For those experiments listed in Table 3 in which analysis was done by gc, equimolar quantities of cyclohexenone complex and diene were stirred in dry solvent according to details in Table 3. Isolation of the mixture of adducts was performed as above and this was followed by gc analysis.

For preparative purposes, two experiments were done in which separation was achieved by column chromotography.

1. Solution of 2-cyclohexenone (0.96 g, 10 mmol), *trans*-piperylene (2.04 g, 30 mmol), and BF_3-etherate (1.42 g, 10 mmol) in dry benzene (20 mL) was stirred for 20 h at 20°C. Work-up with ice-cold aqueous $NaHCO_3$ (5%), followed by washing with saturated brine, drying, and evaporation of solvent gave a yellow oil which was subjected to chromatography on a silica gel column. Elution with 10% ether in hexane gave two combined fractions: (*i*) a colorless oil (0.58 g, 35% yield) which proved to be a mixture of *cis*-**20** and *trans*-**20** in a 15:11 ratio (^{1}Hmr integration of the CH_3 signal); (*ii*) pure oily *cis*-**20** (1.02 g, 62% yield).

The compound (*cis*-**20**) proved homogeneous by tlc, gc, and ^{1}Hmr; ms M^+ calcd. for $C_{11}H_{16}O$: 164.1202; found: 164.1204. For gc and ms data, see Table 4; for ^{1}Hmr data, see Table 5.

2. An experiment similar to the above was performed in which $AlCl_3$ (1.33 g, 10 mmol), freshly sublimed in a stream of dry HCl gas, was used as a catalyst and the reaction was allowed to proceed for 48 h at 20°C. A work-up identical to the above gave, on silica gel chromatography: (*i*) a mixture of *cis*-**20** and *trans*-**20** (0.35 g, 24% yield) in a 15:11 ratio; (*ii*) pure *cis*-**20** (0.56 g, 38% yield); (*iii*) unreacted 2-cyclohexenone (60 mg).

Equilibrations of cis–trans *isomers*

The mixture of *cis*-**20** and *trans*-**20** obtained above (0.5 g) was stirred with neutral alumina (grade I, 2 g) in dry chloroform (25 mL) at 20°C for periods of 1–48 h. The alumina was then filtered, washed repeatedly with methanol, and the combined organic extracts were evaporated *in vacuo*. The residue was subjected to gc analysis. After 24 h, the composition was 92% *trans*-**20**, 8% *cis*-**20**; after 48 h, the composition was 96% *trans*-**20** and 4% *cis*-**20**.

For gc and ms data on compound *trans*-**20**, see Table 4; for ^{1}Hmr data, see Table 5.

Chemiluminescence from the reactions of ozone with sulphur compounds

P. K. ARORA AND J. P. S. CHATHA
Air Monitoring Section, Bhabha Atomic Research Centre, Bombay-400 085, India

Received April 18, 1983

P. K. ARORA and J. P. S. CHATHA. Can. J. Chem. **62**, 417 (1984).

Emissions from excited SO_2 in its singlet state ($^1B_1$ and/or $^1A_2$) and triplet state ($^3B_1$) have been observed in gas-phase chemiluminescent reactions of ozone with a number of sulphur compounds. The compounds studied are carbon disulphide, thiophene, diallyl sulphide, diallyl disulphide, dimethyl sulphide, dimethyl disulphide, and thiophenol. The reaction pathways responsible for the formation of excited molecules are discussed. The remarkable similarity between the emission spectra of the reactions and the chemiluminescence from the SO + O_3 reaction confirms that SO is a precursor for the observed chemiluminescence. Disulphides are found to be more chemiluminescent than monosulphides. The absence of chemiluminescence from HCHO* in the reactions of ozone with allyl sulphide and disulphide indicates that the attack of ozone molecule is on the C—S bond in organic sulphides.

P. K. ARORA et J. P. S. CHATHA. Can. J. Chem. **62**, 417 (1984).

On a observé des émissions à partir du SO_2 excité à l'état singulet ($^1B_1$ et/ou $^1A_2$) et à l'état triplet ($^3B_1$) au cours de réactions chimiluminescentes, en phase gazeuse, de l'ozone avec un certain nombre de composés soufrés. On a étudié les composés suivants: le disulfure de carbone, le thiophène, le sulfure de diallyle, le disulfure de diallyle, le sulfure de diméthyle, le disulfure de diméthyle et le thiophénol. On discute des chemins réactionnels responsables de la formation des molécules excitées. La similitude frappante existant entre les spectres d'émission des réactions et la chimiluminescence à partir de la réaction SO + O_3 confirme que le SO est un précurseur de la chimiluminescence observée. On a trouvé que les disulfures sont plus chimiluminescents que les monosulfures. L'absence de chimiluminescence à partir de HCHO* dans la réaction de l'ozone avec le sulfure et le disulfure d'allyle indique que l'attaque de la molécule d'ozone à lieu sur la liaison C—S des sulfures organiques.

Introduction

Chemiluminescence spectra from the reactions of ozone with H_2S, CH_3SH, and CH_3SCH_3 were first studied by Akimoto *et al.* (1). The emitting species was identified as $SO_2(^1B_1)$. They suggested that SO is a radical intermediate in these reactions and SO_2^* is formed by the reaction

[1] $$SO + O_3 \rightarrow SO_2^* + O_2$$

$$\Delta H = -106 \text{ kcal/mol}$$

Toby *et al.* (2) also observed emissions due to $SO_2(^1B_1)$ in the chemiluminescent reactions of ozone with CS_2 and thiophene. However, no bands due to triplet $SO_2(^3B_1)$ were observed in these reactions as reported by Halstead and Thrush (3) in the chemiluminescent emission from reaction [1]. Recently, Glinski *et al.* (4, 5) have reexamined the reactions of O_3 with CH_3SH and H_2S under beam-gas conditions and shown that the vibrationally resolved phosphorescent spectra are due to first triplet excited state of SO_2.

In this work we report detailed studies on the reactions of ozone with different types of sulphur compounds which provide definite evidence that SO is a common radical intermediate in all these chemiluminescent reactions. All the emission spectra are identical and there is a marked similarity with the spectrum observed by Halstead and Thrush (3) in the reaction of SO with O_3. The effects of reactant concentration on the spectra and on total signal have also been studied in some cases. The possible reaction pathways for formation of SO radicals are discussed.

Experimental

The experimental system used for studying the chemiluminescence spectra has been described in detail elsewhere (6). The reaction cell of 200 cm^3 volume had a 50 mm diameter window and was made of quartz. Ozone in O_2 was produced by a calibrated ozone generator based on the silent electric discharge technique (7). Known concentrations of sulphur compounds were introduced by controlling the flow of a helium stream saturated with the reactant at 0°C. The flows of gases were measured by Matheson rotameters. The pressure in the reaction cell was measured with a MKS Baratron pressure sensor system (Type 310 BHS-1000).

The light emissions from reaction cell were analyzed with a scanning monochromator (Jarrel-Ash 0.25 meter) having two gratings blazed at 300 and 500 nm. Photomultiplier tube EMI 9635 QA was used for uv and visible region and a thermoelectrically cooled EMI 9659 A for the region up to 900 nm. Signal from photomultiplier tube was fed either to a dc amplifier or a photon counter.

CS_2 (E. Merck, Proanalyst), dimethyl sulphide (Fluka AG Purum), and dimethyl disulphide (BDH England) from fresh bottles were used as received. Thiophene and thiophenol were distilled before use. Diallyl disulphide was prepared by the method of Carson and Wong (8). It was purified by vacuum distillation and was found to be more than 98% pure (9). Diallyl sulphide was prepared by the action of allyl chloride (2 mol) on sodium sulphide (1 mol). It was then vacuum distilled and purity was better than 99%.

Results

Chemiluminescence in the region of 200–900 nm was studied from the reaction of ozone with CS_2, C_4H_4S, $(CH_3)_2S$, $(CH_3)_2S_2$, $(CH_2{=}CHCH_2)_2S$, $(CH_2{=}CHCH_2)_2S_2$, and C_6H_5SH. No chemiluminescence was observed from the reaction of ozone with dimethyl sulphoxide. Detailed observations on individual compounds are given below.

Carbon disulphide

The chemiluminescence spectrum from the reaction of ozone with CS_2 is shown in Fig. 1. It consists of a broad continuum from 270 to 470 nm and a number of peaks starting from 380 nm superimposed on the continuum. The broad structureless continuum is due to the fluorescence from excited singlet SO_2 while the bands from 380 nm onwards are due to $SO_2(^3B_1)$.

The effect of CS_2 concentration on the emission bands of $SO_2(^3B_1)$ is shown in Fig. 2. The spectra were recorded at different partial pressures of CS_2 as indicated in the figure. The ozone concentration and the total pressure were kept constant. As the CS_2 concentration was increased the emission from

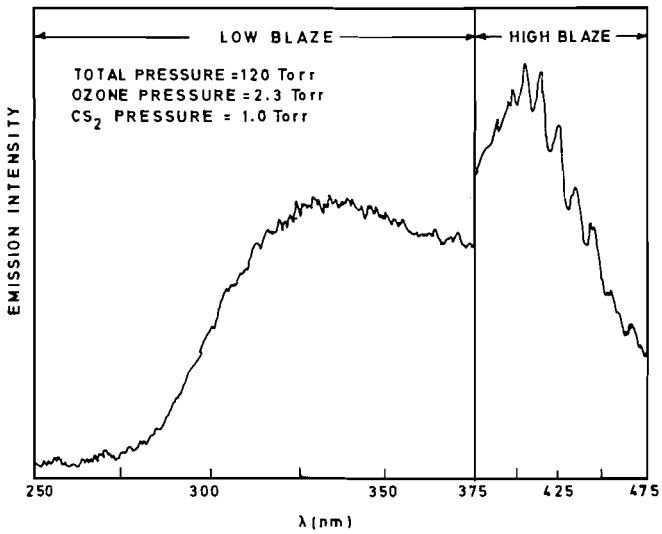

FIG. 1. Chemiluminescence spectrum from the reaction of ozone with carbon disulphide: spectral slitwidth, 0.8 nm; range, 5 nA.

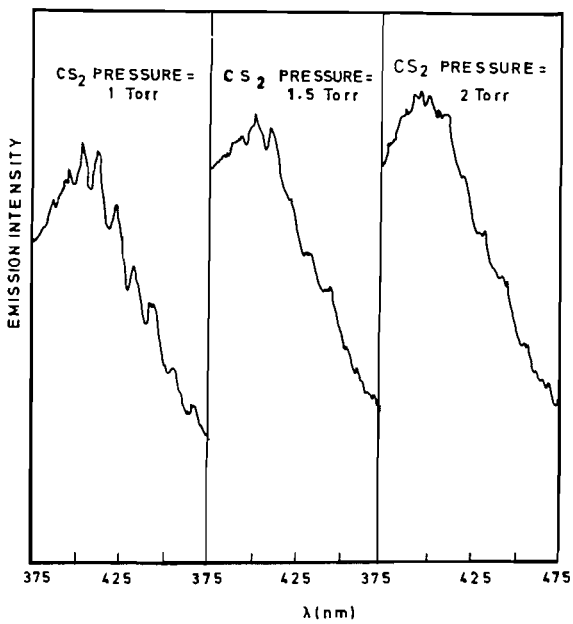

FIG. 2. Effect of CS_2 pressure on triplet SO_2 emission: total pressure, 120 Torr; ozone pressure, 2.3 Torr.

triplet SO_2 became weaker and the structure less well defined.

Figure 3 shows the effect of ozone concentration on the total signal. Ozone concentration from the ozone generator was varied in such a way that O_3/O_2 flow entering the reaction cell did not vary. It is seen that the total signal increases linearly with the square of the ozone concentration.

Thiophene

The chemiluminescence spectrum arising from the reaction of ozone with thiophene is shown in Fig. 4. The emissions are due to the transitions from excited SO_2 in its singlet and triplet state. The intensity of bands due to triplet SO_2 is much stronger than in the case of CS_2. Emissions in the region of 500 to 800 nm were also recorded and number of bands, similar to those reported by Toby *et al.* (2), was observed. These are due to the electronically excited HSO radical ($^2A'$) (10). A brown-coloured coating was formed in the reaction cell and a charred smell was noticed after the experiments.

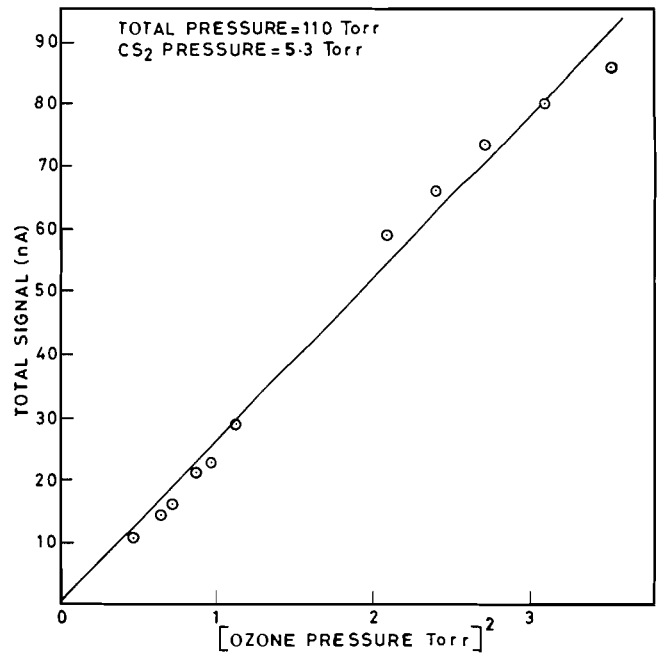

FIG. 3. Effect of ozone concentration on total signal.

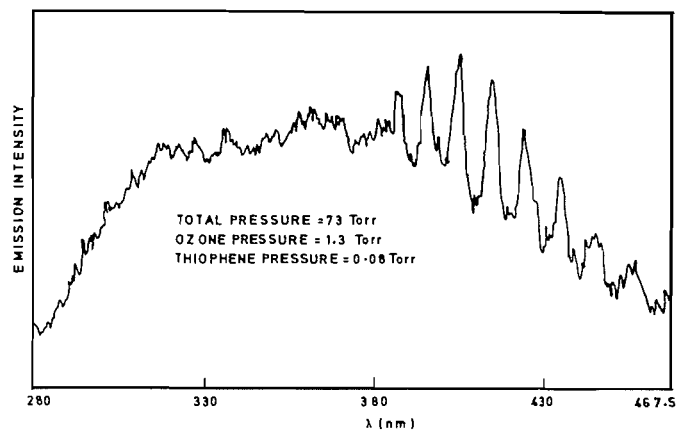

FIG. 4. Chemiluminescence emission from the reaction of ozone with thiophene: spectral slitwidth, 1.65 nm; range, 2 nA.

Dimethyl sulphide and dimethyl disulphide

The chemiluminescence spectra from the reaction of ozone with dimethyl sulphide and dimethyl disulphide are shown in Fig. 5. The partial pressures of dimethyl sulphide and disulphide in these reactions are indicated in the figure. The emissions due to triplet SO_2, superimposed on the continuum, are not as strong as those observed with other sulphur compounds. Keeping other parameters constant when the concentration of DMS was increased to 95 mTorr, the peaks due to triplet SO_2 completely vanished even though the emission intensity increased by a factor of two. In the case of dimethyl disulphide, the emission intensity was very high and the spectrum was taken with a spectral slitwidth of 0.4 nm. No vibrational structure of emission due to singlet SO_2 is observed even at this resolution.

Well-resolved emissions from vibrationally excited OH were also observed in these reactions. These are shown in Fig. 6 for dimethyl disulphide. The peaks are identical to the Meinel bands, thus indicating that the formation of H atoms takes place in these reactions.

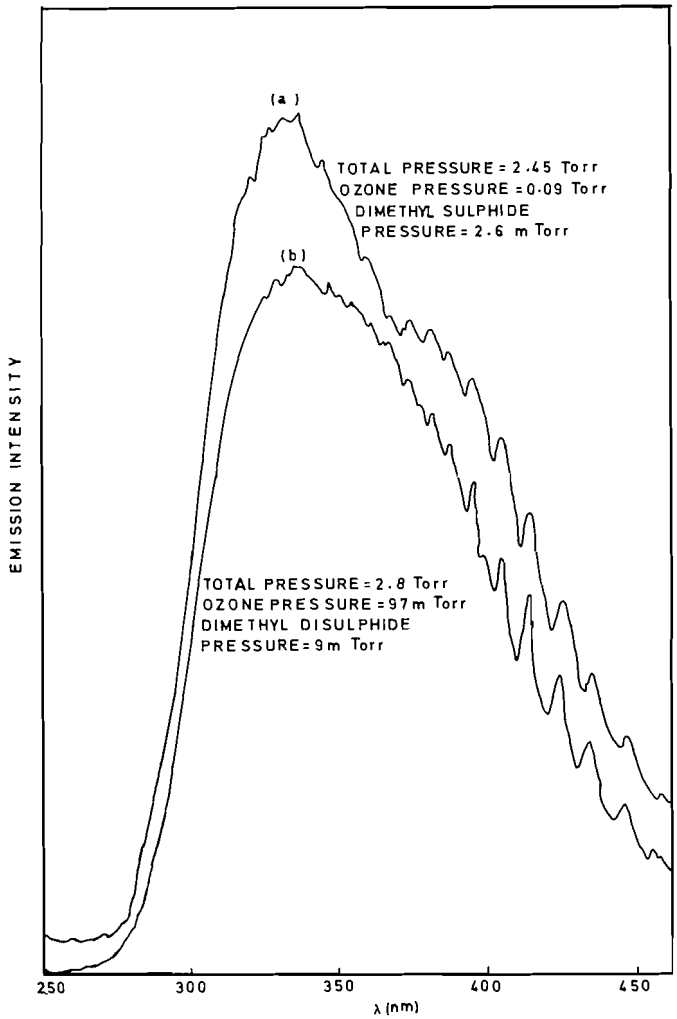

FIG. 5. Chemiluminescence spectra from the reaction of ozone with (*a*) dimethyl sulphide: spectral slitwidth, 1.65 nm; range, 1000 cps; (*b*) dimethyl disulphide: spectral slitwidth, 0.4 nm; range, 2000 cps.

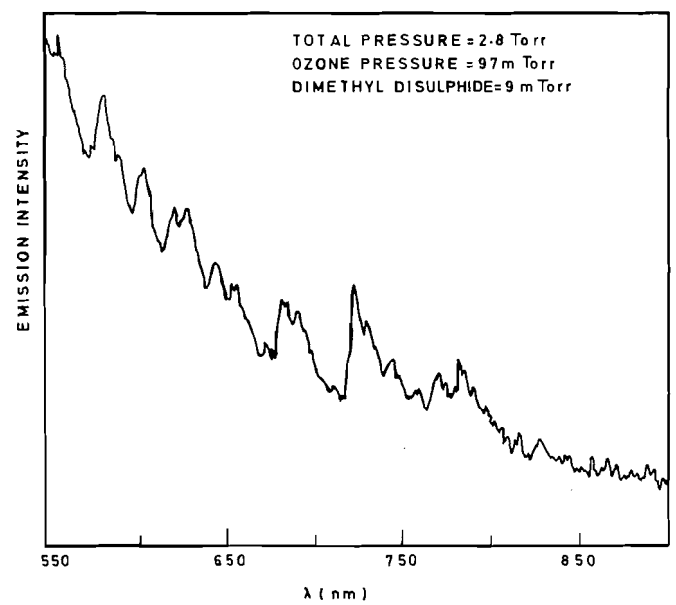

FIG. 6. Chemiluminescence emission from the reaction of ozone with dimethyl disulphide: spectral slitwidth, 3.3 nm; range, 100 pA.

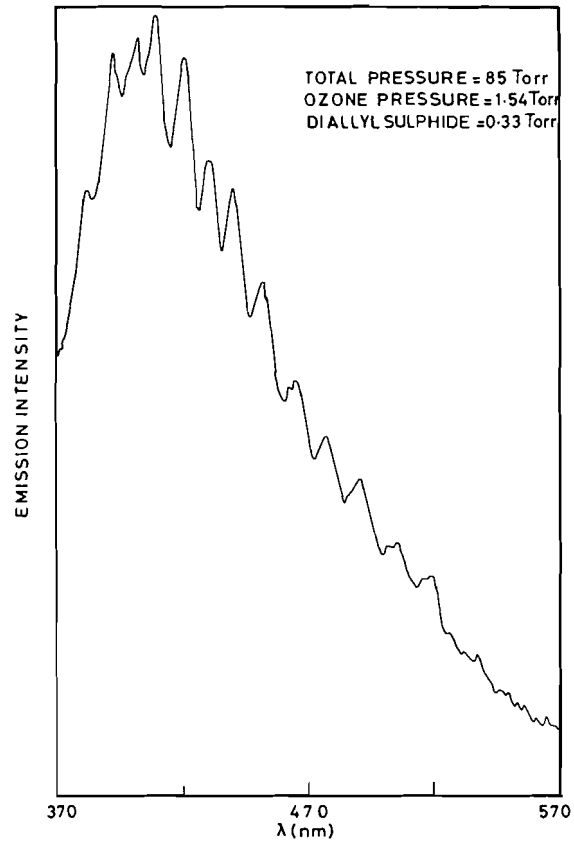

FIG. 7. Emission spectrum from the reaction of ozone with diallyl sulphide; spectral slitwidth, 3.3 nm; range, 5 nA.

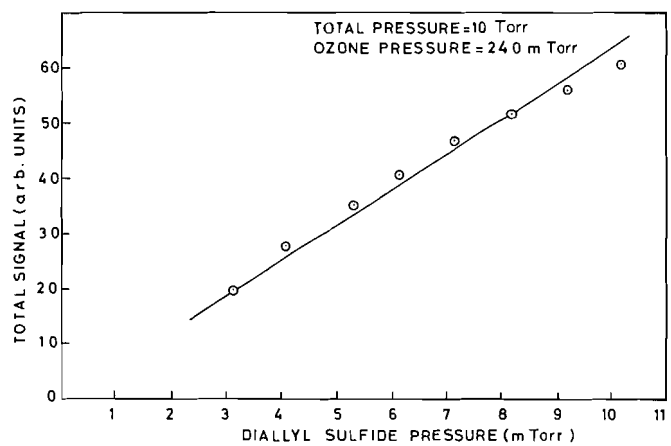

FIG. 8. Effect of diallyl sulphide concentration on total signal.

Diallyl sulphide and diallyl disulphide

The reaction of ozone with diallyl sulphide gave emission similar to that observed in the reactions with other sulphur compounds. However, the emission from triplet SO_2 is quite strong and extremely well defined as is shown in Fig. 7. The effect of diallyl sulphide concentration on the total signal was also studied and is shown in Fig. 8. It is observed that the total signal increases linearly with concentration.

Figure 9(*a*) shows the emission observed in the reaction of ozone with diallyl disulphide. The intensity of peaks due to $SO_2(^3B_1)$ is quite high. No other emission due to either excited HCHO or OH was observed in these reactions in spite of the presence of double bond in the allyl compounds.

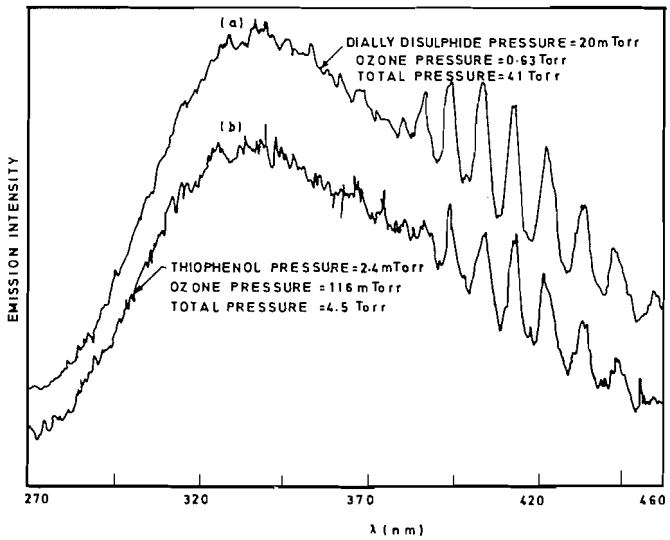

FIG. 9. Chemiluminescence spectra from the reaction of (*a*) ozone with diallyl disulphide: range, 5 nA; (*b*) ozone with thiophenol: range, 2 nA; spectral slitwidth, 1.65 nm.

Thiophenol

The spectrum from this reaction is shown in Fig. 9(*b*). The emissions are identical to those observed with other organic compounds, thus confirming that SO_2^* is the emitting species.

Discussion

Spectroscopic studies of SO_2 yield the following low-lying electronic states (and their origin in cm^{-1}): $X\,^1A_1$ (0,0), $a\,^3B_1$ (25766), $b\,^3A_2$ (26000), $A\,^1A_2$ (27930), and $B\,^1B_1$ (31950) (11). The transition of SO_2 which appears over the region of 260–340 nm was initially believed to be $^1A_1 \rightarrow {}^1B_1$. However, the recent rotational analysis of high resolution absorption spectra (12, 13) shows that the upper state is electronically $^1A_2$ and vibronically $^1B_1$ with the $\nu_3(b_2)$ antisymmetric stretching vibration. Magnetic rotations and Zeeman broadenings are found in the region of 295–325 nm (14), which evidence the additional coupling with triplet and/or ground electronic state. Fluorescence spectra originating from a variety of single vibronic bands have recently been analyzed by Shaw *et al.* (15) in terms of the levels of the zero-order $^1B_1$ electronic state which are vibronically coupled with many $^1A_2$ levels.

The weak absorption in the region of 3400–3900 Å is attributed to the spin-forbidden $a\,^3B_1 \leftarrow X\,^1A_1$ transition (16). The rotational analysis of several absorption bands of this $a \leftarrow X$ system have shown that the bands at higher energy have irregular contours and are strongly perturbed due to vibronic interaction with the nearby $^3A_2$ state.

Brus and McDonald (17) and Su *et al.* (18) measured the fluorescence decay of excited SO_2 and reported that it decays biexponentially with two independent lifetimes: 10–80 μs and 100–600 μs. It was proposed that the short-lived component was due to $^1A_2$ and the long-lived one to $^1B_1$ which was immersed in a large number of ground vibronic levels through the Renner–Teller coupling. Recently, Holtermann *et al.* (19) excited the single rotational level of the *E* band and found that the emission decayed single exponentially with a lifetime of 13 μs. They claimed this to be the lifetime of the pure $^1A_2$ state. Very recently, Watanabe *et al.* (20) have measured the lifetime of rotationally cooled $SO_2(^1A_2)$ and reported biexponential decay with a short lifetime of 3–5 μs and a long one of 15–30 μs. Compared to this the lifetime of triplet $SO_2(^3B_1)$ has been measured to be ~8 ms (21).

We have studied the reaction of ozone with seven different sulphur compounds and find that a common feature of all these chemiluminescent reactions is the nearly identical emission in the region of 270–470 nm. The spectra show a series of sharp bands, starting from 388 nm superimposed on the featureless broad band. These spectra have a strong similarity to the luminescent spectra reported by Strickler (22) and to the chemiluminescence spectra reported by Halstead and Thrush (3) from reaction [1]. Following the work of Gaydon (23) and Halstead and Thrush (3), these bands can easily be assigned to transitions from the first excited triplet state of SO_2 to the ground state. We have observed only those transitions which originate from $V' = (0,0,0)$ of the $^3B_1$ state to various $V'' = (n,m,0)$ of the $^1A_1$ ground state. This corresponds to a fully relaxed vibrational distribution at ambient temperature. This is due to the fact that at the higher pressures used in the present studies the molecules will undergo multiple collisions before they can radiate since the phosphorescence lifetime is so long. However, Glinski *et al.* (4) have recently observed emission from higher vibrational levels of SO_2 excited triplet in the low pressure chemiluminescent reaction of ozone with methyl mercaptan.

The spectrum which appears as a continuous emission from 270 nm to 470 nm with a maximum at 340 nm can be attributed to transitions from $^1B_1$ and/or $^1A_2$ state to ground state. No band structure due to any of these states could be observed even in the reaction of ozone with dimethyl disulphide where the spectral slitwidth was 0.4 nm. The short wavelength limit of 270 nm in the observed chemiluminescence is set by the energetics of the reaction [1] which is 106.5 kcal/mol exothermic.

The formation of triplet $SO_2(^3B_1)$ takes place from singlet $SO_2(^1B_1$ and/or $^1A_2)$ by collisionally-induced intersystem crossing. The spin and thermodynamically allowed process

$$[2]\quad SO(^3\Sigma) + O_3(^1A) \rightarrow {}^3SO_2 + O_2(^1\Delta_g) \qquad \Delta H = -10 \text{ kcal/mol}$$

does not seem to operate since Halstead and Thrush failed to discover $O_2(^1\Delta_g)$ or $O_2(^1\Sigma_g{}^+)$ in their original work. Recently, Glinski *et al.* (4) have observed emission from $SO_2(^3B_1)$ and attributed it to the collisions of He atoms with excited singlet state of SO_2 inducing a transfer to this triplet state. They have also studied the effect of ozone pressure on the fluorescence and phosphorescence intensity of SO_2. From the correlation of the onset of phosphorescence with the loss of fluorescence they have suggested that $^1A_2$ state is the precursor state to much of observed phosphorescence. The persistence of fluorescent intensity at higher pressure has been attributed to emission from $^1B_1$ state. In the present studies it is difficult to suggest whether the emission is from $^1B_1$ state or $^1A_2$ state. However, taking into account the lifetime of $^1A_2$ state and the high pressures used it is probably the $^1B_1$ state which is responsible for the broad featureless band observed in the present studies. The following reaction steps can be written for the formation of excited singlet and triplet states of SO_2.

$$[3]\quad SO + O_3 \rightarrow {}^1SO_2(^1B_1 \text{ and/or } {}^1A_2) + O_2$$

$$[4]\quad SO + O_3 \rightarrow SO_2(^1A_1) + O_2$$

$$[5]\quad {}^1SO_2 \rightarrow SO_2(^1A_1) + h\nu_f$$

$$[6]\quad {}^1SO_2 \rightarrow SO_2(^1A_1)$$

[7] $^1SO_2 \rightarrow SO_2(^3B_1)$

[8] $^1SO_2 + M \rightarrow SO_2(^1A_1) + M$

[9] $^1SO_2 + M \rightarrow SO_2(^3B_1) + M$

[10] $SO_2(^3B_1) \rightarrow SO_2(^1A_1) + h\nu_p$

[11] $SO_2(^3B_1) \rightarrow SO_2(^1A_1)$

[12] $SO_2(^3B_1) + M \rightarrow SO_2(^1A_1) + M$

where M represents some quencher molecule including SO_2.

The efficiency with which $SO_2(^3B_1)$ molecules are formed in the spin inverting reaction is of primary importance and has been measured by Wampler *et al.* (24) for O_2 and other atmospheric gases. They reported the values of bimolecular intersystem crossing ratio $k_9/(k_8 + k_9)$ to be 0.03, 0.034, 0.025, 0.052, and 0.045 for O_2, N_2, Ar, CO_2, and CO respectively. This explains why emission from $SO_2(^3B_1)$ is very weak compared to the total integrated emission observed from $SO_2(^1B_1)$.

The quenching rate constants of $SO_2(^3B_1)$ with a variety of chemically reactive and unreactive molecules have been determined by Wampler *et al.* (25). Becker *et al.* (10) have measured the rate constants for the quenching of triplet SO_2 by various sulphur compounds. They report values of 3×10^{10}, 5×10^{10}, 9×10^{10}, and 14×10^{10} L/mol s for H_2S, CS_2, CH_3SH, and $(CH_3)_2S$, respectively.

The quenching rate constants of $SO_2(^1B_1)$ have been measured for SO_2, O_2, and CO_2 and their values are 1.5×10^{10}, 4.7×10^9, and 1.1×10^{10} L/mol s, respectively (26).

Carbon disulphide

The reaction of ozone with CS_2 probably takes place via

[13] $CS_2 + O_3 \rightarrow CS + SO + O_2$

$\Delta H = -5.5$ kcal/mol

$SO + O_3 \rightarrow SO_2^* + O_2$

Olszyna and Heicklen (27) have studied the reaction of ozone with CS_2 and postulated that the SO radicals arise from reaction of oxygen atoms, produced by ozone decomposition, with CS_2.

[14] $CS_2 + O \rightarrow CS + SO$

However, thermochemical calculations show that even reaction of ozone with CS_2 can produce SO radicals directly (reaction [13]). The intensity of SO_2^* will then be proportional to the square of the ozone concentration. This agrees with the experimental observation where emission from SO_2^* was found to be second order in ozone (Fig. 3).

The effect of increasing the CS_2 concentration was found to be the reduction of the emission from triplet SO_2. This is due to the very high quenching rate constant of CS_2 with $SO_2(^3B_1)$. This rate constant ($k = 5 \times 10^{10}$ L/mol s) (10) is even higher than the highest reported rate constant of $SO_2(^1B_1)$ with ground state SO_2 ($k = 1.5 \times 10^{10}$ L/mol s) (26).

Thiophene

The reaction between ozone and thiophene has been studied by Kaduk and Toby (28) at low pressure; they found the most abundant product to be O_2 with smaller amounts of CO_2 and SO_2. The mass balance for O_2 and sulphur was found to be 100% while that for carbon was found to be 25%. Since they did not observe any H-containing product, it was suggested that the missing product is a hydrocarbon which may be a polymer. The following mechanism was proposed.

[15] 
The HSO radical may undergo the following reactions leading to the formation of excited HSO and SO_2.

[16] $HSO + O_3 \rightarrow HS + 2O_2$

$\Delta H = -13$ kcal/mol

[17] $HSO + O_3 \rightarrow HO + SO + O_2$

$\Delta H = -36$ kcal/mol

[18] $HS + O_3 \rightarrow HSO + O_2$

$\Delta H = -56$ kcal/mol

[1] $SO + O_3 \rightarrow SO_2^* + O_2$

The enthalpy of the reactions has been calculated on the basis of $\Delta H_f^0(HSO) = 13$ kcal/mol (10). Reaction [18] is sufficiently exothermic to produce HSO in an electronically excited state. The short wavelength limit of 517 nm agrees well with the enthalpy of the reaction. Formation of excited SO_2 takes place via reaction [1]. The emission due to $SO_2(^3B_1)$ is quite strong. This is because of the reduced quenching rate due to the small concentration of thiophene in the reaction chamber.

Dimethyl sulphide

The gas phase reaction of ozone with dimethyl sulphide (DMS) has been studied at low pressure by Martinez and Herron (29). The major products of this reaction were found to be H_2CO, H_2O, CO, and SO_2. This shows that C—S bond scission takes place in the gas phase reaction contrary to the general trend in solutions where ozonolysis of organic sulphides leads to the formation of sulphoxides and sulphones. The initial product yield was found to be

$$1.0\ DMS \xrightarrow{O_3/O_2} 0.93H_2CO + 0.32SO_2 + 0.43H_2O + 0.34CO + 0.07CO_2$$

It was proposed that the initial attack of ozone on DMS gives rise to radicals which act as chain carrier.

[19] $DMS + O_3 \rightarrow CH_3O + CH_3SO_2$

$\Delta H = -82$ kcal/mol

[20] $\rightarrow CH_2O + H + CH_3SO_2$

$\Delta H = -61$ kcal/mol

[21] $\rightarrow CH_3O_2 + CH_3SO$

$\Delta H = -6.6$ kcal/mol

[22] $\rightarrow (CH_3)_2SO + O_2$

$\Delta H = -60$ kcal/mol

We propose that the formation of SO takes place by reaction of ozone with CH_3SO

[23] $CH_3SO + O_3 \rightarrow CH_3O + SO + O_2$

$\Delta H = -41$ kcal/mol

[24] $\rightarrow CH_3OO + SO_2$

$\Delta H = -110$ kcal/mol

[25] $\rightarrow CH_3S + 2O_2$

$\Delta H = -13.5$ kcal/mol

Reaction of CH_3S with ozone can also lead to the formation of SO.

[26] $CH_3S + O_3 \rightarrow CH_3OO + SO$

$\Delta H = -58$ kcal/mol

The reaction of SO with ozone will lead to the formation of excited SO_2 by reaction [1]. It is seen that reaction [24] can directly lead to the formation of excited SO_2. This may be responsible for the high intensity of SO_2 emission observed in the DMS + O_3 reaction.

The triplet SO_2 emission is not very strong and vanishes on increasing the concentration of DMS. This is due to very high quenching rate of $SO_2(^3B_1)$ with DMS ($k = 1.4 \times 10^{11}$ L/mol s) (10).

Dimethyl disulphide

The reaction of ozone with dimethyl disulphide gives rise to very intense emission due to SO_2^*. It is also noted that the short wavelength limit in this chemiluminescence is less than 260 nm which corresponds to 110 kcal/mol. The following mechanism is proposed to explain these features.

[27] $(CH_3)_2S_2 + O_3 \rightarrow CH_3SO + CH_3SO_2$

$\Delta H = -78$ kcal/mol

[28] $\rightarrow CH_3 + SO + CH_3SO_2$

$\Delta H = -53$ kcal/mol

[29] $\rightarrow CH_3S + CH_3SO + O_2$

$\Delta H = -16$ kcal/mol

The SO and CH_3SO thus formed may react again with ozone giving rise to excited SO_2.

[30] $CH_3SO + O_3 \rightarrow CH_3OO + SO_2$

$\Delta H = -110$ kcal/mol

The formation of SO_2^* via reaction [30] explains the high intensity of chemiluminescence observed in this reaction since SO_2^* is formed in two steps only. This also explains why more emission is observed in disulphide than in DMS since each of the two reaction pathways [27] and [28] may lead to the formation of excited SO_2. The short wavelength limit of less than 260 nm observed in this reaction is due to the exothermicity of reaction [30]. Intense Meinel bands were observed in this reaction. This is due to the very efficient formation of H atoms in the system which are formed by

[31] $CH_3 + O_3 \rightarrow HCHO + O_2 + H$

$\Delta H = -39$ kcal/mol

This reaction is similar to the reaction of an O atom with a CH_3 radical which leads to the formation of H atoms and HCHO. The reaction of H atoms with O_3 leads to the formation of the Meinel bands

[32] $H + O_3 \rightarrow OH^\dagger + O_2$

$\Delta H = -77$ kcal/mol

Diallyl sulphide and diallyl disulphide

The reactions of ozone with diallyl sulphide and diallyl disulphide give emissions due to singlet and triplet SO_2. No emission due to excited HCHO was observed in these reactions as was observed in the reaction of ozone with allyl chloride and allyl alcohol (30). This indicates that the attack of ozone takes place on the S atom instead of —C=C— bond as in olefins. This leads to the scission of the —C—S bond in organic sulphides. The mechanism of formation of SO should follow pathways which are similar to those in the reactions of ozone with dimethyl sulphide and dimethyl disulphide. The intensity of SO_2^* was found to be comparable in the two reactions even though the concentration of diallyl disulphide was about 15 times less than that of diallyl sulphide. This also agrees with the earlier observation that disulphides give rise to more emission than sulphide. However, no $OH^\dagger$ emission was observed in the reaction. This is due to the absence of methyl group in the reacting molecule.

Thiophenol

The reaction of ozone with thiophenol gives rise to emission from excited SO_2. The following mechanism is proposed.

[33] $C_6H_5SH + O_3 \rightarrow C_6H_5SO_2 + OH$

[34] $\rightarrow C_6H_5O + SO + OH$

[35] $\rightarrow C_6H_5SO + HO_2$

Reaction of C_6H_5SO with ozone may also lead to the formation of excited SO_2 via reactions which are similar to those postulated for the reactions with CH_3SO. However, the short wavelength limit of 275 nm suggests that excited SO_2 is formed by the reaction of SO radicals with ozone.

We have shown that radical cations generated by photoinduced electron transfer (ET) in 1,2-diarylethanes, aryl pinacols, and their derivatives undergo fragmentation reactions. In the presence of oxygen oxidative products are obtained. Time-resolved laser flash photolysis and other ancillary techniques have permitted us to define the mechanisms of certain oxidative processes observed.

L. W. REICHEL, G. W. GRIFFIN, A. J. MULLER, P. K. DAS et SEYHAN N. EGE. Can. J. Chem. **62**, 424 (1984).

Nous avons montré que les cations radicalaires générés par transfert d'électron (TE) dans les diaryl-1,2 éthanes, les pinacols aryliques et leurs dérivés subissent des réactions de fragmentation. En présence d'oxygène, on obtient des produits d'oxydation. La photolyse flash ou laser résolue en fonction du temps, et d'autres techniques ancillaires nous permettent de définir le mécanisme de certaines réactions d'oxydation observées.

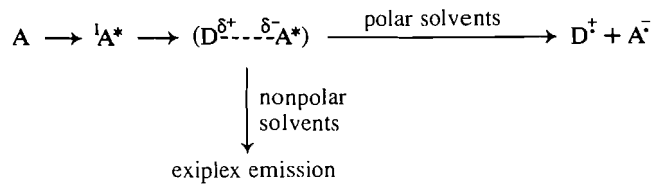
Introduction

The classic work by Weller and co-workers (2*a*–*c*) on charge-transfer processes, exciplexes, and the dissociation of the latter has captured the attention of photochemists and has stimulated extensive research in the field of photoinduced electron transfer (ET) reactions (1–15). The primary focus in this field has revolved around ET reactions induced by excitation of specific compounds (so called "sensitizers") to the singlet state possessing augmented electron donor (D) or electron acceptor (A) properties (i.e., enhanced oxidation or reduction potentials). In most cases studied to date, and in those described in this communication, the electron acceptor species is designated as the "sensitizer". The excited singlet state of this "sensitizer" or acceptor (A) has a greater tendency to be reduced than the ground state and may accept an electron from a suitable ground state donor substrate with concomitant formation of a radical cation ($D^{\ddagger}$) and an acceptor radical anion ($A^{\bar{\cdot}}$) (Scheme 1) in their ground states. Such processes proceed directly through an encounter complex in polar solvents where potential exciplex formation may be circumvented. In contrast, donor–acceptor exciplexes, which may be characterized by emission spectroscopy, are observed in nonpolar solvents where dissociation is unfavorable.

Fragmentation of donor radical cations in polar solvents to a cation and radical is a reaction of primary significance. Among other reactions observed for radical cations generated by photoinduced ET are the following: (a) coupling with the radical anion followed by cyclization and/or rearrangement to give a neutral adduct (3), (b) addition to alkenes (4), cyclodimerization (5), and cross-cycloaddtion (5*f*, 6), (c) reduction of radical cations derived from arenes with metal hydrides (7), (d) reaction with nucleophiles, alcohols, and cyanide ion, to give saturated products (i.e., ethers and nitriles, respectively (4*a*, 5*a*, 8)), (e) rearrangement of cyclopropanes and cyclopropenes (9), (f) coupling with triplet ground state oxygen (10), singlet oxygen and/or superoxide (3*d*, 11) and (g) isomerization of alkenes (11*g*), oxiranes, (1*b*, 12) and cyclopropanes (13).



SCHEME 1

The radical anions derived by ET in turn may serve to reduce the fragment cation and/or radical formed by fragmentation of the initial radical cation to a radical and/or anion, respectively, a process loosely designated as "back electron donation". Competitive reactions include (a) interaction with the donor radical cation as noted above (3), (b) reduction of triplet oxygen to superoxide anion which is capable of oxidizing radical cations of alkenes and alkynes (11*a*–*c*, *e*–*j*), polyaryl oxiranes as well as cyclopropanes (11*k*), and sulfur compounds (11*b*, *d*), (c) reductive cleavage of protecting groups (14), and (d) reduction of arenes (15).

Our interest in the area of fragmentation reactions which proceed through photoinduced ET mechanisms had its inception in continuing studies on the photocycloelimination and isomerization reactions of small-ring systems, such as vicinal diaryl substituted oxiranes and cyclopropanes, to give reactive transients (carbenes (16), carbonyl ylides (17), and diradicals (18)). The isomerization of stilbene oxides by electron transfer "sensitization" reported by Albini and Arnold (12) impinged upon current photochemical studies being conducted in our laboratory (1*a*) and we were encouraged by Arnold to expand our efforts in this area.

Arnold's work (19) on the photoinduced ET-sensitized

[1]For preliminary reports of our work in this area, see ref. 1.

For personal use only.

cleavage of 2,2-diphenylethyl 2-propyl ether in acetonitrile–methanol, using 1,4-dicyanobenzene (DCB) as sensitizer, established that the radical cation of the ether undergoes C—C bond cleavage to give the benzhydryl radical and an α-alkoxycarbocation.[2] Reduction of the benzhydryl radical to the benzhydryl anion by "back electron transfer" from the radical anion of 1,4-dicyanobenzene and subsequent protonation is advanced to explain diphenylmethane formation. Solvolysis of the carbocation with methanol would explain the formation of the other product, namely the 2-propyl methyl acetal of formaldehyde.

Arnold recognized that stilbene oxides also incorporate a key structural element in common with the diphenylethyl 2-propyl ether, namely an Ar—C— C—O bond sequence, and found that irradiation of either *cis*- or *trans*-stilbene oxide in CH_3CN solution containing 1,4-dicyanonaphthalene (DCN) resulted in a common mixture (1:5, respectively) of both isomers (12).[3] "Equilibration" of the stilbene oxides is attributed to cleavage of the oxirane C—C bond of an initially-formed cyclic radical cation to give open planar isomeric 1,3-radical cations which may recyclize or undergo reduction by "back electron transfer" in the formal sense to the radical site to give the carbonyl ylide.[4] The intermediate carbonyl ylide(s) in the interconversion of stilbene oxides may be intercepted with electron-poor dipolarophiles, affording tetrahydrofuran (THF) adducts. Carbonyl ylides of 2,3-dimethylstilbene oxides formed through photoinduced ET conditions have also been trapped with dipolarophiles (1*a*).

Concurrent isomerization of the open radical cation cannot be excluded despite the fact that carbonyl ylides are intercepted. A case has been reported where the open radical cation of *trans*-stilbene oxide may be intercepted with an electron-rich dipolarophile, 2,5-dimethoxy-2,5-dihydrofuran, in an electron transfer reaction induced by singlet excited DCB (20). Evidence for recyclization of the open radical cation of this stilbene oxide followed by "back electron transfer" has been obtained from laser flash spectroscopy. Clearly the timing of the radical cation reduction, orbital topology, and the species responsible for recyclization (carbonyl ylide, zwitterions, or diradical) (21) remain to be clarified and may be a function of the system.

Substituents exert a marked influence on the ET photoinduced *cis–trans* isomerization of vicinal diaryl oxiranes bearing electron-withdrawing carbomethoxy and cyano groups at the 2 and 3 positions of the oxirane ring (1*c*, 22). The parent 2,3-dicarbomethoxy-2,3-diphenyl oxiranes fail to undergo ET photoinduced interconversion with DCN, unlike stilbene oxides (12) and 2,3-dimethylstilbene oxides (1*a*); however, the oxiranes that embody electron-donating 4-methyl and 4-methoxy substituents on the aromatic nuclei do isomerize upon ET sensitization with DCN. Clearly the presence of the electron-donating substituents on the *para* position of the phenyl rings alters the oxidation potential of these systems to a more favorable level for ET, as evidenced by fluorescence quenching rate studies conducted with DCN (22). Oxiranes bearing the better donor 4-methoxy substituents on the aromatic nuclei quench DCN flourescence 200 times as fast as the parent oxirane, *trans*-2,3-dicarbomethoxystilbene oxide, while only a 2.5 increase in the DCN quenching efficiency is observed with the 4-methyl substituted oxiranes. The cyano substituted oxiranes still proved unreactive even when substituted by methyl groups on the aryl rings; however, unexpectedly, *trans*-2,3-dicyano-2,3-bis(4-methoxyphenyl)-oxirane proved labile and decomposed to 4-methoxy benzoyl cyanide (22).

Despite the magnitude of the difference in quenching rates measured for the methoxy and methyl substituted oxiranes, isomerization still proceeds in both cases and we can only speculate on why isomerization of the parent oxirane becomes unfavorable. Perhaps, in the absence of the donor substituents, we reach a point where destabilization of the open radical cation by the α-carbomethoxy groups is sufficient to preclude C—C bond cleavage despite electron transfer to give a radical cation of the parent oxirane i.e., the relative oxidative potentials do not appear to be the controlling factor.

Aryl substituted cyclopropanes which undergo isomerization upon direct irradiation through a diradical-like intermediate also undergo photoinduced ET interconversions in the presence of 1-cyanonaphthalene (MCN) (13). Hixson *et al.* confirmed that an ET mechanism is implicated by observing the fluorescence quenching of MCN. Photo-CIDNP studies confirm that radical ions and 1,3-diradical species are produced in the ET process (23). As with the oxiranes, steric strain should provide additional driving force for the requisite C—C bond cleavage.

The DCN photoinduced ET isomerizations and opening of selected stilbene oxides (1, 12, 20, 22), as well as of vicinal diaryl substituted cyclopropanes (13), stimulated our interest in the potential cleavage of C—C bonds flanked by aryl substituents in other less complex systems such as substituted bibenzyls. The detailed results of our studies of substituted bibenzyls, as well as of several other systems incorporating similar structural elements, are described below.

Results and discussion

The selection of the activated bibenzyls, 1,2-bis(4-methoxyphenyl)ethane (**1***a*) and 1,2-bis(4-methylphenyl)ethane (**1***b*) as potential reactive candidates in ET reactions was predicated on our experience with diaryl oxiranes (1*a*) and the premise that a favorable decrease in oxidation potential of bibenzyl (**1***c*) should accompany the introduction of electron donor aryl substituents, i.e., CH_3O and CH_3 groups (Scheme 2). This expectation was validated by comparison of DCN singlet fluorescence quenching rates of **1***a* and **1***b* as determined by Stern–Volmer methods ($k_q = 1.7 \times 10^{10}\ M^{-1}\ s^{-1}$ and $1.3 \times 10^{10}\ M^{-1}\ s^{-1}$, respectively).[5,6] These values approach the dif-

[2]Cleavage in the gas phase, as in a mass spectrometer, gives the more highly delocalized diphenylmethyl carbonium ion; however, in solution, the more localized α-alkoxycarbocation is stabilized by solvation.

[3]The oxidation potentials of 2,2-diphenylethyl ethers are considerably lower than those of aliphatic ethers; however, they are essentially identical with that of 1,1-diphenylethane suggesting that the aromatic nuclei serve as the electron donor sites rather than the oxygen atom in the electron transfer process.

[4]It remains to be established if orbital topology plays a role in dictating the course of electrocyclic opening of such odd electron systems. In the absence of data to the contrary we are prejudiced (1*a*, 1*b*, 21*d*) in favor of the thermally more stable *exo–exo* isomer for the ring-opened stilbene oxides.

[5]Steady state fluorescence measurements were carried out using a photon counting spectrofluorimeter from SLM. The description of the apparatus is given in ref. 24.

[6]The measured fluorescence lifetime (τ_F) for DCN is 9.5 ns which is in agreement with the previously reported value 10.06 (19).

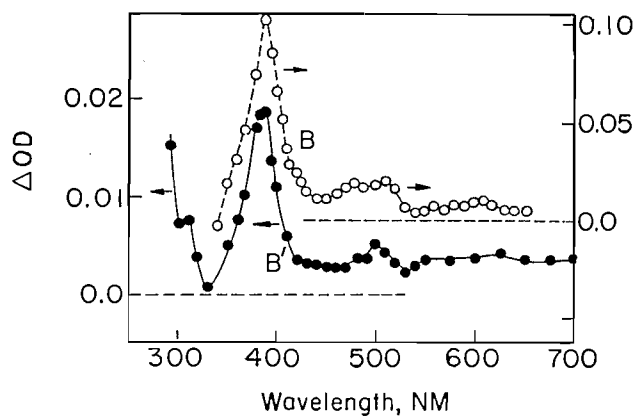

FIG. 1. B-$DCN^{\cdot-}$ observed by pulse radiolysis of DCN in 2-propanol. B'-$DCN^{\cdot-}$ observed by electron transfer from triethylamine to ^{1}DCN.

fusion controlled rate constant of 1.8×10^{10} M^{-1} s^{-1} for CH_3CN solutions at 20°C (19).

Time-resolved laser flash studies (the description of the flash photolysis set-up is given in ref. 25) were performed in CH_3CN (deoxygenated) to confirm that electron transfer mechanisms are responsible for DCN fluorescence quenching by **1***a* and **1***b* and to characterize, through spectral absorption techniques, those transients produced. The absorption spectrum of the transient radical anion ($DCN^{\cdot-}$) is characterized by a sharp intense spectral peak at 390 nm, observed upon near total quenching of excited singlet DCN in deoxygenated acetonitrile by ET from triethylamine and 1,2,4-trimethoxybenzene. Furthermore, pulse radiolysis (26) of DCN in 2-propanol gives rise to a transient having similar spectral features (Fig. 1).

Upon laser excitation of DCN in CH_3CN (deoxygenated), transient spectral phenomena are observed which consist of a strong band at 275 nm and a less intense broad absorption at 400–500 nm (maximum at 455 nm) attributed to DCN triplet–triplet transitions. A spectrum with a maximum at 455 nm is also observed upon DCN quenching of triplet benzophenone in CH_3CN.

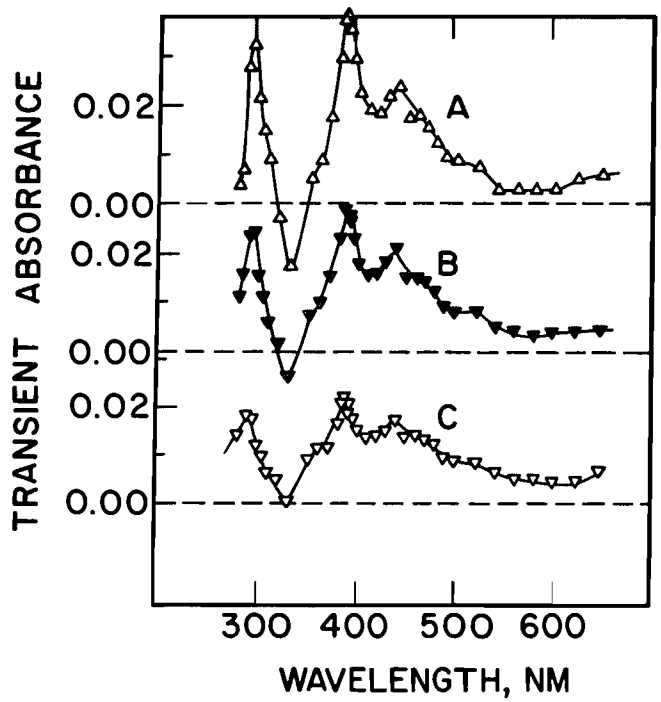

FIG. 2. Transient absorption spectra observed upon 337.1 nm laser flash photolysis of a deoxygenated acetonitrile solution of the bibenzyl **1***a* (12.4 m*M*) and DCN (0.25 m*M*) at approximately 0.4 (A), 1.4 (B), and 3.4 (C) μs following the laser flash.

The transient spectra obtained upon laser flash photolysis of bibenzyls **1***a* and **1***b* (and indeed of all the other substrates discussed later in this paper) in CH_3CN (deoxygenated) containing DCN display the well-defined band for $DCN^{\cdot-}$ (390 nm) in addition to bands at 295 nm and 400–500 nm assignable to ^{3}DCN and radical cations from **1***a* and **1***b* (Fig. 2), constituting clear evidence that ET occurs from **1***a* and **1***b* to excited DCN. Despite our efforts to increase the concentraton of the electron donor substrate to ensure that ET from ^{1}DCN competes effectively with intersystem crossing to its triplet, the $DCN^{\cdot-}$ spectrum is always accompanied by the broad absorption char-

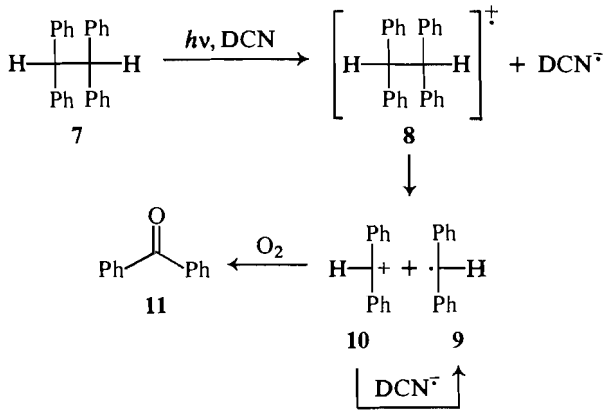
acteristic of ^{3}DCN, which may obscure spectral bands for other transients. Within our detection limits, no spectral characteristics of the benzylic radical **4***a*, anticipated as a fragmentation product of the radical cation **2***a*, are observed in the laser flash spectrum of **1***a*. This species, which absorbs at 310 nm, was generated independently by flash photolysis of di-*tert*-butyl peroxide in the presence of 4-methylanisole.

Crossover experiments were conducted in an attempt to discern if the radical cations **2** do in fact fragment to solvent-separated cations **3** and radicals **4** which, for reasons unknown at this time, escape spectroscopic detection. No crossover product, namely 4-methyl-4′-methoxy-1,2-diphenylethane (**1***d*), was detected by glc when an equimolar mixture of **1***a* and **1***b* in CH_3CN (deoxygenated) containing DCN was irradiated. Conversely, the bibenzyls **1***a* and **1***b* were not detected as products upon irradiation of an authentic sample of **1***d* under similar conditions, though the unsymmetrically substituted bibenzyl **1***d* quenches the fluorescence of DCN by electron transfer at near diffusion-controlled rates in acetonitrile (19) (k_q = $1.3 \times 10^{10}\ M^{-1}\ s^{-1}$) (24).

Products identified as aldehydes were formed in trace amounts upon steady state irradiation of CH_3CN solutions of **1***a–c* when samples were not deoxygenated carefully. In order to evaluate the potential significance of this observation, solutions of **1***a* and **1***b*, as well as **1***d*, respectively, in CH_3CN (oxygenated) containing DCN were irradiated for prolonged periods. Under these conditions, 4-anisaldehyde (**6***a*) (83%) and 4-tolualdehyde (**6***b*) (58%) are obtained (Scheme 2). In contrast, only a trace of benzaldehyde (**6***c*) is produced from bibenzyl (**1***c*) under similar conditions. This affirms the significance of the relative efficiency of the initial ET step to form the radical cations **2** derived from **1***a*, **1***b*, and **1***d*, respectively, as well as of enhanced stabilization of the transition state leading to fragment cations **3** and radicals **4** for the compounds with electron-donating substituents on the aryl rings.

Oxygen may play a dual role in the oxidative conversions of **1***a*, **1***b*, and **1***d* to the corresponding aldehydes **6***a*, **6***b*. It is known that 9,10-dicyanoanthracene (DCA) radical anion is capable of reducing ground state oxygen to superoxide anion ($O_2^{\cdot-}$) in a reaction which is exothermic (−6.9 kcal/mol), while the corresponding reaction for $DCN^{\cdot-}$ is more exothermic (−17.6 kcal/mol).[7] Ground state oxygen may act as an electron sink by accepting an electron from $DCN^{\cdot-}$, thus suppressing "back electron transfer" to the initial radical cation, which then enjoys an extended lifetime and enhanced opportunity for cleavage. Our experiments show a decrease in lifetime for $DCN^{\cdot-}$ upon flash photolysis of **1***a*, **1***b*, and **1***d* in CH_3CN (air saturated) relative to that observed under deoxygenated conditions. Oxygen in its ground or excited singlet state and/or superoxide also may be responsible for intercepting the fragments produced; however, a discussion of the oxidation process at this time would be premature and speculative.

Our studies were then expanded to include 2,3-dimethyl-2,3-diphenylbutane (**1***e*) in an effort to ensure that the oxidation products generated from **1***a*, **1***b*, and **1***d* do not arise in whole or in part by oxidation of stilbenes (11*b*, *h*) produced initially from the bibenzyls **1**. Continuous irradiation of **1***e* CH_3CN (oxygenated) containing DCN affords acetophenone (**6***e*) (60%) (Scheme 2). Despite the moderate conversion level observed and incomplete product identification, the results confirm that photooxidative cleavage of 1,2-diphenylethanes may occur even in the absence of benzylic hydrogens; this precludes an oxidation mechanism involving initial formation and subsequent cleavage of isomeric stilbenes by $O_2^{\cdot-}$.



SCHEME 3

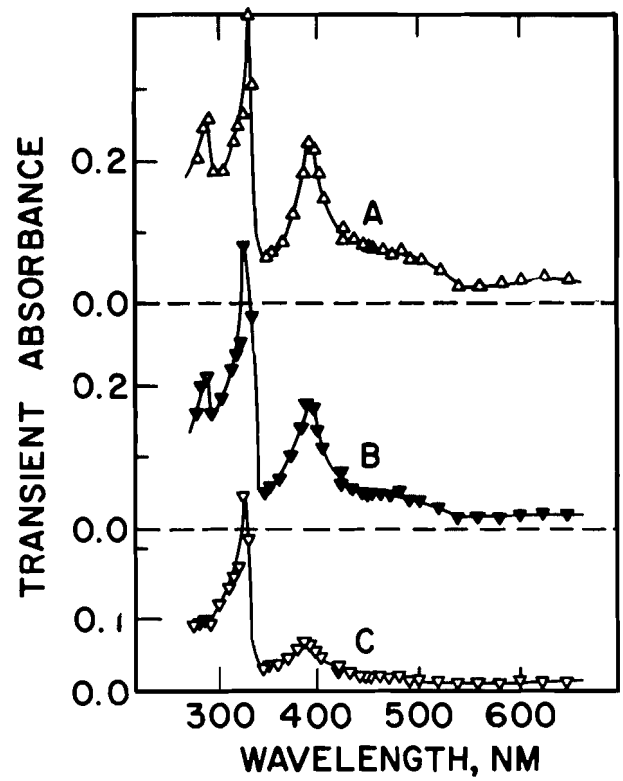


FIG. 3. Transient absorption spectra observed upon 337.1 nm laser flash photolysis of a deoxygenated acetonitrile solution of **7** (22.9 m*M*) and DCN (0.25 m*M*). A: end-of-pulse; B: 0.4 μs; and C: 3.4 μs (following laser flash).

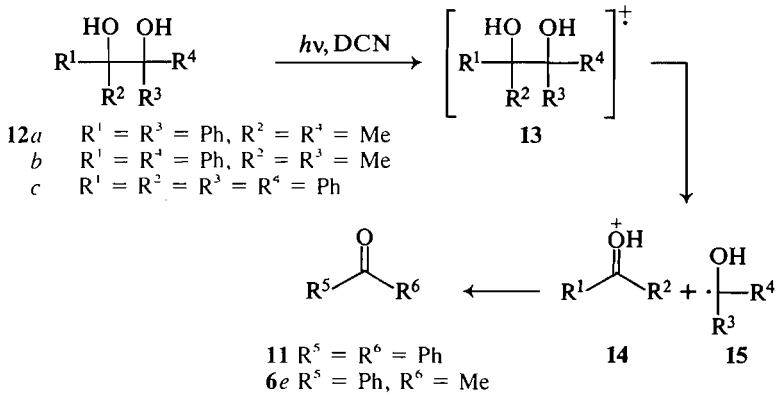
The transient phenomena induced upon laser flash photolysis (25) of 1,1,2,2,-tetraphenylethane (**7**) (Scheme 3) proved more informative than those observed for the bibenzyl systems **1**. Singlet quenching of DCN by **7** occurs with a rate constant of $k_q = 1.0 \times 10^{10}\ M^{-1}\ s^{-1}$. In addition to the transient absorption bands for ^{3}DCN and $DCN^{\cdot-}$; an intense band at 330 nm, which is attributed to benzhydryl radical **9**, is observed in the laser flash spectrum of **7** obtained in CH_3CN (deoxygenated) containing DCN (Fig. 3). Laser flash studies of diphenylmethane

[7]The reversible reduction potential for DCA in acetonitrile vs. SCE is −0.87 V (ref. 27). The reduction potential of DCN is −1.67 V (19) in CH_3CN vs. Ag/0.1 *M* $AgNO_3$. Reduction potential for oxygen $E^0_{1/2}$ = −0.57 V vs. SCE in water (11*b*).



SCHEME 4

in benzene containing di-*tert*-butylperoxide affords benzhydryl radical **9**, the absorption spectrum of which corresponds to that of the transient generated from **7**. Our success in observing the benzhydryl radical **9** derived from **7** by laser flash spectroscopy, when we failed to detect the benzylic radicals **4** under similar conditions, may be ascribed to enhanced stabilization of the incipient benzhydryl cation **10** and radical **9** centers in the transition state leading to fragmentation of the radical cation **8**. It remains to be established if the benzhydryl cation **10** and/or the radical **9** derived from **7** contributes to absorption in the region of 400–500 nm. Experiments are in progress to determine if efficient electron transfer from $DCN^{\cdot-}$ to cation **10** to form the radical **9** may account for our inability to observe an absorption band for the cation **10** in the absence of oxygen and for possible augmentation of the spectral band assigned to **9** (330 nm) (Fig. 3).

The steady-state irradiation of **7** in CH_3CN (oxygenated) containing DCN gives benzophenones (**11**) (41%) (Scheme 3). While many mechanisms may be envisioned for the conversion of benzhydryl radical **9** and cumyl radical **4***e* and/or their respective cations to benzophenone (**11**) and acetophenone (**6***e*) respectively, with active oxygen ($^3O_2$, $^1O_2$, $O_2^{\cdot-}$), no attempt has yet been made to determine which species is or are implicated in this oxidations. Obviously, elimination of two methyl groups must accompany oxidation leading to **6***e*, and the absence of detectable cumyl hydroperoxide or dicumyl peroxide as products suggests that ET-induced decomposition may be implicated in the homolysis of hydroperoxy and/or peroxy intermediates to oxy radicals such as **5***e*, i.e., the conversion of hydroperoxy or peroxy intermediates to products must be efficient (28).

Pinacols and pinacol ethers derived from aryl ketones constitute another class of readily available compounds which incorporate the Ar—C—C—Ar bond sequence. Steady-state irradiation of samples of the racemic and *meso* pinacols **12***a* and **12***b*, respectively, in CH_3CN (deoxygenated) containing DCN gives acetophenone (**6***e*) (Scheme 4) in moderate yields (65%) which increase to 81% when the CH_3CN is saturated with oxygen. The conversion proceeds through initial formation of the radical cation **13**, followed by fragmentation to give the cation **14** and ketyl radical **15**, observed upon laser flash photolysis by its characteristic absorption band at 275 nm. Acetophenone (**6***e*) could be derived from either **14** (by deprotonation) or **15** (by loss of a hydrogen atom) (29).

When benzopinacol (**12***c*) is irradiated under conditions identical to those employed with the pinacols **12***a* and **12***b* in deoxygenated and oxygenated CH_3CN, benzophenone (**11**) is produced in high yields (72% and 100%, respectively) (Scheme 4). All of the pinacols are converted more efficiently to ketone when oxygen is present, conceivably because ET from $DCN^{\cdot-}$ to oxygen occurs to give superoxide anion, a less efficient donor to the radical cation **13**, prolonging its lifetime while increasing the opportunity to fragment. Not surprisingly, no silver chloride precipitate was observed under these conditions. Finally, fragmentation does not occur upon irradiation of CH_3CN solutions of **12***c* for prolonged periods in the absence of DCN.

In an attempt to define the mechanism of this pinacol cleavage we investigated a series of *O*-methyl substituted derivatives to assess the effect of such groups on the fragmentation process. Racemic acetophenone pinacol dimethyl ether **16** undergoes cleavage to acetophenone (**6***e*) (53%) and epimerization to the *meso* isomer **17** (16%) upon irradiation in CH_3CN (deoxygenated) containing DCN (Scheme 5). Control experiments confirm that **16** is photostable upon irradiation in the absence of the electron acceptor DCN under otherwise identical conditions. It is reasonable to assume that the epimerization of the pinacol dimethyl ether **16** occurs through initial fragmentation of the radical cation **18** to cation **19** and radical **20** which recombine Re, Si (or Si, Re) (30) prior (Path a) or subsequent (Path b) to reduction. Acetophenone (**6***e*) formation competes effectively with recombination and may arise by loss of methyl radicals from **20** if electron transfer precedes β-scission of a methyl cation, a process not without precedent for α-methoxy radicals of type **20** (31). Conversely, fragmentation may intercede and **19** may give methyl cation and acetophenone (**6***e*) directly. In order to discern whether an energy transfer mechanism from triplet acetophenone (**6***e*) initiates cleavage and epimerization in these systems, samples of **16** were irradiated in CH_3CN (deoxygenated) containing acetophenone (**6***e*), and, in the absence of DCN, no cleavage or epimerization is observed. Thus a triplet excited state mechanism may be discounted for the conversions observed with **16** and **17**.

Acetophenone (**6***e*) (80%) is the sole product formed when the *meso* isomer **17** is irradiated under conditions similar to those employed with **16** (Scheme 5). In contrast to **16**, however, solubility problems in CH_3CN were encountered with **17** and it was necessary to stir the mixture throughout the course of the irradiation and to extend the time period ten-fold in order to achieve conversion of **17** to **6***e* at levels commensurate with that observed with **16**.

We attribute the absence of racemization upon photoinduced fragmentation of **17** to the greater steric encumbrance of the

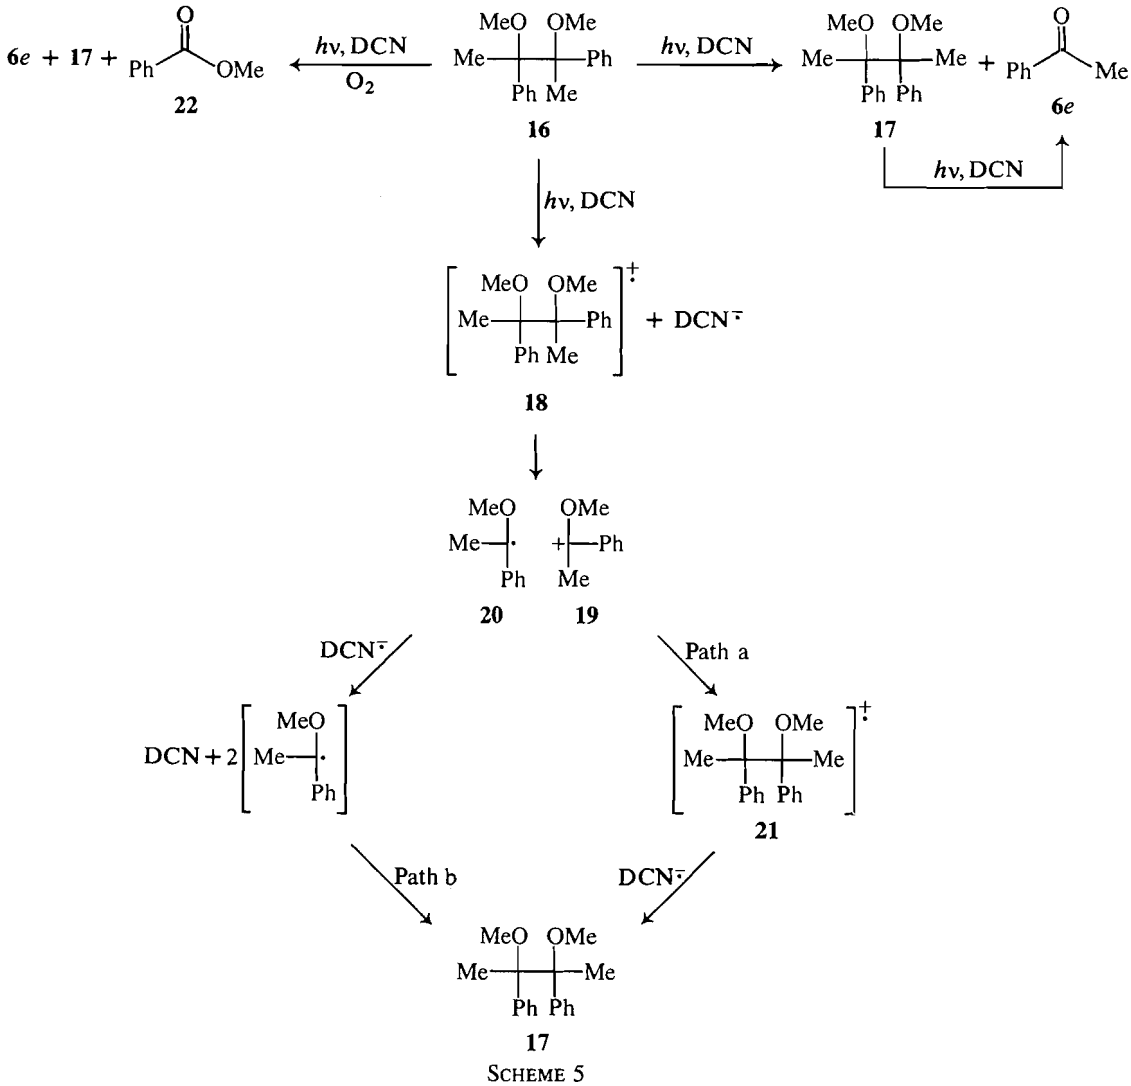

SCHEME 5

transition state for the requisite recombination, to give racemic pinacol dimethyl ether **16** regardless of the specific mechanism of inversion (Path a and/or Path b), than that leading to *meso* pinacol dimethyl ether **17**. *meso* Acetophenone pinacol **12***b* is formed preferentially upon peroxide-induced thermal pinacolization of acetophenone (**6***e*) (32), which validates this conclusion. Furthermore, the *meso* pinacol dimethyl ether **17** is formed to the exclusion of the racemic modification **16** upon free radical induced coupling of methyl α-phenethyl ether (33).

Oxidative cleavage to methyl benzoate (**22**) competes with fragmentation to acetophenone (**6***e*) in the case of the racemic and *meso* diastereomeric acetophenone pinacol dimethyl ethers **16** and **17**, respectively, when irradiated in CH_3CN (oxygenated) containing DCN (Scheme 5). The conversion to acetophenone (**6***e*) and methyl benzoate (**22**) appears more efficient with **16** (95% total conversion) than with the *meso* counterpart **17** (78% total conversion). Control experiments with oxygen and DCN in CH_3CN were performed in order to ensure that methyl benzoate (**22**) is not a secondary oxidation product formed from acetophenone (**6***e*) and $O_2^{\cdot-}$. That an ET mechanism is operate in these conversions was demonstrated in control experiments by irradiating CH_3CN solutions (oxygenated) of both **16** and **17** in the absence of DCN. No detectable epimerization or oxidative cleavage is observed under these control conditions.

4-Tolualdehyde (**6***b*) is formed under photoinduced ET conditions in the absence of oxygen in CH_3CN containing DCN and *meso*-1,2-bis(4-methylphenyl)-1,2-dimethoxyethane (**23**) (Scheme 6). A second product, namely methyl 4-toluate (**24**) (55%) is formed in addition to 4-tolualdehyde (**6***b*, 35%) when **22** is irradiated in the presence of oxygen. We presume that the ester **24** is formed through interception of the α-methoxy benzyl cation **25** and radical **26** (Scheme 6) by triplet ground state oxygen or perhaps an activated state ($^1O_2$ or $O_2^{\cdot-}$).

The behavior observed for the benzopinacol dimethyl ether **27** when subjected to photoinduced ET cleavage under deoxygenated conditions parallels that observed for benzopinacol (**12***c*) and *meso* acetophenone pinacol dimethyl ether (**17**) and the sole product isolated is benzophenone (**11**) (34%) (Scheme 7). Extensive quantities of intractable product(s) were formed and the amount of starting material **27** recovered was high (33%). It is interesting that no ester is detected when **27** is irradiated under oxygenated conditions, though more benzophenone (**11**) is formed (54%). This reaction also gives intractable product(s), less starting material is recovered, and the material balance is low. When **27** is thermolyzed (34) in the presence of oxygen, methyl benzoate (**22**) is formed by way of α-methoxybenzhydryl radicals **28**, characterized by esr spectroscopy. No methyl benzoate (**22**) is formed from **27** under ET conditions. We infer from these data that β-scission competes

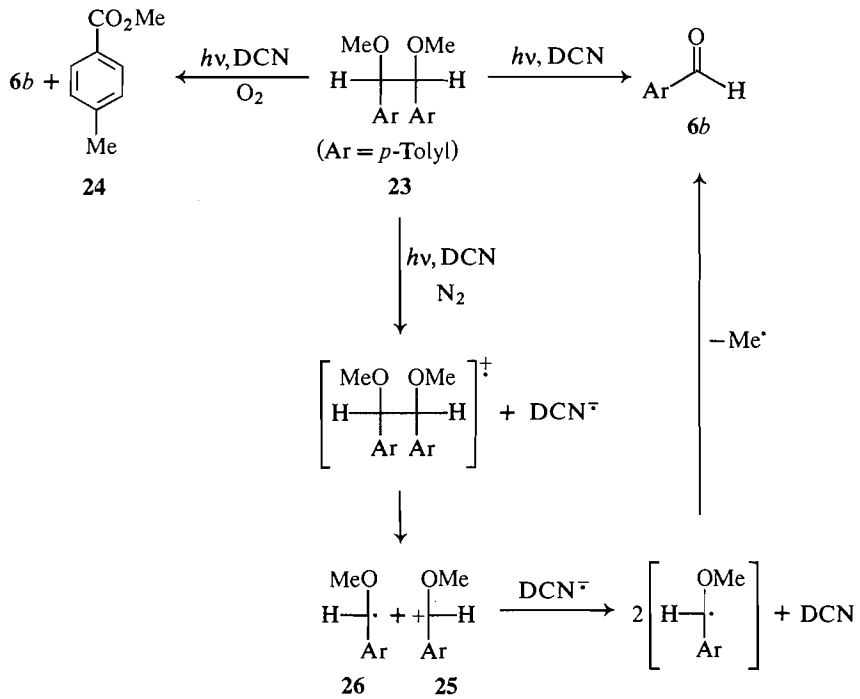
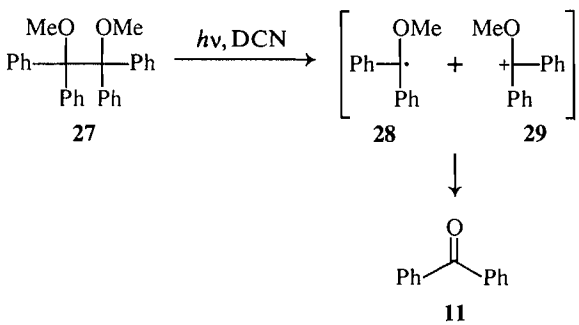
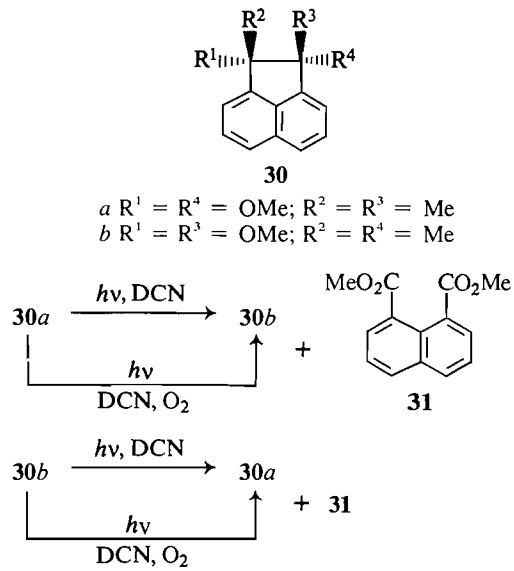


SCHEME 6



SCHEME 7



SCHEME 8

favorably with oxidation of the α-methoxy benzhydryl radical **28**. No products are found in control experiments when a deoxygenated CH_3CN solution of **27** is irradiated in the absence of DCN; however, benzophenone (**11**) is formed in CH_3CN (oxygen saturated). Perhaps the conversion of **27** in an oxygen atmosphere occurs through an electron transfer mechanism in which radical cations of **27** are generated through photoexcitation of a charge transfer (CT) complex between oxygen and the pinacol dimethyl ether **27**. Tokumaru and co-workers (35) have reported that the photooxidation of hexamethylbenzene and the dimerization of 4-methoxystyrene to cyclobutane dimers proceeds through a radical cation mechanism in which oxygen behaves as the electron acceptor in a polar solvent.

The presence of the *meso* isomer **17** among the ET-induced oxidation products of racemic acetophenone pinacol dimethyl ether **16** indicates that cation and radical or radical recombination competes with oxidation. How effectively remains to be determined. This observation led us to study the cyclic acenaphthene pinacol dimethyl ethers **30***a* and **30***b* (Scheme 8) which are constrained in such a manner as to enhance recombination of the cation and radical and/or radical centers with the objective of decreasing the efficiency of β-scission, loss of methyl cation, and addition of oxygen, while enhancing epimerization. Irradiation of *meso*-1,2-dimethyl-1,2-dimethoxyacenaphthene (**30***a*) in CH_3CN (deoxygenated) containing DCN affords the racemic modification **30***b* (23%). It is significant that no diketone is produced and the material balance is high (91%). Less dramatic results are obtained with the corresponding racemic pinacol dimethyl ether **30***b* where recyclization via an open radical cation or diradical mechanism to form the *meso* isomer **30***a* (7.4%) is sterically less favorable than recyclization to the enantiomeric pair **30***b*. The *meso* isomer **30***a* is photostable upon irradiation in the absence of DCN; however, the racemic substrate **30***b* undergoes limited epimerization to **30***a* (2.5%). This is undoubtably due to direct absorption of radiation by **30***b* which incorporates an acenapthene moiety (36).

Dramatically different results are observed when the di-

methyl acenaphthene pinacol dimethyl ethers **30***a* and **30***b* are irradiated in the presence of DCN in CH_3CN (oxygen saturated) (Scheme 8). Under these conditions substantial amounts of dimethyl 1,8-naphthalate (**31**) are obtained (30% and 16%, respectively). The presence of this oxidation product **31** attests to the fact that interception of the open radical cation by ground state oxygen or an activated form ($^1O_2$ or $O_2^{\cdot-}$) competes with β-scission, recyclization, and, conceivably, reduction of the radical cation by "back electron transfer". An open diradical cannot be excluded as a viable mechanistic alternative responsible for the observed results if "back electron transfer" is competitive with recyclization.

The conversion levels of **30***a* and **30***b* (37% and 62%, respectively) to the alternate isomer and diester **31** in each case are higher with the more sterically strained *meso* isomer **30***a*. These results are comparable to those obtained with the open chain acetophenone pinacol dimethyl ethers **16** and **17** (Scheme 5) where the racemic form constitutes the sterically less favorable substrate in this case.

It is noteworthy that oxygen should exert such a marked influence on the ET-sensitized isomerization and oxidation of the *meso* isomer **30***a*. The course of this reaction was monitored by thin-layer chromatography and the isomerization to **30***b* (46%) maximized, i.e., the extent of epimerization is enhanced by a factor of two when the CH_3CN is saturated with oxygen rather than nitrogen. Furthermore, no such enhancement is observed upon irradiation of the enantiomeric pair **30***b* under similar conditions, even when the irradiation period is extended. The mechanism by which oxygen enhances epimerization of *meso* diether **30***a* to **30***b* is of great interest. Conceivably, superoxide anion, a less efficient electron donor, is formed when oxygen is present, which intercepts the electron transferred from $DCN^{\cdot-}$, delaying its return to the radical cation, and thus exerts a favorable influence on the extent of the isomerization process by extending the radical cation lifetime (11*j*).

A control experiment was run with the *meso* isomer **30***a* in CH_3CN (oxygen saturated) in the absence of DCN, and limited epimerization (9%) was observed upon irradiation. In the case of the racemic modification, however, the extent of isomerization is equivalent to that observed with DCN present, and some diester **31** (6.7%) is also formed. Presumably cleavage, isomerization, and oxidation here are due to direct absorption and reaction through the singlet and/or triplet state. It is noteworthy, however, that irradiation of the *meso* pinacol dimethyl ether **30***a* in deoxygenated acetonitrile in the absence of DCN with added benzophenone (**11**) (in polar solvents E_T = 69.2 kcal/mol) (37, 38) induced only 8.2% isomerization to the racemic modification **30***b*. Thus a triplet mechanism cannot explain the more extensive isomerization observed with DCN, although the irradiation time was longer in the latter case. Certainly, triplet sensitization of the isomerization of **30***a* to **30***b* by DCN may be excluded on the basis of relative triplet energies, i.e., the DCN triplet energy (E_T = 55.5 kcal/mol) (19) is lower than that estimated for **30***a* (59.2 kcal/mol) (38, 39), based on the parent hydrocarbon acenaphthene. Intersystem crossing then provides the only mechanism for populating the triplet manifold of **30***a* and, while this is a relatively efficient process (Φ_{ISC} = 0.45−0.58 for acenapthene) (37, 40, 41), the triplet state cannot be implicated in the isomerization of **30***a* to **30***b*, based on the negative results obtained with benzophenone as a sensitizer.

rac-9,10-Dimethoxy-9,10-dimethyl-9,10-dihydrophenanthrene (**32**), another cyclic pinacol dimethyl ether, was irradiated in acetonitrile containing DCN under conditions analogous to those employed with the acenaphthene counterparts **30***a* and **30***b*. In a nitrogen atmosphere, **32** is converted in low yield (9%) to the *meso* epimer **33** and 84% of the precursor **32** was recovered (eq. [1]). We attribute the low conversion levels achieved, once again, to unfavorable thermodynamic factors, i.e., recyclization of the open radical cation (or diradical) to the *meso* radical ion corresponding to **33** is sterically less favorable than recyclization of the original enantiomeric radical cations of **32**. In CH_3CN (oxygenated) the conversion of **32** to **33** is enhanced to 24% upon irradiation in the presence of DCN and over half the substrate **32** (56%) is recovered. The effect of oxygen is thus general in all of the examples presented. It remains to be established whether the postulate of electron relay from DCN radical anion to oxygen, forming superoxide anion to explain the extended lifetime of the radical cation, is correct. Oxidation products, in particular the diester, are conspicuously absent in this case, a result which may be due to more rapid recyclization. Experimental difficulties were encountered with the preparation of the *meso* isomer **33** which precluded studies in this case. Control experiments with **32** under deoxygenated conditions revealed no isomerization; however, in oxygenated acetonitrile in the absence of DCN, 21% of **33** was observed, which is nearly equivalent to that achieved with DCN present, probably as a result of absorption by the 9,10-dihydrophenanthrene chromophore (42). The diether **32** was irradiated in the presence of benzophenone (**11**) in acetonitrile under similar deoxygenated conditions and detectable isomerization was observed. It is unlikely, however, that ^{3}DCN can transfer energy to **32** in view of the magnitude of its triplet energy (E_T = 55.5 kcal/mol) (19).

[1] 
32 **33**

On the basis of the foregoing data it should be possible to design unsymmetrical reactive substrates which, like the substituted bibenzyl systems described above, would undergo facile fragmentation of the corresponding radical cations generated by photoinduced electron transfer reactions to give cations and free radicals.

Our initial endeavors in this area were devoted to a study of substrates incorporating the pyrazolinone nuclei in which a radical center at C-4 displays marked stability as a consequence of merostabilization (also known as captodative and push−pull stabilization) (43). The pyrazolinone nucleus should impart fragmentation lability to radical cations embodying this moiety coupled to a substituent capable of manifesting independent existence as a cationic species.

1-Phenyl-3-methyl-4-benzhydryl-2-pyrazolin-5-one (**34**) was selected as the initial member of these series to be evaluated. Upon irradiation of **34** in CH_3CN (oxygen saturated) containing DCN, 1-phenyl-3-methyl-2-pyrazolin-4,5-dione (**35**) (27%)

[2] 
34 **35**

(44) and benzophenone (**11**) (41%) are produced (eq. [2]). The oxidative cleavage of **34** to the dione **35** and benzophenone (**11**) under electron transfer conditions is consistent with the results obtained with 1,1,2,2-tetraphenylethane (**7**) in which benzhydryl radical **9**, identified by laser flash spectroscopy, and benzhydryl cation **10**, are presumably oxidized to benzophenone (**11**) under similar conditions. On the basis of this experiment it is clear that a host of other substituted pyrazolinone and related heterocyclic systems will also cleave in a similar fashion when converted to their respective radical cations by electron transfer process.

Experimental

The 60 MHz proton magnetic resonance spectra were obtained on a Varian A-60, Hitachi Perkin–Elmer R-20B, or a Varian EM-360A spectrometer with 1% tetramethylsilane as an internal standard. Mass spectra were recorded on a Hitachi Perkin–Elmer RMU-6E spectrometer. Infrared spectra were determined using either a Perkin–Elmer 257 or 735B instrument. All melting point determinations were performed using a Thomas–Hoover capillary melting point apparatus and are uncorrected.

Silica Gel G (PF 254; Brinkman Co.) coated on glass plates was used for all preparative thick-layer chromatographic separations. Eastman Chromagram sheets (silica gel) were employed in analytical thin-layer applications. Visualization of resolved bands was achieved utilizing short-wavelength ultraviolet lamps (Black–Ray UVL-21). Preparative gas chromatographic separations were accomplished using a Varian Aerograph Model 90P gas chromatograph equipped with a 10 ft × 0.25 in. SE-30 (30% on Chromosorb P) column. All elemental combustion analyses were performed by Galbraith Laboratories, Inc., (Knoxville, TN) and were found to be within acceptable limits.

Acetonitrile (Bardick and Jackson Spectro Grade), the solvent of choice for all electron transfer sensitization experiments conducted, was dried over activated silica gel, then distilled from P_2O_5 in an atmosphere of dry nitrogen. Other anhydrous solvents, when required, were purified and dried just prior to use by standard procedures (45). 1,4-Dicyanonaphthalene was prepared by heating 1,4-dibromonaphthalene (Eastman) with cuprous cyanide and pyridine according to a modification of the procedure described for the conversion of 1-bromonaphthalene to the corresponding α-naphthonitrile and purified by column chromatography on neutral alumina followed by recrystallization from toluene (46). The results of the photoinduced electron transfer cleavage reactions are described in Table 1.

*Preparation of 1,2-bis(4-methoxyphenyl)ethane (**1**a)*

The substituted bibenzyl **1***a* was prepared from 4-methoxybenzyl bromide (47) (from 4-methylanisole and *N*-bromosuccinimide) by the general method of Trahanovsky and Brixius (48) or by a reduction of 4,4′-dimethoxy stilbene (Aldrich); mp 122–123°C (ethanol, lit (48) mp 125–126°C).

*Preparation of 1,2-bis(4-methylphenyl)ethane (**1**b)*

The Grignard coupling method described above for the preparation of **1***a* was used to convert 0.64 g (2.7 mmol) of 4-methylbenzyl bromide (Aldrich) to the hydrocarbon **1***b*, 1.2 g (21%); mp 81–82°C (ethanol, lit. (48) mp 83–84°C).

*Preparation of 1-(4-methylphenyl)-2-(4-methoxyphenyl)ethane (**1**d)*

trans-4-Methyl-4′-methoxy stilbene (49) (prepared from the Wittig reaction of 4-methylbenzyltriphenylphosphonium bromide (50) with 4-anisaldehyde in the presence of lithium ethoxide) was hydrogenated (H_2, 45 psi, 10% Pd/C) in ethanol. After removal of the volatile solvents under reduced pressure, the residual solid was recrystallized from ethanol to afford 0.38 g (63%) of the desired 1,2-diphenylethane **1***d*: mp 63–64°C ir (Nujol): 1610 (s), 1510 (s), 1380 (s), 1300 (s), 1250 (s), 1178 (s), 1038 (m), 830 (m), 820 (s) cm^{-1}; nmr ($CDCl_3$) δ: 2.28 (s, 3H, CH_3), 2.81 (s, 4H), 3.77 (s, 3H, OCH_3), 7.05 (m, ArH). *Anal.* calcd. for $C_{16}H_{18}O$: C 84.91, H 8.02; found: C 85.09, H 8.14.

*Preparation of 2,3-dimethyl-2,3-diphenylbutane (**1**e)*

To a mixture of 6.8 g of sodium hydroxide, 100 mL of bleach, and 5 drops of the phase transfer agent Aliquot 336 in 100 mL of hexane was added 2.0 g (6.00 mmol) of *N*,*N*′-bis(1-methyl-1-phenylethyl)sulfamide (51). The mixture was allowed to stir at room temperature for a period of 72 h. The resulting hexane solution was washed in turn with water, 5% hydrochloric acid, 5% sodium bicarbonate, and finally water, and then dried over magnesium sulfate. The solvent was removed under reduced presure at room temperature and the remaining solid was added to 50 mL of toluene and subsequently heated at the reflux temperatue for 24 h. Toluene was removed under reduced pressure and the residue was recrystallized from 95% ethanol to provide 1.3 g (46%) of **1***e*: mp 120–121°C (lit. (52) mp 115°C).

Preparation of rac- *and* meso-*2,3-dimethoxy-2,3-diphenylbutane (**16** and **17**, respectively)*

The methylation procedure of Gillis (53) was used for the conversion of the corresponding pinacols *rac*- and *meso*-2,3-butanediols, **12***a* and **12***b*, to the diethers **16** and **17**, respectively. The corresponding racemic or *meso* pinacol (54) (500 mg, 2.1 mmol) was added to a finely powdered suspension of sodium hydroxide (0.67 g, 18 mmol) in 15 mL of DMSO. Methyl iodide (1.2 g, 8.2 mmol) was then introduced and the resulting mixture was stirred at room temperature for 30 min and then quenched with 10 mL of water. The desired product was extracted using three 10-mL portions of chloroform and the combined organic extracts were washed twice with water and then dried over magnesium sulfate. Removal of the solvent under reduced pressure and recystallization of the residue from methanol afforded white crystals of the desired diol dimethyl ether **16** or **17**. Racemic diol dimethyl ether **16**: mp 111.0–111.5°C (0.46 g, 80%); ir (KBr): 3050 (m), 3010 (m), 2970 (s), 2930 (m), 2830 (s), 1440 (w), 1360 (m), 1140 (s), 1090 (s), 1150 (s), 880 (s), 800 (s), 760 (s), 710 (s) cm^{-1}; nmr ($CDCl_3$) δ: 1.65 (s, 6H, CH_3), 3.10 (s, 6H, OCH_3), 6.73–7.28 (m, 10H, ArH); mass spectrum, *m/e*: 135 ($M^+ - C_9H_{11}O$), 105 ($M^+ - C_9H_{11}O - CH_2O$), 77, 43, 51. *Anal.* calcd. for $C_{18}H_{22}O_2$: C 79.96, H 8.20; found: C 79.95, H 8.03. *meso* Diol dimethyl ether **17**: mp 164–166°C (377 mg, 67%) (lit. (55) mp 171–173°C); nmr ($CDCl_3$) δ: 1.43 (s, 6H, CH_3), 3.01 (s, 6H, OCH_3), 7.25 (s, 10H, ArH).

Preparation of meso-*1,2-bis(4-dimethylphenyl)-1,2-dimethoxyethane (**23**)*

The procedure for methylation devised by Gillis (53) was used to convert 1,2-bis(4-methylphenyl)-1,2-dihydroxyethane (56) to the diether **23**. To a finely powered suspension of sodium hydroxide (0.32 g, 8.0 mmol) in 15 mL of dimethyl sulfoxide was added the pinacol (0.24 g, 1.0 mmol), followed by methyl iodide (0.57 g, 4.0 mmol). The resulting reaction mixture was allowed to stir for 30 min and then 10 mL of water were added. The combined chloroform extracts were washed twice with water and dried over magnesium sulfate. Removal of the solvent under reduced pressure and recystallization of the residue from ligroin afforded 0.23 g (85%) of the diether **23** in the form of white crystals: mp 126–128°C; ir ($CHCl_3$): 2990 (m), 2940 (m), 2830 (s), 1515 (s), 1455 (m), 1100 (w), 830 (m) cm^{-1}; nmr ($CDCl_3$) δ: 7.09 (s, 8H, ArH), 4.23 (s, 2H), 3.12 (s, 6H, OCH_3), 2.32 (s, 6H, CH_3). *Anal.* calcd. for $C_{18}H_{22}O_2$: C 79.96, H 8.20; found: C 80.17, H 8.29.

*Preparation of 1,2-dimethoxy-1,1,2,2-tetraphenylethane (**27**)*

This pinacol dimethyl ether was prepared in an indirect manner by free radical induced coupling of diphenylmethyl methyl ether according to the procedure described by Hartzell and Huyser (33). In our hands, this conversion gave an overall yield of 5.2% based on benzhydrol: mp 155–158°C (lit. (57) mp 157–159°C).

Preparation of meso- *and* rac-*1,2-dimethoxy-1,2-dimethylacenaphthene (**30**a and **30**b, respectively)*

The method of Gillis (53) was employed for the methylation of the isomeric 1,2-dimethylacenaphthane-1,2-diols (58). To a fine suspension of sodium hydroxide (0.74 g, 19 mmol) in 15 mL of dimethyl sulfoxide was added the diol (0.56 g, 2.3 mmol) and then methyl iodide (1.3 g, 9.2 mmol). The mixture was then stirred for 30 min and

					35 (27%)	tlc (chloroform)

*Difficulty was encountered in separating the racemic and *meso* diethers **16** and **17** and analyses of mixtures of these substrates were achieved by integration of the resolvable methyl protons of the mixture of the isomeric pair.

†Reference 60.

‡Compound **33** was characterized by the following spectral data: ir ($CHCl_3$(; 2980 (m), 2930 (m), 2810 (m), 2730 (m), 1450 (m), 1360 (m), 1220 (m), 1200 (m), 1110 (s), 1060 (s), 1040 (s), 850 (s), 800 (s), 760 (s), 750 (s) cm^{-1}; nmr ($CDCl_3$) δ: 1.40 (s, 6H, CH_3), 3.15 (s, 6H, OCH_3), 7.18–7.33, 7.63–7.80 (m, 8H, ArH); mass spectrum, *m/e*: 268 (M^+), 253 ($M^+ - CH_3$), 209, 197.

quenched with 10 mL of water. The desired products in each case were extracted using three 10-mL portions of chloroform. The combined organic extracts were washed with water, dried over magnesium sulfate, and concentrated by removal of the solvent under reduced pressure. The *meso* diol dimethyl ether **30***a* was separated on a silica gel column using 1:1 hexane–chloroform as the eluent to give a very light yellow oil (0.36 g, 64%) which was not induced to crystallize. The racemic diol dimethyl ether **30***b* was recrystallized from hexane to give 0.27 g (48%) of white crystals; mp 107–108°C (102–103°C, MeOH). *meso* Diol dimethyl ether **30***a*: ir (neat): 2950 (m), 2800 (s), 1430 (s), 1360 (m), 1260 (m), 1200 (m), 1100 (m), 880 (s), 830 (s), 780 (s), 760 (s) cm^{-1}; nmr ($CDCl_3$) δ: 1.63 (s, 6H, CH_3), 3.3 (s, 6H, OCH_3), 7.20–7.75 (m, 6H, ArH); mass spectrum, *m/e*: 242 (M^+), 227 ($M^+ - CH_3$), 195 ($M^+ - CH_3 - CH_2O$), 165, 162. Racemic dimethyl ether **30***b*: ir (KBr): 2930 (m), 2830 (s), 2730 (m), 1450 (w), 1360 (m), 1250 (w), 1200 (m), 1110 (w), 1040 (m), 860 (s), 840 (s),

For personal use only.

800 (s) cm^{-1}; nmr ($CDCl_3$) δ: 1.70 (s, 6H, CH_3), 2.90 (s, 6H, OCH_3), 7.35−7.80 (m, 6H, ArH); mass spectrum, as for **30***a*. *Anal.* calcd. for $C_{16}H_{18}O_2$: C 79.31, H 7.49; found: C 79.12, H 7.36.

Preparation of rac-*9,10-dimethoxy-9,10-dimethyl-9,10-dihydrophenanthrene (32)*

rac-9,10-Dihydroxy-9,10-dimethyl-9,10-dihydrophenanthrene (59) (1.0 g, 4.2 mmol) was added to a suspension of finely divided sodium hydroxide (1.3 g, 33 mmol) in a 15 mL of dimethyl sulfoxide and then methyl iodide (2.3 g, 16.2 mmol) was introduced (53). The resulting mixture was stirred at room temperature for 30 min and quenched with 10 mL of water. The resulting slurry was extracted using three 10-mL portions of chloroform and the combined organic extracts were washed twice with water and dried over magnesium sulfate. Removal of the solvent under reduced pressure and recrystallization of the residue from hexane afforded 0.44 g (40%) of **32**: mp 110−114°C; ir (KBr): 2980 (m), 2930 (s), 2810 (m), 2730 (m), 1450 (m), 1360 (m), 1200 (w), 1110 (s), 1060 (m), 1040 (m), 850 (s), 750 (s) cm^{-1}; nmr ($CDCl_3$) δ: 1.58 (s, 6H, CH_3), 3.03 (s, 6H, OCH_3), 7.10−7.80 (m, 8H, ArH); mass spectrum, *m/e*: 268 (M^+), 253 ($M^+ - CH_3$), 209, 179. *Anal.* calcd. for $C_{18}H_{20}O_2$: C 80.56, H 7.51; found: C 80.67, H 7.62.

Preparation of 1-phenyl-3-methyl-4-benzhydryl-2-pyrazolin-5-one (34)

3-Methyl-1-phenyl-2-pyrazolin-5-one (Aldrich, 1.70 g, 10 mmol) was heated for 2.5 h with benzhydrol (1.84 g, 10 mmol) in glacial acetic acid (35 mL) with 4 drops of concentrated hydrochloric acid. Dilution of the solution with water gave 1.40 g (41%) crystals, mp 221−221.5°C dec. (ethanol, lit. (61) mp 220°C).

Conventional method for sample preparation and irradiation in the photoinduced electron transfer reactions

Samples to be irradiated and DCN were placed in 15 × 1.2 cm (id) Pyrex test tubes and 20 mL of acetonitrile were added. The vessel was then sealed with a serum cap which was wired in place. The solution was deoxygenated or oxygenated by inserting hypodermic needles to introduce either nitrogen or oxygen (15 to 30 min), respectively, and to provide an exit port. Irradiations were conducted in an air-cooled Rayonet RPR-100 Chamber Reactor (The Southern New England Ultraviolet Co., Middletown, Conn.) equipped with sixteen F8T5/BLB broad emission (280−420 nm) 8-W low pressure mercury lamps (General Electric Company) operating at a temperature of approximately 40°C. Utilization of the F8T5/BLB lamps (emission max. 350 nm,) coupled with a Pyrex filter (opaque below 290 nm) effectively precludes excitation of the substrate and ensures that the electron transfer sensitizer is excited preferentially. Control experiments were conducted under similar conditions in the absence of the electron transfer sensitizer. In order to ensure uniform exposure of individual samples during multiple irradiations and kinetic experiments, the same reactor was fitted with a continuously rotating MGR-100 Merry-Go-Round adapter (Southern New England Ultraviolet Co.). The residue obtained after removal of solvent under reduced pressure was analyzed by tlc and/or nmr. The results of these experiments are summarized in Table 1.

*Attempted triplet−triplet energy sensitized isomerizations of **16**, **30**a, and **32***

A procedure similar to that used for the foregoing electron transfer sensitized reactions was employed, with the exception that acetophenone (**6***e*) (10 mg, 0.08 mmol) was used as a sensitizer in the case of **16** (0.1 g, 0.4 mmo), and benzophenone (**11**) (10 mg, 0.05 mmol) for **30***a* (0.1 g, 0.4 mmol) and **32** (0.1 g, 0.4 mmol) in the place of the electron transfer agent DCN. Solutions of the various substrates in 20 mL of acetonitrile contained in a Pyrex test tube were deoxygenated with nitrogen in the specified manner. The resulting solutions **16**, **30***a*, and **32** were irradiated for 71 h, 56 h, and 48 h, respectively, and the volatile solvent was then removed. The nmr analysis of the resulting residues revealed that no isomerization had occurred with **16** and **32**; however, 8.2% of the racemic compound was found in the case of **30***a*.

Acknowledgements

This investigation at the University of New Orleans (G.W.G.) was supported in part by the National Science Foundation (Grant CHE 78-00615). Those phases of the project conducted in the Radiation Laboratory at the University of Notre Dame were financed by funds from the Office of Basic Energy Science of the United States Department of Energy (P.K.D.). This is document No. NDRL 2373 from the Radiation Laboratories. Appreciation is also expressed to Ms. Tekla Teleshak, Karen Deogracias, and Frances Caldwell for their assistance in the preparation of the manuscript and Dr. Eleanor Elder for technical library assistance. Drawings were done by Dr. David Lankin and we are indebted to Dr. Pesi Umrigar for technical assistance.

A new glucosinolate synthesis

THOMAS H. KELLER, LOIS J. YELLAND, AND M. H. BENN
Chemistry Department, The University, Calgary, Alta., Canada T2N 1N4

Received July 25, 1983

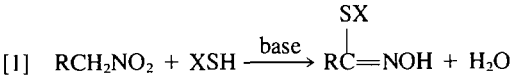
THOMAS H. KELLER, LOIS J. YELLAND, and M. H. BENN. Can. J. Chem. **62**, 437 (1984).

The *tert*-butyldimethylsilyl nitronate derived from 1-nitropropane was condensed with 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosylthiol to yield two geometrically isomeric thiohydroximates; the Z-isomeric form was then converted by conventional procedures into potassium ethylglucosinolate ("glucolepidiin").

THOMAS H. KELLER, LOIS J. YELLAND et M. H. BENN. Can. J. Chem. **62**, 437 (1984).

La condensation du nitronate de *tert*-butyldiméthylsilyle, provenant du nitro-1 propane, sur le tétra-*O*-acétyl-2,3,4,6 β-D-glucopyrannosylthiol conduit à deux isomères géométriques thiohydroximates; on a transformé l'isomère Z à l'aide de méthodes conventionnelles, en éthylglucosinolate de potassium ("glucolépidiin").

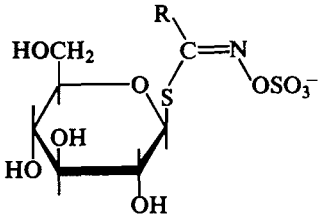
Some years ago Copenhaver (1) recorded the preparation of some thiohydroximates (**1**) by means of a base-induced condensation of primary nitroalkanes with thiols (eq. [1]).



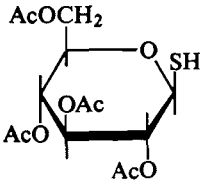
[1] $RCH_2NO_2 + XSH \xrightarrow{base} \underset{\displaystyle SX}{\underset{|}{RC}}{=}NOH + H_2O$

1

We thought of using this reaction to make glucosinolates, a compact group of naturally occurring thiohydroximate derivatives characterized by the structure **2** (2).



2

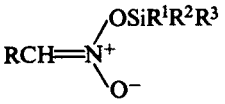


3

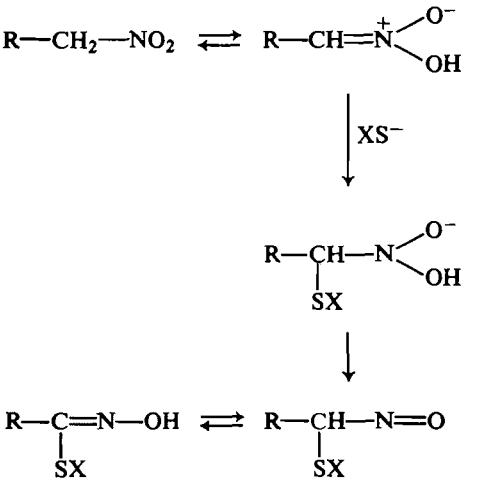
Our idea was to condense a primary nitroalkane with 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosylthiol (**3**) to provide the corresponding thiohydroximate (**1**, X = tetraacetyl-β-D-glucopyranosyl) which could then be converted to **2** by established procedures involving sulphonation and subsequent deacetylation (3). However, in its original form, the Copenhaver reaction did not seem well suited to our purpose since the drastic conditions employed (refluxing tributylamine, or hot aqueous solutions containing alkali metal hydroxide) were unlikely to be compatible with **3**. This supposition was borne out by experiments: the reaction of 1-nitropropane with tetraacetyl-β-D-glucosylthiol under "typical" Copenhaver conditions yielded only small amounts of the desired thiohydroximate (detected by tlc), and much tarry material. Milder conditions were also unpromising.

As shown in Scheme 1, a plausible mechanism for the Copenhaver reaction involves the intermediacy of an *aci*-nitroalkane, or nitronate anion (4).

With this in mind, we decided to try modifying the Copenhaver reaction by replacing the nitroalkane with a nitronate. For this purpose we selected the trialkylsilyl derivatives (**4**), which are relatively readily available (5). What follows is



4



SCHEME 1. A possible mechanism for the Copenhaver reaction.

an account of our experiences with the use of the *tert*-butyldimethylsilyl nitronate **5** (**4**, R = Et, $R^1 = R^2 = Me$, R^3 = *t*-Bu) derived from 1-nitropropane for the synthesis of potassium ethylglucosinolate ("glucolepidiin"), the putative parent of ethyl isothiocyanate formed by *Lepidium menziesii* DC (6).

As outlined in Scheme 2, the slow addition of the trialkylsilyl nitronate **5** to a solution of equimolar amounts of tetraacetyl-β-D-glucopyranosylthiol and triethylamine in tetrahydrofuran, at room temperature, afforded two thiohydroximates. These were separated by flash chromatography, and obtained as homogeneous crystalline solids **6***a* (28%) and **6***b* (56%). Complete characterization of these isomers by spectroscopic methods and combustion analyses established their relationship as a pair of geometric isomers. The reaction of nitrile oxides (generated *in situ* from hydroxamoyl halides and triethylamine) with thiols affords *Z*-thiohydroximates (7), and authentic **6***b* was thus prepared from **3** and **7**. (It may be noted that this observation excludes the intermediacy of a nitrile oxide intermediate in the formation of the thiohydroximates from the silyl nitronates; i.e., if the mechanism of that reaction involved eliminative loss of silanol to generate a nitrile oxide which then reacted with thiolate to give the thiohydroximate, **6***b* would be the product formed.)

The *E*-isomer **6***a* was indefinitely stable in the crystalline form in the dark at 0°C, but underwent slow thermal or photochemical isomerization to **6***b* in solution.

It is known that there is rapid O → O migration of the silyl group in trialkylsilyl nitronates (5), and this may be invoked to

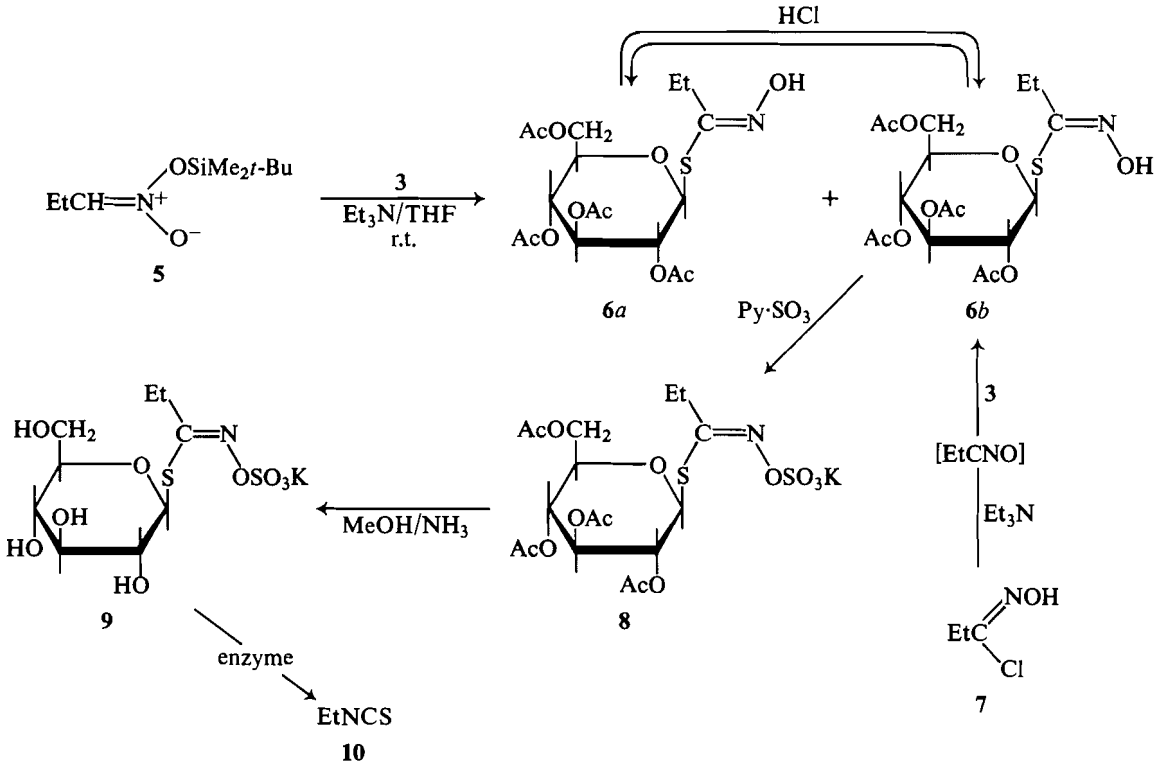


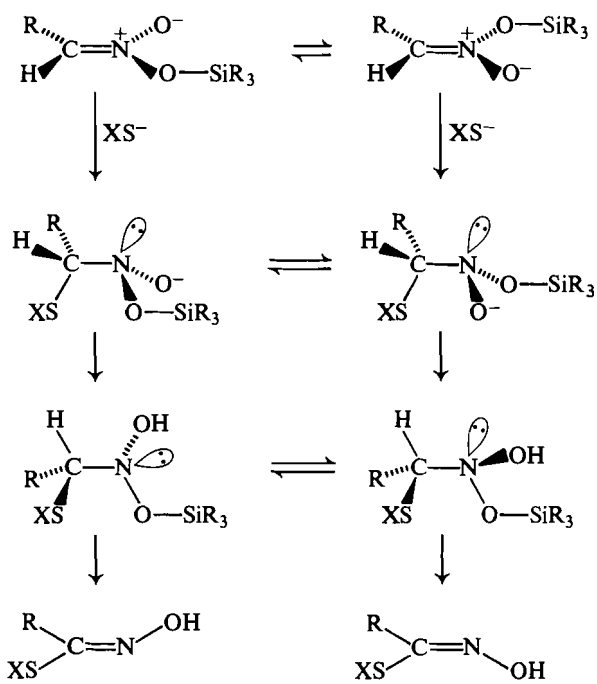
SCHEME 2. The silylnitronate route to ethylglucosinolate.

provide a rationalization for the formation from **3** and **5** of **6***a* and **6***b* in comparable amounts (Scheme 3).

The success of our modification of the Copenhaver reaction was pleasing: we had had some worries that although the thiolate nucleophile was soft, and the Si—S bond weak (8), it might attack at silicon rather than carbon, leading to desilylation and regeneration of the nitroalkane.

The formation of both geometrical isomers of the thiohydroximate, although at first sight inconvenient since only one of these (**6***b*) has the requisite stereochemistry for conversion to the natural (*Z*)-glucosinolates, was not unwelcome. Apart from the fact that the *E*-isomer can be isomerized to the *Z*-form, and then utilized for glucosinolate synthesis, there has been considerable speculation on the catabolic consequences of changing the configuration of glucosinolates from *Z* to *E* (9, 10), but no direct experimental tests of these hypotheses. Although geometrically isomeric pairs of *S*-alkyl thiohydroximates have been made before, usually via photoequilibration of the *Z*-isomer (11), no *E*-glucosinolates have been prepared. (Photolysis of an indolylglucosinolate has been reported to lead to extensive decomposition (12), and our own, unpublished, attempts to achieve the photoisomerization of *E*-**1** (R = $PhCH_2$, X = tetraacetyl-β-D-glucopyranosyl) were unsuccessful.[1]) Thus it appears likely that our modified Copenhaver reaction will make the "unnatural" *E*-glucosinolates accessible, for the first time.

Sulphonation of **6***b* with pyridine – sulphur trioxide and subsequent treatment with potassium hydrogen carbonate gave the nicely crystalline potassium tetraacetylethylglucosinolate (**8**), which was then deacetylated with methanolic ammonia to afford potassium ethylglucosinolate **9** as an amorphous, but homogeneous, solid whose spectroscopic and analytical properties were in accord with expectation. When an aqueous solution of **9** was stirred with white mustard seed flour, ethyl isothiocyanate **10** was released, demonstrating that ethylglucosinolate can indeed function as a source of that mustard oil.



SCHEME 3. *E*- and *Z*-thiohydroximates from silylnitronates.

Experimental

The instruments and operating conditions were as previously described (13). In the ^{13}C nmr spectrum of **8**, methanol (δ = 49.0) was used as an internal reference.

[1]P. K. Oommen and M. H. Benn, unpublished results.

The tert-*butyldimethylsilyl ester of* aci-*1-nitropropane (5)*

To a stirred solution of diisopropylamine (3.03 g, 30 mmol) in dry THF (70 mL), at −78°C, under an atmosphere of dry nitrogen, was added a solution of butyllithium in hexane (1.0 *M*, 30 mL, 30 mmol). After the addition was complete, the cooling bath was removed and the mixture stirred for 30 min. The reaction mixture was then again cooled to −78°C, and 1-nitropropane (2.5 g, 28 mmol) was added. This yielded a gel which was kept at −78°C for a further 30 min. To this, at the same temperature, was then added a solution of *tert*-butyldimethylsilyl chloride (4.82 g, 32 mmol) in dry THF (10 mL) and the mixture was stirred for 30 min.

The cooling bath was removed and the mixture was allowed to warm to room temperature and stirred overnight. The stirrer-bar was then removed and the reaction mixture concentrated at room temperature (rotatory evaporator) under reduced pressure (oil pump, ca. 15 Torr) to a semi-solid residue. This material was suspended in dry pentane (100 mL) and filtered through a Celite pad. The reaction flask and filter were washed with dry pentane (4 × 20 mL). Removal of solvent from the combined filtrate and washings (room temperature, ca. 0.1 Torr) left a residual orange liquid which was purified by bulb-to-bulb distillation (48°C, 0.03 Torr) to yield **5** as a colourless oil (4.0 g, 70%); ν_{max} (film): 3100 (w), 1615 (s), 1250 (s), 1110 (s), 835 (vs), and 790 (s) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.25 (6H, s), 0.89 (9H, s), 1.05 (3H, t, J = 7 Hz), 2.21 (2H, q, J = 7 Hz), and 5.95 (1H, t, J = 7 Hz).

The preparation of S-*(2',3,4',6'-tetra-*O*-acetyl-*β*-D-glucopyranosyl)-propiothioydroximates, **6**a and **6**b*

(a) *From preformed* tert-*butyldimethylsilyl nitronate **5***

A solution of the *tert*-butyldimethylsilyl nitronate **5** (1.02 g, 5 mmol) in dry THF (10 mL) was added dropwise, under an atmosphere of dry nitrogen, over 12 h and at room temperature, to a solution of 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosylthiol (1.82 g, 5 mmol) and triethylamine (0.5 g, 5 mmol) in dry THF (30 mL). The reaction mixture was concentrated (<40°C; aspirator, ca. 15 Torr) to a semi-solid residue which was then kept under high vacuum (ca. 0.1 Torr) for 1 h to remove *tert*-butyldimethylsilanol, after which it was subjected to flash chromatography (Merck silica gel 60, with hexane − ethyl acetate 1:1 v/v as eluant). This afforded **6***a* and **6***b* as colourless crystalline solids. After recrystallization from hexane − ethyl acetate, **6***a* had mp 134−135°C; $[\alpha]_D$ +8.4° (*c* 1.0, $CHCl_3$); ^1H nmr ($CDCl_3$) δ: 1.15 (3H, t, J = 7 Hz), 2.01, 2.02, 2.05, and 2.07 (4 × 3H, s), 2.48 (1H, dq, J = 7 and 16 Hz), 2.61 (1H, dq, J = 7 and 16 Hz), 3.77 (1H, ddd, J = 9, 4, and 2 Hz), 4.15 (1H, dd, J = 12.5 and 2 Hz), 4.32 (1H, dd, J = 12.5 and 4 Hz), 5.2 (4H, m), and 8.22 (1H, s); ^{13}C nmr ($CDCl_3$) δ: 10.4 (q), 20.6 (q, $4CH_3$), 24.1 (t), 61.8 (t), 68.0 (d), 69.5 (d), 73.9 (d), 75.9 (d), 81.1 (d), 158.3 (s), 169.4 (s, 2C=O), 170.2 (s), and 170.7 (s). *Anal.* calcd. for $C_{17}H_{25}NO_{10}S$: C 46.89, H 5.79, N 3.22; found: C 47.21, H 5.82, N 3.29%. The yield of **6***a* was 28% (0.61 g). Similarly, **6***b* had mp 155−156°C; $[\alpha]_D$ −16.4° (*c* 1.0, $CHCl_3$); ^1H nmr ($CDCl_3$) δ: 1.22 (3H, t, J = 7 Hz), 2.02, 2.04, 2.05, and 2.07 (4 × 3H, s), 2.54 (1H, dq, J = 7 and 16 Hz), 2.67 (1H, dq, J = 7 and 16 Hz), 3.75 (1H, ddd, J = 9, 5, and 3 Hz), 4.15 (2H, m), 5.0−5.4 (4H, m), and 8.18 (1H, bs); ^{13}C nmr ($CDCl_3$) δ: 11.7 (q), 20.6 (q, $4CH_3$), 26.1 (t), 62.3 (t), 68.2 (d), 70.2 (d), 73.8 (d), 76.0 (d), 79.9 (d), 154.4 (s), 169.2 (s), 169.4 (s), 170.2 (s), and 170.5 (s). *Anal.* calcd. for $C_{17}H_{25}NO_{10}S$: C 46.89, H 5.79, N 3.22; found: C 46.65, H 5.83, N 3.10%. The yield of **6***b* was 56% (1.23 g).

(b) *From propanaldoxime*

A slow stream of chlorine gas was passed into a solution of propanaldoxime (6.2 g, 50 mmol) in dry Et_2O (250 mL), cooled in an ice−salt bath, for 1 h. Excess chlorine and some Et_2O were then removed under aspirator vacuum until the solution changed colour from green to blue. To this was then added a solution of tetraacetyl-β-D-glucopyranosylthiol (5 g, 14 mmol) in EtOH (10 mL) and Et_2O (200 mL) followed, with swirling, by a solution of triethylamine (15 mL, 100 mmol) in Et_2O (15 mL). The reaction mixture was kept at room temperature for 30 min, then poured into 1.5 *M* aqueous H_2SO_4 (300 mL) and ice. After shaking this mixture, the Et_2O phase was separated, washed with more 1.5 *M* aqueous H_2SO_4 (100 mL), then H_2O (100 mL), dried ($MgSO_4$), and evaporated to a crystalline residue. This material was recrystallized from ethanol−hexane to provide **6***b*, mp 156°C (2.0 g, 34%), identical in all respects with **6***b* prepared as in (a).

*Interconversion of **6**a and **6**b*

When a solution of **6***a* in $CHCl_3$ was kept in a 5-mm ^1H-nmr tube, in sunlight, slow isomerization occurred to produce **6***b*. Attempts to accelerate this process by uv irradiation resulted in extensive decomposition. If a trace of HCl was added to a $CHCl_3$ solution of **6***a* or **6***b*, an equilibrium mixture of the two isomers was attained within 1 h, at room temperature, 3:7 **6***a*/**6***b* as revealed by ^1H and ^{13}C nmr and tlc.

Potassium tetraacetylethylglucosinolate (8)

Freshly prepared pyridine−SO_3 complex (0.9 g, 5.6 mmol) was added to a solution of **6***b* (1.8 g, 4 mmol) in dry pyridine (ca. 35 mL). This mixture was stirred at room temperature for 48 h, then poured in H_2O (250 mL) containing $KHCO_3$ (1.7 g, 7 mmol). The mixture was filtered and then extracted with Et_2O (2 × 200 mL). The aqueous phase was then freeze-dried. The residue so obtained was then extracted with boiling 95% (v/v) aqueous EtOH and filtered hot. The filtrate was chilled to 0°C and the crystalline precipitate which separated was collected and recrystallized from 95% EtOH to yield a product, mp 205−207°C (dec.) (1.9 g, 98%); $[\alpha]_D$ −18.6° (*c* 1.0, H_2O); ^1H nmr (DMSO-d_6) δ: 1.14 (3H, t, J = 7 Hz), 1.96, 2.00, 2.01, and 2.02 (4 × 3H, s), 2.65 (2H, q, J = 7 Hz), 4.1 (3H, m), 4.92 (1H, dd, J = 9 Hz), 5.5 (1H, dd, J = 9 Hz), 5.8 (1H, d, J = 9 Hz); ^{13}C nmr (D_2O) δ: 11.4 (q), 20.0 (4 × CH_3, q), 26.2 (t), 62.1 (t), 68.1 (d), 70.1 (d), 74.0 (d), 75.2 (d), 79.4 (d), 163.8 (s), 172.3 (s), 172.6 (s), 173.0 (s), and 173.6 (s). *Anal.* calcd. for $C_{17}H_{24}NO_{13}S_2K$: C 36.88, H 4.37, N 2.53; found: C 36.91, H 4.42, N 2.43%.

Potassium ethylglucosinolate (9)

Potassium tetraacetylethylglucosinolate (200 mg, 0.6 mmol) was dissolved in dry MeOH (15 mL) saturated with NH_3. The solution was stirred overnight at room temprature, then evaporated to dryness (aspirator vacuum, <40°C) and the residue extracted with $CHCl_3$ (30 mL). The residue was dissolved in methanol, the solution so obtained was evaporated to dryness as before, and the residue again extracted with $CHCl_3$ (30 mL). This process was repeated once more and the glassy $CHCl_3$-insoluble residue thus obtained was then dissolved in water (ca. 3 mL), and the solution freeze-dried to yield **9** as an amorphous white powder (120 mg, 86%); $[\alpha]_D$ −20.5° (*c* 0.6, H_2O); ^1H nmr (D_2O) δ: 1.25 (3H, t, J = 7.4 Hz), 2.74 (2H, q, J = 7.4 Hz), 3.40−4.0 (6H, m), and 5.01 (1H, d, J = 9.4 Hz); ^{13}C nmr (D_2O) δ: 11.5 (q), 26.1 (t), 60.7 (t), 69.2 (d), 72.0 (d), 77.2 (d), 80.0 (d), 81.7 (d) and 165.0 (s). *Anal.* calcd. for $C_9H_{18}NO_9SK$: C 28.04, H 4.18, N 3.63; found: C 27.85, H 4.39, N 3.41%. This material was homogeneous by tlc (on Merck silica gel 60-F254, using n-PrOH − EtOAc−H_2O (7:1:2 v/v) as the solvent system) (ref. 14); R_f 0.53; under these conditions potassium allylglucosinolate had R_f 0.61.

Enzymatic cleavage of ethylglucosinolate

To a solution of **9** (50 mg, 0.13 mmol) in phosphate buffer (3 mL, pH 6.7) was added white mustard seed flour (20 mg, prepared by pulverizing the seeds, and then regrinding the flour in hexane to remove fats, after which it was air-dried at room temperature). This mixture was cooled in an ice bath, and stirred for 1 h, after which Et_2O (3 mL) was added. Gas chromatographic and gc−ms analyses (on 3% OV-17 at 65°C) of the Et_2O phase revealed the presence of ethyl isothiocyanate (identical R_t and fragmentation pattern as an authentic reference specimen). The Et_2O layer was separated, dried ($MgSO_4$), and aniline (5 drops) added. After 48 h the Et_2O solution was washed with 1 *M* aqueous HCl (1 mL), dried ($MgSO_4$), and evaporated. The residue recrystallized from EtOH−hexane yielded crystals (5 mg), mp 105−107°C, with an ir spectrum superimposable upon that of an authentic specimen of *N*-ethyl-*N'*-phenylthiourea, mp 105−107°C, prepared from ethyl isothiocyanate and aniline.

We have developed a new IR-ATR spectroscopic technique for the identification and quantification of fibers collected on PVC filters. This nondestructive method has a detection limit of about 10 μg, involves no sample preparation, and is relatively insensitive to nonserpentine dusts normally associated with the asbestos mining and milling industries.

An analysis of the ATR phenomena for a fiber matt indicates that the logarithmic ratio of the reflectivity varies with the surface concentration C as:

$$\log \frac{R_0}{R} = A\alpha \frac{C_S}{2r} \lambda \left[1 - \exp\left(-\frac{7.2rC}{\lambda}\right)\right]$$

where C_S is the concentration for a monolayer of fiber, r the mean fiber diameter. Thus, the absorption should reach a plateau when a sufficient thickness is obtained, and this nonlinear region should be attained at lower wavelength, and at lower concentrations for long fibers having a high aspect ratio. We further predict that the relative absorption $A(\lambda_1)/A(\lambda_2)$ where $\lambda_1 < \lambda_2$, should decrease with fiber dimension.

The ATR signal at 303 cm^{-1}, corresponding to a lattice vibration, varies linearly with fiber concentration up to 100 $\mu g/cm^2$, whereas the intensity of this band relative to the OH stretching band at 3690 cm^{-1} is a monotonic function, representing the fiber morphology. Dust levels and fiber morphology established from the IR-ATR spectroscopy are consistent with measurements by light and electron microscopy.

F. M. KIMMERLE, L. NOËL et J. KHORAMI. Can. J. Chem. **62**, 441 (1984).

Nous avons développé une nouvelle technique par spectroscopie IR-ATR pour l'identification et la quantification des fibres collectées sur des membranes de PVC. Cette méthode est non destructive, la limite de détection se situe vers les 10 μg et les échantillons ne requièrent aucun traitement. De plus, la présence de poussière autre que celle du groupe de la serpentine associée à l'amiante ne semble pas être un obstacle pour les mines et les industries.

Une analyse du phénomène ATR pour un certain recouvrement de fibres indique que le rapport logarithmique de la réflectivité varie avec la concentration à la surface C tel que:

$$\log \frac{R_0}{R} = A\alpha \frac{C_S}{2r} \lambda \left[1 - \exp\left(-\frac{7.2rC}{\lambda}\right)\right]$$

où C_S est la concentration pour une monocouche de fibre et r le diamètre moyen de la fibre. Pour une concentration de surface suffisante, un plateau sera obtenu plus rapidement pour les courtes longueurs d'ondes et pour les fibres ayant un rapport longueur/diamètre élevé. Nous pouvons prédire que l'absorption relative $A(\lambda_1)/A(\lambda_2)$, où $\lambda_1 < \lambda_2$, doit diminuer en fonction de la dimension des fibres.

Le signal ATR à 303 cm^{-1}, caractéristique de la vibration de la maille cristalline, varie linéairement avec une concentration de 100 $\mu g/cm^2$ de fibres tandis que les rapports des bandes d'absorption de 303 cm^{-1}/3690 cm^{-1} (3690 cm^{-1} = vibration OH) nous donnent plutôt une fonction monotone représentative de la morphologie des fibres.

Les niveaux d'empoussiérage et la morphologie moyenne des fibres peuvent être établis par ATR, et les résultats sont compatibles avec ceux de la microscopie optique et de la microscopie électronique.

Introduction

The accepted analytical technique for asbestos fiber control in the workplace or the environment has traditionally involved fiber counting by phase contrast light microscopy and, more recently, by electron microscopy (TEM and SEM) (1). X-ray diffraction of air samples collected on membrane filters has been variously proposed (2–4), but IR analysis has not found very wide acceptance. It has been shown to be sufficiently sensitive (detection limit 10–20 μg) to monitor present legal dust levels (5, 6), but suffers from three apparent drawbacks. The possible interference due to other airborne pollutants is not well established, the IR signal will respond to fibrous and nonfibrous serpentine materials, and the sample preparation has been relatively tedious since it was felt necessary to incorporate the fibers collected on a membrane filter in a KBr disk prior to IR analysis.

The IR spectra of chrysotile asbestos and related materials are well known (7) although accurate wavelength tabulations are relatively scarce (8), particularly those below $\bar{\nu}$ = 500 cm^{-1}.

Coates (9) recently examined the IR spectra of various asbestos varieties and proposed a classification scheme which would allow the identification of amphibole and serpentine materials. The sharp peak of the hydroxyl doublet at 3690 cm^{-1} has been used traditionally (6, 10–12) for quantitative analysis of chrysotile asbestos, although it was not always adequately resolved from the asymmetric OH vibration at 3646 cm^{-1}. The silicate triplet (ν_{as}(Si—O—Si) at 1080 cm^{-1}, ν_{Si-O} at 1020 cm^{-1}, and ν_{Si-O} at 945 cm^{-1}) constitutes by far the most prominent feature of the IR spectra (13), but overlaps the major, broad bands of all silicate materials, including quartz, to such an extent that it becomes practically useless. Flick (14) suggested that several peaks should be examined to minimize interferences. Luce (15) confirmed Brindley and Zussmanns' (10) observation that the fibrous chrysotile could be distinguished from the host rock, antigorite, which lacks the central silicate bond.

Typically, chrysotile fibers were collected as for microscopy examination (11), on a 47 mm diameter Millipore membrane,

TABLE 1. Morphology of reference fibers

Parameter	Value				
	Very short chrysotile	UICC-B Chrysotile	Calidria COF-25	Plastibest #20	−35 + 200 Paperbestos #3
Specific surface ($m^2\ g^{-1}$)	37.7	24.3	55.4	14.2	12.9
Average fiber diameter (nm)	41.8	72.2	28.4	111	122
Mean fiber length (μm)	0.8	11.6	8.0	100	370
Aspect ratio	19	160	280	910	3025
C_S^a ($\mu g\ cm^{-2}$)	8.4	14.4	5.6	22.2	24.4
C_S^r ($\mu g\ cm^{-2}$)	0.56	0.115	0.026	0.031	0.010
C_S ($\mu g\ cm^{-2}$)	2.16	1.28	0.38	0.831	0.501
C^* ($g\ cm^{-3}$)	0.52	0.177	0.134	0.075	0.041

the filter was calcinated and the residue incorporated in a KBr disk. Heidermanns' technique (16) used in the Staubforschungsinstitut at Bonn probably constitutes the most successful version of this approach. Similar techniques (12), where separation of the asbestos fibers was attempted through a centrifugation step in a high density liquid, suffer from a reduced detection limit.

Results

Chrysotile reference materials

Some of the reference materials related to the chrysotile fibers used in this study have been described in the literature (16–19) and others have been isolated in our laboratory (20). Although the Calidria chrysotile contains more trace metals and less brucite than the Quebec chrysotiles, no major differences in composition are evident. The rather high brucite content of the UICC-B chrysotile might be attributed to fibers from the Carey mine incorporated in the original sample; the other three chrysotile samples have been isolated from fibers of the Jeffrey mine.

The fiber length distribution for the shortest and the longest fraction were calculated from the transmission micrographies and optical microscopy measurements respectively. Results for the other materials are taken from the literature and are presented as % cumulative volume fractions in Fig. 1. The fiber diameter distributions are less reliably established, except for the electron microscopy results. The mean diameter of the Quebec monofibril has been given as 350 Å, that of the Calidria fibril as 280 Å (21), but we preferred to calculate an "average" diameter for all five materials from indirect measurements (22).

If the fibers and fiber bundles can be approximated as cylinders of length l and radius r, their specific surface area S is given as:

$$[1] \quad S = \frac{\pi r l + 2\pi r^2}{\rho \pi r^2 l}\ (m^2\ g^{-1})$$

where ρ, the density of chrysotile asbestos $\simeq 2.54 \times 10^6\ g\ m^{-3}$. Except for extremely short fibers with a very low aspect ratio, $l/2r$, the average diameter is inversely proportional to the surface area and can be estimated immediately. The surface area measured from nitrogen adsorption isotherms, the calculated average diameter, and the mean length estimated from optical and electron micrographies (50% volume shorter or longer than $\langle l \rangle$ for the reference fibers) are given in Table 1.

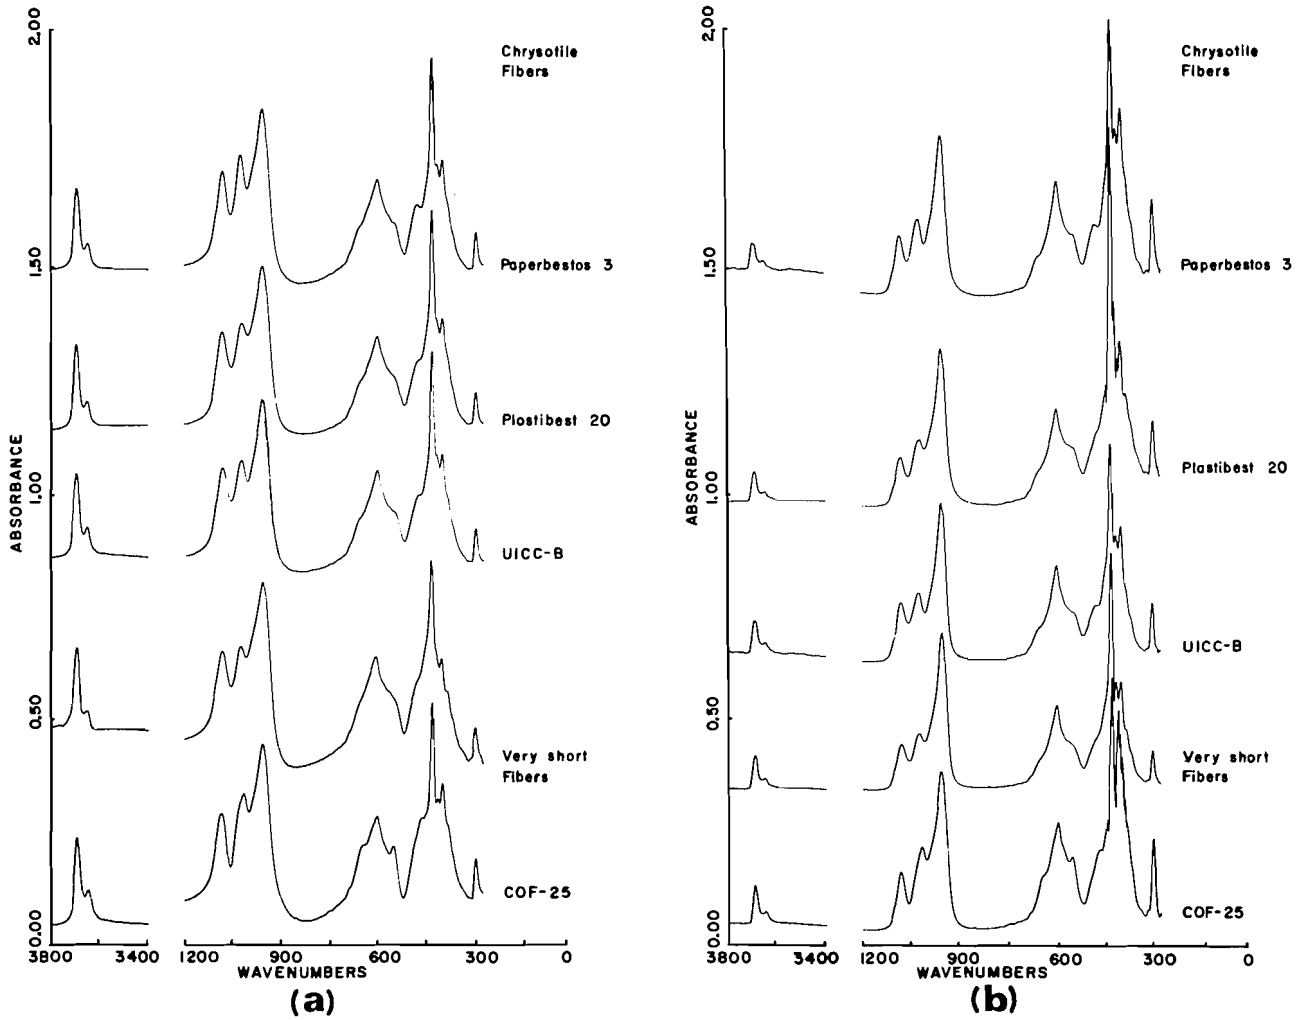

FIG. 2. Infrared spectra of different chrysotile fibers; (*a*) transmission spectra obtained from a KBr disk; (*b*) multiple internal reflection obtained with a IRE KRS-5.

IR spectra — transmission versus reflectance

Compared to the transmission spectra, Fig. 2*a*, obtained from a KBr disk, the IR spectra in the reflectance mode, Fig. 2*b*, shows relatively sharper peaks at lower wave numbers and relatively lower peaks at higher wave numbers. The increased noise level above $\bar{\nu} = 3000\ cm^{-1}$, due to the absorption characteristics of the Internal Reflection Element (IRE) and the beam splitter of the Nicolet MX-1 Fourier Transform Spectrophotometer, is practically without consequence except for the lowest chrysotile concentrations.

Variations of the IR transmission spectra with fiber type may reflect differences in impurity levels and crystal structure. Increased geometric size will eventually cause peak broadening and degradation of the signal, due to light dispersion and reflection, as was elegantly shown for calcite particles by Duyckaerts (23). Since aspect ratios $l/2r \simeq 200$ are not common, fibers almost 1 mm long may be encountered. Their thickness, $\ll$ 5 μm, would otherwise pose few optical problems, but their length makes them most difficult to incorporate in a transparent KBr disk. Extensive grinding would defiberize the material and eventually shorten the length of the fiber bundles, defeating the purpose of this study (24).

The IR spectra of all five materials are very similar and a detailed examination is necessary to identify their distinguishing features. The Calidria COF-25 chrysotile shows significant differences in the far-infrared region (Fig. 2, note that the peak at 303 cm^{-1} is considerably higher than for other chrysotiles). Since its chemical and mineralogical composition varies little from the other reference materials, these differences would be consistent with minor alteration in the crystal structure. Whereas the others occur as crossfibers in ultrabasic rocks, the Calidria chrysotile consists of extremely short fibers dispersed in a carbonate deposit. The differences in crystal structure could be attributed to an average fibril diameter some 100 Å smaller than that of Quebec chrysotile monofibers, and manifested by slightly different lattice vibrations.

Because of the characteristics of the ATR (attenuated total reflectance) technique (25), the morphology of the fibers has a much greater intrinsic effect. The signal will vary with the depth of penetration into sample, which can be expected to vary with fiber size and wavelength. We have undertaken this study in order to evaluate whether the reflectance mode can be used to quantitatively measure chrysotile fibers of respirable dimension (aerodynamic diameter < 7 μm). Before examining the experimental results, it is perhaps useful to analyse the predictions of a simplified model of the ATR phenomena.

IR spectra ATR mode comparison of reference fibers

For a uniform film of sufficient thickness, d, deposited on the surface of an appropriate internal reflectance element, it has

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

been established (25) that the depth of penetration of the photon into the sample, d_p, varies with the wavelength (measured in vacuum), refractive index, n, and the angle of incidence, θ, as:

$$[2] \quad d_p = \frac{\lambda}{2\pi (\sin^2 \theta - n_{21}^2)^{1/2}}$$

For $\theta = 45°$, n_1(KRS-5) = 2.4, $n_{2\,(\text{chrysotile})} = 1.55$, we can estimate:

$$[3] \quad n_{21} = \frac{n^2}{n_1} \text{ and } d_p \simeq 0.55\lambda$$

The amplitude of the electromagnetic radiation extending out of the internal reflection element into the sample should decrease exponentially with distance x according to:

$$[4] \quad E = E_0 \exp\left(-\frac{x}{d_p}\right)$$

Thus parts of the sample with an intimate contact at the surface will absorb a far greater fraction of the energy, E, than parts of sample lying at $x > d_p$.

A comprehensive treatment of the ATR has been given recently on the basis of the Lorentz–Lorentz's law and Fresnel equations for thick sample films (26), i.e., absorbing molecules dispersed in a nonabsorbing medium. Another recent evaluation of the measured absorbance values as a function of various sample parameters, including the surface morphology of a sample film, using a 45° KRS-5 internal reflection element, approaches our problem (27). However, for discrete particles in general, and fibrous materials in particular, no such complete analysis is available. We are dealing with fiber diameters of the order of 0.03 to 0.15 μm (where the thin layer approximation would normally hold for a continuous film), which are discrete particles where the "concentration" takes on a new meaning.

Following Harrick's approach in relating the reflectivity R logarithmically to the concentration C^*

$$[5] \quad R = R_0 \exp(-N\epsilon C^* d_{\text{eff}})$$

where ϵ is the extinction coefficient, N, the number of reflections in the IRE, and d_{eff}, the effective layer thickness which has been calculated by considering the interaction of the electromagnetic field of the incident light wave and sample media. For limited adsorption

$$[6] \quad d_{\text{eff}} = \frac{n_{21}}{\cos\theta} \int_0^d E^2\, dx = \frac{n_{21}}{\cos\theta} \int_0^d E_0^2 \exp\left[\frac{-2x}{d_p}\right] dx$$

where we suppose that the medium has a finite thickness d.

For $d \ll \lambda$ or $d \gg \lambda$, the thin and thick layer approximations are well known. For materials where the sample thickness is of the same order as the penetrating depth d_p, we estimate:

$$[7] \quad d_{\text{eff}} \simeq \frac{n_{21}}{4\pi \cos\theta} E_0^2 \frac{\lambda}{(\sin^2\theta - n_{21}^2)^{1/2}} \left(1 - \exp\left[-\frac{2d}{d_p}\right]\right)$$

where E_0, the relative electric field amplitude, is greater for $\parallel$ polarization than for $\perp$ polarization. For $n_1 = 2.4$, $n_2 = 1.55$, $n_3 = 1$, $E_\perp$ will vary from 1.55 to 1.8 and $E_\parallel$ from 1.59 to 2.6 for thin and thick films respectively. Taking 1.8 as an approximate value for E_0, we calculate for unpolarized radiation:

$$[8] \quad d_{\text{eff}} \simeq 0.52\lambda\left(1 - \exp\left[-\frac{3.6d}{\lambda}\right]\right)$$

This expression, plotted in Fig. 3, indicates an initial linear variation between effective thickness and sample thickness and an eventual limiting value $d_{\text{eff}} \simeq 0.52\lambda$. It also indicates that the thin layer approximation may be valid at low wavelengths, e.g., $\lambda_1 = 2.5$ μm ($\bar{\nu} = 4000$ cm^{-1}) and hold for longer wavelengths, e.g., $\lambda_2 = 25$ μm ($\bar{\nu} = 400$ cm^{-1}).

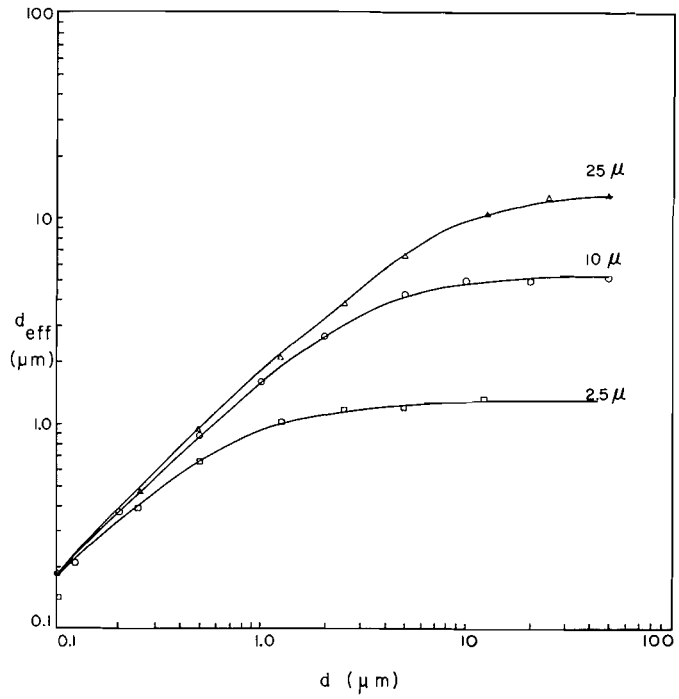

FIG. 3. Variation of effective thickness with sample thickness.

As indicated schematically in Fig. 4*a*, if the sample thickness $d \gg d_p$, then the reflectivity will not vary with a further increase in sample thickness. If $d_p(\lambda_1) \ll d$ and $d_p(\lambda_2) \gg d$, then the absorbance will continue to increase for sample thickness at λ_2 only. For a fixed number of discrete sample particles, Fig. 4*b*, it is expected that the amount of energy absorbed will be proportional to their surface concentration. Thin samples should absorb less than thicker samples, subject to the constraint $d_p > d$.

Surface concentration of chrysotile fibers

For a monolayer coverage, $\theta = 1$, illustrated in Fig. 4*c*, by perfectly aligned cylindrical fibers of uniform length and diameter, we would estimate a surface concentration

$$[9] \quad C_S^a \simeq \frac{\pi r^2 l}{2rl}\rho = \frac{\pi r}{2}\rho$$

or 200 μg/cm^2 for a fiber 1 μ thick.

If full rotational freedom (Fig. 4*d*) were allowed during fiber settling on the membrane surface, some overlapping of fibers would occur beyond a surface concentration

$$[10] \quad C_S^r = \frac{\pi r^2 l\rho}{\pi l^2/4} = \frac{4r^2\rho}{l}$$

or 2.54 μg/cm^2 for fibers 1 μ thick having an aspect ratio $l/2r = 100$. A better estimate of the mean surface concentration is probably given by

$$[11] \quad C_S = \sqrt{C_S^r \cdot C_S^a} = \left(\frac{2\pi r}{l}\right)^{1/2} r\rho \text{ (g cm}^{-2}\text{)}$$

and the "bulk" concentration as employed in eq. [5] is given by $C^* = C_S/2r$ (g cm^{-3}).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

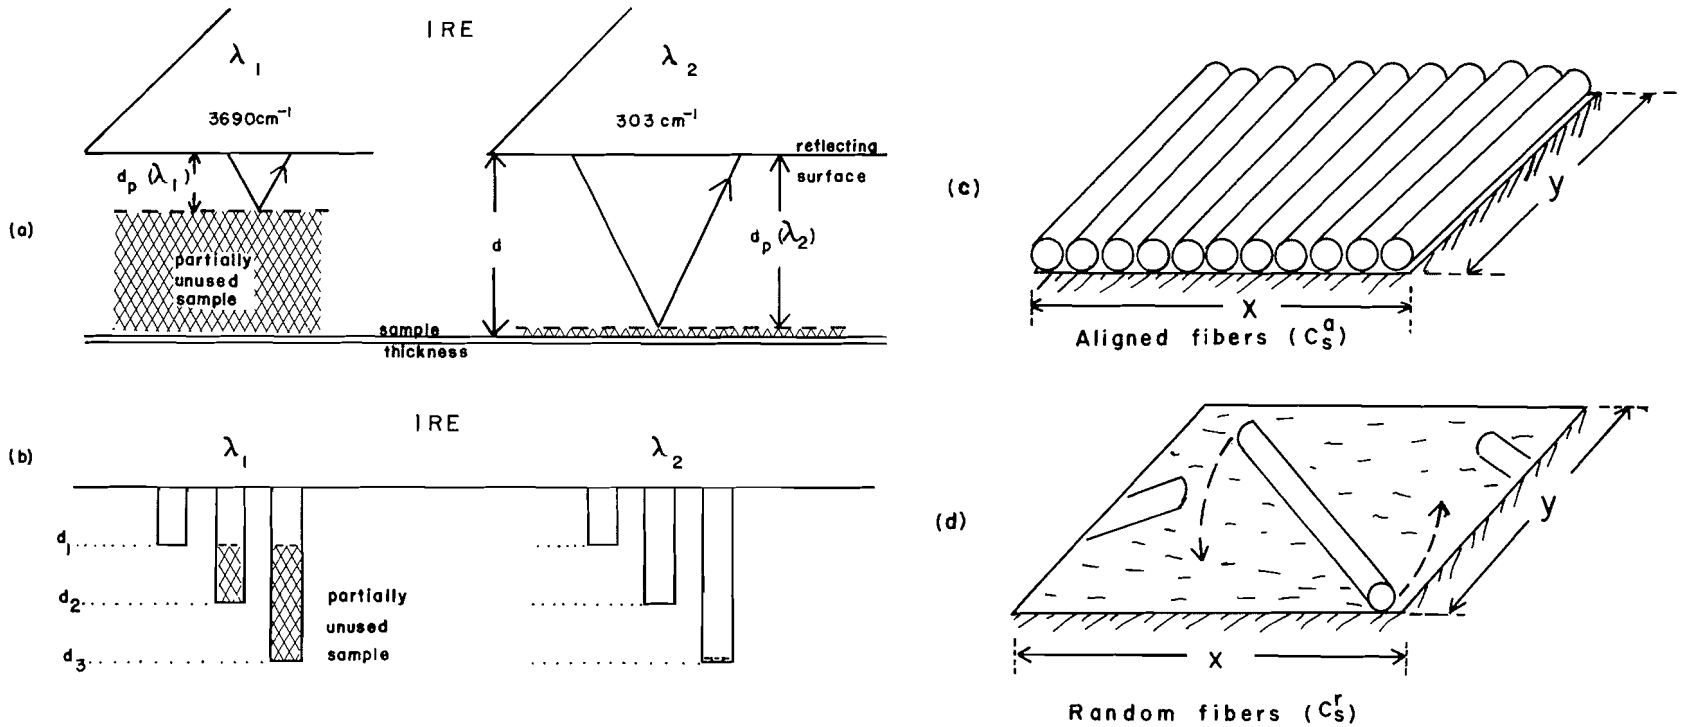

FIG. 4. (*a*) Scheme of sample thickness for $d \gg dp$; (*b*) the energy absorbed is proportional to the surface concentration for a fixed number; (*c*) concentration for aligned fibers (C_s^a) at the surface membrane (eq. [9]); (*d*) concentration for a random fibers (C_s^r) at the surface membrane (eq. [10]).

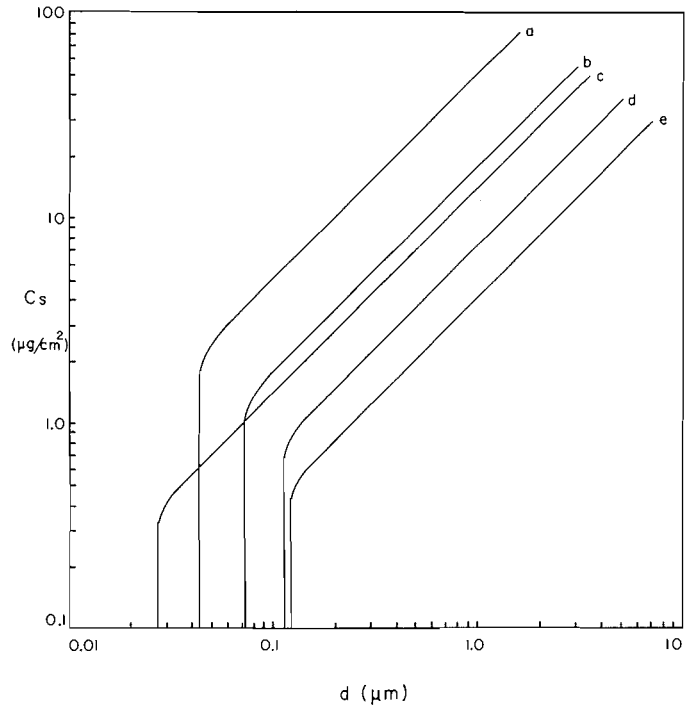

FIG. 5. Correlation between sample concentration, C_S, and thickness of the fiber matt for the five reference fibers; (*a*) very short chrysotile; (*b*) UICC-B chrysotile; (*c*) Calidria COF-25; (*d*) Plastibest #20; (*e*) Paperbestos #3.

For $\theta > 1$, closepacked, aligned fibers, the surface concentration would increase linearly with thickness of the fiber matt and independently of fiber length. For randomly aligned fibers the surface concentration would increase linearly but the slope would depend on the square root aspect ratio. For the five reference fibers, Table 1, both the mean diameter and the mean length vary. Thus, below $\theta < 1$, the thickness of the fiber matt will be determined by the diameter of the fibers, and the surface concentration can be given as θC_S. Beyond monolayer coverage the thickness can be approximated as $2r\theta$, where θ will vary according to eq. [11] with fiber type. The correlation between sample weight and thickness of the fiber matt is illustrated in Fig. 5 for the five reference fibers.

Thus, for a fiber deposit 10 μg/cm² of the longest reference fiber, the matt would be some 2.5 μm thick. At this thickness, according to Fig. 3, we are approaching the limiting value for d_{eff} at $\lambda = 2.5$ μm, but the entire sample will still absorb photons at $\lambda = 25$ μm. Similarly, for the shortest fibers we would estimate a thickness from Fig. 5, of 0.2 μm for the fiber matt for a deposit of 10 μg/cm², according to Fig. 3, and the entire sample would absorb radiation over the entire IR range.

The variation of absorbance with sample weight can be predicted by combining eqs. [5], [8], and [11]. Thus

$$[12] \quad A = \ln \frac{R_0}{R} = N\epsilon C^* d_{eff}$$

$$= 0.52\, N\epsilon \frac{C_S}{2r} \lambda \left(1 - \exp\left[-\frac{3.6d}{\lambda}\right]\right)$$

where C^* is the concentration on the membrane (specific to the density of the fiber, see Table 1) and C is the weight of fiber deposited on the membrane surface. In fact d represents the thickness of the fiber at the film surface, where

$$d = \frac{C}{C^*} = \frac{2rC}{C_S} = \frac{2}{\rho} \frac{C}{\sqrt{2\pi r/l}}$$

Equation [12] will be examined below.

Undoubtedly, these predictions are grossly oversimplified; the diffraction and reflection at the air/sample and air/reflectance element interfaces have been neglected, fibers and fiber bundles have been treated as a continuous film, the surface concentration for monolayer coverage has only been estimated, etc. Nevertheless, this simple model indicates that: (*i*) the absorption curve should plateau out when sufficient sample thickness is attained; (*ii*) this nonlinear region should be attained at much lower concentrations at $\lambda_1 < \lambda_2$, and at lower concentrations for long fibers of high aspect ratio than for short fibers having a low aspect ratio; and (*iii*) the relative absorption $A(\lambda_1)/A(\lambda_2)$, where $\lambda_1 < \lambda_2$ should decrease with fiber dimension.

If such be the case, it should be possible to use the ATR technique not only to measure fiber concentrations, but also to estimate mean fiber dimensions.

Variation of reflectivity with concentration

The calibration curves for three of the reference fibers, illustrated in Fig. 6, show a linear relationship between the measured absorbance $A = \log R_0/R$ and the sample weight at low concentrations for all three wavelengths investigated (3690, 960, and 303 cm⁻¹). At 303 cm⁻¹ the sensitivity (absorbance/(μg/cm²)) is relatively independent of fiber type and linear over the range investigated <1.2 mg/filter (or ~150 μg/cm²). At the longer wavelengths the sensitivity becomes increasingly dependent on fiber type. At 3690 cm⁻¹, for a given sample weight, the shortest fibers yield a signal twice as high as that observed for the longest fibers investigated. Moreover, the deviation from linearity occurs at lower surface concentrations, as predicted for the longer fibers.

The agreement of this rather complicated behavior with semiquantitative calculations is surprisingly good. The absorbance values predicted by eq. [12] are plotted in Fig. 7 on a log–log scale. This treatment emphasizes the difference in behavior at different wavelengths and attributes the differences between fiber types to differing aspect ratios. Since natural fibers consist of bundles having varying lengths and diameters, the concentration corresponding to monolayer coverage may differ somewhat from that calculated from eq. [11], which would shift the concentration where the deviation from linearity occurs (to somewhat higher or lower values).

The comparison between the experimental results and the model predictions is well illustrated in Fig. 8 for $\bar{\nu} = 3690$ cm⁻¹. Deviation from linearity occurs at higher concentrations than predicted. This observation is consistent with the fact that thin fibers can be readily accommodated within the thicker bundles without substantially increasing the thickness of the fiber matt. At $\bar{\nu} = 303$ cm⁻¹ our predictions indicate a linear correlation between absorbance and concentration up to about 100 μg/cm², with a higher sensitivity for the very short fibers.

Thus at $\bar{\nu} = 303$ cm⁻¹ the absorbance varies linearly with concentration, whereas at higher wavenumbers the reflectivity depends not only on concentration but also on fiber type. Let us examine in somewhat more detail this dependence on fiber morphology at sufficiently low concentrations, $C_S < 10$ μg/cm², where a linear concentration dependence still holds.

Variation of relative reflectivity with fiber type and incident wavelength

The intensity of the peaks in the ATR mode vary with the degree of contact, and thus the applied pressure, the angle of incidence, and the number of reflections; hence it is difficult to

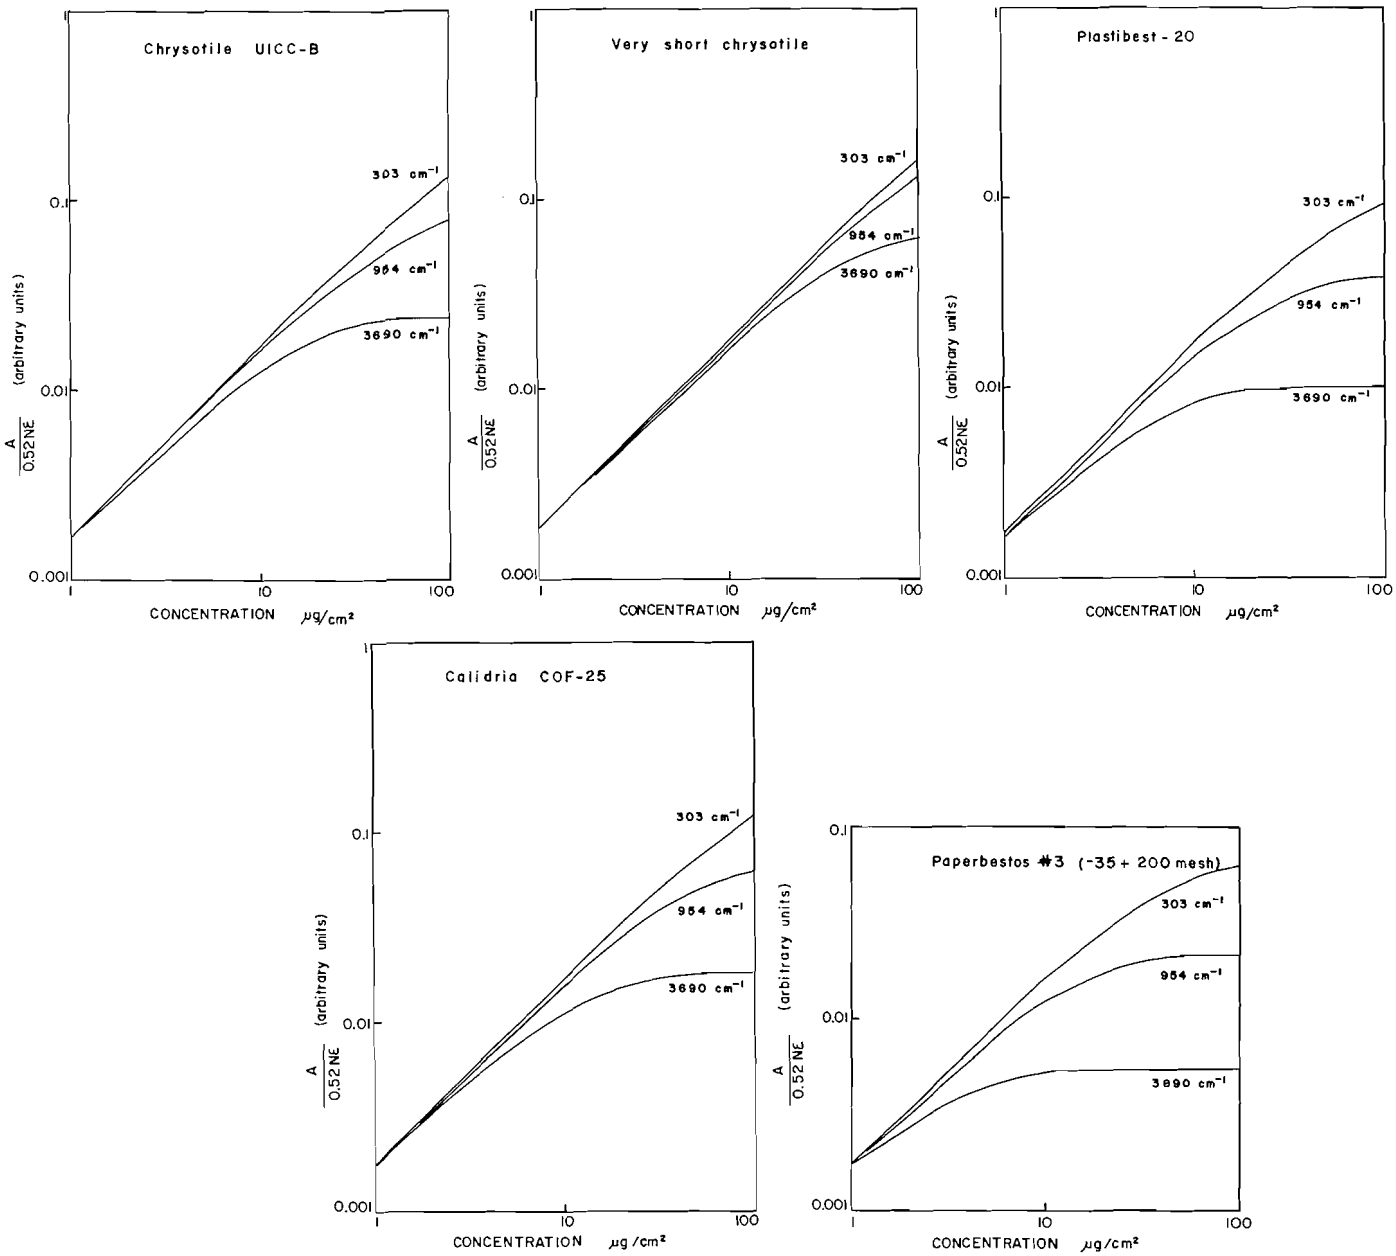

FIG. 6. Variation of the multiple internal reflection with concentration for the five reference fibers.

compare absolute values of the extinction coefficients, except as they pertain to a particular experimental ATR system (S_{ATR}). In order to eliminate the possibility of spectral interference, we preferred to deposit the fibers directly on the IRE without a backing plate. We therefore normalized the absorbance values with respect to one major peak ($\bar{\nu}$ = 954 cm^{-1}) and minimized effects of minor variations in fiber concentration.

These absorbance ratios are given in Table 2 for the major absorption peaks. By definition, both the normalized signal

$$[13] \quad S_{ATR} = \log \frac{R_0(\bar{\nu})}{R(\bar{\nu})} \Big/ \log \frac{R_0(954\ \text{cm}^{-1})}{R(954\ \text{cm}^{-1})}$$

and for the transmission system (S_T or KBr disk),

$$[14] \quad S_T = A(\bar{\nu})/A(954\ \text{cm}^{-1})$$

both are equal to 1.00 at $\bar{\nu}$ = 954 cm^{-1}. The absorbance ratios in the transmission mode are consistent, except for the Calidria chrysotile. A trend seems to exist between fiber length and peak height at 303 cm^{-1}. The ratio of the peak heights at 3690 cm^{-1} and 3645 cm^{-1} increases from a value of 3 : 1 for the long fiber bundles to 4 : 1 for the shortest fibers. This would be consistent with the assignment of the peak at 3645 cm^{-1} to the interstitial hydroxyl stretching bond, since the relative number of surface OH bonds increases for highly defiberized material.

The ratio of the absorbance values in the ATR mode vary in a monotone fashion for the remaining four fiber types. When classified in order of absorbance ratios $A(\bar{\nu})/A(954\ \text{cm}^{-1})$, the shortest fibers have the largest ratios at the shortest wavelengths (e.g. $\bar{\nu}$ = 3690 cm^{-1}) and the longest fibers have the largest ratios at the longest wavelengths (e.g. $\bar{\nu}$ = 303 cm^{-1}).

It is possible to normalize the ATR results by dividing them by peak height in the transmission mode. The normalized data should reflect primarily the effect of morphology since, for nonpolarised radiation, it may be presumed that the extinction coefficient for the evanescent wave is similar to that found for the same IR band for transmitted radiation. These normalized

	Paperbestos #3 (*e*)					
3690	0.17	0.50	0.34			
3646	0.06	0.17	0.37			
1080	0.36	0.61	0.59			
1025	0.47	0.69	0.68			
605	0.70	0.57	1.22			
303	0.60	0.25	2.40			

values are plotted in Fig. 9 as a function of the fiber length. The trends noted above in Table 2 become evident and reflect the effective depth of penetration with respect to the major silicate band at $\bar{\nu} = 954\ cm^{-1}$. Even the Calidria COF-25 data fall in the line with the remaining points when plotted in terms of average fiber length, as in Fig. 9, or as a function of the aspect ratio.

The ratio S_{ATR} (303 cm^{-1})/S_{ATR} (3690 cm^{-1}) varies linearly with log (fiber length) as in Fig. 9 RHS ordinate scale. This result provides a very simple means to characterize the asbestos samples collected on the air filter. The absorbance at 303 cm^{-1} could be used to establish the concentration ($\mu g/cm^2$) independent of fiber dimension. The absorbance ratio with respect to the peak at 3690 cm^{-1} would allow an estimate of the mean length (Fig. 9) and hence eventually the number of fibers collected (Fig. 8).

Received August 5, 1982[3]

DAO CONG DONG, WINNIE WONG-NG, STANLEY C. NYBURG, PIK YUEN SIEW, and J. T. EDWARD. Can. J. Chem. **62**, 452 (1984).

The crystal structures of two *endo-endo*-dienes, 5,6,7,8,9,9-hexachloro-1,4,4*a*,5,8,8*a*-hexahydro-*endo-endo*-1,4-ethano (and propano)-5,8-dimethanonaphthalene, **I***b* and **I***c* have been determined. These, together with the methano-homolog **I***a* (of known structure), are shown to exhibit decreasing across-space double-bond/double-bond repulsion which correlates with the observed decrease in the ease of cyclization in solution.

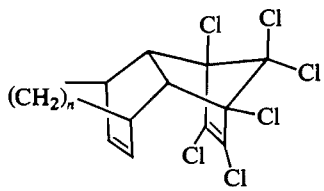
DAO CONG DONG, WINNIE WONG-NG, STANLEY C. NYBURG, PIK YUEN SIEW et J. T. EDWARD. Can. J. Chem. **62**, 452 (1984).

On a déterminé les structures cristallines de deux dienes *endo-endo*, les hexachloro-5,6,7,8,9,9 hexahydro-1,4,4*a*,5,8,8*a* éthano-1,4 (et propano)-*endo-endo* diméthano-5,8 naphtalène (**I***b* et **I***c*). On démontre que ces composés, ainsi que l'homologue méthano **I***a* (de structure connue) présentent des répulsions double liaison/double liaison à travers l'espace qui vont en décroissant: ceci est en accord avec les facilités relatives de cyclisation en solution qui ont été observées.

[Traduit par le journal]

Introduction

This paper reports the crystal and molecular structures of two hexachlorinated *endo-endo*-dienes, **I***b*, **I***c* which, together with **I***a* of known structure (1), form a homologous series. Interest



I*a,b,c*, ($n = 1,2,3$)

in these compounds lies in the marked differences in their ease of cyclization in which the opposing double bonds are opened to form a four-membered ring. Dong and Edward (2) have shown that when bromine is added to carbon tetrachloride solutions of the dienes which are then irradiated with uv light, the speed of cyclization is in the order **I***a* > **I***b* > **I***c*. These authors attribute this sequence to decreasing molecular strain with increasing n, an interpretation supported by the results reported here.

Experimental

Both crystal specimens were prepared as described by Dong and Edward (2). The crystals were, in both cases, colorless and well formed. Unit cell dimensions were determined from diffractometer setting angles of seven or more centered reflections using Zr-filtered MoKα radiation. Intensity data were collected on a Picker four-circle diffractometer in θ−2θ scan mode at 2° min^{-1} in the range θ < 25°. In both cases the initially colorless crystals became cloudy and there was loss in reflection intensity. Corrections linear in time were applied to compensate for these intensity losses. Reflections were considered to be of significant intensity on the criterion $F_o > 2\sigma(F_o)$ where $\sigma(F)$ was taken as $\{[\sigma(I)\cdot Lp]^2 + 0.02F_o^4\}^{1/2}/2F_o$, Lp being the Lorentz-polarization factor.

The structures were solved by direct methods using the SHELX (3) package. Anisotropic least-squares refinement was by SHELX using the atomic scattering factors and anomalous dispersion corrections (for chlorine) provided by the program.

5,6,7,8,9,9-Hexachloro-1,4,4a,5,8,8a-hexahydro-endo-endo-*1,4-ethano-5,8-dimethanonaphthalene*, ***I***b

A fragment ca. 0.04 × 0.46 × 0.21 mm was cut for X-ray structure analysis. Crystal data are as follows:

$C_{13}H_8Cl_6$ $M_r = 376.95$

Orthorhombic, *Pbca*, $a = 15.01(4)$, $b = 13.27(3)$, $c = 15.00(4)$ Å, $U = 2988$ Å^3, $Z = 8$ molecules per cell, $D_c = 1.68$, D_m (not det.) Mg m^{-3}, μ(MoKα) = 10.4 cm^{-1}.

Out of 2488 reflections 1528 were deemed significant. Structure solution was based on the most probable set of phases derived from the 286 *E* values greater than 1.6. In the penultimate refinement cycle, hydrogen atoms were added in theoretical positions using d(C—H) = 1.08 Å. Their temperature factors were refined overall to $U = 0.068$ Å^2. Final atomic co-ordinates are given in Table 1. (Anisotropic temperature factors and the F_o, F_c table have been deposited.)[4] The final unweighted and weighted *R* values were 0.057 and 0.063, respectively. The molecule of **1***b* is illustrated in Fig. 1.[5,6]

5,6,7,8,9,9-Hexachloro-1,4,4a,5,8,8a-hexahydro-endo-endo-*1,4-propano-5,8-dimethanonaphthalene*, ***I***c

A fragment ca. 0.87 × 0.54 × 0.17 mm was cut for X-ray structure analysis. Crystal data are as follows:

$C_{14}H_{12}Cl_6$ $M_r = 392.97$

Monoclinic, $P2_1/c$, $a = 9.42(2)$, $b = 12.30(4)$, $c = 27.84(10)$ Å, $\beta = 97.27(6)°$, $U = 3200$ Å^3, $Z = 8$ molecules per cell, $D_c = 1.63$, D_m (not det.) Mg m^{-3}, μ(MoKα) = 10.61 cm^{-1}.

Out of 5557 reflections, 3945 were considered of significant intensity. There was a 15% loss in reflection intensity during data collection. Structure solution was from the most probable set of phases obtained from the 286 *E* values greater than 1.7.

There are two molecules **A**, **B** in the asymmetric unit whose atomic designations are unprimed and primed, respectively. The former molecule presented no refinement problems but molecule **B** had initially a virtually coplanar propanobridge system and large anisotropic temperature factors for atom C(13)′. This was attributed to disorder and it was possible to resolve and separately refine the two positions for this atom. The positions are named C(13)′ and C(13)″. Refinement of occupancy gave 0.46(5) and 0.54(5); these were then

‡Clearly the disordered positions of C(13) given by least-squares refinement are very inaccurate.

both set to 0.5 and kept fixed. Separate, resolvable positions could not be found for C(12)′ or for C(14)′.

All hydrogen atoms of molecule **A** and all those of **B** (apart from those attached to C(12)′, C(13)′, C(13)″, and C(14)′) were found on the ΔF map with density 0.3–0.7 e Å^{-3}. Their positions were fixed theoretically and their individual isotropic temperature factors, U, refined. Temperature factors for the remaining hydrogen atoms of molecule **B** were refined overall to a U value of 0.11 (1) Å^2. Final atomic co-ordinates are listed in Table 2. (Anisotropic temperature factors and the F_o, F_c table have been deposited.)[4] The final unweighted and weighted R values were 0.052 and 0.061, respectively. Molecule **A** is illustrated in Fig. 2 (molecule **B** is not illustrated).

No unusually short intermolecular contacts were reported for the crystal structure of **I***a* and none were found in the crystal structures of **1***b* or **I**c.

Discussion

All four molecules **I***a*, **I***b*, **I***c***A**, and **I***c***B** show nearly exact (non-crystallographic) *m* (C_s) symmetry. This can be shown by using the best molecular fitting program BMFIT (4), which gives the following small sums of the squared atomic displacements from *m* symmetry: **I***a*, 0.065, **I***b*, 0.011, **I***c***A**, 0.02 Å^2. Accordingly, in the lower part of Table 3, pseudo-*m* related bond lengths are paired off, some being designated by lower case letters to facilitate discussion. It will be seen that, for molecules **I***b*, **I***c***A**, and **I***c***B**, all bond lengths agree well (except for the disordered atom in positions C(13)′ and C(13)″). The bond lengths of **I***a* match less well, especially those of types *b* and *c*. In fact, there seems to be a number of bond lengths of **I***a* which are not in good accord with those of **I***b* or

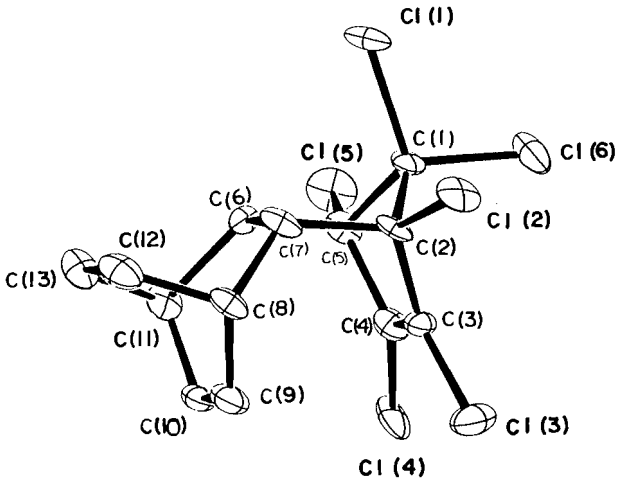

FIG. 1. ORTEP plot (10) of molecule **1***b* showing atomic numbering and 50% probability ellipsoids.

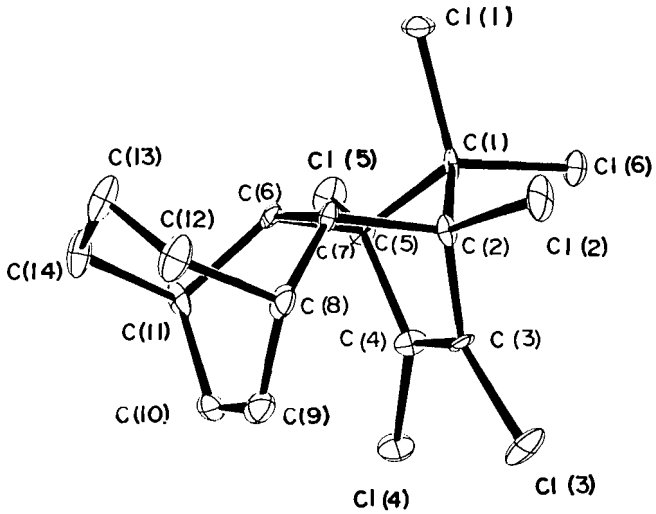

FIG. 2. ORTEP plot of molecule **1***cA*.

I*c*. Accordingly, we carried out a structure analysis on a specimen of **I***a*, but the rapid deterioration of the crystal in X-rays prevented a good data set from being collected. Indeed, we found the same general differences in bond lengths with molecules **I***b* and **I***c* as were found by Kennard *et al.*(1), in particular, that bonds of types *c* and *c'* are, on average, longer than in molecules **I***b* and **I***c*. This effect appears to be directly related to the decreasing repulsion between bonds *a* and *a'* which appears to bring in its train a second effect, a change in the state of hybridization of atoms C(2) and C(5) involved in the *c'*-type bonds. There is a steady increase in the dihedral between planes I and II (see Figure in Table 4): 112°, 119°, and 120°. This, in turn, causes Cl(6) to be brought into repulsive conflict with Cl(2) and Cl(5) causing C(1)—Cl(6) to stretch. It is because of this stretching (which decreases through the series, see Table 3) that the mean distance between Cl(6) and the conflicting chlorine atoms Cl(2) and Cl(5) remains approximately constant: 3.36, 3.40, and 3.45 Å. In the absence of this stretching these distances would have been unacceptably short.

Our main preoccupation is with the nature of the interaction between the double bonds *a*, *a'*. For molecules **I***a* and **I***b* it is possible, using known geometries of suitable molecular fragments, to infer what the geometries of these molecules would have been in the absence of any interaction between bonds *a* and *a'*. Table 4 shows the sources from which the required bond lengths and angles have been taken. Each molecule can be considered to be made up of two parts at bond *d* (i.e. C(6)—C(7)), one part being the same in all three molecules, the other varying with *n*, the number of bridging methylene groups. In the case of molecule **I***c* we could find no precedent for this second half so we have used the geometry of the molecule itself and connected it to the idealised constant part. We find that this molecule shows the least double-bond/double-bond interaction of the three so that, probably, the hypothetical molecule (completely free from this interaction) would have similar bond lengths and angles to those found experimentally.

¶This paper.

From the dimensions assumed in Table 4 it is possible to calculate exactly what the distances between the mid-points of bonds *a* and *a'* would have been in the absence of any double-bond/double-bond interaction across space. The results are 2.03, 2.37, and 2.67 Å for **I***a*, **I***b*, and **I***c*, respectively. The experimental distances are: **I***a*, 2.87 (calculated from ref. 1), **I***b*, 2.94, **I***c***A**, 2.99 and **I***c***B**, 3.01 Å. These results imply that there is a repulsive interaction between the double bonds in these molecules which decreases through the homologous series, the differences between observed and hypothetical distances decreasing: 0.84, 0.57, and 0.33 (mean) Å. (It is possible that changes in the state of hybridization of atoms C(9) and C(10) also play some part in this trend. The mean bond angle *a* ^ *b* increases significantly through the series: 108.0°, 114.9°, 119.1°.)

In conclusion, since the double-bond/double-bond interaction across space decreases in the order **I***a* > **I***b* > **I***c*, the strain within the molecules must decrease in the same order. Dong and Edward (2) came to the same conclusion using

Dreiding molecular models and, as noted earlier, attributed this decreasing strain to the decreasing speed of cyclization in uv-irradiated solutions.

Phase diagrams and thermodynamic properties of five additive molten salt ternary systems and nine reciprocal molten salt ternary systems containing the ions Li^+, Na^+, K^+/CO_3^{2-}, SO_4^{2-}, OH^- are calculated from the thermodynamic properties of their binary subsystems which were obtained previously by a critical assessment of the thermodynamic data and the phase diagrams in these binary systems. Thermodynamic properties of ternary liquid phases are estimated from the binary properties by means of the Conformal Ionic Solution Theory. The ternary phase diagrams are then calculated from these thermodynamic properties by means of computer programs designed for the purpose. It is found that a ternary phase diagram can generally be calculated in this way with a maximum error about twice that of the maximum error in the binary phase diagrams upon which the calculations are based. If, in addition, some reliable ternary phase diagram measurements are available, these can be used to obtain small ternary correction terms. In this way, ternary phase diagram measurements can be smoothed and the isotherms drawn in a thermodynamically correct way. The thermodynamic approach permits experimental data to be critically assessed in the light of thermodynamic principles and accepted solution models. A critical assessment of error limits on all the calculated ternary diagrams is made, and suggestions as to which composition regions merit further experimental study are given.

A. D. PELTON, C. W. BALE et P. L. LIN. Can. J. Chem. **62**, 457 (1984).

On a calculé les diagrammes de phase et les propriétés thermodynamiques de 5 systèmes ternaires additifs de sels fondus et de 9 systèmes ternaires réciproques de sels fondus contenant des ions Li^+, Na^+, K^+/CO_3^{2-}, SO_4^{2-}, OH^-; ces calculs ont été effectués à partir des propriétés thermodynamiques de leurs sous-systèmes binaires que l'on a obtenues antérieurement par un évaluation critique des données thermodynamiques et des diagrammes de phase de ces systèmes binaires. On a évalué les propriétés thermodynamiques des phases liquides ternaires en faisant appel à la théorie des solutions ioniques conformales. On calcule alors les diagrammes de phases ternaires à partir de ces propriétés thermodynamiques au moyen de programmes d'ordinateurs réalisés dans ce but. On a trouvé qu'un diagramme de phase ternaire peut généralement être calculé de cette façon avec une erreur maximale qui n'est que le double de l'erreur maximale obtenue avec les diagrammes de phases binaires sur lesquels reposent ces calculs. De plus, si on dispose de mesures fiables pour les diagrammes de phases ternaires, on peut alors utiliser ces mesures pour déduire des petits termes de correction ternaires. De cette façon, on peut raffiner les mesures de diagrammes de phases ternaires et tracer les isothermes d'une manière qui est thermodynamiquement correcte. L'approche thermodynamique permet d'évaluer les données expérimentales d'une façon critique à la lumière de principes thermodynamiques et de modèles acceptables pour les solutions. On a fait une évaluation critique des limites d'erreur sur tous les diagrammes ternaires calculés et on fait des suggestions relatives aux zones de composition qui méritent des études expérimentales plus approfondies.

[Traduit par le journal]

Introduction

In the molten carbonate fuel cell being developed by the U.S. Department of Energy, the electrolyte consists nominally of a mixture of liquid lithium and potassium carbonates. It has been proposed that sodium carbonate might also be added. The gas phase contains a mixture of hydrocarbons, H_2, CO, CO_2, O_2, N_2, etc. Significant quantities of sulfur may also be present as impurity in the gas phase as SO_2, SO_3, S_2, H_2S, etc. Since the gas is recirculated between electrode compartments, the sulfur can accumulate in the electrolyte.

Reaction between the gas and liquid phases can result in changes in electrolyte composition through the appearance of OH^- and SO_4^{2-} ions dissolved in the molten carbonate and through volatilization of hydroxides. Under certain conditions, S^{2-} ions may also be present, but the principal ions expected in solution will be Li^+, K^+, Na^+, CO_3^{2-}, OH^-, and SO_4^{2-}. The composition of the electrolyte is important to the operating characteristics of the cell. In particular, too large a shift from the nominal $Li_2CO_3-K_2CO_3$ composition could result in the precipitation of solid phases. In addition, volatilization of the electrolyte can occur through the formation of hydroxide vapour species such as LiOH and $Li_2(OH)_2$.

The composition of the electrolyte depends upon the composition of the gas phase with which it is in contact. The entire system cannot be at equilibrium since the gases in the anode and cathode compartments are different. Hence, composition gradients will be observed in the electrolyte. At the high operating temperature (650°C) of the cell, however, it is likely that local gas–liquid equilibrium is attained.

It would be desirable to have a complete thermodynamic analysis of the system such that, for a given temperature and total pressure, a given overall gas composition, and a given Li/K ratio in the electrolyte one could find, at equilibrium, (*i*) the partial pressures of all the species in the gas phase and the extent of electrolyte volatilization, and (*ii*) the composition of the electrolyte. It would also be desirable to have the phase diagram of the Li, Na, K/CO_3, OH, SO_4 system, especially near the nominal alkali composition of the operating cell, to know whether the precipitation of any solid phases is expected. The results should be important for fully defining the chemistry of cell operation and for understanding how different variables (e.g. changes in fuel composition) influence the chemistry of the cell and volatilization.

Such a complete thermodynamic analysis has recently been performed by the authors (1) using the facilities of the F*A*C*T computerized thermodynamic data bank and data treatment center (2). The results of the first stage of this project, the optimizational analysis of the phase diagrams and thermodynamic properties of the 18 binary systems containing the ions Li^+, Na^+, K^+/SO_4^{2-}, CO_3^{2-}, OH^-, was reported in a previous publication (3). In the present article are reported the results of the second stage, the calculation of the thermodynamic properties and phase diagrams of 14 ternary additive and reciprocal fused salt systems containing these ions.

The calculation of phase diagrams of ternary fused salt systems — general methodology

The calculation of the ternary phase diagrams was carried out in the following manner. First, all available thermodynamic data and measured phase diagrams of the binary subsystems of each ternary system were critically assessed and an optimization analysis (4) was carried out in order to obtain mathematical expressions for the Gibbs energies of all phases as functions of temperature and composition which "best" reproduce the experimental thermodynamic properties and phase diagrams. Second, interpolation procedures were used to estimate the Gibbs energies of the ternary liquid phases from the Gibbs energies of the binary liquid phases. Finally, the ternary phase diagrams were calculated from these estimated ternary thermodynamic properties.

This type of calculation has been carried out for a large number of ternary salt systems by the present authors (5−10) and by others (11−14). This experience has shown that, in general, the maximum uncertainty in an estimated ternary phase diagram is about twice that of the binary phase diagrams upon which the calculations are based. If the binary phase diagrams have been measured to ±5°C, then the ternary diagram estimated therefrom is probably accurate to ±10°C.

If, in addition, some ternary phase diagram measurements have been made, a small adjustable ternary term can be added to the expression for the Gibbs energy in order to increase the precision. Even when ternary phase diagram data are available, this type of approach serves to smooth the data and to yield ternary isotherms whose interpolated shape is consistent with basic thermodynamic principles.The data can be checked for internal consistency, discrepancies can be identified and frequently resolved, and areas in which further experimentation is required can be identified.

Thermodynamic properties of the pure components

Thermodynamic properties of the nine pure salts are listed in Table 1. Data are taken mainly from ref. 15. Details of the sources and accuracy of these data are given in refs. 1 and 3.

Temkin ideal mixing terms

The Gibbs energy of a molten salt solution can be written as the sum of ideal and excess terms. For the ideal terms, experience has shown that the Temkin model in which cations and anions mix randomly on their respective sublattices, regardless of charge, invariably gives the best results and is consistent with observations in the limiting dilute concentration regions. In the Temkin model, the ideal entropy of mixing referred to the pure neutral salts is given by:

$$[1] \quad \Delta S = -R\Sigma n_k \ln X_k$$

where n_k is the number of moles of ions k in solution, and X_k is either the cationic or anionic molar fraction of ion k defined as:

$$[2] \quad X_k = n_k / \sum_{\text{cations}} n_i$$

in the case of a cation, or

$$[3] \quad X_k = n_k \Big/ \sum_{\text{anions}} n_j$$

in the case of an anion.

It is also necessary for the following discussion to define the equivalent ionic fraction, Y_k, of ion k as:

$$[4] \quad Y_k = q_k n_k / \Sigma q_i n_i$$

where q_k is the absolute value of the charge on ions k, and the summation in eq. [4] is over all cations if k is a cation or over all anions if k is an anion.

Thermodynamic/phase diagram analysis of binary systems

There are nine binary common anion systems (e.g.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

$Li_2CO_3-K_2CO_3$) and nine binary common cation systems (e.g. $LiOH-Li_2CO_3$) formed among the ions Li^+, Na^+, K^+/CO_3^{2-}, SO_4^{2-}, OH^-. Expressions were obtained (3) for the thermodynamic properties of all phases in these systems as functions of temperature and composition.

In the liquid binary phases and in any binary solid solutions, the enthalpy of mixing, Δh^{mix}, and the excess entropy of mixing, s^E, per equivalent of solution, are expressed as power series in the equivalent ionic fractions as follows:

$$[5] \quad \Delta h^{mix} = \sum_{i,j} h_{ij} Y_A^i Y_B^j$$

$$[6] \quad s^E = \sum_{i,j} s_{ij}^E Y_A^i Y_B^j$$

and so the equivalent excess Gibbs energy is given as:

$$[7] \quad g^E = \sum_{i,j} \phi_{ij} Y_A^i Y_B^j = \sum_{i,j} (h_{ij} - T s_{ij}^E) Y_A^i Y_B^j$$

where Y_A, Y_B are the equivalent ionic fractions of the anions in the case of a common-cation binary system, or the equivalent ionic fractions of the cations in the case of a common-anion system.

h_{ij} and s_{ij}^E are empirical coefficients found by a least-squares optimization procedure to be discussed shortly. The number of coefficients required to give a satisfactory representation varies from system to system. Experience has shown that the use of equivalent ionic fractions rather than molar ionic fractions in the polynomial expansions frequently reduces the number of coefficients required to yield a satisfactory fit. In the present study, no more than three terms were ever required.

Δh^{mix}, s^E, and g^E in eqs. [5], [6], [7] are expressed per equivalent of solution. One equivalent of solution contains one equivalent of anions and one equivalent of cations. Hence, this method of representation is unambiguous, whereas normalization in terms of a "mole of solution" would be ambiguous since, with ions of different absolute charges, the number of moles of cations and the number of moles of anions in solution are not necessarily equal.

Dilute binary solid solutions are treated as Henrian solutions. The Henrian activity coefficient γ^0 is expressed as:

$$[8] \quad RT \ln \gamma^0 = A + BT$$

where A and B are adjustable parameters. Often, B can be set equal to zero. Values of A and B are generally calculated so as to reproduce the measured solubilities in the binary solid phases.

Finally, it is necessary to obtain expressions for the Gibbs energies of fusion of all known binary intermediate solid compounds, $(M_mX)_x(N_nY)_{(1-x)}$, as follows:

$$[9] \quad \Delta g^0_{fusion} = a + bT$$

For many of the 18 binary systems, Δh^{mix} has been measured calorimetrically for the liquid phases. For all but one of the systems, experimental phase diagrams are available. For a few intermediate compounds, Δg^0_{fusion} has been measured. A critical optimization analysis of all these data was performed (3) in order to find the "best" set of coefficient h_{ij}, s_{ij}^E, A, B, a, b of eqs. [5]–[9] for each system. For those intermediate compounds for which Δg^0_{fusion} has not been measured, the coefficients a, b of eq. [9] were found from phase diagram analysis after all the other coefficients had been determined. The choice of which coefficients are "best" is based upon the authors' judgment of the reliability of the various sets of data, of whether certain values of thermodynamic properties are plausible or not based upon experience with similar systems, and so on. The choice is made partially subjectively and partially objectively. A computer program called "FITBIN" (2) has been written to assist in this critical analysis. The different sets of data (thermodynamic data and parameters, liquidus compositions, etc.) are read directly into the computer interactively along with appropriate weighting factors. The computer program linearizes the data and performs a least-squares optimization procedure. The operator can interact with the program until the "best" analysis is obtained. This interaction can involve changing the weighting factors for certain data points or data sets, varying the numbers of coefficients used in the polynomial expansions and so on. The choice of the "best" coefficients must always be made with a large measure of subjectivity based upon an assessment of the reliability of the various data sets, upon a knowledge of the behaviour of similar systems, and upon experience. However, the computer-assisted analysis assures thermodynamic consistency and plausibility, permits the thermodynamic data and the phase diagram data to be treated simultaneously, and ensures that the rules of solution theory such as adherence to Raoult's Law in concentrated solutions are obeyed. The interactive nature of the computer programs takes the tedium out of the calculations and permits the operator to concentrate on the analysis itself rather than on the mechanical details.

Complete details of the analysis for all 18 binary systems are given in ref. 3. A summary of the optimized parameters is given in Table 2. Binary phase diagrams calculated from these parameters are given in ref. 3 and are also shown as the edges of the ternary diagrams in Figs. 3–16 of the present article. The optimization analysis also aids in the assessment of the accuracy of the calculated diagrams. These accuracies are listed in Table 2 as "probable maximum deviations". This is the estimated probable maximum difference between the true diagrams and the calculated diagrams which can be regarded as the best present estimates of the true diagrams.

Procedures used for the calculation of ternary phase diagrams

Once all the binary systems have been analysed, the thermodynamic properties of the ternary systems may be estimated by means of interpolation procedures.

Additive ternaries

The additive ternary systems in the present study are those composed of three salts with a common cation such as $Li_2CO_3-Li_2SO_4-LiOH$, or three salts with a common anion such as $Li_2CO_3-Na_2CO_3-K_2CO_3$. Compositions are expressed on the standard "Gibbs triangle".

The interpolation formulae for estimating ternary Gibbs energies from binary Gibbs energies which have proved successful in the case of additive fused salt systems are the Conformal Ionic Solution (CIS) equation (16) and a group of "geometrical" formulae, most notably the Kohler (17) and Toop (18) equations.

CIS equation

The CIS equation, which is based upon statistical mechanical perturbation theory, for the excess Gibbs energy of an additive ternary molten salt system with components 1–2–3 is derived (16) as:

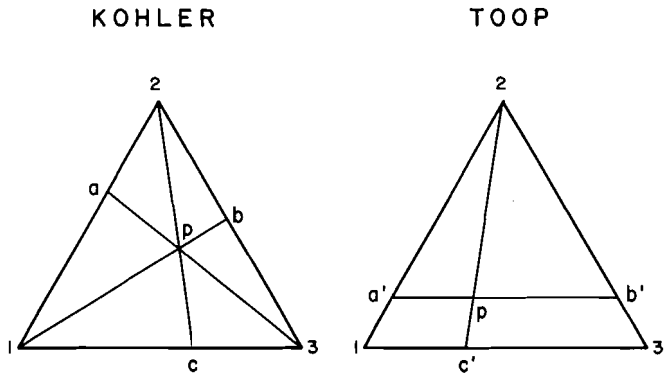

FIG. 1. Composition triangle illustrating the geometrical basis of the Kohler and Toop equations [11], [12].

$$[10]\quad g^E = \sum_m \sum_{n<m} \phi_{11(mn)} Y_m Y_n + \sum_{m \neq n} \phi_{21(mn)} Y_m^2 Y_n + \sum_{m<n} \phi_{22(mn)} Y_m^2 Y_n^2 - (\phi_{21(12)}^{1/3} + \phi_{21(13)}^{1/3})(\phi_{21(23)}^{1/3} + \phi_{21(21)}^{1/3}) \times (\phi_{21(31)}^{1/3} + \phi_{21(32)}^{1/3}) Y_1 Y_2 Y_3 + \sum_{m \neq n < k} 2(\phi_{22(mn)} \phi_{22(mk)})^{1/2} Y_m^2 Y_n Y_k$$

where g^E is expressed per equivalent of solution and where Y_1, Y_2, Y_3 are the equivalent ionic fractions of the non-common ions. Hence, g^E in the ternary can be calculated from a knowledge of the coefficients $\phi_{11(mn)}$, $\phi_{21(mn)} = -\phi_{21(nm)}$, and $\phi_{22(mn)} = \phi_{22(nm)}$ of the three binary subsystems.

Kohler and Toop equations

The Kohler equation (17) for the ternary excess Gibbs energy is

$$[11]\quad g^E_{(P)} = (1 - X_3)^2 g^E_{(a)} + (1 - X_1)^2 g^E_{(b)} + (1 - X_2)^2 g^E_{(c)}$$

The Toop equation (18) is as follows:

$$[12]\quad g^E_{(P)} = \frac{X_1}{X_1 + X_3} g^E_{(a')} + \frac{X_3}{X_1 + X_3} g^E_{(b')} + (1 - X_2)^2 g^E_{(c')}$$

where, in the 1–2–3 ternary system of Fig. 1, $g^E_{(P)}$ is the excess Gibbs energy at point p in the ternary system and $g^E_{(a)}$, $g^E_{(a')}$, ... are the excess Gibbs energies in the binary systems at the points indicated. X_1, X_2, X_3 are the molar ionic fractions of the non-common ions, and g^E in eqs. [11], [12] is expressed per mol of non-common ions in the solution.

Equations [11], [12] are based on regular solution theory, and both equations are exact if the binary and ternary solutions are regular. The Kohler equation has the advantage over the Toop equation of being symmetrical with respect to the three components. Therefore, the Kohler equation is preferred over the Toop equation for charge symmetrical additive ternary systems. For ternary charge asymmetrical fused salt systems such as $MOH-M_2SO_4-M_2CO_3$, the Toop equation is preferred over the Kohler equation, with the asymmetrical component (MOH) as component 2 in Fig. 1. In this case, the first two terms on the right hand side in eq. [12] represent a linear interpolation between the two asymmetrical binary systems 2–1 and 2–3 at the same mole fraction X_2, while the third term, which is the same as the third term in eq. [11], represents the contribution from the charge-symmetrical 1–3 system.

The CIS equation [10] applies equally to charge symmetrical and charge-asymmetrical systems and is, in general, to be preferred over both the Kohler and Toop equations for fused salt solutions since it is based on firmer theoretical ground and has been developed specifically for liquid salt solutions, whereas the Kohler and Toop equations are more general and are semi-empirical. However, for solid solutions, the more general equations are preferable, since the theoretical basis for the CIS equations no longer holds. In the present study for dilute ternary solid solutions which extend a short distance into the ternary system from one side of the composition triangle, the Toop equation, asymmetric in the third component, is preferable on grounds of symmetry.

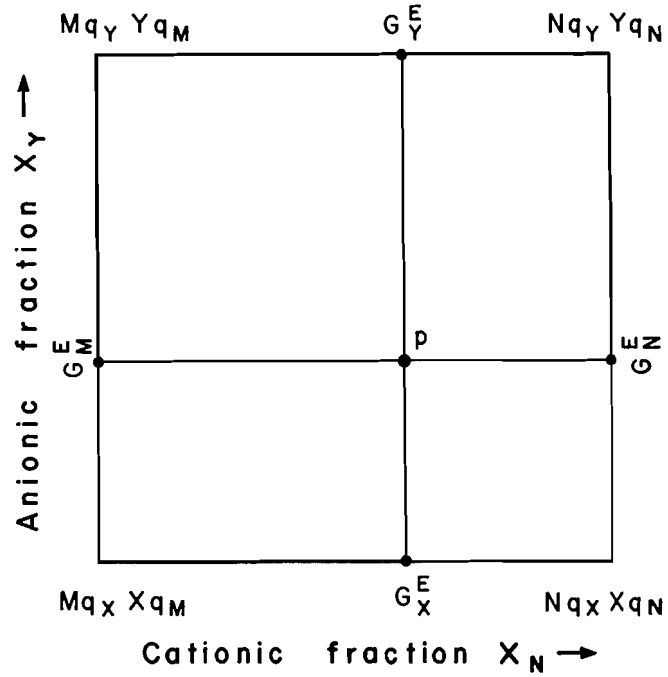

FIG. 2. Composition square of a reciprocal ternary system illustrating the geometrical basis of the CIS equation [13].

Equations [10], [11], [12] have been shown (4–14) to give good approximations for a large number of ternary salt systems.

If a measured ternary phase diagram is available, and if the calculated and measured diagrams do not agree within the experimental error limits of the latter, then ternary terms of the form $\phi_{ijk} Y_1^i Y_2^j Y_3^k$ with adjustable parameters ϕ_{ijk} ($i, j, k \geq 1$) can be added to eqs. [10], [11], [12], although this was not required in the present study.

Reciprocal ternaries

A reciprocal ternary system is defined as one containing two cations, M, N and two anions, X, Y. Although such a system contains four ions, the condition of charge neutrality removes one degree of freedom. Concentrations in a reciprocal ternary system are most conveniently plotted on a composition square as shown in Fig. 2 in which the horizontal and vertical axes are the cationic and anionic mole fractions, X_N and X_Y. The corners of this square represent compositions corresponding to the pure neutral salts $M_{q_X} X_{q_M}$, etc. (where q_M, q_N, q_X, q_Y are the absolute charges on the ions), and the edges of the square represent compositions in the binary subsystems.

The extended CIS theory (19, 20) for reciprocal ternary systems has been applied with success (6, 9, 21–23) to calculate the thermodynamic properties of a large number of ternary reciprocal systems from the properties of the binary subsystems. The excess Gibbs energy per equivalent of solution at a point P (see Fig. 2) within the ternary system relative to the

$\frac{1}{2}K_2CO_{3(l)} + LiOH_{(l)} = \frac{1}{2}Li_2CO_{3(l)} + KOH_{(l)}$	$11900 - 34.235T + 3.72T \ln T$	$-4502 + 3.802T$
$\frac{1}{2}Li_2CO_{3(l)} + NaOH_{(l)} = \frac{1}{2}Na_2CO_{3(l)} + LiOH_{(l)}$	$-4375 + 1.065T + 0.15T \ln T$	$-1469 + 1.19T$
$NaOH_{(l)} + \frac{1}{2}K_2CO_{3(l)} = KOH_{(l)} + \frac{1}{2}Na_2CO_{3(l)}$	$7525 - 33.17T + 3.87T \ln T$	$-910 + 0.802T$
$\frac{1}{2}K_2SO_{4(l)} + NaOH_{(l)} = \frac{1}{2}Na_2SO_{4(l)} + KOH_{(l)}$	$6730 - 15.42T + 1.83T \ln T$	$-2452 + 1.781T$
$\frac{1}{2}Li_2SO_{4(l)} + KOH_{(l)} = \frac{1}{2}K_2SO_{4(l)} + LiOH_{(l)}$	$-13930 + 14.23T - 1.38T \ln T$	$-12928 + 8.237T$
$\frac{1}{2}Li_2SO_{4(l)} + NaOH_{(l)} = \frac{1}{2}Na_2SO_{4(l)} + LiOH_{(l)}$	$-7200 - 1.19T + 0.45T \ln T$	$-4722 + 3.412T$

pure components $M_{q_X}X_{q_M}$, $N_{q_X}X_{q_N}$ and $N_{q_Y}Y_{q_N}$, is given by the CIS theory as:

$$[13] \quad g^E = Y_M Y_Y \Delta G^{EX} + (Y_M g_M^E + Y_N g_N^E + Y_X g_X^E + Y_Y g_Y^E) + Y_M Y_N Y_X Y_Y \Lambda$$

where g_M^E, g_N^E, g_X^E, g_Y^E are the excess equivalent Gibbs energies in the four binary subsystems at the ends of horizontal and vertical lines passing through point P in Fig. 2, and where ΔG^{EX} is the Gibbs energy of the "exchange reaction" among one equivalent of each of the pure salts according to:

$$[14] \quad (q_M q_X)^{-1} M_{q_X} X_{q_M} + (q_N q_Y)^{-1} N_{q_Y} Y_{q_N} = (q_M q_Y)^{-1} M_{q_Y} Y_{q_M} + (q_N q_X)^{-1} N_{q_X} X_{q_N}$$

The factor Λ in eq. [13] is composition-independent. It has been shown (19, 20) that, for liquid salts, to a first approximation Λ is given by:

$$[15] \quad \Lambda = -(\Delta G^{EX})^2 / 2ZRT$$

where the parameter Z is commonly taken as $Z = 6$.

For solid reciprocal ionic phases, larger deviations from the CIS equation are to be expected since the theoretical assumptions on which the CIS model are based are not as good for solids. In particular, there is probably little justification to the use of eq. [15] for solid phases. If a measured ternary diagram of sufficient accuracy is available, and if the measured and calculated diagrams do not agree within the experimental error limits, then Λ can be taken as an adjustable ternary parameter. Although for a liquid phase the value of Λ should not deviate too far from that given by eq. [15] and should in theory always be negative, in the case of a solid reciprocal salt phase much larger deviations are to be expected.

Values of ΔG^{EX} taken from ref. 15 for the exchange reactions (expressed in terms of one equivalent of each reactant and product) for the nine reciprocal systems in the present study are listed in Table 3. Values of Λ from eq. [15], linearized with respect to temperature over the temperature range of interest, are also listed in Table 3.

It is to be noted that the most important term in eq. [13] as regards its influence upon g^E and hence upon the calculated phase diagram is the term containing ΔG^{EX}. The "binary terms" are of lesser importance, and the term containing Λ is generally of least significance.

Detailed calculations for ternary systems

The techniques discussed above cannot, of course, predict the existence of ternary compounds. If a ternary compond is known to exist, then it can be included in the calculations. In general, for systems treated here, the existence of unknown ternary compounds with large negative Gibbs energies of formation from neighouring compounds which could significantly affect the liquidus surface is unlikely.

Details of the calculations of the 14 ternary additive and reciprocal phase diagrams considered in the present study will now be given. Calculated polythermal projections of the liquidus surfaces are presented along with the values of any ternary parameters. Reproductions of measured ternary diagrams are also given for each system when available. The calculated diagrams were prepared with the computer programs TERNFIG and RECIPFIG which are available as part of the F*A*C*T (2) interactive computer system.

The accuracy of the calculated phase diagrams depends strongly upon the composition region in question. In general, near any binary subsystem the error in the ternary diagram is about the same as that given in Table 2 for the binary system. Accuracies quoted in the following discussions of individual ternary systems are given as estimated "probable maximum deviations" between the calculated diagrams and the true diagrams ("true" diagram means the real correct diagram, not the experimental diagram). However, in most composition regions, the probable deviation will generally be less than the quoted "maximum" value.

In the calculated polythermal projections, temperatures are in °C. The symbols e, p, and m refer to binary eutectics, peritectics, and minima, and the symbols E and P refer to ternary eutectics and peritectics. The maximum extent of solid solubility in the binary subsystems is indicated by hatching along the axes of the diagrams. In Figs. 11, 12, 13, 16, for certain systems containing OH^-, the components are indicated as $(LiOH)_2$, $(NaOH)_2$, and $(KOH)_2$. In these cases the anionic fraction axes are not the anionic molar fractions, X_{OH} but rather the anionic equivalent fractions, Y_{OH}. This was done in order to facilitate comparison with the measured diagrams which are drawn in this way.

$Li/CO_3,SO_4,OH$ (Fig. 3)
$Na/CO_3,SO_4,OH$ (Fig. 4)
$K/CO_3,SO_4,OH$ (Fig. 5)

No measured phase diagrams were found. The phase diagrams were calculated via the CIS equation [10]. When the calculations were repeated with the Toop equation [12] with the hydroxide as the "asymmetric component" the results agreed with those of the CIS theory within 2°C.

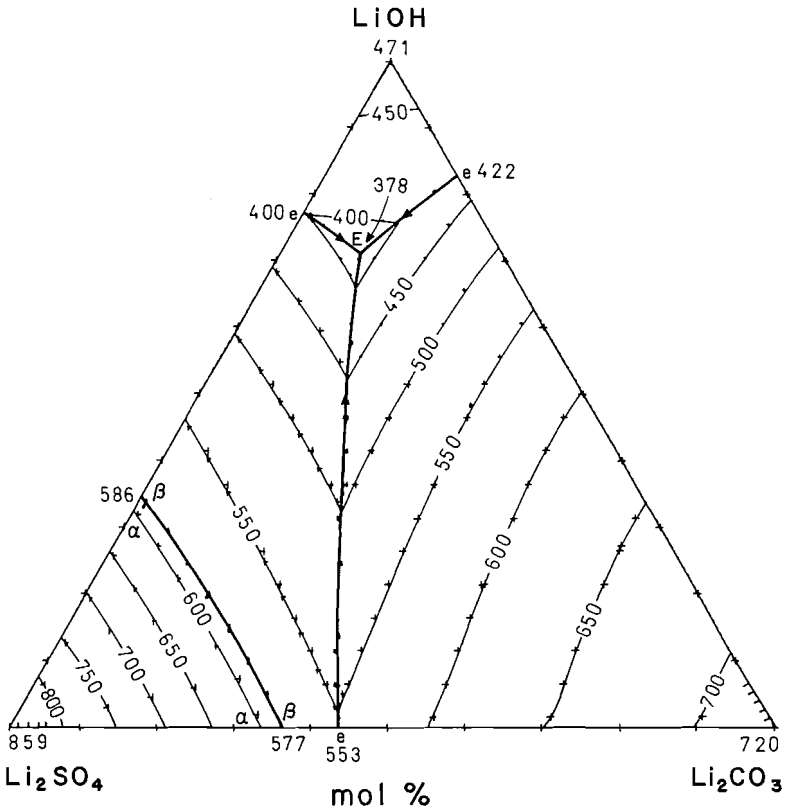

FIG. 3. $Li_2CO_3-Li_2SO_4-LiOH$ phase diagram calculated via the CIS equation (°C).

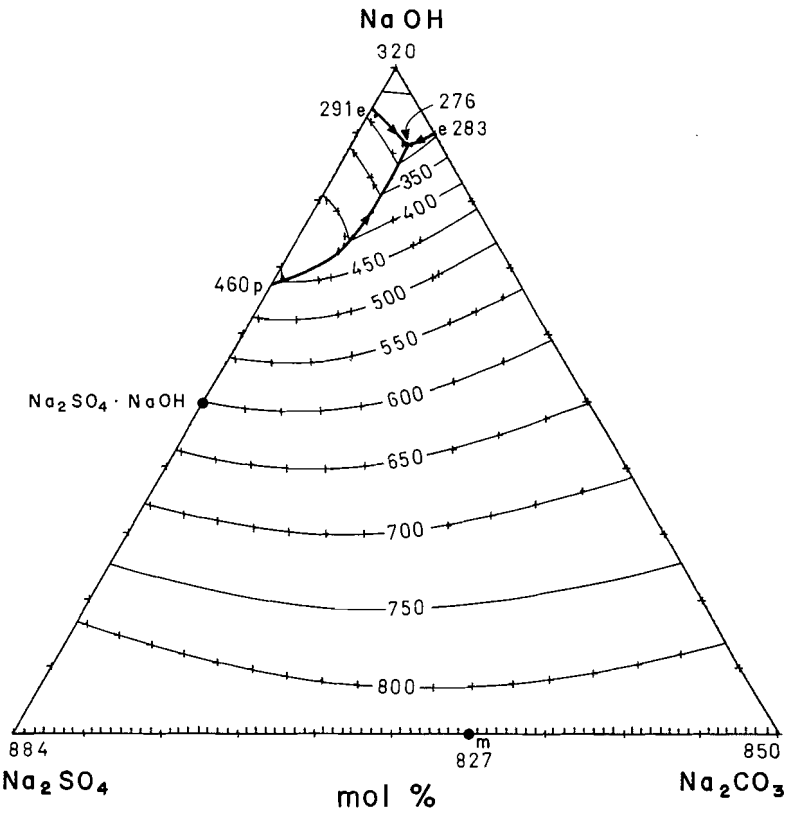

FIG. 4. $Na_2CO_3-Na_2SO_4-NaOH$ phase diagram calculated via the CIS equation (°C).

Probable maximum deviations: for all three diagrams near a binary side, the accuracy is about the same as that given in Table 2 for that binary system. Maximum deviations in the calculated ternary eutectics are estimated as follows:

$Li/CO_3,SO_4,OH$: ±35°C, ±5 mol%

$Na/CO_3,SO_4,OH$: ±20°C, ±2 mol%

$K/CO_3,SO_4,OH$: ±20°C, ±2 mol%

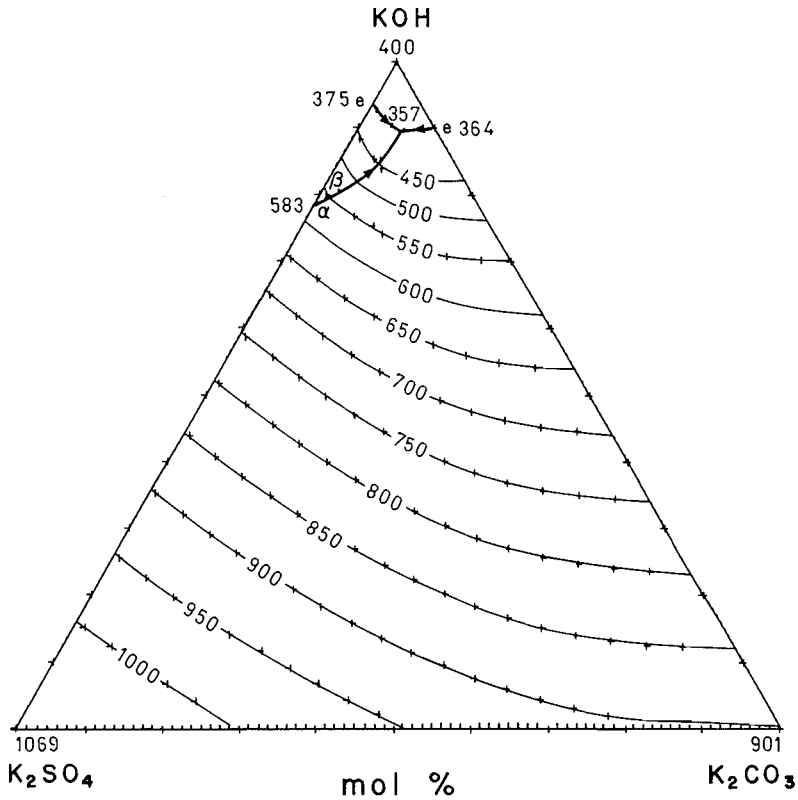

FIG. 5. $K_2CO_3-K_2SO_4-KOH$ phase diagram calculated via the CIS equation (°C).

Li,Na,K/CO₃ (Fig. 6)

Three measured diagrams (25–27) are available which agree with each other within ±10°C. That of Janz and Lorenz (25) is probably the most accurate. For the solid solution which extends into the ternary from the $K_2CO_3-Na_2CO_3$ binary, the Toop equation [12] was used. For the ternary liquid phase, two equations were used: the Kohler equation [11] and the CIS equation [10] without ternary terms. Both equations gave ternary diagrams which were virtually indistinguishable from each other except right at the ternary eutectic where the Kohler equation gave 401°C and the CIS gave 406°C. The measured (25) eutectic temperature is 397°C. Both calculated ternary eutectic compositions and the measured agree within 1 mol%. The measured ternary eutectic temperature of 397°C has been marked on the calculated diagram.

Probable maximum deviation: ±5 to 10°C

Ternary eutectic: ±5°C, ±2 mol%

Li,Na,K/SO₄ (Fig. 7)

A ternary phase diagram has been measured by Akopov and Bergman (28) who report the existence of eight ternary phase fields, but who do not identify the composition of the ternary compounds associated with each. Only one of these compounds, that labelled "VII" by the authors (28), appears to affect the liquidus surface significantly, since for all other reported ternary phase fields the liquidus isotherms bend only very slightly as they cross the univariant lines between these fields. Indeed, in the analysis of this system by Janz *et al.* (29), all the compounds "I to VI" are simply grouped together into one "ternary" field which has little influence on the liquidus isotherms, and compound "VIII" is not reported at all. Only compound VII is significant.

Since the compositions of the ternary compound(s) are unknown, they were not included in the present calculations. Hence, the central portion of the calculated diagram is not reported. More experimental work must be done on this system in this region.

In the calculations, the CIS equation [10] was used for the liquid phase, and the Toop equation [12] was used for the solid phase which extends into the ternary from the $K_2SO_4-Na_2SO_4$ binary. The calculated diagram agrees within 10 to 15°C with that of Akopov and Bergman (except, of course, for the central portion). However, it should be noted that the $Na_2SO_4-Li_2SO_4$ and $Na_2SO_4-K_2SO_4$ binaries reported on their measured ternary diagram already disagree by over 10°C with the calculated binaries from the present study.

Probable maximum deviation: ±30° near Li_2SO_4 corner; ±20°C elsewhere (except in central region)

Li,Na/CO₃,SO₄ (Fig. 8)

The liquidus has been measured (30). However, the reported diagram is thermodynamically incorrect. If one follows the diagonal from Li_2CO_3 to Na_2SO_4, the liquidus descends to 500°C and then rises again to 517°C within the phase field of stoichiometric Li_2CO_3.Hence, the measured diagram is probably not very reliable. There is a ternary solid phase extending into the ternary system from the $Na_2SO_4-Na_2CO_3$ binary as well as a small ternary solid phase near the Li_2SO_4 corner. When the CIS equation [13] was applied to both the liquid and the solid phases with Λ calculated via eq. [15] for both solid and liquid, the calculated diagram at its central point was 20°C higher than the measured. This agreement is within the error limits of the measurements. However, as discussed previously, when dealing with a solid solution phase there is little justification for calculating Λ via eq. [15]. Hence, it was decided in the present case to treat Λ for the solid phases as an adjustable

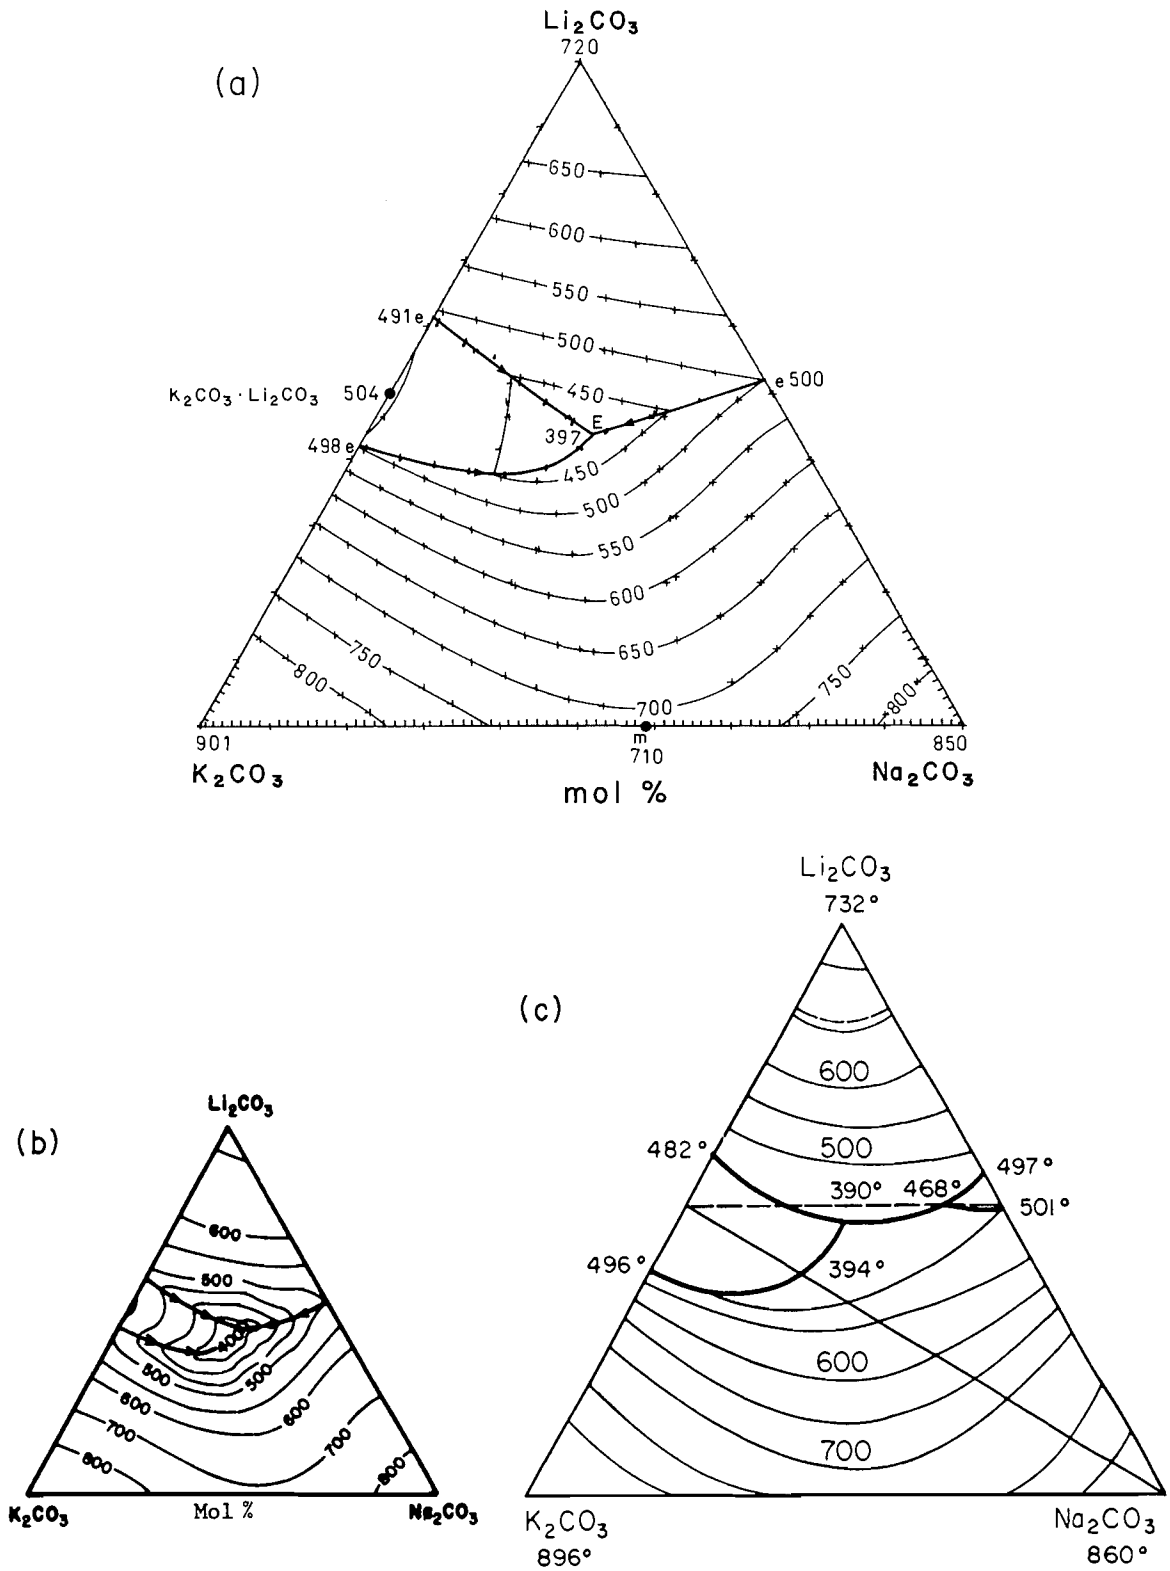

FIG. 6. $Li_2CO_3-Na_2CO_3-K_2CO_3$ phase diagram (°C): (*a*), calculated; (*b*), ref. 25; (*c*), ref. 26, taken from ref. 24.

parameter in order to reproduce the measured diagram more closely in the central region. However, Λ for the liquid was calculated via eq. [15]. With Λ^{solid} set equal to +3200 cal for both solid phases, the calculated and measured diagrams agree within ±5°C except in the Li_2SO_4 corner. The maximum deviation occurs at the ternary eutectic where the calculated diagram is 39°C higher than the measured although the position of the ternary eutectic agreed within 2 mol%. However, this eutectic is near the Li_2SO_4 corner of the system and, as discussed in ref. 3, there were large inaccuracies observed in all binary systems at high concentrations of Li_2SO_4. The calculated $Li_2SO_4-Li_2CO_3$ binary and that reported on the measured (30) ternary diagram are already in disagreement by 14°C.

In shape of the isotherms and in position of the invariants,

the calculated and measured diagrams agree very well.

Ternary data

Λ^{solid} = +3200 cal for both solid phases

Probable maximum deviation: ±20°C
except at ternary eutectic: ±40°C, ±3 mol%

$Li,K/CO_3,SO_4$ (Fig. 9)

No measured diagram was found for this system. There exists one solid ternary phase extending slightly into the ternary system from the $K_2CO_3-K_2SO_4$ binary. The CIS equation [13] with Λ calculated via eq. [15] was applied to both solid and liquid phases. The two intermediate solid binary compounds $K_2SO_4 \cdot Li_2SO_4$ and $K_2CO_3 \cdot Li_2CO_3$ were assumed to be immis-

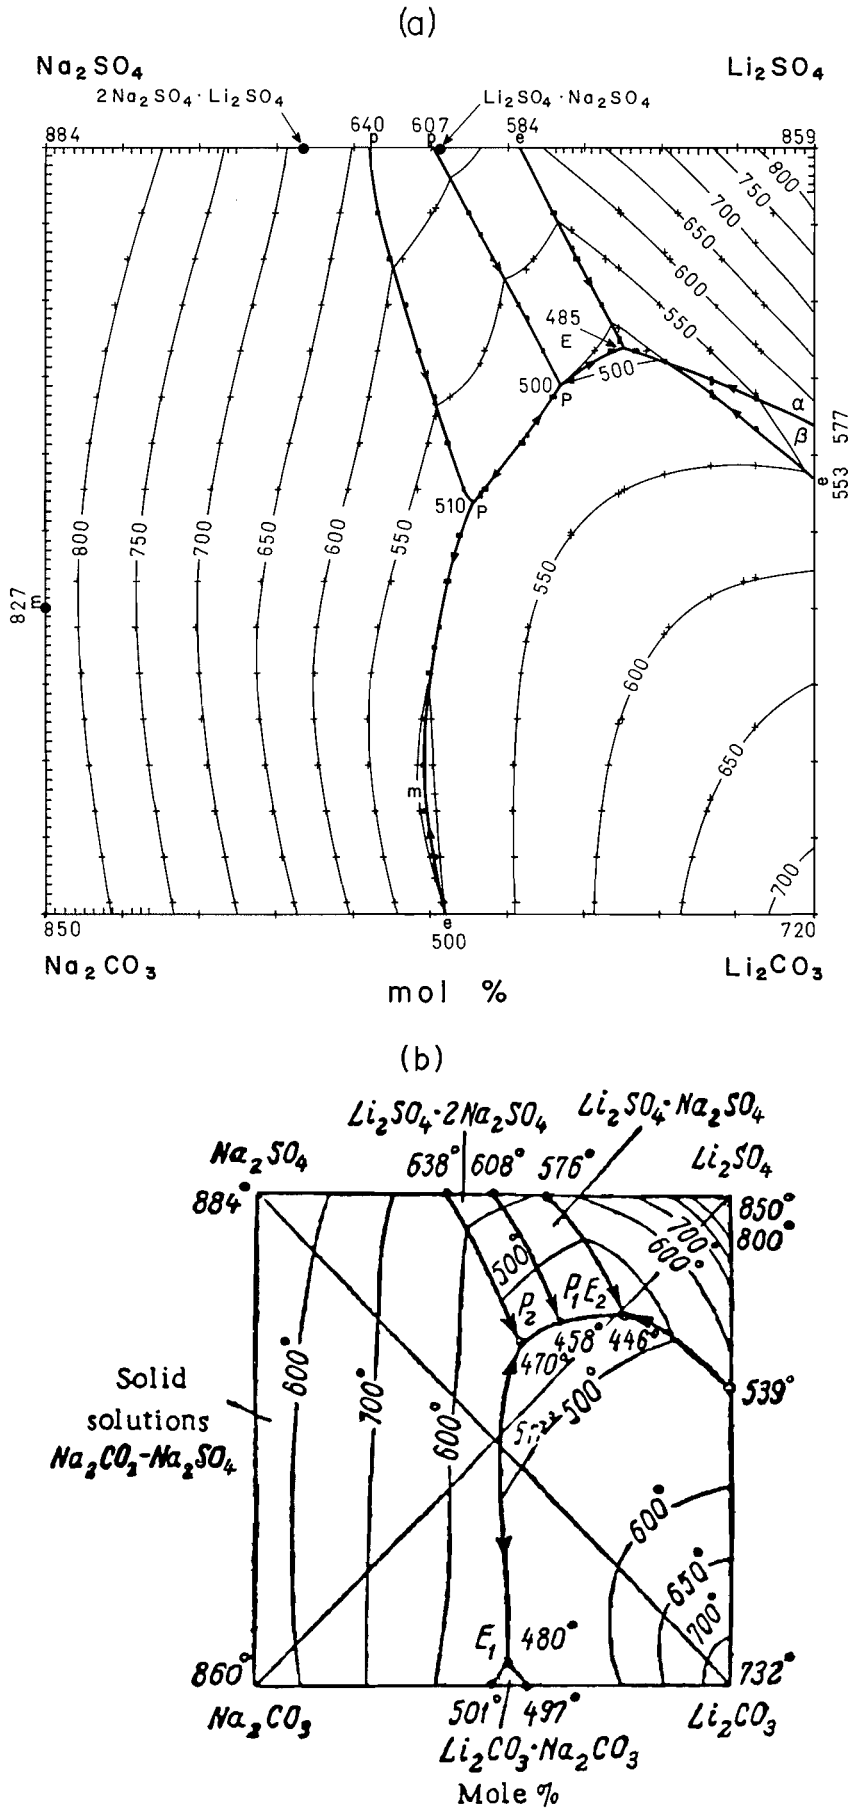

FIG. 8. Li,Na/CO_3,SO_4 phase diagram (°C); (*a*), calculated; (*b*), ref. 30, taken from ref. 24.

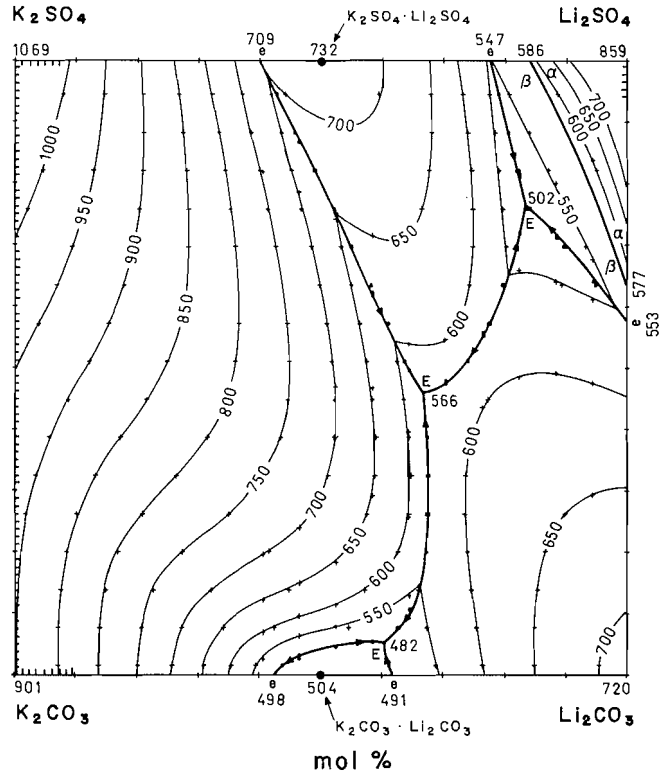

FIG. 9. Li,K/CO_3,SO_4 phase diagram calculated from the CIS equation (°C).

cible. However, in view of the complete solid solubility observed between K_2CO_3 and K_2SO_4, and in view of the similar stoichiometry of these two intermediate 1:1 compounds, the existence of quasi-binary solid solution between them is possible. (In this connection it should be noted, however, that Li_2SO_4 and Li_2CO_3 are immiscible in the solid state.) Hence, the ternary diagram was re-calculated under the assumption of complete solid solubility between the two compounds with $\Delta h^{mix(s)}$ and $s^{E(s)}$ taken to be the same as for the K_2CO_3–K_2SO_4 binary. This probably represents the other extreme possibility. The diagram so calculated agreed with the diagram calculated for no solubility within 6°C everywhere. The greatest difference (6°C) occurred at one ternary eutectic which was changed from 482 to 488°C. The correct value is most likely closer to 482°C.

From the results of the calculations on the other two reciprocal systems containing CO_3^{2-} and SO_4^{2-} (Na,Li/CO_3,SO_4 and Na,K/CO_3,SO_4) for which measured diagrams are available, the calculated liquidus in the present system may be somewhat high, but the general shape of the isotherms and the position of the invariant points are probably quite accurate.

Probable maximum deviation: ±20°C
(±30°C near Li_2SO_4 corner)

Na,K/CO_3,SO_4 (Fig. 10)

This system exhibits complete miscibility in the solid state. One experimental determination of the liquidus (31) is available which, on the basis of experience with measurements on similar systems by these authors, is probably correct to within ±10 to 20°C.

The CIS equation [13] with Λ for the solid and liquid phases calculated via eq. [15] was applied to both the solid and liquid phases. The calculated diagram agreed very well in shape of the

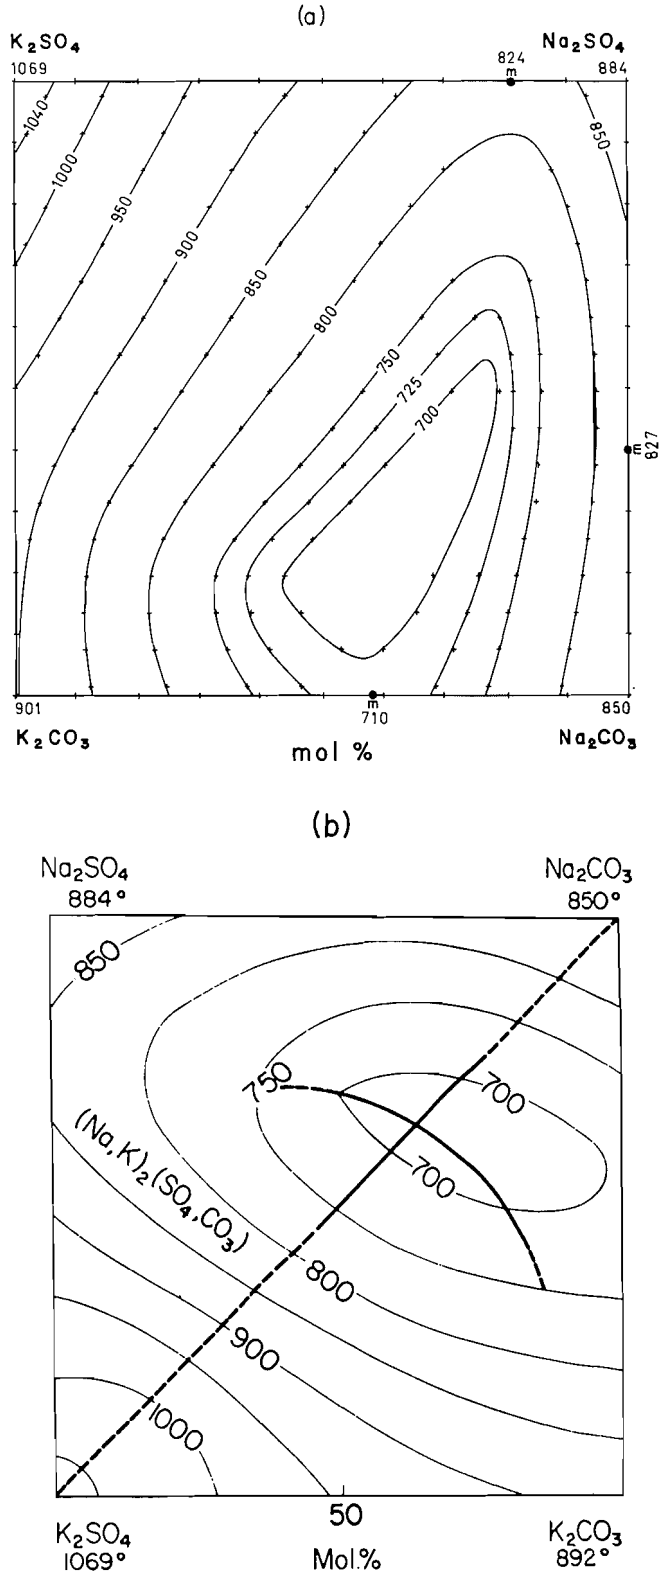

FIG. 10. Na,K/CO_3,SO_4 phase diagram (°C): (*a*), calculated; (*b*), ref. 31, taken from ref. 24.

isotherms with the measured, but near the centre of the ternary system the calculated was up to 40°C higher than the measured. Since, as discussed above, there is reason to believe that the measurements are more accurate than this and since, for a solid phase, deviation from the CIS equations are expected, Λ for the solid phase was taken as an adjustable parameter. (For the

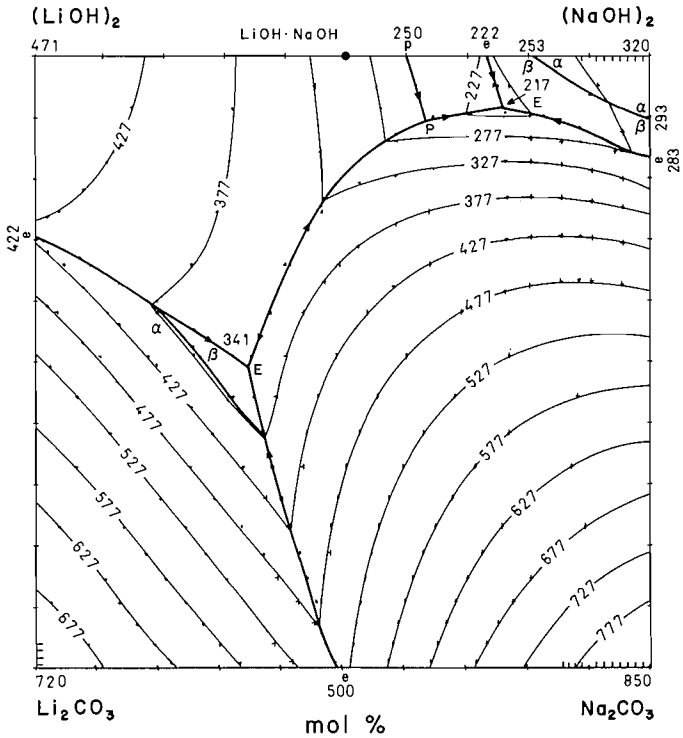

FIG. 11. Li,Na/CO_3,OH phase diagram calculated from the CIS equation (°C).

liquid phase, however, Λ was calculated by eq. [15].) With Λ^{solid} set equal to +3000 cal, the measured and calculated diagrams agreed within ±5°C everywhere.

Ternary data

Λ^{solid} = 3000 cal

Probable maximum deviation: ±20°C

Li,Na/CO_3,OH (Fig. 11)

No measured diagram was found for this system. The diagram was calculated from the CIS equation [13] for the liquid with Λ given by eq. [15]. The dilute solid solutions were assumed to be strictly binary.

Probable maximum deviation at ternary eutectic:

±25°C and ±5 mol%

Li,K/CO_3,OH (Fig. 12)

One measured phase diagram (32) exists for this system. The binary K_2CO_3–Li_2CO_3 data reported on the ternary diagram differ by 30°C from the most recent binary data used in the present study, and the LiOH–Li_2CO_3 binary data reported on the ternary diagram would seem to be equally inaccurate as discussed in ref. 3. Hence, the measured ternary diagram is probably not very accurate. One ternary compound, $Li_2CO_3 \cdot K_2CO_3 \cdot 8LiOH$, has been reported (32) with a congruent melting point of 425°C. The enthalpy of fusion of this compound was chosen so as to fit the measured ternary diagram as well as possible. The calculated and measured diagrams agree very well in the shape of the isotherms, and along the LiOH–K_2CO_3 diagonal the maximum deviation is 20°C.

Ternary data

$\Delta g^0_{fusion} = 2792 - 4.00T$ cal/mol for $K_{0.2}Li_{1.0}(OH)_{0.8}(CO_3)_{0.2}$

Probable maximum deviation: ±25°C

Na,K/CO_3,OH (Fig. 13)

One measured phase diagram (33) exists for this system, but three of the binary subsystems on the reported diagram differ by 10 to 30°C from the most recent binary diagrams chosen in the present study. Hence, the accuracy of the measured ternary diagram is no better than this. The calculated and measured diagrams do agree well in shape of the isotherms, however, and across the KOH–Na_2CO_3 diagonal, the maximum deviation is 20°C.

Probable maximum deviation: ±25°C

Li,Na/SO_4,OH (Fig. 14)

Since LiOH and Li_2SO_4 are immiscible and since NaOH and Na_2SO_4 are immiscible in the solid state, it may be assumed that the two solid 1:1 compounds LiOH·NaOH and $LiNaSO_4$ are also immiscible. No measured diagram was found. The diagram was calculated from the CIS equation [13] for the liquid with Λ given by eq. [15].

Probable maximum deviation: ±40°C with the largest uncertainty near the Li_2SO_4 corner

Li,K/SO_4,OH (Fig. 15)

No measured diagram was found. The diagram was calculated from the CIS equation [13] for the liquid with Λ given by eq. [15]. The dilute solid solution was assumed to be strictly binary.

Probable maximum deviation: ±40°C with the largest uncertainty near the Li_2SO_4 corner

Na,K/SO_4,OH (Fig. 16)

One measured phase diagram (34) exists for this system, but the work appears to be imprecise. A phase field of the compound $3K_2SO_4 \cdot Na_2SO_4$ is reported as being stable below 750°C. However, the reference for the K_2SO_4–Na_2SO_4 binary system (35) indicates that no intermediate phases exist in this system above 500°C. Since the ternary phase field for this compound below 500°C is very small, it has been ignored in the calculations. The calculated and measured diagrams agree quite well in general shape of the isotherms. The maximum deviation is about 20°C, but this is probably within the experimental error limits.

Probable maximum deviation: ±30°C

Calculation of iso-activity curves in reciprocal ternary systems at 650°C

From the CIS equation [13], the Gibbs energies of the liquid phases in the reciprocal ternary systems were calculated, and from these Gibbs energy expressions the reciprocal ternary phase diagrams were calculated as has been discussed. The same Gibbs energy expressions can also be used to calculate the activities of the components in the reciprocal ternary liquid phases.

Iso-activity curves for all four components at 650°C, which is the temperature of operation of the molten carbonate fuel cell, were presented in ref. 1. These plots are very useful in the computation of fuel gas–liquid electrolyte equilibria as was discussed in ref. 1.

The iso-activity curves at 650°C in the Li,K/CO_3, SO_4 and Li,K/CO_3,OH systems, which are the two most important systems from a practical standpoint, are shown in Figs. 17, 18.

Conclusions and identification of areas where further measurements are desirable

Once its binary subsystems have been analysed by a coupled thermodynamic/phase diagram analysis, the phase diagram of a ternary system can usually be calculated with a maximum error no greater than about twice that of the maximum error in any of the binary phase diagrams. Hence, in order to minimize the experimental effort, one should concentrate on re-measuring regions of the binary diagrams where required. The ternaries and quaternaries can then be re-calculated.

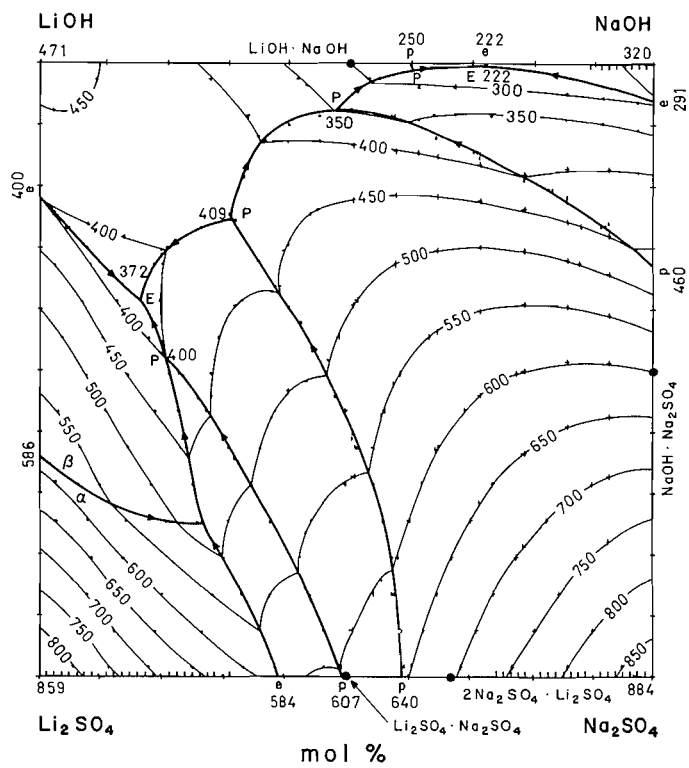

FIG. 14. $Li,Na/SO_4,OH$ phase diagram calculated from the CIS equation(°C).

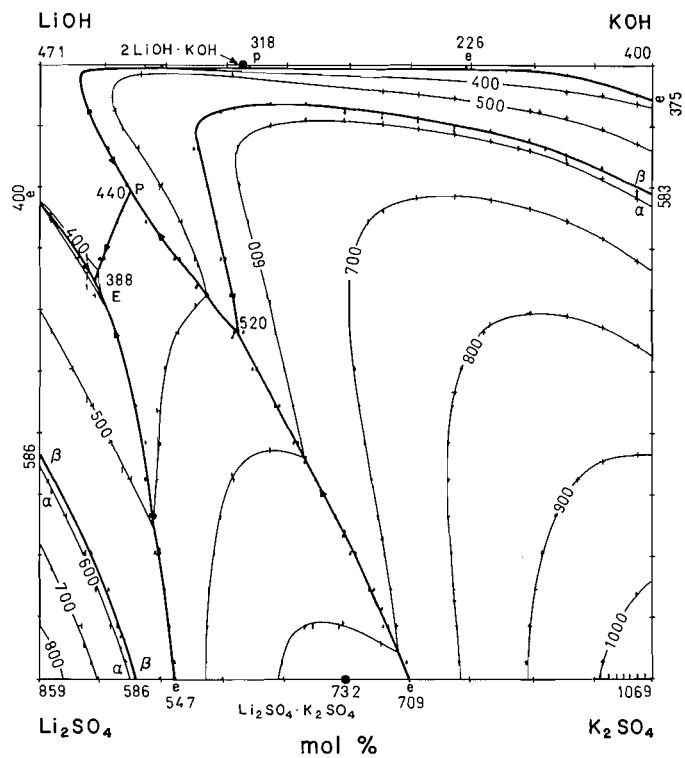

FIG. 15. $Li,K/SO_4,OH$ phase diagram calculated from the CIS equation (°C).

Furthermore, the general shape of the isotherms of the calculated ternary diagrams and the compositions of the calculated ternary invariant points are quite insensitive to relatively large changes in the thermodynamic parameters. Calculated and measured diagrams nearly always agree well in this regard. Hence, the experimental measurement of one or two ternary phase diagram temperatures (often just a ternary eutectic temperature) is sufficient to permit an adjustable ternary term to be determined so as to result in a very good calculated ternary diagram. Usually, only one such ternary term is required.

With these points in mind it is proposed that the following

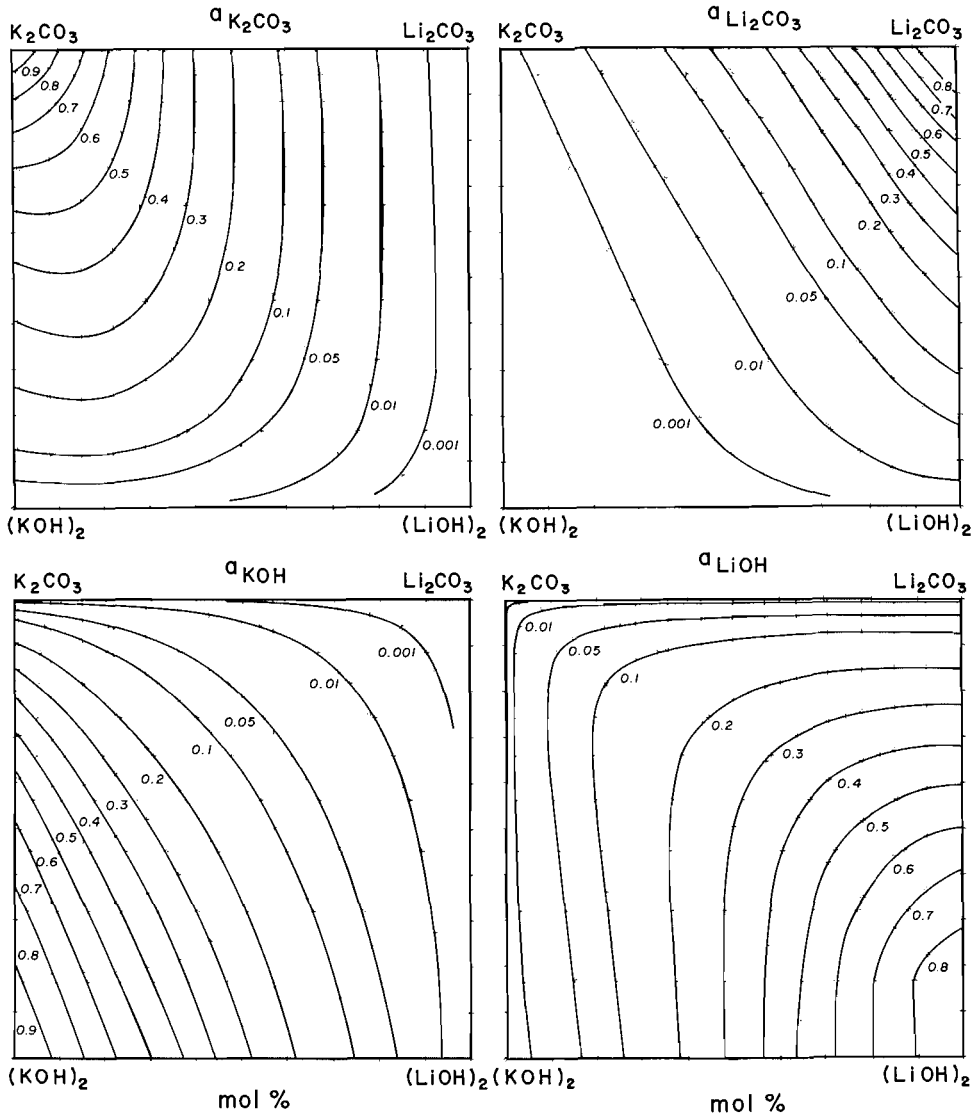

FIG. 18. Iso-activity curves at 650°C in the Li,K/CO_3,OH system calculated via the CIS equation.

regions of the binary and ternary phase diagrams could profitably be re-measured. The greatest uncertainties in all the binary and ternary diagrams center around the component Li_2SO_4. Diagrams for the same system measured by different authors are usually in large disagreement for compositions rich in Li_2SO_4. Furthermore, some of the measured diagrams are thermodynamically inconsistent with the enthalpy of the $\alpha-\beta$ transformation of Li_2SO_4. Possibly, the metastable solidification of β in regions where α is thermodynamically stable is responsible for some of the discrepancies. The $Li_2CO_3-Li_2SO_4$ and $Li_2SO_4-K_2SO_4$ binary liquidus should thus be re-examined in the Li_2SO_4-rich regions and particularly around the eutectics, care being taken to identify the $\alpha-\beta$ phase transition. The $LiOH-Li_2SO_4$ system has never been measured. The $Li_2SO_4-Na_2SO_4$ system should be completely re-examined particularly in the central regions. The solidus of this system should also be re-measured. The ternary eutectic temperature of the Li,Na/CO_3,SO_4 system should be re-measured in order to resolve a seemingly too large discrepancy in this system. The entire central region of the Li,Na,K/SO_4 system should be re-examined, and the compositions of the ternary compound(s) identified. For *any* of the ternary phase diagrams, one simple experimental determination of the ternary eutectic temperature would permit a large increase in the accuracy of the calculated diagram to be made. In view of the importance of the Li,K/CO_3,SO_4 system to the DOE carbonate fuel cell project, it is suggested that the ternary eutectic temperature (for the ternary eutectic near the $Li_2CO_3-K_2CO_3$ binary) be carefully re-measured.

Optical and magnetic resonance studies of the interaction of metallo tetraphenylporphyrins with nitrobenzofuroxan

T. K. CHANDRASHEKAR AND V. KRISHNAN[1]

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore-560012, India

Received January 20, 1983[2]

T. K. CHANDRASHEKAR and V. KRISHNAN. Can. J. Chem. **62**, 475 (1984).

Metallo tetraphenylporphyrins form 1:1 molecular complexes with 4,6-dinitrobenzofuroxan. The molecular association is described in terms of $\pi-\pi$ interaction with porphyrins functioning as donors. The association constants and thermodynamic parameters have been evaluated using optical absorption and ^1H nmr spectral methods. Based on the binding constants, the donor ability of various metalloporphyrins can be arranged in the following order: Pd(II) > Co(II) > Cu(II) > Ni(II) ~ VO(IV) ~ 2H > Zn(II). Electron paramagnetic resonance studies of the complexes reveal that the π-complexation results in changes in the electronic structure of the central metal ions which are reflected in the changes in the M–N σ bonding. The dipolar contribution to the acceptor proton chemical shifts in the CoTPP complex has been partitioned from ring current contributions using the shifts observed in the ZnTPP complex. The shifts, along with the line broadening ratios observed for the CoTPP complex, are used to arrive at the possible solution structures of the complexes.

T. K. CHANDRASHEKAR et V. KRISHNAN. Can. J. Chem. **62**, 475 (1984).

Les métallotétraphénylporphyrines forment des complexes moléculaires 1:1 avec le dinitro-4,6 benzofuroxane. On décrit l'association moléculaire en fonction des interactions $\pi-\pi$ avec les porphyrines agissant comme donneurs. On a évalué les constantes d'association et les paramètres thermodynamiques en faisant appel à l'absorption optique et à la rmn du ^1H. En se basant sur les constantes de liaison, on peut établir la capacité des diverses métalloporphyrines en tant que donneur dans l'ordre suivant: Pd(II) > Co(II) > Cu(II) > Ni(II) ~ VO(IV) ~ 2H > Zn(II). Les études de rpe des complexes révèlent que la complexation π est due à des changements dans la structure électronique de l'ion métallique central qui se réflète dans les variations de la liaison σ M–N. On a partagé la contribution dipolaire aux déplacements chimiques de l'accepteur de proton dans le complexe CoTPP, à partir du courant de cycle, en utilisant les déplacements observés dans le complexe ZnTPP. On a utilisé les déplacements chimiques ainsi que le taux d'élargissement des raies observé dans le complexe CoTPP pour arriver à déterminer les structures possibles des complexes.

[Traduit par le journal]

Introduction

The molecular interactions of porphyrins with neutral organic molecules is either donor–acceptor type or coordinative, depending on the functional groups present in the organic molecules. Nitroaromatics essentially function as π-acceptors and form donor–acceptor complexes with porphyrins (1). Among the nitroaromatics, the most widely used acceptor is sym. trinitrobenzene (TNB). Earlier we employed TNB as an acceptor and investigated the donor properties of tetraphenylporphyrin, phthalocyanin, pheophytin, and their metallo derivatives (2). 4,6-Dinitrobenzofuroxan is another member of the nitroaromatics and an examination of its structure reveals two canonical forms indicating planar structure of the compound. (Fig. 1). This bears a close resemblance to the structure of TNB. It is known that nitrobenzofuroxans form highly coloured complexes with aromatic donors exhibiting charge transfer bands in the visible region (3). The π-acceptor behaviour of benzofuroxans towards Co(II) derivatives of *meso*-porphyrin IX dimethyl ester and etioporphyrin has earlier been reported (4). In our continuing interest in the study of donor ability of porphyrins and their metallo derivatives with various acceptors, we chose to investigate the acceptor behaviour of 4,6-dinitrobenzofuroxan (BFO) in the expectation that near coplanarity of BFO may promote plane–plane overlap with the donor, thereby contributing significantly to the stability of the complexes. Moreover, such a study would make a comparative study with the TNB complexes more meaningful and help to delineate any specific site interaction that may prevail in the complexes.

The various donor porphyrins employed in the study are

association constants and thermodynamic parameters, the use of the ^1H nmr method is exploited for the determination of binding constants of BFO with ZnTPP and CoTPP's. The choice of ZnTPP as a donor is to apportion the ring current contributions to the proton chemical shifts of BFO in the CoTPP complex to evaluate the dipolar shifts. The esr measurements, coupled with the magnitude of the dipolar shifts and line broadening effects in the paramagnetic TPP's, are useful in arriving at the possible solution structures of the molecular complexes. The paramagnetic resonance parameters of the complexes provide information regarding the manner in which the $\pi-\pi$ interaction is transmitted through the metal–porphyrin bonding framework.

Experimental

The donor porphyrin (TPP) was procured from Aldrich, USA. The metal derivatives of TPP have been prepared according to the published procedures (5). 4,6-Dinitrobenzofuroxan was prepared from the nitration reaction of nitrosobenzene (6). It was crystallized twice from acetic acid, mp 172°C. All the solvents employed in the study were distilled before use. The preparation of solutions and all manipulations were carried out in dim light under a blanket of nitrogen. The spectra of the solutions were recorded immediately after mixing.

The optical absorption method employed for the evaluation of association constants involves the measurements of absorbance of the Q bands of porphyrin and its derivatives in the solvent CH_2Cl_2 on increasing addition of BFO. The concentration of the donor porphyrins is held constant ($\sim 10^{-5}$ *M*) and the range of concentration of BFO employed is 1.0×10^{-4} to 2.0×10^{-2} *M*. The spectrometer used was the same as described previously (2).

The ^1H nmr spectra were recorded on a WH-Bruker 270 MHz FT instrument using $CDCl_3$ as a solvent and TMS as an internal standard. The nmr titration experiment was performed as follows. To a constant volume of $CDCl_3$ solution of BFO (1×10^{-2} *M* varying amounts of ZnTPP/CoTPP in $CDCl_3$ were added, and the ^1H nmr spectra recorded, the temperature of measurement being 27°C. The shifts are with respect to TMS and the accuracy of the shifts lies in the range ± 0.005 δ. In both the optical and ^1H nmr experiments, the spectra of several sets of solutions were recorded to check reproducibility of the data obtained.

Electron spin resonance measurements of the solutions containing the donors and acceptors were recorded on a Varian E 109 esr spectrometer using toluene as the solvent. The spectra reported are at a temperature of 100 K. The field strength was calibrated using an nmr probe.

Results

BFO in CH_2Cl_2 exhibits well-defined intense absorption bands at 422 mm ($\log \epsilon = 2.87$), 333 nm ($\log \epsilon = 2.77$), 276 nm ($\log \epsilon = 3.14$), 261 nm ($\log \epsilon = 3.11$), and 233 nm ($\log \epsilon = 2.96$). Addition of increasing amounts of BFO to the donor porphyrins in CH_2Cl_2 causes a progressive decrease in the absorbance of Q bands in the region 500 to 600 nm (Fig. 2). Association constants were evaluated using the method of Nash (7). A typical plot of C_A^{-1} versus $d^0 (d^0 - d)^{-1}$ where C_A, d^0, and d denote the concentration of BFO, the absorbance value of the pure donor, and the absorbance value of the donor in presence of acceptor respectively, is shown in Fig. 3. The linearity of the plots suggests that the complexes formed are of 1:1 stoichiometry. The absorbance measurements taken at different temperatures permit the evaluation of thermodynamic parameters. The values of *K* and related parameters obtained in the present study are given in Table 1. The reliability of the *K* values is tested using Deranleau's saturation factor criterion (8). This is defined as the ratio of the concentration of the

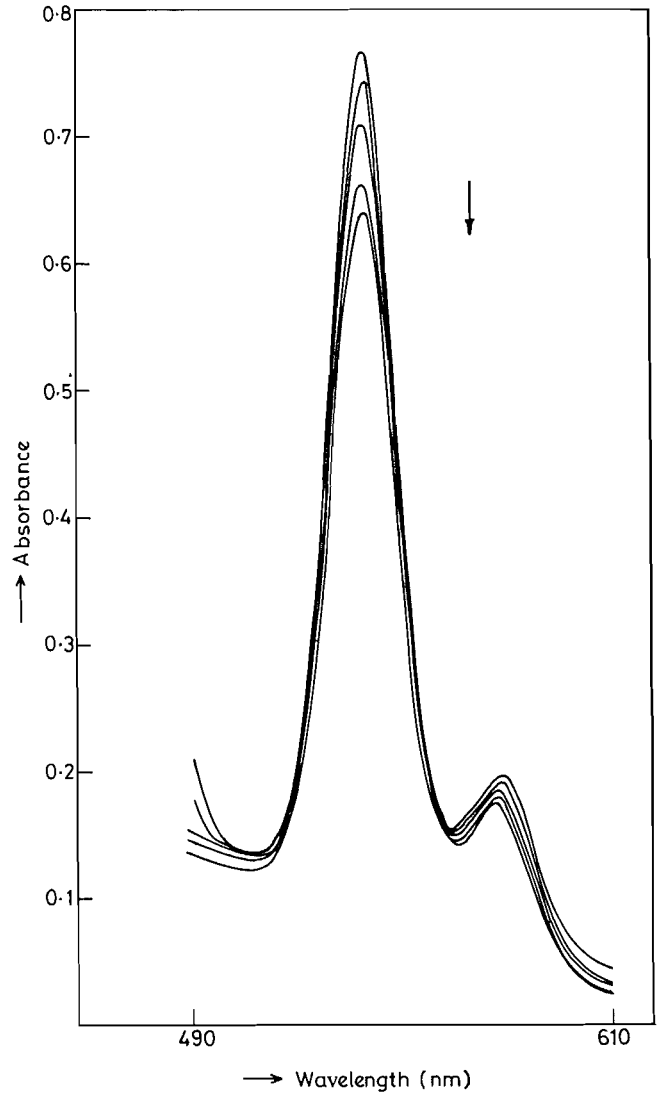

FIG. 2. Visible spectrum of (a) ZnTPP (5.6×10^{-5} *M*) containing increasing amounts of BFO in CH_2Cl_2 (3.9×10^{-4} to 5.5×10^{-2} *M*).

complex to that of the acceptor and in the present study this is within the range of 0.2–0.8 for well-defined K values.

The ^{1}H nmr spectrum of BFO in $CDCl_3$ consists of resonances centered at δ 9.150 and δ 8.847, corresponding to H_7 and H_5 protons respectively. On increasing addition of MTPP, the acceptor resonances are shifted to higher fields (Fig. 4). The multiplet structure of H_7 and H_5 proton resonances remains unaffected on addition of ZnTPP. On the other hand, these resonances are broadened and shifted to higher fields (relative to the ZnTPP complex) on addition of CoTPP (Table 2). The appearance of only one set of resonances in the ^{1}H nmr spectra of the complexes reveals that the rate of exchange between the free and complexed BFO is fast in the time scale. It can be shown that the observed proton resonance shifts (Δ) of the acceptor on increasing addition of donor porphyrins are related to the association constant, K, through the expression

$$[1]\quad \frac{1}{\Delta} = \frac{1}{D\Delta_c} A\left(1 - \frac{\Delta}{\Delta_c}\right) + \frac{1}{\Delta_c} + \frac{1}{KD\Delta_c}$$

where D and A represent the concentration of donor porphyrins and acceptor respectively and Δ_c is the shift in the fully formed complex. To obtain the best values of K and Δ_c we adopted a procedure similar to that described in the literature (1). This involves an initial neglect of the first term in eq. [1] to obtain

$$[2]\quad \frac{1}{\Delta} = \frac{1}{\Delta_c} + \frac{1}{KD\Delta_c}$$

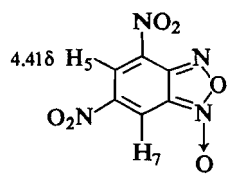
Plots of $1/\Delta$ vs. $1/D$ for both H_5 and H_7 protons of BFO in the ZnTPP and CoTPP addition versus the concentration of donor porphyrin yield straight lines, with a slope of $1/K\Delta_c$ and an intercept of $1/\Delta_c$. The least-squares fit of these values thus obtained is fitted into expression [1] in a manner to get the best fit. A regression analysis programme was employed to arrive at the best values of K and Δ_c satisfying expression [1]. The values of K and Δ_c obtained for H_5 and H_7 protons are listed in Table 3.

The values of K obtained for H_5 and H_7 protons are similar in magnitude, indicating that the π-complexation effect is felt by the protons equally. The magnitudes of K obtained using the nmr method are at variance with those obtained by the visible spectral method. We attribute the variance in K values to the different concentration ranges employed in the respective methods.

The values of Δ_c are composed of ring current and dipolar effects. Thus

$$[3]\quad \Delta_c = \Delta_{(ring)} + \Delta_{(dipolar)}$$

where $\Delta_{(ring)}$ are the shifts due to the ring current of the porphyrin and $\Delta_{(dipolar)}$ are the additional shifts due to the single unpaired electron in CoTPP. A reasonable assumption, that the shift due to the ring current in CoTPP is identical to that of ZnTPP owing to their structural similarity except for the metal ion, permits the calculation of the contribution from the dipolar term to the shifts. The pseudo contact shifts obtained for H_5 and H_7 protons are represented below. It is seen that both H_5 and H_7 protons of BFO experience shifts of similar magnitude unlike



those reported for other acceptor systems (1).

The esr spectra of the BFO complexes of Cu and VOTPP's are highly characteristic, permitting an evaluation of esr parameters (Table 4). Addition of BFO shifts the signals to higher fields, thereby decreasing the values of $g_\parallel$ and $g_\perp$ (Fig. 5). The small changes observed in metal hyperfine coupling constants and a decrease in $A_\parallel^M$ relative to the MTPP's signify molecular complexation. In the case of the CuTPP complex, a simultaneous increase in $A_\parallel^N$ and $A_\perp^N$ values is observed. The esr spectrum of the CoTPP–BFO complex is often plagued with the

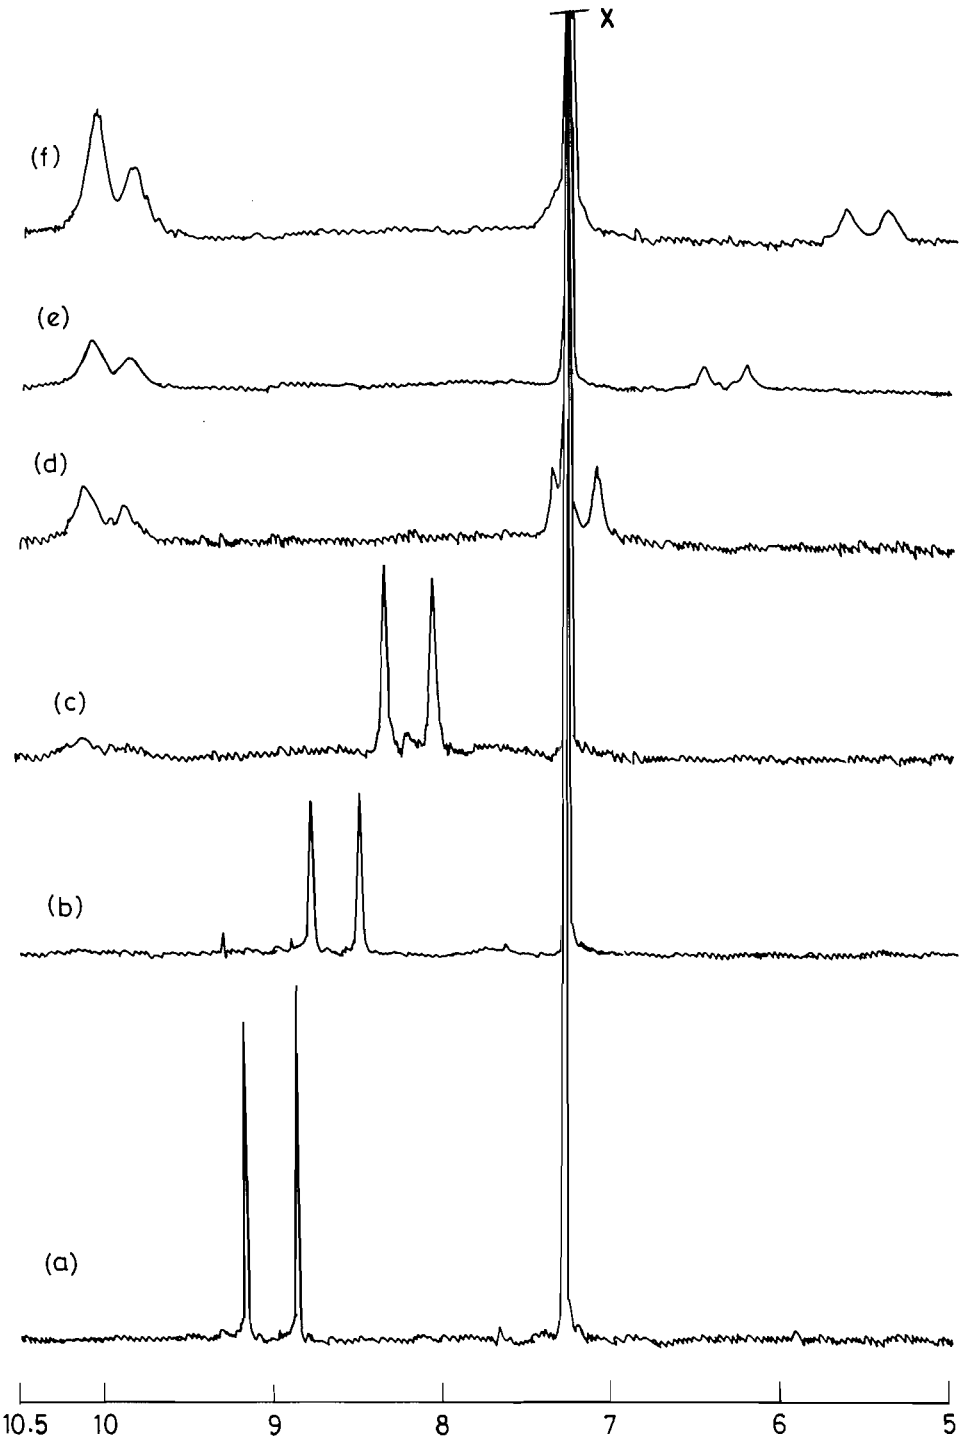

FIG. 4. Chemical shifts of BFO (1.09×10^{-2} *M*) proton resonances with increasing addition of CoTPP; (a) nil; (b) 7.5×10^{-4} *M*; (c) 2.55×10^{-4} *M*; (d) 4.51×10^{-3} *M*; (e) 6.01×10^{-3} *M*; and (f) 7.51×10^{-3} *M*. Mark (X) denotes solvent peak.

signals arising from its molecular oxygen adduct. The spectrum obtained exhibits a strong signal at $g \simeq 2.08$, typical of an oxygen adduct (9), and weak signals in the low-field region, resembling closely that of the CoTPP–TNB complex (2) and indicating the existence of a mixture of pure CoTPP–BFO complex and its oxygen adduct. In view of this, the esr parameters of the oxygen-free CoTPP–BFO complex could not be calculated unambiguously. The π-complexation by metal TPP's causes a change in the electron distribution over the porphyrin core, affecting the electronic energy levels of the central metal ions. Though a manifestation of this effect is seen only in the changes of $A_{\parallel}^{M}$ values to VOTPP, it has been possible to quantitatively assess this in the CuTPP complexes. The perturbance of electronic levels of Cu is seen in the slight decrease in the value of the covalency factor α^2. It is calculated using the procedure described by Kievelson and Neiman (10); the change in the α^2 value relative to CuTPP is found to be -0.01391, signifying that the σ bonding is slightly more covalent in the molecular complex. Such changes are interpreted in terms of a small increase in the π-electron density of N or in

the increase in electronic charge on copper in the molecular complex relative to CuTPP (2).

Discussion

An examination of Table 1 reveals that the association constants for the BFO interaction with MTPP's follow the order $Pd^{2+} > Co^{2+} > Cu^{2+} > Ni^{2+} \sim VO^{2+} \sim 2H > Zn^{2+}$, similar to that observed for the corresponding complexes of TNB. However, the magnitudes of *K* are higher than those observed for the TNB complexes. This can be interpreted in terms of the planar disposition of the NO_2 groups in BFO. Shinomiya (11) has pointed out that a maximum stability in the complexes can

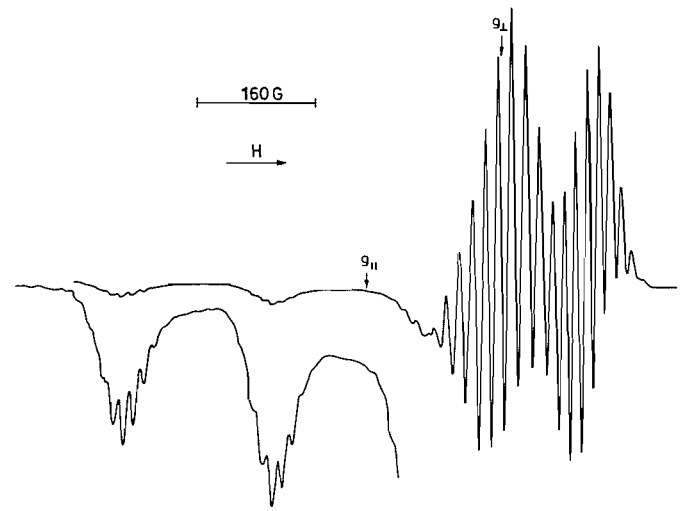

FIG. 5. The esr spectrum of the CuTPP–BFO complex in toluene at 110 K.

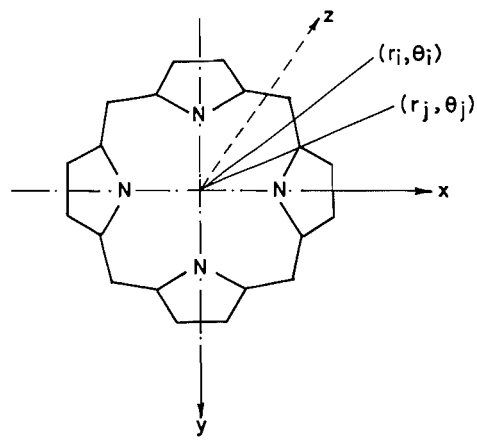

FIG. 6. Coordinate system for metal and acceptor protons.

be accomplished if the nitro groups are allowed to be coplanar with the benzene ring to which they are attached. It is worthwhile to point out that the magnitudes of *K* are lower than those observed for polynitro fluorenone complexes (12). We attribute this to the relatively smaller size of BFO. The thermodynamic parameters of the MTPP–BFO interaction are not significantly different on variation of the metal. It is worthy to mention here that the decreases in ΔH values observed in the present study are higher than those observed for TNB complexes. In molecular complexing systems, the values of ΔH signify the efficiency of packing of donor and acceptor in the complex. This can be enhanced if the molecules involved in the complex formation are planar, such that plane-to-plane overlap leads to a better packing of the donor and acceptor. We believe such effects are operative in the present study. Attempts to obtain single crystals of these complexes have so far been unsuccessful.

In order to demonstrate that the interaction of BFO with MTPP is not of the coordinative type, we studied the ir spectra of the complexes. The strong band, ~1550 cm^{-1}, in BFO has been assigned to the N→O stretching frequency (13). The —C=$\overset{+}{N}$— stretching vibration in BFO occurs as a weak band at 1625 cm^{-1}, while the asymmetric and symmetric stretching vibrations of the NO_2 groups appear at 1530 and 1320 cm^{-1}, respectively. In the complexes, these vibrations remain virtu-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

ally unaffected. Further, the donor porphyrin vibrations are only marginally affected. These observations indicate the absence of any specific site interaction of BFO with MTPP's. Moreover, the esr spectral changes, i.e. decrease in g values and increase in A values, are in contrast to those observed in the interaction of MTPP's with axially coordinating ligands (14).

An attempt has been made here to probe into possible solution structures of the molecular complexes using ^{1}H nmr and esr data of the complexes. The dipolar shifts and broadening of the acceptor proton signals in the CoTPP–BFO complex are used to locate the protons of BFO with respect to the Co(II) centre in the complex. The linewidths of the BFO proton resonances on addition of CoTPP are given in Table 2. The broadening ratios are obtained using the expression of Sternlicht (15). The estimates of broadening ratios were obtained at 270 MHz by subtracting the diamagnetic line widths of BFO multiplets from those in the presence of CoTPP. This indicated that both H_5 and H_7 proton resonances were about seven times as broad as in free BFO. The absence of any preferential broadening of acceptor protons underscores the plane–plane overlap of the acceptor with donor in these complexes. The dipolar shifts experienced by the acceptor protons in the CoTPP–BFO complex are all to higher fields, justifying that there exists no direct spin-transfer. Calculation of such shifts is based on the evaluation of the geometric factors, $(3\cos^2\theta - 1)\,r^{-3}$, where θ is the angle the acceptor proton subtends with Co(II) and the said proton (Fig. 6). The X-ray structure of CoTPP (14) was taken to define the stereochemistry, and the bond angles and bond lengths of BFO are approximated to that of TNB. The molecular framework of the complex is then defined by placing BFO parallel to CoTPP at a distance R, such that the centre of the aryl ring passes through the Co(II) ion. Moreoever, for a fixed distance R, tilt angles are varied from 0 to 30°. The distances r_0 and r_j from Co(II) to H_5 and H_7 protons of the acceptor and the angles subtended are computed for various values of R (3.5–4.0 Å) and tilt angles. The dipolar shifts are calculated using the geometric factors according to ref. 16.

$$[4]\quad \left(\frac{\Delta H}{H}\right)_i \Big/ \left(\frac{\Delta H}{H}\right)_j = (3\cos^2\theta_i - 1)\,r_i^{-3}/(3\cos^2\theta_j - 1)\,r_j^{-3}$$

Most of the structures scanned in this fashion do not fit well into the experimentally observed ratio of dipolar shifts, probably because of the random orientations of the molecules in the solvent. The determination of structure must, however, await a detailed X-ray examination. The present study points out that the interaction of BFO with porphyrins occurs only in the periphery.

For personal use only.

In 1975, the aluminium chloride catalyzed Diels–Alder reaction of 2-methyl-2-cyclohexenone with isoprene was described (1). The reaction produced in high yield an adduct to which structure **1** was assigned. This structural assignment has been suspected to be in error in light of its violation of the "*para*" rule (2) for Diels–Alder addition. The incorrectness of the assignment has been pointed out in a recent report (3) which provided spectral evidence in support of structure **2** for the adduct resulting from the normal mode of "*para*" addition. Concurrently, we have reached the same conclusion on the basis of the following chemical correlation which confirms unambiguously this structural assignment.

In the presence of stannic chloride, the reaction of 2-carbomethoxy-2-cyclohexenone with isoprene gave a 61% yield of a single adduct **3** (4) showing thirteen lines in the ^{13}Cmr spectrum. Its regiochemistry was unambiguously determined as follows. Keto ester **3** was subjected to decarbomethoxylation with lithium iodide dihydrate in refluxing 2,4,6-collidine (5, 6) to give a mixture of two epimeric ketones **4** in 40% yield. Oxidation of this mixture with *N*-bromosuccinimide in refluxing carbon tetrachloride in the presence of a small amount of benzoyl peroxide (7, 8) gave aryl ketone **5** in 64% yield. The ^{1}Hmr spectrum of this compound displayed a signal due to a *peri*-proton (C-8 H) (6, 8, 9) as a doublet (J = 8 Hz) at δ 7.92. Such a coupling is in agreement only with structure **5**.

Ketalization of keto ester **3** under standard conditions afforded a 92% yield of ketal ester **6** which was reduced with lithium aluminium hydride to the corresponding alcohol **7** (96% yield). Conversion of alcohol **7** to its phosphorodiamidate derivative **8** using *n*-butyllithium, *N*,*N*-dimethylphosphoramidic dichloride, and dimethylamine (10), followed by lithium–ethylamine reduction (11) of **8** gave ketal **9** in an overall yield of 40%. Upon treatment with *p*-toluenesulfonic acid in acetone, ketal **9** was transformed quantitatively to the corresponding ketone **2** which was shown to be identical in all respects with the adduct prepared from 2-methyl-2-cyclohexenone and isoprene according to the described procedure (1).

Experimental

General

Elemental analyses were performed by the microanalytical laboratory of the Department of Chemistry, University of Alberta. Infrared spectra were recorded on a Nicolet 7-199 FT-IR spectrophotometer. The ^{1}Hmr spectra were recorded on a Varian HA-100, Bruker WH-200, or WH-400 spectrometer and, except where otherwise stated, were obtained on solutions in deuteriochloroform with tetramethylsilane as internal reference. The ^{13}Cmr spectra were recorded on a Bruker WP-60/Nicolet BNC-12 system or a Bruker WH-400 spectrometer and were obtained on solutions in deuteriochloroform using tetramethylsilane as internal reference. Mass spectra (ms) were recorded using A.E.I. model MS12 or MS50 mass spectrometers. Anhydrous magnesium sulfate was used for drying organic solutions.

Preparation of keto ester 3

At 0°C, anhydrous stannic chloride (1.16 g, 4.45 mmol) was added to a solution of 2-carbomethoxy-2-cyclohexenone (12) (1.37 g, 8.9 mmol) and isoprene (6.10 g, 89 mmol) in ether (20 mL). After stirring under an argon atmosphere for 6 h, the reaction mixture was poured into ice-cold water and extracted with ether. The organic solution was dried, filtered, and concentrated. Flash chromatography (13) of the residue on silica gel, eluting with 7% ethyl acetate in petroleum ether, gave keto ester **3** (1.2 g; 61% yield); ir (film): 1743 (ester) and 1715 (ketone) cm^{-1}; ^{1}Hmr δ: 1.63 (s, 3H, —CH_3), 3.73 (s, 3H, —OCH_3), and 5.32 (m, 1H, =CH—); ^{13}Cmr δ: 208.3 (C-1), 172.8 (—COO—), 131.5 (C-6), 116.8 (C-7), 60.6 (C-8a), 52.3

(—OCH_3), 37.5 (C-4a), 23.6 (—CH_3), 38.1, 32.2, 27.8, 27.0, and 24.1 (C-2, C-3, C-4, C-5, and C-8); ms M^+: 222.1256 (calcd. for $C_{13}H_{18}O_3$: 222.1256). *Anal.* calcd. for $C_{13}H_{18}O_3$: C 70.23, H 8.17; found: C 70.20, H 8.20.

Decarbomethoxylation of keto ester 3

Finely divided anhydrous lithium iodide (750 mg, 5.6 mmol) was suspended in 2,4,6-collidine (5 mL) wth vigorous stirring. Water (202 μL, 11.2 mmol) was added and the suspension rapidly dissolved. Keto ester **3** (580 mg, 2.6 mmol) was dissolved in this solution under an atmosphere of argon. The mixture was heated at reflux for 16 h. The mixture was cooled to room temperature, poured into ice-cold aqueous 1 *N* hydrochloric acid, and extracted with ether. The extracts were washed with water, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with 5% ethyl acetate in petroleum ether, gave a mixture of epimeric ketones **4** (170 mg; 40% yield); ir (film): 1714 (C=O) cm^{-1}; ^{1}Hmr (CCl_4) δ: 1.60 (br s, 3H, —CH_3) and 5.37 (m, 1H, =CH—); ms M^+: 164.1197 (calcd. for $C_{11}H_{16}O$: 164.1197).

Dehydrogenation of ketones 4

The mixture of epimeric ketones **4** (140 mg, 0.85 mmol) was dissolved in carbon tetrachloride (10 mL). Benzoyl peroxide (5 mg, 0.02 mmol) and *N*-bromosuccinimide (310 mg, 1.74 mmol) were added.The reaction mixture was heated at reflux for 16 h under an atmosphere of argon. Filtration and concentration gave an oily residue which was subjected to flash chromatography on silica gel. Elution with 5% ethyl acetate in petroleum ether afforded aryl ketone **5** (87 mg, 64% yield); ir (film): 1682 (C=O) and 1608 (aromatic C=C) cm^{-1}; ^{1}Hmr δ: 2.11 (m, 2H, —$CH_2CH_2CH_2$—), 2.37 (s, 3H, —CH_3), 2.61 (dd, 2H, J = 8, J' = 6 Hz, =C—CH_2—), 2.90 (t, 2H, J = 6 Hz, —CH_2CO—), 7.04 (s, 1H, C-5 H), 7.10 (d, 1H, J = 8 Hz, C-7 H) and 7.92 (d, 1H, J = 8 Hz, C-8 H); ^{13}Cmr δ: 197.9 (C-1), 144.5 (C-4a), 144.1 (C-8a), 130.6 (C-6), 129.2, 127.6, 127.4 (C-5, C-7, and C-8), 39.2 (C-2), 29.9 (C-4), 23.5 (C-3), and 21.6 (—CH_3); ms M^+: 160.0879 (calcd. for $C_{11}H_{12}O$: 160.0887).

Ketalization of keto ester 3

A solution of keto ester **3** (750 mg, 3.38 mmol), ethylene glycol (2.09 g, 33.7 mmol), and *p*-toluenesulfonic acid (10 mg, 0.05 mmol) in benzene (50 mL) was refluxed with a Dean–Stark water separator under an argon atmosphere for 55 h. After cooling to room temperature, the resulting mixture was made basic with 10 mL of saturated aqueous sodium bicarbonate. The organic layer was separated and washed with water. Drying, filtration, and concentration gave an oil which was purified by flash chromatography on silica gel. Elution with 5% ethyl acetate in petroleum ether gave 101 mg of the starting material **3**. Further elution with the same solvent system afforded ketal ester **6** (713 mg; 92% yield based on consumed starting material); ir (film): 1728 (C=O) cm^{-1}; ^{1}Hmr δ: 1.60 (s, 3H, —CH_3), 3.70 (s, 3H, —OCH_3), 3.86 (m, 4H, —OCH_2CH_2O—), and 5.28 (m, 1H, =CH—); ms M^+: 266.1517 (calcd. for $C_{15}H_{22}O_4$: 266.1512). *Anal.* calcd. for $C_{15}H_{22}O_4$: C 67.63, H 8.33; found: C 67.25, H 8.27.

Reduction of ketal ester 6

At 0°C, lithium aluminium hydride (236 mg, 6.21 mmol) was added to a solution of ketal ester **6** (550 mg, 2.07 mmol) in ether (10 mL). After stirring at room temperature under an argon atmosphere for 10 h, the reaction mixture was cooled to 0°C and water was slowly added. The resulting mixture was extracted with methylene chloride. The extracts were dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with 15% ethyl acetate in petroleum ether, gave alcohol **7** (474 mg; 96% yield); ir (film): 3550 (OH) cm^{-1}; ^{1}Hmr δ: 1.66 (s, 3H, —CH_3), 3.41, 3.75 (both d, 1H each, J = 12 Hz each, —CH_2OH), 3.76 (s, 1H, —OH), 4.02 (m, 4H, —OCH_2CH_2O—), and 5.21 (m,. 1H, =CH—); ms M^+: 238.1565 (calcd. for $C_{14}H_{22}O_3$: 238.1563). *Anal.* calcd. for $C_{14}H_{22}O_3$: C 70.54, H 9.30; found: C 70.55, H 9.35.

Preparation of phosphorodiamidate 8

At 0°C, to a solution of ketal alcohol **7** (220 mg, 0.93 mmol) in *N*,*N*,*N'*,*N'*-tetramethylethylenediamine and 1,2-dimethoxyethane (1:4; 10 mL), was added a 2.35 *M* solution of *n*-butyllithium in hexane (1 mL, 2.35 mmol) under an argon atmosphere. After stirring for 15 min, *N*,*N*-dimethylphosphoramidic dichloride (2.5 g, 15.7 mmol) was added. The reaction mixture was stirred at room temperature for 24 h and an excess of dimethylamine (3 mL) was added at 0°C. After 30 min, the resulting mixture was poured into water and extracted with ether. The extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with ether, afforded 30 mg of starting alcohol **7**. Further elution with 5% methanol in ether gave phosphorodiamidate **8** (290 mg; 98% yield based on consumed starting material); ir (film): major absorption bands at 2926, 1458, 1300, 1227, 1180, 1090, 1047, 995, and 751 cm^{-1}; ^{1}Hmr δ: 1.68 (s, 3H, —CH_3), 2.69 (d, 12H, J = 10 Hz, 2 × —$N(CH_3)_2$), 3.75 (dd, 1H, J = 11, J' = 3 Hz, —OC*H*H—), 3.90–4.12 (m, 5H, —OCH_2CH_2O— and —OC*H*H—), and 5.23 (m, 1H, =CH—); ms M^+: 372.2181 (calcd. for $C_{18}H_{33}N_2O_4P$: 372.2170).

Reduction of phosphorodiamidate 8

Lithium ribbon (349 mg; 55 g-at.) was added in small pieces over a 10-min period to 5 mL of ethylamine (freshly distilled from calcium hydride) at 0°C under an atmosphere of argon. After 30 min, a solution of phosphorodiamidate **8** (188 mg, 0.51 mmol) and *tert*-butyl alcohol (75 mg, 1.01 mmol) in tetrahydrofuran (3 mL) was added dropwise over 5 min and stirring was continued for 30 min. Water was slowly added and the resulting mixture extracted with ether. After washing with water, the organic solution was dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with 3% ethyl acetate in petroleum ether, afforded ketal **9** (46 mg; 41% yield); ir (film): major absorption bands at 2924, 2853, 1464, 1171, 1095, 1063, 955, and 896 cm^{-1}; ^{1}Hmr δ: 0.80 (s, 3H, —CH_3), 1.81 (br s, 3H, =C—CH_3), 3.85 (s, 4H, —OCH_2CH_2O—) and 5.17 (m, 1H, =CH—); ms M^+: 222.1617 (calcd. for $C_{14}H_{22}O_2$: 222.1614). *Anal.* calcd. for $C_{14}H_{22}O_2$: C 75.62, H 9.98; found: C 75.59, H 10.06.

Deketalization of ketal 9

Ketal **9** (30 mg, 0.14 mmol) was dissolved in acetone (2 mL) and *p*-toluenesulfonic acid (13 mg, 0.07 mmol) was added. After stirring at room temperature under an argon atmosphere for 2 h, the reaction mixture was made basic with saturated aqueous sodium bicarbonate and extracted with methylene chloride. The extracts were washed with water, dried, and filtered. Concentration gave the crude product which was purified by column chromatography on silica gel. Elution with 20% ethyl acetate in petroleum ether gave ketone **2** (24 mg; quantitative yield); ir (film): 1705 (C=O) cm^{-1}; ^{1}Hmr δ: 1.12 (s, 3H, —CH_3), 1.68 (s, 3H, =C—CH_3), and 5.32 (m, 1H, =CH—); ms M^+: 178.1356 (calcd. for $C_{12}H_{18}O$: 178.1353). Ketone **2** was shown to be identical with the adduct prepared from 2-methyl-2-cyclohexenone and isoprene according to the reported procedure (1), by direct comparison of their chromatographic and spectral properties.

Thermodynamics of solution of gypsum and anhydrite in water over a wide temperature range

HORACIO R. CORTI AND ROBERTO FERNANDEZ-PRINI[1]

Departamento Química de Reactores, Comisión Nacional de Energía Atómica, Av. Libertador 8250, CP-1429, Capital Federal, Argentina

Received June 29, 1983

HORACIO R. CORTI and ROBERTO FERNANDEZ-PRINI. Can. J. Chem. **62**, 484 (1984).

The solubility of calcium sulphate in water at different temperatures is important for the description of chemical processes occurring in heat exchangers as well as in geothermal processes. Great discrepancies have been reported between experimental and predicted solubilities at high temperature and the transition temperature for the phase transition process (gypsum → anhydrite) is ill-defined.

We have analyzed the available data for the solubility of calcium sulphate in water with no added electrolyte. Ion-pairing has been taken into account to calculate the standard thermodynamic properties of the solution process.

It is found that the solubility data for gypsum and anhydrite are thermodynamically very consistent. It is possible to obtain the thermodynamic properties of the phase transition from solution data and, at 298.15 K and 101.325 kPa, they are in very good agreement with reported values from measurements with the pure phases. The transition temperature is calculated to be 315.7 ± 0.4 K.

It is also shown that the experimental data agree with values predicted for high temperature by employing well-established methods of calculation of solution thermodynamic properties (e.g., principles of correspondence and of constant charge).

HORACIO R. CORTI et ROBERTO FERNANDEZ-PRINI. Can. J. Chem. **62**, 484 (1984).

La solubilité du sulfate de calcium dans l'eau à diverses températures est importante pour la description de processus chimiques se produisant dans des échangeurs de chaleur de même que dans des processus géothermiques. De grandes disparités ont été rapportées entre les solubilités prédites et expérimentales à haute température et la température de transition pour le processus de transition de phase (gypse → anhydrite) est mal défini.

Nous avons analysé les données disponibles pour la solubilité du sulfate de calcium dans de l'eau où il n'y a pas d'électrolytes ajoutés. On a tenu compte des paires d'ions pour calculer les propriétés thermodynamiques standards des processus en solution.

On a trouvé que les données de solubilité pour la gypse et l'anhydrite sont thermodynamiquement très consistantes. Il est possible d'obtenir les propriétés thermodynamiques de la phase de transition à partir des données en solution; pour 298.15 K et 101,325 kPa, ces propriétés sont en très bon accord avec les valeurs rapportées pour ces quantités lorsqu'elles ont été mesurées avec les phases pures. On a calculé que la température de transition est 315,7 ± 0,4 K.

On a aussi montré que les données expérimentales sont en accord avec les valeurs que l'on peut prédire pour les hautes températures en employant des méthodes bien établies pour le calcul de propriétés thermodynamiques en solution (par exemple, les principes de correspondance et de charge constante).

Introduction

Knowledge of the thermodynamics of aqueous solutions of calcium sulphate is of great practical importance because of its influence in scale formation on surfaces exposed to heat exchange. Moreover, it is also of interest in geothermal and hydrothermal processes.

The solubilities of anhydrite ($CaSO_4$) and gypsum ($CaSO_4 \cdot 2H_2O$) are known over a wide temperature range. They have been determined by several authors studying either the pure binary systems (1–6) or their mixtures with other strong electrolytes (6, 7). However, when these data were compared to those calculated by well-established methods for prediction of thermodynamic properties at high temperatures, no agreement was found (e.g., at 573 K they differ by a factor greater than 10^3) (8). Consequently, doubts have been expressed regarding the reliability of experimental solubility data for calcium sulphate aqueous solutions; this in turn makes uncertain the choice of the values for the solubility of anhydrite at high temperature which must be employed to model the chemistry in heat exchangers (9). Even the phase transition process between both crystalline calcium sulphates is not yet well established, as witnessed (10) by an uncertainty of about 22 K in the transition temperature at 101.325 kPa.

The purpose of the present work was to reassess the available experimental information about the solubility of anhydrite and gypsum in pure water up to 573 K. From this analysis we conclude that there is very good thermodynamic consistency among the solubility data available in the literature, those calculated with methods which predict the solubility at high temperatures on the basis of thermodynamic properties for room temperature, and the values established for the standard thermodynamic properties of the phase transition process at 298.15 K.

Since one of the methods used to predict thermodynamic properties makes use of the solubility data of barite ($BaSO_4$), the thermodynamic properties of solution of $BaSO_4$ also had to be considered in this work. It was found to be consistent with the rest of the thermodynamic information.

Calculation of standard thermodynamic properties of solution

The dissolution of calcium sulphate may be described by the following two processes:

$$[I] \quad CaSO_4 \cdot nH_2O(s) \rightleftharpoons Ca^{2+}(aq) + SO_4^{2-}(aq) + nH_2O(l)$$

$$[II] \quad Ca^{2+}(aq) + SO_4^{2-}(aq) \rightleftharpoons CaSO_4(aq)$$

The second process describes the association of oppositely charged ions to form ion pairs.

In order to calculate the standard Gibbs free energies of solution, $\Delta_{sol}G^0$, from solubility data, it is necessary to correct

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

the experimental solubilities for the effect of ion association. If K_I and K_A represent the equilibrium constants characterizing reactions [I] and [II], respectively, the solubility s may be expressed by

$$[1] \quad s = K_I K_A + \frac{K_I^{1/2}}{\gamma_\pm}$$

The association constant was calculated with Bjerrum's expression for ion-pair formation (11–13):

$$[2] \quad K_A = 4\pi N_A \int_a^d r^2 \exp\left\{\frac{(ze)^2}{\epsilon kT}\right\} dr$$

where d, the distance of closest approach of free ions, was fixed at the value $(ze)^2/2\epsilon kT$. If the contact distance of ion pair, a, is assumed to be temperature independent, it is only necessary to know K_A at one temperature to establish ionic association over all the temperature range from eq. [2]. Using K_A = 209 mol kg^{-1} at 298.15 K, which was obtained from conductivity (14) and emf (15) measurements for calcium sulphate aqueous solutions, the value 4.45 Å was calculated for a from eq. [2]. This result, when compared to the sum of crystal radii (3.72 Å), shows that solvent-separated pairs predominate in solution, a conclusion which agrees with evidence from relaxation spectrometry (16).

The mean activity coefficients, $\gamma_\pm$, in eq. [1] were calculated by means of the extended Debye–Hückel equation

$$[3] \quad \ln \gamma_\pm = -\frac{AI^{1/2}}{1 + dBI^{1/2}}$$

where I is the ionic strength of the saturated solution, and A and B have the usual meaning (12). To ensure consistency (13), the distance parameter in eq. [3] must be the same as that in eq. [2]. The dielectric constant of water, ϵ, at different temperatures was obtained from ref. 17.

A strong support for the method used here to calculate K_A is the fact that the values determined for pK_A in all the temperature range differed less than 0.3 units from those reported by Yeatts and Marshall (7), whose results were obtained from solubility measurements in aqueous solutions of calcium sulphate in Na_2SO_4–$NaNO_3$ mixtures having ionic strengths between 0.25 to 6 molal in the temperature range 273 to 623 K. These experimental conditions enabled the authors to obtain K_I and K_A by means of an extrapolation procedure, which entails more uncertainty than the method employed in this work to deal with the pure binary system.

Gardner and Glueckauf (18, 19) have used previously a similar method to treat the solubility of calcium sulphate in water up to 473 K. They have employed a more complicated equation for $\gamma_\pm$ and have required the additional assumption that triplet and quadruplet ions exist in solution. In spite of using more adjustable parameters, their agreement with experimental data was not too satisfactory at high temperatures (7, 19).

Figures 1 and 2 show the temperature dependence of the solubility of the binary systems containing either gypsum or anhydrite in pure water. The transition temperature for the reaction

$$[III] \quad CaSO_4 \cdot 2H_2O(s) \rightleftharpoons CaSO_4(s) + 2H_2O(l)$$

is in the vicinity of 313 K (*vide infra*). Nevertheless, there are a number of solubility data corresponding to both solid phases above and below the transition temperature. These solids can

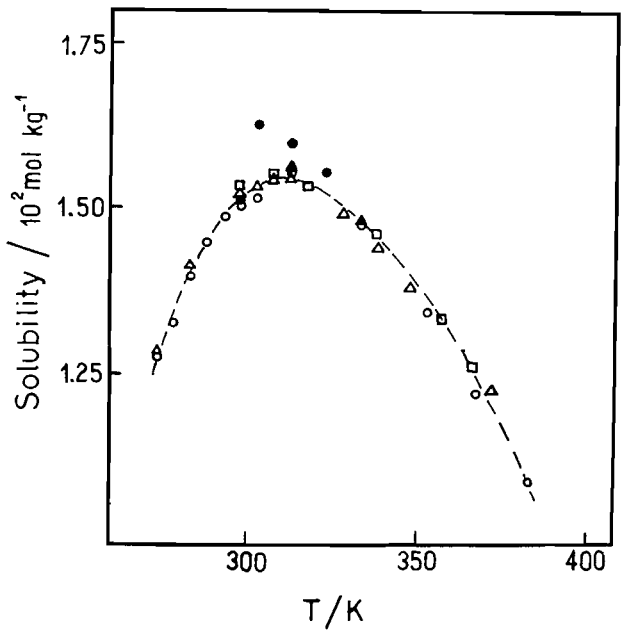

FIG. 1. Solubility of gypsum in water versus temperature. Sources of data: ▲, ref. 1; ○, ref. 2; □, ref. 3; △, ref. 4; ●, ref. 5.

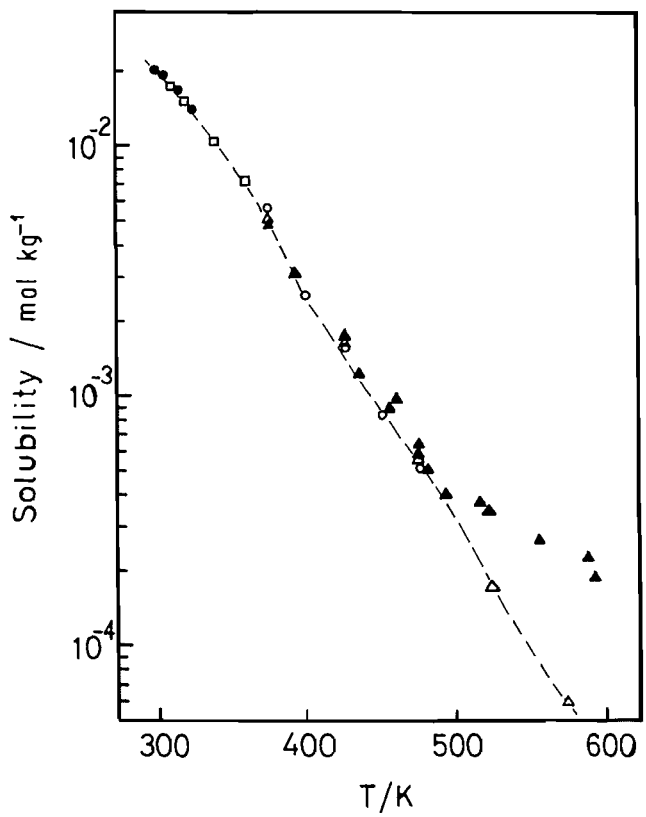

FIG. 2. Solubility of anhydrite in water versus temperature. Sources of data: ○, ref. 1; □, ref. 3; ▲, ref. 4; ●, ref. 5; △, ref. 6.

exist under metastable conditions; thus it is possible to cover a temperature range which extends outside the stability region for each solid. The solubility data for gypsum between 273 and 383 K (Fig. 1) show good agreement among the different sources of data, except for those reported by Bock (5) which differ markedly from all the rest and were not included in the present analysis. For anhydrite, the agreement among different

	Circ. 500 NBS (21)	This work
$\Delta_{trs}G^0$ (kJ mol^{-1})	−0.807	−0.958 ± 0.075
$\Delta_{trs}H^0$ (kJ mol^{-1})	−16.52	−16.2 ± 2.6
$\Delta_{trs}S^0$ (J (mol K)$^{-1}$)	−52.7	−51.0 ± 8.8

authors is reasonably good up to 493 K. Above this temperature we have only considered the solubility data of Blount and Dickson (6) after a careful analysis of the experimental procedures convinced us that the precautions of these authors to ensure the attainment of equilibrium give great reliability to their solubility data at high temperatures.

In order to calculate the standard thermodynamic quantities describing process [I] over the temperature range, the values of ln (K_I) for gypsum and for anhydrite were fitted to a polynomial in the reduced temperature according to Clarke and Glew (20).

For gypsum it was found that the whole set of data could be well represented by the four-parameter equation

$$[4] \quad \ln K_I(T) = b_0 + b_1u_1 + b_2u_2 + b_3u_3$$

where

$$u_1 = \frac{x}{1 - x}$$

$$u_2 = x^2 \sum_{n=1}^{\infty} \frac{n}{n+1}(-x)^{n-1}$$

$$u_3 = x^3 \sum_{n=1}^{\infty} \frac{n}{n+2}(-x)^{n-1}$$

and the reduced temperature $x = (T/\theta - 1)$, θ being the reference temperature here, taken as 298.15 K. Coefficients b_0, b_1, b_2, and b_3 are simply related to $\Delta_{sol}G^0(\theta)$, $\Delta_{sol}H^0(\theta)$, $\Delta_{sol}S^0(\theta)$, and $\Delta_{sol}C_p^0(\theta)$, respectively (20).

For anhydrite dissolution, eq. [4] was found to describe adequately the two sets of data corresponding to the lower temperature range (298 to 373 K) (3, 5). The deviation from eq. [4] increased when all the data were considered together, as a result of increased experimental uncertainty in the data at higher temperatures. In order to calculate the standard thermodynamic properties at 298.15 K for anhydrite, only those data up to 373 K, which are believed to be the most accurate ones, were considered. Table 1 reports the coefficients of eq. [4] for gypsum and two sets of coefficients for anhydrite, one corresponding to the low temperature range and the other obtained from the whole set of data with a somewhat reduced precision.

TABLE 3. Standard thermodynamic properties for the solution of gypsum in water in the range of 273 to 383 K

T (K)	$\Delta_{sol}G^0$ (kJ mol^{-1})	$\Delta_{sol}H^0$ (kJ mol^{-1})	$\Delta_{sol}S^0$ (J (mol K)$^{-1}$)
273.15	23.94 ± 0.04	6.40 ± 1.05	−64.2 ± 3.7
298.15	25.80 ± 0.02	0.59 ± 0.29	−84.5 ± 1.0
323.15	28.17 ± 0.03	−5.98 ± 0.38	−105.6 ± 1.2
348.15	31.08 ± 0.03	−13.30 ± 0.33	−127.5 ± 1.0
373.15	34.55 ± 0.04	−21.4 ± 1.2	−149.9 ± 3.2
383.15	36.09 ± 0.07	−24.8 ± 1.8	−159.0 ± 4.7

Table 2 gives the values found for the standard thermodynamic properties of solution at 298.15 K. A comparison between the values of the thermodynamic properties of the phase transition process [III] given in the literature (21) with those calculated here from solubility data is shown in Table 2. The good agreement observed lends strong support to the consistency of the thermodynamic properties calculated for gypsum and anhydrite from solubility data because the values reported for this phase transition process in Circular 500 of NBS come from experimental data obtained for the pure solid phases and for water. From eq. [4] for gypsum and anhydrite, it was possible to calculate the transition temperature of [III] to be 315.7 ± 0.4 K at atmospheric pressure; this value is close to that reported by Marshall and Slusher (2).

Tables 3 and 4 list the thermodynamic properties for the dissolution of gypsum and anhydrite in water at different temperatures calculated from eq. [4] for ln (K_I). It is of interest to mention the good agreement between the values of the thermodynamic properties calculated for anhydrite and those reported by Yeatts and Marshall (7) on the basis of measurements of calcium sulphate solubility at constant ionic strength, because there have been previous reports (8) of a lack of agreement.

Prediction of ln K_I for anhydrite at high temperatures

It is important to compare ln K_I calculated from the $\Delta_{sol}G^0$ ($CaSO_4$(s)) values at different temperatures in Table 4, with those calculated by well-established predictive methods. This is because previous calculations have yielded doubtful results (8) and also because good predictive procedures are of practical importance to obtain reliable values of the solubility outside the experimental temperature range.

Both the correspondence principle introduced by Criss and Cobble (22) and the principle of constant charge (8) have been employed in this work.

(a) Correspondence principle

The modification proposed by Lewis (23) of the correspondence principle has been followed. It relates the standard molar heat capacity of ion i in solution to its standard entropy at a reference temperature, i.e.,

$$[5] \quad C_{p,i}^0 = (k + lS_i^0(\theta))T$$

573.15	9.08	9.21	9.03	8.93
623.15	10.24[d]	10.27	10.06	9.95

[a] With $\Delta_{sol}S^0$ (298.15 K) = −144.7 J (mol K)$^{-1}$ and $\Delta_{sol}C_p^0$ = −70.20 − 0.7806 T J (mol K)$^{-1}$ (21).
[b] With $\Delta_{sol}S^0$ (298.15 K) = −139.7 J (mol K)$^{-1}$ and $\Delta_{sol}C_p^0$ = −70.20 − 0.7639 T J (mol K)$^{-1}$ (24).
[c] With $\Delta_{sol}S^0$ and $\Delta_{sol}C_p^0$ calculated in this work (cf. Table 4 and text).
[d] Extrapolated with eq. [4].

where k and l are the correspondence principle constants (22) for that ionic class. The change of heat capacities of process [I] may be expressed by

$$[6]\quad \Delta_{sol}C^0_{p,I} = \alpha + \beta T + \gamma T^{-2}$$

This leads to the following expression for ln K_I:

$$[7]\quad \ln K_I(T) = \frac{\theta}{T}\ln K_I(\theta) + \frac{1}{R}\left\{\frac{x}{x+1}\Delta_{sol}S^0(\theta)\right\} - \alpha\left\{\frac{x}{x+1} - \ln(x+1)\right\} - \frac{\beta}{2}\left\{\frac{\theta x^2}{x+1}\right\} - \frac{\gamma}{2}\left\{\frac{x(x+2)}{\theta^2(x+1)^2}\right\}$$

with θ = 298.15 K. The value of ln $K_I(\theta)$ = −10.022 was obtained from the value for $\Delta_{sol}G^0(\theta)$ reported in Table 2. For $\Delta_{sol}S^0(\theta)$ we have used the value obtained in this work (cf. Table 2) as well as those calculated from the ionic entropies reported by Cobble *et al.* (21, 22) and those given by Wagman *et al.* (24) which have been recently used by Cobble and coworkers (8).

Table 5 compares the values of ln K_I calculated with the correspondence principle to the experimental ones. It may be noted that the correspondence principle with any of the $\Delta_{sol}S^0(\theta)$ values used in this work predicts a temperature dependence for ln K_I which is very close to that experimentally observed even at temperatures above 573 K. Furthermore, the pK_I value reported by Yeatts and Marshall (7) for 623.15 K is 10.30, in good agreement with the value 10.24 extrapolated with eq. [4] as reported in Table 5.

Table 5 appears to contradict the observation of Cobble and Murray (8) because it shows that the thermodynamic pattern emerging from the analysis of solubility measurements is quite consistent and in agreement with the behaviour predicted at high temperature.

(b) Constant charge principle

When an equilibrium involving ionic species is written in such a way that the process does not imply change in the number of charges, the assumptions on the values of ΔC_p^0 are greatly simplified (25). Cobble and Murray (8) have used this method for $CaSO_4$ solution by combining reaction [I] with that describing the dissolution of barite. Hence, the process they studied was

$$[IV]\quad BaSO_4(s) + Ca^{2+}(aq) \rightleftharpoons Ba^{2+}(aq) + CaSO_4(s)$$

The values of K_I for $CaSO_4$ which they obtained differ by more than three orders of magnitude from the experimental values.

We have calculated the equilibrium constant K_{IV} of process [IV] with the correspondence principle (23) and with the constant charge principle (8) with various choices for the change of heat capacity. Table 6 reports these values and compares them to experimental ones obtained from the solubility measurements of Blount (26).[2] Table 6 confirms the very good agreement between the solubility measurements and the predicted pK_{IV}, the only exception being the principle of constant charge with $\Delta C_p^0 = 0$, which is a rather extreme assumption.

Conclusions

A great consistency is observed in the thermodynamic data evaluated in the present work. The standard thermodynamic properties for the solution of gypsum and anhydrite in water at 298.15 K obtained from the solubility data are in good agreement with those reported in the literature. It was possible to establish the phase transition temperature within 0.4 K.

The principles of correspondence and of constant charge used with appropriate values for the heat capacities are good enough for predicting the solubilities of anhydrite and barite up to 573 K. The values of the thermodynamic properties of solution of anhydrite in water above 573 K, which may be obtained by extrapolation with eq. [4], should be considered as highly reliable. In fact, the value for pK_I quoted for 623 K in Table 5

[2] For $BaSO_4$ solutions it is not necessary to correct solubilities for ion pair formation because the saturated solutions are very dilute.

is close to that reported by Yeatts and Marshall (7) from the study of mixed electrolyte solutions.

It is recommended that the values of the thermodynamic properties of solution for high temperature, which are reported here, be used in the calculations involved in the modelling of chemical processes that take place on heat exchanging surfaces or in hydrothermal processes.

Received January 10, 1983[1]

H. DUGAS, P. KEROACK, and M. PTAK. Can. J. Chem. **62**, 489 (1984).

The synthesis of *syn* and *anti* chiral dinitroxide [18]-crown-6 ethers and of a tetranitroxide crown ether is described. The existence of a spin–spin interaction for the *syn* isomer makes this spin-labeled crown ether probe particularly useful to follow by epr the effects of K^+ ion binding, pH, solvent, and temperature. These observations are discussed in terms of a global dynamical fluctuation of the substituted crown ether.

H. DUGAS, P. KEROACK et M. PTAK. Can. J. Chem. **62**, 489 (1984).

Cet article décrit la synthèse de dinitroxydes couronne-[18]-éthers-6 chirales, *syn* et *anti* et un éther couronne tétranitroxyde. La présence d'interactions spin–spin pour l'isomère *syn* rend cet éther couronne marqueur de spin particulièrement utile pour suivre par rpe les effets de fixation d'ions K^+, de pH, de solvant et de température. Ces observations sont discutées en terme d'une fluctuation dynamique et globale de l'éther couronne substitué.

Introduction

Precise conformational data on free and complexed crown ethers are obtainable mainly from X-ray structure determinations. Studies in solution using spectroscopic methods are often rather limited because of the reduced number of parameters which change significantly with various conformations and interactions. These features are inherent in the $—CH_2—O—CH_2—CH_2—O—CH_2—$ sequence and in the symmetry properties of the corresponding crown ether. We have recently developed methods of labeling crown ethers with nitroxide radicals with the following in mind: (a) synthesis of doubly labled crown ethers to prepare subtituted macrocyclic molecules with different complexing abilities, and (b) to take advantage of the spin–spin exchange interaction to investigate conformations and motions of these molecules.

We have reported in a communication (1) the first synthesis of two stereochemically distinct chiral dinitroxide crown ethers, the *syn* isomer **2** and the *anti* isomer **3**. In the present paper we would like to expand this work to the corresponding tetranitroxide molecule **4** which is symmetric relative to the crown ether ring. It should be particularly interesting to compare this compound with the di-SL-*syn* isomer **2** (SL for spin label) in which there is a dissymmetry in the molecule that can be referred to as "face discriminated" relative to the crown ether plane (2). That is, one face of the molecule can be selectively modified (ionized for instance) while the paramagnetic

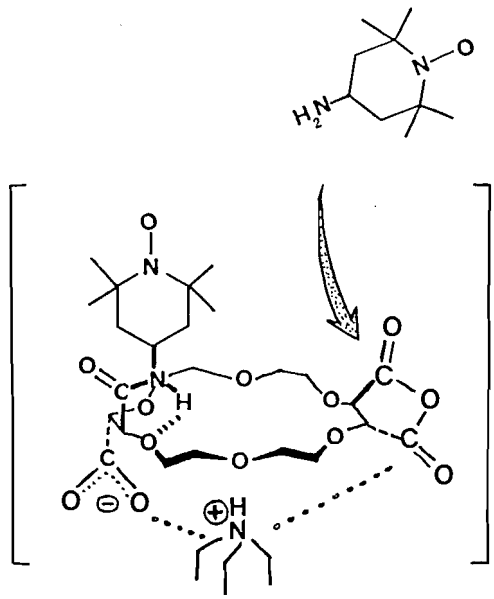


SCHEME 1

probes on the other face could act as reporters to monitor structural and dynamical perturbations. Such an architecture of the molecule should also confer toposelectivity in complexation processes with chiral organic cations (3).

In a first step we report here how the epr spectra of these molecules are affected by solute–solvent interactions, temperature, K^+ binding, and the state of ionization of the carboxyl groups (for the dinitroxide derivative).

This study should serve as a basis for further detailed investigations of complexation processes.

Results and discussion

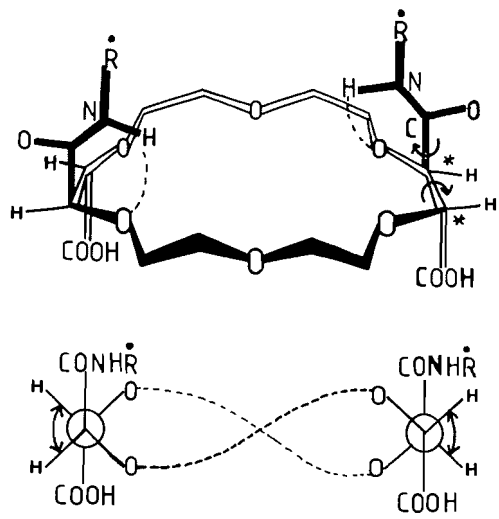
Chemistry

The tetraacid-bis-tartro-[18]-crown-6 **1** was readily obtained from (+)-*R*,*R*-tartaric acid by well-established procedures (4, 5). The corresponding anhydride **6** was used to prepared the dinitroxides **2** and **3** by reaction with tempamine **7** following the methodology developed by Lehn's group (2). Mixtures were separated by column chromatography and, when the reaction with **6** was performed in the presence of triethylamine, only one isomer (*syn* **2**) was formed (1). The reason for this probably lies in the fact that, in the transition state of the reaction (Scheme 1), the base is involved in electrostatic interactions with the carboxylate group newly formed on one side of the macrocyclic ring, and thus tempamine **7** can approach and react with the second anhydride function only from the opposite (top side) face of the crown ether ring. Esterification of **2** with diazomethane gave **5** in almost quantitative yield.

The tetranitroxide **4** was obtained by reaction of tempamine **7** with the tetraacid chloride (via PCl_5) of **1** in dichloromethane (3). The neutral product was purified by chromatography.

Generalities

The global conformation of the spin-labeled [18]-crown-6 ethers depends on three sets of parameters: (a) 18 intracyclic rotations around $(O—CH_2—CH_2—O)_4$ and $(O—\overset{*}{C}HX—\overset{*}{C}HY—O)_2$ bonds describing the conformation of the crown ring (X, Y = side chains); (b) 6 side-chain rotations around $(\overset{*}{C}H—COOH)_2$, $(\overset{*}{C}H—CONH\dot{R})_2$, $(CONH—\dot{R})_2$ bonds where $\dot{R}$ = 2,2,6,6-tetramethylpiperidine-1-oxyl; and



SCHEME 2

(c) 6 internal rotations of the $\dot{R}$ piperidine ring. Scheme 2 shows a three-dimensional presentation and a Newman projection of the di-SL-*syn* isomer **2**.

A priori, one could assume that the global conformation of the free and complexed compounds remains of C_2 symmetry. The shape of the epr signal of biradicals and tetraradicals will depend strongly on the exchange integral $\bar{J}$ and on the modulation of this integral by internal motions. It is particularly important to recall that for a biradical, the linewidth of $M_I = \pm 1$ lines and of two components of the central line depends on the ratio: $j(\bar{J})/(\bar{J})^2$ (6). Unfortunately, the exact dependence of $\bar{J}$ on the conformation and on the nature of motions determining the spectral density $j(\bar{J})$ is not available. Therefore, the positions of the epr signals and the linewidths will depend simultaneously on parameters such as temperature, pH, and solvent, all having an effect on the internal motions and the average conformation of the molecule.

Spectra of the different spin-labeled crown ethers

Figure 1 represents the epr spectra of dinitroxides, *syn* **2** and *anti* **3**, and of the tetranitroxide **4**, in water at ambient temperature. Because of the orientation of the nitroxide groups on opposite faces of the crown ether ring, the spectrum of the *anti* isomer **3** does not reveal any spin–spin interaction. On the other hand, such an interaction is clearly detected for the *syn* isomer **2** by the appearance of small intermediate lines between the three main lines where the intensity, the position, and the shape depend on $\bar{J}$ and $j(\bar{J})$. Such spectra have been described before for different families of linear flexible biradicals (7, 13). The spectrum of the tetranitroxide **4** is more complex since thirteen lines are readily distinguished. Assuming a nearly axial position (8) for the spin-labeled side chains with respect to the plane of the crown ether ring, one should consider this tetraradical as two independent biradicals since all *trans* spin–spin interactions (opposite side) should be negligible compared with the *cis* ones (same side) (*trans* nitroxide–nitroxide distances $\geqslant$ 12 Å). The position of satellite and intermediate small lines is very similar to the spectrum of a biradical with a weak exchange interaction with $J \approx 2a$ (a = isotropic hyperfine splitting) (7). Their intensities, however, seem to be too small, as compared to the three main lines, to correspond to a unique species which would be a rigid biradical with a fixed nitroxide–nitroxide distance.

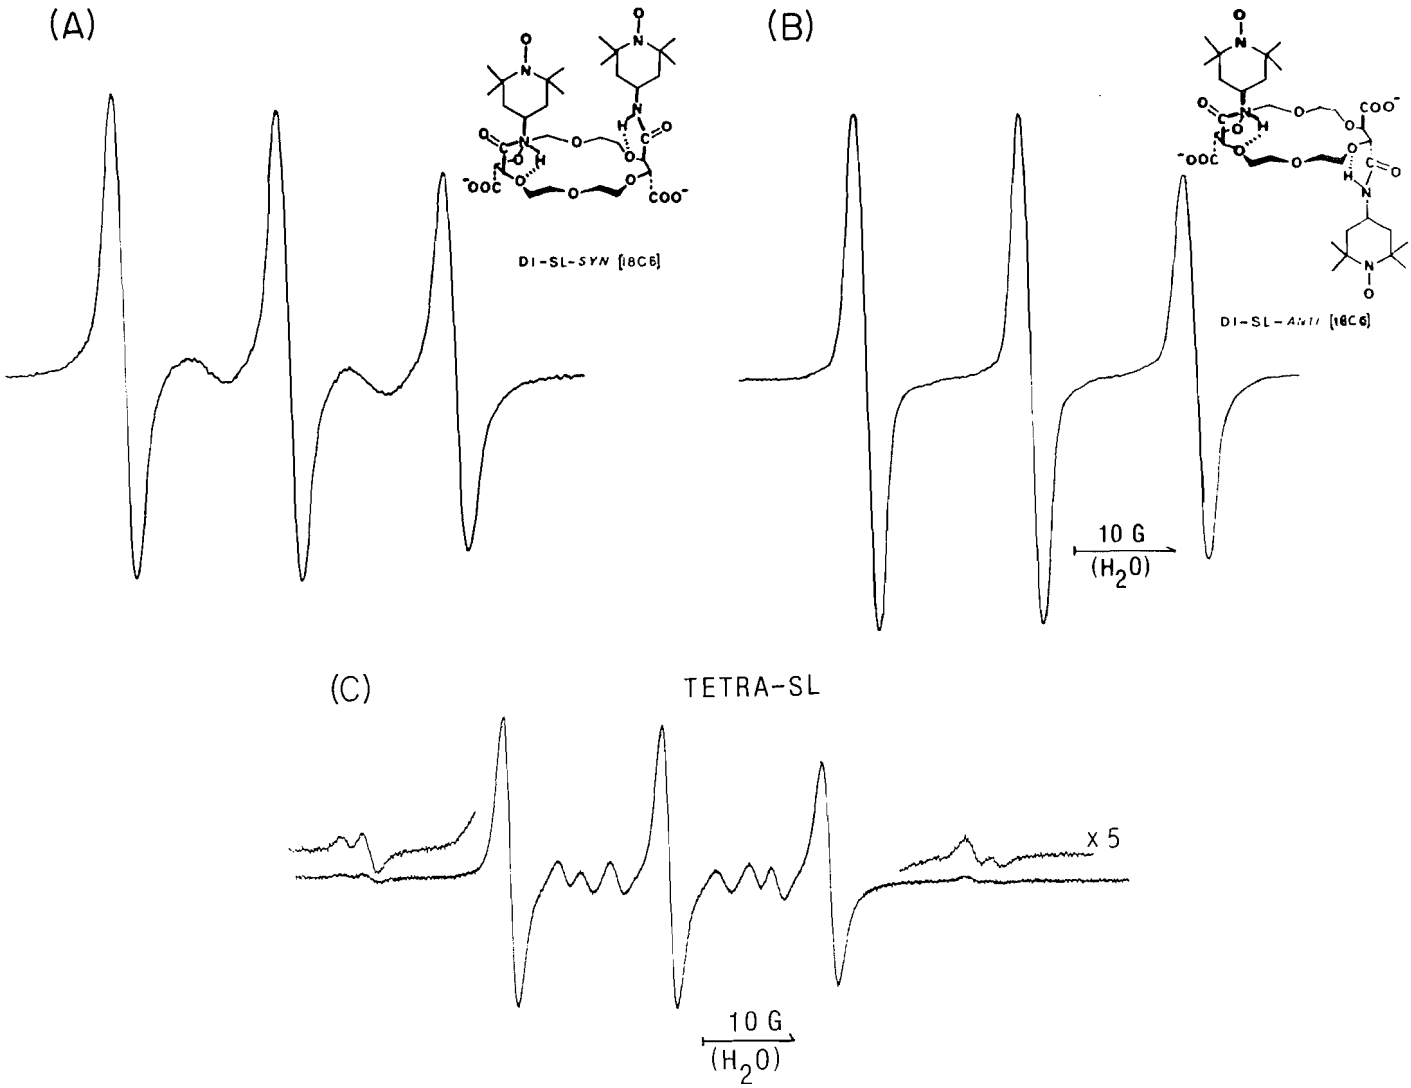

FIG. 1. Electron paramagnetic resonance spectra in water at room temperature of di-SL-*syn* **2** (A), di-SL-*anti* **3** (B), and tetra-SL **4** (C).

More likely one has to consider the existence of a slow equilibrium ($\tau \leq 10^{-7}$ s) between a so-called "closed" conformation where two *syn* nitroxides are interacting and an "open" one where they are more distant. The presence of four bulky substitutents and the absence of a strong effect upon K^+ complexation suggest a limited flexibility of the crown ether ring. Therefore, the spin–spin interactions seem to depend more on the motions and the conformations of the side chains which are also sensitive to solute–solvent interactions since in ethanol only six small broad intermediate lines are observed.

The temperature has only small effects on the spectra. This could be explained by the symmetry of the internal motions; that is, an increase in the interaction between the nitroxide group on one face of the crown ether ring is compensated by an opposite effect on the other side. The internal molecular motions should be significantly different for the dinitroxide-*syn* **2** because of the dissymmetry of the molecule. Furthermore, the flexibility of the crown ether is expected to be greater and the presence of two carboxylic groups should make the molecule particularly sensitive to ionization and to interaction with the solvents and ions (see below).

Solute–solvent interactions

At room temperature, the positions and the shape of the small intermediate lines in the epr spectrum of di-SL-*syn* isomer **2** change when going from $CHCl_3$ or DMSO to ethanol and water, as seen in Fig. 2. Clearly the solvation has an effect on the exchange integral $\bar{J}$ as well as on the spectral density $j(\bar{J})$, i.e., on the nature and the frequency of the intramolecular motions and on the related averaged conformations. Traces of water in $CHCl_3$ have significant effects on the spectrum, certainly because of a preferential solvation of the two carboxyl groups. Furthermore, if traces of acid are present one should also consider the possibility of complexation of the H_3O^+ oxonium cation by the crown ether (9).[2]

In bulk water, both carboxyl groups are ionized and their repulsion affects the interactions of the nitroxide groups on the other face of the macrocylic ring. Therefore, in addition to global effects of the solvent similar to those just described for the tetranitroxide, there are specific effects on the two acidic groups located on one side of the molecule. A comparison with the nmr of non-paramagnetic di-anilide *syn* analogue (2) brings supplementary information. In $CDCl_3$ and DMSO-d_6, the two $\dot{C}HX$—$\dot{C}HY$ protons appear as well-separated doublets in 250 MHz ^1H nmr spectra, with different values for the coupling

[2]Also, J. M. Lehn, personal communication.

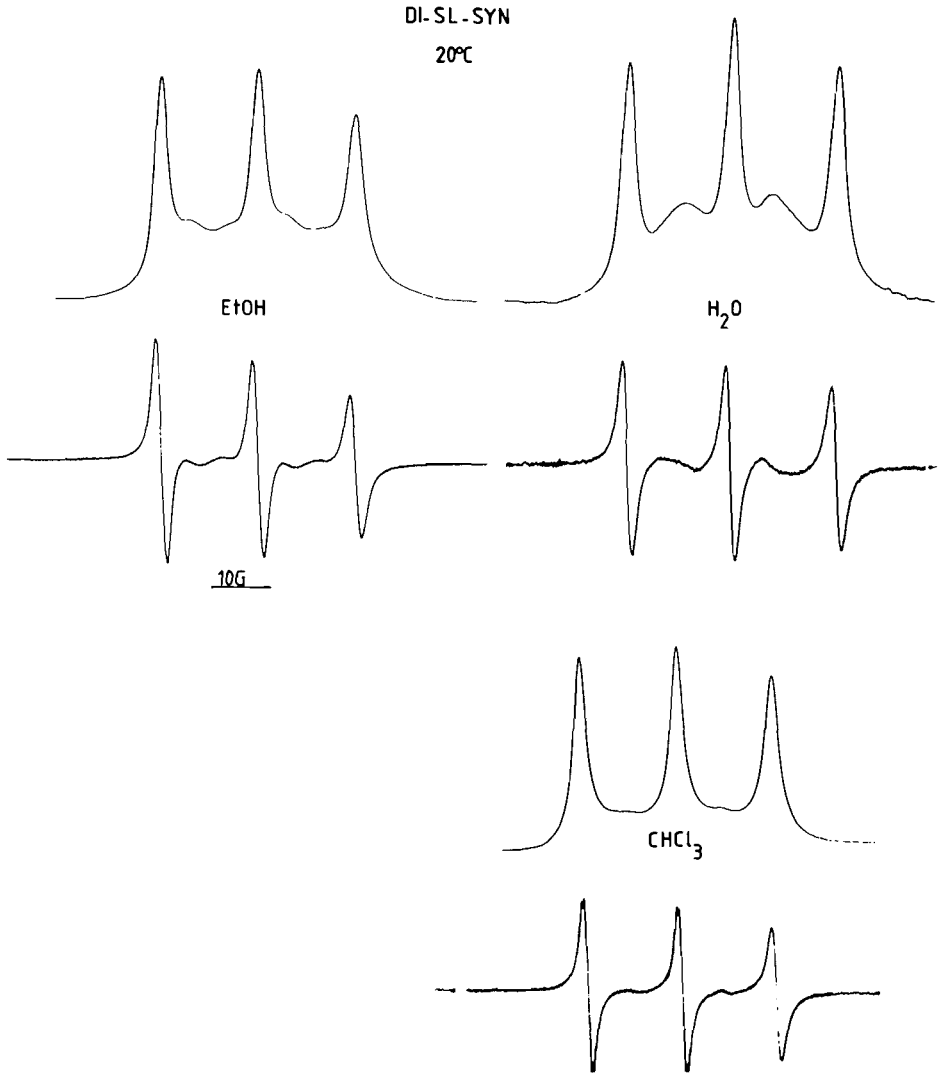

FIG. 2. Electron paramagnetic resonance spectra (first derivative and absorption) of di-SL-*syn* **2** in three different solvents (degassed) at room temperature (20°C).

constant: ^3J = 2.0 Hz ($CDCl_3$), ^3J = 4.7 Hz (DMSO). In D_2O, these doublets coalesce into a singlet. These coupling constants are sensitive to traces of water which, as noted previously, have an effect on spin–spin interactions. Such observations further corroborate how critically the conformation of the crown ether can be influenced by the nature of the solvent.

Assuming a nearly *trans*-diaxial orientation of the CONHR and COOH side chains (Scheme 2), one relates an increase in the coupling constant ^3J to a decrease of the corresponding dihedral angle, according to the classical Karplus relationship (10). Such a change in the conformation of the crown ether backbone does not influence appreciably the nitroxide–nitroxide distance in the spin-labeled compound since the epr spectra of di-*syn* **2** in $CHCl_3$ and DMSO are very similar and correspond to a smaller interaction than in more polar solvents. The most important solute–solvent interactions certainly involve the two *syn* acidic chains, while in $CHCl_3$ and also in DMSO these groups are probably implicated in a strong intramolecular hydrogen bond, COOH····OCOH, which stiffens the conformation of the whole molecule and does not favor nitroxide–nitroxide interactions on the opposite side of the crown ether. On the other hand, more polar solvents (ethanol and water) weaken the interaction between the carboxyl groups, producing a global conformational change and resulting in the closeness of the spin-labeled side chains.

Temperature effects

Figure 3 shows that the positions and the shape of the intermediate lines in the epr spectra of di-SL-*syn* **2** in organic solvents, as well as in water, depend on the temperature. Similar effects have been previously observed for flexible biradicals for which there was extensive line broadening (11). For the more rigid spin-labeled crown ether, the spectral change indicates that the exchange integral J increases with temperature. One can assume that an increase of temperature very likely induces a conformational change of the whole molecule and not only a modification of the intramolecular motions, i.e., on $j(\bar{J})$ and linewidth.

As for the solvent effects, an ^1H nmr study of the di-anilide *syn* again provided some useful information on the conformational behaviour of the spin-labeled analogue. In $CDCl_3$ and in DMSO-d_6 the $\overset{*}{C}HX—\overset{*}{C}HY$ coupling constants remain independent of temperature between 20° and 50°C. This shows that this chiral barrier fragment is thus relatively rigid and consequently the fluctuations observed in the epr spectra should be related to a more flexible portion of the molecule, mainly the

For personal use only.

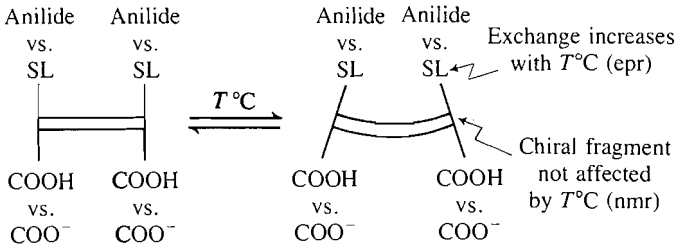
macrocylic ring itself. Such molecular perturbations induced by temperature can be schematized in the following way:



Another spectroscopic observation worth mentioning is that the chemical shift of the amide N*H* decreases as the temperature increases. Therefore, the temperature-dependent N*H* shielding ($\Delta\delta_{NH}/\Delta T$) was used to evaluate the accessibility of the amide proton by the solvent. In DMSO-d_6, this temperature coefficient has a value of 2.3×10^{-3} ppm/degree, a value currently found for groups screened from the solvent or engaged in internal hydrogen bonds. On the other hand, in $CDCl_3$, $\Delta\delta_{NH}/\Delta T$ is about 9.5×10^{-3} ppm/degree. Such a high value is usually found when both the internal motion of the solute and the thermal motion of the solvent dictate simultaneously the accessibility of the N*H* protons. The accessibility of the spin-labeled face seems to depend on the nature (structure and size) of the solvent, this effect being combined with a more selective solvation of the acidic groups on the opposite face of the crown ether ring.

Since the temperature acts simultaneously on several conformational parameters and spectral parameters (isotropic splitting, linewidth) it is especially difficult to quantify the corresponding epr spectral changes. One of the major difficulties is to maintain the instrumental sensitivity strictly constant and to avoid small changes of the linewidth in successive experiments. Very small variations of the linewidth of the three main lines due, for instance, to remaining traces of oxygen have similar consequences. Independent of such experimental conditions, two isoclinic points (12) were always found between the three main epr lines (Fig. 3). We have verified that the maxima of the three main lines in the corresponding absorption curve remain at constant values of the magnetic field while the shape of the absorption spectrum for the intermediate isoclinic points is significantly modified in these regions. In ethanol, changes occur progressively from two small intermediate lines to a unique higher line when the temperature is raised. In water, principally a progressive decrease of the linewidth of the intermediate lines is seen while the total spectrum gradually takes on the appearance of a five-line spectrum corresponding to a biradical with strong exchange. The two intermediate lines remain small due to symmetric linewidth variation and because of conformational equilibria.

A more quantitative interpretation of such spectra would require simulation in which one would introduce symmetric linewidth variations and conformational changes.

pH Effects

To confirm that the degree of ionization of the carboxyl groups could have an effect on the epr signal, the spectra were recorded at different pH values; three of them are presented in Fig. 4. Ionization of the carboxyl groups in water significantly increases the intensity of the intermediate lines of the di-SL-*syn* **2**. A similarity with the effect of temperature was at the origin of a controversy on the interpretation of spectral changes induced by temperature and pH for linear flexible biradicals (11, 13). For the spin-labeled crown ether **2**, the ionization of the carboxyl groups results in a strong electrostatic charge–charge repulsion on one face of the molecule, which induces a conformational change and then a modification of the exchange integral $\bar{J}$. Notice also the presence of isoclinic points, which could be considered as characteristic of an equilibrium between a neutral and an ionic form. As expected, such nitroxide–nitroxide interactions depend on the ionic strength since addition of an excess of TMA (tetramethylammonium), which is not complexed by the crown ether, causes a decrease of the intermediate lines.

The pK_a and pK_s values for the complexed (with K^+) and non-complexed forms of di-SL-*syn* **2** and di-SL-*anti* **3** have been measured (5) by Fyles and a more complete study on the effect of pH will be reported separately. Suffice to say that this preliminary result indicates that compounds such as **2** could be used as pH-sensitive spin probes. Only a few mono-spin-label compounds display this property (14, 15).

K^+ complexation

As stressed in a previous paper (1), the complexation of K^+ ion by the di-SL-*syn* **2** significantly modifies the spin–spin interaction. The nitroxide–nitroxide distance is reduced and the symmetric broadening is diminished. Two types of interaction are taking place in such a complexation process: (a) binding of K^+ within the cavity of the crown ether (internal position); and (b) a simultaneous interaction of another K^+ ion with some crown oxygen atoms and the two lateral carboxyl groups, corresponding to an external position of the cation. The existence of these two positions was recently established by Lehn and co-workers (16) on the crystal structure of the tetradimethyl amide of the **1**-K^+ complex. For the dimethyl ester derivative **5**, the cavity effect corresponding to the first type of interaction should be predominant. As shown in Fig. 5, the presence of the K^+ ion does not drastically modify the epr spectrum since the intermediate lines are undetectable. The esterification of the carboxyl groups seems to modify appreciably the spectral density $j(\bar{J})$, leading to extreme symmetric broadening even in the presence of K^+, as compared to free acidic side chains (compound **2**) (1).

The K^+ complexation also has an effect on the conformation of the crown ether since in the ^1H nmr spectrum (2), the dianilide-*syn* shows a decrease of the $\dot{C}HX—\dot{C}HY$ coupling constant; i.e. an increase in the dihedral angle. Moreover, in DMSO-d_6, the addition of K^+ ion produces an increase of the $\Delta\delta_{NH}/\Delta T$ coefficient for the N*H* protons (4.6×10^{-3} ppm/degree); i.e. an increase of their accessibility to the solvent. Clearly, the binding of K^+ in the crown ether weakens the interaction by hydrogen bonds of the N*H* protons with the proximal ether oxygen atoms.

These observations reinforce several features previously described, namely that any modification in the environment of the carboxyl groups located on one face of the crown ether ring profoundly affects the distance between the two nitroxide groups on the other side.

Conclusion

It is certainly premature to try to give a complete view of the conformational properties of the spin-labeled crown ethers from the present study. Nevertheless, several fundamental features do emerge. First of all, the interactions between the acidic side chains of di-SL-*syn* **2** on one face of the crown ether ring

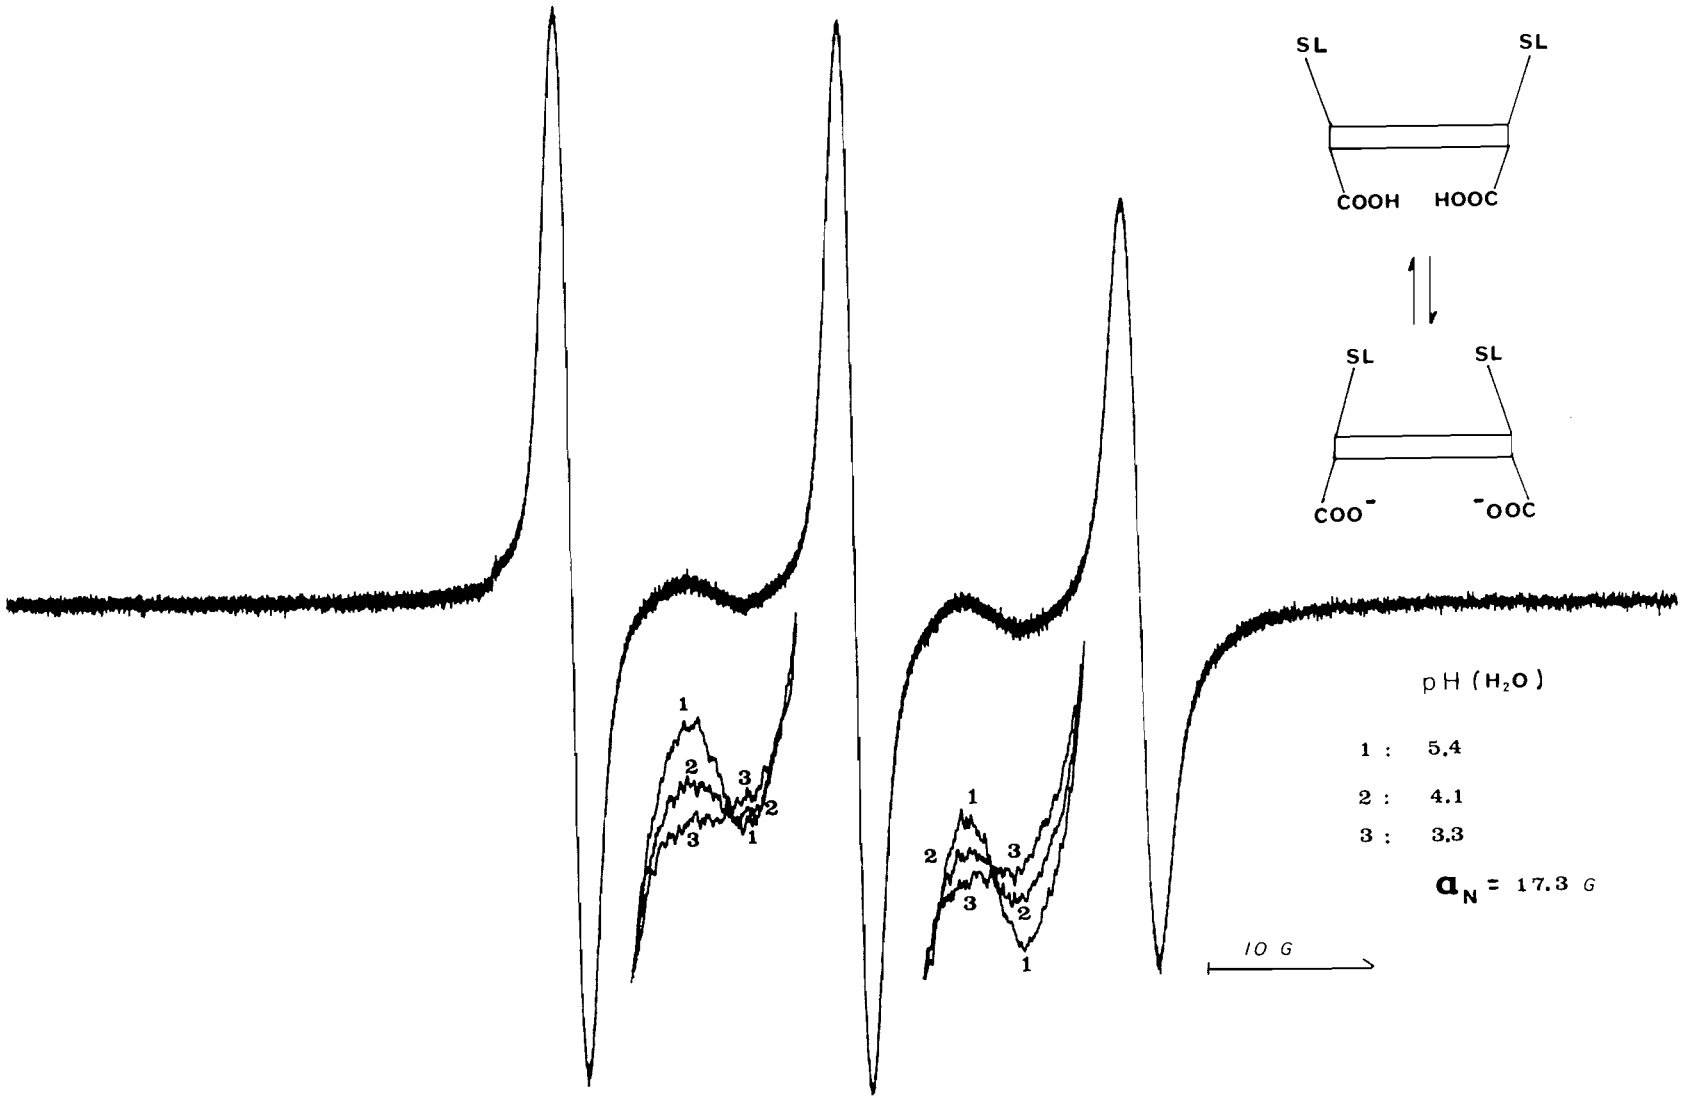

FIG. 4. Electron paramagnetic resonance spectra of di-SL-*syn* **2** in water at pH 5.9, 20°C, and at three different pH values (expanded scale by a factor of 5). The diagram is a schematic representation of the relative position of the nitroxide group (SL for spin label) before and after ionization of the carboxyl group.

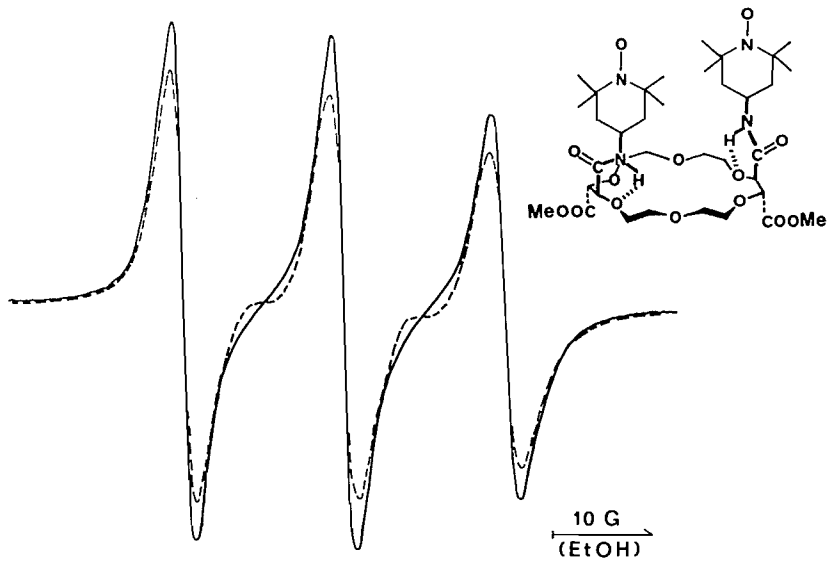

FIG. 5. Electron paramagnetic resonance spectra of the di-SL-*syn* dimethyl ester **5** in ethanol at room temperature in the presence of KSCN (dotted lines); complex 1:1.

play a major role on the global conformation of the whole molecule. Any modifications induced by either the solvent, the complexation with K^+, or by the degree of ionization have a profound effect on the nitroxide–nitroxide distance on the other face. Secondly, the crown ether backbone is rather flexible and changes of its conformation are readily detected by measuring the CHX—CHY coupling constant in ^1H nmr. Interestingly, it is to be noted that temperature does not modify the conformation of this chiral fragment, contrary to solvation, pH, or K^+ complexation.

Thirdly, the nitroxide–nitroxide interactions depend in a complex manner on all the parameters describing the conformation. In fact, one of the most striking features is the presence of a so-called "conformational reflex effect" (3) in which perturbation of the interactions between the carboxyl groups on one side of the crown results in a modification of the spin–spin interaction on the other side. The dinitroxide **2** is a very flexible molecule and the population of spin–spin interacting states increases with the temperature without reaching a point equivalent to a biradical with a strong interaction with a five-line spectrum (6). Nevertheless, the way is now open for a more complete analysis of interactions with different substitutents on spin-labeled crown ether receptors in order to see how the dissymmetry of the molecules influences the binding process.

Experimental

General details

Melting points were taken using a Reichart hotstage microscope and are uncorrected. The ir spectra were recorded using a Perkin–Elmer 710A spectrometer in $CHCl_3$ as solvent unless otherwise stated. The proton nmr spectra were recorded using a Varian 360 (60 MHz), a Bruker-WH90 (90 MHz), and a Cameca (250 MHz) spectrometer, using $CDCl_3$ or DMSO-d_6 as solvent, and containing tetramethylsilane (TMS) as internal standard. Specific rotations were calculated from optical rotation values obtained using a Perkin–Elmer 241 polarimeter and a 1-dm cell. Microanalyses were performed by H. Seguin of the National Research Council of Canada, Ottawa. For tlc, commercial plates of silica gel (Eastman or Macherey–Nagel) were used. Nitroxide groups give white spots on a blue background with molybdenum blue (Zinzadze) reagent.

The epr spectra were taken on a Bruker 414S or ER-200D spectrometer, equipped with a temperature control unit.

Procedure for the preparation of syn- *and* anti-*dinitroxide [18]-crown-6 diacid (2 and 3)*

A solution of dry tempamine **7** (1.2 g, 8 mmol) in 9 mL of dichloromethane was added dropwise over a 10-min period to a stirred solution of the dianhydride **6** (1.85 g, 4 mmol) in 15 mL of dry dichloromethane. After 2 hours at room temperature in the dark, the mixture was evaporated to dryness to yield 3.9 g of a crude orange foamy mixture of dinitroxide diacids. Chromatography on Kieselgel 60 Merck (5 × 15 cm) and elution with 30:8:5 $CHCl_3/CH_3OH/NH_4OH$ allowed the *anti* isomer **3** (0.35 g) to be eluted first, followed by elution with 70:30:7:1 $CHCl_3/CH_3OH/H_2O/NH_4OH$ to elute a mixture of *anti* and *syn* isomers (0.84 g) (that can be rechromatographed) and finally the *syn* isomer **2** (0.42 g), all as ammonium salts. Passage over Dowex 50-X8 (H^+ form) resin in 8:2 CH_3OH/H_2O yielded, after crystallization from C_2H_5OH/H_2O mixture, 127 mg of *anti* isomer **3** as orange needles (mp 235–240°C) and 269 mg of the *syn* isomer **2** as a pink crystalline material (mp 157–159°C); ir: 3500–3000 (OH), 1720 (COOH), 1660 (CONH) cm^{-1} for both compounds. The purity of both compounds was verified by hplc (Perkin–Elmer Series 3B) with a HS-SC18 column using 70:30:4 $CH_3OH/H_2O/NH_4Cl$ as eluant; $[\alpha]_D^{24}$ +58.9° (*c* 1.0, CH_2Cl_2) for **3** and +45.3° (*c* 1.5, C_2H_5OH) for **2**. *Anal.* calcd. for $C_{34}H_{58}N_4O_{14}\cdot 3H_2O$ for **3**: C 51.32, H 7.30, N 7.04; found: C 50.74, H 7.66, N 7.70 and for $C_{34}H_{58}N_4O_{14}\cdot 4H_2O$ for **2**: C 50.18, H 7.13, N 6.88; found: C 49.62, H 7.95, N 6.89.

Procedure for the preparation of only the syn *isomer (2): 2R,3R,11R,12R–(+)-N,N'-di-4'(2',2',6',6'-tetramethylpiperidine-1'-oxyl)-2-11-dicarboxamido-3,12-dicarboxyl-1,4,7,10,-13,16-hexaoxacyclooctadecane*

A solution of the dianhydride **6** (200 mg, 0.49 mmol) in 2 mL of dry dichloromethane was added dropwise to a solution of tempamine **7** (70 mg, 0.4 mmol) and triethylamine (20 drops) in 1 mL of dichloromethane. After stirring in the dark for 30 min the reaction mixture was evaporated to dryness to give a crude pink foam which was passed on a Kieselgel 60 Merck (1 × 10 cm) column. The excess tempamine was eluted first with CH_2Cl_2 and the *syn* isomer **2** (150 mg) with 30:8 CH_2Cl_2/CH_3OH. The material was shaken for a few minutes with a small amount of Dowex 50-X8 (H^+ form) resin to remove traces of remaining tempamine and to convert the *syn* isomer **2** (99 mg) in the carboxylic acid form as a glassy orange oil that can be crystallized from wet methanol (mp 160°C); epr: a_N = 16.3 G (C_2H_5OH), 17.2 G (H_2O). *Anal.* calcd. for $C_{34}H_{58}N_4O_{14}\cdot 2CH_3OH\cdot H_2O$: C 52.14, H 8.30, N 6.76; found: C 52.17, H 7.92, N 6.26.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

Dimethyl ester (5)

A small amount of **2** was esterified in methanol with diazomethane in the usual way to give a semi-solid yellow compound **5**: ir: 1650 (CONH), 1745 ($COOCH_3$) cm^{-1}; $[\alpha]_D^{20}$ +36.0° (*c* 1.0, C_2H_5OH). *Anal.* calcd. for $C_{36}H_{62}N_4O_{14}$: C 55.870, H 8.07, N 7.23; found: C 55.96, H 8.49, N 7.02.

Tetranitroxide [18]-crown-6 (4): 2R,3R,11R,12R-(+)-N,N',N'',N'''-2,3,11,12-tetrakis-4'-(2',2',6',6'-tetramethylpiperidine-1'-oxyl)-2,3,11,12-tetracarboxyamido-1,4,7,10,13,16-hexaoxacyclooctadecane

To the tetraacid **1** (85 mg, 0.2 mmol) in 2 mL of dry dichloromethane was added freshly sublimed PCl_5 (100 mg) and the solution was stirred at room temperature overnight so as to dissolve most of the PCl_5. This clear solution was added to the tempamine **7** (120 mg, 0.8 mmol) and triethylamine (200 mg, 2 mmol) in 2 mL of dichloromethane. After 1 hour, 1 g of alumina and 2 mL of methanol were added and the mixture evaporated *in vacuo*. Purification by passage over an alumina column (2 × 5 cm) using $CHCl_3$, followed by 10:1 $CHCl_3/CH_3OH$ as eluant, afforded 85 mg of a reddish oil. After elution on a Bio-Rad AG 50W-X8 (H^+ form) resin with CH_3OH, 70 mg of **4** as a clean orange oil was obtained. The oil solidified upon scratching the wall of the flask (mp 106–109°C); $[\alpha]_D^{24}$ +42.7° (*c* 1.0, C_2H_5OH). *Anal.* calcd. for $C_{52}H_{92}N_8O_{14}$: C 59.29, H 8.80, N 10.64; found: C 59.52, H 9.10, N 9.85.

The extraction and transport of alkaline earth cations from a basic to an acidic solution across an artificial membrane by crown ether carboxylic acids are reported. Monocarboxylate carriers achieve the transport via 2:1 complexes or by ternary complexes in the presence of readily extractible anions, while dicarboxylate carriers transport cations as 1:1 complexes. Both types of carrier exhibit two regimes of kinetic behaviour depending on the relative concentrations of the carrier and the metal ion: a zero order regime in which the rate depends only on the carrier concentration, and a reversible consecutive first order regime in which the rate depends only on the metal ion concentration. In the former, the rate of adsorption of the carrier on the interface is presumed to be rate limiting while in the latter, the diffusion of metal ion to the interface is rate limiting. Carrier structure exerts a general influence over both the rate and selectivity of transport but this influence varies with the kinetic regime considered.

LYNN M. DULYEA, THOMAS M. FYLES et DENNIS M. WHITFIELD. Can. J. Chem. **62**, 498 (1984).

On rapporte des extractions et des transports de cations d'alcalino-terreux de solutions basiques vers des solutions acides à travers une membrane artificielle effectués par des éthers couronnes d'acides carboxyliques. Les transporteurs monocarboxylés permettent d'effectuer les transferts via des complexes 2:1 ou par le biais de complexes ternaires en présence d'anions qui peuvent être extraits facilement; par ailleurs, les transporteurs dicarboxylés effectuent le transport des cations sous forme de complexes 1:1. Les deux types de transporteurs présentent deux régimes de comportement cinétique différents suivant les concentrations relatives de transporteur et d'ion métallique: un régime d'ordre zéro dans lequel la vitesse dépend uniquement de la concentration de transporteur et un régime du premier ordre consécutif et réversible dans lequel la vitesse dépend uniquement de la concentration de l'ion métallique. Dans le premier régime, on suppose que la vitesse d'adsorption du transporteur à l'interface est l'étape déterminante alors que dans le dernier régime, la diffusion de l'ion métallique à l'interface serait l'étape déterminante. La structure du transporteur exerce une influence générale à la fois sur la vitesse et sur la sélectivité du transport mais cette influence varie avec le régime cinétique considéré.

The extraction and transport of ionic species across membranes is central to the functioning of biological systems and is of increasing importance for the recovery and upgrading of resources using artificial membranes (1–6). One approach to the development of practical separation schemes seeks inspiration from the processes which occur in natural systems and, in particular, the behaviour of certain carboxylate antibiotics (7). These ionophores are capable of transporting a cation against its concentration gradient using a coupled counterflow of protons to drive the process. Numerous studies of these antibiotics *in vivo* and *in vitro* have confirmed a carrier mechanism in which proton loss and cation uptake occur to give a complex which diffuses across the membrane (8). Artifical systems incorporating the more readily available of these antibiotics have been examined in detail (9–11).

Extending this concept to a completely artificial system could follow one of several routes. Carriers might be designed to mimic structural features of the antibiotic ionophores (12–14) or, alternatively, the essential features of the transport might be adapted to other ionophoretic materials such as crown ethers or cryptands. From the point of view of synthesis, the latter approach based on crown ethers represents an important compromise. Candidate structures are of sufficient complexity to achieve the necessary control of ion bindings and physical properties, yet are sufficiently simple so that structural modifications throughout a series can be investigated without a massive investment of synthetic effort for each carrier. This approach has been investigated for the countertransport of alkali metal cations and protons (15–19). A schematic mechanism of the process is given in Fig. 1, A. At the basic interface the carrier is deprotonated and cation complexation occurs to give a neutral complex which can diffuse across the membrane. At

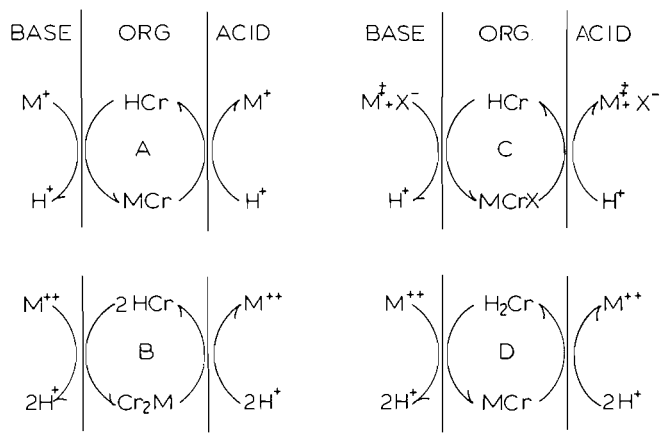

FIG. 1. Schematic mechanisms of cation–proton coupled countertransport. A: Monocarboxylate carrier/alkali metal cation. B: Monocarboxylate carrier/alkaline earth cation, 2:1 complexes. C: Monocarboxylate carrier/alkaline earth cation/extracted anion, ternary complex. D: Dicarboxylate carrier/alkaline earth cation.

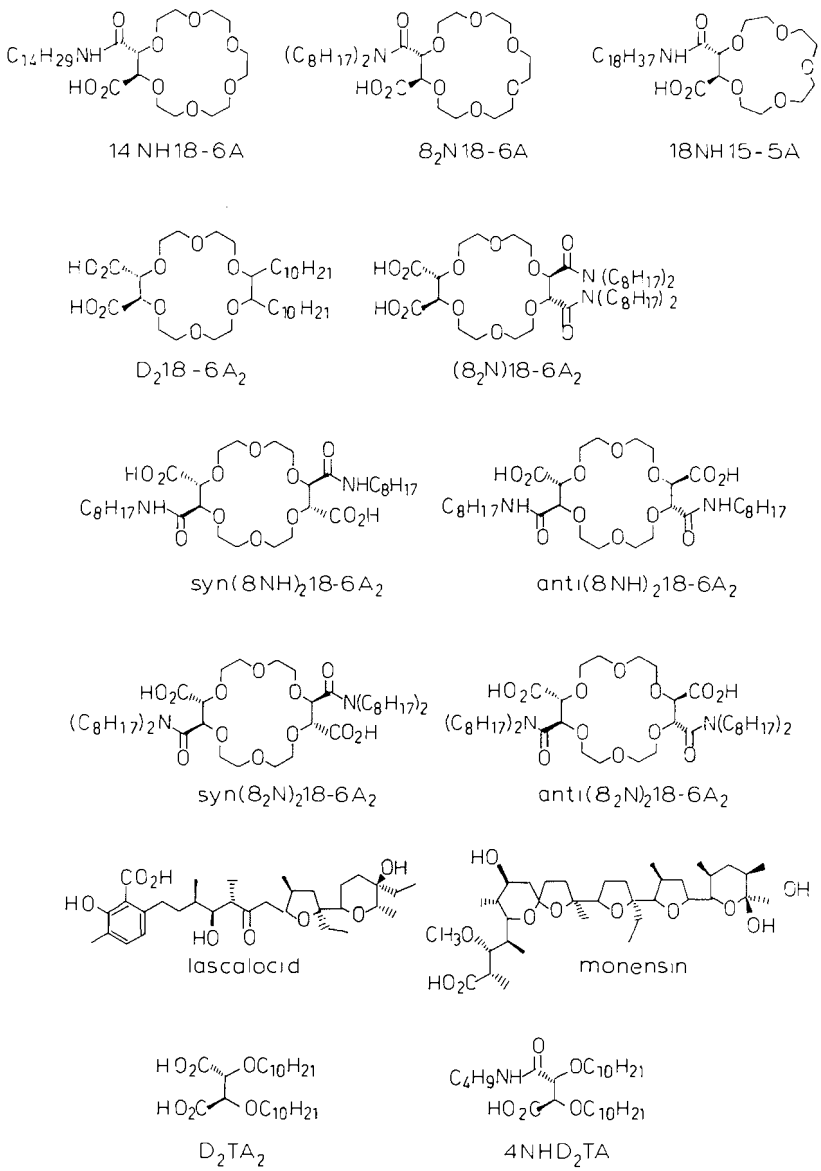
the acidic interface the reverse process occurs; protonation and metal ion loss regenerates the carrier and completes the cycle. In the systems studied to date, ion extraction is rate limiting under most circumstances (16, 17) and two different kinetic regimes can be recognized. One type is a "zero order" regime in which the transport rate depends only on the carrier concentration in the membrane phase while the other type is a "consecutive first order regime" in which the rate depends on the interfacial concentration of a carrier/metal ion complex (17). A mechanism consistent with these observations involves rate limiting adsorption of carrier or desorption of complex



from the interface (17).

Recently we have prepared a number of dicarboxylic acid carriers (20) which we anticipated would be capable of the extraction and transport of alkaline earth cations in exchange for two protons countertransported. For purposes of comparison we have also examined divalent ion transport by the monocarboxylic acid carriers previously prepared. This report outlines the transport behaviour of these two types of carriers and further probes the details of the interfacial exchange of cations and protons. Formulae of the carriers considered are shown, together with line notations indicating general structural features. Thus 14NH18-6A is a tetradecyl 1° amide (14NH) on an 18-crown-6 periphery (18-6) and a monocarboxylic acid (A), while *syn* (8NH)$_2$18-6A$_2$ is an 18-crown-6 diacid (18-6A$_2$) bearing two octyl 1° amides (8NH)$_2$. Positional isomerism is generally ignored (2,3 vs. 2,11 diacids) except for the important differences noted by the prefixes *syn* or *anti*.

Results and discussion

The transport of alkaline earth cations was examined using a U-tube cell (16, 17). The membrane phase was a chloroform solution of the carrier in the base of the U separating aqueous phases floating on the chloroform in the arms of the U. Transport of cations was followed by analysis of aliquots withdrawn from the aqueous phases. Initially, the two aqueous phases were at equal concentration but during the countertransport the concentration on the acidic side increased at the expense of a decrease of concentration on the basic side. Typical curves are shown in Figs. 2 and 3. As previously, two distinctly different kinetic regimes were noted. An excess of metal ion produces the zero order behaviour noted in Fig. 2 while approximately equal concentrations of metal ion and carrier produce nonlinear behaviour (Fig. 3). The two kinetic regimes are controlled by selection of the initial conditions but the concentration ranges accessible within each regime are limited by the tendency for most carriers to emulsify the cell contents at concentrations greater than 5×10^{-3} *M* and by the limits of the sampling and analysis protocols used (experimental section).

Zero order kinetic regime

In order to preserve electroneutrality the transport of divalent ions by monocarboxylate carriers requires either 2:1 carrier/metal ion complexes (Fig. 1, B) or anion dependent transport via ternary complexes (Fig. 1, C). Despite the

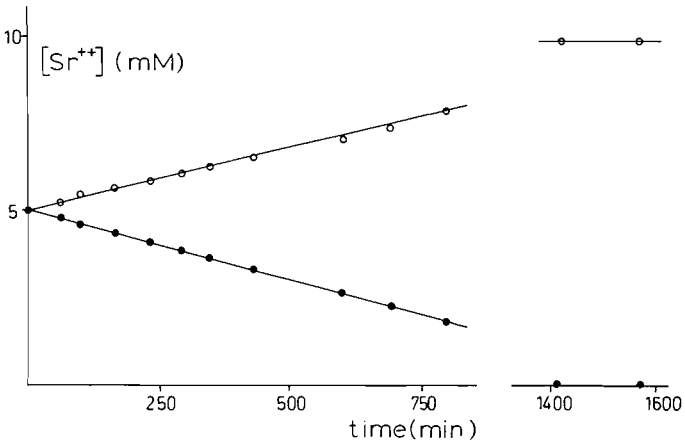

FIG. 2. Transport of strontium by the dicarboxylate carrier $D_2$18-6A_2 (Table 3, entry 35). Lower line, solid circles = basic phase; upper line, open circles = acidic phase. This experiment is typical of the zero order kinetic behaviour.

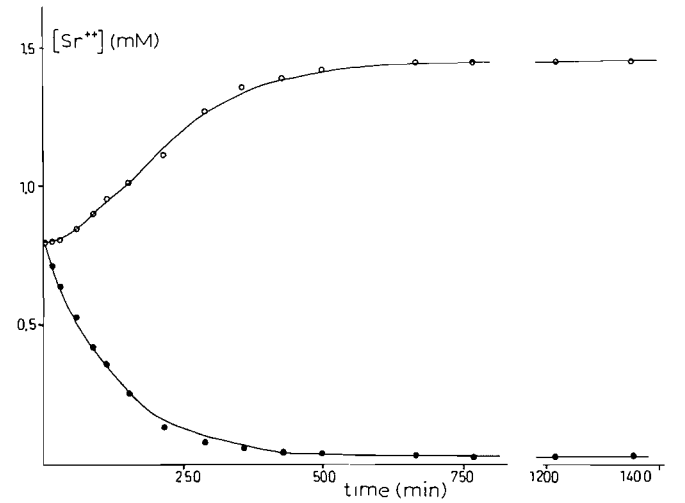

FIG. 3. Transport of strontium by the dicarboxylate carrier *anti* $(8NH)_2$18-6A_2 (Table 4, entry 9). Lower line, filled circles = basic phase; upper line, open circles = acidic phase. This experiment is typical of reversible consecutive first order kinetic behaviour.

demands of the structural organization required, transport of divalent ions occurs readily at rates comparable to the rates of monovalent ions (Table 3, 1–33). Typically, 10^{-3} *M* carrier and 10^{-2} *M* cation solutions produce transport behaviour which can be described as zero order in transported cation for all cases. Zero order behaviour at these concentrations is directly comparable to the alkali metal cation transport examined previously utilizing the same carriers (16, 17). In order to further explore the similarities, we considered the effect of pH on transport rate (Table 3, 8–13, no significant variation) as well as the effect of carrier concentration. As previously (17), the extraction in the zero order regime is presumed to follow the rate law:

[1] $\text{rate} = k[\text{HCr(org)}]^c$

where c is the order in carrier, which yields at time = 0.

[2] $\log(\text{rate})_0 = c \log([\text{HCr(org)}]_0) + \text{const.}$

where the subscripts denote initial values. The cell consisted of fixed concentrations of Ca^{2+} and buffers with variable initial

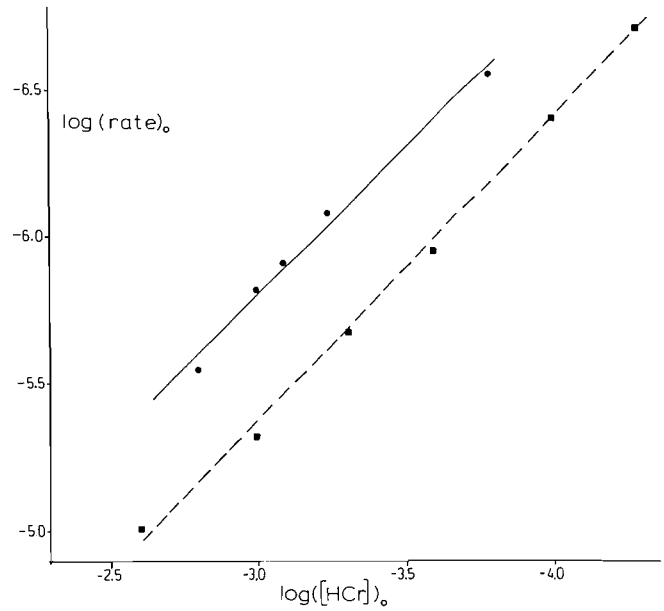

FIG. 4. A plot of log $(\text{rate})_0$ as a function of log $([\text{HCr}]_{org})$ for the zero order transport of Ca^{2+} by 14NH18-6A (upper curve, –●–, Table 3; 1, 5, 6, 7, 16) and of Sr^{2+} by *anti* $(8NH)_2$18-6A_2 (lower curve, –■–, Table 3; 47, 49, 51–54).

concentrations of 14NH18-6A. A graph of initial transport rate according to [2] is given in Fig. 4 (solid line) which shows a line of slope 0.98 (r^2 = 0.991) clearly indicating that calcium transport is first order in carrier. The very close similarities between these experiments and the transport of K^+ by 14NH18-6A suggests that the transport rate in this case is similarly rate limited by the adsorption of the carrier at the interface (17).

Although this result clarifies the extraction kinetics, it sheds no light on the nature or stoichiometry of the complexes which traverse the membrane. The two principal possibilities are sketched in Fig. 1 (B and C). The two choices are distinguished by different cation–proton stoichiometries ($2H^+ = M^{2+}$ vs. $H^+ = M^{2+}X^-$) and by their anion dependencies. The cycle described in Fig. 1, C would be expected to depend on the nature of the extracted anion as observed in other systems (21); more liposoluble anions (picrate, I^-) would be expected to enhance the rate while more hydrophilic anions (F^-, SO_4^{2-}) would retard the rate. Various buffers were prepared in which the normally available anion (Cl^-) was replaced by NO_3^-, ClO_4^-, or SO_4^{2-} but these substitutions did not significantly alter the rate (Table 3; 16–19). Moreover, addition of an extremely liposoluble anion such as picrate or 1-naphthylacetate did result in rate increases (typically 2 to 2.5-fold enhancement, Table 3; 14, 15, 30, 31). These results suggest that under normal conditions the major mode of transport is via 2:1 complexes (Fig. 1, B) while the anion dependent cycle may be induced with readily extracted anions (Fig. 1, C). The accompanying paper (32) examines this point in more detail and we propose a structure based on nmr studies for the 2:1 complex in which the metal ion occupies one macrocycle while the other macrocycle provides a coordinating carboxylate. Thus the second carrier is simply a liposoluble anion which presumably could be replaced by ion exchange with picrate or 1-naphthylacetate when present.

Unlike the monocarboxylate carriers, the dicarboxylate carriers could provide electrically neutral transport via 1:1 com-

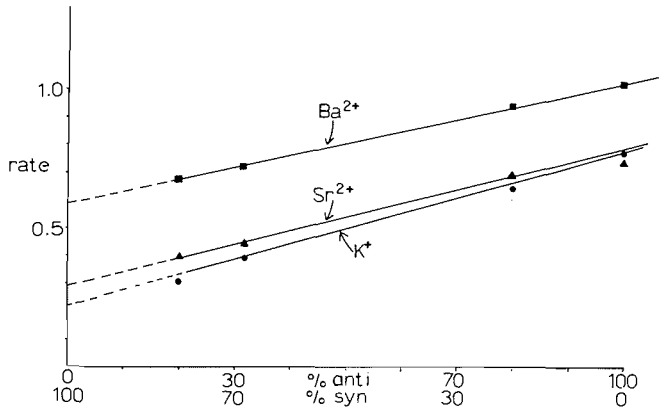

FIG. 5. Transport rates, normalized to 5×10^{-4} *M*, for mixtures of *syn* and *anti* $(8_2N_2)18\text{-}6A_2$. Data from Table 3; 57–72, (Ca^{2+} omitted for clarity of presentation).

plexes which require two protons per metal ion transferred (Fig. 1, D). At a divalent ion concentration of 10^{-2} *M* and a carrier concentration of 10^{-3} *M*, transport occurred readily with the concentration vs. time curves similar to the one shown in Fig. 2. The transport in this case is zero order in divalent ion and independent of pH. The kinetic order in carrier may be assessed by the same methods outlined above and the results are present in Fig. 4 (dashed line). The line in this case has a slope of 1.04 ($r^2 = 0.998$) and indicates the transport is first order in carrier. By analogy with the other cases examined, the adsorption of carrier is presumably rate limiting in this case as well.

In the majority of cases the carriers were available in reasonable quantity and high purity. Unfortunately the separation of *syn* and *anti* $(8_2N)_218\text{-}6A_2$ gave only the *anti* isomer isomerically pure. The *syn* isomer was available only in mixtures although these mixtures were chemically pure. The isomer composition of each mixture was obtained from the ^1H nmr spectrum by integration and the overall transport rate for the mixture was obtained in the normal fashion. The observed rates, normalized to a common carrier concentration, were plotted as a function of mixture composition to give the transport rate for pure *syn* $(8_2N)_218\text{-}6A_2$ by extrapolation as shown in Fig. 5. In most cases the experimental points lie directly on the least-squares line, hence the values obtained for *syn* $(8_2N)_218\text{-}6A_2$ are presumed to be about as reliable as those directly determined (±15%).

Transport selectivities

The issue of transport selectivity can be examined utilizing the normalized data of Tables 1 and 2. Selectivity among ions is easily indicated as a ratio relative to some reference, e.g. Ca^{2+} in Tables 1 and 2. By this criterion the selectivities observed are modest at best, while for some carriers, notably *anti* $(8NH)_218\text{-}6A_2$, the transport is essentially nonselective. In most cases 18-crown-6 derivatives exhibit some preference for Sr^{2+} over the other alkaline earth cations. This is in agreement with stability constant data for these carriers (accompanying paper) and crown ethers in general, which show optimal binding of the cation whose radius matches that of the macrocycle (22). As noted previously (16), binding selectivity does not directly result in transport selectivity of the same magnitude, although overall complex stability and selectivity both play a role in the transport process (23). In this system, the rate is controlled by the ability of the ligand to adsorb to the interface but, once in position, equilibrium considerations will govern the fraction of the surface crown ether which will be occupied by metal ion, hence will control the amount of metal ion extracted. The selectivity, or lack of it, among the alkaline earth cations is comparable to other crown ether based systems (24).

Comparisons between carriers reveal more substantial differences. One of the most important comparisons is between the acyclic carriers $4NHD_2TA$ and D_2TA_2 and the other cyclic carriers for Ca^{2+} transport. The acyclic carriers have only two possible donor atoms for cation complexation, yet transport at a significant fraction of the rate of much more elaborate carriers (Table 1). This must indicate that the important interaction for cation transport is primarily electrostatic and that a relatively simple complex is sufficient to permit the extraction to occur. This is also consistent with the lack of selectivity noted above, since electrostatic effects will note only the charge and only indirectly the size of the ion.

In general, the effect of carrier concentration on selectivity is relatively minor (Tables 1 and 2), especially for 14NH18-6A which is essentially the same at the two concentrations. Larger differences can be noted for other carriers and carriers with similar structures such as $D_218\text{-}6A_2$ and $(8_2N)_218\text{-}6A_2$. The major changes in selectivity are for *syn/anti* pairs and K^+ transport. The more lipophilic carriers *syn/anti* $(8_2N)_218\text{-}6A_2$ transport K^+ more readily and are more Ba^{2+} selective than the comparable $(8NH)_218\text{-}6A_2$ homologs. This may be a result of steric factors rather than differences in lipophilicity similar to the difference between $8_2N18\text{-}6A$ and 14NH18-6A. The steric effect might take the form of direct blocking of the binding site or might simply be due to blocking of positions normally occupied by coordinated water.

The naturally occurring ionophore antibiotics lascalocid (X537A) and monensin are included for comparison with the synthetic ionophores. Monensin is a sodium specific ionophore which is incapable of transporting Ca^{2+} (Table 3; 80). Lascalocid is a calcium selective ionophore which is presumed to transport using 2:1 complexes in both artificial and natural systems (7, 10, 11). Our initial attempts to achieve Ca^{2+} transport using X537A were uniformly unsuccessful, and we recovered only lascalocid as the free acid at the end of the transport experiments (judged by nmr (25)). The problem was traced to the use of Tris[1] as a buffer component. Lascalocid is known to complex and transport primary amines (8) and in this case must form a complex at the interface which blocks Ca^{2+} transport. With Tricine[1] as buffer component the rate of transport is comparable to the rate reported in a similar but smaller U-tube cell (10) (1.44 μmol/h our cell; 1.35 μmol/h calculated from (10) normalized to 10^{-3} *M* and corrected for interfacial area). The difference might have been expected to be greater as the two experimental protocols are different; our system examines transport against a gradient in total Ca^{2+} while previous workers examined transport down the concentration in Ca^{2+} (ref. 10, also refs. 8, 11).

On closer examination this distinction is not as marked, due to the composition of our buffer system. On the acidic side, the major buffer components all form complexes with Ca^{2+} and Sr^{2+} and will diminish the concentration of "free" metal on the acidic side. The analytical concentrations of the acidic buffer

[1] Tris = tris(hydroxymethyl)aminomethane; Tris H^+ = protonated Tris; Tricine = *N*-tris(hydroxymethyl)methylglycine; MES = 2-(*N*-morpholino)ethane sulfonic acid; TEA = triethanolamine; $TEAH^+$ = protonated TEA.

[a] Rates normalized to 5×10^{-4} M in carrier assuming first order dependence for carrier concentration.

components (Ca^{2+} or Sr^{2+}, phosphate, TEA, pH) and the stability constants of the species formed in solution[2] (26–28) allow the concentration of free Ca^{2+} or Sr^{2+} to be calculated (29). The major Ca^{2+} or Sr^{2+} species at pH 2.3 was $M^{2+}HPO_4^{2-}$ and the free metal ion concentration was typically 3×10^{-4} M for the total concentrations of metal ion typical of those encountered in the course of an experiment (1 to 2×10^{-2} M). On the basic side of the cell the free metal ion concentration is not substantially altered by complex formation with buffer components, although a weak complex with Tris (28) diminishes the concentration to about 60% of the analytical values at all points during a typical transport run (10^{-2} to 10^{-4} M). Thus, at least in the initial stages, the transport of M^{2+} occurs *up a concentration gradient in TOTAL* M^{2+} but *down a concentration in FREE* M^{2+}. Despite this potential problem there is no evidence to suggest any additional complications. Transport rates in the zero order regime are insensitive to pH, to buffer type and concentration, and to stirring rate. In this respect, the zero order transport regime is very well defined and quite selective for metal ions in the presence of large excesses of buffer components.

Consecutive first order kinetic regime

With the zero order behaviour closely similar to previously examined cases, we anticipated that it would be possible to alter the initial concentrations to enter a kinetic regime of consecutive first order reactions (16, 17). In fact, at metal ion and carrier concentrations about 10^{-3} M, nonlinear curves of concentration as a function of time were observed as shown in Fig. 3. However, the curves did not fit with the irreversible cases examined previously, notably late in the transport where the basic phase was not entirely depleted in metal ion and the mass balance indicated that substantial amounts of metal ion were still held in the membrane. Considering only the early portions of the curves, the irreversible consecutive first order kinetic analysis used previously gave an adequate fit to the data. The final concentrations attained did not vary over a considerable time, which suggests that the overall behaviour could be an example of reversible consecutive first order reactions. This would give a kinetic scheme as in [3].

$$[3]\quad [M^{2+}]_{basic} \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} [M^{2+}]_{org} \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} [M^{2+}]_{acidic}$$

The general case of two reversible consecutive first order reactions has been discussed in detail and methods for the calculation of species concentrations for a given set of rate constants have been outlined (30). Utilizing these procedures, a nonlinear optimization program for the calculation of rate constants from concentration vs. time data was written. The experimental value for $[M^{2+}]_{org}$ was calculated from the mass balance equation, utilizing the analytical concentrations in both aqueous phases and the total concentration initially. The experimental values were compared with calculated concentrations and the set of rate constants was varied to minimize the differences between the experimental and calculated values. The solid line drawn in Fig. 3 is the calculated curve derived for the experimental data shown. Since the experimental value for $[M^{2+}]_{org}$ is obtained indirectly, the uncertainty in this concentration is greater than for directly determined concentrations. Consequently the degree of uncertainty in the rate constants derived, especially k_{21} and k_{23}, is greater than was

(from 6.0–9.0, Table 4; 1–10, 13–17) and is also independent of carrier concentration. Thus the kinetic scheme [3] completely describes the transport kinetics with no additional concentration terms for protons or carrier concentration. In this regime the rate limiting step must be remote from the interface and adsorbed carrier, hence must lie in the water layer on the basic side of the cell. One possibility is that the rate is limited by diffusion of the metal ion across the unstirred boundary layer near the interface. If this deduction is correct, the rate should depend on stirring conditions, which was found to be the case (Table 4; 9, 19, 20); increased stirring enhanced the rate while decreased stirring retarded the rate. The U-tube cells utilized in this work are suitable for achieving a relatively reproducible set of stirring conditions but are incapable of permitting detailed control of hydrodynamic conditions at the interface. Further studies of this aspect of transport are in progress, utilizing a different cell with more closely controlled hydrodynamic parameters.

Nonetheless, some transport results have been obtained for a limited selection of carriers and ions (Table 4). Complex stability again plays a role in the transport process as the various carriers transport at differing rates. The diffusion rate will depend on the concentration gradient in the diffusing ion. If the complex formed at the interface is stable, the free ion concentration will be low and the gradient established will provide a higher flux of ions. By this argument the apparent complex stabilities follow the sequence $D_2$18-6A_2 > *anti*~*syn* $(8NH)_2$18-6A_2. A similar sequence is noted in the stability constants for complexation in homogeneous solution (accompanying paper).

To summarize the results of the transport, it is important to note that the simple mechanisms outlined in Fig. 1 adequately present the overall stoichiometry of the countertransport, but the extraction steps involve considerably more complexity when examined in detail. At least three distinct types of behaviour have been noted for a given carrier and two different, but closely related, ions (e.g. 14NH18-6A/K^+ or Sr^{2+}). For each of these, the structures of the carriers play a role with respect to both overall shape and ion binding, but the essential structural components remain relatively poorly defined. The carrier must be able to complex ions, but it is not essential that the complex be structurally well defined (e.g. D_2TA/Ca^{2+}). The carrier must have some surfactant activity, but even poorly arranged carriers (*anti* $(8NH)_2$18-6A_2) are active. Ultimately, the structural requirements will depend on the source phase concentrations and the separation required, as this will in part dictate where the rate limiting step of the transport will appear.

Experimental

Transport experiments were performed in a U-shaped apparatus constructed of 15-mm id Pyrex tubing bent to a 20-mm radius bend. The U-tube had a total volume of 35 mL and was jacketted and thermostatted at 25 ± 0.1°C. The membrane phase was 12 mL of $CHCl_3$ in the base of the U and aqueous phases of 10 mL each were placed in the arms of the U. All three phases were stirred at 400 ± 1 rpm. The interfaces were 1.54 cm^2 and remained quiescent throughout the experiments. The general methods for purification of carriers and kinetic analyses were as previously described (15, 16, 17, 20, 31). The syntheses of the carriers D_2TA_2 and $4NHD_2TA$ are described below. Details of experiments (concentrations, buffers) and the transport rates are in Tables 3 and 4. Kinetic data reported were determined in duplicate. Experiments for the determination of kinetic order were conducted in a preliminary fashion to determine optimal sampling times and analytical procedures but these results are not included in the final values. Care is required in setting up the cell so that the interfaces always lie in the same position in the U and the stirring is regular. Under typical, controlled conditions, reproducibility between duplicates from the same stock solution of carrier was better than ±4% for the values reported in Table 3. Due to the sensitivity of the consecutive reversible first order regime to stirring conditions, the reproducibility between duplicates was ±10% for the values reported in Table 4. Longer term reproducibility, working from different preparations of carriers, different stock solutions, and different dates was somewhat poorer (±6% Table 3; ±15% Table 4). High purity carriers must be used; minor impurities, particularly ammonium salts from the synthesis, decrease the transport rate. The reported behavior should be regarded as system dependent; other sizes or shapes of U tube with different relative phase volumes will influence the conditions necessary to provoke a particular kinetic regime. The synthesis of the two carriers prepared for this work followed general procedures previously described.

R,R-*Di*-O-*decyltartaric acid (D_2TA_2)*

To a solution of 4.5 g of *R,R-N,N,N',N'*-tetramethyltartaramide in 60 mL of DMF under an argon atmosphere at ambient temperature was added 3.7 mL of thallous ethoxide followed by 11.8 g of n-decyl iodide. The mixture was stirred and heated at 50–55°C for 14 h, cooled, diluted with 100 mL of water, and filtered to removed Tll. The filtrate was evaporated, passed down a short alumina column with 600 mL of CH_2Cl_2, evaporated, and pumped to remove traces of DMF. The product was purified by column chromatography on alumina using a toluene–$CHCl_3$ gradient to give 5.3 g (50% yield) of a waxy solid, mp 48–49°C; ir (cm^{-1}): 1640, 1100; $[\alpha]_D$ +53.8 (*c* 0.08, $CHCl_3$); ^{1}H nmr: 0.89 (6H, bt), 1.25, −1.55 (32H, bs), 2.84 (6H, s), 3.14 (6H, s), 3.52 (4H, bt), 4.68 (8H, s); ^{13}C nmr: 13.9, 22.5, 26.0, 29.3(m), 29.9, 35.6, 37.1, 64.7, 77.3, 169.7; ms (*m/e*): 485 (M + 1,100), 440 (19), 412 (3). *Anal.* calcd. for $C_{28}H_{56}N_2O_4$: C 69.38, H 11.54, N 5.78; found: C 69.42, H 12.10, N 5.73.

The tetramethyldiamide was hydrolysed in 25% aqueous HCl at reflux for 36 h, the mixture was cooled, and the diacid was isolated by solvent extraction (100 mL CH_2Cl_2) and purified by chromatography on alumina using 10% CH_3OH in $CHCl_3$ as eluent to give the diacid D_2TA_2 as a solid, mp 56–58°C; ir (cm^{-1}): 3600–2400, 1725, 1110; $[\alpha]_D$ +21.8 (*c* 0.106, $CHCl_3$); ^{1}H nmr: 0.87 (6H, bt), 1.24 (32H, bs), 3.49 (2H, dt, *J* = 9, 7), 3.68 (2H, dt, *J* = 9, 7), 4.37 (2H, s); ^{13}C nmr: 14.0, 22.6, 25.7, 29.5 (m), 31.8, 73.1, 79.4, 174.0; ms (*m/e*): 431 (M + 1, 1), 141(100). *Anal.* calcd. for $C_{24}H_{46}O_6$: C 66.94, H 10.77, found: C 66.90, H 10.78.

R,R-N-*Butyl-di*-O-*decyltartaric acid ($4NHD_2TA$)*

The monoamide of D_2TA_2 was prepared from the diacid in a manner identical to previously published procedures for crown ether monoacid – monoamides (15, 31) to give $4NHD_2TA$ as a viscous oil. Infrared (cm^{-1}): 3600–2400, 1725, 1670, 1530, 1090; $[\alpha]_D$ +25.2 (*c* 0.52, $CHCl_3$); ^{1}H nmr: 0.86 (9H, m), 1.23 (36H, bs), 3.30 (2H, bq), 3.49–3.63 (4H, m), 4.20 (1m, bs), 4.39 (1H, bs), 6.70 (1H, bt); ^{13}C nmr: 13.6, 20.0, 31.6, 39.8 (butyl), 14.0, 22.6, 26.0, 29.5 (m), 31.9, 73.3, 73.4, 80.4, 81.2, 169.3, 172.1; ms (*m/e*): 486 (M + 1, 100). *Anal.* calcd. for $C_{28}H_{58}NO_5$: C 69.23, H 11.41, N 2.90; found: C 69.36, H 11.24, N 2.88.

Membrane transport systems. VI. Complexation of cations by lipophilic crown ether carboxylic acids

THOMAS M. FYLES AND DENNIS M. WHITFIELD
Department of Chemistry, University of Victoria, P.O. Box 1700, Victoria, B.C., Canada V8W 2Y2

Received June 30, 1983

THOMAS M. FYLES and DENNIS M. WHITFIELD. Can. J. Chem. **62**, 507 (1984).

The complexation of alkali metal and alkaline earth cations by crown ether carboxylic acids has been studied by potentiometric titration and by infrared and nuclear magnetic resonance spectroscopy. Complexation in methanol–water solution is governed by the electrostatic interactions between the cation and the carboxylate, hence discrimination among cations on the basis of ionic radius is poor. The isomers *syn* and *anti* $(8NH)_2$18-6A_2 exhibit differing complexation behaviour towards cations with the *anti* isomer giving the stronger complexes. Interaction between the carboxylates across the face of the macrocycle of *syn* $(8NH)_2$18-6A_2 can be inferred from the potentiometric data. Combined infrared and nuclear magnetic resonance studies of the complexes in chloroform solution show that the cation is held as an asymmetric tight ion pair with the carboxylate. The dimeric salt $(4NH18\text{-}6)_2Ca$ exhibits both a tight and a symmetric or loose ion pair between the cation and the two carboxylates. The substituents on the macrocycle are pseudoaxially disposed and in some cases *gauche* ethylenedioxy units can be recognized from the spectra. The complexes are monomeric in solution and in most cases the conformations are unaffected by small amounts of water in the chloroform solution. The structural results correlate with observations from transport experiments.

THOMAS M. FYLES et DENNIS M. WHITFIELD. Can. J. Chem. **62**, 507 (1984).

On a étudié la complexation de cations de métaux alcalins et alcalino-terreux par des acides carboxyliques d'éthers couronnes en faisant appel à des titrages potentiométriques et à la spectroscopie infrarouge et rmn. La complexation dans une solution eau–méthanol dépend des interactions électrostatiques entre le cation et le carboxylate; il en résulte que la discrimination entre les cations sur la base du rayon ionique est faible. Les isomères *syn* et *anti* du $(8NH)_2$18-6A_2 présentent des comportements de complexation différents vis-à-vis les cations; l'isomère *anti* donne les complexes les plus forts. L'interaction entre les carboxylates *syn* à la surface du macrocycle $(8NH)_2$18-6A_2 peut être déduite des données potentiométriques. La combinaison des études infrarouges et rmn des complexes en solution dans le chloroforme montre que le cation est maintenu dans une paire intime d'ions avec le carboxylate. Le sel dimère $(4NH18\text{-}6)_2$ Ca présente à la fois une paire d'ion intime et symétrique ainsi qu'une paire d'ion plus lâche entre le cation et les deux carboxylates. Les substituants du macrocycle sont disposés de façon pseudoaxiale et dans certains cas on peut reconnaître, dans le spectre, des unités d'éthylènedioxy *gauche*. Les complexes sont monomères en solution et, dans la plupart des cas, les conformations ne sont pas affectées par de faibles quantités d'eau dans le chloroforme. Les résultats structuraux sont en accord avec les expériences de transport.

The discovery of the complexing properties of synthetic macrocyclic polyethers (crown ethers) has sparked a wide range of activity in fields ranging from synthesis of related compounds to analytical applications (1–3). An important property of crown ethers is their ability to dissolve ionic solids in nonpolar media leading to solutions of "naked anions" for synthetic applications (1, 2) to phase transfer catalysis (4) and to cation extraction and membrane transport across artificial membranes (5). The structures of the ligands and their complexes in the solid state and in solutions have been the subject of numerous studies (1, 2). In a "typical" complex the metal ion occupies a site in the center of the macrocycle with ligating donor atoms from the ring providing a full or partial inner coordination sphere for the ion. The exterior of the complex is lipophilic to provide for dissolution in the nonpolar solvent.

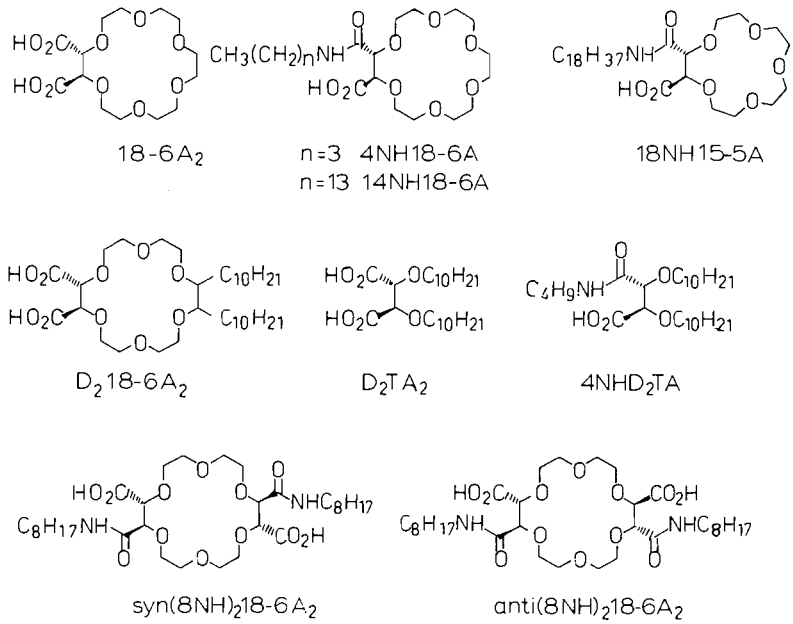
Our interest in crown ethers centers on a series of lipophilic crown ether carboxylic acids (6–10) which are capable of mediating cation–proton coupled countertransport (11). Representative structures of the carriers examined to date are shown below together with a line notation (10) indicating structural features. A simple schematic mechanism for the net countertransport of monocations and protons is given in Fig. 1. At the basic interface, the carrier gives up a proton in exchange for a cation from the aqueous phase. The resultant complex is neutral and readily traverses the membrane phase to the acidic interface, whereupon the reverse ion exchange process occurs. The net result is the exchange of a cation for a proton across the membrane barrier. As long as the proton gradient exceeds the cation gradient the system will "pump" cations against their concentration gradient. This strategy has potential application for the recovery of metal ions from dilute solution and related systems have been developed for copper and uranium recovery using acyclic complexing agents (12–14).

Our continuing studies are directed toward the synthesis and characterization of carriers for multivalent ions and as a first step we have prepared carriers for alkaline earth cations. Transport kinetics studies of the extraction step for alkali metal (8) and alkaline earth (10) cations generally support the schematic mechanism described above. However, such studies have provided relatively little information on the nature of the complexes which traverse the membrane beyond the apparent stoichiometry of the complex. Structural information is more readily available from common spectroscopic methods such as infrared and nuclear magnetic resonance spectroscopy and from potentiometric titrations. Our goal in this report is to build up an overview of the structures of the carriers and their complexes in the bulk membrane phase. The key questions concern the nature of the ion binding site, the overall conformations of the carrier, the role of water in the complexation, and the degree of aggregation of the carriers.

Results and discussion

Complex formation in methanol/water solution

Although the membrane phase of the transport experiments is typically chloroform (7, 10), equilibrium complexation studies require a more polar solvent to produce observable



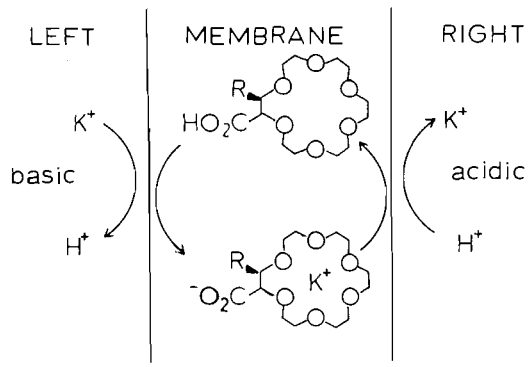


FIG. 1. A schematic mechanism for cation–proton coupled countertransport.

concentrations of free ligand. Accordingly the complexation behaviour was examined in 90:10 methanol–water (v/v). As previously (6), the complexation is examined using a generalized cumulative association constant β_{lmh} defined as $\beta_{lmh} = [L_lM_mH_h]/[L]^l[M]^m[H]^h$ (charges omitted) where the integers *l*, *m*, and *h* refer to the number of ligands, metal ions, and protons bound in a given complex. Note that this association constant is defined in terms of concentrations rather than activities. The ligand is defined as the most deprotonated form of the carrier, thus β_{110} refers to a complex of the monoanion of a monocarboxylate carrier or the dianion of a dicarboxylate carrier with a single metal ion in each case. The overall charge on the complex will thus depend on the specific case being considered. The experiment involves two stages: acid/base titration of the ligand alone to determine its acidity constant(s), followed by an acid/base titration of the ligand in the presence of the metal ion. Computer analysis of the titration curves (6) gave a set of β_{lmh} values for each of the systems examined. The results are presented in Table 1. For the dicarboxylate carriers, stepwise association constants for defined equilibria are more informative than the cumulative constant calculated. In particular, the apparent stability of complexes of the monoprotonated ligand may be calculated from the β_{lmh} values by subtraction of the first pK_a from log β_{lmh} (6, 15); thus for $LH^- + M^{2+} \rightleftharpoons LHM^+$, $\log K = \log \beta_{111} - \log \beta_{101}$ (pK_1). These results appear in parentheses where appropriate in Table 1. The complexes of ammonium are proton ambiguous in a fashion similar to polyammonium and polyguanidinium/anion complexes (15); the overall stoichiometry of the complex is known but it is not known if the proton is associated with the ligand or the ammonia. For the dicarboxylate carriers it is productive to assume that the complex whose β_{111} is calculated refers to $NH_4^+ + L^{2-}$ rather than $NH_3 + LH^-$. Thus the appropriate stepwise association constants may be calculated from log β_{111} by subtraction of the pK_a of NH_4^+, determined by titration to be 9.38 in 90:10 methanol–water. These values are given in Table 1 as well.

The difference between pK_1 and pK_2 has been used to characterize the structures of the isomers *syn* and *anti* $(8NH)_2$18-6A_2 (9), and this difference can be further utilized to infer solution structures for these two carriers. Acidity constants for dicarboxylic acids reflect a mixture of statistical and electrostatic factors (16, 17); in general, as the distance and local dielectric between the two carboxylates decreases, the difference in their two pK_a's (ratio of K_a's) increases due to electrostatic destabilization of the dianion. The principles are well-developed for simple diacids in water and may be presumed to extend at least qualitatively to 90:10 methanol–water and more complex diacids. Considering the 2,3-dicarboxylic acids 18-6A_2 and $D_2$18-6A_2, the pK_a differences are similar (2.16 and 2.02) and comparable to the values for fumaric acid (15) (pK_1 7.44, pK_2 5.23, difference 2.21). Structural studies of tetra-carboxy crown ethers have amassed considerable evidence for pseudo axial dispositions of substituents (18–21). The pK_a differences noted here are consistent with such a diaxial arrangement of carboxylates but not with a diequatorial interaction between the carboxylates. The fragment derived from tartaric acid thus retains the same conformation as the parent acid in aqueous solution (22).

An examination of CPK models of *syn* and *anti* $(8NH)_2$18-6A_2 in a variety of plausible conformations suggests that the separation of the carboxylates is about 6.5–7.5 Å for both isomers. A fully extended (all *anti*) conformation of adipic acid provides a model for 6.5 Å separation of carboxylates and the pK_a's were found to be pK_1 7.88, pK_2 6.82 (difference 1.06) in 90:10 methanol–water. The difference observed for adipic acid is greater than that observed for the *anti* isomer

[a] In 90:10 methanol/water (v/v), total ionic strength = 0.05 *M* (Me_4NCl) at 25 ± 0.1°C. Values in parentheses are stepwise formation constants. The symbol * indicates the complex stoichiometry is not applicable; the symbol < indicates a complex of the given stoichiometry is not required to model the experimental curve, thus is too weak to be detected. Values precise to log β_{lmh} ± 0.2.

[b] Determined at I = 0.10 *M* (6).

[c] $K^+/D_2$18-6A_2 β_{120} = 9.5.

[d] K^+/*syn* $(8NH)_2$18-6A_2 β_{120} = 8.1.

[e] pK_a (NH_4^+) = 9.38. Complexes are proton ambiguous (ref. 15, text) but assume NH_4^+ is the complexed species.

[f] NH_4^+/*syn* $(8NH)_2$18-6A_2 β_{122} = 26.8 (8.1 for L^{2-} + $2NH_4^+$).

[g] NH_4^+/4NH18-6A β_{122} = 24.7 (6.0 for L^- + $2NH_4^+$).

(0.78), thus it is likely that *anti* $(8NH)_2$18-6A_2 represents a case where there is no direct interaction between carboxylates other than the general effect of a second charge about 7 Å away.

The case of *syn* $(8NH)_2$18-6A_2 is clearly an anomaly; pK_1 is in the expected range for carboxylate on a crown ether periphery, but pK_2 is too low for an electrostatic effect alone. The monoanion is thus stabilized relative to the diacid, presumably by some interaction across the face of the macrocycle. A direct hydrogen bond ($CO_2H\cdots\bar{O}_2C$) can be accommodated with CPK models but a water-bridged structure ($CO_2H\cdots O(H)\cdots\bar{O}_2C$) involves minimal distortion of the crown ether periphery. This may also be viewed as a weak complex of H_3O^+ by the dianion. In any event, the interaction will destabilize metal ion complexes of the monoanion if the complexation disrupts whatever structural organization is present.

The notable feature of the rest of the stability constant data is the lack of selectivity exhibited by the carriers. This is most marked in the case of the 18-6 diacid with alkaline earth cations; the ligand is incapable of distinguishing among Ca^{2+}, Sr^{2+}, and Ba^{2+} even though the neutral parent, 18-crown-6, shows a range of stability constant in water of over three orders of magnitude along the same series (23). It is clear that the complexation is governed to a large extent by electrostatic attraction of the carboxylates for the metal ion, while the size selectivity of the ligand plays a minor role. The ion binding might not even involve the ring donor sites and be simply an ion-pairing interaction. Transport data for simple carriers such as D_2TA_2 show that the ring structure is not essential for transport (10) although the range of transport rates observed suggests that the ring does provide additional stabilization for the extracted ion. A metal binding structure which emerges is primarily an ion-pairing arrangement with the carboxylate plus additional ligation by the oxygen donors of the macrocycle.

Not only is a given ligand relatively unselective, among the dicarboxylate carriers there are only relatively minor differences in the complexation of a given cation. The additional decyl groups of $D_2$18-6A_2 clearly do not perturb the parent 18-6A_2 structure since the complexation constants of these two ligands are so closely similar. The largest differences occur between the isomers *syn* and *anti* $(8NH)_2$18-6A_2 with the complexes of the *syn* isomer uniformly less stable by an order of

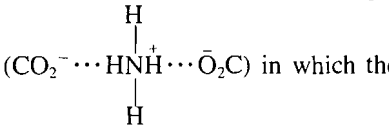
magnitude than the complexes of the *anti* isomer. These results are in direct contradiction to the assertion that "*syn* isomers . . . complex cations much more strongly than the corresponding *anti* isomers" (19), which refers to the complexation of NH_4^+ in water by *syn* and *anti* dianilide dicarboxylate crown ethers. Significantly, the stability constants of the ammonium complexes of *syn* and *anti* $(8NH)_2$18-6A_2 are more closely similar than for any of the other cations examined. The *syn*/K^+ data more closely parallel the *syn*/NH_4^+ data than occurs with the *anti*/K^+ or NH_4^+ data. Both *anti* $(8NH)_2$18-6A_2 and 4NH18-6A complex K^+ more readily than NH_4^+; thus it appears that the *syn* isomer has a higher relative affinity for NH_4^+ than would be predicted from an examination of the complexation data for spherical metal ions alone. The ammonium complexes of *syn* $(8NH)_2$18-6A_2 must thus possess additional stabilization. Along with the pK_a anomaly noted above, a likely candidate structure for the ammonium complex is a bridging structure

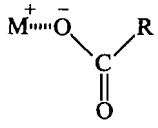


bridging H_2O or H_3O^+. The close similarity between K^+ and NH_4^+ binding by *syn* $(8NH)_2$18-6A_2 further suggests that the bridging site is the "normal" binding site for K^+ as well. In any event, the binding of NH_4^+ does not correctly reflect the binding of all other metal cations. Together with the differences in ligand, solvent, conditions, and method, these results are reconciled with previous observations.

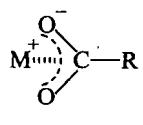
To place the potentiometric results in the context of bulk membrane transport experiments (7, 10) it is essential to note that, even in relatively polar media (methanol–water), electrostatic effects dominate metal ion complexation. In the less polar membrane solvent chloroform, the electrostatic effects will be even more pronounced; hence a very close association between cations and the carrier carboxylate is highly likely.

Site of cation binding

The lack of size selectivity for ion complexation in homogeneous solution and the observation that relatively simple carriers could extract and transport alkaline earth cations suggest that the primary interaction is electrostatic. There are a variety of ways this might be accomplished both between different ligands and within a given complex. The two limiting structures to consider are one in which the metal ion lies near the center of the macrocycle as in a "typical" crown ether complex and the other in which the metal ion lies out of the macrocycle but closely ion-paired with the carboxylate. Between these extremes are asymmetric structures with variable ligation of the metal ion by the crown ether donor sites and/or additional water molecules. The environment of the carboxylate can be probed using infrared spectroscopy. A free carboxylate ion exhibits two bands: a strong asymmetric stretching band (ν_{AS}) near 1650–1550 cm^{-1} and a weaker symmetric stretching band (ν_S) near 1400 cm^{-1} (24). Interaction of a metal ion with carboxylate can occur with a variety of geometries and radii of interactions. The two main types are shown below:



A



B

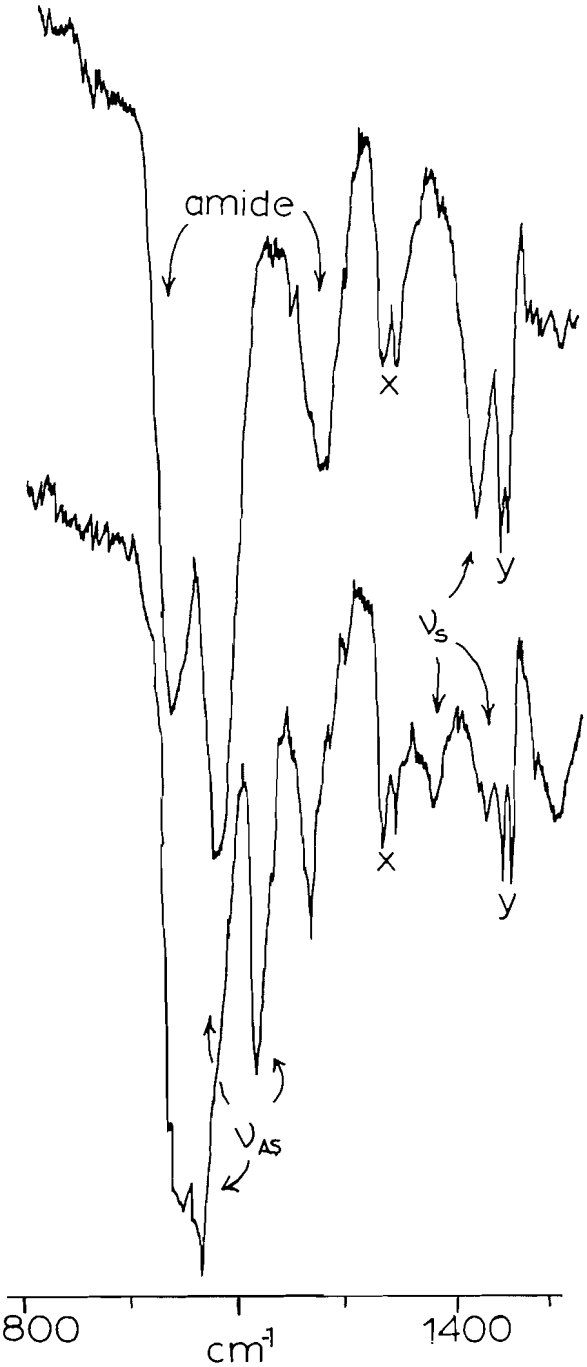


FIG. 2. Infrared spectra of carriers and complexes in chloroform solution (5×10^{-2} *M*). Upper Curve, 4NH18-6 Na; lower curve, $(4NH18\text{-}6)_2Ca$.

The type A interaction will increase ν_{AS} toward the frequency of a C=O group while the ν_S will fall towards the frequency of a C—O group (25). As a consequence $\Delta\nu = \nu_{AS} - \nu_S$ will measure the asymmetry of the interaction; $\Delta\nu$ larger than 225 cm^{-1} is characteristic of a tight ion pair of type A geometry (25) while values of $\Delta\nu$ lower than 225 cm^{-1} indicate a looser ionic interaction, either of the type B geometry or a solvent-separated ion pair (25).

The key bands are shown in Fig. 2. The free acid 4NH18-6A shows bands at 1755 (CO_2H), 1670, and 1530 cm^{-1} (amide I and II) and a pair of bands marked x and y due to —CH_2— groups in the molecule. Formation of the sodium salt

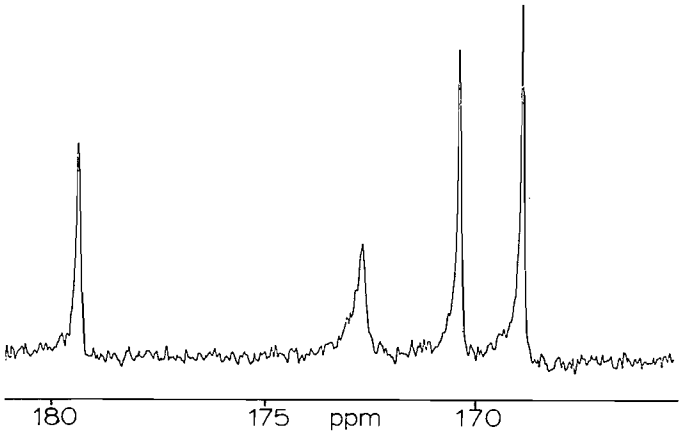

FIG. 3. Carbonyl region of the ^{13}C nmr spectrum of $(4NH18\text{-}6)_2Ca$.

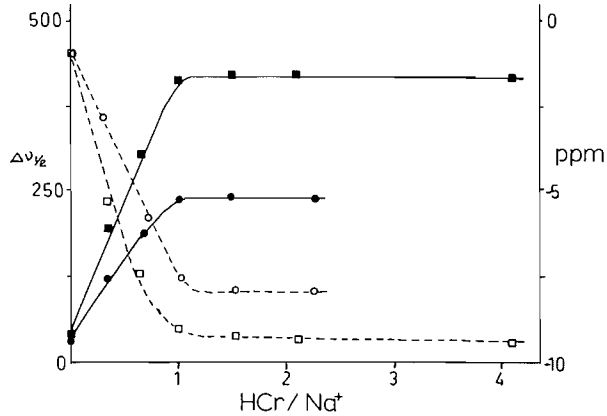

FIG. 4. ^{23}Na chemical shift (dashed lines) and linewidth ($\Delta\nu_{1/2}$) (solid lines) as a function of added 4NH18-6A. $[Na^+] = 5 \times 10^{-2}$ *M* in CD_3OD/H_2O (90:10 v/v); circles, pH* = 2.0 (HCl); squares pH* = 8.0 (Tris).

4NH18-6A Na results in a shift of the principal carboxylate band to 1625 cm^{-1} in the range typical of ν_{AS}. The two amide bands, and x and y, are unaffected and leave only a weak band at 1385 cm^{-1} assigned as ν_S. The value of $\Delta\nu$ = 240 cm^{-1} suggests an asymmetric, type A ion pair. More importantly, the calcium salt $(4NH18\text{-}6A)_2Ca$ shows two sets of carboxylate bands: ν_{AS} at 1635 and 1585 cm^{-1} and ν_S at 1430 and 1380 cm^{-1}. The pair of bands which resemble the sodium salt have $\Delta\nu$ = 255 cm^{-1} while the remaining pair give $\Delta\nu$ = 1585 − 1430 = 155 cm^{-1}. The two distinct sets of carboxylate bands suggest two different metal–carboxylate interactions; one, like the sodium salt of the asymmetric tight ion-pair type and the other, a looser or symmetrical ion pair (type B).

Both the ^1H and ^{13}C nmr spectra of $(4NH18\text{-}6A)_2Ca$ show two sets of resonances for two distinctly different types of ligand within the complex. As an example, Fig. 3 shows the carbonyl region of the ^{13}C nmr spectrum of $(4NH18\text{-}6A)_2Ca$ showing four carbonyl resonances (two amide and two carboxylate). In a wide range of ligands and complexes the amide resonances occur at 170 ± 1 ppm and for simple salts the carboxylate resonances occur at 172 ± 3 ppm. The carboxylate resonance is typically broadened, possibly due to interaction with the metal ion nuclear quadrupole. In Fig. 3 the sharp resonance at 179.5 ppm is anomalous for the range of complexes examined and is presumed to be the type B or loosely bound carboxylate.

Taken together, these results suggest that $(4NH18\text{-}6)_2Ca$ exists as a dimer with the metal ion occupying one of the two crown ether rings and bound in a tight ion pair with the carboxylate of that ring. The second carboxylate is more loosely coordinated and the macrocycle of that carboxylate is empty. From the transport studies conducted, the normal transport of calcium by 4NH18-6A may be disrupted in the presence of extractible anions such as picrate or 1-naphthylacetate. As judged by infrared and nmr, 14NH18-6 and its calcium salt are strongly similar to the 4NH18-6A case discussed above. However, extraction of calcium into $CDCl_3$ from solutions containing picrate gave a different type of complex containing 1:1 picrate–14NH18-6 by integration. The ligand present was of the asymmetrical ion-pair type characterized by high ν_{AS} and a broadened carbonyl resonance in the ^{13}C nmr. The loosely bound macrocycle has evidently been exchanged for the picrate anion as an additional counterion in the ternary complex.

Cation binding in the remaining complexes can be compared with one or the other of the two modes identified with $(4NH18\text{-}6)_2Ca$: asymmetric, tight ion pair ν_{AS} ~ 1630 cm^{-1} and broad carbonyl resonance ~ 172 ppm; or symmetric, loose ion pair ν_{AS} ~ 1580 cm^{-1} and sharp carbonyl resonance ~ 180 ppm. By these criteria the majority of the salts prepared (listed in Experimental) and are tightly ion-paired in chloroform solution. Exceptions are $D_2$18-6 Ca and 18-6 Ca, which presumably cannot allow close contact of both carboxylates simultaneously. Consequently, at least one carboxylate is only loosely bound to the metal ion.

The symmetry of ion binding with respect to the metal ion may be assessed by direct nmr observation of a complexed ion; of the group I and II cations the most convenient is sodium (^{23}Na, I = 3/2, 100% abundance). Sodium nmr has been used to probe solvation and complexation of sodium by synthetic and naturally occurring ionophores (26–29). The relaxation of the ^{23}Na nucleus, hence the linewidth of the resonance, is dominated by the interaction of the nuclear quadrupole moment with the electric field gradient at the nucleus. In a symmetric environment, the quadrupole coupling constant will be low and the linewidth will be narrow; as the asymmetry of the environment increases, the linewidth will increase proportionately. The sodium chemical shift is also sensitive to complexation and the upfield shift of the sodium resonance line on addition of complexing agents can be used to determine complex stability constants (29).

Figure 4 shows the evolution of ^{23}Na chemical shift and peak width at half maximum for the addition of 4NH18-6A to sodium chloride in $CD_3OD–H_2O$ (90:10) containing excess acid or base. Considering the chemical shift data, the complex is virtually completely formed after the addition of one equivalent of 4NH18-6 in either acidic or basic solution. The complexation shifts are comparable and indicate roughly the same shielding electron density, hence roughly the same coordination at the sodium nucleus in both acidic and basic solution. The linewidth parameter, however, shows a larger difference between acidic and basic complexation; the limiting $\Delta\nu_{1/2}$ values are 425 Hz for the basic case and 230 Hz for the acidic case. It is clear that the deprotonation increases the asymmetry of the environment about the sodium ion. The values of $\Delta\nu_{1/2}$ for other crown ether complexes in methanol are in the range 200–250 Hz (28, 29) which presumably is typical of a complex with the sodium ion near the center of the macrocycle and axially ion-paired with a counter ion (28). Since the value observed for acidic 4NH18-6A is in this range, it is likely that the carrier is simply behaving as other crown ethers. The basic complex is more

For personal use only.

closely similar to the antibiotics nigericin and monensin which have carboxylates as donor sites for sodium complexation ($\Delta\nu_{1/2} > 300$ Hz) (ref. 28). A shift of position of the metal ion within the macrocycle towards the carboxylate on deprotonation is a plausible explanation for the differences noted in the ^{23}Na nmr experiments and is completely consistent with the infrared experiments described above.

Conformations of identifiable structural fragments

In principle, ^{1}H nmr provides a powerful method for the determination of the conformations of the carriers and their complexes but, in practice, the spectra obtained are highly overlapped in the regions of interest and provide relatively little information. Nonetheless, certain structural fragments may be identified which permit a general picture to be built up from results at a variety of temperatures and concentrations and by careful comparisons between the carriers and their salts. The experimental section outlines the range of cases examined.

The most readily observable unit is the —CHX—CHY— unit derived from tartaric acid in various carriers where X and Y are the amide and carboxylate groups. Vicinal coupling constants for all carriers are typically 2–3 Hz. Binding of metal ions results in some slight broadening of the resonances and a clear shift to smaller vicinal coupling constant (<1 Hz); many salts exhibit only singlets for the methine resonances. The small coupling constant is consistent with a diaxial conformation of the amide and carboxyl groups as noted in X-ray crystal structures (19, 20) and by nmr (18, 19) of related derivatives. The shift to smaller coupling constant on ion complexation could represent a shift of equilibrium from a minor diequatorial conformer (18) or a decrease in the O—CHX—CHY—O dihedral angle to produce a HCCH dihedral angle near to 90°. In view of the requirement that the carboxylate be ion-paired with the metal ion, which probably will involve distortion, the latter possibility is appealing.

Variation of the temperature results in general changes in the ^{1}H nmr spectra of carriers and complexes but few of the changes are well-defined. The ring protons in particular broaden and shift somewhat in chemical shift as the temperature is lowered but no clearly defined limit is attained. The most clearly defined changes are noted with the 1° amide groups. At high temperatures (>35°C), the methylenes adjacent to the amide appear as a broad quartet. On cooling, this collapses to a multiplet which separates further on cooling to a pair of multiplets. This is attributed to the onset of slow exchange between *cis* and *trans* conformations of the amide. Infrared spectra show the amide N—H to be hydrogen bonded over a range of concentration. An intermolecular hydrogen bond would be expected to show a concentration or temperature dependence of the NH chemical shift in the ^{1}H nmr spectrum. Over a wide range of solvents, concentrations, and conditions the NH singal is virtually invariant suggesting that the hydrogen bond is intramolecular. Hydrogen bonding of the amide hydrogen to the adjacent ether oxygen (bent 5-membered ring) has been inferred from the crystal structures of *syn* and *anti* dianilide crown ethers (19) and it is reasonable to propose that this structure is retained in solution as a general feature throughout the series examined.

The conformational possibilities for the ethylenedioxy fragments have been described for simple crown ethers as deduced from crystal structures, nmr, and force-field calculations (30–32). In general, these units adopt conformations with a *gauche* relationship between the oxygens although distortions are common. As a closely related example, the *syn* dianilide crown ether adopts an all-*gauche* arrangement in the solid state but the *anti* isomer contains two eclipsed fragments (19). A recurring feature of many variable temperature spectra is the appearance of a broad triplet downfield of the main CH_2O multiplets. This is shown in Fig. 5 for the case of *anti* $(8NH)_2$18-6Ca. Decoupling experiments establish that the downfield feature is coupled to a multiplet on the upfield edge of the CH_2O multiplet; the downfield signal consists of two large couplings (10 and 12 Hz) plus smaller couplings (~2 Hz) while the upfield signal contains the 12 Hz coupling plus smaller couplings (2 × 2 Hz). With reference to the *gauche* ethylenedioxy fragment pictured in Fig. 5, the coupling pattern observed is the one expected for the geminal pair H_a, H_b. Pseudoaxial H_a shows two large couplings ($J_{ab} \sim 12$ Hz, $J_{ad} \sim 10$ Hz) with a smaller coupling J_{ac}, while the equatorial proton H_b shows one large coupling (J_{ab}) with two smaller coupling ($J_{bc} \sim J_{bd} \sim 2$ Hz). Integration shows the downfield signal to be only one of the sixteen ring protons. This is tentatively identified as one axial proton in the shielding region of the acid carbonyl; the bent hydrogen bonding of the NH rigidifies the amide CH—OCH unit and brings one of the ring protons into the shielding zone of the carbonyl. If this is the case, the overall conformation of the macrocycle must be restricted to one major conformer only at one "end" of the macrocycle; the other end is unconstrained. The features discussed with particular reference to *anti* $(8NH)_2$18-6Ca may be identified in most of the other spectra but are usually less well defined. The conclusion which may be drawn is that essentially all the cases examined exhibit the same overall conformation.

The samples examined typically contained small amounts of water, usually less than one molar equivalent. Completely anhydrous samples were prepared in some cases which exhibited the same behaviour as did slightly more hydrated samples. The only exception found was *anti* $(8NH)_2$18-6A_2 and its salts, shown in Fig. 5 for a partly hydrated sample. Samples with excess water failed to show the downfield multiplet described above and had a markedly different overall lineshape for the CH_2O multiplets. It may therefore be suggested that the conclusions drawn above refer to a conformation which requires some small amount of additional water for stabilization. A further discussion of the role of hydration by bulk water is given below.

Degree of aggregration

The carriers and their salts are amphiphilic molecules and might be expected to form aggregrated species in solution. As the acid, dimerization might occur but is somewhat improbable due to unfavourable steric factors. Infrared spectra of various carriers at concentrations up to 10^{-1} *M* failed to indicate any dimerization (2650 cm^{-1}, 920 cm^{-1} dimer bands) (24, 25). This result is consistent with kinetic studies (8, 10) where the rate is a first order process in carrier; higher nonintegral orders would be expected for aggregrated species.

Aggregration of the complexes might occur to form reversed micelles within the chloroform phase during the transport. The general phenomenon of aggregation may be followed by observation of a discontinuity in some parameter as a function of concentration (33). A convenient probe for ionophores is the dependence of proton spin-lattice relaxation times (T_1) on concentration. This technique has been used to probe dimerization of acids (34), micellization of phospholipids (35), and aggregation of calcium ionophores (36). On a qualitative level, a

TABLE 2. Selected spin-lattice relaxation times for carboxylate crown ethers[a]

[a]In s^{-1} determined in $CDCl_3$ at 25°C, values reported are averages obtained at different concentrations and for different portions of the multiplet when more than one proton is involved. Ranges: methines ± 0.05, ring methylenes ± 0.04, chain methylenes ± 0.1.

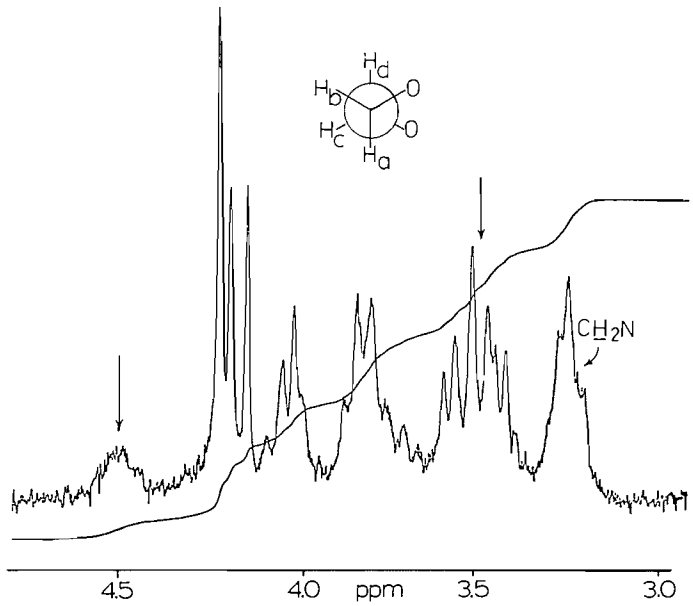

FIG. 5. Ring proton region of the ^1H nmr spectrum of *anti* $(8NH)_218\text{-}6A_2$ in $CDCl_3$ at 25°C. Arrows indicate mutually coupled upfield and downfield multiplets.

freely diffusing, rotating molecule in solution will be characterized by a set of T_1's which would be expected to dramatically diminish as association occurs to provide a larger aggregate with a longer correlation time. Typical values for the carriers are given in Table 2 and, in general, confirm that the carriers behave as surfactants. The head group and closely held protons have short T_1's which gradually lengthen along the hydrocarbon tail (35).

The data reported apply over a range of concentration from 10^{-3} to 10^{-4} *M*; throughout this range the values vary slightly but there are no discontinuities. Minor effects are noted in changing an acid to its salt, which probably reflect changes in overall conformation. The general conclusion is that aggregation is unimportant for these complexes under the transport conditions. The one case where dimerization is clearly evident from other data, namely $(4NH18\text{-}6)_2Ca$, is the one case where the T_1's differ substantially from the free acid to the complex. The change is very marked, indicating that this technique would be sufficient to detect any aggregation had it occurred.

Effect of hydration

Water is soluble in chloroform to the extent of about 5×10^{-3} *M* at equilibrium, hence under the transport conditions there is an excess of water available in the membrane phase. Salts of the carriers are readily prepared by extraction of the cation from basic aqueous solutions (9). The amount of extracted water may be determined by integration of the proton nmr spectrum of these extraction solutions. The metal salts of the carriers apparently enhance the solubility of water in the chloroform; typically a solution of carrier salt (1×10^{-3} *M*) contains a tenfold excess of water (1×10^{-2} *M* H_2O). It is likely that this additional water is associated with the crown ether and the metal ion and provides additional ligation. With one exception, these water saturated solutions are identical with samples prepared with minimal amounts of water (above), thus the additional water does not perturb the conformational preferences deduced. The principal exception is *anti* $(8NH)_218\text{-}6A_2$ and its salts, which give variable spectra which depend on the amount of water present. The solid state structure shows both carboxylates closely coordinated to the central cation (19) which results in ring distortions. As the amount of water increases, the necessity for ion-pairing is relaxed, water molecules can take up the role of metal ligation and carboxylate stabilization, and the macrocycle can relax to the more stable all-*gauche* arrangement of ethylenedioxy units.

Summary of solution structures

Taken together, the experiments described above lead to a relatively simple picture of the solution structures of the carriers and their complexes. The solution species are monomeric but will have some associated water under the conditions of the membrane experiment. The crown ether portion adopts a single predominant conformation incorporating at least four sets of *gauche* OCCO fragments, axially disposed groups at the tartrate derived positions, and, when amides are present, an intramolecular N—H hydrogen bond possibly within a 5-membered ring. When required by stoichiometry, dimeric complexes form in which the metal ion occupies one macrocycle while the other carrier provides a liposoluble counterion which may be exchanged for another counterion such as picrate. In all the complexes the carboxylate forms an asymmetric contact ion pair with the metal ion in the macrocycle. It is encouraging to note that this simple picture is essentially the one considered at the design stage of the project (6) based on simple extrapolations from previous data on crown ether complexes, stability constants, and X-ray crystal structures.

Experimental

The syntheses, purification, and characterization of carriers were previously described (6, 9). All samples were purified just prior to use and were pumped at high vacuum to remove volatile impurities. An-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

hydrous samples were prepared by drying the material at 80°C and 0.1 Torr over P_2O_5 for 16 h.

Stability constant determinations

The general procedures outlined previously for the determination of association constants from pH metric titration (6) were used in this study, but the apparatus consisted of a fully automatic titration system programmed for equilibrium aliquot titrations. The buret (Metrohm 655) and pH/mV meter (Metrohm 632) were linked to an HP85 microcomputer which controlled all functions of the buret. In one cycle of program control, the pH/mV data are examined until equilibrium is established in the cell, the buret volume and current cell potential are recorded, and the buret adds a further aliquot of titrant (typically 5 or 10 μL). The data file may be plotted, stored, printed, edited, and endpoints may be determined. The pH electrode (Metrohm EA 109) was conditioned for use in 90:10 v/v methanol–water. The reference electrode (Fisher calomel electrode) was linked to the cell via a porous plug salt bridge containing 0.1 *M* Me_4NCl. Standardization of pH*, procedures, and calculations utilizing the modified version of SCOGS (37) followed previously outlined procedures (6).

Infrared experiments

All infrared spectra were recorded using a Perkin–Elmer 283 infrared spectrometer and the spectral calibration was checked with polystyrene. Solution spectra in $CHCl_3$ were recorded using matched KBr cells with 0.1 or 0.5-mm path lengths. The discussion in the text summarizes the following set of carriers and counterions: 4NH18-6A, Li, Na, K, Ca, Ba; 14NH18-6A, K, Ca; 18-6A_2, Ca; $D_2$18-6A_2, Ca; *syn* and *anti* $(8NH)_2$18-6A_2, Ca, Sr, Ba.

Nuclear magnetic resonance experiments

All spectra were recorded on a Bruker WM 250 spectrometer at 250 MHz for ^1H, 62.84 MHz for ^{13}C, and 66.16 MHz for ^{23}Na. Spectral data are relative to TMS (^1H, ^{13}C) or external 3 *M* NaCl in water (^{23}Na). The temperature controller was calibrated using a methanol–water standard. All samples involving consideration of linewidths, for relaxation measurement, and for ^{23}Na experiments were degassed immediately prior to recording the spectra. Spin-lattice relaxation times were determined by inversion recovery and calculated using an integral program of the WM 250. The conclusions drawn in the text summarize the following set of experiments.

^1H in $CDCl_3$: 18NH15-5A, K, Ca; 4NH18-6A (VT, T_1), Na (VT), K (VT, T_1), Ca (VT, T_1), Ba (VT, T_1), 1/2 equiv. KPF_6 (VT), excess KPF_6 (VT); 14NH18-6A (T_1), Na, K, Ca; 18-6A_2 (T_1, VT), Ca (T_1, VT); $D_2$18-6A_2 (T_1, VT), Ca (T_1, VT); *syn* $(8NH)_2$18-6A_2 (T_1, VT), Ca + 10% CD_3OD; *anti* $(8NH)_2$18-6A_2 (T_1, VT), Ca (VT, T_1) Sr, Ba; D_2TA$_2$, Ca (VT).

^{13}C in $CDCl_3$: 4NH18-6A, Na, K, Ca, Ba; ^{14}NH18-6A, K, Ca; $D_2$18-6A_2, Ca; *syn* $(8NH)_2$18-6A_2, Ca, Ba; *anti* $(8NH)_2$18-6A_2, Ca, Sr, Ba.

^{23}Na in CD_3OD: H_2O (90:10 v/v): 4NH18-6A + NaCl.

Extraction from basic aqueous buffers ^1H and ^{13}C: no carrier, 14NH18-6A, Na, Ca, Ca + picrate, Sr, Ba; 18NH15-5A, K, Ca, Ca + 1-naphthylacetate; $D_2$18-6A_2, Ca; *syn* $(8NH)_2$18-6A_2, K, Ca; *anti* $(8NH)_2$18-6A_2, K, Ca, Sr.

Concentration dependence 10^{-1} to 10^{-5} *M* (^1H) and 10^{-1} to 10^{-3} *M* (^{13}C): 4NH18-6A, K, Ca; 14NH18-6A, K, Ca; *anti* $(8NH)_2$18-6A_2, Ca.

Received July 25, 1983

WOLFGANG KLIEGEL, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **62**, 515 (1984).

Crystals of 1,7-dimethyl-3,5-diphenyl-2,4,6-trioxa-7-aza-1-azonia-3-bora-5-boratabicyclo[3.3.0]octane are triclinic, a = 10.559(2), b = 15.156(3), c = 10.338(2) Å, α = 99.14(1), β = 89.90(1), γ = 96.73(1)°, Z = 4, space group $P\bar{1}$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to R = 0.032 and R_w = 0.038 for 2396 reflections with $I \geq 3\sigma(I)$. The structure consists of two crystallographically independent, but virtually identical, molecules containing sterically lengthened N—B coordinative bonds (mean 1.740(3) Å). The structurally inequivalent (in the solid state) pairs of N-methyl and B-phenyl groups are observed by variable temperature ^{1}H nmr to be magnetically equivalent in solution, implying a rapid interconversion of "valence tautomers" at temperatures down to −60°C.

WOLFGANG KLIEGEL, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **62**, 515 (1984).

Les cristaux de diméthyl-1,7 diphényl-3,5 trioxa-2,4,6-aza-7 azonia-1 bora-3 borata-5 bicyclo[3.3.0] octane sont tricliniques, a = 10,559(2), b = 15,156(3), c = 10,338(2) Å, α = 99,14(1), β = 89,90(1), γ = 96,73(1)°, Z = 4, groupe d'espace $P\bar{1}$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs de R = 0,032 et R_w = 0.038 pour 2396 réflexions avec $I \geq 3\sigma(I)$. La structure comprend deux molécules qui sont cristallographiquement indépendantes mais qui sont pratiquement identiques; elles comportent des liaisons coordinantes N—B qui sont stériquement allongées (valeur moyenne de 1,740(3) Å). Par rmn du proton à température variable, on peut observer que les paires de groupes *N*-méthyle et B-phényle, qui structuralement ne sont pas équivalents, sont équivalents en solution; ce résultat implique une interconversion rapide des "tautomères de valence" à des températures allant jusqu'à −60°C.

Introduction

The condensation of phenylboronic acid, *N*-methylhydroxylamine, and formaldehyde leads to the isolation of a stable crystalline compound. Both the elemental analysis and spectroscopic data for this material indicate an eight-membered ring system, the structure of which could not be unambiguously determined (1). "Magnetic equivalence" of the identical functional groups in the molecule would correspond to the simple cyclocondensate **1**, to the strained tricyclooctane system **2** (containing a pair of transannular N—B coordinative bonds), or to the less strained dimer of **1** with the pentacyclohexadecane structure **3**.

In addition, the transannular mono-coordinated structure **4** had to be considered, at least in the solid state, by analogy to the very stable compounds possessing a bicyclo[3.3.0]octane structure such as **5** (2) and **6** (3, 4) or similar compounds such as **7** (5) and **8** (6). ^{1}H nmr spectra of $CDCl_3$ solutions of **4**, however, showed only one methyl and one phenyl signal, even at temperatures as low as −60°C.[2] The ^{11}B nmr spectrum as well indicated only one type of boron atom, which could not be clearly assigned to trigonal sp^2 or to tetrahedral sp^3 boron (1). This situation could arise from a temperature-dependent equilibrium between two virtually identical valence tautomers ("coordination topomers") **4** which would cause coalescence of the nmr signals (1). In order to determine unambiguously the solid state structure of this compound an X-ray crystallographic analysis was performed.

Experimental

*1,7-Dimethyl-3,5-diphenyl-2,4,6-trioxa-7-aza-1-azonia-3-bora-5-boratabicyclo[3.3.0]octane, **4***

The compound was prepared by reported (1) methods. Suitable crystals were obtained by recrystallization from benzene/petroleum ether, mp 179–181°C. ^{1}H nmr (400 MHz, $CDCl_3$/TMS) δ (ppm) at 0, −10, −20, −30, and −40°C without change: 2.70 (s, $2CH_3$), 3.77 (s, N—CH_2—N), 7.37 (m, 6 phenyl-H, *meta* and *para*), 7.79 (d, 2 phenyl-H, *ortho*); at −60°C: 2.70 (s, $2CH_3$), 3.88 (s, N—CH_2—N), 7.37 (m, 6 phenyl-H, *meta* and *para*), 7.79 (d, 2 phenyl-H, *ortho*).

X-ray crystallographic analysis

A crystal bounded by the six faces (followed by their distances in mm from a common origin): ±(0 1 0), 0.05, ±(0 1 −1), 0.13, ±(3 0 1), 0.18 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 25–36°) measured on a diffractometer with Mo-Kα_1 radiation (λ = 0.70903 Å). Crystal data at 22°C are:

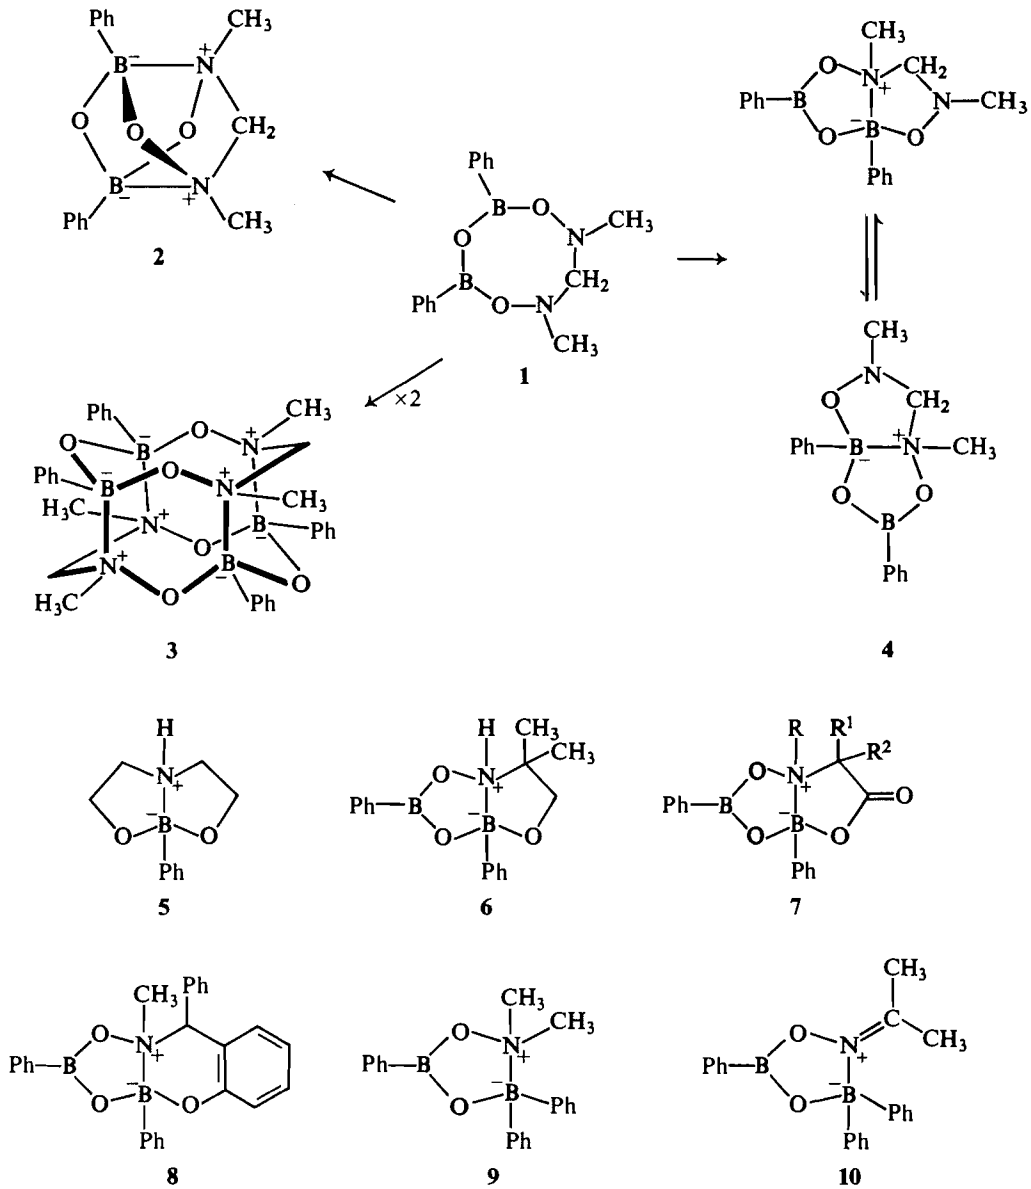
$C_{15}H_{18}B_2N_2O_3$ fw = 295.94

Triclinic, a = 10.559(2), b = 15.156(3), c = 10.338(2) Å, α = 99.14(1), β = 89.90(1), γ = 96.73(1)°, V = 1621.9(5) Å^3, Z = 4, ρ_c = 1.212 g cm^{-3}, $F(000)$ = 624, μ(Mo-Kα) = 0.77 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ (C_i^1, No. 2, reduced cell) from structure analysis.

Intensities were measured with graphite-monochromated Mo-Kα radiation (λ = 0.71073 Å) on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 0.57–6.71° min^{-1} over a range of (0.55 + 0.35 tan θ) deg in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The

[1] Part XVIII: ref. 14.

[2] See Experimental section for low temperature ^{1}H nmr data, further information in ref. 1.



intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within ±3.5%. Of the 7417 independent reflections measured and processed,[3] 2396 (32.3%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The structure was solved by direct methods in the centrosymmetric space group $P\bar{1}$ which was strongly indicated by the E-statistics, the coordinates of all non-hydrogen atoms being determined from an E-map. Full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters reduced R to 0.103, at which point a difference map clearly revealed the positions of all hydrogen atoms. Due to the relatively small number of observed reflections, hydrogen atoms were included as fixed atoms in idealized positions (C(sp^2)—H = 0.97, C(sp^3)—H = 0.98 Å) in subsequent cycles of refinement. These positions and thermal parameters were readjusted after each least-squares cycle. The scattering factors of ref. 7 were used for non-hydrogen atoms and those of ref. 8 for hydrogen atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of refinement. Convergence was reached at $R = 0.032$ and $R_w = 0.038$ for 2396 reflections with $I \geq 3\sigma(I)$. For all 7417 reflections $R = 0.182$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.04 and 0.23σ, respectively. The mean error in an observation of unit weight was 1.678. A final difference map showed maximum fluctuations of ±0.12 e Å^{-3}. The final positional and thermal parameters appear in Tables 1 and 5,[4] respectively. Measured and calculated structure factors have been placed in the Depos-

[3] The computer programs used include locally written programs for data processing and locally modified versions of the following: MULTAN 80, multisolution program by P. Main, S. J. Fiske, S. E. Hull, L. Lessinger, G. Germain, J. P. Declercq, and M. M. Woolfson; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

[4] The structure factor table, Table 5 (anisotropic thermal parameters) and other material mentioned in the text are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

itory of Unpublished Data.[4]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (9). The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0018 Å^2. For each of the two independent molecules analysis of the entire molecule indicated significant independent motion of the phenyl rings. The 7-atom BPh group and 12-atom group consisting of the bicyclo[3.3.0]octane backbone plus all atoms directly bonded to it were separately analysed (rms ΔU = 0.0024–0.0048 Å^2). The appropriate bond distances have been corrected for libration (9, 10), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 2 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 3. Intra-annular torsion angles defining the conformations of five-membered rings are

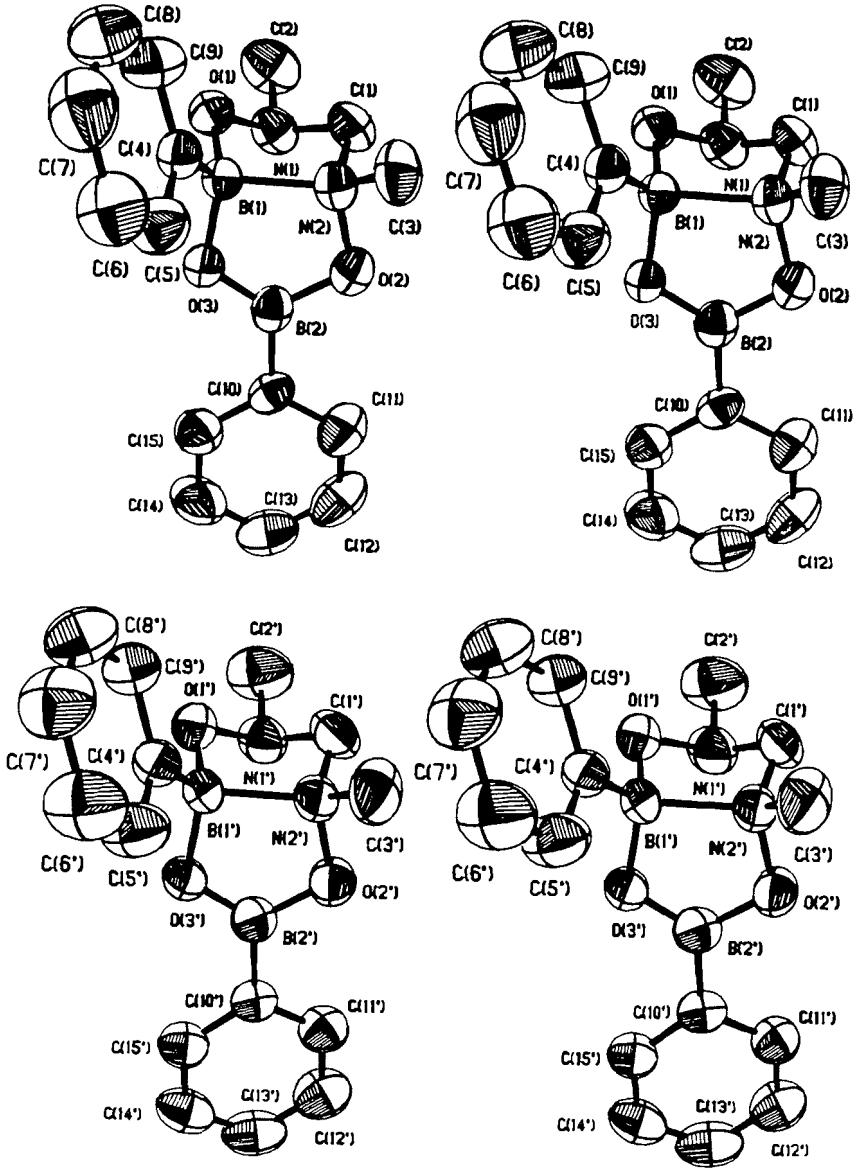

FIG. 1. Stereoscopic views of two independent 1,7-dimethyl-3,5-diphenyl-2,4,6-trioxa-7-aza-1-azonia-3-bora-5-boratabicyclo[3.3.0]octane molecules. 50% probability thermal ellipsoids are shown for the non-hydrogen atoms. The (1*S*,5*R*,7*S*) isomers are shown; for molecule B (primed labels) this is the mirror image of the molecule whose coordinates are presented in Table 1.

listed in Table 4. Calculated hydrogen coordinates and thermal parameters and a complete listing of torsion angles (Tables 6, 7) are included as supplementary material.

Results and discussion

The X-ray crystallographic analysis confirms the bicyclo[3.3.0]octane structure **4** in the solid state. In solution the compound must exist either as the cyclocondensate **1** or must undergo rapid interconversion between the two valence tautomers **4** in order to be consistent with the observed variable temperature ^{1}H nmr data. Based on the known structures and stabilities of the related molecules **5**–**8** (2–6), the latter situation seems most likely.

The centrosymmetric crystal structure of **4** contains equal numbers of (1*S*,5*R*,7*S*)- and (1*R*,5*S*,7*R*)-1,7-dimethyl-3,5-diphenyl-2,4,6-trioxa-7-aza-1-azonia-3-bora-5-boratabicyclo-[3.3.0]octane molecules, the former depicted in Fig. 1. The two crystallographically independent molecules which comprise the asymmetric unit are essentially equivalent, differing only slightly from one another in both the orientation of the B(2)-phenyl group and in the conformation of the BOBON ring. These small, but statistically significant, differences between molecules **A** and **B** (the latter denoted by primed atom labels) may safely be ascribed to differences between the packing environments. Intermolecular distances generally correspond to normal van der Waals interactions, the only nonbonded intermolecular contacts of any possible significance being a pair of C—H···O contacts (C(1′)—H(1′a)···O(3) ($1-x, -y, 1-z$), C···O = 3.279(3), H···O = 2.46 Å, C—H···O = 141°; C(1′)—H(1′b)···O(1) ($1-x, -y, -z$), C···O = 3.267(3), H···O = 2.57 Å, C—H···O = 128°).

The markedly folded bicyclo[3.3.0]octane molecular backbone consists of the pair of *cis*-fused five-membered rings, structurally very similar to those observed in **5** (2) and **6** (3). In

both molecules **A** and **B** the BONCN rings have slightly distorted N(1)-envelope conformations (see Table 4). The now well-characterized five-membered BOBON rings are significantly non-planar although not greatly so (mean and maximum deviations from the mean planes being 0.024 and 0.047(2) Å), the rings having flattened B(2)- and O(3′)- envelope conformations in molecules **A** and **B** respectively. The corresponding rings in **6** (3) and **10** (12) are planar, that in **8** (6) slightly less planar than in **4**, while that in **9** (11) is markedly non-planar. Steric factors responsible for distortions of the BOBON rings from planarity have been discussed at length for **8** (6), analogous arguments pertaining to the present structure.

The long mean[5] transannular N—B bond of 1.740(3) Å in **4** lies between the values of 1.728(3) Å in **9** and 1.754(3) Å in **8**, both of which are lengthened by NMe–BPh steric interactions as is that in **4**. These values may be compared with those of 1.666(3), 1.692(2), and 1.676(4) Å in **5**, **6**, and **10** wherein this particular interaction is absent. Bond distances involving the trigonal planar boron atom are essentially equal in all five structures containing the BOBON ring; the very short

[5] Here and elsewhere in this report mean values refer to weighted means with rms deviations from the mean in parentheses.

anhydridic B—O(B) distance of 1.341(3) Å and the shortened B—O(N) and B—C distances of 1.408(2) and 1.551(3) Å may be compared with the corresponding mean values of 1.337(3), 1.412(9), and 1.553(4) Å for the closely related structures **6**, **8**, **9**, and **10**. The B(sp^3)—O bond lengths do not differ significantly from those observed in **5**, **6**, and **8** (in which the boron atom is similarly coordinated). It is noteworthy that the N—O bonds involving the trivalent N atoms are significantly longer than those involving the tetrahedral N atoms (mean values of 1.463(1) and 1.449(2) Å, respectively).

The trigonally coordinated B(2) and B(2′) atoms are displaced 0.013(3) and 0.001(3) Å from the planes of their substituents. The B(2) phenyl groups (both of which are planar to within experimental error) are twisted out of the respective B(2/2′) coordination planes by 1.1(1) and 8.6(1)°, these values being normal for derivatives of phenylboronic acid (refs. 3, 6, 11, 12, and references therein). The two B(1) phenyl rings are slightly, but significantly, non-planar (χ^2 = 21.9 and 23.7, maximum deviation from the mean plane 0.010(4) Å). The B—C distances and the substituent induced geometrical distortions of the phenyl rings are normal (13).

"Through-space" spin–spin coupling between thallium and hydrogen in *o*-alkylphenylthallium compounds

BRUCE VICTOR CHEESMAN[1] AND RAYMOND FREDERICK MARTIN WHITE

Department of Chemistry, Sir John Cass School of Science and Technology, City of London Polytechnic, Jewry Street, London, England EC3N 2EY

Received October 25, 1982[2]

BRUCE VICTOR CHEESMAN and RAYMOND FREDERICK MARTIN WHITE. Can. J. Chem. **62**, 521 (1984).

In this study a comparison was made of the Tl···H sidechain coupling constants for mono- and di-arylthallium derivatives in which a series of alkyl groups (CH_3, C_2H_5, i-C_3H_7, *t*-C_4H_9) are *o*- and *p*- to the thallium atom. The results provide evidence of "through-space" coupling between thallium and hydrogen in some of the *o*-alkylphenylthallium compounds, with the "through-space" contribution to $^5J(Tl\cdots C(CH_3)_3)$ in the *o-tert*-butylphenylthallium derivatives being considerable.

BRUCE VICTOR CHEESMAN et RAYMOND FREDERICK MARTIN WHITE. Can. J. Chem. **62**, 521 (1984).

Dans ce travail, on compare les constantes de couplage Tl···H des chaînes latérales des dérivés mono- et di-arylthallium dans lesquels une série de groupes alkyles (CH_3, C_2H_5, i-C_3H_7, *t*-C_4H_9) sont en positions *ortho* et *para* par rapport à l'atome de thallium. Les résultats révèlent un couplage à "travers l'espace" entre le thallium et l'hydrogène dans certains composés *o*-alkylphénylthallium avec une contribution considérable à "travers l'espace" au $^5J(Tl\cdots C(CH_3)_3)$ dans les dérivés *o-tert*-butylphénylthallium.

[Traduit par le journal]

Introduction

"Through-space" coupling can occur if the internuclear distance between a pair of coupled nuclei is abnormally small (1, 2). Observation of a coupling constant which is larger than might otherwise be expected is taken to be indicative of a "through-space" mechanism (3–6). Unambiguous examples of "through-space" coupling involving nuclei other than hydrogen and fluorine are few. Petrakis and Sederholm (1) suggested "through-space" coupling involves lone pair orbitals, but this has led in most cases to the existence of lone pair orbitals, on one or both of the atoms involved in coupling, being taken as indicative that the important mechanism in such couplings is "through-space". McFarlane (7) suggested this type of coupling is likely between fluorine and the magnetic nuclei of elements larger than helium, in their *o*-trifluoromethyl derivatives, because of van der Waals penetration which depends upon the extent to which other substituents allow close approach of the trifluoromethyl group. Mercury and phosphorus(III) are favourable in this respect and evidence for "through-space" coupling in *o*-trifluoromethyl derivatives of these nuclei has been reported by McFarlane (7) and Grim *et al.* (8) respectively.

Values of J_{Tl-H} for arylthallium compounds were first reported by Maher and Evans (9), who proposed that the coupling involves essentially the same mechanism as that involved in hydrogen–hydrogen coupling, that is, via Fermi contact, by using the 6*s*-orbital of the thallium atom. They also observed (9, 10) an increase in the magnitude of J_{Tl-H} in the series Ar_3Tl, Ar_2Tl^+, and $ArTl^{2+}$ (where Ar is aryl), which was qualitatively interpreted on the basis of the Fermi contact term as due to the increase in both the effective nuclear charge (Z_{eff}) of the thallium atom and the *s*-character of the outer electrons of the thallium atom, an interpretation supported by other workers (11, 12). McKillop *et al.* (13) have measured the magnitude of $J_{Tl\cdots H}$ and $J_{Tl\cdots CH_3}$ for a range of arylthallium trifluoroacetates prepared by the direct thallation technique, and the results of their studies were in complete agreement with those of Maher and Evans (9, 10). The very large differences in the coupling constants for Tl—*o*H, Tl—*m*H, and Tl—*p*H make possible the unambiguous determination of the orientation of the carbon–thallium bond in both mono- and di-arylthallium compounds, and distinguish between the two types of organothallium compounds. Ernst (14) has measured ^{13}C chemical shifts, $^nJ(^{13}C, ^{205}Tl)$, where $n = 2-6$, for some alkyl-substituted arylthallium trifluoroacetates, and $^6J_{Tl\cdots pH}$ for *p*-Me, *p*-Et, and *p*-i-Pr-phenylthallium bis(trifluoroacetates). He discussed substituent effects on chemical shifts and coupling constants for the ^{13}C data and found $^6J_{Tl\cdots pC}$ was dependent upon the conformation of the *p*-alkyl side-chains.

The aim of the present work was to investigate the possibility of "through-space" coupling in suitable *o*-alkylphenylthallium compounds. To detect the effects of "through-space" coupling it is necessary to compare coupling constants in structurally similar compounds which differ only in the proximities of possible interacting groups. In this study, mono- and diarylthallium compounds in which the groups of interest are *o*- and *p*- to the thallium atom, are compared. "Through-space" coupling might be expected for the *o*-substituted derivatives, as the alkyl groups would be close to the thallium atom, whereas in the *p*-substituted compounds there is no possibility of a "through-space" contribution to the coupling because of the distance separating the coupled nuclei. Thus the *p*-substituted compounds act as a control for investigating "through-space" effects in the *o*-derivatives. Compounds in which the alkyl control groups are *p*-, rather than *m*-, to thallium were used for two reasons. Firstly, $J_{(Tl-H(p\text{-}R))}$ is larger than $J_{(Tl-H(m\text{-}R))}$, where R is an alkyl group, so any "through-space" effects would be more difficult to evaluate if $J_{(Tl-H(o\text{-}R))}$ was being compared with $J_{(Tl-H(m\text{-}R))}$. Secondly, the preparation of *p*-alkylphenylthallium bis(trifluoroacetates) is more convenient since *p*-thallation is easier than at the *m*-position, *p*-substitution occurring at room temperature rather than at elevated temperatures. In general, *p*-alkylphenylthallium compounds are more readily obtained than the *m*-substituted ones, even via other preparative routes. Evidence is presented of "through-space" coupling between thallium and hydrogen in some of the *o*-alkylphenylthallium compounds, with the "through-space" contribution to

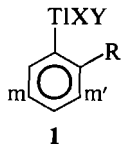
$^5J(Tl\cdots C(CH_3)_3)$ in the *o-tert*-butylphenylthallium derivatives being considerable.

Results

All spectra were assigned on a first-order basis. In the alkyl sidechains, $^3J_{H\cdots H}$ was in the order of 7 Hz. The results for the Tl···H sidechain coupling constants in the *o*-alkylphenylthallium **1** and *p*-alkylphenylthallium compounds are presented



1

X = Cl, Y = Cl for a monoarylthallium compound
X = *o*-alkylphenyl (same as existing one),
Y = Cl, for a diarylthallium compound
R = alkyl group

in Table 1. Only in three bis(*p*-alkylphenyl)thallium compounds, containing ethyl and isopropyl groups, the methylene/methine peaks are broad and fine structure was not resolved. Line broadening in these large molecules could be due to $^{203}Tl/^{205}Tl$ isotopes ($^{205}\gamma/^{203}\gamma = 1.0098$) (11) and some self association process, or the ^1H T_1 values may be short enough to give broad peaks. Estimation of $^6J_{Tl\cdots pH}$ from these broad peaks is highly uncertain and values obtained are not presented here since their inclusion is unnecessary for confirmation of "through-space" coupling in the *o*-alkylphenylthallium compounds.

Computer programmes were used to calculate thallium···hydrogen internuclear distances (on the assumption of free rotation of the alkyl groups) in the *o*-alkylphenylthallium derivatives discussed. The range of carbon–thallium bond lengths employed in these calculations would cover both mono- and di-compounds. It was assumed that carbon–hydrogen bond lengths, carbon–carbon bond lengths (for C_2 and above), and HCH bond angles were constant in the alkyl sidechains. The thallium···hydrogen internuclear distances ($R_{Tl\cdots H}$) for hydrogens on the carbon atom at position 4 (Fig. 1) in *o*-methyl, *o*-ethyl-, and *o*-isopropylphenylthallium compounds were calculated using a five-atom chain for thallium···hydrogen dihedral angles at intervals of rotation of 60° (about the C3—C4 bond (Fig. 1)) in the range 0–300°. A six-atom chain was used in the calculation of $R_{Tl\cdots H}$ for hydrogens (on the carbon atom at position 5 (Fig. 1)) of methyl groups in *o*-ethyl, *o*-isopropyl-, and *o-tert*-butylphenylthallium compounds, which involved consideration of both thallium···carbon and thallium···hydrogen dihedral angles. The same range, 0–300° (represented by the subscript 0–5), and interval, 60°, were used for both dihedral angles, so the five-atom chain produced six values of $R_{Tl\cdots H}$, J_0–J_5. Thirty six values of $R_{Tl\cdots H}$, I_{00}–I_{55}, obtained from the different combinations of thallium···carbon and thallium···hydrogen dihedral angles, were produced by the six-atom chain. The two subscripts indicate thallium···carbon and thallium···hydrogen dihedral angle, in units of 60°, respectively. The use of these thallium···hydrogen internuclear distances for the *o*-methyl- and *o*-isopropylphenylthallium derivatives is illustrated (Fig. 2). The values of $R_{Tl\cdots H}$ produced for both the five- and six-atom chain calculations were then averaged and are presented, together with $R_{Tl\cdots H_{min}}$ and $R_{Tl\cdots H_{max}}$ (Table 2), for three carbon–thallium bond lengths.

TABLE 1. Tl···H sidechain coupling constants for solutions of mono- and di-arylthallium compounds at 23°C

Compound	$^4J_{Tl\cdots oH}$ (Hz)	$^5J_{Tl\cdots oH}$ (Hz)
o-$CH_3C_6H_4TlCl_2$	95 (P)[a]	—

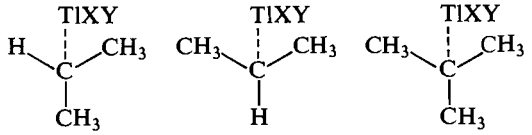
6 Atom $R_{Tl\cdots H_{ave}}$ (nm)	0.391	0.395	0.399

Discussion

The thallium···proton coupling constants (Table 1) for the *p*-alkylphenylthallium bis(trifluoroacetates) indicate that $^6J_{Tl\cdots pH}$ decreases as the methyl hydrogens in *p*-tolylthallium bis(trifluoroacetate) are replaced by methyl groups. An analogous situation exists for dialkylthallium halides,[3] where further alkyl substitution effects a reduction of $^2J_{Tl\cdots H}$. For the mono- and bis- *p*-Et, *p*-i-Pr, and *p*-*t*-Bu-phenylthallium derivatives, $^7J_{Tl\cdots pH}$ could not be observed and must be smaller than 1 Hz, as concluded previously (14) for *p*-*tert*-butylphenylthallium bis(trifluoroacetate). Comparing the results for the *o*-alkylphenylthallium compounds with those of the *p*-compounds, it is found that the change in $^4J_{Tl\cdots oH}$ for *o*-alkylphenylthallium dichlorides, as *ortho*-hydrogens are replaced by methyl groups, is much less than the change in $^6J_{Tl\cdots pH}$ for *p*-alkylphenylthallium bis(trifluoroacetates). Considering $^5J_{Tl\cdots oH}$, the replacement of the methine hydrogen in *o*-isopropylphenylthallium dichloride by a methyl group, as in *o*-*tert*-butylphenylthallium dichloride, results in an increase in $^5J_{Tl\cdots oH}$ from 3 to 22 Hz. In the bis(*o*-alkylphenyl)thallium chlorides $^4J_{Tl\cdots oH}$ *increases* when methyl groups are substituted for hydrogen atoms and for the *o*-isopropylphenylthallium compounds both $^4J_{Tl\cdots oH}$ and $^5J_{Tl\cdots oH}$ are larger in the diarylthallium derivatives than in the monoarylthallium derivatives. Replacement of the methine hydrogen in bis(*o*-isopropylphenyl)thallium chloride by a methyl group, as in bis(*o*-*tert*-butylphenyl)thallium chloride, leads to an increase in $^5J_{Tl\cdots oH}$ from 5 to 19 Hz. Additionally, $^5J_{Tl\cdots oH}$ in *o*-$(CH_3)_3CC_6H_4TlX_2$ is practically insensitive to the nature of X. These unusual results suggest the possibility of a substantial "through-space" contribution involving coupling between thallium and hydrogen in some of the *o*-alkylphenylthallium derivatives. For the *o*-*tert*-butylphenylthallium derivatives the indications are that the "through-space" component to $^5J_{Tl\cdots oH}$ is considerable. In the *o*-isopropylphenylthallium compounds there must be a slight preference for a conformation such as **2** rather than **3**, but there can be no preferred conformation in the *o*-*tert*-butylphenylthallium derivatives, where thallium is adjacent to three methyl groups **4**. There is no experimental evidence of non-equivalence of the hydrogen nuclei in the methyl groups of these arylthallium derivatives, so their overall rate of rotation must be rapid on the nmr time scale. Changes with temperature, not detailed here (15), are not large enough to be significant; this suggests that conformational preferences are small.



2 **3** **4**

X = Cl, Y = Cl for a monoarylthallium derivative
X = *o*-alkylphenyl (same as existing one),
Y = Cl, for a diarylthallium derivative

The calculation of internuclear distances and penetration of van der Waals radii of nuclei have frequently been used to support cases of "through-space" coupling (16). A reliable covalent radius for Tl(III) is not available; for the halides, TlX_3, a value of 0.133 nm is obtained, whilst a value ranging from 0.145 to 0.155 nm is evaluated from complexes possessing six halogen neighbours. The radius of Tl(III) is calculated as 0.141 nm (17) for diethyl(salicylaldehydato)thallium(III), by subtraction of the single bond radius of carbon from the average thallium–carbon bond length. This value lies within the range determined for the six-coordinate halide complexes.

It is impossible to calculate accurate internuclear distances for $ArTl^{2+}$ or Ar_2Tl^+ (Ar is aryl), firstly because there have been relatively few measurements of thallium–carbon bond energies or bond lengths. Nevertheless carbon–thallium bond lengths, for the compounds measured so far, lie within the range 0.207–0.227 nm. Secondly, van der Waals radii of Tl^+ and Tl^{2+} are not known accurately. Hence, measurements and deductions of internuclear distances involving thallium are tentative. The smallest ($R_{Tl\cdots H_{min}}$) and average ($R_{Tl\cdots H_{ave}}$) thallium···hydrogen internuclear distances for the *o*-alkylphenylthallium derivatives are presented (Table 3) for three carbon–thallium bond lengths.

In the *o*-alkylphenylthallium compounds and for a carbon–thallium bond length of 0.218 nm, the average $Tl\cdots CH_3$ internuclear distances are ca. 0.350 nm (*o*-methylphenylthallium derivatives) and ca. 0.400 nm for the others, while the shortest instantaneous thallium···hydrogen separations are only ca. 0.260 nm (*o*-methylphenylthallium derivatives) and ca. 0.130 nm (others); these are probably the more significant figures since McFarlane (7) suggests it is likely "through-space" coupling depends upon $\langle r^{-n} \rangle$ where r is the internuclear distance between a pair of coupled nuclei exhibiting "through-space" coupling, and n is fairly large. Furthermore, $R_{Tl\cdots H_{ave}}$ has been calculated assuming no conformational preference, so the shortest instantaneous thallium···hydrogen separations are probably more important.

Van der Waals radii of Tl^+ and Tl^{2+} (the ionic radius of which was taken as half-way between Tl^+ and Tl^{3+}) have been approximately deduced (at 0.08 nm greater than the ionic radii) as 0.229 nm and 0.201 nm respectively. Since the van der Waals radius of the hydrogen atom is 0.12 nm, the sums of the van der Waals radii are 0.349 nm (for Ar_2Tl^+) and 0.321 nm (for $ArTl^{2+}$). This indicates the possibility of steric overcrowding both for an *o*-methyl group and terminal methyl groups in *o*-ethyl-, *o*-isopropyl-, and *o*-*tert*-butylphenylthallium compounds. The effect is more pronounced in Ar_2Tl^+ than in $ArTl^{2+}$, where penetrations of van der Waals radii (for *o*-alkylphenylthallium derivatives having a carbon–thallium bond length of 0.218 nm) are, Ar_2Tl^+: *o*-methyl 0.093 nm, terminal methyl 0.224 nm; $ArTl^{2+}$: *o*-methyl 0.065 nm, terminal methyl 0.196 nm. It might reasonably be expected that all these derivatives would show "through-space" coupling. The "through-space" interaction between thallium and hydrogen occurring in *o*-alkylphenylthallium derivatives is more significant in bis(*o*-alkylphenyl)thallium chlorides because of a larger van der Waals radius and hence greater overlap of orbitals than in *o*-alkylphenylthallium dichlorides.

TABLE 3. Tl···H internuclear distances for methyl groups in *o*-alkylphenylthallium derivatives

	o-Me			*o*-Et			*o*-i-Pr			*o*-*t*-Bu		
C—Tl (nm)	0.208	0.218	0.228	0.208	0.218	0.228	0.208	0.218	0.228	0.208	0.218	0.228
$R_{Tl\cdots H_{min}}$	0.252	0.256	0.260	0.122	0.125	0.129	0.122	0.125	0.129	0.122	0.125	0.129
$R_{Tl\cdots H_{ave}}$	0.348	0.354	0.359	0.391	0.395	0.399	0.391	0.395	0.399	0.391	0.395	0.399

The main points of this discussion of thallium − sidechain hydrogen coupling constants are summarized below.

(a) Calculations, using a range of carbon−thallium bond lengths that would cover both mono- and di-arylthallium derivatives, indicate that sidechain hydrogen atoms five or six atom distances from the thallium atom can approach within the sum of the thallium and hydrogen van der Waals radii.

(b) When an ethyl or isopropyl group is *ortho* to thallium, the conformational preference is for the hydrogen rather than the methyl group to be *gauche* (or closer) to thallium.

(c) The pattern of $J_{Tl\cdots H}$ suggests a "through-space" effect is occurring. For an *ortho* ethyl or isopropyl group, the conformational preference results in CH_2 or CH showing the effect, while in the case of *o*-*tert*-butylphenylthallium derivatives, all conformations are equally probable and thus the methyl groups show the effect.

(d) The "through-space" effect is less pronounced for *o*-alkylphenylthallium dichlorides than for bis(*o*-alkylphenyl)-thallium chlorides.

Experimental

Instrumentation

The ^1H nmr spectra (measured in dimethyl sulphoxide-d_6 or pyridine-d_5 solution) were obtained on a JEOL C-60-H spectrometer operating at 60 MHz, using 5-mm spinning samples. Spectra were recorded in the field-sweep mode with the field-frequency stabilization circuitry activated by the signal from an external water sample. The coupling constants were virtually independent of concentration for the moderately (0.08−1 *M*) concentrated solutions used.

Sample preparation

The dependence of $J_{Tl\cdots H}$ and ^1H chemical shifts for arylthallium compounds on concentration, temperature, the addition of a common ion, and water in the solvent was investigated (15) during the primary study of "through-space" coupling. It was evident that the coupling constants and chemical shifts for pyridine or dimethyl sulphoxide solutions are not strongly dependent on the concentration of arylthallium compound present, although the low solubility of some of the compounds restricted this study. The main factors affecting coupling constants were found to be water (or deuterium oxide) concentration, concentration of thallic chloride, and soluble chloride anion concentration. Thorough washing and drying (under vacuum) of organothallium compounds before recording spectra eliminates the last two factors. Both pyridine-d_5 and dimethyl sulphoxide-d_6 as supplied contained water/deuterium oxide. In the case of pyridine this could have been removed by refluxing over sodium hydroxide pellets followed by distillation under nitrogen, and dimethyl sulphoxide may be dried over calcium hydride followed by distillation under reduced pressure. A more practical and more economical approach adopted in the present work is to use the solvents as supplied and monitor the water peak as a guide. It should be noted that in the interpretation of the results, variations in coupling constants of about 2% (15) may arise from differences in the water content of the solvent. The low solubilities of some of the arylthallium compounds prepared for the "through-space" study restricted the number of solutions that could be examined.

Chemicals

Where a number of compounds were prepared by a particular procedure, full details are given for one compound and, if necessary, comments are given on cognate preparations. Analyses are reported for new compounds only. A starting material for the preparation of *o*-isopropylphenylboronic acid, *o*-bromoisopropylbenzene, was synthesized from *o*-isopropylaniline by the method of Kiersznicki *et al.* (18). The synthesis of *o*-bromo-*tert*-butylbenzene, used in the preparation of *o*-*tert*-butylphenylboronic acid, involved four preparative stages; nitration of *tert*-butylbenzene (Nelson and Brown (19)), bromination of *p*-nitro-*tert*-butylbenzene (Derbyshire and Walters (20)), reduction of 2-bromo-4-nitro-*tert*-butylbenzene (using granulated tin and concentrated hydrochloric acid), and deamination of 2-bromo-4-amino-*tert*-butylbenzene (Crawford and Stewart (21)).

All arylboronic acids were prepared by the method of Bean and Johnson (22) which involves reaction of an aryl Grignard reagent with tri-n-butyl borate at −60°C and subsequent hydrolysis to give the arylboronic acid, $ArB(OH)_2$. These acids were prepared for Ar = p-$CH_3C_6H_4$, o-$C_2H_5C_6H_4$, o-i-$C_3H_7C_6H_4$, and o-t-$C_4H_9C_6H_4$; experimental data are summarized in Table 4 for *o*-isopropylphenyl- and *o*-*tert*-butylphenylboronic acid.

Syntheses of organothallium compounds

Monoarylthallium compounds were prepared by the following methods: (a) direct thallation of substituted benzenes by thallic trifluoroacetate; (b) reaction of an arylboronic acid with thallic chloride.

Diarylthallium compounds were synthesized as follows: (a) reaction of a monoarylthallium derivative with trimethyl phosphite; (b) reaction of thallic chloride with excess arylboronic acid; syntheses of arylthallium compounds are detailed below.

Monoarylthallium bis(trifluoroacetates)

These were prepared by the method of McKillop *et al.* (23). Arylthallium bis(trifluoroacetates) can be recrystallized from 1,2-dichloroethane, but most were analytically pure as isolated. In a number of cases of thallation the development of intense colours was noted. This is most probably due[4] to a small amount of oxidation of the aromatic substrate by thallic trifluoroacetate. Arylthallium bis(trifluoroacetates), $ArTl(OCOCF_3)_2$, were prepared for Ar = p-$CH_3C_6H_4$, p-$C_2H_5C_6H_4$, and p-i-$C_3H_7C_6H_4$.

Diarylthallium trifluoroacetates

These were prepared by the method of McKillop *et al.* (13) which involves addition of the solid arylthallium bis(trifluoroacetate) to trimethyl phosphite. Diarylthallium trifluoroacetates, $Ar_2TlOCOCF_3$, were prepared for Ar = p-$CH_3C_6H_4$, p-$C_2H_5C_6H_4$, and p-i-$C_3H_7C_6H_4$.

Arylthallium chlorides

(a) *Using arylboronic acids*

These syntheses are based on the method developed by Challenger and Parker (24), which is suitable for the preparation of both monoaryl and diarylthallium chlorides. The product obtained depends on the relative quantities of the reactants. Details of typical preparations, for phenylthallium chlorides, are given below.

Diphenylthallium chloride

Thallic chloride (0.0048 mol) in 6 mL of water was refluxed with 0.0098 mol of phenylboronic acid, giving a white solid after one minute. Diphenylthallium chloride so obtained was filtered off, washed with cold water, recrystallized from pyridine, and dried. This method was satisfactory for the preparation of all diarylthallium chlorides, with the exceptions of bis(*o*-isopropylphenyl)thallium chloride

[a] o-$C_2H_5C_6H_4TlCl_2$ reported (without analysis) in ref. 25, which states that satisfactory analysis was obtained for o-$C_2H_5C_6H_4B(OH)_2$; see also ref. 26.
[b] Insufficient sample for determination of thallium.

and bis(*o-tert*-butylphenyl)thallium chloride. In these cases, reaction of the appropriate arylboronic acid with thallic chloride produced a mixture of monoarylthallium chloride and unreacted arylboronic acid, so the compounds were synthesized from the monoarylthallium dichloride and trimethyl phosphite, the method for diarylthallium trifluoroacetates.

Phenylthallium dichloride

Thallic chloride (0.0145 mol) in 6 mL of water was refluxed with 0.00492 mol of phenylboronic acid for one minute, giving a precipitate of phenylthallium dichloride. The product was filtered off, washed with a small quantity of cold water, recrystallized from methanol, and dried.

Arylthallium chlorides, $ArTlCl_2$ and $(Ar)_2TlCl$, were prepared by reaction of arylboronic acid with thallic chloride for Ar = p-$CH_3C_6H_4$, o-$C_2H_5C_6H_4$, o-i-$C_3H_7C_6H_4$ (only $ArTlCl_2$), and o-t-$C_4H_9C_6H_4$ (only $ArTlCl_2$); experimental data are summarized in Table 4 for Ar = o-$C_2H_5C_6H_4$, o-i-$C_3H_7C_6H_4$, and o-t-$C_4H_9C_6H_4$.

(b) *Using arylthallium dichlorides and trimethyl phosphite*

Bis(*o*-isopropylphenyl)thallium chloride and bis(*o-tert*-butylphenyl)thallium chloride were prepared from the arylthallium dichlorides and trimethyl phosphite using the method (13) for preparation of diarylthallium trifluoroacetates. A larger volume of trimethyl phosphite was found necessary for reaction than for arylthallium bis(trifluoroacetates), reaction times were longer, and the diarylthallium chlorides produced required washing with large quantities of water to remove traces of trimethyl phosphite/phosphate. Experimental data for these diarylthallium chlorides, Ar_2TlCl, Ar = o-i-$C_3H_7C_6H_4$ and o-*tert*-$C_4H_9C_6H_4$, are summarized in Table 4.

La butanedione réagit à chaud avec la diamino-1,2 anthraquinone pour donner, non pas la diméthyl-2,3 naphto[2,3-*f*]quinoxalinedione-7,12 **3** attendue, mais l'(hydroxy-2 méthyl-2 oxo-3 butyl)-2 méthyl-3 naphto[2,3-*f*]quinoxalinedione-7,12 **4***a* dont la structure est établie par diffraction de rayons-X. Elle cristallise dans le groupe d'espace triclinique $P\bar{1}$ avec les dimensions de maille a = 9,091 (1), b = 16,966 (4), c = 12,375 (3) Å, α = 100,75 (2), β = 101,83 (2), γ = 100,29 (2)°, V = 1789 Å^3, Z = 4. La structure a été résolue par des méthodes directes et affinée jusqu'à une valeur de R = 0,039 pour 3027 réflexions indépendantes. La conformation générale de la molécule est sensiblement plane. La caractéristique principale est la présence de deux cycles potentiels dûs à une liaison hydrogène bifurquée intramoléculaire. La diméthyl-2,3 naphto[2,3-*f*]quinoxalinedione-7,12 est l'intermédiaire de la réaction.

MICHEL BARON, SYLVIANE GIORGI-RENAULT, JEAN RENAULT, PATRICK MAILLIET, DANIEL CARRÉ, and JEAN ETIENNE. Can. J. Chem. **62**, 526 (1984).

Butanedione reacts on heating with 1,2-diaminoanthraquinone to give, not the expected 2,3-dimethylnaphtho[2,3-*f*]quinoxaline-7,12-dione **3**, but 2-(2-hydroxy-2-methyl-3-oxobutyl)-3-methylnaphtho[2,3-*f*]quinoxaline-7,12-dione **4***a* whose structure was established by X-ray diffraction. This compound crystallizes in the triclinic $P\bar{1}$ space group with unit cell dimensions of a = 9.091 (1), b = 16.966 (4), c = 12.375 (3) Å; α = 100.75 (2), β = 101.83 (2), γ = 100.29 (2)°, V = 1789 Å^3, Z = 4. The structure was resolved by the direct method and refined to R = 0.039 for 3027 independent reflections. The overall conformation of the molecule is essentially planar. The principal characteristic is the presence of two cyclic arrangements caused by intramolecular hydrogen bonding. 2,3-Dimethylnaphtho[2,3-*f*]quinoxaline-7,12-dione is the intermediate in this reaction.

[Journal translation]

Introduction

Dans un travail précédent (2), il a été constaté que les quinoxalinediones-5,8 sont peu cytotoxiques. Leur manque d'activité a été attribué à la trop faible surface de la molécule par rapport à celle des acridinediones-1,4 (3). Nous avons donc préparé des benzo[*g*]quinoxalinediones-5,10, dont certaines se montrent très actives (à paraître). Pour augmenter encore la surface de la molécule, nous avons tenté la synthèse de la diméthyl-2,3 naphto[2,3-*f*]quinoxalinedione-7,12 **3** par condensation classique de la diamino-1,2 anthraquinone **1** avec la butanedione **2** selon le schéma 1. Or quelles que soient les conditions opératoires (réaction de l'amine **1** avec la dicétone **2** en quantités équimolaires en présence d'acide acétique à 80°C ou mieux chauffage de l'amine **1** dans la butanedione à l'ébullition), on n'obtient pas le dérivé diméthylé **3** mais un seul produit qui, d'après les résultats de la microanalyse et les données spectrales (ir et rmn) répond à la formule d'un des racémiques **4***a* ou **4***b*. La diffraction de rayons-X permet de lui attribuer la structure **4***a*. Cette molécule essayée selon la technique décrite dans la réf. 3 ne possède aucune cytotoxicité sur la cellule leucémique L1210.

Résultats et discussion

A. *Structure*

Le spectre ir montre la présence d'une liaison hydrogène intramoléculaire forte (bande intense fine à 3400 cm^{-1}). La rmn corrobore ce fait: le proton alcoolique est déblindé à 7,41 ppm. On constate également que les deux protons du CH_2 sont inéquivalents ($\Delta\delta \simeq 0{,}7$ ppm) et fortement couplés (J = 20 Hz) par la présence du carbone chiral en α qui les rend diastéréotopiques. Ces données sont compatibles avec les structures **4***a* ou **4***b*.

La structure **4***a* a été établie sans ambiguité par diffraction de rayons-X. Les coordonnées atomiques relatives et les facteurs d'agitation thermique isotropes équivalents obtenus sont rassemblés dans le tableau 1. L'unité asymétrique comprend deux molécules indépendantes, chacune correspondant à un énantiomère. La lettre A identifie les atomes correspondant à une molécule et la lettre B à l'autre molécule. Les distances interatomiques et les angles sont représentés sur les Figs. 1(*a*) et (*b*).

La structure **4***a*, dont la vue stéréoscopique de l'unité asymétrique est indiquée sur la Fig. 2, montre la présence d'une liaison hydrogène intramoléculaire bifurquée entre l'hydroxyle de la chaîne latérale et les atomes O(2) et N(1). En effet, H(O3) se trouve à une distance similaire des atomes O(2) et N(1) bien inférieure aux distances de Van der Waals. Les différentes grandeurs intéressant cette liaison hydrogène sont précisées sur

SCHÉMA 1

les Figs. 1(*a*) et (*b*).

L'intérêt de cette liaison hydrogène bifurquée est d'engendrer la formation de deux cycles potentiels de six atomes H(O3), N(1), C(2), C(13), C(14), O(3) et H(O3), N(1), C(12b), C(12a), C(12), O(2). Ce type de liaison a été décrit par la réf. 4 et les angles et distances relatives à cette liaison ont été rapportés aux calculs *ab initio* de Newton *et al.* (5). Dans le cas présent, les distances et les angles observés sont en accord avec ceux indiqués par ces auteurs.

Les molécules A et B présentent la même conformation qui est globalement plane. Une étude de planéité des différents cycles ou groupes d'atomes a été réalisée. Elle consiste à calculer par la méthode des moindres carrés le plan moyen déduit d'un ensemble d'atomes. Pour chaque plan moyen calculé, le tableau 2 indique l'équation de ce plan, la valeur du χ^2 et la distance de l'atome qui s'en écarte le plus, ce qui permet d'évaluer les éventuelles distorsions dans les cycles.[3]

Des angles dièdres entre plans moyens complètent la description: cycle IV et le plan formé par les atomes C(13)—C(2)—N(1)—H(O3)—O(3): A 7,55°; B 12,86°. Cycles IV et VI: A 11,87°; B 11,31°. Cycles VI et le plan formé par les atomes C(13)—C(2)—N(1)—H(O3)—O(3): A 4,35°; B 3,38°.

Ces différents résultats montrent que les molécules A et B présentent de légères dissemblances au plan typologique, les distorsions des cycles par rapport à la planéité attendue étant légèrement plus grandes pour la molécule B. Cette constatation se retrouve aussi au niveau des oxygènes O(1) et O(2) qui s'écartent très significativement du plan moyen du cycle II mais de manière plus importante pour la molécule B (O(1)B: 0,19 Å; O(2)B: 0,27 Å) que pour la molécule A (O(1)A: 0,06 Å; O(2)A: 0,14 Å).

La seule liaison hydrogène possible étant intramoléculaire, les deux molécules A et B indépendantes dans la maille cristalline sont reliées par des liaisons de van der Waals.

B. *Origine de* **4**a

Le dérivé **4***a* provient de la condensation de deux moles de butanedione avec une mole de diamine **1**. Deux hypothèses peuvent rendre compte de la formation de **4***a*.

La première admet la dimérisation préalable de la dicétone **2** suivie de la condensation avec la diamine **1**. Diels *et al.* (6) ont montré que la butanedione se dimérise en présence de base forte (KOH) pour donner un composé qui, selon Birch et Moyle (7), est l'acétyl-5 diméthyl-2,5 hydroxy-2 oxo-3 tétrahydrofuranne, susceptible de réagir comme l'hydroxy-5 méthyl-5 heptatrione-2,3,6. Si cette dimérisation de la butanedione a lieu avec une base faible comme la diamine **1**, elle devrait également se produire avec la diamino-2,3 anthraquinone. Or, Gorelik (8) a montré que les pK_a de ces deux amines sont voisins (pK_a respectifs: 5,68 et 5,8) et que la diamine en −2,3 réagit normalement avec la butanedione.

Dans la deuxième hypothèse, le dérivé diméthylé **3** se forme et réagit ensuite sur une deuxième mole de dicétone **2**. Cette origine peut être retenue puisqu'en opérant la condensation à froid dans le tétrahydrofuranne, il est possible d'isoler une faible quantité de composé **3** dont la structure a été établie par rmn. Dans la butanedione à reflux, il se transforme rapidement en dérivé **4***a*.

L'un de nous (9) a proposé un mécanisme de cette réaction anormale.

Partie expérimentale

Etude chimique

Les spectres ^{1}H rmn sont enregistrés dans $CDCl_3$ sur appareil Brucker 270 MHz, les déplacements chimiques sont exprimés en ppm par rapport au HMDS pris comme référence interne; s = singulet, d = doublet, m = multiplet. Le spectre ir est réalisé sur spectromètre Perkin–Elmer 157G (KBr). Les résultats d'analyses (C,H,N) correspondent aux valeurs théoriques ± 0,4%.

(Hydroxy-2 méthyl-2 oxo-3 butyl)-2 méthyl-3 naphto[2,3-f]quinoxalinedione-7,12 **4**a

On chauffe à reflux sous azote pendant deux heures une solution de 11,9 g (0,05 mol) de diamino-1,2 anthraquinone dans 220 mL de butanedione. Après élimination de la cétone sous vide, on lave le solide à l'eau. On le chromatographie sur colonne de silice Merck

(0,2–0,5 mm) (solvant: chloroforme); (8 g) 43%; F = 213°C (chlorure de méthylène – éther de pétrole); ir: 1670 et 1705 (C=O), 3400 (O—H lié) cm^{-1}; ^{1}H rmn, δ: 1,47 (s, 3, CH_3—C(=O)—O), 2,37 (s, 3, CH_3—C(=O)—), 2,73 (s, 3, CH_3 en 3), 3,08 (d, 1, 1H du CH_2, J(H—C—H) = 20 Hz), 3,79 (d, 1, 1H du CH_2), 7,41 (s, 1, OH, éch D_2O), 7,77 (m, 2, H-9, -10), 8,27 (m, 3, H aromatiques), 8,55 (d, 1, H-5 ou -6, J(H-5/H-6) = 8,5 Hz).

Diméthyl-2,3 naphto[2,3-f]quinoxalinedione-7,12 3

On agite à la température ambiante sous azote pendant 21 jours une suspension de 0,5 g (0,0021 mol) de diamino-1,2 anthraquinone dans un mélange de 0,18 g de butanedione (0,0021 mol) et de 200 mL de tétrahydrofuranne (THF). Après évaporation du THF, on lave le solide à l'eau puis l'extrait au CH_2Cl_2 que l'on évapore sous pression réduite. Le produit obtenu (0,13 g) est chromatographié sur colonne d'alumine Merck (0,063–0,200 mm) (solvant: éther de pétrole/CH_2Cl_2 65:35). On obtient 3 mg (0,5%) d'un dérivé beige clair monotache en chromatographie sur couche mince d'alumine GF 254 Merck (solvant: benzène/$CHCl_3$ 35:65); F = 180°C (décomposition); ^{1}H rmn, δ: 2,73 (s, 3, CH_3 en 3), 2,85 (s, 3, CH_3 en 2), 7,77 (m, 2, H-9, -10), 8,27 (m, 3, H aromatiques), 8,55 (d, 1, H-5 ou -6, J(H-5/H-6) = 8,5 Hz).

Etude cristallographique

$C_{22}H_{18}N_2O_4$ M = 374,3

Triclinique, a = 9,091 (1), b = 16,966 (4), c = 12,375 (3) Å, α = 100,75 (2), β = 101,83 (2), γ = 100,29° (2), V = 1789 Å^3, Z = 4, d_c = 1,39, d_o = 1,40 (2) g cm^{-3}, 20°C, MoK$_\alpha$ λ = 0,707 Å, μ = 1,03 cm^{-1}.

Les cristaux sont obtenus par évaporation lente, à l'abri de la lumière, d'une solution de **4*a*** dans un mélange de chloroforme et de propanol.

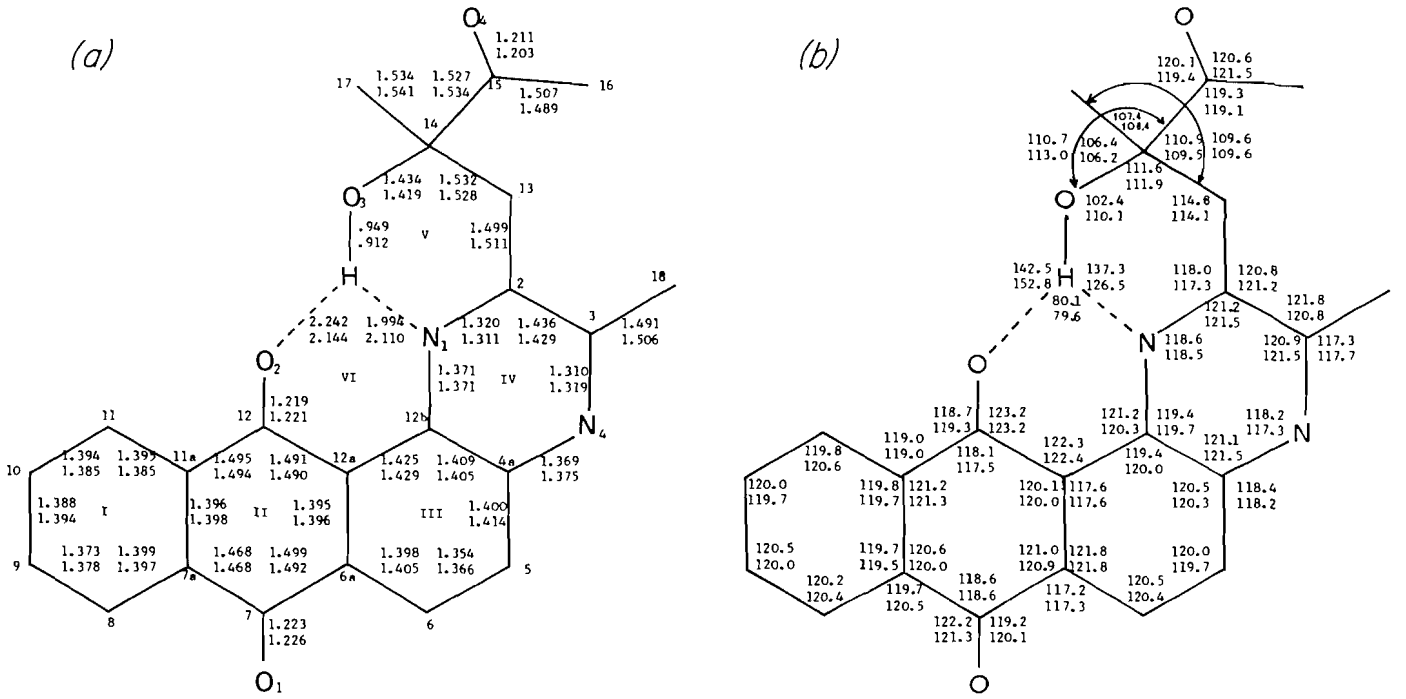

FIG. 1. (*a*) Distance (Å) entre les différents atomes lourds. La valeur supérieure correspond à la molécule A et la valeur inférieure à la molécule B. Les écart-types sont de 0,005 Å. (*b*) Angles (°) entre les différents atomes lourds. La valeur supérieure correspond à la molécule A et la valeur inférieure à la molécule B. Les écart-types sont de 0,3°.

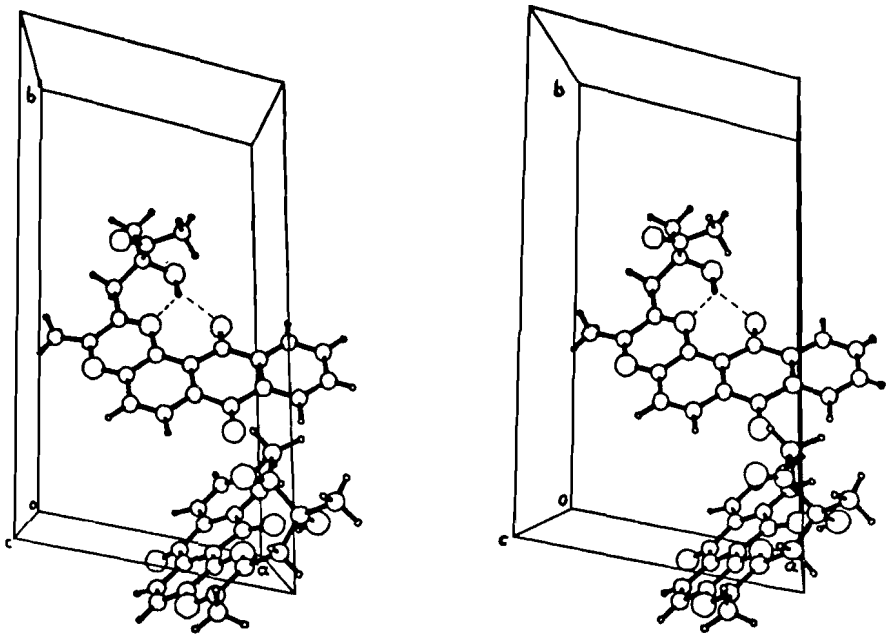

FIG. 2. Vue stéréoscopique de l'unité asymétrique. La liaison hydrogène bifurquée est en pointillé.

L'étude de la structure est effectuée sur un monocristal ayant la forme d'une aiguille allongée parallèlement à C, de dimensions 150 × 200 × 500 μm. L'absence de symétrie observée sur les clichés de Weissenberg correspond aux deux seuls groupes $P1$ et $P\bar{1}$. 5000 réflexions indépendantes telles que $2\theta \leq 50°$ sont mesurées sur un diffractomètre automatique à quatre cercles Syntex en utilisant le rayonnement K_α du molybdène (monochromateur de graphite). Seules sont conservées les 3027 réflexions indépendantes dont les intensités I sont telles que $I > 3\sigma(I)$, $\sigma(I)$ étant l'écart-type sur la mesure de l'intensité I. Ces intensités sont corrigées des facteurs de Lorentz polarisation et mises en échelle absolue par la méthode statistique de Wilson. Les facteurs de structure normalisés E sont calculés pour toutes les réflexions en prenant comme facteur d'agitation thermique celui obtenu par la méthode statistique de Wilson, soit $B = 4{,}3$ Å^2. La distribution statistique de ces facteurs de structure normalisés permet de prévoir la présence d'un centre de symétrie, ce qui nous conduit à choisir le groupe d'espace $P\bar{1}$. La structure est déterminée par utilisation des méthodes directes (programme MULTAN (10)). Le calcul de la densité électronique correspondant à la meilleure figure de mérite permet de déterminer la position de 48 atomes lourds sur 56. Les 8 atomes lourds restant ainsi que tous les atomes d'hydrogène sont positionnés par examen de différences de Fourier. Les facteurs de

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

diffusion sont ceux donnés par la réf. 11. L'affinement de la structure est effectué avec le programme à matrice complète ORFLS (12) en faisant varier indépendamment et successivement d'une part les coordonnées atomiques de tous les atomes, y compris les atomes d'hydrogène, et d'autre part les facteurs de température anisotropes des seuls atomes lourds. Nous donnons aux atomes d'hydrogène les facteurs de température isotropes équivalents de l'atome lourd correspondant. Après correction de l'extinction secondaire, on obtient pour l'ensemble des 3027 réflexions un facteur $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ de 0,039 et un facteur $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$ de 0,40.

Studies on the biosynthesis of the sterpurenes[1]

WILLIAM A. AYER, THOMAS T. NAKASHIMA, AND M. HOSSEIN SAEEDI-GHOMI
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 29, 1983

WILLIAM A. AYER, THOMAS T. NAKASHIMA, and M. HOSSEIN SAEEDI-GHOMI. Can. J. Chem. **62**, 531 (1984).

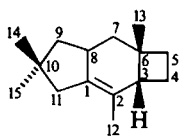
The sterpurenes are a unique group of sesquiterpenes produced by the fungus *Stereum purpureum*. Biosynthetic studies utilizing [1-^{13}C] and [2-^{13}C] acetate indicate that sterpuric acid (**2**) and sterpurene-3,12,14-triol (**3**) are formed from acetate via humulene (**5**) and the protoilludane cation (**6**) by one of the paths shown in Scheme 2.

WILLIAM A. AYER, THOMAS T. NAKASHIMA et M. HOSSEIN SAEEDI-GHOMI. Can. J. Chem. **62**, 531 (1984).

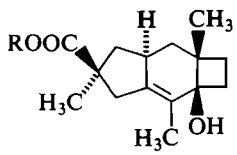
Les sterpurènes sont un groupe unique de sesquiterpènes qui sont produits par le *Stereum purpureum*. Des études de biosynthèse utilisant des acétates [1-^{13}C] et [2-^{13}C] indiquent que l'acide sterpurique (**2**) et que le sterpurènetriol-3,12,14 (**3**) se forment à partir de l'acétate via l'humulène (**5**) et que le cation protoilludane (**6**) se forme par une des voies représentées dans le schéma 2.

[Traduit par le journal]

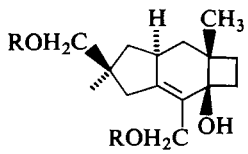
The sterpurenes are a unique type of sesquiterpene possessing the carbon skeleton **1** (1, 2). They are produced by the fungus *Stereum purpureum* (class Basidiomycetes), the causative agent of the so-called silver leaf disease of many fruit and ornamental trees (3). The hydrocarbon **1** has been isolated from the mycelium of *S. purpureum* (2), while sterpuric acid (**2**) and sterpurene-3,12,14-triol (**3**) are the major components of the broth extract (1, 2). The latter two compounds have been utilized in the biosynthetic studies described below.



1



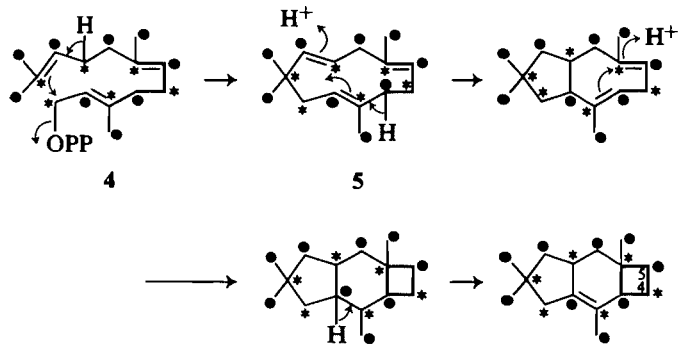
2 R = H
2*a* R = CH_3



3 R = H
3*a* R = $COCH_3$

The sterpurene skeleton may be derived from farnesyl pyrophosphate via humulene without rearrangement as shown in Scheme 1. In fact, this "biogenetic" consideration was useful in the determination of the structure of sterpuric acid (**2**) (1). Farnesyl pyrophosphate is derived in nature from acetate via mevalonic acid[2] and "active isoprene". To determine whether a pathway such as is shown in Scheme 1 is followed, we have undertaken a study of the incorporation of ^{13}C-labelled acetate by *S. purpureum* into sterpuric acid (**2**) and sterpurenetriol (**3**).

In order to follow the labelling pattern of ^{13}C enriched metabolites, it was first necessary to assign the chemical shifts of the carbons of methyl sterpurate (**2***a*, the ester is much more soluble in $CDCl_3$ than sterpuric acid itself) and the 12,14-*O*,*O*-diacetyl derivative (**3***a*) of sterpurenetriol (**3**) (again chosen for solubility reasons). The chemical shift assignments are shown in Table 1. These assignments are based largely on off-



SCHEME 1

resonance and single frequency decoupling (selective proton decoupling) experiments (5). The assignments of sp^2 carbons and the quaternary carbons are based on comparison of the chemical shifts of these centers with reference compounds reported in the literature (6).

Incorporation of ^{13}C-labelled acetate by cyclization of farnesyl pyrophosphate (**4**) to humulene (**5**) and subsequent cyclization as depicted in Scheme 1 would give rise to labelling as shown, where the asterisked carbons arise from the carboxyl group of acetate, and the dotted carbons originate from the methyl group. *S. purpureum* was grown in liquid culture in the presence of [1-^{13}C] acetate and, separately, in the presence of [2-^{13}C] acetate. Examination of the proton noise decoupled ^{13}C nmr spectrum of methyl sterpurate (**2***a*) isolated from the culture containing [1-^{13}C] acetate showed that carbons 2, 5, 6, 8, 10, and 11 were enriched (about 5% incorporation) relative to the natural abundance spectrum. This is consistent with the pathway shown in Scheme 1 *except that this route predicts enrichment at C-4 rather than C-5*. The spectrum also exhibits induced couplings between C-5 and C-6, indicating that rearrangement has occurred at some point during the formation of sterpuric acid. To our disappointment, when *S. purpureum* was grown in the presence of [2-^{13}C] acetate, we were unable to isolate sufficient sterpuric acid to obtain a ^{13}C nmr spectrum. Fortunately, however, it was possible to isolate sufficient quantities of enriched sterpurene-3,12,14-triol (**3**) from both the [1-^{13}C] and the [2-^{13}C] acetate experiments. The ^{13}C nmr spectra of the diacetyl triol **3***a* derived from [1-^{13}C] acetate showed the same labelling pattern as that of methyl sterpurate (**2***a*); again C-2, C-5 (and not C-4), C-6, C-8, C-10, and C-11 were

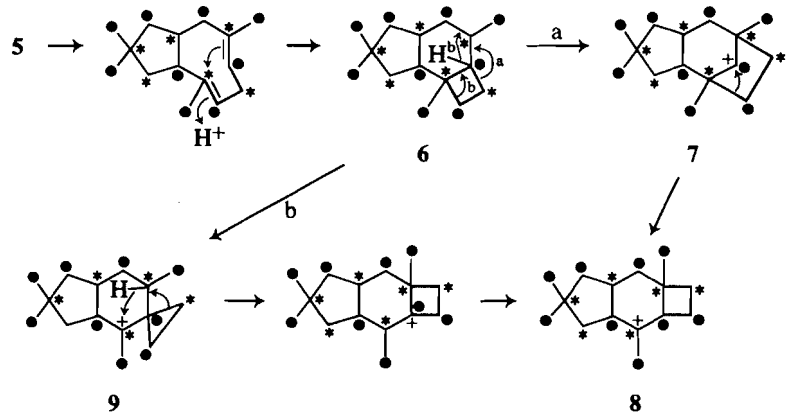

SCHEME 2

TABLE 1. Carbon-13 chemical shifts of methyl sterpurate (**2***a*) and 12,14-*O*,*O*-diacetylsterpurene-3,12,14-triol (**3***a*)

Carbon	**2***a* δ (multiplicity)	**3***a* δ (multiplicity)
1	138.3 (s)	147.6 (s)
2	127.8 (s)	127.2 (s)
3	73.4 (s)	72.9 (s)
4	34.4 (t)	35.3 (t)
5	22.1 (t)	22.1 (t)
6	43.9 (s)	44.2 (s)
7	34.9 (dd)	35.2 (dd)
8	36.8 (d)	37.1 (d)
9	44.3 (t)	42.9 (dd)
10	47.1 (s)	40.6 (s)
11	41.3 (dd)	40.0 (t)
12	12.8 (q)	62.1 (t)
13	23.4 (q)	23.9 (q)
14	178.6 (s)	72.4 (t)
15	25.4 (q)	24.9 (q)
2 × —O—C(=O)—CH$_3$		171.2 (s)
—O—C(=O)—CH$_3$		21.0 (q)
—O—C(=O)—CH$_3$		20.9 (q)
—C(=O)—O—CH$_3$	51.9 (q)	

enriched. This spectrum also exhibits induced coupling between C-5 and C-6 (J = 29.1 Hz) and C-10 and C-11 (J = 34.3 Hz). The ^{13}C nmr spectrum of **3***a* obtained from the [2-^{13}C] acetate labelling experiment shows enrichment at C-1, C-3, C-4, C-7, C-9, and at the C-methyl and hydroxymethyl carbons. Again this is as expected for the pathway illustrated in Scheme 1, *except that C-4 is enriched rather than C-5*. Induced coupling between C-3 and C-4 (J = 31.4 Hz) is observed in this case. These findings indicate that a molecular rearrangement is occurring at some point in the transformation of farnesyl pyrophosphate to the sterpurenes.

Many sesquiterpenoid metabolites of fungi of the class Basidiomycetes arise via humulene (**5**) and the so-called protoilludane cation (**6**, Scheme 2) (7). Rearrangement of cation **6** to the bicyclo[3.2.1]octane cation **7**, followed by another 1,2-shift as indicated in Scheme 2 leads to the sterpurane cation **8** in which the labelling pattern is that observed in the labelling studies. Alternatively, the protoilludane cation **6** may undergo rearrangement to the illudane cation **9** which on ring expansion as shown in Scheme 2 also leads to the sterpurane skeleton. Provided that the latter rearrangement is stereoselective, this would also account for the observed labelling pattern. We thus feel that the sterpurenes arise via humulene (**5**) and the protoilludane cation (**6**) by one of the pathways illustrated in Scheme 2.

Finally, it is worthwhile to point out that we have previously suggested that the sterpurane cation **8** may be the precursor of the so-called isolactarane sesquiterpenoids (8).

Experimental

Instrumentation

The ^{13}C nmr spectra were determined in chloroform-d_1 (1% tetramethylsilane as standard) at a concentration of 3.6% w/v for methyl sterpurate (**2***a*) and 5.6% w/v for samples of 12,14-*O*,*O*-diacetylsterpuren-3,12,14-triol (**3***a*) in 5-mm sample tubes using a Bruker WH-400 spectrometer operating in the Fourier transform mode.

Materials

Sodium [1-^{13}C] acetate and sodium [2-^{13}C] acetate (90% enriched) were purchased from Merck, Sharp and Dohme Canada Ltd. Column chromatography was carried out using Macherey Nagel Kieselgel (0.08 mm, 100 g/g substrate). Flash chromatography was carried out using Merck silica gel 60 (0.040–0.063 mm). All compounds for which spectral data are reported showed single spots on tlc using at least two different solvent systems.

*Incorporation of ^{13}C-labelled acetate into sterpuric acid (**2**) and sterpurene-3,12,14-triol (**3**)*

Stereum purpureum (strain C-663, Canadian Forestry Service) was grown in liquid still culture at room temperature in a medium of malt extract (25 g/L), dextrose (13 g/L), and peptone (0.7 g/L) in 2.8-L Fernbach flasks (1 liter of medium per flask). After ten days of growth, sodium [1-^{13}C] acetate (0.082 g, 1 mmol) dissolved in sterile water (5 mL) was injected into each flask. After a further 7, and then 14, days another 1.0 mmol of labelled acetate was injected into each flask. After a total of 30 days of growth the mycelium was removed by filtration and the broth was extracted three times with an equal volume of ethyl acetate. The ^{13}C-enriched samples of sterpuric acid and sterpurenetriol were isolated as previously described (1, 2). Methyl sterpurate (**2***a*) (1) and 12,14-*O*,*O*-diacetylsterpurene-3,12,14-triol (**3***a*) (2) were prepared as previously described.

The experiments with sodium [2-^{13}C] acetate were carried out in the same way as described above for [1-^{13}C] acetate.

Ambident nucleophilic reactivity in σ-complex formation. Part 5.[1] Reaction of 1-phenyl-2,4,6-trinitrobenzene with methoxide and phenoxide ions

ERWIN BUNCEL, SURESH KUMAR MURARKA, AND ALBERT RICHARD NORRIS
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received June 13, 1983

ERWIN BUNCEL, SURESH KUMAR MURARKA, and ALBERT RICHARD NORRIS. Can. J. Chem. **62**, 534 (1984).

The reactions of 1-phenyl-2,4,6-trinitrobenzene (**4**) with methoxide and phenoxide ions in DMSO and DMSO–methanol solutions have been investigated. MeO^- gives rise to a 1,3 adduct through kinetic control and a 1,1 adduct through thermodynamic control. These processes persist also in the reaction of **4** with potassium phenoxide in DMSO–methanol. However, reaction of **4** with potassium phenoxide in DMSO gives rise to a 1,3 adduct as the only observed species in which phenoxide is bonded to the nitroaromatic moiety via the *para* phenoxy carbon, in accord with previous observations on the ambident reactivity of phenoxide ion. The results are considered in terms of various steric and electronic effects and it is concluded that *F*-strain, relief of steric compression, and delocalizability considerations play dominant roles in accounting for the observed reaction course.

ERWIN BUNCEL, SURESH KUMAR MURARKA et ALBERT RICHARD NORRIS. Can. J. Chem. **62**, 534 (1984).

On a étudié les réactions du phényl-1 trinitro-2,4,6 benzène (**4**) avec les ions méthanolates et phénolates en solution dans le DMSO et dans le mélange DMSO–méthanol. L'ion MeO^- donne des adduits 1,3 qui sont des produits de contrôle cinétique et des adduits 1,1 résultant du contrôle thermodynamique. Ce processus se manifeste également dans la réaction du composé **4** avec le phénolate de potassium dans le mélange DMSO–méthanol. Cependant, cette même réaction effectuée dans le DMSO conduit à un adduit 1,3; c'est la seule espèce observée dans laquelle l'ion phénolate est lié à la portion nitroaromatique par l'intermédiaire du carbone en position *para* du groupe phénoxy en accord avec les observations antérieures relatives à l'ion phénolate qui possède deux positions de réaction. On considère ces résultats en fonction des effets stériques et électroniques et on conclut que l'encombrement *F*, la décompression stérique et la possibilité de délocalisation jouent un rôle majeur dans l'évolution de la réaction.

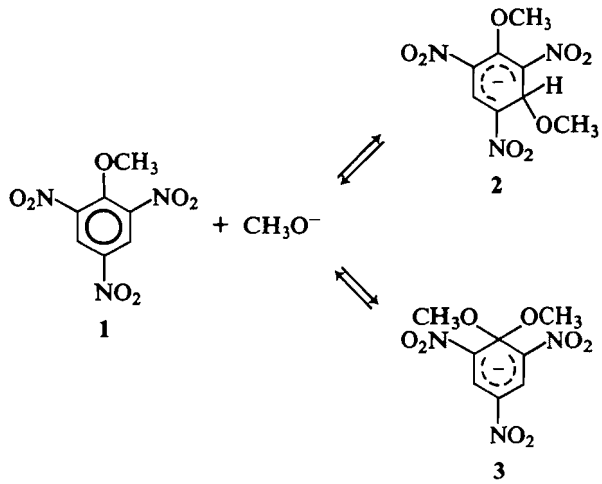
As part of a continuing study on the interactions of nitroaromatic compounds with bases (1–3), in this paper we present results pertaining to the formation of 1,1 and 1,3 σ-complexes and the ambident reactivity of phenoxide ion (4).

Among the various structure–reactivity relationships in σ-complex formation processes (5–11), one which has received considerable attention is the generally observed kinetic preference for 1,3, and thermodynamic preference for 1,1 adduct formation, in the reactions of bases with 1-X-2,4,6-trinitrobenzenes and related substrates. The first instance of this type of result was the discovery by Servis in 1965 (12) through ^1H nmr spectroscopy that 2,4,6-trinitroanisole (TNA, **1**), on reaction with methoxide ion in dimethyl sulfoxide (DMSO) – methanol solution (90:10 v/v), yielded initially the 1,3 adduct (**2**), which then decayed and was replaced by the more stable 1,1 adduct (**3**), Scheme 1.

While in the majority of subsequent studies this trend in kinetic versus thermodynamic control was confirmed, several exceptions have been observed (13–15). Hence it appeared that a unique theory for this phenomenon could not apply and several proposals evolved to account for its origin (*vide infra*). It occurred to us that structural modification could produce useful information and, while use of alkyl substituted nitroaromatics could be considered, study of 2,4,6-trinitrotoluene has shown that alkoxide ion can partake in proton abstraction to give a nitrobenzylic anion in addition to σ-complex formation (16–19). On the other hand, use of 1-phenyl-2,4,6-trinitrobenzene (**4**) would preclude proton abstraction from occurring, while providing a model to test the importance of steric and delocalization effects. In addition to choosing methoxide as the standard nucleophile, we selected phenoxide ion in the expectation that this could act either as an oxygen nucleophile

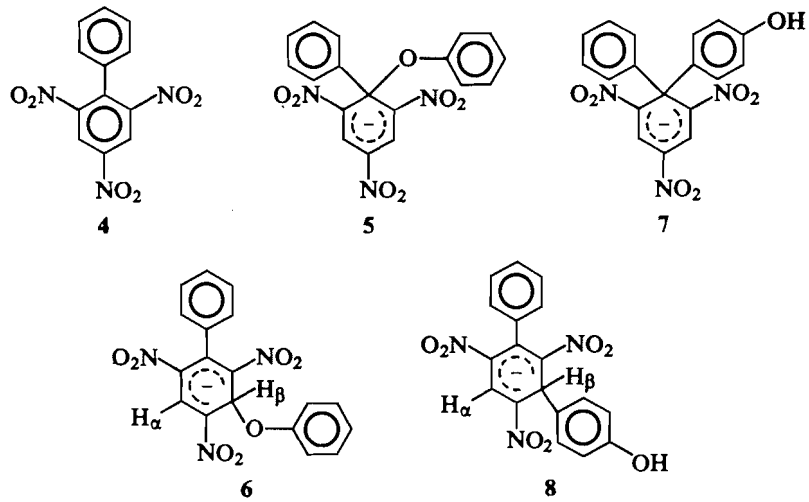


SCHEME 1

to yield **5** and/or **6**, or as a carbon nucleophile to give **7** and/or **8**. The ability of phenoxide to act as an ambident nucleophile towards 1,3,5-trinitrobenzene (TNB) has been reported previously (20–23). Similar observations have been made with naphthoxide (24) and indolide (25) anions.

Previous work on anionic σ-complexes (5–7) has shown that structural characterization of these species can generally be accomplished through ^1H nmr spectroscopy. However, uv–visible absorption spectroscopy can provide valuable supporting evidence, especially in differentiating between bonding via oxygen or via carbon in the case of a potential ambident nucleophile such as phenoxide ion. As will be shown in the following, the results of these studies have in fact allowed complete structural characterization of the σ-complexes formed in the reaction of **4** with methoxide and phenoxide ions as nucleophiles. The significance of the findings is considered.

[1] Parts 3 and 4: see refs. 39 and 40.

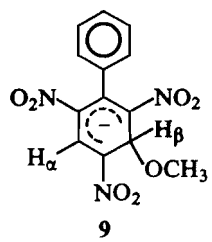


Results

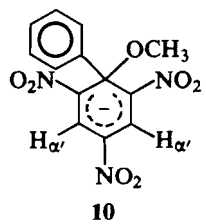
σ-Complex formation between 4 and methoxide

An orange-red colored solution resulted on addition of equimolar methanolic sodium methoxide to **4** in $(CD_3)_2SO$ (final solvent composition, 90:10 v/v $(CD_3)_2SO$/MeOH; reactant concentrations, 0.46 *M*). An nmr spectrum recorded 3 min after mixing showed the absence of a signal at δ 9.10 due to H-3(5) of **4**, and the appearance of new peaks at δ 8.68 (d, J = 1.5 Hz) and δ 6.25 (d, J = 1.5 Hz), integral ratio 1.1:1. An unresolved multiplet centered around δ 7.3 (5H) also present could be ascribed to the phenyl ring protons of the resulting complex. The region below δ 4.5 was blanked out by the solvent. On further monitoring of the spectra with time, the doublets at δ 6.25 and δ 8.68 were found to decrease while a singlet at δ 8.72 increased in intensity; after 8 h only the δ 8.72 singlet was present and had an integral value twice that of the doublets at δ 8.68 and δ 6.25 seen initially.

The above spectral changes can be interpreted as follows. The appearance of two doublets at δ 8.68 and 6.25 is ascribed to the H_α and H_β protons of **9**, while the singlet at δ 8.72 is assigned to $H_{\alpha'}$ of **10**. The chemical shift values observed correspond closely to literature data obtained for these types of protons (5–7). As well, the rapid formation of **9** followed by its slow transformation into **10** is in accord with previous observations on the kinetic preference for formation of 1,3 adducts, and their transformation into the thermodynamically more stable 1,1 complexes.



9



10

Complementary evidence was obtained by following the reaction course through uv–visible spectroscopy. In Fig. 1 are shown the visible absorption spectra, as a function of time, of solutions in DMSO–MeOH (90:10 v/v) obtained by ca. 1000-fold dilution of a reaction mixture having the same composition as in the nmr experiment. It is seen that initially the spectra exhibit absorption maxima at 428 and 506 nm but in time these maxima shift to 436 and 520 nm with a concurrent

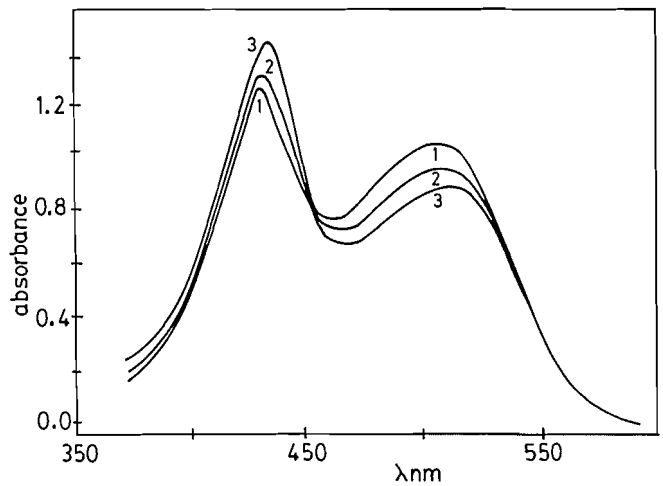


FIG. 1. Ultraviolet–visible absorption spectra as function of time in reaction of 1-phenyl-2,4,6-trinitrobenzene with methoxide ion in DMSO–methanol indicating transformation of 1,3 and 1,1 σ-complexes: (1) 1.5 min; (2) 3.5 h; (3) 24 h.

change in intensities. Addition of acid caused the absorptions to disappear. The acid lability and the general characteristics of these spectra, i.e. two absorptions with the one at lower wavelength the more intense, are typical of methoxide adducts of trinitrobenzene derivatives. Though these spectra do not differentiate between 1,3 and 1,1 adducts, they are, however, in complete agreement with our assignment. It is also of interest that, in the majority of systems studied in the past, the 1,3 adduct was formed as a transient intermediate whose visible spectrum could only be reconstructed through repeated stopped-flow experiments performed as a function of wavelength. Thus the present system appears to be one of the few where the spectrum of the metastable species, as well as its transformation, were readily measurable by standard spectrophotometric techniques.

Another estimate of the relative stabilities of the complexes **9** and **10** was obtained as follows. The diluted solutions whose spectra are given in Fig. 1 were kept in the dark for 24 h, following which the spectra were again recorded. The resulting spectra correspond exactly, in the positions of the absorption maxima and their relative intensities, to the final spectrum shown in Fig. 1. Thus the 1,3 adduct **9** decomposed on standing, while the 1,1 adduct **10** was completely stable for the extended period of time.

σ-Complex formation by phenoxide ion

Due to the ambident nature of phenoxide ion, its reaction with **4** can potentially lead to the formation of both oxygen-bound and carbon-bound σ-complexes. The use of nmr and electronic absorption spectroscopy, when coupled with other properties such as stability (or lack of) to acidification, enables one to differentiate among the various possibilities.

The nmr spectrum of a solution of **4** and potassium phenoxide in $(CD_3)_2SO$ (final concentrations 0.49 *M* and 0.57 *M*, respectively), when recorded immediately on mixing and then monitored with time, was found to exhibit no further changes during the next 24 h. A typical spectrum showed two somewhat poorly resolved doublets at δ 8.60 and δ 5.65 with integral ratios of 1.1:1.0. A complex multiplet between δ 6.2 and δ 7.8 was also present, arising from the phenyl protons in the complex as well as any excess phenoxide ion that was present.

The appearance of the doublets at δ 8.60 and 5.65 is indicative of the formation of a 1,3 complex but not of a 1,1 complex. The two possibilities consistent with these features are the O-bound complex **6** and the C-bound complex **8**. The following considerations serve to differentiate between these possibilities. The shielding of the H_β protons in **6** and **8** will depend on the electronegativity of the atom bonded to C-3. On the basis of literature data (5–7), one would expect δ values close to 6.2 for **6**, and 5.7 for **8**. The observed value, δ 5.65 for the resonance assigned to H_β, is thus in accord with complex **8**. Furthermore, literature data indicate that the difference in the H_α and H_β shieldings for O-bound complexes lies between 2.2 and 2.6 ppm, whereas for C-bound complexes this value is ~3.0 ppm. The observed value in the present case is 2.95 ppm, which again favors structure **8**.

Further evidence concerning the nature of the complexes was obtained from their uv–visible spectral characteristics. When the reaction between **4** and PhOK in DMSO was monitored by uv–visible spectroscopy, a characteristic spectrum was obtained immediately on mixing and then underwent no further changes for the duration of the experiment (24 h), as had previously been found in the nmr experiment. The resulting spectrum exhibited maxima at 465 and 556 nm, the former being the more intense. From literature data (5–7) one would predict that for an O-bound complex the two absorption maxima should lie in the region of 430 and 495 nm, which is not in accord with the present result. In the case of the C-bound phenoxide adduct of TNB (20), the corresponding absorption maxima occurred at 468 and 570 nm (broad). Thus the uv–visible spectra are strongly indicative of the formation of a carbon-bound complex, **8**, rather than an oxygen-bound complex, **6**. Assuming that the molar extinction coefficient of **8** is of the same order of magnitude as that of the phenoxide adduct of TNB, one estimates that **8** was formed in ~25% yield.

Acidification of the solutions from the reaction of **4** with phenoxide caused no change in the spectrum of the resulting solution. This result rules out the possibility of formation of an O-bound complex since such species are known to be destroyed by acid. Thus the evidence from nmr and uv–visible spectroscopy fully supports structure **8** for the phenoxide complex of **4**.

A contrasting result from the TNB–phenoxide system was found when the reaction of **4** with potassium phenoxide was conducted in DMSO–methanol (80:20 v/v). In the TNB system it was found (20) that reaction gave rise immediately to the TNB–methoxide σ-complex, through solvolysis, which was then slowly transformed to the TNB–phenoxide adduct. When the reaction was performed with **4** and followed by both nmr and uv–vis spectroscopy, as above, it was found that the methoxide complex **9** was immediately obtained and was replaced over 1 h by **10**, which then remained stable over an extended period (24 h). Thus formation of the C-bounded phenoxide adduct was not detected in this system. The significance of this result will be considered further in the following discussion.

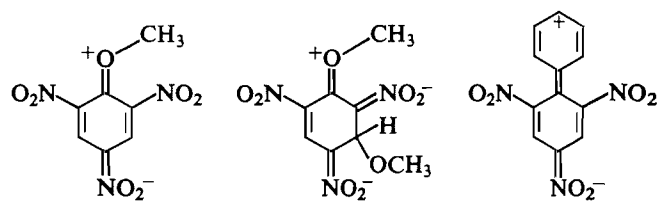
Discussion

Steric and electronic effects in σ-complex formation

A number of theories have been proposed to explain the origin of the generally observed kinetic preference for 1,3 adduct formation and the thermodynamic preference for 1,1 adduct formation (26–29). The nitroaromatic substrate under investigation in this study differs structurally from compounds previously investigated in σ-complex formation, which enables us to critically assess the various proposals, as discussed under the five headings below.

1. *Resonance stabilization involving alkoxy and nitro groups*

Resonance structures involving conjugation between the methoxy and nitro functionalities could potentially contribute towards stabilization of the reactants as well as products in nitroaromatic–base interactions. Thus contribution by structures **1***a* and **2***a* would serve to stabilize the ground state of TNA (**1**) and the 1,3 adduct (**2**), respectively, but this interaction would no longer be possible in the 1,1 adduct (**3**). The transition state leading up to **2** could similarly benefit from this stabilization, but not that for formation of **3**. Therefore the transition state for 1,3 adduct formation would be effectively lowered in energy relative to that for 1,1 adduct formation.

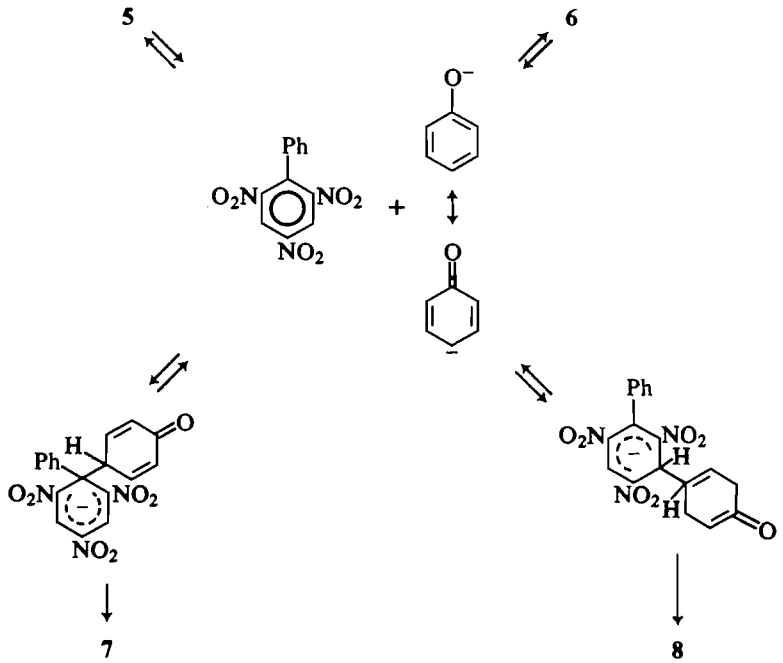


1*a* **2***a* **4***a*

In the present system, for ground state stabilization to be effective, one would have to invoke structure **4***a* as a contributing form. However, it could be expected that the phenyl group in **4** would be disposed substantially out-of-plane relative to the TNB ring, noting that one *ortho* nitro group in biphenyl derivatives results in an angle of rotation between the two rings of the order of 50–60° (30–32). On this basis, the extent of contribution by **4***a* would be minimal. One can hence effectively eliminate this possibility as a source of the kinetic preference for 1,3 adduct formation in this system.

2. *Geminal alkoxy substitution as a stabilizing effect*

Multiple substitution by electronegative groups at an sp^3 carbon center is recognized as a stabilizing electronic influence through a negative type of hyperconjugation (33, 34), and this has been considered to contribute to the greater stability of 1,1 relative to 1,3 dimethoxy complexes. However, although the phenyl group can be considered as an electron-withdrawing substituent, it appears unlikely that this could assume a role similar to OMe, F, etc. since resonance structures involving a phenyl anion would be prohibitively high in energy. It is also noted that in the case of attack by CN^- on TNA, the 1,1 adduct was found to be of lower stability than the 1,3 adduct (13),



SCHEME 2

which could indicate that two unlike electron-withdrawing substituents are not effective in stabilizing σ-complexes by this type of mechanism.

3. *Structural effects on delocalizing ability*

A variety of evidence points to the fact that, in σ-complex formation by 1-X-2,4,6-trinitrobenzene, negative charge is predominantly delocalized onto the nitro group which is *para* with respect to the formed sp^3 carbon center. In 1,1 adduct formation, this *para* nitro group bearing negative charge can achieve maximum coplanarity with respect to the overall π electron system. However, in a 1,3 complex, the NO_2 situated *para* to the sp^3 carbon is also *ortho* to the substituent X, which will result in deviation from coplanarity depending on the degree of steric interaction between X and NO_2. In the present system, steric inhibition of resonance should be of considerable importance due to the large steric requirement of the C-1 phenyl, thus leading to stabilization of the 1,1 adduct **10** relative to the 1,3 adduct **9**.

4. *Relief of steric strain*

A substituent X in 1-X,2,4,6-trinitrobenzene will tend to cause the *ortho* nitro groups to deviate from coplanarity with the ring as a result of steric compression. For example, in 1-ethoxy-2,4,6-trinitrobenzene, the 2- and 6-nitro groups are rotated from the ring plane by 32° and 61° respectively (35). Formation of the σ-complex results in relief of this steric interaction as the C-1 centre becomes tetrahedral. In the present system, the phenyl ring in **4** could be expected to be substantially out-of-plane relative to the TNB ring and there can only be slight relief of this type of steric strain on formation of the 1,1 adduct. However, there will nevertheless be an appreciable increase in librational motion compared to the reactant where rotation about the C-1 bond should be severely restricted. This effect will serve to stabilize the 1,1 adduct relative to the 1,3 adduct since in the latter case this relief of steric strain would not arise.

5. F *strain*

Formation of a 1,1 adduct will in general be subject to greater steric hindrance (*F* strain) in the approach of the nucleophile compared to formation of a 1,3 adduct. Since the nucleophile will approach from a direction perpendicular to the TNB ring plane, this effect will be particularly important in the present system owing to interaction between the approaching nucleophilic reagent and the phenyl group at C-1. On the other hand, attack at C-3 will be relatively unhindered, thus favoring 1,3 adduct formation. We conclude that *F*-strain is probably a dominant factor leading to kinetic preference for 1,3 adduct formation in this system.

The ambident reactivity of phenoxide ion

The results obtained in the reaction of **4** with phenoxide can be discussed in relation to Scheme 2 which considers both oxygen-bound and carbon-bound σ-complexes. Of the various possibilities shown in this scheme, the pathway leading to formation of **8** is the only one which was detected in the PhOK/DMSO system. The finding of the C-bonded adduct is in agreement with the results obtained by us previously for the TNB/PhOK/DMSO system (20), but contrasts with the report of Shein *et al.* (22, 23) that reaction of TNB gives rise initially to the O-bonded phenoxide adduct observable by standard nmr techniques. On the other hand, 2,4,6-trimethylphenoxide ion was found by us to react with TNB to give the O-bonded σ-complex (21).

When the present reaction was performed in DMSO–MeOH (80:20 v/v) we observed the formation, through solvolysis, of the methoxy complexes **9** and **10** as the intial and final products of reaction, respectively. A phenoxy complex was not obtained in this system, contrasting with the course of reaction observed with TNB under corresponding conditions (20).

It has been shown by Bernasconi and Muller (15), using fast reaction techniques (stopped flow and T-jump), that the reaction of TNA with phenoxide ion in DMSO–water media gives rise in a rapid process to the O-bonded 1,1 phenoxide adduct as a transient species which is then converted to the 1,3 hydroxide adduct of TNA. Comparison with the results for reaction of MeO^- with TNA showed that PhO^- attack (H_2O) is faster than MeO^- attack (MeOH) by a factor of 2.9, but PhO^- expulsion is faster by 4.5×10^6, with the result that the equilibrium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

constant for 1,1 phenoxide adduct formation is smaller than for 1,1 methoxide adduct formation by 1.5×10^6.

Our own observation, that in the PhOK/DMSO–MeOH system MeO^- attack on **4** is preferred over PhO^- attack, contrasts with Bernasconi's report (15) that $k_{PhO^-} > k_{MeO^-}$ for reaction with TNA, although the different time scales of the two studies could affect the overall result. It could thus be possible that, at extremely short reaction times, attack by PhO^- to form an O-bonded complex might be detected in our system as well, and that the observed result is the outcome of a secondary rather than a primary process. However, our observation in the PhOK/DMSO–MeOH system of the initial 1,3 and subsequent 1,1 MeO^- adduct formation, with the latter *not* replaced by a C-bonded phenoxide adduct, is remarkable in view of the contrasting result observed in the TNB/PhOK/DMSO–MeOH system (20), and may reflect widely different stabilities of the MeO^- adducts in the two cases.

Perhaps the most significant difference between the present work and the results obtained by Bernasconi (15) is that attack by PhO^- on TNA occurs preferentially at C-1 whereas PhO^- attacks **4** at C-3. Presumably attack by phenoxy oxygen at C-1 of **4** to give **5** would be subject to steric interactions fairly comparable to those for attack by MeO^-, although attack at C-1 of **4** through carbon of phenoxide to give **7** would be sterically much less favorable. This result further demonstrates the importance of *F*-strain in the present system. It appears that this factor overrides the delocalizability criterion which normally results in 1,1 adducts being thermodynamically more stable than 1,3 adducts.

Conclusions

The study has shown that the title compound **4** reacts with phenoxide ion in DMSO to form a carbon-bonded σ-complex **8** through an irreversible process, whereas oxygen attack by phenoxide would occur reversibly (Scheme 2). This is in accord with our previous observations with TNB (20). In contrast to the observations with TNB, reaction of **4** with potassium phenoxide in DMSO–methanol gives rise, through solvolysis, only to the 1,3 and 1,1 methoxy adducts **9** and **10**, formed sequentially. Under the same conditions, TNB gave rise first to the methoxy adduct and then, in a slower process, to the phenoxy adduct. The ease of formation of the 1,1 methoxy adduct of **4** indicates that **4** reacts in a conformation in which the C-1 phenyl and the C-2,6 nitro groups are oriented in a propeller-like configuration, thus minimizing steric hindrance to approach of the nucleophile. The σ-complex formation reaction is expected to occur through an early transition state, as should be the case also for S_NAr processes (36, 37) in highly activated nitroaromatics such as 1-X-2,4,6-trinitrobenzene derivatives where X is a bulky substituent ($C_5H_5N^+$, SO_2Ph, etc.).

While reaction of **4** with methoxide ion gives rise to the 1,3 adduct **9** and the 1,1 adduct **10** through kinetic and thermodynamic control, as in the case of TNA, the two sets of observations differ in origin. Dominant factors in the present system are believed to be the delocalizing ability of *para* nitro substituents in absorbing of negative charge, *F*-strain with respect to approach of nucleophile, and the relief of steric compressions in the ground state in passing to the transition state for σ-complex formation.

Experimental

Materials and methods

Dimethyl sulfoxide was distilled from calcium hydride under nitrogen at reduced pressure. Methanol was distilled from magnesium metal. Potassium phenoxide was prepared according to Kornblum and Lurie (4). Sodium methoxide solutions were prepared from freshly cut sodium metal and methanol, or methanol-O-*d*, and standardized before use. DMSO-d_6 was dried before use over molecular sieves.

1-Phenyl-2,4,6-trinitrobenzene (**4**) was prepared by the Ullmann synthesis from picryl chloride, iodobenzene, and copper bronze using the method described by Gull and Turner (38). The product, recrystallized from ethanol, was obtained as pale yellow needles, mp 129° (lit. (38) mp 130°C); nmr $(CD_3)_2SO$, δ: 9.12 (s, 2H), 7.22–7.56 (m, 5H).

The nmr spectra were recorded on a Varian EM360 or HA100 spectrometer. Chemical shifts are given in ppm downfield from tetramethylsilane (TMS) used as an internal standard. Ultraviolet–visible spectra were recorded on a Unicam SP800B spectrophotometer.

*Reaction of **4** with methoxide ion in DMSO–MeOH*

For the nmr experiments, reaction solutions were prepared by addition of NaOMe/MeOH to **4** in $(CD_3)_2SO$, giving a solution 0.46 *M* in **4** and in NaOMe, and a solvent composition 90:10 (v/v) DMSO–MeOH. Visible spectra were taken following 7×10^3 dilution with DMSO of reaction solutions with concentrations of **4** and NaOMe of same order as in the nmr experiments. The uv–vis spectra were recorded immediately on dilution and again after standing for 1 day.

*Reaction of **4** with potassium phenoxide in DMSO*

The $(CD_3)_2SO$ solution in the nmr experiment was 0.49 *M* in **4** and 0.57 *M* in PhOK. Ultraviolet–vis spectra were obtained following 3×10^3 dilution. To test the reversibility of complex formation, 3 mL of the diluted solution was acidified with 50 μL 1 *N* HCl and the uv–visible spectrum recorded.

*Reaction of **4** with potassium phenoxide in DMSO–MeOH*

The experiments were performed as above but the solution in the nmr experiment was prepared using $(CD_3)_2SO$ and methanol-O-*d* (80:20 v/v). The concentration of PhOK was varied between 0.51 and 0.98 *M* while keeping **4** constant at 0.46 *M*.

Aminosulfonic acids. Part 1. Crystal structures of *N*-methylaminomethanesulfonic acid, $MeNHCH_2SO_3H$, and disodium *N*-methyliminobis(methanesulfonate) dihydrate, $MeN(CH_2SO_3Na)_2 \cdot 2H_2O$

T. STANLEY CAMERON, WALTER J. CHUTE, AND OSVALD KNOP[1]

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received May 30, 1983

T. STANLEY CAMERON, WALTER J. CHUTE, and OSVALD KNOP. Can. J. Chem. **62**, 540 (1984).

The crystal structure of *N*-methylaminomethanesulfonic acid ($P2_12_12_1$, a = 5.455(1) Å, b = 7.791(1) Å, c = 11.925(2) Å, Z = 4) consists of $^+MeNH_2CH_2SO_3^-$ zwitterions hydrogen-bonded to form infinite chains about screw axes parallel to a. In the structure of $MeN(CH_2SO_3Na)_2 \cdot 2H_2O$ (*Pbcn*, a = 10.469(1) Å, b = 6.039(3) Å, c = 17.549(3) Å, Z = 4), layers of $MeN(CH_2SO_3^-)_2$ anions alternate with layers of Na^+ ions parallel to (001). The anions are linked by O—H···O bonds between the water molecules and the O(2) atoms of the sulfonate groups. Because of the twofold orientational disorder of the N—CH_3 groups the space group *Pbcn* is only statistical.

The S—C, C—N, and S—O bond lengths in solid aminosulfonic acids and their salts are discussed with a view to detecting the existence of effects due to deprotonation of the amino group and to hydrogen bonding.

T. STANLEY CAMERON, WALTER J. CHUTE et OSVALD KNOP. Can. J. Chem. **62**, 540 (1984).

La structure cristalline de l'acide *N*-méthylaminométhanesulfonique ($P2_12_12_1$, a = 5,455(1) Å, b = 7,791(1) Å, c = 11,925(2) Å; Z = 4) consiste en des zwitterions $^+MeNH_2CH_2SO_3^-$ liés par des liaisons hydrogène; ces liaisons forment des chaînes infinies autour des axes hélicoïdaux parallèles à a. Dans la structure du $MeN(CH_2SO_3Na)_2 \cdot 2H_2O$ (*Pbcn*, a = 10,469(1) Å, b = 6,039(3) Å, c = 17,549(3) Å; Z = 4), les couches d'anions $MeN(CH_2SO_3^-)_2$ alternent avec des couches d'ions Na^+ parallèles à (001). Les anions sont liés par des liaisons O—H···O entre les molécules d'eau et des atomes d'oxygène O(2) des groupes sulfonates. La symétrie *Pbcn* n'est que statistique du fait que deux orientations alternatives équivalentes sont disponibles à chaque groupe N—CH_3.

On discute des longueurs des liaisons S—C, C—N et S—O des acides aminosulfoniques solides et de leurs sels dans le but de déceler l'existence d'effets dûs à le déprotonation du groupe amino et à la liaison hydrogène.

For personal use only.

The main aim of this series of investigations is to study, by X-ray and nmr methods, some of the changes which free aminosulfonic acids undergo on deprotonation of the amino group, i.e., on conversion of the zwitterion to the corresponding sulfonate anion.

The effect of the deprotonation on bond lengths is a natural object of attention. In principle, it can be followed in a straightforward manner by determining and comparing pairs of structures, the structure of the free acid with that of one of the corresponding normal (i.e., non-chelated, preferably alkali) salts. However, for reasons to be discussed in more detail in a subsequent paper of this series, the alkali salts of aliphatic amino acids in general are notoriously difficult to obtain in the solid state.[2] In the specific case of the aminoalkanesulfonic acids, the simplest member of that class, sulfamic acid, presents little problem in this regard as its salts can be readily obtained, but this is not so with its homologues. Condensation of $^-O_3S(CH_2)_nNRH_2^+$ (R = H or alkyl) to $NR[(CH_2)_nSO_3^-]_2$ tends to take place in aqueous solution at high pH, with the result that the alkali salt obtained on crystallization is that of the dibasic anion instead of the desired $RNH(CH_2)_nSO_3^-M^+$. The existence of this process seriously hinders the prospect of determining the effect of deprotonation by direct comparison of zwitterion/anion pairs, since it renders the required "monomer" salt inaccessible. However, the effects of deprotonation associated with the formation of the $NR[(CH_2)_nSO_3^-]_2$ anions are equally little known, and as no structure containing these sulfo analogues of the iminodicarboxylate anions appears to have been reported, it seemed worthwhile to compare the molecular structures and dimensions of at least one such zwitterion/iminodisulfonate anion pair.

In the following, $^+MeNH_2CH_2SO_3^-$ is compared with the $MeN[CH_2SO_3^-]_2$ anion as present in the dihydrate of the disodium salt, and the structure features of these two species are further compared with those of the aminosulfonic acids and their salts that have been investigated to date.

Experimental

The preparation of all the compounds used in this series of investigations (including the two title compounds) will be described in Part 2.

A CAD-4 diffractometer was used in the determination of the unit-cell dimensions and to collect intensities (θ = 2–25°). The intensities were reduced by routine procedures (2). Lorentz and polarization factors were applied but not absorption or extinction corrections. The scattering factors for neutral atoms were taken from ref. 3. The structures were solved by the heavy atom method using the SHELX system (4). Full-matrix least-squares ($w\Delta F^2$ = minimum) refinements were carried out with isotropic temperature factors on heavy atoms until R was reduced to a suitably low value. After appropriate intervention (see below) the refinements were continued with anisotropic temperature factors on the non-hydrogen atoms and isotropic factors on the hydrogens until the final R values (Table 1). Least-squares weights were calculated from expressions of the type $w^{-1} = \sigma|F_o| + kF_o^2$, where σ is the weight for an individual reflection derived from the diffractometer counting statistics and k is a refined variable. The anisotropic temperature factor is defined as $T = \exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{23}klb^*c^* + 2U_{13}hla^*c^* + 2U_{12}hka^*b^*)]$.

The crystal data and particulars of the refinements are listed in Table 1.

$MeNHCH_2SO_3H$

The crystal used in the determination was 0.3 × 0.3 × 0.4 mm^3 in size. In the late stages of the refinement the bond lengths and angles

involving H atoms were constrained (4) to be chemically reasonable: C—H at 1.08(2) Å, N—H at 1.02(2) Å, and the bond angles at the appropriate near tetrahedral values. The CH_2 and CH_3 groups were refined as rigid bodies. No other geometric restrictions were placed on the molecule.

The positional and thermal parameters are listed in Table 2, structure factors in Table 3,[3] and interatomic distances and bond angles in Table 4.

$MeN(CH_2SO_3Na)_2 \cdot 2H_2O$

The size of the crystal used was 0.4 × 0.3 × 0.8 mm^3. As in the case of $MeNHCH_2SO_3H$, the C—H bond lengths and bond angles were constrained in the later stages of the refinement. However, the twofold orientational disorder of the N—C_{Me} groups (see below) imposed these additional constraints: C_{CH_2}—N at 1.47(1) Å (in analogy with $MeNHCH_2SO_3H$), N—C_{CH_3} at 1.50(1) Å, and the C—N—C angles at 110(2)°.

The positional and thermal parameters are listed in Table 5, structure factors in Table 6,[3] and interatomic distances and bond angles in Table 7.

Description of the structures

$MeNHCH_2SO_3H$

As would be expected, the structure consists entirely of the zwitterions $^+MeNH_2CH_2SO_3^-$. These are arranged in chiral symmetry ($P2_12_12_1$) and are joined by hydrogen bonds involving the O(1) and O(2) oxygens and both N-hydrogens to form infinite chains about screw axes parallel to the a-axis. One of the hydrogen bonds (N(C)—H(2C)···O(1A″) in Fig. 1) is nearly straight, with an H···O separation of only 1.76 Å (Table 4). The bond involving H(1) is nominally trifurcated, but two of the H···O distances are much longer than the third (2.47 and 2.51 as against 1.97 Å) and the NHO angle corresponding to the largest of these H···O distances is only 102°. This angle would correspond to an intramolecular hydrogen bond between H(1) and O(1), but in view of its smallness and of the considerable H···O distance the H(1)···O(1) interaction must be very weak.

The only hydrogen-bond interaction between the infinite zwitterion chains is through one of the components of the trifurcated N—H(1)···3O bond, involving the H(1) atoms of one chain and O(3) atoms of the adjacent chains. The interchain H···O distance is only 2.47 Å and the NHO angle, 117°. The trifurcated bond might thus be more correctly viewed as a

[a] Librational corrections for distances involving two non-hydrogen atoms do not exceed 0.002 Å and are thus entirely within the stated esd's.

highly-bent (NHO = 133°) rather than a trifurcated hydrogen bond.[4]

Some of the $H_C\cdots O$ distances are quite short, the shortest being 2.48 Å (Table 4). The organization of the structure resembles in its main features that reported for ^{+}i-$PrNH_2CH_2SO_3^{-}$ (7).

$MeN(CH_2SO_3Na)_2\cdot 2H_2O$

The structure consists of layers of $MeN(CH_2SO_3^{-})_2$ anions alternating with layers of Na^{+} ions parallel to (001) (Fig. 2). The anions are linked by the water molecules through $O_w—H\cdots O_S$ hydrogen bonds to the O(2) atoms. Each H_2O is four-coordinated, more or less tetrahedrally, by two O(2) atoms and two Na^{+} ions (Fig. 3). The Na^{+} ion is surrounded by two O_w and four O_S atoms to form an irregular $NaO_4(H_2O)_2$ octahedron; the two H_2O oxygens are *cis*, as are the two O(1) and the two O(3) atoms (Na(D), O(1D), O(1F), O(3B), O(3F′), O(4D), and O(4H) in Fig. 2).

The space group symmetry requires the anion to have the symmetry C_2. However, the N atom of an individual anion is not on a twofold axis, consequently the $N—C_{Me}$ bonds in the crystal are orientationally disordered (Fig. 2). The existence of the disorder is consistent with the expected sp^3 geometry at the N atom. The CH_3 group and the two O(1) oxygens of an anion are *cis* to the N atom; the O(2) and O(3) pairs are coplanar ‖ (010) on the opposite side of N.

Since the anion was refined in its average, pseudo-C_2 conformation, only the average bond lengths and angles can be calculated. Specifically, the effect of the CH_3 group on O(1) will not be the same as that of the lone pair on the N atom. The shortest (average) $H_{Me}\cdots O(1)$ distances (Fig. 2) are quite different, H(22)···O(1A) ~ 2.7 Å, H(21)···O(1B) ~ 3.2 Å, which makes the significance of the value of the S—C(1)—N angle, 126° (Table 7), uncertain. Similarly, the N—C(1) and N—C(2) bond lengths and the C(1)—N—C(1) angle must be interpreted with caution, especially when attempting comparison between the dimensions of the zwitterion and the anion.

Nevertheless, it is found that the C(1)—N—C(1) angle of ~115° is, perhaps not surprisingly, in the range of C—N—C angles reported for iminodiacetic acid and its salts, 109–116° (refs. 8 and 9 and further references therein). Furthermore, the S—C bond length, 1.797(5) Å, coincides with the mean of the S—C bond lengths in the aminosulfonic acids and their salts listed in Table 8, 1.791(29) Å, and there is no indication from these data that a class difference in d(S—C) exists between the zwitterions and the anions. The S—C(1)—N angle of 126°, which is significantly larger than the corresponding angles in $^{+}MeNH_2CH_2SO_3^{-}$, ^{+}i-$PrNH_2CH_2SO_3^{-}$ and the two Na salts **15**

[4] This situation is reminiscent of taurine, $^{+}H_3N(CH_2)_2SO_3^{-}$, where H(7) is involved in a bifurcated bond, $H(7)\cdots O(3)_{intra}$ ~ 2.3 Å (NHO ~ 133°), $H(7)\cdots O(3)_{inter}$ ~ 2.4 Å (NHO ~ 132°) (5). The stretching frequency of the N—H(7) bond exhibits a temperature dependence characteristic of strongly bent hydrogen bonds (6).

and **16** of Table 8, 110–114°, and even than the S—C—S angle in $CH_2(SO_3^-)_2$, 116–120° (10, 11), may be the consequence of the *cis*-O(1), CH_3 conformation of the anion (see above). It may be noted that the P—O—C angle in **23** is also quite large, 119° (12).

Discussion of bond lengths

S—C bond lengths

The S—C bond lengths in the two title compounds are indistinguishable. Furthermore, there is no indication from the available evidence (only two salts, cf. Table 8) that a class difference exists between the free-acid zwitterions and the sulfonate anions. A more definite statement on this point can only be made when direct comparisons are available for matching $^+H_3N\cdots SO_3^-/H_2N\cdots SO_3^-$ pairs. At present it would seem that any zwitterion/anion difference that may exist will be absorbed in the d(S—C) variation due to the *chemical* differences between zwitterions and to the bond-length uncertainties of the individual structure determinations.

S—O bond lengths[5]

By itself, comparison of d(S—O) in the two title compounds is not illuminating, although the S—O bond length involving the non-hydrogen-bonded oxygen O(3) in $^+MeNH_2CH_2SO_3^-$ appears to be slightly shorter than the corresponding S—O(1) and S—O(3) bond lengths in the Na disulfonate. On the other hand, the shorter hydrogen-bonded S—O(2) bond in the zwitterion is shorter than the hydrogen-bonded S—O(2) bond in the disulfonate anion, but then the particulars of the two hydrogen bonds are different.

To obtain a clearer idea of the effect of hydrogen bonding on d(S—O) it is necessary to extend the comparison to other aminosulfonic acids. Table 9 lists the d(S—O) values (uncorrected for thermal motion)[6] in all the ω-aminosulfonic and related acids and their salts we have found in the literature. In some of the structures one (or even two) of the oxygens can be clearly identified as non-hydrogen-bonded, while in others all three oxygens engage in hydrogen bonding. The unbiased means of the S—O bond lengths are as follows (with the number of values in brackets):

All values [72]	1.450(14) Å
Oxygen clearly identified as non-hydrogen-bonded [10]	1.451(8) Å
Oxygen clearly identified as hydrogen-bonded [26][7]	1.455(11) Å

From these means we cannot conclude that hydrogen bonding produces a lengthening of the S—O bond. However, if the comparison is restricted to those structures in which both hydrogen-bonded and non-bonded oxygens are known to be simultaneously present (nine determinations in all), then the following result is obtained:

Oxygen non-hydrogen-bonded [10]	1.451(8) Å
Oxygen hydrogen-bonded [17]	1.460(7) Å

Analysis of variance as well as a paired t test show that the hypothesis that these two sample means come from the same population can be rejected at the 0.5% significance level. Thus for the self-consistent sets of d(S—O) determinations the available evidence strongly suggests that there is a class effect, i.e., hydrogen bonding causes the S—O bonds in the aminosulfonic acids and their salts to be lengthened.

[5] In the following, *sample* standard deviations of the unweighted means are quoted in parentheses.

[6] Librational corrections for the three S—O bonds in $^+MeNH_2CH_2SO_3^-$ amount to 0.001 Å (cf. Table 4). This order of magnitude may be taken as representative of the corrections for the S—O bonds listed in Table 9.

[7] When determinations by photographic methods are not included, the mean is 1.457(10) Å.

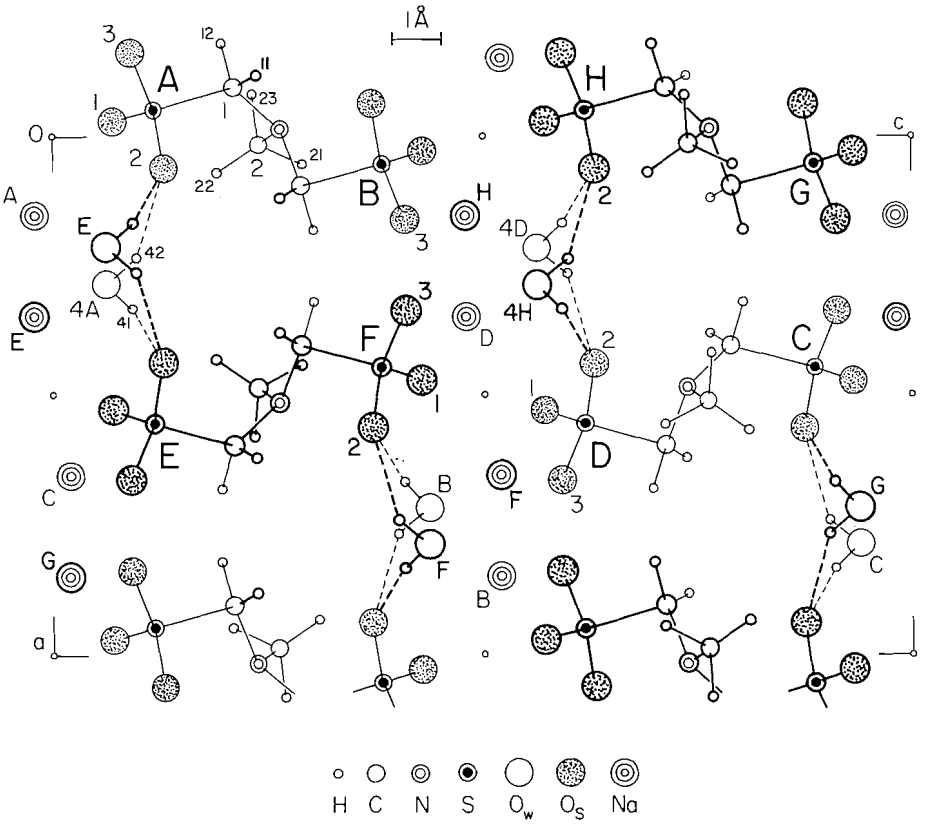

FIG. 2. Projection of the $MeN(CH_2SO_3Na)_2 \cdot 2H_2O$ structure on (010). Note the twofold orientational disorder of the N—CH_3 groups with respect to the twofold axes (parallel to *b*, midway between the C(1) atoms). O_w—H···O_S hydrogen bonds are indicated by dashed lines, centres of symmetry by the smallest circles. For symmetry code, interatomic distances and bond angles see Table 7.

The data of Table 9 are insufficient in number and quality for an investigation of the possible existence of a class difference between the zwitterions and the anions. Nevertheless, a weak indication that such a difference *may* exist is obtained when the above set of ten S—O bond lengths involving non-hydrogen-bonded oxygens is split into a subset of six (zwitterions) and one of four (sulfonate anions). The respective sample means are 1.446(4) and 1.459(6) Å. These are different at the 0.5% significance level, suggesting the order of magnitude to be expected if the class difference proves to be real.

C—N bond lengths in the S···N chains

The *d*(C—N) value in $^+MeNH_2CH_2SO_3^-$, 1.473(3)Å, is within 1σ of the unbiased mean for the zwitterions of Table 8 (excluding **7**), 1.483(17) Å. The corresponding value in $MeN(CH_2SO_3^-)_2$, 1.447(5) Å, is lower, but the difference must be viewed with caution because of the uncertainties in the positional parameters resulting from having to refine a structure containing orientational disorder.

The only two salts in Table 8 that can be contrasted with the zwitterions, **15** and **16**, have a *d*(C—N) mean, 1.423(5) Å, indisputably lower than the mean for the zwitterions. However, the comparison is not informative on the effect of deprotonation. The bond shortening is undoubtedly due to the aromatic substitution at the nitrogen, similar to that in the zwitterion **7**, and is consistent with the observed C—N—C_{Ph} angles in **15** and **16**, ~122° and ~126° respectively, which are larger than the corresponding C—N—C_{alkyl} angles in the other compounds, ~113–~116°, and with the N—C_{Ph} bonds in **15** and **16**, which are significantly shorter than the corresponding N—C_{alkyl} bonds.

The question of whether the C—N bond length in the zwitterionic acids undergoes observable change on deprotonation of the amino group thus remains unanswered.

Comparison of aminoalkanesulfonic and aminoalkanephosphonic acids

Only the zwitterion forms (Table 8) can be compared, as no phosphonate structures appear to have been determined.

The means of the uncorrected S—C and P—C distances are statistically indistinguishable, 1.799(34) Å as against 1.813(8) Å. Similarly, the means of the C—N bond lengths in the two classes of acids are statistically not different, 1.491(11) Å compared with 1.495(16) Å. However, comparing only $^+H_3N(CH_2)_nSO_3^-$ and $^+H_3N(CH_2)_nPO_3H^-$, $n = 1-3$, and using $^+MeNH_2CH_2SO_3^-$ instead of $^+H_3NCH_2SO_3^-$ (the structure of which has not been reported), the means are 1.778(16) Å for S—C and 1.811(6) Å for P—C, and these are significantly different at the 5% level. Clearly, both a more extensive and more accurate set of bond lengths would be required to estimate the actual difference between the mean values of *d*(S—C) and *d*(P—C) in the two groups of acids.

The means of the C—N bond lengths in the two classes of zwitterions, 1.483(17) Å and 1.495(16) Å, are statistically indistinguishable. The P—O distances have not been scrutinized.

Concluding remarks

Analysis of the currently available bond lengths leads to

[a] The esd's of the original papers are given in parentheses. For numbering of compounds and references see Table 8.

disappointing results, in that the volume of data and the assortment of compounds are not adequate to permit definite conclusions about the effect of deprotonation of the amino group. This is in striking contrast with the effect of deprotonation and condensation on the S—N bond length and on bond angles in sulfamic acid (Table 8), where the reasons for the large variation have been discussed, in terms of the presence or the absence of a d_π–p_π overlap, by Cruickshank (11).

Alternaric acid. Proof of biosynthesis via condensation of two polyketide chains. Complete assignment of the ^1H and ^{13}C magnetic resonance spectra by 2D techniques[1,2]

ALBERT STOESSL AND J. B. STOTHERS

London Research Centre, Agriculture Canada and the Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received August 12, 1983

ALBERT STOESSL and J. B. STOTHERS. Can. J. Chem. **62**, 549 (1984).

Incorporation studies utilizing [1,2-$^{13}C_2$]acetate have established that the fungal phytotoxin alternaric acid is biosynthesized by an uncommon condensation of two polyketide chains rather than from a single chain undergoing an a priori possible, albeit improbable, rearrangement. Unequivocal assignments for the ^{13}Cmr spectra followed from the results of three 2D experiments, namely, homonuclear (^{1}H) and heteronuclear (^{1}H, ^{13}C) correlation spectra and double quantum coherence (^{13}C). Attempts to distinguish between the two possible loci of the chain junction were unsuccessful, suggesting that the synthesis may proceed on a single enzyme complex, without intervention of discrete intermediates.

ALBERT STOESSL et J. B. STOTHERS. Can. J. Chem. **62**, 549 (1984).

Des études d'incorporation d'acétates [$^{13}C_2$-1,2] ont permis d'établir que la biosynthèse de l'acide alternarique de la phytotoxine fongique se produit par le biais d'une condensation peu commune de deux chaînes de polycétides plutôt qu'à partir d'une chaîne unique subissant une transposition qui est a priori possible mais qui est peu probable. On a fait des attributions non-ambigues des spectres rmn du ^{13}C en faisant appel à trois expériences en 2D, soit des spectres de corrélation homonucléaire (^{1}H) et hétéronucléaire (^{1}H, ^{13}C) et une cohérence quantique double (^{13}C). On a essayé en vain de localiser les deux points éventuels de jonction des chaînes; ceci suggère que la synthèse peut se produire sur un complexe enzymatique unique sans l'intervention d'intermédiaires discrets.

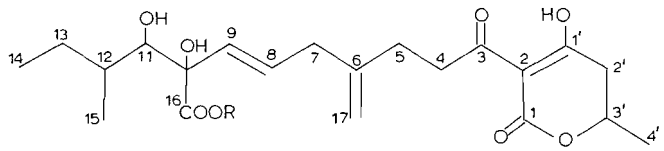
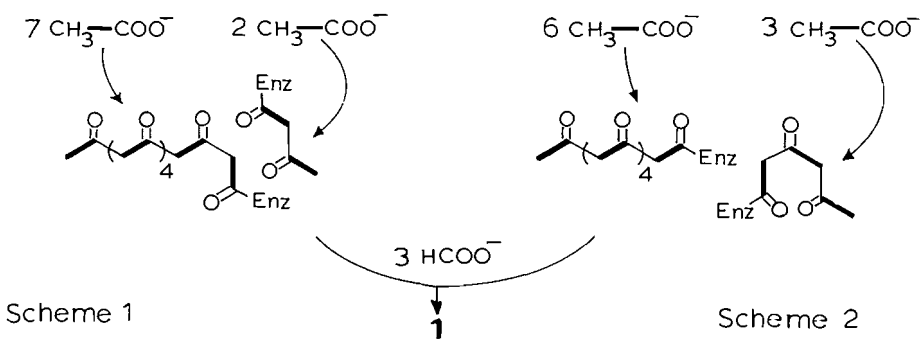
Alternaric acid (**1***a*) (1–3) is a phytotoxic metabolite of the fungus *Alternaria solani* (4–6). Its biosynthesis has been investigated by Turner (7) who showed, in an elegant application



1 a R = H
b R = Me

of radiotracer techniques, that the odd-numbered carbon atoms, 1,3,5 . . . . 13, 1′, and 3′, are derived from C-1 and the even-numbered carbons, 2,4,6 . . . . 14, 2′, and 4′, from C-2 of acetate, while C-15, -16, and -17 originate from the C_1 pool. Mevalonate was not incorporated into **1***a* in significant amount. Alternaric acid is, therefore, a polyketide but it remained unknown whether it was the product of an uncommon condensation of two chains as in either Scheme 1 or 2 (8) or by rearrangement of a single nonaketide as in Scheme 3. In seeking an answer to this question, we have examined **1**, isolated from incorporation experiments with [1,2-$^{13}C_2$]acetate and some likely competitors, using nmr spectroscopic methods.

A prerequisite for these studies was the complete assignment of the signals in the ^{13}Cmr spectra of **1***a* or its more soluble methyl ester **1***b*. This problem was facilitated by heteronuclear correlation with the ^{1}Hmr spectrum which itself was readily assigned as follows. For **1***b*, the four olefinic absorptions consisted of two broadened singlets, δ 4.77 and 4.81, attributable to the C-17 protons, and a pair of doublets of triplets at δ 6.02 (J = 7.3, 15.5 Hz) and 5.58 (J = 2.5, 15.5 Hz), assignable to H-8 and -9, respectively, with each multiplet exhibiting long range coupling. A broadened doublet of doublets (δ 2.81 (2H), J = 2.5, 7.3 Hz) was easily ascribed to the protons on C-7. Methyl absorptions at δ 0.86 (d, J = 6.8 Hz), 0.865 (t, J = 7.3 Hz), and 1.45 (d, J = 6.3 Hz) could be directly assigned to the 15-, 14-, and 4′-methyl protons, respectively. A sharp doublet, J = 1.8 Hz, at δ 3.92 arose from the carbinyl proton on C-11,



SCHEMES 1 AND 2

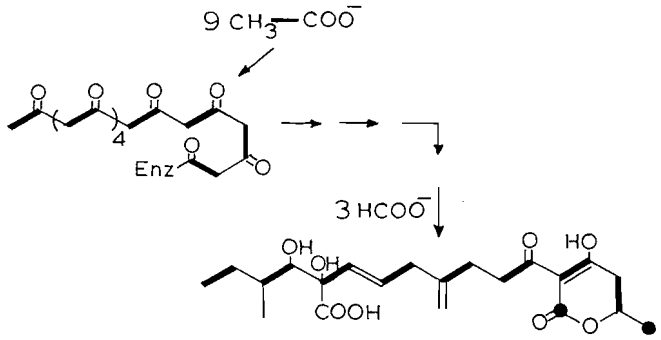
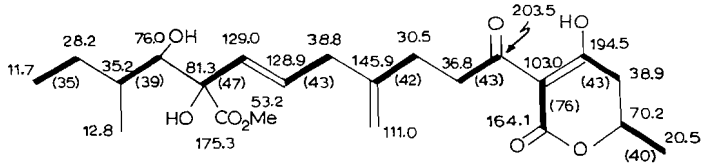


SCHEME 3

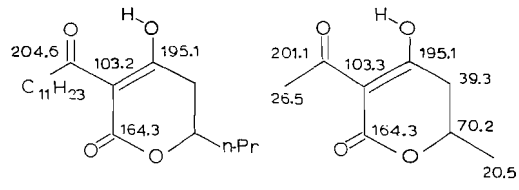
close to a methoxyl singlet at δ 3.82. A one-proton multiplet at δ 4.53 could be attributed to H-3′ which was coupled to a 2-proton multiplet near 2.6 ppm. These two absorption patterns were duplicated by spin simulation calculations to show that the C-2′ protons absorb at 2.60 and 2.63 with $J = -12.0$ Hz and are coupled at H-3′ with $J = 4.3$ and 11.0 Hz, respectively. The remaining one-proton multiplet at δ 1.65 ($J = 1.8$, 6.8, 7.2 Hz) must arise from H-12 while 2-proton multiplets at δ 3.2, 2.35, and 1.27 were assignable to the 4-, 5-, and 13-methylene protons, respectively. All of these assignments were confirmed through a homonuclear correlation experiment (9) using the HOMCOR pulse sequence of the XL-200 software.

The ^{13}Cmr spectrum of **1***b* in $CDCl_3$ contained 22 sharp signals indicating either rapid equilibration between various tautomeric forms or its existence as a single tautomer; in CD_3CN solution, six of these signals are significantly broadened.[3] For **1***a*, all 21 signals are sharp in $CDCl_3$ while six are markedly broadened[3] in CD_3OD solution. Of the 22 signals for **1***b*, eight were readily assigned after the APT spectrum (10) was recorded; these included the $COOCH_3$ group at 175.3 and 53.2 ppm, the $C{=}CH_2$ group at 145.9 and 111.0 ppm, C-2, -4′, -10, and -12 at 103.0, 20.5, 81.3, and 35.2 ppm, respectively. Definitive assignments for the other sp^3 carbons, all of which are protonated, were obtained by a $^{13}C-^1H$ chemical shift correlation experiment (11) using the HETCOR pulse sequence of the XL-200 software. Thus the carbinyl methine signals at 70.2 and 76.0 ppm were found to arise from C-3′ and C-11, respectively, while the methyl signals at 11.7 and 12.8 ppm were readily assigned to C-14 and -15, respectively. The five methylene signals at 28.2, 30.5, 36.8, 38.8, and 38.9 ppm were found to be correlated with the methylene proton multiplets centred at δ 1.27, 2.34, 3.17, 2.6, and 2.81, respectively, thereby leading to the ^{13}C assignments at C-13, -5, -4, -2′, and -7, respectively, since the proton assignments had been established as described above. Unequivocal assignments for the five remaining signals for **1***b* were obtained by the double quantum coherence technique (12) with **1***b*-$^{13}C_x$ isolated from the incorporation experiments utilizing [1,2-$^{13}C_2$]acetate. The key feature of the ^{13}Cmr spectrum of this material was the fact that each of the absorptions for the carbons in the main skeleton contained ^{13}C satellites confirming the polyketide origin of the skeleton and establishing the incorporation of nine intact doubly labelled acetate units. In principle, one can identify the individual acetate units by pairing the coupling constants given by the satellite separations provided the J values are significantly different. For **1***b*, this is not the case since the methylene carbons at 30.5, 36.8, 38.8, and 38.9 ppm each exhibited satellites separated by 42–43 Hz. In a two-dimensional INADEQUATE experiment, however, coupled spins are identified by the double quantum coherence which is equal to the sum of the chemical shifts of the two carbon sites measured with respect to the transmitter frequency. This technique with natural abundance material can establish the connectivity of the carbons in a molecular skeleton, as was first illustrated for 5α-androstane (13), but relatively large samples are required because of the low probability of occurrence, ca. $(0.01)^2$, of contiguous ^{13}C nuclei. In an enriched compound obtained from experiments utilizing doubly labelled acetate, however, the double quantum coherence of the pairs of carbons arising by incorporation of intact acetate units is much more readily determined even at low incorporation levels and, thus, smaller samples are required to identify these coupled pairs. With this technique it was found that the four methylene signals at 30.5, 36.8, 38.8, and 38.9 ppm are directly bonded to the carbons absorbing at 145.9, 203.5, 128.9, and 194.5 ppm, respectively, and that the 129.0 ppm olefinic carbon is bonded to C-10 (81.3 ppm). This information completed the ^{13}C assignments as set out in **2** for which the individual coupling constants for the bonds labelled by intact acetate units are given in parentheses.



2

It may be noted that the observed shieldings for C-1′, -1, -2, and -3 in **1***b* are very similar to those found for the corresponding centres in podoblastin A (**3**) (14) and in 5,6-dihydrodehydroacetic acid (**4**).[4] The assignments shown in **4** were



3 **4**

obtained by a 2D INADEQUATE experiment which provided the required double quantum frequencies. Similar shieldings have also been reported for 2-acetyldimedone (15) for which the endo- and exo-cyclic "carbonyl" carbons were found to absorb at δ 196.3 and 201.6, respectively. Although drawn as a 3-acyl-4-hydroxy-6-methylpyrone in **2**, **1***b* can exist in a variety of tautomeric forms (see **5**). The absence of a protonated carbon signal for C-2 shows that **5***a* is a very minor contributor but a clear distinction between **5***b* and *c* is not possible from the available data.

[3] The broadening (for the C-1, -2, -3, -4, -1′, and -2′ signals, see below) is presumably due to a change in tautomeric equilibration rate with solvent.

[4] A generous sample of **4** was kindly provided by D. Figueroa, University of Alberta, for the spectroscopic studies.

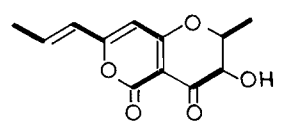
5

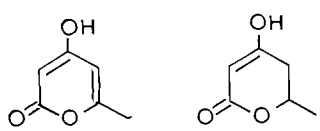
The ^{13}Cmr spectra of samples of **1**-$^{13}C_x$, isolated from still cultures of *A. solani* that had been amended with sodium [1,2-$^{13}C_2$]acetate at the time of maximal alternaric acid synthesis, showed that the labelled precursor had been incorporated in the pattern shown in **2** where the heavy bars indicate nine intact acetate units. For each of the labelled carbons the relative intensities of the satellites and the central signal corresponding to the absorption of natural abundance material provided a measure of the ^{13}C enrichment (16). For carbons 1–12 as well as 1′ and 2′, the incorporation level was found to be 0.5 ± 0.1% while C-13, -14, -3′, and -4′ were more highly labelled, ca. 0.8%. The latter values constitute distinct starter effects establishing that **1** must arise by condensation of two polyketide chains. In addition, the rearrangement required for the genesis of **1** from a single nonaketide chain (Scheme 3) would lead to enhanced singlet signals lacking pronounced satellites for C-1 and -4′, and common couplings for C-1′ and -2 as well as for C-2′ and -3′. The absence of all of these features proves that **1** does not arise from a single chain precursor.

In principle, a distinction between the alternatives shown in Schemes 1 and 2 is possible if the acetate incorporation levels differ for the two polyketide chains. Unfortunately, several incorporation experiments with [1,2-$^{13}C_2$]acetate failed to provide **1**-$^{13}C_x$ with significantly different degrees of labelling of the pertinent carbon atoms. In other words, these experiments did not reveal whether the C-1, -2 unit was a terminal unit for either the C-3 to -14 or the C-1′ to -4′ chains. An exactly analogous failure has been reported (17) from a study of [1,2-$^{13}C_2$]acetate incorporation into radicinin (**6**) which, like **1**, is one of very few compounds whose origin from two polyketide chains is indicated.[5]

In further attempts to obtain differential incorporation into



6



7 8

[5]Other recent cases are those of citreothiolactone and citreopyrone from *Penicillium viride* (18) and the podoblastins from the higher plant *Podophyllum peltatum* (14).

the two moieties of **1**, labelled acetate was administered to fungal cultures together with unlabelled compounds which had some promise as possible competitors. Thus, in separate experiments, [1,2-$^{13}C_2$]acetate was administered together with triacetic acid lactone (**7**) and its dihydro derivative (**8**) as well as with sodium acetoacetate and 3-hydroxybutyrate as possible specific precursors for a C_6 or C_4 chain, respectively. In all four cases, the alternaric acid which was isolated exhibited essentially equal labelling in both moieties, as in the earlier experiments. Alternaric acid isolated from fungal cultures amended only with either dideuteriotriacetic acid lactone or 3-deuterio--3-hydroxybutyrate was unlabelled according to ^{2}Hmr spectroscopy.

The consistent absence of differential labelling by acetate, other than that arising from starter effects, both in these experiments and in those described by Seto and Urano (17) suggests that both molecules may be biosynthesized rapidly on one multiple enzyme complex, with the intervention of intermediates in a manner analogous to that presumably operative in fungal fatty acid synthesis (19).

Experimental

Melting points were determined on the Kofler hot stage. Organic solvents were reagent grade and redistilled before use. Ethanol was the 96% product. Thin layer chromatography was done on precoated plates of silica gel (Macherey–Nagel Polygram SIL N-HR/UV$_{254}$; 0.2 mm) with MeOH/$CHCl_3$ (3:7) or concentrated ammonia solution/EtOH (1:9) as irrigants and detection by uv light, I_2 vapour, or vanillin (1%) in 50% phosphoric acid at 120°C.

Sodium [1,2-$^{13}C_2$]acetate (90% ^{13}C), sodium borodeuteride, and deuterated solvents were obtained from Merck, Sharp, and Dohme Canada Ltd., Pointe Claire-Dorval. Triacetic acid lactone (4-hydroxy-6-methyl-2-pyrone (**7**)) was used as received from Aldrich Chem. Co., Milwaukee, U.S.A. Its 5,6-dihydro derivative **8** was prepared by hydrogenation in EtOAc over Pd/C as described in the literature (20); it had mp 128°C (lit. (20) mp 120–121°C; 124°C) and contained a little unreduced pyrone even after recrystallization from EtOH (^{1}Hmr spectrum). Material enriched in 5,6-dideuterio-4-hydroxy-6-methyl-2-pyrone, mp 123–124°C, was prepared analogously with $^2H_2$ (99.6%; Canada Liquid Air Ltd., Montreal), analysis of its ^{1}Hmr spectrum indicating that it consisted mainly of the expected 5,6-dideuterio compound (ca. 33%) and, for unclarified reasons, the 5,6-dihydro compound (ca. 66%). Sodium acetoacetate was prepared by hydrolysis of redistilled ethyl acetoacetate with the calculated volume of aqueous 0.93% NaOH at 4°C during 3 days, the crude product being diluted with EtOH (2.2 vol.) before use. Sodium (±)-3-deuterio-3-hydroxybutyrate was prepared by reduction of ethyl acetoacetate (1.3 g) with an excess of sodium borodeuteride (126 mg) in ice-cold MeOH (10 mL), hydrolysis of the resulting ester (^{13}Cmr, δ_C: 13.9, 22.2, 42.8, 60.4, 63.7 (J_{CD} = 22 Hz), 172.5) with the calculated volume of 1 *M* NaOH (room temperature; 2 days), and recrystallization from absolute EtOH; mp 162–165°C; ^{13}Cmr, δ_c: 25.4, 50.2, 69.1 (J_{CD} = 22 Hz), 184.3.

Alternaria solani (Ell. & Mart.) Sorauer, strain ATCC 11078, was obtained from the American Type Culture Collection, Rockville, Maryland, and maintained on V8 juice agar slants (23). Inocula were prepared by culturing mycelium scraped from one or more slants on Brian's medium T (23) (25 mL) in 100-mL Delong flasks for 10 days, collecting the mycelial mats, washing with several rinses of sterile distilled water, and homogenizing in a Waring blender in sterile distilled water. The homogenates were used without delay, at the rate of 2 mL/bottle, to inoculate fresh medium T contained in 1-L Roux bottles (100 mL/bottle). Cultures were maintained at room temperature (ca. 24°C) in diffuse artificial light, alternaric acid production being monitored by tlc of the $CHCl_3$ extracts of filtrates, obtained from 2 cultures at a time, at intervals. Concentrations were estimated by relating the product [spot area × intensity (determined photo-

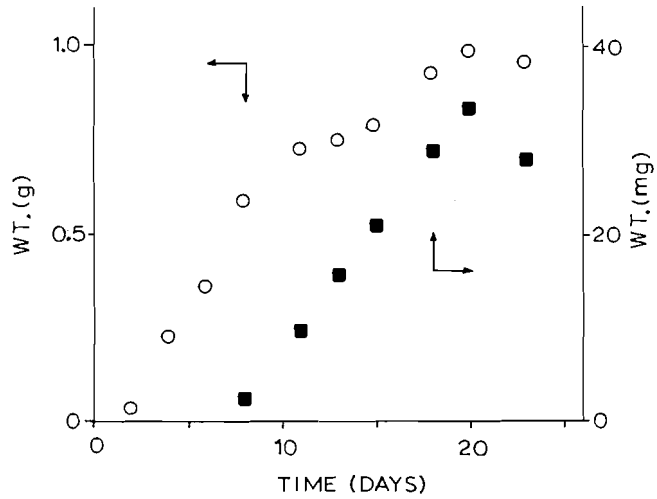

FIG. 1. Mycelial growth rate and alternaric acid production by *Alternaria solani*. ○ dry weight of mycelium (g/Roux bottle); ■ alternaric acid (mg/Roux bottle).

densitometrically)] to a calibration curve constructed likewise with reference samples of known concentration. The results (Fig. 1) indicated that production of **1***a* occurred at a maximal rate about 15 to 20 days after inoculation. Essentially identical observations were made consistently in other experiments which, however, were limited to visual inspection of the tlc's.

*Isolation of alternaric acid (**1**a) and methyl alternarate (**1**b)*

Culture filtrates were acidified (few drops HCl), extracted with $CHCl_3$ (3 × 1 vol.), the extracts reextracted in turn with 5% $NaHCO_3$ (2 × 0.2 vol.), the combined alkaline extracts acidified and extracted with $CHCl_3$ (3 × 0.5 vol.). The washed acidic $CHCl_3$ extracts were evaporated (15 Torr), the residue being crystallized from EtOAc or C_6H_6 and recrystallized (when necessary) from aqueous MeOH. Pure samples had mp 135–136°C but material with mp > 130°C is sufficiently pure for spectroscopy. The methyl ester, mp 103–105°C, was prepared as in the literature (1).

Incorporation experiments

(a) A sterile solution of sodium [1,2-$^{13}C_2$]acetate (669 mg; ca. 8 mmol) in H_2O (162 mL) was added in equal portions to four sets of four Roux bottle cultures 16 days after inoculation. Three of the sets were further supplemented immediately with either (*i*) triacetic acid lactone, (*ii*) its 5,6-dihydro derivative, or (*iii*) its 5,6-dideuterated derivative as 0.084 *M* solutions in EtOH (1 mL/bottle). The cultures were extracted after another 6 days and the purified alternaric acid which was obtained (110 ± 10 mg from each set of 4 bottles) was converted into the methyl ester **1***b* for spectroscopic study.

(b) In a similar series, three sets of three cultures each were supplemented 15 days after inoculation with sodium [1,2-$^{13}C_2$]acetate (0.05 *M* in H_2O, 10 mL/bottle) together with (*i*) 70% EtOH (1 mL/bottle), (*ii*) (±)-3-hydroxybutyrate (0.14 *M* in 70% EtOH, 1 mL/bottle), or (*iii*) sodium acetoacetate (0.78 *M* in 70% EtOH, 1 mL/bottle). Alternaric acid, isolated after 3 days' further incubation, was obtained only in greatly reduced yields (2–4 mg/bottle) and was used for spectroscopy without conversion to the ester. Similarly low yields were obtained also from unamended cultures, nor were they improved by the use of newly obtained cultures of the strain.

(c) Six cultures were amended with sodium (±)-3-deuterio-3-hydroxybutyrate (0.068 *M* in 4% EtOH, 2 mL/bottle) 14 days and, again, 15.5 days after inoculation. The alternaric acid (6.4 mg) isolated after another 2 days did not contain detectable amounts of deuterium (^{2}Hmr spectrum).

Nuclear magnetic resonance spectra

A Varian XL-200 spectrometer was used to record the ^{1}H and ^{13}C spectra at 200 and 50.3 MHz, respectively. Although initially some selective decoupling experiments were done to aid the analysis of the ^{1}H spectra, all of the coupling interactions were identified by homonuclear correlation using the HOMCOR pulse sequence resident in the XL-200 software. The correlated spectrum was obtained using a 512 × 1024 data point matrix transforming 1024 points in both domains with a spectral width of 1200 Hz in both domains. The ^{13}Cmr spectra of **1***a* and *b* in $CDCl_3$ solution contained 21 and 22 signals, respectively, and the degree of protonation of each was determined by recording the APT spectrum for each. Specific assignments of the protonated carbon signals shown in **2** were obtained by heteronuclear correlation with the proton spectrum using the HETCOR pulse sequence of the XL software. The ^{13}C–^{1}H chemical shift correlation utilized a 2048 × 256 data matrix with a 3600 Hz spectral width for ^{13}C and a 1 KHz width for ^{1}H, tranforming 2048 and 512 points, respectively. The results of this experiment unequivocally identified the five individual methylene signals. To complete the ^{13}C assignments, a clear distinction between C-1′ and C-3 was required. As noted in the text, **1**-$^{13}C_x$ isolated from the [1,2-$^{13}C_2$]acetate incorporation experiments gave rise to ^{13}Cmr spectra in which nine pairs of carbons exhibited AX patterns of satellites characteristic of bonded labelled carbons. However, the similar J_{AX} values for four of the methylene carbons precluded positive identification of their labelled partners and a third 2D experiment was required in which the double quantum coherence of the pairs of labelled carbons was determined. With the CCC2D pulse sequence of the XL software a 2K × 128 data point matrix transforming 2048 and 256 points, respectively, with 10 000 Hz sweep widths in both domains, was employed to obtain the double quantum frequencies for the labelled carbons. Through this 2D INADEQUATE spectrum, the labelled pairs of carbon atoms arising from incorporation of intact doubly labelled acetate units were unequivocally identified as shown in **2**. It may be noted that the J_{AX} values were most readily determined with a one-dimensional INADEQUATE spectrum using the C13SAT sequence of the XL software. The spin simulation program used to analyse the proton pattern for the 2′, 3′, and 4′ protons is supplied with the XL software. The 2D INADEQUATE experiment for **4** utilized 2048 × 128 data matrix, 10 KHz in both dimensions, transforming 2K and 512 points, respectively.

Received March 29, 1983[4]

D. S. WULFMAN, JAMES ROBERTS, DENNIS K. HENDERSON, J. C. ROMINE, R. S. MCDANIEL, JR., L. CARVER, and D. W. BEISTEL. Can. J. Chem. **62**, 554 (1984).

Electron impact (EI) mass spectral studies of methyl diazoacetate, ethyl diazoacetate (**1**), methyl diazoacetoacetate (**2**), and dimethyl diazomalonate (**3**) indicate that loss of N_2 is exceedingly difficult from the parent ion and was observed only with **3**. Diazoacetylacetone exhibits an appreciable $(M - 28)^+$. *Exact Mass* and metastable transitions indicate fragmentation occurs in part via 1,2,3-oxadiazolium ion-radicals (**6**) or α-lactones (**7**) to furnish N_2O and hyponitrite esters. $(M - 28)^+$ from **1** results from loss of ethylene.

D. S. WULFMAN, JAMES ROBERTS, DENNIS K. HENDERSON, J. C. ROMINE, R. S. MCDANIEL, JR., L. CARVER et D. W. BEISTEL. Can. J. Chem. **62**, 554 (1984).

Des études de spectrométrie de masse par impact électronique du diazoacétate de méthyle, du diazoacétate d'éthyle (**1**), du diazoacétoacétate de méthyle (**2**) et du diazomalonate de diméthyle (**3**) indiquent que la perte d'azote moléculaire est difficile à partir des ions moléculaires; on ne l'observe qu'avec **3**. Avec la diazoacétylacétone, il y a un pic important à $(M - 28)^+$. Les masses exactes et les transitions métastables indiquent que la fragmentation se produit en partie par le biais des ions radicaux oxadiazolium-1,2,3 (**6**) ou des lactones-α (**7**) qui fournissent du N_2O et des esters hyponitreux. L'ion à $M - 28^+$, obtenu à partir de **1**, provient d'une perte d'éthylène.

There are surprisingly few studies of the mass spectra of diazo compounds (2–12). Frequently the generation of the ion $[RCN_2]^+$ occurs (presumably the diaza analog of the cyclopropenium ion) (2, 3, 5, 6, 11, 12). The reported spectrum of diazomethane (2) exhibited this as a peak of 8.4% intensity and interestingly, possesses an M^+ of 96.5%. Paulett and Ettinger (2) also found a value for $D(CH_2 - H_2)$ of 1.9 eV and for $D(CH_2 - N_2)^+$, 3.3 eV.

Our observation (10) that dimethyl diazomalonate failed to lose N_2 to form a $(M - 28)^+$ ion is somewhat unique since the M^+ ion might be expected to readily lose N_2 to furnish a carbene-cation-radical stabilized by its substituents. This would have mimicked the reported photochemical behavior (13), a common occurrence in photochemistry and mass spectroscopy (14). The lack of mimicry here is especially surprising since the π system is fully conjugated. Ions possessing the necessary lifetime to pass through a mass spectrometer might be expected to have sufficient time to undergo electronic decay to the most stable cation radicals regardless of which electron had been ejected by electron bombardment. (Luinenberg *et al.* (12) failed to observe any $(M - N_2)^+$ with four diazomethylsulphones.)

We have now completed a study of the series of structurally related diazo carbonyl compounds, ethyl diazoacetate (**1**), methyl diazoacetoacetate (**2**), dimethyl diazomalonate (**3**), and 3-diazopentane-2,4-dione (**4**). Their low and medium-high resolution EI mass spectra are tabulated in Tables 1–5. Spectra were obtained at ~75, ~30, and ~13 eV. The experiments were performed using a JEOL-D100 double focussing mass spectrometer equipped with a JEOL data system and a JEOL ion defocussing attachment capable of scanning accelerating voltage and thus observing metastable transitions (15). The D-100 can be operated in either a low resolution mode or a medium-high resolution mode (up to ~10 000 resolution). For the mass ranges and compositions encountered here, it was possible to distinguish between the various elemental compositions for the ions of interest. The inlet system is all glass up to the gap before the ionizing source. Thus, this study was free from the plague of metal catalyzed processes to be expected of diazo compounds and observed in some of the earlier studies in this area (3). Table 6 reveals some of the common fragmentations observed. Table 7 is a listing of all of the nitrogen-containing fragments found in the ms of methyl diazoacetoacetate.

Schemes 1–3 reveal the fragmentation sequences obtained by ion defocussing.

All of the esters exhibit the typical fragmentation patterns associated with esters, e.g., loss of alkoxyl and, with **1**, elimination of olefin from the ester alkyl group (21). In some cases it was not possible to observe metastable transitions. This does not preclude a possible pathway. Such transitions are shown by – – – lines. With the metastable ion determination of the source of $m/z = 59$ in the mass spectrum of **3** some difficulty was encountered. However, we were able to find low intensity metastable ions showing that some (and perhaps all) $m/z = 59$ derived from ions having $m/z = 102$ and 74.

The decomposition of **3** via the pathways 158–130–102–74–59; 102–59; 74–43, and presumably 102–43 is of particular note in that it requires the stepwise loss of three molecules of CO from a material possessing only two initial carbonyl groups, migration of CH_3O to N and CH_3 to N′. Although we were unable to obtain an acceptable *Exact Mass* at $m/z = 102$ from **3**, it must contain N_2 since one of the two paths from it to $m/z = 59$ furnishes CH_3ON_2. Similarly, $m/z = 43$ (CH_3N_2) had its origin in $m/z = 74$ which arose from $m/z = 102$. Since the daughter ions possessed N_2, the parent did as well. The loss of ethylene is not possible in this case and the loss of 28 amu must therefore be attributed to loss of CO. We presume that an oxygen migration has occurred via an

α-lactone intermediate (**7**) which then successively loses two CO to furnish an azo-carbamate (**8**) which can collapse via CO loss to the species $CH_3N_2OCH_3$ or loss of N_2OCH_3 to CO_2CH_3.

It is clear from the fragmentation pathways of both **1** and **3** that initial retention of N_2 is highly favored. Thus we see that, in all cases where N_2 is present, either *Exact Mass* measurements were possible or, when such measurements were not possible due to closeness in mass with the PFK standards, subsequent daughters were found containing N_2.[5] Similar behavior was observed for **3**.

The generation of oxadiazolium ion radicals (**6**) will account for the generation of the ions $(N_2O)^+$ and $(N_2OR)^+$ (Scheme 4). The relatively low intensities of these ions is consistent with this not being an important pathway. Historically, the structure of α-diazo ketones had been questioned and the 1,2,3-oxadiazole structure proposed (16, 17). However, currently no 1,2,3-oxadiazoles are known and the alternate structure has been discarded (18). The related radical cation clearly offers an adequate representation of ionized diazo esters.

In the case of ethyl diazoacetate, an $(M - 28)^+$ ion was observed. At 72 eV *Exact Mass* measurements indicated that this ion resulted solely from loss of ethylene. Due to sensitivity problems, we were not able to ascertain if this was also the case at the lower ionizing voltages. At 30 eV, one would expect less fragmentation and the $(M - 28/M)$ ratio decreased. Unfortunately, at 13 eV it increased. Thus, the possibility existed that loss of N_2 might occur at the lowest ionizing voltage for **1**. (The $M - 28$ ion from **3** arises via a rearrangement process. Such processes have small frequency factors and low activation energies and consequently will become more important at lower energies.) Although the authors consider it unlikely, the argument can be made that failure to lose N_2 by cleavage of what is traditionally viewed as a weak C—N bond is a consequence of the excess energy leading to cyclization to oxadiazolium ion radicals (**6**). The failure to lose N_2 from **2** or **3** at low voltages might seem to argue against such an interpretation. The counter argument that ethyl diazoacetate behaves differently than **2** and **3** could be made. The related ester,

[5] The nature of the JEOL computer program for high resolution studies precludes the use of other *Exact Mass* standards. The program is written in machine language and a listing is not available.

methyl diazoacetate (**5**) was prepared. The data at 72, 30, and 13 eV are given in Table 5. No loss of N_2 to furnish $(M - 28)^+$ is observed.

The failure to lose N_2 from the diazoesters is consistent with the thermal chemistry of these same compounds (for discussions of this point, see ref. 19). Both **1** and **3** can withstand prolonged heating in refluxing toluene solutions. One might suspect that much of the instability of pure diazo compounds results from chain reactions. In solution these chains are interrupted by solvent molecules. The retention of N_2 when bombarded with electrons of 300, 960, and 1656 kcal/g-at. should cast considerable doubt as to the ability of photons in the energy range 80–115 kcal/g-at. to generate nitrogen-free species such as carbenes. Indeed, the observation by Voigt and Meier (20) that photolysis of diazo isatin furnished a diazirine points in the same direction as the observation of a temperature dependence of the photolysis of **3** by Wulfman *et al.* (10), the observation by Tomioka *et al.* (22) of a non-carbenic path C—H inseration product in the course of the photolysis of the diethylamide of diazoacetic acid, and the observation of a diazoacetylonium ion intermediate in the photolysis of **1** in isopropyl alcohol (23). As noted previously (1), the carbene pathway rationale is extremely attractive but is a house-of-cards. No one has demonstrated where along the reaction coordinate N_2 is lost and addition to substrate occurs. There most probably exists a broad range of reactivities amongst diazo compounds in which carbenes represent only an extreme case. The various substitution patterns available would be expected to modify the ease with which N_2 is lost. What is clear, is that diazo esters and diazo ketones behave differently from each other under thermal, photochemical, and mass spectral conditions. In the case of diazoacetoacetic esters, the ester functionality is controlling.

Clearly, strong parallels do exist, and in the case of the mass spectral behavior, N_2 is not readily lost from diazo esters. Thus, the cautionary statement of Wolfgang Kirmse (24) – "The long-lasting fascination of the carbene concept for organic chemists appears to have emotional rather than empirical grounds" – appears to have been prescient.

The mass spectrum of dimethyl diazomalonate has been reported previously (*6b*). However, we were unable to observe the reported ions having m/z of 39, 86, and 92. In most instances, we also failed to observe m/z = 130 $(M - N_2)^+$ and found its appearance was more frequent as the temperature of the glass inlet was raised and as the age of the instrument increased. (In 1974 typically the M^+ ion at 75 eV would reach intensities of 50+ percent and there would be no $(M - N_2)^+$.) The differences between the present low resolution work on **3** and that of Zeller *et al.* (6) are minor and most probably reflect instrumental factors.

The mass spectra of *p*-substituted phenyl triazines derived from glycine ethyl ester (**9**) exhibit of an ion $C_4H_6N_2O_2$ which appears to be isomeric with that derived from the diazo ester.

p-X—C_6H_4N=N—$NHCH_2CO_2C_2H_5$

9

This phenomenon is currently under investigation along with the fragmentation behavior of a variety of 1,2,3-triazenes, triazolones, diazoacetamides and anilides, and aliphatic diazoketones.

Structure determination of the hexosulose dimers

PEDRO ANTONIO GARCÍA RUIZ,[1] INMACULADA CARTAGENA TRAVESEDO, AND ANTONIO SOLER MARTÍNEZ
Department of Organic Chemistry, Faculty of Science, University of Murcia, Murcia, Spain

Received October 21, 1982[2]

PEDRO ANTONIO GARCÍA RUIZ, INMACULADA CARTAGENA TRAVESEDO, and ANTONIO SOLER MARTÍNEZ. Can. J. Chem. **62**, 561 (1984).

The structure determination of the dimers of three hexosuloses has been achieved by mass spectrometry of their acetates and trimethylsilyl derivatives. The analysis of the mass spectra and the chemical evidence for the claim that the dimers are 1,2′:2,1′-di-hexosulofuranose dianhydrides have been reported.

PEDRO ANTONIO GARCÍA RUIZ, INMACULADA CARTAGENA TRAVESEDO et ANTONIO SOLER MARTÍNEZ. Can. J. Chem. **62**, 561 (1984).

On a determiné la structure des dimères de trois hexosuloses en faisant appel à la spectrométrie de masse de leurs acétates et de leurs derivés triméthylsilylés. On rapporte l'analyse de leurs spectres de masse et les preuves chimiques qui confirment que les dimères sont des dianhydrides de di-hexosulofurannoses-1,2′:2,1′.

[Traduit par le journal]

Introduction

It is very well known that upon concentration of hexosulose solutions, or upon dehydration of the osone by heating at 56°C, under vacuum (1), a dimerization process occurs, but there are no studies of the structure of the osulose dimers.

Also, it is known that mass spectrometry is now a conventional method for the structural analysis of monosaccharides (2–4), disaccharides, and dialdose dianhydrides (5–7).

In the present paper, the dimers of three hexosuloses previously isolated as their monomers by gas–liquid and paper chromatography, are studied. The structural elucidation of the osulose dimers is carried out on the basis of the mass spectral data obtained from their acetate and trimethylsilyl derivatives. In addition, some chemical evidence for the proposed structures is reported.

Results and discussion

The structures of the D-*arabino*, D-*lyxo*, and L-*xylo* hexosulose dimers were identified as the 1,2′:2,1′-dianhydrides of the 2,5-hexosulofuranoses (Fig. 1), by means of the interpretation of their mass spectrometric behaviour.

Some of the more abundant peaks, upon which the identification of D-*arabino* hexosulose dimer as the peracetate or pertrimethylsilyl derivative was based, are given in Table 1 (see Fig. 1). These peaks occur also in the spectrum of the corresponding derivatives of D-*lyxo* and L-*xylo* hexosulose dimers. The relative intensities of the peaks have not been corrected for the isotopic contribution of peaks of lower masses.

The assignment of structure was made on the basis of the presence or absence of characteristic fragments. Moreover, the mass spectra of the structurally analogous compounds have been used to confirm the proposed fragmentations.

The assignment of structure will be discussed in the following sections.

A. *The molecular weight determination*

In accordance with the bibliographic criteria, when no molecular ion peak is present, the molecular weight can be deduced for trimethylsilyl derivatives (8) and acetates (2, 3, 9) from the fragment ions in the region near the molecular weight.

Table 1 shows fragments at $M^{+\cdot} - OR$, $M^{+\cdot} - Me - OR$, $M^{+\cdot} - R - OR$, $M^{+\cdot} - 2OR$, and $M^{+\cdot} - 3OR$, which are indicative of a molecular weight of 932 for the trimethylsilyl derivatives (R = $SiMe_3$), and fragments at $M^{+\cdot} - R$, $M^{+\cdot} - OR$, $M^{+\cdot} - R - OR$, and $M^{+\cdot} - 2OR - R$, which are indicative of a molecular weight of 692 for the acetates (R = $CO—CH_3$).

Also, the molecular weight is confirmed by other characteristic fragments obtained from the molecular ion peak, such as those described in the following sections ($M^{+\cdot} - a$, (see Fig. 1), $M^{+\cdot} - a - R$, $M^{+\cdot} - a - OR$, $M^{+\cdot} - c - OR$, etc.).

B. *The CH_2OR group determination*

The loss of the substituents alpha (α) to the ring oxygen gave rise to the most significant fragment series. As is typical of this group (2, 3, 6, 8–10), the fragments at $M^{+\cdot} - CH_2OR$ ($M^{+\cdot} - a$), $M^{+\cdot} - CH_2OR - Me$ ($M^{+\cdot} - a - Me$), $M^{+\cdot} - a - R$, $M^{+\cdot} - a - OR$, $M^{+\cdot} - a - R - OR$, $M^{+\cdot} - b - R$, a, b + H, and b − Me reported in Table 1 (see Fig. 1) confirm its presence. Moreover, the fragments at $M^{+\cdot} - 2a - 2OR$, $M^{+\cdot} - c - b - OR$, $M^{+\cdot} - h - a$, $h - a - R$, and $g - a - OR - CHO$ are indicative of the presence of two CH_2OR groups. Although some of these fragments (e.g. $h - a - R$) can be considered as derived from some other isomeric structures having only one CH_2OR group, the simultaneous detection of all of them and their complementary fragments (e.g. $M^{+\cdot} - h$) is only possible when the molecule contains two CH_2OR groups.

C. *The furanose ring determination*

In accordance with the results obtained for other mono and oligosaccharide derivatives (11–15), the fragments $M^{+\cdot} - c - OR$ and $M^{+\cdot} - d - OR$ and their corresponding series (see Table 1) are characteristic of the fragmentation of the furanose rings, as well as the abundances of the peaks of the lowest ratio *m/e*: protonated furan, protonated furaldehyde, b − Me, and the abundance ratio for the fragments at *m/e* 217 and *m/e* 204, in the case of TMS derivatives.

Furthermore, as can be seen in Fig. 1 (Table 1), all of them present the fragments $M^{+\cdot} - h$, $M^{+\cdot} - h - OR$, and $h - R$, corresponding to the loss of the lactonic moiety of a pentonic acid which may lose one CH_2OR group (fragments $h - a - R$ and $M^{+\cdot} - h - a$). Also, the symmetric fragmentation g gave rise to two moieties of six carbon atoms (fragments $g - OR$, $g - OR - OR$) which may lose the CH_2OR and CHO groups

(fragments g − OR − OR − CHO, g − OR − ROH − CHO, g − OR − a − CHO), in accordance with the presence of two 2,5-furanose rings.

D. *Fragmentation data and elimination of alternative structures*

In the preceding sections A–C were determined unambiguously the molecular weight and the presence of the unsubstituted 2,5-furanose rings exclusively. The assigned structure is the only one which explains all the facts observed, because other glycosidic links (such as 1,2′:2,3′) should give different molecular weights, should present other groups (such as —$CH(OR)_2$) which give strong peaks when present in the structures, or should present the peaks corresponding to substituted furans which are absent in the spectra.

For similar reasons other alternative structures should be excluded.

E. *The 1,2′:2,1′-glycosidic links*

The intensities of the peaks that appeared in the high-mass region were relatively low and the aA_i fragments (g − OR and their fragment series) had high intensities as occur in the spectra of the peracetates (5, 15) and trimethylsilyl derivatives (14, 16, 17) of 1→2-linked disaccharides.

The furanose ring fragmentations (2, 13) at $M^{+\cdot}$ − d − OR, $M^{+\cdot}$ − c − OR, f, f − OR, and i − R are those expected because the fragmentation of oligosaccharides generally takes place in such a way that the constituent sugar residues are degraded independently (3, 4, 18, 19).

Other fragmentations, such as the one assigned to the permethylated dialdose 1,2′:2,1′-dianhydrides (6), are the fragments $M^{+\cdot}$ − 2c, f, f − OR, and i − R, which are indicative of the two 1,2-glycosidic links.

On the other hand, the absence of the fragments from the free monomer of the aldehydic aldosulose excludes the presence of only one 1→2-glycosidic link, and the absence of the fragments from the alternative dioxane rings confirms the structure.

F. *Mass spectra analogies with the pertrimethylsilyl 1,2′:2,1′-di-D-fructofuranose dianhydride*

In the trimethylsilyl derivatives, the fragments that contain the intact dianhydride ring require a shift of 176 mass units more (changing two —CH_2— groups for two —CHOR— groups) for the osulose dimers in relation to D-fructofuranose dianhydride. When the fragements contain only one —CH_2— group, the required shift (to —CHOR—) is 88 mass units more.

On the basis of the preceding shifts, the fragments at $M^{+\cdot}$ − OR, $M^{+\cdot}$ − Me − OR, $M^{+\cdot}$ − 2OR, $M^{+\cdot}$ − OR − a, $M^{+\cdot}$ − R − b, $M^{+\cdot}$ − 3OR, $M^{+\cdot}$ − 3OR − CHO, and those others marked with an asterisk in Table 1, are analogous in both cases.

However, it was concluded that other types of linkage are not formed (as occur in the fructose anhydrides) because only a single peak in glc and a single spot in paper chromatography are detected, while the di-D-fructose anhydrides show one peak and one spot for each isomer.

G. *Structure of the osulose monomers*

Structure of the osulose monomers (1) and their derivatives (20–23), and the facile formation of formyl acetals (24–26), are in agreement with the assigned structures for the osulose dimers.

H. *Chemical evidence*

The following evidence is in accordance with the presence of two glycosidic linkages of the nonreducing sugar type.

(*i*) Paper chromatography, using solvents containing water and some acid, causes partial hydrolysis of the dimers (as readily as some nonreducing disaccharides).

(*ii*) Color reactions for paper chromatography (see experimental analytical methods) show nonreducing character under the normal conditions used for paper chromatographic determination of reducing sugars.

(*iii*) In the Raney nickel reduction, the hexoses are effectively hydrogenated while the osulose dimers (like the disaccharides (27)) are more difficult to convert into their polyols.

(*iv*) Aldoses and ketoses are not detected as reduction, nor as reduction and hydrolysis, products of the inulobiose (reduction is not possible without hydrogenolysis) and osulose dimers (as occur for their monomers), while D-glucose is detected in the maltose reduction and hydrolysis. This is in accordance with the nature of the linkages between the two molecules of the osulose.

Experimental

Starting products

The mono and oligosaccharides were obtained commercially: D-glucose anhydrous, Fluka A.G. Puriss p.a. Ref. 49140; D-galactose, Fluka A.G. Puriss p.a. Ref. 48260; L-sorbose, Fluka A.G. Puriss p.a. Ref. 85542; D-maltose monohydrate, Fluka A.G. Puriss p.a. Ref. 63419.

The 1,2′:2,1′-di-D-fructose anhydrides were prepared according to the literature methods (28, 29) using commercial D-fructose (Fluka A.G. Puriss p.a. Ref. 47740).

Inulobiose was isolated from the hydrolysis of inulin, by paper chromatography. Inulin Merck, Ref. 4733.

The hexosuloses were prepared by the benzaldehyde method (30, 31) from the phenylosazones of D-glucose, D-galactose, and L-sorbose. D-*arabino* hexosulose, mp 103.3°C (dec.); uv λ_{max}: 245 nm and 279 nm. *Anal.* calcd. for $C_6H_{12}O_7$: C 36.73, H 6.12; found: C 37.38, H 6.14. D-*lyxo* hexosulose, mp 89.9°C (dec.); uv λ_{max}: 220 nm and 275 nm. *Anal.* found: C 36.01, H 5.92. L-*xylo* hexosulose, mp 92.1°C (dec.); uv λ_{max}: 218 nm and 282 nm. *Anal.* found: C 36.41, H 5.84.

Preparation of the volatile derivatives

For the preparation of the TMS derivatives (32), the solvent (pyridine) was replaced by *N,N*-dimethylformamide (1, 33).

The acetates (34) were prepared by the acetic anhydride – sodium acetate method.

Analytical methods

Paper chromatography was accomplished by the descending method in a 20°C thermostated chamber by the use of Whatman no. 1 paper irrigated with acetone – *n*-butanol – water (7:2:1). The detection reagents were (35): aniline hydrogen phthalate, orcinol–HCl, orcinol–CCl_3COOH, anthrone, and ammoniacal $AgNO_3$ and triphenyltetrazolium chloride for reducing sugars.

Gas–liquid chromatography was performed on a Perkin–Elmer F-30 gas chromatograph equipped with a flame-ionization detector and stainless steel columns (6 ft × 1/8 in.) packed with 3% SE-30 or SE-52 on a support such as Chromosorb W HP 80–100. The carrier gas was nitrogen at a flow rate of 30 mL/min.

For the glc–ms analyses, a Hewlett–Packard 5980-A gas chromatograph was employed in combination with a Hewlett–Packard 5710-A mass spectrometer, operating at 70 eV under the conditions described above for glc; the carrier gas was helium.

Isolation of hexosulose dimers

The isolation of the dimers was effected by paper chromatography on Whatman no. 1 paper strips, according to the method of Flood *et al.* (36) from each osulose sirup obtained by the following procedures. I. Osulose (2.5 g) was dissolved in 25 mL of water and concentrated

at 60°C under reduced pressure. II. Osulose (2.5 g) was refluxed 20 h with 20 mL of HCl (0.1 *M* in water), passed through IR-45 Amberlite resin (20–50 mesh, OH form), and concentrated at 60°C under reduced pressure.

The dimers isolated by both methods were identical, although a greater amount was obtained by the second method.

Raney nickel reduction

The reduction was performed for maltose, inulobiose, and the three osulose dimers studied, by reflux (3 and 7 hours) under atmospheric pressure (37). The resulting products obtained by reduction, and reduction followed by hydrolysis, are identified (by comparison of pure standards using glc and mass spectrometry) as the corresponding isomeric hexitols (in all cases), D-glucose (only of reduction and hydrolysis of maltose), and the starting products (in the 3-hour reaction).

The formation of Mannich bases from the electrochemical oxidation of 4-substituted *N*,*N*-dimethylaniline in the presence of silyl enol ether was studied. The yield of bases obtained depended on the relative oxidation potentials of the starting amine compound and the base formed. An electron-donating substituent on the amine showed a large difference in the oxidation potentials and gave the highest yield of product. On the other hand, the oxidation potentials were very close with an electron-withdrawing substituent and the yield in base was relatively much lower. Furthermore, the main product in the case of an electron-withdrawing group in the presence of 1-trimethylsilyloxy-1-cyclohexene was 4-substituted 2-(2-oxocyclohexyl)-*N*,*N*-dimethylaniline. Some side products were also isolated and were identified as *N*,*N*-diketonic compounds.

ROGER N. RENAUD, CAMPBELL J. STEPHENS et GAÉTAN BROCHU. Can. J. Chem. **62**, 565 (1984).

On a étudié la formation des bases de Mannich par oxydation électrochimique de *N*,*N*-diméthylanilines substituées en position 4 en présence d'éthers énoliques silylés. Les rendements en bases dépendent des potentiels relatifs d'oxydation des amines de départ et des bases formées. Un substituant électrodonneur sur l'amine provoque une grande différence dans les potentiels d'oxydation et conduit à un rendement plus élevé en produit. D'un autre coté, avec des substituants électro-affinitaires, les potentiels d'oxydation sont très voisins et les rendements en base sont relativement beaucoup plus faibles. De plus, le produit majoritaire obtenu dans le cas d'un réactif portant un groupe électroaffinitaire réaggisant en présence du triméthylsilyloxy-1 cyclohexène-1 est une(oxo-2 cyclohexyl)-2 *N*,*N*-diméthylaniline substituée en position 4. On a également isolé quelques produits secondaires et on les a identifiés comme étant des composés *N*,*N*-dicétoniques.

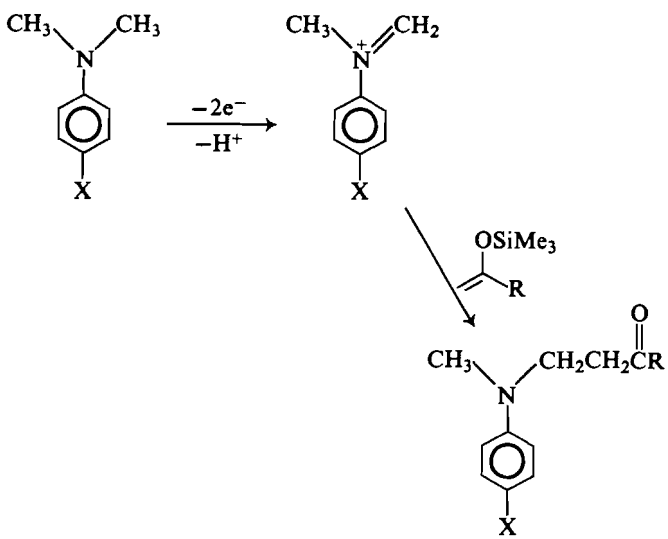
The first paper of this series (1) described the synthesis of Mannich bases from the electrochemical oxidation of *N*,*N*-dimethylmesidine in the presence of silyl enol ethers. It was noticed that the reaction depended upon the relative electrochemical oxidation potentials of the silyl enol ether, the amine, and the product. In this paper, a selection of 4-substituted *N*,*N*-dimethylanilines was chosen in order to examine the effect of the substituent on the formation of the Mannich base:

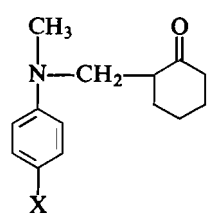


1*a* X = CH_3
b X = OCH_3
c X = $COOCH_3$
d X = $COCH_3$
e X = H

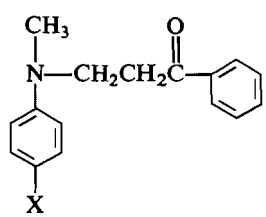
Results and discussion

In order to compare the effect of the substituent on the yield of Mannich base formed, the experimental conditions for all the runs were kept constant. The only variable was the reaction oxidation potential (E). This potential was controlled at such a voltage that a current of 100 mA was attained at the beginning of the electrolysis (Fig. 1, arrows). Then, the current dropped slowly to about 50 mA or less after the passage of 2 F/mol.

The silyl enol ethers chosen for this study, 1-trimethylsilyloxy-1-cyclohexene **3** and 1-phenyl-1-trimethylsilyloxyethylene **4**, are known from the previous study to give good yield of Mannich bases in the presence of the iminium salt of *N*,*N*-dimethylmesidine. The halfwave potentials ($E_{1/2}$'s) of the two silyl enol ethers are 1.25 V and 1.30 V vs. $Ag/AgNO_3$ respectively. The $E_{1/2}$'s of the amino compounds **1** are shown in Table 1 and they are all much less anodic than those of the silyl enol ethers **3** and **4**. On the other hand, the halfwave potentials of the amines **1** are, as expected, relatively more anodic for an electron-withdrawing substituent than for an electron-donating substituent. The yield of products **5** and **8** was markedly higher with an electron-donating group (Tables 1 and 2).



5



8

The oxidation potentials of at least three compounds must also be considered: the silyl enol ether, the amine **1**, and the Mannich base formed. As for the silyl enol ethers **3** and **4**, their E's are somewhat much too anodic to affect the result of the

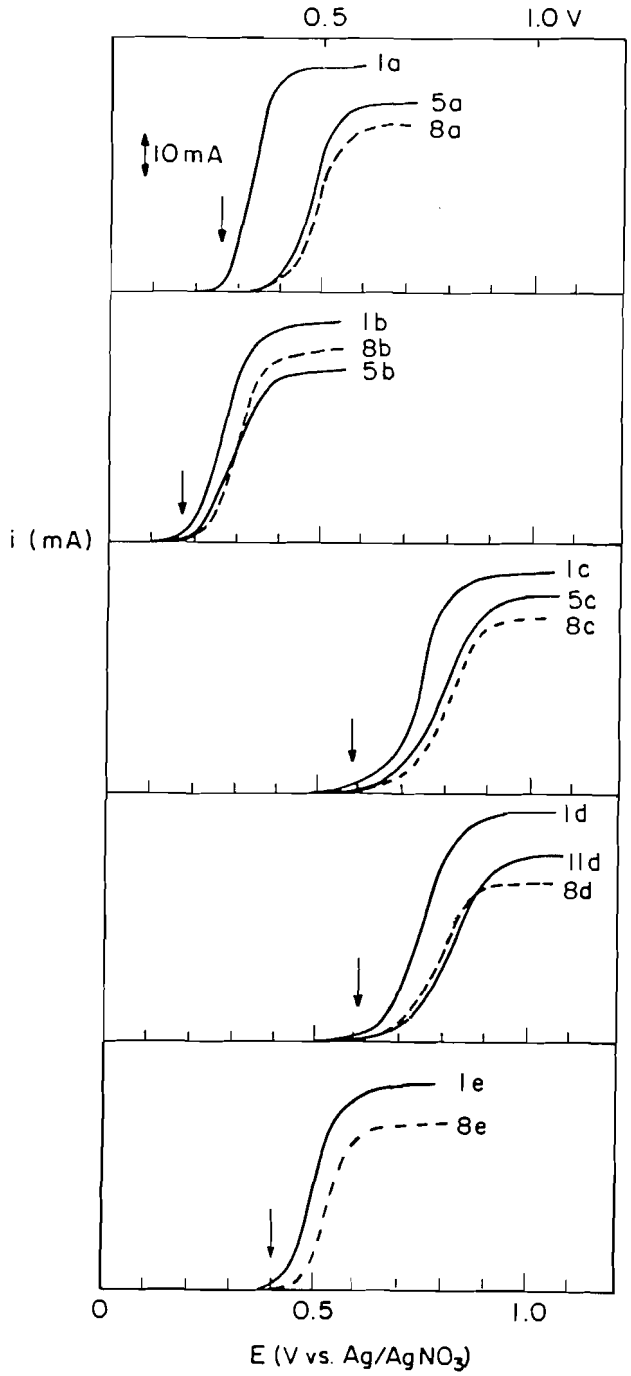

FIG. 1. Current–potential curves of 4-substituted *N*,*N*-dimethylanilines and the corresponding Mannich bases. The arrows indicate the reaction oxidation potentials *E*. Concentration: $\approx 10^{-3}$; scan rate: 2 mV/s.

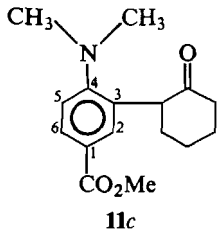
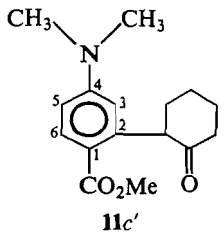
reaction. Therefore, the relative *E*'s of the amine **1** and the products **5** and **8** are most important. The current–potential curves for the amine **1** and the products **5** and **8** are shown in Fig. 1. The *E*'s of the amines having an electron-donating substituent (**1***a* and **1***b*) are more cathodic than the *E*'s of the corresponding products **5** and **8** (Fig. 1, arrows) and the Mannich bases were obtained in good yield. However, the difference between the *E*'s of the amine **1***c* and the product **5***c* was very small and the yield in Mannich base was low. The main compound obtained from this reaction was methyl 3-(2-oxocyclohexyl)-4-*N*,*N*-dimethylaminobenzoate **11***c*. The structure of **11***c* was determined by nuclear magnetic resonance spectroscopy. Two structures are plausible:

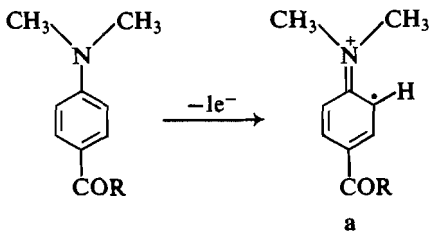


11*c*

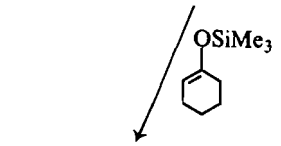


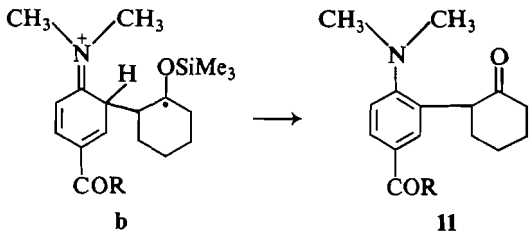
11*c*′

The broad singlet for the proton at the position 2 is at the low field side of the AB system of the two protons at positions 5 and 6. Therefore, it corresponds to a proton *ortho* to the carbonyl group (structure **11***c*). A proton at position 3 (structure **11***c*′) would show the singlet at the high-field side of the AB system. No product corresponding to **5***d* was observed from **1***d*. The main compounds isolated, in this case, were the amine **1***d*, the product **11***d*, and polymers. The mechanism for the formation of **11** is still not clear but it is most likely the attack of a radical intermediate **a** on the silyl enol ether to give a stabilized ether radical **b** (2, 3).



a





b **11**

The electrochemical oxidation of **1***c*–**1***e* in the presence of the silyl enol ether **4** gave low yields of **8***c*–**8***e* as the main products. No compound corresponding to **11** was observed.

Besides the major products **5** and **8**, some side products **6**, **7**, **9**, and **10** were also obtained in low yield. They are formed as a result of further oxidation of **5** and **8** to give a new iminium salt, which reacts either with another molecule of silyl enol ether to give **6** and **9** respectively or with residual water in the medium to give **7** and **10** respectively. Compounds **7** and **10** may also be formed from the hydrolysis of the iminium salt formed from **1**, followed by the electrolysis of the resulting *N*-methylaniline derivative[3] to give another iminium salt which

[3]The infrared spectrum showed that the starting compound **1***b* was free of monomethylanisidine.

Y = ketonic substituent

can react with the silyl enol ether. The yields of compounds **6***c*, **6***d*, and **9***d* were very low and these compounds could not be obtained pure enough for identification. However, **6***a*, **9***a*, and **9***c* were isolated pure, and identified. With X = OCH_3 (**1***b*), demethylated product **7***b* and a mixture of **9***b* and **10***b* in a 1:1 ratio were obtained.

Experimental

The *para*-substituted *N*,*N*-dimethylanilines were obtained from Aldrich or prepared by the methylation of *para*-substitued anilines (4). The silyl enol ethers were prepared according to methods described in the literature (5). The acetonitrile was purified as reported in the literature (6). Flash chromatography was performed using silica gel 230–400 mesh (7). All melting points reported are uncorrected. Infrared spectra were recorded on a Perkin–Elmer Model 267 spectrophotometer. Proton magnetic resonance spectra were taken in deuteriochloroform on a Varian Associates spectrometer model E.M. 360 or a Bucker WP-80 apparatus and are reported in the δ scale. The mass spectra were obtained from a Hewlett–Packard model 5585 gc–ms spectrometer or from a VG 7070 type mass spectrometer. The molecular weight determinations were done on a Mechrolab vapor pressure osmometer model 301A. The electrochemical instrumentation is described in the previous publication (1) with two modifications. The source of energy for the preparative scale synthesis was obtained from a 100-V 10-A Kepco power supply and the potential of the working electrode was controlled by an esc potentiostatic controller model 410.

General procedure

The anodic solution was a well-stirred mixture of $LiClO_4$ (1.34 g), Na_2CO_3 (2.12 g), silyl enol ether (3 mL), and *para*-substituted

N,N-dimethylaniline (0.005 mol) in acetonitrile (125 mL). The cathodic solution was $LiClO_4$ (0.1 *M*) in acetonitrile. The potential was controlled at such a voltage that 100 mA was obtained. That potential was kept constant until 2 F/mol has been passed. At the end of the electrolysis the current dropped to about 50 mA. The anodic solution was filtered and concentrated on a high vacuum system. The solvent was collected in a cold trap. The oily residue was extracted with two 100-mL portions of boiling n-pentane or until the pentane solution was negative to tlc. Sometimes an extraction with ether was necessary, but less pure product was isolated. The organic solvent was removed on the vacuum system and the residue pumped under a pressure of 10^{-2} Torr for 3–5 h at room temperature in order to remove the excess of silyl enol ether. The combined low vapor pressure oil or solid was fractionated by flash chromatography (7) using a column of 2-cm diameter by 40 cm long. The residue of the different fractions was purified further either by a bulb-to-bulb distillation at 10^{-2} Torr or by recrystallization from ethanol in a Craig tube.

Physical properties of the products

(A) *Electrolysis of the amine* **1** *in the presence of 1-trimethylsilyloxy-1-cyclohexene* **3**

From **1***a*: the crude mixture, obtained after the evaporation of the high vapor pressure fraction, showed one major and three minor spots on the tlc plate. The separation of the products by flash chromatography using hexane – ethyl acetate (8:1) gave four fractions. First fraction: a very small quantity of starting amine **1***a*. Second fraction: an oil corresponding to **5***a*. It was further purified by a bulb-to-bulb distillation at 80°C under a pressure of 10^{-2} Torr to give 0.54 g (50.5%) of a white solid melting at 27–28°C; ir ($CHCl_3$): 1710 (C=O) cm^{-1}; ^1H nmr δ: 1.70 (broad m including the aromatic CH_3 group, 12H), 2.90 (s, 3H), 3.42 (AB q, 2H), 6.86 (AB q, 4H); ms *m/e*: 231 (M^+, 29), 134 ($M^+ - C_6H_9O$, 100). *Anal.* calcd. for $C_{15}H_{21}NO$: C 77.92, H 9.09, N 6.06; found: C 77.88, H 9.26, N 6.17. Third fraction: a white solid (0.21 g; 13.8%) melting at 96–97°C which corresponded to **6***a*; ir ($CHCl_3$): 1705 (C=O) cm^{-1}; ^1H nmr δ: 1.20–3.90 (broad m including the aromatic CH_3 group, 25H), 7.02 (q, AB, 4H); ms *m/e*: 327 (M^+, 10), 2.30 ($M^+ - C_6H_9O$, 100). *Anal.* calcd. for $C_{21}H_{29}NO_2$: C 77.06, H 8.87, N 4.28; found: C 76.96, H 8.88, N 4.37. Fourth fraction: impure oil (**7***a*) (10 mg); ir (neat): 3400 (NH), 1705 (C=O) cm^{-1}; ms *m/e*: 217 (M^+, 5) 129 ($M^+ - C_6H_{10}O$, 100).

From **1***b*: the oily residue (1.07 g) obtained after the removal of the high vapor pressure fraction showed one major and one minor spots on the tlc plate. Two fractions were obtained by flash chromatography. First fraction: an oil corresponding to **5***b*. It was purified further by a bulb-to-bulb distillation at 60°C under a pressure of 10^{-2} Torr to give a yellow oil (0.43 g; 34.6%); ir (film): 1703 (C=O) cm^{-1}; ^1H nmr δ: 1.20–2.45 (m, 9H), 2.83 (s, 3H), 3.15 and 3.86 (2d, AB, 2H), 3.70 (s, 3H), 6.71 (m, 4H); ms *m/e*: 247 (M^+, 19) 150 ($M^+ - C_6H_9O$, 100). *Anal.* calcd. for $C_{15}H_{21}NO_2$: C 72.87, H 8.50, N 5.67; found: C 73.41, H 8.56, N 5.51. Second fraction: a white solid melting at 61–62°C after a bulb-to-bulb distillation at 100°C (10^{-2} Torr). The compound analyzed as **7***b* (154 mg; 13.1%); ir ($CHCl_3$): 3395 (NH), 1702 (C=O) cm^{-1}; ^1H nmr δ: 1.20–2.52 (m, 9H), 3.02 (m, 3H), 3.51 (broad s, 1H), 3.73 (s, 3H), 6.66 (m, 4H); ms *m/e*: 233 (M^+, 51), 136 ($M^+ - C_6H_9O$, 100). *Anal.* calcd. for $C_{14}H_{19}NO_2$: C 72.10, H 8.15, N 6.01; found: C 71.86, H 8.23, N 6.11.

From **1***c*: the crude product showed three major spots on the tlc plate. They were separated by flash chromatography. First fraction: a white solid melting at 99–101°C corresponding to **1***c* (170 mg). Second fraction: a white solid (**5***c*) melting at 82–83°C (88 mg; 6.4%); ir ($CHCl_3$): 1700 (C=O) cm^{-1}; ^1H nmr δ: 1.2–2.7 (broad m, 9H), 3.08 (s, 3H), 3.59 (q, AB, 2H), 3.85 (s, 3H), 7.18 (q, 4H); ms *m/e*: 275 (M^+, 18), 178 ($M^+ - C_6H_9O$, 100). *Anal.* calcd. for $C_{16}H_{21}NO_3$: C 69.82, H 7.64, N 5.09; found: C 69.85, H 7.71, N 5.05. Third fraction: an oil (**11***c*) (0.23 g; 16.7%); ir (neat): 1720 (C=O), 1705 (C=O) cm^{-1}; ^1H nmr δ: 1.05–2.40 (m, 8H), 2.61 (s, 6H), 3.00 (m, 1H), 3.80 (s, 3H), 7.05 (d, 1H), 7.80 (d and s, 2H); molecular weight determination: 273: ms *m/e*: 275 (M^+, 100), 260 ($M^+ - CH_3$, 6). *Anal.* calcd. for $C_{16}H_{21}NO_3$: C 69.82, H 7.64, N 5.09; found: 69.90, H 7.75, N 5.15.

From **1***d*: the tlc of the crude material showed two major spots which were separated by flash chromatography. First fraction: recovered amine **1***d* (0.21 g). Second fraction: a white solid corresponding to **11***d* (0.26 g; 20.0%) which melted at 93–94°C after recrystallization from ethanol; ir ($CHCl_3$): 1705 (C=O) 1670 (C=O) cm^{-1}; ^1H nmr δ: 1.50–24.0 (m, 7H), 2.58 (s, 3H), 2.69 (broad s, 7H), 7.28 (m, 2H), 7.90 (m, 2H); ms *m/e*: 259 (M^+, 100), 244 ($M^+ - CH_3$, 31), 216 ($M^+ - CH_3CO$, 40). *Anal.* calcd. for $C_{16}H_{21}NO_2$: C 74.13, H 8.11, N 5.41; found: C 73.94, H 8.13, N 5.29.

From **1***e*: practically only polymeric compounds were obtained. A very small quantity of soluble material in ether was isolated and no compound could be obtained pure enough for proper identification.

(B) *Electrolysis of the amine* **1** *in the presence of 1-phenyl-1-trimethylsilyloxy-ethylene* **4**

From **1***a*: the crude product showed two major and two minor spots on the tlc plate, which were separated by flash chromatography. First fraction: a white solid melting at 56–57°C and corresponding to **8***a* (0.57 g; 45.2%); ir ($CHCl_3$): 1680 (C=O) cm^{-1}; ^1H nmr δ: 2.21 (s, 3H), 2.90 (s, 3H), 3.14 (t, 2H), 3.78 (t, 2H), 6.40–7.92 (m, 9H); ms *m/e*: 253 (M^+, 57), 134 ($M^+ - C_8H_7O$, 100). *Anal.* calcd. for $C_{17}H_{19}NO$: C 80.63, H 7.51, N 5.53; found: C 80.46, H 7.45, N 5.60. Second fraction: a white solid melting at 91–92°C. It analyzed as **9***a* (0.17 g; 9.1%); ir ($CHCl_3$): 1680 (C=O) cm^{-1}; ^1H nmr δ: 2.21 (s, 3H), 3.16 (t, 4H), 3.86 (t, 4H), 6.40–7.90 (m, 14H); ms *m/e*: 371(M^+, 14), 252 ($M^+ - C_8H_7O$, 100). *Anal.* calcd. for $C_{25}H_{25}NO_2$: C 80.86, H 6.74, N 3.77; found: C 80.56, H 6.62, N 3.92. The two minor products could not be obtained pure enough for identification.

From **1***b*: the crude product was obtained from an ether extraction after addition of water to the reaction mixture. One major and two minor spots showed on the tlc plate. The compounds were separated by flash chromatography. First fraction: a white solid (**8***b*) melting at 57–58°C (0.43 g; 31.9%); ir ($CHCl_3$): 1680 (C=O) cm^{-1}; ^1H nmr δ: 2.50–4.10 (m, including the two CH_3 groups, 10H), 6.41–7.95 (m, 9H); ms *m/e*: 269 (M^+, 38), 150 ($M^+ - C_8H_7O$, 100). *Anal.* calcd. for $C_{17}H_{19}NO_2$: C 75.84, H 7.06, N 5.20; found: C 75.98, H 7.04, N 5.28. Second fraction: a white solid (87 mg) which melted at 99–100°C after recrystallization from ethanol. The analysis of this solid indicated a mixture of **9***b* and **10***b* by mass spectrometry. The analysis was done by direct injection and the temperature was programmed from 60–270°C.

From **1***c*: water (50 mL) was added to the reaction mixture which was then extracted with ether. The crude product (two important spots on tlc) was purified by a bulb-to-bulb distillation at 10^{-2} Torr. First fraction (60°C): 50 mg of starting amine **1***c*. Second fraction (140°C): an oil corresponding to **8***c*, which crystallized on standing. It was purified further by recrystallization from ethanol in a Craig tube. A white solid melting at 78–79°C (0.29 g; 19%) was obtained; ir ($CHCl_3$): 1700 (C=O), 1690 (C=O) cm^{-1}; ^1H nmr δ: 3.03 (s, 3H), 3.31 (m, 2H), 4.09 (m, including the single of N—CH_3), 6.89 (d, 2H), 7.60 (m, 3H), 8.10 (m, 4H); ms *m/e*: 297 (M^+, 21), 178 ($M^+ - C_8H_7O$, 100). *Anal.* calcd. for $C_{18}H_{19}NO_3$: C 71.58, H 6.67, N 4.91; found: C 71.65, H 6.56, N 4.79. A small amount of solid, not very soluble in ether, was also obtained. This compound (**9***c*) melted at 150–151°C after recrystallization from ethanol (78 mg; 3.1%). *Anal.* calcd. for $C_{26}H_{25}NO_4$: C 75.18, H 6.02, N 3.37; found: C 75.06, H 6.24, N 3.41.

From **1***d*: the crude product showed two spots on the tlc plate. First fraction from flash chromatrography: the amine **1***d* (66 mg; 8%). Second fraction: a white solid (**8***d*) melting at 93–94°C (85 mg; 6%); ir ($CHCl_3$): 1680 (C=O), 1660 (C=O) cm^{-1}; ^1H nmr δ: 2.47 (s, 3H), 3.03 (s, 3H), 3.25 (t, 2H), 3.89 (t, 2H), 6.72 (d, 2H), 7.39 (m, 3H), 7.82 (m, 4H); ms *m/e*: 281 (M^+, 53), 162 ($M^+ - C_8H_7O$, 100). *Anal.* calcd. for $C_{18}H_{19}NO_2$: C 76.87, H 6.76, N 4.98; found: C 76.67, H 6.67, N 5.02.

From **1***e*: to the gummy residue, obtained after the evaporation of the high vapor pressure fraction, was added water (50 mL), and the resulting mixture was extracted with two portions of 50 mL of ether. The crude product gave one major and many minor spots on the tlc plate. The major compound was isolated by flash chromatography. A white solid melting at 58−59°C was obtained after recrystallization from ethanol. This compound corresponded to **8***e* (0.16 g; 13.4%); ir ($CHCl_3$): 1678 (C=O) cm^{-1}, ^1H nmr δ: 2.98 (s, 3H), 3.20 (t, 2H), 3.85 (5, 2H), 6.52−8.00 (m, 10H); ms *m/e*: 239 (M^+, 19), 120 ($M^+ - C_8H_7O$, 100). *Anal.* calcd. for $C_{16}H_{17}NO$: C 80.33, H 7.11, N 5.86; found: C 80.15, H 7.22, N 5.68.

Acknowledgements

We wish to thank Mr. H. Séguin for the elemental analyses and the molecular weight determination, and Dr. J. L. Holmes of the University of Ottawa for the mass spectral determinations.

The crystal structures of the title compounds have been determined from diffractometric X-ray data and refined by full-matrix least-squares to final *R* factors of 0.047 and 0.060 from 830 and 620 independent reflections above background, respectively. The space group and the number of molecules per unit cell are the same in both cases: $P2_12_12_1$ and $Z = 4$. Cell dimensions are: $a = 7.982(2)$, $b = 9.538(3)$, $c = 18.785(3)$ Å for the *S* form and $a = 10.339(3)$, $b = 11.510(3)$, and $c = 11.886(6)$ Å for the *R* form. The molecules, produced simultaneously in the same chemical reaction, have essentially identical configuration except for the location of the chlorine atoms at C-11 (in the *S* case) and at C-10 (in the *R* case). This difference gives rise to a completely different molecular packing of the structures. In each compound the two cyclopropane rings present a *cis* relationship to one another, with an identical dihedral angle of 77.0°.

J. Zukerman-Schpector, E. E. Castellano, G. Oliva, Timothy John Brocksom et Elisabete Terezinha Canevarolo. Can. J. Chem. **62**, 570 (1984).

Faisant appel à la diffraction de rayons-X, on a déterminé les structures cristallines des composés mentionnés dans le titre et on les a affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs conventionnelles de $R = 0{,}047$ et de 0,060 pour 830 et 620 réflexions indépendantes observées au-dessus de l'état fondamental. Le groupe d'espace et le nombre de molécules par maille sont les mêmes dans les deux cas soit: $P2_12_12_1$ et $Z = 4$. Les dimensions de la maille sont: $a = 7{,}982(2)$, $b = 9{,}538(3)$, $c = 18{,}785(3)$ Å pour la forme *S* et $a = 10{,}339(3)$, $b = 11{,}510(3)$ et $c = 11{,}886(6)$ Å pour la forme *R*. Les molécules, qui sont produites simultanément par la même réaction chimique, ont essentiellement la même configuration sauf en ce qui a trait à la position des atomes de chlore en C-11 (dans le cas de la forme *S*) et à celle du groupe C-10 (dans le cas de la forme *R*). Cette différence conduit à un entassement moléculaire des structures complètement différent. Dans chaque composé, les deux cycles cyclopropanes sont en position *cis* avec un angle dièdre identique de 77,0°.

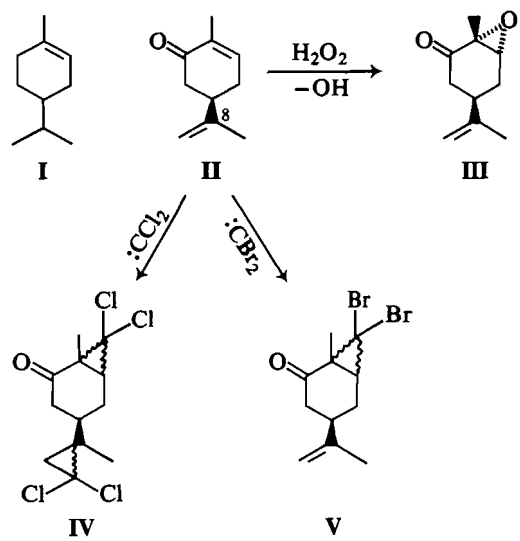
Introduction

In connection with recent studies on the synthesis of biologically active sesquiterpenes using simple monoterpenes as starting materials (1), we have investigated the stereochemistry of the addition of carbenes to *p*-menth-1-ene monoterpenes (**I**). Apart from helping to elucidate the reaction mechanism, the structure of the adducts is important in the prediction of the structures of products in subsequent reactions. We have prepared a series of adducts from the reaction of dichlorocarbene and dibromocarbene with simple monoterpenes such as limonene, α-terpineol, and carvone. However, the only product which presents crystals in an adequate form for three-dimensional structure determination is the bis-adduct of dichlorocarbene with (−)-*R*-carvone (**II**), which forms the subject matter of the present article.

A literature search on these carbene−monoterpene adducts (2−6), demonstrates clearly the lack of concrete information about their stereochemistry. Occasional comments (6) suggest a preferential *trans* relationship between the bulky isopropenyl group and the incoming carbene unit, by analogy with the well defined stereochemistry of epoxidation of carvone (7). In this regioselective and stereoselective reaction, epoxidation occurs exclusively at the conjugated double bond with the formation of the epoxi-carvone (**III**) indicated. The reaction of dichlorocarbene with carvone, in our hands, is not regioselective as the



attack of the carbene occurs at both double bonds (**IV**), whereas the dibromocarbene adduct (**V**) is formed regioselectively (5).

Stereochemical analysis of the bisdichlorocarbene adduct (**IV**) suggests nonstereoselective formation of dichlorocyclopropanes at the nonconjugated double bond (Δ-8 of carvone (**II**)). Thus, by analogy with the completely stereo-

selective epoxidation of carvone, one expects to obtain two diastereomers in approximately equal amounts (diastereomeric at C-9).[1] On the other hand, partially stereoselective attack of the carbene at the conjugated double bond should lead to two pairs of the four possible diastereomers formed in unequal amounts. Careful gas chromatographic analysis of the product obtained indicated the presence of one component only (one peak). As no conventional spectroscopic method or chemical correlation would really define the full stereochemical structure, we chose to perform a three-dimensional crystal structure analysis.

[1]We have used standard *p*-menthane numbering for carvone (**II**), whereas the products obtained in the reaction were given conventional IUPAC numbering as in Figs. 1 and 2.

Experimental

The compounds were prepared as described elsewhere (1). Crystals were grown from ether solution by slow evaporation at 8°C. Visual inspection of the crystalline material showed the presence of two shades of yellow samples which turned out to correspond to the *S* and *R* forms of the compound. Crystal data are given in Table 1. Intensities were measured on an Enraf-Nonius CAD-4 diffractometer by the ω-2θ scan technique, with scan rates determined from fast prescans on each reflection, using graphite monochromated MoKα (λ = 0.71069 Å) radiation. The intensities of two standard reflections were essentially constant over the duration of both experiments. Data were corrected for Lorentz and polarization effects but not for absorption or extinction.

Structures solution and refinements

Both structures were solved using MULTAN-80 (8) and refined by full-matrix least-squares with the SHELX-76 (9) system of programs.

C-10—C-11	1.46(2)	1.46(2)

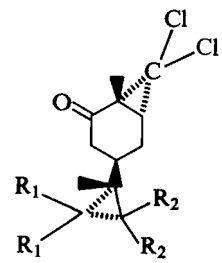
The usual sequence of isotropic and anisotropic refinement, using unit weights, was followed. All hydrogen atoms were then located from a difference Fourier synthesis. Further anisotropic refinement proceeded with all hydrogen atom positions fixed and their isotropic temperature factors set to the common value of 4.0 Å^2. The final weighting schemes used are described in Table 1. In both cases refinement was considered complete when the shifts/esd ratios were less than 0.01. Bonded H-atom scattering factors (10) and complex neutral scattering factors (11, 12) for the remaining atoms were employed. No unusually high correlations were noted in either refinement. A final difference Fourier map showed no features of chemical significance. Measured and calculated structure factors, anisotropic thermal parameters for non-hydrogen atoms, and H-atoms parameters have been deposited. Atomic coordinates together with calculated isotropic temperature factors are given in Tables 2 and 3, where the expression for B_{iso} is of the form:

$$B_{iso} = \frac{4}{3}\sum_{ij} T_{ij}B_{ij}$$

where T_{ij} are the elements of the metric tensor and B_{ij} are the elements of the thermal tensor usually obtained by least-squares refinement (13).

Discussion

The main result of the present paper is the unambiguous determination of the existence of the two forms (*S* and *R*) of the reaction product mentioned in the Introduction, which are diastereomeric at C-9, according to **VI**, where **VI***a* and **VI***b* correspond to the *S* and *R* forms, respectively. It should be pointed out that the fact that the two compounds produced crystals of different colours is really a fortunate situation, since no standard organic chemistry method would have distinguished and allowed separation between the two forms. Indeed, careful gas chromatographic analysis does not separate these diastereomers.



VI*a* R_1 = Cl, R_2 = H
VI*b* R_1 = H, R_2 = Cl

Figures 1 and 2 are stereoscopic projections (14) of the two molecules, showing the numbering scheme, displayed in similar orientations to facilitate comparison. Since the absolute configuration was not determined (the Hamilton test was insensitive to enantiomorph reversal) we choose for both molecules the same configuration as that of natural (−)-*R*-carvone (**II**). Interatomic distances and bond angles are given in Tables 4 and 5. The two molecules have essentially the same configuration except for the location of the chlorine atoms at C-11 in the *S* case and C-10 in the *R* case. This difference, however, gives rise to a completely different molecular packing of the structures. Superposition of the two molecules (excluding hydrogens and chlorines Cl-3 and Cl-4) using the best least-squares orthogonal transformation as defined by Kabsch (15), gave a root-mean-square distance between equivalent atoms of 0.26 Å. The cyclopropane rings are in a *cis* relationship to one another with the same dihedral angle of 77.0° in both

structures.

The rather poor quality of the crystals, especially that of the *R*-form, prevented us from obtaining a good number of reflections per parameter ratio. As a result, the standard deviations for bond distances and angles are rather large, as expected after Cruickshank (16).

Synthesis and spreading behaviour of some reactive derivatives of long-chain alcohols and carboxylic acids

DAVID A. HOLDEN
Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received September 12, 1983

DAVID A. HOLDEN. Can. J. Chem. **62**, 574 (1984).

Procedures are described for the synthesis of several azides, diimides, and azodiformates from long-chain alcohols and fatty acids. These reactive compounds have potential applications as thermal and photochemical curing agents, and as surface-modifying agents for the preparation of filled plastics and chromatographic packings. The surface activity of the compounds was characterized by investigations of their spreading behaviour in monolayers on water. Unlike the single-chain azides and azo compounds, which give well-defined monolayers at all temperatures, monolayers of diacyl diimides and dialkyl azodiformates with two long-chain substituents are unstable with respect to collapse to the bulk solid. The photoreaction of monolayers of octadecanoyl azide to give a mixture of products derived from an intermediate isocyanate was demonstrated by ir and mass spectrometry.

DAVID A. HOLDEN. Can. J. Chem. **62**, 574 (1984).

On décrit des méthodes de synthèse de plusieurs azotures, diimides et azodiformates à partir d'acides gras et d'alcools à longues chaînes. Ces composés réactifs peuvent éventuellement être utilisés comme agents de durcissement thermique ou photochimique ou comme agents modifiant la surface lors de la préparation de garnissages chromatographiques ou de plastiques remplis. On a caractérisé l'activité de surface des composés en étudiant leur comportement lorsqu'ils se répandent sous forme de monocouches sur l'eau. Contrairement aux composés azotures et azo ne comportant qu'une seule chaîne, qui donnent des monocouches bien définies à toutes les températures, les monocouches des diimides de diacyles et des azodiformates de dialkyles portant comme substituants deux longues chaînes carbonées ne sont pas stables. On a démontré par ir et par spectrométrie de masse que la photoréaction de monocouches de l'azoture d'octadécanoyle conduit à un mélange de produits qui proviennent d'un intermédiaire isocyanate.

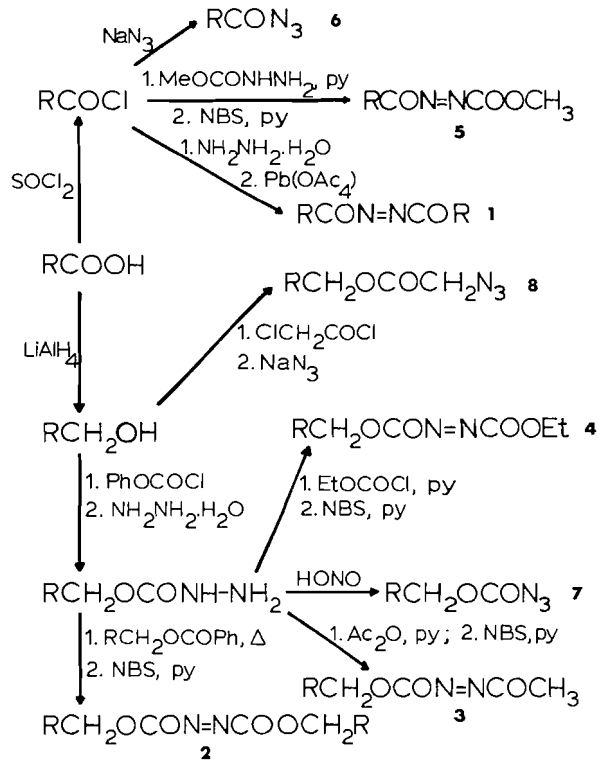
Introduction

There is considerable scientific and technical interest in the reactions of compounds incorporated into thin layers at interfaces. Recent activity in this field is concentrated in several areas: in efforts to duplicate or imitate biological processes in synthetic bilayer membranes (1–3), in photochemically cured coatings designed to avoid the use of toxic solvents (4), and in potential applications of monomolecular films in the optical and electronics industries (5).

In a number of applications involving amphiphilic molecules it is necessary to introduce a complex functional group into a surface-active molecule without destroying the surface activity. This surface activity causes the molecules to organize spontaneously into structures such as monolayers at interfaces or bilayer vesicles resembling simple cell membranes, while the functional group remains intact and available for subsequent reaction. In particular it may be desirable to have long-chain compounds with the same potential for surface reactions as octadecyltrichlorosilane, for example, but with higher surface activity and greater resistance to hydrolysis.

The present publication describes the synthesis from fatty acids and alcohols of a number of surface-active derivatives containing reactive functional groups. These include the azo compounds **1** and **2** having two long hydrocarbon chains and the related compounds **3** to **5** having only a single long hydrocarbon chain. Such compounds are potential thermal and photochemical sources of free radicals for curing and polymerization reactions in thin films. Several long-chain azides **6**–**8**, with potential applications as surface-modifying agents, were also synthesized. The spreading behaviour of these new compounds in monolayers is reported, as well as the results of an investigation of the photochemistry of octadecanoyl azide in monolayers.

Scheme 1 shows the sequence of reactions by which the



SCHEME I

compounds were prepared. While procedures exist for the synthesis of short-chain analogues of these compounds, it was necessary to modify these procedures substantially in several cases. The lower solubility of fatty acids and alcohols in organic solvents required more vigorous reaction conditions. New solvent systems were necessary in several cases because

the long-chain starting materials had negligible solubility in water. Distillation of the unstable products was not practical and washing of organic solutions of the products often gave intractable emulsions. Instead, suitable solvent systems for purification of the products by low-temperature recrystallization were found. It is hoped that such procedures may be more easily scaled up than purification steps requiring liquid chromatography.

Experimental

Melting points of compounds were recorded in capillaries using a Büchi oil immersion apparatus and are uncorrected. The ^{1}H nmr spectra were recorded on JEOL or Perkin–Elmer R-12B 60 MHz instruments using $CDCl_3$ as solvent and Me_4Si as internal reference. Infrared spectra were recorded on Perkin–Elmer 457 and Beckman Acculab 10 instruments, either as melts or in paraffin oil mulls.

Materials

Stearic acid (99%) was obtained from Sigma Chemicals. Myristic and lauric acids (Merck) were used as received. Palmitic acid (Fisher reagent grade) was recrystallized twice from acetone between 50°C and 0°C. Acid chlorides were obtained by overnight stirring of the corresponding acid with 1.1 equivalents of $SOCl_2$ catalysed by the addition of one drop of *N*,*N*-dimethylformamide. The excess $SOCl_2$ was removed on a water aspirator and the acid chloride was fractionally distilled under high vacuum. 1-Hexadecanol was obtained by $LiAlH_4$ reduction of palmitic acid in refluxing THF. All of the following compounds were stored in the dark at −20°C.

1,2-Dihexadecanoyl hydrazine

Symmetric hydrazides were prepared by a modification of the Sonntag method (6). A solution of 0.56 NaOH and 0.337 g 85% hydrazine hydrate in 25 mL H_2O was stirred at 0°C while 3.13 g palmitoyl chloride in 5 mL CH_2Cl_2 was added dropwise over 30 min. The reaction mixture was stirred overnight at room temperature and the precipitate was filtered by suction. The dried product was recrystallized several times from toluene between its boiling point and room temperature to give 2.7 g (92%) of crystals melting at 144.5–145°C; ir (Nujol): 3260, 1610 cm^{-1}.

Dihexadecanoyl diimide (7)

Lead tetraacetate (Merck) was washed free of excess acetic acid with dry hexanes, dried by suction, and used immediately. Benzene was purified by distillation from P_2O_5 under nitrogen. A suspension of 2.0 g 1,2-dihexadecanoyl hydrazine in 250 mL purified benzene was heated to the boiling point of the solvent and stirred vigorously while 1.8 g lead tetraacetate was added all at once. After 15 s the hot solution was filtered by suction through a medium porosity sintered glass funnel and the benzene was evaporated off at 20°C under reduced pressure. The product was recrystallized twice from 50 mL 2:1 CH_2Cl_2–hexane solution between 30°C and −20°C. The yield of yellow crystals was 1.0 g (51%), mp 69–71°C with decomposition; ir (Nujol): C=O at 1750 cm^{-1}; no NH or amide C=O bands remaining; ^{1}H nmr δ: 0.86 (t, 6H, $2CH_3$), 1.27 (m, 52H, $26CH_2$), 2.55 (t, 4H, $2CH_2CO$); uv (1:1 hexane–dichloromethane, Cary 118) λ_{max}: 454 nm (ε 23.0 M^{-1} cm^{-1}). Other long-chain diacyl diimides were obtained from the corresponding hydrazides by the same procedure. High purity of the starting materials was necessary, otherwise the diimides decomposed rapidly at room temperature.

Ditetradecanoyl diimide

Melting point 70–71°C with gas evolution (oil bath preheated to 65°C); ir (Nujol): 1755 cm^{-1}; nmr δ: 0.88 (t, 6H) 1.22 (m, 44H), 2.52 (t, 4H); uv (distilled THF) λ_{max}: 452 nm (ε 24.4 M^{-1} cm^{-1}). The extinction coefficient at 254 nm is 342 M^{-1} cm^{-1}. *Anal.* calcd. for $C_{28}H_{54}N_2O_2$: C 74.61, H 12.08, N 6.21%; found: C 74.25, H 12.33, N 6.20%.

Didodecanoyl diimide

Melting point 62–63°C with gas evolution (oil bath preheated to 55°C); ir (Nujol): 1755 cm^{-1}; nmr δ: 0.85 (t, 6H), 1.22 (m, 36H), 2.56 (t, 4H); uv (purified THF) λ_{max}: 452 nm (ε 24.3 M^{-1} cm^{-1}). The extinction coefficient at 254 nm is 322 M^{-1} cm^{-1}. *Anal.* calcd. for $C_{24}H_{46}N_2O_2$: C 73.04, H 11.75, N 7.10%; found: C 72.99, H 12.09, N 7.13%.

Dioctadecanoyl diimide

Melting point 79.5–80.5°C with decomposition (oil bath preheated to 75°C); ir (Nujol): 1760 cm^{-1}; nmr δ: 0.90 (t, 6H), 1.27 (m, 60H), 2.55 (t, 4H); uv (cyclohexane) λ_{max}: 450 nm (ε 22.9 M^{-1} cm^{-1}). The extinction coefficient at 254 nm is 350 M^{-1} cm^{-1}. *Anal.* calcd. for $C_{36}H_{70}N_2O_2$: C 76.81, H 12.53, N 4.98%; found: C 76.93, H 12.88, N 4.91%.

Phenyl hexadecyl carbonate (8)

To a stirred solution of 8.0 g 1-hexadecanol and 5.0 g *N*,*N*-dimethylaniline in 50 mL CH_2Cl_2 at room temperature, 5.2 g phenyl chloroformate (Eastman) was added over 2 hours. After overnight stirring the solution was extracted twice with 50 mL water, three times with 1 *M* HCl, twice with 5% Na_2CO_3 solution, and once with water, and was dried over Na_2SO_4. Removal of the solvent left a crystalline product, mp 33–34°C, following recrystallization from ethanol; ir (melt): 1760 cm^{-1}.

Hexadecyl carbazate (8)

A mixture of 11.0 g phenyl hexadecyl carbonate and 2.8 g 85% hydrazine hydrate was stirred at 80°C for 16 h. The product was dissolved in 150 mL CH_2Cl_2 and the organic layer was extracted four times with 50-mL lots of 2.5 *M* NaOH and twice with water. The solution of the product was dried over Na_2SO_4 and the solvent was removed on a rotary evaporator. The product was recrystallized from methanol between its boiling point and 0°C, filtering the hot solution. The yield of colourless crystals having mp 79–80°C was 7.1 g (74%); ir (Nujol): 3320, 1690, 1610 cm^{-1}.

Hexadecyl azidoformate (9)

A solution of 3.0 g hexadecyl carbazate in 150 mL glacial acetic acid was cooled in ice until the acid began to freeze, at which point a solution of 0.76 g $NaNO_2$ in 3 mL H_2O was added dropwise with stirring. The mixture was allowed to warm up to room temperature overnight. The solution was diluted to 600 mL with water and was extracted three times with 50-mL lots of CH_2Cl_2. The combined organic extracts were washed with three 50-mL volumes of 3% $NaHCO_3$ and once with water, and were dried over Na_2SO_4. Evaporation of the solvent left a white solid which was dissolved in 8 mL CH_2Cl_2, diluted to 50 mL with hexanes, and cooled to 0°C. A small amount of a solid, mainly unreacted starting material, was filtered off and discarded. Cooling the filtrate to −78°C gave pure white crystals, which were filtered by suction and dried *in vacuo*. The yield of product, mp 33°C, was 2.2 g; ir (melt): 2180, 2130, 1725 cm^{-1}; nmr δ: 0.95 (t, 3H) 1.30 (m, 28H), 4.24 (t, 2H); uv (abs. ethanol): shoulder at 255 nm (ε 175 M^{-1} cm^{-1}), shoulder at 218 nm (ε 3180 M^{-1} cm^{-1}).

1,2-Bis(hexadecyloxyformyl) hydrazine

A mixture of 1.50 g phenyl hexadecyl carbonate and 1.24 g hexadecyl carbazate was melted in an oil bath and maintained at 80–100°C for 4 days. The cooled product was dissolved in 50 mL hot $CHCl_3$, and the solution was treated with Norite and filtered. Chilling the solution in Dry Ice initiated crystallization. The filtered product was recrystallized a second time from 30 mL hot ethanol to give 1.1 g of colourless crystals, mp 67–68°C; ir (Nujol): 3280 cm^{-1}, split carbonyl band with maxima at 1740, 1720, 1710 cm^{-1}.

Dihexadecyl azodiformate (10)

A suspension of 0.5532 g 1,2-bis(hexadecyloxyformyl) hydrazine and 0.0805 g dry pyridine in 25 mL dry CH_2Cl_2 was stirred at room temperature and 0.165 g *N*-bromosuccinimide was added all at once. After 5 minutes the solution was filtered to remove a small amount of precipitate. The clear filtrate was evaporated to dryness at reduced pressure and the solids were transferred to a filter funnel and washed many times with water. Recrystallization of the insoluble product from 50 mL 95% ethanol between 50°C and 0°C, filtering the warm

solution, gave 0.37 g (67%), mp 37.5–38°C; nmr δ: 0.87 (t, 6H), 1.24 (m, 56H), 4.38 (t, 4H); uv (hexanes) λ_{max}: 401 nm (ε 35.6 M^{-1} cm^{-1}). The extinction coefficient at 250 nm is 480 M^{-1} cm^{-1}.

1-Hexadecyloxyformyl 2-acetyl azene **3**

A solution of 6.2 g hexadecyl carbazate in 75 mL pyridine at 40°C was stirred while 5 mL (5.5 g) of acetic anhydride in 20 mL pyridine was added all at once. After 1 hour of stirring the solution was diluted to 300 mL with ice water and the product was filtered by suction and washed with water. The hydrazide was recrystallized from 200 mL 95% ethanol to give 6.0 g of product, mp 82.5–83°C; ir (Nujol): 3200, 1720, 1670, 1610 cm^{-1}.

A suspension of 2.00 g of the above hydrazide in 75 mL CH_2Cl_2 containing 0.475 mL dry pyridine was stirred while 1.045 g *N*-bromosuccinimide was added all at once. After 5 minutes further stirring the solvent was removed on the rotary evaporator. The product was taken up in hexanes and filtered by suction from insoluble by-products and residual starting material. Evaporation of the solvent at reduced pressure left 1.55 g (78%) of an orange oil, n_D^{24} = 1.4507; ir (neat): 1765 cm^{-1}; nmr δ: 0.89 (t, 3H), 1.29 (m, 28H), 2.38 (s, 3H), 4.45 (t, 2H); uv (cyclohexane) λ_{max}: 430 nm (ε 29.2 M^{-1} cm^{-1}). Attempts to recrystallize this compound at low temperature gave material of much lower purity.

Ethyl hexadecyl azodiformate **4**

A solution of 1.30 g hexadecyl carbazate and 0.45 mL pyridine in 75 mL dichloromethane was stirred at room temperature while 0.50 g ethyl chloroformate was added dropwise over 5 minutes. After overnight stirring the solution was washed with 1 *M* HCl, 5% $NaHCO_3$ solution and water, and was dried over Na_2SO_4. Following evaporation of the solvent the hydrazide was recrystallized from 75 mL absolute ethanol between 75°C and 0°C to give 1.1 g white crystals, mp 71.5–73°C; ir (Nujol): 3220, 1740, 1680 cm^{-1}.

To a stirred suspension of 1.0 g of the above product in 75 mL CH_2Cl_2 containing 1.1 equivalents of dry pyridine, 0.48 g *N*-bromosuccinimide was added all at once. After all of the starting material had dissolved, the clear orange solution was washed with 0.5 *M* HCl and water and was dried over Na_2SO_4. The yield of pure ethyl hexadecyl azodiformate after two low-temperature recrystallizations was 0.20 g (20%), mp 29.5–30°C; ir (Nujol): 1770 cm^{-1}; nmr δ: 0.85 (t, 3H), 1.1–1.9 (m, 31H, $14CH_2$ and $1CH_3$), 4.2–4.7 (m, 4H, 2 overlapping —CH_2—O—); uv (cyclohexane) λ_{max}: 404 nm (ε 35.3 M^{-1} cm^{-1}).

1-Octadecanoyl 2-methoxyformyl azene **5**

A solution of 10 g stearoyl chloride in 50 mL benzene was added to a stirred solution of 3.0 g methyl carbazate in 20 mL dry pyridine. After 1 hour further stirring the reaction mixture was poured into 750 mL water and the product was filtered by suction and washed with water. The yield of product following recrystallization from 200 mL 95% ethanol was 8.7 g, mp 103–103.5°C; ir (Nujol): 3200, 1730, 1700, 1670, 1645, 1600 cm^{-1}.

This hydrazide was converted to the azo-compound **5** following the procedure for compound **4**. The product was recrystallized twice from 60 mL 1:2 CH_2Cl_2–hexanes between room temperature and −78°C to give 2.65 g (87%) orange crystals, mp 39–40°C; ir (Nujol): 1765 cm^{-1}; nmr δ: 0.88 (t, 3H), 1.26 (m, 30H), 2.63 (t, 2H), 4.05 (s, 3H); uv (cyclohexane) λ_{max}: 429 nm (ε 32.0 M^{-1} cm^{-1}).

Octadecanoyl azide (11)

A solution of 5.0 g distilled stearoyl chloride in 30 mL acetone was added dropwise with stirring to a solution of 3.1 g sodium azide in 75 mL H_2O cooled to 5–10°C. After three hours stirring at 10°C the reaction mixture was diluted with 100 mL H_2O and the white solid was filtered by suction and washed several times with water. The product was dissolved in 150 mL 1:1 ether–ethanol at 30°C, filtered through a filter cone filled with Na_2SO_4, and cooled to −20°C. The filtered crystals were dried for one hour over P_2O_5 under high vacuum to give 4.3 g of a white crystalline solid which decomposes with nitrogen evolution at 42–43°C; ir (Nujol): 2145, 1710 cm^{-1}. The 2275 cm^{-1} band of 1-heptadecyl isocyanate is virtually absent; nmr δ: 0.090 (t, 3H), 1.23 (m, 30H), 2.35 (t, 2H); uv (cyclohexane): no absorption maxima above 220 nm. The extinction coefficient at 254 nm is 162 M^{-1} cm^{-1}. The half-life of the solid azide at 20°C is approximately 72 h. Following prolonged storage the compound was repurified by recrystallization from acetone between 30°C and −20°C.

Hexadecyl 2-chloroacetate (12)

A solution of 15.0 g 1-hexadecanol and 7.5 g *N*,*N*-dimethylformamide in 75 mL dry CH_2Cl_2 was stirred at 0°C while 7.1 g chloroacetyl chloride (Merck) was added dropwise over 15 min. After one hour the solution was washed three times with 10% HCl, twice with 5% $NaHCO_3$, and once with water. After overnight drying over Na_2SO_4 the solvent was removed at reduced pressure, leaving 18.5 g (94%) of a solid, mp 28.5–29°C; ir (neat): 1745 cm^{-1}. The crude product was used directly in the following reaction.

Hexadecyl 2-azidoacetate (13)

A solution of 10.0 g crude hexadecyl 2-chloroacetate in 60 mL acetone was added at room temperature to a stirred solution of 5.0 g sodium azide in 40 mL H_2O. The two-phase system was refluxed gently for 18 h, after which the bath temperature was raised to 70°C and 50 mL acetone was distilled off. The residual liquids were diluted to 100 mL with water and the product was separated. The aqueous layer was extracted three times with ether and the combined organic layers were washed twice with water and once with saturated NaCl and were dried over Na_2SO_4. Removal of the solvent left a solid, which was recrystallized twice from 75 mL hexanes between 25°C and −20°C. A total of 7.1 g (70%) colourless crystals, mp 35.5–36.5°C, was obtained; ir (melt): 2100, 1740 cm^{-1}; nmr ($CDCl_3$) δ: 0.90 (t, 3H), 1.24 (m, 28H), 3.88 (s, 2H), 4.22 (t, 2H). *Anal.* calcd. for $C_{18}H_{35}N_3O_2$: C 66.42, H 10.84, N 12.91%; found: C 68.2, H 11.4, N 12.2%. It is probable that slight decomposition of the product occurred in the several days which elapsed between removal of the sample from the freezer and performing the elemental analysis.

Methods

Measurements of surface spreading behaviour

Two commercial Langmuir troughs, one a rectangular trough (MGW Lauda) and the other a Fromherz circular trough (14), were used in studies of monolayers. Temperature control of the subphase was provided by a Lauda Model K4R constant temperature bath and circulating pump. Compounds were spread as dilute (1 mg/mL) solutions in chloroform or hexane on the surface of pure unbuffered water. After five minutes to allow the spreading solvent to evaporate completely, the surface pressure – area curves were recorded continuously at a compression rate of 0.05 nm^2 $molecule^{-1}$ min^{-1}. All measurements were performed at least twice. The reproducibilities of the surface pressure and surface area values for consecutive measurements were typically 0.5 mN m^{-1} and 0.005 nm^2 $molecule^{-1}$ respectively.

Irradiation of monolayers of octadecanoyl azide on water

For photochemical studies the cover of the Lauda trough was modified to hold a 250-mA low-pressure mercury lamp (Gräntzel, Karlsruhe), which was driven at a constant current of 120 mA. Octadecanoyl azide was spread from a fresh cold (0°C) solution in chloroform on the subphase. The solvent was allowed to evaporate for two minutes and the monolayer was irradiated at 254 nm at a constant surface area of 0.65 nm^2/molecule for 20 min. The lamp was switched off and the surface pressure – area curve of the irradiated monolayers recorded at a compression rate of 0.05 nm^2 $molecule^{-1}$ min^{-1}.

Analysis of photoproducts from irradiation of monolayers of octadecanoyl azide

The entire water surface below the low-pressure lamp of the Lauda trough was used as a reaction surface. Monolayers were irradiated at a constant area of 0.25 nm^2/molecule for 30 min. They were then compressed to a 0.5-cm strip, removed from the surface with a clean metal spatula, and dried *in vacuo* over P_2O_5. A total of 8 monolayers was collected to yield about 1 mg of a white solid, mp 69–74°C. The infrared spectrum of the product was recorded in carefully dried KBr against a KBr reference pellet; ir (Perkin–Elmer 457): 3300, 2900, 2840, 1760, 1710, 1635, 1540, 1464, 1373, 1235, 1090, 1035, 718

cm^{-1}; ms (electron impact, 200°C sample holder, main peaks only) *m/z:* 565 (relative intensity 2), 564 (5), 537 (4), 536 (10), 522 (10), 521 (28), 520 (7), 394 (2), 380 (3), 366 (6), 353 (6), 352 (5), 338 (5), 324 (7), 312 (3), 310 (22), 298 (19), 297 (75), 284 (24), 283 (7), 282 (23), 268 (5), 267 (6), 256 (14), 255 (8), 254 (17), 241 (5), 240 (5), 226 (4), 212 (4), 198 (5), 185 (6), 184 (5), 170 (5), 156 (6), 142 (7), 129 (14), 128 (10), 114 (20), 113 (19), 112 (27), 99 (59), 98 (19), 97 (21), 57 (93), 43 (100).

Thermal stability of diacyl diimides

Dilute solutions of dihexadecanoyl diimide in xylenes (J. T. Baker) were maintained at constant temperature in an air-free microcell in the thermostatted sample compartment of a Cary 118 uv–visible spectrometer. The decrease of the sample absorbance at 450 nm was recorded continuously.

Results and discussion

Surface spreading behaviour

Figure 1 shows the surface pressure – area diagrams of hexadecyl azidoformate, hexadecyl azidoacetate, and octadecanoyl azide on pure water. All three compounds form stable monolayers, but show individual behaviour reflecting the interplay between the length of the hydrocarbon chain and the polarity of the head group. Both hexadecyl azidoformate and hexadecyl azidoacetate show expanded phases over part of the accessible temperature range. Above 15°C the azidoformate forms liquid-analog monolayers similar to those of oleic acid. Monolayers of hexadecyl azidoacetate undergo a transition from a solid-analog to an expanded state at 8.5°C. At all temperatures a steep increase in the surface pressure at 0.24 nm^2 $molecule^{-1}$ corresponds to transition from an expanded phase to a closest-packed solid-analog phase. This behaviour is reminiscent of that of fatty acids of intermediate chain length, such as pentadecanoic acid, and was shared by 1-diazo-2-pentadecanone, as described in a previous publication (15). Monolayers of octadecanoyl azide exhibit quite different behaviour, showing only solid-analog phases up to 30°C, which was considered to be the maximum temperature at which spreading behaviour could be investigated without contamination by thermal decomposition products. Here the longer hydrocarbon chain resists the formation of liquid-analog phases, so that curves similar to those of stearic acid are observed.

None of the new compounds having two hydrocarbon chains form stable monolayers by themselves. Monolayers of dihexadecyl azodiformate have borderline stability, so that at high compression rates $\pi-\sigma$ diagrams with collapse areas close to 0.40 nm^2 $molecule^{-1}$ are observed. At normal compression rates collapse of the monolayer under pressure is able to keep pace with the change in surface area until much lower surface areas are reached, as shown in Fig. 2. Monolayers of the four diacyl diimides are unstable at all experimentally accessible rates of compression. This instability may be attributed to the high symmetry and insufficient polarity of the head-group.

Figure 3 shows the surface pressure – area curves of the azo-compounds **4** and **5**. The spreading behaviour of the unsymmetrical azodiformate **4** is similar to that of hexadecyl azidoformate, except that there does not appear to be a transition to a more compact monolayer at low temperatures in the case of compound **4**. Compound **5** gives solid-analog monolayers at all experimentally accessible temperatures, reflecting the greater length of the hydrocarbon chain in this derivative. The curves of Fig. 3 show that it is possible to build the aliphatic azo chromophore into a molecule having only a single long hydrocarbon chain and still retain high surface activity.

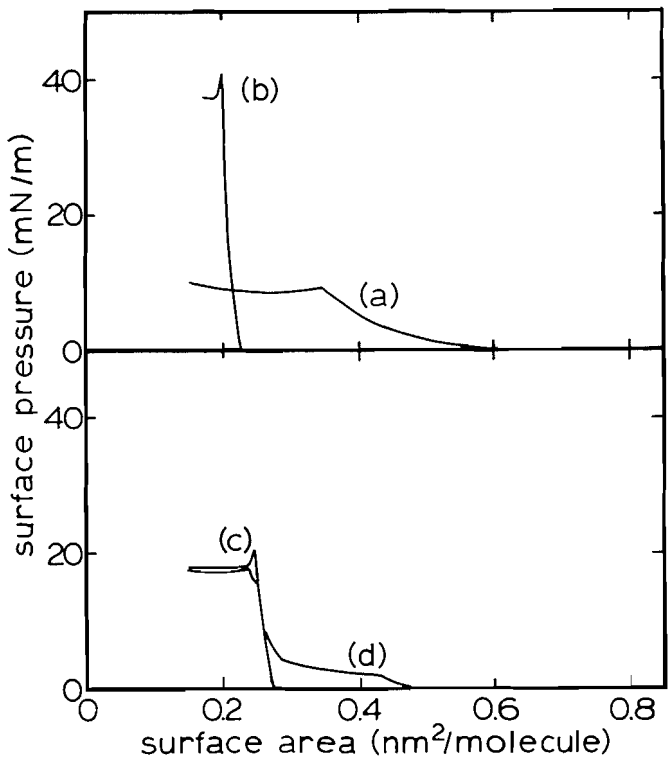

FIG. 1. Surface pressure – area diagrams of monolayers on pure water. (a) Hexadecyl azidoformate, 24.0°C; (b) octadecanoyl azide, 12.9°C; (c) hexadecyl azidoacetate, 4.1°C; (d) hexadecyl azidoacetate, 10.1°C.

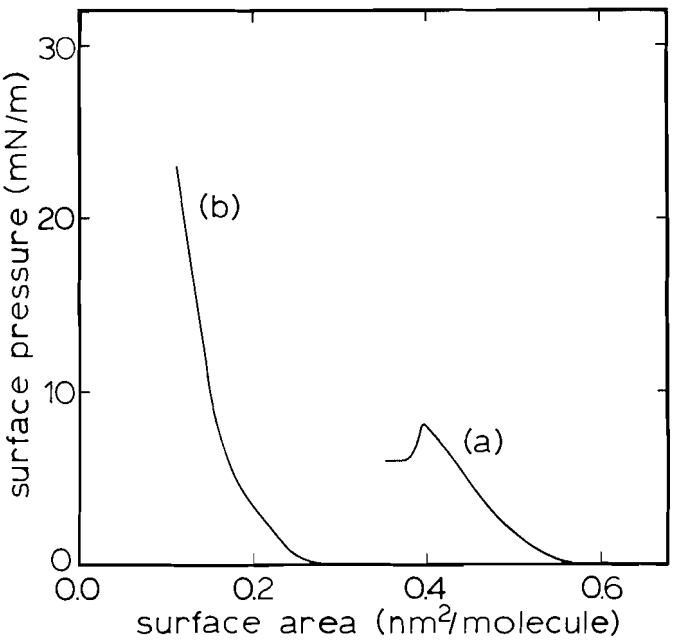

FIG. 2. Surface pressure – area diagrams of dihexadecyl azodiformate on pure water at 24.0°C. (a) Compression rate 0.52 nm^2 $molecule^{-1}$ min^{-1}; (b) compression rate 0.025 nm^2 $molecule^{-1}$ min^{-1}.

Thermal stability of diacyl diimides

A Japanese patent which described the synthesis of aliphatic diacyl diimides suggested that these compounds were useful polymerization initiators (7). Initial attempts to prepare diacyl diimides from fatty acid hydrazides by the same route gave impure products which were indeed very unstable, often de-

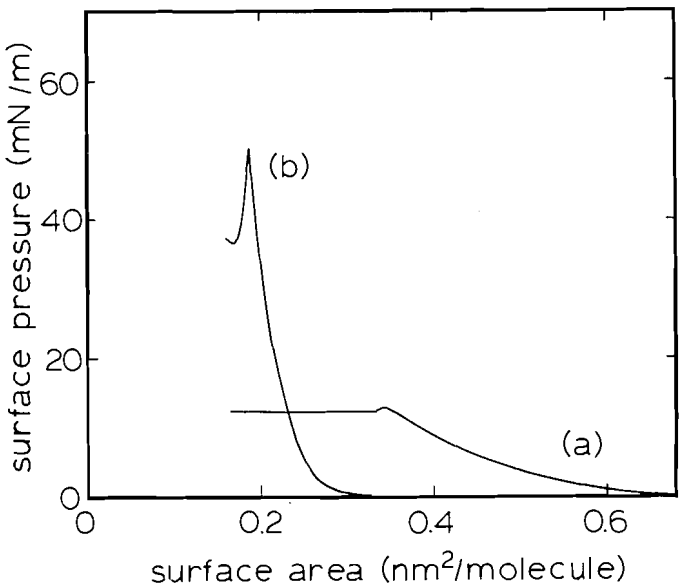

FIG. 3. Surface pressure – area diagrams of monolayers of single-chain azo-compounds on water. (a) Compound **4**, 10.1°C; (b) compound **5**, 10.1°C.

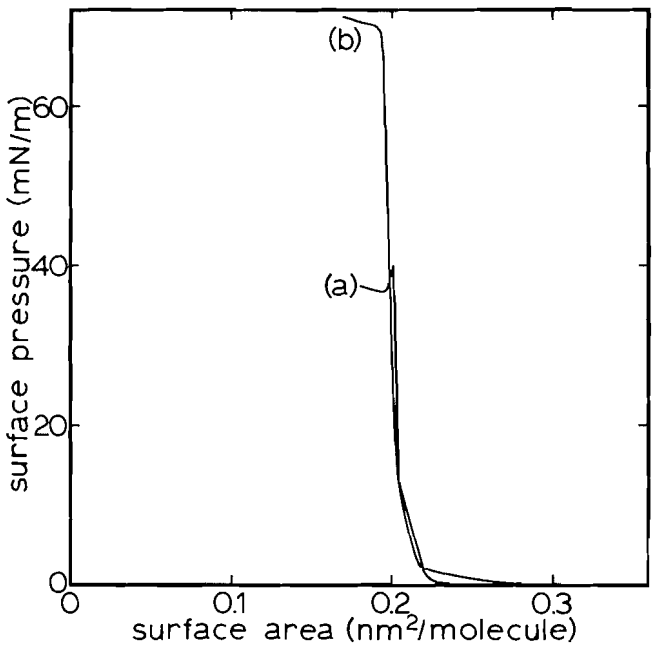

FIG. 4. Surface pressure – area diagrams of monolayers of octadecanoyl azide on pure water at 20.1°C. (a) Before irradiation; (b) after 20 minutes of 254 nm irradiation in air at 0.65 nm^2 $molecule^{-1}$ min^{-1}.

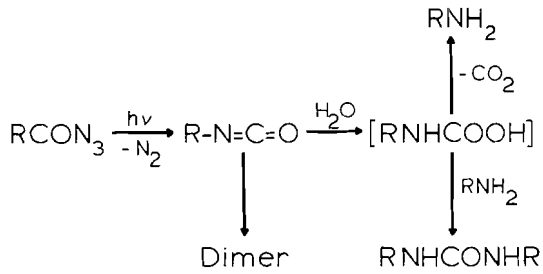
composing unpredictably in solution with the evolution of nitrogen. It was found that if the newly-formed diimide is removed as quickly as possible from the solution in which it is prepared and freed from acetic acid and lead compounds by several low-temperature recrystallizations, it is quite stable. Dihexadecanoyl diimide, for example, has a half-life of 40 h at 73°C in xylene solution. Such decomposition temperatures are too high for these compounds to function as thermal initiators of polymerization in mixed monolayers on water, but they may be used to initiate radical reactions at solid surfaces.

Photochemistry of octadecanoyl azide in monolayers

Figure 4 shows the changes in the surface spreading behaviour of octadecanoyl azide which occur on 20-min 254-nm irradiation of monolayers at a constant surface area of 0.65 nm^2 $molecule^{-1}$. Unlike the long-chain diazoketones investigated previously (15), long irradiation times are necessary to achieve complete decomposition of the azide. This is merely a consequence of the low absorbance of a monolayer of the azide at 254 nm and has little to do with differences in quantum yield of photoreaction between the two classes of compounds. As Fig. 4 shows, the photoreaction of the azide leads to a pronounced increase in the collapse pressure of the monolayer, but without the appearance or disappearance of an expanded phase.



SCHEME 2

An infrared spectrum of the photoproduct mixture indicates that complete decomposition of the azide has occurred, as shown by the absence of the $—N_3$ band at 1710 cm^{-1}. The photoproduct possesses new carbonyl bands at 1760, 1710, and 1635 cm^{-1} and a weak NH band at 3300 cm^{-1}. Notably absent is the 2275 cm^{-1} band of the aliphatic isocyanate.

Further insight into the photochemistry of octadecanoyl azide is obtained from the mass spectrum of the product mixture. A peak at m/z 536 corresponds to sym-diheptadecyl urea. This compound arises by the photochemical conversion of the azide to an isocyanate (16), followed by reaction with water and addition of the resulting amine to a second mole of isocyanate. At higher mass ratios a second molecular ion peak at m/z 564 corresponds to the unexpected isocyanate dimer. In this respect the photoreactions of monolayers of aliphatic acyl azides and α-diazoketones are similar. One of the products of the irradiation of monolayers of 1-diazo-2-nonadecanone, for example, was the β-lactone formed by dimerization of the primary photoproduct, a long-chain ketene (15). Thus even though the ketene or isocyanate functional groups are in contact with pure water, their concentration and mobility within the surface layer are sufficiently high for dimerization to compete successfully with hydrolysis. At lower mass ratios the characteristic breakup pattern of a long hydrocarbon chain, with peaks separated by 14 mass units, is evident. A moderately strong peak at m/z 255 corresponds to heptadecylamine, formed by hydrolysis of the long-chain isocyanate, while at still lower mass ratios is the pattern of peaks corresponding to disintegration of the second alkyl chain.

Scheme 2 summarizes the photochemistry of octadecanoyl azide monolayers on water. With the exception of the dimer, the products are similar to those reported for an aromatic acyl azide in a previous communication (15). In that case, however, the high susceptibility of the aromatic amine to further photodegradation and photooxidation gave a much more complex product mixture.

The risk of explosion normally prevents the isolation of primary aliphatic acyl azides, which are converted directly to isocyanates by controlled heating of solutions. Nevertheless the present work shows that azides containing a long hydrocarbon

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

chain are sufficiently stable to be isolated and purified by low-temperature recrystallization, and their physical and chemical properties may be investigated safely up to room temperature.

Summary

The goal of this research was to create compounds with reactive functional groups which retained the high surface activity of their fatty-acid and long-chain alcohol precursors. It was important for the range of proposed applications that these derivatives retain their reactivity in contact with water. Three long-chain azides were synthesized which fulfilled these requirements, ranging from the highly reactive octadecanoyl azide to the much more stable hexadecyl azidoacetate. The compound hexadecyl azidoformate, which has intermediate reactivity as a grafting agent, is a surface-active analog of *tert*-butyl azidoformate, a blocking agent used extensively in peptide synthesis. One promising application of this compound is therefore as a grafting agent for attaching bilayer membranes to supports, and proteins to these synthetic membranes.

The need for long-chain radical initiators having higher purity and greater resistance to hydrolysis than commercial diacyl peroxides has led to the successful synthesis of several new diacyldiimides and azodiformates. While not all of these compounds gave stable monolayers on water, they may still have applications as polymerization initiators in thin films on solid supports.

Formation and spectra of flavin radicals in the presence of β-mercaptoethanol at pH 9 and 10

PARMINDER S. SURDHAR, RIZWAN AHMAD, AND DAVID A. ARMSTRONG
Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received July 25, 1983

PARMINDER S. SURDHAR, RIZWAN AHMAD, and DAVID A. ARMSTRONG. Can. J. Chem. **62**, 580 (1984).

Spectral changes and rates of reaction of flavins and several radical species have been investigated at pH 7, 9, and 10 in the presence and absence of β-mercaptoethanol. The radicals $\cdot CO_2^-$, e_{aq}^-, and $LS_2^{\cdot -}$ reacted with FAD at pH 10 to give a spectrum of FAD $\cdot Fl^-$ with rate constants of $7 \pm 1 \times 10^8$ and $4 \pm 1 \times 10^8\ M^{-1} s^{-1}$ for $\cdot CO_2^-$ and $LS_2^{\cdot -}$ respectively. At pH 7 only $\cdot FlH$ was observed and at pH 9 a mixture of $\cdot FlH$ and $\cdot Fl^-$.

Interactions between flavin radicals and sulphydryl at $10^{-4}\ M$ concentration did not cause perturbations in the uv–visible spectra until either the radical and/or the sulphydryl were ionized. With FAD at pH 9 or 10 and LFl at pH 10 the 370 nm peak of $\cdot Fl^-$ was enhanced by about 15% and a second larger growth occurred near 450 nm in the presence of 10^{-4} to $10^{-2}\ M$ sulphydryl. We attribute this to the formation of labile intermediate $RSHFl\cdot^-$, which must also be involved in the reduction of Fl by $RS\dot{S}R^-$ at pH 9 or 10.

The second order rate constant k_{13} for reaction of $RS\dot{S}R^-$ with FAD at pH 9 and 10 was found to be $4.2 \pm 0.5 \times 10^8\ M^{-1} s^{-1}$ and $2.0 \pm 0.4 \times 10^8\ M^{-1}\ s^{-1}$ respectively. The rate constant for the reaction between $RS\dot{S}R^-$ and LFl at pH 10 was slightly faster, $7 \pm 1 \times 10^8\ M^{-1}\ s^{-1}$, probably reflecting the fact that LFl lacks the bulky negatively charged adenine dinucleotide group of FAD.

PARMINDER S. SURDHAR, RIZWAN AHMAD et DAVID A. ARMSTRONG. Can. J. Chem. **62**, 580 (1984).

Opérant à des pH de 7, 9 et 10 et en présence ou en l'absence de β-mercaptoéthanol, on a étudié les changements spectraux et les vitesses de réaction de flavines et de plusieurs espèces radicalaires. Les radicaux $\cdot CO_2^-$, e_{aq}^- et $LS_2^{\cdot -}$ réagissent avec FAD à un pH de 10 pour donner un spectre de FAD $\cdot Fl^-$ avec des constantes respectives de vitesses de $7 \pm 1 \times 10^8$ et $4 \pm 1 \times 10^8\ M^{-1}\ s^{-1}$ pour $\cdot CO_2^-$ et $LS_2^{\cdot -}$. A un pH de 7, on n'observe que $\cdot FlH$ alors qu'à un pH de 9, il y a formation d'un mélange de $\cdot FlH$ et $\cdot Fl^-$.

Les interactions entre les radicaux flavines et sulfhydryles à des concentrations de $10^{-4}\ M$ ne provoquent pas de perturbations dans les spectres uv–visible tant que le radical et/ou le sulfhydryle n'est pas ionisé. Avec le FAD à un pH de 9 ou 10 et avec le LFl à un pH de 10, il y a une augmentation d'environ 15% du pic à 370 nm dû au $\cdot Fl^-$ et une deuxième augmentation plus importante se produit près de 450 nm en présence de sulfhydryle à des concentrations allant de 10^{-4} à $10^{-2}\ M$. On attribue ces résultats à la formation de l'intermédiaire labile $RSFl\cdot^-$ qui doit aussi être impliqué dans la réduction de Fl par $RS\dot{S}R^-$ à des pH de 9 ou 10.

On a trouvé que les constantes de vitesse du deuxième ordre, k_{13}, pour la réaction de $RS\dot{S}R^-$ avec FAD à des pH de 9 et 10 sont respectivement de $4{,}2 \pm 0{,}5 \times 10^8\ M^{-1}\ s^{-1}$ et $2{,}0 \pm 0{,}4 \times 10^8\ M^{-1}\ s^{-1}$. La constante de vitesse pour la réaction entre RSSR et LFl à un pH de 10 est légèrement supérieure, $7 \pm 1 \times 10^8\ M^{-1}\ s^{-1}$; ceci est probablement dû au fait que LFl ne porte pas le volumineux groupe chargé négativement qu'est l'adénine dinucléotide du FAD.

[Traduit par le journal]

Introduction

The chemistry of disulphide anions has been investigated in several laboratories (1–7). Anions for cyclic disulphides and protein disulphides are relatively stable (3, 4, 6, 7), and can be formed by reactions with solvated electrons (e_{aq}^-) or formate radical anions ($\cdot CO_2^-$). Typical examples of cyclic disulphides are dithiothreitol and lipoamide, viz. $\overline{S—S—CH_2-CHOHCHOHCH_2}$ and $\overline{S—S—CH_2CH_2CH(CH_2)_4CONH_2}$, which are represented below by the abbreviated formulae DS_2 and LS_2 respectively. Formation of the anions occurs, for example, in reaction [1]:

[1] $$\cdot CO_2^- + LS_2 \rightarrow CO_2 + LS\dot{S}^-$$

Non-cyclic disulphides (RSSR) also form anions. However, here reactions [2] and [−2] are both rapid, and $RS\dot{S}R^-$ is only observed in the presence of appreciable concentrations of

[2]/[−2] $$RS\cdot + RS^- \rightleftharpoons RS\dot{S}R^-$$

thiolate (RS^-) ion, which drives equilibrium [2] to the right. Examples of K_2 are $1.8 \times 10^3\ M^{-1}$ for β-mercaptoethanol (1,5) and $(1.3 \times 10^3\ M^{-1}$ (3) for β-mercaptopropionic acid.

Apart from their intrinsic interest to the field of sulphur chemistry, it has been recognised that disulphide anions may be involved in electron transport (4, 8). Flavin molecules are important prosthetic groups for a large variety of redox enzymes (9, 10) and in the specific cases of glutathione reductase, lipoamide dehydrogenase, and thioredoxin reductase protein-bound disulphides are involved in the *two-electron-transfer* pathways, which in the direction of substrate oxidation can be represented as (11–13):

[3] $$\text{Substrate} \xrightarrow{1} S—S \xrightarrow{2} Fl \xrightarrow{3} NAD^+$$

Here Fl represents a strongly bound flavin molecule and NAD^+ is the oxidized nicotinamide cofactor. From biochemical studies it is apparent that step 1 leaves the enzyme disulphide doubly reduced (11–13), while step 2 transfers the electrons to the flavin. The structures existing before and after step 2 are thus taken to be:

[4] $$\begin{array}{ccc} SH & S^- \cdots Fl & \xrightarrow{2} \\ \llcorner\!\!\lrcorner & \llcorner\!\!\lrcorner & \end{array} \quad \begin{array}{cc} S—S & FlH^- \\ \llcorner\!\!\lrcorner & \llcorner\!\!\lrcorner \end{array}$$

Chan *et al.* (4) and more recently Ahmad and Armstrong (14) have pointed out that disulphide anion – flavin one-electron transfers are rapid and relatively clean. Hence, as in the mechanisms proposed for monoamine (15, 16) and alcohol (9), oxidations by flavin cofactors in enzymes, one should consider the possibility that step 2 occurs through a sequence of two one-

electron transfers with a radical pair, such as I, as a short-lived intermediate:

$$[4a] \quad SH \quad S^- \cdots Fl \rightleftharpoons \underset{I}{S^{\cdot} \cdots S^- \cdots FlH} \rightleftharpoons S{-}S \quad FlH^-$$

The preceding discussion has made it apparent that adjacent thiolate ions would stabilize a protein RS· ($\Delta G_2 = -18.2 \pm 0.4$ kJ mol^{-1} for the examples cited). Thiolate ion or RSH might also interact with flavin radicals and this could have an important effect on the stability of I and the rate of step 2. As a means of determing whether such interactions occur, the spectra of flavin radicals $\cdot Fl^-$ and $\cdot FlH$ have been investigated in the presence and absence of a sulphydryl solute at several pH's. The experiments were performed by the technique of pulse radiolysis (17). The flavin radicals were produced via the following reactions (17, 18):

$$[5] \quad 4.2H_2O \rightsquigarrow 2.7e_{aq}^- + 0.6\cdot H + 2.8\cdot OH + 2.7H^+ + 0.5H_2 + 0.7H_2O_2$$

$$[6] \quad e_{aq}^- + N_2O + H_2O \rightarrow N_2 + OH^- + \cdot OH$$

$$[7] \quad \cdot OH(or \cdot H) + HCO_2^- \rightarrow H_2O(or\ H_2) + \cdot CO_2^-$$

$$[8] \quad \cdot CO_2^- + Fl \rightarrow CO_2 + \cdot Fl^-$$

$$[9] \quad e_{aq}^- + Fl \rightarrow \cdot Fl^-$$

$$[10]/[-10] \quad \cdot FlH \rightleftharpoons \cdot Fl^- + H^+$$

In addition, the rate of the reaction between $\dot{L}S_2^-$ and $RS\dot{S}R^-$ and Fl was also investigated and the species produced by electron transfer from these anions to flavins were shown to be similar to those formed by $\cdot CO_2^-$. The flavins used were flavin adenine dinucleotide (FAD) and lumiflavin (LFl). The sulphydryl compound was β-mercaptoethanol, which has a low vapour pressure, is water soluble, and has been studied extensively in previous radiation chemical investigations (1, 5). It possess a pK of 10.0 ± 0.2 (1.5).

Experimental

The pulse radiolysis experiments were performed by utilizing 2-μs pulses of electrons with a dose of 0.2 to 0.4 gray from the 1.5-meV Van de Graaff generator described earlier (19). A 1.0-cm path-length optical cell was used with a fresh solution for each pulse. Dosimetry was based on absorbance changes in N_2O-saturated 7×10^{-3} M potassium ferrocyanide solutions with ($G \times \epsilon_{420}$) taken as 6.4×10^3 molecules (100 eV)$^{-1}$ M^{-1} cm^{-1} (20). Here G is the yield of the product (ferricyanide) in molecules per 100 eV of radiation energy and ϵ_{420} the difference in molar absorbance coefficients of ferri- and ferrocyanide at 420 nm.

Flavin adenine dinucleotide (FAD) and lumiflavin (LFl) were used as supplied by the Sigma Chemical Co. All other chemicals were the purest available commercial products.

All solutions were prepared from triply distilled water and purged with N_2O or argon as indicated. These gases were first passed through a column of Ridox (Fisher Scientific Co.) to remove traces of oxygen. All solutions were buffered with 10 mM phosphate, and protected from light as much as possible before pulsing.

Solutions requiring RSH were prebubbled before addition of the RSH. This was done to minimize air oxidation of the sulphydryl. The solutions were then adjusted to the required pH and purged again with the required gas before irradiation.

Absorption spectra of FAD and LFl in deaerated solutions at pH 9 and 10 were taken on a Cary 219 spectrophotometer. They were found to be stable over the time of our experiments in the absence and presence of ten millimolar concentrations of RSH. Values of ΔA, the change in absorbance per unit dose observed at any given time after the radiation pulse, were converted to [ε(Fl radical) − ε(Fl)] at each wavelength by dividing ΔA by the concentration of radicals produced per kilogray. Values of ε(Fl radical) were obtained by adding ε(Fl). Radical yields used were 6.6×10^{-4} M and 7.0×10^{-4} M for 20 mM and 0.2 M formate solutions respectively and 7.0×10^{-4} M for 10^{-2} M RSH. These were estimated from solute–radical reactivities (21), and are concentrations per kilogray of absorbed radiation energy.

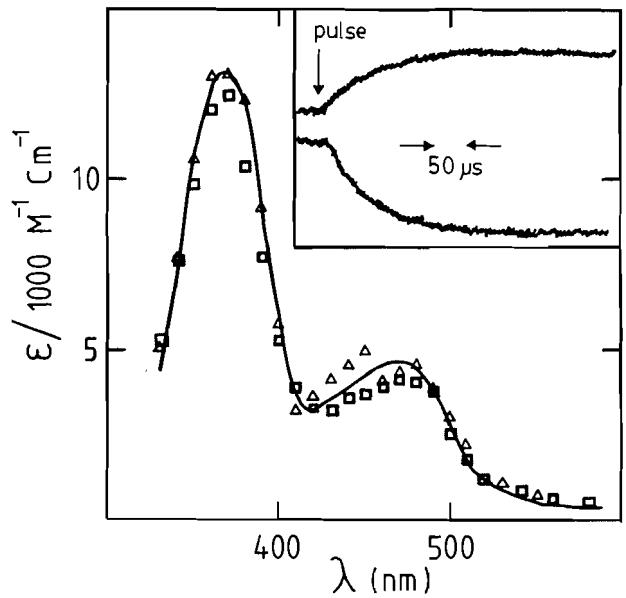

FIG. 1. Absorption spectra following pulse radiolysis of FAD at pH 10, in phosphate buffer. Reacting radicals: (—) CO_2^- in formate solutions (20×10^{-3} M and 0.2 M), N_2O-saturated; (Δ) e_{aq}^- + $\cdot CO_2^-$ in formate solution, argon-saturated; (□) $LS_2^{\cdot -}$ in 0.2 M formate solution containing 2 mM LS_2, argon-saturated. Inserted are oscilloscope traces of transmission changes at 370 nm (top) and 440 nm (bottom). Spectra were independent of [FAD] over the range used, 10–40 μM.

Results and discussion

Initial experiments were performed at pH 7, where both the flavin radical (p$K_{10} \simeq 8.4$ (22)) and β-mercaptoethanol are protonated. Both the FAD and LFl the spectra of the $\cdot FlH$ radicals formed via reactions [8] and [−10] were the same in the presence and absence of RSH at a concentration of 10^{-4} M. It is conceivable that interactions causing spectral changes might occur at higher concentrations. However, since $\cdot CO_2^-$ reacts with RSH with a rate constant of about 1×10^8 M^{-1} s^{-1} (22) and k_8 is 1 to 4×10^9 M^{-1} s^{-1} at pH 7 (ref. 23 and references therein, and ref. 24), the use of larger [RSH] would have caused complications and was not pursued.

Attention is now focused on experiments performed at pH 10, where the flavin radicals should be fully ionized and the sulphydryl about 50 percent ionized, and pH 9, where the former is still largely ionized and the latter about 10 percent ionized. The series of experiments carried out with FAD at both pH's and with LFl at pH 10 were very similar and are not all described in detail.

FAD at pH 10

Reaction with $\cdot CO_2^-$, e_{aq}^-, and $LS_2^{\cdot -}$

The solid line in Fig. 1 is the absorption spectrum of the FAD radical produced in reactions [5]–[8] in N_2O-saturated solutions. This spectrum, which is the mean of five determinations,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

was independent of formate and FAD concentrations over the ranges 0.02 to 0.2 M and 10 to 40 μM respectively. The triangular data points demonstrate that a similar spectrum, was obtained in argon-saturated solutions, where e_{aq}^- and $\cdot CO_2^-$ would have reacted with FAD in approximately equimolar amounts.

It should be noted that the peak at 370 nm was reproducible to within about 5 percent between experiments, but absorbances in the wavelength range 410 to 480 nm tended to scatter more, both in N_2O- and argon-saturated solutions. That feature has been illustrated by the data points shown.

The major characteristics of the spectrum, a strong peak at 370 nm and a second weaker broad peak in the region of 470 nm, resemble those reported for the negative $\cdot Fl^-$ ion of lumiflavin-3-$CH_2COOC_2H_5$ by Ehrenberg *et al.* (ref. 25, Fig. 3). As reported by Land and Swallow (24) the riboflavin radical anion also has a strong peak near 370 nm and a weaker one at 480 nm. The riboflavin radical $\cdot FlH$ has a pK of 8.3 (24), and one would assume a similar pK for FAD $\cdot FlH$. Therefore it seems clear that the spectrum in Fig. 1 is that of FAD $\cdot Fl^-$ formed in reaction [8] or [9].

The insert in Fig. 1 illustrates changes in absorbance with time for a 20 μM FAD solution on reaction with $\cdot CO_2^-$. These changes were found to be first order in time, and a second order rate constant was obtained from a plot of the pseudo first order rate constant versus FAD concentration in the range 10 to 40 μM. The value at ionic strength 0.06 was $7 \pm 1 \times 10^8\ M^{-1}\ s^{-1}$.

Although the transients in the inset of Fig. 1 exhibited no evidence of decay on the time scale shown at the above given ionic strength, significant decay was seen when it was increased to 0.24. That observation is consistent with bimolecular decay of a species bearing a negative charge. The buildup was faster as well. This was not pursued in detail here, but would be expected as $\cdot CO_2^-$ and FAD are both negatively charged at pH 10.

The squares in Fig. 1 exhibit the spectrum of the species produced on completion of the reaction between $LS_2\cdot^-$ and FAD. It is the mean of results at two FAD concentrations and is, within experimental error, the same as that formed by $\cdot CO_2^-$ and $\cdot CO_2^- + e_{aq}^-$. The initial spectrum was that of $LS_2\cdot^-$, and the spectral changes during reaction were very similar to those described below for $RS\dot{S}R^-$ (Figure 3a). From analysis of these at different FAD concentrations, the rate constant for reaction [11] was found to be

$$[11] \qquad LS_2^{\cdot -} + Fl \rightarrow LS_2 + Fl\cdot^-$$

$$k_{11} = 4 \pm 1 \times 10^8\ M^{-1}\ s^{-1}$$

Reaction with $\cdot CO_2^-$ in the presence of 10^{-4} M β-mercaptoethanol[1]

At pH 10 in these solutions one has $[RS^-] = [RSH] = 5 \times 10^{-5}\ M$. As shown by a comparison of the data points and dashed line in Fig. 2a, when $\cdot Fl^-$ was formed by reaction [8] in 0.02 M formate containing the above sulphydryl–thiolate ion mixture, the spectrum exhibited an enhancement of the 370 nm peak and the absorption in the 400 to 480 nm region was almost doubled. However, the rate of growth of the transient species, as given by traces like those in the inset of Fig. 1, remained the same as in the absence of RSH and RS^-. These results suggest that $\cdot Fl^-$ was still formed in reaction [8], but subsequently underwent a rapid secondary reaction with either RS^- or RSH to form the species responsible for the new spectrum. For practical purposes this is subsequently referred to as $RSHFl\cdot^-$.

Reaction with $RS\dot{S}R^-$ in 10^{-2} M β-mercaptoethanol

When these N_2O-saturated solutions containing flavin were pulsed, the initial absorbance was that of $RS\dot{S}R^-$, which would have been formed in reactions [5]–[7], [12], and [2] (1).

$$[12] \qquad \cdot OH(\text{or } \cdot H) + RSH \rightarrow H_2O(\text{or } H_2) + RS\cdot$$

This has been illustrated in Fig. 3a, where the circles represent the initial absorbances for $10^{-2}\ M$ RSH solutions containing 10 μM FAD and the line through them is the absorption spectrum of $RS\dot{S}R^-$ obtained under the same conditions with no flavin present. The spectrum agrees with that in ref. 1.

The absorbance changed with time, exhibiting a small growth between 340 and 380 nm and a strong decrease between 400 and 500 nm. The signals were constant from 140 μs to at least 400 μs. The triangles in Fig. 3a display the absorbances at 400 μs. An abolute spectrum calculated from these and the absorption spectrum of the unirradiated flavin solution is shown by the solid line in Fig 2a.

Comparison of the solid line and circles in Fig. 2a shows that at 400 μs the 370 nm peak of the products of the $RS\dot{S}R^-$ and $\cdot CO_2^-$ reactions with FAD in the presence of $10^{-4}\ M$ total sulphydryl were the same. The 420–480 nm absorptions were slightly different from each other, but both exhibited strong enhancement over the peak height seen in the absence of sulphydryl. Therefore the species formed by $RS\dot{S}R^-$ in $10^{-2}\ M$ β-mercaptoethanol is probably structurally similar to $RSHFl\cdot^-$. Furthermore, since one-electron reductions of flavins by $LS_2^{\cdot -}$ above and other cyclic disulphides (23) have been observed to produce flavin radicals in the absence of RS^- or RSH, it is reasonable to propose that reaction [13] occurred and was followed by a process similar to that which produced $RSHFl\cdot^-$ in

$$[13] \qquad RS\dot{S}R^- + Fl \rightarrow RSSR + \cdot Fl^-$$

the $10^{-4}\ M$ β-mercaptoethanol solutions.

The rate of reaction between $RS\dot{S}R^-$ and Fl was calculated in the following way from oscilloscope traces at 420 to 460 nm. The difference, a, between the absorbance at time t and at 400 μs (i.e. $t = \infty$) was divided by the same difference for $t = 0$ (i.e. a_∞) to give (a/a_∞). As demonstrated in Fig. 3b, plots of $\ln(a/a_\infty)$ versus time were linear, indicating that the reaction was pseudo first order. For a given FAD concentration the plots were independent of RSH concentration in the range 10^{-2} to $2 \times 10^{-2}\ M$ (see squares and circles in Fig. 3b). The second order rate constant k_{13} for reaction of $RS\dot{S}R^-$ with FAD was found from a plot of the pseudo first order rate constants against [FAD] to be $2.0 \pm 0.4 \times 10^8\ M^{-1}\ s^{-1}$.

FAD at pH 9

Reaction with $\cdot CO_2^-$

As shown in Fig. 2b, the spectrum produced on reaction of $\cdot CO_2^-$ with FAD in the absence of mercaptan at this pH exhibits a much smaller peak at 370 nm and stronger absorbance in the 500 to 600 nm region. Neutral flavin radicals possess

[1] If the rate constant of the reaction $\cdot CO_2^- + RSH \rightarrow HCO_2^- + RS\cdot$ is similar to that for abstraction of H from dithiothreitol, which is 1×10^8 (22), then at pH 10 in $10^{-4}\ M$ RSH with $[Fl] \geq 4 \times 10^{-5}\ M$, 15% or less of the $\cdot CO_2^-$ would react with RSH and the remainder with Fl. The spectral intensities of $\cdot Fl^-$ observed here suggest that the proportion of $\cdot CO_2^-$ undergoing reaction with RSH is actually much less.

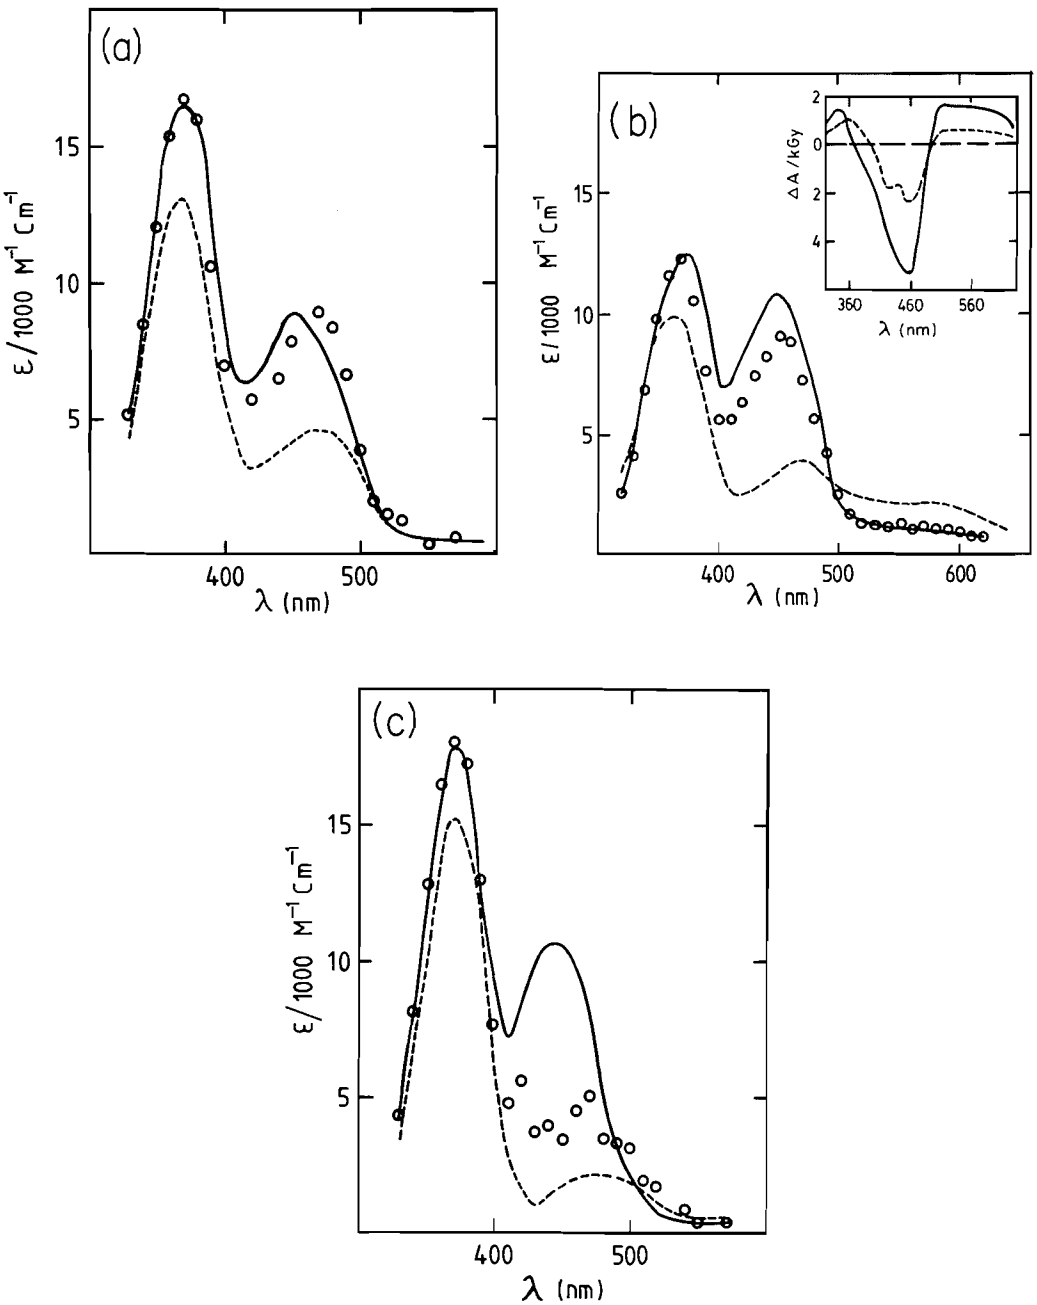

FIG. 2. Spectra of flavin solutions following pulse radiolysis of N_2O-saturated solutions. Reacting radicals: (----) $\cdot CO_2^-$ in formate solutions, (○) $\cdot CO_2^-$ in formate solution with 1×10^{-4} *M* RSH and (—) $RSS\dot{R}^-$ in 10^{-2} *M* RSH solution. (a) FAD at pH 10; (b) FAD at pH 9; (c) LFl at pH 10. The inset in (b) shows difference spectra following pulse radiolysis of FAD (36×10^{-6} *M*) in 20×10^{-3} *M* sodium formate measured 20 μs after pulse (----) and 400 μs after pulse (—).

stronger absorbtions ($\epsilon \sim 4000\ M^{-1}\ cm^{-1}$) in the 500–600 nm region and lower absorptions from 330 to 400 nm ($\epsilon_{max} \sim 8000\ M^{-1}\ cm^{-1}$ at 340 nm) than $\cdot Fl^-$ (24, 25). Thus both of the above features are consistent with the presence of a significant proportion of $\cdot FlH$ at pH 9. A second feature worth noting was that the spectrum did not grow homogeneously. This has been illustrated in the inset of Fig. 2b by the absorbance changes measured at 20 and 400 μs. The 20 μs difference spectrum exhibited much smaller changes in intensity at 460 and 560 relative to that at 360 nm and would correspond more closely to the absolute spectrum of $\cdot Fl^-$ in Fig. 2a. It would appear, therefore, that $\cdot Fl^-$ was formed first in reaction [8], and then the equilibrium [10] was established.

Reaction with $\cdot CO_2^-$ and $RSS\dot{R}^-$ in the presence of 10^{-4} M and 10^{-2} M β-mercaptoethanol respectively

As was the case at pH 10, the absorption of the flavin radical over the 350 to 480 nm region was enhanced in the presence of 10^{-4} *M* mercaptan. A further but much smaller enhancement was seen from 380 to 470 nm when $RSS\dot{R}^-$ was the reducing species in 10^{-2} *M* mercaptan solutions. The rate constant for the reaction of FAD with $RSS\dot{R}^-$ was now larger, viz. $k = 4.2 \pm 0.5 \times 10^8\ M^{-1}\ s^{-1}$, when calculated by the same method as used at pH 10.

LFl at pH 10

The results obtained with LFl are in principle similar to

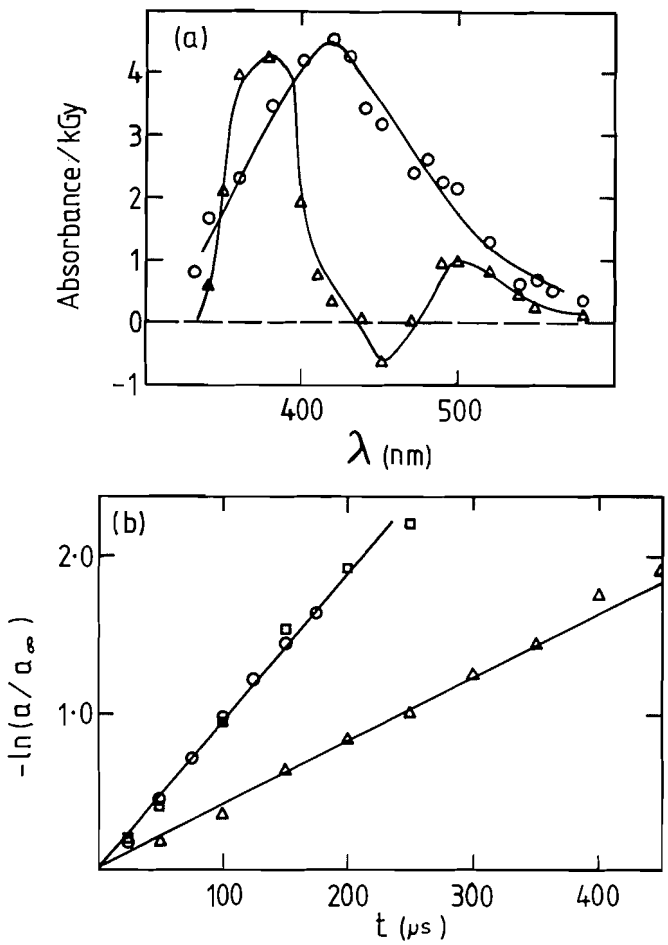

FIG. 3.(a) Difference spectra following the pulse radiolysis of FAD (10×10^{-6} *M*) at pH 10 in N_2O-saturated phosphate buffer containing 1×10^{-2} *M* RSH. The spectra were measured (○) 20 μs after pulse and (Δ) 400 μs after pulse. The line through the circles is the spectrum of $RSS\dot{R}^-$ in N_2O-saturated phosphate buffer containing 1×10^{-2} *M* RSH at pH 10 and no flavin. (b) Plot of ln (a/a_∞) vs. time for the formation of transient species produced following the pulse radiolysis of 10×10^{-6} *M* FAD containing 1×10^{-2} RSH (Δ); 40×10^{-6} *M* FAD containing 2×10^{-2} *M* RSH (○); and 1×10^{-2} *M* RSH (□). All the solutions were in N_2O-saturated phosphate buffer.

those observed with FAD and need only a cursory discussion. As shown by the dashed line in Fig. 2c, the spectrum of $Fl\cdot^-$ for this flavin has a stronger absorption at 370 nm and the extinction coefficient more closely matches that of Ehrenberg *et al.* for lumiflavin-3-$CH_2COOC_2H_5$ $Fl\cdot^-$ (ϵ = 17 500 M^{-1} m^{-1} (25)). At the same time, the 480 nm peak was weaker than that of FAD $\cdot Fl^-$.

As in the case of FAD, the peak heights were enhanced in the presence of β-mercaptoethanol. Also the enhancement was fully saturated in 10^{-4} *M* solutions for the wavelength region 330 to 380 nm. However, this did not apply in the 400 to 500 nm region. Furthermore, the data there exhibited considerable scatter for 10^{-4} *M* solutions.

The rate constant for the reaction between $RSS\dot{R}^-$ and LFl in 10^{-2} *M* β-mercaptoethanol solutions was $7 \pm 1 \times 10^8$ M^{-1} s^{-1}, as calculated from absorption changes over the 420 to 460 nm range. That it was larger than for FAD probably reflects the fact that LFl lacks the bulky negatively charged adenine dinucleotide group of FAD.

Summary and conclusions

The complexation of flavin radicals by various amino acids has been reported before and flavins are known to bind up to two ligands per molecule (26). However, we are unaware of publications dealing with sulphydryl species interacting with $\cdot Fl^-$ or $\cdot FlH$.

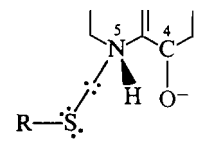
The present study has demonstrated that interactions between flavin radicals and β-mercaptoethanol at the 10^{-4} *M* level do not cause measurable perturbations in the uv–visible spectra until either the radical and/or the sulphydryl are appreciably ionized. At pH 9 and 10 with FAD and at pH 10 with LFl 330 to 370 nm absorption was enhanced in the presence of β-mercaptoethanol, and the effect in all three cases was saturated at 10^{-4} *M* mercaptan. In addition, the sulphydryl compound caused the growth of a strong peak with a maximum near 450 nm, and at pH 9 there was a factor of two reduction in the absorbance above 500 nm. These observations imply that the perturbations in the spectral regions are probably due to sulphydryl–FlH or $\cdot Fl^-$ interactions which form a species $RSHFl^{\cdot-}$. However, it may be that more than one mercaptan is bound to the flavin radical in the 10^{-2} *M* solutions, and the present results do not resolve that point.

In addition, one cannot state whether the formation of $RSHFl\cdot^-$ is a reversible process or not. However, it is evident that this species would have to be an intermediate in the two-electron reduction of Fl by $RSS\dot{R}^-$ in the presence of RSH at pH 9 or 10, and the only significant product of that reaction was FlH^- (14). Therefore it is evident that $RSHFl\cdot^-$ is a fairly labile species, possible reacting with RS· as follows.

[14] $\quad RS\cdot + RSHFl\cdot^- \rightarrow RSSR + FlH^-$

That process would be the equivalent of the second half of step 2 (reaction [4*a*] of Introduction).

Extensive speculation concerning the structure of $RSHFl\cdot^-$ is not warranted here, but it should be pointed out that one type of interaction may involve a three-electron bond between N-5 and the thiolate ion, viz.



The structure would be rendered more stable with N-5 protonated as shown, and could be formed by reaction of RS^- and $\cdot FlH$ or RSH and $Fl\cdot^-$. Hiller and Amus (27) have postulated a transitory S—N three-electron bond to explain aspects of methionine chemistry and Musker *et al.* (28) have observed such bonds in cyclic amino-thio ethers.

As a final point, in our view the tendency for scatter in the 410- to 480-nm range may be an indication that other substances, also capable of causing spectral perturbations, bind to Fl radicals. Fluctuations in the concentrations of trace reaction products or impurities may cause the pulse-to-pulse variations. Studies of spectral perturbations by species other than mercaptans will be undertaken.

Chemical behavior of an α-azidosulfide, and the related sulfoxide and sulfone, in the tetrahydrothiophene series[1,2]

IAN W. J. STILL,[3] WILLIAM L. BROWN,[4] ROBIN J. COLVILLE,[4] AND GERALD W. KUTNEY

J. Tuzo Wilson Research Laboratories and Department of Chemistry, University of Toronto, Mississauga, Ont., Canada L5L 1C6

Received July 15, 1983

IAN W. J. STILL, WILLIAM L. BROWN, ROBIN J. COLVILLE, and GERALD W. KUTNEY. Can. J. Chem. **62**, 586 (1984).

The thermal, photochemical, base-catalyzed, and Lewis acid-catalyzed reactivity of 2-azidotetrahydrothiophene (**1***a*) and the related α-azidosulfoxide and sulfone have been found to lead to a number of interesting rearrangement products. The ^{13}C nmr data for these compounds are also reported and discussed and the results of attempted deoxygenation of the α-azidosulfoxide **1***b* with a variety of reagents are compared.

IAN W. J. STILL, WILLIAM L. BROWN, ROBIN J. COLVILLE et GERALD W. KUTNEY. Can. J. Chem. **62**, 586 (1984).

On a trouvé que les réactions thermique et photochimique de l'azido-2 tétrahydrothiophène (**1***a*) et des α-azido-sulfoxyde et sulfone correspondants ainsi que leurs réactions catalysées par les bases ou par les acides de Lewis conduisent à un certain nombre de produits de transposition intéressants. On rapporte aussi des données de la rmn du ^{13}C relatives à ces composés et on les discute; on compare les résultats obtenus lors de divers essais effectués en vue de désoxygéner l'α-azido-sulfoxyde **1***b* à l'aide de divers réactifs.

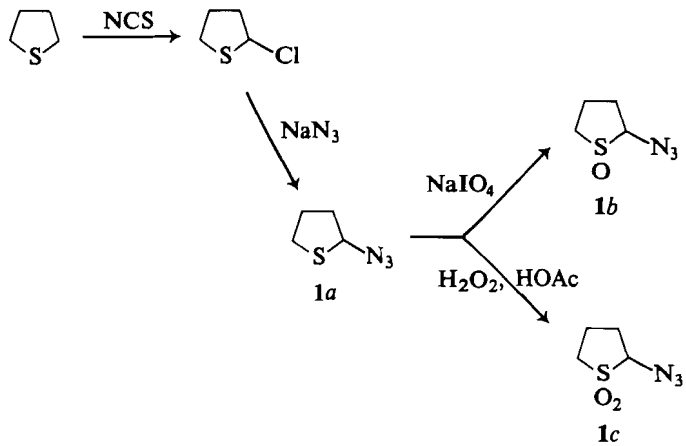
Introduction

The stimulus for the work described below arose from our own earlier work with organic azides (1, 2). In addition, successful attempts to trap nitrene intermediates using divalent sulfur compounds (3, 4) and the first reports of the preparation of the α-azidosulfide class of compounds by Böhme *et al.* (5, 6) combined to induce us to embark upon a detailed study of the thermal, photochemical, and acid- and base-catalyzed reactions of 2-azidotetrahydrothiophene (**1***a*) and its related sulfoxide (**1***b*) and sulfone (**1***c*), the results of which are described below. Since this study was initiated interesting reports on some aspects of this relatively new type of bifunctional organosulfur compound have appeared from two sets of authors. Trost *et al.* have studied the effects of Lewis acids upon α-azidosulfides (7) and, more recently, the potential synthetic utility of phenylthiomethyl azide as a synthon for NH_2^+ (8). Jarvis *et al.* have reported on the thermal (9) and base-catalyzed (10) decomposition reactions of α-azidosulfides, sulfoxides, and sulfones.

Results and discussion

The syntheses of 2-azidotetrahydrothiophene (**1***a*) and its 1-oxide (**1***b*) and 1,1-dioxide (**1***c*) analogs were generally unremarkable and were carried out as outlined in Scheme 1. The replacement of chloride by azide ion is considerably facilitated by the use of a quaternary ammonium salt as a phase-transfer catalyst. In order to produce **1***b* or **1***c* in reasonable yields, oxidation must be carried out *subsequent* to the introduction of the azide group. The ^1H nmr and ^{13}C nmr data for each compound are listed in Table 1, along with the corresponding data for the related 2-azido-4-thiochromanone 1-oxide (**2***b*) and 2-azido-4-thiochromanone 1,1-dioxide (**2***c*)[5] prepared by us earlier (1, 2), for comparison. From the data in Table 1, while



SCHEME 1

it appears that the substituent chemical shift (S.C.S.) effects for the N_3 group are somewhat conformation dependent, the α-effect produces deshielding ranging between 23–39 ppm, with the high value of +39 being observed only for one α-azidosulfide (**1***a*), most values falling in the range 23–29 ppm. The β-effect of the N_3 group is also deshielding, but this time typically in a relatively narrow range from ~5–8 ppm. The γ-effect observed for N_3, in contrast, is small and shielding in nature, ranging from −2.3 to −4.0 ppm. This pattern of S.C.S. effects is reminiscent of that noted by us for the phenyl group in an earlier study (11), at least in so far as the α- and β-deshielding effects are concerned, although the α-effect is not as great for phenyl (~14–18 ppm). Further data are clearly needed before more detailed conclusions can be drawn, but Table 1 provides useful qualitative insight into the S.C.S. effects of the previously little studied azide group.

Attempts were also made to synthesize 2-cyanotetrahydrothiophene **3** as another suitable model for the ^{13}C nmr study. Reaction of 2-chlorotetrahydrothiophene with cyanide ion, however, under conditions similar to those used for the preparation of the azide, always seemed to give **3** contaminated by 2,3-dihydro-4-(2-thiolanyl)thiophene **4**. Presumably this known compound (12) arises as a result of partial dehydrochlorination of the chloro compound in the presence of the

more basic cyanide ion, followed by dimerization, as shown in Scheme 2.

Turning to the reactivity of the azido derivatives **1***a–c*, it has been found that the thermal decomposition of 2-azidotetrahydrothiophene **1***a* at 130°C, in the absence of solvent, afforded a product with a strong ir band at 1610 cm^{-1}, characterized as tetrahydrothiophen-2-imine **5**, in 4% yield, accompanied by material of higher molecular weight. Better yields of the imine (21–25%) were obtained when the thermal reaction was carried out in refluxing toluene and slightly higher yields (25–30%) when one equivalent of bromobenzene was present.[6] The reaction presumably involves a [1,2] sigmatropic rearrangement of the initially formed singlet nitrene (13). In a series of attempts to trap the intermediate nitrene, tetrahydrothiophene, 1-butanol, dimethyl acetylenedicarboxylate, and 1-octene were all tried, but only the 1-octene was successful in leading to an identifiable product, presumably the 1-(2-thiolanyl)-2-hexylaziridine **7**, in 22% yield. It is not certain that the formation of **7** requires the intermediacy of a nitrene, since one of the two possible regioisomeric triazolines **6** might first be formed (Scheme 3). Similar thermal decomposition reactions of the somewhat more stable α-azidosulfoxide and sulfone (**1***b, c*) led mainly to recovered starting materials or, at higher temperatures, to uncharacterizable products of higher molecular weight. While these results are somewhat disappointing, it must be borne in mind that the mechanism proposed by Jarvis *et al.* (9) for the decomposition of an α-azidosulfide is probably not available in our system (**1***a*) because of steric constraints. It is also quite likely that the product (**8**) which one would expect from this mechanism would be much less stable than the diaryl-substituted sulfenamide obtained by the earlier

[6] This increase in yield on adding bromobenzene is probably insufficient to conclude that diversion of the mechanistic pathway from a singlet to a triplet manifold is occurring here, via the heavy-atom effect.

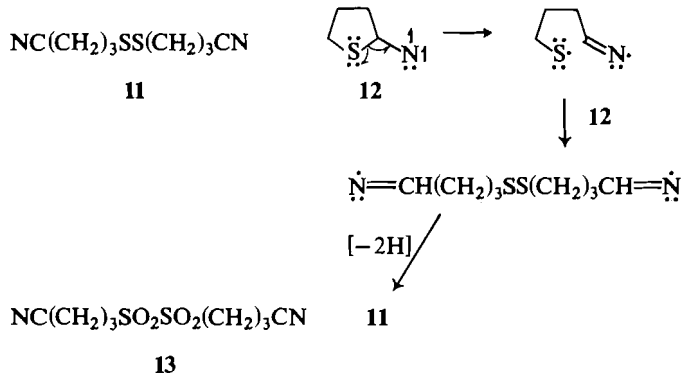
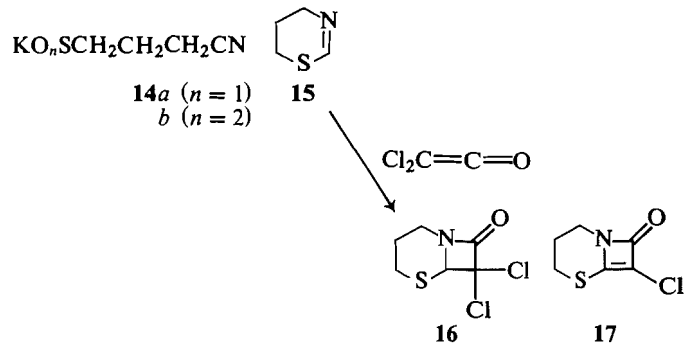


SCHEME 4



SCHEME 5

workers. Similar comments may apply to the decomposition of **1***b, c*.

Extensive attempts to carry out the base-catalyzed methylation of tetrahydrothiophen-2-imine under a wide variety of conditions have met with little success and neither the expected product of N-methylation **9** nor of S-methylation **10** has been characterized. Some (^{1}H nmr) spectral evidence for C-methylation of **5** was noted under very strongly basic conditions, but as the yields were very low no further work was attempted.

The photochemical decomposition of **1***a* was next carried out. Irradiation in various solvents (including cyclohexane, methanol, and acetonitrile) afforded a liquid product with a strong C≡N band in the ir at 2250 cm^{-1}, eventually characterized by further spectral and elemental analyses, as the previously known 4,4′-dithiodibutanenitrile **11** (14), in yields ranging from 12–26%. Some starting material was usually recovered, even after irradiation for 20 hours. Attempted sensitization of the reaction by the addition of triplet sensitizers such as acetophenone or benzophenone led only to lesser amounts of **11** being formed. At first sight it appears surprising that none of the imine **5** formed in the thermal reaction, nor its open-chain γ-mercaptonitrile tautomer, was observed. To explain this dichotomy we propose that a pathway via the triplet nitrene **12** may be involved (Scheme 4). Again, as was the case for the corresponding thermolyses, the azidosulfoxide and azidosulfone analogs **1***b* and **1***c* were much more stable towards irradiation (in acetonitrile), but mass spectral evidence indicated the formation of the α-disulfone analog **13** in very low (<2%) yield, accompanying large amounts of recovered **1***c*.

The recent work of Jarvis and Nicholas (10) on the base-catalyzed conversion of α-azidosulfides, sulfoxides, and sulfones to nitriles, prompted us to examine the effects of base upon **1***a–c*. Jarvis has noted that the utility of this procedure is limited by the fact that many nitriles may not be stable under the basic conditions used. Exposure of **1***a* to potassium *tert*-butoxide led only to high molecular weight materials, but comparable treatment of **1***b* and **1***c* with *tert*-butoxide for short periods of time at 0°C led to the isolation of uncrystallizable solid materials, tentatively identified by analogy with the work above as the expected **14***a, b*, in yields of 60 and 68%, respectively. As expected, since the acidity of the methine proton in even **1***c* is significantly less than the corresponding (benzylic) protons in some of Jarvis' compounds, milder bases such as triethylamine were without effect.

Somewhat more interesting results were obtained from attempts to rearrange the azidosulfide **1***a* in the presence of acids. Trost *et al.* (7) have recently shown that cyclic α-azidosulfides, prepared by the novel reaction of a thioketal with iodine azide, can be converted to the corresponding ring-expanded lactams on treatment with trifluoroacetic acid or the corresponding cyclic imino-sulfides with a Lewis acid such as $SnCl_4$. Treatment of **1***a* with trifluoroacetic acid was unfruitful, but with $SnCl_4$ or $TiCl_4$, **1***a* could be converted smoothly to 5,6-dihydro-4*H*-1,3-thiazine **15** in 85–90% yields. Somewhat lower yields were obtained with other Lewis acids such as $AlCl_3$ or BF_3 etherate. The characteristic C-2 proton of **15** is visible at δ 9.85 and other ^{1}H and ^{13}C nmr, as well as mass spectral, data support this assignment. The reaction of **15** with dichloroketene, generated from trichloroacetyl chloride by the improved procedure of Krepski and Hassner (15), was next attempted as a route to the interesting β-lactam system **16**. The initial product, however, appears to undergo unusually facile dehydrochlorination. Attempts to extend this approach to 2-substituted analogs of **15** have so far not met with success.

Another reaction which we were interested in trying was the reduction of 2-azidotetrahydrothiophene 1-oxide **1***b*, given our previous interest in sulfoxide reduction (16–18) and since the effect of the various literature methods available on the azide group has never been explored. Interestingly contrasting results were obtained with the procedures employed. The use of phosphorus pentasulfide (16) proved to be the most effective method for the conversion of **1***b* to **1***a*, in 81% yield, although iodotrimethylsilane (19) also afforded **1***a*, in 60% yield. In sharp contrast, the use of thiophosphoryl bromide (17) or the triphenylphosphine–iodine – sodium iodide procedure of Olah *et al.* (20) led to the rapid destruction of **1***b*. Treatment of **1***b* with the $TiCl_4$–Zn reagent described by Drabowicz and Mikolajczyk (21), even for brief periods, led only to the isolation of 5,6-dihydro-4*H*-1,3-thiazine **15** in 30% yield, presumably by Lewis acid-catalyzed rearrangement of the initially formed α-azidosulfide. A small amount (10%) of **15** also accompanied the deoxygenation of **1***b* to **1***a* (34%) using the trifluoroacetic anhydride – sodium iodide procedure of Drabowicz and Oae (22), and **15** was detectable in very small amount (3%) in the more successful reduction of **1***b* to **1***a* using phosphorus pentasulfide already discussed above. Somewhat surprisingly, no reaction was observed between **1***b* and diazomethane. Perhaps less surprisingly, the attempted reduction of the α-azidosulfone **1***c* on a small scale, using our two-step diazonium salt – sodium borohydride procedure (23), produced a violent decomposition and is not recommended.

In summary, we have shown in our study of the, presumably typical, cyclic α-azidosulfur derivatives **1***a–c* that these interesting bifunctional compounds reveal unusual aspects of chemical reactivity but also maintain in certain reactions the patterns of reactivity expected from simple organosulfur compounds or organic azides.

Experimental

Infrared spectra were recorded in chloroform on a Perkin–Elmer 298 grating spectrophotometer and the uv spectra in acetonitrile on a Unicam SP-8000 spectrophotometer. The ^{1}H nmr spectra were obtained on a Varian T-60 or EM-360 spectrometer in $CHCl_3$-*d* solution unless otherwise indicated and the natural abundance ^{13}C nmr spectra on either the Varian XL-200 or CFT-20 instruments, at 32 ± 3°C. Routine (low-resolution) mass spectra were obtained with a Bell and Howell 21-490 spectrometer and the high-resolution data on the AEI-MS 3074 instrument. Column chromatography and tlc (analytical and preparative) were carried out on silica gel supplied by E. Merck (Darmstadt). Elemental analyses were performed by the Scandinavian Microanalytical Laboratory, Box 25 DK2730, Herlev, Denmark. Melting points are uncorrected.

Synthesis of 2-azidotetrahydrothiophene, **1**a

To 2.00 g (22.73 mmol) of tetrahydrothiophene in 30 mL of benzene was added 3.03 g (22.69 mmol) of *N*-chlorosuccinimide, over a 15 min period. The mixture was stirred for a further 30 min, filtered, and the solvent removed *in vacuo*. The resulting 2-chlorotetrahydrothiophene was quickly added to 6.94 g (106.75 mmol) of sodium azide in 30 mL of distilled water containing a few drops of Adogen® 464 (Aldrich, phase transfer reagent). After 21 h of vigorous stirring at 25°C, the aqueous solution was extracted three times with 25 mL of dichloromethane. The organic layers were combined and dried. Column chromatography and elution with carbon tetrachloride – dichloromethane (9:1) yielded 2-azidotetrahydrothiophene (45%) as a yellow liquid, bp 50–52°C/6 Torr; ir ν: 2110(N_3) cm^{-1}; uv λ_{max}: 222 (log ϵ, 2.95) nm; ^{1}H nmr δ: 2.05 (m, 4H), 2.90 (m, 2H), 5.10 (t, 1H, J = 2 Hz) ppm; ms m/z: 101 ($M^+ - N_2$). *Anal.* calcd. for $C_4H_7N_3S$: C 37.19, H 5.46, N 32.53, S 24.82; found: C 37.16, H 5.40, N 32.58, S 24.77.

2-Azidotetrahydrothiophene 1-oxide, **1**b

2-Azidotetrahydrothiophene (1.29 g, 10 mmol) was added to a solution of $NaIO_4$ (2.25 g,10.50 mmol) in 210 mL of water, at 0°C. After stirring for 20 h, the aqueous solution was filtered and extracted thoroughly with chloroform to give a yellow oil which could be crystallized from petroleum ether – dichloromethane as white crystals (1.01 g, 72%), mp 31–31.5°C; ir ν: 2120 (N_3), 1055 (SO) cm^{-1}; uv λ_{max}: 223 (log ϵ, 2.98), 286 (1.80) nm; ^{1}H nmr δ: 2.15 (m, 4H), 2.89 (m, 2H), 4.88 (t, 1H, J = 4 Hz) ppm; ms m/z: 117 ($M^+ - N_2$). *Anal.* calcd. for $C_4H_7N_3OS$: C 33.07, H 4.87, N 28.95, S 22.09; found: C 32.73, H 4.95, N 28.47, S 21.55.

2-Azidotetrahydrothiophene 1,1-dioxide, **1**c

To a solution of **1***a* (2.58 g, 20 mmol) in glacial acetic acid (50 mL) was added a solution of 30% hydrogen peroxide (7.20 g, 60 mmol) in acetic acid (50 mL), dropwise over a period of 45 min. After stirring for 48 h, the reaction mixture was diluted with water and extracted with dichloromethane. Washing of the organic extract (10%Na_2SO_3, $NaHCO_3$, H_2O), drying, and evaporation gave a colorless oil, which could be crystallized from petroleum ether – benzene as a white solid (2.46 g, 85%), mp 36–37°C; ir ν: 2120 (N_3), 1335 and 1115 (SO_2) cm^{-1}; uv λ_{max}: 229 (log ϵ 3.69), 253 (3.48), 283 (3.38) nm; ^{1}H nmr δ: 2.10 (m, 4H), 2.95 (m, 2H), 4.33 (t, 1H, J = 5 Hz) ppm; ms m/z: 133 ($M^+ - N_2$). *Anal.* calcd. for $C_4H_7N_3O_2S$: C 29.81, H 4.38, N 26.07, S 19.89; found: C 29.86, H 4.71, N 25.63, S 20.02.

2-Azidothiochroman-4-one 1-oxide, **2**b

Thiochromone 1-oxide (24) (0.4 g, 2.2 mmol) was dissolved in chloroform (30 mL) and a solution of HN_3 (9 mmol) in chloroform, prepared from sodium azide by the method of Fieser (25), was added slowly with stirring. After stirring 4 h at 25°C, removal of the solvent left a dark residue which was redissolved in chloroform and treated with charcoal to remove the colored impurities. Evaporation of the solvent and recrystallization of the solid residue from hexane – carbon tetrachloride gave **2***b* as yellow crystals (50%), mp 116–118°C. The ir and ms data were similar to those reported previously (2), but the ^{1}H nmr indicated a mixture of *trans* and *cis* isomers in a 60:40 ratio, as estimated from the ratio of the methine protons; δ: 3.1–3.4 (m), 3.5–3.9 (m), 5.18 (dd, J = 3, 6 Hz, *cis*), 5.38 (dd, J = 2, 4 Hz, *trans*), 7.3–8.2 (m) ppm.

2-Azidothiochroman-4-one 1,1-dioxide, **2**c

The preparation and characterization of this compound have been described previously (2).

Thermolysis of **1**a

(a) 2-Azidotetrahydrothiophene (1.50 g, 11.7 mmol) was refluxed for 20 h in degassed toluene under nitrogen, in the presence of bromobenzene (1.83 g, 11.7 mmol). Preparative tlc (hexane–acetone 2:1) afforded tetrahydrothiophene-2-imine **5** (0.72 g, 62%) as a yellow oil; ir ν: 1610 (C=N) cm^{-1}; ^{1}H nmr δ: 2.2 (m, 4H), 3.1 (t, 2H, J = 4 Hz), 7.85 (br s, 1H) ppm; ^{13}C nmr δ: 16.5 (C-4), 26.1 (C-5), 29.4 (C-3), 157.2 (C=NH) ppm; ms m/z: 101 (M^+). *Exact Mass* calcd. for C_4H_7NS: 101.0299; found (high resolution ms): 101.0299.

Attempts to carry out the methylation of **5** using methyl iodide or dimethyl sulfate in the presence of various bases, including potassium carbonate, DBU, sodium hydride, and even LDA, in anhydrous acetone or THF, were unsuccessful.

(b) 2-Azidotetrahydrothiophene (0.50 g, 3.88 mmol) in 100 mL of degassed 1-octene was refluxed under nitrogen for 20 h. Column chromatography yielded the aziridine **7** (0.12 g, 22%); ms m/z: 213 (M^+). *Exact Mass* calcd. for $C_{12}H_{23}NS$: 213.1553; found (high resolution ms): 213.1551.

Photolysis of **1**a *(typical procedure)*

2-Azidotetrahydrothiophene (0.50 g, 3.88 mmol) in 100 mL of degassed acetonitrile was irradiated with a 400-W medium pressure lamp for 20 h. Thick layer chromatography yielded 4,4′-dithiodibutanenitrile **11** (14), (0.10 g, 26%); ir ν: 2250 (CN) cm^{-1}; ^{1}H nmr δ: 1.9–3.75 (m, 12H) ppm. *Exact Mass* calcd. for $C_8H_{12}N_2S_2$: 200.0445; found (high resolution ms): 200.0442. *Anal.* calcd. for $C_8H_{12}N_2S_2$: C 47.97, H 6.04, N 13.98, S 31.95; found: C 47.80, H 6.74, N 13.81, S 31.73.

Similar irradiation of **1***c* produced mainly recovered starting material, along with a small amount (2%) of a compound which appeared from the mass spectrum (m/z = 264) to be **13**.

Base-catalyzed reactions of **1**b *and* **1**c

To a solution of 2-azidotetrahydrothiophene 1-oxide (0.50 g, 3.5 mmol) in 40 mL of dry tetrahydrofuran at 0°C, potassium *tert*-butoxide (0.56 g, 5.0 mmol) was added. After stirring for 30 min under N_2, water (20 mL) was added to quench the reaction. After evaporation to dryness, the product was dissolved in a small amount of water which was re-extracted with dichloromethane. Evaporation of the organic layer gave only starting material (0.20 g, 40%). Evaporation of the aqueous phase afforded a pale brown solid (0.19 g, 60%), which could not be recrystallized; ir (KBr) ν: 2270 (CN) cm^{-1}; ^{1}H nmr (D_2O) δ: 1.85 (m, 2H), 2.35 (m, 4H) ppm.

Reaction of **1***c* under identical conditions afforded a similar, water-soluble, non-crystalline solid (68%), suspected to be **14***b*; ir (KBr) ν: 2280 (CN), 1040, 970 cm^{-1}; ^{1}H nmr (D_2O) δ: 2.0 (m, 2H), 2.5 (m, 4H) ppm.

Lewis acid-catalyzed rearrangement of **1**a*: 5,6-dihydro-4H-1,3-thiazine,* **15**

To a solution of α-azidosulfide **1***a* (0.69 g, 5 mmol) in dry acetonitrile (25 mL), anhydrous stannic chloride (1.42 g, 5.50 mmol) was added slowly under N_2. After stirring 1.5 h a yellow solid appeared, mp 90–95°C (dec.), believed to be the $SnCl_4$ complex of **15**. Upon dissolution in water (200 mL), addition of a few drops of concentrated hydrochloric acid, and stirring for 0.5 h, extraction with dichloromethane, drying, and evaporation afforded a yellow oil (0.46 g, 85%). (Similar results were obtained with $TiCl_4$ as the catalyst.) Spectral data were ^{1}H nmr δ: 2.0 (m, 2H), 2.7 (m, 4H), 9.85 (t, 1H, J = 1 Hz) ppm; ^{13}C nmr (CH_3NO_2-d_3) δ: 15.0 (C-5), 24.4 (C-6), 36.3 (C-4), 118.3 (C-2) ppm; ms m/z: 101 (M^+).

Reaction of **15** *with dichloroketene*

The preparation of trichloroacetyl chloride from the acid and the

activation of the zinc were carried out according to the procedure of Krepski and Hassner (15). To a mixture of compound **15** (0.54 g, 5.4 mmol) and activated zinc (0.69 g, 10.5 mmol) in anhydrous diethyl ether (25 mL), was slowly added a mixture of trichloroacetyl chloride (1.83 g, 10.0 mmol) and phosphorus oxychloride (1.53 g, 10.0 mmol) dissolved in anhydrous ether (10 mL). After refluxing 1 h, work-up according to the literature procedure led to the isolation of a yellow oil (possibly the dehydrochlorination product **17**) in low yield; ^{1}H nmr δ: 2.10 (m, 2H), 2.75 (m, 4H) ppm.

*Reduction of 2-azidotetrahydrothiophene 1-oxide, 1*b

These reactions, the results of which are summarized in the text, were carried out according to the respective literature procedures (16–22).

A ^{19}F, ^{119}Sn nuclear magnetic resonance and ^{119}Sn Mössbauer study of the SnF_2-MF-H_2O system

THOMAS BIRCHALL[1] AND GEORGES DÉNÈS
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received October 20, 1983

THOMAS BIRCHALL and GEORGES DÉNÈS. Can. J. Chem. **62**, 591 (1984).

^{19}F and ^{119}Sn nmr spectroscopy has been used to study the SnF_2-MF-H_2O (M = Li^+, Na^+, K^+, Rb^+, Cs^+, and $[NH_4]^+$) system. The nmr data have been supplemented by frozen solution ^{119}Sn Mössbauer measurements. The evidence suggests that the dominant species in the SnF_2-H_2O system is a hydrated stannous fluoride, probably $SnF_2 \cdot H_2O$ having Mössbauer parameters of δ = 3.46 mm s^{-1} and Δ = 1.70 mm s^{-1}. When F^- is added to these solutions rapid F^- exchange occurs with the hydrated SnF_2 and the dominant species becomes $[SnF_3]^-$. The ^{119}Sn nmr chemical shift of $[SnF_3]^-$ is ~ -700 ppm from $(CH_3)_4Sn$. The ^{119}Sn Mössbauer parameters for frozen solutions of $[SnF_3]^-$ are $\delta = \sim 3.1$ mm s^{-1}, Δ = 1.9 mm s^{-1}. These spectroscopic data are cation dependent. We could find no strong evidence for high concentrations of $[Sn_2F_5]^-$ in any of these solutions.

THOMAS BIRCHALL et GEORGES DÉNÈS. Can. J. Chem. **62**, 591 (1984).

L'étude du système SnF_2-MF-H_2O (M = Li^+, Na^+, K^+, Rb^+, Cs^+ et $[NH_4]^+$) a été entreprise à l'aide de la rmn ^{19}F et ^{119}Sn ainsi que par spectroscopie Mössbauer ^{119}Sn sur des solutions gelées. Il est suggéré que l'espèce prédominante dans le système SnF_2-H_2O est un hydrate du fluorure stanneux, probablement $SnF_2 \cdot H_2O$ ayant les paramètres Mössbauer suivants: δ = 3,46 mm^{-1} et Δ = 1,70 mm s^{-1}. L'addition d'ions F^- à ces solutions entraîne un échange rapide du fluor entre ions F^- et SnF_2 hydraté, l'espèce prédominante en solution étant maintenant $[SnF_3]^-$. Le déplacement chimique de $[SnF_3]^-$ en rmn ^{119}Sn est ~ -700 ppm par rapport à $(CH_3)_4Sn$. Les paramètres Mössbauer ^{119}Sn pour les solutions gelées de $[SnF_3]^-$ sont $\delta = \sim 3,1$ mm s^{-1} et Δ = 1,9 mm s^{-1}. Les résultats spectroscopiques montrent une certaine variation avec la nature du cation. Il n'a pas éte observé d'évidence pour l'existence de fortes concentrations en $[Sn_2F_5]^-$ dans aucune de ces solutions.

Introduction

The structure of α-stannous fluoride is now well established (1, 2) and consists of cyclic tetramers of SnF_2. In this structure there are two different tin environments which may be represented as SnF_3E and SnF_5E, where E represents a non-bonding electron pair and only one F, on each tin, is of the terminal type, the others being bridging fluorines. The ^{119}Sn Mössbauer spectrum of α-SnF_2, the monoclinic form, has been reported by several researchers (3–5) with some variation in the parameters reported by the various groups. Stannous fluoride forms salts of the general type, $M[Sn_2F_5]$ and $M[SnF_3]$ with alkali metal fluorides, (6, 7) but $Na_4[Sn_3F_{10}]$ has also been characterized (8). The X-ray crystal structure of $Na[Sn_2F_5]$ has been reported (9) and consists of $[Sn_2F_5]^-$ units in which each tin has three close fluorines, one of them bridging the two tin atoms to give a distorted tetrahedral environment to the Sn(II) and the non-bonding 5*s* electron pair occupying the fourth coordination site. Weaker fluorine bridges link the $[Sn_2F_5]^-$ units into a polymeric chain. For the $M[SnF_3]$ composition the X-ray crystal structures of $[NH_4][SnF_3]$ (10, 11) and $K[SnF_3] \cdot 0.5H_2O$ (12) have been reported. In $[NH_4][SnF_3]$ there are isolated $[SnF_3]^-$ ions while $K[SnF_3] \cdot 0.5H_2O$ consists of infinite chains of $[SnF_4]^{2-}$ pyramids connected at corners. In both cases the non-bonding electron pair is stereochemically active and occupies the vacant site of each polyhedron. ^{119}Sn Mössbauer spectra for both series of solids, $M[Sn_2F_5]$ and $M[SnF_3]$, have been reported (13) and interpreted in terms of the geometries discussed above. The Mössbauer parameters for the two series are not very different but the trends in each series appear to be cation dependent.

The salts of $[Sn_2F_5]^-$ and $[SnF_3]^-$ were prepared from aqueous solution and while evidence for the existence of these anions in solution has been presented (14, 15) only one frozen solution Mössbauer study has been reported for Sn^{2+} in $HF-H_2O$ (16). Since the nmr and Mössbauer methods can provide unique information about the degree of Sn–ligand interaction we decided to examine the $MF-SnF_2-H_2O$ system using ^{19}F and ^{119}Sn nmr and ^{119}Sn Mössbauer spectroscopy in the hope that we could further quantify the evidence for the $[Sn_2F_5]^-$ and $[SnF_3]^-$ ions in aqueous solution, and to see what evidence, if any, there was for species such as $SnF_2 \cdot H_2O$. The results presented below appear to confirm the earlier results for the existence of $[SnF_3]^-$ but that of $[Sn_2F_5]^-$ appears more doubtful. There is clearly rapid exchange of F^- occurring in these solution and equilibria of the type [1] and [2] undoubtedly exist. Rapid exchange of F^-

$$[1] \quad [SnF_3]^- + H_2O \rightleftarrows SnF_2 \cdot H_2O + F^-$$

$$[2] \quad [Sn_2F_5]^- + H_2O \rightleftarrows [SnF_3]^- + SnF_2 \cdot H_2O$$

with $[SnF_3]^-$ and $[GeF_3]^-$ in aqueous solution has already been reported by Meutterties using ^{19}F nmr techniques (17). Similar results have recently been published for SnF_2 in donor solvents such as DMSO and HMPA (18). The concentration of $[Sn_2F_5]^-$ present at any one time could be quite low and the isolation of $M[Sn_2F_5]$ salts from aqueous solution could occur only because it is the least soluble.

Experimental

The α-SnF_2, monoclinic form, was used as supplied by O.S.I.; ^{119}Sn Mössbauer spectra show that this contains a small amount of Sn(IV) impurity. The alkali metal fluorides were supplied by Ventron Corpn. Mössbauer spectra were recorded with a Promeda multichannel analyzer and ancilliary equipment which has already been described (19). The Mössbauer source, $Ca^{119m}SnO_3$ supplied by Spire Corporation, was maintained at room temperature for all measurements while the samples were quenched in liquid nitrogen and then transferred to an Air Products Heli-Trans system precooled to 80 K. Periodic checks were made on the frozen samples to ensure that no crystallization of the tin fluoride salts had occurred. Spectra were fitted using the computer program of Ruebenbauer and Birchall (20). The spectra were referenced against a standard $CaSnO_3$ absorber and

calibrated using a ^{57}Co source and a standard iron foil absorber. The concentration of the solutions used for Mössbauer spectroscopy was usually ~1 *M* in Sn except for the potassium salts where a concentration of ~0.1 *M* in Sn was used because of their low solubility. ^{19}F and ^{119}Sn nmr spectra were recorded on a Bruker W.H.90 at 84.669 MHz and 33.545 MHz, respectively. The ^{19}F spectra were referenced against CCl_3F and the ^{119}Sn spectra against $(CH_3)_4Sn$ as zero chemical shift, negative shifts being to higher magnetic field strength.

Results and discussion

The ^{119}Sn Mössbauer data for α-SnF_2 solid and for the frozen aqueous solutions of SnF_2 and MF are given in Table 1. We have shown that a small Sn(IV) impurity is present in the α-SnF_2 used in these studies. A freshly prepared solution of commercial α-SnF_2 in water which has been frozen to 80 K, within ~30 min of dissolution, and its Mössbauer spectrum recorded, shows no growth in intensity of this Sn(IV) component. After this solution had stood for 48 h in air at room temperature and the frozen solution spectrum recorded again the spectrum showed that some augmentation of the Sn(IV) component had occurred (Table 1), indicating that oxidation of Sn(II) to Sn(IV) had taken place. It is clear that this process is not fast as has been claimed (21), and our findings corroborate those of Muetterties (17) who also found this process to be slow.

On dissolution in water there is a small increase in the isomer shift and a significant increase in the quadrupole splitting, indicating a small increase in *s* electron density at tin while at the same time a more asymmetric tin environment is produced. This suggests that the cyclic tetrameric α-SnF_2 structure has been disrupted perhaps to give $SnF_2 \cdot H_2O$ with the oxygen coordinated to the tin to maintain the pyramidal geometry. Addition of MF ($M = NH_4^+, Li^+, Na^+, K^+, Rb^+, Cs^+$) to these solutions results in a decrease in isomer shift and an increase in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

quadrupole splitting. These changes indicate a greater involvement of the Sn(II) 5*s* electrons in the bonding between the tin and the ligands surrounding it. If the species in solution prior to the addition of MF was indeed $SnF_2 \cdot H_2O$, we assume that the water molecule is displaced by the F^- added. These changes are progressive as the amount of MF is increased but appear to reach more or less constant values for each alkali metal or ammonium ion at $MF:SnF_2$ ratio $> 1:1$, i.e., when there is an excess of F^- over the composition of $MSnF_3$. The Mössbauer parameters at this stage are very similar to the data reported for the corresponding solid $M[SnF_3]$ species (13) after allowance is made for the different isomer shift references that have been used. This supports the idea that the $[SnF_3]^-$ anion is the dominant tin species present in these frozen solutions. The solid state data appeared to show a smooth variation in the values of the Mössbauer parameters as the size of the cation was increased and this was interpreted as reflecting the decreasing polarizing power of the cation: in the case of the $[NH_4]^+$ cation the differences were attributed to hydrogen bonding to the $[SnF_3]^-$ anions (13). In the frozen aqueous solutions of composition $M[SnF_3]$ the Mössbauer parameters follow the solid state trends but are of smaller magnitude. For example, from $[NH_4]^+$ to Cs^+ the isomer shift of the $M[SnF_3]$ species decreases by 0.25 mm s^{-1} while the quadrupole splitting decreases by 0.12 mm s^{-1}: the corresponding changes in the frozen aqueous solutions are 0.15 mm s^{-1} and 0.08 mm s^{-1}. These latter changes are barely outside the 3σ standard deviation of errors involved in the measurement. This suggests that the degree of cation–anion interaction in these frozen systems is small. In the $LiF-SnF_2-H_2O$ system the Mössbauer parameters obtained for all compositions are very close to those obtained for frozen solutions of SnF_2 in water (Table 1). This suggests that the tin species present is $SnF_2 \cdot H_2O$ and not $[SnF_3]^-$ or $[Sn_2F_5]^-$. The lithium ion, being strongly polarizing, must form a strong ion pair with the fluoride ion and so prevent the coordination of F^- to SnF_2 to produce the fluorostannate(II) ions. This could be the reason why no solid lithium fluorostannate salts have been obtained from aqueous solutions.

For the composition corresponding to $M[Sn_2F_5]$, similar trends in Mössbauer parameters are also noted with changing cation, that is, the isomer shifts decrease as the cation size increases. Isomer shifts vary by ~0.2 mm s^{-1} while quadrupole splittings change by ~0.1 mm s^{-1}. In view of the fact that all frozen solutions did not have the same concentration of tin, due to solubility problems for some salts, it is difficult to compare these results absolutely. The isomer shifts for the $M[Sn_2F_5]$ composition appear to be slightly more positive that those for the $M[SnF_3]$ composition, particularly for the smaller cations such as $[NH_4]^+$, Na^+, K^+, but the quadrupole splittings for these two compositions are virtually the same. On the basis of Mössbauer spectroscopy it is unlikely that $[SnF_3]^-$ and $[Sn_2F_5]^-$ can be distinguished in these frozen aqueous solutions. This is disappointing, but perhaps not surprising, since the measurements on the pure solid compounds only show isomer shift differences of 0.2 mm s^{-1}. At higher ratios of SnF_2 to MF the Mössbauer parameters approach those for the SnF_2-H_2O frozen solutions, the isomer shift being the most sensitive in this regard. In addition there is a noticeable broadening of the low velocity component of the quadrupole doublet in these cases, indicating the presence of overlapping, unresolvable peaks (Fig. 1). The species present probably are due to $[SnF_3]^-$ and $SnF_2 \cdot H_2O$ with the possibility that $[Sn_2F_5]^-$ is also present, although nmr data presented below seem to eliminate the latter possibility. We attempted to fit these spectra to two overlapping doublets without success.

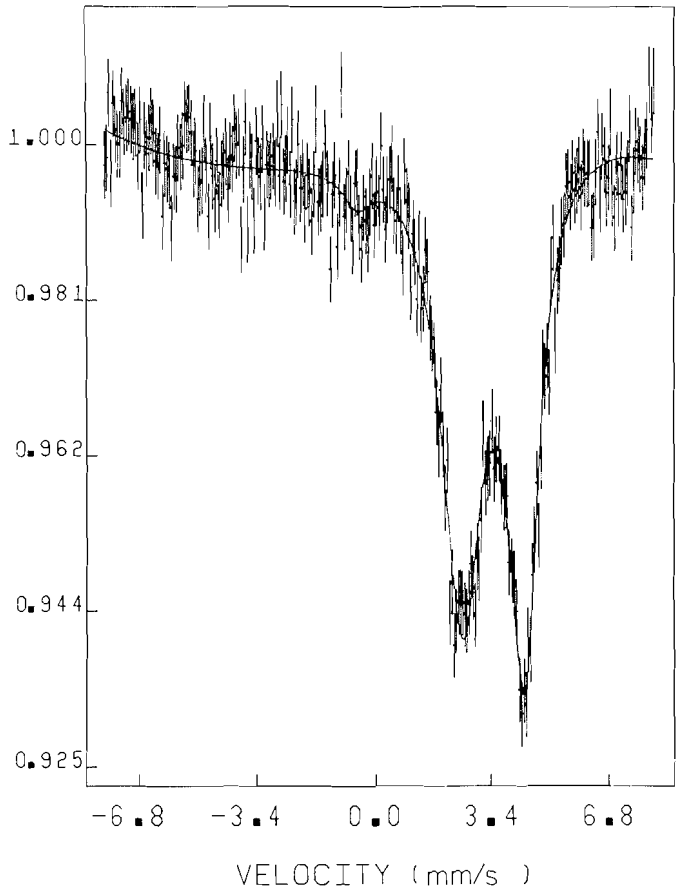

FIG. 1. ^{119}Sn Mössbauer spectrum of a frozen aqueous solution of $K[Sn_4F_9]$ composition at 80 K.

Nuclear magnetic resonance data

In an attempt to obtain further information on the species present in solution, ^{19}F and ^{119}Sn nmr measurements were carried out at ambient temperature. The ^{19}F nmr spectra of solutions of stannous fluoride in water consisted of one major, fairly broad peak (~30 Hz wide) at −80 to −90 ppm from $CFCl_3$, with minor peaks (<5%) at ~−128, −141, −148, and −154 ppm. The nature of these minor components is not clear but they probably arise from the small amount of the Sn(IV) impurity detected by Mössbauer spectroscopy in the SnF_2 used. The main fluorine signal is broad, suggesting that a slow exchange process is taking place. Some of these solutions were cooled to ~−10°C in an attempt to slow down the exchange process but the ~40°C reduction in temperature produced no visible effect on the spectra.

Figure 2 shows a plot of ^{19}F chemical shifts vs. concentration of SnF_2 in water, which is linear from 4 *M* to ~0.5 *M*. At lower concentrations the plot deviates from linearity and extrapolates to a chemical shift of ~−93 ppm at infinite dilution. This value represents the chemical shift of the $SnF_2 \cdot (x + 1)H_2O$ species where at least one of the water molecules is strongly bound to the tin.

Addition of MF to these solutions results in a narrowing of the ^{19}F resonance, which would be expected since an easy mechanism for fluorine exchange is now possible via [3].

[3] $SnF_2 \cdot (x + 1)H_2O + F^- \rightleftarrows [SnF_2F]^- \cdot (x)H_2O + H_2O$

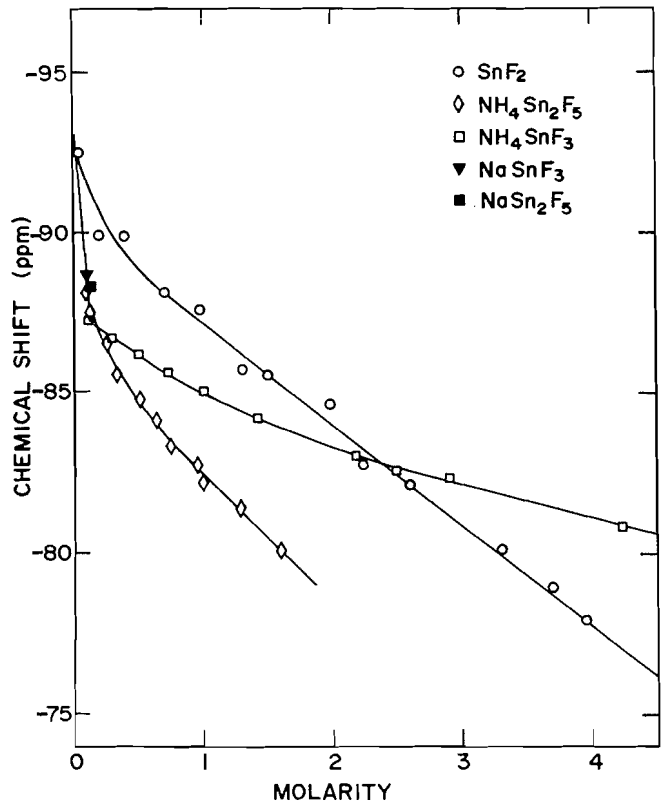

FIG. 2. ^{19}F nmr chemical shift of solutions of SnF_2, $[NH_4][SnF_3]$, $[NH_4][Sn_2F_5]$ vs. concentration.

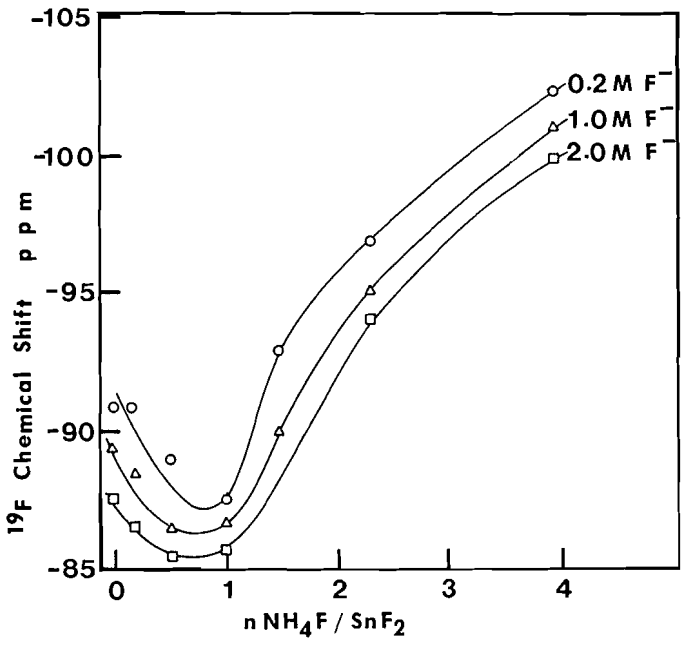

FIG. 3. ^{19}F nmr chemical shift of solutions of SnF_2 vs. amount of $[NH_4]F$, for three constant concentrations in fluoride ion.

No coupling of fluorine to tin is observed, confirming rapid exchange. Plots of ^{19}F chemical shift vs. concentration for solutions of composition $[NH_4][SnF_3]$ and $[NH_4][Sn_2F_5]$ in water are also shown in Fig. 2. These plots are not linear and since ^{19}F exchange is rapid, represent the time-averaged chemical shift of the $[SnF_3]^-$, SnF_2, F^-, and $[Sn_2F_5]^-$, $[SnF_3]^-$, SnF_2,

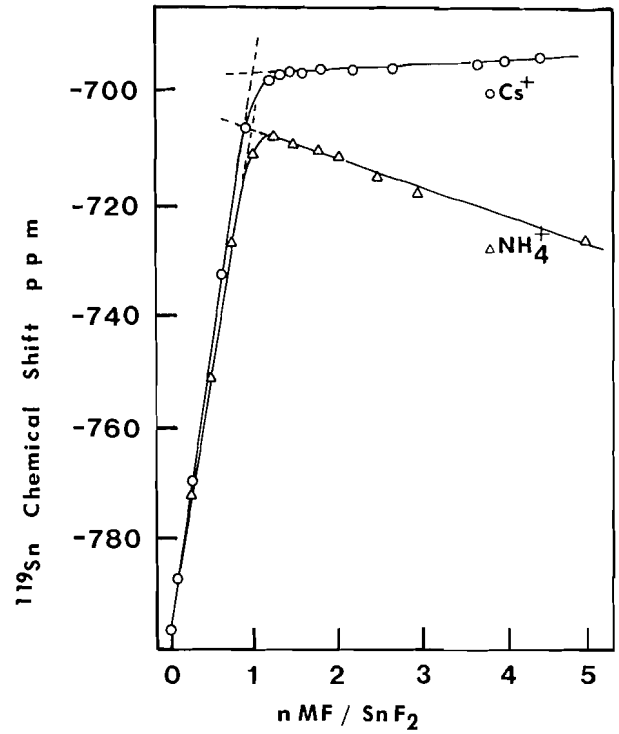

FIG. 4. ^{119}Sn nmr chemical shift of solutions of SnF_2 vs. amount of CsF and $[NH_4]F$, for a constant concentration (2 *M*) in tin.

and F^- for the $[NH_4][SnF_3]$ and $[NH_4][Sn_2F_5]$ solutions as in [3] and [4], respectively,

[4] $[Sn_2F_5]^- \rightleftarrows [SnF_3]^- + SnF_2$

with all Sn—F species presumably also interacting and exchanging with the solvent water molecules. At concentrations less than 0.2 *M* the curves for $[SnF_3]^-$ and $[Sn_2F_5]^-$ appear to merge with the extrapolated value at infinite dilution being ~ -97 ppm. This would suggest complete dissociation of both $[SnF_3]^-$ and $[Sn_2F_5]^-$ into SnF_2 and F^- whose chemical shifts at low concentration are ~93 ppm and ~ -118 ppm, respectively. Increasing the pH of both SnF_2 and $[SnF_3]^-$ solutions above pH = 6 causes the ^{19}F chemical shift to become more negative until at pH 10.7 the resonance has almost reached that of free F^-. Under those conditions hydrated $Sn(OH)_2$ and/or $[Sn(OH)_3]^-$ are probably the dominant tin species with all fluoride ions having been displaced.

Figure 3 shows the effect of added $[NH_4]F$ to solutions containing three different concentrations of SnF_2. As $[NH_4]F$ is increased from zero the ^{19}F chemical shift first decreases and after a 1:1 molar ratio of F^-:SnF_2 is reached there is a steady increase in ^{19}F shifts. For all three SnF_2 concentrations the minimum in the curve occurs close to a 1:1 ratio, this minimum being sharper for the less concentrated solution. These data indicate that $[SnF_3]^-$ is the dominant species at the 1:1 ratio. The more concentrated solution results in a broader, less well-defined minimum, and probably reflects the presence of larger amounts of $[Sn_2F_5]^-$ and an increasing contribution from equilibrium [4].

Equilibria such as [3] and [4], since they affect the ^{19}F chemical shifts, should certainly have an influence on the ^{119}Sn resonance. Dean (22) has noted the large range of ^{119}Sn chemical shifts for compounds of tin(II) and we were therefore hopeful of obtaining evidence for the hydrated SnF_2, $[SnF_3]^-$,

and $[Sn_2F_5]^-$ species. Solutions of SnF_2 (2 *M*) have a linewidth of ~20 Hz and as with the ^{19}F spectra, no $J_{^{119}Sn-^{19}F}$ coupling is observed. Addition of F^- causes a broadening which reaches a maximum of about ~30 Hz, again at a 1:1 mole ratio of $MF:SnF_2$, but excess F^- causes this to decrease as exchange according to [3] becomes more prevalent. The ^{119}Sn chemical shift of a 2 *M* solution of SnF_2 in water is ~−800 ppm from $(CH_3)_4Sn$. As F^- ion is added the resonance shifts to lower field strength, as was observed for the ^{19}F shifts, and reaches a minimum value of ~−700 ppm at the composition $M[SnF_3]$, Fig. 4. The ^{119}Sn chemical shift of the $CsF-SnF_2$ system remains fairly constant once the $Cs[SnF_3]$ composition has been reached, but the shift observed for the $[NH_4]F-SnF_2$ system reaches a lower minimum value and begins to increase again as the amount of $[NH_4]F$ is increased. This may be attributed to a stronger cation–anion interaction in the ammonium ion case via H—F hydrogen bonds. Figure 4 shows an essentially linear relationship between $\delta^{119}Sn$ and MF concentration up to the $M[SnF_3]$ composition with no noticeable break at the $M[Sn_2F_5]$ composition, perhaps indicating that the concentration of $[Sn_2F_5]^-$ is never very significant. This contrasts with the earlier evidence presented by Donaldson and co-workers (14) who suggested that the concentration of $[Sn_2F_5]^-$ anion was appreciable in aqueous solutions of this composition.

The cathodic reduction of PbO in the passive layer on lead in aqueous sulphuric acid

R. G. BARRADAS AND D. S. NADEZHDIN

The Ottawa–Carleton Institute for Graduate Studies and Research in Chemistry, Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received August 2, 1983

R. G. BARRADAS and D. S. NADEZHDIN. Can. J. Chem. **62**, 596 (1984).

The cathodic reduction of the lead monoxide layer formed on lead in 30% aqueous H_2SO_4 under anodic oxidation at 0.6 V (vs. $Hg/HgSO_4$ reference electrode) was investigated by linear sweep voltammetry, potential step and admittance measurements. The experimental data were analyzed respectively in terms of thin-layer electrochemistry, electrocrystallisation, and changes of resistance of the PbO layer under reduction. The results seem to be best interpreted from the theory of three-dimensional electrocrystallisation as PbO is reduced to Pb. At sub-zero temperatures the PbO peak observed on our voltammograms and potentiostatic current time transients reveals the splitting of the curves into two peaks, which may be a result of reduction of the same material but of different phases, namely, orthorhombic and tetragonal PbO.

R. G. BARRADAS et D. S. NADEZHDIN. Can. J. Chem. **62**, 596 (1984).

Faisant appel à la voltamétrie à balayage lineaire, au palier de potentiel et aux mesures d'admission, on a étudié la réduction cathodique de la couche de monoxyde de plomb qui se forme sur le plomb en solution aqueuse de H_2SO_4 à 30% sous oxydation anodique à 0,6 V (par rapport à une électrode de référence de $Hg/HgSO_4$). On a analysé les données expérimentales en fonction respectivement de l'électrochimie de la couche mince, de l'électrocristallisation et des variations de la résistance de la couche de PbO lors de la réduction. Les résultats semblent mieux s'interpréter à partir de la théorie de l'électrocristallisation en 3 dimensions lorsque le PbO est réduit en Pb. A des températures sous zéro, le pic de PbO observé sur nos voltamogrammes et le temps provisoire de courant potentiostatique révèlent le dédoublement des courbes en deux pics qui peuvent résulter de la réduction du même produit mais dans des phases différentes soit les PbO orthorhombique et tétragonal.

[Traduit par le journal]

Introduction

It is well established that the passive layer on lead formed under anodic oxidation in a certain potential region between the equilibrium potentials of $Pb/PbSO_4$ and $PbO_2/PbSO_4$ systems consists of an outer porous layer of $PbSO_4$ and an inner layer of lead monoxide (PbO). According to Ruetschi (1), the inner part of the solution in the pores is separated from the bulk of the solution with a semipermeable $PbSO_4$ membrane.

Ruetschi and Angstadt (2) showed that the process of the cathodic reduction of the PbO under galvanostatic conditions is highly irreversible. A number of publications have shown a cathodic peak for PbO on cyclic voltammograms (3–7).

In this paper we wish to report some new experimental data on the cathodic reduction of the PbO layer.

Experimental

The experiments consisted of the anodic passivation of pure lead (99.997% Pb, Cominco of Canada Ltd.) in a 30% solution of H_2SO_4 (Aristar) in triply distilled water at the constant potential of 0.6 V (all potential vs. Hg/Hg_2SO_4, 30% H_2SO_4 reference electrode) followed by cathodic reduction under potential linear sweep at different sweep rates or under potential step conditions. Duration of the passivation and temperature of the solution were varied. The apparent electrode area was 0.040 cm^2. The experimental technique has been described in a previous communication (8).

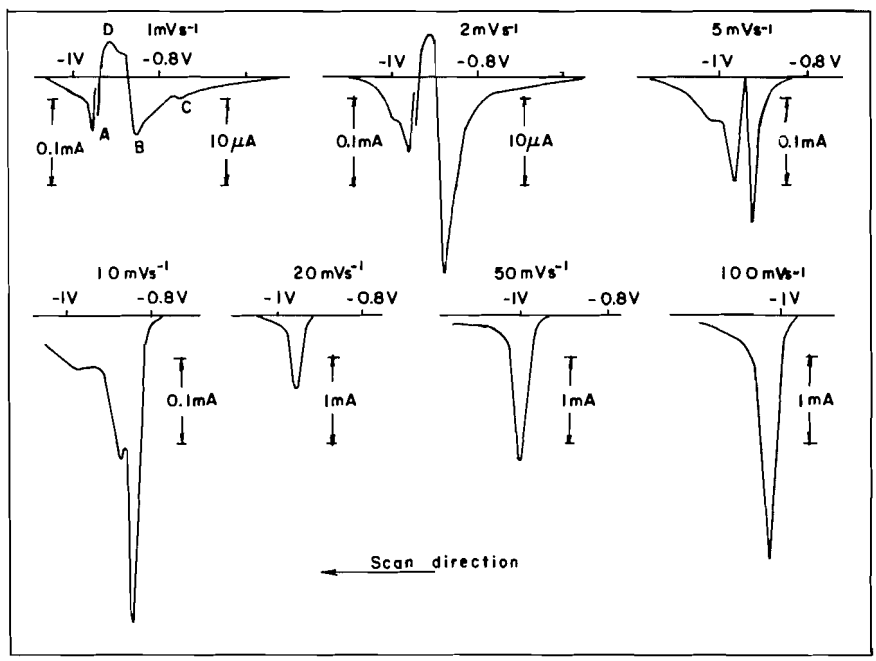

FIG. 1. Cathodic linear sweep voltammogram (LSV) at different scan rates after passivation for 20 min at 0.6 V and 22°C.

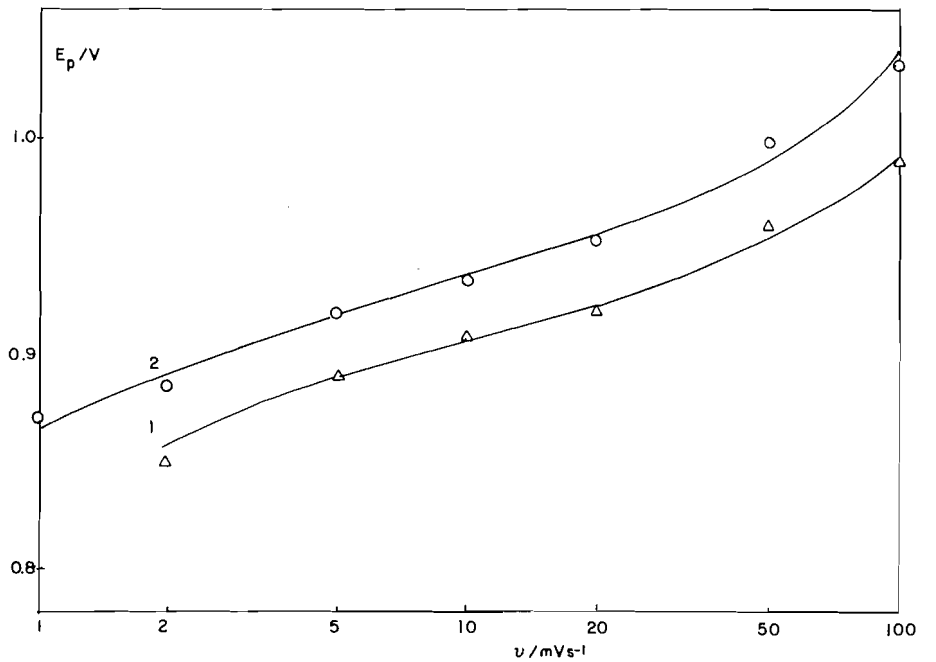

FIG. 2. Dependence of the PbO peak potential on scan rate for the LSV after passivation for 10 (*1*) and 20 (*2*) min.

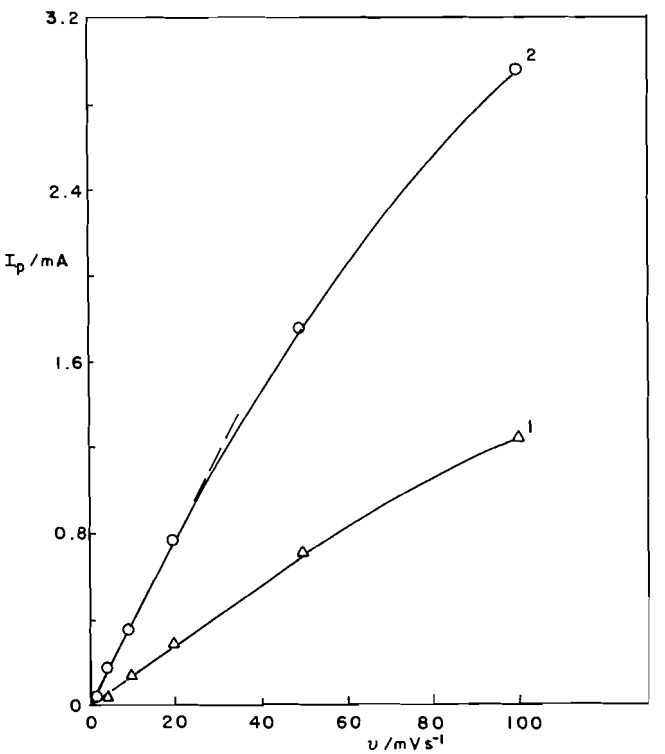

FIG. 3. Dependence of the PbO peak current on scan rate for the LSV after passivation for 10 (*1*) and 20 (*2*) min.

Admittance measurements were carried out at a frequency of 1 kHz and a peak-to-peak amplitude of 11 mV using an EG&G PARC Lock-in-Amplifier, Model 128A, a Hewlett-Packard 3310B Function Generator, and a Hewlett-Packard 7123A Chart Recorder.

Results and discussion

(a) Linear sweep voltammograms

Figure 1 shows cathodic linear sweep voltammograms (LSV) obtained at different sweep rates (from 1 to 100 mV s^{-1}) after passivation for 20 min at 22°C. The LSV at scan rates 1, 2, 5, and 10 mV s^{-1} show two cathodic peaks A and B, which can be related to the reduction of $PbSO_4$ and PbO, respectively (3–7). With increasing scan rate the peak potential (E_p) for peak A has not changed; however, the E_p for peak B has shifted significantly towards more negative potentials. The peak current (I_p) for both peaks A and B has increased, but the increase for peak B is much larger. This peak, whose height is relatively small at a scan rate of 1 mV s^{-1}, has become equal to and significantly larger than peak A at a scan rate of 5 and 10 mV s^{-1}, respectively. At a scan rate of 20 mV s^{-1} peak B has overlapped peak A and a resulting peak has shifted towards negative potentials and its height increased with scan rate from 50 to 100 mV s^{-1}. A small cathodic peak C on the LSV for 1 mV s^{-1} at a potential around −0.75 V will be considered later in context of our experiments at low temperatures. A small anodic excursion D between peaks A and B appears to be similar to that reported by Valeriote and co-workers (4) and is believed to represent re-oxidation of metallic lead formed by reduction of PbO at peak B, volume contraction due to reduction creating pores and thereby exposing such lead to the electrolyte.

Figures 2 and 3 present dependencies of the E_p and I_p for the PbO peak on scan rate (v) for LSV after passivations for 10 and 20 min. Both dependencies have a linear part in the middle region of v, which can be expressed, respectively, as

$$[1] \quad E_p = a - b \cdot \log v$$

and

$$[2] \quad I_p = cv$$

where a, b, and c are constants. The electrochemical reduction of thin oxide films may be described in terms of an analogous mathematical treatment of the theory of thin layer electrochemistry (9), which is consistent with eqs. [1] and [2]. However, detailed calculations based on such a treatment gave

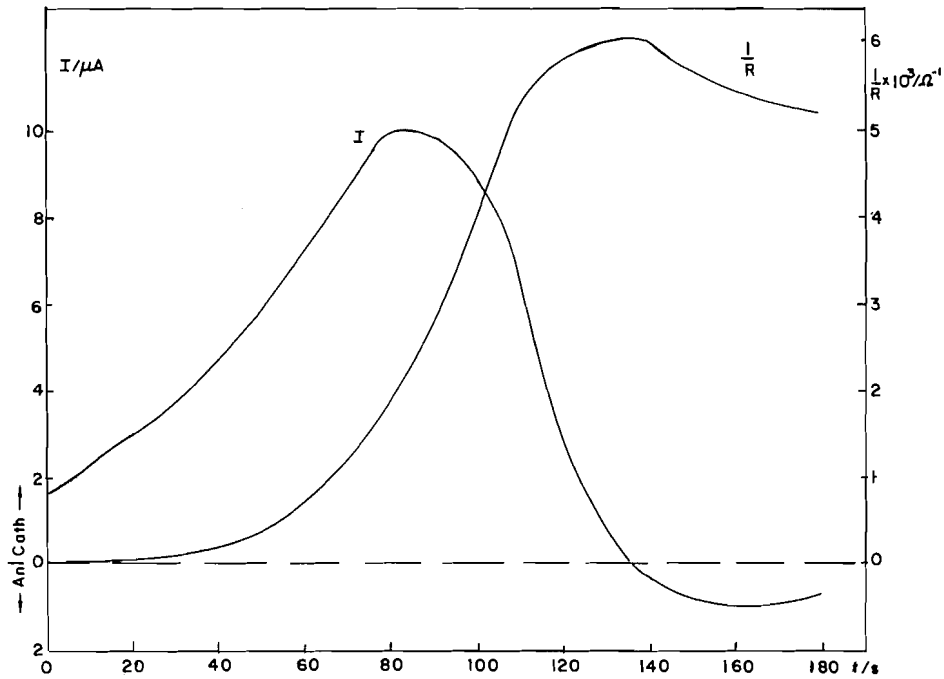

FIG. 4. Current (I) and admittance ($1/R$) transients for the potential step to −0.85 V after passivation at 0.6 V and 22°C for 20 min.

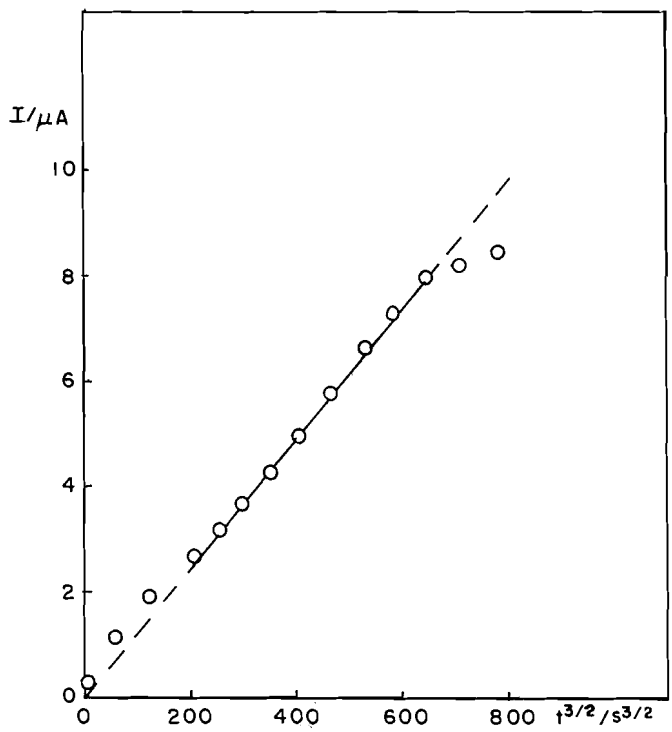

FIG. 5. Plot of the net current vs. $t^{3/2}$ for the ascending branch of the current transient on Fig. 4.

I_p values considerably smaller than the ones obtained experimentally.

(b) Potential step transient

Figure 4 (curve I vs. t) presents a current transient for a potential step from the potential of passivation, 0.6 V (passivation for 20 min at 22°C) to the potential of reduction, −0.85 V. The rising form of the transient permits one to consider the reduction process on the basis of the nucleation and growth model of electrocrystallisation (10). In our case it represents the three-dimensional crystallisation and consequent deposition of metallic lead as the reduction of PbO proceeds to completion.

Figure 5 shows that the dependence of the net current on time for the ascending branch of the transient is

$$[3] \quad I = kt^{3/2}$$

where k is a constant. This is characteristic of the model of progressive nucleation and three-dimensional growth with slow diffusion (10). It is interesting to note that a similar type of transient was reported by Valeriote and Gallop (11) for oxidation of PbO to α-PbO_2 in a passive layer on lead in sulphuric acid. A possible explanation for the positive deviation of the current in the initial portion of the transient could be that the proper diffusion conditions are established with some time lag. At the end of the transient the current becomes anodic (Fig. 4). It corresponds with the aforementioned anodic excursion D on the LSV (Fig. 1).

Figures 6 and 7 present plots of the I_p and E_p vs. $v^{1/2}$ for the PbO peak. The shapes of the curves are similar to those for the I_p and E_p vs. $v^{1/2}$ dependence obtained by a computer simulation of the voltammogram describing the nucleation and growth of a three-dimensional deposit by electrocrystallisation (12).

(c) Admittance measurements

Another reason for the rising potentiostatic transient lies in a decrease of the PbO layer resistance resulting from conversion of the highly resistive PbO into less resistive metallic Pb.

Figure 4 presents direct current and the in-phase component of the electrode admittance transients obtained simultaneously at the potential step to −0.85 V after passivation at 0.6 V. The value of the in-phase component ($1/R$) at the end of passivation lies around $5 \times 10^{-5}\ \Omega^{-1}$. Taking into account the charge passed for layer reduction (Q = ca. 800 μC) and assuming that the PbO layer is uniformly distributed on the electrode area, the value of conductivity of the PbO layer (σ) calculated from

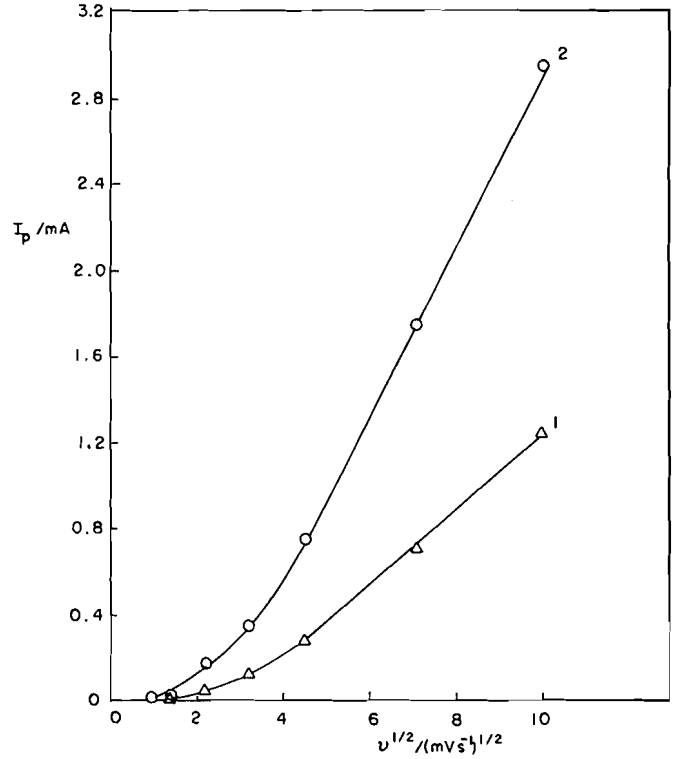

FIG. 6. Plot of the PbO peak current vs. $v^{1/2}$ after passivation for 10 (*1*) and 20 (*2*) min.

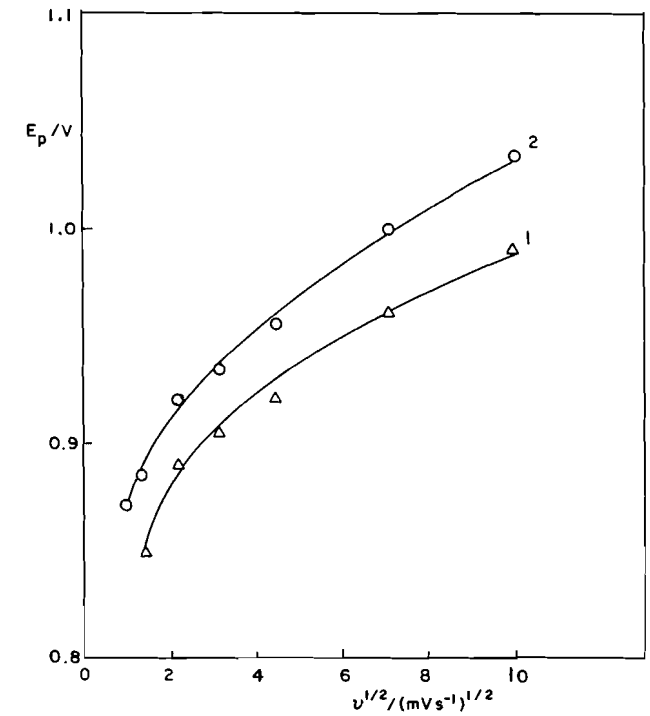

FIG. 7. Plot of the PbO peak potential vs. $v^{1/2}$ after passivation for 10 (*1*) and 20 (*2*) min.

$$[4] \quad \sigma = \frac{M_{PbO}Q}{2Fd_{PbO}A^2}\frac{1}{R}$$

(M_{PbO} = 223; F = 96 500; d_{PbO} = 9.5 g cm^{-3} (13); A = 0.04 cm^2) is equal to 0.3 × 10^{-8} Ω^{-1} cm^{-1}.

Recently, Peter's admittance measurements have estimated

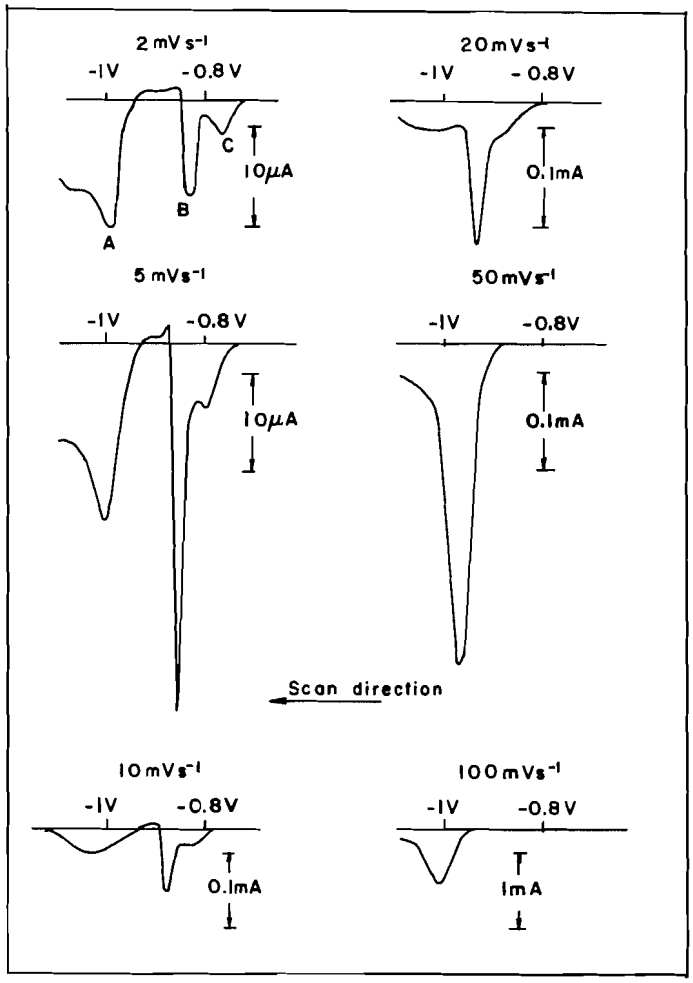

FIG. 8. Cathodic LSV at different scan rates after passivation for 20 min at 0.6 V and −20°C.

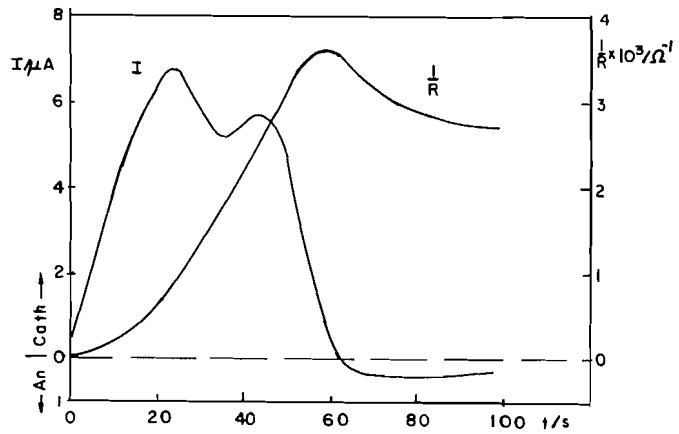

FIG. 9. Current (*I*) and admittance ($1/R$) transients for the potential step to −0.85 V after passivation at 0.6 V and −20°C for 20 min.

the conductivity of a reduced α-PbO_2 film, formed and reduced in aqueous sodium tetraborate, to be lower than 10^{-7} Ω^{-1} cm^{-1} (14).

Using direct current measurements, Laws (15) obtained the value of resistance of ca. 60 kΩ at 20°C for a PbO layer of area 3.1 cm^2 and of thickness 9.6 μm formed by anodic oxidation of lead in H_2SO_4, then removed from the solution and dried. Calculations from Laws' data give the value of conductivity σ

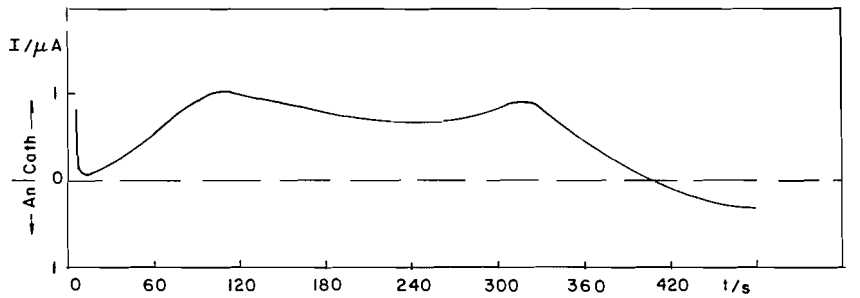

FIG. 10. Current transient for the potential step to −0.75 V after passivation at 0.6 V and −11°C.

of ca. $0.5 \times 10^{-8}\ \Omega^{-1}\ cm^{-1}$, which is close to the σ value found in the present investigation. It suggests that the ohmic resistance of the PbO layer is the major component of the impedance measured.

The conductance transient (Fig. 4, curve $1/R$ vs. t) shows a maximum, which corresponds with the region on the current transient where current changes from cathodic to anodic. This is probably associated with the anodic excursion designated as point D on the LSV (Fig. 1) which represents an oxidation of Pb to $PbSO_4$. The passive layer conductance decreases accordingly to this process. The ascending branches of both I and $1/R$ transients have similar character (although they are not parallel).

In the process of reduction the conductance has increased ca. 120 times, while the current has increased only ca. 7 times, thus one can infer that the conductance is a function of the current, but not vice versa. The current is determined by a process other than changes in the layer resistance and most likely by the process of electrocrystallisation of metallic lead as described in section (*b*).

(d) Low temperature effects

Figure 8 shows cathodic LSV produced at different scan rates after passivation for 20 min at −20°C. The LSV are in general similar to those after passivation at 22°C. However, the cathodic peak C at −0.75 V which at 22°C was observed as a very small one only at a scan rate of 1 mV s^{-1}, has become quite distinctive at −20°C and is observed at scan rates up to 5 mV s^{-1}, as a peak and up to 20 mV s^{-1} as a shoulder.

A similar observation was detected in experiments at −11°C.

The dependences I_p and E_p vs. $\nu^{1/2}$ for the PbO peak are comparable to the ones for 22°C (Figs. 6 and 7).

Figure 9 presents direct current and in-phase component of the electrode admittance transients for the potential step from 0.6 to −0.85 V, i.e. to the potential corresponding to the peak B on the LSV (Fig. 8). The current transient reveals two peaks, which corresponds with two cathodic peaks on the LSV. The shape of the conductance transient does not show the appearance of the second peak.

A splitting of the PbO peak, especially at low temperatures, was obtained on cyclic voltammograms by Chang *et al.* (4). These authors found the splitting to be more pronounced with an increase of the potential shift in a positive direction into the PbO_2 region. A probable explanation for the split peak may be a reduction of two different basic divalent lead formed beneath $PbSO_4$ due to an alkalinity gradient within the film.

The two forms may be related to PbO and some form of basic lead sulphate or to orthorhombic and tetragonal polymorphs of PbO. Bullock *et al.* (16) have recently shown, using microprobe laser Raman spectroscopy, that both orthorhombic and tetragonal form of PbO may be simultaneously present in the passive layer on lead. Figure 10 presents a current transient for the potential step from 0.6 V to −0.75 V, i.e. to the potential corresponding to the peak C on the LSV (Fig. 8). The transient shows two peaks in this case also. It ean conceivably be that both peaks may be related to the same material.

Introduction

The chemistry of indium in the +II oxidation state has been the subject of a number of recent studies. The dihalides are now known to be mixed oxidation state ionic dimers (1), but both the anionic complexes $In_2X_6^{2-}$ (X = Cl, Br, I) (2) and the adducts of In_2X_4 (3, 4) have been formulated as genuine compounds of indium(II), all involving indium–indium bonds. The general trend here is very similar to that of gallium(II), for which X-ray studies have demonstrated the presence of Ga—Ga bonding in $Ga_2X_6^{2-}$ anions (5, 6), and in the 1,4-dioxane and pyridine adducts of Ga_2Br_4 (7, 8).

We now report the crystal structure of the compound $In_2Br_3I.2tmen$ (tmen = *N*,*N*,*N*′,*N*′-tetramethylethanediamine) prepared by the low temperature reaction of InI and $InBr_3$ in toluene/tmen mixtures (9). The structural determination confirms the presence of the postulated indium–indium bond. In addition to the parameters of the I(Br)InInBr$_2$ moiety, there are some features of interest in the structure of the ligand, and these are compared with previous results in the literature.

Experimental section

A small prismatic yellow crystal of $In_2Br_3I.2tmen$ (see Table 1 for dimensions and other relevant data) was sealed in a capillary and mounted on a Syntex P2$_1$ diffractometer for X-ray data collection. The crystals decompose slowly on exposure to the atmosphere. Details of the data collection procedures have been given previously (10, 11). During the data collection, the intensity of three monitor reflections decreased by approximately 3.5%, and an appropriate scaling factor was used to correct for this. We observed a rapid decrease in intensities beyond 2θ = 30°, ascribed to disorder (see below) and to the high thermal motion of the carbon atoms. Most of the reflections beyond 2θ = 30° were rejected on the basis of peak profile test during data reduction, and were accordingly not used in subsequent calculations, resulting in only 44% of the measured reflections being given "observed" status (see Table 1). The data were further corrected for Lorentz and polarization effects, and analytical absorption corrections were applied. The systematic absences ($0kl$, $k = 2n + 1$; $h0l$, $l = 2n + 1$, and $hk0$, $h = 2n + 1$) indicated the space group *Pbca*.

The positions of the indium atoms were obtained from a sharpened Patterson synthesis, which showed evidence of I/Br disorder, since the In—I and I—I vectors did not have the expected height. In addition, the magnitude of the In—X vectors was approximately equal, suggesting disorder at all four halogen sites. A similar situation was observed earlier (12) in the structures of the $InBrCl_3^-$ and $InBr_3Cl^-$ anions, and there, as here, the model on which the refinement was based assumed that each halide ligand could be treated as 75% Br + 25% I. Subsequent refinement of the data justified this assumption.

The positions of the remaining non-hydrogen atoms were obtained from subsequent difference Fourier synthesis based on the coordinates of the two indium atoms. The structure was then refined by full-matrix least-squares methods, with all the non-hydrogen atoms being treated anisotropically. This refinement converged at R = 0.0467 and R_w = 0.0523, at which stage some peaks appeared in the difference map at plausible hydrogen atom locations. All hydrogen atoms were subsequently included in idealized positions (C—H = 0.95 Å), with the thermal parameters being assigned the same values as those of the appropriate bonded carbon atoms. After six more cycles of refinement, convergence was achieved with the final R = 0.0409 and the final R_w = 0.0433 for 1527 unique "observed" ($I > 2\sigma(I)$) reflections. The final difference map showed no features of any chemical significance, with the largest peak being 0.8 e Å^{-3}, and close to the halide species X (2). In the final cycle of refinement, the largest shift:error ratio was 0.1. The computer programmes and scattering factor tables used were those given previously (11).

Positional and thermal parameters are given in Table 2 and interatomic distances and bond angles in Table 3. Figure 1 shows the molecule, with the atomic numbering scheme, and Fig. 2 gives the cell packing; hydrogen atoms are excluded from these figures for the sake of clarity.

Tables of structure factors, anisotropic thermal parameters, and hydrogen atom coordinates are available as supplementary data.[2]

Results and discussion

The results show that the structure of $In_2Br_3I.2tmen$ consists of discrete molecules, with no significant intermolecular interactions. Each indium atom is coordinated by two halogen atoms and a bidentate tmen ligand.

Perhaps the most interesting feature of the molecule is the indium–indium bond, of length 2.775(2) Å. There have been

[a] $\bar{U}_{eq}$ is calculated from the refined anisotropic thermal parameters (supplementary material) ($U_{eq} = (1/3)\Sigma_{i=1}^{3}(\text{rmsd})_i^2$, with rmsd values taken from ORTEP output).
[b] X = 75% Br, 25% I.

no previous structural results on this bond, but relevant values are available for the solids In_6S_7 and In_6Se_7, in which short In—In distances of 2.741(2) Å and 2.760(5) Å have been found (13, 14), suggesting the presence of In_2^{4+} cations. Further evidence of indium–indium bonding was found in the solids In_4Se_3 and In_4Te_3 (15), whose structures show the presence of the catenated species [In—In—In]$^{5+}$, with In—In distances averaging 2.78 Å. These values agree well with the In—In distance reported in the present work. In the complex lattice of the mixed oxide $In_6La_{10}O_6S_{17}$, pairs of indium atoms are found to be 2.863(4) Å apart (16), implying a somewhat weaker bond than in the previous cases. Comparison with the Sn—Sn distance of 2.770(4) Å found from the X-ray study of hexaphenyldistannane (17) demonstrates the similarities in the M—M bonding properties of indium and tin. Finally we note that the distance of 2.775 Å yields a covalent radius of 1.39 Å for the indium atom. The values reported previously (12, 18) for r(In—Cl), r(In—Br), and r(In—I), when combined with standard values for the covalent radii of the halogen atoms, give r(In) = 1.36(2) Å, in reasonable agreement with the above result, although it should be emphasised that In—X bonds are not in practice purely covalent (19).

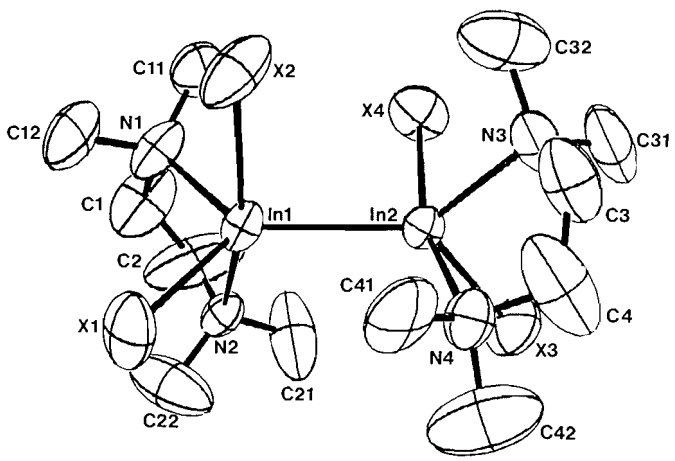

FIG. 1. The molecular structure of $In_2Br_3I.2tmen$ (X = 75% Br, 25% I).

It is unfortunate that the disorder problem (see Experimental section) prevented the measurement of the individual In—Br and In—I bond distances, so that we cannot compare the lengths of these bonds as they appear in In(III) and In(II) complexes. One significant feature is the difference between the equatorial and axial indium–halogen bonds, with the axial bonds 0.185 Å longer than those in the equatorial plane (see below for a discussion of the indium stereochemistry). A similar effect is found in the In—N bonds, with the (average) In—N distances 2.48(2) and 2.33(2) Å in the axial and equatorial positions, respectively. Previously reported values for In—N are 2.276(4) and 2.299(4) Å in $InCl_2$(acac)(bpy) (acac = 2,3-pentanedionate, bpy = 2,2′-bipyridine) (20); 2.238(3), 2.268(3), and 2.228(3) Å in $InCl_3$.terpy (terpy = 2,2′,2″-terpyridine (21); 2.442(3) and 2.482(2) Å in bis{2-[(dimethylamino)methyl]phenyl}chloroindium(III) (10); 2.250(5) and 2.300(6) Å in dichloro(benzoato)bispyridineindium(III) (11); 2.32(3), 2.31(2), and 2.28(3) Å in $InBr_3$.3py (py = pyridine)

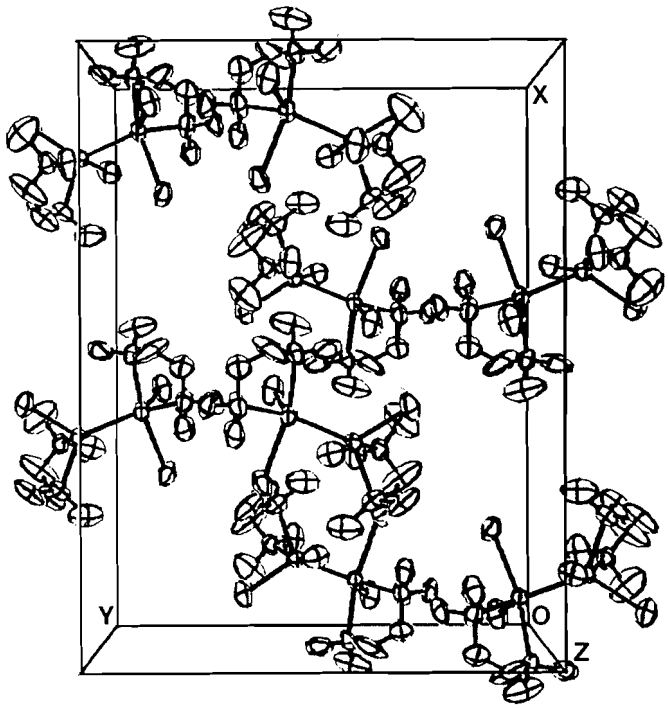

FIG. 2. The unit cell packing for $In_2Br_3I.2tmen$.

(22); and 2.271(16) and 2.288(15) Å in the oximate complex $[(CH_3)_2In(ON{=}CHC_5H_4N)]_2$ (23). With the exception of the six-coordinate $InCl_2$ (acac) (bpy) and $InCl_3.3py$, these compounds all involve indium(III) in a (distorted) trigonal–bipyramidal coordination kernel. The range of In—N bond distances in this group of five-coordinate compounds is 2.48–2.23 Å (ave. 2.31 Å), and the present results are clearly compatible with this range of values despite the different oxidation state involved.

The coordination at each indium atom is distorted trigonal bipyramidal, with an $In(In'N_2X_2)$ kernel. The equatorial plane of this kernel contains In(1), In(2), X(1), and N(1), with the In(1) atom lying 0.0537 Å off the least-squares plane and pointing towards the axial X(2) atom (see Table 4 for least-squares planes). In the second moiety the equatorial plane consists of In(2), In(1), X(3), and N(3), with In(2) 0.0463 Å off this plane and again towards the axial halogen substituent X(4). The geometrical relationship between these two moieties, shown in Fig. 1, places these two planes almost perpendicular to one another, a situation which presumably minimises the interactions between ligands on the different indium atoms. Not surprisingly, the observed angles in the $In(In'N_2X_2)$ kernel show considerable distortion from the ideal values for trigonal bipyramidal stereochemistry. No doubt both ligand–ligand interactions, and the constraint imposed by the bidentate tmen ligand, contribute to these distortions.

The geometry of the tmen ligand

The results in Table 2 show that the C—C and $C—N_{tet}$ bond distances in the coordinated tmen ligand are considerably shorter than the normal average values of 1.537(5) and 1.479(5) Å recommended for such bonds (24). The first reservation to be made is that the accuracy of these values is rather low, since most of the X-ray scattering is by the heavy indium and halogen atoms in the molecule. Such short bonds are not however unique. Maslen and Waters (25) reviewed this and related matters in 1975, and pointed out the considerable number of structures then known for which the same situation applies. A number of reports since that time have confirmed that tmen complexes show such results (e.g. the copper complexes: $[Cu(tmen)Cl_2]_2$ (26), $Cu(NO_3)_2.tmen$ (27), $Cu(ClH_2CO_2)_2.tmen$ (28), $[Cu(tmen)SO_4(H_2O)_2].H_2O_2$ (29), and the sodium complex (30) $C_5H_5Na.tmen$), but without identifying the underlying reasons. Maslen and Waters (25) conclude that such results are not due to disorder, are not due to enhanced thermal motion, and cannot be explained away as artefacts. The present results show that the phenomenon is in no way confined to transition metal complexes, but do nothing to aid in understanding the phenomenon.

Comparison with earlier work

In a previous paper (3), the vibrational spectra of $In_2Br_4.2tmen$, $In_2I_4.2tmen$, and the analogous benzene solvates, were interpreted in terms of a centrosymmetric In_2X_4 unit with coordinated bidentate tmen ligands. The only feature of this analysis which is not confirmed by the present crystallographic work concerns the In_2X_4 kernel, which is clearly not centro-symmetric. For example, the X(2)—In(1)—In(2) angle of 92.0(1)° is substantially smaller than that at In(1)—In(2)—X(3) (128.1(1)°). There seems to be no obvious rationalisation of these earlier conclusions in terms of the present results.

Received September 9, 1983

PAVEL HOBZA and CAMILLE SANDORFY. Can. J. Chem. **62**, 606 (1984).

The equilibrium for a water dimer (modelling an O—H···O hydrogen bond in a biomolecule) interacting with CH_4, CH_3Cl, CH_2Cl_2, $CHCl_3$, or CCl_4 is examined by quantum chemical and statistical thermodynamic means. It is shown that the presence of an acidic hydrogen in the molecule as well as its relatively high polarizability are the necessary conditions for anesthetic activity.

PAVEL HOBZA et CAMILLE SANDORFY. Can. J. Chem. **62**, 606 (1984).

Nous avons examiné, par les méthodes de la chimie quantique et de la thermodynamique statistique, l'interaction entre CH_4, CH_3Cl, CH_2Cl_2, $CHCl_3$ ou CCl_4 et la liaison hydrogène dans un dimère de la molécule d'eau. Les résultats montrent que la présence d'un hydrogène "acide" et une polarisabilité relativement élevée sont des conditions nécessaires pour qu'une molécule ait un pouvoir anesthésique appréciable.

Introduction

According to our present knowledge, anesthesia is due to temporary changes in molecular associations which insure the right structure of macromolecules (lipids and proteins) at the membrane of the nerve cell (see refs. 1, 2 for reviews). The effect of anesthetics on the ion channels and the permeability of the membrane are of particular interest (3, 4). Infrared spectroscopic studies led us to suggest that both polar and non-polar interactions are involved in the mechanisms of anesthesia. While non-polar or hydrophobic interactions can provide weak anesthetic action, potent anesthetics induce changes in polar interactions, among them associations by hydrogen bonds (H-bonds), in or around the macromolecules (5–8).

In two theoretical papers (9, 10) we investigated the perturbation of O—H···:O and N—H···:O=C< type H-bonds by a strong anesthetic, $CHCl_3$, and by CHF_3 which does not possess anesthetic potency. In conformity with this, our calculations have shown that the Gibbs free energy actually favors the "breaking" of the H-bonds and association with chloroform but not with fluoroform. The ΔG^0 in question is related to equilibria of the type

$$[1]\quad HOH\cdots OH_2 + A \overset{K_T}{\rightleftharpoons} H_2O\cdots A + H_2O$$

where A (anesthetic) is chloroform or fluoroform in our case and

$$[2]\quad \Delta G_T^0 = -RT \ln K_T$$

Conditions favoring the right hand side in [1] were found to be: (*a*) favorable changes in polar interactions in the Hartree–Fock energy, (*b*) dispersion interactions, and (*c*) favorable (i.e. relatively small) changes in interaction entropy. It was not easy, however, to sort out the various contributions by comparing two widely different systems like $CHCl_3$ and CHF_3. Therefore we decided to study the effect of the series of molecules CH_4, CH_3Cl, CH_2Cl_2, $CHCl_3$, and CCl_4 on the H-bond in the water dimer.

To a first approximation, the equilibrium constant in [1] and the change in free energy are determined by the properties of the complexes on the left and right hand sides of eq. [1]. If ΔG_T^0 of $H_2O\cdots A$ is more negative than that of $(H_2O)_2$, then A is able to break a part of the H-bonds. ΔG_T^0 is determined as the difference of an enthalpy and an entropy term:

$$[3]\quad \Delta G_T^0 = \Delta H_T^0 - T\Delta S_T^0$$

Essentially, the enthalpy term is determined by the change in internal energy, ΔE. If the change in entropy is small then the equilibrium is determined by the ΔE balance of the two complexes.

Computations

The 4-31G basis set (11) was used in all the calculations. The SCF interaction energy (ΔE^{SCF}) was determined as the difference between the energies of the geometry optimized complex and its geometry optimized subsystems. The basis set superposition error (BSSE) was evaluated at the potential energy minimum. The dispersion energy (E^D) was calculated by using the atom–atom formula:

$$[4]\quad E^D = -\sum_i \sum_j c_{ij}\, r^{-6}$$

where the summations are extended to all atoms of both molecules. The coefficients C_{ij} for H, C, O, and Cl were determined from C_6 terms of the $(H_2O)_2$ and $CCl_3H\cdots OH_2$ complexes which, in turn were evaluated by using the non-empirical Unsöld approximation (12–14). It is clear from the definition of the dispersion energy that this represents the lower limit of the actual value. (Contributions of terms of higher order to the dispersion energy are rather important.) The procedure has been described in detail in our previous publications (9, 10) as well as the standard procedure used for the calculation of the thermodynamic characteristics of the equilibria (15).

Results and discussion

Geometry

The geometries of all subsystems, optimized on the 4-31G level, are given in Fig. 1. The structures and coordinates of the

complexes investigated are shown in Fig. 2. The six intermolecular coordinates and the C—H intramolecular coordinate were optimized; the remaining intramolecular coordinates were kept fixed during optimization and were taken from the subsystems. The optimized bond lengths and angles are collected in Table 1. It appears from Fig. 2 and Table 1 that the H-bonds in the $CClH_3 \cdots OH_2$ complex are surprisingly non-linear. The non-linearity amounts to 29.7°; hence the complex can be char-

$CCl_3H\cdots OH_2$	29.29[a]	4.10[a]	8.69	33.88
$CCl_4\cdots OH_2$	6.90	3.06	0.75	4.59

[a] Taken from ref. 9.

acterized as cyclic. The non-linearity of the H-bonds in $CCl_2H_2\cdots OH_2$ is much smaller and amounts to only 2.6°. The C—H...O bonds in $CH_4\cdots OH_2$ and $CCl_3H\cdots OH_2$ are linear. Investigating the intermolecular distances we find rather dramatic differences between the $CH_4\cdots OH_2$ and $CClH_3\cdots OH_2$ complexes, whereas further halogenation (until CCl_3H) leads only to a small decrease of R. Formation of a H-bond is characterized by a lengthening of the X-H bond; from Table 1 and Fig. 1 it is evident that only with $CCl_2H_2\cdots OH_2$ and $CCl_3H\cdots OH_2$ complexes does some lengthening of the C—H bond occur (by 0.2 and 0.3 pm).

Interaction energy

The energy characteristics are collected in Table 2. Here again the difference in ΔE^{SCF} between $CH_4\cdots OH_2$ and $CClH_3\cdots OH_2$ is much greater than that between the remaining complexes (except for $CCl_4\cdots OH_2$). Furthermore, the importance of the presence of an "acidic" hydrogen in the "anesthetic" molecule is clearly demonstrated. From the values of the 4-31G electronic charge at the hydrogen it appears that halogenation of CH_4 increases the charge rather dramatically (from 0.20 in CH_4 to 0.28, 0.35, and 0.43 in $CClH_3$, CCl_2H_2, and CCl_3H respectively).

The BSSE is almost constant for all complexes, i.e. it does not depend on the ΔE value. The constancy of the BSSE comes from the fact that with all the complexes the lowering of the energy of H_2O by the "ghost" functions of CCl_mH_n is much more important than the lowering of the energy of CCl_mH_n by the "ghost" functions of H_2O.

The dispersion energy increases upon halogenation from $CH_4\cdots OH_2$ to $CCl_3H\cdots OH_2$. The very small value of E^D with $CCl_4\cdots OH_2$ is not surprising in light of the very large intermolecular distance of the complex. It is necessary to point out here that optimizing the total interaction energy of the complex (instead of ΔE^{SCF} only) does not change either the intermolecular distance, or ΔE. From Table 2 it is further evident that compensation of BSSE and E^D is not fulfilled every time.

The values of the total interaction energy presented in Table 2 should be compared with that of $HOH\cdots OH_2$, which amounts (9) to −33.9 kJ/mol. Without the entropy term only the chloroform . . . water complex is of comparable strength to the water . . . water complex. It means that only chloroform is able to perturb the hydrogen bond in the water dimer.

Analyzing the ability of CCl_mH_n systems to break the hydrogen bonds in the water dimer, we can state: (*i*) the presence of an "acidic" hydrogen is indispensable; (*ii*) halogenation plays a favorable role in making the hydrogen more acidic as well as in increasing the polarizability of the molecule (what makes E^D of the complex more negative). The $CCl_4\cdots OH_2$ complex clearly demonstrates the high polarizability of a molecule is not enough for giving it anesthetic potency. On the other hand, the mere presence of hydrogens in a molecule is not sufficient to render it anesthetic either (e.g. CH_3Cl).

The above conclusions are based on energy characteristics only. Calculation of the ΔG term is, owing to the need to evaluate entropy (and especially of its vibrational contribution), tedious. We have shown previously (16) that the sum of vibrational frequency dependent terms (zero point energy, vibrational contribution to the entropy, and temperature dependence of enthalpy) of a H-bonded complex can be estimated on the basis of its interaction energy. Adding the rotational and translational contributions to the entropy (their evaluation is straightforward), if atomic masses and geometry of all the systems are known) we obtain an estimate of ΔG_{298} (for the quality of this estimate see ref. 16). The estimated $\Delta\Delta G_{298}$ for equilibrium [1] for A = CH_3Cl and CH_2Cl_2, respectively, amount to 13.7 and 14.1 kJ/mol. $\Delta\Delta G_{298}$ for the same equilibrium for A = $CHCl_3$, calculated previously (5), equals 2.2 kJ/mol; this value indicates that approximatively 40% of the H-bonds in the $H_2O\cdots H_2O$ are broken. The values of $\Delta\Delta G_{298}$ clearly demonstrate that CH_3Cl as well as CH_2Cl_2 are far from being able to perturb the H-bonds in the water dimer.

Conclusions

On the basis of the above analysis we can try to "design" a general anesthetic: (*i*) it must contain an "acidic" hydrogen; (*ii*) polarizability of the molecule must be large; (*iii*) polar interactions of the anesthetic molecule with a part of the target (which plays a crucial role) can be magnified if more interaction sites (both proton donor and proton acceptor) are present in the molecule simultaneously. All these conditions conform to empirical knowledge and the spectroscopic evidence related to anesthetics (5–8, 17–20).

While only one target H-bond was used in this study, the O—H...:O bond is of the strength typical of many biologically important H-bonds; it is actually stronger than the most

For personal use only.

important N—H...:O=C$\langle$ bond. The results described in this paper give additional weight to the suggestion that molecular associations of both the polar (H-bonding) and non-polar types are important for the mechanism of anesthesia.

The successful synthesis and chlorinolysis of α-mercaptodimethyl sulfone have provided additional support for our contention that Pummerer rearrangements may occur during the chlorinolyses of α-sulfonyl sulfinyl chlorides. Further exploration of chlorinolyses of α-sulfonyl systems has uncovered the first observations of CS bond cleavage during the chlorinolyses of (*i*) a sulfinyl chloride and (*ii*) a sulfinate ester.

TERENCE PATRICK AHERN, MICHAEL FRANCIS HALEY, RICHARD FRANCIS LANGLER et JUNE ELLEN TRENHOLM. Can. J. Chem. **62**, 610 (1984).

Le fait que des α-mercaptodiméthylsulfones aient pu être chlorolysées fournit une preuve additionnelle à notre suggestion que des transpositions de Pummerer peuvent se produire lors de la chlorolyse de chlorures d'α-sulfonylsulfinyles. Une étude plus poussée de chlorolyses de systèmes α-sulfonyles a permis de mettre en évidence les premières observations de rupture de liaisons C—S au cours de chlorolyses (*i*) d'un chlorure de sulfinyle et (*ii*) d'un ester sulfinate.

Introduction

Some time ago (1), we reported the results of a study on the chlorinolysis of the sulfone-sulfide **1** as shown in eq. [1].

[1] $PhCH_2SCH_2SO_2CH_3 \xrightarrow[HOAc]{Cl_2/H_2O} CH_3SO_2CCl_2SO_2Cl + PhCH_2Cl$

1 **2**

Our proposal for the pathway of this reaction involved the intermediacy of the sulfenyl chloride **3***a* and the sulfinyl chloride **3***b*.

$CH_3 \cdot SO_2 \cdot CH_2 \cdot S \cdot Cl$ **3***a*

$CH_3 \cdot SO_2 \cdot CHCl \cdot SO \cdot Cl$ **3***b*

$CH_3 \cdot SO_2 \cdot CH_2 \cdot S \cdot S \cdot Ph$ **3***c*

$CH_3 \cdot SO_2 \cdot CH_2 \cdot S\ H$ **3***d*

$CH_3 \cdot S \cdot CH_2 \cdot S\ H$ **3***e*

$CH_3 \cdot SO_2 \cdot CCl_2 \cdot S \cdot O\ CH_3$ **3***f*

Subsequently, we have undertaken the synthesis of a variety of potential intermediates and intermediate precursors which resulted in the successful preparation of **3***c* (2). Chlorinolysis of **3***c*, as we have pointed out (2), is very likely to produce **3***a* and does furnish the sulfone-sulfonyl chloride **2** as we had hoped.

We wished to pursue this problem further in the hope that we could establish the intervention of an unprecedented process in the chlorinolysis of sulfinyl chlorides, viz. facile Pummerer rearrangement of a dichlorooxosulfonium cation (3*a*).

Results and discussion

Our initial efforts were focused on the preparation of the mercaptosulfone **3***d*. One of the earlier attempts is shown in eq. [2].

[2] $CH_3SCH_2Cl + AcSH \xrightarrow{Pyridine} CH_3SCH_2SAc \xrightarrow{m\text{-CPBA}} CH_3SO_2CH_2SAc$

Attempts to deacetylate the sulfone-thiolacetate with $H_2O/^-OH$, $LiAlH_4$, or $NaBH_4$ furnished complex mixtures and were abandoned. The successful conversion of the sulfide-thiolacetate into the corresponding sulfone-thiolacetate suggests that acetyl groups may have use in protecting mercaptans when peroxidic oxidation of substrates is intended to alter other functional groups.

The successful synthesis of **3***d* was accomplished as shown in Eq. [3].

[3] $CH_3SO_2CH_2SSPh + PhSH \xrightarrow[CH_2Cl_2]{Pyridine} CH_3SO_2CH_2SH + (PhS)_2$

3*c* **3***d*

The mercaptosulfone **3***d* appears to be the first known α-mercaptosulfone. As expected on the basis of the properties of the corresponding α-mercaptosulfide **3***e* (4), the oily mercaptosulfone **3***d* decomposed at room temperature depositing crystalline material which was insoluble in all common organic solvents ($t_{1/2}$ = 6 days). We presume that the crystalline material was polymeric thioformaldehyde.

Aqueous chlorinolysis of freshly prepared **3***d* produced the sulfone-sulfonyl chloride **2** in a reaction which must involve the sulfone-sulfenyl chloride **3***a* as shown in eq. [4].

[4] $CH_3SO_2CH_2SH \xrightarrow[HOAc]{Cl_2/H_2O} [CH_3SO_2CH_2SCl] \rightarrow CH_3SO_2CCl_2SO_2Cl$

3*d* **3***a* **2**

While the results shown in eq. [4] prove our contention that **3***a* would be transformed into **2** under the reaction conditions employed for the reaction shown in eq. [1], thus confirming **3***a* as a possible intermediate for that reaction, further examination of the pathway followed by **3***a* in this reaction would require the preparation and chlorinolysis ("in an anhydrous medium" (2)) of other potential intermediates (e.g. the sulfone-sulfinyl chloride **3***b*).

Early synthetic efforts aimed at **3***c* were unsuccessful until we adopted an approach which accomplished skeletal modification using a chlorinolysis step followed by a dechlorination step carried out on the appropriate ester. Consequently, we began our efforts to produce the possible sulfone-sulfinyl chlo-

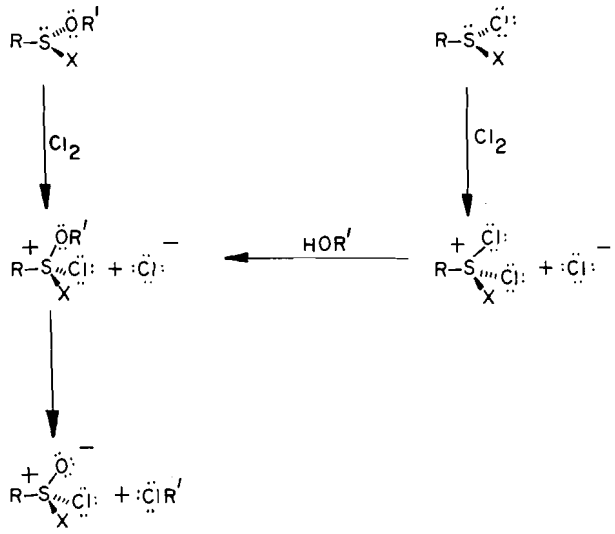
[2]Revision received September 23, 1983.



SCHEME 1

ride intermediates for the reaction in eq. [1] by preparing the sulfone-sulfinate ester **5** as shown in eq. [5].

$$[5]\quad \underset{\textbf{3}f}{CH_3SO_2CCl_2\cdot S\cdot OCH_3} \xrightarrow[CH_2Cl_2]{Cl_2} \underset{\textbf{4}}{CH_3SO_2CCl_2\cdot SO\cdot Cl} \xrightarrow{CH_3OH} \underset{\textbf{5}}{CH_3SO_2CCl_2\cdot SO\cdot OCH_3}$$

In addition to the spectroscopic evidence obtained for the structure of **4**, we have subjected it to hydrolysis which was accompanied by desulfinylation as shown in eq. [6].

$$[6]\quad \underset{\textbf{4}}{CH_3SO_2CCl_2\cdot SO\cdot Cl} + H_2O \rightarrow \underset{\textbf{6}}{CH_3SO_2CHCl_2}$$

This behaviour parallels that observed for the hydrolysis of **2** (1) and is entirely consistent with the intermediacy of a sulfinic acid which has anion stabilizing groups on C(1) (5).

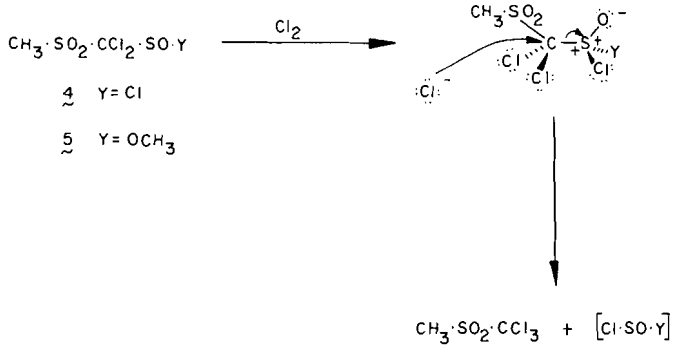
While the chlorinolysis of sulfenate esters (*vide* eq. [5]) is precedented (6, 7), previous groups were unable to isolate the expected sulfinyl chlorides. Our conversion of **3***f* to **4** appears to be the first report of the successful isolation of a sulfinyl chloride from a sulfenate ester chlorinolysis. Chlorinolysis of a sulfenate ester produces an O-alkylated oxochlorosulfonium cation. Douglass and Poole (8) have produced O-alkylated oxochlorosulfonium cations by the alcoholysis of dichlorosulfonium cations. The two approaches for generating O-alkylated oxochlorosulfonium cations are depicted in Scheme 1 (X = :).

O-Alkylated dioxochlorosulfonium cations may be produced in similar manner (see Scheme 1; X = O). The usual fate of O-alkylated dioxochlorosulfonium cations involves nucleophilic attack at carbon with resultant CO bond cleavage (3*b*).

$$[7]\quad PhCH_2CH_2\cdot SO\cdot OCH_3 \xrightarrow[CH_2Cl_2]{Cl_2} PhCH_2CH_2SO_2Cl + [CH_3Cl]$$

Expecting to obtain the sulfonyl chloride **2**, we have chlorinated the sulfinate ester **5** in order to obtain some simple chemical support for the structure of **5**. The unexpected observation of CS bond cleavage in the chlorinolysis of **5** prompted us to chlorinate the sulfinyl chloride **4** which furnished a similar result, as shown in Scheme 2.

CS bond cleavage is a well-known process in the chlorinolysis of sulfoxides (3). α-Polychlorosulfoxides are particularly prone to undergo CS bond rupture pursuant to oxochlorosulfonium cation formation. Nucleophilic attack on the oxochlorosulfonium cation at the α-carbon bearing chlorine is usually the exclusive process. It is clear, however, that severe steric hindrance at the α-carbon bearing chlorine can shift some nucleophilic attack to the α′-carbon (9). A reasonably close sulfoxide relative of **4** has been shown to furnish 1,1,1-trichloro-2-thiapropane-2,2-dioxide in good yield (9) (see Scheme 3, pathway b).



SCHEME 2

In view of the results available from sulfoxide chlorinolyses, the rupture of a CS bond during the chlorinolysis of **4**, while unprecedented, is not surprising. However, the results from the chlorinolysis of the sulfone-sulfinate ester **5** are remarkable indeed. Not only is the methyl group attached to oxygen (the usual electrophilic site in an O-alkylated dioxochlorosulfonium cation) much less crowded, but it bears a superior leaving group, viz. **2** as opposed to the $Cl\cdot SO\cdot OCH_3$ attached to the alternative electrophilic carbon. There can be no question that the trichlorosulfone is an authentic chlorinolysis product since (*i*) both hydrolysis and alcoholysis of the sulfinate ester **5** furnish the dichlorosulfone **6**, (*ii*) hydrolysis of the sulfonyl chloride **2** furnishes **6**, and (*iii*) one- to two-hour chlorinolysis of simple sulfones like **6** affords unchanged starting material (10).

We were unaware of any examination of possible reactions between sulfinyl chlorides and molecular chlorine and were thus unable to judge whether the CS bond cleavage observed during the chlorinolysis of the sulfinyl chloride **4** was a typical or unusual result. Consequently, we have prepared a series of simple sulfinyl chlorides 7*a* → 7*c* and subjected them to chlorinolysis in aprotic media.

$$\begin{array}{ll} & R\cdot SO\cdot Cl \\ 7a & R = ClCH_2— \\ 7b & R = CH_3— \\ 7c & R = PhCH_2CH_2— \end{array}$$

The chlorinolysis of chloromethanesulfinyl chloride[3] 7*a* in methylene chloride produced unchanged sulfinyl chloride quantitatively. A second run conducted in carbon tetrachloride showed no methylene chloride present in the product.

Chlorinolysis of methanesulfinyl chloride[3] 7*b* produced unchanged sulfinyl chloride along with a 13.5% yield of methanesulfonyl chloride, presumably arising from hydrolysis of the oxodichlorosulfonium cations by moisture present in the methylene chloride employed as solvent.

[3] Both chloromethansulfinyl chloride 7*a* and methanesulfinyl chloride 7*b* were produced free of the corresponding sulfonyl chlorides using our previously published method (11).

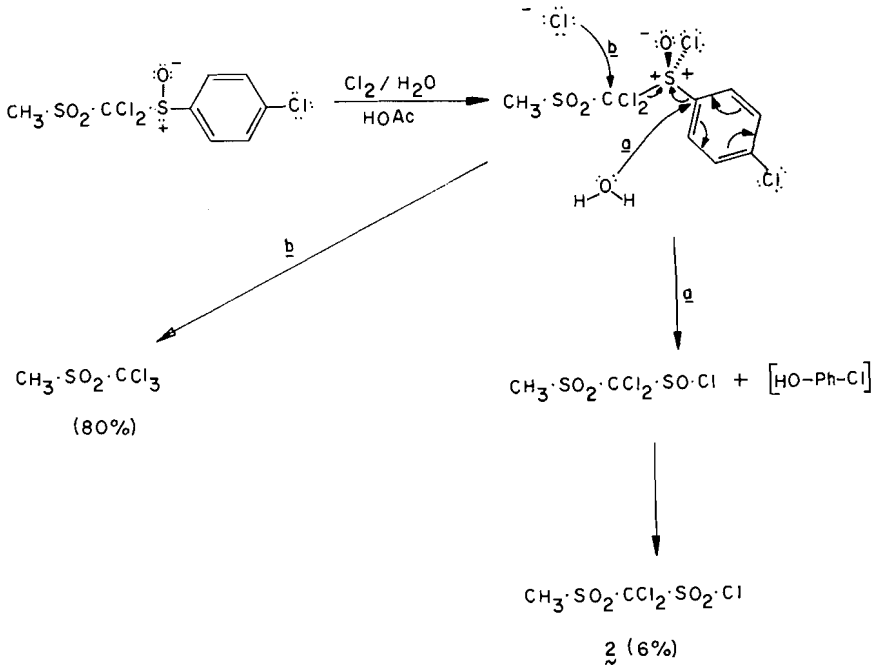


SCHEME 3

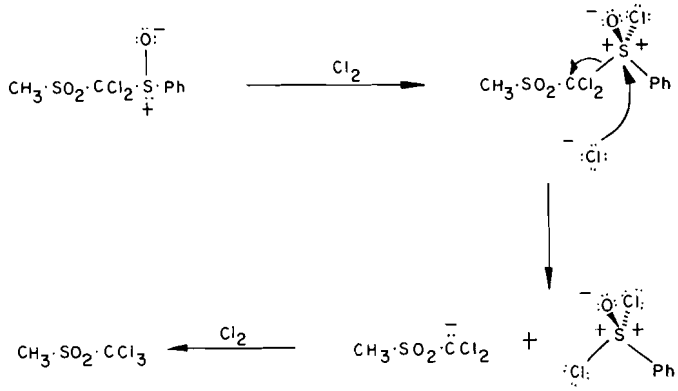
The phenethyl sulfinyl chloride 7*c* employed in our study was prepared by chlorinolysis of phenethyl thiolacetate following the procedure of Kee and Douglass (12). Hydrolysis of a sample of 7*c* prepared in this way showed it to contain ca. 20% phenethyl sulfonyl chloride. Chlorinolysis of phenethyl sulfinyl chloride 7*c* did not furnish any phenethyl chloride. The product was, in fact, ca. 50% 7*c* and ca. 50% phenethyl sulfonyl chloride.

These results indicate that the CS bond cleavage observed during the chlorinolysis of **4** is not a routine feature of sulfinyl chloride chlorinolyses.

Since our initial report of CS bond cleavage during the chlorinolyses of α-polychlorosulfoxides (13), we have been concerned about the probability that a nucleophile would be capable of attacking such severely hindered electrophilic carbon atoms. Our subsequent report (9) (see Scheme 2, Y = Ph) in which the substantially more crowded electrophilic carbon atoms in the sulfonium salts derived from α-sulfonyl-α-polychlorosulfoxides appeared to suffer nucleophilic attack, albeit more slowly, heightened our concern. In fact, on a number of occasions, referees of our papers have suggested an alternative mechanism for CS bond cleavage in these reactions (see Scheme 4). This mechanism would circumvent steric problems, although we have had serious reservations about the likelihood that the requisite ion pair formed in the cleavage step of Scheme 4 would actually form. In order to test this proposal we have carried out the following reaction.

$$[8]\quad CH_3SO_2CCl_2\cdot SO\cdot Ph + Cl_2|HCl \xrightarrow{CH_2Cl_2} CH_3SO_2CCl_3 + [CH_3SO_2CCl_2\cdot SO\cdot Cl] + ClPh$$

The absence of the dichlorosulfone, which would arise from proton capture by the carbanion pictured in Scheme 4, suggests that this mechanism is an unlikely one. Because the reaction pictured in eq. [8] is very slow (chlorination time 8 h), we have carried out a chlorination on 1,1-dichloro-2-thiapropane-2,2-dioxide.



SCHEME 4

$$[9]\quad CH_3SO_2CHCl_2 + Cl_2 \xrightarrow{CH_2Cl_2} CH_3SO_2CHCl_2 + CH_3SO_2CCl_3$$
$$86\% \qquad 14\%$$

The absence of dichlorosulfone in the product mixture (eq. [8]) cannot be rationalized by assuming that it was quantitatively converted to trichlorosulfone under the reaction conditions.

The results depicted in eq. [8] are of some interest. That reaction is the first example of an α-polychlorosulfoxide chlorinolysis in which attack at the α′-carbon is the major pathway. The absence of benzenesulfinyl or benzenesulfonyl chlorides in the product mixture implicates the dichlorosulfone-sulfinyl chloride as the intermediate leading to the trichlorosulfone. Despite our dissatisfaction with the Scheme 4 mechanism, the results from the chlorinolysis of the sulfinate ester **5**, in our view, require a more complex mechanism than the simple picture presented in Scheme 2. The revised mechanism would apply to the cleavage steps in the chlorinolyses of all the α-sulfonyl systems we have studied (*vide* Schemes 2 and 3). At this stage, the most reasonable modification of the cleavage step mechanism would likely involve a complexing interaction between the incoming chloride ion and the α-sulfonyl group.

Since we have recently initiated a program of theoretical calculations designed to clarify mechanistic details for the various steps of the Sulfohaloform reaction (see ref. 14, for example), we shall defer a more detailed proposal for cleavage step transition states for α-sulfonyl substituted systems until supporting calculations can be carried out.

In conclusion, we have prepared and chlorinated α-mercaptodimethyl sulfone which has established that the sulfenyl chloride **3***a* is transformed into **2** upon aqueous chlorinolysis, as we had proposed earlier (1). The role of Pummerer rearrangements in the transformations involved in the conversion **3***a* → **2** remains to be established. The chlorinolyses of both the sulfinyl chloride **4** and the sulfinate ester **5** have revealed unprecedented CS bond cleavage for these functional groups, indicating a need to revise the simple mechanism advanced previously for CS bond rupture during chlorinolysis of α-sulfonyl sulfoxides (9).

Experimental

General

Details have been provided previously (10).

Preparation of CH_3SCH_2SAc

A solution of thioacetic S-acid (0.739 g) in dry pyridine (25 mL) was cooled and chloromethyl methyl sulfide (1.002 g) in carbon tetrachloride (2 mL) was added dropwise over 3 min. The reaction mixture was stirred at ambient temperature for 1 h. Methylene chloride (100 mL) was added and the resultant solution washed with 5% HCl (100-mL aliquots) until the aqueous pH remained acidic. The organic layer was dried and concentrated and the residue distilled at reduced pressure, affording the sulfide-thiolacetate (0.544 g, bp 78–80°C/2.4 Torr); ir ($CHCl_3$): 1695 cm^{-1}; nmr ($CDCl_3$) δ: 4.13 (2H, s), 2.46 (3H, s), and 2.26 (3H, s); ms *m/e*: 136 (M^+, 35.1%), 61 (63.7%), and 43 (100%).

Preparation of $CH_3SO_2CH_2SAc$

m-Chloroperoxybenzoic acid (85%, 3.145 g) was added to a cooled solution of the sulfide-thiolacetate (1.002 g) in chloroform (30 mL). The reaction was allowed to reach ambient temperature while stirring overnight. Methylene chloride (170 mL) was added and the resultant solution washed with 1% NaOH (two 50-mL aliquots). The organic layer was dried and concentrated, affording clean sulfone-thiolacetate (1.20 g); ir ($CHCl_3$): 1720, 1320, and 1110 cm^{-1}; nmr ($CDCl_3$) δ: 4.50 (2H, s), 3.03 (3H, s), and 2.56 (3H, s); ms *m/e*: 168 (M^+, 0.9%), 89 (13.6%), and 43 (100%).

*Preparation of $CH_3SO_2CH_2SH$ 3*d

The sulfone-disulfide **3***c* (0.200 g) (2) was dissolved in a solution containing methylene chloride (10 mL), pyridine (0.1 mL), and benzenethiol (0.200 g). The reaction mixture was stirred at ambient temperature for 2 h and the solvent evaporated. The residue was chromatographed on silica gel (10 g) employing chloroform elution (5-mL fractions). Fractions 4 and 5 contained diphenyl disulfide and unreacted benzenethiol. Fractions 7–13 contained oily α-mercaptodimethyl sulfone **3***d*[4] (0.078 g) which had ir ($CHCl_3$): 2590, 1320, and 1125 cm^{-1}; nmr ($CDCl_3$) δ: 3.83 (2H, d), 3.33 (3H, s), and 2.30 (1H, t); ms *m/e*: 126 (M^+, 23.6%), 93 (24.7%), 81 (100%), and 65 (62.5%).

*Aqueous chlorinolysis of 3*d

Mercaptosulfone **3***d* (0.100 g) was dissolved in glacial acetic acid (25 mL) and water (5 mL). Cl_2 (ca. 200 mL/min) was bubbled into the reaction mixture for 0.5 h. Methylene chloride (100 mL) and water (50 mL) were added and the layers separated. The organic layer was washed with 2.5% w/v sodium hydroxide solution (two 50-mL aliquots), dried, and concentrated. The residue was the sulfone-sulfonyl chloride **2** (0.186 g) which was identical with authentic material (1) by ir, nmr, and tlc.

Hydrolysis of 2

The dichlorosulfone-sulfonyl chloride (0.186 g) obtained from the chlorinolysis of **3***d* (described above) was dissolved in water (10 mL) and the reaction mixture refluxed for 1 h. Chloroform (200 mL) was added, and the mixture dried with $MgSO_4$ and filtered. The chloroform was evaporated, affording clean dichloromethyl methyl sulfone (0.072 g) which was identical to authentic material by ir, nmr, and mp (1).

Preparation of $CH_3SO_2CCl_2 \cdot SO \cdot Cl$ 4

The dichlorosulfone-sulfenate ester **3***f* (2) (1.045 g) was dissolved in methylene chloride (25 mL) and Cl_2 (ca. 200 mL/min) bubbled into the reaction mixture for 0.5 h. The solvent was evaporated and the crude residue recrystallized from CCl_4, affording pale yellow crystals of sulfone-sulfinyl chloride (0.637 g, mp 38–40°C). The sulfinyl chloride **4** had ir ($CHCl_3$): 1350, 1166, and 1175 cm^{-1}; λ_{max} (hexanes):[5] 226 (ε 3 488), 274 (ε 377); nmr ($CDCl_3$) δ: 3.36 (s); ms *m/e*: 79 (35.5%) and 63 (100%). *Anal.* calcd. for $C_2H_3Cl_3O_3S_2$: C 9.78, H 1.23; found: C 9.31, H 1.37.

Preparation of $CH_3SO_2CCl_2 \cdot SO \cdot OCH_3$ 5

The sulfone-sulfinyl chloride **4** (1.003 g) was dissolved in methanol (25 mL) and the reaction mixture stirred at ambient temperature for 0.5 h. The solvent was evaporated, the residue dissolved in chloroform (5 mL), and the resultant mixture filtered. The chloroform was evaporated and the residue crystallized from methanol, affording clean **5** (0.820 g, mp 56–58°C). The product had ir ($CHCl_3$): 1345, 1200, and 1150 cm^{-1}; nmr ($CDCl_3$) δ: 3.33 (3H, s) and 4.10 (3H, s); ms *m/e*: 79 (100%) and 63 (27.8%). *Anal.* calcd. for $C_3H_6Cl_2O_4S_2$: C 14.94, H 2.51; found: C 14.86, H 2.59.

Hydrolysis of $CH_3SO_2CCl_2 \cdot SO \cdot Cl$ 4

The sulfinyl chloride **4** (0.985 g) was added to distilled water (10 mL) and the reaction mixture refluxed gently for 0.5 h. The reaction mixture was homogeneous by the time reflux began. The reaction mixture was cooled to room temperature and poured into chloroform (300 mL). The chloroform was dried ($MgSO_4$) and concentrated, affording the dichlorosulfone **6** (0.535 g). After recrystallization, the dichlorosulfone **6** was shown to be identical with authentic material by ir, nmr, mp, and mixture mp.

Chlorinolysis of $CH_3SO_2CCl_2 \cdot SO \cdot OCH_3$ 5

The sulfinate ester **5** (0.991 g) was dissolved in methylene chloride (25 mL) and Cl_2 (ca. 200 mL/min) was bubbled into the solution for 1 h. The solvent was evaporated and the residue recrystallized from 95% ethanol, affording 1,1,1-trichloro-2-thiapropane-2,2-dioxide (0.464 g) which was identical with authentic material by nmr, ir, mp, and mixture mp.

Chlorinolysis of $CH_3SO_2CCl_2 \cdot SO \cdot Cl$ 4

The sulfinyl chloride **4** (1.000 g) was dissolved in methylene chloride (25 mL) and Cl_2 (ca. 200 mL/min) was bubbled into the reaction mixture for 2 h. The solvent was evaporated. The residue was recrystallized from 95% ethanol, affording 1,1,1-trichloro-2-thiapropane-2,2-dioxide (0.202 g) which was identical with authentic material by ir, nmr, and ms. The mother liquor from the recrystallization contained 1,1-dichloro-2-thiapropane-2,2-dioxide (0.210 g) and residual trichlorosulfone (0.197 g).

Thus the sulfinyl chloride had been converted to the trichlorosulfone (50% yield) by the 2-hour chlorinolysis.

Preparation of $PhCH_2CH_2SAc$

The mesylate of 2-phenyl ethanol (9.2278 g) and thioacetic S-acid (3.517 g) were added to dry pyridine (100 mL) and the reaction mixture stirred at ambient temperature for 7 days.[6] Chloroform (200

[4] This compound was too unstable for analysis, but its spectra provide unambiguous evidence for the structure.

[5] Compare with $CH_3 \cdot SO \cdot Cl$, λ_{max} (hexane): 196 (ε 6 320) and 289 (ε 600) (15).

[6] A run terminated after 3 days at room temperature afforded a mixture of thiolester (75%) and unchanged mesylate (25%).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

mL) was added and the resultant mixture washed with 5% HCl (100-mL aliquots) until the aqueous pH remained acidic. The organic layer was dried ($MgSO_4$) and concentrated. The residue was rectified at reduced pressure, affording clean thiolester (5.096 g, bp 80–84°C/0.3 Torr). The product had ir ($CHCl_3$): 1695 cm^{-1}; nmr ($CDCl_3$) δ: 7.26 (5H, s), 3.00 (4H, m), and 2.30 (3H, s); ms *m/e*: 180 (M^+, 3.8%), 104 (78.2%), 91 (36.9%), and 43 (100%). *Anal.* calcd. for $C_{10}H_{12}OS$: C 66.62, H 6.70; found: C 66.83, H 6.74.

Preparation of $PhCH_2CH_2 \cdot SO \cdot Cl$ 7c

Cl_2 (ca. 200 mL/min) was bubbled into a solution of 2-phenethyl thiolacetate (5.00 g) in acetic anhydride (2.83 g) for 0.5 h. The reaction temperature was maintained just above the freezing point with an acetone/Dry Ice bath as necessary. By the end of the reaction, the mixture had taken on a persistent orange color. The reaction mixture was concentrated *in vacuo* and the residue rectified, affording impure sulfinyl chloride (1.24 g, bp 128–130°C/0.5 Torr). The sulfinyl chloride[7] had ir (CCl_4): 1155 cm^{-1}; nmr ($CDCl_3$) δ: 7.30 (5H, s) and 3.45 (4H, m).

The purity of the sulfinyl chloride sample was established as follows. A sample of the sulfinyl chloride (1.0 g) was added to a solution of glacial acetic acid (25 mL) and water (5 mL) and the reaction mixture stirred at ambient temperature for 0.5 h. Water (35 mL) was added and the resultant mixture washed with chloroform (three 50-mL aliquots). The combined organic extracts were washed with 2.5% NaOH (50-mL aliquots) until the aqueous pH remained basic. The organic layer was dried ($MgSO_4$) and concentrated. The residue was 2-phenethyl sulfonyl chloride (0.187 g) which was identical with authentic material by ir and nmr. Thus the original sulfinyl chloride sample was ca. 81% (by weight) sulfinyl chloride and 19% sulfonyl chloride.[8]

Preparation of $CH_3 \cdot SO \cdot Cl$ 7b and $ClCH_2 \cdot SO \cdot Cl$ 7a

The sulfinyl chlorides **7*a*** and **7*b*** were prepared using our published procedures (11). The sulfinyl chlorides prepared in this way were not contaminated with the corresponding sulfonyl chlorides.

Chlorinolyses of 7a, 7b, 7c

The appropriate sulfinyl chloride (1.0 g) was dissolved in methylene chloride (25 mL) and Cl_2 (ca. 200 mL/min) was bubbled into the reaction mixture for 2 h. The solvent was evaporated.

Chloromethane sulfinyl chloride **7*a*** was recovered unchanged from the chlorinolysis.

Crude product from the chlorinolysis of **7*c*** was subjected to hydrolysis in aqueous acetic acid as described under "Preparation of $PhCH_2CH_2 \cdot SO \cdot Cl$ **7*c***". Phenethyl sulfinyl chloride **7*c*** was converted into a mixture containing **7*c*** (0.450 g) and phenethyl sulfonyl chloride (0.536 g).

Methanesulfinyl chloride **7*b*** was converted into a mixture of methanesulfinyl chloride (0.688 g) and methanesulfonyl chloride (0.158 g).

Chlorinolysis of $CH_3SO_2CCl_2 \cdot SO \cdot Ph$

Run 1

The dichlorosulfone-sulfoxide (0.5582 g) was dissolved in methylene chloride (50 mL). Cl_2 (ca. 200 mL/min) and HCl (ca. 200 mL/min) were simultaneously bubbled into the reaction mixture for 8 h. The solvent was evaporated. The crude contained no 1,1-dichloro-2-thiapropane-2,2-dioxide as indicated by nmr. The crude product was chromatographed on silica gel (45 g) employing carbon tetrachloride elution (thirty-one 50-mL fractions). Fractions 13–20 were combined and concentrated, affording 1,1,1-trichloro-2-thiapropane-2,2-dioxide (0.0835 g) which was identical with authentic material by ir, nmr, and mp. Further elution with chloroform (six 50-mL fractions) furnished a mixture of unchanged dichlorosulfone-sulfoxide (0.191 g) and 1,1-dichloro-2-thiapropane-2,2-dioxide (0.038 g).[9] The identity of the dichlorosulfone was confirmed by addition of authentic material to the mixture, which increased the relative intensity of the appropriate signals in the nmr spectrum of the mixture.

Run 2

The dichlorosulfone-sulfoxide (0.5190 g) was dissolved in methylene chloride (50 mL). Cl_2 (ca. 300 mL/min) and HCl (ca. 100 mL/min) were bubbled into the reaction mixture for 8 h. The reaction mixture was evaporated to ca. 20 mL. Gas chromatography carried out on the solution indicated the presence of chlorobenzene (peak intensity increased upon addition of authentic material). The solution was concentrated. Nuclear magnetic resonance indicated a 1:1 mixture of chlorobenzene (relative intensity of chlorobenzene signal increased upon addition of authentic material) and 1,1,1-trichloro-2-thiapropane-2,2-dioxide. Reflux of the crude in water (10 mL) for 1 h did not furnish any dichlorosulfone, indicating that the chlorinolysis had gone to completion. Product was isolated by pouring the aqueous mixture into methylene chloride (500 mL), drying ($MgSO_4$), and concentrating the organic phase. The residue was recrystallized from methanol, affording 1,1,1-trichloro-2-thiapropane-2,2-dioxide (0.1714 g).

Chlorinolysis of $CH_3SO_2CHCl_2$

The dichlorosulfone (0.4799 g) was dissolved in methylene chloride (50 mL). Cl_2 (ca. 300 mL/min) was bubbled into the reaction mixture for 8 h and the solvent evaporated. The crystalline crude was a mixture of 1,1-dichloro-2-thiapropane-2,2-dioxide (86%) and 1,1,1-trichloro-2-thiapropane-2,2-dioxide (14%). Identity of the trichlorosulfone was confirmed by the addition of authentic material which increased the relative intensity of the appropriate signal in the nmr of the mixture.

[7] The ir indicated contaminating sulfonyl chloride was present. Moderate intensity bands were present at 1385 and 1170 cm^{-1}.

[8] There is little or no hydrolysis of sulfonyl chlorides under the conditions employed. Such conditions permit the isolation of sulfonyl chlorides in high yields (16).

[9] The origin of the dichlorosulfone was very likely from hydrolysis of sulfinyl chloride **4** present in the crude.

A ^{31}P and ^{199}Hg nuclear magnetic resonance and vibrational spectroscopic study of triarylphosphine complexes of $HgCl_2$

TIM ALLMAN AND RAM G. GOEL[1]

Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received March 1, 1983[2]

TIM ALLMAN and RAM G. GOEL. Can. J. Chem. **62**, 615 (1984).

Complexes of the type $[HgCl_2P(4\text{-}XC_6H_4)_3]_2$ and $HgCl_2(P(4\text{-}XC_6H_4)_3)_2$ (X = Me_2N, MeO, Me, H, F, Cl) have been prepared. The tertiary phosphines have similar steric requirements but vary greatly in their basicities. The vibrational spectra of the complexes were measured and each complex was found to have the expected bridging dimeric (1:1) or pseudotetrahedral monomeric (1:2 Hg/P) structure. Their ^{31}P and ^{199}Hg nmr parameters were investigated and it was found that ^1J(Hg—P) increases with increasing phosphine basicity, decreasing temperature, and decreasing sample concentration in dichloromethane solution. It is concluded that changes in the hybridisation on the P and Hg atoms may be largely responsible for the increases of ^1J(Hg—P) with increasing phosphine basicity.

TIM ALLMAN et RAM G. GOEL. Can. J. Chem. **62**, 615 (1984).

On a préparé des complexes du type $[HgCl_2P(4\text{-}XC_6H_4)_3]_2$ et $HgCl_2(P(4\text{-}XC_6H_4)_3)_2$ (X = Me_2N, MeO, Me, H, F, Cl). Les phosphines tertiaires ont des effets stériques semblables mais leurs basicités varient d'une façon considérable. On a mesuré les spectres vibrationnels des complexes et on a trouvé que chaque complexe possède la structure attendue, soit dimère ponté (1:1) ou pseudotétraèdre monomère (1:2 Hg/P). On a étudié leurs paramètres de rmn du ^{31}P et du ^{199}Hg et on a trouvé que la valeur de ^1J(Hg—P) augmente avec une augmentation de la basicité de la phosphine, une diminution de la température et une diminution de la concentration de l'échantillon en solution dans le dichlorométhane. On en conclut que des changements d'hybridisation des atomes de P et Hg sont les principaux responsables de l'augmentation de ^1J(Hg—P) avec l'augmentation de la basicité des phosphines.

Introduction

Recently we reported a study in which the basicities of various tertiary phosphines were measured by titration in nitromethane (1). Most of the phosphines in the group were *para*-substituted triarylphosphines and it was shown that within this series a very wide range of basicities could be obtained.

The donor ability of the phosphine has often been used to explain observed trends in ^1J(Hg—P) (2–7). The most common trend seen in pseudotetrahedral 1:2 (Hg/P) complexes is for ^1J(Hg—P) to increase with increasing basicity of the phosphine. An unusual exception is the $[Hg(phosphine)_2](ClO_4)_2$ series (8–10), in which the coupling constant decreases markedly.

Unfortunately, while the phosphines used in most of these studies indeed had different basicities, they also had different steric requirements, thus making the interpretation of the data somewhat ambiguous. In order to isolate the electronic effects, our series of *para*-substituted triarylphosphines was used to synthesise 1:1 and 1:2 complexes of $HgCl_2$. Their vibrational and nmr spectroscopic parameters were investigated and are reported herein.

Although some of the complexes described in this study have been previously reported (5, 6) there has been little agreement about their exact ^1J(Hg—P) values, the variation in the reported values often being well beyond any expected experimental and instrumental uncertainties. For example, ^1J(Hg—P) of $HgCl_2(P(C_6H_5)_3)_2$ has been reported to be 4740 Hz (5) but is reported herein to be 4829 Hz. In order to investigate this problem, both the temperature and concentration dependences of ^1J(Hg—P) were studied. The temperature effect has already been studied by others (6, 11), who noted a linear increase in ^1J(Hg—P) with decreasing temperature. However, the variation of ^1J(Hg—P) with sample concentration has not been reported before.

Results and discussion

Vibrational spectra

Because the structures of complexes of this type have been well established, the interpretation of their vibrational spectra has become much more certain. The 1:1 complex $[HgCl_2P(C_6H_5)_3]_2$ has been found to have a chloro bridging dimeric structure (12) and the 1:2 complex $HgCl_2(P(C_6H_5)_3)_2$ is pseudotetrahedral and monomeric (13). It is isostructural with the analogous iodo complex (14). A rigorous treatment of the vibrational spectra of the $P(C_6H_5)_3$ complexes has been done previously (15). The similarity of the vibrational spectra of the complexes reported in this study shows that the structures remain the same through each series. The data are given in Tables 1 and 2.

The infrared spectra of the 1:1 complexes each contain a strong band between 270 cm^{-1} and 300 cm^{-1}. Similarly, the Raman spectra each contains a corresponding weak to strong band. These bands are assigned to the antisymmetric and symmetric terminal Hg—Cl stretching modes (16, 17). Very strong and broad ir bands, assigned to ν_b(Hg—Cl), are seen for each member of the series near 170 cm^{-1} although only two contain corresponding Raman bands and these are weak. The symmetric and antisymmetric Hg—P stretching frequencies are found, as expected, in the 130 cm^{-1} to 170 cm^{-1} region. Some of these bands are not seen because of their inherent weakness and their being hidden by the extremely broad ν_b(Hg—Cl) bands at slightly higher frequencies. Below about 110 cm^{-1} are some medium to strong bands which are assigned to skeletal deformations. Although there are several deformation modes predicted for this type of structure (17), only one fairly broad

[1] Because of the untimely death of Professor Ram G. Goel on November 8, 1982, the two consecutive papers in this volume will be the last in which he is an author. Through patience and understanding, Ram helped to generate interest and develop research skills in chemistry for many students over his 15 years at the University of Guelph. He will be deeply missed.

[2] Revision received October 18, 1983.

TABLE 1. The vibrational data of the 1:1 complexes*

Complex	ν_t(Hg—Cl) ir	ν_t(Hg—Cl) R	ν_b(Hg—Cl) ir	ν_b(Hg—Cl) R	ν(Hg—P) ir	ν(Hg—P) R	δ ir	δ R
$[HgCl_2P(4\text{-}Me_2NC_6H_4)_3]_2$	271s	268vw	163	—	—	—	89s	95vs
$[HgCl_2P(4\text{-}MeOC_6H_4)_3]_2$	287s	287m	158	160vw	—	—	107s

band is seen in those spectra where this absorption is seen at all. The most likely explanation is that the predicted bands are very close in frequency and therefore not resolved.

In the 1:2 complexes, both the symmetric and antisymmetric stretching modes are predicted to be both ir and Raman active. With the exception of the spectrum of $HgCl_2(P(4\text{-}ClC_6H_4)_3)_2$, both Hg—Cl stretching bands are clearly separated and assignable because of their strength and previously observed frequencies (16, 17). A comment on the assignment of the symmetries of the two bands is important at this point, however. We have assumed in the past that the stronger Raman band is the symmetric mode and the stronger ir band is the antisymmetric mode (16). The fact that the same band was found to be the stronger in both spectra in several cases in this study shows that this is not a valid method of assignment. The symmetries therefore remain unassigned. The frequencies observed in the 1:2 series (200 cm^{-1} to 240 cm^{-1}) are significantly lower than those observed in the 1:1 series. This is expected because of the greater competition from the extra phosphine donor. The Hg—P bands appear in the same region as before. The bands get progressively weaker as the basicity of the phosphine increases, to the point that in the spectra of $HgCl_2(P(4MeOC_6H_4)_3)_2$ and $HgCl_2(P(4\text{-}Me_2NC_6H_4)_3)_2$ there are no bands which could be reasonably assigned to these modes. Again, some low frequency bands are seen which are most likely deformation modes but further assignment is not possible for the same reasons as before. Their presence in the solution spectra confirms that they indeed arise from skeletal modes and not lattice modes. The similarity of not only the general features of the solution and solid state spectra but of their absolute frequencies indicates that the structures do not change significantly upon dissolution.

It was hoped, perhaps naively, that the systematic changes in the basicity of the phosphines would show up as trends in the vibrational spectroscopic parameters. Inspection of the data shows generally this is not the case. This is without doubt due to extensive coupling of the vibrational modes which is masking any trends which may otherwise have been present. The data do show, however, that there is consistency of structure through the two series as the phosphine is changed.

^{31}P and ^{199}Hg nuclear magnetic resonance spectra

The nmr data are given in Tables 3 and 4. The ^{31}P and ^{199}Hg nmr spectra of each 1:2 complex were run at the concentrations and temperatures given in the tables. They were dissolved in CH_2Cl_2 containing about 10% CD_2Cl_2 to provide a lock signal.

$HgCl_2(P(4\text{-}ClC_6H_4)_3)_2$	28.4	37.1	−364	4780	50	−60

* Samples were run at measured concentrations at the indicated temperatures in CH_2Cl_2/10% $CDCl_2$. Chemical shifts are reported with respect to 85% H_3PO_4 (^{31}P) or $(CH_3)_2Hg$ (^{199}Hg) on the delta scale. The coupling constants in the ^{31}P and ^{199}Hg spectra agreed to within 15 Hz and the numbers reported are averages of the two values.

† Saturated solution.

Because of the very low solubilities of the 1:1 complexes, they were run as saturated, but very dilute, solutions in the same solvent. Collection of their spectra at 24.4 MHz at low temperatures was judged impractical because of the time involved – about 2 days each. However, the complexes of the three most basic phosphines,[3] $P(4\text{-}Me_2NC_6H_4)_3$, $P(4\text{-}MeOC_6H_4)_3$, and $P(4\text{-}MeC_6H_4)_3$, are sufficiently non-labile to permit observation of the ^{199}Hg satellites at ambient probe temperature, about 30°C. The ambient temperature ^{31}P spectrum of $[HgCl_2\text{-}P(C_6H_5)_3]_2$ consisted of one broad peak and coupling was not observed. The 1:1 complexes of the two least basic phosphines, $P(4\text{-}FC_6H_4)_3$ and $P(4\text{-}ClC_6H_4)_3$, gave no observable signals after 200 000 pulses.

When the ^{31}P spectrum was measured at 163 MHz, the ^{199}Hg satellites in the spectrum of the $P(C_6H_5)_3$ complex were observed after about 10 000 transients were collected at −60°C. Attempts to obtain the ^{31}P spectra of $[HgCl_2P(4\text{-}FC_6H_4)_3]_2$ and $[HgCl_2P(4\text{-}ClC_6H_4)_3]_2$ at high field yielded only sharp singlets with very poor signal-to-noise ratios that did not allow the observation of the ^{199}Hg satellites.

Variation of the nuclear magnetic resonance parameters with phosphine basicity

Throughout the 1:2 series, ^1J(Hg—P) increases with increasing phosphine basicity although the values for $HgCl_2(P(C_6H_5)_3)_2$ and $HgCl_2(P(4\text{-}FC_6H_4)_3)_2$ are out of order. The coordination chemical shift, Δ, (δ complex − δ phosphine) follows ^1J(Hg—P) even to the point of the same two values being out of order. The ^{199}Hg chemical shifts show that the Hg atom becomes more shielded as the phosphine becomes more basic. As expected, the ^{199}Hg nmr spectra consisted of 1:2:1 triplets with spacing of ^1J(Hg—P).

The reasons for the trends in ^1J(Hg—P) as the phosphine or other ligands are changed have been a matter of much discussion (3–11). In Hg(II)–phosphine complexes, the expected

[3] Taken from ref. 1, the phosphines, in order of increasing basicity have pK_a values as follows: $P(4\text{-}XC_6H_4)_3$, (X = Me_2N, 8.65; MeO, 4.57; Me, 3.84; H, 2.73; F, 1.97; Cl, 1.03).

increase in the *s* electron density at the nuclei as the donor ability of the ligand is increased has usually been invoked to explain trends. However, some recent work has shown that this may not be as important as was once thought (18).

Indeed, in some Sn—Sn compounds it has been found that the *s* electon density, as reflected in the Mossbauer spectra, changes very little even though ^1J(Sn—Sn) varies greatly (19). We have previously proposed (1) that hybridisation changes, consistent with Bent's rule[4] could be responsible for the decrease in ^1J(P—H) with increasing basicity in some protonated phosphines and the same mechanism seems to be at work in a series of $P(C_6H_5)_3$ complexes: $HgX_2(P(C_6H_5)_3)_2$; X = NO_3, SCN, I, CN (20). Crystal structures of these compounds show that as X becomes more electronegative, the P—Hg—P angle opens up and the X—Hg—X angle closes. This rehybridisation, assuming only *s* and *p* orbitals are being used by Hg, is consistent with Bent's rule. That is, as X becomes more electronegative, the Hg orbitals directed towards X gain more *p* character. Therefore the orbitals bonding to the phosphines gain in their *s* character and ^1J(Hg—P) is increased.

It is reasonable to suspect that changing the basicity (electronegativity) of the phosphorus ligand in the presence of a constant X should lead to similar results. The Hg orbitals directed towards the more basic phosphines should increase their *s* character and thereby increase ^1J(Hg—P). This, of course, is consistent with the data presented in this study and in previous work. Currently, single crystal X-ray studies are underway to test this hypothesis.

The 1 : 1 complexes all have much higher coupling constants. The small bridging Cl—Hg—Cl angle in $[HgCl_2P(C_6H_5)_3]_2$ (<90°) (12) shows that there is little, if any, *s* character in these Hg orbitals. It therefore must be concentrated in the Hg—P and Hg—Cl (terminal) bonds. This helps to explain the large increase in ^1J(Hg—P) over the 1 : 2 complexes. It also indicates that because the *s* character is already concentrated in the terminal Hg orbitals, any small hybridisation changes would have little effect on the *s* character in them and therefore in these complexes ^1J(Hg—P) should be less sensitive to the basicity of the phosphine. No trend is apparent at all in the data in Table 1. This is not unexpected, however. Since the effect of substituting more electropositive groups on the phosphorus atom is to decrease the *s* character of the lone pair (and hence to decrease ^1J(Hg—P)), the rehybridisation effects on the two atoms (P and Hg) are opposite. It therefore appears that the two effects are of similar size and largely cancel whereas in the 1 : 2 series the hybridisation changes on the Hg atom are dominant.

The concentration and temperature dependence of ^1J(Hg—P)

During our work on Hg(II)–phosphine complexes it was found that, while both δ(P) and δ(Hg) were highly reproducible, ^1J(Hg—P) often varied by as much as 100 Hz. This occurred even when both nmr solutions were prepared from the same solid sample. An investigation revealed that, apart from the previously reported temperature dependence, ^1J(Hg—P) was also dependent upon the concentration of the sample.

The two complexes, $HgCl_2(P(4\text{-}MeC_6H_4)_3)_2$ and $HgCl_2(P(4\text{-}Me_2NC_6H_4)_3)_2$, were chosen for study because of their unusually high solubilities. Plots of ^1J(Hg—P) vs. temperature at various concentrations are shown in Figs. 1 and 2. They both show the familiar decrease of ^1J(Hg—P) with increasing temperature but there are significant deviations from the linearity described by Grim *et al.* (6).

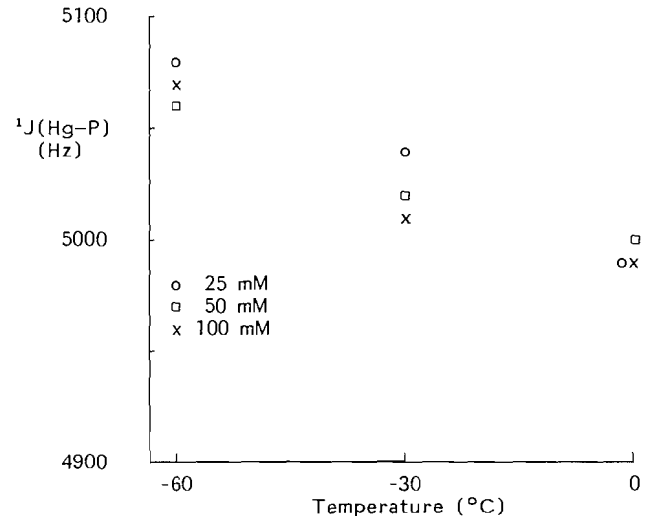

FIG. 1. Concentration and temperature dependences of ^1J(Hg—P) for $HgCl_2(P(4\text{-}Me_2NC_6H_4)_3)_2$.

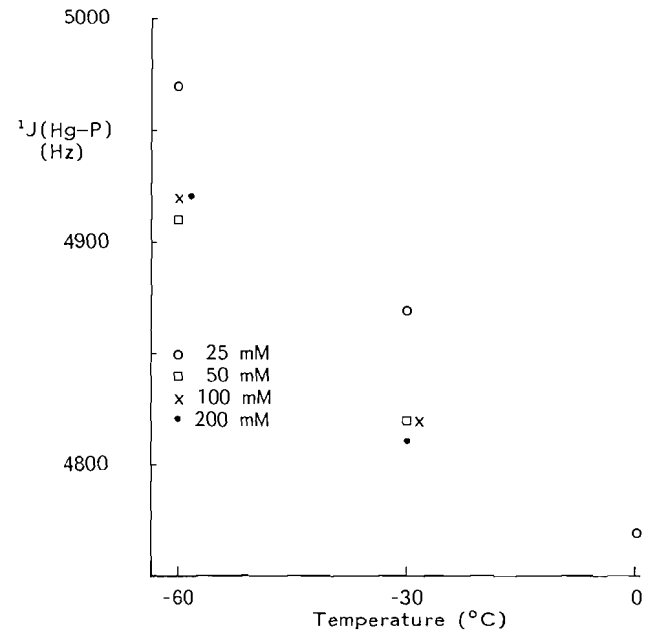

FIG. 2. Temperature and concentration dependences of ^1J(Hg—P) for $HgCl_2(P(4\text{-}MeC_6H_4)_3)_2$.

Because the ^{31}P spectra were proton decoupled, uncertainty in the sample temperature due to inductive r.f. heating from the decoupler was considered to be a possibility. Because of this, some experiments were carried out with the "phosphine thermometer" described in the experimental section. It was found that while continuous decoupling with 5.0 W of power did raise the sample temperature, there was no observable increase if the decoupler was gated, as described in the experimental section, to give an 11.3% duty cycle.

The concentration dependence appears to be greatest at low concentrations. The line for $HgCl_2(P(4\text{-}Me_2NC_6H_4)_3)_2$ at 25 mmol dm^{-3} is a large distance from the others which are almost

[4] Bent's rule predicts that the orbitals directed towards the most electropositive substituents will have the most *s* character and that the electronegative substituents will bond to orbitals with higher *p* character. See ref. 24.

†%N = 8.2 (8.0).

coincident. $HgCl_2(P(4\text{-}Me_2NC_6H_4)_3)_2$ shows a smaller concentration effect.

Two reasons for the temperature effect have been put forward but they both appear untenable. Phosphine exchange (11) cannot be responsible because the ^{199}Hg satellites are sharp, sometimes at 0°C, showing that the exchange process has become slow on the nmr time scale. Yet, $^1J(Hg—P)$ continues to increase unabated 60°C below this temperature. Halogen exchange is also known to proceed (21). It was shown that when the nmr spectrum of a mixture of $HgCl_2(P(n\text{-}butyl)_3)_2$ and $HgBr_2(P(n\text{-}butyl)_3)_2$ was taken, cooling to −120°C was necessary to see three species, the starting materials and the mixed halide complex. Cooling to −50°C sufficed for the analogous $P(4\text{-}Me_2OC_6H_4)_3$ complexes. We find that a mixture of $HgBr_2(P(4\text{-}MeC_6H_4)_3)_2$ and $HgCl_2(P(4\text{-}MeC_6H_4)_3)_2$ gives a ^{31}P nmr spectrum at −40°C which shows the three species present. Again, the exchange process has become slow but the variation of $^1J(Hg—P)$ continues. Solvation almost certainly plays a role in this phenomenon but exactly what it is and why mercury has this unique property remain unclear.

Experimental

Materials

The phosphines were prepared and purified as described previously (1). Solvents and mercuric chloride were reagent grade and used as received. Analyses were performed by Guelph Chemical Laboratory, Guelph. Melting points were measured using a Gallenkamp apparatus with a calibrated thermometer. Analytical data are summarised in Table 5.

Preparation of the complexes

1:1 Complexes

The 1:1 complexes can be prepared by stirring a slurry of $HgCl_2$ in a dichloromethane solution of the phosphine and filtering off the insoluble product. However, this tends to be slow and it is difficult to tell when the reaction is complete. Therefore the following method was used. $HgCl_2$ (1 mmol) was dissolved in THF (10 mL) and added slowly to a solution of the phosphine in CH_2Cl_2 (100 mL). The complex precipitated immediately and was filtered off and dried. The yield is quantitative.

1:2 Complexes

The 1:2 complexes of all the phosphines except $P(4\text{-}ClC_6H_4)_3$ and $P(4\text{-}FC_6H_4)_3$ were prepared as follows. A solution of $HgCl_2$ (1 mmol) in THF (10 mL) was added to a solution of the phosphine (2 mmol) in CH_2Cl_2 (20 mL). The solution was reduced in volume until crystallization commenced and a small amount of Et_2O was added to precipitate the complex. The crude complex was recrystallized from CH_2Cl_2/Et_2O to give white crystalline products. The yield was about 50–60%. Attempts to prepare $HgCl_2(P(4\text{-}ClC_6H_4)_3)_2$ and $HgCl_2(P(4\text{-}FC_6H_4)_3)_2$ by this method yielded only the 1:1 complexes. Grim *et al.* (6) noted similar difficulties in trying to prepare these complexes. To prepare them, the phosphine (10 mmol) was dissolved in hot 1,2-dichloroethane (10 mL) and powdered $HgCl_2$ (1 mmol) was added. After a few minutes the solution cleared and it was allowed to cool. Stirring with a glass rod helped to initiate the crystallization of the complex along with much free phosphine. The crude product was filtered off and washed with Et_2O to leave a white crystalline product. The yield was about 70–80%.

Nuclear magnetic resonance measurements

The ^{31}P nmr spectra of the 1:1 complexes $[HgCl_2P(4\text{-}Me_2NC_6H_4)_3]_2$, $[HgCl_2P(4\text{-}MeOC_6H_4)_3]_2$, and $[HgCl_2P(4\text{-}MeC_6H_4)_3]_2$ were collected on a Bruker WP-60 nmr spectrometer operating at 24.4 MHz. The ambient probe temperature was about 30°C. The recycle time was 2 s with the decoupler being gated on during acquisition only.

The ^{31}P and ^{199}Hg nmr spectra of all the other complexes were obtained using $CH_2Cl_2/10\%$ CD_2Cl_2 solutions in non-spinning 10-mm tubes at the temperatures and concentrations given on a Bruker WH-400 nmr spectrometer. Usually the same samples were used for measurements of both nuclei. To ensure the accuracy of the temperature measurements the ^{31}P nmr spectrum of a solution of $P(C_6H_5)_3$ and $OP(C_6H_5)_3$ (0.1 mmol dm^{-3} each) in toluene was measured at each temperature (22). Because the chemical shift difference of these compounds is a linear function of temperature, the sample temperature could be found directly. Usually the temperature found this way was within 1 K of the controller's reading and this is believed to be the uncertainty in the temperature. It was found that 20 min were necessary to ensure that thermal equilibrium was reached after inserting the samples and this delay was used for all the samples. In order to prevent the precipitation of $[HgCl_2P(4\text{-}ClC_6H_4)_3]_2$ from solutions of $HgCl_2(P(4\text{-}ClC_6H_4)_3)_2$, one extra mole of phosphine was added to the solutions.

^{31}P nuclear magnetic resonance spectra

The spectra were acquired into 4K blocks. The FIDs were given an exponential line-broadening of 3 Hz and were zero filled to 8K before Fourier transformation. The sweep width used was 6024 Hz giving an acquisition time of 0.340 s and a digital resolution of 1.5 Hz. 90° (32 μs) pulses were used. The broadband decoupler was gated on during

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

acquisition only and a preacquisition delay was added to give a total recycle time of 3 s. The reference was 85% H_3PO_4.

^{199}Hg nuclear magnetic resonance spectra

The spectra were acquired into 4K blocks. They were given an exponential line broadening of 50 Hz and were zero filled to 8K before Fourier transformation. A sweep width of 15.151 kHz was used, giving an acquisition time of 0.135 s and a digital resolution of 3.7 Hz. 90° pulses were used with no relaxation delay. Preliminary experiments showed that use of the decoupler had no effect on the line widths (about 100–500 Hz) so the spectra were collected with no decoupling. The chemical shifts were referenced by observing internal TMS and using its absolute frequency to calculate the frequency of $(CH_3)_2Hg$ (23). Shifts are reported on the delta scale with respect to this frequency.

Vibrational measurements

The solid Raman samples were contained in melting point capillary tubes and were run on a Jarrell–Ash spectrophotometer. The 514.5 nm line of an Ar^+ laser was used for excitation and the spectra were calibrated from the known frequencies of the plasma lines. The conditions were: scan speed, 1 cm^{-1}/s; time constant, 1 s; laser power, 0.5 W; slit width, 3.0 cm^{-1}. Attempts to obtain solution Raman spectra of the most soluble complexes failed because of insufficient solubility.

All infrared spectra were obtained on a Perkin–Elmer 180 spectrometer with the far ir option. The solid samples were run as paraffin oil mulls spread on polyethylene disks. The solution spectra were obtained using sealed polyethylene cells of our own construction containing concentrated $CHCl_3$ solutions. The Hg lamp, probably because of its high uv emission, decomposed some samples so the Globar was used exclusively.

A ^{31}P and ^{199}Hg nuclear magnetic resonance and vibrational spectroscopic study of phosphine complexes of $Hg(ClO_4)_2$

TIM ALLMAN AND RAM G. GOEL[1]

Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received May 3, 1983

TIM ALLMAN and RAM G. GOEL. Can. J. Chem. **62**, 621 (1984).

Cationic complexes of the type $[Hg(phosphine)_n](ClO_4)_2$ (n = 2, 3, 4) (phosphine = P(t-Bu)$_3$, PCy_3, P(4-$Me_2NC_6H_4$)$_3$, P(4-$MeOC_6H_4$)$_3$, P(4-MeC_6H_4)$_3$, P(3-MeC_6H_4)$_3$, P(2-MeC_6H_4)$_3$, P(4-FC_6H_4)$_3$, P(4-ClC_6H_4)$_3$) have been prepared and studied by vibrational spectroscopy in the perchlorate and low frequency regions, as well as by ^{31}P and ^{199}Hg nmr. The skeletal Hg—P frequencies have been assigned in both solution and the solid state. It was found that ^1J(Hg—P) decreases with increasing phosphine basicity and that it is also dependent upon sample concentration and temperature.

TIM ALLMAN et RAM G. GOEL. Can. J. Chem. **62**, 621 (1984).

On a préparé des complexes cationiques du type $[Hg(phosphine)_n](ClO_4)_2$ (n = 2, 3, 4) (phosphine = P(t-Bu)$_3$, PCy_3, P(4-$Me_2NC_6H_4$)$_3$, P(4-$MeOC_6H_4$)$_3$, P(4-MeC_6H_4)$_3$, P(3-MeC_6H_4)$_3$, P(2-MeC_6H_4)$_3$, P(4-FC_6H_4)$_3$ et P(4-ClC_6H_4)$_3$) et on les a étudiés par spectroscopie vibrationnelle dans les régions du perchlorate et des basses fréquences ainsi que par rmn du ^{31}P et du ^{199}Hg. On a attribué les fréquences du squelette Hg—P tant en solution qu'en phase solide. On a trouvé que la valeur de J(Hg—P) diminue avec une augmentation de la basicité des phosphines et que cette valeur varie aussi avec la température ainsi qu'avec la concentration de l'échantillon.

Introduction

In phosphine complexes of Hg(II) usually both the phosphines and the anions are strongly coordinated to the metal centre. There are, however, some cationic complexes of $HgCl_2$ with trimethylphosphine in which one or both of the chloro ligands have been displaced by the phosphines (1–3). A very weakly coordinating anion will also produce cationic species and in a previous communication (4) we reported some ^{31}P nmr data on nine complexes of the general formula $[Hg(phosphine)_2](ClO_4)_2$. The most striking aspect of this series was that ^1J(Hg—P) decreased with increasing phosphine basicity, opposite the trend usually seen in Hg(II)–phosphine complexes (5).

Colton and Dakternieks (6) studied these complexes by ^{31}P and ^{199}Hg nmr but they were not characterised by other spectroscopic techniques. Most recently, the electrochemical reduction of these complexes was used in an attempt to study ligand exchange reactions (7).

In the present work, some *para*-substituted triarylphosphines which have very different basicities but similar steric requirements (8), as well as other tertiary phosphines of current interest, were used to prepare complexes of $Hg(ClO_4)_2$ in stoichiometries of 1:2, 1:3, and 1:4 (Hg/P). Their ^{31}P and ^{199}Hg nmr parameters are reported as well as their characterisation by vibrational spectroscopy in both the perchlorate and the low frequency regions.

It has been shown (5) that ^1J(Hg—P) in the $HgCl_2P_2$ series has a significant concentration dependence in addition to the previously known temperature dependence (9, 10). The $Hg(ClO_4)_2$ complexes also have this property and an investigation of this effect is presented.

[1] Because of the untimely death of Professor Ram G. Goel on November 8, 1982, the two consecutive papers in this volume will be the last in which he is an author. Through patience and understanding, Ram helped to generate interest and develop research skills in chemistry for many students over his 15 years at the University of Guelph. He will be deeply missed.

Results and discussion

Vibrational spectra and structures

Perchlorate region

In an environment of perfect tetrahedral symmetry the vibrational spectra of the perchlorate ion consist of four bands: ν_1(ν_s(Cl—O)), (A_1 symmetry); ν_2(δ(Cl—O)), (E); ν_3(ν_a(Cl—O)), (T_2); and ν_4(δ(Cl—O)) (T_2). All are Raman active. The modes ν_3 and ν_4 are also infrared active (11). Lowering the symmetry, either by coordination or by placing the ion in a site of low symmetry, causes splitting of the formerly degenerate ν_3 and ν_4 modes and the appearance of ν_1 and ν_2 in the ir spectrum.

The ir spectra of the 1:2 complexes (see Table 1) indicate that in almost every case there is a significant lowering of the perchlorate symmetry. The crystal structure of $[Hg(PCy_3)_2](ClO_4)_2$ shows that there is some Hg—O interaction even though the distance is large (12). There is significant deviation from linearity ($\angle$P—Hg—P = 170°) which was attributed to the intrusion of the anions. The loss of T_d symmetry causes the splitting of ν_3 and the appearance of ν_1 in the ir in the solid state. The structure of Pt(P(t-Bu)$_3$)$_2$ shows (13) that the phosphine completely enshrouds the metal atom. It is reasonable to assume that the Hg complex is very similar, making Hg—O interactions impossible. Yet, the ir spectrum of this complex shows a large splitting of ν_3 and both ν_1 and ν_2 are active. Clearly, band counting in the solid state spectra is not a very useful way of determining whether the anion is coordinated in these complexes. More meaningful conclusions can be drawn from the spectra run in solution. Although the conductivities of the complexes in nitromethane show that they are all 1:2 electrolytes, the solution ir spectra in CH_2Cl_2 still show a lowering of the perchlorate symmetry. This lowering of symmetry appears most in the complexes with the least basic phosphines, indicating that in these complexes there is some sort of anion–cation interaction.

The 1:3 complexes give spectra that are closer to the ideal. The ν_1 band remains active in the spectra of most of the complexes in both the solid state and in solution, but splitting of ν_3

is seen in only the $P(4\text{-}MeC_6H_4)_3$ and $P(4\text{-}ClC_6H_4)_3$ complexes. The crystal structure of $[Hg(P(4\text{-}MeOC_6H_4)_3)_3](ClO_4)_2$ (14) shows that there is no Hg—O interaction.

Each of the 1:4 complexes gives an infrared spectrum which is consistent with perfect tetrahedral ClO_4 symmetry in both solution and the solid state.

Low frequency region

The only studies of phosphine complexes of Hg(II) in which the anion is not coordinated to the metal have placed ν(Hg—P) near 350 cm^{-1} (1, 2). This region was examined very carefully by both ir and Raman techniques and no such bands were found in the spectra of the complexes reported herein. Because the complexes were expected to have very high symmetries, polarization measurements of the solution Raman spectra, where solubility permitted, were used to locate ν_s(Hg—P) and help to confirm the structures.

A linear P—Hg—P system ($D_{\infty h}$) should give rise to one Raman active polarized band due to ν_s(Hg—P), (Σ_g^+); one ir active band due to δ(Hg—P), (Π_u); and one ir active band due to ν_a(Hg—P), (Σ_u^+) (11). With the exception of the spectrum of $[Hg(P(4\text{-}FC_6H_4)_3)_2](ClO_4)_2$, all the spectra of the 1:2 complexes are consistent with this structure (see Table 2). For example, the solution Raman spectrum of $[Hg(P(4\text{-}Me_2NC_6H_4)_3)_2](ClO_4)_2$ has a polarized band at 129 cm^{-1} (130 cm^{-1} in the solid state) which is assigned to ν_s(Hg—P). Its solution ir spectrum contains a band at 159 cm^{-1} (ss 154 cm^{-1}) which is assigned to ν_a(Hg—P), and a broad band at 100 cm^{-1} (ss 106 cm^{-1}) which is assigned to δ(Hg—P). Similar assignments can be made for the other complexes.

The solid state ir spectrum of $[Hg(P(4\text{-}FC_6H_4)_3)_2](ClO_4)_2$ contains two skeletal bands at 168 cm^{-1} and 180 cm^{-1} and its Raman spectrum has a band at 165 cm^{-1}. The activity of both ν_s and ν_a in the ir spectrum and the correspondence of bands between the two spectra suggests a deviation from linearity in the solid state. Unfortunately the complex is not soluble enough for solution measurements. Interestingly, the spectra of $[Hg(PCy_3)_2](ClO_4)_2$, which is bent (12), are entirely consistent with the linear model.

The trigonal planar (D_{3h}) structure (which is now known for $[Hg(P(4\text{-}MeOC_6H_4)_3)_3](ClO_4)_2$) (14), should give rise to four skeletal bands. The first, ν_s(Hg—P), (A_1), is Raman active and

* Solution values are underscored (CH_2Cl_2 for ir, $CHCl_3$ for R). All bands were of medium to weak intensity.

polarized. Another, ν_a(Hg—P), (E) is both Raman and ir active, as is one of the deformation modes δ (Hg—P), (E). The other deformation mode (A_2) is ir active only. Unfortunately, the bands were often very weak, especially ν_a(Hg—P), and the low solubilities often prevented solution measurements so that no single complex has an ideal set of spectra. However, taken as a group, all the essential features are there and no spectrum contained unexplainable "extra" skeletal bands. All of the 1:3 complexes are therefore assigned the trigonal planar structure found in the $P(4\text{-MeOC}_6H_4)_3$ complex.

No preliminary X-ray data are available for a 1:4 complex but the presence of the polarized Raman bands (ν_s(Hg—P), (A_1)) is strong evidence for a tetrahedral structure. In only one case is ν_a(Hg—P), (T_2) seen, but this is most likely a problem of low intensity. The deformation modes give rise to bands in the 100 cm^{-1} region as before.

There appears to be no simple trend that relates the vibrational parameters to phosphine basicity although often the highest frequencies are associated with the least basic phosphines. The sterically hindered $P(2\text{-MeC}_6H_4)_3$ ligand produces the highest value of ν_s(Hg—P) of the series. Why this occurs is not clear. The low pK_a of $P(4\text{-ClC}_6H_4)_3$ (8), along with the fact that its 1:4 complex does not form, even in solution, shows that it must be a very weak donor but it gave complexes with high ν_s(Hg—P) values. The greatest value of the spectra appears to be in their help in the structural assignments.

^{31}P and ^{199}Hg nuclear magnetic resonance spectra

The ^{31}P and ^{199}Hg data are given in Table 3. As expected, the ^{199}Hg spectra consist of 1:2:1 triplets, 1:3:3:1 quartets, and 1:4:6:4:1 quintets for the 1:2, 1:3, and 1:4 complexes respectively. The mercury chemical shift is most dependent upon the coordination number of the Hg atom with the shielding following the order 1:2 ≫ 1:4 > 1:3. There are, however, no obvious trends that relate to the basicity of the phosphine. The ^{31}P chemical shifts are also highly dependent upon the Hg coordination number with a shielding order 1:4 > 1:3 > 1:2. Neither the ^{31}P nor the ^{199}Hg chemical shift was found to vary much with either temperature or concentration.

The coupling constant, ^1J(Hg—P), decreases with increasing coordination number in a more or less linear fashion (see Fig. 1). This trend was observed in the series of trimethylphosphine complexes (1, 2) and reflects the decrease in s character of the Hg orbitals. ^1J(Hg—P) also decreases with increasing phosphine basicity although this effect diminishes as the coordination number increases.

It has been previously shown (8) that as the electron donating groups on the phosphorus atom become more electron donating, ^1J(P—X), where X is a fourth atom bonded to P, decreases. This was attributed to a lowering of the s character of the lone pair orbital. Such a rehybridisation would be in agreement with Bent's rule (15).

The Hg atom has been shown to respond similarly to electronic effects in the pseudotetrahedral HgX_2P_2 complexes (5, 16). The result of this is to increase ^1J(Hg—P) as the basicity of the phosphine increases and as the electronegativity of the anion decreases. Because the effects on ^1J(Hg—P) are opposite at the Hg and P atoms, it is apparent that the effects at mercury are dominant in determining ^1J(Hg—P).

In the cationic complexes the Hg atom cannot rehybridise in response to changes in the phosphine; the skeletal structures remain the same. Therefore only the effect of the phosphorus atom is seen and ^1J(Hg—P) decreases with increasing phosphine basicity. A plot of ^1J(Hg—P) vs. pK_a is given in Fig. 2. This gives a clue to the reason that this same trend is seen almost exclusively in complexes of transition metals with partially filled d orbitals but not in the main group of d^{10} complexes (17). The former have very highly preferred geom-

*All shifts are on the delta scale and are referenced to 85% H_3PO_4 (^{31}P) or $(CH_3)_2Hg$ (^{199}Hg). The spectra were measured at the concentrations and temperatures indicated using CH_2Cl_2/20% $CDCl_3$ as the solvent. The solution of $[Hg(P(C_6H_5)_3)_2](ClO_4)_2$ was found to be saturated at 30 m*M*. The chemical shifts are believed to be accurate to ±1 in the last digit, the coupling constants to ±15 Hz.

etries, which precludes any significant hybridisation changes, while the latter have considerable flexibility.

The concentration and temperature dependences of ^{1}J(Hg—P)

The nmr parameters of phosphine complexes of the mercuric halides have been found to be both temperature and concentration dependent. Both phosphine exchange (9, 10) and halogen exchange (18) have been proposed as possible reasons for this effect. We critized these reasons as being untenable because both of these processes could be made slow on the nmr time scale by cooling without affecting the dependences (5).

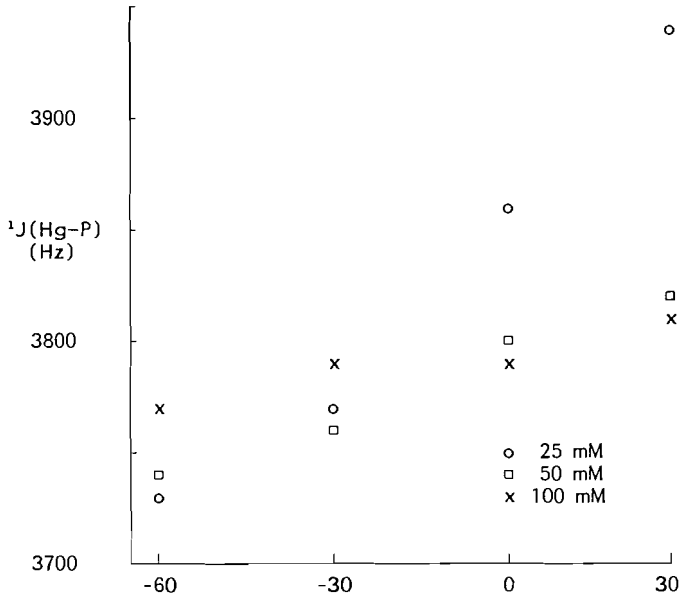

FIG. 3. Concentration and temperature dependence of ^1J(Hg—P) for $[Hg(P(4\text{-}Me_2NC_6H_4)_3)_2](ClO_4)_2$.

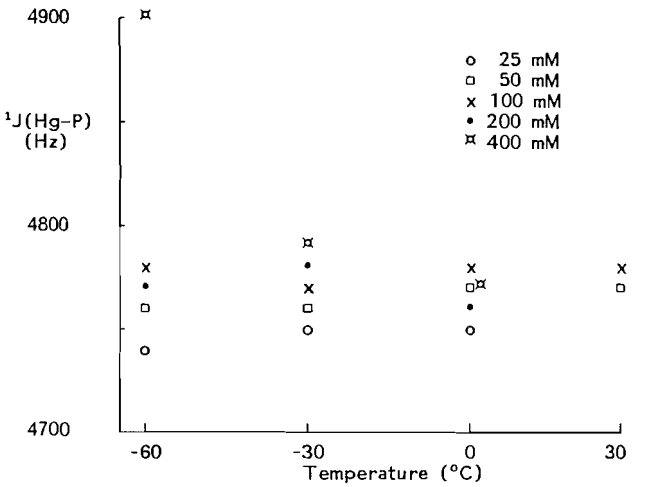

FIG. 4. Concentration and temperature dependence of ^1J(Hg—P) for $[Hg(P(4\text{-}MeOC_6H_4)_3)_2](ClO_4)_2$.

We then suggested solvation as a possibility. The data in this study confirm the above. The phosphines in these complexes exchange more slowly; coupling can be seen at 30°C for the 1:2 complexes. While the perchlorate anion probably interacts with the cations, the interaction is certainly very weak and is not expected to be significant in determining the nmr parameters. As can be seen in Figs. 3 and 4, the dependences vary with the complex and are not linear. They are also markedly different for each complex.

Experimental

Materials

The phosphines were prepared as previously reported (8). All other reagents and solvents were reagent grade and were used as received.

Preparation of the complexes

Complexes of P(t-Bu)$_3$ and P(2-MeC$_6$H$_4$)$_3$

To a solution of the phosphine (2.5 mmol) in 1:1 v/v CH_2Cl_2/ethanol (20 mL) was added solid $Hg(ClO_4)_2 \cdot 4H_2O$ (1 mmol). The solid dissolved and the solution was filtered if necessary. The complex was precipitated by the addition of diethylether. The crude products

§ Addition of more phosphine to the solutions of the 1:2 complexes did not change their conductances significantly.

were recrystallized from CH_2Cl_2/hexane, using a small amount of the crude product to initiate crystallization. The white products were filtered off and dried in vacuum to remove trapped solvent. Yield = 50–60%.

This method often led to the deposition of mercury metal and badly contaminated products when used with the other phosphines. As a result, the following metathetical synthesis was used for those phosphines for which the starting material $HgCl_2P_2$ exists.

1:2 Complexes of the other phosphines

To a solution of $HgCl_2$(phosphine)$_2$ (5) (1 mmol) in CH_2Cl_2 (30 mL) was added a solution of silver perchlorate (2 mmol) in ethanol (10 mL). The AgCl was filtered off after 5 minutes stirring to yield a clear solution. The complexes were precipitated by reduction of the volume of the solution and, if necessary, the addition of hexane. They were recrystallized from CH_2Cl_2/hexane to yield crystalline products. The $P(4\text{-}Me_2NC_6H_4)_3$ complex was bright yellow. The others were white. Yield = 50–70%.

1:3 Complexes

To a solution of the appropriate 1:2 complex (1 mmol) in CH_2Cl_2 was added phosphine (2 mmol of $P(4\text{-}FC_6H_4)_3$ and $P(4\text{-}ClC_6H_4)_3$, 1 mmol of the others). The complexes were isolated as before, taking care to wash away the excess phosphine with diethylether. All were white crystalline solids except the $P(4\text{-}Me_2NC_6H_4)_3$ complex which was yellow. Yield = 60–70%.

1:4 Complexes

The complexes of all the phosphines except $P(C_6H_5)_3$ were prepared in an analogous manner but excesses of phosphine (2–6 mmol) were found to be necessary to ensure the purity of the $P(4\text{-}MeOC_6H_4)_3$ and $P(4\text{-}MeC_6H_4)_3$ complexes. Excesses of $P(4\text{-}Me_2NC_6H_4)_3$ often led to deposition of mercury metal.

Even with large excesses of phosphine, the $P(C_6H_5)_3$ complex was found by ^{31}P nmr to contain much 1:3 product. This crude mixture was added to a solution of $P(C_6H_5)_3$ (20 mmol) in 1,2-dichloroethane (5 mL) and was refluxed over a steam bath overnight.[2] A ^{31}P spectrum showed a small amount of 1:3 complex still to be present.

When excesses of phosphine were added to nmr solutions of 1:3 complexes of $P(4\text{-}FC_6H_4)_3$ and $P(4\text{-}ClC_6H_4)_3$, only peaks attributable to the 1:3 complex and free phosphine were seen. $P(3\text{-}MeC_6H_4)_3$ forms a 1:4 complex which could not be isolated. Yield = 60–80%.

Nuclear magnetic resonance measurements

Both the ^{31}P and ^{199}Hg nmr spectra were acquired on a Bruker WH-400 nmr spectrometer using conditions previously reported (5). CH_2Cl_2 containing 20% $CDCl_3$ was used as the solvent. The linewidths were typically 100–1000 Hz, with the greater values being associated with the higher concentrations. The loss in sensitivity due to line broadening often more than offset any gains expected from the increased concentrations. As a result, the times required to obtain reasonable signal-to-noise ratios tended not to increase upon dilution of the samples. About 2 000 transients were averaged for the 1:2 complexes, 4 000 for the 1:3 complexes, and 9 000 for the 1:4 complexes in order to give good S/N ratios for the weakest lines in the multiplets.

Where both ^{31}P and ^{199}Hg chemical shifts are reported, the corresponding value of ^1J(Hg—P) is the average obtained from the two spectra. The values of ^1J(Hg—P) always agreed to within 15 Hz and this is believed to be the uncertainty in the reported values.

[2] In light of the known explosion hazard of metal perchlorates in organic solvents, this is probably a dangerous procedure. It is wise therefore to shield the apparatus and to keep the reaction size small.

Vibrational measurements

The infrared spectra were measured on a Perkin–Elmer 180 spectrometer with the far-ir option. The solid samples were run as paraffin oil mulls between KBr disks in the mid-ir region or on polyethylene disks below 500 cm^{-1}. Solution measurements in the mid-ir region were made using CH_2Cl_2 solutions contained in sealed 0.2-mm NaCl cells. Far-ir solution measurements were made on $CHCl_3$ solutions in sealed 0.5-mm polyethylene cells of our own construction. Because it was found that the Hg arc source decomposed some of the samples, the Globar was used exclusively.

For Raman measurements, both the solid state and CH_2Cl_2 solution samples were contained in flame-sealed glass melting point tubes and were run on a Jarrell–Ash spectrometer. The 514.5 nm line of an argon laser was used for excitation and the spectra were calibrated from the known frequencies of the plasma lines. The conditions were: scan speed, 1 cm^{-1}/s; time constant, 1 s; laser power, 0.5 W; slit width, 3.0 cm^{-1}.

Other measurements

Elemental analyses were performed by Guelph Chemical Laboratories; the results, along with conductivity data, are given in Table 4. When melting point measurements were attempted, the complexes exploded near 200°C. Conductivities were measured in a cell with platinized Pt electrodes connected to a Yellow Springs bridge.

Acknowledgements

The Natural Sciences and Engineering Research Council of Canada is thanked for its support. Thanks also go to Dr. E. C. Alyea for reading the manuscript and making helpful comments. The nmr spectra were run at the South Western Ontario NMR centre.

COMMUNICATIONS

Intrazeolite photochemistry. I. Phosphorescence enhancement of aromatic ketones included in silicalite.[1]

H. L. CASAL AND J. C. SCAIANO
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received October 28, 1983

H. L. CASAL and J. C. SCAIANO. Can. J. Chem. **62**, 628 (1984).

The triplet lifetime of β-phenylpropiophenone at room temperature is enhanced by ca. five orders of magnitude upon inclusion in the channels of silicalite, a hydrophobic zeolite. This behaviour is attributed to restrictions to mobility in this medium, and it is suggested that photochemical probes can provide a rather unique insight in the study of intrazeolite chemical processes.

H. L. CASAL et J. C. SCAIANO. Can. J. Chem. **62**, 628 (1984).

La vie de l'état triplet du β-phénylpropiophenone mesurée à température ambiante est approx. cinq ordres de grandeur plus longue lorsque ce composé est inclus dans des canaux de silicalite, un zéolite à caractéristiques hydrophobes. Ce comportement est attribué à des restrictions de la liberté de réorientation dans le zéolite; de même il est suggéré que les systèmes photochimiques donnent une vue unique des processus chimiques dans les zéolites.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

Photochemical processes in organized media have received considerable attention during the last few years (1–3). In spite of this, and of the technological importance of zeolites, photoprocesses in zeolites have received virtually no attention; in fact, the few reports that we did find are concerned, directly or indirectly, with the cleavage of water (4, 5).

In this communication we explore the possibility of using aromatic ketones as probes of molecular mobility in zeolite cavities. Notably, we find that the lifetime of β-phenylpropiophenone (β-PP) at room temperature is enhanced by over five orders of magnitude by inclusion in silicalite cavities. At the same time, changes of this magnitude strongly suggest that photoreactions on zeolites can be expected to lead to chemical changes different from those in homogeneous or other organized media.

Silicalite (≥99% SiO_2) forms part of a class of zeolite-molecular sieves with a new topologic type of tetrahedral framework (6). The channel system of this zeolite consists of near-circular zig-zag channels which are cross-linked by elliptical straight channels. The diameter of the circular channels is 5.4 ± 0.2 Å and the free cross-section of the elliptical ones is 5.75 × 5.15 Å^2. Therefore, the limiting size for adsorption is ~6 Å at room temperature. One of the remarkable properties of this zeolite is its hydrophobicity which ensures no deactivation effect due to water.

The solution photochemistry of β-PP has been reported to involve efficient triplet deactivation involving interaction of the β-phenyl ring with the excited carbonyl group (7–9). Thus the triplet lifetime of β-PP in toluene at room temperature is ca. 1 ns (9). By contrast, propiophenone triplets have a much longer lifetime and frequently decay via reactive pathways involving hydrogen abstraction from the solvent (10). On the other hand, β-PP is photostable (9).

Silicalite S-115 (average particle size 1–2 μm), obtained from Union Carbide Canada, was calcined at 450 ± 50°C for 24 h and kept under vacuum for 12 h prior to use. The ketones studied were included in silicalite according to the following procedure: 3 g of silicalite were mixed with 80 mg of β-PP and 4 mL of 2,2,4-trimethylpentane in air at room temperature; the resulting slurry was stirred for approximately 3 h. The excess solvent was then removed by filtration and the solid washed with a further 4 mL of 2,2,4-trimethylpentane and allowed to dry in air for 10–16 h. In the case of liquid ketones, the amounts used were consistent with ~75% occupancy of the void volume of silicalite (0.19 mL/g). 2,2,4-Trimethylpentane was chosen due to its kinetic diameter (~6.5 Å) which is large enough to restrict the access of this molecule into ~6 Å channels (11).

Phosphorescence emission spectra (uncorrected, front face) were recorded using a computer-controlled Perkin-Elmer LS-5 fluorescence spectrometer. The excitation (at 254 nm) and emission bandpasses were 10 nm; the samples (under nitrogen) were contained in 3 × 7 mm Suprasil cells and an interference filter (254 nm) was placed in the excitation beam while a microscope slide was used as 300 nm emission cut-off.

Figure 1 compares the phosphorescence emission spectra of acetophenone and β-PP in silicalite (parts *A* and *B*, respectively) with that of β-PP in a methylcyclohexane glass at 77 K (Fig. 1*C*). The spectra observed are typical of aromatic ketones. The vibrational structure is evident; the differences between the spectra in parts *B* and *C* are the widths of the bands reflecting the temperature difference and the relative intensities of the bands. This latter effect seems to be also due to the temperature differences since a spectrum of β-PP in silicalite at 77 K is identical to that shown in Fig. 1*C*. The luminescence spectrum of silicalite itself was ca. 25 times weaker than those shown in Fig. 1 and no attempt was made to subtract this background. Silicalite is strongly reflecting, but does not absorb significantly in the region of interest; preliminary time-resolved diffuse reflectance measurements are consistent with these optical properties.

The initial phosphorescence lifetimes for β-PP and acetophenone in silicalite at room temperature were (0.18 ± 0.02) and (0.14 ± 0.02) ms, respectively. These values are to be compared with ca. 1 ns for β-PP at room temperature and ~1.0 ms in a methylcyclohexane glass at 77 K. We believe that the enhanced lifetime of the β-PP carbonyl triplet at room temperature is due to the steric restrictions imposed on the β-PP molecules in the channels of silicalite. Since the kinetic diameter of β-PP should be comparable to that of benzene (5.85

[1] NRCC No. 22764.

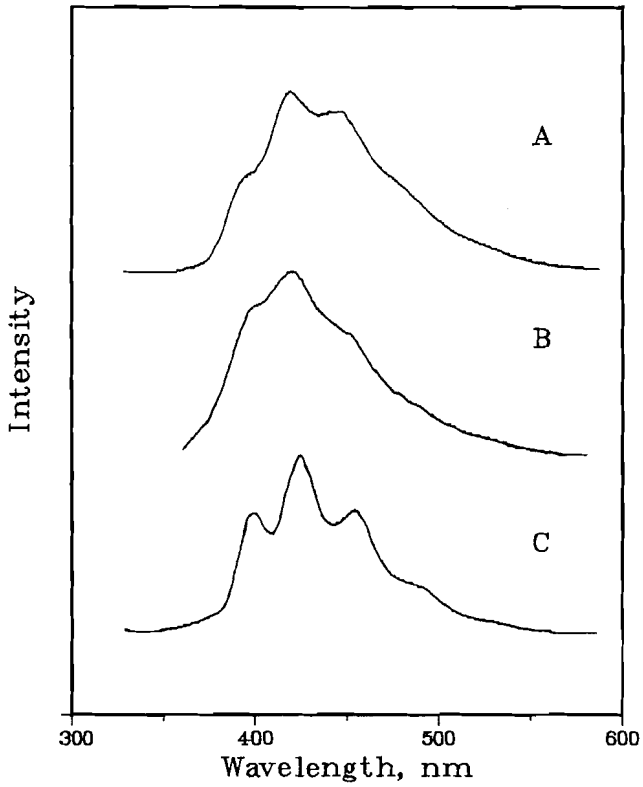

FIG. 1. Phosphorescence emission spectra (λ_{ex} = 254 nm) of *A*: acetophenone in silicalite at room temperature; *B*: β-PP in silicalite at room temperature; and *C*: β-PP in a methyl cyclohexane glass at 77 K.

Å), we can assume that β-PP has been included in the channel structure of silicalite. We suggest that the β-PP phosphorescence observed is not due to simple surface phenomena; to prove this point we subjected a sample of activated silica gel (Merck, 70–230 mesh) to the same experimental protocol with β-PP and found no phosphorescence emission comparable to that of Fig. 1*B*. We also examined a sample of β-PP adsorbed on Mordenite (Norton) which has a larger pore diameter (~9 Å) and observed no phosphorescence emission from β-PP. Thus, the phosphorescence emission of β-PP seems to depend critically on the channel dimensions of the supporting matrix.

The stabilization of triplet β-PP in the channels of silicalite can be ascribed to the impossibility of the molecule to adopt a conformation which would allow quenching by the β-phenyl group.

The channel dimension of silicalite is comparable to that found in urea inclusion complexes (12), albeit the crystal of silicalite is much more stable than urea adducts. In the case of urea inclusion adducts we found that alkanones undergo photodecomposition via the Norrish Type II mechanism and lead to a larger cyclization to fragmentation ratio than in homogeneous solution (13). We expect that included ketones in silicalite, with linear hydrocarbon chains, will also undergo photodecomposition. Indeed, we find that a sample of valerophenone included in silicalite shows increasing phosphorescence emission after uv irradiation (~300 nm), i.e., the included (non-luminescent) valerophenone is converted to acetophenone which yields strong phosphorescence emission.

Since silicalite and other zeolites are not only efficient molecular sieves or solid matrices but also very potent catalysts, further studies of the photochemical behaviour of zeolite supported molecules are expected to yield unique opportunities for understanding reaction mechanisms and provide new photocatalytic pathways.

Annulation via donor–acceptor reagents. An efficient total synthesis of (±)-$\Delta^{9(12)}$-capnellene

EDWARD PIERS AND VERANJA KARUNARATNE

Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6

Received November 25, 1983

EDWARD PIERS and VERANJA KARUNARATNE. Can. J. Chem. **62**, 629 (1984).

A short, efficient total synthesis of the racemic form of the marine sesquiterpenoid (−)-$\Delta^{9(12)}$-capnellene (**1**) is described. The key steps of the synthesis are two methylenecyclopentane annulation sequences (**14** → **16**; **22** → **24**) involving the

$CuBr \cdot Me_2S-BF_3 \cdot Et_2O$ catalyzed conjugate addition of the Grignard reagent **13** to the enones **14** and **22**, followed by intramolecular alkylation (KH, tetrahydrofuran) of the resultant adducts **15** and **23**, respectively.

EDWARD PIERS et VERANJA KARUNARATNE. Can. J. Chem. **62**, 629 (1984).

On décrit une synthèse totale qui est à la fois courte et efficace de la forme racémique du sesquiterpènoide marin, (−)-$\Delta^{9(12)}$-capnellène (**1**). Les étapes clés de la synthèse sont deux séries d'annellation de méthylènecyclopentanes (**14** → **16**; **22** → **24**) impliquant l'addition conjuguée, catalysée par le $CuBr \cdot Me_2S-BF_3 \cdot Et_2O$, du réactif de Grignard **13** aux énones **14** et **22**, qui est suivie par une alkylation intramoléculaire (KH, tétrahydrofuranne) des adduits **15** et **23** qui en résultent.

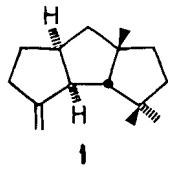
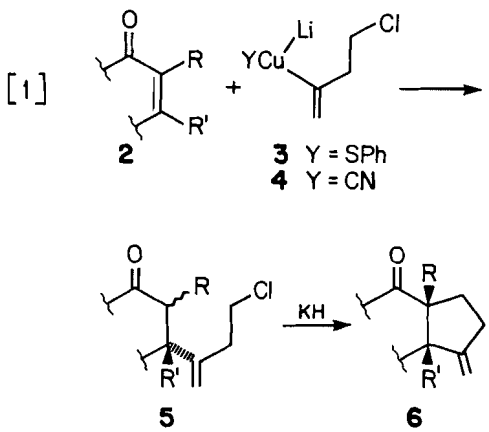
The $C_{15}H_{24}$ hydrocarbon (−)-$\Delta^{9(12)}$-capnellene, isolated by Djerassi and co-workers from the soft coral *Capnella imbricata* (Quoy and Gaimard, 1833) and shown to possess the substituted tricyclo[6.3.0.$0^{2,6}$]undecane structure **1** (1), is the parent



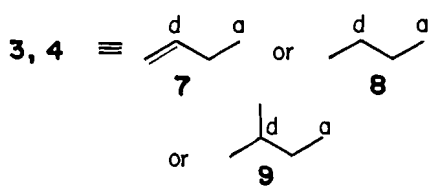
1

substance of a number of capnellane-type sesquiterpenoids (2). This structurally interesting natural product has received considerable attention from the community of synthetic organic chemists and a number of elegant syntheses of (±)-**1**, via a variety of interesting approaches, have been reported (3).

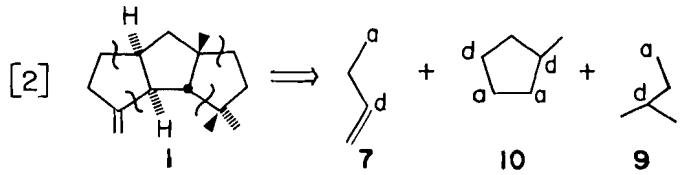
Recently, we described (4*a*) a new methylenecyclopentane annulation sequence illustrated in general terms by eq. [1] (**2** → **5** → **6**). In this process, the novel cuprate reagents **3** and **4** serve



as efficient equivalents to the 1-butene d^2, a^4 synthon **7**. However, it should be recognized that suitable synthetic manipulation (e.g. hydrogenation or cyclopropanation–hydrogenation) of the carbon–carbon double bond of **7** would make reagents **3** and **4** equivalent to the synthons **8** and **9** as well. Therefore,



it appeared that a synthesis of (±)-$\Delta^{9(12)}$-capnellene (**1**) might be achieved expeditiously via the synthetic combination of substances equivalent to the synthons **7**, **10**, and **9**, derived from **1** by the retrosynthetic disconnections shown in eq. [2]. In such an approach, both of the "outside" five-membered rings



would be added to the central ring via the recently developed annulation sequence mentioned above (cf. eq. [1]).

Transmetallation (MeLi, tetrahydrofuran, −78°C) of 4-chloro-2-(trimethylstannyl)-1-butene (**11**) (4*b*, 5), followed by successive addition of anhydrous $MgBr_2$ (1.2 equiv.), $CuBr \cdot Me_2S$ (0.25 equiv.), 2-methyl-2-cyclopenten-1-one (**14**)[1] (0.83 equiv.), and $BF_3 \cdot Et_2O$ (1.0 equiv.) to the resultant solution of 4-chloro-2-lithio-1-butene (**12**) (4), afforded, after a reaction time of 2 h and suitable work-up, the chloro ketone **15** (80% yield).[2,3] Treatment of the latter substance with KH in tetrahydrofuran at room temperature provided, in 75% yield, the annulation product **16**.

Reduction of **16** ($LiAlH_4$, ether) gave the alcohols **17** (95%, mixture of epimers) which, upon reaction with $CH_2I_2-Et_2Zn$ (toluene, 50–60°C, dry air) (7), was converted into the cyclopropanes **18** (76%).[4] Hydrogenation (H_2, Pt, HOAc, room temperature) of the latter substance, followed by oxidation ($C_5H_5N \cdot CrO_3 \cdot HCl$, NaOAc, CH_2Cl_2 (8)) of the resultant mixture of alcohols **19**, afforded (81% overall) the bicyclic ketone **20**.

In order to allow for the addition of the second five-membered ring, the ketone **20** had to be converted into the corresponding enone **22**. Thus, compound **20** was transformed (Me_3SiI (9), Et_3N, CH_2Cl_2, −78°C, 15 min) into the enol ether **21** which, upon reaction with $Pd(OAc)_2$ (1 equiv.) in acetonitrile (3 h, room temperature) (10), provided the required enone **22** in 74% overall yield.

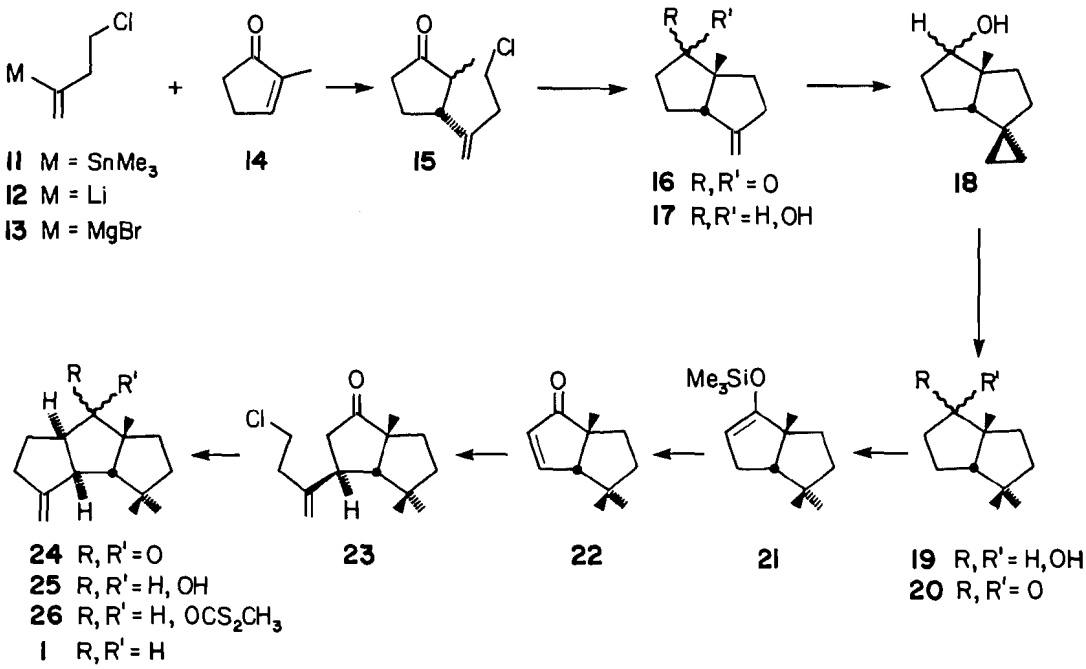
On the basis of steric considerations, conjugate addition of nucleophilic species to the enone **22** would be expected to take place from the convex side of the molecule. Indeed, subjection of **22** to reaction conditions very similar to those involved in the transformation of **14** into **15** produced a single addition product **23**, which was converted readily into the annulation product **24**

[1] We are grateful to Professor A. B. Smith III and Dr. M. D. Taylor for a generous sample of this material and for detailed procedures regarding its preparation (see ref. 6).

[2] This procedure, involving $CuBr \cdot Me_2S-BF_3 \cdot Et_2O$ catalyzed addition of the Grignard reagent **13** to the enone **14**, was more consistently successful than the corresponding additions employing the cuprate reagents **3** and **4**.

[3] All compounds reported herein exhibited spectral data in full accord with structural assignments. In addition, new compounds were fully characterized and gave satisfactory high resolution mass spectrometric molecular mass determinations.

[4] Subjection of the keto alkene **16** to similar reaction conditions gave very poor yields (~25–30%) of the corresponding keto cyclopropane.



(69% from **22**). Subjection of the latter substance to reduction ($LiAlH_4$, ether), followed by deoxygenation (NaH, CS_2, MeI, tetrahydrofuran; *n*-Bu_3SnH, toluene, reflux (11)) of the resultant mixture of alcohols **25** via the methyl xanthates **26**, afforded (56% from **24**) (±)-$\Delta^{9(12)}$-capnellene (**1**). The synthetic material, purified by column chromatography and distillation, exhibited spectral data (ir, ^1H nmr) and chromatographic behavior (thin-layer and gas–liquid chromatography) identical with those of a sample of (±)-**1** obtained from Professor R. D. Little.[5]

Synthesis and crystal structure of tri(μ-carbonyl)bis[methyltris(1-pyrazolyl)gallato]dirhodium – benzene (1:1)

BRENDA M. LOUIE, STEVEN J. RETTIG, ALAN STORR, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received July 11, 1983

BRENDA M. LOUIE, STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **62**, 633 (1984).

The synthesis, physical properties, and crystal structure of the dirhodium species $[MeGa(N_2C_3H_3)_3]_2Rh_2(\mu\text{-}CO)_3$ containing three carbonyl bridges are reported. Crystals of tri(μ-carbonyl)bis[methyltris(1-pyrazolyl)gallato]dirhodium – benzene (1:1) are monoclinic, a = 11.660(4), b = 15.2917(7), c = 11.750(4) Å, β = 119.09(1)°, Z = 2, space group $P2_1$. The structure was solved by conventional heavy-atom techniques and was refined by full-matrix least-squares procedures to R = 0.030 and R_w = 0.033 for 2604 reflections with $I \geq 3\sigma(I)$. The molecule contains a Rh—Rh single bond of 2.5818(8) Å bridged by three CO ligands, the overall molecular symmetry being close to D_{3h}. Other important mean structural parameters are: Rh—C = 2.007(10), Rh—N = 2.181(14) Å, Rh—C—Rh = 80.1(5)°, and Rh—C—O = 140.0(7)°.

BRENDA M. LOUIE, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **62**, 633 (1984).

On rapporte la synthèse, les propriétés physiques et la structure cristalline des dérivés du dirhodium $[MeGa(N_2C_3H_3)]_2$-$Rh_2(\mu\text{-}CO)_3$ contenant trois groupes carbonyles en position de ponts. Les cristaux de tri(μ-carbonyl)bis[méthyltris(pyrazolyl-1)gallato]dirhodiumbenzène (1:1) appartiennent au groupe d'espace monoclinique $P2_1$ avec a = 11,660(4), b = 15,2917(7) et c = 11,750(4) Å, β = 119,09(1)°, Z = 2. On a résolu la structure par les techniques conventionnelles de l'atome lourd et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'a des valeurs de R = 0,030 et de R_w = 0,033 pour 2604 réflexions avec $I \geq 3\sigma(I)$. La molécule contient une liaison simple Rh—Rh de 2,5818(8) Å maintenue en position de pont par trois ligands CO, la symétrie moléculaire globale est voisine de D_{3h}. Les principaux autres paramètres strueturaux moyens sont: Rh—C = 2,007(10), Rh—N = 2,181(14) Å, Rh—C—Rh = 80,1(5)° et Rh—C—O = 140,0(7)°.

[Traduit par le journal]

Introduction

Our continuing investigations into the coordinating properties of pyrazolyl-gallate ligands have recently entered the fertile field of rhodium chemistry. Subtle differences between the cyclopentadienyl, $C_5H_5^-$, and methyltris(1-pyrazolyl)gallate, $MeGa(N_2C_3H_3)_3^-$, ligands have been discussed in a previous publication (1). The present paper extends this theme in reporting the synthesis and structure of a unique dimeric rhodium system with three bridging carbonyl groups and end-capping $MeGa(N_2C_3H_3)_3^-$ ligands, a compound having no counterpart in cyclopentadienyl rhodium carbonyl chemistry.

Experimental

Starting materials

Air-sensitive materials were handled in oxygen-free dry nitrogen. Tetrahydrofuran (THF) was dried by refluxing over sodium/benzophenone and used immediately following distillation. Benzene was dried by refluxing over molten potassium followed by distillation and methylene chloride by refluxing over P_2O_5 prior to distillation. $[Rh(CO)_2Cl]_2$ (Strem Chemicals) was sublimed *in vacuo* before use. The sodium salt of the methyltris(1-pyrazolyl)gallate ligand, $Na^+[MeGa(N_2C_3H_3)_3]^-$, was prepared as a THF solution as described earlier (1).

Synthesis of $[MeGa(N_2C_3H_3)_3]_2Rh_2(\mu\text{-}CO)_3$

The ligand, $Na^+[MeGa(N_2C_3H_3)_3]^-$ (1.790 mmol in 100 mL THF), was added to a stirred solution of $[Rh(CO)_2Cl]_2$ (0.348 g, 0.895 mmol) in 20 mL THF. The resulting mixture was refluxed for 8 h during which time the initially orange-colored solution turned lemon yellow. The mixture was filtered and the solvent allowed to evaporate slowly from the filtrate to yield a yellow product. This was recrystallized from CH_2Cl_2/C_6H_6 as lemon-yellow needles in 80% yield. The use of an excess of the gallate ligand in the reaction gave $[MeGa(N_2C_3H_3)_3]_2$-$Rh_2(\mu\text{-}CO)_3$ as the only isolable rhodium product. The analysis figures for the crystalline product indicated a 1:1 benzene solvate complex, as found in the crystal structure determination. The analysis results reported below are for the finely ground product after pumping *in vacuo* for 36 h at 45°C. *Anal.* calcd. for $[MeGa(N_2C_3H_3)_3]_2$-$Rh_2(\mu\text{-}CO)_3$: C 32.05, H 2.79, N 19.51; found: C 31.75, H 2.90, N 19.20%. ν_{CO} 1825 cm^{-1} (Nujol), 1827 cm^{-1} (CH_2Cl_2). ^1H nmr (C_6D_6; Fig. 1) τ = 9.83 s (Ga—Me), 3.88 t (pz—H^4), 2.78 d (pz—H^5), 1.93 d (pz—H^3) (τ values refer to $\tau_{C_6H_6}$ = 2.84 ppm, pz = pyrazolyl $N_2C_3H_3$, J_{HCCH} = ~2 Hz for pz protons. Assignment of pz—H^3 and pz—H^5 follows from assignment of other pyrazolyl complexes (1, 2)). The mass spectrum of the title compound showed clearly the parent ion, P^+ (28%), and a strong signal due to the $P - 2CO - 2Me^+$ ion (91%) based upon the most intense peak $N_2C_3H_4^+$ (100%).

Spectra

Mass spectra were collected on a (Kratos) AEI MS 50 spectrometer at 70 eV with an ion source temperature of 200°C. Infrared spectra were recorded on a Perkin-Elmer 598 spectrometer and the ^1H nmr spectrum on a Bruker WP80 spectrometer using FT techniques.

X-ray crystallographic analysis of tri(μ-carbonyl)bis[methyltris(1-pyrazolyl)gallato]dirhodium – benzene (1:1)

A crystal bounded by the 8 faces (followed by their distances in mm from a common origin): ±(1 0 0), 0.056, ±(0 1 0), 0.250, ±(0 0 1), 0.056, ±(1 0 −1), 0.063 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 35–41°) measured on a diffractometer with Mo-Kα Radiation (λ(Kα$_1$) = 0.70930, λ(Kα$_2$) = 0.71073 Å). Crystal data at 22°C are:

$C_{29}H_{30}Ga_2N_{12}O_3Rh_2$ fw = 939.89

Monoclinic, a = 11.660(4), b = 15.2917(7), c = 11.750(4) Å, β = 119.09(1)°, V = 1830.6(9) Å^3, Z = 2, ρ_c = 1.705 g cm^{-3}, $F(0\,0\,0)$ = 928, μ(Mo-Kα) = 23.70 cm^{-1}. Absent reflections: $0k0$, k odd, space group $P2_1$ (C_2^2, No. 4) from structure analysis.

Intensities were measured with graphite-monochromated Mo-Kα radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 1.26–10.06° min^{-1} over a range of (0.65 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 3%.

After data reduction,[1] an absorption correction was applied using

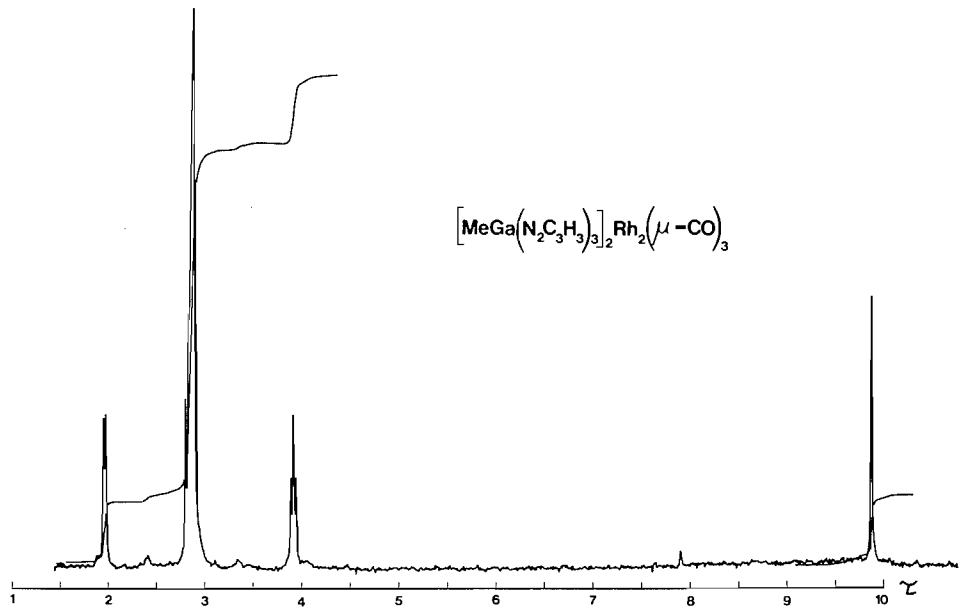

FIG. 1. ^{1}H nmr spectrum of $[MeGa(N_2C_3H_3)_3]_2Rh_2(\mu\text{-}CO)_3$.

the Gaussian integration method (3, 4). Transmission factors ranged from 0.729 to 0.789 for 96 integration points. Of the 4339 independent reflections measured, 2604 (60.0%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The systematic absences allow space groups $P2_1$ or $P2_1/m$, the former being indicated by the Patterson function and verified by subsequent calculations. The coordinates of the Rh and Ga atoms were determined from the Patterson function and those of the remaining atoms from subsequent difference syntheses. Full-matrix least-squares refinement of all non-hydrogen atoms except those associated with the solvate with anisotropic thermal parameters resulted in $R = 0.046$. A difference map calculated at this point revealed a twofold disorder of the solvent benzene molecule as well as the positions of most of the hydrogen atoms. The disordered benzene was included in the refinement as two rigid groups having idealized geometry. The site occupancies were initially fixed at 0.5 and later adjusted to 0.6 and 0.4 to give nearly equal group temperature factors. Hydrogen atoms associated with the ordered complex molecule were included as fixed atoms with idealized positions (C—H = 0.97 Å, $U_H = 1.1\,U_C$ for trigonal-planar H, C—H = 0.98 Å, $U_H = 1.2\,U_C$ for methyl H). The scattering factors of ref. 5 were used for non-hydrogen atoms and those of ref. 6 for hydrogen atoms. Anomalous scattering factors from ref. 7 were used for the Rh and Ga atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of refinement. Unobserved reflections were not included in the refinement. Convergence was reached at $R = 0.030$ and $R_w = 0.033$ for 2604 reflections with $I \geq 3\sigma(I)$. For all 4339 reflections $R = 0.079$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma\||F_o| - |F_c|\|/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.04 and 0.70σ, respectively. The mean error in an observation of unit weight was 1.328. A final difference map showed a maximum residual density of 0.53 e Å^{-3} in the vicinity of the disordered solvent. The mirror-image structure refined to slightly higher values of both R and R_w. The final positional and thermal parameters appear in Tables 1 and 4[2], respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2] Calculated hydrogen coordinates and thermal parameters and rigid group parameters (Tables 5 and 6) are included as supplementary material. Selected bond distances and angles appear in Tables 2 and 3, respectively.

[2] The structure factor table, Table 4 (anisotropic thermal parameters), and other material mentioned in the text are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Results and discussion

The title compound, $[MeGa(N_2C_3H_3)_3]_2Rh_2(\mu\text{-}CO)_3$, is the first dirhodium complex containing three carbonyl bridges to be structurally characterized. The compound crystallizes as air-stable lemon-yellow needles which begin to darken in color at ~240°C. The crystals are slightly soluble in benzene and soluble in THF and CH_2Cl_2. The proton nmr spectrum (Fig. 1), the single absorption in the bridging carbonyl region and the absence of any terminal metal carbonyl bands in the ir spectrum, all indicated a very symmetrical structure for the dimeric species in solution. The crystal structure determination (see below) confirmed our predictions of a dirhodium species containing three carbonyl bridges (Fig. 2). Earlier reports (8,9) on a similar boron compound, $([HB(N_2C_3H_3)_3]_2Rh_2(CO)_3)$, suggested the possibility of a dimeric $(\mu\text{-}CO)_3$ bridged structure as found for the present title compound, but a polymeric structure, befitting the insoluble nature of the complex, was felt more likely. It is interesting to compare our findings with those reported in the related field of cyclopentadienyl rhodium carbonyl complexes. In this area the cyclopentadienyl rhodium dicarbonyl compound, $(\eta^5\text{-}C_5H_5)Rh(CO)_2$ (10), and its pentamethylcyclopentadienyl analog, $(\eta^5\text{-}C_5Me_5)Rh(CO)_2$, are quite stable at room temperature but may be converted by various techniques into a variety of associated rhodium species (11–15). In contrast the corresponding $[MeGa(N_2C_3H_3)_3]$-$Rh(CO)_2$ compound has proven to be elusive although earlier reports have mentioned the isolation of the corresponding tris(3,5-dimethylpyrazolyl)borate complex, $[HB(N_2C_5H_7)_3]$-$Rh(CO)_2$, as a stable entity (16, 17). Our attempts to prepare a gallium analog of this species, viz. $[MeGa(N_2C_5H_7)_3]Rh(CO)_2$, have so far resulted only in the appearance of the dimeric rhodium complex, $[Rh(N_2C_5H_7)(CO)_2]_2$, with bridging 3,5-dimethylpyrazolyl moieties. The cyclopentadienyl rhodium complex with the formulation directly analogous to the title compound, $(\eta^5\text{-}C_5H_5)_2Rh_2(CO)_3$, has been structurally character-

ized by Mills and Nice (12). It displays a markedly different geometrical arrangement, however, in that only one bridging carbonyl group is present with the other two carbonyls appearing as terminal CO ligands, one on each rhodium atom. Both the $[MeGa(N_2C_3H_3)_3]_2Rh_2(\mu\text{-}CO)_3$ and the $(\eta^5\text{-}C_5H_5)_2Rh_2(\mu\text{-}CO)(CO)_2$ complexes have a Rh—Rh single bond, in addition to the bridging ligands, holding the dimeric unit together. It is conjectured that the more sterically demanding $MeGa(N_2C_3H_3)_3^-$ ligand forces a $(\mu\text{-}CO)_3$ arrangement on $[MeGa(N_2C_3H_3)_3]_2Rh_2(\mu\text{-}CO)_3$.

Steric interactions have been held responsible for a similar terminal vs. bridging CO structural arrangement in a series of related compounds. Thus removal of CO from $(\eta^5\text{-}C_5Me_5)Rh(CO)_2$ can lead to the dirhodium complex, $(\eta^5\text{-}C_5Me_5)_2Rh_2(CO)_2$, having two bridging carbonyls and a formal double bond between the rhodium centres (14, 15). Addition of diazoalkanes to this dimeric rhodium species has led to products of two structural types depending on the R groups attached to the bridging carbene moiety. In the first type the arrangement is similar to the $(\eta^5\text{-}C_5H_5)_2Rh_2(CO)_3$ complex with a bridging carbene and two terminal CO ligands (one per Rh). In the second type, where the bridging carbene does not allow the $\eta^5\text{-}C_5Me_5$ groups to tilt from their positions at right angles to the Rh—Rh bond axis, a system containing three bridging ligands, analogous to that of $[MeGa(N_2C_3H_3)_3]_2Rh_2(\mu\text{-}CO)_3$, is observed, viz $(\eta^5\text{-}C_5Me_5)_2Rh_2(\mu\text{-}CO)_2(\mu\text{-}CR_2)$ (15).

The title compound might also be compared with other "$M_2(\mu\text{-}CO)_3$" systems such as $(\eta^5\text{-}C_5Me_5)_2Re_2(\mu\text{-}CO)_3$ (18), $(\eta^4\text{-}C_4R_4)_2Fe_2(\mu\text{-}CO)_3$ (19), and $(\eta^6\text{-}C_6H_6)_2Cr_2(\mu\text{-}CO)_3$ (20), although, rather than a single M—M bond, these three examples all require a formal M≡M triple bond for an eighteen electron configuration about the transition metal centres. Attempts to prepare the dirhenium complex, $[MeGa(N_2C_3H_3)_3]_2Re_2(\mu\text{-}CO)_3$, by uv irradiation of the complex $[MeGa(N_2C_3H_3)_3]Re(CO)_3$, have so far proven unsuccessful, unreacted starting material being recovered in high yield (21).

The crystal structure of $[MeGa(N_2C_3H_3)_3]_2Rh_2(\mu\text{-}CO)_3 \cdot C_6H_6$ consists of well separated complex and benzene solvate molecules. Although there is no crystallographically imposed molecular symmetry, the $[MeGa(N_2C_3H_3)_3]_2Rh_2(\mu\text{-}CO)_3$ molecule displays approximate D_{3h} symmetry in the solid state, consistent with the evidence discussed above for the complex in solution. There are a number of small, but statistically significant departures from this idealized symmetry (see Tables 2 and 3), but none of these are believed to be of any chemical importance. The complex features a face-shared bioctahedral geometry, the metal–metal bond resulting in a 7-coordinate capped octahedral arrangement about each Rh atom. The relevant

mean[3] geometrical parameters are: Rh—Rh = 2.5818(8), Rh—N = 2.181(14), Rh—C = 2.007(10) Å, C—Rh—C = 83.1(8), N—Rh—N = 90.3(8), C—Rh—N = 93.2(10) (*cis*) and 174.9(9) (*trans*), Rh—C—Rh = 80.1(5), and Rh—C—O = 140.0(7)°.

Cowie and Dwight, in discussing "A-frame" dirhodium species with a single bridging carbonyl ligand and a Rh—Rh single bond (22), list 2.617–2.8415 Å as a range for such single bond distances. The title complex has a Rh—Rh bond of 2.5818(8) Å, significantly shorter than the lowest values quoted and considerably shorter than the value of 2.681(2) Å observed in the singly carbonyl bridged species $(\eta^5\text{-}C_5H_5)_2Rh_2(CO)_3$ (12). The Rh—Rh and mean Rh—C(O) distances of 2.612(2) and 2.039 Å and the mean Rh—C(O)—Rh angle of 80.4° found in the carbene bridged complex $(\eta^5\text{-}C_5Me_5)_2Rh_2(\mu\text{-}CO)_2(\mu\text{-}CR_2)$ (where CR_2 = tetrabromocyclopentadienylidene) (15) may be compared to those presented here for

[3] Here and elsewhere in this report, mean values refer to weighted means with rms deviations from the mean in parentheses.

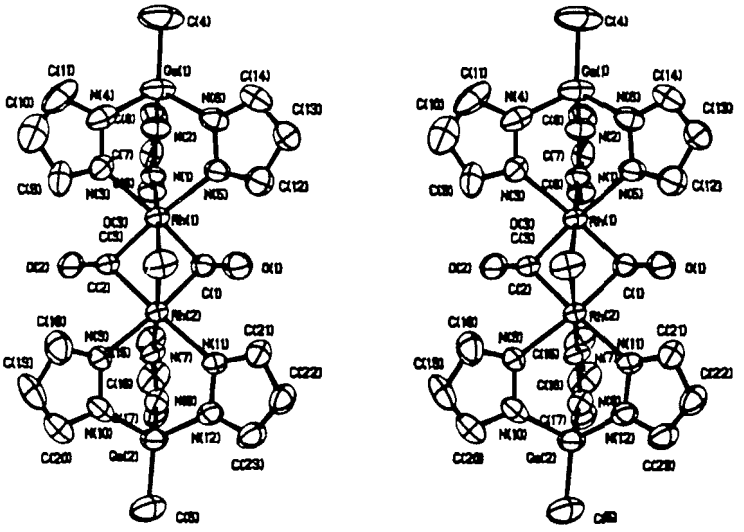

FIG. 2. Stereoscopic view of the $[MeGa(N_2C_3H_3)_3]_2Rh_2(\mu\text{-}CO)_3$ molecule. 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

$[MeGa(N_2C_3H_3)_3]_2Rh_2(\mu\text{-}CO)_3$. In this μ-carbene complex, the only other triply-bridged dirhodium complex of this type to be structurally characterized, it was argued that the strictly planar C_5Br_4 bridge forces the CO ligands into the bridging positions. The alternative structure, with a bridging carbene and one terminal CO on each Rh (as observed for R = COOMe (15)), would lead to severe steric interactions between the Me groups of the (η^5-C_5Me_5) ligands and the bromo substituents of the carbene.

The geometry of the tris(1-pyrazolyl)gallate ligand is similar to that noted previously (1, 23). All six pyrazolyl groups are planar to within experimental error, as are the three Rh_2CO moieties.

$[MeGa(N_2C_3H_3)_3]_2Rh_2(\mu\text{-}CO)_3$ remains unchanged when stirred in THF or C_6H_6 overnight in an N_2 atmosphere. However, under reflux temperatures all bridging carbonyls are lost and the dimer $[Rh(\mu\text{-}N_2C_3H_3)(CO)_2]_2$ is isolated. Similarly, stirring the title compound with PPh_3 in THF overnight effects no change in the starting materials, but refluxing the reaction mixture for 8 h produces >90% yield of the dimer $[Rh(\mu\text{-}N_2C_3H_3)(CO)(PPh_3)]_2$. Stirring $[MeGa(N_2C_3H_3)_3]_2Rh_2(\mu\text{-}CO)_3$ for 0.5 h in C_6H_6 with 2 molar equivalents of I_2 produces a deep red–orange solution from which a black solid can be isolated. Based upon ir data, this black solid contains no carbonyl groups. Preliminary experiments suggest that neither the di-iodide $[MeGa(N_2C_3H_3)_3]RhI_2$, nor the iodine bridged dimer $[MeGa(N_2C_3H_3)_3]_2Rh_2(\mu\text{-}I)_2$, are present in the reaction products. Investigations are continuing in this and related areas.

Received July 21, 1983

J. M. CAMPELO, A. GARCIA, D. LUNA, and J. M. MARINAS. Can. J. Chem. **62**, 638 (1984).

The basic properties of Al_2O_3, $AlPO_4$, $AlPO_4-Al_2O_3$, $AlPO_4-SiO_2$, and SiO_2, determined by the adsorption of acid compounds using a spectrophotometric method, were investigated. The surface concentration of basic sites varied greatly from one to another of the solid systems.

An attempt was made to relate the activity toward diacetone alcohol retroaldolisation with the surface basic properties determined by this spectrophotometric method, from the irreversible adsorption of different organic acids in cyclohexane at 298 K. It has been shown that the total basicity (vs. acrylic acid) of the catalyst is the most influential property in the retroaldolisation activity. Experimental results show a zero-order kinetics when the acid sites of the samples are blocked. Al_2O_3 shows the highest basic site concentration and the distance between the number of acid and basic sites seems to control the catalytic activity.

J. M. CAMPELO, A. GARCIA, D. LUNA et J. M. MARINAS. Can. J. Chem. **62**, 638 (1984).

On a étudié les propriétés basiques du Al_2O_3, du $AlPO_4$, du $AlPO_4-Al_2O_3$, du $AlPO_4-SiO_2$ et du SiO_2 par adsorption de composés acides en faisant appel à une méthode spectrophotométrique. La concentration des sites basiques à la surface varie beaucoup avec les systèmes solides.

On a essayé de relier l'activité vis-à-vis de la rétroaldolisation du diacétone alcool avec les propriétés basiques des surfaces telles que déterminées par cette méthode spectrophotométrique, appliquée à l'adsorption irréversible de divers acides organiques dans le cyclohexane à 298 K. On montre que la basicité totale (vs. l'acide acrylique) du catalyseur est la propriété la plus importante dans l'activité vis-à-vis la rétroaldolisation. Les résultats expérimentaux montrent une cinétique d'ordre zéro quand on bloque les sites acides des échantillons. Le Al_2O_3 possède la plus grande concentration de sites basiques et la distance entre le nombre de sites acides et basiques semble contrôler l'activité catalytique.

Introduction

The acid properties of solids have been extensively studied in connection with their catalytic activity, while surface basicity has scarcely been investigated. In this sense, the retroaldolisation of diacetone alcohol (4-hydroxy-4-methyl-2-pentanone) is known to be catalyzed exclusively by bases, and the activity of catalysts in this reaction is therefore believed to be a measure of their basicity (1–6). Thus, the retroaldolisation of diacetone alcohol has been proposed as a test for basic catalysts (3, 4, 6).

Amorphous aluminium orthophosphates, $AlPO_4$, and $AlPO_4-Al_2O_3$ and $AlPO_4-SiO_2$ systems possess acid surface sites of different strengths, capable of taking part in catalytic processes, viz. dehydration, isomerization, alkylation, etc. (7–9). We have shown a correlation between the acidity and the alcohol dehydration activity, as well as the skeletal isomerization of cyclohexene (8–10).

The purpose of this work is to determine the basic properties of these solids by a spectrophotometric method already developed for the determination of acid sites, in order to attempt to correlate them to their catalytic acitivity in the retroaldolisation of diacetone alcohol.

The basicity of $AlPO_4$, $AlPO_4-Al_2O_3$, $AlPO_4-SiO_2$, Al_2O_3, and SiO_2 catalysts has been determined by the spectrophotometric method using acid compounds as titrants. Since the use of titrants with different pK_a and steric hindrance lets us obtain the total surface basicity as well as the relative number of sites accessible to adsorbed molecules, acrylic acid, phenol, and 2,6-di-*tert*-butyl-4-methylphenol were employed as titrant agents. All details concerning adsorption of probe molecules have been reported elsewhere (10–12).

The correlation between surface basicity and catalytic activity in the liquid phase retroaldolisation of diacetone alcohol is fulfilled for all catalysts examined, which leads us to the conclusion that the method described can be used for the characterization of basic properties of solid catalysts.

Experimental

Catalysts

Eight different catalysts were used: three $AlPO_4$ (Al/P = 1) that were obtained through precipitation, from aluminum chloride and phosphoric acid aqueous solutions, with aqueous ammonia (F), ethylene oxide (B), and propylene oxide (BP); a chemically pure alumina (AL) obtained by precipitation from aluminium nitrate by aqueous ammonia; a commercial silica (S) from Merck (Kieselgel 60, 70–230 mesh); two $AlPO_4-Al_2O_3$ (75:25 wt.%) systems obtained by gelification of aluminium orthophosphate with ethylene oxide (BA) and propylene oxide (BPA) on alumina AL; an $AlPO_4-SiO_2$ (20:80 wt.%) system (BS) obtained by gelification of $AlPO_4$ with ethylene oxide on silica S.

These solids, screened between 200–250 mesh, were dried at 380 K in air for 24 h, then calcined 3 h at 923 K in an electric muffle furnace, and stored in a desiccator.

Textural properties (surface area, pore volume, and main pore diameter, determined by nitrogen adsorption (BET method)) and surface acidity, determined by the spectrophotometric method (10–12), are summarized in Table 1.

Surface basicity measurement

The surface basicity was determined on the basis of the irreversible adsorption on the catalyst surface of appropriate acid substrates, following the same experimental procedure that was used previously for the determination of surface acidity (10). The adsorbates used (all from Merck, p.a.) were acrylic acid (AA, pK_a = 4.25), phenol (PH, pK_a = 9.9), and 2,6-di-*tert*-butyl-4-methylphenol (DTMPH, pK_a = 11.1). Adsorption was carried out from cyclohexane solutions (spectroscopic grade, Merck) at 298 K, and the solids were dried prior to each measurement at 390 K.

In each experiment, a freshly prepared titrant agent solution (10

mL) was pipetted into a cylindrical glass tube that previously was loaded with the solid (about 0.1 g). The tube was fitted with a ground glass stopper, shaken for 1 h at constant temperature, and the concentration of the organic acid was determined spectrophotometrically.

Since the amount of titrant adsorbed on the surface of the solid was determined spectrophotometrically, the validity of the Lambert–Beer law for the solution was checked, and the sorption experiments were developed at the wavelength of the maximum absorption (λ_{max}, nm).

The time required for the system to reach the equilibrium, at constant temperature (298 K), was checked for each solid and it was never more than 45 min.

Once the adsorption remains constant, a monolayer is assumed to have been formed. The chemical interaction, acid compound – surface, may be accomplished by applying the linear transformed Langmuir adsorption isotherm:

$$[1]\quad C/X = (1/b\,X_m) + (C/X_m)$$

where C is the concentration of acid substrate in solution in equilibrium with the adsorbed substrate, b is a constant, X is the amount of adsorbed substrate per gram of basic solid, and X_m is the saturation coverage in a monolayer, which corresponds to the theoretical amount of solute adsorbed by 1.0 g of solid system, if all the basic sites are covered.

The X_m value was assumed to be the number of molecules necessary to saturate the basic sites with pK_a equal to or greater than that from the acid adsorbate used. Thus, the irreversible adsorption of the acid compound was taken as a count of basic sites corresponding to a specific pK_a.

Finally, this method let us determine the basicity of white as well as deeply coloured solids.

Catalytic activity

In all cases, the catalytic acitivity measurements were carried out in a magnetically stirred 100-mL glass reactor, at 335 ± 1 K. Reactions were accomplished with 40 mL of 0.1 *M* cyclohexane solution of diacetone alcohol (DAA) and the amount of catalyst was varied between 0.3–1.0 g (≤ 0.07 mm). The operating variables, stirring rate and particule size, were so chosen as to eliminate diffusion control on the reaction rate.

The reaction rate was obtained by following the consumption of DAA with time and, as the plots of the drop of the DAA concentration vs. time were always linear, when the acid sites were blocked, the determination of the initial slope was straightforward.

The reproducibility for different samples was checked experimentally, and the measurements were repeated 2–3 times. The relative error was approximately 10%.

The retroaldolisation of DAA was followed by gas–liquid chromatography using a stainless steel column of 2 m, packed with 10% Carbowax 20M on Chromosorb P 80/100. The temperature of the column and injector was 370 K and that of the detector was 473 K. The detected reaction products were acetone and mesityl oxide. The latter appeared only when the acid sites were not blocked.

Cyclohexane and DAA, both Merck p.a., were used without further purification.

Results and discussion

Surface basicity measurement

From the plots of C/X vs. C we obtained straight lines, as can be seen in Fig. 1 where, as an example, the adsorption of PH on F, BP, and BPA samples appears so that, in all cases, the adsorption of acid titrants is consistent with the linear transformed Langmuir adsorption isotherm. Nevertheless, the adsorption is supposed to be of complex character because the surface exhibits centres of different strength, and the consistency with the Langmuir isotherm should be explained by formation of different bonds between the adsorbate and catalyst surface, which are approximately equivalent energetically, since a unique straight line is obtained.

The monolayer, X_m, was obtained from the slope of the plot C/X vs. C, and the distribution of the basic sites of various strengths on the catalyst surface are collected in Table 2. All experimental values are reproducible to within about 6% and the sequence obtained in all cases was: AA > PH > DTMPH, which is in accord with the pK_a of the titrant agent. Thus, because of their pK_a, by definition, the acrylic acid measured the total basicity of the samples. Moreover, the differences between the adsorbate values are a measure of both the number of weaker sites and the number of sites most accessible to adsorbed acid molecules, since the adsorption of DTMPH is influenced mainly by the steric effect of *t*-Bu groups.

The results obtained show that surface concentrations of

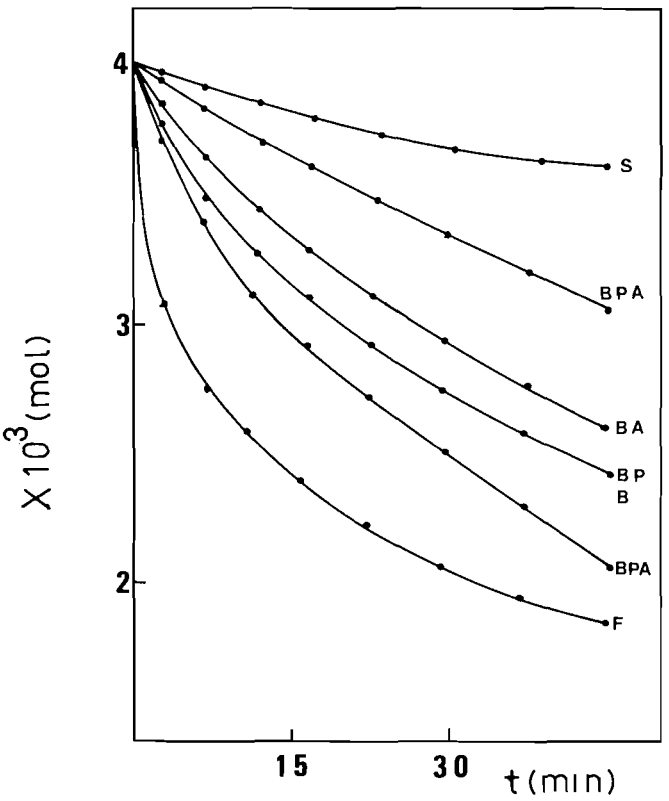

FIG. 2. Time dependence of consumption of DAA (X) in cyclohexane as solvent and at 335 K ($[DAA]_0 = 0.1$ *M*; 40 mL) with 520 mg of S, 343 mg of BPA, 524 mg of BA, 534 mg of BP, 544 mg of B, 537 mg of BPA, and 680 mg of F.

basic sites varied largely with the solid system. Thus the BP, AL, and BPA samples exhibit practically the same high total basicity (vs. acrylic acid) although the number of strong basic sites (vs. phenol) is different, the AL sample being the most basic solid.

Catalytic activity

In the catalytic action of bases in the retroaldolisation of DAA, it was found that the reaction rate is proportional to the concentration of hydroxy groups in the solutions of hydroxides in the concentration range 0.01–0.10 *M* (1). Tanabe *et al.* (2) had first applied this reaction to examining the properties of solid catalysts, beginning with the oxides of alkali earth metals (CaO, BaO, MgO, and SrO). Also, Nondek and Malek (6) chose this reaction to test the strength of basic sites on the surface of Al_2O_3, MgO, and Al_2O_3–MgO catalysts previously used in the aldol condensation of butyraldehyde (13).

It is worth mentioning that Tanabe (2) reported first-order kinetics for the retroaldolisation of DAA catalyzed by alkali earth metal oxides, while Nondek (6) found zero-order kinetics for the same reaction catalyzed by Al_2O_3, MgO, and Al_2O_3–MgO in nonpolar solvents, although for polar solvents, like 2-propanol, the kinetics of acetone formation is altered.

On the other hand, Malinowski and co-workers (14) found that, at 313 K, diacetone alcohol did not react on aluminosilicates and they attributed this result to strong acid sites of the catalysts that may hamper the retroaldolisation of DAA to acetone.

Because $AlPO_4$, Al_2O_3, SiO_2, $AlPO_4$–Al_2O_3, and $AlPO_4$–SiO_2 catalysts possess acid and basic sites capable of taking part in catalytic processes, an attempt has been made to correlate the activity to DAA retroaldolisation with the surface basicity determined by the spectrophotometric method developed by us.

In this sense, Fig. 2 shows the DAA consumption vs. time, with cyclohexane as solvent, for all catalysts studied. As can be seen, there exists a significant dependence between the solid system and its activity in the reaction of DAA.

The analysis of the reaction mixtures by means of glc shows that for the AL catalyst the only product detected was acetone, while for the remaining catalysts the reaction products were acetone and mesityl oxide, the latter appearing as a consequence of the dehydration of DAA on the acid sites of the catalysts.

The AL catalyst shows the greatest activity in the DAA retroaldolisation to acetone. Thus the distance between acidic sites and basic sites seems to control the catalytic activity. Therefore the kinetic study of the DAA retroaldolisation was carried out with the AL catalyst.

Figure 3 clearly demonstrates the independence of the reaction rate, r (mol min^{-1}), of the concentration of DAA and the dependence between the catalytic activity and the concentration of basic sites on the AL catalyst. The concentration of basic sites was varied by using different amounts of catalyst.

On the other hand, the plot of log r vs. log w, where w is the catalyst weight, is linear with a slope of 1.04, as can be seen in Fig. 4.

This result, together with those obtained with different stirring speeds where the reaction rate was independent of the stirring speed above 200 rpm, indicated that, in the range of operating variables, the reaction rates are controlled by the surface reaction and the data are free from transport influences. On the other hand, the reaction rates are zero order in DAA concentration.

During the reaction we did not observe a light brown substance deposited on the catalyst surface, reported by Tada (4) and Malinowski (5) as a consequence of the subsequent condensation reaction. This is probably because the DAA solution is so dilute.

The increase in the activity with an increasing number of basic sites leads us to conclude that the reaction proceeded in similar stages to those of aldol condensation, the proton abstraction from an undissociative adsorbed DAA molecule being the most probable rate-determining step:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

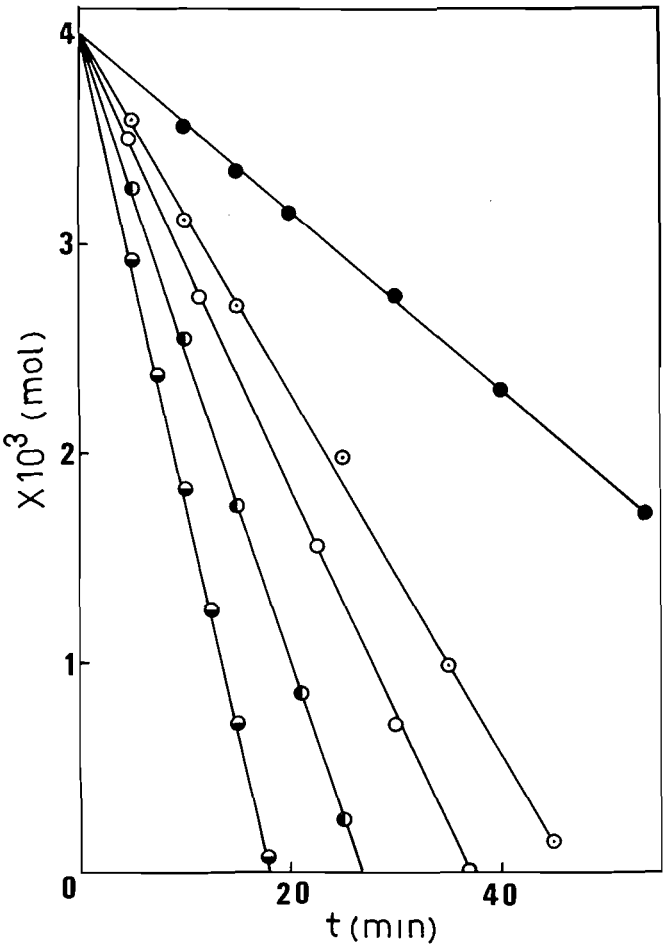

FIG. 3. Time dependence of consumption of DAA (X) as a function of AL loading ([DAA]$_0$ = 0.1 *M* in cyclohexane; 40 mL; 335 K). (●) 151 mg; (⊙) 310 mg; (○) 357 mg; (◐) 529 mg; (◒) 731 mg.

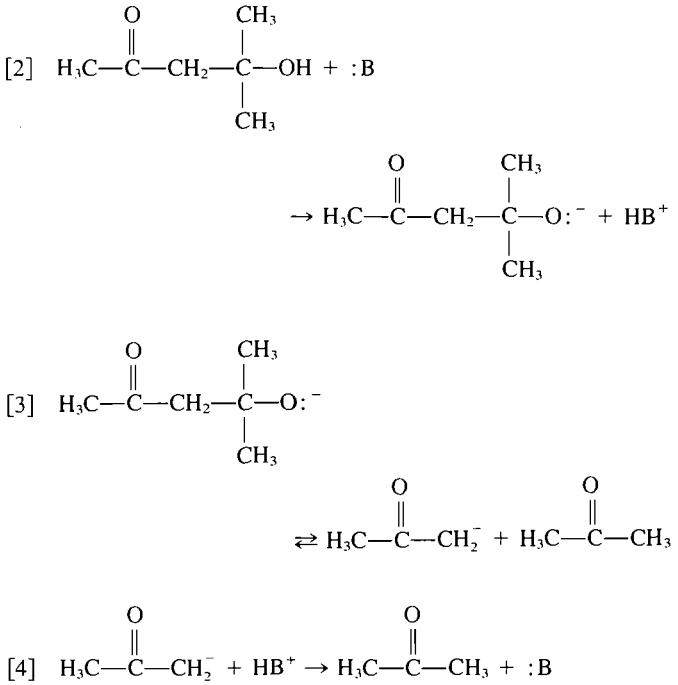

For the remaining catalysts, this reaction competes with the dehydration to mesityl oxide:

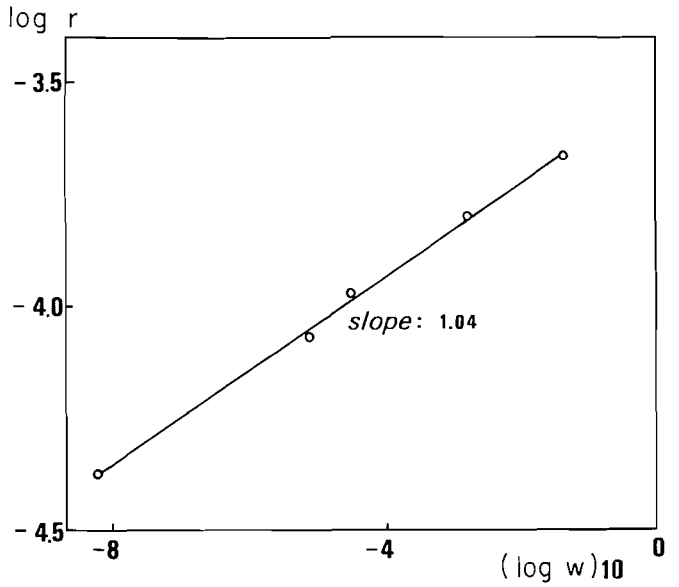

FIG. 4. Reaction order for catalyst weight.

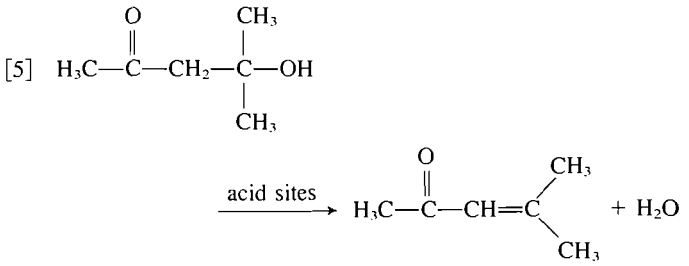

so that the consumption of DAA vs. time is not linear.

Much information about active sites can also be obtained by the blocking of the probable active sites by the adsorption of poisons associated with a simultaneous investigation of the reaction run in presence of the poisoned catalyst. In the present case, the active sites in the reaction have been identified by comparing the changes in the reaction rate of the alumina (AL) poisoned with different amounts of acrylic acid. The partial poisoning of the basic sites on the surface of the AL catalyst was performed as follows: a sample of dried catalyst was shaken in a cyclohexane solution of acrylic acid, which contained an amount of adsorbate lower than the stoichiometric amount of the surface basic sites. After 1 h, the excess of solution was removed and the solid was washed with cyclohexane. On this prepared catalyst, the retroaldolisation of DAA was carried out following the standard procedure; the results obtained are given in Table 3 and Fig. 5.

The progressive decrease of the reaction rate was parallel to the progressive increase in the acrylic acid added. Therefore there exists a significant dependence between the surface basicity measured with acrylic acid and the activity in the DAA retroaldolisation.

Furthermore, the plot of the reaction rate of DAA retroaldolisation vs. basicity of AL catalysts (vs. acrylic acid) is linear with regression coefficient above 0.99 and a slope of $1.055 \times 10^{-2}\ s^{-1}$. A "t-test" of significance shows that this is significant at a level better than 1%.

This correlation between the changes in concentration of the total surface basic sites and the activity of the reaction allows us to state unequivocally that these sites are active in the reaction.

[c] Nickel supported AL catalysts at 20 wt.% Ni with different basicity vs. acrylic acid (12).

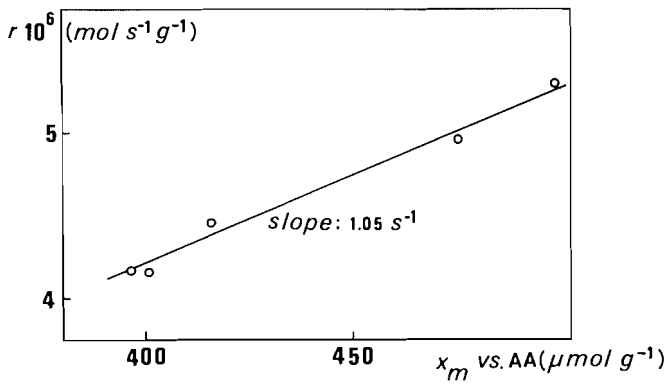

FIG. 5. Reaction rate vs. basicity of AL catalysts listed in Table 3 (basicity vs. acrylic acid).

As a consequence of the results obtained, a second step in this study was the poisoning of the acid sites on the surface of the solids, which was performed as follows: a sample of the dried catalyst was shaken in a cyclohexane solution of cyclohexylamine, which contained the adsorbate in the stoichiometric amount for the surface acid sites. After one hour, the excess of solution was removed and the catalyst was washed with cyclohexane. The retroaldolisation of DAA was then carried out on this prepared catalyst.

The rates of reaction of DAA retroaldolisation on catalysts with blocked acid sites, except AL, were independent of the concentration of DAA (Fig. 6). Thus, the retroaldolisation of DAA on all poisoned catalysts was found to follow zero-order kinetics, as in the case of the AL catalyst. The rates of reaction of retroaldolisation of DAA in this series of investigated catalysts are given in Table 4.

The changes of the reaction rates in the catalysts investigated are similar to those in the concentration of basic sites, although this relation is not linear as in the AL case, as correlations between X_m and r can exist only in a series of catalysts having the same strength of sites, since the Brönsted relationship must hold

$$[6] \quad r = G K_{diss}^{\alpha} \qquad \alpha \neq 1$$

This is valid for the AL catalysts of Table 3 where K_{diss} is more or less constant, but not for the remaining catalysts (Table 2 vs. Table 4) where acid sites of different strength are being compared.

From the intercept at the origin in the plot of C/X vs. C, we have obtained the b values that depend on the site strength. These values, although displaying a large experimental error,

are very different from one catalyst to another. Thus, no single-line correlation for all catalysts shown in Table 4 should be obtained. Furthermore, the different porous texture of the solids may also alter the adsorption of DAA and/or the titrant agent.

However, the activity – surface basicity correlation vs. acrylic acid is better than for other titrants, especially in the case of DTMPH, which is mainly influenced by steric hindrance of t-Bu groups. Thus the total basicity seems to be mainly responsible for the retroaldolisation of DAA, the sample AL being the most active catalyst.

Conclusions

The present investigation has provided conclusive evidence

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

that a correlation between surface basicity of solid systems, determined by a spectrophotometric method from the irreversible adsorption of organic acids in cyclohexane solution, and their activity in the retroaldolisation of DAA is established for catalysts when their acid sites are blocked.

The poisoning of active basic sites with acrylic acid demonstrated that the total surface basicity is the predominant factor in determining the activity of the catalyst.

The results obtained lead us to the conclusion that the method described above can be used for characterization of solid bases. When the solid catalysts exhibit strong acid sites, the retroaldolisation of DAA is accompanied by the formation of mesityl oxide as a consequence of the dehydration reaction.

Synthesis of tri- and tetrasaccharide haptens related to the *Asialo* forms of the gangliosides G_{M2} and G_{M1}[1]

SUBRAMANIAM SABESAN AND RAYMOND U. LEMIEUX
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 10, 1983

SUBRAMANIAM SABESAN and RAYMOND U. LEMIEUX. Can. J. Chem. **62**, 644 (1984).

Synthesis of βDGalNAc(1→4)βDGal(1→4)βDGlc—$O(CH_2)_8COOCH_3$ (**21**) and βDGal(1→3)βDGalNAc(1→4)βDGal-(1→4)βDGlc—$O(CH_2)_8COOCH_3$ (**33**) are presented starting from βDGal(1→4)βDGlc—$O(CH_2)_8COOCH_3$ (**1**) and D-galactose. Improvements in the preparations of D-galactal triacetate (**7**) and tri-*O*-acetyl-2-azido-2-deoxy-α-D-galacto-pyranosyl bromide (**11**) are reported. The syntheses proceeded by way of the tri-*O*-acetyl-2-deoxy-2-phthalimido-β-D-galacto-pyranosyl and 4,6-di-*O*-acetyl-3-*O*-(tetra-*O*-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-β-D-galactopyranosyl bromides (**18** and **30**), which, in turn, were prepared from the corresponding allyl glycosides (**15** and **23**). The ^{13}C chemical shifts for the tri- and tetrasaccharide portions of **21** and **33** are assigned from the chemical shifts that were observed for the carbon atoms in the disaccharides which make up these structures. The trisaccharide (**21**) only very weakly inhibited the agglutination of human A red cells by the lectin of *Dolichos biflorus*. The tetrasaccharide (**33**) was inactive.

SUBRAMANIAM SABESAN et RAYMOND U. LEMIEUX. Can. J. Chem. **62**, 644 (1984).

On propose des synthèses des βDGalNAc(1→4)βDGal(1→4)βDGlc—$O(CH_2)_8COOCH_3$ (**21**) et βDGal(1→3)βDGalNAc-(1→4)βDGal(1→4)βDGlc—$O(CH_2)_8COOCH_3$ (**33**) à partir du βDGal(1→4)βDGlc—$O(CH_2)_8COOCH_3$ (**1**) et du D-galactose. On rapporte des améliorations aux préparations du triacétate de D-galactal (**7**) et du bromure de tri-*O*-acétyl azido-2 déoxy-2 α-D-galactopyrannosyle. Les synthèses impliquent la préparation des bromures de tri-*O*-acétyl déoxy-2 phthalimido-2 β-D-galactopyrannosyle et de di-*O*-acétyl-4,6 *O*-(tétra-*O*-acétyl β-D-galactopyrannosyl)-3 déoxy-2 phthalimido-2 β-D-galacto-pyrannosyle (**18** et **30**) qui sont eux-mêmes préparés à partir des glycosides allyliques correspondants (**15** et **23**). On a attribué les déplacements chimiques du ^{13}C des portions tri- et tétrasaccharidiques des composés **21** et **33** en se basant sur les déplacements chimiques observés pour les atomes de carbones des disaccharides qui composent ces structures. Le trisaccharide (**21**) n'inhibe que très faiblement l'agglutination des cellules rouges A humaines par la lectine de *Dolichos biflorus*. Le tétrasaccharide **33** est inactif.

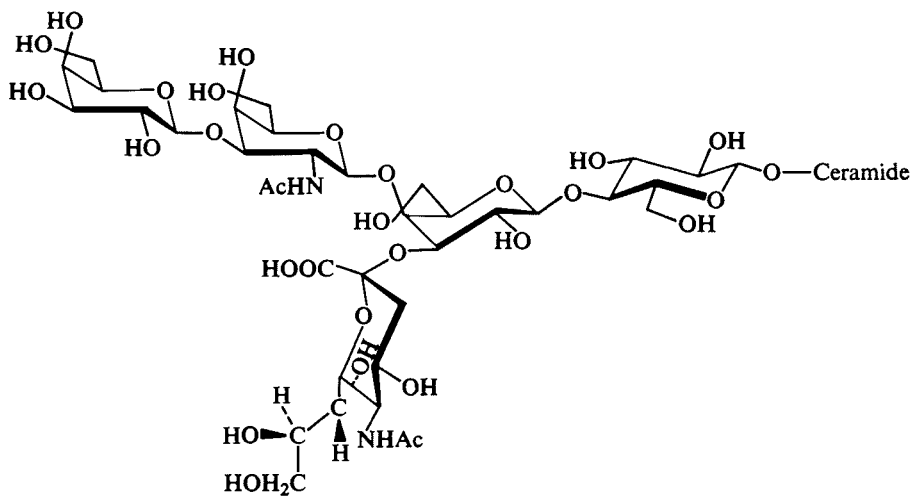
Introduction

This paper is concerned with the synthesis of structures related to the gangliosides (1) known as G_{M2} and G_{M1} (2), compounds which are also referred to as II^3-NeuAcGgOSe$_3$ and II^3-NeuAcGgOSe$_4$ (3).

The ganglioside G_{M2} differs from G_{M1} in that it lacks the terminal βDGal residue. Treatment of these gangliosides either with neuraminidase or aqueous acids removes the acidic neuraminic acid (sialic acid) residues to provide the so-called *asialo* forms. *Asialo*-G_{M1} and *asialo*-G_{M2} are also referred to as gangliotetraosylceramide and gangliotriosylceramide, respectively (3).

The distribution of gangliosides in tissues has become a subject of major interest (4). *Asialo*-G_{M2} occurs in certain tumor cells (5) and in increased amounts in the brain in Tay Sachs disease (6). Evidence has recently been acquired (7) that the terminal disaccharide (βDGalNAc(1→4)βDGal) unit of G_{M2} occurs as a terminal unit in the human blood group Sd^a active Tamm–Horsfall urinary glycoprotein. This glycoprotein reacts with a lectin from *Dolichos biflorus* which was known to react



G_{M1}

βDGal(1→3)βDGalNAc(1→4)[αDNeuAc(2→3)]βDGal(1→4)βDGlc-O-ceramide

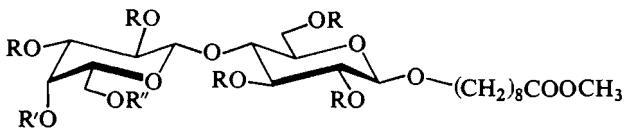
with the blood group A determinant (αDGalNAc(1→3)[αLFuc-(1→2)]βDGal) but now known (8) to react much more strongly with the Forssman determinant which terminates with an αDGalNAc(1→3)βDGalNAc(1→4)βDGal trisaccharide unit. The lectin reacts only very weakly with βDGalNAc(1→3)-βDGal(1→4)βDGal(1→4)DGlc (globoside) (8). *Asialo*-G_{M1} occurs at the surface of killer cells (9).

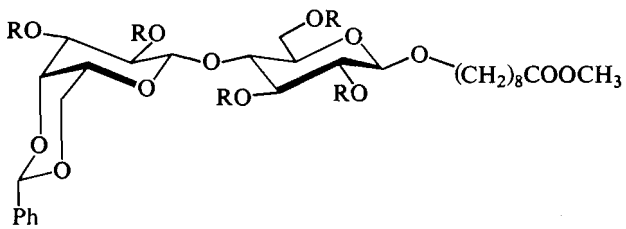
Since antibodies raised against the *asialo* forms of G_{M2} and G_{M1} have proven useful for the detection and distribution of these structures in tissues (see ref. 10), the methodology based on chemical synthesis of haptens suitable for the preparation of artificial antigens and immunoadsorbents (11–13) was of interest. Furthermore, it was of interest to examine the reaction of the *asialo*-G_{M2} structure with the lectin of *Dolichos biflorus* (7) and possibly other lectins with specificities related to terminal DGalNAc residues. To these ends, we report herein the synthesis of the haptens βDGalNAc(1→4)βDGal(1→4)-βDGlc—$O(CH_2)_8COOCH_3$ (**21**) and βDGal(1→3)βDGalNAc-(1→4)βDGal(1→4)βDGlc—$O(CH_2)_8COOCH_3$ (**33**). The availability of these compounds was also of interest for conformational studies based on ^1H and ^{13}C nmr measurements (14) of the carbohydrate portions of G_{M2} and G_{M1}. The results of these studies will be reported separately.

Discussion of results

The 8-methoxycarbonyloctyl β-D-lactoside (**1**) that was used as starting material had been reported by Banoub and Bundle



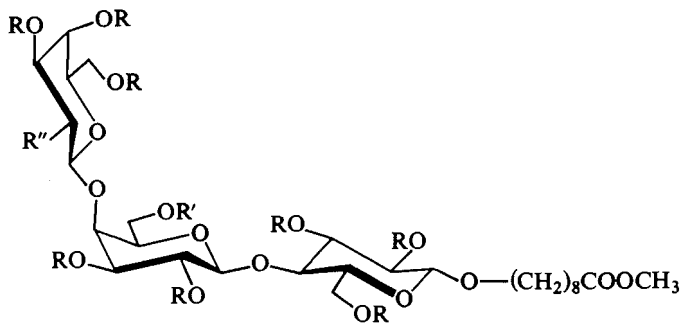
1 R = R′ = R″ = H
2 R = R′ = R″ = Ac
5 R = Ac, R′ = R″ = H
6 R = Ac, R′ = H, R″ = Bz



3 R = H
4 R = Ac

(15). A Koenigs–Knorr condensation using silver carbonate as promoter and followed by treatment with mercuric bromide to rearrange orthoester intermediates (detected by ^1H nmr) proved, in our hands, a more convenient procedure for the preparation of **1** which was characterized as the heptaacetate **2**. Compound **1** was converted to the diol **5** by way of the 4′,6′-O-benzylidiene derivative **3** and the acetate **4** following conventional methods (16–18). The structure of compound **3** was evident from the appearance of only one signal (at 60.31 ppm and assigned to C-6) in the region of the ^{13}C nmr spectrum characteristic for free hydroxymethyl groups in D_2O (19). The ^1H nmr spectrum for the diol **5** in DMSO-d_6 showed signals at 5.12 (doublet) and 5.05 (triplet) ppm which could be assigned to OH groups by exchange with D_2O and to arise from OH-4′ and OH-6′ by spin decoupling experiments. The preferential (20) *O*-benzoylation of the 6′-hydroxyl of **5** provided **6** in 80% yield. The ^1H nmr spectrum confirmed the composition and showed a doublet signal for OH-4′ (5.55 ppm with a spacing of 5.2 Hz) which was shown to be coupled to H-4′ at 3.98 ppm by addition of D_2O.

In order to prepare the *asialo*-G_{M2} related hapten (**21**), the 4′-alcohol (**6**) was condensed with tri-*O*-acetyl-2-deoxy-2-phthalimido-α,β-D-galactopyranosyl bromide (**18**) under the conditions developed in this laboratory (21). The yield of the blocked trisaccharide **19** was 64%. Removal of the blocking groups by way of the phthalimido compound **20** followed well-established procedures (22, 23). In the case of the phthalimido



19 R = Ac, R′ = Bz, R″ = NPhth
20 R = R′ = H, R″ = NPhth
21 R = R′ = H, R″ = NHAc

compounds **19** and **20**, as expected (21), both H-1″ and H-3″ were strongly deshielded (more than 0.9 ppm to lower field than either H-1 or H-1′). The β-configuration for the newly formed glycosidic bond in **19** was evident from the ^1H nmr spectrum (H-1″ at 5.32 ppm with a spacing of 7.8 Hz). The 1″→4 linkage can be assigned since the glycosylation changed the chemical shift of H-4′ from 3.98 ppm for the alcohol **6** to 4.18 ppm for **19**. A much larger shift would have occurred had acyl migration occurred.

The preparation of the phthalimidobromide (**18**) warrants special attention. The starting material, tri-*O*-acetyl-D-galactal (**7**) could be prepared in near quantitative yield under the same buffered conditions used for the preparation of tri-*O*-acetyl-D-glucal (24) which employs a zinc–copper couple rather than the zinc-platinum couple recommended by Shafizadeh (25). Furthermore, the purity of the crude syrupy product (**7**) was estimated by ^1H nmr to be greater than 90% and this level of purity was not improved by distillation (25). As noted by Lemieux and Ratcliffe (26), the azidonitration of **7** produces an about 10% yield of the 1-acetamido compound **10**. The chromatographic separation of **10** from the 1-nitrates (**8** and **9**) complicates the preparation of the bromide **11**. It is now found that the treatment of the crude reaction mixture with Vilsmeier reagent (*N*,*N*-dimethylbromoforminium bromide (27)) rapidly converts **10** to **11**. This reaction is followed by the addition of the lithium bromide to convert the nitrates **8** and **9** into the desired bromide **11** which was isolated as a syrup by column chromatography in 40% overall yield. However, the crude syrupy bromide could be used directly for the preparation of the allyl tri-*O*-acetyl-2-azido-2-deoxy-β-D-galactopyranoside (**12**) under Koenigs–Knorr conditions to provide **12** in about 29% yield from tetra-*O*-acetyl-α-D-galactopyranosyl bromide.

The azide **12** was deacetylated to **13** prior to reduction with

hydrogen sulphide (28, 29) to provide the amine **14**. The crude amine was converted to the acetylated phthalimido glycoside **15** in 70% overall yield under previously reported conditions (29). Removal of the allyl group of **15** by way of the 1-propenyl intermediate (**16**) (30, 31) to provide the alcohol **17** proceeded without complication in 78% yield. The Vilsmeier bromide was used to convert **17** to the mixture of anomeric bromides **18** (29).

In view of the reliability of the so-called phthalimidobromide glycosylation reaction (32), it was decided to prepare the blocked tetrasaccharide **31** by condensation of the disaccharide phthalimidobromide **30** with the alcohol **6**.

The allyl glycoside (**13**) was condensed with α,α-dimethoxytoluene to provide the 4,6-*O*-benzylidene derivative **22** in 79% yield. The structure of this crystalline compound was evident from its ^1H nmr spectrum in pure $CDCl_3$ which displayed a doublet (8.0 Hz) for OH-3 at 2.59 ppm which caused H-3 to produce a sextet which collapsed to a quartet (spacings 3.5 and 10.0 Hz) on deuterium exchange. It is noteworthy that the signal for H-5 (3.41 ppm) appears as a broad doublet with a spacing of about 2 Hz and a half-band width of 4.4 Hz since the small couplings of H-5 appear characteristic for 4,6-*O*-benzylidene derivatives of galactopyranosides.

The condensation of **22** with tetra-*O*-acetyl-α-D-galactopyranosyl bromide to form **23** proceeded in 70% yield using the silver trifluoromethanesulfonate – *sym*-collidine complex (21). A slight deficit of the *sym*-collidine was used, as described by Garegg and Norberg (33), to ensure the rearrangement of the orthoester intermediates that normally occur. When the condensation was promoted with mercuric cyanide using toluene nitromethane as solvent (34), an about equimolar mixture of the α and β glycosides was obtained in 80% yield. The β-configuration for **23** was readily assigned since H-1′ occurred as a doublet at 4.80 ppm with spacing of 7.8 Hz.

The blocked allyl disaccharide **23** was converted to the mixture of phthalimidobromides **30** under the same conditions discussed above for the conversion of **12** to **18**. Condensation of **30** with the alcohol **6** provided **31** in 62% yield as a chromatographically pure amorphous solid. The ^1H and ^{13}C nmr spectra required a high state of purity. A comparison of the chemical shifts for H-1′, H-3′, H-4′, and H-4″ of compounds **19** and **31** show these to have a close correspondence. Since for both compounds the chemical shifts for H-4′ are identical, it is likely that these compounds do not differ in the conformational preference about the 1″→4′ glycosidic linkage. On the other hand, the chemical shifts for H-1″ were substantially different, 5.32 ppm for **19** and 5.11 ppm for **31**. However, this difference is not surprising since it is well established (21) that an equatorial phthalimido group has a strong deshielding effect on neighboring axial hydrogen atoms and, therefore, a slight change in the time-averaged orientation of the phthalimido group could cause this change in the chemical shift. In fact, a change in the orientation of the phthalimido group could cause this change in the chemical shift. In fact, a change in the orientation of the phthalimido group is to be expected (35) since the group must be in nonbonded interaction with the C-3″ substituent and, in the case of **19**, the substituent is an acetoxy group whereas, in the case of **31**, the substituent is the much bulkier acetylated β-D-galactopyranosyl group. This influence on chemical shift should also occur for the allyl glycosides **15** and **27** and, in fact, the signals for H-1 of these compounds differed in chemical shift by 0.17 ppm. A change in the orientation of the phthalimido group should also cause a change in the chemical shift of H-2″. In fact, H-2″ gave its signal at 4.53 ppm in the case of **19** but at 4.48 ppm for **31**. In the case of the allyl glycosides **15** and **27**, the change in chemical shift for H-2

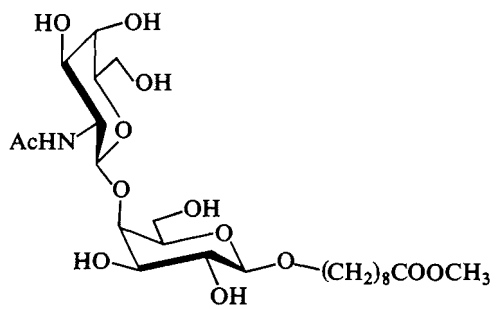
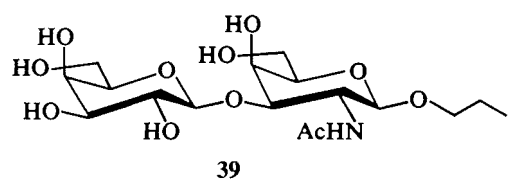
31 R = Ac, R′ = Bz, R″ = NPhth
32 R = R′ = H, R″ = NPhth
33 R = R′ = H, R″ = NHAc

was similar, namely, 0.04 ppm. The small change of 0.05 ppm as compared to the 0.20 ppm change for H-1″ atoms of **19** and **31** is not unexpected since inspection of a molecular model shows that a given rotation about the C—N bond must provide a greater increase (or greater decrease) for the distance between the neighboring carbonyl oxygen and H-1″ than for the distance between H-2″ and the other carbonyl oxygen. Lemieux and Bock (36) have discussed similar influences on chemical shift resulting from substitutions that influence the orientation of an acetamido group.

Deblocking of **31** by way of the phthalimido intermediate **32** under the usual conditions to form the free amine and followed by *N*-acetylation provided the *asialo*-G_{M1} related hapten **33** as a colorless solid with ^1H and ^{13}C nmr spectra in good general agreement with expectations for a pure substance. In order to assign ^{13}C nmr chemical shifts for the haptens **21** and **33**, the disaccharides **38** and **39** were synthesized. Table 1 contains an assignment of ^{13}C chemical shifts based on assignments for the disaccharides **1**, **38**, and **39** from the shifts observed for the



38



39

simple model alkyl glycosides. The chemical shifts thus assigned for the disaccharides were then used to assign the signals observed in the ^{13}C nmr spectra of **21** and **33**. Examination of Table 1 shows that excellent correspondence is obtained and these data are taken as unequivocal confirmation of the structural assignments.

Under the conditions used, the agglutination of human A red cells was completely inhibited by 16 μg of the Forssman related hapten αDGal(1→3)αDGalNAcO$(CH_2)_8COOCH_3$ (8) and by 500 μg of the A blood group related hapten αLFuc(1→2)-[αDGalNAc(1→3)]βDGalO$(CH_2)_8COOCH_3$ (37). In contrast, 3000 μg of the *asialo*-G_{M2} related hapten **21** were required. The disaccharide hapten **38** was an even weaker inhibitor (2600 μg showed only partial inhibition). The tetrasaccharide **33** was inactive.

Experimental

All solvents and reagents were purified according to standard procedures (38). Transesterifications were effected using the specified volumes of a 0.5 *M* solution of sodium methoxide in dry methanol.

Thin layer chromatograms (tlc) were performed on precoated silica gel 60-F254 plates (E. Merck. Darmstadt) and visualized by charring after spraying with 5% sulphuric acid in ethanol. For column chromatography, silica gel H (type 60) (E. Merck, Darmstadt) and distilled solvents were used and the columns were loaded in the range 1:30−1:50.

Unless otherwise stated, ^1H nmr spectra were recorded on a Bruker 360 MHz or 400 MHz at 296 K. The ^{13}C nmr spectra were recorded on a Bruker WH-200 (50.3 MHz) or WH-400 (100.6 MHz) at 305 K. For organic solvents, ^1H and ^{13}C nmr chemical shifts are in parts per million (ppm) relative to internal 1% tetramethylsilane (TMS). The ^1H chemical shifts for solutions of compounds in deuterium oxide (D_2O) are expressed relative to the HOD signal (4.81 ppm at 296 K). The ^{13}C chemical shifts were determined by using the deuterium signal as the reference. Whenever comparison of ^{13}C chemical shifts among compounds is made, the same spectrometer and temperatures were used. The melting points are uncorrected.

8-Methoxycarbonyloctyl 4-O-(β-D-galactopyranosyl)-β-D-glucopyranoside (1)

A solution of acetobromolactose (39) (72.0 g, 103 mmol) in dichloromethane (400 mL) was added to a vigorously stirred suspension of anhydrous silver carbonate (56.5 g, 206 mmol), anhydrous calcium sulphate (40 g), and 8-methoxycarbonyloctanol (40) (36.2 g, 192.5 mmol) in dichloromethane (600 mL). After 16 h, the reaction mixture was filtered through a bed of diatomaceous earth (10 g) and evaporated to a syrup which was dissolved in a mixture of toluene−nitromethane (1:1, 800 mL) containing anhydrous mercuric bromide (1.0 g). After

*Measured at 100 MHz in D_2O at 305 K with external tetramethylsilane as reference signal (0 ppm).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

stirring for 24 h at 50°C, the reaction mixture was diluted with dichloromethane and washed with an aqueous potassium iodide solution and then with water. Evaporation left a colorless syrup which was extracted with cyclohexane (4 × 100 mL) to remove the excess 8-methoxycarbonyloctanol (16.0 g).

Sodium methoxide in methanol (10 mL) was added to a solution of the syrup (75.0 g) in methanol (500 mL) and the solution was stirred at room temperature for 6 h. Precipitation was completed by cooling to 0°C prior to filtration. The solid was washed with methanol and crystallized from methanol (31.2 g, 59% yield); mp 164–165°C (lit. (15) mp 159°C). The chemical shifts for H-1 and H-1′ agreed with those reported (15); ^{13}C nmr (D_2O) δ: 178.17 (C=O), 103.22 (C-1′), 102.31 (C-1), 78.81 (C-4), 75.62 (C-5′), 75.02 (C-5), 74.76 (C-3), 73.14 (C-2), 72.85 (C-3′), 71.25 (C-2′), 70.97 (aglyconic carbon), 68.84 (C-4′), 61.27 (C-6′), 60.45 (C-6), 53.22 (—COO*C*H_3), 33.97, 28.94, 28.65, 28.44, 28.39, 28.34, 25.17 and 24.51 (remaining carbons of aglycon).

8-Methoxycarbonyloctyl 2,3,6-tri-O-*acetyl-4*-O-*(2,3,4,6-tetra*-O-*acetyl-β-D-galactopyranosyl)-β-D-glucopyranoside (2)*

8-Methoxycarbonyloctyl β-lactoside (**1**) (1.0 g) was dissolved in 10 mL of pyridine – acetic anhydride (1:1) and stirred at room temperature for 24 h. The product, isolated in the usual manner (1.40 g, 90% yield), was amorphous but homogeneous by tlc; $[\alpha]_D^{25}$ −15.0° (*c* 1.33, $CHCl_3$). The ^{13}C nmr was in accord with that reported by Banoub and Bundle (15).

8-Methoxycarbonyloctyl 4-O-*(4,6*-O-*benzylidene-β-D-galactopyranosyl)-β-D-glucopyranoside (3)*

A suspension of compound **1** (24.0 g, 46.8 mmol) in acetonitrile (500 mL) was refluxed with α,α-dimethoxytoluene (14.25 g, 93.75 mmol) and *p*-toluenesulphonic acid monohydrate (50 mg) for 6 h. After neutralization with triethylamine (0.2 mL), the reaction mixture was evaporated to dryness. The residue, after extraction with *n*-hexane (3 × 50 mL) to remove the excess α,α-dimethoxytoluene, crystallized from acetonitrile (22.0 g, 78.2% yield); mp 186–188°C; $[\alpha]_D^{25}$ −32.1° (*c* 1.04, CH_3OH); ^{13}C nmr (DMSO-d_6) δ: 173.26(*C*=O), 138.46, 128.54, 127.83, 126.16 (aromatic), 102.97, 102.59 (two anomeric carbons), 99.75 (benzylic carbon), 79.03 (C-4), 75.68, 74.83, 74.78, 73.25, 71.63, 69.82, 68.69, 68.43, 66.24, 60.31 (remaining carbons of the sugar units and the aglyconic carbon), 51.02, 33.22, 29.14, 28.61, 28.53, 25.34, 24.34 (remaining carbons in aglycon). *Anal.* calcd. for $C_{29}H_{44}O_{13}$: C 57.96, H 7.38; found: C 57.69, H 7.21.

8-Methoxycarbonyloctyl 2,3,6-tri-O-*acetyl-4*-O-*(2,3-di*-O-*acetyl-4,6*-O-*benzylidene-β-D-galactopyranosyl)-β-D-glucopyranoside (4)*

A solution of compound **3** (21.0 g) in pyridine – acetic anhydride (4:1, 125 mL) containing 4-*N*,*N*-dimethylaminopyridine (10 mg) was stirred at 60°C for 12 h. It was then poured over ice (100 g) and extracted with dichloromethane (3 × 200 mL). Work-up in the usual manner left solid (28.3 g, 90% yield). The analytical sample was prepared by crystallization from ether – ethyl acetate – *n*-hexane; mp 160–162°C; $[\alpha]_D^{25}$ +32.0° (*c* 1.03, $CHCl_3$). The ^1H nmr spectrum was in general accord with expectation; ^{13}C nmr ($CDCl_3$) δ: 174.12, 170.51, 170.34, 170.27, 169.51, 168.86 (6C=O), 137.75, 129.18, 128.25, 126.3, 101.36 and 101.22 (C-1 and C-1′), 100.88 (benzylic carbon), 77.50 (C-4), 73.33, 73.06, 72.77, 72.36, 72.22, 71.89, 70.06, 69.34, 68.54, 66.63, 62.30 (remaining carbons of sugar units and aglyconic carbon), 51.32–20.40 (9 lines, carbons in aglycon and CH_3 of acetyls). *Anal.* calcd. for $C_{39}H_{54}O_{18}$: C 57.74, H 6.71; found: C 57.50, H 6.66.

8-Methoxycarbonyloctyl 2,3,6-tri-O-*acetyl-4*-O-*(2,3-di*-O-*acetyl-β-D-galactopyranosyl)-β-D-glucopyranoside (5)*

Aqueous trifluoroacetic acid (90%, 10 mL) was added to a cold

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

(0°C) solution of crude **4** (4.3 g) in dichloromethane (100 mL) and stirred at 0°C for 1 h. The reaction mixture was then washed with water, aqueous saturated sodium bicarbonate, and finally with water. Evaporation left a residue which was chromatographed on silica gel (100 g) using ethyl acetate – *n*-hexane – acetonitrile (2:2:1) as eluant. Evaporation of the second fraction left a solid (3.16 g, 82% yield); $[\alpha]_D^{25}$ −7.4° (*c* 1.05, $CHCl_3$); ^{1}H nmr (DMSO-d_6) δ: 5.12 (d, 1H, 4′-OH, J = 3.0 Hz), 5.05 (t, 1H, 6′-OH, J = 6 Hz), 4.88 (dd, 1H, H-2′, $J_{2',1'}$ = 7.8 Hz, $J_{2',3'}$ = 10 Hz), 4.68 (dd, 1H, H-3′, $J_{3',2'}$ = 10 Hz, $J_{3',4'}$ = 3.0 Hz), 4.62 (m, 3H, H-2, H-3, H-1), 4.47 (d, 1H, H-1′, $J_{1',2'}$ = 7.8 Hz), 4.25 (broad d, 1H, H-6a, $J_{6a,6b}$ = 12.0 Hz), 4.05 (dd, 1H, H-6b, $J_{6a,6b}$ = 12.0 Hz, $J_{6b,5}$ = 6.3 Hz), 3.90 (broad t, 1H, H-4′, J = 3.0 Hz), 3.80−3.30 (m, remaining sugar hydrogens, O—C*H*$_3$, O—C*H*$_2$ of aglycon), 2.30 (t, 2H, C*H*$_2$—COOCH$_3$, J = 8 Hz), 2.10−1.95 (15H, 5C*H*$_3$ of acetyls), 1.5−1.25 (12H, hydrogens in aglycon); ^{13}C nmr ($CDCl_3$) δ: 170.50, 170.08, 169.61, 169.41 (6C=O), 101.01, 100.60 (C-1′ and C-1), 77.23 (C-4), 74.57, 73.50, 73.46, 72.70, 71.96, 70.09, 69.84, 68.17, 62.47, 62.41 (remaining carbons of sugar units and aglyconic carbon), 51.41−20.64 (carbons in aglycon and C*H*$_3$ of acetyls).

*8-Methoxycarbonyloctyl 2,3,6-tri-*O*-acetyl-4-*O*-(2,3-di-*O*-acetyl-6-*O*-benzoyl-β-*D*-galactopyranosyl)-β-*D*-glucopyranoside (**6**)*

A solution of benzoyl chloride (0.640 g, 0.528 mL, 4.5 mmol) in dichloromethane (3 mL) was added to a cooled (−78°C) solution of compound **5** (2.96 g, 4.1 mmol) in dichloromethane (25 mL) containing anhydrous pyridine (0.363 mL, 4.5 mmol). Most of the starting diol (**5**) was consumed, as evidenced by tlc using ethyl acetate – *n*-hexane – acetonitrile (2:2:1), after stirring at −78°C for 3 h and then at −20°C for 6 h. The reaction mixture was washed with ice-cold water, ice-cold *N*-hydrochloric acid, and finally with aqueous saturated sodium bicarbonate. Solvent removal left a solid foam which was purified by flash chromatography on a column of silica gel (60.0 g) using ethyl acetate – *n*-hexane – acetonitrile (2:2.5:0.5). Evaporation of the first main fraction left a colorless foam (2.8 g, 84% yield). An analytical sample was prepared by crystallization from acetone – *n*-hexane; mp 145−146°C; $[\alpha]_D^{25}$ +1.62° (*c* 0.986, $CHCl_3$). The ^{1}H nmr spectrum was in general accord with expectation and essentially identical to that for the crude product. ^{1}H nmr (DMSO-d_6) δ: 8.04, 7.70 7.58 (m, 5H, benzoate), 5.18 (t, 1H, H-3, $J_{3,2}$ = $J_{3,4}$ = 9 Hz), 5.00 (dd, 1H, H-3′, $J_{2',1'}$ = 7.8 Hz, $J_{2',3'}$ = 10 Hz), 4.85 (dd, 1H, H-3′, $J_{3',2'}$ = 10 Hz, $J_{3',4'}$ = 3.0 Hz), 4.68 (m, 3H, H-1, H-1′, H-2), 4.48 (dd, 1H, H-6′a, $J_{6'a,5'}$ = 5.25 Hz, $J_{6'a,6'b}$ = 11.5 Hz), 4.36−4.26 (m, 2H, H-6a, H-6′b), 4.10 (dd, 1H, H-6b, $J_{6b,5}$ = 5.5 Hz, $J_{6b,6a}$ = 11.50 Hz), 4.03 (broad t, 1H, H-5′, $J_{5',6'}$ = 6.0 Hz), 3.98 (broad d, 1H, H-4′, $J_{4',3'}$ = 3.0 Hz), 3.82 (m, 1H, H-5), 3.75−3.64 (m, 5H, H-4, —O—C*H*$_3$, —O—C*H*$_2$ of aglycon), 3.43 (m, 1H, O—C*H*$_2$ of aglycon), 2.28 (t, 2H, C*H*$_2$—COOCH$_3$, J = 8.0 Hz), 2.02−1.94 (15H, 5C*H*$_3$ of acetyl), 1.5 and 1.24 (12H, hydrogens in algycon); ^{13}C nmr ($CDCl_3$) δ: 174.21, 170.39, 170.19, 169.44, 169.38, 166.40 (7C=O), 133.52, 129.74, 129.59, 128.70 (benzoate carbons), 100.75, 100.17 (C-1 and C-1′), 76.41 (C-4), 73.57, 72.80, 72.67, 72.56, 71.75, 70.13, 69.60, 66.95, 62.37, 62.18 (remaining carbons of sugar units and aglyconic carbon), 51.40−20.63 (10 lines, carbons in aglycon and C*H*$_3$ of acetyls). *Anal.* calcd. for $C_{39}H_{54}O_{19}$: C 56.65, H 6.58; found: C 56.90, H 6.64.

*3,4,6-Tri-*O*-acetyl-2-azido-2-deoxy-α-*D*-galactopyranosyl bromide (**11**)*

D-Galactal triacetate was converted by azidonitration to the product which contains compounds **8**, **9**, and **10** under the conditions reported by Lemieux and Ratcliffe (26). This crude product (45.0 g) was dissolved in dichloromethane (300 mL) and Vilsmeier bromide (27) (10.0 g, 46 mmol) was added. After the solution was stirred at 0°C for 1 h, a solution of anhydrous lithium bromide (25.0 g) in dry acetonitrile (360 mL) was added and the stirring was continued for 6 h. Work-up in the usual manner left a yellow syrup (40.0 g), a portion of which (10.0 g) was chromatographed on a column of silica gel (300 g) using ethyl acetate – *n*-hexane (3:7) as eluant. The main fraction provided material (7.0 g, 60% yield) which crystallized from diethyl ether – hexane, mp 96−98°C. The melting point and the ^{1}H nmr spectrum were in accordance with those reported by Lemieux and Ratcliffe (26).

A comparison of the ^{1}H nmr spectra indicated that the crude product was about 75% pure; ^{13}C nmr ($CDCl_3$) δ: 170.22, 169.70, 169.43 (3C=O), 89.07 (C-1), 71.53 (C-5), 69.84, 66.72 (C-4 and C-3), 60.78 (C-6), 58.75 (C-2).

*Allyl 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-β-*D*-galactopyranoside (**12**)*

A solution of the crude bromide **11** (30.0 g, 7.61 mmol) in dichloromethane (125 mL) was added slowly to a vigorously stirred suspension of anhydrous silver carbonate (20.0 g, 7.25 mmol) and anhydrous calcium sulphate (25.0 g) in allyl alcohol (200 mL). After 16 h, the reaction mixture was filtered through a bed of diatomaceous earth (10.0 g) and the filtrate was evaporated to a syrup. Chromatography on silica gel (600 g) using ethyl acetate – *n*-hexane (3:7) and evaporation of the first main fraction provided a pale yellow syrup (15.97 g, 29% based on acetobromogalactose) which appeared homogeneous by tlc; $[\alpha]_D^{25}$ −12.4° (*c* 1.5, $CHCl_3$); ^{1}H nmr ($CDCl_3$) δ: 5.96 (m, 1H, O—CH$_2$—C*H*=CH$_2$), 5.42 (m, 1H, O—CH$_2$—CH=C*H*$_2$), 5.40 (broad d, 1H, H-4, $J_{4,3}$ = 3 Hz), 5.32 (m, 1H, O—CH$_2$—CH=C*H*$_2$), 4.84 (dd, 1H, H-3, $J_{3,4}$ = 3 Hz, $J_{3,2}$ = 10.5 Hz), 4.46 (d, 1H, H-1, $J_{1,2}$ = 7.8 Hz), 4.45 and 4.24 (m, 2H, O—C*H*$_2$—CH=CH$_2$), 4.3−4.2 (m, 2H, H-6a, H-6b), 3.88 (broad t, 1H, H-5, $J_{5,6}$ = 6.75 Hz), 3.75 (dd, 1H, H-2, $J_{2,1}$ = 7.8 Hz, $J_{2,3}$ = 10.5 Hz), 2.08−2.04 (3s, 9H, C*H*$_3$ of acetyls); ^{13}C nmr ($CDCl_3$) δ: 170.30, 170.04, 169.77 (3C=O), 133.14 (O—CH$_2$—*C*H=CH$_2$), 118.25 (O—CH$_2$—CH=*C*H$_2$), 101.17 (C-1), 71.14 (C-5), 70.73, 70.64 (C-3 and C-4), 66.44 (O—*C*H$_2$—CH=CH$_2$), 61.29 (C-2), 60.93 (C-6), 20.59 (3*C*H$_3$ of acetyls). *Anal.* calcd. for $C_{15}H_{21}N_3O_{18}$: C 48.49, H 5.70, N 11.32; found: C 47.98, H 5.66, N 10.65.

*Allyl 2-azido-2-deoxy-β-*D*-galactopyranoside (**13**)*

Sodium methoxide in methanol (5 mL) was added to a solution of 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-β-D-galactopyranoside (**12**) (18.0 g) in methanol (150 mL) and stirred for 90 min. The solution was then neutralized with IRA-110 H^+ resin, decolorized with charcoal (5.0 g), and evaporated. The residue was crystallized from ethyl acetate – *n*-hexane to obtain 11.0 g (92.3%) of the product; mp 117−118°C; $[\alpha]_D^{25}$ +13.9° (*c* 0.98, CH_3OH); ^{1}H nmr (CD_3OD) δ: 6.04−5.90 (m, 1H, O—CH$_2$—C*H*=CH$_2$), 5.35 and 5.18 (m, 2H, O—CH$_2$—CH=C*H*$_2$), 4.34 (d, 1H, H-1, $J_{1,2}$ = 7.8 Hz), 3.78 (dd, 1H, H-4, $J_{4,5}$ = 1.5 Hz, $J_{4,3}$ = 3.5 Hz), 3.74 (m, 2H, H-6a, H-6b), 3.48 (m, 2H, H-2, H-5), 3.42 (dd, 1H, H-3, $J_{3,4}$ = 3.5 Hz, $J_{3,2}$ = 10.5 Hz); ^{13}C nmr (DMSO-d_6) δ: 134.37 (O—CH$_2$—*C*H=CH$_2$), 116.43 (O—CH$_2$—CH=*C*H$_2$), 100.41 (C-1), 75.20 (C-5), 71.55 (C-3), 68.80 (C-4), 67.55 (O—*C*H$_2$—CH=CH$_2$), 64.22 (C-2), 60.26 (C-6). *Anal.* calcd. for $C_9H_{15}N_3O_5$: C 44.06, H 6.16, N 17.14; found: C 43.59, H 6.21, N 17.00.

*Allyl 3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-β-*D*-galactopyranoside (**15**)*

A stream of hydrogen sulphide was slowly bubbled through an ice-cold solution of the azide (**13**) (14.0 g, 57.14 mmol) in pyridine (150 mL) and triethylamine (45 mL) for 4 h. The solution was then stirred at room temperature for 6 h. Evaporation left a residue which was treated with methanol−water (1:1) and the solids removed by filtration through a bed of diatomaceous earth. Solvent removal left a residue (crude **14**) which was dissolved in pyridine (50 mL). Phthalic anhydride (4.86 g, 32.83 mmol) was added and the solution was heated at 60°C for 30 min. Triethylamine (5.9 g, 57.28 mmol) and phthalic anhydride (4.86 g, 32.83 mmol) were added and the heating was continued for 2 h. Methanol (50 mL) was added and the solution was evaporated to a dry residue which was taken up in a mixture of pyridine – acetic anhydride (2:1, 60 mL) containing 4-*N*,*N*-dimethylaminopyridine (10 mg). The solution was stirred at 60°C for 24 h. Work-up in the usual manner left a solid which was purified by flash chromatography on a column of silica gel (600 g) using ethyl acetate – *n*-hexane – acetonitrile (2:2.5:0.5). Evaporation of the

For personal use only.

main fraction left an amorphous solid (19.0 g, 70% yield) homogeneous on tlc; $[\alpha]_D^{25}$ −10.7° (*c* 1.0, $CHCl_3$); ^{1}H nmr ($CDCl_3$) δ: 7.80−7.72 (m, 4H, phthalimido), 5.8 (dd, 1H, H-3, $J_{3,2}$ = 11 Hz, $J_{3,4}$ = 3.5 Hz), 5.78−5.66 (m, 1H, O—CH_2—CH=CH_2), 5.50 (broad d, 1H, H-4, $J_{4,3}$ = 3.5 Hz), 5.35 (d, 1H, H-1, $J_{1,2}$ = 7.8 Hz), 5.14 and 5.08 (m, 2H, O—CH_2—CH=CH_2), 4.60 (dd, 1H, H-2, $J_{2,1}$ = 7.8 Hz, $J_{2,3}$ = 11.0 Hz), 4.34−4.04 (m, 5H, H-6a, H-6b, H-5, O—CH_2—CH=CH_2), 2.22, 2.1, 1.86 (3s, CH_3 of acetyls); ^{13}C nmr ($CDCl_3$) δ: 170.39, 169.79 (C=O), 134.27, 131.53, 123.78, 123.58 (aromatic carbons), 133.32 (O—CH_2—CH=CH_2), 117.84 (O—CH_2—CH=CH_2), 97.56 (C-1), 70.87, 70.17, 68.15 (C-5, C-4, C-3), 66.83 (O—CH_2—CH=CH_2), 61.50 (C-6), 51.46 (C-2), 20.70, 20.50, 20.36 ($3CH_3$—COO). *Anal.* calcd. for $C_{23}H_{25}NO_{10}$: C 58.10, H 5.30, N 2.94; found: C 57.82, H 5.30, N 2.90.

*3,4,6-Tri-*O*-acetyl-2-deoxy-2-phthalimido-*D*-galactopyranose (**17**)*

Tris-triphenylphosphine rhodium(I) chloride (300 mg, 0.32 mmol) and 1,4-diazabicyclooctane (100 mg, 1.1 mmol) were added to a solution of compound **15** (2.5 g, 5.26 mmol) in ethanol−benzene−water (7:3:1, 300 mL) and refluxed for 36 h (31). Solvent removal left a residue which was dissolved in aqueous acetone (90%, 50 mL) containing mercuric chloride (5 g) and yellow mercuric oxide (100 mg). After stirring at room temperature for 60 min, the reaction mixture was diluted with water (50 mL) and extracted with chloroform (2 × 75 mL). The chloroform layer was washed with aqueous potassium iodide (10%, 2 × 50 mL) and then with water. Evaporation left a black residue which was purified on a column of silica gel (100 g) using ethyl acetate − *n*-hexane − acetonitrile (2:2.5:0.5). Evaporation of the second and main fraction left a residue (1.88 g, 78%) which was a mixture of α and β anomers of **17** in the ratio 3:7 as estimated from the ^{1}H nmr spectrum; ^{1}H nmr ($CDCl_3$) δ: 7.90−7.70 (m, 4H, phthalimido), 6.36 (dd, H-3α, $J_{3\alpha,2\alpha}$ = 11 Hz, $J_{3\alpha,4\alpha}$ = 3.0 Hz), 5.86 (dd, H-3β, $J_{3\beta,2\beta}$ = 11 Hz, $J_{3\beta,4\beta}$ = 3.5 Hz), 5.60−5.46 (m, H-4, H-1α, H-1β), 4.84−3.06 (H-2α, H-2β, H-5, H-6a, H-6b), 1.84−2.16 (CH_3 of acetyls).

*3,4,6-Tri-*O*-acetyl-2-deoxy-2-phthalimido-β-*D*-galactopyranosyl bromide (**18**)*

Vilsmeier bromide (27) (1.31 g, 6.05 mmol) was added to an ice-cold solution of compound **17** (1.88 g, 4.32 mmol) in dichloromethane (25 mL) and stirred. *sym*-Collidine (0.802 mL, 6.05 mmol) was added dropwise to the reaction mixture. After stirring for 2 h at 0°C and 12 h at room temperature, the reaction mixture was washed with ice-cold water (15 mL), ice-cold hydrochloric acid (1 *N*, 10 mL), and finally with water. Evaporation of the solvent left a residue (1.88 g, 84% yield) containing α and β anomers of **18**. Pure β-bromide crystallized from ethyl acetate − *n*-hexane; mp 136−137°C; $[\alpha]_D^{25}$ +29.2° (*c* 0.98, $CHCl_3$); ^{1}H nmr ($CDCl_3$) δ: 7.86−7.70 (m, 4H, phthalimido), 6.36 (d, 1H, H-1, $J_{1,2}$ = 10 Hz), 5.76 (dd, 1H, H-3, $J_{3,2}$ = 11.0 Hz, $J_{3,4}$ = 3.50 Hz), 5.52 (broad d, 1H, H-4, $J_{4,3}$ = 3.50 Hz), 4.8 (dd, 1H, H-2, $J_{2,3}$ = 11 Hz, $J_{2,1}$ = 10 Hz), 4.17 (m, 3H, H-5, H-6a, H-6b), 2.28, 2.08, 1.84 (3s, CH_3 of acetyls); ^{13}C nmr ($CDCl_3$) δ: 170.27, 170.09, 169.45 (3C=O), 134.53, 131.30, 123.83 (aromatic), 78.08 (C-1), 75.88, 67.88, 66.66 (C-5, C-3, C-4), 61.38 (C-6), 54.61 (C-2), 20.64, 20.38 (CH_3 of acetyls) *Anal.* calcd. for $C_{20}H_{20}BrNO_9$: C 48.20, H 4.04, N 2.82; found: C 48.01, H 4.10, N 2.81.

*8-Methoxycarbonyloctyl 2,3,6-tri-*O*-acetyl-4-*O*-[2,3-di-*O*-acetyl-6-*O*-benzoyl-4-*O*-(3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-β-*D*-galactopyranosyl)-β-*D*-galactopyranosyl]-β-*D*-glucopyranoside (**19**)*

3,4,6-Tri-*O*-acetyl-2-deoxy-2-phthalimido-D-galactopyranosyl bromide (**18**) (225 mg, 0.45 mmol) in nitromethane (5 mL) was added to a solution of **6** (340 mg, 0.41 mmol), *sym*-collidine (54.4 μL, 0.411 mmol), and silver triflate (115 mg, 0.45 mmol) in dry nitromethane (5 mL) cooled to −25°C. The mixture was stirred at −25°C for 6 h and then at room temperature for 12 h. The solids that were deposited after the addition of dichloromethane (20 mL) were removed by filtration and the filtrate was washed with sodium thiosulphate solution, cold water, dilute aqueous HCl, and saturated sodium bicarbonate solution. Solvent removal and purification by preparative high pressure liquid chromatography on a column of silica gel using ethyl acetate − *n*-hexane − acetonitrile (2:2.5:0.5) provided a colorless amorphous solid (330 mg, 64.5% yield), $[\alpha]_D^{25}$ −19.9° (*c* 2.7, $CHCl_3$); ^{1}H nmr ($CDCl_3$) δ: 8.1−7.5 (m, 9H, phthalimido, benzoate), 5.92 (dd, 1H, H-3″, $J_{3'',4''}$ = 3.5 Hz, $J_{3'',2''}$ = 11 Hz), 5.44 (broad d, 1H, H-4″, $J_{4'',3''}$ = 3.5 Hz), 5.32 (d, 1H, H-1″, $J_{1'',2''}$ = 7.8 Hz), 5.15 (t, 1H, H-3, $J_{3,2}$ = $J_{3,4}$ = 10 Hz), 4.84 (m, 2H, H-2, H-3′, $J_{2,3}$ = 10 Hz, $J_{2,1}$ = 7.8 Hz, $J_{3',2'}$ = 10 Hz, $J_{3',4'}$ = 3.0 Hz), 4.70 (dd, 1H, H-6′a, $J_{6'a,6'b}$ = 11 Hz, $J_{6'a,5'}$ = 7.0 Hz), 4.53 (q, H, H-2″, $J_{2'',3''}$ = 11 Hz), 4.50 (q, H, H-2′, $J_{2',3'}$ = 10 Hz), 4.40 (m, 3H, H-6a, H-1, H-6′b), 4.28 (d, 1H, H-1′, $J_{1',2'}$ = 7.8 Hz), 4.18 (broad d, 1H, H-4′, $J_{4',3'}$ = 3.0 Hz), 4.12−3.94 (m, 4H, H-5″, H-6b, H-6″a, H-6″b), 3.8 (m, 2H, H-5′, O—CH_2 of aglycon), 3.70 (m, 4H, O—CH_3, H-4), 3.51 (m, 1H, H-5), 3.4 (m, 1H, O—CH_2 of aglycon), 2.3 (t, 2H, CH_2—$COOCH_3$, *J* = 8.0 Hz), 2.2−1.74 (8s, 24H, acetyl CH_3), 1.6 and 1.20 (12H, aglyconic hydrogens); ^{13}C nmr ($CDCl_3$) δ: 174.21 ($COOCH_3$), 170.33, 170.30, 170.27, 170.07, 169.72, 169.18, 168.59, 167.98, 167.16, 166.26, (10C=O), 134.28, 133.97, 133.44, 131.71, 129.97, 128.77, 124.58, 123.07 (phthalimido, benzoate carbons), 100.92, 100.41, 98.46 (C-1, C-1′, C-1″), 77.28 (C-4), 75.42 (C-4′), 72.89, 72.48, 72.25, 72.15, 71.83, 71.04, 70.04, 69.57, 67.49, 66.67, 62.13, 62.12, 61.41, 51.38 (remaining carbons of sugar units and the O—CH_2 of aglycon), 51.28−20.29 (12 lines, remaining carbons in aglycon, CH_3 of acetyls).

*8-Methoxycarbonyloctyl 4-*O*-[4-*O*-(2-deoxy-2-phthalimido-β-*D*-galactopyranosyl)-β-*D*-galactopyranosyl]-β-*D*-glucopyranoside (**20**)*

A freshly prepared solution of sodium methoxide in methanol (0.5 mL) was added to a solution of compound **19** (364 mg, 0.289 mmol) in methanol (20 mL) and stirred under a nitrogen atmosphere for 5 h. The reaction mixture was neutralized with dry IRA-20 H^+ resin and evaporated to a residue (220 mg, 97% yield) which was homogeneous on tlc (ethyl acetate − ethanol−water, 7:2:1); ^{1}H nmr (CD_3OD) δ: 8.0−7.7 (m, 4H, phthalimido), 5.15 (d, 1H, H-1″, $J_{1'',2''}$ = 8.0 Hz), 4.59 (dd, 1H, H-3″, $J_{3'',2''}$ = 11 Hz, $J_{3'',4''}$ = 3.50 Hz), 4.33 (dd, 1H, H-2″, $J_{2'',1''}$ = 8.0 Hz, $J_{2'',3''}$ = 11.0 Hz), 4.23−4.15 (2d, 2H, H-1, H-1′, $J_{1',2'}$ = $J_{1,2}$ = 7.8 Hz), 3.9−3.25 (m, remaining sugars and aglycons except H-2 and H-2′), 3.18 (t, 1H, H-2, $J_{2,3}$ = 9.0 Hz, $J_{1,2}$ = 7.8 Hz), 3.07 (dd, 1H, H-2′, $J_{2',1'}$ = 7.8 Hz, $J_{2',3'}$ = 9.5 Hz), 2.27 (t, 2H, CH_2COOCH_3, *J* = 8.0 Hz), 1.55 and 1.29 (12H, hydrogens in aglycon).

*8-Methoxycarbonyloctyl 4-*O*-[4-*O*-(2-acetamido-2-deoxy-β-*D*-galactopyranosyl)-β-*D*-galactopyranosyl]-β-*D*-glucopyranoside (**21**) − asialo-G_{M2} hapten*

Hydrazine (95%, 100 μL) was added to a solution of compound **20** (219 mg, 0.272 mmol) in methanol (20 mL). After refluxing for 2 h, the solution was evaporated to dryness and the residue was taken up in 11 mL of methanol − acetic anhydride (10:1). After stirring at room temperature for 3 h, the solution was taken to dryness and the residue was dissolved in ethanol−water (9:1) for application to a Biogel P-2 column. Elution with the same solvent provided a main fraction which was lyophilized to a colorless material (155 mg, 80% yield); $[\alpha]_D^{25}$ −0.1° (*c* 0.3); ^{1}H nmr (D_2O) δ: 4.58 (d, 1H, H-1″, $J_{1'',2''}$ = 9.0 Hz), 4.43, 4.39 (2d, 2H, H-1, H-1′, $J_{1',2'}$ = $J_{1,2}$ = 7.7 Hz), 4.04 (broad d, 1H, H-4′, $J_{4',3'}$ = 2.2 Hz), 4.0−3.35 (20H, remaining 15 ring hydrogens except H-2′ and H-2, O—CH_3, O—CH_2 of aglycon), 3.36 (dd, 1H, H-2′, $J_{2',1'}$ = 7.7 Hz, $J_{2',3'}$ = 9.9 Hz), 3.24 (dd, 1H, H-2, $J_{2,1}$ = 7.7 Hz, $J_{2,3}$ = 9.0 Hz), 2.4 (t, 2H, CH_2—$COOCH_3$), 2.05 (s, 3H, CH_3 of N-acetyl), 1.6 and 1.30 (12H, aglyconic hydrogens).

The ^{13}C nmr spectrum is reported in Table 1.

*Allyl 2-azido-2-deoxy-4,6-*O*-benzylidene-β-*D*-galactopyranoside (**22**)*

A solution of compound **13** (11.0 g, 44.8 mmol) in dry acetonitrile (200 mL) containing α,α-dimethoxytoluene (11.0 g, 72.3 mmol) and *p*-toluenesulphonic acid (150 mg, 0.87 mmol) was stirred at room

For personal use only.

temperature for 16 h. The solution was then neutralized with triethylamine and evaporated to dryness. A solution of the residue in dichloromethane (150 mL) was washed with water (50 mL), dried, and evaporated to leave a pale yellow solid which was crystallized from toluene (11.8 g, 79% yield); mp 129–131°C; $[\alpha]_D^{25}$ −15.3° (*c* 1.03, $CHCl_3$); ^1H nmr ($CDCl_3$) δ: 7.48–7.34 (m, 5H, aromatic), 6.02–5.9 (m, 1H, O—CH_2—C*H*=CH_2), 5.56 (s, 1H, benzylic), 5.34 and 5.22 (m, 2H, O—CH_2—CH=CH_2), 4.44 and 4.14 (m, 3H, H-4, O—CH_2—CH=CH_2), 4.31 (m, 2H, H-1, H-6a), 4.04 (bd, *J* = 12.2 Hz, 1H, H-6b), 3.64 (dd, *J* = 8.0, 10 Hz, 1H, H-2), 3.56 (ddd, *J* = 10.0 Hz, 8.0, 3.5 Hz, 1H, H-3), 3.41 (broad s, 1H, H-5), 2.59 (d, *J* = 8.0 Hz, 1H, —O—*H*); ^{13}C nmr ($CDCl_3$) δ: 133.58 (O—CH_2*C*H=CH_2), 129–126.0 (3 lines, aromatic carbons), 117.76 (O—CH_2—CH=*C*H_2), 101.46, 100.93 (C-1, benzylic carbon), 74.61 (C-4), 71.55 (C-5), 70.23 (C-3), 69.03 (C-6), 66.56 (O—*C*H_2—CH=CH_2), 64.10 (C-2). *Anal.* calcd. for $C_{16}H_{19}N_3O_5$: C 57.62, H 5.74, N 12.61; found: C 57.48, H 5.85, N 12.58.

*Allyl 2-azido-2-deoxy-4,6-*O*-benzylidene-3-*O*-(2,3,4,6-tetra-*O*-acetyl-β-*D*-galactopyranosyl)-β-*D*-galactopyranoside (**23**)*

A solution of tetra-*O*-acetyl-α-D-galactopyranosyl bromide (41) (7.36 g, 19.7 mmol) in dry nitromethane (30 mL) was added to a cooled (−25°C) solution of the alcohol **22** (5.97 g, 17.9 mmol), silver trifluoromethanesulphonate (5.067 g, 19.7 mmol), and *sym*-collidine (2.37 mL, 17.9 mmol) in dry nitromethane (100 mL). After stirring at −25°C for 8 h, the reaction mixture was diluted with dichloromethane (200 mL) and filtered through a bed of diatomaceous earth. The filtrate was washed with water, aqueous saturated sodium bicarbonate, and finally with water. Evaporation of the solvent left a residue which was purified by flash chromatography on a column of silica gel (300 g) using ethyl acetate − *n*-hexane − acetonitrile (2:2.5:0.5). The main fraction contained a solid (8.3 g, 70% yield) which appeared homogeneous on tlc. The analytical sample was prepared by crystallization from methanol; mp 141–144°C; $[\alpha]_D^{25}$ +13.7° (*c* 0.96, $CHCl_3$). The ^1H nmr spectrum of the crude product indicated it to be essentially pure and hence it was used in following steps; ^1H nmr ($CDCl_3$) δ: 4.80 (d, 1H, H-1′, $J_{1',2'}$ = 7.8 Hz), 4.33 (d, 1H, H-1, $J_{1,2}$ = 7.8 Hz); ^{13}C nmr ($CDCl_3$) δ: 170.27, 170.10, 169.28 (4 lines expected, 3 lines observed, 4 O—*C*OCH$_3$), 137.86, 128.89, 126.31 (aromatic carbons), 133.7 (O—CH_2—*C*H=CH_2), 117.61 (O—CH_2—CH=*C*H_2), 102.32 (C-1′), 101.23 (C-1), 100.82 (benzylic), 78.63 (C-3), 75.11 (C-4), 71.03, 70.10, 69.01, 68.95, 67.17, 66.70, 62.44, 61.47 (9 lines expected, 8 lines observed, the remaining carbons of sugar units and the aglyconic carbon), 20.65, 20.52 (*C*H$_3$ of acetyls). *Anal.* calcd. for $C_{30}H_{37}N_3O_{14}$: C 54.27, H 5.62, N 6.33; found: C 54.37, H 5.72, N 6.11.

*Allyl 4,6-di-*O*-acetyl-2-azido-2-deoxy-3-*O*-(2,3,4,6-tetra-*O*-acetyl-β-*D*-galactopyranosyl)-β-*D*-galactopyranoside (**24**)*

Aqueous trifluoroacetic acid (90%, 10 mL) was added to a solution of compound **23** (5.0 g) in dichloromethane (100 mL) kept at 0°C. After stirring for 30 min, the solution was washed with ice-cold water (50 mL), aqueous saturated sodium bicarbonate, and finally with water. Solvent removal left a syrup which was dissolved in dry dichloromethane (100 mL) containing pyridine (5 mL) and acetic anhydride (5 mL). 4-*N*,*N*-Dimethylaminopyridine (10 mg) was added and the mixture was stirred at room temperature for 12 h. The reaction mixture was then washed with ice-cold hydrochloric acid (1 *N*), saturated aqueous sodium bicarbonate, and finally with water. The dried solution was evaporated to a syrup and dissolved in dichloromethane for chromatography using a short silica gel column (20 g). Evaporation of the main fraction left a solid (3.9 g, 80% yield) which appeared homogeneous on tlc; mp 111–112°C; $[\alpha]_D^{25}$ +10.0° (*c* 1.89, $CHCl_3$); ^1H nmr ($CDCl_3$) δ: 6.0–5.88 (m, 1H, O—CH_2—C*H*=CH_2), 5.4–5.22 (m, 4H, H-4, H-4′, O—CH_2—CH=CH_2), 5.15 (dd, 1H, H-2′, $J_{1',2'}$ = 7.8 Hz, $J_{2',3'}$ = 10.5 Hz), 5.0 (dd, 1H, H-3′, $J_{3',2'}$ = 10.5 Hz, $J_{3',4'}$ = 3.5 Hz), 4.71 (d, 1H, H-1′, $J_{1',2'}$ = 7.8 Hz), 4.42 (m, 1H, O—CH_2—CH=CH_2), 4.33 (d, 1H, H-1, $J_{1,2}$ = 8.0 Hz), 4.22–4.04 (m, 5H, H-6a, H-6b, H-6′a, H-6′b, O—CH_2—CH=CH_2), 3.90 (broad t, 1H, H-5′, $J_{5',6'}$ = 7.0 Hz), 3.75 (broad t, 1H, H-5, $J_{5,6}$ = 7.0 Hz), 3.64 (dd, 1H, H-2, $J_{2,1}$ = 8.0 Hz, $J_{2,3}$ = 10.0 Hz), 3.54 (dd, 1H, H-3, $J_{3,2}$ = 10.0 Hz, $J_{3,4}$ = 3.5 Hz), 2.2–2.04 (6s, 18H, C*H*$_3$—COO); ^{13}C nmr ($CDCl_3$) δ: 170.47, 170.34, 170.25, 170.07, 169.75, 159.26 (6C=O), 133.22 (O—CH_2—*C*H=CH_2), 118.09 (O—CH_2—CH=*C*H_2), 101.47, 101.00 (anomeric carbons C-1 and C-1′), 77.26 (C-3), 71.42, 70.84, 70.66, 70.47, 68.85, 68.10 (C-5, C-5′, C-3′, C-2′, C-4′, C-4), 66.83 (O—*C*H_2—CH=CH_2), 63.34 (C-2), 62.29, 61.02 (C-6, C-6′), 20.70, 20.65, 20.63, 20.53 (6 *C*H$_3$ of acetyls). *Anal.* calcd. for $C_{27}H_{37}N_3O_{16}$: C 49.16, H 5.65, N 6.37; found: C 49.27, H 5.68, N 6.27.

*Allyl 2-azido-2-deoxy-3-*O*-(β-D-galactopyranosyl)-β-D-galactopyranoside (**25**)*

Sodium methoxide in methanol (2.5 mL) was added to a solution of **24** (4.0 g) in anhydrous methanol (75 mL) and stirred at room temperature for 6 h. After neutralization with IRA-120 H^+ resin, the solution was evaporated to a residue (2.3 g, 93.5% yield) which was homogeneous on tlc (ethyl acetate − ethanol−water, 7:2:0.5). The analytical sample was prepared by crystallization from ethanol−ether; mp 168–170°C (dec.); $[\alpha]_D^{25}$ −12.0° (*c* 0.64, H_2O); ^1H nmr (D_2O) δ: 5.98 (m, 1H, O—CH_2—C*H*=CH_2), 5.34 and 5.25 (m, 2H, O—CH_2—CH=CH_2), 4.54 and 4.48 (2d, 2H, H-1′, H-1, $J_{1',2'}$ = $J_{1,2}$ = 7.8 Hz), 4.10 (dd, 1H, H-4, $J_{4,3}$ = 3.5 Hz, $J_{4,5}$ = 1.5 Hz), 3.85 (broad d, 1H, H-4′, $J_{4',3'}$ = 3.5 Hz), 3.78–3.44 (m, 10H, remaining hydrogens of sugar units); ^{13}C nmr (D_2O) δ: 133.33 (O—CH_2—*C*H=CH_2), 118.98 (O—CH_2—CH=*C*H_2), 104.44 (C-1′), 100.82 (C-1), 80.29 (C-3), 75.20 (C-5′), 75.00 (C-5), 72.69 (C-3′), 70.87 (C-2′, O—*C*H_2—CH=CH_2), 68.73 (C-4′), 68.07 (C-4), 62.77 (C-2), 61.15 and 60.96 (C-6′ and C-6).

*Allyl 2-amino-2-deoxy-3-*O*-(β-D-galactopyranosyl)-β-D-galactopyranoside (**26**)*

Hydrogen sulphide was slowly bubbled through an ice-cold solution of the crude **25** (2.3 g) in pyridine (30 mL) and triethylamine (10 mL) for 4 h. After stirring at room temperature for 12 h, the solution was taken to dryness and the residue was extracted with water. The extract was filtered through a bed of diatomaceous earth (5.0 g) and evaporated to a residue (2.3 g) which was not further purified; ^1H nmr (D_2O) δ: 6.0–5.88 (m, 1H, O—CH_2—C*H*=CH_2), 5.35 and 5.25 (m, 2H, O—CH_2—CH=CH_2), 4.50 (d, 1H, H-1′, $J_{1',2'}$ = 7.8 Hz), 4.36 (d, 1H, H-1, $J_{1,2}$ = 7.8 Hz), 4.36 and 4.18 (m, 2H, O—CH_2—CH=CH_2), 4.12 (broad d, 1H, H-4, $J_{4,3}$ = 3.50 Hz), 3.91 (broad d, 1H, H-4′, $J_{4',3'}$ = 3.5 Hz), 3.80–3.54 (m, 9H, remaining ring hydrogens except H-2), 3.0 (dd, 1H, H-2, $J_{2,1}$ = 7.8 Hz, $J_{2,3}$ = 10.0 Hz); ^{13}C nmr (D_2O) δ: 134.11 (O—CH_2—*C*H=CH_2), 119.25 (O—CH_2—CH=*C*H_2), 105.23 (C-1′), 102.90 (C-1), 83.74 (C-3), 75.59, 75.38 (C-5, C-5′), 73.17 (C-3), 71.54 (C-2), 71.14 (O—*C*H_2—CH=CH_2), 69.15 (C-4′), 68.01 (C-4), 61.56, 61.49 (C-6 and C-6′), 52.42 (C-2).

*Allyl 4,6-di-*O*-acetyl-3-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-β-D-galactopyranoside (**27**)*

Phthalic anhydride (478 mg, 3.4 mmol) was added to a solution of the amine **26** (2.3 g, 6.0 mmol) in pyridine (20 mL). The solution was heated to 60–75°C for 20 min. Triethylamine (593 mg, 5.88 mmol) and more phthalic anhydride (478 mg, 3.4 mmol) were then added and the heating was continued for 2 h. Methanol (10 mL) was added and the solution was evaporated to a dry residue which was taken up in 15 mL of a mixture of pyridine − acetic anhydride (2:1). 4-*N*,*N*-Dimethylaminopyridine (10 mg) was added and the mixture was heated to 60°C for 12 h prior to evaporation. A solution of the residual syrup in dichloromethane (150 mL) was washed with ice-cold hydrochloric acid (1 *N*), aqueous saturated sodium carbonate, and finally with water. Solvent removal left a residue which was applied (flash chromatography) to a column of silica gel using ethyl acetate − *n*-hexane − acetonitrile (2:2:0.5). Evaporation of the first and main fraction left a solid (2.7 g, 62% yield) which appeared homogeneous on tlc. The analytical sample was prepared by crystallization from

ethanol; mp 165–166°C; $[\alpha]_D^{25}$ +16.0° (*c* 1.06, $CHCl_3$); ^1H nmr ($CDCl_3$) δ: 7.94–7.88 (m, 4H, phthalimido), 5.76–5.64 (m, 1H, O—CH_2—C*H*=CH_2), 5.50 (broad d, 1H, H-4, $J_{4,3}$ = 3.0 Hz), 5.27 (broad d, 1H, H-4′, $J_{4',3'}$ = 3.0 Hz), 5.18 (d, 1H, H-1, $J_{1,2}$ = 7.8 Hz), 5.03 (dd, 1H, H-2′, $J_{2',1'}$ = 7.8 Hz, $J_{2',3'}$ = 10.8 Hz), 5.18–5.0 (m, 2H, O—CH_2—CH=CH_2), 4.80 (dd, 1H, H-3′, $J_{3',2'}$ = 10.8 Hz, $J_{3',4'}$ = 3.0 Hz), 4.76 (dd, 1H, H-3, $J_{3,2}$ = 10.8 Hz, $J_{3,4}$ = 3.0 Hz), 4.56 (dd, 1H, H-2, $J_{2,1}$ = 7.8 Hz, $J_{2,3}$ = 10.8 Hz), 4.44 (d, 1H, H-1′, $J_{1',2'}$ = 7.8 Hz), 4.24 (dd, 1H, H-6a, $J_{6a,5}$ = 5.25 Hz, $J_{6a,6b}$ = 12.0 Hz), 4.12 (dd, 1H, H-6b, $J_{6b,5}$ = 6.75 Hz, $J_{6b,6a}$ = 12.0 Hz), 4.08–3.92 (m, 3H, H-5, H-6′a, H-6′b), 3.78 (m, 1H, H-5′), 2.22–1.54 (6s, 18H, 6CH_3 of acetyls); ^{13}C nmr ($CDCl_3$) δ: 170.54, 170.27, 170.00, 169.02 (8 lines expected, 4 lines observed, 8C=O), 134.37, 131.70, 123.72, 123.38 (phthalimido carbons), 133.43 (O—CH_2—C*H*=CH_2), 117.68 (O—CH_2—CH=CH_2), 100.72 (C-1′), 97.46 (C-1), 73.52 (C-3), 71.55 (C-5′), 70.93 (C-5), 70.85 (C-3′), 69.89 (C-2′), 68.73, 68.54 (C-4′ and C-4), 66.73 (O—CH_2—CH=CH_2), 62.47, 60.88 (C-6′ and C-6), 52.62 (C-2), 20.83, 20.76, 20.63, 20.44, 20.00 (6CH_3 of acetyls). *Anal.* calcd. for $C_{35}H_{41}NO_{18}$: C 55.05, H 5.41, N 1.83; found: C 54.98, H 5.40, N 1.85.

*4,6-Di-*O*-acetyl-3-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-α,β-galactopyranose (**29**)*

A solution of compound **28** (1.50 g, 1.96 mmol) in ethanol–benzene–water (7:3:1, 200 mL) containing tris-triphenylphosphine rhodium(I) chloride (200 mg, 0.432 mmol) and 1,4-diazabicyclooctane (66 mg, 0.59 mmol) was refluxed for 24 h. Further processing as described for the preparation of **17** left a syrup which was applied on a short column of silica gel (30 g). Evaporation of the main fraction left a solid (1.20 g, 84.6% yield) which appeared homogeneous on tlc. The ^1H nmr spectrum was in general accord with expectation.

*4,6-Di-*O*-acetyl-3-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-α,β-galactopyranosyl bromide (**30**)*

Vilsmeier bromide (27) (720 mg, 3.31 mmol) was added to a solution (0°C) of compound **29** (1.2 g, 1.65 mmol) in dichloromethane (15 mL). *sym*-Collidine (440 μL, 3.63 mmol) was added dropwise and the mixture was stirred at 0°C for 6 h and then at room temperature for 18 h. After washing with ice-cold water, dilute hydrochloric acid, saturated aqueous sodium bicarbonate, and finally with water, the solvent was evaporated to leave a solid (1.063 g, 82% yield) which was a mixture of the anomeric bromides; ^1H nmr ($CDCl_3$) δ: 7.87–7.6 (m, 4H, phthalimido), 6.5 (d, H-1α, $J_{1\alpha,2\alpha}$ = 3.5 Hz), 6.1 (d, H-1β, $J_{1\beta,2\beta}$ = 9.0 Hz), 5.66 (broad d, H-4α, $J_{4\alpha,3}$ = 3.0 Hz), 5.44 (broad d, H-4β, $J_{4\beta,3}$ = 3.0 Hz), 5.38 (dd, H-3α, $J_{3\alpha,2}$ = 10.5 Hz, $J_{3\alpha,4}$ = 3.0 Hz), 5.16 (broad d, H-4′β, $J_{4'\beta,3'}$ = 3.0 Hz), 4.94 (dd, H-2β, $J_{2\beta,1}$ = 9.0 Hz, $J_{2,3}$ = 10.5 Hz), 4.68 (dd, H-3′β, $J_{3'\beta,2'}$ = 10.5 Hz, $J_{3'\beta,4'}$ = 3.0 Hz), 4.60 (dd, H-3β, $J_{3\beta,2}$ = 10.5 Hz, $J_{3,4}$ = 3.0 Hz), 4.30 (d, H-1′β, $J_{1'\beta,2'}$ = 8.0 Hz), 4.26–3.66 (remaining hydrogens of sugar units), 2.18–1.60 (CH_3 of acetyls).

*8-Methoxycarbonyloctyl 2,3,6-tri-*O*-acetyl-4-*O*-[2,3-di-*O*-acetyl-6-*O*-benzoyl-4-*O*-{4,6-di-*O*-acetyl-3-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-β-D-galactopyranosyl}-β-D-galactopyranosyl]-β-D-glucopyranoside (**31**)*

4,6-Di-*O*-acetyl-3-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl)-2-deoxy-2-phthalimido-α,β-D-galactopyranosyl bromide (**30**) (531 mg, 0.648 mmol) in nitromethane (5 mL) was added to a solution of the alcohol **6** (465 mg, 0.562 mmol), *sym*-collidine (86 μL, 0.648 mmol), and silver triflate (167 mg, 0.648 mmol) in dry nitromethane (5 mL) cooled to −25°C. The mixture was stirred at −25°C for 6 h and then at room temperature for 12 h. The solid that was deposited after the addition of dichloromethane (30 mL) was removed and the filtrate was washed with aqueous sodium thiosulphate, cold water, aqueous HCl, and then aqueous sodium bicarbonate. Solvent removal left a solid which was purified by hplc on a column of silica gel using ethyl acetate – *n*-hexane – acetonitrile (2:2:0.75). Evaporation of the second and main fraction left a solid (548 mg, 62% yield) which was homogencous on tlc; $[\alpha]_D^{25}$ −8.3° (*c* 1.6, $CHCl_3$); ^1H nmr ($CDCl_3$) δ: 8.06–7.46 (broad m, 9H, phthalimido, benzoate), 5.44 (broad d, 1H, H-4″, $J_{4'',3''}$ = 3.5 Hz), 5.24 (broad d, 1H, H-4‴, $J_{4''',3'''}$ = 3.5 Hz), 5.12 (d, 1H, H-1″, $J_{1'',2''}$ = 8.0 Hz), 5.12 (t, 1H, H-3, $J_{3,2}$ = $J_{3,4}$ = 9.0 Hz), 5.0 (dd, 1H, H-2‴, $J_{2''',1'''}$ = 8.0 Hz, $J_{2''',3'''}$ = 10.5 Hz), 4.86–4.74 (m, 4H, H-2, H-3′, H-3″, H-3‴), 4.70 (dd, 1H, H-6′a, $J_{6'a,5'}$ = 7.0 Hz, $J_{6'a,6'b}$ = 11.0 Hz), 4.53–4.30 (m, 6H, H-2″, H-2′, H-1‴, H-1, H-6a, H-6′b), 4.24 (d, 1H, H-1′, *J* = 8.0 Hz), 4.18–4.08 (m, 2H, H-4′, H-6″a), 4.03–3.86 (m, 5H, H-6‴a, H-6‴b, H-6b, H-6″b, H-5″), 3.78–3.70 (m, 3H, H-5′, H-5‴, O—CH_2 of aglycon), 3.64 (t, 1H, H-4, $J_{4,5}$ = $J_{4,3}$ = 9.0 Hz), 3.48 (m, 1H, H-5), 3.38 (m, 1H, O—CH_2 of aglycon), 2.28 (t, 2H, CH_2COOCH_3), 2.12–1.2 (45H, 11CH_3 of acetyls, 12 aglyconic hydrogens); ^{13}C nmr ($CDCl_3$) δ: 174.24, 170.59, 170.31, 170.24, 170.03, 169.94, 169.47 169.34, 169.04, 168.05, 166.92, 166.28, (15C=O, 15 lines expected, 12 lines observed), 134.50, 134.03, 133.38, 131.73, 131.61, 129.95, 129.71, 128.72, 125.22, 124.67 (phthalimido, benzoate carbons), 100.97, 100.88, 100.30, 98.37 (anomeric carbons), 75.33, 72.98, 72.83, 72.30, 72.24, 72.01, 71.74, 70.92, 70.87, 70.04, 69.48, 68.72, 68.60, 66.82, 63.26, 62.41, 62.06, 60.97, 52.51 (20 lines expected, 19 lines observed, remaining carbons of sugar units and the aglyconic carbon), 51.0–19.59 (16 lines).

*8-Methoxycarbonyloctyl 4-*O*-[4-*O*-{2-deoxy-3-*O*-(β-D-galactopyranosyl)-2-phthalimido-β-D-galactopyranosyl}-β-D-galactopyranosyl]-β-D-galactopyranoside (**32**)*

Sodium methoxide in methanol (0.5 mL) was added to a solution of compound **31** (548 mg, 0.357 mmol) in anhydrous methanol (25 mL). After stirring at room temperature under dry nitrogen atmosphere for 4 h, the solution was neutralized with IRA-120H^+ resin and evaporated to a colorless residue (350 mg, 91% yield); ^1H nmr (CD_3OD) δ: 8.1–7.81 (m, 4H, phthalimido), 5.23 (d, 1H, H-1″, $J_{1'',2''}$ = 8.0 Hz), 4.93 (dd, 1H, H-3″, $J_{3'',2''}$ = 10.0 Hz, $J_{3'',4''}$ = 3.0 Hz), 4.52–4.35 (m, 4H, H-1, H-2″, H-1′, H-1‴), 4.1–3.30 (remaining pyranose ring hydrogens and O—CH_2 of aglycon, except H-2′), 3.04 (dd, 1H, H-2′, $J_{1',2'}$ = 7.8 Hz, $J_{2',3'}$ = 9.0 Hz), 2.41 (t, 2H, CH_2COOCH_3), 1.64 and 1.33 (remaining hydrogens of aglycon).

*8-Methoxycarbonyloctyl 4-*O*-[4-*O*-{2-acetamido-2-deoxy-3-*O*-(β-D-galactopyranosyl)-β-D-galactopyranosyl}-β-D-galactopyranosyl]-β-D-glucopyranoside (**33**)*

A solution of compound **32** (350 mg, 0.357 mmol) and 95% hydrazine hydrate (~120 μL) in methanol (20 mL) was refluxed for 8 h. Solvent removal left a syrup which was redissolved in methanol (5 mL) containing acetic anhydride (1 mL) and stirred at room temperature for 3h. The solution was then evaporated to dryness and dissolved in water (5 mL). The precipitate was removed and the filtrate was concentrated to 2 mL for passage through a P-2 Biogel column by elution with water–ethanol (9:1). Lyophilization of the first and main fraction left a colorless powder (215 mg, 61.7% yield), $[\alpha]_D^{25}$ −9.2° (*c* 0.3, H_2O); ^1H nmr (D_2O) δ: 4.64 (d, 1H, H-1″, $J_{1'',2''}$ = 8.2 Hz), 4.42 (m, 3H, H-1, H-1′, H-1‴), 4.11 (broad, d, 1H, H-4′, $J_{4',3'}$ = 2.2 Hz), 4.05 (broad d, 1H, H-4″, $J_{4,3}$ = 2.2 Hz), 3.95 (dd, 1H, H-2″, $J_{2'',1''}$ = 8.0 Hz, $J_{2'',3''}$ = 10.5 Hz), 3.90–3.50 (remaining ring protons and O—CH_2 of aglycon, except H-2′ and H-2), 3.55 (dd, 1H, H-2′, $J_{2',1'}$ = 8.2 Hz, $J_{2',3'}$ = 10.1 Hz), 3.23 (dd, 1H, H-2, $J_{2,1}$ = 7.7 Hz, $J_{2,3}$ = 8.2 Hz), 2.4 (t, 2H, CH_2—COOCH_3), 2.1 (3H, CH_3 of N-acetyl), 1.68–1.38 (remaining 12H of aglycon).

The ^{13}C nmr spectrum is reported in Table 1.

*8-Methoxycarbonyloctyl 2,3-di-*O*-acetyl-4,6-*O*-benzylidene-β-D-galactopyranoside (**34**)*

A solution of 8-methoxycarbonyloctyl 4,6-*O*-benzylidene-β-D-galactopyranoside (40) (753 mg) in dichloromethane (15 mL) containing pyridine (3 mL), acetic anhydride (3 mL), and *N*,*N*-dimethylaminopyridine (10 mg) was stirred for 24 h at room temperature. Work-up in the usual manner afforded a syrup (880 mg, 98% yield) which was homogeneous as examined by tlc; ^1H nmr ($CDCl_3$) δ:

7.5–7.3 (m, 5H, aromatic), 5.50 (s, 1H, benzylic), 5.38 (dd, 1H, $J_{2,1}$ = 8.0 Hz, $J_{2,3}$ = 10.5 Hz, H-2), 4.95 (dd, 1H, $J_{3,2}$ = 10.5 Hz, $J_{3,4}$ = 3.6 Hz, H-3), 4.48 (d, 1H, $J_{1,2}$ = 8.0 Hz, H-1), 4.37 (bd, 1H, H-4), 4.33 (dd, 1H, $J_{6a,5}$ = 1.4 Hz, $J_{6a,6b}$ = 12.4 Hz, H-6a), 4.07 (dd, 1H, H-6b), 3.91 (m, 1H, O—CH_2 of aglycon), 3.66 (s, 3H, $COOCH_3$), 3.51 (d, 1H, H-5), 3.46 (m, 1H, CH_2 of aglycon), 2.29 (t, 2H, J = 7.3 Hz, CH_2—$COOCH_3$), 2.07, 2.05 (2s, 6H, $2CH_3$—COO), 1.60 and 1.29 (12H, remaining hydrogens in aglycon).

*8-Methoxycarbonyloctyl 2,3-di-*O*-acetyl-β-D-galactopyranoside (**35**)*

A solution of compound **34** (603 mg) in dichloromethane (20 mL) containing 90% aqueous trifluoroacetic acid (1.5 mL) was stirred at 0°C for 3 h. Work-up in the usual manner and the purification of the crude product on a column of silica gel afforded a colorless solid (402 mg, 80% yield).

The ^{1}H nmr was in accordance with structure **35**.

*8-Methoxycarbonyloctyl 2,3-di-*O*-acetyl-6-*O*-benzoyl-β-D-galactopyranoside (**36**)*

A solution of benzoyl chloride (332 mg, 274 μL, 2.36 mmol) in dichloromethane (1 mL) was added to a cooled (−78°C) solution of compound **35** (932 mg, 2.14 mmol) in dichloromethane (15 mL) containing anhydrous pyridine (186 μL, 2.36 mmol). After 6 h, the solution was warmed to −30°C and stirred for another 18 h. Work-up of the reaction mixture followed by purification on a column of silica gel afforded a colorless solid (725 mg, 62.7% yield); ^{1}H nmr ($CDCl_3$) δ: 8.0–7.38 (m, 5H, benzoate), 5.26 (dd, 1H, $J_{2,1}$ = 7.8 Hz, $J_{2,3}$ = 10.2 Hz, H-2), 4.99 (dd, 1H, $J_{3,4}$ = 3.1 Hz, H-3), 4.62 (dd, 1H, $J_{6a,5}$ = 6.6 Hz, $J_{6a,6b}$ = 11.2 Hz, H-6a), 4.53 (dd, 1H, $J_{6b,5}$ = 6.3 Hz, H-6b), 4.48 (d, 1H, $J_{1,2}$ = 7.8 Hz, H-1), 4.11 (dd, 1H, $J_{4,O-H}$ = 5.3 Hz, H-4), 3.90 (bt, 1H, H-5), 3.86 (m, 1H, O—CH_2 of aglycon), 3.66 (s, 3H, $COOCH_3$), 3.48 (m, 1H, O—CH_2 of aglycon), 2.40 (d, 1H, 4-O*H*), 2.29 (t, 2H, J = 7.5 Hz, CH_2COOCH_3), 2.10, 2.05 (2s, $2CH_3$—COO), 1.58 and 1.27 (m, 12H, remaining hydrogens of aglycon).

*8-Methoxycarbonyloctyl 2,3-di-*O*-acetyl-6-*O*-benzoyl-4-*O*-(3,4,6-tri-O-acetyl-2-deoxy-2-phthalimido-β-D-galactopyranosyl)-β-D-galactopyranoside (**37**)*

A solution of the phthalimidobromide **18** (437 mg, 0.87 mmol) in nitromethane (5 mL) was added to a solution of **36** (393 mg, 0.73 mmol), *sym*-collidine (105.6 mg, 0.87 mmol), and silver triflate (225 mg, 0.87 mmol) in dry nitromethane (5 mL) at −25°C. The mixture was stirred at this temperature for 12 h and then at room temperature for another 24 h. Work-up of the reaction mixture and purification on a column of silica gel afforded a colorless solid (360 mg, 48% yield); ^{1}H nmr ($CDCl_3$) δ: 8.07–7.40 (m, 9H, benzoate, phthalimido), 5.91 (dd, 1H, $J_{3',2'}$ = 11.4 Hz, $J_{3',4'}$ = 3.4 Hz), 5.45 (d, 1H, H-4′), 5.29 (d, 1H, $J_{1',2'}$ = 8.5 Hz, H-1′), 4.89 (dd, 1H, $J_{3,4}$ = 2.9 Hz, $J_{3,2}$ = 10.2 Hz, H-3), 4.72 (dd, $J_{2,1}$ = 7.8 Hz, H-2), 4.69 (dd, 1H, $J_{6a,5}$ = 5.6 Hz, $J_{6a,6b}$ = 11.5 Hz, H-6a), 4.62 (dd, 1H, H-2′), 4.45 (dd, 1H, $J_{6b,5}$ = 6.6 Hz), 4.33 (d, 1H, $J_{1,2}$ = 7.8 Hz, H-1), 4.14 (d, 1H, H-4), 4.11–3.99 (m, 3H, H-6′a, H-6′b, H-5′), 3.82 (t, 1H, H-5), 3.73 (m, 1H, O—CH_2 of aglycon), 3.66 (s, 3H, $COOCH_3$), 3.39 (m, 1H, OCH_2 of aglycon), 2.29 (t, 2H, J = 7.3 Hz, CH_2COOCH_3), 2.21–1.66 (5s, 15H, 5 CH_3COO), 1.58 and 1.25 (12H, remaining hydrogens of aglycon).

*8-Methoxycarbonyloctyl-4-*O*-(2-acetamido-2-deoxy-β-D-galactopyranosyl)-β-D-galactopyranoside (**38**)*

Removal of the *O*- and *N*-protecting groups of **37** and the *N*-acetylation of the resulting amine was accomplished under the conditions described earlier for the conversion of **19** to **21**. This afforded compound **38** in 77% overall yield. The indentity of **38** was established on the basis of comparison of ^{1}H and ^{13}C nmr data of an authentic sample of **38** provided by Dr. R. M. Ratcliffe of Chembiomed Ltd. (unpublished); ^{1}H nmr (D_2O) δ: 4.59 (d, 1H, $J_{1',2'}$ = 8.5 Hz, H-1′), 4.32 (d, 1H, $J_{1,2}$ = 8.2 Hz, H-1), 4.03 (d, $J_{4,3}$ = 2.2 Hz, H-4), 3.91–3.33 (16H, remaining hydrogens of sugar units, $COOCH_3$, OCH_2 of aglycon), 2.40 (t, 2H, CH_2—$COOCH_3$), 2.04 (s, 3H, NH($COCH_3$)), 1.61 and 1.33 (12H, remaining hydrogens of aglycon).

The ^{13}C nmr spectrum is reported in Table 1.

*n-Propyl 2-acetamido-2-deoxy-3-*O*-(β-D-galactopyranosyl)-β-D-galactopyranoside (**39**)*

A solution of compound **25** (46 mg, 0.11 mmol) in 95% ethanol (4 mL) containing palladium on carbon (10%, 10 mg) was stirred under an atmosphere of hydrogen for 3 h. The reaction mixture was filtered and evaporated to dryness. The residue (38 mg) was taken up in a mixture of methanol – acetic anhydride (10:1, 1 mL) and stirred at room temperature for 3 h. Examination of the reaction mixture at this time (EtOAc–EtOH–H_2O, 16:8:5) indicated the presence of a single compound. It was then evaporated to a dry residue which was redissolved in water and freeze-dried. This afforded a colorless material (40 mg, 0.09 mmol, 89% yield), $[\alpha]_D^{25}$ 8° (*c*, 0.09); ^{1}H nmr (D_2O) δ: 4.53 (d, 1H, $J_{1,2}$ = 10.0 Hz, H-1), 4.46 (d, $J_{1',2'}$ = 7.7 Hz, 1H, H-1′), 4.01 (dd, 1H, $J_{2,3}$ = 11.2 Hz, 1H, H-2), 3.95–3.51 (remaining sugar hydrogens and OCH_2—CH_2—CH_3), 2.02 (s, 3H, NHCO—CH_3), 1.56 (m, 2H, O—CH_2—CH_2—CH_3), 0.88 (t, J = 7.3 Hz, 3H, O—CH_2—CH_2—CH_3).

The ^{13}C nmr spectrum is presented in Table 1.

ERIC PICQUENARD, JACQUES RIAND, and JEAN-PIERRE BRUN. Can. J. Chem. **62**, 655 (1984).

The fragmentation under electron impact of various methyl-2-pyrimidones is investigated. The fragmentation is markedly influenced by the methyl substituent in the 4- or 5-position and the main fragmentation pathways of the molecular ion involve the loss of carbon monoxide or methyl radical. The latter fragmentation process shows that the methyl groups are more labile in the 4- and(or) 6-position than in the 5-position. This is corroborated by the study of trideuteriomethylated analogues. One can thus distinguish by mass spectrometry the different isomers of position, 4-methyl and 5-methyl or 4,5-dimethyl and 4,6-dimethyl-2-pyrimidones.

ERIC PICQUENARD, JACQUES RIAND et JEAN-PIERRE BRUN. Can. J. Chem. **62**, 655 (1984).

On a étudié les processus de fragmentation de différentes méthylpyrimidone-2. Ceux-ci sont nettement influencés par le groupement méthyle en position 4 ou 5 sur le cycle et les fragmentations majeures de l'ion moléculaire font intervenir la perte d'une molécule neutre CO ou d'un radical méthyle. Dans ce dernier cas, les groupements méthyles en position 4 et (ou) 6 sont plus mobiles que celui en position 5, ce qui est confirmé par l'étude des dérivés trideutériométhylés. Il est alors possible de distinguer par spectrométrie de masse les différents isomères de position, méthyl-4 et méthyl-5 ou diméthyl-4,5 et diméthyl-4,6 pyrimidone-2.

Introduction

Mass spectra of 4-pyrimidones or uracil derivatives which are of great interest in connection with biologically important nucleic acids have already been examined thoroughly (1–4). However, few studies of the mass spectral behaviour of 2-pyrimidones have been reported, with the exception of one very recent work (5).

Analysis of the mass fragmentation of such compounds may provide a convenient means of structure determinations. In continuation of our previous work dealing with the methyl-2-pyrimidones (6, 7), we present results on mass spectral studies of these compounds. Those investigated are listed in Table 1. Our study of the physical properties of these compounds has led us to show that the methyl group attached to C-4 or C-6 of 2-pyrimidone undergoes hydrogen–deuterium exchange reactions in D_2O medium (6) and even in the solid phase (7). In connection with these results, we expect that studies of the fragmentation patterns could show the extent of hydrogen or methyl loss in the 4(or 6)- and 5-position. For this purpose, the 4,6-bis(trideuteriomethyl)-5-methyl-2-pyrimidone(1*D*) **7** will be used to corroborate the fragmentation process of CH_3 loss only. Furthermore, the methoxypyrimidine **9** has been studied for the sake of comparison with the *N*-methyl compound **8**.

Results and discussion

The mass spectra of methyl-2-pyrimidones show the great stability of the aromatic ring. The base peaks always correspond to the molecular ion (Table 2). Important differences between the mass spectral behaviour of these compounds and that of unsubstituted 2-pyrimidone (5) show that the fragmentation patterns are affected by the presence of a methyl group attached to the ring. As an example, the fragmentation pathways of compound **3** are outlined in Scheme 1. Transitions substantiated by an appropriate metastable peak (directly observed on the 70 eV mass spectrum) are indicated by an asterisk.

Loss of CO

A noteworthy feature of pyrimidone fragmentation is the preferential loss of carbon monoxide from the molecular ion. This loss can be characterized by the observation of a metastable ion and yields a *m/z* 82 ion for **1** and **2** and a *m/z* 96 ion for **3** and **4**. This is corroborated by exact mass measurement; the peak at *m/z* 96 in the spectrum of **3** corresponds mainly to the CO loss process ($C_5H_8N_2^{+\bullet}$, 93%) and for a minor part to another process ($C_5H_6NO^+$, 7%) which will be discussed later. This is most conveniently interpreted as arising from the keto form of the molecular ion. In agreement with this fragmentation, compounds **5** and **6** yield respectively the *m/z* 110 and

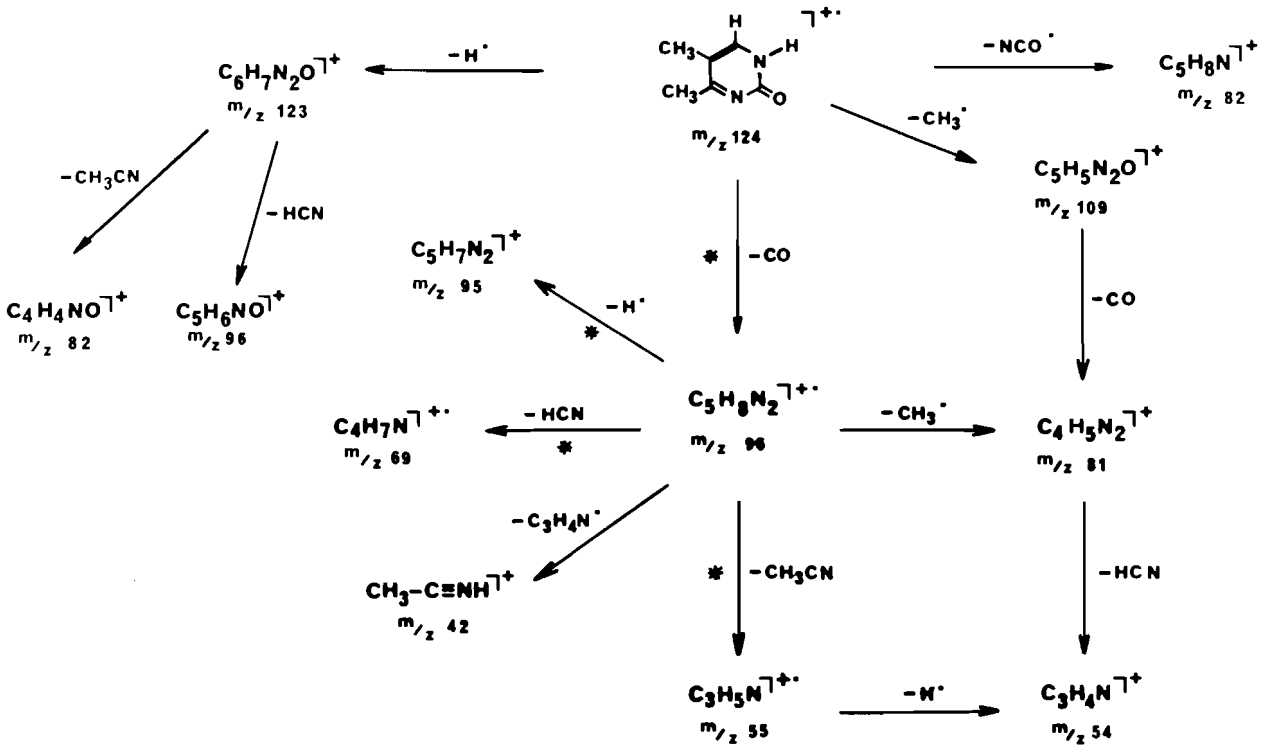


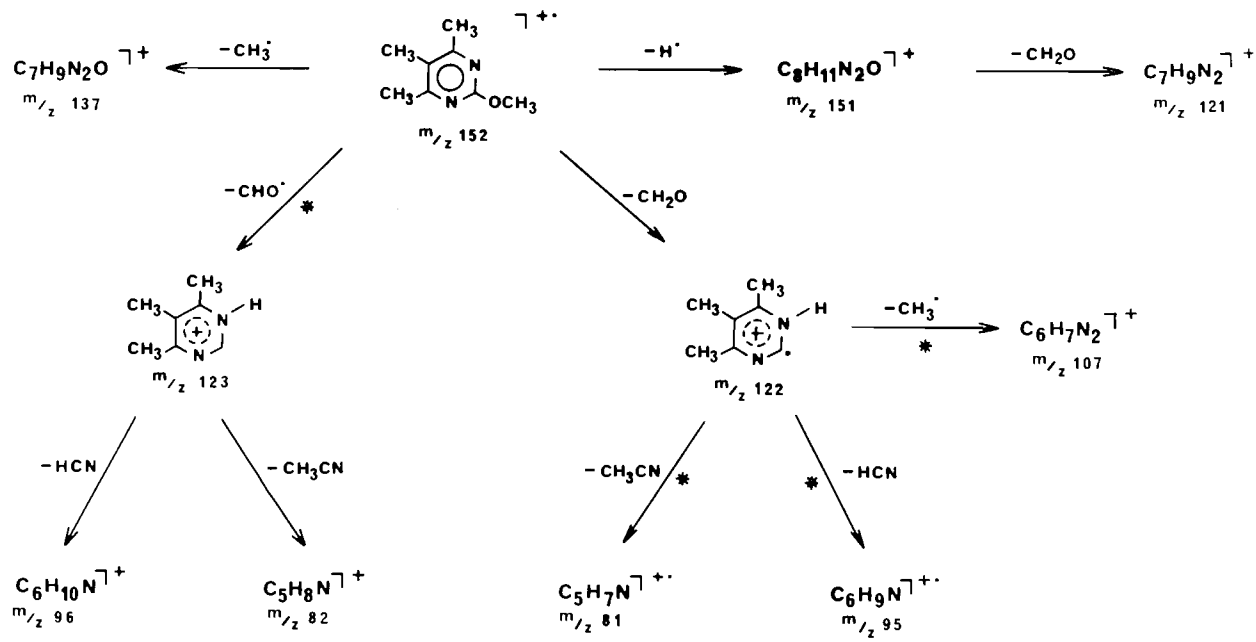
SCHEME 1. Major fragmentation processes of 4,5-dimethyl-2-pyrimidone.

113 ions. The *N*-methyl derivative **8**, in which tautomerism is prevented, displays the expected expulsion of carbon monoxide to give the *m/z* 124 ion.

This fragmentation process is of lesser importance than that observed for unsubstituted 2-pyrimidone and its *N*-methylated analogue (5) but is equivalent to the process observed for 2-methyl-4-pyrimidone and its *N*-methyl derivative (4). Therefore it appears that CO loss is a general main fragmentation process for 2- and 4-pyrimidones (2, 4, 5). The decrease in the loss of CO is then induced by the presence of the methyl group attached to the ring in the 4- or 5-position.

Loss of H·

The primary loss of H· occurs to a lesser extent for methyl-2-pyrimidones (**1** to **7**) than for unsubstituted 2-pyrimidone and is nearly negligible for compound **8**. Kazdan *et al.* (5) have concluded that this loss occurs specifically from the 4-position of unsubstituted 2-pyrimidone. Our results obtained for **3** ($M - H^{+}$: 13.5%) and **4** ($M - H^{+}$: <5%) confirm without any ambiguity that this loss occurs from the 4-position and not at all from the 5-position. Furthermore, the fragmentation study for compound **6** enables us to show that neither the loss of a hydrogen atom from the 4- or 6-methyl group nor a deuterium atom from the 5-trideuteriomethyl group is promoted. As a matter of fact, the relative intensities of $M - H^{+}$ and $M - D^{+}$ peaks for this compound are weak (5% and <5% respectively). For compound **7**, we are unable to determine the respective proportion of H loss and D loss from the 4- or 6-CD_3 groups and the 5-CH_3 group. As expected for this compound, the H/D exchange reaction occurs in the inlet and ion source, which explains the important relative intensities of $M - H^{+}$ and $M - D^{+}$ peaks compared to those of compounds **5** and **6**. Metastable peaks for these H· (D·) losses were not observed, so that no abundance measurements could be done. For 4-methyl-



SCHEME 2. Major fragmentation processes of 2-methoxy-4,5,6-trimethylpyrimidine.

2-pyrimidone, H loss is noticeable (8.5% for the m/z 109 ion) whereas an analogous loss in the spectrum of 6-methyl-4-pyrimidone is not observed (2), which indicates the influence of the position of the carbonyl function on this fragmentation process. This can be compared with the results on the H/D exchange of methyl groups for pyrimidones, in spite of the lack of correlation. As a matter of fact, the study of isotopic exchange allows us to compare the relative mobility of methyl hydrogens in a molecule. Thus, if the 4- and (or) 6-methyl groups undergo exchange reactions in substituted 2-pyrimidones (6, 8), no exchange occurs for the methyl group in 6-methyl-4-pyrimidone.[2]

A very intense M − $H^{\cdot+}$ peak is present in the spectrum of compound **9** (Scheme 2). It has been shown that this is usual for methoxypyrimidines, the loss of a hydrogen atom coming from the methoxy group (2, 4).

Hydrogen loss is less important from the molecular ion than from the M − $CO^{\cdot+}$ ion. This last fragmentation leads to the following ions: m/z 81 for **1** and **2**, m/z 95 for **3** and **4**, and m/z 109 for **5**, with relative intensities between 10 and 27%. For compound **6**, the M − $CO^{\cdot+}$ ion loses a hydrogen and a deuterium atom to lead to the peaks at m/z 112 and 111 respectively, with the same intensity (18%). This elimination involves the 4-methyl and 5-methyl groups in the same way. For the *N*-methyl derivative **8**, the M − $CO^{\cdot+}$ ion also loses a hydrogen atom, which corresponds to the m/z 123 ion (24%).

Loss of CH_3

The loss of a methyl radical is greater for the 4- or 6-position than for the 5-position. This result enables us to distinguish unambiguously the 4-methyl-2-pyrimidone from its isomer, the 5-methyl-2-pyrimidone. The relative intensity of the M − CH_3^+ ion (m/z 95) is 49.5% for the first compound and 5% for the second one. Likewise, for dimethylated derivatives, CH_3 loss leading to the m/z 109 ion is more pronounced for 4,6-dimethyl-2-pyrimidone (46%) than for 4,5-dimethyl-2-pyrimidone (23%). Additional support for the above results comes from the spectrum of the trimethylated compound **7** in which no CH_3 loss from the 5-position is noticeable: the M − CH_3^+ ion (m/z 130) is not observed, while the relative intensity of the M − CD_3^+ ion (m/z 127) is 20%. These results are in good agreement with those obtained for dimethylpyrimidines, i.e., preferential elimination of the methyl groups attached to C-4 or C-6 rather than to C-2 or C-5 of the pyrimidine ring (9). For the 6-methylpyrimidine series, methyl loss depends on the nature of the other substituents but remains weak, especially for 2- and 4-amino substituents (2, 3).

The loss of a methyl radical from the molecular ion is greater for the *N*-methyl compound **8** than for its corresponding *N*-hydrogenated **5** (m/z 137, 81% and m/z 123, 17% respectively). Then, the ring nitrogen atom is the principal site of CH_3 loss rather than a ring carbon atom. This is similar to what is observed for dimethylaminopyrimidines. For these compounds, after the loss of the methyleneimine group, the methyl radical is expelled also from the ring nitrogen atom (10, 11). This CH_3 loss also occurs for the methoxy derivative **9**, but to a lesser extent than for **5** (Scheme 2). Such an elimination is seldom observed for methoxypyrimidines (4, 11), which is in good agreement with our results.

A CH_3 loss is also observed from the M − $CO^{\cdot+}$ ion. This loss is weaker than from the molecular ion and gives the m/z 67 ion for compounds **1** and **2**, the m/z 81 ion for **3** and **4**, and the m/z 95 ion for **5**. Exact mass measurements indicate that the m/z 81 and 95 peaks for compounds **3** and **5** respectively are solely due to the $C_4H_5N_2^+$ and $C_5H_7N_2^+$ ions. Likewise, the M − $CO^{\cdot+}$ ion of **6** can expel a CH_3 or a CD_3 radical, leading to the m/z 98 and 95 ions respectively. For the *N*-methyl derivative **8**, this fragmentation leads to a m/z 109 ion with a relative intensity weaker than for compound **5**.

Loss of HCN and CH_3CN

It has been shown that for 2-pyrimidone (5) the loss of a neutral molecule of HCN or the loss of CH_3CN for 2-methyl-4-pyrimidone (4) are the usual fragmentation processes. These processes are not significant for methyl-2-pyrimidones, since the relative intensities of the corresponding

[2] E. Piequenard, unpublished results.

ion peaks (m/z 83 ($C_4H_5NO^{\neg+\bullet}$) for compounds **1** to **4** and m/z 97 ($C_5H_7NO^{\neg+\bullet}$) for **5**) are lower than 7%. Likewise, compound **8** does not eliminate CH_3CN, no peak at m/z 111 being noticeable. Similar behaviour has been observed for the 1,2-dimethyl-4-pyrimidone (4). CH_3CN loss is then negligible compared to that of the corresponding N-hydrogenated derivative. However, such a HCN or CH_3CN loss is greater from the $M - H^{\neg+}$ and $M - CO^{\neg+\bullet}$ ions than from the molecular ion, where it is negligible. Thus, by eliminating HCN, the $M - H^{\neg+}$ ion leads to the m/z 82 ion ($C_4H_4NO^{\neg+}$) for compounds **1** and **2**, and by eliminating CH_3CN, leads to the m/z 68 ion ($C_3H_2NO^{\neg+}$) for **2**, the m/z 82 ion for **3** and **4**, and the m/z 96 ion for **5**. The relative intensities for monosubstituted compounds **1** and **2** are large (Table 2). For compound **6**, CH_3CN loss from the $M - H^{\neg+}$ and $M - D^{\neg+}$ ions leads to the m/z 99 and 98 ions respectively, with the same relative intensity (14.5%). Exact mass measurements on the m/z 96 peak for compounds **3** and **5** have been performed. For compound **5**, the contribution of the $C_5H_6NO^{\neg+}$ ion to this peak is only 33%. For compound **3**, the elimination of HCN from the $M - H^{\neg+}$ ion is a minor process since the contribution of the $C_5H_6NO^{\neg+}$ ion is only 7%.

Likewise, by loss of HCN, the $M - CO^{\neg+\bullet}$ ion generates the m/z 55 ion ($C_3H_5N^{\neg+\bullet}$) for **1** and **2** and the m/z 69 ion ($C_4H_7N^{\neg+\bullet}$) for **3**. In the spectrum of **3**, the presence of an intense peak at m/z 69 (36%) enables us to distinguish compound **3** from its isomer of position, compound **4**. By eliminating CH_3CN, the $M - CO^{\neg+\bullet}$ ion leads to the following ions: m/z 41 ($C_2H_3N^{\neg+\bullet}$) for **1**, m/z 55 ($C_3H_5N^{\neg+\bullet}$) for **3** and **4**, and m/z 69 ($C_4H_7N^{\neg+\bullet}$) for **5**, as confirmed for the last compound by exact mass measurements. The elimination of acetonitrile for deuterated derivatives, CH_3CN for **6** and CD_3CN for **7**, gives intense peaks at m/z 72(52%) and m/z 73 (68%) respectively.

Other fragmentation processes

The loss of HNCO from the molecular ion via the retro Diels–Alder mechanism is certainly, for our compounds, a minor fragmentation process, contrary to what is observed for 2-pyrimidone (5). Thus, the expected $C_5H_7N^{\neg+\bullet}$ and $C_6H_9N^{\neg+\bullet}$ ions for compounds **3** and **5** respectively do not take part in the m/z 81 and 95 peaks, as mentioned above.

The loss of a NCO radical from the molecular ion is observed as for 2-pyrimidone (5), corresponding to the peaks at m/z 68, 68, 82, 82, 96, 99, 103, and 110 respectively for compounds **1** to **8**, with weak relative intensities except for **1** (Table 2). For compound **5**, exact mass measurement shows that the corresponding ion $C_6H_{10}N^{\neg+}$ contributes to 66% of the m/z 96 peak, the other ion being $C_5H_6NO^{\neg+}$ (see above).

In the lower region of the spectra of methyl-2-pyrimidones, there are many ion peaks characteristic of pyrimidines, m/z 79, 67, 53, 52, 51, 42, and 41, among which the m/z 42 ion is largely predominant (1–5). High resolution mass measurements on compounds **3** and **5** show that the elemental composition of this last ion is $C_2H_4N^{\neg+}$ which corresponds to the acetonitrile cation; this is very usual for pyrimidines with 2-, 4-, or 6-methyl groups (4, 9). As expected, this m/z 42 ion is not observed for compound **2**. This ion comes from the molecular ion or from the $M - CO^{\neg+\bullet}$ ion, as is observed for 2-methyl-4-pyrimidone (4). For the methoxy derivative **9**, the m/z 42 ion comes either from the predominant m/z 122 ion with loss of $C_5H_6N^{\bullet}$ or from the m/z 123 ion with loss of $C_5H_7N^{\bullet}$.

2-Methoxy-4,5,6-trimethylpyrimidine

Other fragmentation processes specific for this compound will be detailed in this section. This compound can eliminate formaldehyde via the four-membered cyclic transition state to yield the large 4,5,6-pyrimidine ion (m/z 122, 91.5%), as was observed in several 4-methoxypyrimidines(2, 4). This loss is also observed from the $M - H^{\neg+}$ ion to give the m/z 121 ion. Another important process is the loss of formyl radical from the molecular ion, which yields a m/z 123 ion (46%) (Scheme 2). Elimination of acetonitrile from the molecular ion should result in the formation of a m/z 111 ion which, however, was neither detected for this compound nor for the *N*-methyl derivative **8**. However, the m/z 122 and 123 ions eliminate HCN or CH_3CN respectively to give m/z 95 and 81 ions or m/z 96 and 82 ions (Table 2). Finally, the $M - OH^{\neg+\bullet}$ ion observed for methoxybipyrimidine (11) is not obtained for compound **9**, which has a single pyrimidine ring.

The fragmentation processes for compound **9** are so characteristic of alkoxy-substituted pyrimidines that we cannot expect to obtain, with this technique, information on lactam–lactim tautomerism by comparing compound **8** with compound **9** as models for the lactam and lactim forms of **5**, respectively.

Conclusion

The detailed analysis of the mass spectra of various substituted methyl-2-pyrimidones indicates the important influence of the methyl group in the fragmentation processes of the heterocycles. This is clearly shown by the differences between the behaviour of these compounds and that reported in the literature for 2- and 4-pyrimidones. The loss of a neutral CO molecule remains a predominant fragmentation process; however, it is less so than for unsubstituted 2-pyrimidone. The loss of a methyl radical from the molecular ion is a very important fragmentation process when this methyl group is attached to C-4 or C-6, and not to C-5, of the pyrimidone ring. Then the different fragmentation behaviour, according to the substitution site, enables us to distinguish by mass spectrometry 4-methyl from 5-methyl-2-pyrimidone and 4,5-dimethyl from 4,6-dimethyl-2-pyrimidone. Finally, the loss of HCN or CH_3CN does not occur from the molecular ion but only from the $M - CO^{\neg+\bullet}$ ion.

Experimental

Syntheses of the following compounds **3** (12*a*), **4** (12*b*), **5** (6), **8** (6), and **9** (12*c*) have already been described. 5-Methyl-2-pyrimidone was obtained by two steps: commercial thymine (Aldrich Europe) by reaction with P_2S_5 yielded 4-thiothymine (13*a*), then 4-thiothymine in the presence of Raney nickel gave 5-methyl-2-pyrimidone (13*b*). The best neutralization of commercial 4-methyl-2-pyrimidone hydrochloride (Aldrich Europe) is described by Franke and Kraft (14). Syntheses of compounds **6** and **7**, deuterated analogues of **5**, are briefly described in ref. 7; full details of deuteration can be found in ref. 15. All compounds, except **7**, were purified before use by sublimation under vacuum. Isotopic purity of compound **6** (97% d_3) and compound **7** (99% d_7) was measured by mass spectrometry (10 eV). It was confirmed for **6** by infrared and ^1H nmr spectrometries. Before introduction of **7**, the inlet mass spectrometer was purged with D_2O.

The mass spectra were measured on a Hitachi–Perkin–Elmer RMU-6E simple focusing mass spectrometer operating at 70 eV with an ion source temperature of 250°C. Samples were introduced through an inlet system heated to the given temperature. Exact mass determinations were made on an AEI MS 50 instrument (Centre de Spectrochimie Organique, Université P. et M. Curie, Paris) using the peak matching technique. The relative intensities (>5%) of the ions are given in Table 2.

The crystal and molecular structure of *syn*-9-phenyl-2,11-dithia[3,3]metacyclophane

WILLEM ANKER, KATHY A. BEVERIDGE, GORDON W. BUSHNELL, AND REGINALD H. MITCHELL[1]
Chemistry Department, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received March 9, 1983[2]

WILLEM ANKER, KATHY A. BEVERIDGE, GORDON W. BUSHNELL, and REGINALD H. MITCHELL. Can. J. Chem. **62**, 661 (1984).

The crystal structure of *syn*-9-phenyl-2,11-dithia[3,3]metacyclophane, **6**, has been determined by single crystal X-ray diffraction and refined to an *R* value of 0.0723. The crystal structure is triclinic with a = 9.573(2), b = 12.010(4), c = 8.433(2) Å, α = 108.02(2)°, β = 95.95(2)°, γ = 102.25(3)°, and the space group is $P\bar{1}$ with two molecules per cell, $D_{(meas)}$ = 1.313 g cm^{-3}, $D_{(calc)}$ = 1.306 g cm^{-3}. The bridging S atoms differ in their conformations so that the S . . . S distance is 6.391 Å. The metacyclophane rings have a distance of 3.57 Å between their centres and form a dihedral angle of 20.5°. The phenyl substituent forms an angle of 78.6° with the adjacent ring and has an *ortho* H-atom very close to the internal H-atom of the opposite ring. The phenyl substituted aromatic ring is non-planar and in a shallow boat form, the ring atoms C(11) (internal) and C(14) being 0.038(4) and 0.037(5) Å out-of-plane on the outside, the methylene C substituents are 0.212(5) and 0.199(5) Å out-of-plane on the inside. The first atom of the phenyl group is in the bowsprit position and is 0.274(4) Å above the mean plane on the outer side of the molecule. The opposite metacyclophane ring is less strained but in a similar boat form with the methylene C-atoms 0.092(4) and 0.067(6) Å to the inside. The mean bond angle at S is 103.5(2)°, the angles at C (methylene) range from 113.3(3)° to 118.0(3)°.

The variable temperature ^{1}Hmr spectra results are consistent with the *syn* conformer **6** being dominant in solution and frozen at temperatures <60°C as conformer **A**, with only relatively restricted further twisting of the biphenyl being found at ambient temperature.

WILLEM ANKER, KATHY A. BEVERIDGE, GORDON W. BUSHNELL et REGINALD H. MITCHELL. Can. J. Chem. **62**, 661 (1984).

On a déterminé la structure cristalline du phényl-9 dithia-2,11 [3,3]métacyclophane-*syn*, **6**, par diffraction de rayons-X sur un cristal unique et on l'affinée jusqu'à une valeur de *R* de 0,0723. La structure cristalline est triclinique avec a = 9,573(2), b = 12,010(4), c = 8,433(2) Å, α = 108,02(2)°, β = 95,95(2)° et γ = 102.25(3)°; le groupe d'espace est $P\bar{1}$ avec deux molécules par maille, D(mesuré) = 1,313 g/cc et D(calculé) = 1,306 g/cc. Les atomes de soufre faisant le pont sont différents dans leur conformation; leur distance S . . . S est égale à 6,391 Å. La distance entre les centres des cycles métacyclophanes est de 3,57 Å et ils forment un angle dièdre de 20,5°. Le substituant phényle forme un angle de 78,6° avec le cycle adjacent et un de ses H-*ortho* est très près d'un H interne du cycle opposé. Le cycle aromatique substitué par un phényle n'est pas plan et il existe sous une forme bateau aplatie; les atomes du cycle C(11) (interne) et C(14) sont respectivement 0,038(4) et 0,037(5) Å hors du plan vers l'extérieur alors que les C des substituants méthylènes sont respectivement 0,212(5) et 0,199(5) Å hors du plan vers l'intérieur. Le premier atome du groupement phényle est en position "beaupré"; il est à 0,274(4) Å au-dessus du plan moyen sur la face extérieure de la molécule. Le cycle métacyclophane opposé est moins tendu, mais il est aussi dans une forme bateau avec les atomes de C des méthylènes à 0,092(4) et 0,067(6) Å vers l'intérieur. L'angle moyen de liaison au niveau du S est 103,5(2)° alors que les angles au niveau du C (méthylène) varient de 113,3(3)° à 118,0(3)°.

Les spectres de rmn du proton à température variable sont en accord avec l'hypothèse que la conformation *syn* (**6**) est prépondérante en solution et qu'à des températures <60°C, le produit est figé sous la conformation **A** alors que l'on ne peut observer que des variations relativement faibles du biphényle à la température ambiante.

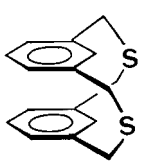
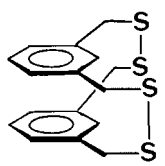
Introduction

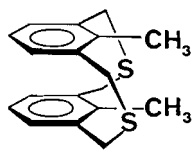
Higher metacyclophanes[3] do not always adopt the *anti*-stepped conformation preferred by [2,2]-metacyclophane (1). For example, we have recently shown that the dithia[3,3]-metacyclophane, **1**, exists in the crystal state as the *syn* conformer (2) while the tetrathia [4,4] metacyclophane, **2**, prefers an *anticlinal* conformation which is neither true *syn* nor *anti* from a ^{1}Hmr viewpoint (3). Indeed, ^{1}Hmr can sometimes be somewhat misleading in determining conformations, although generally reliable in extreme cases, such as **3** and **4**, where both conformers are known. However, in the case of



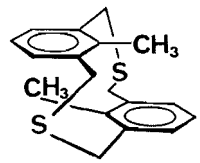
1



2



3



4

9-phenyl-2,11-dithia[3,3]metacyclophane, **5**, a clear distinction between the *syn* conformer **6**, in which the internal hydrogen H-18[4] would probably be shielded by the 9-phenyl substituent (depending on the angle of twist between the diphenyl unit), and the *anti* conformer **7**, in which H-18 would certainly be shielded by the opposite aryl ring, is difficult. Indeed Vogtle et al. (4) who first prepared **5** were not able to assign its stereochemistry, though they suggested that by com-

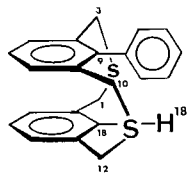
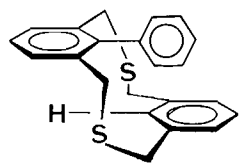
parison of the chemical shift of H-18 for **5**, (δ 5.44) with that of **8** (X = H, Y = NO_2, δ 6.50, presumed *syn*) and **9** (X = H, Y = NH_2, δ 4.70, presumed *anti*), **5** is probably the *syn* con-



6



7

former **6**. Since we have studied the variable temperature ^{1}Hmr spectra of the internally methyl substituted compounds **10**, for which both *syn* and *anti* conformers exist (5), we also were interested in establishing the conformational preference of **5**, Thus in this paper we report the results of its X-ray determined crystal structure and variable temperature ^{1}Hmr results.

X-ray structure results

Experimental

Weissenberg and precession photography using CuK_α radiation gave a triclinic unit cell and approximate cell dimensions. The crystal was then transferred to a Picker 4-circle diffractometer (automated with a PDP-11/10 eomputer) on which all subsequent measurements were made. The crystal data are:

$C_{22}H_{20}S_2$ fw = 348.52

Triclinie, space group $P\bar{1}$, unit cell a = 9.573(2), b = 12.010(4), c = 8.433(2) Å, α = 108.02(2)°, β = 95.95(2)°, γ = 102.25(3)°, eell volume = 886.0(4) Å^3, $D_{(meas)}$ = 1.313 g cm^{-3} (flotation in CCl_4/*m*-xylene), $D_{(calc)}$ = 1.306 g cm^{-3}, Z = 2, absorption coeffi-cient (MoK_α) = 2.95 cm^{-1}. The colourless crystal was mounted approximately along the *b*-axis, and had dimensions 0.67 × 0.66 × 0.51 mm.

The unit cell was refined by least squares using 20 pairs of ±2θ measurements obtained by an automatic centering routine. The centering results were also used in a least-squares refinement of the diffractometer matrix. A scan of 200 steps of 0.01° in 2θ, counting for 0.25 s at each step, and two background counts of 25.0 s at each end of the scan were used for intensity measurement. A reciprocal space hemisphere ($h \geq 0$) was measured out to 2θ = 45° (2552 reflections), using Zr-filtered MoK_α radiation (λ = 0.71069 Å). Three standards (400, 060, 005) were measured after every batch of 50 reflections. The very weak reflections, for which $I < \sigma(I)$, were rejected. The Lorentz and polarization corrections were applied. There were 2117 reflections in the final dataset.

Structure determination

The SHELX-76 program (6) was used to solve and refine the crystal structure. The initial phasing was done by the centrosymmetric direct methods routine. The atomic scattering factors were for uncharged atoms (7). The development of the structure was by standard Fourier methods, using difference maps. Refinement was by least squares, minimizing $\Sigma w\Delta^2 = \Sigma w\ (||F_o| - |F_c||)^2$ where $w = 1/(\sigma^2(F) + 0.001\ F^2)$. Anisotropic temperature parameters were used for the S and C atoms. The hydrogen atoms were located by the use of a difference map and their positional and isotropic temperature parameters were refined by least squares. The scale factor and atomic parameters gave a total of 297 variables.The refinement proceeded normally and converged to R = 0.0723 and $R_w = \Sigma\Delta\sqrt{w}/\Sigma F_o\sqrt{w}$ = 0.0836, with the maximum shifts/esd being 0.100. The final difference map gave no evidence of misplaced atoms (max. 0.33 e Å^{-3}, min. −0.50 e Å^{-3}). Supplementary tables, containing the structure factors, temperature parameters, and some hydrogen atom coordinates, have been placed in the Depository for Unpublished Data.[5]

Discussion

The atomic parameters of the crystal structure are given in Table 1. The bond lengths in Table 2 are in agreement with those found previously in similar compounds (2, 3, 8). The molecular structure, shown in Fig. 1, is clearly that of the *syn* conformer, and establishes without doubt that *syn* is the preferred conformation. The reason why is less obvious, particularly since for other examples of [3,3]metacyclophanes substituted at the internal position(s), the *anti* conformer is normally thermodynamically preferred (4). In the case of the dimethyl substituted compound, for the less stable *syn* conformer **3**, the interactions between the two methyl groups must be more severe than between the methyl and opposite ring of the *anti* conformers **4**. The reverse appears to be true for the much smaller internal H substituents of **1**. Normally with the substituents (other than H), including probably even F (9), the *anti* conformer appears to be preferred (for a review, see ref. 10).

	X	Y
11	H	CH_3
12	Ø	Ø
13	Ø	CH_3

For a single substituent, the preference is not as strong; for example, **11** is reported (on ^{1}Hmr basis) to be *anti* (11). *A priori* it would be more reasonable to assume that a *syn* conformer would be more stable for **11**, since interaction between a methyl and a hydrogen substituent would not be expected to be as large as between a methyl and a ring. In fact, the $-CH_3$ signal of **11** is found at δ 2.18, which is only marginally different from those of *syn*-**3** (δ 2.54) and substantially less shielded than those of *anti*-**4** (δ 1.30) (12). The internal hydrogen atoms are shielded to δ 5.50 in contrast to those of **1** at δ 6.6 (2); however, in the *syn* conformer of **6** the signal due to H-18 appears from δ 5.5 to δ 4.6, varying with temperature (see below). Thus a definite X-ray structural assignment of **11** would be most helpful in interpreting **5**. A further complication for phenyl substituents is the interaction of the *ortho*-ring hydrogens of the 9-phenyl substituent with the methylene bridges (see ref. 5, and below). This interaction may differ in magnitude for the *syn* and *anti* conformers. For two phenyl substituents, **12**, or for one phenyl and one methyl substituent **13**, the *anti* conformers are preferred (5).

Table 3 gives selected bond angles which are of interest in showing molecular strain. The benzenoid ring angles lie in the range 120 ± 2°, and have been deposited. The angles at the

[5]Copies of these tables may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

sulphur atoms are similar to the values 104.5(3)° and 103.3(2)° found in *syn*-2,11-dithia[3,3]metacyclophanes **1** (2). The angles at the methylene C atoms are considerably larger than the ideal tetrahedral value and agree with previously determined values in similar compounds (2, 8, 13). The external angles at C(21) differ by 7.2°, showing that phenyl ring 2 is pushed outwards from the centre of molecule presumably by repulsion between H(26) and H(31). The adjacent atoms C(32) and C(4) have angles which are strained to an unusual extent.

The conformation of the C—S—S bridges differs from that found in the crystal structure of **1** (2) which has both S atoms turned outwards and back toward C(14) and C(34) giving a larger S . . . S distance of 6.974 Å. In the title compound, one of the C—S—C groups is placed in the alternative position and the S . . . S distance is thus reduced to 6.391 Å. In this process S(1) comes closer to ring 2, but the methylene H atoms on C(1) and C(4) are turned away from ring 2, and this is probably the dominant effect in determining the conformation.

The mean plane results are given in Table 4. Ring 1 is clearly nonplanar and in a shallow boat form with C(11) and C(14) at the prows and displaced to the outside of the molecule. Intramolecular close contacts involving H(26) probably promote the boat form of ring 1, and C(11) and C(14) are well to the outside of mean plane 1. The methylene C atoms C(1) and C(2) are out of mean plane 1 on the inside, to a much greater extent than C(3) and C(4) with respect to ring 3. Ring 2 is essentially planar. Ring 3 is in a very shallow boat form similar to that of ring 1, but the displacements of the six ring atoms are only marginally significant; however, the existence of a similar, but much smaller, effect on this side of the molecule seems likely.

The dihedral angle between the mean planes of rings 1 and 3 is 20.5°, and the distance between the centres of these rings is 3.57 Å, surprisingly similar to the values 20.6° and 3.50 Å found in **1** (2), considering the replacement of a small H substituent by a large phenyl. It is also remarkable that the phenyl substituent, ring 2, forms dihedral angles of 78.6° with ring 1, and 85.1° with ring 3 because this brings H(26) close to H(31). Assuming a C—H bond length of 1.07 Å and extrapolating the line from the ring centres to the C atoms we find 2.00 Å between the calculated H atom positions; alternatively the distance is 2.30 Å between observed H atom positions. The accuracy with which these H atom locations are known is low, but both figures are less than twice the van der Waals radius of 1.2 Å for hydrogen (14). However, the calculated distances between S(1) and H(26) of 2.96 Å and S(1) and H(31) of 2.71 Å are also below the sum of the van der Waals radii (3.05 Å (14)), and thus the molecule is clearly compressed in several directions.

Nuclear magnetic resonance results

Although the ^{1}Hmr spectrum of **1** has been reported (4), distinction of the *ortho*-protons H-2′,6′ of the 9-phenyl substituent could not be made because of the low (60 MHz) field used. Use of 90 and 250 MHz spectrometers and low temperature spectra enables H-2′ (and at some temperatures H-6′) to be seen clearly, as shown in Fig. 2.

At ca. 20°C, H-2′ can be observed at δ 6.67 with H-6′ at ca. δ 6.92 and with H-18 at δ 5.47. As the temperature is lowered (Fig. 2) H-2′ and H-18 both steadily move upfield, and reach δ 5.82 and δ 4.60 respectively at −100°C. The shift difference between H-2′ and H-18 stays constant (ca. 1.2 ppm) over the whole temperature range. H-6′ progressively moves into the aromatic multiplet and below −55°C cannot be clearly distin-

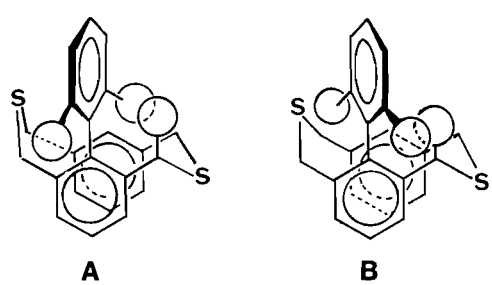
guished even at the higher field strength. After 40°C both H-2′ and H-6′ are in the aromatic multiplet, hence the exact point at which they coalesce could not be determined accurately, although it could be estimated at ca. 60°C. We thus interpret the dynamic behavior of **6** to be analogous to *syn*-**10** (5) except that



A B

for **6** T_c is ca. 60°C whereas for *syn*-**10** it is −8°C. Thus **6** exists in a relatively frozen conformation below 60°C, e.g., (**A**) rather than (**B**), although some rotation of the phenyl substituent can occur. We believe that as the temperature is lowered, the phenyl substituent rotates slightly, thereby increasing the angle between the biphenyl rings (which reaches 78.5° in the crystal). This has the effect of moving H-2′ into the shielding region between the two phane rings (15). It also probably allows the dihedral angle between the two phane rings (20° in the crystal) to increase such that H-18 likewise gets progressively more shielded. Tables S3−S6[5] give the calculated positions of the various H atoms of **6** relative to the centres of the three aromatic rings. Applying Johnson−Bovey type calculations of ring current shielding (15) to the values for H(31)[H-18], H(26)[H-2′], and H(22)[H-6′] gives the calculated ring current shielding

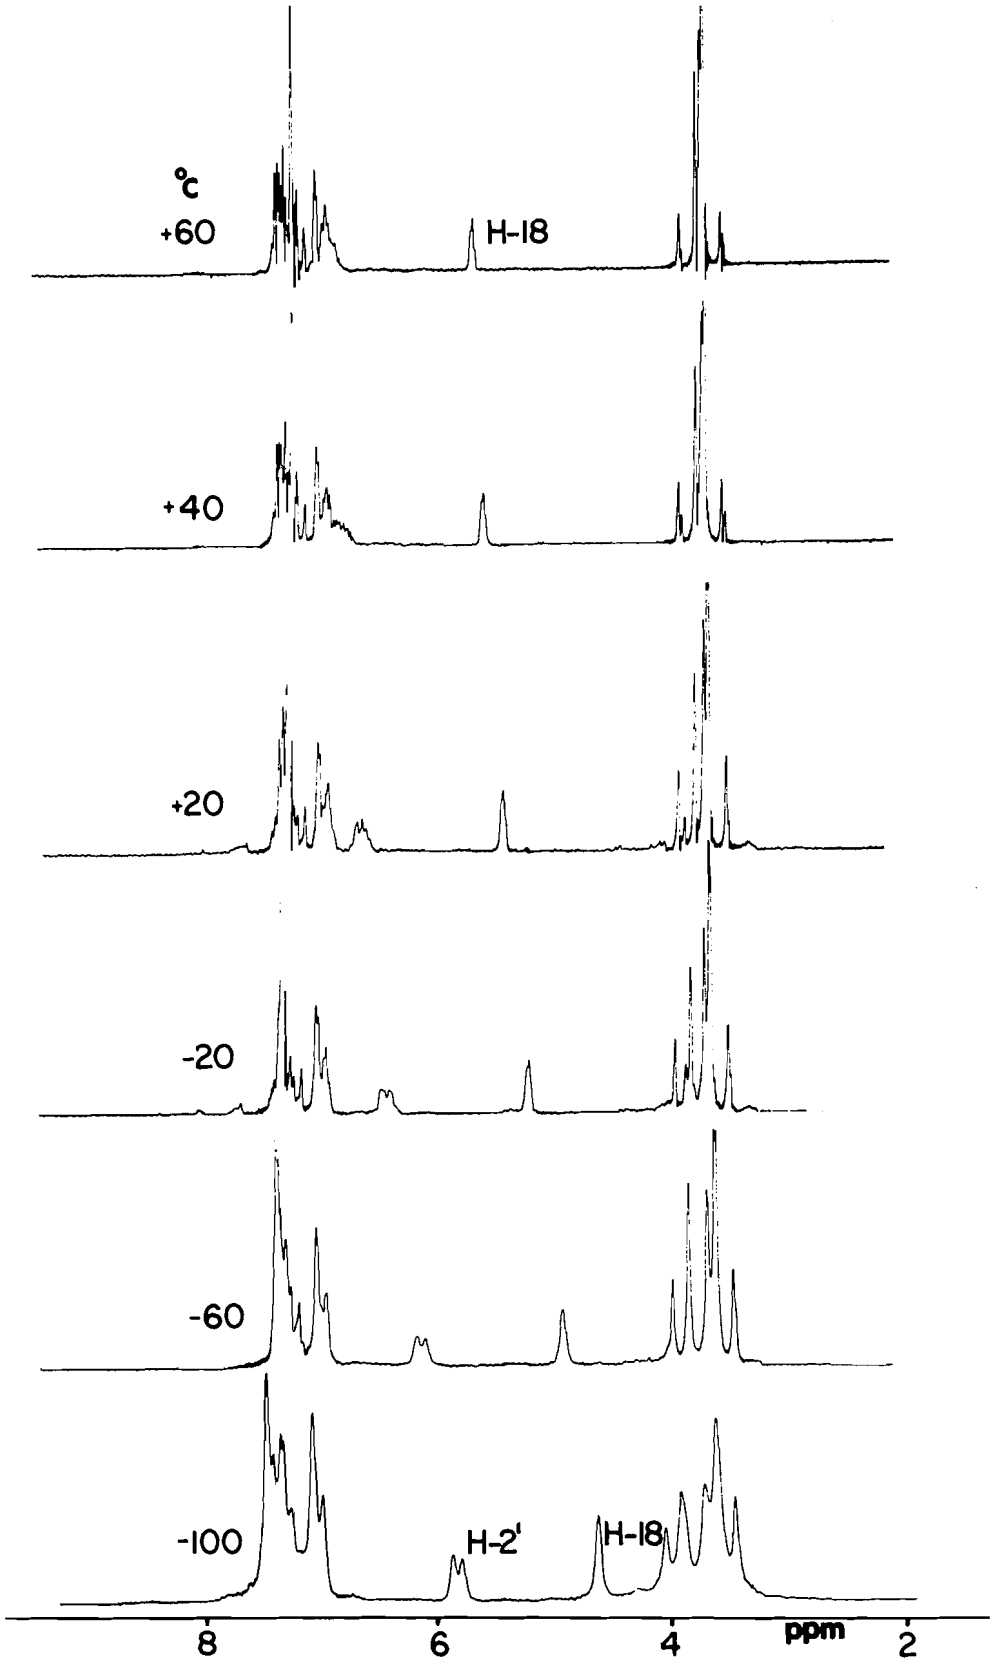


FIG. 2. Variable temperature ^{1}Hmr (90 MHz) spectrum of **6**.

(negative) or deshielding (positive) increments caused by the adjacent/opposite benzene rings (Table 5). Surprisingly good agreement between theory and experiment is obtained: H-18 is predicted to be shielded relative to H-2′ by about 1 ppm, which was found to be the case, and H-2′ is predicted to be shielded relative to H-6′, which it is, though the quantitative agreement

is not as close. This gives us considerable confidence in the assignment of stereochemistry of **5** to be *syn* in solution as well as in the crystalline state.

The disulphone of **5** has also been reported by Vogtle *et al.* (4); in that work H-18 appeared at δ 5.49, so it was assigned the *anti* conformation. However, since both H-2′ (δ 6.10) and H-6′ (δ 6.70) as well as H-18 appear at analogous positions to the signals of **6** (*syn*-**5**), it seems likely that the disulphone is also *syn*.

Sample preparation

The cyclophane **6** was prepared in a manner analogous to that of Vogtle *et al.* (4) by high dilution coupling of 2,6-bis-(mercaptomethyl)biphenyl (4,5) and α,α′-dibromo-*m*-xylene. We found that by increasing the reaction temperature to 60°C, the yield of product could be improved substantially to 40%, with mp 144°C (lit. (4) mp 134°C).

Experimental

The melting point was determined on a Kofler hot stage and is uncorrected. The ^{1}Hmr spectra were determined on a Perkin−Elmer R32 (90 MHz) or Bruker-WM250 (250 MHz) spectrometer. The ^{13}Cmr spectra were determined on the Bruker-WM250 operating at 62.9 MHz. Mass spectra were determined on a Finnigan 3300 mass spectrometer at 70 eV.

9-Phenyl-2,11-dithia[3,3]metacyclophane, syn-*5(6)*

A solution of 2,6-bis(mercaptomethyl)biphenyl (4, 5) (429 mg, 2 mmol) and α-α′-dibromo-*m*-xylene (538 mg, 2 mmol) in N_2-purged benzene (400 mL) was added dropwise over 30 h to a well-stirred solution of KOH (320 mg, 6 mmol) in N_2-purged 95% aqueous ethanol (500 mL) held at 60°C under N_2. After stirring for a further hour, the solvent was removed and the residue acidified (dilute aqueous HCl) and extracted with dichloromethane. The organic extract was washed, dried, and evaporated, and the resultant residue was pre-adsorbed on Celite and chromatographed over silica gel using pentane (500 mL) and then dichloromethane−pentane (1:9) as eluants.

Recrystallization of **6** from cyclohexane gave colourless crystals, 276 mg (40%), mp 144°C (lit. (4) mp 134°C); ^{1}Hmr (250 MHz) δ: 7.34−7.16 (m, 7H, ArH) 6.99−6.90 (m, 3H, ArH), 6.67 (dd, $J \sim 5.7$ Hz, 2.0 Hz, 1H, H-2′), 5.47 (s, 1H, H-18), 3.81 and 3.62 (AB q, $J = 12.5$ Hz, 4H, —CH_2S-), 3.74 and 3.62* (ABq, $J = 15.1$ Hz, 4H, —CH_2S—) (*at −55°C this peak moves upfield relative to the other 3.62 resonance); ^{13}Cmr δ: 143.4 (C-9), 137.7 (C-1′), 139.6, 135.0 (C-4, C-13), 130.4, 126.5 (C-5, C-14), 130.1 (C-2′), 129.5 (C-6′), 128.6 (C-18), 128.3, 127.7, 127.4 (C-6, C-15, C-4′), 127.3 (C-3′, 5′), and 35.3, 34.2 (C-1, C-3); $M^{+\cdot}$ *m/e* (relative intensity): 348 (50), 211 (19), 180 (24), and 179 (100). *Anal.* calcd. for $C_{22}H_{20}S_2$: C 75.82, H 5.78; found: C 75.70, H 5.92.

Conclusions

The stereochemistry of **5** has been found to be *syn* (i.e., **6**) both in the crystal state and in solution by X-ray and ^{1}Hmr studies respectively. This is the first reported example of an unambiguously *syn*-dithiametacyclophane with an internal substituent other than hydrogen. At temperatures below 60°C, **6** exists in a relatively frozen conformation, e.g. (**A**), where restricted rotation of the phenyl substituent occurs.

Destruction des oxydes d'azote à pression atmosphérique

ODILE DESSAUX, PIERRE GOUDMAND, GÉRARD MOREAU ET BRIGITTE MUTEL

Laboratoire de Spectroscopie de la réactivité chimique. Université des Sciences et Techniques de Lille, 59655 Villeneuve d'Ascq Cedex, France

Reçu le 27 juillet 1983

ODILE DESSAUX, PIERRE GOUDMAND, GÉRARD MOREAU et BRIGITTE MUTEL. Can. J. Chem. **62**, 667 (1984).

Ce travail illustre l'intérêt de l'utilisation d'une décharge microonde pour l'amélioration du coût énergétique de destruction des oxydes d'azote par l'azote activé à pression atmosphérique. Les facteurs déterminants dans l'optimisation de ce coût sont précisés: il importe d'effectuer l'introduction de NO_x dans une zone visuellement bien limitée où la concentration en atomes d'azote est optimale, le coût énergétique de destruction de NO_x est alors très proche du coût théorique.

ODILE DESSAUX, PIERRE GOUDMAND, GÉRARD MOREAU, and BRIGITTE MUTEL. Can. J. Chem. **62**, 667 (1984).

Active nitrogen produced at atmospheric pressure by a microwave discharge is found to require less energy consumption for the decomposition of nitrogen oxides. Important parameters improving the energy cost are described: NO_x must be introduced in a visually well-limited zone where the nitrogen atom concentration is maximum, the energy cost is then nearly equal to the theoretical cost.

Introduction

Les industries de l'acide nitrique rejettent dans l'atmosphère de grandes quantités d'oxydes d'azote (NO_2, NO, N_2O). Ces rejets, souvent très localisés, ont des teneurs comprises entre 500 et 2000 ppm. Etant donnée la très grande toxicité de NO_2 et NO, le risque de pollution est très élevé à proximité de ces usines. Plusieurs méthodes sont utilisées permettant de réduire les teneurs en oxydes d'azote contenus dans les effluents gazeux avant leur rejet dans l'atmosphère (1–3).

Un procédé de destruction des oxydes d'azote basé sur la génération d'azote activé à pression atmosphérique a été mis au point au laboratoire (4). Il existe essentiellement deux agents réactifs dans l'azote activé: les atomes d'azote $N(^4S)$ et les molécules d'azote à l'état électronique fondamental vibrationnellement excité. Cette dernière espèce est impliquée dans la synthèse des oxydes d'azote selon une réaction de nature essentiellement hétérogène (5). Sa concentration décroit rapidement lorsque la pression augmente. Les atomes d'azote constituent par contre un agent destructif efficace de NO_x suivant la réaction:

$$[1] \quad N + NO_x \rightarrow N_2 + \frac{x}{2} O_2 \text{ avec } x = 1 \text{ ou } 2$$

Cette réaction est très rapide, la réaction inverse étant environ 10^{20} fois plus lente. Une décharge haute tension à pression atmosphérique (6) permet de détruire complètement les oxydes d'azote contenus dans les mélanges (N_2 + NO_x) tels que $[NO_x]/[N_2] < 1000$ ppm. Pour des teneurs supérieures, la destruction n'est que partielle (83% à 1600 ppm). D'autre part, l'énergie électrique dépensée pour la destruction d'une mole de NO est évaluée à 1,5 kW-h. Ce rendement est peu satisfaisant, l'énergie théorique nécessaire étant de 0,13 kW-h.

L'objet de ce travail est d'étudier l'incidence de l'utilisation d'un générateur de microondes sur le coût énergétique de destruction des oxydes d'azote à pression atmosphérique et de préciser les facteurs déterminants permettant d'optimiser ce coût. Les oxydes d'azote purs sont introduits dans le flux d'azote activé. La mesure des quantités de NO non détruites après leur réaction avec les atomes d'azote est effectuée pour les deux oxydes NO et NO_2 suivant des procédures expérimentales appropriées.

Procédure expérimentale

Production des atomes d'azote

Le flux d'azote circulant dans un tube de quartz de 15 mm de diamètre intérieur, est excité par une cavité résonnante conçue et réalisée au laboratoire (7) reliée à un générateur d'ondes centimétriques Thomson CSF 1211C pouvant délivrer une puissance de 1500 watts à la fréquence ν = 2450 MHz ± 25 MHz. Un wattmètre permet de contrôler les puissances incidente (P_i) et réfléchie (P_r). On désigne par $P_t = P_i - P_r$ la puissance transmise à la cavité. La connaissance de P_r est très importante car elle renseigne sur l'état de couplage de la cavité: l'adaptation est optimale lorsque P_r est minimale. L'obtention d'un plasma à pression atmosphérique nécessite $P_i \geq 300$ watts. P_r reste faible (< 40 watts) tant que P_i est ≤ 500 watts puis augmente en fonction de P_i pour $P_i > 500$ watts. La valeur P_i = 500 watts correspond donc à la valeur minimale de P_r et maximale de P_t. Le tube à décharge est refroidi à l'air comprimé. Les gaz sont directement évacués dans l'atmosphère.

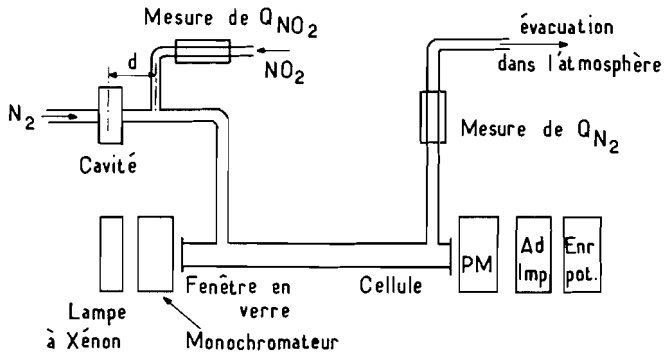

FIG. 1. Dispositif expérimental d'étude de la destruction de NO_2; d: distance entre la décharge et le conduit d'admission de NO_2; PM: photomultiplicateur; Ad Imp: adaptateur d'impédance; Enr pot: enregistreur potentiométrique.

Dosage du NO_2 détruit

Après la réaction de NO_2 avec l'azote activé, l'étude du spectre d'absorption de NO_2 permet la détection des quantités de NO_2 non détruites. Le dispositif de mesure spectroscopique utilisé est décrit dans la Fig. 1. Une lampe à Xe alimentée sous 15 volts par un générateur de courant continu éclaire la fente d'un monochromateur à réseau couvrant la gamme proche uv–visible–ir. La cellule de mesure, longue de 80 cm a un diamètre interne de 40 mm. Elle est peinte en noir afin d'éviter les lumières parasites et est munie de fenêtres en verre. Le photomultiplicateur de type RCA 1P21, dont la réponse spectrale est maximale dans la gamme 400–500 nm, est relié à un enregistreur potentiométrique.

Le spectre d'absorption de NO_2 ayant été préalablement enregistré, le monochromateur est réglé sur la bande d'absorption la plus intense située à 448 nm et la variation d'intensité de cette bande est enregistrée

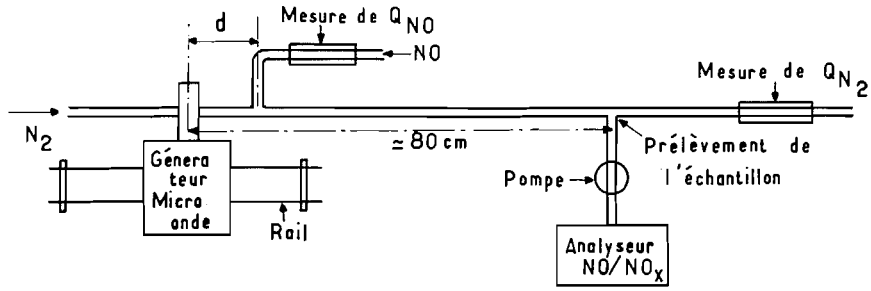

FIG. 2. Dispositif expérimental d'étude de la destruction de NO; d: distance entre la décharge et le conduit d'admission de NO.

en fonction du débit de NO_2 (Q_{NO_2}) ajouté à l'azote activé. Le débit maximal de NO_2 pouvant être décomposé par réaction avec $N(^4S)$ est noté $Q^0_{NO_2}$.

Dosage de NO détruit

La méthode utilisée consiste en un dosage "en retour" de la concentration du NO ([NO]) restant après sa réaction avec l'azote activé. Le dispositif expérimental est décrit dans la Fig. 2. [NO] est directement mesurée par un analyseur NO/NO_x Beckman modèle 951 A, basé sur le principe de la chimiluminescence de l'ozone, et dont la gamme de réponse est 0–10 000 ppm. L'échantillon est prélevé à une distance d'environ 80 cm de la décharge et est envoyé dans l'analyseur avec un débit de l'ordre de 2 L/min assuré par une pompe. Le taux de destruction τ, exprimé en %, est défini par $\tau = (ppm_i - ppm_r)/ppm_i$ où ppm_i et ppm_r désignent respectivement les teneurs du mélange en NO, exprimées en particules par million, avant et après réactions avec l'azote activé; $ppm_i = (Q_{NO} \times 10^6)/(Q_{N_2} + Q_{NO})$; Q_{NO} et Q_{N_2} désignent respectivement les débits de NO et de N_2, mesurés avec des débitmètres respectivement Rota et Brooks; ppm_r est déterminé à l'aide de l'analyseur Beckman. Les erreurs relatives $\Delta Q_{NO}/Q_{NO}$ et $\Delta ppm_r/ppm_r$ sont faibles (~1%). La mesure de Q_{N_2} effectuée à l'aide d'un débitmètre à flotteur est moins précise: $\Delta Q_{N_2}/Q_{N_2} \simeq 10\%$. L'erreur relative sur τ est de 12%.

Résultats et discussion

Le calcul du coût énergétique minimal de destruction des oxydes d'azote implique la détermination préalable des paramètres expérimentaux permettant d'optimiser d'une part, le taux de dissociation de l'azote et d'autre part, le rendement de la réaction des atomes d'azote sur NO_x, c'est-à-dire la probabilité de collision entre ces espèces. Les techniques de dosage des NO_x mises en oeuvre dans ce travail ont permis, par l'étude du débit maximal de NO_2 détruit, de préciser les conditions d'optimisation du rendement en $N(^4S)$, et par celle du taux de destruction de NO de définir les conditions favorables aux collisions $N–NO_x$.

L'azote est de qualité U, Air liquide. La distance (dénommée d, Fig. 1) entre la décharge et le conduit d'admission de NO_2 est égale à 30 mm. L'incidence sur le coût énergétique de destruction de NO_x de l'adaptation de la cavité est mise en relief en étudiant l'évolution de $Q^0_{NO_2}$ en fonction de Q_{N_2}. La cavité utilisée ne permet pas d'annuler P_r pour toutes les valeurs de Q_{N_2}, aussi la construction d'une nouvelle cavité permettant de remédier à cette insuffisance a-t-elle été entreprise postérieurement à ce travail (8). Pour la valeur $P_i = 500$ watts qui, à pression atmosphérique, correspond à la valeur minimale de P_r, la valeur du débit d'azote pour laquelle $P_r = 0$ est 700 L/h. Le tableau 1 résume l'évolution de $Q^0_{NO_2}$ en fonction de Q_{N_2} pour $P_i = 500$ watts. La valeur maximale de $Q^0_{NO_2}$ est observée pour le débit d'azote (700 L/h) pour lequel P_r s'annule. Cette optimisation de la destruction de NO_2 est attribuable essentiellement à une parfaite adaptation de la cavité (7). Aussi, la puissance incidente adoptée dans la suite du travail est-elle choisie de façon à correspondre à la valeur maximale de P_t permettant de minimiser P_r ($P_i = 500$ watts).

TABLEAU 1. Variation de $Q^0_{NO_2}$ en fonction de Q_{N_2}[a]

Q_{N_2} (L/h)	350	710	800	1240	1300	1600	1640
$Q^0_{NO_2}$ (L/h)	5,2	11	10,7	6,4	5,3	2,4	2,1

[a] $P_i = 500$ watt; $d = 30$ mm.

TABLEAU 2. Influence sur $Q^0_{NO_2}$ de la pureté de l'azote et évolution de $Q^0_{NO_2}$ après 48 h[a]

Qualité d'azote (Air liquide)	Pureté (%)	$Q^0_{NO_2}$ (L/h) $t = 0$	$Q^0_{NO_2}$ (L/h) $t = 48$ h
N 48	>99,998	19,5	
U	>99,995	22,8	13,5
R	>99,5	26	17,4

[a] $Q_{N_2} = 700$ L/h; $d = 30$ mm; $P_i = 500$ watt.

Une augmentation de la teneur en O_2 ou en H_2O dans l'azote soumis à la décharge améliore le rendement de destruction de NO_2 (Tableau 2). Ces résultats s'interprètent aisément dans le cadre d'une augmentation du taux de dissociation de la molécule d'azote en présence de traces de O_2 ou de H_2O (9). On remarque que la valeur de $Q^0_{NO_2}$ obtenue avec l'azote U: 22,8 L/h diffère de celle correspondant aux mêmes conditions expérimentales et figurant dans le tableau 1: 11 L/h. Cette divergence témoigne de l'influence d'un facteur important: l'état des parois. On observe une diminution de la quantité de NO_2 détruite au cours du temps. Les parois sont traitées à l'acide fluorhydrique dilué à 50%, puis rincées à l'eau, au méthanol et à l'éther et enfin séchées. Si cette précaution n'est pas respectée, la valeur de $Q^0_{NO_2}$ est nettement moins élevée. Dans un même tube, deux séries de mesures sont effectuées, l'une aussitôt après ce traitement, l'autre 48 heures plus tard; les résultats sont résumés dans le tableau 2. Une dégradation de l'état des parois entraîne donc une diminution de la probabilité de destruction de NO_x. Un nouveau dispositif récemment mis au point (8) permet d'éviter une telle dégradation. Dans la suite de cette étude, les tubes sont "traités" avant chaque mesure. L'azote utilisé est de qualité R.

L'influence du lieu d'adjonction de NO ou NO_2 sur l'efficacité de leur destruction a été envisagée.

Pour une puissance incidente donnée, quels que soient Q_{NO_x} et Q_{N_2} les conditions optimales de destruction de NO_x correspondent à $(30 < d < 40)$ mm. Pour des valeurs de d supérieures, on observe une décroissance rapide du taux de destruction. La figure 3 représente, en fonction de d, les évolutions de: (a) $Q^0_{NO_2}$ ($Q_{N_2} = 890$ L/h); (b) $\tau(Q_{N_2} = 700$ L/h, $Q_{NO} = 4,1$ L/h). La concentration en atomes d'azote est donc maximale et

25	91	87	88	86	55	47	38	35	24
30	—	—	—	—	—	—	—	40	—

[a] d = 30 mm; P_i = 500 watt.

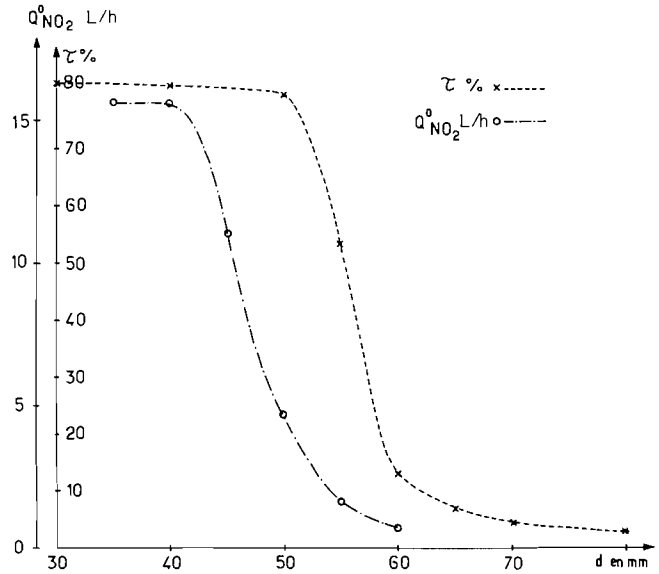

FIG. 3. Etude du débit maximal de NO_2 détruit: $Q^0_{NO_2}$ (Q_{N_2} = 890 L/h) et du taux de destruction de NO: τ (Q_{N_2} = 800 L/h, Q_{NO} = 4,1 L/h) en fonction de la distance décharge – zone d'introduction de NO_x (d); P_i = 500 watt.

constante pour ($30 < d < 40$) mm. Cette zone de concentration optimale en N(^4S) peut d'ailleurs être aisément visualisée; elle correspond à une extension du plasma, de forme conique, en dehors de la limite en aval de la cavité. Cette zone est dénommée dard. En conclusion les molécules de NO_x présentes dans le dard ont une probabilité plus élevée de rencontrer les atomes N(^4S) et donc d'être détruites. Les conditions expérimentales d'optimisation de cette probabilité de collision sont déterminées en envisageant l'influence de Q_{NO} et Q_{N_2} sur τ.

L'observation de l'evolution de τ en fonction de Q_{N_2} à Q_{NO} donné (Q_{NO} = 25 L/h) met en évidence les caractéristiques suivantes (Tableau 3): pour ($300 < Q_{N_2} < 650$) L/h, τ est approximativement constant (eu égard à la précision des mesures) et très élevé (86 à 91%); pour ($1200 < Q_{N_2} < 2600$) L/h les valeurs de τ sont beaucoup plus faibles et τ est une fonction décroissante de Q_{N_2}. L'étude n'a pu être menée pour des valeurs de débits d'azote intermédiaires ($650 < Q_{N_2} < 1200$) L/h, ppm_r étant alors >10 000 et donc non mesurable dans nos conditions expérimentales.

Dans l'hypothèse d'une répartition homogène des molécules de NO dans le milieu réactionnel, les résultats ci-dessus peuvent s'interpréter de la façon suivante. Lorsque [N(^4S)] est supérieur à [NO], τ est proportionnel à la fraction du volume total occupé par le dard et donc indépendant de Q_{NO} et Q_{N_2}. Par augmentation de Q_{N_2}, la diminution de la densité d'énergie

TABLEAU 4. Variation de τ en fonction de Q_{NO} et Q_{N_2}[a]

	Q_{N_2} (L/h)			
	300	440	590	645
Q_{NO} (L/h)	τ (%)			
10	84	81	85	82
15	87	83	86	84
20	89	86	87	85
25	91	87	88	86
30	92	90	88	87
100	96	95		

[a] d = 30 mm; P_i = 500 watt.

(P_t/Q_{N_2}) peut conduire à une valeur de [N(^4S)] inférieure à [NO] et donc à une diminution de τ. Dans le cadre de cette hypothèse postulant une répartition homogène des molécules NO on devrait également observer dans le domaine où [N(^4S)] est inférieur à [NO] une diminution de τ par augmentation de Q_{NO} à Q_{N_2} donné. Les résultats du tableau 3 font apparaître une évolution inverse et conduisent donc à rejeter l'hypothèse d'une répartition homogène de NO dans l'azote activé.

Les répartitions de NO et N(^4S) dans le milieu ne sont donc pas homogènes et τ, dont l'évolution est parallèle à celle de Q_{NO}/Q_{N_2}, représente le pourcentage de molécules de NO pénétrant dans le dard.

Les résultats précédents mettent en évidence les paramètres expérimentaux permettant d'optimiser la destruction de NO_x. Ils sont énumérés ci-après, les conditions spécifiques à la présente étude sont précisées pour chacun d'eux: la valeur de P_i doit permettre de minimiser P_r (P_i = 500 watts); présence d'impuretés oxygénées (~0,5%) dans l'azote (azote qualité R, Air liquide); il faut éviter la dégradation des parois du réacteur (l'azote est véhiculé dans des tubes récemment "traités", cf. ci-dessus); l'adjonction de NO_x doit s'effectuer dans le dard ce qui implique une contrainte d'une part sur le lieu d'adjonction de NO_x (d = 30 mm) et d'autre part sur les valeurs respectives de Q_{N_2} et Q_{NO} ($Q_{N_2} < 1000$ L/h, la condition expérimentale de détection de NO: $ppm_i < 10\,000$ suppose en outre de limiter les valeurs maximales de Q_{NO} à 30 ou 100 L/h suivant Q_{N_2}).

Les valeurs de τ pour différentes valeurs de Q_{N_2} et Q_{NO} sont reportées dans le tableau 4. Le taux de destruction maximum (Q_{N_2} = 300 L/h, Q_{NO} = 100 L/h) correspond à un coût énergétique de 0,14 kW-h/mol de NO, valeur très proche du coût théorique (0,13 kW-h/mol de NO).

La valeur optimale de $Q^0_{NO_2}$ (26 L/h) correspond à un coût énergétique de 0,43 kW-h/mol de NO_2. En réalité NO_2 n'étant jamais pur mais en équilibre avec son dimère, les valeurs de

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

$Q^0_{NO_2}$ sont sous-estimées et le coût énergétique est surestimé. En outre, le coût énergétique théorique de destruction de NO_2 ne peut être défini étant donné que la réaction globale de destruction de NO_2 n'est pas stoechiométrique. On peut seulement affirmer qu'il est supérieur à 0,13 kW-h/mol de NO_2.

Conclusion

L'énergie microonde permet une destruction efficace de NO_x à pression atmosphérique puisque le rendement énergétique peut être, dans certaines conditions, proche du rendement théorique. Ce travail met en relief des facteurs déterminants dans l'optimisation de cette destruction. Le dard constitue la zone préférentielle de destruction de NO_x; il convient donc d'une part de rendre son volume maximal et d'autre part, en agissant sur les valeurs respectives des débits gazeux et sur la géométrie de la chambre de mélange, d'effectuer une introduction de NO_x dans cette région fortement réactive. En outre il importe de concevoir une cavité dont les facilités d'adaptation sont telles que P_r puisse s'annuler pour les différents débits d'azote. Enfin la détérioration des parois du tube à décharge doit être minimisée. Une cavité récemment réalisée (8) permet de satisfaire à ces différents critères et laisse espérer une amélioration sensible du coût de destruction de NO_x dans une large gamme de débits gazeux.

WALTER A. SZAREK, GEORGE W. HAY, DOLATRAI M. VYAS, EDWARD R. ISON, and LUCJAN J. J. HRONOWSKI. Can. J. Chem. **62**, 671 (1984).

L-Glucose has been synthesized from D-glucose by a convenient method involving methyl 2,3-*O*-isopropylidene-β-D-gulofuranosiduronic acid (**6**) as a key intermediate. Compound **6** was converted into L-glucono-1,5-lactone (**8**), which, by a selective reduction, afforded L-glucose (**9**).

WALTER A. SZAREK, GEORGE W. HAY, DOLATRAI M. VYAS, EDWARD R. ISON et LUCJAN J. J. HRONOWSKI. Can. J. Chem. **62**, 671 (1984).

On a synthétisé de façon convenable le L-glucose à partir du D-glucose par une méthode faisant appel à l'intermédiaire de l'acide méthyle 2,3-*O*-isopropylidene-β-D-gulofuranosiduronique (**6**). On a transformé le composé **6** en L-glucono-lactone-1,5 (**8**), qui conduit par la suite au L-glucose (**9**) par une réduction sélective.

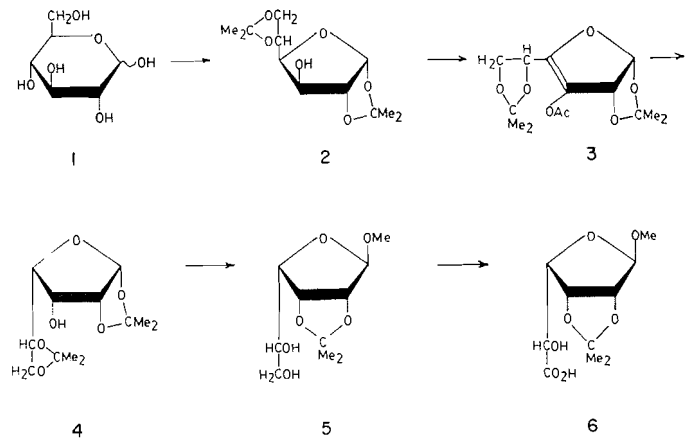
Introduction

The natural sugars occur with an enormous predomination of one of the enantiomeric configurations, the other being rare or purely artificial. There is, at present, a growing interest in the study of the less-common enantiomers of the carbohydrates because of their potential organoleptic, and other biochemical, properties (1).

It has been known for more than a quarter of a century that the L-isomer of certain hexoses elicits a taste similar to, and frequently as intense as, the D-isomer (2). Although there have been claims that L-glucose occurs as a component of certain complex carbohydrates (3), the evidence is inconclusive as yet. Moreover, most studies of the metabolism of L-glucose by microorganisms have indicated that it is not metabolized (4); an enzyme catalyzing the oxidation of L-glucose has been isolated from cell-free extracts of *Pseudomonas caryophylii* IFO 13694 (5). These data suggested that certain of the enantiomers of naturally occurring sugars may be safe, effective, non-nutritive sweeteners.

The synthesis of L,L-sucrose (β-L-fructofuranosyl α-L-glucopyranoside) in this laboratory (6) permitted this hypothesis to be assessed. The compound was found to be not only indistinguishable in taste from natural sucrose (6) but also resistant to hydrolysis catalyzed by the sucrase of the jejunal brush border membrane of the hamster (7). These observations indicated that L-sugars may be useful as non-caloric or low caloric sweeteners. The need for an improved method for the synthesis of L-glucose stimulated the investigation reported below.

The first reported chemical synthesis of L-glucose was that of Fischer (8) who prepared the compound from L-arabinose by a Kiliani synthesis. Since then each of Richtmyer and Hudson (9) and Sowa (10) has published a synthesis of L-glucose starting from D-glucose by way of a chain extension and subsequent degradation. In addition, Takahata *et al.* (11) produced racemic glucose in low yield from a complex reaction of ethylene carbonate, tetrachloromethane, and sodium cyanide. However, none of these procedures has gained the relatively extensive application achieved by that of Sowden and Fischer (12) who prepared L-glucose from L-arabinose by condensation with nitromethane, hydrolysis of the 1-deoxy-1-nitroalditols, and separation of the L-mannose and L-glucose so produced. The present paper describes a new synthesis of L-glucose from D-glucose which does not involve chain extension.



SCHEME 1

Results and discussion

The synthesis of L-glucose from D-glucose that is described in this paper involves the intermediacy of a D-glucose derivative and is an attractive one from the point of view of both the operational simplicity and the low costs of reagents.

The acid-catalysed conversion of **1** into **2** is a facile, routine method (13) which afforded the required intermediate compound (Scheme 1) in satisfactory yield. The synthesis then required the oxidation of **2** and treatment of the resultant product with acetic anhydride in pyridine to afford the enol acetate **3**, followed by reduction of **3** to give 1,2:5,6-di-*O*-isopropylidene-α-D-gulofuranose (**4**). Although **2** could be oxidized to 1,2:5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose hydrate in 95% yield using dimethylsulfoxide and acetic anhydride (14), the reduction of **3**, which was prepared from the oxidation product (15), was inhibited, presumably by traces of dimethylsulfoxide or dimethylsulfide which would poison the catalyst. Consequently, the ulose hydrate was prepared from **2** by catalytic oxidation (16) using a ruthenium tetraoxide catalyst (17), a method which gave only minor side products.

Compound **3** could be reduced quantitatively to 3-*O*-acetyl-1,2:5,6-di-*O*-isopropylidene-α-D-gulofuranose by the method

[1] Present address: Bristol Laboratories, Syracuse, NY 13201, U.S.A.

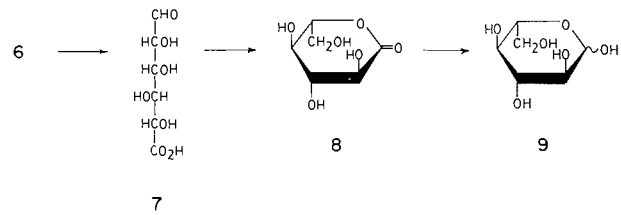
of Lemieux and Stick (18) using a palladium-on-carbon catalyst, and the product was deacetylated to afford **4**. Treatment of compound **3** with sodium borohydride gave lower yields as a result of a competing, base-catalyzed β-elimination which afforded 4,5-unsaturated compounds (15, 19). Even in buffered reaction solutions only moderate yields of product (**4**) were obtainable using sodium borohydride.

The acid-catalyzed hydrolysis of **4** to give 1,2-*O*-isopropylidene-α-D-gulofuranose was investigated. The influence of structure on the relative ease of hydrolysis of acetal rings has been well documented (20) and the conditions for the selective removal of the 5,6-*O*-isopropylidene group of such compounds as **2** (21), and the 1,2:5,6-di-*O*-isopropylidene acetals of L-idose (22) and D-allose (23), have been defined. Brimacombe *et al.* (24) have reported that the use of 70% acetic acid for the selective hydrolysis of 3-acetamido-3-deoxy-1,2:5,6-di-*O*-isopropylidene-α-D-gulofuranose gave the desired product, namely 3-acetamido-3-deoxy-1,2-*O*-isopropylidene-α-D-gulofuranose, but that it was mixed with both the starting compound and the free acetamido sugar. Similarly, it has been reported (25) that selective deacetalation of 1,2:5,6-di-*O*-isopropylidene-α-D-gulofuranose could not be achieved, but that the corresponding 3-*O*-benzyl derivative could be converted into 3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-gulofuranose in 55% yield by treatment with aqueous acetic acid in 1,4-dioxane. The rationalization of these data is, at present, inadequate. A range of acidic conditions was explored in an attempt to effect the conversion of **4** into 1,2-*O*-isopropylidene-α-D-gulofuranose, but in each case the major product was the free sugar.

The high-yield conversion of D-glucose into methyl 2,3-*O*-isopropylidene-β-D-gulofuranoside (**5**) had been shown (26) to proceed through the intermediacy of methyl 2,3:5,6-di-*O*-isopropylidene-β-D-gulofuranoside. This selectivity in hydrolysis was noted (27) also in the preparation of methyl 2,3-*O*-isopropylidene-α-D-mannofuranoside from methyl 2,3:5,6-di-*O*-isopropylidene-α-D-mannofuranoside. However, methyl 2,3:5,6-di-*O*-isopropylidene-β-D-mannofuranoside was much more sensitive to acid and selective hydrolysis was unattainable (27). In the present work, the reaction of **4** with methanol, 2,2-dimethoxypropane, acetone, and hydrochloric acid produced **5** in high yield.

The catalytic oxidation of **5** to **6** was effected by the method of Perlin *et al.* (28), using a platinum-on-carbon catalyst in an aqueous reaction medium at 50°C. The pH of the reaction solution was monitored continuously and maintained at 7.5 by the addition of small increments of sodium hydrogen carbonate until a stoichiometric quantity had been utilized. Compound **6** was isolated in 91% yield as its sodium salt, and characterized by conversion (29) into its dicyclohexylammonium salt and into L-glucono-1,4-lactone. The lactone was obtained by the conversion of **6** into barium D-guluronate, which was converted, using sodium borohydride, into L-gluconic acid, the lactonization of which afforded the product. Perry and Hulyalkar (30) have established a gas–liquid chromatographic technique for the unambiguous characterization of glycono-1,4-lactones. The sample of L-glucono-1,4-lactone prepared from **6** exhibited a retention time identical to that of an authentic reference sample, obtained by way of acid-catalyzed hydrolysis of alginic acid (31), but clearly distinguishable from those of authentic samples of D-galactono-1,4-lactone, D-glucono-1,5-lactone, D-gulono-1,4-lactone, and D-mannono-1,4-lactone (32).

The synthesis now required the preparation of L-glucono-1,5-lactone (**8**) (Scheme 2). Thus, methyl 2,3-*O*-isopropylidene-β-D-gulofuranosiduronic acid (**6**) was subjected to an acid-catalyzed hydrolysis, and the resultant product (**7**) was reduced by hydrogenation over Raney nickel; from the product solution, crystalline L-glucono-1,5-lactone (**8**) was obtained by the method of crystallization described by Isbell and Frush (33) for the D-enantiomer of **8**. Catalytic reduction of **8** by the method of Glattfeld and Schimpff (34) afforded L-glucose (**9**) only in low yield. Consequently, the method of Wolfrom and Thompson (35), using sodium borohydride, was employed and a high yield of **9** was obtained. The product **9** had a melting point in agreement with that of D-glucose and exhibited the expected specific rotation; the ir and ^{1}Hmr spectra were indistinguishable from those of D-glucose. Thus, the conversion of D-glucose into L-glucose has been achieved in an unoptimized, overall yield of 12%.



SCHEME 2

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Optical rotations were measured with a Perkin–Elmer model 141 automatic polarimeter at 23 ± 3°C. Infrared spectra were recorded with a Beckman Acculab 6 or a Perkin–Elmer 598 spectrophotometer. The ^{1}Hmr spectra were recorded on a Bruker HX-60 (60 MHz) or a Bruker CXP-200 (200 MHz) spectrometer with tetramethylsilane (TMS) as the internal standard; chemical shifts (δ) are given in ppm downfield from TMS. Thin-layer chromatography (tlc) was performed using Merck plates precoated with silica gel 60 F-254 in the following solvent systems (v/v): (*A*) ethyl acetate – benzene, 1:1; (*B*) ethyl acetate; (*C*) 1-propanol – ethyl acetate – water, 3:1:1. The developed plates were dried and compounds located by heating the plates at ~150°C after they had been sprayed with 10% aqueous sulfuric acid containing 1% cerium sulfate and 1.5% molybdic acid.

1,2:5,6-Di-O-*isopropylidene*-α-D-*glucofuranose (2)*

The acetalation of anhydrous **1** (200 g) by the method of Stevens (13) produced **2** (160 g, 55%), mp 108–110°C; $\{\alpha\}_D$ −13.6° (*c* 2.0, $CHCl_3$) (lit. (13, 21) mp 110–111°C, $\{\alpha\}_D$ −13.5° ($CHCl_3$)).

3-O-*Acetyl-1,2:5,6-di*-O-*isopropylidene*-α-D-erythro-*hex-3-enofuranose (3)*

The oxidation of **2** (10 g) with ruthenium tetraoxide in the presence of potassium periodate (17) gave 1,2:5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose hydrate (13) (9.5 g), mp 109–110°C; $\{\alpha\}_D$ +39.5° (*c* 1.5, $CHCl_3$). The last named compound (6.1 g) was converted into **3** (15) (5.2 g, 75%), mp 62–63°C, $\{\alpha\}_D$ −32.7° (*c* 1, $CHCl_3$), by treatment with pyridine and acetic anhydride as described by Meyer zu Reckendorf (15).

1,2:5,6-Di-O-*isopropylidene*-α-D-*gulofuranose (4)*

The reduction of **3** (4.2 g) by the action of 5% palladium-on-carbon in a hydrogen atmosphere (room temperature, atmospheric pressure) (18) afforded 3-*O*-acetyl-1,2:5,6-di-*O*-isopropylidene-α-D-gulofuranose (36) (4.2 g), mp 72–74°C, $\{\alpha\}_D$ +66.5° (*c* 1.5, $CHCl_3$), a 3-g sample of which was deacetylated by stirring with Amberlite IRA-400 anion-exchange resin (OH^- form) (18) for 40 h at room temperature (~20°C) to give a quantitative yield (2.5 g) of **4** (15), mp 103–104°C; $\{\alpha\}_D$ +9.8° (*c* 2.0, $CHCl_3$).

Methyl 2,3-O-isopropylidene-β-D-gulofuranoside (5)

A solution containing **4** (500 mg) in 2,2-dimethoxypropane (1.6 mL), acetone (1.35 mL), methanol (1.35 mL), and concentrated hydrochloric acid (0.04 mL), was heated at reflux temperature for 2 h (26). The solution was cooled to room temperature, diluted with water (4 mL), and the organic solvents were removed under reduced pressure at 35°C. A white precipitate formed in the residual aqueous phase; this was dissolved by the addition of methanol (4 mL). Thin-layer chromatography of this solution revealed the presence of a new component (R_f 0.89, solvent *A*), but no **4** (R_f 0.58, solvent *A*) was detectable. Concentrated hydrochloric acid (1 mL) was added and the formation of product (R_f 0.2, solvent *A*) was monitored by tlc (~3 h at room temperature). The solution was neutralized with aqueous sodium hydrogen carbonate, concentrated to ~5 mL, and extracted with chloroform (3 × 5 mL). The aqueous layer was saturated with sodium chloride and extracted with chloroform (3 × 5 mL). The combined extracts were dried (anhydrous sodium sulfate) and evaporated to a syrup from which there were obtained 340 mg (76%) of crystalline **5** (26), mp 77–79°C (from $CHCl_3$–hexane); $\{\alpha\}_D$ −82.8° (*c* 1.2, CH_3OH).

Methyl 2,3-O-isopropylidene-β-D-gulofuranosiduronic acid (6)

To an aqueous solution (500 mL) of **5** (9.3 g) was added 10% platinum-on-carbon (0.9 g). A pH electrode was immersed in the mixture and a stream of oxygen was passed through the liquid at a rate sufficient to keep the catalyst uniformly suspended. The reaction mixture was held at 55–60°C, and the pH maintained at 7.5 by the addition, as required, of solid sodium hydrogen carbonate (2.19 g, total). After 5 h, **4** was not detectable by tlc (R_f 0.51, solvent *B*), but a new compound (R_f 0.50, solvent *C*) was observed. Evaporation of the reaction solution, after filtration, afforded 9.8 g (91%) of **6** (sodium salt), $\{\alpha\}_D$ −82.5° (*c* 1.5, H_2O); ν_{max} (KBr): 1590 (COO^-) cm^{-1}; ^{1}Hmr (60 MHz, DMSO-d_6) δ: 1.3 and 1.5 (s's, 6H, CMe_2), 3.3 (s, 3H, OMe), 3.6–4.2 (4H, H-4, H-5, 2 OH's), 4.5 (d, 1H, $J_{2,3}$ = 6 Hz, H-2), 4.7 (dd, 1H, $J_{3,4}$ = 2.5 Hz, H-3), 4.9 (s, 1H, H-1).

Compound **6** (sodium salt) decomposed before melting and was further characterized by treatment with dicyclohexylamine as described by Zissis *et al.* (29) to give **6** (dicyclohexylammonium salt), mp 158–159°C; $\{\alpha\}_D$ −45.9° (*c* 0.5, H_2O); ν_{max} (KBr): 3400 (OH), 1620, 1540 (COO^-) cm^{-1}; ^{1}Hmr (60 MHz, $CDCl_3$) δ: 1.2 and 1.4 (s's, 6H, CMe_2), 1.4–2.3 (22H, cyclohexyl protons), 1.5 (s, 3H, OMe), 4.7 (s, 1H, H-1). *Anal.* calcd. for $C_{22}H_{37}O_7$: C 51.77, H 5.62; found: C 52.01, H 5.66.

A solution of **6** (sodium salt) (650 mg) in water (5 mL) was heated on a steam bath for 3 h with Amberlite IR-120 cation-exchange resin (H^+ form) (5 mL). The resin was removed by filtration. The filtrate was neutralized with barium carbonate and evaporated to give the barium salt (540 mg) of D-guluronic acid (**7**) as a light-yellow solid, $\{\alpha\}_D$ −24.7° (*c* 2.0, H_2O); ν_{max} (KBr): 1595 (COO^-) cm^{-1}. The barium salt was converted, using sodium borohydride, into L-gluconic acid, which was then identified in the form of L-glucono-1,4-lactone by gas–liquid chromatography (see ref. 32) as described by Perry and Hulyalkar (30).

Acidification of a cold (<3°C), concentrated, aqueous solution of a sample of the sodium salt of **6** with 2 *M* hydrochloric acid yielded **6** as colorless crystals, mp 175–176°C; $\{\alpha\}_D$ −79.0° (*c* 1.01, MeOH); ^{1}Hmr (200 MHz, DMSO-d_6) δ: 1.23 and 1.36 (s's, 6H, CMe_2), 3.25 (s, 3H, OMe), 3.91 (dd, 1H, $J_{4,5}$ = 8.6 Hz, $J_{3,4}$ = 3.5 Hz, H-4), 4.08 (br d, 1H, $J_{4,5}$ = 8.6 Hz, H-5), 4.53 (d, 1H, $J_{2,3}$ = 6.0 Hz, H-2), 4.75 (dd, 1H, $J_{2,3}$ = 6.0 Hz, $J_{3,4}$ = 3.5 Hz, H-3), 4.87 (s, 1H, H-1), 5.87 (br s, 1H, exchanged in D_2O, OH), 12.59 (br s, 1H, exchanged in D_2O, CO_2H). *Anal.* calcd. for $C_{10}H_{16}O_7$: C 48.39, H 6.50; found: C 48.15, H 7.01.

L-Glucono-1,5-lactone (8)

A solution of **6** (0.516 g) in water (30 mL) was treated with Dowex 50W-X8 cation-exchange resin (H^+ form) (1 mL, 1.7 mequiv.) with constant stirring for 29 h at 60–70°C. The process was repeated with fresh resin for 17 h. The resin was removed and the filtrate evaporated to a clear, oily residue which was dissolved in water (20 mL). Alcohol-free Raney nickel (37) (0.4 mL) was added and the mixture shaken (240 cpm) in an atmosphere of hydrogen (60 psig) at room temperature for 18 h. The catalyst was removed by filtration, washed with water (30 mL), and the combined filtrate and wash solution were cooled in an ice-water bath and stirred with Dowex 50W-X8 cation-exchange resin (H^+ form) (15 mL, 27 mequiv.) for 1 h. After removal of the resin the filtrate was concentrated to 1–2 mL and treated, as described by Isbell and Frush (33) for the D series, to give **8** (254 mg, 68.5%) as colorless prisms, mp 149–151°C; $\{\alpha\}_D$ −63.6° (2 min) → −12.6° (11 h) (*c* 5, H_2O) (lit. (33) for D-enantiomer, mp 150–152°C, $\{\alpha\}_D$ +66.2° → +8.8° (24 h) (*c* 5, H_2O)).

L-Glucose (9)

Immediately following the dissolution of **8** (0.5 g) in cold (<3°C) water (5 mL), a solution of sodium borohydride (0.080 g) in water (3 mL) and 0.15 *M* sulfuric acid were added concurrently, dropwise, with stirring, over a 20-min period, in such a manner as to maintain a pH of 3–4, while keeping the temperature at <3°C (35). Five minutes after the end of the addition of sodium borohydride, 0.15 *M* sulfuric acid (0.5 mL) was added and the solution was stirred for 5 min; the solution was diluted with water to 15 mL and stirred with Amberlite IR-120 cation-exchange resin (H^+ form) (5 mL) for 15 min. The resin was removed by filtration and washed with water (3 × 5 mL). The combined filtrate and wash solutions were stirred with Amberlite IR-45 anion-exchange resin (OH^- form) (5 mL) for 1 h; the resin was removed and washed as before. The sequential treatment with fresh cation- and anion-exchange resins was repeated twice more. The solvent was evaporated and boric acid removed by distillation with an excess of dry methanol (35). The clear, oily residue was dissolved in water (0.5 mL) and the solution was diluted with methanol (5 mL) and 2-propanol (10 mL). On standing at room temperature, compound **9** was obtained (refs. 8, 12, 38) (0.270 g, 53.7%), mp 143–150°C; $\{\alpha\}_D$ −52.9° (*c* 5.48, H_2O). A second crop of **9** (0.056 g, total yield 64.8%), mp 141–148°C, was isolated from the mother liquor. The ir and ^{1}Hmr spectra were indistinguishable from those of D-glucose.

Gas phase negative ion chemistry of alkylchloroformates. A convenient method for bimolecular generation of chloride ion adducts and determination of chloride affinities from ion cyclotron resonance thermal equilibrium measurements

J. W. LARSON[1] AND T. B. MCMAHON

Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 6E2

Received August 25, 1983

J. W. LARSON and T. B. MCMAHON. Can. J. Chem. **62**, 675 (1984).

A new method for production of chloride ion adducts, MCl^-, via a sequence of bimolecular ion molecule reactions involving chloroformate esters is described. These reactions have been used in trapped-ion ion cyclotron resonance thermal equilibrium studies to determine the relative chloride ion affinities of twenty compounds with Cl^- binding energies in the range 10–25 kcal mol^{-1}. The present results are found to be in good agreement with chloride affinities obtained by other methods. The resulting chloride affinity scale establishes a convenient framework for the systematic investigation of effects of molecular structure and chemical properties on the binding energy of Cl^- to both Lewis and Brønsted acids.

J. W. LARSON et T. B. MCMAHON. Can. J. Chem. **62**, 675 (1984).

On décrit une nouvelle méthode de produire des adduits d'ions chlorures, MCl^-, par le biais d'une série de réactions bimoléculaires ion-molécule impliquant des esters chloroformates. On a utilisé ces réactions pour effectuer des études d'équilibre thermique par ions piégés grâce à la résonance ionique dans un cyclotron; ces études ont été réalisées afin de déterminer les affinités relatives de l'ion chlorure pour vingt composés dans lesquels les énergies de liaison du chlorure varient de 10 à 25 kcal/mol. On trouve que nos résultats sont en bon accord avec les valeurs obtenues par d'autres méthodes pour les affinités du chlorure. L'échelle d'affinité de chlorure qui en résulte établit un modèle pour l'étude systématique des effets de structure moléculaire et des propriétés chimiques sur l'énergie de liaison du chlorure avec des acides de Lewis et de Brønsted.

[Traduit par le journal]

Introduction

The development of methods for studying ion molecule thermochemistry in the gas phase has resulted in important contributions to a number of areas of chemistry (1). The gas phase acidities and basicities of molecules (2–7) have been extensively studied and have led to a better understanding of the intrinsic factors affecting molecular acid–base properties as opposed to those relating to solvation phenomena. In addition, the direct study of solvation of cations and anions (8–11) has further shown the utility of gas phase data in explaining both chemical and physical interactions affecting solution processes.

The study of binding of anions to neutral molecules (12–18) has proven particularly useful. In addition to increasing the understanding of basic factors affecting stability of hydrogen bonds and structural factors influencing binding of anions to Lewis acids, a number of new anions have been generated in the gas phase with sufficiently great apparent stability to predict the probable ability to synthesize them in condensed phase (16–21). The potential of anion affinity data as a guide in engineering the molecular structure of compounds analogous to crown ethers and cryptates is another motivation for this laboratory's past interest in fluoride affinities (16, 17, 21) and the present work on chloride ion binding energetics of neutral molecules.

The ability to carry out ICR thermal equilibrium measurements of chloride affinities for a wide range of molecules at low pressure is dependent on three factors: (*i*) there must be a compound capable of producing a chloride ion adduct of some molecule either by dissociative electron attachment or by a sequence of bimolecular reactions; (*ii*) the compound used to generate primary chloride ions adducts in the system must itself have a sufficiently low Cl^- binding energy so that formation of Cl^- adducts of this compound does not interfere with generation of other desired adducts; (*iii*) there must exist at least one compound for which accurate thermochemical data for Cl^- attachment is available.

The first of these conditions is met by several compounds already described in the literature. Riveros *et al.* (22, 23) have demonstrated that $ClCO^-$ may be generated by dissociative electron attachment to Cl_2CO and this ion subsequently transfers Cl^- to species as weakly acidic as xenon and methylchloride. The cross section for $ClCO^-$ production is, however, exceedingly low, necessitating the use of high Cl_2CO pressures and thus rendering the ICR trapping experiment inoperative. Brauman (24) has shown that $CF_3Cl^{\cdot -}$ may be generated from CF_3COCl and this ion again acts as a facile Cl^- transfer agent. Our attempts to use CF_3COCl as a source of Cl^- adducts failed, again due to the exceedingly low cross section for $CF_3Cl^{\cdot -}$ production. The SO_2Cl^- ion has been shown by Sullivan and Beauchamp (18) to be readily generated by dissociative electron attachment to SO_2Cl_2 and SO_2ClF. In addition, mixtures of SF_6 and HCl have been shown to lead to the facile production of $FHCl^-$ (25) which subsequently acts as a Cl^- donor to compounds binding Cl^- more strongly than does HF. Unfortunately, these latter two methods for producing Cl^- donors, as well as the previous two (already unacceptable for our purposes), fail to satisfy the second condition. Each of the compounds involved, Cl_2CO, CF_3COCl, SO_2, SO_2Cl_2, SO_2ClF, and HCl, binds Cl^- more strongly than most of the substrates which we wished to examine. The final condition, availability of absolute Cl^- binding thermochemistry, is met for several compounds using high pressure mass spectrometric (HPMS) methods. Very recently, Kebarle (15) has examined clustering equilibria, eq. [1], for a variety of compounds and examined the effect of molecular structure, gas phase acidity, and charge distribution on the enthalpy of Cl^- binding, ΔH^0_1.

[1] $\quad RH + Cl^- \rightarrow RHCl^-$

These data provide convenient anchor points for the construction of our ladder of ICR thermal equilibrium Cl^- transfer measurements, eq. [2].

[2] $R_1HCl^- + R_2H \rightleftharpoons R_2HCl^- + R_1H$

In the present work, we wish to report a new class of compounds, chloroformate esters, which satisfy the conditions above for convenient generation of Cl^- adducts for use in ICR thermal equilibrium experiments. These new reagents have been used to generate a scale of Cl^- binding energetics for ten new compounds, chosen because of their availability, volatility, chemical inertness, and low tendency to be absorbed on surfaces. These compounds thus provide ideal reference species for determination of chloride affinities of all other compounds with Cl^- binding energies between those of benzene and formic acid. These new compounds also fill gaps in the chloride affinity scale not yet filled by the HPMS experiments, such that no new compound in this range would have a chloride affinity more than 1 kcal mol^{-1} from these reference species.

Experimental

All experiments were conducted at ambient temperature using an ICR spectrometer of basic Varian V-5900 design extensively modified to permit ion-trapping experiments (26). Details of design and operation of both conventional and trapped-ion ICR experiments have been described in detail previously (27, 28).

Methylchloroformate, ethylchloroformate, and ethylthiochloroformate were obtained from ICN Pharmaceuticals Inc. All other liquid materials were commercial samples of highest purity obtainable. Gases used were obtained from Matheson Canada Ltd. (sulfurdioxide, methylchloride, hydrogenchloride, and fluoroform), P.C.R. Inc. (phosphorous trifluoride, pentafluoroethane, *t*-butylfluoride and pentafluoroacetone), and Alfa Products Inc. (triethylborane). Hydrogen cyanide was prepared by condensing gaseous HCl into a concentrated aqueous solution of KCN. All samples were used following degassing by several freeze–pump–thaw cycles.

Results and discussion

1. Negative ion chemistry of chloroformate esters

Dissociative attachment of electrons to methylchloroformate and ethylchloroformate produces only Cl^-, eq. [3].

[3] $e^- + ClCO_2R \rightarrow Cl^- + RCO_2^{\cdot}$

Subsequent reaction of Cl^- with the neutral esters yields $ClCO_2^-$ via an apparent nucleophilic displacement reaction, eq. [4].

[4] $Cl^- + ClCO_2R \rightarrow ClCO_2^- + RCl$

The observed rate constants for this reaction were 1.1×10^{-10} cm^3 $molecule^{-1}$ s^{-1} for the methyl ester and 0.8×10^{-10} cm^3 $molecule^{-1}$ s^{-1} for the ethyl ester. Variation of relative negative ionic abundances with trapping time is shown in Fig. 1 for ethylchloroformate. As seen from this figure, in the absence of any other chloride acceptor molecules, the $ClCO_2^-$ reacts further with the neutral ester to generate a dichloroalkoxide ion, eq. [5].

[5] $ClCO_2^- + ClCO_2R \rightarrow Cl_2C(OR)O^- + CO_2$

The rate constant for this reaction is roughly 1.5×10^{-10} cm^3 $molecule^{-1}$ s^{-1} for both the methyl and ethyl esters.

Double resonance experiments revealed that $^{35}Cl^-$ is reactively coupled to both $^{35}ClCO_2^-$ and $^{37}ClCO_2^-$ with similar results for $^{37}Cl^-$. This result is consistent with either direct S_N2 attack at the α carbon of the ester alkyl group, or intermediate

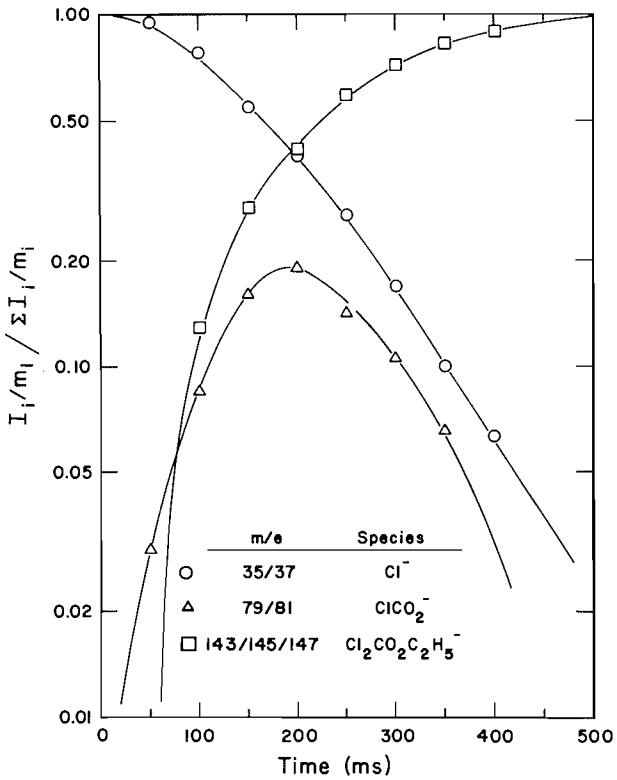

FIG. 1. Variation of relative negative ionic abundances with reaction time for $ClCO_2C_2H_5$ at 2.4×10^{-6} Torr following a 5 ms, 70 eV electron beam pulse.

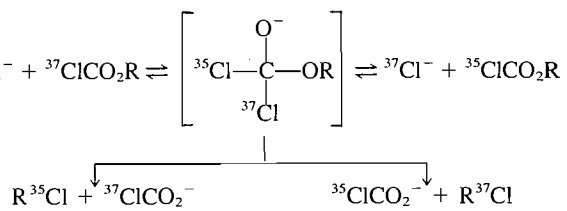

SCHEME 1

formation of a dichloroalkoxide ion followed by dissociation to $ClCO_2^-$ and RCl, Scheme 1. In this case, halide interchange very probably also occurs via formation of this intermediate complex. It is estimated that roughly 5% of encounters of Cl^- with $ClCO_2R$ lead to $ClCO_2^-$ production.

Reaction of F^- in mixtures of NF_3 and chloroformate esters also yield $ClCO_2^-$, eq. [6].

[6] $F^- + ClCO_2R \rightarrow ClCO_2^- + RF$

Reaction with Br^- showed no observable reaction products.

In the presence of an additional chloride acceptor molecule, M, with Cl^- binding energy in excess of that for either CO_2 or $ClCO_2R$, a Cl^- transfer is readily observed to yield a new chloride adduct, eqs. [7] and [8].

[7] $ClCO_2^- + M \rightarrow MCl^- + CO_2$

[8] $Cl_2CO_2R^- + M \rightarrow MCl^- + ClCO_2R$

A typical result is that shown in Fig. 2 for a mixture of fluoroform, CF_3H, and methylchloroformate.

For compounds with chloride affinities between those of CO_2 and the chloroformate esters, eq. [7] competes favourably with eq. [5] when the relative pressure of M is greater than that of

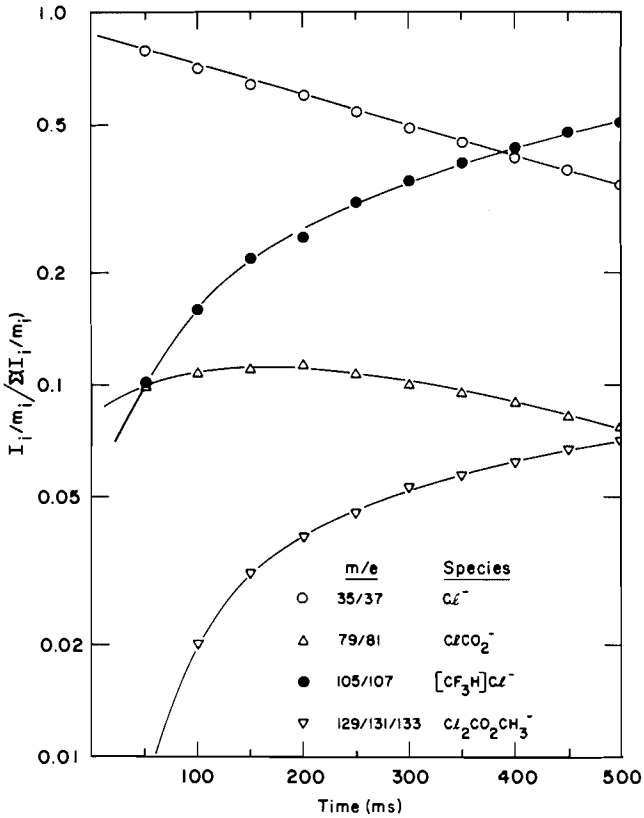

FIG. 2. Variation of relative negative ionic abundances with reaction time for a 1:1 mixture of $ClCO_2CH_3$:CHF_3 at 1.2×10^{-6} Torr total pressure following a 5 ms, 70 eV electron beam pulse.

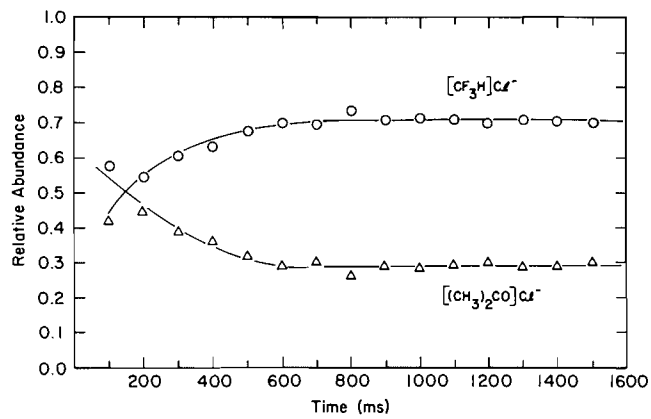

FIG. 3. Variation of relative negative ionic abundances with reaction time for a 2.7:1:5.5 mixture of $ClCO_2CH_3$:CHF_3:$(CH_3)_2CO$ at a total pressure of 2.4×10^{-6} Torr following a 5 ms, 70 eV electron beam pulse.

$ClCO_2R$. In this way Cl^- transfer could be observed to compounds such as cyclohexane and ethylene, both of which bind Cl^- less strongly than does benzene. No Cl^- transfer could be observed, however, to Xe or CO, placing the chloride affinity of CO_2 between benzene and xenon. This is consistent with the chloride affinity of benzene determined in the present work and elsewhere (15), the chloride affinity of CO_2 determined by Keesee, Lee, and Castleman (29) as 8.0 kcal mol^{-1}, and the chloride affinity of Xe estimated by Riveros *et al.* (23) to be 7.5 kcal mol^{-1}.

2. Chloride ion transfer equilibrium measurements

A quantitative scale of chloride affinities has been established from a series of multiple overlap chloride transfer equilibrium measurements. A typical chloride transfer equilibrium is shown in Fig. 3 for a mixture of acetone and fluoroform of accurately known partial pressure ratio in the presence of methylchloroformate. The equilibrium constant for eq. [9] may

[9] $CF_3HCl^- + (CH_3)_2CO \rightleftharpoons [(CH_3)_2CO]Cl^- + CF_3H$

then be determined from the observed steady-state ionic abundances and the known neutral pressure ratio. In general, the chloride exchange reactions were established by time-delayed ion ejection experiments to be an order of magnitude faster than the formation of $ClCO_2^-$ via eq. [4]. As a result, equilibrium steady-state was readily achieved within 300 ms of initial ion formation.

Although attainment of a persistent steady-state was taken to be the initial indication that thermal equilibrium had been established, this was confirmed by a number of other routes: (*i*) a calculated equilibrium constant that was invariant to changes in neutral pressure ratio and to total pressure; (*ii*) multiple overlap experiments which gave the difference in free energy of attachment of Cl^- for any two compounds by at least two independent paths; (*iii*) double resonance and ion ejection experiments carried out at long reaction times to verify the occurrence of reaction in both forward and reverse directions and in some cases to obtain rate constants. This last condition was particularly important in confirming equilibria in compounds with chloride affinities less than methylchloroformate. In cases where competing chloride transfer to methylchloroformate was especially severe, no quantitative conclusions regarding the binding energies of these low chloride affinity species were drawn.

Standard free energy changes for each of the chloride transfer equilibria observed may be calculated from eq. [10].

[10] $\Delta G_2^0 = -RT \ln K_{eq}$

These values are reported in Table 1. The uncertainty associated with each of these ΔG_2^0 values is at maximum ± 0.2 kcal mol^{-1}. The value for free energy of binding of Cl^- to *tert*-butanol of 11.1 kcal mol^{-1} (12, 13, 15) has been adopted as the primary reference standard for the chloride binding energy scale since this value is roughly in the middle of the scale of chloride affinities and since the value for free energy of binding has remained unchanged after repeated measurements by HPMS. The free energy of binding of Cl^- for each of the compounds studied, ΔG_{11}^0, is thus obtained from the value of

[11] $MCl^- \rightarrow M + Cl^-$

ΔG_2^0 relative to 11.1 kcal mol^{-1} for t-C_4H_9OH. These values are also summarized in Table 1. For the most part, values of ΔG_{11}^0 obtained in the present work agree within ± 0.4 kcal mol^{-1} with those obtained by other methods. This uncertainty is well within the combined uncertainties of the individual techniques.

Fehsenfeld and Ferguson (30) have determined ΔG_{12}^0 from measurements of the forward and reverse rate constants for eq. [12] in a flowing afterglow apparatus. Their value of

[12] $Cl^- \cdots HOH + SO_2 \rightleftharpoons ClSO_2^- + H_2O$

6.0 kcal mol^{-1} is in excellent agreement with our present one of 6.5 kcal mol^{-1}, especially considering the experimental difficulty associated with measurement of the extremely slow rate of the reverse reaction. The value of ΔG_{11}^0 for SO_2 of 14.7 kcal mol^{-1} obtained by us is also in excellent agreement with that of

14.9 kcal mol^{-1} obtained by Keesee and Castleman (31) in a temperature dependent study of clustering equilibria of Cl^- with SO_2. In addition, our value of 8.4 kcal mol^{-1} for ΔG_{11}^0 for H_2O is in excellent agreement with that of Kebarle and co-workers (15) of 8.2 kcal mol^{-1} from an HPMS temperature dependent study of clustering equilibria, and in reasonable agreement with the values of 8.8 kcal mol^{-1} and 9.0 kcal mol^{-1} obtained by Burdett and Heyhurst (32) and Keesee and Castleman (31) respectively. Excellent agreement between our work and that of Kebarle and co-workers (15) is also obtained for ΔG_{11}^0 values for chlorobenzene, acetone, and methanol, and good agreement for data for HCl and acetic acid. The single case where serious disagreement between the present data and other studies of clustering equilibria occurs is for formic acid. In early work, Yamdagni and Kebarle (13) reported a value of ΔG_{11}^0 of 25.4 kcal mol^{-1} employing neat formic acid. However, in a more recent study (15), this value has been revised to 20.1 kcal mol^{-1} using formic acid as a constituent in methane bath gas. This value is still somewhat larger than the presently obtained value of 18.4 kcal mol^{-1}. Given the known tendency of formic acid to undergo pyrolysis (33) at the highest temperatures employed in the HPMS study, it may be that partial decomposition of formic acid is occurring above 600 K leading to an erroneous van't Hoff plot. We thus believe the ICR value for formic acid is more reliable.

Entropies of association, ΔS_{11}^0, for hydrogen bonded chloride adducts were calculated by a statistical thermodynamic method derived previously (34) using eq. [13].

$$[13]\quad \Delta S_{11}^0 = R\left(8.98 + 1.5 \ln \Delta H_{11}^0 - 2 \ln l + \ln \frac{\sigma_{MCl^-}}{\sigma_M}\right) + \Delta S_v'$$

The enthalpy change ΔH_{11}^0 is obtained by successive iterations using ΔG_{11}^0 and calculated ΔS_{11}^0 values; l, the hydrogen bond distance is estimated from *ab initio* calculations; σ is the symmetry number of the molecule or ion; and $\Delta S_v'$ is a small negative correction to ΔS_{11}^0 due to low frequency vibrations of hydrogen bonded species using formulae for classical oscillators. The value of ΔS_{11}^0 for SO_2Cl^- was calculated using the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

known vibrational frequencies (35) and estimated bond distances while values for PF_3Cl^- and $ClB(Et)_3^-$ were estimated from similar compounds. These entropy values are all also summarized in Table 1. In addition the enthalpy changes, ΔH^0_{11} determined from the experimental ΔG^0_{11} values and calculated ΔS^0_{11} values are included in Table 1.

Conclusions

The experiments described above provide the methodology for the convenient generation of chloride ion adducts of both Lewis and Brønsted acids at low pressures via bimolecular reaction sequences. The quantitative scale of chloride ion binding energetics developed provides a convenient series of reference compounds relative to which chloride affinities of most common organic and inorganic species may be readily determined. We are currently in the process of determining chloride affinities of a wide variety of compounds in order to determine intrinsic factors affecting hydrogen bond strengths and anion binding energies.

Reçu le 8 juillet 1983

JEAN-PIERRE MONTI, MARCEL SARRAZIN et PIERRE BROUANT. Can. J. Chem. **62**, 680 (1984).

Les auteurs étudient les protonations du phosphate d'isaxonine au moyen des méthodes quantiques CNDO/2 et CNDO/S et comparent les résultats théoriques aux résultats expérimentaux publiés précédemment. Les indices de Wiberg et les pourcentages de caractère *S* calculés à partir des populations électroniques permettent de prévoir correctement les variations des longueurs et des angles de liaisons ainsi que les valeurs des constantes de couplage $J_{^{13}C-H}$. Enfin, le calcul de la constante d'écran conduit à une bonne prédiction des variations des déplacements chimiques des protons lors des protonations de la molécule.

JEAN-PIERRE MONTI, MARCEL SARRAZIN, and PIERRE BROUANT. Can. J. Chem. **62**, 680 (1984).

Protonations of isaxonine phosphate are studied by performing CNDO/2 and CNDO/S molecular orbital calculations. Results are compared with previously published data. Wiberg's bond indices and *S* character percentages calculated using electronic populations are shown to correctly predict variations of bond lengths and bond angles as well as $J_{^{13}C-H}$ coupling constants. A good prediction of proton chemical shift variations using a calculation of the screening constant was obtained.

Introduction

Récemment est apparue une nouvelle molécule, le phosphate d'isaxonine (isopropyl amine pyrimidine phosphate; IAPP), spécifiquement neurotrope et susceptible de favoriser la croissance et la régénération des neurones (1). Cette activité parait liée à une augmentation de la synthèse de la tubuline ou à une accélération de sa polymérisation (2).

L'isaxonine est actuellement la seule molécule présentant cette propriété, ce qui lui a permis d'être utilisé dans le traitement de certaines neuropathies. Une première étude par des méthodes spectrales (3) nous a déjà permis de mieux connaître la réactivité de l'isaxonine en solution. Cependant, il nous a paru nécessaire, dans un deuxième temps, de faire appel aux méthodes de calcul de la chimie théorique afin de préciser la structure et la réactivité de cette molécule.

Ceci nous amenera à vérifier la qualité des résultats théoriques par comparaison avec les résultats expérimentaux obtenus précédemment (3).

I. Méthodes théoriques et géométrie

Nous avons appliqué les méthodes quantiques CNDO/2 de Pople *et al.* (4, 5) et CNDO/S de Del Bene et Jaffe (6) sans interaction de configuration, et avec leur paramétrisation originale. Ces deux méthodes, compte tenu du niveau d'approximation, conduisent à de bons résultats qualitatifs. Cependant, un type de paramétrisation ne peut, en général, rendre compte quantitativement de plusieurs grandeurs à la fois. En effet, les propriétés moléculaires où les orbitales π jouent un rôle prépondérant sont mieux décrites par la CNDO/S, alors que la répartition électronique au voisinage des atomes d'hydrogène est meilleure à l'aide de la CNDO/2 (7).

En l'absence de résultats expérimentaux en phase non condensée (microondes, diffraction électronique), nous avons utilisé pour le calcul de l'isaxonine base (IAP) la géométrie du cycle amino-2 pyrimidine déterminée par Scheinbeim et Schempp (8) en phase solide au moyen des rayons X.

La valeur de la constante de couplage $^3J_{NH-CH}$ égale à 8,0 Hz (3), nous a amené à adopter un angle diédre entre les liaisons N—H et C—H de 155°, valeur calculée en utilisant une relation de type Karplus (9).

Pour les deux groupements méthyles nous avons utilisé des angles et des longueurs de liaisons habituels (10).

Les spectres rmn montrent que les deux atomes d'azote intracycliques sont suceptibles d'être protonés et font apparaître le rôle joué par la taille du substituant alkyle (3). De ce fait, nous avons choisi d'effectuer le calcul des formes monoprotonée en N_1 (IAPP) et diprotonée en N_1 et N_3 (IAPDP) en adoptant des longueurs de liaison N^+—H égales à 1,083 Å (10).

La numérotation et le système d'axes employés dans les calculs sont donnés dans la figure 1.

II. Résultats et discussion

1. *Les énergies des niveaux occupés*

En l'absence de résultats expérimentaux quant aux potentiels d'ionisation de l'isaxonine, nous avons choisi de comparer nos résultats théoriques avec les potentiels d'ionisation obtenus pour la pyrimidine, expérimentalement (11) et par une méthode *ab initio* STO-3G (12).

En effet, la présence de la chaîne alkyle ne doit perturber que faiblement l'énergie des niveaux supérieurs, essentiellement de symétrie *n* ou π.

Les énergies des dernières orbitales moléculaires occupées sont présentées dans la figure 2.

On note tout d'abord le bon accord entre le classement des niveaux de la méthode CNDO/S et celui de la méthode *ab initio:* $\pi_3 < n_A < \pi_2 < n_S$. De plus ces deux méthodes conduisent à des coefficients des fonctions d'onde peu différents. Comparativement aux valeurs du premier potentiel d'ionisation (P.I.) (8,98 eV en STO-3G et 9,58 eV en CNDO/S), on observe une augmentation de la stabilité des niveaux n_A, π_2 et n_S de

[1]Auteur à qui la correspondance doit être envoyée.

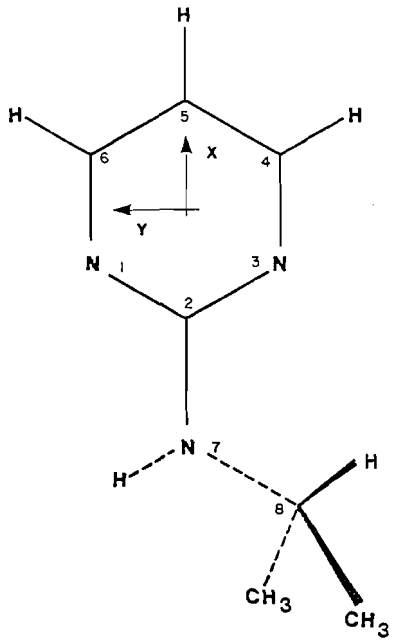

FIG. 1. Structure moléculaire de l'isaxonine (IAP) et numérotation employée.

l'IAP, alors que les différences d'énergie de ces niveaux sont conservées. Notons que pour la molécule d'IAP, calculée en CNDO/S, l'orbitale dans laquelle intervient principalement le doublet libre de l'azote N_7 est située entre les niveaux π_2 et n_S.

Le méthode CNDO/2 fournit des résultats indiquant une stabilisation apparemment plus forte des niveaux ($P.I._{\pi_3}$ = 11,10 eV), tout en perturbant leur ordre: $\pi_3 < n_A < n_S < \pi_2 < \pi$.

Ainsi la méthode CNDO/S conduit à des résultats plus proches de ceux obtenus pour la pyrimidine à l'aide de la méthode *ab initio*. Cependant cette dernière méthode ne permettait pas de rendre compte de l'ordre expérimental des potentiels d'ionisation de la pyrimidine: $n_A < \pi_3 < n_S < \pi_2$. Du fait de sa paramétrisation qui déstabilise les niveaux π, la CNDO/S ne donne pas non plus le classement attendu pour la molécule d'IAP, tout en conduisant à des valeurs des énergies plus cohérentes que celles obtenues par CNDO/2.

2. *Les charges électroniques et les grandeurs associées*

(a) *Les charges électroniques*

Le tableau 1 regroupe les valeurs des charges électroniques des atomes de l'IAP, l'IAPP et de l'IAPDP calculées par les méthodes CNDO/2 et CNDO/S. La protonation sur les atomes d'azote intracycliques est confirmée par les valeurs des densités de charge en N_1, N_3, et N_7. En effet, les deux méthodes de calcul attribuent pour la forme non protonée les charges électroniques les plus élevées aux atomes N_1 et N_3. Mais ces deux valeurs, peu différentes, ne permettent pas de prévoir le site de la protonation. Cependant, le calcul effectué sur les formes monoprotonée en N_1 et monoprotonée en N_3 montre que cette dernière est la moins stable, ce qui donne du poids à l'hypothèse de la protonation sur l'atome d'azote intracyclique le moins encombré. De plus, la formation de la liaison N^+—H s'accompagne d'une diminution de la densité de charge de l'azote, diminution qui est le reflet de la transformation du doublet libre de l'hétéroatome en l'orbitale σ de la liaison N^+—H.

Les protonations successives entrainent la diminution des charges totales de tous les protons à l'exception de celle de l'hydrogène 8 de la forme IAPDP. Cette variation des charges est en bon accord avec les déblindages observés en rmn pour tous les protons lorsque l'on passe de la forme IAP non protonée à la forme IAPP monoprotonée puis à la forme IAPDP diprotonée (3). En effet, pour des séries homogènes de molécules, il est classique de considérer que la constante d'écran des protons dépend essentiellement du terme diamagnétique, lui même proportionnel à la densité électronique du noyau (13). A une diminution de la densité électronique correspond alors une diminution de la constante d'écran ce qui traduit bien le déblindage observé par rmn pour chacun des protons.

L'examen du tableau 1 fait également apparaître une diminution de la charge totale de chacun des atomes de carbone aromatique lors des protonations successives. Cette diminution, notable pour les carbones C_2, C_4 ou C_6 (de l'ordre de −0,060 en CNDO/2 et −0,080 en CNDO/S), est nettement plus faible pour le carbone C_5 (de l'ordre de −0,013 en CNDO/2 et −0,036 en CNDO/S). Des effets analogues ont déjà été mis en évidence par Pugmire *et al.* (14) dans le cas de la pyrimidine en utilisant la méthode EHT ou dans le cas d'hétérocycles azotés apparentés par la méthode CNDO-SCF-MO (15, 16). Mais contrairement aux protons, dans le cas des atomes de carbone, il est plus difficile de relier ces variations des charges aux variations des déplacements chimiques. En effet, il n'est plus possible de négliger l'effet des orbitales *p* donc du terme paramagnétique de la constante d'écran dont le calcul fait intervenir les populations de liaison entre les atomes voisins. Nous discuterons de la validité des approximations mises en oeuvre pour ce calcul dans le paragraphe se rapportant aux déplacements chimiques des atomes de carbone.

(b) *Les déplacements chimiques des protons*

Il est classique d'essayer de corréler le déplacement chimique des protons avec les charges électroniques des atomes qui les portent. Dans notre cas, la corrélation étendue à tous les protons n'est pas significative, tant en CNDO/2 (r = 0,467) qu'en CNDO/S (r = 0,678). Par contre, la corrélation est d'une bonne qualité si l'on considère seulement les protons de l'hétérocycle (r = 0,969 en CNDO/2; r = 0,984 en CNDO/S) pour lesquels l'effet des charges sur les déplacements chimiques provient essentiellement des charges π (r = 0,964 en CNDO/2; r = 0,974 en CNDO/S).

L'impossibilité de corréler les déplacements chimiques de tous les protons avec les densités de charge provient du fait que celles-ci n'interviennent que pour une part dans l'expression de la constante d'écran (17–20).

$$[1] \quad \sigma_{ppm} = \sigma_q + \sigma_{CC} + \sigma_{CE} + \sigma_A + \sigma_{solv.}$$

où σ_q est l'effet dû aux charges, σ_{CC} l'effet dû au courant de cycle, σ_{CE} l'effet dû aux doublets non partagés, σ_A l'effet dû à l'anisotropie des hétéroatomes et enfin $\sigma_{solv.}$ est l'effet dû à la solvatation. Nous avons utilisé pour le calcul de chacune de ces contributions les expressions classiques suivantes (21–25):

$$[2] \quad \sigma_q = 12{,}5 \sum_i \frac{\Delta q_i \cos\theta_i}{R_i^2} - 17{,}0 \left(\sum_i \frac{\Delta q_i}{R_i^2} \right)^2$$

où Δq_i: excès de charge p_z sur l'atome i; R_i: distance H$\cdots i$; θ_i: angle C—H$\cdots i$.

$$[3] \quad \sigma_{CC} = \frac{12(2Z_N^2 - \rho_N)}{a(\rho_N^2 + Z_N^2)^{5/2}}$$

où a: rayon moyen du cycle; ρ_N et Z_N: coordonnées cylindriques

* Valeurs moyennes.

du proton par rapport au centre du cercle (en unité de rayon).

$$[4] \quad \sigma_{CE} = -2{,}7 \times 10^{-12} \frac{\mu}{R^3} (3 \cos \phi_1 \cos \phi_2 - \cos \phi_3)$$

où ϕ_1: angle entre le moment dipolaire $\vec{\mu}$ dû au doublet libre de l'azote et la direction N···H; ϕ_2: angle entre N···H et la liaison C—H; ϕ_3: angle entre $\vec{\mu}$ et C—H.

$$[5] \quad \sigma_A = \frac{1}{3NR^3} \sum_i \chi_i (1 - 3 \cos^2 \theta_i)$$

où χ_i: composantes de la susceptibilité magnétique moléculaire de l'hétéroatome; θ_i: angle entre la direction i et la direction N···H.

$$[6] \quad \sigma_{solv.} = -2{,}7 \times 10^{-12} \frac{2(\epsilon - 1)(n^2 - 1)}{3(2\epsilon + n^2)\alpha} \mu \cos \theta$$

où ϵ: constante diélectrique du solvant; n: indice de réfraction du soluté; α: polarisabilité du soluté; θ: angle entre $\vec{\mu}$ et la liaison C—H.

Nous avons rapporté dans la figure 3 les déplacements chimiques expérimentaux en fonction des constantes calculées à partir des résultats de la CNDO/S. Cette figure nous a conduit encore une fois à considérer séparement les protons de l'hétérocycle de ceux de la chaîne isopropylamine. On obtient alors les relations linéaires suivantes:

$$\delta_{H_{cycle}} = -0{,}36\,\sigma + 6{,}44 \qquad r = 0{,}990$$

$$\delta_{H_{chaîne}} = -0{,}96\,\sigma + 2{,}38 \qquad r = 0{,}973$$

Les valeurs des coefficients de corrélation, plus élevées que précedemment, notamment dans le cas des protons de la chaîne pour lesquels aucune relation significative n'avait été obtenue, traduisent l'amélioration dûe à l'introduction des termes σ_{CC},

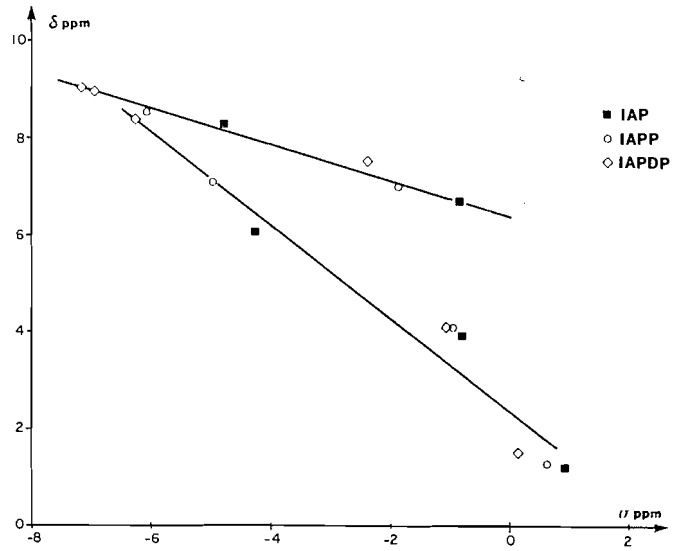

FIG. 3. Correlation entre les déplacements chimiques expérimentaux des protons et les constantes d'écran calculées (CNDO/S).

σ_{CE}, σ_A, $\sigma_{solv.}$.

Ainsi, seul le calcul de tous les termes de la constante d'écran conduit pour les deux classes de protons à une excellente estimation des déplacements chimiques et de leurs variations lors des protonations successives de la molécule d'IAP.

Notons enfin que les résultats obtenus à partir des calculs de la méthode CNDO/2 sont voisins mais que les regressions sont moins significatives.

(c) *Les déplacements chimiques des carbones*

Dans un premier temps, nous avons essayé d'établir des relations classiques entre les déplacements chimiques et les charges électroniques des carbones. Aucune de ces relations ne s'est révélée significative.

Nous avons alors envisagé un calcul plus élaboré de la constante d'écran qui peut être décomposée en une somme de termes (26, 27):

$$[7] \quad \sigma = \sigma_{dia} + \sigma_{para} + \sigma_A + \sigma_{solv.}$$

où σ_{dia} et σ_{para} sont respectivement les contributions diamagnétiques et paramagnétiques de l'atome considéré, σ_A est la contribution due à l'anisotropie des atomes voisins et $\sigma_{solv.}$ est la contribution due au solvant.

Là encore, les calculs n'ont pas permis d'obtenir de relations fortement significatives tant pour les atomes de carbone aromatique que pour les atomes de carbone aliphatique. ($r < 0{,}94$ en CNDO/S). Cet échec semble provenir du terme paramagnétique dont la contribution est prépondérante (28). En effet, la protonation de l'atome d'azote conduit à une diminution des populations des liaisons engagées par celui-ci. Ceci a pour effet de diminuer la valeur du terme d'écran paramagnétique (16). De plus la protonation élimine les niveaux de basse énergie associés aux doublets libres des atomes d'azote ce qui augmente l'énergie moyenne d'excitation et diminue encore la contribution paramagnétique (16, 17). Ces deux effets conduisent à prévoir pour tous les atomes de carbone un déplacement vers les champs forts consécutif à la protonation. Le calcul rend bien compte du blindage observé pour les carbones de l'IAPP mais il n'est pas vérifié expérimentalement dans le cas des carbones C_4, C_5 et C_6 de la molécule diprotonée IAPDP ni dans le cas des carbones C_8 des formes IAPP et IAPDP pour lesquels on observe un déplacement vers les champs faibles lors des protonations (3).

Il faut noter que Fliszar *et al.* (29) ont montré que, dans une série de molécules aromatiques, les charges σ et π varient en sens contraire. À ces variations sont associées des variations des déplacements chimiques, une diminution de la charge σ se traduisant par un effet de blindage. Les résultats portés dans le tableau 1 et inteprétés selon les conclusions de Fliszar (29) nous permettent de prédire qualitativement le blindage du carbone C_2 lors des deux protonations et le blindage du carbone C_4 lors de la première protonation puis son déblindage lors de la seconde. Cependant, il n'est pas possible de rendre compte des déplacements chimiques des carbones C_5 et C_6.

Au contraire, dans le cas de carbones sp^3, à l'augmentation de la densité de charge de l'orbitale $2s$ correspond un déplacement vers les champs faibles (29). Dans ces conditions les variations de la charge de l'orbitale $2s$ des carbones des groupements méthyl et du carbone C_8 (Tableau 2) permettent de prédire qualitativement le blindage observé pour les premiers et le déblindage observé pour le dernier lors des protonations.

3. *Les liaisons et les grandeurs associées*

(a) *Les indices de liaison*

Plusieurs indices de liaison ont été proposés par les auteurs afin de rendre compte des liaisons dans les molécules (30–32). Nous avons pour notre part choisi d'utiliser l'indice de Wiberg (30) dont l'application peut être étendue au calcul de l'hybridation (33). Dans le cas d'une liaison A—B, l'indice W_{AB} est égal à la somme des carrés des populations électroniques $P_{\mu\nu}$, où les orbitales atomiques μ et ν appartiennent aux atomes A et B.

$$[8] \quad W_{AB} = \sum_{\mu \in A} \sum_{\nu \in B} P_{\mu\nu}^2$$

Les valeurs des indices de liaison de l'IAP, l'IAPP et l'IAPDP calculées en utilisant les populations électroniques de la CNDO/S sont données dans le tableau 3. La comparaison des indices des liaisons C—C et C—N permet de constater que la valeur la plus faible est obtenue pour la liaison N_7—C_8 et que cette valeur diminue encore lors des protonations du cycle pyrimidique. Il est difficile de relier la valeur d'un indice qui reflète la stabilité intrinsèque d'une liaison (34, 35) avec l'énergie requise pour rompre celle-ci en spectrométrie de masse. Toutefois, l'énergie de chacune des liaisons est un des facteurs intervenant dans la production des différents fragments (36). Aussi, sans vouloir en tirer de règles générales, nous constaterons simplement que les valeurs faibles de l'indice de Wiberg pour les liaisons N_7—C_8 vont de pair avec la possibilité de rupture de ces liaisons mise en évidence par spectrométrie de masse pour l'IAP et l'IAPP (3).

La déstabilisation de cette liaison va de pair avec le gain de stabilité de la liaison C_2—N_7. En effet, pour l'IAP, la valeur de l'indice de la liaison C_2—N_7, intermédiaire entre celles d'une liaison σ et celle d'une liaison π, traduit la faible conjugaison du doublet libre de l'azote N_7. Cette valeur se trouve très fortement accrue par les deux protonations. L'augmentation du caractère π est bien retrouvée experimentalement. En effet, les spectres rmn montent que la libre rotation autour de la liaison C_2—N_7 de l'IAP, ralentie par la première protonation, est empêchée dans le cas de la molécule d'IAPDP (3).

L'analyse des indices des liaisons du cycle pyrimidique permet ainsi de noter l'augmentation de la valeur obtenue pour la liaison entre le carbone en position *ortho* et le carbone en

N_3—C_4	1,4061	1,4047	1,2139
C_4—C_5	1,4365	1,3349	1,4561
C_5—C_6	1,4360	1,5720	1,4562
C_6—N_1	1,4069	1,2012	1,2135
C_2—N_7	1,1215	1,1945	1,3531
N_7—C_8	0,9726	0,9493	0,9288
C_8—Me	1,0809	1,0041	0,9970

position *meta* de l'azote protoné, ce qui traduit le raccourcissement de cette liaison. De plus, la formation de la liaison N^+—H s'accompagne d'une perte partielle de la conjugaison des liaisons engagées par l'atome d'azote et de la liaison entre le carbone *méta* et le carbone *para*, donc d'un allongement de celles ci, comme en témoigne la diminution des valeurs des indices de ces liaisons.

Ces effets mis en évidence par la méthode CNDO/S ont déjà été observés dans le cas de la protonation de la purine, experimentalement au moyen des rayons X (37) et théoriquement par un calcul CNDO-SCF-MO (15, 16).

Les résultats obtenus à partir des populations électroniques de la CNDO/2 conduisent aux mêmes conclusions.

À des modifications des longueurs de liaisons lors des protonations correspondent des modifications des angles internucléaires et interorbitaux.

(b) *Les angles interorbitaux*

Dans le cas d'une liaison de type sp_2 entre les atomes A et B, le rapport des populations électroniques:

$$[9] \quad S_{A\to B} = \frac{\sum_{\nu} P^2_{2s_A - \nu_B}}{\sum_{\nu} (P^2_{2s_A - \nu_B} + P^2_{2px_A - \nu_B} + P^2_{2py_A - \nu_B})}$$

est une mesure du pourcentage du caractère *S* de l'orbitale hybride centrée sur A et dirigée vers B (33). Connaissant les pourcentages $S_{A\to B}$ et $S_{A\to C}$ on peut alors calculer l'angle interorbital η_{B-A-C} en utilisant la formule (38):

$$[10] \quad \cos \eta_{B-A-C} = -\frac{S_{A\to B} \times S_{A\to C}}{(1 - S_{A\to B})(1 - S_{A\to C})}$$

Seules les valeurs correspondant à la géométrie de l'hétérocycle, qui présentent les plus fortes variations, sont reportées dans le tableau 4.

TABLEAU 4. Angles interorbitaux du cycle pyrimidique calculés à partir des résultats de la méthode CNDO/S

Angles	IAP	IAPP	IAPDP
N_1—C_2—N_3	122,2	121,5	121,1
C_2—N_3—C_4	113,3	110,7	120,0
N_3—C_4—C_5	120,5	119,9	119,3
C_4—C_5—C_6	122,0	120,9	120,0
C_5—C_6—N_1	120,5	119,8	119,3
C_6—N_1—C_2	111,4	121,2	120,3

On observe principalement une augmentation de l'angle interorbital porté par l'atome d'azote protoné. Une variation analogue de l'angle internucléaire C—N—C de la purine a été mise en évidence théoriquement par la méthode MNDO (39) et expérimentalement au moyen des rayons X (37).

Les valeurs calculées pour les angles portés par les atomes de carbone laissent supposer une tendance à la fermeture lors des protonations. Bien qu'ici cette variation soit faible, elle a été observée dans le cas de l'angle internucléaire N—C—C de la pyrimidine (39).

(c) *Les constantes de couplage* J^{13}_{C-H}

En première approximation, la constante de couplage entre les spins nucléaires d'un atome de carbone ^{13}C et d'un atome d'hydrogène qui lui est lié est directement proportionnelle au pourcentage de caractère *S* de l'orbitale hybride assurant la liaison (40). Cependant, de nombreux auteurs ont montré qu'un terme constant, corrigeant certaines approximations, devait être soustrait afin d'obtenir une bonne concordance entre les valeurs expérimentales et les valeurs calculées (41–44).

Les pourcentages de caractères *S* calculés utilisant la relation (33):

$$[11] \quad S_{C-H} = \frac{P^2_{2S_C - S_H}}{\sum_{\nu \epsilon C} P^2_{\nu - S_H}}$$

ont été corrélés aux valeurs expérimentales de J_{C-H}.

La méthode des moindres carrés conduit aux relations linéaires:

$$J_{C-H_{exp.}} = 709\, S_{C-H} - 41 \qquad r = 0{,}976$$

dans le cas de la CNDO/2, et

$$J_{C-H_{exp.}} = 685\, S_{C-H} - 38 \qquad r = 0{,}983$$

dans le cas de la CNDO/S (Fig. 4).

Les paramètres des deux relations sont trés proches de ceux obtenus dans le cas de travaux similaires utilisant la méthode INDO et un calcul plus élaboré des constantes de couplage (45) on une méthode adoptant le critère du recouvrement maximal (46, 47).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

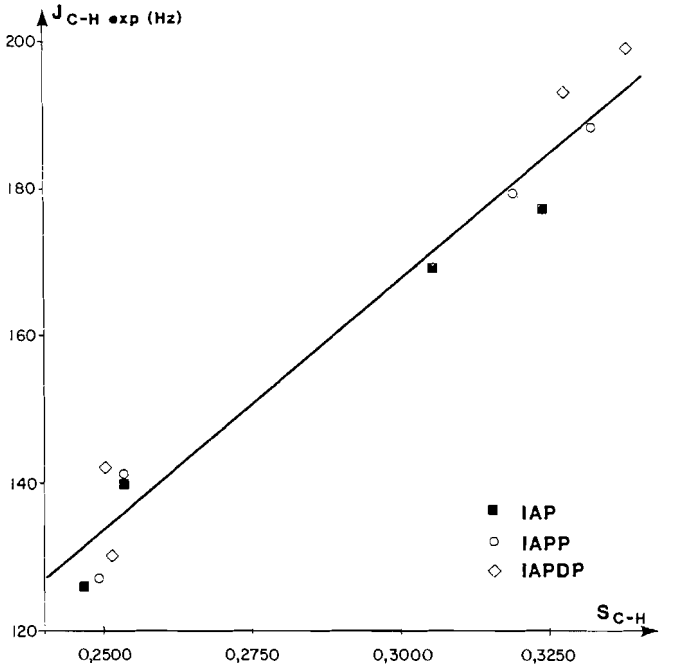

FIG. 4. Correlation entre les constantes de couplages $J_{^{13}C-H}$ expérimentales et les pourcentages de caractère S calculés (CNDO/S).

L'augmentation des valeurs expérimentales des constantes de couplage lors des protonations, plus marquée pour les liaisons C—H de l'hétérocycle, est bien traduite par les deux relations. Elle peut être attribuée sans ambiguité à une augmentation du caractère S consécutive aux variations de la géométrie et au transfert des charges électroniques que nous avons précédemment mis en évidence.

Conclusions

Aucune des méthodes CNDO n'a permis de rendre compte de l'énergie des niveaux électroniques correspondant aux doublets libres des atomes d'azote. L'échec provient de l'incapacité des deux méthodes à décrire les électrons des doublets libres.

L'analyse des charges électroniques montre qu'à leurs variations lors des protonations correspondent des modifications des déplacements chimiques des protons. Ces résultats expérimentaux ont été bien rendus par un calcul de la constante d'écran.

Il n'a pas été possible, dans le cas des atomes de carbone de rendre compte des déplacements chimiques par le calcul. Il convient de noter qu'une comparaison des variations des densités de charge permet de prédire avec succés les déplacements chimiques de la majorité des atomes de carbone.

Les deux protonations successives de la molécule d'IAP augmentent la stabilité de la liaison C_2—N_7 et déstabilisent la liaison N_7—C_8. Les valeurs des indices de liaison ont permis de vérifier et de préciser les résultats expérimentaux obtenus (3).

De plus, le calcul des pourcentages de caractère S a fait apparaître l'augmentation de l'angle interorbital C—N—C lors de la protonation de l'atome d'azote et a permis de rendre compte des valeurs des constantes de couplage $J_{^{13}C-H}$.

Enfin si en général les deux paramétrisations de la méthode CNDO, appliquées à la géométrie adoptée, conduisent à des résultats théoriques qualitativement peu différents, on peut noter que la méthode CNDO/S s'est révélée mieux adaptée au calcul des grandeurs associées aux charges ou aux pourcentages de caractère S.

Ainsi notre travail nous a conduit à une meilleure connaissance de la structure électronique et de la géométrie de l'isaxonine en solution et à définir les domaines d'application de la CNDO dans l'étude de cette molécule. Cette premiére approche de la réactivité de l'isaxonine va nous permettre, dans un second temps, de mieux appréhender l'activité biologique de cette molécule.

Remerciements

Nous tenons à exprimer nos remerciements à Monsieur le Professeur A. Crevat pour les discussions fructueuses que nous avons eues et le soutien constant qu'il nous a apporté. Nous remercions également Monsieur H. Bouteille et Mademoiselle S. Lorenzi pour leur collaboration technique.

Received July 28, 1983

MARIA LUISA CASTELLANOS, SANTIAGO OLIVELLA, NURIA ROCA, JAVIER DE MENDOZA, and JOSÉ ELGUERO. Can. J. Chem. **62**, 687 (1984).

A theoretical study of fourteen *N,N*-linked biazoles has been carried out using the MNDO method with full optimization of the geometries. The variation of energy as a function of the conformation around the central *N*—*N* bond shows in all cases the higher stability of the orthogonal or near-orthogonal form. The contribution of the three main types of "*ortho*" interactions (H...H, N̈...N̈, and H...N̈) and the effect of quaternization have been evaluated. Of the electronic properties calculated, one must emphasize the excellent agreement of dipole moments with experimental values.

MARIA LUISA CASTELLANOS, SANTIAGO OLIVELLA, NURIA ROCA, JAVIER DE MENDOZA et JOSÉ ELGUERO. Can. J. Chem. **62**, 687 (1984).

Une étude théorique de quatorze *N,N*-biazoles a été conduite en utilisant la méthode MNDO avec optimisation complète de la géométrie. La variation de l'énergie en fonction de la conformation autour de la liaison centrale *N*—*N* montre dans tous les cas la plus grande stabilité des formes orthogonales ou proches de l'orthogonalité. La contribution des trois types d'interactions "*ortho*" (H...H, N̈...N̈ et H...N̈) a été évaluée, ainsi que l'effet de la quaternarisation. Parmi les propriétés électroniques calculées on note l'excellent accord des moments dipolaires avec les valeurs expérimentales.

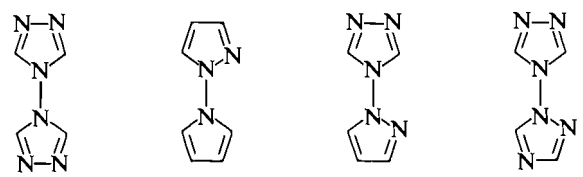
Introduction

Conformation about a single bond linking two aromatic rings, i.e., about a C_{sp^2}—C_{sp^2} bond, has been extensively studied in biphenyl derivatives (atropoisomerism) (1–5). These studies, both experimental and theoretical, have been extended to heterocyclic derivatives, like phenylpyridines and bipyridines (6–11). However, the case of a single bond of the N_{sp^2}—C_{sp^2} type connecting two aromatic rings (*N*-phenylazoles) has received much less attention, and only two theoretical studies have been published: one by Galasso and Alti (12) on *N*-phenylpyrrole, and another by Avignon, Bouscasse, and Elguero (13) on eight *N*-arylazoles. The E.H.T. method was used in both calculations.

The third general case, a single bond between two N_{sp^2}—N_{sp^2} atoms belonging to neutral aromatic rings can be found only in *N,N*-linked biazoles (14, 15). To the best of our knowledge, only 1,1′-bipyrrole has been calculated by Galasso (16) and by Flitsch, Rademacher and co-workers in order to assign its photoelectron spectrum (17). In the former paper, the E.H.T. method was again used, but in the latter the authors adopted the MNDO/2 approximation. Both concluded that an angle of twist of 90° between rings was about 13 kJ/mol more stable than a coplanar conformation.

The present paper deals with this original class of heterocyclic derivatives. The following fourteen compounds have been studied:



1 **2** **3** **4**

[1]To whom all correspondence should be addressed.

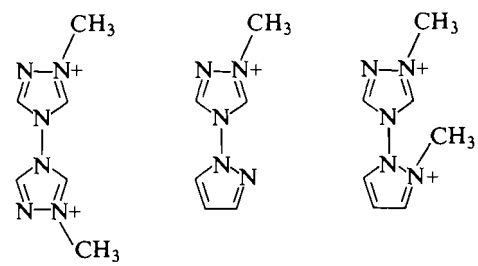
9 **10** **11**



12 **13** **14**

Calculations

The calculations were performed using the LCAO-MO-SCF MNDO method with standard parameters (18). All equilibrium geometries were determined by minimizing the total energy with respect to the geometrical variables using the Davidon–Fletcher–Powell (DFP) algorithm (19, 20). All computations were carried out on the UNIVAC 1108 computer of the C.P.D. of "Ministerio de Educación y Ciencia (Madrid)", using a

the planar conformation represented in the above formula) are described in Tables 1 and 2. The only compound in the series with a known experimental geometry is 4,4′-bi-1,2,4-triazole, **1**, for which a crystalline structure has been determined by Domiano (21). In the crystal, **1** shows an angle of twist of 91.9° between the two triazolyl moieties. The differences in bond lengths and bond angles with our calculations at any conformation are indeed small: maximum deviation in bond length

lies within a range of ±0.15 Å, and bond angles do not deviate more than 3.3°. The rest of values of Tables 1 and 2 must be taken as normal for these kinds of heterocycles, and are not appreciably distorted by a twist in conformation. In every case, however, the N—N bond linking both heterocycles is slightly shortened (by c.a. 0.01 Å) at $\theta = 90°$ with respect to any of the planar conformations.

The effect of quaternization (compounds **11**–**14**) in bond angles and distances, although small in absolute terms, causes enough distortion to the whole *N*-methylated ring as to make significant the variation of internuclear distances between the hydrogen atoms situated "*ortho*" to the N—N bonded nitrogen in each of the rings with respect to the same atoms on the neighbouring ring in the planar conformations. For example, in the monocation **13** ($\theta = 0°$), the distance between the two hydrogen atoms situated more distant to the methyl groups

(those labelled *11* and *18* in Table 1) is 0.18 Å *shorter* than the same distance in the neutral molecule **1**. No such effect is observed in the distance between the hydrogen atoms situated at the same side of the methyl groups (labelled as *14* and *15*), which remains essentially unchanged with respect to the neutral molecule. The same effect, though even more pronounced, is found in compound **14** ($\theta = 0°$): the H...H distance (labels *11* and *18* in Table 1) is reduced by 0.26 Å in comparison with the neutral compound **3**. Finally, in compound **14**, at $\theta = 180°$ (labelled atoms *14* and *15*), the shortening is about 0.24 Å.

2. Energies

All molecules are found to be more stable at conformations near orthogonality, as values of heats of formation clearly indicate (Table 3). In those molecules having a plane of symmetry at 90° (**1**–**4**, and **8**–**11**), the energy minima correspond

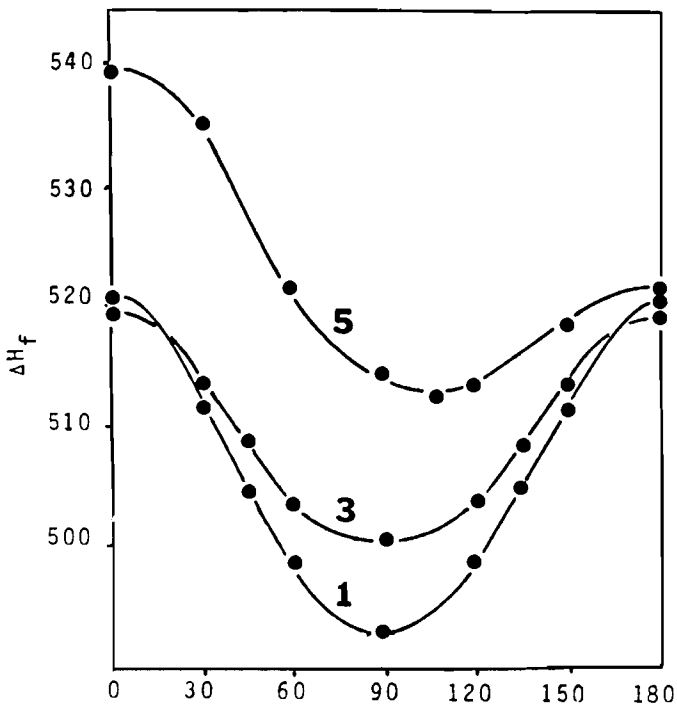

FIG. 1. Plot of energy (kJ mol^{-1}) vs. angle of twist in 4,4′-bi-1,2,4-triazole (**1**), 4-(1-pyrazolyl)-1,2,4-triazole (**3**), and 1,1′-bipyrazole (**5**).

to that angle of twist. There is no reason, however, for the same situation to hold for less symmetric compounds (**5**–**7** and **12**–**14**). For example, 1,1′-bipyrazole, **5**, shows an energy minimum at 107.76°. A plot of energy vs. angle of twist can be drawn for compounds such as **1**, **3**, and **5**, calculated for a large enough number of dihedral angles[3] (Fig. 1).

The scarce experimental data available for *N*,*N*-linked biazoles are also in good agreement with an orthogonal conformation of both rings. We have already mentioned the crystallographic data of 4,4′-bi-1,2,4-triazole, **1** (21). From the splittings of the π_2-ionizations of the photoelectron spectrum of 1,1′-bipyrrole it has been also concluded that this compound has the most stable conformation at 90° (17).

Thus the preference for a perpendicular or quasi perpendicular conformation seems to be quite general for this family of compounds, and has no equivalent in other series, like biphenyls, bipyridines, or phenylazoles. In particular, *N*-phenylpyrrole shows a minimum at an angle of twist of about 40° (12). On the other hand, calculations on 2,2′-bipyridine revealed the existence of two minima, the lower one corresponding to an "*anti*" conformation (both nitrogen atoms 180° apart from each other) in agreement with experimental evidence, and the other situated *not* at θ = 0°, but in a "*cisoid*" conformation, at an angle of 35° (7). This behaviour can be interpreted as a compromise between coplanarity, favored by the conjugation across the bond linking the rings together, and the repulsive interaction of the two lone pairs of the heteroatoms.

In addition to the differences in conjugation, another factor must be taken into account when comparing biphenyles, *N*-phenylazoles, and *N*,*N*-linked biazoles: the shortening of the interannular distance, C—C, 1.48 Å (7), C—N, 1.40 Å (13), and N—N, 1.36 Å (this work).

3. Interactions at the planar conformations

The presence of a singular minimum of energy, far from the planar conformations, makes *N*,*N*-linked biazoles particularly suitable models for the study of internuclear interactions in five-membered dimers. The three main interactions to be considered are those arising from (*i*) pairs of hydrogen atoms situated "*ortho*" at each ring (H...H interactions), (*ii*) pairs of electrons of the nitrogen atoms (N̈...N̈ interactions), and (*iii*) hydrogen atoms of one ring interacting with lone pairs of the other ring (H...N̈ interactions).

Since the planar conformations can be associated with transition states (see Fig. 1), the energy differences between the most stable conformation (θ = 90°, or some value near this) and maxima at 0° and 180°, can be directly related to the magnitude of the interaction. According to the number and type of existing interactions, the neutral molecules **1**–**10** can be classified into seven groups, **A**–**G** (Table 4).

The only representative compound with two H...H interactions is 4,4′-bi-1,2,4-triazole, **1**. The calculated energy barrier (difference of heat of formation between the conformations at 0° and 90°) is 27.45 kJ/mol. That gives a value of about 13.7 kJ/mol for the H...H interaction. At the other end of the table, compound **10** represents an example of two N̈...N̈ interactions. The calculated barrier gives now a value of 8.54 kJ/mol for a single interaction of this type.

The concordance of these values with those found for the rest of situations in Table 4 is far from being perfect, however. For example, compounds **5**–**7** (at θ = 0°), having one H...H and one N̈...N̈ interaction each (group **C**) show too high barriers in comparison with the prediction from the above values (c.a. 22.24 kJ/mol). On the other hand, the value for a H...N̈ interaction deduced in groups **B** and **F** by subtraction of 13.7 and 8.54 kJ/mol, respectively, lies betwen 4.7 and 6.49 kJ/mol, which is also too high if we compare it with the value derived from groups **D** and **E**, where only H...N̈ interactions exist. We do not have a single explanation for these differences, but must note that the presence of other factors may influence the magnitude of the barriers. In particular, the effect of other heteroatoms situated at the β positions can be relevant in this discussion. A multilinear regression analysis with the whole set of values in Table 4 gives a mean value for each interaction, namely 15.4 kJ/mol for H...H, 10.3 kJ/mol for N̈...N̈, and 3.2 kJ/mol for H...N̈.

Although these values, when applied additively, deviate in some cases from those calculated for each particular compound, they afford an order of magnitude that can explain, for example, the lower barriers at 180° than at 0° for compounds **5**, **6**, and **7**. In other words, it explains that the "preference" of two nitrogen lone-pairs is to be "*anti*" to each other (θ = 180°), a situation that closely parallels the results found in 2,2′-bipyridine.

The effect of quaternization on the magnitude of the interactions can be discussed only in compounds **11**–**13**, since the steric effect of the methyl groups situated "*ortho*" in the pyrazolyl moiety of compound **14** largely determines the height of the barrier. In bitriazoles **11** and **12**, the barriers are 29.37 (**11**), 41.03 (**12**, θ = 0°), and 38.16 (**12**, θ = 180°) kJ/mol. These high values, especially in the case of the dication **12**, indicate a progressive destabilization of the planar conformations as the number of positive charges is increased from the neutral mole-

[3]For compound **1**, the points fit the equation ΔH_f = 493.7 (±0.2) + 4.8 (±0.6) cos θ + 22.5 (±0.6) $\cos^3$ θ, r = 0.9999.

TABLE 4. Interactions between "*ortho* substituents" at the planar conformations

Group	Type and number of interactions H...H	N...N	H...N	Representative compounds in the series	$\Delta E^{\ddagger}$ (kJ mol^{-1})
A 	2	0	0	**1** (θ = 0° and 180°)	27.45
B 	1	0	1	**2** (θ = 0° and 180°) **3** (θ = 0° and 180°) **4** (θ = 0° and 180°)	19.89 18.85 18.40
C 	1	1	0	**5** (θ = 0°) **6** (θ = 0°) **7** (θ = 0°)	28.69 25.26 28.57
D 	0	0	2	**5** (θ = 180°) **6** (θ = 180°) **7** (θ = 180°)	7.65 7.79 3.79
E 	0	0	2	**8** (θ = 0° and 180°)	5.42
F 	0	1	1	**9** (θ = 0° and 180°)	15.03
G 	0	2	0	**10** (θ = 0° and 180°)	17.09

cule. Moreover, the distortion in the geometry of the triazolyl cation with respect to the neutral species, which causes the H...H distance to be shorter and, therefore, the interaction to be greater, can also explain the magnitude of the effect.

4. Electronic properties

The ionization potentials, dipole moments, and total charges on ring atoms of compounds **1**−**14**, in all the conformations studied, are listed on Table 3. The overall electronic distribution of the molecules is well reflected in the values of their dipole moments.

The agreement of the MNDO calculations with the experimental data available is quite good, and much better than the values calculated by the CNDO/2 approach (14). For example, the experimental values for 1-(1-pyrrolyl)pyrazole, **2**, and 4-(1-pyrazolyl)-1,2,4-triazole, **3** (2.04 and 5.33 D, respectively), are very close to the calculated values at 90° for the same compounds (Table 3). We must then conclude that dipole moments, measured experimentally and calculated by MNDO at different dihedral angles, can be used as a tool for the prediction of the preferred conformation of *N*,*N*-linked biazoles, especially when the calculated values show large differences between 0° and 180°.

Crystal and molecular structure and ^{31}P and ^{195}Pt nmr spectroscopy of $[Pt_3S_2(PMe_2Ph)_6][BEt_4]_2$; a trinuclear complex containing triply-bridging sulphide ligands

GORDON WILLIAM BUSHNELL,[1] KEITH ROGER DIXON,[1] REIKO ONO, AND ALAN PIDCOCK[2]
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received June 30, 1983

GORDON WILLIAM BUSHNELL, KEITH ROGER DIXON, REIKO ONO, and ALAN PIDCOCK. Can. J. Chem. **62**, 696 (1984).

An X-ray diffraction study of $[Pt_3S_2(PMe_2Ph)_6][BEt_4]_2$ shows that it crystallises in the monoclinic space group, $C2/c$, with a = 15.447(2), b = 18.033(3), c = 26.505(5) Å, β = 96.73(2)°. The cation consists of three, distorted, square-planar *cis*-$PtS_2(PMe_2Ph)_2$ moieties combined by sharing of the two sulphur atoms to produce a central Pt_3S_2 unit with C_2 symmetry and Pt—Pt distances of 3.182(1) Å (one edge) and 3.108(1) Å (two edges). Complete analysis and computer simulation of $^{31}P\{^1H\}$ and $^{195}Pt\{^1H\}$ nuclear magnetic resonance spectra give values for ^1J(Pt—P), 3202 Hz; ^3J(Pt—P), −25 Hz; and ^2J(Pt—Pt), 476 Hz. The structure is compared with previous results for analogous Ni and Pd complexes and the structural and nmr parameters are discussed with reference to the possibility of metal−metal interactions.

GORDON WILLIAM BUSHNELL, KEITH ROGER DIXON, REIKO ONO et ALAN PIDCOCK. Can. J. Chem. **62**, 696 (1984).

Une étude par diffraction des rayons-X du $[Pt_3S_2(PMe_2Ph)_6][BEt_4]_2$ montre que ce produit cristallise dans le groupe d'espace monoclinique, $C2/c$, avec a = 15,447(2), b = 18,033(3), c = 26,505(5) Å, β = 96,73(2)°. Le cation comporte trois groupes déformés, plan-carré de $PtS_2(PMe_2Ph)_2$-*cis* combinés par le partage des deux atomes de soufre pour produire une unité centrale de Pt_3S_2 possédant une symétrie C_2 et des distances Pt—Pt de 3,182(1) Å (un côté) et de 3,108(1) Å (deux côtés). Une analyse complète et une simulation par ordinateur des spectres de RMN du $^{31}P\{^1H\}$ et $^{195}Pt\{^1H\}$ permet de déterminer les valeurs de ^1J(Pt—P) (3202 Hz), ^3J(Pt—P) (−25 Hz) et ^2J(Pt—Pt) (476 Hz). On compare cette structure avec celles déterminées antérieurement pour des complexes analogues du Ni et du Pd; on discute des paramètres rmn et structuraux pour évaluer l'existence d'interactions métal−métal.

Introduction

Complexes in which an M_3 triangle is capped by two sulphide ligands to form an approximately trigonal bipyramidal M_3S_2 unit are relatively common among the later transition elements. The metal−metal distances vary widely, from strongly bonded examples such as the $[Co_3S_2(\eta^5\text{-}C_5H_5)_3]^+$ cation (1), Co—Co 2.474(2) and 2.649(1) Å, through intermediate cases such as $[Ni_3S_2(\eta^5\text{-}C_5H_5)_3]$ (2), Ni—Ni 2.801(5) Å, to distances over 3 Å as found in the $[Pd_3S_2(PMe_3)_6]^{2+}$ cation (3). There is also a dichotomy between complexes having three approximately equal metal−metal distances and those in which one distance differs significantly from the other two. An extreme example of the latter type is $[Fe_3S_2(CO)_9]$, where two edges of the metal triangle are clearly bonding distances, 2.60 Å, and the third is non-bonding 3.37 Å(4). A more subtle example is the $[Co_3S_2(\eta^2\text{-}C_5H_5)_3]^+$ cation mentioned above which has one short edge, 2.474(2) Å, and two long edges, 2.649(1) Å, and forms an interesting contrast to the neutral molecule, $[Co_3S_2(\eta^5\text{-}C_5H_3)_3]$, in which the metal triangle is approximately equilateral, 2.687(3) Å(1). In these more subtle examples, especially cases such as $[Pd_3S_2(PMe_3)_6]^{2+}$ where very long metal−metal distances are involved (see below), it is difficult to say whether the asymmetry is due to some fundamental molecular factor or merely to packing and crystal symmetry effects.

In view of the above considerations the $[Pt_3S_2(PMe_2Ph)_6]^{2+}$ cation represents an interesting opportunity to complete a comparative study of analogous complexes for all three members of a transition metal triad. The cation was prepared in 1970 by reaction of sodium sulphide with *cis*-$[PtCl_2(PMe_2Ph)_2]$ and a trinuclear structure proposed on the basis of ^1H nmr evidence (5). Recent papers have reported diffraction studies of the analogous $[Ni_3S_2(PEt_3)_6]^{2+}$ (6) and $[Pd_3S_2(PMe_3)_6]^{2+}$ (3) cations, the former having three approximately equal metal−metal distances (2.91(3) Å) and the latter one short (3.011(2) Å) and two long (3.144(3), 3.178(2) Å), but the platinum structure has not been confirmed by an X-ray study. Moreover, the presence of the spin-1/2 ^{31}P (abundance, 100%) and ^{195}Pt (abundance, 33.8%) nuclei presents the possibility of a detailed nmr study of the solution structure with parameters such as ^2J(Pt—Pt) and ^3J(Pt—P) available as probes of the metal−metal interaction. In the present paper we report such a dual study, with complete $^{31}P\{^1H\}$ and $^{195}Pt\{^1H\}$ nmr and X-ray diffraction characterization of the complex, $[Pt_3S_2(PMe_2Ph)_6][BEt_4]_2$.

Experimental

(a) Synthesis

The synthesis of $[Pt_3S_2(PMe_2Ph)_6][BF_4]_2$ was conducted under an atmosphere of dry nitrogen using tetrahydrofuran (THF) which had been dried and deoxygenated by reflux over potassium/benzophenone. Sublimed sulphur was obtained from Matheson, Coleman and Bell and $Li[BHEt_3]$ from Aldrich as a 1 *M* solution in THF. *cis*-$[PtCl_2(PMe_2Ph)_2]$ was prepared as previously described (7). Microanalysis was by the Canadian Microanalytical Service, Vancouver, B.C.

A solution (8 mL, 1 *M*) of $Li[BHEt_3]$ in THF was added dropwise to a stirred slurry of sulphur (0.12 g, 3.7 mmol) in THF. After 15 min the resulting clear yellow solution of Li_2S (8) was added dropwise to a stirred suspension of *cis*-$[PtCl_2(PMe_2Ph_2]$ (2.0 g, 3.7 mmol) in nitrogen-purged ethanol (70 mL). After stirring for 3 h, the resulting yellow solid was collected by filtration, washed with water and ethanol, and recrystallized twice from CH_2Cl_2/EtOH to yield $[Pt_3S_2(PMe_2Ph)_6][BEt_4]_2$ as air stable, pale yellow crystals (1.8 g, 1.0 mmol, mp 147−150°C). *Anal.* calcd. for $C_{64}H_{106}B_2P_6Pt_3S_2$: C 44.3, H 6.2, S 3.7; found: C 44.3, H 6.0, S 4.2.

(b) Nuclear magnetic resonance

Phosphorus-31 and platinum-195 nmr spectra were recorded in CD_2Cl_2 solution at 101.3 and 53.5 MHz respectively, using a Bruker

WP250 Fourier transform spectrometer locked to the solvent deuterium resonance. Protons were decoupled by broad band ("noise") irradiation at appropriate frequencies. ^{31}P chemical shifts were measured relative to external $P(OMe)_3$ and are reported in ppm relative to 85% H_3PO_4 using a conversion factor of +141 ppm. Positive values are downfield of the reference. ^{195}Pt chemical shifts (Ξ) are reported in MHz standardised to $[Si(CH_3)_4]$ at 100 MHz. Simulated nmr spectra were calculated on an IBM 3031 computer and plotted on a Calcomp 1039 plotter. The programmes used were a locally constructed package based on the UEAITR and NMRPLOT programmes from the literature (9, 10).

(c) X-Ray diffraction

Crystals of $[Pt_3S_2(PMe_2Ph)_6][BEt_4]_2$ suitable for study by X-ray diffraction were prepared by solvent diffusion. A sample was dissolved in dichloromethane in a small tube and an equal volume of ethanol placed carefully on top to form a double layer. Crystallization occurred as the solvents mixed over a period of ~15 h.

Preliminary photographic work was done using Weissenberg and precession cameras with CuKα radiation. The crystals were monoclinic, space group $C2/c$ (No. 15), a = 15.447(2), b = 18.033(3), c = 26.505(5) Å, β = 96.73(2)°, V_{cell} = 7332(2) Å^3, D_{calcd} = 1.569 g cm^{-3} for $C_{64}H_{106}B_2P_6Pt_3S_2$, M = 1732.4, D_{meas} = 1.568 g cm^{-3} (flotation in CCl_4/*m*-xylene), asymmetric unit = 1/2 molecule. The pale yellow crystal (0.37 × 0.46 × 0.38 mm) was mounted in a capillary tube and measurements were done at 23°C on a Picker 4-circle diffractometer automated with a PDP-11/10 computer. The unit cell was refined by least squares using 13 pairs of centering measurements (±2θ). Intensity measurements were done over a hemisphere and out to 2θ = 40° (7289 reflections) using MoKα radiation (λ = 0.71069 Å). The scans were 160 steps of 0.01° in 2θ counting for 0.25 s per step, and background counting was for 20 s at each end. Absorption corrections were applied by numerical integration using a 10 × 10 × 10 Gaussian grid, μ = 62.22 cm^{-1}, transmission range 0.048–0.160. Lorentz and polarisation corrections were applied and equivalent reflections were averaged to give a file containing 3427 independent reflections.

The crystal structure was found and refined using the SHELX-76 program package supplied by Dr. G. M. Sheldrick (11). The atomic scattering factors used were those contained in the program, with the addition of the Pt curve (12). The solution was by centrosymmetric direct methods, and the refinement by Fourier methods and least squares minimizing $\Sigma w(|F_o| - |F_c|)^2$. The weights were obtained from counting statistics using $w = 1/(\sigma^2(F) + 0.001F^2)$. All atoms were treated anisotropically and convergence was attained with a maximum (shift/esd) ratio of 0.055. The residuals were R = 0.0545 and $R_w = (\Sigma w\Delta^2/\Sigma wF_o^2)^{1/2}$ = 0.0641. The final difference map had a maximum of 2.08 e Å^{-3} and a minimum of −0.79 e Å^{-3}, but gave no indication that any material had been overlooked. The hydrogen atom positions were not determined. Supplementary tables containing structure factors, anisotropic temperature parameters, selected inter- and intra-molecular distances and mean plane results have been deposited.[3]

Results

(a) Synthesis

The complexes $[Pt_3S_2(PMe_2Ph)_6][X]_2$, X = ClO_4^-, BF_4^-, or BPh_4^-, had been previously synthesized by Chatt and Mingos (5) using the reaction of *cis*-$[PtCl_2(PMe_2Ph)_2]$ with sodium sulphide followed by treatment with $HClO_4$, HBF_4, or $NaBPh_4$ as appropriate. The yields were, however, very low (~10%) and the structure of the cation was not fully characterised prior to this work. We have used the method of Gladysz *et al.* (8) to generate Li_2S *in situ* by reduction of elemental sulphur with $Li[BHEt_3]$ and find that the resulting solution, which also contains BEt_3, reacts with *cis*-$[PtCl_2(PMe_2Ph)_2]$ to give the trinuclear complex in high yield (>80%).

U_{eq} = the equivalent isotropic temperature parameter; $U_{eq} = (1/3)\Sigma_i\Sigma_j U_{ij}a_i^*a_j^*(a_i.a_j)$; $T = \exp[-(8\pi^2U_{iso} \times \sin^2\theta/\lambda^2)]$.

(b) Crystal and molecular structure

The $[Pt_3S_2(PMe_2Ph)_6]^{2+}$ cation and the two $[BEt_4]^-$ anions exist as discrete entities in the crystal. A stereoscopic view of the cation structure is shown in Fig. 1 which also gives the atom labelling scheme and the thermal vibration ellipsoids. The fractional atomic coordinates, interatomic distances, and bond angles are given in Tables 1–3, respectively. The asymmetric unit is one half of the formula unit.

The structure of the cation is best described as three, distorted, square-planar *cis*-$PtS_2(PMe_2Ph)_2$ moieties combined together by sharing of the two sulphur atoms. This creates a central Pt_3S_2 unit which has a crystallographic C_2 symmetry axis passing through Pt(2) and the mid-point of Pt(1)—Pt(1)′. Thus the three platinum atoms form an isosceles triangle with

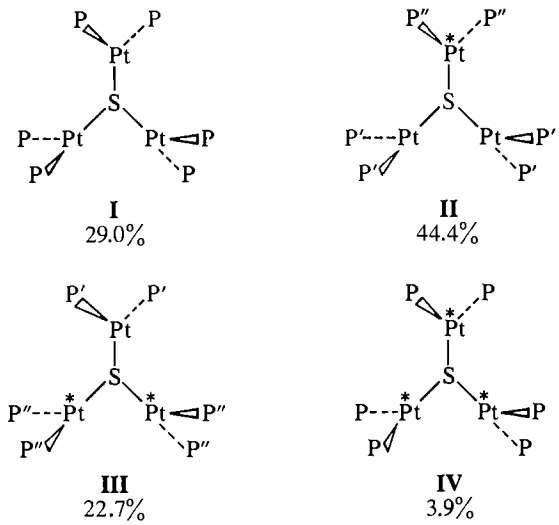
metal−metal distances 3.182(1) Å for Pt(2)—Pt(1) and 3.108(1) Å for Pt(1)—Pt(1)′. The angle between the square planes of Pt(1) and Pt(2) is 121.8° and that between the square planes of Pt(1) and Pt(1)′ is 116.4°. The principal distortion of the square planes is compression of the S—Pt—S angles to 79.0(1)° at Pt(1) and 79.6(1)° at Pt(2), accompanied by widening of the P—Pt—P angles to 96.9(1)° and 103.0(2)°, respectively. These distortions are very similar to those reported previously for the $[Ni_3S_2(PEt_3)_6]^{2+}$ and $[Pd_3S_2(PMe_3)_6]^{2+}$ cations. There is also some distortion of the Pt(2) coordination from planarity ($\chi^2 = \sum_i p_i^2/\sigma^2(p_i) = 352$ over 5 atoms), probably caused by steric repulsion between C(38) and C(38′), 3.267 Å. The coordination around Pt(1) is much more closely planar ($\chi^2 = 50$). The platinum−sulphur bond lengths are all closely similar and average 2.365(3) Å, which is in accord with the metal−sulphur distances in the nickel (2.11−2.23 Å) (6) and palladium (2.312−2.358 Å) (3) analogues, and is also closely comparable with other platinum−sulphur distances where the sulphur is *trans* to phosphorus, both in mononuclear complexes containing terminal RS groups (13) and in RS-bridged trinuclear complexes (14, 15).

The PMe_2Ph groups are placed so that the phenyl group is on one side of the Pt square plane, one methyl is on the opposite side, and the third methyl is close to the Pt coordination plane. Evidence of steric repulsion of these in-plane methyl groups is seen in the Pt—P—C angles which are 116.2°, 120.7°, and 123.3° for C(17), C(27), and C(38), respectively, much larger than the other values in the range 110.5−113.8°. The disparity in the three wider angle values can be understood in terms of the various interactions involved (see Fig. 1). Adjacent (*cis*) PMe_2Ph groups have their phenyl groups on opposite sides of the appropriate coordination planes.

The tetraethylborate anion has angles at boron which are within 5° of the ideal tetrahedral value, and angles at the inner carbon atoms which are slightly larger (mean 114.7°), presumably owing to a steric effect similar to that observed in NEt_4^+ (16).

(c) Nuclear magnetic resonance

For the purposes of analysis of the $^{31}P\{^1H\}$ and $^{195}Pt\{^1H\}$ nmr spectra of the title compound, we may assume that the $Pt_3P_6S_2$ core effectively possesses D_{3h} symmetry in solution. It is then necessary to consider spectra due to four different isotopomers:



*Denotes magnetically active platinum-195

A fully rigorous treatment of these spectra would require the analysis of some rather complex spin systems, involving up to nine magnetically non-equivalent nuclei (see Appendix). Fortunately, considerable simplification is possible by introducing the assumption that $^4J(P—P)$ is effectively zero. Previous re-

sults (14, 17, 18) would lead to the expectation of a very small value (<5 Hz) for the coupling and, since the observed spectra have linewidths ca. 10 Hz (^{31}P) and ca. 90 Hz (^{195}Pt), such a small coupling will not affect the analysis. This assumption leads to effective magnetic equivalence of the geminal phosphorus atoms (for example, the pair labelled P″ in isotopomer **II**) and to a considerable simplification of the spin systems (see Appendix). Also, at the effective signal/noise of the observed spectra it is not necessary to consider the very low abundance isotopomer **IV** in the analysis, although its contribution has been included in the final computer simulations.

With the adoption of these assumptions, we proceeded with an analytical solution of the ^{31}P{^{1}H} spectrum as detailed below. The correctness of the analysis was then confirmed by direct use of the derived parameters in a successful simulation of the ^{195}Pt{^{1}H} spectrum. The spectra are shown in Figs. 2 and 3 together with the computer simulations and the derived parameters are collected in Table 4.

(i) $^{31}P\{^{1}H\}$ spectrum. In Fig. 2 the intense central resonance (line 6) is clearly due to isotopomer **I**. Moreover, because of the very different magnitudes of ^{1}J(Pt—P) and ^{3}J(Pt—P) and the effectively zero value of ^{4}J(P—P), the P′ and P″ regions of the spectrum of isotopomer **II** are essentially independent. Each consists of a doublet, as is illustrated by the computer simulation, and the values of ^{1}J(Pt—P) 3201.4 Hz and ^{3}J(Pt—P) 25.2 Hz can be directly measured as the separations of lines 2 and 10, and 5 and 7, respectively.

A similar independence pertains for isotopomer **III** but the P′ region is expected to lie under the other central peaks and is not resolved. With the assumptions outlined above, the P″ region is effectively the A part of an $A_2XX'A_2'$ spin system which, in the limit of small J(AA′), i.e. ^{4}J(P—P), will be identical with the A part of an AXX′A′ system. We have previously treated this last system in detail for dinuclear platinum and palladium complexes of phosphorus ligands (17) and the same methods may be applied to the present example. In general the A region may be divided into two components: (*a*) a strong doublet of separation $2K$, (*b*) two symmetrical quartets, which are mutually coincident when $|J(XX')| \gg |J(AA')|$, a condition which is met in the present case since $|^{2}J(Pt—Pt)| \gg |^{4}J(P—P)|$. The line positions of the coincident quartets relative to δ(A) are given by $\pm\{S \pm (S^2 + L^2)^{1/2}\}$ and the secondary parameters are defined as follows:

$$2K = J(AX) + J(AX') = {}^{1}J(Pt—P) + {}^{3}J(Pt—P)$$

$$2L = J(AX) - J(AX') = {}^{1}J(Pt—P) - {}^{3}J(Pt—P)$$

$$2S \simeq J(XX') \simeq {}^{2}J(Pt—Pt)$$

In the present case the major doublet is easily assigned as lines 3 and 9, separation 3176.4 Hz, and the coincident quartets to lines 1, 4, 8, and 11, which are positioned at ±1394.1 and ±1869.8 Hz relative to δ(P).

The magnitudes of ^{1}J(Pt—P) and ^{3}J(Pt—P) obtained from isotopomer **II** suggest 3226.6 or 3176.2 Hz as the possible

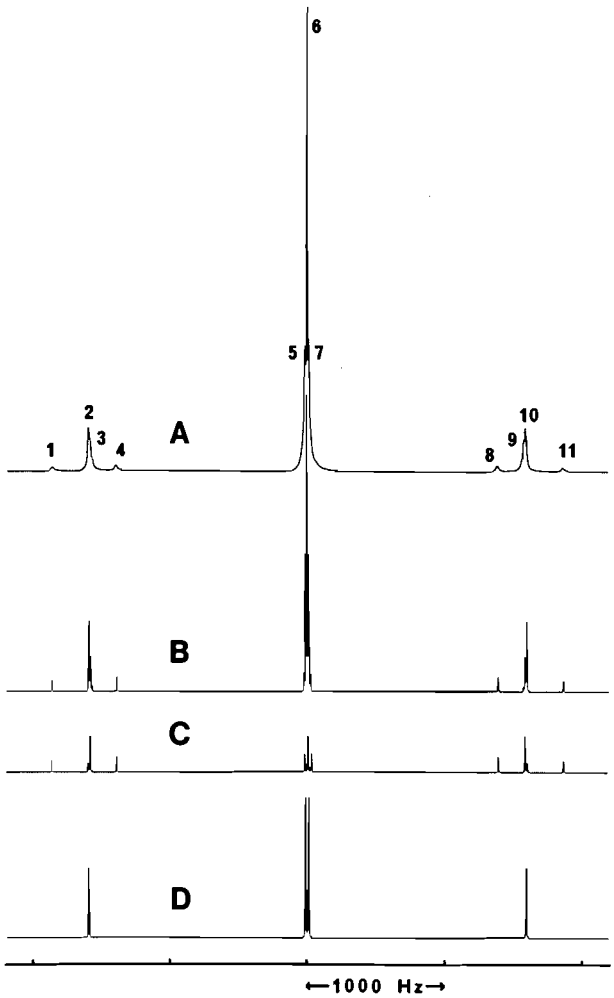

FIG. 2. $^{31}P\{^1H\}$ nmr spectra of the $[Pt_3S_2(PMe_2Ph)_6]^{2+}$ ion at 101.3 MHz. (*A*) Observed spectrum; (*B*) computer simulation of the composite spectrum produced by summation of contributions from isotopomers **I**, **II**, **III**, and **IV**; (*C*) computer simulation of the contribution from isotopomer **III**; (*D*) computer simulation of the contribution from isotopomer **II**.

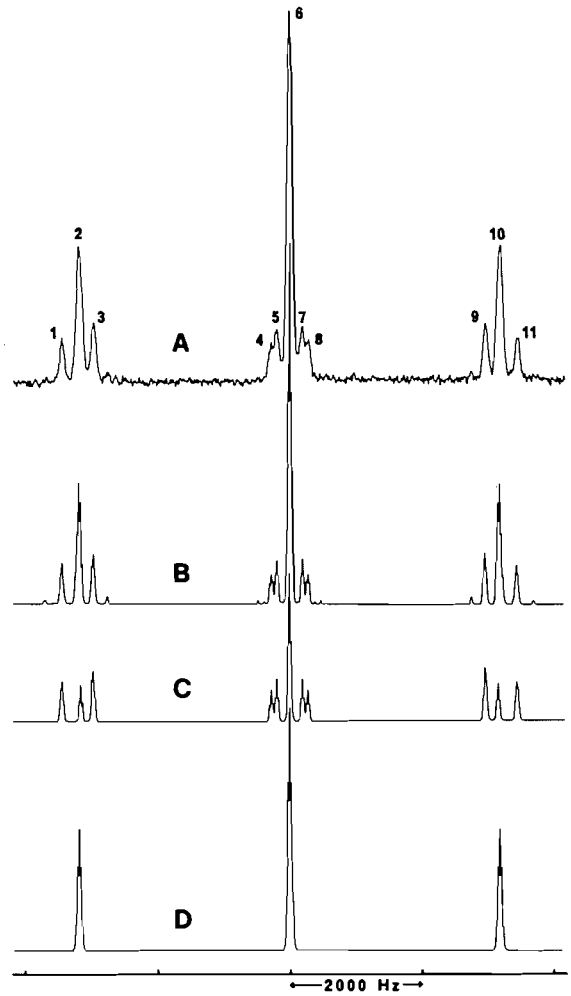

FIG. 3. $^{195}Pt\{^1H\}$ nmr spectra of the $[Pt_3S_2(PMe_2Ph)_6]^{2+}$ ion at 53.5 MHz. (*A*) Observed spectrum; (*B*) computer simulation of the composite spectrum produced by summation of contributions from isotopomers **II**, **III**, and **IV**; (*C*) computer simulation of the contribution from isotopomer **III**; (*D*) computer simulation of the contribution from isotopomer **II**.

TABLE 4. Nuclear magnetic resonance parameters for the $[Pt_3S_2(PMe_2Ph)_6]^{2+}$ cation

Chemical shift	Value	Coupling constant	Value (Hz)
^{31}P (ppm)	−16.7	^1J(Pt—P)	3202
		^3J(Pt—P)	−25
^{195}Pt (Ξ, MHz)	21.404075	^2J(Pt—Pt)	476
		^4J(P—P)	<5

values for $2K$ depending on the relative signs of the direct and indirect couplings. Thus the measured value of $2K$ establishes ^3J(Pt—P) as opposite in sign to ^1J(Pt—P) and presumably negative since directly bonded Pt—P couplings are known to be positive (19). Moreover, substitution of the positions of lines 1, 4, 8, and 11 into the above relationships leads to 3229.0 Hz as the value of $2L$, in excellent agreement with the 3226.6 Hz which the values of ^1J(Pt—P) and ^3J(Pt—P) would predict. Finally, the line positions 1, 4, 8, and 11 lead to a value of 475.7 Hz for $2S$, in excellent agreement with the 476.6 Hz obtained by measurement of ^2J(Pt—Pt) in the platinum spectrum (see below). This result also confirms our assumption of an essentially zero value for ^4J(P—P) since the quartets are coincident and $2S \simeq {}^2J$(Pt—Pt) only when ^4J(P—P) can be neglected (17).

(ii) $^{195}Pt\{^1H\}$ spectrum. The spectrum of isotopomer **II** is expected to consist basically of a triplet due to coupling of the single magnetically active platinum with the two directly bonded phosphorus nuclei. Assignment of lines 2, 6 and 10 (see Fig. 3) to this triplet gives a value of 3201.8 Hz for ^1J(Pt—P), in excellent agreement with the value derived from the ^{31}P spectrum. The width at half-height of line 6 is ~90 Hz and hence further splitting of the triplet due to ^3J(Pt—P), −25.2 Hz, is evidently not resolved. Assuming as before that ^4J(P—P) is unimportant, the remaining lines in the $^{195}Pt\{^1H\}$ spectrum should be assignable as the X region of an $A_2A_2'A_2''XX'$ spin system due to isotopomer **III**. All the couplings (except ^4J(P—P) which is assumed zero) are known from analysis of the $^{31}P\{^1H\}$ spectrum and can be used in a computer simulation of the $^{195}Pt\{^1H\}$ spectrum. The results of this simulation are shown in Fig. 3. The fit to the observed spectrum is excellent and the correctness of the analysis for the

TABLE 5. Metal–metal distances in $[M_3S_2L_6]^{2+}$ cations

Cation	M—M distances (Å)	Space group	R	Reference
$[Ni_3S_2(PEt_3)_6]^{2+}$	2.96(2), 2.88(2), 2.89(3)	$P2_1/a$	0.18	6
$[Pd_3S_2(PMe_3)_6]^{2+}$	3.011(2), 3.178(2), 3.144(2)	$P2_1/c$	0.102	3
$[Pt_3S_2(PMe_2Ph)_6]^{2+}$	3.108(1), 3.182(1)	$C2/c$	0.0545	This work

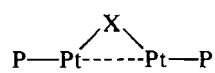
$^{31}P\{^1H\}$ spectrum is thus confirmed. It is noteworthy for the purposes of simple interpretation that the separations of lines 1 and 3, 4 and 7, 5 and 8, and 9 and 11 are all approximately equal to ^2J(Pt—Pt) and yield an average value of 476.6 Hz, again confirming the value derived from the $^{31}P\{^1H\}$ spectrum. The simulations also confirm the negative, relative sign of ^3J(Pt—P) since only this sign combination leads to the observed splitting of lines 4 and 5, and 7 and 8. The spectra are insensitive to the choice of relative sign for ^2J(Pt—Pt).

Discussion

The shortest, well-determined, platinum–platinum bond lengths appear to be those in the bridged complexes, $[Pt_2(SO_4)_2(OSMe_2)_2]^{2-}$, 2.471 (1) Å, and $[Pt_2(HPO_4)_4(H_2O)_2]^{2-}$, 2.486 (2) Å, where there is a formal single bond between Pt^{III} centres (20, 21). However, a very wide range of Pt—Pt lengths has been reported and it is clear that significant interactions persist at much longer distances. In cluster complexes containing Pt_3 triangles, distances in the range 2.6–2.8 Å are generally found (22, 23). In α-pyridone blue (24), and in related complexes containing two Pt atoms bridged by pyrimidine bases (25), values up to 2.98 Å have been considered short enough to suggest metal–metal bonding. A correlation between partial oxidation states and the resonating valence bond theory of metals has shown that some weak interactions may persist to about 3.2 Å (26), and SCF-Xα-SW calculations on $[Rh_2Cl_2(CO)_4]$ have suggested a metal–metal interaction as the explanation for the "bent" structure (27). This last example is especially relevant to the present situation since the Rh—Rh distance is 3.12 Å and the metal–metal bonding, actually a subtle effect caused by mixing of d_{z^2} character into a bonding d_{xz}—d_{xz} combination, is proposed to account for an observed dihedral angle of 124° between the two Rh square planes (27). Both the dihedral and the metal–metal distance are similar to those found here for $[Pt_3S_2(PMe_2Ph)_6]^{2+}$ and it is therefore clear that, although the distances in the present complex, 3.108(1) and 3.182(1) Å, are certainly too long to imply formal bonding, the possibility of weak interactions sufficient to influence the core geometry cannot be discounted. For example, for a three atom cluster in the point group D_{3h} there are two sets of orbitals of symmetry e' and one set of symmetry e'' which are cluster valence orbitals, near to the LUMO level and derived from s and p atomic orbitals (28). A Jahn–Teller type distortion involving these double degenerate levels could account for the main features of the observed structures.

The alternative point of view is that any metal-to-metal interactions are weak enough that low energy external forces, such as crystal packing, suffice to produce variations in metal-to-metal distances. The available crystallographic data are given in Table 5. The nickel structure is not accurate enough for detailed bond length comparisons. The palladium structure is based on a large set of intensity measurements and, although not fully refined, indicates three significantly different metal–metal distances, one considerably shorter than the other two. This does suggest that influences external to the Pd_3S_2 core are having an effect, despite the minimal steric requirements of the PMe_3 ligands. In the platinum compound with its bulkier PMe_2Ph ligands, the intramolecular distances C(27)—C(33), 3.89 Å, and C(37)—C(16), 3.84 Å, give a possible explanation for the long Pt(1)—Pt(2) distance since they are counteracted only by C(18)—C(27), 4.16 Å, C(22)—C(22′), 4.27 Å, and C(23)—C(23′), 4.22 Å.

The nmr spectra were analyzed in terms of D_{3h} symmetry for the $Pt_3S_2P_6$ core rather than the C_2 symmetry suggested by the X-ray work. This could reflect a truly more symmetrical structure in solution or could be due to dynamic interchange between C_2 structures, possibilities which would be difficult to distinguish even with extensive low temperature studies. This problem notwithstanding, the nmr parameters remain a potential source of information on bonding interactions. Unfortunately, the J(Pt—Pt) value (476 Hz) is of little assistance. It is consistent with previous results for thio-bridged dinuclear compounds (18, 29) but it is known that in general J(Pt—Pt) coupling constants show no correlation with Pt—Pt distance or even with the presence or absence of a metal–metal bond (29). However, there is evidence that longer range couplings are increased when metal–metal bonds are present. Thus, in complexes containing the grouping **1**, both ^{3-4}J(P—P) and ^{2-3}J(Pt—P) are markedly dependent on the Pt—Pt interaction.



1

In dinuclear complexes bridged by chloro (18), phosphido (17, 18, 30), and thiolato (14, 18) groups there is essentially no question of significant metal–metal interaction and both ^4J(P—P), <5 Hz, and ^3J(Pt—P), 7–63 Hz, are of small magnitude. By contrast, magnitudes in trinuclear clusters, where the geometry is essentially similar but there is a metal–metal bond, are much larger: ^3J(P—P), 20–160 Hz; ^2J(Pt—P), 120–519 Hz (17, 23, 31, 32). Clearly the values for the present complex, ^4J(P—P) < 5 Hz, ^3J(Pt—P) = −25 Hz, fall into the non metal–metal bonded ranges.

Overall, it appears to be most satisfactory to regard the $[Pt_3S_2(PMe_2Ph)_6]^{2+}$ cation, and its Ni and Pd analogues, as formed from three 16 electron square planes joined by sharing of the sulphide ligands. The crystal packing and metal–metal bonding arguments are not mutually exclusive and both may contribute to the slight deviations from trigonal symmetry, but it seems unlikely that the latter is an important component of the primary bonding.

Appendix

The use of existing standard nomenclature to describe the spin systems involved in these isotopomers is not entirely straightforward. For example, **II**, **III**, and **IV** could be described as AA′A″A‴A⁗A⁗′X, AA′A″A‴A⁗A⁗′XX′, and AA′A″A‴A⁗A⁗′XX′X″, respectively. This is accurate but not especially helpful since specification of all the coupling constants is necessary to make apparent the symmetry of the systems. The more recent symmetry related nomenclature proposed by Haigh (33) (and now in common use) gives an elegant representation of **IV** as an $[[A]_2X]_3$ system, but is unable to deal with **II** or **III** because these contain isochronous, magnetically non-equivalent nuclei which are not related by a symmetry element. Although this situation is of common occurrence in isotopomers, the nomenclature makes no provision for it and introduction of a distinctive symbol (an asterisk is here proposed) is necessary for a really useful description. Thus, using inner brackets to represent the symmetry plane containing the three Pt atoms and outer brackets for the C_2 axis, we obtain $[[A]_2A^*]_2X$ as a description of the spin system in isotopomer **II**. There are several possible choices for **III** but the most concise is probably $[A[A^*]_2X]_2$, where the brackets have the same significance as for **II**. In the interests of consistency, A* in both cases refers to phosphorus directly bonded to magnetically active platinum but this choice is not essential to the description.

The analysis in the main text has been simplified by assuming that ^4J(P—P) is zero. This is effectively the same as assuming magnetic equivalence of phosphorus atoms which are related by the plane of symmetry containing the three Pt atoms. Under these conditions, isotopomers **II**, **III**, and **IV** could be represented as $[A_2]_2A^*{}_2X$, $A_2[A^*{}_2X]_2$, and $[A_2X]_3$ respectively. Brackets in the first two cases represent the C_2 axis and in the last example represent the C_3 axis.

Solvent and temperature dependence of absorption and phosphorescence of *trans*-diisothiocyanate (bis)ethylenediaminechromium(III) ion[1]

COOPER H. LANGFORD[2] AND THOMAS M. SCHEAR

Department of Chemistry and Canadian Picosecond Flash Photolysis Centre, Concordia University, 1455 de Maisonneuve W., Montreal, P.Q., Canada H3G 1M8

Received August 9, 1983

COOPER H. LANGFORD and THOMAS M. SCHEAR. Can. J. Chem. **62**, 703 (1984).

An unusual case of absorption and fluorescence bands shifting in the same direction as solvent varies is reported. Solvent shifts in the quartet absorption maximum and doublet or phosphorescence emission maximum of *trans*-$Cren_2(NCS)_2^+$ ion are related to the Gutmann solvent donor number. The correlation is discussed in terms of solvent effects on the vibrations identified as responsible for the vibronic transitions and are in agreement with Hollebone's notion of "vibronic" intersystem crossing. The activation parameters for decay of phosphorescence in eight solvents correlate by a Barclay–Butler plot and are consistent with the possibility of a single common dominant mechanism for the *T*-dependent decay path. They do not, however, depend on solvent donor numbers as quantum yields for substitution do. Therefore, they offered no new support for the notion that the pathway is by chemical reaction. The activation parameters also fail to correlate with solvent fluidity.

COOPER H. LANGFORD et THOMAS M. SCHEAR. Can. J. Chem. **62**, 703 (1984).

On rapporte un cas inusité où les bandes d'absorption et de fluorescence se déplacent dans la même direction lorsqu'on fait varier le solvant. On a établi une relation entre le nombre donneur de Gutman relatif aux solvants et les déplacements dus aux solvants dans le quartet d'absorption maximale ainsi que l'émission maximale double ou de phosphorescence de l'ion $Cren_2(NCS)_2^+$-*trans*. On discute de la corrélation en termes d'effets de solvant sur les vibrations que l'on a identifiées comme responsables des transitions vibroniques et ils sont en bon accord avec la notion de Hollebone concernant les croisements entre systèmes vibroniques. Une bonne corrélation entre les paramètres d'activation pour la disparition de la phosphorescence dans huit solvants peut être établie grâce à une courbe de Barclay–Butler et ces paramètres sont en accord avec la possibilité d'un seul mécanisme commun dominant pour les voies de disparition de la phosphorescence qui dépendent de *T*. Ils ne dépendent toutefois pas des nombres donneurs des solvants comme c'est le cas pour les rendements quantiques pour la substitution. Ils n'offrent donc aucun support pour la notion que la voie est une réaction chimique. Il n'existe pas non plus de corrélation entre les paramètres d'activation et la fluidité du solvant.

[Traduit par le journal]

Introduction

Despite the common notion that the ligand field bands in the spectra of transition metal complexes are insensitive to solvent, there have been several interesting discussions of solvent effects on the decay of the phosphorescent doublet state of Cr(III) complexes (1–4). In particular, some authors (2) have felt that trends identified in solvent effects were best interpreted in terms of a photosubstitution pathway as the dominant mode of relaxation, whereas others (1, 3) have tended to regard back intersystem crossing to the quartet as the dominant pathway of relaxation of the doublet (i.e. the doublet fate is analogous to delayed fluorescence). A third possible path is, of course, direct "intersystem crossing" to the quartet ground state.

The complex ion *trans*-$Cren_2(NCS)_2^+$ shows a particularly simple and dramatic dependence of photoreaction quantum yield on solvents. The yields are linearly related to a "nucleophilicity" correlated parameter, the Gutmann donor number (5).

Since the factor, which has led both to the suggestion of a dominant reactive decay of the doublet and to the suggestion of a dominant back intersystem crossing process, is the relatively high apparent activation energy for decay of the doublet, it seemed useful to see if this activation energy also correlated with a single solvent parameter. An affirmative result could lend considerable support to the claims that one decay mechanism is dominant.

Experimental

Materials

The solvents used included spectrograde reagent CH_3OH, CH_3NO_2, CH_3CN, $(CH_3)_2CO$, dimethylsulfoxide (DMSO), *N*,*N*-dimethylformamide (DMF), and $(CH_3CO)_2O$ used without further purifications. Water was distilled and deionized.

The complex was prepared from $Cren_3(SCN)_3$ (6). A quantity of reagent grade chromium(III) sulfate was dried to the pentahydrate as indicated by water insolubility. A sample of 0.137 mol were mixed with 0.898 mol of ethylene diamine (98%) and refluxed at 105°C. A period of 4–5 h of manual agitation is necessary as the mixture tends to solidify. Once the mixture is dark brown, agitation is no longer necessary and refluxing is continued for an additional 20 h. The product is yellow–brown (yield 115 g). $[Cren_3]_2(SO_4)_3$ is converted to the chloride by dissolution in a mixture of 18 mL concentrated HCl and 110 mL of H_2O which was preheated to 65°C. The hot solution is quickly filtered into an ice-cold solution of 96 mL concentrated HCl mixed with 160 mL of 95% ethanol. The yellow solid is collected after about 30 min and washed with absolute ethanol and ether (yield 72 g). The $Cren_3Cl_3$ is dissolved in 225 mL of water at 60°C NH_4NCS (87 g) is dissolved in 100 mL of water and added. The resulting solution is held in an ice bath for 30 min to precipitate $[Cren_3](SCN)_3$ which is collected and washed with absolute ethanol and ether. Yield is 57 g, 49% based on $Cr_2(SO_4)_3 \cdot 5H_2O$.

trans-$[Cren_2(NCS)_2]SCN$ was prepared by heating 10 g of finely powdered $Cren_3(SCN)_3$ in an oven at a carefully controlled temperature of 130–134°C. The mass, spread thinly on a plate, is broken up every hour. When 16% of the weight has been lost the reaction is deemed suitably complete. The crude thiocyanate salt (8.4 g) is warmed with 120 mL of concentrated HCl (45–55°C) until evolution of HSCN is almost complete. The hot mixture is filtered quickly and the filtrate is held at 5°C for 30 min to complete precipitation. The resulting product, *trans*-$[Cren_2(NCS)_2]Cl$, is washed well and recrystallized from a minimum amount of hot water (yield 2.3 g). Parameters of the visible spectrum are given in Table 1. These param-

eters (7) and the ir spectrum (8) are in good agreement with literature values.

The chloride salt was used in studies in H_2O, DMF, DMSO, and CH_3OH. It was converted to the perchlorate salt for use in CH_3NO_2, CH_3CN, $(CH_3)_2CO$, and $(CH_3CO)_2O$ by recrystallization with 70% $HClO_4$.

Spectroscopy

Absorption spectra were obtained on a Perkin-Elmer 552. Emission spectra were recorded on a Perkin-Elmer MPF-44B equipped with a differential corrected spectra unit. Temperature control of samples was achieved by circulating either hot water or refrigerated ethylene glycol through the cell holder. The exact temperature of the solution was monitored by placing a precise thermometer in a cell of the same solvent placed in the spectrophotometer sample cell holder ($T \pm 0.1$°C).

A temperature dependence run was initiated by a half-hour warm-up period. The concentration of the complex was always in the range of $3.00-7.00 \times 10^{-4}$ *M* where emission intensity was linear in concentration. Care was taken to avoid suspended scattering matter in the solutions. The solution and the *T* monitor cell were mounted in two positions of the sample holder. When *T* had stabilized (~30 min), emission was monitored as a function of time at the wavelength maximum shown in Table 1. Corrected spectra indicate that the excitation maximum matches the absorption maximum. Excitation wavelength was set at 492 nm throughout. At temperatures below room temperature, a stream of dry N_2 was used to prevent fogging. After a point was complete, the shutters were closed and solutions were replaced from the stock. Generally, 10 to 15 temperatures were investigated for each run. Since values used for study of *T* dependence are relative to others within one solvent, instrument parameters were optimized for each solvent.

Results

Spectroscopic parameters and solvent characteristics at 25°C are collected in Table 1. It is clear that there is a measurable change in positions of the absorption and emission ligand field band maxima with solvent. The values in the table are precise (not necessarily absolutely accurate) to ± 25 cm^{-1}. There is a correlation that is "statistically significant" (95%) between increasing energy of both transitions and increasing Gutmann donor number (correlation coefficients: $R_{abs} = 0.78$, $R_{em} = 0.95$). But donor number (DN) is not indicated to be the dominant solvent characteristic controlling measurable differences. DN and fluidity give a reasonable model. (Multiple regression $R^2 = 0.697$, significant at 94%, *but* standard error of estimate 60 cm^{-1} or greater than 2×25.)

In more comprehensive temperature-dependence studies than this (down to 77 K), two distinct regions of temperature dependence of phosphorescence intensity are seen to be well

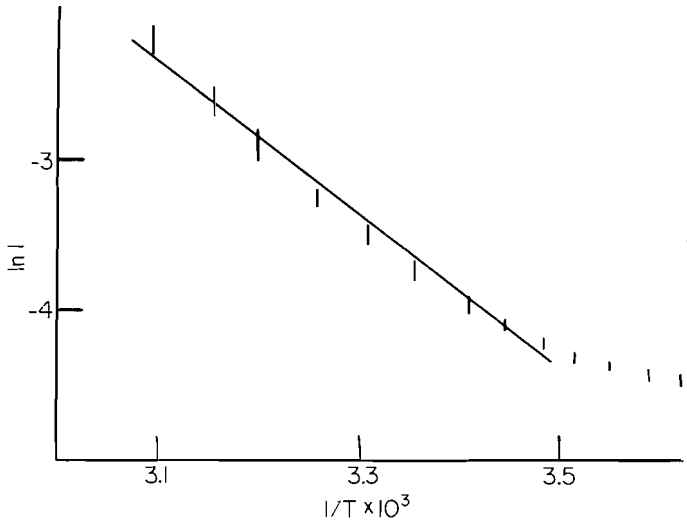

FIG. 1. Plot of (natural log emission intensity)$^{-1}$ (log I^{-1}) vs. reciprocal absolute *T* in CH_3OH.

defined (9, 10). From 77 K to above 200 K, phosphorescence intensity is independent of temperature but quantum yields of emission are well below unity (9, 10). This region reveals the radiationless deactivation from the lowest vibrational level of the doublet state by a weak coupling mechanism. At higher temperature, the phosphorescence intensity decreases with increasing temperature in a manner consistent with the Arrhenius equation. In the present study, an effort was made to ensure that deviation from the Arrhenius slope at lower temperature where the temperature-independent mechanism becomes important was not ignored. This was done by fitting the higher temperature points to a straight line by eye and being careful to determine if lower temperature points deviated significantly from the line. Where they did, an appropriate small number of low temperature points were excluded from consideration and the remaining points were fitted to a straight line Arrhenius relation by linear regression using eq. [1].

$$[1] \quad \ln (1/I) = \ln A - E_a/RT$$

Two typical cases are shown in Figs. 1 and 2. In the case of CH_3CN shown in Fig. 1, five points were excluded from the linear regression as indicating contributions of the temperature-independent mechanism. In the case of DMSO shown in Fig. 2, no points were excluded from the linear regression. Temperature dependence parameters for all solvents as obtained from the linear regression are collected in Table 2. The activa-

tion parameters in Table 2 deviate from some values reported earlier for water (1, 2). This is attributed to the exclusion here of some low temperature points from the Arrhenius equation linear fit.

Discussion

The original purpose of this study was to use the complex for which a simple relation between solvent and photochemical reactivity had been established by Cusumano and Langford to search support for Adamson's hypothesis of "reactive" doublet relaxation via analysis of the large activation energies. As will be seen in section 2 below, no such unequivocal evidence was forthcoming. In the process, we noticed another point of considerable interest. Contrary to the common case where solvent effects alter absorption and luminescence band positions in *opposite* directions (because the solvent is equilibrated around the ground state in the first case and around the excited in the second), we find luminescence and absorption shifting in the *same* direction with solvent. This strongly suggests *dynamic* effects. We cannot give a full account of this very interesting phenomenon but section 1 provides some initial speculations which may help to orient research on the problems.

1. Solvent shifts

The wavelength shift in the position of the absorption maximum of the spin-allowed band indicates that solvents affect the vibronic processes which relax the Laporte forbidden character of the $d-d$ transition. We can make some speculative remarks which show how this could arise. In the case of $Cr(OH_2)_6^{3+}$, Hollebone *et al.* have shown that the t_{1u} "buckle" vibration is involved in the quartet–quartet transition (11). It appears that the potential surface of this type of vibration is sensitive, at least in part, to the donor number of the solvent. The shift to higher energy with higher donor number could arise if the force constant increased with donor number and the absorption maximum remained at about the fifth term in the vibrational progression where it is found in $Cr(OH_2)_6^{3+}$. The shift to lower energy paralleling fluidity has a less evident origin.

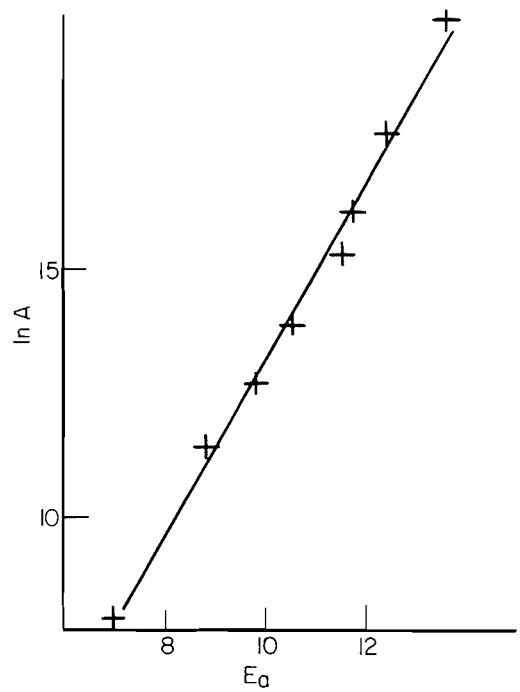

FIG. 3. Barclay–Butler plot of parameters of Arrhenius equation from Table 2.

The details of the solvent effects on the absorption maximum and our speculative explanations are not as important as the interesting *parallel* between the solvent dependence of the absorption maximum and the emission maximum. The weakness of spin–orbit coupling in Cr(III) has caused some puzzles with respect to the efficiency of intersystem crossing from the excited quartet to the excited doublet. Hollebone *et al.* (11) have recently shown that angular momentum may be associated with vibrational basis functions by subduction from spherical symmetry just as it is in the case of electronic basis functions. Consequently, the analysis of Hollebone *et al.* suggests that the quartet and doublet of an octahedral Cr(III) complex couple via an asymmetric stretch t_{1u} vibration if the maximum remains at the same vibrational state. This provides a consistent explanation for the otherwise surprising observations of a common trend between absorption where solvent is in an equilibrium arrangement around the ground state and emission where solvent is in an equilibrium configuration around the excited state. It is significant that solvent dependence supports the vibronic mechanism of intersystem crossing.

2. Temperature dependence

We now turn to the less speculative and more immediately significant part of this work. Figure 3 shows a Barclay–Butler

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

plot (enthalpy–entropy correlation) which gives some support to the notion that the temperature-dependent mechanism for non-radiative relaxation of the doublet is the same in all the solvents. However, neither the values of E_a nor ln A correlate with donor numbers (this is evident without a plot). Thus, the support sought for the idea that the T-dependent pathway is reactive is not found. In contrast to the close relation of SCN^- substitution quantum yield to donor number, no simple correlation emerged here. Looking in another direction, it is also interesting that no simple correlation is found with solvent fluidity (reciprocal of viscosity) which seemed to control substitution yield in $[Cr(NH_3)_2(NCS)_4]^-$ (5).

The final question is to ask whether the results support the model in which back intersystem crossing dominates the doublet relaxation pathways. Two points are mildly favourable. The Barclay–Butler plot suggests that a single relaxation may well dominate throughout. As well, the low temperature behaviour suggests a weak coupling pathway for the direct radiationless decay of the doublet so that attention is directed to the search for an alternative mechanism for the temperature dependent path. The energetics are consistent. The splitting in absorption between the states labelled ^4T and ^2E in O_h symmetry is near 19 kcal mol^{-1}. But the large Stokes shifts of quartet fluorescence observed for those few complexes which are fluorescent (12) suggest that vibrationally relaxed quartet levels are much closer to the doublets. In fact, the best estimates of the location of the zero–zero band in the present compound comes from Adamson's suggestion (12) that it is at the point in the absorption band where intensity is 5% of the maximum or from the MCD analysis of the vibrational progression of $Cr(OH_2)_6^{3+}$ in water at 25°C by Hollebone *et al.* (11). These make it feasible to assign the E_a values here to the barrier to back intersystem crossing. However, it must be stated that the evidence favouring back intersystem crossing as a dominant mechanism for doublet relaxation remains quite weak.

The theory of regular solutions applied to molar excess enthalpies and volumes of binary mixtures containing stannic bromide

S. K. SURI[1] AND R. C. MAHESHWARI

Chemistry Department, Indian Institute of Technology, New Delhi — 110016, India

Received May 9, 1983

S. K. SURI and R. C. MAHESHWARI. Can. J. Chem. **62**, 707 (1984).

The molar excess enthalpies, H_m^E, at 313.15 K and molar excess volumes, V_m^E, at 303.15, 308.15, and 313.15 K for the binary mixtures of stannic bromide with benzene, cyclohexane, and tetrachloromethane have been determined. Both H_m^E and V_m^E for the three sets of binary mixtures are positive over the entire range of composition. The experimental results have been compared with those predicted by regular solution theory. It is observed that H_m^E calculated for regular solutions are highly sensitive to the estimation of C_{12}. The calculated V_m^E are in good agreement with the experimental data if it is assumed that $(\partial E/\partial P)_T = 0$; and the ratio of the internal pressures to the cohesive energy density are the same for unmixed and the mixed components.

S. K. SURI et R. C. MAHESHWARI. Can. J. Chem. **62**, 707 (1984).

On a determiné les enthalpies molaires en excès, H_m^E à 313,15 K et les volumes molaires en excès, V_m^E, à 303,15, 308,15 et 313,15 K de mélanges binaires de bromure stannique avec le benzène, le cyclohexane et le tétrachlorométhane. Les valeurs de H_m^E et de V_m^E sont positives pour les trois mélanges dans tout l'intervalle des compositions. On a comparé les résultats expérimentaux avec ceux prévues par la théorie des solutions régulières. On observe que les valeurs de H_m^E calculées pour des solutions régulières sont fortement influencées par l'évaluation de C_{12}. Les valeurs de V_m^E calculées sont en bon accord avec les données expérimentales si l'on admet que $(\partial E/\partial P)_T = 0$ et que les rapports des pressions internes sur la densité d'énergie de cohésion sont les mêmes pour les composants sous formes de mélanges ou non mélangés.

Introduction

In our earlier studies (1, 2), we have reported the solubilities and partial molar volumes of arsenic, antimony, bismuth, and stannic bromides in various non-polar organic solvents. It was observed that the behaviour of these bromide solutions conform to the broader theories of non-electrolytes solutions proposed by Hildebrand and co-workers (3, 4). As an extension to our investigation on such solutions, we have measured the molar excess enthalpies (H_m^E) and molar excess volumes (V_m^E) of the binary mixtures of stannic bromide with benzene, cyclohexane, and tetrachloromethane. Attempts have been made to compare our results with those predicted by Hildebrand's regular solution model to see if the excess functions for these solutions can be described within the framework of this theory.

Experimental

Stannic bromide was synthesised by refluxing a slight excess of tin metal (A. R. Grade) with bromine in tetrachloromethane media till the solution was no longer coloured brown. The solution was filtered hot, the solvent distilled off, and the residue distilled over the metal *in vacuo*. The sample obtained was crystallised from anhydrous tetrachloromethane and dried at ~300 K under reduced pressure for an extended period of time. It was stored in brown bottles in a desiccator. Analytical reagent grade benzene, cyclohexane, and tetrachloromethane were purified according to standard procedures (5) and subjected to fractional distillation immediately before use. Some measured physical properties of the liquids have been compared with the literature values (6–12) in Table 1.

The molar excess enthalpies were determined in the calorimeter used in our earlier studies (13). The maximum uncertainty in the H_m^E data reported here is estimated to be around 2% for very small heat exchange.

The molar excess volumes have been calculated from the experimental densities of the binary mixtures determined pycnometrically. We preferred this method for the estimation of V_m^E over the direct dilatometric measurements because of the chemically aggressive nature of stannic bromide towards the blocking fluid mercury. The details of pycnometer used and experimental procedure for the preparation of solutions and measurement of densities have been described earlier (11). The maximum uncertainty in molar excess volumes is expected to be less than 0.010 $cm^3\ mol^{-1}$.

[1]To whom all correspondence should be addressed.

Results and discussion

The experimental results for H_m^E and V_m^E are represented graphically in Figs. 1 and 2, respectively. Each set of data were fitted by the method of unweighed least-squares to a polynomial of the form

$$[1] \quad X_m^E = x_1 x_2 \sum_{i=0}^{n-1} C_i (x_1 - x_2)^{i-1}$$

where X_m^E is either H_m^E or V_m^E and x_1 and x_2 are the mole fractions of stannic bromide and the organic component, respectively. The values of the coefficients for each function are given in Table 2 along with the standard deviation $\sigma(X_m^E)$. Since the standard deviation for all sets of data is of the same order of magnitude, as the estimated uncertainty in the respective experimental results, eq. [1] can be taken to represent the experimental results.

It is observed from Fig. 1 that H_m^E for the three sets of binary mixtures are positive over the entire composition range and show a maximum at $x_i \simeq 0.4$. The H_m^E for the benzene solution as estimated from freezing point data at eutectic point (i.e. 174.15 K and $x_1 = 0.371$) has been reported to be $1071 \pm 523\ J\ mol^{-1}$ (14). The uncertainty reported in this value renders any comment about it difficult. To the best of our knowledge, there is no other literature report on the molar enthalpies of mixing for these mixtures to compare our results.

All three sets of binary mixtures exhibited expansion on mixing over the entire composition range with the V_m^E maxima around $x_1 \simeq 0.4$ (Fig. 2). V_m^E is found to be large for solutions containing benzene, and cyclohexane as compared to those containing tetrachloromethane. The $(\partial V_m^E/\partial T)_P$ was positive for binary mixtures containing tetrachloromethane and nega-

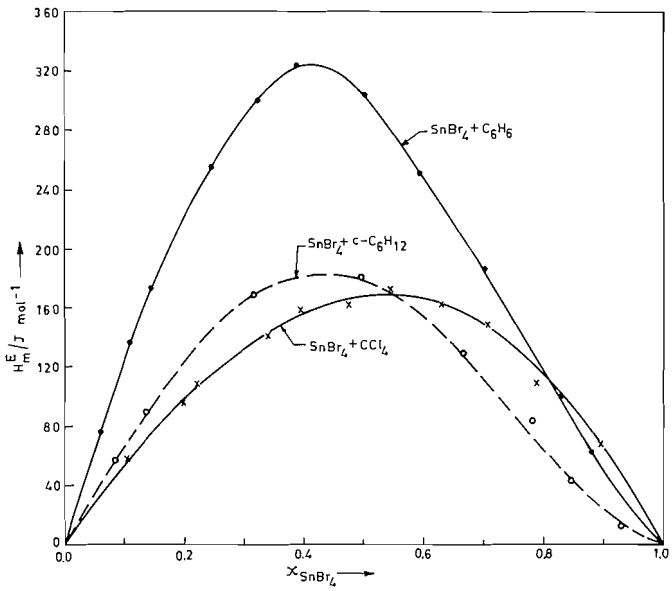

FIG. 1. Molar excess enthalpies, H_m^E, as a function of composition for the binary mixtures at 313.15 K.

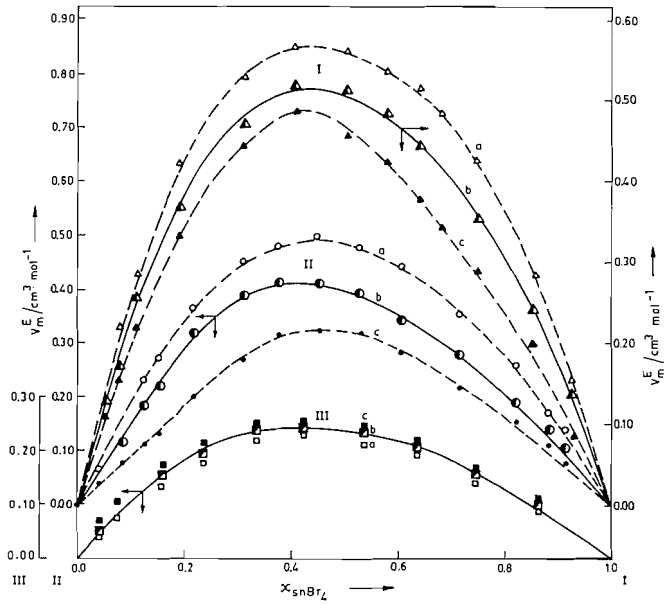

FIG. 2. Molar excess volumes, V_m^E, as a function of composition for the binary mixtures.

tive for the other two sets of binary mixtures. The V_m^E for the binary mixture of stannic bromide and tetrachloromethane at 308.15 K and $x_1 = 0.467$ reported by Hildebrand and Carter (15) is 0.002 cm^3 mol^{-1} higher than the one obtained by eq. [1] using the constants given in Table 2. We are not aware of any other volumetric studies on these binary mixtures.

It is observed that the magnitude of both H_m^E and V_m^E decreases as the ionization potential of the organic component increases.

The experimental H_m^E values were converted to respective molar excess energies at constant volume using the thermodynamic relationship (16)

$$[2] \quad E_m^E = H_m^E - T\frac{\alpha_m}{\beta_m} V_m^E$$

where α_m and β_m are the coefficients of thermal expansion and isothermal compressibilities for the binary mixtures, respectively. For the purpose of our calculations, these parameters were estimated from the data for pure components (Table 3) assuming additivity on volume fraction basis. The E_m^E values so obtained have been compared with those corresponding to a regular solution calculated using the expression (3)

$$[3] \quad E_m^E = (x_1 v_1 + x_2 v_2)(C_{11} + C_{22} - 2C_{12})\phi_1\phi_2$$

where ϕ_i and V_i are the volume fractions and molar volumes for the component molecules and the cohesive energy densities, C_{ii}, are given by

$$[4] \quad C_{ii} = \delta_i^2 = (\Delta H_i^{vap} - RT)/V_i$$

δ_i being the solubility parameter. The term C_{12} in eq. [3] was eliminated using the Berthalot relationship

$$[5] \quad C_{12} = (C_{11}C_{22})^{1/2}$$

It is observed from Fig. 3 that while for benzene solutions the experimental E_m^E values are ~4–5 times higher than those predicted from eq. [3], for the other two sets of binary mixtures these were significantly lower (~one-third of eq. [3] values for cyclohexane solutions and ~two-thirds for tetrachloromethane solutions).

In order to investigate the effect of geometric mean assumption (eq. [6]), the unlike interaction parameter, C_{12}, was estimated following Kohler (16):

$$[6] \quad C_{12} = \frac{16P_1P_2}{V_1V_2(V_1^{1/3} + V_2^{1/3})^3}\frac{\mu_1\mu_2}{\mu_1 + \mu_2}$$

and

$$[8] \quad \mu_i \frac{C_{ii}V_i^3}{P_i^3}$$

ϵ and N being the dielectric constant and Avogadro's number, respectively. In deriving eq. [6], it has been assumed that the interactions between unlike molecules occur between point centres only. The C_{12} values obtained from eqs. [5] and [6] have been compared with those required to fit the experimental results in Table 4. Though both approaches offer a good estimate of C_{12}, it is observed that an uncertainty of ~1% in its estimation propagates an appreciable difference in the evaluation of E_m^E using eq. [3]. The deviations from geometic mean law have been explained using an empirical binary coefficient, l_{12}, defined by (4)

$$[9] \quad C_{12} = (1 - l_{12})(C_{11}C_{22})^{1/2}$$

For the three binary mixtures containing stannic bromide, we found l_{12} to be dependent on composition. It increased with an increase in the mole fraction of stannic bromide for tetrachloromethane solutions and decreased for benzene and for cyclohexane solutions (Fig. 4). The sign and magnitude of l_{12} for these mixtures cannot be explained on the basis of intermolecular interactions and/or difference in shapes of the component molecules (4).

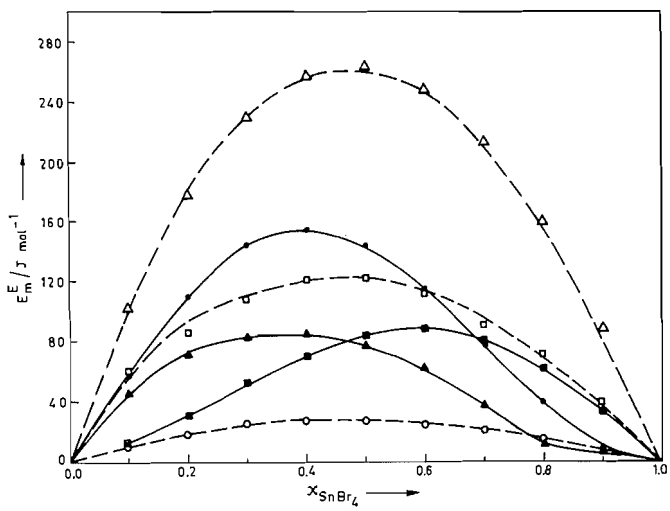

FIG. 3. Comparison of experimental molar excess energies, E_m^E, at 313.15 K with those obtained by eq. [3].

It is established that in the absence of electron−donor,

TABLE 4. Unlike interaction parameters, C_{12} (J mol^{-1}) at 313.15 K

System (*1*) + (*2*)	C_{12} from eq. [5]	C_{12} from eq. [6]	C_{12} required to fit experimental data
$SnBr_4$ + C_6H_6	353.2	350.8	351.4±0.7
$SnBr_4$ + c-C_6H_{12}	315.4	312.6	318.5±0.8
$SnBr_4$ + CCl_4	332.3	331.0	333.1±0.7

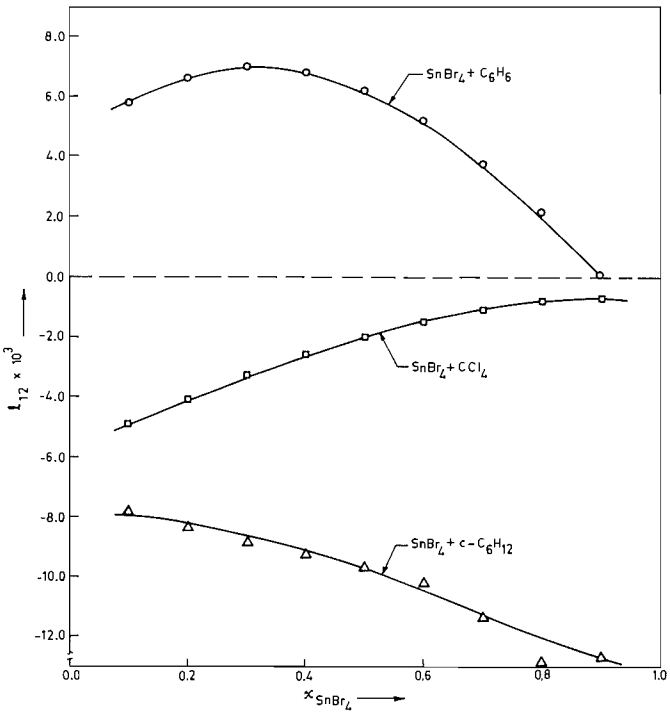

FIG. 4. Dependence of the empirical binary co-efficient, l_{12}, on composition at 313.15 K.

−acceptor interactions, normal liquids ordinarily expand on mixing (4). The V_m^E for all the three sets of binary mixtures under investigation exhibited a volume fraction dependence given by the expression

$$[10] \quad V_m^E = k\phi_1\phi_2$$

indicating that these systems approximate to regular solutions. We observed a linear correlation between k and ΔH_2^{vap} or $(\Delta H_1^{vap} - \Delta H_2^{vap})/(\Delta H_1^{vap} + \Delta H_2^{vap})$. At 313.15 K, the numerical value of k were 1.90 ± 0.03, 1.23 ± 0.04, and 1.05 ± 0.05 cm^3 mol^{-1} for benzene, cyclohexane, and tetrachloromethane solutions, respectively. The organic component having higher ΔH^{vap} exhibited higher k and hence higher V_m^E (for stannic bromide solutions). For V_m^E, Scott derived the expression (3, 21):

$$[11] \quad V_m^E = \eta_m\beta_m G_P^E \qquad (i)$$

$$- T(\partial S_v^E/\partial P)_T \qquad (ii)$$

$$- (\eta_m\beta_m E_m - x_1\eta_1\beta_1 E_1 - x_2\eta_2\beta_2 E_2) \qquad (iii)$$

$$- \eta_m\beta_m T S_v^E \qquad (iv)$$

where η_m is the ratio of internal pressure to the cohesive energy density for the mixture. He observed that the contributions from terms (*ii*) and (*iii*) of eq. [11] approximately cancel each other. If we assume the same to hold good for the binary mixtures under investigation, the apparent volumetric effects

System	$\frac{\alpha_m}{\delta_{m^2}}T \times 10^4$ (cm^3 J^{-1})	$\frac{V_m^E}{H_m^E} \times 10^4$ (cm^3 J^{-1})
$SnBr_4$ + C_6H_6	9.0	15.3
$SnBr_4$ + c-C_6H_{12}	10.2	17.7
$SnBr_4$ + CCl_4	9.2	15.3

show an excellent agreement with the one predicted by eq. [11] (Table 5). Various researchers (21) proposed an approximate formula equivalent to the first term of eq. [11] for V_m^E. For stannic bromide solutions, this by itself could reproduce neither the magnitude nor the shape of the experimental molar excess volumes. It was observed (Table 6) that for the three sets of binary mixtures, the experimental (V_m^E/H_m^E) are ~70% higher than α_m^T/δ_m^2, where $\delta_m^2 = \delta_1\delta_2$. This leads us to the conclusion that the volumetric effects in these mixtures arise from similar phenomena.

Synthetic and kinetic studies of the reversible addition of a bridging NSN fragment to the electron-rich heterocycles $(R_2PN)(SN)_2$ (R = Me, Ph, F)

NEIL BURFORD, TRISTRAM CHIVERS,[1] RICHARD T. OAKLEY,[2] AND TOM OSWALD
Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received September 26, 1983

NEIL BURFORD, TRISTRAM CHIVERS, RICHARD T. OAKLEY, and TOM OSWALD. Can. J. Chem. **62**, 712 (1984).

The oxidative addition of Cl_2 (using SO_2Cl_2) to the six-membered ring $(R_2PN)(SN)_2$ (R = Me, Ph) produces the mixed phosphazene–thiazyl heterocycles, $(R_2PN)(NSCl)_2$, which react with $Me_3SiNSNSiMe_3$ to give the bicyclic compounds $R_2PS_3N_5$. The latter undergo thermal decomposition, at ca. 100°C in toluene, via reductive elimination of an NSN unit to regenerate $(R_2PN)(SN)_2$ in high yield. Kinetic measurements of this process, using ^{31}P nmr spectroscopy, yield an activation energy of 102.4 ± 6.0 kJ mol^{-1} for the release of the NSN fragment from $Me_2PS_3N_5$. The thermolysis route has been used to prepare the thermally unstable $(F_2PN)(SN)_2$, characterized as a 1:1 adduct with norbornadiene.

NEIL BURFORD, TRISTRAM CHIVERS, RICHARD T. OAKLEY et TOM OSWALD. Can. J. Chem. **62**, 712 (1984).

L'addition oxydative du chlore (utilisant le SO_2Cl_2) aux cycles à six chaînons $(R_2PN)(SN)_2$ (R = Me, Ph) conduit aux hétérocycles mixtes phosphazène–thiazyles $(R_2PN)(NSCl)_2$ qui réagissent avec le $Me_3SiNSNSiMe_3$ pour donner les composés bicycliques $R_2PS_3N_5$. Ces derniers subissent une décomposition thermique, à environ 100°C dans le toluène, via une élimination réductrice d'une unité de NSN pour regénérer le $(R_2PN)(SN)_2$ avec un bon rendement. Des mesures cinétiques de ce processus, faisant appel à la spectroscopie RMN du ^{31}P, ont permis de déterminer que l'énergie d'activation, pour l'élimination du fragment NSN à partir du $Me_2PS_3N_5$ s'établit à 102,4 ± 6,0 kJ/mol. On a utilisé la voie de la thermolyse pour préparer le composé $(F_2PN)(SN)_2$ qui est thermiquement instable et que l'on a caractérisé sous forme d'adduit 1:1 avec le norbornadiène.

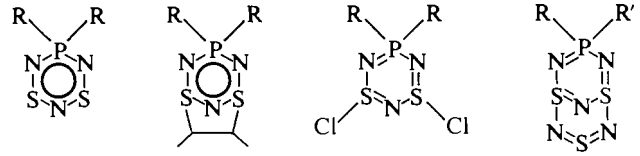
Introduction

We have recently reported the preparation and the molecular and electronic structure of π-electron-rich heterocycles containing the PS_2N_3 ring, **1** (R = Me, Ph), which undergo a reversible cycloaddition reaction with norbornadiene (NBD) (1). In the adduct, **2**, the olefin is symmetrically bound to the sulfur atoms of **1**, a mode of addition which has been explained by the primarily sulfur-based character of the HOMO and LUMO of **1** (1). We now report that **1** (R = Me, Ph) undergoes oxidative addition reactions with halogenating agents, e.g., SO_2Cl_2, to give $(R_2PN)(NSCl)_2$, **3**, which is converted to the bicyclic compound $R_2PS_3N_5$, **4**, on treatment with $Me_3SiNSNSiMe_3$ (2).



1 **2** **3** **4**

Derivatives of **4** (R = R′ = F; R = Ph, R′ = F) have previously been prepared by the reaction of $Me_3SiNSNSiMe_3$ with PF_5 (3, 4) (or $PhPF_4$ (4, 5)) and their thermal decomposition in benzene at ca. 70°C was reported to give the radical anion N_2S^- on the basis of a five line esr spectrum (4, 6).[3] We find, however, that the thermolysis of **4** (R = Ph, Me) regenerates **1** in high yield via the reductive elimination of a neutral NSN unit. The latter molecule has never been characterized but it is a frequent reaction fragment in cyclothiazene chemistry.[4] We have carried out a kinetic study of this decomposition, using ^{31}P nmr spectroscopy, in order to determine the activation energy for the release of NSN and we have used the thermolysis of **4** (R = R′ = F) to prepare the previously unknown difluoro derivative, **1** (R = F), as an adduct with NBD (**2**, R = F).[5]

Experimental

Reagents and general procedures

Solvents were dried (toluene (sodium) and acetonitrile (CaH_2 and P_2O_5)) and freshly distilled before use. All reactions were conducted under an atmosphere of nitrogen (99.98% purity passed through Ridox and silica gel).

Sulfuryl chloride (Aldrich) was freshly distilled before use and phosphorus pentafluoride (Penwalt) was used as received. The following reagents were prepared by the literature procedures: $Me_3SiNSNSiMe_3$ (8), $(R_2PN)(SN)_2$ (R = Me, Ph) (1), and $F_2PS_3N_5$ (4). The latter reagent was purified by sublimation (10^{-3} Torr) onto a cold finger (0°C).

Instrumentation

Infrared spectra (4000–250 cm^{-1}) were recorded as Nujol mulls (CsI windows) on a Perkin-Elmer 467 grating spectrophotometer, Ultraviolet–visible spectra were obtained using a Cary 15 instrument. All nmr spectra were recorded with a Varian XL-200 spectrometer using the following references: ^1H and ^{13}C (internal Me_4Si), ^{19}F (external CF_3COOH), ^{31}P (external 85% H_3PO_4). Chemical analyses were performed by MHW Laboratories, Phoenix, AZ.

Preparation of $(Ph_2PN)(NSCl)_2$

Sulfuryl chloride (0.7 mmol) was added dropwise, by syringe, to a stirred solution of $(Ph_2PN)(SN)_2$ (0.20 g, 0.7 mmol) in acetonitrile (20 mL). The purple solution turned yellow immediately. The volume of the mixture was reduced to 10 mL by removal of solvent *in vacuo*. The solution was cooled to −20°C and a few moisture-sensitive, yellow–orange crystals of $(Ph_2PN)(NSCl)_2$ were deposited. *Anal.*

[2]Present address: Department of Chemistry, University of Guelph, Guelph, Ont., Canada N1G 3G5.

[3]The observed esr spectrum establishes that the radical contains two nitrogen atoms but *does not* define the number of sulfur atoms, which could be more than one.

[4]The most stable arrangement of two nitrogen and one sulfur atoms is linear NNS ($C_{\infty v}$) (7).

[5]The related heterocycles **1** (R = CF_3, C_2F_5) have recently been prepared by the reaction of $R_2PN(SiMe_3)_2$ with $S_3N_2Cl_2$ and the NBD adduct of the CF_3 derivative has been structurally characterized by X-ray crystallography (H. W. Roesky, J. Lucas, M. Noltemeyer, and G. M. Sheldrick. Private communication).

calcd. for $C_{12}H_{10}Cl_2N_3PS_2$: C 39.79, H 2.78, N 11.60, Cl 19.57; found: C 40.39, H 3.32, N 11.78, Cl 19.89. Infrared (major bands): 1440(vs), 1125(vs), 1074(vs), 1028(m), 1000(m), 898(vs), 756(m), 737(vs), 692(s), 637(m), 543(vs), 499(s), 416(s), 311(m), 299(m) cm^{-1}.

Preparation of $Ph_2PS_3N_5$

Sulfuryl chloride (1.0 mmol) was added dropwise, by syringe, to a stirred solution of $(Ph_2PN)(SN)_2$ (0.30 g, 1.0 mmol). A solution of $Me_3SiNSNSiMe_3$ (0.21 g, 1.0 mmol) in acetonitrile (10 mL) was slowly added to the resulting yellow solution, which became orange–red. The volume of the solvent was reduced to 10 mL by removal of solvent *in vacuo* and, on cooling to −30°C, orange needles were obtained. Recrystallization from acetonitrile gave orange–brown crystals of $Ph_2PS_3N_5$ (0.25 g, 0.7 mmol). *Anal.* calcd. for $C_{12}H_{10}N_5PS_3$: C 41.00, H 2.87, N 19.92, S 27.35: found: C 40.93, H 3.35, N 20.09, S 26.73. Infrared (major bands): 1440(s), 1130(s), 1116(s), 1091(vs), 1076(s), 991(m), 809(s), 724(s), 697(m), 687(m), 567(s), 504(s), 468(m) cm^{-1}. $\{^1H\}$ ^{31}P nmr ($CDCl_3$) δ: −21.3 ppm.

Preparation of $Me_2PS_3N_5$

Sulfuryl chloride (1.5 mmol) was added dropwise, by syringe, to a solution of freshly sublimed $(Me_2PN)(SN)_2$ (0.24 g, 1.4 mmol) in acetonitrile (20 mL). The resulting yellow–green slurry was filtered to remove a small amount of a pale brown solid. A solution of $Me_3SiNSNSiMe_3$ (0.31 g, 1.5 mmol) in acetonitrile (15 mL) was added dropwise to the yellow filtrate which immediately became red–brown. Removal of solvent *in vacuo* gave a red–brown oil which was recrystallized from acetonitrile to give shiny brown crystals of $Me_2PS_3N_5$ (0.13 g, 0.6 mmol). Infrared: 1410(m), 1295(vs), 1090(vs), 1070(vs), 980(vs), 948(vs), 920(vs), 870(vs), 797(s), 756(m), 722(vs), 713(vs), 680(s), 635(s), 580(vs), 540(vs), 475(vs), 418(vs), 382(vs), 270(m) cm^{-1}. $\{^1H\}$ ^{31}P nmr ($CDCl_3$) δ: −4.4 ppm. Satisfactory elemental analyses could not be obtained due to the thermal instability of $Me_2PS_3N_5$.

Thermal decomposition of $Ph_2PS_3N_5$

A solution of $Ph_2PS_3N_5$ (0.20 g, 0.60 mmol) in toluene (25 mL) was heated at reflux for 3 h. The resulting purple solution was reduced in volume to ca. 10 mL, by removal of solvent *in vacuo*, and eluted down a Bio Beads S-X8 chromatography column (30 × 500 mm). Two bands, purple and yellow, were observed. The purple fraction was collected and solvent was removed *in vacuo* to give $(Ph_2PN)(SN)_2$ (0.12 g, 0.40 mmol) after recrystallization from acetonitrile. The yellow fraction contained a very small amount of S_4N_4 (ir spectrum) (9).

Thermal decomposition of $Me_2PS_3N_5$

A solution of $Me_2PS_3N_5$ (0.25 g, 1.0 mmol) in toluene (25 mL) was heated at reflux for 2 h. The resulting red–purple solution was reduced in volume to ca. 10 mL and eluted down a Bio Beads S-X8 chromatography column (30 × 500 mm) to give yellow (S_4N_4) and purple fractions. Removal of solvent from the latter fraction gave a purple oil from which purple crystals of $(Me_2PN)(SN)_2$ (ir spectrum) (1) were obtained by sublimation onto a cold finger (0°C). An accurate yield could not be obtained due to the thermal instability of the product.

Preparation of $(F_2PN)(SN)_2$ by the thermal decomposition of $F_2PS_3N_5$

A solution of $F_2PS_3N_5$ (0.10 g, 0.4 mmol) in Nujol (5 mL) was placed in a flask connected to the vacuum line via an empty flask cooled in liquid nitrogen. The system was evacuated and the Nujol solution was warmed to ca. 90°C using an oil bath. The yellow solution quickly became blue–green and a very volatile blue product condensed in the liquid nitrogen-cooled flask. After 3 h, the product was allowed to warm up to room temperature to give $(F_2PN)(SN)_2$ as a thermally unstable blue oil, λ_{max} (CH_2Cl_2, 23°C) 573 and 410 nm; ^{31}P nmr ($CDCl_3$) δ: −7.6 ppm, J_{PF} = 1055 Hz. ^{19}F nmr δ: −22.2 ppm. $(F_2PN)(SN)_2$ was also characterized as an adduct with norbornadiene (NBD).

Preparation of $(F_2PN)(SN)_2 \cdot C_7H_8$

A slight excess of norbornadiene was added dropwise to a solution of $(F_2PN)(SN)_2$ in diethyl ether. The purple solution became colorless immediately and a white precipitate was deposited. The crude product was crystallized from CH_3CN/CH_2Cl_2 containing norbornadiene to give an almost quantitative yield of $(F_2PN)(SN)_2 \cdot C_7H_8$. *Anal.* calcd. for $C_7H_8F_2N_3PS_2$: C 31.46, H 3.02, N 15.72; found: C 31.02, H 3.11, N 15.07. ^1H nmr ($CDCl_3$) δ: 1.32, 1.80 (AB, 10.0), 3.33, (t, 1.8), 4.66 (d, 1.6), 6.40; $\{^1H\}$ ^{13}C nmr ($CDCl_3$) δ: 41.1, 43.9, 85.0, 139.2; ^{19}F nmr ($CDCl_3$) δ: −43.8, −79.4 ppm. ($^1J_{PF}$ = 1001 Hz; $^2J_{FF}$ = 82.0 Hz).

^{31}P nmr spectroscopic monitoring of the thermal decomposition of $R_2PS_3N_5$

A flask containing a solution of $Ph_2PS_3N_5$ (0.30 g) in toluene (20 mL) was placed in a warm oil bath (95–100°C). Five minutes were allowed for the solution to reach the temperature of the oil bath and then samples were taken by syringe at regular intervals during a 100 min period. These samples were immediately cooled and their ^{31}P nmr spectra (500 scans) were recorded at −60°C. A similar procedure was used to monitor the thermal decomposition of $Me_2PS_3N_5$.

Kinetic measurements[6]

All solutions were handled in a dry, inert atmosphere. To determine the order of the reaction, solutions of various concentrations were obtained by dilution of a stock solution of $Ph_2PS_3N_5$ (0.1 *M*) in toluene at 23°C using a syringe. The reaction rates at different temperatures were measured by adding a known weight of $Ph_2PS_3N_5$ to each of five aliquots of toluene to give a 0.01 *M* solution. Temperatures were accurate to ±0.5°C. Samples were removed from the reaction vessels at suitable intervals, placed in an nmr tube, and cooled rapidly to −60°C to quench the reaction. The formation of $(Ph_2PN)(SN)_2$ was followed by the ^{31}P nmr spectrum and the amount present at a given time was determined from the percentage of the total area of the two peaks due to **1** and **4**.

Results and discussion

Preparation of $(Ph_2PN)(NSCl)_2$, 3 (R = Ph)

The eight π-electron heterocycle **1** reacts instantaneously with SO_2Cl_2 (as a source of Cl_2) to give $(R_2PN)(NSCl)_2$, **3** (R = Ph), as yellow, moisture-sensitive crystals characterized by chemical analyses and infrared spectroscopy. The reactions of **1** with Br_2 or I_2 also occur readily but the oily products could not be obtained pure. The heterocycle **3** can be considered as a hybrid of the well-known cyclotriphosphazene, $(Ph_2PN)_3$, and cyclotrithiazyl chloride, $(NSCl)_3$, ring systems and is the missing member of the series $(Ph_2PN)_{3-x}(NSCl)_x$ (x = 0–3). The other mixed phosphazene–thiazyl six-membered ring $(Ph_2PN)_2(NSCl)$ was recently prepared by the reaction of Ph_2PCl with S_4N_4 (3:1 molar ratio) in acetonitrile (10).

Preparation of the bicyclic compounds $R_2PS_3N_5$, 4

In view of the unusual range of reactions observed for $(Ph_2PN)_2(NSX)$ derivatives (10–13) the bifunctional nature of **3** offers interesting synthetic possibilities. We have found that the reaction of **3** with $Me_3SiNSNSiMe_3$ produces the bicyclic compounds **4** in good yields (cf. $Cl_3S_3N_3 + Me_3SiNSNSiMe_3 \rightarrow S_4N_5Cl + 2Me_3SiCl$) (14). The preparation of **4** from **3** supports a structure for **3** in which each sulfur is attached to one chlorine substituent. However, it is not possible to conclude that these substituents adopt a *cis* configuration in **3** based on this evidence. For example, it is known that the reaction of $Me_3SiNSNSiMe_3$ with 1,5-$Cl_2S_4N_4$, in which the chlorine at-

For personal use only.

oms are in *exo*, *endo* positions, produces S_5N_6 in which the NSN bridge enforces an *endo*, *endo* configuration (15). Thus it is possible for inversion to occur at sulfur in these metathetical reactions of bifunctional cyclothiazyl halides. However, the chlorine substituents are on the same side of the ring in the related six-membered heterocycles, $(Me_2NCN)(NSCl)_2$ (16) and $[(NSO_2)(NSCl)_2]^-$ (17), and an all *cis* geometry is found for $(NSCl)_3$ (18).

We also attempted to prepare **4** by the reaction of R_2PCl_3 (R = Me, Ph) with $Me_3SiNSNSiMe_3$. The ^{31}P nmr spectra of the reaction mixtures revealed the presence of many phosphorus-containing products, including **4**, which could not be separated as a pure compound. The reaction of $Me_3SiNSNSiMe_3$ with PCl_5 produces the six-membered ring $(Cl_2PN)_2(ClSN)$ (19). Thus the preparation of **4** from $Me_3SiNSNSiMe_3$ and phosphorus(V) reagents appears to be limited to the use of PF_5 (3, 4) or $PhPF_4$ (4).

Thermal decomposition of $R_2PS_3N_5$

A notable structural feature of **4** (R = R′ = F) is the relative length of the S—N bonds (1.69 Å) connecting the NSN unit (d(S—N) = 1.55 Å) to the six-membered $R_2PS_2N_3$ ring (average d(S—N) = 1.61 Å). This suggests a tendency to thermal breakdown of **4** via loss of an NSN unit, a process which is known to occur readily for many sulfur–nitrogen heterocycles (e.g. $S_4N_5^- \xrightarrow{-N_2S} S_3N_3^-$) (20).

We have monitored the thermolysis of **4** (R = Me, Ph) in toluene at ca. 100°C by ^{31}P nmr spectroscopy. The singlet due to **4** is gradually replaced by another singlet at lower field attributed to **1**. This conversion is complete after ca. 1.5 h and no other phosphorus-containing products can be detected in the ^{31}P nmr spectrum. In the case of **4** (R = Ph), the product **1** was isolated in ca. 70% yield. Thus the thermal breakdown of **4** must involve loss of a neutral NSN fragment, which has a low energy barrier to decomposition to N_2 and S (estimated to be 15–25 kcal for linear NSN ($D_{\infty h}$) and 9–15 kcal for bent (90°) NSN (C_{2v}) (7*a*)). The isolation of small amounts of S_4N_4 suggests that an alternative decomposition pathway exists for **4**, which may account for the formation of N_2S_x in sufficient concentration to be detected by its esr spectrum (4, 6).[3]

From an electronic point of view the reductive elimination of an NSN fragment from **4** can be understood in the same context as the reversible cycloaddition of norbornadiene to **2** (1). In essence, the NSN unit represents an isolobal analogue of a simple olefin. The N—N $\sigma(4a_1)$ and $\sigma^*(3b_2)$ orbitals of NSN (C_{2v}) (7*a*) are of the correct symmetry to interact with the LUMO and HOMO of **1**, respectively. Figure 1 illustrates the Hartree–Fock–Slater energy levels for the two reaction products (using $H_2PS_2N_3$ as a model for **1**) and correlates the interacting frontier orbitals.

Kinetic measurements

The formation of **1** (R = Ph) from **4** (R = R′ = Ph) as a function of temperature was followed by ^{31}P nmr spectroscopy. At 100°C the reductive elimination was found to follow first order kinetics with the rate constants being independent of the initial concentration of **4**. These simple kinetics are due to the rapid decomposition of NSN (7*a*) which precludes the second order back reaction. The rate constants, k, for the process

$$R_2PS_3N_5 \xrightarrow{k} (R_2PN)(SN)_2 + NSN$$

were obtained from the slopes of the first order kinetic plots in Fig. 2. Using the Arrhenius equation, a plot of ln k vs. T^{-1} (Fig. 3) yielded an activation energy of 102.4 ± 6.0 kJ mol^{-1} for the reductive elimination reaction. We have been unable to find similar data for S—N compounds with which to compare this value.

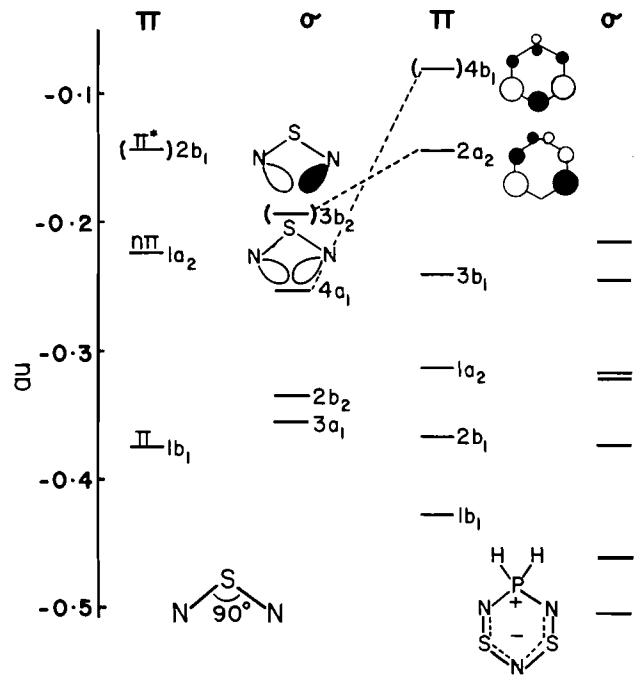

FIG. 1. Frontier orbitals of NSN (with NSN = 90°) and $H_2PS_2N_3$ taken from refs. 7*a* and 1, respectively. For clarity, the σ and π orbitals are separated. Virtual orbitals are indicated with parentheses ( ).

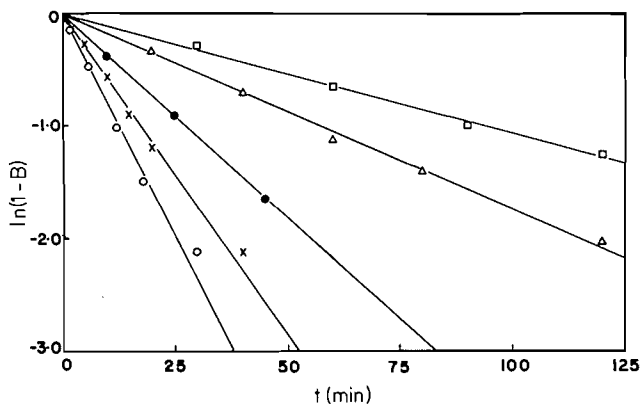

FIG. 2. Plots of ln $(1 - B)$ vs. time at various temperatures for the thermolysis of **4** (R = R′ = Ph); B = $[(Ph_2PN)(SN)_2]/[(Ph_2PN)(SN)_2 + (Ph_2PS_3N_5)]$ (see Experimental section); □, 86°C; △, 92°C; ●, 98°C; ×, 102°C; ○, 110°C.

Preparation of $(F_2PN)(SN)_2$ and $(F_2PN)(SN)_2 \cdot NBD$

The thermal decomposition of **4** (R = R′ = F) in Nujol at ca. 100°C produces **1** (R = F) as a volatile blue oil, which exhibits a strong visible absorption band at 573 nm, characteristic of cyclophosphadithiatriazenes and attributed to the π*HOMO → π*LUMO transition (1). The availability of a range of molecules (**1**, R = Me, Ph, PhO, F) provides a unique opportunity to examine the effects of different substituents R on the energy of this π* → π* transition. In the π-electron precise cyclophosphazenes, $(R_2PN)_x$, the HOMO (π) → LUMO (π*) transition occurs below 200 nm, so that substituent effects are

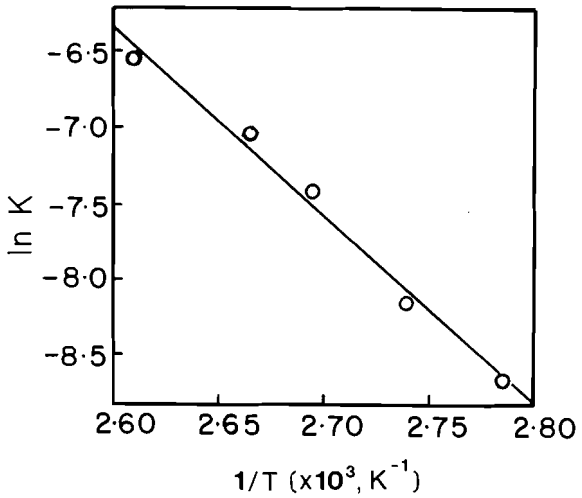

FIG. 3. Plot of $\ln k$ vs. $1/T$ for the thermolysis of **4** (R = R′ = Ph).

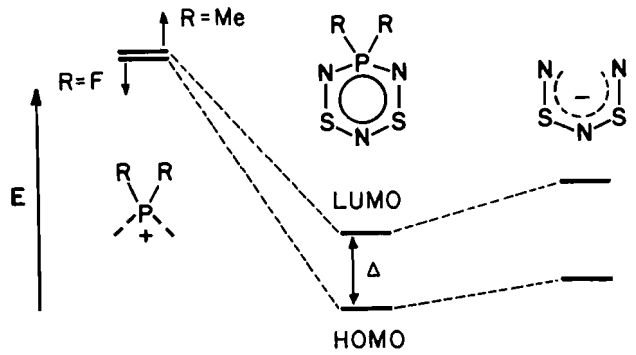

FIG. 4. Effect of exocyclic ligands attached to phosphorus on the HOMO−LUMO separation (△) of $(R_2PN)(SN)_2$.

not easily assessed. To the extent that the participation of $3d$ orbitals on phosphorus is important in describing the electronic structure of **1**, the involvement will be most pronounced in systems containing electronegative ligands (e.g. R = F, OPh). As indicated in Fig. 4, all orbitals will be stabilized under these circumstances, but the effect will be greater for the LUMO than the HOMO. Hence the bathochromic shift observed for R = F, OPh (λ_{max} 573 and 583 nm) relative to R = Me, Ph (λ_{max} 543 and 550 nm) finds a satisfactory correlation with the expected trend in the excitation energies.

In distinct contrast to **1** (R = Ph), which is a crystalline solid stable towards air, heat, and water, the fluoro derivative (**1**, R = F) is very moisture-sensitive and decomposes within ca. 1 h at 22°C under nitrogen. It can, however, be conveniently stored as a readily formed, crystalline adduct with norbornadiene (**2**, R = F). The ^1H and ^{13}C nmr spectra of this adduct closely resemble those reported for **2** (R = Ph (1), CF_3)[5] for which X-ray structural determinations have established an S,S mode of addition.

The values of the ^{19}F nmr chemical shift (−22.2 ppm) and J_{P-F} (1055 Hz) for **1** (R = F) are fairly typical for fluorocyclophosphazenes (21). The ^{19}F nmr spectrum of **2** (R = F) shows non-equivalent fluorine atoms as was found for the methyl substituents in **2** (R = Me) (1).

Conclusion

The bicyclic compounds $R_2PS_3N_5$ (R = Me, Ph) have been prepared from $(R_2PN)(SN)_2$, **1**, via a two-step synthesis involving the oxidative addition of Cl_2 followed by treatment with $Me_3SiNSNSiMe_3$. The thermolysis of these bicyclic systems regenerates the six-membered rings via reductive elimination of NSN, a process which is similar to the reversible cycloaddition of olefins to **1** in terms of frontier orbital concepts.

Introduction

In this paper, the general theory derived in Part 2 of this series is implemented, and the effect of edge diffusion on the cyclic voltammetric response at very small electrodes is examined. The use of very small electrodes for cyclic voltammetric experiments has usually been limited to specialized investigations, for example, in neurochemical studies (1, 2). There are obvious advantages in using very small electrodes. In theory, the ratio of the faradaic to the double layer charging current increases with decreasing electrode area. Small electrodes are suited for experiments where available volumes of analyte are limited. In general, several effects have been observed in various systems as the electrode size was reduced. Thus increased faradaic peak separation (3), little or no reverse sweep currents (4, 5), and a steady-state current plateau (6) have been observed. In the case of a small hanging mercury drop electrode, anomalous behavior was observed when the reduced species was soluble in the mercury drop (7–9). The resulting ratio of the reverse peak current to the forward peak current was found to be greater than one.

Examination of the so-called "edge-effect" has been carried out for chronoamperometric experiments (10, 11). The analysis by various workers has led to a correction term σ to the Cottrell equation

$$[1] \quad i = nFAC^0\left(\frac{D}{\pi t}\right)^{1/2}\left[1 + \sigma\left(\frac{Dt}{r_0^2}\right)^{1/2}\right]$$

where r_0 is the electrode radius, and σ varies between 1.772 and 2.257 (11, 12). Using implicit finite difference methods, Heinze developed an analogous equation for the cyclic voltammetric response with contribution from edge effects (6):

$$[2] \quad \chi_{total} = \chi_{i,d}(at) + \rho(at)\sqrt{\beta'}/\sqrt{\pi}$$

with $\beta' = D/ar_0^2$, $a = nFv/RT$, v = sweep rate. $\chi_{i,d}(at)$ is the planar diffusion current function and the second term is the radial diffusion current function. In this work, we give the results for the voltammetric response in terms of the efficient orthogonal collocation technique (13, 14), the results of which, in many cases, are exact.

The term "very small electrodes" (e.g. 3–300 μm radius (5)) is used herein to differentiate them from microelectrodes, diffusion to which is purely hemispherical. The case examined here is that where the amount of hemispherical diffusion to a planar disk electrode is large enough to cause significant departure in the response from semi-infinite linear diffusion theory. Extensions to the two limiting cases will be discussed.

The solution of the non-linear partial differential equations describing this case has been treated in Part 2 (15). The general method is the simulation of the concentration profiles in the diffusion layer by approximate trial functions in distance whose time-dependent coefficients are selected by weighted residual techniques such that the differential equation is satisfied at chosen fixed (collocation) points in the distance coordinate. These points are also chosen purposely as the roots of orthogonal polynomials, combinations of which best approximate the expected profiles and the boundary conditions. The model used herein accounts for planar and lateral diffusion. As has been pointed out (16), it is a simple matter to add homogeneous reactions to the overall scheme once the basic model is developed. The reliability and accuracy of the model have been verified in Part 3 (17) of the series, where the chronoamperometric response was simulated.

Theory

The full description of the theory is given in Part 2, (15) and is briefly summarized here. The mechanism considered was an EC type:

$$[3] \quad A \underset{+ne^-}{\overset{-ne^-}{\rightleftharpoons}} B \qquad E^\circ$$

$$[4] \quad B \rightarrow C \qquad k$$

In this paper, we will not consider the effects of [4], i.e. we let $\alpha = 0$ and the electrode geometry is a planar disk electrode of radius r_0, flush mounted in an insulating cylinder. The diffusion coefficients D_i for all of the species are assumed to be equal, even though the treatment is only slightly different if

[1]To whom all correspondence should be addressed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

different D_i are used (13). For this system, the current density will not be homogeneous across the electrode surface, but will be greater near the edges due to additional diffusion to the edge from the region over the insulator. Dimensionless diffusion equations describing the model are

$$[5]\quad \frac{\partial c^*_{A_1}}{\partial T'} = \beta\frac{\partial^2 c^*_{A_1}}{\partial X^2} + \frac{\beta'}{R}\frac{\partial c^*_{A_1}}{\partial R} + \beta'\frac{\partial^2 c^*_{A_1}}{\partial R^2}$$

$$[6]\quad \frac{\partial c^*_{B_1}}{\partial T'} = \beta\frac{\partial^2 c^*_{B_1}}{\partial X^2} + \frac{\beta'}{R}\frac{\partial c^*_{B_1}}{\partial R} + \beta'\frac{\partial^2 c^*_{B_1}}{\partial R^2} - \alpha c^*_{B_1}$$

$$[7]\quad \frac{\partial c^*_{C_1}}{\partial T'} = \beta\frac{\partial^2 c^*_{C_1}}{\partial X^2} + \frac{\beta'}{R}\frac{\partial c^*_{C_1}}{\partial R} + \beta'\frac{\partial^2 c^*_{C_1}}{\partial R^2} - \alpha c^*_{C_1}$$

where the subscript 1 denotes the concentrations above the electrode surface. A similar set of equations exists for the area above the insulator.

The terms in the equations are:

$$[8]\quad \beta = \frac{D}{aL^2},\ \beta' = \frac{D}{ar_0^2},\ \beta'' = \frac{D}{a(M - r_0)^2},\ \alpha = \frac{k}{a},\ c^* = \frac{c}{c^0_A}$$

where $a = nFv/RT$. L represents that distance out in solution above the electrode where no diffusion occurs and M the radial distance out into solution from the center of the electrode where no diffusion occurs. These terms need to be included to normalize the equations later to a (0, 1) distance coordinate so that Legendre polynomials might be used to represent the concentration solutions (15, 17). r_0 is the radius of the electrode and the other terms have their usual significance.

The constant β' is a quantity given by experimental parameters. For simplicity herein we let $\beta = \beta''$. This is a sensible approximation since both L and M are $\gg r_0$. The choice of β may be optimized by various procedures already described (18, 19). β in essence defines a "window" on the diffusion phenomena. If β is too small, the diffusion layer will be small compared to the collocation point span, and it will be poorly simulated or missed entirely. If, on the other hand, β is chosen too large, then the diffusion effects may be present at L or M and the boundary conditions will be violated. This is the intuitive reason for optimization of β values. The procedure for optimization depends on the integration method used for solution of the set of differential equations. Each such integration method will have a corresponding set of stability and accuracy criteria which vary significantly from method to method. In the Hammings predictor–corrector method used herein, the stability criterion (20) takes the form

$$[9]\quad h \le \frac{0.65}{|f_y|}$$

where h is the independent variable stepwidth chosen for the integration, and f_y is the Jacobian or derivative of the differential equation $f(x,y)$ with respect to the independent variable at each point of interest. Thus, accuracy and curve shape relax as h is made very small, whereas unstable oscillation will occur if h is too large.

The corresponding first-order differential equations for the problem (Part 2 (15)) are:

$$[10]\quad \left.\frac{dc^*_{A1}}{dT'}\right|_{X_i,R_k} = \beta\left\{-\frac{B_{i,1}\theta_{A/B}S_\lambda(T')}{A_{1,1}[1+\theta_{A/B}S_\lambda(T')]}\left[A_{1,N_x+2} + \sum_{j=2}^{N_x+1} A_{1,j}[c^*_{A1}(X_j,R_k,T') + c^*_{B1}(X_j,R_k,T')]\right] + B_{i,N_x+2} + \sum_{j=2}^{N_x+1} B_{i,j}c^*_{A1}(X_j,R_k,T')\right\}$$
$$+ \frac{\beta'}{G_1}\left\{\sqrt{\frac{\beta''}{\beta'}}I_{1,k}C'_{N_R+2,1} + \sum_{l=2}^{N_R+1}\left[J_{l,k}\left(\sqrt{\frac{\beta''}{\beta'}}C'_{1,1} - C_{N_R+2,N_R+2}\right) - I_{1,k}C_{l,N_R+2} + I_{l,k}C_{1,N_R+2}\right]c^*_{A1}(X_i,R_l,T')\right.$$
$$\left. + \sum_{l=2}^{N_{R'}+1}\sqrt{\frac{\beta''}{\beta'}}I_{1,k}C'_{l,1}\,c^*_{A2}(X_i,R'_l,T')\right\}$$

$$[11]\quad \left.\frac{dc^*_{B1}}{dT'}\right|_{X_i,R_k} = \beta\left\{-\frac{B_{i,1}}{A_{1,1}[1+\theta_{A/B}S_\lambda(T')]}\left[A_{1,N_x+2} + \sum_{j=2}^{N_x+1} A_{1,j}[c^*_{A1}(X_j,R_k,T') + c^*_{B1}(X_j,R_k,T')]\right] + \sum_{j=2}^{N_x+1} B_{i,j}c^*_{B1}(X_j,R_k,T')\right\}$$
$$+ \frac{\beta'}{G_1}\left\{\sum_{l=2}^{N_R+1}\left[J_{l,k}\left(\sqrt{\frac{\beta''}{\beta'}}C'_{1,1} - C_{N_R+2,N_R+2}\right) - I_{1,k}C_{l,N_R+2} + I_{l,k}C_{1,N_R+2}\right]c^*_{B1}(X_i,R_l,T') + \sum_{l=2}^{N_{R'}+1}\sqrt{\frac{\beta''}{\beta'}}I_{1,k}C'_{l,1}c^*_{B2}(X_i,R'_l,T')\right\} - \alpha c^*_{B1}$$

$$[12]\quad \left.\frac{dc^*_{A2}}{dT'}\right|_{X_i,R'_k} = \frac{\beta}{A_{1,1}}\left\{K_{i,N_x+2} + \sum_{j=2}^{N_x+1} K_{i,j}c^*_{A2}(X_j,R'_k,T')\right\} + \frac{\beta''}{G_1}\left\{L'_{N_{R'}+2,k} + \sum_{l=2}^{N_R+1} F'_{1,k}H_l c^*_{A1}(X_i,R_l,T') + \sum_{l=2}^{N_{R'}+1} L'_{l,k}c^*_{A2}(X_i,R'_l,T')\right\}$$

$$[13]\quad \left.\frac{dc^*_{B2}}{dT'}\right|_{X_i,R'_k} = \frac{\beta}{A_{1,1}}\left\{\sum_{j=2}^{N_x+1} K_{i,j}c^*_{B2}(X_j,R'_k,T') + \frac{\beta''}{G_1}\sum_{l=2}^{N_R+1} F'_{1,k}H_l c^*_{B1}(X_i,R_l,T') + \sum_{l=2}^{N_{R'}+1} L'_{l,k}c^*_{B2}(X_i,R'_l,T')\right\} - \alpha c^*_{B2}$$

The A_i, B_i, C_i, F_i, G_i, H_i, J_i, K_i, and L_i are discretization matrix elements which have been defined previously (15, 17).

The Jacobians of each of these expressions are

$$[14]\quad f_1 = \frac{\partial}{\partial c^*_{A_1}}\left(\frac{dc^*_{A_1}}{dT'}\right);\qquad f_2 = \frac{\partial}{\partial c^*_{B_1}}\left(\frac{dc^*_{B_1}}{dT'}\right)$$

$$f_3 = \frac{\partial}{\partial c^*_{A_2}}\left(\frac{dc^*_{A_2}}{dT'}\right);\qquad f_4 = \frac{\partial}{\partial c^*_{B_2}}\left(\frac{dc^*_{B_2}}{dT'}\right)$$

We then specify the two limiting cases at $S_\lambda(T') = 1$ (at the beginning of the experiment), and $S_\lambda(T') = 0$ (at the end of the experiment). Thus there are six total conditions to be treated by the iteration procedure described previously (14, 19) so that the optimum value of β for a given steplength is obtained.

Results and discussion

The program was first tested under conditions of semiinfinite linear diffusion and the resulting values of the current function

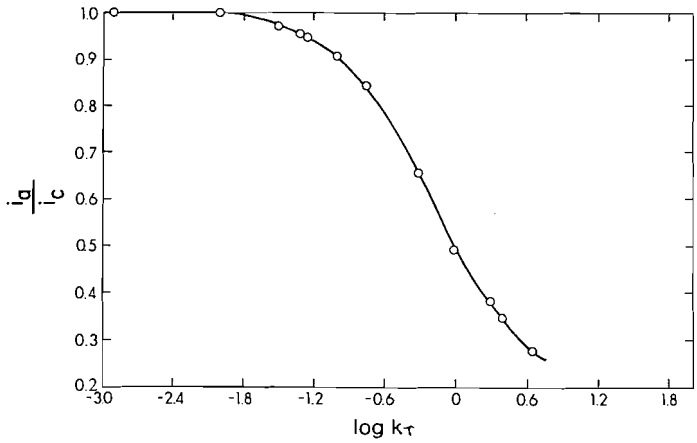

FIG. 1. Ratio of peak currents as a function of log ($k\tau$) curve from Nicholson and Shain; points calculated at $\beta' = 10^{-6}$ and β optimized at 0.01089.

$\chi(at)$ compared well with those of Nicholson and Shain (21) ($\chi(at) = 0.44627$ at $\beta' = 10^{-10}$, $\beta = 0.05$, and $\Delta E_p = 0.057$ V). Various combinations of α and switching potentials were used to vary the parameter log ($k\tau$) where τ is the time between E° and E_λ governed by the scan rate, and k is the homogeneous rate constant for the follow-up reaction. The results are shown in Fig. 1. This verifies the consistency of the model at low values of β'. For any value of β' chosen, the corresponding value of β is optimized by iteration and it makes little difference what original value of β is input since rapid convergence to the optimum value is manifested.

The general shape of the voltammograms may be predicted with reference to the factor β. When β is small, the corresponding value of L is large and the radius is small with respect to L. Thus the factor

$$[15] \quad \beta' = \left[\frac{D}{\left(\frac{nFv}{RT}\right) r_0^2}\right]$$

contributes more to the current function and we reach a steady state at faster times.

If, on the other hand, β is large then L is small relative to r_0 so that the spherical diffusion effects are less and more classical voltammogram is expected. The ratio $\sqrt{\beta/\beta'}$ equals r_0/L and the effect of this factor on the shape and magnitude of the current function are shown in Fig. 2. Curves *a* and *b* are calculated for the case when β is not optimized. Thus they have the appearance of voltammograms from microelectrodes. However, r_0 for curve *a* is 113 μm whereas for curve *c* is 9 μm ($D_0 = 10^{-6}$ cm^2/s, $v = 1$ V/s). The effect of optimizing the parameter β for curve *c* is the scaling down of the surrounding dimensions to accommodate the small radius. Thus the voltammogram has a classical shape. This does not occur physically and for very small radii a voltammogram of the form *a* is observed which can be easily simulated with the appropriate value of β.

Figure 3 shows the effect of β' on the current function. At small values of β' the classical value of 0.4463 is obtained. At large values there is an asymptotic approach to hemispherical diffusion values.

Anomalous forward/reverse peak current ratios have been observed at small hanging mercury drop electrodes. Beyerlein and Nicholson (7) have pointed out that these are caused by

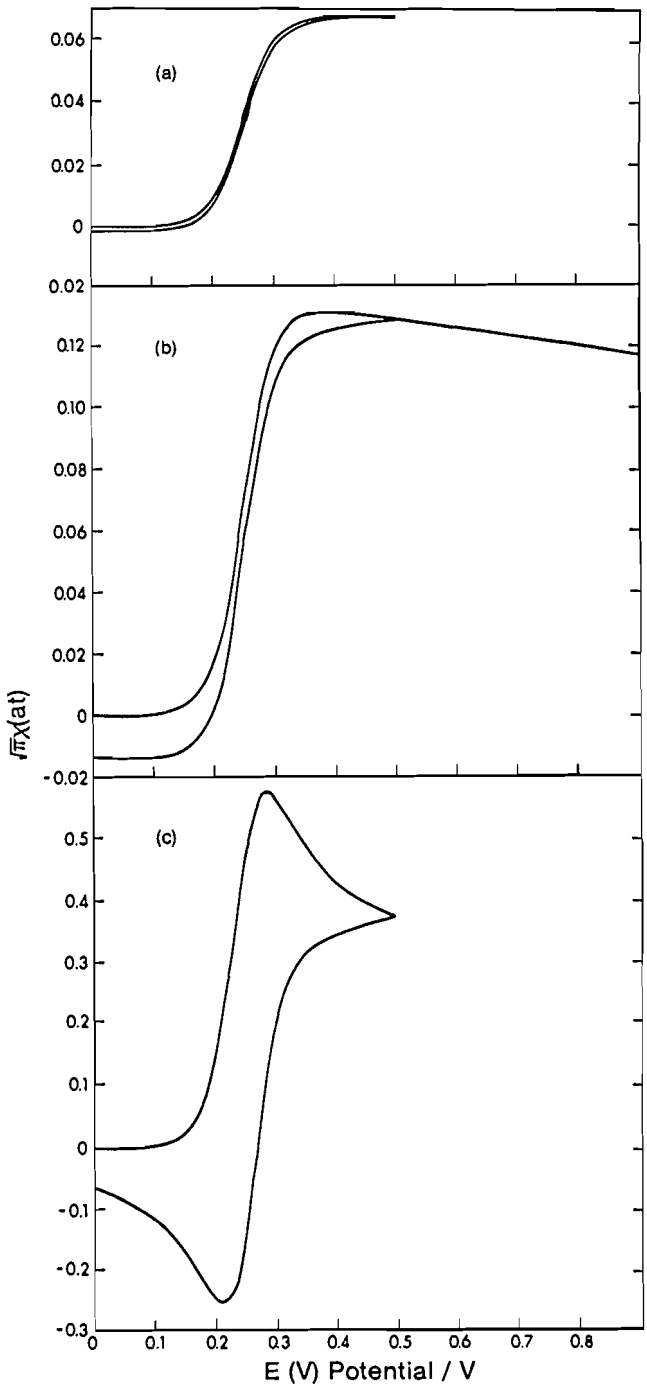

FIG. 2. Curve *a*: $\beta = 2.5 \times 10^{-6}$, $\beta' = 2 \times 10^{-4}$, $r_0/L = 0.112$. Curve *b*: $\beta = 10^{-5}$, $\beta' = 2 \times 10^{-4}$, $r_0/L = 0.223$. Curve *c*: $\beta = 0.0081$, $\beta' = 0.03162$, $r_0/L = 0.506$. (β optimized).

both sphericity and amalgam formation and have demonstrated the dependance of the magnitude on $\sqrt{\beta'}$. Guminski and Galus (8) developed an experimental equation for the resulting ratio

$$[16] \quad \frac{i_{pf}}{i_{pr}} = \left[1 + 3.2\sqrt{\frac{D_{red}(E_{pc} - E_\lambda)}{vr_0^2}}\right]$$

The spherical correction obviously becomes less at large drop sizes and/or high sweep rates.

Galus has presented a spherical correction equation for small planar disks (22)

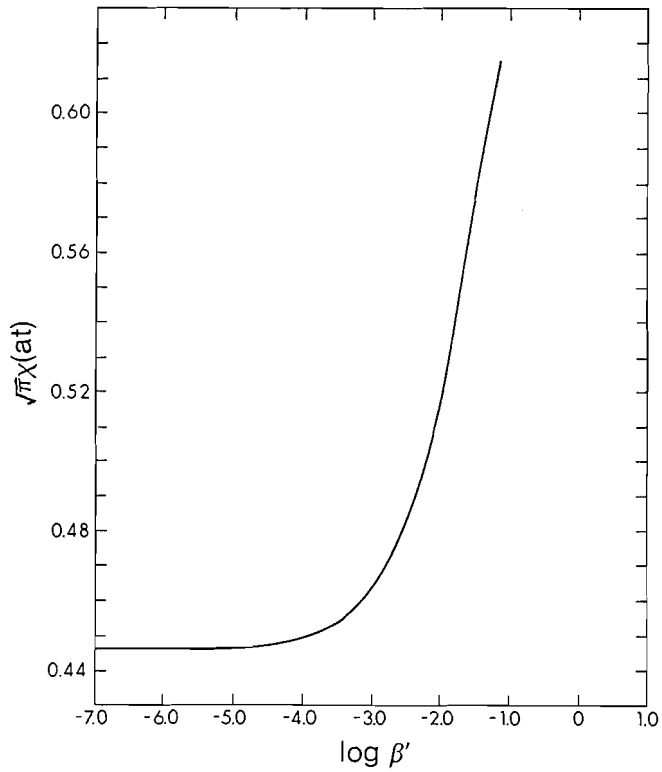

FIG. 3. Effect of β' on the magnitude of peak current function (β optimized).

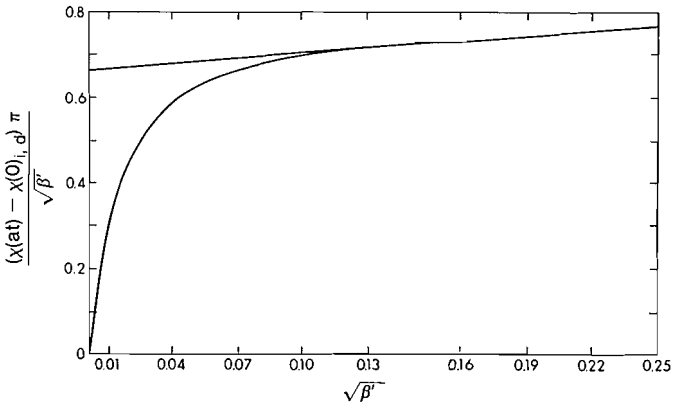

FIG. 4. Plot of $\pi(\chi - \chi_{id})/\sqrt{\beta'}$ against $\sqrt{\beta'}$ showing the transition between the two limiting cases of semi-infinite linear diffusion and hemispherical diffusion.

$$[17] \quad \frac{i_{pf}}{i_{pr}} = \{1 + Q'\sqrt{\beta'}\}$$

Q' was estimated as 0.92 by oxidizing ferrocyanide at a graphite paste planar disk electrode (r_0 = 81 μm). At low scan rates, however, there was no reverse current observable.

In the model presented herein for small planar disks there is no evidence for departure from the current ratio of unity due to edge effects. In practice, it is probably true that the small but not negligible charging current contributes to the observed results.

Beyerlein and Nicholson (7) have presented an equation for the current function at a hanging mercury drop electrode in terms of a linear combination of planar and spherical components:

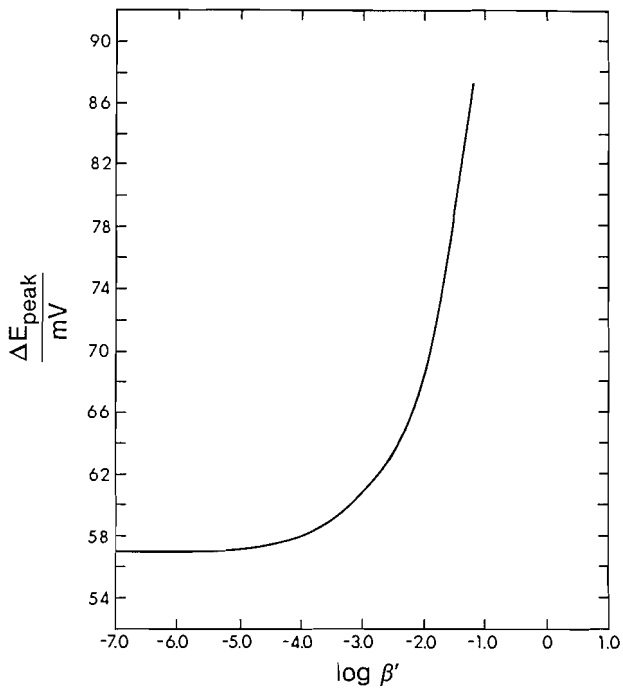

FIG. 5. Working curve for determining D from ΔE where $\beta' = D/ar_0^2$ ($a = nFv/RT$) (β optimized; T = 25°C).

$$[18] \quad \chi(at) = \chi(0)_{i,d} + A\beta' + B\sqrt{\beta'}$$

If the equation is rearranged, it is seen that a plot of

$$[19] \quad \frac{\chi(at) - \chi(0)_{i,d}}{\sqrt{\beta'}}$$

vs. $\sqrt{\beta'}$ should yield a straight line for a system having spherical diffusion contribution. It is seen in Fig. 4 that such a plot constructed with the present model leads to an intercept, when extrapolation is made from large β' values (small r_0). This intercept is equivalent to the value obtained by Beyerlein and Nicholson for a peak current function value. This indicates the model is correctly providing currents consistent with pure hemispherical diffusion at large values of β'.

Recently an expression for the current in the following form was proposed (23):

$$[20] \quad i(t) = i_{i,d}(t) + \frac{i_1(t)}{r_0} + \frac{i_2(t)}{r_0^2}t + \ldots.$$

the second term being found analytically in the case of the potential scan. The calculated value for B from the first two terms compares well with that of Beyerlein and Nicholson (7).

It is observed that, as different values of the integration stepwidth h were chosen, the product of the optimized value of β and h is a constant. The reason for this becomes clear as the following points are considered. We assume that the diffusion layer thickness δ

$$[21] \quad \delta^2 = \pi D\Delta t$$

has grown to some value after some time interval Δt. It is noted again that L^2 is related to δ^2 through the definition of β. Thus any change in Δt by a factor Q' implies a necessary $1/Q'$ factor change in β to preserve the relative values of δ and L. This, of course, is true only at the optimized β value for a given h. Thus if an optimized β, h pair is known, it is unnecessary to re-optimize β if a new value of h is used, or conversely, it is

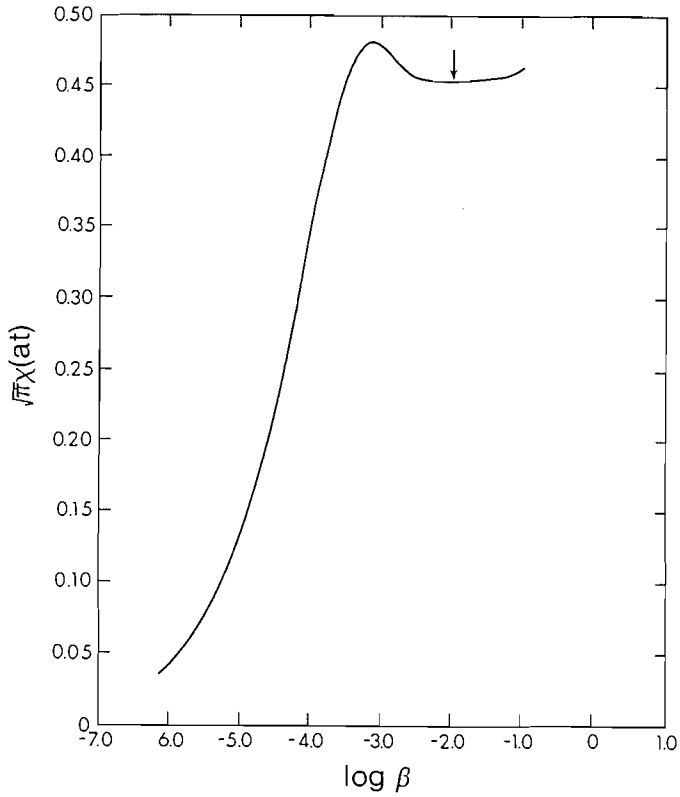

FIG. 6. The effect of changing the parameter β on the current function.

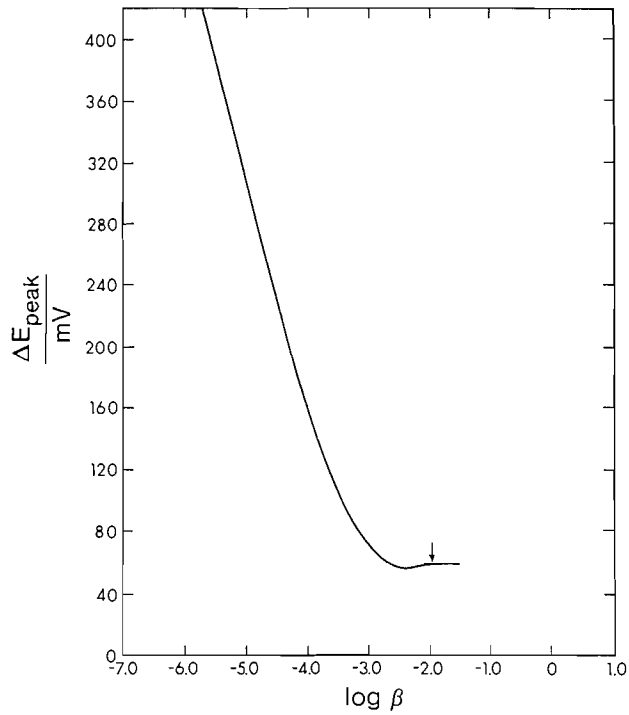

FIG. 7. The effect of changing β on the peak separation.

unnecessary to calculate a new h by trial and error if it is desired to use a specific value of β.

The model also provides a convenient method for obtaining diffusion coefficients or n values. Such a working curve is presented in Fig. 5. The predicted change in ΔE_p is plotted vs. log β′. The diffusion coefficient is then given by

$$[22] \quad D = \frac{\beta' n F v r_0^2}{RT}$$

where β′ is obtained at the observed value of ΔE_p on the working curve.

Figures 6 and 7 demonstrate the effect on the current function and peak separation of changing the value of the parameter β for a given value of β′. The optimized values of β are indicated.

On a synthétisé et caractérisé le ferène: le sel de (pyridyl-2)-3-bis-5,6-(furyl-2-acide sulfonique-5)-triazine-1,2,4-disodium monohydraté. On rapporte les résultats de l'étude de la formation d'un complexe avec le fer(II), parmi lesquels on retrouve les valeurs de λ_{max}, ϵ_{max} et log K.

[Traduit par le journal]

Introduction

Bidentate chelating agents containing the α-diimine or ferroin group have been used for many years as chromogenic reagents for the determination of iron and copper (1–5). A major step forward in the development of reagents of this type came with a discovery by Case and Smith and their respective coworkers (6–8). They found that the incorporation of phenyl groups in positions *para* to the ferroin group led to greatly enhanced absorption by the metal chelates, resulting in considerable improvements in the sensitivity of the resulting reagents. Following this discovery, the widely used reagents bathophenanthroline (6, 7), bathocuproine (9), terrosite (10), PPDT (11), and PDT (12) were introduced. These phenyl-substituted compounds and their metal chelates all suffer from the disadvantage of having very low solubilities in water. This makes them unsuitable for use in the rapid, highly automated procedures necessary for dealing with large numbers of samples.

The sulfonation of bathophenanthroline by Trinder (13) led to a water soluble derivative which retained the favourable chromogenic characteristics of the parent compound even after sulfonation. Subsequently, the sulfonated, water-soluble derivatives of bathocuproine (14), PDT (15), and terrosite (16, 17) have all been reported, as well as those of a series of new phenyl-substituted triazines recently synthesized by Case (18, 19). The chromophoric enhancement observed in the phenyl-substituted reagents is presumably a result of the phenyl groups acting in such a way as to favor the charge transfer process which causes the intense colors of the iron(II) and copper(I) complexes. This being the case, it was considered that the introduction of furyl groups into the chelating molecules might well lead to a similar chromophoric enhancement. The compound 3-(2-pyridyl)-5,6-bis(2-furyl)-1,2,4-triazine containing two furyl groups was therefore synthesized. Sulfonation of this triazine has led to the isolation of a new, highly sensitive and water-soluble colorimetric reagent for iron, the disodium salt of 3-(2-pyridyl)-5,6-bis(2-(5-furyl sulfonic acid))-1,2,4-triazine, hereafter referred to as Ferene (Fig. 1).

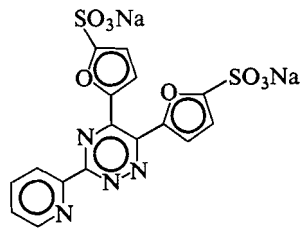

FIG. 1. Structure of Ferene.

Ferene reacts with iron(II) to form a stable, deep blue complex which is also very soluble in water. This new reagent constitutes an attractive alternative to the commonly used Ferrozine for the determination of serum iron.

Experimental

Synthesis of 3-(2-pyridyl)-5,6-bis(2-furyl)-1,2,4-triazine

To a stirred suspension of 16 g (0.84 mol) of furyl in 130 mL of isopropyl alcohol heated to 60°C, 13 g (0.96 mol) of picolinamidrazone (20) (called 2-pyridyl hydrazidine in the reference) was added portion-wise over a period of 5 min. The stirring at 60°C was continued for 1/2 h. The solid product obtained by filtration and washing with water was suspended in 140 mL of 0.06 *N* hydrochloric acid. After stirring for 2½ h the slurry was filtered. The product was washed with water, then with hexane, and was air dried. Melting point, 155–157°C. *Anal.* calcd. for $C_{16}H_{10}N_4O_2$: C 66.21, H 3.47, N 19.31; found: C 66.16, H 3.45, N 19.24.

Synthesis of the monosodium salt of 3-(2-pyridyl)-5,6-bis(2-(5-furyl sulfonic acid)-1,2,4-triazine

To 22 mL of 30% fuming sulfuric acid heated to 60°C, 16.5 g (0.57 mol) of the triazine was added portion-wise with stirring so that the temperature remained at 65 ± 3°C. The mixture was then warmed to 75°C for 3/4 h after which it was poured cautiously into 44 mL of stirred water. With the resulting solution at 60°C, 90 mL of 25% aqueous sodium chloride at the same temperature was added with stirring. After standing overnight under refrigeration, the solid product was collected by filtration, then washed with 3 × 35 mL of 10% aqueous sodium chloride and 2 × 35 mL of 70% aqueous ethanol, after which it was air dried.

Synthesis of the disodium salt of 3-(2-pyridyl)-5,6-bis(2-(5-furyl sulfonic acid)-1,2,4-triazine (Ferene)

The air-dried monosodium salt was suspended in 13 mL of water

and with stirring brought to pH 8.5 by careful addition of 50% aqueous sodium hydroxide. The mixture was warmed to 70°C, filtered, brought again to 70°C, and then 75 mL of boiling ethanol added. After standing overnight under refrigeration the product was collected by filtration and washed with small amounts of ethanol and methanol. Recrystallization by solution in two parts of hot water followed by addition of seven parts of boiling ethanol with subsequent refrigeration yielded 15.2 g of bright yellow crystalline Ferene. After drying for several hours at 110°C, Ferene was obtained as the yellow monohydrate. *Anal.* calcd. for $C_{16}H_8N_4O_8S_2Na_2 . H_2O$: C 37.51, H 1.97, N 10.93, S 12.51; found: C 37.41, H 1.94, N 10.83, S 12.32.

The ^1H nmr spectrum of Ferene shows absorptions typical of pyridine ring protons along with four other aromatic protons, in two coupled pairs. The narrow range spectrum shows the couplings to be 3.54 and 3.42 Hz, typical of 3–4 couplings in furans, but much larger than 2–3 couplings, or any cross-ring coupling. We therefore conclude that the sulfonation has taken place in the 2-positions of both furyl rings, as indicated in Fig. 1. This assignment is supported by the ^{13}C nmr spectrum, which shows absorptions due to four protonated furyl carbon atoms at between 110 and 120 ppm, indicating that the furyl protons occupy the 3- and 4-positions in each ring, and confirming that sulfonation has occurred in the 2-positions.

Characterization of the Ferene–iron(II) complex

Reagents

Stock iron solution — A typical stock iron solution (1.79×10^{-4} *M*) was prepared by taking 10 mL of an atomic absorption standard (1 mg/mL, Fisher Scientific Co.) and 50 mL of the reducing agent, and making up to 1 L with distilled water.

Iron complexing reagent — A typical stock Ferene solution (6.38×10^{-4} *M*) was prepared by dissolving 0.35 g of Ferene (Diagnostic Chemicals Limited) in distilled water, adding 50 mL of the acetate buffer, and making up to 1 L with distilled water.

Iron standards — The standards were prepared by making serial dilutions of the stock iron solution in 100 mL volumetric flasks topped to the mark with distilled water.

Acetate buffer — The acetate buffer was prepared by dissolving 61.2 g (1 mol) of acetic acid and 82.0 g (1 mol) of sodium acetate in distilled water, and making up to 1 L.

Reducing agent — A 10% solution of hydroxylamine hydrochloride was prepared by dissolving 100 g of the material in 900 mL of distilled water.

Apparatus

A Cary Model 210 spectrophotometer was used for the absorbance measurements; cells were 1 cm (TSL). A Fisher model 620 pH meter with glass and calomel electrodes was used for the pH measurements.

Determination of conditional formation constant

To determine the conditional formation constant of the Ferene–iron complex, two types of runs were carried out. In the first, the concentration of Ferene was varied while the concentration of iron was held constant, and in the second, the conditions were reversed.

In the series where the concentration of the ligand was varied, stock solutions of iron (4×10^{-4} *M*, containing 50 mL of reducing agent solution per L) and Ferene (5×10^{-4} *M*, containing 50 mL of acetate buffer solution per L) were prepared as described above. To each of a series of 100 mL flasks was added 10 mL of stock iron solution, followed by a varying amount (5 – 80 mL) of stock Ferene solution. The flasks were topped up to the mark with distilled water. A second series was run with 5 mL of iron solution, and 5–40 mL of Ferene solution in each flask, topped to the mark with distilled water.

In the runs where the iron concentration was varied, the stock Ferene solution was 1.2×10^{-3} *M* (with 50 mL acetate buffer solution per L) and the stock iron solution was 1.25×10^{-4} *M* (with 50 mL of reducing agent solution per L). To each 100 mL flask was added 10 mL of the stock Ferene solution, followed by a varying amount (10–80 mL) of the stock iron solution. The flasks were made up to the mark with distilled water.

All absorbance readings were taken after allowing 5 min for the colour of the complex to fully develop.

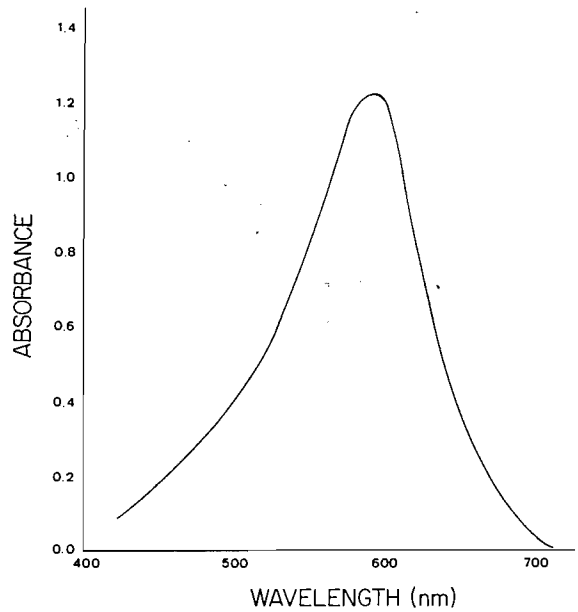

FIG. 2. Visible absorption spectrum of ferrous complex of Ferene.

Determination of log *K* (ie. log β_3) values were made as described by Gibbs (21).

Continuous variations study

A continuous variations series with a total concentration of 1.79×10^{-4} *M* was performed. Ferene and iron solutions of equal concentration (1.79×10^{-4} *M*) were combined such that the total volume was always 100 mL, i.e., 90 mL Ferene solution and 10 mL iron solution; 80 mL Ferene solution and 20 mL iron solution, etc. Again, a period of about 5 min was allowed to ensure full color development of the complex in each instance.

Variation of absorbance with pH

This was carried out in the manner described by Gibbs (21).

Several solutions, each having a total volume of 100 mL, were made up to contain 15 mL of 10^{-3} *M* Ferene, 5 mL of 5×10^{-4} *M* iron, 2 mL of 1 *M* reducing agent, and 5 mL of 2 *M* acetate buffer solution. The amount of acid (1 *M* HCl) or base (1 *M* NaOH) added to each flask was varied so as to give a broad range of pH values. The remainder of each flask was filled to the mark with distilled water. A period of 15 min was allowed for full color development of the various solutions, at which time absorbance readings were taken on the spectrophotometer at 593 nm.

Results and discussion

The visible absorption spectrum of the iron(II) complex of Ferene exhibits a single sharp peak with a maximum absorbance at 593 nm (Fig. 2). At this wavelength, the molar absorptivity is 34 500 L cm^{-1} mol^{-1} and the Beer–Lambert law is obeyed up to iron concentrations of 15 mg/L (a 1 mm cell was used for the highly concentrated solutions).

The Ferene molecule would be expected to behave as a bidentate chelating agent, probably via the pyridyl and 2-triazine nitrogen atoms, like the Ferrozine molecule (15, 21). However, with the presence of the oxygen atoms in the furyl rings, there is also the possibility that Ferene could behave as a planar tridentate chelating agent via the pyridyl nitrogen, the 4-triazine nitrogen, and a furyl oxygen atom. If this were to be the case, then a *bis* rather than a *tris* iron(II) complex would be formed. The results of the continuous variations study (Fig. 3) show that the maximum absorbance occurs at a point corresponding to a value of the mole fraction for iron of 0.25, indicating that a *tris* Ferene iron(II) complex is formed. This

confirms that Ferene behaves as a bidentate rather than a tridentate chelating agent under these conditions.

Spectrophotometric titration experiments were carried out with the iron concentration held at two different constant values, and also with the Ferene concentration held constant. The results of these experiments are summarized in Figs. 4 and 5. In each case, confirmation of the 3:1 Ferene:iron ratio present in the complex was obtained. Furthermore, since excess reagent was required for complete complex formation to be achieved, it was possible to evaluate *K*, the conditional formation constant, by straightforward means. The concentrations measured and the log *K* values obtained are given in Table 1. The mean log *K* value obtained was 14.9. This may be compared with the values reported for: bipyridine, 16.4–17.6; 1,10-phenanthroline, 20.2–21.5, and Ferrozine, 15.6 (21, 22).

The intense blue color of the Ferene–iron(II) complex was found to be fully developed within 3 min at 25°C, over a pH range of 2–7.5 in acetate buffer (Fig. 6). This is virtually the same range as reported for formation of the Ferrozine–iron(II) complex in acetate buffer (21). Thus it would seem that a pH range of 3–6 could be relied on to give the best test results.

Apart from iron, the only metal normally present in serum which forms a coloured complex with Ferene is copper. Inter-

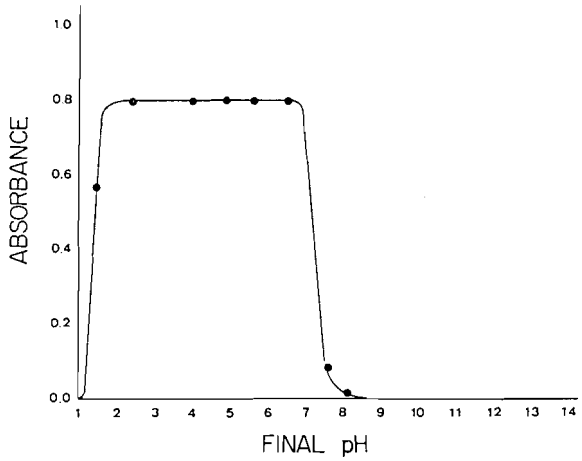

FIG. 6. Effect of pH on formation of ferrous complex of Ferene.

ference studies with Na^+, K^+, Ca^{2+}, Mg^{2+}, Hg^{2+}, and Pb^{2+} have shown that the presence of these ions, even in concentrations as high as 100 mg/L, has no effect on iron determinations using Ferene (26). Copper interference with Ferene is similar to that reported for Ferrozine (27) and may be suppressed in a similar way. The effects of copper interference can be almost entirely eliminated by the addition of thiourea, which preferentially binds the copper in a copper(I) complex (26).

Ferene is one of the most sensitive colorimetric reagents for iron(II) yet reported. Both the reagent itself and its iron(II) complex are highly water soluble, making Ferene very suitable for completely automated analyses on a practical scale. Two reports on such uses have already appeared (23, 24), and there will doubtless be many more in the future. Ferene has been used as the basis of a kit for determination of serum iron since 1979 (25).

J. ZUKERMAN-SCHPECTOR, E. E. CASTELLANO, G. OLIVA, A. C. MASSABNI, and A. DERBLI PINTO. Can. J. Chem. **62**, 725 (1984).

The crystal structures of the title compounds have been determined from diffractometric X-ray data and refined by full-matrix least-squares to final *R* factors of 0.057 and 0.071 for the oxalic and perchloric adducts respectively.

The space groups and cell dimensions are: (oxalic) $C2/c$, $a = 16.516(3)$, $b = 11.685(2)$, $c = 12.587(3)$ Å, $\beta = 107.11(2)°$ with $Z = 4$; (perchloric) *Pbca*, $a = 16.204(3)$, $b = 15.329(6)$, $c = 10.296(3)$ Å with $Z = 8$.

In both structures the complex is stabilized by a strong hydrogen bond between the N(2) of the 1-phenyl-3,5-dimethylpyrazole (PDMP) group and an oxygen of the acid. In the oxalic adduct the PDMP group is neutral and the N(2) atom acts as a proton acceptor, while in the perchloric complex the PDMP group is positively charged with the N(2) atom acting as a proton donor.

J. ZUKERMAN-SCHPECTOR, E. E. CASTELLANO, G. OLIVA, A. C. MASSABNI et A. DERBLI PINTO. Can. J. Chem. **62**, 725 (1984).

On a déterminé les structures cristallines des composés mentionnés dans le titre en faisant appel à des données de diffraction de rayons-X affinées par le méthode des moindres carrés (matrice complète) jusqu'à des valeurs finales de *R* de 0,057 et 0,071 respectivement pour les adduits oxalique et perchlorique.

Les groups d'espace et les dimensions cellulaires sont: (oxalique) $C2/c$, $a = 16,516(3)$, $b = 11,685(2)$ et $c = 12,587(3)$ Å, $\beta = 107,11(2)°$ avec $Z = 4$; (perchlorique) *Pbca*, $a = 16,204(3)$, $b = 15,329(6)$ et $c = 10,296(3)$ Å avec $Z = 8$.

Dans chacune des structures, le complexe est stabilisé par une liaison hydrogène forte entre le N(2) du groupement phényl-1 diméthyl-3,5 pyrazole (PDMP) et un oxygène de l'acide. Dans l'adduit oxalique, le groupement PDMP est neutre et l'atome N(2) agit comme accepteur de proton alors que dans le complexe perchlorique le groupement PDMP est chargé positivement avec un atome N(2) agissant comme donneur de proton.

Introduction

The structure of 1-phenyl-3,5-dimethylpyrazole (PDMP) has been determined in some metal complexes (1–4) where it appears as a neutral group. In the adduct with nitric acid (5) it has been found to be positively charged, forming a strong ionic complex with the nitrate anion. In this system, the ions are hydrogen-bonded, with the N(2) atom of the PDMP group acting as a proton donor and one of the anion oxygens acting as acceptor.

When complexed with different acids, it is conceivable that the net charge of the PDMP group could depend on the ionic strength of the acid, i.e. that the N(2) atom may behave as a donor or as an acceptor in the hydrogen bonding interactions. To investigate this point, the crystal structure determination of the title compounds, in which PDMP has been complexed with a strong and a weak acid, has been undertaken.

Experimental

Synthesis

$(PDMP)_2 . C_2O_4H_2$

A solution of oxalic acid in ethanol was added to a hot solution of PDMP in ketone so that the final molar proportion was 2:1 (base:acid). The solution was stirred for 10 min and after cooling a small volume of petroleum ether (bp 60–80°C) was added. Crystals were obtained by slow evaporation of the solution at room temperature.

$[PDMPH]^+ClO_4^-$

A solution of perchloric acid was added to a boiling solution of PDMP in ketone to obtain a final molar proportion of 1:1. The solution was continuously stirred and evaporated to half its original volume. The same volume of petroleum ether (bp 60–80°C) was then added. Crystals were obtained by slow evaporation of this solution at room temperature.

Structural solution and refinements

Crystal data are given in Table 1. Intensities were measured on an Enraf-Nonius CAD-4 diffractometer by the $\omega-2\theta$ scan technique, with scan rates determined from fast prescans on each reflection, using graphite monochromated MoKα ($\lambda = 0.71073$ Å) radiation. The intensities of two standard reflections were essentially constant over the duration of both experiments. Data were corrected for Lorentz and polarization effects. The perchlorate data were also corrected for absorption by the method of Busing and Levy (7) (minimum and maximum transmission factors are 0.9737 and 0.9591).

The $(PDMP)_2 . C_2O_4H_2$ structure was solved using MULTAN-80 (6) and the $[PDMPH]^+ClO_4^-$ structure with SHELX-76 (7). Both structures were refined by full-matrix least-squares with the SHELX-76 (7) system of programs. The usual sequence of isotropic and anisotropic refinement, using unit weights, was followed. After convergency all H-atoms were located from a difference Fourier synthesis and assigned, in both cases, a common isotropic temperature factor of 5.0 Å^2. Further anisotropic refinement for the non-hydrogen atoms and with the methyl groups set as rigid groups was carried out. During the process of refinement of the $[PDMPH]^+ClO_4^-$ considerable apparent thermal motion of the O atoms of the perchlorate ion was revealed. The final weighting schemes used are described in Table 1. In both

cases refinement was considered complete when the shifts/esd ratios were less than 0.01. Bonded H-atom scattering factors (8) and complex neutral scattering factors (9, 10) for the remaining atoms were employed. A final difference Fourier map showed no features of chemical significance. Measured and calculated structure factors, anisotropic thermal parameters for non-hydrogen atoms and H-atom parameters have been deposited.[1]

Atomic coordinates, together with calculated isotropic temperature factors, are given in Tables 2 and 3, where the expression for B_{iso} is of the form:

$$B_{iso} = \frac{1}{3}\sum_{ij} T_{ij} B_{ij}$$

where T_{ij} are the elements of the metric tensor and B_{ij} are the elements of the thermal tensor usually obtained by least-squares refinement (11).

Discussion

The oxalic acid molecule is sited on a center of symmetry; its crystallographic independent moiety and a neighbour PDMP group are depicted in Fig. 1, which also shows intramolecular bond distances and atomic numbering. Angles between non-hydrogen bonded atoms are given in Table 4. The phenyl and pyrazole rings and the COOH group are planar to within experimental accuracy. Least-squares planes referred to the conventional orthogonalized coordinates; deviations of atoms from the planes and dihedral angles are given in Table 5. The OH group is in the *syn*-planar conformation; the overall geometry of the acid is in good agreement with the averages reported in an exhaustive study of carboxylic acids made by Leiserowitz (12).

Even though corrected for absorption, the perchlorate adduct

O(3)—Cl—O(4)	—	111.7(7)

data did not allow a structure analysis as precise as that of the previous structure.This is due to a somewhat high thermal disorder, as shown by the oxygen's *B* values given in Table 3 and by the smaller number of independent observed reflections, with the consequence that the standard deviations of bond distances and angles are rather large, as expected after Cruickshank (13). The perchlorate complex is depicted in Fig. 2, which also shows intramolecular bond distances and atom labeling. Angles between non-hydrogen bonded atoms are given in Table 4. The phenyl and pyrazole rings are planar, to within experimental accuracy, as can be seen in Table 5. The perchlorate anion is in an approximate tetrahedral configuration with a mean C—O distance of 1.36 Å, somewhat shorter than expected (14), due to the fact that the high apparent thermal motion causes the distance between the mean atomic positions to be less than the corresponding mean interatomic separation, which is the quantity of chemical significance (15).

In both structures the complex is stabilized by a strong hydrogen bond. The relevant parameters are given in Table 6. It can be seen from this table that in the oxalic complex, the N(2) atom acts as a proton acceptor while in the perchlorate complex it acts as a donor. This fact is reflected in the geometric configuration of the pyrazole ring. In the oxalic case the C(2)—C(3) distance is shorter than the C(1)—C(2) as expected in neutral pyrazole (1, 16, 17). In the perchlorate case where the two nitrogen atoms behave as pyrrolic, the C(2)—C(3) distance is essentially identical to the C(1)—C(2) as it was found in $[PDMPH]^+NO_3^-$(5). As has been pointed out (5), this is to be expected due to the fact that the dihedral angle (56.2° in the present case) between benzene and pyrazole rings does not favour a strong $\pi-\pi$ interaction between them.

Kinetics and mechanism of disproportionation and ferricyanide oxidation of the 10-methylacridinium cation in aqueous base

JOHN W. BUNTING AND GLENN M. KAUFFMAN[1]
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received October 5, 1983

JOHN W. BUNTING and GLENN M. KAUFFMAN. Can. J. Chem. **62**, 729 (1984).

The kinetics of disproportionation and ferricyanide ion oxidation of the 10-methylacridinium cation have been measured spectrophotometrically over the pH range 9–14 in 20% CH_3CN – 80% H_2O (v/v) and ionic strength 1.0 at 25°C. Disproportionation is kinetically second-order in total acridine species. The pH–rate profile is consistent with the rate-determining reaction of one acridinium cation with the pseudobase alkoxide anion derived from a second acridinium cation. Ferricyanide ion oxidation is kinetically first-order in each of ferricyanide ion and total acridine species. The pH–rate profile requires three distinct pathways for the ferricyanide ion oxidation of the 10-methylacridinium cation. For pH < 9.7, rate-determining attack of ferricyanide ion on the neutral pseudobase predominates, while for pH > 12.8 the predominant oxidation pathway involves reaction of ferricyanide ion with the pseudobase alkoxide ion. Between pH 9.7 and 12.8, the major oxidation pathway involves initial disproportionation of the acridinium cation followed by ferricyanide ion oxidation of the 9,10-dihydro-10-methylacridine product. This latter route accounts for a maximum of 69% of the total ferricyanide ion oxidation at pH 11.1.

JOHN W. BUNTING et GLENN M. KAUFFMAN. Can. J. Chem. **62**, 729 (1984).

Faisant appel à une méthode spectrophotométrique et opérant à 25°C, à une force ionique de 1,0 et à des pH allant de 9 à 14 dans des solutions à 20% (v/v) d'acétonitrile dans l'eau, on a mesuré les cinétiques de disproportionation et d'oxydation par l'ion ferricyanure du cation méthyl-10 acridinium. La disproportionation est cinétiquement du deuxième ordre en espèces acridines totales. Le profil de la courbe pH/vitesse est en accord avec une réaction impliquant, comme étape déterminante, la réaction d'un cation acridinium avec un anion alcoolate pseudobase qui serait dérivé d'un deuxième cation acridinium. L'oxydation par l'ion ferricyanure est du premier ordre à la fois en ion ferricyanure et en espèces acridines totales. Le profil de la courbe pH/vitesse requiert trois voies distinctes pour l'oxydation du cation méthyl-10 acridinium par l'ion ferricyanure. A des pH < 9,7, l'étape déterminante implique principalement l'attaque d'un ion ferricyanure sur une pseudobase neutre alors qu'à des pH > 12,8, la voie d'oxydation prédominante implique une réaction de l'ion ferricyanure sur un ion alcoolate de la pseudobase. A des pH allant de 9,7 à 12,8, la voie majeure d'oxydation implique une disproportionation initiale du cation acridinium qui est suivie par une oxydation, par l'ion ferricyanure, de la dihydro-9,10 méthyl-10 acridine qui est produite. A un pH de 11,1, cette dernière voie rend compte de 69% de l'oxydation totale due à l'ion ferricyanure.

[Traduit par le journal]

Heteroaromatic cations have long been known to undergo both a disproportionation reaction and oxidation by ferricyanide ion in basic aqueous solutions (1). The ferricyanide oxidation is of some synthetic utility and has become known as the Decker Oxidation (2). Although both of these reactions have been known for over 90 years, it is only recently that there has been any attempt to characterize their mechanisms via kinetic studies. A detailed kinetic study of the ferricyanide ion oxidation is now available for 5-nitroisoquinolinium cations (3), while the disproportionation mechanism has been investigated via a "crossed disproportionation" involving two isoquinolinium cations bearing different substituents (4). For both disproportionation and ferricyanide oxidation, it has been concluded that the rate-determining transition state involves hydride abstraction from the alkoxide ion that is obtained upon deprotonation of the appropriate isoquinoline pseudobase species.

Acridinium cations are of some historical interest in this area, since they were among the first group of heteroaromatic cations for which these two reactions were recognised (5–7). Furthermore, the pseudobases derived from acridinium cations are formally 1,4-dihydropyridine derivatives rather than the 1,2-dihydropyridines that are produced upon pseudobase formation from isoquinolinium cations. Acridinium cations therefore provide a suitable system for further exploring the generality of the mechanisms of disproportionation and ferricyanide oxidation that have been indicated for the isoquinolinium cations. For acridinium cations, disproportionation (eq. [1]) occurs readily in dilute aqueous base (7), and so this system provides the opportunity for a mechanistic comparison of a true disproportionation with the "crossed disproportionation" that is currently the best studied example of this class of reaction (4). Clark and Bakavoli (8) have shown by deuterium labelling experiments that disproportionation of the 10-methylacridinium cation occurs via direct transfer of the hydrogen nucleus between the C-9 atoms of the two acridine moieties without exchange with solvent protons.

[1] 
In the current work we report a detailed kinetic study of the disproportionation (eq. [1]) and ferricyanide oxidation (eq. [2]) of the 10-methylacridinium cation over the range pH 9–14. In general we find that the mechanistic details of these reactions in the acridine system are analogous to those deduced earlier in the 5-nitroisoquinoline series. However, in the more weakly basic solutions, the reduction of ferricyanide ion may also proceed via the reaction of ferricyanide with 9,10-dihydro-10-methylacridine (10-methylacridan) which is a product of the disproportionation reaction.

[2] 
Experimental

10-Methylacridinium chloride

Acridine was methylated with dimethyl sulfate, and the methylsulfate salt was converted to the chloride as described by Albert (9).

Reagents and solvents

The following chemicals were all used in ACS Reagent Grade purity: $K_3Fe(CN)_6$, $K_4Fe(CN)_6$, KCl, KOH, Na_2CO_3, $Na_2B_4O_7$, HCl, and CH_3CN. All kinetic studies were carried out in 20% CH_3CN − 80% H_2O (v/v) adjusted to ionic strength 1.0 (KCl + buffer). Standard solutions of KOH were used as buffers for pH > 11, while lower pH buffers were prepared by appropriate neutralization of Na_2CO_3 or $Na_2B_4O_7$ solutions with hydrochloric acid. It was noted that pH-meter calibration with a standard aqueous pH 10 buffer solution led to pH readings that were uniformly 0.28 pH units too high relative to the known hydroxide ion concentration for standard KOH solutions (pH 11−13) in this mixed solvent reaction medium. In order to provide a uniform pH scale for carbonate and borate buffers and standard hydroxide solutions we have therefore chosen to calibrate the pH meter using a reading of 9.72 for the standard aqueous pH 10 buffer.

Kinetic studies

All kinetic studies were carried out spectrophotometrically in the above standard reaction medium at 25°C, by recording the time-dependence of the absorbance at 409 nm on a Cary 210 spectrophotometer in cells of either 1-cm or 1-mm path length. Extinction coefficients measured for the various species in this solvent are, 10-methylacridinium cation: 3700 M^{-1} cm^{-1}; ferricyanide ion: 1000 $M^{-1}cm^{-1}$; 10-methyl-9-acridone: 8300 $M^{-1}cm^{-1}$; all other species: 0. Absorbance vs. time data were recorded over 75% (very slow reactions) to greater than 90% reaction, and were digitized into approximately 20 data points and fitted to standard second-order kinetic equations. Such data were linear over the above reaction regions (see Fig. 2), although the ferricyanide ion oxidations showed some curvature in these fits at very long reaction times due to a slow decomposition of ferricyanide ion in very basic solutions. Second-order rate constants were evaluated from least-squares slopes of these kinetic plots.

Results

Disproportionation

The time-dependence of the electronic absorption spectrum of the 10-methylacridinium cation at pH 12 in 20% CH_3CN − 80% H_2O is shown in Fig. 1. Other workers (7, 8) have isolated 10-methyl-9-acridone and 9,10-dihydro-10-methylacridine (10-methylacridan) as the only products obtained from basic aqueous solutions of this cation. The spectral changes observed in Fig. 1 are quite consistent with this result. At pH 12, the 10-methylacridinium cation (pK_{R^+} = 10.01 in aqueous solution at 25°C (10)) is present essentially completely as its pseudobase, 9,10-dihydro-9-hydroxy-10-methylacridine, having λ_{max} = 280 nm, which corresponds to the initial spectrum in Fig. 1. The final spectrum in Fig. 1 is similar, but not identical, to that of 10-methyl-9-acridone in this solvent (λ_{max}(log ϵ) = 257(4.79), 391(3.92), 409(3.92)), but the intensity of each of these maxima corresponds to only 0.5 mole of acridone product per mole of acridinium cation initially present, consistent with the stoichiometry of eq. [1]. The other product, 9,10-dihydro-10-methylacridine has λ_{max}(log ϵ) = 286(4.05) in the current solvent. This peak is so much weaker than that at 257 nm in the acridone spectrum that it appears only as a shoulder in the vicinity of 280 nm in the product spectrum. We have shown that the disproportionation product spectrum is identical with that of a genuine 1:1 mixture of these two reaction products.

Rates of acridine pseudobase disproportionation were measured spectrophotometrically from the time-dependent increase in absorbance at 409 nm which is a measure of 10-methyl-9-acridone product formation. Such absorbance increases proved to be kinetically second-order (Fig. 2) in the total concentration of reactant acridine species for all solutions in the pH range 9−14. Second-order rate constants (k_{dis}) are independent of total acridine species concentration (Table 1).

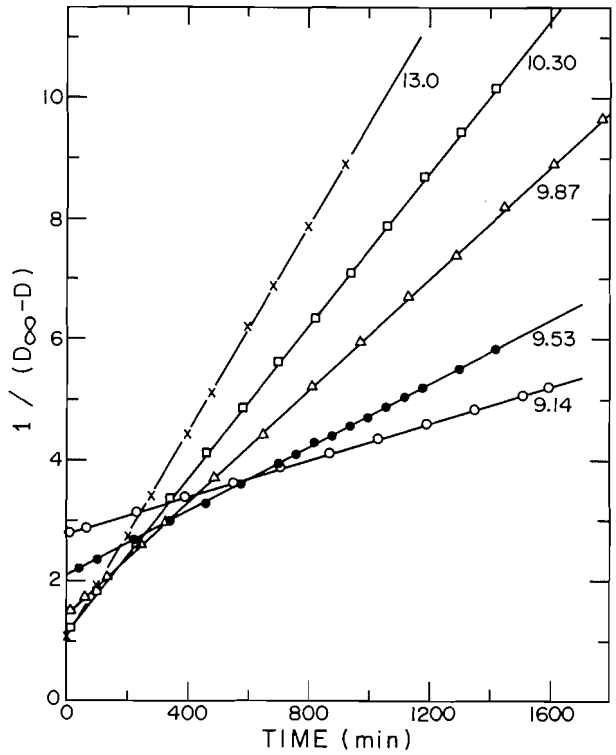

FIG. 2. Second-order kinetic plots for disproportionation of the 10-methylacridinium cation (0.25 mM) at various pH as shown. D represents absorbance at time t during the course of the reaction, and D_∞ is the absorbance of the product; all data at 409 nm. Variation in the ordinate intercept arises from differing cation/pseudobase ratios at low pH.

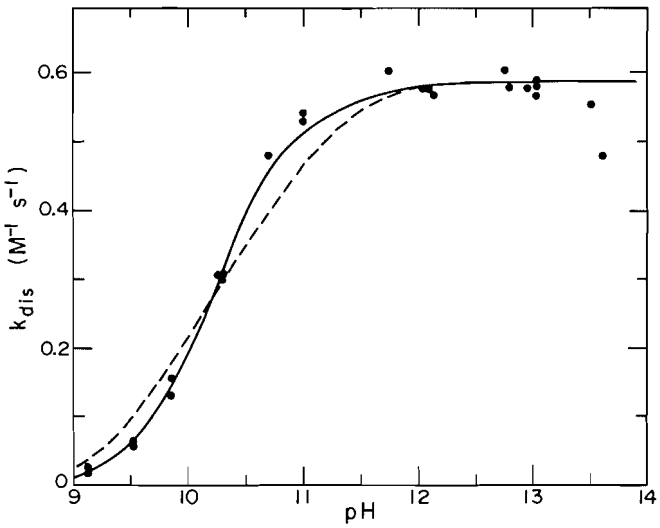

FIG. 3. The pH-dependence of k_{dis}. Broken line represents a titration curve for pK 10.3. Solid line calculated according to eq. [5] using the parameters in the text.

The pH-dependence of these second-order rate constants is displayed in Fig. 3, and suggests that the pseudobase species is more reactive towards disproportionation than the acridinium cation. However, the apparently sigmoidal curve in the region pH 9–12 is not simply a titration curve of an acid of pK 10. Attempts to fit these data to a titration curve give the best fit indicated by the broken line in Fig. 3 which is based on an acid ionization of pK 10.3. This broken line is, at best, a poor fit to the data. Furthermore, since the reaction is kinetically second-order in acridine species, any simple interpretation in terms of the pseudobase as the reactive species would require construction of a mechanism in which two molecules of the pseudobase are involved in (or appear prior to) the rate-determining transition state. We have been unable to conceive of any such disproportionation mechanism that would be chemically reasonable.

In an earlier study (4) of a "crossed disproportionation", it was shown that the alkoxide ion that is derived from the pseudobase of the 2-benzyl-5-nitroisoquinolinium cation acts as hydride donor towards the 2-methylisoquinolinium cation. An analogous mechanism can be postulated in the current 10-methylacridinium cation disproportionation. Thus, a rate-determining reaction of the pseudobase alkoxide ion **2** with acridinium cation would be consistent with the overall kinetically second-order reaction that is observed. Such a mechanism would have the rate law:

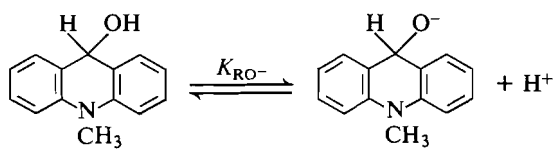
$$[3] \quad d[P]/dt = k_1[AO^-][A^+] = k_{dis}[A_T]^2$$

where $[A_T]$ represents the total concentration of all reactant acridine species, and A^+ and AO^- represent the acridinium cation and pseudobase alkoxide ion respectively. Thus:

$$[4] \quad k_{dis} = \frac{k_1}{(1 + [H^+]/K_{RO^-} + [H^+]^2/K_{R^+}K_{RO^-})(1 + K_{R^+}/[H^+] + K_{R^+}K_{RO^-}/[H^+]^2)}$$

where K_{RO^-} represents the acid ionization constant of the pseudobase **1** to give its alkoxide ion conjugate base **2**.

Equation [4] predicts that k_{dis} should pass through a maximum value at pH = $(pK_{R^+} + pK_{RO^-})/2$. The pH profile in Fig. 3 does seem to indicate that k_{dis} is decreasing in the most basic solutions that are readily investigated. However, it should be noted that data at pH > 13.5 may possibly be influenced by specific ion effects as chloride ion is replaced by hydroxide ion



1 **2**

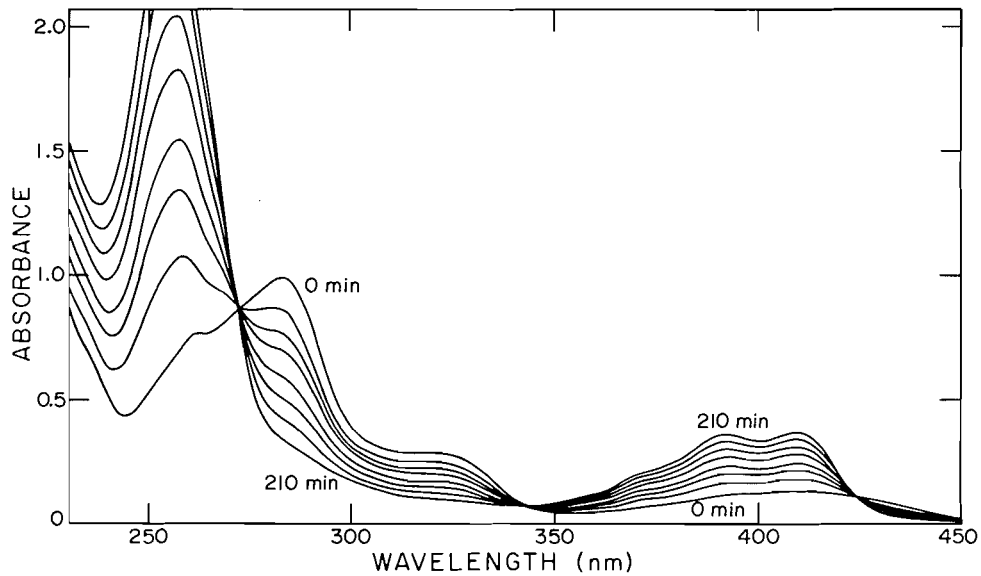


FIG. 4. Reaction of ferricyanide ion (1.0 mM) with the 10-methylacridinium cation (0.5 mM) at pH 13.0 (1-mm cell). Spectra determined at: 0, 10, 20, 30, 50, 80, 120, 210 minutes.

in order to maintain constant ionic strength in these basic solutions.

The pseudobase **1** is a secondary alcohol containing no strongly acidifying substituents. Thus pK_{RO^-} is certainly expected to be greater than 14. Takahashi *et al.* (11) have estimated that diphenylmethanol (benzhydrol) should have pK_a = 15.34. Alternatively, suitable modification of the dependence of pK_a on σ^* reported by Ballinger and Long (12) for primary alcohols allows an estimate of pK_a = 14.9 for benzhydrol. These values are in reasonable agreement and should be reasonably close to the pK_{RO^-} value for the pseudobase **1**. Thus the assumption $K_{RO^-} \ll [H^+]$ should be valid throughout the pH range in Fig. 3. Under this assumption, eq. [4] becomes:

$$[5] \quad k_{dis} = \frac{k_1 K_{RO^-}}{[H^+](1 + [H^+]/K_{R^+})(1 + K_{R^+}/[H^+])}$$

When the data in Fig. 3 are fitted to eq. [5] by an iterative curve-fitting procedure, the parameters $k_1K_{RO^-}$ = 8.0 (± 0.2) × 10^{-11} s^{-1} and K_{R^+} = 1.35 (± 0.04) × 10^{-10} M are obtained. This latter parameter corresponds to pK_{R^+} = 9.87 and is in reasonable agreement with pK_{R^+} = 10.01 reported for this cation in aqueous solution at ionic strength 0.1 (10). The curve in Fig. 3 is drawn using eq. [5] and these parameters which produce a reasonable fit to the experimental data as judged by an average deviation of only 5% between calculated and experimental data points. As a further test of these parameters it can be noted that for $[H^+] \ll K_{R^+}$, eq. [5] simplifies to $k_{dis} = k_1K_{RO^-}/K_{R^+}$. This condition certainly holds for pH 12–13.5, for which k_{dis} appears to be pH-independent (Fig. 3). The average experimental value of k_{dis} in this region is 0.58 ± 0.02 which is in good agreement with the value of 0.59 calculated from the ratio of the above two parameters.

Ferricyanide oxidation

The time-dependence of the electronic absorption spectrum of a mixture of 10-methylacridinium cation and potassium ferricyanide in 1:2 molar ratio (i.e. stoichiometric ratio according to eq. [2]) at pH 13 is shown in Fig. 4. The final spectrum shown is essentially that of 10-methyl-9-acridone at the same concentration as the original acridinium cation. Ferrocyanide ion, the other reaction product, absorbs only weakly in this spectral region.

Rates of ferricyanide ion oxidation of the 10-methylacridinium cation were evaluated at 409 nm and proved to be kinetically first-order in each of ferricyanide ion and total acridine reactant species present. Second-order rate constants (k_{ox}) at several concentrations of each species in stoichiometric ratio are shown in Table 2. These rate constants appear to be unaffected by the presence of significant initial concentrations of ferrocyanide ion (Table 2). The pH–rate profile for k_{ox} is shown in Fig. 5.

In the region pH 9–12.5, k_{ox} for ferricyanide ion oxidation in Fig. 5 is of similar magnitude, although not identical, to k_{dis} for the disproportionation reaction in Fig. 3. Thus in this region the disproportionation reaction competes with the ferricyanide ion oxidation of the 10-methylacridinium cation. One of the products of disproportionation, namely 10-methyl-9-acridone, is identical to the ferricyanide ion oxidation product, and we have observed that the second disproportionation product, 9,10-dihydro-10-methylacridine, is itself readily susceptible to ferricyanide ion oxidation. We will report later on the kinetics of this latter oxidation which formally regenerates the acridinium cation. Thus the sequence of reactions shown in Scheme 1 exists.

The overall stoichiometry of the combined reactions in Scheme 1 is identical to that shown in eq. [2] for the usually assumed mechanism of direct ferricyanide ion attack upon the pseudobase. Provided the ferricyanide ion oxidation of 9,10-dihydro-10-methylacridine is faster than the rate of disproportionation, the overall rate of ferricyanide oxidation via these two pathways is then given by:

$$[6] \quad d[P]/dt = k_{dis}[A_T]^2 + k_{Fe}[Fe(CN)_6^{3-}][A_T]$$

For stoichiometric ratio of reactants, $[A_T] = [Fe(CN)_6^{3-}]/2$, and:

$$[7] \quad d[P]/dt = (k_{dis}/2 + k_{Fe})[Fe(CN)_6^{3-}][A_T] = k_{ox}[Fe(CN)_6^{3-}][A_T]$$

Thus:

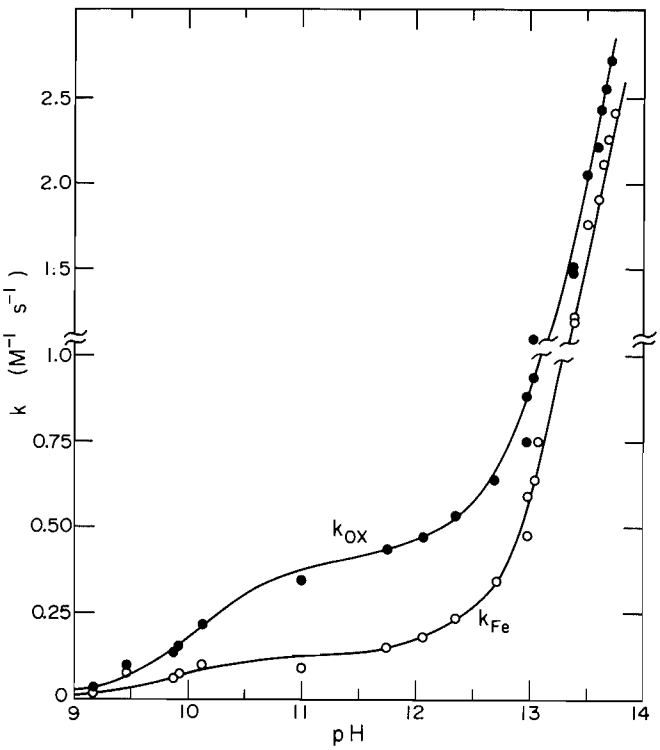

FIG. 5. The pH-dependence of k_{ox} and k_{Fe}. The k_{ox} curve is calculated as $k_{Fe} + k_{dis}/2$ using eqs. [5] and [11] and the parameters in the text. The k_{Fe} data points are calculated from eq. [8], while the k_{Fe} line is calculated from eq. [11].

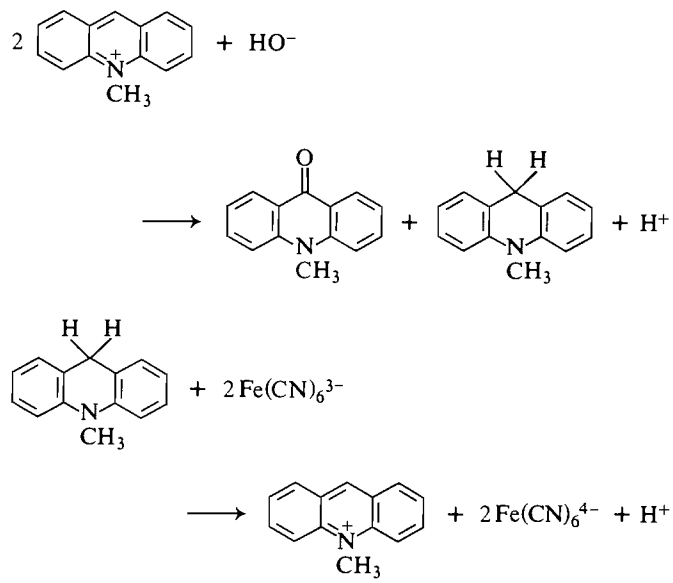
$$[8] \quad k_{Fe} = k_{ox} - k_{dis}/2$$

The pH-dependence of k_{Fe} calculated from eq. [8], making use of experimental values of k_{ox} and values of k_{dis} calculated from eq. [5], is included in Fig. 5. In the region pH 9−10, k_{ox} is larger than k_{dis}, and so it is clear that the pathway shown in Scheme 1 cannot account for the complete rate of ferricyanide ion oxidation of the 10-methylacridinium cation in this region, nor in the region pH 10−12 where k_{Fe} is smaller than the rate of disproportionation, but is not insignificant. Above pH 12, k_{Fe} begins to increase dramatically with increasing pH, with the rate of ferricyanide ion oxidation becoming much faster than the rate of disproportionation in the most basic solutions.



SCHEME 1

The pH-dependence of k_{Fe} in Fig. 5 suggests that direct ferricyanide oxidation can occur either via the pseudobase (**1**) or its conjugate base alkoxide ion (**2**). Thus:

$$[9] \quad d[P]/dt = k_2[Fe(CN)_6^{3-}][AOH] + k_3[Fe(CN)_6^{3-}][AO^-] = k_{Fe}[Fe(CN)_6^{3-}][A_T]$$

Therefore, using K_{R^+} and K_{RO^-} as defined above:

$$[10] \quad k_{Fe} = \frac{k_2 + k_3K_{RO^-}/[H^+]}{[H^+]/K_{R^+} + 1 + K_{RO^-}/[H^+]}$$

For $K_{RO^-} \ll [H^+]$, eq. [10] becomes:

$$[11] \quad k_{Fe} = \frac{k_2 + k_3K_{RO^-}/[H^+]}{[H^+]/K_{R^+} + 1}$$

Attempts to fit eq. [11] to the data for k_{Fe} in Fig. 5 by evaluating the three parameters k_2, $k_3K_{RO^-}$, and K_{R^+} by an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

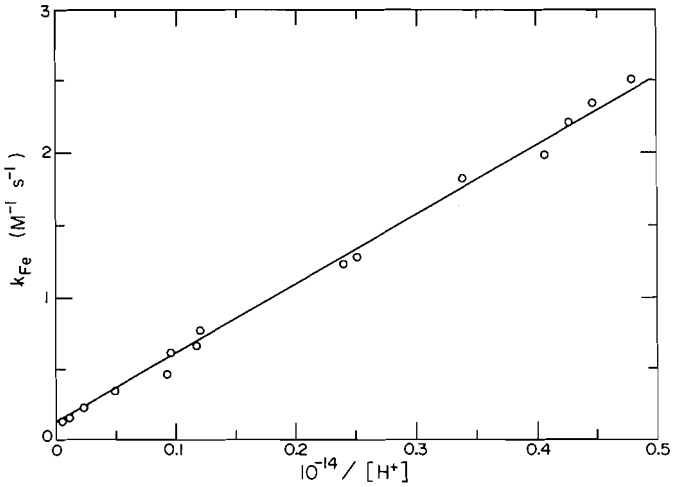


FIG. 6. Variation of k_{Fe} with $1/[H^+]$ as in eq. [12].

iterative curve-fitting routine gave fits which were relatively insensitive to the value of K_{R^+}. This result can be traced to the fact that the values of k_{Fe} at pH values in the vicinity of pK_{R^+} are quite small relative to k_{Fe} at high pH. We have therefore fixed K_{R^+} at 1.35×10^{-10} M as determined above for the disproportionation reaction, and have obtained the best fit using the other two parameters. When this is done, the values $k_2 = 0.12 \pm 0.02$ M^{-1} s^{-1} and $k_3K_{RO^-} = 4.7 (\pm 0.2) \times 10^{-14}$ s^{-1} are obtained. The curves through the data points for k_{Fe} and k_{ox} in Fig. 5 make use of these parameters and eq. [11] and fit the data with an average deviation of 8% from the experimental data points.

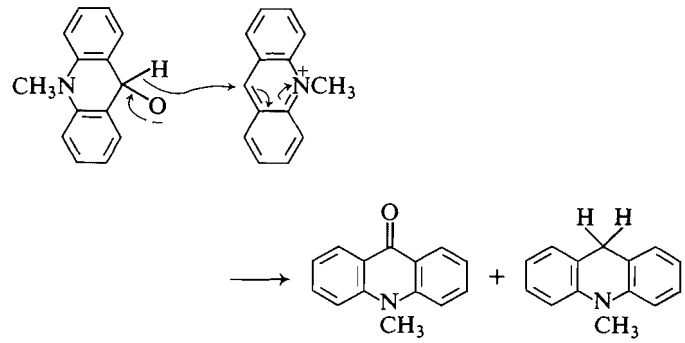
The condition $K_{RO^-} \ll [H^+]$ is further supported by the following analysis. For $[H^+] \ll K_{R^+}$ (i.e. pH > 12), eq. [11] may be further simplified to:

$$[12] \quad k_{Fe} = k_2 + k_3K_{RO^-}/[H^+]$$

A plot of k_{Fe} vs. $1/[H^+]$ is shown in Fig. 6 for pH > 12. This plot is quite linear, and of slope $4.8 (\pm 0.2) \times 10^{-14}$ s^{-1}, which is in good agreement with the value of $k_3K_{RO^-}$ reported above for a fit to the complete data in the range pH 9–13.7. Significant deviations from linearity would be expected for the data at high pH in Fig. 6 if the condition $K_{RO^-} \ll [H^+]$ did not hold.

Discussion

The pH-dependence of the disproportionation reaction of the 10-methylacridinium cation in basic solution is quite consistent with the reaction occurring between the pseudobase alkoxide ion and acridinium cation. Clark and Bakavoli (8) have established that this disproportionation occurs with direct transfer of a hydrogen atom from C-9 of one acridine species (alkoxide ion) to C-9 of the other acridine species (acridinium cation) without exchange with solvent protons. Thus the one-step direct hydride transfer shown in Scheme 2 is consistent with the experimental data, although we cannot rule out kinetically equivalent mechanisms involving one-electron transfer steps ($e^- + H^\cdot$ or $e^- + H^+ + e^-$) provided that the hydrogen transfer step in such a mechanism occurs within a radical pair cage intermediate. We note that the "crossed disproportionation" previously studied for two isoquinolinium cations is only consistent with the direct hydride transfer mechanism (4). However, in view of the uncertainty (13–17) surrounding the mechanisms of other reactions which involve formal hydride transfers to or from acridine derivatives, we cannot unambiguously



SCHEME 2

establish the direct one-step hydride transfer for the acridinium cation disproportionation at the present time. We also note that a general base-catalyzed termolecular process, involving hydroxide ion, neutral pseudobase, and acridinium cation, is kinetically equivalent to Scheme 2. Such a mechanism seems less likely, however, in view of the lack of any buffer catalysis in carbonate buffers of several different concentrations for either the disproportionation or ferricyanide ion oxidation reactions (Table 2).

The above kinetic analysis of the pH profile for k_{dis} gives only the parameter $k_1K_{RO^-}$. Evaluation of k_1 requires the value of pK_{RO^-} which lies outside the pH range of the current investigation. However, the use of $pK_{RO^-} = 15.34$ estimated for benzyhydrol (11), allows the estimation of $k_1 = 1.8 \times 10^5$ M^{-1} s^{-1}. This value indicates that the acridine pseudobase alkoxide ion is far more reactive as a hydride donor towards the 10-methylacridinium cation than either 1-benzyl-1,4-dihydronicotinamide (second-order rate constant 400 M^{-1} s^{-1} (13))[2] or 9,10-dihydro-10-methylacridine (0.051 M^{-1} s^{-1} in acetonitrile at 30°C (14)).

The base-catalyzed oxidation of 5-nitroisoquinolinium cations by ferricyanide ion has been established to occur via a mechanism which is kinetically first-order in each of ferricyanide ion and the pseudobase alkoxide ion (3). A similar reaction predominates in the ferricyanide ion oxidation of the 10-methylacridinium cation in the most basic solutions investigated (k_3 in eq. [9]). However, in more dilute base two further pathways for ferricyanide ion oxidation have been identified in the current work. One of these pathways is kinetically first-order in each of ferricyanide ion and neutral pseudobase (k_2 in eq. [9]), while the other occurs via an initial disproportionation as outlined in Scheme 1. The relative importance of each of these pathways over the pH range 9–14 is indicated in Fig. 7. Below pH 9.7 the k_2 path predominates, while above pH 12.8 the k_3 path becomes the major oxidation route. In the pH 9.7–12.8 region, the predominant ferricyanide ion oxidation route for the 10-methylacridinium cation occurs via initial disproportionation as outlined in Scheme 1, with the maximum contribution from this route reaching 69% at pH 11.1.

It is clear that the neutral pseudobase is much less susceptible to oxidation by ferricyanide ion than is the pseudobase alkoxide ion. A quantitative estimate of the relative reactivities of these two species can be made by using $k_3K_{RO^-} = 4.7 \times 10^{-14}$ M^{-1}

[2]Unless otherwise indicated, all comparisons of rate constants in this discussion involve data obtained under the same experimental conditions, namely in 20% CH_3CN – 80% H_2O, ionic strength 1.0, at 25°C.

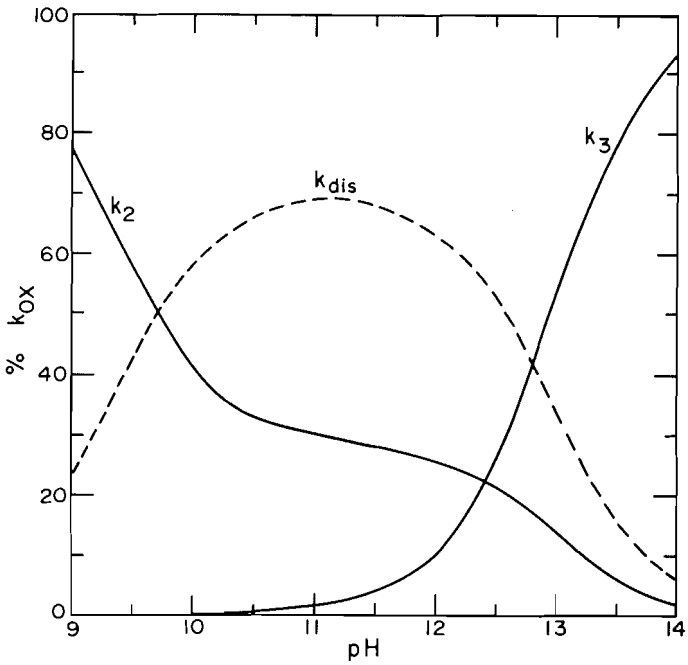

FIG. 7. Variation of contributions (as percentages) to k_{ox} from the k_2, k_3, and k_{dis} routes for pH 9–14.

s^{-1} and the estimated value of $pK_{RO^-} = 15.34$. Thus the value of k_3 can be estimated to be 100 M^{-1} s^{-1}, and the ratio $k_3/k_2 = 800$ is obtained.

This $k_3 = 100\ M^{-1}\ s^{-1}$ is only slightly smaller than the second-order rate constant of 238 M^{-1} s^{-1} found (3) for reaction of the pseudobase alkoxide ion of the 2-benzyl-5-nitroisoquinolinium cation with ferricyanide ion. This latter reaction is only readily interpretable (3) as involving hydride abstraction from the alkoxide ion by ferricyanide. An analogous interpretation for k_3 for the acridine alkoxide ion requires only 2-fold lower reactivity for the acridine system than for the 5-nitroisoquinoline system. The only related reaction that we are aware of that allows a similar comparison of reactivity is the loss of hydroxide ion from the pseudobases to regenerate these heteroaromatic cations. In this case the 2-benzyl-5-nitroisoquinoline system is over 2000-fold more reactive than the 10-methylacridine species (10, 17). On this basis it seems unlikely that both the above pseudobase alkoxide ion oxidations involve hydride abstraction by ferricyanide ion, although it is difficult to assess the possible role of steric differences in these reactions. The enhanced reactivity in the acridine system would seem to point towards a mechanism other than direct hydride abstraction in this case. An analogous enhanced reactivity (almost 40 000-fold relative to isoquinolinium cations) in the reduction of acridinium cations by 1,4-dihydronicotinamides has been noted (13), and has been suggested as being due to the occurrence of one of the kinetically equivalent one-electron mechanisms for hydride transfer in the acridine case. It should be noted that acridanyl radicals seem to be readily accessible from both acridinium cations and 9,10-dihydroacridines (13, 19–26).

It is also of interest to compare the relative reactivities of the acridine pseudobase alkoxide ion towards ferricyanide ion (k_3) and towards the 10-methylacridinium cation (k_1). This comparison can be made without an explicit value for K_{RO^-}, and gives $k_1/k_3 = 1700$. Thus the 10-methylacridinium cation is 1700-fold more reactive than ferricyanide ion for the oxidation of the alkoxide ion to the acridone. While this is an interesting observation, it is complicated by the fact that while one reaction involves a monoanion and a monocation, the other involves a monoanion reacting with a trianion. A much lower selectivity between the 10-methylacridinium cation and the ferricyanide ion as oxidants is obtained if one compares their relative reactivities for the oxidation of a neutral molecule such as 1-benzyl-1,4-dihydronicotinamide. In an unpublished study we have obtained a second-order rate constant of 30 M^{-1} s^{-1} for ferricyanide ion oxidation of the latter compound (20% CH_3CN – 80% H_2O, ionic strength 1, 25°C). Comparison of this value with the second-order rate constant of 400 M^{-1} s^{-1} for the oxidation of 1-benzyl-1,4-dihydronicotinamide by the 10-methylacridinium cation (13) indicates that the 10-methylacridinium cation is only 13-fold more reactive than ferricyanide ion in the oxidation of this neutral molecule.

Calcul des intensités des transitions laser dans $^{12}C^{16}O_2$ et ses molécules isotopiques

PHILIPPE MILLIE
Département de Physico-chimie, CEN/Saclay, 91191 Gif-sur-Yvette-Cedex, France

Reçu le 8 juillet 1983

PHILIPPE MILLIE. Can. J. Chem. **62**, 736 (1984).

Les intensités des raies lasers à 9 et 10 μm de $^{12}C^{16}O_2$ et ses molécules isotopiques sont calculées théoriquement. Les fonctions d'ondes vibrationnelles sont obtenues par diagonalisation directe à partir d'une fonction potentiel determinée antérieurement. Une comparaison avec les valeurs expérimentales est présentée. Le rôle de l'anharmonicité électrique est discuté ainsi que les erreurs dues à la méthode de transformation de contact dans le calcul des niveaux d'énergie.

PHILIPPE MILLIE. Can. J. Chem. **62**, 736 (1984).

The laser emission-line intensities of $^{12}C^{16}O_2$ and several isotopes were theoretically calculated. The vibrational wave functions were obtained to a direct diagonalization by utilizing a previously known potential function. These values are compared to the experimental ones. The effect of electrical anharmonicity is discussed. The validity of the contact transformation method is briefly analyzed.

Introduction

Les lasers CO_2 constituent encore une des seules sources de rayonnement cohérent de puissance dans l'infra-rouge. Pour en augmenter l'accordabilité ou couvrir des domaines que ne permet pas d'atteindre l'isotope usuel $^{12}C^{16}O_2$, l'attention s'est portée depuis quelques années sur la possibilité de lasers "isotopiques". Ainsi, fonctionnent déjà ceux utilisant les molécules $^{12}C^{18}O_2$, $^{13}C^{16}O_2$ et $^{12}C^{16}O^{18}O$ (1). Or, la possibilité d'obtenir un effect laser et le gain qu'on peut escompter sont étroitement liés aux moments dipolaires de transition (1). Si certains sont connus expérimentalement, il n'en est pas de même pour les molécules isotopiques les moins abondantes (2).

Par ailleurs, d'un point de vue théorique, le calcul précis de tels moments dipolaires exige la détermination de très bonnes fonctions d'ondes, donc l'utilisation d'une fonction potentielle la meilleure possible. A notre connaissance, aucun calcul n'a utilisé jusqu'à présent la fonction potentielle déterminée par A. Chedin (3), dont la convergence est très bonne et où le terme du troisième ordre par rapport au potentiel harmonique qui joue un rôle non négligeable dans le couplage de Fermi a été explicitement introduit contrairement aux déterminations antérieures (4, 5). Sa valeur a été testée aussi bien en ce qui concerne les constantes moléculaires sur des transitions jusqu'alors inobservées (6, 7) que sur l'analyse des intensités Raman des raies laser d'un certain nombre de molécules isotopiques (8).

Enfin, comme on le verra par la suite, cette étude permet de comparer la méthode de la transformation de contact à la méthode "brutale" de diagonalisation et de discuter de leurs mérites respectifs.

I. Obtention des fonctions d'ondes

1. *Nécessité de fonctions d'ondes précises*

Les deux transitions impliquées sont les transitions (0, 0°, 1) → I et (0, 0°, 1) → II, où I et II sont, en première approximation, des combinaisons linéaires des états harmoniques (1, 0°, 0) et (0, 2°, 0) entre lesquels existe un très fort couplage de Fermi (ν_1 correspond à l'allongement symétrique Σ_g^+, ν_3 à l'allongement dissymétrique Σ_u^+ et ν_2 au bending de symétrie π_u). L'opérateur moment dipolaire de transition est lui-même de symétrie Σ_u et peut s'écrire à l'ordre zéro $\mu = aQ_3$ (où Q_3 est la coordonnée normale sans dimension associée au mode ν_3). On voit que si on ne tient compte que du couplage de Fermi et qu'on néglige l'anharmonicité du moment dipolaire, on trouve des intensités nulles: ces deux transitions ne sont permises que grâce aux anharmonicités mécaniques et électriques (9) et la détermination de leurs intensités exige donc des fonctions d'ondes précises.

2. *Méthode utilisée*

Elle consiste simplement à écrire les fonctions d'ondes comme somme de produits des fonctions harmoniques et donc à diagonaliser l'opérateur énergie cinétique + potentiel harmonique + potentiel anharmonique dans cette base. Nous avons négligé l'interaction rotation−vibration, ce qui semble raisonnable pour des niveaux vibrationnels aussi bas, compte tenu par ailleurs de la précision du potentiel utilisé (cf. *infra*) et de la complexité que son introduction entraîne pour le calcul. Dans ces conditions, pour les molécules symétriques, la matrice à diagonaliser se scinde en deux sous-matrices correspondant aux états de symétrie Σ_g^+ $[n_1\nu_1, 2n_2\nu_2, 2n_3\nu_3]$ et $\Sigma_u^+[n_1\nu_1, 2n_2\nu_2, (2n_3 + 1)\nu_3]$.

3. *Etude de la convergence*

La qualité de la fonction d'onde obtenue dépend bien entendu de la dimension de la base utilisée. Pour éviter tout arbitraire, il semble qu'une bonne façon de procéder soit d'étudier comment varient les valeurs propres, c'est à dire les énergies des niveaux vibrationnels, en fonction de la dimension de la base. Pour cela, on effectue la diagonalisation en agrandissant progressivement la base utilisée (méthode des matrices "emboîtées"): on sait que, dans ces conditions, les différentes valeurs propres tendent, de façon monotone et par valeur supérieure, vers leur valeur limite pour une dimension infinie (10). Deux critères ont été retenus pour cet agrandissement: un critère énergétique d'un part, et le fait que l'on doive diagonaliser ensemble tous les états correspondant à une même valeur $(2\nu_1 + \nu_2)$ à cause du couplage de Fermi, d'autre part. On trouvera dans l'annexe I, les bases utilisées dans le cas des molécules symétriques.

L'examen de la table 1 montre clairement que l'énergie d'un niveau donné se stabilise à partir d'un certaine dimension, dimension d'autant plus élevée que le niveau étudié est plus haut en énergie. Dans notre cas, on a convergence du niveau fondamental et des niveaux I et II (construits sur 1, 0°, 0 et 0, 2°, 0) à partir de la dimension 34. Au total, en base 90, l'énergie des dix premiers niveaux a convergé à mieux que 0,1 cm^{-1} près. Il en résulte que les vraies observables, c'est à dire les niveaux d'énergies rapportées au niveau fondamental, ont aussi convergé avec une précision quasiment identique. Les mêmes constatations pourraient être faites pour la symétrie Σ_u^+.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

Ajoutons qu'en supposant, ce qui est raisonnable, que le niveau fondamental converge au moins aussi vite que les autres, on obtient ainsi des valeurs des niveaux d'énergies rapportées au fondamental qui sont supérieures aux énergies que l'on obtiendrait en diagonalisant une matrice infinie.

Une étude similaire, quoique moins poussée, a été effectuée dans le cas des molécules non symétriques. En effet, il n'y a plus séparation en Σ_g^+ et Σ_u^+ et, pour obtenir des résultats de qualité similaire, il faudrait diagonaliser des matrices de dimension environ 200. L'étude du cas symétrique montrant qu'en fait, une convergence raisonnable est atteinte des la dimension 34 pour les niveaux qui nous intéressent, on peut penser qu'une dimension de l'ordre de 92 est amplement suffisante, ce que confirme l'examen de la table 2. Il faut, cependant, noter que les critères pour agrandir progressivement la base sont nettement moins clairs que précédemment. Si les termes de couplage anharmonique, nuls dans le cas des molécules symétriques, sont très petits devant les autres, il est clair qu'il faut simplement juxtaposer les bases utilisées précédemment pour les cas Σ_g^+ et Σ_u^+. C'est le principe utilisé pour les bases 20, 48 et 68 (respectivement égales à 10 + 10, 24 + 24, 34 + 34). Si, par contre, tous les termes de couplage sont du même ordre, le critère énergétique est prépondérant; c'est lui que l'on a utilisé au moins en partie pour passer de la base 68 à la base 92 (ceci explique qu'il y ait plus de niveaux de type (v_1, v_2, 0) que de type (v_1, v_2, 1) ayant convergé).

4. *Comparaison avec la méthode de transformation de contact*

La méthode de la transformation de contact consiste, par des changements de base appropriés, à annuler certains éléments de matrice non-diagonaux du potentiel. Ceci revient, en fait, à diagonaliser une matrice infinie par perturbation, puis à diagonaliser par une méthode exacte l'interaction de Fermi (voir par example référence 11). Si cette méthode semble de loin la plus praticable pour extraire un potentiel de données expérimentales, par contre, à cause notamment de la très grande valeur de la constante de couplage anharmonique k_{133} ($\sim$250 cm^{-1}), l'erreur introduite par le traitement de perturbation peut être importante et augmente de façon significative avec le nombre quantique v_3 (voir table 15 de la référence 3). Les différences entre les énergies expérimentales et les énergies obtenues par diagonalisation directe ont été rassemblées dans la table 3. Les erreurs sont de l'ordre de 0,5 à 1.2%, sont significativement plus grandes pour les niveaux (v_1, v_2,- 1) que pour les niveaux (v_1, v_2, 0) et augmentent avec ($2v_1 + v_2$). Il en résulte que l'erreur sur la fonction potentielle est du même ordre de grandeur et ce résultat peut justifier dans une certaine mesure le fait de négliger l'interaction rotation–vibration.

Au total, la méthode de la transformation de contact semble supérieure à celle de la diagonalisation directe, au moins en ce qui concerne CO_2 (11), mais elle a le désavantage de ne pas fournir directement les fonctions d'onde.

II. Calcul des forces oscillatrices de transition

1. *Expressions théoriques*

La force oscillatrice d'une transition donnée entre deux états vibrationnels φ_i et φ_j est donnée par:

$$f = \langle \varphi_i | M | \varphi_j \rangle^2$$

où M est l'opérateur de moment dipolaire.

Cet opérateur M peut lui-même être développé en série en fonction des coordonnées normales sans dimension tandis que

$\left[\frac{\langle 0, 0°, 1\|Q_3\|1, 0°, 0^{I}\rangle}{\langle 0, 0°, 1\|Q_3\|1, 0°, 0^{II}\rangle}\right]^2$	1,5378	1,5131	1,4012	1,3916	1,3912	1,3914

φ_i et φ_j sont obtenues comme des sommes de produits de fonctions harmoniques.

Dans le cas des transitions laser qui sont des transitions parallèles, M peut donc s'écrire:

$$M = \lambda_1(a_3Q_3 + a_1Q_1) + \lambda_2(a_{13}Q_1Q_3 + a_{11}Q_1^2 + a_{33}Q_3^2) + \ldots$$

Par ailleurs, pour une molécule linéaire triatomique XYZ, on peut écrire, au premier ordre, si X et Z sont deux isotopes:

$$M = \frac{\partial M}{\partial r}(\Delta X + \Delta Z - 2\Delta Y)$$

où ΔX, ΔY et ΔZ sont les déplacements suivant l'axe internucléaire des trois atomes.

On peut exprimer $\Delta X + \Delta Z - 2\Delta Y$ en fonction des coordonnées normales sans dimension: $\Delta X + \Delta Z - 2\Delta Y = b_3Q_3 + b_1Q_1$, où b_3 et b_1 sont fonctions de l'isotope considéré alors que $\partial M/\partial r$ est une caractéristique de la molécule étudiée.

Dans le cas où $X \equiv Z$, $a_1 = a_{11} = a_{33} = 0$. Dans le cas non-symétrique, on a donc a_{11}, $a_{33} \ll a_{13}$ et on peut négliger leur contribution (voir aussi la référence 12). Par contre, on ne peut négliger, a priori, le terme $\lambda_2a_{13}Q_1Q_3$ devant le terme $\lambda_1a_3Q_3$: si les différentes études antérieures (12 − 16) montrent que $-0,05 < \lambda_2a_{13}/\lambda_1a_3 < 0,0$, par contre il est évident que:

$$\langle\varphi_i|Q_1Q_3|\varphi_j\rangle \gg \langle\varphi_i|Q_3|\varphi_j\rangle$$

pour ce qui concerne les transitions lasers. Comme nous ne nous intéressons qu'aux intensités de ces transitions rapportées à celles de $^{12}C^{16}O_2$, les seuls coefficients à déterminer sont $a_3 \equiv b_3$ et $a_1 \equiv b_1$ que l'on trouvera rassemblés dans l'annexe. Le terme correctif $\lambda_2a_{13}/\lambda_1a_3$ sera pris comme un paramètre, supposé en première approximation indépendant de l'isotope.

2. *Etude de la convergence*

Comme dans le cas des énergies, nous avons étudié la variation des éléments de matrice des opérateurs Q_3, Q_1 et Q_1Q_3 en fonction de la dimension de la base utilisée. Les résultats sont rassemblés dans la table 4 pour $^{12}C^{16}O_2$ et la table 5 pour $^{12}C^{16}O^{18}O$. Comme on pouvait s'y attendre, les éléments de matrice convergent beaucoup moins vite que les énergies car le test est beaucoup plus sévère et basé directement sur la qualité des fonctions vibrationnelles obtenues. On obtient une précision supérieure à 1% avec une base 90 dans le cas des molécules symétriques, de l'ordre de 1% avec une base 92 pour les non-symétriques sauf pour les éléments de matrice de Q_1 qui dépendent beaucoup des tout petits coefficients dans le développement de la fonction vibrationnelle (erreur d'environ 3%). Au total, cependant, compte tenu de la précision des valeurs expérimentales et de l'imprécision sur l'anharmonicité du moment dipolaire, la convergence peut être considérée comme suffisante.

3. *Discussion des résultats*

Sont rassemblés dans la table 6, un certain nombre de résultats théoriques et expérimentaux concernant les moments dipolaires des deux transitions laser pour l'isotope $^{12}C^{16}O_2$. Le critère retenu est le rapport des forces oscillatrices des deux transitions calculé pour trois valeurs du rapport $K = \lambda_2a_{13}/\lambda_1a_3$: 0,0, −0,03 et −0,05.

On voit que, bien que les valeurs théoriques ne diffèrent guère entre elles de plus de 10%, l'écart sur le rapport des forces oscillatrices peut être considérable et seules permettent d'encadrer les résultats expérimentaux les valeurs de la réfé-

rence 16 et celles de ce travail.

Ce bon accord avec l'expérience est aussi valable pour d'autres isotopes (voir table 7), compte tenu du fait que la valeur expérimentale tirée des tables Geisa (2) pour $^{12}C^{16}O^{18}O$ nous semble entachée d'une erreur importante. On peut remarquer en effet, que la valeur expérimentale de R diminue régulièrement de $^{12}C^{16}O_2$ à $^{12}C^{18}O_2$, comme d'ailleurs la valeur théorique, sauf pour $^{12}C^{16}O^{18}O$. L'accord est nettement moins bon en ce qui concerne les forces oscillatrices des deux transitions laser rapportées à celles de $^{12}C^{16}O_2$ et il ne nous semble pas simple de départager entre les erreurs dues aux approximations faites dans ce travail et les erreurs expérimentales. Au total, cependant, on doit pouvoir accorder une assez grande confiance aux résultats théoriques obtenus pour d'autres iso-

For personal use only.

topes qui sont rassemblés dans la table 8 et qui permettent de déceler quelles seront les transitions sur lesquelles on peut espérer obtenir un effet laser.

Conclusion

On a montré que les erreurs dues à l'emploi de la méthode de transformation de contact pour la détermination de la fonction potentielle à partir des valeurs expérimentales se traduisent, au niveau des énergies calculées, par une erreur relative de l'ordre de $1°/_{oo}$. L'emploi d'un bon potentiel est tout à fait crucial en ce qui concerne la détermination théorique des moments dipolaires de transition. Le potentiel déterminé dans la référence 3 donne des résultats en bon accord avec l'expérience en ce qui concerne les intensités des raies laser. L'anharmonicité électrique joue un rôle considérable dans le rapport des intensités des deux transitions laser; il joue, par contre, un rôle négligeable en ce qui concerne les intensités de ces deux raies pour les molécules isotopiques à condition de les rapporter à celles de l'isotope $^{12}C^{16}O_2$.

Remerciements

Je tiens à remercier Messieurs A. Chedin, B. Levy et G. Salvetat pour les nombreuses discussions que nous avons pu avoir, Messieurs Weulersse et Botter pour avoir attiré mon attention sur l'intérêt du problème et Madame Vinh pour m'avoir facilité l'accès du centre de calcul de l'ENSJF.

Open-chain nitrogen compounds. Part V. Hydroxymethyltriazenes: synthesis of some new alkyl homologues of the anti-tumour 3-methyl-3-hydroxymethyltriazenes and preparation of the derived acetoxymethyl-, benzoyloxymethyl-, and methoxymethyltriazenes

CHANTAL M. HEMENS, HARTFORD W. MANNING, KEITH VAUGHAN,[1] RONALD J. LAFRANCE, AND YORK TANG
Department of Chemistry, Saint Mary's University, Halifax, N.S., Canada B3H 3C3

Received August 16, 1983

CHANTAL M. HEMENS, HARTFORD W. MANNING, KEITH VAUGHAN, RONALD J. LAFRANCE, and YORK TANG. Can. J. Chem. **62**, 741 (1984).

The synthesis of some new 1-aryl-3-alkyl-3-hydroxymethyltriazenes is described. The method of coupling a diazonium salt with an alkylamine/formaldehyde mixture has been extended to (a) some diazonium ions with *para* substituents other than —M groups, (b) those with substituents in the *ortho* position, and (c) to homologous alkylamines (e.g. ethylamine, propylamine, etc.). Hydroxymethyltriazenes can also be prepared by the reaction of a 1-aryl-3-methyltriazene with formaldehyde. Several new derivatives of the hydroxymethyl function have been prepared. Reaction with acetic anhydride or benzoyl chloride in pyridine affords respectively the acetoxymethyl- and benzoyloxymethyl-triazenes; the acetates and benzoates react readily with methanol to give the novel methoxymethyltriazenes. This is the first report of a series of dialkyltriazenes with an ether linkage in the α position. An ether of this type has also been obtained directly from the diazonium fluoroborate salt by coupling with a mixture of benzylamine and formaldehyde in ethanolic solution.

CHANTAL M. HEMENS, HARTFORD W. MANNING, KEITH VAUGHAN, RONALD J. LAFRANCE et YORK TANG. Can. J. Chem. **62**, 741 (1984).

On décrit la synthèse de quelques nouveaux aryl-1 alkyl-3 hydroxyméthyl-3 triazènes. On a élargi les possibilités offertes par la méthode de couplage d'un sel de diazonium avec un mélange alkylamine/formaldéhyde de façon à inclure (a) quelques ions diazonium portant des substituants en *para* qui soient différents de —M, (b) ceux portant des substituants en position *ortho* et (c) les alkylamines homologues (comme l'éthylamine, la propylamine, etc.). On peut aussi préparer les hydroxyméthyltriazènes par réaction d'un aryl-1 méthyl-3 triazène avec le formaldéhyde. On a aussi préparé plusieurs nouveaux dérivés de la fonction hydroxyméthyle. Les réactions avec l'anhydride acétique ou le chlorure de benzoyle dans la pyridine conduisent respectivement aux acétoxyméthyl- et benzoyloxyméthyl-triazènes; les acétates et benzoates réagissent facilement avec le méthanol pour conduire à les nouveaux méthoxyméthyltriazènes. Ceci constitue la première publication relative à une série de dialkyltriazènes portant une liaison éther en position α. On a aussi pu obtenir ce type d'éther directement à partir d'un sel fluoroborate de diazonium par couplage avec un mélange de benzylamine et de formaldéhyde en solution dans l'éthanol.
[Traduit par le journal]

Introduction

1-Aryl-3-alkyl-3-hydroxymethyltriazenes (**1**) have been a subject of interest in recent chemical and pharmacological literature. The biological importance of these molecules stems from their assumed role in the metabolism of the anti-tumour dimethyltriazenes; the hydroxymethyltriazene **1** is the oxidative intermediate en route to the proposed active metabolite, the monomethyltriazene, Ar.N=N—NHMe (1). The potential anti-neoplastic property of the hydroxymethyltriazenes has stimulated activity aimed at devising methods for their synthesis. The reaction of an arenediazonium salt with a mixture of methylamine and formaldehyde has been shown (2) to afford crystalline hydroxymethyltriazenes, which are surprisingly stable and possess significant anti-tumour activity (3).

Recent studies (4, 5) have shown that the diazonium coupling reaction with methylamine/formaldehyde mixtures is more complex. The hydroxymethyltriazene **1** is not always the only product and frequently a significant yield of a second compound, a bis(1-aryl-3-methyltriazen-3-ylmethyl-)methylamine **2**, is obtained. The formation of these novel heptazanonadienes arouses some intriguing speculation regarding the equilibrium species present in the formaldehyde/methylamine solution and is the subject of the following paper in this series. In this paper, we report an investigation of further aspects of the synthesis of the hydroxymethyltriazenes, in which variations of the 3-alkyl and 1-aryl moieties have been explored. In addition, we have studied the derivatization of the hydroxymethyltriazene functional group as acetate and benzoate esters and alkyl ethers; these derivatives may be useful as pro-drugs for the anti-tumour hydroxymethyltriazenes.

Discussion

The first objective of this study was to establish that the synthesis of 3-methyl-3-hydroxymethyltriazenes first described by us (2) is extendable to other 3-alkyl homologues. An aqueous solution of a diazonium chloride, in which the aryl group carries a strongly electron-withdrawing substituent in the *para* position, reacts readily with a mixture of formaldehyde and methylamine or ethylamine to afford a good yield of the corresponding hydroxymethyltriazene. The minimum molar proportion of formaldehyde/alkylamine required for optimum hydroxymethyl triazene yield is approximately 15:1; below this ratio appreciable amounts of the corresponding bis-triazene **2** may be produced (5, 6). In the synthesis of these 3-methyl- and 3-ethyltriazenes, there was no apparent difference in the yield

between neutralization before or after mixing the diazonium salt with the carbinolamine solution. Several new triazenes in the 3-methyl- and 3-ethyl series are reported in Table 1.

When this method was extended to the 3-n-propyl- and 3-n-butyl-3-hydroxymethyltriazene, some minor modifications to the procedure were necessary. Formaldehyde solution reacts

somewhat vigorously with propylamine and butylamine and the formation of an oil as a separate layer is frequently evident. Several modifications have been attempted in order to facilitate reaction of these mixtures with the diazonium salt, as follows: (a) the alkylamine/formaldehyde mixture is stirred vigorously so that the oil is dispersed during the addition of the diazonium salt; or (b) the alkylamine/formaldehyde mixture is diluted with the minimum volume of absolute methanol required to create a single layer prior to mixing with the diazonium salt solution; or (c) the alkylamine is dissolved in water, acidified to pH 2, mixed with formaldehyde, then with the diazonium salt, and finally neutralized to pH 7–8. The 3-n-propyl- and 3-n-butyl-3-hydroxymethyltriazenes were isolated initially as oils, some of which produced crystals on standing.

When the procedures described above were applied to the reaction of diazonium salts without a —M group in the *para* position, such as *p*-bromobenzene diazonium chloride, the hydroxymethyltriazene was not the only major product. A significant yield of the *p*-bromophenyl bis-triazene was obtained, along with the hydroxymethyltriazene, when the ratio of formaldehyde to methylamine is in the range 5:1 to 15:1. The optimum yield of the *p*-bromophenyl-3-hydroxymethyltriazene is obtained by coupling the diazonium salt with a 50:1 formaldehyde/methylamine mixture and by slow neutralization of the mixture. The effect of the formaldehyde/methylamine ratio on the yields of the two products has been studied in more detail and is described in the following paper (6), wherein the implications of these observations to the mechanism of formation are discussed.

It has been claimed that the use of the arenediazonium fluoroborate, in place of the chloride, may improve the method of hydroxymethyltriazene synthesis (7). Although it has now been shown (4, 5) that the products described by these authors are in fact bis-triazenes, we have explored the potential of the fluoroborate method and in general there is no real advantage to this method. However, in extending the hydroxymethyltriazene synthesis to the n-propyl analogues, the products are frequently oils which are not easy to purify. In method E (see experimental), the diazonium fluoroborate is employed and the propylamine is used in the form of the hydrochloride salt; this combination, together with careful control of pH, affords relatively clean 3-propyl-3-hydroxymethyl triazenes.

In addition to studying the extension of the hydroxymethyl triazene synthesis to 3-alkyl homologues and to substituents in the aryl group which are not —M in character, we have also explored the effect of relocation of the aryl substituent to the *ortho* position. This has not turned out to be a trivial modification. It had previously been shown that location of the COOMe group in the *ortho* position gives an unstable hydroxymethyltriazene, which decomposes by loss of formaldehyde and cyclization of the methyl *o*-3-methyltriazenobenzoate to a benzotriazinone (2, 3). However, reaction of *o*-trifluoromethylbenzene diazonium chloride with methylamine/formaldehyde by method A gives an excellent yield of the hydroxymethyltriazene, which is quite stable. The reaction has also been extended successfully to the *o*-cyanophenyl-3-hydroxymethyltriazene.

Kolar et al. have reported (8, 9) that hydroxymethyltriazenes may be prepared by reaction of the monomethyltriazene (Ar.N=N—NH—Me) with formaldehyde, but have not elaborated on the general application of the method, which may be a useful entry to hydroxymethyltriazenes not accessible by the route described here (such as those with electron-donating groups in the aryl moiety). Accordingly, a sample of the 1-*p*-cyanophenyl-3-methyltriazene was prepared (10) and was found to react in suspension in aqueous formaldehyde at 0°C very readily to afford an excellent yield of 1-*p*-cyanophenyl-3-hydroxymethyl-3-methyltriazene (**1** X = CN, R = Me), which was identical with a sample prepared by Method A. This method is now being explored more extensively in this laboratory and will be reported more fully at a later date.

Characterization of the hydroxymethyltriazenes listed in Table 1 is based on infrared and nmr spectroscopy and on comparison with previously reported data on the 3-methyl analogues (3). The presence of the OH stretching band in the range 3250–3460 cm^{-1} is diagnostic for the *N*-hydroxymethyl group. The nmr spectra compare favourably with previous observations; the hydroxyl proton is not always observed in deuteriochloroform, but is usually clearly observed in solution in DMSO-d_6. The methylene protons of the hydroxymethyl group are always seen at ca. 5.2 ppm; coupling to the hydroxylic proton is often observed, resulting in a broad doublet appearance of the methylene singlet, which collapses after addition of deuterium oxide. An obvious but important observation in the nmr spectrum is to confirm the incorporation of the appropriate alkyl group at N-3.

The mass spectrum of 1-*p*-bromophenyl-3-hydroxymethyl-3-methyltriazene (**1***l*) does not show the molecular ion at *m/e* 243/245, but does show a fragmentation pattern consistent with the presence of a single bromine atom in the hydroxymethyltriazene molecule. Loss of the formaldehyde unit is indicated by a pair of fragments at *m/e* 213/215 with relative intensities close to 1:1, and further loss of the *N*-methyl group by fragments at *m/e* 198/200. There are also strong peaks in the mass spectrum of **1***l* arising from the *p*-bromobenzenediazonium ion (*m/e* 183/185) and the *p*-bromophenyl cation (*m/e* 155/157). These fragmentations are consistent with the behaviour of other triazenes which can undergo fragmentation via the monomethyltriazene (3).

Several new derivatives of the hydroxymethyltriazene functionality have now been synthesized. The reaction of the hydroxymethyltriazenes with benzoyl chloride in pyridine, first reported for the 1-*p*-methoxycarbonylphenyltriazene (**1** X = COOMe, R = Me) by us (2), has now been extended to other substituents and a series of 3-benzoyloxymethyltriazenes ("benzoates") **4** has been characterized (Table 3). These derivatives are not always easy to crystallize and do not usually have sharp melting points, even after several recrystallizations; the products appear to be spectroscopically pure. A much better series of derivatives are the 3-acetoxymethyltriazenes ("acetates") (**3**) (Table 2), which are readily obtained by reaction of the hydroxymethyltriazene with acetic anhydride in pyridine and are sharply-melting crystalline compounds. The use of pyridine as a solvent is essential in these preparations, since it neutralizes the acidic by-products of the reactions which otherwise would cause degradation of the triazenes.

The acetates and benzoates are characterized by ir and nmr spectroscopy. Hydroxyl group absorption bands are absent in the ir spectra; the acetates exhibit C=O stretch at 1735–1755 cm^{-1} and the benzoates at ca. 1720 cm^{-1}. In the nmr spectra, the *N*-methylene group produces a signal at ca. 6.1 ppm in the benzoates and 5.8 ppm in the acetates, compared to 5.2 ppm for the analogous protons in the hydroxymethyltriazenes. Other signals in the nmr are consistent with the assigned structures (see Tables 2 and 3).

Recrystallization of the acetates and benzoates was carried

out in non-protic solvents since it was found that both types of ester derivative react with alcohols. The products of these reactions were not the expected products of a simple transesterification, i.e. the hydroxymethyltriazene and methyl acetate or benzoate. The products were clearly identified as the methyl ethers **5**, and the reaction was shown to be general for a number of aryl substituents (Table 4). These are the first examples of triazene derivatives with an ether function in the α position of one of the alkyl groups to be reported. Structural assignment is based on the absence of OH and acetoxy- or benzoyloxy-carbonyl absorption in the ir and on the nmr spectra. The ether linkage is clearly indicated by an *O*-methyl signal at 3.2 ppm, almost coincident with the *N*-methyl signal at 3.3 ppm; the *N*-methylene signal is at 5.15 ppm, which is very similar to the methylene signal of the hydroxymethyltriazenes.

The structures of all the acetates, benzoates, and methyl ethers reported here have been confirmed by C-13 nmr spectroscopy (Table 5). The chemical shift of the *N*-methylene carbon appears at 78–79 ppm in the acetates, benzoates, and hydroxymethyltriazenes, but is shifted slightly downfield to 86.5 ppm in the methyl ethers. The *N*-methyl carbon is found at 33–34 ppm in all series and the *O*-methyl carbon of the ethers appears at 55.7 ppm.

The mechanism of formation of the methyl ethers is most likely that represented in Scheme 1. The triazene N-3 nitrogen is capable of using its electron lone-pair to displace the acetate or benzoate leaving group affording the intermediate methylene-triazenium ion **8**. Reaction of **8** with methanol then leads to the methyl ether. The solvating capability of the alcohol might also facilitate the initial ionization. This type of reaction has not so far been observed with the hydroxymethyltriazene itself; no ether formation is evident when hydroxymethyltriazenes are treated with methanol. Evidently the electron lone-pair push from N-3 is not sufficient to eject the hydroxyl group; derivatization to the acetate or benzoate changes the nature of the leaving group so that formation of **8** is facilitated. The observed reaction of **8** with methanol suggests that similar reactions of the acetoxymethyltriazenes with different nucleophiles could lead to the synthesis of other α-substituted alkyltriazenes, e.g. the α-cyanomethyltriazenes **7**.

The possible intermediate existence of the triazenium ion **8** has important implications to the understanding of the metabolism and pharmacology of a wide range of drugs and xenobiotic molecules. The formation of carbinolamines from substituted amines has been proposed to take place during the intermediary oxidative metabolism of a number of drugs (11). The carbinolamines are thought to exist in equilibrium with iminium ions (12), analogous to the intermediate **8**. Studies on the oxidative metabolism of nicotine, benzylpyrrolidine, methapyrilene, and phencyclidine have provided strong evidence for the formation of electrophilic iminium ions through characterization of the corresponding α-cyano adducts formed by their in vitro reaction with nucleophilic cyanide ion (13). In chemical studies, *N*-nitrosoimminium ions have been invoked as intermediates in the formation of α-acetoxy-*N*-nitrosamines from the corresponding nitrosamino acids (14); the acetoxynitrosamines, which are very close structural analogues of the acetoxyalkyltriazenes reported here, have proven to be invaluable as model compounds in metabolism studies of the carcinogenic dimethylnitrosamines (15). The acetoxyalkyltriazenes similarly should be useful as model compounds for the metabolites of the anti-tumour dimethyltriazenes. A signifi-

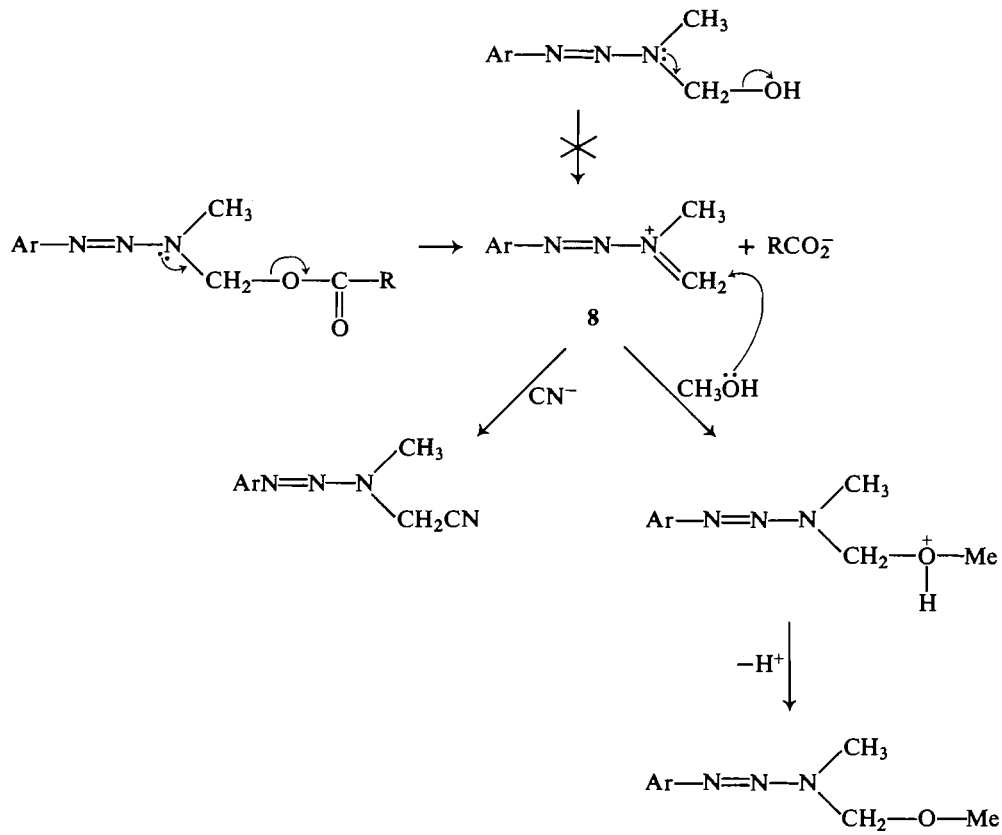

SCHEME 1

cant advantage of the triazene series for such experiments is the relative stability of the hydroxymethyltriazenes shown in our studies; the analogous hydroxymethylnitrosamines have been shown to have very short half-lives (several seconds) under physiological conditions (16).

The results reported here show clearly that the iminium ion type of intermediate, such as **8**, cannot be formed directly from the carbinolamine, which cannot follow this pathway directly because of the poor leaving-group character of the hydroxide ion. In the triazene system the reaction is facilitated by chemical conversion to the acetate leaving group; in metabolism experiments, the carbinolamine OH must be conjugated in some form to facilitate the formation of an iminium ion. Thus, we suggest that the contention that carbinolamines give rise to iminium ions during metabolism without some modification to the α-hydroxyamine functional group should be reconsidered.

The success of the reaction of the acetates with methanol as a synthetic method for the methoxymethyltriazenes encouraged us to search for other approaches to ethers of this type. If it is possible to generate triazenium ions of type **8** in non-aqueous media, then it should be possible to trap such species with a variety of agents such as alcohols. This approach has been successful in the synthesis of α-alkoxyalkylnitrosamines by nitrosation of the carbinolamine ether, generated *in situ* from a mixture of the alkylamine, aldehyde, alcohol, and acetic acid (17). Accordingly the *p*-cyanobenzenediazonium fluoroborate was reacted with a mixture of benzylamine, hydrochloric acid, formaldehyde, and ethanol, and the mixture neutralized with pyridine. Purification of the product by repeated column chromatography afforded a substance which had the nmr spectrum corresponding to the 3-benzyl-3-ethoxymethyltriazene (**6**). The success of this reaction is very encouraging for further study as a synthetic method for new types of α-oxidized alkyltriazenes and is now being investigated for general application.

Experimental

Melting points were determined on a Koffler hot-stage apparatus, calibrated with Fisher thermetric standards. Infrared spectra were recorded with liquid films or Nujol mulls on Perkin–Elmer 299 and 1330 spectrophotometers. Proton magnetic resonance spectra were recorded on a Varian EM360 spectrometer and uv spectra recorded with a Unicam SP8-400 spectrophotometer. Mass spectra were obtained with a Dupont CEC-104 medium resolution spectrometer and carbon-13 spectra were recorded at 90 MHz on the Nicolet 360 NB spectrometer.

1-Aryl-3-alkyl-3-hydroxymethyltriazenes (1)

Method A

This method, which has been described in a previous report (3), is applicable to the synthesis of 3-methyl- and 3-ethyl-3-hydroxymethyltriazenes with a —M substituent in the aryl group. An aqueous solution of the arenediazonium chloride was coupled with a mixture of formaldehyde and methylamine or ethylamine, and neutralized with aqueous sodium bicarbonate to afford the solid hydroxymethyltriazene. New hydroxymethyltriazenes obtained by this method are shown in Table 1.

Method B

This method is a modification of Method A and is applicable to the synthesis of 3-n-propyl and 3-n-butyl-3-hydroxymethyltriazenes with a —M substituent in the aryl group. The appropriate arylamine (13 mmol) was diazotized in hydrochloric acid with sodium nitrite. The alkylamine, either n-propyl- or n-butylamine (13 mmol), was mixed with 37% aqueous formaldehyde (10.6 g, 130 mmol), whereupon a separate oily layer was observed. The mixture was stirred vigorously, so that the oil was dispersed throughout the aqueous layer, while the cold arenediazonium salt solution was added dropwise. After stirring for 0.25 h, the brown oil which had formed was extracted into chloro-

form. Evaporation of the dried chloroform extract afforded the crude hydroxymethyltriazene, usually as an oil; purification was achieved in most cases by trituration and recrystallization. The triazenes obtained in this way are shown in Table 1.

Method C

This method is identical to Method B for propyl- and butylamine with a minor modification; after mixing the alkylamine and the formaldehyde solution, the mixture was treated with the minimum volume of methanol required to dissolve the carbinolamine and give a homogeneous mixture. This solution was then added to the diazonium salt solution and the reaction completed as described in Method B.

Method D

This method is applicable to the synthesis of hydroxymethyltriazenes with substituents in the aryl group which are not strongly electron withdrawing. The preparation of the *p*-bromo derivative will be described in detail to illustrate the procedure.

p-Bromoaniline (2.25 g, 13 mmol) was dissolved in hydrochloric acid (4.0 mL concentrated HCl + 26 mL water) and diazotized at 0°C with sodium nitrite (1.0 g) in water over a period of 1 hour. The solution was filtered and the clear filtrate was treated with a pre-cooled mixture of 40% aqueous methylamine (1.02 g) and 37% aqueous formaldehyde (53.2 g) over a period of 15 min. The pH was adjusted to 6–7 by the addition of saturated sodium bicarbonate and the mixture stirred for a further 15 min before raising the pH to 7.5–8.0 with bicarbonate. The mixture was stirred until precipitation was complete (up to 1 h) and the product filtered, dried, and recrystallized from petroleum ether to afford the 1-*p*-bromophenyl-3-methyl-3-hydroxymethyltriazene (2.5 g, 77%), mp 72.5–74°C.

Method E

Propylamine (0.9 g) was dissolved in water (10 mL), acidified to pH 2 with concentrated hydrochloric acid, and mixed with 37% aqueous formaldehyde (16.7 g). The propylamine/formaldehyde mixture was added to a suspension of the *p*-nitro- or *p*-cyanobenzenediazonium fluoroborate (10 mmol) in water (25 mL). The combined mixture was cooled to 0°C and rendered slightly basic (pH ~8) with saturated sodium bicarbonate solution (approximately 10 mL). After stirring for 0.5 h, the precipitate was filtered, dissolved in ether, separated from a water layer, dried over anhydrous magnesium sulphate, and evaporated to give an oil. The nmr spectra indicated that the products were clean samples of the 1-*p*-cyanophenyl- and 1-*p*-nitrophenyl-3-hydroxymethyl-3-n-propyltriazenes. The cyano derivative seems to be stable under refrigeration, but the nitro compound decomposed at room temperature giving off a gas.

*Reaction of 1-*p*-cyanophenyl-3-methyltriazene with formaldehyde*

1-*p*-Cyanophenyl-3-methyltriazene was prepared by reaction of *p*-cyanobenzene diazonium chloride with methylamine, according to our published method (10). The monomethyltriazene (0.7 g) was suspended in water (20 mL) at 0°C and 37% aqueous formaldehyde (17.7 g) was added to the suspension. The mixture was stirred for 6 h and the insoluble product filtered and dried to afford 1-*p*-cyanophenyl-3-hydroxymethyl-3-methyltriazene (**1**, X = CN, R = Me) (0.69 g, 83%), which was identical (ir, nmr, and mp) with an authentic sample prepared by Method A described above.

1-Aryl-3-methyl-3-acetoxymethyltriazenes (3)

General procedure

1-Aryl-3-methyl-3-hydroxymethyltriazene (1.6 mmol) was dissolved in anhydrous, redistilled pyridine (1.33 mL). Freshly distilled acetic anhydride (0.24 mL) was added slowly to the stirred pyridine solution, and the mixture stirred in an ice-bath for one hour. The clear solution was poured over crushed ice (3.0 g) and stirred for 0.5 h. (In some cases, the pyridine solution was filtered prior to the treatment with ice to remove insoluble material.) The product usually appeared as a precipitate in the aqueous pyridine and was separated by filtration, washing with cold water, drying overnight under vacuum, and recrystallization from an appropriate solvent mixture to afford the triazene acetate. Yields, physical and spectroscopic data are given in Table 2.

*1-Aryl-3-methyl-3-benzoyloxymethyltriazenes (**4**)*

General procedure

The hydroxymethyltriazene (4.5 mmol) was dissolved in dry pyridine (4.0 mL) at room temperature in a vessel fitted with a drying tube. Freshly distilled benzoyl chloride (0.66 g) was added to the pyridine solution, slowly with stirring; the mixture was stirred in an ice-bath for 1 h, filtered by gravity, and the clear filtrate poured onto crushed ice (8.3 g). A precipitate was usually observed at once; after stirring in the cold for up to 0.5 h the product was filtered, dried, and recrystallized to afford the benzoate. Yields, physical and spectroscopic data are given in Table 3.

*1-Aryl-3-methyl-3-methoxymethyltriazenes (**5**)*

Method A. General procedure

The 3-acetoxymethyltriazene (0.2 g) was dissolved in absolute methanol (5.0 mL) and stirred at room temperature until the reaction was complete. The reactions were followed by tlc on silica gel with 50:50 ether/petroleum ether as the mobile phase. The reaction time varied with the aryl substituent as follows: X = CN, 23 h; X = Ac, 18 h; X = nitro, 48 h; X = COOMe, 6 h; X = Br, 2.5 h. After completion of the reaction, the methanol was evaporated *in vacuo* and the residue dissolved in ether (30 mL). The ether solution was washed successively with aqueous sodium bicarbonate (5 mL of a saturated solution + 15 mL of water), water (20 mL), and saturated sodium chloride (20 mL), then dried over anhydrous sodium sulphate before evaporation *in vacuo* to afford the pure methyl ethers. The products were usually oils, except in the case of the *p*-methoxycarbonyl- and *p*-acetyl derivatives, which crystallized readily. Yields, physical and spectral data are given in Table 4.

Method B. General procedure

The procedure described in Method A above was followed exactly using the 3-benzoyloxymethyltriazene instead of the acetate as the starting material. The reaction times were as follows: X = CN, 26 h; X = COOMe, 21 h. Yields and other data are given in Table 4.

*1-*p*-Cyanophenyl-3-benzyl-3-ethoxymethyltriazene (**6**)*

Benzylamine (0.55 g) was dissolved in absolute ethanol (10 mL), acidified with an equivalent quantity of concentrated hydrochloric acid, and mixed with 37% aqueous formaldehyde (8.3 g). The *p*-cyanobenzenediazonium fluoroborate (5 mmol) was dissolved in absolute ethanol (50 mL) and added slowly to the stirred ethanolic benzylamine/formaldehyde mixture. The clear solution was cooled to 0°C and neutralized with pyridine (1.0 mL). The ethanol was removed under vacuum, the residue was diluted with water and extracted with ether. The residue from the dried ether extract was a dark oil (1.0 g), which was purified by column chromatography on 60/200 mesh Hi-flosil (80 g). Elution with 15% chloroform in hexane gave an oil (0.80 g), which was rechromatographed on the same adsorbent; elution with 25% chloroform in petroleum ether gave the pure ethoxymethyltriazene (oil, 0.50 g, 35%), nmr spectrum (deuteriochloroform): 1.2(t), 3.5(q), 5.05(s), 5.2(s), and 7.0–7.9(m) ppm.

Received August 16, 1983

HARTFORD W. MANNING, CHANTAL M. HEMENS, RONALD J. LAFRANCE, YORK TANG, and KEITH VAUGHAN. Can. J. Chem. **62**, 749 (1984).

The synthesis of a series of *N,N*-bis(1-aryl-3-methyltriazen-3-ylmethyl) methylamines from coupling diazonium salts with mixtures of methylamine and formaldehyde is described. These novel bis-triazenes, or heptazanonadienes, have significant anti-tumour activity against the TLX5 lymphoma in mouse. The mechanism of formation of these triazenes is discussed with reference to the implication to the presumed equilibria taking place in the methylamine/formaldehyde solution. The formation of the bis-triazene is usually accompanied by the formation of a 3-hydroxymethyltriazene, and it has been shown that the hydroxymethyltriazene can be transformed into the bis-triazene. The proportions of the two products are strongly influenced by the relative amounts of methylamine and formaldehyde. Coupling the *p*-bromobenzenediazonium salt to a 1:1 methylamine/formaldehyde mixture affords mainly the bis-triazene, whereas a 1:50 mixture gives almost totally the hydroxymethyl triazene. These results suggest that the two triazenes arise from diazonium coupling to different species in the amine/formaldehyde mixture; this hypothesis is supported by the formation of identical product mixtures from coupling the diazonium ion with (a) a 1:1 $MeNH_2/CH_2O$ mixture, and (b) the cyclic trimer of the carbinolamine $MeNHCH_2OH$, and by the identification of a minor product from the reaction of *p*-chlorobenzenediazonium fluoroborate with $MeNH_2/CH_2O$ as bis(1-*p*-chlorophenyl-3-methyltriazen-3-yl) methane.

HARTFORD W. MANNING, CHANTAL M. HEMENS, RONALD J. LAFRANCE, YORK TANG et KEITH VAUGHAN. Can. J. Chem. **62**, 749 (1984).

On décrit la synthèse d'une série de *N,N*-bis-(aryl-1 méthyl-3 triazène-3 ylméthyl) méthylamines provenant du couplage de sels de diazonium avec des mélanges de méthylamine et de formaldéhyde. Ces nouveaux bis-triazènes ou heptazanonadiènes ont une activité anti-tumorale importante contre les lymphomes TLX5 chez la souris. On discute du mécanisme de formation de ces triazènes en se référant à l'implication possible de l'équilibre qui est sensé s'établir dans une solution de méthylamine/formaldéhyde. La formation du bis-triazène est habituellement accompagnée par la formation de l'hydroxyméthyl-3 triazène et on a montré que l'hydroxyméthyltriazène peut être transformé en bis-triazène. Les proportions des deux produits sont fortement influencées par les quantités relatives de méthylamine et de formaldéhyde. Le couplage du sel de *p*-bromobenzènediazonium avec un mélange 1:1 de méthylamine/formaldéhyde conduit presqu'exclusivement au bis-triazène alors qu'un mélange 1:50 fournit presque complètement l'hydroxyméthyltriazène. Ces résultats suggèrent que ces deux triazènes proviennent d'un couplage du diazonium avec diverses espèces présentes dans un mélange amine/formaldéhyde; cette hypothèse est supportée par le fait qu'il y a formation de mélanges identiques de produits lorsqu'on couple l'ion diazonium avec (a) un mélange 1:1 d'amine et de formaldéhyde et (b) le trimère cyclique de la carbinolamine $MeNHCH_2OH$ ainsi que par le fait que l'on a pu identifier un produit mineur de la réaction du fluoroborate de *p*-chlorobenzènediazonium avec un mélange de $MeNH_2/CH_2O$; ce produit est le bis(*p*-chlorophényl-1 méthyl-3 triazène-3 yl) méthane.

Introduction

The reaction of diazonium ions with mixtures of formaldehyde and methylamine has been the subject of considerable interest in the recent literature. The importance of this reaction stems in part from the potential pharmacological significance of the expected products, the 3-hydroxymethyl-3-methyl-1-aryltriazenes (**2**), which have been postulated as metabolites of the anti-tumour dimethyltriazenes ($ArN{=}N{-}NMe_2$) (1). In addition to the anticipated biological activity of such hydroxymethyltriazenes, there is considerable interest in the chemistry of the diazonium coupling reaction with the carbinolamine, $RNHCH_2OH$, which may be generated *in situ* from the amine and formaldehyde.

The synthesis and characterization of stable hydroxymethyltriazenes were reported first by us in 1978 (2). The hydroxymethyltriazenes were formed in good yield when a solution of a diazonium chloride, with —M substituents in the aryl group, was treated with an aqueous solution of methylamine and formaldehyde, the latter being in large excess. Subsequently, a minor variation of our method was published by Julliard *et al.* (3); the latter group employed the diazonium fluoroborate (instead of the chloride) and claimed that this modification afforded hydroxymethyltriazenes with other than —M substituents (e.g. Cl and Br). Concurrent reinvestigations of this reaction by Iley and co-workers (4) and by us (5) have shown that the diazonium coupling reaction with methylamine/formaldehyde solutions affords mixtures of **2** and a novel type of bis-triazene, the heptazanonadienes **1**, and

that the products described by Julliard *et al.* (3) are of type **1**, not **2**.

This paper gives a more detailed account of the synthesis of the bis-triazenes **1** reported in a preliminary communication (5) and reports some new evidence which provides an insight into the mechanism of formation of the triazenes of types **1** and **2**.

Discussion

The reaction of diazonium ions with mixtures of methylamine and formaldehyde affords the bis-triazenes **1**, in addition to the hydroxymethyltriazenes **2**. In the preceding paper in this series (6), the synthesis and chemistry of the hydroxymethyltriazenes **2** were explored, whereas in this paper the emphasis is on the conditions for synthesis of **1** and on the mechanism whereby **1** is produced. In the preparation of the bis-triazenes, the ratio of formaldehyde/methylamine required for optimum yield varies from 1:2 to 12:1 and is dependent on the substituent in the aryl group (see details in Table 1). In most cases the optimum yield was obtained using the diazonium chloride method, but in two instances, the *p*-nitro- and *p*-cyanobenzenediazonium fluoroborates gave good yields. In all cases, the bis-triazenes had to be separated from the hydroxymethyltriazene. This was achieved by recrystallization from an appropriate solvent; the bis-triazene invariably recrystallized in the first crop and two or three crystallizations were sufficient to remove the hydroxymethyltriazene. Details of yields, and physical properties, are given in Table 1.

The characterization of the bis-triazenes is based on spectroscopic evidence. Absence of OH absorption in the ir spectra confirms that these products are not hydroxymethyltriazenes. The nmr spectra clearly indicate the presence of two types of *N*-methyl proton at 3.2–3.3 ppm (6 protons for N-3 and N-7 methyl groups) and at 2.4–2.5 ppm (3 protons for N-5 methyl), and the *N*-methylene protons at 4.63–4.73 ppm. Detailed nmr data are shown in Table 1. The structure of the *p*-chloro, *p*-bromo-, and *p*-cyanophenyl bis-triazenes was confirmed by ^{13}C nmr spectroscopy (see Table 2). The presence of two *N*-methyl signals at ca. 34 and 37 ppm, and the methylene signal at ca. 74 ppm, confirms the bis-triazene structure. The bis-triazene structure was also confirmed by mass spectroscopy and elemental analysis. The mass spectra of the bis-*p*-chlorophenyltriazene (**1***b*) (see Table 3) show the molecular ion at 393/395/397, showing clearly the presence of two chlorine atoms in the molecule. The principal fragments in the spectrum occur at *m/e* 225/227 and 169/171, each containing a single chlorine atom, and suggesting that the major fragmentation of the bis-triazene occurs at the N3—C4 bond. Analogous fragmentation is seen in the mass spectrum of the *p*-bromo analogue (**1***a*), indicated by the fragments at *m/e* 269/271 and 213/215.

Thus the structure of these novel bis-triazenes (**1**), or "heptazanonadienes", has been established beyond doubt and corroborates the observations reported by Iley and co-workers (4). However, the mechanism of formation of the bis-triazenes has not been clearly established in previous reports (4, 5) and the elucidation of this mechanism became a principal objective of this study. It seemed logical that the diazonium coupling reaction provides a means to establish the nature of the dominant species in the methylamine/formaldehyde mixtures; the identification of the products of this coupling reaction might serve as a "probe" for determining the position of equilibrium

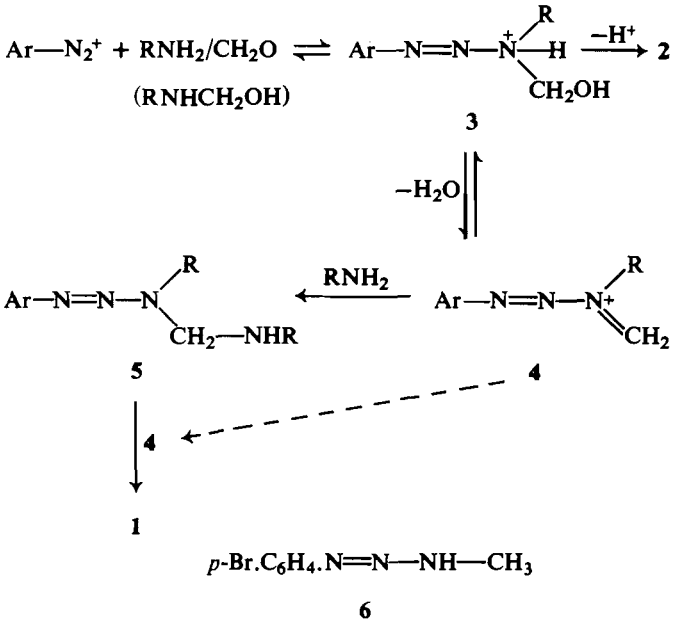
(Ar = *p*-chlorophenyl)

in the mixture.[2]

A possible mechanism to account for the formation of the triazenes **1** and **2**, shown in Scheme 1, has been proposed by other workers (4). This is an attractive scheme because of its simplicity; direct coupling to the carbinolamine ($RNHCH_2OH$), generated *in situ*, affords the protonated methyloltriazene **3** which might readily deprotonate to give product **2**, or undergo dehydration to give the reactive intermediate "methylenetriazenium" species **4**. The latter species is an essential element in this route to **1** and would be expected to react with any free methylamine to give the triazene **5** which could then couple to a second unit of **4** to give the observed bis-triazene **1**. However, there are several objections to this proposal, not least of which is the absence of triazenes of type **5** in the reaction mixtures.

An important factor in the proposed scheme is that the conversion of **3** → **2** is not reversible (4), although the reverse reaction **2** → **3** should be a facile protonation in aqueous solution. The evidence for this proposal is that **2** does not interconvert to **1** under the conditions of the reaction (4). However,

[2]This is true only if *either* coupling to each species occurs at the same rate (which is a reasonable assumption) *or* coupling to each species is at least an order of magnitude faster than the rates at which they interconvert.



SCHEME 1

we have found that the hydroxymethyltriazene **2***a* can be converted to the bis-triazene **1***a* under certain conditions, but not vice versa. When **2***a* was treated with a dilute solution of methylamine/formaldehyde (1:5 molar ratio), no reaction occurred. However, reaction of **2***a* with a 1:1 methylamine/formaldehyde mixture, at a concentration equivalent to the reaction conditions used for the synthesis of **1***a*, afforded a mixture of the two triazenes **1***a* and **2***a*; the proportion of the two products was similar to the mixture obtained when the diazonium salt was treated with a 1:1 mixture of methylamine/formaldehyde. Reaction of **2***a* with methylamine alone affords only the monomethyltriazene **6** in high yield; Cheng and Iley have recently shown that this reaction is an excellent general method for the synthesis of monomethyltriazenes (7).

Perhaps the most convincing argument against the mechanism in Scheme 1 is that there is evidently no free methylamine in the formaldehyde/methylamine mixtures, since there is no evidence for formation of the monomethyltriazene in the diazonium coupling reaction. An essential component of Scheme 1 is the reaction of **4** with *free* methylamine to give **5**, the immediate precursor of the bis-triazene in this scheme.

An alternative mechanism is shown in Scheme 2 and involves a series of complex equilibria which are known to exist in mixtures of aldehydes and amines. This complex subject has been extensively reviewed (8). The first step is the addition of the amine to the carbonyl group to produce the α-hydroxyamine ("carbinolamine") **7**, which is usually not capable of isolation and may react by dehydration to give the Schiff base **8**. Either **7** or **8** may be involved in further condensation steps to give more complex species as shown in Scheme

2, such as the bis-alkylaminomethane **9** and the bis-(alkylaminomethyl) alkylamine **10**. Further condensation of **10** with formaldehyde gives cyclic trimer **11**; a significant question is whether or not the latter step is reversible.

Faced with the multitude of species in Scheme 2, it is not surprising that a diazonium coupling reaction with methylamine/formaldehyde mixtures leads to more than one product. Indeed it is surprising that only two products arise, since there are three species in the scheme which could couple with a diazonium ion to give stable triazenes. There is no doubt that the hydroxymethyltriazene **2** arises from coupling to the carbinolamine **7**, and bis-diazonium coupling to **10** would afford the bis-triazene, **1**. The intermediate species **9** should also be capable of diazonium coupling to afford the bis-triazenylmethane **12**.

A test of the mechanism in Scheme 2 would be to determine the effect of the methylamine/formaldehyde ratio on the proportions of the product **1** and **2** obtained, since it is reasonable to expect that a higher methylamine/formaldehyde ratio should favour the bis-triazene. Indeed, we have found this to be the case. The *p*-bromobenzenediazonium chloride was treated with mixtures of formaldehyde/methylamine ranging from 50:1 to 1:1 in composition. The relative yields of **1***a* and **2***a* are easily measured from the relative integrals of the methylene group protons at ca. 4.7 and 5.2. The results are shown in Table 4. It is clear that the yield of **1***a* goes down and of **2***a* goes up as the amount of formaldehyde decreases. We have shown that this is not a dilution effect by carrying out the experiment with the 1:10 ratio, diluted to the same volume as the 1:50 experiment; essentially the same yield and molar ratio were observed.

TABLE 5. In vivo anti-tumour activity of the bis-triazenes against the TLX5 lymphoma

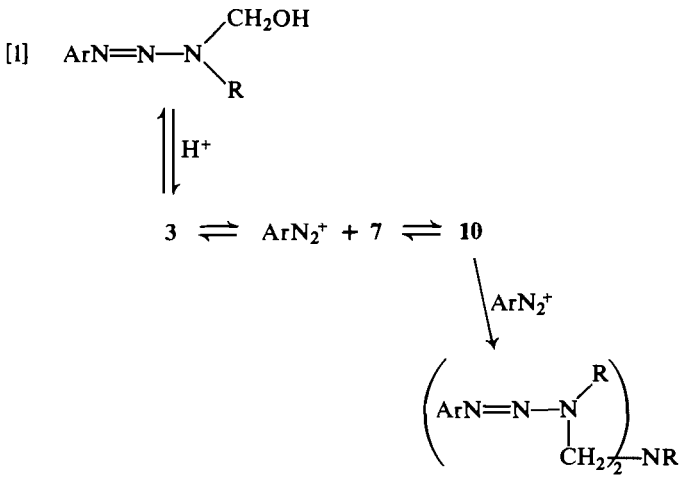
Compound No.	Max ILS (% T/C)	Optimal dose (mg/kg; five daily doses)
1*b*	190	160
1*d*	150	80

The same trend was observed when the series of experiments was carried out with the *p*-cyanobenzenediazonium salt (Table 4). However, it is significant that the yield of bis-triazene, at a given ratio of methylamine/formaldehyde, is much lower when the substituent is a cyano group than when it is a bromo group, which corroborates our previous observation (2) that the formation of hydroxymethyltriazenes is favoured by —M groups in the aryl moiety. The results in Table 4 unequivocally show that the coupling reaction is influenced quite strongly by the methylamine/formaldehyde ratio and thus is convincing evidence in favour of the mechanism proposed in Scheme 2.

It has been suggested (4) that the mechanism proposed in Scheme 2 is unlikely to be involved in the formation of bis-triazenes since the end product of this equilibrium is the cyclic trimer **11** which cannot couple to the diazonium ion. The crucial question is whether the final step leading to **11** is reversible. Accordingly, a sample of the cyclic trimer was prepared by distillation of the methylamine/formaldehyde mixture over solid KOH(8). Compound **11** was treated in aqueous solution with the *p*-cyanobenzenediazonium salt; the product was a mixture of the hydroxymethyltriazene (**2**, X = CN) and the bis-triazene **1***d*, and had almost the same composition as the mixture obtained from reaction of the same diazonium salt with a 1:1 mixture of methylamine and formaldehyde. These results clearly show (a) that the equilibrium in Scheme 2 is valid, (b) that the same equilibrium mixture arises either when methylamine and formaldehyde are mixed 1:1 or when the cyclic trimer (**11**) is dissolved in water, and (c) that the mechanism of the formation of the bis-triazenes **1** most likely involves reaction of **10** with the diazonium ion.

Further evidence for the mechanism in Scheme 2 was provided by the reaction of *p*-chlorobenzenediazonium fluoroborate with a 10:1 mixture of formaldehyde/methylamine. The major product, not surprisingly, was the bis-triazene (**1***b*), but a minor product (0.5% yield) was isolated from the residue in the recrystallization mother liquor and was identified from its nmr spectrum as the bis-(triazenyl) methane (**12**, Ar = *p*-chlorophenyl). The nmr spectrum shows two equivalent *N*-methyl groups at 3.15 ppm and a single methylene group at 5.65 ppm, in addition to the protons of two equivalent aromatic rings. Although this is the only example of a triazene of type **12** that we have obtained, its formation implies that the bis-(alkylamino) methane **9** is a minor constituent of the equilibrium mixture from methylamine/formaldehyde and is further strong evidence for the mechanism in Scheme 2.

The mechanism proposed in Scheme 2 also explains the experimental observation that **2***a* reacts with a methylamine/formaldehyde mixture to give the bis-triazene **1***a*. Under protic conditions, the hydroxymethyltriazene should behave like a dialkyltriazene and protonate at N-3 (9), thereby catalyzing fragmentation to the diazonium ion and the carbinolamine (**7**), which then exists in equilibrium with all the species in Scheme 2, including **10**. Reaction of the diazonium salt with **10** affords the bis-triazene (eq. [1]):



In addition to the fascinating chemistry of the bis-triazenes, their pharmacological properties are worthy of investigation because of their structural similarity to the anti-tumour dimethyltriazenes (1). Julliard *et al.* (3) did record that these products, although mis-identified as triazenes of type **2**, did not have significant activity in vitro. This observation is not surprising; compounds of type **1** should be anti-tumour agents, but will require metabolic activation to exhibit a cytotoxic effect in vitro. Two of the compounds in the bis-triazene series (**1***b* and **1***d*) have been tested against the TLX5 lymphoma in vivo, according to a published method (10), and have comparable activity (Table 5) to other methylalkyltriazenes.

Experimental

Melting points were determined on a Koffler hot-stage apparatus, calibrated with Fisher thermetric standards. Infrared spectra were recorded with liquid films in Nujol mulls on Perkin—Elmer 299 and 1330 spectrophotometers. Proton magnetic resonance speetra were recorded on a Varian EM360 spectrometer and mass spectra were obtained with a Dupont CEC-104 medium resolution spectrometer.

N,N-*Bis(1-aryl-3-methyltriazen-3-ylmethyl) methylamines. General procedure*

Method A

The appropriate arylamine (6.5 mmol) was dissolved in hydrochloric acid (2 mL concentrated HCl + 13 mL water) and diazotized at 0°C with sodium nitrite (0.5 g) in water. The diazonium salt solution is then treated with a mixture of 40% aqueous methylamine and 37% aqueous formaldehyde; the proportions of aqueous methylamine and formaldehyde necessary for optimal yield of bis-triazene depended on the substituent present in the aryl group of the diazonium salt (see Table 1). After stirring for 15 min in the cold, the mixture was neutralized rapidly with saturated sodium bicarbonate and stirring continued until precipitation of the product was complete. The product was then either filtered, if the solid was sufficiently crystalline to be handled in this way, or, in those cases when the precipitate was sticky and gummy, it was extracted into chloroform. Work-up of the product by immediate recrystallization in the case of solids or by trituration and recrystallization in the case of chloroform residues afforded pure crystalline bistriazenes. Yields and physical data are shown in Table 1.

Method B

This method is identical to Method A except that the diazonium fluoroborate is used in place of the chloride.

Effect of methylamine/formaldehyde ratio on the coupling reaction with p-*bromobenzenediazonium chloride*

For the purpose of this experiment, the *p*-bromoaniline (0.013 mol) was diazotized at 0°C in hydrochloric acid (4 mL concentrated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

HCl + 26 mL water) with sodium nitrite (1.0 g) in water. The diazonium salt solution was treated with a pre-cooled mixture of 40% aqueous methylamine and 37% formaldehyde over a period of 15 min and the pH was then adjusted to 6–7 by the addition of saturated sodium bicarbonate. The mixture was stirred for 10–15 min, then adjusted to pH 7.5–8.0 with saturated $NaHCO_3$ and stirred until precipitation and/or formation of oil was complete. The product was separated by either filtration or extraction into chloroform, depending on the general condition (varying from a flocculent white precipitate to a sticky semi-solid mass). The composition of the product mixture was determined from the nmr spectrum by measurement of the relative integration of the *N*-methylene protons at ca. 5.15 and 4.7 ppm. The results of these experiments are shown in Table 4.

Effect of the methylamine/formaldehyde ratio on the coupling reaction with p-*cyanobenzenediazonium chloride*

A solution of *p*-aminobenzonitrile (0.77 g, 6.5 mmol) in hydrochloric acid (2.0 mL of concentrated HCl + 13.0 mL water) was diazotized at 0°C with sodium nitrite (0.5 g) in water over a period of 1.5 h. The solution was filtered and the appropriate mixture of 40% aqueous methylamine and 37% aqueous formaldehyde was added to the clear filtrate, which was stirred for a further 0.5 h at 0°C. The pH of the mixture was then raised to ~7 with saturated sodium bicarbonate and the solid product isolated by vacuum filtration. After drying in a vacuum desiccator, the composition of the product was determined from the nmr spectrum in deuteriochloroform. The results of these experiments are shown in Table 4.

*Bis(1-*p*-chlorophenyl-3-methyltriazen-3-yl) methane (**12**, Ar = p-Cl.$C_6H_4^-$)*

p-Chlorobenzenediazonium fluoroborate (0.03 mol) was dissolved in water (70 mL) at room temperature and added to a premixed solution of 40% aqueous methylamine (1.55 g) and 37% aqueous formaldehyde (15.5 g). The mixture was neutralized with saturated sodium carbonate and an immediate reaction was observed giving a reddish brown oil, which was extracted into $CHCl_3$. Evaporation of the dried chloroform extract gave 3.7 g of crude product, which was recrystallized from ether to give the bis(1-*p*-chlorophenyl-3-methyltriazen-3-ylmethyl) methylamine (**1***b*) (0.8 g, 14%). Evaporation of the ether mother liquors from recrystallization gave an oil. After several days standing, a small quantity of crystalline substance grew in the oil; separation of this product and washing with hexane afforded the bis(1-*p*-chlorophenyl-3-methyltriazen-3-yl) methane (50 mg, 0.5%), mp 124–126°C; nmr ($CDCl_3$): 3.15 (s, 6H, N—Me), 5.65 (s, 2H, N—CH_2—N), and 7.4 (m, 8H, aromatic) ppm.

*Reaction of 1-*p*-bromophenyl-3-hydroxymethyl-3-methyltriazene with formaldehyde/methylamine*

The hydroxymethyltriazene (**2***a*) (0.25 g) was suspended in a mixture of 40% aqueous methylamine (80 mg) and 37% aqueous formaldehyde (85 mg) with water (5.0 mL) and stirred at room temperature for three days. The insoluble material was recovered by filtration and was identified by the nmr spectrum as a mixture of the hydroxymethyltriazene (**2***a*, 45%) and the bis-triazene (**1***a*) (34%). Total yield = 0.2 g.

*Reaction of 1-*p*-bromophenyl-3-hydroxymethyl-3-methyltriazene with methylamine*

The hydroxymethyltriazene (**2***a*) (100 mg) was added to a solution of 40% aqueous methylamine (34 mg) in water (5.0 mL) and the suspension stirred for 2 days at room temperature. The insoluble solid was filtered and dried to afford a pure sample of 1-*p*-bromophenyl-3-methyltriazene (74 mg, 84%), mp 86°C (lit. (11) mp 86–87°C).

*1,3,5-Trimethylhexahydro-1,3,5-triazine (**11**, R = Me)*

37% Aqueous formaldehyde (16.2 g), 40% aqueous methylamine (20.9 g), and solid sodium hydroxide (8 g) were mixed and refluxed for 4 h. The mixture was cooled to room temperature and extracted with chloroform. Evaporation of the dried chloroform extracts gave the triazine (**11**, R = Me) (8.3 g, 96%) as a yellow oil; nmr ($CDCl_3$): 2.3 (s, 3H) and 3.2 (s, 2H) ppm.

Reaction of 1,3,5-trimethylhexahydro-1,3,5-triazine with p-*cyanobenzenediazonium chloride*

p-Aminobenzonitrile (0.005 mol) was diazotized in hydrochloric acid with sodium nitrite at 0°C. The trimethylhexahydrotriazine (0.65 g) was added directly to the diazonium salt solution and the mixture stirred in the cold for 2 h. The insoluble solid was filtered and dried to give a mixture of the bis-triazene (**1***d*) (14%) and the hydroxymethyltriazene (**2**, X = CN) (32%), total yield 0.45 g.

Received August 24, 1983

SARA ARIEL, DAVID DOLPHIN, GEORGE DOMAZETIS, BRIAN R. JAMES, TAK W. LEUNG, STEVEN J. RETTIG, JAMES TROTTER, and GREGORY M. WILLIAMS. Can. J. Chem. **62**, 755 (1984).

The ruthenium(II) porphyrin complex $Ru(OEP)(PPh_3)_2$ (OEP = the dianion of octaethylporphyrin) has been prepared from Ru(OEP)(CO)EtOH, and the X-ray crystal structure determined; as expected, the six-coordinate ruthenium is situated in the porphyrin plane and has two axial phosphine ligands. Synthesized also from the carbonyl(ethanol) precursors were the corresponding tris(*p*-methoxyphenyl)phosphine complex, and the $Ru(TPP)L_2$ (TPP = the dianion of tetraphenylporphyrin, L = PPh_3, $P(p\text{-}CH_3OC_6H_4)_3$, P^nBu_3) and $Ru(TPP)(CO)PPh_3$ complexes. Optical and ^1H nmr data are presented for the complexes in solution. In some cases dissociation of a phosphine ligand to generate five-coordinate species occurs and this has been studied quantitatively in toluene at 20°C for the $Ru(OEP)L_2$ and $Ru(TPP)L_2$ systems.

SARA ARIEL, DAVID DOLPHIN, GEORGE DOMAZETIS, BRIAN R. JAMES, TAK W. LEUNG, STEVEN J. RETTIG, JAMES TROTTER et GREGORY M. WILLIAMS. Can. J. Chem. **62**, 755 (1984).

On a préparé les complexes ruthénium(II)–porphyrines, $Ru(OEP)(PPH_3)_2$ (OEP = le dianion de l'octaéthylporphyrine), à partir du Ru(OEP)(CO)EtOH et on a déterminé leur structure par diffraction des rayons-X; comme ou pouvait le prévoir, le ruthénium est hexacoordonné, il se trouve dans le plan de la porphyrine et deux ligands phosphines lui sont attachés en position axiale. Partant des précurseurs carbonyles(éthanol) appropriés, on a aussi synthétisé les complexes tris(*p*-méthoxyphényl)-phosphines correspondants ainsi que les complexes $Ru(TPP)L_2$ (TPP = le dianion de la tétraphénylporphyrine et L = PPh_3, $P(p\text{-}MeOC_6H_4)_3$ ou P^nBu_3) et $Ru(TPP)(CO)PPh_3$. On rapporte des données optiques et de rmn du proton relativement à ces complexes en solutions. Dans quelques cas, il se produit une dissociation d'un ligand phosphine et il y a génération d'espèces pentacoordonnées; on a étudié ces réactions quantitativement en solution dans le toluène à 20°C en utilisant les systèmes $Ru(OEP)L_2$ et $Ru(TPP)L_2$ comme exemples.

[Traduit par le journal]

Introduction

Our continuing interest in, and development of, ruthenium porphyrin chemistry (1) led us to discover that ruthenium(II) porphyrins containing tertiary phosphines as axial ligands were efficient catalysts for the decarbonylation of aldehydes (2), as well as for oxidation of substrates such as phosphines and sulfides by molecular oxygen through generation of hydrogen peroxide (3). The complexes also undergo two successive one-electron electrochemical oxidations to yield first a ruthenium(III) bisphosphine cation and then a ruthenium(III) π-cation radical (4).

We report here the details of the preparation and characterization of some of the ruthenium porphyrin – tertiary phosphine complexes, including the X-ray structure of $Ru(OEP)(PPh_3)_2$.[2] The dissociative equilibrium involving the loss of a phosphine ligand from the $Ru(porp)L_2$, L = PPh_3, $P(p\text{-}CH_3OC_6H_4)_3$, complexes in toluene solution is also considered. Other groups (5, 6) have described the synthesis of $Ru(TPP)(PPh_3)_2$, but the reported solution optical spectral data did not make allowance for the dissociation of phosphine.

Experimental

The solvents (toluene, heptane, hexane, MeOH, EtOH, 2-(2-methoxyethoxy)ethanol, CH_2Cl_2) were spectroscopic grade and were distilled prior to use, the CH_2Cl_2 being distilled from CaH_2. All manipulations, including preparation of the complexes, were carried out under an atmosphere of argon with the use of Schlenk techniques. Optical spectra were recorded on a Cary 17D that could be thermostatted, infrared on a Perkin Elmer 598, and ^1H nmr spectra on a Varian XL-100 operating in the Fourier transform mode. Mass spectral data were taken on a Kratos-AEI MS 902, source temperature 220–240°C, direct insertion probe, electron energy 70 eV.

The ruthenium was obtained as $RuCl_3 \cdot 3H_2O$ from Johnson, Matthey Ltd.; $Ru_3(CO)_{12}$ was either purchased from Strem Chemicals or synthesized according to a literature method from the trichloride (7). H_2TPP (8), H_2OEP (9), and the Ru(porp)(CO)EtOH precursors via $Ru_3(CO)_{12}$ were prepared according to literature procedures (4, 10). A method of synthesizing the carbonyl(ethanol) precursors directly from $RuCl_3 \cdot 3H_2O$ is described below.[3] The phosphines were Strem products: PPh_3 and $P(p\text{-}CH_3OC_6H_4)_3$ were recrystallized from ethanol, while P^nBu_3 was distilled at reduced pressure and stored under Ar. Microanalyses were performed by Mr. P. Borda of this department and by the Canadian Microanalytical Service Ltd.

Preparation of complexes

The yields in the synthetic procedures described below for the phosphine complexes were always >80%.

Ru(porp)(CO)EtOH from $RuCl_3 \cdot 3H_2O$

$RuCl_3 \cdot 3H_2O$ (0.5 g, 1.9 mmol) and H_2(porp) (0.5 g, 0.8–0.9 mmol) were refluxed in 2-(2-methoxyethoxy)ethanol (200 mL) overnight under a CO stream. After removing ~90% of the solvent by vacuum distillation and cooling to room temperature, EtOH (20 mL) was added and the solution stirred for 30 min. Some product (~300 mg) precipitated and was collected. The ethanol was evaporated off from the filtrate, and CH_2Cl_2 (50 mL) added; the resulting solution was extracted with H_2O (4 × 50 mL) and the CH_2Cl_2 layer dried with

TABLE 2. ^{1}H nmr data for some ruthenium(II) porphyrin – tertiary phosphine complexes in $CDCl_3$ at 20°C

Complex	Chemical shifts, ppm downfield from TMS
Ru(OEP)$(PPh_3)_2$	1.70 (t, CH_3), 3.68 (q, CH_2), 4.02 (d, *o*-H), 6.2–6.8 (m, *m*- and *p*-H), 8.80 (s, meso-H)
Ru(OEP)(CO)PPh_3[a]	1.75 (t, CH_3), 3.63 (m, CH_2),[b] 3.80 (m, *o*-H), 6.31 (m, *m*-H), 6.67 (t, *p*-H), 9.60 (s, meso-H)
Ru(OEP)$\{P(p\text{-}CH_3OC_6H_4)_3\}_2$	1.71 (t, CH_3), 3.60 (s, OCH_3), 3.63 (q, CH_2), 3.88 (d, *o*-H), 5.87 (d, *m*-H), 8.73 (s, meso-H)
Ru(TPP)$(PPh_3)_2$	4.25 (d, *o*-H), 6.3–7.0 (m, *m*- and *p*-H), 7.60 (br s, porphyrin phenyl), 8.11 (s, pyrrole-H)
Ru(TPP)(CO)(PPh_3)	4.08 (m, *o*-H), 6.4–7.0 (m, *m*- and *p*-H), 7.5–8.3 (m, porphyrin phenyl), 8.50 (s, pyrrole-H)
Ru(TPP)$(P^nBu_3)_2$	0.15–0.50 (m, ^{n}Bu), 8.2 (br s, porphyrin phenyl), 8.90 (s, pyrrole-H)
Ru(TPP)$\{P(p\text{-}CH_3OC_6H_4)_3\}_2$	3.53 (s, OCH_3), 4.13 (d, *o*-H), 6.00 (d, *m*-H), 7.53 (br s, porphyrin phenyl), 8.01 (s, pyrrole-H)

[a]The synthesis and optical spectra of this complex were presented in ref. 4.
[b]At 400 MHz, the multiplet is resolved into a 12-line multiplet.

$MgSO_4$, filtered, and evaporated to dryness. The solid crude products were combined and purified by column chromatography (grade III alumina, Merck) using 1:1 CH_2Cl_2/EtOH as elutant (~20% yield).

Ru(OEP)$(PPh_3)_2$

Ru(OEP)(CO)EtOH (0.5 g, 0.71 mmol) and PPh_3 (2.0 g, 7.6 mmol) were dissolved in 150 mL toluene and the solution refluxed for 24 h. After removal of solvent, the product was recrystallized from 1:5 CH_2Cl_2/MeOH three times. Crystals suitable for X-ray work were obtained by layering a concentrated solution in CH_2Cl_2 with heptane. *Anal.* calcd. for $C_{72}H_{74}N_4P_2Ru$: C 74.60, H 6.46, N 4.84, P 5.35; found: C 74.00, H 6.37, N 4.55, P 5.5. *Mass spec.*: *M/e* 896 (100), Ru(OEP)$(PPh_3)^+$; 634 (80), Ru(OEP)$^+$.

Ru(TPP)$(PPh_3)_2$

This complex was prepared from Ru(TPP)(CO)EtOH by the procedure described above for the OEP analogue. *Anal.* calcd. for $C_{80}H_{58}N_4P_2Ru$: C 77.59, H 4.72, N 4.52, P 5.00; found: C 77.29, H 4.84, N 4.35, P 5.10. *Mass spec.*: *M/e* 976 (80), Ru(TPP)$(PPh_3)^+$; 714 (100), Ru(TPP)$^+$.

Ru(TPP)(CO)PPh_3

Ru(TPP)(CO)EtOH (0.4 g, 0.56 mmol) and PPh_3 (0.2 g, 0.76 mmol) were stirred in 30 mL CH_2Cl_2 for 1 h. After reducing the volume to 5 mL, 25 mL hexane were added and the solution reduced in volume and cooled by passing Ar over the solution. The product dropped out as purple crystals that were collected by filtration. *Anal.* calcd. for $C_{63}H_{43}N_4OPRu$: C 75.36, H 4.32, N 5.58; found: C 75.17, H 4.18, N 5.35. *Mass spec.*: *M/e*: 1004 (1), Ru(TPP)(CO)PPh_3^+; 976 (90), Ru(TPP)$(PPh_3)^+$; 742 (50), Ru(TPP)(CO)$^+$; 714 (100), Ru(TPP)$^+$. *Infrared*: ν_{CO} 1956 cm^{-1} (Nujol).

Ru(TPP)$\{P(p\text{-}CH_3OC_6H_4)_3\}_2$

Ru(TPP)(CO)EtOH (0.3 g, 0.42 mmol) and $P(p\text{-}CH_3OC_6H_4)_3$ (0.4 g, 1.1 mmol) were refluxed in 150 mL toluene for 24 h. On slowly removing the solvent at room temperature, the product crystallized out eventually leaving a colourless solution; the crystals, which were then collected, washed with ethanol and air-dried, contained a toluene solvate molecule. *Anal.* calcd. for $C_{86}H_{69}O_6N_4P_2Ru \cdot C_7H_8$: C 73.94, H 5.13, N 3.71, P 4.10; found: C 74.69, H 4.82, N 4.27, P 4.0.

Ru(OEP)$\{P(p\text{-}CH_3OC_6H_4)_3\}_2$

This complex was prepared from Ru(OEP)(CO)EtOH by the procedure described above for the TPP analogue. *Anal.* calcd. for $C_{78}H_{86}N_4P_2O_6Ru$: C 69.98, H 6.48, N 4.19; found: C 69.66, H 6.39, N 4.23.

Ru(TPP)$(P^nBu_3)_2$

This complex was prepared from Ru(TPP)(CO)EtOH and excess phosphine on the scale used, and with the procedure described earlier (4), for the OEP analogue. *Anal.* calcd. for $C_{68}H_{82}N_4P_2Ru$: C 73.03, H 7.38, N 5.01, P 5.54; found: C 71.97, H 7.39, N 4.94, P 6.1. *Mass spec.*: *M/e* 1118 (1), Ru(TPP)$(P^nBu_3)_2^+$; 916 (100), Ru(TPP)$(P^nBu_3)^+$; 714 (90), Ru(TPP)$^+$.

The optical and ^{1}H nmr spectra data for the complexes are given in Tables 1 and 2, respectively.

Equilibrium constant measurements

Equilibrium constants for phosphine dissociation in toluene solution, eq. [1], were measured by a spectrophotometric titration technique using a standard 1-cm optical cell fitted with a serum cap.

$$[1]\quad \mathrm{Ru(porp)L_2} \overset{K}{\rightleftharpoons} \mathrm{Ru(porp)L} + \mathrm{L}; \qquad \mathrm{L} = \text{phosphine}$$

In sufficiently dilute solution ($\leq 10^{-6}$ *M*), the six-coordinate complexes dissociate completely as evidenced by a single band in the Soret region that on addition of aliquots (μL) of 10^{-2} *M* phosphine in toluene, subsequently decreases in intensity with concomitant formation of a new Soret band at higher wavelengths. Phosphine added in sufficient excess ($\geq 10^{-2}$ *M*) generates the limiting spectrum of the six-coordinate species.

The data were fitted to the equation

$$[2]\quad \log\{[\mathrm{Ru(porp)L_2}]/[\mathrm{Ru(porp)L}]\} = \log[\mathrm{L}] - \log K$$

using $(A - A_0)/(A_\infty - A)$ to calculate the concentration ratio, where A_0 and A_∞ are the absorbances for the five- and six-coordinate species, respectively, and A is the absorbance at any intermediate added phosphine concentration. Values of log *K* were determined from the intercept of the line (least-squares method) for a plot of log $(A - A_0/A_\infty - A)$ vs. log [L]; the slopes were 1.0 ± 0.1, consistent with a simple ligand association according to eq. [1]. Values of *K* were independent of the wavelength used, but were most conveniently determined from data at the wavelength of a Soret maximum. Equilibrium [1] was evident also in CH_2Cl_2 solution over similar complex and ligand concentration ranges.

X-ray crystallographic analysis

A dark red single crystal of $Ru(OEP)(PPh_3)_2$ was mounted on an Enraf-Nonius CAD4-F diffractometer in a non-specific orientation. Final unit cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections having 30° < 2θ < 39° measured with MoKα$_1$ radiation (λ = 0.70930 Å); cell reduction revealed no higher symmetry. Crystal data (at 22°C) were:

$C_{72}H_{74}N_4P_2Ru$ fw = 1158.4

a = 12.139(2), b = 12.120(2), c = 20.878(4) Å; α = 86.51(1), β = 86.25(1), γ = 79.90(1)°; space group $P\bar{1}$; V = 3013(1) Å^3, Z = 2, D_c = 1.277 g cm^{-3}, μ(MoKα) = 3.04 cm^{-1}.

Intensities were measured with graphite-monochromatized MoKα radiation. An ω−2θ scan at 0.7−10.1° min^{-1} was employed over a range of (0.55 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurements). Data were collected for ±*h*, ±*k*, *l* for 0° < 2θ < 50°; the aperture used was (2.0 + tan θ) × 4 mm, 173 mm from the crystal. Three reflections (613, 36$\bar{1}$, $\bar{1}$17) were monitored every hour of exposure time for random intensity fluctuations (±2%), and were recentered every 150 reflections for orientation control. A total of 9163 independent reflections was measured, with 5697 having intensities greater than 1.5σ(I) ($\sigma^2(I) = S + 2B + [0.04(S-B)]^2$ with S = scan count and B = background count); these were employed in the structure solution and refinement procedure using the SHELX computer program (12). The indices for boundary planes (10 faces) were {011}, {01$\bar{1}$}, {10$\bar{1}$}, {001}, and {101}, with distances from crystal centre of 0.17, 0.17, 0.20, 0.10 and 0.17 mm.

The coordinates of the Ru and P atoms were determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference Fourier map. There are two independent half molecules, A and B, in the asymmetric unit, and in each of these the Ru atom coincides with a crystallographic inversion centre. Two ethyl groups in molecule B are disordered, with the methyl carbon atoms each distributed over two sites, C(32), C(32′) and C(34), C(34′); these four disordered C atoms were refined isotropically. All other non-hydrogen atoms were refined anisotropically. Refinement of atomic parameters was carried out using block-diagonal least-squares techniques on F, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$ where $w = 1/\sigma^2(F_o)$. Neutral-atom scattering factors were taken from ref. 13.

Four vinyl hydrogens, H(23) and H(28) of molecules A and B, were located in a difference Fourier map. No attempt was made to locate the remaining H atoms; these were included at "ideal" positions, recalculated after each cycle of the refinement, and their isotropic thermal parameters were refined. Methyl hydrogen atoms, except for the disordered methyl groups that were kept fixed, were each refined as a rigid group possessing a local C_3-symmetry.

Convergence was reached at R = 0.0454 and R_w = 0.0372 for the 5697 reflections and 820 variables. Final positional and equivalent thermal parameters (U_{eq} = (1/3) trace U) for the non-hydrogen atoms are listed in Table 3, while the anisotropic thermal parameters are given in Table 4.[4] The calculated hydrogen atom positional and isotropic thermal parameters are given in Table 5.[4]

Bond lengths and angles for the non-hydrogen atoms appear in Tables 6 and 7, respectively, while those involving the H atoms are given in Tables 8 and 9.[4] Measured and calculated structure factors have been placed in the Depository of Unpublished Data.

Results and discussion

The bis(tertiary phosphine) complexes were readily synthesized in high yields from the carbonyl(ethanol) precursors and excess phosphine (up to 10:1) by a reflux procedure in toluene; in the case of the more basic P^nBu_3 systems (4), a room temperature treatment, preferably in CH_2Cl_2, is sufficient to effect the substitution process. The photolysis procedure required to effect replacement of the carbonyl by nitrogen- and oxygen-donors is not necessary (1, 15). Earlier syntheses of $Ru(TPP)(PPh_3)_2$ (5, 6) had used a thermal procedure (refluxing benzene or CH_2Cl_2 at room temperature), but we found that the use of a higher temperature gave better yields. Replacement of the ethanol only from the carbonyl(ethanol) complex by a phosphine to give, for example, $Ru(TPP)(CO)PPh_3$ is readily accomplished at room temperature using a slight excess of the phosphine. The direct synthesis of the Ru(porp)(CO)EtOH precursors from $RuCl_3 \cdot 3H_2O$ is convenient and obviates the use of $Ru_3(CO)_{12}$ as an intermediate, but the overall yield based on the trichloride is greater via the two-stage procedure (40 vs. 20%).

Structure description

The crystal structure of $Ru(OEP)(PPh_3)_2$ reveals an inversion centre at the ruthenium which is thus constrained to be in the plane of the four nitrogens of the octaethylporphinato (OEP) ligand. The two axial PPh_3 ligands complete the essentially octahedral coordination of the metal. Figure 1 shows the atomic numbering scheme of the molecule, while Fig. 2 shows a stereoscopic packing drawing. The molecular conformation of the ethyl groups within OEP structures generally, including Ru species, has been considered usually to depend on molecular packing within the crystal (14, 15), but the disorder noted in the present bis(phosphine) complex and some recent work on $[Ru(OEP)(OH)]_2O$ (16) suggest a more random choice of upward or downward from the pyrrole planes.

The structure of $Ru(OEP)(PPh_3)_2$ is the second one reported for a bis(phosphine) of a Ru(II) porphyrin, the earlier on of $Ru(TPP)(dpm)_2$ containing monodentate dpm ligands also coming from these laboratories (17). The only other six-coordinate Ru(II) porphyrin structures of which we are aware are those of $Ru(OEP)py_2$ (15), Ru(TPP)(CO)py (18), and Ru(TPP)(CO)(EtOH) (10). The average Ru—P distance of 2.428 Å found in the present structure is typical for *trans* P

[4]The structure factor table and Tables 4, 5, 8, and 9 are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

atoms on Ru(II) (17), and the mean P—C distance of 1.84 Å is also normal. The average Ru—N distance (2.050 Å) corresponds to those reported in other ruthenium(II)–porphyrin complexes (10, 15–17), and the geometry of the OEP ligand is as expected (14, 16).

The finding that the $Ru(OEP)(PPh_3)_2$ complex dissociates a triphenylphosphine ligand in dilute solution (see below), which has implications in catalysis (1–3), may be a common property of low-spin ruthenium(II) species containing essentially *trans* phosphine ligands with Ru—P distances of greater than about 2.40 Å (for example, as with $RuCl_2(PPh_3)_3$ (19, 20)), while related complexes such as $RuHCl(PPh_3)_3$ and $RuHCl(diop)_2$ with somewhat shorter *trans* Ru—P distances (in the range 2.329–2.393 Å (21, 22) do not measurably dissociate (23). A somewhat long Ru—N_{py} bond of 2.193 Å within Ru(TPP)(CO)py has been similarly considered to reflect enhanced lability of the pyridine ligand in this complex compared to that in $Ru(OEP)py_2$, where Ru—N_{py} = 2.10 Å (15, 18).

Solution species

As described in the Experimental section, noted spectral changes on adding phosphine to dilute solutions of the $Ru(porp)L_2$ complexes were consistent with a dissociation equilibrium (eq. [1]). Figure 3 shows the spectral changes observed for the spectrophotometric titration for the $Ru(OEP)(PPh_3)_2/PPh_3$ system in toluene at 20°C and the inset log–log plot shows the excellent agreement with analysis according to eq. [2]. The data do not analyze for dimer formation (eq. [3]), although such metal–metal bonded dimers are known (24, 25); further, the electronic spectra of the dimers (24) are quite different to those of the suggested five-coordinate species (Fig.3, Table 1).

[3] $2Ru(porp)L_2 \rightleftharpoons [Ru(porp)L_n]_2 + (4 - 2n)L; \qquad n = 0, 1$

For personal use only.

The existence of the five-coordinate Ru(porp)(CO) complexes seems well substantiated (10), and thus the lower wavelength Soret maximum of the spectrophotometric titration data (Fig. 3) is assigned to the Ru(OEP)(PPh_3) species; the familiar two-peak maxima of the low spin, six-coordinate, bis(ligand) species in the 500−600 nm region (1, 4, 10, 26) is replaced by a somewhat broader, single, and more intense band (Fig. 3, Table 1). The spectra of the bis(phosphine) complexes, therefore, in general will be concentration dependent; visible spectra reported previously for Ru(TPP)(PPh_3)$_2$ correspond more closely to that of the five-coordinate species, although the concentrations used were not stated (5, 6).

The abscissa intercept of Fig. 3 (inset) gives $K = 1.2 \times 10^{-5}$ M. For the tris(*p*-methoxyphenyl)phosphine system, $K = 5 \times 10^{-6}$ M, while the corresponding values for the TPP systems were 1.35×10^{-4} M (PPh_3) and 3.7×10^{-6} M (P(*p*-$CH_3OC_6H_4$)$_3$). Excellent data were obtained for all four systems, and the values are considered accurate to ±15%. Because tri-*n*-butylphosphine is a required cocatalyst in the decarbonylation of aldehydes using the Ru(TPP)(PPh_3)$_2$ complex (2), equilibria [1] with L = P^{n}Bu$_3$ were studied also. The bis(tri-*n*-butylphosphine) complexes of the TPP and OEP systems at $<10^{-6}$ M gave spectra of the six-coordinate species only (Table 1, and Table 1 in ref. 4, respectively) implying much smaller dissociation constants ($<10^{-8}$ M); the much higher basicity of the trialkylphosphines compared to triphenylphospine (>7 pK_a units (27)) readily accounts for this difference, but steric factors could be as important. Within either porphyrin system, the less basic PPh_3 compared to P(*p*-$CH_3OC_6H_4$)$_3$, by ~2 pK_a units (27), accounts for larger K values with the PPh_3 system, although the factors differ considerably (~2.5 and ~35 for the OEP and TPP systems, respectively). The difference in porphyrin basicities is one factor (OEP, pK_a ~ 6; TPP, pK_a ~ 3 (28)), and while normally within a related series of porphyrins (such as TPP derivatives containing *p*-substituents on the phenyl rings), axial ligand binding is enhanced with decreasing porphyrin basicity (28, 29), this has not been established for porphyrins as diverse as OEP and TPP, where contacts with the phenyl or ethyl groups on TPP and OEP, respectively, may also be important. Limited data on binding of a single amine ligand to four-coordinate cobalt(II) porphyrins show little difference in the binding constants for OEP and TPP systems (28). In the present Ru systems (a five- to six-coordinate equilibrium), the P(*p*-$CH_3OC_6H_4$)$_3$ ligand binds to much the same extent with both porphyrin systems, while PPh_3 binds more strongly (×10) to the more basic OEP system. Within these four systems, steric factors should be of little consequence; differences in solvation by toluene of the five- and six-coordinate species and the ligand could certainly play a role (30). The factors affecting axial ligand binding to metalloporphyrins are many and complex (particularly π-bonding effects); further data on the ruthenium systems are essential for a better understanding of equilibria such as [1], but the individual K values are important in estimating catalytic potential of the systems where the concentration of the 16*e* five-coordinate species is likely to be essential, for example, in abstracting CO from aldehydes with concomitant formation of Ru(porp)(CO)L (2). Dilute solutions of the (carbonyl)phosphine complex Ru(TPP)(CO)PPh_3 similarly show dissociation of the phosphine ligand and reveal the spectrum of Ru(TPP)(CO), that is formed also in dilute solutions of the ethanol precursor Ru(TPP)(CO)EtOH (10). The spectrum of the six-coordinate (carbonyl)phosphine is generated in the presence of excess phosphine (Table 1); the dissociation equilibrium was not studied quantitatively but is of the order of 2×10^{-6} M in toluene at room temperature.

[a]C(19*) is related to C(19) by the inversion centre.

In relation to the catalysis, the reactions of six-coordinate Ru(porp)L_2 complexes generally (L = phosphine, CH_3CN, THF, etc.) with gas molecules such as CO, and sometimes O_2 (3), go via the dissociative mechanism shown in eq. [4] (1, 31−34), exactly analogous to corresponding Fe(II) systems (28, 35).

$$[4]\quad \text{Ru(porp)L}_2 \underset{k_{-1},\ +\text{L}}{\overset{k_1,\ -\text{L}}{\rightleftharpoons}} \text{Ru(porp)L} \underset{k_{-2},\ -\text{gas}}{\overset{k_2,\ \text{gas}}{\rightleftharpoons}} \text{Ru(porp)(gas)L}$$

Standard kinetic analysis of such systems allows for deter-

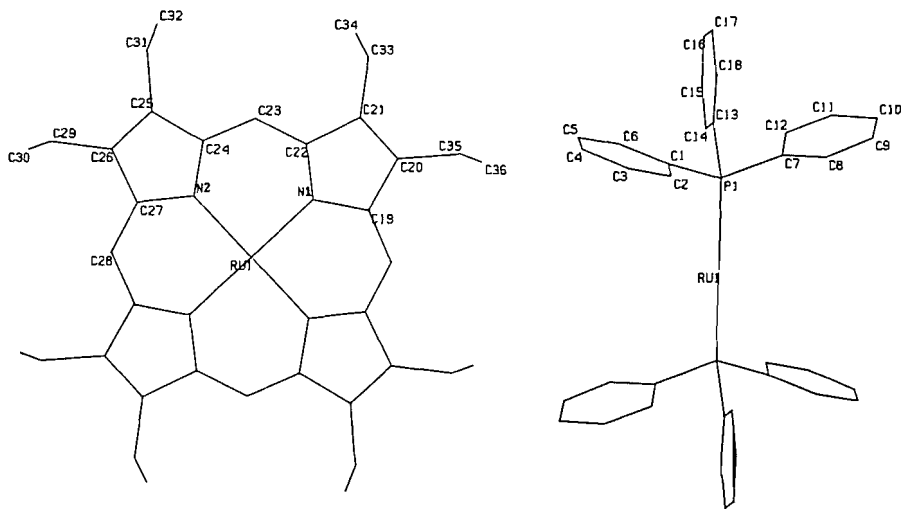

FIG. 1. The atomic numbering scheme for the $Ru(OEP)(PPh_3)_2$ molecule.

mination of the rate constants k_1, k_{-2}, and the ratio k_{-1}/k_2 (28); independent measurement of K (i.e. k_1/k_{-1}), as discussed above, thus provides for evaluation of both k_{-1} and k_2. Factors affecting the fixing of the gas molecule at the Ru centre can thus be better elucidated. These kinetic studies, presently described in the theses of Walker and Tarpey (33, 34), will be published later.

Exposure to air of solutions of the bis(phosphine) complexes

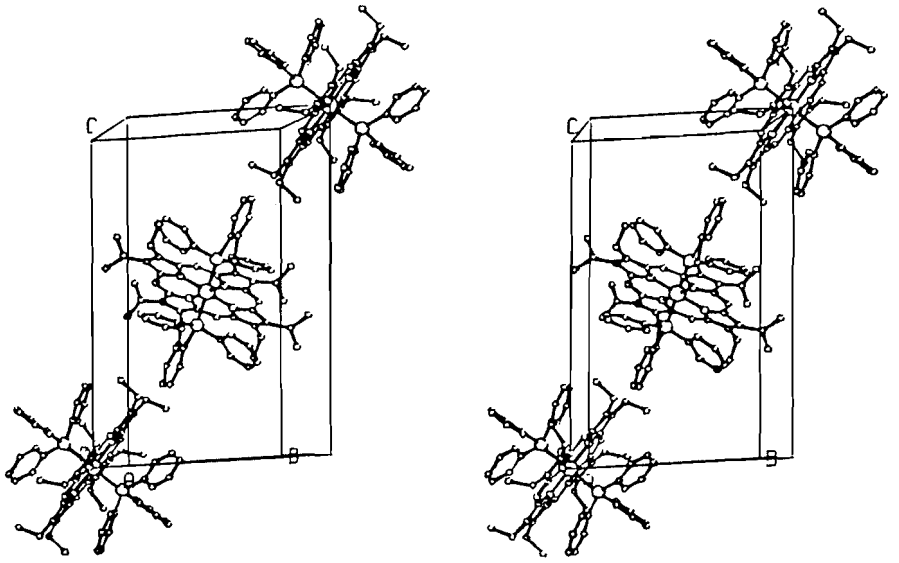

FIG. 2. Stereoscopic view of the unit cell contents (both positions are shown for disordered carbon atoms in molecule B).

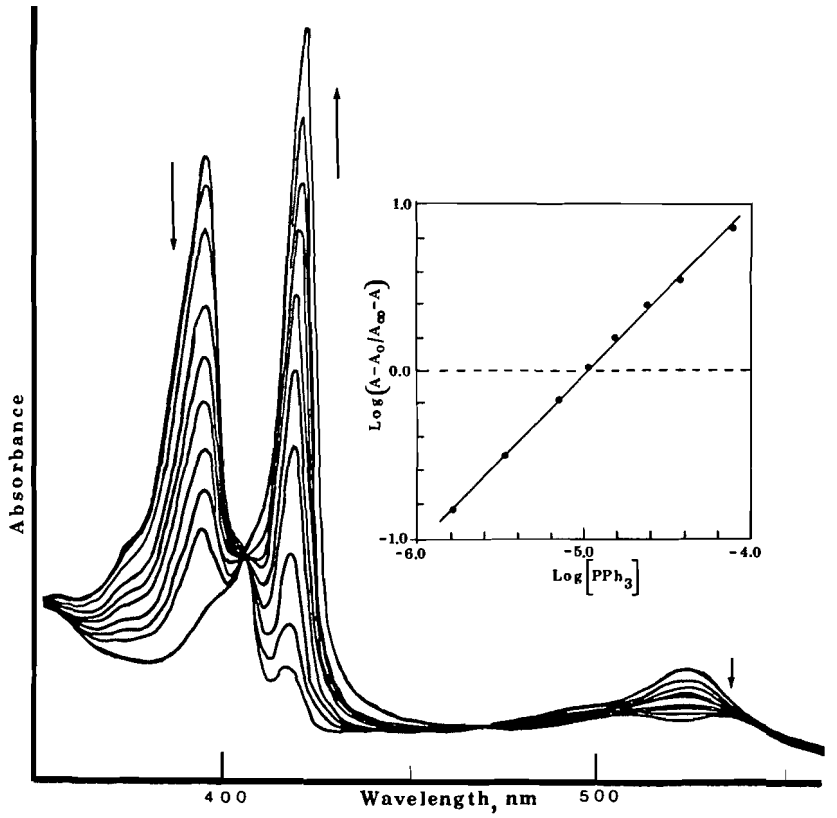

FIG. 3. Spectrophotometric titration for the $Ru(OEP)(PPh_3)_2/PPh_3$ system. Addition of the PPh_3 to $\sim 10^{-6}$ *M* of $Ru(OEP)(PPh_3)_2$ gives conversion from the five-coordinate (λ_{max} 395 nm) to six-coordinate species (λ_{max} 420 nm); absorbance (*A*) measured at 420 nm. Inset shows the log/log plot according to eq. [2].

led to slow generation over a few days of the ruthenium(IV) μ-oxo dimer $[Ru(porp)(OH)]_2O$, as evidenced by the uv/vis spectrum (16, 24).

Evidence has been presented elsewhere for dissociation of a phosphine from $Ru(OEP)(CO)PPh_3$ (4) and $Ru(OEP)(dpe)_2$ (17, 36) complexes in non-coordinating solvents such as toluene or CH_2Cl_2. Dissolution of the bis(monodentatephosphine) complexes, including the *n*-butylphosphine complex, in these solvents containing a few percent by volume of a coordinating solvent such as DMSO or CH_3CN generated a six-coordinate type spectrum that was slightly blue-shifted from that of the bis(phosphine) species. The species present is almost certainly Ru(porp)(phosphine)(coordinating solvent). In the case of adding $Ru(OEP)(P^nBu_3)_2$ to CH_2Cl_2 containing ~0.3 *M* DMSO, the species generated (λ_{max} at 406 nm) would be Ru(OEP)(P^nBu_3) (DMSO); support for this is that the same spectrum is generated on reducing solutions of $Ru(OEP)(P^nBu_3)Br$ (4) by borohydride or superoxide in DMSO solution, and that

upon further treatment with excess P^nBu_3 the spectrum of Ru(OEP)(P^nBu_3)$_2$ is regenerated via a clean isosbestic system. The spectrum of Ru(OEP)(DMSO)$_2$ (15) is not generated at any stage.

The ^{1}H nmr data were measured using solution of the complexes at $10^{-2}-10^{-1}$ *M*, when the only detectable species are the six-coordinate bis(phosphine) or carbonyl(phosphine) species (Table 2). Based on fairly extensive literature data for OEP and TPP complexes including Ru systems (6, 10, 15, 24, 36, 37), the shifts are typical for diamagnetic species and are readily assigned. The symmetry of the bis(phosphine) species is revealed by the equivalence of corresponding protons on the two axial ligands, for example, the *o*-hydrogens of the PPh_3 and P(*p*-$CH_3OC_6H_4$)$_3$ ligands (the shifts are at relatively high field, (3.8−4.2)δ, due to the ring current effect exerted by the porphyrin; the *m*- and *p*-hydrogens are similarly shifted but less so, (5.8−7.0)δ). In the symmetrical OEP complexes, the methylene protons of the ethyl groups appear as the expected quartet. The asymmetry present in the Ru(OEP)(CO)(PPh_3) complex leads to the methylene protons becoming diastereotopic and their detection as an ABX_3 pattern within the ethyl group (24, 36); the 12-line multiplet detected at 400 MHz is essentially identical to one reported previously for a [Nb(OEP)]$_2$(μ-O)$_3$ complex (38). The asymmetry in the Ru(TPP)(CO)(PPh_3) complex is probably reflected in the resonances of the porphyrin phenyl ring; in the symmetrical bis(phosphine) complexes, the *o*-, *m*-, and *p*-protons appear as slightly broadened singlets at ~7.6δ for the two triarylphosphine systems, and at 8.2 δ for the P^nBu_3 system, while the carbonyl derivative gives a complex pattern at (7.5−8.3)δ.

Concluding remarks

Details for the synthesis of some bis(tertiary phosphine) and carbonyl(tertiary phosphine) of Ru(II) are presented, together with their characterization by uv/vis and ^{1}H nmr spectra. The crystal structure of Ru(OEP)(PPh_3)$_2$ is reported also. Several of the complexes have been reported in previous papers from this laboratory dealing with their catalytic and redox chemistry (2−4, 31, 36), but in most cases details of their syntheses and characterization were not presented. The quantitative determination of the equilibrium constants for phosphine dissociation from the bis(phosphine) complexes is critical for an understanding of their solution chemistry, which is currently being developed.

N-acylglycine dithioesters form enethiolates near pH 9[1]

H. LEE, P. R. CAREY, AND A. C. STORER
Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received September 26, 1983

H. LEE, P. R. CAREY, and A. C. STORER, Can. J. Chem. **62**, 763 (1984).

It is demonstrated that *N*-acylglycine ethyl dithioesters have fairly acidic α-CH protons, and that ionization leads to the formation of enethiolate anions. For example, the pK_a's of *N*-benzoyl- and *N*-(β-phenylpropionyl)glycine ethyl dithioesters are 9.04 and 9.62, respectively. *N*-acylglycine papain dithioesters are formed during the papain catalyzed hydrolysis of the corresponding methyl thionoesters. However, for the papain dithioesters, no evidence was found for the formation of enethiolate anions.

H. LEE, P. R. CAREY et A. C. STORER. Can. J. Chem. **62**, 763 (1984).

On a démontré que les protons α-CH des dithioesters d'éthyle et de *N*-acylglycine sont assez acides et que leur ionisation conduit à la formation d'anions ènethiolates. Par exemple, les pK_a des dithioesters d'éthyle et soit de *N*-benzoyl- ou de *N*-(β-phénylpropionyl)-glycine sont respectivement 9,04 et 9,62. Les dithioesters de papaine et de *N*-acylglycine se forment lors de l'hydrolyse catalysée par la papaine des thionoesters méthyliques correspondants. Toutefois, on n'a pas pu mettre en évidence de formation d'anions ènethiolates avec les dithioesters de papaine.

Introduction

The present work originates in our resonance Raman, kinetic, and X-ray crystallographic studies of *N*-acylglycine papain dithioesters and their corresponding model compounds (1). The papain catalysed hydrolysis of *N*-acylglycine thionoesters proceeds via the formation of a dithioacyl enzyme intermediate which may be monitored by either spectrophotometry or resonance Raman (RR) spectroscopy (2). The use of the RR spectra to elucidate the events occurring in the enzyme's active site requires an in-depth understanding of the RR specroscopy and the chemistry of dithioesters. To this end there have been several spectroscopic (3, 4), kinetic (5), and X-ray crystallographic (6) studies on model dithioesters of varying degrees of complexity. In one recent kinetic study (5), concerning the hydrolysis of simple dialkyl dithioesters (e.g. ethyl dithioacetate), it was shown that hydrolysis is in competition with a second process. It was suggested that, due to the high acidity of the α-CH protons, this second process most probably involves the formation of a quasi-stable enethiolate anion. However, since the evidence presented was entirely kinetic, it was impossible to rule out completely the alternative explanation that the second process is due to the formation of a stabilized tetrahedral intermediate. One objective of the present work was to see if the hydrolysis of *N*-acylglycine dithioesters exhibits similar kinetic behaviour to that of the simple dithioesters. Moreover, unlike the simple dithioester case, we are able to use RR data to identify the quasi-stable intermediates formed during the hydrolysis of *N*-benzoylglycine ethyl dithioester (I) and *N*-(β-phenylpropionyl)glycine ethyl dithioester (II).

Finally, we use the RR spectroscopic information gained on model *N*-acylglycine dithioesters to search for evidence of α-CH ionization in the glycine portion of *N*-acylglycine papain dithioester intermediates.

Experimental

The dithioesters and their isotopically substituted analogues were synthesized as described in refs. 3 and 4. The reactions of the dithioesters in borate buffer pH 8.5–10.5 were monitored using a Cary 219 spectrophotometer. Plots of log ($OD_\infty - OD_t$) against time were linear for >90% of the reaction and the rate constants were obtained by a linear least-squares treatment of the data. At higher pH's the hydroxide ion concentration was varied by making direct additions of a standard NaOH solution to the reaction mixture, using distilled, deionized water throughout. For the buffered solutions the [OH^-] values were calculated from the measured pH, whereas for the unbuffered solutions the [OH^-] values were obtained by adding a known quantity of the standard NaOH solution. No attempt was made to keep the ionic strength constant due to the complex variation in buffer ionic strength with pH and the modest range of ionic strength used. Because of the higher rate of reaction above pH 10.5, the absorption changes were monitored using a Cantech (Winnipeg, Canada) stopped-flow spectrometer. This instrument was coupled to a PET microcomputer via a transient recorder. The transmission changes were <5% and the data (256 data points with 8-bit resolution) were fitted to a single exponential decay using a non-linear least-squares procedure (7). Dithioester I was monitored at 360 nm and dithioester II at 295 nm. All reactions were carried out at 20°C. The RR spectra were obtained using 324 nm Kr^+ laser excitation and a diode array based detection system described previously (4, 8).

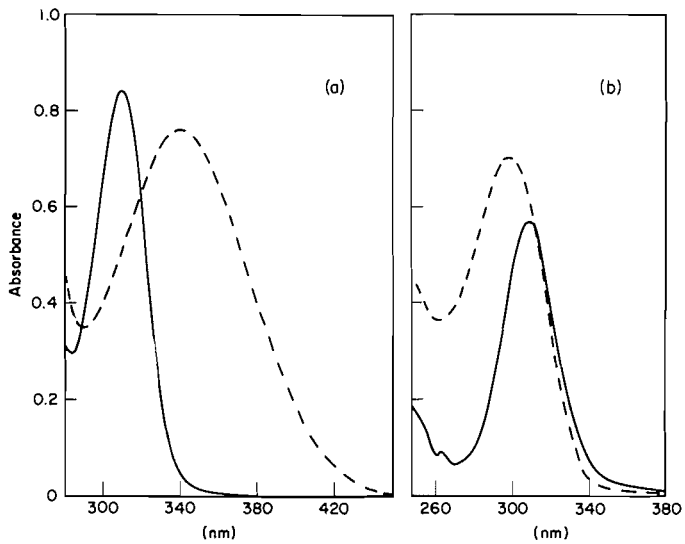

FIG. 1. Absorption spectra of (a) *N*-benzoylglycine ethyl dithioester (I) (8.4×10^{-5} *M*, 1-cm cell) and (b) *N*-(β-phenylpropionyl)glycine ethyl dithioester (II) (5.3×10^{-5} *M*, 1-cm cell) at pH 7 (———) and in 0.01 *N* NaOH (– – –).

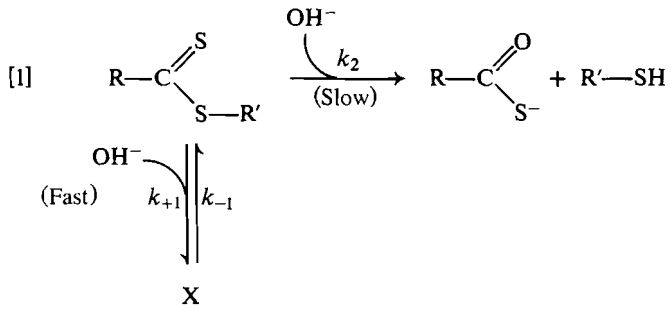
Results and discussion

Figures 1(a) and (b) show absorption spectral changes that

[1]NRCC No. 22861.

occur on placing the *N*-acyl glycine dithioesters in 0.01 *N* NaOH solution. For dithioester I there is a red shift in the near uv peak from 308 nm to 340 nm, whereas for dithioester II there is a blue shift in the peak from 308 nm to 298 nm. The spectral changes are complete within a few seconds. The shifted peaks then decay away in a second process that takes several hours ($t_{1/2} \simeq 5$ h). These biphasic spectral changes are comparable with those observed for simple dialkyl dithioesters (5). In the case of the dialkyl dithioesters a rapid spectral change is observed as a new form of the dithioester is reversibly produced at high pH and that is followed by a slow spectral change as the residual dithioester hydrolyses irreversibly:[2]

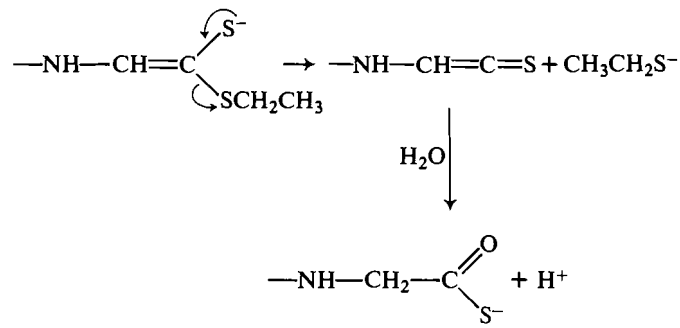


For dithioesters I and II the initial rapid spectral changes can also be shown to be reversible, since on changing the pH to neutral the spectrum reverts to that of the original dithioester. Therefore for dithioesters I and II the scheme proposed for the dialkyl dithioesters is believed to apply also. Provided the base concentration is far in excess of the dithioester concentration, the rate constant (k_{meas}) defining the initial equilibration process is:

$$[2] \quad k_{meas} = k_{-1} + k_{+1} \cdot b$$

where b = hydroxide ion concentration (see ref. 5 for more details). The rapid spectral shifts were followed, in the 10-m*M* to 200-m*M* range of hydroxide concentration, using a stopped-flow spectrometer. A typical trace is shown in Fig. 2 for dithioester I, and a plot of k_{meas} against b is shown in Fig. 3 for

[2]An alternative suggestion put forward by a referee is that the slow spectral change may not be due to hydrolysis of the residual dithioester but rather an elimination–addition mechanism involving the enethiolate, i.e.



The data presently available cannot distinguish between the two possibilities although the authors prefer the simple hydrolysis mechanism. This preference is based on the fact that in order for the alternative mechanism to make a significant contribution to the rate of disappearance of the dithioester, the rate of hydrolysis of dithioesters must be much slower than that of esters and thioesters rather than just 6- to 8-fold slower as suggested in ref. 5.

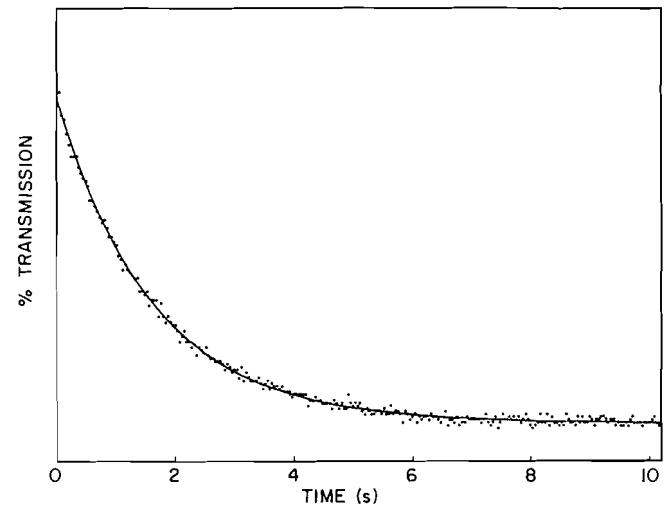


FIG. 2. Stopped flow trace of 5 μ*M* dithioester (I) in 39.2 m*M* NaOH monitored at 360 nm. The total transmission change is <5%. The solid line represents the best fit of the data to a single exponential function using a non-linear least-squares fitting procedure (7).

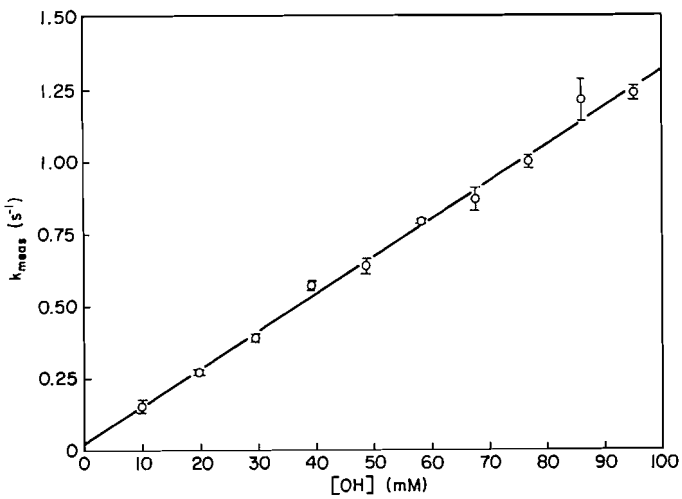

FIG. 3. Plot of k_{meas} against b ([OH^-]) for dithioester (II); k_{meas} values are the averages of at least three determinations and the error bars represent the standard deviations. The solid line represents a linear least-squares fit to the data weighted according to their standard deviations.

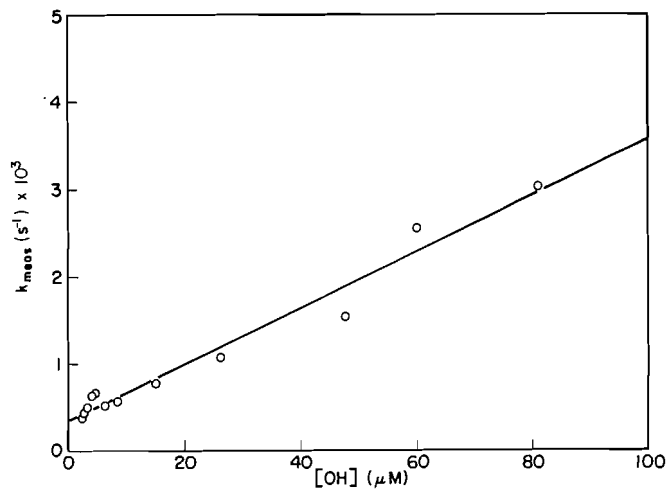

FIG. 4. Plot of k_{meas} against b ([OH^-]) for dithioester (I) obtained in 50 m*M* borate buffer. The solid line represents an unweighted linear least-squares fit to the data.

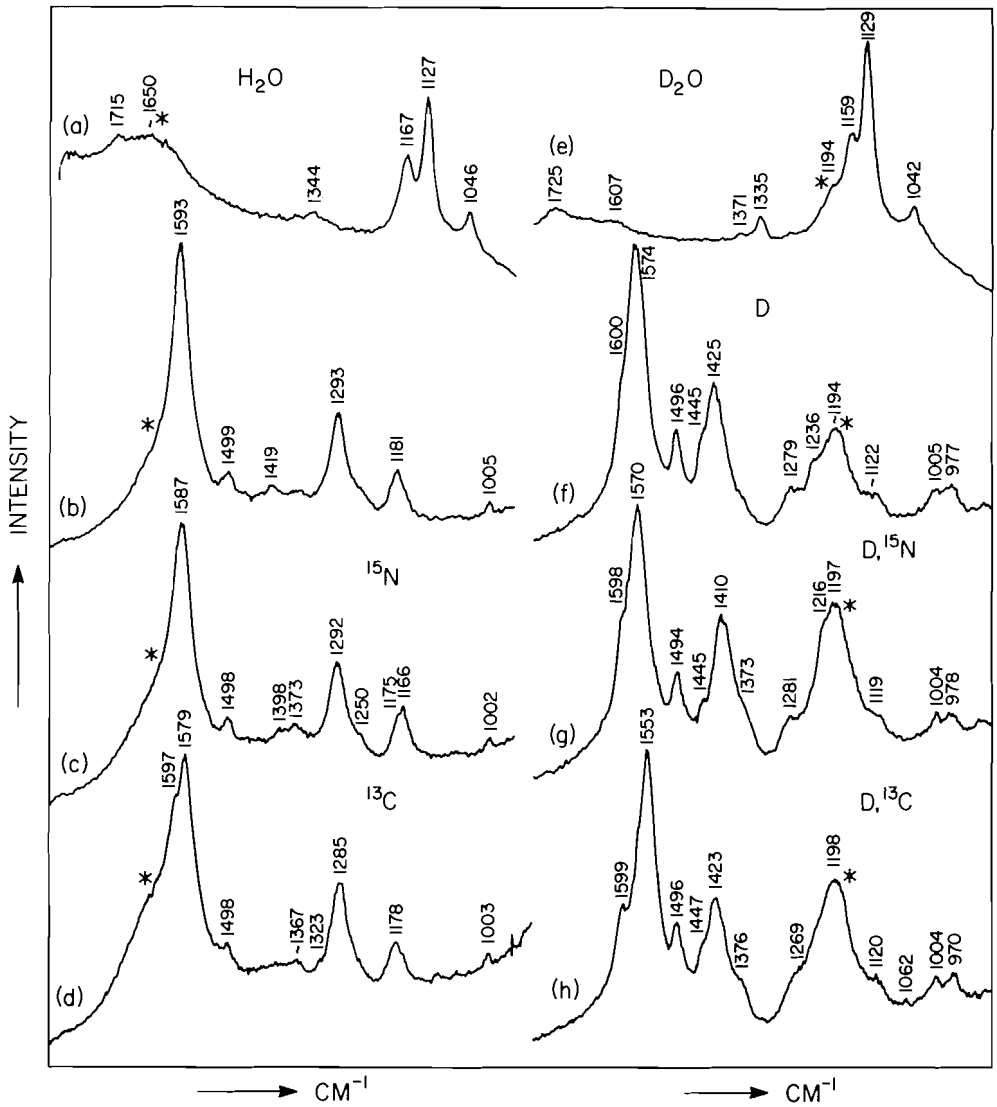

FIG. 5. Resonance Raman spectra of 4×10^{-4} *M* *N*-benzoylglycine ethyl dithioester (I) near neutral pH in H_2O (a) and neutral pD in D_2O (e), at high pH (b–d) or pD (f–h). Isotopic substitutions ^{15}N and $^{13}C{=}S$ are indicated on figure. Each spectrum was obtained using 80 mW of 324 nm Kr^+ excitation, spectral slit 12 cm^{-1}, 1 min total acquisition (4 s × 15). H_2O or D_2O contribution marked by an asterisk.

dithioester II. The error bars represent the standard deviations of the data points which are the averages of at least three determinations. The line was obtained by a linear least-squares analysis of the data weighted according to the standard deviations. From the slopes of the plots, values for k_{+1} of 15.81 ± 0.03 M^{-1} s^{-1} and 12.91 ± 0.03 M^{-1} s^{-1} were obtained for dithioesters I and II, respectively. These values are approximately one order of magnitude greater than the value of 1.36 M^{-1} s^{-1} obtained for ethyl dithioacetate (5). Although values for k_{-1} can also be obtained from the plots they are not reliable since accurate intercept values (Fig. 3) cannot be obtained with the range of concentrations used. In order to determine k_{-1} more accurately, the reactions were also monitored, using a spectrophotometer in the pH range 8.5–10.5 using 50 m*M* borate buffer. Under these conditions, since *b* does not vary appreciably with time, eq. [2] still applies. The data for dithioester I are shown in Fig. 4.

The values of k_{+1} are 32.2 ± 1.9 M^{-1} s^{-1} and 23.0 ± 1.1 M^{-1} s^{-1} for I and II, respectively, approximately twice the values obtained in the absence of borate. This difference could possibly be due to the different methods of obtaining the $[OH^-]$ concentrations or possibly some degree of buffer catalysis. The values of k_{-1} are 0.35 (±0.06) ± 10^{-3} s^{-1} and 0.95 (±0.13) × 10^{-3} s^{-1} for I and II, respectively. From the k_{+1} and k_{-1} values obtained in borate buffer it is possible to calculate pK_a's of 9.04 and 9.62 for dithioesters I and II, respectively. These pK_a values are unusually low for the α-CH of a depsipeptide but can be rationalized on the basis that the α-CH protons of dithioesters are more acidic than those of the corresponding esters or thiolesters (5, 9, 10). The fairly slow rates of proton transfer from the dithioesters to hydroxide (k_{+1}) are within the range normally encountered for carbon acids, i.e. the comparable rates for acetone and acetylacetone are 0.27 and 4×10^4 M^{-1} s^{-1}, respectively (11).

The identity of species X in eq. [1] can be established with reasonable probability from the RR data. Figures 5 and 6 compare the neutral- and high-pH RR spectra of I and II, respectively, along with the RR spectra of various isotopically-substituted forms at high pH. There are major spectral changes upon going to high pH; the characteristic intense RR bands of the neutral species in the 600 (data not shown) and 1150 cm^{-1} regions (3, 4) are replaced by a dominant feature near 1600

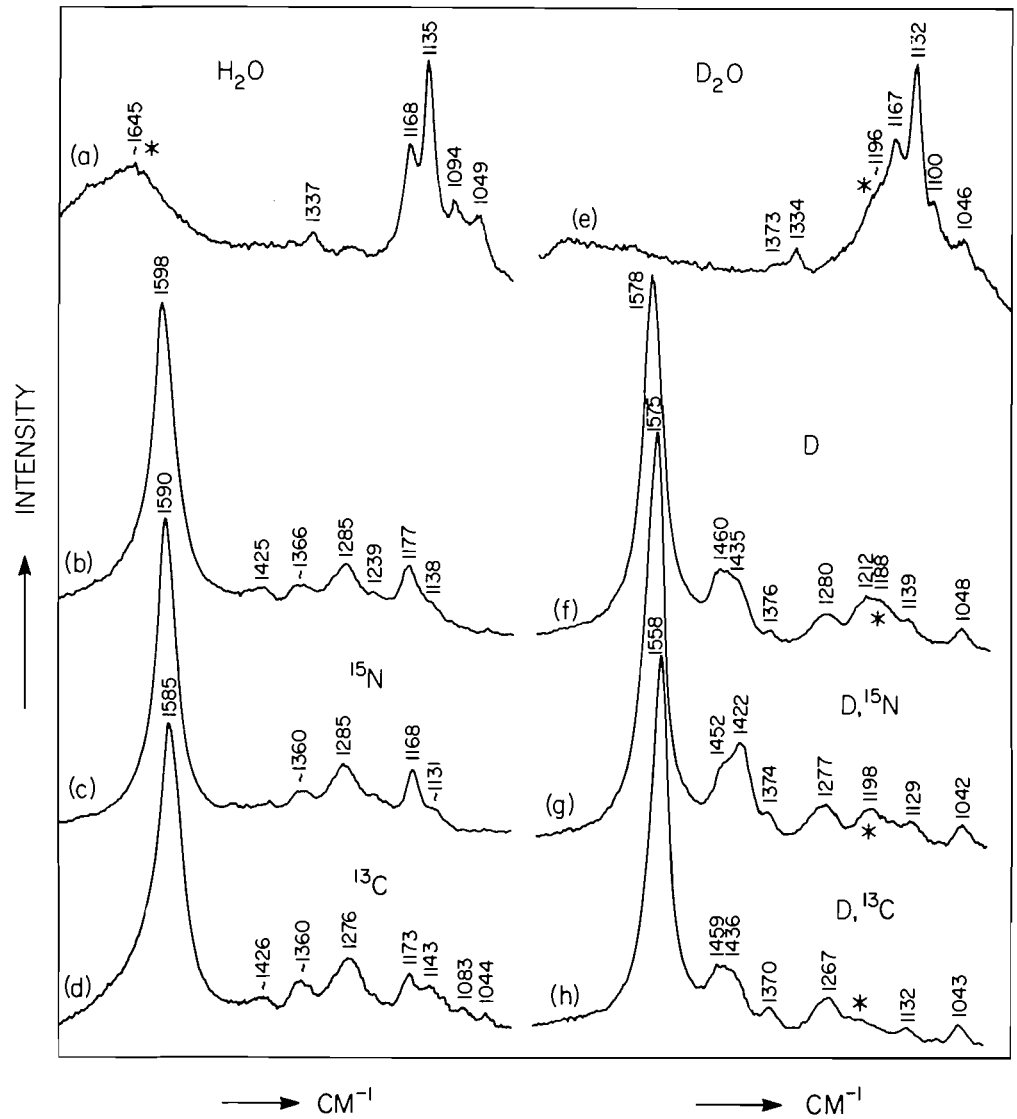

FIG. 6. Resonance Raman spectra of 10^{-3} *M* *N*-(β-phenylpropionyl)glycine ethyl dithioester (II) near neutral pH in H_2O (a) and neutral pD in D_2O (e), at high pH (b–d) or pD (f–h). Isotopic substutitons ^{15}N and $^{13}C{=}S$ are indicated on figure. Conditions as for Fig. 5. H_2O or D_2O contribution marked by an asterisk.

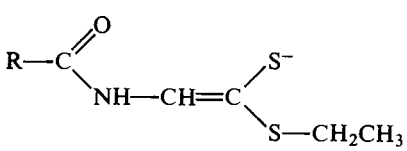
cm^{-1} at high pH. Isotopic substitution demonstrates that the latter feature is not due to a localized mode. Upon ^{15}N or ^{13}C (C=S) replacement the intense band shifts to lower frequency by 6 and 14 cm^{-1}, respectively for I; and by 8 and 13 cm^{-1}, respectively, for II. The position of the band, near 1600 cm^{-1}, suggests that the mode possesses double bond character but the relatively low sensitivity to ^{13}C replacement, taken with the ^{15}N results, suggests that the mode is delocalized through the glycine linkages. These findings are consistent with the species X being an enethiolate of the type:



Thus, although *N*-acylglycine dithioesters are quite stable at neutral pH in the thione form (in contrast to thioketones which enolize readily if there is an α-H present), they deprotonate above pH ≃ 9.5 to form a stable enethiolate.

Further evidence for the enethiolate can be found in the spectra of the deuterated compounds. The enethiolate form has two labile hydrogens (i.e. the amide and vinyl hydrogens). In NaOD solution both are exchanged for deuterons. The mode near 1600 cm^{-1} for I and II shows a 20 cm^{-1} shift upon deuteration. In general, the C=C stretching mode of a vinyl group is sensitive to the C-deuteration because of vibrational mixing with the CH in-plane rocking mode (12). The 20 cm^{-1} shift of the 1600 cm^{-1} mode is comparable with that reported for the $C_9{=}C_{10}$ stretch of all-*trans* retinal (13). Thus, the deuteration results support the assignment of the intense 1600 cm^{-1} peak to a delocalized double bond stretching motion having some $\nu_{C=C}$ character.

Several other peaks in the high-pH RR spectra are sensitive to isotopic substitution. Features near 1290 cm^{-1} for both I and II are sensitive to ^{13}C, but not ^{15}N, replacement. The bands near 1180 cm^{-1} are sensitive to ^{15}N substitution in both compounds. In NaOD/D_2O, weak to medium bands appear near 1430 cm^{-1} for both I and II, and these bands shift upon ^{15}N substitution. It is possible that the latter bands possess some amide II′

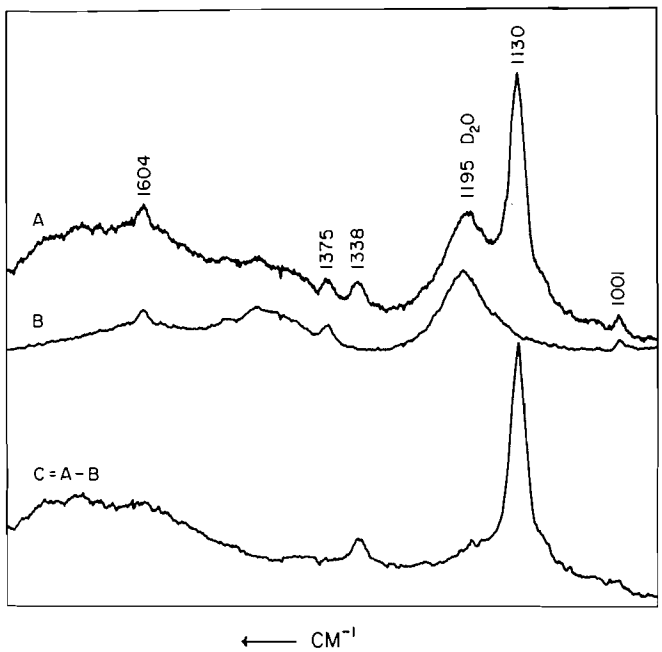

FIG. 7. Resonance Raman spectra of reaction mixture containing (A) *N*-benzoylglycine dithioacyl papain in D_2O at pD 9.2, (B) substrate alone, and (C) B subtracted from A. Conditions are given in ref. 15.

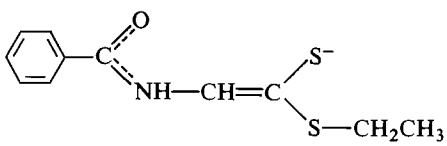
character but given the unknown nature of the force field for the enethiolate species we do not feel confident in assigning any band except the most intense feature near 1600 cm^{-1}.

Strong support for electron delocalization is seen in the RR spectra of compound I. The high-pH spectra in Fig. 5 have phenyl ring modes around 1000 cm^{-1} and 1500 cm^{-1} (14) along with a shoulder near 1600 cm^{-1} which is also due to a ring mode. Equivalent features are not seen in the high-pH spectra of compound II (Fig. 6). The appearance of the phenyl modes for I indicates that the π-electrons are delocalized throughout the acyl group and that the phenyl ring is, at least to a degree, part of the chromophore:



For the dithioester II, the phenyl ring is insulated from the conjugated amide–enethiolate system by two methylene groups and the phenyl group is not part of the chromophore. This difference is reflected in the frequencies of the band near 1600 cm^{-1} of the two enethiolates in that for any isotopomer the frequency, for I, is always a few wavenumbers lower, as a consequence of the greater electron delocalization, than that for II. The presence of the conjugated systems also explains the increasing red shift in λ_{max} for the series of enethiolates formed from ethyl dithioacetate (258 nm) (5), dithioester II (298 nm), and dithioester I (340 nm) since the degree of conjugation involving the enethiolate increases throughout the series. In addition, part of the variation in the α-CH pK_a's (12.5, 9.62, 9.04 for the same series) can be explained on the same basis, with increasing conjugation leading to a decrease in pK_a, since the anions formed are stabilized to a greater extent.

N-acylglycine dithioesters are formed in the active site of papain during the catalysed hydrolysis of *N*-acylglycine thionoesters (1) and it is of interest to search for the possible ionization of the glycine α-hydrogens in this environment. Thus, the intense enethiolate RR feature at approximately 1600 cm^{-1} was used as a marker in an attempt to detect the presence of an enethiolate anion form in a dithioacyl enzyme population. For the enzyme work, D_2O solutions were used in order to eliminate the possibility of the broad H_2O peak at 1650 cm^{-1} (Figs. 5 and 6) obscuring weak dithioacyl enzyme features. We were able to detect dithioacyl papain RR features at pD 9.2 (due to the decrease in activity and increase in instability of the enzyme at high pH (pD), higher values were not tried). At this pD the model dithioester I would be ca. 70% in the enethiolate form. However, as shown in Fig. 7, no peak at or around 1600 cm^{-1} ascribable to an enethiolate could be detected in the RR spectrum of *N*-benzoyl glycine dithioacyl papain. Although a weak peak at 1604 cm^{-1} was observed, this peak, based on its isotopic insensitivity and its presence in substrate spectra obtained in the absence of enzyme, was assigned to a benzene ring mode of the substrate which is present in the reaction mixture at relatively high concentrations. The absence of any enethiolate features in the dithioacyl papain spectra can be due to one or more of the following reasons: (*i*) based on the solution kinetics at pH 9.2, the uncatalysed rate of enethiolate formation would be approximately 10^2 times slower than the catalysed deacylation rate of the dithioacyl enzyme (unpublished work, this laboratory); (*ii*) in the enzyme's active site the pK_a of the α-CH protons may be very different from the value in solution (the α-CH acidity of ethyl dithioacetate is environment dependent (5)); and (*iii*) the geometry of the active site may be such that it is sterically difficult for the acyl group to undergo the conformational change associated with the ionization of the α-CH protons. Whatever the reason, it may be concluded that there is no significant ionization of the dithioacyl groups in the intermediates formed during the papain catalysed hydrolysis of *N*-acylglycine thionoesters.

The electrochemical reduction of *N*-fluorourethans in acetonitrile. The generation of carbethoxynitrene[1,2]

JEAN LESSARD[3] AND DENIS BÉRUBÉ[4]

Département de chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received August 18, 1983

JEAN LESSARD and DENIS BÉRUBÉ. Can. J. Chem. **62**, 768 (1984).

The electrochemical reduction of *N*-fluoro-*N*-methylurethan (**1***a*) and *N*-fluorourethan (**2***a*) in acetonitrile generates the amide anion and a fluoride ion. Both the fluoride and the amide anion can react with the starting *N*-fluoroamide either as bases or as nucleophiles. Many products are formed and the coulometric results are low (0.5 to 0.7 F/mol). In the case of NFU (**2***a*), abstraction of the proton on nitrogen both by the urethan anion and the fluoride anion generates the conjugate base EtOCONF (**7**) which immediately undergoes α-elimination of the fluoride ion to give carbethoxynitrene (**11**). This nitrene was generated also by treating NFU (**2***a*) with a base such as triethylamine or lithium hydride. The α-elimination of F^- from EtOCONF is much easier than the α-climination of Cl^- from EtOCONCl.

JEAN LESSARD et DENIS BÉRUBÉ. Can. J. Chem. **62**, 768 (1984).

La réduction électrochimique du *N*-fluoro-*N*-méthyluréthane (**1***a*) et du *N*-fluorouréthane (**2***a*) conduit à l'anion d'amide et à l'ion fluorure. Ces deux anions peuvent réagir avec le *N*-fluoroamide de départ comme bases ou comme nucléophiles, ce qui engendre de nombreux produits et des coulométries observées faibles (0,5 à 0,7 F/mol). Dans le cas du NFU (**2***a*), l'anion de l'uréthane et l'ion fluorure arrachent le proton de l'azote pour former la base conjuguée EtOCONF (**7**) qui perd immédiatement l'ion fluorure (élimination α) en donnant le carbéthoxynitrène (**11**). Ce nitrène est obtenu également en traitant le NFU (**2***a*) par une base telle la triéthylamine ou l'hydrure de lithium. L'élimination α de F^- à partir de EtOCONF est beaucoup plus facile que l'élimination α de Cl^- à partir de EtOCONCl.

We have recently reported (1) that the electrochemical reduction of *N*-bromo- and *N*-chloroamides (ZCONRX) in acetonitrile leads to the amide anion (eq. [1]). In the case of *N*-halo-*N*-alkyl(aryl)amides, the amide anion abstracts a proton from the medium to give the parent amide and strong bases or nucleophiles (eq. [2]) which react with the starting *N*-haloamide to regenerate the amide anion (eq. [3]).

[1] $ZCONRX + 2e^- \rightarrow ZCO\bar{N}R + X^-$

[2] $ZCO\bar{N}R + SH \rightarrow ZCONHR + S^-$

[3] $ZCONRX + S^- \rightarrow ZCO\bar{N}R + SX$

In the case of *N*-halo-*N*-hydroamides (R = H), the amide anion reacts with an incoming *N*-halo-*N*-hydroamide molecule to give the parent amide and the conjugate base of the *N*-haloamide (eq. [4], father–son protonation). If water is present in the double layer, the conjugate base can be reduced to the parent amide (eq. [5]).

[4] $ZCO\bar{N}H + ZCONHX \rightarrow ZCONH_2 + ZCO\bar{N}X$

[5] $ZCO\bar{N}X + 2\,H_2O + 2e^- \rightarrow ZCONH_2 + 2\,HO^- + X^-$

This paper reports on the electrochemical reduction of *N*-fluoro-*N*-methylurethan (NFMU) (**1***a*) and *N*-fluorourethan (NFU) (**2***a*) and on their reaction with bases. These *N*-fluorourethans are compared to their *N*-chloro analogues, *N*-chloro-*N*-methylurethan (NCMU) (**1***b*) and *N*-chlorourethan (NCU) (**2***b*), studied previously (1).

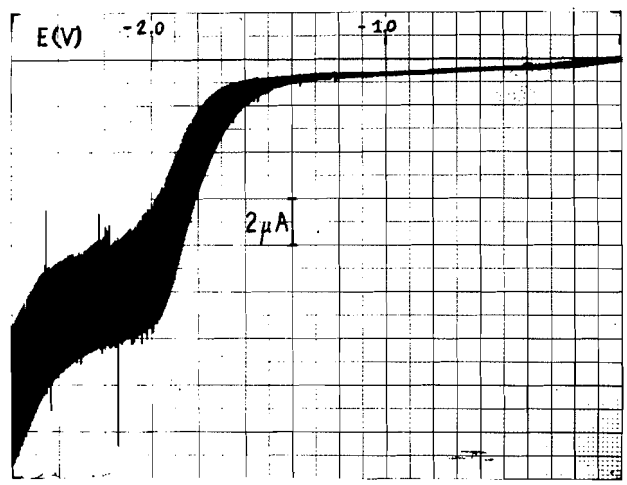

FIG. 1. Polarogram of NFMU (**1***a*) (1.52 m*M*) in acetonitrile–TEAP (0.1 *M*) (sweep rate: 10 mV/s; t = 0.5 s).

Results and discussion

N-*Fluoro*-N-*methylurethan (1*a*)*

In acetonitrile containing tetraethylammonium perchlorate (TEAP) 0.1 *M* as supporting electrolyte,[5] the polarogram of **1***a* (Fig. 1) shows one irreversible (αn value of 0.25–0.28) and diffusion-controlled reduction wave at $E_{1/2}$ = −1.75 V vs. a saturated calomel electrode (sce).[6] An N—F bond is stronger than an N—Cl bond (2) and, indeed, **1***a* is more difficult to reduce than its *N*-chloro analogue **1***b* by about 1.4–1.6 V (1).

Both NFMU (**1***a*) and NCMU (**1***b*) are consumed by secondary reactions during their electrochemical reduction as shown by low coulometric n values: 0.66 F/mol for **1***a*; 0.49–0.57 F/mol for **1***b* (1). These secondary reactions are minimized or

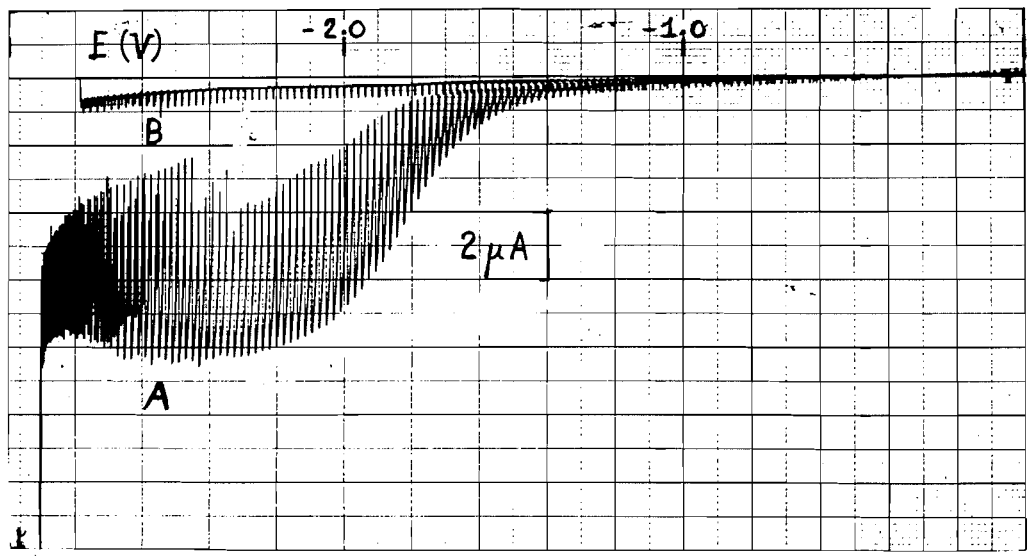

FIG. 2. Curve A: polarogram of NFU (**2***a*) (2.21 m*M*) in acetonitrile–TEAP (0.1 *M*) (sweep rate: 10 mV/s; t = 2 s); curve B: acetonitrile–TEAP (0.1 *M*) (background current).

suppressed in the presence of acetic acid: coulometries of 1.8 F/mol or higher; increase of 30–36% of the limiting current of the polarographic wave(s).[7] Controlled potential electrolysis of NCMU (**1***b*) gave *N*-methylurethan (**3**) in high yield (90%) and reaction [3] has been suggested to be responsible for the low n values (1). In the case of NFMU (**1***a*), other reactions must be involved since the controlled potential electrolysis gave both *N*-methylurethan (**3**) and urethan (**4**) in 26% and 25% yields, respectively, together with about 1% each of the amidals **5** and **6** (Scheme 1); polymers were formed also, according to ^{1}H nmr spectroscopy. The parent amide **3** comes from reduction of the N—F bond (eq. [1]) followed by abstraction of a proton from the medium by the anion of *N*-methylurethan (eq. [2]). The formation of urethan and of amidals **5** and **6** can be accounted for by the reactions shown in Scheme 1. The reactions of NFMU (**1***a*) with tetraethylammonium fluoride (TEAF) in acetonitrile gave 22% of urethan but no amidals were detected. Reactions such as reaction [6] could be partly responsible for the low material balance in both the electrochemical reduction of **1***a* and its reaction with TEAF. Analysis of the cathode and anode compartments for fluoride ions after exhaustive electrolysis of **1***a* gave 70%. Polarographic analysis showed the disappearance of the NFMU wave and the appearance of a

[6] $\underset{\mathbf{1}a}{\mathrm{EtOCON(CH_3)F}} + 2\ \mathrm{F^-} \rightarrow \mathrm{COF_2} + \mathrm{CH_3\bar{N}F} + \mathrm{EtO^-}$

wave at $E_{1/2} = -2.4$ V with a limiting current corresponding to about 15% of that of the NFMU wave of the initial solution. This wave probably corresponds to the reduction of amides.

N-*Fluorourethan* (*2*a)

Voltammetry

The polarogram of NFU (**2***a*) in acetonitrile–TEAP (0.1 *M*) (Fig. 2) shows one irreversible (αn = 0.20–0.23) and diffusion controlled wave at $E_{1/2} = -1.81$ V. The close similarity of the reduction potentials ($E_{1/2}$) and transfer coefficients (αn) for NFU (**2***a*) and NFMU (**1***a*) strongly suggests that the N—F bond (eq. [7]), and not the N—H bond of NFU (eq. [8]), is reduced. This is confirmed by the absence of hydrogen evolution during the preparative electrolysis of NFU on mercury

[7] $\underset{\mathbf{2}a}{\mathrm{EtOCONHF}} + 2\ \mathrm{e^-} \rightarrow \mathrm{EtOC\bar{O}NH} + \mathrm{F^-}$

[8] $\underset{\mathbf{2}a}{\mathrm{EtOCONHF}} + \mathrm{e^-} \rightarrow \mathrm{EtOC\bar{O}NF^-} + \tfrac{1}{2}\ \mathrm{H_2}$

and on platinum. Thus although (*i*) NFU (pK_a = 5.69 in water) is more acidic than NCU (pK_a = 8.02) (3), and (*ii*) an N—F bond is more difficult to reduce than an N—Cl bond, the reduction of NFU involves the cleavage of the *N*-halogen bond (eqs. [1] and [7]) as with the other *N*-halo-*N*-hydroamides

[7] The time scale of a polarographic experiment is much shorter than that of a coulometric determination. Therefore secondary reactions consuming the *N*-fluorourethans **1***a* and **1***b* that are slower than the dropping time should have no influence on the polarographic limiting current but do have an influence on the coulometric n value.

studied (1). Also, as for NCU (**2***b*) and the other *N*-halo-*N*-hydroamides (1), reaction [7] must be followed by reaction [9] (see eq. [4], father–son protonation).

[9] $\underset{\mathbf{2}a}{EtOCO\bar{N}H} + \underset{\mathbf{4}}{EtOCONHF} \rightarrow \underset{\mathbf{4}}{ETOCONH_2} + \underset{\mathbf{7}}{EtOCO\bar{N}F}$

The addition of 1 equiv. or more of acetic acid causes a small change of αn (0.25–0.28) and a 55% increase of the limiting current of the NFU polarographic wave. With *N*-chloro- and *N*-bromo-*N*-hydroamides (1), a 100% increase of the first polarographic wave (eq. [1], R = H) was observed in the presence of 1 equiv. or more of acetic acid because all the *N*-haloamide reaching the electrode is reduced whereas, in a neutral medium, 50% only is reduced due to the father–son protonation [4]. In the case of NFU, the fluoride ion is a base strong enough to abstract a proton from NFU (see the section entitled *Reaction with bases*) and, therefore, two father–son protonations (eqs. [9] and [10]) can follow the reduction step (eq. [7]). The sum of reactions [7], [9], and [10] gives [11] according to which 33% only of the NFU reaching the electrode should be reduced. Assuming that, in the presence of 1 equiv.

[10] $\underset{\mathbf{2}a}{EtOCONHF} + F^- \rightarrow \underset{\mathbf{7}}{EtOCO\bar{N}F} + HF$

[11] $3\ \underset{\mathbf{2}a}{EtOCONHF} + 2\ e^- \rightarrow \underset{\mathbf{4}}{EtOCONH_2} + 2\ \underset{\mathbf{7}}{EtOCO\bar{N}F} + HF$

of acetic acid or more, the father–son protonation [9] is suppressed[8] (replaced by protonation [12]) but not the father–son protonation [10], reaction [13] (the sum of reactions [7], [12], and [10]) is obtained. According to eq. [13], 50% of the NFU reaching the electrode should be reduced, which is 1.5 times more (50% increase) than in a neutral medium. These figures agree quite well with the observed 55% increase of the limiting current with the addition of acetic acid (see above).[9]

[12] $\underset{\mathbf{4}}{EtOCO\bar{N}H} + AcOH \rightarrow \underset{\mathbf{4}}{EtOCONH_2} + AcO^-$

[13] $\underset{\mathbf{2}a}{2\ EtOCONHF} + AcOH + 2\ e^- \rightarrow \underset{\mathbf{4}}{EtOCONH_2} + \underset{\mathbf{7}}{EtOCO\bar{N}F} + HF + AcO^-$

The cyclic voltammogram of NFU on mercury is shown in Fig. 3. The peak corresponding to the reduction of NFU is at −2.0 V. The reversible system with E_{eq} = 0.0 V corresponds to the oxidation of mercury in the presence of anions. There are two small reduction peaks at −0.2 V (shoulder, reduction of **14**, Scheme 2) and −0.7 V (reduction of **12**, Scheme 2). On a platinum electrode (Fig. 4), the reduction peak of NFU appears between −1.25 and −1.4 V, there is an oxidation peak at −0.1 V (unidentified), and a small reduction peak at −0.5 V

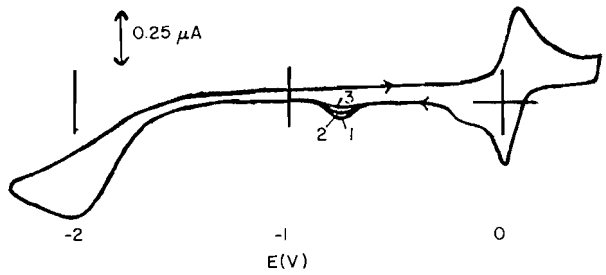

FIG. 3. Cyclic voltammogram of NFU (**2***a*) (0.25 m*M*) in acetonitrile–TEAP (0.1 *M*) on a hanging mercury drop electrode (sweep rate: 100 mV/S); three consecutive scans.

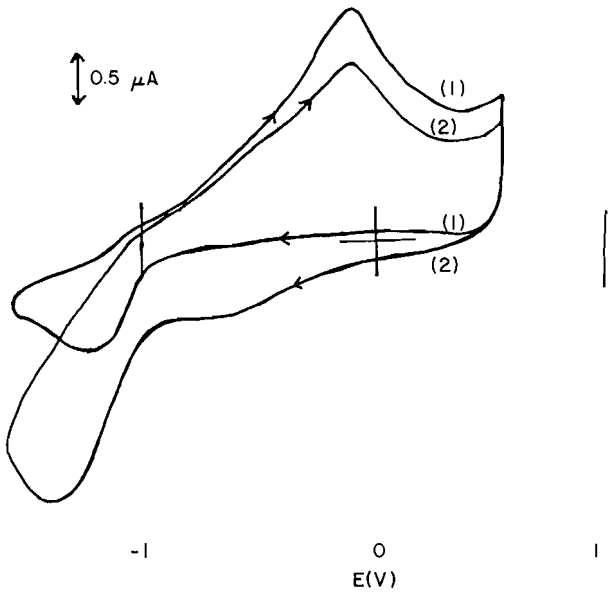

FIG. 4. Cyclic voltammogram of NFU (**2***a*) (0.3 m*M*) on platinum in acetonitrile–TEAP (0.1 *M*). For the oxidation scans, the sweep rate was 10 V/S. For the reduction scans, the sweep rates were (1) 1 V/s; (2) 10 V/S.

(reduction of **12**, Scheme 2). On a rotating disc platinum electrode (ω = 600 rpm, sweep rate = 5 mV/s), the half-wave potential for the reduction of NFU is −1.0 V.[10]

Controlled potential electrolyses

The results are summarized in Table 1. In a neutral medium, the controlled potential electrolysis of NFU (**2***a*) requires between 0.6 and 0.7 F/mol (electrolyses 1 and 3) in agreement with eq. [11]. According to eq. [13], the electrolysis should require 1 F/mol in the presence of 0.5 equiv. or more of acetic acid and the coulometric results (electrolysis 2) do agree with eq. [13].

However, the analysis of products (see Table 1) showed that the situation is far more complex than that described by eqs.

[8] In water, the acetate ion (pK_a = 4.74) is a stronger base than the fluoride ion (pK_a = 3.18) and we have to assume that the order of relative basicities remains the same in acetonitrile–TEAP (0.1 *M*) or/and in the double layer.

[9] In order to suppress the father–son protonation [10], we tried trifluoracetic acid and pyridinium perchlorate. Unfortunately these acids are more easily reduced ($E_{1/2}$ = −1.70 V and −1.30 V respectively) than NFU. The polarographic wave of acetic acid appears at −2.3 V.

[10] Usually, electron-transfer reactions at a solid electrode are slower (are less reversible) and potentials are more negative than at a mercury electrode (4). The slowness of electron transfer was recently ascribed to the partial blocking of the surface of the solid electrode (5). In our case, the potentials are less negative at a platinum electrode. No electrochemical pretreatment of the electrode (5) was made. The electrode was polished before each use on a Buehler Carbimet 600 abrasive paper.

[11] and [13]. The material balance is low.[11] The yield of urethan (**4**) is much lower than that predicted by eqs. [11] and [13]. In fact, in electrolyses 1 and 3, the urethan present in the starting NFU is consumed: about 1 mol% in electrolysis 1 and up to 11 mol% in electrolysis 3. The yield of inorganic fluoride is somewhat higher than predicted: 46% (neutral medium, electrolysis 1) compared to 33% predicted by eq. [11]. The complexity of the reaction is due to the very facile α-elimination of the fluoride ion from the conjugate base **7** to give the reactive carbethoxynitrene (**11**) (eq. [14]) (see also the reaction of NFU with bases) and could be due also the reactivity of NFU and some of the electrolysis products towards nucleophiles.[12]

[14] $\underset{\mathbf{7}}{EtOCO\bar{N}F} \rightarrow \underset{\mathbf{11}}{EtOCO\ddot{N}:} + F^-$

The oxadiazole **8** arises from 1,3-dipolar cycloaddition of carbethoxynitrene (**11**) to acetonitrile (eq. [18] and ref. 6). Smith

[18] $\underset{\mathbf{11}}{EtOC(O^-)=N^+} + CH_3CN \rightarrow$ 
8

[11] In addition to the products shown in Table 1, the vpc and thin-layer chromatographic (tlc) analysis showed the presence of at least eight other products formed in small amounts and not identified. Furthermore, TEAP was removed by extraction with water and some of the electrolysis products might be more soluble in water than in ether. Finally, volatile products were probably lost when removing ether in the rotatory evaporator.

[12] For instance, the nucleophilic addition of fluoride ions to NFU could lead to the reactive carbonyl fluoride and the $\bar{N}HF$ anion (eq. [15]); the nucleophilic reaction of urethan or its anion with NFU could lead to the azamalonate **10** (eq. [16]). However, fluoramine could not be detected (eqs. [15] and [16]). Furthermore, in the electrochemical reduction of NFMU (**1***a*) discussed in the preceding section, ethyl *N*-methylazamalonate (**17**), which could have been formed by nucleophilic addition of *N*-methylurethan or its anion to NFMU (eq. [17]), was not detected.

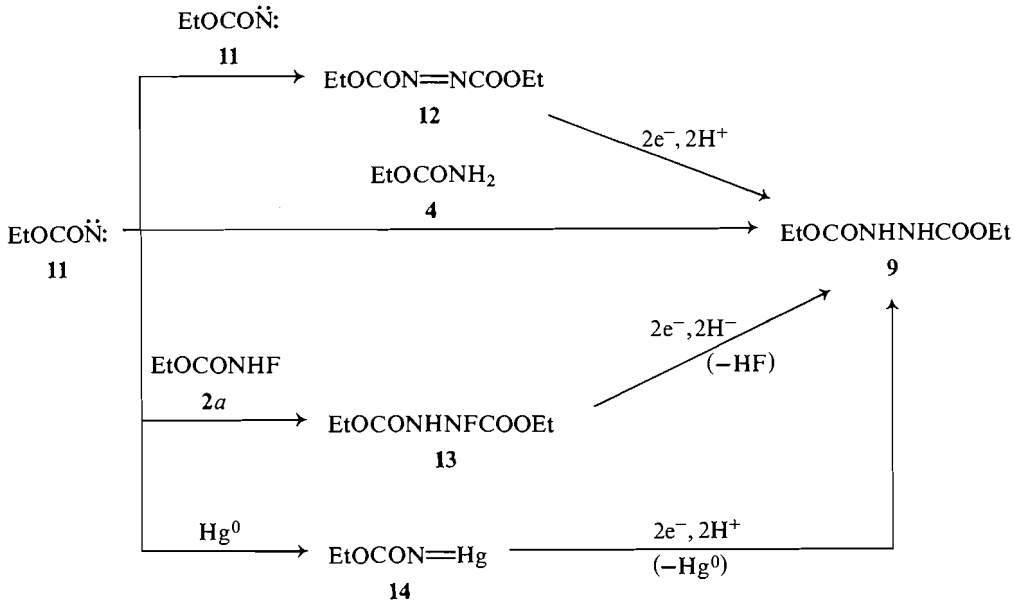

SCHEME 2

and Rogers (7) have shown that oxadiazoles are reduced electrochemically to saturated and ring-opened products in dimethylformamide in the presence of a proton donor. The oxadiazole **8** shows two polarographic waves in acetonitrile–TEAP (0.2 *M*) ($(E_{1/2})_1$ = −1.61 V and $(E_{1/2})_2$ = −2.5 V) and it should be reduced at the electrolysis potential (−1.9 V) until no more NFU, acting as the proton donor, is available. Oxadiazole **8** could be consumed also by the fluoride ions produced during the electrolysis, NFU acting again as an acid. Thus, oxadiazole **8** reacts with tetraethylammonium fluoride (TEAF) provided an acid is present.[13]

Four plausible routes for the formation of diethyl hydrazodicarboxylate (**9**) are shown in Scheme 2. The coupling of two carbethoxynitrenes (**11**) leads to diethyl azodicarboxylate (**12**) $E_{1/2}$ = −0.5 V, which is then reduced to **9** at the electrolysis potential (−1.9 V). In the cyclic voltammograms of NFU, the peak at −0.7 V on a mercury electrode (Fig. 3) and the peak at −0.5 V on a platinum electrode (Fig. 4) are attributed to the azo compound **12**.[14] Further evidence for the intermediacy of **12** comes from its formation in the reaction of NFU with bases (see below). The hydrazo derivative **9** can be formed also by insertion of carbethoxynitrene (**11**) into an N—H bond of urethan. This reaction would account for the consumption of the urethan present in the starting NFU during the electrolyses carried out in a neutral medium (Table 1, electrolyses 1 and 3). The insertion of **11** into the N—H bond of NFU would give **13** which should then be reduced to **9**. Finally, the reaction of carbethoxynitrene (**11**) with mercury followed by reduction of the organomercuric derivative **14** represents another route to **9** (Scheme 2). The shoulder at −0.2 V in the cyclic voltammogram of NFU on mercury (Fig. 1) can be attributed to **14**; this peak is absent when a platinum electrode is used (Fig. 2).

[13] Oxadiazole **8** did not react with TEAF in acetonitrile. However, the addition of sulfuric acid (0.5 mol per mol of **8**) led to the complete disappearance of **8** after 4 h.

[14] The controlled potential reduction of diethyl azodicarboxylate (**12**) on mercury at −0.7 V in acetonitrile–TEAP (0.1 *M*) gave diethyl hydrazodicarboxylate (**9**) in a 41% yield.

In order to confirm the formation of carbethoxynitrene (**11**) as an intermediate, the electrolysis of NFU was carried out at −1.9 V in the presence of cyclohexene (cyclohexene/acetonitrile–TEAP (0.1 *M*) = 0.5): the aziridine **15** and

15 **16**

N-cyclohexenylurethan (**16**) were obtained in 5.4% and 0.6% yield (vpc) respectively. The other products identified were urethan (20%) and diethyl hydrazodicarboxylate (**9**) (20%). The oxadiazole **8** and the azamalonate **10** were not detected. The iodometric analysis gave 9.4%.

The origin of the iodometric activity at the end of the electrolyses is discussed below.

Reaction with bases

The reaction of NFU (**2***a*) with bases (eq. [19]) is followed by loss of fluoride ion to form carbethoxynitrene (**11**) (eq. [14]). The α-elimination of the fluoride ion must be quite facile. Indeed, aliquots taken immediately after mixing NFU

[19] $EtOCONHF + B^- \rightleftarrows EtOCO\bar{N}F + BH$

with one equivalent of base in acetonitrile and analysed by polarography did not contain any NFU. The following bases did react with NFU: triethylamine, lithium hydride, tetraethylammonium fluoride, and lithium trichloroacetate. Surprisingly pyridine, which is more basic (pK_a = 5.29) than the trichloroacetate ion (pK_a = 0.65) in water, did not react with NFU.

Since the fluoride ion can act as a base and is generated in reaction [14], a catalytic amount of base should have been sufficient to cause the complete reaction of NFU (chain reaction). However, for the reaction of NFU with TEAF in acetonitrile, 0.75 equivalent of TEAF was needed to cause the complete disappearance of NFU (polarography). Some fluoride ions must be consumed in competitive reactions and/or react with HF to give the HF_2^- anion, which then would not be basic enough to abstract a proton from NFU. Also, the fact that lithium chloroacetate reacts with NFU shows that the acetate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

ion should induce the decomposition of NFU. Therefore in order to account for the polarographic and coulometric behavior of NFU (see eq. [13]), the reaction of the acetate ion with NFU must be relatively slow.

A comparison between controlled potential electrolyses of NFU (Table 1) and its reaction with bases in acetonitrile (Table 2), with and without added cyclohexene, shows that essentially the same products are obtained.[11] In the reaction with bases, the iodometric activity could be due to the formation of diethyl *N*-fluoro-hydrazodicarboxylate (**13**) resulting from the insertion of carbethoxynitrene (**11**) into the N—H bond of NFU (Scheme 2). The iodometric activity at the end of the electrolyses (Table 1) cannot be due to **13** since it should be reduced to **9** (Scheme 2). Furthermore, the iodometric activity is present only when the electrolyses are carried out on mercury and in a neutral medium. The presence of the organomercuric compound **14** arising from the reaction of carbethoxynitrene (**11**) with mercury (Scheme 2) could be responsible for the iodometric activity and for the presence of a polarographic wave at ca. 0 V after completion of the electrolyses. We believe that the reduction of **14** requires a proton donor. In a neutral medium, NFU would act as the proton donor (eq. [20]). Since side reactions (see [15] and [17]) are consuming NFU during the electrolyses, a substantial amount of **14** could still be present (Table 1, entry 1) when all the NFU has disappeared (polarographic analysis).

[20] $\underset{\mathbf{14}}{\text{EtOCONHg}} + \underset{\mathbf{2}a}{\text{EtOCONHF}} + 2\,e^- \rightarrow \underset{\mathbf{4}}{\text{EtOCONH}_2} + 2\,\underset{\mathbf{7}}{\text{EtOCO}\bar{\text{N}}\text{F}}$

When NFU was treated with triethylamine in acetonitrile in the presence of mercury (Table 2, entry 2), the polarographic wave at 0 V attributed to the organomercuric derivative **14** (see above) did appear (Fig. 5) whereas that of NFU disappeared. The same wave was observed also when carbethoxynitrene (**11**) was generated from *N*-paranitrobenzenesulfonoxyurethan (**18**) and triethylamine (6) in acetonitrile and in the presence of mercury. In order to account for the low iodometric activity, we propose the protonolysis of **14** by NFU (eq. [21]).

[21] $\underset{\mathbf{14}}{\text{EtOCONHg}} + 2\,\underset{\mathbf{2}a}{\text{EtOCONHF}} \rightarrow \underset{\mathbf{4}}{\text{EtOCONH}_2} + 2\,\underset{\mathbf{7}}{\text{EtOCO}\bar{\text{N}}\text{F}} + \text{Hg}^{2+}$

We have compared the reaction of NFU and that of *N*-paranitrobenzenesulfonoxyurethan (**18**) with triethylamine in cyclohexene. The results are recorded in Table 3. The main feature is the nearly identical ratio of insertion (**16**) to addition (**15**): 0.15 with **2***a*, 0.17 with **18** (8). This ratio is close to that observed in the electrochemical reduction of NFU in acetonitrile in the presence of cyclohexene: **16**/**15** = 0.11. However, when NFU was reacted with triethylamine and cyclohexene in acetonitrile, the insertion-to-addition ratio was much higher: **16**/**15** = 1.1 (Table 2, entry 3). This higher ratio (or the lower yield of aziridine **15**) is due to the reaction of aziridine **15** with triethylammonium fluoride which was shown to give *trans-N*-(2-fluorocyclohexyl)urethan (**19**) and *trans-N*-(2-acetamidocyclohexyl)urethan (**20**) (Scheme 3).

If one compares the reaction of NFU and the reaction of *N*-paranitrobenzenesulfonoxyurethan (**18**) with triethylamine in acetonitrile, the yield of oxadiazole **8** is much higher with **18**

TABLE 2. Reaction of NFU (**2***a*) with bases[a]

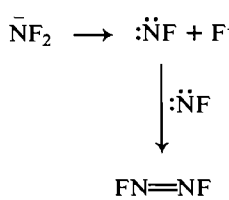
[c] The NFU contained 10.5 mol% of urethan.
[d] Taken from ref. 8.

(32%) than with NFU (1.3%, Table 2, entry 1). This is most probably due to the reaction of oxadiazole **8** with triethylammonium fluoride when carbethoxynitrene (**11**) is generated from NFU. Indeed, polarography did show the complete disappearance of **8** after 4 h when **8** was treated with triethylammonium fluoride in acetonitrile.

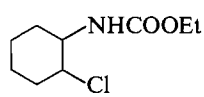
α-Elimination of fluoride ion

The α-elimination of a fluoride ion has been proposed to explain the decomposition of difluoramine in the presence of a base and the formation of difluorodiazene (eq. [22]) (9). It is noteworthy that the α-elimination of a chloride ion is much

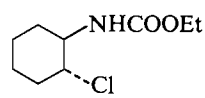


[22]

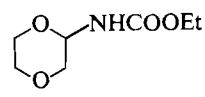
more difficult. The decomposition of the lithium salt of *N*-chlorourethan in acetonitrile is a slow process and no oxadiazole **8** could be detected. The same observation holds for the conjugate base of NCU generated electrochemically (1). When NCU, in cyclohexene, was treated with triethylamine, no aziridine **15** nor *N*-cyclohexenylurethan (**16**) could be detected. The *cis* 1,2-adduct **21** and the *trans* 1,2-adduct **22** were isolated in 14% and 4% yield respectively and the *cis*-to-*trans* ratio suggests that they could result from a radical chain reaction of NCU with cyclohexene (10). Recently, Torimoto *et al.* (11) have obtained the compound **23** from the thermolysis (50–70°C) of the sodium salt of NCU in dioxane and they gave evidence that **23** results from a radical chain reaction.



21



22



23

The more facile α-elimination of a fluoride ion from —N̄—F as compared to that of a chloride ion from —N̄—Cl could be explained by electron delocalization into the *d* orbitals of the chlorine atom (—N=Cl⁻) and by a stronger repulsion between the 2*p* electrons of nitrogen and those of fluorine than between the 2*p* electrons of nitrogen and the 3*p* electrons of chlorine. The same explanation would hold for the relative acidity of fluoroform (pK_a = 25.5), chloroform (pK_a = 15), and bromoform (pK_a = 9) (12).

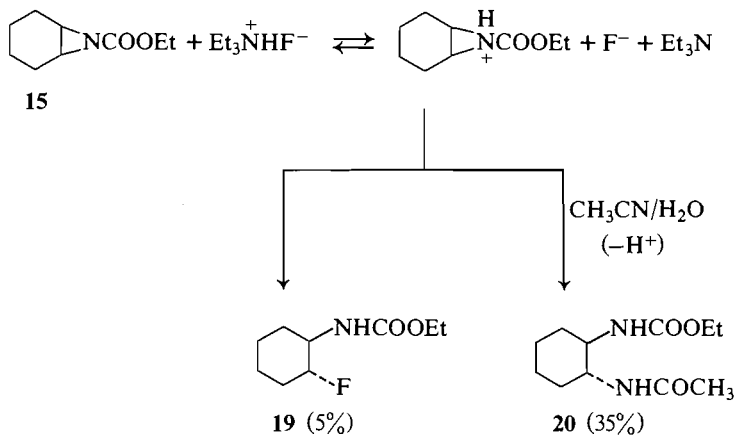

SCHEME 3

Experimental

The pertinent information concerning *acetonitrile, electrolytes, and the electrochemical instrumentation and methods* has been given in ref. 1. The general information concerning the analysis of products is the same as that given in refs. 1 and 13.

N-*Fluorourethan* (**2**a)

A mixture of fluorine (20%) and nitrogen (80%) was bubbled through a solution of urethan (25 g, 0.28 mmol) in water (350 mL) (14). The reaction was followed by ^{1}H nmr and stopped when the ratio of NFU (*t* at 1.36 ppm) to ethanol reached a maximum value (6.5 h). Some urethan was left. Nitrogen was bubbled through the reaction mixture for 15 min. It was extracted with methylene chloride (8 × 50 mL). The organic phases were kept overnight over sodium fluoride in the refrigerator, then dried over sodium sulfate. Evaporation of the solvent followed by distillation gave N-*fluorourethan* (**2***a*), bp 95–98°C (20 Torr) (93% active fluorine by iodometry, 16% yield); δ ($CDCl_3$): 1.36 (t, J = 7 Hz), 4.46 (q, J = 7 Hz), and 10.35 (d, J = 56 Hz) ppm.

N-*Fluoro*-N-*methylurethan* (**1**a)

N-Fluorourethan (4.5 g, 88% active fluorine, 37 mmol) in ether (25 mL) was treated with diazomethane (100 mL of a 3% solution in ether, 3 g, 71 mmol) until cessation of nitrogen evolution. The excess of diazomethane was removed with a stream of nitrogen. Ether was distilled, methylene chloride (50 mL) was added, and the mixture was washed with brine. The solvent was distilled and the residue was purified by distillation to give N-*fluoro*-N-*methylurethan* (**1***a*), bp 50°C (20 Torr) (1.5 g, 33%). It was identical (ir and ^{1}H nmr) to a sample prepared by the method of Grakauskas and Baum (15); ν_{max} ($CHCl_3$): 1750 and 1725 cm^{-1}; δ ($CDCl_3$): 1.30 (t, J = 7 Hz), 3.31 (d, J = 28 Hz), and 4.22 (q, J = 7 Hz) ppm.

Authentic samples

The preparation of *N*-methyl-*N,N'*-methylene-*bis*-urethan (amidal **5**) has been described in ref. 10 and that of diethyl azamalonate (**10**) and diethyl *N*-methylazamalonate (**17**) in ref. 1.

N,N'-*Methylene-bis-urethan (amidal* **6***)*

This compound was prepared from urethan, formaldehyde, and hydrochloric acid (16), mp 128–129°C (lit. (16) mp 131°C); ν_{max} ($CHCl_3$): 3470, 1710, and 1495 cm^{-1}; δ ($CDCl_3$): 1.23 (t, J = 7 Hz), 4.13 (q, J = 7 Hz), 4.48 (t, J = 7 Hz), and 5.85 (m) ppm; *m/e*: 190 (M^+).

2-Ethoxy-5-methyl-1,3,4-oxadiazole (8)

N-Paranitrobenzenesulfonoxyurethan (**18**) was prepared according to the method of Lwowski and Maricich (8), mp 114–115°C (lit. (8) mp 116°C) (43% yield). To a solution of **18** (5 g, 17.3 mmol), in acetonitrile (50 mL) under a nitrogen atmosphere, triethylamine (1.8 g, 17.8 mmol) was added dropwise (20 min). The mixture was stirred at room temperature for 1.5 h and the solvent was removed in a rotatory evaporator. The residue was dissolved in methylene chloride (50 mL) and the solution was washed with ice-cold water (2 × 25 mL), then dried over sodium sulfate. The solvent was evaporated and the resulting oil was purified by preparative vpc (OS-138, 15%; 150°C) to give the *oxadiazole* **8** as a colorless liquid; ν_{max} ($CHCl_3$): 1630, 1580, and 1225 cm^{-1}; δ ($CDCl_3$): 1.49 (t, J = 7 Hz), 2.43 (s), and 4.62 (t, J = 7 Hz) ppm; *m/e*: 128 (M^+). The yield determined by analytical vpc was 32%.

Diethyl hydrazodicarboxylate (9)

This compound was prepared according to an Organic Synthesis procedure (17), mp 133–134°C (lit. (17) mp 131–133°C); ν_{max} ($CHCl_3$): 3410, 1730, and 1490 cm^{-1}; δ ($CDCl_3$): 1.30 (t, J = 7 Hz), 4.31 (q, J = 7 Hz), and 6.62 (broad s) ppm; *m/e*: 176 (M^+).

7-Carbethoxy-7-aza-bicyclo[4.1.0]heptane (aziridine **15***)*

This compound was prepared from cyclohexene and iodine isocyanate according to the method described by Hassner *et al.* (18) with a yield of 43%, bp 94°C (20 Torr); δ ($CDCl_3$): 1.28 (t, J = 7 Hz), 1.90 (m, 4H), 2.70 (m, 2H), and 4.23 (q, J = 7 Hz) ppm; *m/e*: 169 (M^+).

N-*(2-Cyclohexenyl)urethan (16)*

This compound was prepared from 3-bromocyclohexene according to the method described by Lwowski and Mattingly (19) and was purified by vpc (OS-138, 15%; 200°C); ν_{max} ($CHCl_3$): 3450, 1710, and 1500 cm^{-1}; δ ($CDCl_3$): 1.24 (t, J = 7 Hz, 3H), 4.22 (m + q, J = 7 Hz, 3H), 4.80 (m, NH), and 5.87 (m, 2H) ppm; *m/e*: 169 (M^+).

Mass electrolyses

These were carried out under a nitrogen atmosphere as described in ref. 1. All the products were identified with respect to authentic samples by ir and ^{1}H nmr spectroscopy, vpc, and/or tlc. A few electrolyses are described below.

Reduction of N-*fluoro*-N-*methylurethan* (**1**a)

NMFU (**1***a*) (483 mg, 3.91 mmol) was added to the cathode compartment containing 150 mL of a 0.1 *M* solution of TEAP in acetonitrile. The anode compartment contained 25 mL of the 0.1 *M* electrolyte solution. A potential of −1.9 V (Hg cathode) (i_0 = 1.65 mA/cm^2) was applied until the current reached a near zero value (4 h, 249 C). The polarographic analysis showed the complete disappearance of **1***a* and a new wave at $E_{1/2}$ = −2.4 V (its limiting current did correspond to about 20% of the limiting current of the starting solution). The anolyte was filtered to remove the magnesium fluoride. The anolyte and catholyte were combined and the solvent was evaporated. Water was added and the resulting mixture extracted with ether. The organic phase was dried, then concentrated in a rotatory evaporator. The resulting solution was transferred into a 50-mL volumetric flask. The vpc analysis (OS-138, 15%; 110°C) gave 26% of *N*-methylurethan, 25% of urethan, 1% of amidal **5**, and 1% of amidal **6**. An aliquot was separated by preparative vpc for comparison to authentic samples.

Reduction of N-*fluorourethan* (**2**a) *in the presence of cyclohexene*

NFU (**2***a*) (510 mg, 85% active fluorine, 4.05 mmol) and cyclohexene (50 mL) were added to the cathode compartment containing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

100 mL of the 0.1 *M* electrolyte solution. The anode compartment contained 25 mL of the electrolyte solution. A potential of −1.9 V (Hg cathode) was applied for 5 h ($i \simeq 0$, 344 C). After the usual work-up (see above), the vpc analysis gave 20% urethan (**4**) (corresponding to the amount present in the starting solution), 20% diethyl hydrazodicarboxylate (**9**), 5.4% of aziridine **15**, 0.6% of *N*-(2-cyclohexenyl)urethan (**16**), and about 1% each of oxadiazole **8** and azamalonate **10**.

Reduction of diethyl azodicarboxylate (12)

Diethyl azodicarboxylate (**12**) (635 mg, 3.65 mmol) in 50 mL of acetonitrile–TEAP 0.1 *M* (the anodic compartment contained 25 mL) was reduced at −0.7 V for 0.5 h (102 C). During the electrolysis, the solution became yellow and a gas was evolved. The usual work-up was followed by continuous extraction with methylene chloride. The ^{1}H nmr of the crude product (301 mg) showed that it consisted essentially of diethyl hydrazodicarboxylate (**9**) (41% yield by vpc; OS-138, 15%, 200°C). After recrystallization, it proved identical to the authentic sample.

Reactions with fluoride ions

All reactions were carried out at room temperature and under nitrogen.

N-*Fluoro*-N-*methylurethan (1*a*) and tetraethylammonium fluoride (TEAF)*

To NFMU (242 mg, 2.0 mmol) in acetonitrile–TEAP (0.1 *M*) (10 mL) was added dropwise a 0.5 *M* solution of TEAF in acetonitrile (2.3 mL, 1.15 mmol). A polarogram taken after 4.5 h showed that half of the NFMU had disappeared. An additional 2.3 mL of the TEAF solution (total amount: 2.3 mmol) was added and the mixture stirred at room temperature. A polarogram taken after 24 h showed the presence of 10% of NFMU and a new wave at $E_{1/2} = -2.4$ V. After 40 h no more NFMU was left. The amount of fluoride ion determined with a lanthanum fluoride electrode was 2.3 mmol. The reaction was repeated on a smaller scale (0.71 mmol) and TEAF (1.09 mmol) was added rapidly. The reaction was followed by vpc (UCON-2000, 80°C). After 1 h the reaction was almost complete and after 4 h, no NFMU was left. Water (10 mL) was added and the mixture extracted with methylene chloride (4 × 50 mL). After the usual work-up, the crude product (33 mg) was analysed by ^{1}H nmr and vpc. The sole product identified was urethan (**4**) (22%). No amidal **5** nor amidal **6** could be detected by vpc. The ^{1}H nmr spectrum of the crude product showed absorptions corresponding to those of amidals **5** and **6** but they were probably due to the presence of polymers.

N-*Fluorourethan (2*a*) and TEAF*

To NFU (314 mg, 85% active fluorine, 2.49 mmol) in acetonitrile (10 mL) a 0.53 *M* solution of TEAF (4.7 mL, 2.49 mmol) was added very slowly (24 h). The reaction was followed by polarography. The solvent was evaporated. Water (25 mL) was added and the mixture was extracted with ether (4 × 50 mL). After the usual work-up, the ^{1}H nmr spectrum of the crude product showed the presence of urethan (**4**), oxadiazole **8**, and diethyl hydrazodicarboxylate (**9**) as the main products. Their yields were not determined.

Oxadiazole 8 and triethylammonium fluoride

In a polarographic cell containing 10 mL of acetonitrile–TEAP (0.1 *M*), oxadiazole **8** (15 mg, 0.117 mmol) was treated with a 0.5 *M* solution of Et_3NHF in acetonitrile (0.3 mL, 0.15 mmol). After 4 h the oxadiazole waves ($E_{1/2} = -1.61$ V and −2.5 V) had disappeared.

Oxadiazole 8 and TEAF

In a polarographic cell containing 10 mL of acetonitrile–TEAP (0.1 *M*), oxadiazole **8** (15 mg, 0.117 mmol) was treated with a 0.53 *M* solution of TEAF in acetonitrile (0.2 mL, 1.06 mmol). After 0.5 h, no change was observed in the polarogram. A 66 m*M* solution of sulfuric acid was added (1.1 mL, 0.073 mmol). After 1 h, there was about 25% oxadiazole **8** left and it had disappeared completely after 4 h.

Aziridine 15 and triethylammonium fluoride

Triethylamine (511 mg, 5.06 mmol) in acetonitrile–TEAP (0.1 *M*) (50 mL) was treated with anhydrous HF. The excess HF was removed with a stream of nitrogen. The aziridine **15** (852 mg, 5.04 mmol) in acetonitrile (20 mL) was added slowly (80 min) to the previous solution. After 7.5 h, the solvent was evaporated. Ether (50 mL) was added. The solids were removed by filtration and the solution was washed with saturated sodium bicarbonate (15 mL). The residue (506 mg) obtained after the usual work-up was separated by plc on silica gel (methylene chloride – ether 1:1) to give two main fractions. The less polar fraction (50 mg) consisted of trans N-*(2-fluorocyclohexyl)-urethan* (**19**), mp 62–65°C (5%); ν_{max} ($CHCl_3$): 3440, 1720, and 1510 cm^{-1}; δ ($CDCl_3$): 1.26 (t, J = 7 Hz), 3.8 (m, $H_1 + H_2$), 4.21 (q, J = 7 Hz), and 5.00 (m, H_2 + NH) ppm; m/e: 189 (M^+).

The other fraction (408 mg) consisted of trans N-*(2-acetamidocyclohexyl)urethan* (**20**), mp 133–135°C (35%). It was recrystallized from ether–cyclohexane (1:1) to afford the analytical sample, mp 136.5–137°C (lit. (20) mp 134–135°C); ν_{max} ($CHCl_3$): 3440, 3340, 1705, 1665, and 1510 cm^{-1}; δ ($CDCl_3$): 1.26 (t, J = 7 Hz), 1.99 (s), 3.58 (m, $H_1 + H_2$), 4.20 (q, J = 7 Hz), 5.56 (m, NH), and 6.66 (m, NH) ppm; m/e: 228 (M^+). *Anal.* calcd. for $C_{11}H_{20}N_2O_3$: C 57.87, H 8.83; found: C 57.71, H 9.12.

Reactions with bases

All reactions were carried out under a nitrogen atmosphere at room temperature.

N-*Fluorourethan (2*a*) and triethylamine in acetonitrile*

To a solution of NFU (500 mg, 91% active fluorine, 4.25 mmol) in acetonitrile (15 mL) was added a solution of triethylamine (516 mg, 5.11 mmol) in acetonitrile (10 mL). The reaction mixture became yellow as soon as triethylamine was added and no more NFU was present (polarography) as soon as the addition of triethylamine was completed. After 1 h, the iodometric activity was 2%. The solvent was evaporated and the residue was dissolved in methylene chloride (50 mL) and washed with water (2 × 25 mL). The aqueous layers were combined and continuously extracted with methylene chloride (36 h). The organic phases were dried and the solvent was evaporated. The ^{1}H nmr spectrum of the crude product showed the presence of urethan (**4**), oxadiazole (**8**), and diethyl hydrazodicarboxylate (**9**). The yields determined by vpc (OS-138, 15%) are given in Table 2, entry 1. The urethan content was 7 mol% compared to 12 mol% in the starting NFU.

N-*Fluorourethan (2*a*) and triethylamine in acetonitrile–TEAP (0.1* M*) in the presence of mercury*

To NFU (524 mg, 85% active fluorine, 4.16 mmol) in mercury (25 g) in acetonitrile–TEAP (0.1 *M*) (100 mL), a solution of triethylamine (451 mg, 4.47 mmol) in acetonitrile (10 mL) was added over 10 min (yellow solution). The polarogram showed the absence of NFU and a wave at ca. 0 V. After 1.5 h (2% iodometric activity) hydrochloric acid (25 mL of a 5% solution) was added (the reaction mixture became colorless). Mercury was decanted, was washed with acetonitrile, and the solvent was evaporated. Water (50 mL) was added and continuously extracted with ether (36 h). The crude product was analysed by vpc and the yields are given in Table 2, entry 2. The urethan content was 20 mol% compared to 21 mol% in the starting NFU.

N-*Fluorourethan (2*a*) and triethylamine in acetonitrile–TEAP (0.1* M*) in the presence of cyclohexene*

Triethylamine (418 mg, 4.14 mmol) in acetonitrile (5 mL) was added over 25 min to a solution of NFU (483 mg, 92% active fluorine, 4.15 mmol) in cyclohexene (10 mL) and acetonitrile–TEAP (0.1 *M*) (20 mL). After 1.5 h (3% iodometric activity), the solution was concentrated to ca. 5 mL and ether (100 mL) was added. The solution was washed with saturated aqueous sodium bicarbonate, dried, then concentrated. The yields determined by vpc analysis are given in Table 2, entry 3. The urethan content was 2.5 mol% compared to 10.5 mol% in the starting NFU.

N-*Fluorourethan (2*a*) and triethylamine in cyclohexene*

Triethylamine (561 mg, 5.55 mmol) in cyclohexene (5 mL) was added dropwise (50 min) to a solution of NFU (643 mg, 92% active fluorine, 5.53 mmol) in cyclohexene (25 mL). Two phases were

formed. After 1.5 h, ether (75 mL) was added (homogeneous solution) and the solution washed with saturated sodium bicarbonate. After the usual work-up, the yields were determined by vpc (OS-138) and are given in Table 3. The urethan content was 4 mol% compared to 10.5 mol% in the starting NFU.

N-Fluorourethan (2a) and lithium hydride in acetonitrile

To lithium hydride (200 mg, 29 mmol) in acetonitrile (10 mL), NFU (9 mL of a 15.3 m*M* solution, 1.38 mmol) was added slowly (1.5 h). The reaction mixture was stirred until the cessation of hydrogen evolution (12 h). The iodometric activity was 5%. After filtration and solvent evaporation, water (50 mL) was added and the mixture extracted with ether (2 × 25 mL). The yields (vpc, OS-138) are given in Table 2, entry 4. The urethan content was 6% compared to 12% in the starting NFU.

N-Chlorourethan (2b) and triethylamine in the presence of cyclohexene

Triethylamine (597 mg, 5.91 mmol) in methylene chloride (10 mL) was added dropwise (45 min) to a solution of NCU (800 mg, 91% active chlorine, 5.89 mmol) in cyclohexene (20 mL) and methylene chloride (20 mL). After 10 h, a white precipitate was formed and the iodometric activity was 7%. The reaction mixture was washed with 5% hydrochloric acid (2 × 25 mL), then with water (25 mL). After the usual work-up, the crude product (554 mg) was separated by plc on silica gel (hexane–ether 3:1) to afford cis *N-(2-chlorocyclohexyl)urethan* (**21**), mp 52–54°C (lit. (21) mp 57.5–58°C) (178 mg, 14%), identical to an authentic sample (22), and trans *N-(2-chlorocyclohexyl)urethan* (**22**), mp 82–85°C (lit. (23) mp 96°C) (54 mg, 4%), identical to an authentic sample (22).

Alkaloids of *Aconitum columbianum* Nutt.[1]

VITO BOIDO,[2] OLIVER E. EDWARDS, KASHMIRI L. HANDA,[3] RALPH J. KOLT, AND KOZIPARAMBIL K. PURUSHOTHAMAN[4]

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received August 26, 1983

VITO BOIDO, OLIVER E. EDWARDS, KASHMIRI L. HANDA, RALPH J. KOLT, and KOZIPARAMBIL K. PURUSHOTHAMAN. Can. J. Chem. **62**, 778 (1984).

The most abundant readily isolated alkaloids of the aerial portion of *Aconitum columbianum* Nutt. were found to be talatisamine and cammaconine. New spectral data for known derivatives of these alkaloids and descriptions of new derivatives are presented. Less abundant alkaloids identified included the known ones sachaconitine, talatizidine, isotalatizidine, and 14-*O*-acetyltalatisamine, and the new ones 8-*O*-methyltalatisamine and a tetrahydroxymonomethoxy alkaloid, columbianine, with the same oxygenation pattern and stereochemistry as cammaconine.

VITO BOIDO, OLIVER E. EDWARDS, KASHMIRI L. HANDA, RALPH J. KOLT et KOZIPARAMBIL K. PURUSHOTHAMAN. Can. J. Chem. **62**, 778 (1984).

On a trouvé que, parmi les alcaloïdes facilement isolables de la portion aérienne du *Aconitum columbianum* Nutt., les plus abondants sont la talatisamine et la cammaconine. On rapporte de nouvelles données spectrales de dérivés connus de ces alcaloïdes ainsi que la description de nouveaux dérivés. Parmi les alcaloïdes moins abondants, on a pu identifier la sachaconitine, la talatizidine, l'isotalatizidine et la *O*-acétyl-14 talatisamine qui étaient déjà connus en plus de deux nouveaux alcaloïdes, la *O*-méthyl-8 talatisamine et un dérivé tétrahydroxymonométhoxy de l'alcaloïde columbianine qui possède la même stéréochimie et le même arrangement d'oxydation que la cammaconine.

[Traduit par le journal]

There are only two native Canadian aconites, *A. columbianum* Nutt. which grows in central British Columbia, and *A. delphinipholium* D. C. which grows at medium altitudes in the Rocky Mountains of Alberta. The alkaloids of the latter have been the subject of recent study (1), but those of *A. columbianum* only received brief attention years ago by Beath (2).

The aerial portions of the plant, collected just before flowering, were found to contain around 0.45% of alkaloids (of air-dried weight).

The two principal bases were methoxylated hexacyclic bases with *N*-ethyl groups. Oxidation studies showed that they both had a tertiary hydroxyl group and that the major difference between them was the presence of a primary hydroxyl group in one, and the corresponding methyl ether in the other. This was confirmed by conversion of both to the identical tetramethoxy compound (**2**). Both alkaloids could be fully acetylated under forcing conditions, and the resulting acetates underwent the "pyro" reaction characteristic of the aconine[5] family of diterpenoid alkaloids (4). Finally, their mass spectra had *M*-31 as base peak, characteristic of the aconite alkaloids with a 1-methoxyl group.

From its formula ($C_{24}H_{39}NO_5$), melting point, and the above evidence it appeared that the less polar base was talatisamine **1** whose structure had been assigned by the Yunusovs (5). This was confirmed by comparison kindly made by Professor Yunusov, who also sent a reference sample. The structure and stereochemistry of this alkaloid has been confirmed by total synthesis by Wiesner *et al.* (6).

The main more-polar base thus had structure **5**, isomeric with that originally assigned to cammaconine (7) but identical to that attributed to the base from hydrolysis of aconorine (8). Comparison of samples established the identity of our alkaloid with this hydrolytic base.[6] However, recent work (9) has revised the structure of cammaconine to **5**. Identity with our alkaloid was suggested by comparison of ^{13}C nmr spectra. The identity of a pentamethyl ether **3**, prepared from talatisamine and our alkaloid, with one prepared by Mollov and co-workers[7] (7) from cammaconine confirmed this. Since the name cammaconine was assigned first, the name columbianine (8) which we had tentatively given to our alkaloid has been transferred to a new monomethoxy base described below. It follows that aconorine (8) is 18-*O*-(*N*-acetylanthranoyl) cammaconine.

We were able to prepare a didehydroxocammaconine (**6**) which must be the same as the "diketolactam" prepared by Mollov's group (7). They were unable to detect the formyl group of this derivative, which may well be due to its hydration. We observed just such a phenomenon in a transformation product of lycoctonine, which was also a formylacetamide (10). We sublimed **6** under high vacuum. This may have dehydrated a hydrate (marked rise in melting point) so that the aldehyde proton was observable.

The minor alkaloids from *A. columbianum* were partly separated by chromatography on alumina and preparative thin-layer chromatography on silica gel plates. The alkaloids identified in this way were talatizidine (**10**), isotalatizidine (**11**), 14-*O*-acetyltalatisamine (**4**), and the new ones, 8-*O*-methyltalatisamine (**12**) and the very polar columbianine (**14**). Sachaconitine (**9**) was only obtained as its derivatives oxosachaconitine (**9***a*) and 14-dehydrooxosachaconitine, obtained by separation of permanganate oxidation products from mixtures rich in the alkaloid.[8]

[2]Postdoctoral Fellow of the Consiglio Nazionale delle Ricerche (Rome).

[3]Columbo Plan Research Fellow.

[4]N.R.C. Postdoctoral Fellow.

[5]The term "aconine" is used to denote the sub-family of hexacyclic C_{19} diterpenoid alkaloids having 7-hydrogen and 8-oxygen substituents, while the lycoctonine sub-family (3) has oxygen functions on both C-7 and C-8.

[6]We thank Professors M.S. and S. Yu. Yunusov for this comparison.

[7]We thank Professor Mollov for a reference sample of the ether.

[8]We have so far been unable to obtain reference samples of sachaconitine or its derivatives.

Columbianine had mp 202–205°C and $[\alpha]_D$ −6° in ethanol. Its mass spectrum had $M - 17$ as its base peak, showing that a 1-hydroxyl group was present. This and its ^{13}C nmr spectrum (Table 1) suggested that it was 1-des-*O*-methylcammaconine. Methylation of the base gave the hitherto unknown tetramethyl ether **13** (8,14-di-*O*-methylisotalatizidine), while more vigorous methylation gave the same pentamethyl ether that had been obtained from cammaconine and talatisamine. Thus columbianine had structure **14**. It is conceivable that before the polarity and low solubility in organic solvents of bases like columbianine was recognized, much was lost on columns and in aqueous solution.

Oxidation of mixtures of minor alkaloids with permanganate in wet acetone containing acetic acid gave *N*-desethyl-*N*-formyl derivatives of several bases in addition to the simple lactams. However, there was no ^1H nmr evidence for the presence of *N*-methyl alkaloids. We conclude that oxidative removal of the *N*-ethyl groups followed by formylation was the source of these formyl derivatives. Pelletier *et al.* have recently produced strong evidence for this phenomenon (11). However, the very rapid oxidation of C_{19} diterpenoid alkaloids by permanganate in 50% aqueous acetone gave nearly clean lactams (12), so should be used for analogous studies. As was found by Katsui and Hasegawa (13) for sachaconitine, the *N*-desethyl bases were by-products of these oxidations.

New derivatives of talatisamine characterized in this work were 14-dehydrotalatisamine (**7**), and *N*-desethyl-*N*-formyl-14-dehydrotalatisamine (**8**) and its 14-*O*-methyl ether **2** (1,14-dimethylisotalatizidine). New well-characterized derivatives of cammaconine were its triacetate and demethoxyisopyrocammaconine.

The ^{13}C nmr shifts for the bases recorded in Table 1 are based on multiplicities, correlations with other bases in our laboratory, and the extensive correlations by Jones and Benn (14) and by Pelletier and co-workers (9). The spectra of a few lactams have been recorded previously (12, 15) but many more are

listed in Table 2. The use of C_6D_6 as solvent in recording spectra of bases is recommended since reaction with deuteriochloroform often occurs during long runs. In the case of columbianine and talatizidine, however, low solubility precluded the use of C_6D_6. The major modification of the assignments made previously for related alkaloids (9, 16) is in those for C-9 and C-13. This was done to fit the expected downfield shift (6–8 ppm) when the 14-hydroxyl was transformed to a carbonyl. This modification of the assignments by Pelletier and co-workers had previously been suggested by Sakai *et al.* (17). A few chemical shift differences are noteworthy. The transition from hydroxyl to methoxyl on C-8 produces an upfield shift for C-7 of 6 ppm (β effect). The oxidation of the 19-methylene to a carbonyl giving the oxo compounds had its major effect on the N—CH_2 group (8 ppm upfield), C-4 (12 ppm downfield), and C-18 (5 ppm upfield).

Based on biogenetic postulates and the natural occurrence of the C_{19} alkaloids of the aconine sub-family,[5] it is possible to suggest a sequence for the introduction of oxygen functions in their biosynthesis.[9] The ubiquitous 8-oxygen is very probably introduced during formation of the 7,17 bond from a precursor with a 7,8 double bond (4a) and the 14-oxygen is introduced when one carbon of the original C_{20} skeleton is removed. Thus both must appear at an early stage in the biosynthesis. The nearly universal 16-oxygen must also appear early, followed by the very common one on C-1. An 18-oxygen is common, and is probably introduced next. A 6-oxygen is missing in the alkaloids of many aconite species, indicating the absence or suppression of the requisite enzyme system. It appears likely that it is introduced late in the biosynthesis.

On the same grounds, it appears that methylation of the oxygens is in the sequence 16, 6 and 18, 1, then 14. The rare 8-methoxyl probably arises from participation of methanol instead of the more common water or acetic acid in the formation of the 7,17 bond (4a).

Experimental

Infrared spectra were taken in dichloromethane solutions unless otherwise stated. The ^1H nmr spectra were taken of solutions in deuteriochloroform unless otherwise stated. Preparative plate separations were done on 20 cm × 20 cm 1000-μ SiO_2 plates with fluorescent indicator. The ^1H nmr spectra were obtained at 80 MHz and ^{13}C nmr spectra at 20.15 MHz on a Bruker WP-80 FT spectrometer. Rotations were determined at room temperature (25 ± 2°C).

Aconitum Columbianium *Nutt.*

Aerial portions of *A. columbianium* collected just before flowering in central British Columbia were air-dried, then ground. The extractives were obtained by soaking in 95% ethanol, followed by percolation until little was extracted. The ethanol solution was evaporated under reduced pressure, then the residue separated into neutral, basic, and acidic components. In this way 11.8 kg dried plant yielded a large neutral fraction, 53 g alkaloids (0.45%), and 19 g of acids (0.16%).

The crude alkaloid mixture was separated into two fractions by dissolving it in an excess of dilute sulfuric acid, raising the pH to 7 by addition of sodium carbonate, extracting the less polar bases (fraction A) with dichloromethane, then taking the aqueous layers to pH 11 and extracting the more polar bases (fraction B) with dichloromethane.

Fraction A crystallized in part from ether giving talatisamine. The

[9]H. Hikino and co-workers have used similar arguments based on the alkaloid content of *A. carmichaeli* (18).

*Legend for Table 2: A, oxotalatisamine (**1***a*); B, 14-dehydrooxotalatisamine (**7***a*); C, 8-*O*-methyloxotalatisamine (**12***a*); D, 14-dehydro-8-*O*-methyloxotalatisamine (**12***a*, 14-carbonyl); E, 14-dehydrooxosachaconitine (**9***a*, 14-carbonyl); F, *N*-desethyl-*N*-formyl-14-dehydrotalatisamine (**8**; ref. 16); G, *N*-desethyl-*N*-formyl-8-*O*-methyltalatisamine (**12**, *N*-formyl).

bases in the mother liquors were partially separated by adsorption on a 20-fold ratio of neutral alumina (activity III). Benzene–ether mixtures eluted 14-*O*-acetyltalatisamine followed by a mixture of bases. Ether eluted talatisamine, and 2% methanol in ether eluted more talatisamine and other bases. Finally methanol containing ammonia eluted a fraction containing talatizidine and isotalatizidine.

Fraction B crystallized in part from aqueous methanol giving a hydrate of cammaconine, mp 88–95°C. The bases from the mother liquor were adsorbed on a 10-fold ratio of neutral alumina (Act IV). Benzene eluted much talatisamine and other less polar bases, while methanol in chloroform eluted fractions rich in cammaconine followed by a fraction rich in columbianine.

Non-crystalline mixtures of less polar bases from A and B were further separated on a 20-fold ratio of alumina (Act IV). Only 8-*O*-methyltalatisamine (eluted with 25% dichloromethane in benzene) and more talatisamine (1% methanol in chloroform) were obtained in a reasonable state of purity. No crystalline perchlorate, hydrochloride, or hydriodide could be obtained from these base mixtures. Hence resort was made to oxidation with permanganate, with hope of separating lactams. The use of permanganate in acetone containing 5–10% water and 1% acetic acid was a poor choice. Mixtures of lactams, keto-lactams, *N*-desethyl-*N*-formyl derivatives, and *N*-desethyl bases were obtained. The neutral products were then oxidized with Jones' reagent in acetone giving keto lactams and *N*-formyl ketones. Oxidation by permanganate in 50% aqueous acetone, however, was rapid under controlled conditions (see oxidation of cammaconine, ref. 12) and mixtures of the lactams and *N*-desethyl bases were the major products. The neutral products were separated on silica gel plates using 5% methanol in chloroform. In this way 8-*O*-methyl-14-dehydroxotalatisamine, *N*-desethyl-*N*-formyl-14-dehydrooxotalatisamine, oxosachaconitine, and 14-dehydrooxosachaconitine were isolated and characterized.

Talatizidine, isotalatizidine, and columbianine were isolated by purification of the appropriate fractions (see above) on silica gel plates using 7% methanol and 10% diethylamine in benzene for development.

The yield of talatisamine was approximately 0.06% and cammaconine 0.05% of the dry weight of plant. The other bases were less abundant and yields were not obtained. It is likely that much polyhydroxy base was lost during extractions and chromatography.

Cammaconine

The initially-observed hydrate, mp 88–95°C, when dried, crystallized from methanol as rods, mp 136–138°C (lit. (7) mp 135.7°C) and had $[\alpha]_D$ 0° (*c*, 1.0 in chloroform) and pK_a 9.55 in 50% methanol. It gave a hydriodide, mp 225–227°C. *Anal.* calcd. for $C_{23}H_{36}INO_5$: C 51.78, H 6.80, N 2.63; found: C 51.70, H 6.93, N 2.65.

*14,18-Didehydrooxocammaconine (**6**)*

Oxocammaconine (100 mg) was dissolved in 3 mL of pyridine. To this was added the complex from 80 mg of chromium trioxide and 1 mL of pyridine. The mixture was stirred for 18 h at room temperature, then evaporated to near dryness *in vacuo*. Crushed ice was added, then sulfur dioxide bubbled through the solution until it became green. The products were extracted into chloroform, then this was washed with dilute sodium carbonate solution. The neutral product from the chloroform (96 mg) crystallized from benzene–hexane. It melted at 194–196°C. This was sublimed at 175°C, 1×10^{-5} Torr. It then melted at 218°C and had ν_{max}: 3400, 1755, 1725 cm^{-1}. Its ^1H nmr spectrum had signals at δ: 10.15 (1H, s), 3.35 (6H, s), and 1.23 (3H, t, J = 7 Hz). *Anal.* calcd. for $C_{23}H_{31}NO_6$: C 66.16, H 7.48; found: C 65.62, H 7.42. This is undoubtedly identical to the "diketolactam", mp 194–195°C of Mollov and co-workers (7).

Cammaconine triacetate

A mixture of 300 mg of cammaconine, 150 mg of *p*-toluenesulfonic acid, and 3 mL of acetic anhydride was heated at 100°C for 1 h. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

product was adsorbed onto 7 g of neutral alumina, activity III, from benzene. Benzene eluted 280 mg of ester which crystallized from hexane. The triacetate had mp 105–107°C. It gave ^{1}H nmr signals at δ: 4.84 (1H, t, J = 5 Hz), 3.80 (2H, s), 3.34 and 3.30 (3H singlets), 2.05, 2.04 and 1.95 (3H singlets), and 1.05 (3H, t, J = 7 Hz). *Anal.* calcd. for $C_{29}H_{43}NO_8$: C 65.27, H 8.12; found: C 65.33, H 8.11.

Pyrolysis of cammaconine triacetate

The triacetate was heated at 210–230°C under 10 Torr during 5 min, by which time bubbling had stopped. The product was dissolved in chloroform, washed with a small volume of sodium carbonate solution, dried, and the solvent removed. The residue was distilled at 215°C, 1×10^{-4} Torr. It gave ^{1}H nmr signals at δ: 5.9 (1H, m), 4.75 (1H, t), 3.86 (2H, s), 3.30 and 3.18 (3H singlets), 2.06 and 2.00 (3H singlets), and 1.04 (3H, t, J = 7 Hz). *Anal.* calcd. for $C_{27}H_{39}NO_6$: C 68.47, H 8.30; found: C 68.81, H 8.51.

Demethoxyisopyrocammaconine

Pyrocammaconine (50 mg) in 10 mL of ether was stirred overnight with 200 mg of lithium aluminum hydride. The excess reagent was destroyed with methanol, then a small amount of water was added. The ether was decanted from the solids, and these were extracted thoroughly with dichloromethane. The 33 mg of product was dissolved in chloroform and filtered through a short bed of activity IV alumina. After removal of the chloroform, the product crystallized from solution in acetone–hexane giving 12 mg, mp 194–198°C. It had ^{1}H nmr signals at δ: 5.8 (2H, br, m), 4.1 (1H, br), 3.29 (3H, s), 1.08 (3H, t, J = 7 Hz). *Anal.* calcd. for $C_{22}H_{33}NO_3$: *Mol. Wt.* 359; C 73.50, H 9.25; found: C 73.34, H 9.05. Its mass spectrum gave M^+ 359 and the base peak at 328 (M − 31).

*Talatisamine (**1**)*

This crystallized from ether as small prisms. It could be recrystallized from acetone–hexane or methanol giving prisms with mp 142–143°C. In an evacuated capillary it had mp 148°C and showed no mp depression with a sample with mp 148.5°C (evacuated capillary) obtained from S. Yu. Yunusov (5). It had $[\alpha]_D$ 0° (c, 1.0 in ethanol) and pK_a 9.05 in 50% methanol. Its hydrochloride, hydriodide, or perchlorate would not crystallize readily. The base gave ^{1}H nmr signals at δ: 4.81 (1H, d, J = 5 Hz, OH), 4.29 (1H, t, J = 5 Hz), 3.68 (1H, s, OH), 3.44, 3.38, 3.34 (3H singlets), and 1.07 (3H, t, J = 7 Hz).

*Talatisamine 14-O-acetate (**4**)*

Talatisamine was slowly acetylated in 1 : 1 acetic anhydride – pyridine. After 20 h reaction was complete. The amorphous product (ref. 5 reports mp 97°C) gave ^{1}H nmr signals at δ: 4.82 (1H, t, J = 5 Hz), 3.29, 3.27 and 3.23 (3H singlets), 2.05 (3H, s), and 1.06 (3H, t, J = 7 Hz) (see ref. 14). Its mass spectrum had M^+ 463.2793 ($C_{26}H_{41}NO_6$ requires 463.2934) and a base peak at m/e 432 (M − 31).

Talatisamine diacetate

Talatisamine (150 mg) in 4 mL of acetic anhydride containing 75 mg of *p*-toluenesulfonic acid hydrate was heated at 95°C for two hours. The crude product was adsorbed on 3 g of alumina (Act. III). The diacetate was rapidly eluted with benzene. It crystallized from hexane, mp 120–122°C (ref. 5 gives mp 122–123°C). It gave ^{1}H nmr signals of δ: 4.80 (1H, t, J = 5 Hz), 3.32, 3.29, 3.28 (3H singlets), 2.02, 1.94 (3H singlets), and 1.06 (3H, t, J = 7 Hz). It lost acetic acid when heated at 150°C *in vacuo* to give a mixture of pyro and isopyro compounds (see also ref. 5).

*14-Dehydrotalatisamine (**7**)*

Twenty-five mg of chromium trioxide was added to a stirred solution of 85 mg of talatisamine in 1 mL of acetic acid. After 4 h at room temperature the solution was evaporated under reduced pressure, then the residue was dissolved in 1 *N* sulfuric acid. A chloroform extraction removed traces of neutral and acidic products, after which the solution was made basic with sodium carbonate. The bases extracted into dichloromethane weighed 80 mg. This was adsorbed on 1.8 g of neutral alumina (Act. III). The base eluted with benzene (48 mg) crystallized from benzene–hexane giving 25 mg, mp 124–127°C. This had ν_{max}: 3300 and 1750 cm^{-1} and had a pK_a in 50% methanol of 8.1. *Anal.* calcd. for $C_{24}H_{37}NO_5$: C 68.70, H 8.89; found: C 68.70, H 8.75.

*14-Dehydrooxotalatisamine (**7**a)*

A solution of 0.30 g of talatisamine in 8 mL of pyridine was added to a solution of 1.2 g of chromium trioxide in 12 mL of dry pyridine. The mixture was stirred for 16 h at room temperature. The excess chromium trioxide was reduced by sulfur dioxide, then the pyridine was removed under reduced pressure. The residue was dissolved in cold 2 *N* sulfuric acid, then extracted with dichloromethane (4 × 20 mL). The organic layers were washed with water, then sodium bicarbonate solution. The dichloromethane was removed, leaving 240 mg of gum which crystallized from acetone–hexane. This was separated on two silica gel plates (10% methanol in chloroform) into 14-dehydrooxotalatisamine (R_f 0.56) and *N*-desethyl-*N*-formyl-14-dehydrotalatisamine (**8** R_f 0.3, see below). The lactam crystallized from acetone–hexane as laths, mp 195–198°C. It had ν_{max}: 3575, 1752, and 1631 cm^{-1} and $[\alpha]_D$ −41°C (c, 0.66). It gave ^{1}H nmr signals at δ: 3.92 (1H, br, s), 3.59 (1H, s), 3.33 (9H, br, s), and 1.19 (3H, t, J = 7 Hz). *Anal.* calcd. for $C_{24}H_{35}NO_6$: C 66.49, H 8.14; found: C 66.36, H 7.99.

*Oxotalatisamine (**1**a)*

14-Dehydrooxotalatisamine was reduced with excess sodium borohydride in methanol. The product crystallized from acetone as rods, mp 196–198°C (lit. (5) mp 197–200°C); ν_{max} ($CHCl_3$): 1619 cm^{-1}; $[\alpha]_D$ −42°C (c, 1.09 in ethanol). Its ^{1}H nmr spectrum had signals at δ: 4.98 (1H, d, J = 4.4 Hz, OH), 3.73 (1H, s), 3.60 (probably 2H, s), 3.37, 3.33 and 3.24 (3H singlets), 1.6 (3H, t, J = 7 Hz).

N-*Desethyl*-N-*formyl-14-dehydrotalatisamine (**8**)*

This product from the chromium trioxide – pyridine oxidation of talatisamine (see above) crystallized from acetone. It had mp 270°C and ν_{max}: 3580, 1752, and 1662 cm^{-1}. Its ^{1}H nmr spectrum had signals at δ: 8.0 (1H, s), 4.33 (1H, s), 3.89 (br, 2H, s), 3.30, 3.27 and 3.24 (3H singlets). *Anal.* calcd. for $C_{23}H_{33}NO_6$: C 65.85, H 7.93, N 3.34; found: C 65.81, H 7.79, N 3.29.

*8-O-Methyltalatisamine (**12**)*

This was obtained as a new alkaloid from *A. columbianum*. A reference sample was obtained by reduction of 8-*O*-methyloxotalatisamine by lithium aluminium hydride in refluxing dioxane. It gave ^{1}H nmr signals at δ: 4.10 (1H, br, t), 3.17, 3.14, 3.08 and 2.96 (3H singlets), 2.89 (probably 2H, s), and 1.05 (3H, t, J = 7 Hz). Its mass spectrum had peaks at m/e: 435.3046 (5%, M^+), 406.0 (7%), 405 (41%), and 404.0 (100%). M^+ calcd. for $C_{25}H_{41}NO_5$: 435.2985.

*8-O-Methyloxotalatisamine (**12**a)*

This was obtained by oxidation of alkaloid fractions rich in 8-*O*-methyltalatisamine using permanganate in 50% acetone or by reduction of 14-dehydro-8-*O*-methyloxotalatisamine by sodium borohydride in methanol. It was purified on silica gel plates using 5% methanol in chloroform (R_f 0.5). It was not obtained crystalline. It had ν_{max}: 3480 and 1629 cm^{-1} and gave ^{1}H nmr signals at δ: 3.86 (1H, OH), 3.56 (2H, s), 3.38, 3.33, 3.25 and 3.14 (3H singlets), and 1.15 (3H, t, J = 7 Hz). Its mass spectrum had peaks at m/e: 450.1 (6%), 449.2771 (19%, M^+), 435.1 (27%), and 434.1 (100%). M^+ calcd. for $C_{25}H_{39}NO_6$: 449.2777.

*8-O-Methyl-14-dehydrooxotalatisamine (**12**a, 14-carbonyl)*

This was obtained by oxidation of alkaloid fractions rich in 8-*O*-methyltalatisamine by permanganate in acetone containing 10% water and 1% acetic acid, followed by Jones oxidation in acetone, or by methylation of 14-dehydrooxotalatisamine (see below). It crystallized from acetone–hexane as rods, mp 156–158°C. It had ν_{max}: 1755 and 1632 cm^{-1} and gave ^{1}H nmr signals (80 MHz) at δ: 3.84 (1H, s), 3.58 (2H, s), 3.34, 3.32, 3.29 and 3.24 (3H singlets), and 1.1 (3H, t, J = 7 Hz). *Anal.* calcd. for $C_{25}H_{37}NO_6$: C 67.09, H 8.33, N 3.13; found: C 66.92, H 8.50, N 3.24.

N-*Desethyl*-N-*formyl*-8-O-*methyltalatisamine* (**12**, *NCHO*)

This product of oxidation of 8-*O*-methyltalatisamine by permanganate in acetone (containing 10% water and 1% acetic acid) ran just behind 8-*O*-methyloxotalatisamine on silica gel plates (5% methanol in chloroform). It crystallized from acetone–hexane as prisms or needles, mp 197°C. It had ν_{max}: 3500 and 1658 cm^{-1} and gave ^1H nmr signals at δ: 7.96 (1H, s), 3.35, 3.27, 3.16 and 3.10 (3H singlets). Its mass spectrum gave peaks at *m/e*: 436(33), 435.2617(100, M^+), 420(13), 405(42), 404(80), 403(39), etc. M^+ calcd. for $C_{24}H_{37}NO_6$: 435.2622.

Methylation of 14-dehydrooxotalatisamine (**7**a)

A solution of the keto lactam **7***a* (61 mg) in 2 mL of dry peroxide-free dimethoxyethane was added to 126 mg of sodium hydride. After addition of 2 mL of methyl iodide the mixture was stirred under argon for 18 h. It was then filtered and evaporated to dryness under reduced pressure. Water was added to the residue, and the product extracted into dichloromethane. The nearly pure 8-*O*-methyl compound was separated from impurities on a silica gel plate using 5% methanol in chloroform. The 63 mg of product had mp 158°C and had spectra identical to those of the corresponding product (**12***a*) from the new alkaloid **12**.

Methylation of cammaconine

A mixture of 200 mg of cammaconine, 225 mg of sodium hydride, and 1.4 mL of methyl iodide in 10 mL of dioxane was refluxed under nitrogen for 7.5 h. The suspension was filtered through Celite and the filtrate evaporated. The residue was distributed between 1 *N* hydrochloric solution, then the bases extracted into dichloromethane. The 204 mg of product was extracted with hexane, giving 110 mg of non-polar ethers. This was adsorbed on 3.3 g of Act I neutral alumina. Hexane–ether (4:1) eluted 11 mg, rich in pentamethoxy compound. This solvent and hexane–ether (1:1) eluted 53 mg of tetramethyl ether which crystallized readily from pentane.

Methylation of talatisamine

Methylation of 200 mg of talatisamine as for cammaconine, followed by alumina chromatography, gave 30 mg rich in pentamethoxy compound and 84 mg of nearly pure tetramethyl ether. The early eluates from several runs were remethylated to enrich the pentamethoxy content.

14,18-Di-O-*methylcammaconine = 14*-O-*methyltalatisamine* (**2**)

This crystallized from pentane as rectangular plates with mp 103–105°C. It showed no mp depression with the tetramethoxy compound from talatisamine and their X-ray powder patterns, mass spectra, and ^1H nmr spectra were identical. The ether **2** gave ^1H nmr signals at δ: 3.71 (1H, t), 3.39, 3.30, 3.29 and 3.26 (3H singlets), and 1.06 (3H, t, J = 7 Hz). *Anal.* calcd. for $C_{25}H_{41}NO_5$: *Mol. Wt.* 435; C 68.93, H 9.49, N 3.22; found: C 68.51, H 9.47, N 3.29. Its mass spectrum had *m/e*: 435 (M^+) and 404 (M − 31, base peak).

8,14,18-Tri-O-*methylcammaconine = 8,14-Di*-O-*methyltalatisamine* (**3**)

The pentamethyl ether-rich fractions from cammaconine and talatisamine were purified by chromatography on activity I alumina (40-fold) from which the ether was eluted with 1:1 benzene–hexane. It crystallized from aqueous methanol as flat needles, mp 103–114°C. The ether **3** gave ^1H nmr signals at δ: 3.36 (6H, s), 3.30, 3.27 and 3.13 (3H singlets), and 1.06 (3H, s, J = 7 Hz). In C_6D_6 it gave signals at δ: 3.44, 3.20, 3.15, 3.10 and 3.095 (3H singlets) and 1.075 (3H, t, J = 7 Hz). Its mass spectrum had *m/e* 449 (M^+) and the base peak *m/e* 418 (M − 31). M^+ calcd. for $C_{26}H_{43}NO_5$: 449. A sample of fully methylated cammaconine kindly sent by Professor N. V. Mollov crystallized from aqueous methanol, mp 103–107°C. Its mixture mp with the above pentamethoxy compound was 103–114°C, and the mass spectra and X-ray powder patterns were identical.

Columbianine **14**

The most polar base from *A. columbianum* that was characterized crystallized from methanol, mp 202–205°C, and had $[\alpha]_D$ −6° (*c*, 0.5 in ethanol). It gave ^1H nmr signals at δ: 4.22 (1H, t, J = 4.5 Hz), 3.73 (1H, br, s), 3.34 (3H, s), 2.81 (1H, s), and 1.12 (3H, t, J = 7 Hz). *Anal.* calcd. for $C_{22}H_{35}NO_5$: *Mol. Wt.* 393: C 67.14, H 8.97, N 3.56; found: C 66.98, H 8.83, N 3.69. Its mass spectrum had *m/e* 393 (M^+) and 376 (M − 17).

Methylation of columbianine

A mixture of 54 mg of columbianine, 200 mg of sodium hydride, and 1 mL of methyl iodide in 7 mL of dioxane was refluxed under argon for 4 h, then left for 48 h at room temperature. After work-up as for cammaconine, the product was purified on a 1000-μ SiO_2 plate using 10:1 benzene–diethylamine for development. The main zone gave 35 mg of tetramethoxy base **13** (8,14,18-tri-*O*-methylcolumbianine). Repetition of the above experiment on 30 mg of columbianine but refluxing for 17 h gave 20 mg of pentamethoxy base which proved identical (^1H nmr, ^{13}C nmr) to 8,14-di-*O*-methyltalatisamine (**3**).

8,14,18-Tri-O-*methylcolumbianine* (**13**)

This new tetramethoxy base from the methylation of columbianine gave ^1H nmr signals at δ: 3.37 (6H, s), 3.32 and 3.15 (3H singlets), and 1.12 (3H, s, J = 7 Hz). Its mass spectrum gave *m/e*: 435.2997 (M^+) and 418.2958 (base peak, M − 17). M^+ calcd. for $C_{25}H_{41}NO_5$: 435.2985.

14-Dehydrooxosachaconitine (**9**a, *14-carbonyl*)

This crystallized as small plates from acetone, mp 235–236°C (recrystallized as rods before melting). It had $[\alpha]_D$ −30° (*c*, 0.69 in ethanol) and ν_{max}: 3570, 1751, and 1633 cm^{-1}. It gave ^1H nmr signals at δ: 3.93 (1H, s), 3.34 and 3.30 (3H singlets), 1.20 (3H, t, J = 7 Hz), and 1.17 (3H, s). Reference 13 gives mp 239°C and $[\alpha]_D$ +35.7° (note the reversed sign).

Oxosachaconitine (**9**a)

14-Dehydrooxosachaconitine was reduced by excess sodium borohydride in methanol. The product crystallized as laths from acetone–hexane, mp 197–199°C; $[\alpha]_D$ −35° (*c*, 0.36 in ethanol). Its ^1H nmr spectrum had signals at δ: 4.04 (1H, d, J = 4 Hz, OH), 4.18 (1H, m), 3.71 (1H, s, OH), 3.60 (1H, s), 3.38 and 3.24 (3H singlets), and 1.17 3H, t, J = 7 Hz). Its mass spectrum had peaks at *m/e*: 405.2518 (M^+), 390 (M − 15), 376, 375, 374, 373 (base peak, M − 32). M^+ calcd. for $C_{23}H_{35}NO_5$: 405.2515. Reference 13 gives mp 196°C and $[\alpha]_D$ −37.8°.

Surface reactions and catalysis at *alcohol vapour/3d transition metal oxide* interfaces at $T \leq 475$ K. Part I. Dehydration and dehydrogenation of isopropanol over V_2O_5 and V_2O_3

JOSEPH CUNNINGHAM, MOHAMMAD ILYAS, AND JOHN NUNAN
Chemistry Department, University College, Cork, Ireland

Received April 15, 1983

JOSEPH CUNNINGHAM, MOHAMMAD ILYAS, and JOHN NUNAN. Can. J. Chem. **62**, 785 (1984).

Pseudo steady-state conversions of alcohol vapours observed in a differential flow microcatalytic reactor provide the basis for comparing catalytic activities for a minor dehydrogenation ($-H_2$) process and for a dominant dehydration ($-H_2O$) process over both oxygenated and deoxygenated *alcohol vapour/vanadium oxide* interfaces. Effects of surface pre-reduction or pre-oxidation upon sample activity and ir spectra are consistent with an involvement of quadrivalent vanadium in the surface sites responsible for ($-H_2$) and ($-H_2O$) activities. Different sensitivities towards poisoning by phenol point to important differences in the environment of V^{IV} in the ($-H_2$) and ($-H_2O$) sites. Observations by ir and X-ray diffraction show extensive reduction by alcohol vapour at deoxygenated, but not at oxygenated interfaces.

JOSEPH CUNNINGHAM, MOHAMMAD ILYAS et JOHN NUNAN. Can. J. Chem. **62**, 785 (1984).

On utilise les conversions à un pseudo état stationnaire de vapeurs alcooliques dans un réacteur microcatalytique à flux différentiel comme base pour comparer les activités catalytiques pour un processus de déshydrogénation mineur ($-H_2$) et pour un processus déshydratation ($-H_2O$) majeur sur des interfaces *vapeur d'alcool/oxyde de vanadium* oxygénées ainsi que désoxygénées. Les effets de pré-réduction ou de pré-oxydation de la surface sur l'activité des échantillons et les spectres ir sont en accord avec une implication de vanadium quadrivalent dans les sites de surface responsables des activités ($-H_2$) et ($-H_2O$). Des différences de sensibilités vis-à-vis l'empoisonnement par le phénol suggèrent qu'il existe de grandes différences dans l'environnement du V^{IV} dans les sites responsables de ($-H_2$) et ($-H_2O$). Des observations par ir et par diffraction des rayons X montrent qu'il se produit une réduction importante des interfaces désoxygénées par les vapeurs d'alcool; ce n'est pas le cas au niveau des interfaces oxygénées.

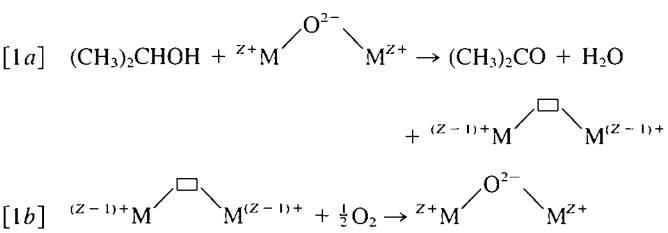
Introduction

The following features of catalytic activity identified in published work with oxides of 3*d*-transition metals prompted the work to be described in this series of papers: (*i*) indications that oxygen content at the oxide surfaces can vary in a complex manner with temperature and with oxygen overpressure (1–3); (*ii*) results from these and other laboratories showing that the activity and/or selectivity of some pure unsupported oxides for dehydration ($-H_2O$) and/or dehydrogenation ($-H_2$) of secondary alcohols could be strongly altered by prior reduction or oxidation of the oxide surface (4); (*iii*) proposals that sustained high catalytic activity attainable for oxidative catalytic processes over various oxides in the presence of gaseous oxygen can involve reaction and removal of lattice oxygen in an initial step followed by fast re-oxidation by gaseous oxygen of metal oxide sites reduced in the first step (5–7), e.g.



[1*a*] $(CH_3)_2CHOH + {}^{Z+}M(O^{2-})M^{Z+} \rightarrow (CH_3)_2CO + H_2O + {}^{(Z-1)+}M(\square)M^{(Z-1)+}$

[1*b*] ${}^{(Z-1)+}M(\square)M^{(Z-1)+} + \tfrac{1}{2}O_2 \rightarrow {}^{Z+}M(O^{2-})M^{Z+}$

and (*iv*) evidence for some cases, such as Mn_2O_3 or V_2O_5, that surface redox processes may be effectively restricted to the topmost surface layers (8) — provided that suitably moderate temperatures could be utilised. Interesting possibilities which emerge from the foregoing and which have come under mainly kinetic study in the work to be described in this series of papers include the following: (*A*) Identification of moderate oxygen overpressures capable of contribution added surface oxygen species sufficient to drive surface reoxidation similar to [1*b*] but insufficient to favour processes of type [1*c*] or [1*d*].

[1*c*] $O_{2(ads)} + M_{(s)}^{(Z-1)+} \rightarrow O_{2(ads)}^{-} + M_s^{Z+}$

[1*d*] $O_{2(ads)} + (CH_3)_2CHOH_{ads} \rightarrow (CH_3)_2CO + H_2O_2$

(*B*) Identification of moderate temperature conditions such that surface reduction–oxidation cycles (c.f. eq. [1*a*] followed by [1*b*] or [1*c*]) may be restricted to topmost surface layers, thereby allowing the underlying bulk oxide to remain in a chemically and structurally unaltered state. Results in the present paper will show that this latter possibility is not realised in V_2O_5 due to extensive reduction of the bulk by isopropanol even at 400 K. Interesting effects relevant to possibility (*A*) do, however, emerge in the present study for oxygenated isopropanol/vanadium oxide systems.

Experimental

Materials

Spectrochemically pure (>99.99%) V_2O_5 powder (surface area 2.6 $m^2\ g^{-1}$) was used as supplied (Spex), as also was reagent grade V_2O_3 (Ventron). Isopropanol was Aristar grade and *t*-butanol reagent grade which were absorbed onto a column of molecular sieve pellets and the purified vapour extracted therefrom by a flow of argon carrier gas. Prior to contact with alcohol vapour, the metal oxide powders were preheated either in a flow of argon alone (to remove surface water), or in a flow of argon admixed with oxygen in order also to preoxidize the surface when that was desired. Usually such pretreatments were at the temperature of subsequent reaction. However, when extensive surface dehydroxylation was required, samples were pretreated for 16 h at 675 K either in argon alone (which also yielded some pre-reduction of the surface) or in a 1 : 1 flow of argon plus oxygen (which yielded well pre-oxidised surfaces). When extensive surface pre-reduction was required this was achieved by heating in a flow of 3% H_2 in N_2 at 675 K. Bulk reduction of V_2O_5 to V_2O_3 was accomplished (9) by heating in a flow of pure H_2 at 873 K.

Procedures

Observations were made in a continuous reactant flow (c.r.f.) mode and involved the establishment of a continuous flow of argon carrier gas, *plus* alcohol vapour at a set pressure (*plus* O_2 whenever required), through the preconditioned sample at a fixed reaction temperature in the range 375–475 K. In this c.r.f. mode a gas-sampling valve was utilised intermittently to sample exit gases from the reactor at desired intervals and pass them to a gas chromatograph for analysis using a flame ionization detector. The minimum feasible exposures of samples to alcohol vapour were moderately high in this c.r.f. mode, e.g. net exposure of 200 molecules per surface ion pair (m/s.i.p.) when a sample of exit gases was extracted after only 10 min continuous flow. Net yields of $(-H_2O)$ or $(-H_2)$ products could be calculated as turnover per surface ion pair (t/s.i.p.) from known total flow times and rates of conversion evaluated from samples analysed over that time. Blank runs with the empty reactor pretreated in identical fashion to that used for studying reaction with metal oxide in the reactor were made in all cases. Any minor conversions observed with the blanks have been taken into account in arriving at the corrected values for the rates of $(-H_2O)$ and $(-H_2)$ processes catalysed by the vanadium oxide surfaces. Linearity of plots of yield vs. reciprocal of the flow rate was also checked for both the $(-H_2O)$ and $(-H_2)$ processes in order to confirm that reaction on the surface was the rate limiting process — rather than diffusional limitation in arrival of reactant(s) or departure of product(s).

Surface areas were evaluated from measurement of N_2 adsorption at 77 K with a vacuum microbalance and BET plots. The rather small surface areas found in this way (2.6 $m^2 g^{-1}$ for V_2O_5) militated against adequate transmission of ir through self supporting discs and it was necessary to disperse appropriately pretreated samples into KBr discs for ir examination.

Results and discussion

1. Parallel $(-H_2O)$ and $(-H_2)$ from isopropanol on V_2O_5

Data taken previously in the c.r.f. mode at 395 K, with non-oxygenated isopropanol as reactant over a high-purity oxide of initial stoichiometry V_2O_5, were reported elsewhere (4) and established unusually high initial $(-H_2O)$ activity for conversion to propene with selectivity ~95%. Although selectivity for $(-H_2)$ was only ~5%, that did correspond to substantial and accurately measurable steady-state rates of conversion to acetone. A progressive decay with time was observed in that earlier work for both $(-H_2O)$ and $(-H_2)$ activities of V_2O_5 at 395 K in the c.r.f. mode whilst the net yield of propene increased to t/s.i.p. ~10 in the absence of $O_{2(g)}$. Similar rapidly-decaying activity profiles were again observed at 410 and 395 K in the present study. One general view of declining activity profiles of the type shown in Fig. 1 for temperatures ca. 400 K would be: (*i*) that active sites present in topmost layers of V_2O_5 experienced non-selective and partially reversible degradation of both $(-H_2O)$ and $(-H_2)$ activities whilst net yield for the latter process increased to t/s.i.p. ~10; and (*ii*) that such non-selective degradation involved decreases in oxidation state of vanadium at certain sites in the surface layer(s) (e.g. cf. eq. [1*a*]). This was examined here by the introduction of oxygen at various pressures into the reactant flow in a set of experiments prompted in part by a report (8) that the re-oxidation sequence depicted in reaction [2] could be restricted to surface layers of V_2O_5 if temperature was limited to <475 K.

$$[2]\quad V^{III} \xrightarrow[E_{act} = 6.3\ kJ]{+O_2} V^{IV} \xrightarrow[E_{act} = 21\ kJ]{+O_2} V^{V}$$

In efforts to evaluate the influence of oxygen upon *steady-state* activities, the V_2O_5 catalyst was first brought to its steady-state (working) activity in a flow of isopropanol alone, then oxygen

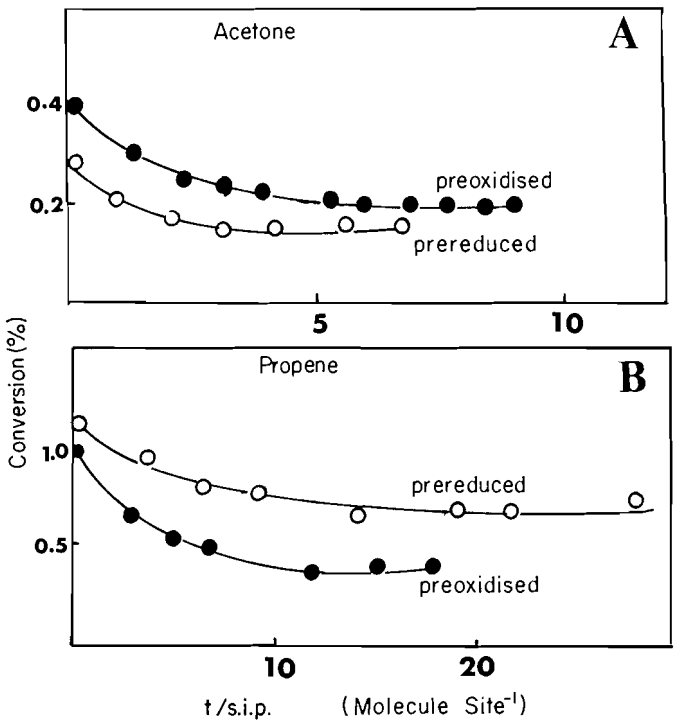

FIG. 1. Declining $(-H_2)$ and $(-H_2O)$ activity profiles for deoxygenated $(CH_3)_2CHOH/V_2O_5$ at 395 K. Results were obtained from rates measured after various contact times but are related in this plot to net yield expressed as turnover per surface ion pair (t/s.i.p.). The V_2O_5 surfaces had been either preoxidised in O_2 at 673 K (data points ●) or midly prereduced in argon at 673 K (data points ○). Plots *A* and *B* represent activity for dehydrogenation to acetone and dehydration to propene, respectively.

was introduced at a selected low pressure, which was maintained until a new altered steady-state activity was reached, whereupon the oxygen pressure was altered to a new value and another steady-state value was measured. Figure 2*A* summarises results demonstrating the manner in which the enhancing effects of oxygen upon steady-state rates of $(-H_2)$ and $(-H_2O)$ conversions varied with P_{O_2}. Rapid enhancement is apparent for both the $(-H_2)$ and $(-H_2O)$ activities in the 20 to 50 Torr pressure range for P_{O_2} and would be consistent with progressive reversal by oxygen of an extensive initial surface reduction experienced by the V_2O_5 sample in the flow of deoxygenated isopropanol (see below). Figure 2*A* also shows a lack of additional enhancing effect, rather indeed a small decline in activity, as P_{O_2} increased to values >150 Torr. Overall the dependence of P_{O_2} would be qualitatively consistent with [2] on the basis that low P_{O_2} promoted $V^{III} \rightarrow V^{IV}$ whilst higher pressures of O_2 further oxidise $V^{IV} \rightarrow V^{V}$, thereby causing maximum surface concentration of V^{IV} to occur at $P_{O_2} \sim 50$ Torr. Also consistent with the idea of an oxygen-sensitive, dynamic steady-state concentration of V^{IV} at the surface of the working catalyst were observations made upon changes in activity when gas-phase O_2 was suddenly removed from or reintroduced into the reactant flow. These are summarised in Fig. 2*B*; both parts of which show that activity dropped when gas-phase oxygen was removed from the flow of oxygenated alcohol vapour over the vanadium oxide catalyst having initially the stoichiometry of V_2O_5. The initial segments of both plots in Fig. 2*B* demonstrate that, — unlike preoxidized V_2O_5 material which had shown an initial rapid decay in $(-H_2)$ activity (cf. Fig. 1*A*) when exposed to deoxygenated alcohol vapour — preoxidized

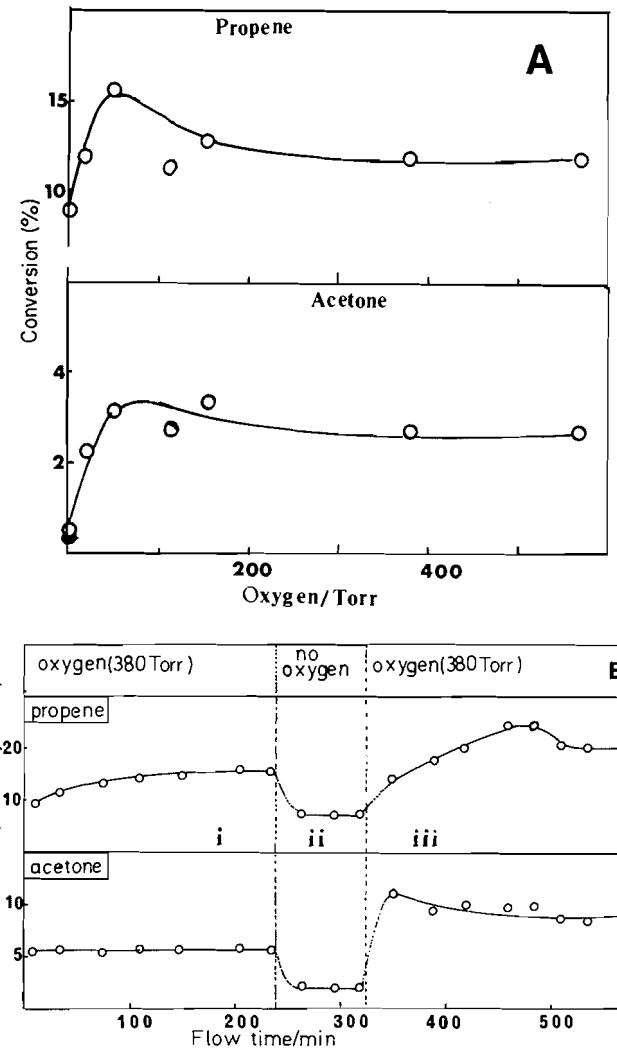

FIG. 2. Enhancing effects of oxygen upon activity of V_2O_5 at 433 K. (*A*): enhancing effects observed upon steady-state ($-H_2$) and ($-H_2O$) activities when indicated pressures of O_2 were admixed with 20 Torr of $(CH_3)_2CHOH$ in the c.r.f. procedure over V_2O_5. (*B*): (*i*) stable ($-H_2$) activity and slightly rising ($-H_2O$) activity observed with 380 Torr O_2 admixed with 20 Torr $(CH_3)_2CHOH$ up to 240 min; (*ii*) diminished activity when O_2 removed; (*iii*) enhanced activities upon re-introducing O_2.

V_2O_5 which was maintained instead of a premixed flow of isopropanol *plus* O_2 showed almost no decay in activity. The final segments of the plots in Fig. 2*B* show that when O_2 was introduced following a temporary interruption, activities for both ($-H_2O$) and ($-H_2$) processes were again increased. Enhancement of *both* the ($-H_2O$) and ($-H_2$) activity of V_2O_5 towards isopropanol through the operation of sample re-oxidation processes was thus clearly established for the $[(CH_3)_2CHOH + O_2]$–V_2O_5 interfaces and appeared consistent with oxygen enhancement of the dynamic surface concentration of V^{IV}.

A diligent search was made for appearance of new products which might be expected in the oxygenated system, and particularly for acetaldehyde which might arise from V_2O_5-catalysed attack by oxygen upon propene (10), or upon a surface isopropoxy radical formed by homolytic rupture of the vanadium–oxygen bond of a chemisorbed isopropoxide ion (11). Even at the high sensitivity of the f.i.d., however, no

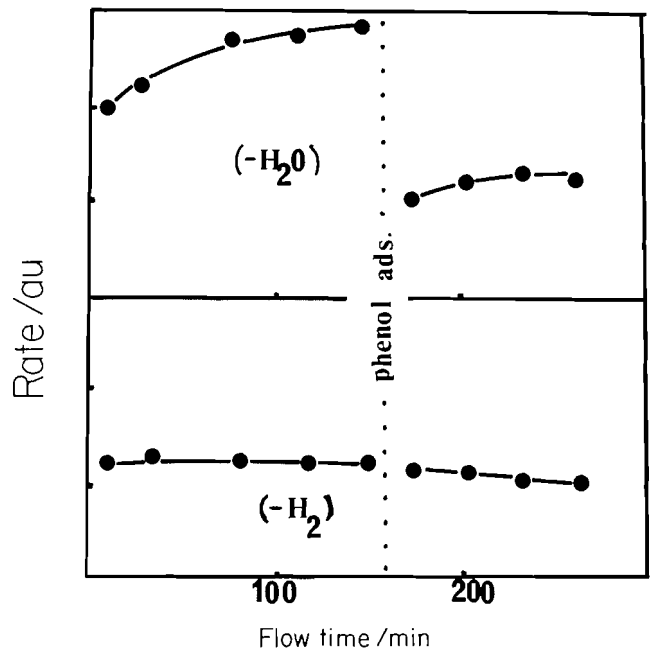

FIG. 3. Selective inhibition of dehydration upon exposure to phenol vapour at an oxygenated $(CH_3)_2CHOH/V_2O_5$ interface in the c.r.f. mode at 433 K.

measurable amounts of acetaldehyde were detected in the exit gases for the oxygenated $(CH_3)_2CHOH/V_2O_5$ system at temperatures to 433 K. The following additional experiments lent added confidence that the absence of significant CH_3CHO from the $(CH_3)_2CHOH/V_2O_5$ system was a real effect rather than an experimental artifact: (*i*) when acetaldehyde pulses were injected into the reactor, swept over the V_2O_5 catalyst, and analysed by gc in the normal manner, they were readily detected; (*ii*) independent checks made by mass spectrometric sampling from a closed glass reactor containing $(CH_3)_2CHOH$ at 10 Torr over V_2O_5 at 475 K confirmed that propene was the major gas-phase product (ca. 95%), accompanied by smaller but readily measurable yield of acetone, but that no detectable gas-phase acetaldehyde resulted from isopropanol over either preoxidized or mildly prereduced V_2O_5 or when 10 Torr of O_2 was present together with isopropanol vapour. It was concluded that, even for the oxygenated systems, acetone and propene remained the only significant hydrocarbon products at the moderate temperature employed here.

Experiments were made to test whether the oxygen-enhanced ($-H_2O$) and ($-H_2$) activities would respond in the c.r.f. mode to preadsorption of phenol in similar fashion to that noted previously (4) for deoxygenated $(CH_3)_2CHOH/V_2O_5$ in a pulsed mode, viz. that phenol poisoned ($-H_2O$), but not ($-H_2$), activity. Our new results for the oxygenated system in c.r.f. mode are presented in Fig. 3 and show a much stronger poisoning effect of phenol adsorption upon the oxygen-enhanced ($-H_2O$) activity than upon oxygen-enhanced ($-H_2$) activity. The main implication to be drawn from our combined phenol-poisoning results is that different sites continued to be responsible for ($-H_2O$) and ($-H_2$) activities in the presence of oxygen — as was also the case in the deoxygenated system. On the other hand, the parallel behaviour noted above for the ($-H_2O$) and ($-H_2$) activities in respect of initially rapid decline in deoxygenated conditions (cf. Fig. 1*A*), and of oxygen enhancement in steady-state rates (cf. Fig. 2*A*), point towards involvement of quadrivalent vanadium in each type of site.

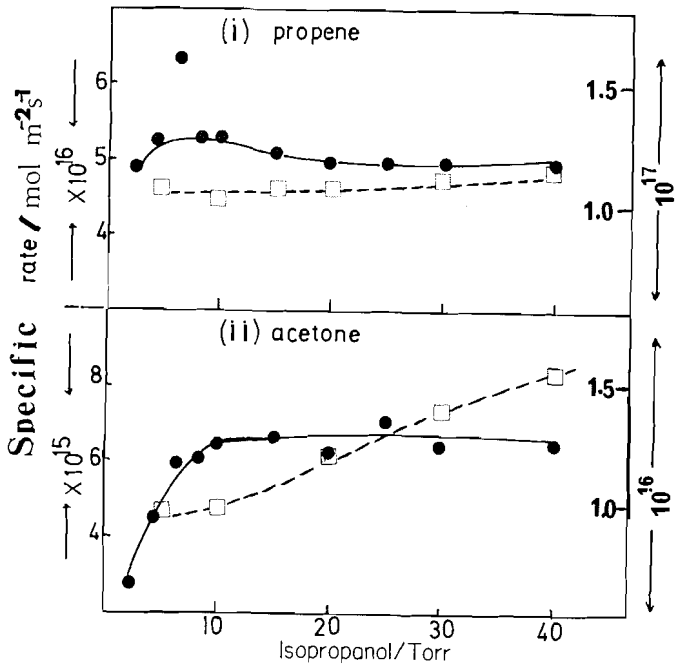

FIG. 4. Alcohol pressure dependence of steady-state, specific rates of conversion to $(-H_2O)$ or to $(-H_2)$ products at over V_2O_5 (molecules m^{-2} min^{-1}). Comparison of deoxygenated (unbroken plots, left hand scale) with oxygenated (dashed plots; right hand scale) for dehydration (part *i*) and dehydrogenation (part *ii*), respectively.

Various dual-site models could be envisaged featuring V^{IV} in both sites, but with important differences in its local environment for the sites active for $(-H_2O)$ and $(-H_2)$, e.g. $(V^{IV}-O)$ surface ion-pairs acting as acid–base type catalytic sites to promote E_2-type dehydration, but $V^{IV}-V^{IV}$ pairs (12) at surface-defect locations, acting to promote E1-type dehydrogenation. Efforts to discriminate between various dual-site models by electron spin resonance were unsuccessful since the unsupported oxides in their working catalytic state gave a very broad unresolved resonance.

Differences of detail shown in Fig. 4 between the alcohol pressure dependence of steady-state rates of $(-H_2O)$ and $(-H_2)$ conversions for oxygenated and deoxygenated $(CH_3)_2CHOH/V_2O_5$ systems lend support to the idea of important differences in the sites responsible for the two processes. Thus the comparison attempted in Fig. 4*A* for alcohol pressure dependence of $(-H_2O)$ activities for the oxygenated and deoxygenated systems (cf. broken and unbroken plots) indicate little or no dependence upon P_{ROH} and could be consistent with an approach to saturation coverage of $(V^{IV}-O)$ ion-pair sites for dehydration across the alcohol pressure range 2–40 Torr. The $(-H_2)$ type activity, on the other hand, continued to rise with alcohol pressure across the range 10 to 40 Torr in systems oxygenated by 380 Torr of O_2 (cf. broken line in Fig. 4*B*) whilst little dependence of the $(-H_2)$ rate was evidenced by the deoxygenated systems across that pressure range.

One final point in favour of an acid–base type, ion-pair site for $(-H_2O)$ activity emerged from a comparison made at 408 K between the steady-state $(-H_2O)$ activities displayed in the c.r.f. mode by identically pretreated samples of V_2O_5 towards *t*-butanol, isopropanol, and isobutanol. This yielded the following values when expressed as molecules m^{-2} s^{-1}: 4.2×10^{17} for $(CH_3)_3COH$, 4.7×10^{15} for $(CH_3)_2CHOH$, and 3.8×10^{13} for $(CH_3)_2CHCH_2OH$. These exhibit the order expected if ease of formation/stability of the corresponding carbonium ion via loss of the alcoholic-OH group were important for the $(-H_2O)$ activity.

2. Oxygen enhancement on V_2O_3

It could be argued on the basis of eq. [2] and ideas outlined above: (*i*) that if the pure sesquioxide, V_2O_3, were used negligible catalytic activity for $(-H_2O)$ or $(-H_2)$ would be expected and (*ii*) that exposure to oxygen in appropriate conditions might lead to surface oxidation. Alternative hypotheses by which gaseous oxygen could promote V^{III} oxidation were envisaged as in reactions [3] or [4]. The former envisaged non-dissociative adsorption of oxygen which then became involved in diatomic form both in surface oxidation and oxidative dehydrogenation:

$$[3a] \quad O_{2(g)} \rightleftharpoons O_{2(ads)}$$

$$[3b] \quad V_s^{III} + O_{2(ads)} \rightarrow (V_s^{IV} \text{ - - - } O_2^-)_s$$

$$[3c] \quad (V_s^{IV} \text{ - - - } O_2^-) + (CH_3)_2CHOH_{(ads)} \rightarrow V_s^{III} + H_2O_2 + (CH_3)_2CO$$

The alternative hypothesis, based upon dissociative chemisorption of oxygen and involvement of the monatomic oxygen fragments in both surface oxidation and oxidative dehydrogenation, was envisaged as follows:

$$[4a] \quad \tfrac{1}{2}O_{2(g)} \rightleftharpoons O_{(ads)}$$

$$[4b] \quad O_{(ads)} + 2V^{III} \rightarrow O_s^{2-} + 2V^{IV}$$

$$[4c] \quad 2V^{IV} + O_s^{2-} + (CH_3)_2CHOH \rightarrow 2V^{III} + H_2O + (CH_3)_2CO$$

Experiments were first made to test whether prolonged prereduction of V_2O_5 by H_2 in conditions which have been reported to yield the sesquioxide (9) would result in negligible $(-H_2)$ activity. This was confirmed with deoxygenated isopropanol at temperatures up to 433 K over V_2O_5 pre-reduced to V_2O_3 at 873 K. Negligible $(-H_2)$ or $(-H_2O)$ activity was also confirmed upon loading commercially available V_2O_3 into the reactor, pretreating in non-oxidising conditions, and testing with deoxygenated isopropanol up to 433 K (cf. Fig. 5*A*). Data to test the alternative hypotheses given in reactions [3] and [4] were sought by comparing the steady-state rates of the elimination reactions as progressively increasing pressures of oxygen were introduced into the flow of argon whilst maintaining a constant pressure of isopropanol over the sesquioxide materials at 433 K. Results confirming the progressive enhancement of steady-state $(-H_2)$ and $(-H_2O)$ activities as P_{O_2} increased are shown in Fig. 5*B*. Inspection of the possible mechanism represented by reaction [3] for oxygen-enhancement of $(-H_2)$ activity readily reveals one limiting case in which steps [3*b*] and [3*c*] are rate-limiting whilst [3*a*] is in rapid equilibrium. Then the equilibrium surface coverage, θ_{O_2}, by non-dissociatively chemisorbed oxygen can well be approximated by eq. [3*d*], provided also that alcohol reactants and products do not compete for the same sites as oxygen.

$$[3d] \quad \theta_{O_2} \simeq KP_{O_2}/(1 + KP_{O_2})$$

The condition for dynamic steady-state surface concentration of $(V^{IV} \text{ - - - } O_2^-)_s$ in this limiting case may then be approximated by

$$[3e] \quad k_{3b}\theta_{O_2} V^{III} \simeq k_{3c}\theta_{(V^{IV} \cdots O_2^-)} \theta_{ROH}$$

from which it is clear that the steady-state surface concen-

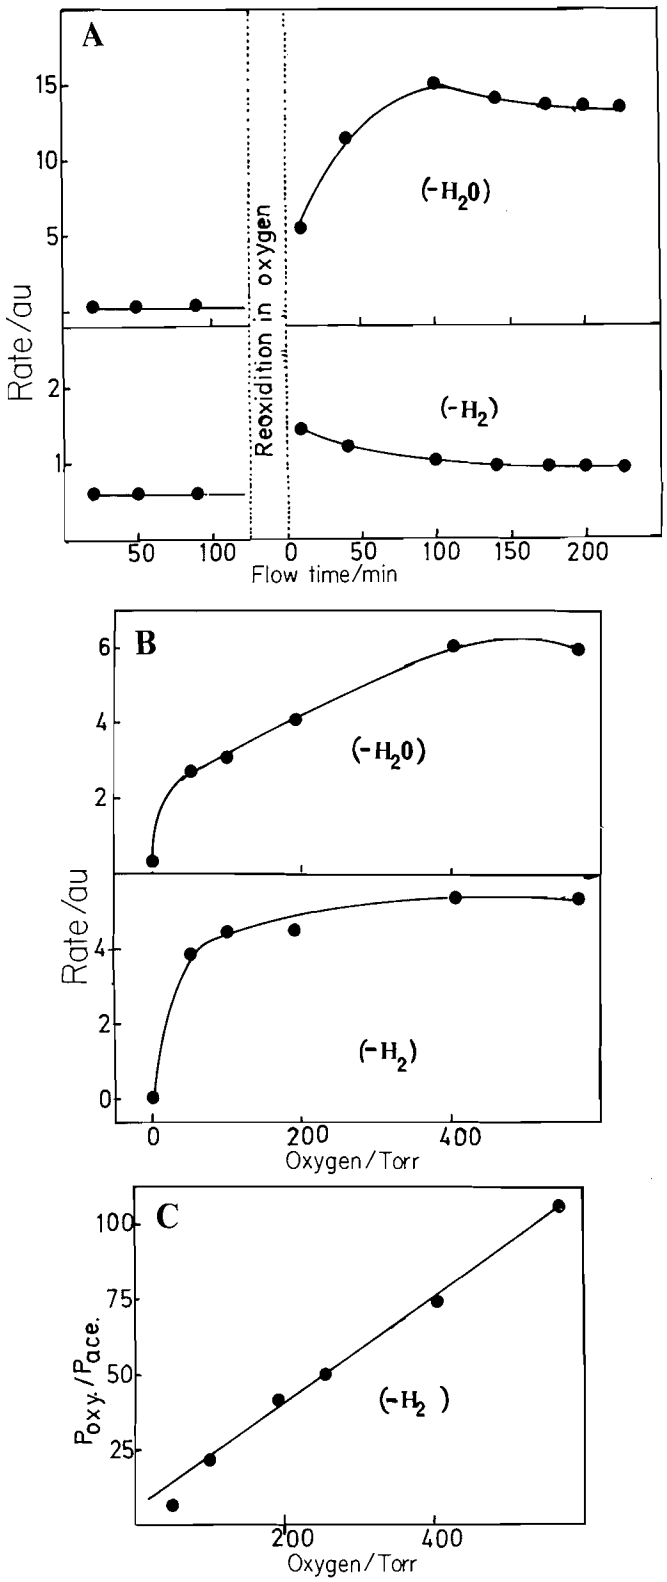

FIG. 5. Data obtained in c.r.f. mode over vanadium sesquioxide and illustrating: (*A*) initially low ($-H_2$) and ($-H_2O$) activities up to 100 min over deoxygenated $(CH_3)_2CHOH/V_2O_3$ at 433 K, but enhancement of activities subsequent to the sample being oxidised in O_2 for 3 h at 873 K; (*B*) enhancing effects of indicated pressures of P_{O_2} upon steady-state ($-H_2O$) and ($-H_2$) activities at 433 K; (*C*) linearization achieved at P_{O_2} 50 to 550 Torr by plotting inverse of steady-state ($-H_2$) rate, (expressed by $P_{acetone}$), in manner appropriate for θ_{O_2} and the rate of acetone production increasing with P_{O_2} according to $\theta_{O_2} = KP_{O_2}/(1 + KP_{O_2})$.

trations of V^{IV} and V^{III} species are influenced by the surface coverage by alcohol species. Under conditions of fixed alcohol pressure and surface coverage, however, the influence of P_{O_2} originates mainly from the θ_{O_2} term in [3*e*] and thus from eq. [3*d*]. An appropriate graphical test showing a degree of consistency with this kinetic analysis is represented in Fig. 5*C* for the data from Fig. 5*B* on oxygen-enhanced steady-state ($-H_2$) activities at 433 K. The least-squares regression co-efficient (0.984) for linearization in the manner of Fig. 5*C* was significantly better than that obtained (0.855) in the linearization of the same data based upon reaction [4] and the involvement of dissociatively chemisorbed oxygen in surface oxidation and alcohol dehydrogenation. (i.e. assumptions similar to those applied above to reaction [3] are readily shown to lead, in the case of reaction [4] to a dependence of rate upon $\theta_{O^\cdot}$ which should be well approximated by $\theta_{O^\cdot} \simeq KP_{O_2}^{1/2}/(1 + KP_{O_2}^{1/2})$ but that was less successful as a basis for linearizing the data). The significance of the somewhat better agreement of the oxygen-enhanced steady-state ($-H_2$) rates with non-dissociative oxygen adsorption should not be exaggerated, however, in view of (*i*) known difficulties of kinetic analysis when diatomic and monatomic oxygen species are simultaneously present on oxide surfaces and (*ii*) insufficiency of our data for a rigorous kinetic test of P_{O_2}-dependence.

3. *Structure studies*

The question of whether opposing processes of catalyst reduction by alcohol and reoxidation by O_2 over vanadium oxides were restricted to surface regions, or whether they caused major modifications of the vanadium oxide bonding and crystal structure down to great depths within the solid, were examined by observing changes brought about in the ir spectra and X-ray diffraction patterns when flows of alcohol and/or O_2 were established over preoxidised V_2O_5 (*Ar + O_2 at 675 K*). The ir spectra shown in Fig. 6*A* demonstrate that, whilst a flow of isopropanol alone over the sample at 435 K caused marked ir changes in the range 1000–600 cm^{-1} relative to V_2O_5 preoxidised at 675 K, no such changes occurred whenever 380 Torr of O_2 was admixed with 40 Torr of isopropanol. These differences once again lend support to an efficient reoxidising role of gas-phase O_2. In terms of detailed ir spectra reported by Frederickson and Hausen (13) for V_2O_3, V_2O_4, and V_2O_5, the predominance of ir at ca. 1020 cm^{-1} and 825 cm^{-1} in spectra *A* and *B* of Fig. 6 indicate persistence of a mainly V_2O_5-type oxide in samples exposed to O_2 only, or to O_2 admixed with isopropanol. Alterations of the spectrum to that in 6*C* after exposure to alcohol vapour alone at 350 K — viz. appearance of a strong band at ca. 900 cm^{-1}, a weaker narrow band at 850 cm^{-1} and a broad absorbance at 750 cm^{-1} — would be consistent with predominance of V_2O_4 in the surface regions examined by the ir beam. (It is worth noting that our spectrum for V_2O_3, like that reported by Frederickson and Hausen, gave no significant absorbance at the values just assigned to V_2O_4, but rather lacked any absorbances standing out well against a generally low transmittance.)

Comparisons of X-ray diffraction patterns yielded similar conclusions to the ir studies, viz. that diffraction lines from V_2O_5 predominated for preoxidised V_2O_5 (*O_2, 675 K*) and for V_2O_5 maintained in a flow of O_2 + isopropanol at 350 K, whereas diffraction lines characteristic of V_2O_4 were clearly distinguishable in vanadium oxide treated only with alcohol vapour at 375 K. Thus, it became clear from both the ir and X-ray diffraction studies that treatment with isopropanol alone,

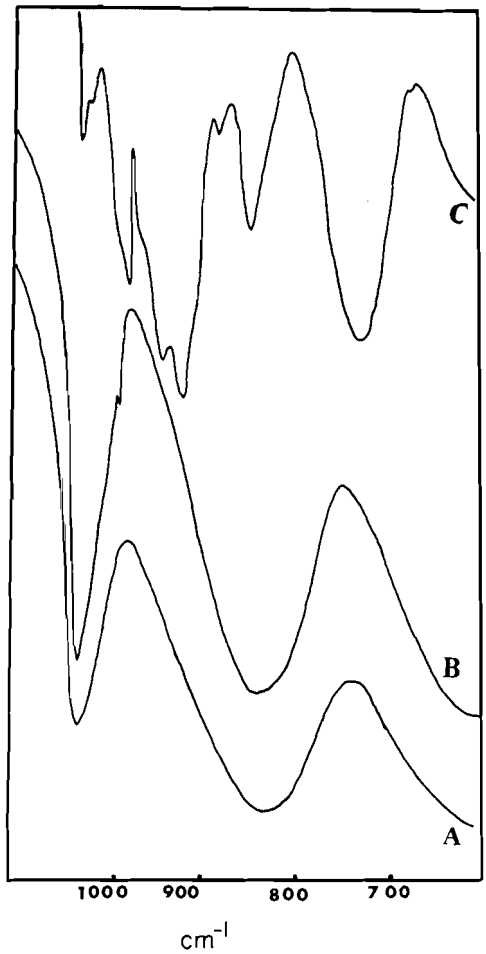

FIG. 6. Infrared spectra of V_2O_5. *A*, V_2O_5 treated in O_2 flow at 673 K overnight, then cooled down to room temperature in O_2; *B*, sample after passing isopropanol + O_2 (40:380 Torr) at 433 K for 7 h, then cooled down to room temperature to argon; *C*, sample after treating in isopropanol (40 Torr) + argon for 7 h, then cooled down to room temperature in argon flow. After cooling to room temperature the V_2O_5 samples were mixed with KBr.

even at 375 K, produced V_2O_4 to depths much greater than the topmost few layers of oxide. Conversely, the absence of any V_2O_4 discernible by ir or X-ray when O_2 was present together with the alcohol vapour, supports the occurrence of a fast and efficient re-oxidation process in the presence of $P_{O_2} \sim 380$ Torr even at the moderate temperatures here employed.

4. Kinetic parameters at vacuum/V_2O_5 and $(CH_3)_2CHOH$/V_2O_5 interfaces

Comparisons of the rates of loss of oxygen from the surface with rates of the $(-H_2O)$ and $(-H_2)$ processes in the same temperature range provide evidence that the latter could not have arisen from spontaneous breakdown of the V_2O_5 lattice at the reaction temperature and subsequent attack by oxygen fragments upon adsorbed alcohol. Thus the rate of loss of oxygen at 435 K, as evaluated by downward extrapolation of weight loss vs. outgassing temperature data taken with a vacuum microbalance, corresponded to ca. one monolayer equivalent h^{-1} whereas the net yield of $(-H_2O)$ and $(-H_2)$ products from isopropanol during one hour of reaction at 435 K corresponded to 260 and 50 monolayer equivalents, respectively. Further indications of involvement of other activated processes in elimination reactions at the surface came from large differences between an activation energy of ca. 20 kJ mol^{-1} estimated for surface lattice breakdown (from the vacuum microbalance data) and activation energy values of 84 ± 3 for $(-H_2O)$ and 59 ± 4 kJ mol^{-1} for $(-H_2)$. These were obtained for deoxygenated isopropanol from linear Arrhenius plots of steady-state rate data over the temperature range 375 to 475 K but activation energies obtained in similar fashion for the corresponding oxygenated systems were 105 ± 5 and 83 ± 4 kJ mol^{-1}. The increase in E_{act} (by ca. 20 kJ mol^{-1} in each case) upon oxygenation provides evidence for operation of an additional activated step involving oxygen. However, as already noted, propene and acetone continued to be the sole significant products and rates of their production were increased in the oxygenated system. The proportionate oxygen-induced increases in pre-exponential terms necessary to compensate for the increased E_{act} values and so achieve the rate increases observed at 433 K corresponded to $e^{7.1}$ for the $(-H_2O)$ and $e^{7.4}$ for the $(-H_2)$ process. Such increases are qualitatively consistent with the roles deduced earlier for sites containing quadrivalent vanadium and for oxygen in promoting their dynamic surface concentrations (cf. eqs. [3] and [4]). It is interesting that the increase of ca. 20 kJ mol^{-1} in E_{act} in each case corresponds to what could be expected if removal of oxygen from V_2O_5 were the additional activated step (e.g. in the manner of eq. [1*a*]).

Metal-catalyzed rearrangements of allylic esters[1,2]

A. C. OEHLSCHLAGER, P. MISHRA, AND S. DHAMI
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received May 20, 1983[3]

A. C. OEHLSCHLAGER, P. MISHRA, and S. DHAMI. Can. J. Chem. **62**, 791 (1984).

It has been shown that $Pd(CH_3CN)_2Cl_2$ catalyzes the rearrangement of allylic esters. Carbamates rearrange more rapidly than acetates which in turn rearrange more rapidly than carbonates. Allylic carbamates are more rapidly isomerized by $Pd(CH_3CN)_2Cl_2$ than by $Hg(OCOCF_3)_2$. The rearrangement proceeds well except in cases where the central carbon of the allylic system is fully substituted.

In contrast to the reported rearrangement of allylic carbamates by Hg^{2+} and previous reports of Pd^{2+}-catalyzed rearrangements of allylic esters, this work showed the latter are extremely *E* specific; thus, *E* allylic acetates yield equilibrium mixtures free of *Z* allylic isomers, under conditions in which *Z* allylic acetates are unreactive. This *E* specificity is applied to stereospecific 1,3-diene synthesis from bis *E,Z*-allylic acetates.

A. C. OEHLSCHLAGER, P. MISHRA et S. DHAMI. Can. J. Chem. **62**, 791 (1984).

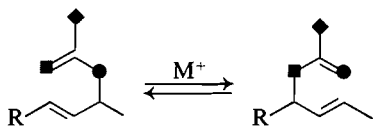
On a démontré que le $Pd(CH_3CN)_2Cl_2$ catalyse la transposition des esters allyliques. Les carbamates se transposent plus rapidement que les acétates qui se transposent à leur tour plus rapidement que les carbonates. Les carbamates allyliques sont isomérisés plus rapidement par le $Pd(CH_3CN)_2Cl_2$ que par le $Hg(OCOCF_3)_2$. La transposition se produit facilement dans tous les cas excepté lorsque le carbone central du système allylique est complètement substitué.

Par opposition aux transpositions des carbamates allyliques par le Hg^{2+} et des transpositions des esters allyliques catalysées par le Pd^{2+} qui ont été rapportées antérieurement, on démontre dans le présent travail que ces dernières réactions sont extrèmement spécifiques aux isomères *E*; ainsi, les acétates allyliques *E* fournissent des mélanges à l'équilibre qui ne contiennent pas d'isomères allyliques *Z* dans des conditions où les acétates allyliques *Z* ne sont pas réactifs. On a appliqué cette spécificité *E* à une synthèse stéréospécifique des dienes-1,3 à partir de bis-acétates allyliques-*E,Z*.

[Traduit par le journal]

Introduction

Soft electrophilic metal ions dramatically catalyze rearrangement of allylic esters (1), 1,5-dienes (2), and *S*-allylthioimidates (3). The catalyst systems that have received most attention are based on mercuric(II) and palladium(II) salts.

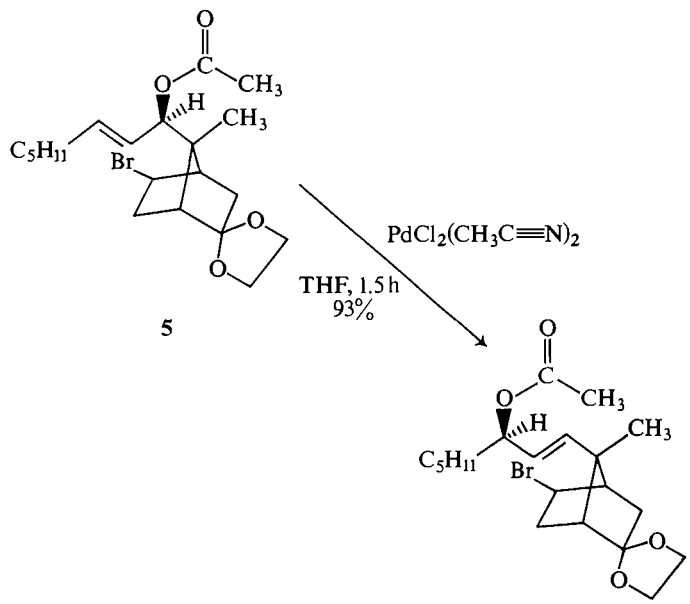


Mercuric trifluoroacetate has been shown to be a particularly effective catalyst for rearrangement of allylic *N,N*-dimethyl carbamic esters (**1***a*–**3***a*) at room temperature (1*a*).

The lack of formation of an amine product and the inversion of the allylic fragment which is observed in the rearrangement of thionocarbamates were considered to be consistent with a mechanism in which the mercury(II) catalyst interacted with the carbon–carbon π-bond to promote intramolecular cyclization to yield a 1,3-dioxanium ion intermediate **4***a* (1*a*).

Organic soluble palladium salts (especially $Pd(CH_3C{\equiv}N)_2Cl_2$) catalyze the rearrangement of allylic acetates at room temperature (1*b*–*e*, 4).

These reactions produce mixtures except when the allylic π-bond in one isomer is conjugated or where relief of steric compression (3° acetate → 1° acetate) attends the rearrangement (1*b*, 4). The most compelling evidence that the palladium-catalyzed process involves transfer of the acetate via a 1,3-dioxanium intermediate (**4***b*, Scheme 1) is the complete retention of optical purity in the palladium(II)-catalyzed rearrangement of the chiral allylic acetate **5** to **6** (4*a*).



5 **6**

A similarly striking transfer of chirality occurs in the palladium(II)-catalyzed rearrangement of 1,5-dienes and is consistent with a similar cyclization-induced rearrangement mechanism (2).

The present investigation was undertaken to extend the metal ion-catalyzed rearrangement to cyclic and bicyclic terpenoid allylic esters and investigate the selectivity for rearrangement of *E* allylic esters vs. *Z* allylic esters. Since such selectivity was observed, we pursued selective dienylacetate synthesis via this route. In the course of this investigation we also found palladium(II) more facile than mercury(II) catalysis of carbamates.

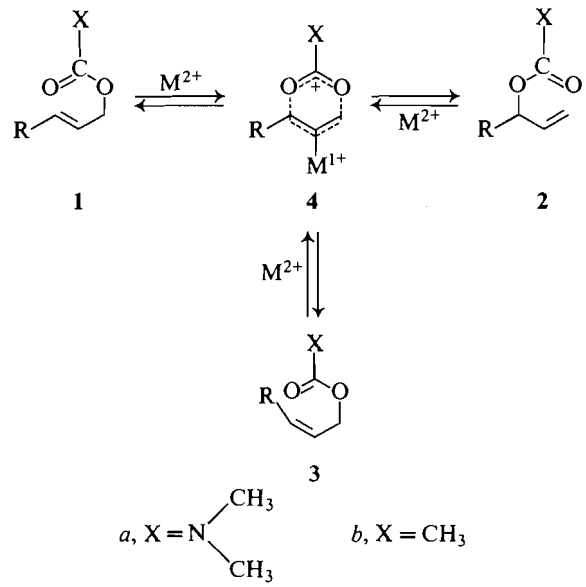

SCHEME 1

Results and discussion

Reaction of several straight chain and cyclic allylic esters with bis(acetonitrile)palladium(II)chloride gave equilibrium mixtures of allylic isomers, usually in less than ten minutes at room temperature. Table 1 gives the examples studied. Although acyclic (e.g., **7**, **8**, **10**, **11**, **12**, **28**, and **30**) and cyclic (**14**, **15**, **17**, **22**, **24**, and **25**) esters underwent facile reaction, we were unable to induce rearrangement in cyclic acetate **16** and bicyclic esters **19**–**21**. Heating of these latter reactions to reflux (THF) resulted in formation of palladium metal and gave no rearrangement. In an effort to keep the palladium catalyst in the oxidized state, we repeated the rearrangement of **19** (X = CH_3) and **20** with $PdCl_2(CH_3CN)_2$ in the presence of one equivalent (per acetate) of cupric chloride. These conditions resulted in formation of many chlorinated products. Use of $LiPdCl_3$ in acetic acid (1*c*) also gave no rearrangement of esters **19**–**21**. Overman et al. (2) noted palladium(II)-catalyzed Cope rearrangements of 1,5-dienes failed in systems substituted at both positions 2 and 5 (2). Similarly, palladium(II)-catalyzed 3,3-sigmatropic rearrangement of *S*-allylthioimidates failed when there was a substituent at position 2 of the allyl group (3).

The failure of the palladium(II) catalyst to induce rearrangement in these systems is probably due to steric requirements of the presumed intermediate (**4**). It is also probable that systems requiring formation of a tertiary carbon–palladium bond suffer metal hydride elimination more easily than those in which a secondary carbon–palladium bond is involved. That this latter condition is important can be gauged from the ease of rearrangement of **24** and **25** compared to **16**. During work using alkyl–rhodium(I) complexes to alkylate acid chlorides, Hegedus *et al.* (5) noted a greater tendency of secondary carbon–rhodium systems to suffer β hydride elimination compared to primary carbon–rhodium systems.

In an effort to circumvent the sluggishness of rearrangement of bicyclic esters **19**–**21**, we examined the effect of metal ion and ester structure on the rates of rearrangement in those systems where the rates of rearrangement were amenable to time course analysis by glpc. Thus we examined the effect of metal ion on the rate of rearrangement of carbamates **12** and **17**. The palladium(II) catalyst is superior to mercuric trifluoroacetate

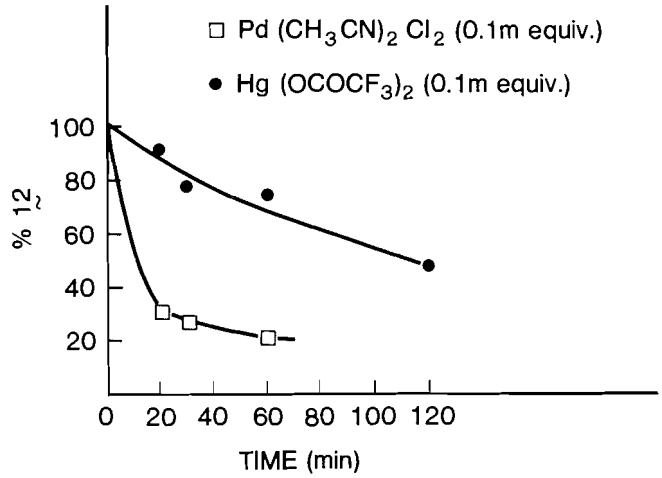

FIG. 1. Palladium(II) vs. mercury(II) catalysis of carbamate **12** in THF at 31°C.

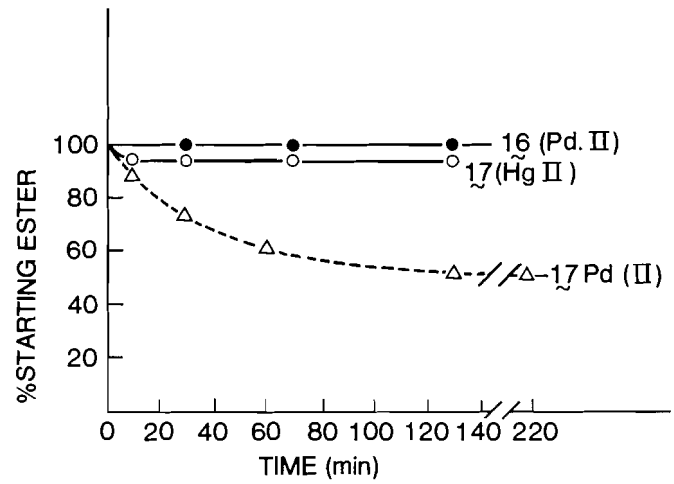

FIG. 2. Palladium(II)-catalyzed rearrangement of acetate **16** and carbamate **17** (THF, 31°C, 0.1 *M* equiv. PdII) and mercury(II)-catalyzed rearrangement of carbamate **17** (THF, 31°C, 0.1 *M* equiv. HgII).

for this rearrangement (Figs. 1 and 2). The relative rates of palladium(II)-catalyzed rearrangement of allylic carbamates, acetates, and carbonates (Figs. 2 and 3) were found to be those expected (carbamates > acetates, **17** > **16**, and acetates > carbonates, **7** > **10**; **8** > **11**) if the reaction proceeds via a cyclization-induced rearrangement involving an intermediate such as **4**. In such a mechanism the better the "X" group stabilizes the positive charge on the ester carbonyl carbon, the faster the rearrangement.

The above suggests that palladium(II)-catalyzed rearrangement of allylic carbamates offers the best chance of achieving allylic rearrangement under mild conditions in hindered systems such as **19**. We attempted rearrangement of both α and β isomers of **19** (X = $N(CH_3)_2$) using $Pd(CH_3C{\equiv}N)_2Cl_2$ without success.

The rate of palladium(II)-catalyzed rearrangement of *Z* acetate **9** is very slow compared to the *E* isomer **8** and allylic isomer **7** (Fig. 3). The formation of **9** is not observed to any significant extent during the equilibration of **7** or **8**. These observations, coupled with evidence that palladium(II)-catalyzed rearrangement of 1,5-dienes (2) proceeds via a cyclization-induced rearrangement involving an intermediate

similar to **4**, lead us to suggest that in the present process, both addition and elimination of palladium (**1**, **3**, **2**–**4**) are subject to rigid stereochemical bias. Thus, if we presume a 1,3-dioxanium ion (**4**) with a chair conformation is formed via *trans* addition of palladium(II) and the carbonyl oxygen to the carbon π-bond of a *Z* allylic ester (e.g. **9**, R^1 = H; R^2 = alkyl), unfavorable axial interactions occur for substituents at C1 (R^1, R^3). These interactions do not occur when *E* allylic esters (e.g. **8**, R^1 = alkyl, R^2 = H) react with palladium(II) to form the dioxanium intermediate. Possible mechanisms for $Z \rightarrow E$ isom-

erization are by (*a*) rotation around the C2—C3 bond of the 1,3-dioxanium intermediate or (*b*) equilibration with the terminal vinyl isomer which returns to form either *E*(fast) or *Z*(slow).[4] Comparison of the *Z*/*E* ratio (1:99) obtained in the palladium(II)-catalyzed rearrangement of **8** with the *Z*/*E* ratio (12:88) reported for mercuric(II) ion-catalyzed rearrangement of analogous allylic carbamates (1*a*) reveals either (*a*) that the palladium(II)-catalyzed reaction is significantly more selective for the *E* isomer or (*b*) that equilibrium was obtained with mercuric(II) ion but not palladium(II).

The differential rate of palladium(II)-catalyzed rearrangements of *Z* and *E* allylic acetates can be employed to generate specific dienyl acetates (1*f*). Thus, **28** smoothly rearranges to **29** to the exclusion of **32**. The allylic acetate **30** smoothly rearranges to **31** and not **33**. The mildness of these reactions, coupled with their high selectivity, makes their use in synthesis a decided advantage.

[4] Suggested by Professor Overman.

Experimental

The nmr spectra were recorded on Varian EM360 and Bruker WM400 spectrometers. Unit resolution mass spectra were obtained using a Hewlett–Packard 5985B GC/MS/DS system operating at 70 eV. High resolution mass spectra were obtained on an MS-50 by Dr. G. Eigendorf at the University of British Columbia.

Ester preparation

Alcohols (3–6 mmol) were stirred with 5 mL dry pyridine and 5 mL acetic anhydride, or molar equivalents of ethyl chlorocarbonate at room temperature for 1 (1° alcohols) to 3 (3° alcohols) days. The reactions were quenched with 10 mL H_2O and extracted with three 15-mL portions of ether. The ether was washed with 25 mL 5% HCl, 25 mL 5% $NaHCO_3$, and finally, 25 mL H_2O. The ether was dried over anhydrous $MgSO_4$, filtered, concentrated, and the products distilled *in vacuo*. In the case of acetylation of **24**, the reaction was 50% complete after 18 days. It was worked up as above and the acetate purified by preparative tlc (SiO_2; 1:9 EtOAc/hexane).

Acetates **7** (6), **8** (6, 7), **9** (7), **14** (8), **15** (9), **16** (10), **21** (11), **24** (12), and **25** (13) have been previously reported.

The α- and β-alcohol precursors of **19** were prepared by rearrangement of carene α- and β-epoxides with tri-isobutyl aluminum (14). The α-isomer has been previously reported (15), as has the alcohol precursor of **20** (16).

Carbonate **10** was formed in 49% yield, bp (0.5 Torr) 27–31°C; ^{1}Hmr ($CDCl_3$) δ: 0.87 (t, 3H), 1.27 (t, 3H), 1.17–1.56 (m, 8H), 4.17 (q, 2H), 5.4 (m, 4H). *Exact Mass* calcd. for $C_{11}H_{20}O_3$: $(M - C_4H_9)^+$, 144.0785; found (ms): 144.0793.

Carbonate **11** was formed in 55% yield, bp (0.5 Torr) 29–32°C; ^{1}Hmr ($CDCl_3$) δ: 0.88 (t, 3H), 1.35 (t, 3H), 1.25–1.42 (m, 6H), 2.16 (q, 2H), 4.20 (q, 2H), 4.78 (q, 2H), 5.62 (m, 1H), 5.84 (m, 1H). *Exact Mass* calcd. for $C_{11}H_{20}O_3$: M^+, 200.1412; found (ms) 200.1409.

Carbamate **12** was prepared (1*a*) in 94% yield, bp (0.1 Torr) 55–56°C; ^{1}Hmr ($CDCl_3$) δ: 0.95 (t, 3H), 1.3–1.7 (m, 8H), 2.95 (s, 6H), 5.1–5.5 (m, 2H), 5.6–6.3 (m, 1H). *Exact Mass* calcd. for $C_{11}H_{21}O_2N$: M^+, 199.1572; found (ms): 199.1571.

Carbamate **17** was prepared (1*a*) in 76% yield, bp (0.1 Torr) 62–63°C; ^{1}Hmr ($CDCl_3$) δ: 1.2–2.4 (m, 8H), 2.83 (s, 6H), 4.68 (m, 2H), 5.33 (m, 1H). *Exact Mass* calcd. for $C_{10}H_{17}O_2N$: M^+, 183.1260; found (ms): 183.1258.

Carbamate **19** (α isomer) was prepared (1*a*) in 66% yield, bp (0.1 Torr) 72–77°C; ^{1}Hmr ($CDCl_3$) δ: 0.97 (s, 3H), 1.08 (s, 3H), 0.8–2.7 (m, 6H), 3.00 (s, 6H), 4.93 (m, 2H), 5.11 (t, 1H). *Exact Mass* calcd. for $C_{13}H_{21}O_2N$: M^+, 223.1572; found (ms): 223.1564.

Carbamate **19** (β isomer) was prepared (1*a*) in 20% yield, bp (0.05 Torr) 74–78°C; ^{1}Hmr ($CDCl_3$) δ: 0.90 (s, 6H), 0.5–2.7 (m, 6H), 3.0 (s, 6H), 4.63 (m, 2H), 4.93 (m, 1H). *Exact Mass* calcd. for $C_{13}H_{21}O_2N$: M^+, 223.1572; found (ms): 223.1595.

The isomeric purity of each ester was verified by glass capillary glpc on a 15 m × 0.21 mm id methyl silicone column; in each instance (except **24**) the esters were >95% isomerically pure. Acetate **24** rearranged slowly to **25** on standing. Its isomeric purity was ≈80% for the reactions reported in Table 1.

General procedure for bis(acetonitrile)palladium(II)chloride rearrangements

(a) *Preparative scale*

Solutions (0.2–0.3 *M*) of ester in dry THF under argon were treated with 0.03–0.1 molar equivalents of $Pd(CH_3CN)_2Cl_2$. The reactions were stirred for 30 min to several days as indicated in Table 1, concentrated to ≈1/5 the original volume under a stream of nitrogen, and filtered through a short column of silica using an ether wash. The filtrate was concentrated (N_2) and subjected to vacuum distillation. Isomer ratios changed very little (<5%) before and after distillation. The isomer ratios and yields reported in Table 1 were determined on distilled product.

Rearrangement of 0.2 g **12** by $Pd(CH_3CN)_2Cl_2$ gave 0.198 g distilled product (bp (0.1 Torr) 54–62°C) which was a 1:2 mixture of **12** and (*E*)-2-octen-1-yl *N*,*N*-dimethylcarbamate (**13**). The two carbamates were separated by preparative tlc on Silica Gel G (0.5 mm × 20 cm × 20 cm plates) containing 20% $AgNO_3$ using hexane/ethyl acetate, 95:5, as the development solvent (development four times). Carbamate **12** was isolated from the R_f 0.21–0.30 band and **13** from the R_f 0.36–0.52 band by elution of each band with ether. Carbamate **13** had bp (0.1 Torr) 56–60°C; ^{1}Hmr ($CDCl_3$) δ: 0.92 (t, 3H), 1.33 (m, 6H), 2.1 (m, 2H), 2.93 (s, 6H), 4.53 (d, 2H), 5.66 (octet, 2H). *Exact Mass* calcd. for $C_{11}H_{21}O_2N$: M^+, 199.1572; found (ms): 199.1577.

Rearrangement of 0.2 g carbamate **17** with $Pd(CH_3C{\equiv}N)_2Cl_2$ gave 0.164 g distilled product (bp (0.1 Torr) 59–60°C) which was a 57:42 mixture of **17** and 1-cyclohexene-1-methanol *N*,*N*-dimethylcarbamate (**18**) respectively. The two carbamates were separated by preparative tlc on Silica Gel G with 20% $AgNO_3$ using hexane/ethyl acetate, 90:10, as the development solvent (double development). Carbamate **17** was recovered from the R_f 0.17–0.29 band and the allylic isomer from the R_f 0.32–0.45 band by elution of each band with ether. The latter carbamate gave bp (0.1 Torr) 54–58°C; ^{1}Hmr ($CDCl_3$) δ: 1.4–2.2 (m, 8H), 2.98 (s, 6H), 4.48 (s, 2H), 5.73 (m, 1H). *Exact Mass* calcd. for $C_{10}H_{17}O_2N$: M^+, 183.1260; found (ms): 183.1264.

(b) *Analytical scale*

The kinetic data in Figs. 1–3 were obtained on 0.1 *M* solutions of esters in dry THF (≈5 mL). Solutions were treated with stock solutions of dodecane and, subsequently, either 0.1 *M* $Pd(CH_3C{\equiv}N)_2Cl_2$ or $Hg(OCOCF_3)_2$ in dry THF. (The entire addition operation was performed under argon.) Each reaction was kept at 31 ± 1°C in a water bath (under argon). Samples were withdrawn and passed through short alumina columns (≈1 cm × 0.75 cm diameter) which were washed with 2 mL ether. The filtrates were analyzed by glpc (methyl silicone 30 m × 0.21 mm id fused silica capillary column, HP5880A glpc unit.) Electronically-integrated peak areas were corrected for relative responses determined for dodecane–ester solutions prepared independently and passed through alumina prior to analysis.

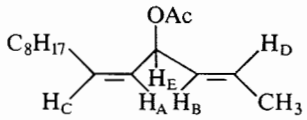
Preparation of (E)-*tetradec-2-en-5-yn-4-ol,* **26**

Dec-1-ynyl lithium (dec-1-yne, 6.9 g, 0.05 mol; 20.8 mL, 2.4 *M* butyl lithium) in 100 mL of THF was treated with freshly-distilled crotonaldehyde (3.85 g, 0.05 mol) at 0° to 15°C (17). The reaction was warmed over 30 min to room temperature and worked up as described for the preparation of tridec-1-en-4-yn-3-ol below. Distillation gave 8.5 g, 82% yield, bp (0.15 Torr) 94–95°C; ^{1}Hmr ($CDCl_3$) δ: 0.87 (t, 3H), 1.28 (m, 12H), 1.7 (m, 12H), 1.71 (m, 2H), 1.71 (d, 3H), 2.2 (m, 1H), 4.77 (m, 1H), 5.5–6.0 (m, 2H).

Acetylation gave 92% (*E*)-tetradec-2-en-5-yn-4-yl acetate, **26**, bp (0.1 Torr) 103–104°C; ^{1}Hmr ($CDCl_3$) δ: 0.88 (t, 3H), 1.27 (m, 12H), 1.72 (d, 3H), 2.03 (s, 3H), 2.20 (m, 2H), 5.30–6.30 (m, 3H).

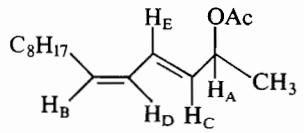
Preparation of (E, Z)-*tetradec-2,5-dien-4-yl acetate,* **28**

To 1 g of $Ni(OAc)_2 \cdot 4H_2O$ in 50 mL ethanol under H_2 purge was added 5 mL of a solution prepared by filtering the solution from 1 g $NaBH_4$ in 24 mL ethanol and 1.25 mL 2 *N* NaOH (18). After H_2 evolution had ceased (≈15–20 min), 0.7 mL ethylenediamine was added, followed by 0.354 g (1.7 mmol) of (*E*)-tetradec-2-en-5-yl-4-ol. After 1.5 h the reaction was stopped by addition of 75 mL 20% NaCl and extracted into three 75-mL portions of ether. The ether was dried over anhydrous $MgSO_4$, filtered, concentrated *in vacuo*, and distilled (bulb-to-bulb), bp (0.2 Torr) 85–89°C, to give 0.28 g, 78% yield; ^{1}Hmr ($CDCl_3$) δ: 0.87 (t, 3H), 1.27 (br s, 12H), 1.50 (d, 3H), 1.71 (s, 1H, exch.), 2.07 (m, 2H), 4.90 (m, 1H), 5.5 (m, 4H). Acetylation gave **28**, 97%, bp (0.2 Torr) 106–107°C; ^{1}Hmr ($CDCl_3$, 400 MHz) δ: 0.86 (t, 3H, CH_3), 1.24 (m, 12H, CH_2), 1.69 (d, 3H, J = 7.2 Hz, CH_3—C=), 2.02 (s, 3H, Ac), 2.12 (br q, 2H, $J \simeq 7 \pm 1$ Hz, CH_2—C=), 5.36 (q, 1H, J = 8, 12 Hz, vinyl, A), 5.47 (q of d, 1H, J = 2.8, 16 Hz, vinyl, B), 5.55 (d of t, 1H, J = 6.4, 6.4, 12 Hz, vinyl, C), 5.73 (sextet, 1H, vinyl, D), 5.94 (br q, 1H, $J \cong 6, 8$ Hz, C*H*—O). *Exact Mass* calcd. for $C_{16}H_{28}O_2$: M^+, 252.2089; found (ms): 252.2090.



Rearrangement of (E,Z)-*tetradeca-2,5-dien-4-yl acetate,* ***28***

A 0.2 *M* solution of **28** in dry THF was treated with 0.8 mmol equiv. $Pd(CH_3C{\equiv}N)_2Cl_2$ for 2 h at room temperature. The usual work-up gave 91% distilled product (bp (0.1 Torr) 72–76°C) which gave one major (>95% by glpc) acetate (**29**), ^{1}Hmr ($CDCl_3$, 400 MHz) δ: 0.84 (t, 3H, CH_3), 1.23 (m, 12H, CH_2), 1.29 (d, 3H, J = 7.2 Hz, O—CH—CH_3), 2.00 (s, 3H, Ac), 2.13 (q, 2H, J = 7 Hz, CH_2—C═), 5.4 (m, 2H, vinyl, B, C*H*O), 5.58 (q, 1H, J = 7, 16 Hz, vinyl, C), 5.90 (5, 1H, J = 11.6 Hz, vinyl, D), 6.48 (q, 1H, J = 11.6, 16 Hz, vinyl, E). *Exact Mass* calcd. for $C_{16}H_{28}O_2$: M^+, 252.2089; found (ms): 252.2085.



Preparation of tridec-1-en-4-yn-3-yl acetate, ***27***

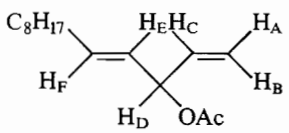
Dec-1-ynyl lithium (6.9 g; 0.05 *M* dec-1-yne, 20.8 mL 2.4 *M* butyl lithium) in 100 mL THF was treated at 0° to −15°C with 2.8 g (0.05 mol) freshly-distilled acrolein in 10 mL dry THF. The reaction was stirred 30 min at 0°C, then warmed to room temperature (17). The reaction was quenched with 50 mL of aqueous NH_4Cl and extracted with three 50-mL portions of ether. The ether was dried over anhydrous $MgSO_4$, filtered, concentrated *in vacuo*, and the concentrate distilled to yield 8.05 g (83%) tridec-1-en-4-yl-3-ol, bp (0.2 Torr) 88–90°C; ^{1}Hmr ($CDCl_3$) δ: 0.73 (t, 3H), 1.30 (m, 12H), 2.23 (m, 3H), 4.9 (m, 1H), 5.23 (d of t, 1H), 5.57 (m, 1H), 6.05 (d of q, 1H).

Acetylation gave tridec-1-en-4-yn-3-yl acetate (**27**) in 84% yield, bp (0.1 Torr) 90–91°C; ^{1}Hmr ($CDCl_3$) δ: 0.72 (t, 3H), 1.27 (m, 12H), 2.08 (s, 3H), 2.22 (m, 2H), 5.1–6.0 (m, 4H). *Exact Mass* calcd. for $C_{15}H_{24}O_2$: M^+, 236.1776; found (ms): 236.1778.

Preparation of (E)-*trideca-1,4-dien-3-yl acetate,* ***30***

Tridec-1-en-4-yn-3-ol (1.5 g, 7.7 mmol) was treated with $LiAlH_4$ (0.58 g, 15 mmol) in ether/THF at reflux for 22 h (17). The reaction was quenched by addition of ethyl acetate and worked up by sequential addition of 50 mL 20% NaOH, extraction with three 50-mL portions of ether, drying of the ether over anhydrous Na_2CO_3, filtration, concentration *in vacuo*, and vacuum distillation (bp (0.05 Torr) 78–82°C) to yield 1.36 g (90%) (*E*)-trideca-1,4-dien-3-ol; ^{1}Hmr ($CDCl_3$) δ: 0.87 (t, 3H), 1.25 (m, 12H), 2.00 (m, 2H), 4.52 (5, 1H), 4.70 (s, 1H), 5.0–6.0 (m, 5H); ms (rel. int.): 178(4%), 83(100%), 79(29%), 70(51%), 55(38%).

Acetylation gave (*E*)-trideca-1,4-dien-3-yl acetate (**30**) in 94% yield, bp (0.05 Torr) 75–78°C; ^{1}Hmr ($CDCl_3$) δ: 0.87 (t, 3H), 1.2–2.0 (m, 14H), 2.02 (s, 3H), 5.05 (d of t, J = 10, 1.5, 1.5 Hz, H_A), 5.14 (d of t, J = 17, 1.5, 1.5 Hz, H_B), 5.34 (dd, J = 15, 7 Hz, H_E), 5.51 (br t, $J \approx 7$ Hz, H_D), 5.65 (d of t, J = 15, 7, 7 Hz, H_F), 5.72 (m, J = 17, 10, 6 Hz, H_C). *Exact Mass* calcd. for $C_{15}H_{26}O_2$: M^+, 238.1933; found (ms): 238.1935.



Rearrangement of (E)-*trideca-1,4-dien-3-yl acetate,* ***30***

A 0.2 *M* solution of **30** in dry THF was treated with 0.08 mol equiv. $Pd(CH_3CN)_2Cl_2$ for 2 h at room temperature. The usual work-up gave 96% **31**, bp (0.05 Torr) 65–70°C (bulb-to-bulb) (>97% one isomer by glpc); ^{1}Hmr ($CDCl_3$) δ: 0.87 (t, 3H), 1.25–1.67 (m, 14H), 2.03 (s, 3H), 5.07 (dd, J = 10, 2 Hz, H_A), 5.19 (dd, J = 15, 2 Hz, H_B), 5.22 (g, J = 6.8 Hz, H_F), 5.57 (dd, J = 15, 6.8 Hz, H_E); 6.21 (m, H_CH_D). *Exact Mass* calcd. for $C_{15}H_{26}O_2$: M^+, 238.1933; found (ms): 238.1933.

The halogenation of β-ketosulfones such as α-methylsulfonylacetophenone (**1**) and benzenesulfonylacetone (**10**) can be effected with sulfuryl chloride or pyridinium bromide perbromide. Regiochemical control can be achieved by control of stoichiometry and/or the reaction conditions. Detailed ^1H and ^{13}C nmr, and mass spectra are recorded for a series of halogenated β-ketosulfones, together with structures by X-ray crystallography for **1**, 2-chloro-2-methylsulfonyl-1-phenylethanone (**2**), chloromethyl methyl sulfone (**4**), and α-chloroacetophenone (**21**). Results from these studies are used to suggest a reason for the difficulty associated with substitution reactions of α-halosulfones.

J. STUART GROSSERT, PRAMOD K. DUBEY, GLEN H. GILL, T. STANLEY CAMERON et PATRICK A. GARDNER. Can. J. Chem. **62**, 798 (1984).

L'halogénation des β-cétosulfones comme l'α-méthylsulfonylacétophénone (**1**) et la benzènsulfonylacétone (**10**) peut être effectuée avec le chlorure de sulfuryle ou le perbromure du bromure de pyridinium. On peut exercer un contrôle régiochimique en controlant la stoichiométrie et/ou les conditions de la réaction. On a enregistré des spectres détaillés de la rmn du proton et du carbone-13 ainsi que les spectres de masse d'une série de β-cétosulfones; de plus, faisant appel à la diffraction des rayons-X, on a déterminé les structures de **1**, de la chloro-2 méthylsulfonyl-2 phényléthanone (**2**), de la chlorométhyl méthyl sulfone (**4**) et de l'α-chloroacétophénone (**21**). On utilise les résultats de ces études pour suggérer une raison pour la difficulté associée aux réactions de substitutions des α-halosulfones.

Introduction

The chemistry of β-ketosulfones has not been explored in detail and much of the reported chemistry involves the incorporation of the functionality into directed alkylation sequences from which the sulfone is later discarded (1–4). Even less has been reported on derivatives such as α-halo-β-ketosulfones (5–7). A systematic study of these functionalities could be useful; for example, it could provide information about halogenation of ketones with an adjacent sulfonyl group which would complement traditional studies on halogenation reactions of ketones with an adjacent electron-withdrawing group (8). However, the potential of these functionalities as precursors of α-sulfenylated-β-ketosulfones was of particular interest to us.

In this paper we report on the controlled halogenation of two β-ketosulfones together with the alkaline cleavage reactions of the resulting α-halo-β-ketosulfones. The range of polyfunctional sulfones obtained in this study forms a useful series in which to study spectroscopic properties and we have, in addition, determined crystal structures of certain selected compounds by X-ray diffraction techniques. In subsequent papers we will describe reactions of α-halo-β-ketosulfones with nucleophiles having varying degrees of hardness on the HSAB scale,[3] and report on direct sulfenylation reactions to give α-sulfenylated-β-ketosulfones (9).

Results and discussion

Preparations and reactions

The present study has focussed on the chemistry of two known, structurally isomeric β-ketosulfones, **1** and **10**. These were chosen partly for their convenience of preparation, but also to represent the two possible extremes in structure of β-ketosulfones, namely a ketone with α-hydrogens only between the ketone and sulfonyl groups (**1**) and a ketone with hydrogens both in such a position and also in a methyl group α′ to a ketone (**10**).

Monohalogenation of the methylene in **1** was readily achieved using either sulfuryl chloride or pyridinium bromide perbromide, in either neutral or acidic reaction media. The products, provided stoichiometry was controlled, were either the known monochloro compound, **2**, or the previously unreported monobromo compound, **3**. Compound **2** has been prepared previously by Bohlmann and Haffer, using a different route (7). Both **2** and **3** possess a relatively strongly-acidic

5 X = Br

methine proton that is easily abstracted by triethylamine in deuterochloroform solution. Deuterium oxide exchange of these methine protons in a basic solution was extremely rapid but did not occur in deuterochloroform containing ca. 20% trifluoroacetic acid, even after 48 hours at room temperature. Careful examination by ^{13}C nmr yielded no detectable enol formation in an acidic medium and, furthermore, infrared spectroscopy showed no sign of enolization in either chloroform solution or a potassium bromide pellet, the two spectra being

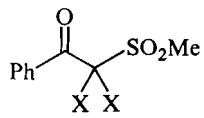
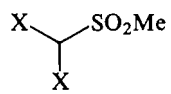
quite similar. Similar deuterium oxide exchange of the methylene protons in **1** was observed. Halogenation of ketones in neutral or acidic media proceeds by way of reaction between the enol and a source of positive halogen (8, 10). Hence when **1** is halogenated in this manner, enolization of **2** or **3** does not occur, and further halogenation is thus not possible.

We have examined reactions of **2** and **3** involving attack by hydroxide or alkoxides, and found that in both cases reactions are exclusively at the carbonyl with subsequent displacement of the halosulfonyl carbon. This reaction has potential as a synthesis of halomethylsulfones (RSO_2CH_2X or RSO_2CHX_2, X = Cl or Br), although the dibromomethyl sulfones tended to be readily reduced to monobromoethyl compounds. Thus, for example, aqueous alkaline hydrolysis of **2** gave the known (11) chloromethyl methyl sulfone (**4**) and benzoic acid, whereas ethanolic sodium ethoxide alcoholysis gave **4** and ethyl benzoate. Similar reactions with **3** gave **5** and benzoic acid or ethyl benzoate.

Dichlorination of **1** was accomplished readily with sulfuryl chloride in a basic reaction medium to give **6** which was accessible also by similar chlorination of **2**. Saponification of **6** gave **7** and benzoic acid only, no traces of **4** being detectable. Dibromination of **1** gave the expected dibromo-β-ketosulfone (**8**)



6 X = Cl
8 X = Br



7 X = Cl
9 X = Br

together with a small amount of the dibromosulfone **9**. This small amount of **9** was most likely formed by hydrolysis of **8** during work-up of the reaction. Aqueous alkaline treatment of the reaction products resulted in both hydrolysis and reduction, with **5** being the only isolable sulfone product; it is known that α,α-dibromosulfones are readily reduced (12). We have found that compounds such as **4**, **5**, and dimethyl sulfone have appreciable water solubility, which complicated their isolation in high yields during work-up of reactions from the saponification process.

Halogenation of **1**, under the conditions we have employed, was possible only at a single center. By contrast, halogenation of **10** presented a more interesting problem for regiocontrol of reaction. Bromination of **10** with one mole equivalent of pyridinium bromide perbromide in dichloromethane – acetic acid led to the formation, in high yield, of the previously unreported, crystalline α′ monobromo compound, **11**. By changing the solvent to pyridine–dichloromethane, either compounds **12** (α-monobromo) or **14** (α,α-dibromo) could be obtained, depending on the reaction stoichiometry. Spectral characterization of these was followed by cold aqueous alkaline hydrolysis to the respective brominated phenyl sulfones, $PhSO_2CH_2Br$ (**13**) and **15**, although **14** always yielded a mixture of **15** and its reduction product **13**. It should be noted that both the tribromo- and triiodomethyl phenyl sulfones have been reported (13), apparently as stable products, from haloform reactions on **10**.

Chlorination of **10** with sulfuryl chloride has been reported previously (14) as yielding α-chloro-α-phenylsulfonylacetone (**16**). We have been unable to obtain **16** in a pure form; the best chlorination conditions involved chlorination with sulfuryl chloride in acetic acid – methylene chloride and the products were shown by nmr spectroscopy to be **16**, always contaminated with about 20% of its regioisomer, **17**. Chlorination of **10** in the presence of triethylamine gave the unstable dichlorocompound **18**, which could be saponified readily to dichloromethyl phenyl sulfone (**19**).

These reactions demonstrate clearly that the sulfonyl group exerts a powerful directing effect on the course of β-ketosulfone reactions. The regiochemistry of halogenation parallels that of α-haloketones (8). In addition, the α-halo-β-ketosulfones show a strongly electrophilic carbonyl group and the major reaction that we have described is the alkoxide-induced cleavage of the C_α—CO bond, undoubtedly due to the stabilization of $^-$:CHCl.SO_2R which is a good leaving group. This trend is evident even in **1**, which is slowly hydrolyzed in alkaline solution. It has been shown previously (15) that α-halosulfones are reduced by attack of alkoxide at halogen. In all the cases described here, except **14**, the α-halo-β-ketosulfones were attacked at the carbonyl rather than at halogen and were cleaved, but were not reduced. Precise delineation of the relative activation energies for these competing reactions remains to be made.

Mass spectra

Although some of the compounds reported in this paper have been described previously, they have invariably not been fully characterized by modern spectroscopic techniques. Exceptions are the β-ketosulfone (**1**) and its monochloro derivative (**2**), mass spectra for which have been reported by Bohlmann and Haffer (7). The fragmentation patterns of compounds **4**, **5**, **7**, and **9** are all similar and are in agreement with the fragmentations of simple sulfones (16).

The mass spectra of **11** and **12** are similar to those of **1**–**3** in that predominant fragmentations occur either by McLafferty rearrangement or by α-cleavage, in this latter case, however, to $PhSO_2]^+$ as compared to $PhCO]^+$ for **1**–**3**, indicative of the controlling influence exerted by the phenyl group. These fragmentations are outlined in Scheme 1. It is interesting to note that ions of *m/z* 94 were not observed in these spectra, which indicates that the rearrangement processes operating in simple phenylsulfonyl sulfones (16) are not important in these compounds.

Nuclear magnetic resonance spectra

The ^{1}H nmr spectra of these compounds were all quite routine, especially in that the observed chemical shifts all fall within the ranges normally expected. The methylsulfonyl compounds **1**–**3** showed 4-bond, proton–proton couplings of less than 1 Hz across the sulfonyl group. This has been observed previously in similar cases (17, 18). These couplings are appar-

ently dependent on the oxidation level of the sulfur atom, as we have not observed them to be present across sulfenyl sulfur atoms (19). Also of note is the remarkably precise chemical shift coincidence of the two methylene sets in **17**, although this is an agreement with a Strehlow-type calculation of chemical shifts (20) using a value of $S(\delta) = 2.0$ for a $PhSO_2$ group at position 2.

Whenever possible, ^{13}C nmr spectra of the compounds described were measured also, although in some cases compounds were not sufficiently stable to permit accumulation of an adequate number of transients. Parameters from these spectra, which were recorded under conditions described previously (19), are given in Table 1. The chemical shifts of carbons in all the compounds studied fall within acceptable ranges but several observations are noteworthy.

The series provides for interesting comparisons of γ-effects in acyclic compounds, and these are highlighted in Table 2. The values observed for Δδ are intermediate between those reported (21) for acyclic and for rigid cyclic compounds. For example, the motionally averaged γ-effect for an acyclic chlorine is a 4-ppm upfield shift (21), whereas γ-*gauche* effects for chlorine range from −6.88 ppm[4] on methylene carbons in conformationally rigid cyclohexanes (21) to −5.72 ppm for the axial methyl and −3.45 ppm for the equatorial methyl in

[4] The negative sign denotes an upfield shift.

*With respect to the chemical shift of the methyl carbon in **1**.

2-chloro-1,1-dimethylcyclohexane (22). These authors caution that whereas distinctions between *gauche* and *anti* geometries can be made using γ-shielding effects, there is no general, precise correlation between the γ-effect and dihedral angles. From the magnitude of the effects exhibited by **2** and **4**, it is likely that the methyls and chlorines are largely in a *gauche* orientation, which are the conformations adopted by **2** and **4** in the solid state (*vide infra*). Similar conclusions concerning both the solid- and liquid-state conformations of sulfones with polar groups in the α-position have been reached by Engberts, Exner, and Vos (23). Study of a model of **2** leads to the conclusion that the solid-state conformation is likely to be adopted by the molecule (at least in solutions of low or moderate polarity) due to the considerable steric demands by the benzoyl and sulfonyl groups. One might then expect the γ-effect in **6** to parallel that in **7**, yet such is not the case, indicating again (22) that the origins of the effect do not lend themselves to simple explanations. Finally, it is reasonable to assume a smaller steric demand by a carbonyl group versus a sulfonyl group, with a resulting greater freedom of rotation likely in **16** versus **2**; the γ-effect in **16** is 1.68 ppm less than that in **2**.

Also of interest in this series of compounds are the chemical shifts of the carbonyl carbons. Using acetophenone as a base model for **1**, we have observed an upfield shift of −9.0 ppm due to the replacement of a hydrogen atom by a methylsulfonyl group.[5] The carbonyl absorption in α-chloroacetophenone (**21**) is at δ 190.9 (24), which therefore shows an upfield shift of −7.2 ppm due to the replacement of a hydrogen by a chlorine. As seen in Table 1, further halogenation (compounds **2**, **3**, and **6**) results in further upfield shifting of the carbonyl absorption, albeit not in a linear manner.

It was possible in a number of cases to record the ^{13}C nmr spectra under conditions of gated decoupling. From these spectra, values for $^1J_{CH}$ were measured and are recorded in Table 1. The values obtained are in general agreement with trends recorded in the literature (ref. 20, pp. 375–376 and references therein). We had previously reported sizeable 3-bond carbon–proton couplings across sulfenyl sulfur (19). Such couplings have apparently not been reported across sulfonyl groups and we have not observed them previously. However, by careful recording of spectra and data processing using the spectrometer computer, we were able to observe small, 3-bond proton–carbon couplings for both the methyl and methylene carbons in **4**, and for the methyl carbon only in **3**. The observation of these long-range couplings, the origins of which are complex (21), is of interest but their value is limited by their small magnitude and the consequent difficulties of observing them.

Structural studies

Only a few structures of acyclic sulfones with a polar group in the α position have been determined (23, 25–28). Given this fact and the complexities of nucleophilic displacement reactions in these compounds (*vide infra*), we wished to determine structural parameters for some of the compounds made available by this study. In particular, a comparison of solid-state and solution structural parameters for **2** was thought to be worth obtaining, with a long-term view of potential correlations between such sulfone structures and their reactivity.

Structures were determined for $PhCOCH_2SO_2Me$ (**1**), for its α-chlorinated derivative, **2**, and for the hydrolysis product of **2**, CH_2ClSO_2Me (**4**). The structure of α-chloroacetophenone ($PhCOCH_2Cl$) (**21**) was also included in order to compare bond distances, bond angles, and torsional angles involving the benzoyl group when the sulfonyl group is not present. Preparation of the crystals is described under Experimental.[6] Crystal data of the four compounds are presented in Table 3, dimensions of the molecules are given in Table 4; pictures of the molecules are shown in Figs. 1 to 4, selected torsional angles are given in Fig. 5, and the packing of the molecules in their unit cells is given in Figs. 6–9.[7]

A CAD-4 four-circle diffractometer with an $\omega/2\theta$ scan was used for all crystals to establish unit-cell dimensions and to collect intensities. Since α-chloroacetophenone proved to be unstable at room temperature, intensities for this crystal alone were collected at −140°C. Reflection data were reduced by routine procedures which are described in ref. 29. Lorenz, polarization, but not absorption corrections were applied; two reflections were omitted from the data for compound **4** because of extinction. Scattering factors were taken from ref. 30.

Partial structures were determined from the *E*-maps in each case, using direct centrosymmetric methods for compounds **2** and **4** and by applying the multisolution tangent formula for compounds **1** and **21**. Other atoms were found on subsequent Fourier maps. Full matrix least-squares refinements ($\omega\Delta F^2$ = min) were carred out with anisotropic temperature factors on the non-hydrogen atoms and isotropic temperature factors on the hydrogens. The SHELX 76 system was used for all calculations (31).

The structure of α-chloroacetophenone (**21**) was reported in 1966 (32) based on 327 visually estimated intensities. A poor *R* value of 0.16 prompted us to repeat the structure determination at −140°C. This gave similar cell parameters and the same space group but a different arrangement of the molecules in the unit cell. We were unable to confirm the structure as reported in 1966 since adequate reflection data could not be obtained at room temperature.

Molecular geometries

The principal bond distances, bond angles, and torsional

[5] We have measured δCO in acetophenone as 198.1 ppm.

[6] A commercial sample of **21** (Aldrich) was recrystallized to constant mp (54–55°C).

[7] A complete list of atomic parameters, distances, angles, and torsional angles (Table 4), a list of structure factors (Tables 5–8), and unit cell packing diagrams (Figs. 6–9) are available from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

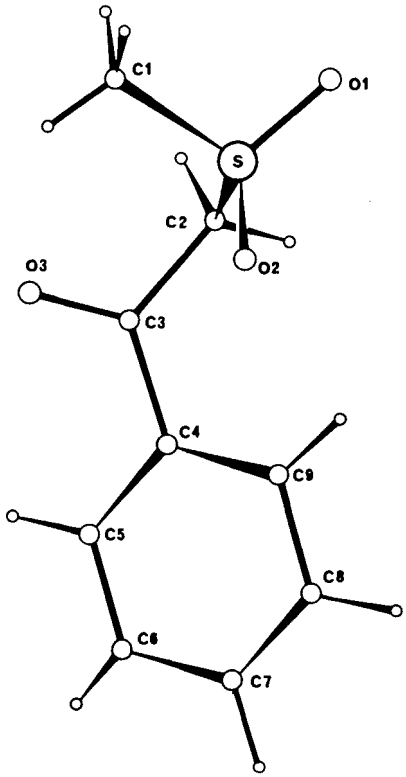

FIG. 1. The crystal structure of $PhCO.CH_2SO_2CH_3$, (**1**).

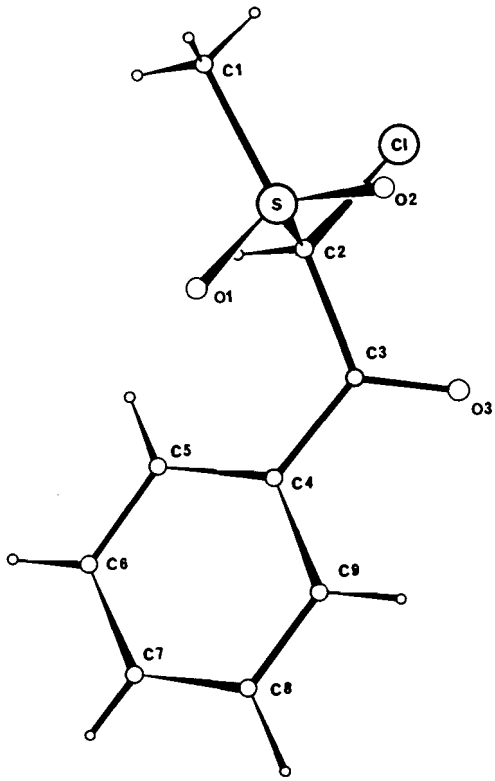

FIG. 2. The crystal structure of $PhCO.CHCl.SO_2CH_3$, (**2**).

angles are listed in Table 4 and presented graphically in Fig. 5. The main features can be summarized as follows.

The S—C_α distances in compounds **1**, **2**, and **4** are 1.787(4), 1.815(4), and 1.781(9) Å. The lengthening of this bond in **2** is a consequence of the substitution of hydrogen by the electron-withdrawing chlorine, which also causes the C_α—C_β bond to be longer in **2** than in **1** (1.525(5), **1**; 1.553(6) Å, **2**). The S—C_α bond in **4** should be shorter than that of **2**, since **4** lacks the benzoyl group, but it should be longer than the S—C bond in dimethyl sulfone (**20**) (1.774(3) Å) (26); the S—C_α distance observed in **4** (1.781(9) Å) falls within this range but it could not be determined very accurately. The C—Cl distances in **2**, **4**, and **21**, 1.754(4), 1.761(8), and 1.70(3) respectively, are not significantly different and compare with those in vinyl chloride (1.728(7) Å) and methyl chloride (1.784(3) Å) (33), both values having been determined by electron diffraction techniques. The S—Me distances in **1**, **2**, and **4** (1.759(4), 1.760(5), 1.765(9) Å) are equivalent and similar to a previously reported compound (34), yet possibly significantly shorter than those observed in dimethyl sulfone (1.774(3) Å) (26). The structural results for **21** gave a clear picture of the molecular conformation in the crystalline state (Fig. 5), but the molecular dimensions could not be determined sufficiently accurately to merit detailed comment.

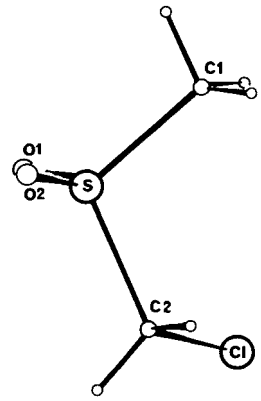

FIG. 3. The crystal structure of $ClCH_2SO_2CH_3$, (**4**).

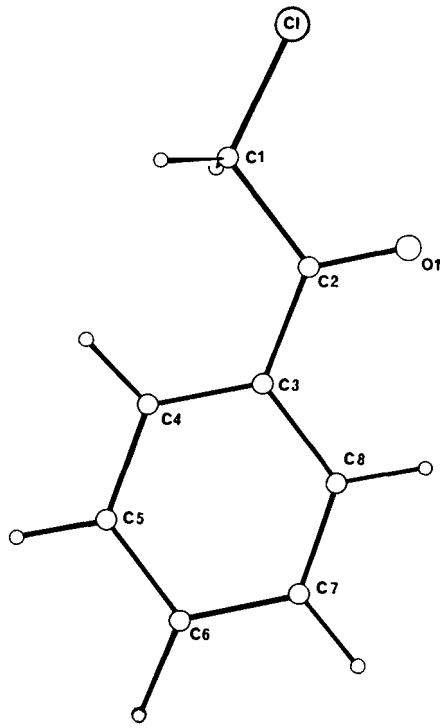

FIG. 4. The crystal structure of $PhCO.CH_2Cl$, (**21**).

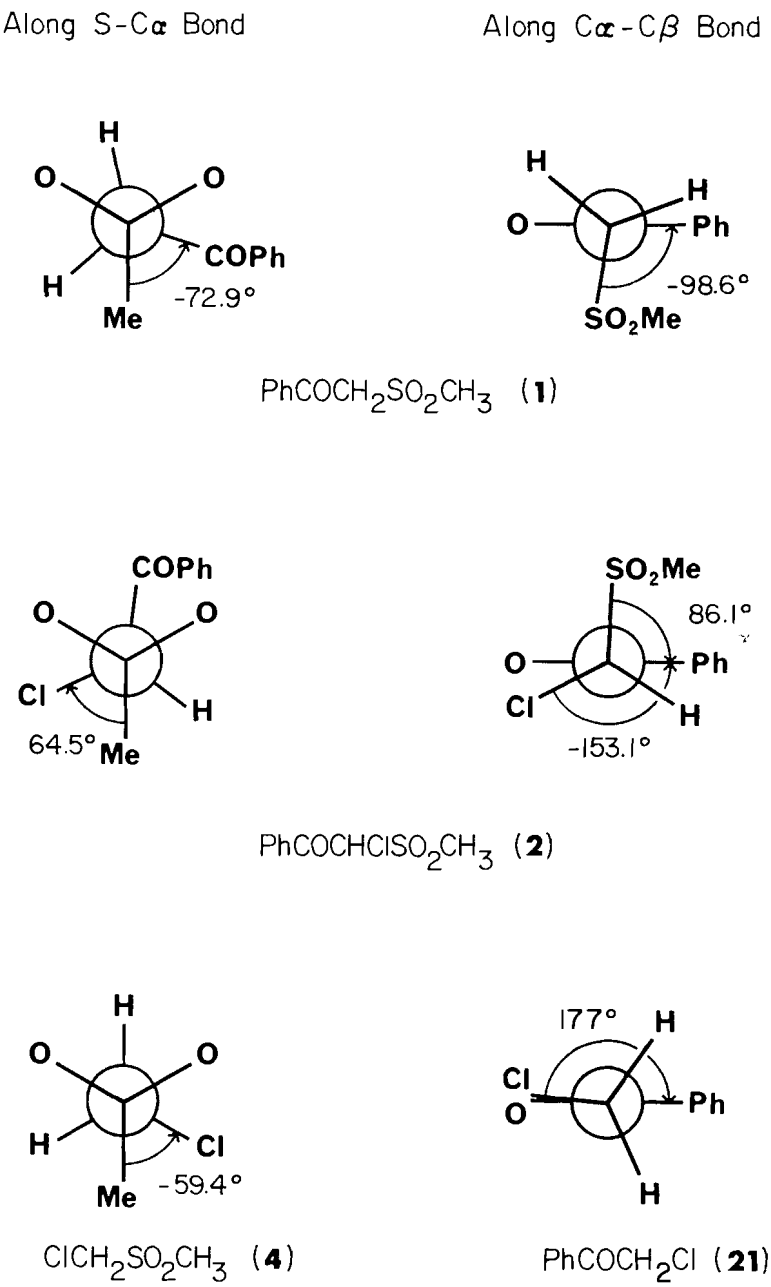

FIG. 5. Torsional angles for $PhCOCH_2SO_2CH_3$ (**1**), $PhCOCHClSO_2CH_3$ (**2**), $ClCH_2SO_2CH_3$ (**4**) and $PhCOCH_2Cl$ (**21**).

The two S—O distances in a sulfone are normally equivalent (23, 26–28, 34, 35), the mean of some reported values being 1.439(14) Å, (26). The S—O distances in **1**, **2**, and **4** range from 1.425(3) to 1.445(8) with a mean of 1.433(8). The two S—O distances in **1** are significantly different, although the causes of this are obscure.

The electron-withdrawing property of the chlorine atom also shows in a slight closure of the $S—C_\alpha—C_\beta$ angle from 112.3(3)° in **1** to 109.2(3)° in **2**; the same effect is less marked at the $C_\alpha—C_\beta—Ph$ angle which decreases slightly from 119.9(3) to 118.0(4)°. Loss of the benzoyl group from the α-chloro-β-ketosulfone (**2**) increases the angle between chlorine and sulfur at the α-carbon: the $S—C_\alpha—Cl$ angle in **4** was 111.6(5)° as compared to 108.8(2)° in **2**. Electron repulsion also explains an apparent widening of the $Cl—C_\alpha—C_\beta$ angle of 112.3(3)° when the methylsulfonyl group in **2** is replaced by a hydrogen, although the 114(2)° figure for α-chloroacetophenone (**21**) is not very precise.

The compounds **1**, **2**, **4** comprise a series that permits useful structural comparisons to be made between sulfonyl groups with polar substituents at an α-carbon. These results can then be compared with those from the carbonyl compound, **21**. Two α-bromosulfones have been reported as having a bromine *gauche* to both sulfonyl oxygens (25). However, sulfones with a polar group at C_α usually adopt a conformation in the crystalline state in which the polar group is *gauche* to only one of the sulfonyl oxygens (23, 27, 28, 34). Dipole moment evidence by Exner and Engberts suggests that this same conformation is predominant in solution (the *gauche* effect) although in such molecules the causes of this phenomenon are obviously more complex than in simple molecules like 1,2-dihaloethanes or dialkyl disulfides (23). It was thus gratifying to find that the methyl group and chlorine in both **2** and **4** were in a *gauche* orientation about the $S—C_\alpha$ bond (Fig. 5). This same con-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

formation was apparently predominant in solutions of these molecules (*vide supra*).

A more subtle conformational effect was observed by examining the S—C_α—C_β—Ph torsional angles[7] in **1** and **2** and comparing these with the Cl—C—C—Ph angle in **21** (Fig. 5). It was found that the chloro and carbonyl groups in **21** were almost synperiplanar; such conformations of α-haloketones have been studied by infrared spectroscopy (36). Presumably this synperiplanar arrangement of the chloro and carbonyl groups derives from the fact that the electron density in the carbonyl group is rather different from that in a polar group involving only σ bonds. Furthermore, since the phenyl and carbonyl groups must be coplanar, a *gauche* orientation of the carbonyl and chlorine in **21** would produce severe nonbonded repulsion between a hydrogen of the chloromethyl group and one of the *ortho* hydrogens on the phenyl ring. The corresponding projection of **1** was quite different from that of **21**, reflecting the much greater bulk of a methylsulfonyl versus a chloro group. The S—C_α—C_β—Ph angle in **2** was 12.5° less than the corresponding angle in **1**, thus permitting the chloro and carbonyl groups to be in closer proximity to each other.

Conclusions

A consideration of the above conformational effects offers the possibility of some intriguing speculation concerning the fact that the intermolecular displacement of a leaving group from a carbon adjacent to a sulfonyl group is a difficult and often complex process (2, 15, 37, 38). Among displacement reactions, a small number of efficient substitutions involving the reaction of thiolate anions with chloromethyl sulfones are known (15, 39), but the mechanism of these substitution reactions has not been unequivocally established. More commonly, nucleophiles reduce α-halosulfones which must require attack at halogen rather than at carbon. This is in contrast to α-haloketones which generally (37, 40), although not always (41), undergo facile nucleophilic substitution reactions at carbon. A regular S_N2-type mechanism has only been demonstrated to operate when sulfones with exceptionally powerful adjacent leaving groups (triflate and $-N_2^+$) are attacked by nucleophiles (42).

If the predominant conformation of an α-halosulfone is that in which the halogen is *gauche* to only one of the sulfonyl oxygens, then the other oxygen must be *anti*. Thus the trajectory of attack at carbon by a nucleophile must approach close to this other oxygen, and furthermore the nucleophile must pass parallel to the polar S—O bond (see Fig. 10). Such a conformation and trajectory would undoubtedly result in a greater activation energy for an S_N2-type displacement in α-halosulfones as compared to one, for example, in alkyl halides.[8] In fact, if the activation energy for attack at carbon becomes sufficiently large, substitution reactions would then preferentially occur in a two-step process, initiated by attack at halogen.[9] Since thiolate anions are the only nucleophiles that have been reported to give substitution products from α-halosulfones, it is indeed likely that attack at halogen rather than at carbon is the lower energy pathway. We are actively engaged in studies to cast light on these speculations.

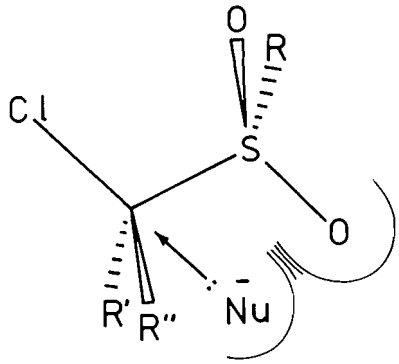

FIG. 10. The postulated path of attack by a nucleophile on carbon in an α-halosulfone.

Experimental

General

Thin-layer chromatographic analyses were carried out on Eastman silica sheets, containing a fluorescent indicator, and developed with EtOAc–ligroin, bp 40–60°C (1:1) or i-PrOH – toluene (1:9). Infrared spectra were run in chloroform solution on a P-E 237 spectrometer. Other details have been reported previously (19). All ^{13}C spectral results are collected in Table 1; conditions for recording spectra have been reported previously (19).

Preparation of 2-methylsulfonyl-1-phenylethanone, 1

This preparation was carried out with ethyl benzoate (50 mmol), sodium hydride (100 mmol), and dimethyl sulfone (100 mmol) using the procedure developed by Corey and Chaykovsky (44). Residual amounts of dimethyl sulfone were removed by washing the final dichloromethane extract thoroughly with water to give **1** in 85% yield. After 2 recrystallizations (toluene), **1** was tlc pure and had mp 106–107°C (lit. (45) mp 107.5–108°C, (3) mp 104–106°C); ir: 3030 (m), 1670 (s), 1590 (m), 1320 (vs), 1155 (s); ^1H nmr, δ: 3.15 (3H, t, J = 0.8 Hz), 4.60 (2H, q, J = 0.8 Hz), 7.43–8.07 (m, 5H).

Preparation of 2-chloro-2-methylsulfonyl-1-phenylethanone, 2

Sulfuryl chloride (1.6 mL, 20 mmol) was dropped into an ice-cold solution of **1** (3.96 g, 20 mmol) in CH_2Cl_2 (25 mL), which was then stirred for 4 h at 25°C. Rotary evaporation gave a crude solid, a CH_2Cl_2 solution of which was washed (water, 5% $NaHCO_3$, water), dried, and evaporated to give **2** (3.95 g, 86%). Two recrystallizations (ether) gave the pure **2**, mp 103–104°C (lit. (7) mp 105°C); ir: 3040 (w), 3015 (w), 2985 (m), 2940 (w), 1690 (s), 1590 (m), 1315 (s), 1130 (s); ^1H nmr δ: 3.22 (3H, d, J = 0.7 Hz), 5.98 (1H, q, J = 0.7 Hz) 7.53–8.08 (5H, m); ms, *m/z*: 234 (1.0), 232 (2.4), 156 (2), 154 (6), 127 (11), 125 (31), 106 (42), 105 (100), 90 (9), 89 (20), 78 (22), 77 (100), 63 (26), 51 (73).

Preparation of 2-bromo-2-methylsulfonyl-1-phenylethanone, 3

A solution of **1** (3.96 g, 20 mmol) in CH_2Cl_2 (100 mL) was added to a solution of pyridinium bromide perbromide ($PyHBr_3$) (7.00 g, 22 mmol) in CH_2Cl_2 (600 mL) and glacial HOAc(50 mL). After stirring (4 h at 25°C), the solution was washed and worked up (as above for **2**) to give **3** (5.0 g, 90%). Two recrystallizations (ether) gave **3** as prisms, mp 90–91°C; ir: 3040 (m) 1680 (vs), 1590 (m), 1320 (vs), 1270 (vs); ^1H nmr, δ: 3.35 (3H, s), 6.13 (1H, s), 7.5–8.2 (5H, m); ms, *m/z*: 278(1) 276(1) $M^{+\cdot}$, 198(1.5), 171(3), 169(3), 106(10), 105(100), 90(5), 89(4), 79(2), 77(26), 63(27). *Anal.* calcd. for $C_9H_9BrO_3S$: C 39.01, H 3.27, Br 28.8, S 11.57%; found: C 38.93, H 3.27, Br 27.7, S 11.14%.

Hydrolyses of 2 or 3 in aqueous alkali

A mixture of either **2** or **3** (10 mmol) and 10% aqueous NaOH (100 mL) was stirred at room temperature for 2 h. Extraction with

[8] It should be noted that these speculations assume reaction through the major conformer. Obviously, the Curtin–Hammett principle (43) needs to be considered in making such a postulation.

[9] This possibility has been considered previously (15), but ruled out due to the high reactivity of α-sulfonyl carbanions with hydroxylic solvents. However, it is possible for reaction between the α-sulfonyl carbanions and the intermediate sulfenyl halide to occur before the latter has diffused out of the solvent cage.

CH_2Cl_2 (3 × 50 mL) gave, after routine processing, chloromethyl methyl sulfone, **4** (0.86 g, 68% from **2**) or bromomethyl methyl sulfone **5** (1.20 g, 70% from **3**); **4** had mp (from ether) 56°C (lit. (11) mp 57.2–58.2°C); ^{1}H nmr ($CDCl_3$) δ: 3.07 (s, 3H), 4.50 (s, 2H); **5** had mp (from ether) 34°C (lit. (46) mp 35°C); ^{1}H nmr ($CDCl_3$) δ: 3.17 (s, 3H), 4.48 (s, 2H); ms, *m/z*: 174 (7), 172 (7), 159 (4), 157 (4), 95 (88), 93 (97), 79 (11), 63 (100), 48 (11), 45 (12). The aqueous alkaline solutions from these reactions were acidified (HCl); routine processing gave pure (by ^{1}H nmr) benzoic acid (1.01 g, 82% from **2**; 1.03 g, 83% from **3**) which was recrystallized for comparison with an authentic sample.

*Reaction of **1** with sulfuryl chloride – triethylamine*

Sulfuryl chloride (0.32 mL, 4 mmol) was cautiously dropped into an ice-cooled solution of **1** (396 mg, 2 mmol) and Et_3N (0.6 mL, 4 mmol) in CH_2Cl_2 (25 mL). The solution was allowed to warm to room temperature and was then stirred for 12 h. Work-up, as described for the preparation of **2**, gave oily 2,2-dichloro-2-methylsulfonyl-1-phenylethanone, **6**, 490 mg (91%); ^{1}H nmr ($CDCl_3$) δ: 3.47 (s, 3H), 7.4–8.4 (m, 5H); the mass spectrum could not be recorded as the spectrum changed continually with time as the compound decomposed under electron impact.

Aqueous alkaline hydrolysis of the crude **6**, as described above, gave benzoic acid (184 mg, 82%) and dichloromethyl methyl sulfone, **7** (0.266 g, 88%); mp (ex CCl_4) 69–71°C (lit. (11) mp 72.0–72.3°C); ir: 3030 (m), 2960 (w), 2940 (w), 1340 (vs), 1330 (sh); ^{1}H nmr ($CDCl_3$) δ: 3.20 (s, 3H), 6.23 (s, 1H); ms, *m/z*: 164 (3.8), 162 (5.0), 149 (12), 147 (16), 85 (648), 83 (1000), 79 (102), 63 (143), 48 (372).

*Reaction of **1** with pyridinium bromide perbromide – pyridine*

A solution of **1** (396 mg, 2 mmol), and dry pyridine (2 mL) in CH_2Cl_2 (25 mL) was added slowly to $PyHBr_3$ (1.32 g, 4.13 mmol) in CH_2Cl_2 (50 mL). The mixture was stirred at 25°C for 12 h and then worked up as described for **2** to give an unstable crude product (567 mg, 88%) that was a mixture of **8** (0.58 mmol) and **9** (1.17 mmol) in a ratio of 1:2 respectively, from ^{1}H nmr ($CDCl_3$) δ: 3.30 (s, $Br_2CHSO_2CH_3$), 3.37 (s, $PhCOCBr_2SO_2CH_3$), 6.30 (s, $Br_2CHSO_2CH_3$), 7.47–8.47 (m, 5H). The total crude mixture was hydrolyzed in aqueous alkali as described above to give benzoic acid (87 mg, 0.71 mmol, 61% based on **8**) as the only alkali-soluble product and **5** (132 mg, 43% based on **8** and **9**) as the only isolable neutral product.

*Preparation of 1-methyl-2-phenylsulfonylethanone, **10***

Sodium benzenesulfinate and chloroacetone were reacted (47) in refluxing ethanol to give **10**, which was crystallized from ether to give plates, mp 53.3–55°C (lit. (47) mp 57–58°C); ir: 3030 (m), 1715 (s), 1585 (w), 1445 (m), 1325 (s), 1230 (s); ^{1}H nmr ($CDCl_3$) δ: 2.40 (s, 3H), 4.15 (s, 2H), 7.55–7.96 (m, 5H); ms, *m/z*: 198 (7), 156 (13), 141 (20), 134 (45), 125 (13), 91 (39), 77 (100).

*Preparation of 1-bromomethyl-2-phenylsulfonylethanone, **11***

A solution of **10** (396 mg, 2 mmol) in CH_2Cl_2 (10 mL) was added to a solution of $PyHBr_3$ (700 mg, 2.2 mmol) in CH_2Cl_2 (60 mL) and glacial acetic acid (10 mL). After stirring the orange-red solution at 25°C for 5 h, work-up as described above gave **11** (500 mg, 90%), mp (colourless needles from ether) 90.0–90.5°C; ir: 3030 (m), 2940 (w), 1730 (s), 1580 (w), 1330 (s), 1300 (sh); ^{1}H nmr ($CDCl_3$) δ: 4.16 (s, SO_2—CH_2—CO—), 4.41 (s, —CH_2Br), 7.6–8.2 (m, 5H); ms, *m/z*: 278 (3), 276 (3), 214 (1), 212 (1), 197 (6), 183 (16), 141 (49), 125 (9), 95 (3), 93 (3), 91 (6), 77 (100), 51 (41), 42 (11).

*Preparation of 2-bromo-1-methyl-2-phenylsulfonylethanone, **12***

Bromination of **10** (2 mmol) with $PyHBr_3$ (2.2 mmol) in CH_2Cl_2 (60 mL) containing pyridine (2 mL) gave **12** (503 mg, 90%) as a brown oil which could not be purified, ^{1}H nmr ($CDCl_3$) δ: 2.60 (s, 3H), 5.18 (s, 1H), 7.6–8.2 (m, 5H); ms, *m/z*: 278 (13), 276 (13), 236 (18), 234 (18), 171 (5), 169 (5), 141 (44), 125 (7), 77 (100).

Hydrolysis of **12** in aqueous alkali (*vide supra*) gave bromomethyl phenyl sulfone, **13** (390 mg, 91%), mp (ether–hexane) 49–50°C (lit. (48) mp 50–52°C); ^{1}H nmr ($CDCl_3$) δ: 4.50 (s, 2H), 7.60–8.27 (m, 5H).

*Preparation of 2,2-dibromo-1-methyl-2-phenylsulfonylethanone, **14***

Bromination of **10** (2 mmol) with $PyHBr_3$ (4.4 mmol) in CH_2Cl_2 (60 mL) and pyridine (2 mL) gave **14** (677 mg, 95%) as an unstable brown-tinged syrup; ^{1}H nmr ($CDCl_3$) δ: 2.78 (s, 3H), 7.47–8.17 (m, 5H); $M^{+\cdot}$ at *m/z* 358, 356, and 354 (39:87:41).

Hydrolysis of this oil in aqueous alkali (same conditions as above) gave a mixture of **13** and **15** (510 mg) in a ratio of 56:44 (by nmr); ^{1}H nmr ($CDCl_3$) δ: 4.50 (s, —CH_2Br), 6.33 (s, —$CHBr_2$), 7.62–8.62 (m, 5H).

*Reaction of **10** with sulfuryl chloride in dichloromethane – acetic acid*

Sulfuryl chloride (0.2 mL, 2.5 mmol) was dropped into an ice-cold solution of **10** (396 mg, 2 mmol) in CH_2Cl_2–HOAc (20 mL, 1:1). After stirring at 25°C for 4 h the reaction mixture was worked up as before to give an oily mixture of products (430 mg) which consisted of **16** and **17** (9:2, by nmr); ^{1}H nmr ($CDCl_3$) δ: 2.55 (s, —$COCH_3$), 4.42 (s, —CH_2—CO—CH_2Cl), 5.22 (s, —SO_2—$CHCl$—CO—), 7.25–8.25 (m, 5H).

*Preparation of 2,2-dichloro-1-methyl-2-phenylsulfonylethanone, **18***

An ice-cold solution of **10** (2 mmol) in CH_2Cl_2 (30 mL), containing Et_3N (0.6 mL, 4 mmol) was chlorinated for 3 h with SO_2Cl_2 (0.32 mL, 4 mmol). Work-up as before gave **18** as an unstable, brown-tinged oil (509 mg, 95%), ^{1}H nmr ($CDCl_3$) δ: 2.73 (s, 3H), 7.55–8.12 (m, 5H).

The crude **18** was hydrolyzed with aqueous alkali (*vide supra*) to give dichloromethyl phenyl sulfone, **19** (331 mg, 77%), mp (CH_2Cl_2–hexane) 79–81°C (lit. (49) mp 81.5–83.0°C); ^{1}H nmr ($CDCl_3$) δ: 6.10 (s, 1H), 7.5–8.1 (m, 5H); ms, *m/z*: 226 (0.8), 224 (1.1), 191 (0.5), 189 (0.8), 162 (2.0), 160 (4.0), 156 (3), 141 (54), 125 (9), 85 (6), 83 (9), 77 (100).

Received July 6, 1983

THOMAS C. W. MAK, KHALID S. JASIM, and CHUNG CHIEH. Can. J. Chem. **62**, 808 (1984).

The syntheses of bisdithiocarbamates from diamines and CS_2 are described, and possible complications in these reactions explained. Ethylenebisdithiocarbamate was prepared from ethylenediamine and CS_2 in basic solution, but the same reaction using *o*-phenylenediamine led to a cyclization product, *o*-phenyleneimidazolidine-2-thione or benzimidazolidine-2-thione. In these reactions, if slightly insufficient amounts of CS_2 are used, bisdithiocarbamates will not be formed; instead, the cyclization reactions will occur, leading to the formation of thiones. Crystallographic studies were carried out for disodium ethylenebisdithiocarbamate and imidazolidine-2-thione or ethylenethiourea. The hexahydrate crystals of the former, $Na_2[S_2CNHCH_2CH_2NHCS_2]\cdot 6H_2O$, F.W. 364.42, are triclinic with a = 5.766(1), b = 7.212(1), c = 10.074(1) Å, α = 88.53(1), β = 98.41(1), γ = 105.50(1)°, V = 399.3(1) Å^3, and Z = 1. The structure was determined from 2259 unique reflections, (2θ[Mo-Kα] < 65°) to an R factor of 0.022. The bisdithiocarbamate ion has a center of symmetry between the two CH_2 groups, and therefore the two NCS_2^{2-} groups are separated as far apart as possible. Each Na^+ ion is octahedrally surrounded by five water molecules with Na...O distances ranging from 2.373 to 2.446 Å, and a sulphur atom of the thiocarbamate group with Na...S = 3.060 Å. The two C—S bonds of the CS_2^- group are 1.710(1) and 1.727(1) Å, and ∠SCS = 121.9(1)°. Crystals of imidazolidine-2-thione, $(CH_2NH)_2CS$, are monoclinic, with a = 5.800(1), b = 14.516(3), c = 5.780(1) Å, β = 101.33(2)°, V = 477.2(2) Å^3, and Z = 4. This structure, first determined thirty years ago, has been refined by full-matrix least-squares to R = 0.031, using 975 new Mo-Kα data.

THOMAS C. W. MAK, KHALID S. JASIM et CHUNG CHIEH. Can. J. Chem. **62**, 808 (1984).

On décrit des synthèses de bisdithiocarbamates à partir de diamines et de sulfure de carbone; on explique certaines complications possibles dans ces réactions. On a préparé l'éthylènebisdithiocarbamate à partir de l'éthylènediamine et du sulfure de carbone en milieu alcalin; toutefois, la même réaction appliquée à l'*o*-phénylènediamine conduit à un produit de cyclisation, l'*o*-phénylèneimidazolidinethione-2 ou benzimidazolidinethione-2. Dans ces réactions, si on utilise une quantité légèrement déficiente de sulfure de carbone, les bisdithiocarbamates ne se forment pas; les réactions de cyclisation se produiront alors de préférence et il y aura formation des thiones. On a effectué des études cristallographiques sur l'éthylènebisdithiocarbamate de disodium et sur l'imidazolidinethione-2 ou éthylène thiourée. Les cristaux hexahydratés du premier, $Na_2[S_2CNHCH_2CH_2NHCS_2]\cdot 6H_2O$, P.M. = 364,42, sont tricliniques, a = 5,766(1), b = 7,212(1), c = 10,074(1) Å, α = 88,53(1), β = 98,41(1), γ = 105,50(1)°, V = 399,3(1) Å^3 et Z = 1. On a affinée la structure jusqu'à une valeur de R = 0,022 pour 2259 réflexions uniques (2θ[Mo-Kα] < 65°). L'ion bisdithiocarbamate a un centre de symétrie entre les deux groupements méthylènes et la séparation entre les deux groupements NCS_2^{2-} est donc maximale. Chaque cation de sodium est entouré du façon octaédrique par cinq molécules d'eau (les distances Na...O varient de 2,373 à 2,446 Å) et par un atome de soufre du groupement thiocarbamate (distance Na...S = 3,060 Å). Les longueurs des deux liaisons C—S du groupement CS_2^- sont respectivement 1,710(1) et 1,727(1) Å alors que ∠SCS = 121,9(1)°. Les cristaux de l'imidazolidinethione-2, $(CH_2NH)_2CS$, sont monocliniques, a = 5,800(1), b = 14,516(3), c = 5,780(1) Å, β = 101,33(2)°, V = 477,2(2) Å^3 et Z = 4. Cette structure, qui a été déterminée pour la première fois il y a trente ans, a été affinée par la méthode des moindres carrés (matrices complètes) jusqu'à une valeur de R = 0,031 en faisant appel à 975 nouvelles données Mo-Kα.

[Traduit par le journal]

Introduction

Although the reaction of ethylenediamine with CS_2 was reported by Hofmann in 1872 (1), the disodium salt of ethylenebisdithiocarbamate, Na_2(Hbisdtc), was not prepared in the pure state until 1943 (2), and its crystal and molecular structure has not been elucidated till now. Shah and Jones (3) claimed the preparation of *o*-phenylenebisdithiocarbamate from the reaction of *o*-phenylenediamine, CS_2, and NaOH; however, neither elemental analysis nor spectroscopic data for this compound was reported. We tried the same reaction, but failed to obtain the bisdithiocarbamate; instead, the reaction always gave a thione as a cyclization by-product.

The formation of thiones from similar reactions of diamine and CS_2 in acidic medium has been reported (4), but we found that the cyclization reactions can be promoted purely by putting insufficient amounts of CS_2 in the reaction flasks in basic media. The production of *N,N'*-dimethylimidazolidine-2-thione has been observed under various conditions (5) and its structure has been determined (6).

This paper reports the first structure determination of a bisdithiocarbamate. The crystal structure of imidazolidine-2-thione, commonly known as ethylenethiourea, was determined by Wheatley (7) in 1953 by means of successive three-dimensional differential syntheses, using photographic data when electronic computers were in their infancy; however, the structure was determined carefully and accurately, to an R of 0.12. It would be interesting to compare results obtained then with those based on least-squares refinement using new diffractometer data.

Our attempt to prepare various bisdithiocarbamates has led to an improvement of the synthetic method and a better understanding of their chemistry. The lack of success in the preparation of a bisdithiocarbamate from *o*-phenylenediamine and CS_2 in an alkaline solution will be explained.

Experimental

Infrared spectra were recorded as 2% KBr and CsBr disks on the

following instruments: Beckman Acculab 10, and Perkin–Elmer 457 and 180. The ^1H and ^{13}C nmr spectra were recorded on a Brüker WP-80 FT nmr spectrometer. Elemental analyses were carried out by Guelph Chemical Laboratories Ltd. Reagent grade chemicals were used without further purification except where specified.

Prepartion of disodium ethylenebisdithiocarbamate

Disodium ethylenebisdithiocarbamate was prepared by a modification of the literature method (8) by adding CS_2 drop-wise to a basic solution of ethylenediamine. The reaction mixture was stirred for three hours in a water bath at 308–318 K, cooled to room temperature, and separated into two layers by the addition of excess acetone. The top acetone layer was discarded; the lower one was stirred again with additional acetone until crystallization occurred. The liquid phase was decanted and reserved, whereas the solid residue was dissolved in a minimum amount of water and again treated with acetone. This treatment was repeated 5 to 10 times until a colorless or pale yellow solution was obtained from which slow evaporation yielded colorless plate-like crystals of $Na_2(Hbisdtc) \cdot 6H_2O$. Some white particles suspended in the acetone wash were collected and subsequently shown to be identical to the sample from crystallization. Since we have determined the crystal structure, no elemental analysis was performed. The ^1H nmr (80 MHz, D_2O) consisted of δ: 3.71 (CH_2, s) ppm and the ^{13}C nmr (80 MHz, D_2O), δ: 49.10 (CH_2) and 214.69 (CS_2) ppm.

Preparation of imidazolidine-2-thione

Imidazolidine-2-thione was prepared according to the method for its *N,N'*-dimethyl analogue, as described in ref. 5. The ^1H nmr (80 MHz, D_2O) consisted of δ: 3.62 (CH_2, s) ppm and ^{13}C nmr δ: 46.42 (CH_2) ppm in acetone-d_6 and 47.01 ppm in D_2O.

Attempts to prepare disodium o*-phenylenebisdithiocarbamate*

Attempts to prepare *o*-phenylenebisdithiocarbamate by the same method (3) were not successful. Application of the modified procedure used for the ethylenebisdithiocarbamate also failed to produce the desired compound. In prolonged reactions, a white powder was obtained and identified as Na_2CO_3. A detailed account of these reactions will be given later (see Results and discussion).

Preparation of benzimidazolidine-2-thione

When 8 mL (0.13 mol) CS_2 was added dropwise to a mixture of 13.5 g (0.125 mol) of *o*-phenylenediamine and 5 g (0.125 mol) of NaOH in 200 mL of water at room temperature, in a three-necked flask equipped with dropping funnel and a mercury-sealed condenser, during a period of 30 min, there was a visible but slow reaction. The temperature was then slowly increased to 303–313 K while stirring continued, but the reaction rate was not much faster and eventually the temperature was raised to a gentle reflux for 30 min. The solid formed was filtered, washed with water, and dried under vacuum over silica gel. The ^1H nmr (80 MHz, acetone-d_6) showed δ: 7.22 (CH), 7.20 (CH), 2.85 (NH) ppm, and ^{13}C (80 MHz, acetone-d_6) δ: 110.14 (CH), 123.20 (CH), 133.27 (C), and 170.67 (CS) ppm. *Anal.* calcd. for $C_7H_6N_2S$: C 56.00, H 4.00, N 18.67; found: C 55.98, H 4.14, N 18.35.

Crystallographic studies

As crystals of disodium ethylenebisdithiocarbamate hexahydrate, $Na_2(S_2CNHCH_2CH_2NHCS_2) \cdot 6H_2O$, rapidly turn opaque in air, a specimen for diffraction work was sealed in a Lindemann glass capillary. Suitable crystals of the two compounds were selected and then centered on a Nicolet R3m automatic diffractometer. The determinations of the crystal class, orientation matrix, and accurate cell dimensions were performed according to standard procedures (9). Crystal data and parameters used in the structural determination are given in Table 1.

Normalized structure factors were calculated from $|F_o|$ values and

the statistical distributions of the $|E|$ values for both compounds were consistent with those of centrosymmetric crystals. Both structures were solved by direct method and the positions of the non-hydrogen atoms were found from the E-maps. The coordinates and anisotropic temperature factors were then refined by full-matrix least-squares methods, using the SHELXTL program package (10, 11) on a General Corporation Nova 3/12 minicomputer. All hydrogen atoms appeared on a difference map; they were assigned isotropic thermal parameters and their positions were varied in the least-squares cycles. Analytic expressions of neutral-atom scattering factors (12, 13) were employed. Atomic parameters for the two compounds are given in Tables 2 and 3 respectively.[1]

Results and discussion

Disodium ethylenebisdithiocarbamate, $Na_2(Hbisdtc)$, is very soluble in water but only sparingly so in dry acetone, dichloromethane, chloroform, and ethanol. The solubility difference in water and acetone was fully exploited in the separation of $Na_2(Hbisdtc)$ from the reaction mixture which contained an excess of NaOH. The dried solid sample is very unstable and decomposes at room temperature, 295 K, to isothiocyanate. After a day, its ir spectrum exhibits the two characteristic bands of isothiocyanate: N=C=S at 2080 cm^{-1} and C=N at 1620 cm^{-1} (14). Imidazolidine-2-thione and benzimidazolidine-2-thione are insoluble in benezene, toluene, and aliphatic hydrocarbons, but are soluble in chlorinated solvents, ethanol, and acetone. In water, the solubility of the former increases rapidly with temperature, whereas the latter is insoluble in both cold and hot water.

The two thiones are thermally very stable; samples heated at temperatures ranging from 293 to 513 K showed no change in their ir spectra. Heating of $Na_2(Hbisdtc)$ accelerated its decomposition to isothiocyanate, rather than to thione as in the case of its group IIB metal complexes (15).

The low yield (50–60%) of $Na_2(Hbisdtc)$ is probably due to the following reasons. (*a*) In basic medium, the alkali metal dithiocarbamates formed from primary amines may decompose according to the reaction:

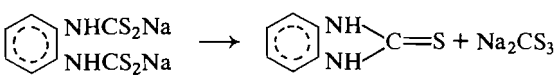
$$(CH_2—NH—CS_2Na)_2 \rightarrow (CH_2—NCS)_2 + H_2S + Na_2S$$

(*b*) During the course of the reaction, the sulphide ion S^{2-} resulting from (*a*) reacts with CS_2:

$$Na_2S + CS_2 \rightarrow Na_2CS_3$$

thereby reducing its availability for bisdithiocarbamate production. The formation of Na_2CS_3 can easily be seen from its orange colour in the reaction mixture.

We were not able to prepare *o*-phenylenebisdithiocarbamate by the method of reference (3), nor by the modified procedure used for $Na_2(Hbisdtc)$. In all preparative attempts in a nitrogen atmosphere, benzimidazolidine-2-thione and Na_2CS_3 were the products. The instability may be due to the constrained proximity of the two NCS_2^- groups leading to the cyclization:



The release of the S^{2-} species is obvious from the odor released during the reaction, and from the subsequent lead acetate paper test. If the reaction mixture is exposed to air for a prolonged period, the Na_2CS_3 so formed is hydrolyzed to Na_2CO_3, by the reaction (15):

$$2Na_2CS_3 + 2H_2O + O_2 \rightarrow Na_2CO_3 + Na_2S_2O_3 + CS_2 + H_2S$$

We expected the white powder in the mixture to be the bisdithiocarbamate, but elemental and spectroscopic analyses confirmed it as Na_2CO_3. The imidazolidine-2-thione was identified by its ir and nmr spectra.

Selected ir and Raman bands for three thiones and two bisdithiocarbamates are given in Table 4. Assignments of these bands were made with reference to the literature (16, 17). The N—H stretching frequencies in $CHCl_3$ are higher by about 210 cm^{-1} than those observed in the solid state, due to the presence of hydrogen bondings. For $Na_2(Hbisdtc)\cdot 6H_2O$, the N—H stretching came close to that of the hydrated water molecules and the assignment became ambiguous. On the whole, the RN—C stretching frequencies are lower for compounds with a methyl or phenylene group attached to the N than those with a H atom. The same is also observed for the C=S stretching for the thiones, but the reverse is observed for the C=S symmetric or asymmetric stretching frequencies for the bisdithiocarba-

mates. The presence of a doublet in the C=S stretching region in both the ir and Raman spectra of bisdithiocarbamates is a good indication that the C=S bonds are different in the CS_2^- group, and this is confirmed by the structural results.

Although the structures of many dithiocarbamates have been reported (18, 19), the configuration of ethylenebisdithiocarbamate, especially in its alkali metal salt, is of particular interest as it may change upon complexation with metal ions. The present study reveals that the Hbisdtc anion is centrosymmetric and the two NCS_2^- groups are separated as much as possible, an expected conformation. The bond lengths and angles for the bifunctional anion and other relevant data are given in Table 5, and an ORTEP plot of the anion is shown in Fig. 1. The two C—S bond lengths are significantly different, C(1)—S(1) 1.710(1), and C(1)—S(2) 1.727(1) Å. The difference may be a result of the weak interaction of Na...S(2) = 3.060 Å, but there is no close Na...S(1) contact in the crystal. Thus it is not surprising that two bands for C=S stretching were observed. This feature is also found in the crystal structure of dimethylammonium dimethyldithiocarbamate (18), in which the two C—S bonds are 1.706 and 1.715 Å. In this compound, the sulphur atom with two strong S...H—N hydrogen bonds has a longer distance than the one with one strong, and one weak S...H—N hydrogen bonds. Similar asymmetric bonding modes have also been observed in $Cu(S_2CN(CH_3)_2)_2$ (20) and other dithiocarbamate complexes (21).

Even though distorted, each sodium ion is surrounded octahedrally by the oxygen atoms of five water molecules at distances ranging from 2.373 to 2.446 Å, and by a sulfur atom from the dithiocarbamate with Na...S(2) = 3.060 Å. Two water molecules are bridged between two Na^+ ions, rather symmetrically, and the Na...O...Na angles are 91.7 and 94.8° respectively; see Table 5. The Na^+ ions are thus linked together forming chains with neighboring Na...Na distances of 3.421 and 3.574 Å. A packing diagram showing this relationship is given in Fig. 2.

resulting from the full-matrix least-squares refinement (this work) and from differential analysis (7) are compared in Table 6. Our more accurate parameters may be of some interest in theoretical studies relating to bond order charge density calculations (22) for this simple cyclic thione. An ORTEP plot of the

molecule excluding the hydrogen atoms is shown in Fig. 3. The longest axes of the thermal ellipsoids for all non-hydrogen atoms point in the direction normal to the plane of the molecule, indicating that there is considerable molecular thermal motion in the crystal. A detailed description of this structure can be found in ref. 7.

Vapor-phase charge-transfer complexes. 12. Dimethyl ether – iodine

S. J. Lo and M. Tamres
Department of Chemistry, University of Michigan, Ann Arbor, MI 48109, U.S.A.

Received June 6, 1983

S. J. Lo and M. Tamres. Can. J. Chem. **62**, 814 (1984).

Both a modified Benesi–Hildebrand method and the constant activity method were used to study the spectral and thermodynamic properties of the dimethyl ether – iodine complex in the vapor phase and in *n*-heptane solution. Comparison is made of these results with those for the diethyl ether – iodine complex. The solvent effects on ether – iodine, a relatively weak complex, are compared with those on stronger complexes.

S. J. Lo et M. Tamres. Can. J. Chem. **62**, 814 (1984).

On a utilisé la méthode modifiée de Benesi–Hildebrand ainsi que la méthode d'activité constante pour étudier les propriétés spectrales et thermodynamiques du complexe iode – éther méthylique en phase vapeur ainsi qu'en solution dans le *n*-heptane. On a fait une comparaison de ces résultats avec ceux obtenus pour le complexe iode – éther éthylique. On compare les effets de solvant sur le complexe iode – éther, un complexe relativement faible, avec ceux observés avec des complexes plus forts.

Introduction

There is very little in the literature on the characterization of the spectral and thermodynamic properties of iodine complexes with ethers in the vapor phase. Only the complex with diethyl ether (1–6) has been studied rather thoroughly while that with furan (7) has been studied partially.

The present work reports an extensive study of the dimethyl ether – iodine complex in the vapor phase and in *n*-heptane solution using both the conventional (modified Benesi–Hildebrand) method (8–10) and the constant activity method (11–13).

Experimental

Material

The purification of iodine and the synthesis of tetramethylammonium pentaiodide and of tetramethylammonium enneaiodide have been described elsewhere (14–16).

n-Heptane (Eastman Spectro Grade) and dimethyl ether (Matheson) were used without further purification.

Apparatus and procedures

Spectral measurements were made with a Cary 14 spectrophotometer. Experimental details of the apparatus and of the procedures used to study the complexes in the vapor phase and in solution have been presented in earlier papers (17–21) (and in the thesis of S. J. Lo (22)). The handling of gaseous reagents also has been described (23).

Calculations

The pertinent equations for donor (D) interaction with an acceptor (A) to form a complex (C) are summarized as follows (24).

(1). For the conventional (modified Benesi–Hildebrand) method:

$$[1]\quad \frac{D_0 l A_0}{\mathrm{ABS}} = \frac{D_0 + A_0}{\epsilon_c} + \frac{1}{K_c \epsilon_c} - \frac{\mathrm{ABS}}{l \epsilon_c^2}$$

Here K_c is the equilibrium constant, D_0 and A_0 are the initial concentrations of donor and acceptor, l is the cell path, ABS is absorbance, and ϵ_c is the molar absorptivity (corrected for the contribution of free donor and free acceptor). For weak complexes, such as ether – iodine, the last term may be dropped (25, 26).

(2). For the constant activity method, the iodine concentration was controlled by the equilibrium between tetramethylammonium polyiodides.

$$[2]\quad 1/2\ \mathrm{TMAI_9}\ (\mathrm{solid}) \rightleftarrows 1/2\ \mathrm{TMAI_5}\ (\mathrm{solid}) + \mathrm{I_2}\ (\mathrm{vapor})$$

and

$$[3]\quad \mathrm{TMAI_5}\ (\mathrm{solid}) \rightleftarrows \mathrm{TMAI_3}\ (\mathrm{solid}) + \mathrm{I_2}\ (\mathrm{solution})$$

In the usual case of using a large excess of donor, the equation which applies is

$$[4]\quad \mathrm{ABS} = K_c \epsilon_c l D_0 [\mathrm{I_2}]_{0,T}$$

where $[\mathrm{I_2}]_{0,T}$ is the fixed iodine concentration at equilibrium for eq. [2] or [3] at temperature T.

Taking the logarithm of eq. [4] and differentiating with respect to $1/T$ gives for the vapor phase

$$[5]\quad \frac{\Delta E_c^0}{2.303\,R} = \frac{\mathrm{d}\log K_c + \mathrm{d}\log \epsilon_c}{\mathrm{d}(1/T)} = \frac{\mathrm{d}\log \mathrm{ABS}}{\mathrm{d}(1/T)} - \frac{\mathrm{d}\log [\mathrm{I_2}]_{0,T}}{\mathrm{d}(1/T)}$$

and for the solution phase

$$[6]\quad \frac{\Delta H_c^0}{2.303\,R} = \frac{\mathrm{d}\log K_c + \mathrm{d}\log \epsilon_c}{\mathrm{d}(1/T)} = \frac{\mathrm{d}\log \mathrm{ABS}}{\mathrm{d}(1/T)} - \frac{\mathrm{d}\log [\mathrm{I_2}]_{0,T}}{\mathrm{d}(1/T)} - \frac{\mathrm{d}\log D_0}{\mathrm{d}(1/T)}$$

ΔE_c^0 is the change in internal energy of complexation, and ΔH_c^0 is the heat of complexation. They can be determined from plots of (*a*) log K_c vs. $1/T$, (*b*) log $K_c \epsilon_c$ vs. $1/T$ (assuming constancy in ϵ over the temperature range), and (*c*) log ABS vs. $1/T$ (provided the other terms in eqs. [5] and [6] are determined separately). The last method allows determination of ΔE_c^0 or ΔH_c^0 from just a single mixture of donor and acceptor (19, 27). The method also is applicable in the conventional study provided $D_0 \gg A_0 \gg C$, so that $[A_0 - C]$ does not vary greatly over the temperature range, as is the case for weak complexes (6).

Results

Results of a study via the conventional method in the vapor phase are shown in Fig. 1 for the ultraviolet region. The charge-transfer band, with a peak at 222.5 nm, decreased in intensity as the temperature increased. A regression analysis of a plot of log ABS (at the band maximum) versus $1/T$ (Fig. 2) gave a ΔE_c^0 value of -4.27 ± 0.2 kcal mol^{-1} (correlation constant 0.999). The low equilibrium constant for this system made it impossible to separate the terms in the $K_c \epsilon_{max}^{CT}$ product by the usual procedure according to the criteria established by Person (28) and others (26, 29, 30).

Two experiments were performed using the constant activity method with $\mathrm{TMAI_9/TMAI_5}$ as the iodine source. The dimethyl ether concentrations were 0.0332 *M* and 0.0340 *M* in 100-cm cells. The complex was studied over the relatively low temperature range of 49°C to 73°C because the free iodine concentration at higher temperatures causes the slit width to open rapidly in the visible region. The entire spectrum from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

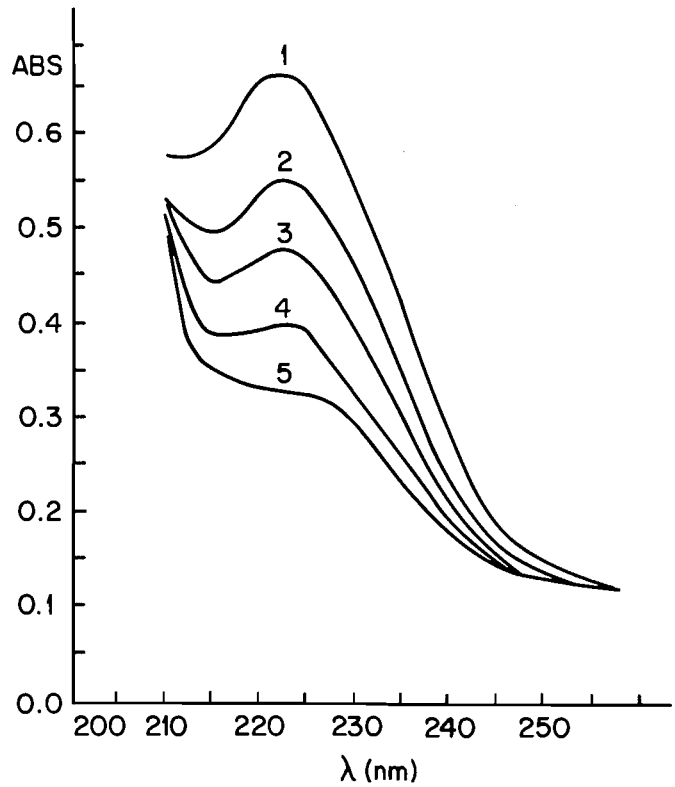

FIG. 1. The temperature dependence of the vapor-phase charge-transfer band of dimethyl ether ($3.41 \times 10^{-2} M$) and iodine ($3.259 \times 10^{-5} M$); λ_{max}^{CT} = 222.5 nm; cell path = 100 cm: (1) 60°C; (2) 70°C; (3) 78°C; (4) 88°C; (5) 100°C.

200 nm to 500 nm is shown in Fig. 3 at 53°C, 60°C, and 69°C. The charge-transfer band maximum occurred at 222.5 nm, as was obtained also by the conventional method. Just as had been reported in the literature for the diethyl ether donor (5, 19), the dimethyl ether donor gave a complexed visible iodine band spectrum which appeared to level off in the vicinity of 500 nm. The spectrum could not be studied above 500 nm due to the onset of the vibrational band structure of iodine. The maximum was obtained by extrapolating the absorbance data in the continuum region (from 450–497.5 nm) assuming a Gaussian band shape and using a computer program similar to that of Fraser and Suzuki (31–34). The complexed visible iodine band maximum was determined to occur at 495 ± 3 nm. (For the diethyl ether – iodine complex, the extrapolated band maximum occurred at 509 ± 3 nm (5, 19).)

Data for the temperature dependence of the absorbance at the charge-transfer band maximum and the complexed visible iodine band maximum are shown in Table 1, along with $K_c\epsilon_{max}^{CT}$, $K_c\epsilon_{max}^{BS}$, and the $\epsilon_{max}^{CT}/\epsilon_{max}^{BS}$ ratio. The $K_c\epsilon_{max}^{CT}$ and $K_c\epsilon_{max}^{BS}$ products were calculated from eq. [4]. The average $\epsilon_{max}^{CT}/\epsilon_{max}^{BS}$ ratio was 5.3. The variation in this ratio at the different temperatures is probably due to small instrument fluctuations in the low absorbance in the visible region.

From the temperature dependence of log ABS and the saturation pressure curve for the equilibrium, 1/2 $TMAI_9 \rightleftarrows$ 1/2 $TMAI_5 + I_2$, the ΔE_c^0 can be calculated using eq. [5]. The ΔE_{sat} for this polyiodide system in the vapor phase was determined by Tamres and Bhat (19) to be -13.65 ± 0.09 kcal mol^{-1}. The log ABS at 222.5 nm in the ultraviolet spectral region, and at the extrapolated value at 495 nm in the visible spectral region, were plotted versus $1/T$ as shown in Fig. 4. A regression

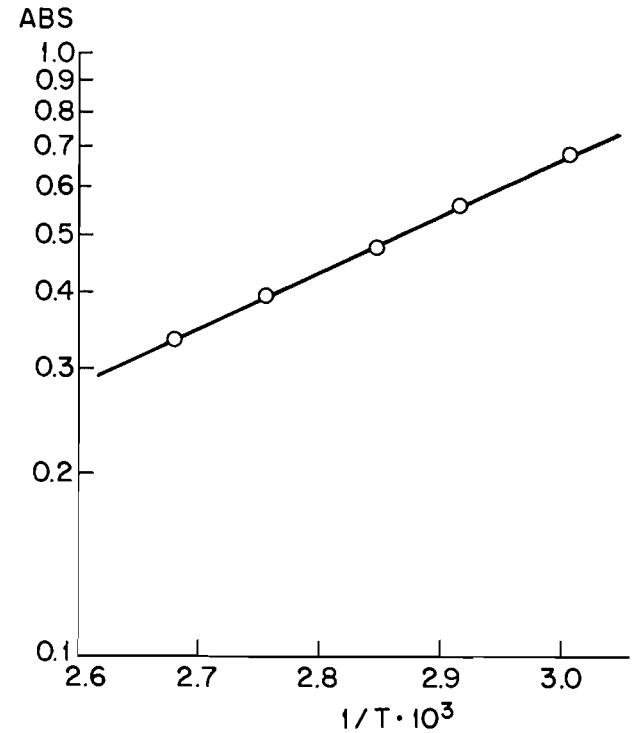

FIG. 2. Semilog plot of the temperature dependence of absorbance for dimethyl ether ($3.41 \times 10^{-2} M$) and iodine ($3.259 \times 10^{-5} M$) in the vapor phase at λ_{max}^{CT} = 222.5 nm; cell path = 100 cm.

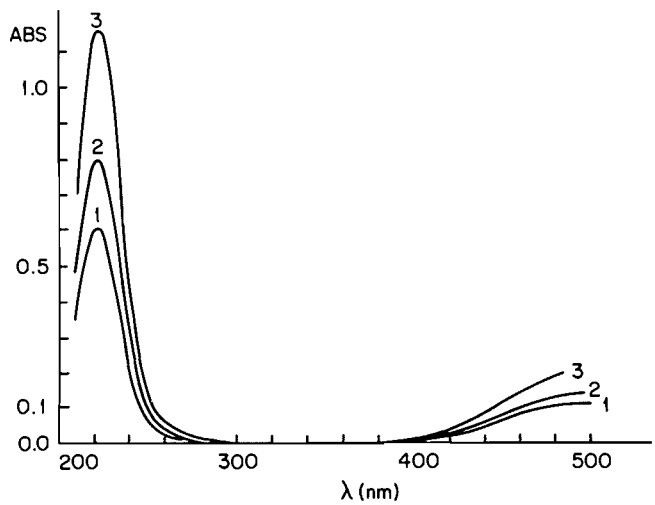

FIG. 3. The charge-transfer band and complexed visible iodine band of the dimethyl ether – iodine complex in the vapor phase: cell path = 100 cm; $[(CH_3)_2O] = 3.40 \times 10^{-2} M$; (1) 53°C, $[I_2] = 2.11 \times 10^{-5} M$; (2) 60°C, $[I_2] = 3.28 \times 10^{-5} M$; (3) 69°C, $[I_2] = 6.05 \times 10^{-5} M$. This is a difference spectrum with $TMAI_9/TMAI_5$ in the sample and reference cells.

analysis of these data, corrected for ΔE_{sat}, gave a ΔE_c^0 of -4.72 ± 0.7 kcal mol^{-1} at 222.5 nm and a value of -5.58 ± 0.5 kcal mol^{-1} at λ_{max}^{BS} at 495 nm. The ΔE_c^0 obtained from the data at 495 nm is probably less accurate for three reasons. First, the very low absorbance in the visible region makes the data more sensitive to baseline shifts. Second, the ultraviolet absorbance was read at the charge-transfer band maximum, while the visible absorbance was an extrapolated value. Third, the large free iodine absorption causes the slits on the spectrophotometer to open appreciably in the visible region from 480–500 nm.

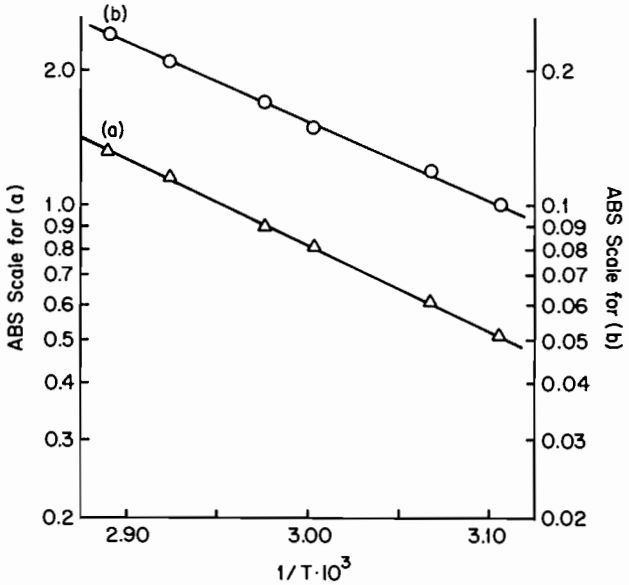

FIG. 4. A semilog plot of the temperature dependence of absorbance for dimethyl ether ($3.40 \times 10^{-2}\ M$) and iodine (from $TMAI_9/TMAI_5$) in the vapor phase; cell path = 100 cm; (a) absorbance at 222.5 nm; (b) absorbance at λ_{max}^{BS} (extrapolation to 495 nm).

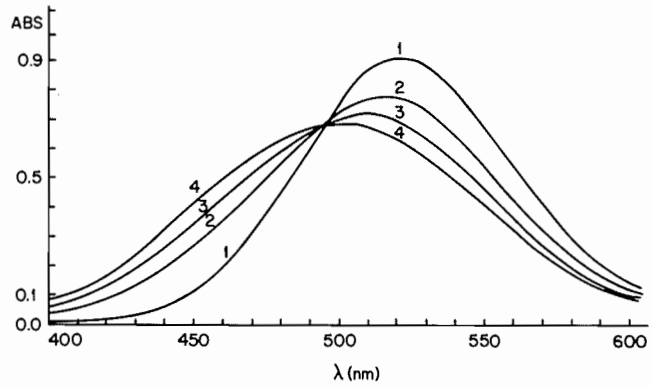

FIG. 5. The visible spectra for the dimethyl ether – iodine complex at 24.4°C in *n*-heptane; isosbestic point at 494 nm; cell path = 1.000 cm; $[I_2] = 1.001 \times 10^{-3}\ M$; $[(CH_3)_2O]$ increases $1 < 2 < 3 < 4$.

The properties of the complex also were studied in solution. The isosbestic point for the dimethyl ether – iodine complex in the visible spectral region was determined at 24.4°C in *n*-heptane using 1.000-cm glass-stoppered silica cells. An iodine solution ($1.001 \times 10^{-3}\ M$) was placed in the sample cell and its spectrum was run (curve 1 in Fig. 5). An unknown quantity of dimethyl ether was then bubbled directly into the 1.000-cm cell. The spectrum of this solution was scanned (Fig. 5, curve 2). This procedure was repeated two more times yielding curves 3 and 4, respectively. The isosbestic point occurred at 494 ± 1 nm. A molar absorptivity of 679 ± 17 M^{-1} cm^{-1} was calculated from the absorbance of the initial iodine solution at this wavelength. Precise determination of the wavelength of the isosbestic point was difficult because some solvent and iodine might have been lost through evaporation each time dimethyl ether was bubbled into the cell.

Results also were obtained in solution via the constant activity method. Approximately 0.08 g of $TMAI_5/TMAI_3$ was placed in matched Teflon-stoppered silica cells 2.00 cm in length. Rubber caps were placed over the Teflon stoppers to minimize evaporation of ether, iodine, and *n*-heptane. Dimethyl ether was bubbled directly into the sample cell three times. After each addition the difference spectrum was run in the ultraviolet and visible regions. The spectrum of the complex at 24.4°C in *n*-heptane is shown in Fig. 6. Curves 1, 2, and 3 show the increase in complex concentration as the dimethyl ether concentration is increased. The ether concentration was not determined for this experiment (although this was done approximately in one experiment to be discussed). The charge-transfer band maximum occurred at 239 nm, while the complexed visible iodine band maximum occurred at ~474 nm. The $\epsilon_{max}^{CT}/\epsilon_{max}^{BS}$ ratio was calculated to be 7.51, 7.42, and 7.35 for curves 1 through 3, respectively. Since the isosbestic point (494 ± 1 nm) and the molar absorptivity (679 M^{-1} cm^{-1}) at this wavelength are known for the dimethyl ether – iodine complex, the individual ϵ_{max}^{CT} and ϵ_{max}^{BS} values can be calculated. Data for ABS^{iso}, ABS^{CT}, and ABS^{BS} for each of the three curves in Fig. 6 are listed in Table 2 along with the ϵ_{max}^{CT} and ϵ_{max}^{BS} results. The average ϵ_{max}^{CT} and ϵ_{max}^{BS} values are 6150 M^{-1} cm^{-1} and 828 M^{-1} cm^{-1}, respectively.

The constant activity method enables the heat of complexation, ΔH_c^0, to be determined from the temperature dependence of the absorbance of a single mixture of donor and polyiodide via eq. [6]. The energy value obtained from a plot of log ABS versus $1/T$ must be corrected for the d log $[D]_0$/d$(1/T)$ term, which represents the density change of the solution with temperature, and for the saturation pressure curve of the polyiodide

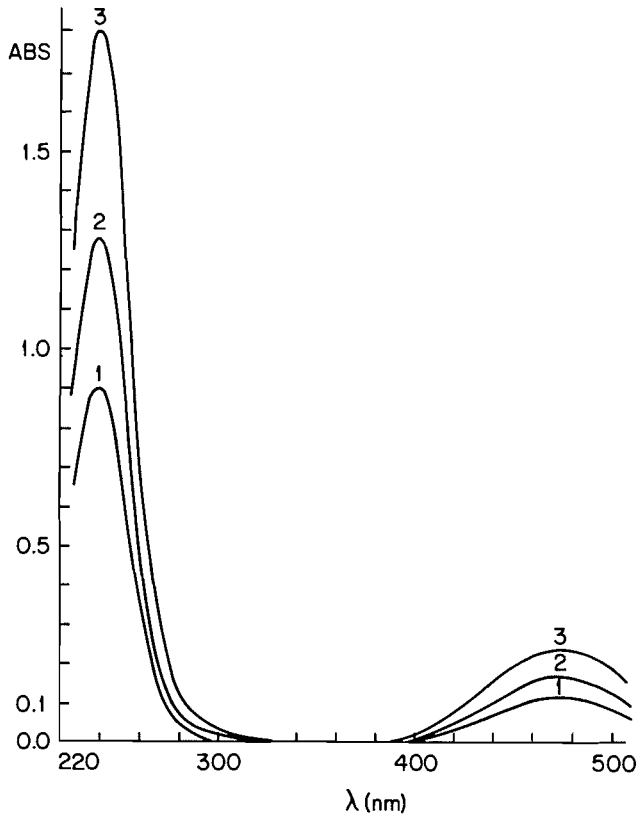

FIG. 6. The charge-transfer band and complexed visible iodine band of the dimethyl ether – iodine complex at 24.5°C in *n*-heptane; cell path = 2.00 cm: $[I_2] = 1.97 \times 10^{-4} M$, $[(CH_3)_2O]$ increases 1 < 2 < 3. These are difference spectra with $TMAI_5/TMAI_3$ in the sample and reference cells.

(i.e., the d log $[I_2]_{0,T}$/d(1/T) term). For a dilute solution, the value for d log $[D]_0$/d(1/T) corresponds to the density change of the solvent with temperature, which for *n*-heptane (35) is −0.22 kcal mol^{-1}. Tse (31) has determined the heat of solution for $TMAI_5/TMAI_3$ in *n*-heptane to be 8.18 ± 0.14 kcal mol^{-1}. A preliminary experiment was run to test the effect of the volatility of the donor in determining the enthalpy of the dimethyl ether – iodine complex. Solutions were made up at room temperature in matched Beckman 1.000-cm glass-stoppered cells. A short time was allowed for equilibrium and the absorbance was recorded at 24.4°C. The system then was cooled to 9.6°C whence, after allowing twenty-four hours for equilibration, the complex spectrum was recorded. Returning the system to 24.4°C showed that the absorbance had diminished, indicating some of the ether had evaporated. Thus, the system was studied at only two temperatures. The procedure adopted is based on the assumption that the ether probably evaporates from the cell at the same rate during the heating and cooling stages, if the time elapsed for each stage is the same. Thus, the enthalpy should be the average of those obtained from the two stages. This is tantamount to using the absorbance at 9.6°C and the average absorbance at 24.4°C at the start and end of the experiment. The average absorbance read at the charge-transfer band maximum was 0.767 at 24.4°C, while the absorbance was 1.086 at 9.6°C. This gives an uncorrected ΔH of 3.93 kcal mol^{-1}. Subtracting the corrections for the density change of the solvent (35) with temperature (−0.22 kcal mol^{-1}), along with the heat of solution for $TMAI_5/TMAI_3$ (8.18 ± 0.14 kcal mol^{-1}) (31), yields a heat of complexation for the dimethyl ether – iodine complex in *n*-heptane of −4.0 kcal mol^{-1}. This value is probably good to ±0.5 kcal mol^{-1}.

Calculation of the equilibrium constant of the dimethyl ether – iodine complex requires that the initial concentration of dimethyl ether be determined. This was done in one experiment using a Finnigan gc mass spectrometer. Immediately after the uv–visible spectrum of the solution was run, it was decanted from the excess polyiodide in the cell and poured into a small glass tube covered with a rubber septum. Using a micro syringe, very small quantities of the solution were injected into the gc mass spectrometer and the relative percentage of ether and *n*-heptane was analyzed. The technique was standardized using a solution of known concentration of diethyl ether in *n*-heptane. The percentages were determined to be good within ±1% from the analysis of several injections into the mass spectrometer. The average of all the percentages was taken as the concentration of the dimethyl ether (0.339 M).

From the absorbance at the isosbestic point and using eq. [4] the equilibrium constant was determined to be 3.0 M^{-1} at 25°C. This value establishes the order of magnitude for the equilibrium constant. However, a 1% change in the analysis of a solution containing 2% dimethyl ether leads to a 50% change in the equilibrium constant.

Discussion

The complete spectral and thermodynamic properties of the iodine complexes with diethyl ether and with dimethyl ether are summarized in Table 3. The effect of the solvent on the properties of these relatively weak complexes is apparent by comparing the data in the vapor phase with the data in *n*-heptane solution. To facilitate comparison with the solvent effect on a relatively strong complex, literature data are included in Table 3 for trimethylamine – sulfur dioxide (36).

The results for the ether – iodine complexes contrast in several ways with those for the corresponding sulfide–iodine

complexes (see preceding paper (24)). Comparison of the spectral and thermodynamic properties (such as K_c and $K_c\epsilon_{max}^{CT}$) indicated that diethyl sulfide is a stronger donor towards iodine than dimethyl sulfide. The situation is less clear-cut for the dimethyl ether – I_2 and diethyl ether – I_2 complexes. Comparison of their properties shows that the former probably is the stronger complex. Even allowing for a 50% error in determining K_c at 25°C for $(CH_3)_2O-I_2$ in *n*-heptane, the value is greater than that reported for $(C_2H_5)_2O-I_2$ under the same conditions. The $K_c\epsilon_{max}^{CT}$ product, both in the vapor phase and in *n*-heptane, is larger for the $(CH_3)_2O-I_2$ complex, as is also the $K_c\epsilon_{max}^{BS}$ product in solution. Only for $K_c\epsilon_{max}^{BS}$ in the vapor phase, does the value seem slightly larger for $(C_2H_5)_2O-I_2$. (Extrapolated results have to be compared with some caution because of the slightly different ΔE_c^0 and ΔH_c^0 values.)

One factor which could influence the strength of interaction is the dipole moment of the donor. The dipole moment for dimethyl ether (1.30 Debye) is greater than that for diethyl ether (1.15 Debye), whereas this is not the case for the sulfides (1.5 Debye for dimethyl sulfide and 1.54 Debye for diethyl sulfide) (39). Another factor is the inductive effect, i.e., ethyl substituents increase donor strength relative to methyl substituents. For the dimethyl and diethyl ethers, these two effects operate in opposing directions, which may make their donor ability more comparable. For the sulfides, both factors favor diethyl versus dimethyl sulfide.

It may be noted that, on comparing dissociation constants, dimethyl ether forms a stronger adduct with boron trifluoride in the vapor phase than does diethyl ether (40), while the reverse is true for the corresponding sulfides (41). Drago *et al.* (42–45) have developed a four-parameter equation for the enthalpy of adduct formation

$$\Delta H = E_A E_B + C_A C_B$$

where E and C are electrostatic and covalent parameters, respectively, for the acceptor (A) and the donor (base B). For the $(C_2H_5)_2O-I_2$ adduct, the experimental ΔH and calculated ΔH are the same (46), but for $(C_2H_5)_2O-BF_3$ the calculated value of 14.8 kcal mol^{-1} is larger (46) than the experimental value (of 11.9 kcal mol^{-1}) (47). Drago *et al.* have used this difference as a measure of a steric effect.

A linear correlation has been reported (48) for the enthalpy of adduct formation of diethyl ether, tetrahydrofuran, and tetrahydropyran with iodine in *n*-heptane solution and that of the same donors with BF_3 in the vapor phase. The point for dimethyl ether – iodine and dimethyl ether – boron trifluoride would fall on the line if the value for the enthalpy of complexation with iodine were 4.5 kcal mol^{-1}. The value of 4.0 kcal mol^{-1} cited in Table 3 is in reasonable agreement considering the crudeness of the determination.

Another point of contrast between the iodine complexes with ethers and with sulfides (24) is in the effect of *n*-heptane on their molar absorptivities. For both types of complexes, ϵ_{max}^{CT} is enhanced in solution relative to the vapor phase. However, the effect on ϵ_{max}^{BS} is quite different. There is very little effect of the solvent on ϵ_{max}^{BS} for ether–I_2, but the presence of the solvent approximately doubles the value of ϵ_{max}^{BS} for sulfide–I_2. As a consequence, the $\epsilon_{max}^{CT}/\epsilon_{max}^{BS}$ ratio is higher in the vapor phase relative to the solution phase for sulfide–I_2, but is the reverse for ether–I_2.

From the data so far available (6), it appears that the magnitude and even the direction of the solvent effect on the change in thermodynamic and spectral properties (e.g., K_c, ΔH_c^0, and λ_{max}^{CT}) depend on the strength of complexation, as may be seen by comparing the data in Table 3. The sulfide–iodine complexes are intermediate in strength between those of ether – iodine and of trimethylamine – sulfur dioxide, and the solvent effect is observed to be intermediate as well (24). A solvent cage model (49) seems to account satisfactorily for many of the effects observed (24). The solvent cage effect has been likened to pressure effects on these complexes (49, 50). A study by Suzuki and co-workers (51, 52) of the effect of pressure on complexes of varying strength in *n*-heptane parallels the changes observed between the solution and vapor phases. Thus, with an increase in pressure from 1 to 3300 bar, λ_{max}^{CT} for the iodine complexes of the relatively weak donors benzene, toluene, mesitylene, and diethyl ether was red shifted. For iodine complexes with donors of intermediate strength, hexamethylbenzene, diethyl sulfide, and diethyl selenide, the initial increase in pressure caused red shifts, but increasing the pressure still further reversed the trend and caused blue shifts. For strong complexes of iodine with triethylamine, tri-*n*-propylamine, and tri-*n*-butylamine, only blue shifts were observed as the pressure increased. Suzuki and co-workers (52) conclude that their observations could be interpreted by a sum of two effects: (1) increased polarity of the solvent with pressure which always causes a red shift, and (2) decreased intermolecular distance with pressure which contributes a red shift in a weak complex and a blue shift in a strong one. The latter explanation, proposed by Offen and Nakashima (53), is based on the relative importance of the terms Δ^2, $\beta_0\beta_1$, and S_{01} for weak and strong complexes in the Mulliken equation (54*a*).

$$h\nu^{CT} = \sqrt{\frac{\Delta^2 + 4\beta_0\beta_1}{1 - S_{01}^2}}$$

Suzuki and co-workers (55) have also examined the effect of increasing pressure on the visible iodine band for its complexes with diethyl ether, diethyl sulfide, and diethyl selenide in *n*-heptane solution. In each case, an increase in pressure produced a greater blue shift in the visible iodine band. Pressure increase enhanced the molar absorptivity of the complexed visible iodine band for the diethyl sulfide – iodine and the diethyl selenide – iodine complexes, but gave no enhancement for diethyl ether – iodine. These results confirm the finding of the solvent effect on these complexes when the phase is changed from vapor to solution. The lack of solvent enhancement of the molar absorptivity of the blue-shifted iodine band in complexes with donors containing oxygen (ethers (14) and alcohols (21, 31)) remains an anomaly (54*b*).

Received August 25, 1983

ALAN R. SANGER. Can. J. Chem. **62**, 822 (1984).

Mononuclear complexes of Hg^{II} of 1:1 stoicheiometry are formed with the chelating ligands $Ph_2P(CH_2)_nSPh$ (n = 1, 2) or $(PhS)_2(CH_2)_n$ (n = 1–4). In contrast to the behaviour of *trans*-[RhCl(CO)(PPh_3)$_2$], reactions of *trans*-[RhCl(CO)(PPh_2R)$_2$] (R = Et, Pr^i, or CH_2SPh) with $HgCl_2$ give the corresponding oxidative addition complexes [$RhCl_2$(HgCl)(CO)(PPh_2R)$_2$]. For [$RhCl_2$(HgCl)(CO)(PPh_2CH_2SPh)$_2$] the pendant thioether groups coordinate to mercury. Reactions of $HgCl_2$ with [MCl_2(Ph_2PCH_2SPh)$_2$] (M = Pd, Pt) give the corresponding heterodinuclear, Ph_2PCH_2SPh bridged complexes, [$MHgCl_4$(μ-Ph_2PCH_2SPh)$_2$]. The ^{199}Hg nmr spectrum of [$RhCl_2$(HgCl)(CO)($PEtPh_2$)$_2$] has been obtained, and the first value for $^1J(^{103}Rh—^{199}Hg)$ has been measured.

ALAN R. SANGER. Can. J. Chem. **62**, 822 (1984).

Le Hg^{II} forme des complexes mononucléaires de stoichiométrie 1:1 avec les ligands chélatants $Ph_2P(CH_2)_nSPh$ (n = 1, 2) ou $(PhS)_2(CH_2)_n$ (n = 1 à 4). Par opposition avec le comportement du [RhCl(CO)(PPh_3)$_2$-*trans*, les réactions du [RhCl(CO)(PPh_2R)$_2$]-*trans* (R = Et, Pr^i ou CH_2SPh) avec le $HgCl_2$ conduisent aux complexes d'addition oxydative correspondants [$RhCl_2$(HgCl)(CO)(PPh_2R_2)]. Dans le cas du [$RhCl_2$(HgCl)(CO)(PPh_2CH_2SPh)$_2$], les groupes thioéthers se coordonnent au mercure. Les réactions du $HgCl_2$ avec le [MCl_2(Ph_2PCH_2SPh)$_2$] (M = Pd, Pt) conduisent aux complexes hétérodinucléaires correspondants pontés par Ph_2PCH_2SPh, [$MHgCl_4$(μ-Ph_2PCH_2SPh)$_2$]. On a déterminé les spectres rmn du ^{199}Hg du [$RhCl_2$(HgCl)(CO)($PEtPh_2$)$_2$] et on a mesuré la première valeur de $^1J(^{103}Rh—^{199}Hg)$.

Introduction

Synthetic and structural aspects of the chemistry of complexes containing bonds between dissimilar metal atoms are of continuing interest (1, 2). A series of heterobinuclear complexes has been described in which the metal atoms are bridged by either bis(diphenylphosphino)methane (3) or 2-(diphenylphosphino)pyridine ligands (4), and in some of these complexes there exists a metal–metal bond. The catalytic utility of heteropolynuclear materials may differ significantly from that of materials containing one of the metals alone (e.g. refs. 5–7).

The reactions of mercury(II) complexes with complexes of transition metals are various (2). When the transition metal complex is electron-rich it may act as a Lewis base, forming a donor–acceptor complex with a mercury complex, e.g. [RhCp(cod)·$HgCl_2$] (8). When the transition metal complex is less basic, and amenable to oxidation, oxidative addition (e.g. eq. [1]) (9), which can include ligand exchange (e.g. eq. [2]) (10) or oxidative elimination (e.g. eq. [3]) (11), may occur.

[1] $IrCl(CO)(PPh_3)_2 + HgCl_2 \rightarrow IrCl_2(HgCl)(CO)(PPh_3)_2$

[2] $[RhCl(nbd)]_2 + 2Hg(Pr^iNCHNPr^i)_2 \rightarrow [Rh(nbd)(Pr^iNCHNPr^i)HgCl]_2$

[3] $Fe(CO)_3(PPh_3)_2 + HgCl_2 \rightarrow FeCl(HgCl)(CO)_2(PPh_3)_2 + CO$

Oxidation of *trans*-[$IrCl(CO)(PPh_3)_2$] by mercury(II) halides or pseudohalides is facile, but similar reactions of *trans*-[RhCl(CO)(PPh_3)$_2$] do not occur (9). Indeed, very few reactions are known in which complexes of rhodium are oxidized by complexes of mercury(II) (2). Nevertheless, a series of Rh—Hg bonded complexes and the cluster complex [$Hg_6Rh_4(PMe_3)_{12}$] have been synthesized by alternate routes (2, 12, 13).

Herein the reactions of $HgCl_2$ with complexes of rhodium(I) containing phosphines more basic than PPh_3 will be described. In some cases the complexes of mercury(II) halides with the pertinent phosphines were previously unknown, and so they too will be described.

Experimental

All reactions were carried out under ambient conditions in dry solvents under an atmosphere of nitrogen or carbon monoxide. The ligands Ph_2PCH_2SPh (14) and $Ph_2PCH_2CH_2SPh$ (15) and the complexes *trans*-[RhCl(CO)(PR_3)$_2$] (R_3 = $EtPh_2$, Pr^iPh_2, $Ph_2(CH_2SPh)$, or $Ph_2(CH_2CH_2SPh)$) (14, 16) were prepared according to published procedures. Spectra were obtained using the following instruments: ir, Perkin-Elmer 283; nmr, Brüker WP80. The ^{199}Hg nmr spectrum was determined by Brüker Spectrospin, Canada Ltd., Milton, Ontario, using a 200 MHz instrument.

The following examples illustrate the preparative procedures.

Example 1: synthesis of [$HgCl_2$(Ph_2PCH_2SPh)]

Under an atmosphere of nitrogen $HgCl_2$ (0.154 g, 0.567 mmol) and Ph_2PCH_2SPh (0.172 g, 0.558 mmol) were successively added to stirred acetone (20 mL) to form a colourless solution. The solution was allowed to stand under a stream of nitrogen for 30 min, during which the solvent partially evaporated, and then was filtered to give, as white crystals [$HgCl_2$(Ph_2PCH_2SPh)] (0.263 g, 81%).

Analytical and spectroscopic data for this and other complexes of mercury with phosphinoalkylthioethers or dithioethers are in Table 1.

Example 2: reaction of $HgCl_2$ with trans-*[RhCl(CO)(Ph_2PCH_2SPh)$_2$]*

Under an atmosphere of carbon monoxide $HgCl_2$ (0.168 g, 0.619 mmol) was added to a suspension of *trans*-[RhCl(CO)(Ph_2PCH_2SPh)$_2$] (0.480 g, 0.613 mmol) in acetone (40 mL) to rapidly form initially an orange solution and subsequently a white precipitate. The mixture was stirred (15 min) and then filtered to give [$RhCl_2$(HgCl)(CO)(Ph_2PCH_2SPh)$_2$] as white crystals. Subsequent further evaporation of solvent gave additional material (total yield 76%).

Analytical and spectroscopic data for this and other Hg—Rh bonded complexes are in Table 2.

Example 3: reaction of $HgCl_2$ with trans-*[RhCl(CO)($Ph_2PCH_2CH_2SPh$)$_2$]*

Under an atmosphere of nitrogen $HgCl_2$(0.075 g, 0.276 mmol) was added to a suspension of *trans*-[RhCl(CO)($Ph_2PCH_2CH_2SPh$)$_2$] (0.210

g, 0.259 mmol) in acetone (30 mL) to initially form a deep yellow solution. The mixture was stirred (1 h) during which a yellow precipitate formed. The precipitate was removed by filtration and dried under vacuum to give a pale orange powder (0.073 g) which has not yet been identified. The mother liquor was allowed to evaporate to dryness under nitrogen, and the golden mass so formed was taken up in dichloromethane (1 mL) to form a golden–orange solution and leave, as a grey residue, a trace of mercury, identified by X-ray fluorescence analysis. The solution was diluted with diethylether to form, as a yellow powder, $[RhCl_2(HgCl)(Ph_2PCH_2CH_2SPh)_2]$ (0.107 g, 39%), contaminated with a small amount of $[RhCl_3(Ph_2PCH_2CH_2SPh)_2]$.

Results and discussion

(A) Complexes of Mercury (II) with $Ph_2P(CH_2)_nSPh$ (n = 1, 2)

Under an atmosphere of nitrogen equimolar amounts of either $HgCl_2$ or HgI_2 and either Ph_2PCH_2SPh or $Ph_2PCH_2CH_2SPh$ were dissolved in acetone. Slow evaporation of the solvent gave the complexes $[HgX_2 \cdot PR_3]$ as white crystals. The complexes were characterized by elemental analysis, molecular weight, and ir and ^{31}P nmr spectroscopy (Table 1). In each case the complexes are mononuclear. All ^{31}P nmr spectroscopic parameters are of value similar to those expected for a 1:1 tertiary phosphine complex; the values of $^1J(^{199}Hg—^{31}P)$ for 2:1 complexes $[HgX_2(PR_3)_2]$ are universally lower than those for the corresponding, usually dinuclear, 1:1 complexes, $[Hg_2X_2(\mu\text{-}X)_2(PR_3)_2]$ (17). The above complexes must therefore contain $Ph_2P(CH_2)_nSPh$ (n = 1, 2) as bidentate (P, S), chelating ligands. However, the interaction of the thioether function with the mercury centre must be relatively weak to have such a slight influence on the value of ^1J(Hg—P). Complexes of mercury halides with the dithioethers $(PhS)_2(CH_2)_n$ (n = 1–4) are formed, but molecular weight determinations indicate facile dissociation in solution in either acetone or dibromomethane (Table 1). I have been unable to isolate complexes of the dithioethers (n = 5, 6), either because they are extremely labile or because the product is an oil which is different to manipulate.

(B) Reactions of $HgCl_2$ with complexes of rhodium(I)

In contrast to the lack of reaction of $HgCl_2$ with *trans*-[$RhCl(CO)(PPh_3)_2$], and in reactions analogous to those of iridium complexes, an acetone solution of either *trans*-[$RhCl(CO)(PEtPh_2)_2$] or *trans*-[$RhCl(CO)(PPh_2CH_2SPh)_2$] reacted with $HgCl_2$ under an atmosphere of CO to form a 1:1 oxidative addition complex [$RhCl_2(HgCl)(CO)(PR_3)_2$] (Table 2). Slow evaporation of the solvent under a stream of CO gave the product as yellow (PR_3 = $PEtPh_2$) or white (PR_3 = Ph_2PCH_2SPh) crystals. Traces of green impurity were due to decomposition to Hg and [$RhCl_3(CO)(Ph_2PR)_2$] and could be removed by recrystallization.

The ir spectrum of [$RhCl_2(HgCl)(CO)(Ph_2PCH_2SPh_2)$] exhibits three metal–chlorine bands at 325, 295, and 272 cm^{-1}. A strong band at 2040 cm^{-1} is appropriate for a carbonyl ligand in an oxidized complex. There is only one environment for phosphorus in the ^{31}P nmr spectrum of the complex, which at 300 K shows only a broad doublet (δ_p 23.0 ppm (versus 85% H_3PO_4); $^1J(^{103}Rh—^{31}P)$ 77.5 Hz). At 223 K the spectrum is sharper, and $^{199}Hg—^{31}P$ coupling is observed (δ_p 23.2 ppm; ^1J(Rh—P) 76.3 Hz; ^2J(Hg—P) 306 Hz). The value of the Rh—P coupling constant is also appropriate for Rh in a higher oxidation state than that of the starting material (^1J(Rh—P) 125.7 Hz) (14). The Hg—P coupling constant is considerably lower than ^1J(Hg—P) for tertiary phosphine complexes of Hg^{II} (e.g. ref. 17), and is therefore appropriately assigned as a two-bond coupling constant. The complex is a nonelectrolyte in acetone solution.

The ^{199}Hg nmr spectrum of [$RhCl_2(HgCl)(CO)(PEtPh_2)_2$] consists of a doublet of triplets. The rhodium–mercury coupling constant is 426 Hz.This represents the first such value determined, and so no conclusions can be drawn from its magnitude.

The ir and nmr parameters of each product are consistent with a complex with mutually *trans* phosphine ligands and *cis* chloro ligands. For the Rh—Hg bonded complex containing $PEtPh_2$ ligands the ^{31}P chemical shift is +5.2 ppm (upfield) from that of the parent Rh^I complex (Table 2). For the Ph_2PCH_2SPh complexes the corresponding difference is only +1.2 ppm. For each Rh—Hg bonded complex three metal–chlorine bands are observed in the ir spectrum, but the positions of the bands are very different (Table 2). These comparisons indicate that, although the structures of the complexes are similar about rhodium, a significant difference exists. The ligand Ph_2PCH_2SPh is capable of bridging two similar nuclei (14, 18). Dithioether complexes of $HgCl_2$ have been made (Table 1). Consequently, the differences between the above products are possibly due to coordination of the thioether function of the Ph_2PCH_2SPh ligands to the mercury centre (Fig. 1). The $PEtPh_2$ complex will be similar, but without coordination of pendant ligands to Hg.

If this postulate is correct, the difference in change in ^{31}P chemical shift could be due to a "ring contribution" (19) of approximately +4 ppm for the Ph_2PCH_2SPh complex. However, this value is so small that it cannot be considered as strong evidence.

Although the formation of Hg—S bonds may stabilize the product in Fig. 1, it is doubtful that the presence of the pendant thioether groups alone will promote oxidative addition of $HgCl_2$ to *trans*-[$RhCl(CO)(Ph_2PCH_2SPh)_2$]. The successful synthesis of the analogous $PEtPh_2$ complex indicates that the reaction is favoured by the presence in the parent rhodium complex of phosphine ligands which are both less bulky and more basic.

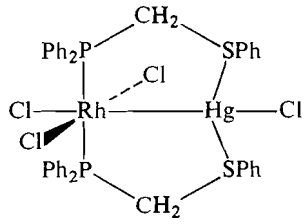

FIG. 1. Structure of [$RhCl_2(HgCl)(CO)(Ph_2PCH_2SPh)_2$].

In contrast to the above phenomena the reaction of $HgCl_2$ with *trans*[$RhCl(CO)(PPr^iPh_2)_2$] gave [$HgCl_2(PPr^iPh_2)]_2$ as the only pure, isolable product. The phosphine ligands are sufficiently basic that oxidative addition of $HgCl_2$ should be favoured, but the high steric requirements of PPr^iPh_2 mitigate against formation of a stable, six-coordinate rhodium complex (20). The reaction was repeated in acetone and the solvent was allowed to evaporate off completely to leave a mass which was then triturated under ethanol to give an orange powder. The ^{31}P nmr spectrum of a dichloromethane solution of this powder showed signals due to *trans*-[$RhCl(CO)(PPr^iPh_2)_2$], [$HgCl_2(PPr^iPh_2)]_2$, some minor components, and a new species. The parameters of the new species (δ_p 15.6 ppm; ^1J(Rh—P) 86.3 Hz; ^2J(Hg—P) 360 Hz) are sufficiently similar to the above oxidative addition products to suggest that they are due to [$RhCl_2(HgCl)(CO)(PPr^iPh_2)_2$], but no such complex has been isolated.

The reaction of equimolar amounts of $HgCl_2$ and *trans*-[$RhCl(CO)(Ph_2PCH_2CH_2SPh)_2$] in acetone gave a yellow precipitate which was not the starting material, [$HgCl_2(Ph_2CH_2CH_2SPh)$] (Table 1), or [$RhCl(CO)(Ph_2PCH_2CH_2SPh)$] (14). Although the material analyzed approximately as a 1:1 addition product of the reagents, the spectra indicated the presence of more than one product. The material showed *two* carbonyl bands of similar intensity in the ir spectrum (2040 and 1972 cm^{-1}), but, surprisingly, no band of significant intensity that could be assigned as a metal–chlorine stretch. The ^{31}P nmr of a dichloromethane solution of the products showed a singlet (δ_p 31.4 ppm), and a doublet (δ_p 43.1 ppm; ^1J(Rh—P) 107 Hz). There was also a broad minor doublet (δ_p 52.8 ppm; J, 107 Hz) downfield from the major doublet.

Evaporation of the solvent from the mother liquor from the above reaction gave [$RhCl_2(HgCl)(Ph_2PCH_2CH_2SPh)_2$] contaminated with a small amount of [$RhCl_3(Ph_2PCH_2CH_2SPh)_2$], as shown by the elemental analysis (Table 2). This impurity arises by elimination of mercury, which was separated as metal in trace amounts. The structure of [$RhCl_2(HgCl)(Ph_2PCH_2CH_2SPh)_2$] has not yet become clear. The ir spectrum shows no carbonyl band, and the only band (250–400 cm^{-1}) is a relatively weak feature at 290 cm^{-1}. The ^{31}P nmr of a solution in dichloromethane exhibits two major signals, a doublet (δ_p 43.0 ppm, ^1J(Rh—P) 107 Hz) and a broad singlet (δ_p 25.0 ppm) of equal intensity, and a minor signal due to the impurity. These data indicate that only one half of the phosphine ligands in this material are coordinated to Rh. It is interesting to note that the doublet in this spectrum is virtually identical with the doublet in the spectrum of the major, precipitated, product of this reaction.

(C) Reactions of [$MCl_2(Ph_2PCH_2SPh)_2$] (M = Pd, Pt) with $HgCl_2$

Neither [$MCl_2(Ph_2PCH_2SPh)_2$] (M = Pd, Pt) nor $HgCl_2$ is very soluble in acetone, and $HgCl_2$ is of very low solubility in

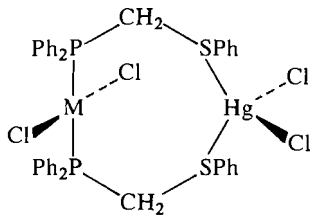

FIG. 2. Structure of $[MCl_2(\mu\text{-}Ph_2PCH_2SPh)_2HgCl_2]$ (M = Pd, Pt).

dichloromethane. However, a 1:1 mixture of either the palladium or platinum complex with $HgCl_2$ dissolves readily in a 1:1 mixture of these solvents to form a golden-yellow (Pd) or pale yellow (Pt) solution. In the case of the palladium complex, slow evaporation of the solvents gave yellow crystals which analyzed[1] as $[HgPdCl_4(Ph_2PCH_2SPh)_2]$, but for platinum the product was a pale yellow intractable oil.

The ir spectrum of the product containing palladium differed from that of the parent complex. The ^{31}P nmr spectrum exhibited one major signal (δ_p 30.4 ppm), which did not show coupling to ^{199}Hg, and which was not due to the starting material (δ_p 16.5 ppm).[2] Although the chemical shift is close to the value for $[PdCl_2(Ph_2PCH_2SPh)]_4$ (δ_p 30.7 ppm) (14), the elemental analysis is not correct for this material, and no $[HgCl_2(Ph_2PCH_2SPh)]$ (Table 1) is formed.

Attempts to obtain crystalline materials from the oily platinum product by recrystallization from various solvents such as acetone or diethylether gave only the parent platinum complex. The ^{31}P nmr of a dichloromethane solution prepared from equimolar amounts of $[PtCl_2(Ph_2PCH_2SPh)_2]$ and $HgCl_2$ exhibited signals due to only one species (δ_p 8.6 ppm; ^1J(Pt—P) 3750 Hz) which was neither the starting material (δ_p 8.1 ppm; ^1J(Pt—P) 3691 Hz) (14) nor $[HgCl_2(Ph_2PCH_2SPh)]$ (Table 1).

On the basis of the above evidence, and by analogy with complexes of Pd^{II} or Pt^{II} and Hg^{II}, bridged by two $Ph_2PCH_2PPh_2$ ligands (3), it is tentatively proposed that heterobinuclear complexes of Pd^{II} or Pt^{II} with Hg^{II} are formed which are bridged by Ph_2PCH_2SPh ligands, and that the phosphine groups coordinate to Pd or Pt (^{31}P nmr) and the thioether groups coordinate to Hg, $[MCl_2(\mu\text{-}Ph_2PCH_2SPh)_2HgCl_2]$ (M = Pd, Pt) (Fig. 2). The products are, therefore, effectively dithioether complexes of Hg^{II}, similar to those in Table 1. The Hg—S bonds are relatively labile as demonstrated by the molecular weight of the palladium product in dibromomethane (*M*, 794; calculated: 1066), and the reformation of the parent complex on treatment of the oily platinum product with donor solvents. Alternative structures of the form $[HgCl_2 \cdot MCl_2(Ph_2PCH_2SPh)_2]$ (M = Pd, Pt) are unprecedented for palladium or platinum, although similar donor–acceptor complexes are known for other metals (2).

[1]*Anal.* calcd. for $[HgPdCl_4(Ph_2PCH_2SPh)_2]$: C 42.83, H 3.22; found: C 43.74, H 3.65.

[2]The chemical shift for this complex was incorrectly reported as +43.5 ppm in ref. 14.

Shikimic acids from furan; methods of stereocontrolled access to 3,4,5-trioxygenated cyclohexenes

D. RAJAPAKSA, B. A. KEAY, AND R. RODRIGO[1]

Department of Chemistry, Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received August 12, 1983

D. RAJAPAKSA, B. A. KEAY, and R. RODRIGO. Can. J. Chem. **62**, 826 (1984).

Oxabicycloheptenes **1** and **2** are converted to 3,4,5-oxygenated cyclohexenes by stereocontrolled hydroxylations and epoxidations coupled with reverse-Michael cleavage of the oxabicyclo system. Three epimers of shikimic acid are synthesized by these methods.

D. RAJAPAKSA, B. A. KEAY et R. RODRIGO. Can. J. Chem. **62**, 826 (1984).

On a transformé les oxabicycloheptènes **1** et **2** en cyclohexènes oxygénés en positions-3,4,5 grâce à des hydroxylations et des époxydations stéréocontrolées couplées à une scission de type rétro-Michael du système oxabicyclique. On a synthétisé trois épimères de l'acide shikimique par ces méthodes.

[Traduit par le journal]

In a current paper (1) we report the general occurrence of some 5-*endo-trig* reversals of 7-oxabicyclo[2.2.1]heptenes and provide a stereoelectronic rationale for the violations of Baldwin's Rules (2) observed in these cases. The reverse-Michael reactions (1, 3) of such compounds, coupled with standard epoxidations and hydroxylations, offer significant opportunities for the generation of multi-oxygenated cyclohexenes with virtually complete control of stereochemistry. We illustrate herein the application of these procedures to the efficient synthesis of some shikimic acids (4).[2]

Oxabicycloheptenes **1** and **2**, easily obtained from furan (5), were employed as starting materials. Conversion (1) of cyanide **2** to cyclohexadiene **3** followed by osmylation (osmium tetroxide/pyridine) produced diol **4** with complete regio and stereoselectivity. There is little doubt that the bulky TBDMS group is responsible for directing hydroxylation from the lower face of the 3,4 double bond. The synthesis of (±) shikimic acid **5** was then completed by the standard procedures of desilylation (tetrabutylammonium fluoride/THF) and alkaline hydrolysis in 31% overall yield from **2**.

If the osmylation is conducted before the reverse-Michael fission, the stereochemistry of the *cis*-diol function thereby introduced is reversed and 5-epishikimic acid should result. Accordingly, bicyclo ester **1** was osmylated as before and the resulting *exo*-diols **6** converted to the acetonides **7**. Reverse-Michael cleavage of the latter (LDA, THF, 0°C) provided the expected cyclohexenol **8** (86%). Hydrolysis of the acetonide (aqueous acetic acid, 16 h, 20°C) and saponification produced (±) 5-epishikimic acid **9** in 39% overall yield from **1**. This epimer of shikimic acid has not been previously synthesized but its methyl ester (6) and a related triacetate **10** are known (7). Hydrolysis of the acetonide **8**, as before, and acetylation confirmed the identity (^{1}Hmr) and stereochemistry of our product.

Expoxidations of the double bond similarly timed can produce the other two isomers to shikimic acid. Thus *exo*-epoxides **11** obtained by MCPBA treatment of **1** reacted with LDA at −78°C to afford a 1:1 mixture of two products (86%). These were separated by distillation and identified as epoxycyclohexenol **12** (bp 110°C/0.05 Torr) and cyclopropane **13** (bp 92–100°C/0.05 Torr). The former has recently been con-

verted (8) into (±) methyl 4-epishikimate. Epoxidation of the diene **15** (1) with MCPBA and CH_2Cl_2 (73%), followed by desilylation (tetrabutylammonium fluoride), provided a 7:1 mixture (400 MHz ^{1}Hmr) of **14** and **12**. The former has recently been isolated and synthesised (9).[3]

We are proceeding with our experiments to convert **14** into the all-*trans* 3-epishikimic acid and to employ these techniques in the synthesis of other shikimate related metabolites.[4]

Intramolecular alkylation of cyclopentenones: a general route to conjoint ring systems

KAZIMIERZ ANTCZAK,[1] JOHN F. KINGSTON, SANDRA J. ALWARD, AND ALEX G. FALLIS
Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received July 13, 1983

KAZIMIERZ ANTCZAK, JOHN F. KINGSTON, SANDRA J. ALWARD, and ALEX G. FALLIS. Can. J. Chem. **62**, 829 (1984).

The intramolecular alkylation of several bromo- and epoxy-2-methylcyclopentenones, **18**–**23** and **33**, are described. In all cases, except **33**, alkylative cyclization occurs at the γ′ position to the conjoint ring systems **25**–**31**. The "blocked" bromide **33** (γ′ geminal dimethyl substituent) cyclizes to the fused ring hydrindenones **35** and/or **34** depending upon conditions. Enolate anion generation from 3-ethyl-2-methyl-2-cyclopentenone (**36**) with various bases (KH, LDA, Et_3N) is described and the anion populations determined by quenching with chlorotrimethylsilane to afford the enol ethers **39**–**41**. The intramolecular alkylations are discussed.

KAZIMIERZ ANTCZAK, JOHN F. KINGSTON, SANDRA J. ALWARD et ALEX G. FALLIS. Can. J. Chem. **62**, 829 (1984).

On décrit l'alkylation intramoléculaire de plusieurs bromo- et époxy-méthyl-2 cyclopenténones (**18**–**23** et **33**). Dans tous les cas, excepté **33**, la cyclisation alkylative se produit en position γ′ pour conduire aux systèmes cycliques conjoints **25** à **31**. Le bromure **33** "bloqué" (par un *gem*-diméthyle en γ′) se cyclise pour conduire aux cycles condensés hydrindénones **35** et/ou **34** suivant les conditions expérimentales. On décrit la génération de l'anion énolate de l'éthyl-3 méthyl-2 cyclopentène-2 one (**36**) en faisant appel à diverses bases (KH, LDA, Et_3N) et on a déterminé les populations d'anions en les piégeant avec le chlorotriméthylsilane pour obtenir les éthers énoliques **39** à **41**. On discute des alkylations intramoléculaires.

Introduction

Interest in polycyclopentanoid natural products has stimulated the development of new methodology for the construction of condensed five-membered ring systems (1). The synthesis of functionalized bicyclo[3.3.0]octane synthons (2) for the elaboration of more complex targets has received particular attention, since the preparation of simple systems has proven particularly challenging (3). We wished to develop a general intramolecular alkylation sequence to these and related rings, such as the diverse ring assemblies found in cuparanes, trichothecanes, and guaianolides based on the internal cyclization of cyclopentenones.

Previous studies (4) with α,β-unsaturated ketones have established that kinetically controlled formation of the α′ enolate anion results from treatment with strong nonnucleophilic bases under aprotic conditions. Intermolecular alkylation then affords the α′ alkylation product provided anion equilibration is relatively slow. In contrast, equilibrating conditions (protic solvent) favour thermodynamic control so that alkylation at the α-carbon generally results. In addition to the effect of the base–solvent combination, the balance between competing pathways in intramolecular alkylation is influenced by the nature of the electrophile and the length of the sidechain. This is exemplified by the octalones **1** and **2** studied by Piers *et al.* (5) (Scheme 1). They found that the product distribution (α′ = **3**, α = **4**, γ = **5**) could be partially controlled by the reaction conditions. Thus the α′ and α products predominated for $n = 3$, whereas for $n = 1$ only the γ and α products were encountered. Johnson and Vajs (6) found that the related cyclohexenone **6** afforded only α alkylation product **7** with potassium *tert*-butoxide (*t*BuOH), whereas conditions which facilitated proton transfer (KOH, H_2O, dimethyl sulfoxide) gave the γ alkylation product **8**.

In contrast to cyclohexenones, enolate anion generation and intramolecular alkylation of cyclopentenones have received much less attention. However, Cargill and Jackson (7) demonstrated that treatment of **9** with potassium *tert*-butoxide (*t*BuOH) resulted in selective formation of the α′ product **10**.

Clearly, substrate structure and the experimental conditions have a significant influence on the site of intramolecular alkylation of α,β-unsaturated cycloenones. As Scheme 2 illustrates, intramolecular alkylation of **11** could afford a complex product mixture. Excluding α′ and O-alkylated products, both of which are improbable due to the anti-Bredt olefins which would result, the most likely bicyclic systems are **F** to **I**. If the initial enolate is **A** or **B** it may be regarded as a masked cyclopentadiene and treatment with a second mole of strong base should generate **D** to give a different product ratio.

A variety of dianion systems have been gainfully employed in synthesis (8) and cyclopentenones appear to satisfy the general criteria for generation of a dianion species. However, with the exception of a methoxyindanone example (9), a report of some reactions of the dianions from 3-isobutoxy-2-cyclopentenones (10), and the *in situ* generation of the dianion of 3-methyl-2-cyclopentenone in an early hydroxyferrocene preparation (11), their potential as versatile synthetic intermediates remains unexplored.

Our initial investigations into the behaviour of a series of 3-substituted 2-methyl-2-cyclopentenones and their internal alkylation with bromides and epoxides are reported herein. These results provide a general entry into conjoint[2] ring systems (**I**) such as those found in bazzanene (**12**) and cuprenenol (**13**), as well as related β-cyclopropyl cyclopentenones, which are useful synthetic intermediates for cyclopentane ring annulation (12). At present, direct entry to fused cyclopentane ring systems (**F**, **G**) is feasible only in certain cases such as that leading to **34**. No spiro products (**H**) were encountered.

Preparation of cyclopentenones

The substrates required for this study were prepared by alkyl

[1]On leave from the Department of Chemistry, Merchant Marine Academy, Gdynia, Poland.

[2]IUPAC Rule A-5.1. states that two or more cyclic systems (single rings or fused systems) which are directly joined to each other by double or single bonds are named "ring assemblies". This is a very broad definition and we feel there is merit in having a simple descriptive class name to describe two or more cyclic systems joined directly by a single bond so they are neither fused nor bridged rings but "conjoint rings".

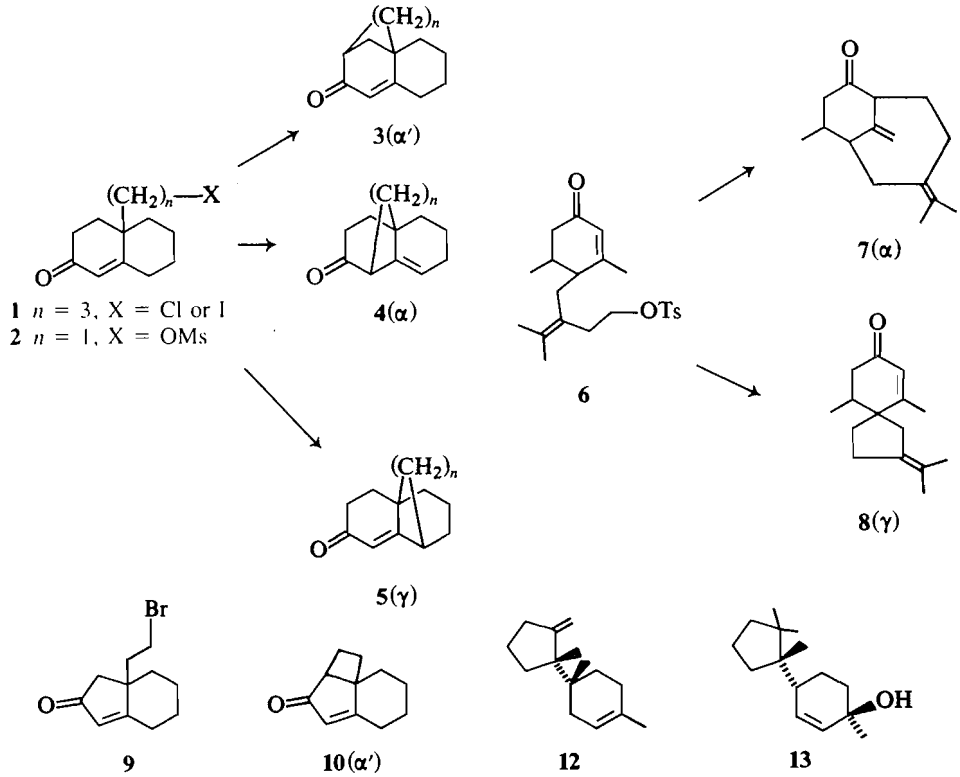
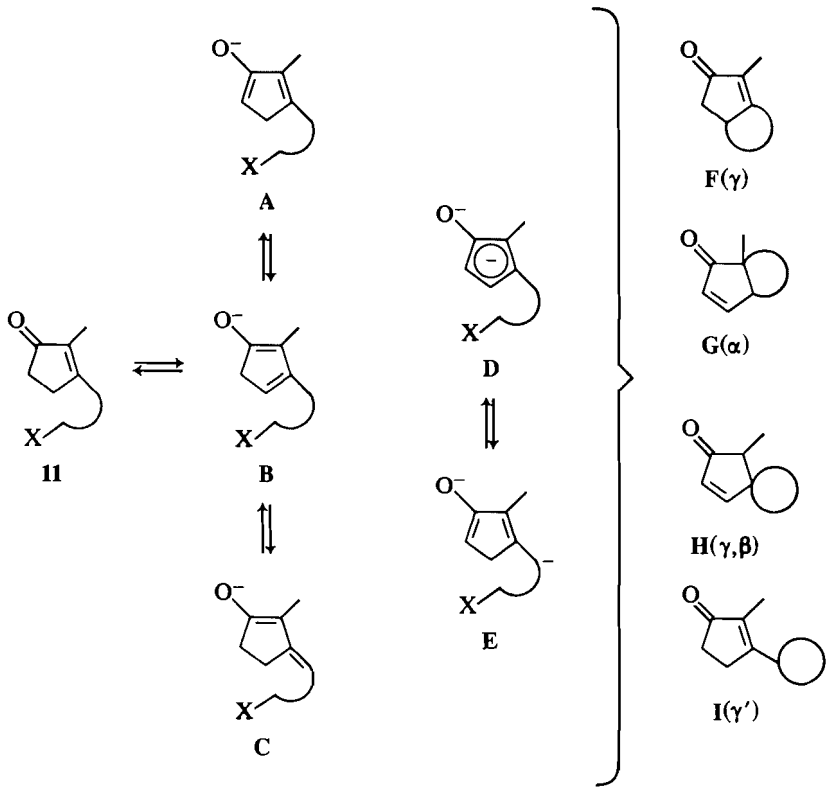
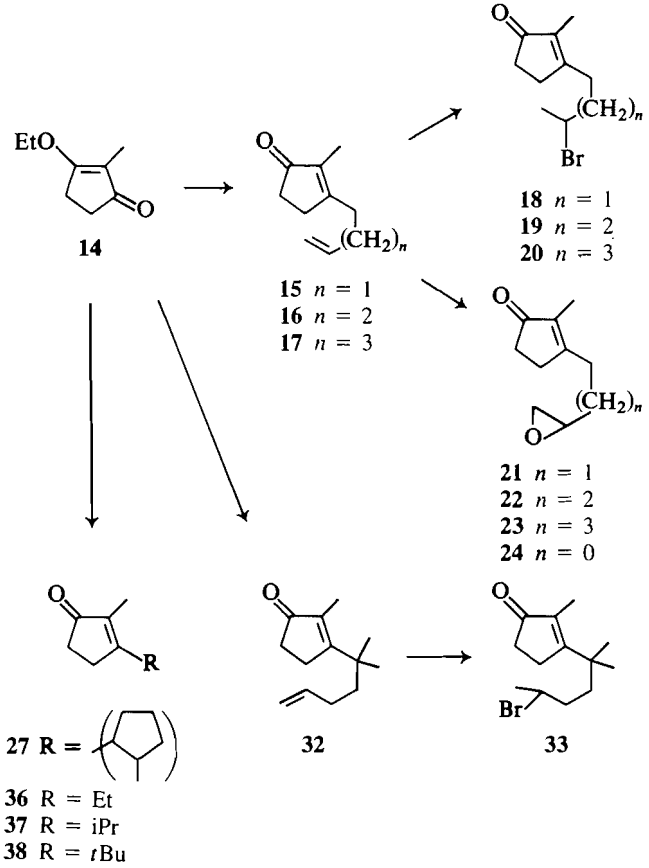


SCHEME 1

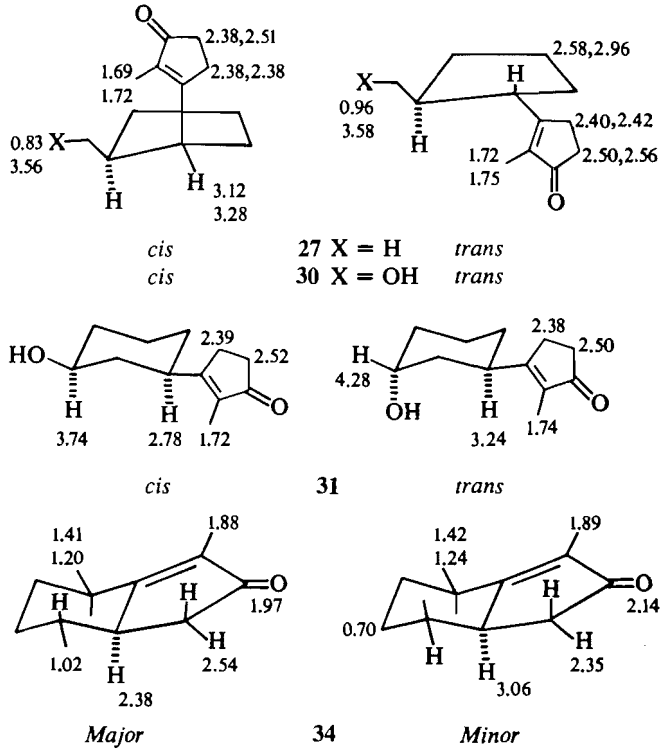


SCHEME 2

lithium addition of the requisite sidechain to the enol ether **14** followed by aqueous acid work-up as outlined in Scheme 3. The resulting dienones **15** to **17** afforded the bromides **18** to **20** regioselectively in good yields (87–93%) upon treatment with $HBr/ZnBr_2$ in acetic acid. Selective epoxidation of the terminal olefins with *m*-chloroperbenzoic acid in chloroform proceeded cleanly to give **21** to **23** (70–75%). In similar fashion the γ′-dimethylated bromide **33** was synthesized, as were authentic samples of the related 3-substituted cyclopentenones **27**, **36–38**.



SCHEME 3



SCHEME 4

Results

Intramolecular alkylations

Table 1 summarizes the results from the intramolecular alkylation of the bromides **18**–**20** and the epoxides **21**–**23**. Except for entry 12, which proved inert to cyclization, all the products were conjoint ring systems of type **I**. The course of these cyclizations, using potassium hydride, was independent of chain length and leaving group. The structures were established on the basis of their spectral features and, in the case of **27**, by comparison with an authentic sample. The ^{1}H nmr features for **27**, **30**, and **31** are summarized in Scheme 4. Generally, axial protons resonate at higher field (~0.5 ppm) than equatorial protons and methyl signals are often significantly shifted by olefinic anisotropic effects (e.g, the *syn* and *anti* bridge methyls, δ 0.72 and 1.23 in β-pinene). This information combined with the observation that "authentic" **27** (entry 5) possessed a different major isomer to entry 3 permitted the assignment of the *cis* stereochemistry to the product with the pseudo-equatorial *tert*-allylic proton. In addition, the secondary methyl group appears to be slightly shielded by the cyclopentenone moiety. The stereochemical differences between the isomers of **31** were assigned on the basis of ^{1}H nmr (400 MHz) spectra and relevant decoupling experiments.

In addition to their synthetic utility for the introduction of hydroxyl functionality, the epoxides provided a probe for Baldwin's rules (13) in cyclizations of this type. In principle these oxiranes may be opened from either end as a result of either an *exo*- or *endo*-tet displacement. In practice the *endo* mode was only encountered with the longer sidechain present in **23** which allowed intramolecular attack of the epoxide at both ends. At the other extreme, **24** did not cyclize but opened to the allylic alcohol 3-(3-hydroxyprop-1-enyl)-2-methyl-2-cyclopentenone. For **22** there was insufficient freedom in the sidechain to achieve the necessary geometry for ring opening, although **21** cyclized to a single *trans* isomer. The failure of **22** to react thus differs from related epoxy-nitriles which afforded cyclobutanes as the preferred product (14*a*; for a discussion, see ref. 14*b*).

Bromide **33** was examined in order to ascertain if fused ring formation was feasible, once γ′ anion formation was blocked. As anticipated, it afforded a 70% yield of the fused ring system **34** (type **F**) with potassium hydride. The major isomer has the stereochemistry depicted (Scheme 4), in which the *tert*-allylic proton appears as a complex multiplet at δ 2.38 (400 MHz) ($W_{1/2}$ = 25 Hz) coupled to the two cyclopentane α protons (J = 4, 2.5 Hz) and the adjacent axial proton (J = 11 Hz). In the minor isomer this proton is shifted to lower field δ 3.06 ($W_{1/2}$ = 17 Hz), appearing as a complex multiplet from overlapping coupling with the three adjacent protons (J = 7, 2.5, and 5 Hz). The secondary methyl group lies in the shielding cone of the π system and is therefore shifted upfield (δ 0.70 vs. 1.02), while in each case the vinyl methyl signal appears as a doublet due to coupling (J = 1.8 Hz) with the *tert*-allylic proton.

In contrast to the behaviour of potassium hydride, it has been well established (4, 5) that lithium diisopropylamide (LDA) results in kinetically controlled deprotonation at the α′ position. Thus, under conditions where anion equilibration is slow, no internal alkylation should occur with bromides **20** and **33** upon treatment with LDA. This was confirmed experimentally (entries 6 and 15). Increasing the polarity of the medium (added hexamethylphosphoramide, HMPA) facilitated anion equilibration resulting in the conjoint product (entry 7). However, 2 molar equivalents of LDA promoted elimination (entries 8 and 9), implying that a dianion of type **E** was reluctant to cyclize. Treatment of the blocked system **33** with 2 molar

TABLE 2. Enolate anion quenching of 3-ethyl-2-methyl-2-cyclopentenone (**36**)

Entry	Conditions*	Product distribution		
						39	**40**	**41**
1	LDA(1.1 equiv.) DME TMSCl, Et_3N $-78° \rightarrow 22°C$	83% (~5:1)		—
2	KH(1.1 equiv.) DME TMSCl, Et_3N $0° \rightarrow 22°C$	—	—	41%
3	Et_3N, $ZnCl_2$ Benzene TMSCl 22°C	66% (~4:1)		—

*TMSCl = Me_3SiCl; LDA = lithium diisopropylamide; DME = 1,2-dimethoxyethane.

equivalents of LDA afforded the γ alkylation product **34** (type **F**) and the α alkylation product **35** (type **G**) from the dianion **D**. Finally, proton transfer conditions (NaOH, H_2O, dimethyl sulfoxide) which favour enolate anion equilibration should parallel the pattern for potassium hydride, as was found (entry 10).

*Alkylation of 3-ethyl-2-methyl-2-cyclopentenone (**36**)*

In order to further establish the generality of the cyclopentenone anion reactions described above, the behaviour of 3-ethyl-2-methyl-2-cyclopentenone (**36**) with chlorotrimethylsilane and different bases was investigated. Quenching experiments provide a useful comparison of enolate anion populations even though equilibration competes with alkylation and with saturated cyclic ketones the ratio may be affected by the nature of the enol ether (15).

Table 2 summarizes the results. It was significant that the single exocyclic enol ether **41** was formed with potassium hydride whereas LDA and triethylamine/zinc chloride both afforded only the endocyclic species **39** and **40** (interconverting via a 1,5-sigmatropic rearrangement) and none of **41**. The latter result was surprising since some of the thermodynamic enol was expected, although this result was analogous to the results of Snowden (16). Apparently under these conditions quenching was more rapid than equilibration.

Unfortunately, intermolecular alkylation of **36** with methyl iodide and potassium hydride in dimethoxyethane was not selective and afforded a mixture of **36**, **37**, and **38** which may also contain some α′ alkylation product. This mixture could not be fully resolved but the structures were established by spectral comparison with authentic samples.

Discussion

The competition between the rate of enolate anion equilibration and their intramolecular alkylation is important in understanding these reactions. Scheme 2 provides a framework for the various pathways.

Lithium enolates equilibrate slowly and internal α′ alkylation of the kinetically generated enolate anion **A** is inhibited by the incorporation of a bridgehead double bond. However, under equilibrating conditions cyclization from anion **C** to the conjoint ring system **I** occurs readily. Apparently cyclization from **B** to the fused ring system **F** is less rapid (facile) and cannot compete. Similarly, generation of the α alkylation product **G** from either enolate **B** or **C** is disfavoured.

In comparison with the lithium salts potassium enolates equilibrate rapidly. It is not entirely clear whether the α′ or γ′ proton is abstracted preferentially but the experimental result is consistent with the preferential formation of enolate anion **C** either directly or by rapid equilibration. Consistent with the Curtin–Hammett principle (17)[3] cyclization to **I** must be slower than equilibration but anion **C** itself cyclizes faster than the other enolates.

The "blocked" system **33** permits the behaviour of the enolate anions **A** and **B** to be distinguished. As above, direct cyclization from **A** does not occur but generation of **B** with potassium hydride proceeds to the γ alkylation product **F** since the preferred pathway to **I** is no longer available.

Generation of the dianion intermediate **D** in the "blocked" bromide **33** affords the fused ring systems **F** and **G** (~2:1) representing γ and α alkylation respectively. Apparently the transition state leading to the spiro system **H** is of higher energy and thus cannot compete.

Conclusions

These studies have established that the preferred mode of intramolecular alkylation of compounds **18** to **23** is to the conjoint ring products arising from γ′ alkylation. When this pathway was blocked, the fused ring system from γ alkylation resulted. Fused ring products corresponding to α alkylation were only encountered from dianion intermediates in which the γ′ site was blocked. Thus some control over the product distribution may be exercised by variation of the experimental conditions and judicious choice of substrate.

The use of enol ethers via a cyclopentadiene anion inter-

[3]This principle applies when two or more isomers in rapid equilibrium react so that each isomer gives a unique product. The ratio of these products is independent of the relative energies of the original isomers and depends only on the relative energy levels of the transition states leading to these products provided the activation energy for product formation is large compared to that for isomerization.

mediate should allow selective generation of fused ring skeletons. We are currently examining this possibility as well as alternative applications of cyclopentenones to natural product total synthesis.

Experimental

Melting points were determined in capillary tubes with a Thomas–Hoover Uni-Melt apparatus, or a Fischer–Johns melting point apparatus and are uncorrected. Infrared spectra were recorded on a Perkin–Elmer 237B or 451 grating spectrophotometer, and were calibrated with the 2850 and 1601 cm^{-1} bands of polystyrene film. Ultraviolet spectra were recorded on a Perkin–Elmer 202 uv–visible spectrophotometer and were calibrated with a 279.4 nm band of a Holmium oxide filter. Proton magnetic resonance spectra were measured at 80 MHz with a Bruker model WP 80 spectrometer employing a chloroform lock or at 60 MHz with a Varian model EM 360 spectrometer or at 400 MHz with a Bruker WH 400 spectrometer at the University of Alberta. Signal positions are reported in ppm downfield from tetramethylsilane (δ scale) as an internal standard; the number of protons, multiplicity, coupling constants, and proton assignments are indicated in parentheses. Mass spectra were determined on a V.G. Micromass 7070 HS instrument using an ionization energy of 70 electron volts. Gas–liquid chromatographic analyses were conducted on a Hewlett Packard 402B chromatograph equipped with a column (3 m × 6 mm, id) containing 1.5% OV-17 supported on Gas Chrom Q using helium as the carrier gas. Thin-layer chromatographic analyses were carried out on commercial precoated silica gel plates with fluorescent indicator (Eastman Kodak silica gel 13181). Preparative thin-layer chromatography was conducted on 20 × 20 cm glass plates coated with silica gel $PF_{254+366}$ type 60 (E. Merck). Flash chromatography using BDH silica gel Kieselgel 60, 230–400 mesh was employed for all column chromatography.

Solutions in organic solvents were dried over anhydrous magnesium sulphate and stripped of solvent with a Büchi rotary evaporator connected to a water aspirator. Unless otherwise indicated all reactions were conducted under argon.
