added $NaBH_3CN$ (1.5 g, 23.8 mmol) in ethanol (20 mL) over a period of 2 min. The mixture was stirred for a further 30 min and the yellow solid, which deposited, was filtered off and washed with ethanol (~10 mL) and *n*-hexane (~10 mL). Work-up of the wine-red filtrate is described in (*b*) above. The crude product was reprecipitated from CH_2Cl_2 with rapid addition of *n*-hexane followed by drying under reduced pressure. The complex produces yellow solutions in CH_2Cl_2, $CHCl_3$, and THF but decomposes and turns brown in all solvents fairly rapidly. Immediate decomposition occurs in DMF. A synthesis of the deuterated complex using $NaBD_3CN$ was also carried out. *Anal.* calcd. for $[Ni_2(BH_3CN)_3(Diphos)_2]ClO_4$: C 61.4, H 5.3, N 3.9; found: C 61.8, H 5.3, N 4.1. ^{31}P nmr (CH_2Cl_2) δ 63.30.

(b) $X = Cl^-$. $NiCl_2 \cdot 6H_2O$ (0.5 g, 2.10 mmol) and Diphos (1.67 g, 4.20 mmol) were mixed in ethanol (20 mL) and to the stirred pink solution an ethanolic solution (10 mL) of $NaBH_3CN$ (0.224 g, 3.57 mmol) was added dropwise over a period of 4 min. The mixture was stirred for 3 h at room temperature and the yellow precipitate separated and purified as described for the ClO_4^- salt. The deuterated complex was prepared from $NaBD_3CN$. *Anal.* calcd. for $[Ni_2(BH_3CN)_3(Diphos)_2]Cl$: C 61.7, H 5.3, N 3.9, Cl 3.3; found: C 61.7, H 5.3, N 4.0, Cl 3.3. ^{31}P nmr (CH_2Cl_2) δ 63.30(s).

Alternatively, the chloride product can be obtained from the following reaction in which much larger amounts of $NaBH_3CN$ are used.

$NaBH_3CN$ (0.93 g, 14.71 mmol) in ethanol (10 mL) was added dropwise over a period of 5 min to a stirred mixture of $NiCl_2 \cdot 6H_2O$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

(0.5 g, 2.10 mmol) and Diphos (1.64 g, 4.20 mmol) in ethanol (20 mL). The mixture was stirred for 4.5 h and the yellow solid was separated and purified as above.

Dichlorobis(cyanotrihydroborato)tetrakis[bis(1,2-diphenylphosphino)ethane]dinickel(II), $Ni_2Cl_2(BH_3CN)_2(Diphos)_4$

To a stirred mixture of $NiCl_2 \cdot 6H_2O$ (0.5 g, 2.10 mmol) in ethanol (20 mL) and Diphos (1.67 g, 4.20 mmol) in ethanol (20 mL) was added $NaBH_3CN$ (0.925 g, 14.72 mmol) in ethanol (20 mL) over a period of 10 min. The mixture was stirred for 48 h, during which time the initial brown colour changed to orange (after 18 h), then to green (after 36 h), and finally to greenish yellow. A greenish yellow solid was filtered off, washed with ethanol (~10 mL) and *n*-hexane (~5 mL), and dried under reduced pressure for 24 h. The product is soluble in CH_2Cl_2, $CHCl_3$, THF, and DMF and the resulting solutions are stable for several hours. The crude product was purified by reprecipitation from CH_2Cl_2 with addition of *n*-hexane. The addition of *n*-hexane had to be such as to maintain a constant volume of solution and a constant time interval between the additions, otherwise decomposition occurred. The complex is air stable in the solid state. *Anal.* calcd. for $Ni_2Cl_2(BH_3CN)_2(Diphos)_4$: C 68.4, H 5.5, N 1.5, Cl 4.9; found: C 68.5, H 5.5, N 1.5, Cl 4.8. ^{31}P nmr (CH_2Cl_2) δ 29.34, 28.03; mol. wt. ($CHCl_3$) calcd. 1860; found 1845.

Dichlorobis(cyanotrihydroborato)bis[bis(1,2-diphenylphosphino)ethane]dinickel(II), $Ni_2Cl_2(BH_3CN)_2(Diphos)_2 \cdot EtOH$

An ethanolic solution (20 mL) of $NaBH_3CN$ (0.93 g, 14.72 mmol) was added dropwise over a period of 5 min to a stirred mixture of $NiCl_2 \cdot 6H_2O$ (0.5 g, 2.10 mmol) and Diphos (1.67 g, 4.20 mmol) in ethanol (40 mL). The brown mixture was then heated at 55°C for a further 30 min and then filtered. This produced solid $Ni(Diphos)_2$ and a dark brown filtrate which, after 5 days at 0°C, produced brown crystals. These were filtered off, washed with ethanol (~10 mL) and *n*-hexane (~5 mL), and then dried under reduced pressure for several hours. The solid was recrystallized from CH_2Cl_2 with slow addition of *n*-hexane and is soluble in CH_2Cl_2, $CHCl_3$, and THF with some solution stability. The solid is stable in air. An identical synthesis using $NaBD_3CN$ has also been carried out. *Anal.* calcd. for $Ni_2Cl_2(BH_3CN)_2(Diphos)_2 \cdot EtOH$: C 60.5, H 5.4, N 2.5, Cl 6.7; found: C 60.7, H 5.5, N 2.4, Cl 6.6. ^1H nmr ($CDCl_3$) EtOH at δ 1.25(t), 3.75(q); integration EtOH:Diphos 1:2; ir, ν_{OH} from EtOH 3360(b) cm^{-1}; ^{31}P nmr (CH_2Cl_2) δ 43.86.

Bis[bis(1,2-diphenylphosphino)ethane]nickel(0), $Ni(Diphos)_2$

This known (4) complex has been isolated in varying amounts from almost all filtrates of the reactions described for Diphos, but the yield increases in the higher temperature reactions.

Results and discussion

As expected, it has proved possible to isolate and identify a range of products from Ni(II)–phosphine–$NaBH_3CN$ reactions provided careful attention is paid to the reactant ratios, the rate of addition of $NaBH_3CN$, and the time of the reaction. Of particular interest is the mode of co-ordination of the BH_3CN^- group in those products which contain this group and the frequency of the B—H stretching mode is of fundamental importance in determining this. Of the five known examples of metal—BH_3CN^- complexes where the mode of BH_3CN^- coordination has been determined by crystallographic methods, three, $(Me_5Dien)Cu(BH_3CN)_2$ (5), $CoH(BH_3CN)(PPh_3)_3$ (6), and $Cu_2(BH_3CN)_2(Diphos)_3$ (7), have metal—$NCBH_3$ arrangements with B—H stretching frequencies in the range 2330–2346 cm^{-1} (2320 cm^{-1} in $NaBH_3CN$). On the other hand, two complexes, $[trenNi(BH_3CN)]_2^{2+}$ (8) and $[Cu(BH_3CN)(PPh_3)_2]_2$ (9), are binuclear species containing two bridging metal—HBH_2CN—metal linkages with analogous B—H_t frequencies in the significantly different 2376–2380 cm^{-1} range. In addition, these dimeric compounds show M—H—B bridging modes underlying the ν_{CN} region at ~2200 cm^{-1}. These ir differences between monodentate and bridging BH_3CN^- have been discussed elsewhere (8) and will be utilized in structural assignments of some of the new complexes reported here.

Dppm complexes

The most significant aspect of the Ni(II)–Dppm–$NaBH_3CN$ reactions is that Ni(II) is rapidly reduced to Ni(I), accompanied by cleavage of the B—C bond to produce Ni—CN complexes. This can be prevented only, it seems, by stopping the reaction very shortly after the addition of the $NaBH_3CN$. Thus, the brown $[Ni(BH_3CN)(Dppm)_2]ClO_4$ is formed under conditions where the Ni:Dppm:$NaBH_3CN$ ratio of 1:2:2 was adjusted to keep a relatively small excess of BH_3CN^- and the time allowed for the reaction was only 2 min. In fact, the formation of this complex is particularly sensitive to these factors. The solid must be filtered off immediately and is stable only for short periods (30 min) in solvents. The presence of ionic perchlorate in the solid complex is confirmed by the strong broad peak at 1100 cm^{-1} in the ir spectrum. Involvement of the CN group in coordination is shown by the position of the CN stretching frequency at 2190 cm^{-1} (a shift of 11 cm^{-1} from 2179 cm^{-1} in the spectrum of $NaBH_3CN$), and in the B—H region, the strong BH_t absorption appears at 2320 cm^{-1} with a weak shoulder at 2265 cm^{-1}. In the deuterated complex the B—D frequency occurs, as expected from isotopic shift calculations, at 1755 cm^{-1}. All these data are strong evidence for the presence of Ni—$NCBH_3$ type of coordination in this complex. ^{31}P nmr spectra in methylene chloride, run immediately on freshly prepared samples, show a strong peak at δ −62.75. The P atoms are clearly equivalent in solution and the position of the signal is consistent with chelating Dppm ligands since the structurally related $PtCl_2(Dppm)_2$ (10) shows δ ^{31}P at −64.3. In addition, there is a weak signal at δ −34 in the ^{31}P spectrum which increases in intensity with time while the −62.75 signal decreases to disappear completely after several hours. This decomposition can be represented as:

$$[Ni(BH_3CN)(Dppm)_2]^+ \rightarrow [Ni(Dppm)_2]^{2+}$$

since the ^{31}P nmr spectrum of $Ni(Dppm)_2(ClO_4)_2$ (formed by reacting $Ni(ClO_4)_2$ with Dppm) shows a singlet at δ −34. All the available evidence, therefore, is consistent with a five-coordinated Ni(II) ion with chelating ligands and N-bound BH_3CN^-.

When either the reaction time, the amount of $NaBH_3CN$, or the temperature is increased, three interrelated Ni(I) complexes are produced. Very careful adjustments to reaction conditions are necessary in order to isolate pure species, which have been characterized as the greenish-brown $Ni_2(BH_3CN)(CN)(Dppm)_2 \cdot 0.5EtOH$, the deep green crystalline $Ni_2(CN)_2(Dppm)_3 \cdot 4EtOH$, and the violet crystalline $Ni_2(CN)_2(Dppm)_2 \cdot S$ (S = EtOH or benzene). The first two complexes are very difficult to isolate, as they are slowly converted into the violet compound in solution. Thus, while coordinated BH_3CN^- seems reasonably stable in the Ni(II)/Dppm system (as in $[Ni(BH_3CN)(Dppm)_2]ClO_4$ described above), cyanide abstraction from coordinating BH_3CN^- occurs very readily when Ni(II) is reduced to Ni(I). In order to assign unambiguously the important ir bands in these Ni(I) complexes, the deuterium and ^{15}N-labelled species were also synthesized. All complexes retained ethanol (even after extensive drying under reduced pressure), the amount of which was established

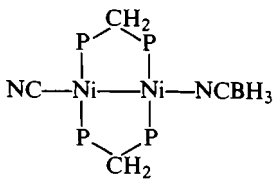
For personal use only.

from ^{1}H nmr spectra (experimental). Extensive decomposition of the complexes occurs in $CDCl_3$ and estimation was simply made on the basis of the ratio of aromatic : ethanol protons. The presence of the ethanol was also clear from broad OH bands at ~3400 cm^{-1} in the ir spectra of the complexes.

The ir spectrum of $Ni_2(BH_3CN)(CN)(Dppm)_2 \cdot 0.5EtOH$ shows three major peaks in the 2000–2400 cm^{-1} region at 2020, 2190, and 2320 (with a weak shoulder at 2265 cm^{-1}). The 2320 cm^{-1} peak shifts to 1755 cm^{-1} on deuteration and is therefore ν_{B-H}, in the position consistent with non-involvement of the hydrogens in coordination. The sharp peak at 2190 cm^{-1} is the ν_{CN} associated with the BH_3CN group and its position supports a Ni—$NCBH_3$ arrangement. This peak shifts to 2155 cm^{-1} in the ^{15}N-labelled species. The remaining sharp peak at 2020 cm^{-1} is consistent with a terminal Ni—CN group; it shifts to 1990 cm^{-1} when labelled with ^{15}N, as expected. The ir evidence is therefore consistent with the proposed formulation. It should be noted that although the C≡N stretching frequency is rather low for a metal cyanide (normally, *ca.* 2080–2100), it has been observed (11) that cyanides of metals in lower than normal oxidation states do show these vibrations at lower values.

The ir spectrum of $Ni_2(CN)_2(Dppm)_3 \cdot 4EtOH$ in the same region shows only a sharp peak at 2020 cm^{-1} and a weak peak at 2110 cm^{-1}. These shift to 1970 and 2070, respectively, when labelled with ^{15}N and confirm their assignment as terminal Ni—CN frequencies. Similarly, the ir spectrum of the violet crystals shows a single peak at 1975 cm^{-1} which shifts to 1940 cm^{-1} when labelled with ^{15}N. (Several recrystallizations are necessary to remove traces of a Ni—H impurity, ν_{Ni-H} 1987 cm^{-1}, which vanishes on deuteration.) Thus both complexes have Ni—CN groups present. Attempts were made to determine the molecular weight in chloroform solution of the relatively stable violet complex. However, while a molecular weight in good agreement with a dimeric formulation was obtained, ^{1}H nmr examination of a chloroform solution of the complex over a time period similar to that required for molecular weight measurements showed that sufficient decomposition occurs to render the molecular weight results unreliable.

The interrelationship among the three complexes is seen in ^{31}P nmr studies. $Ni_2(BH_3CN)(CN)(Dppm)_2 \cdot 0.5EtOH$, which in ethanol has two peaks at δ 29.30 and 28.42 of approximately equal area (29.56 and 28.48 in methanol), clearly has two sets of very similar but not identical P atoms. The position of the signals is more consistent with bridging rather than chelating Dppm (10) ligands and the structure of the complex is probably best represented as **1**. However, the apparent simplicity of the ^{31}P spectra requires some discussion.

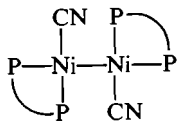


1

Structure **1** would be expected to show P—P coupling by analogy with similar unsymmetrical Pt(I) dimeric systems in the literature (12) and the simplicity of the ^{31}P spectrum could indicate the presence of two distinct compounds in roughly equal amounts. That this is almost certainly not the case is shown by the fact that if a sample pure enough to show only these two peaks in the ^{31}P spectrum is allowed to undergo solution decomposition in the strict absence of oxygen, only one phosphorus-containing product (the violet complex mentioned above and discussed further below) is obtained in significant quantity as shown by the ^{31}P nmr spectrum.

Considering now the coupling problem, the expected coupling pattern for **1** could be AA′BB′ by analogy with related Pt(I) complexes (12) but could be as simple as AB if coupling between non-equivalent P atoms occurs only through the carbon backbone and not the two metal centres. This suggests that the two peaks observed could be the inner two lines of an AB pattern for the situation where $^2J_{P-P}$ is fairly large and signal separation is small as in the case here. Computer-simulated spectra (Bruker ITRCAL program) show that for the signal-to-noise ratios (dictated by the solution instability of the complex) and line broadening observed in the real spectrum, the outer two lines of such an AB pattern would probably not be observable if $^2J_{P-P}$ were significantly greater than about 35 Hz. A search of the literature shows (12, 13) that in similar Pt(I) complexes, $^2J_{P-P}$ values of greater than 40 Hz are quite normal. Unfortunately, spectra with better signal-to-noise ratios could not be obtained because of the rapid decomposition of the complex in solution.

Within a very short time, the intensities of these two peaks observed in the ^{31}P spectrum of $Ni_2(BH_3CN)(CN)(Dppm)_3 \cdot 0.5EtOH$ decrease and a new sharp signal appears at δ 1.4. Eventually the two peaks disappear completely, and the solution turns violet in colour. The spectrum of the pure violet complex $Ni_2(CN)_2(Dppm)_2 \cdot EtOH$ shows this same signal at δ 1.4 and it appears that the interconversion takes place by loss of BH_3 from the former complex. However, the upfield shift of ~27 ppm suggests that a major structural change accompanies the interconversion, the δ 1.4 signal being more consistent with chelating Dppm (10). The most reasonable structure for the violet crystals, therefore, appears to be **2** containing two tetrahedral Ni(I) atoms thereby rendering the P atoms equivalent



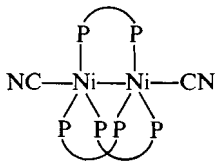
2

as indicated by the ^{31}P spectrum. In this context, it is interesting to note that there appears to be only one other chelate Dppm complex of a tetrahedral metal ion in the literature (14).

There are many examples of the alternative phosphine-bridged type of structure in the literature and this is particularly true for Pt(I) systems (15) for which δ ^{31}P are close to 0 (16). Since it appears that Ni(I) species of comparable structure would be expected (10) to show ^{31}P shifts at about 15 ppm to lower field, the phosphine-bridged alternative to **2** can probably be ruled out.

The ^{31}P spectrum of a freshly prepared deep green solution of $Ni_2(CN)_2(Dppm)_3 \cdot 4EtOH$ shows a single peak at δ = 15.98, but the intensity of this decreases rapidly with time and new signals appear at δ 1.4 (violet complex) and −21 (free phosphine). Again, the solution turns violet as the interconversion takes place and, as expected from the stoichiometries of the two complexes, free Dppm would be expected as one of the products of the interconversion. The position of the signal at δ 15.98 is, on the basis of the above argument, probably more

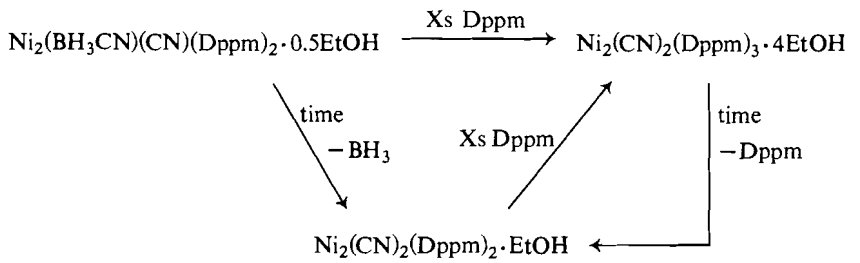
consistent with bridging Dppm ligands as in the five-coordinate species **3**.



3

This raises the question of why two CN vibrations are observed in the ir spectrum of **3**. They are 90 cm^{-1} apart and this separation, together with the fact that the lower frequency peak is much more intense, suggests that these absorptions represent symmetrical and asymmetrical vibrations. Unfortunately, neither of the compounds formulated as **2** and **3** forms sufficiently good crystals for X-ray work.

Further evidence for interconversions between these complexes was obtained from additional ^{31}P studies. Solutions of both $Ni_2(BH_3CN)(CN)(Dppm_2 \cdot 0.5EtOH$ and $Ni_2(CN)_2(Dppm)_2 \cdot EtOH$ in the presence of added Dppm show the appearance of weak signals at δ 16, suggesting the formation of a small amount of $Ni_2(CN)_2(Dppm)_3 \cdot 4EtOH$ although many other signals, including some which indicate the formation of complexes containing monodentate Dppm, also appear in the spectra upon addition of free Dppm. These interconversion reactions are summarized below.



One last comment regarding these Ni(I) complexes should be made. Thus, ^1H nmr spectra might be considered to be helpful in establishing the bridging or chelating nature of the Dppm ligand since criteria have been established for similar Pt complexes which allow this distinction (16, 17). However, this is based upon the coupling of ^{195}Pt with the PCH_2P protons of the ligand and would not apply to Ni complexes. A literature survey shows that chemical shifts of the CH_2 protons of bridging or chelating Dppm are quite similar and would therefore offer little information here. Nevertheless, attempts were made to record ^1H spectra on very freshly prepared samples in C_6D_6 and $CDCl_3$. Two of the complexes decomposed so rapidly that no data could be obtained. The violet complex showed more stability and spectra in C_6D_6 showed the PCH_2P protons as a broad unresolved signal centred on δ 4.3. No further information was obtainable from proton spectra.

Diphos complexes

In marked contrast to the Dppm products, products from similar Diphos reactions are exclusively Ni(II) or Ni(0) complexes. The latter, in the form of $Ni(Diphos)_2$, occurs in most reactions but only in significant yields when reaction mixtures are heated or when large amounts of $NaBH_3CN$ are used for longer times. No Ni–CN–Diphos species has been identified, although reproducible evidence for such a product was obtained from $NiCl_2$/Diphos/$NaBH_3CN$ (1:2:7 mole ratios) reactions over 17 h. This product is isolated in low yields as an extremely air-sensitive yellow solid, the major product of the reactions being $Ni(Diphos)_2$. The occurrence of coordinated BH_3CN^- in the products of these reactions is common and the formation of particular compounds appears to depend more on whether $NiCl_2$ or $Ni(ClO_4)_2$ is used as a starting material rather than on such factors as the amount of BH_3CN^-, its rate of addition, or the solvent. Without X-ray diffraction, the formulation of structures for some of these complex products was difficult.

The $[NiH(Diphos)_2]^+$ cation is well-known (1) and is formed here as the ClO_4^- (1) and BH_3CN^- (minor product) salts from reactions between $Ni(ClO_4)_2$/Diphos and $NaBH_3CN$ where small and large amounts of $NaBH_3CN$ respectively are used. ^{31}P and ^1H (upfield of TMS) nmr spectra for the two complexes are identical, and the ir spectrum of the BH_3CN^- salt is entirely consistent with ionic BH_3CN^-.

The yellow, diamagnetic, and isomorphous solids $[Ni_2(BH_3CN)_3(Diphos)_2]^+X^-$ (X = Cl^- or ClO_4^-) are formed from short time reactions involving Ni(II) chloride or perchlorate. In fact, the perchlorate salt is the major product in the reaction leading to the above BH_3CN^- salt. These products decompose rapidly in solution but can be reprecipitated rapidly from CH_2Cl_2 to achieve purification. In the ir spectra, a broad peak at 1100 cm^{-1} confirms the presence of ionic ClO_4^- in one of the complexes, and the absence of an absorption in the 200–400 cm^{-1} region of the spectrum of the chloride complex is consistent with ionic Cl^-. Both complexes have a single sharp peak at 2207 cm^{-1} due to $\nu_{C\equiv N}$, the shift of 28 cm^{-1} from $NaBH_3CN$ being indicative of Ni–$NCBH_3$ interaction. There is also a strong, broad absorption in the 2360–2370 cm^{-1} region (with weak shoulders) due to terminal ν_{B-H}, and this position is strongly indicative of Ni–HBH_2CN interaction as discussed earlier. Indeed, the stoichiometry of the complex alone strongly suggests three bridging BH_3CN^- groupings. The peak appears at 1770 cm^{-1} in the deuterated complexes as has been observed for similar bridged structures (8, 9). There is no peak which can be assigned to the Ni–H–B group analogous to the very broad band observed in the 2000–2200 cm^{-1} region seen in the confirmed bridging structures mentioned earlier although there is evidence of underlying weak peaks, which vanish on deuteration, in this region. Freshly prepared solutions of the chloride (4×10^{-3} *M*) in $CHCl_3$ conduct electricity at room temperature (11 ohm^{-1} cm^2 mol^{-1}) although with a conductivity less than expected for a 1:1 electrolyte. This value decreases rapidly with time as the solution changes colour from yellow to brown (see later).

^{31}P nmr spectra in CH_2Cl_2 of both compounds show, initially, a sharp signal at δ 63.3, indicating the presence of equivalent P atoms in Diphos units acting as chelating (10) ligands

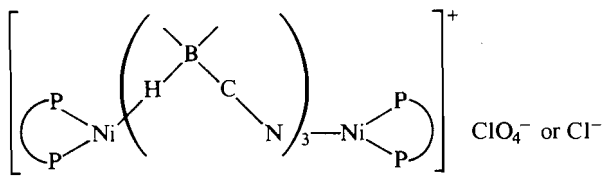
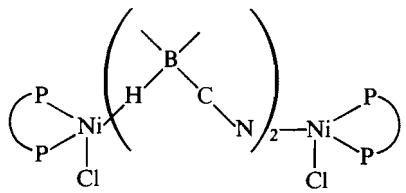
to Ni. Considering this, and the ir data, the molecule must have a high degree of symmetry, and the most reasonable structure would be as shown in **4** which contains three bridging BH_3CN^- groups. Normally, in such bridging structures, the bridges are arranged in a head-to-tail manner (8, 9). However, in this case,



4

at least two bridges would have to be head-to-head giving some asymmetry to the system. This might be expected to lead to two ^{31}P signals in the nmr spectrum. However, as discussed below, one BH_3CN^- bridge is fairly readily displaced in a spontaneous reaction and it may well be that some fluxionality of the bridging BH_3CN^- units is allowed in solution giving rise to equivalent P atoms.

There are two further Diphos complexes which arise from these reactions and for which, due to conflicting data, definite structural assignments have not been possible. Thus, the δ 63.3 signal in the ^{31}P spectrum disappears completely after 48 h as the yellow compounds gradually decompose to new brown species each with a sharp signal at δ 44. Small amounts of solid could be isolated only from the chloride solution. This same compound, analyzing reproducibly over several preparations as $Ni_2Cl_2(BH_3CN)_2(Diphos)_2 \cdot EtOH$ (^{31}P nmr δ 44), is better prepared (along with $Ni(Diphos)_2$) from reactions between $NiCl_2$, Diphos, and $NaBH_3CN$ after 30 min under reflux. Air-stable, brown, poorly formed crystals slowly precipitate from the filtrate over a 5-day period and these can be recrystallized from CH_2Cl_2. The solution stability allowed molecular weight measurements which indicate a dimeric structure. The chloride appears to be covalently bound since the complex is a non-electrolyte in CH_2Cl_2. This would also account for the fact that the solution decomposition of the precursor $[Ni_2(BH_3CN)_3(Diphos)_2]^+Cl^-$ is accompanied by a rapid decrease in conductivity. The ^{31}P shift and the ir spectrum (ν_{B-H} 2370, 2290sh, ν_{B-D} 1770, $\nu_{C\equiv N}$ 2207 cm^{-1}) suggest the presence of chelating Diphos (10) and bridging BH_3CN^- and the structure might therefore be **5**.



5

However, questions such as why the decomposition of **4** (ClO_4^-) leads to the same (δ 44) nmr signal and what the other products of decomposition (having no detectable ^{31}P signal) are remain unanswered but may be resolved if attempts to obtain crystals of **5** suitable for X-ray work are successful.

The second complex of uncertain structure is produced from reactions between $NiCl_2$, Diphos, and $NaBH_3CN$ (1:2:7) over long periods (48 h). After a series of colour changes, the air- and solution-stable, diamagnetic $Ni_2(BH_3CN)_2(Diphos)_4Cl_2$ is formed. The dimeric nature of this is again strongly suggested by molecular weight data and the compound is a non-electrolyte in CH_2Cl_2. These results are consistent only with non-ionic chlorines. (No similar compound was observed (^{31}P nmr) in reactions with $Ni(ClO_4)_2$.) The infrared spectrum is consistent with terminal $Ni-NCBH_3$ groups, with peaks at 2330 (ν_{B-H}) [1755 (ν_{B-D})] and 2200 cm^{-1} ($\nu_{C\equiv N}$). The ^{31}P nmr spectrum shows peaks at δ = 29.34 and 30.03, the two peaks being of approximately equal area but with the lower field peak broadened and rounded and the higher field peak sharp and intense. The chemical shifts are small for chelating Diphos (although much depends upon the coordination number of the metal and the number of coordinated ligands (10)) and the best that can be said at present is that the structure possibly contains bridging Diphos units and terminal BH_3CN groups.

It is clear that these reactions are closely related to similar reactions involving $NaBH_4$ (1) in that Dppm and Diphos behave in a fundamentally different way. The former results in the formation of mostly Ni(I) complexes and the latter forms Ni(II) and Ni(0). This is presumably related to the different bites of the two ligands and the propensity of Dppm to act primarily as a bridging ligand. Just how interaction of Dppm with Ni(II) (and Cu(I) (7)) leads to such ready production of cyanides is not yet clear. Certainly, with Diphos, much more forcing conditions are needed for only small amounts of cyanide complex production.

The only reasonable interpretation of data for several BH_3CN^- complexes involves this group acting as a bridging ligand which, it is hoped, will be confirmed by X-ray crystallography. It is, however, disturbing that no ν_{M-H-B} of comparable intensity to those seen previously (8, 9) has been observed.

Pyrolysis products of 1-(1-phenylcyclohexyl)piperidine (PCP)

RODNEY W. BEAVER AND LOUIS A. JONES[1]

Department of Chemistry, North Carolina State University, Raleigh, NC 27650, U.S.A.

Received September 9, 1983

RODNEY W. BEAVER and LOUIS A. JONES. Can. J. Chem. **62**, 1022 (1984).

PCP was pyrolyzed in air at 400°, 600°, and 800°C and the yield of HCN produced was barely detectable at 400°C, 2.3% at 600°C, and 5.1% at 800°C. Gas chromatography (gc) and gc/mass spectrometry (gc/ms) showed the only pyrolysis products produced at 400°C to be phenylcyclohexane and 1-phenylcyclohexene with 60–70% of the PCP recovered. Only trace amounts of PCP survived the 600°C pyrolysis, the majority of the pyroproducts being polynuclear aromatics (PNAs) with three or fewer rings. The 800°C pyrolysis yielded minor amounts of four-ring PNAs, the remainder being similar to the 600°C products but differing in the relative amounts. Minor amounts of aza-arenes were produced in the 600°C and 800°C pyrolyses and separation techniques are described.

RODNEY W. BEAVER et LOUIS A. JONES. Can. J. Chem. **62**, 1022 (1984).

On a effectué la pyrolyse de la PCP dans l'air à des températures de 400, 600 et 800°C; les rendements en HCN, qui sont à peine détectables à 400°C, sont respectivement de 2,3% et 5,1% à 600 et 800°C. A l'aide de la chromatographie en phase gazeuse (cpg) et de la cpg/spectrométrie de masse (cpg/sm), on a pu montrer que les seuls produits de pyrolyse à 400°C sont le phénylcyclohexane et le phényl-1 cyclohexène alors que l'on récupère 60–70% de la PCP. Il n'y a que des traces de PCP qui survivent à la pyrolyse à 600°C; la majorité des produits formés sont des composés aromatiques polycondensés (APC) comportant au maximum trois cycles. Les pyrolyses à 800°C conduisent à de faibles quantités de composés APC comportant quatre cycles; le reste des produits est qualitativement le même quoique l'on peut observer des différences au point de vue quantitatif. Au cours des pyrolyses à 600 et à 800°C, il se produit de faibles quantités d'aza-arènes; on décrit les techniques de séparation.

Introduction

The illicit drug 1-(1-phenylcyclohexyl)piperidine (PCP, **1**) is a popular drug of abuse, frequently ingested by smoking PCP-impregnated cigarettes (1, 2). Although the variable effects of PCP use have been well-documented (3), no detailed studies have been carried out on the pyrolysis of PCP and conceivably the high-temperature degradation or rearrangement products could contribute to the physiological activity of "smoked" PCP.

In a recent study of these products, Freeman and Martin (1) recovered an average of ca. 40% PCP in the mainstream smoke of parsley cigarettes containing 3–50 mg of tritiated PCP.HCl/cigarette. The only pyrolysis product identified was 1-phenylcyclohexene (**2**), present in the smoke condensate in nearly equimolar concentrations with PCP. Cook *et al.* (2) pyrolyzed 1-(1-phenyl-3-^{3}H cyclohexyl)piperidine.HCl in air at 300, 600, and 800°C by inserting a quartz boat containing ca. 30 mg of the test compound into a horizontal tube furnace and pyrolyzing until all the drug had disappeared from the boat (30 seconds to 5 minutes). Reportedly, >93% of the radioactivity was contained in 1-phenylcyclohexene (**2**) at all temperatures, while for the free base pyrolyzed at 300°C, 57.8% of the recovered radioactivity was found in undecomposed **1** and 34.3% as **2**. The presence of unlabelled piperidine was noted. No other pyrolysis products were reported. The smoke condensate from tritiated (phenyl-3-^{3}H) **1** and PCP.HCl laced parsley cigarettes was similarly studied and 57–59% of the radiolabel was found in the surviving PCP with the remaining 36–41% in **2**.

We chose to study the pyrolysis of pure **1** at temperatures approximating those of the burning zone of a cigarette to determine if the pyrolysis products could be responsible for the variable effects attributed to its use (3). It was felt that the smoke condensates obtained from parsley cigarettes (1, 2) could have been complicated by the large number of compounds originating from the pyrolysis of parsley itself, thus masking the occurrence of other compounds, while the quartz boat pyrolysis method (2) could have allowed unpyrolyzed **1** to distill from the heated pyrolysis zone before being fully subjected to the desired temperature. In our studies, pure **1** was pyrolyzed in an apparatus designed to assure maximum exposure of the test compound to the desired temperature and the pyrolyzate thus produced was separated and analyzed. We now wish to report the results of this study.

Results and discussion

The pyrolysis of approximately 9 g of rigorously purified PCP, synthesized as described by Kalir *et al.* (4), was carried out in a packed, vertically mounted tube and the pyrolyzate collected in a series of three traps: T1, a cold trap; T2, an aqueous acid trap; and T3, an aqueous base trap.

Triplicate samples of PCP were pyrolyzed at 400, 600, and 800°C with average mass yields (T1) of 92.5%, 75.5%, and 41.0% respectively, the 800°C temperature chosen to approximate the maximum burning zone temperature of a cigarette (5). The contents of T1 were analyzed for PCP and its degradation products, while T3 was examined to determine the amount of HCN produced in the pyrolysis (6). The intermediate trap T2 contained aqueous HCl to trap the minor amounts of volatile amines but was not characterized since it contained less than 5% of the pyrolyzate yield (*vide infra*).

After sample pyrolysis had been completed, the cold bath of T1 was removed and the trap gently warmed while the entire apparatus was still being swept with air to insure that any HCN condensed in T1 (bp HCN = 26°C) (7) would be swept into T3 containing a known amount of NaOH. The presence of cyanide in T3 was qualitatively determined via the Prussian blue test (8) and quantification was accomplished by the method of Barakat *et al.* (9). The mean yield for the 800°C pyrolyses was 4.6%, equivalent to 51 mg of HCN per 10 g of PCP, while at 600°C the mean yield of 2.1% corresponded to 23.3 mg of HCN per 10 g of PCP. No HCN was detected in the 400°C pyrolyzate.

TABLE 1. Preliminary fractionation scheme for silica gel clean-up of 600 and 800°C PCP pyrolyzate

Fraction number	Eluent	Compound class eluted	600°C yield	800°C yield
1	100% Hexane	Alkanes	0	0
2	1:1 Hexane–benzene	Alkanes and alkenes	0.1%	0
3	100% Hexane–benzene	Aromatic hydrocarbons with 3 or fewer rings	97%	95%
4	100% CH_2Cl_2	Aromatic hydrocarbons with more than 3 rings	1.0%	2.0%
5	2:1 CH_2Cl_2–methanol	Aromatic hydrocarbons (>3 rings) and oxygenated aromatics	0.1%	0.1%
6	1:2 CH_2Cl_2–methanol	Aza-arenes and bases	0.1%	0.1%
7	100% Methanol	Aza-arenes and bases	1.0%	1.5%

The pyrolytic generation of HCN from nitrogen-containing organic compounds has been studied by Johnson and Kang (10) who also found that the amount of HCN increased substantially with temperature. Piperidine was shown to yield 33% HCN at 700°C, 47% HCN at 800°C, and 62% HCN at 1000°C. Substantially lower yields of HCN were obtained in our study of the *N*-substituted piperidine of PCP, in accord with Johnson and Kang (10) who found that pyrrolidine gave a 95% yield of HCN at 1000°C, while at the same temperature *N*-methyl pyrrolidine produced only 35% HCN. They proposed that HCN was generated from pyrrolidine. With the *N*-methyl derivative, however, the preferred cleavage to the methyl radical and the pyrrolidine radical subsequently yielded methane and the Δ^1-pyrroline, the latter compound producing HCN in reduced yield (10). The analogous reaction of PCP could initially yield the relatively stable benzylic radical (**3**) and the piperidyl *N*-radical:

[1] 
1 **3** **4**

Structure **3** conveniently accounts for some other observed pyrolysis products of PCP (*vide infra*), while **4** gives rise to HCN.

Despite the well-known toxicity of HCN (11), it is unlikely that the level of production contributes significantly to the toxic effects of PCP. A typical PCP-laced cigarette containing 50 mg of PCP (1) would yield only about 0.3 mg of HCN if all of the PCP were subjected to 800°C and presuming the maximum yield of approximately 5% was realized. A standard tobacco cigarette yields as much as 3–5 mg of HCN from the burning of the tobacco alone (6).

The cooled trap (T1) contained a brown to back vile-smelling semi-solid after each pyrolysis and the amount of pyrolyzate produced decreased with increasing temperature, indicative of more complete degradation of the PCP and its pyrolysis products at higher temperatures. Badger *et al.* (12) reported similar results in the pyrolysis of n-butylbenzene and noted that, at 400°C, n-butylbenzene gave ca. 85% pyrolyzates, while at 800°C this yield decreased to less than 10%.

The 400°C pyrolyzate collected in T1 proved to consist of three major components. Gas chromatographic/ms analysis and co-injection of authentic samples on a capillary gc column showed these compounds to be PCP (**1**), range 58.0–73.4%; 1-phenylcyclohexene (**2**), range 21.4–34.4%; and phenylcyclohexane (**5**), range 1.3–9.2%. Piperidine was not detected under the gc conditions used and is presumed not to have survived the pyrolysis (*vide infra*).

The previously postulated phenylcyclohexyl radical (**3**) from eq. [1] can account for the formation of both **2** and **5** as shown in eq. [2]:

[2] 
2 **3** **5**

That more of **2** is generated is not unexpected, due to the enhanced stability acquired through the conjugated system produced. It should be noted that PCP has been shown to decompose to **2** at temperatures as low as 250°C with no evidence of **5** (13) and two additional elimination pathways appear reasonable to account for the amounts of **2** produced. First, similar to the mechanism proposed for the radical-induced β-elimination of phosphoranyl radicals (14), is the attack of the piperidinyl radical (eq. [1]) on **1** (eq. [3]), while the second possibility involves the internal *syn*-β-elimination of **1** to give **2** and piperidine, analogous to the pyrolytically induced Ei *cis*-elimination of esters, alkyl halides, and amine salts (15). In either case, the generated piperidine would proceed to generate HCN (10) and the precursor for butadiene.

[3] 
1 **2**

The 600 and 800°C pyrolyzates were substantially more complex than those obtained at 400°C and, before gc/ms or capillary column gc analysis could be undertaken, necessitated a preliminary silica gel fractionation with increasingly polar solvents to give the compound class separation (16) and approximate yields shown in Table 1. These individual fractions

Acenaphthene	1.000	<1.0 (11)	Not present	—
Phenanthrene	Not present	(12)	1.000	3.2 (9)
Anthracene	Not present	—	0.999	0.8 (10)

[a] Retention Index experimental/Retention Index standard, average of three or more determinations.
[b] Numbers in parenthesis refer to numbered gc peaks in Fig. 1 (SP-2100 capillary column), Fig. 2(SE-52 capillary column) respectively.
[c] Mass spectral library match >98% but no standards available.

were examined by gc/ms and preliminary compound identity was based on matching the mass spectra obtained for selected peaks with those obtained by a computer assisted mass spectral library search. Positive peak identification required the combination of mass spectral library match (>97%) with high-resolution chromatographic retention data (17*a*) (i.e. capillary gc) and relied on the retention index system designed specifically by Novotny and co-workers for programmed temperature capillary gc conditions (18) for relative retention time identification.

Capillary column gc of the individual fractions (Table 1) of the 600°C pyrolysis showed that only Fraction 3 (polynuclear aromatics) and Fraction 7 (aza-arenes and bases) contained detectable gc peaks. The chromatograms of Fraction 3 obtained from each of the triplicate 600°C pyrolyses gave the same peak pattern (Fig. 1) with essentially the same relative peak in-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

tensities and demonstrated the excellent reproducibility of the silica gel fractionation/gc separation procedure. Predictably, gc/ms analysis of these samples indicated that all of the peaks from Fraction 3 were due to aromatic hydrocarbons (16) (identified in Table 2). One internal standard, naphthalene, was present in the pyrolyzate while the second, phenanthrene, was not present and was added to the samples as a retention index standard.

Fraction 7, the aza-arene/base fraction from the silica gel clean-up of the 600°C pyrolyzate, gave an extremely complex chromatogram constituting only a minor portion (<1%) of the total pyrolyzate (based on FID responses for equal injection volumes). Due to the complexity of the sample, accurate retention index measurements and "clean" mass spectra proved difficult to obtain but methylpyridines, methylquinolines, and methylisoquinolines were tentatively identified. A very small amount of PCP (confirmed by co-injection of authentic PCP) also proved to be present.

After subjecting the 800°C PCP pyrolyzate to the silica gel clean-up (Table 1), each fraction was examined by gc and Fig. 2 illustrates the easily reproducible capillary gas chromatogram obtained for Fraction 3 of an 800°C pyrolyzate. Table 2 lists the identities of the numbered peaks in Fig. 2 which were confirmed by gc and gc/ms. These results suggest that anthracene and phenanthrene are produced at the expense of phenylcyclohexene (**2**) and phenylcyclohexane (**5**), since these aromatics become present while **2** and **5** disappeared.

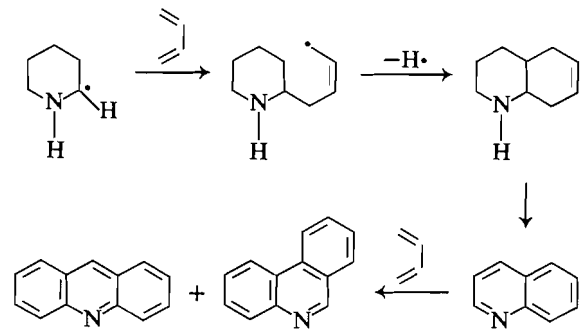
Fractions 4 and 5 were found to contain very low levels of polynuclear aromatics with 4 or more rings. These included pyrene, fluoranthene, and chrysene while Fraction 6 contained 1-napthylacetonitrile, phenanthridine, acridine, 1-cyanonaphthalene, and 2-cyanonaphthalene.

The chromatogram of the aza-arene/base fraction, Fraction 7, from the 800°C pyrolyzates was even more complex than the corresponding fraction from the 600°C pyrolyzates and necessitated further simplification of the mixture. Novotny and coworkers (19) reported the synthesis and use of an alkyl-amino bonded silica in the hplc (high performance liquid chromatography) fractionation of the basic fraction of marijuana smoke condensate. Fraction 7 was further separated on a hplc column packed with this prepared (19) alkyl-amino bonded phase and repetitive injections provided sufficient sample for gc and gc/ms analyses. Identified were benzo[*h*]quinoline, 2-phenylquinoline, and a methylphenylquinoline.

As previously noted, Fraction 3 obtained from the silica gel clean-up (Table 2) of the 600°C and 800°C pyrolyses contained aromatic hydrocarbons with fewer than three fused rings and gc detector response indicated that more than 95% of the pyroproducts were contained in this fraction. Minor nitrogen-containing aromatic compounds found in Fraction 7 included the tentatively identified methylpyridines, methyl quinolines, and isoquinolines, and, more confidently (gc/ms) identified, phenanthridine with some cyanonaphthalenes and 1-naphthylacetonitrile. It would appear, therefore, that the major pyrolytic pathway involves the formation of stable polyaromatic compounds, the heterocyclic compounds originating from a less favored pathway. The work of Badger and Kimber in their definitive mechanistic studies on the pyrolysis of arylalkenes, accounts for the pyrogenesis of the arenes identified and requires butadiene as their precursor (20). The pyrolysis of butadiene itself has been reported to yield ethylbenzene and styrene as well as naphthalene and tetralin (21). In the results reported herein, the origin of butadiene is proposed to derive from the piperidyl moiety (as in eq. [3]) as well as from the cyclohexyl group. The increase in naphthalene and absence of 1-phenylcyclohexene (**2**) in the 800°C pyrolysis (Table 2) would appear to support the increased generation of butadiene with increased temperature.

The enhanced generation of the nitrogen-containing aromatics with increasing pyrolysis temperature can be accounted for by the reaction of piperidine and butadiene (eq. [4]) analogous to that reported for piperidine with terminal olefines (22). Subsequent ring closure, aromatization, and further butadiene/quinoline coupling produces acridine and phenanthridine similar to the polynuclear aromatic pyrogenesis described by Badger and Kimber (20). The relatively low concentration of these heteroaromatic compounds can be accounted for by noting that the HCN generation increased with increasing temperature, thus decreasing the piperidyl moiety concentration.

[4]



In conclusion, the major pyrolysis products of PCP obtained at 400, 600, and 800°C have been identified. Except for the PCP found in the 400 and 600°C pyrolyzates, no compounds analogous to PCP were detected which would be expected to result in hallucinogenic or other PCP-like activity, although many of the pyrolysis products identified are known to be toxic and/or carcinogenic (17*b*).

Experimental

Pyrolysis apparatus and procedure

A 55 cm × 28-cm id Vycor tube (Fisher) was fitted with a very coarse quartz frit (Type T08, Porosity 00; Heraeus–Amersil, Sayreville, NJ) 11 cm from the bottom, upon which was deposited an 8-cm deep bed of quartz chips, consisting of 6 mm × 6 mm Type T08 quartz rods (Heraeus–Amersil). The top of the Vycor tube was fitted with a quartz female 14/20 joint to which was fitted a male 14/20 quartz joint equipped with a side-arm gas inlet and septum adapter. The Vycor pyrolysis tube was vertically mounted in a Hoskins Tube Furnace (FD303A) such that the quartz frit was located 11 cm from the bottom end of the furnace. The temperature was controlled by a variable transformer and monitored by an indicating pyrometer with a Chromel/Alumel thermocouple (Fisher 13-902) molded into a 28/15 standard joint which fitted a mating joint located on the pyrolysis tube 12 cm below the oven. When inserted into the tube, the end of the thermocouple was 0.5 mm below the quartz frit. Prior to each pyrolysis the oven was brought to temperature with the thermocouple in place and allowed to equilibrate for 2–3 hours, after which the thermocouple was removed and the joint sealed. The oven temperature was determined to be homogeneous throughout. Traps were constructed of 40-mm Pyrex O-ring joints and were sealed with Buna-N O-rings. The entire system was sealed when the injection septum was in place and the O-ring joints clamped. Trap 1 (T1) was located directly beneath the oven and was cooled in a Dry Ice/$CHCl_3$ bath; T1 was connected to Trap 2 (T2), which contained 10% HCl (aqueous), and which in turn was connected to Trap 3 (T3) containing 200.0 mL

of 0.5 *M* aqueous NaOH.

In all pyrolyses, the apparatus was swept with breathing grade air at a flow rate of 40 ± 2 mL/min during sample introduction. Triply vacuum-distilled PCP (bp of third distillate = 127°C at 0.8 Torr) was prepared according to the method of Kalir *et al.* (4) and approximately 9 g of the gently warmed, liquefied PCP was dripped onto the quartz beads (syringe, ca. 10 drops/min) such that the entire sample was introduced in 30 ± 3 minutes. Following the pyrolysis, the apparatus was allowed to cool and the cold bath removed from T1 which was subsequently gently warmed (ca. 40°C) with continued air flow to assure that any HCN condensed in T1 would be swept into T3. T1 and T3 were then examined as described below.

Determination of cyanide

A 10.00-mL aliquot of T3 (total volume T3 = 200.0 mL) was removed and buffered with 50.0 mL of aqueous 0.1 *M* NaH_2PO_4. Cyanide was determined according to the method of Baraket *et al.* (9) using freshly prepared 0.01*XXX M* aqueous n-bromosuccinimide (NBS) for the 800°C pyrolyses and 0.005*XXX M* NBS for the 600°C pyrolyses.

Gas chromatography

All gas chromatography (gc) was carried out on a Hewlett–Packard 5880A instrument equipped with a flame ionization detector and a Level IV microprocessor which allowed for the measurement of retention times to the thousandth of a minute. Gas chromatographic analyses utilized temperature programming from 40 to 250°C or 40 to 280°C at 4°C/min. Helium (zero grade) was used as a carrier gas at a flow rate of 0.8 mL/min. Injections were split 1 : 00 with an injection volume of 1 μL. Columns were 12-meter fused silica capillary columns (0.2-mm id) deactivated with Carbowax 20M and coated with either SP-2100 (methyl silicone) or SE-52 (5% phenyl methyl silicone). Retention indices were calculated by the method of Novotny and co-workers (18) as previously described. Standards were obtained from various commercial sources and were purified where necessary.

Gas chromatography/mass spectrometry

All gc/ms analyses were carried out on a Hewlett–Packard 5985B instrument equipped with a 25-meter SP-2100 fused silica capillary column programmed from 40 to 250°C at 4°C/min. The spectrometer used a Probability Based Search routine (23) to search the EPA–NIH mass spectral data base (24).

Pyrolyzate fractionation on silica gel

Silica gel (70–230 mesh) was slurried in hexane and slurry packed to a depth of 6 cm in a 1-cm diameter glass column equipped with a Teflon stopcock. All solvents were either commercial distilled-in-glass or were redistilled in this laboratory. Fractionation was carried out by carefully placing ca. 50 mg of pyrolyzate on top of the silica bed and pipetting 4 mL of successively more polar solvents into the column (see Table 1). Fractions of 4 mL were collected in chromic acid washed vials equipped with Teflon lined septum caps. After initial gc and gc/ms runs to determine their presence in the pyrolyzate, retention index standards (naphthalene, phenanthrene, chrysene) were spiked into the fractions and triplicate gc runs made for retention index calculations. Crude weights were obtained by evaporating one of the separation sequences to dryness and weighing (Table 1).

Preparation of and chromatography with alkyl-amine bonded silica

The reaction of 25 g of *N*-(2-aminoethyl-3-aminopropyl)trimethoxysilane, $(H_2N(CH_2)_2NH(CH_2)_3Si(OEt_3)$ (Alfa Products, Danvers, MA) with hydrated silica gel was carried out as described (19) and analysis of the product showed the alkyl-amino bonded silica to contain 5.1% C and 2.6% N by weight. A 60 cm long × 7.8-mm id hplc column was packed with the above described alkyl-amino silica (ca. 20 g required) using the "tap-fill" method (25). With 100% heptane at a flow rate of 9.9 mL/min and nitrobenzene as the solute ($k' = 1.5$), the column was found to exhibit 500 theoretical plates.

Fraction 7 from the silica gel clean-up of the 800°C pyrolyzate was reduced from 4 mL to dryness and made up to 1 mL with 3.5% CH_2Cl_2 in heptane. Five injections of 200 μL each of this solution were made onto the above hplc column with a mobile phase of 3.5% CH_2Cl_2 in heptane at a flow rate of 3.5 mL/min. Fractions were collected as follows: Fraction A, 22 mL; Fraction B, 5 mL; Fraction C, 15 mL; Fraction D, 10 mL; Fraction E, 20 mL. After combining Fraction A from each injection, the solvent was removed by rotary evaporation, the sample transferred to a 1-mL cone-tipped vial with 5 × 200 μL of CH_2Cl_2, and the $CHCl_2$ reduced to 50 μL under a gentle stream of N_2. Injections of 1 μL of this 50-μL solution were used for the gc analysis.

JOSEPH ARMAND, LINE BOULARES, CHRISTIAN BELLEC, CLAUDETTE BOIS, MICHÈLE PHILOCHE-LEVISALLES, and JEAN PINSON. Can. J. Chem. **62**, 1028 (1984).

The electrochemical reduction of fluoflavine **2** gives compound **9** to which we had previously assigned a hexahydroquinoxalino[2,3-*b*]quinoxaline structure. A crystallographic study of a diacetylated derivative of **9** shows that **9** is in fact 2-(*o*-aminoanilinomethyl)benzimidazole. This result permits us to propose a detailed reduction mechanism for **2** and its diacetyl derivative **25**.

JOSEPH ARMAND, LINE BOULARES, CHRISTIAN BELLEC, CLAUDETTE BOIS, MICHÈLE PHILOCHE-LEVISALLES et JEAN PINSON. Can. J. Chem. **62**, 1028 (1984).

La réduction électrochimique de la fluoflavine **2** conduit à un composé **9** auquel nous avions attribué la structure d'une hexahydroquinoxalino[2,3-*b*]quinoxaline. Une étude cristallographique d'un dérivé diacétylé de **9** montre que **9** est en réalité le 2-(*o*-aminoanilinomethyl)benzimidazole. Ce résultat nous permet de proposer des mécanismes de réduction détaillés pour **2** et son dérivé diacétylé **25**.

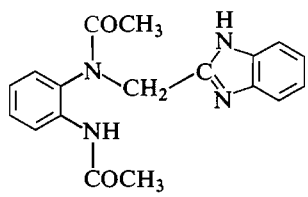
For personal use only.

In a preceding paper (1) dealing with the electrochemical reduction of quinoxalino[2,3-*b*]quinoxaline and its derivatives, we have shown that the 5,12-dihydro derivative **2** — known as fluoflavine — is reduced in acidic medium through a $4F$/mol process into **9** to which we had assigned the structure 5,5*a*,6,11,11*a*,12-hexahydroquinoxalino[2,3-*b*]quinoxaline. In order to establish the conformation of **9** we carried out a crystallographic study of **9′**, a diacetyl derivative of **9**. The structure of **9′** is shown in Fig. 1. It shows that **9** is in fact 2-(*o*-aminoanilinomethyl)benzimidazole, a compound as yet unknown. The nmr spectrum of **9**(1) is in agreement with this structure. Indeed, the aromatic protons of *o*-phenylene diamine appear as a singlet at 6.75 ppm and that of 2-methylbenzimidazole as an AA′BB′ pattern between 7.4 and 7.85 ppm. In the case of **9** the aromatic protons appear as two multiplets, one of them between 6.4 and 6.7 ppm and the other between 7 and 7.8 ppm (AA′BB′ pattern).



9′

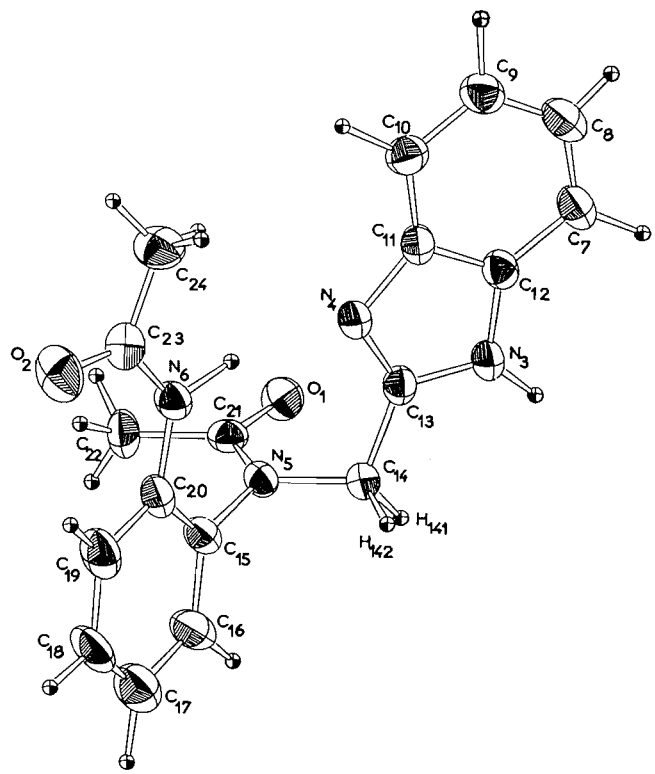


FIG. 1. ORTEP diagram of the crystal structure of **9′**.

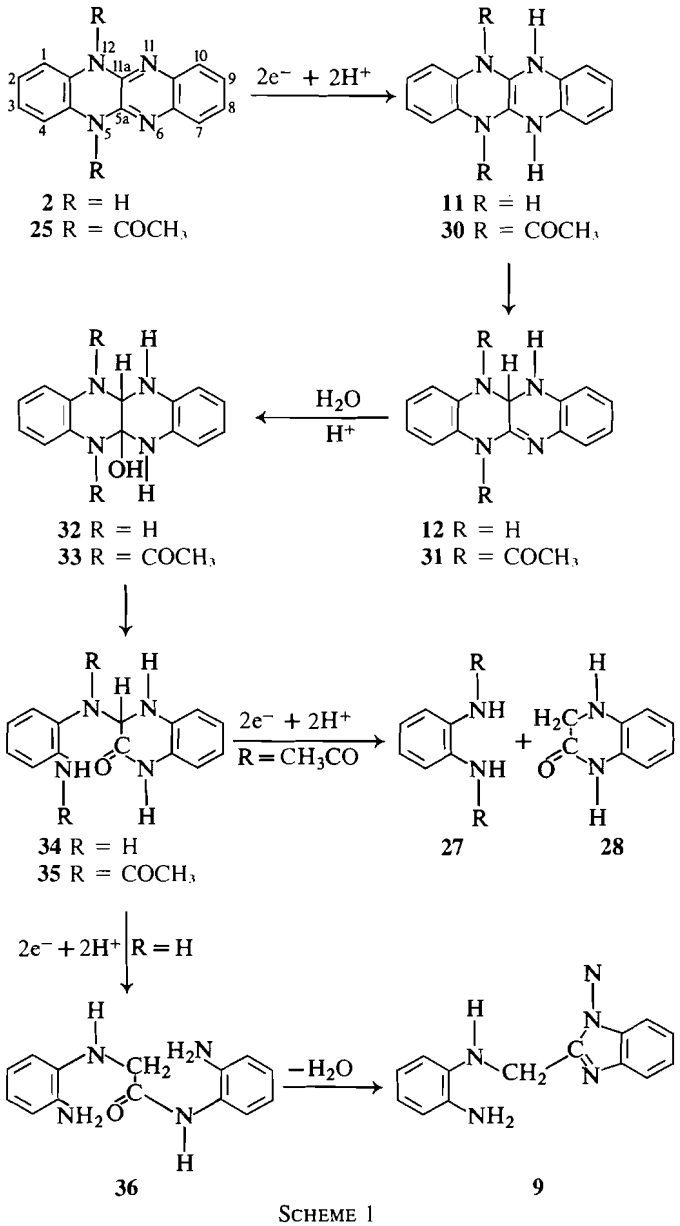
Reduction mechanism

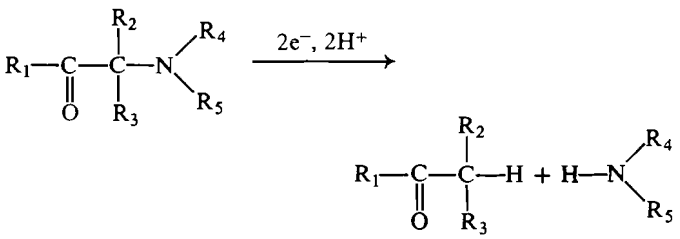
Reduction of 2 in acidic medium

Scheme 1 shows a possible reduction mechanism leading to **9**. The first step leads to the tetrahydro derivative **11**, which is in agreement with the results of cyclic voltammetry (1). The next step, the isomerisation of **11** into **12**, is frequently observed in 1,4-dihydroquinoxalines (2) or 1,4-dihydropyrazines (3, 4). The hydration of the C=N double bond leading to **32**



SCHEME 1

is an often encountered reaction during the electrochemical reduction (5*a*) and oxidation (5*b*) of pteridines and during the oxidation of uric acid (5*c*). The next step is an hydrolytic cleavage of the C_{5a}—N_5 bond, giving **34** which is further electrochemically reduced into **36**. This electrochemical reduction involving the cleavage of C_{11a}—N_{11} bond is analogous to that of α-aminoketones. It is indeed well established (6–8) that α-aminoketones are electrochemically reduced according to



The last step, the cyclization of **36** into **9**, is similar to the formation of 2-methyl benzimidazole from *N*-acetyl-*o*-phenylenediamine (9).

*B_{iso} for the non-H atoms is calculated by the expression: $B_{iso} = (4/3)\ \Sigma_i\Sigma_j\beta_{ij}(a_i a_j)$.

Reduction of 5,12-diacetyl-5,12-dihydroquinoxalino[2,3-b]-quinoxaline, 25

Scheme 1 also rationalizes the formation of **27** and **28** by electrochemical reduction of **25**. The first four steps are common to **2** and **25**; they lead to **34** in the case of **2** and to **35** in the case of **25**. As stated above, the electrochemical reduction of α-aminoketones in acidic medium leads to the cleavage of the C—N bond. In the case of **34** and **35** there are two C—N bonds on carbon C_{11a}. As **27** and **28** are obtained from **35** the reduction must involve the cleavage of the C_{11a}—N_{12} bond. This means that replacing R = H by R = $COCH_3$ on N_{12} favours the cleavage of C_{11a}—N_{12} bond at the expense of the C_{11a}—N_{11} bond.

As a whole, Scheme 1 presents quite an original mechanism in the quinoxaline series, leading to the unexpected compound **9**.

Experimental section

The crystals of **9′**, a diacetyl derivative of **9**, are obtained by slow evaporation of a methanolic solution of **10** the triacetyl derivative of **9** (1). In methanol, the triacetyl derivative **10** loses an acetyl group; the thorough evaporation of the methanolic solution leaves only the diacetyl derivative **9′** with the following ^{1}H nmr spectrum (DMSO-d_6): $\rangle$N—$COCH_3$, $NHCOCH_3$: two singlets at 1.66 and 2.30 ppm (2 × 3H); CH_2: two doublets centered at 4.52 and 5.36 ppm (2 × 1H); aromatic protons: multiplet, 7−8.2 ppm (8H); N_1H: singlet 12.6 ppm exchanged with D_2O (1H).

Crystallographic study of 9′

Crystal data are as follows:

$C_{18}H_{18}N_4O_2$ fw = 322

Monoclinic, a = 12.660(2), b = 8.466(2), c = 15.172(3) Å, β = 94.21(1)°, V = 1621.8 Å^3, Z = 4, ρ_c = 1.32 g cm^{-3}, ρ_0 = 1.32(2) g cm^{-3} (20°C), MoK$_\alpha$ λ = 0.7107 Å, μ = 0.93 cm^{-1}.

Preliminary X-ray photographs showed the following systematic absences: $h0l$, $l = 2n + 1$, $0k0$, $k = 2n + 1$; a statistical analysis of the intensity data indicated the centrosymmetric space group $P2_1/c$. A crystal (0.35 × 0.75 × 0.25 mm) was mounted with the b axis parallel to the ϕ axis of a Philips automated diffractometer equipped with a graphite monochromator. The intensities of all reflections having 2θ less than 50° were measured using the variable $\omega-2\theta$ scan technique. During the course of the data collection three standard reflections were measured every 54 reflections. A total of 1743 independent reflections was measured, 1353 of which had $I > 4\sigma(I)$. The data were reduced to $|F_o|$ by the routine procedure. Lorentz and polarization but no absorption or extinction corrections were applied.The scattering factors for neutral atoms were taken from ref. 10. The structure was determined by direct methods (MULTAN) (11) and refined by large block least squares $\Sigma\omega(F_o - |F_c|)^2$ = minimum with $\omega = 1/\sigma^2$. The refinement with anisotropic thermal parameters on the non-hydrogen atoms converged to R = 0.084. At this stage, a difference Fourier map revealing the positions of all the hydrogen atoms was calculated; refinement of their positional parameters was carried out using the thermal parameters of the corresponding heavy atoms at the end of isotropic refinement. The refinement converged with R = 0.057 and R_w = 0.056.

Positional parameters and isotropic thermal parameters are given in Table 1. Tables of bond lengths (Table 2), bond angles (Table 3), temperature factors (Table 4), and observed and calculated structure factor amplitudes were put in the Depository of Unpublished Data.[1]

Olefins, dienes, and trienes can be hydrogenated in an aqueous–organic two-phase medium using the dimer of chloro-(1,5-hexadiene)rhodium as the catalyst. Selective reduction of the double bond of α,β-unsaturated carbonyls occurs in high yields. These reactions occur at room temperatures and atmospheric pressure, and are simple to work-up.

KRZYSZTOF R. JANUSZKIEWICZ et HOWARD ALPER. Can. J. Chem. **62**, 1031 (1984).

Opérant dans un milieu aqueux–organique en deux phases, on peut hydrogéner des oléfines, des dièmes et des triènes en utilisant le dimère du chloro[hexadiène-1,5]rhodium comme catalyseur. On peut réaliser, avec d'excellents rendements, la réduction sélective des doubles liaisons des composés carbonylés non-conjugués en α,β.

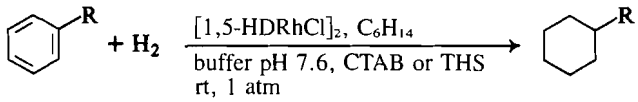
Recently, we described the hydrogenation of aromatic hydrocarbons and heterocyclic compounds using the dimer of chloro(1,5-hexadiene)rhodium ((1,5-HDRhCl)$_2$) as the metal catalyst, cetyltrimethylammonium bromide (CTAB) or tetrabutylammonium hydrogen sulfate (THS) as the phase transfer catalyst, with benzene, hexane, or methylene chloride used as the organic phase, and a buffer solution of pH 7.6 as the aqueous phase. This authentic phase transfer reaction occurs under remarkably mild conditions (room temperature, 1 atm) (1). We now wish to report the application of this process to the reduction of olefins, dienes, trienes, and α,β-unsaturated ketones and aldehydes.



When *p*-methoxystyrene was reacted for 7 h, as described above (hexane as the organic phase), *p*-ethylanisole was formed in quantitative yield. Reduction of the arene ring occurs, but only after an extended period of reaction (48 h). In contrast to arene hydrogenation, the reduction of the double bond of *p*-methoxystyrene, and of other olefins, dienes, and α,β-unsaturated carbonyls does *not* require a phase transfer agent. In other words, these are biphasic and not phase transfer reactions.

In Table 1 are listed results for the hydrogenation of olefins. There are several noteworthy features of these reactions. First, an olefin can be hydrogenated in the presence of bromide (6-bromo-1-hexene). Second, while the three double bonds of methyl linolenate are reduced in a facile manner, cycloheptatriene affords cycloheptene as the major product and no reaction occurs with 5-methyl-1,3,6-heptatriene possibly because the double bonds are strongly complexed to rhodium. Third, non-conjugated and conjugated dienes experience partial or complete reduction.

It was previously demonstrated that cyclohexene is hydrogenated more readily than 1,3- or 1,4-cyclohexadiene which in turn is more easily reduced than benzene (1). The stereochemistry of hydrogenation of cyclohexenes was examined using a series of isomeric dimethylcyclohexenes. Although these reductions were not stereospecific, they did show *cis* selectivity, the highest being realized for the tetrasubstituted olefin, 1,2-dimethylcyclohexene (7.3/1.0 *cis/trans*-1,2-dimethylcyclohexane). The clear preference for *cis*-dimethylcyclohexanes from 1,6- and 1,3-dimethylcyclohexenes is probably a consequence of the allylic methyl group of the rhodium complex of the olefin, in each case, existing in an axial or pseudo-axial conformation. For 1,4-dimethylcyclohexene there is no allylic methyl substituent and hence little discrimination. These stereochemical results are similar, but not identical, to those observed with rhodium in *t*-butanol(2). The reactivity and stereochemistry are clearly different from the hydrogenation of dimethylcyclohexenes effected with rhodium on carbon (3), or with Wilkinson's catalyst (4). These observations are in accord with experiments indicating that the biphasic process is heterogeneous as far as the metal species is concerned (i.e., a highly active form of colloidal rhodium) (5).

α,β-Unsaturated ketones can be selectively hydrogenated to saturated carbonyl compounds using similar reaction conditions to those described for olefins. Fine yields of products were obtained (Table 2) and the reactions can be followed very simply using thin layer chromatography (tlc), appropriate developing solvents,and a 5% solution of vanillin (in 96% H_2SO_4) for visualization (Table 3). Reactions were usually faster when hexane was used as the organic phase instead of benzene. These reactions are quite facile for substrates containing a disubstituted or trisubstituted double bond (2-cyclohexen-1-one, 3-penten-2-one, 3-methyl-2-cyclopenten-1-one), *provided* the carbonyl group is not attached to a fully substituted unsaturated carbon atom (e.g., 1-acetyl-1-cyclohexene) in which case a much slower reaction occurred. In addition, conjugation of a phenyl group with the α,β-unsaturated carbonyl unit (4-phenyl-3-buten-2-one) slows down the reaction appreciably when compared with an alkyl analog.

The principal product formed from the room temperature hydrogenation of cinnamaldehyde is hydrocinnamaldehyde. The latter can also be obtained using Wilkinson's catalyst, but drastic conditions are required (6). Elevated temperatures and/or pressures are usually necessary for the reduction of α,β-unsaturated aldehydes by rhodium on alumina (7, 8).

Finally, while the reduction of arene hardly occurs (4%) using water instead of the buffer as the aqueous phase, the hydrogenation of α,β-unsaturated ketones still takes place, but at a reduced rate. Specifically, the reduction of 2-cyclo-

TABLE 1. Hydrogenation of olefins, dienes, and trienes

Reactant	Organic phase[a]	Reaction time (h)	Products[b]	Yield (%)
p-Methoxystyrene	A	7	*p*-Ethylanisole	100
6-Bromo-1-hexene	A	4	1-Bromohexane	78
1,6-Dimethylcyclohexene	B	13	1,2-Dimethylcyclohexane (3.0:1.0 *cis*:*trans*)	70
1,2-Dimethylcyclohexene	B	6	1,2-Dimethylcyclohexane (7.3:1.0 *cis*:*trans*)	79
1,3-Dimethylcyclohexene	B	8	1,3-Dimethylcyclohexane (3.75:1.00 *cis*:*trans*)	80
1,4-Dimethylcyclohexene	B	9	1,4-Dimethylcyclohexane (3.0:2.0 *cis*:*trans*)	84
1,4-Octadiene	B	4	4-octene, *n*-octane (1:1)	100
	B	7	*n*-octane	67
1,4-Diphenyl-1,3-butadiene	C	20	1,4-Diphenylbutane	91
2,3-Dimethyl-1,3-butadiene	B	2	2,3-Dimethyl-2-butene	27
			2,3-Dimethyl-1-butene	22
			2,3-Dimethylbutane	25
Cycloheptatriene	B	31	Cycloheptene	46
			Cycloheptane	9
Methyl linolenate	A	9	Methyl stearate	100
5-Methyl-1,3,6-heptatriene	A or B	20	No reaction	—

[a] A = C_6H_{14}; B = neat; C = benzene.
[b] Products were identified by comparison of spectral (ir, nmr (^1H, ^{13}C), ms) and physical data with those for authentic materials.

TABLE 2. Hydrogenation of α,β-unsaturated carbonyl compounds

Reactant	Organic phase[a]	Reaction time (h)	Products[b]	Yield (%)
2-Cyclohexen-1-one	A or B	1.25	Cyclohexanone	91
1-Acetyl-1-cyclohexene	A	14	Acetylcyclohexane	80
	B	26	Acetylcyclohexane	86
3-Methyl-2-cyclopenten-1-one	A	1.5	3-Methylcyclopentanone	67
	B	5.5	3-Methylcyclopentanone	61
Santonin	B	24	1,2-Dihydrosantonin	100
$PhCH{=}CHCOCH_3$	A	39	$PhCH_2CH_2COCH_3$	90
$CH_3CH{=}CHCOCH_3$	A	3.0	$C_3H_7COCH_3$	71
$PhCH{=}CHCHO$	A	20	$PhCH_2CH_2CHO$	68
			$PhCH{=}CHCH_2OH$	14
			$Ph(CH_2)_2CH_2OH$	12

[a] A = C_6H_{14}; B = C_6H_6.
[b] Products were identified by comparison of spectral and physical data with those for authentic materials.

TABLE 3. Monitoring the hydrogenation of α,β-unsaturated carbonyls on tlc using 5% vanillin in sulfuric acid (96%)[a]

	Color[b]		R_f	
Reactant	Reactant	Product	Reactant	Product
2-Cyclohexen-1-one	Blue	Green	0.33	0.49
1-Acetyl-1-cyclohexene	Red	Blue	0.47	0.51
3-Methyl-2-cyclopenten-1-one	Brown	Green	0.33	0.62
$PhCH{=}CHCOCH_3$	Red	Blue	0.16	0.26
$PhCH{=}CHCHO$	Grey	Violet	0.46	0.57

[a] Developing solvent mixture was 3:1 C_6H_6/ether (except cinnamaldehyde where a 5:1 C_6H_6/ether ratio was used).
[b] Color refers to the color of the spot on the tlc plate.

hexen-1-one in benzene using buffer (75 min) is essentially twice as fast when compared with water. The one-phase reaction (i.e., using benzene only) is considerably slower than the buffer process, requiring more than 7 h to reach completion.

In conclusion, the biphasic rhodium(I) catalyzed hydrogenation of olefins, dienes, and α,β-unsaturated carbonyl compounds occurs under very gentle conditions, affording reduced products in good yields. Execution and work-up of these reac-

tions are remarkably simple. This method compares favorably with other biphasic and phase transfer hydrogenation reactions (9, 10).

Experimental

General procedures for the biphasic hydrogenation of unsaturated hydrocarbons and α,β-unsaturated carbonyl compounds

To the organic phase (15 mL) was added $(1,5\text{-HDRhCl})_2$ (0.028 g, 0.063 mmol) and then a buffer solution of pH 7.6. After 1 min, the substrate (6.25 mmol) was added, followed by an additional 5 mL of the organic phase. Hydrogen was bubbled through the stirred solution at room temperature and atmospheric pressure until reaction was complete (see Tables 1 and 2 for reaction times). The phases were separated, the aqueous phase was extracted with hexane or benzene (10 mL), and the combined organic phase was dried ($MgSO_4$), concentrated by rotary evaporation, and pure products were isolated by chromatography or distillation.

In the event that the reactant also functions as the organic phase, one adds 56 mg (0.126 mmol) of $(1,5\text{-HDRhCl})_2$ to 25 mmol of the substrate, followed by 3 mL of the buffer solution of pH 7.5.

The conformational properties of the gangliosides G_{M2} and G_{M1} based on ^1H and ^{13}C nuclear magnetic resonance studies

SUBRAMANIAM SABESAN,[1] KLAUS BOCK,[2] AND RAYMOND U. LEMIEUX
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received October 18, 1983

SUBRAMANIAM SABESAN, KLAUS BOCK, and RAYMOND U. LEMIEUX. Can. J. Chem. **62**, 1034 (1984).

A comparison of the ^1H and ^{13}C nmr parameters for the disaccharide derivatives βDGal(1→4)βDGlcO$(CH_2)_8COOCH_3$ (**1**), βDGalNAc(1→4)βDGalO$(CH_2)_8COOCH_3$ (**2**), and βDGal(1→3)βDGalNAcO$(CH_2)_2CH_3$ (**3**) allowed assignments of the signals observed for the *asialo*-G_{M2}- and *asialo*-G_{M1}-related synthetic haptens, βDGalNAc(1→4)βDGal(1→4)βDGlcO$(CH_2)_8COOCH_3$ (**4**) and βDGal(1→3)βDGalNAc(1→4)βDGal(1→4)βDGlcO$(CH_2)_8COOCH_3$ (**5**). ^1H nuclear Overhauser enhancement studies confirmed the conformational preferences for **2** and **3** predicted by HSEA calculation. Comparison of the ^1H and ^{13}C spectra indicate that these preferences and that previously known for the lactoside (**1**) are closely maintained in the haptens **4** and **5**. HSEA calculation indicates that the methyl group of methyl *N*-acetyl-α-D-neuraminic acid (**10**) prefers the orientation wherein the carboxyl group is near *anti*-periplanar to the methyl group. However, this orientation was not confirmed by saturation of the methyl group since no enhancement of either Ha-3 or He-3 was observed. On the other hand, saturation of Ha-3^e of the αDNeuAc unit of the G_{M1}-related pentasaccharide, βDGal(1→3)βDGalNAc(1→4)[αDNeuAc(2→3)]-βDGal(1→4)α,βDGlc, caused strong enhancement of the signal for the aglyconic hydrogen, H-3^b of the βDGal(1→4) unit. This observation, along with those of other nuclear Overhauser experiments, established that this pentasaccharide has the carboxyl group *anti*-periplanar to C-3^b. Furthermore, the C-7^e to C-9^e chain of the αDNeuAc unit adopts nearly the same conformation for the compound in aqueous solution as exists for *N*-acetylneuraminic acid in the crystalline state. The HSEA calculation indicates important attractive interaction between this chain and the βDGalNAc unit of the aglycon. These conlcusions were extended to the G_{M2} and G_{M1} gangliosides by the comparison of chemical shift data. In these compounds, the carboxyl group projects over the hydrophobic α-side of the βDGalNAc unit and the polar OH-4^e, NAc-5^e, OH-7^e groups project over the hydrophobic β-side of the lactose unit. Comments are made on the possible bearing of these topographical features on certain biological properties of gangliosides.

SUBRAMANIAM SABESAN, KLAUS BOCK et RAYMOND U. LEMIEUX. Can. J. Chem. **62**, 1034 (1984).

Une comparaison des paramètres de la rmn du ^1H et du ^{13}C des dérivés suivants de dissaccharides βDGal(1→4)βDGlcO$(CH_2)_8COOCH_3$ (**1**), βDGalNAc(1→4)βDGalO$(CH_2)_8COOCH_3$ (**2**) et βDGal(1→3)βDGalNAcO$(CH_2)_2CH_3$ (**3**) a permis de faire une attribution des signaux observés pour les haptènes de synthèse *asialo*-G_{M2} et l'*asialo* G_{M1} qui leur sont reliés soit les βDGalNAc(1→4)βDGal(1→4)βDGlcO$(CH_2)_8COOCH_3$ (**4**) et βDGal(1→3)βDGalNAc(1→4)βDGal(1→4)βDGlcO$(CH_2)_8$-$COOCH_3$ (**5**). Des études d'augmentation par effet Overhauser nucléaire du ^1H confirment les préférences conformationnelles qui avaient été prédites par des calculs HSEA pour les composés **2** et **3**. Une comparaison des spectres rmn du ^1H et du ^{13}C indique que ces préférences et celle qui avait été déterminée antérieurement pour le lactoside **1** sont bien maintenues dans les haptènes **4** et **5**. Les calculs HSEA indiquent que dans son orientation préférentielle, le groupe méthyle de l'acide méthyl *N*-acétyl α-D-neuraminique (**10**) est presque *anti* périplanaire par rapport au groupe carboxylique. Cependant cette orientation n'est pas confirmée par la saturation du groupe méthyle puisqu'on n'observe pas d'accroissement de Ha-3 ou de He-3. Par ailleurs, la saturation du Ha-3^e de l'unité αDNeuAc du pentasaccharide apparenté au G_{M1}, βDGal(1→3)βDGalNAc(1→4)[αD-NeuAc(2→3)]]βDGal(1→4)α,βDGlc, provoque un fort acroissement du signal de l'hydrogène aglyconique, H-3^b, de l'unité βDGal(1→4). Cette observation ainsi que celles d'autres expériences d'effet nucléaire Overhauser établissent que dans ce pentasaccharide le groupe carboxylique est *anti* périplanaire par rapport à C-3^b. De plus, en solution aqueuse, la chaîne C-7^e à C-9^e de l'unité αDNeuAc adopte pratiquement la même conformation que celle de l'acide *N*-acétylneuraminique à l'état cristallin. Des calculs HSEA indiquent qu'il existe une interaction attractive importante entre cette chaîne et l'unité βDGalNAc de l'aglycone. On a étendu ces conclusions aux gangliosides G_{M2} et G_{M1} par comparaison des données de déplacement chimique. Dans ces composés, le groupe carboxyle se retrouve au-dessus du côté α hydrophobe de l'unité βDGalNAc et les groupes polaires OH-4^e NAc-5^e, OH-7^e se retrouvent au-dessus du côté β hydrophobe de l'unité lactose. On discute de l'incidence possible de ces caractéristiques topographiques sur certaines propriétés biologiques des gangliosides.

Introduction

Sillerud and Yu (1) have recently published a comparison of the ^{13}C nmr spectra of the ganglioside G_{M1} with those of *asialo*-G_{M1} and the G_{M1}-pentasaccharide. The earlier literature was reviewed and the interest in sialic acid-containing, cell-surface glycolipids was outlined.

More recently, Koerner *et al.* (2*a*) have reported the use of homonuclear two-dimensional spin-echo *J*-correlated ^1H nmr spectroscopy for the determination of the compositions and anomeric configurations of the gangliosides G_{M4}, G_{M3}, G_{M2}, and G_{M1}. Although these studies were conducted using dimethyl-d_6 sulfoxide as solvent, of particular interest to our present contribution is their observation of long range effects on chemical shifts of the βDGalNAc unit arising from the introduction of the αDNeuAc group at the 3-position of the βDGal(1→4) unit of both G_{M2} and G_{M1}. The occurrence of these specific through-space interactions between the αDNeuAc and βDGalNAc units was taken as an indication that some secondary structure involving these two units stabilizes their conformational preference. In a second paper, Koener *et al.* (2*b*) applied two-dimensional nuclear Overhauser coupling studies to confirm the primary structures of these gangliosides. Inter-residue couplings were observed which were shown to allow

the complete sequencing of these oligosaccharides. It was suggested that quantitative experiments may limit the range of possible secondary structures.

We have recently reported (3) the syntheses of both the trisaccharide unit of *asialo*-G_{M2} and the tetrasaccharide unit of *asialo*-G_{M1} in the form of haptens wherein the aglycon is the potential linking arm $(CH_2)_8COOCH_3$ (4). In G_{M2} and G_{M1}, these neutral core structures form the aglycon of the sialic acid known as *N*-acetyl-D-neuraminic acid (NeuAc) (5). It is well established that these occur as the α-D-glycosides wherein the carboxyl group is in axial orientation at C-2 of the αDNeuAc group (6).

In this communication, we report a reinvestigation of the ^{13}C nmr spectra of G_{M1} (**8**) and the G_{M1}-oligosaccharide (**9**) and extend these studies to include the ^{13}C nmr spectrum of the G_{M2}-oligosaccharide (**7**). In addition, we report the first detailed ^1H nmr study of the G_{M1}-oligosaccharide (**9**) including ^1H nuclear Overhauser enhancement experiments in the difference mode (7) on this and related compounds that firmly establish its conformational preference in aqueous solution. The results obtained are shown to be in agreement with the molecular model for G_{M1} predicted by hard-sphere, *exo*-anomeric (HSEA) calculations (8).

Discussion

HSEA calculations were conducted in the usual manner (8) to estimate the conformational preference for the oligosaccharide portion of *asialo*-G_{M1}. Since all the interactions are between only two sugar units about each of the three intersugar glycosidic bonds, the calculations were first made for the three constituent disaccharide units, namely, βDGal^b(1→4)βDGlc^a (**1**), βDGalNAc^c(1→4)βDGal^b (**2**), and βDGal^d(1→3)βDGalNAc^c (**3**).[3] As expected, the results did not change when the calculations were made using the intact tetrasaccharide. The results of these calculations are presented in Fig. 1. These ϕ^H and ψ^H values for the core tetrasaccharide were then maintained throughout the calculations to assess the orientation of the αDNeuAc unit at position 3 of the βDGal^b(1→4) unit of the ganglioside G_{M1}.

In order to calculate the orientation of the αDNeuAc unit, the atomic coordinates for this unit were synthesized from the crystal structure of *N*-acetyl-β-D-neuraminic acid dihydrate provided by Flippen (9). The synthesis involved only the exchange of the carboxyl and hydroxyl groups at C-2 while preserving the same bond lengths (C—O = 1.400 Å and C—C = 1.531 Å). The lengths of the two carbon-to-oxygen bonds in the carboxylate group were taken as 1.198 Å. Hard-sphere calculations for the conformers arising from rotation about the carboxylate (C-1—O^{A}O^B) to C-2 bond indicated a preference for the orientation that sets a torsion angle of +80° for C—O^A and −100° for C—O^B with the C-2^c to O-2^c bond of the αDNeuAc unit. This orientation was maintained throughout the calculations that followed, setting the C-2^c—O—C-3^b (τ) bond angle at 117° (10). This αDNeuAc unit (attached to O-3^b of the core neutral tetrasaccharide) was then rotated, at 5° intervals, about the C-2^c—O-3^b bond to change the $\phi^{C\text{-}1^c,C\text{-}3^b}$ torsion angle after having set the $\psi^{H\text{-}3^b,C\text{-}2^c}$ torsion angle. The calculation (8) was then repeated setting this angle at 5° intervals through the 360° range. These calculations suggested the existence of only two energy minima which were separated by 4.38 kcal/mol in favor of conformer A as presented in Table 1. Examination of Table 2 shows that conformer A is favored over conformer B about equally for reasons of lesser forces of repulsion and greater forces of attraction between the αDNeuAc unit and the βDGalNAc(1→4)βDGal portion of the aglycon. The repulsive non-bonded interactions indicated for conformer A are listed in Table 2. The interaction of HA-6^c of the βDGalNAc unit with O-9^c of the αDNeuAc unit arises because no effort was made to minimize the conformational energy of conformer A by rotation about the C-8^c to C-9^c bond. This rather hard interaction does highlight the fact that this HSEA-favored conformer places the C-7^c to C-9^c side chain of the αDNeuAc unit in close proximity to the βDGalNAc(1→4) unit (c). The possible bearing of this orientation on the stability of conformer A can be judged from the attractive interactions listed in Table 2. Only attractive interactions of 10 cal and over are included, in order to limit the list. It is noteworthy, however, that there were a total of 1026 attractive interactions involving the αDNeuAc unit for a total of −8.33 kcal/mol, in contrast to the 205 attractive interactions which total −6.04 kcal/mol presented in Table 2. With specific regard to possible involvement of the C-7^c to C-9^c side chain of the αDNeuAc unit, the HSEA calculation shows a total of 178 attractive interactions with the βDGalNAc unit which contribute to the stabilization of conformer A by −2.01 kcal/mol. Of these, 57 have values of 10 cal or more, distributed as follows (atom (number of interactions) calories): C-7^c (7) −95; O-7^c (2) −20; C-8^c (9) −285; O-8^c (4) −95; H-8^c (11) −435; C-9^c (10) −289; O-9^c (7) −243; HA-9^c (2) −21; HB-9^c (5) −149; for a total of −1.63 kcal/mol. Thus, as pointed out by Salem (11), a large number of weak but multipoint van der Waals forces between large complementary surfaces can add to a large attractive force. Certainly, these play an important role in establishing conformational preferences by HSEA calculation (12). It is noteworthy in this regard that hard interactions between atoms in van der Waals conflict are much more sensitive to errors in the geometry imposed on the molecule from crystal data than are the attractive forces. As will be seen below, the HSEA calculation placed G_{M1} in a conformer that proved to be in fine accord with the ^1H nmr data obtained for the pentasaccharide portion of this ganglioside.

We have recently reported (3) the synthesis of the haptens βDGalNAc(1→4)βDGal(1→4)βDGlcOR (**4**) and βDGal(1→3)βDGalNAc(1→4)βDGal(1→4)βDGlcOR (**5**) wherein R = $(CH_2)_8COOCH_3$. These compounds are related to the *asialo*-forms of the gangliosides G_{M2} (**6**) and G_{M1} (**8**), respectively. Following the trivial nomenclature introduced by Sillerud and Yu (1), these haptens are referred to as ASG_{M2}-Hp (**4**) and ASG_{M1}-Hp (**5**). The preparation of the component disaccharide units of **5** as simple glycosides, namely, compounds **1**–**3** of Table 3, was also reported. The assignments of the ^1H chemical shifts presented in Table 3 for these disaccharides were in general agreement with expectations based on the ^1H nmr spectral assignments for the component sugar units as methyl β-D-hexopyranosides (7). The nmr parameters given in Table 3 for the haptens **4** and **5** could then be based on these assignments. It is of interest in this regard to compare the spectra for compounds **1**–**5** which are reproduced in Fig. 1. In all cases, the assignments were confirmed by spin-decoupling experiments. In view of the coupling constants listed, there can be no doubt that the pyranose rings are all held in the $^4C_1$ conformation. In view of the generally good agreements in chemical shifts, the conclusion is drawn that the conformational

[3] These sugar units will be labelled a, b, c, and d as shown throughout this discussion.

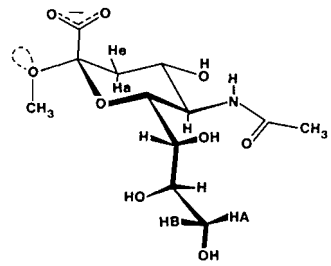
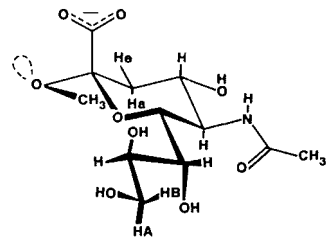
preferences for the glycosidic linkages of **4** and **5** are those for the component disaccharides. As will be seen below, the preferences in the case of the disaccharide compounds **2** and **3**, suggested by HSEA calculation (Table 1), were well confirmed by the nuclear Overhauser experiments.

In view of the internuclear distances listed in Table 1, saturation of H-1^b of compound **1** should cause enhancements of H-4^a, H-2^b, H-3^b, and H-5^b. However, because of the nearly identical chemical shifts (13) for H-4^a and H-3^a and for H-3^b and H-5^b, all of which are strongly coupled to vicinal hydrogens, the results obtained from these experiments provided no useful information on the magnitude of the enhancement of the signal for H-4^a. Thus, the torsion angles $\phi^{H-1^b}/\psi^{H-4^a}$ = 55°/0° rest on the results of the HSEA calculation which are supported by studies of closely related structures (10) and are confirmed by the H-1^b—^{13}C-4^a and H-4^a—^{13}C-1^b coupling constants for methyl β-lactoside (13). In contrast, saturation of H-1^c of compound **2** provided useful results. In view of the internuclear distances provided by the HSEA model given in Table 1, the signals for H-4^b, H-2^c, H-3^c, and H-5^c should be enhanced. However, except for the signal for H-4^b, these signals are overlapped by other signals and the difference spectrum showed some residue of positive signals arising from hydrogens other than H-2^c, H-3^c, and H-5^c. Thus, their relative enhancements could not be determined with precision. However, an 8% positive enhancement was found for H-4^b, a result which is in accord with the HSEA conformer A. Enhancements of approximately 4% were found for H-2^c and H-3^c, and likely greater than 4% for H-5^c. The nOe experiments were highly successful for the disaccharide derivative **3**. In this case, saturation of H-1^d resulted in enhancements of H-3^c (9%), H-2^d (7%), and H-3^d + H-5^d (17%). These results are in good accord with the conformational preferences given in Table 1.

Two of the conformers for methyl αDNeuAc that result from changes in the orientation of the methoxy group and the conformation of the C-7—C-9 side chain are displayed by formulae **10***a* and **10***b*. HSEA calculation, to estimate the preferred



10*a*



10*b*

orientation about the anomeric center of the αDNeuAc unit of G_{M1}, placed the oligosaccharide aglycon in the *syn*-axial-like orientation to Ha-3^e (i.e., C-1^e *anti*-periplanar to C-3^b) and similar to the orientation shown for the methyl group in structure **10***a*. However, HSEA calculation also placed the methyl group of **10** in the orientation shown in **10***a* and not that in **10***b* which is normally found for methyl aldopyranosides (14). Since saturation of the methyl group of **10** caused no observable enhancement of the signals for either Ha-3 or He-3 (Table 3), as may have occurred for conformation **10***a*, this indication was not confirmed. As will be seen below, the remarkable orientation of the aglycon in G_{M1} that is predicted by HSEA calculation received unequivocal experimental justification.

As mentioned above, the conformation for the αDNeuAc unit of G_{M1} was taken as that for *N*-acetyl-β-D-neuraminic acid in the crystalline state except that the orientation of the carboxyl and hydroxyl groups at C-2 were interchanged. Thus, the orientation for the C-7—C-9 group shown in **10***b* was maintained, rather than the conformational preference suggested by Czarniecki and Thornton (15). This latter conformation is presented in **10***a* in order to display that H-5 is in close proximity (2.3 Å) to H-8. Therefore, in this conformation, saturation of H-5 should enhance the signal for H-8. However, this could not be ascertained since the difference in chemical shifts for these hydrogens was too small (0.07 ppm) for the experiment using methyl αDNeuAc. However, in the case of *N*-acetyl-β-D-neuraminic acid, the difference in the chemical shifts (0.18 ppm) for H-5 and H-8 was sufficient, but no enhancement of H-8 (at 3.75 ppm) was observed on saturation of H-5 (at 3.93 ppm). It seemed possible, therefore, that this acid has the same conformation in aqueous solution as in the crystalline state where H-5 and H-8 are separated by 4.528 Å. This possibility was reinforced by the observation that saturation of H-5 caused enhancement not only of the *syn*-axial Ha-3 but also of H-7 at 3.56 ppm. Indeed, the crystalline structure for β-D-neuraminic acid has H-5 and H-7 separated by only 3.016 Å. In the light of these observations, H-5 of methyl αDNeuAc (**10**) was saturated and, in fact, an enhancement of H-7 was observed similar in intensity to that observed for the β-acid. Thus, there remains no doubt that the conformational preference suggested by Thornton and co-workers (15, 16) and which has gained widespread acceptance (17–19) should be abandoned for sialoside

units in their conformational ground states. Instead, the original proposal by Brown *et al.* (20), which is now confirmed, should be adopted.

In order to test the validity of the HSEA conformer for G_{M2} (**6**) and G_{M1} (**8**), the oligosaccharides $G_{M2}OS$ (**7**) and $G_{M1}OS$ (**9**) were prepared in the usual manner by mild base degradation of the products of ozonolysis (21). No effort was made to purify these oligosaccharides since the ^1H nmr spectra (that for $G_{M1}OS$ is reproduced in Fig. 2) required the crude preparation to be of sufficient purity for the present investigation. The signal assignments presented in Table 3 for $G_{M2}OS$ (**7**) were made on the basis of simple inspections and confirmed by appropriate spin-decoupling experiments. The pentasaccharide $G_{M1}OS$ (**9**), was chosen for the more detailed ^1H nmr examination. In this case, a number of signals which could not be assigned directly were assigned using nuclear Overhauser enhancements. The chemical shifts and coupling constants derived from these experiments are reported in Table 3. The signal for H-7^e was overlapped in the case of $G_{M1}OS$ (**9**) but clearly visible as a quartet at 3.52 ppm (spacings 2.2 and 11 Hz) in the spectrum for $G_{M2}OS$ (**7**). Since the signal for H-7^e was at 3.59 ppm (spacings 1.6 and 9.3 Hz) for methyl αDNeuAc (**10**), it is apparent that the two NeuAc residues do not differ appreciably in their conformational preferences for the C-7 and C-9 side chain. These

*Located by nuclear Overhauser enhancements.

observations support the conformation used in the HSEA calculation for G_{M1}.

Nuclear Overhauser experiments were conducted to investigate the hydrogen environments of Ha-3[e], H-1[e], and He-3[e] in the pentasaccharide $G_{M1}OS$ (**9**). Also, an experiment was performed wherein H-3[b] and H-4[b], which have near identical chemical shifts, were simultaneously saturated. The results obtained proved to be in fine agreement with expectations based on the HSEA model (Table 1). All the enhancements were negative, as would be expected (7), since such a large polar molecule in water should be tumbling slowly and anisotropically as seems likely from the ^{13}C nmr spectrum for $G_{M1}OS$ (1).

1. *Saturation of Ha-3[e]*

The percentages of the enhancements relative to the signal for Ha-3[e] could not be measured since the signal is overlapped by the signals for the two acetamido groups. However, signals were enhanced that definitely could be assigned to H-3[b], He-3[e], and H-5[e] at the positions given in Table 3. The relative intensities of these signals were 1:1.25:~1, respectively. The strong enhancement of H-3[b] (relative to the geminal He-3[e]) is particularly noteworthy since this enhancement alone eliminates conformer B wherein Ha-3[e] and H-3[b] are separated by 4.221 Å. Only extremely weak enhancement was observed for H-4[b] as compared with H-3[b] and, therefore, Ha-3[e] does not reside between H-3[b] and H-4[b] but only in close proximity to H-3[b] as predicted by the HSEA calculations for conformer A.

2. *Saturation of He-3[e]*

The signal for He-3[e] was well disposed for an nOe experiment. For conformer A, the nucleus of this hydrogen is separated from H-3[b] by 3.378 Å. Consequently, saturation of He-3[e] would be expected not to enhance H-3[b] appreciably. In fact, relative to the strong enhancements found for Ha-3[e] and H-4[e], the enhancement of H-3[b] was barely discernible at the noise level and could not be measured.

3. *Simultaneous saturation of H-3[b] and H-4[b]*

On the basis of conformer A, saturation of H-3[b] should enhance Ha-3[e] (2.045 Å), H-5[e] (3.350Å), H-1[b] (2.565 Å), H-5[b] (2.502 Å), and H-2[b] (3.050 Å); and saturation of H-4[b] should enhance H-5[b] (2.468 Å), HB-6[b] (3.133Å), and H-1[e] (2.460 Å). In fact, the experiment led to strong, readily assigned enhancements of the signals for Ha-3[e], H-1[b], H-2[b], and H-1[e]. The relative enhancements of these signals were ~0.5:0.7:0.8:1, respectively. Other enhancements occurred in the region 3.40–4.00 ppm but these could not be assigned because of overlap and also because the saturation undoubtedly affected atoms, including H-2[c] at 4.02 ppm, other than H-3[b] and H-4[b].

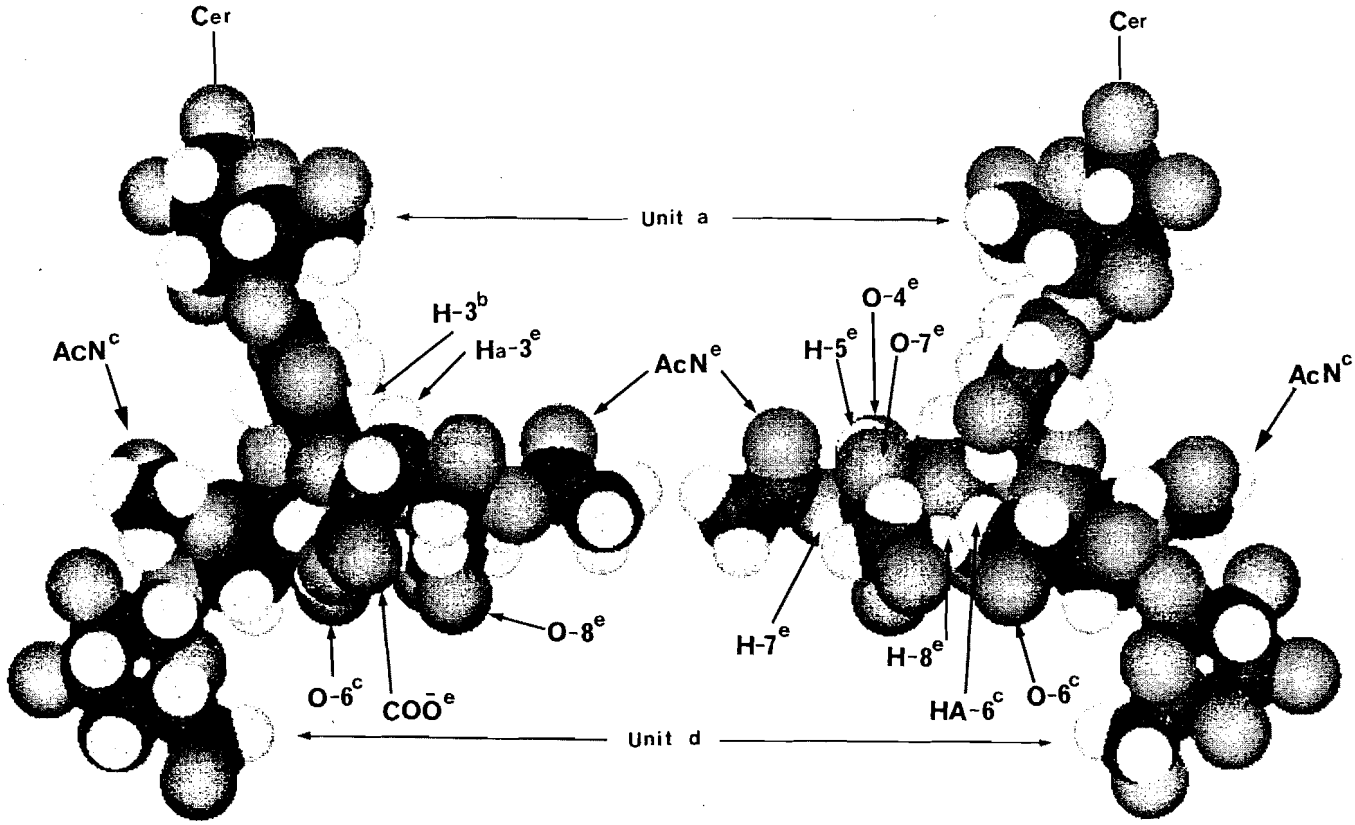

FIG. 3. Computer-drawn conformer A (Table 1) showing both sides for the oligosaccharide portion of G_{M1}. The hydrogen atoms of the hydroxyl groups are not shown. Note that H-3^b/Ha-3^e and HA-6^c/H-8^e are in van der Waals contact, that the carboxyl group ($C\bar{O}O^e$) extends toward the lipophilic side of the c-d unit, that the NC=O^e, OH-4^e, and OH-7^e groups extend toward the lipophilic side of the a-b unit, and that H-5^e and H-7^e define a torsion angle of near 120°. Note, for example, that, although O-6^c may appear to be close to the carboxyl group in one projection, the other shows that it is in fact on the other side of the molecule. The construction of a model using these projections for reference is recommended.

4. *Saturation of H-1^c*

As expected from the internuclear distances given in Table 1, this experiment caused enhancements of H-4^b, H-2^c, H-3^c, and H-5^c which provided the assignments of the chemical shifts reported in Table 3, except for H-2^c which could be assigned by spin-decoupling of H-1^c. The spacings in the enhanced signals at 3.82 ppm allowed its assignment to H-3^c with confidence. The enhancement at 4.15 ppm was then assigned to H-4^b and it followed that the enhanced signal at 3.76 ppm arose from H-5^c.

Consideration of the ^{1}H chemical shifts presented in Table 3 clearly suggests that the conformation of the core tetrasaccharide present in G_{M1}OS (**9**) is very similar to that in the hapten **5**. This matter will be discussed in more detail below in connection with the ^{13}C nmr data presented in Tables 4 and 5. At this point, it is of interest to examine the computer-drawn CPK model for the pentasaccharide portion of G_{M1} shown in Fig. 3. The main purpose of this drawing is to enable the reader to readily construct a CPK space-filling model for conformer A. However, the drawing helps to highlight a number of topographical features of interest to receptor binding specificities exhibited by G_{M1} and related receptor molecules. Examination of the model shows that the carboxylate group is extended near a large lipophilic region which involves the α-sides of both the c (βDGalNAc) and d (βDGal) units. Thus, it can be expected that the introduction of the αDNeuAc unit at position 3^b of *asialo*-G_{M1} strongly changes a region of *asialo*-G_{M1} which can be expected to express an immunodominant role (22). This, likely, is behind the reason why *anti-asialo*-G_{M1} antibodies do not react with G_{M1} (23). In contrast to the lipophilic α-side, the β-side of the βDGal(1→3)βDGalNAc unit is strongly hydrophilic and an engagement of a receptor with this side of the molecule would encounter ten polar groups of which six are hydroxyl groups. It is noteworthy in these regards that we have found (unpublished results) in several instances that the combining sites of antibodies and lectins bind large lipophilic areas of oligosaccharides that then terminate in a cluster of two or three hydroxyl groups. It is considered that the cluster of hydroxyl groups interacts with a polar grouping at the periphery of the combining site and that this interaction is mainly to provide high specificity to the binding reaction. The establishment of multipoint van der Waals attractions, involving the lipophilic region of the oligosaccharide with nonpolar regions of amino acids that form the combining site, could in principle provide the main driving force leading to complex stability (22). These considerations are noteworthy since evidently the juxtaposition in G_{M1} of the highly polar carboxylate group near the α-side of the βDGal(1→3)βDGalNAc unit provides a similar situation to the cluster of hydroxyl groups mentioned above. Similar considerations apply to the lipophilic β-sides of the βDGal(1→4)βDGlc unit of G_{M1}. Consideration of the projection in Fig. 3 shows that this side is guarded by the 4- and

‡ This signal was assigned twice, which is not in agreement with the published spectrum (1).
§ Reassigned on the basis of the published spectrum (1).

7-hydroxyl groups of the αDNeuAc unit along with the polar carbonyl oxygen of the acetamido group which projects between these two hydroxyl groups. The recent finding (24) that haemagglutinin glycoproteins of influenza virus membranes (which differ in recognizing either αDNeuAc(2→3)βDGal-(1→4)βDGlc (G_{M3}) or αDNeuAc(2→6)βDGal(1→4)βDGlc linkages) differ only in the single substitution of glutamine for leucine may be related to this feature, which is expected (by HSEA calculation) to persist in the ganglioside G_{M3}. It is the G_{M3} structure that reacts with the receptor site which contains the glutamine unit, but not with the receptor site formed by the protein wherein the glutamine unit is replaced by a leucine unit. Evidently, the carboxamido group of the glutamine unit, through an ability to displace water and bind to the above-mentioned hydrated polar grouping, may be allowed to penetrate and thereby gain access to the nonpolar side of the βDGal(1→4)βDGlc unit for an expression of short range van der Waals forces of attraction. On the other hand, the nonpolar isobutyl group of leucine is not expected to readily penetrate the hydrated polar region to come close enough for effective interaction.

Although we have not examined the conformational preference for αDNeuAc^c(2→6)βDGal^b experimentally, HSEA calculations were made based on the assumption that the ω torsion angle H-5^b/O-6^b is +60° as appears demanded for the conformer of βDGal(1→4)βDGlcNAc(1→6)βDGal that is bound by the monoclonal *anti*-I Ma antibody (25). Based on this assumption, two minima are indicated; namely, $\phi^{C\text{-}1^c}/\psi^{HA\text{-}6^a}$ = −70°/5° (1.09 kcal/mol) and −170°/5° (−0.02 kcal/mol). We expect, however, that the energy difference is in fact much greater, since the −70°/5° conformer brings HB-6^b in close proximity to the carboxylate group which must be strongly hydrated, and therefore expresses an effective volume greater than that used in the calculation. We have discussed this matter in relation to the conformational preference exhibited by βDGal(1→4)βDGlcNAc(1→6)6-*SC*CH_3-βDGal (26). It is noteworthy that the preferred conformer (−170°/5°) has HA-6^b in contact with Ha-3^c, much as was found for G_{M1}, and, therefore, an nOe-test for this conformational preference is indicated. The conformer (−170°/5° and ω = 60°) places the carboxyl group much in the mean of the plane defined by the pyranose rings of the βDGal(1→4)βDGlc unit of αDNeuAc(2→6)βDGal(1→4)βDGlc and on the side where it is to be expected (25) that OH-3^a of the βDGlc unit is intramolecularly hydrogen bonded to O-5^b of the βDGal unit.

With reference to Table 4, the assignments of the ^{13}C chemical shifts to the haptens **4** and **5**, on the basis of those found for the component disaccharide units present in compounds **1**–**3**, are straightforward. That essentially the same chemical shifts, when applicable, are found throughout, is in accord with

‖ Reassignment based on published spectrum (1).

the prediction based on HSEA calculation. Exact correspondence is not expected since the degrees of freedom for the flexing of the various pyranose rings will not be constant and this must influence ^{13}C chemical shifts. Our assignments are compared with those reported by Sillerud and Yu (1) for *asialo*-G_{M1}. Considering that the measurements were made at different temperatures and that the compounds differ greatly in the nature of the aglycons, the agreement is excellent. We would only suggest that the assignments for C-1^b and C-1^c be interchanged. Since we have high confidence in the assignments for the hapten **5**, these are compared in Table 5 to those for $G_{M1}OS$ (**9**) and G_{M1} (**8**).

The ^{13}C chemical shifts for G_{M1} (**8**) and $G_{M1}OS$ (**9**) that we determined at 90.56 MHz and 30°C are compared in Table 5 with those reported by Sillerud and Yu (1) at 50.3 MHz and 20°C. Also, the ^{13}C chemical shifts for $G_{M2}OS$ are reported. As noted in Table 5, we recommend a number of changes in assignment. Change A is mandatory since we have already shown (10) that glycosylation at a position neighboring to one that is already glycosylated leads to less deshielding of the new aglyconic carbon than is normally observed, but to a shielding of the aglyconic carbon at the neighboring position. Thus C-4^b, which is at 76.53 ppm in the hapten **5**, should be shielded on introducing the αDNeuAc group at O-3^b. Therefore, its signal must be at 74.71 and not 77.48 ppm. Our other suggested changes (B and C, Table 5) are based on the observation (note the $\delta_A - \delta_9$ values in brackets) that to do so would bring the data into much better overall agreement. The lack of agreement

between our assignment of the ^{13}C chemical shifts for G_{M1} and those reported by Sillerud and Yu is quite remarkable. As seen in Table 5 from the $\delta_B - \delta_8$ values presented in brackets, a much better agreement would be reached on the basis of the changes (D, E, and F) shown. The change D is for the reasons discussed above in relation to the effect of branching. Changes E and F are less secure but are considered appropriate. The $\delta_5 - \delta_8$ values listed in Table 5 only represent the best match between those observed for G_{M1} (**8**) and those assigned in Table 4 for the hapten **5** (ASG_{M1}-Hp). The assignment of the signal at 79.38 ppm for C-4[a] of G_{M1} appears required, as is the assignment of the signal at 79.37 ppm for C-4[a] of the hapten **5**. Thus, on this basis, it might appear that all the ^{13}C atoms of the βDGlc unit would have nearly the same chemical shifts for both **5** and **8**. However, the data do not allow this to be the case and it must be concluded that the aglycons have an influence on the ^{13}C chemical shifts of the βDGlc unit. In fact, this would not be surprising since the ceramide aglycon of G_{M1} is known to lead to micelle formation when G_{M1} is dissolved in water. That the anchoring of the oligosaccharide portion of G_{M1} to a lipid surface would cause a change in the ^{13}C chemical shifts for the first sugar unit, as compared with when the substance is in true solution, would not be surprising. That this effect would not be as important for the terminal βDGal(1→3) unit would be expected and, indeed, it was possible to assign ^{13}C chemical shifts, which produce much more constant $\delta_5 - \delta_8$ values, to this unit. The values for the βDGal(1→4) (b unit) are in general accord with expectation, in that introduction of the αDNeuAc unit at C-3[b] of this unit should lead to deshielding of this atom, but shielding of C-4[b] and likely C-2[b], as is assigned in Table 5. The effect of this substitution on the ^{13}C chemical shifts of the other carbon atoms of the b unit, as well as those of the c unit, cannot be predicted with a high level of confidence. Nevertheless, as seen in Table 5, our assignments for the c unit indicate that the substitution has a considerable effect on the ^{13}C chemical shifts for atoms in this neighboring unit. This effect would not be surprising since our conformational analysis, based on HSEA calculation, indicates that the βDGalNAc unit is extensively and rather strongly bonded through secondary forces of attraction to the αDNeuAc unit. This interaction would be expected to alter the ^{13}C chemical shifts of both the βDGalNAc and the αDNeuAc units. That the latter is the case is apparent from the $\delta_8 - \delta_{10}$ values listed in Table 5 for the atoms C-6[c] to C-9[c]. Indeed, the contrast of these values with those for the $\delta_5 - \delta_8$ values for the terminal d unit of G_{M1} lends support to the conclusion reached by the HSEA calculation that the αDNeuAc unit of G_{M1} is strongly attracted to the βDGalNAc(1→4)βDGal unit of the core tetrasaccharide. As was stated above, Koerner *et al.* (2*b*) surmised an attraction between the αDNeuAc and βDGalNAc units of G_{M2} and G_{M1}. In this connection, it was suggested that dipole-charge, hydrophobic, hydrogen-bond, and counter-ion interactions or combinations of these possibilities are responsible for such secondary structure. We contend that the van der Waals forces of attraction commented upon with reference to Table 2 essentially provide the driving force for the presence of this secondary structure.

Experimental

Methods

The ^1H nmr spectra were conducted in 5-mm degassed and sealed tubes containing the compound (near 0.02 *M*) after exchanging three times with D_2O and dissolution in pure D_2O. Either a Bruker WP-360 or WH-400 spectrometer (360 and 400 MHz, respectively) with 32K points (Aspect 2000 computer) was used. The nuclear Overhauser experiments were performed in the difference mode (27) with a power level of 35 db below 0.2 W. The chemical shifts are relative to the signal for DOH at 4.81 ppm at 296 K for all compounds except for $G_{M2}OS$ (**7**) and $G_{M1}OS$ (**9**) where the spectra were measured at 178 K (δ_{DOH} = 4.99 ppm).

The ^{13}C nmr spectra were measured using the same solutions as for the ^1H nmr measuremetns and the above-mentioned spectrometers operating at 90.56 and 100.63 MHz, respectively, at 303 K. A relaxation delay of 0.5 s was used between 90° pulses. A line broadening factor of 0.5 Hz was introduced before the Fourier transformation of the free induction decay. The chemical shifts are relative to external tetramethylsilane using the deuterium lock of the spectrometer, which set the ^{13}C chemical shift of dioxane in D_2O at 66.88 ppm at 303 K (28).

The atomic coordinates for the a, b, c, d, and e units used in the HSEA calculations were taken from the crystal structures for gentiobiose (29), methyl β-D-galactopyranoside (30), *N*-acetyl-β-D-galactosamine (31), and *N*-acetyl-β-D-neuraminic acid (9).

$G_{M2}OS$ (7) and $G_{M1}OS$ (9)

Samples (32) of G_{M1} (27 mg) and G_{M2} (15 mg)[4] were treated with ozone as described by Wiegandt and Bücking (21). In each case, the ozonide was decomposed with dimethyl sulfide and the solution was evaporated to dryness. The residue was dissolved in a 5% solution of triethylamine in methanol and the solution was kept at 4°C for 24 h. After solvent removal, the residue was triturated with water (5 × 5 mL) and the solution was filtered using a 0.22 μm millipore filter (Millipore Corporation, Bedford, MA, U.S.A.). Freeze-drying left a colorless solid which was redissolved in water (1 mL) for passage through a column of Amberlite IRA-120(H^+) resin (1.0 g). After neutralization with sodium bicarbonate, the solution was freeze-dried to a colorless solid. The ^1H nmr of $G_{M1}OS$ (see Fig. 2) showed the product to be contaminated by material which produced signals at the positions shown. Since these impurities could not be removed by extraction with chloroform, no further purification was attempted.

Pyrrole chemistry. XXVII. 2,3,4-Trisubstituted pyrroles and a second synthesis of porphobilinogen from pyrrole

KURT FABER, HUGH J. ANDERSON,[1] CHARLES E. LOADER, AND ANNETTE S. DALEY
Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received November 8, 1983

KURT FABER, HUGH J. ANDERSON, CHARLES E. LOADER, and ANNETTE S. DALEY. Can. J. Chem. **62**, 1046 (1984).

Changes in some of the key intermediates and procedures used in our earlier total synthesis of porphobilinogen from pyrrole that improve the yield to 11% are reported. Ethyl pyrrole-3-acetate was formylated by the Vilsmeier–Haack method and then iodinated. The desired 2,3,4-substituted pyrrole isomer was isolated in moderate yield and, after conversion of iodide to acrylate and aldehyde to aldoxime, reduction and work-up afforded porphobilinogen lactam ethyl ester. Hydrolysis of the latter gave porphobilinogen in ten steps from pyrrole.

KURT FABER, HUGH J. ANDERSON, CHARLES E. LOADER et ANNETTE S. DALEY. Can. J. Chem. **62**, 1046 (1984).

Grâce à des changements dans quelques intermédiaires clés et dans quelques-unes des procédures utilisées dans notre synthèse totale antérieure du porphobilinogène à partir du pyrrole, il est possible d'améliorer le rendement à 11%. On a formylé le pyrroleacétate-3 d'éthyle par la méthode de Vilsmeier–Haack et on l'a alors iodé. L'isomère désiré du pyrrole substitué en 2,3,4 est isolé avec un rendement modéré; après conversion de l'iodure en acrylate, et de l'aldéhyde en aldoxime, une réduction et une extraction permettent d'isoler l'ester éthylique de la lactame du porphobilinogène. L'hydrolyse de ce dernier conduit au porphobilinogène en dix étapes à partir du pyrrole.

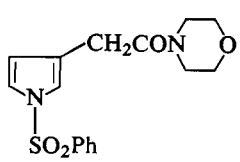
We have recently reported a total synthesis of porphobilinogen (**1**), the precursor of naturally occurring porphyrins and corrins, in nine steps from pyrrole with an overall yield of about 6% (1). In that synthesis, reduction of the cyanide group led to the partial reduction of the pyrrole ring and was a major factor in reducing the yield. Attempts to develop a better procedure for this reduction, using as a model the readily available 4-carbethoxyvinylpyrrole-2-carbonitrile (see the experimental section), failed. The model appeared more susceptible to ring reduction than the porphobilinogen precursor itself under most conditions.

A variation on the earlier synthesis provides both a marked increase in the overall yield of porphobilinogen and also further demonstrates the versatility of this approach to the synthesis of 2,3,4-trisubstituted pyrroles, a type sometimes used as porphyrin building blocks (2). The steps by which a labelled carbon or nitrogen atom could be introduced into the eventual aminomethyl side chain are also simplified.

A general outline of this approach is given in Scheme 1, and follows the philosophy outlined in the earlier paper (1). The aldoxime rather than the cyanide group was used as a precursor to the aminomethyl side chain and the lactam ethyl ester of porphobilinogen (**2**) was the desired final intermediate.

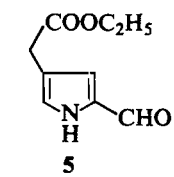
This synthetic approach began, as did the earlier one, with the preparation of ethyl pyrrole-3-acetate (**3**) in three steps from pyrrole (1). Attempts to improve this synthesis by using the Wilgerodt–Kindler rearrangement of the readily available (3, 4) 3-acetyl-1-phenylsulfonylpyrrole failed. Although the rearrangement was successful, the yield of the corresponding morpholide:



was low and this approach was not pursued.

A variety of methods are available for the introduction of the aldehyde group onto the pyrrole nucleus (5). However, the acetic ester side chain in the starting material **3** made acidic conditions undesirable. The method of Clezy *et al.* using trifluoroacetic acid and ethyl orthoformate (6) gave a mixture that showed the presence of the two isomeric aldehyde products, but during work-up a good deal of decomposition occurred. When a catalytic amount of *p*-toluenesulfonic acid was used in place of trifluoroacetic acid, there was still extensive loss of material through polymerization and(or) decomposition. The Vilsmeier–Haack procedure, with dimethylformamide (DMF) and oxalyl chloride as the formylating agent (7), gave an excellent yield of the formylated 3-acetic ester, but the ratio of 2-substitution to 5-substitution was 40:60 at 0°C and unsatisfactory. Lowering the temperature improved this ratio, but at about −20°C the reaction ceased. Inverse addition of the reagents had only a slight effect. The addition of one equivalent of hexamethylphosphoric triamide improved the ratio of the desired 2- (**4**) over the undesired 5-isomer (**5**) to 60:40 at −26°C. For comparison, the Vilsmeier–Haack formylation of 3-methylpyrrole gave a 4:1 ratio of 2- and 5-substitution (8, 9). The combination of the steric and electronic effects of the acetic ester group results in the less favorable ratio, as in the cyanation of the 3-acetic ester (1). Mild hydrolysis of the iminium salt did not hydrolyze the ester group and conversion to the aldehyde product was excellent.

The isomeric aldehydes **4** and **5** could be separated by flash chromatography with less difficulty than the corresponding



5

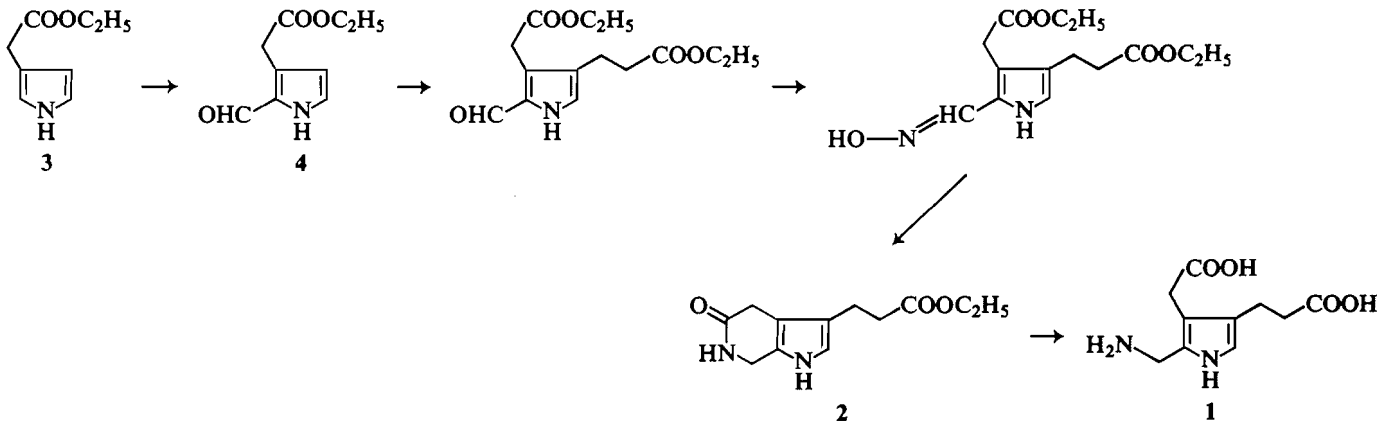


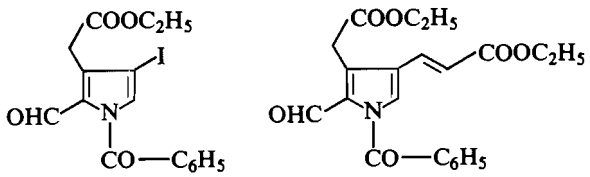
SCHEME 1

nitriles, which required medium pressure liquid chromatography (1). After the initial isolation, purification, and identification, the yields were found to be 59.5% **4** and 37% **5**.

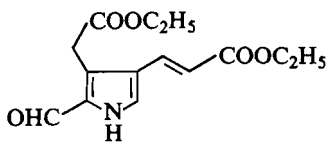
The decarbonylation of the undesired aldehyde **5** using palladized charcoal to give back the starting material **3** for the Vilsmeier–Haack reaction afforded only a 50% yield, in contrast to the almost quantitative yield obtained for the decarbonylation of the corresponding glyoxalate. For this reason, and because the separation of the mixture of isomeric aldehydes was tedious, this procedure was not used to recover the starting material, **3**.

As with the isomeric nitriles (1), the iodination of the reaction product mixture of **4** and **5**, using the iodine/iodic acid (4:1 ratio) method (10), led to a mixture of three compounds (**6**, **7**, and **8**). The desired ethyl 4-iodo-2-formylpyrrole-3-acetate (**6**) could now be easily separated and thus obtained in two steps from the 3-acetic ester, **3**, in a 52.6% yield.

The acidic proton on the pyrrole nitrogen was expected to interfere with the Heck reaction (1, 11, 12) and was replaced by a benzoyl group by the phase-transfer benzoylation of **6**, giving **9**. When compound **9** was condensed with ethyl acrylate an excellent yield of a mixture of products with (**10**), and without (**11**), the *N*-benzoyl group was obtained. More cleavage of the benzoyl group was evident than with corresponding



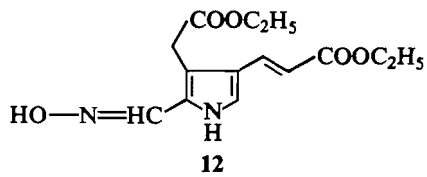
9 **10**



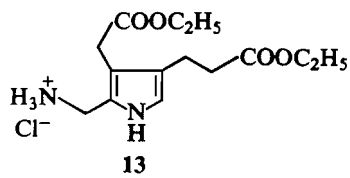
11

nitrile derivative (1). The *N*-benzoyl does not impart any added stability to the reduced material (1) and was conveniently removed during work-up of the Heck reaction product by treatment with ammonia; thus **11** became the only product from the reaction.

The ethyl ester of porphobilinogen lactam (**2**) is stable and gives porphobilinogen in excellent yield on hydrolysis (1). Attempts to obtain this compound directly by the reductive amination of **11** gave the alcohol and only a trace of the desired lactam ester (**2**). Similarly, when the reductive amination was attempted on the model compound, ethyl 2-formylpyrrole-3-acetate (**4**), alcohol formation predominated over lactam formation. In addition, some decarbonylation to the 3-acetic ester (**3**) took place. It appears that in both cases the equilibrium (13, 14) between the aldehyde and the intermediate carbinolamine or imine was unfavorable. While it is possible that a small change in pH might improve the operation, the conventional procedure was used, despite the extra step involved. Thus, **11** was converted to its oxime **12** (88% yield) using a mostly ethanolic solution of hydroxylamine at room temperature rather than the refluxing aqueous solutions used by earlier workers (15–17). The tlc, ir, and nmr properties of the product and those of the known isomeric pyrrole-2-aldoximes showed that the *syn*-isomer was the major isomer in **12**.



12



13

In our previous synthesis (1), platinum oxide catalysis was necessary to reduce the nitrile group. However, reduction of the pyrrole ring lowered the yield of the product substantially. The aldoxime was expected to be more easily reduced to the aminomethyl group than the nitrile. The palladium black catalyzed reduction of **12**, under the same conditions (ethanolic ammonia) used to hydrogenate the corresponding nitrile, failed to give porphobilinogen lactam ester but the starting material was used up. The conditions used and the higher R_f of the major component suggested that the product was possibly the ester of the byproduct of unknown structure reported by Arsenault and MacDonald (16) during reduction of their 2-oxime-3-acetic acid-4-propanoic acid when the solvent was aqueous ammonia. The instability of this product prevented further investigation. Reduction over palladium black in a slightly acidic ethanol solution gave the ammonium salt (**13**), which was easily converted without isolation to the desired lactam ester by treatment

with ethanolic sodium ethoxide. This procedure was a slightly modified version of the MacDonald route (15) which used a similar oxime of a pyrrole containing a propanoic rather than acrylic ester side chain. The yield of the lactam ethyl ester **2** from the oxime **12**, identical to a sample from the earlier nitrile route, was about 80%. As this lactam ester had already been hydrolyzed to porphobilinogen (**1**), the above sequence constitutes another total synthesis of that compound in ten steps from pyrrole with an overall yield of 11%.

Experimental

Melting points are uncorrected. Elemental analyses were by Atlantic Microlabs, GA, U.S.A. The ir spectra were recorded on a Perkin–Elmer 237B grating spectrophotometer as KBr discs, unless otherwise stated. The ^{1}H nmr spectra (nmr) were determined using a Varian EM 360 or a Bruker WP-80 instrument and are expressed in ppm (δ values) relative to tetramethylsilane as internal reference in $CDCl_3$, unless otherwise stated. Mass spectra were recorded on a VG Micromass 7070HS spectrometer. The ^{13}C nmr spectra were determined at 20.122 MHz in $CDCl_3$ on a Bruker WP-80 Fourier transform instrument. All solvents were dried and distilled before use. Throughout, the term "petroleum" refers to the fraction of bp 30–60°C. The term "hexanes" refers to a mixture of isomers bp 65.8–69.0°C (Fisher Scientific). Flash chromatography (18) was carried out using "Baker Analyzed" silica gel for flash chromatography.

Formylation of ethyl pyrrole-3-acetate (3)

The Vilsmeier–Haack complex was generated by adding oxalyl chloride, (1.265 g, 9.97 mmol) in dichloromethane (25 mL) to a cooled (0°C) solution of DMF (0.765 g, 10.5 mmol) in dichloromethane (25 mL) over 10 min, and then the reaction mixture was stirred at 0°C for 15 min and at room temperature for a further 15 min. The complex was then cooled to between −10 and −15°C and hexamethylphosphoric triamide (1.85 g, 10.3 mmol) in dichloromethane (25 mL) was added slowly, keeping the temperature below −10°C. The solution was then cooled to about −30°C and ethyl pyrrole-3-acetate (**3**) (1.02 g, 6.65 mmol) in dichloromethane (50 mL) was added over 30 min. The temperature was then allowed to rise and was held at −26°C for 30 min and then at 0°C for a further 30 min. Thin-layer chromatography showed absence of starting material, and an aqueous solution of sodium acetate (125 mL, 1 mol L^{-1}) was added dropwise at 0°C, followed by vigorous stirring for 1 h at room temperature. The layers were separated, the aqueous layer was saturated with NaCl and then extracted 4 times with dichloromethane (50-mL portions). The organic layers were combined, dried ($MgSO_4$), and the solvent was removed.

I. The crude product was separated by flash chromatography on silica gel using hexanes/ether (elution gradient 4:1, rising to 2:1). The following were obtained in order of elution.

(a) *Ethyl 2-formylpyrrole-4-acetate* (**5**) (450 mg, 37.3%), mp 62.5°C from hexanes/dichloromethane; ir: 1650, 1730, 2900, 2975, 3150 cm^{-1}; nmr δ: 1.28 (3H, t, —CH_3, J = 7 Hz), 3.52 (2H, s, CH_2COO), 4.15 (2H, q, —CH_2—CH_3, J = 7 Hz), 6.93 (1H, m, 3-H), 7.05 (1H, m, 5-H), 9.38 (1H, s, —CHO) 10.5 (1H, b, NH); m/z = 181. *Anal.* calcd. for $C_9H_{11}NO_3$: C 59.66, H 6.16, N 7.73; found: C 59.72, H 6.16, N 7.73.

(b) *Ethyl 2-formylpyrrole-3-acetate* (**4**) (718 mg, 59.5%), mp 59.0°C from hexanes/dichloromethane; ir: 1625, 1730, 2975, 3250 cm^{-1}; nmr δ: 1.25 (3H, t, —CH_3, J = 7 Hz), 3.78 (2H, s, —CH_2COO), 4.15 (2H, q, —CH_2—CH_3, J = 7 Hz), 6.23 (1H, m, 4-H), 7.03 (1H, m, 5-H), 9.60 (1H, s, —CHO), 10.7 (1H, b, NH); m/z = 181. *Anal.* calcd. for $C_9H_{11}NO_3$: C 59.66, H 6.12, N 7.73; found: C 59.53, H 6.15, N 7.69.

II. On a preparative scale, the isomer mixture of **4** and **5** could be freed of hexamethylphosphoric triamide by flash chromatography on a short column using hexanes/ether (2:1). This mixture was then iodinated as follows.

Iodination of the mixture of aldehydes of ethyl pyrrole-3-acetate (4 and 5)

The mixture of aldehyde esters **4** and **5** from II above (1.02 g, 5.62 mmol), iodic acid (198 mg, 1.123 mmol), and iodine (570 mg, 4.49 mmol) in CCl_4 (40 mL) water (1.2 mL), acetic acid (2.8 mL), and sulfuric acid (0.1 mL, concentrated) was stirred vigorously under nitrogen at room temperature for 24 h. The reaction mixture was diluted with dichloromethane (100 mL), the organic layer separated, washed with aqueous sodium thiosulfate (50 mL, saturated), aqueous sodium hydrogen carbonate (50 mL, 5%), saturated aqueous NaCl, and dried ($MgSO_4$). The product mixture from the rotary evaporation was flash chromatographed using an elution gradient of hexanes/ether (3:1) rising to ether as solvent. The following were obtained in order of elution.

(a) *Ethyl 2-formyl-5-iodopyrrole-4-acetate* (**7**) (452 mg, 26.1%), mp 98.5°C from hexanes/dichloromethane; ir: 1625, 1700, 3150 cm^{-1}; nmr δ: 1.30 (3H, t, —CH_3, J = 7 Hz), 3.48 (2H, s, —CH_2COO), 4.23 (2H, q, —CH_2—CH_3, J = 7 Hz), 6.95 (1H, d, 3-H, $J_{1,3}$ = 1.2 Hz), 9.33 (1H, s, —CHO), 10.4 (1H, b, NH); m/z = 307. *Anal.* calcd. for $C_9H_{10}INO_3$: C 35.20, H 3.28, N 4.56; found: C 35.13, H 3.27, N 4.50.

(b) *Ethyl 2-formyl-4,5-diiodopyrrole-3-acetate* (**8**) (25.2 mg, 3%), mp 147.5°C from hexanes/dichloromethane; ir: 1650, 1720, 3175, 3400 cm^{-1}; nmr δ: 1.30 (3H, t, —CH_3, J = 7 Hz), 3.80 (2H, s, —CH_2COO), 4.20 (2H, q, —CH_2—CH_3, J = 7 Hz), 9.38 (1H, s, —CHO); m/z: = 433. *Anal.* calcd. for $C_9H_9I_2NO_3$: C 24.96, H 2.10, N 3.24; found: C 25.15, H 2.12, N 3.21.

(c) *Ethyl 2-formyl-4-iodopyrrole-3-acetate* (**6**) (937 mg, 54.2%), mp 86.5°C from hexanes/dichloromethane; ir: 1670, 1720, 3300 cm^{-1}; nmr δ: 1.30 (3H, t, —CH_3, J = 7 Hz), 3.78 (2H, s, —CH_2COO), 4.25 (2H, q, —CH_2—CH_3, J = 7 Hz), 7.14 (1H, d, 5-H, $J_{1,4}$ = 1.4 Hz), 9.60 (1H, s, —CHO), 10.55 (1H, b, NH); m/z = 307. *Anal.* calcd. for $C_9H_{10}INO_3$: C 35.20, H 3.28, N 4.56; found: C 35.08, H 3.29, N 4.53.

Ethyl 1-benzoyl-2-formyl-4-iodopyrrole-3-acetate (9)

Benzoyl chloride (422 mg, 3 mmol) in dichloromethane (5 mL) was added dropwise over 30 min to a well-stirred and cooled (ice bath) mixture of ethyl 2-formyl-4-iodopyrrole-3-acetate (**6**) (614 mg, 2 mmol), powdered NaOH (136 mg, 3.4 mmol), and tetrabutylammonium hydrogen sulfate (34 mg, 0.1 mmol) in dichloromethane (15 mL) under N_2, then stirred at 0°C for an additional 2 h. The reaction mixture was filtered through Celite, washing with several portions of dichloromethane. The combined organic layer was washed with saturated aqueous NaCl and dried ($MgSO_4$). Evaporation of the solvent[2] afforded a crude product which was flash chromatographed using hexanes/ether (3:1) as eluent to give pure ethyl 1-benzoyl-2-formyl-4-iodopyrrole-3-acetate (**9**) (752 mg, 91.5%), mp 106.5–107°C (hexanes/dichloromethane); ir: 1640, 1700, 1725, 2950, 3100, 3350 cm^{-1}; nmr δ: 1.30 (3H, t, —CH_3, J = 7 Hz), 3.90 (2H, s, CH_2COO), 4.18 (2H, q, —CH_2—CH_3, J = 7 Hz), 7.21 (1H, s, 5-H), 7.5–7.9 (5H, m, phenyl H), 10.05 (1H, s, —CHO); m/z = 411. *Anal.* calcd. for $C_{16}H_{14}INO_4$: C 46.73, H 3.43, N 3.41; found: C 46.78, H 3.47, N 3.41.

Ethyl 2-formyl-4-carbethoxyvinylpyrrole-3-acetate (11)

A mixture of ethyl 1-benzoyl-2-formyl-4-iodopyrrole-3-acetate (**9**) (123 mg, 0.3 mmol), freshly distilled triethylamine (46 mg, 0.45 mmol), ethyl acrylate (45 mg, 0.45 mmol), palladium(II) acetate (2 mg), and acetonitrile (1 mL), was placed in a heavy walled Pyrex tube, sealed at one end and fitted with a Teflon cap. The tube was flushed with dry N_2 and the cap fitted tightly, then inserted into a stirred and preheated (99–100°C) oil bath. The reaction mixture was stirred at that temperature for 40 min, then cooled to room temperature

[2] Note: This product sublimes slowly in a rotary evaporator (45°C, 6 Torr).

and taken up in dichloromethane (15 mL).[3] This solution was washed with dilute aqueous HCl (0.5 mol L^{-1}); saturated aqueous NaCl, and dried ($MgSO_4$). Evaporation of the volatiles gave a crude product that was flash chromatographed using an elution gradient of hexanes/ether (1 : 1) rising to pure ether as solvent. The following were obtained in order of elution.

(a) *Ethyl 1-benzoyl-2-formyl-4-carbethoxyvinylpyrrole-3-acetate* (**10**) (35 mg, 30.5%), mp 126.5°C from hexanes/dichloromethane; ir: 1630, 1650, 1700, 1710, 1730, 3400 cm^{-1}; nmr δ: 1.28 (6H, t, —C*H*$_3$, J = 7 Hz), 4.02 (2H, s, —C*H*$_2$COO), 4.14 (2H, q, —C*H*$_2$—CH$_3$, J = 7 Hz), 4.16 (2H, q, —C*H*$_2$—CH$_3$, J = 7 Hz), 6.10 (1H, d, CH=C*H*, J = 16 Hz), 7.3 (1H, m, 5-H), 7.60 (1H, d, C*H*=CH, J = 16 Hz), 7.45–7.85 (5H, m, phenyl H), 10.01 (1H, s, —CHO). *Mol. Wt.* (high resolution ms) calcd. for $C_{21}H_{21}NO_6$: 383.13689; found: 383.1362.

(b) *Ethyl 2-formyl-4-carbethoxyvinylpyrrole-3-acetate* (**11**) (52 mg, 62.2%), mp 91°C from hexanes/dichloromethane; ir: 1625, 1680, 1725, 2950, 3230 cm^{-1}; nmr δ: 1.25 (3H, t, —C*H*$_3$, J = 7 Hz), 1.32 (3H, t, —C*H*$_3$, J = 7 Hz), 3.88 (2H, s, —C*H*$_2$COO), 4.19 (2H, q, —C*H*$_2$—CH$_3$, J = 7 Hz), 4.25 (2H, q, —C*H*$_2$—CH$_3$, J = 7 Hz), 6.18 (1H, d, CH=C*H*, J = 16 Hz), 7.40 (1H, m, 5-H), 7.61 (1H, d, C*H*=CH, J = 16 Hz), 9.70 (1H, s, —CHO), 10.35 (1H, b, NH). *Mol. wt.* (high resolution ms) calcd. for $C_{14}H_{17}NO_5$: 279.11066; found: 279.1102.

Ethyl 2-[(hydroxyimino)methyl]-4-carbethoxyvinylpyrrole-3-acetate (12) (oxime of 11)

Finely powdered hydroxylammonium chloride (1.5 g) was suspended in dry ethanol (25 mL) and titrated with aqueous NaOH (10 mol L^{-1}) to about pH 6. The NaCl was filtered and the clear solution kept under N_2 for use.

The aldehyde diester (**11**) (121 mg, 0.433 mol), in dry ethanol (5 mL), was treated with a solution of hydroxylamine (0.75 mL, 0.65 mmol) and stirred under N_2 at room temperature for 1.5 h. Then a further amount of the hydroxylamine solution (0.5 mL, 0.43 mmol) was added and, after 30 min stirring, tlc showed complete reaction. The solution was diluted with water (30 mL), the pH adjusted (if necessary) to near 7, then ethanol was removed under reduced pressure (bath temperature about 35°C). After 2 h of refrigeration the oxime was recovered by filtration. The mother liquors were concentrated and refrigerated to give a second crop of oxime. The total recovery of aldoxime diester, **12**, was 113 mg (88%), mp 117.5–118°C from toluene; ir: 1650, 1700, 2900, 3300 cm^{-1}; nmr[4] δ: 1.29 (3H, t, —CH$_3$, J = 7 Hz), 1.35 (3H, t, —CH$_3$, J = 7 Hz), 3.68 (2H, s, —CH$_2$COO), 4.17 (2H, q, —C*H*$_2$CH$_3$, J = 7 Hz), 4.26 (2H, q, —C*H*$_2$CH$_3$, J = 7 Hz), 6.13 (1H, d, CH=C*H*, J = 16 Hz), 7.11 (1H, m, 5-H), 7.63 (1H, d, C*H*=CH, J = 16 Hz), 8.10 (1H, s, —CH=N), 9.4 (1H, b, NH); m/z = 294. *Anal.* calcd. for $C_{14}H_{18}N_2O_5$: C 57.13, H 6.16, N 9.52; found: C 56.98, H 6.18, N 9.47.

*Ethyl 4,5,6,7-tetrahydro-5-oxo-1*H*-pyrrolo-[2,3,c]pyridine-3-propanoate (2)* (porphobilinogen lactam ethyl ester)

An aqueous solution of 1 mol L^{-1} HCl (0.136 mL, 0.136 mmol) was added to the aldoxime diester **12** (40 mg, 0.136 mmol) in dry ethanol (20 mL). Hydrogenation took place at room temperature and atmospheric pressure over palladium black (10 mg) until about 3.1 molar equivalents had been taken up (1.5 to 2 h). The bright yellow solution was filtered from the catalyst, cooled to 0°C, and sodium ethoxide (0.75 mL of a solution of 138 mg Na in 20 mL ethanol) was added to bring the pH to about 8. After stirring 1 h at room temperature in the dark, the solution was brought to pH 5–6 with glacial acetic acid and evaporated under reduced pressure (bath temperature 40°C) until first cloudiness. The mixture was quickly warmed to redissolve the precipitate and refrigerated overnight.[5] The white precipitate was collected and washed with dry ether to give pure porphobilinogen lactam ethyl ester (**2**). A second crop was obtained by further evaporation and refrigeration of the mother liquor. Total yield 25.5 mg (79%), mp 248°C, mixture mp with the product from the earlier route (1), was undepressed. Proton spectra were identical; m/z = 236.

1-Benzoyl-4-iodopyrrole-2-carbonitrile

A mixture of 4-iodopyrrole-2-carbonitrile (1) (2.18 g, 10 mmol), sodium hydroxide powder (0.66 g, 170 mmol), and tetrabutylammonium hydrogen sulfate (0.17 g, 0.50 mmol) in 15 mL of dichloromethane was cooled in an ice bath. A solution of benzoyl chloride (2.10 g, 15 mmol) in dichloromethane was added dropwise over 30 min. The reaction mixture was stirred at the same temperature (ice bath) for 60 min. Dichloromethane (20 mL) was then added, and the organic extract was washed with water (1 × 20 mL), saturated brine (1 × 20 mL), and dried ($MgSO_4$). The solvent was removed, and the pale green solid product was recrystallized from dichloromethane/petroleum to give 1-benzoyl-4-iodopyrrole-2-carbonitrile (2.52 g, 78%), mp 171–172°C; ir: 1715, 2230 cm^{-1}; nmr δ: 7.65 (5H, m), 7.28 (1H, d), 7.15 (1H, d). *Anal.* calcd. for $C_{12}H_7IN_2O$: C 44.75, H 2.19, H 8.70; found: C 44.79, H 2.24, N 8.69.

1-Benzoyl-4-carbethoxyvinylpyrrole-2-carbonitrile and 4-carbethoxyvinylpyrrole-2-carbonitrile

A mixture of 1-benzoyl-4-iodopyrrole-2-carbonitrile (500 mg, 1.6 mmol), palladium(II) acetate (8 mg), triethylamine (260 mg, 2.6 mmol), ethyl acrylate (230 mg, 2.3 mmol), and CH_3CN (1 mL) was stirred and heated at 100°C for 30 min as described above. Following work-up, the crude product was found by ^1H nmr to contain about a 60:40 mixture of 1-benzoyl-4-carbethoxyvinylpyrrole-2-carbonitrile and 4-carbethoxyvinylpyrrole-2-carbonitrile. Conversion to the crude product mixture was about 75%. Flash chromatography gave the following in order of elution.

(a) *1-Benzoyl-4-carbethoxyvinylpyrrole-2-carbonitrile*, mp 138–139°C after sublimation; nmr δ: 1.30 (3H, t, J = 7 Hz), 4.23 (2H, q, J = 7 Hz), 6.23 (1H, d, J = 16 Hz), 7.2–7.8 (8H, m). *Mol. Wt.* (high resolution ms) calcd. for $C_{17}H_{14}N_2O_3$: 294.10044; found: 294.0996.

(b) *4-Carbethoxyvinylpyrrole-2-carbonitrile*, mp 136–137°C after sublimation; nmr δ: 1.32 (3H, t, J = 7 Hz), 4.25 (2H, q, J = 7 Hz), 6.17 (1H, d, J = 16 Hz), 7.07 (1H, m), 7.20 (1H, m), 7.56 (1H, d, J = 16 Hz). *Anal.* calcd. for $C_{10}H_{10}N_2O_2$: C 63.15, H 5.30, N 14.73; found: C 63.01, H 5.31, N 14.70.

Conductance studies in amide–water mixtures. VI. Nitrates of sodium, potassium, and ammonium in *N,N*-dimethylformamide–water mixtures at 25°C

LAL BAHADUR AND M. V. RAMANAMURTI

Department of Chemistry, Faculty of Science, Banaras Hindu University, Varanasi-221005, India

Received July 14, 1983

LAL BAHADUR and M. V. RAMANAMURTI. Can. J. Chem. **62**, 1051 (1984).

Conductance data for the nitrates of sodium, potassium, and ammonium in *N,N*-dimethylformamide (DMF) – water mixtures ($74.39 \geq D \geq 36.11$) at 25°C are reported for the concentration range 0.0003–0.06 mol dm^{-3}. Also densities, viscosities, and dielectric constants of the solvent mixture (DMF–water) are reported at the same temperature. The data have been analysed by the Fuoss (1978) equation excluding the term α. The existence of a maximum in the viscosity at a 1:3 mol ratio of DMF and water is attributed to the formation of a solvated complex $DMF.3H_2O$. The Walden products for all the three salts pass through a maximum while the equivalent conductances show a minimum with the change of DMF content in the solvent mixtures. In any given solvent mixture, the limiting equivalent conductances show the trend $NaNO_3 < KNO_3 < NH_4NO_3$. The existence of a maximum in Walden product is attributed to the dehydration of ions due to presence of the cosolvent (DMF). For all the three salts, the association constant was negligible ($K_A < 10$) in all the solvent mixtures studied.

LAL BAHADUR et M. V. RAMANAMURTI. Can. J. Chem. **62**, 1051 (1984).

Opérant à 25°C, dans des mélanges de *N,N*-diméthylformamide (DMF) – eau ($74{,}39 \geq D \geq 36{,}11$) et à des concentrations allant de 0,0003 à 0,06 mol dm^{-3}, on a mesuré les conductivités des nitrates de sodium, de potassium et d'ammonium. On rapporte aussi, à la même température, les densités, les viscosités et les constantes diélectriques des mélanges de solvants (DMF–eau). On a analysé les données à l'aide de l'équation de Fuoss (1978) en excluant le terme α. C'est à la formation d'un complexe solvaté $DMF.3H_2O$ qu'on attribue la présence d'un maximum dans la viscosité à un rapport molaire de 1:3 de DMF et d'eau. Les produits de Walden, pour les trois sels, passent par un maximum alors que les conductivités équivalentes présentent un minimum avec une variation de la concentration de DMF dans les mélanges de solvants. Dans chacun des mélanges de solvants, les conductivités limites équivalentes varient dans l'ordre suivant: $NaNO_3 < KNO_3 < NH_4NO_3$. On attribue la présence d'un maximum dans le produit de Walden à la déshydratation des ions due à la présence du cosolvant (DMF). Pour les trois sels, la constante d'association est négligeable ($K_A < 10$) pour tous les mélanges de solvants étudiés.

[Traduit par le journal]

Introduction

In our previous works (1–5) in this series of investigations it has been observed that the conductance behaviour of electrolyte solutions in formamide–water (F–H_2O) mixtures (1, 5) is quite different from that observed in *N,N*-dimethylformamide–water (DMF–H_2O) (2) and *N,N*-dimethylacetamide–water (DMA–H_2O) mixtures (3, 4). For salts studied in DMF–H_2O and DMA–H_2O mixtures, Walden product – solvent composition curves show maxima at nearly the same solvent composition (~10 mol% amide). However, for salts studied in F–H_2O mixtures, entirely different trend in Walden product was observed (5). In F–H_2O mixtures, tetralkylammonium bromides showed maxima in Walden product at ~70 mol% formamide solvent composition while cesium bromide does not show any such maximum and in the case of lithium bromide a minimum in Walden product was observed with the change in solvent composition. Apart from this, some unsatisfactory results were obtained in these investigations regarding the distance parameter R. In some cases, it was found that R does not vary systematically with solvent properties while in other cases, almost constant values of R were obtained (5). These R's are physically meaningless, since they are less than the sum of the crystallographic radii of the constituent ions of the electrolyte.

These observations gave the stimulus to study some more electrolytes in aqueous binary mixtures of amides with particular interest to see the trend in Walden product and distance parameter with the variation of solvent composition. This is, therefore, a continuation of an attempt to generalize or categorize, if possible, the observations and to draw some definite conclusions.

The present paper contains the conductance data for the nitrates of sodium, potassium, and ammonium in DMF–H_2O mixtures at 25°C covering the whole range of solvent composition. Solvent properties like densities, viscosities, and dielectric constants (6) are also reported.

Experimental

Water, potassium chloride, and *N,N*-dimethylformamide were purified as described earlier (2). Potassium nitrate, sodium nitrate, and ammonium nitrates (all A.R., B.D.H.) were recrystallized twice from conductivity water. Samples were dried and stored over phosphorus pentoxide under vacuum.

All the experimental techniques and procedures for the measurements of density and viscosity of the solvent mixtures and conductance of electrolyte solution have been described in detail previously (2). Dielectric constants of the solvent mixtures were taken from the literature (6).

Result and discussion

In Table 1 densities, ρ, viscosities, η, and dielectric constants (6), D, of DMF–H_2O mixtures are reported at 25°C. Equivalent conductance, Λ, of electrolyte solutions as a function of concentration, c, is given in Table 2 for sodium nitrate, potassium nitrate, and ammonium nitrate in DMF–H_2O mixture of different concentrations at 25°C. For a given set of conductance data (c_j, Λ_j; $j = 1, n$), three adjustable parameters Λ_0, K_A, and R were obtained by solving the following equations:

$$[1] \quad \Lambda = \nu[\Lambda_0(1 + RX) + EL]$$

$$[2] \quad \nu = 1 - K_A c \nu^2 f^2$$

$$[3] \quad -\ln f = \beta\kappa/2(1 + \kappa R)$$

Here R is the cosphere diameter (7) and RX and EL are the relaxation and hydrodynamic terms, respectively, derived by

TABLE 1. Properties of the solvent mixtures (DMF–H_2O) at 25°C

DMF (mol%)	D*	ρ (g/mL)	η (10^{-2} P)
0	78.39	0.99707	0.8903
10	71.24	0.9973	1.7552
30	58.06	0.9923	2.4998
40	53.06	0.9848	2.2548
50	48.89	0.9766	1.8791
70	43.09	0.9631	1.3078
100	36.71	0.9439	0.8020

* Values taken from the literature (9).

Fuoss (8). Other terms have their usual meaning. Although the expressions used here for *RX* and *EL* were the same as those derived by Fuoss (8) in his 1978 version of concentration–conductance equations, the introduction of a new term α, as suggested by Fuoss (8), and consequently the replacements of ν by $[1 - \alpha(1 - \nu)]$ in eq. [1] and K_A by $K_R/(1 - \alpha)$ in eq. [2] have been avoided here as in our previous publications (3–5). The reason for this has already been given (5). The detailed method of analysis of the data has been described elsewhere (3). Various parameters thus derived from the conductance data are summarized in Table 3.

The viscosity of the solvent mixture (DMF–H_2O) increases rapidly with increasing DMF content to a maximum of nearly 2.8 times the viscosity of water and decreases afterwards with slow rate (Fig. 1). The maximum in η corresponds to ~25 mol% DMF, possibly indicating the maximum amount of structuredness in this binary mixture at 1:3 mole ratio of DMF and water, respectively. Assarsson and Eirich (9) have also observed maximum in η at the same composition of various other dialkylamide–water mixtures. In aqueous *N,N*-dimethylformamide of this composition, an extreme of several other properties of solutions has also been reported (10–13). The present observation clearly indicates the strong structure formation between DMF and water molecules, probably through hydrogen bonding, and a maximum in η can be attributed to the formation of the solvated complex DMF.$3H_2O$. These are in agreement with the findings of other workers (6, 9, 12, 14) who have studied the same solvent mixture through other properties. From the curve η vs. solvent composition, it is clear that the effect of the addition of DMF to water is more pronounced than that of the addition of water to DMF as indicated by the rate of change of viscosity. A similar conclusion was drawn by Visser and Somsen (14) on the basis of their study of heat capacities of DMF–water mixtures. Also the comparison of present observation at 25°C with what has already been reported (2) at 35°C indicates that the percentage composition corresponding to maximum viscosity and the nature of the viscosity curve are not affected by the change in temperature from 25 to 35°C.

The variation of limiting equivalent conductance, Λ_0, with the solvent composition for $NaNO_3$, KNO_3, and NH_4NO_3 in DMF–H_2O mixtures at 25°C is represented in Fig. 1. The values of Λ_0 for the three salts in pure water (15, 16) and DMF (16) are taken from the literature. The limiting equivalent conductance decreases with the corresponding increase in viscosity of the solvent mixture, but it is evident that these variations do not compensate each other to give the Walden product a constant value (Fig. 2). As well, the maximum in viscosity does not coincide with the observed minimum in Λ_0 (Fig. 1). This means that the percentage composition of the solvent for maximum η does not agree with the same for minimum conductance. This indicates the simultaneous control of the other factors on Λ_0 along with the hydrodynamic viscous force which in turn affects the speed of ions. It is obvious that the dielectric constant is not involved in affecting the values of Λ_0 since it controls the ionization which is expected to be complete at zero (limiting) concentration. The shift of minimum in Λ_0 towards the richer region in DMF can partially be explained on the basis of ion–solvent interactions. Since water molecules are smaller than DMF molecules, the hydrodynamic entity of an ion solvated with water will be smaller than a DMF-solvated one provided the solvation numbers are almost the same. Consequently, the mobility of solvated ion in DMF-rich region will be smaller than in water-rich region, resulting in further decrease in Λ_0 in DMF-rich region, as observed. This can also be interpreted as a preferential solvation of ions by DMF. The limiting equivalent conductance, Λ_0, varies in the order $NH_4NO_3 > KNO_3 > NaNO_3$ in any given solvent mixture. For the evaluation of ionic conductances, data for limiting transport numbers of the constituent ions of these electrolytes are not available in DMF–water mixtures and the method proposed by Gill (17) also was not found to be satisfactory for the present systems. However, by applying Kohlrausch's law it can safely be concluded that the independent ionic mobilities of the respective cations also change in the same order, viz., $NH_4^+ > K^+ > Na^+$ since the anion (NO_3^-) is the same. Now, the comparison of this trend in mobility with the crystallographic size of ions, which is in the order (18, 19) $NH_4^+ > K^+ > Na^+$, shows that the larger the size of the bare ion, the greater its ionic mobility; this is contrary to expectation. However, it is well known that these ions do not exist as bare ions in solutions but are solvated. The trend of variation of ionic mobilities should, therefore, indicate the relative actual sizes of ions as they exist in solutions concerned. In other words, the sizes of these cations as they exist in solution follow the order $Na^+ > K^+ > NH_4^+$, which should indicate the extent of solvation, i.e., Na^+ is the most solvated and NH_4^+, the least. This can be attributed to the charge density of these cations which varies in the order $Na^+ > K^+ > NH_4^+$ because their size (18, 19) varies in reverse order. Thus the ion having maximum charge density (Na^+) will be the most solvated while the ion having minimum charge density (NH_4^+) will be the least solvated. Similar trend has been reported (20) in other solvents also.

The variation of the Walden product with solvent composition is shown in Fig. 2. It passes through a maximum at nearly 15 mol% DMF and then decreases rapidly with the increase in DMF content in the solvent mixtures. Nearly twofold variation in Walden product was observed. This large variation in Walden product also indicates strong ion–solvent interaction in the system under study as concluded from the shift of minimum in Λ_0 from the point corresponding to maximum η towards the region rich in DMF (Fig. 1).

That the Walden product varies with the composition of mixed polar solvents is now well established. Several significant reasons were suggested for this variation and their mathematical treatments have also been given by different workers (21–33) from time to time especially during the last two decades. A critical assessment of all these various existing theories regarding ion–solvent interactions clearly indicates that even the latest theory fails to predict (or explain) the experimental results satisfactorily though a few "selected" systems apparently seem to respond. In such circumstances, it is, therefore, desirable that before looking for a better theory, all existing theories should be thoroughly tested for a variety of electrolyte

*$X_{(range)}$ (X being K_A or R) corresponds to $\sigma \leq 1.1\sigma_{min}$ and other values correspond to $\sigma = \sigma_{min}$.

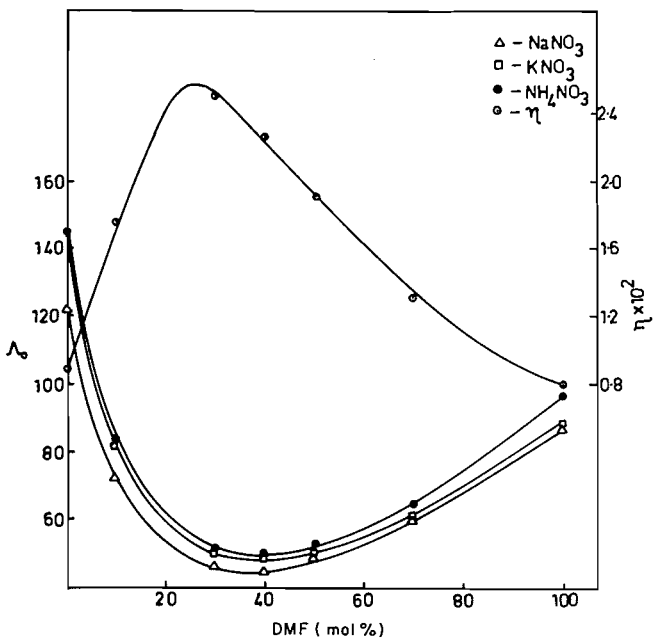

FIG. 1. Variation of viscosity of the solvent, η, and limiting equivalent conductance, Λ_0, with composition of the solvent mixtures.

solutions. We then assess to see if we can find the one theory closest to experimental results for most of the systems so far studied. Then and only then attempts should be made to improve that theory as far as possible. This will be the main object of our future publication and it is the reason for our not testing any one of the existing theories, say even the latest one, here for the limited systems presented in this paper.

Because of reasons mentioned above, it seems difficult at this stage to compare theoretically predicted values of mobility of ions, and in turn Walden product, $\Lambda_0\eta$, with that obtained experimentally. Some plausible interpretations can be given for the qualitative variation of Walden product with solvent composition for the systems in the present work. From Fig. 2 it is clear that the maximum in Walden product is obtained in all the three salts and the height of the maximum from the point corresponding to pure water as solvent is not the same for different salts. But this height shows a trend $NH_4NO_3 \approx KNO_3 < NaNO_3$. If we consider the Λ_0 values in water as the measure of structure breaking effect of the ions, we find the order for cations (anion, NO_3^-, being the same) $NH_4^+ \approx K^+ > Na^+$. If the excess mobility (i.e., maximum in Walden product) is due to a structure-breaking effect of the ions, the magnitude of this effect (i.e., the height of maximum from the point corresponding to pure water as solvent) should follow the order $NH_4^+ \approx K^+ > Na^+$, which is the reverse of the order observed (Fig. 2). Thus the existence and the magnitude of the excess mobility can not be simultaneously explained on the basis of structure-breaking effect of ions. Alternatively, both can be explained on the basis of dehydration of ions due to cosolvent (DMF). Let us consider first the electrolyte in water and then the addition of DMF. The presence of DMF molecules may cause the dehydration of ions giving excess mobility of ions producing a maximum in Walden product in the water-rich region. Moreover, ions may also be solvated with the second component (DMF) of the solvent mixture. This effect will increase with increasing DMF content in the solvent mixture. Thus dehydration of ions will be more effective in the water-rich region giving excess mobility of ions while the solvation of ions with DMF molecules will be more effective in the DMF-rich region, resulting in further decrease of Walden product. This explains the variation of Walden product with solvent composition. Since the maximum in Walden product exists due to dehydration of ions, the height of maximum, therefore, will depend

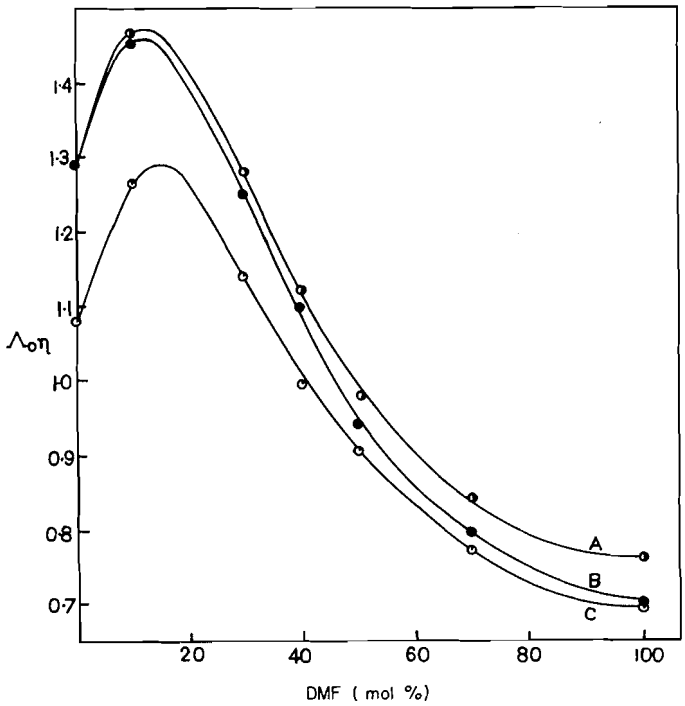

FIG. 2. Variation of Walden product with composition of the solvent mixtures. *A*, NH_4NO_3; *B*, KNO_3; *C*, $NaNO_3$.

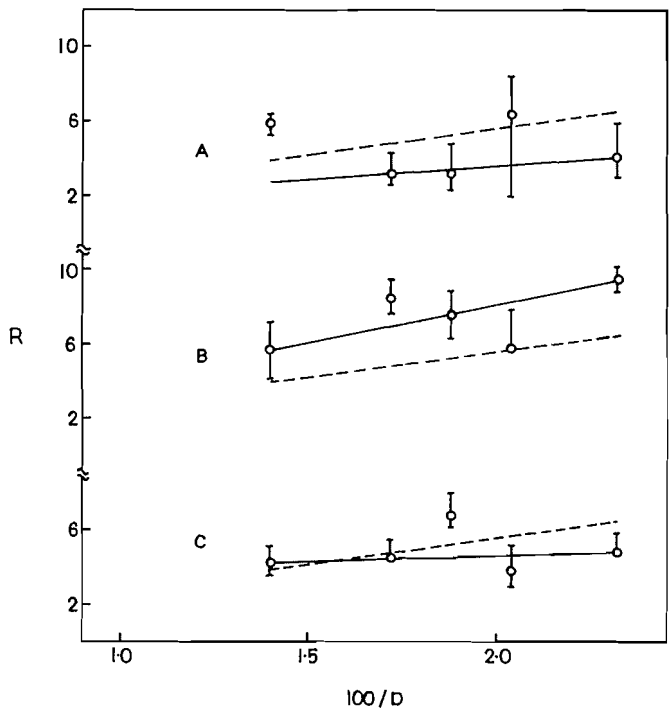

FIG. 3. Variation of pairing radius *R* with reciprocal of the dielectric constant of the solvent mixtures. *A*, NH_4NO_3; *B*, KNO_3; *C*, $NaNO_3$. Dotted line represents $\beta/2$.

upon the extent of dehydration of ions. Now dehydration will be more effective in case of more hydrated ion. Hydration of cations (anion being the same) follows the order $NH_4^+ \approx K^+ < Na^+$ (on the basis of Λ_0 values in water), so the order of dehydration and consequently the order of the height of maximum in Walden product should be the same, as was observed. A similar idea was successfully applied in other electrolytes also (2). Kay and co-workers (34, 35) also explained the existence of similar maxima in Walden product for different electrolytes in other aqueous binary mixtures on the basis of similar mechanism while they proposed salting-out effect in their recent work (36).

Association constants for all the systems are practically negligible (i.e., $K_A < 10$). So the numerical values of K_A should not be taken seriously. One can only conclude that all three electrolytes exist as free ions in the solvent mixtures. This is expected also because dielectric constants of solvent mixtures are fairly high ($36.7 \leq D \leq 78.39$). It is a general practice that $K_A < 10$ is neglected. However, recently Fuoss and co-workers (37) attempted to find the physical significance, rather than the mathematical parameter only, of an association constant even if it was less than 10. They were not able to arrive at any useful conclusion. Variation of the pairing radius *R* with reciprocal of the dielectric constant of the solvent mixture is shown in Fig. 3 for different salts. The dotted line shows the variation of Bjerrum radius ($\beta/2$). Perpendicular lines in this plot show the limits of *R* values corresponding to $\sigma \leq 1.1\sigma_{min}$ and circles correspond to best values (i.e., $\sigma = \sigma_{min}$). An attempt has been made to draw the best possible curves shown by solid lines to show the variation of *R* with $1/D$. However, due to the wider ranges of acceptable *R* values (which reproduce data within $1.1\sigma_{min}$) these lines should not be taken too seriously. Consequently, it is difficult to draw any definite conclusion.

Thus, on the basis of our present as well as previous works (2–4) it can be concluded here that the Walden product for different salts studied in aqueous binary mixtures of DMA and DMF varies systematically with solvent composition, showing a maximum corresponding to the solvent mixture containing 10–15 mol% amide, unlike the behaviour observed in F–H_2O mixture (5) where no similar trend was observed with different electrolytes. Thus, it will require further extensive study to arrive at any general conclusion about the conductance behaviour of various electrolytes in aqueous binary mixtures of different amides (non, mono, and dialkylated). Some more systems are under study and results will appear in future papers.

Received October 19, 1983

BRENDA M. LOUIE, STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **62**, 1057 (1984).

The synthesis and characterization of the complexes $[Me_2Gapz_2]Rh(LL)$ (where LL = COD, $(CO)_2$, $(PPh_3)_2$, or $(PPh_3)(CO)$), incorporating the bidentate, chelating, dimethylbis(1-pyrazolyl)gallate ligand are described. Non-rigidity in solution has been demonstrated by ^1H nmr studies for some of the complexes. A crystal structure determination of the COD complex has confirmed the boat conformation for the Ga—(N—N)$_2$—Rh six-membered ring in this complex in the solid state. In addition, the solid state structures of the 3,5-dimethylpyrazolyl bridged dirhodium complexes $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$ and $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(COD)]_2$ have been determined. Crystals of $[Me_2Gapz_2]Rh(COD)$ are orthorhombic, a = 22.7447(8), b = 11.9776(5), c = 6.4635(3) Å, Z = 4, space group *Pnma*; those of $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$ are monoclinic, a = 8.7403(6), b = 16.3594(6), c = 25.434(2) Å, β = 95.286(3)°, Z = 8, space group $P2_1/c$; and those of $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(COD)]_2$ are triclinic, a = 10.350(2), b = 11.401(2), c = 12.355(2) Å, α = 112.485(7), β = 99.394(9), γ = 105.387(8)°, Z = 2, space group $P\bar{1}$. All three structures were solved by conventional heavy atom techniques and were refined by full-matrix least-squares procedures to final conventional R values of 0.026, 0.024, and 0.037 for 1824, 5135, and 6109 reflections with $I \geq 3\sigma(I)$, respectively. In each case the Rh atoms have distorted square planar coordination geometry. Important mean structural parameters are Rh—N = 2.087(2), Rh—C = 2.129(2), Rh···Ga = 3.5527(5) Å for $[Me_2Gapz_2]Rh(COD)$; Rh—N = 2.063(6), Rh—CO = 1.852(9), Rh···Rh = 3.262(4) Å for $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$; and Rh—N = 2.084(1), Rh—C = 2.131(7), Rh···Rh = 3.1538(3) Å for $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(COD)]_2$.

BRENDA M. LOUIE, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **62**, 1057 (1984).

On décrit la synthèse et la caractérisation de complexes $[Me_2Gapz_2]Rh(LL)$ (où LL = COD, $(CO)_2$, $(PPh_3)_2$ ou (PPh_3) (CO)) incorporant le ligand chélatant bidenté diméthylbis(pyrazolyl-1) gallate. Pour certain de ces complexes, on a démontré l'absence de rigidité en solution grâce à des études de rmn du ^1H. Une détermination de la structure du cristal du complexe avec le COD confirme la conformation bateau, à l'état solide, du cycle à 6 chaînons Ga—(N—N)$_2$—Rh de ce complexe. De plus, on a déterminé les structures, à l'état solide, des complexes pontés du diméthyl-3,5 pyrazolyl dirhodium, $[Rh(\mu\text{-}Me_2\text{-}3,5pz)(CO)_2]_2$ et $[Rh(\mu\text{-}Me_2\text{-}3,5\ pz)(COD)]_2$. Les cristaux du $[Me_2Gapz_2]Rh(COD)$ sont orthorhombiques et appartiennent au groupe d'espace *Pnma* avec a = 22,7447(8), b = 11,9776(5), c = 6,4635(3) Å, Z = 4. Ceux de $[Rh(\mu\text{-}Me_2\text{-}3,5\ pz)(CO)_2]_2$ sont monocliniques avec a = 8,7403(6), b = 16,3594(6), c = 25,434(2) Å, β = 95,286(3)°, Z = 8 et groupe d'espace $P2_1/c$; et ceux de $[Rh(\mu\text{-}Me_2\text{-}3,5\ pz)(COD)]_2$ sont tricliniques, groupe d'espace $P\bar{1}$, avec a = 10,350(2), b = 11,401(2), c = 12,355(2) Å, α = 112,484(7), β = 99,394(9), γ = 105,387(8)° et Z = 2. On a résolu les trois structures par les techniques conventionnelles des atomes lourds et on les a affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs finales de R = 0,026, 0,024 et 0,037 pour respectivement 1824, 5135 et 6109 réflexions avec $I \geq 3\sigma(I)$. Dans chaque cas, les atomes de Rh ont une géométrie de coordination plan carré déformée. Les paramètres structuraux moyens importants sont: Rh—N = 2,087(2), Rh—C = 2,129(2), Rh···Ga = 3,5527(5) Å pour le $[Me_2Gapz_2]Rh(COD)$; Rh—N = 2,063(6), Rh—CO = 1,852(9), Rh···Rh = 3,262(4) Å pour le $[Rh(\mu\text{-}Me_2\text{-}3,5\ pz)(CO)_2]_2$; et Rh—N = 2,084(1), Rh—C = 2,131(7), Rh···Rh = 3,1538(3) Å pour le $[Rh(\mu\text{-}Me_2\text{-}3,5\ pz)(COD)]_2$.

[Traduit par le journal]

Introduction

As part of an ongoing study of pyrazolylgallate ligands our attention has recently focussed on the reactivity of the bidentate ligands, $[Me_2Gapz_2]^-$ and $[Me_2Ga(3,5\text{-}Me_2pz)_2]^-$ (where pz = pyrazolyl, $N_2C_3H_3$, and 3,5-Me_2pz = 3,5-dimethylpyrazolyl, $N_2C_5H_7$) (1–6), towards selected Rh(I) complexes. The new compounds $[Me_2Gapz_2]Rh(CO)_2$, $[Me_2Gapz_2]Rh(CO)(PPh_3)$, $[Me_2Gapz_2]Rh(PPh_3)_2$, and $[Me_2Gapz_2]Rh(COD)$ (COD = 1,5-cyclooctadiene) have been synthesized and shown to be non-rigid in solution by variable temperature ^1H nmr studies. Attempts to prepare analogous complexes using the $[Me_2Ga(3,5\text{-}Me_2pz)_2]^-$ ligand resulted only in the isolation of the bridged dimeric species $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$ and $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(COD)]_2$. X-ray crystallographic analyses of the latter two complexes and that of the $[Me_2Gapz_2]Rh(COD)$ compound are reported.

Experimental

Starting materials

Air-sensitive materials were handled in oxygen-free dry nitrogen. Tetrahydrofuran (THF) was dried by refluxing over sodium/benzophenone and used immediately following distillation. Benzene was dried by refluxing over molten potassium followed by distillation and methylene chloride by refluxing over P_2O_5 prior to distillation. $[Rh(CO)_2Cl]_2$ (Strem Chemicals) was sublimed *in vacuo* before use. $[Rh(COD)Cl]_2$ (Strem Chemicals), $Rh(PPh_3)_3Cl$ (Strem Chemicals), and PPh_3 (MCB) were used as supplied. The sodium salts of the two gallium ligands, $[Me_2Gapz_2]^-$ and $[Me_2Ga(3,5\text{-}Me_2pz)_2]^-$, were prepared as THF solutions as described earlier (1).

Preparation of $[Me_2Gapz_2]Rh(CO)_2$

Two molar equivalents of $Na^+[Me_2Gapz_2]^-$ in THF were added dropwise to a stirred solution of $[Rh(CO)_2Cl]_2$ (0.330 g, 0.849 mmol) in 75 mL THF held at 0°C. The resulting mixture was allowed to warm to room temperature and then stirred overnight. The mixture was filtered and solvent removed *in vacuo* from the orange filtrate to leave an orange oil. Attempted crystallization of this product from methylene chloride and/or benzene resulted only in the recovery of the orange oil which darkened if exposed to air. ^1H nmr and ir data for the complex are reported in Table 1. The mass spectrum (Varian MAT CH4B spectrometer 70 eV, probe at room temperature) of the compound showed a weak signal due to the parent ion, P^+ (1%), with the strongest signals corresponding to the P − Me^+ (100%) ion followed

by signals corresponding to ions resulting from successive loss of CO ligands viz P − Me − CO^+ (50%) and P − Me − $2CO^+$ (53%).

Preparation of [Me_2Gapz_2]Rh(CO)PPh_3

PPh_3 (0.175 g, 0.668 mmol) dissolved in 25 mL benzene was added to [Me_2Gapz_2]$Rh(CO)_2$ (0.25 g, 0.636 mmol) in 25 mL of the same solvent at room temperature. The color of the solution lightened from deep orange to orange–yellow with rapid evolution of CO. After stirring the reaction mixture for 5 min the solvent was removed *in vacuo* to yield the product as an orange–yellow powder in 90% yield, mp 130–131°C. Table 1 collects selected physical data. The mass spectrum (AEI MS50 spectrometer 70 eV, probe temperature 170°C) again displayed a weak signal due to the parent ion P^+ (1%) with stronger signals arising from P − Me^+ (40%), P − Me − CO^+ (33%), and PPh_3^+ (100%).

Preparation of [Me_2Gapz_2]Rh(PPh_3)$_2$

$Rh(PPh_3)_3Cl$ (0.379 g, 0.410 mmol) was stirred in 75 mL C_6H_6 and an equimolar amount of $Na^+[Me_2Gapz_2]^-$ ligand in 10 mL THF added. The reaction mixture was stirred for 3 days at room temperature and then filtered. Evaporation of the solvents from the filtrate left a yellow–orange powder. Free PPh_3 was sublimed from this material under vacuum at 70°C to leave the desired product in 93% yield, mp 127–129°C. Elemental analysis figures and selected ^{1}H nmr data are recorded in Table 1. The mass spectrum (AEI MS50 spectrometer, 70 eV, probe temperature 150°C) contained signals corresponding to the parent ion, P^+ (4%), P − Me^+ (1%), P − Me − PPh_3^+ (17%), and PPh_3^+ (100%).

Preparation of [Me_2Gapz_2]Rh(COD)

Two molar equivalents of $Na^+[Me_2Gapz_2]^-$ in THF were added to $[Rh(COD)Cl]_2$ (0.314 g, 0.637 mmol) in THF at 0°C. The reaction mixture was allowed to warm to room temperature and then stirred for approximately 6 h. The solvent was then removed *in vacuo* and the remaining yellow–orange residue extracted in a minimum amount of benzene and filtered. Slow evaporation of the benzene gave initially orange crystals of the dimer $[Rh(\mu\text{-pz})(COD)]_2$. The lemon yellow solution remaining, on further concentration, produced yellow crystals of the desired product in 40% yield, mp 105–106°C (the residue obtained on complete evaporation of the benzene solvent was shown to be primarily the dimer $[Me_2Ga(\mu\text{-pz})]_2$). The mass spectrum (Varian MAT CH4B spectrometer, 70 eV, probe temperature 80°C) of the desired product showed the presence of the parent ion P^+ (11%) with the strongest signal arising from the P − Me^+ ion (100%). Elemental analyses and ^{1}H nmr data for the complex are reported in Table 1.

Spectra

Infrared spectra were recorded on a Perkin-Elmer 598 spectrometer and ^{1}H nmr spectra on a Bruker WP-80 or Varian XL-100 instrument using FT techniques.

X-ray crystallographic analyses

[Dimethylbis(1-pyrazolyl)gallato-N^2,$N^{2'}$](1,5-cyclooctadiene)-rhodium(I)

A crystal bounded by the 10 faces (followed by their distances in mm from a common origin): (2 − 1 0), 0.138, (−1 1 2), 0.175, ±(1 0 0), 0.188, ±(1 0 −2), 0.200, ±(1 1 0), 0.150, (−3 2 0), 0.138, (−1 −1 −1), 0.163 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 40–49°) measured on a diffractometer with Mo-Kα radiation (λ($K\alpha_1$) = 0.70930, λ($K\alpha_2$) = 0.71073 Å). Crystal data at 22°C are as follows:

$C_{16}H_{24}GaN_4Rh$ fw = 445.02

Orthorhombic, a = 22.7447(8), b = 11.9776(5), c = 6.4635(3) Å, V = 1760.8(1) Å^3, Z = 4, ρ_c = 1.679 g cm^{-3}, F(000) = 896, μ(Mo-Kα) = 24.5 cm^{-1}. Absent reflections: 0kl, $k + l$ odd, and hk0, h odd, space group *Pnma* (D_{2h}^{16}, No. 62) from structure analysis.

Intensities were measured with graphite-monochromatized Mo-Kα radiation on an Enraf-Nonius CAD4-F diffractometer. An ω-2θ scan at 1.34–10.06° min^{-1} over a range of (0.65 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 60°. The intensities of three check reflections, measured every 3600 s throughout the data collection, showed only minor random fluctuations. After data reduction,[1] an absorption correction was applied using the Gaussian integration method (9, 10). Transmission factors ranged from 0.430 to 0.558 for 128 integration points. Of the 2660 independent reflections measured, 1824 (68.6%) had intensities greater than 3σ(I) above back-

ground where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The centrosymmetric space group *Pnma* was indicated by both the Patterson function and the *E*-statistics. The coordinates of the heavy atoms were determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference map. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to $R = 0.036$, a difference map revealed the positions of all 13 unique hydrogen atoms. The methyl and methylene hydrogen atoms were found not to refine satisfactorily and were fixed in idealized positions (C—H = 0.98 Å, recalculated after each least-squares cycle) in the final stages of refinement. The remaining H atoms were refined with isotropic thermal parameters. The scattering factors of ref. 11 were used for non-hydrogen atoms and those of ref. 12 for hydrogen atoms. Anomalous scattering factors from ref. 13 were used for the Rh and Ga atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of refinement. Unobserved reflections were not included in the refinement. Convergence was reached at $R = 0.026$ and $R_w = 0.034$ for 1824 reflections with $I \geq 3\sigma(I)$. For all 2660 reflections $R = 0.055$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.006 and 0.045σ, respectively. The mean error in an observation of unit weight was 1.441. A final difference map showed a maximum fluctuation of +0.50 e Å^{-3} in the vicinity of C(3). The final positional and thermal parameters appear in Tables 2 and 7,[2] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

Bis(μ-3,5-dimethylpyrazolyl-N,N')-bis[dicarbonylrhodium(I)]

Experimental details are as above except where noted. The six bounding faces of the crystal used for data collection were (0 −1 1), 0.144, ±(1 0 0), 0.150, (0 1 −3), 0.144, ±(0 1 1), 0.100 mm. Crystal data are as follows:

$C_{14}H_{14}N_4O_4Rh_2$ fw = 508.10

Monoclinic, a = 8.7403(6), b = 16.3594(6), c = 25.434(2) Å, β = 95.286(3)°, V = 3621.2(4) Å^3, Z = 8, ρ_c = 1.864 g cm^{-3}, $F(000)$ = 1984, μ(Mo-Kα) = 18.2 cm^{-1}. Absent reflections: $0k0$, k odd, and $h0l$, l odd, uniquely indicate the space group $P2_1/c$ (C_{2h}^5, No. 14).

An ω−2θ scan at 0.87−10.06° min^{-1} over a range of (0.50 + 0.35 tan θ)° in ω was employed. Of the 8281 independent reflections measured, 5135 had intensities greater than $3\sigma(I)$ above background and were employed in the solution and refinement of the structure. Transmission factors ranged from 0.607 to 0.727 for 108 sampling points.

The coordinates of the four independent Rh atoms were determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference map. After full-matrix least-squares refinement of the non-hydrogen atoms to $R = 0.038$, a difference map gave the positions of all H atoms, which were placed in idealized locations and included as fixed atoms in subsequent calculations. An isotropic type I extinction correction (Thornley−Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (14−16). The final value of g was 7.8(3) × 10^4. Convergence was reached at $R = 0.024$ and $R_w = 0.030$ for 5135 observed reflections, for all 8281 reflections, $R = 0.065$. The mean and maximum parameter shifts on the final cycle of refinement corresponded to 0.08 and 0.44σ respectively, and the mean error in an observation of unit weight was 1.475. The largest peak on the final difference map corresponded to 0.40 e Å^{-3}.

Bis(μ-3,5-dimethylpyrazolyl-N,N')-bis[(1,5-cyclooctadiene)-rhodium(I)]

The eight bounding faces of the crystal used for data collection were: ±(1 −1 0), 0.109, ±(1 0 −1), 0.121, ±(0 1 −1), 0.071, ±(3 2 6), 0.175 mm. Crystal data are as follows:

$C_{26}H_{38}N_4Rh_2$ fw = 612.42

Triclinic, a = 10.350(2), b = 11.401(2), c = 12.355(2) Å, α = 112.485(7), β = 99.394(9), γ = 105.387(8)°, V = 1240.2(3) Å^3, Z = 2, ρ_c = 1.640 g cm^{-3}, $F(000)$ = 624, μ(Mo-Kα) = 13.3 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ (C_i^1, No. 2, reduced cell) from structure analysis.

An ω−2θ scan at 1.26−10.06° min^{-1} in ω was employed. Of the 8919 independent reflections measured (to 2θ = 60°), 6109 had intensities greater than $3\sigma(I)$. Transmission factors ranged from 0.744 to 0.840 for 96 sampling points.

The centrosymmetric space group $P\bar{1}$ was indicated both by the *E*-statistics and by the Patterson function, from which the heavy atom coordinates were determined. The C and N coordinates were determined from a subsequent difference map. After refinement of all non-hydrogen atoms with anisotropic thermal parameters to R = 0.043, a difference map revealed the positions of all H atoms. As in the case of [Me_2Gapz_2]Rh(COD), the COD methylene H atoms did not refine well and were included as fixed atoms in idealized positions, the remaining H atoms being refined with isotropic thermal parameters. The structure was refined to $R = 0.037$ and $R_w = 0.045$ for 6109 observed reflections, for all 8919 reflections $R = 0.065$. The mean and maximum parameter shifts on the final cycle of refinement corresponded to 0.04 and 0.78σ (the latter for a hydrogen coordinate) respectively, and the mean error in an observation of unit weight was 1.918. A final difference map showed maximum fluctuations of ±1.2 e Å^{-3} near the Rh atoms and ±0.40 e Å^{-3} elsewhere.

Analysis of thermal motion

The thermal motion in all three structures (Fig. 2) has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (17). The rms errors in the U_{ij} (derived from the least-squares analyses) are 0.0016, 0.0024, and 0.0020 Å^2 respectively for the three compounds. The analyses carried out were as follows (rms ΔU_{ij} Å^2 in parentheses): RhGapz (0.0015), GaC_2N_2 (0.0020), and Rh(COD) (0.0041) for [Me_2Gapz_2]Rh(COD); N_2C_5 (0.0019, 0.0016, 0.0014, 0.0014), corrections for $N_2Rh(CO)_2$ approximated from the analysis of the entire molecules (0.0070, 0.0072) of [Rh(μ-3,5-Me_2pz)-$(CO)_2]_2$; all but uncoordinated COD carbons (0.0039), corrections involving COD methylene carbons approximated from two Rh(COD) (0.0052, 0.0090) for [Rh(μ-3,5-Me_2pz)(COD)]$_2$. The appropriate bond distances have been corrected for libration (17, 18), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 4. Intra-annular torsion angles defining the conformations of the M_2N_4 and COD rings are listed in Table 5. Calculated hydrogen coordinates and thermal parameters (Table 6) are included as supplementary material.

Results and discussion

There have been a number of reports dealing with Rh(I) complexes containing polypyrazolyl borate ligands such as [R_2Bpz_2]$^-$ (where R = H, Et, or pz) (19−27). The majority of these complexes incorporate bidentate ligands and display a square planar Rh environment, although a few examples have been reported which contain tridentate borate ligands and a 5-coordinate Rh metal centre. The present paper deals with a number of Rh(I) complexes incorporating the [Me_2Gapz_2]$^-$ ligand.

The complex [Me_2Gapz_2]Rh(CO)$_2$ has been isolated as an orange liquid which darkens in color when exposed to air. It can be compared to the similar boron complexes, [R_2Bpz_2]Rh(CO)$_2$ (R = H (20, 21) or Et (22)), in that it displays

[2] The structure factor table, Table 7 (anisotropic thermal parameters), and other material mentioned in the text are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

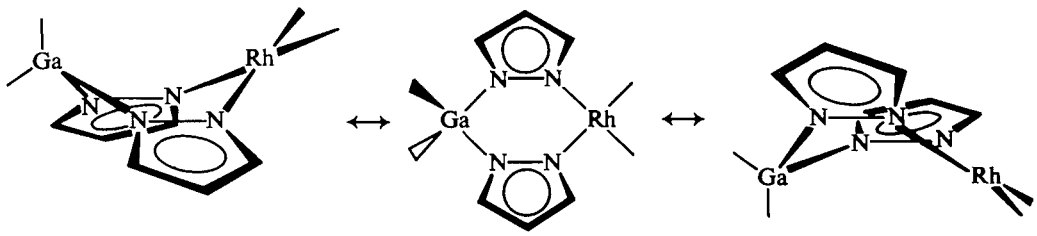
two strong ν_{CO} bands in its ir spectrum and equivalent pyrazolyl groups in its ^{1}H nmr spectrum, both consistent with a square planar arrangement about the Rh(I) metal centre. The dicarbonyl derivative reacts readily with PPh_3 to yield an air-stable solid in which just one carbonyl group is replaced by the phosphine ligand, $[Me_2Gapz_2]Rh(CO)(PPh_3)$. The ^{1}H nmr of this complex indicates two different pyrazolyl groups as expected. The cyclooctadiene (COD) complex, $[Me_2Gapz_2]$-Rh(COD), has been isolated as air-stable yellow crystals and again shows two equivalent pz groups in its ^{1}H nmr spectrum. Interestingly the "Me_2Ga" moiety in each of the above three complexes displays but one sharp singlet in the ^{1}H nmr spectra at room temperature (see Table 1 and Figs. 1 and 2). This would suggest either a planar geometry for the Ga—(N—N)$_2$—Rh six-membered rings in solution or a rapidly inverting boat conformation viz:



Molecular models indicate that the favored structure should be the boat conformation and to probe the solution behaviour of the complexes, low temperature ^{1}H nmr studies on the $[Me_2Gapz_2]Rh(CO)(PPh_3)$ and $[Me_2Gapz_2]Rh(COD)$ compounds were carried out (Figs. 1 and 2). As expected, the single "$GaMe_2$" signal observed at room temperature for each of these compounds collapses as the temperature is lowered and eventually appears as two singlets. This is accompanied by a shift in the signals due to the pyrazolyl protons as can be clearly seen in Fig. 1. In addition the spectra of the COD complex (Fig. 2) show a splitting of the signals due to the protons on the COD ligand at the lower temperatures, particularly noticeable for the olefinic protons closest to the Rh atom at around 5.8 τ. These observations are consistent with a fluxional behaviour in solution at room temperature giving an average planar Ga—(N—N)$_2$—Rh ring as shown above. A similar mechanism has been proposed for the observed fluxional behaviour in solution of the complexes $[Me_2Ga(3,5\text{-}Me_2pz)_2]Ni(\eta^3\text{-}C_3H_5)$ (5) and $[Me_2Gapz_2]_2Ni$ (3). In both these species at higher temperatures a single "$GaMe_2$" resonance is observed but on cooling the solution this signal broadens, collapses, and is replaced by two singlets at lower temperatures consistent with static boat conformations for the Ga—(N—N)$_2$—Ni six-membered rings at these temperatures.

The puckered nature of the Ga—(N—N)$_2$—Rh six-membered ring in the complex $[Me_2Gapz_2]Rh(COD)$ has been clearly demonstrated in the solid state by a crystal structure determination (see below). It is interesting to compare $[Me_2Gapz_2]Rh(COD)$ with the recently reported compound $B(pz)_4Rh(COD)$ (24, 25). For the latter, in the solid state, a crystallographic study has determined that the Rh(I) centre is four-coordinate with two pz groups bridging the B and Rh atoms while the other two pz groups occupy the remaining tetrahedral positions about the B atom. Interestingly, a proton nmr study indicates that all the pz groups are equivalent at room temperature, but at lower temperatures the pz groups are indicated to be of two types in the ratio of 3:1. In this complex it is proposed that all four pz groups exchange in solution at room temperature via a pentacoordinate trispyrazolyl borate rhodium intermediate.

The complex $[Me_2Gapz_2]Rh(PPh_3)_2$ has been prepared by the reaction of the $[Me_2Gapz_2]^-$ ligand with Wilkinson's catalyst, $Rh(PPh_3)_3Cl$. For this complex the room temperature ^{1}H nmr spectrum, in either C_6D_6 or d_6-acetone, shows two broad signals in the "$GaMe_2$" region of the spectrum, suggesting that the fluxional process observed for the three complexes discussed above is somewhat less facile for the present compound. The presence of the two bulky phosphine ligands on the Rh atom might be expected to hinder the fluxional process but varying the temperature of the solutions did lead to the expected changes in the ^{1}H nmr spectra. Thus cooling the solutions caused a significant sharpening of the signals due to the "$GaMe_2$" protons whereas warming the solutions caused further broadening of these signals.

The phosphine complexes prepared in this study, $[Me_2Gapz_2]Rh(CO)(PPh_3)$ and $[Me_2Gapz_2]Rh(PPh_3)_2$, have been investigated as potential catalysts for the hydrogenation of olefins (cyclohexene or 1-hexene) in benzene solution at room temperature. No hydrogen uptake by the olefins was observed in any of the experiments.

Our attempts to prepare the analogous complexes containing the $[Me_2Ga(3,5\text{-}Me_2pz)_2]^-$ ligand were thwarted by the facile formation of the dimer species, $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$ and $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(COD)]_2$. It is speculated that disproportionation of the gallate ligand is occurring and that this is enhanced by the ready incorporation of the pyrazolyl moieties so produced into the very stable bridged Rh dinuclear species. For example:

$$2\ Na^+[Me_2Ga(3,5\text{-}Me_2pz)_2]^- + [Rh(COD)Cl]_2 \rightarrow$$

$$[Me_2Ga(\mu\text{-}3,5\text{-}Me_2pz)]_2 + [Rh(\mu\text{-}3,5\text{-}Me_2pz)(COD)]_2 + 2\ NaCl$$

Corroborative evidence for this proposal comes with the isolation of the bridged gallium dimer species $[Me_2Ga(\mu\text{-}3,5\text{-}Me_2pz)]_2$ (28) from the reaction products.

The rhodium(I) dimers $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$ and $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(COD)]_2$ were first synthesized some years ago by Trofimenko (19) using a more direct synthetic route. The Rh(I) dimers isolated in this study gave analytical and physical data (ir, ^{1}H nmr) in agreement with those reported earlier by Trofimenko (19) and by Banditelli *et al.* (29). The exquisite crystalline nature of these dimers and the general paucity of structural data in the literature on this type of complex (Uson *et al.* have reported the structure of the dimer

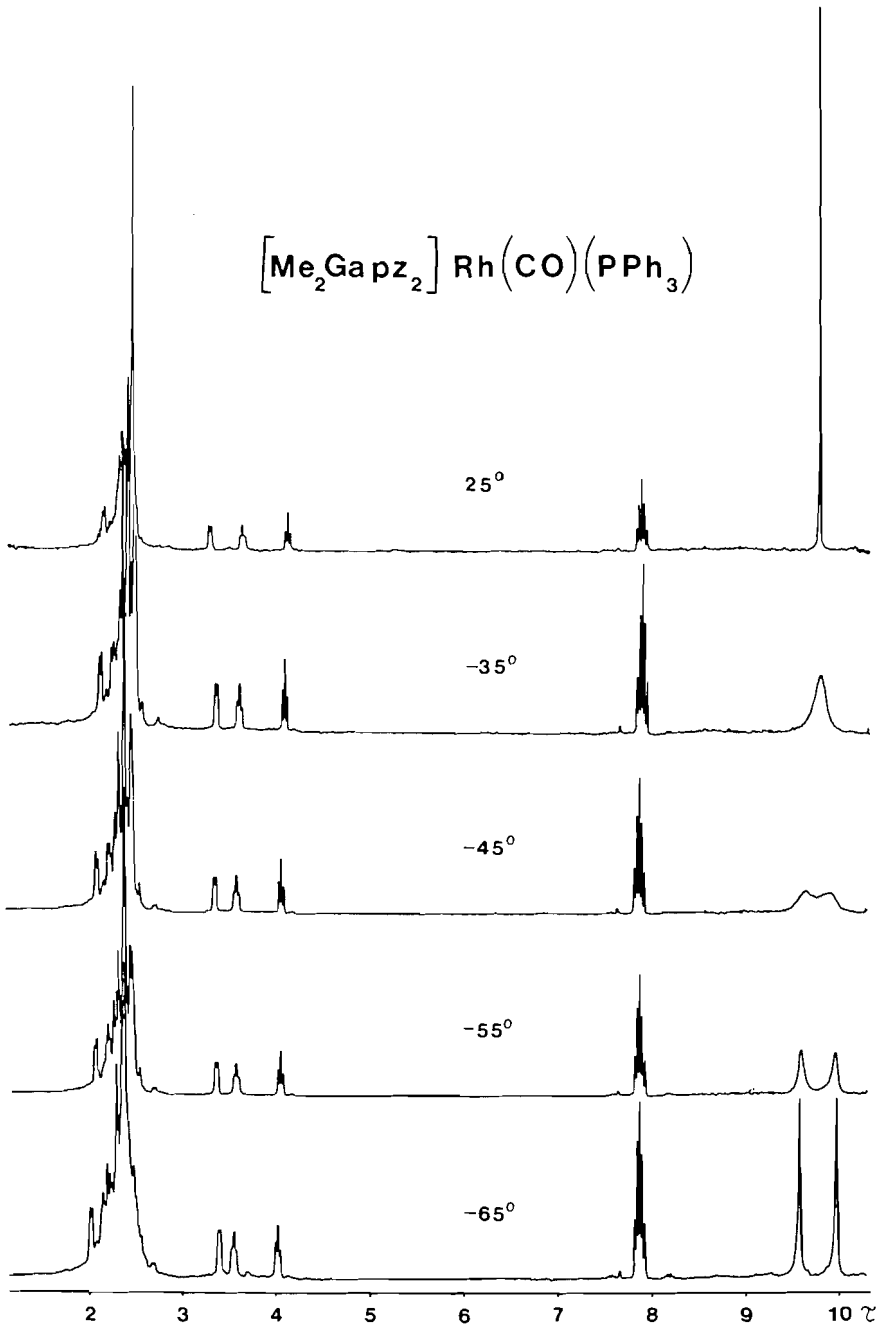

FIG. 1. Low temperature ^{1}H nmr spectra of $[Me_2Gapz_2]Rh(CO)(PPh_3)$ in d_6-acetone.

$[Rh(\mu\text{-}pz)(CO)(P(OPh)_3)]_2$ (30)) prompted us to perform X-ray crystallographic analyses of these two complexes.

Crystal structures of $[Me_2Gapz_2]Rh(COD)$, $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$, and $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(COD)]_2$

Each of the three structures consists of discrete molecules (Fig. 3) separated by normal van der Waals distances. In all three compounds the Rh(I) atoms are in distorted square planar environments. The mean[3] bond lengths involving Rh (Rh—C = 2.129(2), Rh—N = 2.087(2) Å in $[Me_2Gapz_2]Rh(COD)$; Rh—CO = 1.852(9), Rh—N = 2.063(6) Å in $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$; and Rh—C = 2.131(7), Rh—N = 2.084(1) Å in $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(COD)]_2$) are internally consistent and in good agreement with those reported for related molecules (24, 30, and references cited therein). The Rh—N distances in the carbonyl complex are significantly shorter than those in the two COD complexes. Other bond lengths and bond angles in the three structures (Tables 3 and 4) are normal. The pyrazolyl rings are all planar within experimental error or very nearly so, the maximum deviation of any ring atom from the respective N_2C_3 mean plane being 0.010(4) Å.

The central feature of each of the three structures reported here is the boat conformation of the six-membered Rh—(N—N)$_2$—M (M = Ga or Rh) ring. As can be seen by inspection of the intraannular torsion angles in Table 5, these

[3] Here and elsewhere in this report mean values refer to weighted means with rms deviations from the mean in parentheses.

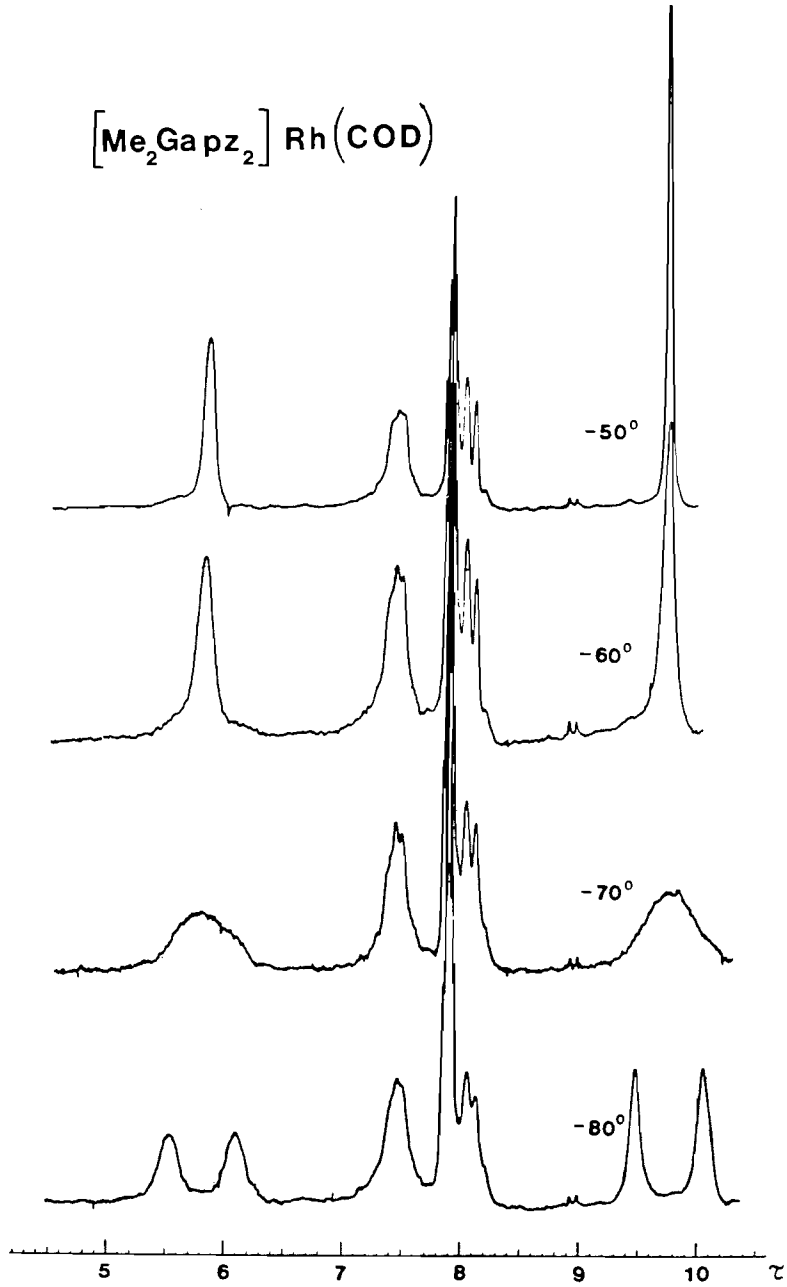

FIG. 2. Low temperature ^{1}H nmr spectra of $[Me_2Gapz_2]Rh(COD)$ in d_6-acetone.

rings differ substantially between the three molecules. This fundamental structural difference is related to the markedly different steric requirements of the ligands.

In the heterobinuclear complex $[Me_2Gapz_2]Rh(COD)$, which possesses exact C_s (mirror) symmetry, folding of the $RhGaN_4$ ring results primarily from steric interaction between the pyrazolyl and COD moieties (H(4)···H(7) = 2.29(4) Å). The Rh···Ga distance is 3.5527(5) Å, the dihedral angle between the pyrazolyl mean planes 114.1°, the maximum deviation from the RhN_2M_2 mean plane (M = midpoint of C=C) 0.016(3) Å, and the deviations of the metal atoms from the pyrazolyl mean plane 0.0124(2) Å for Rh and 0.0748(4) Å for Ga. The folding of the central six-membered ring in $[Me_2Gapz_2]Rh(COD)$ is greater than that observed in the compounds $B(pz)_4Rh(COD)$ and $B(pz)_4Rh(NBD)$ (NBD = norbornadiene) (24) in which ring folding is hindered by steric interaction of the coordinated olefin with the pseudoaxial, nonbridging, pyrazolyl group on the boron atom.

Each of the crystallographically independent (but virtually identical) molecules of $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$ and the $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(COD)]_2$ molecule display approximate C_{2v} symmetry in the solid state. In both of these compounds steric interactions between the bridging 3,5-Me_2pz ligand and the terminal ligands result in folding of the Rh—(N—N)$_2$—Rh rings, the latter compound showing the greatest strain. The resulting cross-ring Rh···Rh distances (mean 3.262(4) Å for the carbonyl and 3.1538(3) Å for the COD complex), although significantly shorter than the Rh···Rh distance of 3.568 Å quoted by Uson *et al.* for $[Rh(\mu\text{-pz})(CO)(P(OPh)_3]_2$ (30), are nevertheless not supportive of any direct bonding interactions between the two Rh metal centres (31). It is interesting to compare these findings with the recently reported structures of

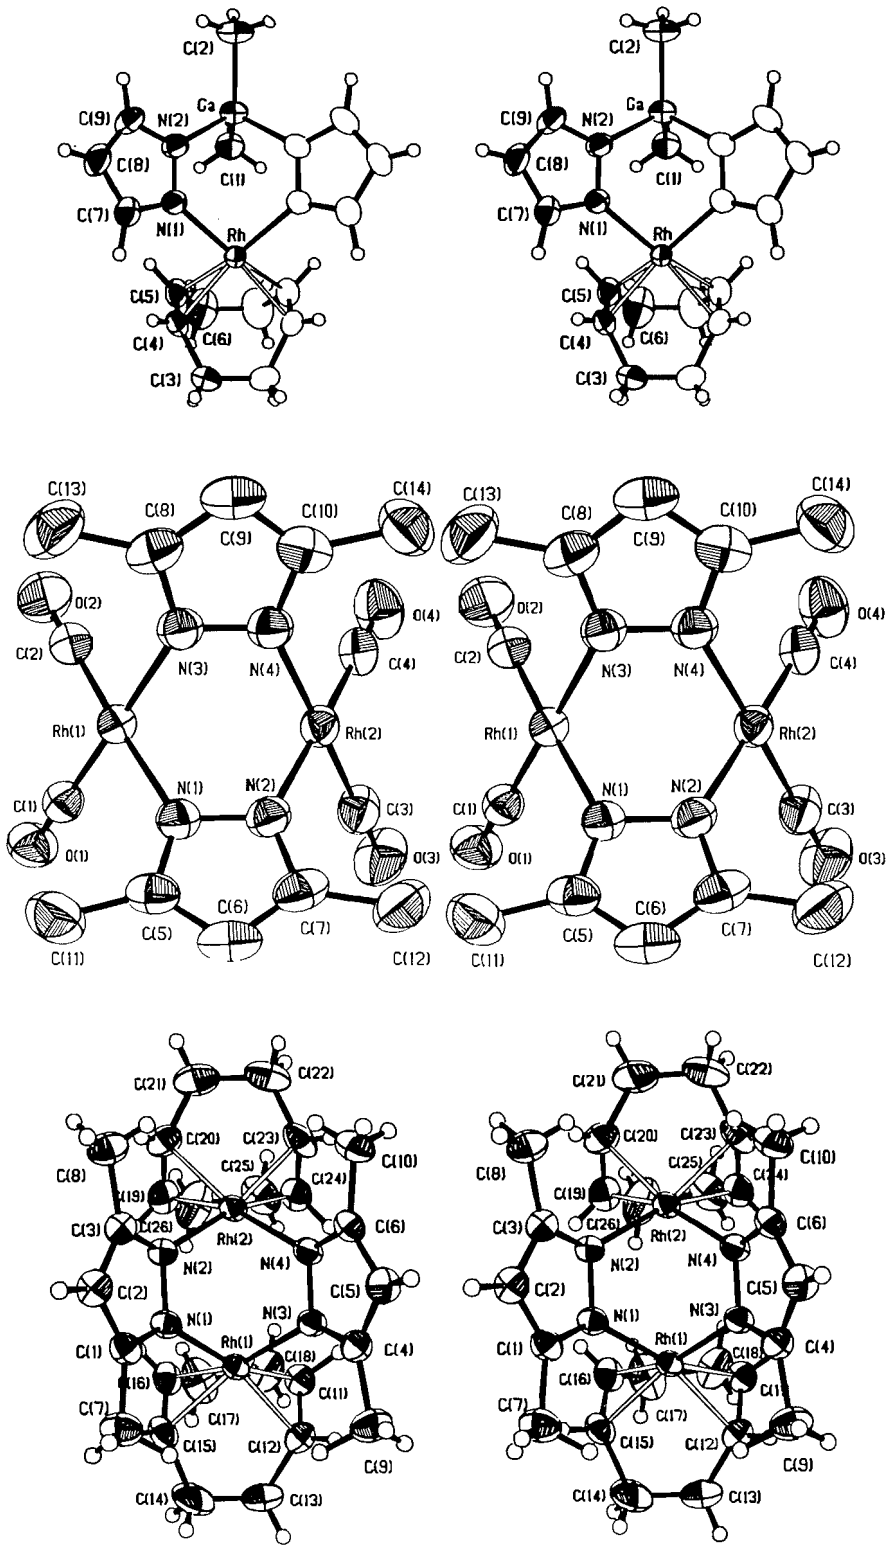

FIG. 3. Stereoscopic views of the $[Me_2Gapz_2]Rh(COD)$ (top), $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$ (middle), and $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(COD)]_2$ (bottom) molecules; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

the pyrazolyl-bridged iridium dimers $[Ir(\mu\text{-}pz)(COD)]_2$ (32) and $[Ir(\mu\text{-}pz)(CO)(PPh_3)]_2$ (33) (Ir···Ir = 3.216 and 3.162(2) Å respectively) which were postulated to possess some degree of direct metal–metal interaction. The structure of the former Ir complex is very similar to that of $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(COD)]_2$ while that of the latter differs markedly in the degree of folding and hence the M···M distance from the $Rh(P(OPh)_3)$ analog (30), presumably as a result of the different steric requirements of the PPh_3 and $P(OPh)_3$ ligands.

The Rh(I) dimers $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(CO)_2]_2$ and $[Rh(\mu\text{-}3,5\text{-}Me_2pz)(COD)]_2$ both show a greater degree of strain than $[Me_2Gapz_2]Rh(COD)$. Dihedral angles between the pyrazolyl mean planes are 110.9 and 70.0°, maximum deviations from the Rh coordination planes 0.037(5) and 0.074(4) Å, and mean

deviations of Rh from the pyrazolyl mean planes 0.136 and 0.416 Å, respectively, for the two molecules. The dihedral angles between the two metal coordination planes of 78.7° for the carbonyl complex and 71.7° for the COD complex are the smallest yet reported for this type of dinuclear Rh complex.

Hydrolysis of trioxaadamantane ortho esters. I. Dialkoxycarbocation – ortho ester equilibrium and acidity function

ROBERT A. MCCLELLAND AND PATRICK W. K. LAM

Department of Chemistry, University of Toronto, Scarborough Campus, Scarborough, Ont., Canada M1C 1A4

Received November 9, 1983

ROBERT A. MCCLELLAND and PATRICK W. K. LAM. Can. J. Chem. **62**, 1068 (1984).

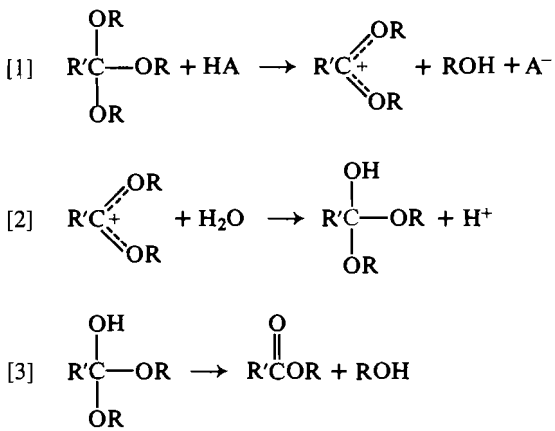
3-Aryl-2,4,10-trioxaadamantane ortho esters (T) undergo a rapid equilibration with a ring-opened dioxan-2-ylium ion (DH^+) prior to hydrolysis to product (a 1,3,5-cyclohexanetriol monobenzoate). The cation is stable in concentrated H_2SO_4 solutions where it has been characterized by nmr spectroscopy. It is observed using uv spectroscopy in dilute acids, and the ratio $[DH^+]/[T]$ at equilibrium has been measured as a function of acidity. Reversibility of the ring opening is established by the pattern of plots of cation absorbance versus acid concentration and by the observation that solutions containing cation on neutralization or dilution yield ortho ester, not hydrolysis product. Equilibrium constants for the reaction $DH^+ \rightleftharpoons T + H^+$ have been measured by obtaining the acidity function H_T for this system. The effects of the aromatic substituent and the steepness of the acidity function plot versus acid concentration are interpreted in terms of a strong intramolecular interaction in the cation between the cationic center and the hydroxyl oxygen.

ROBERT A. MCCLELLAND et PATRICK W. K. LAM. Can. J. Can. J. Chem. **62**, 1068 (1984).

Les ortho esters (T), aryl-3 trioxaadamantane-2,4,10, subissent un équilibre rapide avec le cycle ouvert, l'ion dioxannyl-2 ium (DH^+), avant leur hydrolyse en produit (un monobenzoate du cyclohexanetriol-1,3,5). Le cation est stable dans des solutions concentrées d'acide sulfurique dans lesquelles il a été caractérisé par spectroscopie rmn. Faisant appel à la spectroscopie uv, il est possible de l'observer en solutions acides diluées et on a mesuré le rapport $[DH^+]/[T]$ à l'équilibre en fonction de l'acidité. On a établi que l'ouverture du cycle est réversible en se basant sur l'allure des courbes d'absorption du cation en fonction de la concentration d'acide et aussi par l'observation que, lors de leur neutralisation ou de leur dilution, des solutions contenant du cation conduisent à des ortho esters plutôt qu'à des produits d'hydrolyse. On a mesuré les constantes d'équilibre pour la réaction $DH^+ \rightleftharpoons T + H^+$ en obtenant la fonction d'acidité, H_T, pour ce système. On a interprété les effets des substituants aromatiques et la forte pente de la courbe de la fonction d'acidité en fonction de la concentration en faisant appel à une forte interaction moléculaire entre le centre cationique et l'oxygène hydroxylique dans le cation.

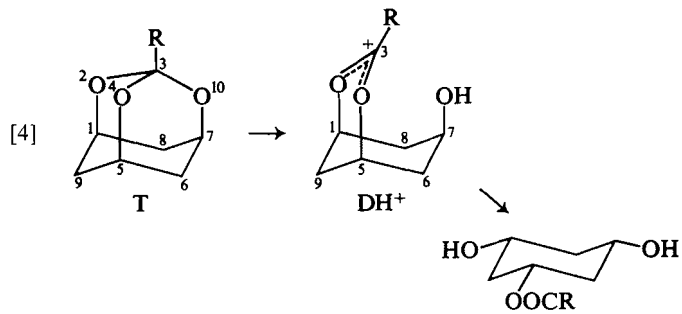
[Traduit par le journal]

Equations [1]–[3] depict the three-stage reaction mechanism now accepted (1, 2) for the hydrolysis of an ortho ester.



Although the first reaction stage is in principle reversible, hydrolyses are usually carried out in a large excess of water, and under these conditions the probability is low that the cation once formed will undergo the back reaction with the small amount of alcohol being released. This situation could be different with cyclic systems, where a ring opens in the first stage. Here the reverse is an intramolecular ring closure, and this could in principle compete with water addition, even with water as solvent. Such a reversible ring opening has been suggested with cyclic acetals as the explanation behind their diminished hydrolytic reactivity (3). Evidence for reversibility has been obtained in two instances (4, 5), although in both cases the rates of water addition and the ring closure were quite similar.

The subject of this paper is the 2,4,10-trioxaadamantane (T) system. These ortho esters are ideally set up for a reversible



ring opening since the departing hydroxyl group is forced to remain in close proximity to the cationic center. Lamaty, Moreau and co-workers (6, 7) were the first to suggest that pronounced reversibility does occur. Their suggestion was based on three kinetic observations: enormously retarded (10^6–10^9) rates of hydrolysis compared with those of acyclic analogs, negative entropies of activation, and a substituent effect, $k(3\text{-H}) > k(3\text{-CH}_3)$, opposite to that expected for rate-limiting cation formation. We have reported (8) in preliminary form verification of reversibility, in the actual observation of the 1,3-dioxan-2-ylium ion DH^+ in equilibrium with ortho ester. Although oxocarbocations can be isolated as stable salts or solutions (9) or observed as transient intermediates (2, 10–12), this represents the first example where equilibration with an acetal or ortho ester precursor is involved. We have now carried out a detailed study of the system. In this paper we discuss the quantitative aspects of the ring-opening equilibrium. The next paper presents a kinetic analysis of the overall hydrolysis.

Experimental

Materials

Substituted trimethyl orthobenzoates were prepared using the benzanilide acetal procedure recently reported by us (13). Compounds prepared, overall yield, and bp are as follows: trimethyl 4-methoxyorthobenzoate, 75%, 85°C/0.3 Torr; trimethyl 4-methylorthobenzoate, 75%, 80°C/0.3 Torr; trimethyl 4-chloroorthobenzoate, 70%, 90°C/0.3 Torr; trimethyl 3-chloroorthobenzoate, 91%, 69°C/0.3 Torr; trimethyl 4-nitroorthobenzoate, 78%, mp 56–57°C. The 2,4,10-trioxaadamantanes were prepared by exchange of the trimethyl ortho ester and cyclohexane-1β,3β,5β-triol (14), using the procedure of Stetter and Steinacker (15). Purification involved recrystallization from methanol. Despite several attempts using various conditions, the procedure failed with trimethyl 4-methoxyorthobenzoate, the major product being the methyl ester of 4-methoxybenzoic acid. The following lists the 3-substitutent, the temperature employed in the exchange, yield, melting point, ^{1}H nmr spectral data for the 3-aryl substituent, and analytical data. The nmr spectra were recorded in $CDCl_3$, $(CH_3)_4Si$ reference. The ^{1}H nmr associated with the trioxaadamantane portion was the same in every case, δ: 4.5–4.6 (3H, wide singlet, H1, H5, H7), 2.75 (3H, d, H6e, H8e, H9e), 1.75 (3H, d, H6a, H8a, H9a).

3-(4-Methylphenyl)-2,4,10-trioxaadamantane: 45°C, 65%, 177–178°C; δ: 7.56 (2H, d, ArH), 7.08 (2H, d, ArH), 2.32 (3H, s, CH_3). *Anal.* calcd. for $C_{14}H_{16}O_3$: C 72.39, H 6.94; found: C 72.51, H 7.11.

3-Phenyl-2,4,10-trioxaadamantane: 25°C, 82%, 176–177°C (lit. (12) mp 176–177°C); δ: 7.5–7.8 (2H, m, ArH), 7.1–7.3 (3H, m, ArH); ^{13}C nmr ($CDCl_3$, $(CH_3)_4Si$), δ: 139.6, 129.0, 128.0, 125.1, 108.9 (C3), 68.9 (C1, C5, C7), 33.0 (C6, C8, C9).

3-(4-Chlorophenyl)-2,4,10-trioxaadamantane: 10°C, 62%, 149–150°C; δ: 7.72 (2H, d, ArH), 7.31 (2H, d, ArH). *Anal.* calcd. for $C_{13}H_{13}O_3Cl$: C 61.79, H 5.19; found: C 61.73, H 5.12.

3-(3-Chlorophenyl)-2,4,10-trioxaadamantane: 5°C, 71%, 135–136°C'; δ: 7.1–7.7 (4H, m). *Anal.* calcd. for $C_{13}H_{13}O_3Cl$: C 61.79, H 5.19; found: C 61.95, H 5.26.

3-(4-Nitrophenyl)-2,4,10-trioxaadamantane: 0°C, 45%, 231.5–233°C; δ: 8.18 (2H, d, ArH), 7.76 (2H, d, ArH). *Anal.* calcd. for $C_{13}H_{13}O_5N$: C 59.31, H 4.98; found: C 59.21, H 4.87.

The cations DH^+ were prepared as stable solutions in 80–100% H_2SO_4 or D_2SO_4 by the slow addition of the solid ortho ester to the stirred acid solution cooled in an ice bath. The nmr spectra were recorded in D_2SO_4 with external $(CH_3)_4Si$ as standard. Chemical shift values (uncorrected for bulk susceptibility differences) recorded for the cation DH^+ with R = phenyl in 75% D_2SO_4 are as follows: ^{1}H nmr, δ: 8.1–8.3 (2H, m, *ortho* ArH), 7.5–7.8 (3H, m, *meta* + *para* ArH), 5.75 (2H, wide singlet, H1, H5), 5.35 (1H, wide singlet, H7), 3.3 (2H, d, H6e, H8e), 2.2–2.6 (4H, m, H9e, H6a, H8a, H9a); ^{13}C nmr, δ: 188.8 (C3), 149.4, 141.2, 139.4, 132.6 (all phenyl), 90.0 (2C, C1, C5), 84.4 (1C, C7), 43.1 (2C, C6, C8), 35.8 (1C, C9).

Cation – ortho ester equilibrium constants

Measurements were performed on a Unicam SP 1800 ultraviolet spectrophotometer equipped with a thermostatically controlled cell-block at 25.0 ± 0.1°C. A methanolic solution of the trioxaadamantane (5.0 μL) was injected into 2.5 mL of the thermostatted acid solution to give final concentrations of approximately 10^{-4} molar ortho ester. The absorbance was recorded at the λ_{max} of the cation DH^+ (4-$CH_3C_6H_4$, 283 nm; C_6H_5, 260 nm; 4-ClC_6H_4, 286 nm; 3-ClC_6H_4, 267 nm; 4-$NO_2C_6H_4$, 272 nm). The plot of absorbance versus time was extrapolated to zero time (time of mixing) to provide the absorbance of the solution before any hydrolysis had occurred.

Results and discussion

Cation identification

Solutions of dialkoxycarbocations can usually be obtained by addition of ortho esters to concentrated sulfuric acid (9, 16–19), taking advantage of the low nucleophilicity of the medium to stabilize the cation. This is true also in the present case, with the cations DH^+ being easily characterized by nmr spectroscopy. Figures 1 and 2 show ^{13}C nmr spectra of 3-phenyl-2,4,10-trioxaadamantane in $CDCl_3$ and 75% D_2SO_4 respectively. The symmetry in the ortho ester results in only three signals, in addition to those associated with the 3-substituent. This symmetry is reduced when the cation forms and this appears as a splitting of the signals due to $C_{6,8,9}$ and to $C_{1,5,7}$ into two signals each in a 2:1 ratio. A large downfield shift in the signal due to the C_3 carbon also occurs. The ^{1}H nmr spectrum of this solution is also consistent with the cation structure (see Experimental), although the complexity of the signals makes the analysis more difficult. The ester product can be ruled out as being responsible for the concentrated acid spectra. This product is obtained in more dilute acids (less than 50% H_2SO_4), and it does have the same number of ^{13}C nmr signals as the cation, but their positions are very different.

Three other comments can be made regarding these concentrated acid solutions. (*i*) The cations DH^+ can tolerate a sizeable amount of water and remain stable in the solution; for instance, the spectrum in Fig. 2 is unchanged after one week. In contrast, other dialkoxycarbocations are stable only in very concentrated acids. The phenyldimethoxycarbocation, for example, is stable above 95% H_2SO_4, but its half-life in 75% H_2SO_4 is only 1 s (18). (*ii*) There is perhaps some indication of a diprotonated species, that is, protonation of the hydroxyl oxygen of DH^+. As the acid concentration is increased from 75% D_2SO_4 to 100% D_2SO_4, the spectral pattern remains unchanged but there are some changes in the relative chemical shifts. A particularly significant change is observed in the relative positions of the two signals due to $C_{1,5}$ and C_7, with the C_7 signal moving downfield at higher acidity. (*iii*) The observation of separate signals for $C_{1,5}$ and C_7 and for $C_{6,8}$ and C_9 indicates that there is no scrambling on the nmr time scale. This could occur by ring closure of the cation to the trioxaadamantane followed by ring opening in another direction. Interestingly, the temperature-jump kinetic measurements (accompanying paper) show that in dilute acids ring closure would be sufficiently rapid (half-lives of 10^{-5} to 10^{-4} s) for this isomerization to be observed in the nmr as a coalescence for signals. The cations unfortunately are not stable enough in these solutions for ^{13}C nmr spectra to be obtained. The slowing down of the ring closure in more concentrated acids may in part be associated with the protonation of the OH group. More importantly in our opinion it represents a requirement for an additional water molecule, functioning as a base to remove the OH proton as the ring closes. The requirement for this base

[5] 
is also seen in the addition of water to protonated esters (20) and dialkoxycarbocations (19). The rates of these reactions fall off considerably more rapidly with increased acid concentration than is expected on the basis of the decrease in water activity, slopes of log k versus log a_{H_2O} being two and greater. This is interpreted (19, 20) in terms of a mechanism in which, in addition to the water molecule which acts as a nucleophile, a second water is present to remove the proton.

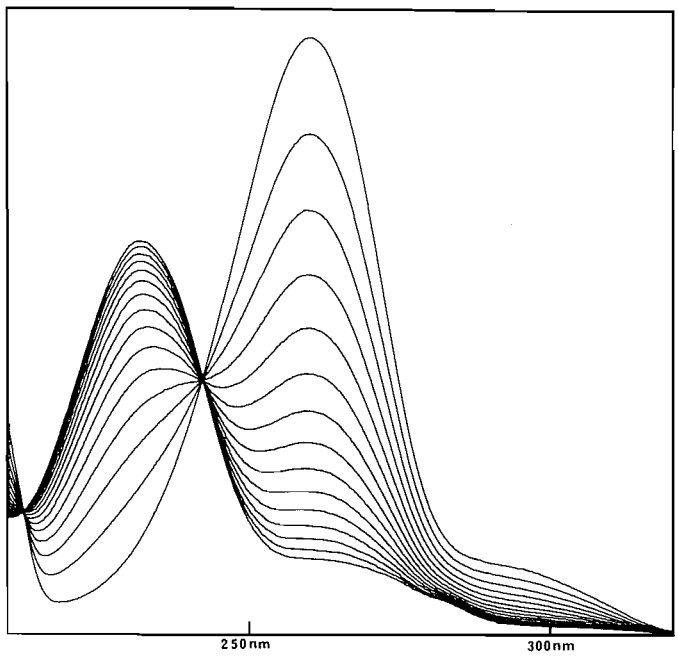

FIG. 3. The uv spectral change for 3-phenyl-2,4,10-trioxaadamantane in 35% H_2SO_4, showing the conversion of the cation DH^+ to ester product. Spectra were recorded at 10-min intervals.

Reversible ring opening

The cations DH^+ can also be observed in more dilute acids, but they are less stable here and have been identified using uv spectroscopy. 3-Phenyl-2,4,10-trioxaadamantane itself exhibits little uv absorbance at wavelengths above 220 nm, except for weak absorbance near 260 nm associated with the benzene chromophore. Hydrolysis in dilute acids (pH > 1) results in the appearance of a strong absorbance with λ_{max} at 232 nm. This new peak is due to the benzoate ester product, and the behavior here is typical of a benzoic acid ortho ester derivative (2, 21–23). What makes the trioxaadamantane very different, however, is the behavior in slightly more concentrated acids, where a new peak with λ_{max} at 260 nm appears (Fig. 3). This peak can be assigned to the cation DH^+ with R = phenyl. The same absorbance is found in more concentrated acids where the cation can be characterized by nmr spectroscopy, as just discussed. Spectra with λ_{max} near 260 nm are also observed with other phenyl substituted dialkoxycarbocations (2, 18, 19, 23). The other trioxaadamantanes also produce cations in moderately concentrated acids (see Experimental for λ_{max}).

The appearance of the cation in these acids is extremely rapid, too rapid in fact to be observed even with stopped-flow spectroscopy. That is, the formation of the cation signal is complete within the stopped-flow dead-time (2 ms) when a neutral aqueous solution of trioxaadamantane is mixed with aqueous H_2SO_4. As shown in Fig. 3, the cation signal slowly disappears, accompanied by the appearance at the same rate of the ester peak at 232 nm. The rate of this reaction varies with acidity, passing through a maximum around 20–30% H_2SO_4. At the maximum the half-life is about 6 min.

A further significant observation is that the relative amount of cation which is produced in the rapid reaction increases with acidity, eventually reaching a maximum value. This is shown in Fig. 4, which plots the initial absorbance at the λ_{max} of the cation for three trioxaadamantanes. "Initial" in this context refers to an extrapolation to zero time on a conventional uv

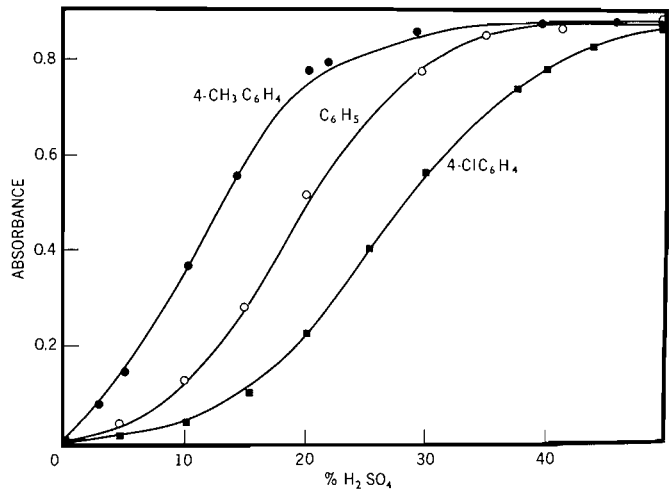

FIG. 4. Initial cation absorbance for solutions of 3-aryl-2,4,10-trioxaadamantanes in aqueous H_2SO_4. Wavelengths: 4-$CH_3C_6H_4$, 283 nm; C_6H_5, 260 nm; 4-ClC_6H_4, 286 nm. The concentration of trioxaadamantane in each system was constant (about 5×10^{-5} mol/L.

spectrophotometer. This represents a situation where cation formation is complete but the subsequent reaction which produces ester has not yet commenced.The sigmoidal shaped curves in Fig. 4 are typical of a system undergoing acid–base equilibration. They suggest that what is being observed is the acid-dependent equilibration of trioxaadamantane and ortho ester. That this process is rapid compared to the further reaction

$$[6] \quad DH^+ \rightleftharpoons T + H^+$$

of the cation to give ester is obvious from the rates of the uv spectral changes, as just discussed. The reversibility of the cation formation is evident from the uv spectral behavior. Moreover, if acid solutions are diluted or neutralized, trioxaadamantane is produced, not ester.

Equilibrium constants and acidity function

The equilibrium in question here has the form of a weak organic base being converted to a conjugate acid in moderately concentrated acids, and it can be analyzed using the acidity function method (24). The ratio of cation to trioxaadamantane, the "ionization ratio", has been calculated from the sigmoidal curves using the standard method (24),

$$[7] \quad \frac{[DH^+]}{[T]} = \frac{A - A_0}{A_a - A}$$

where A, A_0, and A_a represent absorbance values in the acid in question, water, and 60–90% H_2SO_4, respectively. A listing of absorbance and ionization ratio data is given in Table S1.[1] The thermodynamic dissociation constant is defined as

$$[8] \quad K_{DH^+} = \frac{a_{H^+} a_T}{a_{DH^+}}$$

where activities refer to water as the standard state. In the usual way (24), the value of this constant for the 4-methylphenyl compound has been obtained by extrapolation of the quantity $[H^+][T]/[DH^+]$ to zero acid concentration. Values for the other

[1]Supplementary material is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ontario, Canada K1A 0S2.

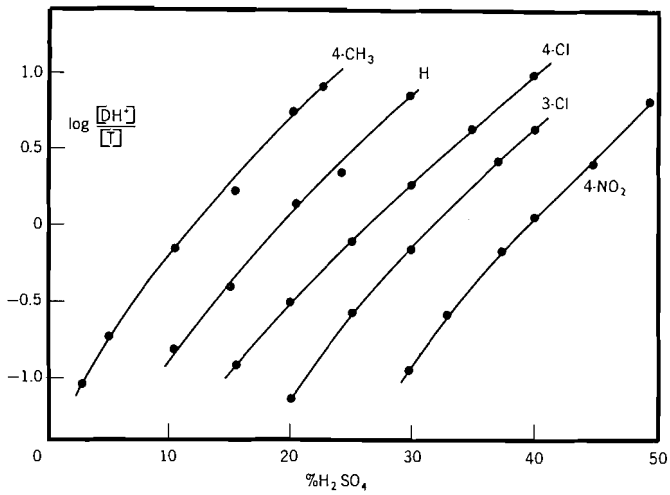

FIG. 5. The logarithm of the ionization ratio $[DH^+]/[T]$ as a function of sulfuric acid concentration.

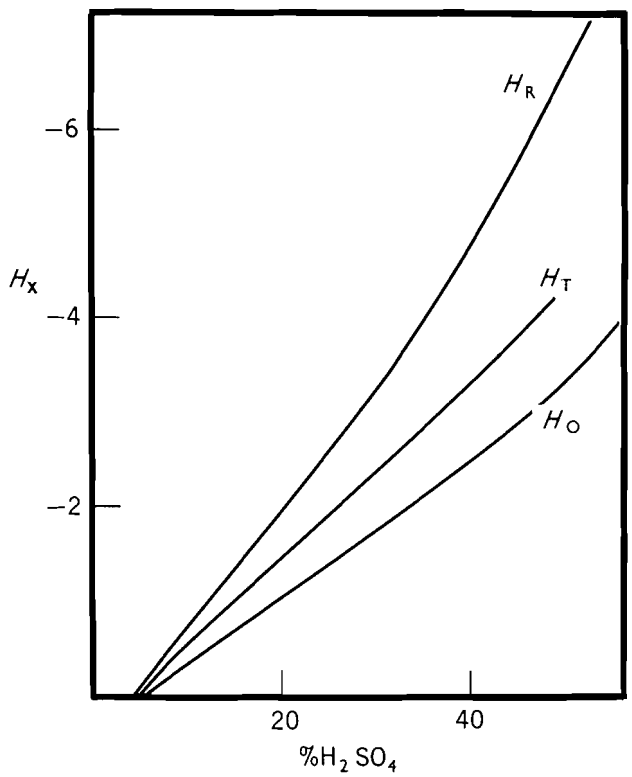

FIG. 6. Acidity functions in aqueous sulfuric acid. Values for H_R, H_T, and H_0 from ref. 25.

ortho esters have then been obtained using the overlap method (24). As seen in Fig. 5, the overlap and parallelism between successive ionization ratio curves is good. Values of pK_{DH^+} obtained in this way are listed in Table 1. The acidity function for this system is defined as

$$[9] \quad H_T = -\log \frac{a_{H^+} f_T}{f_{DH^+}}$$

This has been calculated as $H_T = pK_{DH^+} - \log [DH^+]/[T]$. Values are listed in Table 2, and displayed graphically as a function of acid concentration in Fig. 6.

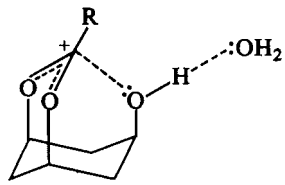
This represents the first time when the equilibrium constants for conversion of an ortho ester to its dialkoxycarbocation have been measured directly under hydrolytic conditions. Values for trimethyl orthobenzoates (eqs. [10], [11]) have been indirectly

$$[10] \quad \overset{+}{\text{ArC}}(\text{OMe})_2 + \text{MeOH} \underset{k_r}{\overset{k_f}{\rightleftharpoons}} \text{ArC}(\text{OMe})_3 + \text{H}^+$$

$$[11] \quad K_{DH^+} = \frac{[\text{ArC}(\text{OMe})_3][\text{H}^+]}{[\text{ArC}(\text{OMe})_2{}^+][\text{MeOH}]} = \frac{k_f}{k_r}$$

estimated (19) as the ratio k_f/k_r. The k_r value is measured; the k_f value is calculated as $k(H_2O)/55$ where $k(H_2O)$ represents the rate constant for cation hydration estimated by extrapolation to water of rate measurements made in concentrated H_2SO_4. Figure 7 shows Hammett plots for the two systems. Although the actual pK values are quite similar, there is a significant difference in the ρ values. This may reflect a strong interaction between the hydroxyl oxygen and cationic center in the trioxaadamantane system. Such an interaction would delocalize positive charge, so that the effect of aromatic substituents would be attenuated.

[12]



The acidity dependence of the equilibrium as seen in the H_T acidity function provides further evidence for this interaction. It is now well established (26) that the steepness of acidity functions in plots of the acidity function versus acid concentration is determined mainly by the solvation requirements of the charged species involved. At one extreme lies the H_R acidity function with a very steep dependence arising because triarylcarbocations, being large and delocalized, require very little solvation. At the other extreme the alcohol acidity function H_{ROH} has a very shallow dependency (27), reflecting the strong solvation of the protonated alcohol through hydrogen bonding of the O^+—H···OH type. The H_T acidity function represents what in principle is an intramolecular analog of the triarylcarbocation−triarylcarbinol equilibrium. It is interesting, therefore, that its dependency on acidity is not nearly as

TABLE 1. Dissociation constants for the equilibration of 3-aryl-2,4,10-trioxaadamantanes and their ring-opened dioxanylium ion forms

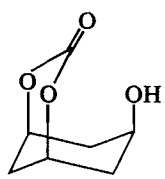
steep, suggesting a much greater solvation in the dioxan-2-ylium cation. The interaction pictured in [12] would place some positive charge on the hydroxyl oxygen. This could result in the cation having some of the characteristics of a protonated alcohol or ether, with a relatively strong hydrogen bond between the OH group and a solvent water molecule. This would cause the acidity function to rise less steeply.

Evidence that a strong intramolecular interaction should exist comes from a crystal structure of a carbonate analog (28). The distance between the carbonyl carbon and hydroxyl



oxygen in this molecule is only 2.93 Å, less than the sum of the van der Waals radii of these groups.

Hydrolysis of trioxaadamantane ortho esters. II. Kinetic analysis and the nature of the rate-determining step

ROBERT A. MCCLELLAND AND PATRICK W. K. LAM

Department of Chemistry, University of Toronto, Scarborough Campus, Scarborough, Ont., Canada M1C 1A4

Received November 9, 1983

ROBERT A. MCCLELLAND and PATRICK W. K. LAM. Can. J. Chem. **62**: 1074 (1984).

A detailed kinetic study of the hydrolysis of a series of 3-aryl-2,4,10-trioxaadamantanes is reported. These ortho esters equilibrate with the ring-opened dialkoxycarbocation, in a very rapid process which could be studied using temperature-jump spectroscopy for aryl = 2,4-dimethylphenyl. Relaxation rate constants are of the order of 10^4 s^{-1}; these could be analyzed to provide the rate constants for both the ring opening and the ring closing. Product formation from this equilibrating mixture is much slower. In acid solutions (0.01 *M* H^+ − 50% H_2SO_4), first-order rate constants for product formation initially increase with increasing acidity, but a maximum is reached at 20−35% H_2SO_4 and the rate then falls. This behavior is explained by a counterbalancing of two factors. Increasing acidity increases the amount of the dialkoxycarbocation in the initial equilibrium, but, outside the pH region, it decreases the rate of hydrolysis of this cation through a medium effect. Rate constants over a range of pH have been measured for two trioxaadamantanes and for the cation DEt^+ derived by treatment of the ortho ester with triethyloxonium tetraafluoroborate. The latter models the cation formed in the ortho ester hydrolysis but it cannot ring close. Rate−pH profiles obtained in these systems are more complex than expected on the basis of rate-determining cation hydration. An interpretation is proposed with a change in rate-determining step between high pH and low pH. Cation hydration is rate determining at high pH but at low pH hemiorthoester decomposition becomes rate determining. Under these conditions the hemiorthoester equilibrates with both the dialkoxycarbocation and with the trioxaadamantane. The change in rate-determining step occurs because acid-catalyzed reversion of the hemiorthoester to dialkoxycarbocation is a faster process than acid-catalyzed hemiorthoester decomposition. This makes the latter rate-determining in acid solutions. Additional pathways available to the decomposition, however, make it the faster process at higher pH. A kinetic analysis furnishes all of the rate and equilibrium constants for the system, and provides support for the mechanistic interpretation. A comparison of these numbers with those obtained for the three stages in the hydrolysis of a simple monocyclic ortho ester underlines the novelty of the trioxaadamantane system.

ROBERT A. MCCLELLAND et PATRICK W. K. LAM. Can. J. Chem. **62**: 1074 (1984).

On rapporte une étude cinétique détaillée de l'hydrolyse d'une série d'aryl-3 trioxa-2,4,10 adamantanes. Ces orthoesters s'équilibrent par un processus très rapide avec le dialkoxycarbocation à cycle ouvert; cette réaction peut être étudiée grâce à la spectroscopie de saut de *T* lorsque l'unité aryle = diméthyl-2,4 phényle. Les constantes de vitesse de relaxation sont de l'ordre de 10^4 s^{-1}; on peut les analyser pour obtenir les constantes de vitesse d'ouverture et de fermeture de cycle. La formation des produits à partir du mélange à l'équilibre est beaucoup plus lente. Dans des solutions acides (0,01 *M* H^+ − 50% H_2SO_4), la constante de vitesse d'ordre un de la formation du produit augmente au départ avec l'acidité mais elle atteint un maximum à 20−35% de H_2SO_4; ensuite, la vitesse diminue. On explique ce comportement par l'effet opposé de deux facteurs. L'augmentation de l'acidité augmente la quantité de dialkoxycarbocation dans l'équilibre de départ, mais, hors de la région du pH, elle diminue la vitesse d'hydrolyse de ce cation via un effet de milieu. On a mesuré les constantes de vitesse pour un grand intervalle de pH pour deux trioxaadamantanes et pour le cation DEt^+ obtenu en faisant réagir l'orthoester avec le tétrafluoroborate de triéthyloxonium. Ce dernier sert de modèle pour le cation qui se forme lors de l'hydrolyse de l'orthoester mais il ne peut pas se refermer pour donner un cycle. Les profils de vitesse vs. pH obtenus das ces systèmes sont plus complexes que ceux auquels on pourrait s'attendre si l'on fait l'hypothèse que l'étape déterminante de la réaction est l'hydratation du cation. On propose une interprétation qui implique l'existence d'étapes déterminantes aux pH fort et faible. A pH élevé, l'hydratation du cation serait l'étape déterminante, mais à pH faible, la décomposition de l'hémiorthoester deviendrait l'étape déterminante. Dans ces conditions, l'hémiorthoester se met en équilibre à la fois avec le dialkoxycarbocation et avec le trioxaadamantane. Les changements dans l'étape déterminante se produisent parce que la reconversion acido-catalysée de l'hémiorthoester en dialkoxycarbocation est un processus plus rapide que la décomposition acido-catalysée de l'hémiorthoester. Ceci fait que ce dernier processus devient l'étape déterminante pour les solutions acides. Cependant, des voies additionnelles de décomposition qui sont disponibles font que ce processus est le plus rapide à pH élevé. Une analyse cinétique fournit toutes les vitesses et toutes les constantes d'équilibre pour le système et apporte des arguments pour l'interprétation du mécanisme. Une comparaison de ces nombres avec ceux obtenus pour ces trois étapes de l'hydrolyse d'un orthoester monocyclique simple souligne la nouveauté du système trioxaadamantane.

[Traduit par le journal]

In the preceding paper (1) we presented our evidence that the hydrolysis of trioxaadamantane ortho esters (T) occurs with reversible formation of the dialkoxycarbocation DH^+, and we provided a quantitative analysis of this equilibration (eq. [1] with R = H).

The trioxaadamantane system is highly unusual in this respect, in that with other ortho esters the dialkoxycarbocation-forming state is irreversible (in water solvent). Reversibility was in fact initially suggested by Lamaty, Moreau and co-workers, on the basis of observations made during kinetic studies (2, 3). These kinetics, however, referred to the overall hydrolysis, and we felt it important, in view of the unusual nature of this system, to see if the kinetics of the individual stages could be analyzed. In this paper we report such a study. Four separate areas of kinetic investigation can be defined: (a) a temperature-jump study of the cation − ortho ester equilibration; (b) a kinetic study in dilute and moderately concentrated H_2SO_4 solutions designed to analyze the effect of the shifting equilibrium between cation and ortho ester; (c) a kinetic study in aqueous solutions covering a range of pH of the cation DEt^+, prepared by treatment of the ortho ester with triethyloxonium tetrafluoroborate; and (d) a study at high temperatures of the ortho ester hydrolysis over a range of pH. The unusual slowness of the hydrolysis − one of the factors suggestive of reversible cation formation (2, 3) − has meant that previous studies have been limited to quite acidic solutions. In addition to the initial reversibility, we show here that there is a change in rate-determining step with changing pH, which is revealed only by studies over the more extended pH regions.

Experimental

Materials

3-(2,4-Dimethylphenyl)-2-4,10-trioxaadamantane was prepared in 30% yield from trimethyl 2,4-dimethylorthobenzoate as described in the previous paper (1), and had mp 130−132°C; ^{1}H nmr, δ: 7.53 (1H, d), 6.91 (2H, m), 4.50 (3H, m), 2.6−2.8 (3H, m), 2.76 (3H, s), 2.15 (3H, s), 1.65−1.85 (3H, m). *Anal.* calcd. for $C_{15}H_{18}O_3$: C 73.15, H 7.37; found: C 73.31, H 7.36. The trimethyl orthoester was prepared[1] in a two-step procedure involving the Friedl−Crafts reaction of aluminum trichloride and carbon tetrachloride with *m*-xylene, followed by substitution of the chlorines with sodium methoxide in methanol. The procedure here was essentially that employed for the preparation of trimethyl 2,4,6-trimethylorthobenzoate (4). Other trioxaadamantanes were described in the previous paper (1).

The cation DEt^+ with Ar = 4-$CH_3C_6H_4$ was prepared by treating 3-(4-methylphenyl)-2-4,10-trioxaadamantane (5 mmol) dissolved in dry CH_2Cl_2 (20 mL) with triethyloxonium fluoroborate (5 mmol). A precipitate forms over a short period of time, and this was filtered to give a hygroscopic white solid, ^{1}H nmr (96% D_2SO_4, external $(CH_3)_4Si$), δ: 8.05 (2H, d, ArH), 7.35 (2H, d, ArH), 5.70 (2H, wide singlet, H1, H5), 5.25 (1H, wide singlet, H7), 4.55 (2H, q, CH_2), 3.15 (2H, d, H6e, H8e), 2.2−2.7 (4H, m, H9e, H6a, H8a, H9a), 1.55 (3H, t, CH_3).

Kinetics

Rates of product formation from the trioxaadamantanes were obtained using a Unicam SP 1800 spectrophotometer thermostatted at 25.0 ± 0.1°C or 76.8 ± 0.2°C. In dilute acids (pH 7 to 10−20% H_2SO_4) the absorbance increase associated with the formation of the benzoate ester product was monitored (4-$CH_3C_6H_4$; 243 nm; C_6H_5, 225 nm; 4-ClC_6H_4, 245 nm; 3-ClC_6H_4, 253 nm; 4-$NO_2C_6H_4$, 267 nm; 2,4-$(CH_3)_2C_6H_3$, 250 nm). In more concentrated acids the absorbance decrease associated with the disappearance of the cation was monitored (4-$CH_3C_6H_4$, 283 nm; C_6H_5, 260 nm; 4-ClC_6H_4, 286 nm; 3-ClC_6H_4, 267 nm; 4-$NO_2C_6H_4$, 272 nm). First-order rate constants were evaluated as the slopes of plots in ln $(A_t - A_\infty)$ or ln $(A_\infty - A_t)$ versus time. Excellent linearity was observed in these plots. In a few cases it was verified that the rate constant was the same whether cation disappearance or product appearance was monitored. Rate constants were obtained in all cases as the average of two or three kinetic runs.

[1]R. A. McClelland and M. Ahmad. Unpublished.

First-order rate constants for the disappearance of the cation DEt^+ were obtained by following the disappearance of the cation at 283 nm. Reactions from pH 1 to pH 4 were carried out using the Unicam spectrophotometer by injecting 2.5 μL of a solution of the cation in CH_3CN into a thermostatted uv cell. Reactions at pH > 4 were carried out using a Durrum−Gibson stopped-flow spectrophotometer. In these experiments the cation solution in CH_3CN was added to a 0.01 *M* HCl solution which had been thermostatted in an external water bath. This solution was rapidly loaded into one syringe of the stopped-flow apparatus, where it was mixed with an appropriate buffer.

Temperature-jump experiments for the equilibrium reaction of 3-(2,4-dimethylphenyl)2-4,10-trioxaadamantane were performed on a Messanlagen Studiengesellschaft Gottingen T-jump spectrometer. A temperature jump of 3.1°C was applied to a microcell prethermostatted at 21.9°C. In order to minimize the extent of further hydrolysis of the equilibrating mixture, solutions were prepared immediately before use. Hydrolysis does occur, but that it is not a problem is demonstrated by the observation that the measured relaxation rate constants do not change with time, although the relaxation amplitude decreases. The chemical relaxation which occurs after the temperature rise produces an absorbance increase. This was displayed on the screen of a storage oscilloscope, and the photographed trace digitized to compute the relaxation rate constants. Good exponential decay curves were obtained. At least five determinations of relaxation time were made from each solution, and the results averaged.

Results and discussion

Equilibration

As mentioned previously (1), the equilibrium reaction of the trioxaadamantanes and the cations DH^+ is extremely rapid, and we turned to temperature-jump spectroscopy in an attempt to study its kinetics. Initial experiments were conducted on equilibrating solutions of 3-phenyl and 3-(4-methylphenyl)-trioxaadamantanes, but these failed to reveal a relaxation and were not further pursued. With the 2,4-dimethylphenyl system, however, a relaxation at the λ_{max} (280 nm) of the cation could be observed. Relaxation rate constants (τ^{-1}), were measured in 0.06 to 0.48 *M* $HClO_4$ with the ionic strength being kept constant at 0.5, and the following relationship observed (see Table S1[2] for raw data).

$$[2] \quad \tau^{-1}(s^{-1}) = (8.7 \pm 0.6) \times 10^3 + (8.5 \pm 0.3) \times 10^3\,[H^+]$$

The first number which will be defined as k_1^0 can be assigned to the acidity-independent ring closure of the cation, with the second number referring to the second-order rate constant for H^+-catalyzed ring opening of the ortho ester. These values lead to an equilibrium constant $K_R = [T][H^+]/[DH^+]$ calculated as

$$[3] \quad T + H^+ \underset{k_{-1}^0}{\overset{k_1^H}{\rightleftharpoons}} DH^+$$

as k_{-1}^0/k_1^H of 1.03. Spectroscopic determination of this constant, carried out as in the previous paper, gives a value of 1.05, in excellent agreement.

For comparison with other systems (see later) we wished to have some idea of the magnitudes of k_1^H and k_{-1}^0 for the parent 3-phenyl system. These can be estimated by assuming that the 2,4-dimethyl substituents exert the same effect here as in an acyclic system. Rate constants for acid-catalyzed dialkoxycarbocation formation from trimethyl 2,4-dimethylorthobenzoate and trimethyl orthobenzoate (eq. [4]) are 120 M^{-1} s^{-1} (see footnote 1) and 74 M^{-1} s^{-1} (5) respectively. There is little

Hammett ρ	−0.8	−2.7	+1.9

[4] $Arc(OMe)_3 + H^+ \rightarrow \overset{+}{Ar}C(OMe)_2$

difference here and we therefore estimate k_1^H for 3-phenyl-2,4,10-trioxaadamantane as 5×10^3 M^{-1} s^{-1}. A larger effect is observed for water addition to the dialkoxycarbocations (eq. [5]), $k(H_2O)$ being $10^{5.1}$ s^{-1} with Ar = phenyl (6) and $10^{3.8}$ with

[5] $\overset{+}{Ar}C(OMe)_2 + H_2O \rightarrow ArC(OH)(OMe)_2$

Ar = 2,4-dimethylphenyl[1]. These numbers are determined by extrapolation to water of rate constants actually measured in H_2SO_4 solutions (6). The slower rate in the 2,4-dimethyl case is undoubtedly associated with a steric inhibition to the nucleophilic addition. Assuming that a similar effect occurs in the trioxaadamantane case, we estimate k_{-1}^0 for 3-phenyl as 10^5. That these estimates are reliable is seen in the agreement between the calculated K_R (k_{-1}^0/k_1^H) of 20 and the spectroscopically observed value (1) of 16. These numbers also reveal why a relaxation could not be observed with the 3-phenyl system. They correspond to a maximum half-life for the relaxation of 7 μs and that is within the rise-time of our temperature-jump apparatus.

Hydrolysis kinetics in acid solutions

The overall hydrolysis in this system represents the formation of ester product from an equilibrating mixture of ortho ester and dioxanylium ion. In dilute acid solutions the relative concentration of the cation in the equilbrium is very small, and first-order rate constants obey the relationship of eq. [6] with values of k_H(app) listed in Table 1 (see Table S2 for raw data[2]).

[6] $k_{obsd} = k_H(app)[H^+]$

Lamaty, Moreau and co-workers (2, 3) conducted their kinetic studies under such conditions and observed the same relationship. This first-order dependency on hydronium ion concentration is of course typical of ortho ester hydrolysis. The values of k_H(app) are abnormally slow (2-phenyl-2-methoxy-1,3-dioxane, for example, has k_H equal to 3.0×10^4 M^{-1} s^{-1} (7) and this led to the original conclusion (2, 3) that the trioxaadamantane system is different. In terms of the mechanism,

[7] $T \underset{K_{DH^+}}{=} DH^+ \overset{k_2^0(app)}{\rightleftharpoons}$ product

the following relationship applies

[8] $$k_H(app) = \frac{k_2^0(app)}{K_{DH^+}}$$

where k_2^0(app) is a first-order rate constant representing the conversion of cation to product. Using values of K_{DH^+} determined spectroscopically in more concentrated acids (1), values

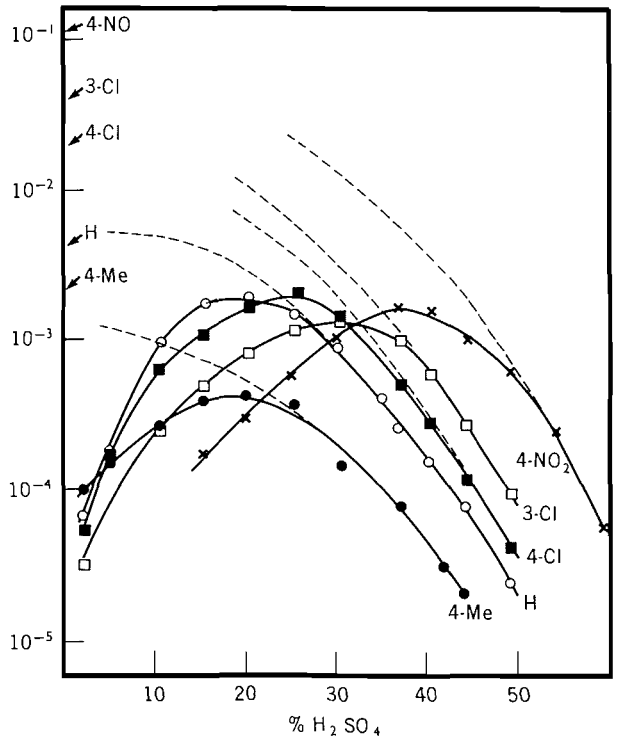

FIG. 1. First-order rate constants (s^{-1}, 25°C) for the hydrolysis of 3-aryl-2,4,10-trioxaadamantanes in sulfuric acid solutions. The dashed lines represent k_2(app) values calculated upon equilibrium correction. The arrows indicate values of k_2^0(app) calculated in water as $k_H(app)\cdot K_{DH^+}$ (Table 1).

of k_2^0(app) can be calculated and these are also listed in Table 1. It can be seen that the substituent effects on k_2^0(app) and K_{DH^+} are in opposing directions. Electron-withdrawing groups decrease the relative concentration of cation but accelerate its further hydrolysis. For the overall rate the former effect is more important.

In more concentrated acid solutions the equilibrium shifts towards the cation. Either the appearance of ester or the disappearance of the cation can be monitored, and within experimental error the same rate constant is obtained. A plot of these rate constants as a function of sulfuric acid concentration is shown in Fig. 1 (see Table S3 for data[2]); in each case the rate rises to a maximum at some intermediate acidity and then falls off in more concentrated acids. This maximum is much like that observed in the bimolecular acid hydrolysis of amides (8) and esters (9), and the explanation here is similar. Increasing acidity increases the relative concentrations of the cation, and thus tends to increase the rate. This is countered by a medium effect on the hydrolysis of the cation which tends to decrease the rate. The following relationship applies to the observed rates.

[9] $$k_{obs} = k_2(app)\left(\frac{[DH^+]}{[T] + [DH^+]}\right)$$

where k_2(app) replaces k_2^0(app) of eq. [7] because of the non-ideality of the reaction medium. The term in brackets represents the changing equilibrium position. This is equal to $h_T/(h_T + K_{DH^+})$ and can be calculated using the acidity function and dissociation constants determined in the previous paper. This allows for the calculation of values of k_2(app) and these are shown as the dashed lines in Fig. 1. (In more concentrated

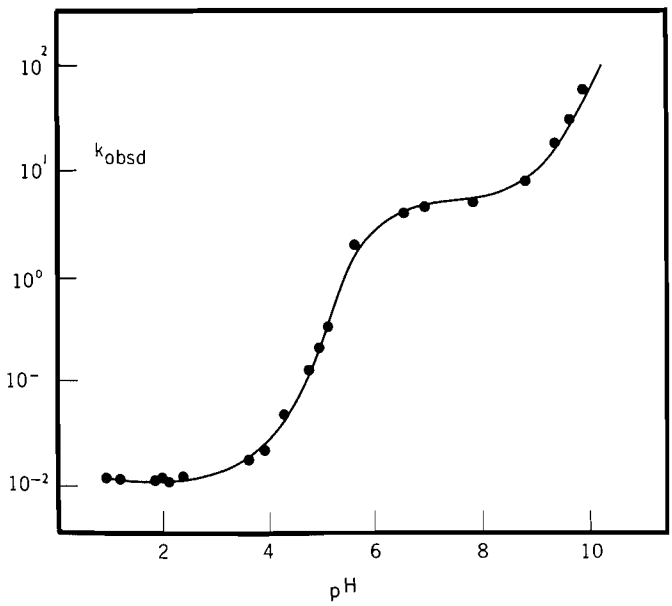

FIG. 2. First-order rate constants (s^{-1}, 25°C) for the hydrolysis of the cation DEt^+, Ar = 4-MeC_6H_4, as a function of pH.

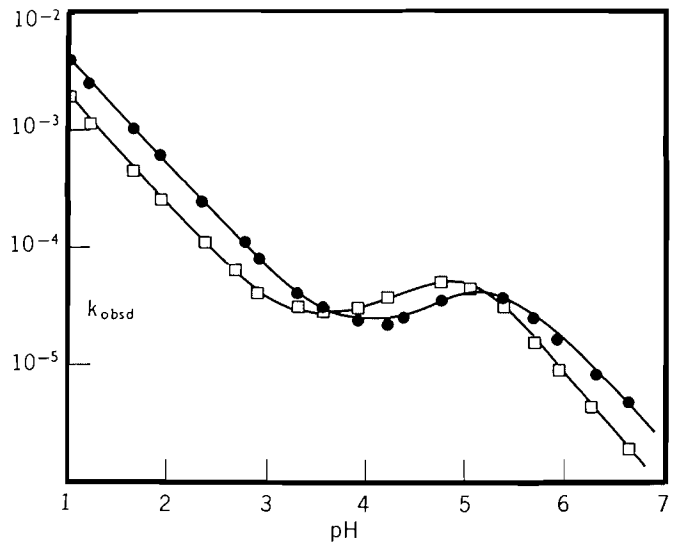

FIG. 3. First-order rate constants (s^{-1}, 76.8°C) for the hydrolysis of 3-aryl-2,4,10-trioxaadamantanes; (●) 4-MeC_6H_4, (◇) 4-ClC_6H_4.

acids where $[DH^+] \gg [T]$, $k_{obs} = k_2(app)$.) A series of parallel curves are produced, showing a monotonic decrease with increasing acidity. Also shown in Fig. 1 are values of $k_2^0(app)$ calculated from the dilute acid rate data as discussed previously, and referring to water alone. Within experimental error the $k_2(app)$ curves do extrapolate to these, as they should.

The simple interpretation of these kinetics is that $k_2(app)$ refers to the rate constant for hydration of the cation, and the decrease in $k_2(app)$ with increasing acidity is caused by a decrease in water activity combined with an activity-coefficient effect (6). The following data, however, indicate that this simple explanation cannot be correct.

Hydrolysis of the cation DEt^+

In the pH region the initial equilibrium favors trioxaadamantane and any addition of cation just results in ring closure. The consequence is that the hydrolysis kinetics for the cation cannot be studied directly. In order to overcome this problem, the cation DEt^+ (with Ar = 4-MeC_6H_4) was prepared as its borofluorate salt. This cation cannot ring close, and the kinetics of its hydrolysis were studied over a range of pH. First-order behavior was observed; rate constants are listed in Table S4[2] and depicted graphically in Fig. 2.

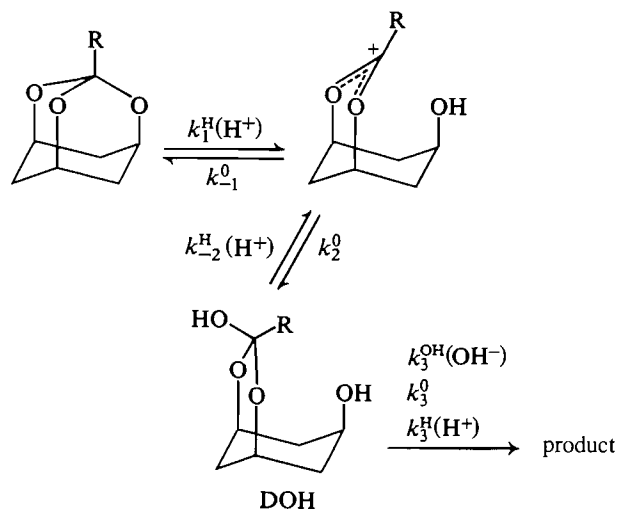
Trioxaadamantane hydrolysis over a range of pH

As will be discussed, the behavior of DEt^+ is not consistent with a simple rate-determining hydration, and we wondered if the ortho ester could be observed to exhibit similar behavior. In consequence, rate constants for two of the trioxaadamantanes were measured over a range of pH at 77°C. The higher temperature was employed in order to speed up the reaction sufficiently to enable the kinetics to be easily studied at the higher pH. Measurements were made under conditions for which eq. [6] had previously been applied; that is, with the initial equilibrium favoring trioxaadamantane. The kinetic data are given in Table S5[2]; rate–pH profiles are shown in Fig. 3. The behavior in acid solutions with pH < 3 does show the first-order dependency in H^+ concentration in accord with eq. [6], but as the pH is increased the profile becomes considerably more complex. In fact, there is a short region of pH where an inverse pH dependency is observed.

Kinetic analysis

Although their profiles are quite different, a common kinetic model explains the behavior of both the trioxaadamantanes and the cation DEt^+, the key feature being a change in rate-determining step between high pH and low pH. Equation [11] presents the appropriate scheme for the ortho ester.

[11]



The rate and equilibrium behavior of the first stage have been discussed. Hydration of the dioxanylium ion occurs via simple water addition; the hemiorthoester DOH can return to cation in the microscopic reverse reaction which is H^+-catalyzed. The equilibrium constant K_R is defined as $[DOH][H^+]/[DH^+]$ and is equal to k_2^0/k_{-2}^H. We also define an equilibrium constant K_{13} as $[DOH]/[T] = K_R/K_{DH^+}$. Product is formed from the hemiorthoester via three pathways, with H^+ catalysis, OH^- catalysis, and water catalysis (a pH-independent process). The first stage is reversible under all conditions and is therefore never rate limiting. This fact is apparent from those experiments in which the cation is added to aqueous solutions and, regardless of pH, trioxaadamantane is generated. The requirement for such reversibility is $k_{-1}^0 \gg k_2^0$; that this condition is met will be

TABLE 2. Rate and equilibrium constant data for the hydrolysis of trioxaadamantanes (77°C) and the cation DEt^+

Constant	Trioxaadamantane T(4-MeC_6H_4)	Trioxaadamantane T(4-ClC_6H_4)	DEt^+
a	14	8.2	4.5
b	3.7×10^{-3}	2.4×10^{-3}	2.5×10^{-3}
c	1.1×10^{-6}	2.9×10^{-6}	4.2×10^{-7}
d	2.5×10^{3}	9.6×10^{3}	3×10^{4}
pK_{DH^+}	−0.77	−2.00	—
k_2^0, s^{-1}	86	8.2×10^{2}	4.5
k_{-2}^H, M^{-1} s^{-1}	2×10^{7}	5×10^{6}	2×10^{6}
pK_R	5.4	3.9	5.6
K_{13}	7×10^{7}	12×10^{-7}	—
k_3^{OH}, M^{-1} s^{-1}	5×10^{10}	5×10^{10}	5×10^{10}
k_3^0, s^{-1}	22	15	0.8
k_3^H, M^{-1} s^{-1}	7×10^{4}	1.2×10^{4}	5×10^{3}
k_2^{OH}, M^{-1} s^{-1}	—	—	5×10^{5}

shown presently. With the trioxaadamantane and cation in equilibrium, a stationary state assumption in hemiorthoester produces the following equation for the observed rate constant.

$$[12]\quad k_{obsd} = k_2^0\left(\frac{[H^+]}{K_{DH^+}}\right) \times \left\{\frac{\frac{k_3^H}{k_{-2}^H}[H^+] + \frac{k_3^0}{k_{-2}^H} + \frac{k_3^{OH}}{k_{-2}^H}[OH^-]}{\left(1 + \frac{k_3^H}{k_{-2}^H}[H^+] + \frac{k_3^0}{k_{-2}^H} + \frac{k_3^{OH}}{k_{-2}^H}[OH^-]\right.}\right\}$$

This has the form

$$[13]\quad k_{obsd} = a[H^+]\left\{\frac{b[H^+] + c + d[OH^-]}{(1+b)[H^+] + c + d[OH^-]}\right\}$$

with $a = k_2^0/K_{DH^+}$, $b = k_3^H/k_{-2}^H$, $c = k_3^0/k_{-2}^H$, and $d = k_3^{OH}/k_{-2}^H$. The profiles in Fig. 3 provide an excellent fit to this equation, giving the constants a–d listed in Table 2.

The change in rate-determining step is a consequence of k_{-2}^H being greater than k_3^H, as seen in the values of the constant b. This produces a situation in which, in acid solutions, the overall rate of the hemiorthoester decomposition stage is slower than the rate of reverse of the hydration stage. Not only are the trioxaadamantane and cation in equilibrium, but included as well is the hemiorthoester. It is the decomposition of this species which is rate determining. The other pathways available for this breakdown mean, however, that at some higher pH its rate becomes greater than the reverse of the second stage, which remains acid catalyzed. At this point cation hydration becomes rate limiting. Figure 4 is a schematic representation of the rate profile, idealizing the various sections by ignoring the regions where changeover from one behavior to another is occurring. The change in rate-determining step occurs near pH 5, at the intersection between C and D in the figure. In more acidic solutions, where hemiorthoester breakdown is rate limiting, the observed rate constant is given simply by $K_{13}(k_3^H[H^+] + k_3^0 + k_3^{OH}[OH^-])$, where K_{13} is the equilibrium constant relating trioxaadamantane and hemiorthoester. The profile in this region shows H^+ catalysis (A), water catalysis (B), and OH^- catalysis (C). As the pH is increased in region C, the third stage has become OH^- catalyzed while the reverse of the second

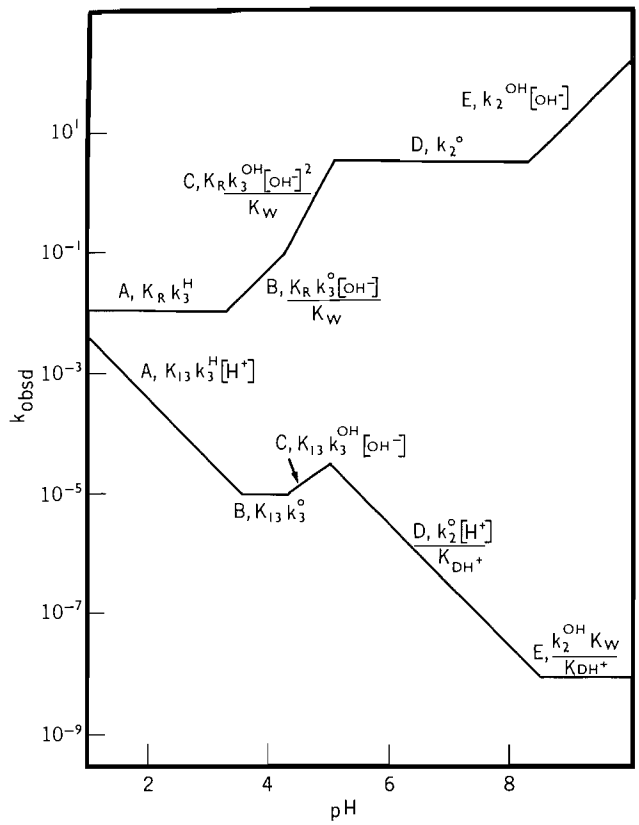


FIG. 4. Schematic representation of rate–pH profiles for the hydrolysis of trioxaadamantanes (bottom trace) and cations DEt^+ (top trace).

stage is still H^+ catalyzed, and an abrupt changeover in the relative magnitudes of the rates of these occurs. Hydration then becomes rate limiting and the observed rate constant in region D returns to an H^+ dependency, being equal to k_2^0 times $([H^+]/K_{DH^+})$, the bracketed term representing the cation–trioxaadamantane equilibrium.

In terms of the rate behavior in more concentrated acids discussed previously, the constant k_2^0 (app) in Table 1 is now seen to be equal to $K_R \cdot k_3^H$. The decrease in k_2 (app) which is seen in more concentrated acids is difficult to explain without going into a detailed analysis which is beyond the scope of this paper. In brief, it is related to a differential medium effect on the cation–hemiorthoester equilibrium position and the rate of acid-catalyzed breakdown of the latter, increasing sulfuric acid concentration shifting the equilibrium more towards the cation than it accelerates the rate.

The behavior exhibited by the trioxaadamantanes has a parallel with that of monocyclic ortho esters. Studies conducted over the past few years (7, 10–16) have shown that the exocyclic alkoxy group OR is lost in the dialkoxy carbocation-forming stage, with the key feature that k_3^H is usually signifi-

TABLE 3. Rate and equilibrium constant data for the hydrolysis of 3-phenyl-2,4,10-trioxaadamantane and 2-phenyl-2-methoxy-1,3-dioxane

Constant	Adamantane	Dioxane
k_1^H, M^{-1} s^{-1}	5×10^3	3×10^{4a}
k_{-1}^0, s^{-1}	10^5	—
pK_{DH^+}	−1.2	—
k_2^0, s^{-1}	10^1	10^{4c}
k_{-2}^H, M^{-1} s^{-1}	10^6	2×10^{4b}
pK_R	5	0.3^a
k_3^H, M^{-1} s^{-1}	3×10^3	3×10^{3a}
k_3^0, s^{-1}	1	1.0^a
k_3^{OH}, M^{-1} s^{-1}	10^{10}	10^{9d}

[a]Reference 7.
[b]Calculated as 0.8 k_1^H (see refs. 10, 15).
[c]$K_R \cdot k_{-2}^H$.
[d]R. A. McClelland and L. J. Santry, unpublished. 2-Phenyl-2-hydroxy-1,3-dioxalane has $k_3^{OH} = 5 \times 10^{10} M^{-1}$ s^{-1} (10).

cantly smaller than both k_1^H and k_{-2}^H. The latter two are in fact quite close in magnitude, since they represent similar processes, loss of an exocyclic OR and OH to form the same cyclic cation. The orgin of the effect is not completely understood. The significant factor appears (16) to be the requirement that a ring must open in the third stage, while the k_1^H and k_{-2}^H processes involve dissociation. It can be noted with the trioxaadamantanes that k_{-2}^H is again greater than k_3^H, and once again the exocyclic−endocyclic comparison applies.

With the monocyclic systems, the consequence of k_3^H being less than k_1^H and k_{-2}^H is that there is a change in slow step with changing pH. At high pH where hemiorthoester breakdown occurs by the other pathways, particularly that involving OH^- catalysis, the first stage is the slow stage. However, at low pH the third stage is rate limiting. In this case the ortho ester is converted to hemiorthoester more rapidly than the latter species goes on to product, so that the hemiorthoester actually accumulates as a transient intermediate. This is a different situation from that encountered with the trioxaadamantanes, where the change in slow step represents a change in the preferred mode of reaction of the hemiorthoester. With the trioxaadamantane, this species does not accumulate to any significant extent. For the monocyclic ortho esters, the appropriate kinetic analyses can furnish all of the rate constants of eq. [14], and these are listed in Table 3 for 2-phenyl-2-methoxy-1,3-dioxane, an appropriate analog of trioxaadamantane. A general feature exhibited by the monocyclic systems is the very large rate constants, usually near the diffusion limit, for the OH^- catalysis of the hemiorthoester breakdown. This has the consequence that this pathway becomes important in quite acidic solutions. As seen in Figs. 3 and 4, this is also observed with the hemiorthoester derived from the trioxaadamantane.

With the trioxaadamantanes the kinetic analysis can furnish k_2^0, since this is equal to $a \cdot K_{DH^+}$, but the other rate constants k_{-2}^H, k_3^H, k_3^0, and k_3^{OH} are provided only as ratios (see eq. [12]). To calculate these we have made the assumption that k_3^{OH} is a diffusion-limited rate constant and set it equal to $5 \times 10^{10} M^{-1}$ s^{-1}, the value found for 2-phenyl-2-hydroxyl-1,3-dioxalane (10). With this number in hand k_{-2}^H can be calculated as k_3^{OH}/d, and then k_3^H as $b \cdot k_{-2}^H$ and k_3^0 as $c \cdot k_{-2}^H$. The K_R value can also be calculated as k_2^0/k_{-2}^H and K_{13} as K_R/K_{DH^+}. Values of these constants are listed in Table 2.

With DEt^+ the kinetic analysis takes a similar form, except that now there is no equilibrium with the ortho ester, the starting point being the dioxanylium ion. Rate constants k_{obsd} are given by eq. [12], except that the term in $[H^+]/K_{DH^+}$ is not present. This means that the form of the equation, eq. [13], does not have the term in H^+ concentration before the bracket, so that the shape of the profile is quite different. The constant "a" is now equal to k_2^0, while b, c, and d have the same meaning as before. Values of these constants which provide the best fit to the experimental data are given in Table 2. Once again the assumption is made that $k_3^{OH} = 5 \times 10^{10} M^{-1}$ s^{-1}, to enable the calculation of the individual constants.

Some justification can be made for the numbers which arise, since the result is a pK_R value of 5.6 for DEt^+. Lower values of k_3^{OH} would mean lower values of k_{-2}^H and in consequence a smaller pK_R value. One can argue, however, that this pK_R is reasonable, or at the very least it cannot be smaller. The argument is based on the consideration that if pK_R were smaller, the kinetics associated with the disappearance of DEt^+ would not be simply first order; under some conditions biphasic kinetics should result. There should be one kinetic phase associated with the equilibration of the cation and the hemiorthoester, followed by a second phase as the equilibrating mixture is converted to product. For this to occur there must be a significant amount of hemiorthoester in the initial equilibrium, or $pH \geq pK_R$; otherwise the initial phase would be small or absent. It also requires conditions where the hemiorthoester decomposition is still rate limiting; that is, this decomposition must be slower than the equilibration. This latter requirement limits us to solutions with $pH < 5$. We did look for biphasic kinetics around this pH but were unable to observe any significant deviation from a simple first-order decay. We conclude therefore that we were not at a pH significantly above the pK_R, or, in other words, the value of pK_R of 5.6 calculated in the kinetic analysis is reasonable.

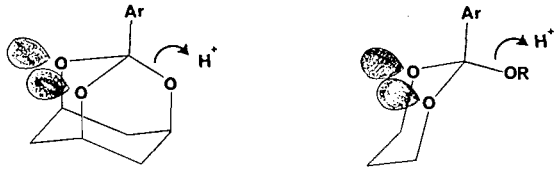
The top trace in Fig. 4 is a schematic representation of the rate profile for DEt^+. As with the trioxaadamantanes, the change in rate-determining step occurs near pH 5, and solutions more acidic than this have rate-determining hemiorthoester breakdown. In these solutions k_{obsd} is given by $(K_R/[H^+]) \times (k_3^H[H^+] + k_3^0 + k_3^{OH}[OH^-])$, the first bracketed term representing the equilibrium with the cation and the second bracketed term the three modes of hemiorthoester breakdown. In more basic solutions k_{obsd} is simply given by k_2^0, the rate constant for water addition. In basic solutions (pH > 8), a further dependency on OH^- is seen. This can be ascribed to a rate-limiting addition of hydroxide ion to the cation, with the symbolism k_2^{OH} for the second-order rate constant. It can be noted that a similar process will occur in basic solutions with the trioxaadamantane, that is, a rate-limiting addition of hydroxide ion to the dioxanylium ion in equilibrium with the ortho ester. The observed rate constant would be pH independent here (region E of the bottom trace in Fig. 4). Using the value of k_2^{OH} obtained with DEt^+, we calculate that the value of this pH-independent rate constant should be of the order to 10^{-8} s^{-1} to 10^{-10} s^{-1}, representing, in other words, a very slow process.

Comparison with other ortho esters

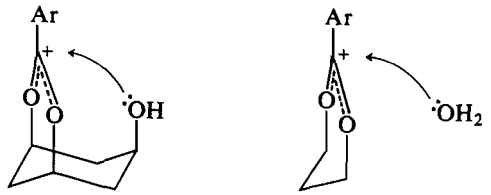
Table 3 compares rate and equilibrium constants for the three stages of the hydrolysis of a trioxaadamantane and a dioxane ortho ester, the numbers for the second and third stages of the former being based on DEt^+. There are several features of these data which can be commented upon.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

(a) In its initial ring-opening reaction, the trioxaadamantane does not differ too greatly in its rate from that associated with the exocyclic cleavage in the first stage of the monocyclic system. The two systems, in fact, have quite similar orientations of the leaving group including the correct lone pair orientation for production of the dioxanylium ion.

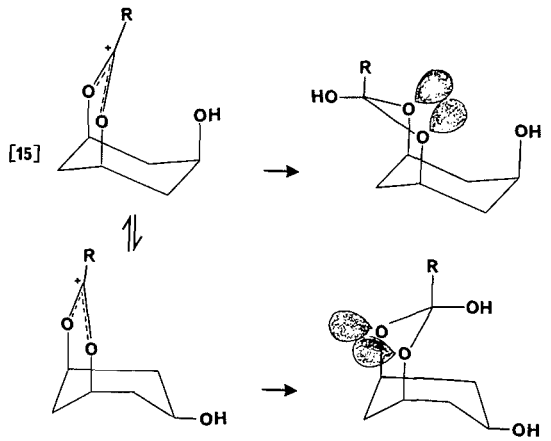


(b) The acceleration associated with the intramolecular nature of the reverse ring closure can be evaluated by comparing the constant k^0_{-1} for the trioxaadamantane with the rate constant k^0_2 for water addition to the dioxanylium ion generated in the dioxane system. Taking into account that the latter refers



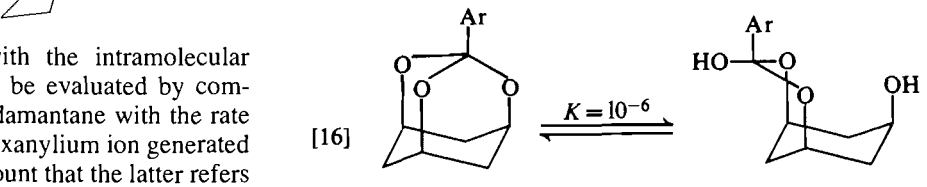
to water as solvent so that the comparison should actually be made with $k^0_2/55$, it is seen that the intramolecular reation is of the order of 10^3 faster. This, is, of course, one of the factors contributing to the reversibility of the ring opening.

(c) The other factor is that the rate constant k^0_2 for water addition to the dioxanylium cation in the trioxaadamantane system is unusually low, by a factor of about 10^3. (Compare here the two k^0_2 values.) That this is the case was suggested by Lamaty, Moreau and co-workers (3), although they were unable to estimate the magnitude of the effect. These authors presented a detailed explanation for the slowness of this reaction (3). The simple basis of their argument is that, for addition to occur with the correct lone pair orientation, one of the cyclohexane rings in the hemiorthoester must be placed in a boat configuration. This problem does not arise with a simple dioxanylium ion.



(d) The magnitude of this effect can be seen in thermodynamic terms in the pK_R values, which differ by approximately 5 log units. If this difference is entirely associated with the stability in the hemiorthoesters, then the hemiorthoester formed in the trioxaadamantane system is about 7–8 kcal/mol less stable than a simple 2-hydroxy-1,3-dioxane. That difference corresponds to the energy required for inversion of a chair to a boat cyclohexane.

(e) This same energy difference is also seen in K_{13}, the equilibrium constant relating trioxaadamantane and hemiorthoester. It can be argued that inherently there should be little difference in energy between an ortho ester and hemiorthoester, since both species have a tetrahedral carbon with three



oxygen atoms attached. That assumption is in fact the basis of Guthrie's method for estimating free energies of hemiorthoester tetrahedral intermediates (17). The difference in the case involved here is once again related to the unusually high energy of the hemiorthoester.

Received August 2, 1983

WOJCIECH J. SZCZEPEK, JACEK W. MORZYCKI, ZBIGNIEW BOŃCZA-TOMASZEWSKI, MICHAŁ CHODYŃSKI, and WŁADYSŁAW J. RODEWALD. Can. J. Can. J. Chem. **62**, 1081 (1984).

Two independent synthetic routes to 10-oxo-5, 10-seco-des-*A*-cholestan-5-oic acid (**5**) are described. The route including the Baeyer–Villiger rearrangement of (10*R*)-des-*A*-cholestan-5-one (**2***a*), followed by hydrolysis of the lactone **3***a* obtained and oxidation of the C-10 hydroxyl group, seems to be superior to ozonolysis of the 5(10)-enol acetate **6** of des-*A*-ketone which resulted in the formation of 5,10-seco-des-*A*-19-norcholestan-5,10-dioic acid (**7**), in addition to the compound **5**. Product **7** and its 6-nor analog **12** have also been obtained by ruthenium tetroxide oxidation of the respective *A*-ring phenols **8**, **9**, and **11**.

WOJCIECH J. SZCZEPEK, JACEK W. MORZYCKI, ZBIGNIEW BOŃCZA-TOMASZEWSKI, MICHAŁ CHODYŃSKI et WŁADYSŁAW J. RODEWALD. Can. J. Can. J. Chem. **62**, 1081 (1984).

Nous avons décrit deux routes synthétiques indépendantes conduisant à l'acide 10-oxo-5,10-seco-des-*A*-cholestanique-5 (**5**). Il nous semble que la route via le réarrangement de Baeyer–Villiger de (10*R*)-des-*A*-cholestan-5-one (**2***a*), l'hydrolyse de lactone **3***a* obtenu et l'oxydation de groupe hydroxylique à C-10 est supérieur que l'autre qui consiste en l'ozonolyse de 5(10)-double liaison dans l'acetate **6** de la forme énolique de des-*A*-cétone. La dernière reaction donne en outre du composé **5** l'acide dicarboxylique **7**. Le produit **7** et son 6-nor analogue **12** ont été preparés aussi par l'oxydation des phenoles du noyau *A*, **8**, **9** et **11**, avec tetraoxyde de ruthenium.

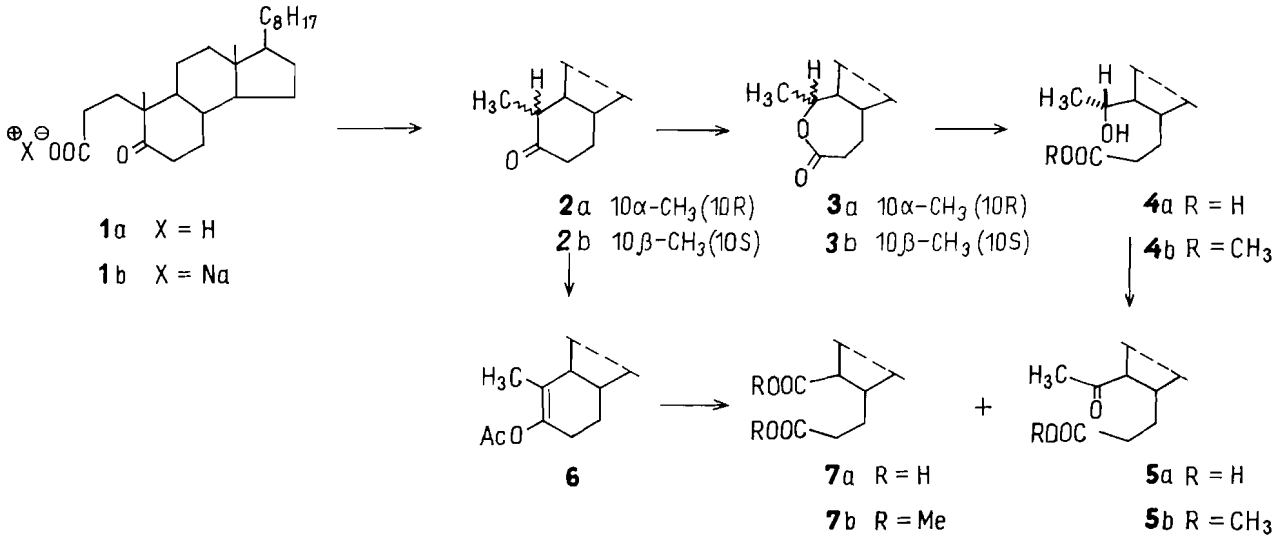
During the last two decades a number of synthetic studies on steroids concerned heteroanalogs of these natural products. These investigations were continued for such a long period because medical tests of many synthetic compounds were very promising. The most interesting heteroanalogs from the point of view of their biological activity seemed to be compounds containing heteroatoms in place of quaternary carbon at ring junctions (i.e. 5, 10, 13 etc). However, such analogs are not readily available and very often their syntheses, although successfully accomplished in many cases (2, 3), are long, tedious, and inefficient. In contrast to these multistep methods, a different approach, consisting in the attachment of a suitable, high molecular weight fragment containing the heteroatom to the partially degraded steroid, could be envisaged. The same steroid component might then be used for the synthesis of many different heteroanalogs.

A few years ago we undertook some studies on an extensive degradation of steroids (1, 4). In the present contribution we describe our recent results in this field. Relatively short and efficient methods for the synthesis of keto-acid **5**, as well as diacids **7** and **12** have been elaborated. The application of these useful compounds in the synthesis of azasteroids will be demonstrated in a future publication.

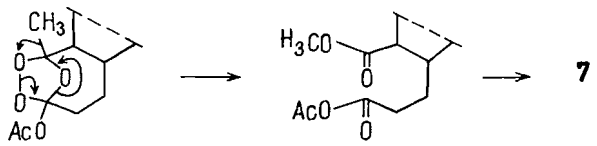
The starting material was des-*A*-ketone **2** (5), obtained by the pyrolysis of the sodium salt **1***b* of *A*-seco-keto-acid (6) in the presence of a basic agent such as sodium phenylacetate or potassium acetate at about 300°C. The main reaction product, (10*R*)-des-*A*-ketone **2***a* (30–40% yield), was accompanied by a number of stereoisomers. The detailed analysis of neighbouring fractions from the chromatography of **2***a* and mother liquors after crystallization showed the presence of at least ten isomeric des-*A*-ketones with various configurations at the chiral centers. Only one of them, (10*S*)-des-*A*-ketone **2***b*, existed in a significant amount (5–8%) and was fully characterized. The cd (circular dichroism) spectra of **2***a* and **2***b* showed the negative Cotton effects, much more distinctive in the case of (10*R*)-des-*A*-ketone **2***a* and thus confirming its configuration at C-10. The equilibration experiment carried out under alkaline conditions proved the epimeric relationship between **2***a* and **2***b*.[2] The Baeyer–Villiger rearrangement of each des-*A*-cholestan-5-one (**2***a* or **2***b*) with *m*-chloroperbenzoic acid (MCPBA) afforded the corresponding des-*A*-lactone (**3***a* or **3***b*) in a very good yield (Scheme 1). The reactions proceeded with the retention of configuration at C-10. This was proved by the ^{1}H nmr spectra of **3***a* and **3***b* showing a broadened quartet for 10α-H in the case of (10*S*)-des-*A*-lactone **3***b* (a small coupling constant between the pseudo-equatorial 10α-H and axial 9α-H), whereas the β-proton at C-10 in the epimeric lactone **3***a* appeared as an unresolved (at 100 MHz) multiplet ($w/2$ = 19 Hz), suggesting a large diaxial coupling constant $J_{9\alpha,10\beta}$. Hydrolysis of the (10*R*)-5a-oxo-des-*A*-*B*-homo-5-oxacholestane (**3***a*) with methanolic–aqueous KOH provided the hydroxy-acid **4***a*. To prevent recyclization to the lactone, hydroxy-acid **4***a* was transformed into its methyl ester **4***b* before oxidation. The reaction of **4***b* with CPA (CrO_3, Py, HOAc, ref. 7) yielded keto-ester **5***b*. It should be emphasized that all transformations from **2** to **5** were very efficient and could be done in principle without any chromatography. However, an alternative, shorter method for the synthesis of compound **5** from des-*A*-ketone **2** seemed possible. It was reasonable to expect that oxidative cleavage of the double bond between C-5 and C-10 in an enol-ester of des-*A*-ketone **2** should provide the same keto-acid **5**. An ozonolysis of the known enol-acetate **6** (5) confirmed this supposition, though the reaction appeared to be less attractive from a synthetic point of view. The primary reaction products had an anhydride character (ir bands at 1760 and 1820 cm^{-1}) and were difficult to purify. The crude products were subjected to alkaline hydrolysis and then treated with diazomethane. The reaction resulted in the formation of two

[1] Part IV in our series on des-*A*- and des-*A*-*B*-secosteroids. For part III, see ref. 1.

[2] The isolation of **2***a* and **2***b* and their equilibration have been effected previously (private communication from Professor Peter Yates, University of Toronto).



SCHEME 1

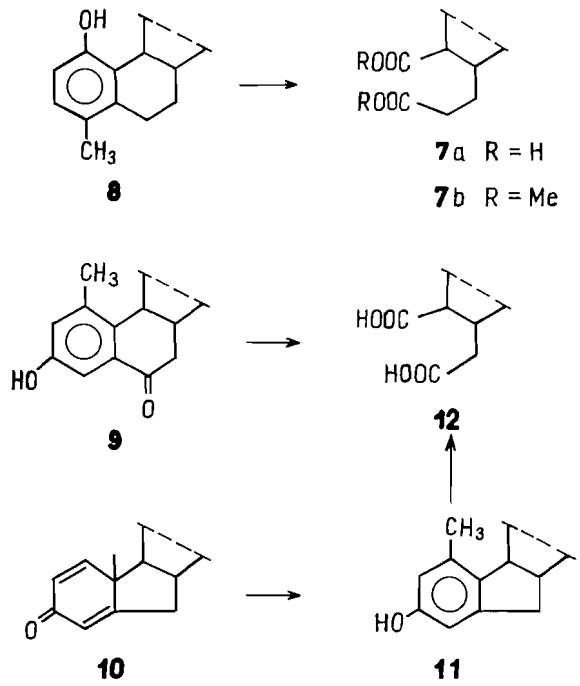


SCHEME 2

main products in almost equal amounts. The more polar product proved to be identical in all respects with a sample of the keto-ester **5***b* prepared as previously described. The second product of the ozonolysis was unexpectedly identified as diester **7***b*. To explain the formation of this product a migration of the methyl group with the pair of electrons from C-10 to an oxygen atom in an intermediary ozonide is proposed (Scheme 2). A similar course of reaction was observed during ozonolysis of α-pinene (8).

In searching for a better route to the diacid **7**, our attention has been drawn to the degradation of aromatic steroids by ruthenium tetroxide (9). 1-Hydroxy-4-methyl-1,3,5(10)-cholestatriene (**8**), obtained from 1,4-cholestadien-3-one by the known dienone–phenol rearrangement (10), when oxidized with RuO_4 afforded diacid **7***a* in 31% yield. The compound **7***a* and its dimethyl ester **7***b* were compared with the respective compounds obtained according to the method described above and proved to be identical.

In the oxidation by ruthenium tetroxide of phenol **8**, the degradation of ring *A* terminated at carbons 5 and 10 as expected. It was anticipated that the oxidation of the 6-oxo and *B*-nor derivatives **9** and **11** would yield the diacid **12**, having one carbon atom less than **7**, and therefore would be more convenient in the synthesis of steroid heteroanalogs. Indeed, 6-oxo-phenol **9** (11), when treated with RuO_4, underwent degradation to diacid **12** (Scheme 3). The same compound **12** was also obtained by oxidation of *B*-nor-phenol **11**, prepared from *B*-nor-1,4-cholestadien-3-one (**10**) (12).[3] The use of ruthenium



SCHEME 3

tetroxide for degradation of aromatic steroids to diacids was found to be superior to the ozonolysis of enol-acetate **6**.

Studies on the reconstruction of steroid systems from the des-*A*-*B*-seco derivatives described, with simultaneous introduction of the heteroatom, are under way.

Experimental

The melting points were determined on a Boetius micro melting point apparatus and are uncorrected. Optical rotations were measured on a Perkin–Elmer 241 polarimeter. The ir spectra were recorded on UR-20 and Unicam SP 1100 spectrophotometers. The ^1H nmr spectra were taken at 100 MHz (JEOL INM-4H-100) in $CDCl_3$ solutions with TMS as an internal standard. The cd spectra were measured on a Jasco ORD/UV-5 apparatus. Column chromatography was performed on silica gel (Kieselgel 60, 70–230 mesh, Merck) and on Alumina IB (Woelm). Thin layer chromatograms were developed on Silica Gel G

[3] It is noteworthy that 1-methyl-*B*-nor-phenol **11** is formed from *B*-nor-dienone **10** by a mechanism involving a simple methyl migration from C-10 to C-1, because a spiran intermediate, which is normally formed in such a rearrangement, would be highly strained (see ref. 13).

(Merck) and visualized with 50% sulfuric acid after heating. All solvents were dried and freshly distilled prior to use. The known 5-oxo-*A*-nor-3,5-secocholestan-3-oic acid (**1***a*) was prepared according to the procedure described in ref. 6.

Des-A-*cholestan-5-ones (2*a *and 2*b)

Variant (a)

To a solution of *A*-seco-keto-acid (**1***a*, 14.0 g) in methanol (100 mL) was added sodium hydroxide (1.5 g) dissolved in the same solvent (with a few drops of water). The methanol was evaporated and the solid residue was dried carefully under reduced pressure at 100°C. The above salt was melted with sodium phenylacetate (56 g) and heated under 15 Torr (1 Torr = 133.322 Pa) to remove easily volatile reaction products. The pyrolysis was contined at 300°C using an oil pump (0.04–0.10 Torr). Under these conditions all reaction products distilled off in the form of a colourless oil. The products were separated on Alumina IB. With a benzene–ether mixture (4:1), dibenzylketone (mp 34°C from hexane, lit. (14) mp 34.5°C) and ketone **2***a* were successively eluted. Compound **2***a* crystallized from hexane (3.5 g, 30% yield), mp 62–63°C (lit. (5) mp 62–63°C); $[\alpha]_D^{25}$ +12.4° (*c* 1.0); ν_{max} ($CHCl_3$): 1711 cm^{-1}; δ: 0.75 (s, 3H, 18-H), 1.00 (d, *J* = 7 Hz, 19-H); cd (hexane, *c* = 4.2 mg/mL): $[\theta]_{295}$ − 7143.

Variant (b)

A-seco-keto-acid (**1***a*, 10.1 g) in methanol was titrated with a methanolic solution of MeONa in the presence of phenolphthalein as an indicator. The solvent was removed and potassium acetate (15 g) was added. The pyrolysis was carried out in the same manner as described above. The crude reaction product was purified by silica gel column chromatography. The benzene elution afforded compound **2***a* in a pure state, yield 3.2 g (39%). Further elution with the same solvent gave (10*S*)-des-*A*-cholestan-5-one (**2***b*), yield 0.56 g (7%), mp 80–81°C (lit. (see footnote 2) mp 71–72°C); $[\alpha]_D^{26}$ +18.1° (*c* 1.0); ν_{max} ($CHCl_3$); 1706 cm^{-1}; δ: 0.75 (s, 3H, 18-H), 1.11 (d, *J* = 7 Hz, 19-H); cd (hexane, *c* = 13.1 mg/mL): $[\theta]_{300}$ − 2183. *Anal.* calcd. for $C_{23}H_{40}O$: C 83.1, H 12.1; found: C 83.0, H 12.2.

Equilibration experiment

A solution of (10*S*)-des-*A*-ketone **2***a* (15 mg) in methanol (10 mL) was treated with aqueous KOH (3 *N*, 1 mL) and refluxed for 30 min. The equilibrium mixture of **2***a* and **2***b* was obtained, as indicated by tlc.

*(10*R*)-5a-Oxo-des*-A-B-*homo-5-oxacholestane (3*a)

(10*R*)-Des-*A*-ketone **2***a* (3.2 g) and *m*-chloroperbenzoic acid (6.4 g) were dissolved in chloroform (100 mL) and allowed to stand for 3 days. The solvent was evaporated and the residue was treated with an ethereal solution of diazomethane. After removal of ether, the crude reaction product was absorbed on a silica gel column to separate the steroidal product from less polar aromatic esters. The rearrangement product, (10*R*)-des-*A*-lactone **3***a*, was eluted with a benzene–ether mixture (9:1) and crystallized from hexane. The compound **3***a* was obtained as colourless needles (2.2 g, 66%), mp 138–139°C; $[\alpha]_D^{25}$ +62.9° (*c* 1.0); ν_{max} ($CHCl_3$): 1729 and 1293 cm^{-1}; δ: 0.71 (s, 3H, 18-H), 1.31 (d, *J* = 7 Hz, 19-H), 4.40 (m, *w*/2 = 19 Hz, 1H, 10β-H). *Anal.* calcd. for $C_{23}H_{40}O_2$: C 79.3, H 11.6; found: C 79.2, H 11.4.

*(10*S*)-5a-Oxo-des*-A-B-*homo-5-oxacholestane (3*b)

(10*S*)-Des-*A*-ketone **2***b* (145 mg) and *m*-chloroperbenzoic acid (290 mg) were dissolved in chloroform (40 mL) and allowed to stand for 24 h. The reaction mixture was extracted twice with a saturated solution of sodium carbonate, washed with water, dried, and evaporated. The chromatography on a silica gel column afforded pure (10*S*)-des-*A*-lactone **3***b* (elution with benzene–ether mixture 9:1; yield 120 mg), mp 109–111°C (from hexane); $[\alpha]_D^{26}$ +28.7° (*c* 1.0); ν_{max} ($CHCl_3$): 1723 cm^{-1}; δ: 0.71 (s, 3H, 18-H), 1.42 (d, *J* = 7 Hz, 19-H), 4.58 (broadened q, *J* = 7 Hz, 1H, 10α-H). *Anal.* calcd. for $C_{23}H_{40}O_2$: C 79.3, H 11.6; found: C 79.1, H 11.6.

*10*R*-Hydroxy-5,10-seco-des*-A-*cholestan-5-oic acid (4*a) *and its methyl ester 4*b

A solution of (10*R*)-des-*A*-lactone **3***a* (1.4 g) in methanol (50 mL) was refluxed for 3 h with a 3% aqueous solution of potassium hydroxide (20 mL). After cooling, it was acidified with 2% hydrochloric acid (200 mL) and quickly extracted with chloroform. The extract was washed with water, dried (anhydrous Na_2SO_4), and evaporated. Crude hydroxy-acid **4***a* crystallized from hexane to yield 1.1 g of pure **4***a*, mp 114–117°C; ν_{max} ($CHCl_3$): 3400–2500 (COOH), 1720 cm^{-1}; δ: 0.69 (s, 3H, 18-H), 1.11 (d, *J* = 7 Hz, 19-H), 4.05 (m, 1H, 10-H), 7.40 (m, 2H, COOH and OH).

Methyl ester **4***b* of the hydroxy-acid was obtained by treating the free acid **4***a* with diazomethane in the usual manner as an amorphous solid, $[\alpha]_D^{25}$ +38.7° (*c* 1.2); ν_{max} ($CHCl_3$): 3612, 1737, 1265, and 1180 cm^{-1}; δ: 0.68 (s, 3H, 18-H), 1.12 (d, *J* = 7 Hz, 3H, 19-H), 3.68 (s, 3H, $COOCH_3$), 4.10 (m, 1H, 10-H). *Anal.* calcd. for $C_{24}H_{44}O_3$: C 75.7, H 11.7; found: C 75.6, H 11.6.

Methyl 10-oxo-5,10-seco-des-A-*cholestan-5-oate (5*b*) and 10-oxo-5,10-seco-des*-A-*cholestan-5-oic acid (5*a)

Chromium trioxide (2.0 g) was slowly added to the vigorously stirred solution of pyridine (3.2 g) in acetic acid (15 mL), maintaining the temperature at 15–20°C. After all CrO_3 had dissolved the reagent was diluted to a volume of 25 mL with acetic acid. Prepared in such a way, the 0.8 *M* solution of CPA was used for the oxidation.

Methyl ester **4***b* (0.8 g) dissolved in AcOH (1 mL) and frozen in the refrigerator was treated with 0.8 *M* CPA (9 mL). The reaction was stirred for 20 min at 20°C, then quenched by addition of water (150 mL). The reaction mixture was extracted 3 times with ether, the combined extracts were rinsed with sodium bicarbonate solution, water, dried over sodium sulfate, and evaporated. The crude material was essentially pure and slowly crystallized from methanol with a few drops of water to afford **5***b* (0.6 g), mp 29–32°C; $[\alpha]_D^{25}$ +36.2° (*c* 1.3); ν_{max} ($CHCl_3$): 1705 and 1730 cm^{-1}; δ: 0.76 (s, 3H, 18-H), 2.07 (s, 3H, $COCH_3$), 3.68 (s, 3H, $COOCH_3$). *Anal.* calcd. for $C_{24}H_{42}O_3$: C 76.1, H 11.2; found: C 76.4, H 11.0.

Hydrolysis of methyl ester **5***b* with methanolic–aqueous KOH carried out in the usual manner gave the free keto-acid **5***a* as a colourless oil; $[\alpha]_D^{26}$ +30.7° (*c* 1.0); ν_{max} ($CHCl_3$): 3450–2420 (COOH), 1716 (C=O) cm^{-1}; δ: 0.73 (s, 3H, 18-H), 2.09 (s, 3H, $COCH_3$), 11.14 (broad s, 1H, COOH).

Ozonolysis of 5-acetoxy-des-A-*5(10)-cholestene (6)*

Enolacetate **6** (1.5 g) was dissolved in tetrachloromethane (100 mL). An excess of ozone was passed through the solution, chilled in an ice-bath, until a blue colour appeared. The excess ozone was removed by a stream of nitrogen, the solvent carefully distilled off under reduced pressure, and the resulting ozonides were decomposed with zinc (dust) in acetic acid. The crude products obtained after the usual work-up of the reaction mixture, and containing the anhydrides, were subjected to KOH hydrolysis in methanolic–aqueous solution. The reaction mixture was diluted with water and extracted with benzene. The extract containing some neutral products was rejected. After acidification, the reaction mixture was extracted with chloroform. Acidic products obtained in such a way were treated with ethereal diazomethane right after isolation. The mixture of methyl esters was separated by silica gel column chromatography. With a benzene–ether (2.5%) mixture, the dimethyl ester of 5,10-seco-des-*A*-19-nor-cholestan-5,10-dioic acid (**7***b*) and the keto-ester **5***b* were eluted successively. Keto-ester **5***b* proved to be identical in all respects with the compound described above. Diester **7***b* did not show any tendency to crystallization; ν_{max} ($CHCl_3$): 1734, 1281, and 1173 cm^{-1}; δ: 0.78 (s, 3H, 18-H), 3.69 and 3.72 (2 × s, 2 × 3H, 2 × $COOCH_3$).

5,10-Seco-des-A-*norcholestan-5,10-dioic acid (7*a)

(a) Hydrolysis of diester **7***b* was carried out in the usual manner. The crude diacid **7***a* crystallized from ethyl acetate in an analytically pure state, mp 162.5–164.5°C; $[\alpha]_D^{25}$ +44.9° (*c* 1.1); ν_{max} (KBr): 3400–2400 (COOH) and 1714 cm^{-1}; δ: 0.77 (s, 3H, 18-H), 11.66 (s, 2H, 2 × COOH). *Anal.* calcd. for $C_{22}H_{38}O_4$: C 72.1, H 10.5; found: C 72.0, H 10.6.

(b) To a stirred solution of ruthenium tetroxide (from 0.4 g of

ruthenium dioxide, 100 mL of acetone, 3.0 g of sodium periodate, and 20 mL of water), 1.0 g of 1-hydroxy-4-methyl-1,3,5(10)-cholestatriene (**8**) was added. A solution of 10.0 g of sodium periodate in 50 mL of water and 50 mL of acetone was used to maintain the yellow color of the reaction. After 3 h of stirring at room temperature a few milliliters of 2-propanol were added to quench the reaction. The mixture was diluted with an equal amount of acetone and then filtered. Most of the acetone was removed *in vacuo*. The steroids were extracted with ether and the acid fraction was isolated in the usual way. Crystallization of the product from ethyl acetate afforded 0.298 g of diacid **7***a*, mp 162–164°C, which was identical in all respects with a sample prepared as previously described.

B-*Norcholesta-1,4-dien-3-one (**10**)*

A solution of *B*-norcholestenone (2 g) and DDQ (2,3-dichloro-5,6-dicyano-*p*-benzoquinone) (1.34 g) in dry dioxan (200 mL) was heated under reflux for 8 h. The solvent was distilled off and the residue was extracted with ether. The ethereal solution was washed with 5% aqueous NaOH and with water, and dried over sodium sulfate. Removal of the solvent under vacuum gave an oil which was chromatographed on alumina. A hexane–benzene (1:9) mixture eluted 1.2 g of dienone **10** which crystallized from methanol, mp 66–67°C; $[\alpha]_D^{25}$ −16° (*c* 1.2); ν_{max} ($CHCl_3$): 1660, 1638, and 1600 cm^{-1}; δ: 0.75 (s, 3H, 18-H), 1.22 (s, 3H, 19-H), 5.72 (s, 1H, 4-H), 6.08 (d, J = 10 Hz, 1H, 2-H), 7.01 (d, J = 10 Hz, 1H, 1-H). *Anal.* calcd. for $C_{26}H_{40}O$: C 84.7, H 10.9; found: C 84.6, H 10.7.

*3-Hydroxy-1-methyl-6,19-dinorcholesta-1,3,5(10)-triene (**11**)*

A solution of dienone **10** (0.6 g) in acetic anhydride (17 mL) was treated with concentrated sulfuric acid (0.3 g) and the reaction mixture was allowed to stand for 4 h. The mixture was poured into ice-water and the product was extracted with ether. The ethereal solution was washed with water and dried over sodium sulfate. Evaporation of the solvent gave a yellow foam. The crude product was hydrolyzed in methanol with 3 mL of 45% methanolic KOH solution for 4 h at reflux. After cooling, the solution was poured into ice-water and acidified with hydrochloric acid and then extracted with ether. The extract was dried over sodium sulfate. The solvent was evaporated and the yellow foam obtained (0.528 g) was chromatographed on a silica gel column. A hexane–benzene (1:9) mixture eluted 0.401 g of a crystalline phenol **11**, mp 129–131°C; $[\alpha]_D^{25}$ +17.4° (*c* 1.0); ν_{max} ($CHCl_3$): 3600, 1600, and 1480 cm^{-1}; δ: 0.65 (s, 3H, 18-H), 2.25 (s, 3H, 1-Me), 4.75 (s, 1H, OH), 6.30 (s, 1H, 4-H), 6.48 (s, 1H, 2-H). *Anal.* calcd. for $C_{26}H_{40}O$: C 84.7, H 10.9; found: C 84.5, H 10.7.

Des-A-*6,19-dinor-5,10-secocholestan-5,10-dioic acid (**12**)*

(a) 3-Hydroxy-1-methyl-1,3,5(10)-cholestatrien-6-one (**9**; 0.5 g) in acetone (30 mL) was added dropwise to a solution of ruthenium tetroxide (from 0.2 g of RuO_2, 25 mL of acetone, 1.5 g of sodium periodate, and 10 mL of water). The yellow colour of the reaction mixture was maintained by the addition of sodium periodate (4.8 g) in water (15 mL) and acetone (15 mL) during 15 h. The reaction was quenched with 2-propanol and the further work-up was identical to our previous experiment with RuO_4. The acid fraction (0.328 g) was crystallized from acetone to give diacid **12**, mp 189–191°C; $[\alpha]_D^{25}$ +32.2° (*c* 1.3); ν_{max} ($CHCl_3$): 3300–2600 (COOH) and 1715 cm^{-1}; δ: 0.69 (s, 3H, 18-H), 11.20 (s, 2H, 2 × COOH). *Anal.* calcd. for $C_{21}H_{36}O_4$: C 71.5, H 10.1; found: C 71.4, H 10.0.

(b) Phenol **11** (0.2 g) was oxidized as above with ruthenium tetroxide prepared from 0.08 g of RuO_2. The usual work-up of the reaction mixture afforded diacid **12** (0.098 g). Crystallization from acetone gave analytically pure **12**, mp 189–191°C, which was identical in all respects with a sample prepared as above.

Acknowledgments

Sincere thanks are extended to Mr. J. Babiński for excellent technical assistance, and to Miss L. Adamczyk and Mr. K. Zwierzyński for their skillful help in a number of experiments. We are very grateful to Dr. S. Zard (I.C.S.N.–C.N.R.S., Gif sur Yvette, France) for correcting the manuscript of this paper. The microanalyses and ir spectra were carried out by the Analytical and Spectral Services Laboratories of our Department to whom we are indebted. We also acknowledge the financial assistance of the Polish Academy of Sciences.

Oxidation of hydrocarbons. 12. Kinetics and mechanism of the oxidation of *trans*-cinnamic acid by ruthenate and perruthenate ions[1]

DONALD G. LEE[2] AND STUART HELLIWELL

Department of Chemistry, University of Regina, Regina, Sask., Canada S4S 0A2

Received May 30, 1983[3]

DONALD G. LEE and STUART HELLIWELL. Can. J. Chem. **62**, 1085 (1984).

Recent theoretical calculations by Rappé and Goddard have pointed to the importance of spectator oxo groups in stabilizing intermediates produced during the reduction of high-valent transition metal oxides; intermediates which contain triply-bonded metal oxo groups are predicted to be unusually stable. In an attempt to test these conclusions experimentally, the rates of oxidation of cinnamate ion by ruthenate and perruthenate ions have been studied. Since the most likely intermediate formed from perruthenate ion (but not ruthenate ion) would contain a stabilizing, triply-bonded spectator oxo group, it would be expected to react faster if the calculations are correct. In agreement with these predictions, it was found that the activation energy ($\Delta G^{\ddagger}$) for the ruthenate reaction was about 7 kcal/mol higher than for the corresponding perruthenate reaction.

DONALD G. LEE et STUART HELLIWELL. Can. J. Chem. **62**, 1085 (1984).

Les récents calculs théoriques de Rappé et Goddard ont mis en évidence l'importance des groupes oxo spectateurs dans la stabilisation des intermédiaires obtenus lors de la réduction d'oxydes de métaux de transition de valence élevée; d'après ces calculs, les intermédiaires qui contiennent les groupes oxo triplement liés au métal seront particulièrement stables. Dans le but de vérifier expérimentalement cette hypothèse, on a étudié les vitesses d'oxydation de l'ion cinnamate par les ions ruthénate et perruthénate. Puisque l'intermédiaire le plus communément formé à partir de l'ion perruthénate (mais non á partir de l'ion ruthénate) contiendrait le groupe spectateur oxo triplement lié, on pourrait s'attendre à ce qu'il soit plus réactif si les calculs sont corrects. En accord avec ces prévisions, on a trouvé que l'énergie d'activation ($\Delta G^{\ddagger}$) de la réaction du ruthénate est d'environ 7 kcal/mol plus élevée que celle de la réaction correspondante du perruthénate.

Introduction

Transition metal oxides and oxyanions have been used extensively as oxidants in both inorganic and organic chemistry (1). The driving force in most such reactions is generally considered to be a lowering of the oxidation number of the oxidant, which may formally be considered as a flow of electrons into the *d* orbitals of the metal. Since many of the high-valent d^0, d^1, and d^2 oxidants are capable of accepting several electrons before reaching a stable oxidation state, these reactions usually proceed in several steps with the formation of a number of intermediates of greater or lesser stability. The reactions are consequently of interest from both a practical and a theoretical point of view.

Rappé and Goddard (2) have recently described results, obtained from a theoretical study, that are extremely useful for predicting which intermediates are most likely to be formed during the course of several of these reactions. By use of *ab initio* methods they found that the metal–oxo bonds present substantially influenced the stability of an intermediate. Metal–oxo groups which have triple bond character were found to impart greater stability to the intermediate than those metal–oxo groups which were doubly bonded.

The metal–oxo double bonds are formed by the overlap of a d_{z^2} orbital on the metal with a p_z orbital on oxygen to give a σ-bond (each element contributing one electron) and the parallel overlap of a d_{xz} orbital on the metal with a p_x orbital on the oxygen to give a π-bond. The metal–oxo triple bonds are formed, however, by the overlap of d_{xz} and d_{yz} orbitals on the metal with p_x and p_y orbitals on the oxygen to give two π-bonds along with a third bond formed by the overlap of a filled p_z orbital on the oxygen with an empty d_{z^2} on the metal. Since the triple bonds lend added stability to the structures under consideration, they would be formed whenever the appropriate orbitals were available. In order to identify these bonds in structural formulas, the convention of using two solid and one broken line was adopted; i.e., M≡O (2).

As an example of the importance of the nature of these spectator oxo groups, Rappé and Goddard pointed to the difference in the energy changes which take place as reactions [1] and [2] occurred. Reaction [1] is endothermic because it involves destruction of a metal–oxo triple bond, whereas reaction [2] is exothermic because it involves formation of a metal–oxo triple bond.

[1] 
1

[2] 
2

Spectator oxo groups with triple bonds can form only when two *d* orbitals are available for bonding to a single oxygen. In the case of chromyl chloride, **2**, a triple bond is not possible because use of both *d* orbitals for one bond would deprive the second oxygen of its π-bond. The bonding in chromyl chloride is thus analogous to the bonding in carbon dioxide, while the bonding in **1** is similar to that in carbon monoxide.

As a further example of the importance of this concept, Rappé and Goddard pointed to the difference in the reactions of chromyl chloride and permanganate ion with alkenes (2). Both oxides react with carbon–carbon double bonds to give the corresponding metallocyclooxetanes, **3** and **4** (3). However, **4** goes on to form the corresponding cyclic manganese(V) diester, **5** (and subsequently to yield diols (4) or cleavage prod-

[3] Revision received January 10, 1984.

ucts (5)), while **3** does not (3, 6) because such a reaction would, presumably, cause disruption of the bonding of the spectator oxo group and thus be energetically unfavorable. In the case of **4**, on the other hand, formation of the cyclic diester is aided by the simultaneous formation of a triply-bonded spectator oxo group.

[3] 
[4] 
In an attempt to apply an independent experimental test to these theoretical conclusions, we have made a kinetic study of the oxidation of cinnamate ion by ruthenate (RuO_4^{2-}) and perruthenate (RuO_4^-) ions. Assuming that the metallocyclooxetane intermediates are formed in rapid equilibrium reactions, it is to be expected that perruthenate ion would react more readily with a carbon–carbon double bond to give an cyclic ruthenium(V) diester, **6**, as in eq. [5]. Such an intermediate would be stabilized by the spectator oxo group. However, a similar reaction would not occur as readily with ruthenate because formation of the corresponding cyclic ruthenium(IV) diester intermediate, **7**, could be achieved only by loss of the stability associated with the presence of a spectator oxo group in the metallocyclooxetane (eq. [6]).

[5] 
[6] 
Since only cleavage products were obtained from the oxidation of either cinnamic or fumaric acids with both ruthenate and perruthenate, it appears likely that both reactions proceed

TABLE 1. Initial reaction rates for the oxidation of cinnamate ion by sodium ruthenate[a]

$[RuO_4]_i$ ($M \times 10^4$)	$Rate_i$ ($M\ s^{-1} \times 10^8$)[b]	$Rate_i/[RuO_4^{2-}]$ ($s^{-1} \times 10^5$)

by way of the cyclic diester intermediates depicted in eqs. [5] and [6]. When both of these reactions were studied under similar conditions (alkaline aqueous solutions) it was found that the rate of reaction of cinnamate ion with perruthenate ion is 5×10^5 times faster than the corresponding ruthenate reaction. This observation is therefore in agreement with the predictions made by Rappé and Goddard using *ab initio* theoretical methods (2). In the following paper we wish to describe our kinetic methods in greater detail and to show how the experimental and theoretical results can be combined to formulate mechanisms for these reactions.

Results and discussion

Ruthenate oxidations

Under conditions where the concentration of cinnamate ion was held in substantial excess, the initial reaction was found to be first order in both ruthenate (Table 1) and cinnamate ions (Table 2), but inversely dependent on hydroxide ion concentration (Fig. 1). The inverse dependence on base concentration could be associated with the fact that the reaction involves electron transfer between two anions; inclusion of a proton would presumably lead to a stabilization of the negatively charged transition state. Alternatively, the oxidation reaction could be preceded by a proton transfer in which the acid ruthenate ion, $HRuO_4^-$, was formed (eq. [7]) (7). Since it is known, for example, that the acid chromate ion, $HCrO_4^-$, is a more

[7] $RuO_4^{2-} + H^+ \rightleftharpoons HRuO_4^-$

vigorous oxidant than CrO_4^{2-}, it is not unlikely that a similar relationship would exist between $HRuO_4^-$ and RuO_4^{2-} (8).

The observed first-order dependence of the initial reaction on ruthenate concentration rules out the possibility that the reaction could involve a prior disproportionation of ruthenate into perruthenate (or ruthenium tetroxide) which would then act as

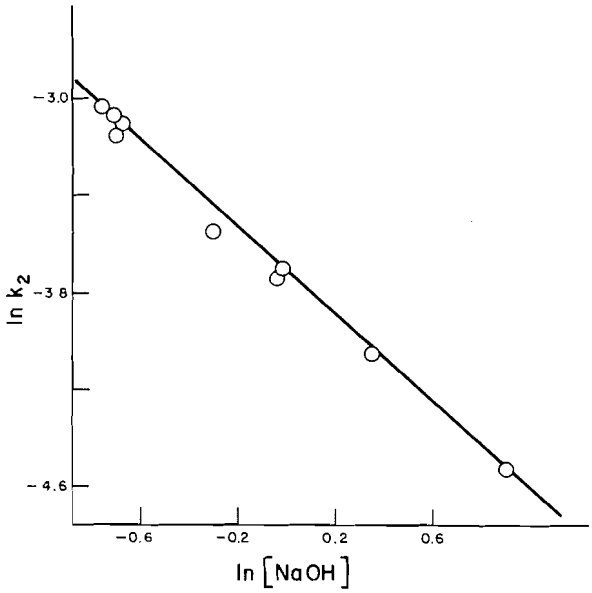

FIG. 1. Dependence of k_2 on base concentration; T = 85°C.

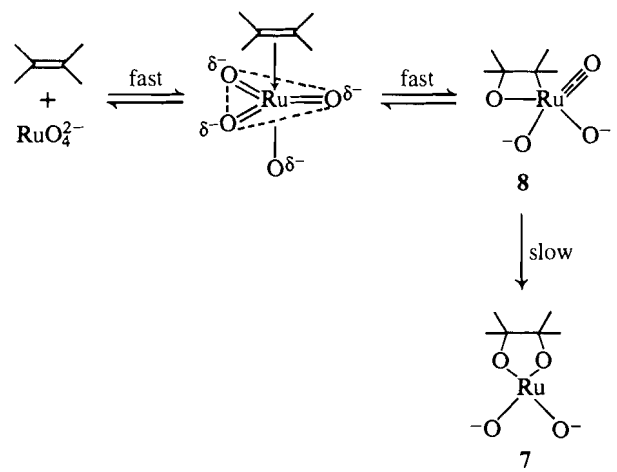
the actual oxidant (9). Occurrence of such a reaction would lead to a kinetic rate law that was initially second order in $[RuO_4^{2-}]$.

Work from several laboratories has indicated that reactions between high-valent transition metal oxides and alkenes proceed via organometallic intermediates which involve the formation of a π-bond between the carbon–carbon double bond and the metal (2, 3, 10). These π-complexes then rearrange to metallocyclooxetanes and eventually to cyclic diesters as in eq. [8]. In the case of ruthenate it is expected that formation of the metallocyclooxetane, **8**, would be quite rapid since it involves

[8]



formation of a ruthenium(VI) compound with a triply-bonded spectator oxo (2). The slow step of the reaction sequence depicted in eq. [8] would therefore be the conversion of **8** into the cyclic ruthenium(IV) diester, **7**. Since this step results in a conversion of ruthenium from a d^2 to a d^4 state, it would be expected to be slower than the previous steps which involve no change in oxidation state.

The inverse secondary isotope effects that are observed when the olefinic hydrogens are sequentially replaced by deuterium (Table 3) establish that the α and β carbons have rehybridized from sp^2–p in the ground state to sp^3 in the transition state (11) and are consistent with the occurrence of the transition state

between structures **7** and **8**. The unfavorable entropy of activation (ΔS = −30.6 ± 1.3 eu) is also consistent with a highly structured transition state (12). The activation entropy for the reaction (Table 4) is, in fact, very similar to that for the oxidation of cinnamate ion by permanganate, which is known to proceed by way of a cyclic manganate(V) diester (13). The larger enthalpy of activation for the ruthenate reaction is probably a consequence of the fact that the cyclic diester, **5**, formed in the permanganate reaction (eq. [4]) is stabilized by the presence of a spectator oxo while the ruthenium(IV) diester, **7**, is not.

The first-order dependence of the rate of reaction on the concentration of ruthenate ion does not extend throughout the entire course of the reaction, as shown by the curvature in the plot of ln $[RuO_4^{2-}]$ vs. time (Fig. 2). This deviation from linearity is indicative of secondary reactions of the initially formed products. Although this could potentially lead to an unwieldly large number of possible reaction schemes, all but one reasonable possibility could be eliminated by the use of computer modeling. Employing a previously published program (14), we examined 28 possible reaction sequences by computing the rate constant for each step that is necessary to give the best fit between experimental and theoretical absorption values at various time intervals. Although several reaction schemes gave excellent fits for a particular set of conditions, only one sequence of reactions gave rate constants that were the same regardless of the initial reactant concentrations. This reaction sequence has been summarized in Scheme 1. The ability of this sequence to reproduce the experimental absorbance values is indicated by the data in Table 5.

The first step of this scheme is assumed to be a reaction between the unsaturated carboxylic acid and ruthenate to accommodate the previously described observation that the initial rate of reaction is first order in both RuO_4^{2-} and cinnamate ion. Since the first step was also observed to be inversely dependent on base concentration, it has been shown in Scheme 1 as being subject to acid catalysis. The value for k_2 could be determined directly from initial rate studies (Table 2); however, the magnitude of k_3 could not be exactly specified since any value large enough to maintain a steady-state concentration of the intermediate **7** was adequate. For the purpose of the computer simulation a rate constant of 80 M^{-1} s^{-1} was used. The values k_5 and k_6 were also assumed to be much larger than k_2 or k_4 and were arbitrarily set at 50 M^{-1} s^{-1}. Reactions [12] and [13] are the product-forming steps and in all likelihood refer to the oxidation of benzaldehyde and glyoxylate ion (which would be formed by the oxidative cleavage of the double bond) to give the corresponding carboxylic acids. Since such reactions were qualitatively found to be extremely fast under these conditions, the assumption that k_5 and k_6 would be large seems justified.

The structure of intermediate **9** is open to more speculation; however, at least one attractive possibility that is consistent

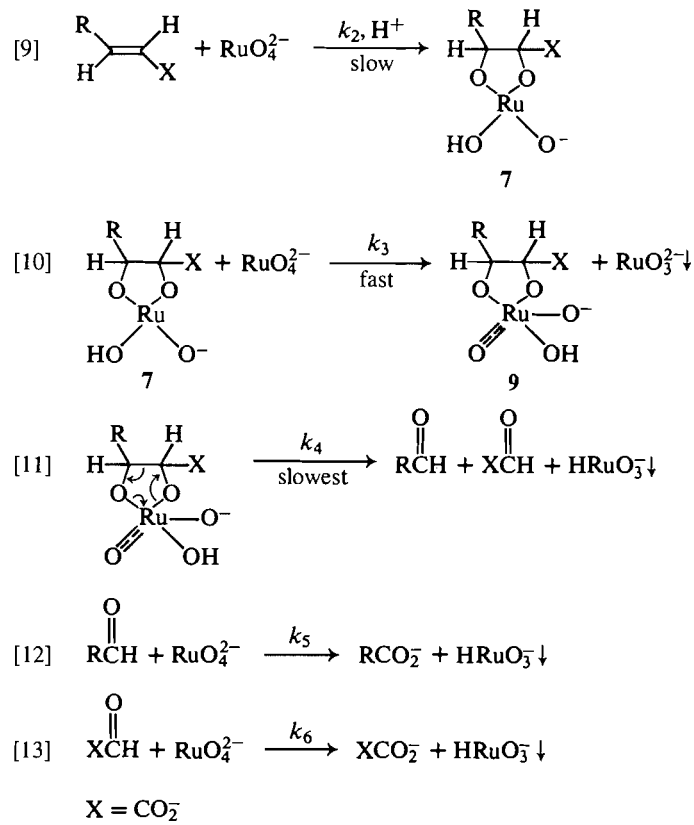
with all of the experimental evidence is available if **9** is assumed to be a cyclic ruthenate(VI) diester formed by the oxidation of **7**. Such a two-electron transfer reaction is consistent with the known properties of ruthenate under these conditions (15). Furthermore, it would not be unreasonable to observe a large rate constant for such a reaction; many similar electron



SCHEME 1

transfer processes between transition metal oxyanions are known to occur rapidly (16). Development of a triply-bonded spectator oxo group as the reaction progresses would also serve to increase its rate (2).

Intermediate **9** could undergo one of two possible reactions: (*i*) it could hydrolyze to give a diol, or (*ii*) it could undergo oxidative decomposition to give cleavage products. Since only compounds resulting from the cleavage of the carbon–carbon double bond could be found among the products of the reaction, it may be assumed that **9** decomposes as depicted in eq. [11].

Other evidence consistent with this suggestion includes the normal secondary kinetic isotope effects (Table 6) which are indicative of a rehybridization of the carbons from sp^3 to sp^2 as the reaction proceeds (11), and a favorable entropy of activation ($\Delta S^{\ddagger} = 7.7 \pm 2.1$ eu) as would be expected for a fragmentation reaction (12). A large enthalpy of activation (31.0 ± 0.7 kcal/mol) for this step is indicative of similar reactions in which σ-bonds are cleaved (12, 13). Finally, when the concentrations of the reactants and intermediates are calculated from the computer model for Scheme 1 and plotted against time it is

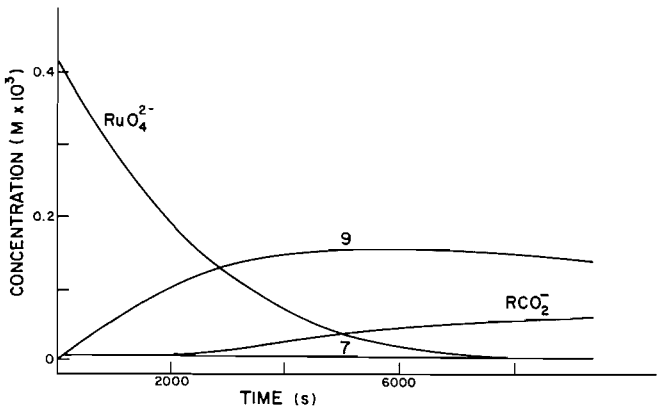

FIG. 3. Calculated concentrations of reactants, intermediates, and products for a reaction proceeding according to Scheme 1.

observed that **9** is the only intermediate which accumulates as the reaction proceeds (Fig. 3). Since this intermediate is in the same oxidation state as RuO_4^{2-}, it is not to be expected that its presence would produce detectable changes in the uv–vis spectrum as the reaction progresses (Fig. 4); oxyanions of a metal with the same oxidation state often have very similar spectra (17).

The rate law for the process summarized by the reactions in Scheme 1 may be derived by noting that reaction [10] does not result in a net change in oxidation state, the property which presumably controls the spectral changes that were used to monitor the rate of reaction. Therefore the experimental rate law would be given by eq. [14].

$$[14] \quad \frac{-d[Ru(VI)]}{dt} = \frac{k_2[RuO_4^{2-}][\text{  }]}{[OH^-]} + k_4[\mathbf{9}]$$

In the initial stages of the reaction, [**9**] will be vanishingly small; i.e., when $[RuO_4^{2-}] = [RuO_4^{2-}]_{initial}$, [**9**] = 0. Consequently, when initial reaction rates are considered, the last term in eq. [14] can be neglected and the rate law for the initial reaction is therefore first order in ruthenate, first order in cinnamate, and inversely dependent on base concentration. This is in accordance with the experimental observations (see Fig. 1 and Tables 1 and 2). As [**9**] increases, this approximation cannot be made and the rate expression becomes one obtained for consecutive reactions of mixed order (18). Such expressions are not amenable to treatment by classical methods and are best handled by numerical methods as has been done in this instance (18).

It may be noted, however, that the second term in eq. [14] will become dominant as the concentration of **9** increases (Fig. 3). When this happens one would expect the reaction to become second order in ruthenate since two moles of RuO_4^{2-} are consumed in the formation of **9**. As a consequence, deceptively

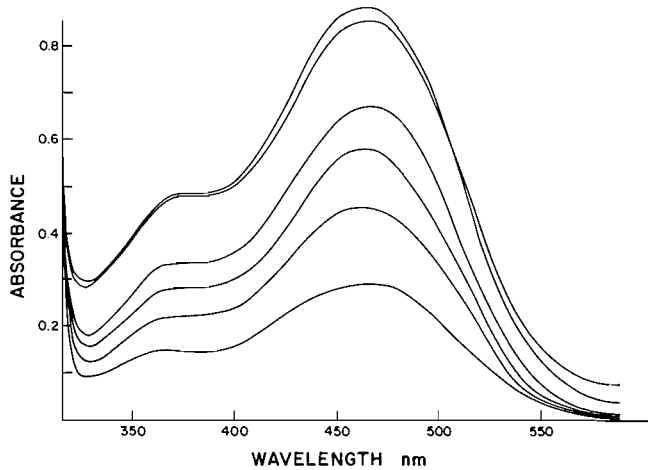

FIG. 4. Sequential scans as the oxidation of cinnamate by ruthenate proceeds. Spectra taken at 0, 196, 634, 1320, 2320, and 5380 s (top to bottom).

good pseudo second-order plots are obtained when the oxidation of an excess of cinnamate is studied under non-initial rate conditions (Fig. 5).

Perruthenate oxidations

Because the reaction of perruthenate ion with cinnamate ion under alkaline conditions is so much faster than the corresponding reaction with ruthenate ions, it was not possible to study the two reactions at the same temperature or in exactly the same way. Whereas it was convenient to follow the rate of ruthenate oxidation at 85°C by use of conventional spectrophotometric methods, the rate of the perruthenate oxidations could only be followed at a lower temperature (21°C) and with the aid of a stopped-flow system.

The reaction was found to be first order in perruthenate (Fig. 6), first order in cinnamate ion (Fig. 7), and independent of base concentration (Table 7). As the reaction proceeded, the green perruthenate solution was rapidly changed into a bright orange solution that exhibited the same uv–vis absorption

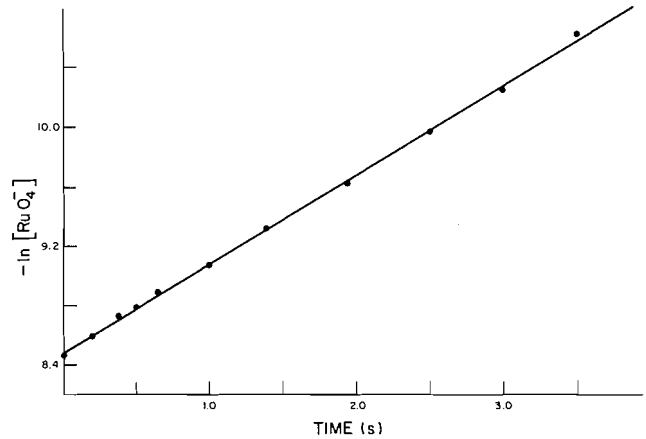

FIG. 6. Pseudo first-order plot for the oxidation of cinnamate by perruthenate. $[RuO_4^-] = 2.10 \times 10^{-4}$ *M*; [cinnamate] = 3.50×10^{-3} *M*; [NaOH] = 0.350 *M*; *T* = 21°C.

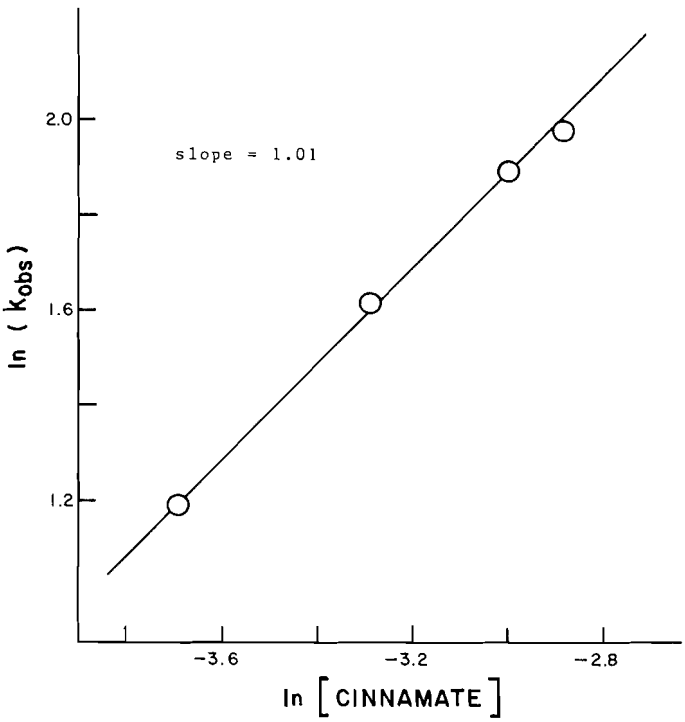

FIG. 7. Dependence of the rate of perruthenate oxidations on cinnamate concentration.

spectrum as ruthenate solutions. These solutions reacted more slowly to give ruthenium dioxide and benzoic acid.

The activation parameters for this reaction were found to be very similar to those observed for the corresponding reaction of permanganate with cinnamic acid (Table 4). Hence it appears as if the reaction likely involves an initial addition of the oxidant to the double bond, giving a ruthenium(V) cyclic diester, **10**, as in eq. [15]. However, since there was no indication of the formation of inorganic products other than RuO_4^{2-} the intermediate, **10**, must undergo a subsequent reaction leading to the formation of ruthenate. A likely possibility is that **10** could, in analogy with the corresponding cyclic manganese(V) diester, oxidatively decompose to give cleavage products and ruthenate(III) as in eq. [16]. The ruthenate(III) could then react with perruthenate to give ruthenate(VI) as in eq. [17].

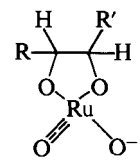
Cinnamate-α-*d* (1.75×10^{-3} *M*)	0.098	222 ± 6
Cinnamate ion (3.40×10^{-2} *M*)	0.282	133 ± 2
Cinnamate-β-*d* (3.40×10^{-2} *M*)	0.282	138 ± 3

[a]Temperature = 21.0°C; μ = 0.500 *M*.

The lack of a substantial secondary deuterium isotope effect for this reaction sequence (Table 8) indicates that the carbon atoms are sp^2–p hybridized in the transition state. Consequently it appears as if the rate-determining step is likely oxidative decomposition of the cyclic ruthenium(V) diester as in eq. [16]. In this respect the mechanism is parallel to the one proposed above for RuO_4^{2-} oxidations, where decomposition of a similar cyclic diester was also found to be the slowest step in the reaction sequence.

[15] 



[16] 
10

[17] $RuO_2^- + 3RuO_4^- + 4OH^- \longrightarrow 4RuO_4^{2-} + 2H_2O$

The difference in activation energies ($\Delta\Delta G^{\ddagger}$) for the oxidation of cinnamate by ruthenate and perruthenate is about 7 kcal/mol. From this it can be calculated that the rate of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

perruthenate reaction is about 5×10^5 times as fast as the corresponding ruthenate reaction at room temperature. Although part of this effect may be due to the higher reduction potential of perruthenate, a large portion must be attributed to a difference in the relative stabilities of the transition and ground states as described above. The fact that ruthenate, although a vigorous oxidant for alcohols, reacts very slowly with carbon–carbon double bonds has made it an excellent reagent for the oxidation of unsaturated alcohols (19). Several examples of its use for this purpose (20–22), as well as for the oxidation of certain saturated alcohols (23), have appeared in the recent literature.

Experimental

Sodium ruthenate (15, 24)

Ruthenium tetroxide (25) was first prepared by reaction of 5.0 g of hydrated ruthenium dioxide with 350 mL of commercial bleach (5.25% sodium hypochlorite). After stirring for approximately 10 min, the RuO_4 which had formed was extracted into carbon tetrachloride (5×75 mL) which in turn was washed with 3×100 mL distilled water to remove excess hypochlorite. An equal volume of 1.0 *M* NaOH was then added to the carbon tetrachloride solution and the heterogeneous mixture stirred for several hours (until the organic layer was colorless) and the deep orange basic ruthenate solution separated. Before being used in a kinetic experiment these solutions were heated at 75°C for several days. This ensures that all of the ruthenium is present in the +6 oxidation state and that the last traces of sodium hypochlorite have been removed. The purity and concentration of these solutions were then assayed using procedures described in the literature (24).

Sodium perruthenate (24, 26)

This reagent was also prepared from the reduction of ruthenium tetroxide. After the oxidation of hydrated ruthenium dioxide by bleach, as described above, a stream of air was used to carry the RuO_4 over into 0.3 *M* NaOH cooled at −3°C. The sodium perruthenate thus formed was allowed to stand at 0°C overnight to ensure complete reduction of ruthenium tetroxide to sodium perruthenate. Because of the instability of perruthenate solutions, these were made up as required.

Product studies

A solution of 4.5×10^{-2} *M* RuO_4^{2-} (170 mL of 1.0 *M* NaOH) was added to 0.30 g of cinnamic acid dissolved in 50 mL of 0.5 *M* NaOH. The reaction was allowed to proceed overnight at 60°C. The black ruthenium dioxide was filtered off and washed with warm distilled water. The basic solution was extracted with 3×75 mL portions of ether, saturated with sodium chloride, and acidified with dilute hydrochloric acid. The resulting solutions were extracted with 3×75 mL portions of ether. Evaporation of the ether after drying with anhydrous $MgSO_4$ left a white residue from the acid extract but nothing from the basic extract. Identification of the white residue indicated that it consisted of benzoic and some unreacted cinnamic acid. The yields based on unrecovered starting material were 99.0 and 99.5% benzoic acid for duplicate runs.

The oxidation of fumaric acid was carried out in a similar manner up to and including the filtering to remove ruthenium dioxide. After neutralizing the filtrate with hydrochloric acid, 10 mL of 10% $CaCl_2$ solution was added. This produced an immediate white precipitate of calcium oxalate. The solution was allowed to stand overnight at 70°C to ensure complete precipitation and coagulation of the calcium oxalate (27). The precipitate was then filtered through a sintered glass crucible, dried at 105°C, and weighed. Powder X-ray photographs taken of both this precipitate and a prepared sample of calcium oxalate were shown to be the same. Samples of the precipitate were then analyzed by dissolving a sample (about 0.2 g) in 20 mL of 1:8 H_2SO_4, diluting it with 70 mL of distilled water, heating to 80–90°C, and titrating with standard $KMnO_4$ solution (28). Yields of 88 and 95% oxalic acid were obtained for duplicate experiments.

When perruthenate ion reacted with cinnamic acid at 0°C, the deep yellow-green RuO_4^- color was instantly replaced by an intense orange color typical of ruthenate ion. The ruthenate color then was observed to disappear as ruthenium dioxide formation took place. Hence it was decided to attempt to quench the ruthenate formed with sodium arsenite in the following way. To 100 mL of 0.3 *M* NaOH (at 0°C) containing 0.40 g of cinnamic acid was added 175 mL of sodium perruthenate solution (0.025 *M*). Immediately following this addition, 125 mL of 0.1 *M* $NaAsO_2$ were added. However, due to the rapidity of the reactions, quenching was only partially successful and only a qualitative estimation of the products of the initial reaction could be made. Both benzaldehyde and benzoic acid were isolated after a work-up as described above. A more quantitative result was obtained when the reaction was allowed to go to completion without quenching. A 99% yield of benzoic acid was then obtained.

Kinetic studies

In the kinetic studies of the oxidation of cinnamic acid by both ruthenate and perruthenate, pseudo order techniques were used throughout; i.e. greater than a ten-times equivalent excess of substrate over oxidant was used. It was found unnecessary to maintain a constant ionic strength for the ruthenate oxidations because varying the ionic strength had little or no effect on the rate of reaction. However, since the rates of the perruthenate reactions were not independent of the ionic strength, it was maintained at a $\mu = 0.500$ *M* by use of sodium perchlorate for these reactions.

In the case of ruthenate oxidations, solutions of the desired base concentrations were made up (2-L batches) and stabilized at 75°C for 2 days. The reactions were then carried out in 125-mL ground glass-stoppered erlenmeyer flasks thermostated in an oil bath at 85°C. In a typical set of experiments, eight flasks, each containing 100 mL of ruthenate solution, were allowed to thermostat for 1 h before the desired amount of substrate was added to start the reaction. Aliquots were removed at appropriate intervals and then quenched by cooling in ice. Absorbance readings were made using a Perkin–Elmer 356 dual wavelength, double beam spectrophotometer. This instrument has the advantage that a reference beam compensates for any precipitate which may have formed during the reaction. The wavelengths used were 460 and 570 nm. Little absorption by ruthenate occurs at 570 nm, hence this wavelength was used as the reference beam. The absorbance readings were converted into ruthenate concentrations using a calibration curve based on ruthenate solutions of known concentrations.

In several experiments the aliquots were first cooled, then centrifuged to remove ruthenium dioxide and scanned from 300 to 600 nm in an attempt to detect possible intermediates. As the plots in Fig. 4 indicate, there was no evidence for the formation of long-lived intermediates. Time vs. absorbance plots obtained in this way were very similar to those obtained using the dual wavelength mode.

The reaction between perruthenate ion and cinnamate ion could be followed spectrophotometrically by monitoring the disappearance of perruthenate ion at 385 nm. Because of the rapid nature of the reaction, all experiments were performed using a Durrum Model D-110 stopped-flow spectrophotometer.

In a typical experiment, 0.5 mL of RuO_4 solution (ca. 0.05 *M*) was pipetted into a 125-mL erlenmeyer flask containing approximately 50 mL of a NaOH solution and a magnetic stirring bar. The flask was stoppered and the solution degassed by reducing the pressure to approximately 95 Torr and stirring. When all of the RuO_4 had been reduced to RuO_4^- (determined spectrophotometrically), one of the stopped-flow syringes was filled with this solution and the other with a solution of the substrate. Equal volumes of the two reactants were forced through the mixing jet and into the cuvette where the absorbance measurements were made. The resulting kinetic curve, traced on an oscilloscope, was then photographed. Determinations were usually carried out in triplicate.

In order to check for the formation of possible intermediates, kinetic curves were run at a number of different wavelengths and spectra synthesized as a function of time (Fig. 8). As may be seen from the

Anomalous 5-*endo-trig* reversals: general reactions of 7-oxabicyclo[2.2.1]heptenes and heptanes

B. A. KEAY, D. RAJAPAKSA, and R. RODRIGO[1]

Guelph–Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received November 15, 1983

B. A. KEAY, D. RAJAPAKSA, and R. RODRIGO. Can. J. Chem. **62**, 1093 (1984).

Two general 5-*endo-trig* reversals of 7-oxabicyclo[2.2.1]heptanes and heptenes are described and discussed. The reverse-Michael reaction occurs with the aldehyde, ketone, ester, and nitrile derivatives while the reverse aldol reaction catalysed by acid is confined to the aldehydes and ketones. These properties of the title compounds are rationalized in terms of the geometric alignments of the bonding and antibonding orbitals of the bridging oxygen atom and its neighboring carbons. New isobenzofuran and cyclohexadiene syntheses form a part of the report.

B. A. KEAY, D. RAJAPAKSA et R. RODRIGO. Can. J. Chem. **62**, 1093 (1984).

On décrit et on discute de deux réactions générales 5-*endo-trig* inversées des oxa-7 bicyclo[2.2.1] heptanes et heptènes. La réaction inverse de Michael se produit dans le cas des dérivés de l'aldéhyde, de la cétone et du nitrile tandis que la réaction aldolique inverse se limite aux aldéhydes et aux cétones. On rationalise ces propriétés des composés mentionnés dans le titre en fonction des alignements des orbitales liantes et antiliantes de l'atome d'oxygène en position de pont et de ses atomes de carbone voisins. On rapporte également de nouvelles synthèses de l'isobenzofuranne et du cyclohexadiène.

Early in our studies of the Diels–Alder reactions of isobenzofurans (1) we made the useful and intriguing discovery that adduct **1***a* was smoothly converted to the dihydronaphthalene **2***a* with methanolic sodium methoxide. The same reaction applied to the closely related adduct **3** was a key transformation in our recent synthesis (2) of (±) daunomycinone. An examination of the process with a variety of oxabicyclo adducts[2] was conducted and the results (Table 1, Entries 1, 3, 6, 8, 11, 13, 16, 18) confirmed the generality of the reaction. A reverse-Michael rationalization shown in Scheme 1 requires the development of some double bond character at a bridgehead and is also a 5-*endo-trig* reversal in violation of rules (3) formulated earlier and illustrated (4) with the furan **9**. No evidence could be obtained, however, to support any alternative mechanism; for example, no products of C(4)—O cleavage were ever observed, thus excluding the possibility of a simple nucleophilic displacement at C(1) and(or) C(4). Deuteration at C(2) took place with esters and nitriles (entries 5, 7, 10, 12, 15, and 17) and the deuterated products were *endo–exo* mixtures even when pure *endo* substrates (**1***c* and **1***d*, entries 5 and 7) were used. Oxabicyclo ketones and aldehydes could not be deuterated cleanly with methanolic methoxide because of the rapid formation of products under the conditions. After 1 h at 20°C with this reagent, **1***a* and **1***b*, for example, were converted to a 1:1 mixture of products (**2***a* and **2***b* respectively) and deuterated starting materials. The lower acidity of the esters and nitriles must be responsible for rapid reprotonation of their enolates in methanolic methoxide, permitting clean deuteration in these cases and revealing the existence of a kinetic barrier to the reverse-Michael fission of the C(1)—O bond. This behaviour is similar to the previously observed (4) deuteration of furan **9** and is interpreted similarly. Unlike the simple furan **9**, however, which was inert to all bases, these compounds do suffer a forbidden 5-*endo-trig* cleavage with the strong base LDA under aprotic conditions (entries 6, 8, 11, 13, 16, and 18). Base-catalysed aromatizations observed in entries 2, 4, and 9 and previously with sodium acetate in refluxing methanol (5) must also occur through an initial reverse-Michael cleavage followed by dehydration. Thus it is clear that the 7-oxabicyclo heptanes and heptenes are susceptible to a general 5-*endo-trig* reversal[3] in violation of Baldwin's rules and that this anomaly cannot be attributed to thermodynamic factors, i.e. release of strain resulting from the reaction.

Again, in the course of our studies on the synthesis of (±) daunomycinone, we obtained the surprising result that the hydrogenolysis of **3** in ethanol containing a few drops of perchloric acid produced not the expected tetralin but the phthalan **10** (95%). In attempting to understand the course of this unusual hydrogenolytic cleavage of the C(1)—C(2) bond, we subjected ketone **1***a* to perchloric acid – methanol treatment at room temperature for 5 min and obtained methoxy phthalan **11** (94%) whose structure was supported by spectroscopic data and by conversion to the Diels–Alder adduct **12** (72%) with dimethyl acetylene dicarboxylate. In the absence of methanol, similar acid treatment resulted in extensive decomposition, probably through the formation of isobenzofuran **13** which polymerizes. No aromatic product (**8***a*) could be detected. Evidently these ketones are extremely prone to reverse-aldol cleavage (Scheme 2) and the resulting oxonium ion is trapped as the alkoxy phthalan which may be isolated (**11**) or hydrogenolysed (**10**). In the absence of an alcohol, the hydroxy phthalan that might be formed instead is easily dehydrated to an unstable isobenzofuran **13**. We have previously observed that hydroxy phthalans (hemi-acetals) are much more unstable to acid than methoxy phthalans (acetals). In accordance with this rationale, we found that the stable isobenzofuran **14** provided a methyl vinyl ketone adduct **15**[4] that in turn produced a stable isobenzofuran **16** (95%) upon treatment with sulfuric acid, and the furanoid adduct **4***a* yielded furan **17** (78%) and acetophenone (13%). Aldehyde **1***b* behaved similarly but the re-

sults were less clear-cut because of the formation and persistence of its dimethyl acetal (80%) under the same conditions. The existence of phthalan **18** (5%) and its dimethyl acetal (15%) was evident in the nmr spectrum of the reaction mixture. Ester and nitriles **1***c*, **1***d*, **4***c*, and **4***d* were indefinitely stable to the same conditions; **1***c* and **1***d* provided napthalenes **8***c* and **8***d* (50 and 69% respectively) after refluxing for 8 h, but **4***c* and **4***d* underwent extensive decomposition and no aromatic product was detected. Furan adducts are known to undergo reverse Diels–Alder reactions at moderate temperatures (7) and this might be responsible for the latter result. Similar ring disruptions of Diels–Alder adducts of both furan (8) and isobenzofuran (9) have been reported. The general reverse-aldol process described above is also a 5-*endo-trig* reversal in violation of Baldwin's rules. Like the reverse-Michael fission previously described, its occurrence cannot merely be a manifestation of strain release because it is difficult to see how **1***a* and **15**, for instance, can be converted into virtually non-aromatic isobenzofurans instead of aromatizing to stable naphthalenes, or how **1***b* can be content with forming an acetal instead of undergoing acid-catalysed aromatization to **8***b* (or the acetal thereof).

Other 5-*endo-trig* cyclizations have been reported (10) and those involving additions to immonium (11) and oxonium (12) double bonds rationalized on the basis of increased flexibility and decreased vectorial specificity, both consequences of the greater single bond character of these double bonds. Such explanations are clearly inapplicable to our reverse-Michael reactions, nor can any increase in carbonium ion character of the oxonium ion intermediate (Scheme 2) of our retro-aldol reactions provide enough flexibility for the reaction to occur in either direction.

X-ray crystallographic analyses (13) of the isobenzofuranoid adducts **1***a* and **1***c* established that the furanoid moiety (C(1)—C(2)—C(3)—C(4)—O) in each compound is rigidly held in two planes (C(1)—O—C(4) and C(1)—C(2)—

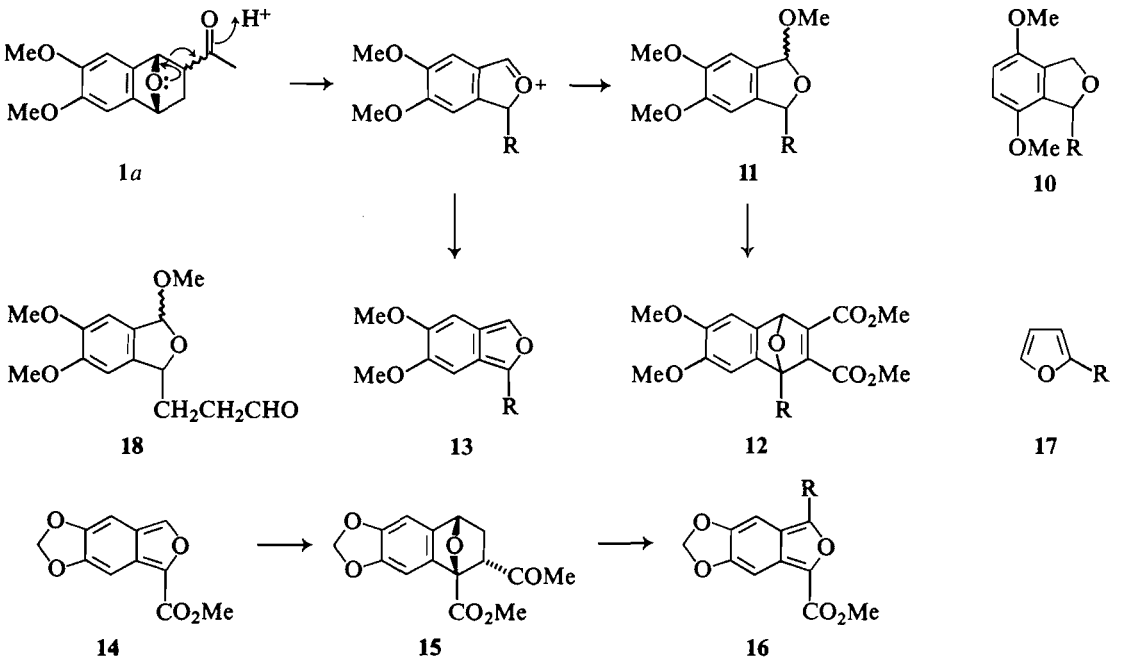

SCHEME 2. Retro-aldol reactions (R = $CH_2CH_2COCH_3$)

C(3)—C(4)) at 121.6° to each other. This geometry, quite unlike the simple furan **9**, is responsible in our opinion for the prevalence of the anomalous 5-*endo-trig* reversals. Enolate ions, formed in the reverse-Michael reaction, have a large coefficient (14) at C(2) in their HOMO and this orbital at C(2) is properly aligned in these systems (but not in the furan **9**) to interact with the relatively low-lying antibonding orbital of the C(1)—O bond (LUMO), weakening this bond and allowing the C(1)—C(2) π-bond to develop as the reaction proceeds (Fig. 1). Such a frontier orbital interaction decreases the kinetic barrier to the reverse-Michael reaction in the oxabicyclo systems. In the norbornyl radical of similar geometry, the well-known *exo*-specificity displayed in its reactions has been attributed (15) to interaction between the C—C bridge orbital and singly occupied *p* orbital at C(2).

The same molecular architecture accounts for the reverse-aldol process. One of the orbitals containing a non-bonded pair of electrons on the bridge oxygen atom is aligned antiperiplanar to the C(1)—C(2) bond. Interaction of this orbital (HOMO) with the antibonding orbital of the C(1)—C(2) bond (LUMO) results in weakening of the C(1)—C(2) bond and the growth of some π-bonding between C(1) and the oxygen (Fig. 2). Similar interactions in axial α-halogenotetrahydropyrans result in bond lengthening (C—X) and shortening (O—C) and have also been invoked to interpret the anomeric effect as a stabilizing influence (16). The presence of a protonated substituent at C(2) (aldehyde or ketone as in **1***a*, **4***a*, and **1***b*) provides a low energy pathway (retro-aldol) for bond breaking (C(1)—C(2)) and bond making (C(1)—O, π-bond) to take place, resulting in the formation of the cyclic oxonium ion. Esters and nitriles (**1***c*, **1***d*, **4***c*, and **4***d*) with their lower basicity are not known to undergo the acid-catalysed retro-aldol reaction and are therefore inert under the conditions. The behaviour of **4***a*, which prefers to form a furan **17** rather than aromatize to acetophenone by a 6:1 margin (78% **17**, 13% acetophenone) when exposed to acid, can thus be understood.

The synthetic potential of the reactions described herein must not be overlooked. We have used the reverse-Michael

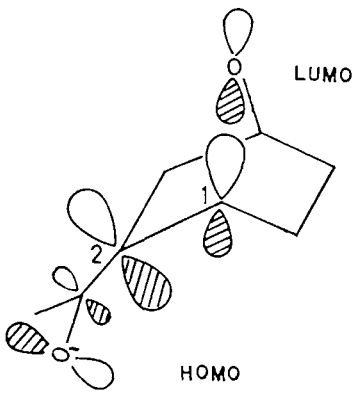

FIG. 1

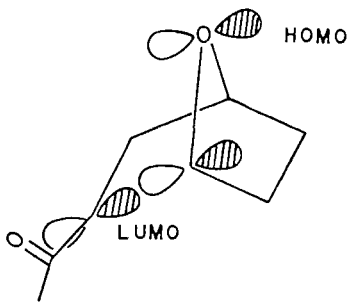

FIG. 2

reaction for short stereocontrolled syntheses (17) of some shikimic acids, and other applications to natural product synthesis are underway. The reverse-aldol reactions represent an unprecedented isobenzofuran → 1-substituted isobenzofuran conversion, which adds an extra element of versatility to our general isobenzofuran synthesis (1).

apparatus and are uncorrected. Infrared spectra were obtained on Beckman Model IR-10 or on Acculab 10 spectrophotometers. Nuclear magnetic resonance spectra were obtained on either Bruker WP-80 or Bruker WH-400 spectrophotometers. Samples were run in $CDCl_3$ solutions containing tetramethylsilane as an internal standard and chemical shifts (δ) and coupling constants (Hz) measured directly. Low and high resolution mass spectra were measured on a Varian VG Organic 7070F Mass Spectrometer. Flash column chromatography was performed using Merck 0.063–0.200 mm (70–230 mesh) Silica Gel 60 which was packed dry into glass columns. Combustion analyses were performed by Guelph Chemical Laboratories, Guelph, Ontario and(or) Canadian Microanalytical Service Ltd., Vancouver, British Columbia.

General procedure for deuteration of **1**c, **1**d, **4**c, **4**d, **6**c, *and* **6**d

The bicyclo adduct dissolved in methanol-d_1 was treated with sodium methoxide (3 equiv. freshly prepared from sodium and methanol-d_1) and the mixture stirred at the appropriate temperature (Table 1) for 2 h. D_2O was added and carbon dioxide bubbled through until the solution was neutral to pH paper. The methanol was removed under reduced pressure, the residue extracted into chloroform, and the solvent removed. The residual material was distilled or crystallized.

3-Acetyl-1,2-dihydro-1-hydroxy-6,7-dimethoxynaphthalene **2**a

The bicyclo ketone **1***a* (1 g), dissolved in methanol (15 mL), was treated with sodium methoxide (3 equiv. freshly prepared from sodium and methanol) and the mixture stirred at room temperature for 2 h. Water was added and carbon dioxide bubbled through until the solution was neutral to pH paper. The methanol was removed under reduced pressure, the residual material extracted with chloroform, and the extracts washed with water. Removal of the solvent and crystallization from dichloromethane gave **2***a* (90%), mp 158–162°C; ir ($CHCl_3$): 3400, 1650 cm^{-1}; ^1H nmr: 2.05 (d, 1H, $J_{1,OH}$ = 5.7 Hz; disappears with D_2O, —OH), 2.44 (s, 3H, —COMe), 2.6–3.2 (m, 2H, C(2)—*H*), 3.92, 3.95 (s, 3H each, 2 × OMe), 4.85 (dt, 1H, $J_{1,OH}$ = 5.7, $J_{1,2\alpha} = J_{1,2\beta}$ = 6.1 Hz, collapses to a triplet with D_2O, C(1)—H), 6.86, 7.04 (s, 1H each, 2 × Ar), 7.42 (broad s, 1H, vinyl-H); mass spectrum (intensity, assignment): 248 (8, M^+), 230 (76, $M^{\cdot+} - H_2O$), 215 (100, $M^{\cdot+} - H_2O - CH_3$). *Anal.* calcd. for $C_{14}H_{16}O_4$: C 67.73, H 6.50; found: C 67.38, H 6.47.

3-Formyl-1,2-dihydro-1-hydroxy-6,7-dimethoxynaphthalene **2**b

The bicyclo aldehyde **1***b* (1.5 g) was treated with sodium methoxide as described. Recrystallization from dichloromethane afforded **2***b* (83%), mp 132–134°C; ir ($CHCl_3$): 3400 (OH), 1660 (C=O) cm^{-1}; ^1H nmr: 2.4–2.9 (m, 3H, C(2)—H's and —OH), 3.9, 3.94 (s, 3H each, 2 × OMe), 4.86 (t, 1H, $J_{1,2}$ = 4.2 Hz, C(1)—H), 6.88, 7.06 (s, 1H each, 2 × Ar), 7.29 (broad s, 1H, vinyl-H), 9.61 (s, 1H, —CHO); mass spectrum (intensity, assignment): 234 (12, $M^{\cdot+}$), 216 (100, $M^{\cdot+} - H_2O$). *Anal.* calcd. for $C_{13}H_{14}O_4$: C 66.66, H 6.02; found: C 66.32, H 6.10.

2-Acetyl-6,7-dimethoxy naphthalene **8**a

The ketone **1***a* (1 g) was treated in the same manner as described for the preparation of **2***a* and the solution refluxed for 4 h. After neutralization and work-up as before, the residue was crystallized from methylene chloride (90%), mp 109–110°C; ir ($CHCl_3$): 1680 cm^{-1}; ^1H nmr: 2.69 (s, 3H), 4.03 (s, 6H), 7.15, 7.23 (s, 2 × 1H, H(5), H(8)), 7.71 (d, 1H, J = 8.5 Hz, H(4)), 7.92 (dd, 1H, J = 8.5 and 1.7 Hz, H(3)), 8.33 (d, 1H, J = 1.7 Hz, H(1)); mass spectrum: 230 ($M^{\cdot+}$), 215 ($M^{\cdot+}$ —CH_3). *Anal.* calcd. for $C_{14}H_{14}O_3$: C 73.03, H 6.13; found: C 73.25, H 6.20.

2-Formyl-6,7-dimethoxynaphthalene **8**b

The aldehyde **1***b* was treated as above and the product **8***b* crystallized from ether (92%), mp 86.5–88°C; ir ($CHCl_3$): 1695 (C=O) cm^{-1}; ^1H nmr: 4.04 (s, 6H), 7.18–7.26 (m, 2H), 7.8–8.19 (m, 3H), 10.10 (s, 1H, CHO); mass spectrum: 216 ($M^{\cdot+}$), 215 ($M^{\cdot+} - H$). *Anal.* calcd. for $C_{13}H_{12}O_3$: C 72.21, H 5.59; found: C 72.51, H 5.69.

3-Carbomethoxy-1,2-dihydro-1-hydroxy-6,7-dimethoxy naphthalene **2**c

Freshly prepared lithium diisopropylamide (1.1 equiv. in dry THF) was added to a solution of the ester **1***c* (0.1 g, 0.38 mmol) in dry THF (5 mL) at 0°C under nitrogen. Water (3 mL) was added after 10 min and the mixture poured into $CHCl_3$ (10 mL). After extraction with $CHCl_3$ (2 × 10 mL) the extracts were dried and the solvent removed to leave a solid which crystallized from ether (72%), mp 148–149°C; ir (KBr): 3450 (OH), 1720 (C=O) cm^{-1}; ^1H nmr: 1.81 (d, 1H, disappears with D_2O, —OH), 2.61–3.15 (m, 2H, C(2)—H's), 3.81, 3.89, 3.93 (s, 3H each, 2 × Ar—*OMe*, 1 × CO_2Me), 4.80 (q, 1H, collapses to a triplet with D_2O, J = 5.7 Hz, C(1)—H), 6.82, 7.01 (s, 1H each, Ar), 7.56 (broad s, 1H, vinyl-H); mass spectrum (intensity, assignment); 264 (18, $M^{\cdot+}$), 246 (100, $M^{\cdot+} - H_2O$). *Anal.* calcd. for $C_{14}H_{16}O_5$: C 63.63, H 6.10; found: C 63.36, H 6.04.

3-Cyano-1,2-dihydro-1-hydroxy-6,7-dimethoxy naphthalene **2**d

The cyanide **1***d* was treated with LDA as above at −78°C and the product **2***d* isolated and crystallized from dichloromethane (79%), mp 147–148°C; ir (KBr): 3480 (OH), 2200 (CN) cm^{-1}; ^1H nmr: 1.81 (d, 1H, disappears with D_2O, —OH), 2.73 (dd, 2H, J = 1.6 and 5.3 Hz, C(2)—H's), 3.90, 3.94 (s, 3H each, 2 × OMe), 4.82 (q, 1H, collapses to a triplet with D_2O, J = 5.3 Hz, C(1)—H), 6.75, 6.93 (s, 1H each, 2 × Ar), 7.19 (t, 1H, J = 1.6 Hz, vinyl-H); mass spectrum (intensity, assignment): 231 (1.5, $M^{\cdot+}$) 213 (100, $M^{\cdot+} - H_2O$). *Anal.* calcd. for $C_{13}H_{13}NO_3$: C 67.52, H 5.67, N 6.06; found: C 67.19, H 5.64, N 5.97.

*Acetophenone from 2-acetyl-7-oxabicyclo[2.2.1]hept-5-ene (***4**a)

Ketone **4***a* (0.25 g) in absolute methanol (3 mL) under nitrogen was treated with sodium methoxide as before and stirred at room temperature for 24 h. After work-up as before acetophenone (90%) was isolated and identified.

*1-*tert*-Butyldimethylsilyloxy-3-carbomethoxy-1,2-dihydrobenzene* **5**c

Freshly prepared LDA (1.2 equiv.) was added to a stirred solution of the ester **4***c* (4 g) in dry THF (25 mL) at 0°C under nitrogen. After 10 min, saturated aqueous ammonium chloride (10 mL) was added, THF removed, and the residue extracted into dichloromethane. The extract was dried (Na_2SO_4) and the solvent removed. The residue was treated with triethylamine (1.2 equiv.), dimethylamino pyridine (1 g), *tert*-butyldimethylsilylchloride (1.1 equiv.), and methylene chloride (100 mL) and stirred at room temperature for 12 h. The reaction mixture was filtered through a short column of silica gel using ethyl acetate – hexane (1 : 1) as the eluant. The solvents were removed and the residue distilled to provide **5***c* (65%), bp 86°C/0.05 Torr; ir (neat): 1712 (C=O); ^1H nmr: 0.04 (s, 6H, 2 × Me), 0.85 (s, 9H, *t*-Bu), 2.61 (dd, 1H, J = 9.0 and 1.7 Hz, —CH_2—), 3.73 (s, 3H, —CO_2Me), 4.48 (dt, 1H, J = 1.7 and 9.0 Hz, C*H*OR), 6.03 (m, 2H, vinyl-H's), 6.96 (m, 1H, vinyl-H); mass spectrum (intensity, assignment): 268 (4, $M^{\cdot+}$), 266 (7, $M^{\cdot+}$ − *t*-Bu). *Anal.* calcd. for $C_{14}H_{24}SiO_3$: C 62.64, H 9.01; found: C 62.55, H 8.89.

*1-*tert*-Butyldimethylsilyloxy-3-cyano-1,2-dihydrobenzene* **5**d

Freshly prepared LDA (1.2 equiv.) was added to a stirred solution of the cyanide **4***d* (3.68 g) in dry THF (25 mL) under nitrogen at −78°C. The reaction was processed as above and the product **5***d* (60%) obtained after distillation, bp 80°C/0.02 Torr; ir (neat): 2200 (CN) cm^{-1}; ^1H nmr: 0.07 (s, 6H, 2 × Me), 0.87 (s, 9H, *t*-Bu), 2.54 (dd, 2H, J = 1.7 and 8.0 Hz, —CH_2—), 4.40 (dt, 1H, J = 1.2 and 8.0 Hz, C*H*OR), 6.05 (m, 2H, vinyl-H's), 6.70 (m, 1H, vinyl-H); mass spectrum (intensity, assignment): 235 (3, $M^{\cdot+}$), 178 (100, $M^{\cdot+}$ − *t*-But). *Anal.* calcd. for $C_{13}H_{21}NOSi$: C 66.33, H 8.99, N 5.95; found: C 66.32, H 8.91, N 5.93.

1-Acetyl-5-hydroxy-cyclohexene **7**a

The ketone **6***a* (1 g) dissolved in dry methanol (5 mL) under nitrogen was treated with sodium methoxide and the reaction worked up as previously; ir (neat): 3400 (OH), 1655 (C=O); ^1H nmr: 1.5–2.8 (m, 6H, 3 × —CH_2—), 2.29 (s, 3H, —COMe), 3.10 (broad s, 1H, disappears with D_2O, —OH), 3.8–4.2 (m, 1H, —C*H*OH), 6.8–7.0

For personal use only.

(m, 1H, vinyl-H); mass spectrum (intensity, assignment): 140 (45, $M^{+\cdot}$), 97 (100, $M^{+\cdot} - C_2H_3O$). *Anal.* calcd. for $C_8H_{12}O_2$: C 61.52, H 7.74; found: C 61.12, H 7.82.

1-Carbomethoxy-5-hydroxy-cyclohexene 7c

The ester **6***c* (1 g) in dry THF (30 mL) under nitrogen, was treated with LDA (1.1 equiv.) at 0°C. The reaction was processed as before to provide the oily product **7***c* which was distilled (50%) bulb-to-bulb; ir (neat): 3400 (OH), 1655 (C=O) cm^{-1}; ^1H nmr: 1.5–2.8 (m, 6H, 3 × —CH_2—), 2.29 (s, 3H, —COMe), 3.10 (broad s, 1H, disappears with D_2O, —OH), 3.8–4.2 (m, 1H, —C*H*OH), 6.8–7.0 (m, 1H, vinyl-H); mass spectrum (intensity, assignment): 140 (45, $M^{+\cdot}$), 97 (100, $M^{+\cdot} - C_2H_3O$). *Anal.* calcd. for $C_8H_{12}O_2$: C 61.52, H 7.74; found: C 61.12, H 7.82.

1-Cyano-5-hydroxy-cyclohexene 7d

The cyanide **6***d* (1 g) in dry THF (30 mL) under nitrogen was treated with LDA (1.1 equiv.) at −78°C. The reaction was processed as before to provide the oily product **7***d* which was distilled (65%) bulk-to-bulb; ir (neat): 3400 (OH), 2208 (CN) cm^{-1}; ^1H nmr: 1.5–2.8 (m, 6H, 3 × —CH_2—), 3.8–4.2 (m, 1H, C*H*OH), 6.55–6.8 (m, 1H, vinyl-H); mass spectrum (intensity, assignment): 123 (1, $M^{+\cdot}$), 105 (100, $M^{+\cdot} - H_2O$), 80 (100 $M^{+\cdot} - C_2H_3O$). *Anal.* calcd. for C_7H_9NO: C 68.27, H 7.37, N 11.37; found: C 68.30, H 7.48, N 11.11.

1,3-Dihydro-4,7-dimethoxy-1-(3-oxobutyl)isobenzofuran **10**

Ketone **4** (400 mg) was placed in ethanol (50 mL) containing 10% Pd/C (80 mg) and perchloric acid (25 drops). The mixture was hydrogenated at 40 psi for 8 h and filtered through Celite. Saturated bicarbonate was added (30 mL) and the ethanol removed *in vacuo*. The residue was extracted into chloroform (20 mL), dried, and the solvent removed to yield an oil (95%) which resisted crystallization; ir (neat): 1730 (C=O) cm^{-1}; ^1H nmr: 2.05 (s, 3H, COC*H*$_3$), 2.0–2.6 (m, 4H, CH_2—CH_2), 3.7 (s, 6H, 2 × OMe), 4.97 (m, 2H, CH_2—O), 5.3 (m, 1H, CH—O), 6.6 (s, 2H, ArH); ^{13}C nmr: 29.0 (t, *C*H$_2$—CH_2COMe), 29.95 (q, CO*C*H$_3$), 39.62 (t, —CH_2*C*H$_2$COMe), 55.79 (q, 2 × Ar—OMe), 71.7 (t, *C*H$_2$—O), 83.4 (d, *CH*—O), 110.3, 110.4 (d each, aromatic *C*—H), 129.4, 130.6 (s each, aromatic *C*—OMe), 208.9 (s, C=O); mass spectrum: 250 (8, $M^{+\cdot}$), 192 (91, $M^{+\cdot} - CH_3COCH_3$), 179 (100, $M^{+\cdot} - CH_2CH_2COCH_3$).

1,3-Dihydro-1,5,6-trimethoxy-3-(3-oxobutyl)isobenzofuran **11**

The ketone **1***a* (50 mg) in methanol (2 mL) was treated with perchloric acid (3 drops) at room temperature. The solution was neutralized with aqueous sodium bicarbonate after 5 min and extracted into ether (2 × 10 mL). The extracts were dried (Na_2SO_4) and the ether removed to leave an oil which was filtered through a column of silica gel with ethyl acetate – ligroin (1:1). The oil did not crystallize and ^1H nmr showed it to be a 1:1 mixture of diastereomers (94% total yield); ir (neat): 1705 (C=O) cm^{-1}; ^1H nmr (a 1:1 mixture of *cis* and *trans* diastereomers): 1.5–2.8 (m, 7H of each isomer, 2 × —CH_2— and COMe), 3.40, 3.50 (s, 3H each, phthalan-OMe of each isomer), 3.91 (s, 6H, 2 × ArOMe of each isomer), 5.0–5.5 (m, 1H of each isomer, C(3)—H), 6.01 (s, 1H, C(1)—H of *cis* isomer), 6.11 (d, 1H, C(1)—H of *trans* isomer), 6.71, 6.88 (s, 1H each of each isomer, Ar); mass spectrum (intensity, assignment): 280 (5, $M^{+\cdot}$), 248 (48, $M^{+\cdot}$ – MeOH), 222 (100, McLafferty rearrangement).

2,3-Dicarbomethoxy-1,4-epoxy-1,4-dihydro-6,7-dimethoxy-1-(3-oxobutyl)naphthalene **12**

The dihydroisobenzofuran **11** (240 mg) dissolved in dimethyl acetylene dicarboxylate (1.5 mL) and glacial acetic acid (0.1 mL) was heated on a steam bath for 1 h. The liquids were removed under high vacuum and residual thick oil crystallized from ether (72%), mp 83–84°C; ir (KBr): 1700 (C=O), 1720 (C=O); ^1H nmr: 2.16 (s, 3H, COMe), 2.68 (broad s, 4H, 2 × —CH_2), 3.77, 33.80 (s, 3H each, 2 × CO_2Me), 3.87 (s, 6H, 2 × ArOMe), 5.85 (s, 1H, bridge-H), 6.95, 7.04 (s, 1H each, Ar); mass spectrum (intensity, assignment): 390 (56, $M^{+\cdot}$), 248 (100, isobenzofuran). *Anal.* calcd. for $C_{20}H_{22}O_8$: C 61.53, H 5.68; found: C 61.39, H 5.72.

1-Carbomethoxy-3-(3-oxobutyl)-5,6-methylenedioxy isobenzofuran **16**

The adduct **15**[4] (100 mg) was heated under reflux in CH_2Cl_2 (20 mL) with concentrated H_2SO_4 (2 drops in 1 mL of MeOH) for 15 min. The reaction mixture was allowed to cool and washed with an aqueous solution of $NaHCO_3$ (10 mL). The aqueous layer was extracted again with CH_2Cl_2 (10 mL). The combined extracts were dried (Na_2SO_4) and the solvent removed. Addition of ether (5 mL) formed an amorphous powder, which was filtered off (95 mg, 95%); ir (KBr): 1690 (C=O), 1740 (C=O) cm^{-1}; ^1H nmr: 2.13 (s, 3H, $COCH_3$) 2.8–3.3 (m, A_2B_2 system —CH_2CH_2—) 3.9 (s, 3H, COOMe), 5.93 (s, 2H, OCH_2O), 6.65, 7.70 (s, 1H each, 2Ar); mass spectrum (intensity, assignment): 290 (67, $M^{+\cdot}$), 259 (22, $M^{+\cdot}$ – OMe) 247 ($M^{+\cdot}$ – COMe).

1-(3-Oxobutyl)furan **17**

Ketone **4***a* (1 g) was dissolved in methanol (2 mL) and treated with perchloric acid (2 drops) at room temperature. The mixture was stirred for 24 h, and saturated bicarbonate added to neutralize the acid. Removal of the methanol, followed by extraction into methylene chloride (2 × 25 mL), drying, and removal of the solvent afforded a 6:1 mixture of **17** and acetophenone. The mixture was separated on a silica gel column using ethyl acetate – ligroin (1:1) as solvent, yielding acetophenone (13%) and the furan **17** (ref. 18) (78%); ir (neat): 1710 (C=O) cm^{-1}; ^1H nmr: 2.21 (s, 3H, COMe), 2.7–3.0 (m, 4H, 2 CH_2's), 6.0, 6.35, 7.32 (broad s, 1H each, 3 furan H's); mass spectrum (intensity, assignment): 138 (3, $M^{+\cdot}$), 123 (100, $M^{+\cdot}$ – CH_3).

2-Carbomethoxy-6,7-dimethoxy naphthalene 8c

Ester **1***c* (0.5 g) was placed in methanol (5 mL), perchloric acid (3 drops) added, and the mixture refluxed for 8 h. It was cooled, neutralized with saturated sodium bicarbonate, the methanol removed, and the residue extracted with chloroform (2 × 10 mL). The extracts were dried and the solvent removed to leave a solid crystallized from chloroform to provide **8***c* (50%), mp 103–105°C; ^1H nmr: 3.95 (s, 3H, CO_2*Me*), 4.00 (s, 6H, 2 × OMe), 7.13, 7.2 (s, 1H each, Ar—H), 7.68 (d, 1H, J_{ortho} = 8.5 Hz, C(4)—H), 7.93 (dd, 1H, J_{ortho} = 8.5 Hz, J_{meta} = 1.4 Hz, C(3)—H), 8.44 (broad s, 1H, C(1)—H); mass spectrum: 246 (100, $M^{+\cdot}$), 215 (53, $M^{+\cdot}$ – OMe). *Anal.* calcd. for $C_{14}H_{14}O_4$: C 68.28, H 5.73; found: C 68.01, H 5.80.

2-Cyano-6,7-dimethoxy naphthalene 8d

Cyanide **1***d* (0.2 g) was treated in the same was as **1***c* and the product isolated similarly (69%), mp 116–118°C; ir (KBr): 2210 cm^{-1}; ^1H nmr: 4.05 (s, 6H, 2 × OMe), 7.15 (s, 2H, C(5)—H and C(8)—H), 7.47 (dd, 1H, J_{ortho} = 8.3 Hz, J_{meta} = 3.8 Hz, C(3)—H), 7.74 (d, 1H, J_{ortho} = 8.3 Hz, C(4)—H), 8.07 (broad s, 1H, C(1)—H); mass spectrum: 213 (100, $M^{+\cdot}$). *Anal.* calcd. for $C_{13}H_{11}NO_2$: C 73.22, H 5.20, N 6.57; found: C 73.34, H 5.12, N 6.38.

The crystal structures of 2-*endo*-acetyl and 2-*endo*-carbomethoxy-1,4-epoxy-6,7-dimethoxy-1,2,3,4-tetrahydronaphthalenes

N. J. TAYLOR, B. A. KEAY, AND R. RODRIGO

Department of Chemistry, Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received November 15, 1983

N. J. TAYLOR, B. A. KEAY, and R. RODRIGO. Can. J. Chem. **62**, 1099 (1984).

Crystals of 2-*endo*-acetyl-1,4-epoxy-6,7-dimethoxy-1,2,3,4-tetrahydronaphthalene are orthorhombic, $a = 5.524(1)$, $b = 8.929(1)$, $c = 25.479(4)$ Å, $Z = 4$, space group $P2_12_12_1$; those of 2-*endo*-carbomethoxy-1,4-epoxy-6,7-dimethoxy-1,2,3,4-tetrahydronaphthalene are monoclinic, $a = 10.878(2)$, $b = 6.634(1)$, $c = 18.224(4)$ Å, $\beta = 92.76(2)°$, $Z = 4$, space group $P2_1/c$. Both structures were solved by direct methods and refined by full-matrix least-squares methods to final R values of 0.041 and 0.036 for 875 and 1327 reflections with $I \geq 3\sigma(I)$ respectively.

N. J. TAYLOR, B. A. KEAY et R. RODRIGO. Can. J. Chem. **62**, 1099 (1984).

Les cristaux de l'acétyl-2 *endo* époxy-1,4 diméthoxy-6,7 tétrahydro-1,2,3,4 naphtalène sont orthorhombiques, $a = 5{,}524(1)$, $b = 8{,}929(1)$, $c = 25{,}479(4)$ Å, $Z = 4$, groupe d'espace $P2_12_12_1$; ceux du carbométhoxy-2 *endo* époxy-1,4 diméthoxy-6,7 tétrahydro-1,2,3,4 naphtalène sont monocliniques, $a = 10{,}878(2)$, $b = 6{,}634(1)$, $c = 18{,}224(4)$ Å, $\beta = 92{,}76(2)°$, $Z = 4$ et groupe d'espace $P2_1/c$. Les deux structures ont été résolues par des méthodes directes et affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs finales respectives de R de 0,041 et 0,036 pour 875 et 1327 réflexions avec $I \geq 3\sigma(I)$.

[Traduit par le journal]

Introduction

In the preceding paper (1) we described two general 5-*endo-trig* reversals of 7-oxabicyclo[2.2.1] heptenes and heptanes. Our rationalization of these processes as reverse-Michael and reverse-aldol reactions in general violation of Baldwin's rules (2) relied heavily upon the geometry of two benzo derivatives determined by X-ray crystallography. Diels–Alder adducts of isobenzofurans have not been previously subjected to X-ray analysis with the exception (3) of one rather exotic adduct of 1,3-diphenylisobenzofuran. In this paper we report the results of our analyses of the *endo* isomers of **1***a* and **1***c*.

Experimental

Crystals of *endo* **1***a* and **1***c* were obtained as described previously (4).

2-endo-*Acetyl-1,4-epoxy-6,7-dimethoxy-1,2,3,4-tetrahydronaphthalene (**1**a)*

A crystal of dimensions 0.22 × 0.40 × 0.41 mm was mounted in a general orientation. Unit cell parameters were refined from the 2θ values of 15 general reflections ($20 < 2\theta < 30°$) measured with MoKα radiation ($\lambda = 0.71069$ Å). Crystal data at 21°C are:

$C_{14}H_{16}O_4$ fw = 248.48

Orthorhombic, $a = 5.524(1)$, $b = 8.929(1)$, $c = 25.479(4)$ Å, $V = 1256.7(3)$ Å^3, $Z = 4$, $\rho_c = 1.312$ g cm^{-3}, $F(000) = 528$, μ(MoKα) = 1.034 cm^{-1}. Systematically absent reflections; $h00$, $h = 2n + 1$; $0k0$, $k = 2n + 1$; $00l$, $l = 2n + 1$; space group $P2_12_12_1$ (D_2^4, No. 19).

Intensity data were measured with graphite-monochromated MoKα radiation on a Syntex $P2_1$ diffractometer using θ–2θ scans ($3.2 < 2\theta \leq 50.0°$) with a variable scan speed of 2.93–29.3° min^{-1} and a scan width of 1.0° below $K\alpha_1$ to 1.0° above $K\alpha_2$. Two standard reflections (120, 104) monitored after every 100 measurements fell by 4% during the data collection. These were used to scale the data to a common level. From a total of 1346 independent reflections measured, 875 (65.0%) with intensities $I \geq 3\sigma(I)$ were considered observed and used in the structure solution and refinement.

The structure was solved by direct methods (MULTAN 80), the positions of all non-hydrogen atoms being determined from an E-map. The structure was refined with anisotropic thermal parameters by full-matrix least-squares methods to an R of 0.079 ($R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$). At this stage, all the hydrogen atoms were located from a difference Fourier synthesis and included in the refinement which converged at $R = 0.041$. In the final cycles of refinement an empirical weighting scheme of $w^{-1} = 2.11 - 0.012|F_o| + 0.0008|F_o|^2$ was utilized to give constant error throughout the various ranges of F_o magnitude and a weighted residual R_w of 0.044 ($R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$). Scattering factors for non-hydrogen atoms were taken from ref. 5 and those for hydrogen from ref. 6. Programs used have been described elsewhere (7). On the final cycle of refinement, the mean and maximum parameter shifts were 0.05 and 0.21σ respectively. A final difference map was featureless with maximum residuals of 0.19 Å^{-3}. Final positional parameters are shown in Table 1. Anisotropic thermal parameters, carbon–hydrogen distances, and observed and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

2-endo-*Carbomethoxy-1,4-epoxy-6,7-dimethoxy-1,2,3,4-tetrahydronaphthalene (**1**c)*

Experimental details are as above except where noted. Crystal dimensions were 0.32 × 0.33 × 0.42 mm. Crystal data are:

$C_{14}H_{16}O_5$ fw = 264.28

Monoclinic, $a = 10.878(2)$, $b = 6.634(1)$, $c = 18.224(4)$ Å, $\beta = 92.76(2)°$, $V = 1313.5(4)$ Å, $Z = 4$, $\rho_c = 1.336$ g cm^{-3}, $F(000) = 560$, μ(MoKα) = 1.095 cm^{-1}. Systematically absent reflections: $0k0$, $k = 2n + 1$; $h0l$, $l = 2n + 1$; space group $P2_1/c$ (C_{2h}^5, No.14).

During the data collection, the two standard reflections monitored (129, 500) showed only minor fluctuations (±2%). From a total of 2313 independent reflections measured ($3.2 < 2\theta \leq 50°$), 1327 (57.4%) with intensities $I \geq 3\sigma(I)$ were considered observed.

After direct methods solution, the structure was refined with anisotropic thermal parameters to an R of 0.090. Hydrogen atoms were located at this stage. The refinement converged at $R = 0.036$ with $R_w = 0.036$ ($w^{-1} = 2.39 - 0.032|F_o| + 0.0013|F_o|^2$). A final difference Fourier was featureless with maximum residuals of 0.18 eÅ^{-3}. Mean and maximum parameter shifts in the final refinement cycle were 0.09 and 0.33σ respectively. Final positional parameters are listed in Table 2. Anisotropic thermal parameters, carbon–hydrogen bond lengths, and observed and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

[1] Structure factor tables, anisotropic thermal parameters (Table 5), and carbon–hydrogen distances (Table 6) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

a (R = $COCH_3$)

c (R = CO_2CH_3)

Discussion

The molecular parameters determined for **1***a* and **1***c* are listed in Table 3 and an ORTEP plot of **1***a* is shown in Fig. 1. Most of the strain in these molecules resides in bond angle distortions; the angles at C(9) and C(10) in particular are severely distorted by C(1) and C(4) being pulled together (C(1) and C(4) are only 2.153(7) and 2.151(4) Å apart in **1***a* and **1***c* respectively) by the oxygen bridge. In general, the bond lengths and angles of the oxabicyclo moieties in **1***a* and **1***c* are comparable to those determined (8) for the furan – maleic anhydride adduct **2**. The only significant difference between the two systems is that the C(1)—O(1)—C(4) plane in **1***a* and **1***c* is tilted towards the benzene ring 7.4° more than the corresponding plane is tilted towards the 5,6-double bond in **2** (Table 4). Whether this discrepancy is a consequence of the

Total synthesis of steroids. Part 2.[1] Preparation of C-10 methylated steroids. Regio- and stereocontrol in a diene addition to methyl Z-2-methyl-4-oxo-2-pentenoate

JAGABANDHU DAS, ROBERT A. DICKINSON, MASATOSHI KAKUSHIMA, GREGORY M. KINGSTON, GARY R. REID, YASUHIKO SATO, AND ZDENEK VALENTA

Department of Chemistry, University of New Brunswick, Bag Service #45222, Fredericton, N.B., Canada E3B 6E2

Received November 14, 1983

JAGABANDHU DAS, ROBERT A. DICKINSON, MASATOSHI KAKUSHIMA, GREGORY M. KINGSTON, GARY R. REID, YASUHIKO SATO, and ZDENEK VALENTA. Can. J. Chem. **62**, 1103 (1984).

A twelve-step total synthesis of 14-epi-androsta-4,9(11),15-triene-3,17-dione from methyl vinyl ketone, 2-methylcyclohexane-1,3-dione, acetylene, and methyl Z-2-methyl-4-oxo-2-pentenoate is described. Crucial steps include a stereo- and regio-selective diene addition, an efficient formation of ring D by C-acylation of an acetyl group, and a selective bromine substitution at C-15 in a 15,17-dione intermediate. The stereo- and regioselectivity of the diene addition is generalized for certain other bifunctional aliphatic dienophiles.

JAGABANDHU DAS, ROBERT A. DICKINSON, MASATOSHI KAKUSHIMA, GREGORY M. KINGSTON, GARY R. REID, YASUHIKO SATO et ZDENEK VALENTA. Can. J. Chem. **62**, 1103 (1984).

On décrit une synthèse totale en douze étapes de l'épi-14 androstatriène-4,9(11),15 dione-3,17 à partir de la méthylvinylcétone, de la méthyl-2 cyclohexanedione-1,3, de l'acétylène et du méthyl-2 oxo-4 pentène-2(Z) oate de méthyle. Les étapes clés comprennent une addition stéréo- et régiosélective de diène, une formation efficace du cycle D par une C-acylation d'un groupe acétyle et une substitution sélective par le brome en position 15 d'une dione-15,17 intermédiaire. On généralise à certains autres diènophiles aliphatiques bifonctionnels, la stéréo- et la régiosélectivité de l'addition de diène.

For personal use only.

The total synthesis of steroids (1) continues to provide useful ground for the testing of new synthetic strategies and methods (2). In particular, the establishment of the correct stereochemistry and the introduction of the desired functionality by an efficient, short route remains an interesting challenge.

We have previously reported (3) a successful elaboration of a "classical" synthetic scheme (4) represented in Fig. 1. Using 6-methoxy-1-vinyl-3,4-dihydronaphthalene as diene and 2,6-dimethyl-1,4-benzoquinone as dienophile, we have been able to complete the synthesis of *d,l*-estrone and of its 16,17-dehydro-17-acetyl derivative. Regiocontrol in the crucial diene addition was achieved by the use of boron trifluoride etherate, which reversed the reactivity of the dienophile (3, 5). The corresponding thermal addition was found to proceed exclusively in the undesired regio-sense.

We now wish to report, in detail, on the elaboration of this strategy to the synthetically more demanding C-10 methylated series.[2] Scheme 1 summarizes the approach in which diene trione monoacetal **13** was prepared from methyl vinyl ketone, 2-methylcyclohexane-1,3-dione, acetylene, and keto ester **10** in nine steps[3] and a 21% overall yield[4] based on dione **2**. The differentiation between the two keto groups in ring D of **13** to give enone **15** was then accomplished in two steps and a 68% yield. Scheme 2 shows the preparation of keto ester **10** (7) in two steps from pyruvic acid and acetone via pseudo acid **16** (8) in a 17% yield based on pyruvic acid.

All of the steps in the preparation of acetoxydienyl diene **9** and of dienophile **10** are precedented and will therefore be discussed only briefly. Triketone **3** (9–12) was obtained as a yellow oil in a Michael addition under mildly acidic reaction conditions. We have confirmed that the yield and purity of the product are significantly increased by using an aqueous medium and by omitting a basic catalyst (10, 11*b*) which is normally used in the standard preparations of **3** (12). Triketone **3** was then cyclized to enedione **4** with pyrrolidine in refluxing benzene (12, 13). Chiral Wieland–Miescher ketone **4** is accessible by an asymmetric synthesis via **3** using (*S*)-proline (9, 10). However, in the synthesis described here, racemic **4** was used and all compounds reported are therefore racemic. Treatment of **4** with lithium acetylide in liquid ammonia (13) gave the crystalline ethynyl carbinol **5** (13, 14), which on hydrogenation in pyridine with 5% palladium on barium sulfate (15) was selectively reduced to the crystalline allyl alcohol **6**.

The dehydration of **6** to **8** requires carefully chosen conditions, since the functionality of **6** is suitable for an undesirable acid-catalyzed reverse aldol reaction. The method of Bell *et al.* (16) proved excellent for the purpose. The intermediate allyl bromide **7** was prepared from **6** in a reaction with phosphorus tribromide in dimethylformamide and methylene chloride at −10°C and was then dehydrobrominated at 100°C after addition of 2 mol equivalents of lithium bromide and 3 mol equivalents of lithium carbonate to give **8** as a yellow oil of high purity. We have previously reported (17) that alcohol **6** can be converted to the corresponding carbamate on treatment with *p*-toluenesulfonyl isocyanate and that a subsequent vacuum distillation (18) leads to the desired diene **8**. The carbamate pyrolysis method has, in our hands, consistently given yields of 55–75% of dienes from **6** and other structurally related tertiary allyl alcohols. While it is thus satisfactory, it is clearly not as efficient as the bromine substitution–dehydrobromination sequence (16).

To complete the synthesis of the required acetoxydienyl di-

[1] For Part 1, see ref. 3.

[2] Part of this work has been reported previously in a preliminary form (6).

[3] The conversion **6** → **8** is considered to be one step since the intermediate allyl bromide **7** is dehydrobrominated to **8** without isolation (*vide infra*). The conversion **1** + **2** → **4** can be accomplished in one operation, but a two-step sequence is more efficient. Furthermore, the isolation of triketone **3** is preferred if a chiral synthesis is intended (9, 10). Similarly, the conversion **4** → **6** can in principle be done in one step using a vinyl Grignard reagent, but the use of acetylene is safer and more convenient.

[4] Yields in parentheses in Scheme 1 denote reactions in which the product was not purified by distillation, crystallization, or chromatography.

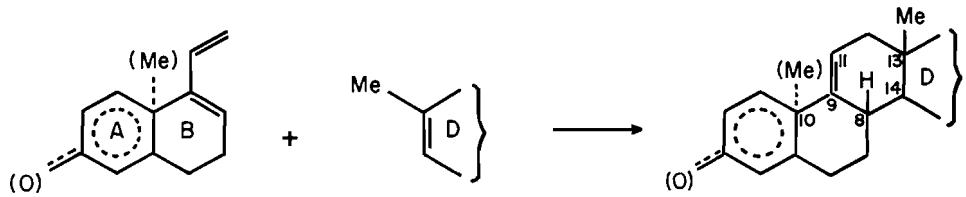

FIG. 1. General scheme for steroid synthesis.

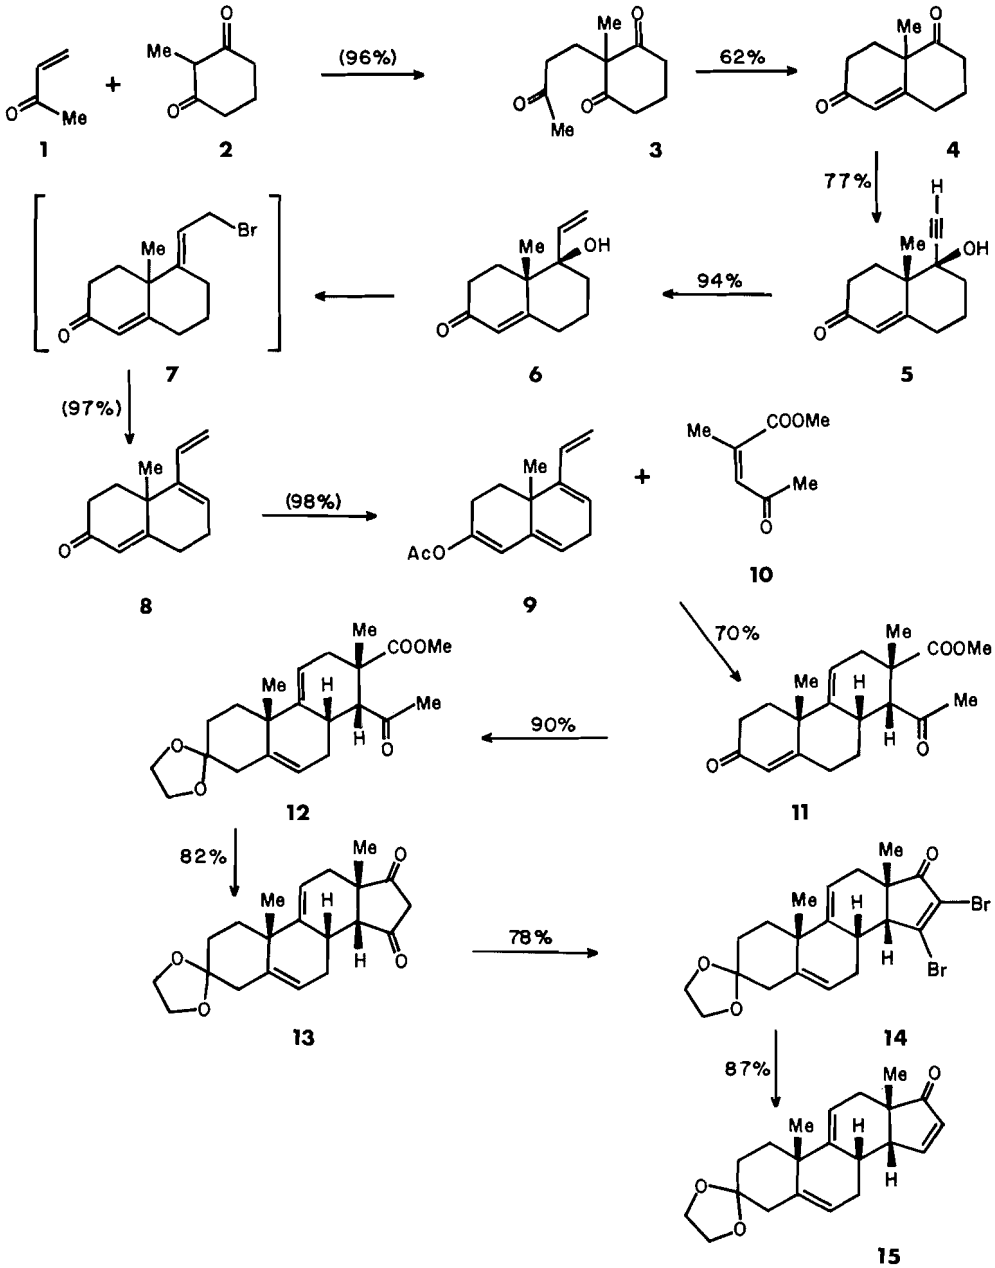

SCHEME 1

ene **9**, enone **8** was treated with anhydrous hydrogen bromide (prepared from 2 parts of 48% hydrobromic acid in 3 parts of acetic anhydride) in acetic anhydride at ambient temperature for 10 h. The resulting light green oil was homogeneous according to its ^{1}Hmr spectrum; since its color rapidly darkened to red on standing, however, it was used immediately after its preparation for the subsequent addition.

In order to prepare the required dienophile **10** (7), pyruvic acid was first condensed with acetone in the presence of 85% phosphoric acid to give the crystalline pseudo acid **16** (8). Treatment of **16** with methyl iodide and potassium carbonate in dry acetone then led to dienophile **10**. During isolation of **10**,

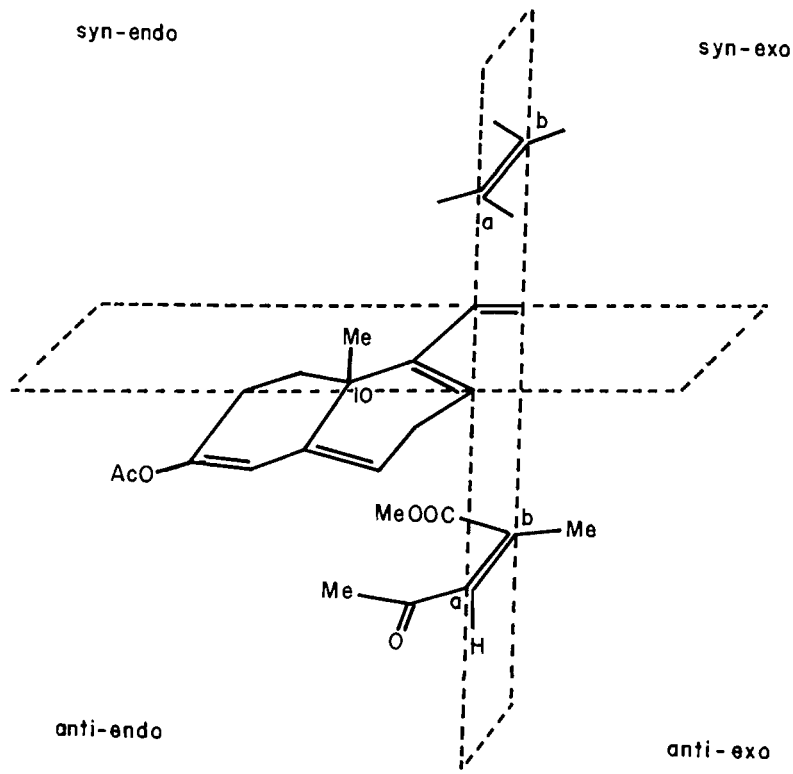

FIG. 2. Possible additions to **9**.

care had to be taken first to remove all potassium iodide formed, since it was found to catalyze the isomerization of **10** to the more stable *E*-isomer, particularly at elevated temperatures. Thus, although pure **10** was obtained in some vacuum distillations, purification by chromatography proved more reliable.

Catalyzed diene addition

The reaction of diene **9** with 2 mol equivalents of dienophile **10** in the presence of 1.5 mol equivalents of anhydrous tin tetrachloride[5] in methylene chloride at 0°C for 1 h gave crystalline adduct **11**, mp 155–156°C, in a conversion of 55% and a yield of 70% based on consumed **9**. The structure of **11** was established by X-ray diffraction. No other adduct could be found in a careful search of mother liquors and of chromatographic fractions. Both the starting diene and the product were isolated as enones (**8** and **11**, respectively), presumably because the corresponding enol acetates are slowly hydrolyzed in the presence of tin tetrachloride by traces of water during the reaction and this hydrolysis is completed during work-up.[6]

A complete regio- and stereoselectivity has thus been achieved in the addition **9** + **10**. The development of this control should now be discussed. As can be seen in Fig. 2, two mutually perpendicular planes intersecting at a straight line connecting the diene termini define four quadrants of space in which the dienophile substituents can be located during addition. Two of the quadrants contain space *syn* to the C-10 methyl group, the other two *anti* to this group. During the addition, a substituent in dienophile **10** (for example, the acetyl group) can then be oriented *endo* or *exo* relative to the diene π-system. This grouping can thus be located in any one of the four quadrants. Since, furthermore, this substituent can be situated at either terminus of the dienophile (a or b, Fig. 2), the two molecules (**9** + **10**) can in principle react via eight different transition states. The one shown in Fig. 2 by a complete drawing of the dienophile leads to the observed adduct **11**.

[5] Boron trifluoride etherate and aluminum chloride proved ineffective in this case.

[6] The 3-acetoxy-3,5-diene corresponding to **11**, mp 129–131°C, could be isolated in a 15–20% yield from a reaction run under scrupulously anhydrous conditions. It then hydrolyzed rapidly on mild acid treatment.

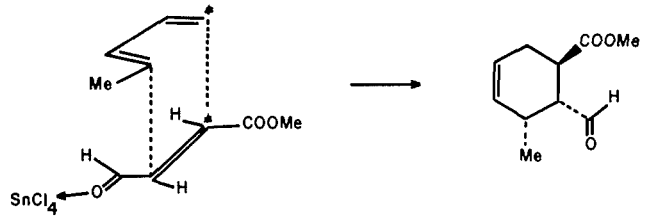

FIG. 3

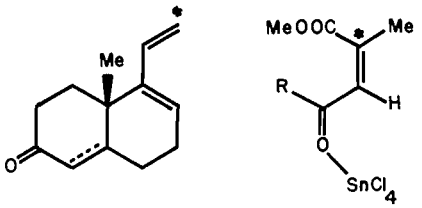

FIG. 4

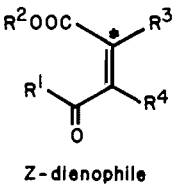
Thus, three independent factors must be controlled: *syn–anti* and *endo–exo* stereochemistry and a–b (Fig. 2) regiochemistry. By studying many systems, we have found that complete regio- and *endo–exo* control can often be achieved with bifunctional dienophiles in which the two functions (at termini a and b) are both activating and in which one of these functions, the carbonyl group of an aldehyde or a ketone, complexes preferentially with a Lewis acid. The crucial finding is represented in Fig. 3. While the thermal addition of piperylene to methyl *E*-4-oxo-2-butenoate gives all four possible adducts, a catalyzed addition proceeds exclusively via that transition state in which the more nucleophilic terminus of piperylene (*) adds β to the formyl group and in which the formyl group is *endo* oriented (19). The simplest explanation for this finding is the postulate that the only reacting dienophile species is complexed at the formyl oxygen atom.

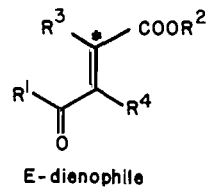
Since 1-vinylcyclohexene (5) and bicyclic dienes of the type indicated in Fig. 4[7] react exclusively in the same sense as piperylene in catalyzed additions,[8] it can be seen that the choice of the dienophile suitable for the construction of steroid rings C and D is clear. It must have an aldehyde, or possibly a ketone, at that dienophile terminus which will become C-14 in the steroid, and an ester group must be *cis* to it in order to establish the correct C-13 configuration (see Fig. 2). A ketone was chosen because it promised a more facile construction of ring D.

It remained to establish which diene(s) would add most efficiently from the side *anti* to the C-10 methyl group (Fig. 2). Clearly, an *anti* addition is required for the establishment of the correct configuration at C-8 and C-13 of the incipient steroid. Using 2,6-dimethyl-1,4-benzoquinone as a probe, we have found[7] that, in catalyzed additions, only acetoxydienyl diene **9** adds exclusively from the *anti* side. Enone **8** shows a slight preference for *syn* addition (17), while of the two ring A saturated ketones corresponding to **8**, the A,B-*trans* ketone adds preferentially *anti* (~2–4:1) and the A,B-*cis* ketone *syn* (~4–6:1). Thus, clearly, diene **9** possesses the A,B-ring geometry most suitable for an *anti* addition.

The exclusive *anti* addition to **9** may be due simply to the efficient flattening of the molecule which could then make the



Z-dienophile



E-dienophile

FIG. 5

hindering effect of the quasi-axial C-10 methyl group the most pronounced. Inspection of models (Fig. 2) shows, however, that the bidentate catalyst could well complex not only with the carbonyl group of the dienophile, but also with the 5,6-double bond of the diene. Such a complexation is sterically only possible from the *anti* side. In this connection, it is interesting to note that the catalyzed addition to **9** is approximately one hundred times faster than a similar one to **8**.[9] The acceleration and stereoselection would both be well explained by a double complexation.

The principles discussed above can be used generally for synthetic planning, since the *endo–exo* as well as the regiopreference in additions of *Z*- and *E*-dienophiles of the type shown in Fig. 5 to suitable dienes in the presence of tin tetrachloride can now be predicted. In these dienophiles, R^1 can be an H-atom (17, 19) or an alkyl group (**10**) and R^3 can be an H-atom (19) or an alkyl group (17) as in **10**. Although we have not as yet studied cases in which R^3 is an H-atom and R^4 an alkyl group (Fig. 5), we are confident that such dienophiles will add well and will follow the rules established here. This confidence is based on the fact that, in certain cases, 2-alkyl-substituted enones undergo catalyzed diene additions, while the corresponding 3-alkyl-substituted enones do not.[10] For example, no catalyzed (or thermal) diene addition to 3-methyl-2-cyclohexenone has been reported, while catalyzed additions to 2-methyl-2-cyclohexenone are reasonably efficient (20). An alkyl substituent at the electrophilic terminus of the dienophile (asterisks in Fig. 5) can thus be expected to be more deactiviting[10] than one at the other terminus. It remains to establish experimentally whether R^3 and R^4 (Fig. 5) can be alkyl groups in the same dienophile.

Available evidence permits the above generalization only for bifunctional dienophiles in which an ester group competes with a ketone or an aldehyde for the catalyst. In all such cases, the complexing group (ketone or aldehyde) controls regiochemistry and *endo* stereochemistry. Clearly, it is of both theoretical and synthetic interest to establish whether comparable selectivities will be achievable using activating groups different from those indicated in Fig. 5. In an important study using a bifunctional dienophile, Danishefsky *et al.* (22) showed that, in thermal additions, the nitro group of *trans*-methyl β-nitroacrylate completely controls regiochemistry, but not *endo* stereochemistry. This result, which preparatively contributes to

[7] R. A. Dickinson and Y. Sato. Unpublished experiments in this department.

[8] Asterisk on diene terminus in Fig. 4 indicates the more nucleophilic center.

[9] The addition of ethyl *E*-2-methyl-4-oxo-2-butenoate to enone **8** under conditions comparable to those described here for the **9** + **10** addition required 4 days (17). This explains why no detectable quantity of a *syn*-adduct is formed in the **9** + **10** addition, although some dione **8** is formed by hydrolysis during the reaction, and **8** adds preferentially *syn*.

[10] In fact, to our knowledge, the only β-alkyl β-disubstituted dienophiles which have undergone a catalyzed diene addition are exceptionally reactive ones (low LUMO). Examples include **10** in this paper, ethyl *E*-2-methyl-4-oxo-2-butenoate (17), 2,6-dimethyl-1,4-benzoquinone (5), and a cross-conjugated cyclohexadienone described by Liotta *et al.* (21).

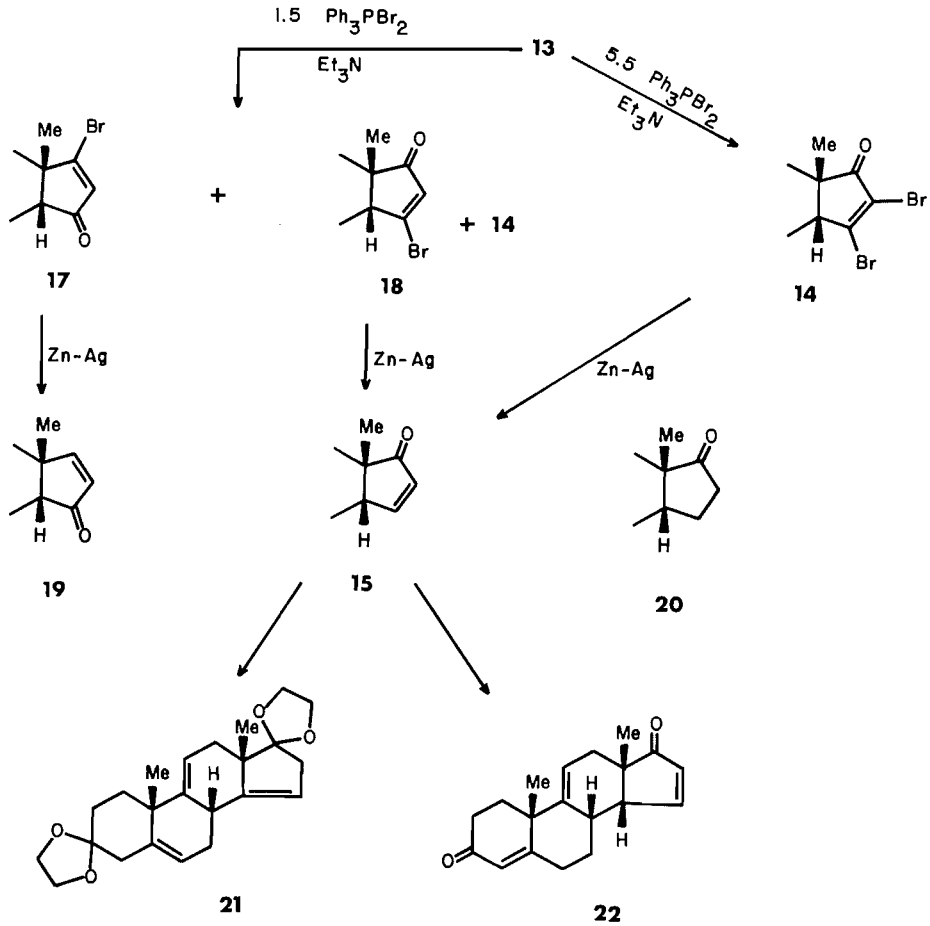

SCHEME 3

the synthesis of previously difficultly accessible cyclohexenes (22), gives a warning that, in general, regiocontrol and *endo* stereocontrol are two different, separable manifestations of the properties of a given activating substituent (23).

The third parameter, the *syn–anti* stereoselectivity (Fig. 2) in any particular addition, will of course depend on the exact nature of the diene and thus cannot be generalized.

Construction of ring D

The adduct **11** contains all C atoms required for the construction of ring D and the *cis*-arrangement of the ester and acetyl groups makes the required C-acylation a favourable process (24). In order to simplify the subsequent cyclization, **11** was first converted to acetal **12** on treatment with ethylene glycol and pyridinium tosylate (25) in boiling benzene or toluene. Mild acid hydrolysis of **12** gave pure adduct **11**, showing that no epimerization had occurred at the (steroid) C-14 position during the formation of **12**. Cyclization was then efficiently achieved by the treatment of acetal **12** with 6 mol equivalents of lithium bis(trimethylsilyl)amide (26) in tetrahydrofuran at 20°C for 2 h.[11] Dione **13** was isolated as a white powder, mp 195°C (dec.), showing the expected spectral properties, including a uv chromophore.

The dithiane derivative corresponding to **12** was also prepared from **11** in a 92% yield and cyclized in a similar manner in an 87% yield to the ring A dithiane corresponding to **13** (see Experimental). Work in the dithiane series was discontinued, however, because in contrast to the dioxalane series no useful ring D transformations could be effected. This lack of success included the method (27) which was found effective with **13** (see below).

It should be noted that the addition **9** + **10** followed by cyclization **12** → **13** is formally equivalent to the direct addition of **9** to 2-methyl-2-cyclopentene-1,4-dione. This latter addition was not attempted, since it was feared that enolization of the dione system on catalysis would diminish or destroy the reactivity of the dienophile or, at best, eliminate the required regioselectivity.[12]

The differentiation between the two keto groups in **13** proved a considerable challenge and its study produced a surprising result. While many methods, including the use of oxalyl chloride (28), failed to yield the desired β-halo enone (or at least a mixture of the two possible β-halo enones), the method developed by Piers and Nagakura (27) employing triphenylphosphine dibromide and triethyl amine in benzene was successful. Treatment of dione **13** with 1.5 mol equivalents of the reagent produced a mixture of bromo ketones **17** and **18** (Scheme 3) together with some dibromoketone **14** and starting material. In

[11] This method represents a significant improvement over our previous cyclization with sodium hydride in dimethylsulfoxide and toluene which gave **13** in a 41% yield (6). It can safely be assumed that the C,D-ring system in **13** is *cis*, not only for thermodynamic reasons, but also because we have evidence that an epimerization of the acetyl group in **12** prior to cyclization leads to an enol lactone via an O-acylation (6).

[12] NOTE ADDED IN PROOF: We have now found that 2-methyl-2-cyclopentene-1,4-dione does not add to **9** in the presence of tin tetrachloride or to piperylene in the presence of boron trifluoride etherate.

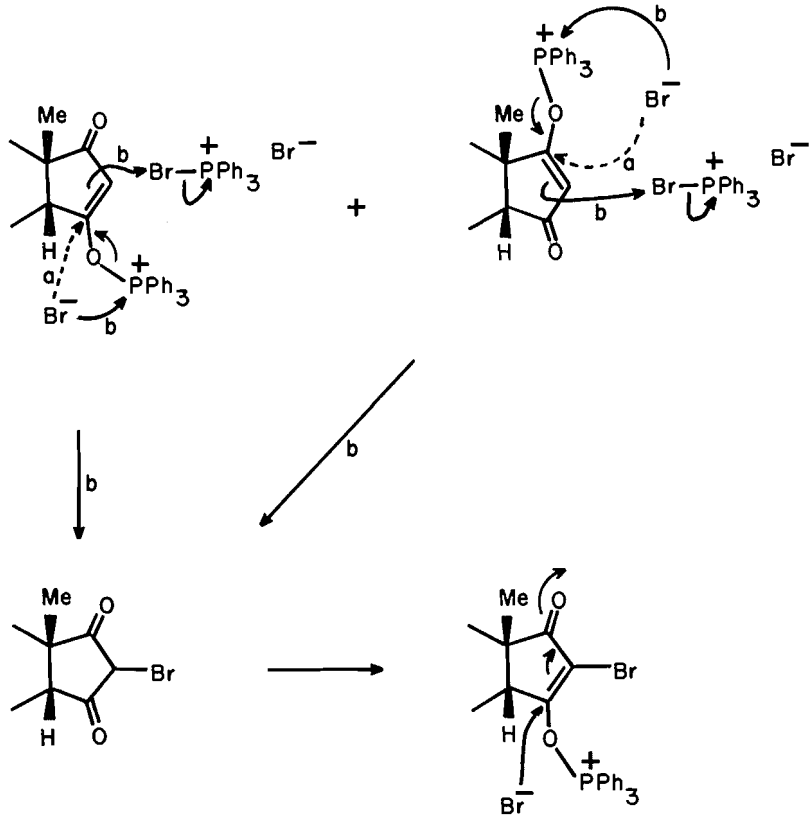

FIG. 6

contrast, treatment of **13** with 5.5 mol equivalents of the reagent gave **14** as the only product! Compounds **17** and **18** were found not to react further with triphenylphosphine dibromide!

Bromo enone **18** and dibromo enone **14** gave the desired enone **15** on reduction with a zinc–silver couple prepared by the method of Clark and Heathcock (28). A similar reduction of bromo enone **17** yielded enone **19**. The reduction of **14** with zinc in acetic acid gave ring D saturated ketone **20**.

The preparation of both possible ring D enones (**15** and **19**) facilitated structure assignments. In particular, the two enone protons were seen as clean doublets (J = 6 Hz) at δ 6.02 and 7.61, in the ^{1}Hmr spectrum of **19**, while the β-proton (C-15) showed as a double doublet (J = 5.9, 2 Hz) at δ 7.46 and the α-proton (C-16) as a double doublet (J = 5.9, 1.6 Hz) at δ 6.14 in the ^{1}Hmr spectrum of **15**. The structure of **15** was further confirmed by its conversion to the diacetal **21**. The accompanying shift of the ring D double bond to the 14,15-position as shown by the ^{1}Hmr spectrum of **21** is, of course, only compatible with a carbonyl group at C-17 in enone **15**. Finally, mild acid hydrolysis produced the dione **22**.

The remarkable action of triphenylphosphine dibromide (27), together with a very efficient zinc–silver couple reduction (28), has thus led to a facile, high yield differentiation between the two carbonyl groups in **13**. Concerning the puzzling events observed during the bromide–enol exchanges (Scheme 3), it can be speculated that subtle kinetic effects have led to an unusual – and very fortunate – result. Inspection of models of diketone **13** and of the two corresponding enols, as well as the consideration of the many abortive attempts to achieve efficient reactions at C-15 or at C-17 of **13**, indicate that both centers are sterically hindered. If the two probable first intermediates in the reaction sequence (27) are considered (Fig. 6), it can be seen that the bromide ion can, by path (a) indicated by dotted arrows in Fig. 6, add β to the carbonyl group and that a subsequent triphenylphosphine oxide elimination would then give the β-bromo enones (27). The relative amounts of the two resulting β-bromo enones **17** and **18** (Scheme 3) would thus be determined by the two velocities by which the first intermediates are formed. However, if the bromide ion attack (path (a)) is slow because of steric hindrance, then it is possible that, in the presence of a sufficient excess of triphenylphosphine dibromide, path (b) (or a nonconcerted equivalent) could be followed. This would then lead to a common bromo diketone intermediate. Since only one dibromo enone is formed (**14**), it must now be postulated that the bromo diketone reacts with the reagent exclusively at the C-15 position as indicated in Fig. 6.[13] The reason for this selectivity (as compared to the nonselectivity of the reaction with **13**) and for the complete absence of a 16-dibromo product is not clear.

In conclusion, a relatively short and efficient total synthesis of potentially useful steroid intermediates has been accomplished. While, to our knowledge, no naturally occurring steroids contain the 14-β-H atom present in **22**, the functionality present in **21** should permit, after a suitable differentiation of the functional groups, the introduction of the important 14-β-hydroxyl group (29). The 9,11-double-bond in **22** should

[13] The above is, however, not the only possible explanation. While it seems obligatory to postulate that the first intermediate bearing the —$OPPh_3$ grouping at C-17 is converted to the bromodiketone (Fig. 6) which can then be "recycled" to give **14**, it is possible that the first intermediate bearing the —$OPPh_3$ grouping at C-15 (Fig. 6) is brominated at C-16 without the loss of PPh_3. Subsequent addition of bromide ion to C-15, followed by elimination of triphenylphosphine oxide, would then give **14** directly. Again, however, it is not obvious why the two intermediates should have a different reactivity.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

be suitable for the preparation of 11-oxygenated steroids (30), while steroids containing a 14-α-H atom should be accessible by catalytic hydrogenation of derivatives of **21** containing a 17-β substituent (31). Finally, chiral compounds are readily available, since the Wieland–Miescher ketone **4** can be prepared in either enantiomeric form using (*S*)- or (*R*)-proline (9, 10).

Experimental

Melting points were determined on a Kofler hot stage and are uncorrected. Ultraviolet (uv) spectra were recorded on a Beckman Model 25 spectrophotometer in ethanol solution. The wavelengths are reported in nanometers (nm) with ε values in parentheses. Infrared (ir) spectra were determined on both the Perkin–Elmer 727B and 598 infrared spectrophotometers in chloroform or carbon tetrachloride solution. Values are given in wave numbers (cm^{-1}) calibrated to the polystyrene band at 1601 cm^{-1}. Proton magnetic resonance (^{1}Hmr) spectra were recorded on a Varian T-60 spectrometer and high resolution ^{1}Hmr spectra were obtained on a Varian XL-200 spectrometer, both using deuterochloroform as solvent; chemical shift values are given in δ (ppm) scale relative to tetramethylsilane (TMS) used as internal reference. Low resolution mass spectra were measured on a Hitachi Perkin–Elmer RMU-6D mass spectrometer. High resolution mass spectra were measured by the Mass Spectrometry Laboratory, Department of Chemistry, University of Alberta, Edmonton, Alberta. Microanalyses were performed by Guelph Chemical Laboratories, Ltd., Guelph, Ontario. Chromatography was performed by flash chromatography (32) using silica gel 60 (230–400 mesh). Solutions were dried over anhydrous calcium chloride. The following abbreviations have been used: s, singlet; d, doublet; dd, double doublet; ddd, double doublet of doublets; q, quartet; b, broad; m, multiplet; dec., decomposition; ether, ethyl ether.

Enol acetylation of diene 8

To a solution of diene **8** (0.990 g, 5.26 mmol) in acetic anhydride (10 mL) at 0°C was added a solution of anhydrous HBr (20 drops) prepared from 48% HBr (4 mL) and acetic anhydride (6 mL). The solution was stirred at 20°C in an atmosphere of N_2 for 10 h and then diluted with a cold saturated solution of $NaHCO_3$ which was extracted with ether–hexanes (1:9). The extracts were washed successively with saturated $NaHCO_3$ solution and brine and then dried. Evaporation of the solvent *in vacuo* at 20°C yielded the acetoxydienyl diene **9** (1.19 g, 98%) as an unstable light green oil which was immediately used in the subsequent addition; ir ν_{max}: 1740, 1360, 1115, 900; ^{1}Hmr δ: 1.21 (3H, s, C(4a)—CH_3), 2.13 (3H, s, C(2)-ester), 2.81 (2H, m, C(7)—H(2)), 4.98 (1H, dd, *J* = 10 and 2 Hz, B proton), 5.31 (1H, dd, *J* = 17 and 2 Hz, A proton), 5.52 (1H, m, C(8)—H), 5.82 (2H, m, C(1)—H, C(6)—H), 6.40 (1H, ddd, *J* = 18, 10, and 1.5 Hz, X proton).

Methylation of pseudo acid 16. Dienophile 10

The known compound **10** (7) was prepared by our modified procedure. Pseudo acid **16** (10.0 g, 0.0780 mol) was taken up in dry acetone (300 mL, distilled from $KMnO_4$) and was stirred with anhydrous K_2CO_3 (37 g) at 20°C for 1 h. Methyl iodide (20 mL) was added and the reaction was stirred at 20°C for 18 h. The excess of K_2CO_3 was filtered and the mixture was diluted with dry pentane (500 mL) and filtered again to remove precipitated KI. The solvent was then evaporated *in vacuo* at 20°C and the residue was again diluted with pentane (50 mL) and more precipitated KI was removed by filtration. Concentration of the solution *in vacuo* at 20°C followed by chromatography using hexanes – ethyl acetate (9:1) as eluent gave **10** (7.35 g, 66%) as a yellow oil.

Catalyzed addition of 9 and 10

To a solution of **10** (1.50 g, 10.5 mmol) in CH_2Cl_2 (50 mL), freshly distilled from K_2CO_3, was added a 1 *M* solution of $SnCl_4$ in CH_2Cl_2 (75 mL, 7.5 mmol) at 0°C in an atmosphere of argon. To this solution was added a solution of enol acetate **9**, freshly prepared from diene **8** (0.990 g, 5.26 mmol) in CH_2Cl_2 (10 mL). The resulting wine red solution was stirred at 0°C for 1 h and then poured into a cold saturated solution of $NaHCO_3$ which was then thoroughly extracted with $CHCl_3$. The extracts were washed successively with saturated $NaHCO_3$ solution and H_2O and dried over anhydrous $MgSO_4$. The solvent was evaporated *in vacuo* and most of the adduct **11** was crystallized from ether while the residual product was chromatographed, eluting with hexanes – ethyl acetate (9:1), to give unreacted diene **8** (215 mg). Elution with hexanes – ethyl acetate (6:4) gave the desired adduct **11** which was crystallized from ether (950 mg, 55%, 70% based on consumed **8**), mp 155–156°C; ir ν_{max} (CCl_4): 1730, 1715, 1680; ^{1}Hmr (200 MHz) δ: 1.23 (3H, s, C—CH_3), 1.37 (3H, s, C—CH_3), 2.22 (3H, s, C(14)—$COCH_3$), 3.29 (1H, d, *J* = 7 Hz, C(14)—H), 3.69 (3H, s, C(13)—CO_2CH_3), 5.71 (2H, m, C(4)—H, C(11)—H); ms *m/e*: 330 (M^+). *Mol. Wt.* calcd. for $C_{20}H_{26}O_4$: 330.1831; found (high resolution ms): 330.1826. The structure of **11** was established by X-ray diffraction.

Acetalization of adduct 11

A mixture of dry benzene (35 mL), ethylene glycol (3.0 mL, 43 mmol), and pyridinium tosylate (PPTS) (25 mg, 0.10 mmol) was stirred at reflux in an argon atmosphere with a Dean–Stark distilling head connected. After water had been removed (ca. 40 mL of solvent replaced), the adduct **11** (200 mg, 0.605 mmol) was added and the reaction was heated at reflux under argon for 5.5 h. The cooled reaction mixture was diluted with ether and washed successively with saturated $NaHCO_3$ and brine solutions. The organic layer was dried and evaporated *in vacuo*. The residue was chromatographed, using hexanes – ethyl acetate (6:4) as eluent, to obtain unreacted adduct **11** (34 mg) and the product acetal **12** (169 mg, 75%, 90% based on recovered **11**) as colourless crystals, mp 155–157°C (hexanes/ether).

In a similar reaction, substituting toluene for benzene as solvent and refluxing under argon for 5 h, a yield of 88% of **12** was achieved with no unreacted adduct detected; ir ν_{max} (CCl_4): 1730, 1715, 1260, 1102; ^{1}Hmr δ: 1.21 (3H, s, C—CH_3), 1.23 (3H, s, C—CH_3), 2.23 (3H, s C(14)—$COCH_3$), 3.22 (1H, d, *J* = 7 Hz, C(14)—H), 3.67 (3H, s, C(13)—CO_2CH_3), 3.93 (4H, s, —OCH_2CH_2O—), 5.42 (1H, m, C—H vinylic), 5.65 (1H, m, C—H vinylic); ms *m/e*: 374 (M^+). *Mol. Wt.* calcd. for $C_{22}H_{30}O_5$: 374.2093; found (high resolution ms): 374.2099.

The dithiane derivative corresponding to **12** was prepared in the following manner. The adduct **11** (240 mg, 0.726 mmol) was suspended in anhydrous ether (10 mL) and stirred at 0°C in an argon atmosphere for 10 min. At this point an excess of 1,3-propanedithiol (0.12 mL, 1.2 mmol) was added, followed by the addition of a large excess of BF_3 etherate (5 mL). The adduct soon went into solution and the reaction was stirred at 20°C, under argon, for 5 h with five further additions of BF_3 etherate (5 × 2 mL) made throughout the reaction. The reaction mixture was carefully diluted with H_2O and extracted with ether. The organic layer was washed with a 5% $NaHCO_3$ solution until neutral, and with brine, dried, and evaporated *in vacuo*. The product dithiane was crystallized from ether (281 mg, 92%) as colourless crystals, mp 205–206°C; ir ν_{max}: 1727, 1716, 1260 (broad); ^{1}Hmr (200 MHz) δ: 1.20 (3H, s, C—CH_3), 1.22 (3H, s, C—CH_3), 2.22 (3H, s, C(14)—$COCH_3$), 3.21 (1H, d, *J* = 7 Hz, C(14)—H), 3.67 (3H, s, C(13)—CO_2CH_3), 5.41 (1H, s, (C(4)—H), 5.61 (1H, m, C(11)—H); ms *m/e*: 420 (M^+). *Mol. Wt.* calcd. for $C_{23}H_{32}S_2O_3$: 420.1793; found (high resolution ms): 420.1792.

Cyclization of acetal 12. Dione 13

To a solution of 1.60 *M* n-butyllithium in hexane (3.13 mL, 5.00 mmol) at −78°C in an atmosphere of argon was added 1,1,1,3,3,3-hexamethyldisilazane (1.05 mL, 5.00 mmol). The resulting white slurry was stirred at −78°C for 30 min, at which point dry THF (10 mL) was added and the solution was allowed to warm to ambient temperature. At this time a solution of acetal **12** (305 mg, 0.814 mmol) in THF (10 mL) was added over a period of 5 min. The reaction mixture was stirred under argon at 20°C for 2 h and was then diluted with ether and extracted with brine. The basic aqueous layer was then neutralized with a 10% oxalic acid solution and extracted thoroughly

with CH_2Cl_2. The organic layer was dried and evaporated *in vacuo*. Crystallization from ethyl acetate afforded **13** (228 mg, 82%) as a white powder, mp 195°C (dec.); uv λ_{max} (EtOH): 251 nm (variable) (13 680); (EtOH–OH^-): 262 nm (25 230); (EtOH–H^+): 247 nm (10 115); ir ν_{max}: 1722, 1590; ^{1}Hmr (200 MHz) δ: 1.22 (3H, s, C—CH_3), 1.23 (3H, s, C—CH_3), 3.95 (4H, m, —OCH_2CH_2O—), 4.53 (b, 1.5 H, C(16)—H(2)), 5.15 (0.5 H, s, C(16)—H vinylic), 5.40 (1H, m, C—H vinylic), 5.51 (1H, m, C—H vinylic); ms *m/e*: 342 (M^+). *Mol. Wt.* calcd. for $C_{21}H_{26}O_4$: 342.1831; found (high resolution ms): 342.1826.

As evidenced in the ^{1}Hmr data, the compound contains a mixture of D-ring dione and enone. In ethanol solution, as evidenced by the uv results, the compound is in equilibrium between the enol and enolate species.

The dithiane derivative corresponding to **13** was also prepared in a similar manner in an 87% yield, mp 181–183°C (ethyl acetate); uv λ_{max} (EtOH): 248–263 nm (variable); (EtOH–OH^-): 263.5 nm (30 260); (EtOH–H^+): 248 nm (22 610); ir ν_{max}: 1722, 1588 (broad); ^{1}Hmr δ: 1.24 (6H, broad s, C(10)—CH_3 and C(13)—CH_3), 2.95 (0.75 H, s, hydroxyl), 5.09 (0.5 H, s, C(16)—H(2)), 5.36 (0.75 H, s, C(16)—H vinylic), 5.47 (2H, m, C(4)—H, C(11)—H); ms *m/e*: 388 (M^+). *Anal.* calcd. for $C_{22}H_{28}S_2O_2$: C 68.00, H 7.26; found: C 67.99. H 7.32.

A D_2O exchange experiment resulted in the disappearance of the ^{1}Hmr signals at δ 2.95 and δ 5.09, representing the enol hydroxyl and the C-16 keto protons.

*Bromination of dione **13**. β-Bromo enones **17** and **18***

To an ice-cold solution of triphenylphosphine (85.0 mg, 0.324 mmol) in freshly distilled (from Na) benzene (10 mL), in an argon atmosphere, was added, dropwise, a 1 *M* solution of Br_2 in benzene (0.30 mL, 0.30 mmol). To the resulting white suspension of triphenylphosphine dibromide was added triethyl amine (0.050 mL, 0.36 mmol) and, finally, a suspension of diketone (70.0 mg, 0.204 mmol) in benzene (10 mL). The mixture was stirred under argon at 70°C for 16 h. The cooled reaction mixture was extracted with 5% NaOH solution and the aqueous layer was neutralized with 10% oxalic acid solution and extracted with CH_2Cl_2 to recover starting material (5 mg). The original organic layer was washed with H_2O and brine, dried, and evaporated *in vacuo*. The crude material was subjected to preparative thin-layer chromatography (1.0-mm silica gel 60 F_{254} plate), developing twice in hexanes – ethyl acetate (4:1). Two bands were collected and extracted with CH_2Cl_2–CH_3OH (10:1) to yield the dibromo ketone **14** (9 mg) and a mixture of bromo ketones **17** and **18** (16.5 mg, 21% based on recovered **13**) with the desired bromo enone **18** predominant (ratio 2:1). However, in two similar experiments the other bromo enone **17** was predominant by the same ratio. Crystallization from ether gave **18**, mp 113–116°C, exclusively; uv λ_{max}: 240 (11 990); ir ν_{max}: 2980, 1705, 1580; ^{1}Hmr (200 MHz) δ: 1.24 (3H, s, C—CH_3), 1.30 (3H, s, C—CH_3), 2.95 (2H, m, $W/2$ = 6 Hz, C—CH_2—), 3.95 (4H, m, —OCH_2CH_2O—), 5.37 (1H, m, C—H vinylic), 5.48 (1H, m, C—H vinylic), 6.40 (1H, s, C(16)—H); ms *m/e*: 404 (M^+), 406 (M^+ + 2). *Mol. Wt.* calcd. for $C_{21}H_{25}O_3Br$: 404.0987 (^{79}Br), 406.0967 (^{81}Br); found (high resolution ms): 404.0973 (^{79}Br) and 406.0986 (^{81}Br).

Bromo enone **17** was isolated as a crude oil from the mother liquors; ^{1}Hmr δ: 1.27 (6H, s, C(10)—CH_3 and C(13)—CH_3), 3.93 (4H, s, —OCH_2CH_2O—), 5.40 (2H, m, C(6)—H and C(11)—H), 6.30 (1H, s, C(16)—H).

The bromo enones **17** and **18** were further characterized by the reduction (see below) to their respective enones **19** and **15**. Bromo enone **18** and dibromo enone **14** both gave **15** upon reduction, while reduction of **17** gave enone **19**; ^{1}Hmr (200 MHz in methanol-d_4) δ: 1.23 (3H, s, C—CH_3), 1.24 (3H, s, C—CH_3), 3.88 (4H, m, —OCH_2CH_2O—), 5.36 (1H, m, C—H vinylic), 5.57 (1H, m, C—H vinylic), 6.02 (1H, d, C(16)—H), 7.61 (1H, d, C(17)—H). Finally, hydrolysis of the dioxalane protecting group gave the corresponding diene dione, mp 125—127°C, identical to the compound reported by us previously (6).

*Bromination of **13**. Dibromo enone **14***

To an ice-cold solution of triphenylphosphine (874 mg, 3.33 mmol) in freshly distilled (from Na) benzene (10 mL) in an atmosphere of argon was added, dropwise, a 1 *M* solution of Br_2 in benzene (3.30 mL, 3.30 mmol). To the resulting suspension was added triethylamine (0.460 mL, 3.30 mmol) and a suspension of diketone **13** (206 mg, 0.602 mmol) in benzene (10 mL). The mixture was refluxed under argon for 1 h, cooled, and filtered to remove excess triphenylphosphine dibromide. The filter cake was thoroughly washed with ether and the organic layer was washed with H_2O and brine, dried, and evaporated *in vacuo*. The crude product was chromatographed, eluting with hexanes – ethyl acetate (4:1), to yield the ring A deblocked derivative of **14** (4.5 mg) and dibromo enone **14** (225 mg, 78%) as colourless crystals, mp 164–166°C (ethyl acetate); uv λ_{max}: 257 nm (7915); ir ν_{max}: 2970, 1710, 1580, 1088; ^{1}Hmr (200 MHz) δ: 1.28 (3H, s, C—CH_3), 1.30 (3H, s, C—CH_3), 3.01 (2H, m, $W/2$ = 6 Hz, C—CH_2—), 3.94 (4H, m, —OCH_2CH_2O—), 5.34 (1H, m, C—H vinylic), 5.49 (1H, m, C—H vinylic); ms *m/e*: 482 (M^+), 484 (M^+ + 2), 486 (M^+ + 4). *Mol. Wt.* calcd. for $C_{21}H_{24}O_3Br_2$: 484.0071 (^{79}Br + ^{81}Br); found (high resolution ms): 484.0055.

The deblocked derivative of **14** was obtained as colourless crystals, mp 145–148°C (ethyl acetate); uv λ_{max}: 244 nm (22 980); ir ν_{max}: 2965, 1710, 1660, 1568; ^{1}Hmr (200 MHz) δ: 1.25 (3H, s, C—CH_3), 1.37 (3H, s, C—CH_3), 5.77 (2H, m, C(4)—H and C(11)—H); ms *m/e*: 438 (M^+), 440 (M^+ + 2), 442 (M^+ + 4). *Mol. Wt.* calcd. for $C_{19}H_{20}O_2Br_2$: 439.9809 (^{79}Br + ^{81}Br); found (high resolution ms): 439.9807.

*Reduction of dibromo enone **14**. Saturated ketone **20***

To the dibromo enone (49.0 mg, 0.101 mmol) in glacial acetic acid (10 mL) was added an excess of freshly acid washed (5% HCl) zinc dust and the mixture was stirred at 20°C, in an argon atmosphere, for 1 h. The mixture was filtered over Celite, diluted with ether, and washed with a saturated $NaHCO_3$ solution, until neutral, and with brine. The organic layer was dried and evaporated *in vacuo*. Crystallization from ether yielded the saturated ketone (31.0 mg, 93%) as colourless crystals, mp 181–182.5°C; ir ν_{max}: 2975, 1730, 1085; ^{1}Hmr (200 MHz) δ: 1.03 (3H, s, C—CH_3), 1.24 (3H, s, C—CH_3), 3.97 (4H, m, —OCH_2CH_2O—), 5.51 (2H, m, C(6)—H and C(11)—H); ms *m/e*: 328 (M^+). *Mol. Wt.* calcd. for $C_{21}H_{28}O_3$: 328.2038; found (high resolution ms): 328.2038.

*Reduction of dibromo enone **14**. Enone **15***

The dibromo enone (150 mg, 0.306 mmol) was refluxed in absolute methanol, under argon, for 16 h with a large excess of zinc–silver couple prepared from Zn dust (3.15 g) and silver acetate (100 mg) according to Heathcock's method (28). The cooled reaction mixture was filtered over Celite, evaporated *in vacuo*, and chromatographed, eluting with hexanes – ethyl acetate (5:1). Crystallization from ether yielded the enone (88.0 mg, 87%) as colourless crystals, mp 143–145°C; uv λ_{max}: 224 nm (8160); ir ν_{max}: 2965, 1695, 1082; ^{1}Hmr (200 MHz) δ: 1.13 (3H, s, C—CH_3), 1.15 (3H, s, C—CH_3), 2.84 (2H, m, $W/2$ = 6 Hz, C—CH_3), 3.91 (4H, m, —OCH_2CH_2O—), 5.55 (2H, m, C(6)—H and C(11)—H), 6.14 (1H, dd, J = 5.9 and 1.6 Hz, C(16)—H), 7.46 (1H, dd, J = 5.9 and 2.0 Hz, C(15)—H); ms *m/e*: 326 (M^+). *Mol. Wt.* calcd. for $C_{21}H_{26}O_3$: 326.1882; found (high resolution ms): 326.1878.

The structure of **15** was further confirmed by its conversion to the diacetal **21** by refluxing in toluene with a large excess of ethylene glycol and a catalytic amount of *p*-toluenesulfonic acid for 20 h. Crystallization from ethyl acetate gave diacetal **21**, mp 164–166°C; ^{1}Hmr (200 MHz) δ: 0.99 (3H, s, C—CH_3), 1.20 (3H, s, C—CH_3), 3.89 (4H, m, —OCH_2CH_2O—), 5.23 (1H, m, C(15)—H), 5.41 (1H, m, C—H vinylic), 5.49 (1H, m, C—H vinylic).

Mild acid hydrolysis (5% HCl/THF) of **15** yielded the dione **22** as colourless crystals, mp 137–138°C; uv λ_{max}: 232.5 nm (16 000); ir ν_{max}: 2960, 1702, 1665; ^{1}Hmr (200 MHz) δ: 1.08 (3H, s, C—CH_3), 1.28 (3H, s, C—CH_3), 5.62 (1H, m, C(11)—H), 5.68 (1H, s, C(4)—H), 6.19 (1H, dd, J = 5.9 and 1.6 Hz, C(16)—H), 7.42 (1H,

dd, J = 5.9 and 2 Hz, C(15)—H); ms m/e: 282 (M^+). *Mol. Wt.* calcd. for $C_{19}H_{22}O_2$: 282.1620; found (high resolution ms): 282.1626.

Etude de la dissolution du bromure cuivreux formé sur le cuivre

ROBERT-LOUIS BROSSARD

Institut de recherche d'Hydro-Québec, C.P. 1000, 1800 Montée Ste-Julie, Varennes (Qué.), Canada J0L 2P0

Reçu le 19 octobre 1983

ROBERT-LOUIS BROSSARD. Can. J. Chem. **62**, 1112 (1984).

La dissolution du bromure cuivreux, formé par oxydation électrochimique du cuivre immergé en solution aqueuse de NaBr, a été étudiée. La concentration en NaBr a été variée de 0,1 *M* à 1,2 *M* alors que le pH était de 4. Le produit de corrosion accumulé sur l'électrode est constitué de cristaux de CuBr γ. La présence de ce composé contribue à l'enrichissement local de la solution en cuivre dissous près de l'électrode. Cet enrichissement se traduit par une tension d'électrode en circuit ouvert bien caractéristique. Elle est égale à environ −149 mV (ECS) sur une électrode en position stationnaire immergée dans une solution 0,2 *M* NaBr. La dissolution complète du CuBr coincide, pour sa part, à une chute rapide de la tension. Cette chute de tension a permis de définir le temps de transition τ à partir duquel la vitesse de dissolution du CuBr a été calculée. Par exemple, la vitesse de dissolution est de 0,074 ± 0,003 mA cm^{-2} en courant équivalent pour une électrode en position stationnaire en présence d'une solution 0,2 *M* NaBr non agitée. Elle est aussi constante jusqu'à la disparition complète du composé. Par ailleurs, l'utilisation de l'électrode à disque tournant a mis en évidence que la dissolution est entièrement dominée par la diffusion des ions en phase liquide. Les résultats expérimentaux sont compatibles avec la présence simultanée du $CuBr_2^-$ et du $CuBr_3^{2-}$ comme espèces diffusantes. Enfin, les courbes de polarisation potentiodynamiques montrent deux vagues d'oxydation. Une portion non négligeable du courant de dissolution, sinon la quasi-totalité, se traduit par la formation de CuBr sur l'électrode qui est le seul produit de corrosion présent.

ROBERT-LOUIS BROSSARD. Can. J. Chem. **62**, 1112 (1984).

The dissolution of cuprous bromide, formed by the electrochemical oxidation of copper immersed in aqueous NaBr, has been studied. NaBr concentration was varied between 0.1 and 1.2 *M* at pH 4. The corrosion product accumulating on the electrode is crystalline γ-CuBr. The presence of this material contributes to the local enrichment of dissolved copper close to the electrode. This enrichment leads to a characteristic electrode voltage in open circuit, which is about −149 mV (ECS) at a stationary electrode immersed in a solution of 0.2 *M* NaBr. The complete dissolution of CuBr coincides with a rapid fall in voltage which permits the definition of the transition time τ from which the speed of CuBr dissolution has been calculated. For example, the speed of dissolution is 0.074 ± 0.003 mA cm^{-2} in a current equivalent for a stationary electrode in the presence of a non-stirred solution of 0.2 *M* NaBr. This is constant until the complete disappearance of the CuBr. On the other hand, use of a rotating disc electrode demonstrates that the dissolution is entirely dominated by the diffusion of ions in the liquid phase. The experimental results are compatible with the simultaneous presence of $CuBr_2^-$ and $CuBr_3^{2-}$ as diffusing species. Finally, the potentiodynamic polarization curves show two oxidation waves. A non-negligible portion of the dissolution current, if not almost all, is associated with the formation of CuBr as the sole corrosion product on the electrode.

Introduction

La formation de bromure cuivreux sur le cuivre à l'abandon dans des solutions bromurées non désaérées a été observée (1 à 3). Dans les solutions désaérées de NaBr légèrement acides, le recouvrement de la surface par le CuBr γ coïncide avec la première vague d'oxydation observée sur les courbes *E* vs. *i* obtenues par balayage de la tension en mode linéaire (4). Cependant, la solubilité relative de ce composé dans les solutions qui contiennent des ions Br^- (5) contribue à le rendre plus ou moins stable en présence de ces solutions.

Le présent travail se propose d'approfondir l'étude de la dissolution du bromure cuivreux fraîchement formé durant l'oxydation du cuivre polarisé anodiquement. Les solutions contiennent entre 0,1 *M* et 1,2 *M* de NaBr.

Partie expérimentale

2.1 *La cellule et ses accessoires*

Les détails relatifs à la cellule et ses accessoires ainsi qu'aux électrodes de travail sont données dans un article précédent (6). L'électrode de cuivre se présentait sous la forme d'un fil de 0,064 cm de diamètre dont la surface était de ~0,4 cm^2, d'une plaque de 4 cm^2 ou d'un disque de 0,71 cm^2. Le fil et la plaque étaient en position verticale et immobile. Pour sa part, le disque était animé d'un mouvement de rotation et était en position horizontale.

2.2 *La préparation des essais*

Un barbottage d'azote de 6 h précédait l'immersion de l'électrode de cuivre dans la solution même si 0,5 h était suffisant. Les solutions contenaient entre 0,1 et 1,2 *M* de NaBr dissout. Un tampon à base de phtalate de potassium a été utilisé pour stabiliser le pH à 4.

La méthode employée par Shoesmith et Lee *et al.* (7, 8) a été retenue pour le polissage du cuivre; l'échantillon était poli mécaniquement par abrasion avec du papier au carbure de silicium pour se terminer par un polissage avec de l'alumine de 1 μm. L'échantillon était alors rinçé à l'alcool, à l'acétone puis à l'eau distillée avant son immersion.

2.3 *Les techniques expérimentales utilisées*

Les courbes tension–courant ont été obtenues en balayage linéaire de la tension. La vitesse de balayage généralement utilisé était de 12 mV s^{-1}. Un coulomètre servait à mesurer la quantité d'électricité qui traversait l'électrode durant l'oxydation et la réduction.

Par ailleurs, l'oxydation et la réduction ont été effectuées en l'absence de toute agitation sur une électrode de travail en position stationnaire. Le cas échéant, l'agitation était imposée par barbotage d'un gaz inerte ou par rotation de l'électrode durant les périodes en circuit ouvert seulement.

Enfin, l'approche expérimentale mise au point pour la mesure de la vitesse de dissolution du bromure cuivreux est décrite plus loin alors que les valeurs de la tension d'électrode sont données par rapport à l'électrode au calomel saturé, sauf indication contraire.

Résultats expérimentaux

3.1 *Apparition du bromure cuivreux*

Les enregistrements *E* vs. *i* reproduits à la figure 1 sont bien représentatifs du comportement de l'électrode de cuivre. La vitesse de balayage de la tension est de 12 mV s^{-1} alors que la solution non agitée contient 0,2 *M* de NaBr. Deux vagues d'oxydation et une vague de réduction bien définies sont obser-

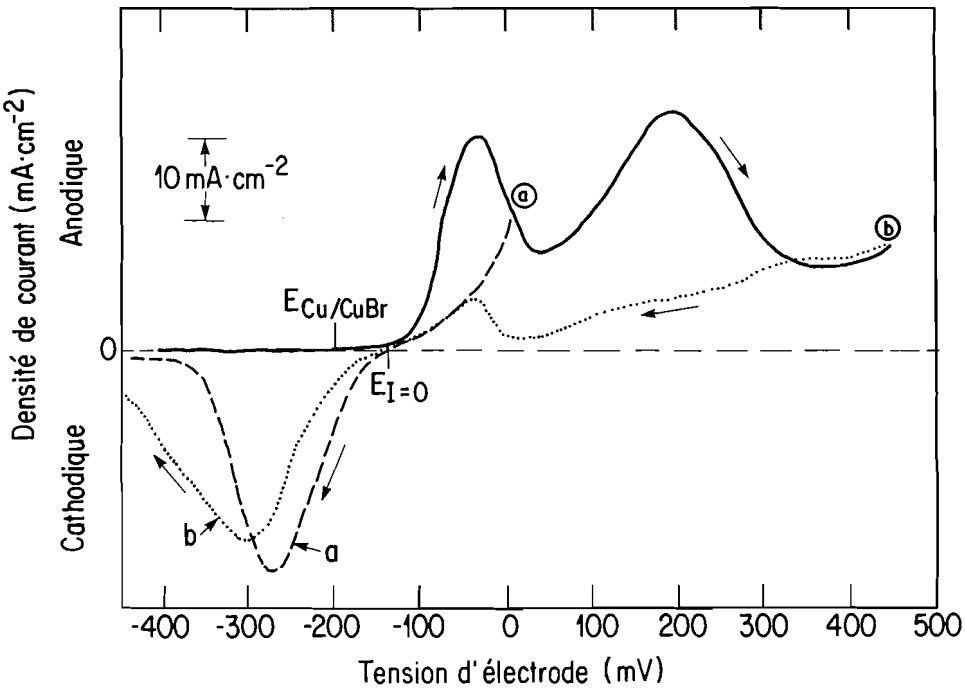

FIG. 1. Courbes de polarisation sur un fil de cuivre dans une solution 0,2 *M* NaBr. La solution est non agitée alors que dE/dt est égal à 12 mV s^{-1}. $E_{Cu/CuBr}$: tension réversible de la réaction Cu + Br^- = CuBr + é. $E_{I=0}$: tension à courant nul.

vées. Le sommet de la première vague d'oxydation a comme coordonnées −35 mV (E_{p1}) et 26 mA cm^{-2} (i_{p1}) alors que le sommet de la seconde coïncide avec +195 mV (E_{p2}) et 30 mA cm^{-2} (i_{p2}). Ainsi, les vagues d'oxydation sont anodiques par rapport à la tension réversible ($E_{Cu/CuBr}$) de la réaction:

[1] $Cu + Br^- = CuBr + e$

qui est donnée par (9, 10)

[2] $E_{Cu/CuBr} = -0{,}239 - 0{,}059 \log_{10} Br^-$

où $E_{Cu/CuBr}$ est en volt par rapport à l'électrode au calomel saturé.

Le CuBr γ fait son apparition sur la surface de l'électrode dans la région de la première vague d'oxydation (4).

Par ailleurs, le courant est légèrement plus élevé lors du balayage de retour entre ~340 mV et 450 mV. Ce comportement est attribué soit à l'oxydation partielle du bromure cuivreux, soit à sa redissolution partielle, soit à des variations dans sa morphologie ou les trois à la fois.

La vague cathodique, pour sa part, a un sommet qui est de 70 mV inférieur à la tension réversible $E_{Cu/CuBr}$. Dans l'exemple illustré à la figure 1, pour lequel la tension limite (E_L) est de 0 mV, les quantités d'électricité mises en jeu sont de 230 mC cm^{-2} du côté anodique (Q_{oxy}) et de 230 mC cm^{-2} du côté cathodique (Q_{red}). Il est alors raisonnable de penser que le CuBr, formé par oxydation anodique du cuivre, est complètement réduit. La réduction quasi complète de ce composé est confirmée par l'examen de la surface de l'électrode retirée après le retour du courant de réduction à une valeur négligeable.

Enfin, la vague de réduction devient visible sur les courbes *E* vs. *i* dès que E_L franchit le pied de la première vague d'oxydation (Fig. 2). Pour des valeurs croissantes de E_L, le profil de la vague de réduction demeure inchangé alors que Q_{red} tend à augmenter. On en déduit qu'il y a augmentation de la quantité de CuBr accumulé sur l'électode pour des valeurs croissantes de E_L.

3.2 *Passivation transitoire du cuivre*

Dans l'éventualité où le bromure cuivreux formé se dissout, dès le retour en circuit ouvert, il est envisageable qu'il y ait enrichissement local de la solution en cuivre dissous. Il est alors prévisible que la tension du cuivre traduise cet enrichissement local, si celui-ci est significatif.

La tension en circuit ouvert (E_{co}) du cuivre, en l'absence de précipité à sa surface, est représentée en fonction de la concentration en cuivre dissous à la fig. 3 alors que E_{co} du cuivre, en présence de précipité à sa surface, est donnée en fonction du temps à la fig. 4. E_{co} du cuivre en présence de précipité montre deux plateaux. Le premier plateau correspond à une tension voisine de −149 mV et est de 19 mV inférieur à la tension à courant nul ($E_{I=0}$) trouvée sur les courbes *E* vs. *i* (Fig. 2). La tension du premier plateau, −149 mV, coïncide avec une concentration en cuivre dissous de $0{,}53 \times 10^{-3}$ *M* d'après la figure 3 alors que la saturation en cuivre dissous est de $1{,}4 \times 10^{-3}$ *M*. Il est ainsi raisonnable de considérer qu'il y a enrichissement de la solution en cuivre dissous près de l'électrode lorsque celle-ci est recouverte de précipité.

Près du temps de transition τ, une chute rapide de la tension est observée et un deuxième plateau, compris entre −232 mV et −236 mV, est atteint. La tension du deuxième plateau dépend de la concentration en cuivre dissous au coeur de la solution. Quant au temps de transition τ, il est défini en suivant la même procédure que Shoesmith et Lee (8) pour l'étude de films d'oxydes du cuivre métastables.

L'examen de la surface au microscope à balayage a mis en évidence la disparition graduelle du produit de corrosion entre $t = 0$ et $t = \tau$ (Fig. 5a, 5b, 5c) alors que sa présence est marginale à partir de τ (Fig. 5d, 5e).

La dissolution du précipité doit aussi se traduire par un enrichissement de la solution en cuivre dissous jusqu'au temps de transition τ. La détermination de la concentration en cuivre

a été obtenue à l'aide de la spectroscopie par absorption atomique entre $t = 0$ et $t = \tau$. Ce qui a permis de confirmer l'enrichissement de la solution en cuivre dissous entre $t = 0$ et $t = \tau$.

3.3 *Mesure de la quantité de bromure cuivreux présent sur le cuivre*

La surface de cuivre, complètement à nue au départ, subissait une oxydation électrochimique par enclenchement d'une tension de −300 mV suivi d'un balayage linéaire de la tension. La vitesse de balayage était de 12 mV s^{-1} alors que l'oxydation était arrêtée à 0 mV. Immédiatement après l'arrêt de l'oxydation, une tension de réduction constante et égale à −300 mV était imposée à l'électrode. Les charges électriques mises en jeu durant l'oxydation (Q_{oxy}) et la réduction (Q_{red})$_{t=0}$ étaient mesurées. Plus précisément, (Q_{red})$_{t=0}$ représente la quantité d'électricité obtenue par réduction complète du CuBr immédiatement après formation de ce composé.

La réduction du bromure cuivreux, réalisée dans ces conditions, est complétée après une demi-minute environ; le courant de réduction devient alors négligeable. La réduction complète de ce composé a été confirmée à partir de l'examen de la

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

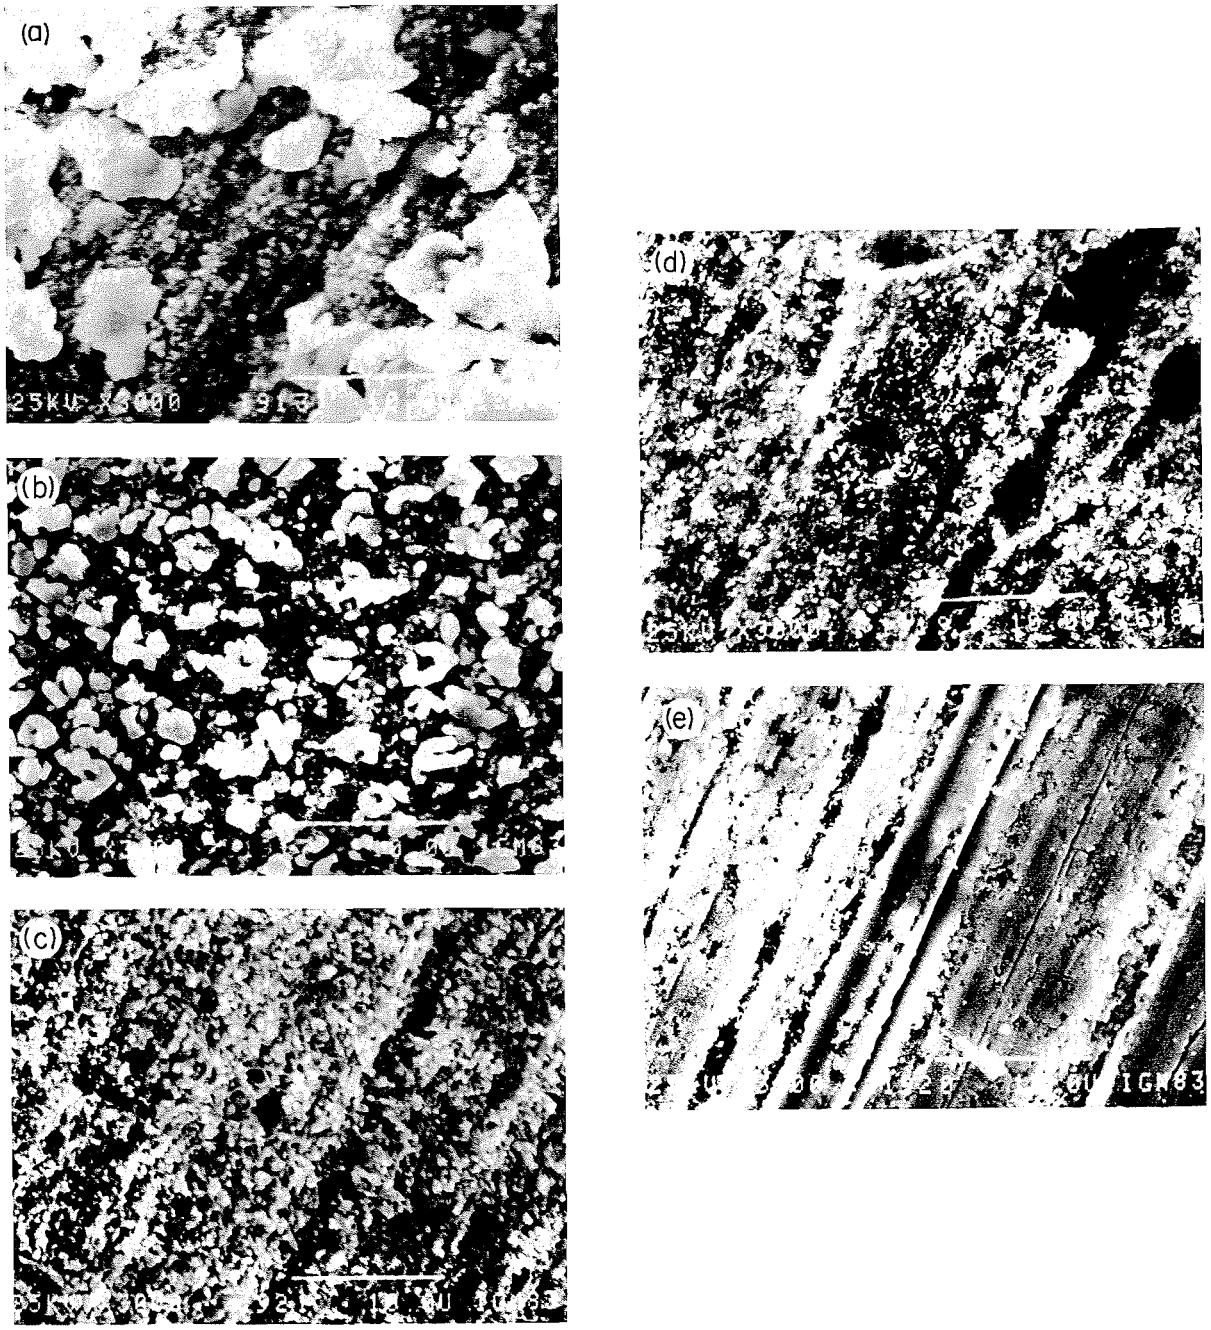

FIG. 5. Aspect de la surface de l'électrode durant la dissolution du CuBr. Les conditions d'oxydation sont celles de la fig. 4. NaBr = 0,2 *M*, solution non agitée. L'électrode est un fil de cuivre. Les durées en circuit ouvert sont: (a) 0,5 τ; (b) 0,88 τ; (c) 0,98 τ; (d) 1,01 τ; (e) 1,06 τ.

surface au microscope et de la mesure de la tension en circuit ouvert. Le comportement du bromure cuivreux soumis à une réduction rappelle celui du $Cu(OH)_2$ en solution alcaline (8).

Par ailleurs, la charge de réduction $(Q_{red})_{t=0}$ dépend de la charge en oxydation (Q_{oxy}) alors que le rapport $(Q_{red})_{t=0}/Q_{oxy}$ est constant lorsque les conditions d'oxydation sont identiques et ce, malgré les variations importantes de Q_{oxy} (Fig. 6) qui ont été observées. Dans l'exemple choisi ici, les charges Q_{oxy} et $(Q_{red})_{t=0}$ ont été mesurées pour plusieurs cycles successifs oxydation–réduction dans une solution non agitée de 0,2 *M* NaBr. Le rapport $(Q_{red})_{t=0}/Q_{oxy}$ demeure voisin de 0,98 alors que Q_{oxy} est compris entre 75,2 mC cm^{-2} et 137,8 mC cm^{-2}. Ce rapport tend à diminuer lorsque l'électrode est en position horizontale. La perte, qui correspond à la différence entre Q_{oxy} et $(Q_{red})_{t=0}$ est attribuée à la non précipitation du cuivre qui va en solution, à la dissolution partielle du précipité et, enfin, au fait que des cristaux de bromure cuivreux sont capables de n'être pas retenus à la surface de l'électrode.

La constance du rapport $(Q_{red})_{t=0}/Q_{oxy}$ permet de déduire la quantité de précipité présent en terme de charge $(Q_{red})_{t=0}$ à partir de la valeur de Q_{oxy}. Le rapport $(Q_{red})_{t=0}/Q_{oxy}$ varie un peu d'un échantillon à l'autre même si les conditions expérimentales sont les mêmes. Par conséquent, ce rapport a été déterminé pour chaque échantillon et la quantité de précipité présent sur le cuivre, dès le retour de l'électrode en circuit ouvert, a été calculée à partir de Q_{oxy}.

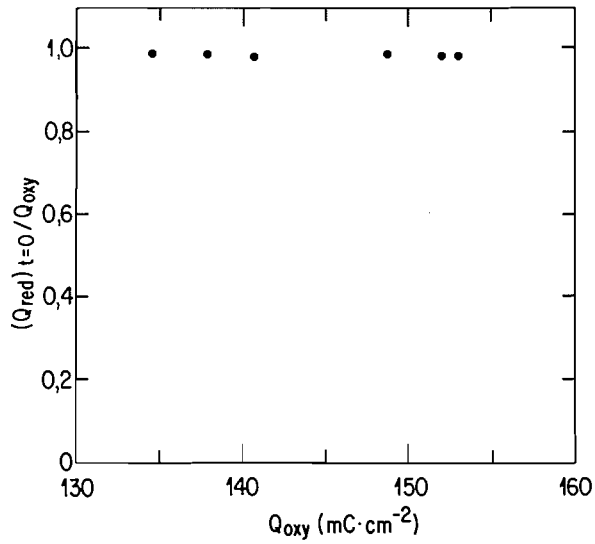

FIG. 6. Rapport $(Q_{red})_{t=0}/Q_{oxy}$ en fonction de Q_{oxy}. Q_{oxy}: quantité d'électricité mesurée durant l'oxydation. $(Q_{red})_{t=0}$: quantité d'électricité mesurée par réduction complète du CuBr immédiatement après oxydation. Condition d'oxydation: balayage en tension de −300 mV à 0 mV avec 12 mV s^{-1}. Condition de réduction: −300 mV durant 2 min. Solution 0,2 *M* NaBr, non agitée. L'électrode est un fil de cuivre.

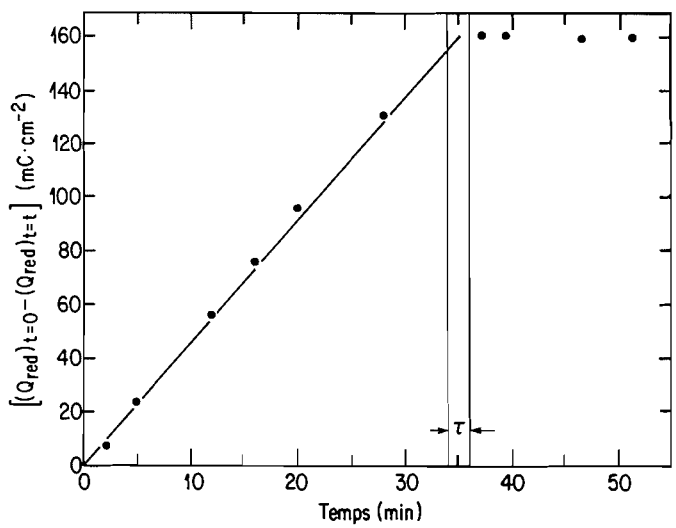

FIG. 7. Quantité de précipité qui passe en solution durant la période en circuit ouvert. $(Q_{red})_{t=t}$: quantité d'électricité obtenue par réduction du précipité après le temps *t*. $(Q_{red})_{t=0} - (Q_{red})_{t=t}$: quantité d'électricité équivalente en précipité qui va en solution durant le temps *t*. Les autres conditions expérimentales sont celles de la fig. 6.

3.4 *Vitesse de dissolution du bromure cuivreux sur une électrode immobile*

On a vue, d'une part, que la quantité de bromure cuivreux présent à la surface de l'échantillon est déterminable et que, d'autre part, la dissolution du CuBr en circuit ouvert s'achève complètement au temps de transition τ. De plus, il y a enrichissement de la solution en cuivre entre $t = 0$ et $t = \tau$.

La réduction du précipité après des durées variables de séjour en circuit ouvert (Fig. 7) a mis en évidence que la vitesse de dissolution (v) du CuBr est constante. La différence entre $(Q_{red})_{t=0}$ et $(Q_{red})_{t=t}$ est associée à la perte de bromure cuivreux durant le temps *t* où l'électrode est en circuit ouvert alors que

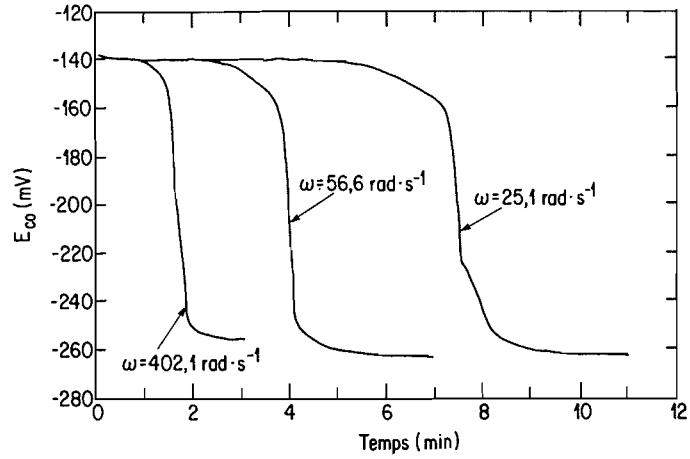

FIG. 8. Influence de la vitesse de rotation de l'électrode sur la tension en circuit ouvert. ω: vitesse de rotation. NaBr = 0,2 *M*. L'électrode est un disque qui tourne. Conditions d'oxydation: Balayage en tension de −300 mV à 0 mV avec 12 mV s^{-1}.

v est calculable à partir de la pente de la droite obtenue.

Pour une solution 0,2 *M* NaBr non agitée, *v* est de 0,077 mA cm^{-2}. De plus, l'ordonnée à l'origine de la relation $[(Q_{red})_{t=0} - (Q_{red})_{t=t}]$ en fonction du temps passe par zéro alors que la perte en CuBr cesse au temps τ où la dissolution de ce composé est complète.

La constance de *v* entre $t = 0$ et $t = \tau$ autorise donc le calcul de *v* à partir du rapport $(Q_{red})_{t=0}/\tau$. Cette approche a donné *v* égal à 0,071 mA cm^{-2} en courant équivalent pour 0,2 *M* NaBr (Fig. 4).

Enfin, la vitesse de dissolution est intimement liée à l'agitation de la solution réalisée à l'aide d'un barbottage d'un gaz inerte, par exemple. L'utilisation d'une électrode à disque tournant en cuivre a permis de fixer les conditions d'agitation et d'établir que la vitesse de dissolution est contrôlée par la diffusion en phase liquide.

3.5 *Vitesse de dissolution du CuBr sur une électrode tournante*

Les enregistrements de la tension en circuit ouvert en fonction du temps, reproduits à la figure 8, confirment que la vitesse de dissolution est étroitement liée à l'intensité de l'agitation. La valeur de *v*, calculée à partir de la variation transitoire de la tension en circuit ouvert, est donnée en fonction de la racine carrée de la vitesse de rotation de l'électrode (Fig. 9) pour ω compris entre 25 et 509 rad s^{-1} alors que la solution contient 0,2 *M* en NaBr dissous.

La linéarité de la relation *v* vs. $\omega^{1/2}$ avec une ordonnée à l'origine qui passe par zéro est la signature d'un processus de dissolution entièrement contrôlé par la diffusion dans la phase liquide (11).

Dans le cas de la figure 9, l'équation est:

[3] $\quad v = 0{,}074\ \omega^{1/2}$

où *v* est exprimé en mC cm^{-2} s^{-1} et ω en rad s^{-1}. La pente, 0,074, est en mC cm^{-2} s$^{-1/2}$.

3.6 *Influence de la concentration en ions bromures*

Pour une électrode immobile, on observe que l'allure des courbes E_{co} vs. temps est inchangée entre 0,08 *M* et 0,8 *M* en NaBr dissous (Fig. 10). Cependant, E_{co} se déplace vers des valeurs plus positives alors que le temps de transition augmente considérablement lorsque la concentration va de 0,8 *M* à 0,08 *M* en NaBr dissous.

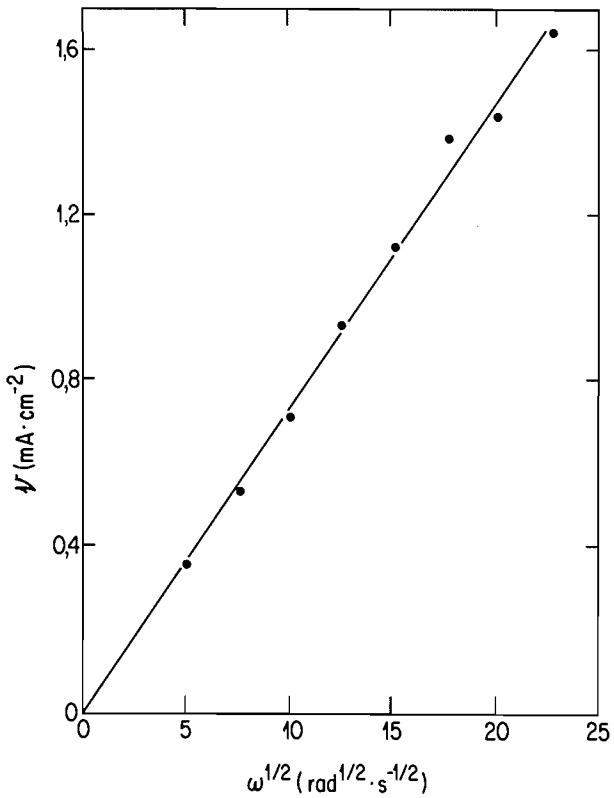

FIG. 9. Vitesse de dissolution en fonction de $\omega^{1/2}$ dans une solution 0,2 *M* NaBr. ν: vitesse de dissolution du CuBr en densité de courant équivalent. Les valeurs de ν sont déduites des courbes de la fig. 8 obtenues sur une électrode qui tourne.

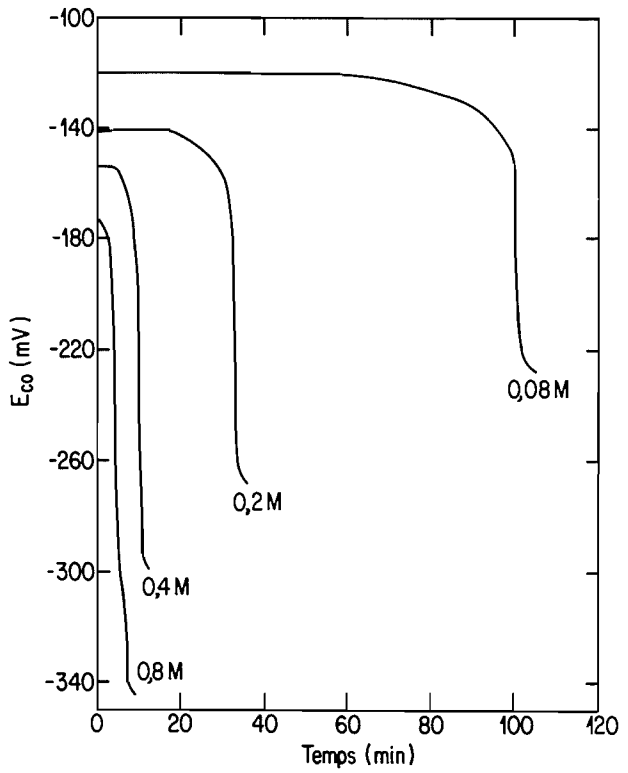

FIG. 10. Influence de la concentration en ions Br^- sur la tension en circuit ouvert. L'électrode est un fil de cuivre immobile et la solution est non agitée. Les échantillons ont été oxydés de telle sorte que $(Q_{red})_{t=0}$ soit de 130 ± 6 mC cm^{-2}.

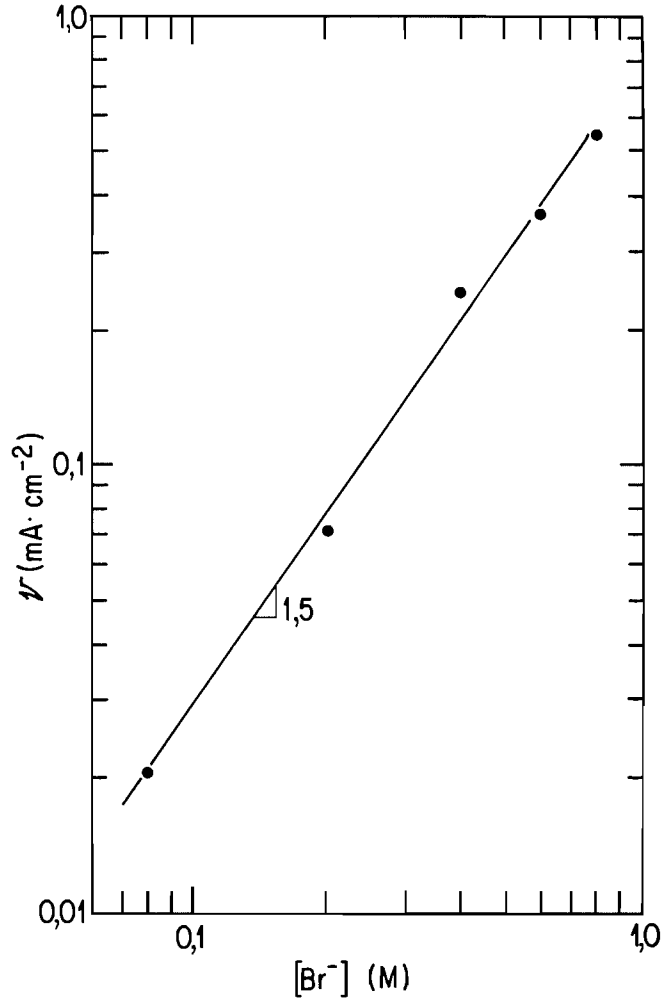

FIG. 11. Influence de la concentration en ions bromures sur la vitesse de dissolution du CuBr. Les valeurs de ν sont déduites des courbes E_{co} vs. temps de la fig. 10.

La valeur de ν, déterminée à partir des relations E_{co} vs. temps montrées à la figure 10, est donnée en fonction de la concentration en ions Br^- à la fig. 11. Ainsi, l'ordre de la réaction par rapport aux ions Br^- est de 1,5.

3.7 *Quantité de bromure cuivreux accumulée durant l'oxydation anodique du cuivre*

Rappelons que Q_{red}, qui correspond à la vague de réduction sur les courbes E vs. i (Fig. 2), tend à augmenter pour des valeurs croissantes de E_L. Pour leurs parts, les enregistrements E_{co} vs. temps, obtenus après oxydation électrochimique dans une solution 0,2 *M* NaBr sont reproduits à la figure 12 pour différentes valeurs de E_L. L'oxydation électrochimique a été réalisée dans les conditions expérimentales données à la fig. 2.

Les relations E_{co} vs. temps sont caractéristiques de la dissolution du bromure cuivreux dès que E_L est égal ou supérieur à −80 mV, environ. Par ailleurs, une augmentation considérable du temps de transition est observée avec un accroissement de E_L entre −80 mV et +450 mV. Les valeurs de τ sont données en fonction de E_L à la fig. 13 alors que les tensions E_{p1} et E_{p2} sont aussi indiquées. La quantité de CuBr a été déterminée en charge équivalente (Q_{CuBr}) à partir du produit de la vitesse de dissolution, qui est voisine de 0,071 mA cm^{-2} (Fig. 2), par le temps de transition.

La relation Q_{CuBr} vs. tension indique que l'accumulation du

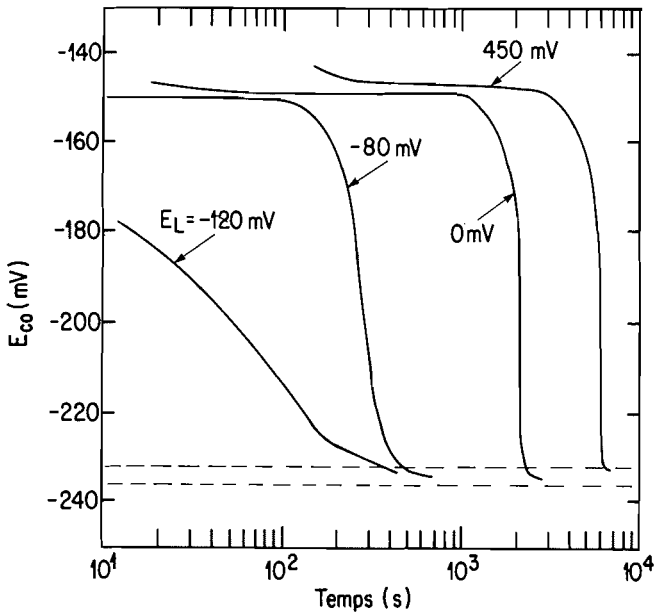

FIG. 12. Courbes E_{co} vs. temps pour différentes valeurs de la tension limite. Conditions de polarisation: Balayage en tension de −450 mV à la tension voulue (tension limite) à la vitesse de 12 mV s^{-1}. Solution: 0,2 *M* NaBr, non agitée. L'électrode est un fil de cuivre immobile.

produit de corrosion commence dans la partie ascendante de la première vague d'oxydation pour se poursuivre avec une tension croissante. Ainsi, Q_{CuBr} est de 95 mC cm^{-2} à E_{p1} comparée à 350 mC cm^{-2} à E_{p2} lorsque dE/dt est égal à 12 mV s^{-1} pour une solution 0,2 *M* NaBr.

Discussion

4.1 *Dissolution du bromure cuivreux*

La relation v vs. $\omega^{1/2}$ (Fig. 9) suggère que la diffusion d'une espèce ionique en solution est l'étape lente de la dissolution du bromure cuivreux (11). Par ailleurs, la formation d'intermédiaires comme le $CuBr_2^-$ (4) et le $CuBr_3^{2-}$ (5) est envisageable dans la gamme de concentration considérée dans le présent travail. Dans ce cas, les étapes les plus probables sont

[4] $\quad CuBr + XBr^- = (CuBr_{1+x}^{x-})_i$ étape rapide

qui est suivie de

[5] $\quad (CuBr_{1+x}^{x-})_i \rightarrow (CuBr_{1+x}^{x-})_s$ étape lente

les indices i et s indiquent la concentration à la surface de l'électrode et au sein de la solution, respectivement. La deuxième étape, qui est l'étape lente, correspond à la diffusion du $(CuBr_{1+x}^{x-})$ depuis la surface jusqu'au sein de la solution. La première étape, qui est une réaction globale, représente la formation du complexe $CuBr_2^-$ lorsque $X = 1$, du complexe $CuBr_3^{2-}$ lorsque $X = 2$ ou un mélange des deux espèces lorsque $1 < X < 2$.

L'étape lente est la diffusion des ions $(CuBr_{1+x}^{x-})_i$ et la vitesse de la réaction formée par les étapes [4] et [5] est donnée par la première loi de Fick, dont la forme simplifiée est:

$$[6] \quad v = XFD \frac{[(CuBr_{1+x}^{x-})_i - (CuBr_{1+x}^{x-})_s]}{\delta}$$

où v est la vitesse de la réaction en courant équivalent.

Lorsque $(CuBr_{1+x}^{x-})_i \gg (CuBr_{1+x}^{x-})_s$ la relation [6] devient:

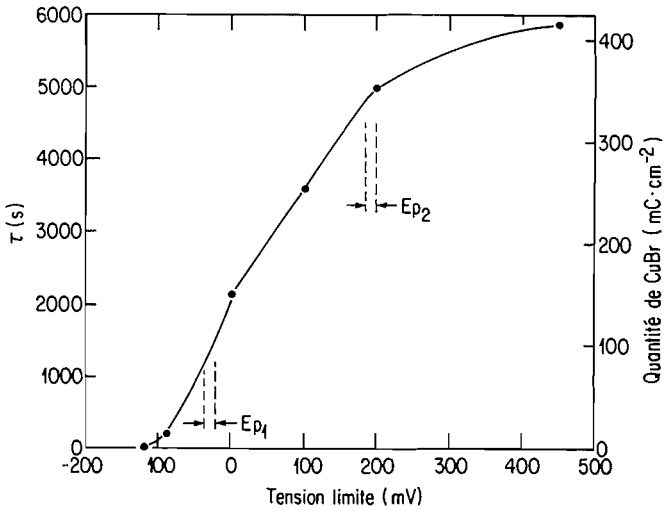

FIG. 13. Temps de transition et quantité de bromure cuivreux accumulé sur le fil de cuivre en fonction de la tension limite. Les conditions expérimentales sont celles de la fig. 12.

$$[7] \quad v = XFD \frac{(CuBr_{1+x}^{x-})_i}{\delta}$$

Pour sa part, l'utilisation de l'électrode à disque tournant permet d'écrire l'équation de Levich (11):

$$[8] \quad \delta = 1{,}61\, D_{CuBr_{1+x}^{x-}}^{1/3} \nu^{1/6} \omega^{-1/2}$$

La substitution de δ dans la relation [7] donne:

$$[9] \quad v = 0{,}62\, XF\nu^{-1/6} D_{CuBr_{1+x}^{x-}}^{2/3} \omega^{1/2} (CuBr_{1+x}^{x-})_i$$

où X, la charge de ou des espèces qui diffusent, est comprise entre 1 et 2; ν, la viscosité cinématique, est voisine de $0{,}96 \times 10^{-2}$ cm^2 s^{-1} (12); $D_{CuBr_{1+x}^{x-}}$ est le coefficient de diffusion de l'espèce $CuBr_2^-$, $CuBr_3^{2-}$ ou des deux espèces à la fois, selon la valeur de X; $(CuBr_{1+x}^{x-})_i$ est la concentration en cuivre à la surface de l'électrode alors que ω est la vitesse de rotation de l'électrode en radians par seconde.

Par ailleurs, la première étape, qui est l'étape rapide, permet d'envisager cette réaction dans un état voisin de l'équilibre, ce qui conduit à écrire:

$$[10] \quad K_e = \frac{(CuBr_{1+x}^{x-})_i}{(Br^-)^x}$$

où K_e est la constante d'équilibre de la réaction [4].

Les relations [9] et [10] permettent d'écrire:

$$[11] \quad v = 0{,}62\, XF\nu^{-1/6} D_{CuBr_{1+x}^{x-}}^{2/3} \omega^{1/2} K_e (Br^-)^x$$

D'après la figure 11, X est égal à 1,5. Pour sa part, le coefficient de diffusion est calculable à partir de l'expression [9] à la condition de connaître la relation expérimentale v vs. $\omega^{1/2}$ ainsi que la concentration en cuivre dissous au voisinage de l'électrode. Dans l'exemple montré à la fig. 8, E_{co} est égal à −140 mV durant la dissolution du CuBr, ce qui permet de déduire une concentration de $0{,}7 \times 10^{-3}$ *M* en cuivre dissous (Fig. 3). La valeur expérimentale de la pente $dv/d\omega^{1/2}$ est de 0,074 mC cm^{-2} $s^{-1/2}$ $rad^{-1/2}$ (Fig. 9). Ces valeurs conduisent à un coefficient de diffusion égal à $1{,}26 \times 10^{-5}$ cm^2 s^{-1}, ce qui est en harmonie avec la valeur de $1{,}4 \times 10^{-5}$ cm^2 s^{-1} trouvée précédemment (4).

Le fait que X soit égal à 1,5 (Fig. 11) tend à confirmer la formation concomittante des intermédiaires $CuBr_2^-$ et $CuBr_3^{2-}$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

en quantités égales. Comme nous venons de le voir, la présence de ces intermédiaires comme espèces ioniques qui diffusent permet d'expliquer l'ensemble des résultats expérimentaux de façon cohérente.

Enfin, d'après la relation [10], la valeur de $(CuBr_{1+x}^{x-})_i$ est déterminée par l'équilibre de la réaction [4]. Il est alors prévisible que la vitesse de dissolution du bromure cuivreux soit indépendante de la quantité de CuBr présent sur le cuivre jusqu'à sa dissolution complète; ce qui est confirmé expérimentalement (Fig. 7).

4.2 *Accumulation du bromure cuivreux*

Les enregistrements E_{co} vs. temps (Fig. 12), obtenus après oxydation électrochimique pour différentes valeurs de E_L, suggèrent que le seul produit de corrosion qui s'accumule sur l'électrode est le bromure cuivreux dans la région de la première et de la deuxième vague d'oxydation.

Par ailleurs, le courant équivalent pour l'accumulation du CuBr sur l'électrode (dQ_{CuBr}/dt) est calculable à partir du produit de (dQ_{CuBr}/dE) (Fig. 13) par la vitesse de balayage imposée, dE/dt. Le courant équivalent ainsi trouvé est de 12,3 mA cm^{-2} entre 0 et 200 mV (Fig. 13). Pour sa part, le courant de dissolution est en moyenne de 18,7 mA cm^{-2} entre 0 mV et 200 mV (Fig. 1). On en déduit qu'une fraction non négligeable du courant de dissolution résulte en la formation de bromure cuivreux sur l'électrode dans la zone de la deuxième vague d'oxydation.

Conclusion

1. La présence de bromure cuivreux sur la surface du cuivre, suite à l'oxydation électrochimique de ce métal, contribue à l'enrichissement de la solution en cuivre dissous en contact avec l'électrode de cuivre. Cet enrichissement se traduit par une tension d'électrode bien caractéristique qui tombe dès la dissolution complète de ce composé.

2. La vitesse de dissolution du CuBr est constante jusque dans les instants qui précèdent sa dissolution complète.

3. La dissolution du bromure cuivreux est entièrement dominée par la diffusion d'une ou de plusieurs espèces ioniques qui se déplacent depuis l'électrode jusqu'au coeur de la solution. Les résultats expérimentaux s'expliquent entièrement à partir de la présence simultanée des espèces $CuBr_2^-$ et $CuBr_3^{2-}$ comme espèces ioniques qui diffusent.

4. Dans la région des vagues d'oxydation le seul produit de corrosion qui s'accumule sur l'électrode est le bromure cuivreux. La quantité d'électricité impliquée dans la région de la première vague se traduit presqu'entièrement par la formation de CuBr à la surface de cuivre alors que la formation de ce composé explique une part importante du courant de dissolution dans la région de la deuxième vague.

Open chain intermediates from the ring-opening reaction of aqueous sodium deuteroxide (2 mol) with 2-chloro-5-nitropyridine (1 mol) and 2-chloro-3-nitropyridine (1 mol) were isolated. These intermediates were purified, analyzed for elemental composition, and characterized by various spectrophotometric techniques. The intermediate formed from 2-chloro-5-nitropyridine and two equivalents of deuteroxide ion reacts with additional deuteroxide in D_2O in various polar solvents to reclose the pyridine ring. The kinetics of the ring closure reaction are reported and are supplemented with observations of salt and solvent effects upon the rate of closure. In addition, a mechanism for the ring closure is presented. The intermediate formed from 2-chloro-3-nitropyridine did not undergo a similar ring closure when reacted with additional deuteroxide, but instead formed various decomposition products. A reason for the failure of this ring closure is suggested.

JOHN D. REINHEIMER, NICOLAS SOURBATIS, ROBERT L. LAVALLEE, DOUGLAS GOODWIN et GEORGE L. GOULD. Can. J. Chem. **62**, 1120 (1984).

On a isolé des intermédiaires à chaîne ouverte formés lors de réactions d'ouverture de cycle, sous l'influence du deutéroxyde de sodium (2 mol), de la chloro-2 nitro-5 pyridine (1 mol) ou de la chloro-2 nitro-3 pyridine (1 mol). On a purifié ces intermédiaires, on en a fait l'analyse élémentaire et on les a caractérisés en faisant appel à diverses techniques spectrophotométriques. L'intermédiaire formé à partir de la chloro-2 nitro-5 pyridine et de deux équivalents d'ion deutéroxyde réagit avec le deutéroxyde dans du D_2O et dans divers solvants polaires pour reformer le cycle de la pyridine. On rapporte la cinétique de la réaction de fermeture de cycle et on fournit comme complément l'observation des effets du sel et du solvant sur la vitesse de fermeture de cycle. De plus, on propose un mécanisme pour cette réaction. L'intermédiaire formé à partir de la chloro-2 nitro-3 pyridine ne subit pas de fermeture de cycle lorsqu'on le fait réagir avec du deutéroxyde additionel; il se forme plutôt plusieurs produits de décomposition. On propose une explication pour l'absence de fermeture de cycle.

Introduction

Nucleophilic attack on heterocyclic rings is well known (1–4). Subsequent reactions may yield ring-opened products (2–4) or the ring may open and close again (ANRORC mechanism) (1). Reinheimer *et al.* (5) found a ring-opening reaction with deuteroxide ion and 2-halo-5-nitropyridine in DMSO-d_6/D_2O solvent which yielded a stable intermediate *in situ*.

The intermediate was not isolated, but was characterized by its ^{13}C and ^1H nmr spectra. When additional NaOD in D_2O was added, the pyridine ring was again formed to yield the salt of 2-hydroxy-5-nitropyridine. We report further information on the isolation of this intermediate and on the cyclization reaction. A similar reaction of the isomer, 2-chloro-3-nitropyridine, with NaOD in D_2O yielded a stable intermediate. This material was also isolated as a solid, but its reaction with additional NaOD in D_2O did not result in cyclization. We report additional information on this reaction.

Experimental

All ^1H nmr spectra were taken on a Varian T-60 instrument with a probe temperature of 38°C. Carbon-13 nmr spectra were taken on a CFT-20 or JEOL FXQ 90 instrument at ambient temperatures. Infrared spectra were taken on a Perkin–Elmer 283B using Nujol mulls or KBr pellets. Raman spectra were obtained on a Beckman Raman spectrophotometer (model 700). All elemental analyses were done by Galbraith Laboratories Inc., Knoxville, Tennessee.

Preparation of the intermediates, 1 and 2

The open chain intermediates are polyfunctional sodium salts. Their water solubility and potential reactivity required the use of mild techniques to remove solvents and impurities. Charcoal treatment removed polymeric and colored impurities; the intermediate **1** was dissolved in acetone and passed through a silica gel column to remove salts; freeze-drying or rotary evaporation at room temperature was used to remove solvents.

1: Purified 2-chloro-5-nitropyridine (5) (Aldrich) (9.00 g) was dissolved in a solvent mixture of 85 mL of DMF, 50 mL of dioxane, and 40 mL of water at room temperature. Next, 40 mL of 2.79 *M* NaOH was added with stirring. Most of the solvent was quickly removed via rotary evaporation over gentle steam, and the mixture was filtered to remove insoluble materials. The filtrate was lyophylized and the solid was dissolved in water. This water solution was filtered through activated decolorizing carbon to yield a yellow solution which was subsequently lyophilized. The yellow solid was dissolved in acetone and passed through a 15 × 2.5 cm silica gel column (silica gel, 60–200 mesh Matheson, Coleman, and Bell) to remove salts. The eluent was placed on a rotary evaporator and concentrated to approximately 30 mL. The solution was then lyophilized to yield a light colored solid in a red oil. This material was dissolved in water and filtered through decolorizing carbon until a golden yellow solution was obtained. Again, this solution was lyophilized to yield a bright yellow solid. Filtration through charcoal and solvent evaporation were repeated until ^1H nmr showed no organic solvent impurities.

The ^{13}C and ^1H nmr spectra of the solid **1** were identical with those reported previously (5); mp 158–160°C (dec.). *Anal.* calcd. for $C_5H_3N_2O_3Na \cdot 1/2\ H_2O$: C 35.21, H 2.34, N 16.28; found: C 35.41, H 2.28, N 16.33.

2: 2-Chloro-3-nitropyridine (2.73 g) was placed in a round bottom flask with 30 mL of water. Sodium hydroxide, 15 mL of 2.33 *M*, was added to the stirred reaction mixture, which was kept at 55–60°C for 1 h. The dark colored reaction mixture was cooled, filtered, and lyophilized. It was then dissolved in water, filtered through decolorizing carbon, and recrystallized from H_2O/NaCl to give a yellow solid; ir ν_{max} (cm^{-1}) (Nujol): 2200 (C≡N), 1600 (HC=O); ^{13}C nmr (D_2O): 109.6, 116.7, 119.8, 146.2, 191.8; ^1H nmr (D_2O) δ: 9.3 (1H, d), 8.9 (1H, d), 5.1 (1H, pair of doublets). *Anal.* calcd. for $C_5H_3N_2O_3Na$: C 37.06, H 1.87, N 17.78; found: C 37.17, H 1.95, N 17.69.

Kinetics for the ring closure of 1 (prepared in situ*)*

A stock solution of 2-chloro-5-nitropyridine (0.408 *M*) was prepared in a solvent of composition ratio 9:1 (DMSO-d_6/D_2O) by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

volume. The intermediate, **1**, was prepared by pipetting 0.500 mL of the stock solution and 0.100 mL of NaOD (4.08 *M*) into a 5-mm nmr tube. Then NaOD (4.08 *M*) and D_2O were pipetted into the nmr tube to give the desired deuteroxide concentration at constant solvent composition, namely, 0.45 mL of DMSO-d_6 + 0.25 mL of D_2O. The ^1H nmr integral trace of the aldehyde peak was observed vs. time. A plot of ln (integral trace) vs. time yielded a first-order plot and k_ψ. The second-order rate constant (k_2) was calculated from eq. [1], for the deuteroxide concentration did not change during a given kinetic run.

$$[1] \quad k_\psi = k_2[OD^-]$$

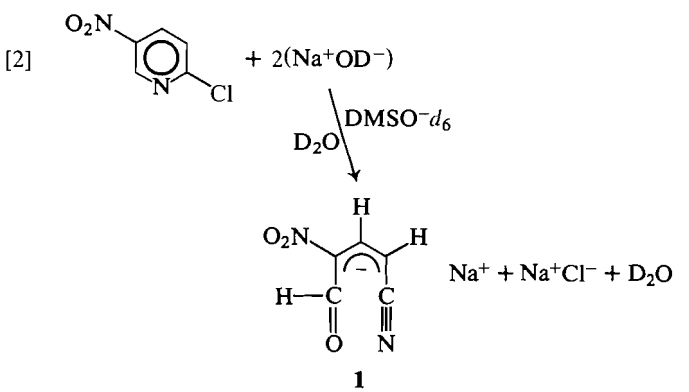
The data of Table 1 demonstrate that the reaction rate was also first order in deuteroxide ion.

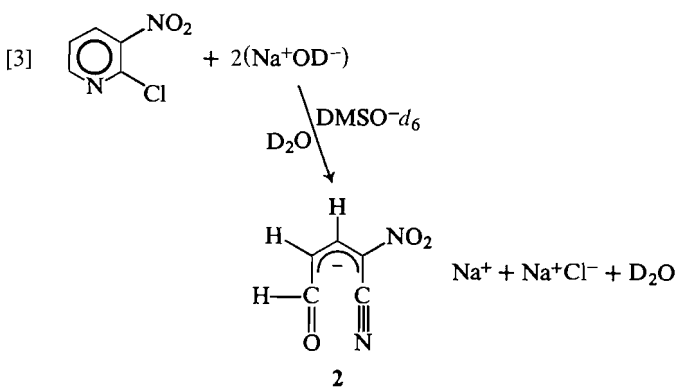
Kinetic procedure with solid 1

The isolated intermediate **1** was weighed and dissolved in D_2O. This solution was diluted to volume with the appropriate solvent, DMSO-d_6, THF, dioxane, methanol, or acetone. A 0.500-mL aliquot was pipetted into a 5-mm nmr tube, and an aliquot of NaOD (4.08 *M*) solution was added. The reaction rate was observed and calculated in the manner given above.

Discussion

The reactions of 2-chloro-5-nitropyridine with deuteroxide ion in DMSO/D_2O solvent to yield ring-opened intermediates are given in eqs. [2] and [3]. Both **1** and **2** can be kept as stable products in solution, and they may also be isolated as analyzable solids.



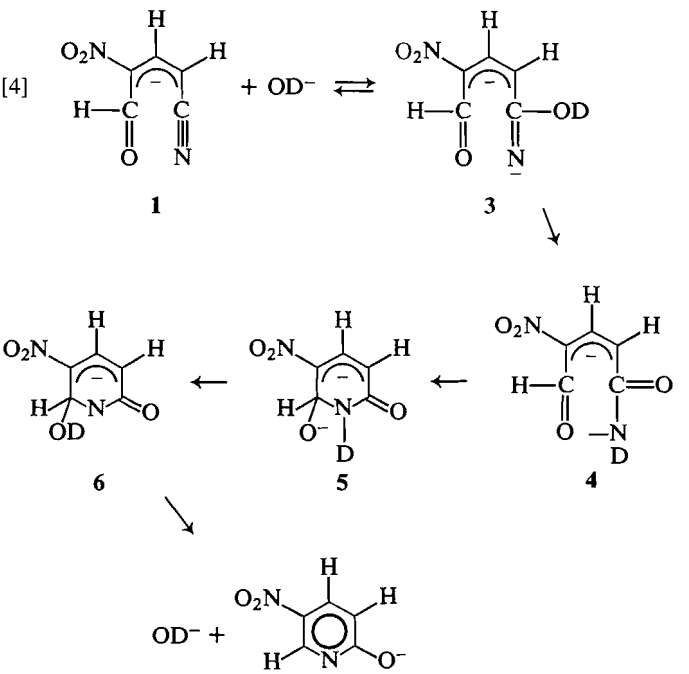


When **1** (prepared *in situ*) was treated with aqueous NaOD, it reacted to close the ring and form the Na^+ salt of 2-hydroxy-5-nitropyridine. The kinetics of this ring closure reaction showed that the reaction was first order in hydroxide ion and first order in 2-chloro-5-nitropyridine. If the rate-determining step of eq. [4] is **1** → **3**, then the rate equation would be eq. [5].

TABLE 1. Rate constants for the reaction of **1** with OD^- in DMSO-d_6/D_2O[a,c]

Compound **1** (mol/L)	$[OD^-]$ (mol/L)	$k_\psi \times 10^{-3}$ (s^{-1})[b]	$k_2 \times 10^{-3}$ (L/mols)
0.291[d]	0.145	0.324	2.23±0.2
0.291[d]	0.291	0.672	2.31±0.2
0.291[d]	0.582	1.34	2.30±0.2
0.31[e]	0.62	1.33	2.15±0.2
0.31[f]	0.62	0.90	1.45±0.2

[a]Temperature was 38°C.
[b]k_ψ was the average of 3 kinetic runs.
[c]Solvent composition was 0.45 mL DMSO-d_6 to 0.25 mL D_2O.
[d]Compound **1** prepared in solution.
[e]Solid **1** with NaCl (0.31 *M*).
[f]Solid **1** with no NaCl added.



$$[5] \quad \frac{d\mathbf{1}}{dt} = k_2[OD^-][\mathbf{1}]$$

Since deuteroxide ion is regenerated, its concentration will be unchanged in a given experiment. Thus, eq. [6] holds true. In Table 1, the values k_ψ and k_2 are calculated from eq. [6]. A

$$[6] \quad \frac{-d\mathbf{1}}{dt} = k_\psi dt, \text{ where } k_\psi = k_2[OD^-]$$

second line of evidence that lends support to eq. [4] is the effect of salt on the reaction rate. In Table 1, the first 3 rows give k_ψ and k_2 for the intermediate which was prepared in solution containing equimolar NaCl (eq. [1]). In rows 4 and 5, the dissolved solid intermediate and the dissolved solid intermediate with added equimolar NaCl were the reagents. The added NaCl caused an increase in rate constant (k_2), from 1.45 to 2.15 × 10^{-3}, which was beyond experimental error. This positive salt effect may be attributed to the reaction of negative ion on a negative ion (6), deuteroxide ion on **1** as required by eq. [3]. The experimental rate constant for the solid **1** duplicated the rate constant for **1** prepared *in situ* only if the correct amount of by-product NaCl was added.

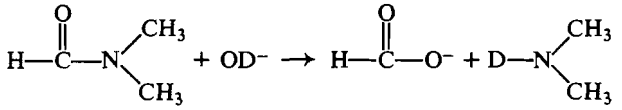
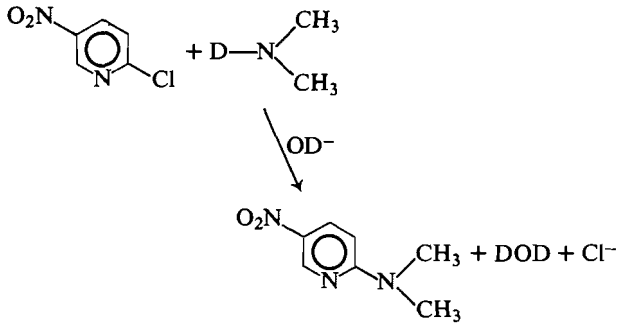
Why does changing $[Na^+Cl^-]$ have a large effect and changing $[Na^+OH^-]$ have little or no salt effect on k_2?. The data of Reinheimer and Hostetler (7) showed that rate constants for an aromatic nucleophilic substitution by hydroxide ion in dioxane/water show little change with increasing $[M^+OH^-]$, where $M^+ = Li^+$, Na^+, and K^+. However, when M^+ was tetrabutylammonium ion, the rate constants showed a very large salt effect with increasing concentration of ionic reagent. Applying this to the present system, the changing sodium deuteroxide concentration would have little effect on the rate constant. On the other hand, Na^+Cl^- does not form intimate ion pairs readily in aqueous solution, and will exert a considerable salt effect. We made no quantitative salt effect calculations, since Benson (6) has indicated that these quantitative theories are questionable in concentrated salt solutions.

The effect of cosolvents on the reaction rate constant of **1** and NaOD was also studied. Some D_2O was required to ensure solubility of the NaOD, and an inert organic solvent was needed to dissolve the reagent. Dioxane, tetrahydrofuran, dimethylsulfoxide, acetonitrile, acetone, and methanol were used as cosolvents. Acetonitrile and water tended to separate into layers, while acetone, **1**, and OD^- showed ^1H nmr lines that indicated a competing condensation reaction as well as ring closure. The remaining cosolvents, DMSO-d_6, dioxane, tetrahydrofuran, and methanol showed the same general trend, namely, that the reaction rate constant for ring closure increased with increasing water content, as seen in Table 2. This qualitative result is compatible with eq. [4], for the attack of a negative ion on a negative ion is favored by the more polar solvent (8). The hydrolysis of DMF in aqueous base provided a competing reaction. In the ring-closure reaction this hydrolysis caused complication, so that DMF was not a suitable solvent for ring closure. However, this hydrolysis could be used to advantage in the isolation of the ring-opened intermediate. The reaction of eq. [2] was very rapid, and the ring-closure reaction (eq. [4]) was much slower. DMF performed two functions, that of dissolving the organic reagent and that of preventing an excess of OD^-. The equation [6] indicates that the hydrolysis and substitution reactions have the requirement



[6]



of 2 mol OD^- for 1 mol of 2-chloro-5-nitropyridine, so that there was no extra OD^- to initiate ring closure. Removal of the solvent, DMF, was easier than removal of DMSO and the yellow solid, 2-methylamino-5-nitropyridine, crystallized readily. The dimethylamino compound was removed from the ionic intermediate **1** by a methylene chloride extraction or by filtration, and identified by its known melting point and ^1H nmr spectrum.

TABLE 2. Solvent effects on the rate constant for the ring closure of **1**[a]

Solvent[b]	$k_2 \times 10^3$ (L/mol s)	No. of experiments
64% DMSO[c]	2.15	1
64% DMSO	1.50	2
50% DMSO	3.31	7
37% DMSO	10.20	2
100% D_2O	57.00	2
60% Dioxane	3.0	2
45% Dioxane	4.0	2
36% THF	6.9	2
55% Methanol	3.7	2

[a]Temperature was 38°C.
[b]The cosolvent was D_2O.
[c]An amount of NaCl equivalent to **1** was added.

The intermediate can be advantageously prepared and isolated from DMF, for the slower ring-closure reaction permits the hydrolysis reaction of DMF with hydroxide ion to dominate, thus preventing a local excess of hydroxide ion and the competing of the ring closure reaction.

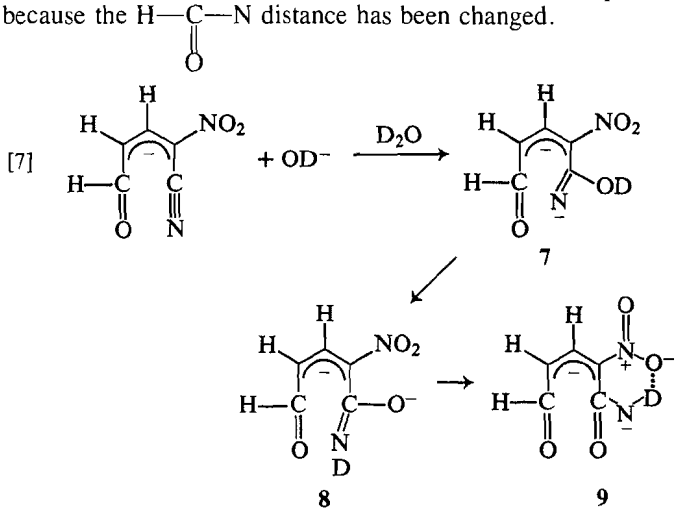
The reaction of **2** with deuteroxide was quite different from **1**. The ^1H nmr spectrum of the reaction mixture gradually changed, not to the known spectrum of 2-hydroxy-3-nitropyridine, but to a singlet, $\delta = 8.3$. The change was slow in DMSO-d_6/D_2O solvent; a week was required to complete the reaction. The same singlet could be obtained in a few minutes by treating the aqueous solution with basic H_2O_2 at about 50°C. A solid was obtained by freeze-drying this reaction mixture. This showed a singlet in the ^{13}C nmr when noise decoupled, and a doublet when undecoupled. It was identified as sodium formate; this was confirmed by ^1H nmr comparisons with an authentic sample and by preparation of a *p*-bromophenacyl derivative. In a separate week-long experiment, the amount of sodium formate was measured by addition of sodium acetate to an nmr sample. The integral trace for this reaction mixture indicated that 1 mol of formate resulted from the H_2O_2 oxidation of **2**. The source of the formate was probably due to the base-induced cleavage of the aldehyde functional group, for the aldehyde hydrogen is not readily exchanged in basic solution. Other possible sources of formate seem to be less likely due to their formation in the solvent D_2O. The hydrolysis of CN^-, CNO^- would result in deuterated molecules which would not be observable in a ^1H nmr spectrum. In addition to the formate, another decomposition product identified from the reaction mixture with basic H_2O_2 was sodium isocyanate.[1] The iso-

[1]Treatment of **2** with basic H_2O_2 in water, a quick isolation of the yellow solid product by freeze-drying, immediately followed by a laser Raman spectrum, showed one line, 2180 cm^{-1} and some fluorescence. Three days later, this line has disappeared. This line did not correspond to ionic NaCN which absorbs at 2070–2090 cm^{-1} (9). Since the absorptions for formate are very weak in the Raman spectrum (10), we concluded that formate was not the cause of the line at 2180 cm^{-1}. We suspected sodium isocyanate and confirmed this by mixing a sample of KOCN and NaOH and lyophilizing. This sample showed two peaks, 2165 cm^{-1} and 2180 cm^{-1}. A ^1H nmr of this solid showed no peaks at $\delta = 8.3$. Our pure KOCN sample yielded one Raman peak at 2165 cm^{-1}. Therefore we feel that sodium isocyanate is a decomposition product of the reaction of **2** with basic H_2O_2, and in all probability a decomposition product of the reaction of **2** with hydroxide ion in DMSO-d_6.

cyanate was probably formed due to cleavage of the nitrile group of **2**. This is consistent with the mechanism presented in eq. [4] which shows the initial attack of deuteroxide ion on the nitrile group of **1**, except that in the case of the attack of **2**, the close proximity of the nitro group may lead to stabilization of the resulting carbanion if the DOCN leaves.

The drastic change in the course of the reaction of **1**, compared to **2**, with deuteroxide was surprising in view of the slight structural difference of **1** and **2**. The extensive resonance delocalization should tend towards planar structures, with the NO_2 group coplanar with the pentadienide moiety. The major difference, σ- vs. ρ-nitro group with respect to the C≡N or HC=O group, seems to be responsible for the changed reactivity. If the rate-determining step is attack on C≡N by deuteroxide for both **1** and **2**, the attack on **2** may be very slow, so that other reactions can compete.

A second possibility is that the deuteroxide ion attacks the C≡N group of **2**, but that cyclization cannot be completed because the H—C—N distance has been changed.



If **8** and **9** are the dominant conformers in solution, cyclization would not occur, for the aldehyde–nitrogen distance becomes larger. In **9**, H-bonding of the (HN--ONO) should enhance stability of **9**. In **8**, the repulsion of the *ortho* NO_2 and C=O would cause a slight rotation about the C—C bond between the carbon #2 (HN—C=O) and carbon #3 (C—NO_2). This rotation would result in a larger separation between N—H and the aldehyde group; this should effectively hinder cyclization. The electron-withdrawing effect of the *o*-nitro group may promote cleavage of the OCN^- moiety through stabilization of the resultant carbanion, thus permanently preventing cyclization. In either case, the specific effect of the NO_2 group may be responsible for blocking cyclization of **2**. If cyclization is very slow, other reactions of **2** become successful competitors.

The epr spectrum of a persistent sulfur nitride radical cation, common to the oxidation of many sulfur–nitrogen compounds, has been obtained from materials highly enriched in both ^{15}N and ^{33}S. Analyses of solution and frozen spectra show that the carrier is planar $S_3N_2^+$ and that its ground state is $^2A_2$ in C_{2v} symmetry.

SHIRLEY A. FAIRHURST, KEITH F. PRESTON et LESLIE H. SUTCLIFFE. Can. J. Chem. **62**, 1124 (1984).

Un radical libre persistant, produit par l'oxydation de divers composés d'azote et de soufre, a été préparé à partir de matériaux enrichis en ^{15}N et ^{33}S. Les analyses de spectres RPE enregistrés en phase solide et liquide démontrent que le radical est $S_3N_2^+$, une molécule planaire à l'état fondamental $^2A_2$ avec symmetrie C_{2v}.

Introduction

A common product of the reaction of sulfuric acid with a number of cyclic sulfur–nitrogen compounds is a persistent free radical having an isotropic g-value of 2.011 and equal isotropic hyperfine interactions of 3.2 G with two ^{14}N ($I = 1$) nuclei (1–3). While there is a consensus of opinion regarding the presence of two spatially equivalent nitrogen atoms and a single positive charge in the carrier, its identity remains in doubt. Following measurements of the g- and ^{14}N-hyperfine interaction tensor components from a powder spectrum, McNeil, Murray, and Symons (2) rejected the original assignment (1) to SN_2^+ in favour of a symmetric (D_{2h}) radical cation $S_2N_2^+$ in which the semioccupied orbital (SOMO) consisted of roughly equal in-plane atomic p-orbital contributions from all four atoms. ^{33}S-labelling experiments (3), which demonstrated the presence of two equivalent spin-bearing sulfur atoms in the free radical, supported this assignment.

In more recent developments, Gillespie and co-workers (4, 5) showed that the same persistent isotropic spectrum arose upon dissolution of diamagnetic $S_6N_4^{2+}$ $(AsF_6^-)_2$ in methylene chloride; the carrier was also detected (6) in solid hexasulfur tetranitrogen dichloride, $S_6N_4Cl_2$, and in solutions of that compound in liquid SO_2. Crystallographic studies (4–6) of these $S_6N_4^{2+}$ salts indicate the presence of loosely bound pairs of $S_3N_2^+$ ions that have a cyclic, planar (C_{2v}) structure. Interestingly, the radical is also generated in high yield (7) during an unusual reaction between tetrahydrofuran and dithionitronium hexafluoroarsenate, S_2NAsF_6 (8).

In this article we report spectroscopic measurements made for liquid and frozen D_2SO_4 solutions of S_4N_4/S_4N_2 mixtures labelled with both ^{15}N ($I = 1/2$) and ^{33}S ($I = 3/2$). The spectra clearly show the presence of two equivalent nitrogens, two equivalent sulfurs and a third, unique sulfur in the free radical. Our data support the contention of Gillespie *et al.* (4, 5) that the spectrum is due to $S_3N_2^+$, a planar π-radical in which unpaired spin density is largely confined to p orbitals located on the nitrogen nuclei and the two equivalent sulfur nuclei.

[1]NRCC No. 23099.

[2]NRCC Research Associate 1981–1983. Present address: Department of Inorganic, Physical and Industrial Chemistry, Liverpool University, Liverpool L69 3BX, U.K.

Experimental

Free-radical spectra were generated by adding a 98% D_2SO_4 solution (>99.5 atom% D) to a small amount of a mixture of S_4N_4 and S_4N_2 contained in an evacuated 1 mm id epr tube. The sulfur nitride mixture enriched to 99 atom% in ^{15}N and to 59.2 atom% in ^{33}S was prepared according to the published procedure of Apter *et al.* (9). Deuterated sulfuric acid was employed to minimize interference from a secondary, proton-containing free radical reported by other workers (3). $^{15}NH_4Cl$ enriched to 99% in ^{15}N and used to prepare $^{15}NH_3$ was obtained from Prochem Ltd., Summit, NJ; elemental sulfur (59.2 atom% ^{33}S) was supplied by Oak Ridge National Laboratories, TN, and D_2SO_4 was obtained from the Aldrich Chemical Co., Milwaukee, WI.

Electron paramagnetic resonance spectra were recorded at 20°C and −196°C on a Varian E-12 spectrometer equipped with standard accessories for the measurement of microwave frequency and magnetic field intensity.

Results

The epr spectra observed at 20°C and −196°C for a D_2SO_4 solution of S_4N_4/S_4N_2 enriched to 99% in ^{15}N are shown in Figs. 1 and 2*a*, respectively. The liquid-phase spectrum (Fig. 1) is clearly due to equal hyperfine interactions (hfi = 4.5 G) of a single unpaired electron with two ^{15}N ($I = 1/2$) nuclei. At high gain, weak satellite absorptions were detectable outside the main spectrum. These were undoubtedly due to hyperfine interaction (8.8 G) with one or more ^{33}S nuclei ($I = 3/2$) present in natural abundance in the free radical. An experiment with sulfur nitride enriched to 59.2% in ^{33}S and to 99% in ^{15}N confirmed the participation of two equal ^{33}S isotropic hyperfine interactions of 8.8 G, and revealed the presence of a third sulfur having a 3 G isotropic hfi. The experimental and simulated liquid-phase spectra of the doubly enriched species are compared in Fig. 3. Resolution of the hyperfine structure in the experimental spectrum (Fig. 3*a*) deteriorates rapidly in the wings, an effect often encountered in ^{33}S spectra and attributable to anisotropy of the ^{33}S-hyperfine tensors (10).

Analysis of the powder spectrum of Fig. 2*a* in terms of colinear g- and ^{15}N-hyperfine tensors was straightforward, and the best simulated spectrum (11) is shown in Fig. 2*b*. The introduction of three additional ^{33}S-hyperfine interaction tensors and the mixture of ^{33}S-containing and ^{33}S-free radicals complicated the powder spectrum of the 59% ^{33}S, 99% ^{15}N sample considerably (Fig. 4). A complete analysis of this spec-

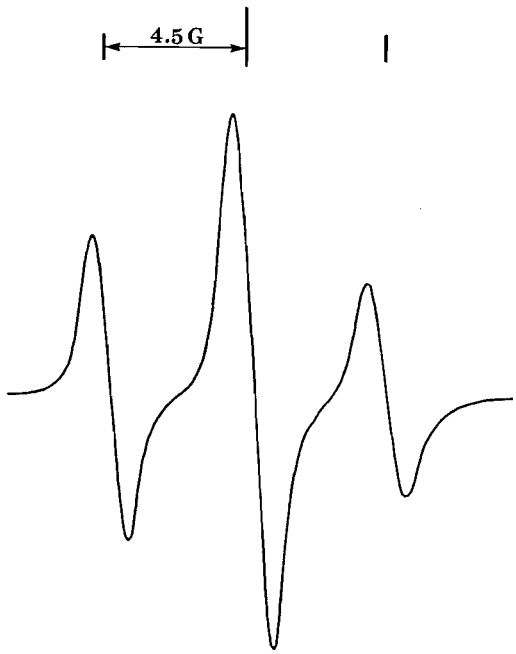

FIG. 1. First derivative epr spectrum at 20°C of D_2SO_4 solution of S_4N_4/S_4N_2 enriched to 99% in ^{15}N.

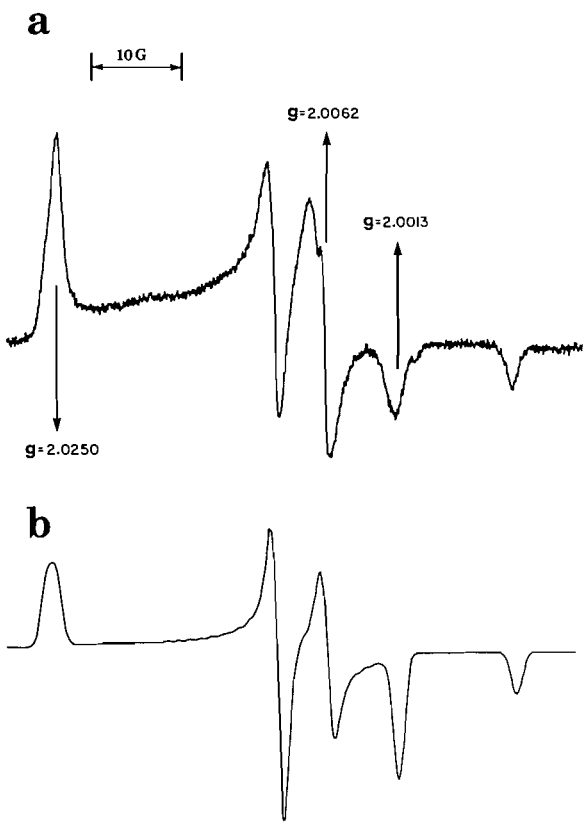

FIG. 2. (*a*) Experimental epr spectrum at −196°C of same sample used for Fig. 1. (*b*) Computer simulated powder spectrum using *g*- and ^{15}N-tensors of Table 1.

trum was not achieved. Tentative values for the components of the ^{33}S hfi tensors are given in Table 1 along with the *g*- and ^{15}N hfi tensors. We hope to achieve an exact analysis when elemental sulfur of higher enrichment in ^{33}S becomes available.

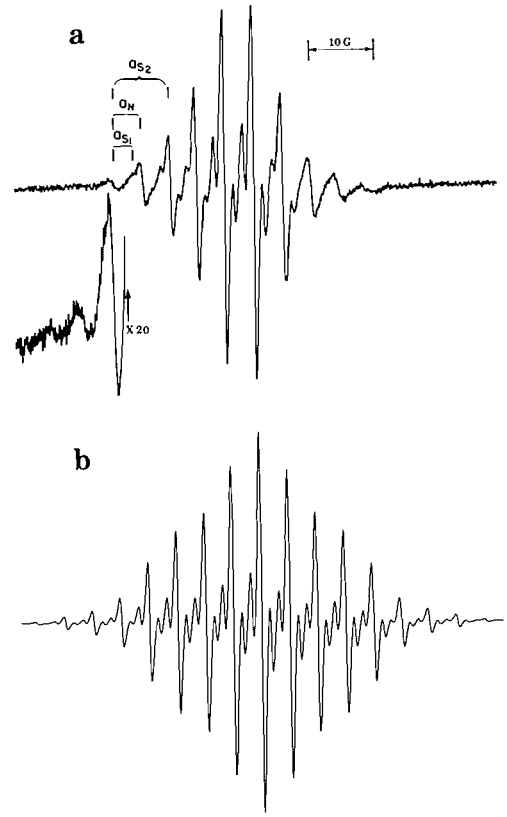

FIG. 3. Experimental (*a*) and simulated (*b*) epr spectra at 20°C of a D_2SO_4 solution of S_4N_4/S_4N_2 enriched to 99% in ^{15}N and to 59% in ^{33}S.

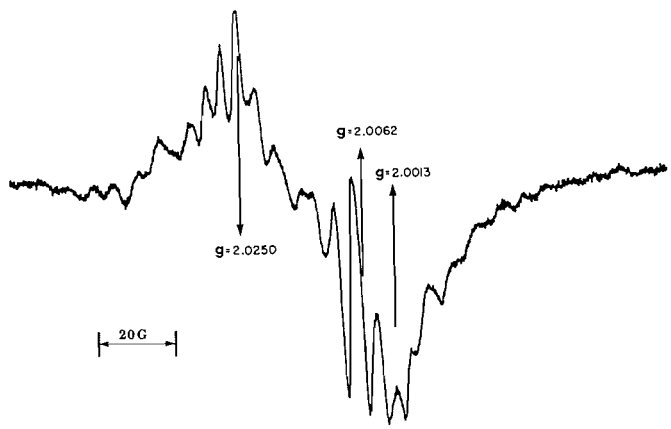

FIG. 4. Powder spectrum of the sample of Fig. 3 obtained at −196°C.

Discussion

Our solution spectra confirm the previous finding (1−3) that the free radical contains a pair of equivalent nitrogen nuclei and a pair of equivalent sulfur nuclei. In addition, we have demonstrated the presence of a unique sulfur nucleus which bears unpaired spin. Taken in conjunction with Gillespie's results (4, 5), these facts leave little doubt that the carrier of the spectrum is $S_3N_2^+$.

The powder spectra of Figs. 2 and 4 strongly suggest that all six tensors are colinear. Simulations of the spectrum of Fig. 2*a* showed that the direction of minimum g departed no more than 5° from the directions of maximum ^{15}N hfi. The situation is less

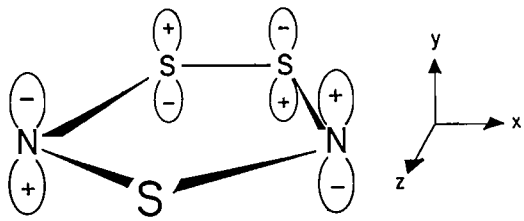
[a]Values in Gauss.
[b]INDO I spin densities in parentheses.

clear for the ^{33}S hfis, but the spectrum of Fig. 4 certainly suggests that they are parallel to the other tensors. This inference and the exceedingly small atomic s-orbital unpaired spin (12) populations (Table 1) lead us to conclude that $S_3N_2^+$ is a π-radical in which unpaired spin density is confined to atomic p_y orbitals directed perpendicular to the molecular (xz) plane:



Extended Hückel MO calculations for a planar C_{2v} structure place the unpaired electron in an a_2 orbital to which the equivalent N($2p_y$) orbitals contribute 30% and the equivalent S($3p_y$) orbitals 70% spin density. The small spin densities detected in the unique sulfur $3p_y$ and in the atomic s orbitals are due to spin polarization. INDO I calculations for the lowest-energy planar configuration of $S_3N_2^+$ predict considerable negative spin density in the unique sulfur $3p_y$ orbital, but the computed unpaired spin densities are not in good agreement with experiment (Table 1).

Acknowledgments

Received October 31, 1983

ROMOLO FAGGIANI, HELEN ELAINE HOWARD-LOCK, COLIN JAMES LYNE LOCK, MARIA LURDES MARTINS, and PHILIP STUART SMALLEY. Can. J. Chem. **62**, 1127 (1984).

The compound dipotassium 3,3,3′,3′-tetramethylcystinate trihydrate, $K_2[C_{10}H_{18}O_4N_2S_2]3H_2O$, has been prepared and characterized by single crystal X-ray diffraction. Crystals were monoclinic, $P2_1$, a = 6.160(1), b = 26.473(8), c = 6.193(1) Å, β = 113.94(1)°, with two formula units in the unit cell. Intensities were measured on a Syntex $P2_1$ diffractometer with use of MoKα radiation. The structure was solved by standard methods and refined to R_1 = 0.0469, R_2 = 0.0472 based on 2303 independent observed reflections. The C—S bonds (1.877(6), 1.891(6) Å) are longer than in many similar compounds although the S—S bond (2.040(2) Å) is not. The C—S—S—C torsional angle (108.7(3)°) is larger than normal in dithiol compounds. Other distances and angles are normal. Two types of potassium coordination are present, one a distorted octahedron, the other a distorted trigonal prism. In addition to the ionic interactions, hydrogen bonds involving the water molecules are important in stabilizing the structure.

ROMOLO FAGGIANI, HELEN ELAINE HOWARD-LOCK, COLIN JAMES LYNE LOCK, MARIA LURDES MARTINS et PHILIP STUART SMALLEY. Can. J. Chem. **62**, 1127 (1984).

On a préparé le trihydrate du tétraméthyl-3,3,3′,3′ cystinate de potassium, $K_2[C_{10}H_{18}O_4N_2S_2]3H_2O$ et on l'a caractérisé par diffraction de rayons-X sur un monocristal. Les cristaux sont monocliniques et appartiennent au groupe d'espace $P2_1$ avec a = 6,160(1), b = 26,473(8), c = 6,193(1) Å, β = 113,94(1)° avec deux unités par maille élémentaire. On a mesuré les intensités à l'aide d'un diffractomètre syntex $P2_1$ en utilisant une radiation MoKα. On a résolu la structure par des méthodes normales et on l'a affinée jusqu'à des valeurs de R_1 = 0,0469 et de R_2 = 0,0472 à partir de 2303 réflexions observées. Les liaisons C—S (1,877(6), 1,891(6) Å) sont plus longues que celles de plusieurs composés analogues bien que la liaison S—S ne le soit pas. L'angle de torsion C—S—S—C (108,7(3)°) est plus grand que ceux observés normalement dans les dithiols. Les autres distances et les autres angles sont normaux. Le potassium possède deux types de coordination, l'un est un octaèdre déformé tandis que l'autre est un prisme trigonal déformé. En plus des interactions ioniques, les liaisons hydrogènes impliquant les molécules d'eau sont importantes pour de la stabilité de la structure.

Introduction

D-Penicillamine is used in the treatment of a large number of diseases (1), of which the best known is Wilson's disease (2). Surprisingly, for a compound so widely used as a drug, it has not been well characterized by physical chemical methods. We have been interested in the use of D-penicillamine as a treatment for rheumatoid arthritis (3) and as a ligand in preparing radiopharmaceuticals (4), and have made extensive physical chemical studies of the compound (5). Studies have shown that metabolites of D-penicillamine excreted in the urine include the disulphide containing compounds 3,3-dimethylcystine and 3,3,3′,3′-tetramethylcystine, which are formed by oxidation and exchange reactions (6, 7). The former metabolite is important in the D-penicillamine treatment of cystinuria since the mixed disulphide is much more soluble than cystine and is thus more readily excreted from the body (6, 7). We have obtained the potassium salt of the latter compound, 3,3,3′,3′-tetramethylcystine, accidentally. As part of our studies on D-penicillamine we attempted to isolate the D-penicillaminate anion. Instead we obtained the title compound which results from the aerial oxidation of the D-penicillaminate anion.

Experiments

Dipotassium 3,3,3′,3′-tetramethyl-D-cystinate trihydrate

D-(−)-Penicillamine (0.7920 g) was dissolved in 1.0 *M* aqueous KOH (5.30 mL), allowed to stand in air for 24 h, and then evaporated to dryness under vacuum. A white solid with very pale purple colour was obtained. The product was recrystallized by slow evaporation in air from H_2O. Large colourless crystals were obtained. The mp was 196°C, at which the crystals turned black and decomposed. A 5,5′-dithiobis(2-nitrobenzoic acid) test for sulphydryl groups was negative (8).

Spectral measurement

Solutions for nmr studies were prepared in D_2O and concentrations were about 100 mg (solid) mL^{-1} of solvent. External TMS was used as the reference. Proton nmr spectra were recorded on a Varian T60 Spectrometer.

Infrared spectra were recorded on both a Nicolet 7199FT-IR and a Perkin-Elmer Model 283 spectrophotometer. The samples were ground with KBr at a concentration of approximately 1% by weight and then pressed into pellets. To confirm that certain peaks were real and not manifestations of the pelleting procedure, the spectra of certain samples were also run in Nujol and again in hexachlorobutadiene. Spectra were calibrated with polystyrene. Raman spectra were excited by means of the 5145 Å radiation from a Spectra-Physics model 164-02 Argon ion laser and recorded on a Spex 14018 double monochromator. Solid samples were contained in glass melting point tubes, and solutions in nmr tubes. The spectrometer was calibrated regularly with a neon lamp; the wavelength readout scale was found not to change (±1 cm^{-1}). Vibrational spectra have been obtained for the following compounds: (*1*) dipotassium 3,3,3′,3′-tetramethyl-D-cystinate trihydrate, (*2*) D-(−)-penicillamine disulphide in H_2O, solutions at several pH values, and (*3*) D-(−)-penicillamine disulphide in D_2O solution.

Collection of the X-ray diffraction data

A plate-like single crystal was sealed in a Lindemann capillary for the X-ray studies. Precession photographs showed that the crystals of the disulphide were monoclinic. Unit cell parameters were obtained from least-squares fit of χ, φ, and 2θ for 15 reflections in the range 19.1° < 2θ < 31.8° measured on a Nicolet P3 diffractometer having graphite-monochromated MoKα_1 radiation (0.70926 Å at 22°C).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

Crystal data are as follows:
$C_{10}H_{24}K_2N_2O_7S_2$ fw = 426.64
Space group $P2_1$ (No. 4), a = 6.160(1), b = 26.473(8), c = 6.193(1) Å, β = 113.94(1)°, V = 923.0(4) Å, Z = 2, ρ_c = 1.54 g cm^{-3}, ρ_o = 1.53(1) g cm^{-3}, linear absorption coefficient, μ = 7.03 cm^{-1}.

The crystal size is 0.23 × 0.30 × 0.37 mm, reflection measurements are on h, $\pm k$, $\pm l$ with systematic absence $0k0$ where $k = 2n + 1$. Standard reflections are 2 −1 −1 (0.032), 1 3 −2 (0.021) with esd in parentheses. Maximum 2θ = 45°, T = 22°C. Number of independent reflections, 2303; number of $I > 0$, 2224; number of variables in last cycle, 168; $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.0469$, $R_2 = \{\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2\}^{1/2} = 0.0472$. Final shift/error max. (ave.), 0.006(0.001); final difference, peak (location) 0.6 e Å^{-3} (0.32, −0.68, 0.39), valley (location), −0.5 e Å^{-3} (0.25, 0.30, 0.32), $w = (\sigma^2 + (0.03F_o)^2)^{-1}$. The density of the crystals was measured by flotation in a benzene–bromoform mixture. Intensities were also measured with use of the Nicolet P3 diffractometer and a coupled θ(crystal)–2θ(counter) scan. The methods of selection of scan rates and initial data treatment have been described (9, 10). Corrections were made for Lorentz polarization effects but not for absorption. This will make a maximum error in F_o of 1.0%.

Solution of the structure

The potassium and sulphur atoms were found from a three-dimensional Patterson map, and electron density difference syntheses revealed all other atoms.[1] Full-matrix least-squares refinement, minimizing $\Sigma w(|F_o| - |F_c|)^2$, was terminated when the maximum shift/error was less than 0.01. All non-hydrogen atoms were refined, the heavy atoms, K, S, and O and the carbon atoms attached to them being given anisotropic temperature factors. Although hydrogen atoms were located, no attempt was made to refine their positions. Throughout the refinement, scattering curves were taken from ref. 11 and anomalous dispersion corrections from ref. 12 were applied to the curves for K, S, O, N, C. The atomic positional parameters and isotropic temperature factors for non-hydrogen atoms are given in Table 1.[2]

Discussion

The isolation of the potassium salt of the 3,3,3′,3′-tetramethyl-D-cystinate anion, **A**, from a basic solution of D-penicillamine is not unexpected in light of the ease of oxidation of RS^- groups. The actual oxidation involved a transient purple species and we assume this was the radical **I**. Attempts to confirm the presence of the radical were unsuccessful. No esr signal could be obtained from solutions at room temperature, frozen solutions decolourized and no signal was obtained at 80 K.

The salt was isolated as the trihydrate and the structure of the anion is shown in Fig. 1. Bond lengths and angles are given in Table 2. The structure of the neutral disulphide has not been determined, although those of neutral *meso*-D-penicillamine disulphide, **B** (16), and of D-penicillamine disulphide, **C**, have been determined (17). We have compared our structure with these structures and also with those of the two forms of cystine (18–20), the protonated chloride and bromide salts of cystine (21–24), and *N*,*N*′-diglycyl-L-cystine (25). Most bond lengths and angles agree remarkably well with equivalent distances in the above compounds. The C—O distances in the carboxylate groups of **A** do not differ significantly (range 1.241(8) to 1.262(7) Å) like the values in the zwitterion cystine (range 1.21(2)–1.25(2) Å) and in contrast to the asymmetry in the protonated carboxylate group in the hydrochloride (C—OH 1.294(9), 1.307(8), 1.308(6) Å vs. C=O, 1.198(9), 1.182(10), 1.205(5) Å). Similarly the C—C—O angles are essentially equal (range 116.2(5)–118.4(5)°), like cystine (range 116(1)–118(1)°) and unlike the hydrohalides (C—C—OH, 112.1(5)–112.9(5)°) vs. C—C=O, 120.6(5)–122.7(3)°.

[a] $U_{iso} = (1/3)(U_{11} + U_{22} + U_{33} + 2U_{13}\cos\beta)$.

[1] The space group chosen was $P2_1$. Space group $P2_1/m$ was not considered because it would have required both enantiomers to be present, and it seemed unlikely that under the mild conditions of preparation we would have racemized the D-penicillamine. The space group choice is justified by the successful solution of the structure.

[2] All calculations were carried out on CYBER 170/730 or CYBER 170/815 computers. Initial data treatment used the XRAY 76 package (13). The structure was solved with the SHELX package (14) and diagrams were prepared with the use of ORTEP-II (15). Tables of anisotropic temperature factors, hydrogen atom positional parameters, bond lengths and bond angles involving hydrogen, torsional angles and the moduli of F_o and F_c have been deposited and are available on request, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

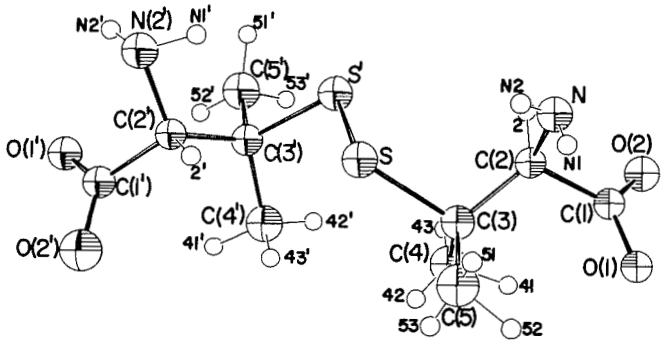

FIG. 1. The anion 3,3,3′,3′-tetramethyl-D-cystinate, showing the atom numbering. Hydrogen atoms are indicated by smaller script and affixes only.

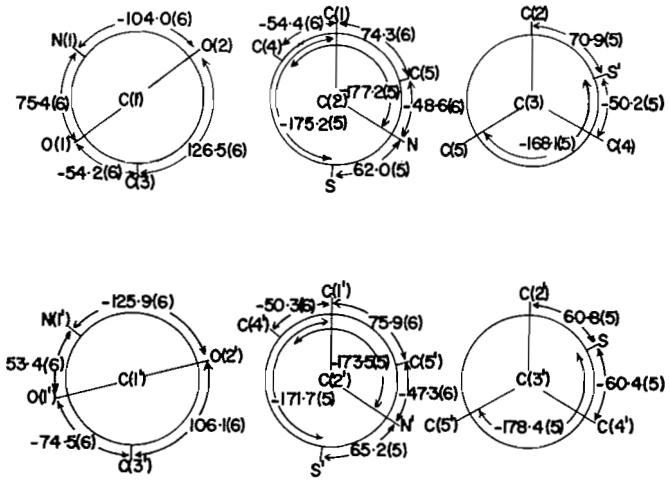

FIG. 2. Torsional angles in the 3,3,3′,3′-tetramethyl-D-cystinate anion.

One difference involves the C—S bonds. C—S bonds in thio-containing amino acids are typically 1.81–1.83 Å (26) but long bonds have been observed previously in disulphide containing amino acids (range 1.852(8) to 1.87(2) Å) (ref. 16 and references therein). However, the values observed for **A** are even larger (1.877(6), 1.891(6) Å). This is presumably because of the steric requirements of the methyl groups, since the S—S bond length (2.040(2) Å) agrees well with the others (range 2.032(4)–2.049(3) Å) (27). The C—S—S angles in **A** (108.3(2), 106.9(2)°) are very similar to the angles in **B** (107.9(3), 108.0(3)°), **C** (105.5(5), 105.5(5)°), cystine hydrochloride (104.0(4)°), and tetragonal cystine (104.1(5), 105.7(5)°) and only differ significantly from the exceptional hexagonal cystine (114.5(5)°).

The molecular anion, as with other symmetric disulphides (17), has roughly C_2 symmetry (see torsional angles in Fig. 2) and has a "right-handed" C—S—S—C conformation (20), like **C** (17) but unlike **B** (16). The C—S—S—C angle in **A**, like those in **B** (112.8(4)°) and **C** (119.4(4)°), is larger (108.7(3)°) than the normal range of 80–100° (16). Like Warner *et al.* (16), and in disagreement with Rosenfeld and Parthasarathy (17), we feel the large torsion angle is caused by repulsion between the methyl groups. Shortest H . . . H distances are H(42) . . . H(43), 2.6(1) Å, H(43) . . . H(42′), 2.6(1) Å comparable to those found by Rosenfeld and Parthasarathy (2.5–2.6(1) Å). We do not accept the argument that "the conformational difference . . . cannot be accounted for in terms of steric repulsion between the methyl groups, since . . . three shortest H . . . H . . . distances, 2.5–2.6(1) Å, are longer than the accepted . . . (Pauling) van der Waals distance of 2.4 Å" (17), since there is some ambiguity about the hydrogen van der Waals radius. Values of 1.2–1.45 Å have been used (28) and it has been argued that the latter value should be used in conformational problems of this type (29).

The carboxylate groups are antiperiplanar to the sulphur atoms, like **B** (16) and half of **C** (17) and unlike D-pencillamine (5). There are small deviations from the ideal staggered arrangements about the C(2)—C(3), C(2′)—C(3′) bonds (up to 16°) but such deviations are common and are caused by different repulsive interactions between the different sized groups.

One noteworthy feature of the conformations is the presence of very large N—C(2)—C(1)—O(1) (75.4(5)°) and N—C(2′)—C(1′)—O(1′) (53.4(6)°) torsional angles. These angles in other sulphur-containing amino acids (ref. 16 and references therein, ref. 5) are small, typically <15°, although in *meso*-penicillamine disulphide they are ~25°. In **A**, the conformation is clearly determined by interaction of the carboxylate groups

S′ . . . H(51′)	2.7(1)	S′ . . . H(2′)	2.7(1)	S′ . . . H(42′)	2.9(1)
S′ . . . H(53′)	2.9(1)	S′ . . . H(43)	3.0(1)	S′ . . . H(43′)	3.0(1)

[a]The atom is related to that in Table 1 by x, y, $1 + z$.

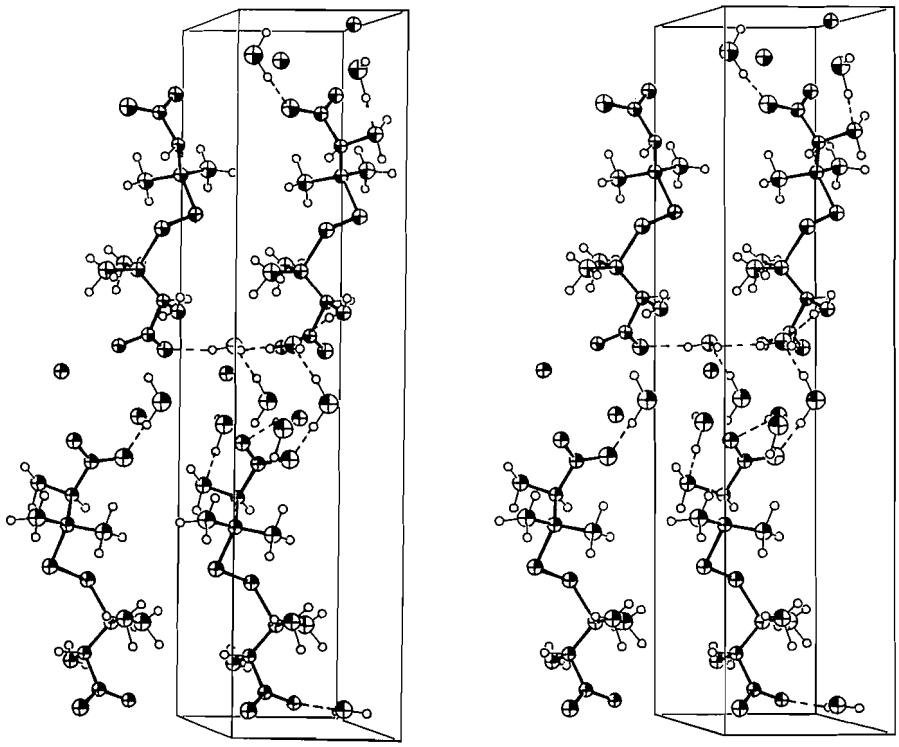

FIG. 3. The packing of dipotassium 3,3,3′,3′-tetramethyl-D-cystinate trihydrate within the unit cell. ***a*** and ***b*** are parallel to the bottom and side of the page respectively and the view is down ***c****.

with the pairs of methyl groups. The shortest O . . . H (methyl) distances are O(1) . . . H(52) 2.5(1) Å and O(1′) . . . H(52′) 2.7(1) Å which are both comparable to the van der Waals distance and any rotation of the carboxylate group to minimize the NCCO(1), O(1′) torsion angles will reduce these distances. It is noteworthy that where the repulsion is smaller (the longer O(1′) . . . H(52′) distance) the torsion angle is smaller. We have seen this effect of long-range non-bonded interactions determining the carboxylate conformation previously (30).

B has a number of S—H distances which are shorter than the van der Waals contact distance (3.05 Å) (17). We also find a number of such distances in **A** (Table 3). Two very short distances in **B** corresponded to internal NH . . . S hydrogen bonds and a similar interaction (S′ . . . H(N1′) 2.5(1) Å) is present in **A**. Otherwise, the distances are generally 0.3–0.1 Å shorter than the van der Waals distance. We find in **A** a somewhat similar distribution of hydrogen atoms to those in **B**; shorter S . . . H—C distances tend to occur in the S—S—C plane and longer distances tend to occur axial to the plane, but the distribution is not so clear-cut for **A**. Both the short H′(N1′) . . . S and long S . . . H(N2) (2.9(1) Å) hydrogen bonds are axial to the plane.

The coordination around the two potassium ions is different. Around K(1) there are six nearest neighbour atoms (O, N) forming a rough octahedron. There are also six atoms (O) around K(2), but these form a very distorted trigonal prism. The reason for the distortion is that two of the atoms are in the carboxylate group and thus are separated by only 2.2 Å. An alternative model for the coordination sphere is a square pyramid in which the apical position is filled by the two oxygen atoms of the carboxylate group.

The packing within the unit cell is shown in Fig. 3. The anions, which spiral up the ***b*** direction form layers parallel to ***ac*** and centred at $y = 1/4, 3/4$. These layers are held together by ionic bonds to potassium and hydrogen bonds to water molecules, which together form layers at roughly $y = 0, 1/2$. The hydrogen bonds, some of which are quite strong, are also important in providing bonding in the ***a*** and ***c*** directions, since the interactions between anions in the ***ac*** plane are only van der Waals. Thus O(1′) . . . O(4) . . . N′ hydrogen bonds anions related by the ***c*** translation. Water molecule, O(5), is very important since it acts as a link between translationally equivalent molecules in the ***b*** direction, through O(2′) . . . O(3) . . . O(5) . . . O(1) and also between equivalent molecules in the ***c*** (through O(7) . . . O(5) . . . N) and ***a*** (through O(1) . . . O(5) . . . O(2)) directions.

[c] Assignment notations: ν = stretching vibration; δ = deformation; s = symmetric; a = antisymmetric; τ = twist; r = rock; ω = wag.

The spectra and assignments for solid D-penicillamine disulphides are shown in Table 4. The spectra are very similar to those for D-penicillamine but show a general doubling of many of the bands. The νS—H and δS—H bands are absent, and the bands of the NH_3^+ group are replaced by those of the NH_2 group which show small shifts. The 700–500 cm^{-1} region is complicated by the fact that bands for the δCOOH, δCO_2^-, νC—S, and νS—S modes all occur in the same region. All these modes are fairly strong in the Raman spectra and should be good diagnostic bands if positively assigned. The fact that the band widths (in both Raman and infrared) differ is a help in the assignment; the CO_2^- and NH_2, NH_3^+ group bands are very broad, and the C—S and S—S bands very sharp.

In the lower frequency region new bands occur because of the disulphide bond: one νS—S and two νC—S are expected as well as a δCSS. These are assigned as shown in Table 4. The νS—S seems surprisingly high at first (very close to νC—S in D-penicillamine), but a search of related work suggests that 540 cm^{-1} is a reasonable value for νS—S in D-penicillamine disulphide (31, 32). Firstly, an examination of ranges of vibrational frequencies observed for νC—S and νS—S shows that these ranges do overlap, and νC—S in one compound can be lower than νS—S in another. For example, trithioacetone has νC—S at 513 cm^{-1}, diphenyl disulphide has νS—S at 542 cm^{-1}, as shown in Table 5. Secondly, work on sulphides and disulphides shows that νC—S decreases and νS—S increases with the number of CH_3 groups substituted adjacent to the sulphur atom. The addition of CH_3 groups may be expected to result in an increase in the C—S bond length, which was observed, with a consequent strengthening and shortening of the S—S bond, although this was not detected. Thus these two bands approach each other, and may even coincide. Table 5 shows that all the tertiary disulphides have an intense νS—S band near 540 cm^{-1}, as do di-*tert*-butyl and di-*tert*-pentyl disulphides. Diphenyl disulphide differs structurally from D-penicillamine disulphide (the phenyl ring substitution differs from tertiary alkyl substi-

[a] Solution ~0.1 *M*.

tution, in geometry and in amount of strain), but in the solid state is known to have conformations with low values (0–20°) of χSS—CC across its C—S bonds (in contrast with solutions). Since diphenyl disulphide has no COOH or CO_2^- group, there is no ambiguity about the assignment of the 542 cm^{-1} band to νS—S. Factors causing variations in frequency of νS—S bands of alkyl and cystine-related disulphides correlate with conformations of the CCSSCC moiety (7, 8).

The proton nmr of **A** is shown in Table 6. The assignment is made by comparison with penicillin (34). The presence of only two methyl signals and one CH signal suggests that the rough C_2 symmetry observed in the solid becomes exact, on average, in solution.

Vibrational spectral studies of solutions at elevated temperatures and pressures. VI. Raman studies of perchloric acid

C. I. RATCLIFFE[1] AND D. E. IRISH

Guelph–Waterloo Centre for Graduate Work in Chemistry, Waterloo Campus, Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received October 24, 1983

C. I. RATCLIFFE and D. E. IRISH. Can. J. Chem. **62**, 1134 (1984).

Raman spectra of perchloric acid in water have been measured for solutions spanning a wide concentration range and, for two specific concentrations, a wide range of temperatures. The acid is completely dissociated down to a water:acid mole ratio of about 1.8 at room temperature. At elevated temperatures it is still a very "strong" acid. As the concentration increases the apparent symmetry of the ClO_4^- ion decreases and a small amount of a new species assigned as associated $ClO_4^- \cdot (H_{aq})^+$ can be detected. The effects on the OH stretching bands of water, of temperature, ClO_4^-, and the excess acid protons are discussed.

C. I. RATCLIFFE et D. E. IRISH. Can. J. Chem. **62**, 1134 (1984).

On a mesuré les spectres Raman de l'acide perchlorique en solution aqueuse pour un large intervalle de concentrations et également, pour deux concentrations spécifiques, pour un large intervalle de températures. A la température ambiante, l'acide est complètement dissocié jusqu'à un rapport molaire eau:acid d'environ 1,8. A des températures plus élevées, l'acide demeure un acide très "fort". Lorsque la concentration augmente, la symétrie apparente de l'ion ClO_4^- diminue et on peut déceler la présence d'une faible quantité d'une nouvelle espèce identifiée comme étant l'ion associé $ClO_4^- \cdot (H_{aq})^+$. On discute des effets de la température, du ClO_4^- et des protons acides en excès sur les bandes d'élongation OH de l'eau.

Introduction

As the temperature of water rises K_w increases (1, 2) and hydrolysis reactions are encountered more frequently in salt–water mixtures (3, 4). Such reactions can be controlled or prevented, of course, by controlling the acidity. At ambient temperatures perchloric acid is often used to control pH because the perchlorate ion does not complex with most cations and the acid is strong. (A recent determination suggests that there is no association above a water:acid mole ratio, $N = n_{H_2O}/n_{acid}$, of 1.8 (5).) Thus competing equilibria can frequently be neglected. When studying the properties of salts in water at elevated temperatures, it is important to know if these useful properties of perchloric acid are retained. Also, for the measurement of relative integrated Raman band intensities, an internal intensity standard is generally employed and at moderate temperatures the ν_1 line of the perchlorate ion is most frequently the preference for the reasons cited above. Thus, for our longer term goals, knowledge of the temperature dependence of the Raman spectra of aqueous solutions of perchloric acid is essential. It was also of interest to see if the much reduced dielectric constant of water at higher temperatures might promote formation of $HClO_4$. (Nitric and sulfuric acids show markedly enhanced association as the temperature increases.)

Swaddle *et al.* (6) have studied the kinetics of decomposition of 1.1–6.6 *m* aqueous perchloric acid in the range 295–332°C. (At 250°C very little, if any, decomposition occurs at these concentrations.) The reaction is autocatalytic and the overall stoichiometry is

$$4H^+ + 4ClO_4^- \rightarrow 2H_2O + 2Cl_2 + 7O_2$$

With two exceptions (7, 8), the Raman spectroscopy of perchloric acid solutions has received little attention in recent years. Most of the early studies (9–13) were attempts to determine the degree of dissociation α at various concentrations, using intensity measurements of the symmetric stretching mode ν_1 of the ClO_4^- ion. Studies were also made of the line broadening on increasing acid concentration; the broadening is thought to be due in part to rapid proton exchange and possibly from changes in solvent structure (14, 15). It will be seen later that the presence of a low frequency asymmetry in the lineshape of the ν_1 band may introduce a complication into the interpretation of the measurements of its intensity and line broadening, which was not recognised at the time. (Kreevoy and Mead (14) were the only ones to remark upon the asymmetry and it may be that the feature was obscured in most instances by the use of large slitwidths.)

There have been several ir and Raman studies of solid perchloric acid monohydrate (16–21) and dihydrate (22). Taylor and Vidale (18) obtained the Raman spectrum of a single crystal of the monohydrate and confirmed that its composition is $H_3O^+ \cdot ClO_4^-$. They also showed that the melt contains a significant proportion of molecular $HClO_4$. The ir of solid, liquid, and gaseous molecular $HClO_4$ and $DClO_4$, and the Raman of the solid and liquid have been studied by Karelin *et al.* (23, 24).

The most relevant works in the current context are as follows. (*a*) The Raman and ir study by Chernykh *et al.* (7). They showed that at higher concentrations the degeneracy of the ν_3 (F_2) mode of ClO_4^- is apparently lifted and ν_1 begins to appear in the ir (not allowed for T_d symmetry). Ion pairing of H_3O^+ and ClO_4^- was postulated. (*b*) The ir study of a large range of compositions ($N = 0 \rightarrow \infty$) by Leuchs and Zundel (5). They monitored the intensity of one of the bands of $HClO_4$ as N increased and found essentially complete dissociation at $N = 1.8$, in agreement with an nmr determination by Duerst (25). Apart from these measurements of α, Leuchs and Zundel were more concerned with the spectroscopy of the OH groups of $HClO_4$, H_2O, and $(H_{aq})^+$. The form of $(H_{aq})^+$ is of great interest, particularly with respect to the question of whether H_3O^+ and $H_5O_2^+$ exist as discrete entities in solution. (*c*) The Raman and ir study of glassy and liquid perchloric acid dihydrate by Thi *et al.* (8). This work, which appeared towards the end of the study being presented here, also included some spectra of the monohydrate and liquid $HClO_4$. They concluded that there is

no $HClO_4$ or H_3O^+ in the $N = 2$ liquid or disordered states and that the acid proton is largely present as $H_5O_2^+$. They note that the lifting of the degeneracy of ν_3 of ClO_4^- implies some kind of interaction and assign shoulders on the low and high frequency sides of the ν_1 band to associated ionic and hydrogen bonded complex species respectively. (While this paper presents some very useful and interesting results we would question some of its conclusions.)

The effect of ClO_4^- on the vibrational bands of water is the subject of much ir and Raman literature (e.g. 26–35), because of the so-called structure-breaking effect; i.e. ClO_4^- produces an increase in the intensity of the high frequency end of the broad OH stretching band of water, implying an increase in the number of more weakly hydrogen bonded OH groups. In the case of the acid this is further complicated by the presence of $(H_{aq})^+$. So far the only spectroscopic work on the effects of ClO_4^- on the bands of water at high temperatures is the ir study of aqueous $NaClO_4$ by Valyashko *et al.* (36).

Experimental

Raman spectra were obtained using a digital drive, Jarrell-Ash 25-100 spectrometer (1 meter double Czerny-Turner monochromator), with an RCA 31034 photomultiplier and an SSR model 1105/1120 photon counting system. The 488.0 nm and 514.5 nm lines of a Spectra Physics Argon Ion Laser, model 165-03 were used for excitation. Instrument control and data collection were performed by means of a 32 K-byte PET Commodore computer.

The solutions were prepared using distilled water, 70–72% $HClO_4$ and 38% HCl (both J. T. Baker Analysed Reagents). The various concentrations were obtained volumetrically by diluting volumes of the stock acid solutions, and the acid concentrations were determined by titration. The densities of the solutions were measured in order to calculate mole ratios. Samples at lower acid concentrations were filtered through Millipore 0.6 μm polyvic filters before injection into the sample tubes. (The filters were attacked by acid at high concentrations.) To obtain spectra at ≈3°C and 25°C the samples were contained in sealed, thin-walled capillary tubes, which were held in a thermostatted copper block. The thick-walled, Pyrex glass capillary cells, high pressure system, and furnace, which have been described earlier (37), were used to obtain spectra of 5 *m* perchloric acid (N = 11.04) up to 300°C and of the 71% acid (N = 2.44) up to 200°C. (When an attempt was made to reach higher temperatures at this latter concentration, the generation of gas bubbles from decomposition of the acid was such that it became impossible to obtain a spectrum.)

The pressures of up to 11 MPa, used to maintain the liquid phase as the temperature was increased, are much too small to maintain a constant density. Consequently the concentration varies with temperature and for this reason the solutions are best characterised by their temperature-independent parameters – molality (mol kg^{-1} solvent) or mole ratio N. The mole ratio N will be used throughout this paper since it has more meaning on the molecular scale.

A sample of the solid perchloric acid monohydrate, under a small excess of concentrated acid (liquid) and sealed in a clear glass vial, was kindly supplied by the G. Frederick Smith Chemical Company. Spectra of the solid and molten monohydrate, and of the concentrated solution were obtained without opening the vial. (It was possible to melt a volume of the solid, *out of contact with the solution*, by resting the vial against the thermostatted copper block held at 60°C.) It is possible to obtain a good estimate of the mole ratio of the concentrated solution: since the solution is in equilibrium with solid monohydrate it should have a melting point at about room temperature (25–26°C). Using the freezing point curve of van Wyk (38) (and see also Brickwedde (39)), this corresponds to a composition of ≈79% $HClO_4$. (The melting point was actually checked by rapidly freezing the liquid, by dipping the vial in ice-water, and then observing the melting range, 22–33°C, though the bulk of the material melted in the range 24–28°C.) For this composition the mole ratio is therefore 1.5 ± 0.1, where the estimated error is rather pessimistic.

The explosive properties of highly concentrated $HClO_4$ and of perchlorates are well known and due care was exercised when handling the monohydrate and during the high temperature experiments.

Parallel ($I_\parallel$) and perpendicular ($I_\perp$) polarised spectra were obtained in many instances in order to observe the depolarisation ratio behaviour and to permit calculation of the isotropic spectra.

$$I_{iso} = I_\parallel - \frac{4}{3} I_\perp$$

$$I_{aniso} = \frac{4}{3} I_\perp$$

This proved to be very useful in clarifying and interpreting a number of features of the spectra.

Results and discussion

The results will be divided into two main sections, one concerning the bands of ClO_4^- and $HClO_4$ below 1400 cm^{-1} and the second concerning the O—H bands of the aqueous medium.

Section I. Vibrations of the ClO_4 unit

(a) Symmetry considerations

Before discussing the spectra it is useful to consider the effects of the possible perturbations on the symmetry of the ClO_4 unit and the corresponding spectroscopic activity of the modes. For equal extension or contraction of all 4Cl—O bonds the T_d symmetry is retained; extension or contraction of one Cl—O bond leads to C_{3v} symmetry; equal distortion of 2Cl—O bonds leads to C_{2v} symmetry; unequal distortion of 2Cl—O bonds leads to C_s symmetry; any other less symmetric distortion leads to C_1 symmetry. The correlation of the mode symmetries is presented in Table 1. Note that *any* distortion from T_d symmetry causes ν_1 and ν_2 to become ir allowed.

(b) Molecular $HClO_4$

At mole ratios down to about $N = 10$ the Raman spectrum of aqueous perchloric acid is essentially the same as that of perchlorate salts, with four well-defined bands which behave according to T_d symmetry. As the mole ratio decreases below $N = 10$, changes appear in the ν_1 and ν_3 region which become progressively more pronounced. Only at the very highest concentrations studied (N = 1.5 and 1) does an entirely *separate* set of bands due to $HClO_4$ begin to appear (see Fig. 1). There was no trace of molecular $HClO_4$ in the $N = 2.44$ solution at 25°C. This observation is in agreement with Zundel's (5) value of $N \leq 1.8$ for the appearance of $HClO_4$ in the ir spectrum. The $HClO_4$ Raman bands decrease in intensity by a factor of about ten relative to the ClO_4^- bands on going from N = 1 to 1.5; using Zundel's (5) value of $\alpha \approx 0.7$ for $N = 1$ a value of $\alpha \approx 0.96$ can be calculated for the $N = 1.5$ solution. This lends further weight to the original estimate of $N \approx 1.5$ for this solution, as this value for α falls at the correct point on Zundel's plot of α versus N.

The Raman spectrum of molecular $HClO_4$ in aqueous medium has not been reported previously, Table 2. It was found possible to subtract a ratio of the $N = 1.5$ spectrum from the $N = 1$ spectrum such that much of the ClO_4^- spectrum was removed. This subtraction enabled the determination of the frequencies of the weaker bands of $HClO_4$, specifically at 432 and 1220 cm^{-1}. The doublet at 578 and 585 cm^{-1} could readily be distinguished by using the isotropic and anisotropic spectra, since the band at 578 cm^{-1} is quite strongly polarised. This spectrum and the polarisation behaviour are consistent with a

very nearly C_{3v} character for the ClO_4 unit vibrations (similarly for pure liquid $HClO_4$ (23)); only when studied in detail in the gas phase does the true C_s character of $HClO_4$ become apparent (23).

In the aqueous mixture the stretching modes all shift to higher frequencies than the values reported for the pure liquid $HClO_4$ (23). The largest shift occurs for the Cl—O(H) stretching mode. It is likely that these shifts are due in part to different hydrogen bonding interactions: in pure $HClO_4$ the hydrogen bonding interaction has to be with other $HClO_4$ molecules, whereas in the aqueous mixtures the interaction is more likely to be with water or protonated water molecules.

In Fig. 1 it is clear that the spectra of ClO_4^- and $HClO_4$ are readily distinguishable. There can then be no doubt that the spectrum of the $N = 2.44$ solution at 200°C (Fig. 2) shows the presence of a very small amount of $HClO_4$. The bands at 757 and 1039 cm^{-1} are quite clear, although it should be noted that *some* of the apparent intensity increase in the 1039 cm^{-1} region is due to increased overlap of the ClO_4^- bands, which are broader at higher temperatures. It is also clear that the ν_2 and ν_4 bands of ClO_4^- show asymmetric broadenings to their low

frequency sides, due to the overlapping $HClO_4$ bands in these regions. It may be estimated, in the same manner as for the $N = 1.5$ solution earlier, that $\alpha \approx 0.99$ for this $N = 2.44$ solution at 200°C. (The amount of $HClO_4$ present can be estimated from the relative band intensities to be about 1/30th of that in the $N = 1$ solution.) The spectra of the $N = 11.04$ solution showed no trace of $HClO_4$ even at 300°C. This evidence indicates that perchloric acid is still a "strong" acid at such elevated temperatures.

Digressing slightly from the main theme, it should be mentioned here that the stretching modes of the dissolved decomposition products of perchloric acid, namely Cl_2 and O_2, could also be readily detected in the Raman spectra after periods at high temperature. The band due to Cl_2 at 542 cm^{-1} is visible in the 200°C spectrum of Fig. 2. The O_2 band was seen at ≈ 1549 cm^{-1}. These frequencies are somewhat lower than the gas phase values of 556 and 1554.7 cm^{-1} given by Herzberg (40).

(c) The ClO_4^- ion

With the exception of one feature the Raman spectra of solutions with $N > 10$ contain the characteristic four lines expected from a tetrahedral species (Table 3). But the ν_1 band has a very pronounced shoulder on its low frequency side. This band could have several origins and many experiments were performed to narrow down the possibilities, but a completely satisfactory explanation has not been found.

So far as we have been able to determine the shoulder appears in *all* spectra of aqueous solutions of ClO_4^- at all concentrations. It is strongly polarised, just as is the main ν_1 band. There is also evidence of its presence in spectra of ClO_4^- in organic solvents (this work and refs. 41 and 42), although overlapping solvent bands frequently mask the observation. For both aqueous perchloric acid and for $NaClO_4$ solutions the

* Values from bandfitting.

‡ For all concentrations with $N > 10$ the four frequencies were essentially constant within the accuracy of the experiment, although the bandwidths increased as N decreased.

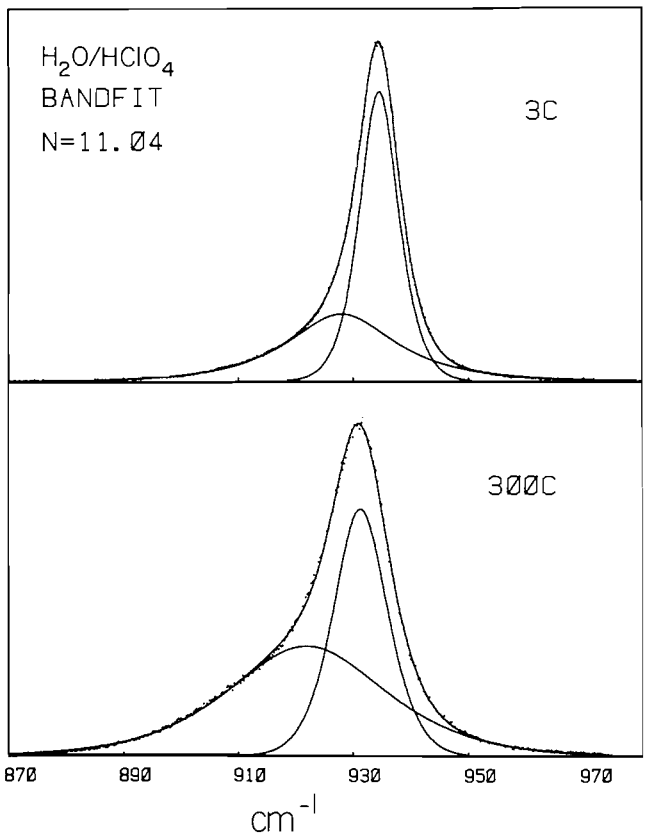

FIG. 3. The effect of temperature and results of bandfitting of the $\nu_1(ClO_4^-)$ band and its low frequency shoulder (N = 11.04).

intensity of the shoulder appears to increase relative to the main ν_1 band as either the concentration or the temperature (Fig. 3) is increased. However, these two effects are complicated by an overall broadening of the entire ν_1 band profile as concentration of acid is increased, attributed to proton transfer (14, 15), and as temperature is increased, in which case all bands of ClO_4^- broaden. Using the program BNDFT (43) good fits to the band profile were obtained with two symmetrical component bands (Fig. 3). These BNDFT results neglect a very much weaker and broader shoulder on the high frequency side of ν_1 which appears for the more concentrated solutions and which will be discussed later.

One explanation of the low frequency shoulder is that it is an enhanced $2\nu_2$ ($A_1 + E$) overtone in Fermi resonance with ν_1 (A_1) (*cf.* the spectrum of CCl_4 (44)). This correlates with the absence of a shoulder on the ν_1 band of SO_4^{2-} ion and IO_4^- ion; for these ions $2\nu_2$ is not sufficiently close in frequency to ν_1. The appearance of $2\nu_2$, sometimes as a distinct band (or bands if crystal field splittings are detected), has been established in spectra of molten perchlorate salts (45) and solids (this work and refs. 46–48).

Two facts are difficult to rationalize if Fermi resonance is invoked. The BNDFT results put the band due to the shoulder at a frequency of 928 cm^{-1}, *above* 2 × ν_2 (924 cm^{-1}) rather than below as expected, with a bandwidth of 22 cm^{-1}, which is *less* than that of ν_2 (26 cm^{-1}). (These values are for solutions at +3°C; at 300°C the frequencies are equal at 922 cm^{-1}.) Admittedly one might question the validity of bandfitting when Fermi resonance is involved. Also the large intensity increase of the shoulder with increase of temperature is not accounted for by Fermi resonance.

A second possibility is that the shoulder arises from a hot band (e.g. hot bands have been observed in the gas phase spectra of $FClO_3$ (49)). This raises the question of why this should occur for ClO_4^- and not for IO_4^- and SO_4^{2-}? Also the temperature dependence of the intensity does not follow the expected pattern: If the sideband is a hot band ν_1', then the intensity ratio of ν_1'/ν_1 should vary with temperature according to the Maxwell–Boltzmann populations of the excited state from which the ν_1' transition occurs and the ground state from which the ν_1 transition occurs; i.e.

$$\frac{I(\nu_1')}{I(\nu_1)} \alpha \exp(-\nu_E/kT)$$

where ν_E is the energy of the excited state relative to the ground state. Assuming that we are dealing with the first excited level of ν_2, a plot of ln $(I(\nu_1')/I(\nu_1))$ vs. $1/T$ should therefore be linear with a slope $-\nu_E/k$. The plot obtained using the intensities from BNDFT for the N = 11.04 sample at different temperatures is distinctly curved with tangential slopes which would give a range for ν_E of 160 to 580 cm^{-1} between 50 and 300°C. (Contrast this with ν_2 = 462 cm^{-1}.) Thus the hot band hypothesis is weakened.

A third possibility is that the shoulder arises from a new

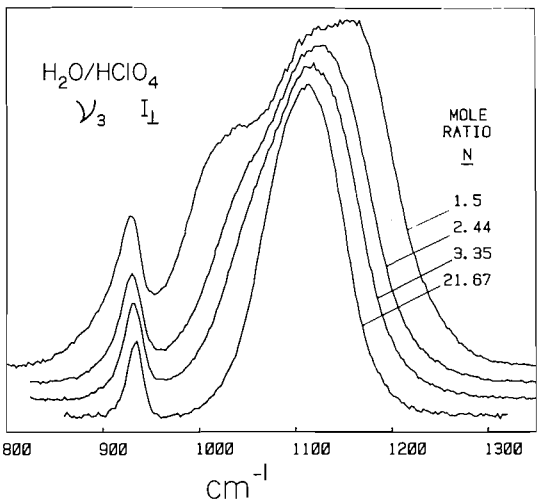

FIG. 4. Raman spectra ($I_\perp$) of the $\nu_3(ClO_4^-)$ band, at the mole ratios indicated and 25°C. A trace of $\nu_1(ClO_4^-)$ appears at ≈930 cm^{-1}.

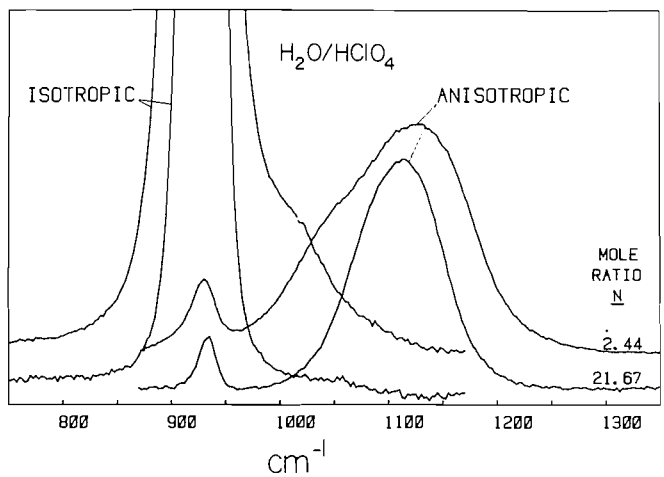

FIG. 5. Raman spectra (isotropic and anisotropic) of the ν_1 and $\nu_3(ClO_4^-)$ region at low and high mole ratios, showing the appearance of the isotropic, high frequency shoulder on ν_1.

species, *viz.* ClO_4^- bound to a cation. No other bands in the spectra give evidence of such a complex when $N > 10$. Furthermore, in cases where an interaction has been detected, for example Na^+ and $Li^+ClO_4^-$ solutions, ν_1 shows a broadening to the *high* frequency side as the concentration is raised (ref. 50 and this work).

The Fermi resonance explanation seems the most attractive of the various explanations, taken on its own. A fourth possibility is that a combination of all three effects contribute to the low frequency shoulder, dependent on the conditions.

We consider now the solutions of concentration $N = 10$ and lower. At these concentrations the Raman spectra are less in accord with a single ClO_4^- species of T_d symmetry. Infrared spectra may be more sensitive than Raman to the perturbation. Thus, although the two recent studies (5, 7) have not reported specific composition values, Zundel's results (5) suggest that the forbidden ν_1 line is detectable at concentrations as low as $N = 23$. Furthermore, as we shall see later, the Raman-active OH stretching bands of water are visibly affected in their high frequency range by perchloric acid at mole ratios as high as $N = 45$. This indicates strong solute–solvent interactions, which may be isotropic such that the symmetry of the ClO_4^- remains apparently T_d.

The lifting of T_d symmetry is indicated in the Raman by the ν_3 band which shows first an asymmetry and then a distinct shoulder on its low frequency side as N decreases below 10. ν_3 is considerably weaker than ν_1 and its appearance in the $I_\parallel$ polarised spectra is distorted by overlap with ν_1. Consequently we will refer mainly to the $I_\perp$ (or anisotropic) spectra, where ν_1 is largely removed (see Fig. 4). The two component appearance continues to $N = 2.44$ but for $N = 1.5$ there appears to be a third component on the high frequency side. Lifting of the degeneracy of ν_3 into two components implies C_{3v} symmetry. However, it is conceivable that a third band, implying even lower symmetry, is present all along but only becomes observable at $N < 2.44$. The bands of ν_2 and ν_4 do not show any discernible lifting of degeneracy until $N < 2.44$, when, like the ν_3 band, they develop an asymmetry to their high frequency sides. (Note that bands of molecular $HClO_4$ would appear at lower frequencies.) In theory, some of the components present when the degeneracies of ν_2, ν_3, and ν_4 are lifted should be polarised, and hence should appear in the isotropic spectra. There were traces of isotropic intensity in the regions of the high frequency shoulders of ν_2 and ν_4 and of the central component of ν_3 but we could not make a definitive assignment, considering the possible magnitude of errors involved in the baseline of the isotropic spectra. It is quite conceivable that the bands are only slightly polarised which, when combined with their weak intensity, makes them virtually invisible in the isotropic spectrum.

Inspection of the isotropic spectra shows that for the same conditions under which ν_3 develops its low frequency shoulder ν_1 develops a shoulder on its high frequency side. Its presence only becomes obvious in the isotropic spectra where it is not obscured by the overlapping anisotropic bands of ν_3 (Fig. 5). This new shoulder is very weak and broad (half width ≈80 cm^{-1}) when compared to ν_1 and its low frequency shoulder, but it clearly is a totally symmetric mode. It was also observed in the $N = 2$ liquid and glass spectra by Thi *et al.* (8). The shoulder also occurs in the spectra of deuterated solutions, and so the possibility that it could be a band of the protonated aqueous medium can be discarded, since a considerable shift would be expected.

Both this high frequency shoulder of ν_1 and the low frequency shoulder of ν_3 can be induced by increasing the acid concentration at constant ClO_4^- concentration (by addition of hydrochloric acid), though both the shoulders are less prominent than for the equivalent acid concentration of perchloric acid alone. These observations clearly show that the shoulders depend on both $[(H_{aq})^+]$ and $[ClO_4^-]$. Increasing temperature did not noticeably affect the shoulders in the $N = 2.44$ solution, apart from slight broadening. A summary of the frequencies of the bands and shoulders discussed above is given in Table 3.

As Thi *et al.* (8) point out, there are now four bands in the region above ν_1. There are no feasible overtone or hotband possibilities and so we will consider two possible origins for this situation, both of which involve the presence of a new ClO_4^- species. (*a*) The isotropic high frequency shoulder of ν_1 could be a polarised ν_3 component arising from a new, ClO_4^- species. Unfortunately this scheme means that there should also be strong ν_1, ν_2, and ν_4 bands arising from the new species (in addition to those of the original species): bands for which there is no positive evidence. Furthermore, it is odd that the isotropic component should be apparently totally polarised,

ν_4	629.5(24.0)	625.0(51.0)	630.0(31.0)	628.0(43.0)
ν_1	934.5(9.3)	931.0(14.8)	931.5(18.0)	929.0(23.0)
ν_3	1111.0(98.0)	1106.0(118.0)	1127.0(145.0)	1127.0(160.0)

separated considerably from the other ν_3 components, and appear to show no significant shift as N is decreased, in contrast to the other new ν_3 components. (*b*) The second explanation is that the isotropic band is a symmetric stretching mode of a new, very dilute species, for which the ν_2, ν_3, and ν_4 modes (or their equivalents) are too weak to be seen. We visualise a species in which the aquated hydrogen ion is ion-paired to the perchlorate anion, analogous to the proton boundary structure II described by Zundel (5). This type of species was proposed by us before (51) to account for changes in the Raman spectrum of nitric acid. It is a consequence of proton transfer from the ionogen, $HClO_4$ in this case, to yield the ionised species $(H_{aq})^+ \cdot ClO_4^-$, which further dissociates to the respective solvated ions which disperse in the solvent as the water content is increased. This brings us close to the situation envisaged by Thi *et al.* (8) who concluded that the new species is an $H_5O_2^+$ ClO_4^- hydrogen-bonded complex in the N = 2 solution. We would prefer to write $(H_{aq})^+ \cdot ClO_4^-$, since we believe that there is insufficient evidence to be so specific. Probably the most essential feature of the complex is the *close* proximity of the positive charge of the excess acid proton to the ClO_4^- ion, which induces the hydrogen bonding.

Aside from these specific features, the overall effects of increasing temperature are a steady increase in width and a slight decrease in frequency. The spectra of the ν_2 and ν_4 bands at the extremes of temperature are shown in Fig. 6. Values of the *peak* frequencies and bandwidths of the four modes at the extremes of temperature are listed in Table 4. The asymmetries and the lifting of degeneracy are neglected in the data of Table 4.

Solid $H_3O^+ClO_4^-$

Included in Table 3 and shown in Fig. 7 are the bands in the

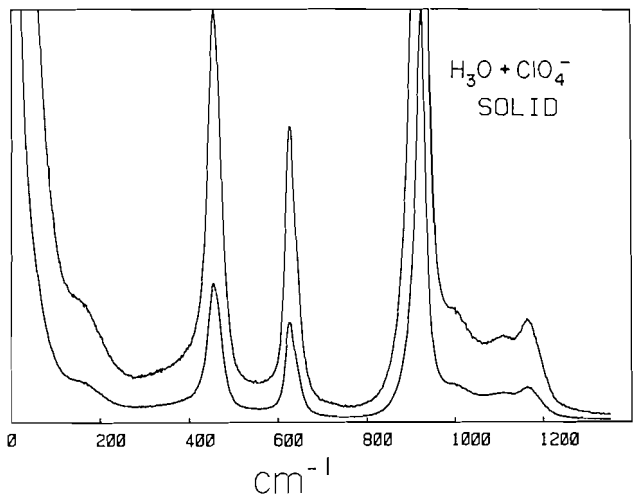

FIG. 7. Raman spectrum of solid $H_3O^+ClO_4^-$ below 1350 cm^{-1}, at 25°C.

ClO_4^- region of the room temperature phase of solid $H_3O^+ClO_4^-$ (at about 25°C). ν_2 and ν_4 show asymmetric broadening to their high frequency sides and there appear to be three components in the ν_3 region. In fact, the spectrum is remarkably similar to the spectra of the concentrated solutions with low values of N. However, the band observed at 995 cm^{-1} in the solid cannot be the equivalent of the isotropic shoulder at $\approx$1010 cm^{-1} in the liquid mixtures (assigned earlier to a new species), since it is quite clear from the crystal structure (52, 53) that there is only one kind of ClO_4^- ion. The structure also shows that the ClO_4^- ion has C_s site symmetry, and hence all degeneracy should be lifted (Table 5); further splittings due to the factor group correlations are not apparent and are therefore presumed to be small. Consequently one might readily assign the bands in the spectrum of the solid to those of a C_s perturbed ClO_4^- ion. However, the expected presence of the ν_2 band of H_3O^+ in the $\nu_3(ClO_4^-)$ region complicates the issue: Taylor and Vidale (18) originally assigned a peak at 1175 cm^{-1} to $\nu_2(H_3O^+)$ and the shoulder at 995 cm^{-1} to a librational mode of H_3O^+, whereas Thi *et al.* (8) assign the latter as $\nu_2(H_3O^+)$. Both of these interpretations seem not to have considered the lifting of the degeneracy of $\nu_3(ClO_4^-)$. Comparison of the new solid spectrum with that of the N = 1.5 liquid shows that the former has additional intensity at 1163 cm^{-1}, hinting that perhaps there are two bands superimposed: one a high frequency component of $\nu_3(ClO_4^-)$ and the other $\nu_2(H_3O^+)$. Obviously a Raman study of $D_3O^+ClO_4^-$ solid would be necessary to resolve this problem.

Another interesting feature of the solid's spectrum, from the point of view of earlier discussion, is the fact that the ν_1 band shows a strong low frequency asymmetry similar to that in the solution spectra. This cannot be due to a second species in this case, but $2\nu_2$ is a reasonable possibility.

The solid also shows a moderately-intense, broad shoulder at 160 cm^{-1} and another weaker one on the low frequency side of ν_2 in the 370–400 cm^{-1} region. These may be assigned to lattice modes (the higher frequency one is very likely a librational mode).

Section II. Vibrations of OH

The effects of increasing perchloric acid concentration on the OH stretching bands are illustrated in Fig. 8 for $N = \infty$ to 2.44 and in Fig. 9 for N = 2.44 to 1. Frequencies of the various

features are given in Tables 6 and 7. In some cases we have also listed the "band edge", measured as the point of maximum slope on the high frequency side of the spectrum, which we introduced before (54) as an indication of the limiting high frequency for an OH oscillator which has minimum hydrogen bonding interactions.

At all mole ratios $N > 1.8$ the acid is dissociated and the constituents are ClO_4^- ions, H_2O, and $(H_{aq})^+$. $((H_{aq})^+$ is used here as a blanket term to cover all possible descriptions of the aquated acid proton.) The spectrum of pure water is quite complex (54), and the additional species present in solution, all interacting with each other, produce further complexity. Another complication is introduced when $HClO_4$ is present at $N < 1.8$. We suggest, by analogy with our interpretation of the spectrum of water (54), that for each species containing OH groups in perchloric acid solution (and indeed all acids), there exists a broad distribution of OH oscillator potentials, arising from the many different hydrogen bonding configurations which must be possible in the liquid state. These distributions and the various possibilities for intra- and inter-molecular correlation interactions which they present, cause a broadening and further complication of the OH stretching bands. All these

* Figures with small underline indicate approximate positions of shoulders.

factors make it very difficult to interpret the spectra comprehensively, although one can attempt to produce a plausible qualitative picture.

(a) Effects of perchlorate ion

The first thing to notice in Fig. 8 is that even at $N = 45.34$ the band has changed from that of pure water. At high mole ratios where there is still a much greater number of H_2O molecules than excess acid protons, there is an overall shifting of intensity towards higher frequency as N decreases; intensity decreases in the 3250 cm^{-1} region and increases in the 3400–3600 cm^{-1} region. These effects are very similar to those observed for ClO_4^- salt solutions (26–35), and the shift of intensity is usually taken to imply that hydrogen bonding of the water surrounding the ClO_4^- ion is weakened (the so-called structure-breaking effect).

It is of interest to note that the spectra in the $N = \infty$ to 11.04 range do not consist of simple combinations of the spectrum of pure water and a spectrum of water interacting with ClO_4^- (i.e. a binary mixture), as it was *not* found possible to reproduce a spectrum at a particular value of N by adding together appropriate fractions of the spectrum of water and a spectrum at lower N.

As N decreases to 9.61 the upward shifting of intensity due to the structure-breaking effect produces a bandshape with a single sharp maximum at about 3535 cm^{-1}.

(b) Effects of the acid protons

The exact nature of the "$(H_{aq})^+$" present in acid solutions is a matter of some controversy. Giguère strongly argues that the proton is present only in H_3O^+ units, albeit hydrogen bonded to other H_2O molecules (55–57). On the other hand, Zundel strongly favours $H_5O_2^+$ groupings (provided there is enough water to form this) (5, 58, 59). He is then able to account for the intensity continuum to the low frequency side of the OH stretching mode, in terms of an easily polarisable hydrogen bond at the centre of the $H_5O_2^+$ unit. This intensity continuum is a characteristic of all acid solutions. We do not wish to go into all the arguments and counter-arguments at this point, but will emphasise a few things which are relevant in the current context.

TABLE 7. Frequencies (in cm^{-1}) of OH bands for $N < 2$

	$N = 1$	
$N = 1.5$	Melt	Solid

≈3100	≈3100	
≈3300	≈3300	3085
3465	3470	3255

The only situations in which the occurrence of distinct H_3O^+ and $H_5O_2^+$ ions has been satisfactorily established are in various solids (52, 53, 60–64) and in some non-aqueous solvent solutions (65, 66). Figure 10 shows the higher frequency bands of H_3O^+ in solid $H_3O^+ClO_4^-$ obtained in the present study.

* Figures in parentheses indicate the ratios of OH groups involved.

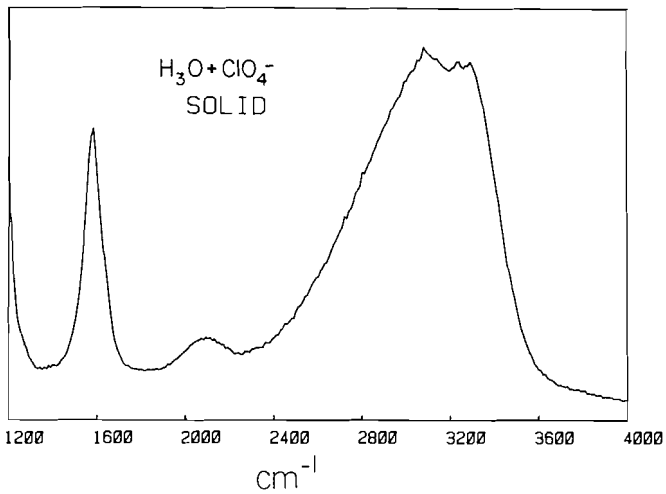

FIG. 10. Raman spectrum of solid $H_3O^+ClO_4^-$ from 1200 to 4000 cm^{-1}.

(These are essentially in agreement with Taylor and Vidale's spectrum (18).) One has only to look at the vibrational frequencies and assignments made for H_3O^+ in various solids (e.g. refs. 67, 68) to realise that the ion is not characterised by a fixed set of frequencies. Indeed the stretching mode frequencies depend very much on the degree of hydrogen bonding to the anions involved, ranging over 2468 to 3509 cm^{-1}. Moreover, it is clear from the structures of the solid higher hydrates of acids that H_3O^+ very readily hydrogen bonds to other H_2O molecules.

Evidence from the structures of the solid hydrates of perchloric acid (52, 53, 60–63), indicates strong hydrogen bonding of water molecules associated with the excess acid proton (i.e., in such units as $H_5O_2^+$, $H_3O^+ \cdot 2H_2O$, etc.), weaker hydrogen bonding interactions between water molecules on adjacent protonated units, and still weaker hydrogen bonding interaction to the ClO_4^- ions. One might expect, as is suggested by Zundel's work (5), that this hierarchy of hydrogen bonding strengths prevails in solution.

The intensity continuum mentioned above becomes clear (Figs, 8, 9) as N decreases below about 10. It increases steadily relative to the intensity at the high frequency end and is apparent in both isotropic and anisotropic spectra. At the same time the peak in the isotropic spectrum moves to lower frequency, which is probably a reflection of the stronger hydrogen bonding conditions introduced by the excess protons. (We also note a similar trend for the band edges, which decrease in frequency as N decreases, but over the whole range of N).

At $N = 1.5$ and 1 there is a dramatic broadening and increase of intensity on the low frequency side of the main peak, quite distinct from the intensity continuum. The OH stretching mode of molecular $HClO_4$ appears in the infrared as a broad band peaking in the region of 3340–3380 cm^{-1} (23). However, this probably accounts for only a small amount of the intensity of the shoulder, since even for the $N = 1$ liquid, where $\alpha = 0.7$, only about 1/10 of the total number of OH groups are present as $HClO_4$. Clearly most of the intensity of the shoulder must be due to an $(H_{aq})^+$ species, since at these very low mole ratios, all the water molecules must be radically affected by the excess protons.

TABLE 9. Main peaks of the OH stretching bands in solid perchloric acid hydrates (cm^{-1})

Hydrates	Band	
$H_3O^+ ClO_4^-$	3085	3255
$H_5O_2^+ ClO_4^-$ (8)	3224	3338
$H_7O_3^+ ClO_4^-$ (8)	3420	3590

It is useful to consider what species could be present. Table 8 lists the ratios of H_3O^+, $H_5O_2^+$, and H_2O which are possible in two limiting cases: (*i*) where there is a maximum amount of H_3O^+ and *no* $H_5O_2^+$ and (*ii*) where there is a maximum amount of $H_5O_2^+$. The ratios of the number of OH groups involved are also indicated in parentheses, since these are assumed to be more closely related to the observed intensities. It may be inferred from this that some H_3O^+ ions *must* be present for $N < 2$, but, if $H_5O_2^+$ is the preferred form, then H_3O^+ should disappear for $N \geq 2$. The intensity of the broad shoulder diminishes rapidly from $N = 1$ to $N = 2.44$; this suggests that it is due to H_3O^+ and that $H_5O_2^+$ does readily form at the expense of H_3O^+. However, since the shoulder can still be detected at $N = 2.44$, the equilibrium $H_2O + H_3O^+ \rightleftharpoons H_5O_2^+$ is not shifted completely to the right. (Although some might prefer to write $H_5O_2^+$ as $H_3O^+ \cdot H_2O$, this species does appear to have a distinctly different spectrum from that of H_3O^+.) Also note that the shoulder in the $N = 1$ and 1.5 spectra corresponds better with the position of the OH stretching bands of $H_3O^+ClO_4^-$ solid than to those of $H_5O_2^+ClO_4^-$ solid (see Table 9).

Another band which appears at the same time as the shoulder discussed above is the weak anisotropic peak at ≈2180 and ≈2150 cm^{-1} in the $N = 1$ and 1.5 spectra (see Fig. 9). A similar band appears in the spectrum of solid $H_3O^+ClO_4^-$, Fig. 10. The spectrum of the $N = 2$ liquid of Thi *et al.* (8) also shows this feature, but curiously it is absent or very much weaker in solid $H_5O_2^+ \cdot ClO_4^-$. This band too might therefore be associated with relatively discreet H_3O^+ units at low values of N. Its origin is likely a combination of a librational mode with the bending mode in the 1600 cm^{-1} region.

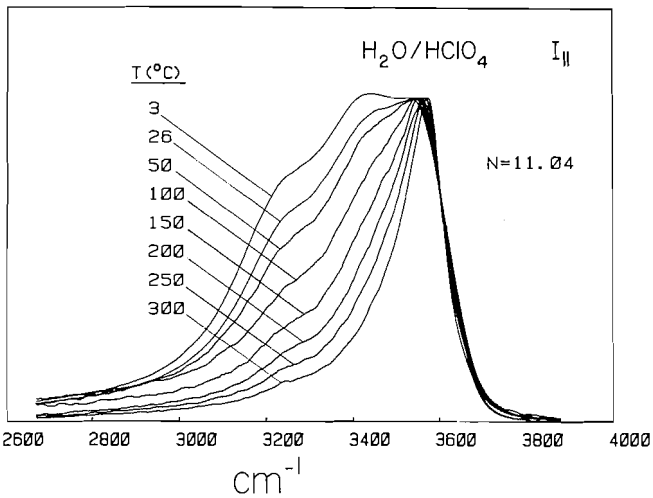

FIG. 11. Raman spectra ($I_{\parallel}$) of $N = 11.04$ perchloric acid in the 2700–3900 cm^{-1} region, at the temperatures indicated (intensity has been normalised on the high frequency maximum).

TABLE 10. Effect of temperature on the OH stretching bands of perchloric acid solution, $N = 2.44$ (values in cm^{-1})

	Isotropic		Anisotropic	
T(°C)	Peak	Band edge	Peak	Band edge
3	3492	3553	3470	3570
100	3517	3575	3482	3617
200	3545	3592	3528	3647

(c) The OH bending modes in the 1600 cm^{-1} region

The Raman spectra in this region show only one band at all values of N, ranging between 1602 cm^{-1} for the $N = 1$ liquid to 1638 cm^{-1} for pure water. This is in marked contrast to the infrared spectra (5, 7). These show a single band in the 1620–1645 cm^{-1} range at low concentration (high N), but as N decreases a new broader band grows in at 1700–1720 cm^{-1} and eventually dominates. Much interpretation has been based on these changes in the infrared (5, 7) and it may need to be reviewed in light of the Raman observations.

(d) Effects of temperature

Figure 11 shows the effect of increasing temperature on the $I_{\parallel}$ OH stretching bands of the $N = 11.04$ solution. At low temperatures the structure-breaking effect of ClO_4^- has already caused a large decrease in the number of the more strongly hydrogen-bonded OH groups, with a resultant increase of relative intensity at the high frequency end of the spectrum as compared to pure water. As the temperature increases the high frequency band edge remains at $\approx 3615 \pm 5$ cm^{-1} right up to 300°C, and all the changes involve a continuous reduction of intensity on the lower frequency side of the band. This observation is consistent with a steady shift in the distribution of hydrogen bond strengths of the water to the weaker end. The fixed position of the band edge is interesting since it once again suggests that this is the limiting high frequency for aqueous OH groups which have a minimum interaction with their surroundings. Another observation is that at 300°C there is very little difference between the spectra of pure water, for which the band edge of the isotropic spectrum is at 3607 cm^{-1}, and that of the $N = 11.04$ perchloric acid solution, though a close inspection reveals that the water spectrum is slightly broader.

The only other high temperature spectroscopic study of the effects of perchlorate in solution is the recent infrared work by Valyashko *et al.* (36) of the OD stretching mode of HDO in $NaClO_4$ solutions. Those spectra show a similar reduction of intensity on the low frequency side of the band.

In the case of the $N = 2.44$ solution versus temperature, the behaviour is somewhat different. At room temperature the main peak (in the isotropic spectrum) is already quite narrow, although there is also the weaker intensity continuum stretching to lower frequencies. However, the peak and band edge are shifted ≈ 40 cm^{-1} lower than for the $N = 11.04$ case. On heating, both the peak and the band edge frequencies increase, as indicated in Table 10. At this mole ratio, of course, one would expect a different behaviour, since the principal species is $(H_{aq})^+$, but even for this composition it is clear that increasing temperature causes an overall weakening of the hydrogen bonding.

Summary

In conclusion we summarise the main points of this work as follows:

(*1*) The Raman spectra of perchloric acid solutions are essentially in agreement with Zundel's infrared study (5) which indicated complete dissociation at water:acid mole ratios $N > 1.8$.

(*2*) The Raman spectrum of molecular $HClO_4$ in an aqueous medium has been reported for the first time.

(*3*) Perchloric acid remains a "strong" acid even at temperatures up to 300°C. However, the appearance of traces of molecular $HClO_4$ in concentrated acid solution at high temperatures shows that association does increase slightly, as might be expected.

(*4*) At $N > 10$ the Raman spectrum of ClO_4^- indicates essentially T_d symmetry. Investigations of the origin of the low frequency shoulder on the ν_1 band of ClO_4^- are still inconclusive.

(*5*) For $N < 10$ the degeneracy of the $\nu_3(ClO_4^-)$ mode lifted, indicating lower symmetry than T_d.

(*6*) The appearance of a new isotropic band on the high frequency side of $\nu_1(ClO_4^-)$ has been interpreted as indicative of a new species, presumed to be an associated ion-pair $(H_{aq})^+ \cdot ClO_4^-$.

(*7*) At low perchloric acid concentration (large N) the OH stretching bands reflect a "structure breaking" effect of the ClO_4^- ion, characteristic of perchlorate salt solutions.

(*8*) Effects on the ν_{OH} bands due to the excess acid protons become apparent at higher concentrations; the bands shift towards lower frequencies, indicating stronger hydrogen bonding conditions. Changes in the Raman spectra also suggest a rapid reduction in H_3O^+ as N increases from 1 to 2.

(*9*) The effect of increasing temperature on the ν_{OH} bands indicates a steady decrease in average hydrogen bonding strengths, just as in pure water.

G. A. MARTYNOV and R. R. SALEM. Can. J. Chem. **62**, 1145 (1984).

A model for the dense part of electrical double layer is proposed using the concept that conduction electrons penetrate into a solution to form an electronic capacitor on the metal surface. The potential drop between the metal and solution, the charge of the metal, its surface tension, and the electron work function for a metal–solution interface are calculated within the framework of the model, and the formulae derived are compared with experiment. It is shown that for a metal–vacuum interface of 38 metals in the left-hand subgroups of the Mendeleev table the discrepancy between the theoretical and experimental values of surface tension and work function does not exceed the experimental error (i.e. it is less than 10%); for six metals in the right-hand subgroups and especially for semimetals the theoretical error is two to three times higher. The density of free electrons in a metal determined in terms of the concepts of the model is shown to vary monotonously with the element number for all 54 metals with available experimental data.

A relationship, previously unknown, between surface tension and zero-charge potential is established, which enabled one to calculate the electronic capacitor charge for mercury (the theoretical value is 33 C/cm^2, and the experimental value is 36–38 C/cm^2). This paper also reports the calculated values of the integral capacity of a mercury electrode in water: the experimental value is 29 F/cm^2 (at the zero-charge point), and the theoretical value is 28 F/cm^2. The model predicts an increase of the capacity in the anodic region and a decrease in the cathodic region, in a good agreement with experiment. It should be stressed that although the theory includes only one fitting parameter, the density of free electrons in the metal, it correctly explains a wide range of phenomena.

G. A. MARTYNOV et R. R. SALEM. Can. J. Chem. **62**, 1145 (1984).

On propose un modèle pour la partie dense de la double couche électrique qui repose sur le concept que les électrons de conduction pénètrent dans une solution pour former une capacitance électronique à la surface métallique. A l'aide du modèle proposé, on a calculé la diminution du potentiel entre le métal et la solution, la charge du métal, sa tension de surface et la fonction de travail de l'électron pour une interface métal–solution; on compare les résultats expérimentaux avec les formules qui ont été dérivées. Pour 38 métaux des sous-groupes à gauche du tableau de Mendéleev dans le cas particulier d'une interface vide–métal, on montre, pour la tension de surface et pour la fonction de travail, que les différences entre les valeurs théorique et expérimentale ne dépassent pas les erreurs expérimentales (soit moins que 10%); pour six métaux des sous-groupes à droite du tableau et particulièrement pour les semimétaux, l'erreur théorique est deux à trois fois plus élevée. On démontre que la densité des électrons libres dans un métal, telle que déterminée en termes des concepts du modèle, varie d'une façon monotone avec le numéro de l'élément pour les 54 métaux pour lesquels des données expérimentales existent.

On a développé une nouvelle relation entre la tension de surface et le potentiel de charge zéro qui permet de calculer la capacité de charge électronique du mercure (alors que la théorie prévoit une valeur de 33 C/cm^2, la valeur expérimentale est de 36–38 C/cm^2). On rapporte aussi les valeurs de la capacité intégrale d'une électrode à mercure dans l'eau: la valeur expérimentale est 29 F/cm^2 (au point de charge zéro) alors que la valeur théorique est 28 F/cm^2. La théorie prévoit une augmentation de la capacité dans la région anodique et une diminution dans la région cathodique; les résultats expérimentaux sont en bon accord avec ces prédictions. Il est important de noter que même si la théorie n'implique que l'ajustement d'un seul paramètre, soit la densité des électrons libres dans le métal, elle permet d'expliquer correctement un grand nombre de phénomènes.

Introduction

Most of the presently available experimental data on the dense part of electrical double layer (EDL) are analysed within the framework of the Stern molecular capacitor model. The procedure is as follows: first, we consider an experimental quantity, say, the capacity of a metal at the interface with a given solution, and then fit the parameters of the model so as to obtain the best agreement with experiment. The agreement thus obtained is, for the most part, quite satisfactory. However, if we attempt to describe a given relationship, for example, the variation of the capacity of a given metal in contact with different solvents by the molecular capacitor model, we see that the model fails (1). This topic will be considered at greater length in a future paper. Contradictions inherent in the Stern model have forced us to resort to an alternative model of the electronic double layer (1) suggested by Frenkel (2) and Rice (3) as early as in 1928. At that time the model had not attracted the attention of electrochemists, for the quantum theory of surface phenomena was only in the incipient stage and could contribute little to the understanding of the properties of the dense part of EDL. On the other hand, these properties were studied insufficiently, so that experimental data did not fit any particular model. Since the Stern model was the most simple and rested upon the already traditional and therefore more customary ideas of Helmholtz, it was given preference; and the ideas of Frenkel and Rice were fully forgotten for a long time. The situation has changed only in the last 3 or 4 years.

The contemporary state of the art in the problem is, briefly, that the existence of the electronic double layer at a metal–vacuum interface is commonly accepted. Furthermore, the electronic double layer seems to play a decisive role in the formation of surface properties of metals, and numerous papers are devoted to the theory of this effect (see, for instance, recent reviews (4–6)). The situation is, however, different for a

metal–solution interface. In electrochemistry, the concept of the electronic capacitor[1] is almost unknown. There are only a few papers where an attempt has been made to calculate the capacity of the dense part of EDL on the basis of this model (7–11) (see also related papers (12–14)).

The concept of the electronic capacitor has not been popular because the theory is rather complicated. The functional density method, on which the theory is based, always leads to a system of non-linear equations which can only be solved by a computer (4–6). Thus to extend the theory to the EDL at a metal–electrolyte interface, one should perform all calculations once more; success is not guaranteed, for it is not clear *a priori* how to incorporate the electrolyte solution into the equations. Comparison of the results thus obtained with experiments is also very complicated, as the parameters appearing in the equations are chosen "blindly". Furthermore, the equations should be solved repeatedly, unless an optimal set of the parameters is found to best describe the experimental data.

In such a situation, it is very important to develop a version of the theory that would give simple analytical expressions. This is, of course, possible only if the phenomenon is simplified to the extent that all secondary effects are neglected. Some information will inevitably be lost, but this will be more than compensated for by the simplicity of the formulae and by the ease of comparison of the results with experiment. This all should help in finding the range of phenomena where the model works and in judging optimal values of the parameters for constructing a more rigorous (and therefore more accurate) theory and should facilitate preliminary treatment of experimental results.

The first attempt at a "simplified" description of the electronic capacitor was made in ref. 1. In this paper we shall try to proceed further. As is shown below, the model developed in ref. 1 permits the description of almost all properties of the dense part of the EDL (surface tension, capacity, zero-charge potentials, etc.) for a very wide range of systems.

Mechanism of formation of the electronic capacitor

A metal may be considered, in the first approximation, as a potential well in which conduction electrons are free to move. When impinging the wall of such a potential well (the role of this wall is played by the interface between a metal and the surrounding medium, electrolyte), the electron density wave undergoes total internal reflection[2] according to laws similar in many respects to the laws of total reflection for light. This is not surprising, because the same principle, namely, the wave nature of matter, underlies both phenomena.

It has long been known that in the total reflection of light the incident wave penetrates into the surrounding medium at a distance of the order of the wavelength (15, 16). The same situation occurs when electrons are reflected from a metal–electrolyte interface.[3] As a result, a negatively charged electron cloud is formed outside the metal in the solution (the outer plate of the electronic capacitor). At the same time, in the inner part of the interface, inside the metal, a layer with a thickness of several angstroms is formed (the inner plate of the electronic capacitor) in which the positive charge of the metal ion core is not compensated, because a fraction of the electrons penetrates from the metal into the solution. It should be noted here that the electroneutrality of the system is by no means violated because the charges of both plates are equal (of course, this is valid only at the zero-charge point; at potentials different from the zero-charge potential the excess charge of the electrode is compensated by ions of the diffuse part of the electrical double layer (EDL)).

Whenever the electronic capacitor exists, a potential difference arises between the metal and the electrolyte bulk,[4] the metal being always charged positively. Since this potential difference is sufficiently high (usually 2–7 V, see below), it mainly determines the potential of the zero-charge point (ZCP) and the capacity of the dense part of EDL. Furthermore, the electrostatic energy stored in the electronic capacitor contributes significantly to the surface energy of the metal–electrolyte interface. At the same time, the electrostatic potential difference across the electronic capacitor does not affect the electrochemical potential of the electrons that form the capacitor, for this electrochemical potential is always equal to that of electrons in the metal bulk (recall that the former and latter electrons are in thermodynamic equilibrium).

The electronic capacitor at the surface of a metal owes its origin to the wave nature of matter, that is, to its fundamental quantum-mechanical properties (17). Therefore, the very fact of the existence of the electronic capacitor requires no additional evidence. The only point that may be discussed is a contribution of the electronic capacitor to some or other parameters of the dense part of EDL. Note in this connection that in the Stern–Grahame molecular capacitor model, now generally accepted, the effect of electrons on the properties of the dense part of EDL is completely disregarded.

Electron density distribution inside the electronic capacitor

Calculation of the surface properties of metals at the interface with vacuum shows that the model of non-interacting electrons in a square potential well describes quite satisfactorily the experimental data. On the contrary, a more accurate description of the electron subsystem with an allowance for many-particle and quantum effects and under complete self-consistency gives results which are in striking discrepancy with experiment (this discrepancy was partly relaxed when lattice discreteness was taken into account (6)). This implies that many-particle and quantum effects do not contribute significantly to the electron density distribution because for various reasons they almost completely cancel one another. Thus, there are two approaches to construct the theory of surface phenomena in metals at the interface with an electrolyte. First, one may attempt, using the simplified model, to achieve the best agreement with experiment. Second, one may repeatedly improve the initial model, which eventually will elucidate the reasons why the "second-order" effects are cancelled out and will explain the discrepancy (insignificant for the most part) between

[1] The term "electronic capacitor" was first introduced in ref. 1 to denote the electronic double layer.

[2] If the reflection were not total, the amplitude of the electron density wave in the surrounding medium would not vanish. This would mean that the electrons permanently leave the metal. This is, of course, in contradiction with the concept of thermodynamic equilibrium of a system.

[3] Since the concentration of electrons at the metal surface is very high, the concentration remains sufficiently high at a distance of several de Broglie wavelengths as well.

[4] This potential difference is an analog of the contact potential difference at the boundary between two metals. The analogy becomes even more convincing if we take into account that in both cases the effect is caused by the change in the electron density at the boundary between the two media.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

the initial model and experiment (the origins of this discrepancy cannot, of course, be understood without improving the model).

We shall choose the first approach and confine ourselves to the simplest model of a metal (the "jelly" model) and the simplest description of this model as suggested by Smith (18).

The "jelly" model implies that the charge of the ion core is uniformly smeared over the entire bulk of the metal up to its boundary $z = 0$ where the charge vanishes jumpwise. The electrons, whose concentration inside the metal is ρ_m, are free to move against the background of this smeared positive charge. From the electroneutrality condition we immediately obtain $\rho_m = k_m n_m$ where n_m is the number of atoms of the metal core per unit volume, and k_m is the number of free electrons per atom.

While solving the problem of electron distribution near the metal surface by the Thomas–Fermi method, Smith derived a complicated non-linear equation for determining the electron density $\rho_e(z)$. He approximated the solution of this equation by the following expression:

$$[1^*] \quad z < 0,\ \rho_e(z) = \rho_m - \frac{1}{2}\rho_m e^{z/R};\ z > 0,\ \rho_e = \frac{1}{2}\rho_m e^{-z/R}$$

Here R is the variational parameter chosen to give the best approximation of the equation obtained (it is assumed in [1*] that the metal occupies the half-space $z < 0$ and the surrounding medium the half-space $z > 0$). Although these formulae are rather simple, they give quite satisfactory results, at least by an order of magnitude. Later on, Timashev (19) considered a more rigorous version of the Thomas–Fermi method and showed that at a large distance from the metal surface $z = 0$

$$[1^{**}] \quad z < 0,\ \rho_e(z) = \rho_m - \rho_m \frac{R_s}{R_s + R_m}\exp(z/R_m)$$

$$z > 0,\ \rho_e(z) = \rho_m \frac{R_m}{R_m + R_s}\exp(-z/R_s)$$

where $R_s = 8.33a_0$ ($a_0 = \hbar^2/me^2 = 0.529$ Å is the Bohr radius) and

$$[2] \quad R_m = \sqrt{\frac{\pi\hbar^2}{4me^2K_F}} = \sqrt{\frac{\pi a_0}{4K_F}}$$

is a characteristic distance at which the electric field inside a metal is screened (20) (R_m is an analog of the Debye radius R_D in an electrolyte). In [2], $\hbar$ is Planck's constant and $K_F = (3\pi^2\rho_m)^{1/3}$ is the Fermi wave vector; e is the charge of an electron and m is its mass.

We shall also describe the electron density distribution by formulae of the type [1*] and [1**], but instead of using various approximate equations for determining the distribution parameter, we shall try to find them from simple and obvious considerations.

The solution of the Schrödinger equation for the motion of a neutral particle of mass m in a potential well of a height W implies that outside the well (i.e. for $z > 0$) the electron density is (17)

$$[3] \quad z > 0,\ \rho_e^s(z) = \rho_0 \exp(-z/R_s)$$

where ρ_0 is the electron density at $z = 0$ and

$$[4] \quad R_s = \hbar/\sqrt{2mW}$$

The potential barrier W appearing in this expression is an independent parameter of the problem. Apparently, the value of this parameter determines the work done in the transfer of an electron from the "bulk" of the well (from point $z = -\infty$, to be exact) into the surrounding medium (point $z = +\infty$). Thus, W has the meaning of the work needed to transfer an electron from the metal to the surrounding medium (the electron work function).

Let us assume that inside the metal

$$[5] \quad z < 0,\ \rho_e^m(z) = \rho_m - (\rho_m - \rho_0)\exp(z/R_m) \times \frac{\cos(2K_Fz + \delta)}{\cos\delta}$$

where R_m is given by [2] and $\cos(2K_Fz + \delta)$ describes the so-called Friedel oscillations (of frequency $2K_F$ (21)) arising as a result of interference of the incident and reflected electron density waves (the constant δ allows for phase shift during the reflection).

The "test" functions ρ_e^s and ρ_e^m include two arbitrary parameters (ρ_0 and δ) which, in principle, can be determined by minimizing the energy function. This minimization leads, however, to very cumbersome expressions. Therefore, to find ρ_0 and δ, we shall use the conditions which are just as important as the conditions for minimum energy function. These conditions are (*i*) continuity of the electron density at $z = 0$

$$[6] \quad \rho_e^s(0) = \rho_e^m(0)$$

(*ii*) continuity of its first derivative

$$[7] \quad \frac{\partial\rho_e^s(0)}{\partial z} = \frac{\partial\rho_e^m(0)}{\partial z}$$

and (*iii*) conservation of the number of electrons

$$[8] \quad \int_{-\infty}^{0}[\rho_m - \rho_e^m(z)]\,dz = \int_0^{+\infty}\rho_e^s(z)\,dz$$

(evidently, this relation is valid only at the zero-charge point which is just considered here). Conditions [6] and [7] have appeared because $\rho_e(z)$ is determined by the electron wave function which, in turn, is a solution of the Schrödinger equation. And since the latter is a second-order differential equation, both its solution and the first derivative of the solution must be continuous. Formulae [3] and [5] are written in such a form that condition [6] is satisfied automatically. From [7] and [8] we find

$$[9] \quad \rho_0 = \frac{2\rho_m\beta}{\alpha^2 + (1+\beta)^2}$$

$$[10] \quad \operatorname{tg}\delta = \frac{1 + \alpha^2 - \beta^2}{\alpha(1 + \alpha^2 + \beta^2)}$$

where $\alpha = 2K_FR_m$, $\beta = R_m/R_s$.

In this manner we have determined all the constants appearing in [3] and [5].

Potential distribution inside the electronic capacitor

If $\rho_e(z)$ is known, one can find the charge density distribution in the electronic capacitor

$$[11] \quad z < 0,\ q_m(z) = e[\rho_m - \rho_e^m(z)] = e(\rho_m - \rho_0)\exp(z/R_m) \times \frac{\cos(2K_Fz + \delta)}{\cos\delta}$$

$$z > 0,\ q_s(z) = -e\rho_e^s(z) = -e\rho_0\exp(-z/R_s)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

and then, using Poisson's equation,

$$z < 0,\ \psi_m''(z) = -\frac{4\pi}{\epsilon_m} q_m(z)$$

[12]

$$z > 0,\ \psi_s''(z) = -\frac{4\pi}{\epsilon_s} q_s(z)$$

calculate the potential distribution $\psi(z)$ inside the electronic capacitor (here ϵ_m and ϵ_s are the dielectric permittivities of the metal and solution, respectively).

Imposing ordinary electrostatic boundary conditions

$$z = -\infty,\ \psi_m = \psi_e^{m-s}$$

[13] $$z = 0,\ \begin{cases}\psi_m = \psi_s \\ \epsilon_m \psi_m' = \epsilon_s \psi_s'\end{cases}$$

$$z = +\infty,\ \psi_s = 0$$

on $\psi(z)$, we obtain after simple calculations

[14] $$z < 0,\ \psi_m(z) = \psi_e^{m-s} - \frac{4\pi e(\rho_m - \rho_0)R_m^2}{\epsilon_m \cos\delta} \exp(z/R_m) \times \left\{\frac{2\alpha}{(1+\alpha^2)^2}\sin(2K_F z + \delta) + \frac{(1-\alpha)^2}{(1+\alpha^2)^2}\cos(2K_F z + \delta)\right\}$$

[15] $$z > 0,\ \psi_s(z) = \frac{4\pi e \rho_0 R_s^2}{\epsilon_s} \exp(-z/R_s)$$

where the constant ψ_e^{m-s} is

[16] $$\psi_e^{m-s} = \frac{4\pi e \rho_m R_s^2}{\epsilon_s} \frac{2\beta}{\alpha^2 + (1+\beta)^2} \times \left\{1 + \frac{\epsilon_s \beta}{2\epsilon_m} \frac{3 - (\alpha^2 + \beta^2)}{1 + \alpha^2}\right\}$$

Calculation using this formula has shown that even for $\epsilon_s = 1$ the contribution of the second term in curly brackets does not exceed 3–5%. If this term is neglected, we obtain

[17] $$\psi_e^{m-s} = \frac{4\pi e \rho_m R_s^2}{\epsilon_s} \frac{2\beta}{\alpha^2 + (1+\beta)^2}$$

Since in real systems ϵ_s is much larger than unity, the error of [17] is even less than 3–5%. Since [17] is more than sufficient to satisfy our purpose, we shall use this formula below.

Surface tension

From the distribution of charge $q(z)$ and potential $\psi(z)$ (see [11], [14], and [15]) one can easily calculate the electrostatic component of surface tension

[18] $$\sigma_e \equiv \frac{1}{2}\int_{-\infty}^{+\infty} q(z)\,\psi(z)\,dz = \frac{1}{2} k Q_e^+ \psi_e^{m-s}$$

In this expression ψ_e^{m-s} is the total potential drop between the metal and solution (see [17]),

[19] $$Q_e^+ = \int_{-\infty}^{0} q_m(z)\,dz = e\rho_m R_s \frac{2\beta}{\alpha^2 + (1+\beta)^2}$$

is the charge of the positive plate of electronic capacitor (according to the electroneutrality condition [8], it is equal to the charge of the negative plate Q_e^-), and the constant k characterizes charge "blurring." Substituting $q(z)$ as [11] and $\psi(z)$ as [14] and [15] into integral [18], we find that k is almost exactly 0.5. We note that in real systems the surface tension has, besides a purely electrostatic component, the exchange–correlation component which contributes significantly to the final expression. The latter can effectively be taken into account by choosing the proper value of the constant k. Indeed, according to ref. 6, if the exchange–correlation interaction is allowed for, σ rises, as compared with the electrostatic case, from 51 to 102 erg/cm^2 for Cs, from 62 to 120 erg/cm^2 for Rb, from 71 to 142 erg/cm^2 for K, and from 114 to 228 erg/cm^2 for Na (these are taken from ref. 22, Table 2.6, p. 52). Thus, in all cases, the surface tension increases twice as compared with the values predicted by the "jelly" model. We shall take, therefore, $k = 1$ instead of $k = 0.5$. As is shown below, the formula

[20] $$\sigma = \frac{1}{2} Q_e^+ \psi_e^{m-s} = \frac{8\pi e^2 \rho_m^2 R_m^2 R_s}{\epsilon_s[\alpha^2 + (1+\beta)^2]^2}$$

gives quite satisfactory agreement with experiment in all cases.

It follows from [17] and [19] that the capacity of the electronic double layer is $K_e^{m-s} = Q_e^+/\psi_e^{m-s} = \epsilon_s/4\pi R_s$. Comparison of this expression with [20] shows that relations [17], [19], and [20] describe the electronic capacitor model in which the positive charge Q_e^+ is localized at the metal surface $z = 0$ (the inner plate of the capacitor) and the negative charge Q_e^- is localized at $z = R_s$ (the outer plate), the space between the plates being filled with a medium of dielectric permittivity ϵ_s.

Electron work function in vacuum

While calculating the surface tension of liquid metals for a metal–vacuum interface, we have found that the quantity $C = (1/\alpha)[\alpha^2 + (1+\beta)^2]$ remains practically constant (with an accuracy of not less than 5%) for all metals when particular values of W and ρ_m are substituted. The value of C (averaged over 50 metals) was estimated to be 3.14. Assuming therefore $C = \pi$ and solving the equation thus obtained for W, we get

$$W = (2e^2\alpha^2/a_0\pi)(\sqrt{\pi\alpha - \alpha^2} - 1)^2$$

Numerical calculations have also shown that for all 50 metals the value of $(\sqrt{\pi\alpha - \alpha^2} - 1)$ lies between 0.50 and 0.55. Therefore, we shall not make a significant error by putting $(\sqrt{\pi\alpha - \alpha^2} - 1) \simeq 1/2$, which gives

[21] $$W = \frac{e^2\alpha^2}{2\pi a_0} = \frac{e^2 K_F}{2\pi} = \frac{1.526}{\epsilon_s}\tilde{\rho}_m^{1/3}\ \text{eV}$$

where $\tilde{\rho}_m = \rho_m \times 10^{-22}$ cm^{-3}.

Substitution into [4] yields $R_s = \pi a_0/\alpha$. Since $\alpha^2 = \pi a_0 K_F = 1.108\tilde{\rho}_m^{1/3}$ and $R_m = \pi a_0/2\alpha$ (see [2]), $\beta = R_m/R_s = 0.5$ and the formula for surface tension takes the form

[22] $$\sigma = \frac{2e^2\rho_m\alpha^3}{3\pi[\alpha^2 + 2.25]^2} = \frac{465.9\,\tilde{\rho}_m^{3/2}}{[\tilde{\rho}_m^{1/3} + 2.031]^2}\left(\frac{\text{erg}}{\text{cm}^2}\right)$$

Correspondingly, from [18] and [19] we obtain

[23] $$\psi_e^{m-s} = \frac{4e\alpha^4}{3\pi^2 a_0[\alpha^2 + 2.25]} = \frac{4.075\,\tilde{\rho}_m^{2/3}}{[\tilde{\rho}_m^{1/3} + 2.031]}\ (\text{V})$$

[24] $$Q_e^+ = \frac{\pi a_0 e \rho_m}{\alpha[\alpha^2 + 2.25]} = \frac{22.82\,\tilde{\rho}_m^{5/6}}{\tilde{\rho}_m^{1/3} + 2.031}\left(\frac{\mu C}{\text{cm}^2}\right)$$

Thus, if the electron gas in a metal is ideal, all the parameters of the electronic capacitor are expressed in terms of the electron density in the metal bulk ρ_m and the dielectric permittivity of the surrounding medium ϵ_s.

The liquid metal – vacuum interface

The formulae derived above become much simpler if the surrounding medium is vacuum, because in this case $\epsilon_s = 1$ and the only parameter of the system is the electron density $\rho_m = K_m (\rho/M) N_A$ (here $N_A = 6.023 \times 10^{23}$ mol^{-1} is Avogadro's number, M is the molecular weight of the metal, and ρ is its density in g/cm^3). In this relation the coefficient k_m is the number of free electrons per one metal atom. Unfortunately, we do not know this parameter; it can by no means be identified with the chemical valence of a given element (21, 22), for in the formation of a metallic bond between atoms, electrons may be adopted from inner shells (this adoption is usually called "hybridization" (23)). For example, in the case of alkali atoms in the crystalline state this effect gives rise to a 25–40% increase in the number of free electrons (as compared with the number of valence electrons) (23). For other metals estimates are difficult to make, since a given substance in different compounds has a different valence, and it is not known relative to which valence the hybridization factor is to be determined.

It seems that the constant k_m could be determined from electroconductivity, thermal conductivity, and other data, but the corresponding expressions always contain the effective electron mass, scattering cross section, and other parameters for which exact values are not now available (the situation is especially poor for liquid metals). We could, of course, determine k_m from Hall measurements (see first two lines of Table 1), but the Hall values are known for only a few metals, and for liquid metals the data are not available at all. Furthermore, comparison of the results of different authors (see Table 1) shows that the Hall k_m values suffer low accuracy. We have therefore calculated k_m from experimental values of σ and W, using formulae [21] and [22]. The last line of Table 1 shows that the values of k_m thus found agree with the Hall data within experimental error.

Table 2 lists the calculated results for liquid metals at the melting point T_m. For the sake of brevity, the table presents data for the 6th period of the Mendeleev table. The dependences of W, σ, and k_m on ρ_m for all metals are shown in Figs. 1–3 (54 metals altogether; experimental data are not available for the others). While choosing the values of k_m, we were guided by two requirements: first, k_m was chosen so that σ and W, as calculated by [21] and [22], would best agree with the experimental values σ_{exp} and W_{exp}; secondly, the values of k_m should vary smoothly both along the rows (periods) and columns (groups) of the Mendeleev table. The values of k_m thus obtained (see Fig. 1) were lower than the maximal valences for nearly all metals (except for the alkali metals), which seems to be quite reasonable. It can also be seen that along a period the values of k_m first rise to a certain maximum (the larger the period number, the higher the maximum) and then decrease.[5] We had to take $k_m = 3.0$, only for the lanthanides, Ce, Pr, Nd, and Gd, whereas for lanthanum $k_m = 3.5$. It seems that for these metals the true values of the density ρ at the melting point are lower than those listed in Table 2 (since the handbook (26) does not report these data, we took the values of ρ from ref. 27). Along a group (from top to bottom), the values of k_m either grow or remain constant (the latter being characteristic of semimetals and metals in the two neighbouring groups; see Fig. 1).

Consider first Table 2. It can easily be seen that for the first 11 metals the error in determining the work function $\delta_W = (W_{theor} - W_{exp})/W_{exp}$ and the error in determining the surface tension $\delta_\sigma = (\sigma_{theor} - \sigma_{exp})/\sigma_{exp}$ never exceed 10% (i.e. δ_W and δ_σ lie within the experimental error). Note that δ_W and δ_σ gradually increase with the element number, particularly in the case of δ_σ. For example, for Bi δ_W is as high as 58%, whereas δ_σ is much less and does not exceed, as a rule, 15% (only for mercury $\delta_\sigma = 34\%$). It is important, however, that the error in determining δ_σ is mainly determined by the inaccuracy of [21] for W. Indeed, if in the initial expression [20] the experimental value W_{exp} is substituted for W found by [21], we obtain, for mercury, $\sigma = 482$ erg/cm^2 which is only 3% less than $\sigma_{exp} = 497$ erg/cm^2. For platinum, a similar substitution reduces σ from 1985 to 1658 erg/cm^2, which is also much closer to σ_{exp} 1746 erg/cm^2 (the error = −5%). It seems that even when [21], the formula for the electron work function becomes invalid, [20], the formula for surface tension, still holds. This is probably due to the fact that [21] has an additional assumption that the electron gas is ideal, the assumption that was not used in the derivation of [20].

In the case of the metals in other periods, the scatter in δ_σ is much less than that in δ_W (see also Figs. 2 and 3). Only for 4 metals (Li, Ge, Zn, and Sb) $\delta_\sigma = 20-25\%$, for 8 metals (Be, Si, K, Ga, Ag, Pt, Mn, and Bi) $\delta_\sigma = 10-20\%$, and for the remaining 41 metals $\delta_\sigma < 10\%$. In other words, for the last group of metals the theoretical values and the experimental values agree to within experimental error. In Fig. 3 the scatter is much larger; only for 30 metals does the condition $\delta_W < 10\%$ hold true. It is remarkable, however, that the discrepancy observed is not of random character. The experimental values W_{exp} exceed the theoretical values for all the metals. This is, of course, true to within experimental accuracy (the highest positive value $\delta_W = 6.7\%$ is for hafnium, which can be attributed to a measurement error). In other words, there is no metal for which the maximal momentum p_e^{max} is less than the Fermi momentum $p_F = \hbar k_F$ (it should be stressed that failure to meet this condition spells disaster for the theory developed, since this would mean that every cell of the phase space contains more than two electrons, which, of course, contradicts Pauli's exclusion principle). Now for many metals $p_e^{max} > p_F$. Many of these metals belong to the right-hand subgroups (subgroups B) in the Mendeleev periodic table (in Fig. 1 these metals occupy five right-hand columns and in Fig. 3 they are ringed with a

[5] The other parameters, melting point, density (see Table 2), boiling point, etc., behave in a similar way.

* The values of T_m, ρ, σ_{exp}, and $(d\sigma/dT)_{exp}$ without an asterisk are taken from ref. 26 and those with an asterisk from ref. 27 (in both cases recommended values were employed).

† The values W_{exp} are taken from refs. 28, 29 (recommended values).

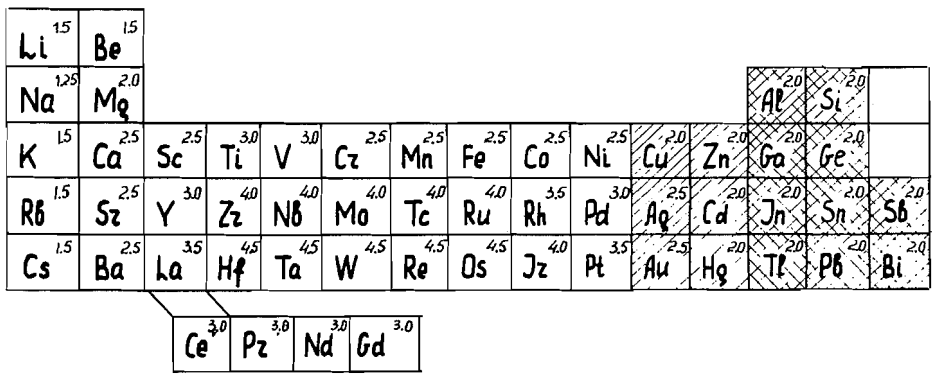

FIG. 1. The number of free electrons k_m per metal atom. The metals in the right-hand columns of the Mendeleev table (metals of subgroup B) are singly cross-hatched; semimetals are doubly cross-hatched.

dashed line). It is known that for at least some of these metals (viz., for mercury (30)) the Fermi surface is highly smeared; this precisely explains why $p_e^{max} > p_F$ for such metals.

Thus, for 30 out of 54 metals with available data, one can fit experimental values of σ and W by adjusting only one parameter, the number of free electrons k_m per atom. For the remaining 24 metals this is impossible, perhaps because the "imperfection" of the electron gas is not taken into account. The non-random character of the discrepancy is confirmed by the fact that the "abnormal" metals are grouped at the end of each period (particularly when they included all semimetals).

Differentiating expression [22] with respect to temperature T at $\epsilon_s = 1$, we obtain

$$[25]\quad \frac{d\sigma}{dT} = 388.5\ \tilde{\rho}_m^{3/2}\ \frac{3.655 + \tilde{\rho}_m^{1/3}}{(2.031 + \tilde{\rho}_m^{1/3})^3}\left[\frac{1}{k_m\rho}\frac{d(k_m\rho)}{dT}\right] \quad (\text{erg cm}^{-2}\ \text{K}^{-1})$$

Since the expression before the square brackets is always positive, the sign of $d\sigma/dT$ is determined by the sign of the derivative $d(k_m\rho)/dT$. And since in all the cases $d\rho/dT < 0$, $d\sigma/dT$ is also negative for k_m = constant, which is indeed the case. But numerical calculations by [25] under k_m = constant give values of $d\sigma/dT$ which are only 30–50% of the experimental values (see Table 2). We have to assume, therefore, that k_m also depends on temperature. Quantitative agreement with experiment may be obtained by putting

$$\frac{1}{k_m}\frac{dk_m}{dT} \simeq \frac{1}{\rho}\frac{d\rho}{dT}$$

Differentiating [21], the work function with respect to T, we find

$$[26]\quad \frac{1}{W}\frac{dW}{dT} = \frac{1}{3}\left[\frac{1}{k_m\rho}\frac{d(k_m\rho)}{dT}\right] \quad (\text{eV K}^{-1})$$

For most liquid metals $(1/\rho)\ (d\rho/dT)$ is of the order of 10^{-4}–10^{-5}, and for solid metals this quantity is about 10^{-5}–10^{-6}. Therefore, $(1/W)\ (dW/dT)$ is of the same order of magnitude, in excellent agreement with experiments (26, 31).

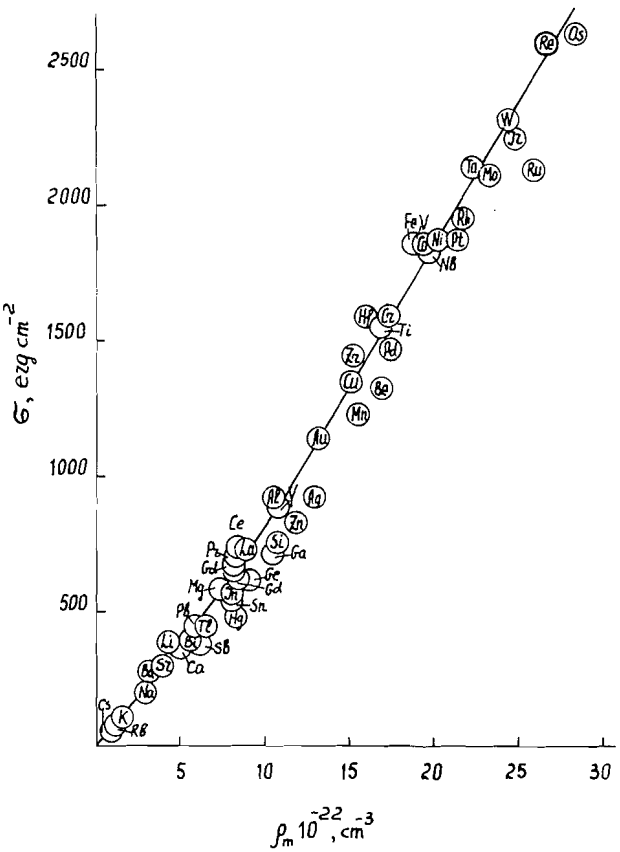

FIG. 2. The surface tension of liquid metals, σ, as a function of the electron density in the metal bulk, ρ_m. Experimental values of σ are taken from ref. 26.

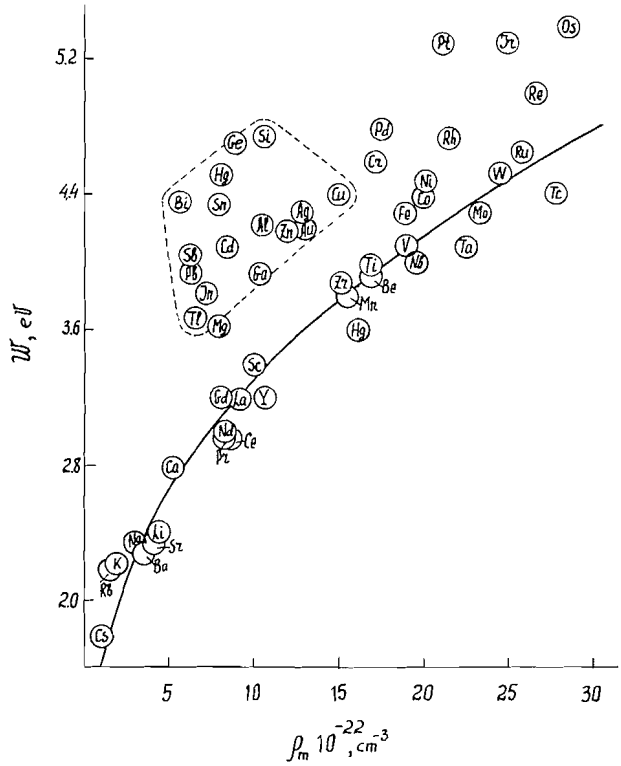

FIG. 3. The electron work function W as a function of the electron density in the metal bulk ρ_m. The metals of subgroup B are singly cross-hatched; semimetals are doubly cross-hatched. Experimental values of W are taken from ref. 28.

During melting, the density of a metal changes by several percent. It is a simple matter to calculate that in this case the change in the work function,

$$\Delta W \simeq \frac{W}{3}\frac{\Delta\rho}{\rho}$$

will be about 0.1 eV, which is also confirmed by experiments (for example, the experimental value of ΔW for copper is 0.13 eV (28)).

Since the derivation of the fundamental equations [20] and [21] does not require the metal to be in solid state or in liquid state, these formulae can be used for the calculation of σ and W both for liquid and solid metals. Furthermore, since the electron work function of a metal is practically the same in the liquid and the solid state, we may safely assume that the values of k_m obtained above for melts are very close to those for crystals. This opens promising potentials for quantitative calculations in the case of solid metals. It should be noted, however, that since the packing density of atoms on different crystal faces is different, the corresponding values of σ and W will also change.[6] This effect (which, of course, is absent in liquid metals) makes it possible to reconstruct, by the formulae derived above, the shape of the Fermi surface, using the values of W measured for different faces.

[6] When saying above that W does not change in going over from the liquid to solid state, we mean the value of W is averaged over all crystal faces. In an experiment, this averaging is attained by using polycrystalline samples.

Qualitative analysis of the properties of the electronic capacitor at the metal–electrolyte interface

Verification of the formulae derived above for the metal–vacuum interface has shown that they are quite reliable for developing a theory of the more complicated metal–electrolyte system. Now we turn to such a system, starting with the analysis of general properties of the dense part of EDL.

It was shown in refs. 32, 33 that for surface-inactive electrolytes the zero-charge potential (ZCP) and the behaviour of the integral capacity curves depend neither on the concentration of an electrolyte nor on its nature.

These facts can naturally be explained within the framework of the electronic capacitor model. Indeed, in dilute solutions there are thousands and even tens of thousands of solvent molecules per ion (for example, concentration 0.01 mol/dm^3 corresponds to 5000 water molecules per ion, and 0.001 mol/dm^3 to 50 000 water molecules per ion). Therefore, the electron work function for the metal – dilute solution interface at the ZCP practically does not differ from that for the metal – pure solvent interface. Hence in a dilute solution the properties of the electronic capacitor should not depend either on the concentration of dissolved ions or on their nature; this has been observed experimentally (but the situation may be quite different in very concentrated solutions).

The electrocapillary and charge curves, as well as the curves of the EDL dense part capacity versus the electrode potential, are always asymmetric about the zero-charge point; this fact is well known. The entropy of the EDL dense part is also asymmetric, its maximum being shifted to the negative potential range (relative to the ZCP) (34). Essentially, this asymmetry is observed for all electrodes and electrolytes.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

The inequality between the anodic and cathodic potential regions is, in fact, predetermined by the properties of the electronic capacitor. Indeed, any metal at the boundary with any solvent is always charged positively because the double layer is formed as a result of the outflow of electrons from the metal. When applying an additional positive potential to the electrode, we further increase the potential drop that already exists. On the contrary, when applying a negative potential, we reduce the drop or even change its sign. Since the electric field in the electronic capacitor is 10^8 V/cm and higher, i.e. it is very strong, any change in the field must lead to a non-linear response of the medium. In this situation it is surprising that the asymmetry observed is not as large as expected.

Special attention should be drawn to specific adsorption. This adsorption, by definition, is determined by specific (i.e. nonelectrostatic) forces. But electrostatic forces are involved, because they prevent positive cations from (and, conversely, promote negative anions in) approaching very closely the surface of the positively charged metal. As a result, most inorganic anions are adsorbed well on an electrode, whereas most cations either are not adsorbed at all or are adsorbed poorly. This fact is a manifestation of the asymmetry mentioned above.

Thus, the most general porperties and governing laws of the structure of the EDL dense part are explained easily and naturally within the framework of the electronic capacitor model.

Surface tension of mercury at the zero-charge point

Consider a system of two solvents (say, H_2O and S) in contact with a mercury electrode (the solvents are not in contact with each other). Suppose that each solvent is kept (with the aid of auxiliary electrodes and batteries) at the zero-charge potential, which is, of course, different for H_2O and S. Since the sum of all potential drops in the circuit $Me/H_2O/Hg/S/H_2O/Me$ is equal to the applied potential difference $V_{Hg}^{H_2O-S}$, we have

$$[27]\quad \psi_e^{Hg-H_2O} - \psi_e^{Hg-S} + \Delta\psi_{lq}^{H_2O-S} = -V_{Hg}^{H_2O-S}$$

where $\Delta\psi_{lq}^{H_2O-S}$ is the liquid potential drop at the H_2O-S interface, ψ_e^{Hg-S} is the electronic potential drop at the electrode–solvent interface, and $V_{Hg}^{H_2O-S}$ is the voltage drop measured by a voltmeter with an infinitely high input resistence. Apparently, this relation can be rewritten in the form

$$[28]\quad \Delta\psi_{e(Hg)}^{H_2O-S} = \psi_e^{Hg-H_2O} - \psi_e^{Hg-S} = -[\Delta\psi_{lq}^{H_2O-S} + V_{Hg}^{H_2O-S}] = -\Delta\psi_{Hg}^{H_2O-S}$$

Calculations by formula [22] have shown that for all solvents at the boundary with mercury the charge Q_e^+ is approximately the same, ~0.33 C m^{-2}. Thus, multiplying the two sides of [28] by $0.5Q_e^+ = 0.165$ C m^{-2} and using $\sigma = 0.5Q\psi$, we obtain

$$[29]\quad \Delta\sigma_{Hg}^{H_2O-S} = \sigma^{Hg-H_2O} - \sigma^{Hg-S} = -\frac{1}{2}Q_e^+\,\Delta\psi_{Hg}^{H_2O-S}$$

The potential difference $V_{Hg}^{H_2O-S}$ can easily be determined in experiment with a high accuracy and the liquid potential drop $\Delta\psi_{lq}^{H_2O-S}$ can be estimated from simple model considerations (35) (unfortunately, the accuracy of such estimates is rather low), thereby making possible a comparison of [29] with experiment.

Figure 4 shows the values of $\Delta\sigma_{Hg}^{H_2O-S}$ and $\Delta\psi_{Hg}^{H_2O-S}$ for 51 different solvents. It can be seen that all these values are located rather closely to a straight line through the origin. Calculation of $0.5Q_e^+$ from the slope of this straight line gives 0.18

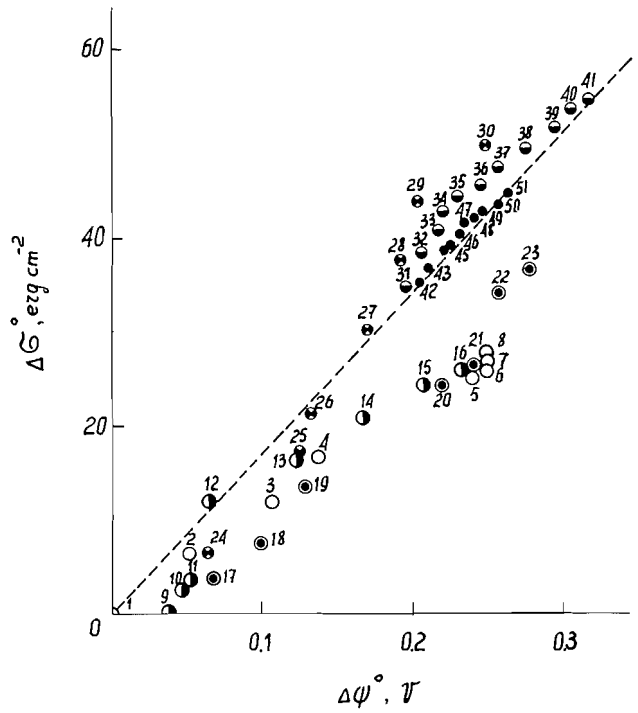

FIG. 4. The shift of the zero-charge potential $\Delta\psi_m^0 = \psi_m^0 - (\psi_m^0)_{H_2O}$ versus the change in surface tension $\Delta\sigma^0 = \sigma^0 - \sigma_{H_2O}^0$ for a mercury electrode at the interface with various solvents. Points *1–8*, saturated solution of NaCl in mixtures of water and ethanol (63); *9–16*, 0.1 *M* solution of HCCONa in mixtures of water and formic acid (64); *17–23*, 0.1 *M* LiCl in mixtures of water and acetone (46); *24–30*, 0.1 *M* LiCl in mixtures of water and diethylene glycol (50); *31–41*, 0.1 *M* LiCl in mixtures of formamide and dimethyl formamide (65); *42–51*, 0.1 *M* LiCl in mixtures of formamide and *N*-methyl formamide (66). The liquid potential drop was estimated from measurements in the following circuits: acetone–water Pt-$|H_2|HCl(H_2O)|KCl(H_2O)|HCl$(acetone + $H_2O)|H_2|$Pt; water – diethylene glycol Ag$|$AgCl$|$0.1 *N* LiCl$(H_2O)|KCl(H_2O)|$0.1 *N* LiCl(DEG + $H_2O)|$AgCl$|$Ag; formamide – dimethyl formamide Na(Hg)-$|NaCl_{sat}$(FA)$|NaCl_{sat}$(FA + DMF)$|$(Hg)Na (a similar circuit was used for studying the system formamide/*N*-methyl formamide).

C m^{-2}, which is very near the theoretical value 0.165 C m^{-2}. The scatter of experimental points may well be attributed to a low accuracy of determining the liquid potential drop.

Integral capacity of the electronic capacitor

By definition, the integral capacity of the electronic capacitor at the zero-charge point is $K_e^{m-s} = Q_e^+/\psi_e^{m-s}$. Substitution of ψ_e^{m-s} from [17] and Q_e^+ from [19] yields

$$[30]\quad K_e^{m-s} = \frac{Q_e^+}{\psi_e^{m-s}} = \frac{\epsilon_s}{4\pi R_s}$$

This formula includes the solvent dielectric permittivity which is to be determined. To find it, we note the time that the conduction electron stays outside the metal (i.e. in the solution) is $\sim 10^{-15}$ s.[7] This time is commensurable with the rotation period of optical electrons of solvent molecules, but is many orders less than the rotation period of the solvent molecule as a whole. Therefore, the solvent responds to an "exiting" electron only through the optical modes. In other words, $\epsilon_s = n_D^2$,

[7] The time of electron "escape" can be estimated by the relation $\tau = R_s/v_F$, where $v_F = P_F/m$ is the Fermi electron velocity.

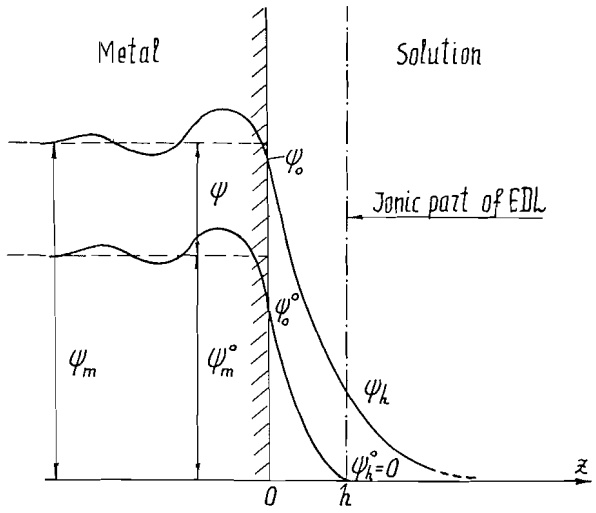

FIG. 5. Potential distribution in the electronic part of EDL for the electrode charge $Q_e \neq 0$.

where n_D is the refractive index. More accurate calculations for a point charge executing Brownian motion confirm this assumption (36).

If we use the tabular values of n_D and calculate K_e^{m-s} by formula [30], we see that it is several times less than the experimental value. However, this comes as no surprise as the measured capacity K_e and the capacity of the electronic capacitor K_e^{m-s} are different entities.

Let ψ_m^0 stand for the potential difference between the metal bulk and electrolyte bulk at the zero-charge point (see Fig. 5). Of course, this quantity cannot be measured directly in experiment; instead one usually measures the potential (at the zero-charge point) against a reference electrode. This potential, however, differs from ψ_m^0 only by a constant which is cancelled out in all further calculations. In what follows we shall use ψ_m^0, rather than the potential measured against a reference electrode.

Now let the charge Q_e be carried to the electrode. In this case its potential (measured against the electrolyte bulk) will be ψ_m, and the so-called total integral capacity of EDL takes the form

$$[31] \quad K_{m-s} = \frac{Q_e}{\psi_m - \psi_m^0}$$

To infer from this quantity the integral capacity of the density part of EDL, we note (see Fig. 5) that

$$[32] \quad \psi_m - \psi_m^0 = [(\psi_m - \psi_0) - (\psi_m^0 - \psi_0^0)] + [(\psi_0 - \psi_h) - (\psi_0^0 - \psi_h^0)] + (\psi_h - \psi_h^0)$$

We have seen above that for $Q_e = 0$, the potential difference $\psi_m^0 - \psi_0^0$ is very low. Since further consideration will be restricted to a potential region very near the zero-charge point, we shall assume, as before, $\psi_m \simeq \psi_0$. Thus,

$$[33] \quad \psi_m - \psi_m^0 = [(\psi_m - \psi_h) - (\psi_m^0 - \psi_h^0)] + (\psi_h - \psi_h^0)$$

Dividing this equality by Q_e and putting $K_e = Q_e/[(\psi_m - \psi_h) - (\psi_m^0 - \psi_h^0)]$ and $K_i = Q_e/(\psi_h - \psi_h^0)$,[8] we arrive at the familiar relation $K_{m-s}^{-1} = K_e^{-1} + K_i^{-1}$. Since $\psi_h^0 = 0$, we finally have

$$[34] \quad K_e = \frac{Q_e}{(\psi_m - \psi_h) - \psi_m^0}$$

[8] K_i is the integral capacity of the diffuse part of EDL.

Apparently, this formula differs significantly from [30]. To distinguish between these two quantities, we shall call K_e^{m-s} the capacity of the electronic capacitor and K_e the capacity of the dense part of EDL.

To calculate K_e, we shall employ the same electron density distribution $\rho_e(z)$ as for $Q_e = 0$

$$[35] \quad \rho_e(z) = \begin{cases} \rho_e^s(z) = \rho_0 \exp(-z/R_s), & z \geq 0 \\ \rho_e^m(z) = \rho_m - (\rho_m - \rho_0) \exp(z/R_m) \times \dfrac{\cos[\alpha(z/R_m) + \delta]}{\cos \delta}, & z \leq 0 \end{cases}$$

As before, the constants ρ_0 and δ of the distribution are found from the condition that the potential and its first derivative are continuous at $z = 0$ (see [6], [7]) and also from the condition that the number of particles is conserved, which in this case is written in the form,

$$[36] \quad \frac{Q_e}{e} = \int_0^\infty \rho_e^s(z)\, dz - \int_{-\infty}^0 [\rho_m - \rho_e^m(z)]\, dz$$

(the non-zero electrode charge Q_e is assumed to be neutralized by the charge of the diffuse part of EDL, Q_i). Substitution of [35] into [6], [7], and [36] yields

$$[37] \quad \rho_0 = \rho_m \frac{2\beta + (1 + \alpha^2)q}{\alpha^2 + (1 + \beta)^2}$$

$$[38] \quad \alpha \operatorname{tg} \delta = \frac{(1 + \alpha^2 - \beta^2) - (1 + \alpha^2)(1 + \beta)q}{(1 + \alpha^2 - \beta^2) - (1 + \alpha^2)q}$$

where the dimensionless charge is

$$[39] \quad q = Q_e/e\rho_m R_s$$

Defining the charge densities $q_m(z)$ and $q_s(z)$ by relations [11] and substituting them into Poisson's equation [12], we find the potential distribution

$$\psi_s(z) = \psi_h - \frac{4\pi Q_e}{\epsilon_s} z + \frac{4\pi e \rho_0 R_s^2}{\epsilon_s} \exp(-z/R_s), \quad z > 0$$

$$[40] \quad \psi_m(z) = \psi_m - \frac{4\pi e(\rho_m - \rho_0)R_m^2}{\epsilon_m \cos \delta} \exp(z/R_m) \times \left\{ \frac{2\alpha}{(1 + \alpha^2)^2} \sin\left[\alpha \frac{z}{R_m} + \delta\right] + \frac{1 - \alpha^2}{(1 + \alpha^2)^2} \cos\left[\alpha \frac{z}{R_m} + \delta\right] \right\}, \quad z < 0$$

The constant ψ_m appearing in this expression is determined from the condition that the potential is continuous at $z = 0$. Disregarding the potential drop inside the metal (i.e. the second term in the expression for $\psi_m(z)$, we obtain

$$[41] \quad \psi_m - \psi_h = \frac{4\pi e \rho_m R_s^2}{\epsilon_s} \frac{2\beta + (1 + \alpha^2)q}{\alpha^2 + (1 + \beta)^2}$$

In general, the work function $W = W_0 + e\psi$ where W_0 is the work function at the zero-charge point and $\psi = \psi_m - \psi_m^0 - \psi_h$. Thus,

$$[42] \quad R_s = R_{s0} \Big/ \sqrt{1 + \frac{e\psi}{W_0}}; \quad \beta = \beta_0 \sqrt{1 + \frac{e\psi}{W_0}}$$

On the other hand, since $\psi_h = 0$ at $Q_e = 0$,

$$\psi_m^0 = \frac{4\pi e \rho_m R_{s0}^2}{\epsilon_s} \frac{2\beta_0}{\alpha^2 + (1 + \beta_0)^2}$$

*This cell represents $\Delta\psi_{Me}^{V-H_2O} = \psi_e^{m-v} - \psi_e^{m-H_2O}$.

†This cell represents $\Delta\psi_{Q_e=0(H_2O)}^{Hg-Ga} = \psi_{e(Q_e=0)}^{Ga-H_2O} - \psi_{e(Q_e=0)}^{Hg-H_2O}$.

Subtracting this expression from [41] and taking into account [42], we find

$$[43]\quad \psi = \psi_m - \psi_m^0 - \psi_h = \frac{8\pi e\rho_m R_{s0} R_m}{\epsilon_s}\left(\frac{1}{Z} - \frac{1}{Z_0}\right) + \frac{4\pi R_{s0}}{\epsilon_s}\frac{1+\alpha^2}{Z} Q_c$$

where we have put, for brevity,

$$[44]\quad Z = \sqrt{1 + \frac{e\psi}{W_0}\left[\alpha^2 + \left(1 + \beta_0\sqrt{1 + \frac{e\psi}{W_0}}\right)^2\right]}$$

$$Z_0 = \alpha^2 + (1 + \beta_0)^2$$

Solving [43] for Q_c, dividing the two sides of the equality by ψ, and using $K_c = Q_c/\psi$, we obtain the final expression for the integral capacity of the electronic part of EDL

$$[45]\quad K_c = \frac{\epsilon_s}{4\pi R_{s0}}\frac{Z}{1+\alpha^2} + \frac{2e\rho_m R_m}{(1+\alpha^2)Z_0}\frac{Z - Z_0}{\psi}$$

At the zero-charge point, where $\psi = 0$ and $Z - Z_0 = 0$, this expression is reduced to

$$[46]\quad K_e^0 = \frac{\epsilon_s}{4\pi R_{s0}}\frac{Z_0}{1+\alpha^2} + \frac{e^2\rho_m R_m}{(1+\alpha^2)W_0}\left[1 + \frac{2\beta_0(1+\beta_0)}{Z_0}\right]$$

Note that the second term in [45] is always positive, since ψ and $Z - Z_0$ change sign simultaneously and $Z \geq Z_0$ for $\psi \geq 0$.

Interface between mercury and non-aqueous electrolyte solution

Expressions [45] and [46] for the capacity of the dense part of EDL include three parameters: ρ_m, ϵ_s, and W^{m-s}. Two of them, ρ_m and $\epsilon_s = n_D^2$, describe the bulk properties of a metal and solution; the third parameter, the electron work function W^{m-s} for a metal–solution interface, is determined by the interaction between the two media and is therefore different for different metal–solution couples. For liquid electrodes (mercury, gallium), W^{m-s} can be found from surface tension data. To this end, we modify formula [20] for σ. Substituting $\epsilon_s = n_D^2$ and taking into account that $R_s = \pi a_0/\alpha\gamma$, $\beta = 0.5\gamma$, where $\gamma^2 = W^{m-s}/W^{m-v}$, and the electron work function for a metal– vacuum interface $W^{m-v} = e^2\alpha^2/2\pi^2 a_0 = 1.256\,\tilde{\rho}_m^{1/3}$ eV (see [21]), we obtain

$$[47]\quad \sigma^{m-s} = \frac{2e^2\alpha^3\rho_m}{3\pi n_D^2\gamma[\alpha^2 + (1+\beta)^2]^2} = \frac{465.9\,\tilde{\rho}_m^{3/2}}{n_D^2\gamma[\tilde{\rho}_m^{1/3} + 0.902(1 + 0.5\gamma)^2]^2}\ \text{erg/cm}^2$$

Assuming n_D^2 and σ^{m-s} known from experiment and substituting $\tilde{\rho}_m = 8.13$ for mercury and 10.5 for gallium, we can find the only unknown quantity W^{m-s}. The results of such calculations for several solvents are listed in Table 3, which also presents the values of K_e^{theor} as calculated by formula [46] with W^{m-s} found from [47]. It can be seen that in most cases calculation results are rather close to experimental values K_e^{exp}. Only for the system Ga–H_2O does the difference $K_e^{exp} - K_e^{theor}$ significantly exceed the experimental error; in the other cases it is close to this error. Here we should point out two facts. First, the values of K_e^{exp} for a mercury – organic solvent interface were determined from the total capacity plots of the respective papers. Such a method of finding K_e suffers, of course, from low accuracy. It is not expected that the true values of K_e differ by more than several microfarads from the values listed in Table 3. Secondly, a large error for gallium seems to indicate that in this case the capacitor is formed via a special mechanism because the experimental value of K_e is unusually high for this metal. At the same time, mercury (as far as capacity is concerned) is a metal in which the capacitor is formed via the mechanism mentioned in the preceding section. Therefore, in the case of mercury all theoretical values of K_e are rather close to experimental ones.

Figure 6 shows the integral capacity K_e as a function of the electrode charge Q_e for the mercury–water system. The theoretical curve was calculated by formula [45] with the value $W^{Hg-H_2O} = 2.61$ eV found from surface tension data. The theory does not, of course, reflect all the features of experimental curves, especially for a large negative electrode charge. This is probably due to the fact that in the calculations we have not taken into account the dependence of the dielectric permittivity $\epsilon_s = n_D^2$ on the electric field in the outer plate of the electronic capacitor. Since this field can be as high as 10^8–10^9 V/cm, it can significantly affect n_D (interestingly, the discrepancy between theory and experiment is observed in the cathodic region where the field grows; in the anodic region the outer plate is "pulled" into the metal (see below) and the field decreases).

There is another way of experimentally verifying the theory

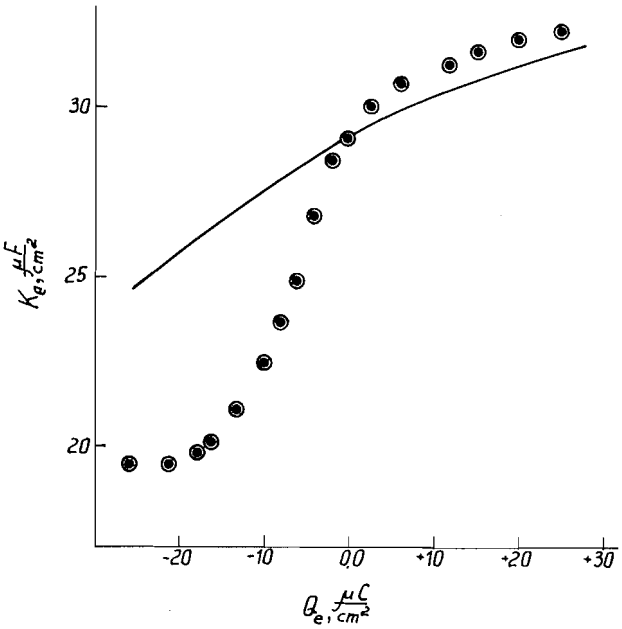

FIG. 6. Dependence of the integral capacity K_e on the electrode charge Q_e.

by the formulae derived above. Indeed, using formula [17], which by analogy with [47] can be written in the form

$$[48] \quad \psi_e^{m-s} = \frac{4e\alpha^4}{3\pi^2 a_0 n_D^2 \gamma[\alpha^2 + (1+\beta)^2]} = \frac{4.075\tilde{\rho}_m^{2/3}}{n_D^2\gamma[\tilde{\rho}_m^{1/3} + 0.902(1+0.5\gamma)^2]} \text{ (eV)}$$

we can calculate the difference of electrostatic potentials ψ_e^{m-s} between a metal and a solvent, and also between the same metal and water ($\psi_e^{m-H_2O}$). This permits calculation of the zero-charge points of mercury in a given solvent and in water $\Delta\psi_{Hg}^{H_2O-S} = \psi_e^{Hg-H_2O} - \psi_e^{Hg-S}$ (the left-hand side of formula [28]). On the other hand, the right-hand side of this formula can be calculated from experimental data. The corresponding results are listed in Table 3. It can be seen that the theory agrees satisfactorily with experiment (it should be noted here that the accuracy of estimating the right-hand side of [28] is very low because the exact values of the liquid potential drop are not presently available).

Metal–aqueous electrolyte solution interface

In the preceding section we have considered liquid electrodes, in which case surface tension data could be used for determining the electron work function. Such an approach is not applicable to crystalline electrodes, for in this case σ^{m-s} cannot be measured. It remains therefore to calculate W^{m-s} from the zero-charge potential. Consider, as in deriving relation [28], a closed electrical circuit which does not contain two solvents, but two metals in contact with the same solvent. Let one metal be platinum (a hydrogen electrode) and the other (Me) be chosen arbitrarily. We also assume that Me is kept at the zero-charge potential by a battery for which one terminal is connected to the hydrogen electrode and the other to the metal Me. Obviously, the sum of all potential drops in the circuit $Me/H_2O/Pt$ is equal to the applied voltage

$$\psi_e^{m-H_2O} + \psi_e^{H_2O-Pt} + \psi_e^{Pt-v} + \psi_e^{v-m} = -V^{Pt-m}$$

Since $\psi_e^{v-m} = -\psi_e^{m-v}$, etc., this expression can be rewritten in the form

$$[49] \quad \psi_e^{m-H_2O} = \psi_e^{m-v} + V^{m-Pt} - C$$

where the constant $C = \psi_e^{Pt-v} - \psi_e^{Pt-H_2O}$ characterizing the hydrogen electrode has the same value for all metals. It can be found from the data for liquid electrodes because in this case all the quantities appearing in [49] are known (see Table 3). Calculation yields $C = 0.31$ V for mercury and 0.38 V for gallium. Allowing for this discrepancy, we have taken the value $C = 0.34$, so that [49] is reduced to

$$[50] \quad \psi_e^{m-H_2O} = \psi_e^{m-v} + V^{m-Pt} - 0.34 \text{ (V)}$$

Since in this formula V^{m-Pt} can be determined experimentally and ψ_e^{m-v} can be calculated by [23], $\psi_e^{m-H_2O}$ is also known. Substituting the value thus obtained into the left-hand side of [48], we can easily find the work function W^{m-H_2O}. The corresponding values are listed in Table 4 which also presents the capacity at the zero-charge point K_e^0 as calculated using the values from ref. 46. It can be seen that for most metals the calculated values are rather close to the experimental ones. Only for four "anomalous" metals (In, Cd, Zn, and Ga) does the discrepancy significantly exceed the experimental error; for all the other metals it falls inside the accuracy limits.

Table 4 also lists the difference between surface tensions at the interface with vacuum and water, $\Delta\sigma$, as calculated by formulae [22] and [47]. The table shows that for almost all metals the theoretical values of $\Delta\sigma$ lie in the interval from 50 erg/cm^2 (mercury) to 165 erg/cm^2 (gallium). Only for four metals (Au, Cu, Rh, and Ir) the values of $\Delta\sigma$ do not fall into this interval. This is probably due to an error in measuring the zero-charge potential V^{Me-Pt}. Indeed, if we place the experimental values of V^{Me-Pt} in the corresponding cells of Mendeleev's table, we observe a distinct correlation. The only exceptions are Cu, Rh, and Au. (The situation is uncertain for Ir because it is located at the very end of the "filled" cells, so that the "correct" V^{Ir-Pt} value cannot be determined by interpolation.) Table 4 also lists $\psi_e^{m-H_2O}$, K_e^0, etc. calculated for these metals from the most probable values of V^{Me-Pt} obtained by interpolation. It can be seen that in this case $\Delta\sigma$ does not exhibit negative values.

To make a concluding remark, it can be seen from Table 2 and Figs. 2 and 3 that the theory developed in this paper is rather accurate only for metals in the left-hand subgroups of Mendeleev's table; for metals in the right-hand subgroups and especially for semi-metals theoretical errors increase significantly. However, for the metal–solution interface, comparison with experiment is performed only for metals in the right-hand subgroups and semi-metals because experimental data are now available only for these elements. The situation is also aggravated by the fact that most of these data are obtained in aqueous solutions, but water is known to be an anomalous solvent. It would be reasonable in this situation to deal with "normal" metals in the left-hand subgroups and with "normal" solvents without hydrogen bonds. Unfortunately, as we have already pointed out, such data are not available in the literature.

Electrocapillary curve

As was shown above, the surface tension of a metal at the zero-charge point, σ^0, is equal to the electrostatic energy of the electronic capacitor $1/2\, Q_e^+ \psi_e^{m-s}$. Therefore, the change in surface tension $\Delta\sigma = \sigma - \sigma^0$ caused by an external potential

difference should also be identified with change in the electronic capacitor electrostatic energy. It is known from electrostatics that the elementary work done during charging a capacitor is $dA = Q d\psi$, where Q is the capacitor charge. Since in our case an external energy source (battery) performs work *over* a system, $d\sigma = -dA = -Q_e d\psi = -K_e \psi d\psi$, where $K_e = Q_e/\psi$ is the electronic capacitor integral capacity defined by [45]. Expressing the latter as a power series in $e\psi/W_0$, we obtain

$$[51]\quad \Delta\sigma = -\int_0^{\psi}\left[K_c^0 + K_c^1\frac{e\psi}{W_0} + \ldots\right]\psi d\psi$$

$$= -\frac{1}{2}K_c^0\psi^2 - \frac{1}{3}K_c^1\frac{e\psi}{W_0}\psi^2 - \ldots = -\frac{1}{2}\chi K_c^0\psi^2$$

where the asymmetry coefficient

$$[52]\quad \chi = 1 + \frac{1}{6}\frac{K_c^1}{K_c^0}\frac{e\psi}{W_0} + \ldots$$

Here K_c^0 is given by relation [46] and

$$[53]\quad K_c^1 \simeq \frac{\epsilon_s}{8\pi R_s}\frac{\alpha^2 + (1+\beta_0)^2 + 2\beta_0(1+\beta_0)}{1+\alpha^2}$$

Since the asymmetry coefficient $\chi > 1$ in the anodic region ($\psi > 0$) and $\chi < 1$ in the cathodic region ($\psi < 0$), the electrocapillary curve should be steeper in the anodic region than in the cathodic region; this is indeed observed experimentally (see Fig. 7).

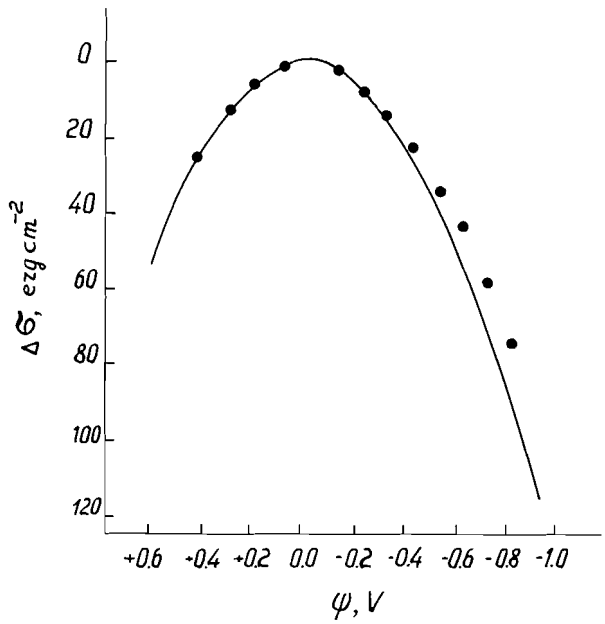

FIG. 7. Dependence of $\Delta\sigma$ on ψ for the system Hg – 1 N aqueous solution of H_2SO_4 + 0.1 N H_2SO_4 (68). Solid curve, theory; points, experiment.

The outer plate of an electronic capacitor

In conclusion, we should like to make several remarks which, in our opinion, could elucidate the physical picture of the phenomenon.

The electron density distribution in the outer plate of the electronic capacitor is described by a very simple formula $\rho_0(z) = \rho_0 \exp(-z/R_s)$ (see [3]). Since for all metals and solvents the value of R_s is very close to 1 Å, all electrons of the outer plate would seem to be localized also in a layer 1 Å thick. In practice, however, they penetrate into the solution to a depth about 10 times larger. Indeed, R_s does not determine the absolute thickness of the outer plate, but only that distance at which the electron density drops "e" times. For most metals, the electron density at the interface with a solution $\rho_0 \simeq 2 \times 10^{22}$ cm^{-3}, which amounts to the rather large value of 40 mol/dm^3. Therefore, at a distance $z = 5$ Å from the metal surface the electron density drops only to 0.8 mol/dm^3, and becomes equal to 0.01 mol/dm^3, i.e. really low, only at a distance of 10 Å. It is a simple matter to estimate that in a 10 Å boundary layer there are, on the average, 25 water molecules per electron. When we

For personal use only.

go over to the far cathodic region the thickness of the outer plate of the electronic capacitor increases by ~20%, and in the far anodic region it decreases by ~10% (see above).

Variation of the electrode potential gives rise to a change not only in R_s but also in ρ_0. Simple estimates show that for the electrode charge $Q_e = 0.2-0.4$ C/m^2, ρ_0 vanishes, and the outer plate of the electronic capacitor disappears (electrons are completely "extracted" from the plate). On the contrary, similar estimates demonstrate that for $Q_e = -(0.2 - 0.3)$ C/m^2, the charge of the positive plate Q_e^+ vanishes.

An analysis of experimental data on the capacity of EDL at the ZCP shows that not only anions, but cations as well, can almost reach the metal surface. Since the radius of most inorganic ions is of the order of 1–2 Å, they can, apparently, penetrate quite easily into the outer plate of the electronic capacitor. This means that there is a transitional region separating the purely ionic part from the purely electronic part, the electrons and ions being present simultaneously inside this region. If the solution concentration is low and the Debye radius is much larger than the thickness of the transitional region, we may consider this region as an infinitely thin (as compared with the Debye radius) layer, characterized by an effective ψ_1-potential, and describe the ionic part of EDL located behind the transitional region (i.e. for $z > h$) by the Gouy–Chapman equations. But as the concentration increases, the situation changes, and a large part of the ionic double layer appears to lie inside the outer plate of the electronic capacitor even for $C \gtrsim 0.5$ mol/dm^3. If this is taken into account, the theory of the ionic part of EDL in concentrated solutions should be revised considerably.

Not only electrolyte ions, but solvent neutral molecules as well penetrate into the outer plate of the electronic capacitor where the electric field near the metal surface may be as high as 10^8-10^9 V/cm. Such a strong field can result not only in the deformation of solvent molecules (which may affect the catalytic activity of a given metal), but also in their decomposition into ions. For example, it was observed (61) that an almost dense monolayer of OH^- ions is formed on the surface of colloidal gold particles in water. In other work (62), this effect was interpreted as very strong (with an energy of about $20kT$ per molecule) adsorption of hydroxyl on the gold surface. It is very probable, however, that in this case we do not deal with ordinary adsorption, but with the decomposition of water molecules into H^+ and OH^- under the metal electric field.

Finally, while penetrating into water, metal electrons would seem to react immediately with it, thereby producing neutral hydrogen. Since the number of electrons in the outer plate of the electronic capacitor is very large, the reaction should proceed rather intensively. This is not the case, however. The reason is very simple; the energy of the electron in a hydrogen atom is much higher than the Fermi energy, so that such a reaction cannot take place. Thus, there is no contradiction in what has just been said.

The synthesis of 3,3-dimethyltricyclo[6.3.0.0^{1,5}]undecan-4-one via β-enolate rearrangement.[1] A new approach to the pentalenene ring system

JEFFREY L. JURLINA,[2] HEMANT A. PATEL, AND J. B. STOTHERS
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received December 21, 1983

JEFFREY L. JURLINA, HEMANT A. PATEL, and J. B. STOTHERS. Can. J. Chem. **62**, 1159 (1984).

The preparation of 3,3-dimethyltricyclo[6.3.0.0^{1,5}]undecan-4-one from 9,9-dimethyltricyclo[5.3.1.0^{1,5}]undecan-8-one by β-enolate rearrangement is described. The required [5.3.1.0^{1,5}]ketone was obtained in six steps from tricyclo[5.2.1.0^{1,5}]-dec-8-ene. This sequence provides a new entry into the tricyclo[6.3.0.0^{1,5}]undecane ring system which is characteristic of a number of recently encountered naturally occurring terpenes. The ^{13}C data for several of these tricyclic derivatives are presented.

JEFFREY L. JURLINA, HEMANT A. PATEL et J. B. STOTHERS. Can. J. Chem. **62**, 1159 (1984).

On décrit la préparation de la diméthyl-3,3 tricyclo[6.3.0.0^{1,5}]undécanone-4 via une transposition β-énolique de la diméthyl-9,9 tricyclo[5.3.1.0^{1,5}]undécanone-8. On a obtenu la cétone [5.3.1.0^{1,5}] requise en six étapes à partir du tricyclo[5.2.1.0^{1,5}]-décène-8. Cette série de réactions fournit une nouvelle voie d'accès au système tricyclo[6.3.0.0^{1,5}]undécane qui est caractéristique d'une certain nombre de terpènes naturels rencontrés récemment. On rapporte des données de rmn ^{13}C pour plusieurs de ces dérivés tricycliques.

[Traduit par le journal]

Over the past decade, several naturally occurring terpenes containing the tricyclo[6.3.0.0^{1,5}]undecane ring system have been described (1). Representative examples having this unusual bridged spirane moiety include pentalenene (**1**) (2), isocomene (**2**) (3), silphinene (**3**) (4), and structure **4**, incorrectly assigned to senoxydene (5). It has been established that **1** is the parent hydrocarbon of the pentalenolactone family of antibiotics (6). The discovery of these compounds has awakened interest in synthetic approaches to various members of the series and several total syntheses of **2** have been described (1),

6

while two methods for each of **1** (2, 7) and **3** (7, 8) have been reported. It may be noted that before the discovery of these natural products the initial synthesis of this ring system was realized in the course of a study directed toward the isomeric [5.2.2.0^{1,6}] system (9). Our interest in the generation of interesting, less accessible polycyclic carbon skeletons by homoenolate rearrangement (10) led us to examine possible routes to the [6.3.0.0^{1,5}] system. We wish to report the preparation of 3,3-dimethyltricyclo[6.3.0.0^{1,5}]undecan-4-one (**5**) in good yield by homoenolization of 9,9-dimethyltricyclo[5.3.1.0^{1,5}]-undecan-8-one (**6**).

Ketone **6** was prepared from the known tricyclic olefin **7** (12) as outlined in Scheme 1, utilizing ring expansion via ketonization of a cyclopropoxide analog (11). Hydroboration of **7** with 9-BBN/THF furnished a 85:15 mixture of alcohols **8** and **9** which were separated by flash chromatography (13). Oxidation of **8** using Collins reagent (14) afforded **10** in 86% yield which, upon treatment with lithium diisopropylamide at −78°C followed by reaction with trimethylsilyl chloride and triethylamine, gave silyl enol ether **11** in 95% yield. Cyclopropanation of **11** using a zinc−silver couple and CH_2I_2 provided the tetracyclic ether **12**. On the basic of our earlier results for the homoketonization of polycyclic cyclopropoxides (10, 11), we anticipated that base-catalyzed cleavage of **12** at low temperature should favour ring expansion to the desired ketone **13**. In the event, treatment of **12** with NaOH−MeOH at 0°C afforded a single ketone lacking methyl absorption in both its ^{1}H and ^{13}Cmr spectra, consistent with expectations; precise mass measurement showed the molecular formula to be $C_{11}H_{16}O$. Treatment of **13** with $NaNH_2$−Et_2O−MeI (15) furnished the desired dimethylated analog **6**.

It can be mentioned that the ring expansion of **10** to **13** is exactly that required to improve the synthetic sequence leading to cedrol and cedrene described by Breitholle and Fallis (16). In fact these authors stated that a better synthesis would be realized if "the carbon bearing oxygen is locked in position in the starting ketone and final product", which is the case in the conversion of **10** → **13**. Although they noted that a closely related ring expansion using ferric chloride in the cleavage of the analog of **12** could be applicable, the required analog was not synthesized to investigate this possibility.

For the series **6**−**13**, ^{13}Cmr spectra were recorded to aid their characterization and these data are collected in Table 1. The assignments followed from the trends observed throughout the

[1]Part 109 in the series "^{13}Cmr studies"; for Part 108 see ref. 25.

[a]In ppm from internal TMS in $CDCl_3$ solutions. Assignments for similar values in parentheses may be reversed.
[b]Assignments obtained from 2D INADEQUATE spectra.

series taking into account the expected effects of the substituents and by comparison with the results for **6** and the 9,9-dimethyl derivative of **10**, available from an earlier study (17), assignments for the latter having been unequivocally established from two-dimensional, double quantum coherence spectra, i.e. 2D-INADEQUATE experiments (18).

With **6** in hand, attention could be turned to its behavior under homoenolization conditions. By analogy with our earlier findings for the model [3.2.1] system (19), we could anticipate β-proton abstraction to occur at either, or both, C-6 and -11, potentially resulting in the formation of β-enolates **14** and **15**, respectively. Subsequent cleavage of these enolates via mode b (Scheme 2) will generate the rearranged ketones **16** and **5**, respectively. Treatment of **6** with *t*-BuO^-/*t*-BuOH at 185°C for extended reaction times gave, upon isolation with ether extraction, a neutral fraction in 80% yield, consisting of a 60:40 mixture of two ketones which were separable by flash chromatography. The minor component was found to be starting material **6**, which was recycled to produce more of the product mixture. The major product having the molecular formula $C_{13}H_{20}O$, as shown by precise mass measurement, is isomeric with **6** but contains a five-membered ring ketone according to its carbonyl absorption (1730 cm^{-1} ($CHCl_3$), δ_C 225.9), distinctly different from that for **6** (1692 cm^{-1}, 219.7). Thus, the product is **5**, arising by rearrangement after proton abstraction from C-6 in **6** to form **15** or an equivalent β-enolate. The ^{1}Hmr spectrum contained two methyl singlets, δ 1.045 and 1.105, two one-proton multiplets, δ 2.405 and 2.155, and complex absorptions, δ 1.24–1.95. As further proof of identity, $^1H/^2H$ exchange under mild conditions was examined. The rearranged ketone was stirred at room temperature in the presence of MeO^-/MeOD for 2.5 h and in the ^{1}Hmr spectrum of the recovered material **5**-d_1 (93% yield) the lowest field multiplet was missing, indicating essentially complete deuteration of the α-bridgehead. It may be noted that no exchange occurs in **6** under these conditions and none would be expected for **16**. Additional confirmation of this structural assignment was obtained from the ^{13}Cmr spectrum of a 1:1 mixture of **5** and **5**-d_1,

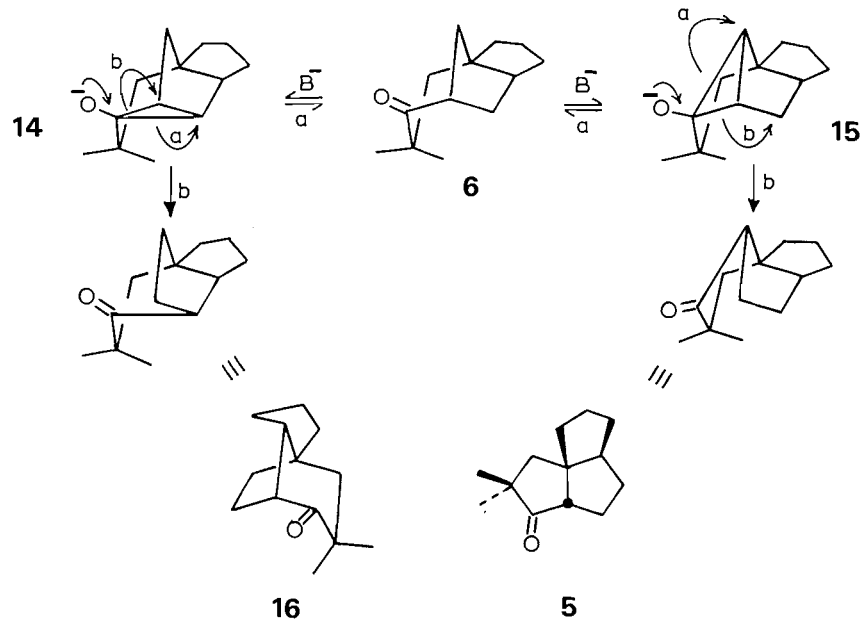

SCHEME 2

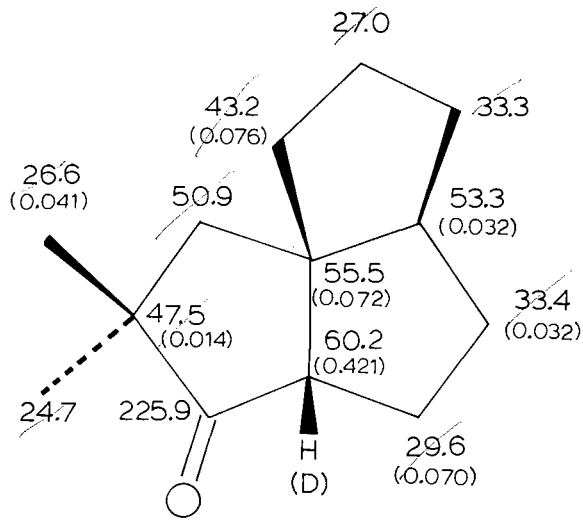

FIG. 1. ^{13}C shielding data for **5** and **5**-d_1 in $CDCl_3$ solution; values in parentheses are the ^2H-induced isotope shifts >0.012 ppm.

the data for which are shown in Fig. 1. Initially the assignments for **5** were made by comparisons with the data for some simpler [3.3.0] analogs (20) and were confirmed by the observed two- and three-bond, ^2H-induced isotope shifts for the **5**/**5**-d_1 mixture.

As expected, C-5 bearing deuterium appeared as a 1:1:1 triplet (J_{CD} = 20.2 Hz) with an α-isotope shift of 0.421 ppm. Of particular interest is the fact that the quaternary carbon at δ_C 55.5 and the methylene carbons at δ_C 29.6 and 43.2 exhibit isotope shifts of ~70 ppb (0.070 ppm), entirely consistent with expectations for structure **5**. The relatively large isotope shift exhibited by the second methylene carbon (δ 43.2), three bonds removed from the deuterium substituent, is indicative of a *syn*-periplanar orientation for these vicinal nuclei (17). The isotope shifted component is a poorly resolved triplet, J_{CD} ~ 0.7 Hz, confirming their vicinal relationship (17).

With structure **5** firmly established, we have shown that this synthetic sequence provides a new entry into the [6.3.0.$0^{1,5}$] ring system having the same stereochemistry as that of the naturally occurring species. The required configuration at C-1 and -8 is present from the outset and the stereochemistry of the rearrangement is constrained to give the correct configuration at the third chiral centre, C-5, because the alternative is too strained. The alternative would, in effect, be a substituted *trans* [3.3.0] system which is known to be disfavored by 6 kcal/mol in the parent bicyclo[3.3.0]octanes (21). Thus, an appropriately substituted analog of **6** could serve as the precursor for the generation of pentalenene (**1**) by β-enolate rearrangement. Studies directed toward this target, as well as others in the same family, are in progress and will be reported in due course.

Experimental

Melting points and boiling points are uncorrected. Thin layer chromatography (tlc) was done on Kiesel gel 60 F_{254} plates and flash chromatography (FC) columns were prepared as described in the literature (13). Tetrahydrofuran (THF) and ether were distilled from Na/benzophenone just before use. Pyridine, *tert*-butyl alcohol, diisopropylamine, and triethylamine were distilled from CaH_2 and stored over 4A molecular sieves. The following compounds were prepared by known methods and gave satisfactory physical and spectral data: pent-4-en-1-ol (22), pent-4-enylcyclopentadienes (12), and **7** (12).

Infrared spectra were recorded with a Beckman 4250 spectrophotometer. Mass spectra were obtained on a Varian MAT-311A system at 70 eV (direct inlet). Routine ^1Hmr spectra were recorded on a Varian T-60 instument, while data for pure samples were obtained with a Varian XL-200 spectrometer.The latter instrument was used to record the ^{13}C spectra (50.3 MHz) and comparison of the fully decoupled spectra with those obtained with either the APT (23) or INEPT (24) sequences served to identify the methyl, methylene, methine, and quaternary signals. The 2D INADEQUATE spectra (18) were obtained with the CCC2D pulse sequence of the XL software using a 2048 × 128 data point matrix transforming 2048 and 512 points respectively, with 2000 (**6**) and 2500 (9,9-Me_2-**10**) kHz sweep widths in both domains. The ^{13}C data are collected in Table 1. The spectrum for the mixture of **5**/**5**-d_1 was obtained using a **5** kHz sweep window, 16 K points, and a 64 K transform to provide digital resolution of 6 ppb (0.006 ppm). Isotope shifts > 12 ppb are presented, measured after resolution enhancement. The isotope shift for the carbonyl carbon was not examined.

exo-Tricyclo[5.2.1.0^{1,5}]decan-8-ol (8)

To a stirred solution of 9-BBN in THF (50 mL, 0.5 *M*) under nitrogen was added **7** (2.68 g, 0.02 mol) in THF (5 mL) at room temperature and the solution refluxed for 16 h. After cooling, the excess 9-BBN was slowly decomposed with cold water (2 mL) before the addition of 3 *M* aqueous NaOH (21 mL), followed by the *cautious* slow addition of H_2O_2 (21 mL, 30%) and MeOH (21 mL). After stirring at room temperature for 24 h, the reaction mixture was saturated with solid NaCl, whereupon the THF layer separated. After ether extraction (3 × 50 mL), the combined organic extracts were dried ($MgSO_4$) and the solvent evaporated under vacuum to give a thick oil (2.6 g, 90%) containing **8** and **9** in a 85:15 ratio. These isomeric alcohols were separated by FC (Et_2O – petroleum ether, 30:70) to furnish pure samples of each. Alcohol **8** (2.1 g): mp 47–49°C (lit. (12) mp 45–49°C); alcohol **9** (0.46 g): mp 35–36°C.

Tricyclo[5.2.1.0^{1,5}]decan-8-one (10)

To a stirred solution of Collins reagent prepared from CrO_3 (96.0 g, 0.06 mol), in pyridine (9.49 g) and methylene chloride (150 mL), was added, in one portion, alcohol **8** (1.52 g, 0.01 mol) in CH_2Cl_2 (5 mL) at room temperature and the stirring continued for 1 h. After decantation of the solvent, the tarry black residue was washed with CH_2Cl_2 (2 × 25 mL). The combined CH_2Cl_2 extracts were washed with aqueous NaOH (2 × 100 mL, 10%), aqueous HCl (100 mL, 10%), aqueous $NaHCO_3$ (100 mL, 10%), and water before drying over $MgSO_4$. After removal of the solvent, the residue was distilled to yield the colorless liquid **10** (1.3 g, 86%), bp 54°C/0.8 Torr; ir ($CHCl_3$): 1735 cm^{-1}.

8-Trimethylsilyloxytricyclo[5.2.1.0^{1,5}]dec-8-ene (11)

To a stirred solution of LDA (prepared from diisopropylamine (2.39 mL, 0.017 mol), THF (25 mL), *n*-BuLi (2.0 *M*, 7.5 mL) at −78°C, 20 min) under nitrogen was added a solution of **10** (1.5 g, 0.01 mol) in THF (3 mL) and the stirring was continued at −78°C for 35 min. The clear quenching solution (prepared by centrifugation of a mixture of trimethylsilyl chloride (2.54 mL) and Et_3N (0.55 mL) inTHF (10 mL) in a N_2-purged tube) was added and stirring continued at −78°C for an additional hour before the mixture was allowed to warm to room temperature over a period of 2 h. After 30 min at room temperature, the mixture was diluted with saturated $NaHCO_3$ solution (30 mL) and extracted with pentane (3 × 30 mL). The combined extracts were washed quickly with cold (0°C) HCl solution (35 mL, 2%), followed by $NaHCO_3$ (2 × 30 mL, 10%) and cold water before drying ($MgSO_4$). Removal of the solvent afforded **11** as a colorless liquid (2.1 g, 95%), bp 61°C/0.8 Torr; ir ($CHCl_3$): 1600 (C=C) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.23 (s, 9H, Me_3Si), 1.40–2.2 (complex absorption, 11H), 2.60 (bs, 1H, H-7), 4.82 (s, 1H, H-9); *m/e* (relative intensity): 222 (M^+, 31), 207 (36), 168 (100), 107 (25), 76 (24), 74 (91). *Exact Mass* calcd. for $C_{13}H_{22}OSi$: 222.1440: found: 222.1434.

8-Trimethylsilyloxytetracyclo[5.3.1.0^{1,5}o^{8,10}]undecane (12)

Methylene iodide (0.9 mL, 8.5 mmol) was added to a mixture of Zn/Ag couple (0.975 g, 0.015 mol) in ether (3 mL) and this mixture was warmed until refluxing occurred without external heating. Upon cessation of reflux, Et_2O (10 mL) was added and the mixture stirred at room temperature for 1 h. Silyl enol ether **11** was then added and the reaction mixture was refluxed for 18 h. After cooling to 0°C, pyridine (1.38 mL) was slowly added with vigorous stirring. The resulting precipitate was removed by filtration and washed with Et_2O. After removal of solvent from the filtrate, the residue was taken up in pentane and the last traces of precipitate removed by further filtration. Evaporation of the solvent gave a colorless liquid **12** (0.76 g, 65%), bp 70–75°C/ 0.6 Torr; ^{1}Hmr ($CDCl_3$) δ: 0.17 (s, 9H, Me_3Si), 0.97 (bs, 2H, H-9), 1.1–2.0 (complex absorption, 12H), 2.40 (bs, 1h, H-7); *m/e* (relative intensity): 236 (M^+, 39), 221 (28), 179 (33), 147 (96), 107 (31), 80 (28), 75 (100), 73 (96). *Exact mass* calcd. for $C_{14}H_{24}OSi$: 236.1596; found: 236.1596.

Tricyclo[5.3.1.0^{1,5}]undecan-8-one (13)

To a stirred solution of **12** (0.76 g, 3.2 mmol) in MeOH (12 mL) was added aqueous NaOH (6 mL, 3 *M*) at 0°C and stirring continued for 2 h. Then the reaction mixture was left overnight in a refrigerator at 0°C. Water (6 mL) was added, the MeOH removed by evaporation, and the product extracted with CH_2Cl_2 (3 × 20 mL). The combined extracts were washed and then dried ($MgSO_4$). Removal of the solvent gave a yellow oil which was purified by FC (Et_2O – petroleum ether, 15:85) to furnish **13** (0.465 g, 88%), bp 58°C/0.2 Torr; ir ($CHCl_3$): 1705 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 2.68 (t, J = 4 Hz, 1H, H-7), 1.2–2.5 (complex absorption, 15H); *m/e* (relative intensity): 164 (M^+, 44), 120 (61), 118 (24), 108 (30), 107 (100), 94 (24), 92 (25), 81 (36), 80 (64), 68 (32). *Exact Mass* calcd. for $C_{11}H_{16}O$: 164.1201; found: 164.1205.

9,9-Dimethytricyclo[5.3.1.0^{1,5}]undecan-8-one (6)

Ketone **13** (0.60 g, 3.7 mmol) in Et_2O (2 mL) was added to a vigorously stirred suspension of $NaNH_2$ (0.702 g, 0.018 mol) in Et_2O (25 mL) under nitrogen at room temperature and the mixture was stirred with gentle reflux for 3 h. After cooling, methyl iodide (1.37 mL, 0.022 mol) was added slowly and the mixture refluxed overnight, before the second addition of MeI (0.46 mL, 7.3 mmol). After refluxing for 3 h, the mixture was cooled and diluted with water (20 mL). The ether layer was separated and the aqueous phase extracted with Et_2O (3 × 25 mL). The combined extracts were dried ($MgSO_4$) and the product recovered by evaporation of the solvent. Distillation gave **6** as a colorless liquid (0.471 g, 67%), bp 62°C/0.2 Torr; ir ($CHCl_3$): 1692 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.125 (s, 3H, Me), 1.170 (s, 3H, Me), 2.79 (dd, 1H, H-7), 1.30–2.25 (complex absorption, 13H); *m/e* (relative intensity): 192 (M^+, 100), 161 (27), 149 (77), 119 (43), 121 (59), 107 (62), 93 (35), 82 (61), 79 (83), 67 (35). *Exact Mass* calcd. for $C_{13}H_{20}O$: 192.1514; found: 192.1519.

3,3-Dimethyltricyclo[6.3.0.0^{1,5}]undecan-4-one (5)

A solution of **6** (0.192 g, 1 mmol) in *t*-BuO^-/*t*-BuOH (prepared from potassium metal (0.157 g) and *t*-BuOH (3.8 mL); H_2O content, 270 μg/mL) was prepared under nitrogen and quickly transferred to a predried, thick-walled glass tube (capacity ~42 mL). The solution was degassed and the tube sealed under vacuum (~0.1 Torr) before heating at 185°C for 480 h. After cooling, the reaction mixture was diluted with water (15 mL) and the neutral product was isolated by ether extraction (3 × 15 mL). Removal of ether furnished a yellow oil which was subjected to FC (Et_2O – petroleum ether, 5:95) to yield starting material **6** (0.059 g) and the new ketone **5** (0.095 g). The recovered **6** was recycled to give **5** (0.027 g) and **6** (0.015 g). Thus, the total yield of **5** was 0.122 g (69% based on recovered **6**) having the following properties: ir ($CHCl_3$): 1730 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.045 (s, 3H, Me), 1.105 (s, 3H, Me), 2.155 (m, 1, H-8), 2.405 (dd, J ~ 6 Hz, 1H, H-5), 1.25–1.95 (complex absorption, 12H), *m/e* (relative intensity): 192 (M^+, 68), 135 (100), 108 (35), 107 (25), 80 (41). *Exact Mass* calcd. for $C_{13}H_{20}O$: 192.1514; found: 192.1519.

Preparation of 5-d$_1$

Ketone **5** (29 mg) was added to a stirred solution of MeO^-/MeOD (prepared from sodium (7 mg) and MeOD (0.5 mL)) at room temperature and the stirring was continued for 2.5 h. After the addition of D_2O (0.1 mL), Et_2O (15 mL) was added and the ethereal solution washed before drying over $MgSO_4$. Evaporation of the solvent afforded *5-d* (27 mg, 93%), the ^{1}Hmr spectrum of which contained no absorption below δ 2.25, indicative of essentially complete deuteration at C-5; ms: 4.5% d_0, 95.4% d_1 (total 0.954 D/molecule).

Substituent effects on benzyl radical hyperfine coupling constants. Part 2. The effect of sulphur substituents

DANIAL D. M. WAYNER AND DONALD R. ARNOLD[1]

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received September 26, 1983

DANIAL D. M. WAYNER and DONALD R. ARNOLD. Can. J. Chem. **62**, 1164 (1984).

Several 4-substituted benzyl radicals of the general form $R(O_n)SC_6H_4CH_2\cdot$ (n = 0, 1, 2; R = Me, Ph, Tol, $COCH_3$, OCH_3) have been investigated by electron spin resonance (esr) spectroscopy. In general, the ability to delocalize spin density onto the substituent decreases as n increases. The effect of R on the spin density depends on the oxidation state of the sulphur. These trends are explained by considering the sulphur to be either a spin donor or a spin acceptor, depending on the oxidation state. The $\sigma^{\cdot}_{\alpha}$ values are determined.

DANIAL D. M. WAYNER et DONALD R. ARNOLD. Can. J. Chem. **62**, 1164 (1984).

Faisant appel à la résonance paramagnétique électronique (rpe), on a étudié plusieurs radicaux benzyles substitués en position 4, de structure générale $R(O_n)SC_6H_4CH_2\cdot$ (n = 0, 1, 2; R = Me, Ph, Tol, $COCH_3$, OCH_3). D'une façon générale, la facilité à délocaliser la densité de spin sur le substituant diminue avec une augmentation de n. L'effet de R sur la densité de spin dépend de l'état d'oxydation du soufre. On peut expliquer ces tendances en considérant le soufre comme étant soit un donneur de spin ou un accepteur de spin dépendant de son état d'oxydation. On a déterminé les valeurs $\sigma^{\cdot}_{\alpha}$.

[Traduit par le journal]

Introduction

Recently, we described the development of a series of substituent constants, sigma dot-alpha ($\sigma^{\cdot}_{\alpha}$), which were defined from the benzylic α-hydrogen hyperfine coupling constant (1) (eq. [1]).

$$[1] \quad \sigma^{\cdot}_{\alpha} = 1 - hfc_x/hfc_0$$

These substituent constants reflect the component of energy that may be attributed to spin delocalization in the substituted benzyl radical, relative to the unsubstituted radical. Other $\sigma^{\cdot}$ scales have been proposed (2). All of these were derived from relative rate data, and the radical substituent parameter was defined only after some assumption of the size of the polar contribution had been made. Furthermore, it was assumed that the measured effects were attributable only to changes in the nature of the transition state. This may be a valid assumption for ionic reactions, where the effects on the transition state relative to those on the starting material are large. Clearly, in free radical reactions this cannot be true (3).

The $\sigma^{\cdot}_{\alpha}$ scale offers major advantages over other $\sigma^{\cdot}$ scales. For example, the measured effects are free from polar factors in the transition state, and the substituent effects are attributable only to effects on the radical, not on the starting material.

The $\sigma^{\cdot}_{\alpha}$ scale has now been extended to include many other substituents (Table 1). Generally, it is found that *para* substituents decrease while *meta* substituents increase the α-hfc (there are exceptions to this generality). In this paper we describe the effect of sulphur-containing substituents on benzyl radical delocalization. The role of sulphur substituents in ionic reactions has been a subject of some controversy (4). Our results complement known ionic effects. Comparison of the free radical and ionic effects leads to an explanation of the trends observed.

Results

The benzyl radicals were generated in the esr (electron spin resonance) cavity by hydrogen atom abstraction from the corresponding toluenes or by bromine atom abstraction from the benzyl bromides. The observed hyperfine coupling constants are given in Table 2. In general, it is found that the order of delocalization of spin density by the substituents is: —SR > —S(O)R > —$S(O_2)$R (4*b*). The effect of R depends on the oxidation state of the sulphur.

4-$S(O_2)$OMe	0.013	3-CF_3	−0.017
4-Et	0.012	3-CN	−0.026

In the case of the sulphide, the 4-methylthio substituent delocalizes spin more effectively than the 4-tolylthio group.[2] This order is reversed for the corresponding sulphinyl and sulphonyl groups. Furthermore, the difference in a_{α} for the 4-methylthio- and the 4-tolylthiobenzyl, the 4-methylsulphinyl- and 4-tolylsulphinylbenzyl, and the 4-methylsulphonyl- and 4-tolylsulphonylbenzyl radicals increases as the oxidation state increases (these differences are −0.07 G, 0.12 G, and 0.22 G, respectively). Any explanation of the interaction of the sulphur-containing substituents with the benzyl radical must rationalize both the direction and magnitude of these trends.

[1]Author to whom correspondence may be addressed.

[2]The 4-tolyl derivatives are frequently more readily available than the phenyl derivatives. In the case of the 4-phenylsulphonylbenzyl radical, where the difference in a_{α} between the methyl and the phenyl derivatives is large, the difference between the phenyl and the tolyl derivatives is insignificant.

Discussion

It is useful to review briefly the effects of sulphur-containing substituents in ionic reactions. The Hammett σ values for some sulphur-containing substituents are shown in Table 3 (6, 4*a*). The electron-withdrawing ability of the substituent increases as the oxidation state increases.

Sulphide may act as an electron-donating group (7) or an electron-withdrawing group (8), depending on the electron demand of the aryl or alkyl group to which it is bound. The ability of sulphide to act as both an acceptor or a donor has been explained by molecular orbital theory (9). The electron-donating ability of the 4-methylthio substituent is indicated by the σ^+ value (7) ($\sigma^+ = -0.60$). The stabilization of an adjacent carbanion by sulphur has been rationalized in terms of polarizability (9*c*) and hyperconjugation (9*a*).

Sulphinyl and sulphonyl groups are electron-withdrawing groups. The degree to which 3*d* orbitals are involved in the stabilization of adjacent carbanions has been a subject of controvesy (4*c*); however, there is convincing evidence that 3*d* orbitals can interact in the sulphone. Ramasamy *et al.* (10) found, from a study of angular correlation of positron annihilation radiation, that a well-marked increase in the region of *d*-orbital radial momentum is observed for arylalkyl sulphones. Such an increase was not found for sulphides. Work by Wolfe and co-workers (11) also has suggested that the role of *d* orbitals in α-sulphinyl and α-sulphonyl carbanions may be more important than previously believed.

The trends observed from the esr parameters of the substituted benzyl radicals are similar to those observed for the analogous methyl radicals (Tables 2 and 4).

Delocalization by —SR

The delocalization of a free radical by an adjacent sulphide group has been studied by esr spectroscopy (5, 12) and molecular orbital theory (13). The observed rotational barriers for XCH_2 radicals (where X = OMe, SMe) suggest that the π-bond formed for X = SMe is stronger than that for X= OMe. This result has been rationalized by Bernardi, Wolfe, and their co-workers (31) who suggest that the two-orbital three-electron interaction (Fig. 1b) is more important than the 3*d*-orbital effects (Fig. 1c). This greater stabilization by sulphur is thought to be a consequence of the lower lone pair ionization potential,

TABLE 3. Hammett σ constants for several sulphur-containing substituents

and hence the greater polarizability, of the sulphur relative to oxygen. The value of a_α for 4-methylthiobenzyl radical is less than that for 4-methoxybenzyl radical. A similar explanation may be offered to rationalize this effect.

The 4-tolylthiobenzyl radical has a slightly larger value of a_α than that value for the 4-methylthiobenzyl radical. While this difference is small (only 0.01 G outside experimental error), direct comparison of the experimental spectra shows the difference of 0.07 G is reproducible and real. Hudson and co-workers (12*a*), on the other hand, found that in the analogous methyl radicals the value of a_α for the phenylthiomethyl radical[2] was smaller than that for the methylthiomethyl radical. In the case of the benzyl radicals, the observed effect may be due to cross-conjugation in the 4-tolylthio derivative, which would decrease the polarizability (ionization potential) of the sulphur and, consequently, decrease the contribution of a valence bond structure such as Fig. 1b. Further support for this reasoning may be found. The value of a_α is larger in the 4-thiolacetylbenzyl radical than that in the 4-tolylthiobenzyl radical. The lone pair on sulphur will be conjugated more

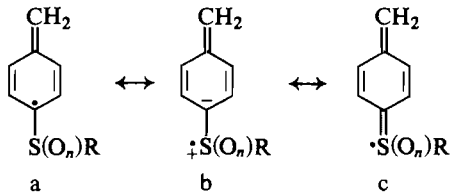

FIG. 1. The delocalization of a free radical by an adjacent sulphur substituent; (a) localized spin; (b) sulphur as a spin donor; (c) sulphur as a spin acceptor.

effectively to acetyl than to tolyl. Clearly, if conjugation through the sulphur were possible (Fig. 1c), the effect would be in the opposite direction (14).

It is found that a_α for 4-methoxybenzyl radical is the same as that for 4-phenoxybenzyl radical. On the other hand, the 4-acetoxybenzyl radical actually is less delocalizing relative to the unsubstituted radical.[3] The weakly conjugating phenyl group is not expected to have a great effect on the polarizability of the oxygen lone pairs. The strongly conjugating carbonyl group, on the other hand, will noticeably decrease the polarizability of the oxygen.

Delocalization by —S(O)R

It is evident from the values of a_α that the 4-methylsulphinyl group is less delocalizing than the 4-methylthio group (Table 2). This trend was also observed in the methyl radical series (5) (Table 4). The sulphinyl group is still able to participate in the two-orbital three-electron delocalization (Fig. 1b) since it has one lone pair of electrons. The delocalizing effect is less than it is for the corresponding sulphide, since the electronegative ligand will contract the orbital containing the lone pair (10). There is some spectroscopic evidence that the methylsulphinyl group is weakly donating; however, if the methylsulphinyl group is *para* to a strong donating group, it becomes a resonance acceptor (15).

In the delocalization of a benzyl radical by a sulphinyl group, is the sulphinyl group predominantly a spin donor or a spin acceptor? The value of a_x (the hyperfine coupling constant assigned to the substituent methyl group) is much less for the 4-methylsulphinylbenzyl radical than those values for either the 4-methylthiobenzyl radical or the 4-methylsulphonylbenzyl radicals. It has been suggested that the coupling to the methyl group in the methylthiomethyl radical is a result of hyperconjugative interactions with the spin on sulphur, while coupling in the methylsulphonylmethyl radical is a result of spin polarization (5). The hyperconjugative mechanism results in positive spin density, while spin polarization leads to negative spin density in the methyl group. In the case of the methylsulphinylmethyl radical, the smaller value for a_x reflects contributions from both of these mechanisms. This trend is also observed in the analogous benzyl radicals, so a similar explanation may be offered. However, since only the magnitude of the hyperfine coupling constant is known, it is impossible to determine from this evidence if the sulphinyl group is predominantly a spin donor or a spin acceptor.

[3]The decreased delocalization by a *para* substituent relative to the unsubstituted benzyl radical is observed only in those cases where the substituent is highly electronegative and a valence bond structure such as that in Fig. 1b is unfavourable (e.g. —F, —CF_3, —OCOMe). In these electron-poor benzyl radicals, the delocalization of spin density to the substituent is less effective than delocalization of spin density to hydrogen.

Replacement of the substituent methyl group with tolyl leads to a decrease in the benzylic hyperfine coupling constant. It is tempting to conclude from this evidence that the sulphinyl group is a spin acceptor, since the cross-conjugative effect found in the sulphide derivative is not observed. Replacement of the methyl group by tolyl can have two opposing effects. The first, which causes a decrease in delocalization of spin density, is cross-conjugation, which has already been discussed. The second effect, which leads to an increase in delocalization of spin density, may be a result of further stabilization of the MO which is accepting the spin (through conjugation). It is possible that the $3d$ orbitals on sulphur, which contract in the presence of the highly electronegative oxygen, contribute. We would suggest, therefore, that the sulphinyl group is a net spin donor.

Delocalization by —S(O_2)R

Since the sulphur in the 4-methylsulphonylbenzyl radical has no lone pairs, delocalization of a free radical is possible only with sulphur as a spin acceptor. Even though the $3d$ orbitals are contracted to a greater extent than those in the 4-methylsulphinylbenzyl radical, very little delocalization results (a_α is only 16.17 G). Under the most favourable conditions for $3d$-orbital interaction, extra delocalization, compared to the unsubstituted radical, amounts to an effect of only 0.08 G (compared to 1.02 G for the corresponding sulphide, where lone pair interactions dominate). The conclusion that the 4-methylsulphinyl group is a net spin donor, therefore, seems reasonable. The extra delocalization gained when the methyl group is replaced by tolyl (or phenyl) is almost twice as large as that found in the sulphinyl derivative. This serves to reinforce the idea that the tolyl group interacts to further stabilize the MO which is accepting the spin density, since through-conjugation with the more highly contracted $3d$ orbitals should be more effective.

Delocalization by —S(O)OMe and —S(O_2)OMe

While it is found that the 4-methylsulphinate group is less delocalizing than the 4-methylsulphinyl group, the corresponding 4-methylsulphonate group is more delocalizing than the 4-methylsulphonyl group. Again, these trends may be rationalized using the simple concepts outlined above. The 4-methylsulphinate group will be more delocalizing than the isomeric 4-methylsulphonyl group, since the former has a lone pair of electrons on the sulphur. The replacement of the methyl with methoxy (in the 4-methylsulphinyl group) will further contract the lone pair, decreasing the contribution of the structure shown in Fig. 1b.

The 4-methylsulphonate group is somewhat different. Since the sulphur has no lone pairs, the effect of the third oxygen is to further contract the $3d$ orbitals. Rather than becoming a less effective spin donor (as in the 4-methylsulphinate group), the 4-methylsulphonate group becomes a more effective spin acceptor.

It is more difficult to interpret the effects of the substituents on the observed esr parameters for the methyl radicals, since the substituents may induce changes in conformation at the radical centre. In addition, the possibility of through-space interactions cannot be precluded. One of the advantages of studying the esr parameters of the benzyl radicals is that the substituent undoubtedly will have a negligible effect on the conformation of the benzylic carbon. We would, therefore, not expect the a_α of the benzyl radicals to correlate with the a_α of the methyl radicals. However, there is a trend, at least, for the

For personal use only.

four substituents in Table 4. There are also obvious differences.

The strong carbon–sulphur π-bond in the methylthiomethyl radical leads to restricted internal rotation at temperatures as high as −20°C (12*a*). There is no evidence for restricted internal rotation in the 4-methylthiobenzyl radical at −30°C (the two *meta* hydrogens still appear to be equivalent).

Sulphur-containing substituents, other than 4-methylthio, have seldom been used as substituents in the study of free radical reactions. As a result, it is difficult to assess how well the derived $\sigma^{\cdot}_{\alpha}$ values correlate with relative reactivity data. We predict, however, that, as in the past, the $\sigma^{\cdot}_{\alpha}$ values will prove to be useful in the Hammett or extended Hammett treatment of kinetic data.

Experimental

General information

The esr spectra were recorded on a Varian Associates E109B electron paramagnetic resonance spectrometer equipped with a liquid nitrogen variable temperature accessory. All spectra were recorded with the aid of the Nicolet 1170 signal averager. Typically, 16 spectra were averaged (2 min per spectrum). Coupling constants were measured directly from the oscilloscope and refined by computer simulation (24) using the IBM-PC. All spectra were reproducible within the experimental error. The estimated error of 0.03 G is the limit of resolution of the recording device used to plot the experimental spectra and the simulations. The ^{1}Hmr spectra were recorded on a Varian T-60 spectrometer and are reported in parts per million downfield from TMS. Infrared spectra were recorded on a Pye Unicam SP1000 infrared spectrometer and are reported in wave numbers. Melting points were recorded on a Sybron Corporation Thermodyne hotstage (uncorrected).

Materials

Di-*tert*-butyl peroxide (DTBP) and triethylsilane were obtained from Pfaltz and Bauer Inc. and were used without further purification. Hexamethylditin was obtained from Alpha Products and used without further purification. 4-Methoxyacetophenone (PMA) was obtained from Aldrich Chemical Company Inc. and was recrystallized twice from 95% ethanol prior to use. 4,4′-Dimethyldiphenylsulphoxide was also obtained from Aldrich and used without further purification. Chlorobenzene (J. T. Baker Chemicals Inc.) was stirred over concentrated sulphuric acid, washed successively with water, saturated sodium bicarbonate, and water, dried over anhydrous magnesium sulphate, and distilled through a Vigreux column.

Preparation of benzyl bromides

The method of Grice and Owen (16) was used for the conversion of substituted benzyl alcohols to the bromides. Typically, the benzyl alcohol (0.02 mol) was dissolved in benzene (100 mL). Hydrogen bromide gas was passed through the solution for 1 h or until the solution was saturated. The reactants were heated to reflux and the water which formed was removed via a Dean–Stark trap. The solution was then dried over anhydrous magnesium sulphate, filtered, and the solvent removed at reduced pressure. The bromide was then purified by sublimation.

4-(Methylthio)benzylbromide

The benzyl alcohol (3.0 g, 0.02 mol, Aldrich) was dissolved in benzene (100 mL). This solution was saturated with anhydrous hydrogen bromide (1 h) and the resulting solution refluxed for 1 h with a Dean–Stark trap. The solution was then dried over anhydrous magnesium sulphate, filtered, and the solvent was removed at reduced pressure. The bromide was purified by vacuum sublimation (40°C, 0.1 Torr) to give colourless crystals. The yield was 2.8 g, 65%; mp 43–44°C (lit. (16) mp 44°C); ^{1}Hmr ($CDCl_3$) δ: 7.21 (s, 4H), 4.43 (s, 2H), 2.45 (s, 3H).

4-(Bromomethyl)phenyl methylsulphone

4-(Methylthio)benzylalcohol (3.0 g, 0.02 mol) was dissolved in dichloromethane (100 mL). To this solution, at 0°C, 3-chloroperbenzoic acid (8.0 g, 0.045 mol) in dichloromethane (50 mL) was added dropwise over 30 min. The mixture was stirred for 18 h, filtered, washed successively with 5% sodium hydroxide and water, then dried over anhydrous magnesium sulphate. Evaporation of the solvent at reduced pressure gave 2.4 g of the benzyl alcohol (67%).

The benzyl alcohol (2.4 g, 0.013 mol) was dissolved in benzene (100 mL) and the solution was saturated with anhydrous hydrogen bromide. The resulting solution was refluxed under a Dean–Stark trap (2 h), dried with anhydrous magnesium sulphate, and the solvent evaporated at reduced pressure. The crude bromide was purified by sublimation (120°C, 0.1 Torr) to give colourless crystals. The yield was 2.0 g, 62%; mp 94–96°C (lit. (17) mp 95–95.8°C); ir ($CHCl_3$) cm^{-1}: 1155(s), 1322(s); ^{1}Hmr ($CDCl_3$) δ: 7.82 (m, 4H), 4.53 (s, 2H), 3.07 (s, 3H).

Preparation of substituted toluenes

The preparation of methyl-4-tolylsulphoxide and methyl-4-tolylsulphonate has been described previously (1).

4,4′-Dimethyldiphenylsulphide

4,4′-Dimethyldiphenylsulphoxide (5.0 g, 0.022 mol) was added to a stirred solution of cobalt(III) chloride hexahydrate (9.6 g, 0.040 mol) in ethanol (300 mL). The solution was cooled to 0°C. Sodium borohydride (7.6 g, 0.2 mol) was added over a 1-h period. The reduction proceeded as outlined by Chasar (18). Water was added, the mixture stirred for one further hour, and then the mixture was poured into water (500 mL). The solution was washed with diethyl ether (three 100-mL portions). The ethereal extracts were dried and the ether removed at reduced pressure, leaving an ethanolic solution from which the product crystallized. The yield was 4.0 g, 85%; mp 55–57°C (lit (19) mp 57.5°C); ^{1}Hmr ($CDCl_3$) δ: 7.17 (m, 8H), 2.30 (s, 6H).

4,4′-Dimethyldiphenylsulphone

4,4′-Dimethyldiphenylsulphoxide (5.0 g, 0.022 mol) in dichloromethane (100 mL) was allowed to sir at 0°C. 3-Chloroperbenzoic acid (4.2 g, 0.024 mol) was added over 1 h. The reaction mixture stirred for 18 h. Work-up consisted of washing the dichloromethane solution with water, 10% sodium bicarbonate solution, and finally with water. The dichloromethane was dried over anhydrous magnesium sulphate, filtered, and the solvent removed at reduced pressure. The product was recrystallized twice from chlorobenzene to give colourless platelets. The yield was 4.4 g, 81%; mp 157–158°C (lit (20) mp 158.1°C); ^{1}Hmr ($CDCl_3$) δ: 7.50 (m, 8H), 2.33 (s, 6H).

4-Methyldiphenylsulphone

4-Tolylsulphonylchloride (5.0 g, 0.03 mol) in benzene (50 mL) was added dropwise to a stirred solution of aluminum chloride (4.0 g, 0.03 mol) in benzene (100 mL) over 20 min. After the addition was complete, the mixture was slowly warmed to 60°C and stirred at that temperature until the evolution of hydrogen chloride has subsided (about 30 min). The mixture was then refluxed for an additional 1-h period after which it was carefully poured onto 200 g of crushed ice. This mixture was heated to break up the complex, the layers were separated, and the organic layer washed successively with 5% sodium bicarbonate and water. The solution was then dried over anhydrous magnesium sulphate and the solvent evaporated at reduced pressure. Recrystallization of the crude product from ethanol afforded colourless crystals. The yield was 4.8 g, 69%; mp 128–129°C (lit. (21) mp 129°C); ir ($CHCl_3$) cm^{-1}: 1161(s), 1320(s); ^{1}Hmr ($CDCl_3$) δ: 7.55 (m, 9H), 2.33 (s, 3H).

Methyl(4-tolylsulphinate)

The sulphinic ester was prepared by the method of Field and Locke (22). To a refluxing solution of ditolyldisulphide (3 g, 0.012 mol, Aldrich Chemical Company Inc.), chloroform (25 mL), and methanol (25 mL) in a 250-mL three-neck flask, lead tetraacetate (25 g) in chloroform (100 mL) was added dropwise over a 1-h period. The solution was allowed to reflux for an additional 24 h. Most of the solvent (100 mL) was distilled from the reaction flask, and water (20

For personal use only.

mL) was added. The mixture was cooled, filtered through Celite, and washed with water until all traces of lead were removed (22). The solution was dried and the solvent was removed at reduced pressure. The yield was 3.8 g, 93%; ir (NaCl disk) cm^{-1}; 1080(s); ^{1}Hmr ($CDCl_3$) δ: 7.42 (m, 4H), 3.40 (s, 3H), 2.37 (s, 3H).

4-Tolylthioacetate

Acetylchloride (4.7 g, 0.06 mol) in benzene (50 mL) was added dropwise to a solution of 4-thiocresol (7.5 g, 0.06 mol) in benzene (100 mL) over 15 min. The solution was warmed to reflux for 1 h. The reaction mixture was cooled, washed three times with 10% sodium hydroxide and twice with water, and then dried over anhydrous magnesium sulphate. The solvent was removed at reduced pressure. The product was purified by distillation (85°C, 0.1 Torr (14)); ir (NaCl disk) cm^{-1}: 1712(s); ^{1}Hmr ($CDCl_3$) δ: 7.22 (bs, 4H), 2.33 (s, 6H).

4-Methyldiphenylether

This ether was prepared by the method of Bacon and Stewart (23). A mixture of 4-cresol (10.8 g, 0.1 mol), bromobenzene (7.85 g, 0.05 mol), and cuprous oxide (7.15 g, 0.05 mol) in 2,4,6-trimethylpyridine (25 mL) was refluxed for 48 h. The mixture was poured into 6 *M* HCl (200 mL) and extracted with ether (2 × 200 mL). The ether layer was then washed with 5% sodium hydroxide solution and water, and dried over anhydrous magnesium sulphate. The solvent was removed at reduced pressure and the product purified by distillation (104°C, 0.1 Torr). The yield was 5.0 g, 55%; ^{1}Hmr ($CDCl_3$) δ: 7.00 (m, 9H), 2.30 (s, 3H).

Electron spin resonance experiments

Toluenes

A static solution of DTBP (0.5 mL) and the toluene (100 mg) with PMA (45 mg) was irradiated in the esr spectrometer cavity using a filtered (methanol in a quartz tube) 1-kW Xe−Hg high pressure lamp. Temperatures ranged from 20°C to −60°C (depending on the solubility), with the majority of the samples examined at −20°C. All samples were purged with nitrogen for 5 min prior to irradiation.

Benzylbromides

Two methods were used to generate the benzyl radicals. In method 1, a static solution of DTBP (0.2 mL), triethylsilane (0.2 mL), and the bromide (50−100 mg), diluted if necessary with chlorobenzene, was purged with nitrogen and irradiated in the esr spectrometer cavity as described above. In method 2, a solution of the bromide (50−100 mg) in *tert*-butylbenzene or chlorobenzene was continuously purged while hexamethylditin (0.1 mL) was injected via the nitrogen purge tube. It was necessary to have a glass wool plug in the purge tube to filter the hexamethylditin. This solution was irradiated as described above. The use of chlorobenzene allowed cooling of the sample to temperatures as low as −20°C without precipitation of the hexamethylditin.

Control experiments

The linearity of the field was checked against the line of $[Cr(NH_3)_5Cl]Cl_2$ doped with 2% $[Co(NH_3)_5Cl]Cl_2$ (25). The accuracy of the field was checked against the coupling constants for Wursters blue perchlorate in ethanol (26). The esr spectra of the benzyl radical, the 3-cyanobenzyl radical, and the 4-fluorobenzyl radical all have been shown to be independent of solvent (up to 50% v/v chlorobenzene or carbon tetrachloride) and temperature (20°C to −60°C) (1). Similarly, the esr spectra of the 4-tolylthiobenzyl radical show no solvent effect (up to 50% v/v chlorobenzene) or temperature effect (20°C to −60°C). The spectra of the 4-methylthiobenzyl radical and the 4-methylsulphonylbenzyl radical show no temperature dependence between 0°C and −60°C. The insolubility of the bromides in DTBP precluded checking the esr spectra in this solvent. However, for each of the bromides, similar spectra were obtained using either chlorobenzene or dimethoxyethane as solvent.

Received August 24, 1983

LOLITA O. ZAMIR and CORINNE LUTHE. Can. J. Chem. **62**, 1169 (1984).

Specifically labeled shikimic acids with tritium or deuterium at positions C-3 or C-4 were synthesized. Commercially available L-shikimic acid was converted to its 3- and 4-ketones, after suitable protection of the hydroxyl groups at C-4,C-5 and C-3,C-5. Reduction of the 3-keto- or 4-keto-shikimic acid derivatives with sodium borodeuteride and deprotection gave mostly 3-D-epi-shikimic acid or 4-D-shikimic acid. An internally assisted inversion of the 3-D-epi-shikimic acid derivative and deprotection gave 3-D-shikimic acid.

LOLITA O. ZAMIR et CORINNE LUTHE. Can. J. Chem. **62**, 1169 (1984).

Les acides shikimiques marqués spécifiquement avec du tritium ou deutérium aux positions C-3 et C-4 ont été synthétisés. Le procédé utilisé était de transformer l'acide L-shikimique de source commerciale en cétones C-3 et C-4 après avoir protégé les hydroxyles aux positions C-4,C-5 et C-3,C-5. La réduction des dérivés cétoniques C-3 et C-4 des acides shikimiques par le borohydrure de sodium deutéré suivie de l'élimination des groupements protecteurs donna en majorité les composés 3-D-epi et 4-D- de l'acide shikimique. Une inversion du composé 3-D-epi de l'acide shikimique accompagnée du retrait des groupements protecteurs donna l'acide 3-D-shikimique.

Introduction

Shikimic acid is a key precursor for an enormous number of aromatic compounds, e.g. aromatic amino acids, vitamins, and a host of secondary metabolites. Shikimic acid is the ideal precursor for tracer type studies because it is generally permeable to cells and is chemically stable. In our laboratory, we will investigate the biochemical intermediates to aromatic amino acids, and in particular, the arogenate (2–5) and spiro-arogenate (6, 7) segments. Synthesis of labeled shikimic acid with deuterium or tritium at C-3 and C-4 is the first step in achieving this objective.

An enzymatic preparation of shikimic acid-6*R*-6T and -6*S*-6T (8) and shikimic acid-2-D (9) has previously been reported. Recently, Christopherson and Morrison (10) prepared 3-^{3}H-shikimic acid, however, as an undefined mixture of both 3-^{3}H-shikimate and 3-^{3}H-epi-shikimate. In this article we describe the synthesis of specifically labeled shikimic acid with deuterium or tritium at position C-3 or C-4. An unexpected observation was made: an intermediary ketone rearranged during purification by flash chromatography.

Results and discussion

The detailed synthetic steps in the preparation of C-3 and C-4 labeled shikimic acids are outlined in Fig. 1.

Synthesis of 3-D- or 3-T-shikimic acid

Our approach consisted of protecting the hydroxyl groups at C-4 and C-5 and generating the 3-keto species. The deuterium or tritium label was introduced by reduction with sodium borodeuteride or tritiated sodium borohydride, respectively. An internally assisted inversion followed by deprotection should then yield 3-D- or 3-T-shikimic acid.

Shikimic acid **1** was esterified (11) in the usual manner, with diazomethane, to afford methyl shikimate **2** (12) which was readily transformed into its corresponding 3,4-orthoformate **3**, without any concurrent reaction at the C-5 alcohol. Protection of the latter as its *tert*-butyldimethylsilyl ether (**4**) (13), followed by an acid hydrolysis of the orthoester moiety, gave diol **12**. The allylic alcohol was selectively oxidized using pyridinium dichromate (14) to afford α,β-unsaturated ketone **10**, which then underwent acetylation in the usual manner (15) to generate acetate **11**. Unfortunately, the reduction of the latter by $NaBH_4$ (or its labeled analogues) yielded predominantly the thermodynamically more stable β-alcohol (β/α = 90:10). In order to re-establish the correct α-stereochemistry of the hydroxyl group at C-3, alcohol **15** was transformed into its allylic mesylate **17**; solvolysis of this acetoxy-mesylate in methanol containing 1.1 equivalents of potassium acetate (16) at 70°C readily afforded orthoacetate **6** with the desired α-stereochemistry at C-3. Flash chromatography (17) of the crude product **6**, followed by acid hydrolysis and re-acetylation, gave diacetate **13** in 25% yield based on ketone **11**. Its 200 MHz ^{1}H nmr spectrum (Fig. 2) was identical to that of an authentic sample of **13**. Furthermore, both mass spectral and 200 MHz ^{1}H nmr data of deuterated diacetate **13** indicated a quantitative incorporation of the label at C-3. Desilylation with tetra-*n*-butylammonium fluoride afforded the desired deprotected alcohol as a mixture of acetates in 83% yield, after flash chromatography. The deacetylation–demethylation sequence was effected by alkaline hydrolysis in methanol–water. The shikimic acid thus obtained (after *in situ* tetra-silylation) was pure

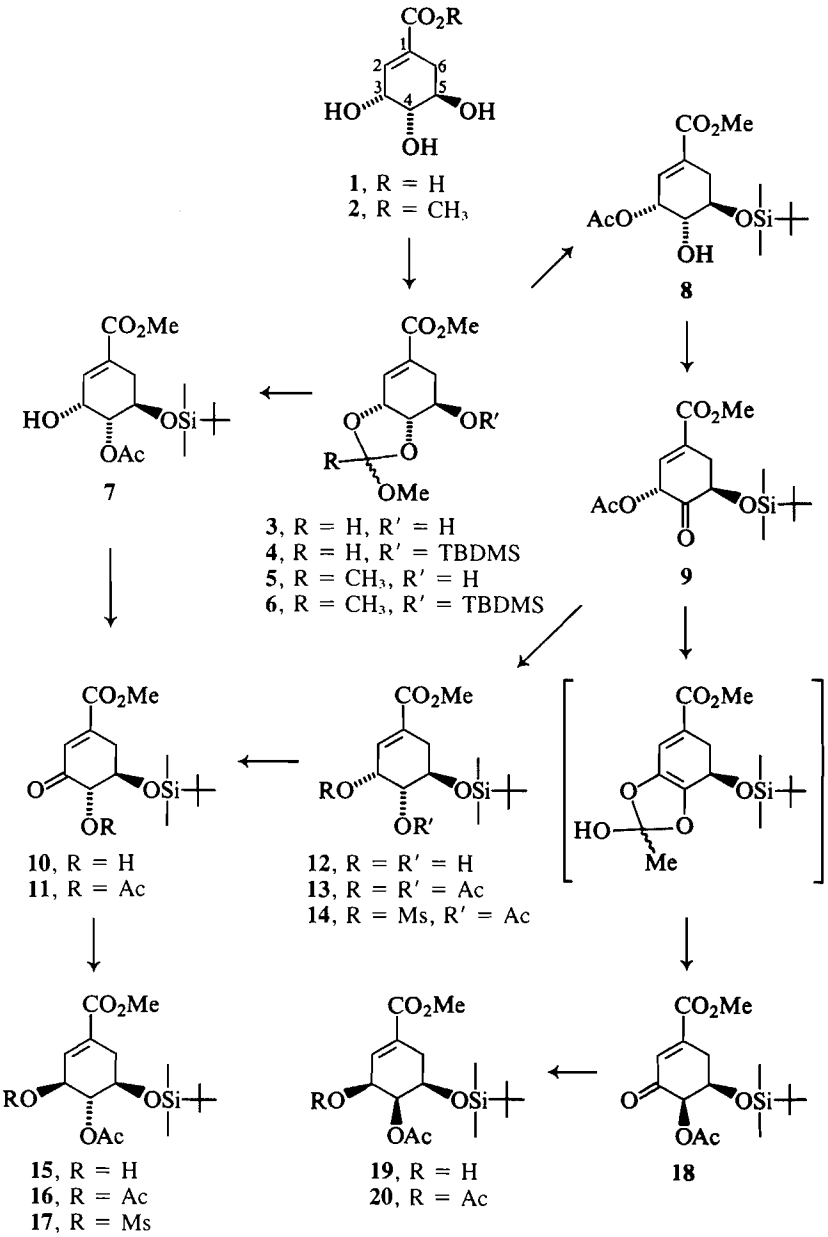

FIG. 1. Synthetic intermediates to specifically labeled shikimic acid at positions C-3 and C-4.

(98%) by gas chromatography, and had an identical mass spectrum to that of an authentic tetra-trimethylsilylated sample. In the case of the labeled shikimic acid derivative, there was no mass spectral evidence for any deuterium loss to have occurred during the final deblocking sequence (Fig. 3).

Synthesis of 4-D- or 4-T-shikimic acid

An oxidation–reduction sequence on the 4-alcohol enables the introduction of deuterium or the tracer tritium at the C-4 position. The protecting groups at C-3 and C-5 were found to be critical in determining the ease of oxidation of the C-4 alcohol. A feasible approach utilized the alcohol **8** having an acetate on C-3 and a *tert*-butyldimethylsilyl group on the C-5 hydroxyl. The 5-hydroxyl function of 3,4-orthoacetate **5** was protected as its *tert*-butyldimethylsilyl ether; the orthoacetate moiety was then hydrolyzed, yielding two monoacetates **7** and **8**, each possessing a free, oxidizable C-4 or C-3 hydroxyl group.

Since these two alcohols displayed very similar mobility on thin-layer chromatography, their separation was most easily effected by selectively oxidizing the allylic one using pyridinium dichromate, prior to chromatography. This allylic oxidation gave ketone **11**, identical to **11** obtained previously.

Alcohol **8** was found to be rather resistant towards most oxidizing reagents. It was finally transformed into its corresponding ketone **9**, albeit in low yield, by reaction with Jones reagent for 5 h. It was very unstable and any attempted purification of crude 4-ketone **9**, by flash chromatography, resulted in its almost complete conversion to α,β-unsaturated ketone **18**, a product thought to arise via enolization, followed by acyl migration and kinetic protonation. Its structure was confirmed by ^{1}H nmr decoupling experiments on both ketones **11** and **18**. Borohydride reduction of this undesired ketone gave predominantly the thermodynamically more stable β-alcohol **19**, which was characterized as its acetate **20**.

Hence, crude ketone **9** (which contained ketone **11**) was

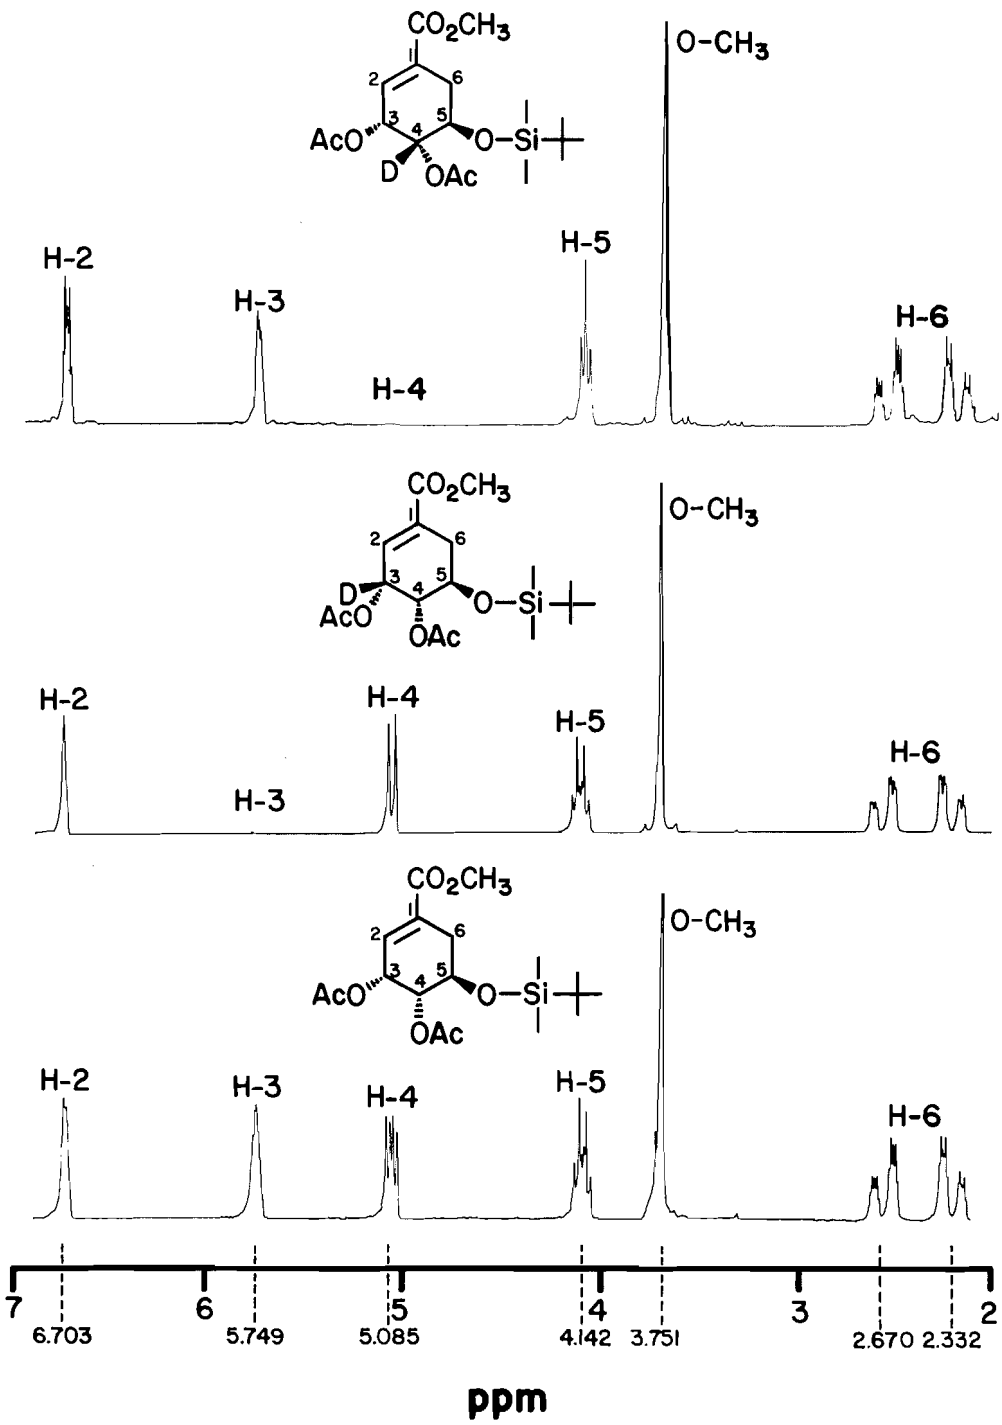

FIG. 2. Analysis of specifically labeled shikimic acid derivative at C-3 and C-4 by proton nmr. The 200 MHz ^{1}H nmr spectrum of unlabeled shikimic acid derivative (**13**) in $CDCl_3$ is shown on the bottom scale. The spectrum shown in the middle represents this derivative labeled with deuterium at C-3. The upper spectrum shows **13** labeled at C-4 with deuterium.

immediately reduced with $NaBH_4$ (or its labeled analogues), seemingly stereospecifically, to give alcohol **8**. The purification of alcohol **8** by flash chromatography was facilitated by a prior pyridinium dichromate oxidation of the allylic alcohols; the purified product **8** (obtained in 12% yield based on starting material, unlabeled **8**) was then acetylated in the conventional manner, thereby rendering it less water soluble, as well as eminently distinguishable from other shikimate isomers by ^{1}H nmr characterization. Mass spectral and 200 MHz ^{1}H nmr data of deuterated diacetate **13** indicated 100% incorporation of the label at C-4 (average of 4 runs) (Figs. 2, 3). Total deprotection, as described earlier for the C-3 labeled series, gave authentic shikimic acid. There was no mass spectral evidence (Fig. 3) of any deuterium loss having occurred in the final deprotection sequence.

Experimental

Mass spectra (ms) were obtained on a HP 5984 or LKB-9000 mass spectrometer, at 70 eV. Infrared (ir) spectra were obtained on a Perkin–Elmer 297 spectrophotometer. Proton magnetic resonance

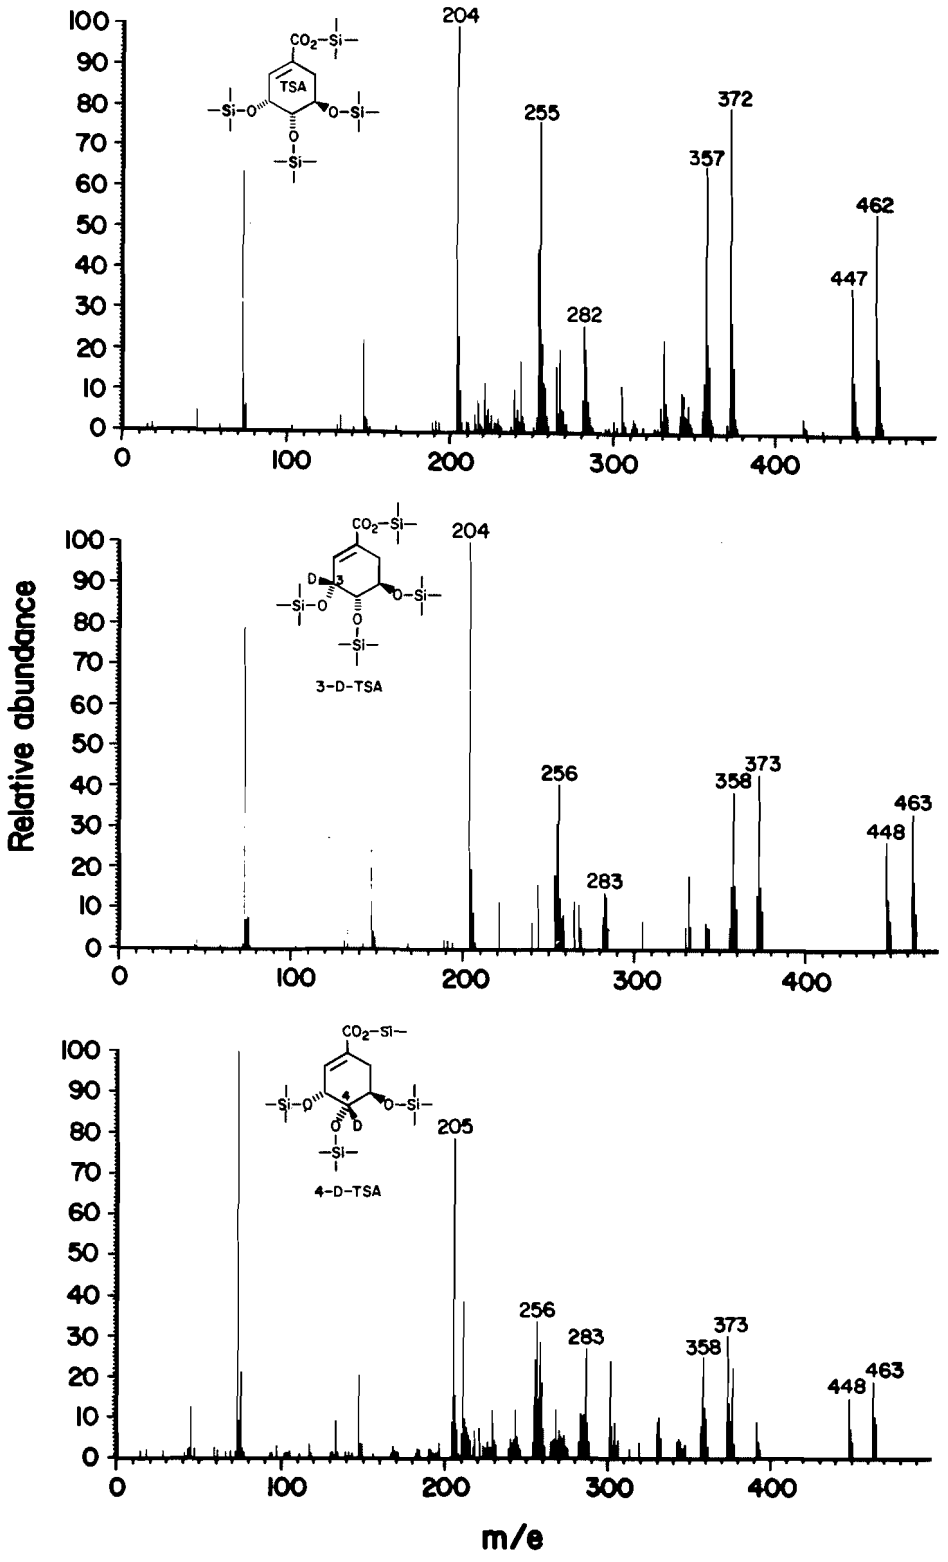

FIG. 3. Analysis by mass spectrometry of shikimic acids specifically labeled at positions C-3 and C-4. The trimethylsilyl derivatives were analysed. The upper mass spectrum shows unlabeled trimethyl silylated shikimic acid. The middle mass spectrum represents trimethyl silylated shikimic acid labeled at C-3. The bottom mass spectrum was obtained from trimethyl silylated shikimic acid labeled at C-4. (Abbreviation: TSA = trimethyl silylated derivative of shikimic acid.)

(^{1}H nmr) spectra were recorded on Varian T-60, T-60A, and XL-200 spectrophotometers. Ultraviolet (uv) spectra were taken on a Perkin–Elmer 559A instrument. Chemical shifts for 60 MHz spectra were measured using either tetramethylsilane as an internal standard or, in the case of compounds containing a TBDMS group, the methyl groups of the latter were set as the standard. Analytical thin-layer chromatography (tlc) was carried out using Merck Silica Gel 60 F_{254} aluminium backed plates. All column chromatography was performed using the "flash chromatography" technique described by Still *et al.* (17) using 32–63 μm (400–230 mesh) silica gel.

Methyl shikimate 2

To a methanolic solution (90 mL) of shikimic acid **1** (2.00 g, 11.48 mmol) was added ethereal diazomethane until the solution remained yellow. The reaction mixture was maintained at room temperature for 15 min and then the solvents were removed at reduced pressure to afford the desired methyl shikimate **2** (2.32 g) in quantitative yield (99%); mp 115–116°C (lit. (18) mp 113–114°C); ms *m/e* (of trimethylsilylated sample): 389 ($M^+ - CH_3$), 373 ($M^+ - OMe$), 314 ($M^+ - Me_3SiOH$), 299 ($M^+ - Me_3SiOH - CH_3$), 204 ($Me_3SiOCH{=}CHOSiMe_3^+$, 100%).

Orthoformates 3 and 4

To a suspension of methyl shikimate **2** (1.14 g, 6.06 mmol) in methylene chloride (20 mL) under a nitrogen atmosphere was added first trimethyl orthoformate (1.5 mL, 15 mmol), then *p*-toluenesulfonic acid (81 mg, 0.42 mmol). After all the starting material was dissolved (1 h), the reaction mixture was cooled at 5°C and excess solid Na_2CO_3 was added. The product was then extracted with ethyl acetate (2 × 400 mL, prewashed with Na_2CO_3); the ethyl acetate extracts were washed with aqueous Na_2CO_3 (5 × 50 mL), water (3 × 50 mL), and dried over $MgSO_4$. Removal of the solvents under reduced pressure gave orthoformate **3** (1.4 g) in quantitative yield (99%). To its solution in dry dimethylformamide (8 mL) under a nitrogen atmosphere, at 5°C, were added *tert*-butyldimethylsilyl chloride (1.01 g, 6.70 mmol) and imidazole (912 mg, 13.4 mmol); the reaction mixture was stirred at room temperature for 1 h. It was then extracted with ether (2 × 300 mL); the ether extracts were washed with aqueous $NaHCO_3$ (2 × 80 mL), H_2O (4 × 50 mL), and dried over $MgSO_4$. Evaporation of the solvents gave orthoformate **4** (2 g) as an oil in 95% yield; ^1H nmr ($CDCl_3$) δ: 0.00 (s, 3H, $SiCH_3$), 0.03 (s, 3H, $SiCH_3$), 0.82 (s, 9H, $SiCMe_3$), 2.1–2.5 (m, 2H, C(6)H), 3.17 (s, 0.6H, OCH_3), 3.27 (s, 2.4H, OCH_3), 3.67 (s, 3H, CO_2CH_3), 3.7–4.3 (m, 2H, C(4)H, C(5)H), 4.6–4.9 (m, 1H, C(3)H, 5.60 (s, 0.8H, $HC(OR)_3$), 5.63 (s, 0.2H, $HC(OR)_3$), 6.6–6.8 (m, 1H, C(2)H).

Diol 12

A solution ($MeOH/H_2O/HCl$ = 100 : 1 : 0.1 (10 mL)) of orthoester **4** (2.0 g, 5.8 mmol) was stirred at room temperature for approximately 20 min (no starting material by tlc); aqueous $NaHCO_3$ (1 mL) and excess solid $NaHCO_3$ were then added to effect a complete hydrolysis of the intermediate formates. The reaction mixture was then extracted with ethyl acetate (2 × 350 mL); the ethyl acetate extracts were washed with water (3 × 100 mL, 3 × 50 mL) until the washings remained neutral, dried over $MgSO_4$, and evaporated to give diol **12** as an oil in 65% yield; ^1H nmr ($CDCl_3$) δ: 0.00 (s, 6H, $SiMe_2$), 0.78 (s, 9H, $SiCMe_3$), 2.1–2.6 (m, 2H, C(6)H), 3.2–4.5 (m, 5H, C(3)H, C(4)H, C(5)H, 2OH), 3.63 (s, 3H, CO_2CH_3), 6.5–6.8 (m, 1H, C(2)H).

Ketones 10 and 11

To diol **12** (1.09 g, 3.61 mmol) in dry dimethylformamide (10 mL) at 15°C under a nitrogen atmosphere was added pyridinium dichromate (1.76 g, 4.68 mmol). After 5 min the cold bath was removed and the reaction mixture was stirred at room temperature for 0.5 h. The product was then extracted with ethyl acetate (2 × 400 mL); the ethyl acetate extracts were washed with water (2 × 100 mL, 3 × 50 mL) till the washings remained neutral, dried over $MgSO_4$, and evaporated to give ketone **10** as an oil in 65% yield (low yield due to water solubility of ketone); ir (film) ν_{max}: 1685 (C=C—C=O), 1720 (CO_2Me), 3500 (OH) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.00 (s, 6H, $SiMe_2$), 0.78 (s, 9H, $SiCMe_3$), 2.4–3.0 (m, 2H, C(6)H, 3.2–4.3 (m, 3H C(4)H, C(5)H, OH), 3.72 (s, 3H, CO_2CH_3), 6.5–6.8 (m, 1H, C(2)H). Ketone **10** was acetylated in the usual manner (acetic anhydride, *N,N*-dimethylaminopyridine in anhydrous ether) to yield quantitatively ketone **11** as an oil; ir (film) ν_{max}: 1700 (C=C—C=O), 1725 (CO_2CH_3), 1750 ($OCOCH_3$) cm^{-1}; uv λ_{max} (EtOH): 233 nm (ε = 69 000); ^1H nmr ($CDCl_3$, 200 MHz) δ: 0.057 (s, 3H, $SiCH_3$), 0.085 (s, 3H, $SiCH_3$), 0.862 (s, 9H, $SiCMe_3$), 2.175 (s, 3H, $COCH_3$), 2.544–3.133 (ABq, 2H, J_{6ax} = 2.622, ddd, $J_{6ax,6eq}$ = 18.6 Hz, $J_{5,6ax}$ = 9.5 Hz, $J_{2,6ax}$ = 3.1 Hz, J_{6eq} = 3.073, dd, $J_{6ax,6eq}$ = 18.6 Hz, $J_{5,6eq}$ = 5.5 Hz, C(6)H), 3.833 (s, 3H, CO_2CH_3), 4.085–4.215 (ddd, 1H, $J_{5,6eq}$ = 5.5 Hz, $J_{5,6ax}$ = 9.6 Hz, $J_{4,5}$ = 11.0 Hz, C(5)H), 5.303 (d, 1H, $J_{4,5}$ = 11 Hz, C(4)H), 6.797 (d, 1H, $J_{2,6ax}$ = 3.1 Hz, C(2)H); ms *m/e*: 285 ($M^+ - CMe_3$), 243 ($M^+ - CMe_3$ —CH_2=C=O), 225 ($M^+ - CMe_3$ —AcOH).

Alcohols 15 and 16

To ketone **11** (684 mg, 2 mmol) in ethanol (10 mL) at 5°C was added sodium borohydride (76 mg, 2 mmol) all at once; the reduction reaction was complete instantaneously. The product was extracted with ether (2 × 600 mL); the ether extracts were washed with pH 4 buffer (4 × 100 mL), water (4 × 100 mL), dried over $MgSO_4$, and evaporated under reduced pressure to give epimeric alcohols **7** and **15** (α/β = 1:9) in 65% yield after flash chromatography (petroleum ether – ethyl acetate = 7:1). The mixture of alcohols **7** and **15** was acetylated in the usual manner to give their corresponding oily acetates **13** and **16**, for spectral identification.

For the introduction of tritium at the 3-position, the above experimental procedure was identical in all respects except that: (1) the reaction was performed on 1 mmol of ketone; (2) 100 mCi of tritiated $NaBH_4$ (5–20 Ci/mmol) (Amersham Searle Corp.) (in 3 mL ethanol) was added to ketone **11** (in 3 mL EtOH); after 10 min, cold sodium borohyride (1 molar equiv.) was added.

Alcohol 15: ^1H nmr ($CDCl_3$) δ: 0.00 (s, 6H, $SiMe_2$), 0.82 (s, 9H, $SiCMe_3$), 2.02 (s, 3H, $COCH_3$), 2.2–2.6 (m, 2H, C(6)H), 3.2–3.5 (m, 1H, OH), 3.69 (s, 3H, CO_2CH_3), 3.8–4.3 (m, 2H, C(3)H, C(5)H), 4.7–5.0 (m, 1H, C(4)H, 6.6–6.8 (m, 1H, C(2)H).

Acetate 16: ^1H nmr (200 MHz, $CDCl_3$) δ: 0.038 (s, 3H, $SiCH_3$), 0.066 (s, 3H, $SiCH_3$), 0.843 (s, 9H, $SiCMe_3$), 2.039 (s, 6H, $2COCH_3$), 2.269–2.827 (bABq, 2H, C(6)H), 3.741 (s, 3H, CO_2CH_3), 3.850–3.973 (ddd, 1H, $J_{5,6eq}$ = 5.8 Hz, $J_{4,5}$ = $J_{5,6ax}$ = 9.5 Hz, C(5)H), 5.070–5.158 (dd, 1H, $J_{3,4}$ = 7.8 Hz, $J_{4,5}$ = 9.8 Hz, C(4)H), 5.490–5.567 (m, 1H, C(3)H), 6.570–6.595 (dd, 1H, $J_{2,3}$ = $J_{2,6}$ = 2.4 Hz).

Mesylates 14 and 17

To a mixture of epimeric alcohols **7** and **15** (433 mg, 1.27 mmol) in dry methylene chloride (10 mL) at 5°C under a nitrogen atmosphere was added first triethylamine (1.05 mL, 7.53 mmol), then methanesulfonyl chloride (0.30 mL, 3.88 mmol); the reaction was over immediately and the product extracted with ether (2 × 175 mL). The ether extracts were washed with cold dilute aqueous HCl (2 × 25 mL), cold aqueous $NaHCO_3$ (3 × 25 mL), H_2O (4 × 25 mL), and dried over $MgSO_4$. Evaporation of the solvents under reduced pressure gave oily allylic mesylates **14** and **17** (531 mg) in quantitative yield (99%). The latter were submitted immediately to the inversion reaction.

Diacetate 13 from mesylate 17

A solution of crude allylic mesylates **17** and **14** (536 mg, 1.27 mmol) and potassium acetate (161 mg, 1.64 mmol), in dry methanol (8 mL) under a nitrogen atmosphere, was stirred at 70°C for 1.5 h. The reaction mixture was cooled to room temperature and excess solid Na_2CO_3 added; the product was then extracted with ether (2 × 175 mL, prewashed with Na_2CO_3); the ether extracts were washed with aqueous Na_2CO_3 (1 × 120 mL, 4 × 60 mL), water (4 × 30 mL), and dried over $MgSO_4$. Evaporation of the solvents followed by flash chromatography (petroleum ether/ethyl acetate/triethylamine = 120:8:0.2) gave orthoester **6** (contaminated with small amounts of hydrolysis products **7** and **8**, which were produced during chromatography) in 30% yield (based on ketone **11**). Its ^1H nmr spectrum was identical to that of authentic orthoester **6**. Hydrolysis, followed by acetylation, as for orthoester **6**, gave diacetate **13** as an oil, which had a 200 MHz ^1H nmr spectrum identical to that of authentic diacetate **13**.

Shikimic acid from silylated diacetate 13

To diacetate **13** (200 mg, 0.52 mmol) in dry tetrahydrofuran (5 mL) at 5°C under a nitrogen atmosphere was added tetra-*n*-butylammonium fluoride (0.7 mmol). After 0.5 h, water (50 mL) was added and the reaction mixture was extracted with ethyl acetate (2 × 600 mL); the ethyl acetate extracts were washed with water (6 × 60 mL), dried over $MgSO_4$, and evaporated to give the desired desilylated alcohol (some

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

acetate migration seemed to have occurred since the product was indicated as two spots of similar R_f on tlc) in 80% yield after flash chromatography (petroleum ether − ethyl acetate = 8:7).

To the desilylated product obtained (117 mg, 0.43 mmol) in MeOH (3 mL) at 5°C was added $NaOH/H_2O$ (86 mg/0.9 mL); after 0.5 h, the reaction mixture was brought to room temperature and stirred for 2 h; it was then neutralized at 15°C with acidic resin (AM − 120 H^+); evaporation of the solvents gave shikimic acid **1** in 90% yield with a mass spectrum identical to that of an authentic sample; ms *m/e* (of trimethylsilylated sample): 462 (M^+), 447 ($M^+ - CH_3$), 372 ($M^+ - Me_3SiOH$), 357 ($M^+ - Me_3SiOH - CH_3$), 282 ($M^+ - 2\ Me_3SiOH$), 204 ($Me_3SiOCH{=}CHOSiMe_3^+$, 100%).

Orthoacetate 5

To a suspension of methyl shikimate **2** (2.24 g, 11.92 mmol) in methylene chloride (90 mL), under a nitrogen atmosphere at room temperature, was added first trimethyl orthoacetate (3.50 mL, 27.85 mmol), then *p*-toluenesulfonic acid (113 mg). After all the starting material was dissolved (1 h), the reaction mixture was cooled (5°C) and excess solid Na_2CO_3 was added. The product was then extracted with ethyl acetate (2 × 600 mL, prewashed with Na_2CO_3); the ethyl acetate extracts were washed with aqueous Na_2CO_3 (5 × 50 mL), water (3 × 50 mL), and dried over $MgSO_4$. Removal of the solvents under reduced pressure gave orthoacetate **5** as an oil in 90% yield; ir (film) ν_{max}: 1715 (CO_2CH_3), 3470 (OH) cm^{-1}; ^1H nmr (CCl_4) δ: 1.35 (s, 3H, CH_3), 2.1−2.6 (m, 2H, C(6)H), 3.02 (s, 0.75H, OCH_3), 3.15 (s, 2.25H, OCH_3), 3.2−4.3 (m, 3H, C(4)H, C(5)H, OH), 3.65 (s, 3H, CO_2CH_3), 4.5−4.9 (m, 1H, C(3)H), 6.6−6.8 (m, 1H, C(2)H).

Orthoacetate 6

To a solution of alcohol **5** (2.8 g, 11.5 mmol) in dry dimethylformamide (10 mL) under a nitrogen atmosphere were added *tert*-butyldimethylsilyl chloride (2.1 g, 13.8 mmol) and imidazole (3.9 g, 57.3 mmol). After 1 h at 45°C, the reaction mixture was extracted with ether (2 × 500 mL); the ether extracts were washed with water (3 × 100 mL, 4 × 60 mL), dried over $MgSO_4$, and evaporated to yield silylated orthoester **6** as an oil in quantitative yield; ^1H nmr (CCl_4) δ: 0.0 (s, 6H, $SiMe_2$), 0.78 (s, 9H, $SiCMe_3$), 1.34 (s, 3H, CH_3), 2.1−2.5 (m, 2H, C(6)H), 3.00 (s, 0.75H, OCH_3), 3.13 (s, 2.25H, OCH_3), 3.65 (s, 3H, CO_2CH_3), 3.7−4.3 (m, 2H, C(4)H, C(5)H), 4.4−4.9 (m, 1H, C(3)H), 6.6×6.9 (m, 1H, C(2)H).

Alcohols 7 and 8

A solution ($MeOH/H_2O/AcOH$ = 90 mL:30 mL:3.0 mL) of orthoester **6** (3.93 g, 11.0 mmol) was stirred at room temperature for 1 h; after this time, 600 mL of toluene were added and the solvents were removed under reduced pressure. This procedure was repeated a total of three times to give a mixture of alcohols **7** and **8**. These were used without prior separation in the subsequent oxidation step. A sample of 3-alcohol **7** was obtained as an oil by flash chromatography (petroleum ether − ethyl acetate = 4:1) for spectral identification; ir (film) ν_{max}: 1720 (CO_2CH_3), 1745 ($OCOCH_3$), 3470 (OH) cm^{-1}; ^1H nmr ($CDCl_3$, 200 MHz) δ: 0.057 (s, 3H, $SiCH_3$), 0.075 (s, 3H, $SiCH_3$), 0.837 (s, 9H, $SiCMe_3$), 2.01−2.07 (bs, 1H, OH), 2.072 (s, 3H, $COCH_3$), 2.218−2.609 (bABq, 2H, C(6)H), 3.747 (s, 3H, CO_2CH_3), 4.176−4.252 (ddd, 1H, $J_{5,4}$ = 6.5 Hz, $J_{5,6ax} = J_{5,6eq}$ = 4.5 Hz, C(5)H), 4.574−4.642 (bs, 1H, C(3)H), 4.929−4.982 (dd, 1H, $J_{4,5}$ = 6.5 Hz, $J_{3,4}$ = 4.2 Hz, C(4)H), 6.781−6.805 (m, 1H, C(2)H); ms *m/e*: 329 ($M^+ - CH_3$), 313 ($M^+ - OCH_3$), 287 ($M^+ - CMe_3$), 284 (M^+ − AcOH), 269 (M^+ − AcOH − CH_3), 227 ($M^+ - CMe_3$ − AcOH), 195 ($M^+ - H_2O - Me_3CSiMe_2O$).

Diacetate 13

To a mixture of alcohols **7** and **8** (172 mg, 0.50 mmol) in anhydrous ether (10 mL) were added *N,N*-dimethylaminopyridine (12 mg, 0.10 mmol), then acetic anhydride (0.14 mL, 1.5 mmol). After 1 h, the reaction mixture was extracted with ether (2 × 175 mL); the ether extracts were washed with H_2O (5 × 20 mL), dried over $MgSO_4$, and evaporated to give oily diacetate **13** in quantitative yield; ir (film)ν_{max}: 1720 (CO_2Me), 1750 (OAc) cm^{-1}; ^1H nmr (200 MHz, $CDCl_3$) δ: 0.066 (s, 3H, $SiCH_3$), 0.085 (s, 3H, $SiCH_3$), 0.853 (s, 9H, $SiCMe_3$), 2.018 (s, 3H, $COCH_3$), 2.047 (s, 3H, $COCH_3$), 2.210−2.716 (bABq, 2H, C(6)H), 3.751 s, 3H, CO_2CH_3), 4.101−4.182 (ddd, 1H, $J_{5,6ax}$ = $J_{5,6eq}$ = 4.6 Hz, $J_{4,5}$ = 7.0 Hz, C(5)H), 5.057−5.112 (dd, 1H, $J_{3,4}$ = 3.9 Hz, $J_{4,5}$ = 7.0 Hz, C(4)H), 5.723−5.776 (m, 1H, C(3)H), 6.681−6.713 (m, 1H, C(2)H); ms *m/e*: 329 ($M^+ - CMe_3$), 269 ($M^+ - CMe_3$ − AcOH), 227 ($M^+ - CMe_3$ − AcOH − $CH_2{=}C{=}O$), 195 (M^+ − AcOH − Me_3CSiMe_2O).

Ketone 11 and alcohol 8

To a mixture of alcohols **7** and **8** (3.58 g, 10.4 mmol) in dry dimethylformamide (10 mL) under a nitrogen atmosphere was added pyridinium dichromate (4.0 g, 10.6 mmol). The reaction mixture was stirred at 45°C for 1 h; following the addition of 110 mL water, the product was extracted with ether (2 × 600 mL); the ether extracts were washed with H_2O (3 × 100 mL, 4 × 70 mL), dried over $MgSO_4$, and the solvent removed under reduced pressure to yield a mixture of 3-ketone **11** and 4-alcohol **8**. These were separated by flash chromatography (petroleum ether − ethyl acetate = 7:1), to give 1.5 g of **11** and 1.45 g of **8** as oils, slightly contaminated with some unoxidized 3-alcohol **7** (traces of **7** on tlc plates).

3-Ketone 11: had the same spectral properties described earlier (identical ir, uv, and ^1H nmr spectra).

4-Alcohol 8: ir (film)ν_{max}: 1720 (CO_2CH_3), 1735 ($OCOCH_3$), 3500 (OH) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.00 (s, 6H, $SiMe_2$), 0.80 (s, 9H, $SiCMe_3$), 2.00 (s, 3H, $COCH_3$)0, 2.2−2.6 (m, 3H, C(6)H, OH), 3.61 (s, 3H, CO_2CH_3), 3.6−4.2 (m, 2H, C(4)H, C(5)H), 5.4−5.6 (m, 1H, C(3)H), 6.4−6.7 (m, 1H, C(2)H); ms *m/e*: 287 ($M^+ - CMe_3$), 269 (M^+ − AcOH − CH_3), 227 ($M^+ - CMe_3$ − AcOH), 195 ($M^+ - H_2O$ − Me_3CSiMe_2O).

Oxidation and reduction of alcohol 8

To alcohol **8** (447 mg, 1.3 mmol) in acetone (10 mL) at room temperature was added Jones reagent (11) (0.35 mL); additional Jones reagent was then added after the following total time intervals: 1 h/0.2 mL; 2.5 h/0.1 mL. After 5 h, the reaction mixture was extracted with ether (2 × 600 mL); the ether extracts were washed with H_2O (5 × 100 mL, 4 × 70 mL), dried over $MgSO_4$, and evaporated to give a mixture of 3-ketone **11** and 4-ketone **9**, as well as a small amount of 3-ketone **18**. This mixture was immediately submitted to borohydride reduction.

To the mixture of ketones obtained above (290 mg, 0.85 mmol) in EtOH (7 mL) at 5°C was added sodium borohydride (32 mg, 0.85 mmol); the reduction reaction proceeded instantaneously and after 10 min the reaction mixture was poured into cold dilute aqueous HCl (80 mL). The product was immediately extracted with ether (2 × 600 mL); the ether extracts were washed with cold dilute aqueous HCl (1 × 100 mL), water (5 × 60 mL), dried over $MgSO_4$, and evaporated under reduced pressure to give a mixture of alcohols **8**, **15**, and **19**. In order to facilitate the separation of these alcohols, the allylic ones were oxidized to their respective ketones using pyridinium dichromate.

A complete oxidation of the allylic alcohols necessitated two successive oxidations with pyridinium dichromate. To a mixture of alcohols **8**, **15**, and **19** (250 mg, 0.73 mmol) in dry dimethylformamide (4 mL) under a nitrogen atmosphere was added pyridinium dichromate (250 mg, 0.67 mmol). The reaction mixture was stirred at 45°C for 1 h; it was then extracted with ether (2 × 500 mL); the ether extracts were washed with H_2O (8 × 50 mL), dried over $MgSO_4$, and evaporated. The crude residue was then oxidized once again, by the same procedure, to give a complete oxidation of the allylic alcohols **15** and **19** to the corresponding 3-ketones **11** and **18**. These were separated from **8** by flash chromatography (petroleum ether − ethyl acetate 4:1). The alcohol **8** isolated was obtained in 12% overall yield.

In order to prepare the derivative with deuterium at the 4-position sodium borodeuteride was used. For the introduction of tritium at the 4-position, the above experimental procedure was identical in all respects except that: (1) total reaction time for the Jones oxidation was kept to 3.5 h; (2) 200 mCi of the tritiated sodium borohydride (5−20 mCi/mmol) (Amersham Searle Corp.) (in 4 mL EtOH) was added to the mixture of ketones (in 4 mL EtOH) over a 10-min period; after 15 min (total reaction time from the beginning of addition), the tritiated

$NaBH_4$ (1 molar equiv.) was added.

Attempts to purify 4-ketone **9** by flash chromatography resulted in its almost complete conversion to 3-ketone **18**. It was reduced with sodium borohydride in the usual manner to liquid alcohol **19**, which was characterized as its oily diacetate **20**.

3-Ketone 18: ir (film) ν_{max}: 1710 (C=C—C=O), 1725 (CO_2Me), 1750 ($OCOCH_3$) cm^{-1}; uv λ_{max} (EtOH): 233 nm (ϵ = 57 000); ^1H nmr (200 MHz, $CDCl_3$) δ: 0.018 (s, 3H, $SiCH_3$), 0.039 (s, 3H, $SiCH_3$), 0.790 (s, 9H, $SiCMe_3$), 2.185 (s, 3H, $COCH_3$), 2.741–2.983 (ABq, $H_{6'}$ = 2.926, ddd, 1H, $J_{2,6'}$ = 0.8 Hz, $J_{5,6'}$ = 2.9 Hz, $J_{6'6''}$ = 19.1 Hz, $H_{6''}$ = 2.803, ddd, 1H, $J_{5,6''}$ = $J_{2,6''}$ = 2.8 Hz, $J_{6',6''}$ = 19.1 Hz, C(6)H), 3.825 (s, 3H, CO_2CH_3), 4.458–4.500 (ddd, 1H, $J_{4,5}$ = 2.4 Hz, $J_{5,6'}$ = $J_{5,6''}$ = 3.0 Hz, C(5)H), 5.375 (d, 1H, $J_{4,5}$ = 2.3 Hz, C(4)H), 6.792–6.809 (dd, 1H, $J_{2,6'}$ = 0.8 Hz, $J_{2,6''}$ = 2.6 Hz, C(2)H); ms *m/e*: 285 (M^+ – CMe_3), 243 (M^+ – CMe_3 – CH_2=C=O), 225 (M^+ – CMe_3 – AcOH).

Syntheses of some pyrimidine N-oxides

MISA V. JOVANOVIC
Department of Chemistry, Southern Methodist University, Dallas, Texas 75275, U.S.A.

Received April 26, 1983[1]

MISA V. JOVANOVIC. Can. J. Chem. **62**, 1176 (1984).

Various monosubstituted pyrimidines and methylpyrimidines were N-oxidized with a number of different peracids. In general, they are more susceptible to side reactions accompanying N-oxidation (i.e., decomposition, annular carbon oxidation, ring opening) than other π-deficient diazine and triazine analogs. Unsymmetrical pyrimidines, which can potentially yield two isomeric products, were N-oxidized preferentially at the site *para* to strong electron-donating substituents. Weaker ring-activating groups, such as methyl, are mainly *ortho* directing and only aid in the N-oxidation of pyrimidine nuclei having *ortho*/*para*-directing substituents.

MISA V. JOVANOVIC. Can. J. Chem. **62**, 1176 (1984).

On a oxydé l'azote de diverses pyrimidines et méthylpyrimidines monosubstituées en faisant appel à un certain nombre de peracides. Par rapport aux analogues déficients en électrons comme les diazines et les triazines, les pyrimidines sont en général plus susceptibles de subir les réactions secondaires (comme la décomposition, l'oxydation des carbones du cycle et l'ouverture du cycle) qui accompagnent les réactions d'oxydation de l'azote. Les pyrimidines non symétriques, qui peuvent éventuellement conduire à deux produits isomères, s'oxydent préférentiellement en position *para* des substituants fortement électrodonneurs. La présence sur le cycle de groupes moins activants, comme le méthyle, provoque une oxydation préférentielle en position *ortho*; ces groupes n'aident à l'oxydation de l'azote des noyaux pyrimidines que s'ils portent des substituants orientant vers les positions *ortho* et *para*.

As part of an extensive study of the halogenation of diazine N-oxides (1, 2), it became necessary to prepare a number of pyrimidine N-oxides. A literature search soon revealed a paucity of these compounds, with major emphasis being placed on the syntheses of polysubstituted pyrimidine N-oxides (3). Among the known monosubstituted compounds are the various monomethyl (4, 5), the 2-methoxy- and 4-methoxypyrimidine N-oxides (6, 7), and a number of 5-substituted derivatives recently prepared by Kobayashi *et al.* (8) and by us (9). The synthesis of pyrimidine 1,3-dioxide via a cyclization reaction has also recently been described (10).

It is well known that pyrimidines yield their corresponding N-oxides in poor yields (3). We have observed earlier that for the 1,2,4-triazine series, 6-aza analogs of pyrimidines, N-oxidation is generally readily accomplished at room temperature (11, 12). Thus, N-oxidation of some pyrimidines was attempted under similarly mild conditions.

Results and discussion

Since 2-methoxypyrimidine 1-oxide, **1**, has been described in the literature without the presentation of experimental details (6), we elected to examine its preparation first. When 2-methoxypyrimidine, **2**, was treated with peracetic acid in acetic acid solution, at room temperature, *three* isomeric products were isolated. The major component of this mixture was the expected N-oxide, **1**, obtained in 18% yield. 1-Methoxy-2-oxo-1,2-dihydropyrimidine, **3**, and 5-hydroxy-2-methoxypyrimidine, **4**, were also isolated. Structural proofs of these compounds rest on their elemental analyses, mass spectral fragmentation patterns, and ^{1}H nmr spectra (see Table 2 and Experimental). The formation of the methoxy derivative, **3**, follows a known pattern in the pyridine series (3) and probably results from an alkylation/dealkylation rearrangement of compound **1**. The isolation of the hydroxy derivative, **4**, is akin to the formation of 5-hydroxy-6-phenylpyrimidine 1-oxide from 4-phenylpyrimidine 1,3-dioxide, upon treatment with acetic anhydride (13).

The N-oxidation of a number of 2-substituted (**2**, **5**–**10**), 2-substituted-4-methyl- (**11**–**13**), 4-substituted (**14**–**20**), and 4-substituted-6-methyl- (**21**–**24**) pyrimidines, under the reaction conditions listed in Table 1, showed that peracetic acid generally gives the desired N-oxides in higher yields than *m*-chloroperbenzoic acid (MCPBA).

Among the 2-substituted pyrimidines (**5**–**10**), 2-aminopyrimidine, **7**, was readily N-oxidized under the reaction conditions given in Table 1. This reactivity decreases with the 2-monomethylamino derivative, **8**, and disappears altogether with 2-dimethylamino-, **9**, and 2-acetamido-, **10**, substituents. Similarly, the 2-chloro compound, **5**, is not reactive enough, while the moderately activating 2-methyl derivative, **6**, is, and yielded the desired 2-methylpyrimidine 1-oxide, **29**.

As expected, the presence of two electron-donating groups (**11**–**13**, **21**–**24**) increases the reactivity of the pyrimidine ring towards N-oxidation, and higher yields of N-oxides were obtained. For the 2-substituted-4-methylpyrimidines and for the 4-substituted-6-methylpyrimidines, the formation of two isomeric mono-N-oxides was possible. In the first instance, N-oxidation of 2-substituted-4-methylpyrimidines (**11**–**13**)

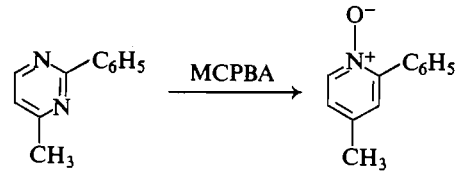
12 R = $NHCH_3$	—	**34** R = $NHCH_3$
13 R = CH_3	**35** R = CH_3	**36** R = CH_3

furnished mainly the 3-oxides, the N-oxides *ortho* to both substituents. Thus, the apparently *more* sterically hindered nitrogen was oxidized, This behaviour is not a sterically controlled one, but reflects the *ortho*-activating effect of the methyl group reinforcing the *ortho*-activating effect of the 2-substituent.

However, 2-phenyl-4-methylpyrimidine, **25**, afforded the 1-oxide, **37**, only (14). In this case, it seems that the size of the R group was the limiting factor for the formation of the 3-oxide.



25 37

In the series of 4-methyl-6-substituted pyrimidines (**21**–**24**), the 1-oxides were formed exclusively. The nitrogen which is *ortho* to the methyl group and *para* to the substituent was oxidized. Thus, in those instances where the substituent R can have either an *ortho*- or a *para*-directing influence, the latter appears to be the controlling factor.

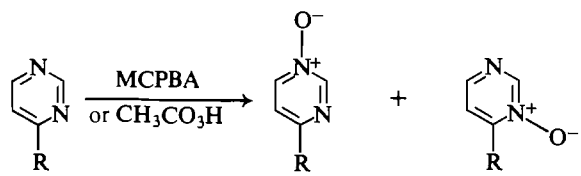
24 R = OCH_3	**41** R = OCH_3	—

The formation of two isomeric mono-N-oxides was also possible with 4-substituted pyrimidines (**14**–**20**). Among the groups examined, only when R = CH_3, **19**, are both isomers obtained in significant amounts. With 4-aminopyrimidine, **14**, the N-oxidation was also achieved *ortho* to the amino group and 4-aminopyrimidine 3-oxide, **43**, was detected and isolated in small quantity (see Table 1). However, neither 4-acetamidopyrimidine, **17**, nor the 4-morpholino derivative, **18**, were N-oxidized under these conditions. No reasonable rationale for this behavior can be offered at this time.

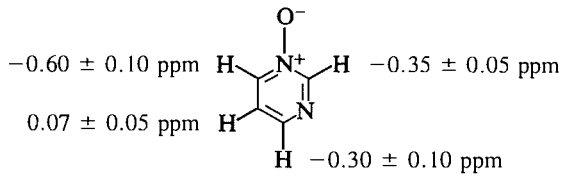


14 R = NH_2	**42** R = NH_2	**43** R = NH_2
15 R = $NHCH_3$	**44** R = $NHCH_3$	—
16 R = $N(CH_3)_2$	**45** R = $N(CH_3)_2$	—
17 R = $NHCOCH_3$	—	—
18 R = NC_4H_8O	—	—
19 R = CH_3	**46** R = CH_3	**47** R = CH_3
20 R = OCH_3	**48** R = OCH_3	—

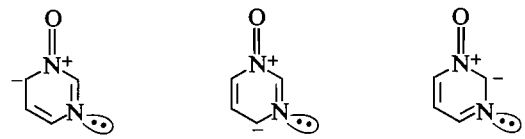
We had observed that with 3-substituted-1,2,4-triazines, the 2-oxides were formed when the substituent was a tautomerizable amino group, while the 1-oxides were obtained with other substituents (12). This selectivity clearly does *not* carry over into the pyrimidine ring system, where only a trace of the analogous 3-oxide, **43**, was obtained when 4-aminopyrimidine, **14**, was oxidized.

Proton nuclear magnetic resonance effects

We have already described the proton chemical shift changes which occur in various 1,2,4-triazines upon oxidation of either N-1 or N-2 (12). In the few known pyrimidine N-oxides, N-1 oxidation caused shielding of H-2, H-4, and H-6 by 0.3, 0.3, and 0.5 ppm, respectively (12). The chemical shift of the proton *meta* to the N-oxide function (H-5) was not affected by N-oxidation. This information was used in a general sense to establish the sites of N-oxidation in this study, where ambiguous (see Table 2). A compilation of all of the now known pyrimidine N-oxides (in $CDCl_3$) affords the following data (δ (ppm) N-oxide − δ (ppm) non-oxide):



Thus, the major proton shielding effect upon N-oxidation of pyrimidines is at H-6 (0.6 ppm), while H-2 and H-4 are similarly shielded (0.3 and 0.35 ppm). Only a negligible deshielding effect occurs at H-5. The difference can well be explained by considering the resonance contributing forms **26**, **27**, and **28** to the ground state of the pyrimidine N-oxides.



26 **27** **28**

Canonical forms **27** and **28** are expected to be less stable than **26** because of the lone-pair repulsion between the nitrogen lone pair of electrons and the charge on C-2 and C-4, respectively. This repulsion does not exist in structure **26**. Thus, it contributes more substantially to the ground state of pyrimidine N-oxides. This, in turn, is reflected by the greater shielding of H-6, as compared to H-2 and H-4.

Experimental

General procedure A

In a typical experiment, 3.40 mmol of 85% *m*-chloroperbenzoic acid dissolved in 60 mL of reagent grade acetonitrile was added dropwise (10 min) to 26.0 mmol of the appropriate pyrimidine in 120 mL of acetonitrile. The reaction mixture was heated at 60–65°C for the time indicated (Table 1). The reaction mixture was then evaporated *in vacuo*, and the residue was sublimed (monosubstituted aminopyrimidine N-oxides) or dissolved in an excess of saturated aqueous Na_2CO_3 solution, and was extracted with methylene chloride (3 × 100 mL portions). The combined extracts were dried over anhydrous K_2CO_3, filtered, and evaporated under reduced pressure to yield the N-oxide.

General procedure B

The N-oxidations with peracetic acid were carried out as described in the literature (14).

N-Oxidation of 2-methoxypyrimidine (2)

To a solution of 3.0 g (27.3 mmol) of 2-methoxypyrimidine (**2**) dissolved in 10 mL of glacial acetic acid was added 5 mL of 34% hydrogen peroxide and the solution was warmed on a water bath at 60–65°C for 7 h. The acetic acid was removed by distillation under reduced pressure (70 Torr). The temperature did not exceed 35°C. The greenish-yellow oily residue was basified with an excess of 20%

[2]The two "isomers" are identical owing to the symmetry of **23**.

[e]The size of the coupling constant (8 Hz), as well as the chemical shifts, suggest that this compound exists in DMSO, at least to some extent, in the imino form.

aqueous K_2CO_3 solution. The mixture was then extracted with chloroform (5 × 30 mL), the combined chloroform extracts were dried over anhydrous K_2CO_3, and the solvent was evaporated *in vacuo*, leaving 1.5 g (43.6%) of white prisms. These crystals contained impurities (starting material and compounds **3** and **4**) in addition to the desired oxide (**1**). The product was dissolved in a mixture of 5 mL CH_2Cl_2/2.5 mL dry methanol and was passed through a short 25-mL column of neutral alumina (grade III). The first fraction which was eluted with CH_2Cl_2 was compound **1**, the second fraction contained compound **2**. Elution with 95% ethylacetate/5% methanol gave substances **3** and **4**, which were further separated by thick-layer chromatography with the same eluent.

As the reaction time was increased to 14–18 h at 60°C (or one week at room temperature), almost all of the starting material was converted to compounds **3** and **4** at the expense of the N-oxide **1**.

^{33}S and ^{17}O nuclear magnetic resonance study of liquid sulfur dioxide

RODERICK E. WASYLISHEN[1], J. BRUCE MACDONALD, AND JAN O. FRIEDRICH
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received November 25, 1983

RODERICK E. WASYLISHEN, J. BRUCE MACDONALD, and JAN O. FRIEDRICH. Can. J. Chem. **62**, 1181 (1984).

The sulfur-33 chemical shift and ^{33}S and ^{17}O nmr relaxation data are reported for liquid sulfur dioxide. The ^{33}S nucleus in SO_2 is highly deshielded, 375 ± 2 ppm to high frequency of the sulfate anion. The rotational correlation time of SO_2 at 294 K, 0.3 ps, is only about twice that calculated using an inertial model. The temperature dependence of the ^{33}S and ^{17}O nmr relaxation data can be described by an average activation energy of 6.3 ± 0.6 kJ mol^{-1}. The effective rotational correlation time derived from ^{33}S nmr line widths is used to calculate the ^{17}O quadrupolar coupling constant, e^2qQ/h = 6.6 ± 0.7 MHz, in SO_2.

RODERICK E. WASYLISHEN, J. BRUCE MACDONALD et JAN O. FRIEDRICH. Can. J. Chem. **62**, 1181 (1984).

On rapporte les déplacements chimiques du soufre-33 et les données de relaxation rmn du ^{33}S et du ^{17}O pour le bioxyde de soufre liquide. Le noyau de ^{33}S du SO_2 est fortement déblindé; par rapport à l'ion sulfate, il apparaît à une fréquence 375 ± 2 ppm plus élevée. Le temps de corrélation rotationelle du SO_2 à 294 K, 0,3 ps, est seulement le double de celui calculé en utilisant un modèle inertiel. On peut décrire l'effet de la température sur les données de relaxation en rmn du ^{33}S et du ^{17}O par une énergie d'activation moyenne de 6,3 ± 0,6 kJ mol^{-1}. On a utilisé le temps de corrélation rotationelle effectif déduit de la largeur des raies en rmn du ^{33}S pour calculer la constante de couplage quandrupolaire du ^{17}O, e^2qQ/h = 6,6 ± 0,7 MHz, dans du SO_2.

[Traduit par le journal]

Introduction

Although oxygen-17 chemical shifts have been previously reported for sulfur dioxide (1, 2), there appear to be no ^{33}S or ^{17}O nmr relaxation data on this simple molecule. Furthermore, we have been unable to find any information in the literature regarding the rotational dynamics of SO_2 in the liquid phase (−10.1 to −75.5°C at atmospheric pressure (3)). Here we wish to report the ^{33}S nmr chemical shift of liquid SO_2 and the temperature dependence of the ^{33}S and ^{17}O nmr relaxation rates.

Theory

Both ^{33}S and ^{17}O are quadrupolar nuclei with rather large quadrupole moments, $I = 3/2$ ($Q = -0.055 \times 10^{-28}$ m^2) and $I = 5/2$ ($Q = -0.026 \times 10^{-28}$ m^2), respectively (2*b*, 4). These properties combined with the low natural abundances of ^{33}S and ^{17}O, 0.76% and 0.037% respectively, have to some extent impeded nmr studies of these isotopes. For quadrupolar nuclei, interactions between the nuclear quadrupole moment and the surrounding electric field gradient, for example, provide an extremely efficient mechanism for nuclear relaxation (5). Under conditions of extreme narrowing ($2\pi\nu\tau_c \ll 1$)

$$[1]\quad \frac{1}{T_1} = \frac{1}{T_2} = \pi\nu_{1/2} = \frac{3\pi^2}{10}\,\frac{2I+3}{I^2(2I-1)}\left(1+\frac{\eta^2}{3}\right) \times (e^2q_{zz}Q/h)^2\tau_c$$

where ν is the Larmor precession frequeny in Hz, τ_c is the effective rotational correlation time (6), $\nu_{1/2}$ is the line width at half maximum height, $e^2q_{zz}Q/h$ is the quadrupolar coupling constant, and η is an asymmetry parameter, $(q_{yy} - q_{xx})/q_{zz}$. For SO_2 the ^{33}S nuclear quadrupolar coupling constant and asymmetry parameter have been measured by Bird and Townes (7) using microwave spectroscopy, $(e^2q_{zz}Q/h)$ = 25.71 ± 0.03 MHz and η = 0.87. The corresponding ^{17}O values have not been reported; however, from the results of the present study we are able to provide an estimate of the ^{17}O quadrupole coupling constant.

[1]Author to whom all correspondence should be directed.

Experimental

All nmr measurements were carried out on a Nicolet 360 NB (B_0 = 8.48 T) using a broad-band variable temperature 10-mm probe. Sulfur-33 line widths were measured at 27.727 MHz using $\pi/2$ pulses (45 μs). The ^{33}S line width of a 4 *m* $(NH_4)_2SO_4$ solution was less than or equal to 5.5 Hz, and we believe that the contribution of magnet field inhomogeneity to the observed line widths was less than 5 Hz at all temperatures. Acquisition times of 0.2 s were used at all temperatures; typically, 5000 scans were used in acquiring each spectrum.

Oxygen-17 spin-lattice relaxation times were carried out at 48.974 MHz using the inversion recovery pulse sequence which uses compensating pulses (8). The $\pi/2$ pulse width was 38 μs. Typically, 16 scans were required for $S/N > 200$. T_1 was calculated using a non-linear three-parameter least-squares fitting procedure available on the Nicolet software.

A special homemade nmr tube was designed and used to minimize diffusion between the gas and liquid phases (9).

Results

(a) *Chemical shifts*

At 294 K the ^{33}S nmr resonance of SO_2 (Fig. 1) is 375 ± 2 ppm to high frequency of the $^{33}SO_4^{2-}$ resonance of 4 *m* $(NH_4)_2SO_4$ solution, or 707 ppm to high frequency of CS_2. This extends the known range of ^{33}S chemical shifts by approximately 340 ppm (10); previously, the least shielded ^{33}S resonance was that of K_2MoS_4 (11). It is of interest to point out that the central ^{7}O nucleus of ozone is also highly deshielded, 1032 ppm, with respect to H_2O (2*b*, 12).

(b) *Rotational correlation times from ^{33}S nuclear magnetic resonance line widths*

Observed ^{33}S nmr line widths as a function of temperature are given in Table 1. From a plot of ln $\nu_{1/2}$ vs. $10^3/T$, Fig. 2, an activation energy of 6.9 ± 0.4 kJ mol^{-1} is evaluated. Such a value is typical of a non-associated liquid (13). By substitution of the ^{33}S quadrupole coupling constant into eq. [1], and the equation describing the straight line of Fig. 2, we obtain the expression (eq. [2]) below which describes the temperature dependence of the rotational correlation time, τ_c.

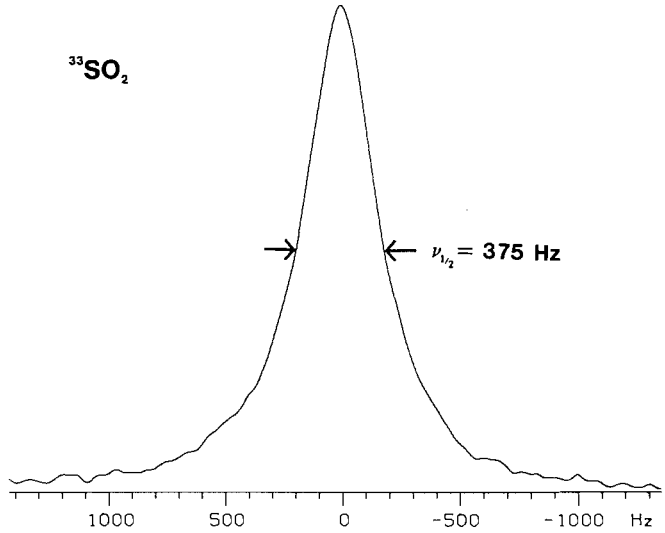

FIG. 1. 27.727 MHz sulfur-33 nmr spectrum of liquid SO_2 (at saturation pressure) at 294 K.

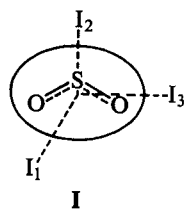
$$[2]\quad \tau_c = 1.791 \times 10^{-14} \exp(833/T)$$

The error bars in Fig. 2 correspond to an estimated error of ±5%. Although this is probably a realistic value at 20°C, ±10% may be more appropriate at the lower temperatures where it is difficult to measure accurate line widths because of acoustic ringing (14). At 202 K the value of T_2^*, $(\pi\nu_{1/2})^{-1}$, is approximately 271 μs, only about six times longer than the $\pi/2$ pulse width of our spectrometer; therefore we expect some lineshape distortions at these lower temperatures.

At the highest temperature studied, 294 K, the effective rotation correlation time calculated using eq. [2] is 0.30 ps. It is of interest to compare this characteristic time with that calculated by an inertial model (6). Sulphur dioxide (**I**) may crudely be approximated as a prolate spheroid since $I_1 = 9.5 \times 10^{-46}$ kg m^2, $I_2 = 8.1 \times 10^{-46}$ kg m^2, and $I_3 = 1.4 \times 10^{-46}$ kg m^2 (7). For a prolate spheroid



I

($I_1 = I_2 > I_3$) we have previously shown (15):

$$[3]\quad \tau_{FR} = (3)^{-1/2}\left(\frac{I_1 I_3}{2\pi kT(I_1 - I_3)}\right)^{1/2} \ln\left[\frac{1 + \left(\frac{I_1 - I_3}{I_1}\right)^{1/2}}{1 - \left(\frac{I_1 - I_3}{I_1}\right)^{1/2}}\right]$$

Substitution of $I_1 = I_2 = 8.8 \times 10^{-49}$ kg m^2 and $I_3 = 1.4 \times 10^{-46}$ kg m^2 into eq. [3] gives $\tau_{FR} = 0.15$ ps. The implication is that the rotational motion of sulfur dioxide cannot be described as small step diffusion since $\chi \simeq 2$(6, 16).

$$[4]\quad \chi = \left(\frac{3\pi}{2}\right)^{1/2} \tau_2 \left(\frac{KT}{I}\right)^{1/2}$$

For small step diffusion $\chi \gg 1$ (6, 16). At 202 K $\tau_c = 1.1 \pm 0.1$ ps, $\tau_{FR} = 0.18$ ps, and $\chi \simeq 7$, suggesting that rotations may be regarded as approaching small step diffusion.

TABLE 1. Temperature dependence of ^{33}S nuclear magnetic resonance line widths and ^{17}O T_1 values in liquid sulfur dioxide

^{33}S nmr data		^{17}O nmr data	
Temperature	$\nu_{1/2}$(±5%)	Temperature	T_1(±5%)
294 K	315 Hz	294 K	0.0789 s
274	410	273	0.0602
270	420	257	0.0528
257	450	243	0.0450
238	615	228	0.0381
223	735	213	0.0329
215	860	202	0.0255
206	1130		
202	1175		

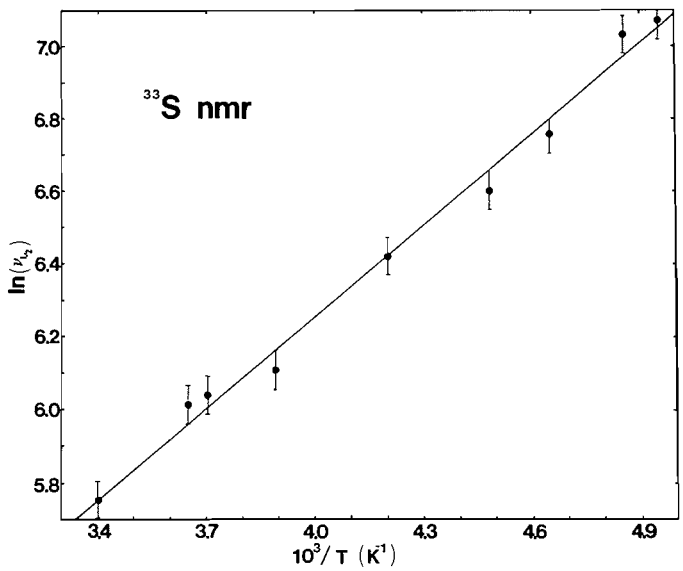


FIG. 2. Plot of ln $\nu_{1/2}$ vs. $10^3/T$ for liquid SO_2. $\nu_{1/2}$ is the ^{33}S nmr line width measured at half maximum height.

At the lower temperatures we have attempted to test the hydrodynamic model of Hu and Zwanzig (6, 17) under the slip boundary condition. Under these conditions, motion about the symmetry axis (labelled 3 in **I**) is relatively free while rotations about the 1 and 2 axes are more hindered because neighbouring molecules must be displaced. Anisotropic rotations of SO_2 have been inferred from vibrational spectroscopy (18). Using standard procedures (6, 15–17) we calculate $\tau_{slip} \simeq 2$ ps at 202 K, which is almost twice the observed correlation time. This agreement is satisfactory in view of our assumptions regarding the geometry of SO_2 (prolate spheroid, $a = b = 1.9$ Å and $c = 2.7$ Å); also it is probably not meaningful to use a hydrodynamic model for a molecule which is probably not undergoing small step rotational diffusion.

(c) *^{17}O nuclear magnetic resonance spin-lattice relaxation times and the quadrupole coupling constant*

The ^{17}O nmr line widths of liquid SO_2 are relatively sharp, less than 15 Hz, at all temperatures and allow accurate measurements of the spin-lattice relaxation time, T_1 (Table 1). An Arrhenius plot of ln T_1^{-1} vs. $10^3/T$ gives a straight line, Fig. 3, of slope 5.7 ± 0.5 kJ mol^{-1}.

Assuming the same effective rotational correlation time for ^{17}O and ^{33}S nuclear spin relaxation, and that the ^{17}O asymmetry parameter is small, substitution into eq. [1] gives an effective

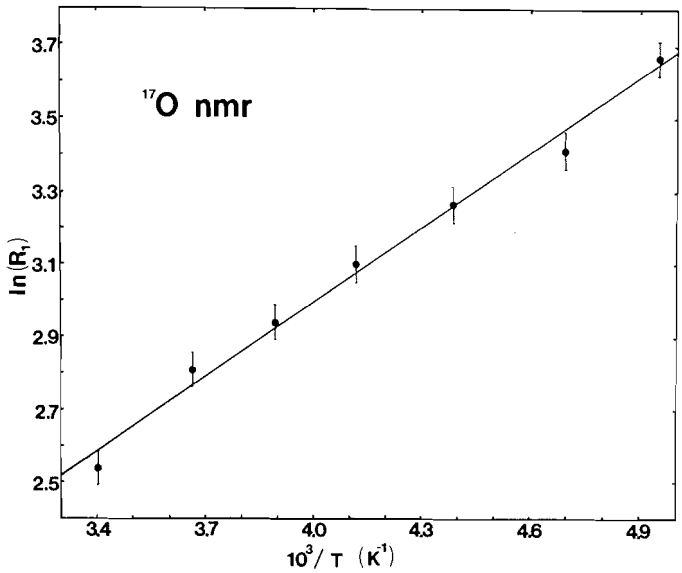

FIG. 3. Plot of ln R_1 vs. $10^3/T$ for liquid SO_2. R_1 is the rate of the ^{17}O spin lattice relaxation.

^{17}O quadrupole coupling constant, e^2qQ/h, of 6.64 MHz. We believe the error in this value is less than ±10%. The oxygen-17 quadrupole coupling constant in SO_2 has not been previously reported; however, Poplett (19) has reported a value 7.340 ± 0.005 MHz for the S=O fragments of solid sulfuric acid. The asymmetry parameter was only 0.06 ± 0.05; therefore our assumption that η is small in SO_2 appears justified.

PELAYO CAMPS and MARTA FIGUEREDO. Can. J. Chem. **62**, 1184 (1984).

The attempts to synthesize dimethyl tricyclo[3.3.0.0^{3,7}]octane-1,5-dicarboxylate, **1**, and some related compounds by formation of a C3—C7 bond from appropriate bicyclo[3.3.0]octane derivatives, either through intramolecular C—H carbene insertion or by ketone-to-cyclopentanol photocyclization, are described. Two alternative syntheses for the key precursor, dimethyl *cis*-3-oxobicyclo[3.3.0]octane-1,5-dicarboxylate, **2**, are included. Also, the formation of dimethyl 3-hydroxytricyclo[3.3.0.0^{3,7}]octane-1,5-dicarboxylate, **24**, by reduction of dimethyl *cis*-3,7,dioxobicyclo[3.3.0]octane-1,5-dicarboxylate, **9**, under Clemensen-like reaction conditions is reported.

PELAYO CAMPS et MARTA FIGUEREDO. Can. J. Chem. **62**, 1184 (1984).

On décrit des essais de synthèse du tricyclo[3.3.0.0^{3,7}]octane dicarboxylate-1,5 de méthyle (**1**) et de quelques composés apparentés qui impliquent la formation d'une liaison C3—C7 à partir des dérivés bicyclo[3.3.0]octane appropriés soit via une insertion intramoléculaire du C—H d'un carbène soit par la photocyclisation d'une cétone en cyclopentanol. On inclut deux modes de synthèse du précurseur fondamental, l'oxo-3 bicyclo[3.3.0]octane dicarboxylate-1,5 de méthyle-*cis* (**2**). On rapporte également la synthèse de l'hydroxy-3 tricyclo[3.3.0.0^{3,7}]octanedicarboxylate-1,5 de méthyle (**24**) par réduction du dioxo-3,7 bicyclo[3.3.0]octane dicarboxylate de méthyle-*cis* (**9**) dans des conditions semblables à celles d'une réaction de Clemensen.

[Traduit par le journal]

The synthesis and chemistry of tricyclo[3.3.0.0^{3,7}]octane derivatives have been matters of continuous interest (1) since the first compound possessing this carbon skeleton was synthesized in 1964 (1*a*). The greatest interest comes from the special behaviour of many of these derivatives that are prone to rearrange (Fig. 1) because of the great strain energy (1*q*, *u*) of this tricyclic skeleton, which might be viewed as a norbornane with a methylene bridge connecting the 2 and 5 positions. Some aspects that have also received attention are the symmetry (1*b*, *p*, *s*, *x*), pharmacology (1*e*), and microbiological reactions (1*v*, *y*) of some of these derivatives.

All of the syntheses of tricyclo[3.3.0.0^{3,7}]octane derivatives that can be found in the literature have been schematically collected in Fig. 2. Only the third procedure has been applied to different substrates and it seems to be a quite general method. Although only one example corresponding to the fourth procedure has been described, this transformation could also be of wide applicability. The rest of the syntheses can not, in principle, be considered as general methods, but as special cases. In particular, in the last one, the tricyclic compound was formed by an anomalous reaction during the attempted pinacol reduction of the starting diketone, and although the same type of reaction has been also observed (2) in related compounds with the [*m*.3.3]propellane skeleton, it was not observed with *cis*-bicyclo[3.3.0]octane-3,7-dione itself.

The strain energy of the tricyclo[3.3.0.0^{3,7}]octane skeleton is clearly shown by the cationic transformations experienced by many of its derivatives (1*c*, *f*, *g*, *k*, *o*, *r*, *w*), and also by the easy conversion of 3,7-dimethyltricyclo[3.3.0.0^{3,7}]octan-1-ol into *cis*-1,5-dimethylbicyclo[3.3.0]octan-3-one (1*j*) and tricyclo[3.3.0.0^{3,7}]octan-2-one into norbornane-2-carboxylic acid (1*d*), by reaction with potassium *tert*-butoxide in *tert*-butyl alcohol. Accordingly, the described syntheses of compounds containing this carbon skeleton generally imply irreversible reactions in the key step.

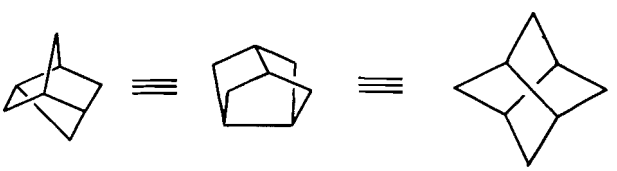

FIG. 1

As part of our interest in the synthesis of polyquinanes we have studied possible synthetic approaches to dimethyl tricyclo[3.3.0.0^{3,7}]octane-1,5-dicarboxylate, **1**. Since the application of the only general method described for the synthesis of diester **1** (third procedure of Fig. 2) would require the use of a not easily accessible starting material, and the rest of the described methods (see Fig. 2) are not general, we considered it more interesting to attempt the synthesis of **1** by developing a new approach to its tricyclic skeleton.

The key step in our synthesis would be the intramolecular insertion of a carbene into the appropriate C—H bond, as shown in Fig. 3. Since the reaction is irreversible, the success of the synthesis would be dependent on the relative rate of this insertion compared with other possible carbene transformations, such as C2(4)—H or C6(8)—H insertions, that would give rise to an alkene or a cyclobutane derivative respectively.

Many examples of intramolecular C—H insertions of carbenes of synthetic interest can be found in the literature (3). Great variations in yields, due to small structural modifications, are often observed. However, among the many fac-

FIG. 3

tors that control the intramolecular insertion of a carbene into a particular C—H bond, the appropriate distance between the divalent carbon atom and the C—H bond in which insertion should take place is of major importance. Taking dimethyl *cis*-3-oxobicyclo[3.3.0]octane-1,5-dicarboxylate, **2**, as a model for the intermediate carbene, the distance between C3 and C7 in the required conformation of **2** to form the C3—C7 bond was calculated (4) to be only ca. 0.3 Å greater than the corresponding distance in compounds in which the insertion does take place in good yields, such as bicyclo[3.3.1]nonan-3-one (3*b*), **3**, and tricyclo[5.2.1.$0^{2,6}$]decan-10-one (3*c*), **4** (Fig. 4). Moreover, a population of 35.5% for that conformation of ketodiester **2** was calculated (4). Also, the fact that *cis*-1,5-dimethylbicyclo[3.3.0]octane-3,7-dione gives, on reduction, a tricyclo[3.3.0.$0^{3,7}$]octane derivative (1*j*) (Fig. 2) shows that the distance between C3 and C7 in some *cis*-1,5-disubstituted bicyclo[3.3.0]octane derivatives is short enough for bond formation.

To generate the intermediate carbene shown in Fig. 3, we prepared ketodiester **2** by two independent routes. The first one, outlined in Fig. 5, makes use of the synthesis of *cis*-1,5-disubstituted bicyclo[3.3.0]octane-3,7-diones (see Fig. 6) developed by Weiss and co-workers (5), and widely used by other authors (6), to synthesize dimethyl *cis*-3,7-dioxobicyclo[3.3.0]octane-1,5-dicarboxylate, **9**, whose conversion into ketodiester **2** requires only the reduction of one of its ketonic functions.

In our case, the required 1,2-dicarbonyl compound was dimethyl 2,3-dioxobutanedioate, **6**, a compound that can be prepared by reaction of disodium dihydroxytartrate, **5**, with anhydrous methanol saturated with gaseous hydrogen chloride (7), in approximately 50% yield of distilled product. To obviate the tedious purification of **6**, we carried out the Weiss reaction with crude **6** as described in the Experimental, isolating a solid that was characterized as hexamethyl *cis*-3,7-dioxobicyclo[3.3.0]-octane-1,2,4,5,6,8-hexacarboxylate, **8** (13.9% yield from **5**), through its spectroscopic and analytical data and its high yield conversion into dimethyl *cis*-3,7-dioxobicyclo[3.3.0]octane-1,5-dicarboxylate, **9**. The 60 MHz ^{1}H nmr spectrum of compound **8** in $CDCl_3$ shows that it exists as a complex mixture of tautomers.

The conversion of compound **8** into dioxodiester **9** was carried out by the method of Krapcho and Lovey (8), by heating a solution of the compound in DMSO containing small amounts of NaCl and water. When hydrolysis and decarboxylation of compound **8** were carried out by refluxing it with aqueous HCl, partial hydrolysis of the methoxycarbonyl groups at C1 and C5 was also observed. The ^{1}H nmr spectrum of compound **9** is very simple, consisting of an AB system for the methylene protons (δ 3.20 and 2.42, J = 18 Hz) apart from the methoxyl absorption.

Since the mother liquors from the crystallization of compound **8** still contained this compound (tlc), we subjected the crude extract of the reaction of compounds **6** and **7** to the Krapcho conditions of decarbomethoxylation (8), isolating **9** in 12% overall yield from salt **5**. Reaction of compound **9** with one equivalent of ethanedithiol catalyzed by boron trifluoride etherate in ethyl acetate yielded a mixture of starting compound **9**, dimethyl *cis*-3,3-ethylenedithio-7-oxobicyclo[3.3.0]octane-1,5-dicarboxylate, **10**, and dimethyl *cis*-3,3,7,7-bisethylenedithiobicyclo[3.3.0]octane-1,5-dicarboxylate, **11**, in the approximate ratio 8:6:1, which was separated by column chromatography. Reaction of compound **10** with Raney Ni in ethanol gave a crude product whose ir spectrum showed that reduction of the ketone function had also taken place. This crude product, after oxidation with Jones reagent, gave dimethyl *cis*-3-oxobicyclo[3.3.0]octane-1,5-dicarboxylate, **2**. Although the yield of compound **10** was acceptable if **9** was recovered, the experimental difficulties of this transformation encouraged us to develop an alternative synthesis through the sequence shown in Fig. 7.

The starting material for this sequence was *cis*-bicyclo-[4.3.0]non-3-ene-1,6-dicarboxylic acid, **13** (9, 10). Reaction of diacid **13** with an excess of an ethereal solution of diazomethane gave, quantitatively, dimethyl *cis*-bicyclo[4.3.0]non-3-ene-1,6-dicarboxylate, **14**.

Potassium permanganate oxidation of diester **14** under phase transfer catalysis conditions (11) gave *meso*-1,2-bismethoxycarbonylcyclopentane-1,2-diacetic acid, **15**, in 75% yield, which on reaction with excess of ethereal diazomethane gave dimethyl *meso*-1,2-bismethoxycarbonylcyclopentane-1,2-diacetate, **16**. Trimethyl *cis*-3-oxobicyclo[3.3.0]octane-1,2,5-tricarboxylate, **17**, was obtained in 91% yield by Dieckmann cyclization of tetraester **16**. Decarbomethoxylation of ketotriester **17** using the Krapcho conditions (8) led to ketodiester **2** in 92% yield. The sequence depicted in Fig. 7 can be easily carried out on a fairly large scale and is thus the method of choice to prepare ketodiester **2**.

Some attempts to convert diacid **15** directly into ketodiester **2** by pyrolysis in the presence of catalytic amounts of barium hydroxide led only to the formation of 3-oxatricyclo-[3.3.3.$0^{1,5}$]undecane-2,4,7-trione, **18**, in 82% yield (Fig. 8). Acid hydrolysis of **2** gave the corresponding *cis*-3-oxobicylo[3.3.0]octane-1,5-dicarboxylic acid, **19**, which was dehydrated using a catalytic amount of concentrated sulfuric acid to give ketoanhydride **18**.

Compound **18** was also obtained, although in lower yield, from anhydride **12**. Potassium permanganate oxidation of compound **12** under phase transfer conditions (11) gave *cis*-2,4-dioxo-3-oxabicyclo[3.3.0]octane-1,5-diacetic acid, **20**, in only 33% yield. Compound **20**, however, was transformed into ketoanhydride **18**, in 84% yield, by pyrolysis in the presence of a catalytic amount of barium hydroxide.

In order to carry out the transformation depicted in Fig. 3, we chose the Bamford–Stevens procedure (3*a*). Ketodiester **2** was transformed into the corresponding tosylhydrazone, **21**, in 84% yield, by reaction with tosylhydrazide in glacial acetic acid at room temperature. Thermal decomposition of its sodium salt **22** (200°C/1 Torr) gave, as the major reaction product (72% isolated yield), dimethyl *cis*-bicyclo[3.3.0]oct-2-ene-1,5-dicarboxylate, **23**. None of the minor products formed in this reaction was the desired diester **1** (glc/ms). Lower yields of compound **23** were obtained by thermal decomposition of salt **22** prepared from tosylhydrazone **21** and less than a molar equivalent of sodium methoxide in anhydrous methanol, or by

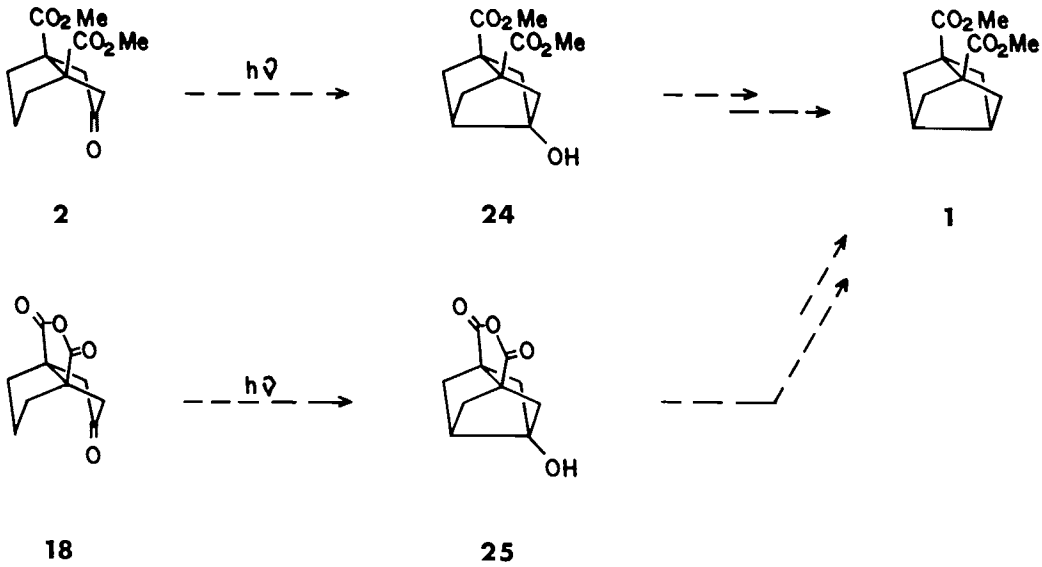

FIG. 10

photochemical decomposition of salt **22** suspended in ether or DME (Fig. 9).

Another approach to the tricyclo[3.3.0.0^{3,7}]octane skeleton, capable of being used to synthesize diester **1**, would be that shown in Fig. 10. It is known that photolysis of ketones can give cyclobutanol derivatives (12) by intramolecular abstraction of a hydrogen atom from the γ-position and combination of the resulting carbon radicals. In special cases, where hydrogen abstraction from the γ-position is difficult or not possible, abstraction from the δ-position can take place with formation of cyclopentanols (13).

Irradiation of ketodiester **2** under the conditions described by Paquette and co-workers (13) (benzene – *tert*-butyl alcohol or *tert*-butyl alcohol, Pyrex filter) left the starting material unchanged. Using a quartz filter, small amounts of compounds of molecular weights that could correspond to the addition of water, methanol, ethanol, propanol, and butanol were detected (glc/ms), the major product being in all cases the starting compound **2**. No formation of dimethyl 3-hydroxytricyclo-[3.3.0.0^{3,7}]octane-1,5-dicarboxylate, **24**, was ever observed. In a similar manner, irradiation of ketoanhydride **18** did not give the desired alcohol **25**. In this case, after irradiating for three days, most of the starting material was consumed, and formation of compounds whose molecular weights (glc/ms) could correspond to the addition of water and methanol was also observed.

Compound **24** could be prepared, although in only 5.4% yield, by reduction of dioxodiester **9** under the conditions (Zn/Ac_2O/gaseous HCl) used by Borden and Ravindranathan (1*j*) to reduce *cis*-1,5-dimethylbicyclo[3.3.0]octane-3,7-dione

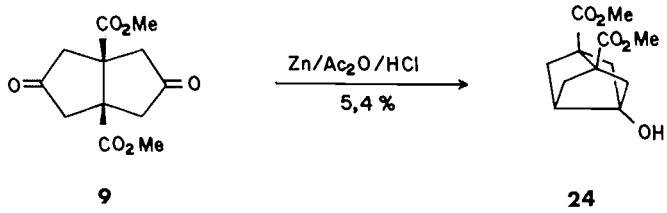

FIG. 11

to 3,7-dimethyltricyclo[3.3.0.0^{3,7}]oct-1-yl acetate. The spectroscopic data of this compound (ir, ^{1}H nmr ^{13}C nmr, ms) and elemental analysis are all concordant with its structure. However, the low yield of this reaction did not make it attractive for the synthesis of diester **1** (Fig. 11).

The low yield conversion of dioxodiester **9** into the hydroxydiester **24**, as compared with similar transformations (1*j*, 2), the failure of the synthesis of diester **1** by intramolecular C—H carbene insertion with formation of a C3—C7 bond from an appropriate bicyclo[3.3.0]octane precursor, and the fruitless attempts to transform bicyclo[3.3.0]octan-3-one derivatives photochemically into the corresponding tricyclo[3.3.0.0^{3,7}]-octan-1-ols, must be the consequence of a too long C3 . . . . C7 distance in the required conformation of the studied bicyclo[3.3.0]octane derivatives to form a C3—C7 bond. Probably the presence of larger substituents at C1 and C5 in the bicyclo[3.3.0]octane precursor and the connection of such substituents to form propellane derivatives make the C3 and C7 atoms closer and favour the formation of the C3—C7 bond as is the case for *cis*-1,5-dimethylbicyclo[3.3.0]octane-3,7-dione (1*j*), [6.3.3]propellane-10,13-dione (2), and [10.3.3]propellane-14,17-dione (2).

Work is in progress to synthesize diester **1** by using the method shown in the second procedure of Fig. 2.

Experimental

Infrared spectra were recorded on a Perkin–Elmer spectrometer model Infracord 720. The ^{1}H nmr spectra were taken at 60 MHz on a Perkin–Elmer R-12A spectrometer, while 80 MHz ^{1}H and 20 MHz ^{13}C nmr spectra were recorded on a Bruker model WP80SY spectrometer. Chemical shifts are given in ppm relative to internal TMS (δ scale). Mass spectra were recorded on Hewlett–Packard spectrometers model 5930A or 5985B, using the electron impact and chemical ionization techniques, always at 70 eV. Microanalyses were carried out at the Analytical Section of the "Instituto de Química Bio-orgánica" of Barcelona (C.S.I.C.) or at the Facultad de Ciencias, Universidad Autónoma de Barcelona. The glc analyses were performed with a Hewlett–Packard, model 5830A, or a Perkin–Elmer, model Sigma-1, chromatograph. Medium pressure 125- or 400-W mercury lamps were used in the photochemical reactions. Melting points were determined on a Kofler hot-stage and are uncorrected. Calculations were carried out at the Computing Center of Hokkaido University, Sapporo, Japan, on a HITAC M-200H system.

Dimethyl cis-*3,7-dioxobicyclo[3.3.0]octane-1,5-dicarboxylate, 9*

A mixture of 100 g (0.44 mol) of disodium dihydroxytartrate, **5**, and 400 mL anhydrous methanol was saturated with hydrogen chloride at 0°C (7), and allowed to stand in the refrigerator (5°C) for five days. The precipitated sodium chloride was filtered and thoroughly washed with anhydrous methanol. The filtrate was concentrated at reduced pressure, keeping the temperature below 40°C, to give 97.37 g of crude dimethyl 2,3-dioxobutanedioate, **6**, as a yellow viscous product that contains some hydrochloric acid.

Part of this product (35.26 g) was placed in a flask fitted with a magnetic stirrer, and 400 mL saturated aqueous $NaHCO_3$ solution (0.33 equiv. of base) plus 5.0 g solid $NaHCO_3$ to compensate the base consumed in neutralizing the acid present in the crude **6** (70 mL of the $NaHCO_3$ solution) were added. To this solution, 55.86 g (0.32 mol) of dimethyl 3-oxoglutarate, was added and the mixture stirred at room temperature for 7 days. The solution was acidified with 6 *N* HCl and extracted with $CHCl_3$ (5 × 150 mL). The extracts were washed with water and dried over anhydrous Na_2SO_4. Evaporation of the solvent gave 59.40 g of a complex mixture that was subjected as such to the Krapcho (8) decarbomethoxylation conditions.

A mixture of the whole crude product obtained before, 100 mL DMSO, 26.5 mL (1.47 mol) water, and 7.2 g (0.12 mol) NaCl was heated at 130–140°C for 4 h. After cooling at room temperature, 150 mL water was added and the mixture extracted with chloroform (3 × 100 mL + 4 × 50 mL). The extracts were washed with saturated aqueous $NaHCO_3$ solution (4 × 50 mL) and water (3 × 50 mL), and dried over anhydrous Na_2SO_4. Evaporation of the solvent gave 17.83 g of crude product which was distilled at reduced pressure. The fraction collected at 160–170°C/0.5 Torr (11.85 g) gave, on crystallization from methanol, 7.63 g of pure ketodiester **9**, sublimed at 125°C/15 Torr, mp 97–98°C (18% overall yield from salt **5**; in other runs the yield was in the range of 12%); ir ($CHCl_3$) ν: 1750 (s) cm^{-1}; ^{1}H nmr (60 MHz, $CDCl_3$) δ: 3.71 (s, 6H), 3.36 and 3.06 (d, *J* = 18 Hz, 4H), 2.56 and 2.26 (d, *J* = 18 Hz, 4H); ^{13}C nmr ($CDCl_3$) δ: 47.0 (t), 52.9 (c), 56.2 (s), 172.8 (s), 210.0 (s); ms: 254 (M$^+$, 35), 226(10), 223(26), 222(9), 194(27), 162(24), 135(29), 127(100), 99(33). *Anal.* calcd. for $C_{12}H_{14}O_6$: C 56.69, H 5.55; found: C 56.59, H 5.57.

Isolation of hexamethyl cis-*3,7-dioxobicyclo[3.3.0]octane-1,2,4,5,6,8-hexacarboxylate, 8*

From a reaction like that described before, starting from 2.0 g of salt **5**, the crude product of the reaction with dimethyl 3-oxoglutarate, **7** (4.38 g), after several crystallizations from ethanol, gave 780 mg of **8** (13.9% yield from **5**), mp 161–163°C; ir (KBr) ν: 3050 (w), 1760 (s), 1740 (s), 1675 (s) cm^{-1}; ^{1}H nmr (80 MHz, $CDCl_3$) δ: 10.52 (broad), 4.93–3.54 (complex absorption); ms: 486 (M$^+$, 3), 455(3), 454(8), 426(16), 394(50), 363(27), 335(75), 303(63), 271(52), 263(33), 244(39), 213(39), 59(100). *Anal.* calcd. for $C_{20}H_{22}O_{14}$: C 49.39, H 4.56; found: C 49.39, H 4.70.

Reaction of ketodiester 9 with ethanedithiol

A mixture of 2.203 g (8.67 mmol) of diketodiester **9** in 50 mL ethyl acetate, 812 mg (8.62 mmol) ethanedithiol, and 2.2 mL boron trifluoride etherate was allowed to stand at room temperature for 16 h. After adding 15 mL water, the organic phase was separated and washed with aqueous $NaHCO_3$ (2 × 10 mL) and water (3 × 10 mL), and dried over anhydrous Na_2SO_4. Evaporation of the solvent yielded 2.411 g of a mixture that was separated by low pressure column chromatography (14), using 50 g silica gel (230–400 mesh) and a mixture of hexanes – ethyl acetate as eluent, into three fractions: 1.130 g starting material; 995 mg monothioketal, **10** (71.4% yield if **9** was recovered), and 200 mg bisthioketal, **11** (11.4% yield if **9** was recovered).

Physical and spectroscopic data of dimethyl cis-*3,3-ethylenedithio-7-oxobicyclo[3.3.0]octane-1,5-dicarboxylate, 10*

Dimethyl cis-*3-oxobicyclo[3.3.0]octane-1,5-dicarboxylate,* **2**

A mixture of 750 mg (2.27 mmol) of monothioketal **10**, 7.5 g Raney Ni, and 20 mL ethanol was heated under reflux for 8 h. The mixture was filtered through a 2-cm pad of silica gel and the residue thoroughly washed with hot ethanol. Evaporation of the solvent gave a crude product that showed hydroxyl absorption in its infrared spectrum. This crude product was dissolved in 20 mL acetone and treated with 1.5 mL of Jones reagent. After stirring for 16 h at room temperature, the acetone was evaporated, the residue was diluted with 5 mL water, neutralized with saturated aqueous $NaHCO_3$ solution, and extracted with chloroform (5 × 5 mL). The organic extracts were washed with water and dried over anhydrous Na_2SO_4. Evaporation of the solvent gave a crude product which, chromatographed through 50 g silica gel (230–400 mesh) (14) using hexanes – ethyl acetate as eluent, gave 302 mg of ketodiester **2** (55.4% yield), bp 150°C(oven)/0.9 Torr; ir ($CHCl_3$) ν: 1740 (s) cm^{-1}; ^1H nmr (80 MHz, $CDCl_3$) δ: 3.69 (s, 6H), 3.14 and 2.91 (d, J = 19 Hz, 2H), 2.63–1.67 (complex absorption, 2.48 and 2.23 (d, J = 19 Hz), total 8H); ^{13}C nmr ($CDCl_3$) δ: 23.1, 36.6, 48.4, 52.3, 60.1, 174.9, 213.3; ms: 240 (M^+, 7), 212(15), 209(13), 152(31), 121(43), 93(100), 91(46), 79(54), 77(50), 59(44), 39(45). *Anal.* calcd. for $C_{12}H_{16}O_5$: C 59.99, H 6.71; found: C 60.17, H 6.72.

A freshly distilled solution of diazomethane in ether was slowly added to 16.49 g (78.5 mmol) of diacid **13** until no nitrogen evolution was observed. Evaporation of the solvent gave a product that, distilled at 145°C/0.15 Torr, gave 19.01 g of diester **14** (quantitative yield); ir (film) ν: 3050 (w), 1735 (s) cm^{-1}; ^1H nmr (60 MHz, $CDCl_3$) δ: 5.8–5.6 (complex absorption, 2H), 3.65 (s, 6H), 2.8–1.6 (complex absorption, 10H); ^{13}C nmr ($CDCl_3$) δ: 18.8 (m), 31.8 (t), 34.7 (t), 51.6 (c), 52.3 (s), 123.3 (d), 176.3 (s); ms: 206 (M^+ – MeOH, 9), 178(30), 119(100), 118(41), 91(82); ms (chemical ionization, isobutane): 239 ($M^+ + 1$) and 207 (M^+ – MeOH + 1). *Anal.* calcd. for $C_{13}H_{18}O_4$: C 65.53, H 7.61; found: C 65.28, H 7.69.

meso-*1,2-Bismethoxycarbonylcyclopentane-1,2-diacetic acid,* **15**

To a cold solution (ice bath) of 5.3 g (33.54 mmol) of $KMnO_4$ in 50 mL water, a solution of 2.35 g (9.87 mmol) of diester **14** and 34 mg (0.11 mmol) tetra-*n*-butylammonium bromide in 33 mL acetic acid, and 165 mL benzene were added, and the mixture was stirred at room temperature for 16 h. The reaction mixture was cooled and treated with 5.83 g Na_2SO_3 followed by 12 mL 6 *N* HCl. The organic phase was separated and the aqueous one extracted with 50 mL benzene. Working up the benzene extracts, a residue of 277 mg, which did not contain starting material or diacid **15**, was obtained. Afterwards, the aqueous phase was extracted with ether (5 × 50 mL), and the ether extracts were washed with water (2 × 20 mL) and dried over anhydrous Na_2SO_4. Evaporation of the solvent gave 2.22 g of diacid **15** (75% yield), mp 177–179°C (ether); ir (KBr) ν: 3600–2400 (m), 1740 (s), 1700 (s) cm^{-1}; ^1H nmr (60 MHz, D_2O/NaOH) δ: 3.67 (s, 6H), 3.18 and 2.90 (d, J = 16.8 Hz, 2H), 2.58–1.49 (complex absorption, 2.41 and 2.13 (d, J = 16.8 Hz), total 8H); ^{13}C nmr (D_2O + dioxane) δ: 20.6 (m), 32.4 (m), 38.3 (t), 53.6 (c), 58.4 (s), 175.8(s), 177.0 (s); ms: 271 (M^+ – MeO, 7), 253(9), 243(9), 239(14), 229(44), 224(21), 211(14), 196(17), 183(23), 165(62), 151(45), 137(70), 91(79), 79(66), 77(57), 59(100); ms (chemical ionization, isobutane): 303 ($M^+ + 1$) and 271 (M^+ – MeOH + 1). *Anal.* calcd. for $C_{13}H_{18}O_8$: C 51.66, H 6.00; found: C 51.80, H 6.03.

Dimethyl meso-*1,2-bismethoxycarbonylcyclopentane-1,2-diacetate,* **16**

A freshly distilled solution of diazomethane in ether was slowly added to 12.7 g (42.05 mmol) of diacid **15** until no nitrogen evolution was observed. Evaporation of the solvent gave a crude product that, crystallized from methanol, yielded 12.72 g of tetraester **16** (92% yield), mp 95–97°C; ir (KBr) ν: 1720 (s) cm^{-1}; ^1H nmr (60 MHz, $CDCl_3$) δ: 3.64 (s, 12H), 3.33 and 3.07 (d, J = 16 Hz, 2H), 2.82–1.47 (complex absorption, 2.44 and 2.18 (d, J = 16 Hz), total 8H); ^{13}C nmr ($CDCl_3$) δ: 20.5, 32.0, 37.9, 51.6, 52.1, 57.6, 171.3, 173.3; ms: 299 (M^+ – MeO, 36), 257(47), 238(32), 225(43), 213(22), 197(39), 179(100), 165(40), 151(66), 91(48), 79(31), 77(33), 59(52); ms (chemical ionization, isobutane): 331 ($M^+ + 1$) and 299 (M^+ – MeOH + 1). *Anal.* calcd. for $C_{15}H_{22}O_8$: C 54.54, H 6.71; found: C 54.33, H 6.48.

Trimethyl cis-*3-oxobicyclo[3.3.0]octane-1,2,5-tricarboxylate,* **17**

A solution of 11 g (33.3 mmol) tetraester **16** in 100 mL anhydrous THF was slowly added to a cold suspension (ice bath) of approximately 2 g (83.3 mmol) of NaH (from 4 g of 50% dispersion of NaH in mineral oil, by washing with anhydrous THF) in 100 mL anhydrous THF. When the addition was finished, the mixture was heated under reflux for 3 h. The cold mixture was neutralized with 6 *N* HCl and made slightly acidic with 0.1 *N* HCl. The organic phase was separated and the aqueous one extracted with $CHCl_3$ (2 × 50 mL + 2 × 25 mL). The $CHCl_3$ extracts and the organic phase were mixed, washed with water (2 × 10 mL), and dried over anhydrous Na_2SO_4. Evaporation of the solvent gave 10.83 g of crude product. Distillation of 1.094 g of this crude product gave 918 mg of **17** (91% yield), bp 130°C (oven)/0.15 Torr; ir (film) ν: 3600–3200 (m), 1740 (s), 1660 (s), 1620 (s) cm^{-1}; ^1H nmr (80 MHz, $CDCl_3$) δ: 10.68 (broad, 1H), 3.81–3.39 (complex absorption, 3.74 (s), 3.66 (s), 3.61 (s), 9H), 2.71–1.54 (complex absorption, 2.48 (d, J = 18.2 Hz), total 8H); ^{13}C nmr ($CDCl_3$) (corresponding to the major enol form) δ: 24.8, 34.4, 40.9, 42.9, 51.3, 52.0, 52.3, 59.4, 66.9, 103.0, 169.0, 174.9, 175.6; ms: 298 (M^+, 2), 266(3), 238(22), 206(33), 179(63), 147(58), 119(100), 117(81), 91(75), 59(33). *Anal.* calcd. for $C_{14}H_{18}O_7$: C 56.37, H 6.08; found: C 56.46, H 5.95.

Ketodiester 2 from ketotriester 17

A mixture of 1.0 g (3.36 mmol) of ketotriester **17**, 212 mg (3.62 mmol) NaCl, 186 mg (10.3 mmol) water, and 2 mL DMSO was heated at 140°C for 2 h. To the cold mixture, 10 mL water was added and the solution extracted with $CHCl_3$ (5 × 10 mL). The chloroform extracts were washed with water and dried over anhydrous Na_2SO_4. Evaporation of the solvent gave a crude product which on distillation yielded 741 mg of pure ketodiester **2** (92% yield), bp 125°C (oven) /0.6 Torr.

cis-*3-Oxobicyclo[3.3.0]octane-1,5-dicarboxylic acid,* **19**

A mixture of 480 mg (2.0 mmol) of ketodiester **2** and 1.5 mL 6 *N* HCl was heated under reflux for 18 h. Evaporation of the volatile products gave a residue that, dried at reduced pressure over anhydrous KOH, gave 410 mg of ketodiacid **19** (97% yield), mp 165–182°C (dec.) (ether–benzene); ir (KBr) ν: 3650–2500 (m), 1735 (s), 1690 (s) cm^{-1}; ^1H nmr (80 MHz, acetone-d_6) δ: 10.33–9.87 (broad), 3.08–1.67 (complex absorption, 3.06 and 2.83 (d, J = 18.3 Hz), 2.55 and 2.32 (d, J = 18.3 Hz)); ^{13}C nmr (acetone-d_6) δ: 23.4, 37.1, 49.1, 60.5, 176.5, 213.7; ms: 212 (M^+, 5) 194(51), 166(38), 152(62), 138(25), 121(55), 94(67), 93(91), 79(98), 77(68), 60(72), 45(76), 39(100). *Anal.* calcd. for $C_{10}H_{12}O_5$: C 56.60, H 5.70; found: C 56.82, H 5.74.

3-Oxatricyclo[3.3.3.0^{1,5}]undecane-2,4,7-trione, **18**

In a 10-mL flask, 100 mg (0.47 mmol) of ketodiacid **19** and a trace of concentrated sulfuric acid were placed. The flask was connected to a rotary microdistillation apparatus and heated at 160°C/15 Torr. The distillate (84 mg) was sublimed at 75°C/0.2 Torr to give 78 mg of pure **18** (86% yield), mp 184–186°C; ir (KBr) ν: 1840 (m), 1780 (s), 1745

cis-2,4-Dioxo-3-oxabicyclo[3.3.0]octane-1,2-diacetic acid, ***20***

To a cold solution (ice bath) of 538 mg (3.4 mmol) $KMnO_4$ in 5 mL water, a mixture of 192 mg (1.0 mmol) anhydride **12** and 3 mg (0.009 mmol) tetra-*n*-butylammonium bromide in 3.5 mL acetic acid and 16.5 mL benzene was added, and the mixture was stirred at room temperature for 1 h (at that time the $KMnO_4$ colour had disappeared). The mixture was treated with 600 mg (4.76 mmol) Na_2SO_3 followed by 1.2 mL 6 *N* HCl. The organic phase was separated and the aqueous one extracted with benzene (2 × 5 mL). Afterwards, the aqueous phase was extracted with ether (6 × 10 mL). The ether extracts were washed with water (2 × 2 mL) and dried over anhydrous Na_2SO_4. Evaporation of the solvent gave 84 mg of diacid **20** (33% yield), mp 173–176°C (ether–pentane). Evaporation of the aqueous phase and extraction of the solid residue with acetone did not give more diacid **20**. Infrared (KBr) ν: 3600–2450 (m), 1840 (w), 1770 (s), 1700 (s) cm^{-1}; ^1H nmr (80 MHz, acetone-d_6) δ: 10.24–8.88 (broad, 2H), 3.28 and 3.05 (d, J = 18.5 Hz, 2H), 3.03 and 2.80 (d, J = 18.5 Hz, 2H), 2.65–1.00 (complex absorption, 6H); ^{13}C nmr (acetone-d_6) δ: 23.5, 37.0, 39.9, 56.2, 173.1, 177.2; ms: 194(20), 184(6), 166(25), 152(23), 138(100), 94(67), 93(80), 91(35), 79(83), 77(45), 45(31), 39(31); ms (chemical ionization, isobutane): 257 (M^+ + 1). *Anal.* calcd. for $C_{11}H_{12}O_7$: C 51.57, H 4.72; found: C 51.38, H 4.75.

Ketoanhydride ***18*** *from diacid* ***20***

A finely ground mixture of 80 mg (0.31 mmol) diacid **20** and 5 mg (0.03 mmol) anhydrous $Ba(OH)_2$ was placed in a 10-mL flask that was connected to a rotary microdistillation apparatus and heated at 185°C/0.5 Torr. The distilled product (60 mg) was sublimed at 160°C/15 Torr to give 51 mg of pure **18** (84% yield).

Ketoanhydride ***18*** *from diacid* ***15***

A finely ground mixture of 400 mg (1.32 mmol) diacid **15** and 10 mg (0.06 mmol) anhydrous $Ba(OH)_2$ was placed in a 25-mL flask that was connected to a distillation apparatus. The flask was immersed in a melted metal bath at 300°C for 5 min. The solid condensed in the neck of the flask was taken up and, crystallized from benzene–hexane, gave 210 mg of **18** (82% yield).

Dimethyl cis-*3-(p-toluenesulfonylhydrazono)bicyclo[3.3.0]octane-1,5-dicarboxylate,* ***21***

A solution of 1.0 g (4.2 mmol) of ketodiester **2** and 1.55 g (8.32 mmol) tosylhydrazide in 40 mL glacial acetic acid was allowed to stand at room temperature for 15 h. Water was added until turbidity appeared, and the mixture was left in the refrigerator (0°C) for 24 h. The precipitated solid was filtered and dried in vacuum over anhydrous KOH, giving rise to 1.44 g tosylhydrazone **21** (84% yield), mp 128–130°C; ir (KBr) ν: 3230 (m), 1730 (s), 1660 (m), 1175 (s), 1095 (s) cm^{-1}; ^1H nmr (60 MHz, $CDCl_3$) δ: 8.1–7.1 (complex absorption, 7.92 and 7.78 (d, J = 8 Hz), 7.37 and 7.23 (d, J = 8 Hz), total 5H), 3.6 (broad singlet, 6H), 3.4–1.5 (complex absorption, 2.42 (s), total 13H); ms: 408 (M^+, 3), 377(10), 349(5), 253(29), 221(31), 193(90), 165(67), 133(48), 105(86), 91(100), 79(33), 77(35), 65(46). *Anal.* calcd. for $C_{19}H_{24}N_2SO_6$: C 55.87, H 5.92, N 6.86, S 7.85; found: C 55.90, H 6.08, N 6.90, S 7.96.

Pyrolysis of the sodium salt of ***21****,* ***22****. Dimethyl* cis-*bicyclo[3.3.0]-oct-2-ene-1,5-dicarboxylate,* ***23***

A mixture of 408 mg (1.0 mmol) tosylhydrazone **21**, 70 mg (1.3 mmol) anhydrous sodium methoxide, and 10 mL anhydrous methanol was heated under reflux for 2 h. The solvent was eliminated at reduced pressure at room temperature and the residue dried at 0.5 Torr for 16 h. The flask containing the salt of the tosylhydrazone **21** was connected to a rotary microdistillation apparatus and heated at 200°C/1 Torr. It distilled 161 mg of alkene **23** (72% yield), sublimed at 80°C/15 Torr, mp 68–70°C (methanol–benzene); ir ($CHCl_3$) ν: 3050 (m), 1730 (s) cm^{-1}; ^1H nmr (80 MHz, $CDCl_3$) δ: 5.79 (dt, J = 5.7 Hz, J' = 2.3 Hz, 1H), 5.48 (dt, J = 5.7 Hz, J' = 2.3 Hz, 1H), 3.65 (s, 3H), 3.63 (s, 3H), 3.20 (dt, J = 17.3 Hz, J' = 2.3 Hz, 1H), 2.52–1.30 (complex absorption, 7H); ^{13}C nmr ($CDCl_3$) δ: 24.3, 36.2, 40.5, 45.1, 51.7, 62.2, 71.1, 131.2, 132.8, 174.9, 176.1; ms: 224 (M^+, 0.2), 192(32), 165(31), 164(100), 105(67). *Anal.* calcd. for $C_{12}H_{16}O_4$: C 64.27, H 7.19; found: C 63.94, H 7.21.

Photochemical decomposition of the sodium salt of ***21***

A suspension of the salt **22**, obtained as described before from 100 mg tosylhydrazone **21**, in 40 mL ether was placed in a Pyrex photoreactor and deoxygenated by bubbling argon. The reactor was stoppered and the mixture irradiated with a 125-W lamp for 17 h. The suspension was filtered and the solvent evaporated from the filtrate to give 82 mg of a complex mixture (glc/ms), which on column chromatography gave 13 mg of alkene **23** (23% yield) as the only identifiable product. None of the other products formed in this reaction could be characterized as diester **1** (glc/ms).

Dimethyl 3-hydroxytricyclo[3.3.0.0^{3,7}]octane-1,5-dicarboxylate, ***24***

Forty milliliters acetic anhydride were saturated with anhydrous hydrogen chloride at −5°C, and then 936 mg (3.69 mmol) of diketodiester **9** were added. Activated zinc (15) was added in small portions, keeping the temperature of the reaction mixture below −10°C, until no more was consumed (15 g). The mixture was stirred at −5°C for 2 h and filtered, washing the residue with cold acetic anhydride. The filtrate was poured into 200 mL methanol at −70°C and allowed to stand for 16 h. The volatile products were evaporated, the residue was dissolved in 50 mL CH_2Cl_2 and washed with water (2 × 50 mL), 10% aqueous $NaHCO_3$ solution (2 × 50 mL), water (50 mL), and dried over anhydrous Na_2SO_4. Evaporation of the solvent gave 639 mg of crude product consisting mainly of starting material. Acidification of the aqueous phase and extraction with CH_2Cl_2 gave, after the usual work-up, 169 mg of a mixture of starting material and a new compound (46% relative area by glc). By column chromatography of this mixture (6 g silica gel, hexanes–$CHCl_3$ as eluent), 48 mg of hydroxydiester **24** was obtained (5.4% yield), bp 135–140°C (oven)/0.2 Torr. On standing, it crystallized, mp 73–76°C; ir (film) ν: 3700–3100 (m), 3020 (m), 1730 (s) cm^{-1}; ^1H nmr (80 MHz, $CDCl_3$) δ: 3.67 (s, 6H), 3.06–2.76 (broad, 1H), 2.38–1.72 (complex absorption, 9H); ^{13}C nmr ($CDCl_3$) δ: 44.9, 49.3, 51.7, 54.7, 55.9, 81.6, 172.5; ms: 209 (M^+ − MeOH, 20), 180(31), 140(100), 121(40), 108(79), 93(51), 91(72), 81(55), 77(69), 59(86); ms (chemical ionization, isobutane): 241 (M^+ + 1) and 209 (M^+ − MeOH + 1). *Anal.* calcd. for $C_{12}H_{16}O_5$: C 59.99, H 6.71; found: C 59.83, H 6.93.

Attempts to photocyclize ketodiester ***2*** *to hydroxydiester* ***24***

(a) *Pyrex filter*

A solution of 85 mg (0.35 mmol) ketodiester **2** in 25 mL benzene – *tert*-butyl alcohol (4:1) was placed in a pyrex photoreactor and nitrogen was bubbled through it for 1 h. The reactor was stoppered and the solution was irradiated with a 125-W lamp for 20 h. Evaporation of the solvent gave a residue which, when analyzed by glc, was shown to be the starting material. Similar results were obtained by carrying out the reaction in *tert*-butyl alcohol as solvent.

(b) *Quartz filter*

A solution of 75 mg (0.31 mmol) ketodiester **2** in 2 mL benzene – *tert*-butyl alcohol (5:1) was placed in a quartz tube. After bubbling in nitrogen for 1 h, the tube was stoppered and the solution was irradiated with a 400-W lamp, using a quartz refrigeration system, for 16 h. Evaporation of the solvent gave a crude product which when analyzed by glc/ms, was shown to contain mainly the starting material and minor amounts of other components with molecular weights of 258, 272, 286, 300, and 314. None of them correspond to the hydroxydiester **24**.

Attempt to photocyclize ketoanhydride ***18*** *to hydroxyanhydride* ***25***

A solution of 23 mg (0.12 mmol) ketoanhydride **18** in 2 mL of a mixture of benzene – *tert*-butyl alcohol (4:1) was placed in a quartz tube. After deoxygenating and irradiating the solution for 3 days with

a 400-W lamp, using a quartz refrigeration system, the solvent was evaporated and the residue analyzed by glc/ms. The major component of the residue had a molecular weight of 212, corresponding to the addition of water. Also, minor amounts of starting material and compounds with molecular weights of 226 and 210 were detected. None of them correspond to the expected **25**.

Six pyrimidonium salts: determination of their crystal structures and studies of their prototropic behaviour in solution[1]

THOMAS W. S. LEE, STEVEN J. RETTIG, ROSS STEWART,[2] AND JAMES TROTTER[2]
Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received October 19, 1983

THOMAS W. S. LEE, STEVEN J. RETTIG, ROSS STEWART, and JAMES TROTTER. Can. J. Chem. **62**, 1194 (1984).

Six methyl-substituted 2-pyrimidonium chloride salts have been prepared and the rates of hydrogen exchange of their reactive methyl groups (at the 4- and 6-positions) have been determined in DCl/D_2O solution. Adjacent methyl groups, whether on nitrogen or carbon, activate the exchanging centres, whereas more distant methyl groups have a deactivating effect. The molecular geometry of the salts has been determined by X-ray crystallography with the view to determining whether the presence of strain in the pyrimidonium ring can account for the activating effect of adjacent methyl. The most reactive compound, the 1,5,6-trimethylpyrimidonium chloride, has a geometry that is consistent with high reactivity, viz. a non-planar ring and short H . . . H intermethyl distance. However, the 1,4,5,6-tetramethyl compound, which also is non-planar and has an extremely short 5–6 intermethyl distance (1.99 Å), is not highly reactive; that is, the heightened strain is unable to overcome the deactivating inductive effect of the additional methyl group. We conclude that deviations from ring planarity and short intermethyl distances are insufficient to account for the activation produced by adjacent methyl though they appear to be contributing factors to this effect.

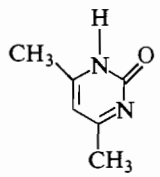
THOMAS W. S. LEE, STEVEN J. RETTIG, ROSS STEWART et JAMES TROTTER. Can. J. Chem. **62**, 1194 (1984).

On a préparé six chlorures de pyrimidonium-2 portant des substituants méthyles et on a déterminé les vitesses d'échange d'hydrogène, catalysées par une solution de DCl/D_2O, de leurs groupes méthyles réactifs (en positions 4 et 6). Les groupes méthyles adjacents qu'ils soient sur l'azote ou sur le carbone activent les centres d'échange tandis que les groupes méthyles plus éloignés ont un effet désactivant. On a déterminé la géométrie moléculaire des sels par cristallographie de rayons-X dans le but de déterminer si la présence de contrainte dans le cycle pyrimidonium peut intervenir dans l'effet activant des groupes méthyles adjacents. Le composé le plus réactif, le chlorure de triméthyl-1,5,6 pyrimidonium a une géométrie qui justifie sa grande réactivité soit l'existence d'un cycle qui n'est pas plan et le fait que les distances H . . . H interméthyliques sont courtes. Dans le cas du composé tétraméthyl-1,4,5,6, le cycle n'est pas plan et la distance entre les méthyles-5,6 est très courte (1.99 Å); malgré ces caractéristiques, ce composé n'est pas très réactif et ceci implique que l'encombrement accru n'est pas suffisant pour contrebalancer l'effet inductif désactivant du groupe méthyle additionnel. Nous concluons que le manque de planéité dans les cycles et le fait que les distances entre les méthyles sont courtes ne sont pas des conditions suffisantes pour expliquer l'activation provoquée par la présence d'un groupe méthyle adjacent même s'il semble qu'ils sont des facteurs qui contribuent à cet effet.

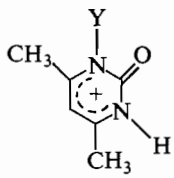
[Traduit par le journal]

Introduction

Methyl groups at the 4- and 6-positions in 2-pyrimidones, **1**, and their protonated or alkylated derivates, **2** (Y = H or alkyl), are activated sites that exchange their protons with those of the solvent (1, 2). They are two of several heterocyclic systems that show unusual effects of neighbouring alkyl substitution (3–9). In brief, introduction of an alkyl group (usually methyl) at a position that is adjacent to the reactive methyl group has an activating effect on proton loss, whereas one introduced at a more distant location has a deactivating effect.

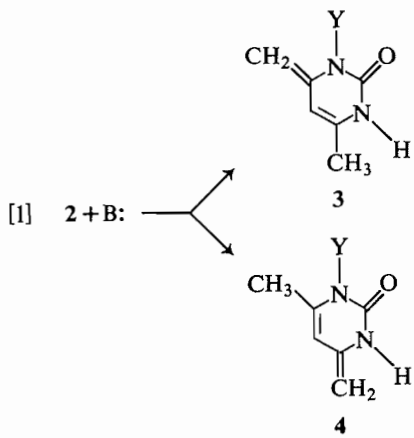


1



2

The deactivating effect of next-but-one methyl, which is commonly of the order of 20 or more, is in the expected direction, although its magnitude is perhaps surprising. Proton exchange involves loss of a proton (eq. [1]) from the active site and the electronic effect of alkyl should stabilize the reactant and decrease the rate.



[1] **2** + B:

3

4

We have considered a number of possibilities (1, 2) for the rate increase produced by an adjacent methyl group. These include the attractive notion that steric strain caused by the interaction of adjacent methyl groups is relieved upon proton loss as the substrate, which is highly resonance stabilized, is converted to the intermediates **3** or **4**, which can adopt a non-planar arrangement without undue loss of stabilization.

In the present work the rates of exchange of activated methyl groups (4- or 6-position) of six pyrimidonium ions have been measured in 0.106 molar DCl in D_2O. This medium was chosen so as to allow both protonated and alkylated species to be studied under identical conditions. The molecular geometry of these cations was then determined by means of an X-ray crys-

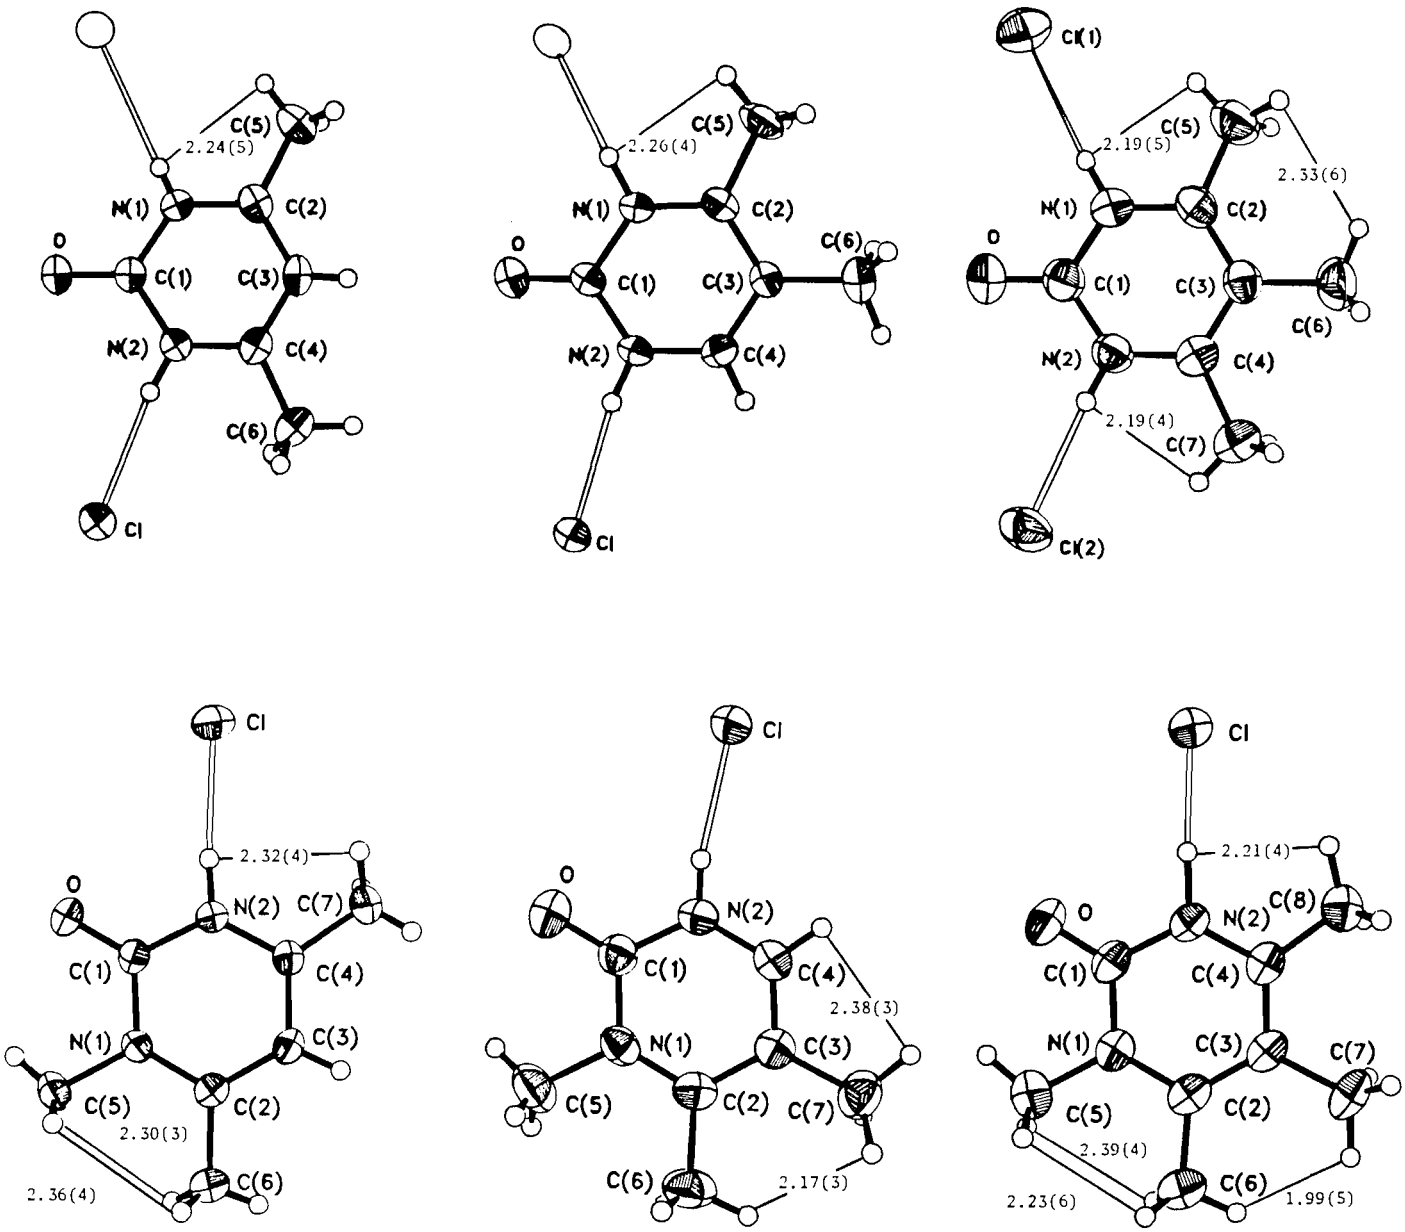

FIG. 1. Views of the molecules **5**, **6**, **7** (top) and **8**, **9**, **10** (bottom).

tallographic study of their chloride salts. The results described herein reveal the presence of significant strain in some of the more reactive species, though this strain falls far short of providing a full explanation of the rate effects that have been observed.

Results

Crystal structures of the 2-pyrimidone hydrochlorides ***5–10***

The results are shown in Tables 1–6. Each of the structures consists of 2-pyrimidonium cations and chloride anions, the packing being dominated by N—H . . . Cl hydrogen bonding (see Table 6). The structures of **5–7** (wherein each cation possesses two NH protons) contain infinite chains of alternating cations and anions linked by N—H . . . Cl hydrogen bonds. In **5** this arrangement is planar, all non-hydrogen atoms residing on a crystallographic mirror plane, while in **6** the chain spirals about the twofold screw-axis. The chains in **7** contain two crystallographically independent Cl^- anions, each of which resides on a crystallographic twofold axis perpendicular to the direction of propagation; thus adjacent cations are related by a twofold rotation about an axis containing the symmetrically bridging chloride anion. The structures of **8–10**, *N*-methylated derivatives of **5–7**, respectively, consist of strongly N—H . . . Cl hydrogen-bonded ion-pairs (Fig. 1) separated from one another by van der Waals distances. The mean N . . . Cl and H . . . Cl distances of 3.03 and 2.08 Å in **8–10** are shorter than the corresponding distances of 3.14 and 2.30 Å in **5–7**, consistent with the fact that each chloride ion is involved in only one hydrogen bond in the compounds **8–10** while those in **5–7** are each involved in two. These N—H . . . Cl hydrogen bonds are all relatively strong, the average N . . . Cl and H . . . Cl distances compiled for a number of such interactions being 3.23 and 2.4 Å, respectively (10, 11).

The most notable structural feature exhibited by this series of compounds is the steric interaction between the methyl substituents. This steric strain arises primarily from intramolecular

van der Waals contacts between hydrogen atoms (shown in Fig. 1) and is relieved by a combination of exocyclic bond angle deformations and deviations of the six-membered rings from planarity. These small (<0.02 Å) but significant deviations from planarity are observed only when two adjacent ring carbon atoms are substituted (**6**, **7**, **9**, and **10**). Thus in **5** (in which there are no adjacent methyl-substituted ring atoms) the ring is planar. The potential steric interaction between the C(2)—methyl groups (common to all six molecules; crystallographic numbering scheme) and the N(1)—methyl substituent in **8**–**10** appears to be relieved primarily by deformation of the exocyclic angles about N(1) (C(5)—N(1)—C(2) = 121.3–121.9°, C(5)—N(1)—C(1) = 114.8–116.4° in **8**–**10**). The six-membered ring of **8** is thus also planar while those in

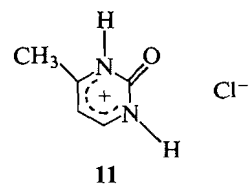
[a]This structure contains two independent Cl atoms, each lying on a crystallographic twofold axis.

6 and **9** adopt irregular conformations approximating flattened N(1)—envelopes, and those in **7** and **10** have flattened chair conformations.

The six cations contain essentially localized C=O double bonds (mean C—O = 1.213(3) Å) and the slightly shortened C(1)—N bonds (mean C(1)—N = 1.387 Å) indicate a bond order of approximately 1.15. Bond lengths in the N—C(2)—C(3)—C(4)—N portions of the rings (mean N—C = 1.350 and mean C—C = 1.381 Å) are similar to those in pyridine, indicating full delocalization of the two double bonds formally present in this portion of the ring. The symmetrically substituted compounds **5** and **7** show the expected twofold symmetry, while the remaining structures show clearly the substituent-induced deviations from twofold symmetry (see Tables 3 and 4). The N—Me distances in **8**–**10** are virtually identical, mean N—C = 1.477(1) Å. The C(3)—Me bonds are significantly longer than the (C(2)/C(4))—Me bonds (means of 1.510(3) and 1.491(6) Å, respectively).

Reaction rates and their relation to ionic structure

The rate constants for the exchange of the hydrogen atoms of the 4- and 6-methyl groups are shown in Table 7 together with five geometrical factors that seem to be the most relevant with respect to the question of strain. These are (*a*) the presence of short intermethyl distances (less than 2.40 Å), (*b*) the sum of the torsional angles given in Table 5 (in order to have a measure of the rings' overall deviation from planarity), (*c*) the torsional angles C(1)—N(1)—C(2)—C(3), (*d*) the torsional angles N(1)—C(2)—C(3)—C(4), and (*e*) the torsional angles C(2)—C(3)—C(4)—N(2). (These particular torsional angles were chosen because they include all the ring atoms to which methyl groups are attached and would be the most likely to show deviations due to crowding.)



11

In order to facilitate comparison of the two kinds of data in Table 7, the rate data have been corrected for symmetry and normalized with respect to compound **11**, which contains no methyl groups other than that undergoing exchange.

Compound **5** is the only one of the six ions that has a completely planar ring. Its low reactivity compared to **11**, which we can assume is also planar, is the result of the electronic effect of the methyl groups on each other. The isomer **6** is some 30 times as reactive as **5** and its torsional angles show it to deviate significantly from planarity, although it does not suffer from intermethyl crowding. The trimethyl species **7** has a comparable degree of non-planarity to that of **6** (torsional angle sum slightly greater, average of the relevant angles slightly less) and, moreover, has a short intermethyl distance. However, this compound has a very low reactivity, due presumably to the electronic effect of the additional methyl group overwhelming any strain that is associated with its presence.

Compound **8** is interesting in that it has an almost planar ring and yet a moderately high reactivity for the 6-methyl group and a very low reactivity for the 4-methyl group. With respect to the 6-methyl group the adjacent *N*-methyl group is activating and the more distant 4-methyl group deactivating, the latter effect being slightly the greater.

Species **9** is an isomer of **7** and **8** and is by far the most reactive of the compounds studied. It does deviate from planar-

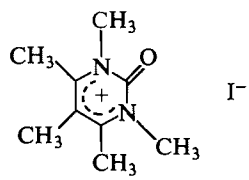
[a] Corrected for symmetry (**5** and **7**) and normalized with respect to compound **11** ($k = 7.3 \times 10^{-5}$ s^{-1}).
[b] From Table 5.
[c] Position 6 is adjacent to the *N*-methyl group.
[d] ω_1 = C(1)—N(1)—C(2)—C(3), ω_2 = N(1)—C(2)—C(3)—C(4), ω_3 = C(2)—C(3)—C(4)—N(2).

ity more than its isomers and does have a shorter intermethyl distance than either of them.

Species **10** shows a comparable degree of deviation from planarity to that of **9** and in addition has one short and one very short intermethyl distance. Its two active methyl groups, however, have reactivities that are little different from those in compound **8**, a species with an almost planar ring. We have also prepared the fully methylated iodide salt **12** and find that its reactivity is low (little different from that of **7**). Unfortunately, we have been unable to prepare the chloride salt of this compound for X-ray analysis.



12

A number of conclusions might be drawn from the above results, depending on which species one chooses to compare. The high reactivity of **6** compared to **5** could be ascribed to loss of planarity in the ring, though not to any crowding of the methyl groups. The high reactivity of **8** (6-methyl) with respect to **5** could possibly be ascribed to a slightly short intermethyl distance but not to a loss of ring planarity. The very high reactivity of **9** might be ascribed to the existence of both a non-planar ring and a short intermethyl distance (2.17 Å). The lower reactivity of **10**, however, shows that an extremely short intermethyl distance (1.99 Å) is not sufficient to overcome the electronic effect of methyl.

Elements of strain are clearly present in some of the more reactive pyrimidonium ions, with the strain being sometimes manifested in a deviation from ring planarity and sometimes in a short intermethyl distance. A large degree of strain, however, is not sufficient to cause high reactivity (compound **10**), nor is a fairly low degree of strain incompatible with high reactivity (compound **9**).

We conclude that the presence of methyl groups on adjacent carbon atoms can destabilize species such as pyrimidonium ion as a result of steric compression or deviations from ring planarity but that these effects seem insufficiently large or consistent to account satisfactorily for the rate reversal that accompanies the relocation of a methyl group from a position that is next-but-one to one that is immediately adjacent to a reactive methyl site. We are presently exploring the effect of size and polarizability of the attacking base in these and other systems to see if a reverse steric effect is present here as well.

Experimental

Materials

All compounds used for kinetic studies and X-ray crystallographic measurement were purified by several recrystallizations in methanol–ethanol.

4,6-Dimethyl-2-pyrimidone hydrochloride (**5**), 5,6-dimethyl-2-

pyrimidone hydrochloride (**6**), 1,4,6-trimethyl-2-pyrimidone hydrochloride (**8**), 1,5,6-trimethyl-2-pyrimidone hydrochloride (**9**), and 1,4,5,6-tetramethyl-2-pyrimidone hydrochloride (**10**) were prepared by treating the respective pyrimidone with dilute hydrochloric acid solution followed by recrystallization. The procedures for preparing these pyrimidones and 1,3,4,5,6-pentamethyl-2-pyrimidone hydroiodide, **12**, were reported in refs. 1 and 12.

4,5,6-Trimethyl-2-pyrimidone hydrochloride, **7**, was obtained by neutralizing 4,5,6-trimethyl-2-pyrimidone with dilute hydrochloric acid solution followed by recrystallization. The pyrimidone was prepared by treating urea with 3-methyl-2,4-pentandione in concentrated hydrochloric acid solution, essentially by the method of Hale (12). Recrystallization of the crude product from ethanol – ethyl acetate gave 4,5,6-trimethyl-2-pyrimidone: mp 248°C; ^{1}H nmr ($CDCl_3$) δ 2.04 (s, 3H), 2.40 (s, 6H). *Anal.* calcd. for $C_7H_{10}ON_2$: C 60.85, H 7.30, N 20.27; found: C 60.88, H 7.14, N 20.35.

6-Methyl-2-pyrimidone hydrochloride, **11**, was prepared by treating urea (0.06 mol) with 1,1-dimethoxy-3-butanone (0.06 mol) in a mixture of ethanol (10 mL) and hydrochloric acid (10 *N*, 10 mL). Within 1 h, the mixture yielded yellow crystals which were recrystallized to give 77% yield of **11**: mp 236°C (decomp.); ^{1}H nmr (D_2O) δ 2.70 (s, 3H), 6.98 (d, 1H), 8.64 (d, 1H). *Anal.* calcd. for $C_5H_7N_2OCl$: C 40.97, H 4.81, N 19.11, Cl 24.19; found: C 40.97, H 4.88, N 18.94, Cl 24.00.

Kinetics

The exchange experiments of methyl protons in **5**–**12** were conducted in DCl/D_2O solution at 30°C using a T-60 nmr spectrometer, essentially as previously described (1).

X-ray crystallographic analyses of the 2-pyrimidone hydrochlorides ***5–10***

Crystallographic data are presented in Table 1. In each case crystals were mounted in general orientations on an Enraf-Nonius CAD4-F diffractometer. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 high-order reflections (2θ = 35–55°) measured at 22°C with Mo-Kα_1 radiation (λ = 0.70930 Å).

Intensities were measured with graphite-monochromated Mo-Kα radiation (λ = 0.71073 Å). An ω–2θ scan at ~1–10.06° min^{-1} over a range of (s_w + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement, with s_w = 0.60, 0.60, 0.60, 0.70, 0.55, and 0.57 for **5**–**10** respectively). The intensities of three check reflections, measured every hour throughout each data collection, showed only small random fluctuations in each case. The data were processed[3] and corrected for absorption using the Gaussian integration method (13, 14). In each case those reflections which had intensities greater than 3σ(I) above background, where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count, were employed in the solution and refinement of the structures.

The structures were solved by direct methods, the coordinates of all non-hydrogen atoms being determined from E-maps and those of the hydrogen atoms from subsequent difference syntheses. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms with isotropic thermal parameters. The scattering factors of ref. 15 were used for the non-hydrogen atoms and those of ref. 16 for the hydrogen atoms. Corrections for anomalous scattering (17) were applied for Cl atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of each refinement. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$. Parameter shifts on the final cycles of refinement did not exceed 0.25 σ and final difference maps were essentially featureless. The final positional and thermal parameters appear in Tables 2 and 8,[4] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[4]

In the case of **5**, the systematic absences allow space groups *Pnma* or $Pn2_1a$; the former was indicated by the E-statistics and the structure was solved and successfully refined in the centrosymmetric space group. However, the thermal parameters (Table 8) indicate possible small displacements from exact mirror symmetry; the rms vibrations normal to ***b*** are in the range 0.17–0.24 Å, and parallel to ***b*** are 0.21–0.35 Å, with the larger values being for O, C(5), and C(6). These vibrations are not exceptionally large, and the greater values parallel to ***b*** may well be a real thermal effect. Refinement in $Pn2_1a$ seems neither profitable nor desirable, since the possible small displacements involved scarcely justify the introduction of additional parameters. The molecule does appear to be virtually planar.

The thermal motion in each of the structures (Fig. 1) has been analyzed in terms of the rigid-body modes of translation, libration, and screw-motion (18). The rms errors in the U_{ij} (derived from the least-squares analyses) are 0.0015, 0.0008, 0.0010, 0.0007, 0.0007, and 0.0015 Å^2 for **5**–**10**, respectively. Analysis of the cations gave physically reasonable rigid-body parameters and rms ΔU_{ij} values of 0.0020, 0.0014, 0.0017, 0.0014, 0.0010, and 0.0014 Å^2 for **5**–**10**, respectively. The appropriate bond lengths have been corrected for libration (18, 19), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3; corrected angles do not differ by more than 1σ from the uncorrected values in Table 4. Intra-annular torsion angles defining the conformations of the six-membered rings are given in Table 5 and details of the N—H . . . Cl hydrogen bonding in Table 6. Uncorrected bond lengths, bond lengths and angles involving hydrogen, and a complete listing of torsion angles (Tables 9–12) have been deposited.[4]

The reaction of methyl radicals with neopentane in flow photolysis at 607–823 K

HIROSHI FURUE, KIM C. MANTHORNE, AND PHILIP D. PACEY
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received October 12, 1983

HIROSHI FURUE, KIM C. MANTHORNE, and PHILIP D. PACEY. Can. J. Chem. **62**, 1203 (1984).

Acetone was photolyzed in the presence of a large excess of neopentane in a flow system at total pressures between 7 and 150 Torr and at 607–823 K. For reactions

[1] $CH_3 + C(CH_3)_4 \rightarrow CH_4 + (CH_3)_3CCH_2$

and

[2] $2CH_3 \rightarrow C_2H_6$

the quotient of rate coefficients, k_1^2/k_2, was calculated from CH_4 and C_2H_6 yields and was extrapolated to the high pressure limit, $k_1^2/k_{2,\infty}$. Taking $k_{2,\infty}$ as 2.2×10^{10} L mol^{-1} s^{1}, Arrhenius parameters for reaction [1] were found to be: $\log_{10} A$ (L mol^{-1} s^{-1}) = 10.0 ± 0.1, E_A = 62 (±2) kJ mol^{-1}. In combination with data from the literature for the temperature range 365–953 K, the Arrhenius plot for $k_1/k_{2,\infty}^{1/2}$ was strongly curved, with a heat capacity of activation of 71 ± 4 J K^{-1} mol^{-1}.

HIROSHI FURUE, KIM C. MANTHORNE et PHILIP D. PACEY. Can. J. Chem. **62**, 1203 (1984).

On a photolysé l'acétone en présence d'un grand excès de néopentane dans un système à écoulement opérant sous des pressions de 7 à 150 Torr et à des températures variant entre 607 et 823 K.

Utilisant les rendements en CH_4 et en C_2H_6, on a calculé le rapport des coefficients de vitesse k_1^2/k_2 et on l'a extrapolé

[1] $CH_3 + C(CH_3)_4 \rightarrow CH_4 + (CH_3)_3CCH_2$

et

[2] $2CH_3 \rightarrow C_2H_6$

jusqu'à la pression limite supérieure, $k_1^2/k_{2,\infty}$. Si on fixe que $k_{2,\infty}$ est égal à $2,2 \times 10^{10}$ L mol^{-1} s^{1}, on a trouvé que les paramètres d'Arrhénius pour la réaction [1] sont: $\log A$ (L mol^{-1} s^{-1}) = 10,0 ± 0,1 et E_A = 62 (±2) kJ mol^{-1}. En combinant ces données avec celles répertoriées dans la littérature pour l'intervalle de température allant de 365 à 953 K, la courbe d'Arrhénius pour $k_1/k_{2,\infty}^{1/2}$ est fortement incurvée avec une capacité calorifique d'activation de 71 ± 4 J K^{-1} mol^{-1}.

Introduction

Hydrogen abstraction by methyl radicals has been studied well at temperatures above 700 K by pyrolysis of hydrocarbons and at temperatures below 600 K by photolysis of acetone, azomethane, and dimethyl mercury in hydrocarbons (1). These studies revealed significant differences in activation energies (for neopentane, 67 kJ mol^{-1} at high temperatures compared to 42–50 kJ mol^{-1} at low temperatures), suggesting that the Arrhenius plots for the reactions are curved. In the present study, data are obtained from 600 to 800 K, where experimental data are scarce, by photochemically generating methyl radicals in a flow reactor. The use of a flow reactor makes photolysis experiments possible at higher temperatures than with conventional, static reactors.

Neopentane, $C(CH_3)_4$, was chosen for this study because only primary hydrogens are transferred. A small amount of acetone (1.0–6.3 mol%) was added to generate the methyl radicals photochemically. The most important sources of CH_4 and C_2H_6 in the system are likely to be the following (2, 3):

[1] $CH_3 + C(CH_3)_4 \rightarrow CH_4 + (CH_3)_3CCH_2$

[2] $2CH_3 \rightarrow C_2H_6$

[3] $CH_3 + (CH_3)_2CO \rightarrow CH_4 + CH_2COCH_3$

Writing down the expressions for the steady-state rates of formation of CH_4 and C_2H_6, and combining these so as to eliminate the concentration of CH_3 and rearranging, one obtains:

$$[4] \quad \frac{k_1^2}{k_2} = \frac{[CH_4]^2}{[C(CH_3)_4]^2[C_2H_6]t\{1 + k_3[(CH_3)_2CO]/(k_1[C(CH_3)_4])\}^2}$$

To use this equation to determine k_1^2/k_2, it is necessary to know the ratio k_3/k_1 and the initial concentrations of neopentane and acetone and it is necessary to measure the concentrations of CH_4 and C_2H_6 formed after photolysis times, t.

A pressure dependence of this quotient is expected, as k_2 is known to depend on pressure. This dependence may be displayed as a function of inverse pressure on a Lindemann–Hinshelwood plot (4). The intercept of such a plot should be approximately equal to the high pressure limiting quotient, $k_1^2/k_{2,\infty}$.

Experimental

A description of most parts of the apparatus has been given elsewhere (4, 5). A quartz flow reactor tube of 11 mm id, having parallel quartz windows at both ends, was heated by 45 cm long nichrome-wound resistive furnace. A thermocouple was placed in a 4 mm od quartz tube beside the reactor, and was moved along the reactor to obtain a temperature profile. During an experiment it was positioned at the midpoint to enable the correction of any drift of temperature.

At one end of the reactor was placed an optical train composed of a 100 W high pressure Hg lamp (Osram HBO 100 w/2), an iris, a mirror, a collimating lens, and a Pyrex filter. The reagent bulbs and tubing were painted black to prevent premature photolysis. The light intensity within the reactor was tested with a thermistor and was found

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

to vary by only 5% from end to end of the reactor and was not found to vary perpendicular to the reactor axis.

Neopentane (Matheson, 99.87%) was degassed at nitrogen-boiling and toluene-melting temperatures. Acetone (A. C. S.) was fractionally distilled, and the middle fraction was degassed at the nitrogen-boiling temperature. Mixtures of acetone in neopentane were prepared and equilibrated overnight before use. The reagent mixture was routinely checked for any impurity from acetone decomposition in the storage containers. Product concentrations were analyzed in a gas chromatograph with a 1 m silica gel column at 50°C.

Results

The reactor extended about 7 cm outside the furnace at both ends. To determine whether reaction could occur in these regions, an experiment was performed with full light intensity but with the furnace off. No formation of CH_4 or C_2H_6 was observed.

Temperature gradients occurred at both ends of the furnace and it was necessary to learn what weight should be given to these regions. Experiments were performed at full light intensity with about 100 Torr of neopentane containing 2.5% acetone at 659, 707, and 770 K. Activation energies were found to be 50 kJ mol^{-1} for C_2H_6 and 85 kJ mol^{-1} for formation of CH_4. Consequently, the various regions of the reactor were weighted by the factor, exp $[-64\ kJ\ mol^{-1}/(RT)]$, using a preliminary estimate of the mean activation energy, in a computer program described elsewhere (6). The experimental temperature profile was interpreted with the aid of this program to determine the average reaction temperature and the effective furnace length. In typical experiments, it was found that 90% of the reaction occurred within 10 K of the average reaction temperature. At 823 K, it was found that the activation energy increased because of thermal initiation and an activation energy of 284 kJ mol^{-1} was used in the above program.

Residence times and reactant conversions had little effect on the quotient in eq. [4]. In experiments[1] at 8 Torr and 608 K and with 12 residence times from 0.9 to 18 s, no significant effect was found. Only at 823 K, where the conversion reached its maximum value of 8×10^{-3}, was a significant effect found. At this temperature the quotient was extrapolated to time $t = 0$ to eliminate the effect of secondary reactions. At all other temperatures, the values of the quotient at different residence times were simply averaged.

The light intensity was varied by restricting the light beam with iris apertures of areas 0.10 and 0.23 cm^2 and by leaving the light beam unrestricted. At 609 K and 7 Torr, the rate of formation of C_2H_6 varied by a factor of 4.7 but the quotient in eq. [4] stayed constant within 6%.

Variation of the total pressure in the range from 7 to 150 Torr while other parameters remained fixed did affect the kinetics. The rate of formation of C_2H_6 increased with increasing pressure. The quotient in eq. [4] decreased slightly at high pressure, as seen in the form of a Lindemann–Hinshelwood plot in Fig. 1 for experiments at 608 K. Here k_3/k_1 was calculated from the recommended Arrhenius parameters of ref. 1. The straight line was determined by least squares. For this and other temperatures, the intercepts, $k_1^2/k_{2,\infty}$, were found to have uncertainties between 4% and 10%. Two experimental pressures, close to 30 and 90 Torr, were used at the other temperatures. The values

[1]Tables of data are available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

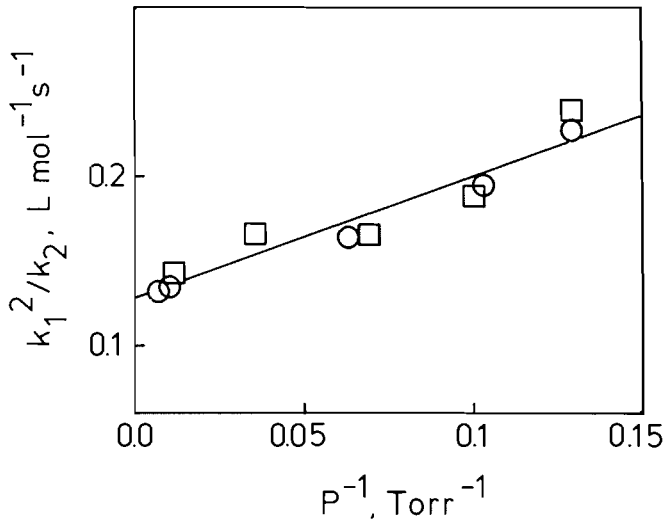

FIG. 1. Lindemann–Hinshelwood plot of the quotient, k_1^2/k_2, calculated from eq. [4], at varying reactant pressures at 608 K; ○, 0.010 mole fraction $(CH_3)_2CO$; □, 0.063 mole fraction $(CH_3)_2CO$; —, least-squares straight line.

of $P_{1/2}$, the ratios of slopes to intercepts of such plots, were 6 ± 1 Torr at 608 K, 7 ± 2 Torr at 659 K, 7 ± 3 Torr at 707 K, 10 ± 2 Torr at 770 K, and 15 ± 3 Torr at 823 K. Here and elsewhere quoted uncertainties are standard deviations.

The mole fraction of acetone in the reagent mixture was varied from 0.010 to 0.063. Values of the quotient $k_1^2/k_{2,\infty}$, calculated from experiments with different mole fractions of acetone, are shown in Fig. 1 to be in good agreement.

The square roots of intercepts of Lindemann–Hinshelwood plots from this work are shown in the form of an Arrhenius plot in Fig. 2, together with data from the literature. Arrhenius parameters for reaction [1], calculated assuming $\log_{10} k_{2,\infty}/L\ mol^{-1}\ s^{-1} = 10.34$ (1, 13), are listed in Table 1. Except for the results of ref. 12, for which the temperature range was narrow, the Arrhenius parameters generally increase with increasing temperature.

Discussion

Any first-order surface termination reaction would be most competitive with reaction [2] in conditions with small radical concentrations (i.e., small intensity and $[(CH_3)_2CO]$). Concentrations of photochemically hot radicals would be most competitive with those of thermal radicals in conditions with short chain lengths (i.e., large intensity and acetone mole fraction). The quotient k_1^2/k_2 was found to be independent of intensity and of acetone mole fraction, indicating that surface terminations and hot radical reactions were unimportant. Furthermore, extrapolation, as in Fig. 1, to the high pressure limit, where chain lengths were long and radical concentrations large, should have eliminated any effect of such processes.

The ratio k_3/k_1 in eq. [4] was extrapolated from low temperature data (1), supposing that any Arrhenius plot curvature is equal for the two reactions. Because of the small acetone mole fractions, if the Arrhenius plot for reaction [3] were straight, the calculated value of k_1 would be affected by 2% or less.

Furimsky and Laidler (7) showed that the concentrations of CH_3 and $(CH_3)_3CCH_2$ radicals were similar to each other at 608 K in the mercury-photosensitized decomposition of neopentane. The $(CH_3)_3CCH_2$ radical, whose relative concen-

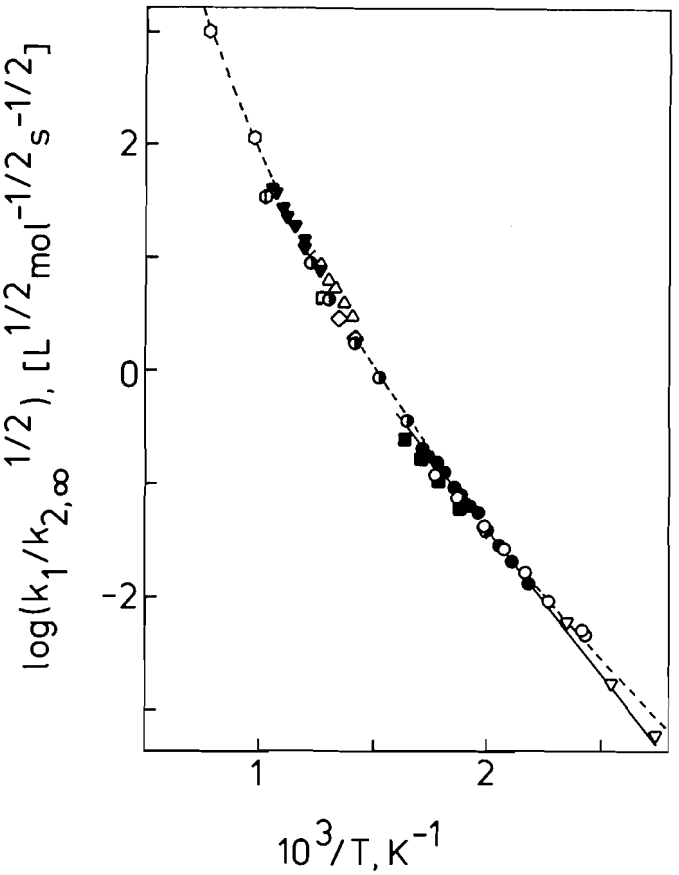

FIG. 2. Arrhenius plot for the quotient $k_1/k_{2,\infty}^{1/2}$, after ref. 1: ○, ref. 2; ●, ref. 3; ▼, ref. 4; ■, ref. 7; ▽, ref. 8; △, ref. 9; □, ref. 10; ⊙, ref. 11; ◇, ref. 12; ×, ref. 13; ⊛, ref. 14; ◑, this work; —, preferred Arrhenius line, ref. 1; - - -, least-squares fit to eq. [5].

tration decreased with increasing temperature, was shown not to interfere with the calculation of k_1^2/k_2 (7). The CH_3CO radical was formed in the photodecomposition step in the present work (15). From Arrhenius parameters in the literature (1, 16), it was calculated that CH_3 was five or more orders of magnitude greater in concentration than CH_3CO. We conclude that CH_3CO and $(CH_3)_3CCH_2$ did not interfere with the calculation of k_1^2/k_2 in the present work.

The method of extrapolation in Fig. 1 may introduce uncertainty into the high pressure value, $k_1^2/k_{2,\infty}$. Forst has shown that this method is justified by theory if the pressures are sufficiently high (17). Experimental values of k_2 as a function of pressure at 823 K are available (13). When values of k_1^2/k_2 at 823 K from the present work were multiplied by values of $k_2/k_{2,\infty}$ from ref. 13, the value of $k_1^2/k_{2,\infty}$ was only 4% less than the value obtained from an analogue of Fig. 1. We conclude that the Lindemann–Hinshelwood extrapolations gave reliable intercepts under the present conditions.

The intercepts agreed well with results in the literature. The following is a list of differences between values of $\log_{10} k_1/k_{2,\infty}^{1/2}$ from this work and those at the same temperatures from data or Arrhenius parameters in the literature: 608 K, +0.09 (7), +0.05(3); 707 K, −0.06 (12); 823 K, −0.10 (4), −0.07 (13).

The data in Fig. 2 and Table 1 confirm an earlier suggestion (4) that the Arrhenius plot for reaction [1] is a curve. Such curves are sometimes (18–20) interpreted by means of the equation

TABLE 1. Arrhenius parameters for reaction [1]

T (K)	Reference	$\log_{10} A$ (L mol^{-1} s^{-1})	E_A (kJ mol^{-1})
365–495	8	8.9±0.1	49±1
411–565	2	8.1±0.1	42±1
458–582	3	8.92±0.04	49.4±0.4
503–608	7	8.7	48
607–823	This work	10.0±0.1	62±2
703–743	12	8.7	43
713–823	9	10.8	72
793–953	4	10.5±0.1	67±2
1030–1300	11	11.8	90

$$[5] \quad k = BT^{C/R} \exp(-D/RT)$$

where C is LaMer's heat capacity of activation (21, 22) and B, C, and D are usually taken as independent of temperature. The logarithmic form of eq. [5] was fitted by non-linear least squares to the photochemical results in Fig. 2 and to the pyrolytic results of refs. 4, 12, and 13. The points in Fig. 2 were given equal weight, corresponding to an assumption that all were subject to similar fractional uncertainties (20); $k_{2,\infty}$ was again given the value of refs. 1 and 13. The parameters were found to be $C = 71 \pm 4$ J K^{-1} mol^{-1}, $D = 14 \pm 3$ kJ mol^{-1} and $\log_{10} B$ (L^{-1} mol^{-1} s^{-1} K$^{-8.5}$) $= 17.8 \pm 1.6$. The resulting dashed curve on Fig. 2 fitted the data within a standard deviation of 0.05 log units.

By differentiating the logarithmic form of eq. [5], one obtains the following expressions for the Arrhenius parameters:

$$[6] \quad E_A = D + CT$$

$$[7] \quad \log_{10} A = \log_{10} Be^{C/R} + (C/R) \log_{10} T$$

Fitting these expressions to the parameters in Table 1, C was found to be 61 ± 12 J K^{-1} mol^{-1} from the activation energies and 65 ± 14 J K^{-1} mol^{-1} from the pre-exponential factors. The three values of C agreed within their uncertainties. To argue that the Arrhenius plot is linear ($C = 0$), it would be necessary to reject all results above 608 K or else to reject all photochemical results.

Sources of the curvature were suggested in ref. 4. If the weak bending modes in the activated complex behave as hindered internal rotations, they could contribute 20 to 30 J K^{-1} mol^{-1} (22). The possibility of enhanced reaction from an excited state is difficult to evaluate (23). Tunnelling can contribute 100 J K^{-1} mol^{-1} or more to C, especially for reactions with high activation barriers (21). We note that certain hydrogen atom transfer reactions of Cl and OH, for which smaller values of C (15 to 50 J K^{-1} mol^{-1}) have been observed (18–20), have lower activation barriers than reaction [1]. Tunnelling calculations on this reaction are recommended.

In conclusion, it has been demonstrated that flow photolysis can extend the range of photolysis temperatures by more than 200 K and can link the previously discordant pyrolytic and photolytic data for reaction [1].

The synthesis of derivatives of lactosamine and cellobiosamine to serve as probes in studies of the combining site of the monoclonal anti-I Ma antibody

TING C. WONG[1] AND RAYMOND U. LEMIEUX

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received November 24, 1983

TING C. WONG and RAYMOND U. LEMIEUX. Can. J. Chem. **62**, 1207 (1984).

Syntheses are reported for a variety of structures used in a continuation of our studies of the combining site of the monoclonal anti-I Ma antibody. These structures include the *N*-acetyl, *N*-formyl, and *N*-pivalyl derivatives of methyl β-D-lactosaminide, the ethyl, propyl, isopropyl, and isobutyl β-glycosides of *N*-acetyllactosamine and the βDGal(1→4)βDGlcNAc(1→6)-, βDGal(1→4)βDGlcNH$_2$(1→6)-, βDGal(1→4)βDGlcNCOCF$_3$(1→6)-, and βDGlc(1→4)βDGlcNAc(1→6)-derivatives of 1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose. Also, preparations of 6-deoxy-βDGal(1→4)βDGlcNAc(1→6)α,βDGal and βDGlcNAc(1→6)βDGal(1→4)βDGlcNAcOCH$_3$ are described.

TING C. WONG et RAYMOND U. LEMIEUX. Can. J. Chem. **62**, 1207 (1984).

On rapporte les synthèses de diverses structures utilisées dans la suite d'études relatives au site de combinaison de l'anticorps monoclonal anti-I Ma. Ces structures comprennent les dérivés *N*-acétyle, *N*-formyle et *N*-pivalyle du β-D-lactosaminide de méthyle, les β-glycosides d'éthyle, de propyle, d'isopropyle et d'isobutyle de la *N*-acétyllactosamine et les dérivés βDGal(1→4)βDGlcNAc(1→6)-, βDGal(1→4)βDGlcNH$_2$(1→6)-, βDGal(1→4)βDGlcNCOCF$_3$(1→6)-, et βDGlc(1→4)-βDGlcNAc(1→6)- du di-*O*-isopropylidène-1,2;3,4-α-D-galactopyrannose. On décrit également les préparations du déoxy-6β-βDGal(1→4)βDGlcNAc(1→6)α,βDGal et βDGlcNAc(1→6)βDGal(1→4)βDGlcNAcOCH$_3$

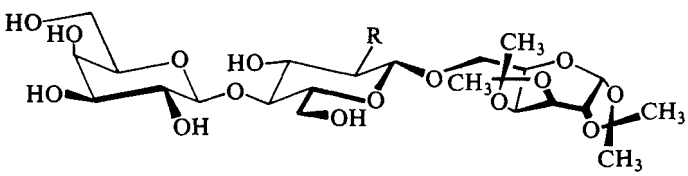
Introduction

In a previous communication (1), we reported the synthesis of the βDGal(1→4)βDGlcNAc(1→6) derivative of 1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (**2**). Evidence had accumulated that only atoms about the C-6 group of the reducing



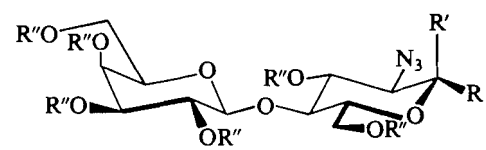
1, R = NH_2; **2**, R = NHAc; **3**, R = $NHCOCF_3$

DGal unit of the trisaccharide βDGal(1→4)βDGlcNAc(1→6)-DGal (2, 3) are involved in binding of this unit with the monoclonal anti-I Ma antibody. Evidence was later presented (4) that the binding involves a surface which extends from the C-6 grouping over the acetamido group of the βDGlcNAc unit to near the C-6″ methylene group of the terminal βDGal unit and which appears compatible for interfacing with a basically non-polar cleft at the surface of the protein.

Since the conformer which is accepted by the combining site places the reducing DGal unit in an orientation where it is not extensively bound and, therefore, largely remaining in the aqueous phase (4), it was to be expected that the di-*O*-isopropylidene derivative **2** would be a good inhibitor unless important steric interactions were encountered between the isopropylidene groups and protein structure other than that involved with the combining site. Indeed, compound **2** proved to be an excellent inhibitor, about 0.76 times that of the trisaccharide itself (5). For this reason and in light of other evidence for only marginal involvement of the reducing DGal unit (2–4), it was decided to test simple alkyl glycosides of *N*-acetyl-β-lactosamine (i.e., βDGal(1→4)βDGlcNAc—OR). Since these, in fact, proved to be superior inhibitors of the binding of the monoclonal anti-I Ma antibody with the OG protein (5), the more convenient examination of modifications of the simple methyl glycoside (**14**) of *N*-acetyl-β-lactosamine was adopted. The purpose of this communication is to report the synthetic efforts in this regard.

Discussion of results

Previously (1), the amine (**1**) formed on hydrazinolysis of the phthalimido derivative of **1** was directly *N*-acetylated to form **2**. The amine (**1**) has now been isolated and converted to the *N*-trifluoroacetyl derivative (**3**). It then became recognized (5) that βDGal(1→4)βDGlcNAcOCH$_3$ (**14**) was 2.8 times superior, as an inhibitor of the anti-I Ma antibody, to the trisaccharide βDGal(1→4)βDGlcNAc(1→6)α,βDGal. Consequently, structural modifications to further examine the engagement of the acetamido group employed the simple methyl glycosides **7** and **8**, which contain *N*-formyl and *N*-pivalyl groups, respectively. In order to prepare these compounds, the acetylated azidobromide (**4**) was synthesized from hexa-*O*-acetyl-D-lactal (6) for conversion by Koenigs–Knorr reaction with methanol to form **5** which was deacetylated to methyl 2-azido-2-deoxy-β-D-lactoside (**6**). Reduction of the azide provided the amine



4, R = H, R′ = Br, R″ = Ac
5, R = OCH_3, R′ = H, R″ = Ac
6, R = OCH_3, R′ = H, R″ = H

which was converted to both its *N*-formyl (**7**) and *N*-pivalyl (**8**) derivatives.

The methyl (**14**), ethyl (**15**), propyl (**16**), and isobutyl (**18**) β-glycosides of *N*-acetyllactosamine were conveniently prepared from the hexa-*O*-acetyl-2-deoxy-2-phthalimido-α,β-D-lactosyl chloride (7) in the usual manner (1, 8).

In order to examine the possible engagement of the

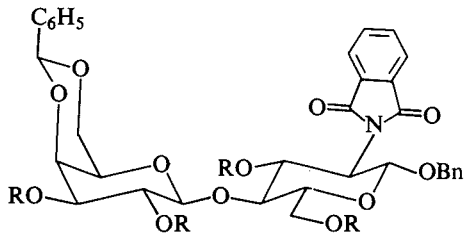
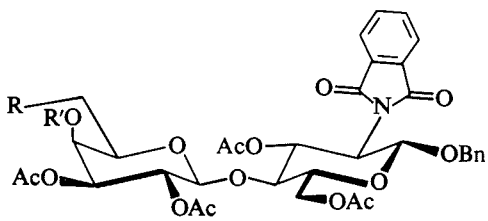
6″-hydroxyl group of βDGal(1→4)βDGlcNAc(1→6)α,βDGal in the binding with anti-I Ma, the 6″-deoxy derivative (**28**) was prepared starting from the 4′,6′-*O*-benzylidene derivative (**20**) of benzyl 2-deoxy-2-phthalimido-β-D-lactopyranoside (**19**).



20, R = H
21, R = Ac

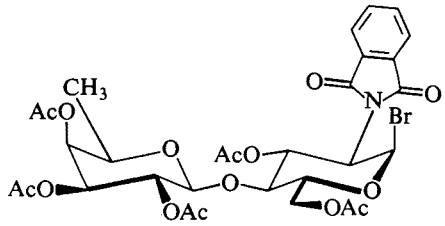
Acetylation to **21** followed by acid hydrolysis of the benzylidene group then provided the 4′,6′-diol (**22**) which could be preferentially mesylated at the 6′-position and the product acetylated to form **23**. As expected (9), replacement of the mesyloxy group was difficult but treatment with potassium iodide in dimethylformamide for 72 h at 80°C provided the 6′-iodide (**24**) in 32% yield. Reduction of the iodide with tri-*n*-butyl tin hydride in the presence of 2,2′-azobisisobutyronitrile (10) was utilized to prepare the acetylated 6′-deoxy compound **25** in 50% yield.



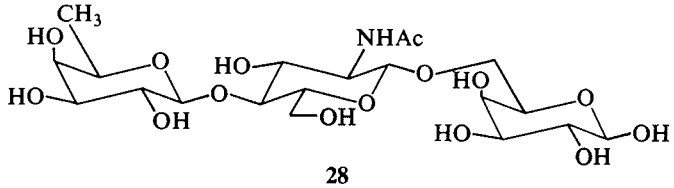
22, R = OH, R′ = H
23, R = OSO_2CH_3, R′ = Ac
24, R = I, R′ = Ac
25, R = H, R′ = Ac

The 6′-deoxy compound (**25**) was then converted to the phthalimidobromide **26** in the usual manner (7) and used for the preparation of the 6″-deoxy-βDGal(1→4)βDGlcNAc(1→6)-α,β-D-galactose (**28**) following well established procedures (11).

In order to gain evidence on the possible involvement of the 4″-hydroxyl group of the terminal βDGal unit in the binding of the trisaccharide derivative **2** with the anti-I Ma antibody, it was decided to synthesize its 4″-epimer (**39**). This was accomplished in a manner very similar to that used to prepare **2** (1). The crude product (**29**) from the azidonitration (6) of hexa-*O*-



26



28

acetyl-D-cellobial was treated with *N*,*N*-dimethylbromoforminium bromide (Vilsmeier reagent) (11) to convert any 1-acetamido-2-azido-1,2-dideoxy derivative (**6**) to the acetylated 2-azidoglycosyl bromide (**30**) and then directly with lithium bromide to convert the 2-azido-1-nitrates to form the major amount of the bromide (**30**) (12). The yield of the crystalline product was 32% from the hexa-*O*-acetyl-D-cellobial. The acetylated azidobromide (**30**) was then converted to the acetylated

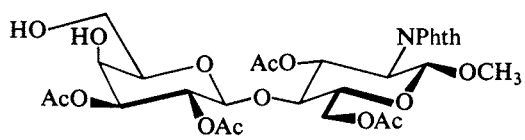
benzyl β-D-glycoside **31** which crystallized in 66% yield. Deacetylation to **32**, followed by reduction of the azide group with hydrogen sulfide, then provided benzyl 2-amino-2-deoxy-β-D-cellobioside (**33**) which was converted by way of **34** and **35**

41



42

to the hexa-*O*-acetyl-2-deoxy-2-phthalimido-α,β-cellobiosyl-chloride (**36**) in the usual manner (11). Condensation of **36** with 1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose using *sym*-collidine – silver trifluoromethanesulfonate as promoter (8) provided the desired product (**37**) in 65% yield after recrystallization. Deblocking of **37** to form the amine **38** and *N*-acetylation provided the desired compound **39**.

Since core structure oligosaccharides of human blood group determinants are known to occur as branched structures which contain βDGlcNAc units at both the 3- and 6-positions of a βDGal unit, the βDGlcNAc(1→6) derivative (**44**) of methyl *N*-acetyl-β-lactosaminide (**14**) was prepared. The 4′,6′-*O*-benzylidene derivative of **9** was prepared and acetylated to form **41**. Acid hydrolysis provided the diol **42** which was glycosylated using tri-*O*-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranosyl bromide under standard conditions (8). A 50% yield of the desired product (**43**) was obtained, which by deblocking and *N*-acetylation in the usual manner provided the desired βDGlcNAc(1→6)βDGal(1→4)βDGlcNAcOCH$_3$ (**44**) in 81% yield.

Experimental

General methods

Thin layer chromatograms (tlc) were performed on precoated silica gel 60-F254 plates (E. Merck, Darmstadt) and visualized by quenching of fluorescence and (or) by charring after spraying with 5% sulfuric acid in ethanol. For column chromatography, silica gel 60 (0.063–0.20 mm) (Fluka AG Chemische Fabrik, CH-9470, Buchs SG) was used for elution under atmospheric pressure and, for medium pressure (flash) chromatography, silica gel 60 (0.040–0.063 mm) (E. Merck, Darmstadt) was used. For high pressure liquid reverse phase chromatography (hplc), a C18 column (5 μm, 8-mm id) (Waters Associates, Milford, MA 01757) was used. For gel filtration, Sephadex LH-20 (Pharmacia Fine Chemicals AB, Uppsala, Sweden) and Bio-Gel P-2 (200–400 mesh) (Bio-Rad Laboratories, Richmond, CA) were used. Membrane dialysis was performed under medium pressure UM05 Diaflo membrane (Amico, Lexington, MA 02173). Dowex 1-X8(OH^-) resin was obtained from J. T. Baker Chemical Co., Phillipsburg, NJ, and Amberlite IR-120(H^+) resin was obtained from Mallinckrodt, Inc., Paris, KY.

In organic solvents (usually $CDCl_3$), the ^1H and ^{13}C chemical shifts (δ, in ppm) are relative either to internal 1% tetramethylsilane (δ = 0) or to chloroform with δ = 7.27. When deuterium oxide was the solvent, the reference was the HOD signal set at 4.80 ppm for ^1H nmr and the external dioxane signal set at 66.88 ppm for ^{13}C nmr.

1,2;3,4-Di-O-isopropylidene-6-O-[2-amino-2-deoxy-4-O-(β-D-galactopyranosyl)-β-D-glucopyranosyl]-α-D-galactopyranose (1)

A solution of 1,2;3,4-di-*O*-isopropylidene-6-*O*-[3,6-di-*O*-acetyl-4-*O*-(tetra-*O*-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-β-D-glucopyranosyl]-α-D-galactopyranose (1) (0.357 g, 0.37 mmol) and 85% hydrazine hydrate (0.12 g, 2.39 mmol) in ethanol (3 mL) was refluxed for 2 h. The white solid obtained after solvent removal was applied directly to a Sephadex LH-20 column and eluted with ethanol–water (1:1). Solvent removal from the main fraction gave a white solid (0.17 g, 0.29 mmol, 78%); ^1H nmr δ: 5.73 (d, 1H, H-1, $J_{1,2}$ = 5.0 Hz), 4.61 (dd, 1H, H-2, $J_{2,3}$ = 2.0 Hz), 4.48 (2d, 2H, H-1′ and H-1″ overlapping, J = 7.6 Hz and 7.6 Hz), 4.16 (m, 2H, H-4 and H-5), 3.05 (dd, 1H, H-2′), 1.60, 1.51, 1.43, 1.42 (4s, 12H, 2 OOC(CH$_3$)$_2$), 4.75, 4.05–3.53 (dd and m, 14H, remaining protons).

1,2;3,4-Di-O-isopropylidene-6-O-[2-acetamido-2-deoxy-4-O-(β-D-galactopyranosyl)-β-D-glucopyranosyl]-α-D-galactopyranose (2)

Compound **1** (30 mg, 0.05 mmol) was taken up in methanol–water (1:1, 2 mL) containing acetic anhydride (0.4 mL) and left at room temperature for about 5 h. The oil obtained after solvent removal was applied to a Sephadex LH-20 column and eluted with ethanol–water (1:1). Solvent removal and freeze-drying of the main fraction gave a white solid (26 mg, 0.042 mmol, 82%); ^1H nmr δ: 5.66 (d, 1H, H-1, $J_{1,2}$ = 5.0 Hz), 4.58 (d, 1H, H-1′, $J_{1',2'}$ = 7.6 Hz), 4.56 (dd, 1H, H-2, $J_{2,3}$ = 2.0 Hz), 4.50 (d, 1H, H-1″, $J_{1'',2''}$ = 7.6 Hz), 4.42 (bd, 1H, H-4), 2.05 (s, 3H, NHAc methyl), 1.60, 1.51, 1.43, 1.42 (4s, 12H, OOC(CH$_3$)$_2$), 4.11–3.53 (m, 16H, remaining protons).

Removal of the isopropylidene groups provided the previously reported (1) trisaccharide, βDGal(1→4)βDGlcNAc(1→6)α,βDGal.

1,2;3,4-Di-O-isopropylidene-6-O-[2-deoxy-2-trifluoroacetamido-4-O-(β-D-galactopyranosyl)-β-D-glucopyranosyl]-α-D-galactopyranose (3)

A solution of compound **1** (30 mg, 0.051 mmol) and *S*-ethyl trifluorothioacetate (13) (90 mg, 0.634 mmol) in methanol (2 mL) was kept at room temperature for 2 days. The oil obtained after solvent removal was applied to a silica gel column and eluted with methanol. The white solid obtained after solvent removal of the first fraction was filtered through a Sephadex LH-20 column in ethanol–water (1:1). Solvent removal and freeze-drying of the main fraction gave a white solid (20 mg, 0.029 mmol, 57%); ^1H nmr δ: 5.66 (d, 1H, H-1, $J_{1,2}$ = 5.0 Hz), 4.73 (d, 1H, H-1′, $J_{1',2'}$ = 7.6 Hz), 4.55 (dd, 1H, H-2, $J_{2,3}$ = 2.0 Hz), 4.50 (d, 1H, H-1″, $J_{1'',2''}$ = 7.6 Hz), 4.41 (dd, 1H, H-4), 1.60, 1.50, 1.42 (3s, 12H, OOC(CH$_3$)$_2$), 4.08–3.54 (m, 16H, remaining protons).

Methyl 3,6-di-O-acetyl-2-azido-2-deoxy-4-O-(tetra-O-acetyl-β-D-galactopyranosyl)-β-D-glucopyranoside (5)

A solution of 3,6-di-*O*-acetyl-2-azido-2-deoxy-4-*O*-(tetra-*O*-acetyl-β-D-galactopyranosyl)-α-D-glucopyranosyl bromide (**4**) (6) (1.0 g, 1.46 mmol), mp 154–155°C, $[\alpha]_D^{23}$ +86.2° (*c* 1.0, chloroform) in dry nitromethane (4 mL) was added dropwise to a stirred mixture of methanol (15 mL), silver carbonate (1.80 g, 6.54 mmol), and Drierite (2.0 g) cooled to −15°C. After stirring at −15°C for 24 h, the solids were removed and the filtrate was worked up in the usual manner. The oily product was applied to a column of silica gel and the chromatogram was developed with ethyl acetate – hexane (3:2). The main fraction left an oil which, on addition of diethyl ether, precipitated a solid (602 mg, 0.95 mmol, 65%), mp 75–77°C; $[\alpha]_D^{23}$ +1.40° (*c* 1.0, chloroform); ^1H nmr ($CDCl_3$) δ: 5.36 (bd, 1H, H-4, $J_{3,4}$ = 2.8 Hz), 5.10 (dd, 1H, H-2′, $J_{1',2'}$ = 7.5 Hz, $J_{2',3'}$ = 10.0 Hz), 5.00 (dd, 1H, H-3, $J_{2,3}$ = 9.5 Hz, $J_{3,4}$ = 8.9 Hz), 4.95 (dd, 1H, H-3′, $J_{3',4'}$ = 3.2 Hz), 4.49 (dd, 1H, H-6a, $J_{5,6a}$ = 1.6 Hz, $J_{6a,6b}$ = 11.0 Hz), 4.45 (d, 1H, H-1′), 4.27 (d, 1H, H-1). 4.21–4.05 (m, 3H, H-6′a, H-6′b, and H-6b overlapping), 3.88 (bt, 1H, H-5′), 3.72 (dd, 1H, H-4, $J_{4,5}$ = 8.9 Hz), 3.57 (s, 3H, OCH$_3$, signal for H-5 underneath the OCH$_3$signal), 3.38 (dd, 1H, H-2), 2.21–1.98 (6s, 18H, OCOCH$_3$).

Methyl 2-azido-2-deoxy-4-O-(β-D-galactopyranosyl)-β-D-glucopyranoside (6)

The acetate (**5**) (500 mg, 0.78 mmol) was dissolved in 0.02 *N*

sodium methoxide – methanol (10 mL) and left at room temperature for 1 h. The solution was neutralized with IR-resin 120(H^+). Evaporation left a colorless solid (285 mg, 0.75 mmol, 96%), mp 227.5–229.5°C; $[\alpha]_D^{24}$ 0° (*c* 0.3, water); ^{1}H nmr (D_2O) δ: 4.50 (d, 1H, H-1′, $J_{1',2'}$ = 8.0 Hz), 4.46 (d, 1H, H-1, $J_{1,2}$ = 8.0 Hz), 4.00 (dd, 1H, H-6a, $J_{5,6a}$ = 2.2 Hz, $J_{6a,6b}$ = 12.0 Hz), 3.94 (bd, 1H, H-4′, $J_{3',4'}$ = 3.0 Hz), 3.61 (s, 3H, OCH_3), 3.55 (dd, 1H, H-2′, $J_{2',3'}$ = 9.5 Hz), 3.35 (dd, 1H, H-2, $J_{2,3}$ = 9.0 Hz), 3.86–3.45 (m, 8H, remaining protons).

*Methyl 2-formamido-2-deoxy-4-*O*-(β-*D*-galactopyranosyl)-β-*D*-glucopyranoside (7)*

A suspension of the azido compound (**6**) (40 mg, 0.11 mmol) in methanol (12 mL) was hydrogenated at atmospheric pressure and room temperature for 4 h using 5% palladium on charcoal (40 mg). The catalyst was removed and the combined filtrates were concentrated to about 5 mL and cooled to 0°C. Formyl acetate (14) (2 mL) was added. Solvent removal left a white solid which was applied to a column of Sephadex LH-20. Elution with ethanol–water (1:1) produced a main fraction as a white solid (32 mg, 0.083 mmol, 75%); ^{1}H nmr (D_2O) δ: 8.23 (s, 0.7H, *Z* formyl proton (15)), 8.02 (s, 0.3H, *E* formyl proton (15)), 4.56 (d, 0.7H, *Z* H-1, $J_{1,2}$ = 7.5 Hz), 4.53 (d, 0.3H, *E* H-1, $J_{1,2}$ = 7.5 Hz), 4.51 (d, 1H, H-1′, $J_{1',2'}$ = 7.5 Hz). The remainder of the signals were in general agreement with expectation and required a high state of purity. However, a very slight trace of a signal for an acetyl group was present.

*Methyl 2-pivalamido-2-deoxy-4-*O*-(β-*D*-galactopyranosyl)-β-*D*-glucopyranoside (8)*

The azido compound (**6**) (20 mg, 0.055 mmol) was hydrogenated in methanol as was described above for the preparation of compound **7** and the solution (1 mL) was added dropwise to a solution of dicyclohexylcarbodiimide (150 mg) and pivalic acid (50 mg) in methanol (9 mL) cooled to 0°C. After stirring at room temperature overnight, the precipitate was removed and the filtrate was evaporated to dryness. The residue was extracted with ethanol–water (1:1, 1.5 mL) and the extract was applied to a column of Sephadex LH-20 which was eluted with ethanol–water (1:1). The main fraction provided a colorless solid (17 mg, 0.038 mmol, 70%); ^{1}H nmr (D_2O) δ: 4.53 (m, 1H, H-1, $J_{1,2}$ = 8.0 Hz), 4.49 (d, 1H, H-1′, $J_{1',2'}$ = 7.5 Hz). The remainder of the spectrum to higher field was essentially the same as that for the *N*-acetyl and *N*-formyl compounds (**14** and **7**) except for the signal for the pivaloyl group at 1.20 ppm (s, 9H).

*Alkyl 3,6-di-*O*-acetyl-4-*O*-(tetra-*O*-acetyl-β-*D*-galactopyranosyl)-2-deoxy-2-phthalimido-β-*D*-glucopyranosides (9–13)*

3,6-Di-*O*-acetyl-4-*O*-(tetra-*O*-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-α,β-D-glucopyranosyl bromide (7) (mp 104–111°C; $[\alpha]_D^{25}$ +35.7° (*c* 1.0, chloroform), 0.293 g, 0.37 mmol) in dry nitromethane (2 mL) was added to a solution of the dry alcohol (1 mL), *sym*-collidine (50 μL), and silver triflate (0.114 g, 0.44 mmol) in dry nitromethane (5 mL) cooled to −15°C. The mixture was stirred at −15°C for 1 h. The reaction mixture was diluted with chloroform (10 mL) and the solid was removed by filtration. The filtrate was washed with saturated sodium thiosulfate solution (10 mL), cold water (10 mL), and saturated sodium bicarbonate solution (3 × 10 mL). The solvent removal after drying with sodium sulfate left a white solid. In each case the yields were in the range 70–80% after recrystallization from ethyl acetate – hexane. The ^{1}H nmr spectra were in general accord with expectation.

Methyl glycoside (9): mp 227.5–229.5°C; $[\alpha]_D^{24}$ + 19.8° (*c* 0.4, chloroform); ^{1}H nmr δ: 5.75 (dd, 1H H-3, $J_{2,3}$ = 10.5 Hz, $J_{3,4}$ = 8.0 Hz), 5.28 (d, 1H, H-1, $J_{1,2}$ = 8.0 Hz), 4.52 (d, 1H, H-1′, $J_{1',2'}$ = 8.0 Hz). *Anal.* calcd. for $C_{33}H_{39}O_{18}N$: C 53.74, H 5.33, N 1.90; found: C 53.23, H 5.34, N 1.94.

Ethyl glycoside (10): mp 249–250°C; $[\alpha]_D^{24}$ + 11.4° (*c* 0.4, chloroform); ^{1}H nmr δ: 5.74 (dd, 1H, H-3, $J_{2,3}$ = 10.5 Hz, $J_{3,4}$ = 8.0 Hz), 5.36 (dd, 1H, H-1, $J_{1,2}$ = 8.0 Hz), 4.52 (d, 1H, H-1′, $J_{1',2'}$ = 8.0 Hz). *Anal.* calcd. for $C_{34}H_{41}O_{18}N$: C 54.33, H 5.30, N 1.95; found: C 54.14, H 5.58, N 1.83.

n-Propyl glycoside (11): mp 227–229°C; $[\alpha]_D$ +13.5° (*c* 0.4, chloroform); ^{1}H nmr δ: 5.73 (dd, 1H, H-3, $J_{2,3}$ = 10.5 Hz, $J_{3,4}$ = 8.0 Hz), 5.32 (d, 1H, H-1, $J_{1,2}$ = 8.0 Hz), 4.52 (d, 1H, H-1, $J_{1',2'}$ = 8.0 Hz). *Anal.* calcd. for $C_{35}H_{43}O_{18}N$: C 54.90, H 5.66, N 1.83; found: C 55.02, H 5.65, N 1.85.

Isopropyl glycoside (12): mp 255.5–258.5°C; $[\alpha]_D^{24}$ +3.6° (*c* 0.4, chloroform); ^{1}H nmr δ: 5.72 (dd, 1H, H-3, $J_{2,3}$ = 10.5 Hz, $J_{3,4}$ = 8.0 Hz), 5.42 (d, 1H, H-1, $J_{1,2}$ = 8.0 Hz), 4.52 (d, 1H, H-1′, $J_{1',2'}$ = 8.0 Hz). *Anal.* calcd. for $C_{35}H_{43}O_{18}N$: C 54.90, H 5.66, N 1.83; found: C 54.56, H 5.65, N 1.81.

Isobutyl glycoside (13): mp 199–203°C; $[\alpha]_D^{24}$ +15.0° (*c* 0.4, chloroform); ^{1}H nmr δ: 5.75 (dd, 1H, H-3, $J_{2,3}$ = 10.5 Hz, $J_{3,4}$ = 8.0 Hz), 5.32 (d, 1H, H-1, $J_{1,2}$ = 8.0 Hz), 4.52 (d, 1H, H-1′, $J_{1',2'}$ = 8.0 Hz). *Anal.* calcd. for $C_{36}H_{45}O_{18}N$: C 55.46, H 5.82, N 1.80; found: C 56.19, H 5.91, N 1.83.

*Alkyl 2-acetamido-2-deoxy-4-*O*-(β-*D*-galactopyranosyl)-β-*D*-glucopyranosides (14–18)*

Compounds **9** to **13** were deacetylated using 0.025 *M* sodium methoxide in methanol. In each case, the solution was acidified with Amberlite IR-120(H^+) and taken to dryness. The residue was dissolved in pyridine and the solution kept at 115°C for 10 h prior to being taken to dryness. This residue was then treated with hydrazine in ethanol and the product *N*-acetylated in the usual manner. The ^{1}H nmr spectra were in general agreement with expectation and the assignments of the signals for the anomeric hydrogens were by spin-decoupling experiments.

Methyl glycoside (14): mp 283–285.5°C; $[\alpha]_D^{24}$ −26.7° (*c* 0.25, water); ^{1}H nmr δ: 4.52 (2d, 2H, H-1, H-1′ overlapping, *J* = 8.0 Hz and 8.0 Hz).

Ethyl glycoside (15): mp 274–275°C; $[\alpha]_D^{24}$ −24.0° (*c* 0.9, water); ^{1}H nmr δ: 4.59 (d, 1H, H-1, $J_{1,2}$ = 8.0 Hz), 4.50 (d, 1H, H-1′, $J_{1',2'}$ = 8.0 Hz).

Propyl glycoside (16): mp 276.5–278°C; $[\alpha]_D^{24}$ −20.7° (*c* 0.35, water); ^{1}H nmr δ: 4.55 (d, 1H, H-1, $J_{1,2}$ = 8.0 Hz), 4.50 (d, 1H, $J_{1',2'}$ = 8.0 Hz).

Isopropyl glycoside (17): mp 264–266°C; $[\alpha]_D^{24}$ −16.7° (*c* 0.25, water); ^{1}H nmr δ: 4.68 (d, 1H, H-1, $J_{1,2}$ = 8.0 Hz), 4.54 (d, 1H, H-1′, $J_{1',2'}$ = 8.0 Hz).

Isobutyl glycoside (18): mp 282.5–284.5°C; $[\alpha]_D^{24}$ −23.5° (*c* 0.25, water); ^{1}H nmr δ: 4.58 (d, 1H, H-1, $J_{1,2}$ = 8.0 Hz), 4.52 (d, 1H, H-1′, $J_{1,2}$ = 8.0 Hz).

*Benzyl 4-*O*-(β-*D*-galactopyranosyl)-2-deoxy-2-phthalimido-β-*D*-glucopyranoside (19)*

Benzyl 3,6-di-*O*-acetyl-4-*O*-(tetra-*O*-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-β-glucopyranoside (7) (0.5 g, 0.62 mmol) was treated with 0.2 *N* sodium methoxide in methanol (150 mL) for 5 min at room temperature. The solution was then neutralized with Amberlite IR-120(H^+), the resin immediately removed, and the filtrate taken to dryness. The residue (0.39 g) was dissolved in dry pyridine (10 mL) for heating at 110°C for 10 h. Solvent removal left a crystalline residue (0.28 g, 82%), mp 254–257°C, $[\alpha]_D$ −44.8° (*c* 0.17, methanol), which appeared homogeneous (tlc) and which was used directly for the preparation of **20**.

*Benzyl 4-*O*-(4,6-*O*-benzylidene-β-*D*-galactopyranosyl)-2-deoxy-2-phthalimido-β-*D*-glucopyranoside (20)*

Compound **19** (0.80 g, 1.42 mmol), α,α-dimethoxytoluene (0.43 g, 2.84 mmol), and *p*-toluenesulfonic acid monohydrate (11 mg) in dry acetonitrile (15 mL) were stirred at room temperature for 7 h. After neutralization with triethylamine, the solvent was removed to leave an oil which was applied to a column of silica gel and eluted with ethyl acetate – methanol (9:1). Solvent removal of the main fraction left a solid (0.78 g) which was redissolved in methanol (5 mL). Diethyl ether was added to turbidity and on storage crystals were deposited (0.54 g, 0.83 mmol, 58%); mp 206–207°C; $[\alpha]_D^{24}$ −72.4° (*c* 1.1, chloroform); ^{1}H nmr (CD_3OD) δ: 7.81 (s, 4H, phthalimido), 7.61–7.25 (m, 5H, benzylidene aromatic), 7.10 (s, 5H, benzyl aromatic), 5.60 (s, 1H, benzylidene methine), 5.20 (d, 1H, H-1); ^{13}C nmr

For personal use only.

δ: 105.5 (C-1′), 101.5 (benzylidene methine), 98.6, 82.0, 77.3, 76.9, 73.8, 71.9, 80.0, 70.3, 69.5, 67.8 (C-6′), 61.7 (C-6), 57.9. *Anal.* calcd. for $C_{34}H_{35}O_{12}N$: C 62.86, H 5.43, N 2.16; found: C 62.22, H 5.28, N 2.14.

*Benzyl 3,6-di-*O*-acetyl-4-*O*-(2,3-di-*O*-acetyl-4-6-*O*-benzylidene-*β*-*D*-galactopyranosyl)-2-deoxy-2-phthalimido-*β*-*D*-glucopyranoside (21)*

Compound **20** (0.62 g, 0.96 mmol) was dissolved in acetic anhydride – pyridine (1:2) and heated at 80°C for 3 h. Solvent removal left a yellowish foam which was decolorized by passing through a short column of silica gel and eluted with ethyl acetate. Removal of the solvent gave a solid which was recrystallized from ethanol. The yield of this pure product was 81%, mp 210–212°C. The ^{1}H nmr spectrum was consistent with the structural assignment. *Anal.* calcd. for $C_{42}H_{43}O_{16}N$: C 61.69, H 5.30, N 1.71; found: C 61.35, H 5.32, N 1.24.

*Benzyl 3,6-di-*O*-acetyl-4-*O*-(2,3,4-tri-*O*-acetyl-6-deoxy-6-iodo-α-*D*-galactopyranosyl)-2-deoxy-2-phthalimido-α-*D*-glucopyranoside (24)*

The benzylidene compound (**21**) (0.47 g, 0.58 mmol) was treated with 80% aqueous acetic acid at 80°C for 3 h. Solvent removal left a foam which was applied to a silica gel column and eluted with ethyl acetate – hexane (4:1). Solvent removal of the main fraction left a solid, in 82% yield, with an ^{1}H nmr spectrum that was consistent with the structural assignment for the desired diol (**22**).

Methanesulfonyl chloride (60 mg, 0.52 mmol) was added in two batches (15-min interval) to a solution of the diol (**22**) (0.3 g, 0.41 mmol) in dry pyridine (2 mL) cooled to −20°C. The reaction mixture was kept at −20°C for 12 h. A few drops of water were added and the solution was allowed to warm to room temperature. Solvent removal left an oil which was applied to a silica gel column and eluted with ethyl acetate – hexane (4:1). The main fraction contained an oil (**23**) (0.18 g) which was treated with potassium iodide (0.5 g) in *N,N*-dimethylformamide (2 mL) at 80°C for 72 h. The reaction mixture was diluted with chloroform (10 mL) and washed with cold water (3 × 10 mL) before drying over sodium sulfate. The residue, after solvent removal, was applied to a column of silica gel and the chromatogram was developed with ethyl acetate – hexane (3:2). The main fraction contained an amorphous solid (0.12 g, 0.13 mmol, 32%) which appeared pure (tlc); ^{1}H nmr δ: 7.83–7.69 (m, 4H, phthalimido), 7.12 (s, 5H, benzyl aromatic), 5.80 (dd, 1H, H-3, $J_{2,3}$ = 10.5 Hz, $J_{3,4}$ = 8.2 Hz), 5.55 (dd, 1H, H-4′, $J_{3',4'}$ = 3.4 Hz, $J_{4',5'}$ = 1.0 Hz), 5.36 (d, 1H, H-1, $J_{1,2}$ = 8.5 Hz), 5.11 (dd, 1H, H-2′, $J_{1',2'}$ = 7.5 Hz, $J_{2',3'}$ = 10.5 Hz), 4.97 (dd, 1H, H-3′), 4.82 (d, 1H, benzyl CH_AH_B, $J_{A,B}$ = 12.0 Hz), 4.58 (dd, 1H, H-6a, $J_{6a,5}$ = 2.0 Hz), 4.55 (d, 1H, H-1′), 4.53 (d, 1H, benzyl-CH_AH_B), 4.28 (d, 1H, H-2), 4.17 (dd, 1H, H-6b, $J_{6b,5}$ = 4.5 Hz), 3.94 (dd, 1H, H-4, $J_{4,5}$ = 10.0 Hz), 3.86 (m, 1H, H-5), 3.76 (m, 1H, H-5′), 3.10 (m, 2H, H-6′a and b), 2.16–1.91 (5s, 15H, 5 $OCOCH_3$). *Anal.* calcd. for $C_{37}H_{41}O_{16}NI$: I 14.42; found: I 14.53.

*Benzyl 3,6-di-*O*-acetyl-4-*O*-(2,3,4-tri-*O*-acetyl-6-deoxy-*β*-*D*-galactopyranosyl)-2-deoxy-2-phthalimido-*β*-*D*-glucopyranoside (25)*

A mixture of the iodo compound (**24**) (0.11 g, 0.12 mmol), tri-*n*-butyl tin hydride (0.14 g, 0.48 mmol), and 2,2′-azobisisobutyronitrile (5 mg) in toluene was heated at 55°C for 20 h. Solvent removal left an oil which was applied to a column of silica gel and the chromatogram was developed with ethyl acetate – hexane (1:1). Removal of solvent from the second fraction gave an oil (48 mg, 0.05 mmol, 50%); ^{1}H nmr δ: 7.86–7.70 (m, 4H, phthalimido), 7.16 (s, 5H, benzyl aromatic), 5.76 (dd, 1H, H-3, $J_{2,3}$ = 10.5 Hz, $J_{3,4}$ = 7.0 Hz), 5.41 (d, 1H, H-1, $J_{1,2}$ = 7.2 Hz), 5.22 (dd, 1H, H-4′, $J_{3',4'}$ = 3.5 Hz, $J_{4',5'}$ = 1.0 Hz), 5.14 (dd, 1H, H-2′, $J_{1',2'}$ = 7.5 Hz, $J_{2',3'}$ = 10.0 Hz), 4.98 (dd, 1H, H-3′), 4.84 (d, 1H, benzyl CH_AH_B, J_{AB} = 12.0 Hz), 4.58 (dd, 1H, H-6a, $J_{6a,5}$ = 1.5 Hz), 4.56 (d, 1H, benzyl CH_AH_B), 4.55 (d, 1H, H-1′), 4.26 (dd, 1H, H-2), 4.17 (dd, 1H, H-6b, $J_{6b,5}$ = 3.5 Hz), 3.88 (dd, 1H, H-4), 3.80 (dd, 1H, H-5), 3.74 (dd, 1H, H-5′, $J_{5',(C'6)H3}$ = 7.0 Hz), 2.15–1.89 (5s, 15H, 5 $OCOCH_3$), 1.26 (d, 3H, (C6′)H3).

*1,2;3,4-Di-*O*-isopropylidene-6-*O*-[3,6-di-*O*-acetyl-4-*O*-(2,3,4-tri-*O*-acetyl-6-deoxy-*β*-*D*-galactopyranosyl)-2-deoxy-2-phthalimido-*β*-*D*-glucopyranosyl]-α-*D*-galactopyranose (27)*

3,6-Di-*O*-4-*O*-(2,3,4-tri-*O*-acetyl-6-deoxy-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-β-D-glucopyranosyl bromide (**26**) (27 mg, 0.037 mmol) was prepared from **25** by the same procedure as was described (7) for the preparation of the corresponding derivative of lactosamine as the glycosyl chloride, except that *N,N*-dimethylbromoforminium bromide (11) was used as the halogenating reagent. The bromide (**26**) was condensed with 1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose in the same manner as was previously described (1) for the preparation of the acetylated form of **2**. The yield was 18 mg (54%) of an oil after chromatography; ^{1}H nmr δ: 7.92–7.68 (m, 4H, phthalimido), 5.81 (dd, 1H, H-3′, $J_{2',3'}$ = 10.5 Hz, $J_{3',4'}$ = 8.0 Hz), 5.46 (d, 1H, H-1′, $J_{1',2'}$ = 8.5 Hz), 5.20 (dd, 1H, H-4″, $J_{3'',4''}$ = 3.5 Hz, $J_{4'',5''}$ = 1.0 Hz), 5.13 (d, 1H, H-1, $J_{1,2}$ = 5.2 Hz), 5.09 (dd, 1H, H-2″, $J_{1'',2''}$ = 7.5 Hz, $J_{2'',3''}$ = 10.5 Hz), 4.96 (dd, 1H, H-3″), 4.53 (dd, 1H, H-6′a), 4.51 (d, 1H, H-1″), 4.40 (dd, 1H, H-3, $J_{2,3}$ = 2.5 Hz, $J_{3,4}$ = 8.0 Hz), 4.22 (dd, 1H, H-2′), 4.15 (dd, 1H, H-6′b), 4.11 (dd, 1H, H-2), 4.00 (dd, 1H, H-4, $J_{4,5}$ = 1.5 Hz), 3.88 (dd, 1H, H-4′), 3.83 (m, 1H, H-5′), 3.74 (m, 1H, H-5″), 3.66 (m, 1H, H-5), 2.16–1.90 (5s, 15H, acetyl methyl), 1.40, 1.22, 1.03, 1.02 (4s, 12H, 2 $OCO(CH_3)_2$), 1.16 (d, 3H, (C6″)H_3, $J_{5'',(C6'')H3}$ = 7.0 Hz).

*6-*O*-[2-Acetamido-2-deoxy-4-*O*-(6-deoxy-*β*-*D*-galactopyranosyl)-*β*-*D*-glucopyranosyl]-*D*-galactopyranose (28)*

Hydrazinolysis of **27** and then *N*-acetylation was carried out by procedures as described for the preparation of compound **1**. Removal of isopropylidene groups by acid hydrolysis, following the procedures described for the preparation of compound **4**, afforded a white solid (4 mg) which was purified by chromatography on a column of Sephadex LH-20; ^{1}H nmr δ: 5.28 (d, 0.35H, H-1α, $J_{1\alpha,2\alpha}$ = 3.5 Hz), 4.63 (d, 0.65H, H-1α, $J_{1\alpha,2\alpha}$ = 8.0 Hz), 4.58 (d, 1H, H-1′, $J_{1',2'}$ = 7.8 Hz), 4.46 (d, 1H, H-1″, $J_{1'',2''}$ = 7.5 Hz), 2.08 (s, 3H, $NCOCH_3$), 1.27 (d, 3H, ($C_{6''}$)$H_{3'}$, $J_{(C6'')H3',5''}$ = 7.0 Hz).

*Crude 3,6-di-*O*-acetyl-2-azido-2-deoxy-4-*O*-(tetra-*O*-acetyl-*β*-*D*-glucopyranosyl)-α,β-*D*-glucopyranosyl nitrate (29)*

Hexa-*O*-acetyl-cellobial (16) (mp 129.5–133°C; $[\alpha]_D^{25}$ −24.5° (*c* 1.1, chlroform)) (45 g, 1.08 mol) in acetonitrile (315 mL) was added to a mixture of sodium azide (8.0 g, 0.124 mol) and ceric ammonium nitrate (135 g, 0.3 mol) cooled to −15°C (6). The resulting suspension was vigorously stirred with cooling for 8 h. The solid was removed by filtration and washed with toluene (700 mL) and the combined filtrate and washings were poured on ice (~500 g). The organic layer was separated and washed with cold water (3 × 500 mL) before drying over sodium sulfate. Solvent removal by evaporation *in vacuo* at 45°C left a solid foam (45 g).

*3,6-Di-*O*-acetyl-2-azido-2-deoxy-4-*O*-(tetra-*O*-acetyl-*β*-*D*-glucopyranosyl)-α-*D*-glucopyranosyl bromide (30)*

N,N-dimethylbromoforminium bromide (13.3 g, 0.061 mol) was added to a solution of the crude product **29** (40 g) in dichloromethane (12) (60 mL). The mixture was stirred at room temperature for 3 h to result in a clear red solution before lithium bromide (50 g, 0.57 mol) was added (12). The suspension was stirred for 7 h. The mixture was then diluted with dichloromethane (60 mL) and the supernatant was decanted onto ice (500 g). The organic layer was separated and washed with saturated sodium bicarbonate solution (4 × 200 mL) and water (200 mL) before drying with anhydrous sodium sulfate. Solvent removal by evaporation left a foam which was redissolved in the minimum amount of ethyl acetate. On cooling, the solution deposited a solid (15.6 g, 0.0228 mol, 32% from hexa-*O*-acetyl-cellobial), mp 136.5–138°C. Recrystallization from ethyl acetate and n-hexane provided the analytical sample, mp 140–141°C; $[\alpha]_D^{24}$ 79.7° (*c* 1.3, chloroform); FTIR ($CHCl_3$Cast) max: 2114 (N_3); ^{1}H nmr δ: 6.35 (d, 1H, H-1, $J_{1,2}$ = 3.8 Hz), 5.45 (dd, 1H, H-3, $J_{2,3}$ = 10.1 Hz, $J_{3,4}$ = 8.4

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

Hz), 5.14 (dd, 1H, H-3', $J_{2',3'}$ = 9.0 Hz, $J_{3',4'}$ = 9.0 Hz), 5.06 (dd, 1H, H-4', $J_{4',5'}$ = 9.0 Hz), 4.91 (dd, 1H, H-2', $J_{1',2'}$ = 7.8 Hz), 4.51 (d, 1H, H-1'), 4.49 (dd, 1H, H-6a), 4.38 (dd, 1H, H-6'a, $J_{6'a,6'b}$ = 12.5 Hz), $J_{6'a,5'}$ = 4.5 Hz), 4.20 (m, 1H, H-5), 4.15 (dd, 1H, H-6b, $J_{6b,5}$ = 4.0 Hz), 4.03 (dd, 1H, H-6'b, $J_{6'b,5'}$ = 2.5 Hz), 3.81 (dd, 1H, H-4, $J_{4,5}$ = 9.0 Hz), 3.66 (dd and m, 2H, H-2 and H-5' overlapping), 2.10–1.94 (6s, 17H, 6 $OCOCH_3$). *Anal.* calcd. for $C_{24}H_{32}O_{15}N_3Br$: C 42.24, H 4.73, N 6.16, Br 11.76; found: C 41.93, H 4.64, N 6.01, Br 11.89.

*Benzyl 3,6-di-*O*-acetyl-2-azido-2-deoxy-4-*O*-(tetra-*O*-acetyl-*β*-D-glucopyranosyl)-*β*-D-glucopyranoside (31)*

A solution of the azidobromide (**30**) (9.75 g, 14.3 mmol) in nitromethane (20 mL) was added in small portions to a stirred mixture of benzyl alcohol (6 mL), silver carbonate (15 g, 54.5 mmol), and Drierite (15 g), which was cooled to −25°C. After stirring at −25°C for 2 h, the solids were removed by filtration and washed with dichloromethane (20 mL). Solvent removal left a syrup which was applied to a column of silica gel and the chromatogram was developed with ethyl acetate – hexane (5:6). Solvent removal of the second fraction gave an oil which crystallized on addition of diethyl ether (6.68 g, 9.4 mmol, 66%), mp 155–158°C; $[\alpha]_D^{24}$ −16.4° (*c* 2.0, chloroform); ^{1}H nmr ($CDCl_3$) δ: 7.32 (s, 5H, benzyl aromatic protons), 4.88 and 4.66 (2d, 2H, benzyl CH_2), 4.47 (d, 1H, H-1', $J_{1',2'}$ = 8.0 Hz), 4.38 (d, 1H, H-1, $J_{1,2}$ = 8.0 Hz), 3.44 (dd, 1H, H-2, $J_{2,3}$ = 10.5 Hz), 2.14–1.96 (4s, 12H, 4 $OCOCH_3$). *Anal.* calcd. for $C_{31}H_{39}O_{16}N_3$: C 52.47, H 5.54, N 5.92; found: C 52.27, H 5.61, N 6.02.

*Benzyl 2-azido-2-deoxy-4-*O*-(β-D-glucopyranosyl)-β-D-glucopyranoside (32)*

Compound **31** (4.0 g, 5.64 mmol) was deacetylated in 0.01 *N* sodium methoxide – methanol (75 mL) and the product isolated in the usual manner. The substance crystallized from methanol (2.37 g, 5.19 mmol, 92%), mp 195–198°C; $[\alpha]_D^{24}$ −7.4° (*c* 0.4, methanol). *Anal.* calcd. for $C_{19}H_{27}O_{10}N_3$: C 49.89, H 5.95, N 9.19; found: C 49.69, H 5.99, N 9.24.

*Benzyl 2-amino-2-deoxy-4-*O*-(β-D-glucopyranosyl)-β-D-glucopyranoside (33)*

A slow stream of hydrogen sulfide was bubbled through an ice-cold solution of the azide (**32**) (2.0 g, 4.38 mmol) in pyridine (25 mL) and triethylamine (15 mL) for 2.5 h. The solution was evaporated to dryness and the residue was extracted with methanol–water (1:1). The extract was filtered through a bed of diatomaceous earth and solvent removal left a dark-colored solid (1.96 g). The solid was taken up in water and clarified by centrifugation. Freeze-drying of the supernatant left a yellowish white solid (1.58 g, 3.67 mmol, 84%); $[\alpha]_D^{25}$ −28.2° (*c* 0.6, water); ^{1}H nmr (D_2O) δ: 7.46 (s, 5H, benzyl aromatic), 4.54–4.50 (2d, 2H, H-1 and H-1' overlapping, *J* = 8.0 Hz and 7.5 Hz), 2.72 (dd, 1H, H-2, $J_{1,2}$ = 8.0 Hz, $J_{2,3}$ = 9.5 Hz).

*Benzyl 3,6-di-*O*-acetyl-4-*O*-(tetra-*O*-acetyl-*β*-D-glucopyranosyl)-2-deoxy-2-phthalimido-*β*-D-glucopyranoside (34)*

Phthalic anhydride (97 mg, 0.65 mmol) was added to a solution of the amine (**33**) (0.489 g, 1.13 mmol) in pyridine (4 mL). The solution was heated to 60°C for 20 min. Triethylamine (0.1 g, 0.99 mmol) and more phthalic anhydride (97 mg, 0.65 mmol) were added and the solution was evaporated to dryness. The residue was taken up in pyridine – acetic anhydride (2:1, 3 mL) and heated at 80°C for 3 h. Solvent removal left a dark solid foam which was applied to a column of silica gel and the chromatogram was developed with ethyl acetate – hexane (1:1). Solvent removal of the main fraction left an oil which was dissolved in diethyl ether for decolorization with charcoal. The resultant solution, on storage in an open flask for 2 days, deposited crystals (0.55 g, 0.69 mmol, 60%), mp 138–140°C; $[\alpha]_D^{24}$ −22.6° (*c* 0.95, chloroform); ^{1}H nmr ($CDCl_3$) δ: 7.80–7.68 (m, 4H, phthalimido), 7.12–7.04 (m, 5H, benzyl aromatic), 5.72 (dd, 1H, H-3, $J_{2,3}$ = 10.0 Hz, $J_{3,4}$ = 8.0 Hz), 5.35 (d, 1H, H-1, $J_{1,2}$ = 8.4 Hz), 5.14 (dd, 1H, H-3', $J_{2',3'}$ = 9.0 Hz, $J_{3',4'}$ = 9.0 Hz), 4.92 (dd, 1H, H-2', $J_{1',2'}$ = 7.6 Hz), 4.81 (d, 1H, benzyl CH_AH_B, J_{AB} = 12.0 Hz), 4.58 (dd, 1H, H-6a), 4.56 (d, 1H, H-1'), 4.51 (d, 1H, benzyl CH_AH_B), 4.33 (dd, 1H, H-6'a, $J_{6'a,6'b}$ = 12.5 Hz, $J_{6'a,5}$ = 5.0 Hz), 4.26 (dd, 1H, H-2), 4.16 (dd, 1H, H-6b, $J_{6a,6b}$ = 12 Hz, $J_{6b,5}$ = 5.0 Hz), 4.02 (dd, 1H, H-6'b, $J_{6'b,5'}$ = 2.0 Hz), 3.87 (dd, 1H, H-4, $J_{4,5}$ = 8.0 Hz), 3.78 (m, 1H, H-5), 3.64 (m, 1H, H-5'). *Anal.* calcd. for $C_{32}H_{37}NO_{18}$: C 57.56, H 5.33, N 1.73; found: C 57.03, H 5.33, N 1.69.

*3,6-Di-*O*-acetyl-4-*O*-(tetra-*O*-acetyl-β-D-glucopyranosyl)-2-deoxy-2-phthalimido-α,β,-glucopyranosyl chloride (36)*

Compound **34** was hydrogenated in ethanol – ethyl acetate (1:1) at 50 psi (1 psi = 6.89 kPa) and room temperature using 5% palladium on charcoal as catalyst for 20 h. The yield of **35** was quantitative; ^{1}H nmr ($CDCl_3$) δ: 7.90–7.70 (m, 4H, phthalimido), 6.00 (dd, 0.2H, H-3α), 5.76 (dd, 0.8H, H-3β), 5.64 (d, 0.8H, H-1β), 5.34 (d, 0.2H, H-1α), 2.21–1.82 (6s, 18H, 6 $OCOCH_3$).

A solution of *N,N*-dimethylchloroforminium chloride (95 mg, 0.74 mmol), the alcohol (**35**) (0.13 g, 0.18 mmol), and *sym*-collidine (0.1 g, 0.82 mmol) in dichloromethane (2 mL) was stirred at room temperature for 1 h. The reaction mixture was diluted with chloroform (10 mL) and washed successively with cold water (10 mL) and saturated sodium bicarbonate solution (3 × 10 mL). Drying with sodium sulfate and solvent removal left a solid (0.122 g, 0.16 mmol, 89%); ^{1}H nmr δ: 7.82–7.66 (m, 4H, phthalimido), 6.48 (dd, 0.2H, H-3α), 6.12 (d, 0.8H, H-1α, $J_{1\alpha,2\alpha}$ = 9.0 Hz), 6.08 (d, 0.2H, H-1α, $J_{1\alpha,2\alpha}$ = 3.6 Hz), 5.66 (dd, 0.8H, H-3β), 2.12–1.82 (6s, 18H, 6 $OCOCH_3$).

*1,2;3,4-Di-*O*-isopropylidene-6-*O*-[3,6-di-*O*-acetyl-4-*O*-(tetra-*O*-acetyl-β-D-glucopyranosyl)-2-deoxy-2-phthalimido-β-D-glucopyranosyl]-α-D-galactopyranose (37)*

The chloride (**36**) (0.1 g, 0.13 mmol) in nitromethane (0.5 mL) was added to a solution of 1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (33 mg, 0.13 mmol), *sym*-collidine (16 mg, 0.13 mmol), and silver triflate (33 mg, 0.13 mmol) in dry nitromethane (1:5 mL) cooled to −20°C. The mixture was stirred for 3 h and then worked up in the usual manner. The yield was 65% after recrystallization from chloroform – diethyl ether, mp 235–237°C; $[\alpha]_D^{23}$ −20.7° (*c* 0.4, chloroform); ^{1}H nmr δ: 7.90–7.66 (m, 4H, phthalimido), 5.78 (dd, 1H, H-3', $J_{2',3'}$ = 10.8 Hz, $J_{3,4}$ = 8.0 Hz), 5.45 (d, 1H, H-1', $J_{1',2'}$ = 9.0 Hz), 5.12 (d, 1H, H-1, $J_{1,2}$ = 5.0 Hz, overlapped), 4.58 (d, 1H, H-1'', $J_{1'',2''}$ = 8.0 Hz, overlapped), 2.17–1.88 (6s, 18H, 6 $OCOCH_3$), 1.40, 1.24, 1.04 (3s, 12H, 2 $OOC(CH_3)_2$). *Anal.* calcd. for $C_{44}H_{55}NO_{23}$: C 54.71, H 5.74, N 1.45; found: C 55.67, H 5.96, N 1.45.

*1,2;3,4-Di-*O*-isopropylidene-6-*O*-[2-acetamido-2-deoxy-4-*O*-(β-D-glucopyranosyl)-β-D-glucopyranosyl]-α-D-galactopyranose (39)*

Hydrazinolysis of **37** to **38** followed by *N*-acetylation as described for the preparation of **1** gave a product which was applied to a column of Sephadex LH-20 and the chromatogram was developed with ethanol–water (1:1). On solvent removal, the main fraction left a white solid (10.6 mg, 0.017 mmol, 71%); ^{1}H nmr δ: 5.64 (d, 1H, H-1, $J_{1,2}$ = 5.0 Hz), 4.55 (m, 3H, H-1', H-1'', H-2 overlapping), 4.40 (dd, 1H, H-4), 2.10 (s, 3H, NHAc methyl), 1.61–1.42 (4s, 12H, 2 $OOC(CH_3)_2$).

*Methyl 3,6-di-*O*-acetyl-4-*O*-(2,3-di-*O*-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-β-D-glucopyranoside (42)*

Deacetylation of **9** as reported for the preparation of **19** provided methyl 4-*O*-(β-D-galactopyranosyl)-2-deoxy-2-phthalimido-β-D-glucopyranoside (**40**) as an amorphous solid in quantitative yield. This product was then converted to the acetylated 4',6'-*O*-benzylidene derivative **41** using the procedure described for the conversion of **19** to **21**. This product was hydrolyzed to the diol **42**, under the conditions used to convert **21** to **22**, and obtained as a syrup, in 48% yield from compound **40**, which appeared pure (tlc and ^{1}H nmr); ^{1}H nmr δ: 7.90–7.75 (m, 4H, phthalimido), 5.35 (d, 1H, H-1, $J_{1,2}$ = 8.0 Hz), 5.34 (dd, 1H, H-2', $J_{1',2'}$ = 8.0 Hz, $J_{2',3'}$ = 10.0 Hz), 4.95 (dd, 1H, H-3', $J_{3',4'}$ = 2.4 Hz), 3.74 (bm, 1H, H-5'), 3.50 (s, 3H, OCH_3), 2.22, 2.16, 2.15, 2.02 (4s, 12H, 4 $OCOCH_3$).

*Methyl 3,6-di-O-acetyl-4-O-[2,3-di-O-acetyl-6-O-(3,4,6-tri-O-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranosyl)-β-D-galactopyranosyl]-2-deoxy-2-phthalimido-β-D-glucopyranoside (**43**)*

3,4,6-Tri-*O*-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranosyl bromide (8) (74 mg, 0.15 mmol) in nitromethane (2 mL) was added to a solution of the diol (**42**) (48 mg, 0.074 mmol), *sym*-collidine (9.0 mg, 0.074 mmol), and silver triflate (19 mg, 0.074 mmol) in dry nitromethane (0.5 mL) cooled to −15°C. The mixture was allowed to warm to room temperature and stirred overnight. The solids were removed by filtration and the solution was diluted with chloroform (5 mL) before washing with sodium thiosulfate solution (5 mL), cold water (5 mL), and sodium bicarbonate solution (2 × 5 mL). Solvent removal, after drying over anhydrous sodium sulfate, left a solid foam which was applied to a column of silica gel and the chromatogram was developed with ethyl acetate – hexane (1:1). Solvent removal of the second fraction left a pure white solid (40 mg, 0.037 mmol, 50%); ^{1}H nmr δ: 7.90–7.70 (m, 8H, phthalimido), 5.82–5.65 (2dd, 2H, H-3 and H-3″), 5.50–5.30 (dd, 2H, H-1 and H-1″), 5.25–3.72 (m, 17H, remaining protons), 3.46 (s, 3H, OCH_3), 2.20, 2.12, 2.10, 1.92, 1.86 (5s, 21H, 7 $OCOCH_3$).

*Methyl 4-O-[6-O-(2-acetamido-2-deoxy-β-D-glucopyranosyl)-β-D-galactopyranosyl]-2-acetamido-2-deoxy-β-D-glucopyranoside (**44**)*

Hydrazinolysis of **43** followed by *N*-acetylation as described for the preparation of **1** provided a solid which was dissolved in water and applied to a Biogel P-2 column. Elution with water–ethanol (9:1) resulted in the isolation of a main fraction which, on evaporation, left a solid (16 mg, 0.027 mmol, 81%); ^{1}H nmr δ: 4.65 (d, 1H, H-1′, $J_{1',2'}$ = 8.0 Hz), 4.50 (2d, 2H, H-1 and H-1″, $J_{1,2} = J_{1'',2''}$ = 7.5 Hz), 3.55 (s, 3H, OCH_3), 2.12, 2.11 (2s, 6H, 2 $NCOCH_3$), 4.05–3.42 (m, 18H); ^{13}C nmr δ: 174.7, 174.6 (2 N*C*OCH_3), 103.2, 102.0, and 101.2 (C-1, C-1′, C-1″), 79.3, 76.0, 74.9, 73.9, 72.7, 72.6, 71.0, 70.1, 68.7, 68.4, 60.09 and 60.2, 57.2 (OCH_3), 55.7, 55.1, 22.5, 22.4. Both the nmr spectra required a high state of purity.

Received November 10, 1983

DONALD W. HUGHES, THOMAS NEILSON, JAN M. CODDINGTON, and RUSSELL A. BELL. Can. J. Chem. **62**, 1214 (1984).

Specific assignment of the non-exchangeable base and ribose anomeric protons is difficult for oligoribonucleotides with a high pyrimidine content. Problems arise from the narrow range of pyrimidine H-6 chemical shifts and the overlap of pyrimidine H-5 resonances with the ribose anomeric proton signals. To solve these problems two multiple pulse methods were used which depend on the scalar coupling between H-6 and H-5. The first method was double-quantum nmr which established the connectivity between specific pyrimidine H-6 and H-5 resonances. A refocussing pulse was added to the end of the double-quantum pulse sequence to improve the identification of several H-6 and H-5 connectivities in a single experiment. The second procedure involved homonuclear decoupled spin echo nmr to remove H-5 signals selectively from the ribose anomeric proton region. These techniques are illustrated by the assignment of the spectra of the oligoribonucleotides UpUpC, UpUpU, GpCpUpC, and UpApGpCpUpU.

DONALD W. HUGHES, THOMAS NEILSON, JAN M. CODDINGTON et RUSSELL A. BELL. Can. J. Chem. **62**, 1214 (1984).

Pour les oligoribonucléotides ayant une forte teneur en pyrimidine, il est difficile de faire des attributions spécifiques pour les protons non échangeables de la base et les protons anomères du ribose. Les problèmes proviennent du domaine étroit des déplacements chimiques du H-6 de la pyrimidine et du recouvrement des résonances des H-5 de la pyrimidine avec les signaux des protons anomères du ribose. Pour solutionner ces problèmes, on a utilisé deux méthodes à pulsation multiple qui dépendent du couplage scalaire entre H-6 et H-5. La première méthode est celle de la rmn à double quantum qui établit la relation entre les résonances spécifiques du H-6 et du H-5 de la pyrimidine. On a ajouté une nouvelle pulsation focalisante à la fin de la séquence de pulsation à double quantum pour améliorer l'identification des différentes fonctions du H-6 et du H-5 dans une expérience unique. La deuxième méthode fait intervenir la rmn à écho de spin avec découplage homonucléaire pour éliminer sélectivement les signaux du H-5 de la région du proton anomère du ribose. On illustre ces techniques par l'identification des spectres des oligoribonucléotides UpUpC, UpUpU, GpCpUpC et UpApGpCpUpU.

Introduction

The ability of nmr spectroscopy to provide information about the solution structure and stability of RNA single strands and double helices depends on the accurate assignment of individual proton resonances. In short oligomers with a heterogeneous base composition, assignment of the non-exchangeable base and ribose anomeric protons at high temperature ($\geq$ 70°C to minimize base stacking and base pairing interactions) can be achieved by a combination of incremental analysis (1, 2) and empirically derived chemical shift parameters (3, 4). As the pyrimidine content of an oligomer increases, the above procedures can become ambiguous when attempting to identify the H-6 and H-5 AX doublets and the anomeric (H-1′) proton resonance of a specific pyrimidine base (Fig. 1). Problems arise from the narrow range of pyrimidine H-6 chemical shifts and the overlap of the H-5 resonance with the ribose H-1′ protons. The situation is further complicated since many of the nmr studies of oligoribonucleotides involve monitoring chemical shift changes as a function of temperature (5, 6), which may result in more severe overlap of pyrimidine resonances. This type of experiment tends to make two-dimensional nmr techniques impractical when the amount of spectrometer time for data acquisition and processing is limited.

In this paper we report on the application of two multiple pulse sequences that can help in analyzing spectra of oligoribonucleotides containing pyrimidine bases. These methods, which depend on the scalar coupling between H-6 and H-5, are double-quantum nmr, which established the connectivity between specific pyrimidine H-6 and H-5 resonances, and homonuclear decoupled spin echo nmr, which removed H-5 signals selectively from the ribose H-1′ region.

The double-quantum nmr experiment uses the DOUBTFUL pulse sequence:

$$90^\circ_x - \tau - 180^\circ_y - \tau - 90^\circ_x - \Delta - 90^\circ_\phi - \mathrm{ACQ}_0$$

developed by Hore *et al.* (7, 8) and is a variation of the INADEQUATE technique (9). Double-quantum coherence is generated by the application of two 90°_x pulses in the $90^\circ_x - \tau - 180^\circ_y - \tau - 90^\circ_x$ portion of the pulse sequence (10–12). The insertion of the 180°_y pulse removes the effects of chemical shift and field inhomogeneity on the magnetization. The coherence is allowed to evolve during the variable delay Δ, after which it is converted into observable transverse magnetization by a 90°_ϕ pulse of variable phase. The 90°_ϕ pulse and receiver undergo 32-step phase cycling to remove any remaining single-quantum coherence (9). A spin echo pulse has been included at the end of the pulse sequence to refocus the AX transitions.

$$90^\circ_x - \tau - 180^\circ_y - \tau - 90^\circ_x - \Delta - 90^\circ_\phi - \tau - 180^\circ_x - \tau - \mathrm{ACQ}_0$$

This modification improves the visualization of the AX connectivities.

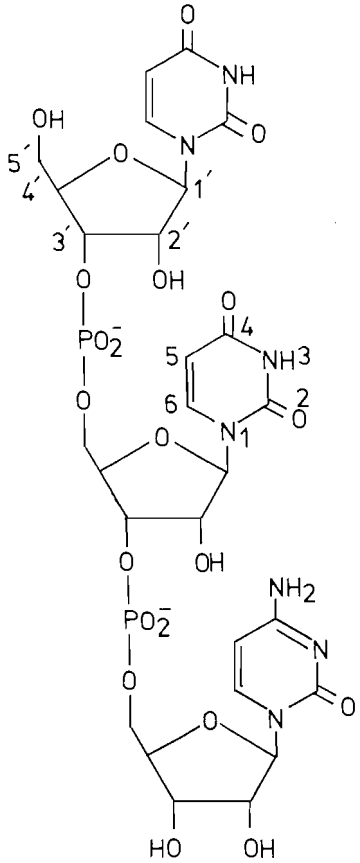

FIG. 1. The structure and numbering of the triribonucleotide diphosphate UpUpC.

The selective nature of the double-quantum experiment results from an amplitude modulation of the double-quantum coherence during the evolution period which is carried over to the observed magnetization. The intensity (I_{DQ}) of the double-quantum coherence for a defined coupling constant J and delay times τ and Δ is given by (7, 10, 12):

$$[1] \quad I_{DQ} = \sin(2\pi J\tau)\cos(\omega_1\Delta)$$

The values of ω_1 represent the relative separation of the sum of the Larmor frequencies for the coupled nuclei ($\Omega_A + \Omega_X$) and the transmitter frequency ω:

$$[2] \quad \omega_1 = (\Omega_A + \Omega_X) - 2\omega$$

When $\omega_1 = 0$ (the transmitter placed at the average frequency of the A and X spins), the double-quantum coherence reaches its optimum intensity at $\tau = 1/4J$ and does not experience any modulation. For non-zero values of ω_1, the observed magnetization displays a modulation whose rate is dependent on ω_1. If a series of spectra is acquired with different values of Δ and added together, only those transitions from coupled spins with a double-quantum frequency identical to the transmitter frequency will be observed, while all other signals will be cancelled. In practice, AX systems with double-quantum frequencies close to the one being excited may produce signals which are out of phase and of reduced intensity. This observation can be used to identify several AX connectivities in a single experiment.

Elimination of the pyrimidine H-5 resonances from the spectrum was achieved by a spin echo method originally proposed by Campbell *et al.* (13) for the measurement of coupling constants. It was later shown by Rabenstein and Nakashima (14) to be an effective procedure for selective removal of unwanted signals. The technique uses the Hahn spin echo (15) pulse sequence

$$90° - \tau - 180° - \tau - \text{echo}$$

with homonuclear decoupling during signal acquisition. Irradiation of the pyrimidine H-6 produces a singlet for H-5 whose intensity is modulated since the spins are coupled during the formation of the echo. This modulation results in the singlet being nulled at $\tau = 1/4J$ (13, 14) and produces a spectrum containing only partially modulated doublets for the anomeric protons. The phase of the H-1′ signals was corrected by displaying the spectrum in the absolute value mode.

The oligoribonucleotides[3] UpUpC, UpUpU, GpCpUpC, and UpApGpCpUpU were examined to demonstrate the use of these procedures in analyzing the spectra of oligomers containing overlapped pyrimidine base and ribose anomeric proton resonances.

Experimental procedures

The oligoribonucleotides used in this study were chemically synthesized by a phosphotriester method (16–18).

The single pulse ^{1}H nmr spectra were recorded at 250.13 MHz on a Bruker WM-250 spectrometer over a sweep width of 1.9 kHz in 32K data points (acquisition time: 8.618 s). Suppression of the HDO resonance was achieved by irradiation for 1.0 s prior to acquisition. Sample temperature was maintained at 70.5 ± 1.0°C by a Bruker BVT-1000 variable temperature unit and the temperature checked by thermocouple measurement. Spectra were accumulated in 80–128 scans and resolution enhanced by Gaussian multiplication.

Double-quantum spectra were acquired in 16K (acquisition time: 4.096 s) using the DOUBTFUL pulse sequence:

$$90°_x - \tau - 180°_y - \tau - 90°_x - \Delta - 90°_\phi - \text{ACQ}_\theta$$

or the modified pulse sequence for refocussing transitions:

$$90°_x - \tau - 180°_y - \tau - 90°_x - \Delta - 90°_\phi - \tau - 180°_x - \tau - \text{ACQ}_\theta$$

The 90° pulse length was 7.0 μs. The value of τ was set to $1/4J$ which for the uridine H-6 and H-5 doublets ($^3J_{5,6} = 8.1$ Hz) was 0.031 s. The variable delay Δ was initially 0.005 s and was incremented 19 times in steps of 0.002 s to a final value of 0.043 s. Each Δ value was accumulated in 32 scans to match the 32-phase cycling sequence of the final $90°_\phi$ detection pulse and the receiver. All the FID's were successively added to a total of 640 scans for each spectrum. The transmitter frequency was positioned either at the double-quantum frequency of the coupled spins (average of the AX-frequencies) or offset a specified distance (see Results and discussion). A delay of 0.5 s was used between pulse sequences.

Spin echo spectra were acquired in 32K using the pulse sequence, $90° - \tau - 180° - \tau - \text{echo}$, with $\tau = 1/4J = 0.031$ s. This value of τ resulted in the uridine H-6 and H-5 doublets appearing 90° out of phase in the absence of spin decoupling. The homonuclear decoupler was gated to provide solvent suppression during the relaxation delay (1.0 s) and to irradiate the pyrimidine H-6 resonances during acquisition. Spectra were accumulated in 200 scans. The free induction decays were processed using Gaussian multiplication for resolution enhancement and the spectra were phased using the absolute value mode.

Samples were lyophilized twice from D_2O and then dissolved in

[3] Abbreviations used: Ribosyl 5′-UpUpC-3′. Oligoribonucleotides are written in the normal 5′→3′ sequence, and the bases are numbered from the 5′ end: $^{\text{UpUpC}}_{1\,2\,3}$.

100% D_2O (Aldrich) which contained 0.01 *M* sodium phosphate buffer (pD 7.0) and 1.0 *M* sodium chloride. The sample concentrations ranged from 0.06–0.015 *M*. Chemical shifts are reported in ppm relative to DSS (sodium 4,4-dimethyl-4-silapentan-1-sulfonate) using *tert*-butyl alchohol-OD (1.231 ppm) as internal reference.

Results and discussion

Double-quantum and spin echo pulse methods were initially used on the triribonucleotides, UpUpC (Fig. 1) and UpUpU. These short oligomers were chosen since their spectra clearly illustrate how the multiple pulse techniques can solve the typical problems encountered when studying pyrimidine-containing sequences. UpUpC was the first sequence to be analyzed because its 70.5°C ^{1}H spectrum (Fig. 2a) was sufficiently resolved to allow a number of preliminary assignments to be made. The cytidine H-6 (7.859 ppm) and H-5 (6.084 ppm) doublets were readily distinguished from the corresponding uridine resonances (Table 1) by both the magnitude of the coupling constant $^3J_{5,6}$ (cytidine: 7.6 Hz; uridine: 8.1 Hz) and the lower field chemical shift usually observed for CH-5 signals relative to UH-5 protons. Centered around the 5.90 ppm region were the two partially overlapped uridine H-5 resonances and the three doublets from the ribose anomeric protons. A complete analysis required the determination of which uridine H-6 and H-5 protons were coupled, resolving and assigning the ribose H-1′ signals, and finally assigning the uridine resonances to a specific nucleotide in the sequence.

When the double-quantum pulse sequence was used to establish the connectivity of several pyrimidine H-6 and H-5 protons, the transmitter was positioned within or near the region of double-quantum frequencies defined by the lowest and highest field pairs of H-6 and H-5 resonances. In the case of UpUpC, the lowest field pair of uridine H-6 (7.837 ppm) and H-5 (5.931 ppm) protons were assumed to be coupled and the transmitter was placed at their double-quantum frequency. The spectrum shown in Fig. 2b resulted from the application of the DOUBTFUL pulse sequence without a refocussing pulse. The specifically excited AX transitions appeared with maximum intensity

and the characteristic up/down pattern (9). This spectrum demonstrates the advantage of the double-quantum experiment over techniques such as spin decoupling, since the coupled protons are clearly shown without the complication of overlapping resonances. The experiment confirmed the assumption of a coupling between the lowest field pair of uridine H-6 and H-5 protons.

With the completion of the analysis of the base protons, it was then possible to examine the ribose anomeric protons. From Fig. 3a it was apparent that the highest field H-1′ doublet was overlapped with a uridine H-5 signal. The H-5 resonances were removed from the spectrum by the application of the homonuclear decoupled spin echo method. The experiment was designed to eliminate signals from pyrimidines which caused the most severe overlap problems. In the case of UpUpC the decoupler was positioned between the U(1) and U(2)H-6 doublets and sufficient decoupler power applied to irradiate both H-6 protons. The resulting spectrum (Fig. 3b) permitted easier identification of the H-1′ doublets. The H-1′ protons were assigned to specific bases by selective irradiation of the H-1′ protons with low levels of decoupling power to remove the five-bond coupling between H-1′ and H-5 ($^5J_{1',5}$ = 0.3–0.5 Hz) (19, 20).

Assigning the proton signals to a particular base in the UpUpC sequence was achieved by considering that the 5′ terminal uridine does not have a 5′ phosphate which would deshield the H-6 and H-5 protons. The resonances at 7.808, 5.867, and 5.861 ppm were therefore assigned to the U(1)H-6, H-5, and H-1′ protons, respectively. The remaining chemical shift assignments are summarized in Table 1. This analysis was in agreement with recently published data on UpUpC, obtained at 500 MHz (21).

The spectrum of UpUpU (Fig. 4a) was difficult to interpret since all the bases were identical and the weak ring current shielding properties of the uridine base (22, 23) resulted in the H-6 resonances being separated by only 0.02–0.01 ppm.

Chemical shifts of the H-5 signals were estimated by locating pairs of transitions which were separated by 8.1 Hz. The remaining transitions were tentatively assigned to H-1′ protons.

Following the procedure discussed in the previous section for the selection of the transmitter frequency, it was found that assuming the two lowest field uridine H-6 doublets at 7.831 and 7.820 ppm were coupled to the overlapped H-5 signals centered near 5.91–5.90 ppm resulted in similar double-quantum frequencies. These pairs of AX systems could be differentiated by either increasing the number of Δ values or exploiting the dependence of signal intensity on the value of ω_1 in the cosine term of eq. [1] (7, 8). Using the latter approach, the transmitter was positioned 3.0 Hz (i.e. ω_1 = 6.0 Hz) to low field of the double-quantum frequency of the H-6 and H-5 protons at 7.831 and 5.911 ppm, respectively. It was expected that the intensities of the three pairs of H-6/H-5 doublets would decrease with increasing separation of the transmitter and double-quantum frequencies. The double-quantum spectrum (Fig. 4b) was recorded with a refocussing pulse at the end of the pulse sequence. The transitions of the lowest field H-6 at 7.831 ppm were of higher intensity than those centered at 7.820 ppm. Although the overlapped H-5 protons near 5.910 ppm were insufficiently resolved to show any intensity differences, the intensity pattern of the H-6 transitions can only arise from the 7.831 ppm H-6 being coupled to the H-5 at 5.911 ppm (Table 1). The presence of the refocussing pulse clearly displayed the connectivity between the uridine doublets at 7.808 and 5.881 ppm, since these transitions were inverted and had lower intensities. These differences in signal phase and intensity illustrated how the position of the transmitter frequency

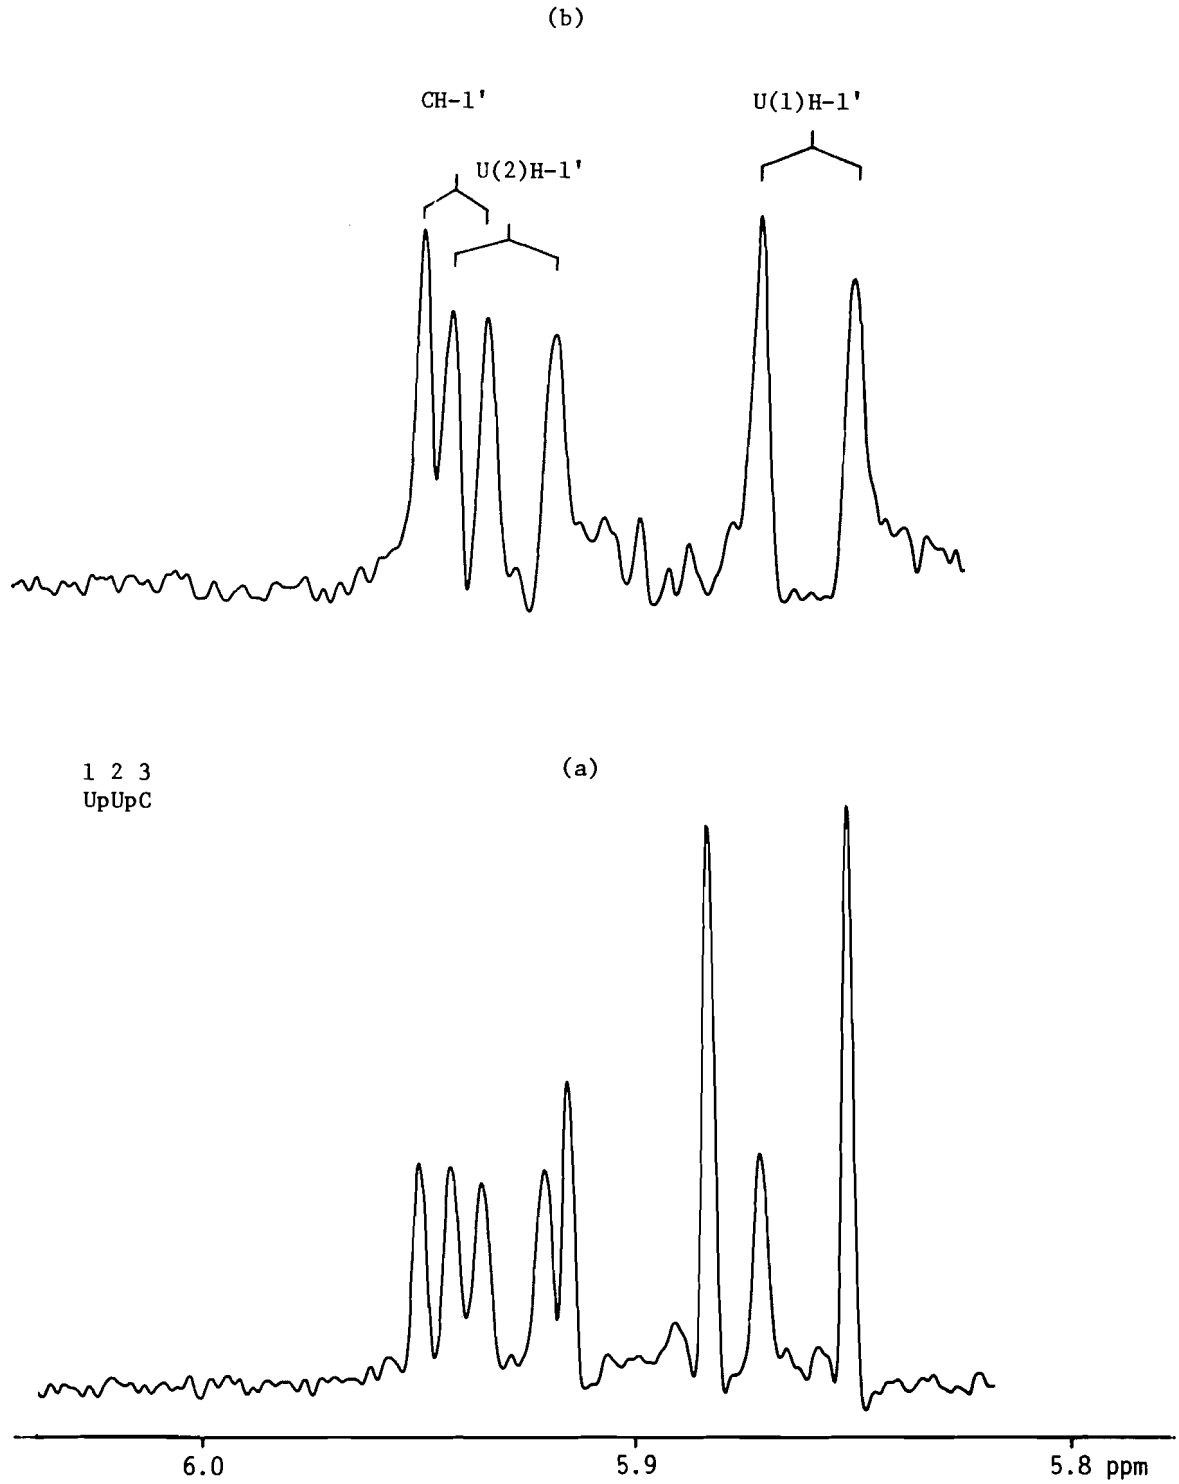

FIG. 3. (a) Expansion of Fig. 2a showing the ribose anomeric and U(2) and U(3)H-5 protons of UpUpC at 70.5°C. (b) Spin echo spectrum of the ribose anomeric protons obtained with irradiation of the U(2) and U(3)H-6 protons. This spectrum was resolution enhanced and phase corrected by displaying the spectrum in the absolute value mode.

can be manipulated to improve the information content of the double-quantum spectrum.

In the region containing the anomeric proton signals of UpUpU only one H-1′ doublet at 5.868 ppm could be identified. Resolution of the H-1′ resonances by the spin echo method took advantage of the overlap of the H-6 doublets since they could all be irradiated simultaneously. From the spin echo spectrum (not shown) it was possible to identify all the H-1′ signals, particularly the doublets at 5.941 and 5.914 ppm which were almost completely obscured by the H-5 signals.

Assignment of the base chemical shifts to specific uridine residues (Table 1) followed the reasoning used for UpUpC with the highest field H-6 and H-5 being assigned to the 5′ terminal position. The H-6 and H-5 chemical shifts for U(1) and U(2) were expected to be similar for both UpUpC and UpUpU, since a pyrimidine at the 3′ terminal should have relatively little

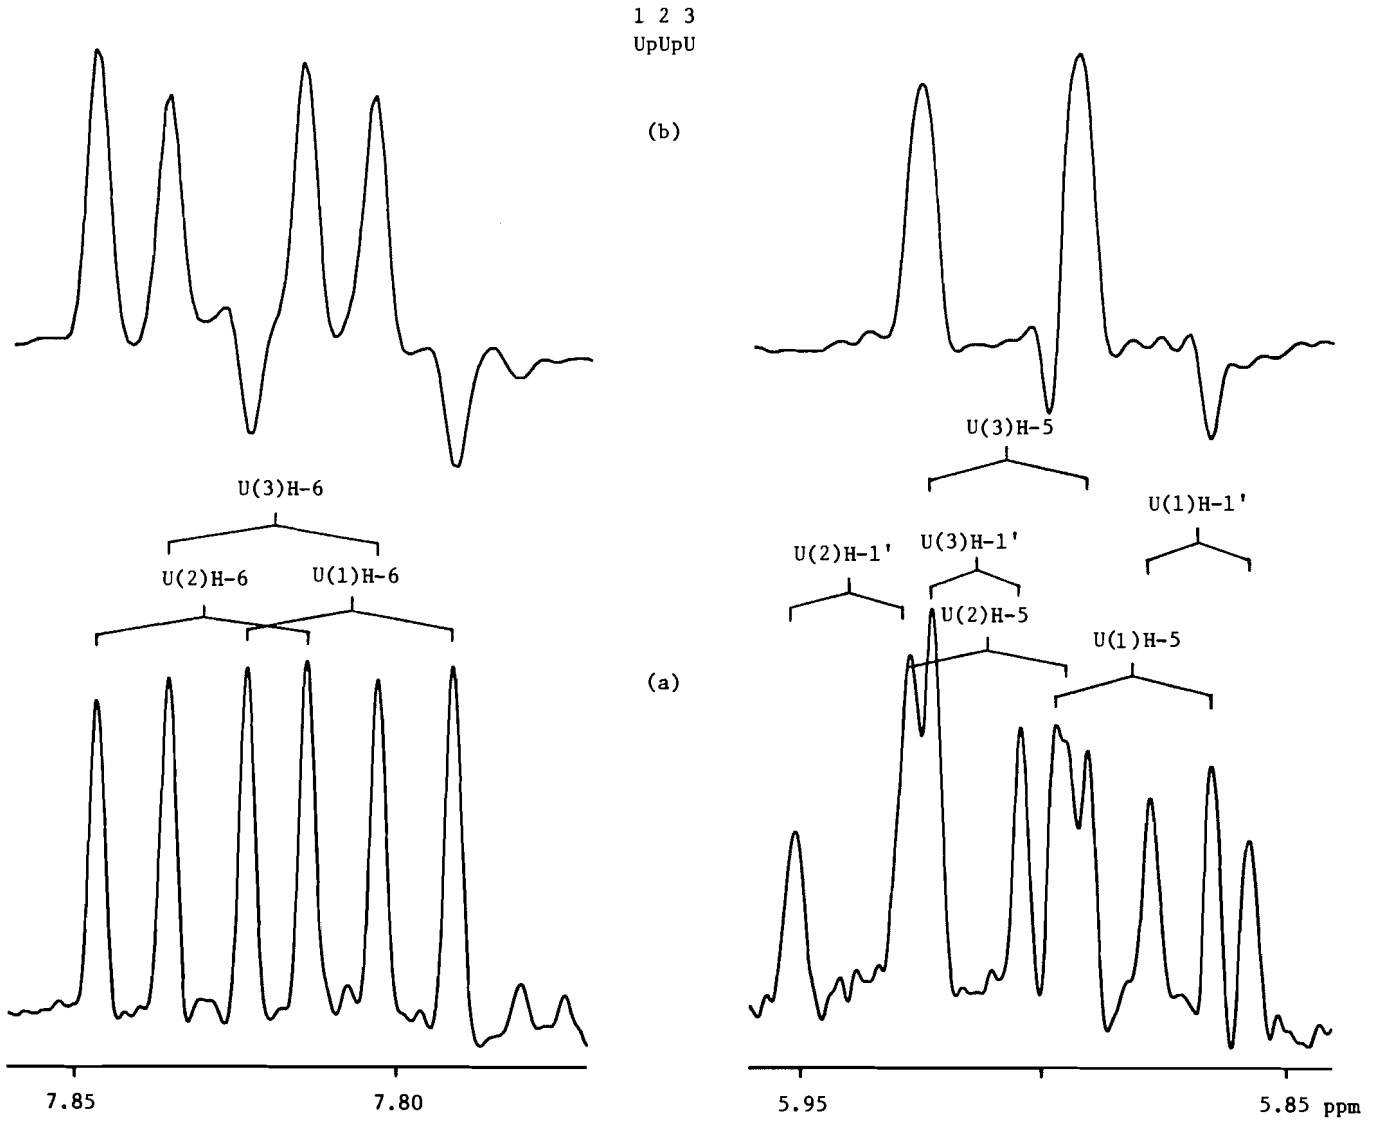

FIG. 4. (a) 250 MHz ^{1}H nmr spectrum of UpUpU at 70.5°C. (b) Resolution enhanced double-quantum spectrum obtained with a refocussing pulse at the end of the DOUBTFUL pulse sequence.

shielding effect on neighbouring bases in a weakly stacked UpUpPy (Py = pyrimidine) sequence at high temperatures (22, 23). The H-1′ resonances were only tentatively assigned by comparison with data from UpUpC and UpU. Definitive connectivities between H-5 and H-1′ protons could not be obtained from low power decoupling experiments because of the overlap of these resonances.

Another example of the use of negative or out-of-phase signals in determining pyrimidine H-6/H-5 connectivity was provided by the spectra of GpCpUpC (Figs. 5a and 5b). This oligomer was first reported in a 90 MHz ^{1}H nmr study of duplex formation by two non-self-complementary tetraribonucleotides (24). The improved resolution at 250 MHz enabled analysis of the H-1′ and H-5 resonances and correction of chemical shift assignments (Table 2). The doublets at 7.77 ppm result from the overlap of the UH-6 and C(2)H-6 resonances. Differentiation of the two cytidine H-6 doublets was based on the shielding effect of the neighbouring guanosine on the C(2) base protons (22, 23). The doublet at 6.024 ppm was assigned to C(4)H-5, while the C(2)H-5 signal was overlapped with H-1′ resonances between 5.87 and 5.94 ppm. The UH-5 doublet was observed at 5.836 ppm.

Confirmation of this analysis was obtained via the double-quantum experiment by setting the transmitter frequency on the double-quantum frequency of the UH-6/H-5 spin system. Using the ω_1 values for each cytidine in the cosine term of eq. [1], it was possible to calculate, by summation of the intensities for all values of Δ used in the experiment, that the C(2)H-6/H-5 doublets would have a significant negative intensity relative to those of C(4). The calculated intensities were verified by the negative C(2)H-5 doublet and the absence of any observable signals for the C(4)H-6 and H-5 at the signal-to-noise level of the spectrum in Fig. 5b. Overlap of the C(2)H-6 transitions with the more intense and positive UH-6 transitions resulted in cancellation of the C(2)H-6 doublet.

The H-1′ resonances were resolved by recording a spin echo spectrum (not shown) with irradiation of the U and C(2)H-6 protons. Removal of the U and C(2)H-5 resonances revealed H-1′ doublets at 5.882 and 5.863 ppm (U and GH-1′, respectively). The H-1′ chemical shifts in Table 2 were assigned by comparison with constituent di- and trinucleotides in the GpCpUpC sequence and use of previously observed shielding

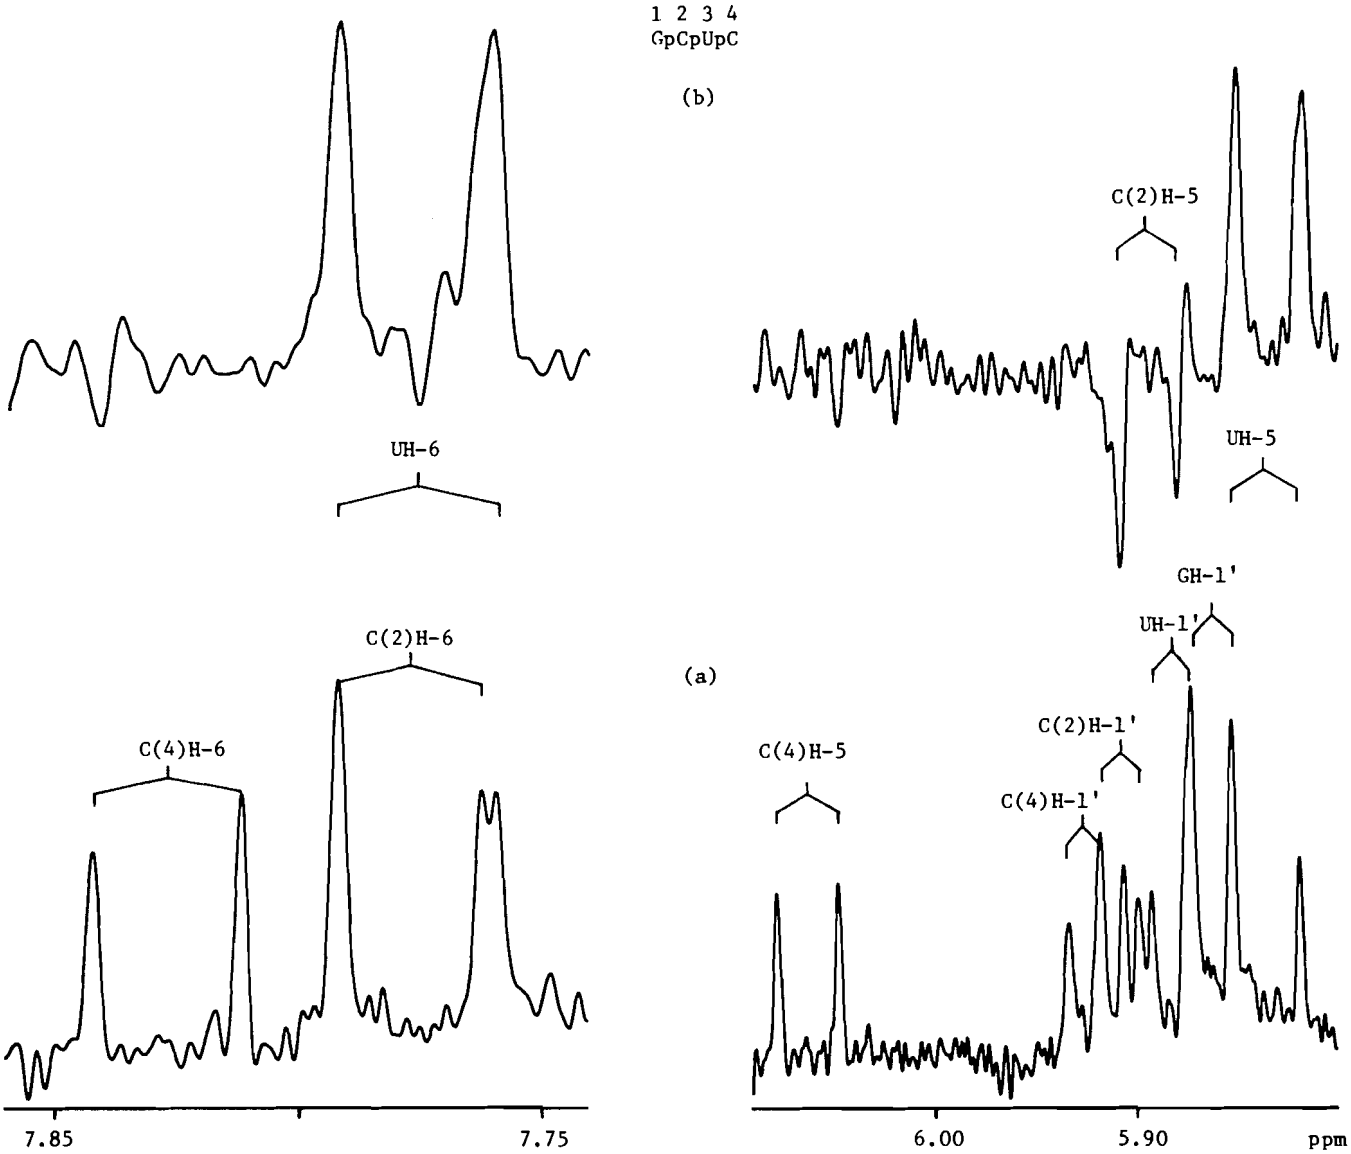

FIG. 5. (a) 250 MHz ^{1}H nmr spectrum of GpCpUpC at 70.5°C. (b) Double-quantum spectrum obtained with the transmitter at the double-quantum frequency of the uridine H-6/H-5 spin system.

trends (22, 23).

The final oligomer examined was the hexaribonucleotide, UpApGpCpUpU. This oligomer is currently being investigated since the bases at positions 2–5 have the potential of forming a self-complementary duplex with opposing unpaired uridines at each end of the duplex. It was therefore necessary to distinguish the H-6 and H-5 resonances of the terminal uridines 1 and 6 from each other and from those of the uridine at position 5. From the 70.5°C spectrum, the purine base protons and adenosine H-1′ could be readily assigned (Table 2). The pyrimidine H-6 resonances (Fig. 6a) were well resolved, which permitted the assignment of the doublet at 7.732 ppm to the CH-6. The region between 5.75 and 5.90 ppm was difficult to interpret since it contained doublets from four pyrimidine H-5 protons and five ribose anomeric protons. Doublets centered at 5.798 and 5.881 ppm were tentatively assigned as UH-5 signals since the peak separation corresponded to the $^3J_{5,6}$ values of 8.1 Hz. The CH-5 and the third UH-5, which had to be located between 5.85 and 5.90 ppm, could not be clearly identified because of overlap with three H-1′ signals.

As a result of the complexity of the H-5 and H-1′ region, two double-quantum spectra were required to assign the four pyrimidine H-6 and H-5 connectivities. In the first experiment the highest field pair of H-6 (7.680 ppm) and H-5 (5.799 ppm) doublets were assumed to arise from U(1) since this assignment agreed with the previous results for 5′ terminal pyrimidines (Table 1). The U(1) protons should also experience the ring current shielding effect of the 3′ adenosine (22, 23). The double-quantum spectrum verified the above assumption; however, no other transitions were observed. The second double-quantum experiment was performed with the transmitter at the double-quantum frequency of the UH-6 and H-5 doublets at 7.773 and 5.834 ppm, respectively. This transmitter position was chosen due to its proximity to the double-quantum frequencies of the cytidine and the third uridine. Signals from these bases could be connected using the relationship of signal intensity and phase with the separation of double-quantum and transmitter frequencies. In Fig. 6b the high intensity and positive signals at 7.773 and 5.834 ppm confirmed the coupling of these uridine protons. The CH-6 at 7.732 ppm and CH-5 at

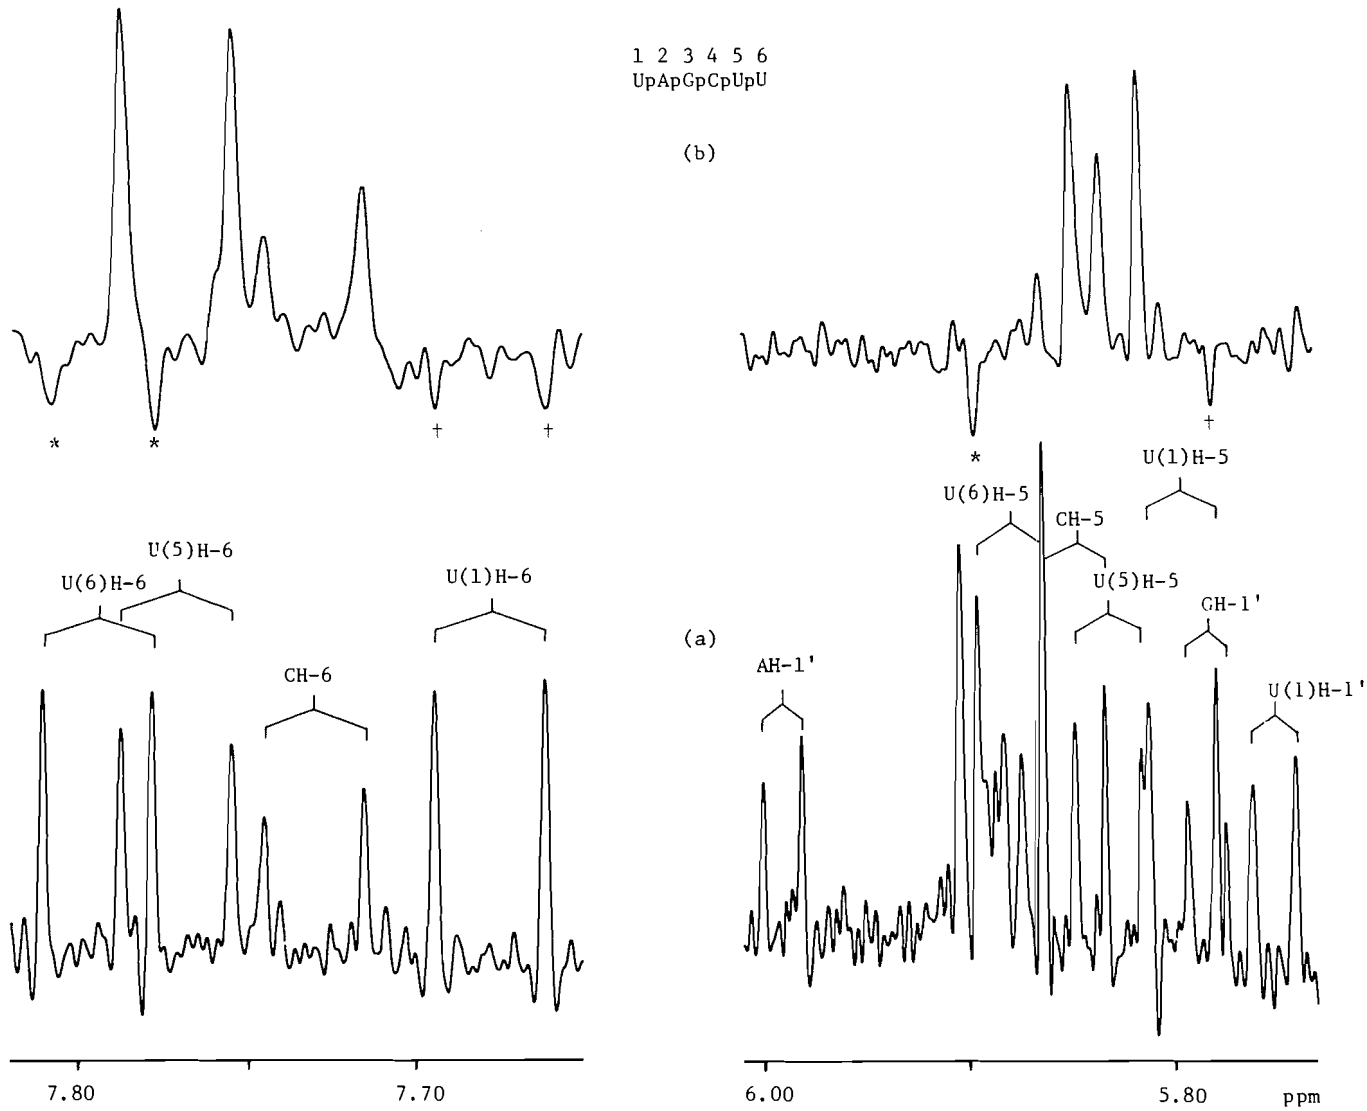

FIG. 6. (a) 250 MHz ^{1}H nmr spectrum (resolution enhanced) of UpApGpCpUpU at 70.5°C. (b) Resolution enhanced double-quantum spectrum showing in-phase transitions for the pyrimidine base protons of U(5) and C and inverted signals for U(6) (*) and U(1) (†).

5.850 ppm were observed as positive signals with lower intensity. The inverted and low intensity transitions marked by the asterisks indicated the connectivity of the UH-6 at 7.797 ppm and the UH-5 at 5.881 ppm. The upfield transition of this UH-5 was cancelled due to overlap with the positive CH-5 transition. Also visible were inverted, low intensity peaks from the U(1)H-6 and H-5 (indicated by the symbol †).

Assignment of the U(5) and U(6) base protons (Table 2) relied on the next-nearest-neighbour shielding effect of G(3) (22, 23) on the chemical shifts of the U(5)H-6 and H-5 protons. These assignments also follow from comparison with data on ApGpCpU (25). With the exception of AH-1′, chemical shift assignments for the remaining ribose anomeric protons were tentative, particularly for the three overlapping anomeric doublets near 5.89 ppm.

Conclusions

The multiple pulse methods presented here offer a superior alternative to spin decoupling when dealing with spectra of RNA sequences containing several pyrimidines. The removal of overlapping signals by the spin echo pulse sequence in combination with homonuclear spin decoupling improved the precision of both the chemical shifts and the coupling constants, $^3J_{1',2'}$, of the ribose anomeric protons. This technique is also applicable to other first order multiplets (14). Double-quantum experiments provided a high degree of specificity not present with spin decoupling when identifying the connectivities of overlapped AX systems. Addition of the refocussing pulse improved the observation of in-phase or inverted signals and permitted the determination of several connectivities in a single experiment. Selectivity in the double-quantum experiment was achieved by using the relationship in eq. [1] between signal intensity and phase and the difference in transmitter and double-quantum frequencies.

M. ADINOLFI, G. BARONE, R. LANZETTA, G. LAONIGRO, L. MANGONI, and M. PARRILLI. Can. J. Chem. **62**, 1223 (1984).

A further component of the glycoside mixture extracted from the bulbs of *Muscari comosum* has been completely characterized by chemical degradative study and spectral investigation. This glycoside, **2**, termed muscaroside B, possesses an α-L-arabinofuranosyl(1→2)-α-L-arabinopyranosyl(1→3)[α-L-rhamnopyranosyl(1→2)]-β-D-glucopyranosyl(1→2)-α-L-arabinopyranosyl(1→6)-β-D-glucopyranosyl chain linked at the 3-position of eucosterol.

M. ADINOLFI, G. BARONE, R. LANZETTA, G. LAONIGRO, L. MANGONI et M. PARRILLI. Can. J. Chem. **62**, 1223 (1984).

Faisant appel à des études spectrales et à des dégradations chimiques, on a complètement caractérisé un nouveau composé du mélange glycosidique extrait des bulbes du *Muscari comosum*. Ce glycoside, **2**, que l'on appelle muscaroside B, possède une chaîne α-L-arabinofuranosyl(1→2)-α-L-arabinopyranosyl(1→3)[α-L-rhamnopyranosyl(1→2)]-β-D-glucopyranosyl-(1→2)-α-L-arabinopyranosyl(1→6)-β-D-glucopyranosyl qui est liée à la position 3 de l'eucostérol.

[Traduit par le journal]

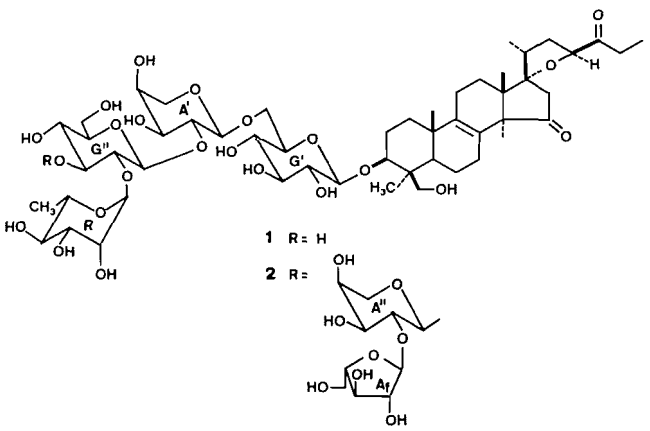
For personal use only.

Continuing our study on glycosides (1–4) of bulbs of *Muscari comosum* Mill. (Liliaceae), from which we extracted muscaroside A, **1**, we report now the structural elucidation of muscaroside B, **2**, which possesses an α-L-arabinofuranosyl-



(1→2)-α-L-arabinopyranosyl(1→3)[α-L-rhamnopyranosyl(1→2)]-β-D-glucopyranosyl(1→2)-α-L-arabinopyranosyl(1→6)-β-D-glucopyranosyl chain as its sugar moiety linked at the 3-carbon of eucosterol.

Muscaroside B was isolated from column (silica gel) chromatography followed by hplc (high performance liquid chromatography) (C-18 reverse phase column) of the crude glycoside mixture extracted from bulbs. It was shown to be homogeneous by spectroscopy (^{1}H nmr and ^{13}C nmr), levorotatory ($[\alpha]_D^{CH_3OH}$ −32°) and melting at 202–206°C upon recrystallization from ethanol. Chemical analysis gave $C_{62}H_{98}O_{31}$, according to the pseudomolecular ion peaks (MNa^+ 1361 *m/e*, MK^+ 1377 *m/e*) in the FAB mass spectrum.

On enzymatic hydrolysis it yielded eucosterol as the aglycone, identified by comparison (tlc, mp, ^{1}H nmr, ms) to an authentic sample, while acid hydrolysis (7% H_2SO_4), which caused decomposition of the aglycone (3), allowed rhamnose, glucose, and arabinose to be identified as the monosaccharide units of the sugar chain by tlc, hplc, and ^{1}H nmr analysis of the water-soluble fraction of the hydrolysate through comparison with the behaviour of equilibrated authentic samples of the monosaccharides. The ^{1}H nmr spectroscopy and hplc also allowed us to establish the 1:2:3 molar ratio of rhamnose, glucose, and arabinose, through integration of the anomeric proton signals in DMSO-d_6 and calculation of the peak areas, respectively. Isolation of the three pure monosaccharides by hplc and determination of their rotation established the D-configuration of glucose and L-configuration of rhamnose and of arabinose. The configuration of arabinose was confirmed by the positive response of a D-galactose dehydrogenase test (5, 6).

Permethylation (DMF/NaI/MeI) of muscaroside B followed by acid hydrolysis (2 *N* HCl/dioxane) yielded, after silica gel column and thin layer chromatography, pure 2,3,4-tri-*O*-methyl-L-rhamnopyranose, 2,3,5-tri-*O*-methyl-L-arabinofuranose, 2,3,4-tri-*O*-methyl-D-glucopyranose, 3,4-di-*O*-methyl-L-arabinopyranose, and 4,6-di-*O*-methyl-D-glucopyranose. All, except the latter, were identified by comparison (tlc, ^{1}H nmr) to authentic samples. The structure of the last product was established by inspection of the ^{1}H nmr spectrum of the triacetate (Ac_2O/pyridine), where the signals of the 1-H (δ 6.28, $J_{1,2}$ = 3.7 Hz), the 2-H (δ 5.01, dd, $J_{1,2}$ = 3.7 Hz, $J_{2,3}$ = 10.0 Hz), and the 3-H (δ 5.43, t, $J_{2,3}$ = 10.0 Hz, $J_{3,4}$ = 10.0 Hz) protons bonded to the positions involved in the interglycosidic linkages were much more clearly distinguished than in the non-acetylated compound.

The above data show that muscaroside B possesses a branched sugar chain, with nodal D-glucopyranose having the branches at its 2- and 3-positions, and with L-rhamnopyranose and L-arabinofuranose as the terminal units. The inner units should be D-glucopyranose, linked at the 6-position, and two L-arabinopyranose units, both linked at the 2-position. The presence of two L-arabinopyranose units was also confirmed when the mixture of 3,4-di-*O*-methyl-L-arabinopyranose and 2,3,4-tri-*O*-methyl-D-glucopyranose was isolated by hplc from the crude permethylation–hydrolysis product and ^{1}H nmr integration established a 2:1 ratio between the anomeric protons of the components.

Having thus established the interglycosidic linkages and the sugar ring size in muscaroside B, the β-configuration at the anomeric centres of both glucose units and the α-configuration at each of the other four were suggested by consideration of the

molecular rotation values in the light of Klyne's rule (7) (Table 1).

The ^{13}C and ^{1}H nmr spectra agreed with all above conclusions and also indicated the attachment position of the sugar chain to the aglycone moiety.

Of the six signals due to the anomeric protons in the ^{1}H nmr spectrum of muscaroside B (see Experimental), the one at δ 6.05 (d, J = 1.5 Hz) was assigned to the anomeric proton of the α-arabinofuranose unit, since it was correlated by heteronuclear selective decoupling to the signal of the A_f-1 carbon at δ 109.99. The signal at δ 5.98 (d, J = 1.8 Hz) was assigned to the anomeric proton of the α-rhamnopyranose unit (8, 9). The signal at δ 4.98 (d, J = 7.7 Hz) may be safely attributed to the anomeric proton of the β-glucopyranose unit linked at the 6-position, because of the coupling constant value (10); in addition, selective decoupling correlated this signal to that of the carbon G′-1 at δ 106.20. Finally, the signal at δ 5.21 (d, J = 7.2 Hz) was attributed to the β-anomeric proton of the G″ unit on the basis of the coupling constant value (10) and the remaining signals at δ 5.29 (d, J = 4.4 Hz) and δ 5.18 (d, J = 6.1 Hz) to the 1-H protons of the two arabinopyranose units. The different $J_{1,2}$ values of the two latter signals may be thought to reflect a difference in the proportion between the two possible conformations $^{4}C_1$ and $^{1}C_4$ (11); the same suggestion was provided by consideration of the ^{13}C-shifts of the carbons of A′ and A″ units (see below). The nmr data do not allow us to draw any conclusion about the configuration of the anomeric centres of the arabinopyranose units. However, application of Klyne's rule safely indicates α-configuration for both centres since the two alternative combinations (obtained by supposing the presence of one or two β-arabinopyranose units in the sugar chain) imply contributions (−186° or +42°, respectively) to the $[M]_D$ of **2** much further from the observed value (−508°).

In the ^{13}C spectrum (Table 2) the signals were assigned by comparison to those of muscaroside A and of appropriate reference compounds. Assignment was facilitated by measuring the chemical shift changes (Table 2, DIS column) in pyridine-d_5 obtained by replacing the hydroxyl protons with deuterium atoms; these allow easy distinction between the carbons which are involved in interglycosidic linkages and those which are not (these latter are shifted to a greater extent). The deuterium-induced isotope shifts (12) have been used only once in the case of a trisaccharide-chain saponin in pyridine for assignment purposes (13).

The glycosylation shift (+8.8) observed for the C-3 of the aglycone moiety revealed (14–17) that the sugar chain is linked at this carbon. Deshielding of G′-6 and of G″-2 and G″-3 and shielding of G′-5 and of G″-4 confirmed the above established interglycosidic linkages involving the glucose units; furthermore, the small value (+1.4) of the glycosylation shift of G″-2 indicated (18) that the nodal glucose unit carries the rhamnopyranose unit directly linked at this position. The unchanged chemical shifts of the carbons of the arabinofuranose and rhamnopyranose units, as compared to those of the corresponding methylglycosides and, for the latter, to the analogue unit in muscaroside A, agreed with their terminal location. In addition, the R-3 and R-5 shift values (δ 72.90 and δ 70.24, respectively) agreed with the α-configuration of the pertinent anomeric centre (the values given for methyl β-rhamnopyranoside are δ 75.3 and δ 73.4, respectively) (8). As for the lines of the two arabinopyranose units, a set of values was tentatively attributed (see Table 2) to the A′ unit, owing to their close similarity to the corresponding values of muscaroside A; with this assumption, the better agreement of the shifts of A″-4 and A″-5, with respect to A′-4 and A′-5, with the values given for methyl α-arabinopyranoside could indicate (11) that the A″ unit possesses the $^{1}C_4$ conformation to a greater extent, according to the suggestion above drawn from consideration of the $J_{1,2}$ values.

The lines of G′-1, R-1, and A_f-1 were correlated to the corresponding anomeric protons by heteronuclear selective decoupling experiments; the J^{1}_{C-H} values of G′-1 and R-1 (159 and 169 Hz, respectively) (19) and the chemical shift of A_f-1 (δ 109.99) (20) agreed with the configuration at the pertinent anomeric centres. Because of the close chemical shifts of the anomeric protons of G″, A′, and A″ units, no clearly interpretable result came from selective decoupling experiments involving these protons and carbons G″-1, A′-1, and A″-1, respectively, whose resonance values therefore remained interchangeable.

As for the sequence of the monosaccharide units in the sugar chain of muscaroside B, a significant Overhauser effect measured for the signal at δ 4.98 of the anomeric proton of the β-D-glucopyranose unit, linked at its 6-position, upon irradiation of the 30-H_3 protons, clearly indicated that this glucose unit is directly attached to the aglycone moiety.

The above data led to only three possible sugar sequences, **3**–**5**, for muscaroside B. Definitive evidence in favour of sequence **3** (≡formula **2**) was obtained by mass spectrometry. As described in detail elsewhere (21), application of FAB technique allowed us to observe a fragmentation pattern in which the consecutive losses of one arabinose, one arabinose, one rhamnose, and one glucose residue were seen. This safely established that one branch of the chain consisted of two, and only two, arabinopyranose units.

Experimental[4]

Melting points were determined with a Kofler block. Rotations were determined on a Perkin–Elmer 141 polarimeter. The hplc was performed with a Varian 5020 instrument using a differential refractometer Waters R 401 as the detector. The tlc was carried out on precoated silica gel layers (0.25 mm, Merck F_{254}). Silica gel 0.05–0.20 (Merck) was used for column chromatography. Sugars and methylated sugars were detected with aniline phthalate or *p*-anisaldehyde, glycoside and aglycone with chromium oxide/sulphuric acid. The ^1H (270 MHz) and ^{13}C nmr (67.88 MHz) spectra were taken on a Fourier transform Bruker instrument WH270 (TMS as internal reference) with an Aspect 2000 computer with 48K memory (32K data). Nuclear Overhauser enhancement effects were obtained in the difference mode as reported in ref. 2. Mass spectra were recorded with a Kratos 902 instrument.

Reference methylated sugars

2,3,4-Tri-*O*-methyl-L-rhamnopyranose, 2,3,4-tri-*O*-methyl-D-glucopyranose, and 3,4-di-*O*-methyl-L-arabinopyranose were prepared as in ref. 4.

2,3,5-Tri-*O*-methyl-L-arabinopyranose was prepared by permethylation (NaH/DMF/MeI) (4) of methyl L-arabinopyranoside (obtained as in ref. 22) followed by acid hydrolysis (1:1 2 *N* HCl/dioxane, 4 h, reflux); ^1H nmr ($CDCl_3$) δ: 5.35 (bs, anomeric proton of α-anomer (23)), 5.31 (d, J = 4.0 Hz, anomeric proton of β-anomer (23)); methoxyl protons appeared at δ 3.48 (3H, s), 3.44 (3H, s), 3.43 (3H, s), 3.42 (6H, s), and 3.40 (3H, s).

Isolation of muscaroside B

Fraction b (ref. 4; 2 g) was three successive times subjected to

semipreparative hplc (Lichrosorb RP-18 (7 μm), 70:30 methanol–water, 5 mL min^{-1}, 75 mg in 1 mL of 70:30 methanol–water), and further purified by recrystallization from ethanol to give muscaroside B, **2** (320 mg); mp 202–206°C; $[\alpha]_D$ −32° (*c* 1, methanol); FAB ms *m/e*: 1361 (MNa^+), 1372 (MK^+). Elemental analysis: C 55.5, H 7.3% ($C_{62}H_{98}O_{31}$ requires C 55.6, H 7.4%). The ^{13}C nmr data are given in Table 2. For the deuterium-induced isotope shift experiment, a sample of **2** (80 mg) was dissolved in pyridine-d_5 (2 mL) and the ^{13}C nmr spectrum was measured (30°C); then the sample was evaporated, dissolved in warm deuterium oxide (1 mL), and freeze-dried; this procedure was repeated three times and then the ^{13}C spectrum was taken (30°C) in pyridine-d_5 (2 mL). The ^1H nmr data, δ: 0.93 and 0.95 (3H, s each, 18-H_3 and 19-H_3), 1.03 (3H, t, $J_{25,26}$ = 7.3 Hz, 26-H_3), 1.05 (3H, d, $J_{20,21}$ = 6.6 Hz, 21-H_3), 1.55 (3H, s, 30-H_3), 1.70 (3H, s, 32-H_3), 1.75 (3H, d, $J_{5,6}$ = 6.1 Hz, R-6-H_3), 2.46 (2H, q, $J_{25,26}$ = 7.3 Hz, 25-H_2), 2.38 and 3.06 (2H, ABq, J_{AB} = 19.0 Hz, 16-H_2), 4.98 (1H, d, $J_{1,2}$ = 7.7 Hz, G′-1-H), 5.18 (1H, d, $J_{1,2}$ = 6.1 Hz, A′-1-H or A″-1-H), 5.21 (1H, d, $J_{1,2}$ = 7.2 Hz, G″-1-H), 5.29 (1H, d, $J_{1,2}$ = 4.4 Hz, A″-1-H or A′-1-H), 5.98 (1H, d, $J_{1,2}$ = 1.8 Hz, R-1-H), 6.05 (1H, d, $J_{1,2}$ = 1.5 Hz, A_f-1-H).

Enzymatic hydrolysis of muscaroside B

Muscaroside B (33 mg) was subjected to enzymatic hydrolysis with digestive juice of *Helix pomatia* by the procedure described in ref. 4. Work-up gave eucosterol (5 mg), identical (mp, tlc, ^1H nmr, and ms) to an authentic sample (3, 24).

Acid hydrolysis of muscaroside B

Acid hydrolysis of muscaroside B, analysis (tlc, hplc, and ^1H nmr) of the resulting monose mixture, separation by hplc of the individual monose components, rotation determination of these latter, and the D-galactose dehydrogenase test for L-arabinose were performed as for muscaroside A (4).

Permethylation of muscaroside B

Muscaroside B (80 mg) was permethylated with MeI/DMF/NaH as described for muscaroside A (4).

Acid hydrolysis of permethylated muscaroside B

Permethylated muscaroside B (80 mg) was hydrolyzed with 1:1 2 *N* HCl/dioxane (10 mL) by refluxing for 6 h. The cooled mixture was neutralized with solid Na_2CO_3 and evaporated. The residue was extracted with chloroform and the chloroform extract was evaporated. The residue (80 mg) was chromatographed on a column of silica gel (12 g). Elution with chloroform containing increasing percentages of ethyl acetate yielded pure 2,3,4-tri-*O*-methyl-L-rhamnopyranose (10 mg), 2,3,5-tri-*O*-methyl-L-arabinofuranose (9 mg), 2,3,4-tri-*O*-methyl-D-glucopyranose (11 mg), 3,4-di-*O*-methyl-L-arabinopyranose (17 mg), and 4,6-di-*O*-methyl-D-glucopyranose (10 mg). All except the latter were identified (tlc, 1:9 methanol–chloroform; ^1H nmr: see above and ref. 4) by comparison with authentic samples.

The 4,6-di-*O*-methyl-D-glucopyranose sample obtained was converted into the triacetate by acetylation with acetic anhydride in dry pyridine (room temperature, 12 h). Usual work-up gave 4,6-di-*O*-methyl-1,2,3-tri-*O*-acetyl-D-glucopyranose (mainly α-anomer); ^1H nmr ($CDCl_3$), δ: 2.00, 2.10 and 2.14 (3H, s each, 3 × CH_3COO—), 3.42 and 3.47 (3H, s each, 2 × CH_3O—), 5.01 (1H, t, $J_{1,2}$ = 3.7 Hz, $J_{2,3}$ = 10.0 Hz, 2-H), 5.43 (1H, t, $J_{2,3}$ = 10.0 Hz, $J_{3,4}$ = 10.0 Hz, 3-H), 6.28 (1H, d, $J_{1,2}$ = 3.7 Hz, 1-H).

The hplc of a sample of the crude permethylation–hydrolysis product (Lichrosorb NH_2 (10 μm) column, 95:5 acetonitrile–water, 5 mL min^{-1}) allowed isolation of the mixture of 3,4-di-*O*-methyl-L-arabinopyranose and 2,3,4-tri-*O*-methyl-D-glucopyranose; a 2:1 ratio between the two components was established by ^1H nmr integration of the anomeric proton signals of the former (δ 4.62 and δ 5.29, α- and β-anomer, respectively) and of the latter (δ 5.32 and δ 4.61, α- and β-anomer, respectively) (4).

Acknowledgments

This investigation was supported by MPI (Ministero della Pubblica Istruzione) and by CNR (Consiglio Nazionale delle Ricerche). The nmr spectra were performed at the Centro di Metodologie Chimico-Fisiche della Università di Napoli.

Page 1747. From a single-crystal structure analysis, the data (X-ray, Raman) given to be characteristic of compound **D** in Fig. 3, p. 1749, have been proven to be those of a new salt: $KInBr_4$ (1). The formulation $K_3In_2Br_9$ was previously proposed from the results of the "wet rest" method, the chemical analysis, and the X-ray powder pattern of the samples.

Furthermore, a synthetic melt $3KBr - 2InBr_3$ had the same powder pattern as the "**D**" compound without any evidence of excess KBr. A new investigation in this area of this very complicated solubility diagram is needed to clear the existence of $K_3In_2Br_9$.

$KInBr_4$, the first compound in which a tetrahedral InX_4^- anion is associated to an alkaline cation, has been obtained by isothermal evaporation (21°C) of a solution containing 80.2 g $InBr_3$ and 2.5 g KBr in 100 g of solution.

Page 594. In our literature search on this system (1) the phase diagrams reported by Perrier and Bellanca (2) and by Eysel (3) escaped our notice. Although there is general agreement between our phase diagram and their diagrams on the major features, these latter authors include a number of unconfirmed solid–solid lines enclosing various solid phase areas which were not detected in our study. It is also to be noted that the phase transition temperatures in the earlier reported diagrams are in agreement with our temperatures for the same features recorded on the cool mode of DTA; otherwise our temperatures are usually higher.

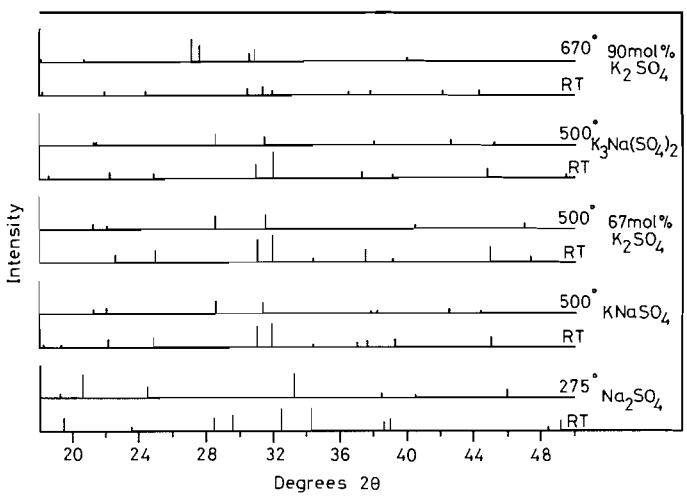

FIG. 1. X-ray diffraction peaks for $Na_2SO_4-K_2SO_4$ system at room temperature and high temperature.

Also reported (1) are X-ray diffraction data for $KNaSO_4$ and $K_3Na(SO_4)_2$ at 25°C and 500°C. Given in Fig. 1 are the redetermined X-ray diffraction pattern for $K_3Na(SO_4)_2$ at 500°C along with X-ray diffraction patterns for additional compositions in the $Na_2SO_4-K_2SO_4$ system. The RT (room-temperature) and high-temperature patterns of $K_3Na(SO_4)_2$ and intermediate compositions resemble very much the patterns of $KNaSO_4$, hence its structure. The earlier high-temperature X-ray diffraction data on $K_3Na(SO_4)_2$ might be explained on the basis that while the sample holder indicated 500°C the $K_3Na(SO_4)_2$ sample was below its transition temperature, thus exhibiting only lattice expansion.

Characterization of a clathrate hydrate of nitrogen trifluoride[1]

D. W. DAVIDSON, S. K. GARG, C. I. RATCLIFFE, J. S. TSE, and S. R. GOUGH
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received November 9, 1983

D. W. DAVIDSON, S. K. GARG, C. I. RATCLIFFE, J. S. TSE, and S. R. GOUGH. Can. J. Chem. **62**, 1229 (1984).

NF_3 is found to form a type I clathrate hydrate with a $Pm3n$ cubic unit cell dimension of 11.91 Å at 110 K and a dissociation pressure of 16.5 atm at 0°C. Dielectric studies below 100 K give, for reorientation of the NF_3 dipole in the structure I cages, an average activation energy of 0.79 kcal mol^{-1}. Well-resolved absorption peaks arising from NF_3 incorporated in small and large cages of the structure II hydrate formed with SF_6 give activation energies of 1.05 and 0.29 kcal mol^{-1}, respectively. ^{19}F nmr lineshapes show in addition the presence of faster reorientation about the NF_3 symmetry axis which is not completely removed even at 1.6 K. The pronounced effect of molecular oxygen impurity on the nmr linewidths at high magnetic fields and very low temperatures is discussed.

D. W. DAVIDSON, S. K. GARG, C. I. RATCLIFFE, J. S. TSE et S. R. GOUGH. Can. J. Chem. **62**, 1229 (1984).

On a trouvé que le NF_3 forme un hydrate de clathrate de type I avec une dimension de maille élémentaire cubique $Pm3n$ de 11,91 Å, à 110 K, et une pression de dissociation de 16,5 atm à 0°C. Les études diélectriques réalisées en-dessous de 100 K sur la réorientation du dipôle NF_3 dans les cages de la structure I, donnent une énergie d'activation moyenne de 0,79 kcal/mol. Les pics d'absorption bien résolus, provenant du NF_3 incorporé dans les petites et les grandes cages de la structure de l'hydrate II formé avec le SF_6, donnent respectivement des énergies d'activation de 1,05 et de 0,29 kcal/mol. La forme des pics en rmn du ^{19}F révèle de plus la présence d'une réorientation plus rapide autour de l'axe de symétrie du NF_3 qui n'est pas complètement éliminée même à 1,6 K. On discute de l'effet prononcé de l'impureté de l'oxygène moléculaire sur la largeur des pics en rmn à haut champ et à très basse température.

[Traduit par le journal]

That nitrogen trifluoride should form a clathrate hydrate is evident from its molecular size and chemical inertness toward water, as was pointed out long ago by von Stackelberg (1). No attempt to form NF_3 hydrate, however, has hitherto been recorded. We report here the identification of a structure I clathrate hydrate of NF_3 and the results of dielectric and ^{19}F nmr studies of reorientation of NF_3 molecules encaged in the structure I lattice as well as in structure II double hydrates formed with tetrahydrofuran, *p*-dioxane, and sulphur hexafluoride.

Experimental methods

NF_3 hydrate samples were prepared by condensing NF_3 (Air Products and Chemicals Inc.) at low temperatures into a pressure vessel containing degassed H_2O or D_2O ice and several stainless steel rods and allowing NF_3 and water to react at the temperatures and (final) pressures given in Table 1. During the reaction period the pressure vessel was rolled so as to subject the solid sample to continuous grinding. Hydrate formation was monitored by the fall in gas pressure, which was normally complete in 24 h.

Tetrahydrofuran (THF), *p*-dioxane (*p*D), and SF_6 individually form hydrates of structure II. Double hydrates of NF_3 with THF and *p*D were prepared by subjecting mixtures which contained 17 mol of D_2O per mole of structure II hydrate-former to the NF_3 pressures shown in Table 1. The SF_6–NF_3 double hydrate was formed from H_2O ice and a gas mixture containing about 44 mol% SF_6. Again reaction was promoted by rolling and grinding.

The NF_3 hydrate dissociation pressure was determined as the constant value to which the pressure rose after each of a series of substantial pressure reductions (2).

X-ray powder diffraction photographs were taken at ~110 K with a flat-plate camera using MoKα radiation and Zr filtering (3).

Sample disks for dielectric study were formed by pressing hydrate powder in a pre-cooled die at 1 kbar pressure. The sample was mounted in a three-terminal cell contained in an Andonian Liquid Helium Cryostat. Measurements were made (4) between 0.1 Hz and 10 MHz at temperatures down to 2 K. The complex permittivities measured were less than the true hydrate permittivities because of the presence of rough surfaces and internal voids related to low sample plasticity at the low temperatures necessary to prevent hydrate decomposition during pressing. The kinetic information given by the frequency and temperature dependence of the complex permittivity is, however, not appreciably affected by these factors.

^{19}F nmr derivative spectra of powder samples were recorded at 56 or 8 MHz with low-level marginal oscillators and 83 Hz amplitude modulation. Normally a number of signal sweeps were accumulated and averaged in a Digital RT11/23 computer programmed for second moment and other calculations. The nmr probe was contained in an Andonian cryostat with the tail-piece positioned between the pole pieces of a Bruker electromagnet. In both the nmr and dielectric studies temperature was controlled and measured by carbon and germanium thermometers below 80 K and by copper–constantan thermocouples at higher temperatures.

The presence of a substantial quantity of molecular oxygen was indicated by the ^{19}F nmr lineshapes observed at very low temperatures. Subsequent gas chromatographic analysis gave 0.71 ± 0.02 mol% O_2 and 0.42 ± 0.02 mol% N_2 as the principal impurities in the NF_3 employed.

Results

Hydrate dissociation pressures

Figure 1 illustrates the sequence of pressure changes following periodic release of NF_3 gas from a pressure vessel containing NF_3 hydrate at 0°C. This method of determining the hydrate dissociation pressure (2) is straightforward but deserves some comment, since it appears that it may be incorrectly applied. Under isothermal conditions the constant pressure reached at 0°C corresponds to the three-phase equilibrium between hydrate, liquid water, and gas. Gas released is made up by decomposition of the necessary amount of hydrate. The small rise of pressure after gas release which occurs at pressures well above the three-phase equilibrium pressure and at pressures too low for hydrate to be present arises from increase in temperature as the gas recovers from the instantaneous cooling produced by pressure reduction.

The dissociation pressure of NF_3 hydrate is 16.5 ± 0.2 atm at 0°C and 3.7 ± 0.2 atm at −40°C. This hydrate is therefore more stable than the hydrates of CH_4 and CF_4 whose dis-

[1]NRCC No. 23098.

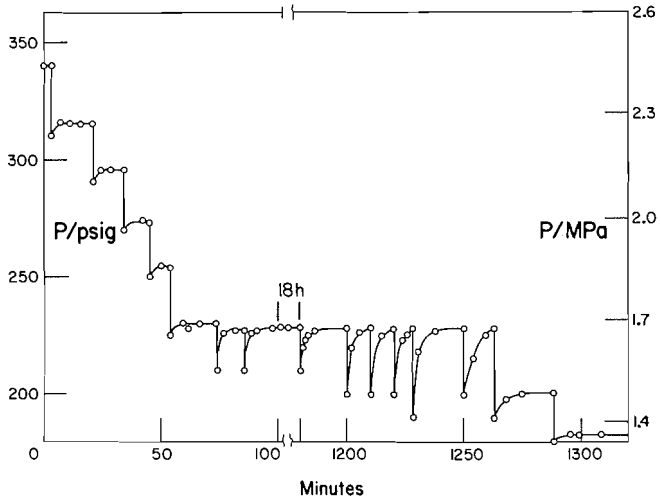

FIG. 1. Pressure changes following pressure reductions over NF_3 hydrate at 0°C.

sociation pressures at 0°C are, respectively, 26.0 (5) and 41.5 atm (6).

Unit cell parameter

The X-ray powder diffraction pattern of the NF_3 hydrate specimen examined was that of a structure I hydrate (space group $Pm3n$), with no lines attributable to ice. Indexing of the 11 most intense lines gave for the unit cell parameter $a = 11.91 \pm 0.02$ Å at 110 K. Values reported by Bertie *et al.* (7–9) for other structure I hydrates at a similar temperature are xenon 11.84 Å, ethylene oxide 11.89 Å, trimethylene oxide 11.95 Å, and cyclopropane 11.98 Å.

Dielectric behaviour

Dielectric dispersion and absorption curves measured below 100 K in NF_3 deuteriohydrate are shown for a number of frequencies in Fig. 2. This low-temperature absorption arises from the relatively weakly hindered reorientation of encaged NF_3 molecules. The absorption is weak because of the small dipole moment of 0.234 D (10) and broad (see Cole–Cole plots of Fig. 3) because of a wide distribution of reorientational relaxation rates. It includes broad, overlapping contributions from NF_3 molecules in both the 14- and 12-hedral cages. In an attempt to resolve these contributions, the low-temperature dielectric behaviour of a number of NF_3-containing structure II double hydrates was examined, with the expectation that NF_3 would almost exclusively occupy only the otherwise empty 12-hedral cages of structure II.

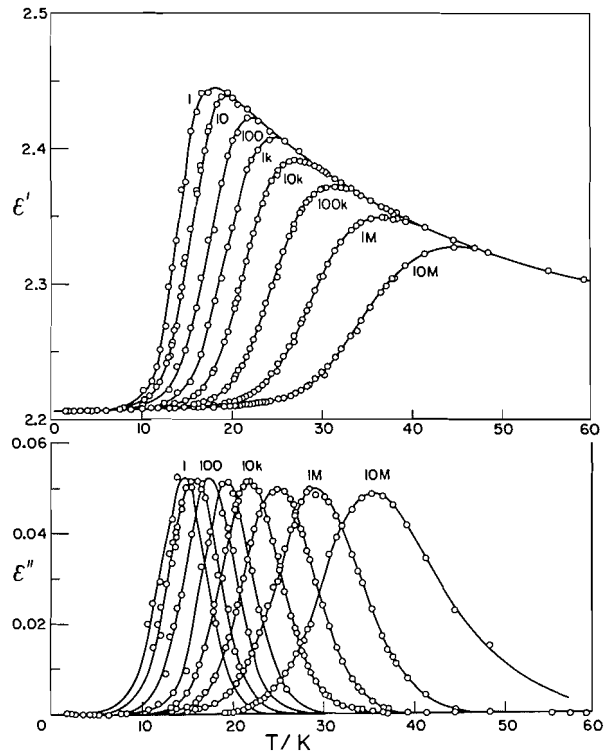

FIG. 2. Low temperature permittivity and loss curves of NF_3–D_2O hydrate. Numbers denote frequencies in Hz.

The absorption seen in THF–NF_3–D_2O hydrate was indistinguishable in its frequency- and temperature-dependence from that shown by THF–H_2O hydrate itself (11); the NF_3 absorption underlay the broad, two-orders-of-magnitude stronger absorption by THF (dipole moment = 1.63 D) for which maximum ϵ'' at 10 kHz occurs at 24 K.

The first-*p*-dioxane double hydrate sample, prepared at high NF_3 pressure (Table 1), proved to contain considerable structure I NF_3 hydrate. The second *p*D–NF_3–D_2O sample was entirely structure II. Its absorption (Fig. 4) apparently consisted of overlapping contributions from *p*D in the 16-hedra and NF_3 in the 12-hedra, together with a distinct region of relatively small absorption below 10 K. As previously reported (12), although the stable chair form of *p*D has no permanent dipole moment, the presence of two large opposed exocentric dipoles in the molecule results in a polarization of the water molecules of the cage which depends on the orientation of the dioxane molecule; the effect is comparable to the presence of a permanent dipole moment of about 0.2 D. Figure 4 shows the

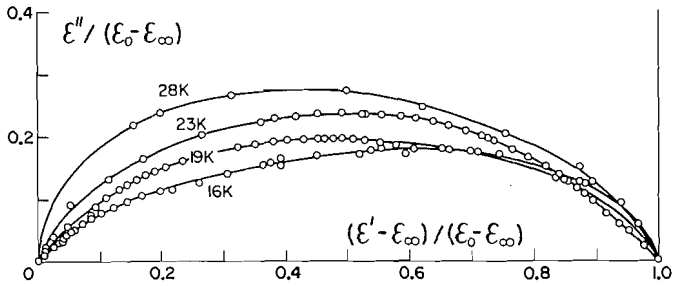

FIG. 3. Normalized Cole–Cole plots of NF_3-D_2O hydrate.

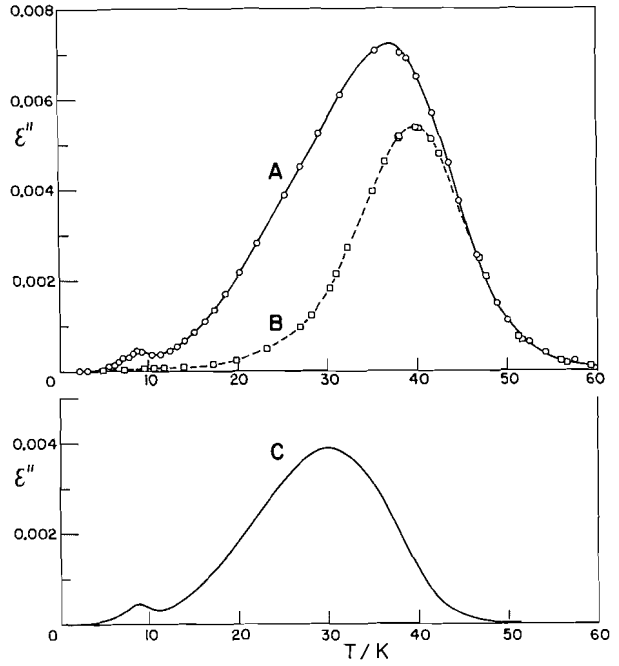

FIG. 4. Dielectric absorption at 10 kHz in *p*-dioxane–NF_3-D_2O hydrate (*A*) and in $pD-H_2O$ hydrate (*B*). Curve *C* is obtained by subtraction of *B* from *A*.

effect of subtracting dielectric absorption previously measured for *p*D hydrate itself (12). Gas chromatographic analysis having shown negligible amounts of impurity in the *p*D employed, the weak absorption below 10 K was assigned to a small population of NF_3 in the 16-hedral cages.

Figure 5 shows the absorption in the double hydrate of SF_6, a molecule which does not give rise to detectable dielectric absorption. Here the two well-resolved absorption regions may be unequivocally assigned to reorientation of NF_3 molecules in the 12- and 16-hedral cages.

Wide-line ^{19}F nmr

The lineshapes of NF_3-D_2O hydrate at a number of temperatures are shown in Fig. 6 and the temperature dependence of the second moment of the linewidth in Fig. 7. The spectra were recorded at 56 MHz (rather than 8 MHz) to take advantage of the greater signal-to-noise ratio realizable at this frequency. The large anisotropy of the magnetic shielding tensor of the fluorine nuclei in NF_3 (13) makes the 56 MHz lineshapes very asymmetric at low temperatures.

The pronounced changes in lineshape which occur below 10 K indicate the presence of a low temperature (i.e. fast) motion which is not dielectrically active in NF_3 hydrate and

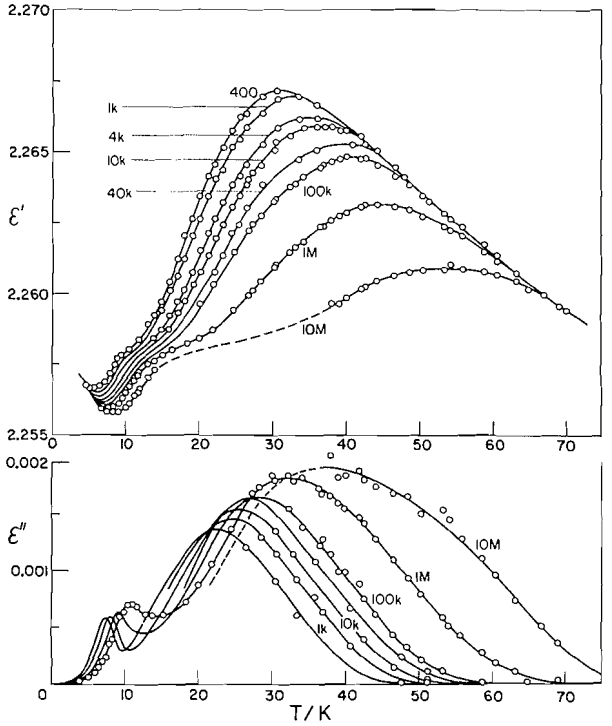

FIG. 5. Permittivity and loss curves of $SF_6-NF_3-H_2O$ hydrate. Many experimental points have been omitted for clarity.

which therefore must arise from reorientation of NF_3 about its symmetry axis. Even at 1.6 K the lineshape (Fig. 6) has a narrow central component which appears to be due to the persistence of three-fold rotation on the part of a small number of NF_3 molecules. The line narrowing which occurs (mainly) between 15 and 30 K correlates well with the dielectric absorption and arises from more general reorientation processes of the NF_3 molecule.

Figures 8 and 9 show low temperature lineshapes of NF_3 encaged in D_2O hydrates of THF (56 MHz) and *p*D (8 MHz). These suggest that there is less persistence at very low temperature of axial rotation of NF_3 molecules in the 12-hedral structure II cages than for molecules primarily in the 14-hedra of structure I.

At 8 MHz the asymmetry of the lineshape is relatively small. The 1.64 K spectrum (Fig. 9*A*) is very nearly that of rigid NF_3 molecules while the 4.26 K spectrum (*B*) includes a substantial contribution from molecules undergoing axial reorientation. Thus the latter may be satisfactorily represented by superposition of the rigid-lattice lineshape calculated (14) from the geometry (15) and shielding tensor (13) of NF_3 with Gaussian broadening (β = 0.8 G) (*C*) and the lineshape calculated (16) for a symmetric three spin-1/2 system rotating about its symmetry axis, with negligible chemical shift anisotropy and β = 0.7 G (*D*). The fields at zero-crossing of the two contributions are slightly shifted with respect to one another.

Discussion

Second moments

Table 2 gives second moments of the ^{19}F linewidth of NF_3 in D_2O hydrates of structures I and II, as calculated from the structures and chemical shielding tensors, for various modes of motion of NF_3 in the rigid hydrate lattice. The shielding tensor σ_{11} = 260, σ_{22} = −60, and σ_3 = −200 ppm with respective

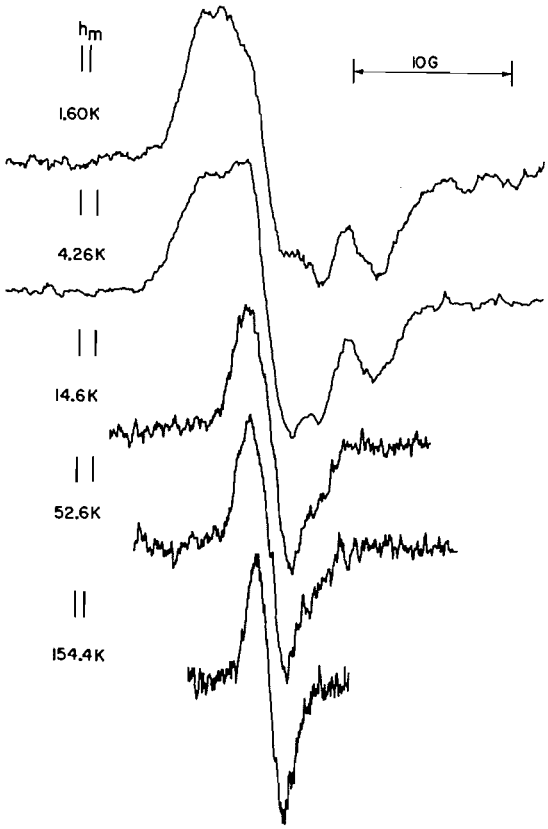

FIG. 6 ^{19}F nmr lineshapes of NF_3-D_2O hydrate at 56 MHz.

components along the NF bond, perpendicular to the plane of symmetry containing NF, and in the plane of symmetry and perpendicular to NF (13), becomes, in the presence of rotation about the three-fold axis, the axially symmetric tensor $\sigma_\parallel = -112$, $\sigma_\perp = 56$ ppm. The tabulated second moments are based on 60% occupancy by NF_3 of the small cages of both structures, 97% occupancy by NF_3 of the large cages of structure I, and 100% occupancy of the large structure II cages by THF or pD. The results are not very sensitive to these assumptions.

There is satisfactory agreement between the calculated rigid-lattice second moments of 56 MHz and those approached at the lowest temperatures of measurement only when the broadening effect of molecular oxygen impurity (17) is taken into account. This effect is treated in the Appendix. However, the second moment of the NF_3-pD-D_2O hydrate at 1.64 K (*cf.* Fig. 9*A*) is 6.9 G^2 at 8 MHz, a frequency low enough that neither oxygen nor chemical shift anisotropy contribute appreciably. The difference between this value and the calculated value of 7.7 G^2 (Table 2) may be largely the result of rotational oscillations of NF_3 (18).

For NF_3 hydrate itself the contribution of O_2 to the second moment at 56 MHz is no more than about 3 G^2 at 1.7 K and above 6 K the fall of second moment (Fig. 7) is mainly the result of increasing rotational mobility of NF_3. The lineshapes show overlap between the contributions of molecules which are still rigid and of molecules undergoing three-fold rotation up to 16 K, and thereafter show overlap between contributions from three-fold rotation and more general reorientational processes. As in other structure I hydrates of guest molecules of less than cubic symmetry (19), reorientation of the guest molecules is not isotropic even at the highest temperature of measurement:

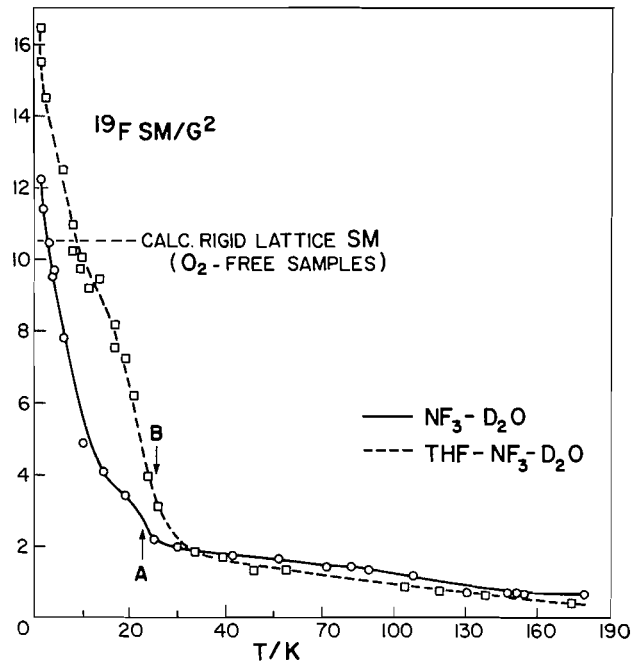

FIG. 7. Second moments of ^{19}F lines of NF_3-D_2O and $THF-NF_3-D_2O$ hydrates at 56 MHz. Temperature scale changes at 50 K. Arrows mark temperatures of maximum 10 kHz dielectric loss in (*A*) NF_3-D_2O and (*B*) $SF_6-NF_3-H_2O$ hydrates.

the second moment at 181 K (0.67 G^2) is more than twice the isotropic value (Table 2). Reorientation takes place between generally inequivalent preferred sites which are anisotropically distributed, especially in the 14-hedral cages. Thus, high-temperature second moments are smaller for NF_3 in the 12-hedra of the THF and pD double D_2O hydrates (~0.47 G^2 at 174 K and 56 MHz and ~0.37 G^2 at 155 K and 8 MHz, respectively).

The reorientational processes

Plots of the frequencies of dielectric measurement versus the reciprocal of the temperature at which maximum dielectric loss occurs are given in Fig. 10. Activation energies E_A obtained from the slopes are shown in Table 3. It is emphasized that these are average values and that NF_3 molecules exhibit a wide distribution of dipolar reorientation rates even within cages of the same size. In the structure I hydrate NF_3 molecules in the 14- and 12-hedra make overlapping contributions to ϵ''. The major contribution to the aggregate activation energy of 0.79 kcal/mol is from molecules in the larger cages which contain perhaps 85% of the NF_3 molecules (see below).

Separate dielectric absorption peaks from the same kind of molecule in different sized cages of a hydrate have hitherto not been observed. The broadness of the absorption arising from molecules within a particular type of cage, particularly within the least spherical 14-hedra, in general precludes such resolution in structure I. However, the case of NF_3 shows that the environments within the structure II 12- and 16-hedral cages are sufficiently different as to give rise to well-separated absorption regions. Since, however, simple type II hydrates are formed by molecules which are too large to fit into 12-hedra, one can expect to observe relaxation of molecules of the same kind in the two kinds of cage only in double hydrates which contain species small enough to occupy the small cages. In such cases the Langmuir constants of the large molecules (e.g.,

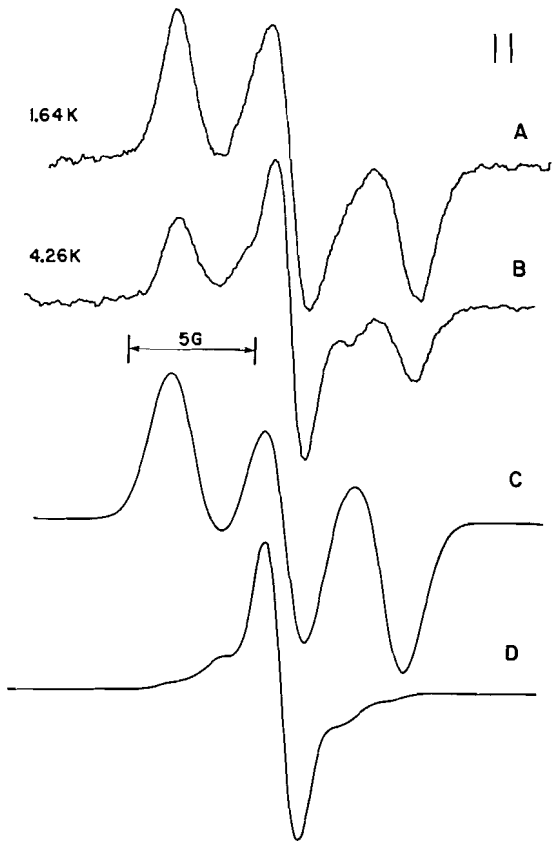

FIG. 9. Low temperature ^{19}F lineshapes of p-dioxane–NF_3–D_2O hydrate at 8 MHz (A, B) and calculated lineshapes for rigid NF_3 molecules (C) and molecules rotating about their three-fold axis (D).

THF, pD, SF_6) for occupancy of the 16-hedra are much larger than for the small molecules (e.g., NF_3). We estimate from the measured permittivities that no more than about 5% of the 16-hedra are occupied by NF_3 under the conditions of preparation of the pD and SF_6 double hydrates.

Figure 10 shows that the reorientation of NF_3 molecules is appreciably slower in the double hydrate of pD than in the double hydrate of SF_6. p-Dioxane is one of the largest molecules (van der Waals diameter 7.2 Å), and SF_6 one of the smallest (5.85 Å), to form a hydrate of structure II. The lattice parameter of pD hydrate (17.28 ± 0.04 Å at 125 K (12)) is consistently larger, on average by 1%, than the comparable values for seven other structure II hydrates (3, 20). It appears that the unit cell of pD hydrate is not uniformly expanded relative to other hydrates but that expansion of the 16-hedral cages to accommodate pD molecules is accompanied by contraction or distortion of other cages so as to make reorientation of NF_3 more difficult.

Reorientation of NF_3 about its symmetry axis is more rapid than reorientation about other axes. In structure I the activation energy for three-fold rotation may be roughly estimated from the temperature $T_{1/2}$ at which the change in second moment due to this rotation has reached its mid-point (21). For $T_{1/2}$ = 7.0

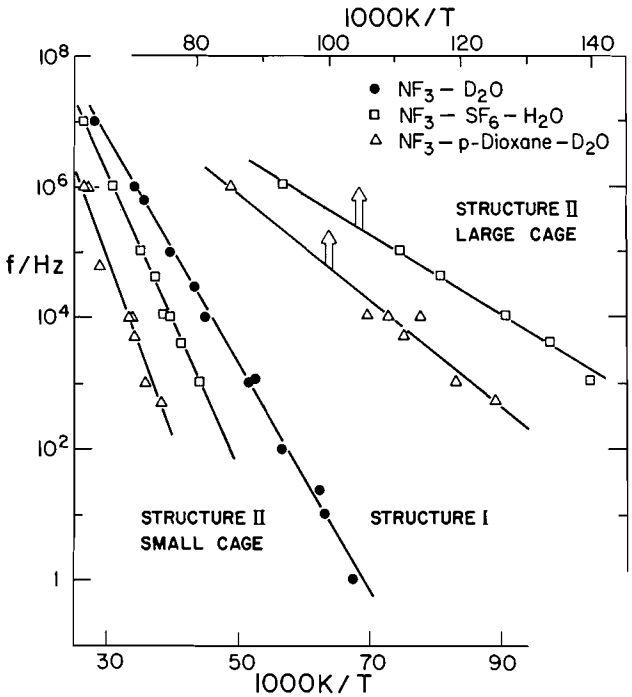

FIG. 10. Arrhenius plots for dielectric absorption by encaged NF_3.

K, one finds an activation energy (~0.23 kcal/mol) about one-third as large as for the dielectrically-active reorientation (Table 3).

Examples of other guest molecules which reorient more rapidly about the symmetry axis than about other axes are known. For the structure II hydrates of CF_3I and cyclobutanone, for example, this is clearly shown by comparison of dielectric relaxation and nmr spin–lattice relaxation times (22). In these cases the moments of inertia are substantially less about the polar symmetry axis than about other axes. For NF_3, however, the moment of inertia is almost twice as great about the symmetry axis as about axes perpendicular to this direction. The N atom of NF_3 appears to be preferentially held to the cage wall by attractive forces to the water molecules. The pyramidal NF_3 molecule best fits the cage contour in this configuration which seems also to be favoured by electrostatic attraction between the NF_3 dipole and the water dipoles.

Cage occupancy

NF_3 hydrate is a structure I hydrate in which the degree of occupancy of the small cages is substantially smaller than of the large cages. The nearly equal ($\theta_S \approx \theta_L$) and nearly complete occupancy of the two kinds of cage by such small molecules as CH_4 and H_2S is not typical of the great majority of the 40 molecules which are known to form structure I hydrates. Although reliable compositions are few (23), the recent studies of Cady (24) show the expected fall of θ_S (measured under hydrate – liquid water – gas equilibrium conditions) with increasing size of the guest molecule. For Xe, SO_2, and CH_3Cl, molecules with maximum van der Waals diameters of 4.60, 5.27, and 5.55 Å, Cady estimates θ_S = 0.65, 0.26, and 0.05, respectively, at 0°C. The low value for Xe has confirmed the results of ^{129}Xe nmr studies (25). There is evidence that CF_4 (diameter 5.35 Å) occupies very few of the small cages (26, 27).

Even though NF_3 hydrate samples in the present study were prepared at higher pressures than correspond to three-phase equilibrium, the consumption of NF_3 (maximum diameter = 5.16 Å) was consistently less than necessary for high cage occupancy. Our results suggest that θ_S is 0.5 to 0.6 for the equilibrium structure I hydrate at 0°C and that this hydrate contains 6.5 to 6.7 water molecules per molecule of NF_3.

Appendix

Effect of oxygen on low-temperature nuclear magnetic resonance lineshapes

It is well known that the solubility of air in clathrate hydrates is extraordinarily large because of the ability of nitrogen and oxygen to occupy the cages (23). This is particularly true of simple structure II hydrates in which the small cages are otherwise unoccupied. The pronounced effects of oxygen on spin–lattice relaxation times and the effect of relatively large concentrations of oxygen on the proton lineshapes and second moments of THF deuteriohydrate have previously been treated (17). The effects of small concentrations of oxygen are qualitatively different, however, and we consider these here in the context of the ^{19}F lineshape of enclathrated NF_3.

The assumption that encaged molecular oxygen makes a gas-like contribution to the magnetic susceptibility leads (17) to a local magnetic field H_{par} in the direction of the applied field H_0

$$H_{par} = \frac{1.660}{T} \cdot \frac{3\cos^2\theta - 1}{r^3} H_0$$

where r is the distance from the O_2 molecule in Å and θ the angle between r and H_0. The resulting paramagnetic contribution to the second moment of a magnetic nucleus at a distance r from an O_2 molecule in a polycrystalline sample is

$$SM_{par} = \frac{2.204 H_0^2}{T^2 r^6}$$

Since cages are located at discrete distances r_i from one another,

$$SM_{par} = \Sigma n_i S_i(r_i)$$

where $S_i(r_i)$ is the second moment due to an O_2 molecule located in the ith set of cages and n_i is the number of O_2 molecules in that set.

For the structure II THF–NF_3 double hydrate we assume that NF_3 and O_2 occupy only the small cages, the large cages being occupied by THF. The contribution to the ^{19}F second moment at 1.75 K and 56 MHz (H_0 = 14000 G) from an O_2 molecule in one of the six nearest neighbour small cages at r_1 = 6.08 Å is S_1 = 2790 G^2; similarly, O_2 in one of the 12 second neighbour cages at r_2 = 10.53 Å contributes S_2 = 103 G^2.

The lineshape at low temperatures is completely dominated by nearest neighbour oxygen molecules *if these are present in sufficient abundance*, as was the case for THF hydrate prepared under 3 atm of oxygen (17). However, for small amounts of oxygen (say a degree of cage occupancy by oxygen of $\theta \leqslant 0.01$) the resonances of only a few NF_3 molecules will be broadened by the fields of first and second neighbour O_2 molecules to give at very low temperatures broad weak signals which are buried in noise.

To estimate the observable effect of more distant oxygen molecules, we assume these to be continuously distributed and take

$$SM_{par} = \frac{2.204 H_0^2}{T^2} \int_{r_0}^{\infty} \frac{4\pi r^2 \rho \, dr}{r^6}$$

where ρ is the probability of an oxygen molecule occurring in 1 $Å^3$. Since the cubic unit cell of 17.2 Å size contains 16 small cages, $\rho = 0.0031\theta$, where θ is the chance that an oxygen molecule occupies any one cage, and

$$SM_{par} = \frac{0.0286\theta H_0^2}{T^2 r_0^3}$$

Here r_0 is the minimum separation at which O_2 gives an observable contribution to the lineshape. Somewhat arbitrarily, we take r_0 = 12 Å and find for the same H_0 and T as before that

$$SM_{par} = 1060\theta$$

A value of θ may be estimated from

$$\theta = \frac{K(O_2)P(O_2)}{1 + K(O_2)P(O_2) + K(NF_3)P(NF_3)}$$

where the K's are the Langmuir constants and the P's the partial pressures of the gases in equilibrium with the hydrate under the conditions of formation. In the absence of information about $K(NF_3)$ we take $K(NF_3) = K(O_2) = 0.16$ atm^{-1} (17) for the small cages of THF hydrate at 0°C. The minimum hydrate oxygen content anticipated from the 0.7 mol% oxygen impurity found by analysis is $\theta = 0.0043$, whence SM_{par} = 4.6 G^2 at 1.75 K for the hydrate formed under 10 atm of NF_3 at 0°C. Maximum oxygen content of the hydrate corresponds to trapping of oxygen from air during the original formation of THF hydrate and its ineffectual removal by freeze pumping. At most, $P(O_2) = (0.20 + 0.07)$ atm in that case, $\theta = 0.017$ and SM_{par} = 18 G^2.

The excess second moment of some 6 G^2 measured for THF–NF_3 hydrate at 56 MHz and 1.75 K (Fig. 7) and its rapid fall with increasing temperature may reasonably be ascribed to the effect of O_2 present at a concentration of $\theta \approx 0.006$ or 0.08% by weight.

At considerably higher temperatures the effects of first and second neighbour O_2 molecules become observable. Thus at 20 K, S_1 and S_2 are 21 and 0.7 G^2 respectively and for $\theta \approx 0.006$ these can contribute some 0.8 G^2 to the second moment, while now the contribution from more remote O_2 molecules becomes less than 0.05 G^2.

For NF_3 hydrate itself the effect of O_2 on the second moment of the sample studied (Fig. 7) was about one-third as great as for the THF–NF_3 hydrate sample.

The structure of merosinigrin confirmed

JOHN F. RICHARDSON AND M. H. BENN
Chemistry Department, The University, Calgary, Alta., Canada T2N 1N4

Received December 20, 1983

JOHN F. RICHARDSON and M. H. BENN. Can. J. Chem. **62**, 1236 (1984).

An X-ray crystallographic study of merosinigrin confirmed the structure as 1,2-*S*,*O*-(1*R*,2*S*-1-cyano-2-methyl-1,2-ethanediyl)-1-thio-β-D-glucopyranose. The compound crystallizes in the space group *P*1 with a = 6.699(1), b = 9.347(1), c = 5.328(2) Å, α = 103.56(2), β = 109.14(3), γ = 86.71(1)°, and Z = 1. The structure was refined by full-matrix least-squares techniques to a final agreement value of R = 0.031. Merosinigrin provides what appears to be the first example of the anomeric effect in a thiane (1,4-oxathiane) system with cyano as the polar substituent.

JOHN F. RICHARDSON et M. H. BENN. Can. J. Chem. **62**, 1236 (1984).

Une étude cristallographique par diffraction des rayons-X a permis de confirmer que la structure de la mérosinigrine est celle du 1,2-*S*,*O*-(cyano-1 méthyl-2 éthanediyl-1*R*,2*S*) thio-1β-D-glucopyrannose. Le composé cristallise dans le groupe d'espace *P*1 avec a = 6,699(1), b = 9,347(1), c = 5,328(2) Å, α = 103,56(2), β = 109,14(3), γ = 86,71(1)° et Z = 1. On a affiné la structure par les techniques des moindres carrés (matrice complète) jusqu'à une valeur de R = 0,031. Il semble que la mérosinigrine offre le premier exemple d'un effet anomère dans un thiane (oxathiane-1,4) portant un groupe cyano comme substituant polaire.

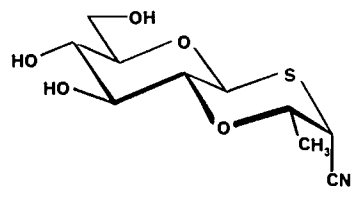
In a communication published in this journal a few years ago (1), structure **1** was proposed for merosinigrin, a product of the reaction of methanolic potassium methoxide with potassium allylglucosinolate (sinigrin) (2).



1

This structure was largely deduced from evidence provided by ir, and ^{1}H and ^{13}C nmr spectroscopy. While this rapidly established the gross features of the bicyclic system[1] and the stereochemistry of the glucopyranose ring, the positioning of the methyl and cyano substituents rested upon nOe (nuclear Overhauser effect) measurements. Crucial was the observation that irradiation of the H(2) proton produced a 17% enhancement of the signal due to H(3),[2] while no such effect was observed upon irradiation of the methyl protons (1).

It seemed worthwhile to check the validity of these nmr analyses, so we recently subjected merosinigrin to an X-ray crystallographic analysis. The results of this study, which we now report, fully confirmed **1** as the structure merosinigrin.

Experimental

Merosinigrin was prepared from sinigrin (U.S. Biochemical Corp.) according to the literature procedure (2) and was obtained in ca. 5% yield, mp 192–194°C. The ir spectrum (KBr disc) of this material was superimposable upon that of our previous preparation (1).

[1]Prof. P. Laur of the RWTH-Aachen reached a similar conclusion. (Personal communication from Prof. Laur.)

[2]The numbering which we use here follows the crystallographic notation as set out in Fig. 1; in the numbering system which we employed before (1), these were designated H-2 and H-9 respectively.

Structure determination

Crystal data

$C_{10}H_{15}NO_5S$ fw = 261.30

Space group *P*1, a = 6.6991(1), b = 9.347(1), c = 5.328(2) Å, α = 103.56(2), β = 109.14(3), γ = 86.71(1)°, V = 306.3(5) Å^3, Z = 1, ρ_c = 1.417 g cm^{-3} (21°C; MoKα, λ = 0.71069 Å, graphite monochromator) and μ(MoKα) = 2.74 cm^{-1}.

A crystal of approximate dimensions 0.5 × 0.5 × 0.4 mm^3 was mounted on an Enraf–Nonius CAD4F diffractometer. Intensity data were collected at room temperature using the ω–2θ scan technique with a scan range of 1.5 (0.70 + 0.347 tan θ). The intensity was calculated as $I = [P - 2(B1 + B2)]\,Q$, where P is the central 64 steps of a 96-step scan, $B1$ and $B2$ are the background counts, and Q is the scan rate. The standard deviation of the intensity, $\sigma(I) = [P + 4(B1 + B2)]^{1/2}\,Q$. Three standard reflections measured every 2500 s of X-ray exposure time showed no decomposition of the crystal had occurred during the data acquisition period. A total of 1796 unique reflections were measured for the octants $+h$, $\pm k$, $\pm l$ to a maximum θ = 25°, of which 1401 were considered observed ($F_o > 3\sigma(F_o)$). The data were corrected for background, Lorentz, and polarization effects, but an absorption correction was not considered necessary.

The coordinates of the SC(1)C(2)O(1) fragment were determined by direct methods (MULTAN 78) (3). Structure factor and difference Fourier calculations revealed the positions of the remaining non-hydrogen atoms. The structure was refined by full-matrix least-squares techniques based on F, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where w was set to 1.0. All computations were performed using the XRAY 76 system of programs (4) implemented on a Honeywell computer with a Multics operating system. Scattering factors for non-hydrogen atoms were those of Cromer and Mann (5) and those for H were taken from ref. 6. Anomalous dispersion corrections were included for non-hydrogen atoms (7). Hydrogen atoms were readily located from a difference Fourier map and included in the model in these positions with isotropic thermal parameters set to 1.1 times the U_{equiv} of the atom to which they are bonded. Hydrogen parameters were not refined. The model converged for 1401 reflections and 151 variables with the agreement factors $R = \Sigma(||F_o| - |F_c||)/\Sigma|F_o| = 0.031$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.032$. In the final cycle, the maximum shift/error was 0.01, the goodness of fit value was 5.4, and the largest peak of residual electron density was 0.30 e Å^{-3} and is of no chemical significance. The absolute stereochemistry of the molecule is uniquely determined by the known chirality of the D-glucopyranose ring.

priate halogen anaerobically, or the hydrogen halide in the presence of air. The latter process occurs via an acid-promoted O_2 oxidation of Ru(II) according to the reactions shown in eq. [1] (5):

$$[1]\quad Ru^{II} + O_2 \rightleftharpoons Ru^{III} + O_2^- \xrightarrow{H^+} HO_2\cdot \rightarrow \tfrac{1}{2}O_2 + \tfrac{1}{2}H_2O_2$$

The O_2 reaction with the Ru(II) complexes is thermodynamically unfavourable but the superoxide product, that has been detected by esr (5), is stabilized as the protonated form, prior to disproportionation to oxygen and hydrogen peroxide. Phosphine oxide is generated as a by-product in the HX/O_2 reactions, presumably via peroxide oxidation of the phosphine. The net stoichiometry is given in eq. [2], although this was not established quantitatively.

$$[2]\quad 2\,Ru^{II}L_2 + O_2 + 2\,HX \rightarrow 2\,Ru^{III}LX + L + LO + H_2O \qquad (L = PPh_3)$$

The formation of Ru(OEP)(EtOH)(OEt) by reaction of O_2 with Ru(OEP)$(EtOH)_2$ (23) probably utilizes the proton of ethanol for the superoxide generation. Access to the $[Ru(OEP)(PPh_3)_2]^+$ cation is obtained by oxidation of Ru(OEP)$(PPh_3)_2$ using $Et_3O^+PF_6^-$.

Bromine or O_2/HX oxidation of Ru(OEP)$(P^nBu_3)_2$ leads to isolation of the ionic species $[Ru(OEP)(P^nBu_3)_2]^+$ as the Br^- or Br_3^- salt. The formation of the bis(phosphine) cationic species as opposed to the bromo(phosphine) species with PPh_3 could result from the stronger basicity and(or) lower cone-angle of the butylphosphine (24, 25). Chlorine oxidation of Ru(OEP)$(P^nBu_3)_2$, which is not described in the experimental section, almost certainly yields $[Ru(OEP)(P^nBu_3)_2]Cl$ as judged by an initial uv/visible spectrum that is identical to that of the bromide salt; a good sample for microanalysis was not obtained, however, because of quite rapid degradation in the solid state to Ru(OEP)$(P^nBu_3)Cl$. This intramolecular ligand exchange process has been described in some detail for the corresponding bromide system (8).

The Ru(OEP)$(P^nBu_3)X$ complexes (X = Br, Cl) are best prepared by halogen oxidation of Ru(OEP)$(CO)P^nBu_3$, formed *in situ* from Ru(OEP)(CO)EtOH. The noted green intermediate in the Br_2 reaction is likely to be a porphyrin cation radical species, either $Ru^{II}(OEP)^{+\cdot}(CO)Br$, which is known to react with 1 equiv. of P^nBu_3 to give Ru(OEP)$(P^nBu_3)Br$ (8), or more

Discussion

Atomic coordinates and $U_{equivalent}$ values for non-hydrogen atoms are given in Table 1 and bond lengths and angles are summarized in Table 2.[3] A perspective view of the molecule is given in Fig. 1. The crystal structure is found to have extensive intermolecular hydrogen bonding interactions. In particular
